The advantage of algebraic constraint satisfaction problems is that the natural "classical" proofs of satisfiability for these problems come in the form of two univariate polynomials of bounded degree, say, f, g, that satisfy some simple constraints. For example, in the PCP construction, the verifier knows some set $H \subseteq \mathbb{F}$ and would like to verify that $g(x) = 0$ for every $x \in H$. The PCPPs for Reed–Solomon codes already show how to prove/verify that the functions f and g are close to some polynomials of bounded degree. In subsection 3.3 we augment this PCPP so as to test that it vanishes on the set H, and this leads us to a proof of Theorem 2.2. Finally, in subsection 3.4 we describe the additional ingredients needed to get a PCPP for NTIME and prove Theorem 2.10 modulo these ingredients.

3.1. PCPPs for Reed–Solomon codes. We start by defining the Reed–Solomon codes and a pair language based on these codes. We then describe two cases of Reed–Solomon codes where we can obtain PCPPs for membership in the language. This yields our main theorem (Theorem 2.13) on LTCs.

DEFINITION 3.1 (Reed–Solomon codes and pair language). *The* evaluation *of a polynomial $P(z) = \sum_{i=0}^{d} a_i z^i$ over $S \subseteq \mathbb{F}, |S| = n$ is the function $p : S \to \mathbb{F}$ defined by*

$p(s) = P(s)$ for all $s \in S$. The formal sum $P(z)$ is called the polynomial corresponding *to (the function) p. The* Reed–Solomon code *of degree at most d over $\mathbb{F}$, evaluated at S, is*

$$\mathrm{RS}(\mathbb{F}, S, d) \triangleq \{p : S \to \mathbb{F} \mid p \text{ is an evaluation of a polynomial of degree } \leq d \text{ over } S\}.$$

The pair language PAIR-RS *is defined as follows. The explicit input is a triple $(\mathbb{F}, S, d)$, where $\mathbb{F}$ is a description of a finite field,*[1] *$S \subseteq \mathbb{F}$, and d is an integer. The size of the explicit input is assumed to be $|S| + O(1)$ field elements because in all our applications both d and $\mathbb{F}$ can be described using $\log |\mathbb{F}|$ bits. The implicit input is a function $p : S \to \mathbb{F}$. The size of the implicit input is $|S|$ field elements. A pair $((\mathbb{F}, S, d), p)$ is in* PAIR-RS *iff $p \in \mathrm{RS}(\mathbb{F}, S, d)$ and the explicit input is in the format described above.*

Notice that $\mathrm{RS}(\mathbb{F}, S, d)$ is the image of a linear $[n, d+1, n-d]_{\mathbb{F}}$-code. To see this, set $S = \{\xi_1, \ldots, \xi_n\}$ and consider the linear map sending $(a_0, \ldots, a_d) \in \mathbb{F}^{d+1}$ to the codeword $(P(\xi_1), \ldots, P(\xi_n))$ for $P(z) = \sum_{i=0}^{d} a_i z^i$.

Next we state our main technical results, namely, quasilinear length proofs of proximity for Reed–Solomon codes. Our results hold for certain "well-behaved" fields and evaluation sets, including fields of characteristic 2 (Theorem 3.2) and multiplicative subgroups that are sufficiently smooth (Theorem 3.4). As is customary when discussing Reed–Solomon codes, our distance measure is the relative Hamming distance over alphabet $\mathbb{F}$, denoted $\mathsf{Hamming}_{\mathbb{F}}$, and our alphabet is the underlying field. In particular, queries are answered by field elements.

3.1.1. Fields of characteristic two.

THEOREM 3.2 (PCPPs for RS-codes over fields of characteristic 2). *Let* PAIR-ADDITIVE-RS *be the restriction of* PAIR-RS *to pairs $((\mathrm{GF}(2^\ell), S, d), p)$, where $\mathrm{GF}(2^\ell)$ is the Galois field of size $n = 2^\ell$ and characteristic 2 and $S \subseteq \mathbb{F}$ is $\mathrm{GF}(2)$-linear. (Recall that S is $\mathrm{GF}(2)$-linear iff for all $\alpha, \beta \in S$ we have $\alpha + \beta \in S$.) Then,*

$$\text{PAIR-ADDITIVE-RS} \in \mathbf{Strong\text{-}PCPP}_{\delta/\operatorname{polylog} n} \left[\begin{array}{l} \mathsf{randomness}\ \log(n \cdot \operatorname{polylog} n), \\ \mathsf{query}\ O(1), \\ \mathsf{distance}\ \mathsf{Hamming}_{\mathrm{GF}(2^\ell)} \end{array} \right].$$

Consequently (using Proposition 2.9), for any $s, \delta \in (0, 1)$,

$$\text{PAIR-ADDITIVE-RS} \in \mathbf{PCPP}_{s,\delta} \left[\begin{array}{l} \mathsf{randomness}\ \log(n \cdot \operatorname{polylog} n), \\ \mathsf{query}\ \operatorname{polylog} n, \\ \mathsf{distance}\ \mathsf{Hamming}_{\mathrm{GF}(2^\ell)} \end{array} \right].$$

Furthermore, the proof queried by the "weak" PCPP-verifier is of the same length as that queried by the "strong" one.

Remark 3.3. The proof of Theorem 3.2 can be modified to obtain (strong) PCPPs with parameters as above for some other fields also. In particular, we can get PCPPs for $\mathbb{F}$ of characteristic $\leq \operatorname{polylog} n$ as long as the evaluation set S is linear over a subfield of $\mathbb{F}$ of size $\operatorname{polylog} n$. For simplicity, and since this suffices for our applications, we prove the result only for characteristic 2.

We prove Theorem 3.2 in section 6. Here we note that Theorem 3.2 immediately leads to a construction of LTCs. In particular, we use it to prove Theorem 2.13 later in this section. But before doing so, we describe a different collection of fields $\mathbb{F}$ and sets S where we can derive PCPPs for Reed–Solomon codes.

[1] An explicit description for such a field could be via a prime a and an irreducible polynomial $g(x)$ over $\mathrm{GF}(a)$.

3.1.2. RS-codes over smooth fields. For this part, and throughout the rest of this paper, let $\mathbb{F}^*$ denote the multiplicative group of a finite field $\mathbb{F}$. The *order* of $\omega \in \mathbb{F}^*$, denoted $\mathrm{ord}(\omega)$, is the smallest positive integer n such that $\omega^n = 1$. The multiplicative group generated by ω is $\langle\omega\rangle \triangleq \{\omega^0, \omega^1, \ldots, \omega^{n-1}\}$.

THEOREM 3.4 (PCPPs for smooth RS-codes). *Let* PAIR-SMOOTH-RS *be the restriction of* PAIR-RS *to pairs* $((\mathbb{F}, \langle\omega\rangle, d), p)$*, where* $\mathrm{ord}(\omega) = n$ *is a power of* 2*. Then,*

$$\text{PAIR-SMOOTH-RS} \in \mathbf{Strong\text{-}PCPP}_{\delta/\operatorname{polylog} n} \left[\begin{array}{l} \mathsf{randomness}\ \log(n \cdot \operatorname{polylog} n), \\ \mathsf{query}\ O(1), \\ \mathsf{distance}\ \mathsf{Hamming}_{\mathbb{F}} \end{array} \right].$$

Consequently (using Proposition 2.9*), for any* $s, \delta \in (0, 1)$*,*

$$\text{PAIR-SMOOTH-RS} \in \mathbf{PCPP}_{s,\delta} \left[\begin{array}{l} \mathsf{randomness}\ \log(n \cdot \operatorname{polylog} n), \\ \mathsf{query}\ \operatorname{polylog} n, \\ \mathsf{distance}\ \mathsf{Hamming}_{\mathbb{F}} \end{array} \right].$$

Furthermore, the proof queried by the "weak" PCPP-verifier is of the same length as that queried by the "strong" one.

Remark 3.5. Examination of the proof of Theorem 3.4 shows that it can be extended to $\langle\omega\rangle$ of size n that is $\operatorname{polylog} n$-smooth; i.e., all prime factors of n are at most $\operatorname{polylog} n$. For simplicity, we state and prove our theorem only for the multiplicative case of a 2-smooth n.

While not immediately evident, prime fields satisfying the requirements of the previous theorem abound. In section 7 we discuss this and provide an alternative proof of the quasilinear PCP Theorem 2.2 that relies on such prime fields. Notice the intersection of PAIR-ADDITIVE-RS and PAIR-SMOOTH-RS is empty. Indeed, a field with a multiplicative subgroup of size 2^k must be of size $c \cdot 2^k + 1$ for integer c, whereas the size of a field of characteristic 2 is a power of 2. Next we show how to construct LTCs using the PCPPs for RS-codes over fields of characteristic two.

3.1.3. Proof of quasilinear LTC—Theorem 2.13.

Proof of Theorem 2.13. Given an integer $n = 2^t$ we use Theorem 3.2 above applied to the field $\mathbb{F}$ of size n, with $S = \mathbb{F}$ and $d = n/8$. The resulting Reed–Solomon code has rate $\Omega(1)$ and relative distance at least 7/8. We then convert the PCPP for this code into an LTC over $\mathbb{F}$ using a standard conversion. Here we simply sketch this step. For a formal proof, see [9, Proposition 4.1].

The codewords of the LTC are in one-to-one correspondence with the codewords of the Reed–Solomon code. The codeword of the LTC corresponding to a polynomial p consists of two parts. The first part is simply the Reed–Solomon encoding of p repeated sufficiently often so that the first part takes at least, say, half of the coordinates of the LTC. The second part consists of the PCPP that p is a member of the language. The LTC-verifier simply simulates the PCPP-verifier using the first half as the oracle for the implicit input and the second half as the proof oracle, along with some spot-checks to verify that the first part repeats the same codeword several times. It is straightforward to see that the rate of this LTC is asymptotically bounded by the length of the Reed–Solomon codewords divided by the length of their PCPP, and the query complexity is similar to that of the PCPP-verifier. It is easy to see that the LTC so obtained has a relative distance of at least 7/16 (i.e., half the relative distance of the Reed–Solomon code).

It remains to convert this code into a binary code. This is also straightforward using the idea of concatenation of codes. We pick a small error-correcting code with $|\mathbb{F}|$ codewords of length $\ell = O(\log |\mathbb{F}|)$ and distance, say, at least $.4\ell$ and represent elements of $\mathbb{F}$ as codewords of this code. This converts the LTC obtained in the previous paragraph into a binary code with relative distance at least .4 times the distance of that code, which yields a relative distance of at least $7/40 > 1/8$. The verifier of the LTC above can now be simulated on this binary code with a multiplicative increase in the query complexity by a factor of $O(\log |\mathbb{F}|)$. □

Thus the PCPP for Reed–Solomon codes immediately leads to short LTCs. Additionally as we discuss in the upcoming sections, it also forms the central ingredient in our PCP and PCPP constructions.

3.2. Algebraic constraint satisfaction problems. To obtain length-efficient PCPs and PCPPs we reduce $L \in \text{NTIME}(t(n))$ to an *algebraic* constraint satisfaction problem. We describe this problem by comparing it to a combinatorial analogue, namely, 3SAT. A 3-CNF formula ψ with n variables and m clauses can be viewed as a mapping $\psi : \{0,1\}^n \to \{0,1\}^m$, sending an assignment to the characteristic vector of the set of clauses satisfied by it. The "natural" proof of satisfiability of a 3-CNF formula is a vector a of n bits. The proof proves the satisfiability of ψ if $\psi(a) = \vec{1}$. The typical advantage of this proof is that verification is a sequence of local steps, i.e., to verify that the jth coordinate of $\psi(a)_j = 1$, we need only examine three coordinates of a.

An instance of an algebraic constraint satisfaction ϕ similarly can be viewed as a mapping $\phi : \mathbb{F}[x] \to \mathbb{F}[x]$ from polynomials to polynomials. A candidate proof for the algebraic problem is a low-degree (univariate) polynomial $A \in \mathbb{F}[x]$ over finite field $\mathbb{F}$, called the *proof polynomial*. The map ϕ would map A to a polynomial P of slightly larger degree. ϕ would be considered satisfiable if $P = \phi(A)$ vanishes on a prespecified subset H of $\mathbb{F}$. Finally, for "local verifiability," we will expect that computing $P(x_0)$ requires knowledge of A at very few places, denoted k. But here we place some very strong restrictions on the local neighborhoods. Whereas in 3SAT, there was no simple relationship between a clause index j and the variables participating in the clause, in algebraic constraint satisfaction problems, we expect $P(x_0)$ to depend on A on some set of points of the form $\{\text{AFF}_1(x_0), \ldots, \text{AFF}_k(x_0)\}$, where $\text{AFF}_i(x) = a_i x + b_i$ is an affine map. Moreover, we insist that the computation of $P(x_0)$ from x_0 and $A(\text{AFF}_1(x_0)), \ldots, A(\text{AFF}_1(x_0))$ itself be algebraically simple. Combining all these ingredients leads to the following definition.

DEFINITION 3.6 (univariate algebraic constraint satisfaction problem (CSP)). *Instances of the language* ALGEBRAIC-CSP *are tuples of the form* $\phi = (\mathbb{F}, \{\text{AFF}_1, \ldots, \text{AFF}_{k'}\}, H, C)$, *where* $\mathbb{F}$ *is a field,* $\text{AFF}_i(x) \triangleq a_i x + b_i$ *is an affine map over* $\mathbb{F}$ *specified by* $a_i, b_i \in \mathbb{F}$, $H \subseteq \mathbb{F}$, *and* $C : \mathbb{F}^{k'+1} \to \mathbb{F}$ *is a polynomial of degree at most* $|H|$ *in its first variable. The* size *of* ϕ *is* $|\mathbb{F}|$.

A polynomial $A \in \mathbb{F}[x]$ *is said to* satisfy *the instance* $\phi \in$ ALGEBRAIC-CSP *iff* $\deg(A) \le |H| - 1$ *and for all* $x \in H$,

$$C(x, A(\text{AFF}_1(x)), \ldots, A(\text{AFF}_{k'}(x))) = 0. \tag{3.1}$$

The instance ϕ *is in* ALGEBRAIC-CSP *iff there exists a polynomial satisfying it.*

For integers k, d, *let* ALGEBRAIC-CSP$_{k,d}$ *be the restriction of* ALGEBRAIC-CSP, *to instances as above where* $k' \le k$ *and the degree of* C *in all but the first variable is at most* d.

Our main theorem on PCPs is obtained by reducing NTIME languages to ALGEBRAIC-CSP, while preserving the length of instances to within polylogarithmic factors.

THEOREM 3.7 (ALGEBRAIC-CSP is NTIME-complete). *There exist integers k, d such that for any proper complexity function $t : \mathbb{N}^+ \to \mathbb{N}^+$ and $L \in \mathrm{NTIME}(t(n))$ the following hold.*

1. *L is reducible to* ALGEBRAIC-CSP$_{k,d}$ *in time* $\mathrm{poly}\, t(n)$.
2. *The reduction maps an instance of L of size n to an instance of* ALGEBRAIC-CSP$_{k,d}$ *over field* $\mathrm{GF}(2^\ell)$ *of size* $2^\ell \le t(n)\,\mathrm{polylog}\, t(n)$ *and characteristic* 2, *where* $100(kd+1)(|H|-1) < 2^\ell \le 200(kd+1)(|H|-1)$.

The proof of this theorem is given in section 5.

Remark 3.8. Inspection of the proof of Theorem 3.7 gives $k = 10$ and $d = 8$. More careful optimization can give $k = 9$ and $d = 1$; i.e., C is multilinear in all but the first variable. Favoring simplicity over constant optimization, we omit this proof. Additionally, one can obtain the theorem for any $\mathbb{F}$ as long as $|\mathbb{F}| > |H|$. However, to derive Theorems 2.2 and 2.10 we need $|\mathbb{F}| \gg |H|$.

Very similar algebraic reductions are prevalent in many previous PCPs [5, 3, 2, 37, 39, 11, 9], starting with [5], and our reduction follows that of Polishchuk and Spielman [37]. However, all previous reductions used multivariate polynomials to perform degree reduction. Namely, a message (or assignment) of length n is encoded by an m-variate polynomial of degree $\approx m \cdot n^{1/m}$ (allowing proximity testing with $n^{1/m}$ queries). In contrast, our reduction does not reduce the degree at all; in fact it slightly increases it. The PCPPs for the RS-code described earlier allow us to tolerate this and verify proximity to high-degree polynomials with very small query complexity—logarithmic in the degree.

For our PCPP construction we need to modify the reduction above so that it works appropriately for pair languages. Suppose we wish for a reduction R from a pair language L to a pair language L'. Note that such a reduction can only work with the explicit input of pair languages. Furthermore, the reduction should say something about (the proximity of) the implicit input to an accepting pair. The following definition of a "systematic reduction" (borrowing a phrase from coding theory) specifies our needs.

DEFINITION 3.9 (systematic reduction). *A* systematic reduction *from a pair language L to L' is given by a pair of functions (R, m), $R : \Sigma^* \to \Sigma^*$, and $m : \Sigma^* \times \mathbb{Z}^+ \to \mathbb{Z}^+$ satisfying the following properties:*

- *For every x, the function $m'(i) = m(x, i)$ restricted to the domain $\{1, \ldots, N\}$ is injective and maps to the range $\{1, \ldots, N'\}$, where N denotes the length of the implicit input associated with x, and N' denotes the length of the implicit input associated with $R(x)$.*
- *If $y \in L_x$, then there exists a $y' \in \Sigma^*$ such that $y' \in L'_{R(x)}$ and $y_i = y'_{m(i)}$ for every $i \in \{1, \ldots, N\}$.*
- *If $y' \in L'_{R(x)}$, then $y \in L_x$, where y is the string given by $y_i = y'_{m(i)}$ for $i \in \{1, \ldots, N\}$.*

The running time of the reduction is the maximum of the computation times of $R(x)$ and $m(x, i)$, measured as a function $|x|$.

We next state a variant of Theorem 3.7 giving systematic reductions from pair languages to a language related to ALGEBRAIC-CSP. To this end, we define PAIR-ALGEBRAIC-CSP to be the pair language whose explicit inputs are instances ϕ as in Definition 3.6 and whose implicit inputs are mappings $y : \mathbb{F} \to \mathbb{F}$. A pair

(ϕ, y) is in PAIR-ALGEBRAIC-CSP iff the polynomial corresponding to y satisfies ϕ. We now state our theorem about the completeness of PAIR-ALGEBRAIC-CSP for PAIR-NTIME.

THEOREM 3.10. *There exist integers k, d such that for any proper complexity function $t : \mathbb{N}^+ \to \mathbb{N}^+$ and $L \in$ PAIR-NTIME$(t(n))$ the following hold.*

1. *L is reducible to* PAIR-ALGEBRAIC-CSP$_{k,d}$ *by a systematic reduction, given by the pair (R, m), in time* poly $t(n)$.
2. *For $x \in \{0,1\}^n$, the instance $R(x)$ is an instance of* ALGEBRAIC-CSP$_{k,d}$ *over field* GF(2^ℓ) *of size $2^\ell \le t(n)\,\mathrm{polylog}\, t(n)$ and characteristic 2, where $100(kd+1)(|H|-1) < 2^\ell \le 200(kd+1)(|H|-1)$.*

Since Theorem 3.10 is proved by a minor modification of the proof of Theorem 3.7, we prove them together in section 5.

3.3. Vanishing RS-codes and the PCP construction. The completeness of ALGEBRAIC-CSP for NP, combined with the PCPPs for Reed–Solomon codes, suggests a natural approach to building PCPs. In order to prove that some input instance x belongs to some NP language L, the verifier transforms x into an instance ϕ of ALGEBRAIC-CSP. To prove that ϕ is satisfiable, the prover can write a table of the assignment function $A : \mathbb{F} \to \mathbb{F}$. Furthermore, the prover can also write a table of the transformed polynomial $P = \phi(A)$. In order to verify that this is a valid proof of the satisfiability of ϕ, the verifier need only verify the following three properties: (1) The degrees of A and P are as specified; (2) A and P satisfy the relationship $P = \phi(A)$; and (3) P vanishes on the set H. The PCPP for Reed–Solomon codes solves the problem in (1) above. The locality in the definition of ALGEBRAIC-CSP turns out to lead to a simple solution to step (2) above as well. This leaves us to solve the problem in step (3). In this section we abstract this problem, calling it the vanishing RS-code problem, and state our result showing how to verify this. We then formalize the argument above to get a formal proof of Theorem 2.2.

We remark that the problem in step (3) is a special case of a common problem in all previous algebraic PCPs [4, 5, 20, 3, 2, 37, 39, 11, 9], where the goal is to test whether an m-variate function f, given as an oracle, is close to some polynomial p that *vanishes* on a set H^m for some prespecified subset $H \subset \mathbb{F}$. Our setting specializes this to the case where the functions are univariate (i.e., $m = 1$) as opposed to multivariate in the above mentioned results. This motivates the following pair language.

DEFINITION 3.11 (vanishing RS-codes). *A polynomial $P(z)$ over field $\mathbb{F}$ is said to* vanish *over $H \subseteq \mathbb{F}$ iff for all $h \in H, P(h) = 0$. For field $\mathbb{F}$, subsets S, H of $\mathbb{F}$, and integer d, the H-vanishing RS-code is*

$$\mathrm{VRS}(\mathbb{F}, S, H, d) \triangleq \{p \in \mathrm{RS}(\mathbb{F}, S, d) : \text{ The polynomial correspoding to } p \text{ vanishes on } H\}.$$

The pair language PAIR-VRS *is defined as follows. The explicit input is a quadruple $(\mathbb{F}, S, H, d)$, where $\mathbb{F}$ is a description of a finite field, $S, H \subseteq \mathbb{F}$, and d is an integer. The implicit input is a function $p : S \to \mathbb{F}$. The size of both the implicit and explicit inputs is $O(|S|)$. A pair $((\mathbb{F}, S, H, d), p)$ is in* PAIR-VRS *iff $p \in \mathrm{VRS}(\mathbb{F}, S, H, d)$.*

Note that in the above definition we do not require H to be a subset of S. The following lemma reduces testing proximity to the vanishing RS-code to testing proximity to the standard RS-code.

LEMMA 3.12 (PCPPs for PAIR-VRS). *Suppose a field $\mathbb{F}$, $S \subseteq \mathbb{F}$, and integer d*

are such that

$$\mathrm{RS}(\mathbb{F}, S, d) \in \mathbf{Strong\text{-}PCPP}_{s(\delta)} \left[\begin{array}{l} \mathsf{randomness}\ r, \\ \mathsf{query}\ q, \\ \mathsf{distance}\ \mathsf{Hamming}_{\mathbb{F}} \end{array} \right].$$

Then, for any $H \subset \mathbb{F}$ *and* $s'(\delta) = \min\{\delta/2, s(\delta/2)\}$,

$$\mathrm{VRS}(\mathbb{F}, S, H, d) \in \mathbf{Strong\text{-}PCPP}_{s'(\delta)} \left[\begin{array}{l} \mathsf{randomness}\ \max\{r, \log |S|\}, \\ \mathsf{query}\ q + 2, \\ \mathsf{distance}\ \mathsf{Hamming}_{\mathbb{F}} \end{array} \right].$$

Applying the previous lemma to Theorems 3.2 and 3.4 we immediately get the following corollary.

COROLLARY 3.13 (quasilinear PCPPs for vanishing RS-codes). *Let* PAIR-ADDITIVE-VRS *be the restriction of* PAIR-VRS *to pairs* $((\mathbb{F}, S, H, d), p))$, *where* $\mathbb{F}, S$ *are as defined in Theorem* 3.2. *Similarly, let* PAIR-SMOOTH-VRS *be the restriction of* PAIR-VRS *to pairs where* $\mathbb{F}, S$ *are as defined in Theorem* 3.4. *Let* $|S| = n$. *Then,*

$$\begin{array}{l}\text{PAIR-ADDITIVE-VRS,} \\ \text{PAIR-SMOOTH-VRS}\end{array} \in \mathbf{Strong\text{-}PCPP}_{\delta/\operatorname{polylog} n} \left[\begin{array}{l} \mathsf{randomness}\ \log(n \cdot \operatorname{polylog} n), \\ \mathsf{query}\ O(1), \\ \mathsf{distance}\ \mathsf{Hamming}_{\mathbb{F}} \end{array} \right].$$

Consequently (using Proposition 2.9*), for any* $s, \delta \in (0, 1)$,

$$\begin{array}{l}\text{PAIR-ADDITIVE-VRS,} \\ \text{PAIR-SMOOTH-VRS}\end{array} \in \mathbf{PCPP}_{s,\delta} \left[\begin{array}{l} \mathsf{randomness}\ \log(n \cdot \operatorname{polylog} n), \\ \mathsf{query}\ \operatorname{polylog} n, \\ \mathsf{distance}\ \mathsf{Hamming}_{\mathbb{F}} \end{array} \right].$$

Furthermore, the proof queried by the "weak" PCPP-verifier is of the same length as that queried by the "strong" one.

Lemma 3.12 generalizes to the case of multivariate polynomials and can replace the sumcheck-based protocols in previous PCP constructions [5, 3, 2, 37, 27, 24, 11, 9]. We describe this problem and our solution to it in subsection 4.4. We remark that our solution is both simpler and somewhat more efficient than the previous solutions (alas we do not need it for any of our own constructions). For our PCP construction the univariate version above suffices, as we show next.

3.3.1. Proof of quasilinear PCP—Theorem 2.2. We now show how to use the PCPP for (vanishing) RS-codes to prove Theorem 2.2, which gives short PCPs for all NTIME languages.

Proof of 2.2. *Overview.* We need to show that $L \in \mathrm{NTIME}(t(n))$ has short PCPs. We start by reducing an instance $\psi, |\psi| = n$ of L to an instance ϕ of ALGEBRAIC-CSP$_{k,d}$ of quasilinear size in n. As our proof, we request an evaluation p_0 of the polynomial A satisfying ϕ. Additionally, we request an evaluation p_1 of the polynomial from (3.1) appearing in Definition 3.6. To verify that A satisfies ϕ, we need only test that (i) p_0 is of sufficiently low degree, (ii) p_0, p_1 are consistent, i.e., p_1 is the evaluation of the polynomial from (3.1), and (iii) the polynomial corresponding to p_1 vanishes on H. We test (i) using Theorem 3.2, (iii) using Corollary 3.13, and (ii) using an additional consistency test with constant query complexity. Details follow.

Let $\phi = \{\mathrm{GF}(2^\ell), \{\textsc{Aff}_1, \ldots, \textsc{Aff}_k\}, H, C\}$ be the instance of ALGEBRAIC-CSP$_{k,d}$ that ψ is reduced to via Theorem 3.7. Let $\mathbb{F} = \mathrm{GF}(2^\ell)$ and notice that $|\mathbb{F}| = \Theta(t(n) \operatorname{polylog} t(n))$.

Probabilistically checkable proof. The verifier expects oracle access to a proof comprised of

- function $p_0 : \mathbb{F} \to \mathbb{F}$ and proof of proximity π_0 to $\mathrm{RS}(\mathbb{F}, \mathbb{F}, |H| - 1)$ as per Theorem 3.2 and
- function $p_1 : \mathbb{F} \to \mathbb{F}$ and proof of proximity π_1 to $\mathrm{VRS}(\mathbb{F}, \mathbb{F}, H, (kd+1)(|H|-1))$ as per Corollary 3.13.

Notice that Theorem 3.2 and Corollary 3.13 imply that the size of the proof is quasilinear in $|\mathbb{F}|$, which is quasilinear in $t(n)$.

Verifier operation. The verifier tosses $\log(t(n) \cdot \mathrm{polylog}\, t(n))$ coins and runs the following subtests using the same random coins in all and accepting iff all subtests accept.

- Invoke the PCPP-verifier for the Reed–Solomon code from the second part of Theorem 3.2 on explicit input $(\mathbb{F}, \mathbb{F}, |H| - 1)$, implicit input p_0, and proof π_0, using proximity parameter $\delta = 1/10k$ and soundness half.
- Invoke the PCPP-verifier for vanishing Reed–Solomon code from the second part of Corollary 3.13 on explicit input $(\mathbb{F}, \mathbb{F}, H, |H| - 1)$, implicit input p_1, and proof π_1, using proximity parameter $1/100$ and soundness half.
- Select random $x \in \mathbb{F}$, query $p_0(x), p_0(\textsc{Aff}_1(x)), \ldots, p_0(\textsc{Aff}_k(x))$ and $p_1(x)$; accept iff

$$p_1(x) = C(x, p_0(x), p_0(\textsc{Aff}_1(x)), \ldots, p_0(\textsc{Aff}_k(x))).$$

Basic parameters. Randomness and query complexity are as claimed, by Theorem 3.2 and Corollary 3.13.

Completeness. Suppose $\psi \in L$. Then $\phi \in \text{ALGEBRAIC-CSP}_{k,d}$ by Theorem 3.7. Suppose A satisfies ϕ as per Definition 3.6. Let p_0 be the evaluation of A on $\mathbb{F}$. Let

$$B(x) \triangleq C(x, A(\textsc{Aff}_1(x)), \ldots, A(\textsc{Aff}_k(x))). \tag{3.2}$$

Notice that $\deg(B) \le \deg_{x_0}(C) + \sum_{i=1}^{k} \deg_{x_i}(C) \cdot \deg(A) \le (kd+1)(|H|-1)$. Furthermore, B vanishes on H because A satisfies ϕ. Let p_1 be the evaluation of B on $\mathbb{F}$. We conclude that $p_0 \in \mathrm{RS}(\mathbb{F}, \mathbb{F}, |H| - 1)$ and $p_1 \in \mathrm{VRS}(\mathbb{F}, \mathbb{F}, H, (kd+1)(|H|-1))$, so by the completeness property of Theorem 3.2 and Corollary 3.13 there exist proofs π_0, π_1 causing the first two subtests of the verifier to accept. Finally, for all $x \in \mathbb{F}$ we have by construction

$$\begin{aligned} p_1(x) = B(x) &= C(x, A(\textsc{Aff}_1(x)), \ldots, A(\textsc{Aff}_k(x))) \\ &= C(x, p_0(\textsc{Aff}_1(x)), \ldots, p_0(\textsc{Aff}_1(x))). \end{aligned}$$

We conclude that the last subtest also accepts with probability 1, completing the proof of the completeness statement.

Soundness. Suppose $\psi \notin L$. Then $\phi \notin$ ALGEBRAIC-CSP by Theorem 3.7. There are several cases to consider:

- If p_0 is $(1/10k)$-far from $\mathrm{RS}(\mathbb{F}, \mathbb{F}, |H| - 1)$ then Theorem 3.2 implies the first subtest rejects with probability $1/2$. Similarly, if p_1 is not $(1/100)$-close to $\mathrm{VRS}(\mathbb{F}, \mathbb{F}, H, (kd+1)(|H|-1))$ then Corollary 3.13 implies the second subtest rejects with probability $1/2$.
- Otherwise, let A be the unique polynomial of degree $\le |H| - 1$ that is closest to p_0 and let $B(x)$ be as defined in (3.2). Let $p_2 : \mathbb{F} \to \mathbb{F}$ be defined by

$$p_2(x) = C(x, p_0(\textsc{Aff}_1(x)), \ldots, p_0(\textsc{Aff}_k(x))).$$

A union bound implies p_2 is $(1/10)$-close to the valuation of B on $\mathbb{F}$ because p_0 is $(1/10k)$-close to the valuation of A and $\text{AFF}_i(x)$ is uniformly distributed on $\mathbb{F}$ when x is uniformly distributed on $\mathbb{F}$.
Let B' be the (unique) polynomial closest to p_1. Notice that $B \neq B'$ because if $B = B'$, then B vanishes on H, implying A satisfies ϕ. Summing up, we have p_1 is $(1/100)$-close to B' and p_2 is $(1/10)$-close to B, where $B \neq B'$ are polynomials of degree $\leq |\mathbb{F}|/100$, so they agree on at most $1/100$ fraction of their entries. Thus, the third subtest accepts with probability at most $(1/10) + (1/100) + (1/100) < 1/2$. The soundness analysis is complete and with it we have proved Theorem 2.2. □

3.4. Systematic RS-codes and quasilinear PCPPs. We now turn to the task of building PCPPs for PAIR-NTIME languages. It is relatively straightforward to convert the PCP-verifier for ALGEBRAIC-CSP constructed in the previous section into a PCPP-verifier for PAIR-ALGEBRAIC-CSP. Unfortunately, this is not sufficient to imply a PCPP-verifier for all PAIR-NTIME languages, despite the systematic reduction given by Theorem 3.10.[2]

To get to the underlying issue, consider pair language L in PAIR-NTIME, and consider the task of proving/verifying if $(x, y) \in L$, where x is explicit and y is given as an oracle. Using the systematic reduction of Theorem 3.10, a PCPP-verifier could convert x to an instance $\phi = R(x)$ of ALGEBRAIC-CSP. It now demands proof oracles for a polynomial A satisfying ϕ, along with other ingredients as in the proof of Theorem 2.2 that prove that A satisfies ϕ. The PCPP-verifier can now verify that A satisfies ϕ with few queries. It still needs to verify that A is consistent with the implicit input y. Using the "systematic" nature of the given reduction, it also knows that y ought to be "contained" in A. More specifically, it knows that there is some subset H of A such that the evaluation of the polynomial A on the set H should be equal to the string y. In what follows we abstract this problem as that of building a PCPP-verifier for "systematic" Reed–Solomon codes. Such a verifier is given two oracles, one for a function $f : H \to \mathbb{F}$ (representing the implicit input y above), and the other for a (supposedly polynomial) function $p : S \to \mathbb{F}$, and attempts to verify that p is a polynomial of the appropriate degree that agrees with the function f. We formalize the task below and state our main result for this task.

DEFINITION 3.14 (systematic RS-codes). *For field $\mathbb{F}$, subsets $S, H \subseteq \mathbb{F}, |H| \leq |S|/2$, and integer $d \leq |S|/2$ let $\text{RS}_{\text{sys}}(\mathbb{F}, S, H, d)$ be the set of pairs of functions $(f : H \to \mathbb{F}, p : S \to \mathbb{F})$, such that $p \in \text{RS}(\mathbb{F}, S, d)$ and the polynomial corresponding to p agrees with f on H. The pair language* PAIR-RS_{sys} *is the set of pairs with explicit input $(\mathbb{F}, S, H, d)$ as above and implicit input $(f, p) \in \text{RS}_{\text{sys}}(\mathbb{F}, S, H, d)$. Similarly, the pair language* PAIR-ADDITIVE-RS_{sys} *(*PAIR-SMOOTH-RS_{sys}*, respectively) is the restriction of* PAIR-RS_{sys} *to pairs with $\mathbb{F}, S$ as in Theorem* 3.2 *(Theorem* 3.4*, respectively).*

Notice in Definition 3.14 we do not require H to be a subset of S, nor do we assume $H \cap S = \emptyset$. Furthermore, we allow d to be greater than $|H| - 1$, in which case there are several polynomials of degree d that all agree with f on H.

Recall that when building PCPP-verifiers we need to specify our distance measure. Since typically $|H| \ll |S|$, the standard Hamming distance is not a good measure because under this measure (f, p) is close to RS_{sys} whenever p is low degree, regardless

[2]Indeed, we do not know of a generic reduction that, when given a pair language L with a systematic reduction to L' and a PCPP-verifier for L', can construct an efficient PCPP-verifier for L.

of the amount of agreement between p and f. To amend this we use the following weighted Hamming distance:

$$\mathsf{Hamming}^{\frac{1}{2}}_{\mathbb{F}}((f,p),(f',p')) = \frac{1}{2}(\mathsf{Hamming}_{\mathbb{F}}(f,f') + \mathsf{Hamming}_{\mathbb{F}}(p,p')).$$

The main theorem of this section gives an efficient PCPP for the language of systematic Reed–Solomon codes. Its proof is deferred to subsection 4.3.

THEOREM 3.15 (PCPPs for systematic RS-codes).

$$\begin{array}{l}\text{PAIR-ADDITIVE-RS}_{\text{sys}},\\ \text{PAIR-SMOOTH-RS}_{\text{sys}}\end{array} \in \mathbf{Strong\text{-}PCPP}_{\delta/\operatorname{polylog} n}\left[\begin{array}{l}\mathsf{randomness}\ \log(n\cdot\operatorname{polylog} n),\\ \mathsf{query}\ \operatorname{polylog} n,\\ \mathsf{distance}\ \mathsf{Hamming}^{\frac{1}{2}}_{\mathbb{F}}\end{array}\right].$$

3.4.1. Proof of quasilinear PCPP Theorem 2.10. We now show how to use Theorems 3.10 and 3.15 to construct efficient PCPP-verifiers for all PAIR-NTIME languages.

Proof of Theorem 2.10. Let (x,y) be an instance of PAIR-$L \in \text{NTIME}(t(n))$ with $|y| = N$. The PCPP-verifier starts by reducing x to an instance $\phi = (\mathbb{F}, \{\text{AFF}_1, \ldots, \text{AFF}_k\}, H, C\}$ of ALGEBRAIC-CSP as in Theorem 3.10. Let $m : \{1,\ldots,N\} \to \mathbb{F}$ be the efficiently computable injective mapping as per Definition 3.9. Let $m([N]) = \{m(1),\ldots,m(N)\} \subseteq \mathbb{F}$. From here on we view y as a function from $m([N])$ to $\mathbb{F}$ by associating $\{0,1\}$ with the same elements in $\mathbb{F}$. Verifier expects oracle access to a proof of proximity comprised of the following:

- A PCP π for x as described in the proof of Theorem 2.2. In particular, the PCP is comprised of functions $p_0, p_1 : \mathbb{F} \to \mathbb{F}$ and subproofs π_0, π_1.
- A proof of proximity for PAIR-ADDITIVE-$\text{RS}_{\text{sys}}(\mathbb{F},\mathbb{F},m([N]),|H|-1)$, denoted π_2.

Verifier operation. The verifier invokes the PCP-verifier described in the proof of Theorem 2.2 on explicit input x and proof π. Reusing randomness, the verifier invokes the PCPP-verifier for the pair language PAIR-ADDITIVE-RS_{sys} described in Theorem 3.15 on explicit input $(\mathbb{F},\mathbb{F},m([N]),|H|-1)$, implicit input pair (y,p_0), and proof π_2. The verifier accepts iff both subverifiers accept. Notice that Theorems 2.2 and 3.15 imply the randomness and query complexity are as claimed.

Completeness. Suppose $(x,y) \in$ PAIR-L and let ϕ be the instance of ALGEBRAIC-CSP that x is reduced to as per Theorem 3.7. By Theorem 3.10, y agrees with p_0 on $m([N])$ and p_0 is an evaluation of a polynomial satisfying ϕ. Completeness now follows from Theorems 2.2 and 3.15.

Soundness. Suppose y is δ-far from L_x in distance measure $\mathsf{Hamming}^{\frac{1}{2}}_{\mathbb{F}}$. There are several cases to consider. First, if $x \notin L$ in which case L_x is empty and $\delta = 1$, then Theorem 2.2 implies the first subtest of our verifier rejects with probability $\delta/\operatorname{polylog} n$. From here on we assume $x \in L$. If p_0 is not $(1/100)$-close to an evaluation of a polynomial of degree $\le |H|-1$ that satisfies ϕ, then the soundness part of the proof of Theorem 2.2 implies the first subtest of our verifier rejects with probability $\ge 1/(100\cdot\operatorname{polylog} n) \ge \delta/\operatorname{polylog} n$. Finally, suppose p_0 is $(1/100)$-close to evaluation of a polynomial A satisfying ϕ and let $y' : m([N]) \to \mathbb{F}$ be the evaluation of A on $m([N])$. Theorem 3.10 implies y' satisfies x, so by assumption y is δ-far from y'. Thus, the pair of functions (y,p_0) is $(\delta/2)$-far from $\text{RS}_{\text{sys}}(\mathbb{F},\mathbb{F},m([N]),|H|-1)$, so

Theorem 3.15 implies that the second subtest rejects (y, p_0) with probability at least $\delta/\operatorname{polylog} n$, completing the proof of Theorem 2.10. □

3.5. Organization of the rest of the paper. We have thus far proved our main theorems (Theorems 2.2, 2.10, and 2.13) assuming the NTIME-completeness result for ALGEBRAIC-CSP (Theorems 3.7 and 3.10) and PCPPs for RS-codes (Theorem 3.2), for vanishing Reed–Solomon codes (Lemma 3.12), and for systematic Reed–Solomon codes (Theorem 3.15). In the following sections we give proofs for these claims. We remark that the sections may be read in any order. The order in which they are sequenced here merely reflects our opinion of the complexity of the proofs.

In section 4 we assume a PCPP for Reed–Solomon codes and give PCPPs for vanishing and systematic Reed–Solomon codes. We also show how to verify vanishing properties of multivariate polynomials in this section (see Lemma 4.7 in subsection 4.4), a result that may be of independent interest. In section 5 we prove the NTIME completeness of ALGEBRAIC-CSP and PAIR-ALGEBRAIC-CSP. In section 6 we give the PCPP for RS-codes over fields of characteristic two, which is our central technical result. Finally, in section 7, we give an analogous PCPP for RS-codes over smooth fields.

4. PCPPs for vanishing and systematic Reed–Solomon codes. In this section, we show how one can test various properties of polynomials given by an oracle, once we have the ability to test that an oracle is close to a polynomial.

The first such property is to verify that a univariate function f is close to some polynomial P that *vanishes* on a prespecified set H. This property was used crucially in building a PCP for NP languages in subsection 3.3.

The PCPP for vanishing RS-codes immediately leads to a PCPP to verify if two given oracles f_1 and f_2 are close to polynomials that agree on the prespecified set of inputs. (This task reduces to verifying whether $f_1 - f_2$ represents a vanishing RS-code.) We refer to this property as "agreeing" Reed–Solomon codes.

We then use the PCPP for agreeing Reed–Solomon codes to get a PCPP for systematic RS-codes. Recall that here, our goal was to take two oracles for functions $f : H \to \mathbb{F}$ and $p : S \to \mathbb{F}$ and verify that p is close to a polynomial P that agrees with f on H. This PCPP was crucial to our PCPP Theorem 2.10.

Finally, we show how to extend our PCPP for vanishing RS-codes to a PCPP for vanishing multivariate polynomial codes even though we do not use this result anywhere in the paper. (However, it was extensively used in previous PCP constructions.)

We note that all the constructions are quite simple and differ from previous such "tests" in a crucial way. Whereas previous tests of properties as above attempt to use the fact that the oracle being tested is close to a polynomial, they do not seem to explicitly use the fact that a low-degree test is available and can be used to test other functions that may be provided by the prover. Our constructions exploit this additional feature to simplify many known tests.

4.1. PCPPs for vanishing Reed–Solomon—Proof of Lemma 3.12. Recall the notion of a vanishing RS-code from Definition 3.11.

LEMMA 4.1 (Lemma 3.12, restated). *Suppose a field $\mathbb{F}$, $S \subseteq \mathbb{F}$, and an integer d are such that*

$$\mathrm{RS}(\mathbb{F}, S, d) \in \mathbf{Strong\text{-}PCPP}_{s(\delta)} \left[\begin{array}{l} \mathsf{randomness}\ r, \\ \mathsf{query}\ q, \\ \mathsf{distance}\ \mathsf{Hamming}_{\mathbb{F}} \end{array} \right].$$

Then, for any $H \subset \mathbb{F}$ and $s'(\delta) = \min\{\delta/2, s(\delta/2)\}$,

$$\mathrm{VRS}(\mathbb{F}, S, H, d) \in \mathbf{Strong\text{-}PCPP}_{s'(\delta)} \left[\begin{array}{l} \mathsf{randomness}\ \max\{r, \log|S|\}, \\ \mathsf{query}\ q+2, \\ \mathsf{distance}\ \mathsf{Hamming}_{\mathbb{F}} \end{array} \right].$$

The key observation in our proof is that a degree-d polynomial $P(z)$ vanishes on H iff the polynomial $g_H(z) \triangleq \prod_{h \in H}(z-h)$ divides $P(z)$, i.e., iff there exists a polynomial $\tilde{P}, \deg(\tilde{P}) \leq d - |H|$ such that $P(z) = g_H(z) \cdot \tilde{P}(z)$.

Proof. The PCPP-verifier for $\mathrm{VRS}(\mathbb{F}, S, H, d)$ has oracle access to implicit input $p : S \to \mathbb{F}$ and a proof combined of two parts: (i) a function $\tilde{p} : S \to \mathbb{F}$ (a supposed evaluation of $\tilde{P}$ on S) and (ii) a proof of proximity $\tilde{\pi}$ to $\mathrm{RS}(\mathbb{F}, S, d - |H|)$. Notice that the proof length is $|S| + |\tilde{\pi}|$. The verifier operates as follows.

- Toss $\max\{r, \log|S|\}$ random coins. Let R denote the random outcome.
- Invoke an assumed RS-verifier using randomness R on explicit input $(\mathbb{F}, S, d - |H|)$, implicit input $\tilde{p}$, and proof $\tilde{\pi}$. Reject if the verifier rejects. Otherwise,
- pick random $\alpha \in S$ (using randomness R); read $p(\alpha)$ and $\tilde{p}(\alpha)$; accept iff $p(\alpha) = g_H(\alpha) \cdot \tilde{p}(\alpha)$.

Notice that $g_H(\alpha)$ can be computed in time $\mathrm{poly}(|H| \cdot \log|\mathbb{F}|)$ by the verifier because H is given as an explicit input. Thus, the running time is as claimed, and so are the randomness and query complexity, by construction. Completeness follows by taking $\tilde{p}$ to be the evaluation of $\tilde{P}(z) \triangleq P(z)/g_H(z)$ and taking $\tilde{\pi}$ to be $\tilde{p}$'s proof of proximity to $\mathrm{RS}(\mathbb{F}, S, d - |H|)$.

As to the soundness, assume p is δ-far from $\mathrm{VRS}(\mathbb{F}, S, H, d)$. If $\tilde{p}$ is $\delta/2$-far from $\mathrm{RS}(\mathbb{F}, S, d - |H|)$, then by assumption the RS-verifier rejects $\tilde{p}$ with probability at least $s(\delta/2)$ and we are done. Otherwise, $\tilde{p}$ is $\delta/2$-close to some polynomial Q of degree $\leq d - |H|$. Let $q : S \to \mathbb{F}$ be the evaluation of Q on S. Notice that the function $\tilde{p} \cdot g_H$ is $\delta/2$-close to $q \cdot g_H$ and the latter function is, by construction, a codeword of $\mathrm{VRS}(\mathbb{F}, S, H, d)$. By assumption, p is $\delta/2$-far from $\tilde{p} \cdot g_H$; hence the last subtest of the verifier rejects with probability at least $\delta/2$. This completes our proof. ∎

4.2. Agreeing Reed–Solomon codes. We now show how to extend the PCPP of the previous section to test if two polynomials agree on a given set. Two polynomials $P_1(z), P_2(z)$ are said to *agree* on $H \subseteq \mathbb{F}$ if $P_1(z) = P_2(z)$ for all $z \in H$. Below we formalize the problem of testing agreement.

DEFINITION 4.2 (agreeing RS-codes). *For field $\mathbb{F}$, subsets $S, H \subseteq \mathbb{F}$, and integers $|S|/2 \geq d_1 \geq d_2$ let $\mathrm{RS}_{\mathrm{agr}}(\mathbb{F}, S, H, d_1, d_2)$ be the set of pairs of functions $p_1, p_2 : S \to \mathbb{F}$, such that $p_1 \in \mathrm{RS}(\mathbb{F}, S, d_1), p_2 \in \mathrm{RS}(\mathbb{F}, S, d_2)$, and the polynomial corresponding to p_1 agrees with the polynomial corresponding to p_2 on H. The pair language* PAIR-$\mathrm{RS}_{\mathrm{agr}}$ *is the set of pairs with explicit input $(\mathbb{F}, S, H, d_1, d_2)$ as above and implicit input $(p_1, p_2) \in \mathrm{RS}_{\mathrm{agr}}(\mathbb{F}, S, H, d_1, d_2)$. Similarly, the pair language* PAIR-ADDITIVE-$\mathrm{RS}_{\mathrm{agr}}$ *(*PAIR-SMOOTH-$\mathrm{RS}_{\mathrm{agr}}$*, respectively) is the restriction of* PAIR-$\mathrm{RS}_{\mathrm{agr}}$ *to pairs with $\mathbb{F}, S$ as in Theorem* 3.2 *(Theorem* 3.4*, respectively).*

LEMMA 4.3. *Assume a field $\mathbb{F}$, $S \subseteq \mathbb{F}$, and integers $d_2 \le d_1 \le |S|/2$ satisfy*

$$\begin{matrix}\mathrm{RS}(\mathbb{F}, S, d_1),\\ \mathrm{RS}(\mathbb{F}, S, d_2),\\ \mathrm{VRS}(\mathbb{F}, S, d_1)\end{matrix} \in \mathbf{Strong\text{-}PCPP}_{s(\delta,|S|)} \left[\begin{array}{l}\text{randomness } r,\\ \text{query } q,\\ \text{distance Hamming}_{\mathbb{F}}\end{array}\right],$$

where s is monotone nondecreasing in δ. Then for any $H \subset \mathbb{F}$,

$$\mathrm{RS}_{\mathrm{agr}}(\mathbb{F}, S, H, d_1, d_2) \in \mathbf{Strong\text{-}PCPP}_{s(\delta/8,|S|)} \left[\begin{array}{l}\text{randomness } r,\\ \text{query } q+2,\\ \text{distance Hamming}_{\mathbb{F}}\end{array}\right].$$

Proof. The main idea is that $P_1(z)$ agrees with $P_2(z)$ on H iff $P_1(z) - P_2(z)$ vanishes on H, so we apply the PCPP from Lemma 3.12 to this difference. Details follow.

The verifier for $\mathrm{RS}_{\mathrm{agr}}(\mathbb{F}, S, H, d_1, d_2)$ has oracle access to implicit inputs $p_1, p_2 : S \to \mathbb{F}$ and proof of proximity comprised of

- proof of proximity π_1 to $\mathrm{RS}(\mathbb{F}, S, d_1)$,
- proof of proximity π_2 to $\mathrm{RS}(\mathbb{F}, S, d_2)$, and
- proof of proximity π_3 to $\mathrm{VRS}(\mathbb{F}, S, d_1)$.

The verifier's operation is to invoke the following three subtests using the same randomness across all tests and accepting iff all of them accept:

- Invoke verifier for $\mathrm{RS}(\mathbb{F}, S, d_1)$ on implicit input p_1 and proof π_1.
- Invoke verifier for $\mathrm{RS}(\mathbb{F}, S, d_2)$ on implicit input p_2 and proof π_2.
- Invoke verifier for $\mathrm{RS}_H(\mathbb{F}, S, d_1)$ on implicit input $p_1 - p_2$ and proof π_3. Querying $p_1 - p_2$ on $\alpha \in S$ is performed by querying $p_1(\alpha), p_2(\alpha)$ and taking their difference.

All properties can be checked as in the proof of Lemma 3.12. For an illustration, consider the soundness. Suppose the pair of functions (p_1, p_2) is δ-far from $\mathrm{RS}_{\mathrm{agr}}(\mathbb{F}, S, H, d_1, d_2)$. If either one of p_1, p_2 is $\delta/8$-far from $\mathrm{RS}(\mathbb{F}, S, d_1), \mathrm{RS}(\mathbb{F}, S, d_2)$, respectively, then (the first/second subtest of) the verifier rejects with probability $s(\delta/8, |S|)$. Otherwise, $q = (p_1 - p_2)$ is $\delta/4$-close to a polynomial of degree d_1 that by assumption does not vanish on H. Since $d_1 \le |S|/2$ and $\delta \le 1$ we conclude q is $1/4$-far from $\mathrm{VRS}(\mathbb{F}, S, H, d_1)$ in which case the third subtest of the verifier rejects with probability $\ge s(1/4, |S|) \ge s(\delta/8, |S|)$. The last inequality follows from monotonicity of s. ∎

The previous lemma combined with Lemma 3.12 and Theorems 3.2 and 3.4 immediately implies the following.

COROLLARY 4.4 (PCPPs for agreeing RS-codes).

$$\begin{matrix}\text{PAIR-ADDITIVE-RS}_{\mathrm{agr}},\\ \text{PAIR-SMOOTH-RS}_{\mathrm{agr}}\end{matrix} \in \mathbf{Strong\text{-}PCPP}_{\delta/\operatorname{polylog} n} \left[\begin{array}{l}\text{randomness } \log(n \cdot \operatorname{polylog} n),\\ \text{query } O(1),\\ \text{distance Hamming}_{\mathbb{F}}\end{array}\right].$$

4.3. PCPP for systematic Reed–Solomon codes: Proof of Theorem 3.15. Recall the definition of the systematic RS-code (Definition 3.14) and the related notation presented in subsection 3.4. We now prove Theorem 3.15, restated below.

THEOREM 4.5 (Theorem 3.15, restated).

$$\begin{array}{l}\text{PAIR-ADDITIVE-RS}_{\text{sys}},\\ \text{PAIR-SMOOTH-RS}_{\text{sys}}\end{array} \in \mathbf{Strong\text{-}PCPP}_{\delta/\operatorname{polylog} n}\left[\begin{array}{l}\text{randomness } \log(n\cdot\operatorname{polylog} n),\\ \text{query } \operatorname{polylog} n,\\ \text{distance Hamming}_{\mathbb{F}}^{\frac{1}{2}}\end{array}\right].$$

To prove the theorem we apply induction to the following lemma, the proof of which appears below. Roughly, the lemma says that if we have PCPPs for systematic and agreeing RS-codes of size $n/2$, then we can construct systematic codes of size n. Intuitively, the proof is as follows. To verify that a message is indeed encoded by a codeword, we split the message into two parts of equal length. We ask for the encoding of each of these submessages and verify agreement of the subencodings with the encoding of the large message. This part uses PCPPs for agreeing codes described in the previous section. Then we pick one of the submessages at random and verify that it is consistent with its supposed subencoding and for this part we use induction. Details follow.

LEMMA 4.6. *If $H, S \subseteq \mathbb{F}$, and $d \le |S|/2$ satisfy the following conditions:*

1. *there exist $S_0, S_1 \subseteq S, |S_0|, |S_1| = |S|/2$, and a partition $H_0 \cup H_1 = H, |H_0|, |H_1| = |H|/2$ and these sets are computable in time t_0,*
2. *we have*

$$\operatorname{RS}(\mathbb{F}, S, d) \in \mathbf{Strong\text{-}PCPP}_{s_1(\delta,|S|)}\left[\begin{array}{l}\text{randomness } r_1,\\ \text{query } q_1,\\ \text{distance Hamming}_{\mathbb{F}}\end{array}\right],$$

3. *for $i = 0, 1$ we have*

$$\operatorname{RS}_{\text{agr}}(\mathbb{F}, S, H_i, d, |H_i|-1) \in \mathbf{Strong\text{-}PCPP}_{s_2(\delta,|S|)}\left[\begin{array}{l}\text{randomness } r_2,\\ \text{query } q_2,\\ \text{distance Hamming}_{\mathbb{F}}\end{array}\right],$$

4. *for $i = 0, 1$ we have*

$$\operatorname{RS}_{\text{sys}}(\mathbb{F}, S_i, H_i, |H_i|-1) \in \mathbf{Strong\text{-}PCPP}_{s_3(\delta,|S_i|)}\left[\begin{array}{l}\text{randomness } r_3,\\ \text{query } q_3,\\ \text{distance Hamming}_{\mathbb{F}}^{\frac{1}{2}}\end{array}\right],$$

and s_3 is subadditive, i.e., $s_3(\delta_0, |S_0|) + s_3(\delta_1, |S_1|) \ge s_3(\delta_0 + \delta_1, |S_i|)$,

then for any $0 < \alpha < 1/16$,

$$\operatorname{RS}_{\text{sys}}(\mathbb{F}, S, H, d) \in \mathbf{Strong\text{-}PCPP}_{s(\delta,|S|)}\left[\begin{array}{l}\text{randomness } r,\\ \text{query } q,\\ \text{distance Hamming}_{\mathbb{F}}^{\frac{1}{2}}\end{array}\right],$$

where

$$\begin{aligned} s(\delta, |S|) &= \min\left\{s_1(\alpha\delta, |S|), s_2(\alpha\delta, |S|)/2, \frac{1}{2}s_3((2-\alpha)\delta, |S|/2)\right\},\\ r &= \max\{r_1, r_2, r_3\} + 1,\\ q &= q_1 + q_2 + q_3. \end{aligned}$$

Proof of Theorem 3.15. Consider first the case of PAIR-ADDITIVE-$\mathrm{RS}_{\mathrm{sys}}$. We need to prove there exists a constant $c \geq 1$ that will be specified later such that for any $\mathbb{F}$ of characteristic 2, linear space $S \subseteq \mathbb{F}$, $|S| = n$, set $H \subset \mathbb{F}, |H| = 2^\ell \leq |S|/2$, and $d \leq |S|/2$ we have

$$\mathrm{RS}_{\mathrm{sys}}(\mathbb{F}, S, H, d) \in \mathbf{Strong\text{-}PCPP}_{\delta/(\log n)^c} \left[\begin{array}{l} \mathsf{randomness}\ \log(n \cdot \mathrm{polylog}\, n), \\ \mathsf{query}\ \mathrm{polylog}\, n, \\ \mathsf{distance}\ \mathsf{Hamming}_{\mathbb{F}} \end{array} \right].$$

Our proof is by induction on n, using Lemma 4.6. The base case of constant n follows because a verifier can query all entries in the implicit input and reject any pair of functions (f, p) that is not in $\mathrm{RS}_{\mathrm{sys}}(\mathbb{F}, S, H, d)$.

As to the inductive step, partition H into two equal sets H_0, H_1 arbitrarily. Let $S_0 = S_1$ be a $(k-1)$-dimensional space. Part 1 of Lemma 4.6 holds by construction. Parts 2 and 3 follow from Theorem 3.2 and Corollary 4.4, respectively, with

$$s_1(\delta, n), s_2(\delta, n) \geq \delta/(\log n)^{c'}, \quad q_1, q_2 = \mathrm{polylog}\, n, \quad r_1, r_2 = \log(n \cdot \mathrm{polylog}\, n),$$

where c' is a constant. Part 4 holds by induction with

$$s_3(\delta, n/2) = \delta/((\log n) - 1)^c, \quad q_3 = \mathrm{poly}((\log n) - 1), \quad r_3 \leq \log(n \cdot \mathrm{polylog}\, n).$$

Notice that s_3 is subadditive. Apply Lemma 4.6 with $\alpha = 1/\log n$. Randomness and query complexities follow immediately and the verifier's running time is polynomial. As to soundness, notice that $\frac{1}{2} s_3((2-\alpha)\delta, n/2) \geq (1 - 1/\log n)\delta/(\log n - 1)^c \geq \delta/\log^c n$. Thus, by selecting $c > c' + 1$ we conclude that

$$s(\delta, n) \geq \min\{\delta/\log^{c'+1} n, \delta/\log^c n\} \geq \delta/\log^c n.$$

This completes the proof.

Regarding PAIR-SMOOTH-$\mathrm{RS}_{\mathrm{sys}}$, change $S = \langle \omega \rangle$ and $S_0 = S_1 = \langle \omega^2 \rangle$, and use Theorem 3.4. The rest of the proof is identical. □

Proof of Lemma 4.6. To prove that p is an evaluation of a polynomial P that agrees with f on H, we request that the prover provide evaluations of the polynomials that agree with P on the two partitions of H. We test agreement of p with these two polynomials, denoted p_0, p_1, and then split f to two corresponding parts and recurse. Details follow. We describe the proof of proximity, followed by the verifier's operation, and conclude with completeness and soundness analysis.

Proof of proximity. The proof for the implicit input pair $f : H \to \mathbb{F}, p : S \to \mathbb{F}$ is defined recursively. In the base case ($|S| = O(1)$) the proof is empty. Otherwise, it is comprised of

- one proof of proximity π to $\mathrm{RS}(\mathbb{F}, S, d)$,
- two functions $p_0, p_1 : S \to \mathbb{F}$,
- two proofs of proximity π_0, π_1 to $\mathrm{RS}_{\mathrm{agr}}(\mathbb{F}, S, H_0, d, |H_0| - 1)$ and $\mathrm{RS}_{\mathrm{agr}}(\mathbb{F}, S, H_1, d, |H_1| - 1)$, respectively, and
- two proofs of proximity π'_0, π'_1 to $\mathrm{RS}_{\mathrm{sys}}(\mathbb{F}, S_0, H_0, |H_0| - 1)$ and to $\mathrm{RS}_{\mathrm{sys}}(\mathbb{F}, S_1, H_1, |H_1| - 1)$, respectively, defined recursively.

Verifier operation. Let $f_i : H_i \to \mathbb{F}$ be the restriction of the function f to domain H_i and let p'_i be the restriction of the function p_i to domain S_i for $i = 0, 1$. The verifier tosses $r = \max\{r_1, r_2, r_3\} + 1$ coins, sets $i \in \{0, 1\}$ according to the first coin, and performs the following subtests reusing the remaining $r - 1$ coins across different tests:

- Invoke verifier for $\mathrm{RS}(\mathbb{F}, S, d)$ on input p and proof π.
- Invoke verifier for $\mathrm{RS}_{\mathrm{agr}}(\mathbb{F}, S, H_i, d, |H_i| - 1)$ on input pair (p, p_i) and proof π_i.
- Invoke verifier for $\mathrm{RS}_{\mathrm{sys}}(\mathbb{F}, S_i, H_i, |H_i| - 1)$ on input pair (f_i, p'_i) and proof π'_i.
- Accept iff all aforementioned tests accept.

Basic properties. The randomness is r, by construction. The query complexity is the sum of queries made by the various subtests, as claimed.

Completeness. Assume $(f, p) \in \mathrm{RS}_{\mathrm{sys}}(\mathbb{F}, S, H, d)$. Since p is of degree $\leq d$ there exists a proof π accepted by the first subtest of the verifier with probability one. Let p_i be the polynomial of degree $|H_i| - 1$ that agrees with f_i (on H_i). By construction p agrees with p_i on H_i. Thus, there exist proofs π_i accepted by the second subtest of the verifier with probability 1. Finally, notice that $(f_i, p'_i) \in \mathrm{RS}_{\mathrm{sys}}(\mathbb{F}, S_i, H_i, |H_i| - 1)$, so there exist subproofs π'_i causing the third test of the verifier to accept with probability one.

Soundness. Assume the distance of (f, p) from $\mathrm{RS}_{\mathrm{agr}}(\mathbb{F}, S, H, d)$ is exactly δ. There are several cases to consider. (i) If p is $\alpha\delta$-far from $\mathrm{RS}(\mathbb{F}, S, d)$, then the first test of the verifier rejects with probability $s_1(\alpha\delta, |S|)$. (ii) If for some $i \in \{0, 1\}$ the distance of (p, p_i) from $\mathrm{RS}_{\mathrm{agr}}(\mathbb{F}, S, H_i, d, |H_i| - 1)$ is greater than $\alpha\delta$, then the second test of the verifier rejects with probability $s_2(\alpha\delta, |S|)/2$. The factor half decrease in rejection probability is due to the random selection of i. (iii) Otherwise, because (i) does not hold and $d \leq |S|/2$ and $\alpha < 1/16$, we conclude that p is $\alpha\delta$-close to a unique polynomial P, so f is $((2 - \alpha)\delta)$-far from the evaluation of P on H. Similarly, because (ii) does not hold, we conclude that each of p_0, p_1 is 1/8-close to the unique polynomial agreeing with P on H_i.

For $i = 0, 1$, let δ_i be the distance of (f_i, p'_i) from $\mathrm{RS}_{\mathrm{sys}}(\mathbb{F}, S_i, H_i, |H_i| - 1)$ using measure $\mathsf{Hamming}^{\frac{1}{2}}_{\mathbb{F}}$. Notice that $\delta_0 + \delta_1 \geq (2 - \alpha)\delta$ because p_i is 1/8-close to the evaluation of P on H, so p'_i is 1/4-close to the evaluation of P on H_i, while f is $((2 - \alpha)\delta)$-far from it. By induction, the rejection probability of the third subtest in this case is at least

$$\frac{1}{2}(s_3(\delta_0, |S|/2) + s_3(\delta_1, |S|/2)) \geq \frac{1}{2} s_3(\delta_0 + \delta_1, |S|/2) \geq \frac{1}{2} s_3((2 - \alpha)\delta, |S|/2).$$

Summing up, our rejection probability is at least as claimed and this completes our proof. □

4.4. PCPPs for multivariate polynomials and vanishing Reed–Muller codes. Finally, we give a generalization of Lemma 3.12 to the case of multivariate polynomials. This generalization would suffice to replace the sumcheck-based protocols in previous PCP constructions [5, 3, 2, 37, 27, 24, 11, 9].

In the multivariate problem we are given sets $S, H \subset \mathbb{F}$ and oracle access to a multivariate function $f : S^m \to \mathbb{F}$. We are asked to verify that f is close to a polynomial of degree $\leq d$ in each variable that evaluates to zero on H^m. Once again, we do not need to assume $H \subset S$. Recall that evaluations of low-degree multivariate polynomials form the well-known *Reed–Muller* code. We denote by $\mathrm{RM}(\mathbb{F}, S, d, m)$ the set of functions $p : S^m \to \mathbb{F}^m$ that are evaluations of m-variate polynomials of maximal individual degree d. We denote by $\mathrm{VRM}(\mathbb{F}, S, H, d, m)$ its subcode consisting of all evaluations of polynomials that vanish on H^m. Our main lemma of this section is the following.

LEMMA 4.7 (multivariate zero testing). *Suppose field $\mathbb{F}$, set $S \subseteq \mathbb{F}$, and integers d, m satisfy*

$$\mathrm{RM}(\mathbb{F}, S, d, m) \in \mathbf{Strong\text{-}PCPP}_{s(\delta)} \left[\begin{array}{l} \text{randomness } r, \\ \text{query } q, \\ \text{distance Hamming}_{\mathbb{F}} \end{array} \right].$$

Then, for any $H \subset \mathbb{F}$ and $s'(\delta) = \min\{s(\delta), 1 - ((m+1)\delta + (\frac{d}{|S|})^m)\}$,

$$\mathrm{VRM}(\mathbb{F}, S, H, d, m) \in \mathbf{Strong\text{-}PCPP}_{s'(\delta)} \left[\begin{array}{l} \text{randomness } r + m \log |S|, \\ \text{query } (m+1)(q+1), \\ \text{distance Hamming}_{\mathbb{F}} \end{array} \right].$$

Notice that the query complexity of previous solutions to this problem depended polynomially on the size of H. Our solution has query complexity that is independent of H and is based on a straightforward characterization of VRM that resembles Alon's combinatorial Nullstellensatz [1]). Before proving the lemma we first recall some (relatively well-known) results on testing proximity to Reed–Muller codes.

Testing proximity to multivariate polynomials. It is easy to extend the PCPP for the RS-code into one for the Reed–Muller code (based on multivariate polynomials), given the extensive literature on testing multivariate polynomials using axis parallel lines [4, 5, 20, 3, 37, 21].

For a set $S \subseteq \mathbb{F}$ and an m-variate function $f : S^m \to \mathbb{F}$, let $\delta_m^d(f)$ be the fractional distance of f from $\mathrm{RM}(\mathbb{F}, S, d, m)$. Let $\delta_{m,i}^d(f)$ denote the fractional distance of f from a polynomial of degree d in the ith variable, and an unbounded degree in all other variables. Finally, let $\mathbb{E}[\delta_{m,i}^d(f)]$ be the expectation of $\delta_{m,i}^d$ over random $i \in [m]$. The following lemma is a rephrasing of [3, Lemma 5.2.1]. Notice that Lemma 6.13 is a special case of it with tighter parameters.

LEMMA 4.8 (see [3]). *There exists a universal constant c such that for every $S \subset \mathbb{F}$ such that $|S| \geq \mathrm{poly}(m, d)$,*

$$\delta_m^d(f) \leq c \cdot m \cdot \mathbb{E}[\delta_{m,i}^d(f)].$$

This lemma and Theorem 3.2 imply short PCPPs for Reed–Muller codes.

LEMMA 4.9 (RM PCP of proximity). *Let $S \subset \mathbb{F}$ and d, m be integers such that $|S| \geq \mathrm{poly}(m, d)$ for the polynomial of Lemma 4.8 and suppose*

$$\mathrm{RS}(\mathbb{F}, S, d) \in \mathbf{Strong\text{-}PCPP}_{s(\delta)} \left[\begin{array}{l} \text{randomness } r, \\ \text{query } q, \\ \text{distance Hamming}_{\mathbb{F}} \end{array} \right].$$

Then

$$\mathrm{RM}(\mathbb{F}, S, d, m) \in \mathbf{Strong\text{-}PCPP}_{s(\delta)/m} \left[\begin{array}{l} \text{randomness } r + \log(m \cdot |S|^{m-1}), \\ \text{query } q, \\ \text{distance Hamming}_{\mathbb{F}} \end{array} \right].$$

Proof. The proof for a purported RM-codeword is the collection of proofs of proximity for each axis parallel line (to the RS-code). A line parallel to the ith axis is $\{(b_1, \ldots, b_{i-1}, x_i, b_{i+1}, \ldots, b_m) : x_i \in S\}$, where $b_1, \ldots, b_m \in S$. The verifier selects a random axis parallel line and invokes the RS-verifier of Definition 6.7 on the line and its proof. The proof follows from Lemma 4.8. □

Remark 4.10. A more query-efficient test can be constructed when $S = \mathbb{F}$. Instead of axis parallel lines, we use an ϵ-biased set of directions as in [11]. This results in proofs of similar length and query complexity and slightly larger randomness, but the soundness is as large as $\Omega(s(\delta))$ and independent of m.

Testing proximity to vanishing multivariate polynomials. We now move to the proof of Lemma 4.7. The catch in immediately extending the univariate verifier of Lemma 3.12 to even the bivariate case is that the "factoring" concept does not extend immediately. Specifically, if we are given that a bivariate polynomial $Q(x, y)$ has a zero at (α, β) this does not imply that $Q(x, y)$ has some nice factors. However, one can abstract a nice property about Q from this zero. Specifically, we can say that there exist polynomials $A(x, y), B(x, y)$ (of the right degree) such that $Q(x, y) = A(x, y) \cdot (x - \alpha) + B(x, y) \cdot (y - \beta)$. Thus to prove that $Q(\alpha, \beta) = 0$, we may ask the prover to give an evaluation of $Q(x, y)$, $A(x, y)$, and $B(x, y)$. We can then test that Q, A, and B are of low degree and that they satisfy the identity above. Extending this idea to m-variate polynomials that are zero on an entire generalized rectangle is straightforward. The technical lemma giving the identity is included below. The lemma is also a key ingredient in Alon's combinatorial Nullstellensatz [1]. We include a proof for completeness.

LEMMA 4.11. *Let $Q(x_1, \ldots, x_m)$ be a polynomial over $\mathbb{F}_Q$ of degree d in each of m variables. Let $H \subseteq \mathbb{F}_Q$ and let $g_H(z) \stackrel{\text{def}}{=} \prod_{\beta \in H}(z - \beta)$. Then Q evaluates to 0 on H^m iff there exist m-variate polynomials $A_1, \ldots, A_m$ of individual degree at most d such that $Q(\vec{x}) = \sum_{i=1}^{m} A_i(\vec{x}) \cdot g_H(x_i)$.*

Remark 4.12. The lemma above is intentionally sloppy with degree bounds. While tighter degree bounds on A_i's can be obtained, this will not be needed for our PCPs.

Proof. One direction is immediate. If $Q(\vec{x}) = \sum_{i=1}^{m} A_i(\vec{x}) \cdot g_H(x_i)$ then $Q(\vec{\alpha}) = 0$ for every $\vec{\alpha} \in H^m$. The other direction is proved in three steps. First, we show that for any polynomial $P(x_1, \ldots, x_m)$ of degree d_j in x_j, and any $i \in \{1, \ldots, m\}$, there exist polynomials $B(x_1, \ldots, x_m)$ and $C(x_1, \ldots, x_m)$ of degree at most d_j in x_j, with the degree of C in x_i being at most $\min\{d_j, |H|-1\}$, such that $P(\vec{x}) = B(\vec{x}) \cdot g_H(x_i) + C(\vec{x})$. Second, we show that there exist polynomials $A_1, \ldots, A_m$ and R with the A_i's having degree at most d in each variable and R having degree at most $|H|-1$ in each variable such that $Q(\vec{x}) = \sum_{i=1}^{m} A_i(\vec{x}) \cdot g_H(x_i) + R(\vec{x})$, where Q is the polynomial from the lemma statement. In the final step, we show that $R(\vec{x}) = 0$, concluding the proof.

Step 1. Recall that any polynomial $f(x_i)$ can be written as $q(x_i) \cdot g_H(x_i) + r(x_i)$, where r has degree less than $|H|$. Applying this fact to the monomials x_i^D for nonnegative D we find that there exist polynomials $q_D(x_i)$ and $r_D(x_i)$, with degree of q_D being at most D and degree of r_D being less than $|H|$, such that $x_i^D = q_D(x_i) \cdot g_H(x_i) + r_D(x_i)$. Now consider any polynomial $P(x_1, \ldots, x_m)$ of degree d_i in x_i. Suppose $P(\vec{x}) = \sum_{D=0}^{d_i} P_i(\vec{x}') \cdot x^D$, where $\vec{x}' = (x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_m)$. Writing the monomials x_i^D in terms of the q_D's and r_D's, we get

$$P(\vec{x}) = \left(\sum_{D=0}^{d_i} P_i(\vec{x}') q_D(x_i) \right) \cdot g_H(x_i) + \left(\sum_{D=0}^{d_i} P_i(\vec{x}') r_D(x_i) \right).$$

Letting $B(\vec{x}) = \sum_{D=0}^{d_i} P_i(\vec{x}') q_D(x_i)$ and $C(\vec{x}) = (\sum_{D=0}^{d_i} P_i(\vec{x}') r_D(x_i))$ yields the polynomials as claimed. In particular, the degrees of B and C in any variable are no more than that of P, and the degree of C in x_i is smaller than $|H|$.

Step 2. We now claim that there exist polynomials $A_1, \ldots, A_m$ and $R_0, \ldots, R_m$ such that for every $j \in \{0, \ldots, m\}$, $Q(\vec{x}) = \sum_{i=0}^{j} A_i(\vec{x}) \cdot g_H(x_i) + R_j(\vec{x})$, with A_i's being of degree at most d in each variable and R_j being of degree less than $|H|$ in $x_1, \ldots, x_j$ and of degree at most d in the remaining variables. The proof is straightforward by induction on j, with the induction step using Step 1 on the polynomial $P() = R_j()$ and the variable x_{j+1}. The final polynomials $A_1, \ldots, A_m$ and $R = R_m$ are the polynomials as required to yield the subclaim of this step.

Step 3. Finally, we note that for every $\vec{\alpha} \in H^m$, we have $R(\vec{\alpha}) = Q(\vec{\alpha}) - \sum_{i=1}^{m} A_i(\vec{\alpha}) \cdot g_H(\alpha_i) = 0 - \sum_{i=1}^{m} 0 = 0$. But R is a polynomial of degree less than $|H|$ in each variable and is zero on the entire box H^m. This can happen only if $R \equiv 0$. Thus we get that $Q(\vec{x}) = \sum_{i=1}^{m} A_i(\vec{x}) \cdot g_H(x_i)$, with the A_i's being of degree at most d in each variable, as required in the completeness condition. ∎

Proof of Lemma 4.7. As a proof of the proximity of $q \in \mathbb{F}^{S^m}$ to the code $\mathrm{VRM}(\mathbb{F}, S, d, m)$ our verifier expects (i) the evaluations of $A_1, \ldots, A_m$ from Lemma 4.11 on S^m, denoted $a_1, \ldots, a_m$, and (ii) for each of $q, a_1, \ldots, a_m$, a proof of proximity of A_i to $\mathrm{RM}(\mathbb{F}, S, d, m)$. Proof length is as claimed. The verifier operates as follows. First, it tests proximity of each of $q, a_1, \ldots, a_m$ to $\mathrm{RM}(\mathbb{F}, S, d, m)$. Then, a random $\langle \alpha_1, \ldots, \alpha_m \rangle \in S^m$ is selected and the verifier accepts iff $q(\vec{\alpha}) = \sum_{i=1}^{m} g_H(\alpha_i) \cdot a_i(\vec{\alpha})$. The query complexity is as claimed. Completeness follows from Lemma 4.11. As to the soundness, if any of $q, a_1, \ldots, a_m$ is δ-far from $\mathrm{RM}(\mathbb{F}, S, d, m)$, the verifier rejects with probability $s(\delta)$. Otherwise, q is δ close to a polynomial Q that does not vanish on H^m. If $A_1, \ldots, A_m$ are the polynomials closest to $a_1, \ldots, a_m$, respectively, then by Lemma 4.11 we get $Q(\vec{x}) \neq \sum_i A_i(\vec{x}) \cdot g_H(x_i)$ and Q has degree at most d in each variable. Thus, the two polynomials agree on $\leq d^m$ points, so the acceptance probability of the verifier is $\leq (m+1)\delta + (\frac{d}{|S|})^m$ as claimed. ∎

5. Quasilinear reductions of NTIME(n) to ALGEBRAIC-CSP.

In this section we show the completeness of ALGEBRAIC-CSP for NTIME classes, thereby proving Theorem 3.7 (restated below). We also show how to modify this proof to get a proof of Theorem 3.10, which shows the completeness of PAIR-ALGEBRAIC-CSP for PAIR-NTIME classes under systematic reductions.

THEOREM 5.1 (Theorem 3.7, restated). *There exist integers k, d such that for any proper complexity function $t : \mathbb{N}^+ \to \mathbb{N}^+$ and $L \in \mathrm{NTIME}(t(n))$ the following hold:*

1. *L is reducible to $\mathrm{ALGEBRAIC\text{-}CSP}_{k,d}$ in time $\mathrm{poly}\, t(n)$.*
2. *An instance of L of size n is reduced to an instance of $\mathrm{ALGEBRAIC\text{-}CSP}_{k,d}$ over field $\mathrm{GF}(2^\ell)$ of size $2^\ell \leq t(n)\,\mathrm{polylog}\, t(n)$ and characteristic 2, where $100(kd+1)(|H|-1) < 2^\ell \leq 200(kd+1)(|H|-1)$.*

5.1. Warmup—quadratic size reduction.

To illustrate the ideas used in the proof of Theorem 3.7, we start with a simpler proof of a weaker version of it, where the size blowup is quadratic rather than quasilinear. Our starting point is the following NP-complete language essentially from Cook's theorem [14]. (See also [36, proof of Theorem 8.2]).

DEFINITION 5.2 (domino tiling). *A domino tiling instance over alphabet Σ is a tuple of constraints $\psi = \{\hat{C}_{ij} : i, j \in \{0, \ldots, n-2\}\}$, where each constraint is a mapping $\hat{C}_{ij} : \Sigma^3 \to \{\mathtt{accept}, \mathtt{reject}\}$. An instance is satisfiable iff there exists a mapping $\hat{A} : \{0, n^2 - 1\} \to \Sigma$ such that for all $i, j \in \{0, \ldots, n-2\}$*

$$\hat{C}_{i,j}(\hat{A}(in+j), \hat{A}(in+j+1), \hat{A}((i+1)n+j) = \mathtt{accept}.$$

The language DOMINO-TILING$_\Sigma$ *is the set of all satisfiable instances over alphabet* Σ.

THEOREM 5.3 (DOMINO-TILING is NTIME-complete [14]). *There exists a finite size alphabet* Σ *such that if* $L \in \text{NTIME}(t(n))$ *for a proper complexity function* $t : \mathbb{N}^+ \to \mathbb{N}^+$, *then* L *is reducible to* DOMINO-TILING$_\Sigma$ *under quadratic size reductions.*

Our warmup version of Theorem 3.7 is the following.

THEOREM 5.4. *For every finite alphabet* Σ, *the language* DOMINO-TILING$_\Sigma$ *is reducible under linear sized reductions to* ALGEBRAIC-CSP$_{4,|\Sigma|}$.

Notice that although the reduction from DOMINO-TILING to ALGEBRAIC-CSP is linear, the reduction from a language $L \in \text{NTIME}(t(n))$ to DOMINO-TILING incurs a quadratic size blowup.

Proof. We reduce an instance ψ of DOMINO-TILING$_\Sigma$ to an instance $\phi = (\mathbb{F}, \{\text{AFF}_1, \ldots, \text{AFF}_4\}, H, C)$ as in Definition 3.6. We will make crucial use of the fact that the constraint $\hat{C}_{ij}$ depends on assignment entries whose indices are *linear functions* of i and j.

Fix $\mathbb{F}$ to be any finite field satisfying $100n^2 < |\mathbb{F}| \leq 200n^2$. Let ω be a generator of $\mathbb{F}^*$. Associate Σ with arbitrary elements of $\mathbb{F}$. View an assignment to ψ as a mapping $\hat{A} : \{w^{in+j} : i, j \in \{0, \ldots, n-1\}\} \to \Sigma$ where the domain and range of this mapping are subsets of $\mathbb{F}$. The arithmetized instance ϕ will be satisfied only by polynomials A that are a low-degree extension of an assignment $\hat{A}$ that satisfies ψ. Thus, the constraint polynomial C will ensure that (i) A takes only values in Σ on $I = \{w^{in+j} : i, j \in \{0, \ldots, n-1\}\}$ and (ii) the evaluation of A on I produces an assignment $\hat{A}$ that satisfies ψ. Details follow.

Define

$$\text{AFF}_1(x) = x;\ \text{AFF}_2(x) = x \cdot \omega^n;\ \text{AFF}_3(x) = x \cdot \omega, \text{AFF}_4(x) = x \cdot \omega^{-n^2},$$

$$H = I \cup \omega^{n^2} \cdot I = \{\{w^{in+j} : i \in \{0, \ldots, 2n-1\}, j \in \{0, \ldots, n-1\}\}.$$

Notice that $|I| = n^2$ and $|H| = 2n^2$. We now define the constraint polynomial C.

Notice that $\hat{C}_{i,j}$ can be interpreted as a function from $\Sigma^3 \subset \mathbb{F}^3$ to $\{0,1\} \subset \mathbb{F}$ and we associate 0 with `accept` and 1 with `reject`. Arithmetize this constraint by a trivariate polynomial $C_{i,j} : \mathbb{F}^3 \to \mathbb{F}$ of degree at most $|\Sigma| - 1$ in each variable, satisfying

$$C_{i,j}(\sigma_1, \sigma_2, \sigma_3) = \hat{C}_{i,j}(\sigma_1, \sigma_2, \sigma_3) \quad \forall \sigma_1, \sigma_2, \sigma_3 \in \Sigma. \tag{5.1}$$

For $\omega^{in+j} \in H$, let $P_{i,j}(x)$ be the unique polynomial of degree $|H| - 1$ that evaluates to 1 on ω^{in+j} and to 0 on every other element in H. Finally, let $P_\Sigma(x) = \prod_{\sigma \in \Sigma}(x - \sigma)$ be the unique monic nonzero polynomial of degree $|\Sigma|$ whose set of roots is precisely Σ. The constraint polynomial is

$$C(x, y_1, \ldots, y_4) = \sum_{i,j=0}^{n-2} P_{i,j}(x) \cdot C_{i,j}(y_1, y_2, y_3) + \sum_{i=n}^{2n-1} \sum_{j=0}^{n-1} P_{i,j}(x) \cdot P_\Sigma(y_4). \tag{5.2}$$

The polynomial $P_{i,j}$ is often used to "bundle" together many constraints and verify that all of them are satisfied, forming the algebraic analogue of an AND gate. The second summand on the right-hand side of (5.2) corresponds to the set of constraints (i) mentioned above, and the first summand corresponds to (ii).

Notice that C has degree $|H|-1$ in its first variable and degree $|\Sigma|$ in the remaining variables. We conclude that ϕ is a legal instance of ALGEBRAIC-CSP$_{4,|\Sigma|}$.

Completeness. Suppose $\psi \in$ DOMINO-TILING$_\Sigma$ and let $\hat{A}$ be a proof for ψ. Let A be the low-degree extension of $\hat{A}$; i.e., A is a polynomial of degree $\leq n^2 - 1$ satisfying $A(\omega^{in+j}) = \hat{A}(in + j)$ for all $i, j \in \{0, \ldots, n-1\}$. We now prove for all $x \in H$

$$C(x, A(x), A(\omega^n x), A(\omega x), A(\omega^{-n^2} x)) = 0.$$

If $x = \omega^{in+j} \in H$ then by definition of $P_{i,j}$ at most one summand of (5.2) can be nonzero. There are two cases to consider:

- $i \leq n-2$: The summand to consider is $P_{i,j}(\omega^{in+j}) \cdot \hat{C}_{i,j}(\hat{A}(\omega^{in+j}), \hat{A}(\omega^{in+j+1}), \hat{A}(\omega^{(i+1)n+j}))$. This summand vanishes because $\hat{A}$ satisfies $\hat{C}_{i,j}$.
- $i \geq n$: The summand to consider is $P_{i,j}(\omega^{in+j}) \cdot P_\Sigma(\hat{A}(\omega^{in+j}))$, which vanishes because $\hat{A}$ evaluates to Σ on I.

We conclude that $\phi \in$ ALGEBRAIC-CSP$_{4,|\Sigma|}$.

Soundness. Suppose $\phi \in$ ALGEBRAIC-CSP$_{4,|\Sigma|}$ and let A witness this. Let $\hat{A} : \{0, \ldots, n^2 - 1\}$ be defined by $\hat{A}(in + j) = A(\omega^{in+j})$. We claim $\hat{A}$ satisfies ψ. First, notice that the range of A on inputs from I is Σ. If this is not the case and $A(\omega^{in+j}) \notin \Sigma$, then $P_\Sigma(A(\omega^{in+j})) \neq 0$, so (5.2) does not vanish on $x = \omega^{n^2+in+j} \in H$.

Since A evaluates to Σ on I and for $\sigma_1, \sigma_2, \sigma_3 \in \Sigma$ (5.1) implies $C_{i,j}(\sigma_1, \sigma_2, \sigma_3) = 0$ iff $\hat{C}(\sigma_1, \sigma_2, \sigma_3) =$ `accept`, we conclude that $\hat{A}$ satisfies ψ so $\psi \in$ DOMINO-TILING$_\Sigma$. This completes our proof. □

5.2. Quasilinear size reduction. In this section we prove Theorem 3.7 and show that ALGEBRAIC-CSP is NTIME($t(n)$)-complete under quasilinear size reductions. Our proof is similar to that of Polishchuk and Spielman [37]; however, our ending point is a problem over univariate polynomials.

Overview. The reason we chose DOMINO-TILING as our starting point in the previous section was because this language was NP-complete and additionally had "nice" structure, in the sense that each constraint ($\hat{C}_{i,j}$) depended on assignment entries whose indices are *linear functions* of the constraint index. The problem with DOMINO-TILING is that the reduction from an arbitrary language in NTIME($t(n)$) to it results in instances of size $t^2(n)$. Thus, we are looking for an NP-complete language that has a similar "nice" structure, yet whose blowup factor, when reducing from a language in NTIME($t(n)$), is only quasilinear.

One such language is DE BRUIJN COLORING, first presented by Polishchuk and Spielman [37], based on a construction of [5]. First we will describe this language and state its completeness. Then we will arithmetize it and reduce it to ALGEBRAIC-CSP. The crucial observation in the arithmetization, given in Proposition 5.11, is that the de Bruijn graph can be embedded in an "affine" graph over a finite field (see Definition 5.9).

DE BRUIJN COLORING. Let $\sigma : \{0,1\}^k \to \{0,1\}^k$ be the cyclic permutation operator; i.e., for $w \in \{0,1\}^k, w = (w_1, \ldots, w_k)$ let $\sigma(w) = (w_k, w_1, \ldots, w_{k-1})$. Let $u \oplus v$ denote the bitwise xor of $u, v \in \{0,1\}^k$ and let $e_i \in \{0,1\}^k$ be the sequence that is zero on all but the ith coordinate, where it is one.

DEFINITION 5.5 (wrapped de Bruijn graph [39]). *The k-dimensional* wrapped de Bruijn graph *is the following directed graph $B_k = (V, E)$. Let m be the smallest power of 2 satisfying $m > 5k$. The vertex set is*

$$V = \{(w, i) : w \in \{0,1\}^k, i \in \{0, \ldots, m-1\}\}.$$

Each vertex $v = (w, i) : w \in \{0,1\}^k, i \in \{0, \ldots, m-1\}$, has two neighbors:

$$N_0(v) = (\sigma(w), (i + 1 \bmod m)), \quad N_1(v) = ((\sigma(w)) \oplus e_1, (i + 1 \bmod m)).$$

Remark 5.6. The definition in [39, section 4.3.2] is slightly different from the above; namely, it fixes $m = 5k + 1$. However, Theorem 5.8 holds for any $m > 5n$, as inspection of [39, section 4.3] reveals.

DEFINITION 5.7 (DE BRUIJN COLORING). *Let* $\hat{\Sigma} = \{0,1\}^4$. *The language* DE BRUIJN COLORING *has as its space of instances tuples of the form* $\psi = \{B_k, \hat{C}\}$, *where* $B_k = (V, E)$ *is a* k*-dimensional wrapped de Bruijn graph, and* $\hat{C} = \{\hat{C}_v : v \in V\}$ *is a set of constraints, where* $\hat{C}_v : \hat{\Sigma}^3 \to \{\texttt{accept}, \texttt{reject}\}$.

An instance is in the language DE BRUIJN COLORING *iff there exists an assignment* $\hat{A} : V \to \hat{\Sigma}$ *such that for all* $v \in V$ *we have* $\hat{C}_v(\hat{A}(v), \hat{A}(N_0(v)), \hat{A}(N_1(v))) = \texttt{accept}$.

THEOREM 5.8. DE BRUIJN COLORING *is NP-complete. Moreover, for any proper complexity function* $t : \mathbb{N}^+ \to \mathbb{N}^+$, *a language* $L \in \mathrm{NTIME}(t(n))$ *is reducible in time* $\mathrm{poly}\, t(n)$ *to an instance* $\psi = \{B_k, \hat{C}\}$ *of* DE BRUIJN COLORING, *where* $k = \lceil \log(t(n) \cdot O(\log^2 t(n))) \rceil$.

Proof. $L \in \mathrm{NTIME}(t(n))$ is reducible in time $\mathrm{poly}\, t(n)$ to an instance of CKTSAT of size $O(t(n) \log t(n))$ [29, 15]. This instance is reducible in time $\mathrm{poly}\, t(n)$ to an instance of DE BRUIJN COLORING of size $t(n)\,\mathrm{polylog}\, t(n)$ [37]. (See [39, section 4.3] for details.) ∎

To arithmetize an instance of DE BRUIJN COLORING we embed B_k in an *affine graph* as defined below. Recall an injective graph homomorphism of G to H is an injective mapping $f : V(G) \to V(H)$ such that if $(u, v) \in E(G)$ then $(f(u), f(v)) \in E(H)$. Further recall an affine map $\mathrm{AFF} : \mathbb{F} \to \mathbb{F}$ is of the form $\mathrm{AFF}(z) = az + b$ for $a, b \in \mathbb{F}$.

DEFINITION 5.9 (affine graph). *Let* $\mathcal{A}$ *be a set of affine maps over a field* $\mathbb{F}$. *The* affine graph $G(\mathbb{F}, \mathcal{A})$ *over* $\mathbb{F}$, *generated by* $\mathcal{A}$, *is the directed graph over vertex set* $\mathbb{F}$, *where each vertex* $v \in \mathbb{F}$ *is connected to* $\mathrm{AFF}(v)$ *for all* $\mathrm{AFF} \in \mathcal{A}$. *Notice that the outdegree of this graph is at most* $|\mathcal{A}|$.

We will use the following elementary properties of primitive polynomials (see [32, section 3.1]).

PROPOSITION 5.10. *Let* $S(x)$ *be a primitive polynomial of degree* s *over* GF(2). *Then, denoting* $\xi_i = x^i (\mathrm{mod}\ S(x))$, *we have that* $\xi_1, \ldots, \xi_{2^s} = \xi_0$ *are distinct polynomials over* GF(2) *of degree less than* s.

We now define a graph homomorphism injecting B_k to an affine graph of outdegree eight over $\mathrm{GF}(2^\ell)$ for any $\ell > k + \log 5k + 2$. Briefly, a vertex $(w, i) \in B_k$ will be mapped to a polynomial $p_{(w,i)} \in \mathrm{GF}(2^\ell)$. We will show that the polynomials corresponding to $(w, i+1)$ and $(w \oplus e_i, i+1)$ can be obtained by applying two out of eight possible affine shifts to $p_{(w,i)}$. In what follows, addition and multiplication are in $\mathrm{GF}(2^\ell)$ and we identify $\{0,1\}$ with GF(2).

PROPOSITION 5.11. *Let* m *be the smallest power of* 2 *satisfying* $m > 5k$. *Let* $\mathrm{GF}(2^\ell) = \mathrm{GF}(2)[x]/q(x)$, *where* $q(x)$ *is an irreducible polynomial of degree* ℓ. *Let* $S(x)$ *be a primitive polynomial of degree* $s = \log m$ *(note that* s *is an integer), and let* ξ_i *be as defined in Proposition* 5.10. *For* $((w_1, \ldots, w_k), i), w_j \in \{0,1\}, i \in [m]$, *let*

$$g(w) = x^s \cdot \sum_{j=1}^{k} w_j x^j \ ; \quad h(i) = \xi_i \ ; \quad f(w,i) = g(w) + h(i). \tag{5.3}$$

Then, the mapping $f : V(B_k) \to \mathrm{GF}(2^\ell)$ *is an injective homomorphism of* B_k

into the affine graph $G(\mathrm{GF}(2^\ell), \mathcal{A})$*, where*

(5.4)
$$\mathcal{A} = \left\{ \textsc{Aff}_b(\alpha) \triangleq x \cdot \alpha + b_1 S(x) + b_2 x^{s+1} + b_3 x^{s+k+1} : b = (b_1, b_2, b_3) \in \{0,1\}^3 \right\}.$$

Proof. Our mapping is injective. Note that $\deg(h(i)) < s$ for all $i \in [m]$, whereas the minimal degree of a nonzero term of $g(w)$ is $s+1$. Thus, $f(w,i) = f(w',i')$ iff $g(w) = g(w')$ and $h(i) = h(i')$. The former happens by definition iff $w = w'$ and the latter happens iff $i = i'$ because Proposition 5.10 implies $\xi_i \neq \xi_{i'}$ for all $i \neq i' \in [m]$.

To prove f is a homomorphism, we need to show that if $((w,i),(w',(i+1 \bmod m)))$ is an edge of $B_{k,m}$ then $f(w',(i+1 \bmod m)) = \textsc{Aff}_b(f(w,i))$ for some $b \in \{0,1\}^3$. There are eight cases to consider. Recall w' is either $\sigma(w)$ or $(\sigma(w)) \oplus e_1$. Note that $\ell > k+s+1$ so for all $w \in \{0,1\}^k$ we have that $x \cdot g(w) \bmod (q(x))$ is equal to $x \cdot g(w)$ as polynomials over $\mathrm{GF}(2)$. By definition of g we get

$$g(\sigma(w)) = \begin{cases} x \cdot g(w), & w_k = 0, \\ x \cdot g(w) + x^{s+k+1} + x^{s+1}, & w_k = 1. \end{cases}$$

Similarly,

$$g((\sigma(w)) \oplus e_1) = \begin{cases} x \cdot g(w) + x^{s+1}, & w_k = 0, \\ x \cdot g(w) + x^{s+k+1}, & w_k = 1. \end{cases}$$

Finally, by definition of h we get

$$h(i+1 \bmod m) = \begin{cases} x \cdot h(i), & \deg(h(i)) < s-1, \\ x \cdot h(i) + S(x), & \deg(h(i)) = s-1. \end{cases}$$

Our claim follows from the definition of $\textsc{Aff}_b$ and the previous equations. ∎

Proof of Theorem 3.7. We prove Theorem 3.7 for $k = 10$ and $d = |\hat{\Sigma}| = 16$, where $\hat{\Sigma}$ is from Definition 5.7. By Theorem 5.8 it suffices to show a polynomial time reduction sending an instance $\psi = \{B_k, \hat{C}\}$ of de Bruijn Coloring to an instance of ALGEBRAIC-CSP over a field of size $2^k \cdot \operatorname{poly} k$. We reduce in time $\operatorname{poly} 2^\ell$ to an instance over $\mathrm{GF}(2^\ell)$ for any $\ell > k + (\log 5k) + 2$ and the reduced instance is of the form

$$\phi = \{\mathrm{GF}(2^\ell), \{\textsc{Aff}', \textsc{Aff}''\} \cup \mathcal{A}, H, C(x, y_0, y_1, z_{000}, \ldots, z_{111})\},$$

where $\textsc{Aff}'(x) = x$, $\textsc{Aff}''(x) = \zeta - x$ (for ζ to be defined later), and $\mathcal{A}$ is as in (5.4).

Embed $\hat{\Sigma}$ in $\mathrm{GF}(2^\ell)$ arbitrarily and associate `accept` with 0 and `reject` with 1. As in the proof of Theorem 5.4, we view the constraint $\hat{C}_v$ as a mapping from $\hat{\Sigma} \subset \mathrm{GF}(2^\ell)$ to $\{0,1\}$. Recall that Proposition 5.11 showed $V(B_k)$ can be embedded in $G(\mathrm{GF}(2^\ell), \mathcal{A})$ via the embedding f from (5.3). Notice that the outdegree of $G(\mathrm{GF}(2^\ell), \mathcal{A})$ is greater than the outdegree of B_k; thus when arithmetizing $\hat{C}_v$ we must take into account which of the eight neighbors of $f(v)$ in $G(\mathrm{GF}(2^\ell), \mathcal{A})$ are maps of the neighbors of v in B_k. Let $b_0(v), b_1(v) \in \{0,1\}^3$ denote the two relevant neighbors of $f(v)$ in $G(\mathrm{GF}(2^\ell), \mathcal{A})$ satisfying $f(N_0(v)) = \textsc{Aff}_{b_0(v)}(f(v))$ and $f(N_1(v)) = \textsc{Aff}_{b_1(v)}(f(v))$. Let $C_v(y, z_{b_0}, z_{b_1})$ be the trivariate polynomial of degree at most $|\hat{\Sigma}| - 1$ in each variable, agreeing with $\hat{C}_v$ on inputs in $\hat{\Sigma}^3$. Let $I = \{f(v) : v \in V\}$. Let $\zeta \in \mathrm{GF}(2^\ell)$ satisfy $(\zeta + I) \cap I = \emptyset$, where $\zeta + I = \{\zeta + \xi : \xi \in I\}$ and set $H = I \cup (\zeta + I)$. Such ζ exists because viewing elements of $\mathrm{GF}(2^\ell)$ as polynomials over $\mathrm{GF}(2)$ modulo an irreducible polynomial of degree ℓ, all elements in I

have degree at most $k+s$. Now, let $P_h(x)$ be the polynomial of degree $|H|-1$, that is, 1 when $x=h$ and 0 for all $x=h' \in H, h' \neq h$. Finally, let $P_{\hat{\Sigma}}(y)$ be the nonzero polynomial of degree $|\hat{\Sigma}|$ whose roots are precisely the elements of $\hat{\Sigma}$. We are ready to define the constraint polynomial of ϕ:

$$C(x, y_0, y_1, z_{000}, \ldots, z_{111}) = \sum_{v \in I} P_v(x) \cdot C_v(y_0, z_{b_0(v)}, z_{b_1(v)}) + \sum_{h \in H \setminus I} P_h(x) \cdot P_{\hat{\Sigma}}(y_1). \tag{5.5}$$

The second summand on the right-hand side checks that all vertices receive colors in $\hat{\Sigma}$ and the first summand checks that all coloring constraints are satisfied. The polynomials P_v, P_h are used to "bundle" all constraints into one polynomial.

Note that $\deg_x(C) \leq |H|-1$ and the degree in the remaining variables is at most $|\hat{\Sigma}|$. Thus, ϕ is a legal instance of ALGEBRAIC-CSP$_{k,d}$.

Completeness. Suppose $\psi \in$ de Bruijn Coloring and let $\hat{A} : V \to \hat{\Sigma}$ witness this. Let A be the polynomial of degree $\leq |V|-1$ satisfying $A(f(v)) = \hat{A}(v)$ for all $v \in V$. We claim A satisfies ϕ. We need to show for all $x \in H$

$$C\left(x, A(x), A(\zeta - x), A(\textsc{Aff}_{000}(x)), \ldots, A(\textsc{Aff}_{111}(x))\right) = 0.$$

As in the proof of Theorem 5.4, when $x \in H$, at most one summand of (5.5) may be nonzero, by definition of P_v. We split the proof into cases.

- $x \in I$: Let $v = x$. The summand to consider is $P_v(v) \cdot C_v(A(v), A(\textsc{Aff}_{b_0(v)}(v)), A(\textsc{Aff}_{b_1(v)}(v)))$, which vanishes because $\hat{C}(\hat{A}(v), \hat{A}(N_0(v)), \hat{A}(N_1(v)) = \texttt{accept}, f(N_0(v)) = \textsc{Aff}_{b_0(v)}(f(v))$, and $f(N_1(v)) = \textsc{Aff}_{b_1(v)}(f(v))$.
- $x \in H \setminus I$: The summand to consider is $P_v(x) \cdot P_{\hat{\Sigma}}(A(\zeta - x))$. By construction of H and selection of ζ we have $\zeta - x \in I$. By construction A takes on values in $\hat{\Sigma}$ on $\zeta - x$, so the summand vanishes.

Soundness. Suppose $\phi \in$ ALGEBRAIC-CSP$_{k,d}$ and let A witness this. Let $\hat{A} : I \to \mathrm{GF}(2^\ell)$ be the evaluation of A on I. First we claim that the range of $\hat{A}$ is $\hat{\Sigma}$. Indeed, assume $A(x) \notin \hat{\Sigma}$ for $x \in I$. Let $x' = \zeta + x$ and notice that $x' \in H \setminus I$. Then the second summand of (5.5) does not vanish on x'. Since all other summands vanish by construction of P_v, we reach a contradiction. We conclude that $\hat{A}$ is a legal assignment to ψ.

Next, we claim that $\hat{A}$ satisfies ψ. Consider the constraint $\hat{C}_v$. Equation (5.5) holds for v and $P_{v'}(v) = 0$ for all $v' \neq v, v' \in H$, implying $C_v(A(v), A(\textsc{Aff}_{b_0(v)}(v)), A(\textsc{Aff}_{b_1(v)}(v))) = 0$. Recall from the previous paragraph that $A(v), A(\textsc{Aff}_{b_0(v)}(v)), A(\textsc{Aff}_{b_1(v)}(v)) \in \hat{\Sigma}$. By construction of C_v we conclude that $\hat{C}_v(\hat{A}(v), \hat{A}(N_0(v)), \hat{A}(N_1(v))) = \texttt{accept}$. This completes our proof. ∎

5.3. Systematic reduction to PAIR-ALGEBRAIC-CSP. We now show how to modify the reduction of the previous section to apply it to pair languages and get a systematic reduction, thus proving Theorem 3.10.

Proof. Consider the sequence of reductions applied to an instance x of L and resulting in an instance ϕ of ALGEBRAIC-CSP. First, we reduce x to an instance C of CktSAT along the lines of [29, 15]. Inspection reveals that this reduction is systematic. Indeed, the implicit input y is embedded into the inputs of C, and C accepts only inputs $y \in L_x$.

In the next step we reduce C to an instance ψ of DE BRUIJN COLORING. Once again, inspection of this reduction shows it is systematic [39, section 4.3]. In particular, this latter reduction embeds all nodes of C including its inputs in the first layer of the wrapped de Bruijn graph and each input node is mapped to a unique vertex. By construction, a coloring of the resulting de Bruijn graph is legal only if the colors of the vertices corresponding to inputs form an assignment satisfying C. Similarly, any assignment satisfying C can be extended to a coloring satisfying the constraints of ψ.

Finally, consider the reduction from DE BRUIJN COLORING to ALGEBRAIC-CSP. Notice that each vertex of the de Bruijn graph is mapped to a distinct element of $\mathbb{F}$ (Proposition 5.11). Additionally, by construction we map the colors of the de Bruijn coloring problem to distinct elements of $\mathbb{F}$. By construction, ϕ is satisfied by A iff A is the low-degree extension of a coloring that satisfies ψ. We have seen that all steps of our reduction are systematic; hence so is their concatenation. This completes our proof. □

6. PCPPs for Reed–Solomon codes over fields of characteristic 2. In this section we give a PCPP-verifier for RS-codes when the field is of characteristic 2 and the set of evaluation points is a linear subspace of the field over GF(2), thereby proving Theorem 3.2 (restated below).

An overview of the proof appears in subsection 6.1. This is followed by a formal description of the proof of proximity and verifier in subsection 6.2 and the analysis of its basic properties in subsection 6.3. The analysis of the soundness follows in subsection 6.4. We conclude with a formal proof of Theorem 3.2 in subsection 6.5.

THEOREM 6.1 (Theorem 3.2, restated). *Let* PAIR-ADDITIVE-RS *be the restriction of the language* PAIR-RS *to pairs* $((\mathrm{GF}(2^\ell), L, d), p)$*, where* $\mathrm{GF}(2^\ell)$ *is the Galois field of size* $n = 2^\ell$ *(and characteristic* 2*) and* $L \subseteq \mathbb{F}$ *is* GF(2)*-linear. Then,*

$$\text{PAIR-ADDITIVE-RS} \in \mathbf{Strong\text{-}PCPP}_{\delta/\operatorname{polylog} n} \begin{bmatrix} \mathsf{randomness}\ \log(n \cdot \operatorname{polylog} n), \\ \mathsf{query}\ O(1), \\ \mathsf{distance}\ \mathsf{Hamming}_{\mathrm{GF}(2^\ell)} \end{bmatrix}.$$

Remark 6.2. For simplicity, we first prove the theorem for the special case of degree $d = |L|/8 - 1$. Then we show in Proposition 6.14 that this implies that the theorem holds for all degrees.

6.1. Sketch of proof of Theorem 3.2. At a high level, we attempt a reduction from the task of testing a univariate polynomial to the task of testing a bivariate polynomial of significantly smaller degree. We then invoke an analysis of a "bivariate low-degree test" by Polishchuk and Spielman [37], which reduces the task of testing bivariate polynomials back to the task of testing univariate polynomials, of much smaller degree than the original. Recursing on this idea leads to the full test. We note that crucial to our obtaining short PCPPs is the evaluation of the bivariate polynomial on a carefully selected, algebraically structured, subset of points. This set is very different from the sets typically used in previous PCP constructions, e.g., in [5, 2, 17], which are product sets usually consisting of the whole field.

We start by considering the polynomial $P(z)$ of degree $< n/8$ evaluated on the linear space $L \subset \mathrm{GF}(2^\ell)$ of cardinality n and address the task of "testing" it. Our starting point is that for any polynomial $q(z)$ of degree $\approx \sqrt{n}$, we can define a bivariate polynomial $Q(x, y)$ of degree $\approx \sqrt{n}$ in each variable that "captures" all the information of P. Specifically, we can reconstruct P from Q using the identity $P(z) = Q(z, q(z))$.

PROPOSITION 6.3. *Given any pair of polynomials $P(z), q(z)$, there exists a unique bivariate polynomial $Q(x,y)$ with $\deg_x(Q) < \deg(q)$ and $\deg_y(Q) = \lfloor \deg(P)/\deg(q) \rfloor$, such that $P(z) = Q(z, q(z))$.*

Proof. We use division over the ring of bivariate polynomials $\mathbb{F}[z,y]$ (see [16] for more details). Fix the lexicographic ordering on terms where $z > y$; i.e., terms are ordered first by their degree in z and then by their degree in y. Divide $P(z)$ by $(y - q(z))$, obtaining

$$P(z) = Q'(z,y) \cdot (y - q(z)) + Q(z,y). \tag{6.1}$$

By the basic properties of division in this ring Q is uniquely defined, and $\deg_y(Q) = \lfloor \deg(P)/\deg(q) \rfloor$ and $\deg_z(Q) < \deg(q)$. To complete the proof set $y = q(z)$ and notice that the first summand on the right-hand side of (6.1) vanishes. □

The presentation of P of degree $\approx n$ as a bivariate polynomial Q of individual degree $\approx \sqrt{n}$ is useful, because testing of bivariate polynomials reduces to testing of univariate polynomials of roughly the same degree using well-known "low-degree tests" and their analysis. This leads us to the hope that Q might provide a good "proof" that P is of low degree. More to the point, to prove that a table of evaluations of P corresponds to the evaluations of a polynomial of low degree, the prover can provide a table of evaluations of a bivariate polynomial Q, prove that Q has degree $\sqrt{n}$ in each variable, and then prove that Q is consistent with the table of evaluations of P.

To completely describe the above approach, all we need to do is describe which set of points we will specify Q on so as to achieve both tasks: (i) verifying that Q has low degree, and (ii) that it is consistent with P. However, this leads to conflicting goals. To test that Q has low degree, using a bivariate verifier, we need to know its values on some subset $X \times Y$, where $X, Y \subseteq \mathrm{GF}(2^\ell)$. To make this efficient, we need to make $|X|, |Y| \approx \sqrt{n}$. On the other hand, to test its consistency with P, the natural approach is to ask for its values on the set

$$T = \{(z, q(z)) | z \in L\}.$$

Unfortunately the set T, which depends on the selection of $q(z)$, is far from being of the form $X \times Y$. For starters, the projection of T onto its first coordinate has cardinality n while we would like this projection to be of cardinality $O(\sqrt{n})$.

Our solution is to ask the prover to provide the evaluation on *both* sets of points. This leads to a problem of checking consistency between the two sets and to do so we pick $q(z)$ in a way that will ensure T is compatible with $X \times Y$. In particular, we choose $q(z)$ to be a special *linearized* polynomial as defined in [32, Chapter 3, section 4]. A polynomial $q(z)$ over $\mathrm{GF}(2^\ell)$ is said to be linearized if $q(x+y) = q(x) + q(y)$ for every $x, y \in \mathrm{GF}(2^\ell)$. A linearized polynomial defines a linear map over $\mathrm{GF}(2^\ell)$ and we abuse notation and use q to denote this map. For $S \subset \mathrm{GF}(2^\ell)$, let $q(S) = \{q(s) : s \in S\}$. The linearized polynomial we use and its useful properties are listed below.

PROPOSITION 6.4. *For L a linear subspace of $\mathrm{GF}(2^\ell)$ that is a direct sum of the linear spaces L_0, L_1, let*

$$q(z) = q_{L_0}(z) \triangleq \prod_{\alpha \in L_0} (z - \alpha).$$

- *The polynomial $q(z)$ is linearized.*
- *The kernel of (the linear map defined by) q is L_0.*
- *$q(L) = q(L_1)$ and $q(L_1)$ is a linear space of dimension $\dim(L_1)$.*

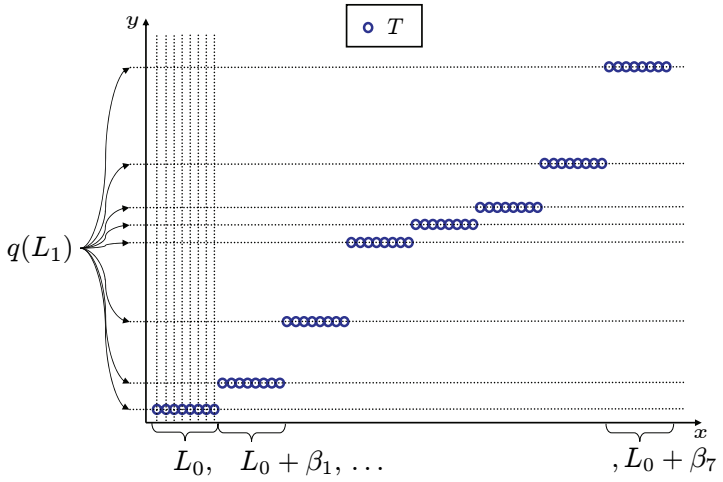

FIG. 1. *Here* $\mathbb{F} = \mathrm{GF}(2^6)$ *is the field with* 64 *elements and* q *is a linearized polynomial of degree* 8. *We plot the set of points* $T \subset \mathbb{F} \times \mathbb{F}$ *defined by* $T = \{(z, q(z)) : z \in \mathbb{F}\}$. *Notice* T *can be partitioned into eight product sets, each set being a product of an affine shift of* L_0 *and some* $\beta \in L_1$.

- q *is a one-to-one map from* L_1 *to* $q(L_1)$*; i.e., for* $\beta \neq \beta'$ *we get* $q(\beta) \neq q(\beta')$.
- q *is an* $|L_0|$ *to one map on* L*, where, for* $\beta \in L_1$*, the affine space* $L_0 + \beta \triangleq \{\alpha + \beta : \alpha \in L_0\}$ *is mapped to* $q(\beta)$.

Proof. The first part is proved by induction on the dimension of L. The base case (dimension zero) is easy, as $q_{L_0}(z) = z$ is clearly linearized. For the inductive step, let $L_0 = \mathrm{span}(\hat{L}, \alpha)$, where $\dim(\hat{L}) = k - 1$ and $\alpha \in \mathrm{GF}(2^\ell)$. Let $\hat{q}(z) = q_{\hat{L}}(z)$ be the linearized polynomial whose set of roots is $\hat{L}$. Clearly, $q_{L_0}(z) = \hat{q}(z) \cdot \hat{q}(\alpha + z)$ because addition and subtraction are the same in fields of characteristic 2. So

$$\begin{aligned} q_{L_0}(x+y) &= \hat{q}(x+y) \cdot \hat{q}(\alpha + x + y) = \hat{q}^2(x) + \hat{q}^2(y) + \hat{q}(\alpha)(\hat{q}(x) + \hat{q}(y)) \\ &= \hat{q}(x) \cdot \hat{q}(\alpha + x) + \hat{q}(y) \cdot \hat{q}(\alpha + y) = q_{L_0}(x) + q_{L_0}(y). \end{aligned}$$

We conclude that q_{L_0} is a linearized polynomial. The second part follows because $\deg(q) = |L_0|$ and the elements of L_0 are all roots of q.

The last three parts follow via basic linear algebra from our previous assertions that q defines a linear map with kernel L_0. ∎

With Proposition 6.4 in hand, we return to the task of providing a proof of proximity for the evaluation of a polynomial on the set of points L. Write L as the direct sum of L_0, L_1, with $\dim(L_0) = \lfloor \dim(L)/2 \rfloor$ and $\dim(L_1) = \lceil \dim(L)/2 \rceil$ (so $|L_0|, |L_1| \approx \sqrt{|L|}$), and take $q(z) = q_{L_0}(z)$ as described above. The last part of Proposition 6.4 implies that q partitions T into the disjoint union of $|L_1|$ lines, where each line is a product of a set of size $\approx \sqrt{|L|}$ with a singleton set (see Figure 1):

$$T = \bigcup_{\beta \in L_1} \{\{L_0 + \beta\} \times \{q(\beta)\}\}.$$

This suggests requesting the evaluation of Q on the set of points $(L_0 \times q(L_1)) \cup T$, the cardinality of which is $\leq 2n$. With such an evaluation in hand we can use the

subset $L_0 \times q(L_1)$ to perform a bivariate low-degree test, by testing proximity to the RS-code of degree $\approx \sqrt{n}$ of a random row/column of this product set. The consistency of Q's evaluation on the product set $L_0 \times q(L_1)$ and on the set T can also be addressed, by reading $Q(x, q(\beta))$ for all points $x \in L_0 \cup (L_0 + \beta)$ for $\beta \in L_1$. This consistency is precisely what is needed to connect the evaluation of P on the set L, that is isomorphic to T, to the evaluation of the bivariate Q on the product set $L_0 \times q(L_1)$. We have reduced our original problem of size n to $O(\sqrt{n})$ identical problems of size $O(\sqrt{n})$.

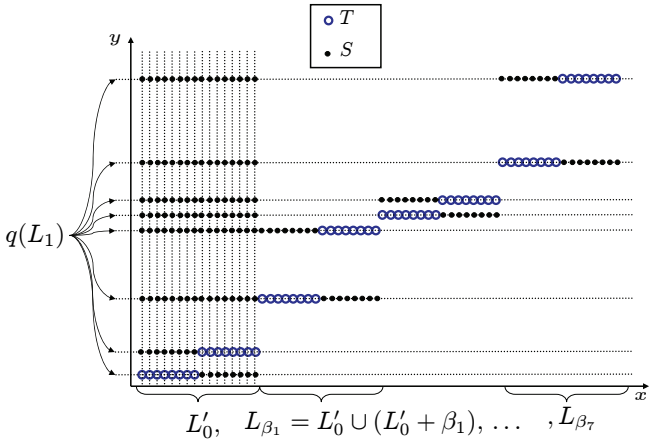

FIG. 2. *The proof of proximity for P is the evaluation of Q on the set of points denoted S. Notice it has a large subset that is the product set $L'_0 \times q(L_1)$, allowing for bivariate low degree testing. Additionally, $S \cup T$ can be partitioned into eight rows and each row is a linear space.*

Our description so far leads to a proof of proximity of size $O(n)$ that can be tested by making $O(\sqrt{n})$ queries. However, the *robustness* of our tests can be used to decrease the query complexity further, at the price of increasing the proof length. Informally, robustness means the following. If a function $f : (L_0 \times q(L_1)) \cup T \to \mathrm{GF}(2^\ell)$ is δ-far from being a low-degree bivariate polynomial, then the expected distance of a random row/column of f from a low-degree univariate polynomial is $\Omega(\delta)$. To apply recursion, notice that all of our tests verify proximity to Reed–Solomon codewords evaluated on *linear subspaces* of $\mathrm{GF}(2^\ell)$. To see this notice that L_0 and $q(L_1)$ are linear spaces, and so is $L_0 \cup (L_0 + \beta) = \mathrm{span}(L_0, \beta)$. Using recursion we conclude that to test proximity to the RS-code of size n it suffices to test proximity to RS-codes of size $\approx \sqrt{n}$, which can be done by testing proximity to the RS-code of size $\approx n^{1/4}$, etc. Applying this recursion a $\log \log n$ number of times reduces the degree to a constant and gives us our proofs of length $n \cdot \mathrm{polylog}\, n$.

From intuition to proof. Our rigorous analysis follows the intuition above, with one technical difference regarding the degree of the bivariate polynomial Q. To use the bivariate low-degree test on Q, we need its evaluation on a product set of points $X \times Y$, where $|X| \gg \deg_x(Q)$ and $|Y| \gg \deg_y(Q)$. In our case Proposition 6.3 gives us only $|X| > \deg_x(Q)$. As to y, we get $|Y| > 8 \deg_y(Q)$, which is sufficient. So we need to enlarge X. This is done by taking a linear space $L'_0 \supset L_0$ of dimension $\dim(L_0) + 2$ and asking for the evaluation of Q on $(L'_0 \times q(L_1)) \cup T$. This causes a new problem, because $L'_0 \cup (L_0 + \beta)$ is not a linear space, as $\dim(L'_0) > \dim(L_0)$. This

problem is fixed by asking for the evaluation of Q on the linear space $L'_0 \cup (L'_0 + \beta)$. The resulting set of points is described in Figure 2.

6.2. The RS proof of proximity and its associated verifier. First we define the structure of the proof of proximity for $\mathrm{RS}(\mathrm{GF}(2^\ell), L, d)$ and then describe the verifier's operation. As explained in the previous section, the proof for a purported low-degree polynomial $p : L \to \mathrm{GF}(2^\ell)$ is an evaluation of a low-degree bivariate polynomial related to p on a carefully chosen subset of $\mathrm{GF}(2^\ell) \times \mathrm{GF}(2^\ell)$, concatenated with a sequence of subproofs for RS-codes of smaller size. To formally define the proof of proximity we use the following notation throughout this section.

Given basis $(b_1, \ldots, b_k)$ for L, let

$$L_0 \triangleq \mathrm{span}(b_1, \ldots, b_{\lfloor k/2 \rfloor}); \quad L'_0 \triangleq \mathrm{span}(b_1, \ldots, b_{\lfloor k/2 \rfloor + 2}); \quad L_1 \triangleq \mathrm{span}(b_{\lfloor k/2 \rfloor + 1}, \ldots, b_k). \tag{6.2}$$

Fix $q(x) \triangleq q_{L_0}(x)$. Notice that $L'_0 \cap L_1 = \mathrm{span}(b_{\lfloor k/2 \rfloor + 1}, b_{\lfloor k/2 \rfloor + 2})$, and, in particular, this intersection is nonempty. For $\beta \in L_1$ let

$$L_\beta \triangleq \begin{cases} \mathrm{span}(L'_0, b_{\lfloor k/2 \rfloor + 3}), & \beta \in L'_0, \\ \mathrm{span}(L'_0, \beta) & \text{otherwise.} \end{cases} \tag{6.3}$$

A *partial* bivariate function f over $\mathrm{GF}(2^\ell)$ is a function with a partial domain $f : S \to \mathrm{GF}(2^\ell)$, where $S \subset \mathrm{GF}(2^\ell) \times \mathrm{GF}(2^\ell)$. The β-row of S is the set $R_\beta = \{\alpha : (\alpha, \beta) \in S\}$ (this set might be empty). The *restriction* of f to the β-row is the univariate function $f|^{\leftrightarrow}_\beta : R_\beta \to \mathrm{GF}(2^\ell)$ that agrees with f on its inputs, i.e., $f|^{\leftrightarrow}_\beta(\alpha) = f(\alpha, \beta)$. Similarly, the α-column of S is $C_\alpha = \{\beta : (\alpha, \beta) \in S\}$, and the restriction of f to it is $f|^{\updownarrow}_\alpha : C_\alpha \to \mathrm{GF}(2^\ell)$ defined by $f|^{\updownarrow}_\alpha(\beta) = f(\alpha, \beta)$.

Definition 6.5 (Reed–Solomon proof of proximity). *The proof of proximity for a purported codeword of the Reed–Solomon code* $\mathrm{RS}(\mathrm{GF}(2^\ell), L, n/8 - 1)$ *is defined by induction on* $k = \dim(L)$. *If* $k \le 6$ *then it is empty. Otherwise, the proof is a pair* $\pi = \{f, \Pi\}$, *where* f *is a partial bivariate function over partial domain* $S \subset \mathrm{GF}(2^\ell) \times \mathrm{GF}(2^\ell)$ *defined next and* Π *is a sequence of proofs of proximity for RS-codes over (smaller) linear spaces.*

Partial domain. *Let*

$$T \triangleq \bigcup_{\beta \in L_1} \{\{L_0 + \beta\} \times \{q(\beta)\}\}; \qquad S \triangleq \left(\bigcup_{\beta \in L_1} \{L_\beta \times \{q(\beta)\}\} \right) \setminus T. \tag{6.4}$$

Auxiliary proofs. *For each* $\beta \in L_1$, *the sequence of proofs* Π *has a unique subproof for an RS-codeword over* L_β *of degree* $|L_\beta|/8 - 1$, *denoted* $\pi^{\leftrightarrow}_\beta$. *For each* $\alpha \in L'_0$, *the sequence* Π *includes a unique subproof for an RS-codeword over* $q(L_1)$ *of degree* $|q(L_1)|/8 - 1$, *denoted* $\pi^{\updownarrow}_\alpha$. *Formally,*

$$\Pi \triangleq \{\pi^{\leftrightarrow}_\beta : \beta \in L_1\} \cup \{\pi^{\updownarrow}_\alpha : \alpha \in L'_0\}.$$

The next proposition shows that $S \cup T$ can be decomposed into rows and columns that are linear spaces (of size $\approx \sqrt{|L|}$). This gives some explanation of our peculiar choice of the set S as described in the previous section and shown in Figure 2.

Proposition 6.6. *The set* $S \cup T$ *is the disjoint union of* $q(\beta)$*-rows for* $\beta \in L_1$. *The* $q(\beta)$*-row of* $S \cup T$ *is the linear space* L_β. *Similarly, for every* $\alpha \in L'_0$, *the* α*-column of* $S \cup T$ *is the linear space* $q(L_1)$.

Proof. By construction of S, to prove the claim about the rows of $S \cup T$ it suffices to show that the $q(\beta)$-row of T is a subset of L_β. By the last part of Proposition 6.4 this row is

$$\{\gamma \in L : q(\gamma) = q(\beta)\} = q^{(-1)}(q(\beta)) \cap L = L_0 + \beta \subset L_\beta.$$

The inclusion above follows by definition from (6.3). This completes the proof of the claim about the rows.

Now consider the α-column of $S \cup T$ for $\alpha \in L_0'$. By (6.3) we have $L_0' \subset L_\beta$ for every $\beta \in L_1$ and $L_\beta \times \{q(\beta)\} \subset S$, so $(\alpha, q(\beta)) \in S$ implying $q(L_1)$ is a subset of the α-column. However, by the first part of our proposition, the only nonempty rows of $S \cup T$ are the $q(\beta)$-rows. So we conclude that the α-column of $S \cup T$ is precisely $q(L_1)$. ∎

DEFINITION 6.7 (RS-verifier). *The verifier for proximity to* $\mathrm{RS}(\mathrm{GF}(2^\ell), L, d = |L|/8 - 1)$ *is denoted* $\mathrm{V_{RS}}^{(p,\pi)}(\mathrm{GF}(2^\ell), L, d)$. *It receives as explicit inputs the description of the field* $\mathrm{GF}(2^\ell)$*, a basis* $(b_1, \ldots, b_k)$ *for* L*, and the degree parameter* $d = |L|/8 - 1$. *The implicit input of the verifier is the purported codeword* $p : L \to \mathrm{GF}(2^\ell)$ *and its purported proof is* $\pi = \{f, \Pi\}$ *as described in Definition* 6.5. *The verifier operates as follows.*

Base case ($|L| \le 64$). *The verifier reads* p *in entirety and accepts iff* $p \in \mathrm{RS}(\mathrm{GF}(2^\ell), L, |L|/8 - 1)$.

Recursion ($|L| > 64$). *Let* $\hat{p} : T \to \mathrm{GF}(2^\ell)$ *be the partial bivariate function corresponding to* p*,*

$$\hat{p}(\gamma, q(\gamma)) = p(\gamma) \text{ for } \gamma \in L. \tag{6.5}$$

Notice that $\hat{p}$ *is well defined because the mapping* $\gamma \mapsto (\gamma, q(\gamma))$ *is a bijection from* L *to* T. *Let*

$$\hat{f} : S \cup T \to \mathrm{GF}(2^\ell) \tag{6.6}$$

be the function that agrees with f *on* S *and with* $\hat{p}$ *on* T. *Notice that* $\hat{f}$ *is well defined because* $S \cap T = \emptyset$. *The verifier sets* $L_0 = \mathrm{span}(b_1, \ldots, b_{\lfloor k/2 \rfloor})$*, computes the coefficients of the polynomial* $q(x) = q_{L_0}(x)$*, and performs one of the following two tests with probability half each.*

Row test. *Pick* $\beta \in L_1$ *at random. Let* L_β *be as in* (6.3). *Invoke*

$$\mathrm{V_{RS}}^{(\hat{f}|^{\rightarrow}_{q(\beta)}, \pi^{\rightarrow}_{\beta})}(\mathrm{GF}(2^\ell), L_\beta, |L_\beta|/8 - 1).$$

Column test. *Pick* $\alpha \in L_0'$ *at random. Let* L_1 *be as in* (6.2). *Compute a basis for* $q(L_1)$ *and invoke*

$$\mathrm{V_{RS}}^{(\hat{f}|^{\updownarrow}_{\alpha}, \pi^{\updownarrow}_{\alpha})}(\mathrm{GF}(2^\ell), q(L_1), |q(L_1)|/8 - 1).$$

Remark 6.8. The "inner" verifiers, i.e., the row and column tests, restrict their attention to special subsets of p and π. To simplify our analysis, we assume these special subsets are copied to an "inner oracle" before invocation of an inner test. This assumption can be made without loss of generality because the verifier is nonadaptive; i.e., its operation does not depend on the implicit input given to it. Furthermore, the indices of the queries needed at the bottom of the recursion can be computed efficiently given the random coins used through the recursion as can be verified by inspection of the proof of Proposition 6.9.

The following subsections analyze the performance of V_{RS}. Specifically, the next subsection analyzes the simple properties including the running time, query complexity, randomness/size complexity, and the completeness. The soundness analysis is addressed in subsection 6.4.

6.3. Basic properties.

PROPOSITION 6.9. $\mathrm{V}_{\mathrm{RS}}{}^{(p,\pi)}(\mathrm{GF}(2^\ell), L, |L|/8-1)$ *makes at most* 64 *queries into* p *and* π. *It tosses at most* $k + O(\log k)$ *random coins (recall that* $k = \dim(L)$*) and runs in time* $\operatorname{poly} \ell$. *The size of the proof* π *accessed by* $\mathrm{V}_{\mathrm{RS}}{}^{(p,\pi)}(\mathrm{GF}(2^\ell), L, |L|/8-1)$ *is* $2^k \cdot \operatorname{poly} k = |L| \cdot \operatorname{polylog} |L|$.

Proof. The query complexity is easy to verify. In the base case, the verifier reads 64 field elements. In the inductive case the verifier invokes V_{RS} which by induction makes 64 queries.

Regarding randomness complexity, in the base case the verifier tosses zero coins. In the inductive case, the verifier tosses one coin to determine which test to perform—row or column. It then tosses $k/2 + O(1)$ coins to determine the inner call and then $(k/2 + O(1)) + O(\log(k/2 + O(1)))$ coins in the recursive call. Adding up, we get a total of $k + O(\log k)$ coins. The size of the proof can be similarly analyzed or bounded by $2^{\text{randomness}}$ to get the same bound.

We now analyze the running time, which is the sum of two processes.

The preprocessing time. This is the time required by the *outer* verifier $\mathrm{V}_{\mathrm{RS}}{}^{(p,\pi)}[\mathrm{GF}(2^\ell), L, |L|/8-1]$ to prepare the explicit input for invoking an *inner* verifier on a row/column. Notice that $q(x)$ can be computed and evaluated in polynomial time in $|L_0|$ and ℓ and so can the bases for L_0, L_0', L_β, L_1, and $q(L_1)$. Thus, the preprocessing time is polynomial.

The index translation time. Suppose the outer verifier conducts an inner row test of the form

$$\mathrm{V}_{\mathrm{RS}}{}^{(\hat{f}|^{\leftrightarrow}_{q(\beta)}, \pi^{\leftrightarrow}_{\beta})}[\mathrm{GF}(2^\ell), q(L_\beta), |L_\beta|/8-1].$$

The case of a column test is analogous. A query to $\hat{f}|^{\leftrightarrow}_{q(\beta)}$ by the inner verifier is indexed by an element $\alpha \in L_\beta$. However, this query needs to be *translated* to a query to $\hat{f}$, which is a pair $(\alpha, \beta) \in S \cup T$. This translation is easily seen to be efficient given α and β. Furthermore, translating a query to $\hat{f}$ into a query to $f : S \to \mathbb{F}$ or $p : T \to \mathbb{F}$ is also easy. If $\beta = q(\alpha)$ we query $p(\alpha)$ because $(\alpha, \beta) \in T$, and otherwise we query $f(\alpha, \beta)$. This translation involves evaluating $q(\alpha)$, which can be done efficiently as argued above.

We conclude that for each level of the recursion, the running time of the preprocessing and index translation is at most polynomial in $|L|$ and ℓ. Since there are $O(\log \ell)$ levels of recursion, we conclude that the running time is as stated, completing our proof. □

Next we move to the completeness part of the proof.

PROPOSITION 6.10 (perfect completeness). *If* p *is the evaluation of a polynomial* P *of degree* $< |L|/8$, *then there exists a proof that causes the RS-verifier to accept with probability one.*

This part is straightforward given the intuition developed in the proof sketch of Theorem 3.2. If p is indeed low-degree, then there exists a proper low-degree bivariate polynomial Q that is consistent with it on all rows. Looking at Figure 2 we argue that S is a union of linear spaces and the restriction of Q to each row is low-degree and consistent with p. The formal proof follows.

Proof. To prove the proposition inductively, it suffices to construct $f : S \to \mathrm{GF}(2^\ell)$ so that the function $\hat{f} : S \cup T \to \mathrm{GF}(2^\ell)$ is such that for every $\beta \in L_1$, the $q(\beta)$-row of $\hat{f}$ is a codeword of $\mathrm{RS}(\mathrm{GF}(2^\ell), L_\beta, |L_\beta|/8 - 1)$, and for every $\alpha \in L_0'$, the α-column of $\hat{f}$ is a codeword of $\mathrm{RS}(\mathrm{GF}(2^\ell), L_1, |L_1|/8 - 1)$.

Using Proposition 6.3 we get $P(x) = Q(x, q(x))$ for $q(x) = q_{L_0}(x)$, where

$$\deg_x(Q) < |L_0| \quad \text{and} \quad \deg_y(Q) = \lfloor \deg(P)/\deg(q) \rfloor < (|L|/8)/|L_0| = |L_1|/8. \tag{6.7}$$

Set $f(\alpha, \beta') = Q(\alpha, \beta')$ for every $(\alpha, \beta') \in S$. If $(\alpha, \beta') \in T$ we have $\beta' = q(\alpha)$, so

$$\hat{p}(\alpha, \beta') = \hat{p}(\alpha, q(\alpha)) = p(\alpha) = P(\alpha) = Q(\alpha, q(\alpha)) = Q(\alpha, \beta').$$

Thus, $\hat{f}$ is the evaluation of Q on $S \cup T$. Consider the $q(\beta)$-row of $\hat{f}$ for $\beta \in L_1$. By Proposition 6.6 the $q(\beta)$-row of $S \cup T$ is L_β. By (6.3) we have $|L_\beta| = 8 \cdot |L_0|$ because $\dim(L_\beta) = \dim(L_0) + 3$. By (6.7) we have $\deg(Q(x, q(\beta)) \le \deg_x(Q) < |L_0|$. We conclude that the $q(\beta)$-row of $\hat{f}$ is indeed a member of $\mathrm{RS}(\mathrm{GF}(2^\ell), L_\beta, |L_\beta|/8 - 1)$.

Similarly, by Proposition 6.6 the α-column of $\hat{f}$ is $q(L_1)$. By Proposition 6.4 $\dim(q(L_1)) = \dim(L_1)$, so $|q(L_1)| = |L_1|$. By construction the α-column of $\hat{f}$ is the evaluation of $Q(\alpha, y)$ on $q(L_1)$. Equation (6.7) completes our proof, because $\deg(Q(\alpha, y)) \le \deg_y(Q) < |L_1|/8$. ∎

6.4. Soundness. Our analysis of the soundness is by induction. Assume $\mathrm{V_{RS}}$ accepts implicit input p and proof $\pi = \{f, \Pi\}$ with high probability. Let $\hat{p}, \hat{f}$ be the partial bivariate functions as defined in (6.5) and (6.6), respectively. We argue by induction that for most $\alpha \in L_0'$ and $\beta \in L_1$, the α-column and $q(\beta)$-row of $\hat{f}$ are close to polynomials of degree roughly $\sqrt{|L|}$. The analysis of Polishchuk and Spielman implies that $\hat{f}$ restricted to the product set $L_0' \times q(L_1)$ is very close to some low-degree bivariate polynomial. Then we claim that $\hat{p}$ is close to an evaluation of the same polynomial on the set of points T. This implies p is close to a degree-$|L|/8$ univariate polynomial, completing the analysis. Formally, we have the following.

LEMMA 6.11 (soundness). *There exists constant $c \ge 1$ such that for every integer k and ϵ, if*

$$\Pr[\mathrm{V_{RS}}^{(p,\pi)}(\mathrm{GF}(2^\ell), \mathrm{span}(b_1, \ldots, b_k), 2^k/8 - 1) = \mathsf{reject}] \le \epsilon,$$

then p is $\left(c^{\log k} \cdot \epsilon\right)$-close to $\mathrm{RS}(\mathrm{GF}(2^\ell), \mathrm{span}(b_1, \ldots, b_k), 2^k/8 - 1)$.

To prove the lemma, we need a version of the analysis of Polishchuk and Spielman of the bivariate test. The following lemma is directly implied by the main theorem in [37]. We defer its proof to section 6.6 below.

DEFINITION 6.12. *For set $S \subseteq \mathbb{F} \times \mathbb{F}$, partial bivariate function $f : S \to \mathbb{F}$, and nonnegative integers d_1, d_2, define $\delta^{(d_1,d_2)}(f)$ to be the fractional distance of f from a polynomial of degree d_1 in its first variable and d_2 in its second variable. Formally,*

$$\delta^{(d_1,d_2)}(f) \triangleq \min_{\{Q : S \to \mathbb{F} \mid \deg_x(Q) \le d_1, \deg_y(Q) \le d_2\}} \{\delta(f, Q)\}.$$

Let $\delta^{(d,*)}(f)$ and $\delta^{(*,d)}(f)$ denote the fractional distances when the degree in one of the variables is unrestricted.

LEMMA 6.13 (bivariate test on product set [37]). *There exists a universal constant $c_0 \ge 1$ such that the following holds. For every $A, B \subseteq \mathbb{F}$ and integers $d_1 \le |A|/4, d_2 \le |B|/8$ and function $f : A \times B \to \mathbb{F}$, it is the case that*

$$\delta^{(d_1,d_2)}(f) \le c_0 \cdot \left(\delta^{(d_1,*)}(f) + \delta^{(*,d_2)}(f)\right).$$

Proof of Lemma 6.11. The proof is by induction on k. Let $L = \mathrm{span}(b_1, \ldots, b_k)$ and let L_0, L_0', L_1, q be as defined in the beginning of subsection 6.2. We use the following constants, where $\hat{c}$ is a parameter to be minimized and c_0 is the universal constant from Lemma 6.13:

$$c_1 \triangleq \hat{c}^{\log(7/6)}/2; \quad c_2 \triangleq \frac{c_1}{3c_0}; \quad c_3 \triangleq \frac{3c_1}{16(3c_0+2)}.$$

We fix c to be the minimal $\hat{c}$ such that $c_3 \geq 2$ and $\frac{1}{c_3} + \frac{16}{c_1} \leq 1$. Notice that c_1, c_2, c_3 are strictly increasing functions of $\hat{c}$, so c is well defined (we do not attempt to minimize it).

The base case $k \leq 6$ is immediate. For the inductive case we assume that the lemma is true by induction for smaller dimension k' and, in particular, for the recursive calls of the RS-verifier, and we now prove it for dimension $k \geq 7$.

Let $\pi = (f, \Pi)$ be as in Definition 6.5 and assume that (p, π) is rejected by the verifier with probability at most ϵ. We assume without loss of generality that $\epsilon \leq c^{-\log k}$, for otherwise there is nothing to prove. We show below that p is within distance $c^{\log k} \cdot \epsilon$ of some RS-codeword. In what follows let $\hat{p}, \hat{f}$ be the partial bivariate functions defined in (6.5) and (6.6), respectively.

Step 1. *Restricting the bivariate function $\hat{f}$ to a product set $L_0' \times q(L_1)$.* Denote by $\epsilon(\alpha)$ the probability that the inner verifier rejects $\hat{f}|_\alpha^\updownarrow$ (and its proof), and similarly let $\epsilon(\beta)$ be the probability verifier rejects $\hat{f}|_{q(\beta)}^\leftrightarrow$. Let ϵ_{col} be the expectation of $\epsilon(\alpha)$ over random $\alpha \in L_0'$ and let ϵ_{row} be the similar expectation of $\epsilon(\beta)$ over random $\beta \in L_1$. By definition of the verifier, we have $\epsilon = \frac{1}{2}(\epsilon_{\mathrm{row}} + \epsilon_{\mathrm{col}})$. Since these quantities are nonnegative we get $\epsilon_{\mathrm{row}}, \epsilon_{\mathrm{col}} \leq 2\epsilon$.

Let $d_1 = |L_0| - 1$ and recall that $|L_\beta| = 8|L_0|$ for every $\beta \in L_1$. This follows from (6.2) and (6.3). First we bound $\delta^{(d_1,*)}(\hat{f})$. This quantity is the expectation over random $\beta \in L_1$ of the fractional distance of $\hat{f}|_{q(\beta)}^\leftrightarrow$ from a degree-d_1 univariate polynomial. Let $\delta^{(d_1)}(\hat{f}|_{q(\beta)}^\leftrightarrow)$ denote this distance. We get

$$\begin{aligned} \delta^{(d_1,*)}(\hat{f}) &= \mathbb{E}_{\beta \in L_1}\left[\delta^{(d_1)}(\hat{f}|_{q(\beta)}^\leftrightarrow)\right] \leq \mathbb{E}_{\beta \in L_1}\left[\epsilon(\beta) \cdot c^{\log(\dim(L_\beta))}\right] \\ &\leq \epsilon_{\mathrm{row}} \cdot c^{\log(\lfloor k/2 \rfloor + 3)} \leq 2\epsilon \cdot c^{\log \frac{6k}{7}} = \frac{\epsilon}{c_1} \cdot c^{\log k}. \end{aligned} \tag{6.8}$$

The first inequality follows by induction, the second follows because $\dim(L_\beta) = \lfloor k/2 \rfloor + 3$ for every $\beta \in L_1$, the third holds for $k \geq 7$, and the last equality is true for our setting of c_1.

Let f' be the restriction of $\hat{f}$ to $L_0' \times q(L_1)$; i.e., $f' : L_0' \times q(L_1) \to \mathrm{GF}(2^\ell)$ is the function that agrees with $\hat{f}$ on its domain. Since $|L_0'| = |L_\beta|/2$ we get from (6.8)

$$\delta^{(d_1,*)}(f') \leq \frac{2\epsilon}{c_1} \cdot c^{\log k}. \tag{6.9}$$

Let $d_2 = |L_1|/8 - 1$. By analogy to (6.8), we get by induction

$$\delta^{(*,d_2)}(f') \leq \epsilon_{\mathrm{col}} \cdot c^{\log(\lfloor k/2 \rfloor + 1)} \leq \frac{\epsilon}{c_1} \cdot c^{\log k}. \tag{6.10}$$

The conditions of Lemma 6.13 hold with respect to f' and $A = L_0', B = q(L_1)$, because $d_1 \leq |L_0'|/4$ and $d_2 \leq |q(L_1)|/8$. Thus, from (6.9), (6.10), Lemma 6.13, and

our setting of c_2, we conclude that f' is "close" to an evaluation of a low degree bivariate polynomial:

$$\delta^{(d_1,d_2)}(f') \leq \frac{\epsilon}{c_2} \cdot c^{\log k}. \tag{6.11}$$

Step 2. *Extending the analysis to the bivariate function* $\hat{p}$. Let Q be the degree-(d_1, d_2) polynomial closest to f'. We wish to bound the probability over random $(\alpha, \tilde{\beta}) \in T$ that $\hat{p}(\alpha, \tilde{\beta}) \neq Q(\alpha, \tilde{\beta})$. Let $\tilde{\beta} = q(\beta)$ and notice that $\tilde{\beta} \in q(L_1)$. This follows from Proposition 6.4. Call $\tilde{\beta}$ *good* if the polynomial closest to $\hat{f}|^{\leftrightarrow}_{\tilde{\beta}}$ is $Q(x, \tilde{\beta})$, and otherwise it is *bad*. We bound the probability as follows:

$$\begin{aligned}\Pr_{(\alpha,\tilde{\beta})\in T}\left[\hat{p}(\alpha,\tilde{\beta}) \neq Q(\alpha,\tilde{\beta})\right] \leq \Pr_{\tilde{\beta}\in q(L_1)}\left[\tilde{\beta} \text{ is bad }\right] \\ + \Pr_{(\alpha,\tilde{\beta})\in T}\left[\hat{p}(\alpha,\tilde{\beta}) \neq Q(\alpha,\tilde{\beta}) | \tilde{\beta} \text{ is good}\right].\end{aligned} \tag{6.12}$$

- *First summand of* (6.12). We start by bounding the probability of bad $\tilde{\beta}$. Let $\hat{f}|^{\leftrightarrow}_{\tilde{\beta}}{}'$ be the restriction of $\hat{f}|^{\leftrightarrow}_{\tilde{\beta}}$ to domain L_0' and let $Q_{\tilde{\beta}}(x)$ be the degree-d_1 polynomial closest to $\hat{f}|^{\leftrightarrow}_{\tilde{\beta}}$. If $\tilde{\beta}$ is bad, i.e., $Q_{\tilde{\beta}}(x) \neq Q(x, \tilde{\beta})$, then $\hat{f}|^{\leftrightarrow}_{\tilde{\beta}}{}'$ is either (3/8)-far from $Q(x, \tilde{\beta})$ or (3/8)-far from $Q_{\tilde{\beta}}(x)$. This is because $Q_{\tilde{\beta}}(x)$ and $Q(x, \tilde{\beta})$ can agree on at most $|L_0'|/4$ locations in L_0'. Thus, by (6.9) and (6.11), we get

  $$\Pr_{\tilde{\beta}\in q(L_1)}\left[\tilde{\beta} \text{ is bad }\right] \leq 2 \cdot \frac{8}{3} \cdot \max\left\{\frac{1}{c_2}, \frac{2}{c_1}\right\} \cdot \epsilon \cdot c^{\log k} \leq \frac{\epsilon}{c_3} \cdot c^{\log k}. \tag{6.13}$$

  The last inequality follows by bounding the maximum of two nonnegative numbers by their sum and holds for our setting of c_1, c_2, c_3.
- *Second summand of* (6.12). Let $T_{\text{good}} = \{(\alpha, \tilde{\beta}) \in T : \tilde{\beta} \text{ is good}\}$. Since $\hat{p}$ is a function on a subdomain of $\hat{f}$ we can bound the second summand in (6.12) as follows:

  $$\begin{aligned}\Pr_{(\alpha,\tilde{\beta})\in T}\left[\hat{p}(\alpha,\tilde{\beta}) \neq Q(\alpha,\tilde{\beta}) | \tilde{\beta} \text{ is good}\right] \leq \Pr_{(\alpha,\tilde{\beta})\in S}\left[\hat{f}(\alpha,\tilde{\beta}) \neq Q(\alpha,\tilde{\beta})\right] \\ \cdot \frac{|S|}{|T_{\text{good}}|}.\end{aligned} \tag{6.14}$$

  We already showed in (6.8) that $\Pr_S[\hat{f} \neq Q]$ is relatively small, so we need only to argue that $|T_{\text{good}}|$ is large relative to $|S|$. By Proposition 6.4 the $\tilde{\beta}$-row of T is an affine shift of L_0 by $\tilde{\beta}$. From the proof of the first part of Proposition 6.6 we conclude that the $\tilde{\beta}$-row of T is 1/8 fraction subset of the $\tilde{\beta}$-row of S, so (6.13) implies

  $$|T_{\text{good}}|/|S| = \frac{1}{8} \cdot (1 - \Pr[\tilde{\beta} \text{ is bad}]) \geq 1/16. \tag{6.15}$$

  The last inequality follows from (6.13) by our assumption that $\epsilon \cdot c^{\log k} \leq 1$ and because we set $c_3 \geq 2$.

Summing up from (6.13), (6.14), and (6.15) we get

$$\Pr_{(\alpha,\tilde{\beta})\in T}\left[\hat{p}(\alpha,\tilde{\beta}) \neq Q(\alpha,\tilde{\beta})\right] \leq \left(\frac{1}{c_3} + \frac{16}{c_1}\right) \epsilon \cdot c^{\log k} \leq \epsilon \cdot c^{\log k}. \tag{6.16}$$

The last inequality holds because we set c_1 and c_3 such that $\frac{1}{c_3} + \frac{16}{c_1} \leq 1$.

Step 3. *From bivariate $\hat{p}$ to univariate p.* Let $P(x) = Q(x, q(x))$. Notice that $\deg(P) \leq |L|/8 - 1$. This follows from the degree of Q and $\deg(q) = |L_0| = |L'_0|/4$. Using (6.16) and the definition $T = \{(\gamma, q(\gamma)) : \gamma \in L\}$ we conclude that for all but a $(\epsilon \cdot c^{\log k})$-fraction of L we have

$$p(\gamma) = \hat{p}(\gamma, q(\gamma)) = Q(\gamma, q(\gamma)) = P(\gamma).$$

The fractional distance of p from a degree-$|L|/8 - 1$ polynomial is as claimed, completing our proof. □

6.5. Proof of Theorem 3.2. In this subsection we complete the formal proof of Theorem 3.2. First consider the case of degree precisely $|L|/8 - 1$, dealt with in the preceding sections. In particular, the proof of proximity and its associated verifier are described in subsection 6.2. The query complexity, randomness, and proof length are argued in Proposition 6.9. Perfect completeness is asserted by Proposition 6.10. Soundness is analyzed in Lemma 6.11. This completes the proof of the special case. The following proposition, Proposition 6.14, generalizes the degree and completes the full proof of Theorem 3.2.

In what follows we say a soundness function $s : [0,1] \times \mathbb{N}^+ \to [0,1]$ is *monotone* if it increases with δ; i.e., for all n we have $\delta \geq \delta' \Rightarrow s(\delta, n) \geq s(\delta', n)$.

PROPOSITION 6.14. *Let L be either of the pair-languages* PAIR-ADDITIVE-RS *and* PAIR-SMOOTH-RS*, and let $L_{\frac{1}{8}}$ be the restriction of L to explicit pairs of the form $(\mathbb{F}, S, |S|/8 - 1)$. Suppose*

$$L_{\frac{1}{8}} \in \mathbf{Strong\text{-}PCPP}_{s(\delta,n)} \left[\begin{array}{l} \mathsf{randomness}\ r(n), \\ \mathsf{query}\ q(n), \\ \mathsf{distance\ Hamming}_{\mathbb{F}} \end{array} \right],$$

where $s(\delta, n)$ is monotone and $r(n) \geq \log n$. Then for $s'(\delta, n) = \min\{\delta/2, s(\delta/64, n)\}$,

$$L \in \mathbf{Strong\text{-}PCPP}_{s'(\delta,n)} \left[\begin{array}{l} \mathsf{randomness}\ r(n), \\ \mathsf{query}\ O(q(n)), \\ \mathsf{distance\ Hamming}_{\mathbb{F}} \end{array} \right].$$

Proof. Let (x, p) be an instance to L with explicit input $x = (\mathbb{F}, S, d')$. Denote $d = \frac{|S|}{8} - 1$ and let $V_{\frac{1}{8}}$ denote the verifier for $L_{\frac{1}{8}}$. We start with the case of $d' < d$. On explicit input $(\mathbb{F}, S, d' < d)$ the verifier expects a (concatenation of) two subproofs for $\mathrm{RS}(\mathbb{F}, S, d)$, denoted π_1, π_2. The verifier operates as follows:

- Toss $r(n)$ coins. Let $\mathcal{R}$ denote the random string.
- Invoke $V_{\frac{1}{8}}$ using randomness $\mathcal{R}$ on explicit input $(\mathbb{F}, S, d)$, implicit input p, and proof π_1.
- Fix $Q(z) \triangleq z^{d-d'}$ and set $p'(z) = p(z) \cdot Q(z)$. Invoke $V_{\frac{1}{8}}$ using randomness $\mathcal{R}$ on explicit input $(\mathbb{F}, S, d)$, implicit input p', and proof π_2.

Notice that querying $p'(\alpha)$ can be simulated by querying $p(\alpha)$ and multiplying the answer by $Q(\alpha)$. Additionally evaluating $Q(\alpha)$ can be done in time polylog $|\mathbb{F}|$. So the running time, query complexity, and randomness are essentially inherited from $V_{\frac{1}{8}}$. Completeness follows by observing that $\deg(p) \leq d'$ implies $\deg(p') \leq d$. As to soundness, there are two cases to consider. If p is $\delta/4$-far from $\mathrm{RS}(\mathbb{F}, S, d)$ then by assumption, the first subtest rejects with probability at least $s(\delta/4, n) \geq s(\delta/64, n)$ (the previous inequality follows from monotonicity). Otherwise, p is within relative distance $\delta/4 \leq 1/4$ of an evaluation of a polynomial P with $d' < \deg(P) \leq d$. In this

case, p' is 1/4-close to the evaluation of $P'(z) = Q(z) \cdot P(z)$, where $d < \deg(P') < |S|/4$. Thus, P' is 3/4-far from $\mathrm{RS}(\mathbb{F}, S, d)$, so the distance of p' from the same code is at least $1/2 > \delta/4$. We conclude that the second subtest rejects with probability $s(\delta/4, n) \geq s(\delta/64, n)$.

Next assume $d' > d$ and notice without loss of generality that $d' \leq 8(d+1)$ because otherwise every implicit input is a codeword. The key observation is that a polynomial $P(z)$ is of degree d' iff it can be written as a sum $P(z) = \sum_{i=0}^{7} z^{i(d+1)} \cdot P_i(z)$, where $\deg(P_i) = d_i \leq d$ can be uniquely and efficiently computed given d and d'. Let $L_{(\leq d)}$ be the restriction of L to instances of degree $\leq d$ and let $V_{(\leq d)}$ denote the verifier for $L_{(\leq d)}$. The proof for explicit input $(\mathbb{F}, S, d')$ consists of eight functions $p_0, \ldots p_7 : S \to \mathbb{F}$ and eight proofs of proximity to $L_{(\leq d)}$ denoted $\pi_0, \ldots, \pi_7$. On explicit input $(\mathbb{F}, S, d')$ and implicit input p, the verifier operates as follows:

- Toss $r(n)$ coins. Let $\mathcal{R}$ denote the random string.
- For $i = 0, \ldots, 7$, invoke $V_{(\leq d)}$ using randomness $\mathcal{R}$ on explicit input $(\mathbb{F}, S, d_i)$, implicit input p_i, and proof π_i.
- Using $\mathcal{R}$, select uniformly at random $\gamma \in S$. Accept iff $p(\gamma) = \sum_{i=0}^{7} \gamma^{i(d+1)} p_i(\gamma)$.

Proof length, randomness, completeness, running time, and query complexity follow from construction. As to soundness, assume that p is δ-far from $\mathrm{RS}(\mathbb{F}, S, d')$. There are two cases to consider. If $p(z)$ disagrees with $\sum_{i=0}^{7} z^{i(d+1)} p_i(z)$ on a $\delta/2$-fraction of $z \in S$, then the second subtest rejects with probability $\geq \delta/2$. Otherwise, $p(z)$ is $\delta/2$-close to $\sum_{i=0}^{7} z^{i(d+1)} p_i(z)$. In this case at least one p_i must be $\delta/16$-far from $\mathrm{RS}(\mathbb{F}, S, d_i)$. So the first part of this proof (for the case $d' < d$) implies the rejection probability is at least $s(\frac{\delta}{4 \cdot 16}, n)$. This completes our proof. ∎

6.6. Proof of Lemma 6.13. The lemma is an immediate corollary of the bivariate testing theorem of Polishchuk and Spielman [37, Theorem 9]. We use here the general version of it appearing in Spielman's thesis.

THEOREM 6.15 (see [39, Theorem 4.2.19]). *Let $\mathbb{F}$ be a field, $S, T \subseteq \mathbb{F}$. Let $R(x, y)$ be a polynomial over $\mathbb{F}$ of degree $(d, |T| - 1)$ and let $C(x, y)$ be a polynomial over $\mathbb{F}$ of degree $(|S| - 1, e)$. If*

$$\Pr_{(x,y) \in S \times T} [R(x, y) \neq C(x, y)] < \gamma^2 \quad \text{and} \quad 2\left(\frac{d}{|S|} + \frac{e}{|T|} + \gamma\right) < 1,$$

then there exists a polynomial $Q(x, y)$ of degree (d, e) such that

$$\Pr_{(x,y) \in S \times T} [R(x, y) \neq Q(x, y) \text{ or } C(x, y) \neq Q(x, y)] < 2\gamma^2.$$

To prove Lemma 6.13 we show the contrapositive form for $c_0 = 128$, making no attempt to optimize constants. We may assume without loss of generality that $\delta^{(d,*)}, \delta^{(*,e)} < 1/c_0$; otherwise the claim is trivial. Correct each row of f to its closest RS-codeword (breaking ties arbitrarily), obtaining a bivariate polynomial $R(x, y)$ of degree $(d, |T| - 1)$. By definition, $\Delta(R(x, y), f) = \delta^{(d,*)}(f)$. Similarly, correct the columns of f to obtain the polynomial $C(x, y)$ of degree $(|S| - 1, e)$ that is within fractional distance $\delta^{(*,e)}(f)$ of f. We get

$$\Pr_{(x,y) \in S \times T} [R \neq C] \leq \delta^{(d,*)}(f) + \delta^{(*,e)}(f) = \gamma^2 < 1/64.$$

Since $\gamma \leq 1/8, d \leq |S|/4$, and $e \leq |T|/8$, both conditions of Theorem 6.15 hold, allowing us to conclude that $R(x, y)$ is $(2\gamma^2)$-close to $\mathrm{RM}(\mathbb{F}, S \times T, (d, e))$. The triangle inequality completes the proof:

$$\delta^{(d,e)}(f) \leq \Delta(f, R) + \Delta(R, \mathrm{RM}(\mathbb{F}, S \times T, (d, e))) \leq 3\delta^{(d,*)}(f) + 2\delta^{(*,e)}(f).$$

7. PCPPs for Reed–Solomon codes over smooth fields. In this section we give a PCPP-verifier for Reed–Solomon codes over smooth fields, when the set S over which the polynomials are evaluated are multiplicative subfields of the field, thereby proving Theorem 3.4 (restated below). We also show it suffices for obtaining quasilinear PCPs (Theorem 2.2). Our presentation mirrors that of the additive case presented in section 6.

THEOREM 7.1 (Theorem 3.4, restated). *Let* PAIR-SMOOTH-RS *be the restriction of* PAIR-RS *to pairs* $((\mathbb{F}, \langle\omega\rangle, d), p)$*, where* $\mathrm{ord}(\omega) = n$ *is a power of* 2*. Then,*

$$\text{PAIR-SMOOTH-RS} \in \mathbf{Strong\text{-}PCPP}_{\delta/\operatorname{polylog} n}\left[\begin{array}{l}\mathsf{randomness}\ \log(n \cdot \operatorname{polylog} n),\\ \mathsf{query}\ O(1),\\ \mathsf{distance}\ \mathsf{Hamming}_{\mathbb{F}}\end{array}\right].$$

7.1. Proof overview. This section should be read as a continuation of subsection 6.1. The crucial property used in our constructions in section 6 was that the linearized polynomial $q(z)$ "nicely partitions" the linear space L. Specifically, $q(z)$ defines a linear map on L, its image is a linear space of size $\approx \sqrt{|L|}$, and for every value in its image, the set of preimages of that value form an affine space of size $\approx \sqrt{|L|}$.

In the smooth case, $\mathbb{F}$ contains a multiplicative subgroup $S = \langle\omega\rangle$ of size n. Assume that $\sqrt{n}$ is an integer and consider a polynomial $P(z)$ evaluated over S. Using Proposition 6.3 with the polynomial $q(z) \triangleq z^{\sqrt{n}}$ we get $P(z) = Q(z, z^{\sqrt{n}})$. Notice that $q(z)$ "nicely partitions" $\langle\omega\rangle$. Specifically, $q(\langle w\rangle) = \langle\omega^{\sqrt{n}}\rangle$ is of size $\sqrt{n}$ (recall $q(S) \triangleq \{q(s) : s \in S\}$), and for every value in the image of q, the set of its preimages is a multiplicative coset of $\langle\omega^{\sqrt{n}}\rangle$.

Thus, to prove proximity of $P(z)$ to $\mathrm{RS}(\mathbb{F}, S, d)$ we may ask for an evaluation of $Q(x, y)$ on the set of points $(X \times Y) \cup Z$, where $Z = \{(z, q(z)) : z \in \langle\omega\rangle\}$ and $X = Y = \langle\omega^{\sqrt{n}}\rangle$. In the additive case we used the fact, implied by Proposition 6.6, that the union of a linear space (L'_0) and an affine shift of it ($L'_0 + \beta$) form a linear space of slightly larger dimension. In the smooth case, it is not true in general that $\langle\omega^{\sqrt{n}}\rangle$ and a coset of it form a small multiplicative group. In fact, the smallest group containing both can be as large as $\langle\omega\rangle$. To overcome this problem, we define the *shifted Reed–Solomon code* (SRS-code), which is formed of evaluations of polynomials over a multiplicative group $\langle\omega\rangle$ and a coset of it of the form $\kappa\langle\omega\rangle \triangleq \{\kappa z : z \in \langle w\rangle\}$.

The crucial observation is that $q(z)$ "nicely partitions" each of $\langle\omega\rangle$ and $\kappa\langle\omega\rangle$ into $\sqrt{n}$ cosets of $\langle\omega^{\sqrt{n}}\rangle$ (see Figure 3). Indeed, the image of $q(\langle\omega\rangle) = \langle\omega^{\sqrt{n}}\rangle$ and $q(\kappa\langle\omega\rangle) = \kappa^{\sqrt{n}}\langle\omega^{\sqrt{n}}\rangle$. Similarly, for an element in $q(\langle\omega\rangle)$ of the form $\omega^{j\sqrt{n}}, j \in [\sqrt{n}]$, we get $q^{(-1)}(\omega^{j\sqrt{n}}) = \omega^j\langle\omega^{\sqrt{n}}\rangle$ and for an element in $q(\kappa\langle\omega\rangle)$ of the form $\kappa^{\sqrt{n}}\omega^{j\sqrt{n}}$ we get $q^{(-1)}(\kappa^{\sqrt{n}}\omega^{j\sqrt{n}}) = \kappa\omega^j\langle\omega^{\sqrt{n}}\rangle$. Thus, we will ask our prover to provide an evaluation of the bivariate polynomial Q on the points (see Figure 4)

$$\{(z, q(z)) : z \in \langle\omega\rangle \cup \kappa\langle\omega\rangle\} \bigcup \left(\langle\omega^{\sqrt{n}}\rangle \times (\langle\omega^{\sqrt{n}}\rangle \cup \kappa^{\sqrt{n}}\langle\omega^{\sqrt{n}}\rangle)\right).$$

By our previous discussion we notice that the restriction of Q to certain rows and columns forms a word of an SRS-code of length $\approx \sqrt{n}$.

This allows us to measure proximity to the SRS-code of length n by measuring proximity to SRS-codes of size $\approx \sqrt{n}$. As in the additive case of section 6 we use the bivariate testing lemma, Lemma 6.13, to apply recursion and obtain quasilinear

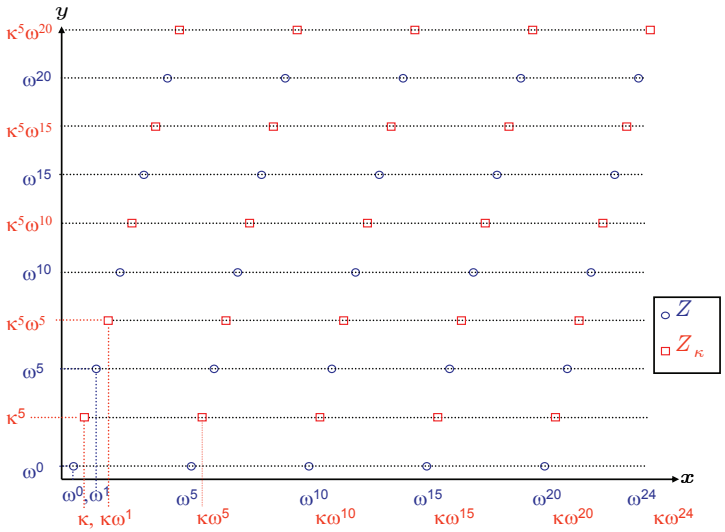

FIG. 3. *In this case,* $\mathbb{F} = \mathbb{Z}_{101}$. *Let* σ *generate* $\mathbb{F}^*$, *let* $\omega = \sigma^4$ *be an element of order* $n = 25$, *and let* $\kappa = \sigma^2$ *and* $q(z) = z^5$. *The elements on each axis are ordered by increasing powers of* σ *and the figure shows the subsets of points* $Z, Z_\kappa \subset \mathbb{F}^* \times \mathbb{F}^*$, *where* $Z = \{(z, q(z)) : z \in \langle\omega\rangle\}$ *and* $Z_\kappa = \{(\kappa z, q(\kappa z)) : z \in \langle\omega\rangle\}$.

sized proofs that can be tested with polylogarithmic query complexity. We need some technical modifications, arising from difficulties similar to the additive case. In particular, the degree of Q in its first variable is too large for applying Lemma 6.13, so we reduce this degree by breaking Q into a sum of several polynomials of sufficiently small degree. Additionally, we will not assume that $\sqrt{n}$ is an integer; rather we use the fact that $n = 2^k$ and work with the multiplicative subgroups generated by $n_0 = 2^{\lceil k/2 \rceil}, n_1 = 2^{\lfloor k/w \rfloor}$ that are of size $\approx \sqrt{n}$.

7.2. The shifted Reed–Solomon code. We prove Theorem 3.4 by proving a stronger statement about testing proximity to shifted RS-codes, defined next.

DEFINITION 7.2 (shifted Reed–Solomon code). *For* $\mathbb{F}$ *a finite field,* $\omega, \kappa \in \mathbb{F}^*, \mathrm{ord}(\omega) = n$, *and integer* d, *the degree-*d shifted Reed–Solomon (SRS)-code *over* $\langle\omega\rangle$ *with* shift κ *is*

$$\mathrm{SRS}(\mathbb{F}, d, \omega, \kappa) \triangleq \mathrm{RS}(\mathbb{F}, \langle\omega\rangle \cup \kappa\langle\omega\rangle, d).$$

Let PAIR-SMOOTH-SRS *be the pair language whose explicit inputs are triples* $(\mathbb{F}, S = \langle\omega\rangle \cup \kappa\langle\omega\rangle, d)$, *where* $\mathrm{ord}(\omega)$ *is a power of* 2 *and whose implicit inputs are functions* $p : S \to \mathbb{F}$. *The size of (explicit and implicit) inputs is* $\mathrm{ord}(\omega)$. *A pair* $((\mathbb{F}, S, d), p)$ *is in* PAIR-*SRS if* $p \in \mathrm{SRS}(\mathbb{F}, \omega, \kappa, d)$.

Notice that $\mathrm{SRS}(\mathbb{F}, \omega, 1, d) = \mathrm{RS}(\mathbb{F}, \langle\omega\rangle, d)$. Thus, Theorem 3.4 follows from the following theorem, the proof of which occupies the rest of the section.

THEOREM 7.3 (SRS PCP of proximity).

$$\text{PAIR-SMOOTH-SRS} \in \mathbf{Strong\text{-}PCPP}_{\delta/\operatorname{polylog} n}\left[\begin{array}{l}\mathsf{randomness}\ \log(n \cdot \operatorname{polylog} n),\\ \mathsf{query}\ O(\log|\mathbb{F}|),\\ \mathsf{distance}\ \mathsf{Hamming}_{\mathbb{F}}\end{array}\right].$$

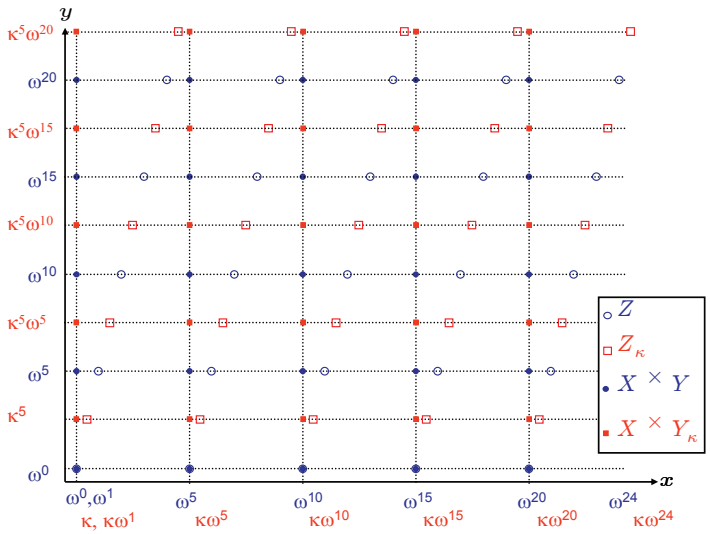

FIG. 4. *The proof of proximity for the smooth RS-code is the evaluation of Q on the set of points $Z \cup Z_\kappa \cup (X \times Y) \cup (X \times Y_\kappa)$. Notice that the restriction of this set to every row and column gives a pair—a multiplicative group of order $\sqrt{n}$ and a coset of it.*

As in the additive case, our proof will focus on the special case of degree $d = n/8 - 1$, and Proposition 6.14 generalizes this to an arbitrary degree.

7.3. The SRS proof of proximity and its associated verifier.

Notation. Recall $\mathrm{ord}(\omega) = n = 2^k$ for integer k. Let $n_0 = 2^{\lceil k/2 \rceil}$ and $n_1 = 2^{\lfloor k/2 \rfloor}$. Note that $n = n_0 \cdot n_1$ and $\sqrt{n/2} \le n_1 \le n_0 \le \sqrt{2n}$. For $r \le \mathrm{ord}(\alpha)$, let $\langle \alpha \rangle_r \triangleq \{\alpha^0, \alpha^1, \ldots, \alpha^{r-1}\}$. When dealing with a purported codeword of $\mathrm{SRS}(\mathbb{F}, \omega, \kappa, d)$ we treat it as a *pair* of functions, $p : \langle \omega \rangle \to \mathbb{F}$ and $p_\kappa : \kappa\langle \omega \rangle \to \mathbb{F}$.

DEFINITION 7.4 (SRS proof of proximity). *The proof of proximity for a purported codeword of the code $\mathrm{SRS}(\mathbb{F}, \omega, \kappa, n/8 - 1)$ is defined by induction on $n = \mathrm{ord}(\omega)$. If $n \le 16$ then it is empty. Otherwise, it is of the form*

$$\pi = (\{f^{(\ell)}, f_\kappa^{(\ell)}, g^{(\ell)}, g_\kappa^{(\ell)}, \{\pi^{(1,\beta,\ell)}, \pi^{(2,\beta,\ell)}\}_{\beta \in \langle \omega \rangle_{n_1}}, \{\pi^{(3,\tilde{\alpha},\ell)}\}_{\tilde{\alpha} \in \langle \omega^{n_1} \rangle}\}_{\ell \in \{0,\ldots,7\}}),$$

where

- $f^{(\ell)}, f_\kappa^{(\ell)} : \langle \omega^{n_1} \rangle \times \langle \omega \rangle_{n_1} \to \mathbb{F}$,
- $g^{(\ell)}, g_\kappa^{(\ell)} : \langle \omega^{n_1} \rangle \times \langle \omega^{n_0} \rangle \to \mathbb{F}$, *and*
- $\pi^{(1,\cdot,\ell)}, \pi^{(2,\cdot,\ell)}, \pi^{(3,\cdot,\ell)}$ *are proofs for* SRS*-codewords (over $\mathbb{F}$) of sizes n_0, n_0, n_1, respectively.*

We are now ready to describe the proximity tester.

DEFINITION 7.5 (SRS-verifier). *The verifier for proximity to* $\mathrm{SRS}(\mathbb{F}, \omega, \kappa, d = \mathrm{ord}(\omega)/8 - 1)$ *is denoted* $\mathrm{V}_{\mathrm{SRS}}^{\langle (p, p_\kappa), \pi \rangle}(\mathbb{F}, \omega, \kappa, d)$. *It receives as explicit input the parameters $\mathbb{F}, \omega, \kappa$ as defined in the statement of Theorem 7.3. The implicit input is a pair of functions $p : \langle \omega \rangle \to \mathbb{F}, p_\kappa : \kappa\langle \omega \rangle \to \mathbb{F}$. The proof π is as described in Definition 7.4. The verifier operates as follows.*

Base case ($n \le 16$). *The verifier reads p and p_κ in entirety and accepts iff $(p, p_\kappa) \in \mathrm{SRS}(\mathbb{F}, \omega, \kappa, 1)$.*

Recursion ($n \geq 32$). *The verifier computes* $n_0 = 2^{\lceil k/2 \rceil}, n_1 = 2^{\lfloor k/2 \rfloor}$ *and performs one of the following four tests with probability* $1/4$ *each.*

Outer. *Pick* $\tilde{\alpha} \in \langle \omega^{n_1} \rangle, \beta \in \langle \omega \rangle_{n_1}$ *uniformly at random; query* $p(\tilde{\alpha} \cdot \beta)$, $p_\kappa(\tilde{\alpha} \cdot \beta)$ *and* $f^{(\ell)}(\tilde{\alpha}, \beta)$, $f^{(\ell)}_\kappa(\tilde{\alpha}, \beta)$ *for every* $\ell \in \{0, \ldots, 7\}$*; accept iff* $p(\tilde{\alpha} \cdot \beta) = \sum_{\ell=0}^{7} (\tilde{\alpha} \cdot \beta)^{\ell n_0/8} \cdot f^{(\ell)}(\tilde{\alpha}, \beta)$ *and* $p_\kappa(\kappa\tilde{\alpha} \cdot \beta) = \sum_{\ell=0}^{7} (\kappa\tilde{\alpha} \cdot \beta)^{\ell n_0/8} \cdot f^{(\ell)}_\kappa(\tilde{\alpha}, \beta)$.

Inner. *Pick* $\ell \in \{0, \ldots, 7\}, \beta \in \langle \omega \rangle_{n_1}$ *at random and invoke*

$$\mathrm{V}_{\mathrm{SRS}}^{\langle (g^{(\ell)}|^{\leftrightarrow}_{\beta^{n_0}}, f^{(\ell)}|^{\leftrightarrow}_{\beta}), \pi^{(1,\beta,\ell)} \rangle}(\mathbb{F}, \omega^{n_1}, \beta, n_0/8 - 1).$$

Inner$_\kappa$. *Pick* $\ell \in \{0, \ldots, 7\}, \beta \in \langle \omega \rangle_{n_1}$ *at random and invoke*

$$\mathrm{V}_{\mathrm{SRS}}^{\langle (g^{(\ell)}_\kappa|^{\leftrightarrow}_{\beta^{n_0}}, f^{(\ell)}_\kappa|^{\leftrightarrow}_{\beta}), \pi^{(2,\beta,\ell)} \rangle}(\mathbb{F}, \omega^{n_1}, \kappa\beta, n_0/8 - 1).$$

Inner$_c$. *Pick* $\ell \in \{0, \ldots, 7\}, \tilde{\alpha} \in \langle \omega^{n_1} \rangle$ *at random and invoke*

$$\mathrm{V}_{\mathrm{SRS}}^{\langle (g^{(\ell)}|^{\updownarrow}_{\tilde{\alpha}}, g^{(\ell)}_\kappa|^{\updownarrow}_{\tilde{\alpha}}), \pi^{(3,\alpha,\ell)} \rangle}(\mathbb{F}, \omega^{n_0}, \kappa^{n_0}, n_1/8 - 1).$$

The remaining subsections analyze the performance of this verifier, thus yielding Theorem 3.4. Specifically, the next subsection analyzes the simple properties including the query complexity, the randomness/size complexity, and the completeness. The hard part, the soundness analysis, is addressed in subsection 7.5.

7.4. Basic properties.

PROPOSITION 7.6. $\mathrm{V}_{\mathrm{SRS}}^{\langle (p, p_\kappa), \pi \rangle}(\mathbb{F}, \omega, \kappa, n/8 - 1)$ *makes at most* 32 *queries into* p, p_κ, π. *It tosses at most* $\log_2 n + O(\log \log n)$ *random coins and runs in time* $\mathrm{poly}\, n$. *The size of the proof* π *is* $O(n \cdot \mathrm{polylog}\, n)$.

Proof. The proof is straightforward from the definition. The query complexity is easy to verify. In the base case, the verifier reads 32 field elements. In the inductive case, if the verifier chooses to execute the **Outer** step, then it makes $18 < 32$ queries; else it makes a recursive query to $\mathrm{V}_{\mathrm{SRS}}^{\langle \rangle}$ which makes 32 queries by induction.

The randomness complexity is similar. In the base case the verifier tosses 0 coins. In the inductive case, the verifier tosses $O(1)$ coins to determine which step to perform. If it chooses the outer test, it picks $\tilde{\alpha}$ and β at random with $\log n + O(1)$ coins. If it chooses one of the inner tests, it tosses $\log \sqrt{n} + O(1)$ coins to determine the inner call, and then $\log \sqrt{n} + O(\log \log \sqrt{n})$ coins in the recursive call. Adding up, we get a total of $\log n + O(\log \log n)$ coins in all. Notice that all computations are simple and can be performed in time $\mathrm{poly}\, n$. Finally, the size of the proof is bounded by $2^{\mathrm{randomness}}$. ∎

Next we move to the completeness part of the proof. This part is straightforward given the intuition developed in subsection 7.1. We first generalize Proposition 6.3 and express a univariate polynomial as a sum of bivariate polynomials of low degree. We then use this to describe a proof π that is accepted with probability 1 when accompanying an SRS-codeword.

PROPOSITION 7.7. *Given positive integers* $d_1, d_2, L,$ *and* d *such that* $d_1 \cdot d_2 \cdot L \geq d$, *the following holds: For every univariate polynomial* $P(x)$ *of degree less than* d *there exists a sequence of* L *bivariate polynomial* $Q^{(0)}(y, z), \ldots, Q^{(L-1)}(y, z)$, *of degree less than* d_1 *in* y *and* d_2 *in* z, *such that*

$$P(x) = \sum_{\ell=0}^{L-1} x^{\ell \cdot d_1} Q^{(\ell)}(x, x^{L \cdot d_1}).$$

Furthermore, such a sequence is unique if $d_1 \cdot d_2 \cdot L = d$.

Proof. Let the a_i's be the coefficients of P; i.e., $P(x) = \sum_{i=0}^{d-1} a_i x^i$. Now let

$$Q^{(\ell)}(y,z) = \sum_{i=0}^{d_1-1} \sum_{j=0}^{d_2-1} a_{i+\ell\cdot d_1 + j\cdot d_1 \cdot L} y^i z^j,$$

where a_i is defined to be 0 if $i \geq d$. It can be verified by inspection that we have

$$P(x) = \sum_{\ell=0}^{L-1} x^{\ell \cdot d_1} Q^{(\ell)}(x, x^{L\cdot d_1}).$$

Uniqueness follows from a counting argument: the set of sequences of polynomials $Q^{(0)}, \ldots, Q^{(L-1)}$ forms a vector space of dimension $L \cdot d_1 \cdot d_2 = d$, the dimension of the space of polynomials of degree less than d. ∎

PROPOSITION 7.8 (completeness). *If* (p, p_κ) *equal the SRS encoding of some polynomial* P *of degree less than* $n/8$*, then there exists a proof that causes the SRS proximity tester to accept with probability one.*

Proof. The proof is by induction on n. Let $Q^{(0)}, \ldots, Q^{(7)}$ be the polynomials as given by Proposition 7.7 applied to P with integers $d_1 = n_0/8$, $d_2 = n_1/8$, $L = 8$, and $d = n/8$. Note that we have $d_1 \cdot d_2 \cdot L = d$, since $n_0 \cdot n_1 = n$. For every $\ell \in \{0, \ldots, 7\}$, we let $f^{(\ell)}(\tilde{\alpha}, \beta) = Q^{(\ell)}(\tilde{\alpha}\beta, \beta^{n_0})$, $f_\kappa^{(\ell)}(\tilde{\alpha}, \beta) = Q^{(\ell)}(\kappa\tilde{\alpha}\beta, \kappa^{n_0}\beta^{n_0})$, $g^{(\ell)}(\tilde{\alpha}, \tilde{\beta}) = Q^{(\ell)}(\tilde{\alpha}, \tilde{\beta})$, and $g_\kappa^{(\ell)}(\tilde{\alpha}, \tilde{\beta}) = Q^{(\ell)}(\tilde{\alpha}, \kappa^{n_0}\tilde{\beta})$ for every $\tilde{\alpha} \in \langle \omega^{n_1} \rangle$, $\beta \in \langle \omega \rangle_{n_1}$, and $\tilde{\beta} \in \langle \omega^{n_0} \rangle$.

Note that the above choice of table $f^{(\ell)}$, $f_\kappa^{(\ell)}$, $g^{(\ell)}$, $g_\kappa^{(\ell)}$ is such that the **Outer** test accepts with probability one. Specifically, we have

$$\begin{aligned} p(\tilde{\alpha}\cdot\beta) &= P(\tilde{\alpha}\cdot\beta) \\ &= \sum_{\ell \in \{0,\ldots,7\}} (\tilde{\alpha}\cdot\beta)^{\ell n_0/8} Q^{(\ell)}(\tilde{\alpha}\beta, \tilde{\alpha}^{n_0}\beta^{n_0}) \\ &= \sum_{\ell \in \{0,\ldots,7\}} (\tilde{\alpha}\cdot\beta)^{\ell n_0/8} Q^{(\ell)}(\tilde{\alpha}\beta, \beta^{n_0}) \\ &= \sum_{\ell \in \{0,\ldots,7\}} (\tilde{\alpha}\cdot\beta)^{\ell n_0/8} f^{(\ell)}(\tilde{\alpha}, \beta). \end{aligned}$$

Similarly we get $p_\kappa(\kappa\tilde{\alpha}\cdot\beta) = \sum_{\ell=0}^{7} (\kappa\tilde{\alpha}\cdot\beta)^{\ell n_0/8} \cdot f_\kappa^{(\ell)}(\tilde{\alpha}, \beta)$.

Now we describe how to set up the rest of the subproofs $\pi^{(\cdot,\cdot,\cdot)}$ such that the inner tests accept. For this part, note that the recursive calls to the SRS proximity verifiers access implicit input pairs that satisfy the completeness condition on smaller inputs. Consider, for example, the invocation

$$\mathrm{V}_{\mathrm{SRS}}^{\langle (g^{(\ell)}|_{\beta^{n_0}}^{\leftrightarrow}, f^{(\ell)}|_{\beta}^{\leftrightarrow}), \pi^{(1,\beta,\ell)} \rangle}(\mathbb{F}, \omega^{n_1}, \beta, n_0/8 - 1)$$

by **Inner** for some $\ell \in \{0, \ldots, 7\}$ and $\beta \in \langle \omega \rangle_{n_1}$. We may relate these implicit inputs to the polynomial $Q^{(\ell)}$ as follows: We have $g^{(\ell)}|_{\beta^{n_0}}^{\leftrightarrow}(\tilde{\alpha}) = g^{(\ell)}(\tilde{\alpha}, \beta^{n_0}) = Q^{(\ell)}(\tilde{\alpha}, \beta^{n_0})$, $f^{(\ell)}|_{\beta}^{\leftrightarrow}(\tilde{\alpha}) = f^{(\ell)}(\tilde{\alpha}, \beta) = Q(\tilde{\alpha}\cdot\beta, \beta^{n_0})$. Thus, if we let $P'(\tilde{\alpha}) = Q^{(\ell)}(\tilde{\alpha}, \beta^{n_0})$ and $\omega' = \omega^{n_1}$, then the pair $f^{(\ell)}|_{\beta}^{\leftrightarrow}, g^{(\ell)}|_{\beta^{n_0}}^{\leftrightarrow}$ is a codeword of the SRS-code $\mathrm{SRS}(\mathbb{F}, \omega', \beta, n_0/8-1)$ corresponding to the encoding of P', and thus (by induction) there exists a proof $\pi^{(1,\beta,\ell)}$ that causes the recursive verifier to accept with probability one. Similar reasoning shows that the verifier also accepts with probability one when invoking $\mathbf{Inner}_\kappa$ or $\mathbf{Inner}_c$. ∎

7.5. Soundness. We now argue the soundness of the SRS-verifier as follows. By induction, for most $\tilde{\alpha}$ and β, the functions $g^{(\ell)}|^{\updownarrow}_{\tilde{\alpha}}$, $g^{(\ell)}|^{\leftrightarrow}_{\beta^{n_0}}$, $g^{(\ell)}_{\kappa}|^{\updownarrow}_{\tilde{\alpha}}$, and $g^{(\ell)}_{\kappa}|^{\leftrightarrow}_{\beta^{n_0}}$ are close to polynomials of degree roughly $\sqrt{n}$. The bivariate testing lemma, Lemma 6.13, implies that $g^{(\ell)}$ and $g^{(\ell)}_{\kappa}$ are very close to some low-degree bivariate polynomials $Q^{(\ell)}$ and $Q^{(\ell)}_{\kappa}$. Furthermore, we will show $Q^{(\ell)} \equiv Q^{(\ell)}_{\kappa}$. Next, we claim the function $f^{(\ell)}(z, z^{n_0})$ is close to the function $Q^{(\ell)}(z, z^{n_0})$ and similarly $f^{(\ell)}_{\kappa}$ is close to $Q^{(\ell)}(\kappa z, (\kappa z)^{n_0})$. Finally, we claim that $p(z)$ is close to $\sum_{\ell=0}^{7} z^{\ell n_0/8} \cdot Q^{(\ell)}(z, z^{n_0})$, i.e., p is close to a low-degree univariate polynomial. Similarly p_κ is close to *the same* low-degree polynomial, where the consistency of p and p_κ follows from the equivalence of Q and Q_κ.

LEMMA 7.9 (soundness). *There exists a constant c such that for every ϵ the following holds. If*

$$\Pr\left[\mathrm{V}_{\mathrm{SRS}}^{\langle (p,p_\kappa),\pi\rangle}(\mathbb{F}, \omega, \kappa, \mathrm{ord}(\omega)/8 - 1) = \texttt{reject}\right] \leq \epsilon,$$

then (p, p_κ) is $(c^{\log\log \mathrm{ord}(\omega)} \cdot \epsilon)$-close to $\mathrm{SRS}(\mathbb{F}, \omega, \kappa, \mathrm{ord}(\omega)/8 - 1)$.

Proof. Let c_0 be as in Lemma 6.13. Let $c_1 = 128 \cdot c_0$, $c_2 = (320 + 2c_1)$, and $c_3 = 8c_2 + 4$. We prove the lemma for $c = c_3^2$, which is a (large) constant. Note that the conditions imply $c > 1$ and $c > (2 \cdot (256 + 4c_1))^2$ as will be used later.

We assume the lemma is true by induction for smaller n and in particular for the recursive calls to the various **Inner** tests, and we now prove it for n. Assume $c^{\log\log n} \cdot \epsilon \leq 1$ or else the claim is vacuously true. We use below the fact that $c^{\log\log n_0} \leq c^{\log\log \sqrt{2n}} \leq c^{\log\log n - \frac{1}{2}}$ for every $c \geq 1$ and $n \geq 16$.

Denote by $\epsilon_O(\tilde{\alpha}, \beta)$ the probability that the **Outer** verifier rejects (p, p_κ, π) on random choice $\tilde{\alpha}$ and β. Let ϵ_O denote the expectation of $\epsilon_O(\tilde{\alpha}, \beta)$ over the choice of $\tilde{\alpha}$ and β. Similarly let $\epsilon_I(\ell, \beta)$, $\epsilon_\kappa(\ell, \beta)$, and $\epsilon_c(\ell, \tilde{\alpha})$ denote the probability that **Inner**, **Inner**$_\kappa$, and **Inner**$_c$ reject on random choice ℓ, β, and $\tilde{\alpha}$. Let $\epsilon_I(\ell)$, $\epsilon_\kappa(\ell)$, and $\epsilon_c(\ell)$ denote the expectations of these quantities over β and $\tilde{\alpha}$, and let ϵ_I, ϵ_κ, and ϵ_c denote the expectations over β, $\tilde{\alpha}$, and ℓ. By definition of the tester, we have $\epsilon = \frac{1}{4} \cdot (\epsilon_O + \epsilon_I + \epsilon_\kappa + \epsilon_c)$. Since these quantities are nonnegative, we get $\epsilon_O, \epsilon_I, \epsilon_\kappa, \epsilon_c \leq 4\epsilon$. Similarly, we have $\epsilon_O(\ell), \epsilon_I(\ell), \epsilon_\kappa(\ell), \epsilon_c(\ell) \leq 32\epsilon$ for every $\ell \in \{0, \ldots, 7\}$.

For $\ell \in \{0, \ldots, 7\}$, denote by $Q^{(\ell)}(x, y)$ the polynomial of degree at most $n_0/8$ in x and $n_1/8$ in y that is closest to $g^{(\ell)}$ (on the domain $\langle \omega^{n_1} \rangle \times \langle \omega^{n_0} \rangle$), where ties are broken arbitrarily. Similarly let $Q^{(\ell)}_{\kappa}$ be the closest polynomial to $g^{(\ell)}_{\kappa}$. Let $P(z) = \sum_{\ell=0}^{7} z^{\ell n_0/8} \cdot Q^{(\ell)}(z, z^{n_0})$ and let $P_\kappa(z) = \sum_{\ell=0}^{7} z^{\ell n_0/8} \cdot Q^{(\ell)}_{\kappa}(\kappa z, z^{n_0})$. We show below that (p, p_κ) is close to the evaluation of P on $\langle \omega \rangle \cup \kappa \langle \omega \rangle$. (Among other facts, we also show that $P_\kappa(z) \equiv P(\kappa \cdot z)$.)

Step 1. *The functions $Q^{(\ell)}$ (and $Q^{(\ell)}_{\kappa}$).* By the inductive hypothesis applied to **Inner**(ℓ, β), we have that $(g^{(\ell)}|^{\leftrightarrow}_{\beta^{n_0}}, f^{(\ell)}|^{\leftrightarrow}_{\beta})$ is $(c^{\log\log n_0} \cdot \epsilon_I(\ell, \beta))$-close to the SRS encoding of some degree $n_0/8$ polynomial. Thus $g^{(\ell)}|^{\leftrightarrow}_{\beta^{n_0}}$ is at most $(2 \cdot c^{\log\log n_0} \cdot \epsilon_I(\ell, \beta))$-close to the RS encoding of some degree-$n_0/8$ polynomial. Averaging over β, we get that $g^{(\ell)}$ is $(2 \cdot c^{\log\log n_0} \cdot \epsilon_I(\ell))$-close to some bivariate polynomial of degree $n_0/8$ in x and arbitrary degree in y. A similar argument based on the **Inner**$_c$ tests yields that $g^{(\ell)}$ is $(2 \cdot c^{\log\log n_1} \cdot \epsilon_c(\ell))$-close to some bivariate polynomial of degree $n_1/8$ in y and arbitrary degree in x. Now applying Lemma 6.13, we get that $g^{(\ell)}$ is close to some polynomial of degree $n_0/8$ in x and $n_1/8$ in y. More specifically, we

have

$$\begin{aligned}\delta^{(n_0/8,n_1/8)}(g^{(\ell)}) &\le c_0 \cdot \left(\delta^{(n_0/8,*)}(g^{(\ell)}) + \delta^{(*,n_1/8)}(g^{(\ell)})\right)\\ &\le c_0 \cdot \left(2 \cdot c^{\log\log n_0} \cdot \epsilon_I(\ell) + 2 \cdot c^{\log\log n_1} \cdot \epsilon_c(\ell)\right)\\ &\le 64 \cdot c_0 \left(c^{\log\log n_0} + c^{\log\log n_1}\right) \cdot \epsilon\\ &\le 128 \cdot c_0 \cdot c^{\log\log n_0} \cdot \epsilon.\end{aligned}$$

Letting $c_1 \stackrel{\text{def}}{=} 128 \cdot c_0$, we have that $\delta(g^{(\ell)}, Q^{(\ell)}) \le c_1 \cdot c^{\log\log n_0} \cdot \epsilon$. A similar argument shows that $\delta(g_\kappa^{(\ell)}, Q_\kappa^{(\ell)}) \le c_1 \cdot c^{\log\log n_0} \cdot \epsilon$.

Step 2. *The functions* $f^{(\ell)}$ *and* $f_\kappa^{(\ell)}$. Next we move to the functions $f^{(\ell)}$ (for any $\ell \in \{0,\ldots,7\}$) and show that for most $\tilde{\alpha}, \beta$ $f^{(\ell)}(\tilde{\alpha},\beta) = Q^{(\ell)}(\tilde{\alpha}\cdot\beta, \beta^{n_0})$ (and similarly for most $\tilde{\alpha}, \beta$, $f_\kappa^{(\ell)}(\tilde{\alpha},\beta) = Q_\kappa^{(\ell)}(\kappa\cdot\tilde{\alpha}\cdot\beta, \beta^{n_0})$.

We first describe the argument informally. Consider a β such that $g^{(\ell)}|^{\leftrightarrow}_{\beta^{n_0}}$ and $f^{(\ell)}|^{\leftrightarrow}_{\beta}$ pass the **Inner** test with high probability *and* the SRS-codeword correspond to the encoding of $Q(\cdot,\beta^{n_0})$. For such β, we have $f^{(\ell)}|^{\leftrightarrow}_{\beta}(\tilde{\alpha},\beta) = Q(\tilde{\alpha}\cdot\beta,\beta^{n_0})$ for most $\tilde{\alpha}$. It remains to make this argument quantitative, and we do so below.

Define a β to be *good* if the fractional distance between $(g^{(\ell)}|^{\leftrightarrow}_{\beta^{n_0}}, f^{(\ell)}|^{\leftrightarrow}_{\beta})$ and the $\mathrm{SRS}(\mathbb{F}, n_0/8, \omega^{n_1}, \beta)$ encoding of $Q^{(\ell)}(\cdot,\beta^{n_0})$ is at most $1/8$. Let $\delta(\beta)$ denote the relative distance of $f^{(\ell)}|^{\leftrightarrow}_{\beta}$ to the projection of the SRS-codeword nearest to $(g^{(\ell)}|^{\leftrightarrow}_{\beta^{n_0}}, f^{(\ell)}|^{\leftrightarrow}_{\beta})$ onto the second half of the coordinates. Note that

$$\begin{aligned}&\Pr_{\tilde{\alpha},\beta}[f^{(\ell)}(\tilde{\alpha},\beta) \ne Q^{(\ell)}(\tilde{\alpha}\cdot\beta,\beta^{n_0})]\\ &\le \mathbb{E}_\beta[\delta(\beta)|\beta \text{ is good}] \cdot \Pr_\beta[\beta \text{ is good}] + \Pr_\beta[\beta \text{ is not good}]\\ &\le \mathbb{E}_\beta[\delta(\beta)] + \Pr_\beta[\beta \text{ is not good}].\end{aligned}$$

Note that the first term above is easily estimated as in Step 1. We get $\mathbb{E}_\beta[\delta(\beta)] \le (2 \cdot c^{\log\log n_0} \cdot \epsilon_I(\ell)) \le 64 \cdot c^{\log\log n_0} \cdot \epsilon$.

Next we describe two sets that cover the case where β is not good. Let S_1 be the set of all β such that the distance of $(g^{(\ell)}|^{\leftrightarrow}_{\beta^{n_0}}, f^{(\ell)}|^{\leftrightarrow}_{\beta})$ from every SRS-codeword is more than $\frac{1}{8}$. For every $\beta \in S_1$ note that the $\epsilon_I(\ell,\beta) \ge \frac{1}{8c^{\log\log n_0}}$. Thus, the probability that $\beta \in S_1$ is at most $8 \cdot c^{\log\log n_0} \cdot \epsilon_I(\ell) \le 256 \cdot c^{\log\log n_0} \cdot \epsilon$. Next, let S_2 be the set of β for which $(g^{(\ell)}|^{\leftrightarrow}_{\beta^{n_0}}, f^{(\ell)}|^{\leftrightarrow}_{\beta})$ is $\frac{1}{8}$-close to an SRS-codeword, but the SRS-codeword is not the encoding of $Q^{(\ell)}(\cdot,\beta^{n_0})$. For every $\beta \in S_2$, we have that $Q^{(\ell)}(\tilde{\alpha},\beta^{n_0})$ and $g^{(\ell)}(\tilde{\alpha},\beta^{n_0})$ disagree for at least $\frac{5}{8}$ fraction of the $\tilde{\alpha}$'s (since $Q^{(\ell)}(\cdot,\beta^{n_0})$ and the other SRS-codeword can agree on at most $n_0/8$ values of the $\tilde{\alpha}$'s). Since the distance between $g^{(\ell)}$ and $Q^{(\ell)}$ is at most $c_1 \cdot c^{\log\log n_0} \cdot \epsilon$, we get that the probability that $\beta \in S_2$ is at most $\frac{8}{5} \cdot c_1 \cdot c^{\log\log n_0} \cdot \epsilon \le 2c_1 \cdot c^{\log\log n_0} \cdot \epsilon$. Finally, we note that if β is not good, then $\beta \in S_1 \cup S_2$. Thus we get

$$\Pr_\beta[\beta \text{ is not good}] \le (256 + 2c_1) \cdot c^{\log\log n_0} \cdot \epsilon.$$

Putting the above together, and recalling $c_2 = (320+2c_1)$, we get $\Pr_{\tilde{\alpha},\beta}[f^{(\ell)}(\tilde{\alpha},\beta) \ne Q^{(\ell)}(\tilde{\alpha}\cdot\beta,\beta^{n_0})] \le c_2 \cdot c^{\log\log n_0} \cdot \epsilon$. Similarly we also get $\Pr_{\tilde{\alpha},\beta}[f_\kappa^{(\ell)}(\tilde{\alpha},\beta) \ne Q_\kappa^{(\ell)}(\kappa\cdot\tilde{\alpha}\cdot\beta,\beta^{n_0})] \le c_2 \cdot c^{\log\log n_0} \cdot \epsilon$.

Step 3. *The functions p and p_κ.* Next we move to the functions p and show that $p(z)$ usually equals $P(z) = \sum_{\ell=0}^{7} z^{\ell \cdot n_0/8} Q^{(\ell)}(z, z^{n_0})$ for $z \in \langle\omega\rangle$. Note that $\langle\omega\rangle$ is in one-to-one correspondence with $\{\tilde{\alpha} \cdot \beta\}$, where $\tilde{\alpha} \in \langle\omega^{n_1}\rangle$ and $\beta \in \langle\omega\rangle_{n_1}$, and so we are interested in estimating the probability that

$$p(\tilde{\alpha} \cdot \beta) \neq \sum_{\ell=0}^{7} (\tilde{\alpha}\beta)^{\ell \cdot n_0/8} Q^{(\ell)}(\tilde{\alpha}\beta, \beta^{n_0}).$$

We consider the following events: For $\ell \in \{0, \ldots, 7\}$, let E_ℓ be the event that $f^{(\ell)}(\tilde{\alpha}, \beta) \neq Q^{(\ell)}(\tilde{\alpha}\beta, \beta^{n_0})$. Further, let E' be the event that $p(\tilde{\alpha}\cdot\beta) \neq \sum_{\ell=0}^{7} (\tilde{\alpha}\beta)^{\ell \cdot n_0/8} \cdot f^{(\ell)}(\tilde{\alpha}\beta, \beta^{n_0})$. For any ℓ, we have that E_ℓ happens with probability at most $c_2 \cdot c^{\log\log n_0} \cdot \epsilon$. Further, E' happens with probability at most $\epsilon_O \leq 4\epsilon \leq 4 \cdot c^{\log\log n_0} \cdot \epsilon$, using $c \geq 1$. Furthermore, if none of the events E', $\{E_\ell\}_\ell$ occurs, then we do have $p(\tilde{\alpha} \cdot \beta) = \sum_{\ell=0}^{7} (\tilde{\alpha}\beta)^{\ell \cdot n_0/8} Q^{(\ell)}(\tilde{\alpha}\beta, \beta^{n_0})$. Thus, recalling $c_3 = 8c_2 + 4$, we get that $\delta(p, P) \leq c_3 \cdot c^{\log\log n_0} \cdot \epsilon$. Similarly, we get $\delta(p_\kappa, P_\kappa) \leq c_3 \cdot c^{\log\log n_0} \cdot \epsilon$. Combining, we get that $\delta((p, p_\kappa), (P, P_\kappa)) \leq c_3 \cdot c^{\log\log n_0} \cdot \epsilon$. By the definition of $c = c_3^2$ and the condition $c^{\log\log n_0} \leq c^{\log\log n - \frac{1}{2}}$, we get that the final proximity above is at most $c^{\log\log n} \cdot \epsilon$, as desired.

All that remains to be shown is that P and P_κ are consistent, i.e., that $P_\kappa(z) = P(\kappa \cdot z)$.

Step 4. *Consistency of the κ shifts.* We prove this part by showing that for every ℓ, Q and Q_κ are consistent, i.e., $Q_\kappa^{(\ell)}(x, y) = Q^{(\ell)}(x, \kappa^{n_0} y)$. This suffices, since we will then have

$$P_\kappa(z) = \sum_\ell z^{\ell n_0/8} Q_\kappa^{(\ell)}(\kappa z, z^{n_0}) = \sum_\ell z^{\ell n_0/8} Q^{(\ell)}(\kappa z, \kappa^{n_0} z^{n_0}) = P(\kappa z).$$

Fix $\ell \in \{0, \ldots, 7\}$. Define $\tilde{\alpha} \in \langle\omega^{n_1}\rangle$ to be *good* if $(g^{(\ell)}|_{\tilde{\alpha}}^{\uparrow}, g_\kappa^{(\ell)}|_{\tilde{\alpha}}^{\uparrow})$ is 1/8 close to some SRS-codeword *and* $g^{(\ell)}|_{\tilde{\alpha}}^{\uparrow}$ is 1/4 close to the evaluations of $Q^{(\ell)}(\tilde{\alpha}, \cdot)$, *and* $g_\kappa^{(\ell)}|_{\tilde{\alpha}}^{\uparrow}$ is 1/4 close to the evaluations of $Q_\kappa^{(\ell)}(\tilde{\alpha}, \cdot)$. It is straightforward to see that if $\tilde{\alpha}$ is good, then $Q_\kappa^{(\ell)}(\tilde{\alpha}, y) = Q^{(\ell)}(\tilde{\alpha}, \kappa^{n_0} y)$. Furthermore, if the fraction of good $\tilde{\alpha}$'s is more than 1/8, then we will have $Q_\kappa^{(\ell)}(x, y) = Q^{(\ell)}(x, \kappa^{n_0} y)$ as desired. So it suffices to bound the probability of $\tilde{\alpha}$ being not good (to be less than 7/8).

The three conditions above can be analyzed in a manner similar to the analysis of the probability of β not being *good* in Step 2. Specifically, we have the following: The probability that $(g^{(\ell)}|_{\tilde{\alpha}}^{\uparrow}, g_\kappa^{(\ell)}|_{\tilde{\alpha}}^{\uparrow})$ is not 1/8 close to some SRS-codeword is at most $8 \cdot c^{\log\log n_1} \cdot \epsilon_c(\ell) \leq 256 \cdot c^{\log\log n_0} \cdot \epsilon$. The probability that $g^{(\ell)}|_{\tilde{\alpha}}^{\uparrow}$ is 1/8 close to some SRS-codeword and not 1/4 close to the evaluations of $Q^{(\ell)}(\tilde{\alpha}, \cdot)$ is at most $2 \cdot c_1 \cdot c^{\log\log n_0} \cdot \epsilon$. Finally, the probability that $g_\kappa^{(\ell)}|_{\tilde{\alpha}}^{\uparrow}$ is 1/8 close to some SRS-codeword and not 1/4 close to the evaluations of $Q_\kappa^{(\ell)}(\tilde{\alpha}, \cdot)$ is at most $2 \cdot c_1 \cdot c^{\log\log n_0} \cdot \epsilon$. Combining the above we get that the probability that $\tilde{\alpha}$ is not good is at most $(256 + 4 \cdot c_1) \cdot c^{\log\log n_0} \cdot \epsilon$. In turn the final quantity is at most $(256 + 4 \cdot c_1) \cdot c^{\log\log n - \frac{1}{2}} \cdot \epsilon \leq \frac{1}{2} c^{\log\log n} \cdot \epsilon \leq \frac{1}{2} < \frac{7}{8}$ as desired. The first inequality follows from the fact that we have $c > (2 \cdot (256 + 4 \cdot c_1))^2$. This concludes the proof that Q and Q_κ and hence P and P_κ are consistent. Combined with Step 3, this concludes the soundness analysis. □

7.6. Proof of Theorem 3.4.

Proof of smooth SRS PCPP Theorem 7.3 (for special case of $d = n/8 - 1$). The verifier is formally defined in subsection 7.3. Its query complexity, randomness, and

proof length are given by Proposition 7.6. Its completeness is asserted by Proposition 7.8. Its soundness is analyzed in Lemma 7.9. □

Proof of Theorem 3.2. The statement for $d = n/8 - 1$ follows from Theorem 7.3 by setting $\kappa = 1$. The generalization to arbitrary degree d follows from Proposition 6.14. □

7.7. Proving Theorem 2.2 using smooth RS-codes. In this section we briefly outline the modifications needed to prove Theorem 2.2 using PCPPs for *smooth* RS-codes (Theorem 3.4). Our motivation is to present a proof of Theorem 2.2 in as general a setting as possible and in particular show that we do not require the underlying field to be of characteristic 2. Our exposition follows that of subsection 3.3.1.

Our first challenge is to show the existence and abundance of fields with a multiplicative subgroup of order that is a power of 2. A second problem is that we cannot embed de Bruijn graphs in an affine graph of constant degree (Proposition 5.11), because our fields are not of characteristic 2. To solve this problem we embed the de Bruijn graph in an affine graph of logarithmic degree. Thus, we end with a weaker version of Theorem 3.7 and we need to prove quasilinear PCPs for this weaker version, using Theorem 3.4. We now elaborate on each of these three issues.

Prime fields with 2*-smooth subgroups.* Theorem 3.4 holds only for Reed–Solomon codes $\mathrm{RS}(\mathbb{F}, \langle\omega\rangle, d)$, where $\mathrm{ord}(\omega)$ is a power of 2. The following (special case of a) theorem due to Linnik [33] shows that there is a polynomial time computable sequence $\{\mathbb{F}_n\}_{n\in\mathbb{N}}$ such that $n \le |\mathbb{F}_n| \le n^{O(1)}$ and $\mathbb{F}_n^*$ has an element ω the order of which is a power of 2.

THEOREM 7.10 (Linnik's theorem [33]). *There exists a constant* $1 < L < 6$ *such that for any sufficiently large* d*, there exists a prime of size* $\le d^L$ *such that* $d|(p-1)$.

Remark 7.11. The general statement of Linnik's theorem says that there exists a universal constant L such that for every pair of integers $0 < a < n$, there exists a prime $p < n^L$ such that $n|(p-a)$. The case stated above is derived from the general statement by setting $a = 1$.

Suppose we wish to find a field $\mathbb{F}_n$ of size $n^{O(1)}$ that has an element ω of order $\Theta(n)$ that is a power of 2. Let d be a power of 2 such that $n < d \le O(n)$. Let $\mathbb{F}_n$ be the prime field $\mathbb{Z}_p$ for p as in Linnik's theorem, Theorem 7.10. We have $|\mathbb{F}_n^*| = p-1 = k\cdot d$. Let σ be a generator of $\mathbb{F}^*$ and set $\omega = \sigma^k$. Then $\mathrm{ord}(\omega) = \Theta(n)$ is a power of 2. Notice that p and ω can be found in polynomial time (in n) by an exhaustive search. Finally, each element of $\mathbb{F}_n$ is represented by $O(\log n)$ bits.

Algebraic constraint satisfaction problems for PAIR-SMOOTH-RS. We now sketch a proof of a weaker version of Theorem 3.7. The weakness of this version refers to the fact that the number of affine functions is not constant but polylogarithmic. However, we will be able to prove this theorem without relying on fields of characteristic 2. Rather, we need our field only to be sufficiently large.

THEOREM 7.12 (ALGEBRAIC-CSP is NP-complete (weak version)). *There exists an integer* d *such that for any proper complexity function* $t : \mathbb{N}^+ \to \mathbb{N}^+$ *and* $L \in \mathrm{NTIME}(t(n))$*, the following hold.*

1. L *is reducible to* ALGEBRAIC-CSP *in time* $\mathrm{poly}\, t(n)$.
2. *Given any field* $\mathbb{F}$ *of size* $\Omega(t(n)\,\mathrm{polylog}\, t(n))$*, an instance of* L *of size* n *is reduced to an instance of* $\mathrm{ALGEBRAIC\text{-}CSP}_{\mathrm{polylog}\, n,d}$ *over* $\mathbb{F}$.

Proof. The reduction underlying Theorem 3.7 and described in subsection 5.2 relied on the existence of a homomorphism of the wrapped de Bruijn graph B_k (see Definition 5.5) into an affine graph (as per Definition 5.9) of constant degree over a

field of characteristic 2. This homomorphism, in turn, relies on the additive structure of the field (see the proof of Proposition 5.11).

As in the proof of Theorem 5.4, we will assume only that the underlying field is sufficiently large. We use the existence of an efficiently computable homomorphism of B_k into the hypercube of dimension $k + O(\log k)$ (for details see [31]). Next we notice the hypercube of dimension k' can be embedded into an affine graph over any finite field $\mathbb{F}, |\mathbb{F}| > 2^{k'}$. Indeed, fix $\omega \in \mathbb{F}^*$ with $\mathrm{ord}(\omega) \geq 2^{k'}$. Consider the affine graph G over vertex set $\langle\omega\rangle$ and edge set generated by $\{\omega^{(-1)^b \cdot 2^\ell}\}_{\ell \in [k'], b \in \{0,1\}}$. To see that the hypercube can be embedded into G, let $\bar{i} \in \{0, \ldots, 2^{k'} - 1\}$ denote the integer with binary representation $i \in \{0,1\}^{k'}$. Associate with i the element $\omega^{\bar{i}} \in \langle\omega\rangle$. We claim that the elements associated with i and $i + e_\ell$ (in the hypercube) are adjacent in G. Indeed, let b denote the ℓth bit of i and notice that i is associated with $\omega^{\bar{i}}$ whereas $i + e_\ell$ is associated with $\omega^{\bar{i}+(-1)^b 2^\ell} = \omega^{(-1)^b \cdot 2^\ell} \cdot \omega^{\bar{i}}$, so the corresponding vertices are adjacent in G.

From here on we follow the proof of Theorem 3.7, using the above defined affine graph G of degree $\mathrm{polylog}\, n$ instead of the constant degree graph used there. All other details are identical. Thus, our reduction results in an instance of ALGEBRAIC-CSP$_{\mathrm{polylog}\, n, O(1)}$. ∎

Quasilinear PCPs via PCPPs for smooth RS-codes. We now provide efficient PCPs for the instances of ALGEBRAIC-CSP given by Theorem 7.12 and thus provide an alternative proof of Theorem 2.2.

Proof of quasilinear PCP Theorem 2.2. Let ψ be an instance of $L \in \mathrm{NTIME}(t(n))$ of size n. Using Theorem 7.12 we reduce ψ to an instance $\phi = \{\mathbb{F}, \{\textsc{Aff}_1, \ldots, \textsc{Aff}_k\}, H, C\}$ of ALGEBRAIC-CSP$_{k,d}$ of size $n' = n \cdot \mathrm{polylog}\, n$, where $k = \mathrm{polylog}\, n, d = O(1)$ and $\mathbb{F}$ is the smallest prime field containing an element ω with $100kdn' < \mathrm{ord}(\omega) \leq 200kdn'$, where $\mathrm{ord}(\omega)$ is a power of 2. Linnik's theorem, Theorem 7.10, implies that $\mathbb{F}$ and ω exist and can be found in polynomial time (by an exhaustive search).

From here on our proof is essentially identical to the proof presented in subsection 3.3.1 and we use the notation given there. Notice that since $k = \mathrm{polylog}\, n$, the first subtest invokes an RS-verifier with proximity parameter $1/\mathrm{polylog}\, n$. However, Proposition 2.9 implies that the query complexity increases only by a factor of $\mathrm{polylog}\, n$. All other details are exactly as in subsection 3.3.1, and this completes the alternative proof of Theorem 2.2. ∎

Acknowledgments. We thank Oded Goldreich, Prahladh Harsha, Salil Vadhan, and Chris Umans for helpful discussions. We thank Don Coppersmith for pointing us to Linnik's theorem, which appears here as Theorem 7.10. We thank Venkatesan Guruswami, Subhash Khot, Jaikumar Radhakrishnan, and an anonymous referee for pointing out errors in previous versions of the paper. Finally, we thank the editor and anonymous referees for remarks that helped improve the clarity of the presentation.

LOWER-STRETCH SPANNING TREES*

MICHAEL ELKIN†, YUVAL EMEK‡, DANIEL A. SPIELMAN§, AND SHANG-HUA TENG¶

Abstract. We show that every weighted connected graph G contains as a subgraph a spanning tree into which the edges of G can be embedded with average stretch $O\left(\log^2 n \log\log n\right)$. Moreover, we show that this tree can be constructed in time $O\left(m \log n + n \log^2 n\right)$ in general, and in time $O(m \log n)$ if the input graph is unweighted. The main ingredient in our construction is a novel graph decomposition technique. Our new algorithm can be immediately used to improve the running time of the recent solver for symmetric diagonally dominant linear systems of Spielman and Teng from $m2^{\left(O(\sqrt{\log n \log\log n})\right)}$ to $m \log^{O(1)} n$, and to $O\left(n \log^2 n \log\log n\right)$ when the system is planar. Our result can also be used to improve several earlier approximation algorithms that use low-stretch spanning trees.

Key words. low-distortion embeddings, probabilistic tree metrics, low-stretch spanning trees

1. Introduction.

Let $G = (V, E, \ell)$ be a weighted connected graph, where $\ell : E \to \mathbb{R}_{>0}$ assigns a positive *length* to each edge. Given a spanning tree T of V, we define the *distance* in T between a pair of vertices $u, v \in V$, denoted $\mathrm{dist}_T(u, v)$, to be the sum of the lengths of the edges on the unique path in T between u and v. We can then define the *stretch*[1] of an edge $(u, v) \in E$ to be

$$\mathrm{stretch}_T(u, v) = \frac{\mathrm{dist}_T(u, v)}{\ell(u, v)},$$

and the average stretch over all edges of E to be

$$\text{ave-stretch}_T(E) = \frac{1}{|E|} \sum_{(u,v)\in E} \mathrm{stretch}_T(u, v).$$

Alon et al. [1] proved that every weighted connected graph $G = (V, E, \ell)$ of n vertices and m edges contains a spanning tree T such that

$$\text{ave-stretch}_T(E) = \exp\left(O(\sqrt{\log n \log\log n})\right)$$

[1]Our definition of the stretch differs slightly from that used in [1]: $\mathrm{dist}_T(u, v)/\mathrm{dist}_G(u, v)$, where $\mathrm{dist}_G(u, v)$ is the length of the shortest path between u and v. See section 1.1 for a discussion of the difference.

and that there exists a collection $\tau = \{T_1, \ldots, T_h\}$ of spanning trees of G and a probability distribution Π over τ such that for every edge $e \in E$,

$$\mathbf{E}_{T \leftarrow \Pi}\left[\text{stretch}_T(e)\right] = \exp\left(O(\sqrt{\log n \log\log n})\right).$$

The class of graphs considered in this context includes multigraphs that may contain self-loops and multiple edges between pairs of vertices. Considering multigraphs is essential for several applications (including some in [1]). Specifically, in some applications it is required to minimize various weighted averages of the stretches, where different edges may have different contributions to the average stretch, rather than a simple average as defined above. By allowing edge multiplicities, one can control the coefficients of these weighted averages, and thus our result is sufficiently general for such applications.

The result of [1] triggered the study of low-distortion embeddings into *probabilistic tree metrics*. Most notable in this context is the work of Bartal [3, 4] which shows that if the requirement that the trees T be *subgraphs* of G is abandoned, then the upper bound of [1] can be improved by finding a tree whose distances approximate those in the original graph with average distortion $O(\log n \cdot \log\log n)$. On the negative side, a lower bound of $\Omega(\log n)$ is known for both scenarios [1, 3]. The gap left by Bartal was recently closed by Fakcharoenphol, Rao, and Talwar [11], who have shown a tight upper bound of $O(\log n)$.

However, some applications of graph-metric approximation require trees that are subgraphs. Until now, no progress had been made on reducing the gap between the upper and lower bounds proved in [1] on the average stretch of subgraph spanning trees. The bound achieved in [1] for general weighted graphs had been the best bound known for *unweighted* graphs (where every edge admits a unit length), and even for *unweighted planar* graphs.

In this paper,[2] we significantly narrow this gap by improving the upper bound of [1] from $\exp(O(\sqrt{\log n \log\log n}))$ to $O(\log^2 n \log\log n)$. Specifically, we give an algorithm that for every weighted connected graph $G = (V, E, \ell)$ constructs a spanning tree $T \subseteq E$ that satisfies $\text{ave-stretch}_T(E) = O(\log^2 n \log\log n)$. The running time of our algorithm is $O(m \log n + n \log^2 n)$ for weighted graphs and $O(m \log n)$ for unweighted graphs. Note that the input graph need not be simple and its number of edges m can be much larger than $\binom{n}{2}$. However, as proved in [1], it is enough to consider graphs with at most $n(n+1)$ edges.

We begin by presenting a simpler algorithm that guarantees a weaker bound, $\text{ave-stretch}_T(E) = O(\log^3 n)$. As a consequence of the result in [1] that the existence of a spanning tree with average stretch $f(n)$ for every weighted graph implies the existence of a distribution of spanning trees in which every edge has expected stretch $f(n)$, our result implies that for every weighted connected graph $G = (V, E, \ell)$ there exists a probability distribution Π over a set $\tau = \{T_1, \ldots, T_h\}$ of spanning trees ($T \subseteq E$ for every $T \in \tau$) such that for every $e \in E$, $\mathbf{E}_{T \leftarrow \Pi}\left[\text{stretch}_T(e)\right] = O(\log^2 n \log\log n)$. Furthermore, our algorithm itself can be adapted to produce a probability distribution Π that guarantees a slightly weaker bound of $O(\log^3 n)$ in time $O(m \cdot \log^2 n)$.

In a subsequent paper, Emek and Peleg [9] proved that every series-parallel unweighted graph admits a spanning tree of average stretch $O(\log n)$. This bound is tight as it matches the lower bound established in [13].

[2] In a previous version of this paper, we proved the weaker bound on average stretch of $O((\log n \log\log n)^2)$. The improvement in this paper comes from rearranging the arithmetic in our analysis. Bartal [5] has obtained a similar improvement by other means.

1.1. Applications. For some of the applications listed below it is essential to define the stretch of an edge $(u,v) \in E$ as in [1], namely, $\text{stretch}_T(u,v) = \text{dist}_T(u,v)/\text{dist}_G(u,v)$. The algorithms presented in this paper can be adapted to handle this alternative definition of stretch, but this requires the computation of $\text{dist}_G(u,v)$ for every edge $(u,v) \in E$. The additional computation can be performed in a preprocessing stage independently of the algorithms themselves, but the time required for this preprocessing stage may dominate the running time of the algorithms.

1.1.1. Solving linear systems. Boman and Hendrickson [6] were the first to realize that low-stretch spanning trees could be used to solve symmetric diagonally dominant linear systems. They applied the spanning trees of [1] to design solvers that run in time

$$m^{3/2} 2^{O(\sqrt{\log n \log\log n})} \log(1/\epsilon),$$

where ϵ is the precision of the solution. Spielman and Teng [18] improved their results to

$$m 2^{O(\sqrt{\log n \log\log n})} \log(1/\epsilon).$$

Unfortunately, the trees produced by the algorithms of Bartal [3, 4] and Fakcharoenphol, Rao, and Talwar [11] cannot be used to improve these linear solvers, and it is currently not known whether it is possible to solve linear systems efficiently using trees that are not subgraphs. By applying the low-stretch spanning trees developed in this paper, we can reduce the time for solving these linear systems to

$$m \log^{O(1)} n \log(1/\epsilon),$$

and to $O(n \log^2 n \log\log n \log(1/\epsilon))$ when the systems are planar. Applying a reduction that was recently introduced by Boman, Hendrickson, and Vavasis [7], one obtains an $O(n \log^2 n \log\log n \log(1/\epsilon))$ time algorithm for solving the linear systems that arise when applying the finite element method to solve two-dimensional elliptic partial differential equations.

1.1.2. Alon–Karp–Peleg–West game. Alon et al. [1] constructed low-stretch spanning trees to upper-bound the value of a zero-sum two-player game that arose in their analysis of an algorithm for the k-server problem: at each turn, the *tree player* chooses a spanning tree T, and the *edge player* chooses an edge $e \in E$, simultaneously. The payoff to the edge player is 0 if $e \in T$ and $\text{stretch}_T(e)+1$ otherwise. They showed that if every n-vertex weighted connected graph G has a spanning tree T of average stretch $f(n)$, then the value of this game is at most $f(n)+1$. Our new result lowers the bound on the value of this game from $\exp\left(O(\sqrt{\log n \log\log n})\right)$ to $O\left(\log^2 n \log\log n\right)$.

1.1.3. MCT approximation. Our result can be used to dramatically improve the upper bound on the approximability of the *minimum communication cost spanning tree* (henceforth, *MCT*) problem. This problem was introduced in [14] and is listed as [ND7] in [12] and [8]. An instance of this problem is a weighted graph $G = (V, E, \ell)$ and a matrix $\{r(u,v) \mid u, v \in V\}$ of nonnegative requirements. The goal is to construct a spanning tree T that minimizes $\text{cost}(T) = \sum_{u,v \in V} r(u,v) \cdot \text{dist}_T(u,v)$.

Peleg and Reshef [16] developed a $2^{O(\sqrt{\log n \cdot \log\log n})}$ approximation algorithm for the MCT problem on metrics using the result of [1]. A similar approximation ratio can be achieved for arbitrary graphs. Therefore our result can be used to produce an efficient $O(\log^2 n \log\log n)$ approximation algorithm for the MCT problem on arbitrary graphs.

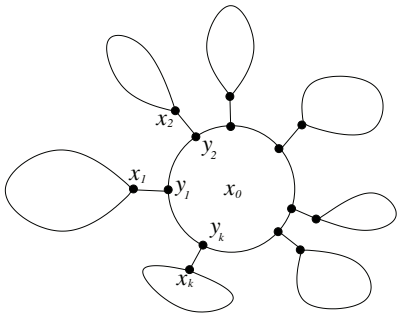

FIG. 1. *Star-decomposition.*

1.2. Our techniques. We build our low-stretch spanning trees by recursively applying a new graph decomposition that we call a *star-decomposition*. A star-decomposition of a graph is a partition of the vertices into sets that are connected into a star: a central set is connected to each other set by a single edge (see Figure 1). We show how to find star-decompositions that do not cut too many short edges and such that the radius of the graph induced by the star-decomposition is not much larger than the radius of the original graph.

Our algorithm for finding a low-cost star-decomposition applies a generalization of the ball-growing technique of Awerbuch [2] to grow *cones*, where the cone at a vertex x induced by a set of vertices S is the set of vertices whose shortest path to S goes through x.

1.3. The structure of the paper. In section 2, we define our notation. In section 3, we introduce the star-decomposition of a weighted connected graph. We then show how to use this decomposition to construct a subgraph spanning tree with average stretch $O(\log^3 n)$. In section 4, we present our star-decomposition algorithm. In section 5, we refine our construction and improve the average stretch to $O\left(\log^2 n \log\log n\right)$. Finally, we conclude the paper in section 6 and list some open questions.

2. Preliminaries. Throughout the paper, we assume that the input graph is a weighted connected multigraph $G = (V, E, \ell)$, where ℓ is a *length* function from E to the positive reals. Unless stated otherwise, we let n and m denote the number of vertices and the number of edges in the graph, respectively. The *cost* of an edge $e \in E$ is defined as the reciprocal of its length,[3] denoted by $\text{cost}(e) = 1/\ell(e)$. The *cost* of a set $F \subseteq E$ of edges, denoted $\text{cost}(F)$, is the sum of the costs of the edges in F.

Let u, v be two vertices in V. We define the *distance* between u and v, denoted $\text{dist}(u, v)$, to be the length of a shortest path between u and v in G. We write $\text{dist}_G(u, v)$ to emphasize that the distance is in the graph G. For a vertex subset $S \subseteq V$, we define the distance between u and S as $\text{dist}_G(u, S) = \min\{\text{dist}_G(u, x) \mid x \in S\}$.

For a set of vertices $S \subseteq V$, $G(S)$ is the subgraph induced on G by vertices in S. We write $\text{dist}_S(u, v)$ instead of $\text{dist}_{G(S)}(u, v)$ when G is understood. $E(S)$ is the set of edges with both endpoints in S. The *boundary* of S, denoted $\partial(S)$, is the set of edges with exactly one endpoint in S. If T is a set of vertices and $S \cap T = \emptyset$, then $E(S, T)$ is the set of edges with one endpoint in S and the other in T.

[3] In order to adapt our algorithms to the stretch definition of [1], we can simply define the cost of an edge as the reciprocal of the distance between its endpoints.

A *multiway partition* of V is a collection of pairwise-disjoint sets $\{V_1, \ldots, V_k\}$ such that $\bigcup_i V_i = V$. The *boundary* of a multiway partition, denoted $\partial(V_1, \ldots, V_k)$, is the set of edges with endpoints in different sets in the partition.

The *volume* of a set F of edges, denoted $\mathrm{vol}(F)$, is the size of the set $|F|$. The *volume* of a set S of vertices, denoted $\mathrm{vol}(S)$, is the number of edges with at least one endpoint in S.

Let v be a vertex in V. The *radius* of G with respect to v, denoted $\mathrm{rad}_G(v)$, is the smallest r such that every vertex of G is within distance (at most) r from v. Given a vertex subset $S \subseteq V$, we may write $\mathrm{rad}_S(v)$ instead of $\mathrm{rad}_{G(S)}(v)$ when G is understood. The *ball* of radius r around v, denoted $B(r, v)$, is the set of vertices at distance at most r from v. The *ball shell* of radius r around v, denoted $BS(r, v)$, is the set of vertices right outside $B(r, v)$; that is, $BS(r, v)$ consists of every vertex $u \in V - B(r, v)$ with a neighbor $w \in B(r, v)$ such that $\mathrm{dist}(v, u) = \mathrm{dist}(v, w) + \ell(u, w)$.

3. Spanning trees of $O(\log^3 n)$ stretch.

We present our first algorithm that generates a spanning tree with average stretch $O(\log^3 n)$. We first state the properties of the graph decomposition algorithm at the heart of our construction. We then present the construction and analysis of the low-stretch spanning trees. We defer the description of the graph decomposition algorithm and its analysis to section 4.

3.1. Low-cost star-decomposition.

Our graph decomposition algorithm produces *star-decompositions* of graphs, which we now define.

DEFINITION 3.1 (star-decomposition). *A multiway partition $\{V_0, \ldots, V_k\}$ is a* star-decomposition *of a weighted connected graph $G = (V, E, \ell)$ with center $x_0 \in V$ (see Figure 1) if $x_0 \in V_0$ and*

1. *for all $0 \le i \le k$, the subgraph induced on V_i is connected; and*
2. *for all $i \ge 1$, V_i contains an* anchor *vertex x_i that is connected to a vertex $y_i \in V_0$ by an edge $(x_i, y_i) \in E$. We call the edge (x_i, y_i) the* bridge *between V_0 and V_i.*

Let $r = \mathrm{rad}_G(x_0)$, and $r_i = \mathrm{rad}_{V_i}(x_i)$ for each $0 \le i \le k$. For $\delta, \epsilon \le 1/2$, a star-decomposition $\{V_0, \ldots, V_k\}$ is a (δ, ϵ)-star-decomposition if

a. *$r_0 \le (1 - \delta)r$;*
b. *$\mathrm{dist}(x_0, x_i) \ge \delta r$ for each $i \ge 1$; and*
c. *$\mathrm{dist}(x_0, x_i) + r_i \le (1 + \epsilon)r$ for each $i \ge 1$.*

The cost *of the star-decomposition is $\mathrm{cost}(\partial(V_0, \ldots, V_k))$.*

Note that if $\{V_0, \ldots, V_k\}$ is a (δ, ϵ)–star-decomposition of G, then the graph consisting of the union of the induced subgraphs on $V_0, \ldots, V_k$ and the bridge edges (y_i, x_i) has radius at most $(1 + \epsilon)$ times the radius of the original graph.

In section 4, we present an algorithm `StarDecomp` that satisfies the following cost guarantee. Let $\boldsymbol{x} = (x_1, \ldots, x_k)$ and $\boldsymbol{y} = (y_1, \ldots, y_k)$.

LEMMA 3.2 (low-cost star-decomposition). *Let $G = (V, E, \ell)$ be a connected weighted graph and let x_0 be a vertex in V. Then for every positive $\epsilon \le 1/2$,*

$$(\{V_0, \ldots, V_k\}, \boldsymbol{x}, \boldsymbol{y}) = \texttt{StarDecomp}(G, x_0, 1/3, \epsilon),$$

in time $O(m + n \log n)$, returns a $(1/3, \epsilon)$–star-decomposition of G with center x_0 satisfying

$$\mathrm{cost}(\partial(V_0, \ldots, V_k)) \le \frac{6\, m \log_2(m+1)}{\epsilon \cdot \mathrm{rad}_G(x_0)}.$$

On unweighted graphs, the running time is $O(m)$.

3.2. A divide-and-conquer algorithm. The basic idea of our algorithm is to use low-cost star-decompositions in a divide-and-conquer (recursive) algorithm to construct a spanning tree. Let $G = (V, E, \ell)$ be the graph input to the current recursive invocation of the algorithm. Recall that we write $n = |V|$ and $m = |E|$. Let $\widehat{n}$ and $\widehat{m}$ denote the number of vertices and number of edges, respectively, in the original graph, input to the first recursive invocation.

Before invoking our algorithm we apply a linear-time transformation from [1] that may decrease the number of edges in the given multigraph (recall that a multigraph of $\widehat{n}$ vertices may have an arbitrary number of edges). Given a weighted connected simple graph $G = (V, E, \ell)$ and a mapping $m : E \to \mathbb{Z}_{>0}$, let $G_m = (V, E_m, \ell_m)$ be the multigraph obtained from G by making $m(e)$ copies of each edge $e \in E$.

LEMMA 3.3 (established in [1]). *Let $G = (V, E, \ell)$ be a weighted connected simple graph. Then for every mapping $m : E \to \mathbb{Z}_{>0}$, there exists a mapping $m' : E \to \mathbb{Z}_{>0}$ such that $|E_{m'}| = \sum_{e \in E} m'(e) \le |V|\,(|V|+1)$ and* ave-stretch$_T(E_m) \le 2$ ave-stretch$_T(E_{m'})$ *for every spanning tree T of G. Moreover, the mapping m' can be computed in time linear in the size of G.*

Consequently, in what follows we assume that $\widehat{m} \le \widehat{n}(\widehat{n}+1)$.

We begin by showing how to construct low-stretch spanning trees for unweighted graphs, that is, when all edges have length 1. In particular, we use the fact that in this case the cost of a set of edges equals the number of edges in the set.

Fix $\alpha = (\log_{4/3}(\widehat{n} + 32))^{-1}$.
$T =$ `UnweightedLowStretchTree`$(G = (V, E), x_0)$.

1. If $|V| \le 2$, then return G. (If G contains multiple edges, return a single copy.)
2. $(\{V_0, \ldots, V_k\}, \boldsymbol{x}, \boldsymbol{y}) =$ `StarDecomp`$(G, x_0, 1/3, \alpha)$.
3. For $0 \le i \le k$, set $T_i =$ `UnweightedLowStretchTree`$(G(V_i), x_i)$.
4. Set $T = \bigcup_i T_i \cup \bigcup_i (y_i, x_i)$.

THEOREM 3.4 (unweighted). *Let $G = (V, E)$ be an unweighted connected graph and let x_0 be a vertex in V. Then*

$$T = \texttt{UnweightedLowStretchTree}(G, x_0),$$

in time $O(\widehat{m} \log \widehat{n})$, returns a spanning tree of G satisfying

$$\mathrm{rad}_T(x_0) \le e \cdot \mathrm{rad}_G(x_0) \tag{1}$$

and

$$\text{ave-stretch}_T(E) \le O(\log^3 \widehat{m}). \tag{2}$$

Proof. For our analysis, we define a sequence of graphs that converges to T. For a graph G, we let

$$(\{V_0, \ldots, V_k\}, \boldsymbol{x}, \boldsymbol{y}) = \texttt{StarDecomp}(G, x_0, 1/3, \alpha)$$

and recursively define

$$R_0(G) = G \quad \text{and} \qquad R_t(G) = \bigcup_i (y_i, x_i) \cup \bigcup_i R_{t-1}(G(V_i)).$$

The graph $R_t(G)$ is what one would obtain if we forced `UnweightedLowStretchTree` to return its input graph after t levels of recursion.

Let $\rho = \mathrm{rad}_G(x_0)$. Definition 3.1 implies $r_i \leq (1-\delta+\epsilon)r$ for every $1 \leq i \leq k$. By substituting $\delta = 1/3$, $\epsilon = \alpha$, and $r = \rho$, and because for all $\widehat{n} \geq 0$, $\alpha = (\log_{4/3}(\widehat{n}+32))^{-1} \leq 1/12$, we have $r_i \leq 3\rho/4$ for every $1 \leq i \leq k$. As $r_0 \leq 2\rho/3$, the depth of the recursion in `UnweightedLowStretchTree` is at most $\log_{4/3}\widehat{n}$, and we have $R_{\log_{4/3}\widehat{n}}(G) = T$. One can prove by induction that for every $t \geq 0$,

$$\mathrm{rad}_{R_t(G)}(x_0) \leq (1+\alpha)^t \mathrm{rad}_G(x_0).$$

Claim (1) now follows as $(1+\alpha)^{\log_{4/3}\widehat{n}} \leq e$. To prove claim (2), we note that

$$\begin{aligned}
(3)\qquad \sum_{(u,v)\in\partial(V_0,\ldots,V_k)} \mathrm{stretch}_T(u,v) &\leq \sum_{(u,v)\in\partial(V_0,\ldots,V_k)} (\mathrm{dist}_T(x_0,u) + \mathrm{dist}_T(x_0,v)) \\
&\leq \sum_{(u,v)\in\partial(V_0,\ldots,V_k)} 2e \cdot \mathrm{rad}_G(x_0), \text{ by (1)}, \\
&\leq 2e \cdot \mathrm{rad}_G(x_0) \left(\frac{6\,\widehat{m}\log_2(\widehat{m}+1)}{\alpha \cdot \mathrm{rad}_G(x_0)} \right), \text{ by Lemma 3.2}, \\
(4)\qquad &\leq 12e\,\widehat{m}\,(\log_2(\widehat{m}+1)) \left(\log_{4/3}(\widehat{n}+32)\right).
\end{aligned}$$

Applying this inequality to all graphs at all $\log_{4/3}\widehat{n}$ levels of the recursion, we obtain

$$\begin{aligned}
\sum_{(u,v)\in E} \mathrm{stretch}_T(u,v) &\leq 12e\,\widehat{m}\,(\log_2(\widehat{m}+1)) \left(\log_{4/3}\widehat{n}\right) \left(\log_{4/3}(\widehat{n}+32)\right) \\
&= O(\widehat{m}\log^3\widehat{m}).
\end{aligned}$$

(To justify the last inequality we remark that each edge ends up in $\partial(V_0,\ldots,V_k)$ on one of the levels of recursion, or it survives all the way down to a component of size two. In the latter case its contribution to the stretch is 1.)

The bound on the running time is obtained by Lemma 3.2 and because the depth of the recursion is $O(\log\widehat{n})$. □

We now extend our algorithm and proof to general weighted connected graphs. We begin by pointing out a subtle difference between general and unweighted graphs. In our analysis of `UnweightedLowStretchTree`, we used the facts that each edge length is 1 and $\mathrm{rad}_G(x_0) \leq n$ to show that the depth of recursion is at most $\log_{4/3} n$. In general weighted graphs, the ratio of $\mathrm{rad}_G(x_0)$ to the length of the shortest edge can be arbitrarily large. Thus, the recursion can be very deep. To compensate, we will contract all edges that are significantly shorter than the radius of their component. In this way, we will guarantee that each edge is active only in a logarithmic number of iterations.

Let $e = (u,v)$ be an edge in $G = (V,E,\ell)$. The contraction of e results in a new graph by identifying u and v as a new vertex whose neighbors are the union of the neighbors of u and v. All self-loops created by the contraction are discarded. We refer to u and v as the preimage of the new vertex.

We now state and analyze our algorithm for general weighted graphs.

Fix $\beta = (2\lceil \log_{4/3}(2\widehat{n} + 32)\rceil)^{-1}$.
$T = \texttt{LowStretchTree}(G = (V, E, \ell), x_0)$.

1. If $|V| \leq 2$, then return G. (If G contains multiple edges, return the shortest copy.)
2. Set $\rho = \mathrm{rad}_G(x_0)$.
3. Let $\widetilde{G} = (\widetilde{V}, \widetilde{E})$ be the graph obtained by contracting all edges in G of length less than $\beta\rho/\widehat{n}$.
4. $\left(\left\{\widetilde{V}_0, \ldots, \widetilde{V}_k\right\}, \widetilde{\boldsymbol{x}}, \widetilde{\boldsymbol{y}}\right) = \texttt{StarDecomp}(\widetilde{G}, x_0, 1/3, \beta)$.
5. For each i, let V_i be the preimage under the contraction of step 3 of vertices in $\widetilde{V}_i$, and let $(y_i, x_i) \in V_0 \times V_i$ be the edge of shortest length for which x_i is a preimage of $\widetilde{x}_i$ and y_i is a preimage of $\widetilde{y}_i$.
6. For $0 \leq i \leq k$, set $T_i = \texttt{LowStretchTree}(G(V_i), x_i)$.
7. Set $T = \bigcup_i T_i \cup \bigcup_i (y_i, x_i)$.

In what follows, we refer to the graph $\widetilde{G}$, obtained by contracting some of the edges of the graph G, as the *edge-contracted graph*.

THEOREM 3.5 (low-stretch spanning tree). *Let $G = (V, E, \ell)$ be a weighted connected graph and let x_0 be a vertex in V. Then*

$$T = \texttt{LowStretchTree}(G, x_0),$$

in time $O(\widehat{m}\log\widehat{n} + \widehat{n}\log^2\widehat{n})$, returns a spanning tree of G satisfying

$$\mathrm{rad}_T(x_0) \leq 2e \cdot \mathrm{rad}_G(x_0) \tag{5}$$

and

$$\text{ave-stretch}_T(E) = O(\log^3 \widehat{m}). \tag{6}$$

Proof. We first establish notation similar to that used in the proof of Theorem 3.4. Our first step is to define a procedure, SD, that captures the action of the algorithm in steps 2–4. We then define $R_0(G) = G$ and

$$R_t(G) = \bigcup_i (y_i, x_i) \cup \bigcup_i R_{t-1}(G(V_i)),$$

where

$$(\{V_0, \ldots, V_k\}, x_1, \ldots, x_k, y_1, \ldots, y_k) = \texttt{SD}(G, x_0, 1/3, \beta).$$

We now prove claim (5). Let $\rho = \mathrm{rad}_G(x_0)$. Let $s = \lceil \log_{4/3}(2\widehat{n})\rceil$ and let $\rho_s = \mathrm{rad}_{R_s(G)}(x_0)$. Each contracted edge is of length at most $\beta\rho/\widehat{n}$, and every path in the graph $G(V_i)$ contains at most n contracted edges; hence the insertion of the contracted edges into $G(V_i)$ increases its radius by an additive term of at most $\beta\rho$. Thus, we may prove by induction that

$$\mathrm{rad}_{R_s(G)}(x_0) \leq (1 + 2\beta)^s \cdot \mathrm{rad}_G(x_0).$$

As $(1 + 2\beta)^s \leq e$, we may conclude that ρ_s is at most $e \cdot \mathrm{rad}_G(x_0)$.

To determine how much larger the radius of T can be, we first note that Definition 3.1 implies $r_i \leq (1 - \delta + \epsilon)r$ for every $1 \leq i \leq k$. By substituting $\delta = 1/3$, $\epsilon = \beta$,

and $r = \rho$, we have $r_i \leq (2/3 + \beta)\rho$. When the contracted edges are inserted into $G(V_i)$, the radius r_i may increase by an additive term of at most $\beta\rho$; hence in each application of `StarDecomp` (actually, in each application of `SD`), $r_i \leq (2/3 + 2\beta)\rho$. Since $\beta = (2\lceil \log_{4/3}(2\widehat{n} + 32)\rceil)^{-1} \leq 1/24$ for all $\widehat{n} \geq 0$, it follows that $r_i \leq 3\rho/4$ for every $1 \leq i \leq k$. As $r_0 \leq 2\rho/3$, each component of G that remains after s levels of the recursion has radius at most $\rho(3/4)^s \leq \rho/2\widehat{n}$. We may also assume by induction that for the graph induced on each of these components, `LowStretchTree` outputs a tree of radius at most $2e(\rho/2\widehat{n}) = e\rho/\widehat{n}$. As there are at most $\widehat{n}$ of these components, we know that the tree returned by the algorithm has radius at most

$$e \cdot \mathrm{rad}_G(x_0) + \widehat{n} \times \frac{e}{\widehat{n}} \mathrm{rad}_G(x_0) = 2e \cdot \mathrm{rad}_G(x_0).$$

We now turn to the claim in (6), the bound on the stretch. In this part, we let $E_t \subseteq E$ denote the set of edges that are present at recursion depth t. That is, their endpoints appear in the same graph, and they are not identified by the contraction of short edges in step 2. We now observe that no edge can be present at more than $\lceil \log_{4/3}((2\widehat{n}/\beta) + 1)\rceil$ recursion depths. To see this, consider an edge (u, v) and let t be the first recursion level for which the edge is in E_t. Let ρ_t be the radius of the component in which the edge lies at that time. As u and v are not identified under contraction, they are at distance at least $\beta\rho_t/\widehat{n}$ from each other. (This argument can be easily verified, although the condition for edge contraction depends on the length of the edge rather than on the distance between its endpoints.) If u and v are still in the same graph on recursion level $t + \lceil \log_{4/3}((2\widehat{n}/\beta) + 1)\rceil$, then the radius of this graph is at most $\rho_t/((2\widehat{n}/\beta) + 1)$; thus its diameter is strictly less than $\beta\rho_t/\widehat{n}$, contradicting the lower bound on the distance between u and v.

Following the proof of the upper bound on $\sum_{(u,v)\in\partial(V_0,\ldots,V_k)} \mathrm{stretch}_T(u, v)$ in inequalities (3)–(4) in the proof of Theorem 3.4, we can show that the total contribution to the stretch at depth t is at most

$$O(\mathrm{vol}(E_t) \log^2 \widehat{m}).$$

Thus, the sum of the stretches over all recursion depths is

$$\sum_t O\left(\mathrm{vol}(E_t) \log^2 \widehat{m}\right) = O\left(\widehat{m} \log^3 \widehat{m}\right).$$

We now analyze the running time of the algorithm. On each recursion level, the dominant cost is that of performing the `StarDecomp` operations on each edge-contracted graph. Let V_t denote the set of vertices in all edge-contracted graphs on recursion level t. Then the total cost of the `StarDecomp` operations on recursion level t is at most $O(|E_t| + |V_t| \log |V_t|)$. We will prove in Lemma 3.6 that $\sum_t |V_t| = O(\widehat{n} \log \widehat{n})$, and as $\sum_t |E_t| = O(\widehat{m} \log \widehat{m})$, it follows that the total running time is $O(\widehat{m} \log \widehat{n} + \widehat{n} \log^2 \widehat{n})$. □

The following lemma shows that even though the number of recursion levels can be very large, the overall number of vertices in edge-contracted graphs appearing on different recursion levels is at most $O(\widehat{n} \log \widehat{n})$. This lemma is used only for the analysis of the running time of our algorithm; a reader interested only in the existential bound can skip it.

LEMMA 3.6. *Let V_t be the set of vertices appearing in edge-contracted graphs on recursion level t. Then $\sum_t |V_t| = O(\widehat{n} \log \widehat{n})$.*

Proof. Consider an edge-contracted graph $\widetilde{G} = (\widetilde{V}, \widetilde{E})$ on recursion level t and let x be a vertex in $\widetilde{V}$. The vertex x was formed as a result of a number of edge contractions (maybe 0). Accordingly, x can be viewed as a *super-vertex*. Let $\chi(x)$ denote the set of original vertices that were identified together to form the super-vertex $x \in \widetilde{V}$.

We claim that for every super-vertex $x \in V_{t+1}$, there exists a super-vertex $y \in V_t$ such that $\chi(x) \subseteq \chi(y)$. To prove it, note that every graph on recursion level $t+1$ corresponds to a single component of a star-decomposition on recursion level t. Moreover, an edge that was contracted on recursion level $t+1$ must have been contracted on recursion level t as well. Therefore we can consider a directed forest $\mathcal{F}$ in which every node at depth t corresponds to some super-vertex in V_t and an edge leads from a node y at depth t to a node x at depth $t+1$, if $\chi(x) \subseteq \chi(y)$. Note that the roots of $\mathcal{F}$ correspond to super-vertices on recursion level 0 and the leaves of $\mathcal{F}$ correspond to the original vertices of the graph G.

In the proof of Theorem 3.5, we showed that every edge is present on $O(\log \widehat{n})$ recursion levels. Following a similar line of arguments, one can show that every super-vertex is present on $O(\log \widehat{n})$ (before it is decomposed into smaller super-vertices, each containing a subset of its vertices). Since there are $\widehat{n}$ vertices in the original graph G, there are $\widehat{n}$ leaves in $\mathcal{F}$. Therefore the overall number of nodes in the directed forest $\mathcal{F}$ is $O(\widehat{n} \log \widehat{n})$, and the bound on $\sum_t |V_t|$ holds. ∎

4. Star-decomposition. Our star-decomposition algorithm exploits two algorithms for growing sets. The first, `BallCut`, is the standard ball-growing technique introduced by Awerbuch [2], and was the basis of the algorithm of [1]. The second, `ConeCut`, is a generalization of ball-growing to cones. So that we can analyze this second algorithm, we abstract the analyses from the works of [15, 10]. Instead of nested balls, we consider *concentric systems*, which we now define.

DEFINITION 4.1 (concentric system). *A* concentric system *in a weighted graph $G = (V, E, \ell)$ is a family of vertex sets $\mathcal{L} = \{L_r \subseteq V : r \in \mathbb{R}_{\geq 0}\}$ such that*

1. *$L_0 \neq \emptyset$;*
2. *$L_r \subseteq L_{r'}$ for all $r < r'$; and*
3. *if a vertex $u \in L_r$ and (u, v) is an edge in E, then $v \in L_{r+\ell(u,v)}$.*

For example, for any vertex $x \in V$, the set of balls $\{B(r, x)\}$ is a concentric system. The *radius* of a concentric system $\mathcal{L}$ is $\operatorname{radius}(\mathcal{L}) = \inf\{r : L_r = V\}$. For each vertex $v \in V$, we define the *norm* of v with respect to $\mathcal{L}$ as $\|v\|_{\mathcal{L}} = \inf\{r : v \in L_r\}$.

LEMMA 4.2 (concentric system cutting). *Let $G = (V, E, \ell)$ be a connected weighted graph and let $\mathcal{L} = \{L_r\}$ be a concentric system. For every two reals $0 \leq \lambda < \lambda'$, there exists a real $r \in [\lambda, \lambda')$ such that*

$$\operatorname{cost}(\partial(L_r)) \leq \frac{\operatorname{vol}(L_r) + \tau}{\lambda' - \lambda} \max\left[1, \log_2\left(\frac{m + \tau}{\operatorname{vol}(E(L_\lambda)) + \tau}\right)\right],$$

where $m = |E|$ and

$$\tau = \begin{cases} 1 & \text{if } \operatorname{vol}(E(L_\lambda)) = 0, \\ 0 & \text{otherwise.} \end{cases}$$

Proof. Note that rescaling terms does not affect the statement of the lemma. For example, if all the lengths are doubled, then the costs are halved. Moreover, we may assume that $\lambda' \leq \operatorname{radius}(\mathcal{L})$, since otherwise, choosing $r = \operatorname{radius}(\mathcal{L})$ implies that $\partial(L_r) = \emptyset$, and the claim holds trivially.

Let $r_i = \|v_i\|_{\mathcal{L}}$, and assume that the vertices are ordered so that $r_1 \leq r_2 \leq \cdots \leq r_n$. We may now assume without loss of generality that each edge in the graph has minimal length. That is, an edge from vertex i to vertex j has length $|r_i - r_j|$. The reason we may make this assumption is that it only increases the costs of edges, making our lemma strictly more difficult to prove. (Recall that the cost of an edge is the reciprocal of its length.)

Let $B_i = L_{r_i}$. Our proof will make critical use of a quantity μ_i, which is defined to be

$$\mu_i = \tau + \operatorname{vol}(E(B_i)) + \sum_{(v_j,v_k)\in E: j\leq i<k} \frac{r_i - r_j}{r_k - r_j}.$$

That is, μ_i sums the edges inside B_i, proportionally counting edges that are split by the boundary of the ball. The two properties of μ_i that we exploit are

$$\mu_{i+1} = \mu_i + \operatorname{cost}(\partial(B_i))(r_{i+1} - r_i) \tag{7}$$

and

$$\tau + \operatorname{vol}(E(B_i)) \leq \mu_i \leq \tau + \operatorname{vol}(B_i). \tag{8}$$

Inequality (8) is trivial, and equality (7) follows from the definition by a straightforward calculation, as

$$\mu_i = \tau + \operatorname{vol}(E(B_{i+1})) - \operatorname{vol}(\{(v_j, v_{i+1}) \in E \mid j \leq i\}) + \sum_{(v_j,v_k)\in E: j\leq i<k} \frac{r_i - r_j}{r_k - r_j}$$

and

$$\operatorname{cost}(\partial(B_i))(r_{i+1} - r_i) = \sum_{(v_j,v_k)\in E: j\leq i<k} \frac{r_{i+1} - r_i}{r_k - r_j}.$$

Choose a and b so that $r_{a-1} \leq \lambda < r_a$ and $r_b < \lambda' \leq r_{b+1}$. Let $\nu = \lambda' - \lambda$. We first consider the trivial case in which $b < a$. (That is, $b = a-1$.) In that case, there is no vertex with norm between λ and λ'. Thus every edge crossing $L_{(\lambda+\lambda')/2}$ has length at least ν, and therefore cost at most $1/\nu$. Therefore, by setting $r = (\lambda + \lambda')/2$, we obtain

$$\operatorname{cost}(\partial(L_r)) \leq \operatorname{vol}(\partial(L_r))\frac{1}{\nu} \leq \operatorname{vol}(L_r)\frac{1}{\nu},$$

establishing the lemma in this case.

We now define

$$\eta = \log_2\left(\frac{m + \tau}{\operatorname{vol}(E(B_{a-1})) + \tau}\right).$$

Note that $B_{a-1} = L_\lambda$, by the choice of a. A similarly trivial case is when $[a, b]$ is nonempty and, in addition, there exists an $i \in [a-1, b]$ such that

$$r_{i+1} - r_i \geq \frac{\nu}{\eta}.$$

In this case, every edge in $\partial(B_i)$ has cost at most η/ν. By choosing r to be $\max\{r_i, \lambda\}$, we satisfy

$$\operatorname{cost}(\partial(L_r)) \le \operatorname{vol}(\partial(L_r))\frac{\eta}{\nu} \le \operatorname{vol}(L_r)\frac{\eta}{\nu};$$

hence, the lemma is established in this case.

In the remaining case that the set $[a, b]$ is nonempty and for all $i \in [a-1, b]$,

$$r_{i+1} - r_i < \frac{\nu}{\eta}, \tag{9}$$

we will prove that there exists an $i \in [a-1, b]$ such that

$$\operatorname{cost}(\partial(B_i)) \le \frac{\mu_i \eta}{\nu}.$$

Choosing $r = \max\{r_i, \lambda\}$ and applying (8), we will prove the lemma.

Assume by way of contradiction that

$$\operatorname{cost}(\partial(B_i)) > \mu_i \eta/\nu$$

for all $i \in [a-1, b]$. It follows, by (7), that

$$\mu_{i+1} > \mu_i + \mu_i(r_{i+1} - r_i)\eta/\nu$$

for all $i \in [a-1, b]$, which implies

$$\begin{aligned}
\mu_{b+1} &> \mu_{a-1} \prod_{i=a-1}^{b} (1 + (r_{i+1} - r_i)\eta/\nu) \\
&\ge \mu_{a-1} \prod_{i=a-1}^{b} 2^{((r_{i+1}-r_i)\eta/\nu)} \\
&= \mu_{a-1} \cdot 2^{(r_{b+1}-r_{a-1})\eta/\nu} \\
&\ge \mu_{a-1} \cdot ((m+\tau)/(\operatorname{vol}(E(B_{a-1})) + \tau)) \\
&\ge m + \tau,
\end{aligned}$$

where the second inequality holds by (9) since $1 + x \ge 2^x$ for every $0 \le x \le 1$ and the last inequality holds by (8). Thus we derive a contradiction. ∎

An analysis of the following standard ball-growing algorithm follows immediately by applying Lemma 4.2 to the concentric system $\{B(r, x)\}$.

$r = \texttt{BallCut}(G, x, \rho, \delta)$.

1. Set $r = \delta\rho$.
2. While $\operatorname{cost}(\partial(B(r,x))) > \frac{\operatorname{vol}(B(r,x))+1}{(1-2\,\delta)\rho}\log_2(m+1)$,
   (a) Find a vertex $v \notin B(r, x)$ that minimizes $\operatorname{dist}(x, v)$ and set $r = \operatorname{dist}(x, v)$.

COROLLARY 4.3 (weighted ball cutting). *Let $G = (V, E, \ell)$ be a connected weighted graph, and let $x_0 \in V$, $\rho = \operatorname{rad}_G(x_0)$, $r_0 = \texttt{BallCut}(G, x_0, \rho, 1/3)$, and $V_0 = B(r_0, x_0)$. Then $\rho/3 \le r_0 < 2\,\rho/3$ and*

$$\operatorname{cost}(\partial(V_0)) \le \frac{3(\operatorname{vol}(V_0) + 1)\log_2(|E| + 1)}{\rho}.$$

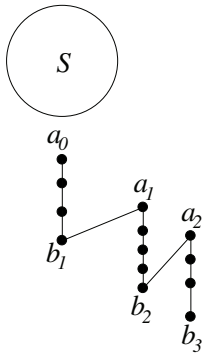

FIG. 2. *The vertex b_3 is in $C_S(l, a_0)$ if $\ell(b_1, a_1) + \ell(b_2, a_2) \leq l$.*

We now examine the concentric system that enables us to construct $V_1, \ldots, V_k$ in Lemma 3.2.

DEFINITION 4.4 (ideals and cones). *For any weighted graph $G = (V, E, \ell)$ and $S \subseteq V$, the set of* forward edges induced by S *is*

$$F(S) = \{(u \to v) : (u, v) \in E, \operatorname{dist}(u, S) + \ell(u, v) = \operatorname{dist}(v, S)\}.$$

For a vertex $v \in V$, the ideal of v induced by S, *denoted $I_S(v)$, is the set of vertices reachable from v by directed edges in $F(S)$, including v itself.*

For a vertex $v \in V$, the cone of width l around v induced by S, *denoted $C_S(l, v)$, is the set of vertices in V that can be reached from v by a path, the sum of the lengths of whose edges e that do not belong to $F(S)$ is at most l. Clearly, $C_S(0, v) = I_S(v)$ for all $v \in V$.*

That is, $I_S(v)$ is the set of vertices that have shortest paths to S that intersect v. Also, $u \in C_S(l, v)$ if there exist $a_0, \ldots, a_{k-1}$ and $b_1, \ldots, b_k$ such that $a_0 = v$, $b_k = u$, $b_{i+1} \in I_S(a_i)$, $(b_i, a_i) \in E$, and

$$\sum_{i=1}^{k-1} \ell(b_i, a_i) \leq l.$$

Refer to Figure 2 for an illustration of a cone.

We now establish that these cones form concentric systems.

PROPOSITION 4.5 (cones are concentric). *Let $G = (V, E, \ell)$ be a weighted graph and let $S \subseteq V$. Then for all $v \in V$, $\{C_S(l, v)\}_l$ is a concentric system in G.*

Proof. Clearly, $C_S(l, v) \subseteq C_S(l', v)$ if $l < l'$. Suppose that $u \in C_S(l, v)$ and $(u, w) \in E$. If $(u \to w) \in F(S)$, then $w \in C_S(l, v)$ as well. Otherwise, the path witnessing that $u \in C_S(l, v)$ followed by the edge (u, w) to w is a witness that $w \in C_S(l + \ell(u, w), v)$. ∎

$r = \texttt{ConeCut}(G, v, \lambda, \lambda', S)$.

1. Set $r = \lambda$.
2. If $\operatorname{vol}(E(C_S(\lambda, v))) = 0$, then set $\mu = (\operatorname{vol}(C_S(r, v)) + 1)\log_2(m + 1)$.
3. Otherwise, set $\mu = \operatorname{vol}(C_S(r, v))\log_2(m/\operatorname{vol}(E(C_S(\lambda, v))))$.
4. While $\operatorname{cost}(\partial(C_S(r, v))) > \mu/(\lambda' - \lambda)$,
   (a) Find a vertex $w \notin C_S(r, v)$ minimizing $\operatorname{dist}(w, C_S(r, v))$ and set $r = r + \operatorname{dist}(w, C_S(r, v))$.

COROLLARY 4.6 (cone cutting). *Let $G = (V, E, \ell)$ be a connected weighted graph, let v be a vertex in V, and let $S \subseteq V$. Then for any two reals $0 \leq \lambda < \lambda'$,* `ConeCut`$(G, v, \lambda, \lambda', S)$ *returns a real $r \in [\lambda, \lambda')$ such that*

$$\operatorname{cost}\left(\partial\left(C_S(r, v)\right)\right) \leq \frac{\operatorname{vol}\left(C_S(r, v)\right) + \tau}{\lambda' - \lambda} \max\left[1, \log_2 \frac{m + \tau}{\operatorname{vol}\left(E(C_S(\lambda, v))\right) + \tau}\right],$$

where $m = |E|$, and

$$\tau = \begin{cases} 1 & \text{if } \operatorname{vol}\left(E(C_S(\lambda, v))\right) = 0, \\ 0 & \text{otherwise.} \end{cases}$$

We will use two other properties of the cones $C_S(l, v)$: that we can bound their radius (Proposition 4.7) and that their removal does not increase the radius of the resulting graph (Proposition 4.8). It is not too difficult to show that for every $S \subseteq V$ and every $x \in S$,

$$\operatorname{rad}_{C_S(l,x)}(x) \leq \max\{\operatorname{dist}(v, S) + 2l \mid v \in V\}.$$

To see this, observe that the $l = 0$ case is easy, and that for larger l, the extra distance traveled along forward edges is at most the distance traveled along nonforward edges.

However, we require a slightly more complicated inequality. Recall that for a vertex v and a real r, the ball shell $BS(r, v)$ consists of every vertex $u \in V - B(r, v)$ with a neighbor $w \in B(r, v)$ such that $\operatorname{dist}(v, u) = \operatorname{dist}(v, w) + \ell(u, w)$.

PROPOSITION 4.7 (radius of cones). *Let $G = (V, E, \ell)$ be a connected weighted graph, let $x_0 \in V$, and let $\rho = \operatorname{rad}_G(x_0)$. Let $r_0 < \rho$ and let $V_0 = B(r_0, x_0)$, $V' = V - V_0$, and $S = BS(r_0, x_0)$. Let x be any vertex in S and let $\psi = \rho - \operatorname{dist}_G(x_0, x)$. Then the cones $C_S(l, x)$ in the graph $G(V')$ satisfy*

$$\operatorname{rad}_{C_S(l,x)}(x) \leq \psi + 2l.$$

Proof. Let u be a vertex in $C_S(l, x)$, and let $a_0, \ldots, a_{k-1}$ and $b_1, \ldots, b_k$ be vertices in V' such that $a_0 = x$, $b_k = u$, $b_{i+1} \in I_S(a_i)$, $(b_i, a_i) \in E$, and

$$\sum_{i=1}^{k-1} \ell(b_i, a_i) \leq l.$$

These vertices provide a path connecting x to u inside $C_S(l, x)$ of length at most

$$\sum_{i=0}^{k-1} \operatorname{dist}_{G(V')}(a_i, b_{i+1}) + \sum_{i=1}^{k-1} \ell(b_i, a_i).$$

As the second term is at most l, we just need to bound the first term by $\psi + l$. To do this consider the distance of each of these vertices from x_0 in the graph G. Since $b_{i+1} \in I_S(a_i)$, and since S is a ball shell around x_0, it follows that

$$\operatorname{dist}_G(x_0, b_{i+1}) = \operatorname{dist}_G(x_0, a_i) + \operatorname{dist}_{G(V')}(a_i, b_{i+1}).$$

By the triangle inequality, we have

$$\operatorname{dist}_G(x_0, a_i) \geq \operatorname{dist}_G(x_0, b_i) - \ell(b_i, a_i).$$

Together, these imply

$$\rho \geq \mathrm{dist}_G(x_0, b_k) \geq \mathrm{dist}_G(x_0, a_0) - \sum_{i=1}^{k-1} \ell(b_i, a_i) + \sum_{i=0}^{k-1} \mathrm{dist}_{G(V')}(a_i, b_{i+1}).$$

The proposition follows since $\psi = \rho - \mathrm{dist}_G(x_0, a_0)$ and since $\sum_{i=1}^{k-1} \ell(b_i, a_i) \leq l$. ∎

PROPOSITION 4.8 (deleting cones). *Consider a connected weighted graph $G = (V, E, \ell)$, a vertex subset $S \subseteq V$, a vertex $x \in S$, and a real $l \geq 0$, and let $V' = V - C_S(l, x)$, $S' = S - C_S(l, x)$, and $\psi = \max_{v \in V} \mathrm{dist}(v, S)$. Then*

$$\max_{v \in V'} \mathrm{dist}_{V'}(v, S') \leq \psi.$$

Proof. Consider any $v \in V'$, and let P be a shortest path between S and v. Note that all the edges of P are forward edges, and thus if P intersects $C_S(l, x)$, then $v \in C_S(l, x)$. So, the shortest path from v to S in V must lie entirely in V'. ∎

The basic idea of `StarDecomp` is to first use `BallCut` to construct V_0 and then repeatedly apply `ConeCut` to construct $V_1, \ldots, V_k$.

$(\{V_0, \ldots, V_k, \boldsymbol{x}, \boldsymbol{y}\}) = \texttt{StarDecomp}(G = (V, E, \ell), x_0, \delta, \epsilon)$.
1. Set $\rho = \mathrm{rad}_G(x_0)$; set $r_0 = \texttt{BallCut}(G, x_0, \rho, \delta)$ and $V_0 = B(r_0, x_0)$.
2. Let $S = BS(r_0, x_0)$.
3. Set $G' = (V', E', \ell') = G(V - V_0)$, the weighted graph induced by $V - V_0$.
4. Set $(\{V_1, \ldots, V_k, \boldsymbol{x}\}) = \texttt{ConeDecomp}(G', S, \epsilon\rho/2)$.
5. For each $i \in [1 : k]$, set y_i to be a vertex in V_0 such that $(x_i, y_i) \in E$ and y_i is on a shortest path from x_0 to x_i. Set $\boldsymbol{y} = (y_1, \ldots, y_k)$.

$(\{V_1, \ldots, V_k, \boldsymbol{x}\}) = \texttt{ConeDecomp}(G, S, \Delta)$.
1. Set $G_0 = G$, $S_0 = S$, and $k = 0$.
2. While S_k is not empty,
   (a) Set $k = k + 1$.
   (b) Let x_k be an arbitrary vertex in S_{k-1} and set $r_k = \texttt{ConeCut}(G_{k-1}, x_k, 0, \Delta, S_{k-1})$.
   (c) Set $V_k = C_{S_{k-1}}(r_k, x_k)$. Set $G_k = G(V - \cup_{i=1}^{k} V_k)$ and $S_k = S_{k-1} - V_k$.
3. Set $\boldsymbol{x} = (x_1, \ldots, x_k)$.

Proof of Lemma 3.2. Let $\rho = \mathrm{rad}_G(x_0)$. By setting $\delta = 1/3$, Corollary 4.3 guarantees $\rho/3 \leq r_0 < (2/3)\rho$; thus $\mathrm{dist}_G(x_0, v) > \rho/3$ for every $v \in V - V_0$, and in particular, $\mathrm{dist}_G(x_0, x_i) > \rho/3$ for every $1 \leq i \leq k$. Applying $\Delta = \epsilon\rho/2$ and Propositions 4.7 and 4.8, we can bound for every i

$$\mathrm{dist}(x_0, x_i) + r_i \leq \rho + 2\Delta = \rho + \epsilon\rho.$$

Thus $\texttt{StarDecomp}(G, x_0, 1/3, \epsilon)$ returns a $(1/3, \epsilon)$–star-decomposition with center x_0.

To bound the cost of the star-decomposition that the algorithm produces, we use Corollaries 4.3 and 4.6 to show

$$\mathrm{cost}(\partial(V_0)) \leq \frac{3(1 + \mathrm{vol}(V_0))\log_2(m+1)}{\rho} \quad \text{and}$$

$$\mathrm{cost}\left(E\left(V_j, V - \cup_{i=0}^{j} V_i\right)\right) \leq \frac{2(1 + \mathrm{vol}(V_j))\log_2(m+1)}{\epsilon\rho}$$

for every $1 \le j \le k$. Thus,

$$\begin{aligned}\operatorname{cost}(\partial(V_0,\dots,V_k)) &\le \sum_{j=0}^{k} \operatorname{cost}\left(E\left(V_j, V - \cup_{i=0}^{j} V_i\right)\right)\\ &\le \frac{2\log_2(m+1)}{\epsilon\rho}\sum_{j=0}^{k}(\operatorname{vol}(V_j)+1)\\ &\le \frac{6\,m\log_2(m+1)}{\epsilon\rho}.\end{aligned}$$

To implement `StarDecomp` in $O(m + n\log n)$ time, we use a Fibonacci heap to implement steps (2) of `BallCut` and `ConeCut`. If the graph is unweighted, this can be replaced by a breadth-first search that requires $O(m)$ time. ∎

5. Improving the stretch. In this section, we improve the average stretch of the spanning tree to $O\left(\log^2 n \log\log n\right)$ by introducing a procedure `ImpConeDecomp` which refines `ConeDecomp`. This new cone decomposition trades off the volume of the cone against the cost of edges on its boundary (similar to Seymour [17]). Our refined star-decomposition algorithm `ImpStarDecomp` is identical to algorithm `StarDecomp`, except that it calls

$$(\{V_1,\dots,V_k,\boldsymbol{x}\}) = \texttt{ImpConeDecomp}(G', S, \epsilon\rho/2, t, \widehat{m})$$

at step 4, where t is a positive integer parameter whose role will be described soon.

$(\{V_1,\dots,V_k,\boldsymbol{x}\}) = \texttt{ImpConeDecomp}(G, S, \Delta, t, \widehat{m})$.

1. Set $G_0 = G$, $S_0 = S$, and $j = 0$.
2. While S_j is not empty,
   (a) Set $j = j + 1$ and $p = t - 1$.
   (b) Set x_j to be a vertex of S_{j-1}.
   (c) While $p > 0$,
      (i) $r_j = \texttt{ConeCut}(G_{j-1}, x_j, \frac{(t-p-1)\Delta}{t}, \frac{(t-p)\Delta}{t}, S_{j-1})$.
      (ii) If $\operatorname{vol}\left(E(C_{S_{j-1}}(r_j, x_j))\right) \le \frac{m}{2^{\log^{p/t}\widehat{m}}}$, then exit the loop; else $p = p - 1$.
   (d) Set $V_j = C_{S_{j-1}}(r_j, x_j)$, set $G_j = G(V - \cup_{i=1}^{j} V_i)$, and set $S_j = S_{j-1} - V_j$.
3. Set $\boldsymbol{x} = (x_1,\dots,x_k)$.

LEMMA 5.1 (improved low-cost star-decomposition). *Let G, x_0, and ϵ be as in Lemma 3.2, let t be a positive integer control parameter, and let $\rho = \operatorname{rad}_G(x_0)$. Then*

$$(\{V_0,\dots,V_k\}, \boldsymbol{x}, \boldsymbol{y}) = \texttt{ImpStarDecomp}(G, x_0, 1/3, \epsilon, t, \widehat{m}),$$

in time $O(m + n\log n)$, returns a $(1/3,\epsilon)$–star-decomposition of G with center x_0 that satisfies

$$\operatorname{cost}(\partial(V_0)) \le \frac{6\operatorname{vol}(V_0)\log_2(\widehat{m}+1)}{\rho},$$

and for every index $j \in \{1,2,\dots,k\}$ there exists $p = p(j) \in \{0,1,\dots,t-1\}$ such that

$$\operatorname{cost}\left(E\left(V_j, V - \cup_{i=0}^{j} V_i\right)\right) \le t \cdot \frac{4\operatorname{vol}(V_j)\log^{(p+1)/t}(\widehat{m}+1)}{\epsilon\rho}, \tag{10}$$

and unless $p = 0$,

$$\text{vol}\left(E(V_j)\right) \leq \frac{m}{2^{\log^{p/t}\widehat{m}}}. \tag{11}$$

Proof. In what follows, we call $p(j)$ the *index-mapping* of the vertex set V_j. We begin our proof by observing that $0 \leq r_j < \epsilon\rho/2$ for every $1 \leq j \leq k$. We can then show that $\{V_0, \ldots, V_k\}$ is a $(1/3, \epsilon)$–star-decomposition as we did in the proof of Lemma 3.2.

We now bound the cost of the decomposition. Clearly, the bound on $\text{cost}\left(\partial\left(V_0\right)\right)$ remains unchanged from that proved in Lemma 3.2 (because the algorithm that computes V_0 did not change), but here we upper-bound $\text{vol}\left(V_0\right) + 1$ by $2 \cdot \text{vol}\left(V_0\right)$. Fix an index $j \in \{1, 2, \ldots, k\}$, and let $p = p(j)$ be the final value of variable p in the loop above (that is, the value of p when the execution left the loop while constructing V_j). Observe that $p \in \{0, 1, \ldots, t-1\}$, and that unless the loop is aborted due to $p = 0$, we have $\text{vol}\left(E(V_j)\right) \leq \frac{m}{2^{\log^{p/t}\widehat{m}}}$ and inequality (11) holds.

For inequality (10), we split the discussion into two cases. First, consider the case $p = t - 1$. In this case, the inequality $\text{cost}\left(E\left(V_j, V - \cup_{i=0}^{j} V_i\right)\right) \leq (\text{vol}\left(V_j\right) + 1)\log(\widehat{m}+1)(t/\Delta)$ follows directly from Corollary 4.6, and inequality (10) holds (recall that $\Delta = \epsilon\rho/2$).

Second, consider the case $p < t - 1$ and let r'_j be the value of the variable r_j set by the previous invocation of Algorithm `ConeCut` (which did not satisfy the test in line 2(c)(ii)). In this case, observe that at the beginning of the last iteration, $\text{vol}\left(E(C_{S_{j-1}}(r'_j, x_j))\right) > \frac{m}{2^{\log^{(p+1)/t}\widehat{m}}}$ (as otherwise the loop would have been aborted in the previous iteration). By Corollary 4.6,

$$\begin{aligned}
&\text{cost}\left(E\left(V_j, V - \cup_{i=0}^{j} V_i\right)\right) \\
\leq &\frac{\text{vol}\left(V_j\right)}{\Delta/t} \times \max\left\{1, \log_2\left(\frac{m}{\text{vol}\left(E\left(C_{S_{j-1}}\left(\frac{(t-p-1)\Delta}{t}, x_j\right)\right)\right)}\right)\right\},
\end{aligned}$$

where $V_j = C_{S_{j-1}}(r_j, x_j)$. Since

$$\frac{(t-p-2)\Delta}{t} \leq r'_j < \frac{(t-p-1)\Delta}{t},$$

it follows that

$$\text{vol}\left(E\left(C_{S_{j-1}}\left(\frac{(t-p-1)\Delta}{t}, x_j\right)\right)\right) \geq \text{vol}\left(E(C_{S_{j-1}}(r'_j, x_j))\right) > \frac{m}{2^{\log^{(p+1)/t}\widehat{m}}}.$$

Therefore

$$\log^{(p+1)/t}\widehat{m} \geq \max\left\{1, \log_2\left(\frac{m}{\text{vol}\left(E\left(C_{S_{j-1}}\left(\frac{(t-p-1)\Delta}{t}, x_j\right)\right)\right)}\right)\right\},$$

and

$$\text{cost}\left(E\left(V_j, V - \cup_{i=0}^{j} V_i\right)\right) \leq \frac{\text{vol}\left(V_j\right)\log^{(p+1)/t}\widehat{m}}{\Delta/t} = t \cdot \frac{2\,\text{vol}\left(V_j\right)\log^{(p+1)/t}\widehat{m}}{\epsilon\rho}.$$

The assertion follows. ∎

Our improved algorithm `ImpLowStretchTree`$(G, x_0, t, \widehat{m})$ is identical to the algorithm `LowStretchTree` except that in step 3 it calls `ImpStarDecomp`$(\widetilde{G}, x_0, 1/3, \beta, t, \widehat{m})$, and in step 5 it calls `ImpLowStretchTree`$(G(V_i), x_i, t, \widehat{m})$. We set $t = \log\log\widehat{m}$ throughout the execution of the algorithm.

THEOREM 5.2 (lower-stretch spanning tree). *Let $G = (V, E, \ell)$ be a connected weighted graph and let x_0 be a vertex in V. Then*

$$T = \texttt{ImpLowStretchTree}(G, x_0, t, \widehat{m}),$$

in time $O(\widehat{m}\log\widehat{n} + \widehat{n}\log^2\widehat{n})$, returns a spanning tree of G satisfying

$$\mathrm{rad}_T(x_0) \le 2e \cdot \mathrm{rad}_G(x)$$

and

$$\text{ave-stretch}_T(E) = O\left(\log^2\widehat{n}\log\log\widehat{n}\right).$$

Proof. The bound on the radius of the tree remains unchanged from that proved in Theorem 3.5.

We begin by defining a system of notation for the recursive process, assigning to each graph $G = (V, E)$ input to some recursive invocation of Algorithm `ImpLowStretchTree` a sequence $\sigma(G)$ of nonnegative integers. This is done as follows. If G is the original graph input to the first invocation of the recursive algorithm, then $\sigma(G)$ is empty. Assuming that the halt condition of the recursion is not satisfied for G, the algorithm continues, and some of the edges in E are contracted. Let $\widetilde{G} = (\widetilde{V}, \widetilde{E})$ be the resulting graph. (Recall that we refer to $\widetilde{G}$ as the edge-contracted graph.) Let $\{\widetilde{V}_0, \widetilde{V}_1, \ldots, \widetilde{V}_k\}$ be the star-decomposition of $\widetilde{G}$. Let $V_j \subseteq V$ be the preimage under edge contraction of $\widetilde{V}_j \subseteq \widetilde{V}$ for every $0 \le j \le k$. The graph $G(V_j)$ is assigned the sequence $\sigma(G(V_j)) = \sigma(G) \cdot j$. Note that $|\sigma(G)| = h$ implies that the graph G is input to the recursive algorithm on recursion level h. We warn the reader that the edge-contracted graph obtained from a graph assigned the sequence σ may have fewer edges than the edge-contracted graph obtained from the graph assigned the sequence $\sigma \cdot j$, because the latter may contain edges that were contracted out in the former.

We say that the edge e is *present* at recursion level h if there exists a graph G with $|\sigma(G)| = h$ such that e is not contracted out in $\widetilde{G}$. An edge e *appears* at the first level h at which it is present, and it *disappears* at the level at which it is present and its endpoints are separated by the star-decomposition or, if this never happens, then at the level of the leaf component of the recursion tree in which e appears. If an edge appears at recursion level h, then a path connecting its endpoints was contracted on every recursion level smaller than h, and no such path will be contracted on any recursion level greater than h. Moreover, an edge is never present at a level after it disappears. We define $h(e)$ and $h'(e)$ to be the recursion levels at which the edge e appears and disappears, respectively.

For every edge e and every recursion level i at which it is present, we let $U(e, i)$ denote the set of vertices $\widetilde{V}$ of the edge-contracted graph containing its endpoints. If $h(e) \le i < h'(e)$, then we let $W(e, i)$ denote the set of vertices $\widetilde{V}_j$ output by `ImpStarDecomposition` that contains the endpoints of e.

Recall that $p(j)$ denotes the index-mapping of the vertex set V_j in the star-decomposition. For each index $i \in \{0, 1, \ldots, t-1\}$, let $I_i = \{j \in \{1, 2, \ldots, k\} \mid p(j) = i\}$. For a vertex subset $U \subseteq V$, let $\mathrm{AS}(U)$ denote the average stretch that

the algorithm guarantees for the edges of $E(U)$. Let $\mathrm{TS}(U) = \mathrm{AS}(U) \cdot |E(U)|$. ($TS$ stands for the "total stretch.") Then by Lemma 5.1, the following recursive formula applies:

$$\begin{aligned}\mathrm{TS}(V) \leq & \left(\sum_{j=0}^{k} \mathrm{TS}(\widetilde{V}_j)\right) \\ & + 4e \times \left(6\,\log(\widehat{m}+1)\cdot \mathrm{vol}\left(\widetilde{V}_0\right) + 4\,\frac{t}{\beta}\sum_{p=0}^{t-1}\log^{(p+1)/t}(\widehat{m}+1)\sum_{j\in I_p}\mathrm{vol}\left(\widetilde{V}_j\right)\right) \\ & + \sum_{e\in E-\widetilde{E}} \mathrm{stretch}_T(e) \\ = & \ 4e \times \left(6\,\log(\widehat{m}+1)\cdot \mathrm{vol}\left(\widetilde{V}_0\right) + 4\,\frac{t}{\beta}\sum_{p=0}^{t-1}\log^{(p+1)/t}(\widehat{m}+1)\sum_{j\in I_p}\mathrm{vol}\left(\widetilde{V}_j\right)\right) \\ & + \sum_{j=0}^{k} \mathrm{TS}(V_j), \end{aligned} \tag{12}$$

where we recall $\beta = \epsilon = (2\lceil \log_{4/3}(2n+32)\rceil)^{-1}$.

For every edge e and for every $h(e) \leq i < h'(e)$, let $\pi_i(e)$ denote the index-mapping of the component $W(e,i)$ in the invocation of Algorithm `ImpConeDecomp` on recursion level i. For every index $p \in \{0,\ldots,t-1\}$, define the variable $l_p(e)$ as follows:

$$l_p(e) = \left|\{h(e) \leq i < h'(e) \mid \pi_i(e) = p\}\right|.$$

For a fixed edge e and an index $p \in \{0,1,\ldots,t-1\}$, every $h(e) \leq i < h'(e)$ such that $\pi_i(e) = p$ contributes $O(t/\beta)\cdot \log^{(p+1)/t}(\widehat{m}+1)$ to the right-hand term in (12) (that is, this is the contribution when an edge e is counted in a $\mathrm{vol}\left(\widetilde{V}_j\right)$ term). Summing p over $\{0,1,\ldots,t-1\}$, we obtain

$$\sum_{p=0}^{t-1} O(t/\beta) l_p(e) \log^{(p+1)/t}(\widehat{m}+1).$$

Soon, we will prove that

$$\sum_{e}\sum_{p=0}^{t-1} l_p(e)\log^{p/t}(\widehat{m}+1) \leq O(\widehat{m}\log_2\widehat{m}), \tag{13}$$

which implies that the sum of the contributions of all edges e in levels $h(e) \leq i < h'(e)$ to the right-hand term in (12) is

$$O\left(\frac{t}{\beta}\cdot \widehat{m}\log^{1+1/t}\widehat{m}\right) = O\left(t\cdot\widehat{m}\log^{2+1/t}\widehat{m}\right).$$

As $\mathrm{vol}\,(V_j)$ counts the internal edges of V_j as well as its boundary edges, we must also account for the contribution of each edge e at level $h'(e)$. At this level, it will be counted twice—once in each component containing one of its endpoints. Thus, at this stage, it contributes a factor of at most $O((t/\beta)\cdot\log\widehat{m})$ to the sum $\mathrm{TS}(V)$. Therefore all edges $e \in E$ at level $h'(e)$ contribute an additional factor of

$O(t \cdot \widehat{m} \log^2 \widehat{m})$. Summing over all the edges, we find that all the contributions to the right-hand term in (12) sum to at most

$$O\left(t \cdot \widehat{m} \log^{2+1/t} \widehat{m}\right).$$

Also, every $h(e) \le i < h'(e)$ such that the edge e belongs to the central component $\widetilde{V}_0$ of the star decomposition contributes $O(\log \widehat{m})$ to the left-hand term in (12). Since there are at most $O(\log \widehat{m})$ such i's, it follows that the contribution of the left-hand term in (12) to $\mathrm{TS}(V)$ sums up to an additive term of $O(\log^2 \widehat{m})$ for every single edge, and $(\widehat{m} \log^2 \widehat{m})$ for all edges.

It follows that $\mathrm{TS}(V) = O(t \cdot \widehat{m} \log^{2+1/t} \widehat{m})$. This is optimized by setting $t = \log \log \widehat{m}$, obtaining the desired upper bound of $O(\log^2 \widehat{n} \cdot \log \log \widehat{n})$ on the average stretch $\mathrm{AS}(V)$ guaranteed by Algorithm `ImpLowStretchTree`.

We now return to the proof of (13). We first note that $l_0(e)$ is at most $O(\log \widehat{m})$ for every edge e. We then observe that for each index $p > 0$ and each $h(e) \le i < h'(e)$ such that $\pi_i(e) = p$, $\mathrm{vol}\left(E(U(e,i))\right) / \mathrm{vol}\left(E(W(e,i))\right)$ is at least $2^{\log^{p/t} \widehat{m}}$ (by Lemma 5.1, (11)).

For $h(e) \le i < h'(e)$, let $g_i(e) = \mathrm{vol}\left(E(U(e,i+1))\right) / \mathrm{vol}\left(E(W(e,i))\right)$ (note that the vertex sets $W(e,i)$ and $U(e,i+1)$ correspond to the same component under different edge contraction. We then have

$$\prod_{1 \le p \le t-1} \left(2^{\log^{p/t} \widehat{m}}\right)^{l_p(e)} \le \widehat{m} \prod_{h(e) \le i < h'(e)} g_i(e);$$

hence $\sum_{p=1}^{t-1} l_p(e) \log^{p/t} \widehat{m} \le \log \widehat{m} + \sum_{h(e) \le i < h'(e)} \log g_i(e)$. We will next prove that

$$\sum_e \sum_{h(e) \le i < h'(e)} \log g_i(e) \le \widehat{m} \log \widehat{m}, \tag{14}$$

which implies (13).

Let E_i denote the set of edges present at recursion level i. For every edge $e \in E_i$ such that $i < h'(e)$, we have

$$\sum_{e' \in E(W(e,i))} g_i(e') = g_i(e) \mathrm{vol}\left(E(W(e,i))\right) = \mathrm{vol}\left(E(U(e,i+1))\right),$$

and so

$$\sum_{\substack{e \in E_i \\ h(e) \le i < h'(e)}} g_i(e) = \mathrm{vol}\left(E_{i+1}\right).$$

As each edge is present in at most $O(\log \widehat{m})$ recursion depths, $\sum_i \mathrm{vol}\left(E_i\right) \le \widehat{m} \log \widehat{m}$, which proves (14). ∎

6. Conclusion. At the beginning of the paper, we pointed out that the definition of stretch used in this paper differs slightly from that used by Alon et al. [1]. If one is willing to accept a longer running time, then this problem is easily remedied, as shown in section 1.1. If one is willing to accept a bound of $O(\log^3 n)$ on the stretch, then one can extend our analysis to show that the natural randomized variant of `LowStretchTree`, in which one chooses the radii of the balls and cones at random, works.

A natural open question is whether one can improve the stretch bound from $O\left(\log^2 n \log\log n\right)$ to $O(\log n)$. Algorithmically, it is also desirable to improve the running time of the algorithm to $O(m \log n)$. If we can successfully achieve both improvements, then we can use the Spielman–Teng solver to solve planar diagonally dominant linear systems in $O(n \log n \log(1/\epsilon))$ time.

As the average stretch[4] of any spanning tree in a weighted connected graph is at least 1, our low-stretch tree algorithm also provides an $O\left(\log^2 n \log\log n\right)$-approximation to the optimization problem of finding the spanning tree with the lowest average stretch. It remains open whether (a) our algorithm has a better approximation ratio and (b) one can in polynomial time find a spanning tree with better approximation ratio, e.g., $O(\log n)$ or even $O(1)$.

IMPROVED APPROXIMATION ALGORITHMS FOR MINIMUM WEIGHT VERTEX SEPARATORS*

URIEL FEIGE†, MOHAMMADTAGHI HAJIAGHAYI‡, AND JAMES R. LEE§

Abstract. We develop the algorithmic theory of vertex separators and its relation to the embeddings of certain metric spaces. Unlike in the edge case, we show that embeddings into L_1 (and even Euclidean embeddings) are insufficient but that the additional structure provided by many embedding theorems does suffice for our purposes. We obtain an $O(\sqrt{\log n})$ approximation for minimum ratio vertex cuts in general graphs, based on a new semidefinite relaxation of the problem, and a tight analysis of the integrality gap which is shown to be $\Theta(\sqrt{\log n})$. We also prove an optimal $O(\log k)$-approximate max-flow/min-vertex-cut theorem for arbitrary vertex-capacitated multicommodity flow instances on k terminals. For uniform instances on any excluded-minor family of graphs, we improve this to $O(1)$, and this yields a constant-factor approximation for minimum ratio vertex cuts in such graphs. Previously, this was known only for planar graphs, and for general excluded-minor families the best known ratio was $O(\log n)$. These results have a number of applications. We exhibit an $O(\sqrt{\log n})$ pseudoapproximation for finding balanced vertex separators in general graphs. In fact, we achieve an approximation ratio of $O(\sqrt{\log \mathsf{opt}})$, where opt is the size of an optimal separator, improving over the previous best bound of $O(\log \mathsf{opt})$. Likewise, we obtain improved approximation ratios for treewidth: in any graph of treewidth k, we show how to find a tree decomposition of width at most $O(k\sqrt{\log k})$, whereas previous algorithms yielded $O(k \log k)$. For graphs excluding a fixed graph as a minor (which includes, e.g., bounded genus graphs), we give a constant-factor approximation for the treewidth. This in turn can be used to obtain polynomial-time approximation schemes for several problems in such graphs.

Key words. graph separators, sparsest cut, embeddings, multicommodity flows

1. Introduction.

Given a graph $G = (V, E)$, one is often interested in finding a small "separator" whose removal from the graph leaves two sets of vertices of roughly equal size (say, of size at most $2|V|/3$) with no edges connecting these two sets. The separator itself may be a set of edges, in which case it is called a *balanced edge separator*, or a set of vertices, in which case it is called a *balanced vertex separator*. In the present work, we focus on vertex separators.

Balanced separators of small size are important in several contexts. They are often the bottlenecks in communication networks (when the graph represents such a network) and can be used in order to provide lower bounds on communication tasks (see, e.g., [37, 35, 9]). Perhaps more importantly, finding balanced separators of small size is a major primitive for many graph algorithms and, in particular, for those that are based on the divide and conquer paradigm [39, 9, 36].

Certain families of graphs always have small vertex separators. For example, trees always have a vertex separator containing a single vertex. The well-known planar separator theorem of Lipton and Tarjan [39] shows that every n-vertex planar graph has a balanced vertex separator of size $O(\sqrt{n})$ and, moreover, that such a separator can be found in polynomial time. This was later extended to show that more general families of graphs (any family of graphs that excludes some minor) have small separators [25, 2]. However, there are families of graphs (for example, expander graphs) in which the smallest separator is of size $\Omega(n)$.

Finding the smallest separator is an NP-hard problem (see, e.g., [15]). In the current paper, we study approximation algorithms that find vertex separators whose sizes are not much larger than the optimal separator of the input graph. These algorithms can be useful in detecting small separators in graphs that happen to have small separators, as well as in demonstrating that an input graph does not have any small vertex separator (and hence, for example, does not have serious bottlenecks for routing).

Much of the previous work on approximating vertex separators piggy-backed on work for approximating edge separators. For graphs of bounded degree, the sizes of the minimum edge and vertex separators are the same up to a constant multiplicative factor, leading to a corresponding similarity in terms of approximation ratios. However, for general graphs (with no bound on the degree), the situation is different. For example, every edge separator for the star graph has $\Omega(n)$ edges, whereas the minimum vertex separator has just one vertex. One can show that approximating vertex separators is at least as hard as approximating edge separators (see [15]). As to the reverse direction, it is known only that approximating vertex separators is at least as easy as approximating edge separators in *directed graphs* (a notion that will not be discussed in this paper).

The previous best approximation ratio for vertex separators is based on the work of Leighton and Rao [36]. They presented an algorithm based on linear programming that approximates the minimum edge separator within a ratio of $O(\log n)$. They observed that their algorithm can be extended to work on directed graphs and hence gives an approximation ratio of $O(\log n)$ also for vertex separators, using the algorithm for (directed) edge separators as a black box. More recently, Arora, Rao, and Vazirani [7] presented an algorithm based on semidefinite programming that approximates the minimum edge separator within a ratio of $O(\sqrt{\log n})$. Their remarkable techniques, which are a principal component in our algorithm for vertex separators, are discussed more in the following section.

In the present work, we formulate new linear and semidefinite program (SDP) relaxations for the vertex separator problem and then develop rounding algorithms for these programs. The rounding algorithms are based on techniques that were developed in the context of edge separators, but we exploit new properties of these techniques and adapt and enhance them to the case of vertex separators. Using this approach, we improve the best approximation ratio for vertex separators to $O(\sqrt{\log n})$. In fact, we obtain an $O(\sqrt{\log \mathsf{opt}})$ approximation, where opt is the size of an optimal separator. (An $O(\log \mathsf{opt})$ approximation can be derived from the techniques of [36].) In addition, we derive and extend some previously known results in a unified way, such as a constant factor approximation for vertex separators in planar graphs (a result originally proved in [5]), which we extend to any family of graphs excluding a fixed minor.

Before delving into more details, let us mention two aspects in which edge and vertex separators differ. One is the notion of a *minimum ratio cut*, which is an

important notion used in our analysis. For edge cuts, all "natural" definitions of such a notion are essentially equivalent. For vertex separators, this is not the case. One consequence of this is that our algorithms provide a good approximation for *vertex expansion* in bounded degree graphs but not in general graphs. This issue will be discussed in section 2. Another aspect where there is a distinction between edge and vertex separators is that of the role of embeddings into L_1 (a term that will be discussed later). For edge separators, if the linear program or SDP relaxations happen to provide such an embedding (i.e., if the solution is an L_1 metric), then they in fact yield an optimal edge separator. For vertex separators, embeddings into L_1 seem to be insufficient, and we give a number of examples that demonstrate this deficiency. Our rounding techniques for the vertex separator case are based on embeddings with small average distortion into a line, a concept that was first systematically studied by Rabinovich [41].

As mentioned above, finding small vertex separators is a basic primitive that is used in many graph algorithms. Consequently, our improved approximation algorithm for minimum vertex separators can be plugged into many of these algorithms, improving either the quality of the solution that they produce or their running time. Rather than attempting to provide in this paper a survey of all potential applications, we shall present one major application, that of improving the approximation ratio for *treewidth*, and discuss some of its consequences.

1.1. Some related work. An important concept that we shall use is the *ratio* of a vertex separator (A, B, S). Given a weight function $\pi : V \to \mathbb{R}_+$ on vertices and a set $S \subseteq V$ which separates G into two disconnected pieces A and B, we can define the *sparsity* of the separator by

$$\frac{\pi(S)}{\min\{\pi(A), \pi(B)\} + \pi(S)}.$$

Indeed, most of our effort will focus on finding separators (A, B, S) for which the sparsity is close to minimal among all vertex separators in G.

In the case of edge separators, there are intimate connections between approximation algorithms for minimum ratio cuts and the theory of metric embeddings. In particular, Linial, London, and Rabinovich [38] and Aumann and Rabani [8] show that one can use L_1 embeddings to round the solution to a linear relaxation of the problem. For the case of vertex cuts, we will show that L_1 embeddings (and even Euclidean embeddings) are insufficient but that the additional structure provided by many embedding theorems does suffice. This structure corresponds to the fact that many embeddings are of *Fréchet type*; i.e., their basic component takes a metric space X and a subset $A \subseteq X$ and maps every point $x \in X$ to its distance to A. This includes, for instance, the classical theorem of Bourgain [14].

The seminal work of Leighton and Rao [36] showed that, in both the edge and vertex cases, one can achieve an $O(\log n)$ approximation algorithm for minimum ratio cuts, based on a linear relaxation of the problem. Their solution also yields the first approximate max-flow/min-cut theorems in a model with uniform demands. The papers [38, 8] extend their techniques for the *edge case* to nonuniform demands. Their main tool is Bourgain's theorem [14], which states that every n-point metric space embeds into L_1 with $O(\log n)$ distortion.

Recently, Arora, Rao, and Vazirani [7] exhibited an $O(\sqrt{\log n})$ approximation for finding minimum ratio edge cuts, based on a known semidefinite relaxation of the problem, and a fundamentally new technique for exploiting the global structure of

the solution. This approach, combined with the embedding technique of Krauthgamer et al. [32], has been extended further to obtain approximation algorithms for minimum ratio edge cuts with nonuniform demands. In particular, using [7, 32] and the quantitative improvements of Lee [34], Chawla, Gupta, and Räcke [17] exhibit an $O(\log n)^{3/4}$ approximation. More recently, Arora, Lee, and Naor [6] have improved this bound almost to that of the uniform case, yielding an approximation ratio of $O(\sqrt{\log n}\log\log n)$.

On the other hand, progress on the vertex case has been significantly slower. In the sections that follow, we attempt to close this gap by providing new techniques for finding approximately optimal vertex separators.

Since the initial (conference) publication of this manuscript, we have learned of two other papers which contain some independently discovered, overlapping results. All three papers first appeared in STOC 2005. In particular, the work of Agarwal et. al. [1] gives an $O(\sqrt{\log n})$-approximation for a *directed* version of the Sparsest Cut problem which implies a similar result for vertex cuts by a well-known reduction (see, e.g., [36]). Their algorithm is also based on rounding an SDP (though they use a different relaxation). Second, the paper of Chekuri, Khanna, and Shepherd [18] shows that the max-multicommodity-flow/min-vertex-cut gap for product demands *in planar graphs* is bounded by a universal constant. As discussed later, we prove this theorem not only for planar graphs but also for any *excluded-minor family of graphs*.

1.2. Results and techniques. In section 2, we introduce a new semidefinite relaxation for the problem of finding minimum ratio vertex cuts in a general graph. In preparation for applying the techniques of [7], the relaxation includes so-called *triangle inequality* constraints on the variables. The program contains strictly more than one variable per vertex of the graph, but the SDP is constructed carefully to lead to a single metric of negative type[1] on the vertices that contains all the information necessary to perform the rounding.

In section 3, we exhibit a general technique for rounding the solution to optimization problems involving "fractional" vertex cuts. These are based on the ability to find line embeddings with small *average* distortion, as defined by Rabinovich [41] (though we extend his definition to allow for arbitrary weights in the average). In [41], it is proved that one can obtain line embeddings with constant average distortion for metrics supported on planar graphs. This is observed only as an interesting structural fact, without additional algorithmic consequences over the known average distortion embeddings into all of L_1 [42, 31]. For the vertex case, we will see that this additional structure is crucial.

Using the seminal results of [7], which can be viewed as a line embedding (see section A.2), we then show that the solution of the semidefinite relaxation can be rounded to a vertex separator whose ratio is within $O(\sqrt{\log n})$ of the optimal separator. For the SDP used in [7] for approximating minimum ratio edge cuts, only a constant lower bound is known for the integrality gap. Recent work of Khot and Vishnoi [30] shows that in the nonuniform demand case, the integrality gap must tend to infinity with the size of the instance. In contrast, we show that our analysis is tight by exhibiting an $\Omega(\sqrt{\log n})$ integrality gap for the SDP in section 5. Interestingly, this gap is achieved by an L_1 metric. This shows that L_1 metrics are not as intimately connected to vertex cuts as they are to edge cuts and that the use of the structural

[1] A metric space (X, d) is said to be of *negative type* if $d(x, y) = ||f(x) - f(y)||^2$ for some map $f : X \to L_2$.

theorems discussed in the previous paragraph is crucial to obtaining an improved bound.

We exhibit an $O(\log k)$-approximate max-flow/min-vertex-cut theorem for general instances with k commodities. The best previous bound of $O(\log^3 k)$ is due to [22] (they actually show this bound for directed instances with symmetric demands, but this implies the vertex case). The result is proved in section 4. A well-known reduction shows that this theorem implies the edge version of [38, 8] as a special case. Again, our rounding makes use of the general tools developed in section 3 based on average-distortion line embeddings. In sections 4.2 and 4.4, we show that any approach based on low-distortion L_1 embeddings and Euclidean embeddings, respectively, must fail since the integrality gap can be very large even for spaces admitting such embeddings. Using the improved line embeddings for metrics on graphs which exclude a fixed minor [41] (based on [31] and [42]), we also achieve a constant-factor approximation for finding minimum ratio vertex cuts in these families. This answers an open problem asked in [19].

By improving the approximation ratios for balanced vertex separators in general graphs and graphs excluding a fixed minor, we improve the approximation factors for a number of problems relating to graph-theoretic decompositions such as treewidth, branchwidth, and pathwidth. For instance, we show that in any graph of treewidth k, we can find a tree decomposition of width at most $O(k\sqrt{\log k})$. This improves upon the $O(\log n)$-approximation of Bodlaender et al. [11] and the $O(\log k)$-approximation algorithm of Amir [4]. A result of Seymour and Thomas [44] shows that a decomposition of width $1.5k$ can be found efficiently in planar graphs. We offer a significant generalization by giving an algorithm that finds a decomposition of width $O(k)$ whenever the input graph excludes a fixed minor. See section 6.3 and Theorem 6.4 and Corollary 6.5 for a discussion of these problems, along with salient definitions, and a list of the problems to which our techniques apply.

Improving the approximation factor for treewidth in general graphs and graphs excluding a fixed minor to $O(\sqrt{\log n})$ and $O(1)$, respectively, answers an open problem of [19] and leads to an improvement in the running time of approximation schemes and subexponential fixed parameter algorithms for several NP-hard problems on graphs excluding a fixed minor. For instance, we obtain the first polynomial-time approximation schemes (PTASs) for problems like *minimum feedback vertex set* and *connected dominating set* in such graphs (see Theorem 6.6 for more details). Finally, our techniques yield an $O(g)$-approximation algorithm for the vertex separator problem in graphs of genus at most g. It is known that such graphs have balanced separators of size $O(\sqrt{gn})$ [25] and that these separators can be found efficiently [28] (earlier, [3] gave a more general algorithm which, in particular, finds separators of size $O(\sqrt{g^{3/2}n})$). Our approximation algorithms thus find separators of size $O(\sqrt{g^3 n})$, but when the graph at hand has a smaller separator, our algorithms perform much better than the worst-case bounds of [25, 3, 28].

2. A vector program for minimum ratio vertex cuts. Let $G = (V, E)$ be a graph with nonnegative vertex weights $\pi : V \to [1, \infty)$. For a subset $U \subseteq V$, we write $\pi(U) = \sum_{u \in U} \pi(u)$. A vertex separator partitions the graph into three parts, S (the set of vertices in the separator), A, and B (the two parts that are separated). We use the convention that $\pi(A) \geq \pi(B)$. We are interested in finding separators that minimize the ratio of the "cost" of the separator to its "benefit." Here, the cost of a separator is simply $\pi(S)$. As to the benefit of a separator, it turns out that there is more than one natural way in which one can define it. The distinction between the

various definitions is relatively unimportant whenever $\pi(S) \le \pi(B)$, but it becomes significant when $\pi(S) > \pi(B)$. We elaborate on this below.

In analogy to the case of edge separators, one may wish to take the benefit to be $\pi(B)$. Then we would like to find a separator that minimizes the ratio $\pi(S)/\pi(B)$. However, there is evidence that no polynomial-time algorithm can achieve an approximation ratio of $O(|V|^{\delta})$ for this problem (for some $\delta > 0$). See section A.1 for details.

For the use of separators in divide and conquer algorithms, the benefit is in the reduction in size of the parts that remain. This reduction is $\pi(B) + \pi(S)$ rather than just $\pi(B)$, and the quality of a separator is defined to be

$$\frac{\pi(S)}{\pi(B) + \pi(S)}.$$

This definition is used in the introduction to our paper and in some other earlier work (e.g., [5]).

As a matter of convenience, we use a slightly different definition. We shall define the *sparsity* of a separator to be

$$\alpha_\pi(A, B, S) = \frac{\pi(S)}{\pi(A \cup S) \cdot \pi(B \cup S)}.$$

Under our convention that $\pi(A) \ge \pi(B)$, we have that $\pi(V)/2 \le \pi(A \cup S) \le \pi(V)$, and the two definitions differ by a factor of $\Theta(\pi(V))$.

We define $\alpha_\pi(G)$ to be the minimum over all vertex separators (A, B, S) of $\alpha_\pi(A, B, S)$. The problem of computing $\alpha_\pi(G)$ is NP-hard (see [15]). Our goal is to give algorithms for finding separators (A, B, S) for which $\alpha_\pi(A, B, S) \le O(\sqrt{\log k})\, \alpha_\pi(G)$, where $k = |\mathrm{supp}(\pi)|$ is the number of vertices with nonzero weight in G.

Let us pause for a moment to discuss an aspect of approximation algorithms for $\alpha_\pi(G)$ that is often overlooked. The optimal solution minimizing $\alpha_\pi(A, B, S)$ is indeed a nontrivial separator in the sense that both A and B are nonempty (unless the underlying graph G is a clique). However, when $\pi(S)$ is large relative to $\pi(B)$ in the optimal separator, sets S', B' that only approximately minimize $\alpha_\pi(A', B', S')$ might correspond to trivial separators in the sense that B' is empty. Hence approximation algorithms for $\alpha_\pi(G)$ might return trivial separators rather than nontrivial ones. Whenever this happens, we assume as a convention that the algorithm instead returns a minimum weight vertex cut in G. These cuts are nontrivial and can be found in polynomial time (see section 3 for example), and the corresponding value of $\alpha_\pi(A, B, S)$ is not larger than that for any trivial separator. (In fact, for trivial separators $\alpha_\pi(A, B, S) = 1/\pi(V)$, whereas for every nontrivial separator, whether optimal or not, one always has $\alpha_\pi(A, B, S) \le 1/\pi(V)$.)

Before we move on to the main algorithm, let us define

$$\tilde{\alpha}_\pi(A, B, S) = \pi(S)/[\pi(A) \cdot \pi(B \cup S)].$$

Note that $\alpha_\pi(A, B, S)$ and $\tilde{\alpha}_\pi(A, B, S)$ are equivalent up to a factor of 2 whenever $\pi(A) \ge \pi(S)$. Hence in this case it will suffice to find a separator (A, B, S) with $\alpha_\pi(A, B, S) \le O(\sqrt{\log k})\, \tilde{\alpha}_\pi(G)$. Allowing ourselves to compare $\alpha_\pi(A, B, S)$ to $\tilde{\alpha}_\pi(G)$ rather than $\alpha_\pi(G)$ eases the formulation of the semidefinite relaxations that follow. When $\pi(S) > \pi(A)$, $\tilde{\alpha}$ no longer provides a good approximation to α. However, in this case $\pi(S) > \pi(B)$, and returning a minimum weight vertex cut provides a constant-factor approximation to $\alpha_\pi(G)$.

2.1. The quadratic program. We present a quadratic program for the problem of finding minimum ratio vertex cuts. All constraints in this program involve only terms that are quadratic (products of two variables). Our goal is for the value of the quadratic program to be equal to $\tilde{\alpha}_\pi(G)$. Let $G = (V, E)$ be a vertex-weighted graph, and let (A^*, B^*, S^*) be an optimal separator according to $\tilde{\alpha}_\pi(\cdot)$, i.e., such that $\tilde{\alpha}_\pi(G) = \tilde{\alpha}_\pi(A^*, B^*, S^*)$.

With every vertex $i \in V$, we associate three indicator 0/1 variables, x_i, y_i, and s_i. It is our intention that for every vertex exactly one indicator variable will have the value 1 and that the other two will have value 0. Specifically, $x_i = 1$ if $i \in A^*$, $y_i = 1$ if $i \in B^*$, and $s_i = 1$ if $i \in S^*$. To enforce this, we formulate the following two sets of constraints.

Exclusion constraints. These force at least two of the indicator variables to be 0:

$$x_i \cdot y_i = 0,\ x_i \cdot s_i = 0,\ y_i \cdot s_i = 0 \text{ for every } i \in V.$$

Choice constraints. These force the nonzero indicator variable to have value 1:

$$x_i^2 + y_i^2 + s_i^2 = 1 \text{ for all } i \in V.$$

The combination of exclusion and choice constraints implies the following *integrality constraints*, which we formulate here for completeness, even though they are not explicitly included as part of the quadratic program: $x_i^2 \in \{0, 1\}$, $y_i^2 \in \{0, 1\}$, $s_i^2 \in \{0, 1\}$ for all $i \in V$.

Edge constraints. This set of $2|E|$ constraints expresses the fact that there are no edges connecting A and B:

$$x_i \cdot y_j = 0 \text{ and } x_j \cdot y_i = 0 \text{ for all } (i, j) \in E.$$

Now we wish to express the fact that we are minimizing $\tilde{\alpha}_\pi(A, B, S)$ over all vertex separators (A, B, S). To simplify our presentation, it will be convenient to assume that we know the value $K = \pi(A^*) \cdot \pi(B^* \cup S^*)$. We can make such an assumption because the value of K can be guessed (since eventually we will need only to know K within a factor of 2, say, there are only $O(\log \pi(V))$ different values to try). Alternatively, the assumption can be dropped at the expense of a more complicated relaxation.

Spreading constraint. The following constraint expresses our guess for the value of K:

$$\tfrac{1}{2} \sum_{i,j \in V} \pi(i)\pi(j)(x_i - x_j)^2 \geq K.$$

Notice that $(x_i - x_j)^2 = 1$ if and only if $\{x_i, x_j\} = \{0, 1\}$.

The objective function. Finally, we write the objective we are trying to minimize:

$$\text{minimize} \qquad \frac{1}{K} \sum_{i \in V} \pi(i) s_i^2.$$

The above quadratic program computes exactly the value of $\tilde{\alpha}_\pi(G)$ and hence is NP-hard to solve.

2.2. The vector relaxation. We relax the quadratic program of section 2.1 to a "vector" program that can be solved up to arbitrary precision in polynomial time. The relaxation involves two aspects.

Interpretation of variables. All variables are allowed to be arbitrary vectors in $\mathbb{R}^d$, rather than in $\mathbb{R}$. The dimension d is not constrained and might be as large as the number of variables (i.e., $3n$).

Interpretation of products. The original quadratic program involved products over pairs of variables. Every such product is interpreted as an inner product between the respective vector variables. The exclusion constraints merely force vectors to be orthogonal (rather than forcing one of them to be 0), and the integrality constraints are no longer implied by the exclusion and choice constraints. The choice constraints imply (among other things) that no vector has norm greater than 1, and the edge constraints imply that whenever $(i, j) \in E$, the corresponding vectors x_i and y_j are orthogonal.

2.3. Adding valid constraints. We now strengthen the vector program by adding more valid constraints. This should be done in a way that will not violate feasibility (in cases where the original quadratic program was feasible) and, moreover, that preserves polynomial-time solvability (up to arbitrary precision) of the resulting vector program. It is known that this last condition is satisfied if we add only constraints that are linear over inner products of pairs of vectors, and this is indeed what we shall do. The reader is encouraged to check that every constraint that we add is indeed satisfied by feasible 0/1 solutions to the original quadratic program.

The 1*-vector.* We add the additional variable v to the vector program. It is our intention that variables whose value is 1 in the quadratic program will have value equal to that of v in the vector program. Hence v is a unit vector, and we add the constraint $v^2 = 1$.

Sphere constraints. For every vector variable z we add the constraint $z^2 = v \cdot z$. Geometrically, this forces all vectors to lie on the surface of a sphere of radius $\frac{1}{2}$ centered at $\frac{v}{2}$ because the constraint is equivalent to $(z - \frac{v}{2})^2 = \frac{1}{4}$.

Triangle constraints. For every three variables z_1, z_2, z_3 we add the constraint

$$(z_1 - z_2)^2 + (z_2 - z_3)^2 \geq (z_1 - z_3)^2.$$

This implies that every three variables (which are points on the sphere $S(\frac{v}{2}, \frac{1}{2})$) form a triangle whose angles are all at most $\pi/2$. We remark that we shall eventually use only those triangle constraints in which all three variables are x variables.

Removing the s_i vectors. In the upcoming sections we shall describe and analyze a rounding procedure for our vector program. It turns out that our rounding procedure does not use the vectors s_i—only the values $s_i^2 = 1 - x_i^2 - y_i^2$. Hence we can modify the choice constraints to

$$x_i^2 + y_i^2 \leq 1$$

and remove all explicit mention of the s_i vectors, without affecting our analysis for the rounding procedure. The full vector program follows.

$$
\begin{array}{lll}
\text{minimize} & \frac{1}{K}\sum_{i\in V}\pi(i)(1-x_i^2-y_i^2) & \\
\\
\text{subject to} & x_i, y_i, v \in \mathbb{R}^{2n}, & i \in V, \\
& x_i^2 + y_i^2 \le 1, & i \in V, \\
& x_i \cdot y_i = 0, & i \in V, \\
& x_i \cdot y_j = x_j \cdot y_i = 0, & (i,j) \in E, \\
& v^2 = 1, & \\
& v \cdot x_i = x_i^2,\ v \cdot y_i = y_i^2, & i \in V, \\
& \frac{1}{2}\sum_{i,j\in V}\pi(i)\pi(j)(x_i - x_j)^2 \ge K, & \\
& (x_i - x_j)^2 \le (x_i - x_h)^2 + (x_h - x_j)^2, & h,i,j \in V.
\end{array}
$$

In the following section, we will show how to use this SDP to obtain a solution which is within an $O(\sqrt{\log k})$ factor of the best vertex separator. In section 5, we show that this analysis is tight, even for a family of stronger (i.e. more constrained) vector programs.

3. Algorithmic framework for rounding. In this section, we develop a general algorithmic framework for rounding solutions to optimization problems on vertex cuts.

3.1. Capacities and demands. In the vector program of section 2, vertices have weights π. These weights served two purposes. One was as a measure of cost for the separator (we are charged $\pi(S)$ in the numerator of α_π). The other was as a measure of benefit of the separator (we get credit of $\pi(A \cup S)\pi(B \cup S)$ in the denominator). Here, we shall not insist on having one weight function serving both purposes. Instead, we allow the cost to be measured with respect to one weight function (say, π_1), and the benefit to be measured with respect to another weight function (say, π_2). It is customary to call these functions *capacity* and *demand*. Let us provide more details.

Vertices are assumed to have nonnegative capacities $\{c_v\}_{v\in V} \subseteq \mathbb{N}$. For simplicity of presentation, we are assuming here that capacities are integer, but all results of this paper can also be extended to the case of arbitrary nonnegative capacities. For a subset $S \subseteq V$, we define $\mathrm{cap}(S) = \sum_{v\in S} c_v$.

In its most general form, we have a *demand function* $\omega : V \times V \to \mathbb{R}_+$ which is *symmetric*, i.e. $\omega(u,v) = \omega(v,u)$. In interesting special cases, this demand function is induced by weights $\pi_2 : V \to \mathbb{R}_+$ via the relation $\omega(u,v) = \pi_2(u)\pi_2(v)$ for all $u, v \in V$.

Given a capacity function and a demand function, we define the *sparsity of* (A,B,S) by

$$\alpha^{\mathrm{cap},\omega}(A,B,S) = \frac{\mathrm{cap}(S)}{\sum_{u\in A\cup S}\sum_{v\in B\cup S}\omega(u,v)}.$$

We define the *sparsity of* G by $\alpha^{\mathrm{cap},\omega}(G) = \min\{\alpha^{\mathrm{cap},\omega}(A,B,S)\}$ where the minimum is taken over all vertex separators. Note that $\alpha_\pi(A,B,S) = \alpha^{\mathrm{cap},\omega}(A,B,S)$ when $c_v = \pi(v)$ and $\omega(u,v) = \pi(u)\pi(v)$ for all $u, v \in V$.

3.2. Line embeddings and distortion. A key feature of the vector program is that its solution is a set of vectors in high dimensional Euclidean space $\mathbb{R}^{2n}$. Moreover, the triangle constraints imply that for the x_i vectors, the square of their Euclidean distance also forms a metric. Technically, such a metric is said to be of *negative type*. Our rounding framework is based on properties of metric spaces.

Let (X, d) be a metric space. A map $f : X \to \mathbb{R}$ is called 1-*Lipschitz* if, for all $x, y \in X$,

$$|f(x) - f(y)| \leq d(x, y).$$

Given a 1-Lipschitz map f and a demand function $\omega : X \times X \to \mathbb{R}_+$, we define its *average distortion under* ω by

$$avd_\omega(f) = \frac{\sum_{x,y \in X} \omega(x, y) \cdot d(x, y)}{\sum_{x,y \in X} \omega(x, y) \cdot |f(x) - f(y)|}.$$

We say that a weight function ω is a *product weight* if it can be written as $\omega(x, y) = \pi(x)\pi(y)$ for all $x, y \in X$, for some $\pi : X \to \mathbb{R}_+$. We now state three theorems which give line embeddings of small average distortion in various settings. The proofs of these theorems are sketched in section A.2.

THEOREM 3.1 (Bourgain [14]). *If (X, d) is an n-point metric space, then for every weight function $\omega : X \times X \to \mathbb{R}_+$, there exists an efficiently computable* 1*-Lipschitz map $f : X \to \mathbb{R}$ with $avd_\omega(f) = O(\log n)$.*

THEOREM 3.2 (Rabinovich [41]). *If (X, d) is any metric space supported on a graph which excludes a K_r-minor, then for every* product weight $\omega_0 : X \times X \to \mathbb{R}_+$*, there exists an efficiently computable* 1*-Lipschitz map $f : X \to \mathbb{R}$ with $avd_{\omega_0}(f) = O(r^2)$.*

THEOREM 3.3 (Arora, Rao, and Vazirani [7]). *If (X, d) is an n-point metric of negative type, then for every* product weight $\omega_0 : X \times X \to \mathbb{R}_+$*, there exists an efficiently computable* 1*-Lipschitz map $f : X \to \mathbb{R}$ with $avd_{\omega_0}(f) = O(\sqrt{\log n})$.*

We also recall the following classical result.

LEMMA 3.4. *Let (Y, d) be any metric space and $X \subseteq Y$. Given a* 1*-Lipschitz map $f : X \to \mathbb{R}$, there exists a* 1*-Lipschitz extension $\tilde{f} : Y \to \mathbb{R}$, i.e., such that $\tilde{f}(x) = f(x)$ for all $x \in X$.*

Proof. One defines

$$\tilde{f}(y) = \sup_{x \in X} [f(x) - d(x, y)]$$

for all $y \in Y$. ∎

3.3. Menger's theorem. The following classical theorem is an important ingredient in our rounding framework.

THEOREM 3.5 (Menger's theorem). *A graph $G = (V, E)$ contains at least k vertex-disjoint paths between two nonadjacent vertices $u, v \in V$ if and only if every vertex cut that separates u from v has size at least k.*

It is well known that a smallest vertex cut separating u from v can be found in polynomial time (in the size of G) by deriving Menger's theorem from the max-flow/min-cut theorem (see, e.g., [45]).

Suppose that, in addition to a graph $G = (V, E)$, we have a set of nonnegative vertex capacities $\{c_v\}_{v \in V} \subseteq \mathbb{N}$. (For simplicity, we are assuming here that capacities are integers.) For a subset $S \subseteq V$, we define $\text{cap}(S) = \sum_{v \in S} c_v$. We have the following immediate corollary.

COROLLARY 3.6. *Let $G = (V, E)$ be a graph with vertex capacities. Then for any two nonadjacent vertices $u, v \in V$, the following two statements are equivalent:*

1. *Every vertex cut $S \subseteq V$ that separates u from v has* $\text{cap}(S) \geq k$.

2. *There exist u-v paths $p_1, p_2, \ldots, p_k \subseteq V$ such that for every $w \in V$,*

$$\#\{1 \le i \le k : w \in p_i\} \le c_w.$$

Furthermore, a vertex cut S of minimal capacity can be found in polynomial time.

Proof. The proof is by a simple reduction. From $G = (V, E)$ and the capacities $\{c_v\}_{v \in V}$, we create a new uncapacitated instance $G' = (V', E')$ and then apply Menger's theorem to G'.

To arrive at G', we replace every vertex $v \in V$ with a collection of representatives $v_1, v_2, \ldots, v_{c_v}$ (if $c_v = 0$, then this corresponds to deleting v from the graph). Now for every edge $(u, v) \in E$, we add edges $\{(u_i, v_j) : 1 \le i \le c_u,\ 1 \le j \le c_v\}$. It is not hard to see that every minimal vertex cut takes either all representatives of a vertex or none, giving a one-to-one correspondence between minimal vertex cuts in G and G'. ∎

Furthermore, given such a capacitated instance $G = (V, E)$, $\{c_v\}_{v \in V}$, along with $u, v \in V$, it is possible to find, in polynomial time, a vertex cut $S \subseteq V$ of minimal capacity which separates u from v.

3.4. Line embeddings and vertex separators. Having presented the tools that we shall be using (line embeddings, Menger's theorem), we present here an algorithmic framework based on an arbitrary line embedding $f : V \to \mathbb{R}$ for finding a vertex cut. Different instantiations of this algorithm may use different line embeddings f. The analysis of this algorithm will use, among other things, Menger's theorem. It will also involve a certain cost function $\mathsf{cost} : V \to \mathbb{R}_+$ that is left unspecified in this section. However, in later sections (e.g., section 3.5) the cost of a vertex will be instantiated to be the contribution of the vertex to the objective function of a relaxation of the minimum vertex separator problem (e.g., $\pi(i)(1 - x_i^2 - y_i^2)$ in the vector program). The key technical property of the algorithm is summarized in Lemma 3.7, and it relates the cost (which is the value of the relaxation) to the sparsity of the cut found by the algorithm. Hence Lemma 3.7 can be used in order to analyze the approximation ratio of algorithms that use this algorithmic framework.

Let $G = (V, E)$ be a graph with vertex capacities $\{c_v\}_{v \in V}$ and a demand function $\omega : V \times V \to \mathbb{R}_+$. Furthermore, suppose that we have a map $f : V \to \mathbb{R}$. We give the following algorithm, which computes a vertex cut (A, B, S) in G.

Algorithm FindCut(G, f)

1. Sort the vertices $v \in V$ according to the value of $f(v)$: $\{y_1, y_2, \ldots, y_n\}$.
2. For each $1 \le i \le n$,
3. Create the augmented graph $G_i = (V \cup \{s, t\}, E_i)$ with $E_i = E \cup \{(s, y_j), (y_k, t) : 1 \le j \le i,\ i < k \le n\}$.
4. Find the minimum capacity s-t separator S_i in G_i.
5. Let $A_i \cup \{s\}$ be the component of $G[V \cup \{s, t\} \setminus S_i]$ containing s, and let $B_i = V \setminus (A_i \cup S_i)$.
6. Output the vertex separator (A_i, B_i, S_i) for which $\alpha^{\mathrm{cap},\omega}(A_i, B_i, S_i)$ is minimal.

The analysis. Suppose that we have a cost function $\mathsf{cost} : V \to \mathbb{R}_+$. We say that the map $f : V \to \mathbb{R}$ is *edge-compatible with the cost function* cost if, for any $(u, v) \in E$, we have

$$|f(u) - f(v)| \le \frac{\mathsf{cost}(u) + \mathsf{cost}(v)}{2}. \tag{1}$$

We now move on to the main lemma of this section.

LEMMA 3.7 (charging lemma). *Let $G = (V, E)$ be any capacitated graph with demand function $\omega : V \times V \to \mathbb{R}_+$. Suppose additionally that we have a cost function $\mathsf{cost} : V \to \mathbb{R}_+$ and an edge-compatible map $f : V \to \mathbb{R}$. If α_0 is the sparsity of the minimum ratio vertex cut output by* FINDCUT(G, f)*, then*

$$\sum_{v \in V} c_v \cdot \mathsf{cost}(v) \geq \alpha_0 \sum_{u,v \in V} \omega(u, v)|f(u) - f(v)|.$$

Proof. Recall that we have sorted the vertices v according to the value of $f(v)$: $\{y_1, y_2, \ldots, y_n\}$. Let $C_i = \{y_1, \ldots, y_i\}$ and $\varepsilon_i = f(y_{i+1}) - f(y_i)$. First we have the following lemma which relates the size of the separators found to the average distance under f, according to ω.

LEMMA 3.8.

$$\sum_{i=1}^{n-1} \varepsilon_i \operatorname{cap}(S_i) \geq \alpha_0 \sum_{u,v \in V} \omega(u, v)|f(u) - f(v)|.$$

Proof. Using the fact that α_0 is the minimum sparsity of all cuts found by FINDCUT(G, f),

$$\begin{aligned} \operatorname{cap}(S_i) &\geq \alpha_0 \sum_{u \in A_i \cup S_i} \sum_{v \in B_i \cup S_i} \omega(u, v) \\ &\geq \alpha_0 \sum_{u \in C_i} \sum_{v \in V \setminus C_i} \omega(u, v). \end{aligned}$$

Note that the second inequality follows from the fact in FINDCUT(G, f) that since C_i contains A_i and $V \setminus C_i$ contains B_i, $A_i \cup S_i$ contains C_i and $B_i \cup S_i$ contains $V \setminus C_i$.

Multiplying both sides of the previous inequality by ε_i and summing over $i \in \{1, 2, \ldots, n-1\}$ prove the lemma. ∎

Now we come to the heart of the charging argument which relates the cost function to the capacity of the cuts occurring in the algorithm.

LEMMA 3.9 (charging against balls).

$$\sum_{v \in V} c_v \cdot \mathsf{cost}(v) \geq \sum_{i=1}^{n-1} \varepsilon_i \operatorname{cap}(S_i).$$

Proof. We first present an interpretation of the quantity $\sum_{i=1}^{n-1} \varepsilon_i \operatorname{cap}(S_i)$. Consider a nonnegative function g defined on the line segment $[f(y_1), f(y_n)]$ whose value at point z is defined as $g(z) = \operatorname{cap}(S_i)$, where i is the unique value such that z is in the half open interval $[f(y_i), f(y_{i+1}))$. Then $\sum_{i=1}^{n-1} \varepsilon_i \operatorname{cap}(S_i)$ is precisely $\int_{\mathbb{R}} g$.

Now, for every v, we present an interpretation of $c_v \cdot \mathsf{cost}(v)$. Consider a nonnegative function g_v whose value is c_v on the interval $[f(v) - \frac{1}{2}\mathsf{cost}(v),\ f(v) + \frac{1}{2}\mathsf{cost}(v)]$ and 0 elsewhere. Then $c_v \cdot \mathsf{cost}(v)$ is precisely $\int_{\mathbb{R}} g_v$. We shall refer to the support of g_v as the *ball* of v (as it is a ball centered at $f(v)$ of radius $\frac{1}{2}\mathsf{cost}(v)$).

Lemma 3.9 can now be rephrased as

$$\int_{\mathbb{R}} g(z)\, dz \leq \sum_v \int_{\mathbb{R}} g_v(z)\, dz.$$

We shall prove this inequality pointwise.

Consider an arbitrary point z, belonging to an arbitrary interval $[f(y_i), f(y_{i+1}))$. Since S_i is a minimum capacity s-t separator, applying Menger's theorem yields a family of s-t paths $p_1, \ldots, p_m$ (where $m = \mathrm{cap}(S_i)$) which use no vertex $v \in V$ more than c_v times. We view each of these paths as contributing 1 to the value of $g(z)$, and hence fully accounting for the value $g(z) = \mathrm{cap}(S_i)$. We now consider the contribution of these paths to the functions g_v.

Consider an arbitrary such path p_j. Since it crosses from C_i to $V \setminus C_i$, there must exist two consecutive vertices along the path (say, u and v) such that $u \in C_i$ and $v \in V \setminus C_i$. The fact that f is edge-compatible with cost implies that the union of the balls of u and v covers the interval $[f(u), f(v)]$ that includes the interval $[f(y_i), f(y_{i+1}))$. Hence z is in at least one of these two balls (say, the ball of v), and then we have p_j contribute one unit to $g_v(z)$. Note that the total contribution of the m disjoint paths to $g_v(z)$ can be at most c_v, because v can occur in at most c_v of these paths.

In summary, based on the disjoint paths, we provided a charging mechanism that accounts for all of $g(z)$, and charges at least as much to $\sum_v g_v(z)$ without exceeding the respective values c_v. This completes the proof of Lemma 3.9. ∎

Combining Lemmas 3.8 and 3.9 finishes the proof of Lemma 3.7. ∎

3.5. Analysis of the vector program. We now continue our analysis of the vector program from section 2.3. Recall that $\pi(i)(1 - x_i^2 - y_i^2)$ is the contribution of vertex i to the objective function. For every $i \in V$, define $\mathsf{cost}(i) = 4(1 - x_i^2 - y_i^2)$. We will consider the metric space (V, d) given by $d(i, j) = (x_i - x_j)^2$ (note that this is a metric space precisely because every valid solution to the SDP must satisfy the triangle inequality constraints). The following key proposition allows us to apply the techniques of sections 3.4 and 3.2 to the solution of the vector program.

PROPOSITION 3.10. *For every edge* $(i, j) \in E$, $(x_i - x_j)^2 \le \frac{\mathsf{cost}(i)+\mathsf{cost}(j)}{2}$.

Proof. Since $(i, j) \in E$, we have $x_i \cdot y_j = x_j \cdot y_i = 0$, and recall that $x_i \cdot y_i = x_j \cdot y_j = 0$. It follows that

$$(x_i - x_j)^2 \le 2[(x_i + y_i - v)^2 + (x_j + y_i - v)^2] \le 2[(1 - x_i^2 - y_i^2) + (1 - x_j^2 - y_i^2)].$$

Note that the first inequality above follows from the fact that $(x_i - x_j)^2 = ((x_i + y_i - v) - (x_j + y_i - v))^2$ and the inequality $(x - y)^2 \le 2(x^2 + y^2)$. Substitute $x = x_i + y_i - v$ and $y = x_j + y_i - v$. Then the second inequality follows from the constraints $vx_i = x_i^2$ and $vy_i = y_i^2$.

Putting y_j instead of y_i in the above equation gives $(x_i - x_j)^2 \le 2[(1 - x_i^2 - y_j^2) + (1 - x_j^2 - y_j^2)]$. Summing these two inequalities yields

$$2(x_i - x_j)^2 \le 4[(1 - x_i^2 - y_i^2) + (1 - x_j^2 - y_j^2)] = \mathsf{cost}(i) + \mathsf{cost}(j). \qquad (2)$$ ∎

Now, let $U = \mathrm{supp}(\pi) = \{i \in V : \pi(i) \neq 0\}$, and put $k = |U|$. Finally, let $f : (U, d) \to \mathbb{R}$ be any 1-Lipschitz map, and let $\tilde{f} : V \to \mathbb{R}$ be the 1-Lipschitz extension guaranteed by Lemma 3.4.

Then for any edge $(u, v) \in E$, we have

$$|\tilde{f}(u) - \tilde{f}(v)| \le d(u, v) = (x_u - x_v)^2 \le \frac{\mathsf{cost}(u) + \mathsf{cost}(v)}{2},$$

where the final inequality is from Proposition 3.10. We conclude that $\tilde{f}$ is path-compatible with cost.

Defining a product demand by $\omega(i,j) = \pi(i)\pi(j)$ for every $i, j \in V$ and capacities $c_i = \pi(i)$, we now apply FindCut$(G, \tilde{f})$. If the best separator found has sparsity α_0, then by Lemma 3.7,

$$\begin{aligned}\frac{1}{K}\sum_{i\in V}\pi(i)(1-x_i^2-y_i^2) = \frac{1}{4K}\sum_{i\in V} c_i \cdot \mathsf{cost}(i) &\geq \frac{\alpha_0}{4K}\sum_{i,j\in V}\omega(i,j)\cdot|\tilde{f}(i)-\tilde{f}(j)| \\ &= \frac{\alpha_0}{4K}\sum_{i,j\in U}\omega(i,j)\cdot|f(i)-f(j)| \\ &\geq \frac{\alpha_0}{2}\cdot\frac{\sum_{i,j\in U}\omega(i,j)\cdot|f(i)-f(j)|}{\sum_{i,j\in U}\omega(i,j)\cdot d(i,j)} \\ &= \frac{\alpha_0}{2\cdot avd_\omega(f)}.\end{aligned}$$

It follows that $\tilde{\alpha}_\pi(G) \geq \alpha_0/(2\cdot avd_\omega(f))$. Since the metric (V,d) is of negative type and $\omega(\cdot,\cdot)$ is a product weight, we can achieve $avd_\omega(f) = O(\sqrt{\log k})$ using Theorem 3.3. Using this f, it follows that FindCut$(G,\tilde{f})$ returns a separator (A,B,S) such that $\alpha_\pi(A,B,S) \leq O(\sqrt{\log k})\,\tilde{\alpha}_\pi(G)$, completing the analysis.

Theorem 3.11. *Given a graph $G=(V,E)$ and vertex weights $\pi: V\to\mathbb{R}_+$, there exists a polynomial-time algorithm which computes a vertex separator (A,B,S) for which*

$$\alpha_\pi(A,B,S) \leq O(\sqrt{\log k})\,\alpha_\pi(G),$$

where $k = |\mathrm{supp}(\pi)|$.

In the next section, we extend this theorem to more general weights. This is necessary for some of the applications in section 6.3.

3.6. More general weights. An important generalization of the minimum ratio vertex cut introduced in section 2 is when a pair of weight functions $\pi_1, \pi_2 : V \to \mathbb{R}_+$ is given and one wants to find the vertex separator (A,B,S) which minimizes

$$\alpha_{\pi_1,\pi_2}(A,B,S) = \frac{\pi_1(S)}{\pi_2(A\cup S)\cdot\pi_2(B\cup S)},$$

where, as a convention, $\pi_2(B) \leq \pi_2(A)$. We let $\alpha_{\pi_1,\pi_2}(G)$ denote the minimum value of $\alpha_{\pi_1,\pi_2}(A,B,S)$ in graph G. Under a common interpretation, π_1 denotes vertex capacities, π_2 induces a *demand* (one needs to route $\pi_2(u)\pi_2(v)$ units of flow between vertices u and v), and then the value of $\alpha_{\pi_1,\pi_2}(G)$ serves as an upper bound on the fraction of demand that can be routed subject to the capacity constraints on the vertices.

In analogy to the discussion in section 2, call a separator *trivial* if $\pi_2(B) = 0$ (and, in particular, when B is empty). Unlike the case in section 2, when π_1 differs from π_2 it may happen that $\alpha_{\pi_1,\pi_2}(G)$ is obtained by a trivial separator. Hence in the current section, algorithms that minimize (or approximately minimize) $\alpha_{\pi_1,\pi_2}(A,B,S)$ are allowed to return a trivial separator.

We now explain how our approximation algorithm can be extended to give an $O(\sqrt{\log k})$ approximation for $\alpha_{\pi_1,\pi_2}(G)$, where here $k = |\mathrm{supp}(\pi_2)|$.

Let

$$\tilde{\alpha}_{\pi_1,\pi_2}(A,B,S) = \pi_1(S)/[\pi_2(A)\cdot\pi_2(B\cup S)],$$

where $\pi_2(A) \geq \pi_2(B)$. Also define $\alpha_{\pi_1,\pi_2}(G)$ and $\tilde{\alpha}_{\pi_1,\pi_2}(G)$ as before. By changing the vector program so that K is defined in terms of π_2 and the objective is to minimize $\frac{1}{K}\sum_{i\in V}\pi_1(i)(1-x_i^2-y_i^2)$, it becomes a relaxation for $\tilde{\alpha}_{\pi_1,\pi_2}(G)$. The rounding analysis goes through unchanged to yield a separator (A,B,S) with

$$\alpha_{\pi_1,\pi_2}(A,B,S) \leq O(\sqrt{\log k})\,\tilde{\alpha}_{\pi_1,\pi_2}(G).$$

One difficulty still remains. It may happen that for the optimal separator (A^*,B^*,S^*), $\pi_2(S^*) \geq \pi_2(A^*)$, and then the values $\alpha_{\pi_1,\pi_2}(A^*,B^*,S^*)$ and $\tilde{\alpha}_{\pi_1,\pi_2}(A^*,B^*,S^*)$, are not within a factor of 2 of each other. In this case we show how to output a (possibly trivial) separator that approximates $\alpha_{\pi_1,\pi_2}(G)$ within constant factors. Observe that in this case

$$\frac{\pi_1(S^*)}{\pi_2(S^*)^2} \leq 4\,\alpha_{\pi_1,\pi_2}(G).$$

Hence it suffices to find an approximation for a different problem, that of finding a subset $S \subseteq V$ which minimizes the ratio $\pi_1(S)/\pi_2(S)^2$. This problem can be solved in polynomial time; see section A.3.

THEOREM 3.12. *Given a graph $G=(V,E)$ and vertex weights $\pi_1,\pi_2 : V \to \mathbb{R}_+$, there exists a polynomial-time algorithm which computes a vertex separator (A,B,S) for which*

$$\alpha_{\pi_1,\pi_2}(A,B,S) \leq O(\sqrt{\log k})\,\alpha_{\pi_1,\pi_2}(G),$$

where $k = |\mathrm{supp}(\pi_2)|$.

4. Approximate max-flow/min-vertex-cut theorems. Let $G=(V,E)$ be a graph with capacities $\{c_v\}_{v\in V}$ on vertices and a demand function $\omega : V\times V \to \mathbb{R}_+$. For every pair of distinct vertices $u,v \in V$, let $\mathcal{P}_{uv}$ be the set of all simple u-v paths in G. For $s,t \in V$, an *s-t flow in G* is a mapping $F : \mathcal{P}_{st} \to \mathbb{R}_+$ where for $p \in \mathcal{P}_{st}$, $F(p)$ represents the amount of flow sent from s to t along path p.

For any simple path p in G, let p_0 and p_1 denote the initial and final nodes of p, respectively. By convention, we will assert that for such a flow F and for every $p \in \mathcal{P}_{st}$, the flow path p uses up $\frac{1}{2}F(p)$ of the capacity of p_0 and p_1 and uses up $F(p)$ of the capacity of all other nodes in p. Intuitively, one can think of the loss in capacity for flowing through a vertex to be charged half for entering the vertex and half for exiting; hence the initial and final vertices of a flow path are only charged half. This is made formal in the linear program (LP) that follows. We remark that this choice (as opposed to incurring a full loss of capacity in the initial and final nodes) is only for simplicity in the dual linear program; it is easily seen that all the results in this section hold for the other setting, with a possible loss of a factor of 2. To simplify notation, we also define, for any $p \in \mathcal{P}_{uv}$ and $w \in p$, the number $\kappa_p(w)$ to be 1 if w is an intermediate vertex of p and $\frac{1}{2}$ if w is the initial or final vertex of p.

The *maximum concurrent vertex flow* of the instance $(G,\{c_v\}_{v\in V},\omega)$ is the maximum constant $\epsilon \in [0,1]$ such that one can simultaneously route an ϵ fraction of each u-v demand $\omega(u,v)$ without violating the capacity constraints. For each $p \in \mathcal{P}_{uv}$, let p^{uv} denote the amount of the u-v commodity that is sent from u to v along p. We now write an LP that computes the maximum concurrent vertex flow:

$$\begin{aligned}
&\text{maximize } \epsilon \\
&\text{subject to } \sum_{p\in\mathcal{P}_{uv}} p^{uv} \geq \epsilon\cdot\omega(u,v), && u,v\in V,\\
&\qquad \sum_{u,v\in V}\sum_{p\in\mathcal{P}_{uv}:w\in p} \kappa_p(w)p^{uv} \leq c_w, && w\in V,\\
&\qquad p^{uv}\geq 0, && u,v\in V, p\in\mathcal{P}_{uv}.
\end{aligned}$$

We now write the dual of this LP with variables $\{s_v\}_{v\in V}$ and $\{\ell_{uv}\}_{u,v\in V}$:

$$\begin{aligned}
&\text{minimize} \sum_{v\in V} c_v s_v \\
&\text{subject to} \sum_{w\in p} \kappa_p(w)s_w \geq \ell_{uv}, && p\in\mathcal{P}_{uv}, \text{for all } u,v\in V,\\
&\qquad \sum_{u,v\in V}\omega(u,v)\ell_{uv}\geq 1,\\
&\qquad \ell_{uv}\geq 0, s_v\geq 0, && u,v\in V.
\end{aligned}$$

Finally, define

$$\mathsf{dist}(u,v) = \min_{p\in\mathcal{P}_{uv}} \sum_{w\in p}\kappa_p(w)s_w.$$

By setting $\ell_{uv} = \mathsf{dist}(u,v)$, we see that the above dual LP is equivalent to the following:

$$\begin{aligned}
&\text{minimize} \sum_{v\in V} c_v s_v \\
&\text{subject to} \sum_{u,v}\omega(u,v)\cdot\mathsf{dist}(u,v)\geq 1.
\end{aligned}$$

Remark 4.1. We remark that the distance function $\mathsf{dist}(u,v)$ is a metric which can be alternatively defined as follows: For any $u,v\in V$, $\mathsf{dist}(u,v)$ is precisely the (edge-weighted) shortest-path distance in G between u and v where the weight of the edge $(u,v)\in E$ is $\frac{1}{2}(s_u+s_v)$.

4.1. Rounding to vertex separators. Any vertex separator (A,B,S) yields an upper bound on the maximum concurrent flow in G via the following expression:

$$\frac{\mathrm{cap}(S)}{\sum_{u\in A,v\in B}\omega(u,v)+\sum_{u,v\in S}\omega(u,v)+\frac{1}{2}\sum_{u\in S}\sum_{v\in A\cup B}\omega(u,v)}. \tag{3}$$

The numerator is the capacity of the separator. Every unit of demand served between $u\in A$ and $v\in B$ must consume at least one unit of capacity from S. Likewise, every unit of demand served between $u\in S$ and $v\in S$ must consume at least one unit of capacity from S. Finally, every unit of demand served between $u\in S$ and $v\in A\cup B$ must consume at least half a unit of capacity from S. Hence the denominator is a lower bound on the amount of S's capacity burned by every unit of concurrent flow. We observe that the quantity (3) is bounded between $\alpha^{\mathrm{cap},\omega}(A,B,S)$ and $2\cdot\alpha^{\mathrm{cap},\omega}(A,B,S)$.

We will write $\alpha = \alpha^{\mathrm{cap},\omega}$ if the capacity and demands are clear from context. For a graph G, we will write $\alpha(G)$ for the minimum of $\alpha(A, B, S)$, where this minimum is taken over all vertex separators in G. We wish to study how tight the upper bound of $2 \cdot \alpha(G)$ is. In order to do so, we take the dual of the maximum concurrent-flow LP from the previous section and round it to a vertex separator. The increase in cost incurred by the rounding provides an upper bound on the worst possible ratio between $\alpha(G)$ and the maximum concurrent flow.

We note that the dual LP is a relaxation of the value $2 \cdot \alpha(G)$, since every vertex separator (A, B, S) gives a feasible solution, where $s_v = 1/\lambda$ if $v \in S$ and $s_v = 0$ otherwise. In this case $\mathsf{dist}(u, v) \geq 1/(2\lambda)$ if $u \in A \cup S$ and $v \in B \cup S$ or vice-versa, so that setting $\lambda = \sum_{u \in A \cup S, v \in B \cup S} \omega(u, v)$ yields a feasible solution.

4.2. The rounding. Before presenting our approach for rounding the LP, let us recall a typical rounding approach for the case of *edge-capacitated* flows. In the edge context [38, 8], one observes that the dual LP is essentially integral when $\mathsf{dist}(\cdot, \cdot)$ forms an L_1 metric. To round in the case when $\mathsf{dist}(\cdot, \cdot)$ does not form an L_1 metric, one uses Bourgain's theorem [14] to embed (V, dist) into L_1 (with $O(\log n)$ distortion, which translates to a similar loss in the approximation ratio), and then rounds the resulting L_1 metric (where rounding the L_1 metric does not incur a loss in the approximation ratio). This approach is not as effective in the case of vertex separators, because rounding an L_1 metric does incur a loss in the approximation ratio (as the example below shows), and hence there is not much point in embedding (V, dist) into L_1 and paying the distortion factor.

The discrete cube. Let $G = (V, E)$ be the d-dimensional discrete hypercube $\{0, 1\}^d$. We set $c_v = 1$ for every $v \in V$, and $\omega(u, v) = 1$ for every pair $u, v \in V$. It is well known that $\alpha(G) = \Theta(1/(2^d\sqrt{d}))$ [27]. On the other hand, consider the fractional separator (i.e., dual solution) given by $s_v = 10 \cdot \frac{4^{-d}}{d}$. Note that $\mathsf{dist}(u, v)$ is proportional to the shortest-path metric on the standard cube, and hence $\sum_{u,v} \mathsf{dist}(u, v) \geq 1$, yielding a feasible solution which is a factor $\Theta(\sqrt{d})$ away from $\alpha(G)$. It follows that even when (V, dist) is an L_1 metric, the integrality gap of the dual LP might be as large as $\Omega(\sqrt{\log n})$.

Rounding with line embeddings. The rounding is done as follows. Let $\{s_v\}_{v \in V}$ be an optimal solution to the dual LP, and let $\mathsf{dist}(\cdot, \cdot)$ be the corresponding metric on V. Suppose that the demand function $\omega : V \times V \to \mathbb{R}_+$ is supported on a set S, i.e., $\omega(u, v) > 0$ only if $u, v \in S$, and that $|S| = k$. Let $f : (S, \mathsf{dist}) \to \mathbb{R}$ be the map guaranteed by Theorem 3.1 with $avd_\omega(f) = O(\log k)$, and let $\tilde{f} : (V, \mathsf{dist}) \to \mathbb{R}$ be the 1-Lipschitz extension from Lemma 3.4.

For $v \in V$, define $\mathsf{cost}(v) = s_v$. Then since $\tilde{f}$ is 1-Lipschitz, for any edge $(u, v) \in E$, we have

$$|\tilde{f}(u) - \tilde{f}(v)| \leq \mathsf{dist}(u, v) = \frac{s_u + s_v}{2} = \frac{\mathsf{cost}(u) + \mathsf{cost}(v)}{2};$$

hence $\tilde{f}$ is path-compatible with cost.

We now apply FindCut$(G, \tilde{f})$. If the best separator found has sparsity α_0, then by Lemma 3.7,

$$\begin{aligned}\sum_v c_v s_v = \sum_v c_v \cdot \mathsf{cost}(v) &\geq \alpha_0 \sum_{u,v \in V} \omega(u, v)\, |\tilde{f}(u) - \tilde{f}(v)| \\ &= \alpha_0 \sum_{u,v \in S} \omega(u, v)\, |f(u) - f(v)|\end{aligned}$$

$$\geq \Omega\left(\frac{\alpha_0}{\log k}\right) \sum_{u,v \in V} \omega(u,v)\,\mathsf{dist}(u,v) \geq \Omega\left(\frac{\alpha_0}{\log k}\right).$$

THEOREM 4.1. *For an arbitrary vertex-capacitated flow instance, where the demand is supported on a set of size k, there is an $O(\log k)$-approximate max-flow/min-vertex-cut theorem. In particular, this holds if there are only k commodities.*

4.3. Excluded minor families. Recall that by Remark 4.1, we can view the metric dist arising from the LP dual as an edge-weighted metric on the graph G. A consequence of this is that if the graph G excludes some fixed graph H as a minor, then the metric dist is an H-excluded metric.

It follows that applying Theorem 3.2 yields a better result when G excludes a minor and the demand function $\omega(u,v)$ is uniform on a subset of the vertices. This special case will be needed later when we discuss treewidth and follows from the following theorem (because product demands include as a special case demand functions that are uniform on a subset of the vertices).

THEOREM 4.2. *When G is an H-minor-free graph, there is an $O(|V(H)|^2)$-approximate max-flow/min-vertex-cut theorem with product demands. Additionally, there exists an $O(|V(H)|^2)$ approximation algorithm for finding minimum quotient vertex cuts in G.*

4.4. More integrality gaps for uniform demands.

Expanders. Our analysis for the integrality gap of the dual LP is tight. Just as in the edge case, constant-degree expander graphs provide the bad example. If $G = (V, E)$ is such a graph, with uniform vertex capacities and uniform demands, then $\alpha(G) = 1/\Theta(n)$, while the dual LP has a solution of value $1/\Omega(n \log n)$ (by setting $s_v = 1/\Omega(n^2 \log n)$ for every $v \in V$).

Euclidean metrics. Even if the vertex-weighted distance function returned by the LP is equivalent to a Euclidean metric, up to a universal constant, there may still be an integrality gap of $\Omega(\sqrt{\frac{\log n}{\log\log n}})$. We sketch the argument here. The idea is to take a fine enough "mesh" on a high-dimensional sphere so that the shortest-path distance along the mesh approximates the Euclidean distance. Using standard isoperimetric considerations on high-dimensional spheres, we are able to determine the structure of the near-optimal vertex separators. Here we will only sketch the proof; one may refer to [40] for a more detailed argument along these lines.

Let S^d be the d-dimensional sphere, let $\epsilon = 1/\Theta(d)$, and let V be an ϵ-net on the sphere S^d. (An ϵ-net in a metric space X is a subset $N \subseteq X$ such that $x, y \in N \implies d(x,y) \geq \epsilon$, and $X \subseteq \bigcup_{x \in N} B(x, \epsilon)$.) Standard arguments show that $n = |V| \leq O(d)^d$. Define a graph G with vertex set V and an edge between $u, v \in V$ whenever $\|u - v\|_2 \leq 10\,\epsilon$. We claim the following facts without proof (see [40] for a similar argument).

CLAIM 4.3. *The following three assertions hold true:*

1. $\alpha(G) = 1/\Theta(n\sqrt{d})$.
2. *Setting $s_v = 1/\Theta(n^2 d)$ in the dual LP yields a feasible solution with value $1/\Theta(nd)$.*
3. *The (vertex-weighted) shortest path metric on G with weights given by $\{s_v\}_{v \in V}$ is equivalent (up to a universal constant) to a Euclidean metric (V, d). (Namely, the metric given by $d(u,v) = \|u - v\|_2/n^2$, recalling that $V \subseteq S^d$.)*

It follows that the integrality gap is at least $\Theta(\sqrt{d}) = \Theta(\sqrt{\frac{\log n}{\log\log n}})$.

5. An integrality gap for the vector program. Consider the hypercube graph. Namely, the n vertices of the graph (where n is a power of 2) can be viewed as all vectors in $\{\pm 1\}^{\log n}$, and edges connect two vertices that differ in exactly one coordinate. Every vertex separator (A, B, S) has $\alpha(A, B, S) \geq 1/O(n\sqrt{\log n})$. This follows from standard vertex isoperimetry on the cube [27]. We show a solution to the vector program with value of $O(n/\log n)$, proving an integrality ratio of $\Omega(\sqrt{\log n})$ for the vector program, and implying that our rounding technique achieves the best possible approximation ratio (relative to the vector program), up to constant multiplicative factors.

In the solution to the vector program, we describe for every vertex i the associated vectors x_i and y_i. The vectors s_i will not be described explicitly, but are implicit, using the relation $s_i = v - x_i - y_i$. Note that the exclusion constraints $s_i \cdot x_i = s_i \cdot y_i = 0$ are implied by the exclusion constraints $x_i \cdot y_i = 0$ and the sphere constraints. Each vector will be described as a vector in $1 + n \log n + 2(n-1)$ dimensions (even though n dimensions certainly suffice). Our redundant representation in terms of the number of dimensions helps clarify the structure of the solution.

To describe the vector solution, we introduce two parameters, a and b. Their exact value will be determined later and will turn out to be $a = 1/2 - \Theta(1/\log n)$ and $b = \Theta(1/\sqrt{n \log n})$. We partition the coordinates into three groups of coordinates:

G1. Group 1 contains one coordinate. This coordinate corresponds to the direction of vector v (which has value 1 in this coordinate and 0 elsewhere). All x_i and y_i vectors have value a on this coordinate.

G2. Group 2 contains n identical blocks of $\log n$ coordinates. The coordinates within a block exactly correspond to the structure of the hypercube. Within a block, each x_i is a vector in $\{\pm b\}^{\log n}$ derived by scaling the hypercube label of vertex i (which is a vector in $\{\pm 1\}^{\log n}$) by a factor of b. Vector y_i is the negation of vector x_i on the coordinates of Group 2.

G3. Group 3 contains two identical blocks of $n-1$ coordinates. The coordinates within a block arrange all the x_i vectors as vertices of a simplex. This is done in the following way. Let H_n be the n by n Hadamard matrix with entries ± 1, obtained by taking the $(\log n)$-fold tensor product [16] of the 2 by 2 matrix H_2 that has rows $(1, 1)$ and $(1, -1)$. The inner product of any two rows of H_n is 0, the first column is all 1, and the sum of entries in any other column is 0. Remove the first column to obtain the matrix H'_n. Within a block, let vector x_i be the ith row of H'_n, scaled by a factor of b. Hence within a block, $x_i x_i = b^2(n-1)$, and $x_i x_j = -b^2$ for $i \neq j$. Vector y_i is identical to x_i on the coordinates of Group 3.

We now show that the triangle constraints are satisfied by our vector solution. Recall (see section 2) that there is some flexibility in the choice of which triangle constraints to include in the vector program (and likewise for many other constraints that are valid for 0/1 solutions but are not used in our analysis). We shall address here a subset of the triangle constraints that is larger than that actually used in the analysis of our rounding algorithm.

There are five sets of vectors from which we can take the three vectors that participate in a triangle constraint: X (the x_i vectors), Y (the y_i vectors), S (the s_i vectors), v, and 0. In our analysis we used only triangle constraints over vectors from X. Here we show that all the triangle constraints that involve only vectors from $X \bigcup Y$ are satisfied. All vectors in $X \bigcup Y$ have the identical value a in their first coordinate, and in every other coordinate they take only values from $\pm b$. Hence *every* quadratic constraint that holds for all ± 1 vectors (including, but not limited to, the

triangle constraints) is satisfied on every coordinate separately, which implies that it is satisfied for all x_i and y_i vectors.

We let $K = \sum_{i,j \in V} (x_i - x_j)^2 = \Theta(n^3 b^2 \log n)$. The value of the parameters a and b is governed by the following three constraints:

1. The exclusion constraints imply that
$$a^2 - nb^2 \log n + 2b^2(n-1) = 0.$$
2. The edge constraints (and the fact that edges connect vertices of Hamming distance 1) imply that
$$a^2 - nb^2(\log n - 2) - 2b^2 = 0.$$
3. The sphere constraints imply that
$$a = a^2 + nb^2 \log n + 2b^2(n-1).$$

Hence we have a system of three equalities in two unknowns (a and b). This system is consistent, because the first two equalities are in fact identical (due to our careful choice of number of blocks in each group). They both give

$$a^2 + (-n \log n + 2n - 2)b^2 = 0.$$

By setting $b = a/\sqrt{n \log n - 2n + 2}$ the first two equalities are satisfied. The third equality now reads $a = a^2(2 + \epsilon)$ for some $\epsilon = \Theta(1/\log n)$. This equality is satisfied by taking a roughly equal to $1/2 - \epsilon/4$, which is $1/2 - \Theta(1/\log n)$.

It follows that in the vector solution all $s_i^2 = 1 - x_i^2 - y_i^2$ is $O(1/\log n)$ for every $i \in V$. Hence our vector solution has value

$$\frac{1}{K} \sum_{i \in V} s_i^2 = \frac{1}{\Theta(n \log n)}.$$

Finally, we note that rather than having only one coordinate in Group 1, we can have $(a/b)^2 = n \log n - 2n + 2$ coordinates, and give the x and y vectors values b in these coordinates. Then all x and y vectors become vertices of a $2n \log n$-dimensional hypercube (of side length b). We see that even in this special case, the integrality gap remains $\Omega(\sqrt{\log n})$.

6. Balanced separators and applications.

6.1. Reduction from minimum ratio cuts to balanced separators. In this section, we sketch a pseudoapproximation for finding balanced vertex separators in a graph $G = (V, E)$. Let $W \subseteq V$ be an arbitrary subset of V. For $\delta \in (0, 1)$, we say that a subset $X \subseteq V$ is a *δ-vertex separator (with respect to W)* if every connected component C of $G[V \setminus X]$ has $|C \cap W| \leq \delta |W|$. Our goal in this section is to show that we can find a $\frac{3}{4}$-vertex separator $X \subseteq V$ whose size is within an $O(\beta)$ factor of the optimal $\frac{2}{3}$-vertex separator of G, whenever we can find approximate minimum ratio cuts in G within factor β. This technique is standard (see [36]).

The algorithm. Let $m = |W|$, and for any subset $U \subseteq V$, define $|U|_W = |U \cap W|$. Let $\pi_1(v) = 1$ for every $v \in V$, and $\pi_2(v) = 1$ if $v \in W$ and $\pi_2(v) = 0$ otherwise. These are the weights for the numerator and denominator, respectively; i.e., we assume that we have a β-approximation for $\alpha_{\pi_1, \pi_2}(\cdot)$. We maintain a vertex separator $S \subseteq V$. Initially, $S = \emptyset$. As long as there exists some connected component $U \subseteq V$ in $G[V \setminus S]$

with $|U|_w \geq \frac{3}{4}|W|$, we use our β-approximation to find a minimum ratio vertex cut S' in $G[U]$ which is within β of optimal. We then set $S \leftarrow S \cup S'$ and continue.

The analysis. Let S be the final vertex separator. By construction, it is a $\frac{3}{4}$-vertex separator since every connected component U of $G[V \setminus S]$ has $|U|_w < \frac{3}{4}|W|$. Let $T \subseteq V$ be an optimal $\frac{2}{3}$-vertex separator.

CLAIM 6.1. $|S| \leq O(\beta)|T|$.

Proof. The fact that T is a $\frac{2}{3}$-vertex separator with respect to W implies that the vertices in $V \setminus T$ can be partitioned into two disjoint sets $A_T, B_T \subseteq V$ such that $|A_T \cup T|_w, |B_T \cup T|_w \geq \frac{1}{3}|W|$, with no edges between A_T and B_T. Suppose we are at a step where $|U|_w \geq \frac{3}{4}|W|$. Let (A', B', S') be the vertex separator in $G[U]$ that we find by running our minimum quotient cut algorithm with ratio β, and suppose that $|A'|_w \geq |B'|_w$. We know that

$$\frac{|S'|}{|A' \cup S'|_w \cdot |B' \cup S'|_w} \leq \beta \frac{|T|}{|(A_T \cup T) \cap U|_w \cdot |(B_T \cup T) \cap U|_w} \leq \frac{18\beta|T|}{m^2},$$

where the final inequality follows because $|U|_w \geq \frac{3m}{4}$. It follows that

$$|S'| \leq \frac{18\beta|T|(|B'|_w + |S'|_w)}{m}.$$

To see that $|S| \leq O(\beta)|T|$, it suffices to see that when we sum $|B'|_w + |S'|_w$ over all iterations, the value is at most $O(m)$. But since we throw away the vertices of $B' \cup S'$ in every iteration (and recurse only on A'), the sum is clearly at most m. ∎

6.2. Getting an $O(\sqrt{\log \mathsf{opt}})$ approximation for vertex separators. In this section, we sketch a proof of how one can obtain an $O(\sqrt{\log \mathsf{opt}})$ pseudoapproximation for finding balanced vertex separators. In other words, given a graph G with a $\frac{2}{3}$-vertex separator of size m, we find a $\frac{3}{4}$-vertex separator whose size is at most $(m\sqrt{\log m})$. The method is based on the following enhancement of Theorem 3.3.

THEOREM 6.2. *Let $C > 0$ be a universal constant. Let (X, d) be an n-point metric space of negative type, and let $\omega_0 : X \times X \to \mathbb{R}_+$ be any product weight. If*

$$\frac{\sum_{x,y} \omega_0(x,y)\, d(x,y)}{\sum_{x,y} \omega_0(x,y)} = 1,$$

and there exists an ε-net $N \subseteq X$ with $|N| \leq m$ and $\varepsilon \leq 1/(C\sqrt{\log m})$, then there exists an efficiently computable map $f : X \to \mathbb{R}$ with $avd_{\omega_0}(f) = O(\sqrt{\log m})$.

Proof. Assume that $\omega_0(x,y) = \pi(x)\pi(y)$ for all $x, y \in X$. As in the proof of Theorem 3.3 (see section A.2), if there exists some point $x_0 \in X$ for which $\pi(B(x_0, \frac{1}{4n^2})) \geq \frac{1}{2}\pi(X)$, then we achieve a map $f : X \to \mathbb{R}$ with $avd_{\omega_0}(f) = O(1)$. If no such x_0 exists, then it must be the case (see the proof of [7, Lemma 14]) that there exists a set $S \subseteq X \times X$ of pairs for which $\sum_{(x,y)\in S} \pi(x)\pi(y) \geq \Omega(1) \sum_{x,y} \omega_0(x,y)$, and $d(x,y) \geq \frac{1}{100}$ for $(x,y) \in S$.

We construct a new weight function $\pi^* : N \to \mathbb{R}_+$ on N as follows. Since N is an ε-net, we have $X \subseteq \bigcup_{y\in N} B(y, \varepsilon)$. For every point $x \in X$, put x into a set S_y for some net point $y \in N$ with $d(x,y) \leq \varepsilon$ (so that $\{S_y\}_{y\in N}$ is a partition of X). Define $\pi^*(y) = \sum_{x\in S_y} \pi(x)$ for every $y \in N$.

We now consider the quantity

$$\bar{d}_N = \frac{\sum_{x,y\in N} \pi^*(x)\pi^*(y)\, d(x,y)}{\sum_{x,y\in N} \pi^*(x)\pi^*(y)} = \frac{\sum_{x,y\in N} \sum_{u\in S_x, v\in S_y} \pi(u)\pi(v)\, d(x,y)}{\sum_{x,y} \omega_0(x,y)}.$$

We claim that $\bar{d}_N = \Omega(1)$. But this follows since

$$\begin{aligned}\sum_{x,y\in N}\sum_{u\in S_x, v\in S_y}\pi(u)\pi(v)\,d(x,y) &\geq \sum_{x,y\in N}\sum_{u\in S_x, v\in S_y,(u,v)\in S}\pi(u)\pi(v)\,d(x,y)\\ &\geq \sum_{x,y\in N}\sum_{u\in S_x, v\in S_y,(u,v)\in S}\pi(u)\pi(v)\ (d(u,v)-2\varepsilon)\\ &\geq \frac{1}{2}\sum_{(u,v)\in S}\pi(u)\pi(v)\,d(u,v) = \Omega(1)\sum_{x,y}\omega_0(x,y).\end{aligned}$$

As discussed in section A.2, the techniques of [7] now show that there exist two subsets $L, R \subseteq N$ for which $d(L,R) \geq 1/O(\sqrt{\log m})$ and $\pi^*(L), \pi^*(R) \geq \frac{1}{10}\pi^*(X)$. Construct sets

$$L' = \{x \in X : x \in S_y \text{ for some } y \in L\} \quad \text{and} \quad R' = \{x \in X : x \in S_y \text{ for some } y \in R\}.$$

Note that $\pi(L') = \pi^*(L)$ and $\pi(R') = \pi^*(R)$; hence $\pi(L'), \pi(R') \geq \frac{1}{10}\pi(X)$. Finally, for any points $x_L \in L'$, $x_R \in R'$, let y_L, y_R be such that $x_L \in S_{y_L}$ and $x_R \in S_{y_R}$, and notice that

$$d(x_L, x_R) \geq d(y_L, y_R) - d(x_L, y_L) - d(x_R, y_R) \geq \tfrac{1}{O(\sqrt{\log m})} - 2\varepsilon \geq \tfrac{1}{O(\sqrt{\log m})},$$

where the last inequality holds for $C > 0$ chosen sufficiently large (and hence ε chosen sufficiently small). Now one simply takes the map $f(x) = d(x, L')$, which has $avd_{\omega_0}(f) = O(\sqrt{\log m})$. □

Next, we make an observation about solutions to the SDP of section 2.3.

LEMMA 6.3. *If $\{x_i, y_i\}$ is a solution to the SDP with $W = \sum_{i\in V}(1 - x_i^2 - y_i^2)$, then in the metric space $(\{x_1, \ldots, x_n\}, d)$ where $d(i,j) = (x_i - x_j)^2$, there exists an ε-net $N \subseteq \{x_1, \ldots, x_n\}$ with $|N| \leq O(W/\varepsilon)$.*

Proof. For each $i \in V$, define $w(i) = 1 - x_i^2 - y_i^2$. For a subset $S \subseteq V$, define $w(S) = \sum_{x\in S} w(x)$. Let $G = (V, E)$ be the original graph, and let $d_G(i,j) = \min_{p\in\mathcal{P}_{ij}} w(p)$, where we recall that $\mathcal{P}_{ij}$ is the set of all simple i-j paths. We claim first that $d(i,j) \leq 4\, d_G(i,j)$. Indeed, let $i = i_1, i_2, \ldots, i_k = j$ be a minimum weight path in G; then

$$d(i,j) = (x_i - x_j)^2 \leq \sum_{h=1}^{k-1}(x_{i_h} - x_{i_{h+1}})^2 \tag{4}$$

$$\leq 2\sum_{h=1}^{k-1}\Big((1 - x_{i_h}^2 - y_{i_h}^2) + (1 - x_{i_{h+1}}^2 - y_{i_{h+1}}^2)\Big) \tag{5}$$

$$= 2\sum_{h=1}^{k-1}(w(i_h) + w(i_{h+1}))$$

$$\leq 4\, d_G(i,j),$$

where (4) follows from the squared triangle inequalities, and (5) follows from line (2) in Proposition 3.10.

Thus it will suffice to find an $\varepsilon/4$-net N in the metric d_G, and the rest of the proof refers to this metric on $X = \{x_1, \ldots, x_n\}$. Choose a maximal set $Y \subseteq \{x_1, \ldots, x_n\}$ among all points $x \in X$ for which $w(B_{d_G}(x, \varepsilon/8)) \geq \varepsilon/16$, subject to the constraint that $x, y \in Y \implies d(x,y) > \varepsilon/8$. By construction, the balls $B_{d_G}(x, \varepsilon/8)$ are disjoint for $x \in Y$; hence $|Y| \leq 16W/\varepsilon$, recalling that $W = w(X)$.

So we are done once we prove that Y is an $\varepsilon/4$-net in (X, d_G). For the sake of contradiction, suppose there is a point $x \in X$ with $d_G(x, Y) > \varepsilon/4$. Let $y \in Y$ be such that $d_G(x, y) = d_G(x, Y)$, and consider any shortest-path $x = y_1, \ldots, y_k = y$ in G. Letting $P = \{y_1, \ldots, y_k\}$, we know that $w(P) = d_G(x, y) > \varepsilon/4$. If we set $P' = \{u \in P : d_G(y, u) > \varepsilon/8\}$, then $w(P') > w(P) - \varepsilon/8 \geq \varepsilon/8$, and for every $u \in P'$, we have $d_G(u, Y) > \varepsilon/8$. So if there exists any point $u \in P'$ with $w(u) \geq \varepsilon/16$, then we could add u to Y, contradicting its maximality. Thus we may assume that for every $u \in P'$, we have $w(u) < \varepsilon/16$. But now let $z \in P'$ be the point of P' which is closest to y. Then $d_G(z, x) = w(P') > \varepsilon/8$; hence we know that

$$w(B_{d_G}(z, \varepsilon/8)) \geq w(B_{d_G}(z, \varepsilon/8) \cap P') \geq \varepsilon/16,$$

because the first point along P' not included in $B_{d_G}(z, \varepsilon/8)$ (which must exist) must be further than $\varepsilon/8$ away from z but also have weight at most $\varepsilon/16$. We again conclude that Y is not maximal, completing the proof. □

Combining Theorem 6.2 and Lemma 6.3, along with the analysis of section 3, yields an $O(\sqrt{\log m})$-approximation to vertex sparsest cut where m is the number of vertices in an optimal $\frac{2}{3}$-vertex separator. Now applying the transformation of section 6.1 yields the desired $O(\sqrt{\log \mathsf{opt}})$ pseudoapproximation for finding balanced vertex separators.

6.3. Applications. The notion of treewidth was introduced by Robertson and Seymour [43] and plays an important role in their fundamental work on graph minors. In addition, it has numerous practical applications (see, e.g., [10]). A large amount of effort has been put into determining treewidth, which is NP-complete even when the input graph is severely restricted (see the discussion in [21] for a brief history).

From the approximation viewpoint, Bodlaender et al. [11] gave an $O(\log n)$-approximation algorithm for treewidth on general graphs. Amir [4] improved the approximation factor to $O(\log \mathsf{opt})$, where opt is the actual treewidth of the graph. Constant-factor approximations for treewidth were obtained on asteroidal triple–free (AT-free) graphs [13, 12] and on planar graphs [44]. The approximation for planar graphs is a consequence of the polynomial-time algorithm given by [44] for computing the parameter *branchwidth*, whose value approximates treewidth within a factor of 1.5. Recently, [5] obtained a new approximation algorithm for treewidth in planar graphs with a constant factor slightly worse than 1.5, and the authors of [21] derived a polynomial-time algorithm for approximating treewidth within a factor of 1.5 for single-crossing minor-free graphs and generalizations of planar graphs. A well-known open problem is whether treewidth can be approximated within a constant factor.

Using our new approximation algorithms for vertex separators, we improve the approximation ratio for treewidth, both in general graphs and in some special families of graphs. Our improvements and some of their implications will be presented after we formally define the notion of treewidth.

Treewidth. The notion of *treewidth* involves a representation of a graph as a tree, called a tree decomposition. More precisely, a *tree decomposition* of a graph $G = (V, E)$ is a pair (T, χ) in which $T = (I, F)$ is a tree and $\chi = \{\chi_i \mid i \in I\}$ is a family of subsets of $V(G)$ such that (1) $\bigcup_{i \in I} \chi_i = V$; (2) for each edge $e = \{u, v\} \in E$, there exists an $i \in I$ such that both u and v belong to χ_i; and (3) for all $v \in V$, the set of nodes $\{i \in I \mid v \in \chi_i\}$ forms a connected subtree of T. To distinguish between vertices of the original graph G and vertices of T in the tree decomposition, we call vertices of T *nodes* and their corresponding χ_i's *bags*. The maximum size of a bag in χ minus one is called the *width* of the tree decomposition. The *treewidth* of a graph G,

which we denote by $\mathrm{tw}(G)$, is the minimum width over all possible tree decompositions of G. A tree decomposition is called a *path decomposition* if $T = (I, F)$ is a path. The *pathwidth* of a graph G is the minimum width over all possible path decompositions of G.

Now we are ready to state our approximation result for treewidth.

THEOREM 6.4. *There exist polynomial time algorithms that find a tree decomposition of width at most* $O(\sqrt{\log \mathrm{tw}(G)}\,\mathrm{tw}(G))$ *for a general graph* G *and at most* $O(|V(H)|^2\,\mathrm{tw}(G))$ *for an* H*-minor-free graph* G.

Proof. The proof follows by plugging our improved approximation ratios for balanced vertex separators into the known approximation algorithms for treewidth. Specifically, the algorithm of [11] finds a tree decomposition by recursively using a balanced vertex separator algorithm. The vertex separator algorithm is applied to subgraphs of the original graph, in a product demand setting. It turns out that the approximation ratio obtained for treewidth is at most a constant factor worse than that of the underlying vertex separator algorithm. Using our bounds from section 6.2 one obtains the first part of Theorem 6.4, and using Theorem 4.2 one obtains the second part of Theorem 6.4. ∎

Improving the approximation factor of treewidth improves the approximation factor for several other problems. We refer the reader to [11] for a discussion of these implications and the relevant definitions.

COROLLARY 6.5. *There exist* $O(\sqrt{\log \mathsf{opt}})$ *(resp.,* $O(|V(H)|^2)$*) approximation algorithms for branchwidth, minimum front size, and minimum size of a clique in a chordal supergraph of a general (resp.,* H*-minor-free) graph* G*. Additionally, there are* $O(\sqrt{\log \mathsf{opt}\,\log n})$ *(resp.,* $O(|V(H)|^2 \log n)$*) approximation algorithms for pathwidth, minimum height elimination order tree, and search number in a general (resp.,* H*-minor-free) graph* G.

We also note that Theorem 3.12 with general weights π_1, π_2 is useful for certain hypergraph partitioning problems [36]. Improving the approximation factor for treewidth has a direct improvement on the running time of approximation schemes and subexponential fixed parameter algorithms for several NP-hard problems on graph families which exclude a fixed minor. In such algorithms finding the tree decomposition of almost minimum width, on which we can run dynamic programming, plays a very important role. More precisely, Demaine and Hajiaghayi [20, 19] introduced the concept of (contraction/minor) bidimensional parameters for planar graphs and more generally for excluded-minor families. Examples of bidimensional parameters include number of vertices, diameter, and the size of various structures, e.g., feedback vertex set, vertex cover, minimum maximal matching, face cover, a series of vertex-removal parameters, dominating set, edge dominating set, r-dominating set, connected dominating set, connected edge dominating set, connected r-dominating set, and unweighted Traveling Salesman tour (a walk in the graph visiting all vertices).

They show how one can obtain PTASs for almost all bidimensional parameters on planar graphs, single-crossing minor-free graphs, and bounded genus graphs. In fact, as they mentioned, their approach can be extended to work on apex-minor-free graphs for contraction-bidimensional parameters and on H-minor-free graphs, where H is a fixed graph for minor-bidimensional parameters (see [20, 19] for appropriate definitions). However, currently they obtain quasi-polynomial-time approximation schemes for these general settings. The only barrier to obtaining PTASs for these general settings is obtaining a constant-factor polynomial-time approximation algorithm for treewidth of an H-minor-free graph for a fixed H (this is posed as an open

problem in [20]). Using Theorem 6.4, we overcome this barrier and obtain PTASs for contraction-bidimensional parameters in apex-minor-free graphs and for minor-bidimensional parameters in H-minor-free graphs for a fixed H. As an immediate consequence, we obtain the following theorem (see [20, 19] for the exact definitions of the problems mentioned below).

THEOREM 6.6. *There are PTASs for feedback vertex set, vertex cover, minimum maximal matching, and a series of vertex-removal problems in H-minor-free graphs for a fixed H. Also, there are PTASs for dominating set, edge dominating set, r-dominating set, connected dominating set, connected edge dominating set, connected r-dominating set, and clique-transversal set in apex-minor-free graphs.*

Among the problems mentioned above, PTASs for vertex cover and dominating set (but not its other variants) using a different approach were known before (see, e.g., [26]).

Appendix.

A.1. A note about approximating vertex expansion. In the case of *edge cuts*, the value of the sparsest cut (under uniform weights) corresponds to *edge expansion* of the graph G. Thus it is perhaps more natural to consider finding the vertex separator (A, B, S) which minimizes the ratio $|S|/|B|$, where, by convention, $|B| \leq |A|$.

We now show that having the $|S|$ term in the denominator, i.e., $|S|/(|B| + |S|)$, is crucial to obtaining polylogarithmic approximation ratios. We present here an argument (essentially due to Shimon Kogan) that demonstrates this fact.

Consider the problem of a balanced bipartite independent set (BBIS). The input is a bipartite graph $G(U \bigcup V, E)$ with $|U| = |V| = n$, and the goal is to find the maximum value of t and sets $A \subset U$, $B \subset V$ with $|A| = |B| = t$ with no edges between A and B. It is known that when t is small compared to n, approximating this problem (the value of t) within a ratio of n^δ for some $\delta > 0$ will have some major algorithmic consequences [23, 24], including subexponential algorithms for all NP problems [29]. Now modify G by making U into a clique and V into a clique, obtaining a graph G'. The set S of vertices not in the maximum BBIS provides a vertex separator (A, B, S) for G'. The ratio $|S|/|B|$ for this separator is the minimum possible up to constant factors. (For every separator (A', B', S'), side U cannot contain vertices both from A and from B. Hence $|S'| = \Omega(n)$ unless both A' and B' are of size nearly n. When t is known to be small, this implies that $|S'| = \Theta(n)$ for all separators. Hence the ratio $|S'|/|B'|$ of any separator in G' is governed by $|B'|$ rather than by $|S|$. The value of $|B'|$ is maximized by taking the separator (A, B, S).) This implies that for the minimum balanced vertex separator the quantity $|S|/|B|$ cannot be approximated within a ratio of n^δ (unless NP has subexponential algorithms).

Remark. For a set B of vertices, let $N(B)$ denote the set of vertices not in B that are neighbors of vertices in B. Then the expansion of B is $|N(B)|/|B|$. The expansion of a graph is the minimum over all sets B up to a certain size of the ratio $|N(B)|/|B|$. The restriction on the size of B is necessary so as to avoid B being the whole graph, giving expansion 0. For bounded degree graph, one typically requires $|B| \leq n/2$. For graphs of unbounded degree, such a requirement is insufficient, as it always bounds the expansion by 1 (taking B to be half the graph), whereas one would like to allow for much higher expansions. A possible restriction on B in this case is to require it to be the smaller side of an (A, B, S)-vertex separator. Under this definition of vertex expansion, the above argument shows that vertex expansion cannot be approximated within a factor of n^δ unless NP has subexponential algorithms.

A.2. Line embedding theorems. We now sketch how the following three theorems follow from their respective sources. We begin with Bourgain's theorem.

THEOREM A.1 (Bourgain [14]). *If (X,d) is an n-point metric space, then for every weight function $\omega : X \times X \to \mathbb{R}_+$, there exists an efficiently computable map $f : X \to \mathbb{R}$ with $avd_w(f) = O(\log n)$.*

In [14], it is shown that every n-point metric (X,d) space embeds into a Hilbert space with distortion $O(\log n)$, but Bourgain actually shows something stronger. He proves that there exists a probability space (Ω,μ) on random subsets $A_\tau \subseteq X$, $\tau \in \Omega$, satisfying the following property: For every $x, y \in X$,

$$\mathbb{E}_\Omega\left[|d(x,A_\tau) - d(y,A_\tau)|\right] \geq \frac{d(x,y)}{O(\log n)}.$$

To show how this implies the theorem, note that by linearity of expectation

$$\mathbb{E}_\Omega\left[\sum_{x,y\in X} \omega(x,y)\cdot|d(x,A_\tau) - d(y,A_\tau)|\right] \geq \frac{1}{O(\log n)}\sum_{x,y\in X}\omega(x,y)\cdot d(x,y).$$

Hence there must exist some subset $A_\tau \subseteq X$ for which the map $f : X \to \mathbb{R}$ given by $f(x) = d(x,A_\tau)$ has $avd_\omega(f) = O(\log n)$. An efficient randomized algorithm for sampling A_τ is given in [38].

THEOREM A.2 (Rabinovich [41]). *If (X,d) is any metric space supported on a graph which excludes a K_r-minor, then for every* product weight *$\omega_0 : X \times X \to \mathbb{R}_+$, there exists an efficiently computable map $f : X \to \mathbb{R}$ with $avd_{\omega_0}(f) = O(r^2)$.*

In [41], Rabinovich proves precisely this fact, although only for the uniform weight function $\omega_0(x,y) = 1$ for all $x, y \in X$. It is easy to see that we can assume arbitrary product form for ω_0 without loss of generality. Suppose that we have vertex weights $\pi : V \to \mathbb{R}_+$. We can replace X by the pseudometric where each copy of $x \in X$ occurs $\pi(x)$ times. Then applying the analysis of [41] immediately yields the desired result.

THEOREM A.3 (Arora, Rao, and Vazirani [7]). *If (X,d) is an n-point metric of negative type, then for every* product weight *$\omega_0 : X \times X \to \mathbb{R}_+$, there exists an efficiently computable map $f : X \to \mathbb{R}$ with $avd_{\omega_0}(f) = O(\sqrt{\log n})$.*

Assume that $\omega_0(x,y) = \pi(x)\pi(y)$ for all $x, y \in X$. We will "mentally" replace every copy of x by $\pi(x)$ copies, but we will ensure that this increase in the number of points does not affect the quality of our map f. Also, suppose that (by scaling) $\left(\frac{1}{\sum_{x,y}\omega_0(x,y)}\right)\sum_{x,y\in X}\omega_0(x,y)\cdot d(x,y) = 1$.

Suppose there exists some point $x_0 \in X$ for which $\pi(B(x_0,\frac{1}{4})) \geq \frac{1}{2}\pi(X)$. In this case, the map $f(x) = d\left(x, B(x_0,\frac{1}{4})\right)$ has $avd_{\omega_0}(f) = O(1)$ (see, e.g., [7, Lemma 14]).

Otherwise, the techniques of [7] show that there exist two subsets $L, R \subseteq X$ for which $d(L,R) \geq 1/O(\sqrt{\log n})$ and $\pi(L), \pi(R) \geq \frac{1}{10}\pi(X)$. The fact that the number of copies of a point $x \in X$ does not affect the analysis is somewhat technical and relies on the fact that an "(ϵ,δ)-cover" has size which is lower-bounded by the number of *distinct* points that it contains. In this latter case, one simply takes the map $f(x) = d(x,L)$, which has $avd_{\omega_0}(f) = O(\sqrt{\log n})$. A simpler algorithm for computing the map f (which consists of choosing a few random hyperplanes) is given in [34].

A.3. Approximating the "densest subgraph." To orient the reader arriving at this section from section 3.6, let us remark that π and ω below can correspond to π_1 and a product distribution $\pi_2 \times \pi_2$ in section 3.6.

Given a set $V = \{v_1, \ldots, v_n\}$ with a positive rational weight function π on V and a nonnegative rational weight function ω on $V \times V$, we need to find a set $S \subseteq V$ of maximum density, where the density of a set is defined as

$$\Delta(S) \equiv \frac{\sum_{i,j \in S} \omega(i,j)}{\pi(S)}. \tag{6}$$

This is a weighted version of the *densest subgraph* problem and can be solved in polynomial time (see, for example, Chapter 4 in [33]). For completeness, we sketch the algorithm.

Construct a bipartite graph with sides U and W, where U has n vertices labeled $\{u_1, \ldots u_n\}$, and W has n^2 vertices labeled w_{ij} for $1 \leq i, j \leq n$. For every i, connect vertex u_i to the vertices w_{ij} and w_{ji} (for all j). All these edges have infinite capacity. Add two special vertices, s and t, to the graph. For every i, connect vertex u_i to s by an edge of capacity $k\pi(i)$, where k is a parameter whose value will be optimized later. For every $1 \leq i, j \leq n$, connect vertex $w_{i,j}$ to t by an edge of capacity $\omega(i,j)$. Now compute the minimum capacity (s,t)-cut in the resulting capacitated graph (a problem that can be solved in polynomial time by using flow techniques).

We now analyze the above algorithm. Observe first that the minimum (s,t)-cut contains only edges that are connected to either t or s, as other edges have infinite capacity. Furthermore, observe that if the parameter k is sufficiently large, then the minimum (s,t)-cut contains exactly those edges connected to t. (Here we used our assumption that $\pi(i) > 0$ for all i, but we remark that this assumption can be made without loss of generality, because all v_i with $\pi(i) = 0$ can be placed in S.) How low should k be so that the cut also cuts edges connected to s? This may happen only when $k \leq \Delta$ (and will necessarily happen when $k < \Delta$), where $\Delta = \min_S \Delta(S)$. The reason is the following. Cutting a set $S \subset U$ from s costs $k\pi(S)$. This needs to be offset by a gain on the t side, resulting from the fact that edges between t and vertices of W labeled by $S \times S$ no longer need to be cut. This gives a saving of $\sum_{i,j \in S} \omega(i,j)$. The saving equals the cost precisely when $k = \Delta$.

Using the above analysis, it follows that by performing a search over the parameter k, one can find the value of Δ and the densest set S achieving this value.

Acknowledgments. We would like to thank the anonymous reviewers for their very useful comments on an earlier version of this manuscript. The second author would like to thank Erik D. Demaine and Mohammad Ali Safari for helpful comments and discussions.

TREE-WALKING AUTOMATA DO NOT RECOGNIZE ALL REGULAR LANGUAGES*

MIKOŁAJ BOJAŃCZYK† AND THOMAS COLCOMBET‡

Abstract. Tree-walking automata are a natural sequential model for recognizing tree languages. It is well known that every tree language recognized by a tree-walking automaton is regular. We show that the converse does not hold.

Key words. tree automata, formal languages, tree-walking automata

AMS subject classifications. 68Q45, 03D05

1. Introduction. A tree-walking automaton is a natural type of finite automaton for trees. At every moment in a run, a tree-walking automaton is located in one node of the tree. In one step, the automaton moves to a neighboring node and changes its state according to the transition relation. The step depends on the current state of the automaton and some local information: the label of the current node, whether or not it is the root, a leaf, a left child, or a right child. The tree is accepted if one of the accepting states is reached. For instance, a tree-walking automaton can check whether all nodes of the tree have the same label by doing a depth-first search.

Even though tree-walking automata were introduced in the early 1970s by Aho and Ullman [1], not much is known about this model.

This situation is different from the "usual" tree automata—branching tree automata—which are well-understood objects. In particular, top-down, bottom-up, and two-way nondeterministic branching tree automata recognize the same class of tree languages. The tree languages of this class are called *regular*, the name being so chosen because the class enjoys many nice properties of regular word languages. A comprehensive introduction to the standard theory of tree automata can be found in [4].

As tree-walking automata are a particular case of two-way branching automata, tree-walking automata recognize regular tree languages. Closure under union and intersection is also simple. Until recently, however, other fundamental questions pertaining to tree-walking automata remained unanswered:

1. Is every regular tree language recognized by a tree-walking automaton?
2. Can tree-walking automata be determinized?
3. Are tree-walking automata closed under complementation?

Much research has been dedicated to tree-walking automata. There are nondefinability results for weakened models of tree-walking automata [9, 11, 2], as well as definability results for strengthened models of tree-walking automata [9, 5, 7]. A line of research is dedicated to logical characterizations of tree-walking automata [11]

and their pebble extensions [6]. There has also been some research on tree-walking automata with an output tape—which define tree-to-word transductions [1]—and on expressiveness issues concerning this model [8].

Question 2 has been answered negatively in [3]. Question 3 is still open, the only known result being closure under complementation of deterministic tree-walking automata [10]. The contribution of this paper is to give a negative answer to the first question.

2. Preliminaries and the separating tree language. In this section we define the basic concepts and state our main result.

2.1. Basic definitions. The trees in this paper are finite, binary trees labeled by a given finite alphabet Σ. A Σ-*tree* is a partial mapping $t : \{0,1\}^* \to \Sigma$ of finite, nonempty, and prefix-closed domain $dom(t)$. Elements of this domain are called *nodes* of the tree; the *label* of a node u is the value $t(u)$. Additionally we assume that if $v0$ is a node of the tree, then so is $v1$, and vice versa. Nodes are partially ordered by the prefix relation; when a node x is the prefix of a node y, we say that x is *above* y, or y is *below* x. The least node ε is called the *root*, and maximal nodes are called *leaves*. The nodes are also ordered lexicographically; we say that x is *to the left* (resp., *right*) of y if x and y are incomparable by the prefix relation, and x is lexicographically before y (resp., after y). Given a node u, the *subtree of* t *rooted in* u—we simply say the *subtree of* u when the tree t is clear from the context—is the Σ-tree t' of domain $\{v : uv \in dom(t)\}$ defined for all nodes v of t' by $t'(v) = t(uv)$. The *depth of a node* u is $|u| + 1$, where $|u|$ is the length of u as a word. The *depth of a tree* is the maximal depth of its nodes. A *balanced tree* is one where all leaves are at the same depth.

A set of trees over a given alphabet is called a *tree language*. A *regular* tree language is a tree language recognized by a bottom-up branching tree automaton. We assume the reader to be familiar with branching automata; see [4] for further reading. We denote by REG the class of regular tree languages.

We now define (nondeterministic) tree-walking automata. The *type* of a node says whether the node is a leaf and whether it is the root. There are four possible types; we denote the set of types by Types.

DEFINITION 1. *A* tree-walking automaton *is a tuple* $\mathcal{A} = (Q, \Sigma, I, F, \delta)$*, where* Q *is a finite set of* states*;* $I, F \subseteq Q$ *are, respectively, the sets of* initial *and* accepting *states; and* δ *is the* transition relation *of the form*

$$\delta \subseteq (Q \times \text{Types} \times \Sigma \times \{\varepsilon, 0, 1\})^2.$$

A *configuration* is a pair of a state and a node. The automaton can go in one step from a configuration (q_1, v_1) to a configuration (q_2, v_2) if δ contains a transition

$$(q_1, t_1, a_1, d_1, q_2, t_2, a_2, d_2)$$

such that the type and label of v_i are t_i, a_i and there is a node u such that $v_i = u \cdot d_i$ for $i = 1, 2$. A *run* is a nonempty sequence of configurations $c_1, \ldots, c_n$ in which every two consecutive configurations are consistent with the transition relation. We say that such a run is *from* c_1 *to* c_n; if both configurations c_1 and c_n are located at the same node u, then the run is called a *loop in* u. A run is *accepting* if it starts and ends in the root of the tree, the first state is initial, and the last state is accepting. The automaton *accepts* a Σ-tree if it has an accepting run in that tree. The set of Σ-trees accepted is called the tree language *recognized* by the automaton. We use TWA to denote the class of tree languages recognized by some tree-walking automaton.

The reader may be surprised by our definition of tree-walking automata. In other texts, the transition relation is of the form

$$\delta \subseteq Q \times \{\text{root, left child, right child}\} \times \{\text{leaf, nonleaf}\} \times \Sigma \times Q \times \{\uparrow, 0, 1, \varepsilon\}.$$

In this definition—which can easily be shown to be equivalent to the one we use—the second coordinate extends Types by saying whether a node is a left or right child, while the $\{\uparrow, 0, 1, \varepsilon\}$ causes the automaton to move to the parent, left child, or right child of the current node (or not move at all). The point of using our slightly more verbose definition is that it allows us to easily define "reversed" automata, which visit the tree in a chronologically (or spatially) opposite manner. We will comment on these reversed automata in the next section.

We would like to point out here that testing whether a node is a left or right child is an essential feature of a tree-walking automaton. Indeed, Kamimura and Slutzki show in [9] that tree-walking automata that do not have access to this information cannot even test whether all nodes in a tree have the same label.

Symmetry principles. As pointed out before, our definition of tree-walking automata—in particular in their nondeterministic form—easily adapts itself to symmetry arguments, which are very convenient in the proofs. There are two symmetries: *time symmetry* and *space symmetry*. Their formal definition is in terms of transformations of a tree-walking automaton; namely, each automaton has a time-reversed and a space-reversed variant. The *time-reversed automaton of* $\mathcal{A}$, denoted $\mathcal{A}^{-T}$, is obtained from $\mathcal{A}$ by replacing each transition

$$(q_1, t_1, a_1, d_1, q_2, t_2, a_2, d_2) \in \delta$$

with the transition

$$(q_2, t_2, a_2, d_2, q_1, t_1, a_1, d_1).$$

On the other hand, the *space-reversed automaton of* $\mathcal{A}$, denoted $\mathcal{A}^{-S}$, is obtained by replacing each transition

$$(q_1, t_1, a_1, d_1, q_2, t_2, a_2, d_2) \in \delta$$

with the transition

$$(q_1, t_1, a_1, s(d_1), q_2, t_2, a_2, s(d_2)),$$

where $s(\varepsilon) = \varepsilon$, $s(0) = 1$, and $s(1) = 0$. One can easily see that

$$(\mathcal{A}^{-S})^{-T} = (\mathcal{A}^{-T})^{-S}.$$

We extend the space symmetry $s : \{\varepsilon, 0, 1\} \to \{\varepsilon, 0, 1\}$ mapping to nodes ($s : \{0,1\}^* \to \{0,1\}^*$) and trees in the natural manner. The following obvious fact encapsulates the properties of the reversed automata.

FACT 2.1. *Let* $(q_1, v_1), \ldots, (q_n, v_n)$ *be a run of* $\mathcal{A}$ *in a tree* t.

- $(q_n, v_n), \ldots, (q_1, v_1)$ *is a run of* $\mathcal{A}^{-T}$ *in* t.
- $(q_1, s(v_1)), \ldots, (q_n, s(v_n))$ *is a run of* $\mathcal{A}^{-S}$ *in* $s(t)$.

We say that an automaton is *isomorphic* to another if there exists a one-to-one mapping i from the states of the first onto the states of the second such that there exists a transition

$$(q_1, t_1, a_1, d_1, q_2, t_2, a_2, d_2)$$

in the first automaton if and only if there exists a transition

$$(i(q_1), t_1, a_1, d_1, i(q_2), t_2, a_2, d_2)$$

in the second automaton. In particular, the isomorphism notion does not involve the initial or the accepting states of the automata.

We say an automaton is *self-symmetric* if it is isomorphic to its time-reversed and also to its space-reversed automaton. By adding (unreachable) states to an automaton, any tree-walking automaton can be made self-symmetric. In what follows, self-symmetric automata will be very convenient in reducing the number of cases to be analyzed. Assume, for instance, that we have proved a statement of the form "for every two states p, q, any run from p in the root to q in a leaf can be transformed into one without loops." If the automaton for which we proved this statement was self-symmetric, we would also get the following statement for free: "for every two states p, q, any run from q in a leaf to p in the root can be transformed into one without loops." This is because the time-reversal of a run from the root to a leaf is a run from a leaf to the root, and being loop-free is invariant under time-reversals.

2.2. The separating language. As mentioned in the introduction, it is well known that all tree languages recognized by tree-walking automata are regular:

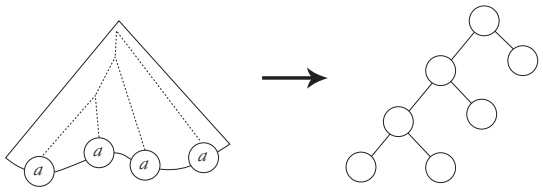
$$\text{TWA} \subseteq \text{REG}. \tag{2.1}$$

Whether this inclusion is strict has long been an open question. Engelfriet, Hoogeboom, and Van Best conjectured that this is indeed the case [7]. The aim of this paper is to establish this conjecture.

In this section we describe a tree language L that is regular, but not accepted by any tree-walking automaton, and therefore witnesses the strictness of the inclusion (2.1).

We consider trees with two possible labels: **a** and **b**. Moreover, **a** is allowed only in the leaves. We sometimes refer to the symbol **b** as the *blank symbol*. Trees containing only the blank symbol are called *blank trees*. In a blank tree, only the set of nodes is important.

Let t be a nonblank tree with **a** occurring only in the leaves. We will now define the *branching structure* $bs(t)$ of t, which is a blank tree (since only the nodes of $bs(t)$, and not their labels, are relevant). We say a node u is a *branching node* of t either if it is an **a**-labeled leaf of t or if both left and right successors of u have **a**-labeled leaves in their subtrees. We define the *branching structure* of t as the (unique) blank tree $bs(t)$ such that there is a bijection between the branching nodes of t and the nodes of $bs(t)$ that preserves the prefix relation and the lexicographic ordering of nodes. The following drawing illustrates this definition with an example:



Let K be the set of blank trees where all leaves are at even depth. The separating tree language L mentioned at the beginning of this section is $bs^{-1}(K)$, i.e., the set

of trees whose branching structures have all leaves at even depth. We now state the main result of this paper as follows.

THEOREM 2. *The tree language L is regular, but is not recognized by any tree-walking automaton.*

Showing that L is regular is not difficult: it is recognized by a bottom-up deterministic automaton with three states recognizing, respectively, the set of blank trees, the set of trees whose branching structure has only branches of even length, and the set of trees whose branching structure has only branches of odd length. For completeness, a fourth "error" state can be added.

Fact 2.2 below shows that a stronger result holds.

FACT 2.2. *The tree language L is definable in first-order logic with the prefix relation and the left and right successor relations.*

Proof. First note that there is a first-order logic formula with one free variable, which is true in exactly the branching nodes of a tree. Therefore, the nodes of the branching structure $bs(t)$ can be interpreted as the branching nodes of t. (Note that for a node interpreted by v, its left successor is interpreted as "first branching node lexicographically after or at the left successor of v," and similarly for the right successor.) It follows that if K is a property of branching structures defined by a first-order formula φ, then $bs^{-1}(K)$ is also defined by a first-order formula. The first-order formula for $bs^{-1}(K)$ is obtained from φ by restricting quantification to branching nodes and replacing the left/right successors by their abovementioned interpretations (the prefix relation is not changed).

Therefore, the statement of the fact will follow if we establish that the language K is definable in first-order logic. This latter result is Lemma 5.1.8 in [12]. For completeness, we provide a proof for it below.

The main idea is that first-order logic can express whether a leaf in $(01)^*(\varepsilon + 0)$ is at even depth or not. We will refer to such a leaf as the *middle leaf* of the tree. A first-order formula can detect the middle leaf by checking that each node above it is either the leaf itself, the father of the leaf, the right child of a left child, the left child of a right child, the left child of the root, or the root itself. The *middle parity* of a tree is defined to be the parity of the depth of the middle leaf; it is definable in first-order logic since the middle leaf is at even depth if and only if it is a left child. The *middle parity* of a node is defined to be the middle parity of the subtree rooted at this node.

Let M be the set of trees whose middle parity is even, and for which all children of any internal node have the same middle parity. We claim that $K = M$. According to the previous remarks, this implies that K is definable in first-order logic.

The inclusion $K \subseteq M$ is obvious. For the other direction, let t be a tree outside K. If all leaves in t have the same depth parity, then the middle parity is odd and $t \notin M$. Otherwise, consider a node in t of maximal depth whose subtree has leaves of both even and odd depth. But then by maximality, the middle parities of this node's children must be different and $t \notin M$. □

The hard part in the proof of Theorem 2 remains: we need to show that the tree language L is not recognized by any tree-walking automaton. The remainder of this paper is devoted to proving this result.

In the next section, we define *patterns*; these are the same as those used in [3]. A pattern is a particular type of tree with distinguished nodes, called ports. As in [3], we consider three particular patterns (the *basic patterns*) that confuse a tree-walking automaton. Then, in section 4, to every blank tree t we associate a tree made out of basic patterns (its *pattern expansion*) whose branching structure—where ports

are considered as **a**-leaves—is t and is confusing for the automaton. We then study throughout sections 5 and 6 the possible runs of the automaton in expansions and their images in the original tree t. This study results in a precise understanding of the behavior of the automaton in expansions: it can perform only a fixed number of simple behaviors—such as left-to-right depth-first search, a move back to the root, or nondeterministic search of a leaf—and can only (nondeterministically) switch between these behaviors a bounded number of times. In section 7, we use this knowledge about the tree-walking automaton for proving that it cannot recognize L. In particular, we show that a simple local transformation, called the *rotation*, applied to a sufficiently big tree cannot be detected by the automaton while it transforms a tree in the language into one which is not in the language.

A more detailed overview of the proof is found in section 4.2, after the concepts of pattern and pattern expansion have been introduced.

We fix for the remainder of the paper a tree-walking automaton

$$\mathcal{A} = (Q, \{\mathbf{a}, \mathbf{b}\}, I, F, \delta).$$

Eventually, we will show that $\mathcal{A}$ cannot recognize the tree language L. As noted in the section on symmetry, we assume without loss of generality that the automaton $\mathcal{A}$ is self-symmetric. We also assume without loss of generality that the automaton has at least two states.

3. Patterns. In this section we define patterns, develop a pumping argument for them, and then study its consequences for the automaton.

Patterns are fragments of trees with holes (called ports) in them. There are two types of ports: leaf ports, which are in the leaves, and the root, which is also called a port. Patterns can be assembled by gluing the root port of one pattern to a leaf port of another pattern. A tree-walking automaton naturally induces an equivalence relation on such patterns: two patterns (with the same number of ports) are equivalent if in any context the automaton cannot detect the difference when one pattern is replaced by another. This equivalence relation (technically, a slightly finer one, which speaks of states of the automaton) is the key notion in the study of patterns.

3.1. Patterns and pattern equivalence. A *pattern* is an $\{\mathbf{a}, \mathbf{b}, *\}$-tree where the labels **a** and $*$ are found only in the leaves. For technical reasons we require that a pattern have at least two nodes and that all $*$-labeled leaves be left children. A *blank pattern* is any pattern with no **a**-labeled leaf. The ith $*$-labeled leaf (numbered from left to right, starting from 0) is called the ith *port*. We number the ports from 0 to be consistent with the usual tree terminology, where a left successor is denoted by 0 and a right successor by 1. *Port* ε stands for the root. The number of leaf ports is called the *arity* of the pattern. In particular, patterns of arity 0 are $\{\mathbf{a}, \mathbf{b}\}$-trees. See Figure 3.1 for an illustration. Given an n-ary pattern Δ and n patterns $\Delta_0, \ldots, \Delta_{n-1}$, the *composition* $\Delta[\Delta_0, \ldots, \Delta_{n-1}]$ is the pattern obtained from Δ by simultaneously substituting each pattern Δ_i for the ith port. We also allow some Δ_i's to be $*$. In this case, nothing is changed for the corresponding ports. We write $\Delta[\Delta_i/i]$ in the particular case where all Δ_j's but Δ_i are $*$; i.e., a single substitution is performed at port i. Given a set P of patterns, we denote by $\mathcal{C}(P)$ the least set of patterns which contains P and is closed under composition.

A run in a pattern is defined just as a run in a tree, except that the ports (both root and leaf) are treated as being nonleaf left children with the blank label. The latter assumption is for technical reasons; it will allow us to compose runs in larger

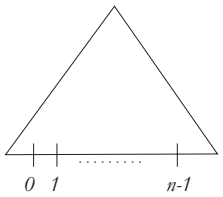


FIG. 3.1. *A pattern of arity n.*

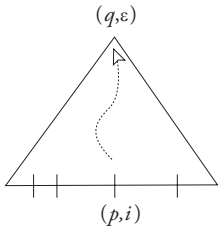

FIG. 3.2. *A pattern* Δ *with* (p, i, q, ε) *in* δ_Δ.

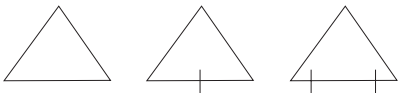

FIG. 3.3. *The patterns* Δ_0, Δ_1, *and* Δ_2.

patterns from runs in smaller ones. Moreover, we require that a run in a pattern visit ports at most twice: a port may occur only in the first and last configurations. In the following definition, illustrated by Figure 3.2, we show how to describe a transition relation corresponding to a pattern for the automaton.

DEFINITION 3. *The* automaton's transition relation over an n-ary pattern Δ,

$$\delta_\Delta \subseteq (Q \times \{\varepsilon, 0, \ldots, n-1\})^2,$$

contains (p, i, q, j) *if in* Δ *there is a run from state* p *in port* i *to state* q *in port* j.

From the point of view of the automaton, the relation δ_Δ sums up all important properties of a pattern, and we consider two patterns *equivalent* if they induce the same δ relation; i.e., patterns Δ and Δ' are equivalent if $\delta_\Delta = \delta_{\Delta'}$. This equivalence relation is a congruence with respect to composition of patterns, thanks to the technical assumptions. The essence of this equivalence is that if one replaces a subpattern by an equivalent one, the automaton is unable to see the difference. Here, we only consider contexts that are consistent with our technical assumptions: the root of the pattern corresponds to a left child, and the nodes plugged into the leaf ports are not leaves and have the blank label.

The following lemma was shown in [3, Lemma 9].

LEMMA 3.1. *There are blank patterns* $\Delta_0, \Delta_1, \Delta_2$*—of respective arities* 0, 1, *and* 2*—such that any pattern in* $\mathcal{C}(\{\Delta_0, \Delta_1, \Delta_2\})$ *of arity* $i = 0, 1, 2$ *is equivalent to* Δ_i.

These patterns will be used a lot in the constructions below. To keep the drawings uncluttered, we omit specifying the names Δ_0, Δ_1, and Δ_2, as this information can be reconstructed from the number of leaves; see Figure 3.3.

Note that the lemma may fail for $i = 3$ when nondeterministic automata are involved; see [3]. The patterns Δ_0, Δ_1, and Δ_2 are the key to our proof. In a sense, their construction encapsulates all of the pumping arguments that we will do with respect to the automaton $\mathcal{A}$. For instance, the pattern Δ_1 is equivalent to a composition of any number of copies of Δ_1 patterns. In particular, if the automaton can go from the leaf port of Δ_1 to the root port, then there must be a state that is used twice along the way. We write $\mathcal{C}_\mathcal{A}$ to denote the set $\mathcal{C}(\{\Delta_0, \Delta_1, \Delta_2\})$; from now on almost all patterns considered will be taken from $\mathcal{C}_\mathcal{A}$.

3.2. Inner loops. Although simply defined, the relation δ_Δ is rather cumbersome to work with. The automaton may do some redundant moves, such as going one step down and then one step up, without any apparent purpose (a phenomenon called oscillation in [3]). It is convenient to eliminate this obfuscating phenomenon. This is the purpose of the inner loop relation introduced in the next definition.

First, however, we state Fact 3.2, which is a consequence of Lemma 3.1. In this statement and elsewhere, by the expression *plugging the Δ_1 pattern into some/any port of a pattern Δ*, we refer to one of the patterns $\Delta_1[\Delta], \Delta[\Delta_1/1], \ldots, \Delta[\Delta_1/n]$, where n is the arity of the pattern Δ. Similarly, the pattern obtained by *plugging Δ_1 into all ports of a pattern Δ* represents the pattern $\Delta_1[\Delta[\Delta_1, \ldots, \Delta_1]]$.

FACT 3.2. *Plugging the Δ_1 pattern into some port of a pattern in $\mathcal{C}_\mathcal{A}$ yields an equivalent pattern.*

Proof. The proof is by induction on the structure of the pattern, using Lemma 3.1 as the basis of the induction. □

Consider now a composition of two patterns $\Delta[\Delta'/i]$ and the junction of these patterns, i.e., the node v that corresponds to port i in Δ. By Fact 3.2, we may well assume that v is on the junction of two Δ_1 patterns: one plugged into the leaf port i of Δ and one plugged into the root port of Δ'. In particular, any loop that can be done on the junction of two Δ_1 patterns can be replicated in $\Delta[\Delta'/i]$. Hence the importance of such loops; we call them "inner loops" in the following definition (see also Figure 3.4 for an illustration).

DEFINITION 4. *The* inner loop relation *over states is the least transitive and reflexive relation $\to_\varepsilon$ over states such that $p \to_\varepsilon q$ holds whenever $(p, \varepsilon, q, \varepsilon)$ or $(p, 0, q, 0)$ belongs to δ_{Δ_1}.*

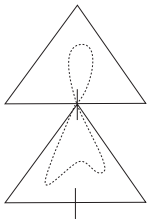

FIG. 3.4. *An inner loop.*

The following lemma formalizes the comments preceding the introduction of the inner loop relation. It shows how $\to_\varepsilon$ describes all possible loops on interfaces between patterns from $\mathcal{C}_\mathcal{A}$.

LEMMA 3.3. *Let $\Delta, \Delta' \in \mathcal{C}_\mathcal{A}$ be patterns of nonzero arity, and let v be the junction node corresponding to the leaf port i of Δ and the root of Δ'. There is an inner loop $p \to_\varepsilon q$ if and only if there is a run from (p, v) to (q, v) in $\Delta[\Delta'/i]$.*

Before proceeding with the proof, we would like to comment on the relevance of this lemma. Recall that by our definition of runs in patterns, the loop from (p, v) to (q, v) is not allowed to visit any of the ports. Therefore, the relation $\to_\varepsilon$ tells us what possible loops can be done on the interface of two patterns without visiting any ports. In particular, the possible types of such loops do not depend on the two patterns Δ and Δ', as long as they are from $\mathcal{C}_\mathcal{A}$.

Another important consequence of this lemma is that it gives us a sort of normal form of runs through patterns in $\mathcal{C}_\mathcal{A}$. Any loop on a junction between patterns can be replaced by the $\to_\varepsilon$ relation; therefore a run through a pattern in $\mathcal{C}_\mathcal{A}$ can be seen as going directly from the source to the target, with all the loops being represented by the $\to_\varepsilon$ relation.

Proof. Assume that $p \to_\varepsilon q$. By definition of $\to_\varepsilon$, there is a run from (p, w) to (q, w) in $\Delta_1[\Delta_1]$, where w is at the junction of the two Δ_1 patterns. But this run can be reused within $\Delta[\Delta'/i]$, since by Fact 3.2 we may assume without loss of generality that both Δ and Δ' have Δ_1 plugged into all their ports.

Reciprocally, assume that there is a run from (p, v) to (q, v) in the pattern $\Delta[\Delta'/i]$. This run can be reused in the same pattern where a Δ_0 has been substituted for all ports except for some leaf port—say port 0—of Δ'. By Lemma 3.1, this new pattern is equivalent to the composition of two Δ_1 patterns. It then follows by definition that $p \to_\varepsilon q$ holds. □

DEFINITION 5. *For a pattern Δ, the relation γ_Δ is the set of tuples (p, i, q, j) such that $p \to_\varepsilon p'$ and $q' \to_\varepsilon q$ for some p', q' satisfying $(p', i, q', j) \in \delta_\Delta$.*

Observe that a consequence of the definition above is that if $p \to_\varepsilon q$, then (p, i, q, i) belongs to γ_Δ for all ports i of Δ.

The γ relation has nicer closure properties than δ; hence from now on we will be using it—and not the δ relation—to describe runs in patterns. For instance, γ satisfies the following "swallowing" property:

$$(p, \varepsilon, q, 0), (q, \varepsilon, r, 0), (r, 0, s, \varepsilon) \in \gamma_{\Delta_1} \qquad \text{implies} \qquad (p, \varepsilon, s, 0) \in \gamma_{\Delta_1}.$$

This is because $(q, \varepsilon, r, 0), (r, 0, s, \varepsilon) \in \gamma_{\Delta_1}$ implies $q \to_\varepsilon s$. Another useful property of the γ relation—resulting from the equivalence of Δ_1 and $\Delta_1[\Delta_1]$—is as follows:

$$(p, \varepsilon, q, 0) \in \gamma_{\Delta_1} \qquad \text{iff} \qquad (p, \varepsilon, r, 0), (r, \varepsilon, q, 0) \in \gamma_{\Delta_1} \text{ for some } r.$$

Note that the left-to-right implication fails for the δ relation, since the state r may require some loops on the junction between the Δ_1 patterns before the run reaches $(q, 0)$.

Obviously, if two patterns are equivalent, then they have the same γ relations. Let us remark also that a form of the converse also holds: if two patterns in $\mathcal{C}_\mathcal{A}$ have the same γ relations, then they are equivalent. However, this fact is of no use in the remainder of the proof, and we need not establish it.

4. Pattern expansions and the proof strategy. In this section we introduce pattern expansions and then give an overview of our proof strategy.

4.1. Pattern expansions. The *pattern pre-expansion* of a blank tree t is the pattern obtained by replacing every inner node of t with the pattern Δ_2 and replacing every leaf with a port $*$. Thus, the pattern pre-expansion has as many leaf ports as t has leaves.

The *pattern expansion* Δ_t of t is the pattern obtained by plugging Δ_1 into all ports of the pattern pre-expansion (see Figure 4.1). Note that the expansion and

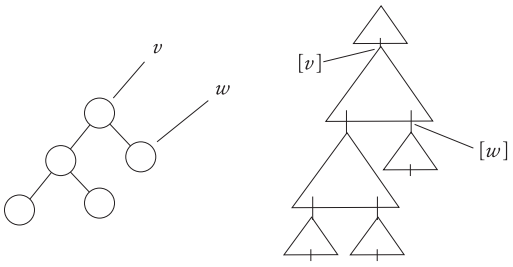

FIG. 4.1. *A blank tree t and its pattern expansion Δ_t.*

the pre-expansion are equivalent as patterns. With every node v of t we associate a node $[v]$ in the pattern Δ_t in the natural way (see Figure 4.1); this node does not depend on t. A *junction node* in a pattern expansion is any node of the form $[v]$; it is called a *junction leaf* when v is a leaf of t. Note that a junction leaf is not a leaf in the pattern Δ_t, since it has Δ_1 as its subtree. The Δ_1 patterns plugged into the pattern expansion are used so that every junction node is on the interface of two patterns of nonzero arity in $\mathcal{C}_{\mathcal{A}}$. In particular, junction nodes are a suitable place for using Lemma 3.3.

We denote by $\Delta_{\mathbf{a}}$ a fixed pattern of arity 0 equal to $\Delta_1[\Delta'_{\mathbf{a}}]$, where $\Delta'_{\mathbf{a}}$ is some zero arity pattern containing exactly one $\mathbf{a}$-labeled leaf. The particular form of $\Delta'_{\mathbf{a}}$ is not important, but we can fix it to be a two-leaf tree with $\mathbf{a}$ in the left leaf and $\mathbf{b}$ in the other nodes. The only two important points concerning $\Delta_{\mathbf{a}}$ are first, that it contains a single leaf labeled by $\mathbf{a}$, and second, that $\Delta_{\mathbf{a}}$ is equivalent to $\Delta_1[\Delta_{\mathbf{a}}]$. This last point is obtained by remarking that $\Delta_{\mathbf{a}}$ equals $\Delta_1[\Delta'_{\mathbf{a}}]$ which is equivalent to $\Delta_1[\Delta_1[\Delta'_{\mathbf{a}}]]$, because $\Delta_1[\Delta_1]$ is equivalent to Δ_1 and equivalence is a congruence with respect to composition.

Given a blank tree t, the tree $\Delta_t^{\mathbf{a}}$ is obtained by plugging $\Delta_{\mathbf{a}}$ into all leaf ports of Δ_t; i.e., $\Delta_t^{\mathbf{a}} = \Delta_t[\Delta_{\mathbf{a}}, \ldots, \Delta_{\mathbf{a}}]$. Clearly the branching structure of $\Delta_t^{\mathbf{a}}$ is t. If the tree-walking automaton were to accept the tree language L, it would have to accept every tree $\Delta_t^{\mathbf{a}}$ for $t \in K$ and reject every tree $\Delta_t^{\mathbf{a}}$ for $t \notin K$. We will eventually show that this is impossible, due to the way tree-walking automata get lost in pattern expansions.

In order to avoid confusion we remark here that $\Delta_t^{\mathbf{a}}$ is treated as a tree and not a pattern of zero arity. Therefore, a run over $\Delta_t^{\mathbf{a}}$ is allowed to visit the root several times, as opposed to runs over patterns of zero arity.

A *junction configuration* is defined to be a configuration of the form $(q, [v])$ for some node $v \in \{0,1\}^*$. We will write such a configuration as $[q, v]$. If v is a node of a blank tree t, then $[q, v]$ can be interpreted as a configuration in either the pattern Δ_t or the tree $\Delta_t^{\mathbf{a}}$. In either case, $[q, v]$ is a configuration whose node is a junction node. Moreover, if v is a leaf of t (i.e., $[v]$ is a junction leaf), the junction configuration is also called a *leaf configuration* (this, of course, is relative to the tree t). We use square brackets for junction configurations; these describe configurations in the branching structure t. On the other hand, normal configurations are written with round brackets; these describe configurations in the pattern expansion Δ_t or in the tree $\Delta_t^{\mathbf{a}}$.

The following two lemmas show that the $\rightarrow_\varepsilon$ relation and the γ_{Δ_2} relation describe the way our fixed tree-walking automaton can move in a pattern expansion, from a junction node to itself or to a neighboring junction node, respectively.

LEMMA 4.1. *Let t be a blank tree and v a node of t. The following statements*

are equivalent for any states p and q:

1. *In the pattern expansion Δ_t there is a run from $[p, v]$ to $[q, v]$.*
2. $p \to_\varepsilon q$.
3. *In the pattern expansion Δ_t there is a run from $[p, v]$ to $[q, v]$ that does not visit any other junction node $[w]$, $w \neq v$.*

Proof. From 1 to 2. By cutting the pattern expansion Δ_t at the junction node $[v]$, we can decompse Δ_t as $\Delta[\Delta'/i]$ for two patterns Δ and Δ' in $\mathcal{C}_\mathcal{A}$ of nonzero arity, and i the number of $[v]$ as a leaf port of Δ. Applying Lemma 3.3 to this decomposition, we get $p \to_\varepsilon q$.

From 2 to 3. Let Δ and Δ' be either Δ_1 or Δ_2, and let i be a leaf port of Δ. Let v' be the port i of Δ. By using $p \to_\varepsilon q$ and applying Lemma 3.3 to $\Delta[\Delta'/i]$, we obtain that there is a run from (v', p) to (v', q) which does not visit the ports of $\Delta[\Delta'/i]$. By definition of the pattern expansion Δ_t, the junction node $[v]$ appears either as port 0 of a Δ_1 pattern or as port 0 or 1 of a Δ_2 pattern. Similarly it is also the root port of a Δ_1 or a Δ_2 pattern. Hence $[v]$ can be identified with node v' in a pattern $\Delta[\Delta'/i]$ above. We can transfer the run we had witnessed on $\Delta[\Delta'/i]$ to Δ_t, obtaining a run from $[p, v]$ to $[q, v]$ that does not visit any other junction node $[w]$, $w \neq v$.

From 3 to 1. The proof is straightforward. □

LEMMA 4.2. *Let t be a blank tree and $v \cdot a, v \cdot b$ nodes of t, with $v \in \{0, 1\}^*$ and $a, b \in \{\varepsilon, 0, 1\}$. The following statements are equivalent for any states p and q:*

1. *In the pattern expansion Δ_t there is a run from $[p, v \cdot a]$ to $[q, v \cdot b]$.*
2. $(p, a, q, b) \in \gamma_{\Delta_2}$.
3. *In the pattern expansion Δ_t there is a run from $[p, v \cdot a]$ to $[q, v \cdot b]$ that does not visit any other junction node $[w]$, $w \notin \{v \cdot a, v \cdot b\}$.*

Proof. From 1 to 2. Assume there is a run in Δ_t from configuration $[p, v \cdot a]$ to configuration $[q, v \cdot b]$. Let us first treat the case $a = b$. In this case $p \to_\varepsilon q$ by Lemma 4.1. Hence $(p, a, q, b) \in \gamma_{\Delta_2}$ (recall the observation following Definition 5). Now let $a \neq b$, and set $c \in \{\varepsilon, 0, 1\}$ to be different from a and b. Let p' be the last state assumed by the run while visiting the junction node $[v \cdot a]$, and let q' be the first state assumed at the junction node $[v \cdot b]$ after crossing $[v \cdot a]$ for the last time. If the corresponding subrun from $[p', v \cdot a]$ to $[q', v \cdot b]$ does not visit $[v \cdot c]$, then (p', a, q', b) belongs to δ_{Δ_2}. Otherwise it visits $[v \cdot c]$, and we let p'' and q'' be the first and last state, respectively, assumed by that subrun at $[v \cdot c]$. Then $p'' \to_\varepsilon q''$, by Lemma 4.1. Also, by construction, (p', a, p'', c) and (q'', c, q', b) are in δ_{Δ_2}. This shows (by plugging Δ_1 into port c of Δ_2) that (p', a, q', b) belongs to δ_{Δ_2}. Moreover, by Lemma 4.1, we have $p \to_\varepsilon p'$ and $q' \to_\varepsilon q$. By definition of γ_{Δ_2}, $(p, a, q, b) \in \gamma_{\Delta_2}$ follows.

From 2 to 3. Since $(p, a, q, b) \in \gamma_{\Delta_2}$, there exist two states p' and q' such that

$$p \to_\varepsilon p', \quad (p', a, q', b) \in \delta_{\Delta_2}, \quad \text{and} \quad q' \to_\varepsilon q.$$

By Lemma 4.1, these three properties provide a run in the pattern expansion Δ_t that successively passes through the configurations

$$[p, v \cdot a],\ [p', v \cdot a],\ [q', v \cdot b],\ [q, v \cdot b]$$

without visiting any junction node other than $[v \cdot a]$ and $[v \cdot b]$.

From 3 to 1. The proof is straightforward. □

The above lemma shows that runs of the automaton between neighboring junction nodes in pattern expansions can be assumed to have a very particular form. Take, for instance, a blank tree t and two nodes v and w, with v above w. If there is a run

in Δ_t that goes from $[v]$ to $[w]$, then, by Lemma 4.2, there is a run that does this by going directly from v to w using the shortest path. This means performing only a series of "steps" of the form $(p, \varepsilon, q, 0), (p, \varepsilon, q, 1) \in \gamma_{\Delta_2}$. A similar characterization holds when v and w are incomparable: the automaton first goes directly from $[v]$ in the up direction, then does one of the steps $(p, 0, q, 1), (p, 1, q, 0) \in \gamma_{\Delta_2}$ (a "go to the sibling" move), and then goes directly downward to $[w]$. This principle is formalized in Lemma 6.1.

4.2. The proof strategy. We are now ready to give an overview of the proof strategy. Recall that our aim is to find trees $s \in L$ and $s' \notin L$ such that any accepting run in s can be transferred to s'. In fact, the trees s, s' will be, respectively, of the form $\Delta_t^{\mathbf{a}}$ and $\Delta_{t'}^{\mathbf{a}}$ for some blank trees $t \in K$ and $t' \notin K$. Therefore, we need to develop a good understanding of runs within trees of the form $\Delta_t^{\mathbf{a}}$.

The remainder of this paper is divided into three sections, which correspond to ever larger parts of a run over a tree of the form $\Delta_t^{\mathbf{a}}$. Such a run can be analyzed on three scales.

The greatest scale is analyzed in section 7. Fix a tree $\Delta_t^{\mathbf{a}}$. In this greatest scale, we will be most interested in runs that connect leaf configurations to one another, without passing through the root of the tree. (This is because, without loss of generality, we may assume the root is visited at most $|Q|$ times.) Consider such a run that goes from one leaf configuration $[p, v]$ to another leaf configuration $[q, w]$. Within such a run, we can isolate all the intermediate leaf configurations:

$$[p, v] = [r_1, u_1], \ldots, [r_n, u_n] = [q, w].$$

Since no leaf configurations are visited in the meantime, a run from $[r_i, u_i]$ to $[r_{i+1}, u_{i+1}]$ corresponds to either (a) a loop in the root of the pattern $\Delta_1[\Delta_{\mathbf{a}}]$, or (b) a run from one junction leaf to another in the pattern Δ_t. Case (a) can be treated as a sort of ε-transition for leaf configurations. The interesting case is (b).

In section 6, we treat the runs of type (b), which correspond to the intermediate scale. These runs are in $\Delta_t^{\mathbf{a}}$, but since no $\mathbf{a}$-labeled leaf is visited during those runs, they are also runs in the pattern expansion Δ_t. We first show that whether or not there is a run of type (b) from $[r_i, u_i]$ to $[r_{i+1}, u_{i+1}]$ does not depend on the tree t but only on the nodes u_i and u_{i+1}. This allows us to consider the notation $[p, v] \to [q, w]$, meaning that there is a run from $[p, v]$ to $[q, w]$ in some (equivalently, every) pattern expansion Δ_t for which v, w are nodes of t. A type of run that realizes $[p, v] \to [q, w]$ is called a *move*; a classification of the possible types of move is the subject of section 6.

As preparation, in section 5, we consider the smallest scale: the pattern Δ_2. By Lemma 4.2, any move within a pattern expansion can be decomposed into a certain number of traversals of the pattern Δ_2. Hence the need for an investigation of the relation γ_{Δ_2}.

Before proceeding, we describe in general terms the results of these investigations in sections 5, 6, and 7.

The main result of section 5 is Proposition 5.10, which gives a characterization of the possible ways the automaton can go from the leaf port to the root port of Δ_1. Generally speaking, this characterization says that the automaton either gets completely lost or must do some sort of depth-first search. Even though stated in terms of the Δ_1 pattern, these results can also be applied to the Δ_2 pattern. Indeed, by Lemma 3.1, any run from a leaf port to the root port in Δ_2 can also be transfered to Δ_1, by simply plugging the unused leaf port with Δ_0.

The main result of section 6 is Proposition 6.10. This proposition roughly says that there are only eleven types of interesting moves between junction leaves in a

pattern expansion. The interesting moves—called elementary moves—are moves such as: "go to the next junction leaf to the left" or "go to any junction leaf to the left." Proposition 6.10 states that if a move is not elementary, then it contains a "shift," a phenomenon of inherent confusion for the automaton.

Finally, in section 7, we show that tree-walking automata cannot detect a properly placed rotation, which concludes the proof. Given a blank tree T and a node x, the *rotation of T with the pivot x* is the tree T' defined as follows: we move the subtrees of $x \cdot 00$, $x \cdot 01$, and $x \cdot 1$ to the new positions $x \cdot 0$, $x \cdot 10$, and $x \cdot 11$ (see Figure 7.1). Clearly doing a rotation in a tree with all leaves at even depth creates a leaf at odd depth. We will show, however, that given a very large balanced blank tree T, one can find a pivot x such that $\Delta^{\mathbf{a}}_{T'}$ cannot be distinguished from $\Delta^{\mathbf{a}}_{T}$ by our fixed tree-walking automaton $\mathcal{A}$.

5. The pattern Δ_2. In this section we investigate the γ relations of the patterns Δ_0, Δ_1, and Δ_2. The main result, Proposition 5.10, uncovers by a case distinction the possible ways the tree-walking automaton can cross the pattern Δ_1. This is important for our analysis of pattern expansions, since by Lemma 4.2 every path through a pattern expansion corresponds to a sequence of traversals of Δ_2 patterns.

FIG. 5.1. *Graphical notation for $\gamma_{\Delta_0}, \gamma_{\Delta_{\mathbf{a}}}, \gamma_{\Delta_1}, \gamma_{\Delta_2}$.*

From now on, instead of the γ_{Δ_0}, $\gamma_{\Delta_{\mathbf{a}}}$, γ_{Δ_1}, and γ_{Δ_2} relations, we will be using the more graphical notation depicted in Figure 5.1. Note that the $p \curvearrowleft q$ notation may be somewhat misleading: we *start* with state p in port 1 and *end* in state q in port 0. The left state is chronologically before the right one, although the movement is in the left direction.

Due to the equivalences in Lemma 3.1, the relations $\gamma_{\Delta_1}, \gamma_{\Delta_2}$ satisfy properties such as the following, which we call swallowing rules:

$$
(p,0,q,1) \in \gamma_{\Delta_2},\ (q,\varepsilon,r,0) \in \gamma_{\Delta_1} \qquad \text{imply} \qquad (p,0,r,1) \in \gamma_{\Delta_2}.
$$

Using our graphical notation, this can be rewritten into the first property among the following ones:

$$
\begin{array}{lll}
p \curvearrowright q \downarrow r & \text{implies} & p \curvearrowright r, \\
p \uparrow q \curvearrowleft r & \text{implies} & p \curvearrowleft r, \\
p \curvearrowleft q \downarrow r & \text{implies} & p \curvearrowleft r, \\
p \uparrow q \curvearrowright r & \text{implies} & p \curvearrowright r.
\end{array} \tag{5.1}
$$

We will now illustrate how time symmetry can be used to show the second implication; the third and fourth are then obtained using space symmetry.

Let then p, q, and r be such that $p \uparrow q \curvearrowleft r$ holds. As the reader may recall, our tree-walking automaton is self-symmetric; i.e., there is an isomorphism $i : Q \to Q$, which maps the automaton onto its time-reversed variant. Let $i(p)$, $i(q)$, and $i(r)$ be the time-reversed counterparts of p, q, and r. By Fact 2.1, every run from p to q can be reversed to obtain a run from $i(q)$ to $i(p)$; likewise for q and r. If we reverse a run witnessing $p \uparrow q$, we obtain a run witnessing $i(q) \downarrow i(p)$. In the same way, there is a run witnessing $i(r) \curvearrowright i(q)$. In particular, we have

$$i(r) \curvearrowright i(q) \downarrow i(p).$$

Now we can apply the already shown first implication in (5.1), to obtain $i(r) \curvearrowright i(p)$. Since the isomorphism i is its own inverse, we obtain the desired $p \curvearrowleft r$.

In a similar way, using space symmetry, we can derive the last two statements of (5.1) from the first two. Later on, we will be using this type of reasoning a lot, omitting the details of the argumentation.

The following lemma shows that the $\circlearrowleft$ and $\circlearrowleft_{\mathbf{a}}$ notation is not misleading in suggesting a loop.

LEMMA 5.1. *The relations $\circlearrowleft$ and $\circlearrowleft_{\mathbf{a}}$ are transitive.*

Proof. We do the proof only for $\circlearrowleft$. We first claim that $p \circlearrowleft q$ holds if and only if either $p \to_\varepsilon q$ holds, or $p \downarrow p' \circlearrowleft^* q' \uparrow q$ holds for some states p', q' (where $\circlearrowleft^*$ is the transitive closure of $\circlearrowleft$).

The left-to-right implication of the claim is shown as follows. If $p \circlearrowleft q$ holds, then there exist p'', q'' such that

$$p \to_\varepsilon p'', \quad (p'', \varepsilon, q'', \varepsilon) \in \delta_{\Delta_0}, \quad \text{and} \quad q'' \to_\varepsilon q.$$

Let us analyze the run corresponding to $(p'', \varepsilon, q'', \varepsilon) \in \delta_{\Delta_0}$ in the pattern $\Delta_1[\Delta_0]$ (which is equivalent to Δ_0), the junction node being v. If this run does not visit v, then we have $p'' \to_\varepsilon q''$, and consequently $p \to_\varepsilon q$. Otherwise, there exist states p' and q' such that $(p'', \varepsilon, p', 0)$ and $(q', 0, q'', \varepsilon)$ belong to δ_{Δ_1}, and there is a path from configuration (p', v) to configuration (q', v) in the pattern $\Delta_1[\Delta_0]$. From this path we deduce $p' \circlearrowleft^* q'$. Hence $p \downarrow p' \circlearrowleft^* q' \uparrow q$.

The right-to-left implication of the claim is shown as follows. If $p \to_\varepsilon q$, we obviously have $p \circlearrowleft q$. Otherwise, assume that there exist states p', q' such that $p \downarrow p' \circlearrowleft^* q' \uparrow q$ holds. Then there are states p'', p''', q''', q'' such that

$$\begin{array}{lll} p \to_\varepsilon p'', & (p'', \varepsilon, p''', 0) \in \delta_{\Delta_1}, & p''' \to_\varepsilon p', \\ q' \to_\varepsilon q''', & (q''', 0, q'', \varepsilon) \in \delta_{\Delta_1}, & \text{and} \quad q'' \to_\varepsilon q. \end{array}$$

From $p''' \to_\varepsilon p' \circlearrowleft^* q' \to_\varepsilon q'''$ we obtain $p''' \circlearrowleft^* q'''$. Together with $(p'', \varepsilon, p''', 0) \in \delta_{\Delta_1}$ and $(q''', 0, q'', \varepsilon) \in \delta_{\Delta_1}$ we obtain a run from state p'' in the root to q'' in the root in $\Delta_1[\Delta_1[\Delta_0]]$ (which is equivalent to Δ_0). Hence $(p'', \varepsilon, q'', \varepsilon)$ belongs to δ_{Δ_0}. Together with $p \to_\varepsilon p''$ and $q'' \to_\varepsilon q$ we obtain $p \circlearrowleft q$. This concludes the proof of the claim.

Let us now show the transitivity of $\circlearrowleft$. Assume $p \circlearrowleft q \circlearrowleft r$. If either $p \to_\varepsilon q$ or $q \to_\varepsilon r$ holds, then we have $p \circlearrowleft r$ by definition of $\circlearrowleft$. Otherwise, according to the claim above, there exist states p', q', q'', r' such that

$$p \downarrow p' \circlearrowleft^* q' \uparrow q \downarrow q'' \circlearrowleft^* r' \uparrow r.$$

Since $q' \uparrow q \downarrow q''$ implies $q' \to_\varepsilon q''$, we obtain $p' \circlearrowleft^* r'$ by transitivity of $\circlearrowleft^*$. Using the other direction of the claim, we get $p \circlearrowleft r$.

For $\circlearrowleft_{\mathbf{a}}$, the proof is identical. The only property required from the pattern $\Delta_{\mathbf{a}}$ is that it is equivalent to $\Delta_1[\Delta_{\mathbf{a}}]$ (and hence to $\Delta_1[\Delta_1[\Delta_{\mathbf{a}}]]$); this fact was observed above while defining the pattern $\Delta_{\mathbf{a}}$. □

5.1. Depth-first search. In this section we define the key concept of depth-first search (DFS). The main result, Lemma 5.5, states that $p \nwarrow p$ can only be realized using a DFS (similarly for $\nearrow$, $\swarrow$, and $\searrow$).

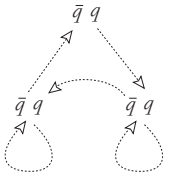

FIG. 5.2. *A right-to-left DFS.*

DEFINITION 6. *A state pair* $(q, \bar{q})$ *is a* right-to-left DFS *(see Figure* 5.2*) if*

$$q \searrow q, \qquad q \circlearrowleft \bar{q}, \qquad \bar{q} \curvearrowleft q, \quad \text{and} \quad \bar{q} \nearrow \bar{q}.$$

The pair is a left-to-right DFS *if*

$$q \swarrow q, \qquad q \circlearrowleft \bar{q}, \qquad \bar{q} \curvearrowright q, \quad \text{and} \quad \bar{q} \nwarrow \bar{q}.$$

Throughout the paper, we will try to keep the convention that if two states $\bar{q}$ and q appear simultaneously, then $\bar{q}$ is a state that is going up in the tree and q is a state that is going down in the tree.

We now illustrate the way a left-to-right DFS allows $\mathcal{A}$ to walk through a pattern expansion. Consider a pattern expansion Δ_t and a left-to-right DFS $(q, \bar{q})$. Using $q \swarrow q$ repeatedly, the automaton can go from q in $[\varepsilon]$ to q in the leftmost junction leaf (all this reasoning is done using Lemma 4.2). If v and w are successive leaves of t, then the automaton can go from $[\bar{q}, v]$ to $[q, w]$. This is done by using a sequence of steps $\bar{q} \nwarrow \bar{q}$, then doing a step of the form $\bar{q} \curvearrowright q$, and then doing a sequence of $q \swarrow q$ steps. Finally, using $\bar{q} \nwarrow \bar{q}$, the automaton can go from $\bar{q}$ in the rightmost junction leaf to $\bar{q}$ in $[\varepsilon]$. Moreover, if we plug Δ_0 into every leaf port of Δ_t, then $q \circlearrowleft \bar{q}$ together with the above observations can be used to obtain a left-to-right DFS of all the junction nodes in the pattern $\Delta_t[\Delta_0, \dots, \Delta_0]$.

In Lemma 5.4, we will also show the converse: without doing a DFS, the automaton cannot systematically visit all junction nodes in a pattern of the form $\Delta_t[\Delta_0, \dots, \Delta_0]$. First, however, we provide some preparatory results. In the following lemma, we say that a run *omits* a node if it never crosses it.

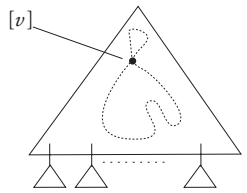
LEMMA 5.2. *Let t be a blank tree, with nodes v, w. Let ρ be a run in $\Delta_t[\Delta_0, \dots, \Delta_0]$ from configuration $[p, v]$ to configuration $[q, w]$ for some states p, q. Then the following hold:*

1. *If $v = w$, then $p \circlearrowleft q$.*
2. *Assume $v = w$, and let u be a node strictly below v. If ρ omits $[u]$, then $p \to_\varepsilon q$.*
3. *Assume v is strictly above w, and let u be a node strictly below w. If ρ omits $[u]$, then $p \downarrow q$.*

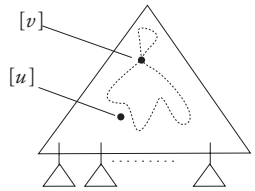
4. *Assume v is strictly above w, let u be a node strictly below w, and let u' be a node to the right of w and strictly below v. If ρ omits $[u]$ and $[u']$, then $p \swarrow q$.*
5. *Assume v is to the left of w, and let u, u' be nodes strictly below v, w, respectively. If ρ omits $[u]$ and $[u']$, then $p \curvearrowright q$.*

Proof. We would like to clarify that $\Delta_t[\Delta_0, \ldots, \Delta_0]$ is treated here as a pattern of arity zero and not a tree. Therefore, by definition of runs in patterns, ρ never visits the root port. Below, we successively treat the five cases. Each explanation is followed by a drawing illustrating the situation.

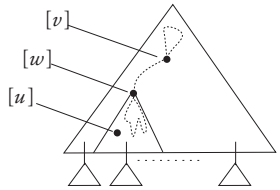
1. By transitivity of $\circlearrowleft$ (Lemma 5.1), it suffices to consider runs ρ where v is visited only in the first and last configurations. If the run never goes below $[v]$, then, by putting a port in the node $[v]$, the run can be replicated in a pattern equivalent to Δ_1, yielding $(p, 0, q, 0) \in \delta_{\Delta_1}$ and hence $p \to_\varepsilon q$. Otherwise, the run visits only nodes below $[v]$ and is therefore a root-to-root run in a pattern equivalent to Δ_0.



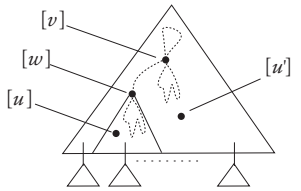
2. Again, by transitivity of the $\to_\varepsilon$ relation, it suffices to consider the case where v is visited only in the first and last configurations. There are two cases. Either the run never goes below $[v]$ and we can reuse the argument of item 1, or the run visits only nodes below $[v]$ but not the node $[u]$. Therefore, if we put a port into node $[u]$, ρ becomes a root-to-root loop in a pattern equivalent to Δ_1, witnessing $(p, \varepsilon, q, \varepsilon) \in \delta_{\Delta_1}$; consequently $p \to_\varepsilon q$.



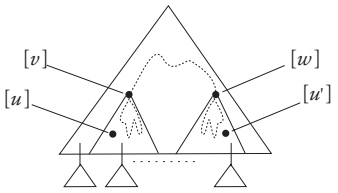
3. First we show that, without loss of generality, we may assume that ρ visits $[v], [w]$ only in the first and last configurations. Indeed, if we take the longest prefix of ρ that is a loop in $[v]$, this prefix satisfies the assumptions of item 2, and can therefore be replaced by an inner loop $\to_\varepsilon$. The same can then be done for the suffix, removing additional visits to $[w]$. Once ρ is assumed to visit $[v]$ and $[w]$ only once, it is easily seen to witness $(p, \varepsilon, q, 0) \in \delta_{\Delta_1}$ and hence $p \downarrow q$: if we put the root port in $[v]$ and a leaf port in $[w]$, we get a pattern equivalent to Δ_1.



4. As in the previous point, we may assume that ρ visits $[v], [w]$ only in the first and last configurations (we use the assumption of the node $[u]$ being omitted and below both $[v]$ and $[w]$). If we put one leaf port (the left port) in $[w]$, one leaf port (the right port) in $[u']$, and the root port in node $[v]$, we get a pattern equivalent to Δ_2. Then the run ρ witnesses $(p, \varepsilon, q, 0) \in \delta_{\Delta_2}$, and hence $p \swarrow q$.



5. Again, we assume that ρ visits $[v], [w]$ only in the first and last configurations (this time, we need to use both $[u]$ and $[u']$). We put the left port in node $[v]$ and the right port in node $[w]$ (the root port stays unchanged).



□

We now need a simple combinatorial result concerning labeling of trees.

LEMMA 5.3. *Let Σ be an alphabet, and consider a balanced Σ-tree t of depth at least $|\Sigma| + 1$. There exist three nodes w, w_0, w_1 with the same label such that w_0 is to the left of w_1 and w is above both w_0 and w_1.*

Proof. Induction on $|\Sigma|$. The base case of $|\Sigma| = 1$ is obvious. Otherwise let a be the root label of t. If both the subtrees of nodes 0 and 1 contain a's, we are done. Otherwise one of these is a $\Sigma \setminus \{a\}$-tree, and the induction hypothesis can be applied to it. □

The following lemma is the first important characterization of runs on patterns. It says that there are only two types of root-to-root runs over the pattern Δ_0: either a run that does not visit anything and only does an inner loop $\rightarrow_\varepsilon$, or a systematic DFS traversal.

LEMMA 5.4. *Let $q, \bar{q}$ be such that $q \circlearrowleft \bar{q}$. Then either $q \rightarrow_\varepsilon \bar{q}$ or there is a (left-to-right or right-to-left) DFS $(r, \bar{r})$ such that $q \downarrow r$ and $\bar{r} \uparrow \bar{q}$.*

Proof. Let t be the blank balanced tree of depth $|Q|^2 + 2$. Let Γ be the pattern obtained from Δ_t by substituting Δ_0 for all leaf ports; i.e., $\Gamma = \Delta_t[\Delta_0, \ldots, \Delta_0]$. By definition of expansions, the pattern Γ can be rewritten as $\Delta_1[\Gamma']$ in which, by Lemma 3.1, the pattern Γ' is equivalent to Δ_0.

By $q \circlearrowleft \bar{q}$, there exists a run in Γ from $[q, \varepsilon]$ to $[\bar{q}, \varepsilon]$. First we show that we can furthermore enforce the following property (*) of ρ: every subrun starting and ending at the same junction node $[v]$ for v a nonleaf node of t visits only junction nodes below $[v]$. This is proved by induction on the number of junction nodes in the run. Indeed, take a minimal loop in some junction node $[v]$ that visits junction nodes not below $[v]$. By minimality, the loop never visits nodes strictly below $[v]$. Hence, by Lemma 5.2 (item 2) and Lemma 4.1, this loop can be replaced by another, with the

same initial and final configurations, which does not visit any junction node other than $[v]$.

Then let ρ be a run from $[q, \varepsilon]$ to $[\bar{q}, \varepsilon]$ that satisfies property (*).

If ρ does not visit some junction node, then by Lemma 5.2, $q \rightarrow_\varepsilon \bar{q}$ holds.

Otherwise, given a node v of t, let $\mathit{first}(v)$ be the state in which the junction node $[v]$ is visited for the first time in the run ρ. Similarly we define $\mathit{last}(v)$. By Lemma 5.3, there are three nonleaf nodes w, w_0, w_1 of t with the same values of *first* and *last*, and such that w is above both w_0 and w_1, and w_0 is to the left of w_1 (see Figure 5.3).

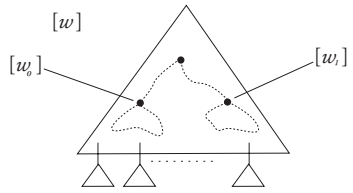


FIG. 5.3. *The nodes* $[w]$, $[w_0]$, *and* $[w_1]$.

First consider the case where $[w_0]$ is visited before $[w_1]$. Let r be $\mathit{first}(w)$ and $\bar{r}$ be $\mathit{last}(w)$. By Lemma 5.2, $r \circlearrowleft \bar{r}$. From property (*) we derive that the run cannot visit $[w_0]$, then $[w_1]$, and then again $[w_0]$. Hence we can apply Lemma 5.2 to configurations $[\bar{r}, w_0]$ and $[r, w_1]$ and obtain $\bar{r} \curvearrowright r$. Also, from the definition of *first* and *last* and Lemma 5.2, we obtain $r \swarrow r$ and $\bar{r} \nwarrow \bar{r}$. Overall $(r, \bar{r})$ is a left-to-right DFS. Furthermore, by Lemma 5.2 (item 2 or 3), either $q \rightarrow_\varepsilon r$ or $q \downarrow r$. In the first case, in combination with $r \downarrow r$, we also obtain $q \downarrow r$. We similarly have $\bar{r} \uparrow \bar{q}$.

If $[w_1]$ is visited before $[w_0]$, a similar argument gives a right-to-left DFS. □

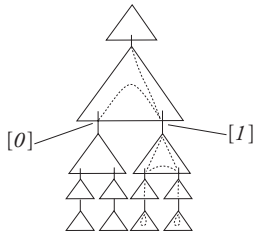
We now proceed to another one of our DFS characterizations: the relation $\leftrightarrows$ can be realized only by doing a DFS.

LEMMA 5.5. *If* $\bar{q} \leftrightarrows \bar{q}$, *then* $(q, \bar{q})$ *is a left-to-right DFS for some state* q.

Proof. Unraveling the definition of $\bar{q} \leftrightarrows \bar{q}$, we have that $\bar{q} \nwarrow \bar{q}$ holds, but $\bar{q} \nearrow \bar{q}$ does not. Let t be the blank balanced binary tree of depth 3 (i.e., with four leaves). Let Γ be the pattern $\Delta_t[\Delta_0, \Delta_0, \Delta_0, \Delta_0]$. Since $\bar{q} \nwarrow \bar{q}$ implies $\bar{q} \uparrow \bar{q}$, and the pattern

$$\Delta_2[*, \Delta_2[\Delta_1[\Delta_0], \Delta_1[\Delta_0]]]$$

is equivalent to Δ_1, there is a run in this pattern from $[\bar{q}, 0]$ to $[\bar{q}, \varepsilon]$:



This run has to visit the junction node [1] since otherwise Lemma 5.2 would give $\bar{q} \nearrow \bar{q}$, a contradiction. Let p be the first state assumed by this run at the junction node [1], and let $\bar{p}$ be the last.

By Lemma 5.2, we have $\bar{q} \curvearrowright p$, $p \circlearrowleft \bar{p}$, and $\bar{p} \nwarrow \bar{q}$. We cannot have $p \rightarrow_\varepsilon \bar{p}$, since we would otherwise get $\bar{q} \nearrow \bar{q}$. By Lemma 5.4, we obtain states $r, \bar{r}$ such that $(r, \bar{r})$

is a DFS and $p \downarrow r$, $\bar{r} \uparrow \bar{p}$. By swallowing, we obtain $\bar{q} \curvearrowright r$, $\bar{r} \nwarrow \bar{q}$ (and we can forget about states p and $\bar{p}$).

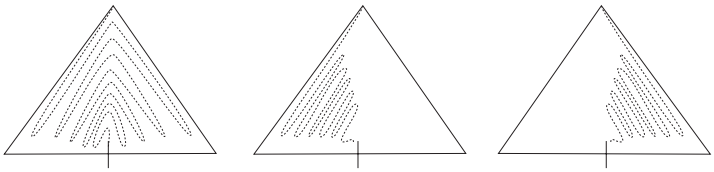
Two cases have to be considered depending on the orientation of the DFS $(r, \bar{r})$.

- Assume first that $(r, \bar{r})$ is a left-to-right DFS. We have $r \downarrow r$ and $\bar{r} \uparrow \bar{q}$. Thus, $r \circlearrowleft \bar{q}$ follows from $r \downarrow r \circlearrowleft \bar{r} \uparrow \bar{q}$. We obtain that $(r, \bar{q})$ is a left-to-right DFS as well.
- Otherwise, $(r, \bar{r})$ is a right-to-left DFS. By $r \searrow r \circlearrowleft \bar{r} \nwarrow \bar{q}$, we get $r \to_\varepsilon \bar{q}$. But then $\bar{q} \curvearrowright r \to_\varepsilon \bar{q} \nwarrow \bar{q}$ gives $\bar{q} \nearrow \bar{q}$, a contradiction. ∎

5.2. Subtree omission. This section is devoted to showing the following proposition.

PROPOSITION 5.6. *For all p and q, $p \uparrow q$ if and only if $p \nwarrow q$ or $p \nearrow q$.*

The right-to-left implication is obvious; the remainder of this section is devoted to showing the left-to-right implication. The intuitive idea is illustrated in the picture below: whenever there is a run as on the left, there is also an equivalent run as in the middle or on the right.



We first show the following intermediate result.

LEMMA 5.7. *If $\bar{q} \uparrow \bar{q}$, then*

- *$\bar{q} \nearrow \bar{q}$ or $\bar{q} \nwarrow \bar{q}$, or*
- *there is a right-to-left DFS $(r, \bar{r})$ such that $\bar{q} \curvearrowright r$ and $\bar{r} \uparrow \bar{q}$.*

Proof. As in the proof of Lemma 5.5, we obtain that $\bar{q} \nearrow \bar{q}$ holds or there are two states $r, \bar{r}$ such that $(r, \bar{r})$ is a DFS and both $\bar{q} \curvearrowright r$ and $\bar{r} \uparrow \bar{q}$ hold. The first case as well as the second when the DFS is right-to-left are conclusions of the lemma.

In the remaining case, $(r, \bar{r})$ is a left-to-right DFS. But then by $\bar{q} \curvearrowright r \circlearrowleft \bar{r} \nwarrow \bar{r}$ we obtain $\bar{q} \uparrow \bar{r}$. Combining this with $\bar{r} \nwarrow \bar{r} \uparrow \bar{q}$, we obtain the desired $\bar{q} \nwarrow \bar{q}$. ∎

A variant symmetric to the one above can be obtained, where $(r, \bar{r})$ is a left-to-right DFS and $\bar{q} \curvearrowleft r$ and $\bar{r} \uparrow \bar{q}$ hold.

LEMMA 5.8. *If $p \uparrow q$, then $p \uparrow r \uparrow r \uparrow q$ for some state r.*

Proof. This results from a pumping argument. Since $\Delta_1[\Delta_1]$ is equivalent to Δ_1, we can expand the Δ_1 pattern into the composition of n times itself for any n. This means that there are states $r_1, \ldots, r_n$ such that $p = r_1 \uparrow \cdots \uparrow r_n = q$.

If n is large enough, some state r is repeated, and the result follows by transitivity of $\uparrow$. ∎

We will now prove Proposition 5.6. Since we have the implication

$$p \uparrow r \nwarrow r \uparrow q \qquad \text{implies} \qquad p \nwarrow q$$

and its symmetric counterpart for $\nearrow$, Lemma 5.8 allows us to restrict our attention to the case where $p = q$. That is, we need to show that $p \uparrow p$ implies $p \nwarrow p$ or $p \nearrow p$.

If in either Lemma 5.7 or its symmetric variant the first case holds, we are done. Otherwise there are states q, $\bar{q}$, r, and $\bar{r}$ such that

$$\begin{array}{llllll} p \curvearrowright q, & q \searrow q, & q \circlearrowleft \bar{q}, & \bar{q} \curvearrowleft q, & \bar{q} \nearrow \bar{q}, & \bar{q} \uparrow p, \\ p \curvearrowleft r, & r \swarrow r, & r \circlearrowleft \bar{r}, & \bar{r} \curvearrowright r, & \bar{r} \nwarrow \bar{r}, & \bar{r} \uparrow p. \end{array}$$

By $p \curvearrowleft r \circlearrowleft \bar{r} \curvearrowright r$ we get $p \to_\varepsilon r$. Together with $\bar{q} \uparrow p$ and $r \downarrow r$, this gives $\bar{q} \to_\varepsilon r$. Together with $q \circlearrowleft \bar{q}$ and $r \circlearrowleft \bar{r}$, this yields $q \circlearrowleft \bar{r}$ by Lemma 5.1. Then $p \curvearrowright q \circlearrowleft \bar{r} \nwarrow \bar{r}$ shows $p \uparrow \bar{r}$. Finally, we combine this with $\bar{r} \nwarrow \bar{r} \uparrow p$ and obtain $p \nwarrow p$.

5.3. A characterization of moves over Δ_1. In this section, we present a classification of the possible ways the automaton can go in Δ_1 from the leaf port to the root port. This is the main result of section 5. Before we proceed with Proposition 5.10, we show a certain "denseness" property of the relations $\upharpoonleft$, $\upharpoonleft$, and $\updownarrow$.

LEMMA 5.9. *For any states p, q and $R = \upharpoonleft, \upharpoonleft, \updownarrow$,*

$$p \; R \; q \qquad \textit{implies} \qquad p \; R \; r \; R \; r \; R \; q \quad \textit{for some state } r.$$

Proof. The case of $\updownarrow$ follows straight from the definition. We do only $\upharpoonleft$; the other case is done symmetrically. If $p \upharpoonleft q$, then $p \nearrow q$, and thus also $p \uparrow q$. By Lemma 5.8, there must be some state r such that $p \uparrow r \uparrow r \uparrow q$. By Proposition 5.6, we must have at least one of $r \nearrow r$, $r \nwarrow r$. But we cannot have $r \nwarrow r$, since this would yield $p \nwarrow q$ and contradict $p \upharpoonleft q$; hence $r \upharpoonleft r$. For similar reasons $p \upharpoonleft r$ and $r \upharpoonleft q$ must also hold. ∎

Note that the converse implication may fail. This is because $p \upharpoonleft q$ requires $p \nwarrow q$ to fail, while there may be some other state s satisfying $p \uparrow s \nwarrow s \uparrow q$.

PROPOSITION 5.10. *If $p \uparrow q$, then*

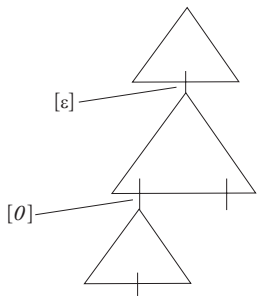
1. *$p \updownarrow q$, or*
2. *$p \upharpoonright q$, or*
3. *$p \upharpoonleft q$, or*
4. *for some states r_1, r_2*
   (a) *$p \uparrow r_1 \upharpoonright r_1 \uparrow q$ and $p \uparrow r_2 \upharpoonleft r_2 \uparrow q$, or*
   (b) *$p \uparrow r_1 \upharpoonright r_1 \nearrow r_2 \upharpoonright r_2 \uparrow q$, or*
   (c) *$p \uparrow r_1 \upharpoonleft r_1 \nwarrow r_2 \upharpoonleft r_2 \uparrow q$.*

Proof. If neither case 2 nor 3 holds, then by Proposition 5.6 we must have both $p \nearrow q$ and $p \nwarrow q$. Let $R^\uparrow(p,q)$ be the set of states r such that $p \uparrow r \uparrow r \uparrow q$ holds; this set is nonempty by Lemma 5.8. Let $R^\nearrow(p,q) \subseteq R^\uparrow(p,q)$ be the set of those states r in $R^\uparrow(p,q)$ such that $r \nearrow r$. Similarly we define $R^\nwarrow(p,q)$. Note that by Proposition 5.6,

$$R^\uparrow(p,q) = R^\nearrow(p,q) \cup R^\nwarrow(p,q).$$

Now a case analysis proves the lemma:

- If $R^\nearrow(p,q) \cap R^\nwarrow(p,q)$ is nonempty, then item 1 holds.
- $R^\nearrow(p,q)$ is empty. By $p \nearrow q$, in the pattern $\Delta_1[\Delta_2[\Delta_1, *]]$, there is a run from state p' in port 0 to state q' in port ε that does not visit port 1, where $p \to_\varepsilon p'$ and $q' \to_\varepsilon q$. This run uses two states q_1, q_2 at the intermediate junction nodes $[\varepsilon]$ and $[0]$. These states satisfy $p \uparrow q_1 \nearrow q_2 \uparrow q$:



The set $R^{\nearrow}(p, q_1)$ is empty, since it is included in $R^{\nearrow}(p, q)$. Furthermore, since $p \uparrow q_1$ holds, the set $R^{\uparrow}(p, q_1)$ must be nonempty, and consequently $R^{\nwarrow}(p, q_1)$ is nonempty by Proposition 5.6. Therefore we can choose r_1 in $R^{\nwarrow}(p, q_1)$ which is not in $R^{\nearrow}(p, q_1)$. This means

$$p \uparrow r_1 \downarrow r_1 \uparrow q_1.$$

Similarly, there is some state r_2 such that

$$q_2 \uparrow r_2 \downarrow r_2 \uparrow q.$$

Since $q_1 \nearrow q_2$, we have $r_1 \nearrow r_2$, and therefore item (b) holds.

- $R^{\nwarrow}(p, q)$ is empty. By reasoning as above, we have item (c).
- Finally, if $R^{\nearrow}(p, q) \cap R^{\nwarrow}(p, q)$ is empty, yet both $R^{\nearrow}(p, q)$ and $R^{\nwarrow}(p, q)$ are nonempty, then clearly item (a) holds. □

The point of characterizing $\uparrow$ and $\downarrow$ is that these are the most basic types of moves the automaton can make in a pattern expansion. Indeed, by Lemma 4.2, in order to move from one junction node to another, the automaton needs to traverse the Δ_2 pattern. Since the pattern Δ_2 can be seen as having Δ_1 plugged into each of its ports, each such traversal must employ one of the moves $\uparrow$ or $\downarrow$. But then we can use Proposition 5.10 in order to uncover other possible moves of the automaton.

When put together, Proposition 5.10 and Lemmas 5.9 and 5.5 give us some idea of how a tree-walking automaton can move upward within a pattern expansion: it may get completely lost (by allowing a move from a node to any node above it, case 1 in Proposition 5.10), allow a DFS in some fixed direction and nothing else (cases 2 and 3), or, finally, do some DFSs coupled with moves in opposing directions (case 4).

6. Moves. In the previous section, we analyzed the way an automaton can move through single instances of the basic patterns Δ_0, Δ_1, and Δ_2. In this section, we consider runs through larger objects built as compositions of Δ_1 and Δ_2 patterns, i.e., pattern expansions. We are especially interested in the way the tree-walking automaton can go from one junction leaf of such an expansion to another. Recall Lemma 4.1, which states that any loop in a junction node can be replaced by the $\rightarrow_\varepsilon$ relation and hence swallowed by the γ relations. This means that any run between two junction nodes in a pattern expansion can be assumed to be a nonlooping sequence of steps consistent with the γ relation. In a tree, a nonlooping path is the shortest possible path.

Note that all patterns considered in this section and the previous ones use only the blank symbol. The **a** label will be introduced only in the final section, section 7. From this perspective, the sections leading up to section 7 can be seen as an analysis of runs that never see the **a** label.

6.1. Pattern paths and moves. Before proceeding with a classification of possible moves, we introduce a more convenient syntax for describing runs between junction nodes within a pattern expansion. Essentially, by Lemma 4.2, such a run can be decomposed as a sequence of moves taken from γ_{Δ_2}. Moreover, by closure properties of γ_{Δ_2}, the runs can be assumed to have a certain normal form.

A *pattern path* (path for short) is a word over the alphabet $\{\varepsilon, 0, 1\} \times \{\varepsilon, 0, 1\}$. A pattern path can be used to go from one junction node to another in a pattern expansion in the following manner. An empty pattern path can stay in the same junction node, while the pattern path $\pi \cdot (a, b)$ can go from $[v]$ to $[u \cdot b]$ if its prefix π can go from $[v]$ to $[u \cdot a]$. We write $v \rightarrow_\pi w$ when π can go from $[v]$ to $[w]$.

The $\to_\pi$ relation can also be annotated with states of the automaton. Given states p, q, and a pattern path $\pi = (a_1, b_1) \cdots (a_n, b_n)$, we write $p \to_\pi q$ if there are states $p = r_1, \ldots, r_{n+1} = q$ such that for all $i = 1, \ldots, n$ the tuple (r_i, a_i, r_{i+1}, b_i) belongs to γ_{Δ_2}. In the special case of $\pi = \varepsilon$, we require $p \to_\varepsilon q$. Given two states p, q and two nodes v, w, we write $[p, v] \to_\pi [q, w]$ if both $p \to_\pi q$ and $v \to_\pi w$ hold.

A pattern path is called *normalized* if it is the shortest path between two junction nodes. For having more understandable normalized paths, we use the following abbreviations: $\swarrow = (\varepsilon, 0)$, $\searrow = (\varepsilon, 1)$, $\nearrow = (0, \varepsilon)$, $\nwarrow = (1, \varepsilon)$, $\curvearrowright = (0, 1)$, and $\curvearrowleft = (1, 0)$. Let us define the following languages:

$$\begin{aligned} \mathrm{Up} &= (\nearrow + \nwarrow)^+, & \mathrm{Down} &= (\swarrow + \searrow)^+, \\ \mathrm{Left} &= (\mathrm{Up} + \varepsilon) \curvearrowleft (\mathrm{Down} + \varepsilon), & \mathrm{Right} &= (\mathrm{Up} + \varepsilon) \curvearrowright (\mathrm{Down} + \varepsilon), \\ \mathrm{Side} &= \varepsilon + \mathrm{Left} + \mathrm{Right}. \end{aligned}$$

The sets Up, Down, Left, Right, Side are called, respectively, the sets of *upward*, *downward*, *left*, *right*, and *sideways* paths. A pattern path is normalized if and only if it belongs to Up + Down + Side. Given nodes of a tree v and w, $\pi(v, w)$ denotes the unique normalized path such that $v \to_{\pi(v,w)} w$. As expected, for nodes v and w, $\pi(v, w) \in \mathrm{Up}$ if and only if w is strictly above v; $\pi(v, w) \in \mathrm{Down}$ if and only if w is strictly below v; $\pi(v, w) \in \mathrm{Left}$ if and only if w is to the left of v; and $\pi(v, w) \in \mathrm{Right}$ if and only if w is to the right of v. A set of normalized pattern paths is called a *move*, and we write vMw if $\pi(v, w) \in M$.

We will now show some results about the possible paths that the automaton can use when going from one node to another; these were mentioned after Lemma 4.2. We begin with the following lemma, which shows how paths correspond to runs of the automaton, at least as far as junction nodes are concerned.

LEMMA 6.1. *The following are equivalent for nodes v, w in a blank tree t.*

1. *There is a run in Δ_t from $[p, v]$ to $[q, w]$.*
2. *$[p, v] \to_{\pi(v,w)} [q, w]$ holds.*
3. *There is a run in Δ_t from $[p, v]$ to $[q, w]$ which visits only junction nodes $[u]$ such that $v \to_\pi u$ for some prefix π of $\pi(v, w)$.*

Proof. This is a generalization of Lemma 4.2, and the same proof works: any loop appearing in a run can be contracted using the $\to_\varepsilon$ relation. □

Since the normalized path connecting v and w does not depend on the tree t but only on the nodes v, w, we obtain the following corollary.

COROLLARY 6.2. *Let v, w be nodes of a blank tree t. Whether or not there is a run from $[p, v]$ to $[q, w]$ in Δ_t depends only on $\pi(v, w)$ and not on t.*

The above corollary justifies the notation $[p, v] \to [q, w]$, where no particular path or tree is mentioned; it is equivalent to $p \to_{\pi(v,w)} q$. We will use this notation often in what follows.

DEFINITION 7. *For states p and q, we define $U(p, q)$ to be the set of upward paths π such that $p \to_\pi q$. Similarly, we define $D(p, q)$, $L(p, q)$, $R(p, q)$, and $S(p, q)$ for downward, left, right, and sideways paths, respectively.*

In particular, a direct consequence of this definition is that for two distinct nodes v and w and states p and q, $[p, v] \to [q, w]$ if and only if

$$\pi(v, w) \in U(p, q) \cup D(p, q) \cup S(p, q).$$

The following lemma will be used several times; it transfers some properties of γ_{Δ_2} to equalities on the sets U, D, L, R. Its meaning is natural, but the statement as well as the proof are slightly clouded by the case of the normalized path ε.

LEMMA 6.3. *The move $R(p,q)$ is the union of $(U(p,p')+\varepsilon) \curvearrowright (D(q',q)+\varepsilon)$ for states p',q' satisfying $p \uparrow p' \curvearrowright q' \downarrow q$. A similar statement holds for L.*

Proof. We do only the case of R. We begin with the right-to-left inclusion. Let p',q' be states such that $p \uparrow p' \curvearrowright q' \downarrow q$, and let

$$\pi \in (U(p,p')+\varepsilon) \curvearrowright (D(q',q)+\varepsilon).$$

We can write π as $\pi_1 \curvearrowright \pi_2$ with $\pi_1 \in U(p,p')+\varepsilon$ and $\pi_2 \in D(q',q)+\varepsilon$.

The first case is when both π_1, π_2 are empty and therefore π is $\curvearrowright$. By assumption, we have $p \uparrow p' \curvearrowright q' \downarrow q$ and hence $p \curvearrowright q$, by swallowing. Consequently $p \to_\pi q$ and $\pi \in R(p,q)$. If neither of π_1, π_2 is empty, then $\pi_1 \in U(p,p')$ and $\pi_2 \in D(q',q)$, which gives the desired result. The remaining cases where only one of π_1 or π_2 is empty are treated by combining the two first cases.

We now treat the left-to-right inclusion. Let π be in $R(p,q)$. By definition of Right, π can be written as $\pi_1 \curvearrowright \pi_2$ with $\pi_1 \in \mathrm{Up}+\varepsilon$ and $\pi_2 \in \mathrm{Down}+\varepsilon$. As above, we first consider the case when π_1, π_2 are both empty. In this case, we have $p \curvearrowright q$. But then, by looking at the path from port 0 to port 1 in the pattern $\Delta_2[\Delta_1, \Delta_1]$ which is equivalent to Δ_2, we can find states p',q' such that $p \uparrow p' \curvearrowright q' \downarrow q$, which completes the proof.

Assume now that both π_1, π_2 are nonempty. Let p',q' be the states such that $p \to_{\pi_1} p' \curvearrowright q' \to_{\pi_2} q$. We need to show that $p \uparrow p'$ and $q' \downarrow q$. But this follows from transitivity of $\downarrow, \uparrow$ and the inclusions $\swarrow, \searrow \subseteq \downarrow$ and $\nwarrow, \nearrow \subseteq \uparrow$. The remaining cases where only one of π_1 or π_2 is empty are treated by combining the two first cases. ∎

Furthermore, there exists a strong link between the set of upward moves (and by time symmetry, downward moves) and the behaviors of the automaton exhibited in the previous section; this is the subject of the next lemma.

LEMMA 6.4. *If $p \updownarrow q$, then $U(p,q) = \mathrm{Up}$. The analogous results hold for $\downdownarrows$, $\uparrow\!\!\!\!\nearrow$, $\uparrow\!\!\!\!\swarrow$, $\downarrow\!\!\!\!\searrow$, and $\downdownarrows$, the corresponding moves being, respectively,* Down, $\nwarrow^+$, $\nearrow^+$, $\swarrow^+$, *and* $\searrow^+$.

Proof. We treat the case $\uparrow\!\!\!\!\nearrow$. If $p \uparrow\!\!\!\!\nearrow q$, then by Lemma 5.9, there is a state r such that $p \uparrow\!\!\!\!\nearrow r \uparrow\!\!\!\!\nearrow r \uparrow\!\!\!\!\nearrow q$. This shows $\nwarrow^+ \subseteq U(p,q)$. The opposite inclusion must also hold, since otherwise we would get $p \nearrow q$. ∎

The next lemma gives other required facts about $U(p,q)$ and $S(p,q)$.

LEMMA 6.5. *If $p \uparrow q$, then $\nwarrow^+ \subseteq U(p,q)$ or $\nearrow^+ \subseteq U(p,q)$. If $p \nearrow q$, then $\nwarrow^* \nearrow \subseteq U(p,q)$ or $\nearrow^+ \subseteq U(p,q)$. If $p \uparrow\!\!\!\!\swarrow p' \curvearrowright q$, then $\varepsilon \in S(p,q)$.*

Proof. First statement: for some r, $p \uparrow r \nwarrow r \uparrow q$ or $p \uparrow r \nearrow r \uparrow q$ by Lemma 5.8 and Proposition 5.6. Second statement: for some p', $p \uparrow p' \nearrow q$ must hold; then use the first statement. Third statement: by Lemmas 5.9 and 5.5, there exist $r, \bar{r}$ such that $p \uparrow \bar{r} \curvearrowleft r \downarrow r \circlearrowleft \bar{r} \uparrow p'$. Hence (by swallowing) $p \curvearrowleft r \downarrow r \circlearrowleft \bar{r} \uparrow p' \curvearrowright q$, and so $p \to_\varepsilon q$, i.e., $\varepsilon \in S(p,q)$. ∎

As hinted by Proposition 5.10 and Lemmas 6.3, 6.4, and 6.5, there are not so many ways that a sideways move can be done. The following eleven moves will play a special role below.

DEFINITION 8. *An* elementary move *is any one of the eleven moves in Figure* 6.1.

6.2. Move offsets. This section is devoted to moves that depend only on the number of junction leaves between the source and destination, i.e., moves that do not really depend on the structure of the tree.

We number the leaves of a tree t from left to right, starting from 0. Formally, given a blank tree t and a leaf v of t, we denote by $\#_t(v)$ the number of leaves in the tree t that are lexicographically before v. For v and w leaves of t, we denote

$$
\begin{array}{ll}
\mathit{Stay} = \varepsilon & \\

\end{array}
$$

FIG. 6.1. *Elementary moves.*

by $\#_t(v, w)$ the offset from v to w within t, i.e., the difference $\#_t(w) - \#_t(v)$. This number is positive when v is to the left of w. If v or w is not a leaf of t, then $\#_t(v, w)$ is not defined.

DEFINITION 9. *A* move offset *of two states p, q is an integer i such that for every tree t and leaves v and w of t, $\#_t(v, w) = i$ implies $[p, v] \to [q, w]$. We write* $\mathrm{moff}(p, q)$ *for the set of move offsets of p, q. We say that p, q admit a* shift *if* $\mathrm{moff}(p, q)$ *contains two successive integers from $\{-2, -1, 0, 1, 2\}$.*

The next lemma shows how move offsets can be described in terms of paths.

LEMMA 6.6. *For every pair of states p, q,*

$$
\begin{array}{rll}
0 \in \mathrm{moff}(p, q) & \textit{iff} & \varepsilon \in S(p, q), \\
1 \in \mathrm{moff}(p, q) & \textit{iff} & \nwarrow^* \curvearrowright \swarrow^* \subseteq S(p, q), \\
2 \in \mathrm{moff}(p, q) & \textit{iff} & \nwarrow^* \nearrow \nwarrow^* \curvearrowright \swarrow^* + \nwarrow^* \curvearrowright \swarrow^* \searrow \swarrow^* \subseteq S(p, q), \\
-1 \in \mathrm{moff}(p, q) & \textit{iff} & \nearrow^* \curvearrowleft \searrow^* \subseteq S(p, q), \\
-2 \in \mathrm{moff}(p, q) & \textit{iff} & \nearrow^* \nwarrow \nearrow^* \curvearrowleft \searrow^* + \nearrow^* \curvearrowleft \searrow^* \swarrow \searrow^* \subseteq S(p, q).
\end{array}
$$

Proof. The case of 0 follows straight from the definition: if $\#_t(v, w) = 0$, then $v = w$ and therefore $\pi(v, w) = \varepsilon$ (and vice versa). The remaining cases follow by listing the paths that can connect nodes separated by $1, 2, -1, -2$ leaves, respectively. ∎

In particular, directly from the definition of elementary moves, we deduce the following corollary.

COROLLARY 6.7. *Every elementary move has an offset among $-1, 0, 1$.*

A typical example of a move offset of 1 is the DFS.

LEMMA 6.8. *If $(p, \bar{p})$ is a left-to-right DFS, then 1 is a move offset of $\bar{p}, p$. If $(p, \bar{p})$ is a right-to-left DFS, then -1 is a move offset of $\bar{p}, p$.*

Proof. If $(p, \bar{p})$ is a left-to-right DFS, then $\bar{p} \nwarrow \bar{p} \curvearrowright p \swarrow p$ holds. Thus the move $S(\bar{p}, p)$ contains $\nwarrow^* \curvearrowright \swarrow^*$, and the move offset 1 follows by Lemma 6.6. The right-to-left case is the same. ∎

The following lemma gathers a number of sufficient conditions for move offsets.

LEMMA 6.9. *For all states $\bar{p}$, $\bar{r}$, and q the following hold:*

1. *If $\bar{p} \leftarrow\!\!\!\!\!\!\leftarrow \bar{p} \curvearrowright q$, then 0 is a move offset of $\bar{p}, q$.*
2. *If $\bar{p} \rightleftarrows \bar{p} \curvearrowright q$, then 1 is a move offset of $\bar{p}, q$.*
3. *If $\bar{p} \rightleftarrows \bar{p} \nearrow \bar{r} \rightleftarrows \bar{r} \curvearrowright q$, then both 1 and 2 are move offsets of $\bar{p}, q$.*
4. *If $\bar{p} \leftarrow\!\!\!\!\!\!\leftarrow \bar{p} \nwarrow \bar{r} \leftarrow\!\!\!\!\!\!\leftarrow \bar{r} \curvearrowright q$, then both -1 and 0 are move offsets of $\bar{p}, q$.*
5. *If $\bar{p} \leftarrow\!\!\!\!\!\!\leftarrow \bar{p} \curvearrowright q \leftrightarrows q$, then both -1 and 0 are move offsets of $\bar{p}, q$.*

Proof.

1. The proof is immediate by Lemmas 6.5 and 6.6.

2. By Lemma 5.5, there is a state p such that $(p, \bar{p})$ is a left-to-right DFS. By Lemma 6.8, $\bar{p}, p$ has offset 1. From $p \swarrow p \circlearrowleft \bar{p} \curvearrowright q$, we have $p \downarrow q$. Using Lemma 6.6, it follows by swallowing that $\bar{p}, q$ also has offset 1.
3. The move offset 1 follows from the previous case, since $\bar{p} \nwarrow\!\!\!\uparrow \bar{p} \curvearrowright q$. By Lemma 6.6, the move offset 2 will follow once we show that $S(\bar{p}, q)$ contains both

$$\nwarrow^* \nearrow \nwarrow^* \curvearrowright \swarrow^* \quad \text{and} \quad \nwarrow^* \curvearrowright \swarrow^* \searrow \swarrow^*.$$

By Lemma 5.5, there are states p, r such that $(p, \bar{p})$ and $(r, \bar{r})$ are left-to-right DFSs. By $r \swarrow r \circlearrowleft \bar{r} \curvearrowright q$, we obtain $r \downarrow q$. Then by

$$\bar{p} \nwarrow \bar{p} \nearrow \bar{r} \nwarrow \bar{r} \curvearrowright r \swarrow r \downarrow q$$

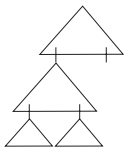
we obtain that $S(\bar{p}, q)$ contains $\nwarrow^* \nearrow \nwarrow^* \curvearrowright \swarrow^*$.
It remains to show that $S(\bar{p}, q)$ contains $\nwarrow^* \curvearrowright \swarrow^* \searrow \swarrow^*$. This will follow once we prove $p \searrow r$, by

$$\bar{p} \nwarrow \bar{p} \curvearrowright p \swarrow p \searrow r \swarrow r \downarrow q.$$

It thus remains to show $p \searrow r$. By $p \swarrow p \circlearrowleft \bar{p} \nearrow \bar{r}$, we get $p \to_\varepsilon \bar{r}$. Finally, if we consider the path in $\Delta_2[\Delta_1, *]$ witnessed by $p \swarrow p \to_\varepsilon \bar{r} \curvearrowright r$, we get the desired $p \searrow r$.
4. By item 1, there is a move offset of 0.
By Lemma 5.5, there are states p, r such that both $(p, \bar{p})$ and $(r, \bar{r})$ are right-to-left DFSs. Using the space-symmetric variant of the proof of $p \searrow r$ in item 3, we obtain $p \swarrow r$. Now, by $p \swarrow r \circlearrowleft \bar{r} \curvearrowright q$, we have $p \downarrow q$. Consequently $\bar{p} \swarrow\!\!\!\uparrow \bar{p} \curvearrowleft p \downarrow q$, and, applying the space-symmetric version of item 2, we obtain an offset of -1 for $\bar{p}, p$.
5. The offset 0 follows from item 1. By Lemma 5.5, there are states $p, \bar{q}$ such that both $(p, \bar{p})$ and $(q, \bar{q})$ are right-to-left DFSs.
Let us show that $\bar{p} \uparrow \bar{q}$. For this, we trace the run

$$\bar{p} \curvearrowleft p \searrow p \circlearrowleft \bar{p} \curvearrowleft p \circlearrowleft \bar{p} \curvearrowright q \circlearrowleft \bar{q} \curvearrowleft q \circlearrowleft \bar{q} \nearrow \bar{q} \nearrow \bar{q}$$

that goes from state $\bar{p}$ in port 0 to state $\bar{q}$ in port ε of the following pattern, which is equivalent to Δ_1:



Now by $\bar{p} \uparrow \bar{q} \nearrow \bar{q} \curvearrowleft q \searrow q$, we obtain that $\nearrow^* \curvearrowleft \searrow^* \subseteq S(\bar{p}, q)$. By Lemma 6.6, we obtain offset -1. □

6.3. Classification of moves. In this section we state and prove Proposition 6.10, which says that if $S(p, q)$ is nonempty, then either it is a union of some of the eleven elementary moves, or there is a shift. This separation of cases is at the core of the argumentation of section 7.

PROPOSITION 6.10. *If $S(p, q)$ is nonempty, then p, q have a move offset in $\{-1, 0, 1\}$. Furthermore, either p, q admit a shift or $S(p, q)$ is a union of elementary moves.*

Proof. By Lemma 6.3, the move $S(p,q)$ is a finite union of sets of the form $\{\varepsilon\}$, which is an elementary move, or

$$(U(p,p')+\varepsilon) \curvearrowright (D(q',q)+\varepsilon), \qquad \text{where } p',q' \text{ satisfy } p \uparrow p' \curvearrowright q' \downarrow q, \qquad \text{or}$$
$$(U(p,p')+\varepsilon) \curvearrowleft (D(q',q)+\varepsilon), \qquad \text{where } p',q' \text{ satisfy } p \uparrow p' \curvearrowleft q' \downarrow q.$$

Letting $M \subseteq S(p,q)$ be a move of one of those forms, we prove that either $S(p,q)$ contains a shift or there is an elementary move E such that $M \subseteq E \subseteq S(p,q)$. If this holds for all such moves M, we directly obtain the statement of the proposition, using Corollary 6.7 for the offset of elementary moves.

By symmetry, we consider only the case $M = (U(p,p')+\varepsilon) \curvearrowright (D(q',q)+\varepsilon)$. We now apply Proposition 5.10 to $p \uparrow p'$. This proposition distinguishes six cases, namely, $\upuparrows$, $\upharpoonright$, $\upharpoonleft$, (a), (b), and (c). Similarly, we can do the time-reversed reasoning for $q' \downarrow q$ and also consider six cases.

If we have (b) or (c) for $p \uparrow p'$, then by items 3 and 4 of Lemma 6.9, respectively, we get a shift. In the case of (a), we get a shift by using items 1 and 2. By the time-space-reverse variant of Lemma 6.9, the same happens if (a), (b), or (c) holds for $q' \downarrow q$.

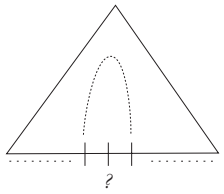
Only the other cases remain. There are nine possibilities:

- If $p \upharpoonright p'$ and $q' \upharpoonleft q$, we get $M = \sqcup\!\!\rightarrow$ by Lemma 6.4. Similarly, if $p \upharpoonright p'$ and $q' \downdownarrows q$, we get $M = \sqcup\!\!\downarrow$, and when $p \upuparrows p'$ and $q' \upharpoonleft q$, we have $M = \sqcap\!\!\rightarrow$.
- If $p \upharpoonleft p'$ and $q' \downdownarrows q$, we have $M \subseteq \sqcap\!\!\downarrow$ by Lemma 6.4. Furthermore, using Lemmas 6.4 and 6.5, we get $\sqcap\!\!\downarrow \subseteq S(p,q)$. Similarly, if $p \upuparrows p'$ and $q' \upharpoonright q$, we obtain $M \subseteq \sqcap\!\!\rightarrow \subseteq S(p,q)$.
- If $p \upharpoonright p'$ and $q' \upharpoonright q$, then p,q admit a shift. Indeed, 1 is a move offset of p,q: by Lemma 5.9, $p \uparrow p'' \upharpoonright p'' \uparrow p'$, and item 2 of Lemma 6.9 gives offset 1. Offset 0 is obtained by the time-space-reverse variant of Lemma 6.5 (i.e., if $\bar{p} \curvearrowright q' \upharpoonright q$, then $\epsilon \in S(p,q)$). The results are similar for $p \upharpoonleft p'$ and $q' \upharpoonleft q$.
- If $p \upharpoonleft p'$ and $q' \upharpoonright q$, then p,q admit a shift by item 5 of Lemma 6.9.
- If $p \upuparrows p'$ and $q' \downdownarrows q$, then p,q clearly admit a shift; 1 and 2 are move offsets. ∎

6.4. Right-skipping moves. The result of this section concerns right-skipping moves. A move is called *right-skipping* if it contains an element of

$$\text{Right} \setminus \sqcup\!\!\rightarrow.$$

A right-skipping move can go to the right in a pattern while omitting (skipping) the junction leaf immediately to the right:



We say that states p,q are *right-skipping* if the move $R(p,q)$ is right-skipping. A *left-skipping* move is defined in the same fashion.

LEMMA 6.11. *Let p,q be states with a maximal move offset k. Let u,v be leaves of a tree t, with $\#_t(u,v) > k$. If $[p,u] \to [q,v]$, then p,q are right-skipping.*

Proof. Note that if the offset k can be arbitrarily large, i.e., there is no maximal offset k, then p,q are right-skipping straight from the definition, thanks to any move

offset larger than 1. By the first clause of Proposition 6.10, $k \geq -1$, and so $\#_t(u,v)$ is at least 0. Furthermore, it cannot be 0, since otherwise we would have $p \to_\varepsilon q$ and therefore $0 \in \mathrm{moff}(p,q)$; this would give $k \geq 0$, a contradiction with $\#_t(u,v) > k$.

If $\#_t(u,v)$ is at least 2, then p, q are right-skipping by definition; the remaining case is 1. The path $\pi(u,v)$ witnesses $p \curvearrowright q$ and, consequently, the existence of p', q' such that $p \uparrow p' \curvearrowright q' \downarrow q$. By Proposition 5.6, either $p \nwarrow p'$ or $p \nearrow p'$ must hold. If $p \nearrow p'$, then $\nearrow\!\!\curvearrowright \in R(p,q)$ is a witness for p, q being right-skipping. Otherwise, $p \upharpoonleft p' \curvearrowright q$. By Lemma 5.9 and item 2 of Lemma 6.9, p, q has offset 1, which gives $k \geq 1$; a contradiction with $\#_t(u,v) > k$. ∎

7. The rotation. We have now gathered enough information about runs of the automaton that never see the label **a**. In this section we consider runs that do see **a**, and conclude the proof of Theorem 2. We will show that the tree-walking automaton $\mathcal{A}$ cannot detect a well-placed rotation in a large balanced tree.

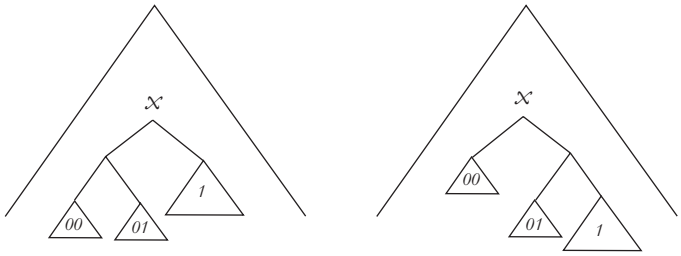


FIG. 7.1. *Rotating at node x.*

We proceed as follows. We start with a blank balanced binary tree T of large even depth. Clearly all leaves of T are at even depth, and therefore $\mathcal{A}$ must accept the tree $\Delta^{\mathbf{a}}_T$. We then choose a pivot node x in T and perform a rotation at that node. Rotation is the operation depicted in Figure 7.1; it moves the subtrees rooted in $x00$, $x01$, and $x1$ to the new positions $x0$, $x10$, and $x11$. One can easily see that the resulting tree T' has some leaves at odd depth, and hence $\mathcal{A}$ should not accept $\Delta^{\mathbf{a}}_{T'}$. We will, however, show that, for a carefully chosen pivot, $\mathcal{A}$ does accept this tree, thereby completing the proof of Theorem 2.

PROPOSITION 7.1. *The tree $\Delta^{\mathbf{a}}_{T'}$ is accepted by $\mathcal{A}$.*

First we describe how to properly choose the height of the tree T and the pivot in it. The remainder of the paper is then devoted to showing Proposition 7.1.

7.1. The pivot. The goal of this section is to construct a tree T, an accepting run of $\mathcal{A}$ over $\Delta^{\mathbf{a}}_T$, and a node x of T (the pivot), such that the properties of Definition 10 are satisfied. Essentially, these properties say that the tree is balanced and large and the path leading to the pivot contains a zigzag. Furthermore, some undesirable parts of the accepting run do not use nodes below the pivot. These properties will be used in the remainder of the paper in order to prove that doing a rotation in the pivot x on the tree T gives a tree T' such that $\Delta^{\mathbf{a}}_{T'}$ is accepted by $\mathcal{A}$. We begin by defining the "undesirable" parts of the run. After that, we state Definition 10 and then show that the tree and pivot can indeed be found, in Lemma 7.3.

Let t be a blank tree. Recall the definitions of junction and leaf configurations from section 4.2. By distinguishing all the configurations whose node is either a junction leaf or the root of $\Delta^{\mathbf{a}}_t$, every accepting run in $\Delta^{\mathbf{a}}_t$ can be decomposed into a sequence of the following form:

$$(q_1, v_1), \ldots, (q_n, v_n), \tag{7.1}$$

where each v_i $(i = 1, \ldots, n)$ is either the root ε or $[u_i]$ for some leaf u_i of t, and in between two such configurations, no junction leaf or the root is visited. In this case the run linking (q_i, v_i) to (q_{i+1}, v_{i+1}) is either

(a) a run visiting at least once the root of $\Delta_t^{\mathbf{a}}$ (and no $\mathbf{a}$-labeled leaf of $\Delta_t^{\mathbf{a}}$);
(b) a loop inside the $\Delta_1[\Delta_{\mathbf{a}}]$ subtree rooted in v_i, which is equivalent to $\Delta_{\mathbf{a}}$ (hence $q_i \circlearrowleft_{\mathbf{a}} q_{i+1}$); or
(c) a run from a junction leaf to another junction leaf in the pattern Δ_t (hence by Lemma 6.1, $[q_i, u_i] \to [q_{i+1}, u_{i+1}]$ holds, where $v_i = [u_i]$ and $v_{i+1} = [u_{i+1}]$).

Such a sequence is called a *rooted leaf run in* $\Delta_t^{\mathbf{a}}$. An *unrooted leaf run* is one that never uses a step of the form (a). By shortcutting each part of the run starting and ending in the root with the same state, we can safely assume that every rooted leaf run uses at most $2|Q|$ steps of the form (a); hence the greater part of a rooted leaf run is unrooted. Since an unrooted leaf run uses only leaf configurations, it can be written as $[q_1, u_1], \ldots, [q_n, u_n]$.

For junction configurations $[p, v]$ and $[q, w]$, we write $[p, v] \Rightarrow_t [q, w]$ if in the tree $\Delta_t^{\mathbf{a}}$ there is a run from $[p, v]$ to $[q, w]$ that does not visit the root. Note that when v, w are leaves, this means that there is an unrooted leaf run in $\Delta_t^{\mathbf{a}}$ from $[p, v]$ to $[q, w]$. As opposed to the relation $[p, v] \to [q, w]$, this run may depend on the tree t and not only on the nodes v and w.

We say that one state q is *leaf reachable* from another state p if they can be connected by an unrooted leaf run in some tree; i.e., $[p, v] \Rightarrow_t [q, w]$ for some tree t and leaves v, w. Equivalently, q is leaf reachable from p if there exist $p = p_1, \ldots, p_n = q$ such that for every $i = 1, \ldots, n-1$ either $S(p_i, p_{i+1})$ is nonempty (which corresponds to case (c)) or $p_i \circlearrowleft_{\mathbf{a}} p_{i+1}$ holds (corresponding to case (b); recall the definition of $\circlearrowleft_{\mathbf{a}}$ from Figure 5.1). (The right-to-left part of this equivalence is a consequence of the existence of a move offset in $\{-1, 0, 1\}$ shown in Proposition 6.10 and is not a priori obvious). A *component* of the automaton is a maximal set of pairwise leaf reachable states; in other words, it is a strongly connected component of the directed graph with Q as nodes and an edge from p to q if and only if $S(p, q)$ is nonempty or $p \circlearrowleft_{\mathbf{a}} q$.

Let us consider a rooted leaf run ρ as in (7.1), which witnesses the acceptance of $\Delta_t^{\mathbf{a}}$ by $\mathcal{A}$. The main point in choosing the pivot is to restrict our attention to fragments of ρ that are unrooted leaf runs and only use states from one component. We say the run *changes components* below a node y of t if it contains two successive leaf configurations (q_i, v_i), (q_{i+1}, v_{i+1}) such that q_i and q_{i+1} are in different components and at least one of v_i, v_{i+1} is below $[y]$. The run is *rooted below* y if there is some i such that $v_i = \varepsilon$ and either v_{i-1} or v_{i+1} exists and is below $[y]$.

DEFINITION 10. *We define the following properties for a node x in a blank balanced tree t with respect to a rooted leaf run of $\mathcal{A}$ in $\Delta_t^{\mathbf{a}}$:*

1. *the subtrees rooted in x and the children of x are $\log_2(|Q|)$-fractal (see below);*
2. *the subtree of x has depth larger than $4 + |Q| + 2\log_2(|Q|)$;*
3. *the node x is below the node* 01010101;
4. *the run does not change components below x;*
5. *the run is not rooted below x.*

Note that since the tree t is balanced, the number of leaves below a node v depends only on its depth. Then let v be a node of t, whose depth $|v| + 1$ is at most $|x| + 2$. From condition 2, it follows that the number of leaves in the subtree of v exceeds all the following thresholds (the constants D, E defined below will be used in the subsequent proofs):

$$|Q|, \quad D = |Q|(|Q|+1), \quad E = 3D + |Q|. \tag{7.2}$$

We will refer to the above property later in the paper.

We will now proceed to show that such a run and a node (called the pivot) can be found (Lemma 7.3) as long as t is a sufficiently large balanced tree of even depth. Before we do so, however, we need to define what a fractal tree is.

Within a tree t, we distinguish five *characteristic types* of nodes: (1) the root, (2) the leftmost leaf, (3) the rightmost leaf, (4) the remaining leaves, and—for the sake of completeness—(5) the remaining nodes. We say a tree t' *simulates* a tree t if for every two junction configurations in t that satisfy $[p, v] \Rightarrow_t [q, w]$ one can find two configurations satisfying $[p, v'] \Rightarrow_{t'} [q, w']$ such that v and v' have the same characteristic type, as well as w and w'. Given a natural number m, a tree is called *m-fractal* if it contains a proper subtree that simulates it and has depth larger than m.

LEMMA 7.2. *For every natural number m, all balanced binary trees of sufficiently large depth are m-fractal.*

Proof. For a tree t and states p, q, we can calculate the characteristic types of nodes v, w satisfying $[p, v] \Rightarrow_t [q, w]$. This information is sufficient to see whether one tree simulates another. Moreover, it can be calculated by a deterministic bottom-up finite tree automaton. In the case of a balanced binary tree, this information is a (regular) property of its depth and is thus ultimately periodic. This means that there exist constants N and k such that every balanced blank tree of depth $n \geq N$ is simulated by the balanced blank tree of depth $n - k$. Hence every balanced tree of depth at least $\max\{m + k, N\}$ is m-fractal. ∎

LEMMA 7.3. *There exist a blank balanced binary tree T, an accepting run ρ of $\mathcal{A}$ in $\Delta_T^{\mathbf{a}}$, and a pivot x such that x satisfies properties* 1–5 *of Definition* 10 *with respect to ρ.*

Proof. Let N be more than the minimum depth of balanced tree obtained from Lemma 7.2 for $m = \log_2(|Q|)$ and also larger than the depth stated in condition 2 of Definition 10. Let K be more than $\log_2(4|Q|) + 1$. Finally, let T be a balanced blank tree of even depth larger than $N + K + 8$. The tree $\Delta_T^{\mathbf{a}}$ is accepted by $\mathcal{A}$ by hypothesis on $\mathcal{A}$.

Consider now an accepting run and its representation as in (7.1),

$$(q_1, v_1), \ldots, (q_n, v_n),$$

where only the root and junction leaf configurations are displayed. We assume that in this run, the root of $\Delta_T^{\mathbf{a}}$ is seen at most $|Q|$ times. If this is not the case, some state appears twice in the root, and hence a configuration is seen twice in the run; one can then shortcut the corresponding part of the run.

Let V_{root} be all those junction leaves v_i such that at least one of v_{i-1}, v_{i+1} is the root ε. One can easily see that the run is rooted below a node y if and only if $[y]$ is above some node in V_{root}. Likewise, let V_{cc} be all those junction leaves v_i such that the state q_i is in a component other than either q_{i-1} or q_{i+1} (or both). Again, the run changes component below a node y if and only if $[y]$ is above some node in V_{cc}. Combining the above, a node x satisfies properties 4 and 5 from Definition 10 if and only if x is not above some node in one of $V_{\text{root}}, V_{\text{cc}}$. By assumption on the run not visiting the root more than $|Q|$ times, the sets $V_{\text{root}}, V_{\text{cc}}$ have together at most $4|Q|$ nodes.

Let us count the number of nodes at depth $K + 8$ in T that are below 01010101. There are 2^{K-1} such nodes, i.e., more than $4|Q|$ by construction of K. In particular,

there is a node x at depth $K+8$ that satisfies conditions 3, 4, and 5. Furthermore, since the whole tree has depth at least $N+K+8$, the subtree of x has depth at least N, and therefore x satisfies conditions 1 and 2. ∎

Detection of the rotation. Throughout the remainder of the paper, the tree T, the run ρ, and the pivot x are fixed according to Lemma 7.3. Let T' be the tree obtained from T by doing a rotation in the pivot x; this tree clearly contains leaves at odd depth. Our objective is to show that $\Delta^{\mathbf{a}}_{T'}$ is accepted by $\mathcal{A}$. For this, we have to show that the run can in some sense be replicated after the rotation. We will use properties 4 and 5 from Definition 10 to show that only unrooted leaf runs that do not change components need be considered.

We say that a component $\Gamma \subseteq Q$ of the automaton $\mathcal{A}$ *cannot detect the rotation* if for every two leaf configurations $[p, v]$, $[q, w]$ with p, q in Γ and v, w not below the pivot

$$[p, v] \Rightarrow_T [q, w] \qquad \text{implies} \qquad [p, v] \Rightarrow_{T'} [q, w]. \tag{7.3}$$

Observe that it makes sense to speak about the configurations $[p, v]$ and $[q, w]$ in the tree T' since the leaves v and w are not below the pivot and hence are not affected by the rotation.

Consequence for Proposition 7.1. Let us show that, under the assumption that no component can detect the rotation, we have Proposition 7.1.

Consider the run ρ and its representation as in (7.1):

$$(q_1, v_1), \ldots, (q_n, v_n).$$

Recall how we classified each of the runs linking (q_i, v_i) to (q_{i+1}, v_{i+1}), for $i = 1, \ldots, n-1$, according to their form, (a), (b), or (c). Also define u_i to be the node of T such that $v_i = [u_i]$, when possible, for $i = 1, \ldots, n$.

We claim the following: for $i < j$ in $\{1, \ldots, n\}$ such that both v_i and v_j are not below $[x]$, there is a run of the automaton $\mathcal{A}$ from (q_i, v_i) to (q_j, v_j) in $\Delta^{\mathbf{a}}_{T'}$. Since neither $v_1 = \varepsilon$ nor $v_n = \varepsilon$ is below $[x]$, our claim yields a run in $\Delta^{\mathbf{a}}_{T'}$ that goes from (q_1, ε) to (q_n, ε). Since the original run from (q_1, ε) to (q_n, ε) in $\Delta^{\mathbf{a}}_{T}$ was accepting, we know that q_1 is initial and q_n is final, and therefore the tree $\Delta^{\mathbf{a}}_{T'}$ is accepted by the automaton.

The proof of the claim is by induction on $j - i$. The induction step is obvious and follows by concatenating runs. The nontrivial case is the base case of the induction, when for every k with $i < k < j$ the node v_k is below $[x]$. We now prove the claim for this case.

Consider first the case when $i + 1 = j$. We now look at the form of the subrun that goes from (q_i, v_i) to (q_{i+1}, v_{i+1}). If this subrun is of the form (b), it can be directly replicated on $\Delta^{\mathbf{a}}_{T'}$ without change. If the subrun from (q_i, v_i) to (q_{i+1}, v_{i+1}) is of the form (c), then we use Corollary 6.2, which shows that a similar run can be used in $\Delta^{\mathbf{a}}_{T'}$ from configuration (q_i, v_i) to (q_{i+1}, v_{i+1}). The last remaining case is when the subrun from (q_i, v_i) to (q_{i+1}, v_{i+1}) is of the form (a), and in particular either $v_i = \varepsilon$, or $v_j = \varepsilon$, or both hold. If $v_i = \varepsilon$, but $v_j \neq \varepsilon$, we decompose the run from (q_i, ε) to (q_j, v_j) into a run from (q_i, ε) to $[q', \varepsilon]$, which does not visit more than once the nodes ε and $[\varepsilon]$, followed by a run from $[q', \varepsilon]$ to $[q_j, u_j]$, which does not visit ε or a junction leaf other than $[u_j]$. This second piece of run can be reused in $\Delta^{\mathbf{a}}_{T'}$ according to Corollary 6.2. Hence there is a run in $\Delta^{\mathbf{a}}_{T'}$ from (q_i, v_i) to (q_j, v_j). The case $v_i \neq \varepsilon$ and $v_j = \varepsilon$ is obtained by time symmetry. Finally, when $v_i = v_j = \varepsilon$,

either the run does not visit $[\varepsilon]$ and can be directly reused in $\Delta^{\mathbf{a}}_{T'}$, or it visits $[\varepsilon]$. In this latter case, let q' be the first and q'' be the last state assumed by the run when visiting $[\varepsilon]$. The piece of run between $[q', \varepsilon]$ and $[q'', \varepsilon]$ does not visit any junction leaf, and consequently by Lemma 4.1, there is a similar run which does not visit any junction node other than $[\varepsilon]$. This run can be reused in $\Delta^{\mathbf{a}}_{T'}$ to obtain a run from (q_i, v_i) to (q_j, v_j).

Otherwise, we have $i + 1 < j$. For all k with $i < k < j$, the node v_k is below $[x]$, which together with condition 5 of Definition 10 gives that no subruns of form (a) happen between (q_i, v_i) and (q_j, v_j). Consequently, all the nodes v_k are junction leaves, and the run from (q_i, v_i) to (q_j, v_j) is an unrooted leaf run:

$$[q_i, u_i] \Rightarrow_T [q_j, u_j].$$

Furthermore, by condition 4 of Definition 10, the states q_i and q_j belong to the same component Γ of the automaton. Also, by hypothesis on i and j, neither u_i nor u_j is below x. It follows that we can apply our assumption that no component can detect the rotation, and get a run corresponding to

$$[q_i, u_i] \Rightarrow_{T'} [q_j, u_j].$$

This completes the proof of the claim and, consequently, of Proposition 7.1. What remains to be done is to establish that no component of the automaton can detect the rotation. The remainder of this paper is dedicated to establishing this.

Using Proposition 6.10, we divide all components into two categories: components with a shift, i.e., containing two states that admit a shift, and components without a shift. Proposition 7.1 is then proved in sections 7.2 and 7.3 for each of the two categories.

7.2. Components with a shift cannot detect the rotation. In this section we fix a component Γ with a shift and prove that it cannot detect the rotation. In order to do this, we extend the definition of move offsets to *run offsets*, where more than one move can be used. The idea is that the shift in the component can be exploited to allow the automaton to move around the tree in an almost arbitrary fashion, independently of the structure of T.

A run offset between state p and state q is defined similarly to a move offset.

DEFINITION 11. *Given a natural number $m \geq 0$ called the* safety margin*, an m-*run offset *of states p, q is an integer i such that $[p, v] \Rightarrow_t [q, w]$ holds for every two leaves v, w of a tree t where $\#_t(v, w) = i$ and v, w both have at least m leaves to their left and right. We write $\mathrm{roff}_m(p, q)$ for the set of m-run offsets of p, q.*

We remark here, slightly ahead of time, that a consequence of x being below 01010101 is that all nodes below the pivot, and even some nodes not below the pivot, have at least m leaves to their left and right for fairly large values of m. This means that those nodes are suitable for using run offsets.

The differences between move offsets and run offsets are that (1) we replace $\to$ with $\Rightarrow_t$ (which depends on t and can read the label $\mathbf{a}$) and (2) the leaves v, w must have a "safety margin" of at least m leaves to their left and to their right; see Figure 7.2.

We now list some basic properties of roff, which hold for any given states p, q, r. First, $\mathrm{moff}(p, q)$ is included in $\mathrm{roff}_0(p, q)$. Furthermore, if $p \circlearrowleft_{\mathbf{a}} q$ holds, then 0 belongs to $\mathrm{roff}_0(p, q)$. Also, if both $i, j \leq 0$ or both $i, j \geq 0$, then

$$i \in \mathrm{roff}_m(p, q),\ j \in \mathrm{roff}_m(q, r) \qquad \Rightarrow \qquad i + j \in \mathrm{roff}_m(p, r).$$

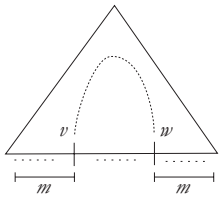

FIG. 7.2. *An m-run offset.*

Finally, if $ij \leq 0$ (i.e., if i, j are of opposite sign), then

$$i \in \mathrm{roff}_m(p,q),\ j \in \mathrm{roff}_m(q,r) \qquad \Rightarrow \qquad i+j \in \mathrm{roff}_{m+\min(|i|,|j|)}(p,r).$$

In particular, if $j \in \{-1,0,1\}$, then $i+j \in \mathrm{roff}_{m+1}(p,r)$.

A consequence of these properties, together with Proposition 6.10, is given in the following lemma.

LEMMA 7.4. *For every component Γ and states p, q in Γ, $\mathrm{roff}_{|Q|-2}(p,q)$ is nonempty and contains a value k with $|k| < |Q|$.*

Proof. For $p = q$, we naturally have $0 \in \mathrm{roff}_0(p,q)$, and hence $0 \in \mathrm{roff}_{|Q|-2}(p,q)$. Now assume $p \neq q$. Since p and q are in the same component, there exists a sequence of states $p = r_1, \ldots, r_n = q$ such that for all $i = 1, \ldots, n-1$ either $r_i \circlearrowleft_{\mathbf{a}} r_{i+1}$ holds or the move $S(r_i, r_{i+1})$ is nonempty. Without loss of generality, we assume that no state is seen twice in this sequence, and therefore $2 \leq n \leq |Q|$.

By induction on $i = 2, \ldots, n$, we will show that $\mathrm{roff}_{i-2}(r_1, r_i)$ contains a value k with $|k| < i$. For $i = n \leq |Q|$, the statement of the lemma follows. For $i = 2$, using the properties described above, if $r_1 \circlearrowleft_{\mathbf{a}} r_2$, then $0 \in \mathrm{roff}_0(r_1, r_2)$, and if $S(r_1, r_2)$ is nonempty, then $\mathrm{moff}(r_1, r_2)$ contains an offset $j \in \{-1, 0, 1\}$ by Proposition 6.10, and hence $j \in \mathrm{roff}_0(r_1, r_2)$. For $i > 2$, by the induction hypothesis, the set $\mathrm{roff}_{i-3}(r_1, r_{i-1})$ contains a value k with $|k| < i-1$. If $r_{i-1} \circlearrowleft_{\mathbf{a}} r_i$ holds, then $\mathrm{roff}_{i-3}(r_1, r_i)$ also contains k, and therefore so does $\mathrm{roff}_{i-2}(r_1, r_i)$. On the other hand, if $S(r_{i-1}, r_i)$ is nonempty, then $\mathrm{moff}(r_{i-1}, r_i)$ contains an offset $j \in \{-1, 0, 1\}$ by Proposition 6.10. In particular, the offset j belongs to $\mathrm{roff}_0(r_{i-1}, r_i)$. Using the properties described above, we obtain that $k + j$ belongs to $\mathrm{roff}_{i-2}(r_1, r_i)$. This concludes the induction step, since $|k + j| < i$. ∎

For a safety margin m and a natural number d called the *threshold*, a pair of states p, q is called an (m,d)-*right-teleport* if $\mathrm{roff}_m(p,q)$ contains all integers not smaller than d. An (m,d)-*left-teleport* is when $\mathrm{roff}_m(p,q)$ contains all the integers not larger than $-d$. An m-*full-teleport* corresponds to $\mathrm{roff}_m(p,q)$ containing all integers. Observe that if p, q is an (m,d)-right-teleport and q, r is an (m,d)-left-teleport, then p, r is an $(m+d)$-full-teleport.

Recall the constant $D = |Q|(|Q|+1)$ defined after Definition 10.

LEMMA 7.5. *If a component Γ contains a shift, either all pairs of states in Γ are $(2|Q|, D)$-right-teleports or all are $(2|Q|, D)$-left-teleports.*

Proof. Let q_1, q_2 be states in the component Γ that admit a shift, i.e., have two consecutive move offsets $i, i+1 \in \{-2, -1, 0, 1, 2\}$. By adding $i, i+1$ to the offset obtained by applying Lemma 7.4 to the pair q_2, q_1, we infer that q_1, q_1 admits two consecutive $|Q|$-run offsets k and $k+1$ with $|k|, |k+1| \leq |Q|+1$.

Without loss of generality, let us assume that $0 \leq k \leq |Q|$. Let

$$m \geq |Q|(|Q|-1) \geq k(k-1).$$

We will show that m belongs to $\mathrm{roff}_{|Q|}(q_1, q_1)$. For $k = 0$, we have $k + 1 = 1 \in \mathrm{roff}_{|Q|}(q_1, q_1)$ and hence, using this run offset m times, $m \in \mathrm{roff}_{|Q|}(q_1, q_1)$. For $k \geq 1$, the number m can be written as $\alpha k + \beta$ with $\beta \in \{0, \ldots, k-1\}$. In particular,

$$m = (\alpha - \beta)k + \beta(k + 1).$$

Let us remark that since $m \geq k(k-1)$, we have that $\alpha \geq k - 1$ and consequently $\alpha - \beta \geq 0$. Hence by using $\alpha - \beta$ times the run offset k, and β times the run offset $k + 1$, one obtains

$$m \in \mathrm{roff}_{|Q|}(q_1, q_1).$$

This proves that q_1, q_1 is a $(|Q|, |Q|(|Q| - 1))$-right-teleport.

Once one pair of states q_1, q_1 is a right-teleport, the same can be shown for all other state pairs in the component Γ. Indeed, we will show that any two states p, q in Γ are a $(2|Q|, |Q|(|Q| + 1))$-right-teleport, which completes the proof of the lemma. We need to show that the automaton can go from $[p, v]$ to $[q, w]$. First, using Lemma 7.4, the automaton can go from $[p, v]$ to a configuration of the form $[q_1, u_1]$, where u_1 is a leaf separated from v by at most $|Q|$ leaves (note that u_1 may be to the left or to the right of v). In the same way, there is a leaf u_2, separated from w by at most $|Q|$ leaves, such that the automaton can go from $[q_1, u_2]$ to $[q, w]$. If the leaves v, w have safety margins of $2|Q|$, then the leaves u_1, u_2 have safety margins of at least $|Q|$. Furthermore, if w is at least

$$|Q|(|Q| - 1) + 2|Q| = |Q|(|Q| + 1) = D$$

leaves to the right of v, then u_2 is at least $|Q|(|Q| - 1)$ leaves to the right of u_1. Therefore the $(|Q|, |Q|(|Q| - 1))$-right-teleport q_1, q_1 can be used to go from $[q_1, u_1]$ to $[q_1, u_2]$. This completes the proof that p, q is a $(2|Q|, D)$-right-teleport.

The left-teleport is obtained in the case when k is negative. □

For the remainder of this section (section 7.2), we assume that the second case in the above lemma holds, i.e., that all pairs of states are $(2|Q|, D)$-left-teleports. The case of right-teleports is symmetric. We now proceed to show that the component Γ cannot detect the rotation, i.e., that the implication (7.3) holds for any two leaves v, w not below the pivot and any two states p, q of the component Γ.

Consider all the leaf configurations of the unrooted leaf run from $[p, v]$ to $[q, w]$:

$$[p, v] = [r_0, u_0] \Rightarrow_T [r_1, u_1] \Rightarrow_T \cdots \Rightarrow_T [r_n, u_n] \Rightarrow_T [r_{n+1}, u_{n+1}] = [q, w]. \tag{7.4}$$

Without loss of generality we can assume that all the leaves $u_1, \ldots, u_n$ are below the pivot; the other parts of the run can be easily replicated in T' (as explained at the end of section 7.1). Note that since Γ is a component, all the states $r_0, \ldots, r_{n+1}$ belong to Γ.

We will do a case analysis. We say the leaf run from $[p, v]$ to $[q, w]$ satisfies property (*) if for some $0 \leq i < j \leq n + 1$ the leaf u_j is at least $|Q|$ leaves to the right of u_i, i.e., $\#_T(u_i, u_j) \geq |Q|$. We do the proof first for leaf runs that do not satisfy this property and then for those that do.

7.2.1. Leaf runs not satisfying (*). Recall that we assume that Γ is a component such that every pair of states in it is a left-teleport. We make a case distinction depending on the relative position of v and w with respect to the pivot.

If v is to the left of the pivot and w is to its right, then all the leaves below the pivot separate v from w. By (7.2), there are more than $|Q|$ of these leaves, which contradicts our assumption on property (*) failing.

Consider now the case when v is to the right of the pivot and w is to the left. If v has more than $2|Q|$ leaves to its right and w has more than $2|Q|$ leaves to its left, we can use the $(2|Q|, D)$-left-teleport and go from $[p, v]$ to $[q, w]$ independently of the rotation, since there are at least D leaves below the pivot x, thanks to (7.2). Let us assume now that v has less than $2|Q|$ leaves to its right and w has less than $2|Q|$ leaves to its left. By (7.2), node 11 has more than $2|Q|$ leaves in its subtree. In particular, if there are less than $2|Q|$ leaves to the right of v, then v must be below 11. Since u_1 is below the pivot x, hence below 01, the path going from $[p, v]$ to $[r_1, u_1]$ is of the form $\pi \nwarrow \curvearrowleft \searrow \pi' \in S(p, r_1)$. It follows that $\pi \curvearrowleft \pi'$ also belongs to $S(p, r_1)$, by swallowing. Hence, the automaton can go from $[p, v]$ to $[r_1, v']$ for some v' below 10. In the same way, if w has less than $2|Q|$ leaves to its left, one shows that there exists a leaf w' below 001 such that the automaton can go in one move from $[r_n, w']$ to $[q, w]$. We are in the situation where v' has more than $2|Q|$ leaves to its right, w' has more than $2|Q|$ leaves to its left, and there are more than D leaves between w' and v'. Now we can use the $(2|Q|, D)$-left-teleport to go from $[r_1, v']$ to $[r_n, w']$. Furthermore, since v', w' are not below the pivot and the teleport is used to jump over the leaves below the pivot, the resulting run cannot detect the rotation. The other cases are a combination of the two previous ones.

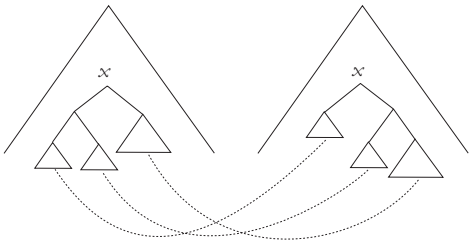

FIG. 7.3. *The bijection f.*

Next we consider the case for which both v and w are to the right of the pivot. Since condition (*) is not satisfied, all leaves $u_1, \ldots, u_n$ are at most $|Q|$ leaves away from w. In particular all these leaves are below $x1$ since the subtree rooted in $x1$ contains at least $|Q|$ leaves by (7.2). Let f be the unique bijection between the leaves of T and the leaves of T' that preserves the leaf numbering (i.e., $\#_T(v) = \#_{T'}(f(v))$; see Figure 7.3). Note that f is the identity function on leaves not below the pivot; in particular $f(v) = v$ and $f(w) = w$. We claim that the unrooted leaf run from $[p, v]$ to $[q, w]$ can be replicated in the tree T' as follows:

$$[p, v] \Rightarrow_{T'} [r_1, f(u_1)] \Rightarrow_{T'} \cdots \Rightarrow_{T'} [r_n, f(u_n)] \Rightarrow_{T'} [q, w].$$

Since all leaves $u_1, \ldots, u_n$ are located below $x1$, the path connecting $f(u_i)$ to $f(u_{i+1})$ is identical to the one connecting u_i to u_{i+1} for $i = 1, \ldots, n-1$. It follows that the run from $[r_1, f(u_1)]$ to $[r_n, f(u_n)]$ is valid in T'. Only the first and last steps remain to be considered. We do only the first one, the other being time-symmetric. Consider the first step in the leaf run, when the automaton goes from $[p, v]$ to $[r_1, u_1]$. Since v is to the right of the pivot and u_1 is below the pivot, the path from v to u_1 is of the

form

$$\pi \ \curvearrowleft \ \pi_1\pi_2 \qquad \text{with} \quad \pi \in \{\nwarrow, \nearrow\}^* \quad \text{and } \pi_1, \pi_2 \in \{\swarrow, \searrow\}^*.$$

Here π_1 is chosen so that $\pi \curvearrowleft \pi_1$ leads from v to the pivot, while π_2 leads from the pivot to u_1. Since u_1 is at a distance at most $|Q|$ from v, it is separated by at most $|Q|$ leaves from the rightmost leaf below the pivot. Therefore, the only left turns $\swarrow$ in π_2 happen in its last $\log_2(|Q|)$ letters. It follows from condition 2 of Definition 10 that π_2 has a prefix $\searrow^k$ with $k \geq |Q|$. Hence some state r has to be used twice in the prefix. Since $\searrow$ is transitive, we deduce that

$$\pi \ \curvearrowleft \ \pi_1 \ \searrow \ \pi_2$$

also belongs to the move $S(p, r_1)$. But this path is the one linking v to $f(u_1)$ in T', proving that $[p, v] \Rightarrow_{T'} [r_1, f(u_1)]$.

The last remaining case is when both v and w are to the left of the pivot. This time we show that from a run of the form $\pi \curvearrowright \pi_1 \swarrow \pi_2$ one can deduce a run of the form $\pi \curvearrowright \pi_1\pi_2$, which can be used after the rotation. This case is, in fact, simpler since Definition 10 need not be invoked, but rather swallowing is used.

7.2.2. Leaf runs satisfying (*). In this case we will show that the component Γ contains a right-skipping move (or a right-teleport). After combining this with the left-teleports from our assumption, we will show that any two leaf configurations with states from Γ and nodes below the pivot can be reached one from the other, which implies that Γ cannot detect the rotation. For this, we will use the assumption that the pivot is below 01010101.

Recall the constant $E = 3D + |Q|$ defined after Definition 10.

LEMMA 7.6. *Either all pairs of states in* Γ *are* E*-full-teleports, or some states* r, r' *in* Γ *are right-skipping.*

Proof. Recall that we are analyzing a run as in (7.4). For $i = 0, \ldots, n$, let k_i be the offset $\#_T(u_i, u_{i+1})$. If some k_i exceeds 1, the corresponding move $R(r_i, r_{i+1})$ is by definition right-skipping and we are done. Furthermore, if some k_i exceeds the maximal move offset of r_i, r_{i+1} (if that exists), then the corresponding move is right-skipping by Lemma 6.11. We assume that neither case happens.

Since (*) is satisfied, there are $i < j$ such that $\#_T(u_i, u_j) \geq |Q|$. We will inspect the run from u_i to u_j and find in it a state used twice, the first configuration involved being to the left of the second one. Since $k_i, \ldots, k_{j-1} \leq 1$, we can assume that $\#_T(u_i, u_j)$ is exactly $|Q|$. Furthermore, if we choose i, j so that $j - i$ is minimal, all the leaves $u_{i+1}, \ldots, u_{j-1}$ are to the right of u_i and to the left of u_j. Since, without loss of generality, we can assume that no leaf is visited more than $|Q|$ times, and using the fact that the automaton has at least two states, we obtain $j - i < |Q|^2$.

Claim. Let $k = 1, \ldots, |Q|$. If $g < h$ in $\{i, \ldots, j\}$ are such that the sequence $r_g, \ldots, r_h$ contains at most k distinct states, and, furthermore, $\#_T(u_g, u_h) \geq k$, then there are $g' < h'$ in $\{g, \ldots, h\}$ such that $r_{g'} = r_{h'}$ and $\#_T(u_{g'}, u_{h'}) \geq 1$.

Proof. The proof is by induction on k. For $k = 1$ the statement is obvious. Consider now $k > 1$. We take a longest suffix $u_m, \ldots, u_h$ of $u_g, \ldots, u_h$ where the leaf u_g is not visited anymore (in particular, all leaves $u_m, \ldots, u_h$ are to the right of u_g). By assumption on all moves going at most one position to the right, the leaf u_m must be the leaf immediately to the right of u_g, and therefore $\#_T(u_m, u_h) \geq k - 1$. If the states $r_m, \ldots, r_h$ do not contain the state r_g, then we apply the induction hypothesis. Otherwise, the position among $m, \ldots, h$ where state r_g is used gives us the desired g' and h', since all nodes $u_m, \ldots, u_h$ are to the right of u_g. ∎

Using this claim with $g = i$ and $h = j$, together with $j - i < |Q|^2$, we find two indices $i' < j'$ such that $r_{i'} = r_{j'} = r$, $j' - i' < |Q|^2$, and $\#_T(u_{i'}, u_{j'}) \geq 1$. We will use this to show that there is also a right-teleport in the component. When combined with the left-teleport from our assumption on Γ, we will get a full-teleport.

By assumption on the values k_l, each pair r_l, r_{l+1} has some move offset $m_l \geq k_l$. (Here we use the convention that there is a move offset $m_l = 0 \geq k_l$ when the run from $[r_l, u_l]$ to $[r_{l+1}, u_{l+1}]$ is of type (b), i.e., when $r_l \circlearrowleft_{\mathbf{a}} r_{l+1}$ holds.) By Proposition 6.10 each nonempty move has a move offset in $\{-1, 0, 1\}$, and we have $m_l \geq -1$. Furthermore, if $m_l > 1$, then r_l, r_{l+1} would be right-skipping; hence we have $-1 \leq m_l \leq 1$. Therefore,

$$1 \leq \#_T(u_{i'}, u_{j'}) = k_{i'} + \cdots + k_{j'-1} \leq m_{i'} + \cdots + m_{j'-1} < |Q|^2.$$

(The last inequality is due to $j' - i' < |Q|^2$ and $m_l \leq 1$.) However, since the sum

$$m = m_{i'} + \cdots + m_{j'-1}$$

is composed only of move offsets, it must belong to $\mathrm{roff}_{|Q|^2}(r, r)$ and therefore also to $\mathrm{roff}_D(r, r)$, since

$$D = |Q|(|Q| + 1) > |Q|^2.$$

We will now show that $\mathrm{roff}_{3D}(r, r)$ contains all integers, and therefore r, r is a $3D$-full-teleport. Indeed, let v and w be two leaves in a tree t, both with safety margin at least $3D$. We will show that the automaton can go from $[r, v]$ to $[r, w]$. Using $m \in \mathrm{roff}_D(r, r)$ (recall that $m \geq 1$), starting from $[r, v]$, we successively move to the right by steps of m leaves. We stop as soon we have reached a configuration $[r, u]$ with u located at least D leaves to the right of w, possibly stopping immediately. Observe that if $u \neq v$ (i.e., u is to the right of v), then the leaf u is numbered at most $\#_T(w) + D + m - 1$, and thus u has at least $3D - (D + m - 1)$ leaves to its right. Since $m < D$, this value is larger than D. Hence, such a leaf u can indeed be reached using $m \in \mathrm{roff}_D(r, r)$. Since both u and v have safety margin at least $D > 2|Q|$, we can therefore use the $(2|Q|, D)$-left-teleport—that all state pairs in Γ have by assumption—to go from $[r, u]$ to $[r, w]$.

Once one state pair r, r has been shown to be a full-teleport, the same can be argued for the other state pairs in Γ. This is done in the same way as in the last part of the proof of Lemma 7.5. As in that lemma, the safety margin must be increased by $|Q|$; hence the value $E = 3D + |Q|$ in the statement of this lemma. □

LEMMA 7.7. *For v, w leaves below the pivot in T', and p, q in Γ, $[p, v] \Rightarrow_{T'} [q, w]$.*

Before we proceed with the proof, we show how this implies that Γ cannot detect the rotation. Indeed, consider the leaf run

$$[p, v] \Rightarrow_T [r_1, u_1] \Rightarrow_T \cdots \Rightarrow_T [r_n, u_n] \Rightarrow_T [q, w]$$

that goes from $[p, v]$ to $[q, w]$. As mentioned before, we assume that all $u_1, \ldots, u_n$ are below the pivot, and hence only the first and last moves cross the pivot. Thanks to the yet unproved Lemma 7.7, it suffices to connect $[p, v]$ with some leaf configuration in T' below the pivot and also connect some leaf configuration in T' below the pivot with $[q, w]$. We will therefore show that there are leaves u'_1 and u'_n in T' below the pivot such that

$$[p, v] \Rightarrow_{T'} [r_1, u'_1] \qquad \text{and} \qquad [r_n, u'_n] \Rightarrow_{T'} [q, w].$$

First consider the path from v to u_1 in T. This path first goes to the pivot, arriving there in some state s, and then moves down to the configuration $[r_1, u_1]$. This implies $s \downarrow r_1$. Hence, by the time-symmetric variant of Lemma 6.5, one of the sets $\swarrow^+$ or $\searrow^+$ is included in $D(s, r_1)$. In the first case we pick u'_1 to be the leftmost leaf below the pivot in T', while in the second case we take the rightmost one. The symmetric reasoning also works for u'_n.

Only the proof of Lemma 7.7 remains. Let v, w be leaves below the pivot, and let p, q belong to Γ. We need to show that $[p, v] \Rightarrow_{T'} [q, w]$ holds.

By Lemma 7.6, either all pairs of states r, r' in Γ are E-full-teleports, or there exists a pair of states r, r' in Γ that is right-skipping. In the first case, there are more than E leaves to the left and to the right of the pivot by (7.2) and hence to the left and to the right of both v and w. The E-full-teleport p, q is usable, and the statement of the lemma follows.

We now treat the case when some state pair r, r' in Γ is right-skipping. By assumption, all state pairs in the component Γ are $(2|Q|, D)$-left-teleports. Our strategy is to combine the left-teleports with the right-skipping move r, r'. First, we use the left-teleport to go from $[p, v]$ to $[r, u]$, with u being a specially chosen leaf to the left of the pivot. We then use the right-skipping move and the properties of u in order to move to $[r', u']$, with u' being a specially chosen leaf to the right of the pivot. Finally, we use the left-teleport to reach the configuration $[q, w]$. This process is illustrated in Figure 7.4.

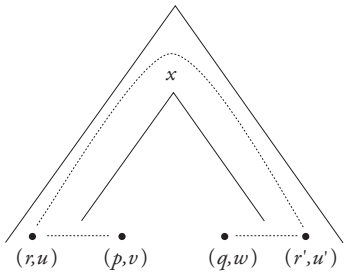

FIG. 7.4. *The leaf run witnessing* $[p, v] \Rightarrow_{T'} [q, w]$.

We need to find leaves u and u' such that the above strategy works. This is the goal of the claim below. The first property in the statement allows us to perform the right-skip, while the last three allow us to use the left-teleport.

Claim. There exist leaves u, u' in T' such that

- the path between u and u' belongs to $S(r, r')$ (r, r' taken from Lemma 7.6);
- there are at least D leaves between u and any node below the pivot;
- there are at least D leaves between any node below the pivot and u'; and
- there are at least $2|Q|$ leaves to the left and right of both u, u'.

Proof. The states r, r' are right-skipping by assumption. Hence, by definition of a right-skipping move and Lemma 6.3, one can find states s, s' with

$$r \uparrow s \curvearrowright s' \downarrow r'$$

such that either $U(r, s) \setminus \nwarrow^+$ or $D(s', r') \setminus \swarrow^+$ is nonempty. First consider the case when $U(r, s) \setminus \nwarrow^+$ is nonempty. This means that $r \nearrow s$ holds. Hence, by Lemma 6.5, $U(r, s)$ contains either $\nwarrow^* \nearrow$ or $\nearrow^+$, and $D(s', r')$ contains either $\swarrow^+$ or $\searrow^+$. By

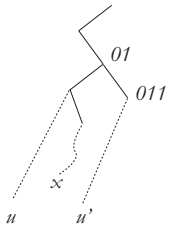

FIG. 7.5. *The move from u to u'.*

time-symmetry, in the case when $D(s', r') \setminus \swarrow^+$ is nonempty, $D(s', r')$ contains either $\searrow^+$ or $\searrow\swarrow^*$, and $U(r, s)$ contains either $\nwarrow^+$ or $\nearrow^+$.

Altogether, we obtain that $R(r, r')$ contains at least one of the following five moves (using swallowing, we have simplified $\nwarrow^*\nearrow$ into $\nwarrow^*$, and $\searrow\swarrow^*$ into $\swarrow^*$):

$$\nearrow^*\curvearrowright\swarrow^*, \quad \nwarrow^*\curvearrowright\searrow^*, \quad \nearrow^*\curvearrowright\searrow^*, \quad \nwarrow^*\nearrow\curvearrowright\swarrow^*, \quad \text{or } \nwarrow^*\curvearrowright\searrow\swarrow^*.$$

We treat each of these cases separately. For $\nearrow^*\curvearrowright\swarrow^*$, take u to be the leftmost leaf below 01 and u' to be the leftmost leaf below 011 (see Figure 7.5). Clearly the path from u to u' belongs to $\nearrow^*\curvearrowright\swarrow^*$; hence the first property of the statement holds. By changing the leaves u and u', we obtain similarly the other cases: for $\nwarrow^*\curvearrowright\searrow^*$, take u to be the rightmost leaf below 0100 and u' to be the rightmost leaf below 010; for $\nearrow^*\curvearrowright\searrow^*$, take u to be the leftmost leaf below 01 and u' to be the rightmost leaf below 010; for the case $\nwarrow^*\nearrow\curvearrowright\swarrow^*$, take u to be the rightmost leaf below 0100 and u' to be the leftmost leaf below 011; for $\nwarrow^*\curvearrowright\searrow\swarrow^*$, take u to be the rightmost leaf below 0100 and u' to be the leftmost leaf below 01011. In each case, the path from u to u' belongs to $S(r, r')$, and therefore the first item of the statement is satisfied.

For the second item of the statement, note that in all five cases above, the leaf u is located below 0100. Using condition 3 of Definition 10, we also know that the pivot is below the node 01010101. Hence, all the leaves below 010100 are to the right of u and to the left of the pivot. Furthermore, by (7.2), there are more than D such leaves. The third item is similar: in all five cases, u' is below 011 or 01011. Hence, the leaves below 0101011 are to the right of the pivot and to the left of u'. And there are more than D of them.

The fourth point is obtained by the same kind of arguments. The leaves below 00 are all to the left of u, and the leaves below 1 are all to the right of u'. And in each case there are more than $2|Q|$ of them. This completes the proof of the claim. □

This completes the proof that no component with a shift can detect the rotation.

7.3. Components without a shift cannot detect the rotation. In this section we consider a component Γ without shifts. This is the second and last case to be considered in the proof of Proposition 7.1. According to Proposition 6.10, every nonempty move $S(p, q)$ with p, q in Γ is a union of the elementary moves

$$\textit{Stay}, \ \sqcup\!\!\downarrow, \ \downarrow\!\sqcup, \ \sqcap\!\!\downarrow, \ \downarrow\!\sqcap, \ \sqcup\!\!\uparrow, \ \uparrow\!\sqcup, \ \sqcap\!\!\uparrow, \ \uparrow\!\sqcap, \ \sqcup\!\sqcap, \text{ and } \sqcap\!\sqcup$$

(see Figure 6.1). Our strategy is as follows. First, we distinguish some elementary moves, called "adjacency moves." Then we show that all other moves can be simulated using adjacency moves. Finally, we show that a component where all moves are adjacency moves cannot detect the rotation.

Two paths in Right are called *right adjacency similar* if one can be obtained from the other by replacing one fragment in $\sqcup\!\!\rightarrow$ by another. More formally, two paths are right adjacency similar if they can be decomposed as

$$y \nwarrow^k \curvearrowright \swarrow^l z \quad \text{and} \quad y \nwarrow^m \curvearrowright \swarrow^n z, \quad \text{where } k,l,m,n \in \mathbb{N},\ y \in \mathrm{Up} + \varepsilon,\ z \in \mathrm{Down} + \varepsilon.$$

Left adjacency similarity is defined in the same way by replacing $\nwarrow$, $\curvearrowright$, and $\swarrow$ by $\nearrow$, $\curvearrowleft$, and $\searrow$, respectively. Two paths are *adjacency similar* if they are either left or right adjacency similar.

Definition 12. *An* adjacency move *is an elementary move closed under adjacency similarity.*

The following simple fact is given without further proof.

Fact 7.8. *Stay,* $\sqcup\!\!\rightarrow$, $\leftarrow\!\!\sqcup$, $\sqcap\!\!\rightarrow$, $\leftarrow\!\!\sqcap$, $\sqcup\!\!\downarrow$, *and* $\downarrow\!\!\sqcup$ *are adjacency moves.*

Adjacency moves are going to be used in conjunction with fractality (see condition 1 of Definition 10). The following lemma presents a typical example of such an argument (fractality is not explicitly mentioned, but the lemma refers to characteristic types and by consequence can be used with fractality).

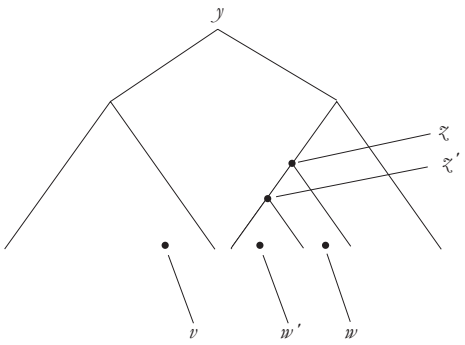

Fig. 7.6. *The nodes* y, v, z, z', w, *and* w'.

Lemma 7.9. *Fix a blank tree* t, *a node* y, *and two nodes* z, z' *on the leftmost branch below* $y1$. *Furthermore, let* w *be a leaf in the subtree of* z *and let* w' *be a leaf in the subtree of* z', *both with the same characteristic types within the subtrees of* z *and* z', *respectively (see Figure* 7.6*). Then, for any given leaf* v *below* $y0$ *and any adjacency move* M,

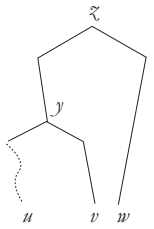
$$\textit{if} \quad vMw, \quad \textit{then} \quad vMw'.$$

Proof. Assume vMw. Since M is an adjacency move and hence also an elementary move, it is of the form $U \curvearrowright D$ with $\pi(y1, w) \in D$. It is sufficient to prove that $\pi(y1, w') \in D$ also holds. Since M is an adjacency move, D is of the form either $\swarrow^*$ or $(\swarrow + \searrow)^*$. If D is $\swarrow^*$, this means that w is the leftmost leaf below $y1$ and consequently also the leftmost leaf below z. Since w' has the same characteristic type (w.r.t. z') as w (w.r.t. z), this means that w' is the leftmost leaf below z'. By consequence $w = w'$, and we have $\pi(y1, w') \in D$. Otherwise D is of the form $(\swarrow + \searrow)^*$. Since w' is below $y1$, this implies $\pi(y1, w') \in D$. □

We will now eliminate the moves $\sqcap\!\!\rightarrow$, $\leftarrow\!\!\sqcap$, $\sqcap\!\!\downarrow$, and $\downarrow\!\!\sqcap$, which are not adjacency moves. This is done by simulating them by a sequence of adjacency moves. The following lemma treats the case of $\sqcap\!\!\rightarrow$, which is simulated by $\sqcap\!\!\rightarrow \leftarrow\!\!\sqcap$. The other cases are symmetric.

LEMMA 7.10. *Let t be a tree and let u, v be two leaves of t. If $u \sqcap\!\!\downarrow v$ and v is not the rightmost leaf of t, then there exists a leaf w such that $u \sqcap\!\!\rightarrow w \sqsubset\!\!\downarrow v$. If there exists a leaf w such that $u \sqcap\!\!\rightarrow w \sqsubset\!\!\downarrow v$, then $u \sqcap\!\!\downarrow v$.*

Proof. We prove here only the first implication; both implications can be seen in the following picture:



Let w be the next leaf in t after v. Since v is not the rightmost leaf, w exists. By the choice of w, we have $w \sqsubset\!\!\downarrow v$. Let us show $u \sqcap\!\!\rightarrow w$.

Let y be the deepest node above both u and v. Since $u \sqcap\!\!\downarrow v$ holds, v is the rightmost leaf below y. Let z be the deepest node above both y and w. Since w is the next leaf after v—which is the rightmost leaf below y—the leaf w is the leftmost one below $z1$. But then we can use $\sqcap\!\!\rightarrow$ to go from u to w (the appropriate path doing a $\curvearrowright$ from $z0$ to $z1$). □

In the remainder of the proof, we use only the fact that for each $p, q \in \Gamma$ the move $S(p, q)$ is a union of elementary moves. We then use Lemma 7.10 in the following manner. We enrich the automaton by allowing (after a nondeterministic choice) each move $\sqcap\!\!\downarrow$ to be possibly replaced by the sequence of $\sqcap\!\!\rightarrow$ followed by $\sqsubset\!\!\downarrow$, likewise for the other moves $\sqcup\!\!\downarrow$, $\sqcup\!\!\rightarrow$, and $\sqcup\!\!\uparrow$, by using time-, space-, and time-space-symmetric variants of this operation. (Note that this transformation requires the use of extra states.) According to the second implication of Lemma 7.10, the resulting automaton is equivalent to $\mathcal{A}$. Furthermore, any unrooted leaf run of the original automaton that uses only states from Γ can be transformed—using the first implication of Lemma 7.10—into an unrooted leaf run of the modified automaton where all moves happening below the pivot (i.e., the source and target leaves of the move are below the pivot) are adjacency moves. For this reason, from now on, we assume that all moves happening below the pivot are adjacency moves.

We proceed to show that Γ cannot detect the rotation. We have to show that

$$[p, v] \Rightarrow_T [q, w] \qquad \text{implies} \qquad [p, v] \Rightarrow_{T'} [q, w]$$

for any states $p, q \in \Gamma$ and nodes v, w not below the pivot. As before (in section 7.2), since T and T' are equal over nodes not below the pivot, it suffices to establish the lemma for unrooted leaf runs where all positions but the initial and final ones are below the pivot. In other words, the first move of the unrooted leaf run is used to enter the subtree of the pivot, the last move is used to exit it, and in between all moves are below the pivot. In this run all moves but the initial and final ones are used between leaf configurations below the pivot. Hence, according to the comment above, we can assume that all the moves used in this unrooted leaf run are adjacency moves, except possibly the first and last ones.

Recall from section 7.2.1 the bijection f that assigns to every leaf in T a leaf in T' and preserves the numbering. Let V_1, V_2, and V_3 be the sets of leaves of T below $x00$, $x01$, and $x1$, respectively. Let W_1, W_2, and W_3 be the sets of leaves of T' below

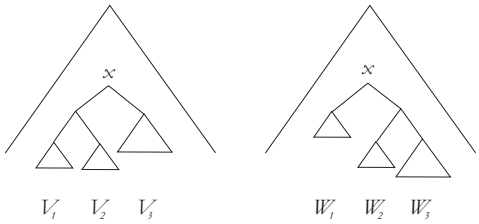


FIG. 7.7. *The trees T and T'.*

$x0$, $x10$, and $x11$, respectively (see Figure 7.7 for an illustration). By definition of rotation, $f(V_i) = W_i$ for $i = 1, 2, 3$. We say that two leaves $v \in V_i$ and $w \in V_j$ are *neighbors* if $|i-j| \leq 1$. If v, w are neighbors, then the path linking v to w and the path linking $f(v)$ to $f(w)$ are adjacency similar. In particular, whenever the automaton can go from v to w in one adjacency move, then it also can do this from $f(v)$ to $f(w)$. Therefore, a leaf run that does only moves between neighbor nodes is mapped by f onto a valid leaf run in the tree T'.

This remark is the key to our proof. The idea is that we will transform the run from $[p, v]$ to $[q, w]$ into one where all moves below the pivot are between neighbor leaves. Let the leaf run corresponding to $[p, v] \Rightarrow_T [q, w]$ be

$$[p, v] = [r_0, u_0], [r_1, u_1], \ldots, [r_n, u_n], [r_{n+1}, u_{n+1}] = [q, w].$$

We will transform it into the following leaf run in T':

$$[p, v] = [r_0, u_0], [r_1, f(u_1)], \ldots, [r_n, f(u_n)], [r_{n+1}, u_{n+1}] = [q, w].$$

For this construction to work, i.e., for this sequence to be a valid leaf run over T', it is sufficient to verify that the step from $[r_0, u_0]$ to $[r_1, u_1]$ can be transformed into a step from $[r_0, u_0]$ to $[r_1, f(u_1)]$ (similarly for the last step) and, furthermore, that the following property (*) holds: for every $1 \leq i < n$, the leaves u_i and u_{i+1} are neighbors. We first establish the first property; then we will show that every run can be transformed into one where (*) holds. (Property (*) may not hold for the original run.)

First step of the leaf run. The move from $[r_0, u_0]$ to $[r_1, u_1]$ is an elementary move, though perhaps not an adjacency move. Hence, there are three ways of entering the subtree of the pivot: by going to the leftmost leaf below the pivot (using one of $\sqcap\!\!\downarrow$, $\sqcap\!\!\rightarrow$, $\sqcap\!\!\circlearrowright$), to the rightmost one (using one of $\sqcap\!\!\downarrow$, $\sqcap\!\!\leftarrow$, $\sqcap\!\!\circlearrowleft$), or anywhere (using one of $\sqcap\!\!\downarrow$, $\sqcap\!\!\downarrow$, $\sqcap\!\!\downarrow$, $\sqcap\!\!\downarrow$). In each of those cases, using the same argument as in Lemma 7.9, it can easily be shown that the same move goes from $[r_0, u_0]$ to $[r_1, f(u_1)]$. The proof for the last step of the leaf run is the same.

Proof of (*). According to the remark above, there are three ways to enter the subtree of the pivot. By time symmetry, there are also three ways to exit this subtree. This results in nine possibilities.

Case leftmost-leftmost. Consider first the case where the automaton enters in the leftmost node of V_1 and leaves by the same node. This means that $u_1 = u_n$ is the leftmost leaf below x.

Since the subtree of the pivot is fractal (condition 1 of Definition 10), it contains a proper subtree that simulates it. Since all subtrees of T are complete binary trees, we may as well assume that there is a node u on the leftmost branch below $x0$ whose

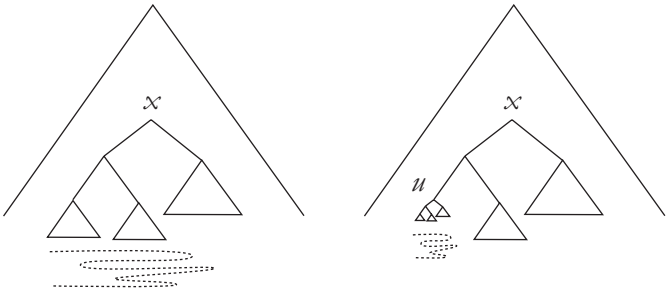

FIG. 7.8. *Moving the leaf run to* V_1.

subtree simulates the subtree of x. Since the leftmost node is one of the characteristic types (from the definition of fractality), the leaf run that went from the leftmost node below the pivot back to this leftmost node can be assumed to visit only nodes below u (see Figure 7.8). Such a leaf run satisfies property (*), since it never leaves $V_1 \cup V_2$.

All other cases are solved using the same argument, except for two: when the automaton enters in the leftmost leaf below the pivot and leaves in the rightmost one, and when the automaton enters in the rightmost leaf below the pivot and leaves in the leftmost one. The first of these is treated in the next item, and the other follows by time symmetry.

Case leftmost-rightmost. This time u_1 is the leftmost leaf of V_1 and u_n the rightmost leaf of V_3. We are going to construct a similar leaf run satisfying (*).

As an intermediate step, we first construct a similar leaf run satisfying the different property (#): once a position in V_3 is encountered during the run, no position in V_1 is visited anymore. Let us prove that we can transform the unrooted leaf run into one that satisfies (#). Let $1 < i \leq j < n$ be positions in the run that witness a violation of (#): the leaves u_{i-1} and u_{j+1} belong to V_3, the leaves $u_i, \ldots, u_j$ belong to $V_1 \cup V_2$, and at least one of $u_i, \ldots, u_j$ belongs to V_1. We will replace this violating subrun with one that does not visit V_1. By iterating this operation, we get a run where property (#) is satisfied.

By condition 1 of Definition 10, we can find on the rightmost branch below $x01$ a node u such that the subtree of u simulates the subtree of $x0$. Hence, one can find leaves u'_i, u'_j below u such that the characteristic type of u_i (resp., u_j) in the subtree of $x0$ is the same as the characteristic type of u'_i (resp., u'_j) in the subtree of u, and there is a run from $[r_i, u'_i]$ to $[r_j, u'_j]$ that uses only leaves below u. By choice of u, all these leaves are in V_2. Therefore, in order to remove the violation of (#) witnessed by i and j, it remains for us to connect $[r_{i-1}, u_{i-1}]$ with $[r_i, u'_i]$ and $[r_j, u'_j]$ with $[r_{j+1}, u_{j+1}]$. This is a direct application of Lemma 7.9 (and its time- and space-reverse variants); note that $[r_{i-1}, u_{i-1}] \to [r_i, u_i]$ and hence $u_{i-1} M u_i$ for some adjacency move $M \subseteq S(r_{i-1}, r_i)$.

Thanks to the above argument, we may assume that the leaf run satisfies property (#). If it already has property (*), then the problem is over. Otherwise, there is some moment in the leaf run where two consecutive leaf configurations are not neighboring. Since after visiting V_3 we never come back to V_1, this can happen at most once, where the source configuration $[r_i, u_i]$ is in V_1 and the target configuration $[r_{i+1}, u_{i+1}]$ is in V_3. Moreover, the only way to go from a position in V_1 to a position in V_3 via an adjacency move is by using $\sqcap\!\!\searrow$. In particular, u_{i+1} is the leftmost leaf

in V_3. However, if we want to use the move $\sqcap\!\!\searrow$ from $[r_i, u_i]$ and satisfy property (*), the only place we can go to is the leftmost leaf of V_2.

In order to complete the proof, we will construct a new leaf run that satisfies property (*) and goes from state r_{i+1} in the leftmost leaf of V_2 to state r_i in some leaf u of V_2. Then we can reuse the move $r_i \sqcap\!\!\searrow r_{i+1}$ to go from u to u_{i+1}, since $\sqcap\!\!\searrow$ does not care about the position of the leaf u within $V_1 \cup V_2$.

The leaf run that goes from r_{i+1} in the leftmost leaf of V_2—call this leaf v—to r_i in some leaf u of V_2 is constructed in two stages. In the first stage, we show that there is some leaf u' in V_2 such that the configuration $[r_n, u']$ can be reached from $[r_{i+1}, v]$. Furthermore, the leaf u' has at least $|Q|$ leaves to the left and to the right that belong to V_2. In the second stage, we use this latter assumption to go from $[r_n, u']$ to state r_i without leaving V_2. This is done simply by using Lemma 7.4 (observe that this lemma does not use any assumption on the component). The node where we arrive is going to be u.

Therefore, in order to complete the proof of Proposition 7.1—and therefore also the proof of Theorem 2—it remains to find some leaf u' in V_2 such that the configuration $[r_n, u']$ can be reached from $[r_{i+1}, v]$ and such that u' has $|Q|$ leaves to the left and right inside V_2. This process is illustrated in Figure 7.9.

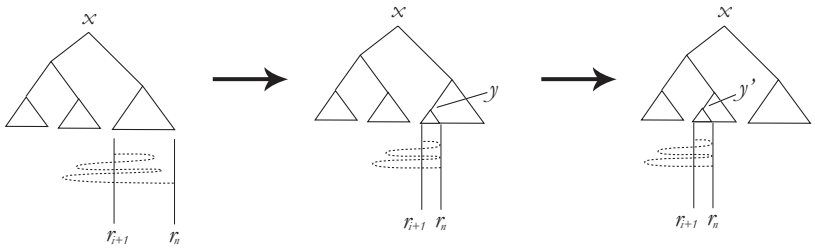

FIG. 7.9. *Transforming the run from r_{i+1} to r_n.*

Recall our assumption that the nodes $u_{i+1}, \ldots, u_n$ are all in $V_2 \cup V_3$. By condition 1 of Definition 10, there is a node y on the leftmost branch below $x10$ whose subtree simulates the subtree of $x1$ and has more than $|Q|$ leaves. Using the same proof as for property (#), we can transform the unrooted leaf run from $[r_{i+1}, u_{i+1}]$ to $[r_n, u_n]$ into an unrooted leaf run from $[r_{i+1}, u_{i+1}]$ to $[r_n, u'_n]$, where only leaves from V_2 or below y are used, and where u'_n is the rightmost leaf below y. (This run is illustrated in the middle picture of Figure 7.9.) Let y' be the node on the leftmost branch below $x01$ such that the subtree of y' is the same as the subtree of y. By using the properties of adjacency moves, one can shift—by $|V_2|$ leaves to the left—the run that goes from $[r_{i+1}, u_{i+1}]$ to $[r_n, u'_n]$ into a run that goes from $[r_{i+1}, v]$ to $[r_n, u']$, where u' is the rightmost leaf below y', which concludes the proof of Proposition 7.1. Note that in V_2, there are more than $|Q|$ leaves to the left and to the right of u', by construction of y.

NEW AND IMPROVED CONSTRUCTIONS OF NONMALLEABLE CRYPTOGRAPHIC PROTOCOLS*

RAFAEL PASS† AND ALON ROSEN‡

Abstract. We present a new constant-round protocol for nonmalleable zero-knowledge. Using this protocol as a subroutine, we obtain a new constant-round protocol for nonmalleable commitments. Our constructions rely on the existence of (standard) collision-resistant hash functions. Previous constructions either relied on the existence of trapdoor permutations and hash functions that are collision resistant against subexponential-sized circuits or required a superconstant number of rounds. Additional results are the first construction of a nonmalleable commitment scheme that is statistically hiding (with respect to opening) and the first nonmalleable commitments that satisfy a strict polynomial-time simulation requirement. Our approach differs from the approaches taken in previous works in that we view nonmalleable zero-knowledge as a building block rather than an end goal. This gives rise to a modular construction of nonmalleable commitments and results in a somewhat simpler analysis.

Key words. cryptography, zero-knowledge, nonmalleability, man-in-the-middle, round-complexity, nonblack-box simulation

1. Introduction.

Consider the execution of two-party protocols in the presence of an adversary that has full control of the communication channel between the parties. The adversary has the power to omit, insert, or modify messages at its choice. It also has full control over the scheduling of the messages. The honest parties are not necessarily aware of the existence of the adversary and are not allowed to use any kind of trusted setup (such as a common reference string).

The above kind of attack is often referred to as a *man-in-the-middle* attack. It models a natural scenario whose investigation is well motivated. Protocols that retain their security properties in the face of a man in the middle are said to be *nonmalleable* [14]. Due to the hostile environment in which they operate, the design and analysis of nonmalleable protocols is a notoriously difficult task. The task becomes even more challenging if the honest parties are not allowed to use any kind of trusted setup. Indeed, only a handful of such protocols have been constructed so far.

The rigorous treatment of two-party protocols in the man-in-the-middle setting has been initiated in the seminal paper by Dolev, Dwork, and Naor [14]. The paper contains definitions of security for the tasks of nonmalleable commitment and nonmalleable zero-knowledge. It also presents protocols that meet these definitions. The protocols rely on the existence of one-way functions, and require $O(\log n)$ rounds of interaction, where $n \in N$ is a security parameter.

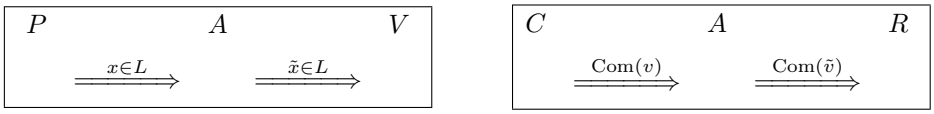
A more recent result by Barak presents constant-round protocols for nonmalleable commitment and nonmalleable zero-knowledge [2]. This is achieved by constructing a coin-tossing protocol that is secure against a man in the middle and then using the outcome of this protocol to instantiate known constructions for nonmalleable commitment and zero-knowledge in the common reference string model. The proof of security makes use of nonblack-box techniques and is highly complex. It relies on the existence of trapdoor permutations and hash functions that are collision resistant against subexponential-sized circuits.

In this paper we continue the line of research initiated by the above papers. We will be interested in constructions of new constant-round protocols for nonmalleable commitment and nonmalleable zero-knowledge and will not rely on any kind of set-up assumption.

1.1. Nonmalleable protocols. In accordance with the above discussion, consider a man-in-the-middle adversary A that is simultaneously participating in two executions of a two-party protocol. These executions are called the *left* and the *right* interaction. Besides controlling the messages that it sends in the left and right interactions, A has control over the scheduling of the messages. In particular, it may delay the transmission of a message in one interaction until it receives a message (or even multiple messages) in the other interaction.



(a) (b)

FIG. 1. *The man-in-the-middle adversary.* (a) *Interactive proofs.* (b) *Commitments.*

The adversary is trying to take advantage of its participation in the left interaction in order to violate the security of the protocol executed in the right interaction, where the exact interpretation of the term "violate the security" depends on the specific task at hand.

A two-party protocol is said to be nonmalleable if the left interaction does not "help" the adversary in violating the security of the right interaction. Following the simulation paradigm [24, 25, 21, 22], this is formalized by defining appropriate "real" and "idealized" executions.

In the real execution, called the *man-in-the-middle* execution, the adversary participates in both the left and the right interactions. In the idealized execution, called the *stand-alone* execution, the adversary is participating only in a single interaction. Security is defined by requiring that the adversary cannot succeed better in the man-in-the-middle execution than he could have in the stand-alone execution. In the specific instances of zero-knowledge and string commitment, the definition of security takes the following forms.

Nonmalleable zero-knowledge [14]. Let $\langle P, V\rangle$ be an interactive proof system. In the left interaction the adversary A is verifying the validity of a statement x by interacting with an honest prover P. In the right interaction A proves the validity of a statement $\tilde{x} \neq x$ to the honest verifier V (see Figure 1(a)). The objective of the adversary is to convince the verifier in the right interaction that $\tilde{x} \in L$. Nonmalleability of $\langle P, V\rangle$ is defined by requiring that, for any man-in-the-middle adversary A, there exists a stand-alone prover S that manages to convince the verifier with essentially

the same probability as A. The interactive proof $\langle P, V\rangle$ is said to be *nonmalleable zero-knowledge* if it is nonmalleable and (stand-alone) zero-knowledge.

Nonmalleable commitments [14]. Let $\langle C, R\rangle$ be a commitment scheme. In the left interaction the adversary A is receiving a commitment to a value v from the committer C. In the right interaction A is sending a commitment to a value $\tilde{v}$ to the receiver R (see Figure 1(b)). The objective of the adversary is to succeed in committing in the right interaction to a value $\tilde{v} \neq v$ that satisfies $\mathcal{R}(v, \tilde{v}) = 1$ for some poly-time computable relation $\mathcal{R}$. Nonmalleability of $\langle C, R\rangle$ is defined by requiring that, for any man-in-the-middle adversary A, there exists a stand-alone committer S that manages to commit to the related $\tilde{v}$ with essentially the same probability as A.

Schemes that satisfy the above definition are said to be nonmalleable *with respect to commitment*. In a different variant, called nonmalleable commitment *with respect to opening* [17], the adversary is considered to have succeeded only if it manages to *decommit* to a related value $\tilde{v}$.

1.2. Our contributions. Our main result is the construction of a new constant-round protocol for nonmalleable $\mathcal{ZK}$. The proof of security relies on the existence of (ordinary) collision resistant hash functions and does not rely on any set-up assumption.

THEOREM 1 (nonmalleable $\mathcal{ZK}$). *Suppose that there exists a family of collision-resistant hash functions. Then there exists a constant-round nonmalleable $\mathcal{ZK}$ argument for every $L \in \mathcal{NP}$.*

Theorem 1 is established using the notion of *simulation extractability*. A protocol is said to be simulation extractable if, for any man-in-the-middle adversary A, there exists a simulator-extractor that can simulate the views of both the left and the right interactions for A while outputting a witness for the statement proved by A in the right interaction. Any protocol that is simulation extractable is also nonmalleable $\mathcal{ZK}$. The main reason for using simulation extractability (which is more technical in flavor than nonmalleability) is that it is easier to work with.

Using our new simulation-extractable protocols as a subroutine, we construct constant-round protocols for nonmalleable string commitment. One of our constructions achieves statistically binding commitments that are nonmalleable with respect to commitment, and the other achieves statistically hiding commitments that are nonmalleable with respect to opening.

THEOREM 2 (statistically binding nonmalleable commitment). *Suppose that there exists a family of collision-resistant hash functions. Then there exists a constant-round statistically binding commitment scheme that is nonmalleable with respect to commitment.*

THEOREM 3 (statistically hiding nonmalleable commitment). *Suppose that there exists a family of collision-resistant hash functions. Then there exists a constant-round statistically hiding commitment scheme that is nonmalleable with respect to opening.*

Underlying cryptographic assumptions. The main quantitative improvement of our construction over the constant-round protocols in [2] is in the underlying cryptographic assumption. Our constructions rely on the existence of ordinary collision-resistant hash functions. The protocols in [2] relied on the existence of both trapdoor permutations and hash functions that are collision resistant against subexponential-sized circuits. The constructions in [14] assumed only the existence of one-way functions but had a superconstant number of rounds.

Statistically hiding nonmalleable commitments. Theorem 3 gives the first construction of a nonmalleable commitment scheme that is statistically hiding and that

does not rely on set-up assumptions. We mention that the existence of collision-resistant hash functions is the weakest assumption currently known to imply constant-round statistically hiding commitment schemes (even those that are not of the nonmalleable kind) [33, 10].

Strict vs. liberal nonmalleability. The notion of nonmalleability that has been considered so far in all works allows the stand-alone adversary S to run in expected polynomial time. A stronger ("tighter") notion of security, called *strict nonmalleability* [14], requires S to run in strict polynomial time. In the context of strict nonmalleability, we have the following result.

THEOREM 4 (strict nonmalleability). *Suppose that there exists a family of collision-resistant hash functions. Then there exists a constant-round statistically binding commitment scheme that is strictly nonmalleable with respect to commitment.*

1.3. Techniques and new ideas. Our protocols rely on nonblack-box techniques used by Barak to obtain the constant-round public-coin $\mathcal{ZK}$ argument for $\mathcal{NP}$ [1] (in a setting where no man in the middle is considered). They are closely related to previous works by Pass [35] and Pass and Rosen [36] that appeared in the context of bounded-concurrent two-party and multiparty computation; in particular our protocols rely and further explore the technique from [35] of using *message lengths* to obtain nonmalleability. Our techniques are different from the ones used by Barak in the context of nonmalleable coin tossing [2].

The approach we follow in this work is fundamentally different from the approach used in [14]. Instead of viewing nonmalleable commitments as a tool for constructing nonmalleable $\mathcal{ZK}$ protocols, we reverse the roles and use nonmalleable $\mathcal{ZK}$ protocols in order to construct nonmalleable commitments. Our approach is also different from the one taken by [2], where a coin-tossing protocol is used to instantiate constructions that rely on the existence of a common reference string.

Our approach gives rise to a modular and natural construction of nonmalleable commitments. This construction emphasizes the role of nonmalleable $\mathcal{ZK}$ as a building block for other nonmalleable cryptographic primitives. In proving the security of our protocols, we introduce the notion of *simulation extractability*, which is a convenient form of nonmalleability (in particular, it enables a more modular construction of proofs). A generalization of simulation extractability, called one-many simulation extractability, has already been found to be useful in constructing commitment schemes that retain their nonmalleability properties even if executed concurrently an unbounded (polynomial) number of times [37].

In principle, our definitions of nonmalleability are compatible with the ones appearing in [14]. However, the presentation is more detailed and somewhat different (see section 3). Our definitional approach, as well as our construction of nonmalleable $\mathcal{ZK}$, highlights a distinction between the notions of nonmalleable interactive proofs and nonmalleable $\mathcal{ZK}$. This distinction was not present in the definitions given in [14].

1.4. Related work. Assuming the existence of a common random string, Di Crescenzo, Ishai, and Ostrovsky [13], and Di Crescenzo et al. [12] construct nonmalleable commitment schemes. Sahai [38] and De Santis et al. [11] construct a noninteractive nonmalleable $\mathcal{ZK}$ protocol under the same assumption. Fischlin and Fischlin [17] and Damgård and Groth [9] construct nonmalleable commitments assuming the existence of a common reference string. We note that the nonmalleable commitments constructed in [13] and [17] satisfy nonmalleability only with respect to opening [17]. Canetti and Fischlin [7] construct a universally composable commitment assuming a common random string. Universal composability implies nonmalleability.

However, it is impossible to construct universally composable commitments without making set-up assumptions [7].

Goldreich and Lindell [20] and Nguyen and Vadhan [34] consider the task of session-key generation in a setting where the honest parties share a password that is taken from a relatively small dictionary. Their protocols are designed having a man-in-the-middle adversary in mind and require only the usage of a "mild" set-up assumption (namely the existence of a "short" password).

1.5. Future and subsequent work. Our constructions (and even moreso the previous ones) are quite complex. A natural question is whether they can be simplified. A somewhat related question is whether nonblack-box techniques are necessary for achieving constant-round nonmalleable $\mathcal{ZK}$ or commitments. Our constructions rely on the existence of collision-resistant hash functions, whereas the nonconstant-round construction in [14] relies on the existence of one-way functions. We wonder whether the collision resistance assumption can be relaxed.

Another interesting question (which has already been addressed in subsequent work—see below) is whether it is possible to achieve nonmalleability under concurrent executions. The techniques used in this paper do not seem to extend to the (unbounded) concurrent case, and new ideas seem to be required. Advances in that direction might shed light on the issue of concurrent composition of general secure protocols.

In subsequent work [37], we show that (a close variant of) the commitments presented here will retain their nonmalleability even if executed concurrently an unbounded (polynomial) number of times. We note that besides using an almost identical protocol, the proof of this new result heavily relies on a generalization of simulation extractability (called "one-many" simulation extractability). This notion has proved itself very useful in the context of nonmalleability, and we believe that it will find more applications in scenarios where a man-in-the-middle adversary is involved. We additionally mention that the presentation of some of the results in this version of the paper incorporate simplification developed by us in [37].

2. Preliminaries.

2.1. Basic notation. We let N denote the set of all integers. For any integer $m \in N$, denote by $[m]$ the set $\{1, 2, \ldots, m\}$. For any $x \in \{0,1\}^*$, we let $|x|$ denote the size of x (i.e., the number of bits used in order to write it). For two machines M, A, we let $M^A(x)$ denote the output of machine M on input x and given oracle access to A. The term *negligible* is used for denoting functions that are (asymptotically) smaller than one over any polynomial. More precisely, a function $\nu(\cdot)$ from nonnegative integers to reals is called *negligible* if, for every constant $c > 0$ and all sufficiently large n, it holds that $\nu(n) < n^{-c}$.

2.2. Witness relations. We recall the definition of a witness relation for an $\mathcal{NP}$ language [18].

DEFINITION 2.1 (witness relation). *A* witness relation *for a language $L \in \mathcal{NP}$ is a binary relation R_L that is polynomially bounded and polynomial-time recognizable and characterizes L by*

$$L = \{x : \exists y \text{ so that } (x, y) \in R_L\}.$$

We say that y is a witness for the membership $x \in L$ if $(x, y) \in R_L$ (also denoted $R_L(x, y) = 1$). We will also let $R_L(x)$ denote the set of witnesses for the membership

$x \in L$, i.e.,

$$R_L(x) = \{y : (x, y) \in L\}.$$

In the following, we assume a fixed witness relation $R_L(x, y)$ for each language $L \in \mathcal{NP}$.

2.3. Probabilistic notation. Denote by $x \stackrel{R}{\leftarrow} X$ the process of uniformly choosing an element x in a set X. If $B(\cdot)$ is an event depending on the choice of $x \stackrel{R}{\leftarrow} X$, then $\Pr_{x \leftarrow X}[B(x)]$ (alternatively, $\Pr_x[B(x)]$) denotes the probability that $B(x)$ holds when x is chosen with probability $1/|X|$. Namely,

$$\Pr_{x \leftarrow X}[B(x)] = \sum_x \frac{1}{|X|} \cdot \chi(B(x)),$$

where χ is an indicator function so that $\chi(B) = 1$ if event B holds and equals zero otherwise. We denote by U_n the uniform distribution over the set $\{0, 1\}^n$.

2.4. Computational indistinguishability and statistical closeness. The following definition of (computational) indistinguishability originates in the seminal paper of Goldwasser and Micali [24].

Let X be a countable set of strings. A *probability ensemble indexed by* X is a sequence of random variables indexed by X. Namely, any $A = \{A_x\}_{x \in X}$ is a random variable indexed by X.

DEFINITION 2.2 ((computational) indistinguishability). *Let X and Y be countable sets. Two ensembles $\{A_{x,y}\}_{x \in X, y \in Y}$ and $\{B_{x,y}\}_{x \in X, y \in Y}$ are said to be* computationally indistinguishable over X *if, for every probabilistic "distinguishing" machine D whose running time is polynomial in its first input, there exists a negligible function $\nu(\cdot)$ so that for every $x \in X, y \in Y$*

$$|\Pr[D(x, y, A_{x,y}) = 1] - \Pr[D(x, y, B_{x,y}) = 1]| < \nu(|x|);$$

$\{A_{x,y}\}_{x \in X, y \in Y}$ and $\{B_{x,y}\}_{x \in X, y \in Y}$ are said to be statistically close *over X if the above condition holds for all (possibly unbounded) machines D.*

2.5. Interactive proofs, zero-knowledge, and witness indistinguishability. We use the standard definitions of interactive proofs (and interactive Turing machines) [25, 18] and arguments [6]. Given a pair of interactive Turing machines, P and V, we denote by $\langle P, V \rangle(x)$ the random variable representing the (local) output of V when interacting with machine P on common input x, when the random input to each machine is uniformly and independently chosen.

DEFINITION 2.3 (interactive proof system). *A pair of interactive machines $\langle P, V \rangle$ is called an interactive proof system for a language L if machine V is polynomial time and the following two conditions hold with respect to some negligible function $\nu(\cdot)$:*

- Completeness: *For every $x \in L$,*

$$\Pr[\langle P, V \rangle(x) = 1] \geq 1 - \nu(|x|).$$

- Soundness: *For every $x \notin L$, and every interactive machine B,*

$$\Pr[\langle B, V \rangle(x) = 1] \leq \nu(|x|).$$

In case that the soundness condition is required to hold only with respect to a computationally bounded prover, the pair $\langle P, V \rangle$ is called an interactive argument system.

Zero-knowledge. An interactive proof is said to be *zero-knowledge* ($\mathcal{ZK}$) if it yields nothing beyond the validity of the assertion being proved. This is formalized by requiring that the view of every probabilistic polynomial-time adversary V^* interacting with the honest prover P can be simulated by a probabilistic polynomial-time machine S (a.k.a. the *simulator*). The idea behind this definition is that whatever V^* might have learned from interacting with P, he could have actually learned by himself (by running the simulator S).

The notion of $\mathcal{ZK}$ was introduced by Goldwasser, Micali, and Rackoff [25]. To make $\mathcal{ZK}$ robust in the context of protocol composition, Goldreich and Oren [23] suggested augmenting the definition so that the above requirement also holds with respect to all $z \in \{0,1\}^*$, where both V^* and S are allowed to obtain z as auxiliary input. The verifier's *view* of an interaction consists of the common input x, followed by its random tape and the sequence of prover messages the verifier receives during the interaction. We denote by $\text{view}^P_{V^*}(x,z)$ a random variable describing $V^*(z)$'s view of the interaction with P on common input x.

DEFINITION 2.4 (zero-knowledge). *Let $\langle P,V\rangle$ be an interactive proof system. We say that $\langle P,V\rangle$ is zero-knowledge if, for every probabilistic polynomial-time interactive machine V^*, there exists a probabilistic polynomial-time algorithm S such that the ensembles $\{\text{view}^P_{V^*}(x,z)\}_{x\in L,z\in\{0,1\}^*}$ and $\{S(x,z)\}_{x\in L,z\in\{0,1\}^*}$ are computationally indistinguishable over L.*

A stronger variant of zero-knowledge is one in which the output of the simulator is statistically close to the verifier's view of real interactions. We focus on *argument* systems, in which the soundness property is guaranteed to hold only with respect to polynomial-time provers.

DEFINITION 2.5 (statistical zero-knowledge). *Let $\langle P,V\rangle$ be an interactive argument system. We say that $\langle P,V\rangle$ is statistical zero-knowledge if, for every probabilistic polynomial-time V^*, there exists a probabilistic polynomial-time S such that the ensembles $\{\text{view}^P_{V^*}(x,z)\}_{x\in L,z\in\{0,1\}^*}$ and $\{S(x,z)\}_{x\in L,z\in\{0,1\}^*}$ are statistically close over L.*

In case that the ensembles $\{\text{view}^P_{V^*}(x,z)\}_{x\in L,z\in\{0,1\}^*}$ and $\{S(x,z)\}_{x\in L,z\in\{0,1\}^*}$ are identically distributed, the protocol $\langle P,V\rangle$ is said to be *perfect* zero-knowledge.

Witness indistinguishability. An interactive proof is said to be *witness indistinguishable* ($\mathcal{WI}$) if the verifier's view is "computationally independent" (resp., "statistically independent") of the witness used by the prover for proving the statement (the notion of statistical $\mathcal{WI}$ will be used in section 4.2). In this context, we focus our attention on languages $L \in \mathcal{NP}$ with a corresponding witness relation R_L. Namely, we consider interactions in which on common input x the prover is given a witness in $R_L(x)$. By saying that the view is computationally (resp., statistically) independent of the witness, we mean that, for any two possible $\mathcal{NP}$ witnesses that could be used by the prover to prove the statement $x \in L$, the corresponding views are computationally (resp., statistically) indistinguishable.

Let V^* be a probabilistic polynomial-time adversary interacting with the prover, and let $\text{view}^P_{V^*}(x,w,z)$ denote V^*'s view of an interaction in which the witness used by the prover is w (where the common input is x and V^*'s auxiliary input is z).

DEFINITION 2.6 (witness indistinguishability). *Let $\langle P,V\rangle$ be an interactive proof system for a language $L \in \mathcal{NP}$. We say that $\langle P,V\rangle$ is witness indistinguishable for R_L if, for every probabilistic polynomial-time interactive machine V^* and for every two sequences $\{w^1_x\}_{x\in L}$ and $\{w^2_x\}_{x\in L}$ such that $w^1_x, w^2_x \in R_L(x)$ for every $x \in L$, the probability ensembles $\{\text{view}^P_{V^*}(x,w^1_x)\}_{x\in L,z\in\{0,1\}^*}$ and $\{\text{view}^P_{V^*}(x,w^2_x)\}_{x\in L,z\in\{0,1\}^*}$ are com-*

putationally indistinguishable over L.

When the ensembles $\{\text{view}^P_{V^*}(x, w^1_x)\}_{x\in L, z\in\{0,1\}^*}$ and $\{\text{view}^P_{V^*}(x, w^2_x)\}_{x\in L, z\in\{0,1\}^*}$ are statistically close over L, the proof system $\langle P, V\rangle$ is said to be *statistically witness indistinguishable*. If the ensembles are identically distributed, the proof system is said to be *witness independent*.

2.6. Proofs of knowledge. Informally an interactive proof is a proof of knowledge if the prover convinces the verifier not only of the validity of a statement but also that it possesses a witness for the statement. This notion is formalized by the introduction of an machine E, called a *knowledge extractor*. As the name suggests, the extractor E is supposed to extract a witness from any malicious prover P^* that succeeds in convincing an honest verifier. More formally, we have the following definition.

DEFINITION 2.7. *Let (P, V) be an interactive proof system for the language L with witness relation R_L. We say that (P, V) is a proof of knowledge if there exist a polynomial q and a probabilistic oracle machine E such that, for every probabilistic polynomial-time interactive machine P^*, there exists some negligible function $\mu(\cdot)$ such that, for every $x \in L$ and every $y, r \in \{0,1\}^*$ such that $\Pr[\langle P^*_{x,y,r}, V(x)\rangle = 1] > 0$, where $P^*_{x,y,r}$ denotes the machine P^* with common input fixed to x, auxiliary input fixed to y, and random tape fixed to r, the following hold:*

1. *The expected number of steps taken by $E^{P^*_{x,y,r}}$ is bounded by*

$$\frac{q(|x|)}{\Pr[\langle P^*_{x,y,r}, V(x)\rangle = 1]},$$

   where $E^{P^*_{x,y,r}}$ denotes the machine E with oracle access to $P^*_{x,y,r}$.
2. *Furthermore,*

$$\Pr[\langle P^*_{x,y,r}, V(x)\rangle = 1 \wedge E^{P^*_{x,y,r}} \notin R_L(x)] \le \mu(|x|).$$

The machine E is called a (knowledge) extractor.

We remark that as our definition considers only computationally bounded provers, we get only a "computationally convincing" notion of a proof of knowledge (a.k.a *argument of knowledge*) [6]. In addition, our definition is slightly different from the definition of [4] in that we require that the expected running time of the extractor is always bounded by $\text{poly}(|x|)/p$, where p denotes the success probability of P^*, whereas [4] allows for some additional slackness in the running time. On the other hand, whereas [4] requires the extractor to always output a valid witness, we instead allow the extractor to fail with some negligible probability. We will rely on the following theorem.

THEOREM 2.8 (see [5, 6]). *Assume the existence of claw-free permutations. Then there exists a constant-round public-coin witness independent argument of knowledge for $\mathcal{NP}$.*

Indeed, standard techniques can be used to show that the parallelized version of the protocol of [5], using perfectly hiding commitments, is an argument of knowledge (as defined above). As usual, the knowledge extractor E proceeds by feeding new "challenges" to the prover P^* until it gets two accepting transcripts. If the two accepting challenges contain the same challenge, or if the prover manages to open up a commitment in two different ways, the extractor outputs `fail`; otherwise it can extract a witness.

2.7. Universal arguments. Universal arguments (introduced in [3] and closely related to the notion of CS-proofs [30]) are used in order to provide "efficient" proofs to statements of the form $y = (M, x, t)$, where y is considered to be a true statement if M is a nondeterministic machine that accepts x within t steps. The corresponding language and witness relation are denoted $L_{\mathcal{U}}$ and $R_{\mathcal{U}}$, respectively, where the pair $((M, x, t), w)$ is in $R_{\mathcal{U}}$ if M (viewed here as a two-input deterministic machine) accepts the pair (x, w) within t steps. Notice that every language in $\mathcal{NP}$ is linear time reducible to $L_{\mathcal{U}}$. Thus, a proof system for $L_{\mathcal{U}}$ allows us to handle all $\mathcal{NP}$-statements. In fact, a proof system for $L_{\mathcal{U}}$ enables us to handle languages that are presumably "beyond" $\mathcal{NP}$, as the language $L_{\mathcal{U}}$ is $\mathcal{NE}$-complete (hence the name universal arguments).[1]

DEFINITION 2.9 (universal argument). *A pair of interactive Turing machines (P, V) is called a universal argument system if it satisfies the following properties:*

- Efficient verification: *There exists a polynomial p such that, for any $y = (M, x, t)$, the total time spent by the (probabilistic) verifier strategy V, on common input y, is at most $p(|y|)$. In particular, all messages exchanged in the protocol have length smaller than $p(|y|)$.*
- Completeness by a relatively efficient prover: *For every $((M, x, t), w)$ in $R_{\mathcal{U}}$,*

$$\Pr[(P(w), V)(M, x, t) = 1] = 1.$$

  Furthermore, there exists a polynomial q such that the total time spent by $P(w)$, on common input (M, x, t), is at most $q(T_M(x, w)) \leq q(t)$, where $T_M(x, w)$ denotes the running time of M on input (x, w).
- Computational soundness: *For every polynomial size circuit family $\{P_n^*\}_{n\in N}$, and every triplet $(M, x, t) \in \{0,1\}^n \setminus L_{\mathcal{U}}$,*

$$\Pr[(P_n^*, V)(M, x, t) = 1] < \nu(n),$$

  where $\nu(\cdot)$ is a negligible function.
- Weak proof of knowledge: *For every positive polynomial p there exist a positive polynomial p' and a probabilistic polynomial-time oracle machine E such that the following holds: for every polynomial-sized circuit family $\{P_n^*\}_{n\in N}$, and every sufficiently long $y = (M, x, t) \in \{0,1\}^*$, if $\Pr[(P_n^*, V)(y) = 1] > 1/p(|y|)$, then*

$$\Pr[\exists w = w_1, \ldots w_t \in R_{\mathcal{U}}(y) \text{ so that } \forall i \in [t],\ E_r^{P_n^*}(y, i) = w_i] > \frac{1}{p'(|y|)},$$

  where $R_{\mathcal{U}}(y) \stackrel{\text{def}}{=} \{w : (y, w) \in R_{\mathcal{U}}\}$ and $E_r^{P_n^*}(\cdot, \cdot)$ denotes the function defined by fixing the random tape of E to equal r and providing the resulting E_r with oracle access to P_n^*.

2.8. Commitment schemes. Commitment schemes are used to enable a party, known as the *sender*, to commit itself to a value while keeping it secret from the *receiver* (this property is called *hiding*). Furthermore, the commitment is *binding*, and thus in a later stage, when the commitment is opened, it is guaranteed that the "opening" can yield only a single value determined in the committing phase. Commitment schemes come in two different flavors, *statistically binding* and *statistically hiding*. We sketch the properties of each one of these flavors. Full definitions can be found in [18].

[1] Furthermore, every language in $\mathcal{NEXP}$ is polynomial-time (but not linear-time) reducible to $L_{\mathcal{U}}$.

Statistically binding: In statistically binding commitments, the binding property holds against unbounded adversaries, while the hiding property holds only against computationally bounded (nonuniform) adversaries. The statistical-binding property asserts that, with overwhelming probability over the coin tosses of the receiver, the transcript of the interaction fully determines the value committed to by the sender. The computational-hiding property guarantees that the commitments to any two different values are computationally indistinguishable.

Statistically hiding: In statistically hiding commitments, the hiding property holds against unbounded adversaries, while the binding property holds only against computationally bounded (nonuniform) adversaries. Loosely speaking, the statistical-hiding property asserts that commitments to any two different values are statistically close (i.e., have negligible statistical distance). In case the statistical distance is 0, the commitments are said to be *perfectly hiding*. The computational-binding property guarantees that no polynomial-time machine is able to open a given commitment in two different ways.

Noninteractive statistically binding commitment schemes can be constructed using any 1-1 one-way function (see section 4.4.1 of [18]). Allowing some minimal interaction (in which the receiver first sends a single random initialization message), statistically binding commitment schemes can be obtained from any one-way function [31, 26]. We will think of such commitments as a *family* of noninteractive commitments, where the description of members in the family will be the initialization message. Perfectly hiding commitment schemes can be constructed from any one-way permutation [32]. However, *constant-round* schemes are known to exist only under stronger assumptions, specifically, assuming the existence of a collection of certified claw-free functions [19].

3. Nonmalleable protocols. The notion of nonmalleability was introduced by Dolev, Dwork, and Naor [14]. In this paper we focus on nonmalleability of zero-knowledge proofs and of string commitment. The definitions are stated in terms of interactive proofs, though what we actually construct are nonmalleable argument systems. The adaptation of the definitions to the case of arguments can be obtained by simply replacing the word "proof" with "argument," whenever it appears.

In principle, our definitions are compatible with the ones appearing in [14]. However, the presentation is more detailed and somewhat different (see section 3.4 for a discussion on the differences between our definition and previous ones).

3.1. Nonmalleable interactive proofs. Let $\langle P, V\rangle$ be an interactive proof. Consider a scenario where a man-in-the-middle adversary A is simultaneously participating in two interactions. These interactions are called the *left* and the *right* interaction. In the left interaction the adversary A is verifying the validity of a statement x by interacting with an honest prover P. In the right interaction A proves the validity of a statement $\tilde{x}$ to the honest verifier V. The statement $\tilde{x}$ is chosen by A, possibly depending on the messages it receives in the left interaction.

Besides controlling the messages sent by the verifier in the left interaction and by the prover in the right interaction, A has control over the scheduling of the messages. In particular, it may delay the transmission of a message in one interaction until it receives a message (or even multiple messages) in the other interaction. Figure 2 describes two representative scheduling strategies.

The interactive proof $\langle P, V\rangle$ is said to be *nonmalleable* if, whenever $x \neq \tilde{x}$, the left interaction does not "help" the adversary in convincing the verifier in the right

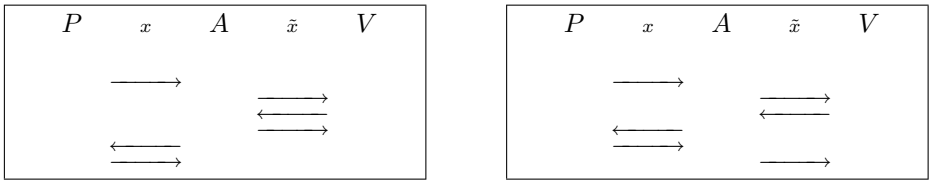


FIG. 2. *Two scheduling strategies.*

interaction.[2] Following the simulation paradigm [24, 25, 21], this is formalized by defining appropriate "real" and "idealized" executions. In the real execution, called the *man-in-the-middle* execution, the adversary participates in both the left and the right interactions with common inputs x and $\tilde{x}$, respectively. In the idealized execution, called the *stand-alone* execution, the adversary is playing the role of the prover in a single interaction with common input $\tilde{x}$. Security is defined by requiring that the adversary cannot succeed better in the man-in-the middle execution than he could have done in the stand-alone execution. More formally, we consider the following two executions.

Man-in-the-middle execution. The man-in-the-middle execution consists of the scenario described above. The input of P is an instance-witness pair (x, w), and the input of V is an instance $\tilde{x}$. A receives x and an auxiliary input z. Let $\mathsf{mim}_V^A(x, w, z)$ be a random variable describing the output of V in the above experiment when the random tapes of P, A, and V are uniformly and independently chosen. In case that $x = \tilde{x}$, the view $\mathsf{mim}_V^A(x, w, z)$ is defined to be $\perp$.

Stand-alone execution. In the stand-alone execution only one interaction takes place. The stand-alone adversary S interacts directly with the honest verifier V. As in the man-in-the-middle execution, V receives as input an instance $\tilde{x}$. S receives instances $x, \tilde{x}$ and auxiliary input z. Let $\mathsf{sta}_V^S(x, \tilde{x}, z)$ be a random variable describing the output of V in the above experiment when the random tapes of S and V are uniformly and independently chosen.

DEFINITION 3.1 (nonmalleable interactive proof). *An interactive proof $\langle P, V\rangle$ for a language L is said to be nonmalleable if, for every probabilistic polynomial-time man-in-the-middle adversary A, there exist a probabilistic expected polynomial-time stand-alone prover S and a negligible function $\nu : N \to N$ such that, for every $(x, w) \in L \times R_L(x)$, every $\tilde{x} \in \{0,1\}^{|x|}$ so that $\tilde{x} \neq x$, and every $z \in \{0,1\}^*$,*

$$\Pr\left[\mathsf{mim}_V^A(x, \tilde{x}, w, z) = 1\right] \;<\; \Pr\left[\mathsf{sta}_V^S(x, \tilde{x}, z) = 1\right] \;+\; \nu(|x|).$$

Nonmalleability with respect to tags. Definition 3.1 rules out the possibility that the statement proved on the right interaction is identical to the one on the left. Indeed, if the same protocol is executed on the left and on the right, this kind of attack cannot be prevented, as the man-in-the-middle adversary can always copy messages between the two executions (cf. the chess-master problem [14]). Still, in many situations it might be important to be protected against an attacker that attempts to prove even the same statement. In order to deal with this problem, one could instead consider a "tag-based" variant of nonmalleability (see [28] for a definition of tag-based nonmalleability in the context of encryption).

[2]Notice that requiring that $x \neq \tilde{x}$ is necessary, since otherwise the adversary can succeed in convincing the verifier in the right interaction by simply forwarding messages back and forth between the interactions.

We consider a family of interactive proofs, where each member of the family is labeled with a tag string $\text{TAG} \in \{0,1\}^m$, and $t = t(n)$ is a parameter that potentially depends on the length of the common input (security parameter) $n \in N$. As before, we consider a MIM adversary A that is simultaneously participating in a left and a right interaction. In the left interaction, A is verifying the validity of a statement x by interacting with a prover P_{TAG} while using a protocol that is labeled with a string TAG. In the right interaction A proves the validity of a statement $\tilde{x}$ to the honest verifier $V_{\text{T}\tilde{\text{A}}\text{G}}$ while using a protocol that is labeled with a string $\text{T}\tilde{\text{A}}\text{G}$. Let $\mathsf{mim}_V^A(\text{TAG}, \text{T}\tilde{\text{A}}\text{G}, x, \tilde{x}, w, z)$ be a random variable describing the output of V in the man-in-the-middle experiment. The stand-alone execution is defined as before with the only difference being that, in addition to their original inputs, the parties also obtain the corresponding tags. Let $\mathsf{sta}_V^S(\text{TAG}, \text{T}\tilde{\text{A}}\text{G}, x, \tilde{x}, z)$ be a random variable describing the output of V in the stand-alone experiment.

The definition of nonmalleability with respect to tags is essentially identical to Definition 3.1. The only differences in the definition is that, instead of requiring nonmalleability (which compares the success probability of $\mathsf{mim}_V^A(\text{TAG}, \text{T}\tilde{\text{A}}\text{G}, x, \tilde{x}, w, z)$ and $\mathsf{sta}_V^S(\text{TAG}, \text{T}\tilde{\text{A}}\text{G}, x, \tilde{x}, z)$) whenever $x \neq \tilde{x}$, we will require nonmalleability whenever $\text{TAG} \neq \text{T}\tilde{\text{A}}\text{G}$. For convenience, we repeat the definition.

DEFINITION 3.2 (tag-based nonmalleable interactive proofs). *A family of interactive proofs $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ for a language L is said to be nonmalleable with respect to tags of length m if, for every probabilistic polynomial-time man-in-the-middle adversary A, there exist a probabilistic expected polynomial-time stand-alone prover S and a negligible function $\nu : N \to N$ such that, for every $(x, w) \in L \times R_L(x)$, every $\tilde{x} \in \{0,1\}^{|x|}$, every $\text{TAG}, \text{T}\tilde{\text{A}}\text{G} \in \{0,1\}^m$ so that $\text{TAG} \neq \text{T}\tilde{\text{A}}\text{G}$, and every $z \in \{0,1\}^*$,*

$$\Pr\left[\mathsf{mim}_V^A(\text{TAG}, \text{T}\tilde{\text{A}}\text{G}, x, \tilde{x}, w, z) = 1\right] \;<\; \Pr\left[\mathsf{sta}_V^S(\text{TAG}, \text{T}\tilde{\text{A}}\text{G}, x, \tilde{x}, z) = 1\right] \;+\; \nu(|x|).$$

Tags vs. statements. A nonmalleable interactive proof can be turned into a tag-based one by simply concatenating the tag to the statement being proved. On the other hand, an interactive proof that is nonmalleable with respect to tags of length $t(n) = n$ can be turned into a nonmalleable interactive proof by using the statement $x \in \{0,1\}^n$ as the tag.

The problem of constructing a tag-based nonmalleable interactive proof is already nontrivial for tags of length, say $t(n) = O(\log n)$ (and even for $t(n) = O(1)$), but is still potentially easier than for tags of length n. This opens up the possibility of reducing the construction of interactive proofs that are nonmalleable with respect to long tags into interactive proofs that are nonmalleable with respect to shorter tags. Even though we do not know whether such a reduction is possible in general, our work follows this path and demonstrates that in specific cases such a reduction is indeed possible.

Nonmalleability with respect to other protocols. Our definitions of nonmalleability refer to protocols that are nonmalleable *with respect to themselves*, since the definitions consider a setting where the same protocol is executed in the left and the right interaction. In principle, one could consider two different protocols that are executed on the left and on the right which are nonmalleable *with respect to each other*. Such definitions are not considered in this work.

3.2. Nonmalleable zero-knowledge. Nonmalleable $\mathcal{ZK}$ proofs are nonmalleable interactive proofs that additionally satisfy the $\mathcal{ZK}$ property (as stated in Definition 2.4).

DEFINITION 3.3 (nonmalleable zero-knowledge). *A family* $\{\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle\}_{\text{TAG}\in\{0,1\}^*}$ *of interactive proofs is said to be nonmalleable zero-knowledge if it is both nonmalleable and zero-knowledge.*

3.3. Nonmalleable commitments. Informally, a commitment scheme is nonmalleable if a man-in-the-middle adversary that receives a commitment to a value v will not be able to "successfully" commit to a related value $\tilde{v}$. The literature discusses two different interpretations of the term "success."

Nonmalleability with respect to commitment [14]. The adversary is said to succeed if it manages to commit to a related value, even without being able to later decommit to this value. This notion makes sense only in the case of statistically binding commitments.

Nonmalleability with respect to opening [13]. The adversary is said to succeed only if it is able to both commit and decommit to a related value. This notion makes sense both in the case of statistically binding and statistically hiding commitments.

As in the case of nonmalleable zero-knowledge, we formalize the definition by comparing a man-in-the-middle and a stand-alone execution. Let $n \in N$ be a security parameter. Let $\langle C, R\rangle$ be a commitment scheme, and let $\mathcal{R} \subseteq \{0,1\}^n \times \{0,1\}^n$ be a polynomial-time computable irreflexive relation (i.e., $\mathcal{R}(v,v) = 0$). As before, we consider man-in-the-middle adversaries that are simultaneously participating in a left and a right interaction in which a commitment scheme is taking place. The adversary is said to succeed in mauling a left commitment to a value v if he is able to come up with a right commitment to a value $\tilde{v}$ such that $\mathcal{R}(v,\tilde{v}) = 1$. Since we cannot rule out copying, we will be interested only in relations where copying is not considered success, and we therefore require that the relation $\mathcal{R}$ is irreflexive. The man-in-the-middle and the stand-alone executions are defined as follows.

The man-in-the-middle execution. In the man-in-the-middle execution, the man-in-the-middle adversary A is simultaneously participating in a left and a right interaction. In the left interaction the man-in-the-middle adversary A interacts with C receiving a commitment to a value v. In the right interaction A interacts with R attempting to commit to a related value $\tilde{v}$. Prior to the interaction, the value v is given to C as local input. A receives an auxiliary input z, which in particular might contain a priori information about v.[3] The success of A is defined using the following two Boolean random variables:

- $\mathsf{mim}^A_{com}(\mathcal{R}, v, z) = 1$ if and only if A produces a valid commitment to $\tilde{v}$ such that $\mathcal{R}(v,\tilde{v}) = 1$.
- $\mathsf{mim}^A_{open}(\mathcal{R}, v, z) = 1$ if and only if A decommits to a value $\tilde{v}$ such that $\mathcal{R}(v,\tilde{v}) = 1$.

The stand-alone execution. In the stand-alone execution only one interaction takes place. The stand-alone adversary S interacts directly with R. As in the man-in-the-middle execution, the value v is chosen prior to the interaction and S receives some a priori information about v as part of its an auxiliary input z. S first executes the commitment phase with R. Once the commitment phase has been completed, S receives the value v and attempts to decommit to a value $\tilde{v}$. The success of S is defined using the following two Boolean random variables:

[3] The original definition by Dolev, Dwork, and Naor [14] accounted for such a priori information by providing the adversary with the value $\mathsf{hist}(v)$, where the function $\mathsf{hist}(\cdot)$ is a polynomial-time computable function.

- $\mathsf{sta}^S_{com}(\mathcal{R}, v, z) = 1$ if and only if S produces a valid commitment to $\tilde{v}$ such that $\mathcal{R}(v, \tilde{v}) = 1$.
- $\mathsf{sta}^S_{open}(\mathcal{R}, v, z) = 1$ if and only if A decommits to a value $\tilde{v}$ such that $\mathcal{R}(v, \tilde{v}) = 1$.

DEFINITION 3.4 (nonmalleable commitment). *A commitment scheme $\langle C, R\rangle$ is said to be nonmalleable with respect to commitment if, for every probabilistic polynomial-time man-in-the-middle adversary A, there exist a probabilistic expected polynomial-time stand-alone adversary S and a negligible function $\nu : N \to N$ such that, for every irreflexive polynomial-time computable relation $\mathcal{R} \subseteq \{0,1\}^n \times \{0,1\}^n$, every $v \in \{0,1\}^n$, and every $z \in \{0,1\}^*$, it holds that*

$$\Pr\left[\mathsf{mim}^A_{com}(\mathcal{R}, v, z) = 1\right] \;<\; \Pr\left[\mathsf{sta}^S_{com}(\mathcal{R}, v, z) = 1\right] \;+\; \nu(n).$$

Nonmalleability with respect to opening is defined in the same way while replacing the random variables $\mathsf{mim}^A_{com}(\mathcal{R}, v, z)$ and $\mathsf{sta}^S_{com}(\mathcal{R}, v, z)$ with $\mathsf{mim}^A_{open}(\mathcal{R}, v, z)$ and $\mathsf{sta}^S_{open}(\mathcal{R}, v, z)$.

Content-based vs. tag-based commitments. Similar to the definition of interactive proofs nonmalleable with respect to statements, the above definitions require only that the adversary should not be able to commit to a value that is related, *but different*, from the value it receives a commitment from. Technically, the above fact can be seen from the definitions by noting that the relation $\mathcal{R}$, which defines the success of the adversary, is required to be irreflexive. This means that the adversary is said to fail if it is able only to produce a commitment to the same value.[4] Indeed, if the same protocol is executed in the left and the right interaction, the adversary can always copy messages and succeed in committing to the same value on the right as it receives a commitment from, on the left. To cope with this problem, the definition can be extended to incorporate tags, in analogy with the definition of interactive proofs nonmalleable with respect to tags. The extension is straightforward and therefore omitted.

We note that any commitment scheme that satisfies Definition 3.4 can easily be transformed into a scheme which is tag-based nonmalleable by prepending the tag to the value before committing. Conversely, in analogy with nonmalleable interactive proof, commitment schemes that are nonmalleable with respect to tags of length $t(n) = \text{poly}(n)$ can be transformed into commitment schemes nonmalleable with respect to content in a standard way (see, e.g., [14, 28]).

3.4. Comparison with previous definitions. Our definitions of nonmalleability essentially follow the original definitions by Dolev, Dwork, and Naor [14]. However, whereas the definitions by Dolev, Dwork, and Naor quantify the experiments over all distributions D of inputs for the left and the right interaction (or just left interaction in the case of commitments), we instead quantify over all possible input values $x, \tilde{x}$ (or in the case of commitments over all possible input values v for the left interaction). Our definitions can thus be seen as nonuniform versions of the definitions of [14].

Our definition of nonmalleability with respect to opening is, however, different from the definition of [13] in the following ways: (1) The definition of [13] does not take into account possible a priori information that the adversary might have about

[4] Potentially, one could consider a slightly stronger definition, which also rules out the case when the adversary is able to construct a *different* commitment to the *same* value. Nevertheless, here we adhere to the standard definition of nonmalleable commitments which allows the adversary to produce a different commitment to the same value.

the commitment, while ours (following [14]) does. (2) In our definition of the stand-alone execution the stand-alone adversary receives the value v after having completed the commitment phase and is thereafter supposed to decommit to a value related to v. The definition of [13] does not provide the simulator with this information.

In our view, the "a priori information" requirement is essential in many situations, and we therefore present a definition that satisfies it. (Consider, for example, a setting where the value v committed to is determined by a different protocol, which "leaks" some information about v.) In order to be able to satisfy this stronger requirement we relax the definition of [13] by allowing the stand-alone adversary to receive the value v before decommitting.

3.5. Simulation extractability. A central tool in our constructions of nonmalleable interactive proofs and commitments is the notion of *simulation extractability*. Loosely speaking, an interactive protocol is said to be simulation extractable if, for any man-in-the-middle adversary A, there exists a probabilistic polynomial-time machine (called the simulator-extractor) that can simulate both the left and the right interaction for A, while outputting a witness for the statement proved by the adversary in the right interaction.

Simulation extractability can be thought of as a technical (and stronger) variant of nonmalleability. The main reason for introducing this notion is that it enables a more modular analysis (and in particular is easier to work with). At the end of this section, we argue that any protocol that is simulation extractable is also a nonmalleable zero-knowledge proof of knowledge. In section 6 we show how to use simulation-extractable protocols in order to obtain nonmalleable commitments.

Let A be a man-in-the middle adversary that is simultaneously participating in a left interaction of $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ while acting as verifier and a right interaction of $\langle P_{\tilde{\text{TAG}}}, V_{\tilde{\text{TAG}}} \rangle$ while acting as prover.

Let $view_A(x, z, \text{TAG})$ denote the *joint* view of $A(x, z)$ and the honest verifier $V_{\tilde{\text{TAG}}}$ when A is verifying a left proof of the statement x, using identity TAG, and proving on the right a statement $\tilde{x}$ using identity $\tilde{\text{TAG}}$. (The view consists of the messages sent and received by A in both the left and the right interaction and the random coins of A, and $V_{\tilde{\text{TAG}}}$.)[5] Both $\tilde{x}$ and $\tilde{\text{TAG}}$ are chosen by A. Given a function $t = t(n)$ we use the notation $\{\cdot\}_{z,x,\text{TAG}}$ as shorthand for $\{\cdot\}_{z \in \{0,1\}^*, x \in L, \text{TAG} \in \{0,1\}^{t(|x|)}}$.

DEFINITION 3.5 (simulation-extractable protocol). *A family* $\{\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle\}_{\text{TAG} \in \{0,1\}^*}$ *of interactive proofs is said to be* simulation extractable *with tags of length* $t = t(n)$ *if, for any man-in-the-middle adversary* A*, there exists a probabilistic expected poly-time machine* $\mathcal{S}$ *such that the following hold:*

1. *The probability ensembles* $\{\mathcal{S}_1(x, z, \text{TAG})\}_{x,z,\text{TAG}}$ *and* $\{view_A(x, z, \text{TAG})\}_{x,z,\text{TAG}}$ *are statistically close over* L*, where* $\mathcal{S}_1(x, z, \text{TAG})$ *denotes the first output of* $\mathcal{S}(x, z, \text{TAG})$.
2. *Let* $x \in L, z \in \{0,1\}^*, \text{TAG} \in \{0,1\}^{t(|x|)}$*, and let* $(view, w)$ *denote the output of* $\mathcal{S}(x, z, \text{TAG})$ *(on input some random tape). Let* $\tilde{x}$ *be the right-execution statement appearing in view, and let* $\tilde{\text{TAG}}$ *denote the right-execution tag. Then, if the right execution in view is accepting AND* $\text{TAG} \neq \tilde{\text{TAG}}$*, then* $R_L(\tilde{x}, w) = 1$.

We note that the above definition refers to protocols that are simulation extractable *with respect to themselves*. A stronger variant (which is not considered in

[5] Since the messages sent by A are fully determined given the code of A and the messages it receives, including them as part of the view is somewhat redundant. The reason we have chosen to do so is for convenience of presentation.

the current work) would have required simulation extractability even in the presence of protocols that do not belong to the family.

We next argue that in order to construct nonmalleable zero-knowledge protocols, it will be sufficient to come up with a protocol that is simulation extractable. To do so, we prove that any protocol that is simulation extractable (and has an efficient prover strategy) is also nonmalleable zero-knowledge (i.e., it satisfies Definitions 3.1 and 3.3).

PROPOSITION 3.6. *Let $\{\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle\}_{\text{TAG}\in\{0,1\}^*}$ be a family of simulation-extractable protocols with tags of length $t = t(n)$ (with respect to the language L and the witness relation R_L) with an efficient prover strategy. Then $\{\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle\}_{\text{TAG}\in\{0,1\}^*}$ is also a nonmalleable zero-knowledge (with tags of length t).*

Proof. Let $\{\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle\}_{\text{TAG}\in\{0,1\}^*}$ be a family of simulation-extractable protocols with tags of length t with respect to the language L and the witness relation R_L. We argue that $\{\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle\}_{\text{TAG}\in\{0,1\}^*}$ is both a nonmalleable interactive proof and stand-alone zero-knowledge.

Nonmalleability. Assume for contradiction that there exist a probabilistic poly-time man-in-the-middle adversary A and a polynomial $p(n)$ such that, for infinitely many n, there exist $x, \tilde{x} \in \{0,1\}^n$, $w, z \in \{0,1\}^*$, and $\text{TAG}, \tilde{\text{TAG}} \in \{0,1\}^{t(n)}$ such that $(x, w) \in L \times R_L(x)$, $\text{TAG} \neq \tilde{\text{TAG}}$, and

$$(3.1)\quad \Pr\left[\mathsf{mim}_V^A(\text{TAG}, \tilde{\text{TAG}}, x, \tilde{x}, w, z) = 1\right] \;\geq\; \Pr\left[\mathsf{sta}_V^S(\text{TAG}, \tilde{\text{TAG}}, x, \tilde{x}, z) = 1\right] \;+\; \frac{1}{p(n)}.$$

By Definition 3.5, there exists a probabilistic polynomial-time machine $\mathcal{S}$ for A that satisfies the definition's conditions. We show how to use $\mathcal{S}$ in order to construct a stand-alone prover S for $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$. On input $\text{TAG}, \tilde{\text{TAG}}, x, \tilde{x}, z$, the machine S runs the simulator-extractor $\mathcal{S}$ on input x, z, TAG and obtains the view *view* and witness $\tilde{w}$. In the event that the *view* contains an accepting right execution of the statement $\tilde{x}$ using tag TAG, S executes the honest prover strategy P_{TAG} on input x and the witness w.

It follows directly from the simulation property of $\mathcal{S}$ that the probability that *view* contains an accepting right-execution proof of $\tilde{x}$ using tag $\tilde{\text{TAG}}$ is negligibly close to

$$p_A = \Pr\left[\mathsf{mim}_V^A(\text{TAG}, \tilde{\text{TAG}}, x, \tilde{x}, w, z) = 1\right].$$

Since $\mathcal{S}$ always outputs a witness when the right execution is accepting and the tag of the right execution is different from the tag of the left execution, we conclude that the success probability of S is also negligibly close to p_A (since $\text{TAG} \neq \tilde{\text{TAG}}$). This contradicts (3.1).

Zero-knowledge. Consider any probabilistic poly-time verifier V^*. Construct the man-in-the-middle adversary A that internally incorporates V and relays its left execution unmodified to V^*. In the right execution, A simply outputs $\perp$. By the simulation-extractability property of $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$, there exists a simulator-extractor $\mathcal{S}$ for A. We describe a simulator S for V^*.

On input x, z, TAG, S runs $\mathcal{S}$ on input x, z, TAG to obtain (view, w). Given the view *view*, S outputs the view of V^* in *view* (which is a subset of *view*). It follows directly from the simulation property of $\mathcal{S}$, and from the fact that S outputs an (efficiently computable) subset of *view*, that the output of S is indistinguishable from the view of V^* in an honest interaction with a prover. ∎

4. A simulation-extractable protocol. We now turn to describing our construction of simulation-extractable protocols. At a high level, the construction proceeds in two steps:

1. For any $n \in N$, construct a family $\{\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle\}_{\mathsf{tag}\in[2n]}$ of simulation-extractable arguments with tags of length $t(n) = \log n + 1$.
2. For any $n \in N$, use the family $\{\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle\}_{\mathsf{tag}\in[2n]}$ to construct a family $\{\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle\}_{\text{TAG}\in\{0,1\}^n}$ of simulation-extractable arguments with tags of length $t(n) = 2^n$.

The construction of the family $\{\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle\}_{\mathsf{tag}\in[2n]}$ relies on Barak's nonblack-box techniques for obtaining the constant-round public-coin $\mathcal{ZK}$ argument for $\mathcal{NP}$ [1], and they are very similar in structure to the $\mathcal{ZK}$ protocols used by Pass in [35]. We start by reviewing the ideas underlying Barak's protocol. We then proceed to presenting our protocols.

4.1. Barak's nonblack-box protocol. Barak's protocol is designed to allow the simulator access to "trapdoor" information that is not available to the prover in actual interactions. Given this "trapdoor" information, the simulator will be able to produce convincing interactions even without possessing a witness for the statement being proved. The high-level idea is to enable the usage of the verifier's code as a "fake" witness in the proof. In the case of the honest verifier V (which merely sends over random bits), the code consists of the verifier's random tape. In the case of a malicious verifier V^*, the code may also consist of a program that generates the verifier's messages (based on previously received messages).

Since the actual prover does not have a priori access to V's code in real interactions, this will not harm the soundness of the protocol. The simulator, on the other hand, will be always able to generate transcripts in which the verifier accepts since, by definition, it obtains V^*'s code as input.

Let $n \in N$, and let $T : N \to N$ be a "nice" function that satisfies $T(n) = n^{\omega(1)}$. To make the above ideas work, Barak's protocol relies on a "special" $\mathbf{NTIME}(T(n))$ relation. It also makes use of a witness-indistinguishable universal argument ($WIUARG$) [16, 15, 27, 30, 3]. We start by describing a variant of Barak's relation, which we denote by R_{sim}. Usage of this variant will facilitate the presentation of our ideas in later stages.

Let $\{\mathcal{H}_n\}_n$ be a family of hash functions where a function $h \in \mathcal{H}_n$ maps $\{0,1\}^*$ to $\{0,1\}^n$ (cf. [29, 8]), and let Com be a statistically binding commitment scheme for strings of length n, where, for any $\alpha \in \{0,1\}^n$, the length of $\text{Com}(\alpha)$ is upper bounded by $2n$. The relation R_{sim} is described in Figure 3.

Instance: A triplet $\langle h, c, r\rangle \in \mathcal{H}_n \times \{0,1\}^n \times \{0,1\}^{\text{poly}(n)}$.

Witness: A program $\Pi \in \{0,1\}^*$, a string $y \in \{0,1\}^*$, and a string $s \in \{0,1\}^{\text{poly}(n)}$.

Relation: $\mathbf{R}_{sim}(\langle h, c, r\rangle, \langle \Pi, y, s\rangle) = 1$ if and only if the following hold:

1. $|y| \le |r| - n$.
2. $c = \text{Com}(h(\Pi); s)$.
3. $\Pi(y) = r$ within $T(n)$ steps.

FIG. 3. *R_{sim}: a variant of Barak's relation.*

Remark 4.1 (simplifying assumptions). The relation presented in Figure 3 is slightly oversimplified and will make Barak's protocol work only when $\{\mathcal{H}_n\}_n$ is

collision resistant against "slightly" superpolynomial-sized circuits [1]. To make it work assuming collision resistance against polynomial-sized circuits, one should use a "good" error-correcting code ECC (i.e., with constant distance and with polynomial-time encoding and decoding) and replace the condition $c = \mathrm{Com}(h(\Pi); s)$ with $c = \mathrm{Com}(h(\mathtt{ECC}(\Pi)); s)$ [3]. We also assume that Com is a one-message commitment scheme. Such schemes can be constructed based on any 1-1 one-way function. At the cost of a small complication, the one-message scheme could have been replaced by the two-message commitment scheme of [31], which can be based on "ordinary" one-way functions [26].

Let L be any language in $\mathcal{NP}$, let $n \in N$, and let $x \in \{0,1\}^n$ be the common input for the protocol. The idea is to have the prover claim (in a witness-indistinguishable fashion) that either $x \in L$, or that $\langle h, c, r\rangle$ belongs to the language L_{sim} that corresponds to R_{sim}, where $\langle h, c, r\rangle$ is a triplet that is jointly generated by the prover and the verifier. As will turn out from the analysis, no polynomial-time prover will be able to make $\langle h, c, r\rangle$ belong to L_{sim}. The simulator, on the other hand, will use the verifier's program in order to make sure that $\langle h, c, r\rangle$ is indeed in L_{sim} (while also possessing a witness for this fact).

A subtle point to be taken into consideration is that the verifier's running time (program size) is not a priori bounded by any specific polynomial (this is because the adversary verifier might run in arbitrary polynomial time). This imposes a choice of $T(n) = n^{\omega(1)}$ in R_{sim} and implies that the corresponding language does not lie in $\mathcal{NP}$ (but rather in $\mathbf{NTIME}(n^{\omega(1)})$). Such languages are beyond the scope of the "traditional" witness-indistinguishable proof systems (which were originally designed to handle "only" $\mathcal{NP}$ languages) and will thus require the usage of a witness-indistinguishable universal argument. Barak's protocol is described in Figure 4.

Common Input: An instance $x \in \{0,1\}^n$.

Security parameter: 1^n.

Stage 1:

$V \to P$: Send $h \overset{\mathrm{R}}{\leftarrow} \mathcal{H}_n$.
$P \to V$: Send $c = \mathrm{Com}(0^n)$.
$V \to P$: Send $r \overset{\mathrm{R}}{\leftarrow} \{0,1\}^{3n}$.

Stage 2 (Body of the proof):

$P \Leftrightarrow V$: A *WI UARG* $\langle P_{UA}, V_{UA}\rangle$ proving the OR of the following statements:
1. $\exists\ w \in \{0,1\}^{\mathrm{poly}(|x|)}$ so that $R_L(x, w) = 1$.
2. $\exists\ \langle \Pi, y, s\rangle$ so that $R_{sim}(\langle h, c, r\rangle, \langle \Pi, y, s\rangle) = 1$.

FIG. 4. *Barak's ZK argument for* $\mathcal{NP}$: $\langle P_B, V_B\rangle$.

Soundness. The idea behind the soundness of $\langle P_B, V_B\rangle$ is that any program Π (be it efficient or not) has only one output for any given input. This means that Π, when fed with an input y, has probability 2^{-3n} to "hit" a string $r \overset{\mathrm{R}}{\leftarrow} \{0,1\}^{3n}$. Since the prover sends c before actually receiving r, and since R_{sim} imposes $|y| \le |r| - n = n$, then it is not able to "arrange" that both $c = \mathrm{Com}(h(\Pi))$ and $\Pi(y) = r$ with probability significantly greater than $2^{2n} \cdot 2^{-3n} = 2^{-n}$ (as $|c| \le 2n$). The only way for a prover to make the honest verifier accept in the *WIUARG* is thus to use a witness w for R_L. This guarantees that, whenever the verifier is convinced, it is indeed the case that $x \in L$.

Zero-knowledge. Let V^* be the program of a potentially malicious verifier. The $\mathcal{ZK}$ property of $\langle P_B, V_B\rangle$ follows by letting the simulator set $\Pi = V^*$ and $y = c$. Since $|c| \leq 2n \leq |r| - n$, and since, by definition, $V^*(c)$ always equals r, the simulator can set $c = \mathrm{Com}(h(V^*); s)$ in Stage 1 and use the triplet $\langle V^*, c, s\rangle$ as a witness for R_{sim} in the $WIUARG$. This enables the simulator to produce convincing interactions, even without knowing a valid witness for $x \in L$. The $\mathcal{ZK}$ property then follows (with some work) from the hiding property of Com and the $\mathcal{WI}$ property of $\langle P_{UA}, V_{UA}\rangle$.

4.2. A "special-purpose" universal argument. Before we proceed with the construction of our new protocol, we will need to present a universal argument that is specially tailored for our purposes. The main distinguishing features of this universal argument, which we call the *special-purpose* argument, are the following: (1) it is *statistically* witness indistinguishable; and (2) it will enable us to prove that our protocols satisfy the proof of knowledge property of Definition 2.7.[6]

Let **Com** be a statistically hiding commitment scheme for strings of length n. Let $\mathbf{R}_{sim}$ be a variant of the relation R_{sim} (from Figure 3) in which the statistically binding commitment Com is replaced with the commitment **Com**, let $\langle P_{sWI}, V_{sWI}\rangle$ be a statistical witness-indistinguishable argument of knowledge and let $\langle P_{UA}, V_{UA}\rangle$ be a four-message, public-coin universal argument where the length of the messages is upper bounded by n.[7] The special-purpose $UARG$, which we denote by $\langle P_{sUA}, V_{sUA}\rangle$, handles statements of the form $(x, \langle h, c_1, c_2, r_1, r_2\rangle)$, where the triplets $\langle h, c_1, r_1\rangle$ and $\langle h, c_2, r_2\rangle$ correspond to instances for $\mathbf{R}_{sim}$. The protocol $\langle P_{sUA}, V_{sUA}\rangle$ is described in Figure 5.

Parameters: Security parameter 1^n.
Common Input: $x \in \{0,1\}^n$, $\langle h, c_1, c_2, r_1, r_2\rangle$, where, for $i \in \{1,2\}$, $\langle h, c_i, r_i\rangle$ is an instance for $\mathbf{R}_{sim}$.
Stage 1 (Encrypted UARG):
$V \to P$: Send $\alpha \stackrel{R}{\leftarrow} \{0,1\}^n$.
$P \to V$: Send $\widehat{\beta} = \mathbf{Com}(0^n)$.
$V \to P$: Send $\gamma \stackrel{R}{\leftarrow} \{0,1\}^n$.
$P \to V$: Send $\widehat{\delta} = \mathbf{Com}(0^n)$.
Stage 2 (Body of the proof):
$P \leftrightarrow V$: A statistical $WIAOK$ $\langle P_{sWI}, V_{sWI}\rangle$ proving the OR of the following statements:
1. $\exists\, w \in \{0,1\}^{\mathrm{poly}(|x|)}$ so that $R_L(x, w) = 1$.
2. $\exists\, \langle \beta, \delta, s_1, s_2\rangle$ so that the following hold:
   - $\widehat{\beta} = \mathbf{Com}(\beta; s_1)$.
   - $\widehat{\delta} = \mathbf{Com}(\delta; s_2)$.
   - $(\alpha, \beta, \gamma, \delta)$ is an accepting transcript for $\langle P_{UA}, V_{UA}\rangle$ proving the following statement:
     – $\exists\, \langle i, \Pi, y, s\rangle$ so that $\mathbf{R}_{sim}(\langle h, c_i, r_i\rangle, \langle \Pi, y, s\rangle) = 1$.

FIG. 5. *A special-purpose universal argument* $\langle P_{sUA}, V_{sUA}\rangle$.

[6] The "weak" proof of knowledge property of a universal argument (as defined in [3]) is not sufficient for our purposes. Specifically, while in a weak proof of knowledge it is required that the extractor succeeds with probability that is polynomially related to the success probability of the prover, in our proof of security we will make use of an extractor that succeeds with probability negligibly close to the success probability of the prover.

[7] Both statistical witness-indistinguishable arguments of knowledge and four-message, public-coin, universal arguments can be constructed assuming a family $\mathcal{H}_n$ of standard collision-resistant hash functions (cf. [18] and [27, 30, 3]).

4.3. A family of $2n$ protocols. We next present $\{\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle\}_{\mathsf{tag}\in[2n]}$, a family of protocols with tags of length $t(n) = \log n + 1$.[8] The protocols are based on $\langle P_B, V_B\rangle$, and are a variant of the $\mathcal{ZK}$ protocols introduced by Pass [35]. There are two key differences between $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$ and $\langle P_B, V_B\rangle$: in the $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$ protocol (1) the prover (simulator) is given two opportunities to guess the verifier's "next message," and (2) the *lengths* of the verifier's "next messages" depend on the tag of the protocol. We mention that the idea of using a multiple slot version of $\langle P_B, V_B\rangle$ already appeared in [36, 35], and the message-length technique appeared in [35]. However, our protocols $\{\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle\}_{\mathsf{tag}\in[2n]}$ differ from the protocol of [35] in two aspects: our protocols are required to satisfy (1) a *statistical* secrecy property and (2) a *proof of knowledge* property. Towards this end, we replace the statistically binding commitments, Com, used in the presentation of $\langle P_B, V_B\rangle$ with statistically hiding commitments and replace the use of a $WIUARG$ with the use of a "special-purpose" $UARG$. Let **Com** be a statistically hiding commitment scheme for strings of length n, where, for any $\alpha \in \{0,1\}^n$, the length of $\mathbf{Com}(\alpha)$ is upper bounded by $2n$. Let $\mathbf{R}_{sim}$ be the statistical variant of the relation R_{sim}, and let $\langle P_{sUA}, V_{sUA}\rangle$ be the special-purpose universal argument (both $\mathbf{R}_{sim}$ and $\langle P_{sUA}, V_{sUA}\rangle$ are described in section 4.2). Protocol $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$ is described in Figure 6.

Common Input: An instance $x \in \{0,1\}^n$.

Parameters: Security parameter 1^n, length parameter $\ell(n)$.

Tag String: $\mathsf{tag} \in [2n]$.

Stage 0 (Setup):

$V \to P$: Send $h \overset{\mathrm{R}}{\leftarrow} \mathcal{H}_n$.

Stage 1 (Slot 1):

$P \to V$: Send $c_1 = \mathbf{Com}(0^n)$.

$V \to P$: Send $r_1 \overset{\mathrm{R}}{\leftarrow} \{0,1\}^{\mathsf{tag}\cdot\ell(n)}$.

Stage 1 (Slot 2):

$P \to V$: Send $c_2 = \mathbf{Com}(0^n)$.

$V \to P$: Send $r_2 \overset{\mathrm{R}}{\leftarrow} \{0,1\}^{(2n+1-\mathsf{tag})\cdot\ell(n)}$.

Stage 2 (Body of the proof):

$P \Leftrightarrow V$: A special-purpose $UARG$ $\langle P_{sUA}, V_{sUA}\rangle$ proving the OR of the following statements:

1. $\exists\ w \in \{0,1\}^{\mathrm{poly}(|x|)}$ so that $R_L(x,w) = 1$.
2. $\exists\ \langle \Pi, y, s\rangle$ so that $\mathbf{R}_{Sim}(\langle h, c_1, r_1\rangle, \langle \Pi, y, s\rangle) = 1$.
3. $\exists\ \langle \Pi, y, s\rangle$ so that $\mathbf{R}_{Sim}(\langle h, c_2, r_2\rangle, \langle \Pi, y, s\rangle) = 1$.

FIG. 6. *Protocol* $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$.

Note that the only difference between two protocols $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$ and $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}}\rangle$ is the length of the verifier's "next messages": in fact, the length of those messages in $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$ is a parameter that depends on tag (as well as on the length parameter $\ell(n)$). This property will be crucial for the analysis of these protocols in the man-in-the-middle setting.

Using similar arguments to the ones used for $\langle P_B, V_B\rangle$, it can be shown that

[8] A closer look at the construction will reveal that it will in fact work for any $t(n) = O(\log n)$. The choice of $t(n) = \log n + 1$ is simply made for the sake of concreteness (as in our constructions it is the case that $\mathsf{tag} \in [2n]$).

$\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ is computationally sound. The main difference to be taken into consideration is the existence of multiple slots in Stage 1 (see Lemma A.1 for a proof of an even stronger statement).

The $\mathcal{ZK}$ property of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ is proved exactly as in the case of $\langle P_B, V_B \rangle$ by letting the simulator pick either $i = 1$ or $i = 2$ and using $\langle V^*, c_i, s_i \rangle$ as the witness for $\langle h, c_i, r_i \rangle \in L_{sim}$ (where L_{sim} is the language that corresponds to $\mathbf{R}_{sim}$). Since for every $\mathsf{tag} \in [m]$, $|r_i| - |c_i| \geq \ell(n) - 2n$, we have that, as long as $\ell(n) \geq 3n$, the protocol $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ is indeed $\mathcal{ZK}$.

We wish to highlight some useful properties of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$. These properties will turn out to be relevant when dealing with a man in the middle.

Freedom in the choice of slot: The simulator described above has the freedom to choose which $i \in \{1, 2\}$ it will use in order to satisfy the relation $\mathbf{R}_{sim}$. In particular, for the simulation to succeed, it is sufficient that $\langle h, c_i, r_i \rangle \in L_{sim}$ for *some* $i \in \{1, 2\}$.

Using a longer y in the simulation: The stand-alone analysis of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ requires only $\ell(n) \geq 3n$. Allowing larger values of $\ell(n)$ opens the possibility of using a longer y in the simulation. This will turn out to be useful if the verifier is allowed to receive "outside" messages that do not belong to the protocol (as occurs in the man-in-the-middle setting).

Statistical secrecy: The output of the simulator described above is *statistically* close to real interactions (whereas the security guaranteed in $\langle P_B, P_B \rangle$ is only computational). A related property will turn out to be crucial for the use of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ as a subroutine in higher-level applications (such as nonmalleable commitments).

Proof of knowledge: $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ is a proof of knowledge. That is, for any prover P^* and for any $x \in \{0,1\}^n$, if P^* convinces the honest verifier V that $x \in L$ with nonnegligible probability, then one can extract a witness w that satisfies $R_L(x, w) = 1$ in (expected) polynomial time.

4.4. A family of 2^n protocols. The protocol family $\{\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle\}_{\mathsf{tag} \in [2n]}$ is replied upon to show how to construct a family $\{\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle\}_{\text{TAG} \in \{0,1\}^n}$ with tags of length $t(n) = n$. The protocols are *constant round* and involve n parallel executions of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$, with appropriately chosen tags. This new family of protocols is denoted $\{\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle\}_{\text{TAG} \in \{0,1\}^n}$ and is described in Figure 7.

Common Input: An instance $x \in \{0,1\}^n$.

Parameters: Security parameter 1^n, length parameter $\ell(n)$.

Tag String: $\text{TAG} \in \{0,1\}^n$. Let $\text{TAG} = \text{TAG}_1, \ldots, \text{TAG}_n$.

The protocol:

$P \leftrightarrow V$: For all $i \in \{1, \ldots, n\}$ (in parallel) do the following:
1. Set $\mathsf{tag}_i = (i, \text{TAG}_i)$.
2. Run $\langle P_{\mathsf{tag}_i}, V_{\mathsf{tag}_i} \rangle$ with common input x and length parameter $\ell(n)$.

V: Accept if and only if all runs are accepting.

FIG. 7. *Protocol* $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$.

Notice that $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ has a constant number of rounds (since each $\langle P_{\mathsf{tag}_i}, V_{\mathsf{tag}_i} \rangle$ is constant round). Also notice that, for $i \in [n]$, the length of $\mathsf{tag}_i = (i, \text{TAG}_i)$ is

$$|i| + |\text{TAG}_i| = \log n + 1 = \log(2n).$$

Viewing (i, TAG_i) as elements in $[2n]$ we infer that the length of verifier messages in $\langle P_{\mathsf{tag}_i}, V_{\mathsf{tag}_i} \rangle$ is upper bounded by $2n\ell(n)$. Hence, as long as $\ell(n) = \text{poly}(n)$, the length of verifier messages in $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ is $2n^2\ell(n) = \text{poly}(n)$.

We now turn to showing that, for any $\text{TAG} \in 2^n$, the protocol $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ is an interactive argument. In fact, what we show is a stronger statement. Namely, the protocols $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ are proofs (actually arguments) of knowledge (as in Definition 2.7). For simplicity of exposition, we will show how to prove the above assuming a family of hash functions that is collision resistant against $T(n) = n^{\omega(1)}$-sized circuits. As mentioned in Remark 4.1, by slightly modifying $\mathbf{R}_{sim}$, one can prove the same statement under the more standard assumption of collision resistance against polynomial-sized circuits.

PROPOSITION 4.2 (argument of knowledge). *Let $\langle P_{sWI}, V_{sWI} \rangle$ and $\langle P_{UA}, V_{UA} \rangle$ be the protocols used in the construction of $\langle P_{sUA}, V_{sUA} \rangle$. Suppose that $\{\mathcal{H}_n\}_n$ is collision resistant for $T(n)$-sized circuits, that* **Com** *is statistically hiding, that $\langle P_{sWI}, V_{sWI} \rangle$ is a statistical witness-indistinguishable argument of knowledge, and that $\langle P_{UA}, V_{UA} \rangle$ is a universal argument. Then, for any $\text{TAG} \in \{0,1\}^n$, $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ is an interactive argument of knowledge.*

Similar arguments to the ones used to prove Proposition 4.2 have already appeared in the works of Barak [1] and Barak and Goldreich [3]. While our proof builds on these arguments, it is somewhat more involved. For the sake of completeness, the full proof appears in the appendix.

5. Proving simulation extractability. Our central technical lemma states that the family of protocols $\{\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle\}_{\text{TAG} \in \{0,1\}^n}$ is simulation extractable. As shown in Proposition 3.6 this implies that these protocols are also nonmalleable zero-knowledge.

LEMMA 5.1 (simulation extractability). *Suppose that* **Com** *are statistically hiding, that $\{\mathcal{H}_n\}_n$ is a family of collision-resistant hash functions, that $\langle P_{UA}, V_{UA} \rangle$ is a special-purpose $WIUARG$, and that $\ell(n) \geq 2n^2 + 2n$. Then $\{\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle\}_{\text{TAG} \in \{0,1\}^n}$ is simulation extractable.*

The proof of Lemma 5.1 is fairly complex. To keep things manageable, we first give an overview of the proof, describing the key ideas used for establishing the simulation extractability of the family $\{\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle\}_{\mathsf{tag} \in [2n]}$. This is followed by a full proof for the case of $\{\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle\}_{\text{TAG} \in \{0,1\}^n}$.

5.1. Proof overview. Consider a man-in-the-middle adversary A that is playing the role of the verifier of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ in the left interaction while simultaneously playing the role of the prover of $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}} \rangle$ in the right interaction. Recall that in order to prove simulation extractability we have to show that, for any such A, there exists a combined simulator-extractor $\mathcal{S} = (\mathsf{SIM}, \mathsf{EXT})$ that is able to simulate both the left and the right interactions for A while simultaneously extracting a witness to the statement $\tilde{x}$ proved in the right interaction.

Towards this goal, we will construct a simulator S that is able to "internally" generate P_{tag} messages for the left interaction of A, even if the messages in the right interaction are forwarded to A from an "external" verifier $V_{\tilde{\mathsf{tag}}}$. The simulator S is almost identical to the simulator of [35] and exploits the difference in message lengths between the protocols $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ and $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}} \rangle$. As the analysis will demonstrate, the left view produced by the simulator S is statistically indistinguishable from A's actual interactions with an honest left prover P_{tag}. Furthermore, we show the following:

1. It will be possible to construct a procedure SIM that faithfully simulates A's view in a man-in-the-middle execution. To do so, we will honestly play the role of $V_{\tilde{\mathsf{tag}}}$ in the right interaction and use S to simulate A's left interaction with P_{tag} (pretending that the messages from the right interaction came from an external $V_{\tilde{\mathsf{tag}}}$).
2. It will be possible to construct a procedure EXT that extracts witnesses for the statements $\tilde{x}$ proved in the right interactions of the views generated by the above SIM. To do so, we will use S to transform A into a stand-alone prover $P^*_{\tilde{\mathsf{tag}}}$ for the statement $\tilde{x}$. This will be done by having $P^*_{\tilde{\mathsf{tag}}}$ internally emulate A's execution while forwarding A's messages to an external honest verifier $V_{\tilde{\mathsf{tag}}}$ and using S to simulate A's left interaction with P_{tag}. We can then invoke the knowledge extractor that is guaranteed by the (stand-alone) proof of knowledge property of $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}}\rangle$ and obtain a witness for $\tilde{x} \in L$.

It is important to have both SIM and EXT use the same simulator program S (with same random coins) in their respective executions. Otherwise, we are not guaranteed that the statement $\tilde{x}$ appearing in the output of SIM is the same one EXT extracts a witness from.[9]

The execution of S (with one specific scheduling of messages) is depicted in Figure 8. In order to differentiate between the left and right interactions, messages m in the right interaction are labeled as $\tilde{m}$. Stage 2 messages in the left and right interactions are denoted u and $\tilde{u}$, respectively.

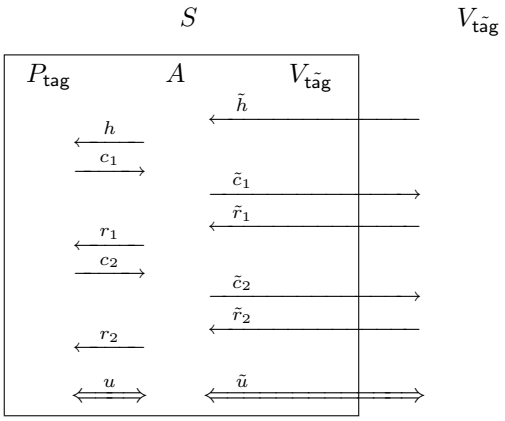

FIG. 8. *The simulator S.*

The main hurdle in implementing S is in making the simulation of the left interaction work. The problem is that the actual code of the verifier whose view we are simulating is only partially available to S. This is because the messages sent by A in the left interaction also depend on the messages A receives in the right interaction. These messages are sent by an "external" $V_{\tilde{\mathsf{tag}}}$, and $V_{\tilde{\mathsf{tag}}}$'s code (randomness) is not available to S.

Technically speaking, the problem is implied by the fact that the values of the r_i's do not necessarily depend only on the corresponding c_i but rather may also depend on the "external" right messages $\tilde{r_i}$. Thus, setting $\Pi = A$ and $y = c_i$ in the simulation

[9]The statement $\tilde{x}$ will remain unchanged because $\tilde{x}$ occurs prior to any message in the right interaction (and hence does not depend on the external messages received by $P^*_{\tilde{\mathsf{tag}}}$).

(as done in section 4.3) will not be sufficient, since in some cases it is simply not true that $r_i = A(c_i)$.

Intuitively, the most difficult case to handle is the one in which $\tilde{r_1}$ is contained in Slot 1 of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ and $\tilde{r_2}$ is contained in Slot 2 of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ (as in Figure 8). In this case $r_i = A(c_i, \tilde{r_i})$, and so $r_i = A(c_i)$ does not hold for either $i \in \{1, 2\}$. As a consequence, the simulator will not be able to produce views of convincing Stage 2 interactions with A. In order to overcome the difficulty, we will use the fact that, for a given instance $\langle h, c_i, r_i \rangle$, the string c_i is short enough to be "augmented" by $\tilde{r_i}$ while still satisfying the relation $\mathbf{R}_{sim}$.

Specifically, as long as $|c_i| + |\tilde{r_i}| \leq |r_i| - n$, the relation $\mathbf{R}_{sim}$ can be satisfied by setting $y = (c_i, \tilde{r_i})$. This guarantees that indeed $\Pi(y) = r_i$. The crux of the argument lies in the following fact.

FACT 5.2. *If* $\mathsf{tag} \neq \tilde{\mathsf{tag}}$, *then there exists* $i \in \{1, 2\}$ *so that* $|\tilde{r_i}| \leq |r_i| - \ell(n)$.

By setting $y = (c_i, \tilde{r_i})$ for the appropriate i, the simulator is thus always able to satisfy $\mathbf{R}_{sim}$ for some $i \in \{1, 2\}$. This is because the "auxiliary" string y used in order to enable the prediction of r_i is short enough to pass the inspection at condition 1 (see Figure 3) of $\mathbf{R}_{sim}$ (i.e., $|y| = |c_i| + |\tilde{r_i}| \leq |r_i| - n$).[10] Once $\mathbf{R}_{sim}$ can be satisfied, the simulator is able to produce views of convincing interactions that are computationally indistinguishable from real left interactions.[11]

The extension of the above analysis to the case of $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ has to take several new factors into consideration. First, each execution of $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ consists of n parallel executions of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ (and not only one). This imposes the constraint $\ell(n) \geq 2n^2 + 2n$ and requires a careful specification of the way in which the left simulation procedure handles the verifier challenges in $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$. Second, and more importantly, the simulation procedure will not be able to handle a case in which $\langle P_{\tilde{\text{TAG}}}, V_{\text{TAG}} \rangle$ messages of the right interaction are forwarded from an external verifier $V_{\tilde{\text{TAG}}}$ (because these messages are too long for the simulation to work).

While this does not seem to pose a problem for the SIM procedure, it suddenly becomes unclear how to construct a stand-alone prover $P^*_{\tilde{\text{TAG}}}$ for the EXT procedure (since this involves forwarding messages from $V_{\tilde{\text{TAG}}}$). The way around this difficulty will be to construct a stand-alone prover $P^*_{\tilde{\mathsf{tag}}}$ for a *single* subprotocol $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}} \rangle$ instead. This will guarantee that the only messages that end up being forwarded are sent by an external verifier $V_{\tilde{\mathsf{tag}}}$, whose messages are short enough to make the simulation work. Once such a $P^*_{\tilde{\mathsf{tag}}}$ is constructed it is possible to use the knowledge extractor for $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}} \rangle$ in order to obtain a witness for $\tilde{x}$.

5.2. Many-to-one simulation extractabiity. We now proceed with the proof of Lemma 5.1. To establish the simulation extractability of $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$, we first consider what happens when a man-in-the-middle adversary is simultaneously involved in the verification of *many* different (parallel) executions of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ on the left while proving a *single* interaction $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}} \rangle$ on the right. As it turns out, as long as the number of left executions is bounded in advance, we can actually guarantee simulation extractability even in this scenario.

[10] This follows from the fact that $\ell(n) \geq 3n$ and $|c_i| = 2n$.

[11] In the above discussion we have been implicitly assuming that $\tilde{h}, \tilde{u}$ are not contained in the two slots of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ (where $\tilde{h}$ denotes the hash function in the right interaction and $\tilde{u}$ denotes the sequence of messages sent in the right $WIUARG$). The case in which $\tilde{h}, \tilde{u}$ are contained in the slots can be handled by setting $\ell(n) \geq 4n$ and by assuming that both $|\tilde{h}|$ and the total length of the messages sent by the verifier in the $WIUARG$ are at most n. We mention that the latter assumption is reasonable and is indeed satisfied by known protocols (e.g., the $WIUARG$ of [3]).

For any $\text{TAG} = (\mathsf{tag}_1, \ldots, \mathsf{tag}_n) \in [2n]^n$ we consider a *left* interaction in which the protocols $\langle P_{\mathsf{tag}_1}, V_{\mathsf{tag}_1}\rangle, \ldots, \langle P_{\mathsf{tag}_n}, V_{\mathsf{tag}_n}\rangle$ are executed in parallel with common input $x \in \{0,1\}^n$ and a *right* interaction in which $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}}\rangle$ is executed with common input $\tilde{x} \in \{0,1\}^n$. The strings $\tilde{\mathsf{tag}}$ and $\tilde{x}$ are chosen adaptively by the man-in-the-middle adversary A. The witness used by the prover in the left interaction is denoted by w, and the auxiliary input used by A is denoted by z.

PROPOSITION 5.3. *Let A be a MIM adversary as above, and suppose that $\ell(n) \geq 2n^2 + 2n$. Then there exists a probabilistic expected polynomial time $\mathcal{S}$ such that the following conditions hold:*

1. *The probability ensembles $\{\mathcal{S}_1(x, z, \text{TAG})\}_{x,z,\text{TAG}}$ and $\{view_A(x, z, \text{TAG})\}_{x,z,\text{TAG}}$ are statistically close over L, where $\mathcal{S}_1(x, z, \text{TAG})$ denotes the first output of $\mathcal{S}(x, z, \text{TAG})$.*
2. *Let $x \in L, z \in \{0,1\}^*, \text{TAG} \in \{0,1\}^{t(|x|)}$, and let $(view, w)$ denote the output of $\mathcal{S}(x, z, \text{TAG})$ (on input some random tape). Let $\tilde{x}$ be the right-execution statement appearing in view, and let $\tilde{\mathsf{tag}}$ denote the right-execution tag. Then, if the right execution in view is accepting AND $\mathsf{tag}_j \neq \tilde{\mathsf{tag}}$ for all $j \in [n]$, then $R_L(\tilde{x}, w) = 1$.*

Proof. As discussed in section 5.1, we construct a "many-to-one" simulator S that internally generates a left view of $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle = (\langle P_{\mathsf{tag}_1}, V_{\mathsf{tag}_1}\rangle, \ldots, \langle P_{\mathsf{tag}_n}, V_{\mathsf{tag}_n}\rangle)$ for A while forwarding messages from the right interaction to an external honest verifier $V_{\tilde{\mathsf{tag}}}$. This simulator is essentially identical to the simulator of [35].[12] We then show how to use S to construct the procedures $(\mathsf{SIM}, \mathsf{EXT})$.

5.2.1. The many-to-one simulator. The many-to-one simulator S invokes A as a subroutine. It attempts to generate views of the left and right interactions that are indistinguishable from A's view in real interactions. Messages in the right interaction are forwarded by S to an "external" honest verifier $V_{\tilde{\mathsf{tag}}}$ for $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}}\rangle$, whose replies are then fed back to A. Messages in the left interaction are handled by n "subsimulators" $S_1, \ldots, S_n$, where each S_j is responsible for generating the messages of the subprotocol $\langle P_{\mathsf{tag}_j}, V_{\mathsf{tag}_j}\rangle$. The execution of the simulator is depicted in Figure 9 (for simplicity, we ignore the messages $h^1, \ldots, h^n, u^1, \ldots, u^n$ and $\tilde{h}, \tilde{u}$).

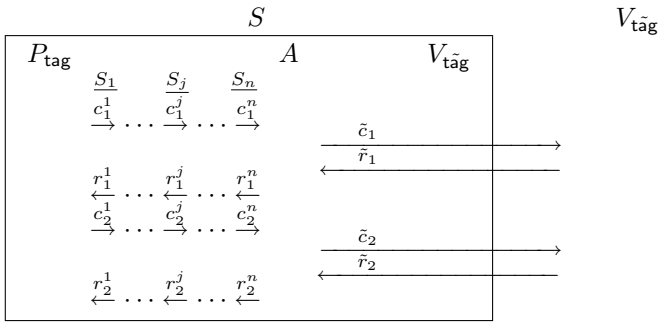

FIG. 9. *The "many-to-one" simulator S.*

The specific actions of a subsimulator S_j depend on the scheduling of Stage 1 messages as decided by A. The scheduling of left and right messages is divided into

[12] In fact, the simulator presented here is somewhat simplified in that we consider only n *parallel* executions of $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$, whereas [35] also shows a simulator for n *concurrent* executions of the protocols.

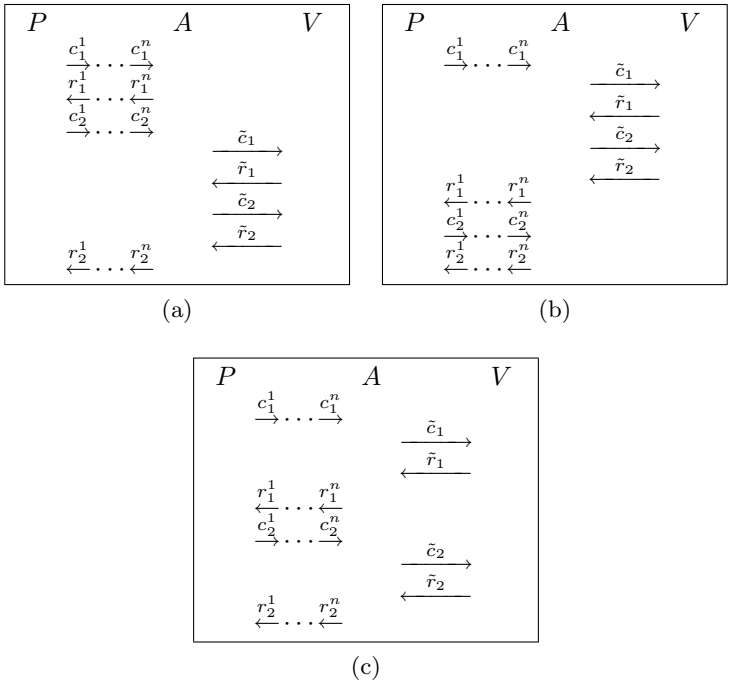

FIG. 10. *Three "representative" schedulings.*

three separate cases which are depicted in Figure 10. In all three cases we make the simplifying assumption that $\tilde{h}$ is scheduled in the right interaction before $h^1 \ldots, h^n$ are scheduled in the left interaction. We also assume that the $\langle P_{sUA}, V_{sUA} \rangle$ messages $\tilde{u}$ in the right interaction are scheduled after the $\langle P_{sUA}, V_{sUA} \rangle$ messages $u^1, \ldots, u^n$ in the left interaction. We later argue how these assumptions can be removed.

Let A_j be a program that acts exactly like A, but for any $i \in \{1, 2\}$ instead of outputting $r_i^1, \ldots, r_i^n$ it outputs only r_i^j. Given a string $\alpha \in \{0,1\}^*$, let $A(\alpha, \cdot)$ denote the program obtained by "hardwiring" α into it (i.e., $A(\alpha, \cdot)$ evaluated on β equals $A(\alpha, \beta)$). We now describe S_j's actions in each of the three cases.

None of $\tilde{r}_1, \tilde{r}_2$ is contained in Slot 1 *of $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$:* Assume for simplicity that $\tilde{c_1}, \tilde{r_1}, \tilde{c_2}, \tilde{r_2}$ are all contained in Slot 2 of $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ (Figure 10(a)). The simulator S_j sets $c_1 = \text{Com}(h(\Pi_1); s_1)$ and $c_2 = \text{Com}(0^n; s_2)$, where $\Pi_1 = A_j(x, \cdot)$. It then sets the triplet $\langle \Pi_1, (c_1^1, \ldots, c_1^n), s_1 \rangle$ as witness for $\langle h^j, c_1^j, r_1^j \rangle \in L_{sim}$.

None of $\tilde{r}_1, \tilde{r}_2$ is contained in Slot 2 *of $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$:* Assume for simplicity that $\tilde{c_1}, \tilde{r_1}, \tilde{c_2}, \tilde{r_2}$ are all contained in Slot 1 of $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ (Figure 10(b)). The simulator S_j sets $c_1 = \text{Com}(0^n; s_1)$ and $c_2 = \text{Com}(h(\Pi_2); s_2)$, where $\Pi_2 = A_j(x, c_1^1, \ldots, c_1^n, \tilde{r_1}, \tilde{r_2}, \cdot)$. It then sets the triplet $\langle \Pi_2, (c_2^1, \ldots, c_2^n), s_2 \rangle$ as witness for $\langle h^j, c_2^j, r_2^j \rangle \in L_{sim}$.

$\tilde{r}_1$ is contained in Slot 1 *and $\tilde{r}_2$ is contained in Slot* 2 *of $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$:* In this case $\tilde{c_1}, \tilde{r_1}$ are both contained in Slot 1 of $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$, and $\tilde{c_2}, \tilde{r_2}$ are both contained in Slot 2 of $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ (Figure 10(c)). The simulator S_j sets $c_1 = \text{Com}(h(\Pi_1); s_1)$ and $c_2 = \text{Com}(h(\Pi_2); s_2)$, where $\Pi_1 = A_j(x, \cdot)$ and $\Pi_2 = A_j(x, c_1^1, \ldots, c_1^n, \tilde{r_1}, \cdot)$. Then the following hold:

- If $\mathsf{tag}_j > \tilde{\mathsf{tag}}$, the simulator sets $\langle \Pi_1, (c_1^1, \ldots, c_1^n, \tilde{r_1}), s_1 \rangle$ as witness for

$\langle h^j, c_1^j, r_1^j\rangle \in L_{sim}$.

- If $\mathsf{tag}_j < \tilde{\mathsf{tag}}$, the simulator sets $\langle \Pi_2, (c_2^1, \ldots, c_2^n, \tilde{r_2}), s_2\rangle$ as witness for $\langle h^j, c_2^j, r_2^j\rangle \in L_{sim}$.

In all cases, combining the messages together results in a Stage 1 transcript $\tau_1^j = \langle h^j, c_1^j, r_1^j, c_2^j, r_2^j\rangle$. By definition of $\langle P_{\mathsf{tag}_j}, V_{\mathsf{tag}_j}\rangle$, the transcript τ_1^j induces a Stage 2 special-purpose $WIUARG$ with common input $(x, \langle h^j, c_1^j, r_1^j\rangle, \langle h^j, c_2^j, r_2^j\rangle)$. The sub-simulator S_j now follows the prescribed prover strategy P_{sUA} and produces a Stage 2 transcript τ_2^j for $\langle P_{\mathsf{tag}_j}, V_{\mathsf{tag}_j}\rangle$.

Remark 5.4 (handling $\tilde{h}$ and $\tilde{u}$). To handle the case in which either $\tilde{h}$ or $\tilde{u}$ is contained in one of the slots, we set $\ell(n) \geq 2n^2+2n$ and let the simulator append either $\tilde{h}$ or $\tilde{u}$ to the auxiliary string y (whenever necessary). This will guarantee that the program committed to by the simulator indeed outputs the corresponding "challenge" r_i^j, when fed with y as input. The crucial point is that, even after appending $\tilde{h}$ or $\tilde{u}$ to y, it will still be the case that $|y| \leq |r_i^j| - n$. This just follows from the fact that the total length of $\tilde{h}$ and the messages $\tilde{u}$ sent in $\langle P_{sUA}, V_{sUA}\rangle$ are upper bounded by, say, n and that the gap between $|r_i^j|$ and the "original" $|y|$ (i.e., before appending $\tilde{h}$ or $\tilde{u}$ to it) is guaranteed to be at least n (this follows from the requirement $\ell(n) \geq 2n^2+2n$).

Output of S. To generate its output, which consists of a verifier view of a $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ interaction, S combines all the views generated by the S_j's. Specifically, letting $\sigma_1^j = (c_1^j, c_2^j)$ be the verifier's view of τ_1^j, and σ_2^j be the verifier's view of τ_2^j, the output of S consists of $(\sigma_1, \sigma_2) = ((\sigma_1^1, \ldots, \sigma_1^n), (\sigma_2^1, \ldots, \sigma_2^n))$.

5.2.2. The simulator-extractor. Using S, we construct the simulator-extractor $\mathcal{S} = (\mathsf{SIM}, \mathsf{EXT})$. We start with the machine SIM. In the right interaction SIM's goal is to generate messages by a verifier $V_{\tilde{\mathsf{tag}}}$. This part of the simulation is quite straightforward and is performed by simply playing the role of an honest verifier in the execution of the protocol (with the exception of cases in which $\mathsf{tag}_j = \tilde{\mathsf{tag}}$ for some $j \in [n]$—see below for details). In the left interaction, on the other hand, SIM is supposed to act as a prover P_{TAG}, and this is where S is invoked.

The machine SIM. On input (x, z, TAG), and given a man-in-the-middle adversary A, SIM starts by constructing a man-in-the-middle adversary A' that acts as follows:

Internal messages: Pick random $M' = (\tilde{h}, \tilde{r}_1, \tilde{r}_2, \tilde{u})$ verifier messages for the right interaction.

Right interaction: The statement $\tilde{x}$ proved is the same as the one chosen by A. If there exists $j \in [n]$ so that $\mathsf{tag}_j = \tilde{\mathsf{tag}}$, use the messages in M' in order to internally emulate a right interaction for A (while ignoring external $V_{\tilde{\mathsf{tag}}}$ messages M). Otherwise, forward A's messages in the right interaction to an external $V_{\tilde{\mathsf{tag}}}$ and send back his answers M to A.

Left interaction: As induced by the scheduling of messages by A, forward the messages sent by A in the left interaction to an external prover P_{TAG}, and send back his answers to A.

Figure 11(a) describes the behavior of A' in case $\mathsf{tag}_j \neq \tilde{\mathsf{tag}}$ for all $j \in [n]$, whereas Figure 11(b) describes its behavior otherwise. The purpose of constructing such an A' is to enable us to argue that for all "practical purposes" the man-in-the-middle adversary never uses a $\tilde{\mathsf{tag}}$ that satisfies $\mathsf{tag}_j = \tilde{\mathsf{tag}}$ for some $j \in [n]$ (as in such cases A' ignores all messages M in the right interaction anyway).

Given the new adversary A', the machine SIM picks random $V_{\tilde{\mathsf{tag}}}$ messages M and invokes the simulator S with random coins $\bar{s}$. The simulator's goal is to generate a view of a left interaction for an A' that receives messages M in the right interaction.

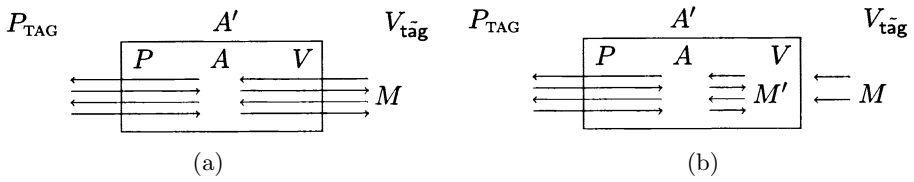

FIG. 11. *The adversary A'.*

Let (σ_1, σ_2) be the view generated by S for the left $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ interaction, and let $\tilde{\mathsf{tag}}$ be the tag sent by A in the right interaction when $(\sigma_1 \sigma_2)$ is its view of the left interaction. If there exists $j \in [n]$ so that $\mathsf{tag}_j = \tilde{\mathsf{tag}}$, then SIM outputs M' as the right view of A. Otherwise, it outputs M. SIM always outputs (σ_1, σ_2) as a left view for A.

The machine EXT. The machine EXT starts by sampling a random execution of SIM using random coins $\bar{s}, M', M$. Let $\tilde{x}$ be the right-hand side common input that results from feeding the output of SIM to A. Our goal is to extract a witness to the statement $\tilde{x}$. At a high level, EXT acts in the following way:

1. If the right session was *not* accepting or $\mathsf{tag}_j = \tilde{\mathsf{tag}}$ for some $j \in [n]$, EXT will assume that no witness exists for the statement $\tilde{x}$ and will refrain from extraction.
2. Otherwise, EXT constructs a stand-alone prover $P^*_{\tilde{\mathsf{tag}}}$ for the right interaction $\langle P_{\tilde{\mathsf{tag}}_i}, V_{\tilde{\mathsf{tag}}_i} \rangle$, from which it will later attempt to extract the witness (see Figure 12).
   In principle, the prover $P^*_{\tilde{\mathsf{tag}}}$ will follow SIM's actions using the same random coins $\bar{s}$ used for initially sampling the execution of SIM. However, $P^*_{\tilde{\mathsf{tag}}}$'s execution will differ from SIM's execution in that it will not use the messages M in the right interaction of A but rather will forward messages receives from an external verifier $V_{\tilde{\mathsf{tag}}}$.

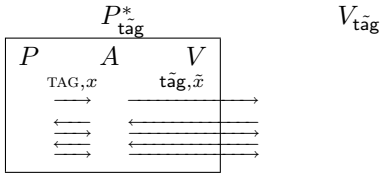

FIG. 12. *The prover $P^*_{\tilde{\mathsf{tag}}}$.*

3. Once $P^*_{\tilde{\mathsf{tag}}}$ is constructed, EXT can apply the knowledge extractor, guaranteed by the proof of knowledge property of $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}} \rangle$, and extract a witness w to the statement $\tilde{x}$. In the unlikely event that the extraction failed, EXT outputs `fail`. Otherwise, it outputs w.

Remark 5.5. It is important to have a prover $P^*_{\tilde{\mathsf{tag}}}$ for the *entire* protocol $\langle P_{\tilde{\mathsf{tag}}_i}, V_{\tilde{\mathsf{tag}}_i} \rangle$ (and not just for $\langle P_{sUA}, V_{sUA} \rangle$). This is required in order to argue that the witness extracted is a witness for $\tilde{x}$ and not a witness to $\langle \tilde{h}, \tilde{c}_1, \tilde{r}_1 \rangle \in L_{sim}$ or to $\langle \tilde{h}, \tilde{c}_2, \tilde{r}_2 \rangle \in L_{sim}$ (which could indeed be the case if we fixed the messages $\langle \tilde{h}, \tilde{c}_1, \tilde{r}_1, \tilde{c}_2, \tilde{r}_2 \rangle$ in advance).

Output of simulator-extractor $\mathcal{S}$. The combined simulator-extractor $\mathcal{S}$ runs EXT and outputs `fail` whenever EXT does so. Otherwise, it outputs the view output by SIM (in the execution by EXT) followed by the output of EXT.

5.2.3. Correctness of simulation extraction. We start by showing that the view of A in the simulation by SIM is statistically close to its view in an actual interaction with P_{TAG} and $V_{\tilde{\mathsf{tag}}}$.

LEMMA 5.6. *The probability ensembles* $\{\mathcal{S}_1(x,z,\text{TAG})\}_{x\in L,z\in\{0,1\}^*,\text{TAG}\in\{0,1\}^m}$ *and* $\{view_A(x,z,\text{TAG})\}_{x\in L,z\in\{0,1\}^*,\text{TAG}\in\{0,1\}^m}$ *are statistically close over* L*, where* $\mathcal{S}_1(x,z,\text{TAG})$ *denotes the first output of* $\mathcal{S}(x,z,\text{TAG})$.

Proof. Recall that $\mathcal{S}$ proceeds by first computing a joint view $\langle(\sigma_1,\sigma_2),M\rangle$ (by running SIM) and then outputting this view only if EXT does not output `fail`. Below we show that the output of SIM is statistically close to the view of A in real interactions. This concludes that, since EXT outputs `fail` only in the event that the extraction fails, and since by the proof of knowledge property of $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}}\rangle$ the extraction fails only with negligible probability, the first output of $\mathcal{S}$ is also statistically close to the view of A.

Let the random variable $\{\mathsf{SIM}(x,z,\text{TAG})\}$ denote the view $\langle(\sigma_1,\sigma_2),M\rangle$ output by $\{\mathsf{SIM}(x,z,\text{TAG})\}$ in the execution by $\mathcal{S}$.

CLAIM 5.7. *The probability ensembles* $\{\mathsf{SIM}(x,z,\text{TAG})\}_{x\in L,z\in\{0,1\}^*,\text{TAG}\in\{0,1\}^m}$ *and* $\{view_A(x,z,\text{TAG})\}_{x\in L,z\in\{0,1\}^*,\text{TAG}\in\{0,1\}^m}$ *are statistically close over* L.

Proof. Recall that the output of SIM consists of the tuple $\langle(\sigma_1,\sigma_2),M\rangle$, where (σ_1,σ_2) is the left view generated by the simulator S and $M=(\tilde{h},\tilde{r}_1,\tilde{r}_2,\tilde{u})$ are uniformly chosen messages that are fed to A during the simulation. In other words,

$$\{\mathsf{SIM}(x,z,\text{TAG})\}_{x,z,\text{TAG}}=\{(S(x,z,\text{TAG}),U_{|M|})\}_{x,z,\text{TAG}}.$$

Let $x\in L,\text{TAG}\in[2n]^n$ and $z\in\{0,1\}^*$. To prove the claim, we will thus compare the distribution $(S(x,z,\text{TAG}),U_{|M|})$ with real executions of the man-in-the-middle adversary $A(x,z,\text{TAG})$.

We start by observing that, whenever M is chosen randomly, a distinguisher between real and simulated views of the left interaction of A yields a distinguisher between $S(x,z,\text{TAG})$ and $view_A(x,z,\text{TAG})$. This follows from the following two facts (both facts are true regardless of whether $\mathsf{tag}_j=\tilde{\mathsf{tag}}$ for some $j\in[n]$):

1. The messages M (resp., M') appearing in its output are identically distributed to messages in a real right interaction of A with $V_{\tilde{\mathsf{tag}}}$ (by construction of SIM).
2. The simulation of the left interaction in SIM is done with respect to an A whose right-hand side view consists of the messages M (resp., M').

In particular, to distinguish whether a tuple $(\sigma_1,\sigma_2),M$ was drawn according to $S(x,z,\text{TAG})$ or according to $view_A(x,z,\text{TAG})$, one could simply take M, hardwire it into A, and invoke the distinguisher for the resulting stand-alone verifier for $\langle P_{\text{TAG}},V_{\text{TAG}}\rangle$ (which we denote by $V^*_{\tilde{\mathsf{tag}}}$). Thus, all we need to prove is the indistinguishability of real and simulated views of an arbitrary stand-alone verifier V^*_{TAG} (while ignoring the messages M). We now proceed with the proof of the claim.

Consider a random variable (σ_1,σ_2) that is distributed according to the output of $S(x,z,\text{TAG})$ and a random variable (π_1,π_2) that is distributed according to the verifier view of $\langle P_{\text{TAG}},V_{\text{TAG}}\rangle$ in $\{view_A(x,z,\text{TAG})\}_{z,x,\text{TAG}}$ (where π_1,π_2 are A's respective views of Stages 1 and 2). We will show that both (σ_1,σ_2) and (π_1,π_2) are statistically close to the hybrid distribution (σ_1,π_2). This distribution is obtained by considering a hybrid simulator that generates σ_1 exactly as S does but uses the witness w for $x\in L$ in order to produce π_2.

SUBCLAIM 5.8. *The distribution* (π_1,π_2) *is statistically close to* (σ_1,π_2).

Proof. The claim follows from the (parallel) statistical-hiding property of **Com**. Specifically, suppose that there exists a (possibly unbounded) D that distinguishes

between the two distributions with probability ϵ. Consider a distinguisher D' that has the witness w for $x \in L$ and $h = V^*_{\text{TAG}}(x)$ hardwired and acts as follows. Whenever D' gets an input $(\bar{c}_1, \bar{c}_2)$, it starts by generating $\bar{r}_1 = V^*_{\text{TAG}}(x, \bar{c}_1)$ and $\bar{r}_2 = V^*_{\text{TAG}}(x, \bar{c}_1, \bar{c}_2)$. It then emulates a Stage 2 interaction between $V^*_{\text{TAG}}(x, \bar{c}_1, \bar{c}_2)$ and the honest provers P_{sUA}, where $(x, \langle h, c_1^j, r_1^j\rangle, \langle h, c_2^j, r_2^j\rangle)$ is the common input for the jth interaction, and P_{sUA} is using w as a witness for $x \in L$. Let π_2 denote the resulting verifier view. D' outputs whatever D outputs on input $(\bar{c}_1, \bar{c}_2, \pi_2)$.

Notice that if $(c_1^j, c_2^j) = (\mathbf{Com}(0^n), \mathbf{Com}(0^n))$ for all $j \in [n]$, then the input fed to D is distributed according to (π_1, π_2), whereas if $(c_1^j, c_2^j) = (\mathbf{Com}(h(\Pi_1^j)), \mathbf{Com}(h(\Pi_2^j)))$, then the input fed to D is distributed according to (σ_1, π_2). Thus, D' has advantage ϵ in distinguishing between two tuples of n committed values. Hence, if ϵ is nonnegligible, we reach contradiction to the statistical-hiding property of **Com**. □

SUBCLAIM 5.9. *The distribution (σ_1, σ_2) is statistically close to (σ_1, π_2).*

Proof. The claim follows from the (parallel) statistical witness-indistinguishability property of $\langle P_{sWI}, V_{sWI}\rangle$ and the (parallel) statistical-hiding property of **Com** (both used in $\langle P_{sUA}, V_{sUA}\rangle$). Let $\sigma_2 = (\sigma_{2,1}, \sigma_{2,2})$, where $\sigma_{2,1}$ corresponds to a simulated view of Stage 1 of $\langle P_{sUA}, V_{sUA}\rangle$ and $\sigma_{2,2}$ corresponds to a simulated view of Stage 2 of $\langle P_{sUA}, V_{sUA}\rangle$. Similarly, let $\pi_2 = (\pi_{2,1}, \pi_{2,2})$ correspond to the real views of Stages 1 and 2 of $\langle P_{sUA}, V_{sUA}\rangle$. We will show that both (σ_1, σ_2) and (σ_1, π_2) are statistically close to the hybrid distribution $(\sigma_1, (\sigma_{2,1}, \pi_{2,2}))$.

Suppose that there exists a (possibly unbounded) algorithm D that distinguishes between (σ_1, σ_2) and $(\sigma_1, (\sigma_{2,1}, \pi_{2,2}))$ with probability ϵ. Then there must exist a Stage 1 view $(\bar{c}_1, \bar{c}_2) = (c_1^1, \ldots, c_1^n, c_2^1, \ldots, c_2^n)$ for $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ and a Stage 1 view $(\bar{\beta}, \bar{\delta}) = (\widehat{\beta}^1, \ldots, \beta^n, \widehat{\delta}^1, \ldots, \widehat{\delta}^n)$ for the subprotocol $\langle P_{sUA}, V_{sUA}\rangle$ so that D has advantage ϵ in distinguishing between $\langle(\sigma_1, \sigma_2)\rangle$ and $\langle(\sigma_1, \pi_2)\rangle$ conditioned on $(\sigma_1, \sigma_{2,1}) = ((\bar{c}_1, \bar{c}_2), (\bar{\beta}, \bar{\delta}))$.

Consider a Stage 2 execution of $\langle P_{sUA}, V_{sUA}\rangle$ with $V^*_{sWI} = V^*_{\text{TAG}}(x, \bar{c}_1, \bar{c}_2, \bar{\beta}, \bar{\delta}, \cdot)$ as verifier. Then a distinguisher $D(\bar{c}_1, \bar{c}_2, \bar{\beta}, \bar{\delta}, \cdot)$ (i.e., D with $(\bar{c}_1, \bar{c}_2, \bar{\beta}, \bar{\delta})$ hardwired as part of its input) has advantage ϵ in distinguishing between an interaction of V^*_{sWI} with n honest P_{sWI} provers that use accepting $\langle P_{UA}, V_{UA}\rangle$ transcripts $(\alpha, \beta, \gamma, \delta)$ and an interaction of V^*_{sUA} with honest P_{sUA} provers that use w as witness.[13] Thus, if ϵ is nonnegligible, we reach contradiction to the (parallel) statistical witness indistinguishability of $\langle P_{sWI}, V_{sWI}\rangle$.

Now suppose that there exists a (possibly unbounded) algorithm D that distinguishes between (σ_1, π_2) and $(\sigma_1, (\sigma_{2,1}, \pi_{2,2}))$ with probability ϵ. Consider a distinguisher D' that has the witness w for $x \in L$ and $(h, \bar{c}_1, \bar{c}_2)$ hardwired and acts as follows. Whenever D' gets an input $(\bar{\beta}, \bar{\delta})$, it starts by generating $\bar{\alpha} = V^*_{\text{TAG}}(x, \bar{c}_1, \bar{c}_2)$ and $\bar{\gamma} = V^*_{\text{TAG}}(x, \bar{c}_1, \bar{c}_2, \bar{\beta})$. It then emulates a Stage 2 interaction between the V_{sWI} verifiers $V^*_{\text{TAG}}(x, \bar{c}_1, \bar{c}_2, \bar{\beta}, \bar{\delta})$ and the honest provers P_{sWI}, where $(x, \langle h, c_1^j, r_1^j\rangle, \langle h, c_2^j, r_2^j\rangle, \langle \alpha, \bar{\beta}, \gamma, \bar{\delta}\rangle)$ is the common input for the jth interaction, and P_{sWI} is using w as a witness for $x \in L$. Let $\pi_{2,2}$ denote the resulting verifier view. D' outputs whatever D outputs on input $(\bar{c}_1, \bar{c}_2, \bar{\beta}, \bar{\delta}, \pi_{2,2})$.

Notice that if $(\widehat{\beta}^j, \widehat{\delta}^j) = (\mathbf{Com}(0^n), \mathbf{Com}(0^n))$ for all $j \in [n]$, then the input fed to D is distributed according to $(\sigma_1, (\pi_{2,1}, \pi_{2,2})) = (\sigma_1, \pi_2)$, whereas if $(\widehat{\beta}^j, \widehat{\delta}^j) = \mathbf{Com}(\beta^j), \mathbf{Com}(\delta^j)\rangle$, for some β^j, δ^j for which $(\alpha^j, \beta^j, \gamma^j, \delta^j)$ is an accepting $\langle P_{UA}, V_{UA}\rangle$, then the input fed to D is distributed according to $(\sigma_1, (\sigma_{2,1}, \pi_{2,2}))$.

[13] In accordance with the specification of $\langle P_{sUA}, V_{sUA}\rangle$, the transcripts $(\alpha, \beta, \gamma, \delta)$ are generated using programs Π_i^j as witnesses, where Π_i^j is the program chosen by the simulator S_j.

Thus, D' has advantage ϵ in distinguishing between two tuples of n committed values. Hence, if ϵ is nonnegligible, we reach contradiction to the statistical-hiding property of **Com**. □

Combining Subclaims 5.9 and 5.8 we conclude that $\{\mathsf{SIM}(x, z, \text{TAG})\}_{x,z,\text{TAG}}$ and $\{view_A(x, z, \text{TAG})\}_{x,z,\text{TAG}}$ are statistically close. □

This completes the proof of Lemma 5.6. □

LEMMA 5.10. *Let $x \in L, z \in \{0,1\}^*, \text{TAG} \in \{0,1\}^m$, and let $(view, w)$ denote the output of $\mathcal{S}(x, z, \text{TAG})$ (on input some random tape). Let $\tilde{x}$ be the right-execution statement appearing in view, and let $\tilde{\mathsf{tag}}$ denote the right-execution tag. Then, if the right execution in view is accepting AND $\mathsf{tag}_j \neq \tilde{\mathsf{tag}}$ for all $j \in [n]$, then $R_L(\tilde{x}, w) = 1$.*

Proof. We start by noting that, since $\mathcal{S}$ outputs `fail` whenever the extraction by EXT fails, the claim trivially holds in the event that the extraction by EXT fails.

Observe that the right-hand side input-tag pair $(\tilde{x}, \tilde{\mathsf{tag}})$ used in EXT is exactly the same as the one generated by SIM. This follows from the following two reasons: (1) Both EXT and SIM use the same random coins $\bar{s}$ in the simulation. (2) The input-tag pair $\tilde{x}, \tilde{\mathsf{tag}}$ is determined before any external message is received in the right interaction. In particular, the pair $(\tilde{x}, \tilde{\mathsf{tag}})$ is *independent* of the messages M (which is the only potential difference between the executions of SIM and EXT).

Since whenever the properties described in the hypothesis hold EXT performs extraction, and since the extraction by EXT proceeds until a witness is extracted (or until the extraction fails, in which case we are already done), we infer that $\mathcal{S}$ always outputs a witness to the statement $\tilde{x}$ proved in the right interaction in the view output. □

We conclude the proof by bounding the running time of the combined simulator-extractor $\mathcal{S}$.

LEMMA 5.11. *$\mathcal{S}$ runs in expected polynomial time.*

Proof. We start by proving that the running time of SIM is polynomial. Recall that the SIM procedure invokes the simulator S with the adversary A'. Thus, we need to show that S runs in polynomial time. To this end, it will be sufficient to show that every individual subsimulator S_j runs in polynomial time. We first do so assuming that $\mathsf{tag}_j \neq \tilde{\mathsf{tag}}$. We then argue that, by construction of the adversary A', this will be sufficient to guarantee polynomial running time even in cases where $\mathsf{tag}_j = \tilde{\mathsf{tag}}$.

CLAIM 5.12. *Suppose that $\mathsf{tag}_j \neq \tilde{\mathsf{tag}}$. Then S_j completes the simulation in polynomial time.*

Proof. We start by arguing that, in each of the three cases specified in the simulation, the witness used by the simulator indeed satisfies the relation $\mathbf{R}_{sim}$. A close inspection of the simulator's actions in the first two cases reveals that the simulator indeed commits to a program Π_i that on input $y = (c_i^1, \ldots, c_i^n)$ outputs the corresponding r_i. Namely, the following hold:

- $\Pi_1(y) = A_j(x, c_1^1, \ldots, c_1^n) = r_1^j$.
- $\Pi_2(y) = A_j(x, c_1^1, \ldots, c_1^n, \tilde{r_1}, \tilde{r_2}, c_2^1, \ldots, c_2^n) = r_2^j$.

Since in both cases $|y| = n|c_j^i| = 2n^2 \leq \ell(n) - n \leq |r_i^j| - n$ it follows that $\mathbf{R}_{sim}$ is satisfied. As for the third case, observe that, for both $i \in \{1, 2\}$, if S_j sets $y = (c_i^1, \ldots, c_i^n, \tilde{r}_i)$, then the following holds:

- $\Pi_i(y) = A_j(c_i^1, \ldots, c_i^n, \tilde{r}_i) = r_i^j$.

Since $\mathsf{tag}_j \neq \tilde{\mathsf{tag}}$ we can use Fact 5.2 and infer that there exists $i \in \{1, 2\}$ so that $|\tilde{r}_i| \leq |r_i^j| - \ell(n)$. This means that for every $j \in [n]$ the simulator S_j will choose the

$i \in \{1, 2\}$ for which

$$\begin{aligned} |y| &= |c_i^1| + \cdots + |c_i^n| + |\tilde{r}_i^i| \\ &= 2n^2 + |\tilde{r}_i^i| \\ &\leq 2n^2 + |r_i^j| - \ell(n) \qquad (5.1) \\ &\leq |r_i^j| - n, \qquad (5.2) \end{aligned}$$

where (5.1) follows from $|\tilde{r}_i| \leq |r_i^j| - \ell(n)$ and (5.2) follows from the fact that $\ell(n) \geq 2n^2 + n$. Thus, $\mathbf{R}_{sim}$ can always be satisfied by S_j.

Since the programs Π_i are of size poly(n) and satisfy $\Pi_i(y) = r_i^j$ in poly(n) time (because A_j does), the verification time of $\mathbf{R}_{sim}$ on the instance $\langle h, c_i^j, r_i^j \rangle$ is polynomial in n. By the perfect completeness and relative prover efficiency of $\langle P_{sUA}, V_{sUA} \rangle$, it then follows that the simulator is always able to make a verifier accept in polynomial time. □

Remark 5.13 (handling the case $\mathsf{tag}_j = \tilde{\mathsf{tag}}$). When invoked by SIM, the simulator S will output an accepting left view even if A chooses $\tilde{\mathsf{tag}}$ so that $\mathsf{tag}_j = \tilde{\mathsf{tag}}$ for some $j \in [n]$.[14] This is because in such a case the A' whose view S needs to simulate ignores all right-hand side messages and feeds the messages M' to A internally. In particular, no external messages will be contained in either Slot 1 or Slot 2 of $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$. A look at the proof of Claim 5.12 reveals that in such cases the simulator can indeed always produce an accepting conversation (regardless of whether $\mathsf{tag}_j = \tilde{\mathsf{tag}}$ or not).

It now remains to bound the *expected* running time of EXT. Recall that EXT uses the view sampled by SIM and proceeds to extracting a witness only if the right interaction is accepting and $\mathsf{tag}_j \neq \tilde{\mathsf{tag}}$ for all $j \in [n]$. Using Claim 5.12, we know that the simulation internally invoked by the stand-alone prover $P^*_{\tilde{\mathsf{tag}}}$ will always terminate in polynomial time (since $\mathsf{tag}_j \neq \tilde{\mathsf{tag}}$ for all $j \in [n]$ and A is a poly-time machine). We now argue that the extraction of the witness from $P^*_{\tilde{\mathsf{tag}}}$ conducted by EXT will terminate in expected polynomial time.

Let p denote the probability that A produces an accepting proof in the right execution in the simulation by SIM. Let p' denote the probability that A produces an accepting proof in the right execution in the internal execution of $P^*_{\tilde{\mathsf{tag}}}$ (constructed in EXT). By the POK property of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ it holds that the expected running time of the knowledge extractor is bounded by

$$\frac{\text{poly}(n)}{p'}.$$

Since the probability of invoking the extraction procedure is p, the expected number of steps used to extract a witness is

$$p\frac{\text{poly}(n)}{p'}.$$

Now in both SIM and EXT the left view is generated by S, and the right view is uniformly chosen. This in particular means that $p = p'$. It follows that the expected

[14] Note that this is not necessarily true in general. For example, when $\mathsf{tag}_j = \tilde{\mathsf{tag}}$ for some $j \in [n]$, and the messages that A sees are forwarded from an external source (e.g., when S is used by EXT in order to construct the stand alone prover $P^*_{\tilde{\mathsf{tag}}}$), we cannot guarantee anything about the running time of S. Indeed, the definition of simulation extractability does not require EXT to output a witness when $\mathsf{tag}_j = \tilde{\mathsf{tag}}$ for some $j \in [n]$.

number of steps used to extract a witness is

$$p\frac{\text{poly}(n)}{p} = \text{poly}(n).$$

This completes the proof of Lemma 5.11. □

This completes the proof of "many-to-one" simulation extractability (Proposition 5.3). □

5.3. "Full-fledged" simulation extractability. Let $\text{TAG} \in \{0,1\}^m$, let $x \in \{0,1\}^n$, and let A be the corresponding MIM adversary. We consider a left interaction in which $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ is executed with common input $x \in \{0,1\}^n$ and a right interaction in which $\langle P_{\tilde{\text{TAG}}}, V_{\tilde{\text{TAG}}}\rangle$ is executed with common input $\tilde{x} \in \{0,1\}^n$. The strings $\tilde{\mathsf{tag}}$ and $\tilde{x}$ are chosen adaptively by the man-in-the-middle adversary A. The witness used by the prover in the left interaction is denoted by w, and the auxiliary input used by the adversary is denoted by z.

PROPOSITION 5.14. *Let A be a MIM adversary as above, and suppose that $\ell(n) \geq 2n^2 + 2n$. Then there exists a probabilistic expected polynomial-time machine $\mathcal{S}$ such that the following conditions hold:*

1. *The probability ensembles $\{\mathcal{S}_1(x, z, \text{TAG})\}_{x,z,\text{TAG}}$ and $\{view_A(x, z, \text{TAG})\}_{x,z,\text{TAG}}$ are statistically close over L, where $\mathcal{S}_1(x, z, \text{TAG})$ denotes the first output of $\mathcal{S}(x, z, \text{TAG})$.*
2. *Let $x \in L, z \in \{0,1\}^*, \text{TAG} \in \{0,1\}^{t(|x|)}$, and let $(view, w)$ denote the output of $\mathcal{S}(x, z, \text{TAG})$ (on input some random tape). Let $\tilde{x}$ be the right-execution statement appearing in view, and let $\tilde{\text{TAG}}$ denote the right-execution tag. Then, if the right execution in view is accepting AND $\text{TAG} \neq \tilde{\text{TAG}}$, then $R_L(\tilde{x}, w) = 1$.*

Proof. The construction of the simulator-extractor $\mathcal{S}$ proceeds in two phases and makes use of the many-to-one simulator-extractor guaranteed by Proposition 5.3. In the first phase, the adversary A is used in order to construct a many-to-one adversary A' with the protocol $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ on its left and with one of the subprotocols $\langle P_{\tilde{\mathsf{tag}}_i}, V_{\tilde{\mathsf{tag}}}\rangle$ on its right. In the second phase, the many-to-one simulation-extractability property of $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ is used in order to generate a view for A along with a witness for the statement $\tilde{x}$ appearing in the simulation.

The many-to-one adversary. On input (x, z, TAG), and given a man-in-the-middle adversary A, the many-to-one adversary A' acts as follows:

Internal messages: For all $j \in [n]$, pick random messages $(\tilde{h}^j, \tilde{r}_1^j, \tilde{r}_2^j, \tilde{u}^j)$ for the right interaction.

Right interaction: The statement $\tilde{x}$ proved is the same as the one chosen by A. If there exists $i \in [n]$ so that $\mathsf{tag}_j \neq \tilde{\mathsf{tag}}_i$ for all $j \in [n]$, forward A's messages in the ith right interaction to an external $V_{\tilde{\mathsf{tag}}_i}$ and send back his answers to A. Use the messages $\{(\tilde{h}^j, \tilde{r}_1^j, \tilde{r}_2^j, \tilde{u}^j)\}_{j\neq i}$ to internally emulate all other right interactions $\{\langle P_{\tilde{\mathsf{tag}}_j}, V_{\tilde{\mathsf{tag}}_j}\rangle\}_{j\neq i}$.

Otherwise (i.e., if for all $i \in [n]$ there exists $j \in [n]$ such that $\mathsf{tag}_j = \tilde{\mathsf{tag}}_i$), pick an arbitrary $i \in [n]$, forward A's messages in the ith right interaction to an external $V_{\tilde{\mathsf{tag}}_i}$, and send back his answers to A. Use the messages $\{(\tilde{h}^j, \tilde{r}_1^j, \tilde{r}_2^j, \tilde{u}^j)\}_{j\neq i}$ to internally emulate all other right interactions $\{\langle P_{\tilde{\mathsf{tag}}_j}, V_{\tilde{\mathsf{tag}}_j}\rangle\}_{j\neq i}$.

Left interaction: As induced by the scheduling of messages by A, forward the messages sent by A in the left interaction to an external prover P_{TAG} and send back his answers to A.

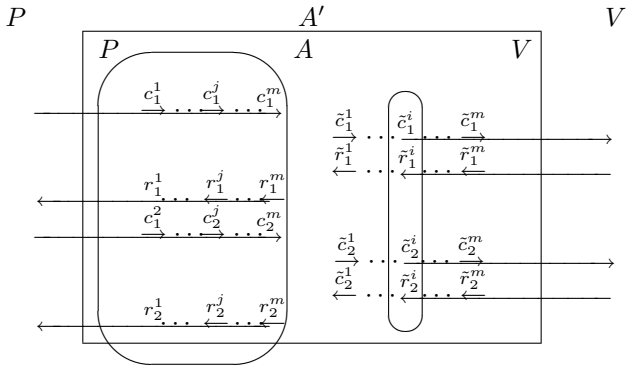

FIG. 13. *The "many-to-one" MIM adversary A'.*

The many-to-one adversary A' is depicted in Figure 13. Messages from circled subprotocols are the ones that get forwarded externally.

The simulator-extractor. By Proposition 5.3 there exists a simulator $\mathcal{S}'$ that produces a view that is statistically close to the real view of A' and outputs a witness, provided that the right interaction is accepting and $\tilde{\mathsf{tag}}$ is different from all the left-side tags $\mathsf{tag}_1, \ldots, \mathsf{tag}_n$.

The simulator-extractor $\mathcal{S}(x, z, \text{TAG})$ for A invokes $\mathcal{S}'(x, z, \text{TAG})$. If $\mathcal{S}'$ outputs `fail`, so does $\mathcal{S}$. Otherwise, let $view', w'$ denote the output of $\mathcal{S}'$. $\mathcal{S}$ now outputs $view, w'$, where $view$ is the view $view'$ (output by $\mathcal{S}'$) augmented with the right-hand side messages $\{(\tilde{h}^j, \tilde{r}_1^j, \tilde{r}_2^j, \tilde{u}^j)\}_{j \neq i}$ that were used in the internal emulation of A'.

CLAIM 5.15. *$\mathcal{S}$ runs in expected polynomial time.*

Proof. Notice that whenever A is polynomial time, then so is A'. By Lemma 5.11, this implies that $\mathcal{S}'$ runs in expected polynomial time, and hence so does $\mathcal{S}$. □

CLAIM 5.16. *The probability ensembles $\{\mathcal{S}_1(x, z, \text{TAG})\}_{x \in L, z \in \{0,1\}^*, \text{TAG} \in \{0,1\}^m}$ and $\{view_A(x, z, \text{TAG})\}_{x \in L, z \in \{0,1\}^*, \text{TAG} \in \{0,1\}^m}$ are statistically close over L, where $\mathcal{S}_1(x, z, \text{TAG})$ denotes the first output of $\mathcal{S}(x, z, \text{TAG})$.*

Proof. Given a distinguisher D between ensembles $\{\mathcal{S}_1(x, z, \text{TAG})\}_{x,z,\text{TAG}}$ and $\{view_A(x, z, \text{TAG})\}_{z,x,\text{TAG}}$, we construct a distinguisher D' between $\{\mathcal{S}_1'(x, z, \text{TAG})\}_{x,z,\text{TAG}}$ and $\{view_{A'}(x, z, \text{TAG})\}_{x,z,\text{TAG}}$. This will be in contradiction to Lemma 5.6. The distinguisher D' has the messages $\{(\tilde{h}^j, \tilde{r}_1^j, \tilde{r}_2^j, \tilde{u}^j)\}_{j \neq i}$ hardwired.[15] Given a joint view $\langle(\sigma_1', \sigma_2'), M'\rangle$ of a left $\langle P_{\tilde{\text{TAG}}}, V_{\tilde{\text{TAG}}}\rangle$ interaction and a $\langle P_{\tilde{\mathsf{tag}}_i}, V_{\tilde{\mathsf{tag}}_i}\rangle$ right interaction, D' augments the view with the right interaction messages $\{(\tilde{h}^j, \tilde{r}_1^j, \tilde{r}_2^j, \tilde{u}^j)\}_{j \neq i}$. The distinguisher D' feeds the augmented view to D and outputs whatever D outputs.

Notice that if $\langle(\sigma_1', \sigma_2'), M'\rangle$ is drawn according to $\{\mathcal{S}_1'(x, z, \text{TAG})\}_{x,z,\text{TAG}}$, then the augmented view is distributed according to $\{\mathsf{SIM}(x, z, \text{TAG})\}_{x,z,\text{TAG}}$. On the other hand, if $\langle(\sigma_1', \sigma_2'), M'\rangle$ is drawn according to $\{view_{A'}(x, z, \text{TAG})\}_{z,x,\text{TAG}}$, then the augmented view is distributed according to $\{view_A(x, z, \text{TAG})\}_{z,x,\text{TAG}}$. Thus D' has exactly the same advantage as D. □

CLAIM 5.17. *Let $x \in L, z \in \{0,1\}^*, \text{TAG} \in \{0,1\}^m$, and let $(view, w)$ denote the output of $\mathcal{S}(x, z, \text{TAG})$ (on input some random tape). Let $\tilde{x}$ be the right-execution statement appearing in view, and let $\tilde{\text{TAG}}$ denote the right-execution tag. Then, if the right execution in view is accepting AND $\text{TAG} \neq \tilde{\text{TAG}}$, then $R_L(\tilde{x}, w) = 1$.*

[15] One could think of D as a family of distinguishers that is indexed by $\{(\tilde{h}^j, \tilde{r}_1^j, \tilde{r}_2^j, \tilde{u}^j)\}_{j \neq i}$ and from which a member is drawn at random.

Proof. Recall that the right interaction in the view output of $\mathcal{S}$ is accepting if and only if the right interaction in the view output of $\mathcal{S}$ is accepting. In addition, the statement proved in the right interaction output by $\mathcal{S}$ is identical to the one proved in the right interaction of $\mathcal{S}'$.

Observe that if $\text{TAG} \neq \tilde{\text{TAG}}$, there must exist $i \in [n]$ for which $(i, \tilde{\text{TAG}}_i) \neq (j, \text{TAG}_j)$ for all $j \in [n]$ (just take the i for which $\tilde{\text{TAG}}_i \neq \text{TAG}_i$). Recall that by construction of the protocol $\langle P_{\tilde{\text{TAG}}}, V_{\tilde{\text{TAG}}} \rangle$, for every $i \in [n]$, the value tag_i is defined as (i, TAG_i). Thus, whenever $\text{TAG} \neq \tilde{\text{TAG}}$ there exists a $\tilde{\mathsf{tag}}_i = (i, \tilde{\text{TAG}}_i)$ that is different from $\mathsf{tag}_j = (j, \text{TAG}_j)$ for all $j \in [n]$. In particular, the tag used by A' in the right interaction will satisfy $\mathsf{tag}_j \neq \tilde{\mathsf{tag}}_i$ for all $j \in [n]$. By Lemma 5.10, we then have that if the right interaction in view output by $\mathcal{S}$ is accepting (and hence also in $\mathcal{S}'$), then $\mathcal{S}'$ will output a witness for $\tilde{x}$. The proof is complete, since $\mathcal{S}$ outputs whatever witness $\mathcal{S}'$ outputs. □

This completes the proof of Proposition 5.14. □

6. Nonmalleable commitments. In this section we present two simple constructions of nonmalleable commitments. The approach we follow is different from the approach used in [14]. Instead of viewing nonmalleable commitments as a tool for constructing nonmalleable zero-knowledge protocols, we reverse the roles and use a nonmalleable zero-knowledge protocol (in particular any simulation-extractable protocol will do) in order to construct a nonmalleable commitment scheme. Our approach is also different from the approach taken by [2].

6.1. A statistically binding scheme (NM with respect to commitment). We start by presenting a construction of a statistically binding scheme which is nonmalleable with respect to commitment. Our construction relies on the following two building blocks:

- a family of (possibly malleable) noninteractive statistically binding commitment schemes,
- a simulation-extractable zero-knowledge argument.

The construction is conceptually very simple: The committer commits to a string using the statistically binding commitment scheme and then proves knowledge of the string committed to using a simulation-extractable argument.

We remark that the general idea behind this protocol is not new. The idea of enhancing a commitment scheme with a proof of knowledge protocol was already explored in [14]. However, as pointed out in [14], this approach cannot work with *any* proof of knowledge protocol, as this proof of knowledge protocol itself might be malleable. (As mentioned above, Dolev, Dwork, and Naor therefore rely on a quite different approach to construct nonmalleable commitments [14].) What we show here is that this approach in fact works if the proof of knowledge protocol is simulation extractable.

Let $\{\text{Com}_r\}_{r \in \{0,1\}^*}$ be a family of *noninteractive* statistically binding commitment schemes (e.g., Naor's commitment [31]), and let $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ be a simulation-extractable protocol. Consider the protocol in Figure 14.[16]

We start by sketching why the scheme is nonmalleable. Note that the commit phase of the scheme consists only of a message specifying an NP statement (i.e., the "statement" $c = \text{Com}_r(v; s)$) and an accompanying "proof" of this statement. Thus,

[16] It is interesting to note that the protocol $\langle C, R \rangle$ is statistically binding even though the protocol $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ is "only" computationally sound. At first sight, this is somewhat counterintuitive since the statistical-binding property is typically associated with all-powerful committers.

Protocol $\langle C, R\rangle$
Security Parameter: 1^n.
String to be committed to: $v \in \{0,1\}^n$.
Commit Phase:
$R \to C$: Pick uniformly $r \in \{0,1\}^n$.
$C \to R$: Pick $s \in \{0,1\}^n$ and send $c = \mathrm{Com}_r(v; s)$.
$C \leftrightarrow R$: Let $\mathrm{TAG} = (r, c)$. Prove using $\langle P_{\mathrm{TAG}}, V_{\mathrm{TAG}}\rangle$ that there exist $v, s \in \{0,1\}^n$ so that $c = \mathrm{Com}_r(v; s)$. Formally, prove the following statement (r, c) with respect to the witness relation:

$$R_L = \{((r, c), (v, s)) | c = \mathrm{Com}_r(v; s)\}.$$

R: Verify that $\langle P_{\mathrm{TAG}}, V_{\mathrm{TAG}}\rangle$ is accepting.
Reveal Phase:
$C \to R$: Send v, s.
R: Verify that $c = \mathrm{Com}_r(v; s)$.

FIG. 14. *A statistically binding nonmalleable string commitment protocol* $\langle C, R\rangle$.

intuitively, an adversary that is able to successfully maul a commitment must be able to maul both the commitment Com and also the accompanying proof $\langle P_{\mathrm{TAG}}, V_{\mathrm{TAG}}\rangle$. The former might be easy, as Com might be malleable. However, as $\langle P_{\mathrm{TAG}}, V_{\mathrm{TAG}}\rangle$ is simulation extractable (and thus nonmalleable), the latter will be impossible.

At first sight, it seems like it would be sufficient to simply assume that $\langle P_{\mathrm{TAG}}, V_{\mathrm{TAG}}\rangle$ is nonmalleable to conclude nonmalleability of $\langle C, R\rangle$. Note, however, that the definition of a nonmalleable proof considers only a setting where the statement proven by the man-in-the-middle adversary is fixed ahead of the interaction. In our scenario, we instead also require security with respect to an *adaptively* chosen statement (as the statement proven is related to the commitment chosen by the adversary). This gap is addressed in the definition of simulation extractability; here the man-in-the-middle adversary is also allowed to adaptively choose the statements it will attempt to prove.

Interestingly, to formalize the above argument, we will be required to rely on the *statistical indistinguishability* property of the definition of simulation extractability. Intuitively, the reason for this is the following. For any given man-in-the-middle adversary we are required to construct a stand-alone adversary that succeeds in committing to "indistinguishable" values. In proving that this stand-alone adversary succeeds in this task, we will rely on the simulator-extractor for the man-in-the-middle adversary; however, to do this, we need to make sure that the simulator-extractor indeed will commit to indistinguishable values. Note that it is not sufficient that the simulator-extractor simply proves a statement that is indistinguishable from the statement proved by the man-in-the-middle adversary, as the value committed to is not efficiently computable from the statement. However, the value committed to is computable (although not efficiently) from the statement. Thus, by relying on the statistical indistinguishability property of the simulator-extractor, we can also make sure that the value committed by the simulator-extractor is indistinguishable from that committed to by the man-in-the-middle adversary.[17]

THEOREM 6.1 ($nm\mathcal{C}$ with respect to commitment). *Suppose that* $\{\mathrm{Com}_r\}_{r\in\{0,1\}^*}$ *is a family of* noninteractive *statistically binding commitment schemes and that* $\langle P_{\mathrm{TAG}}, V_{\mathrm{TAG}}\rangle$ *is simulation extractable. Then* $\langle C, R\rangle$ *is a statistically binding nonmal-*

[17]Note that in the case of nonmalleability with respect to opening, this complication does not arise.

leable commitment scheme with respect to commitment.

Proof. We need to prove that the scheme satisfies the following three properties: statistical binding, computational hiding, and nonmalleability with respect to commitment.

Statistical binding. The binding property of the scheme follows directly from the binding property of the underlying commitment scheme Com: to break the binding property of $nm\mathcal{C}_{\text{TAG}}$ requires first breaking the binding of Com. More formally, given any adversary A that breaks the binding property of $nm\mathcal{C}_{\text{TAG}}$, we construct an adversary A', which on input a message r feeds r to A and then internally honestly emulates all the verification messages in the proof part of $nm\mathcal{C}_{\text{TAG}}$. It follows directly that the success probability of A' is the same as that of A.

Computational hiding. The hiding property follows from the hiding property of Com combined with the $\mathcal{ZK}$ property of $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$. More formally, recall that the notion of simulation extractability implies $\mathcal{ZK}$ (see Proposition 3.6) and that $\mathcal{ZK}$ implies *strong* witness indistinguishability[18] [18]. Since the scheme Com produces indistinguishable commitments, it thus follows directly by the definition of strong witness indistinguishability that the protocol $\langle C, R\rangle$ also produces indistinguishable commitments.

Nonmalleability. Consider a man-in-the middle adversary A. We assume without loss of generality that A is deterministic (this is without loss of generality since A can obtain its "best" random tape as auxiliary input). We show the existence of a probabilistic polynomial-time stand-alone adversary S and a negligible function $\nu : N \to N$ such that, for every irreflexive polynomial-time computable relation $\mathcal{R} \subseteq \{0,1\}^n \times \{0,1\}^n$, every $v \in \{0,1\}^n$, and every $z \in \{0,1\}^*$, it holds that

$$\Pr\left[\mathsf{mim}^A_{com}(\mathcal{R}, v, z) = 1\right] \;<\; \Pr\left[\mathsf{sta}^S_{com}(\mathcal{R}, v, z) = 1\right]. \;+\; \nu(n). \tag{6.1}$$

Description of the stand-alone adversary. The stand-alone adversary S uses A as a black box and emulates the left and right interactions for A as follows: the left interaction is emulated internally, while the right interaction is forwarded externally. More precisely, S proceeds as follows on input z. S incorporates $A(z)$ and internally emulates the left interactions for A by simply *honestly* committing to the string 0^n; i.e., to emulate the left interaction, S executes the algorithm C on input 0^n. Messages from the right interactions are instead forwarded externally. Note that S is thus a stand-alone adversary that expects to act as a committer for the scheme $\langle C, R\rangle$.

Analysis of the stand-alone adversary. We proceed to showing that (6.1) holds. Suppose, for contradiction, that this is not the case. That is, there exist an irreflexive polynomial-time relation $\mathcal{R}$ and a polynomial $p(n)$ such that, for infinitely many n, there exist strings $v \in \{0,1\}^n, z \in \{0,1\}^*$ such that

$$\Pr\left[\mathsf{mim}^A_{com}(\mathcal{R}, v, z) = 1\right] - \Pr\left[\mathsf{sta}^S_{com}(\mathcal{R}, v, z) = 1\right] \geq \frac{1}{p(n)}.$$

Fix generic n, v, z for which the above holds. We show how this contradicts the simulation-extractability property of $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$. On a high level, our proof consists of the following steps:

[18] Intuitively, the notion of strong witness indistinguishability requires that proofs of indistinguishable statements are indistinguishable. This is, in fact, exactly the property we need in order to prove that the commitment scheme is computationally hiding.

1. We first note that, since the commit phase of $\langle C, R\rangle$ "essentially" consists only of a statement (r, c) (i.e., the commitment) and a proof of the "validity" of (r, c), A can be interpreted as a simulation-extractability man-in-the-middle adversary A' for $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$.
2. It follows from the simulation-extractability property of $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ that there exists a combined simulator-extractor $\mathcal{S}$ for A' that outputs a view that is statistically close to that of A' while at the same time outputting a witness to all accepting right proofs which use a different right tag $\tilde{\text{TAG}}$ than the tag TAG of the left interaction, i.e., if $\tilde{\text{TAG}} \neq \text{TAG}$.
3. Since the view output by the simulator-extractor $\mathcal{S}$ is *statistically* close to the view of A' in the real interaction, it also follows that the *value* committed to in that view is statistically close to value committed to by A'. (Note that computational indistinguishability would not have been enough to argue the indistinguishability of these values, since they are not efficiently computable from the view.)
4. It also follows that the simulator-extractor $\mathcal{S}$ will also output the witness to each *accepting* right execution such that $\tilde{\text{TAG}} \neq \text{TAG}$. We conclude that $\mathcal{S}$ additionally outputs the value *committed to* in the right execution (except possibly when the value committed to in the right interaction is the same as that committed to in the left).
5. We finally note that if $\mathcal{R}$ (which is irreflexive) "distinguishes" between the value committed to by A and by S, then $\mathcal{R}$ also "distinguishes" the second output of $\mathcal{S}$ (which consists of the committed values) when run on input a commitment (using Com) to v and the second output of $\mathcal{S}$ when run on input a commitment to 0. But, this contradicts the hiding property of Com.

We proceed to a formal proof. One particular complication that arises with the above proof sketch is that in the construction of $\langle C, R\rangle$ we are relying on a family of commitment schemes $\{\text{Com}_r\}_{r\in\{0,1\}^*}$ and not a single noninteractive commitment scheme. Thus, strictly speaking, A is not a man-in-the-middle adversary for the interactive proof $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$. However, the only difference is that A additionally expects to receive a message $\tilde{r}$ on the right and also to send a message r on the left. To get around this problem we rely on the *nonuniform* computational hiding property of $\langle C, R\rangle$.

Note that, since in both experiments mim and sta the right execution is identically generated, there must exist some *fixed* message $\tilde{r}$ such that, conditioned on the event that the first message sent in the right execution is $\tilde{r}$, it holds that the success probability in $\mathsf{mim}^A_{com}(\mathcal{R}, v, z)$ is $\frac{1}{p(n)}$ higher than in $\mathsf{sta}^S_{com}(\mathcal{R}, v, z)$. In fact, by the statistical-binding property of Com, it follows that there must exist some message $\tilde{r}$ such that $\text{Com}_{\tilde{r}}$ is *perfectly binding*, and, additionally, conditioned on the event that the first message sent in the right execution is $\tilde{r}$, it holds that the success probability in $\mathsf{mim}^A_{com}(\mathcal{R}, v, z)$ is $\frac{1}{2p(n)}$ higher than in $\mathsf{sta}^S_{com}(\mathcal{R}, v, z)$.

Given this message $\tilde{r}$, we must now consider two cases:

1. A (which by assumption is deterministic) sends its first message r in the left interaction directly after receiving $\tilde{r}$ (see Figure 15).
2. Or A first send its first message $\tilde{c}$ in the right interaction.

We first show that, in the second case, A can be used to break the nonuniform hiding property of $\langle C, R\rangle$. Intuitively, this follows from the fact that the value committed to by A on the right is "essentially" determined by the message $\tilde{c}$ sent by A before it has received a single message on the left; it is not "fully" determined by $\tilde{c}$,

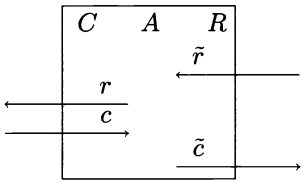

FIG. 15. *An interleaved scheduling of commitments.*

as A can decide whether it fails in the interactive proof and thus potentially change the value determined by $\tilde{c}$ to $\perp$. However, in this case, A can be used to violate the hiding property of $\langle C, R\rangle$ (as the probability of failing the proof must depend on the value it receives a commitment to).

More formally, let $v_{\tilde{c}}$ denote the value committed to in $\tilde{c}$ (using Com). It then holds that the value committed to by A in its right interaction (of $\langle C, R\rangle$) will be $v_{\tilde{c}}$ if A succeeds in the proof following the message $\tilde{c}$ and $\perp$ otherwise. By our assumption that the success probability in $\mathsf{mim}^A_{com}(\mathcal{R}, v, z)$ is $\frac{1}{2p(n)}$ higher than in $\mathsf{sta}^S_{com}(\mathcal{R}, v, z)$, conditioned on the event that the first message sent in the right execution is $\tilde{r}$, it thus holds that A "aborts" the proof in the left interaction with different probability in experiments $\mathsf{mim}^A_{com}(\mathcal{R}, v, z)$ and $\mathsf{sta}^S_{com}(\mathcal{R}, v, z)$, conditioned on the first message in the right interaction being $\tilde{r}$. However, since the only difference in those experiments is that A receives a commitment to v in mim and a commitment to 0^n in sta, we conclude that A contradicts the (nonuniform) computational-hiding property of Com. Formally, we construct a *nonuniform* distinguisher D for the commitment scheme $\langle C, R\rangle$: D incorporates A, z, r, v, and $v_{\tilde{c}}$, emulates the right execution for A by honestly running the verification procedure of $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$, and forwards messages in the left execution externally. D finally outputs $\mathcal{R}(v, v_{\tilde{c}})$ if the proof was accepting and 0 otherwise. The claim follows from the fact that D perfectly emulates $\mathsf{mim}^A_{com}(\mathcal{R}, v, z)$ when receiving a commitment to v and perfectly emulates $\mathsf{sta}^S_{com}(\mathcal{R}, v, z)$ when receiving a commitment to 0^n.

We proceed to considering the first (and harder) case depicted in Figure 15, i.e., when A sends its first left message r directly after receiving the message $\tilde{r}$. In this case, we instead directly use A to contradict the hiding property of Com. Towards this goal, we proceed in three steps:

1. We first define a simulation-extractability adversary A'.
2. We next show that A' can be used to violate the nonmalleability property of $\langle C, R\rangle$.
3. In the final step, we show how to use the simulator-extractor $\mathcal{S}$ for A' to violate the hiding property of Com.

Step 1: *Defining a simulation-extractability adversary* A'. We define a simulation-extractability adversary A' for $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$. On input $x, \text{TAG}, z' = (z, \tilde{r})$, A' internally incorporates $A(z)$ and emulates the left and right interactions for A as follows.

1. A' starts by feeding A the message $\tilde{r}$ as part of its right execution. All remaining messages in the right execution are forwarded externally.
2. All messages in A's left interaction are forwarded externally as part of A''s left interaction, except for the *first* message r.

Step 2: *Show that* A' *violates nonmalleability of* $\langle C, R\rangle$. Towards the goal of showing that A violates nonmalleability of $\langle C, R\rangle$, we define the hybrid experiment $\mathsf{hyb}_1(v')$ (relying on the definition of $v, z, r, \tilde{r}$):

1. Let s be a uniform random string, and let $c = \mathrm{Com}_r(v'; s)$.
2. Let $x = (r, c), \text{TAG} = (r, c), z' = (z, \tilde{r})$. Emulate an execution for $A'(x, \text{TAG}, z')$ by honestly providing a proof of x (using tag TAG and the witness (v', s)) as part of its left interaction and honestly verifying the right interaction.
3. Given the view of A' in the above emulation, reconstruct the view *view* of A in the emulation by A'. If the commitment produced by A in the right execution in *view* is valid, let $\tilde{v}$ denote the value committed to; recall that, by our assumption on $\tilde{r}$, this value is uniquely defined (although it is not efficiently computable). If, on the other hand, the commitment produced by A is invalid, let $\tilde{v} = \perp$.
4. Finally, if $\tilde{v} = \perp$, output 0. Otherwise output $\mathcal{R}(v, \tilde{v})$.

Note that $\mathsf{hyb}_1(v)$ is not efficiently samplable, since the third step is not efficient. However, except for that step, every other operation in hyb_1 is efficient. (This will be useful to us at a later stage.)

We have the following claim.

CLAIM 6.2.

$$\Pr\left[\mathsf{hyb}_1(v) = 1\right] - \Pr\left[\mathsf{hyb}_1(0^n) = 1\right] \geq \frac{1}{2p(n)}.$$

Proof. Note that, by the construction of A' and hyb_1, the following hold directly:

1. The view of A in $\mathsf{hyb}_1(v)$ is identically distributed to the view of A in $\mathsf{mim}^A_{com}(\mathcal{R}, v, z)$, conditioned on the event that the first message in the right execution is $\tilde{r}$.
2. The view of A in $\mathsf{hyb}_1(0^n)$ is identically distributed to the view of A in $\mathsf{sta}^A_{com}(\mathcal{R}, v, z)$, conditioned on the event that the first message in the right execution is $\tilde{r}$.

Since the output of the experiments $\mathsf{hyb}, \mathsf{mim}, \mathsf{sta}$ is determined by applying the same fixed function (involving $\mathcal{R}$ and v) to the view of A in those experiments, the claim follows. □

Step 3: *Show that the simulator for A' violates the hiding property of* Com. We next use the simulator-extractor S' for A' to construct an *efficiently computable* experiment that is statistically close to hyb_1.

Towards this goal, we first consider the following experiment hyb_2, which still is not efficient. $\mathsf{hyb}_2(v')$ proceeds just as $\mathsf{hyb}_1(v')$ except that, instead of emulating the left and right interactions for A', hyb_2 runs the combined simulator extractor $\mathcal{S}$ for A' to generate the view of A'.

CLAIM 6.3. *There exists a negligible function $\nu'(n)$ such that, for any string $v' \in \{0,1\}^n$,*

$$|\Pr\left[\mathsf{hyb}_1(v') = 1\right] - \Pr\left[\mathsf{hyb}_2(v') = 1\right]| \leq \nu'(n).$$

Proof. It follows directly from the statistical indistinguishability property of $\mathcal{S}$ that the view of A generated in hyb_1 is statistically close to the view of A generated in hyb_2. The claim is concluded by (again) observing that the success of both hyb_1 and hyb_2 is defined by applying the same (deterministic) function to the view of A. □

Remark 6.4. Note that the proof of Claim 6.3 inherently relies on the *statistical* indistinguishability property of $\mathcal{S}$. Indeed, if the simulation had only been computationally indistinguishable, we would not have been able to argue indistinguishability

of the outputs of hyb_1 and hyb_2. This follows from the fact that the success in experiments hyb_1 and hyb_2 (which depends on the *actual* committed values in the view of A) is not efficiently computable from the view alone.

We next define the final experiment $\mathsf{hyb}_3(v')$ that proceeds just as $\mathsf{hyb}_2(v')$ with the following modification:

- Instead of letting $\tilde{v}$ be set to the actual value committed to in the view *view* of A, $\tilde{v}$ is computed as follows. Recall that the combined-simulator extractor $\mathcal{S}$ outputs both a view and a witness to each accepting right interaction. If the right execution in *view* is accepting[19] and if $\tilde{\text{TAG}} \neq \text{TAG}$, where $\tilde{\text{TAG}}$ is the tag used in the right interaction in *view*, simply set $\tilde{v}$ to be consistent with the witness output by $\mathcal{S}$ (i.e., if $\mathcal{S}$ outputs the witness (v', s'), let $\tilde{v} = v'$). Otherwise (i.e., if $\tilde{\text{TAG}} = \text{TAG}$, or if the right execution was rejecting), let $\tilde{v} = \perp$.

Note that, in contrast to hyb_2, hyb_3 is efficiently computable. Furthermore, the following claim holds.

CLAIM 6.5. *For any string* $v' \in \{0,1\}^n$,

$$\Pr\left[\mathsf{hyb}_2(v') = 1\right] = \Pr\left[\mathsf{hyb}_3(v') = 1\right].$$

Proof. Recall that the view of A in hyb_2 and hyb_3 is identical; the only difference in the experiments is how the final output is computed. It holds by the definition of the simulator-extractor $\mathcal{S}$ that $\mathcal{S}$ *always* outputs the witness to the statement proved by A' if the right interaction is accepting and if $\tilde{\text{TAG}} \neq \text{TAG}$. Thus, whenever *view* contains an accepting right-execution proof such that $\tilde{\text{TAG}} \neq \text{TAG}$, it follows by our assumption that $\text{Com}_{\tilde{r}}$ is perfectly binding and that the output of hyb_2 and hyb_3 is identical. Furthermore, in case the right-execution proof is rejecting, it holds that $\tilde{v} = \perp$ in both hyb_2 and hyb_3, which again means the output in both experiments is identical. Finally, consider the case when the right execution is accepting but $\tilde{\text{TAG}} = \text{TAG}$. By definition, it holds that hyb_3 outputs 0. Now recall that $\text{TAG} = (r, c)$ and $\tilde{\text{TAG}} = (\tilde{r}, \tilde{c})$; in other words, if $\tilde{\text{TAG}} = \text{TAG}$, it means that A fully copied the initial commitment using Com_r. Since $\mathcal{R}$ is irreflexive and $\text{Com}_{\tilde{r}}$ is perfectly binding, it follows that also hyb_2 outputs 0. We conclude that the outputs of hyb_2 and hyb_3 are identically distributed. ∎

By combining the above claims we obtain that there exists some polynomial $p'(n)$ such that

$$\Pr\left[\mathsf{hyb}_3(v) = 1\right] - \Pr\left[\mathsf{hyb}_3(0^n) = 1\right] \geq \frac{1}{p'(n)}.$$

However, since hyb_3 is efficiently samplable, we conclude that this contradicts the (nonuniform) hiding property of Com_r.

More formally, define an additional hybrid experiment $\mathsf{hyb}_4(c')$ that proceeds as follows on input a commitment c' using Com_r: hyb_4 performs the same operations as hyb_3, except that, instead of generating the commitment c, it simply sets $c = c'$. It follows directly from the construction of hyb_4 that $\mathsf{hyb}_4(c')$ is identically distributed to $\mathsf{hyb}_3(0^n)$ when c' is a (random) commitment to 0^n (using Com_r) and is identically distributed to $\mathsf{hyb}_3(v)$ when c' is a commitment to v. We conclude that hyb_4 distinguishes commitments (using Com_r) to 0^n and v. ∎

[19] Note that, since *view* is a *joint* view of A and the honest receiver R in the right execution, one can efficiently determine whether R indeed accepted the commitment.

Remark 6.6 (black-box vs. nonblack-box simulation). Note that the stand-alone committer S constructed in the above proof uses only black-box access to the adversary A, even if the simulation-extractability property of $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ has been proven using a nonblack-box simulation. Thus, in essence, the simulation of our nonmalleable commitment is *always* black box. However, the analysis showing the correctness of the simulator relies on nonblack-box techniques, whenever the simulator-extractor for $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ is proven using nonblack-box techniques.

Since families of noninteractive statistically binding commitment schemes can be based on collision-resistant hash functions (in fact one-way functions are enough [31, 26]) we get the following corollary.

COROLLARY 6.7 (statistical-binding nonmalleable commitment). *Suppose that there exists a family of collision-resistant hash functions. Then there exists a constant-round statistically binding commitment scheme that is nonmalleable with respect to commitment.*

6.2. A statistically hiding scheme (NM with respect to opening). We proceed to the construction of a statistically hiding commitment scheme $\langle \mathbf{C}, \mathbf{R} \rangle$ which is nonmalleable with respect to opening. Our construction relies on a quite straightforward combination of a (family) of noninteractive statistically hiding commitments and a simulation-extractable argument.[20] Let $\{\mathbf{Com}_r\}_{r \in \{0,1\}^*}$ be a family of *noninteractive* statistically hiding commitment schemes (e.g., [10]), and let $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ be simulation-extractable protocol. The protocol is depicted in Figure 16.

Protocol $\langle \mathbf{C}, \mathbf{R} \rangle$

Security Parameter: 1^n.

String to be committed to: $v \in \{0,1\}^n$.

Commit Phase:

$R \to C$: Pick uniformly $r \in \{0,1\}^n$.

$C \to R$: Pick $s \in \{0,1\}^n$ and send $c = \mathbf{Com}_r(v; s)$.

Reveal Phase:

$C \to R$: Send v.

$C \leftrightarrow R$: Let $\text{TAG} = (r, c, v)$. Prove using $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ that there exists $s \in \{0,1\}^n$ so that $c = \mathbf{Com}_r(v; s)$. Formally, prove the following statement (r, c, v) with respect to the witness relation:

$$R_L = \{(r, c, v), s | c = \mathbf{Com}_r(v; s)\}.$$

R: Verify that $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ is accepting.

FIG. 16. *A statistically hiding nonmalleable string commitment protocol* $\langle \mathbf{C}, \mathbf{R} \rangle$.

THEOREM 6.8 ($nm\mathcal{C}$ with respect to opening). *Suppose that* $\{\mathbf{Com}_r\}_{r \in \{0,1\}^*}$ *is a family of* noninteractive *commitment schemes and that* $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ *is a simulation-extractable argument with an efficient prover strategy. Then* $\langle \mathbf{C}, \mathbf{R} \rangle$ *is a nonmalleable commitment scheme with respect to opening. If, furthermore,* $\{\mathbf{Com}_r\}_{r \in \{0,1\}^*}$ *is statistically hiding, then* $\langle \mathbf{C}, \mathbf{R} \rangle$ *is so as well.*

Proof. We need to prove that the scheme satisfies the following three properties: computational binding, (statistical) hiding, and nonmalleability with respect to opening.

[20] Note that, whereas our construction of statistically binding commitments required that the simulation-extractable argument provides a simulation that is statistically close, here we are content with a computationally indistinguishable simulation.

We start by proving the hiding and nonmalleability properties and then return to the proof of the binding property.

(Statistical) hiding. The hiding property follows directly from the hiding property of **Com**. Note that if **Com** is statistically hiding, then $\langle \mathbf{C}, \mathbf{R} \rangle$ is also statistically hiding.

Nonmalleability. We show that for every probabilistic polynomial-time man-in-the-middle adversary A, there exist a probabilistic *expected* polynomial-time stand-alone adversary S and a negligible function $\nu : N \to N$ such that, for every irreflexive polynomial-time computable relation $\mathcal{R} \subseteq \{0,1\}^n \times \{0,1\}^n$, every $v \in \{0,1\}^n$, and every $z \in \{0,1\}^*$, it holds that

$$\Pr\left[\mathsf{mim}^A_{open}(\mathcal{R}, v, z) = 1\right] \; < \; \Pr\left[\mathsf{sta}^S_{open}(\mathcal{R}, v, z) = 1\right] \; + \; \nu(n).$$

We remark that the stand-alone adversary S constructed here will be conceptually quite different from the one constructed in the proof of Theorem 6.1.

Description of the stand-alone adversary. We proceed to describing the stand-alone adversary S. On a high level, S internally incorporates A and emulates the commit phase of the left execution for adversary A by honestly committing to 0^n while externally forwarding messages in the right execution. Once A has completed the commit phase, S interprets the residual adversary (after the completed commit phase) as a man-in-the middle adversary A' for $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$. It then executes the simulator-extractor $\mathcal{S}$ for A' to obtain a witness to the statement proved in the right execution by A' (and thus A). Using this witness S can then complete the decommit phase of the external execution. (Here we rely on the fact that $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ has an efficient prover strategy.)

More formally, the stand-alone adversary S proceeds as follows on input z:

1. S internally incorporates $A(z)$.
2. During the commit phase S proceeds as follows:
   (a) S internally emulates the left interaction for A by honestly committing to 0^n.
   (b) Messages from the right execution are forwarded externally.
3. Once the commit phase has finished S receives the value v. Let $(r, c), (\tilde{r}, \tilde{c})$ denote the left- and right-execution transcripts of A (recall that the left execution has been internally emulated, while the right execution has been externally forwarded).
4. Construct a man-in-the-middle adversary A' for $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$. Informally, A' will simply consist of the residual machine resulting after the above-executed commit phase. More formally, $A'(x, \text{TAG}, z')$ proceeds as follows:
   (a) Parse z' as $(\tilde{r}, \tilde{c}, z)$.
   (b) Parse x as (r, c, v).
   (c) Internally emulate the commit phase $(r, c), (\tilde{r}, \tilde{c})$ for $A(z)$ (i.e., feed A the message $\tilde{r}$ as part of its right execution and c as part of its left execution).
   (d) Once the commit phase has finished, feed v to A.
   (e) Externally forward all the remaining messages during the reveal phase.
5. Let $\mathcal{S}$ denote the simulator-extractor for A'.
6. Let $x = (r, c, v)$, $\text{TAG} = (r, c, v)$, and $z' = (\tilde{r}, \tilde{c}, z)$.
7. Run $\mathcal{S}$ on input (x, TAG, z') to obtain the view *view* and the witness $\tilde{w}$.
8. Finally, if the statement proved in the right execution of *view* is $\tilde{x} = (\tilde{r}, \tilde{c}, \tilde{v})$ (where $\tilde{v}$ is an arbitrary string), the right-execution proof is accepting and

uses a tag $\tilde{\text{TAG}}$ such that $\tilde{\text{TAG}} \neq \text{TAG}$, and $\tilde{w}$ contains a valid witness for $\tilde{x}$, run the honest prover strategy P_{TAG} on input $\tilde{x}$ and the witness $\tilde{w}$. (Otherwise, simply abort.)

Analysis of the stand-alone adversary. Towards the goal of showing (6.2), we define a hybrid stand-alone adversary $\hat{S}$ that also receives v as auxiliary input. $\hat{S}$ proceeds exactly as S, but, instead of feeding A a commitment to 0^n in the commit phase, $\hat{S}$ instead feeds A a commitment to v.

Since both the experiment sta_{open} and the experiment $\hat{S}$ are efficiently computable, the following claim follows directly from the hiding property of **Com**.

CLAIM 6.9. *There exists some negligible function ν' such that*

$$\left| \Pr\left[\mathsf{sta}^{S}_{open}(\mathcal{R}, v, z) = 1\right] - \Pr\left[\mathsf{sta}^{\hat{S}}_{open}(\mathcal{R}, v, z) = 1\right]\right| \leq \nu'(k).$$

We proceed to showing the following claim, which together with Claim 6.9 concludes (6.2).

CLAIM 6.10. *There exists some negligible function ν'' such that*

$$\left| \Pr\left[\mathsf{mim}^{A}_{open}(\mathcal{R}, v, z) = 1\right] - \left[\mathsf{sta}^{\hat{S}}_{open}(\mathcal{R}, v, z) = 1\right]\right| \leq \nu''(k).$$

Proof. Towards the goal of showing this claim we introduce an additional hybrid experiment $\mathsf{hyb}(\mathcal{R}, v, z)$ which proceeds as follows: Emulate $\mathsf{sta}^{\tilde{S}}_{open}(\mathcal{R}, v, z)$, but, instead of defining $\tilde{v}$ as the value (successfully) decommitted to by S, define $\tilde{v}$ as the value (successfully) decommitted to in the view *view* output by simulator-extractor $\mathcal{S}$ (in the execution by $\hat{S}$). We start by noting that it follows directly from the indistinguishability property of the simulator-extractor $\mathcal{S}$ that the following quantity is negligible:[21]

$$\left| \Pr\left[\mathsf{mim}^{A}_{open}(\mathcal{R}, v, z) = 1\right] - \Pr\left[\mathsf{hyb}(\mathcal{R}, v, z) = 1\right]\right|.$$

To conclude the claim, we show that

$$\Pr\left[\mathsf{hyb}(\mathcal{R}, v, z) = 1\right] = \left[\mathsf{sta}^{\hat{S}}_{open}(\mathcal{R}, v, z) = 1\right].$$

Note that the only difference between experiments $\mathsf{hyb}(\mathcal{R}, v, z)$ and $\mathsf{sta}^{\hat{S}}_{open}(\mathcal{R}, v, z)$ is that, in hyb, the value $\tilde{v}$ is taken from the view output by $\mathcal{S}$, whereas in $\mathsf{sta}^{\hat{S}}_{open}$ it is defined as the value successfully decommitted to by $\hat{S}$. Also recall that $\hat{S}$ "attempts" to decommit to the value $\tilde{v}$ successfully decommitted to in the output by $\mathcal{S}$; $\hat{S}$ is successful in this task whenever $\mathcal{S}$ also is able to extract a witness to the right-execution proof. Note that by the simulation-extractability property of $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ it follows that $\mathcal{S}$ *always* outputs a valid witness if the right execution in *view* is accepting, as long as the tag $\tilde{\text{TAG}}$ of the right execution is different from TAG. Thus, in case $\tilde{\text{TAG}} \neq \text{TAG}$, we conclude by the perfect completeness of $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ that the output of experiments sta and hyb is defined in exactly the same way. In case $\tilde{\text{TAG}} = \text{TAG}$, sta will output 0 (as $\hat{S}$ will not even attempt to decommit). However, in this case, it holds that $\tilde{v} = v$ (since $\text{TAG} = (r, c, v)$ and $\tilde{\text{TAG}} = (\tilde{r}, \tilde{c}, \tilde{v})$); this means that hyb will also output 0 (since $\mathcal{R}$ is irreflexive). The claim follows. □

[21] We remark that here it is sufficient that the simulator-extractor outputs a view that is merely computationally indistinguishable from the view in a "real" execution.

We now return to the binding property.

Computational binding. The binding properties of the scheme intuitively follow from the binding property of the underlying commitment scheme **Com** and the "proof of knowledge" property implicitly guaranteed by the simulation-extractability property of $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$. A formal proof proceeds along the lines of the proof of nonmalleability (but is simpler.) More precisely, assume for contradiction that there exists some adversary A that is able to violate the binding property of $\langle \mathbf{C}, \mathbf{R} \rangle$. We show how to construct a machine $\hat{A}$ that violates the binding property of **Com**. $\hat{A}$ starts by running A, letting it complete the commit phase by externally forwarding its messages. Once A has completed the commit phase, $\hat{A}$ interprets the residual adversary (after the completed commit phase) as a man-in-the middle adversary A' (that ignores all left-execution messages) for $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$; a formal description of this adversary is essentially identical to the one described in the proof of nonmalleability. $\hat{A}$ then executes the simulator-extractor $\mathcal{S}$ for A' to obtain a witness to the statement proved in the right execution by A' (and thus A). Using this witness $\hat{A}$ can then complete the decommit phase of the external execution of **Com**. It follows directly by the indistinguishability property of the simulator-extractor $\mathcal{S}$ that $\hat{A}$ violates the binding property of **Com** with essentially the same probability as A violates the binding property of $\langle \mathbf{C}, \mathbf{R} \rangle$.

This completes the proof of Theorem 6.8. □

Remark 6.11 (black-box vs. nonblack-box simulation). Note that the stand-alone adversary S constructed in the proof of Theorem 6.8 is very different from the stand-alone adversary constructed in the proof of Theorem 6.1. In particular S constructed above in fact runs the simulator-extractor $\mathcal{S}$ (whereas in the proof of Theorem 6.1 the simulator extractor is simply used in the analysis). As a consequence (in contrast to the simulator constructed in 6.1), the stand-alone adversary S constructed above makes use of the man-in-the middle adversary in a nonblack-box way if relying on a simulation-extractable argument with a nonblack-box simulator.

Since families of noninteractive statistically hiding commitments can be based on collision-resistant hash functions [33, 10] we obtain the following corollary.

COROLLARY 6.12 (statistically hiding nonmalleable commitment). *Suppose that there exists a family of collision-resistant hash functions. Then there exists a constant-round statistically hiding commitment scheme which is nonmalleable with respect to opening.*

Appendix. Missing proofs.

Proposition 4.2 (argument of knowledge). Let $\langle P_{sWI}, V_{sWI} \rangle$ and $\langle P_{UA}, V_{UA} \rangle$ be the protocols used in the construction of $\langle P_{sUA}, V_{sUA} \rangle$. Suppose that $\{\mathcal{H}_n\}_n$ is collision resistant for $T(n)$-sized circuits, that **Com** is statistically hiding, that $\langle P_{sWI}, V_{sWI} \rangle$ is a statistical witness indistinguishable argument of knowledge, and that $\langle P_{UA}, V_{UA} \rangle$ is a universal argument. Then, for any $\text{TAG} \in \{0,1\}^n$, $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ is an interactive argument of knowledge.

Completeness of $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ follows from the completeness property of $\langle P_{sUA}, V_{sUA} \rangle$. Specifically, an honest prover P, who possesses a witness w for $x \in L$, can always make the verifier accept by using w as the witness in the n parallel executions of $\langle P_{sUA}, V_{sUA} \rangle$. To demonstrate the argument of knowledge property of $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$, it will be sufficient to prove that $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ is an argument of knowledge. This is because the prescribed verifier in $\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle$ will accept the proof only if *all* runs of

$\langle P_{\mathsf{tag}_i}, V_{\mathsf{tag}_i}\rangle$ are accepting. [22]

LEMMA A.1. *Suppose that $\{\mathcal{H}_n\}_n$ is collision resistant for $T(n)$-sized circuits, that* **Com** *is statistically hiding, that $\langle P_{sWI}, V_{sWI}\rangle$ is a statistical witness-indistinguishable argument of knowledge, and that $\langle P_{UA}, V_{UA}\rangle$ is a universal argument. Then, for any* $\mathsf{tag} \in [2n]$, *$\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$ is an argument of knowledge.*

Proof. We show the existence of an extractor machine E for protocol $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$.

Description of the extractor machine. E proceeds as follows given oracle access to a malicious prover P^*. E, using black-box access to P^*, internally emulates the role of the honest verifier V_{tag} for P^* *until* P^* provides an accepting proof (i.e., if P^* fails, E restarts P^* and attempts a new emulation of V_{tag}). Let σ_s denote the messages received by P^*, in the successful emulation by E, up until protocol $\langle P_{\mathsf{WI}}, V_{\mathsf{WI}}\rangle$ is reached; let P^*_{WI} denote the residual prover $P^*(\sigma_s)$.

The extractor E next applies the witness extractor E_{WI} for $\langle P_{\mathsf{WI}}, V_{\mathsf{WI}}\rangle$ on P^*_{WI}. If $E_{\mathsf{WI}}^{P^*_{\mathsf{WI}}}$ outputs a witness w, such that $R_L(x, w) = 1$, E outputs the same witness w; otherwise it outputs `fail`. (The reason E constructs P^*_{WI} as above is to ensure that P^*_{WI} convinces V_{WI} with nonzero probability; otherwise E_{WI} is not guaranteed to extract a witness.)

Analysis of the extractor. Let P^* be a nonuniform PPT that convinces the honest verifier V_{tag} of the validity of a statement $x \in \{0,1\}^n$ with probability $\epsilon(n)$. We assume without loss of generality that P^* is deterministic. We need to show the following two properties:

1. The probability that P^* succeeds in convincing V_{tag}, but E does not output a valid witness to x, is negligible.
2. The expected number of steps taken by E is bounded by $\frac{\mathrm{poly}(n)}{\epsilon(n)}$.

We start by noting that since E perfectly emulates the role of the honest verifier V_{tag}, E requires in expectation $\frac{\mathrm{poly}(n)}{\epsilon(n)}$ steps before invoking the extractor E_{WI}. Additionally, by the proof-of-knowledge property of $\langle P_{\mathsf{WI}}, V_{\mathsf{WI}}\rangle$ it follows that the expected running time of E_{WI} is $\frac{\mathrm{poly}(n)}{\epsilon(n)}$. To see this, let the random variable T denote the running time of E_{WI} in the execution by E, and let $T(\sigma)$ denote the running time of E_{WI} given that E chooses the prefix σ. We abuse of notation and let σ denote the event that P^* receives the prefix σ in an interaction with V_{tag}; also let accept denote the event that P^* produces a convincing proof. We have

$$E[T] = \sum_{\sigma} E[T(\sigma)]\Pr(\sigma|\mathsf{accept}) = \sum_{\sigma} \frac{\mathrm{poly}(n)}{\Pr[\mathsf{accept}|\sigma]}\Pr(\sigma|\mathsf{accept})$$
$$= \mathrm{poly}(n)\sum_{\sigma}\frac{\Pr[\sigma]}{\Pr[\mathsf{accept}]} = \frac{\mathrm{poly}(n)}{\Pr[\mathsf{accept}]} = \frac{\mathrm{poly}(n)}{\epsilon(n)},$$

where the second equality follows from the definition of a proof of knowledge. We conclude by the linearity of expectations that the expected running time of E is $\frac{\mathrm{poly}(n)}{\epsilon(n)}$ and thus the second of the above properties holds.

We turn to show that also the first property holds. Assume that there exists some polynomial $p(n)$ such that, for infinitely many n, $\epsilon(n) \geq \frac{1}{p(n)}$ but E^{P^*} fails to output a valid witness with probability $\frac{1}{p(n)}$. Note that E^{P^*} can fail for two reasons:

[22] One could turn any cheating prover for $\langle P_{\mathrm{TAG}}, V_{\mathrm{TAG}}\rangle$ into a cheating prover for $\langle P_{\mathsf{tag}_i}, V_{\mathsf{tag}_i}\rangle$ by internally emulating the role of the verifier V_{tag_j} for $j \neq i$ and forwarding the messages from P_{tag_i} to an external V_{tag_i}.

1. Either the extraction by E_{WI} fails, or
2. E_{WI} outputs $\langle \beta, \delta, s_1, s_2 \rangle$ so that
   - $\hat{\beta} = \mathbf{Com}(\beta; s_1)$,
   - $\hat{\delta} = \mathbf{Com}(\delta; s_2)$,
   - $(\alpha, \beta, \gamma, \delta)$ is an accepting transcript for $\langle P_{\mathsf{UA}}, V_{\mathsf{UA}} \rangle$.

If the second event occurs, we say that E_{WI} outputs a *false witness*. Consider an alternative extractor E' which proceeds just as E except that if in the *first* emulation of V_{tag}, P^* fails in producing a convincing proof, E' directly aborts. Note that the only difference between E and E' is that E continues sampling executions until P^* produces a convincing proof, whereas E' samples only once. Since by our assumption, $\epsilon(n) \geq \frac{1}{p(n)}$, it follows that there exists some polynomial $p'(n)$ such that in the execution by E', E_{WI} either fails or outputs a false witness with probability $\frac{1}{p'(n)}$. It directly follows from the proof-of-knowledge property of $\langle P_{\mathsf{WI}}, V_{\mathsf{WI}} \rangle$ that E_{WI} fails only with negligible probability. We show below that E_{WI} outputs a false witness also with negligible probability; this is a contradiction.

PROPOSITION A.2. *In the execution of E'^{P^*}, E_{WI} outputs a false witness with negligible probability.*

Proof. Towards proving the proposition we start by showing the following lemma.

LEMMA A.3. *Let P^*_{sUA} be a nonuniform polynomial-time machine such that $E_{\mathsf{WI}}^{P^*_{\mathsf{sUA}}(\alpha,\gamma)}$ outputs a false witness to the statement $\bar{x} = (x, \langle h, c_1, c_2, r_1, r_2 \rangle)$ with probability $\epsilon(n) = \frac{1}{\mathrm{poly}(n)}$ given uniformly chosen verifier messages α, γ. Then there exists a* strict *polynomial-time machine* $\mathsf{extract}$ *such that, with probability* $\mathrm{poly}(\epsilon(n))$, $\mathsf{extract}(P^*_{\mathsf{sUA}}, \bar{x})$ *outputs*

- *an index $i \in \{1, 2\}$,*
- *strings y, s, z such that $z = h(\Pi)$, $r_i = \Pi(y, s)$, and $c_i = \mathbf{Com}(z; s)$,*
- *a polynomial-time machine M such that $M(j)$ outputs the jth bit of Π (M is called the "implicit" representation of Π).*

Proof. The proof of the lemma proceeds in the following two steps.

1. Using an argument by Barak and Goldreich [3], we use P^*_{sUA} and E_{WI} to construct a prover P^*_{UA} for the UARG $\langle P_{\mathsf{UA}}, V_{\mathsf{UA}} \rangle$ that succeeds with probability $\mathrm{poly}(\epsilon(n))$.
2. Due to the weak proof of knowledge property of *UARG* we then obtain an index $i \in \{1, 2\}$, strings y, s, a hash $z = h(\Pi)$ so that $r_i = \Pi(y, s)$ and $c_i = \mathbf{C}(z; s)$. We furthermore obtain an "implicit" representation of the program Π.

Step 1. *Constructing P^*_{UA}.* P^*_{UA} proceeds as follows.

- P^*_{UA} starts by receiving a message α from the honest verifier V_{UA}.
- P^*_{UA} incorporates P^*_{sUA} and internally forwards the message α to P^*_{sUA}, resulting in a residual prover $P^*_{\mathsf{sUA}}(\alpha)$.
- P^*_{UA} then internally emulates the role of the honest verifier for P^*_{sUA} until protocol $\langle P_{\mathsf{WI}}, V_{\mathsf{WI}} \rangle$ is reached (i.e., P^*_{UA} uniformly choses a random message $\bar{\gamma}$ that it forwards to P^*_{sUA}, resulting in a residual prover $P^*_{\mathsf{sUA}}(\alpha, \bar{\gamma})$). Thereafter, P^*_{UA} honestly emulates the verifier V_{WI} for $P^*_{\mathsf{sUA}}(\alpha, \bar{\gamma})$. If $P^*_{\mathsf{sUA}}(\alpha, \bar{\gamma})$ succeeds in providing an accepting proof, P^*_{UA} invokes the knowledge extractor E_{WI} on the prover $P^*_{\mathsf{sUA}}(\alpha, \bar{\gamma})$.
- In the event that $P^*_{\mathsf{sUA}}(\alpha, \bar{\gamma})$ does not produce an accepting proof, or if E_{WI} does not output an accepting tuple $\langle \beta, \delta, s_1, s_2 \rangle$, P^*_{UA} halts. Otherwise, it externally forwards the message β to V_{UA} and receives as response γ.

- P^*_{UA} now rewinds P^*_{sUA} until the point where it awaits the message γ and internally forwards γ to P^*_{sUA}, resulting in a residual prover $P^*_{\mathsf{sUA}}(\alpha, \gamma)$. As before P^*_{UA} first honestly verifies the WI proof that $P^*_{\mathsf{UA}}(\alpha, \gamma)$ gives and in the case this proof is accepting applies the extractor E_{WI} to $P^*_{\mathsf{sUA}}(\alpha, \gamma)$.
- If E_{WI} outputs an accepting tuple $\langle \beta', \delta', s'_1, s'_2 \rangle$, such that $\beta' = \beta$, P^*_{UA} forwards δ to V_{UA}, and otherwise it halts.

Since $\langle \alpha, \beta', \gamma, \delta' \rangle$ is an accepting transcript of $\langle P_{\mathsf{UA}}, V_{\mathsf{UA}} \rangle$, it follows that unless P^*_{UA} halts the execution, it succeeds in convincing the verifier V_{UA}.

We show that P^*_{UA} finishes the execution with probability $\mathrm{poly}(\epsilon(n))$. Using the same argument as Barak and Goldreich [3] (of counting "good" verifier messages, i.e., messages that will let the prover succeed with "high" probability; see Claim 4.2.1 in [3]), it can be shown that, with probability $\mathrm{poly}(\epsilon(n))$, P^*_{UA} reaches the case where the extractor outputs $\langle \beta', \delta', s'_1, s'_2 \rangle$. Thus it remains only to show that conditioned on this event, $\beta' \neq \beta$ occurs with polynomial probability. In fact, the event that $\beta' = \beta$ can occur only with negligible probability, or else we would contradict the binding property of **Com** (since $\tilde{\beta} = \mathbf{Com}(\beta, s_1) = \mathbf{Com}(\beta', s'_1)$). We thus conclude that P^*_{UA} succeeds in convincing V_{UA} with probability $\mathrm{poly}(\epsilon(n))$.

Furthermore, since the extractor E_{WI} is applied only when P^*_{UA} provides an accepting proof, it follows from the definition of a proof of knowledge that the *expected* running time of P^*_{UA} is a polynomial, say $g(n)$. Finally, if we truncate the execution of P^*_{UA} after $2g(n)$ steps, we get by the Markov inequality that (the truncated) P^*_{UA} still convinces produces convincing proofs with probability $\mathrm{poly}(\epsilon)$.

Step 2. *Extracting the "false" witness.* By the weak proof of knowledge property of $\langle P_{\mathsf{UA}}, V_{\mathsf{UA}} \rangle$ there exists a strict PPT machine E_{UA} such that $E_{\mathsf{UA}}^{P^*_{\mathsf{UA}}}$ outputs an "implicit" representation of a "witness" to the statement $\bar{x} = (x, \langle h, c_1, c_2, r_1, r_2 \rangle)$ proved by P^*_{UA}. Since the values i, y, s, z have fixed polynomial length, they can all be extracted in polynomial time. Note, however, that since there is not a (polynomial) bound on the length of the program Π, we can extract only an implicit representation of Π. The concludes the proof of the lemma. □

Armed with Lemma A.3, we now turn to show that E_{WI} outputs a false witness with negligible probability in the execution of E'^{P^*}. Suppose for contradiction that there exists a polynomial $p(n)$ such that, for infinitely many n's, E_{WI} outputs a false witness, with probability at least $\epsilon(n) = \frac{1}{p(n)}$. We construct a $T(n)^{O(1)}$-sized circuit family, $\{C_n\}_n$, that finds collisions for $\{\mathcal{H}_n\}_n$ with probability $\mathrm{poly}(\epsilon(n))$.

More specifically, the following hold:

- On input $h \stackrel{\mathrm{R}}{\leftarrow} \mathcal{H}_n$, the circuit C_n incorporates P^* and internally emulates the honest verifier V for P^* until the protocol $\langle P_{\mathsf{sUA}}, V_{\mathsf{sUA}} \rangle$ is reached (i.e., C_n internally sends randomly chosen messages h, r_1, r_2 to P^*, resulting in a residual prover $P^*(h, r_1, r_2)$).
- C_n then invokes the knowledge extractor $\mathsf{extract}$, guaranteed by Lemma A.3, on $P^*(h, r_1, r_2)$, extracting values i, y, s, z and an implicit representation of Π, given by a machine M.
- If $\mathsf{extract}$ fails, C_n outputs `fail`; otherwise it rewinds P^* until the point where it expects to receive the message r_i and then continues the emulation of the honest verifier from this point (using new random coins).
- Once again, when P^* reaches $\langle P_{\mathsf{sUA}}, V_{\mathsf{sUA}} \rangle$, C_n invokes $\mathsf{extract}$ on the residual prover, extracting values i', y', s', z' and an implicit representation of Π', given by a machine M'.
- If the extraction fails or if $i' \neq i$, C_n outputs `fail`.

It remains to analyze the success probability of C_n. We start by noting that $y = y'$ occurs only with negligible probability. This follows from the computational binding property of **Com**. Since the probability that E_{WI} outputs a false witness is $\epsilon(n)$ it must hold that for a fraction $\epsilon(n)/2$ of the verifier messages before protocol $\langle P_{\mathsf{sUA}}, V_{\mathsf{sUA}}\rangle$, E_{WI} outputs a false witness with probability $\epsilon(n)/2$ when given oracle access to P^* having been fed messages in this set of "good" messages. Due to the correctness of $\mathsf{extract}$ it holds that when C_n selects verifier messages from this "good" set, the probability that extraction succeeds (in outputting a false witness) on P^* is

$$\epsilon' = \mathrm{poly}(\epsilon).$$

Thus, given that C_n picks random verifier messages, it holds that the probability that $\mathsf{extract}$ succeeds is at least

$$\epsilon'' = \frac{\epsilon}{2}\epsilon' = \mathrm{poly}(\epsilon).$$

Thus, there exists an index $\sigma \in \{1, 2\}$ such that the extraction outputs the index $i = \sigma$ with probability $\epsilon''' = \epsilon''/2$. Again, for a fraction $\epsilon'''/2$ of verifier messages before slot σ (when $\sigma = 1$, there is only one message, namely h, while when $\sigma = 2$, the messages are h, r_1), the residual prover ($P^*(h)$ when $\sigma = 1$, or $P^*(h, r_1)$ when $\sigma = 2$) succeeds in convincing the verifier with probability $\epsilon'''/2$. We conclude that with probability

$$\epsilon'''/2 \cdot (\epsilon'''/2)^2 = \mathrm{poly}(\epsilon)$$

C_n obtains an implicit representation of programs Π, Π' such that $\exists y, y' \in \{0,1\}^{(|r_i|-n)}$ for which $\Pi(y) = r_i$, $\Pi'(y') = r'_i$, and $h(\Pi) = h(\Pi')$. Using a simple counting argument it follows that with probability $(1 - 2^{-n})$ (over the choices of r_i, r'_i), $\Pi \neq \Pi'$.[23] Thus, by *fully* extracting the programs (from the implicit representation) C_n finds a collision with probability

$$\mathrm{poly}(\epsilon) \cdot (1 - 2^{-n}) = \mathrm{poly}(\epsilon).$$

Note that the time required for extracting these programs is upper bounded by $T(n)^{O(1)}$. Thus, any poly-time prover P^* that can make V accept $x \notin L$ with nonnegligible probability can be used in order to obtain collisions for $h \stackrel{\mathrm{R}}{\leftarrow} \mathcal{H}_n$ in time $T(n)^{O(1)}$ (note that here we additionally rely on the fact that $\mathsf{extract}$ is a strict polynomial-time machine), in contradiction to the collision resistance of $\{\mathcal{H}_n\}_n$ against $T(n)$-sized circuits.[24] This concludes the proof of the proposition. □

This completes the proof of Lemma A.3. □

Basing the construction on "standard" collision-resistant hash functions. Although the above analysis (for the proof of knowledge property of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$) relies on the assumption that $\{\mathcal{H}_k\}_k$ is a family of hash functions that is collision resistant against $T(k)$-sized circuits, we note that, by using the method of Barak and Goldreich [3], this assumption can be weakened to the (more) standard assumption of collision resistance against polynomial-sized circuits. The main idea in their approach is to replace the arbitrary hashing in Slots 1 and 2 with the following two-step hashing procedure:

[23] Fix Π, Π', y, r_i. Then, with probability 2^{-n} over the choice of r'_i, there exist a $y' \in \{0,1\}^{(|r'_i|-n)}$ so that $\Pi'(y') = r'_i$.

[24] We mention that by slightly modifying the protocol, following the approach by Barak and Goldreich [3], one can instead obtain a polynomial-sized circuit C_n finding a collisions for $\mathcal{H}_k$. More details follow after the proof.

- Apply a "good"[25] error-correcting code ECC to the input string.
- Use tree hashing [29, 8] to the encoded string.

This method has the advantage that, in order to find a collision for the hash function in the "proof of knowledge" proof, the full description of programs Π, Π' is not needed. Instead it is sufficient to look at a randomly chosen position in the description (which can be computed in polynomial time from the implicit representation of Π, Π'). The analysis here relies on the fact that two different codewords differ in random position i with a (positive) constant probability.

Acknowledgments. We are grateful to Johan Håstad and Moni Naor for many helpful conversations and great advice. Thanks to Boaz Barak for useful clarifications of his works. The second author would also like to thank Marc Fischlin, Rosario Gennaro, Yehuda Lindell, and Tal Rabin for insightful discussions regarding nonmalleable commitments. Thanks to Oded Goldreich for useful feedback on an earlier version of this work and to the anonymous referees for their thoughtful comments. Finally, thanks to Huijia Lin for pointing out a subtlety in the proof of Proposition 4.2.

TENSOR NORMS AND THE CLASSICAL COMMUNICATION COMPLEXITY OF NONLOCAL QUANTUM MEASUREMENT*

YAOYUN SHI† AND YUFAN ZHU†

Abstract. We initiate the study of quantifying nonlocality of a bipartite measurement by the minimum amount of classical communication required to simulate the measurement. We derive general upper bounds in terms of some *tensor norms* of the measurement operator. As applications, we show that (a) if the amount of communication is a constant, then quantum and classical communication protocols with an unlimited amount of shared entanglement or shared randomness compute the same class of functions; and (b) it requires only a constant amount of communication to classically generate an approximation of the output distribution resulting from local measurements on an entangled quantum state, as long as the number of measurement outcomes is a constant.

Key words. quantum entanglement, classical simulation, communication complexity, tensor norms, Bell inequality

1. Introduction and summary of results.

1.1. Background. Although Einstein himself made significant contributions to the development of quantum mechanics, he famously questioned the "completeness" of the theory with a "paradox" that he formulated with Podolsky and Rosen [17]. Following Bohm [7], the essence of the paradox is that two "quantum coins," possessed by two parties called Alice and Bob, may correlate in a state

$$\frac{1}{\sqrt{2}}\left(|\texttt{Head}\rangle_A|\texttt{Tail}\rangle_B - |\texttt{Tail}\rangle_A|\texttt{Head}\rangle_B\right).$$

If each party measures his or her coin, with 1/2 probability, one of the two outcomes is observed. However, once a measurement is made by one party, say, Alice, then Bob would always observe the opposite outcome with certainty. A unique property of the state is that no matter what physical property of the coins is measured—whether it be their positions or their velocities—Bob's outcome is always opposite to that of Alice's *with certainty*. It appeared to Einstein that this consequence could not be fully explained by quantum mechanics, since the uncertainty principle implies that not all pairs of properties can be determined with certainty.

The Einstein–Podolsky–Rosen (EPR) paradox does not show that quantum mechanics is inconsistent. In the far-reaching paper [3], Bell formulated a set of inequalities, now referred to as *Bell inequalities*, that must be satisfied by the correlations produced by any so-called *hidden variable model* of classical physics but nevertheless would be violated by some quantum correlations. The violation has been confirmed by several experiments (see, e.g., [40]). The EPR paradox instead reveals the essential

property of quantum states—quantum entanglement—that underlies the many counterintuitive properties and powerful applications of quantum information. A seminal example is the *quantum teleportation* protocol [4], which makes use of one EPR state to transmit a quantum bit by sending two classical bits. Another example is the construction of *unconditionally secure* quantum key distribution protocols [5, 18, 28, 30].

Given its importance, quantum entanglement has been the subject of numerous studies (see, e.g., the books [33, 34]). The focus has been on understanding the inherent quantitative trade-offs among various resources involved in the creation and conversion of entangled states. As entanglement is the result of nonlocal quantum interactions, understanding various aspects of the nonlocality of quantum operations is also of fundamental importance. Quantifying nonlocality of quantum operators is precisely the purpose of this paper.

1.2. Main result. A natural nonlocality measure of a quantum operation is its *generating capacity*, which is the maximum entanglement increase that it can create (see, e.g., [6]). Another approach, from more of a computational point of view, is to measure nonlocality by the amount of resources, such as the time for evolving elementary Hamiltonians or the number of elementary gates, required to simulate the operator (see, e.g., [11, 12]).

In this paper, we take a different approach and investigate a nonlocality measure in the framework of communication complexity. Our work is not the first to apply communication complexity to the study of entanglement. There are studies, which we will review shortly, on the classical communication complexity of simulating quantum correlations. Nevertheless, our emphasis is on quantum operators. Although we focus on measurement operators, our approach can be extended to the most general quantum operations.

Consider the following quantum process. Alice and Bob share a bipartite state $|E\rangle_{AB}$. They apply local operations R_A and R_B to their systems, before a final measurement Q is applied to the joint system, producing a distribution $\mu = \mu(Q, |E\rangle, R_A, R_B)$ of measurement outcomes.

Imagine now that Alice and Bob can process only classical information. However, they both have a classical description of Q and $|E\rangle$. In addition, Alice has a classical description of R_A, and Bob has that of R_B. They hope to simulate the quantum process by producing a random output whose distribution is close to μ. Since Alice does not know R_B and Bob does not know R_A, the simulation requires communication. We allow Alice and Bob to share an unlimited supply of random bits. We define the *classical communication complexity* of Q, denoted by $\mathrm{Com}(Q)$, to be the minimum number of bits that need to be exchanged by a simulating protocol that works for all $|E\rangle$, R_A, and R_B.

Intuitively, $\mathrm{Com}(Q)$ reflects how nonlocal Q is. Consider, for example, the extremal case that Q is the tensor product of two local operations. If there is no quantum correlation in the initial state, it is clear that Alice and Bob could simulate the quantum process without interaction. We shall see that even if the initial state is entangled, they need only exchange a constant number of bits.

On the other hand, $\mathrm{Com}(Q)$ would be much larger for highly nonlocal Q. Let $n \geq 1$ be an integer. Consider the following operator:

$$\mathrm{IP}_n \stackrel{\mathrm{def}}{=} \sum_{\substack{x,y\in\{0,1\}^n \\ x\cdot y=1}} |x\rangle\langle x| \otimes |y\rangle\langle y|. \tag{1}$$

When R_A creates a state $|x\rangle$, $x \in \{0,1\}^n$, and R_B creates $|y\rangle$, $y \in \{0,1\}^n$, then $(IP)_n$ determines if $x \cdot y = 1$. This is the so-called "inner product" function, which is well studied in the communication complexity literature. It is well known that any classical communication protocol for solving the inner product requires $\Omega(n)$ bits of communication. In fact, Cleve et al. [14] proved that $\Omega(n)$ quantum bits are necessary, too. Thus $\mathrm{Com}(\mathrm{IP}) = \Omega(n)$. We do not know if this bound for $\mathrm{Com}(\mathrm{IP})$ is tight.

The goal of this paper is to give a general estimation of $\mathrm{Com}(Q)$ and its applications. It is not immediately clear if $\mathrm{Com}(Q)$ is finite for all Q acting on a finite space, since the dimension of the initial state $|E\rangle$ could be arbitrarily large. Our main result is to derive a general upper bound on $\mathrm{Com}(Q)$ in terms of a certain operator norm $\|Q\|_\diamond$ on Q, which is bounded from above by a polynomial in the dimension of Q.

THEOREM 1.1 (informally). *For any bipartite measurement Q, $\mathrm{Com}(Q) = O(\|Q\|_\diamond^2)$. In particular, if K is the dimension of the space that Q acts on, $\mathrm{Com}(Q) = O(K^2)$.*

The diamond norm $\|\cdot\|_\diamond$ was originally defined on superoperators and has been a powerful tool in the study of quantum interactive proof systems [22] and quantum circuits on mixed states [1]. We use a natural mapping from bipartite operators to superoperators to define the diamond norm on the former based on the diamond norm on the latter.

The approach in proving Theorem 1.1 can be extended to obtain general upper bounds on $\mathrm{Com}(Q)$ in terms of other operators norms. Those norms belong to so-called *tensor norms*, i.e., norms $\|\cdot\|_\alpha$ that satisfy $\|P\|_\alpha \le \|A\| \cdot \|B\|$ whenever $P = A \otimes B$. Tensor norms have been studied for decades and have yielded a great deal of rich concepts and deep results (see, e.g., [16]). In recent years, they have been applied to quantum information theory to characterize and quantify the nonlocality of quantum states [37, 38]. The tensor norms that appear in our upper bounds capture the nonlocality of bipartite operators in their own ways and may have further applications.

1.3. Applications on quantum communication complexity. After obtaining general upper bounds on $\mathrm{Com}(Q)$, we show that they in turn have useful applications on quantum communication complexity. Recall that in the setting of communication complexity [42, 43], Alice and Bob wish to compute a function $f(x, y)$, of which x is known only to Alice and y is known only to Bob. The communication complexity of f is the minimum amount of information that Alice and Bob need to exchange in order to compute f correctly for any input. Communication complexity has been a major research field (see, e.g., the book [27]), with a wide range of applications.

A concrete application of our result is on the advantage of sharing entanglement in quantum protocols, a question that has puzzled many researchers [13, 9, 24, 31]. It is known that sharing entanglement could give a constant additive advantage [13, 9] or save a half of the communication [14]. However, little is known on the limit of the advantage. This is in sharp contrast with the classical case of sharing randomness, where we know that it can only save at most a logarithmic additive term [32]. If there is a quantum protocol that exchanges q qubits with m qubits of prior entanglement, then the best classical simulation we know (see, e.g., [25]) is $\exp(\Omega(q + m))$. This is embarrassingly large, especially when $q \ll m$. Using our upper bound on the classical communication complexity of nonlocal operators, we prove the following result. Recall that in the *simultaneous message passing (SMP)* model with shared randomness, the two parties holding the inputs share an arbitrarily long random string and send a

single message to a third party, who is required to determine the outcome correctly with high probability.

THEOREM 1.2. *If a two-party quantum protocol uses q qubits of communication and m qubits of share entanglement, then it can be simulated by a classical protocol using* $\exp(O(q))$ *bits with shared randomness. The simulation does* not *depend on m. Furthermore, it can be carried out in the SMP model with shared randomness.*

Notice that the exponential dependence on q cannot be improved because of the existence of an exponential gap between the quantum and classical communication complexities for partial functions [35]. As a consequence of the above theorem, we have the following corollary.

COROLLARY 1.3. *If a communication complexity problem has a constant cost quantum communication protocol with shared entanglement, it also has a constant cost classical SMP protocol with shared randomness.*

It is interesting to contrast the above with the following recent result by Yao [44].

THEOREM 1.4 (see [44]). *If a communication complexity problem of input size n has a constant cost classical SMP protocol with shared randomness, then it has an* $O(\log n)$ *cost quantum SMP protocol* without *shared entanglement.*

Combining this result with ours, we have the next corollary.

COROLLARY 1.5. *If a communication complexity problem of input size n has a constant cost two-party quantum protocol with shared entanglement, it has an* $O(\log n)$ *cost quantum SMP protocol without shared entanglement.*

1.4. Applications on simulating quantum correlations. Yet another application of our result is in the classical simulation of quantum correlations. Suppose that two parties, Alice and Bob, are given an entangled quantum state $|E\rangle$. Alice then applies a local measurement Q_A to her system and Bob applies Q_B to his. The result is a correlated joint distribution $\mu(|E\rangle, Q_A, Q_B)$ on both measurement outcomes. If Alice and Bob do not communicate, the resulting distribution may violate the Bell inequalities, and hence may be impossible to generate by the hidden variable model of classical physics [3].

A natural question following from the above work of Bell is how much communication is required for Alice and Bob to simulate the quantum correlation. Most works in this direction focus on the exact simulation and on measurements applied to a constant number of qubits [41, 2, 15, 39, 8, 29]. We study the *approximate* simulation of quantum correlations, where the measurement outcomes take a constant number of possible values while the dimension of the shared entangled state may be arbitrarily large.

THEOREM 1.6 (informally). *Let $\delta \in (0, 2)$, and let $|E\rangle$ be a bipartite state. Then there exists a randomized communication protocol that exchanges an* $O\left(\log \frac{1}{\delta}/\delta^2\right)$ *number of bits, and for each pair of local measurements $(R_A,\ R_B)$, the protocol outputs a distribution that is within δ deviation in statistical distance from $\mu(|E\rangle, R_A, R_B)$.*

1.5. Organization. The rest of the paper is organized as follows. We start with the description of a general framework for classical simulation of quantum protocols. The cost parameter of this framework is then optimized in the next section, giving the main theorem. In the section that follows we give applications of the theorem. Finally, we conclude with several open problems.

2. A simulation framework. Our classical simulation of quantum protocols falls into the following framework. Let p be the acceptance probability (i.e., the probability of outputting 1) of a given quantum protocol (which arises either from a

communication task or from a bipartite measurement). We use $p = \langle\psi_A|\psi_B\rangle$ to denote two vectors $|\psi_A\rangle$ and $|\psi_B\rangle$ that can be prepared by Alice and Bob, respectively. Note that the lengths of the two vectors may be very large in general. Indeed, the shorter their lengths are, the better the simulation is.

More precisely, if for some number C, $\||\psi_A\rangle\| \le C$ and $\||\psi_B\rangle\| \le C$, then the following simulation uses $O(C^4)$ bits. Alice and Bob send Charlie $\||\psi_A\rangle\|$ and $\||\psi_B\rangle\|$, respectively, up to $O(1/C)$ precision. This requires $O(\log C)$ bits. They then proceed to estimate $\cos\theta$ for the angle θ between $|\psi_A\rangle$ and $|\psi_B\rangle$ up to a precision of $O(1/C^2)$. The protocol in Kremer, Nisan, and Ron [26], which is based on the following observation of Goemans and Williamson [20], gives a protocol that accomplishes the latter task using $O(C^4)$ bits.

Assume for simplicity that all vectors are real (the complex number case can be easily reduced to the real case). If $|\psi\rangle$ is a random unit vector in the same space of $|\phi_A\rangle$ and $|\phi_B\rangle$, then

$$\text{Prob}\left[\text{sign}(\langle\psi|\psi_A\rangle) \neq \text{sign}(\langle\psi|\psi_B\rangle)\right] \;=\; \theta/\pi. \tag{2}$$

Hence, in order to estimate $\cos\theta$ with error term δ', it suffices to estimate θ/π to some error term $O(\delta')$ using the above equality checking of signs. This can be achieved by a simple SMP protocol that repeats the following: Alice and Bob interpret the shared randomness as a unit vector $|\psi\rangle$; they then send $\text{sign}(\langle\psi|\psi_A\rangle)$ and $\text{sign}(\langle\psi|\psi_B\rangle)$, respectively, to Charlie. By a simple application of the Chernoff bound, an $O\left(\log\frac{1}{\epsilon}/\delta'^2\right)$ number of repetitions is sufficient to give an estimation of p with δ' accuracy, and the protocol may fail with $\le \epsilon$ probability. With $\delta' = O(\delta/C^2)$, this is $O\left(C^4\log\frac{1}{\epsilon}/\delta^2\right)$ bits.

We note that, using a similar approach, Toner and Bacon [41] gave a protocol that produces a random ±1 variable whose expectation is precisely $\cos\theta$. Their protocol is not asymptotically more efficient than the above. We summarize the above simulation result as follows.

THEOREM 2.1 (see [26, 20]). *Suppose that the acceptance probability p of a quantum protocol can be expressed as $p = \langle\psi_A|\psi_B\rangle$, where $|\psi_A\rangle$ and $|\psi_B\rangle$ are vectors that can be prepared by each party individually and $\||\psi_A\rangle\|,\ \||\psi_B\rangle\| \le C$ for some $C > 0$. Then there is a randomized SMP protocol with shared randomness in which* (a) *Alice and Bob send $O\left(C^4\log\frac{1}{\epsilon}/\delta^2\right)$ bits to Charlie, and* (b) *Charlie outputs a number p' such that $|p' - p| \le \delta$ with probability $\ge 1 - \epsilon$.*

3. The main theorem. In this section, we formally define the classical communication complexity and the diamond norm of bipartite quantum operators, and derive an upper bound on the former in terms of the latter. We shall focus on the case when the measurement gives two outcomes and the dimensions of the two systems are the same. Our results can be extended trivially to more general cases.

We use script letters, $\mathcal{N}$, $\mathcal{M}$, $\mathcal{F}$, ..., to denote Hilbert spaces and use $\mathbf{L}(\mathcal{N})$ to denote the space of operators on $\mathcal{N}$. The identity operator on $\mathcal{N}$ is denoted by $I_{\mathcal{N}}$, and the identity superoperator on $\mathbf{L}(\mathcal{N})$ is denoted by $\mathbf{I}_{\mathcal{N}}$. Recall that a *positive-operator-valued measurement (POVM)* on a Hilbert space $\mathcal{H}$ is a set of positive semidefinite operators $\{Q_1, Q_2, \ldots, Q_m\}$ on $\mathcal{H}$ such that $\sum_{i=1}^m Q_i = I_{\mathcal{H}}$. Each Q_i is called a *measurement element* and corresponds to the measurement outcome i. We may refer to a semidefinite operator Q, $0 \le Q \le 1$, as a *measurement element* of the implicit binary POVM $\{Q, I - Q\}$. In this paper, *physically realizable operator* means a completely positive superoperator that does not increase the trace. For more details on the basic notions of quantum information processing, see the textbooks [33, 34].

3.1. Classical simulation of bipartite measurement. In this subsection we define the central concept of this paper, which is the classical communication complexity of quantum measurement.

DEFINITION 3.1. *Let $\delta, \epsilon \in (0, 1/2)$, and let $Q \in \mathbf{L}(\mathcal{N}_A \otimes \mathcal{N}_B)$ be a measurement element. The* classical communication complexity *of Q with precision δ and success probability $1-\epsilon$, denoted by $\mathrm{Com}_{\delta,\epsilon}(Q)$, is the minimum integer k such that there is a randomized communication protocol between two parties Alice and Bob with shared randomness that uses k bits and satisfies the following conditions for any bipartite state $|E\rangle \in \mathbf{L}(\mathcal{M}_A \otimes \mathcal{M}_B)$ and physically realizable operators $R_A : \mathbf{L}(\mathcal{M}_A) \to \mathbf{L}(\mathcal{N}_A)$ and $R_B : \mathbf{L}(\mathcal{M}_B) \to \mathbf{L}(\mathcal{N}_B)$:*

1. *Alice's input is a classical description of $|E\rangle$ and R_A; similarly, Bob's input is a classical description of $|E\rangle$ and R_B.*
2. *The protocol outputs a real number p such that*

$$|p - \mathrm{tr}(Q(R_A \otimes R_B)(|E\rangle\langle E|))| \le \delta$$

with probability at least $1-\epsilon$. The probability is over the shared randomness.

3.2. The diamond norm on bipartite operators. Let $\mathcal{N}$ be a Hilbert space and $T : \mathbf{L}(\mathcal{N}) \to \mathbf{L}(\mathcal{N})$ be a superoperator. The *diamond norm* on superoperators is defined as [23]

$$\|T\|_\diamond \stackrel{\mathrm{def}}{=} \inf\{\|A\|\|B\| : \mathrm{tr}_{\mathcal{F}}(A \cdot B^\dagger) = T,\ A,\ B \in \mathbf{L}(\mathcal{N}, \mathcal{N} \otimes \mathcal{F})\}.$$

For our application, the following alternative characterization of the diamond norm is more convenient.

LEMMA 3.2 (see, e.g., [23]). *For any superoperator T,*

$$\|T\|_\diamond = \inf\left\{ \left\|\sum_t A_t^\dagger A_t\right\|^{1/2} \cdot \left\|\sum_t B_t^\dagger B_t\right\|^{1/2} : A_t,\ B_t \in \mathbf{L}(\mathcal{N}),\ T = \sum_t A_t \cdot B_t^\dagger \right\}.$$

Let $\mathcal{N}_A$, $\mathcal{N}_B$, and $\mathcal{N}$ be Hilbert spaces of the same dimension. We fix an isomorphism between any two of them. For an operator in one space, we use the same notation for its images and preimages, under the isomorphisms, in the other spaces.

Let $Q \in \mathbf{L}(\mathcal{N}_A \otimes \mathcal{N}_B)$ be a bipartite operator, and let $Q = \sum_t A_t \otimes B_t^\dagger$ for some $A_t \in \mathbf{L}(\mathcal{N}_A)$ and $B_t \in \mathbf{L}(\mathcal{N}_B)$. Define a mapping $\mathcal{T}$ from bipartite operators on $\mathcal{N}_A \otimes \mathcal{N}_B$ to superoperators $\mathbf{L}(\mathcal{N}) \to \mathbf{L}(\mathcal{N})$ by mapping $Q \mapsto \mathcal{T}(Q) \stackrel{\mathrm{def}}{=} \sum_t A_t \cdot B_t^\dagger$. By direct inspection, the mapping is independent of the choice of the decomposition of Q and is in fact an isomorphism.

DEFINITION 3.3. *Let $Q \in \mathbf{L}(\mathcal{N}_A \otimes \mathcal{N}_B)$ be a bipartite operator. The* diamond norm *of Q, denoted by $\|Q\|_\diamond$, is $\|Q\|_\diamond \stackrel{\mathrm{def}}{=} \|\mathcal{T}(Q)\|_\diamond$.*

By Lemma 3.2, for any Q,

$$\|Q\|_\diamond = \inf\left\{ \left\|\sum_t A_t^\dagger A_t\right\|^{1/2} \cdot \left\|\sum_t B_t^\dagger B_t\right\|^{1/2} : \right.$$
$$\left. A_t \in \mathbf{L}(\mathcal{N}_A),\ B_t \in \mathbf{L}(\mathcal{N}_B),\ Q = \sum_t A_t \otimes B_t^\dagger \right\}.$$

Note that if a superoperator $T = A \cdot B$ for some $A, B \in \mathbf{L}(\mathcal{N})$, $\|T\|_\diamond = \|A\| \cdot \|B\|$. Therefore the diamond norm on bipartite operators is a tensor norm.

LEMMA 3.4. *For all* $A, B \in \mathbf{L}((N))$, $\|A \otimes B\|_\diamond = \|A\| \cdot \|B\|$.

A nice property of the superoperator diamond norm is that it is "stable"; i.e., it remains unchanged when tensored with the identity operator on an additional space [23].

LEMMA 3.5. *Let* $\mathcal{N}$, $\mathcal{M}$, *and* $\mathcal{F}$ *be Hilbert spaces, and let* $T : \mathbf{L}(\mathcal{N}) \to \mathbf{L}(\mathcal{M})$ *be a superoperator. Then* $\|\mathbf{I}_\mathcal{F} \otimes T\|_\diamond = \|T\|_\diamond$.

This stability property carries over to our diamond norm and is important for our applications. Let $\mathcal{F}_A$ and $\mathcal{F}_B$ be Hilbert spaces of the same dimension, and let $Q \in \mathbf{L}(\mathcal{N}_A \otimes \mathcal{N}_B)$. Denote by $Q_{\mathcal{F}_A,\mathcal{F}_B}$ the bipartite operator $Q \otimes I_{\mathcal{F}_A \otimes \mathcal{F}_B}$, where the two subsystems are $\mathcal{N}_A \otimes \mathcal{F}_A$ and $\mathcal{N}_B \otimes \mathcal{F}_B$.

LEMMA 3.6. *For any* Q, $\|Q_{\mathcal{F}_A,\mathcal{F}_B}\|_\diamond = \|Q\|_\diamond$.

If Q is a measurement element of a POVM acting on a Hilbert space of dimension K, then we have the following upper bound on $\|Q\|_\diamond$.

PROPOSITION 3.7. *Let* Q *be a bipartite measurement element acting on* $\mathcal{H}_A \otimes \mathcal{H}_B$. *Then* $\|Q\|_\diamond \leq \dim(\mathcal{H}_A \otimes \mathcal{H}_B)$.

Proof. Let $K_{\min} = \min\{\dim(\mathcal{H}_A), \dim(\mathcal{H}_B)\}$, and let $K = \dim(\mathcal{H}_A \otimes \mathcal{H}_B)$. Fix a pure state $|u\rangle \in \mathcal{H}_A \otimes \mathcal{H}_B$ and denote its Schmidt decomposition as

$$|u\rangle = \sum_{i=1}^{K_{\min}} \sqrt{p_i}|i\rangle_A|i\rangle_B,$$

where $p_i \geq 0$, $\sum p_i = 1$, and $\{|i\rangle_A : 1 \leq i \leq \dim(\mathcal{H}_A)\}$, $\{|i\rangle_B : 1 \leq i \leq \dim(\mathcal{H}_B)\}$ are orthonormal bases for the two subsystems, respectively. Then

$$|u\rangle\left\langle u| = \sum_{i,j=1}^{K_{\min}} \sqrt{p_i p_j}|i\right\rangle_A \langle j|_A \otimes |i\rangle_B\langle j|_B.$$

Let $A_{i,j} = \sqrt{p_i}|i\rangle_A\langle j|_A$ and $B_{i,j} = \sqrt{p_j}|j\rangle_B\langle i|_B$. We have

$$\left\| \sum_{i,j=1}^{K_{\min}} A_{i,j}^\dagger A_{i,j} \right\| = \left\| \sum_{i,j} p_i \langle i|_A |i\rangle_A |j\rangle_A \langle j|_A \right\| = 1.$$

Similarly, $\| \sum_{i,j} B_{i,j}^\dagger B_{i,j} \| = 1$. Thus,

$$\||u\rangle\langle u|\|_\diamond = \|\mathcal{T}(|u\rangle\langle u|)\|_\diamond \leq \sqrt{\left\| \sum_{i,j} A_{i,j}^\dagger A_{i,j} \right\|} \sqrt{\sum_{i,j} B_{i,j}^\dagger B_{i,j}} \leq 1.$$

Since Q a is measurement element, $Q = \sum_{i=1}^K c_i |u_i\rangle\langle u_i|$ for some $c_i \in [0,1]$ and an orthonormal basis $\{u_i : 1 \leq i \leq K\}$. Thus $\|Q\|_\diamond \leq \sum_{i=1}^K c_i \||u_i\rangle\langle u_i|\|_\diamond \leq K$. ∎

This bound is not far from being optimal for IP_n, in which case $K = 2^{2n}$. To prove a lower bound on $\|\mathrm{IP}_n\|_\diamond$, we use a fundamental characterization of the diamond norm (see [23, Theorem 11.1]).

THEOREM 3.8 (see [23]). *Let* $T : L(\mathcal{N}) \to L(\mathcal{N})$ *be a superoperator and* $\mathcal{G}$ *be a space of the same dimension as* $\mathcal{N}$. *Then*

$$\|T\|_\diamond = \sup_{\rho \in L(\mathcal{N} \otimes \mathcal{G}), \rho \neq 0} \frac{\|(T \otimes \mathbf{I}_\mathcal{G})(\rho)\|_{\mathrm{tr}}}{\|\rho\|_{\mathrm{tr}}}. \tag{3}$$

PROPOSITION 3.9. *For the* IP_n *operator defined in* (1), $\|\mathrm{IP}_n\|_\diamond \geq 2^{n/2-1} - 1/2$.

Proof. By definition,

$$\mathcal{T}(\mathrm{IP}_n) = \sum_{\substack{x,y\in\{0,1\}^n \\ x\cdot y=1}} |x\rangle\langle x| \cdot |y\rangle\langle y|.$$

Setting $\rho = \sum_{x,y} |x\rangle\langle y| \otimes I_{\mathcal{G}}$ in (3), we have

$$\|\mathcal{T}(\mathrm{IP}_n)\|_\diamond \;\geq\; \frac{1}{2^n} \left\| \sum_{\substack{x,y\in\{0,1\}^n \\ x\cdot y=1}} |x\rangle\langle y| \right\|_{\mathrm{tr}}.$$

Let $A = \sum_{x,y\in\{0,1\}^n,\ x\cdot y=1} |x\rangle\langle y|$, J be the all-one matrix, and let H be the Hadamard matrix (i.e., $\sum_{x,y\in\{0,1\}^n}(-1)^{x\cdot y}|x\rangle\langle y|$). Then $A = \frac{1}{2}(J - H)$. The largest eigenvalue of J is 2^n and all other eigenvalues are 0; thus $\|J\|_{\mathrm{tr}} = 2^n$. All of the eigenvalues of H are $\pm 2^{n/2}$; thus $\|H\|_{\mathrm{tr}} = 2^{3n/2}$. Therefore,

$$\|A\|_{\mathrm{tr}} \geq \frac{1}{2}(\|H\|_{\mathrm{tr}} - \|J\|_{\mathrm{tr}}) = \frac{1}{2}(2^{3n/2} - 2^n).$$

Thus $\|\mathrm{IP}_n\|_\diamond \geq 2^{n/2-1} - 1/2$. □

We conclude this subsection by noting that our diamond norm on bipartite operators appears natural in connection with the following matrix analogy of the Cauchy–Schwarz inequality.

THEOREM 3.10 (see Jocić [21]). *For any operators* A_t *and* B_t,

$$\left\| \sum_t A_t \otimes B_t^\dagger \right\| \leq \left\| \sum_t A_t^\dagger A_t \right\|^{1/2} \cdot \left\| \sum_t B_t^\dagger B_t \right\|^{1/2}. \tag{4}$$

Inequality (4) may actually be proved by the same approach that we use to prove Theorem 3.11 below.

3.3. Upperbounding Com(Q) by the diamond norm. We now use the diamond norm to derive an upper bound on $\mathrm{Com}_{\delta,\epsilon}(Q)$. Recall that if $\mathcal{M}$ and $\mathcal{N}$ are two Hilbert spaces, an *isometric embedding* $U : \mathcal{M} \to \mathcal{N}$ is a linear map that satisfies $U^\dagger U = I_{\mathcal{M}}$.

THEOREM 3.11. *For any bipartite measurement element* Q,

$$\mathrm{Com}_{\delta,\epsilon}(Q) = O\left(\|Q\|_\diamond^2 \cdot \log \frac{1}{\epsilon} \Big/ \delta^2 \right). \tag{5}$$

In particular, $\mathrm{Com}_{\delta,\epsilon}(Q) = O(K^2 \log \frac{1}{\epsilon}/\delta^2)$, *where* K *is the dimension of the space on which* Q *acts. Furthermore, this upper bound can be achieved by an SMP protocol with shared randomness.*

Proof. Fix a bipartite state $|E\rangle \in \mathcal{M}_A \otimes \mathcal{M}_B$ and physically realizable operators $R_A : \mathbf{L}(\mathcal{M}_A) \to \mathbf{L}(\mathcal{N}_A)$, $R_B : \mathbf{L}(\mathcal{M}_B) \to \mathbf{L}(\mathcal{N}_B)$. We first consider the case when $R_A = U \cdot U^\dagger$ for an operator $U : \mathcal{M}_A \to \mathcal{N}_A$ with $\|U\| \leq$, and similarly, $R_B = V \cdot V^\dagger$

for $V : \mathcal{M}_B \to \mathcal{N}_B$ with $\|V\| \le 1$. Without loss of generality, we assume that Alice and Bob have agreed on a Schmidt decomposition,

$$|E\rangle = \sum_{i=1}^{\min\{\dim(\mathcal{N}_A),\dim(\mathcal{N}_B)\}} \sqrt{p_i}|i\rangle_A \otimes |i\rangle_B,$$

for some $p_i \ge 0$, $\sum_i p_i = 1$, for an orthonormal basis $\{|i\rangle_A\}_i$ of $\mathcal{N}_A$, and for an orthonormal basis $\{|i\rangle_B\}_i$ of $\mathcal{N}_B$. Denote by $|i_A\rangle \stackrel{\text{def}}{=} U|i\rangle$, and $|i_B\rangle \stackrel{\text{def}}{=} V|i\rangle$. Then Q is applied to $|\bar{E}\rangle \stackrel{\text{def}}{=} (U \otimes V)|E\rangle = \sum_i \sqrt{p_i}|i_A\rangle \otimes |i_B\rangle$.

Suppose $\|Q\|_\diamond$ is achieved under the decomposition $Q = \sum_t A_t \otimes B_t^\dagger$ with which, if $Q_A \stackrel{\text{def}}{=} \sum_t A_t^\dagger A_t$ and $Q_B \stackrel{\text{def}}{=} \sum_t B_t^\dagger B_t$, we have $\|Q_A\| = \|Q_B\| = \|Q\|_\diamond$. With those definitions, we have

$$p = \langle \bar{E}|Q|\bar{E}\rangle = \sum_{i,j,t} \sqrt{p_i p_j}\ \langle i_A|A_t|j_A\rangle \cdot \langle i_B|B_t^\dagger|j_B\rangle.$$

Define two vectors

$$|\psi_A\rangle \stackrel{\text{def}}{=} \sum_{i,j,t} \sqrt{p_j}\ \langle j_A|A_t^\dagger|i_A\rangle\ |i,j,t\rangle, \tag{6}$$

$$|\psi_B\rangle \stackrel{\text{def}}{=} \sum_{i,j,t} \sqrt{p_i}\ \langle i_B|B_t^\dagger|j_B\rangle\ |i,j,t\rangle. \tag{7}$$

Then $p = \langle \psi_A|\psi_B\rangle$. With $\rho_A \stackrel{\text{def}}{=} \sum_j p_j |j_A\rangle\langle j_A|$,

$$\langle \psi_A|\psi_A\rangle = \sum_{i,j,t} p_j |\langle j_A|A_t^\dagger|i_A\rangle|^2 \le \operatorname{tr}(\rho_A Q_A) \le \|Q_A\| = \|Q\|_\diamond.$$

Similarly, $\langle \psi_B|\psi_B\rangle \le \|Q_B\| = \|Q\|_\diamond$. Therefore, by Theorem 2.1, there is an SMP protocol that outputs an δ-approximation of p with probability $\ge 1 - \epsilon$ using $O\left(\|Q\|_\diamond^2 \cdot \log \frac{1}{\epsilon}/\delta^2\right)$ bits. This bound is $O(K^2 \log \frac{1}{\epsilon}/\delta^2)$ as $\|Q\|_\diamond \le K$ by Proposition 3.7.

In general, $R_A = \operatorname{Trace}_{\mathcal{F}_A}(U \cdot U^\dagger)$ for an operator $U_A : \mathcal{M}_A \to \mathcal{N}_A \otimes \mathcal{F}_A$ with $\|U\| \le 1$, and similarly, $R_B = \operatorname{Trace}_{\mathcal{F}_B}(V \cdot V^\dagger)$ for $V : \mathcal{M}_B \to \mathcal{N}_B \otimes \mathcal{F}_B$. Then $p = \operatorname{tr}(Q \otimes I_{\mathcal{F}_A \otimes \mathcal{F}_B}(U \otimes V)|E\rangle\langle E|(U^\dagger \otimes V^\dagger))$. Thus this case reduces to the first case, since $\|Q_{\mathcal{F}_A,\mathcal{F}_B}\|_\diamond = \|Q\|_\diamond$, by Lemma 3.6. □

Remark 3.12. One may improve the above upper bound on $\operatorname{Com}_{\delta,\epsilon}(Q)$ by a more carefully chosen $|\psi_A\rangle$ and $|\psi_B\rangle$ in (6) and (7). More specifically, let $\alpha \in [0,1]$, define

$$|\psi_A^\alpha\rangle = \sum_{i,j,t} \sqrt{p_i^\alpha p_j^{1-\alpha}}\ \langle j_A|A_t^\dagger|i_A\rangle\ |i,j,t\rangle$$

and

$$|\psi_B^\alpha\rangle = \sum_{i,j,t} \sqrt{p_i^{1-\alpha} p_j^\alpha}\ \langle i_B|B_t^\dagger|j_B\rangle\ |i,j,t\rangle.$$

One can verify that minimizing $\||\psi_A\rangle\| \cdot \||\psi_B\rangle\|$ over all decompositions of Q gives rise to a tensor norm; we do not know if is stable under tensoring with identity

superoperators. Although we have not found any useful application of an $\alpha \neq 0$, we cannot rule out the possibility that a carefully chosen α may give a better bound.

Remark 3.13. In the case that $|E\rangle$ is not entangled, the approach in Theorem 3.11 can be used to derive a systematic classical simulation. More specifically, in this context we would like to estimate $p = \langle\phi_A|\otimes\langle\phi_B|Q|\phi_A\rangle\otimes|\phi_B\rangle$ for a state $|\phi_A\rangle$ known only to Alice and a state $|\phi_B\rangle$ known only to Bob. For a decomposition of $Q = \sum_t A_t \otimes B_t^\dagger$, we define

$$|\psi_A\rangle = \sum_t \langle\phi_A|A_t^\dagger|\phi_A\rangle|t\rangle \quad \text{and} \quad |\psi_B\rangle = \sum_t \langle\phi_B|B_t^\dagger|\phi_B\rangle|t\rangle.$$

Then $p = \langle\psi_A|\psi_B\rangle$. It can be verified that

$$\|Q\|_\otimes \stackrel{\text{def}}{=} \inf\left\{\|\psi_A\| \cdot \|\psi_B\| : Q = \sum_t A_t \otimes B_t^\dagger\right\}$$

is a tensor norm and $\|Q\|_\otimes \leq \|Q\|_\diamond$. This approach gives a constant cost simulation of the elegant quantum fingerprint protocol of Buhrman et al. [10] for testing equality of two input strings.

4. Applications. We now apply Theorem 3.11 to derive classical upper bounds on quantum communication complexity.

4.1. Quantum SMP with shared entanglement. If the quantum protocol is in the SMP model with shared entanglement, we immediately have the following.

COROLLARY 4.1 (of Theorem 3.11). *If, in a quantum SMP protocol, Charlie applies a measurement P, then the protocol can be simulated by a classical SMP protocol with shared coins and using $O(\|P\|_\diamond^2)$ bits.*

4.2. Two-party interactive quantum communication with shared entanglement. Now consider the general two-party interactive quantum communication. We need the following lemma by Razborov [36] and Yao [43].

LEMMA 4.2 (see [36, 43]). *Let $\mathcal{P}$ be a two-party interactive quantum communication protocol that uses q qubits. Let $\mathcal{H}_A$ and $\mathcal{H}_B$ be the state spaces of Alice and Bob, respectively. For an input (x, y), denote by $|\Phi_{x,y}\rangle_{AB}$ the joint state of Alice and Bob before the protocol starts. Then there exist linear operators $A_h \in \mathbf{L}(\mathcal{H}_A)$ and $B_h \in \mathbf{L}(\mathcal{H}_B)$ for each $h \in \{0,1\}^{q-1}$ such that*

(a) *$\|A_h\| \leq 1$ and $\|B_h\| \leq 1$ for all $h \in \{0,1\}^{q-1}$;*

(b) *the acceptance probability of $\mathcal{P}$ on input x and y is $\|P|\Phi_{x,y}\rangle\|^2$, where*

$$P \stackrel{\text{def}}{=} \sum_{h\in\{0,1\}^{q-1}} A_h \otimes B_h.$$

We are now ready to prove Theorem 1.2.

Proof of Theorem 1.2. Let $|E\rangle \in \mathcal{N}_A \otimes \mathcal{N}_B$ be the shared entanglement. For an n-bit binary string x, denote by $U_x : \mathcal{N}_A \to \mathcal{H}_A$ the isometric embedding that maps $|\phi\rangle \mapsto |\phi\rangle\otimes|x\rangle\otimes|0\cdots0\rangle$. The isometric embedding $V_y : \mathcal{N}_B \to \mathcal{H}_B$ is defined similarly. Then $|\Phi_{x,y}\rangle = (U_x\otimes V_y)|E\rangle$. Let P, A_h, and B_h be the quantum protocol and the linear operators described in Lemma 4.2. To simulate the quantum protocol is to simulate the measurement element $P^\dagger P$ on $|E\rangle$, $U_x \cdot U_x^\dagger$, and $V_y \cdot V_y^\dagger$. By Theorem 3.11, the acceptance probability can be estimated with $O(\|P^\dagger P\|_\diamond^2)$ bits of communication in

the SMP model with shared randomness. Since

$$\|P^\dagger P\|_\diamond \le \sum_{h,h'} \| \left((A_{h'})^\dagger A_h\right) \otimes \left((B_{h'})^\dagger B_h\right) \|_\diamond = \sum_{h,h'} \|A_h\|\|A_{h'}\|\|B_h\|\|B_{h'}\| \le 2^{2(q-1)},$$

the number of bits communicated in the protocol is $\exp(O(q))$. ∎

Corollary 1.3 follows trivially from the above by setting q to be a constant. Corollary 1.5 follows immediately from Theorem 1.4 and Corollary 1.3.

4.3. Simulating quantum correlations. We shall define precisely what we mean by simulating quantum correlations.

DEFINITION 4.3. *A* quantum measurement game *is a tuple* $G = (|E\rangle_{AB}, \mathcal{P}_A, \mathcal{P}_B, \mathcal{V}_A, \mathcal{V}_B)$*, where* $|E\rangle_{AB}$ *is a bipartite quantum state,* $\mathcal{P}_A$ *(*$\mathcal{P}_B$*) is a set of POVM measurements on the system A (B), and the union of their measurement outcomes is* $\mathcal{V}_A$ *(*$\mathcal{V}_B$*).*

We denote by $\{P_A^v : v \in \mathcal{V}_A\}$ the measurement elements for $P_A \in \mathcal{P}_A$ (and similarly for $P_B \in \mathcal{P}_B$), where P_A^v is the measurement element yielding outcome v. For $P_A \in \mathcal{P}_A$ and $P_B \in \mathcal{P}_B$, denote by $\omega_G(P_A, P_B)$ the distribution on $\mathcal{V}_A \times \mathcal{V}_B$ when $P_A \otimes P_B$ is applied to $|E\rangle$. Recall that the statistical distance between two distributions $\pi = (p_1, \ldots, p_n)$ and $\tilde{\pi} = (\tilde{p}_1, \ldots, \tilde{p}_n)$ is $\|\pi - \tilde{\pi}\|_1 \stackrel{\text{def}}{=} \sum_i |p_i - \tilde{p}_i|$.

DEFINITION 4.4. *Let* $\delta \in (0, 2)$*. A* classical simulation *of a quantum measurement game* $G = (|E\rangle_{AB}, \mathcal{P}_A, \mathcal{P}_B, \mathcal{V}_A, \mathcal{V}_B)$ *with statistical distance* δ *is a randomized communication protocol with shared randomness between two parties Alice and Bob such that*

(a) *Alice's input is a classical description of an element* $P_A \in \mathcal{P}_A$*, and Bob's input is a classical description of an element* $P_B \in \mathcal{P}_B$*;*
(b) *at the end of the protocol, Alice (resp., Bob) outputs some* $v \in \mathcal{V}_A$ *(*$v' \in \mathcal{V}_B$*), resulting in a distribution* $\tilde{\omega}(P_A, P_B)$ *on* $\mathcal{V}_A \times \mathcal{V}_B$*;*
(c) *for all* $(P_A, P_B) \in \mathcal{P}_A \times \mathcal{P}_B$*,* $\|\tilde{\omega}(P_A, P_B) - \omega(P_A, P_B)\|_1 \le \delta$*.*

We are now able to rigorously state Theorem 1.6.

THEOREM 4.5. *Let* $G = (|E\rangle_{AB}, \mathcal{P}_A, \mathcal{P}_B, \mathcal{V}_A, \mathcal{V}_B)$ *be a quantum measurement game. Let* $m = |\mathcal{V}_A| \cdot |\mathcal{V}_B|$*, and let* $\delta \in (0, 2)$*. There is a classical simulation of* G *with* δ *statistical distance that exchanges an* $O(\frac{m^3}{\delta^2} \cdot \log \frac{m}{\delta})$ *number of bits. In particular, the simulation cost is* $O(\log \frac{1}{\delta}/\delta^2)$ *if* $m = O(1)$*.*

Proof. Let $\epsilon = \delta/4$. Fix a pair of measurements $(P_A, P_B) \in \mathcal{P}_A \times \mathcal{P}_B$. In the classical simulation protocol, for each $(v, v') \in \mathcal{V}_A \times \mathcal{V}_B$, Alice and Bob first compute the probability of outputting (v, v') to be within $\frac{\delta}{2m}$ deviation with probability at least $1 - \epsilon/m$. Then with probability $\ge 1 - \epsilon$, all those computed probabilities are within $\frac{\delta}{2m}$ deviation to the correct values. They then output a random (v, v') according to the probabilities computed. Then

$$\|\tilde{\omega}(P_A, P_B) - \omega(P_A, P_B)\|_1 \le \epsilon \cdot 2 + (1 - \epsilon) \cdot \frac{\delta}{2} \le \delta.$$

Now fix a pair of possible outcome (v, v'). The estimation of $\omega_G(P_A, P_B)$ becomes the simulation of the identity operator, with the initial state being $|E\rangle$ and the local physically realizable operators being $\sqrt{P_A^v} \cdot \sqrt{P_A^v}$ and $\sqrt{P_B^{v'}} \cdot \sqrt{P_B^{v'}}$ for some $P_A \in \mathcal{P}_A$ and $P_B \in \mathcal{P}_B$.

Note that the identity operator has diamond norm 1 (this follows from Definition 3.3 and Theorem 3.8). By Theorem 3.11, the probability of observing outcome (v, v') can be calculated with precision $\frac{\delta}{2m}$ and with probability at least $1 - \epsilon/m$

by a classical protocol using $O(\frac{m^2}{\delta^2}\log(\frac{m}{\epsilon}))$ bits. Thus the overall simulation cost is $O(\frac{m^3}{\delta^2}\log(\frac{m}{\delta}))$ bits, which is $O(\log\frac{1}{\delta}/\delta^2)$ when $m = O(1)$. □

5. Conclusion and open problems. We introduce an alternative measure of nonlocality of bipartite quantum measurement, which is the minimum amount of classical communication required to simulate the quantum measurement. We give an upper bound of this nonlocality measure by constructing in terms of a tensor norm. Variants of our upper bound protocol also lead to variants of the main upper bound in terms of other tensor norms. We then apply our upper bound to the classical simulation of quantum communication protocols and the approximation of quantum correlations by local hidden variable models augmented with classical communication. In particular, we show that quantum and classical communication protocols with unlimited shared entanglement or randomness compute the same set of functions if the amount of communication is a constant. We also show that local measurement of an entangled state can be simulated by a local hidden variable model with a constant amount of communication, as long as the number of measurement outcomes is a constant.

Our study is only the first step toward understanding the classical communication complexity of bipartite measurement. An obvious open problem is to prove or disprove that the bound in Theorem 3.11 is tight. Another basic problem is to prove a strong lower bound (exponential in the number of qubits) on $\mathrm{Com}(Q)$ for some Q.

It would be interesting to relate $\mathrm{Com}(Q)$ to other measures of nonlocality, such as entanglement capacity and the minimum number of elementary gates required, or the amount of time for evolving an elementary Hamiltonian, in order to approximate Q. It is conceivable that the comparison of those measures may lead to a unique and representative measure of operator nonlocality.

Gavinsky [19] made recent progress on the question of the usefulness of quantum entanglement. He showed that entanglement is responsible for the exponential quantum saving in performing some communication task in a restricted communication model. Whether or not entanglement could result in exponential savings for the two-party interactive communication model and for the computation of functions remains open. Can Theorem 1.2 be strengthened so that the amount of entanglement need not exceed a linear size of the messages?

The cost of our protocol for simulating quantum correlations depends linearly on the number of measurement outcomes. Is this dependence necessary or can one dramatically reduce it?

Finally, it appears a very promising direction to us to explore further the connections of tensor norms and nonlocality of quantum states and operations.

Acknowledgments. We are indebted to Wei Huang, Amnon Ta-Shma, and the anonymous reviewers for their valuable suggestions on improving the presentation of this paper.

I/O-EFFICIENT PLANAR SEPARATORS*

ANIL MAHESHWARI† AND NORBERT ZEH‡

Abstract. We present I/O-efficient algorithms for computing optimal separator partitions of planar graphs. Our main result shows that, given a planar graph G with N vertices and an integer $r > 0$, a vertex separator of size $O(N/\sqrt{r})$ that partitions G into $O(N/r)$ subgraphs of size at most r and boundary size $O(\sqrt{r})$ can be computed in $O(\text{sort}(N))$ I/Os. This bound holds provided that $M \geq 56r \log^2 B$. Together with an I/O-efficient planar embedding algorithm presented in [N. Zeh, *I/O-Efficient Algorithms for Shortest Path Related Problems*, Ph.D. thesis, School of Computer Science, Carleton University, Ottawa, ON, Canada, 2002], this result is the basis for I/O-efficient solutions to many other fundamental problems on planar graphs, including breadth-first search and shortest paths [L. Arge, G. S. Brodal, and L. Toma, *J. Algorithms*, 53 (2004), pp. 186–206; L. Arge, L. Toma, and N. Zeh, *I/O-efficient algorithms for planar digraphs*, in Proceedings of the 15th ACM Symposium on Parallelism in Algorithms and Architectures, ACM, New York, 2003, pp. 85–93], depth-first search [L. Arge et al., *J. Graph Algorithms Appl.*, 7 (2003), pp. 105–129; L. Arge and N. Zeh, *I/O-efficient strong connectivity and depth-first search for directed planar graphs*, in Proceedings of the 44th IEEE Symposium on Foundations of Computer Science, IEEE Press, Piscataway, NJ, 2003, pp. 261–270], strong connectivity [L. Arge and N. Zeh, *I/O-efficient strong connectivity and depth-first search for directed planar graphs*, in Proceedings of the 44th IEEE Symposium on Foundations of Computer Science, IEEE Press, Piscataway, NJ, 2003, pp. 261–270], and topological sorting [L. Arge and L. Toma, *Simplified external memory algorithms for planar DAGs*, in Proceedings of the 9th Scandinavian Workshop on Algorithm Theory, Lecture Notes in Comput. Sci. 3111, Springer-Verlag, Berlin, New York, 2004, pp. 493–503; L. Arge, L. Toma, and N. Zeh, *I/O-efficient algorithms for planar digraphs*, in Proceedings of the 15th ACM Symposium on Parallelism in Algorithms and Architectures, ACM, New York, 2003, pp. 85–93]. Our second result shows that, given I/O-efficient solutions to these problems, a general separator algorithm for graphs with costs and weights on their vertices [L. Aleksandrov et al., *Partitioning planar graphs with costs and weights*, in Proceedings of the 4th Workshop on Algorithm Engineering and Experiments, Lecture Notes in Comput. Sci. 2409, Springer-Verlag, Berlin, New York, 2002, pp. 98–107] can be made I/O-efficient. Many classical separator theorems are special cases of this result. In particular, our I/O-efficient version allows the computation of a separator as produced by our first separator algorithm, but without placing any constraints on r in relation to the memory size.

1. Introduction.

I/O-efficient graph algorithms have received considerable attention because massive graphs arise naturally in many applications. Recent Web crawls, for example, produced graphs of on the order of 200 million nodes and 2 billion edges. Recent work in Web modeling uses depth-first search (DFS), breadth-first search (BFS), and the computation of shortest paths and connected components as primitive operations for investigating the structure of the Web [12]. Massive graphs

are also often manipulated in geographic information systems (GIS), where many fundamental problems can be formulated as basic graph problems. Yet another example of a massive graph is AT&T's phone call graph [13]. When working with such large data sets, the transfer of data between internal and external memory, and not the internal-memory computation, is often the bottleneck. Thus, I/O-efficient algorithms can lead to considerable run time improvements.

Planar graphs are a natural abstraction of many real-world problems. For example, the graphs arising in GIS are often planar or "almost planar." On the theoretical side, planar graphs are among the fundamental combinatorial structures used in algorithmic graph theory. Planar separators have played the key role in designing divide-and-conquer algorithms for planar graphs. The classical separator theorem for planar graphs by Lipton and Tarjan [27], coupled with linear-time planar embedding algorithms [10, 18, 24, 26], has led to phenomenal developments in algorithmic graph theory. Numerous research results that followed describe efficient algorithms for computing a variety of separators of other sparse graphs and discuss applications of separators such as lower bounds on the size of Boolean circuits, approximation algorithms for NP-complete problems, nested dissection of sparse systems of linear equations, load balancing in parallel numerical simulations based on the finite element method, partitioning triangular irregular networks in the field of GIS, and encoding graphs.

In external memory, planar separators have been the key to obtaining I/O-efficient algorithms for a variety of problems on embedded planar graphs, including BFS and single-source shortest paths [5, 8], DFS [6, 9], strong connectivity [9], and topological sorting [8, 7].

Existing internal-memory algorithms for computing planar separators (see, e.g., [2, 3, 27]) are not I/O-efficient because they use BFS to gather structural information about the graph, and BFS and DFS are among those fundamental graph problems for which truly I/O-efficient solutions on general graphs are still lacking. The existing I/O-efficient BFS-algorithms for planar graphs [5, 8] are separator-based; hence, using them in a separator algorithm creates a circular dependency. In this paper, we present a new algorithm that applies BFS only to a compressed version of the given graph and combines this with graph contraction techniques to obtain an optimal separator partition in an I/O-efficient manner. An added benefit of our algorithm is that it does not rely on a planar embedding of the given graph.

1.1. Model of computation and previous work. The algorithms in this paper are designed and analyzed in the I/O-model of Aggarwal and Vitter [1]. This model quite accurately captures the characteristics of current hard drives and yet is simple enough to allow the I/O-complexity of complex algorithms to be analyzed. In the I/O-model, the computer is equipped with two levels of memory. The *internal memory* (or *memory* for short) is of limited size, capable of holding M data items. The disk-based *external memory* is of conceptually unlimited size and is divided into blocks of B consecutive data items. All computation has to be performed on data in internal memory. The transfer of data between internal and external memory happens by means of *I/O-operations* (or *I/Os* for short), each of which transfers one block of data to or from the disk. The complexity of an algorithm is the number of I/O-operations it performs.

For surveys of results obtained in the I/O-model and its extensions, we refer the reader to [28, 32]. The following results are relevant to the work presented in this paper.

It has been shown in [1] that sorting and permuting an array of N data items

take $\mathrm{sort}(N) = \Theta((N/B)\log_{M/B}(N/B))$ and $\mathrm{perm}(N) = \Theta(\min\{N, \mathrm{sort}(N)\})$ I/Os, respectively; scanning an array of size N takes $\Theta(N/B)$ I/Os.

In internal memory, that is, in the RAM model, the problem of computing planar separators is well studied. Lipton and Tarjan [27] were the first to show that every planar graph with N vertices has a $\frac{2}{3}$-separator of size $\mathrm{O}\big(\sqrt{N}\big)$, that is, a vertex set of size $\mathrm{O}\big(\sqrt{N}\big)$ whose removal partitions G into two subgraphs containing at most $2N/3$ vertices each. They also presented a linear-time algorithm to compute such a separator. In [21], it has been shown that every graph of genus g has a $\frac{2}{3}$-separator of size $\mathrm{O}\big(\sqrt{gN}\big)$ and that such a separator can be computed in linear time. In [2], a linear-time algorithm for computing a t-separator of size $\mathrm{O}\big(\sqrt{(g+1/t)N}\big)$ for an embedded graph of genus g was given; for $0 < t < 1$, a *t-separator* is a vertex set whose removal partitions G into subgraphs of size at most tN. Other results deal with computing small simple-cycle separators of planar graphs [29], edge separators of planar graphs [15], separators of planar graphs with negative or multiple vertex weights [17], and separators of low cost [3, 16].

In [25], the first I/O-efficient algorithm for computing planar separators was presented. This algorithm is an external-memory version of Lipton and Tarjan's algorithm and computes a $\frac{2}{3}$-separator of size $\mathrm{O}\big(\sqrt{N}\big)$; its I/O-complexity is $\mathrm{O}(\mathrm{sort}(N))$, provided that a planar embedding and a BFS-tree of the graph are given. In [5], an external version of Goodrich's multiway separator algorithm [22] has been developed. This algorithm computes a t-separator of size $\mathrm{O}\big((N/B)\log_{M/B}(N/B) + \sqrt{N/t}\big)$ and takes $\mathrm{O}(\mathrm{sort}(N))$ I/Os, again assuming that an embedding and a BFS-tree are given.

A number of subsequent papers develop a hierarchy of reductions that lead to $\mathrm{O}(\mathrm{sort}(N))$-I/O algorithms for a variety of fundamental problems on embedded planar graphs if an optimal separator decomposition can be obtained in $\mathrm{O}(\mathrm{sort}(N))$ I/Os: In [5, 8], separator-based ideas first pioneered in [19] were used to obtain I/O-efficient shortest-path algorithms for undirected and directed planar graphs. These algorithms can, of course, also be used to compute BFS-trees of planar graphs. In [6], a DFS-algorithm for undirected planar graphs was presented; this algorithm uses BFS in a planar graph derived from the dual and, hence, also depends on planar separators. The directed DFS-algorithm of [9] needs to compute directed spanning trees of the graph; currently, the only I/O-efficient algorithm for this problem is the shortest-path algorithm of [8]. Other I/O-efficient algorithms for planar graphs that rely on separators are the strong connectivity algorithm of [9] and the algorithms of [7, 8] for topologically sorting planar directed acyclic graphs.

1.2. New results. The two main results of our paper are the following:

(i) Given a planar graph G with N vertices and an integer $r > 0$, it takes $\mathrm{O}(\mathrm{sort}(N))$ I/Os to compute a vertex separator S of size $\mathrm{O}\big(N/\sqrt{r}\big)$ whose removal partitions G into $\mathrm{O}(N/r)$ subgraphs of size at most r and boundary size $\mathrm{O}(\sqrt{r})$. The bound on the I/O-complexity of the algorithm holds as long as the internal memory has size at least $56r\log^2 B$.

(ii) Using a bootstrapping approach based on our second algorithm, discussed below, the memory requirements of the algorithm can be reduced from $M = \Omega\big(B^2\log^2 B\big)$ to $M = \Omega\big(B^2\big)$ for the special case when $r = B^2$. This special case is important because $r = B^2$ is the granularity of the partition required by all separator-based I/O-efficient algorithms for planar graphs that have been developed so far.

Thanks to our algorithm, a wide variety of problems, as discussed in the previous section, can be solved in $\mathrm{O}(\mathrm{sort}(N))$ I/Os if $M = \Omega\big(B^2\big)$. In particular, a shortest-path tree of a planar graph can be obtained in this complexity. Using this fact, we

show the following I/O-efficient versions of results from [3]:

(iii) Let $G = (V, E)$ be a planar graph with N vertices, let $w : V \to \mathbb{R}^+$ and $c : V \to \mathbb{R}^+$ be assignments of nonnegative weights and costs to the vertices of G, and let $0 < t < 1$ be an arbitrary constant. Let $w(G) = \sum_{x \in V} w(x)$ and $C(G) = \sum_{x \in V} (c(x))^2$. If the size of the internal memory is $\Omega(B^2)$, it takes $O(\mathrm{sort}(N))$ I/Os to compute a vertex separator S of cost $c(S) \leq 4\sqrt{2 \cdot C(G)/t}$ such that no connected component of $G - S$ has weight exceeding $tw(G)$.

If all vertices have weight and cost equal to 1 and we choose $t = r/N$, we obtain a separator of size $O(N/\sqrt{r})$ that partitions the graph into pieces of size at most r. This matches the result produced by our first algorithm, but without requiring that $M \geq 56r \log^2 B$. More precisely, it allows the computation of arbitrarily coarse partitions, while our first algorithm is restricted to computing partitions into pieces of size $O(M/\log^2 B)$ if an I/O-complexity of $O(\mathrm{sort}(N))$ is desired.

(iv) Let $G = (V, E)$ be a planar graph with N vertices, let $w : V \to \mathbb{R}^+$ be an assignment of nonnegative weights to the vertices of G, let $0 < t < 1$ be an arbitrary constant, and let $w(G) = \sum_{x \in V} w(x)$. If $w(x) \leq tw(G)$ for every vertex $x \in V$, there exists an edge separator $S \subseteq E$ of size $|S| \leq 4\sqrt{2(\sum_{x \in V} (\deg(x))^2)/t}$ such that no connected component of $G - S$ has weight exceeding $tw(G)$. Such a separator can be computed in $O(\mathrm{sort}(N))$ I/Os, provided that $M = \Omega(B^2)$.

The algorithm in result (i) performs $O(N \log N)$ work in internal memory. Result (iii) and, thus, also results (ii) and (iv) rely on an I/O-efficient shortest-path algorithm for planar graphs. Currently, the best such algorithm performing $O(\mathrm{sort}(N))$ I/Os is the algorithm of [5], which performs $O(N \log N + BN)$ work in internal memory. The algorithms in result (ii)–(iv) inherit this computational bound, but their computational bound would decrease to $O(N \log N + T(N))$ with the development of a planar shortest-path algorithm that performs $O(\mathrm{sort}(N))$ I/Os and $T(N) = o(N \log N + BN)$ computation in internal memory.

The presentation of our results is organized as follows. In section 2, we introduce the necessary terminology and notation and discuss some technical results that will be useful in our algorithms. In section 3, we discuss a graph contraction procedure that is used many times in our algorithms. Our algorithm for partitioning an unweighted planar graph is presented in section 4. The partition produced by the algorithm does not have all the properties required by the shortest-path algorithm of [5] or by any of the other separator-based I/O-efficient algorithms for planar graphs [7, 8, 9]. In section 5, we explain how to ensure the required additional properties. In section 6, we discuss our I/O-efficient algorithm for computing separators of planar graphs with costs and weights. In section 7, we explain how to combine the algorithms from sections 4 and 6 to reduce the memory requirements of our unweighted separator algorithm to $M = \Omega(B^2)$. We present concluding remarks in section 8.

2. Preliminaries.

2.1. Graphs and planarity.

We assume that the reader is familiar with standard graph-theoretic terms and notation as defined, for example, in [23, 31]. In this paper, all graphs are simple, that is, do not contain parallel edges or loops, even though the results are easy to generalize to multigraphs. Let $G = (V, E)$ be a graph. For a set $W \subseteq V$ of vertices, we use $G[W]$ to denote the subgraph of G whose vertex set is W and whose edge set consists of all edges in G that have both endpoints in W; we call $G[W]$ the subgraph of G *induced* by vertex set W. For a set of vertices $W \subseteq V$, let $G - W = G[V \setminus W]$. For a vertex $x \in V$, let $G - x = G - \{x\}$. For a set

of edges $F \subseteq E$, let $G - F = (V, E - F)$.

For a vertex $x \in G$, the *(open) neighborhood* $\mathcal{N}(x)$ of x is the set of vertices adjacent to x, that is, $\mathcal{N}(x) = \{y \in V : xy \in E\}$; the *closed neighborhood* of x is $\mathcal{N}[x] = \{x\} \cup \mathcal{N}(x)$. We generalize this to vertex sets and subgraphs by defining $\mathcal{N}[V'] = \bigcup_{x \in V'} \mathcal{N}[x]$, $\mathcal{N}(V') = \mathcal{N}[V'] \setminus V'$, $\mathcal{N}[G'] = G[\mathcal{N}[V']]$, and $\mathcal{N}(G') = G[\mathcal{N}(V')]$, where $G' = (V', E')$. We often call $\mathcal{N}(G')$ the *boundary* of G'. The *degree* $\deg(x)$ of a vertex x is the number of edges incident to x. Since we assume that G is simple, we have $\deg(x) = |\mathcal{N}(x)|$.

A graph G is *planar* if it can be drawn in the plane so that the edges of G do not intersect, except at their endpoints. Such a drawing of G is called a *topological embedding* of G; we denote it by $\mathcal{E}(G)$. Every topological embedding of G defines an order of the edges incident to each vertex $x \in G$ clockwise around x. A representation of these orders for all vertices $x \in G$ is called a *combinatorial embedding* of G, which we denote by $\hat{G}$. Given a topological embedding $\mathcal{E}(G)$ consistent with a combinatorial embedding $\hat{G}$ of G, we call the connected regions of $\mathbb{R}^2 \setminus \mathcal{E}(G)$ the *faces* of $\hat{G}$. The *size* of a face of $\hat{G}$ is the number of edges on its boundary. Let F denote the set of faces of $\hat{G}$. By Euler's formula, $|V| + |F| - |E| = 2$. In particular, $|E| \leq 3|V| - 6$. We define the *size* $|G|$ of a planar graph $G = (V, E)$ to be the number of vertices in G.

For an embedded planar graph $G = (V, E)$ and an edge $e \in E$, the *dual* e^* of e is the edge $f_1 f_2$, where f_1 and f_2 are the two faces of $\hat{G}$ that have edge e on their boundaries. The dual of G is the multigraph $G^* = (F, E^*)$, where $E^* = \{e^* : e \in E\}$.

A *partition* of a set S is a collection $\mathcal{S} = \{S_1, \ldots, S_k\}$ of subsets of S so that every element of S belongs to exactly one set S_i, that is, $S_i \cap S_j = \emptyset$ for all $i \neq j$, and $\bigcup_{i=1}^{k} S_i = S$.

Given a graph $G = (V, E)$ and a partition $\mathcal{V} = \{V_1, \ldots, V_k\}$ of the vertex set of G, the *contraction* of $\mathcal{V}$ in G is the graph $G/\mathcal{V} = (\mathcal{V}, E')$, where $E' = \{V_i V_j : \exists\, xy \in E$ such that $x \in V_i$ and $y \in V_j\}$. If the vertices of G have weights, we define $w(V_i) = \sum_{x \in V_i} w(x)$ for all $1 \leq i \leq k$. If the graph $G[V_i]$ is connected for all $1 \leq i \leq k$, we call $G/\mathcal{V}$ an *edge contraction*. If there exist vertex sets $X_1, \ldots, X_k$ such that, for all $1 \leq i \leq k$ and all $x \in V_i$, $\mathcal{N}(x) \setminus V_i = X_i$, that is, if all vertices in V_i have the same neighbors in $V(G) \setminus V_i$, we call $G/\mathcal{V}$ a *vertex bundling*. We will use the following facts. The first one states that edge contractions and vertex bundlings preserve planarity. Intuitively, the second one says that undoing any contraction preserves separators.

FACT 2.1. *If G is planar, then every edge contraction or vertex bundling of G is planar.*

FACT 2.2. *Let $\mathcal{S} \subseteq \mathcal{V}$; $S = \bigcup_{V_i \in \mathcal{S}} V_i$; $V_i, V_j \notin \mathcal{S}$; and $x \in V_i$ and $y \in V_j$. If V_i and V_j belong to different connected components of $(G/\mathcal{V}) - \mathcal{S}$, then x and y belong to different connected components of $G - S$.*

2.2. Graph separators. Given an assignment $w : V \to \mathbb{R}^+$ of weights to the vertices of a graph $G = (V, E)$ and a parameter $0 < t < 1$, we call a set $S \subseteq V$ of vertices a *t-vertex separator* of G if no connected component of $G - S$ has weight greater than $tw(G)$, where $w(G) = \sum_{x \in V} w(x)$ is the weight of G. Similarly, a *t-edge separator* of G is a set $S \subseteq E$ of edges so that no connected component of the graph $G - S$ has weight exceeding $tw(G)$. Since we are mainly interested in vertex separators in this paper, we refer to them simply as *separators*. If G is unweighted, we give every vertex of G weight one and define separators w.r.t. these weights.

In our separator algorithm for unweighted graphs, we apply the following result to a compressed version of the graph we want to partition. This produces a first separator that is then refined during a sequence of refinement steps.

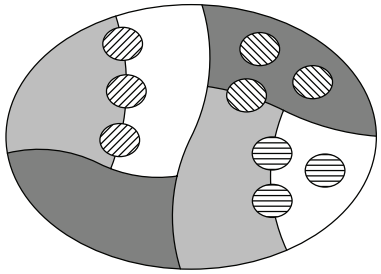

FIG. 2.1. *A regular partition. The solid regions are connected. Each of the hatched regions is disconnected but shares its boundary with at most two solid regions and no hatched region.*

THEOREM 2.1 (Aleksandrov and Djidjev [2]). *Given a planar graph G of size N, an assignment $w : V \to \mathbb{R}^+$ of weights to the vertices of G, and a constant $0 < t < 1$, a t-vertex separator of size at most $4\sqrt{N/t}$ for G can be computed in linear time.*

By grouping the connected components of $G-S$, where G is an unweighted graph and S is a t-separator of G, we obtain a tN-partition of G. More precisely, let $r > 0$ be an integer, let $t = r/N$, and let S be a t-separator of G. Then an *r-partition* of G is a pair $\mathcal{P} = (S, \{G_1, \ldots, G_q\})$ with the following properties:

(i) $G_1, \ldots, G_q$ are vertex-induced subgraphs of G;
(ii) the set $\{V(G_1), \ldots, V(G_q)\}$ is a partition of $V(G) \setminus S$;
(iii) $\mathcal{N}(V(G_i)) \subseteq S$ for all $1 \le i \le q$; and
(iv) $|G_i| \le r$ for all $1 \le i \le q$.

The third condition captures that every subgraph G_i is a collection of connected components of $G - S$; that is, no connected component of $G - S$ has vertices in two such subgraphs.

If G is a planar graph, we call an r-partition $\mathcal{P} = (S, \{G_1, \ldots, G_q\})$ *normal* if $|S| = \mathrm{O}(N/\sqrt{r})$, $q = \mathrm{O}(N/r)$, and $\sum_{i=1}^{q} |\mathcal{N}(G_i)| = \mathrm{O}(N/\sqrt{r})$. A normal r-partition $\mathcal{P} = (S, \{G_1, \ldots, G_q\})$ is *c-proper* for some constant $c > 0$ if $|\mathcal{N}(G_i)| \le c\sqrt{r}$ for all $1 \le i \le q$. If we do not want to specify c, we say that $\mathcal{P}$ is *proper*. A proper r-partition is stronger than a normal r-partition because the latter may contain subgraphs with a large boundary, as long as the total size of all subgraph boundaries is small; in the former, every individual subgraph has to have a small boundary. Finally, we call an r-partition $\mathcal{P} = (S, \{G_1, \ldots, G_q\})$ *regular* if, for every $1 \le i \le q$, one of the following conditions holds:

(i) The graph $\mathcal{N}[G_i]$ is connected, or
(ii) there are at most two indices $1 \le j < k \le q$, $i \notin \{j, k\}$, such that $\mathcal{N}(V(G_i)) \cap \mathcal{N}(V(G_j)) \neq \emptyset$ and $\mathcal{N}(V(G_i)) \cap \mathcal{N}(V(G_k)) \neq \emptyset$. $\mathcal{N}[G_j]$ and $\mathcal{N}[G_k]$ are connected in this case.

This concept is visualized in Figure 2.1, which is reproduced from Frederickson [19], who shows that every planar graph has a proper r-partition and that every planar graph of bounded degree has a regular proper r-partition. The following result states that a proper r-partition of a planar graph can be obtained efficiently.

THEOREM 2.2 (Frederickson [19]). *Given a planar graph G of size N and a normal r-partition $\mathcal{P} = (S, \{G_1, \ldots, G_p\})$ of G, a proper r-partition $\mathcal{P}' = (S', \{G'_1, \ldots, G'_q\})$ of G such that $S \subseteq S'$ can be computed in $\mathrm{O}(N \log N)$ time.*

Frederickson also shows how to obtain a normal r-partition of a planar graph in $\mathrm{O}(N \log N)$ time. Together with Theorem 2.2, this implies that a proper r-partition of a planar graph can be computed in $\mathrm{O}(N \log N)$ time. To prove Theorem 2.2, Fred-

erickson considers each graph G_i in turn and partitions it into subgraphs of boundary size $O(\sqrt{r})$. When partitioning G_i, the algorithm requires knowledge of only $\mathcal{N}[G_i]$. Thus, if $|\mathcal{N}[G_i]| \leq M$ for all $1 \leq i \leq p$, we can implement Frederickson's procedure by loading each graph $\mathcal{N}[G_i]$ into internal memory and partitioning G_i without incurring any further I/Os. Assuming that each graph $\mathcal{N}[G_i]$ is stored in consecutive memory locations, we thus have the following.

COROLLARY 2.3. *Given a planar graph G of size N and a normal r-partition $\mathcal{P} = (S, \{G_1, \ldots, G_p\})$ of G, a proper r-partition $\mathcal{P}' = (S', \{G'_1, \ldots, G'_q\})$ of G such that $S \subseteq S'$ can be computed in $O(N/B)$ I/Os, provided that $|\mathcal{N}[G_i]| \leq M$ for all $1 \leq i \leq p$.*

2.3. Bipartite planar graphs. A graph $G = (V, E)$ is *bipartite* if the vertex set V can be partitioned into two sets U and W such that $x \in U$ and $y \in W$ for every edge $xy \in E$. In this case, we write $G = (U, W, E)$. We use the following two simple results to bound the sizes of certain bipartite planar graphs in different parts of our algorithms.

LEMMA 2.4. *Let $G = (U, W, E)$ be a simple connected bipartite planar graph such that every vertex in W has degree at least three. Then $|W| < 2|U|$.*

Proof. Consider a planar embedding $\hat{G}$ of G. Since G is bipartite, every face of $\hat{G}$ has size at least four and, thus, $|F| \leq |E|/2$. By Euler's formula, $|V| + |F| - |E| = 2$, that is,

$$\begin{aligned} 2 &= |V| + |F| - |E| \\ &\leq |V| - |E|/2, \\ |E| &< 2|V|. \end{aligned}$$

On the other hand, $|E| \geq 3|W|$, so that

$$\begin{aligned} 3|W| &< 2|V| \\ &= 2(|U| + |W|), \\ |W| &< 2|U|. \end{aligned}$$ □

COROLLARY 2.5. *Let $G = (U, W, E)$ be a simple connected bipartite planar graph such that no two vertices $x, y \in W$ of degree at most two have the same open neighborhood. Then $|G| < 7|U|$.*

Proof. We have to prove that $|W| < 6|U|$. To this end, we divide W into three subsets and bound the size of each of these sets. Let W_1 be the set of degree-1 vertices in W, W_2 the set of degree-2 vertices in W, and W_3 the set of vertices of degree at least three in W, that is, $W_3 = W \setminus (W_1 \cup W_2)$.

Since there are no two vertices $x, y \in W$ with $\deg(x) = \deg(y) = 1$ and $\mathcal{N}(x) = \mathcal{N}(y)$, W_1 contains at most $|U|$ vertices, that is, one per vertex in U; see Figure 2.2(a).

To count the vertices in W_3, we consider the bipartite planar graph $G_3 = (U_3, W_3, E_3)$ induced by all edges incident to vertices in W_3; see Figure 2.2(b). By Lemma 2.4 and since $U_3 \subseteq U$, we have $|W_3| < 2|U_3| \leq 2|U|$.

To count the vertices in W_2, consider the graph $H_2 = (U_2, E_2)$, where $U_2 = \mathcal{N}(W_2) \subseteq U$ and $E_2 = \{xz :$ there exists a vertex $y \in W_2$ with $\mathcal{N}(y) = \{x, z\}\}$; see Figure 2.2(d). Since there are no two vertices $x, y \in W_2$ with $\mathcal{N}(x) = \mathcal{N}(y)$, H_2 contains exactly one edge per vertex in W_2, that is, $|E_2| = |W_2|$. Next we argue that H_2 is planar, which, by Euler's formula, implies that $|W_2| = |E_2| < 3|U_2| \leq 3|U|$.

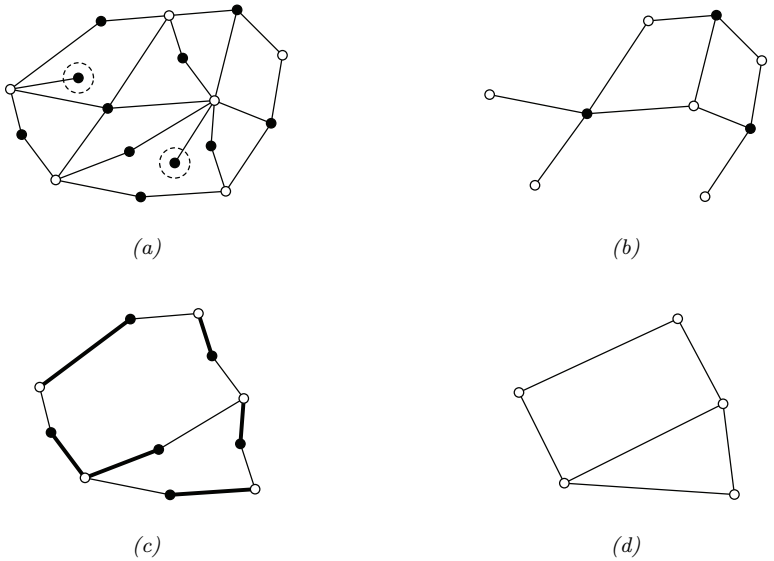

FIG. 2.2. *Illustration of the proof of Corollary* 2.5. (a) *A bipartite planar graph* $G = (U, W, E)$*; the white vertices are in* U*, and the black ones are in* W*. The circled vertices are in* W_1*.* (b) *The subgraph* G_3 *of* G *induced by all edges incident to vertices in* W_3*.* (c) *The subgraph* G_2 *of* G *induced by all edges incident to vertices in* W_2*.* (d) *The graph* H_2 *obtained from* G_2 *by contracting the bold edges in* (c).

To see that H_2 is planar, consider the subgraph G_2 of G induced by all edges incident to vertices in W_2; see Figure 2.2(c). Since G is planar, G_2 is planar. H_2 can be obtained from G_2 by contracting one of the edges incident to each vertex $y \in W_2$. By Fact 2.1, this implies that H_2 is planar.

In summary, we have $|W| = |W_1| + |W_2| + |W_3| < |U| + 3|U| + 2|U| = 6|U|$, that is, $|G| = |U| + |W| < 7|U|$. □

2.4. Primitive operations. Our algorithms make frequent use of a number of primitive operations. In order to avoid repeatedly discussing their implementations, we discuss them here and then refer to this section whenever we make use of such an operation.

Set operations. All elementary operations on two sets A and B—union, intersection, difference, etc.—can be carried out in $O(\mathrm{sort}(N))$ I/Os if the two sets A and B are represented as unordered sequences of elements sort A and B (assuming that every element is represented by a unique integer ID). Then scan the two sorted lists to produce $C = A \odot B$, where $\odot \in \{\cap, \cup, \setminus\}$.

Even though it is not a set operation as such, we want to mention duplicate removal here. Some operations may produce multisets. In order to obtain a proper representation of the set of elements in such a multiset, we need to remove duplicates. This can be done in $O(\mathrm{sort}(N))$ I/Os by sorting and scanning the multiset.

Copying labels. Since pointers are mostly useless in I/O-efficient graph algorithms, graphs are often represented as an (unsorted) list of vertices, each with a unique vertex ID, and as an (unsorted) list of edges, each labeled with the IDs of its two endpoints. Edges do not store any pointers to their endpoints. Thus, if certain labels are assigned to the vertices of the graph, the edges have no knowledge of the labels of their endpoints. However, it takes $O(\mathrm{sort}(N))$ I/Os to label all edges with the labels of

their endpoints. Sort the vertices by their IDs. Designate one endpoint of every edge as being the first endpoint. Then sort the edges by the IDs of their first endpoints. Now scan the sorted vertex and edge sets to label every edge with the label of its first endpoint. To label the edges with the labels of their second endpoints, sort the edges by the IDs of their second endpoints, and repeat the copying process.

Graph contraction. Given a labeling of the vertices of graph G that represents a partition $\mathcal{V} = \{V_1, \ldots, V_k\}$ of the vertex set of G, that is, assigns the same label to two vertices if and only if they belong to the same set $V_i \in \mathcal{V}$, the graph $G/\mathcal{V}$ can be computed in $O(\text{sort}(N))$ I/Os as follows: First, label the edges of G with the labels of their endpoints. Now replace every vertex with its label and every edge xy with the edge ab, where a is the label of x and b is the label of y. Finally, remove duplicates from the resulting vertex and edge sets.

In this paper, we choose the label of a set $V_i \in \mathcal{V}$ to be the ID of a *representative* $x \in V_i$. We will then often refer to the vertex V_i in $G/\mathcal{V}$ as the vertex x, taking the point of view that x has survived the contraction and that all other vertices in V_i have been *contracted into* x.

Connected components. Chiang et al. [14] proved that it takes $O(\text{sort}(N))$ I/Os to compute the connected components of an N-vertex planar graph G, that is, to compute a labeling of the vertices of G such that two vertices have the same label if and only if they are connected by a path in G.

3. Uniform graph contraction. In this section, we discuss a general contraction procedure for planar graphs that is used repeatedly in our algorithms. In general, when using graph contraction, one repeatedly contracts edges until some goal is reached (usually a sufficient reduction of the size of the graph). Since it would not be I/O-efficient to contract edges one at a time, I/O-efficient algorithms based on graph contraction usually contract many edges simultaneously. More precisely, these algorithms compute an edge contraction $G/\mathcal{V}$ of G such that $|\mathcal{V}| \leq c|V|$, for some $c < 1$; that is, $G/\mathcal{V}$ has only a constant fraction of the vertices of G. The algorithms of [5, 14, 30] for computing connected components and minimum spanning trees are based on exactly this idea. However, the partition $\mathcal{V}$ used in these algorithms is nonuniform in the sense that some sets $V_i \in \mathcal{V}$ may be large, while others may be small; that is, some vertices in $G/\mathcal{V}$ represent many vertices in G, and others represent only few. As we will see, our separator algorithm for unweighted graphs relies heavily on the compression being uniform, that is, on every set $V_i \in \mathcal{V}$ having constant size. Our goal in this section is to compute a partition $\mathcal{V}$ such that $|\mathcal{V}| \leq c|V|$ and that every set in $\mathcal{V}$ has constant size. In order to achieve this, we compute $G/\mathcal{V}$ in two phases: First, we compute an edge contraction $G_1 = G/\mathcal{V}_1$ and then a vertex bundling $G_2 = G_1/\mathcal{V}_2$.

In section 3.1, we give a high-level description of our uniform contraction procedure and prove a general bound on the size of the compressed graph it produces. In section 3.2, we show how to implement this procedure in $O(\text{sort}(N))$ I/Os on an N-vertex planar graph.

3.1. The high-level procedure. Our separator algorithm requires not only that $\mathcal{V}$ be a partition of V into subsets of constant size, but also that each subset be of bounded weight according to appropriately chosen weights assigned to the vertices in V. In this section, we assume more generally that the input to our contraction procedure consists of a planar graph G, a constant number of real-valued functions $w_1, \ldots, w_k$ assigning weights to the vertices of G, and a set of weight thresholds $u_1, \ldots, u_k$. Initially, every vertex x satisfies $w_j(x) \leq u_j$ for all $1 \leq j \leq k$; we say that vertex x is *within bounds*. Our goal is to compute a contraction $G/\mathcal{V}$ of G such

that each set V_i in $\mathcal{V}$ is within bounds, that is, $w_j(V_i) = \sum_{x \in V_i} w_j(x) \leq u_j$ for all $1 \leq j \leq k$. We say that a vertex or set x that is within bounds is *light* if $w_j(x) \leq u_j/2$ for all $1 \leq j \leq k$; otherwise, we call it *heavy*. The main result of this section is stated in the following theorem.

THEOREM 3.1. *Let G be a planar graph, $w_1, \ldots, w_k$ real-valued functions assigning weights to the vertices of G, and $u_1, \ldots, u_k$ weight thresholds such that every vertex $x \in G$ satisfies $w_j(x) \leq u_j$ for all $1 \leq j \leq k$. Then it takes $\mathrm{O}(\mathrm{sort}(N))$ I/Os to compute a planar graph G_2 such that G_2 is a contraction of G, all vertices of G_2 are within bounds, and more than $|G_2|/7$ vertices in G_2 are heavy.*

The contraction procedure consists of two phases: The *edge contraction phase* computes an edge contraction $G_1 = G/\mathcal{V}_1$ of G such that all vertices of G_1 are within bounds and every edge of G_1 has at least one heavy endpoint. The *bundling phase* computes a vertex bundling $G_2 = G_1/\mathcal{V}_2$ of G_1 such that all vertices of G_2 are within bounds and there are no two light vertices $x, y \in G_2$ of degree at most two that have the same open neighborhood. Graph G_2 is the final graph we return.

In section 3.2, we prove that the two phases of this procedure can be implemented in $\mathrm{O}(\mathrm{sort}(N))$ I/Os. Here we prove that G_2 has the properties claimed in Theorem 3.1.

By the description of the contraction procedure, the vertices of G_2 are explicitly ensured to be within bounds. Graph G_1 is an edge contraction of G, and G_2 is a vertex bundling of G_1. Hence, G_2 is a contraction of G and, by Fact 2.1, planar. We have to prove that at least every seventh vertex in G_2 is heavy.

LEMMA 3.2. *If h is the number of heavy vertices in G_2, then $|G_2| < 7h$.*

Proof. Consider the subgraph G' of G_2 induced by all edges incident to light vertices in G_2. Since G' contains all light vertices of G_2, it suffices to prove that $|G'| < 7h'$, where $h' \leq h$ is the number of heavy vertices in G'. We use Corollary 2.5 to do so.

First, observe that G' is bipartite: By the definition of G', every edge in G' has at least one light endpoint. If there was an edge with two light endpoints in $G' \subseteq G_2$, then G_1 would have to contain an edge with two light endpoints because G_2 is a vertex bundling of G_1, but we ensure explicitly that G_1 contains no such edge.

Observe also that no two light vertices of degree at most two in G_2 have the same neighbors. Hence, the same is true in G', and G' satisfies the conditions of Corollary 2.5 with U being the set of heavy vertices and W being the set of light vertices in G'. Thus, by Corollary 2.5, $|G'| < 7h'$. ∎

3.2. I/O-efficient implementation. In this section, we discuss how to implement the two phases of the contraction procedure in $\mathrm{O}(\mathrm{sort}(N))$ I/Os.

3.2.1. Edge contraction phase. To implement the edge contraction phase, we compute a set F of edges and define $\mathcal{V}_1$ to be the partition of V corresponding to the connected components of (V, F). We use $\mathcal{V}_F$ to denote this partition. We choose the edges in F so that the graph (V, F) is a forest, which makes the computation of connected components and, thus, the computation of the partition $\mathcal{V}_F$, easy [14].

The set F is not necessarily a subset of E. However, whenever we add an edge xy to F, there exists an edge $x'y' \in E$ such that x and x' belong to the same set V_1, and y and y' belong to the same set V_2 in $\mathcal{V}_F$. Hence, if $G[V_1]$ and $G[V_2]$ are connected, so is $G[V_1 \cup V_2]$, and the addition of edge xy to F maintains that $G/\mathcal{V}_F$ is an edge contraction of G.

We compute the edge set F iteratively, starting with $F = \emptyset$. Each iteration computes a set F' of edges such that $G/\mathcal{V}_{F \cup F'}$ is an edge contraction of G and each of its vertices is within bounds. The edges in F' are then added to F. This iterative

process stops as soon as every edge in $G/\mathcal{V}_F$ has at least one heavy endpoint. At this point, we define $G_1 = G/\mathcal{V}_F$.

To compute the set F' efficiently, each iteration consists of three steps: The first step extracts the subgraph H_1 of $G/\mathcal{V}_F$ induced by all edges in $G/\mathcal{V}_F$ whose endpoints are both light. We call these edges *contractible* and call H_1 the *contractible subgraph* of $G/\mathcal{V}_F$. The second step computes a maximal matching F_1' of H_1 and contracts the edges in F_1', producing the graph $H_2 = H_1/\mathcal{V}_{F_1'}$. We call a vertex in H_2 *matched* if it represents the two endpoints of an edge in F_1'; otherwise, the vertex represents only one vertex in H_1, and we call it *unmatched*. Note that all neighbors of an unmatched vertex are matched because F_1' is maximal. The third step adds edges between matched and unmatched vertices to a set F_2' so that every nonsingleton set in $\mathcal{V}_{F_2'}$ contains exactly one matched vertex. To determine which edges to add to F_2', we inspect each unmatched vertex x in turn. If there is a matched neighbor y of x that is contained in a light set V_y in $\mathcal{V}_{F_2'}$, we add the edge xy to F_2', thereby adding x to V_y. After this third step, we define $F' = F_1' \cup F_2'$ and add the edges in F' to F. This finishes the iteration.

Note that testing the loop condition—whether or not $G/\mathcal{V}_F$ contains two adjacent light vertices—is easy because, by the definition of H_1, this is the case if and only if H_1 is nonempty. It is also unnecessary to compute $G/\mathcal{V}_F$ from scratch after each iteration: Each iteration is interested only in the contractible subgraph of $G/\mathcal{V}_F$. If H_1 and H_1' are the contractible subgraphs of $G/\mathcal{V}_F$ and $G/\mathcal{V}_{F\cup F'}$, respectively, it is easy to see that $H_1' \subseteq H_1/\mathcal{V}_{F'} = H_2/\mathcal{V}_{F_2'}$. Thus, each iteration has to compute only $H_2 = H_1/\mathcal{V}_{F_1'}$ and $H = H_2/\mathcal{V}_{F_2'}$, and the next iteration can extract its contractible subgraph from H. This leads to the contraction procedure shown in Algorithm 1.

Before providing the implementation details and analyzing the I/O-complexity of this procedure, we show that it correctly implements the edge contraction phase of our uniform graph contraction procedure.

LEMMA 3.3. *Let G_1 be the graph produced by procedure* CONTRACTEDGES. *Then G_1 is an edge contraction of G, every vertex of G_1 is within bounds, and every edge of G_1 has at least one heavy endpoint.*

Proof. We prove by induction on the number of iterations that the graph $G/\mathcal{V}_F$ is an edge contraction of G and that all its vertices are within bounds. Since we exit with $G_1 = G/\mathcal{V}_F$ only when every edge in $G/\mathcal{V}_F$ has a heavy endpoint, this proves the lemma.

Before the first iteration, $G/\mathcal{V}_F = G$ is a trivial edge contraction of G because $F = \emptyset$. Moreover, all vertices of G are assumed to be within bounds.

So assume that, before the current iteration, $G/\mathcal{V}_F$ is an edge contraction of G and all its vertices are within bounds. We want to prove that the same is true for $G/\mathcal{V}_{F\cup F'}$.

First, we prove that $G/\mathcal{V}_{F\cup F'}$ is an edge contraction of G. Since $G/\mathcal{V}_F$ is an edge contraction of G, every set in $\mathcal{V}_F$ induces a connected subgraph of G. Every edge xy added to F_1' is an edge of $H_1 \subseteq G/\mathcal{V}_F$. Hence, there exist two sets $V_1, V_2 \in \mathcal{V}_F$ and an edge $x'y' \in E(G)$ such that $x, x' \in V_1$ and $y, y' \in V_2$. By adding edge xy to F_1', the sets V_1 and V_2 are merged into the set $V_1 \cup V_2$ in $\mathcal{V}_{F\cup F_1'}$. Since $G[V_1]$ and $G[V_2]$ are connected, the existence of edge $x'y' \in E(G)$ implies that $G[V_1 \cup V_2]$ is connected, and $G/\mathcal{V}_{F\cup F_1'}$ remains an edge contraction of G after adding edge xy to F_1'.

As for Step 3, every edge added to F_2' is an edge of $H_2 = H_1/\mathcal{V}_{F_1'} \subseteq G/\mathcal{V}_{F\cup F_1'}$. Since we have just argued that $G/\mathcal{V}_{F\cup F_1'}$ is an edge contraction of G, the same argument as in the previous paragraph implies that $G/\mathcal{V}_{F\cup F_1'\cup F_2'}$ is an edge contraction of G.

Algorithm 1 The edge contraction phase.

Procedure ContractEdges

Input: A weighted graph $G = (V, E)$ and a set of weight thresholds based on which every vertex in G is classified as light or heavy.

Output: An edge contraction $G_1 = G/\mathcal{V}_F$ of G.

1: $H \leftarrow G$
2: $F \leftarrow \emptyset$
3: **while** H is not empty **do**
4: Step 1: Extract the contractible subgraph
$H_1 \leftarrow$ the contractible subgraph of H
5: Step 2: Contract a maximal matching
Compute a maximal matching F_1' of H_1
$H_2 \leftarrow H_1/\mathcal{V}_{F_1'}$
6: Step 3: Contract edges incident to unmatched vertices
$F_2' \leftarrow \emptyset$
Let $\mathcal{V}_{F_2'}$ be the partition of $V(H_2)$ defined by F_2'.
for every unmatched vertex $x \in H_2$ **do**
if x has a (matched) neighbor y contained in a light set $V_y \in \mathcal{V}_{F_2'}$ **then**
Add edge xy to F_2' and increase the weights of V_y by the corresponding weights of x.
end if
end for
$F \leftarrow F \cup F_1' \cup F_2'$
$H \leftarrow H_2/\mathcal{V}_{F_2'}$
7: **end while**
8: $G_1 \leftarrow G/\mathcal{V}_F$

To see that all vertices of $G/\mathcal{V}_{F\cup F'}$ are within bounds, we first observe that all vertices of $G/\mathcal{V}_{F\cup F_1'}$ are within bounds. Indeed, each vertex $x \in G/\mathcal{V}_{F\cup F_1'}$ represents one or two vertices in $G/\mathcal{V}_F$. In the former case, x is obviously within bounds. In the latter case, the two vertices represented by x both belong to H_1 and are thus light; hence, x is within bounds in this case as well.

In the third step, when adding an edge xy to F_2', x is an unmatched vertex of H_2, that is, represents a single vertex in H_1 and is thus light. The set V_y containing y is light because otherwise we would not add edge xy to F_2'. Thus, after adding xy to F_2', and thereby x to V_y, the vertex in $G/\mathcal{V}_{F\cup F_1'\cup F_2'}$ representing V_y remains within bounds. Arguing inductively over all edges added to F_2' in Step 3, we obtain that all vertices in $G/\mathcal{V}_{F\cup F_1'\cup F_2'}$ are within bounds. This finishes the proof of the lemma. □

Procedure ContractEdges is fairly easy to implement in O(sort(N)) I/Os. To prove this, we show how to implement every iteration of the while-loop in lines 3–7 in O(sort($|H|$)) I/Os, show that $|H|$ decreases by a factor of at least two from one iteration to the next, and that the rest of the algorithm takes O(sort(N)) I/Os. We start by analyzing the I/O-complexity of one iteration of the while-loop.

Extracting the contractible subgraph. The contractible subgraph of H can be extracted in O(sort($|H|$)) I/Os: First, we label all edges with the weights of their endpoints, and then we scan the edge set to discard all edges that have at least one heavy

endpoint. The result is the edge list of the contractible subgraph. Now we scan this edge list and create a list of the edges' endpoints. To produce the vertex list of H_1, we remove duplicates from the resulting list. As discussed in section 2.4, all steps of this construction take $O(\text{sort}(|H|))$ I/Os.

Computing and contracting a matching. Zeh [33] presents an algorithm that computes a maximal matching of a graph $G = (V, E)$ in $O(\text{sort}(N))$ I/Os, where $N = |V| + |E|$. Since H_1 is planar, we have $N = O(|H_1|)$ when applying this procedure to H_1. Hence, the matching can be computed in $O(\text{sort}(|H_1|))$ I/Os. Once the matching is given, its edges can be contracted in $O(\text{sort}(|H_1|))$ I/Os by using the contraction procedure from section 2.4.

Contracting edges between matched and unmatched vertices. To contract edges between matched and unmatched vertices, that is, to implement Step 3 of the iteration, we start by extracting all edges in H_2 that are incident to unmatched vertices. This is easily done in $O(\text{sort}(|H_2|)) = O(\text{sort}(|H_1|))$ I/Os by labeling all edges with the statuses of their endpoints and discarding all edges that have two matched endpoints. (Recall that every edge in H_2 has at least one matched endpoint.)

For the resulting bipartite graph H', we compute the following information: Let V_m be the set of matched vertices, and let V_u be the set of unmatched vertices in H'. We arbitrarily number the vertices in V_m as $y_1, \ldots, y_r$ and the vertices in V_u as $x_1, \ldots, x_s$. We sort the edges in H' by their unmatched endpoints as primary keys and by their matched endpoints as secondary keys. For every edge $x_i y_j$, we store the unmatched endpoint $x_{i'}$ of the next edge incident to y_j; that is, if y_j is adjacent to vertices $x_{i_1}, \ldots, x_{i_t}$ with $i_1 < \cdots < i_t$, then, for $1 \le h < t$, edge $x_{i_h} y_j$ stores the ID of vertex $x_{i_{h+1}}$. Edge $x_{i_t} y_j$ stores **nil** to indicate that it is the last edge incident to y_j.

This information can easily be computed in $O(\text{sort}(|H'|))$ I/Os: We sort the edges by their matched endpoints as primary keys and by their unmatched endpoints as secondary keys. Then we scan the sorted edge list to compute, for every edge $x_i y_j$, the endpoint of the next edge incident to y_j. (If the next edge in the sorted sequence is $x_{i'} y_j$, then this endpoint is $x_{i'}$. If the next edge is $x_{i'} y_{j'}$ with $j' \neq j$, then edge $x_i y_j$ stores **nil**.) Now we sort the edges by their unmatched endpoints as primary keys and by their matched endpoints as secondary keys.

Given that graph H' has been prepared in this manner, we find the edges in F_2' as follows: We scan the sorted edge list, which is equivalent to inspecting the unmatched vertices in sorted order and scanning their adjacency lists. For every vertex x_i, as soon as we find an edge $x_i y_j$ such that the set V_{y_j} is light, we add edge $x_i y_j$ to F_2' and increase each weight $w_h(V_{y_j})$ by the corresponding weight $w_h(x_i)$ of x_i. The remaining edges in x_i's adjacency list are then ignored. If all neighbors of x_i are contained in heavy sets, no edge incident to x_i is added to F_2'.

In order to implement this procedure correctly, we need a mechanism to inform every edge incident to a vertex y_j about the current weights of the set V_{y_j} at the time when this edge is inspected. We use a priority queue Q to do this. Initially, we have $w_h(V_{y_j}) = w_h(y_j)$ for all h, because $F_2' = \emptyset$ and, hence, $V_{y_j} = \{y_j\}$. For every matched vertex y_j, we insert the initial weights of V_{y_j} into Q, with priority equal to the ID of the first edge incident to y_j. For every edge $x_i y_j$ inspected during the scan, we perform a Delete-Min operation on Q to retrieve the current weights of V_{y_j}. If edge $x_i y_j$ is added to F_2', the weights of V_{y_j} are updated; otherwise, they remain unchanged. Then, if edge $x_i y_j$ stores a vertex $x_{i'} \neq$ **nil** as the next unmatched vertex incident to y_j, we insert the current weights of V_{y_j} into Q, but now with priority $x_{i'} y_j$.

The whole procedure requires one scan of the sorted edge list of H', and two

priority queue operations per edge, once the edges of H' are stored in the right order and store the appropriate successor pointers as defined above. If we use a buffer tree [4] to implement the priority queue, every priority queue operation takes $O((1/B)\log_{M/B}(r/B)) = O((1/B)\log_{M/B}(|H'|/B))$ I/Os amortized. Thus, the construction of F_2' takes $O(\mathrm{sort}(|H'|)) = O(\mathrm{sort}(|H_1|))$ I/Os.

Total cost of the loop. The previous three paragraphs establish that each iteration of the while-loop takes $O(\mathrm{sort}(|H|))$ I/Os. Also observe that $|H| = N$ before the first iteration. To prove that the cost of the whole loop is $O(\mathrm{sort}(N))$ I/Os, it is therefore sufficient to show that $|H|$ decreases by a factor of at least two from one iteration to the next.

LEMMA 3.4. *The loop in lines* 3–7 *of procedure* CONTRACTEDGES *takes* $O(\mathrm{sort}(N))$ *I/Os.*

Proof. Assume that there are k iterations. For $1 \le i \le k$, let $H^{(i)}$ and $H_1^{(i)}$ be snapshots of H and H_1 at the beginning of the ith iteration and after Step 1 of the ith iteration, respectively. Then the total cost of Step 1 over all iterations is $O\bigl(\sum_{i=1}^{k}\mathrm{sort}\bigl(\bigl|H^{(i)}\bigr|\bigr)\bigr)$, and the cost of Steps 2 and 3 over all iterations is $O\bigl(\sum_{i=1}^{k}\mathrm{sort}\bigl(\bigl|H_1^{(i)}\bigr|\bigr)\bigr)$. It is easy to see that $\bigl|H^{(i+1)}\bigr| \le \bigl|H_1^{(i)}\bigr|$ for all $1 \le i < k$. Hence, the total cost of all iterations is $O\bigl(\mathrm{sort}\bigl(\bigl|H^{(1)}\bigr|\bigr) + \sum_{i=1}^{k}\mathrm{sort}\bigl(\bigl|H_1^{(i)}\bigr|\bigr)\bigr)$, which is $O(\mathrm{sort}(N) + \sum_{i=1}^{k}\mathrm{sort}(|H_1^{(i)}|))$ because $H^{(1)} = G$. Next we prove that, for $1 \le i < k$, $\bigl|H_1^{(i+1)}\bigr| \le \bigl|H_1^{(i)}\bigr|/2$. Hence, $\sum_{i=1}^{k}\bigl|H_1^{(i)}\bigr| \le 2\bigl|H_1^{(1)}\bigr| \le 2N$, and the total cost of the loop is $O(\mathrm{sort}(N))$ I/Os.

Consider the ith iteration. After Step 2, there are at most $|H_1^{(i)}|/2$ matched vertices in H_2 because each represents two vertices in $H_1^{(i)}$. To bound the number of vertices in $H_1^{(i+1)}$ by $|H_1^{(i)}|/2$, we argue that every vertex in $H_1^{(i+1)}$ represents a set V' in $\mathcal{V}_{F_2'}$ that contains a matched vertex. In particular, we argue that every vertex in $H^{(i+1)} = H_2/\mathcal{V}_{F_2'}$ that represents a singleton set in $\mathcal{V}_{F_2'}$ containing only an unmatched vertex has only heavy neighbors and, thus, does not belong to the contractible subgraph of $H^{(i+1)}$. To see that this is true, observe that we inspect every unmatched vertex x in H_2 to check whether it has a matched neighbor y whose containing set $V_y \in \mathcal{V}_{F_2'}$ is light; if so, we add the edge xy to F_2', thereby adding x to V_y. Thus, if x remains in a singleton set, all its neighbors in $H^{(i+1)}$ are heavy. This finishes the proof. □

I/O-complexity of the edge contraction phase. To complete the analysis, we have to consider the costs of lines 1, 2, and 8 of the algorithm. Lines 1 and 2 are easy to implement in $O(N/B)$ I/Os. Line 8 requires computing the connected components of the graph $G_F = (V, F)$. This can be done in $O(\mathrm{sort}(N))$ I/Os (see section 2.4). The connected components algorithm identifies components by labeling every vertex in a connected component of G_F with a representative. As argued in section 2.4, the graph $G/\mathcal{V}_F$ can then be computed in $O(\mathrm{sort}(N))$ I/Os. Together with Lemmas 3.3 and 3.4, this proves the following.

LEMMA 3.5. *The edge contraction phase of the uniform graph contraction procedure takes* $O(\mathrm{sort}(N))$ *I/Os.*

3.2.2. Bundling phase. The bundling phase assumes that no two light vertices in the input graph G_1 are adjacent. By Lemma 3.3, this is true for the graph produced by the edge contraction phase. We first extract all light vertices of degree at most two and represent each such vertex x as a triple $(x, y_1, \mathbf{nil})$ or (x, y_1, y_2), depending on whether it has one or two (heavy) neighbors. We sort these triples by their last two

components, thereby storing all vertices with the same neighbors consecutively. Then we scan this sorted list; that is, we scan each group C of vertices with the same neighbors. For each such group, we form subgroups, starting with the first vertex in C. For every subgroup, we record its total weights $W_1, \ldots, W_k$, which are the sums of the corresponding weights of the vertices in the group. For every inspected vertex x, we add it to the current group if $W_h \leq u_h/2$ for all $1 \leq h \leq k$. Otherwise, vertex x starts a new group. Groups are represented by labeling every vertex in a group with the ID of the first vertex in the group. The final grouping represents the partition $\mathcal{V}_2$ of $V(G_1)$, and we compute the graph $G_2 = G_1/\mathcal{V}_2$ using the graph contraction procedure from section 2.4.

LEMMA 3.6. *Given an N-vertex planar graph G_1 that has no two adjacent light vertices and all of whose vertices are within bounds, the bundling phase takes* $\mathrm{O}(\mathrm{sort}(N))$ *I/Os and produces a vertex bundling $G_2 = G_1/\mathcal{V}_2$ of G_1 that contains no two light vertices of degree at most two that have the same open neighborhood. All vertices in G_2 are within bounds.*

Proof. The I/O-bound of the procedure is obvious because we sort and scan the vertex and edge sets of G_1 a constant number of times and then apply the contraction procedure from section 2.4. It is also obvious that $G_1/\mathcal{V}_2$ is a vertex bundling because we add two vertices to the same set in $\mathcal{V}_2$ only if they have the same neighbors.

Next assume that G_2 contains two light vertices x and y of degree at most two and such that $\mathcal{N}(x) = \mathcal{N}(y)$. Then x and y are the representatives of two sets V_1 and V_2 in $\mathcal{V}_2$ that are subsets of the set C of all vertices with neighborhood $\mathcal{N}(x)$, and both sets are light. Assume w.l.o.g. that V_1 is formed before V_2, and let z be the first vertex in C that is not in V_1. Since V_1 is light, z would have been added to V_1, a contradiction.

Now assume that G_2 contains a vertex x that is out of bounds. Since all vertices of G_1 are within bounds, x must represent some set V_1 formed by collecting vertices that belong to a set C of light vertices with the same neighbors. Let y be the last vertex in C that is added to V_1. Since we add y to V_1, V_1 is light before the addition of y. Since y is light, this implies that V_1 remains within bounds after adding y to it, a contradiction. ∎

Lemmas 3.5 and 3.6 together establish the I/O-complexity of the uniform graph contraction procedure claimed in Theorem 3.1 and, thus, finish the proof of Theorem 3.1.

4. An algorithm for partitioning unweighted graphs. In this section, we present our main result: an I/O-efficient algorithm for computing a proper r-partition of an unweighted planar graph G. In particular, we prove the following.

THEOREM 4.1. *Given a planar graph G and an integer $r > 0$, a proper r-partition of G can be computed in* $\mathrm{O}(\mathrm{sort}(N))$ *I/Os, provided that $M \geq 56r \log^2 B$.*

Our algorithm (Algorithm 2) consists of three steps. The first two compute a separator S_0 of size $\mathrm{O}(N/\sqrt{r})$ that defines an $\left(r \log^2 B\right)$-partition of G. The last step then refines this partition to an r-partition by adding at most $\mathrm{O}(N/\sqrt{r})$ more vertices to the separator. The reason for not computing an r-partition immediately in the first two steps is that Step 2 consists of $\log B$ iterations, each of which adds $\mathrm{O}(N/\sqrt{r'})$ vertices to the separator if an r'-partition is desired. By choosing $r' = r \log^2 B$, we ensure that the total number of separator vertices chosen in the first two steps is $\mathrm{O}(N/\sqrt{r})$, and the refinement in Step 3 increases this number by only a constant factor.

Algorithm 2 Computing a separator for an unweighted planar graph.

Procedure SEPARATOR

Input: A planar graph $G = (V, E)$ and an integer $r > 0$.
Output: A proper r-partition $\mathcal{P} = (S, \mathcal{R})$ of G.

1: $\ell \leftarrow \lfloor \log B \rfloor - 1$

2: Step 1: Compute the graph hierarchy

$G_0 \leftarrow G$
for $i = 1, \ldots, \ell$ **do**
Compute a graph G_i that satisfies properties (GH3)–(GH6) from G_{i-1}.
end for

3: Step 2: Compute the separator S_0

Apply Theorem 2.1 to compute a separator $S_\ell \subseteq V(G_\ell)$ of size $O(|G_\ell|/(\sqrt{r} \log B))$ and whose removal partitions G_ℓ into connected components of size at most $r \log^2 B$.
for $i = \ell - 1, \ldots, 0$ **do**
Compute a separator S_i for G_i. Separator S_i consists of two sets S_i' and S_i''. S_i' is the set of vertices represented by the vertices in S_{i+1}. S_i'' is the set of separator vertices introduced in order to partition the connected components of $G_i - S_i'$ into subgraphs of size at most $r \log^2 B$.
end for

4: Step 3: Compute the final partition

Compute the partition $\mathcal{P} = (S, \mathcal{R})$ by dividing the connected components of $G - S_0$ into $O(N/r)$ subgraphs of size at most r and boundary size $O(\sqrt{r})$ and adding the required separator vertices to S_0.

Step 3 is easy to implement I/O-efficiently: Given the assumption that $M \geq 56r \log^2 B$, every connected component of $G - S_0$ fits in internal memory. Hence, we can compute the desired r-partition by loading each component of $G - S_0$ into memory and applying Theorem 2.1 to it without incurring any further I/Os.

In Steps 1 and 2, we apply the same idea iteratively. In Step 1, we construct a hierarchy of $\ell = \lfloor \log B \rfloor - 1$ planar graphs $G_0, \ldots, G_\ell$, where $G_0 = G$ and $|G_\ell| = O(N/B)$. We obtain each graph G_i from the previous graph G_{i-1} using the uniform graph contraction procedure from section 3. Given the reduced size of G_ℓ, we can compute an $\big(r \log^2 B\big)$-partition of G_ℓ in $O(N/B)$ I/Os using Theorem 2.1. Let S_ℓ be the set of separator vertices used in this partition. In Step 2, we undo the contraction steps that produced graphs $G_1, \ldots, G_\ell$ from G_0, one graph at a time. In each iteration, we derive a separator S_i for G_i from the separator S_{i+1} computed for G_{i+1} in the previous iteration. We do this as follows: Since G_{i+1} is obtained from G_i using the uniform graph contraction procedure, every vertex in G_{i+1} represents a set of vertices in G_i. Let S_i' be the set of vertices in G_i represented by the vertices in S_{i+1}. In order to obtain an $\big(r \log^2 B\big)$-partition of G_i, we partition every component of $G_i - S_i'$ into subgraphs of size at most $r \log^2 B$ and add the separator vertices used in this partition to a set S_i''. The separator S_i is the union of sets S_i' and S_i''. S_0 is the separator of $G_0 = G$ obtained at the end of this process.

In order to carry out Step 2 efficiently, and in order to obtain a small separator S_0 at the end of Step 2, the graph hierarchy $G_0, \ldots, G_\ell$ computed in Step 1 has to satisfy a number of properties.

First, we want every graph G_{i+1} to have roughly half as many vertices as G_i. This guarantees that the cost of Steps 1 and 2 is dominated by the cost of the computation on $G_0 = G$ and, since $\ell = \lfloor \log B \rfloor - 1$, that G_ℓ has size $O(N/B)$.

Second, during the construction of the separator S_i from S'_i, we would like to use an internal-memory algorithm to partition each connected component of $G_i - S'_i$; that is, we want each such component to fit in memory. Since S_{i+1} defines an $\left(r \log^2 B\right)$-partition of G_{i+1} and $M \geq 56r \log^2 B$, every connected component of $G_i - S'_i$ fits in memory if every vertex in G_{i+1} represents at most 56 vertices in G_i.

Finally, observe that, once we add a vertex x in G_i to S_i, all vertices in G represented by x belong to S_0. Thus, to guarantee that S_0 is small, we have to ensure that no vertex in G_i represents too many vertices of G.

These conditions are formalized in the following properties which we require the graph hierarchy $G_0, \ldots, G_\ell$ to have:

(GH1) $\ell = \lfloor \log B \rfloor - 1$,
(GH2) $G = G_0$,
(GH3) For $i = 0, \ldots, \ell$, G_i is planar,
(GH4) For $i = 0, \ldots, \ell$, $|G_i| \leq 7N/2^{i-1}$,
(GH5) For $i = 1, \ldots, \ell$, every vertex in G_i represents at most 56 vertices in G_{i-1}, and
(GH6) For $i = 0, \ldots, \ell$, every vertex in G_i represents at most 2^{i+1} vertices in G.

In section 4.1, we show how to compute a graph hierarchy with these properties in $O(\mathrm{sort}(N))$ I/Os. In section 4.2, we show that the desired separator S_0 of G can be computed from this graph hierarchy in $O(\mathrm{sort}(N))$ I/Os. In section 4.3, we provide the details of Step 3 and show that this step can be carried out in the same I/O bound as Steps 1 and 2, thereby establishing the complexity of Algorithm 2 claimed in Theorem 4.1.

4.1. The graph hierarchy. The first step of our algorithm is the computation of a hierarchy of graphs $G_0, \ldots, G_\ell$ that satisfy properties (GH1)–(GH6). We start by setting $G_0 = G$. Then we compute each graph G_i from the previous graph G_{i-1} by using the uniform graph contraction procedure from section 3. To ensure properties (GH5) and (GH6), we assign a *weight* $w(x)$ and a *size* $s(x)$ to every vertex in G_{i-1}; the former is equal to the number of vertices in G represented by x, and the latter is equal to the number of vertices in G_{i-1} represented by x, that is, equal to 1. We then pass a weight threshold $u_w = 2^{i+1}$ and a size threshold $u_s = 56$ to the contraction procedure.

Note that the assignment of weights and sizes to the vertices of G_{i-1} before the construction of G_i is easily accomplished. Initially, we set $w(x) = s(x) = 1$ for every vertex x in $G_0 = G$. Subsequently, before computing G_i from G_{i-1}, the size of every vertex in G_{i-1} can be reset to 1 in a single scan over the vertex set of G_{i-1}; as a result of the construction of G_{i-1} from G_{i-2}, every vertex in G_{i-1} already stores its correct weight.

LEMMA 4.2. *A graph hierarchy $G_0, \ldots, G_q$ with properties* (GH1)–(GH6) *can be constructed in* $O(\mathrm{sort}(N))$ *I/Os.*

Proof. First, we prove that the graph hierarchy computed by the procedure we have just described has the desired properties. Properties (GH1) and (GH2) are trivially satisfied. Property (GH3) is easy to prove by induction: For $i = 0$, $G_0 = G$ and is thus planar. For $i > 0$, the planarity of G_i follows from the planarity of G_{i-1} because, by Theorem 3.1, the uniform contraction procedure preserves planarity.

Properties (GH5) and (GH6) are also easy to show by induction. In particular,

$w(x) = 1 \leq 2$ for every vertex $x \in G_0$, and property (GH5) holds vacuously in this case. When constructing G_i from G_{i-1}, every vertex in G_{i-1} is within bounds because, by the induction hypothesis, it has weight at most 2^i and size 1 (after resetting its size to 1). Hence, by Theorem 3.1, every vertex in G_i is within bounds and, thus, has weight at most 2^{i+1} and size at most 56.

It remains to show property (GH4). For graph G_0, property (GH4) holds because $|G_0| = |G| = N \leq 7N/2^{-1}$. To prove the claim for graphs $G_1, \ldots, G_\ell$, let h_i be the number of heavy vertices in G_i. By Theorem 3.1, each graph G_i has size less than $7h_i$. To prove property (GH4), it is therefore sufficient to prove that $h_i \leq N/2^{i-1}$.

We prove this claim by induction. We partition the heavy vertices into two categories. A heavy vertex of type I has weight exceeding 2^i. A type-II vertex has weight at most 2^i and size greater than 28. Graph G_i contains less than $N/2^i$ type-I vertices and less than $|G_{i-1}|/28$ type-II vertices; that is, $h_i < N/2^i + |G_{i-1}|/28$.

For $i = 1$, we obtain $h_1 < N/2 + N/28 < N/2^0$. For $i > 1$, we obtain

$$h_i < \frac{N}{2^i} + \frac{|G_{i-1}|}{28} \tag{1}$$

$$\leq \frac{N}{2^i} + \frac{h_{i-1}}{4} \tag{2}$$

$$\leq \frac{N}{2^i} + \frac{N}{2^i} \tag{3}$$

$$= \frac{N}{2^{i-1}}. \tag{4}$$

Equation (2) follows from (1) because $|G_{i-1}| \leq 7h_{i-1}$, as argued above. Equation (3) follows from (2) by the induction hypothesis.

To bound the I/O-complexity, we recall that, by Theorem 3.1, the construction of graph G_i from graph G_{i-1} takes $\mathrm{O}(\mathrm{sort}(|G_{i-1}|))$ I/Os. By property (GH4), we have $\sum_{i=0}^{\ell} |G_i| = \mathrm{O}(N)$. Thus, the total I/O-complexity is $\sum_{i=1}^{\ell} \mathrm{O}(\mathrm{sort}(|G_{i-1}|)) = \mathrm{O}(\mathrm{sort}(N))$. □

4.2. The separator hierarchy. In Step 2 of Algorithm 2, we use the graph hierarchy computed in the first step to construct a relatively coarse partition of G. In particular, we compute a separator S_0 of size $\mathrm{O}(N/\sqrt{r})$ whose removal partitions G into connected components of size at most $r \log^2 B$.

First, we compute a partition of G_ℓ into subgraphs of size at most $r \log^2 B$. To do so, we use an arbitrary linear-time planar embedding algorithm (see, e.g., [11]) to compute a planar embedding of G_ℓ, and then we apply Theorem 2.1 to compute the desired partition. Let $S_\ell = S''_\ell$ be the computed separator.

In the loop in Step 2, we apply the following iterative strategy to compute separators $S_{\ell-1}, \ldots, S_0$ for graphs $G_{\ell-1}, \ldots, G_0$: Given the separator S_{i+1} computed for graph G_{i+1} in the previous iteration, we construct the set S'_i of vertices in G_i represented by the vertices in S_{i+1}. Then we apply Theorem 2.1 to each connected component of $G_i - S'_i$ whose size exceeds $r \log^2 B$, in order to partition it into subgraphs of size at most $r \log^2 B$. Let S''_i be the set of separator vertices introduced by partitioning the connected components of $G_i - S'_i$ in this manner. Then $S_i = S'_i \cup S''_i$.

LEMMA 4.3. *The separator S_0 of G computed in Step 2 of Algorithm 2 has size $\mathrm{O}(N/\sqrt{r})$. The connected components of $G - S_0$ have size at most $r \log^2 B$.*

Proof. The bound on the size of the connected components of $G - S_0$ is explicitly guaranteed by the construction. We bound the size of S_0 as follows: For every vertex

$x \in G_i$, let $R_0(x)$ be the set of vertices in G represented by x. From our computation of S_0 it follows that, for every vertex $y \in S_0$, there exists a unique set S_i'' and a unique vertex $x \in S_i''$ such that $y \in R_0(x)$. Hence, we have

$$|S_0| = \sum_{i=0}^{\ell} \sum_{x \in S_i''} |R_0(x)|.$$

By property (GH6), we have $|R_0(x)| = w(x) \leq 2^{i+1}$ for all $x \in S_i''$. Hence,

$$|S_0| \leq \sum_{i=0}^{\ell} 2^{i+1} |S_i''|.$$

Since we compute S_i'' by applying Theorem 2.1 to disjoint subgraphs of G_i, partitioning each into pieces of size at most $r \log^2 B$, we have $|S_i''| \leq 4|G_i|/(\sqrt{r} \log B)$. By property (GH4), this implies that $|S_i''| \leq 28N/(2^{i-1}\sqrt{r} \log B)$. Thus,

$$|S_0| \leq \sum_{i=0}^{\ell} 2^{i+1} \frac{28N}{2^{i-1}\sqrt{r} \log B} = \sum_{i=0}^{\ell} \frac{112N}{\sqrt{r} \log B} = \frac{112N}{\sqrt{r}}. \qquad \square$$

LEMMA 4.4. *Step* 2 *of Algorithm* 2 *takes* $O(\mathrm{sort}(N))$ *I/Os to compute the separator* S_0*, provided that* $M \geq 56r \log^2 B$.

Proof. The computation of the separator S_ℓ takes $O(N/B)$ I/Os by Theorem 2.1 and because graph G_ℓ has size at most $7N/2^{\ell-1} = O(N/B)$. Since the sizes of graphs $G_0, \ldots, G_\ell$ are geometrically decreasing, it suffices to show that the separator S_i can be constructed from S_{i+1} in $O(\mathrm{sort}(|G_i|))$ I/Os. This implies then that Step 2 takes $O(\mathrm{sort}(|G_0|)) = O(\mathrm{sort}(N))$ I/Os.

Since the uniform graph contraction procedure labels every vertex x in G_i with the vertex in G_{i+1} representing x, we can compute the separator S_i' in $O(\mathrm{sort}(|G_i|))$ I/Os: First, we sort the vertices in S_{i+1} by their IDs, and then we sort the vertices in G_i by their representatives in G_{i+1}. Then we scan the two lists and mark all those vertices in G_i as being in S_i' whose representatives in G_{i+1} belong to S_{i+1}. Now it takes $O(\mathrm{sort}(|G_i|))$ I/Os to compute the connected components of $G_i - S_i'$ (see section 2.4).

Since every connected component of $G_{i+1} - S_{i+1}$ has size at most $r \log^2 B$, it follows from property (GH5) and Fact 2.2 that every connected component of $G_i - S_i'$ has size at most $56r \log^2 B \leq M$; that is, each such component fits in memory. Thus, we can load each connected component of $G_i - S_i'$ whose size exceeds $r \log^2 B$ into memory and apply Theorem 2.1 to partition it into connected components of size at most $r \log^2 B$. As the computation of Theorem 2.1 is carried out in internal memory, partitioning the connected components of $G_i - S_i'$ into subgraphs of size at most $r \log^2 B$ takes $O(|G_i|/B)$ I/Os. Thus, the computation of S_i takes $O(\mathrm{sort}(|G_i|))$ I/Os, and the total I/O-bound follows. $\square$

4.3. Computing the final partition. In order to obtain the final partition in Step 3 of Algorithm 2, we have to partition the connected components of $G - S_0$ into subgraphs of size at most r. We also have to merge subgraphs to reduce their number to $O(N/r)$, while maintaining the bounds on their size and boundary size. We do this as follows: First, we use Theorem 2.1 to partition each connected component of $G - S_0$ into pieces of size at most r. This adds $O(N/\sqrt{r})$ vertices to the separator and, thus, increases the separator size by only a constant factor. The resulting partition may

contain more than $O(N/r)$ subgraphs, and the total boundary size of its subgraphs may exceed $O(N/\sqrt{r})$. We group the subgraphs in the current partition to reduce their number to $O(N/r)$ and their total boundary size to $O(N/\sqrt{r})$. Finally, we partition each subgraph in the resulting partition into subgraphs of boundary size $O(\sqrt{r})$. This is similar to Frederickson's approach [19] and, as argued below, increases both the number of subgraphs in the partition and the total boundary size by only a constant factor.

Since every connected component of $G - S_0$ has size at most $r \log^2 B \leq M$, the partition of $G - S_0$ into connected components of size at most r can be computed by loading each connected component of $G - S_0$ into internal memory and applying Theorem 2.1 to it. Let $S' \supseteq S_0$ be the separator produced by this step. Section 4.3.1 discusses how to obtain a normal r-partition $\mathcal{P}' = (S', \{G'_1, \ldots, G'_r\})$ of G from S'. Section 4.3.2 then refines this partition to make it proper.

4.3.1. Grouping components. Intuitively, we compute the partition $\mathcal{P}'$ in two phases: The first phase groups connected components of boundary size at most two with other components that have the same boundary, while ensuring that none of the resulting subgraphs has size greater than r. This phase reduces the total boundary size of all subgraphs to $O(N/\sqrt{r})$. The second phase merges subgraphs that share boundary vertices until no two subgraphs sharing boundary vertices can be merged without producing a subgraph of size greater than r. This reduces the number of subgraphs to $O(N/r)$. Note that merging subgraphs in this manner cannot increase the total boundary size; that is, the total boundary size of all subgraphs in the partition remains $O(N/\sqrt{r})$, and the resulting partition $\mathcal{P}'$ is normal.

To determine which connected components to group in these two phases, we use an auxiliary graph H_0 whose vertices represent separator vertices and connected components of $G - S'$. Both phases operate on H_0, grouping component vertices rather than actual components. After the two phases have been applied to H_0, we obtain $\mathcal{P}'$ by merging the components in the partition that correspond to merged component vertices in H_0.

Graph H_0 contains all vertices in S' and one vertex per connected component of $G - S'$. There is an edge between two separator vertices in H_0 if such an edge exists in G. There is an edge between a separator vertex x and a component vertex representing a component G' of $G - S'$ if $x \in \mathcal{N}(G')$. Finally, every vertex in H_0 has a weight equal to the number of vertices in G it represents.

Graph H_0 is easily constructed from G and S' in $O(\mathrm{sort}(N))$ I/Os: First, we compute the connected components of $G - S'$, thereby labeling every vertex in $G - S'$ with the ID of the component it belongs to; we also label every vertex in S' with its own ID. Then we apply the contraction procedure from section 2.4 to G.

Reducing the total boundary size. Merging components of boundary size at most two that have the same boundary is equivalent to merging component vertices in H_0 that have the same neighbors and degree at most two. The latter is easily achieved using the uniform graph contraction procedure (in fact, only the bundling phase is sufficient). For the purpose of applying this procedure, we change the weight of every separator vertex to r, leave the weights of all component vertices unchanged, and set the weight threshold to r. Then the edge contraction phase does nothing because every edge of H_0 has at least one endpoint that is a separator vertex, that is, is heavy. The bundling phase merges light component vertices that have the same neighbors and degree at most two. By Theorem 3.1, the application of the uniform contraction procedure takes $O(\mathrm{sort}(|H_0|)) = O(\mathrm{sort}(N))$ I/Os. The next lemma proves that this

produces a graph H_1 from H_0 whose component vertices represent subgraphs of $G-S'$ of size at most r each and sufficiently small total boundary size. Note that the bound on the size of H_1 stated in the lemma implies the claimed bound on the boundary size of the corresponding partition of G because the total boundary size is equal to the number of edges between component vertices and separator vertices in H_1. Since H_1 is planar and has size $O(N/\sqrt{r})$, there are only $O(N/\sqrt{r})$ edges in H_1.

LEMMA 4.5. *Applying the uniform contraction procedure to H_0 produces a planar graph H_1 of size $O(N/\sqrt{r})$. Every vertex in H_1 has weight at most r.*

Proof. Since H_0 is an edge contraction of G, Fact 2.1 implies that H_0 is planar. By Theorem 3.1, this implies that H_1 is planar. Before applying the contraction procedure to H_0, all vertices are within bounds, that is, have weight at most r. Hence, by Theorem 3.1, every vertex in H_1 has weight at most r. Finally, to bound the size of H_1, observe that H_1 contains only $O(N/\sqrt{r})$ heavy vertices: $O(N/\sqrt{r})$ separator vertices and $O(N/r)$ heavy component vertices; the latter is true because the total weight of all component vertices in H_1 is at most N. By Theorem 3.1, this implies that H_1 has $O(N/\sqrt{r})$ vertices. ∎

Reducing the number of subgraphs. To reduce the size of H_1 to $O(N/r)$ by further merging vertices, we first reset the weight of every separator vertex to 1 and then apply the uniform contraction procedure to H_1, again with weight threshold r. Since $|H_1| \leq N$, this takes $O(\mathrm{sort}(N))$ I/Os by Theorem 3.1. Since a vertex is heavy if its weight exceeds $r/2$, and the total weight of all vertices in the resulting graph H_2 is N, there are at most $2N/r$ heavy vertices in H_2. By Theorem 3.1, this implies that the total size of H_2 is $O(N/r)$. Moreover, since no vertex in H_1 has weight exceeding r, Theorem 3.1 implies that no vertex in H_2 has weight exceeding r. Thus, we have the following.

LEMMA 4.6. *Applying the uniform contraction procedure to H_1 produces a planar graph H_2 of size $O(N/r)$. Every vertex in H_2 has weight at most r.*

The final grouping. Every component vertex in H_2 now represents a subgraph in the partition $\mathcal{P}'$. We finish the computation of $\mathcal{P}'$ by labeling every nonseparator vertex with the ID of the subgraph it belongs to. This is easily achieved by sorting and scanning the vertex sets of G, H_0, H_1, and H_2 a constant number of times. Indeed, every vertex in $G - S'$ is initially labeled with the connected component of $G - S'$ that contains it, that is, with its representative in H_0. Similarly, every vertex in H_0 is labeled with its representative in H_1, and every vertex in H_1 is labeled with its representative in H_2. Thus, sorting and scanning suffices to label every vertex in H_1, and subsequently every vertex in H_0 and G, with its representative in H_2. This labeling represents the subgraphs in $\mathcal{P}'$.

LEMMA 4.7. *Given the separator S_0, a normal r-partition $\mathcal{P}'$ of G can be computed in $O(\mathrm{sort}(N))$ I/Os.*

Proof. The I/O-bound of computing $\mathcal{P}'$ from S_0 follows from the above discussion of the different steps required to obtain $\mathcal{P}'$ from G and S_0.

There are only $O(N/r)$ subgraphs in $\mathcal{P}'$ because there are only $O(N/r)$ component vertices in H_2 and each of them defines one subgraph in $\mathcal{P}'$. Every subgraph in the partition has size equal to the weight of its representative in H_2; by Lemma 4.6, no vertex in H_2 has weight exceeding r. Finally, by Lemma 4.5, there are only $O(N/\sqrt{r})$ edges in H_1. Each such edge represents an adjacency between a separator vertex and a subgraph in the partition $\mathcal{P}''$ of G represented by H_1. Thus, $\mathcal{P}''$ has total boundary size $O(N/\sqrt{r})$. Since partition $\mathcal{P}'$ is obtained by merging subgraphs in $\mathcal{P}''$, the total boundary size of the subgraphs in $\mathcal{P}'$ cannot be greater than the total boundary size of the subgraphs in $\mathcal{P}''$. ∎

4.3.2. Ensuring small boundary size. In order to obtain a proper r-partition from the normal r-partition $\mathcal{P}'$, we have to reduce the boundary size of each individual subgraph to $O(\sqrt{r})$ by further partitioning each subgraph in $\mathcal{P}'$ whose boundary size exceeds this bound. In order to do so, we apply Corollary 2.3. This, however, requires that each graph $\mathcal{N}[G'_i]$ fit in memory. While $|G'_i| \leq r \leq M$, the graph $\mathcal{N}[G'_i]$ may be big and may not fit in memory.

We solve this problem by first augmenting the separator so that its size increases by only a constant factor, and every graph G''_i in the resulting partition satisfies $|\mathcal{N}[G''_i]| = O(r) \leq M$. This then allows us to apply Corollary 2.3 to obtain the final partition.

To augment the separator, we consider each graph G'_i in the partition $\mathcal{P}'$ in turn. Let $\tilde{G}_i$ be the graph obtained from $\mathcal{N}[G'_i]$ as follows: First, we remove all edges between vertices in $\mathcal{N}(G'_i)$. Then we merge all vertices in $\mathcal{N}(G'_i)$ whose resulting degree is at most 2 that have the same set of neighbors (which all belong to G'_i). For every vertex in $\tilde{G}_i$ that represents more than one vertex in $\mathcal{N}(G'_i)$, we add its neighbors in G'_i to a set S''_i. Then we define $\mathcal{P}'' = (S'', \{G''_1, \ldots, G''_p\})$, where $G''_i = G[V(G'_i) \setminus S''_i]$ and $S'' = S' \cup \bigcup_{i=1}^{p} S''_i$; that is, in $\mathcal{P}''$, the vertices in S''_i are removed from the graph G'_i and are added to the separator.

LEMMA 4.8. *Let $\mathcal{P}'' = (S'', \{G''_1, \ldots, G''_p\})$ be the partition obtained from $\mathcal{P}'$ using the above transformation. Then $\mathcal{P}''$ is normal, and every graph $\mathcal{N}[G''_i]$, $1 \leq i \leq p$, has size $O(r)$.*

Proof. Let $\mathcal{P}' = (S', \{G'_1, \ldots, G'_p\})$. Then $|S'| = O(N/\sqrt{r})$ and $\sum_{i=1}^{p} |\mathcal{N}(G_i)| = O(N/\sqrt{r})$ because $\mathcal{P}'$ is normal. Now consider subgraphs G'_i and G''_i, and let $\mathcal{N}_{\text{sh}}(G'_i) = \mathcal{N}(G'_i) \cap \mathcal{N}(G''_i)$ and $\mathcal{N}_{\text{dis}}(G'_i) = \mathcal{N}(G'_i) \setminus \mathcal{N}(G''_i)$.

We start by proving that $|S''_i| \leq |\mathcal{N}_{\text{dis}}(G'_i)|$. Consider a vertex $x \in S''_i$. This vertex belongs to S''_i because there exists a vertex $y \in \tilde{G}_i$ that represents a set V_y of $h \geq 2$ vertices in $\mathcal{N}(G'_i)$ that are adjacent to x. We charge each such vertex $1/h \leq 1/2$ for the addition of x to S''_i. Since each vertex in V_y is adjacent to at most two vertices in G'_i, each vertex in V_y is charged for at most two vertices, and the charge to each vertex is at most 1. Thus, the total number of charged vertices is an upper bound on $|S''_i|$. Note, however, that all neighbors of a charged vertex that belong to G'_i are added to S''_i. Hence, every charged vertex belongs to $\mathcal{N}_{\text{dis}}(G'_i)$ and $|S''_i| \leq |\mathcal{N}_{\text{dis}}(G'_i)|$. This immediately implies that partition $\mathcal{P}''$ is normal: The size of S'' is $|S''| = |S'| + \sum_{i=1}^{p} |S''_i| \leq |S'| + \sum_{i=1}^{p} |\mathcal{N}_{\text{dis}}(G'_i)| \leq |S'| + \sum_{i=1}^{p} |\mathcal{N}(G'_i)| = O(N/\sqrt{r})$. For each graph G''_i, we have $|\mathcal{N}(G''_i)| \leq |\mathcal{N}_{\text{sh}}(G'_i)| + |S''_i| \leq |\mathcal{N}_{\text{sh}}(G'_i)| + |\mathcal{N}_{\text{dis}}(G'_i)| = |\mathcal{N}(G'_i)|$. Therefore, $\sum_{i=1}^{p} |\mathcal{N}(G''_i)| \leq \sum_{i=1}^{p} |\mathcal{N}(G'_i)| = O(N/\sqrt{r})$.

To bound the size of each graph $\mathcal{N}[G''_i]$, we partition its vertices into two groups: those in G'_i and those in $\mathcal{N}_{\text{sh}}(G'_i)$. Since $|G'_i| \leq r$, $\mathcal{N}[G''_i]$ can contain at most r vertices that belong to G'_i. Next, observe that there are no two vertices x and y of degree at most two in $\mathcal{N}_{\text{sh}}(G'_i)$ such that $\mathcal{N}(x) = \mathcal{N}(y)$: if there were two such vertices, their neighbors in G'_i would have been added to S''_i. Thus, the subgraph of G induced by the edges between vertices in $\mathcal{N}_{\text{sh}}(G'_i)$ and vertices in G'_i satisfies the conditions of Corollary 2.5, and the number of vertices in $\mathcal{N}_{\text{sh}}(G'_i)$ is less than $6|G'_i| \leq 6r$. The size of $\mathcal{N}[G''_i]$ is therefore at most $7r$. ∎

The computation of partition $\mathcal{P}''$ takes $O(\text{sort}(N))$ I/Os. The computation of graph $\tilde{G}_i$, for every graph $\mathcal{N}[G'_i]$, is easily carried out using the uniform graph contraction procedure after assigning weight 1 to every separator vertex and weight $2N$ to every vertex in G'_i; the weight threshold is $2N$. The construction of set S''_i now requires scanning the vertex set of $\tilde{G}_i$ and adding the neighbors of all separator vertices

of weight at least two and degree at most two to S_i''. Thus, the computation for each graph $\mathcal{N}[G_i']$ takes $O(\text{sort}(|\mathcal{N}[G_i']|))$ I/Os, and the total cost is $\sum_{i=1}^{p} O(\text{sort}(|\mathcal{N}[G_i']|))= O(\text{sort}(N))$.

To obtain the final partition, we apply Theorem 2.2 to every subgraph G_i'' in partition $\mathcal{P}''$ whose boundary size exceeds $c\sqrt{r}$, for an appropriate constant $c > 0$. By Corollary 2.3, this can be done in $O(N/B)$ I/Os and increases the size of the separator and the number of graphs in the partition by only a constant factor; that is, this final step produces a proper r-partition of G.

Since we have shown that all three steps of Algorithm 2 can be carried out in $O(\text{sort}(N))$ I/Os and that the final partition we obtain is proper, we have thus shown Theorem 4.1.

5. Regular partitions. Our result from the previous section provides an algorithm for computing proper r-partitions of planar graphs, as long as r is small; but the computed partitions are not necessarily regular. In general, without a bound on the degrees of the vertices in the graph, a regular proper r-partition may not exist. For planar graphs of degree three, however, regular proper r-partitions do exist [19], and the algorithms of [5, 7, 8, 9] rely on the existence of such partitions. In this section, we show how to modify the partition produced by Algorithm 2 to obtain a regular proper r-partition for a planar graph of degree three.

Given such a graph G, we use Algorithm 2 to compute a proper r-partition $\mathcal{P} = (S, \{G_1, \ldots, G_p\})$ of G. We are, however, interested only in the separator S and discard the grouping of the connected components $G - S$ into subgraphs. Next we regroup the connected components of $G - S$ to obtain the desired regular proper r-partition $\mathcal{P}' = (S, \{G_1', \ldots, G_q'\})$. This grouping is again similar to [19].

We use an auxiliary graph H to compute the desired grouping. Graph H contains one vertex per connected component of $G - S$. There is an edge between two vertices in H if the two corresponding components of $G - S$ share a boundary vertex. Since every vertex in G has degree at most three, graph H is planar. We give two weights $s(x)$ and $b(x)$ to each vertex x in H: $s(x)$ is the size, that is, the number of vertices in the connected component represented by x; $b(x)$ is the size of the component's boundary. Note that $s(x) \leq r$ and $b(x) \leq c\sqrt{r}$, for some $c > 0$, because $\mathcal{P}$ is a proper r-partition.

Now we apply the uniform graph contraction procedure to H, with thresholds $u_s = r$ and $u_b = c\sqrt{r}$. This produces a graph H', each of whose vertices represents a set of vertices in H and, thus, a set of connected components of $G - S$. The graphs $G_1', \ldots, G_q'$ in partition $\mathcal{P}'$ are defined as the graphs represented by the vertices in H'. By the arguments in section 4.3, this partition of $G - S$ can be computed in $O(\text{sort}(N))$ I/Os.

THEOREM 5.1. *Given an N-vertex planar graph G none of whose vertices has degree greater than three, and an integer $r > 0$, a regular proper r-partition of G can be computed in* $O(\text{sort}(N))$ *I/Os, provided that* $M \geq 56r \log^2 B$.

Proof. The I/O-complexity of the procedure follows immediately from Theorem 4.1 and our discussion above. Next, we argue that the produced partition $\mathcal{P}'$ is proper. Since the partition $\mathcal{P}$ produced by Algorithm 2 is proper, we have $|S| = O(N/\sqrt{r})$. This implies that the total boundary size of the connected components of $G - S$ cannot exceed $O(N/\sqrt{r})$ because every vertex in G has degree at most three, and, thus, every vertex in S is adjacent to at most three connected components of $G - S$. Therefore, there are only $O(N/r)$ heavy vertices in H': at most $2N/r$ vertices of size greater than $r/2$ and $O(N/r)$ vertices of boundary size greater than $c\sqrt{r}/2$.

By Theorem 3.1, this implies that $|H'| = O(N/r)$, that is, that partition $\mathcal{P}'$ has $O(N/r)$ subgraphs. Since every vertex x in H has weights $s(x) \leq r$ and $b(x) \leq c\sqrt{r}$, Theorem 3.1 implies that the same is true for every vertex in H'. Thus, no subgraph in partition $\mathcal{P}'$ has size exceeding r or boundary size exceeding $c\sqrt{r}$, and partition $\mathcal{P}'$ is proper.

In order to prove that $\mathcal{P}'$ is regular, we analyze the two phases of the computation of H' from H. The edge contraction phase of the uniform contraction procedure merges only vertices that are adjacent. In G, this corresponds to merging connected components of $G - S$ that share boundary vertices. Thus, for every graph G_i'' in the resulting partition, the graph $\mathcal{N}[G_i'']$ is connected. The bundling phase merges only vertices of degree at most two that have the same neighbors. Moreover, these neighbors are heavy, that is, are not merged with any other vertices during the bundling phase. Thus, the merging of vertices during the bundling phase corresponds to producing merged subgraphs that are potentially disconnected but share boundary vertices with at most two other subgraphs G_j' and G_k', which satisfy that $\mathcal{N}[G_j']$ and $\mathcal{N}[G_k']$ are connected. □

6. Low-cost separators and edge separators. In this section, we show that the results from sections 4 and 5 can be used to obtain an I/O-efficient version of the following theorem by Aleksandrov et al. [3].

THEOREM 6.1 (Aleksandrov et al. [3]). *Given a planar graph $G = (V, E)$, a cost function $c : V \to \mathbb{R}^+$, a weight function $w : V \to \mathbb{R}^+$, and a real number $0 < t < 1$, there exists a t-vertex separator S of cost $c(S) \leq 4\sqrt{2C(G)/t}$ for G, where $c(S) = \sum_{x \in S} c(x)$ and $C(G) = \sum_{x \in V} (c(x))^2$. Such a separator can be computed in linear time.*

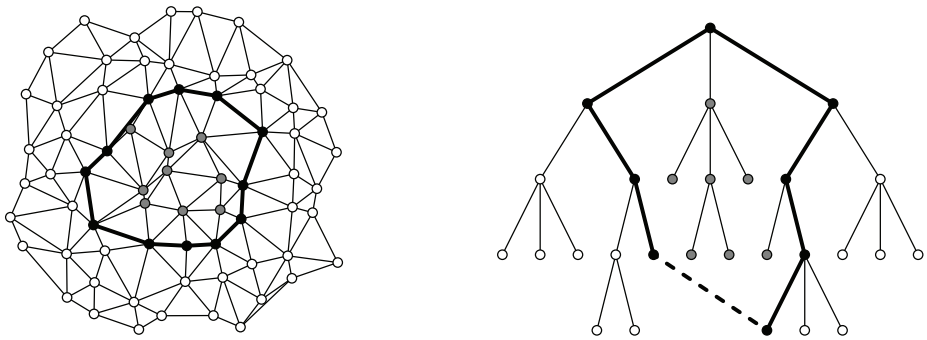
In this theorem, the sizes of the subgraphs in the computed partition are measured in terms of the total *weight* assigned to their vertices by a weight function w. Similarly, the size of the separator S is measured in terms of the total *cost* assigned to the vertices in S by a cost function c. The former is a fairly standard notion already considered in the classical paper by Lipton and Tarjan [27]. The latter is a more recent concept that allows a number of separator theorems to be seen as special cases of Theorem 6.1. Theorem 2.1, for example, can be obtained from Theorem 6.1 by choosing $c(x) = 1$ for all $x \in V$, and Aleksandrov et al. have shown how to obtain a generalization of the edge separator theorem of [15] from Theorem 6.1 (see also Theorem 6.3 in section 6.3). The main result of this section is as follows.

THEOREM 6.2. *Given a planar graph $G = (V, E)$, a cost function $c : V \to \mathbb{R}^+$, and a weight function $w : V \to \mathbb{R}^+$, a separator S as in Theorem* 6.1 *can be computed in* $O(\mathrm{sort}(N))$ *I/Os, provided that* $M = \Omega\big(B^2 \log^2 B\big)$.

Theorem 6.2 is more general than Theorem 4.1 because it takes vertex costs and weights into account; moreover, even in the unweighted case, Theorem 4.1 requires that $r = tN = O\big(M/\log^2 B\big)$, while Theorem 6.2 places no such restriction on r.

Our exposition of the algorithm that proves Theorem 6.2 is organized as follows. In section 6.1, we review the algorithm by Aleksandrov et al., as it forms the basis for our I/O-efficient version. In section 6.2, we provide I/O-efficient implementations of the three main steps of this algorithm, thereby obtaining an I/O-efficient version of the algorithm. This proves Theorem 6.2. In section 6.3, we briefly argue that this also leads to an I/O-efficient version of the edge separator algorithm of [3].

We assume throughout sections 6.1 and 6.2 that the given graph is triangulated; since any planar graph can be triangulated in $O(\mathrm{sort}(N))$ I/Os [25], and a separator



(a) (b)

FIG. 6.1. (a) *The bold cycle separates the white vertices on its outside from the grey ones on its inside.* (b) *The dashed nontree edge defines the bold fundamental cycle.*

of the resulting triangulation is also a separator of the original graph, this is not a restriction.

6.1. The algorithm of Aleksandrov et al. The algorithm of [3] can be seen as a nontrivial extension of Lipton and Tarjan's algorithm [27]. The first observation is that every simple cycle C in G separates the vertices inside C from those outside C in the given embedding of G; see Figure 6.1(a). The central goal then is to compute a collection of cycles that partition G into regions of the desired weight. These cycles are chosen from the set of *fundamental cycles* w.r.t. a spanning tree T of G, where a fundamental cycle $F(e)$ consists of an edge $e \in E(G) \setminus E(T)$ and the path in T connecting the two endpoints of e; see Figure 6.1(b). We refer to an edge $e \in E(G) \setminus E(T)$ as a *nontree edge*, while every edge in T is a *tree edge*.

In order to obtain a separator of low cost in this manner, it is necessary to bound the number of fundamental cycles comprising the separator, as well as the total cost of the vertices on each fundamental cycle. As we will see below, the former is easy, as the number of required cycles is inversely proportional to t. To ensure that each fundamental cycle is of low cost, Aleksandrov et al. compute T as a shortest-path tree w.r.t. appropriate edge weights that guarantee that the depth of every vertex x in T (that is, the weighted distance of x from the root of T) is equal to the total cost of the vertices on the path from the root of T to x; the cost of any fundamental cycle is then at most twice the *radius* of T, where the radius of the tree is the maximum depth of any of its vertices. By itself, this does not yet guarantee low cost of each fundamental cycle because T may have a large radius. To fix this, Aleksandrov et al. first find a set of vertices of low total cost whose removal partitions T into subgraphs $G_0, \ldots, G_p$ of low depth, where the *depth* of a graph G_i is the maximal difference between the depths (in T) of any two vertices in G_i; see Figure 6.2(a). We call these graphs $G_0, \ldots, G_p$ *layers*. They then triangulate each layer and obtain a spanning tree for the resulting triangulation whose radius is bounded by the depth of the layer. Hence, each fundamental cycle w.r.t. this spanning tree has low cost, and the layer can be partitioned using fundamental cycles; see Figure 6.2(b).

In summary, the algorithm therefore consists of two phases. The first phase computes the shortest-path tree T and partitions G into shallow layers by removing an appropriate set of vertices of low total cost. The second phase partitions each layer by

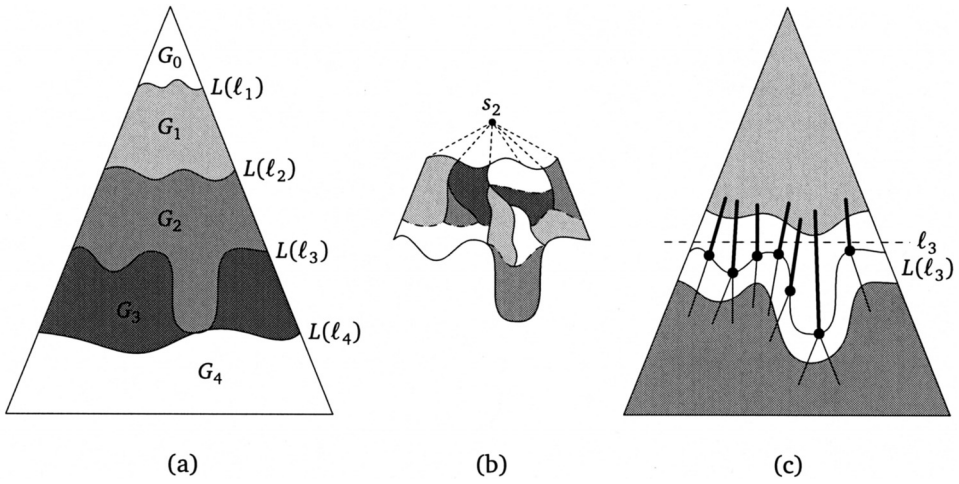


FIG. 6.2. (a) *The partition of G into layers $G_0, \ldots, G_4$ using levels $L(\ell_1), \ldots, L(\ell_4)$.* (b) *The partition of G_2 into subgraphs of weight at most $tw(G)$ using fundamental cycles. The dotted edges are the ones introduced to connect all vertices that were adjacent to vertices in $L(\ell_2)$ to the new root vertex s_2. The dashed edges are the nontree edges defining the fundamental cycles that are used to partition G_2.* (c) *The definition of level $L(\ell_3)$. The bold edges are all edges in T spanning depth ℓ_3. Their bottom endpoints are in $L(\ell_3)$. The sets $V^-(\ell_3)$ and $V^+(\ell_3)$ are shown in light and dark grey, respectively. Note that there are no edges between $V^-(\ell_3)$ and $V^+(\ell_3)$.*

removing the vertices belonging to a small set of fundamental cycles. The separator consists of all vertices removed in these two phases.

Next, we provide more details on the three parts of the algorithm: the computation of the shortest-path tree T, the partitioning of G into shallow layers, and the partitioning of each layer using fundamental cycles.

6.1.1. The shortest-path tree. To compute the spanning tree T used in the separator algorithm, recall that we assume that G is triangulated. The algorithm starts by choosing one face f, adding a new vertex s of cost and weight zero inside this face, and connecting s to the three vertices on the boundary of f.

Next, every edge xy of G is replaced with two directed edges xy and yx, and each directed edge xy is assigned a weight $w'(xy) = c(y)$; that is, the weight of every edge is equal to the cost of its head. Tree T is the shortest-path tree obtained by computing single-source shortest paths from s w.r.t. edge weights w'. It is easy to see that the distance of a vertex x from s in T equals the cost of x's ancestors in T, including x itself. For every vertex $x \in G$, let its *depth* be $d(x) = \text{dist}_T(s, x)$, and let the *radius* of T be $r(T) = \max\{d(x) : x \in V\}$.

6.1.2. Cutting G into layers. The set of vertices used to partition G into shallow layers is the union of a set of *levels* $L(\ell_1), \ldots, L(\ell_p)$, where each level $L(\ell_i)$ is the set of bottom endpoints of all edges spanning depth ℓ_i: $L(\ell_i) = \{y : e = xy \in T \text{ and } d(x) < \ell_i \leq d(y)\}$. See Figure 6.2(c) for an illustration.

Every level $L(\ell_i)$ is a separator of G whose removal partitions the vertex set V of G into two sets $V^-(\ell_i) = \{x \in V : d(x) < \ell_i\}$ and $V^+(\ell_i) = \{x \in V : d(x) \geq \ell_i \text{ and } x \notin L(\ell_i)\}$ so that no vertex in $V^-(\ell_i)$ is adjacent to a vertex in $V^+(\ell_i)$. The set of levels $L(\ell_1), \ldots, L(\ell_p)$ then partitions G into $p+1$ subgraphs $G_0, \ldots, G_p$, where $G_0 = G[V^-(\ell_1)]$, $G_p = G[V^+(\ell_p)]$, and, for $0 < i < p$, $G_i = G[V^+(\ell_i) \cap V^-(\ell_{i+1})]$.

Graphs $G_0, \ldots, G_p$ are the layers we want to compute.

There is obviously a trade-off between the cost of levels $L(\ell_1), \ldots, L(\ell_p)$ and the cost of partitioning the layers $G_0, \ldots, G_p$ using fundamental cycles. By choosing more levels $\ell_1, \ldots, \ell_p$, the layers can be made more shallow, thereby reducing the cost of the fundamental cycles used to partition them. This, however, increases the total cost of levels $L(\ell_1), \ldots, L(\ell_p)$.

As we will see, this trade-off is balanced by partitioning G into $p+1 = \lfloor r(T)/h \rfloor + 1$ layers of depth at most $2h$, where $h = \sqrt{tC(G)/8}$. This is achieved by choosing the value ℓ_i defining each level $L(\ell_i)$ from the interval $((i-1)h, ih]$ so that the level $L(\ell_i)$ has minimal cost among all levels $L(\ell)$ with $(i-1)h < \ell \leq ih$. Indeed, this ensures that two consecutive values ℓ_i and ℓ_{i+1} differ by at most $2h$; that is, every layer has depth at most $2h$. As shown by Aleksandrov et al., it also ensures that the cost of the union S_1 of levels $L(\ell_1), \ldots, L(\ell_p)$ is $c(S_1) \leq C(G)/h = 2\sqrt{2C(G)/t}$.

6.1.3. Partitioning the layers. The removal of levels $L(\ell_1), \ldots, L(\ell_p)$ partitions G into layers $G_0, \ldots, G_p$. If a layer G_i has weight at most $tw(G)$, it does not have to be partitioned further. In general, however, G_i may have a weight exceeding $tw(G)$ and needs to be partitioned into subgraphs of weight at most $tw(G)$. This is done by augmenting G_i to obtain a triangulation that has a spanning tree T_i of diameter not exceeding the depth of G_i; this augmented version of G_i is then partitioned using fundamental cycles w.r.t. T_i.

The augmentation of G_0 involves simply triangulating it. For $i > 0$, graph G_i is augmented in two steps: First, a vertex s_i of weight and cost zero is added to G_i and connected to all vertices in G_i that, in G, are adjacent to vertices in $L(\ell_i)$. The resulting graph is then triangulated, and the edges of G_i are assigned weights as in section 6.1.1. Tree T_i is now chosen to be a shortest-path tree of G_i with root s_i, where $s_0 = s$. See Figure 6.2(b) for an illustration.

The approach for finding the fundamental cycles used to partition G_i into subgraphs of weight at most $tw(G)$ can be explained as follows: Let T_i^* be the dual of T_i. This tree is obtained from the dual G_i^* of G_i by removing all those edges that are dual to edges in T_i. Thus, every edge e^* in T_i^* corresponds to a nontree edge e of G_i and, hence, represents a fundamental cycle $F(e)$ in G_i. If the vertex corresponding to the outer face of G_i is chosen as the root of T_i^*, the descendant vertices and edges of e^* in T_i^* represent the region enclosed by $F(e)$.

The goal now is to assign weights $w^*(e^*)$ to the edges of T_i^* so that the total weight of the edges in T_i^* equals the total weight of the vertices in G_i, and the total weight of the descendant edges of an edge e^* in T_i^* is an upper bound on the weight of the vertices in G_i enclosed by $F(e)$. Given such an assignment of edge weights, it suffices to partition T_i^* into a small number of subtrees of weight at most $tw(G)$ by removing a set of edges from T_i^*; the vertices on the corresponding fundamental cycles then form a separator partitioning G_i into subgraphs of weight at most $tw(G)$.

The weight function w^* is obtained by charging the weight of every vertex x in G_i to some edge e^* of T_i^*: If x has at least one incident nontree edge, edge e^* is chosen to be the dual of one of these edges. Otherwise, e^* is chosen to be the dual of a nontree edge e both of whose endpoints are neighbors of x in T_i. It is easy to see that such an edge always exists.

The weight function is easily seen to have the two properties above: Since every vertex of G_i is charged to exactly one edge of T_i^*, the total weight of the edges in T_i^* equals the total weight of the vertices in G_i. A vertex x in the region enclosed by a fundamental cycle $F(e)$ must have been charged to an edge e_1^* in T_i^* such that e_1 is

also contained in the region enclosed by $F(e)$. Thus, e_1^* is a descendant edge of e^* in T_i^*, and the weight of the descendant edges of e^* is an upper bound on the weight of the vertices in G_i enclosed by $F(e)$. See [2] for a more rigorous argument.

In order to partition T_i^* into subtrees of weight at most $tw(G)$ by removing a set of edges X_i, a leaf of T_i^* is chosen as the root of T_i^*, and the edges of T_i^* are then inspected from the bottom up. For every edge e^*, if the total weight of all its descendant edges, including e^* itself, exceeds $tw(G)/2$, the subtree below e^* is pruned from T_i^* by adding e^* to the edge separator X_i. The edges in the pruned subtree are then no longer counted when determining the total weight of the descendant edges of any ancestor of e^*.

Since the vertices in the dual of a planar triangulation have degree at most three and the root of T_i^* has degree one, T_i^* is a binary tree. Thus, the above procedure ensures that each subtree in the produced partition has weight at most $tw(G)$ and, hence, that the fundamental cycles in the set $\mathcal{F}(X_i) = \{F(e) : e^* \in X_i\}$ partition G_i into subgraphs of weight at most $tw(G)$. To bound the number of fundamental cycles in $\mathcal{F}(X_i)$, observe that every edge e^* in X_i has descendant edges of total weight at least $tw(G)/2$ and that every edge of T_i^* is counted as a descendant edge of at most one edge in X_i. Hence $|\mathcal{F}(X_i)| = |X_i| \leq \frac{2w^*(T_i^*)}{tw(G)} = \frac{2w(G_i)}{tw(G)}$. The total number of fundamental cycles used to partition the layers $G_0, \ldots, G_p$ is therefore at most $\frac{2w(G)}{tw(G)} = 2/t$. Since each layer has depth at most $2h$, the cost of the vertices on one fundamental cycle is at most $4h$ and, hence, the total cost of all fundamental cycles in $\mathcal{F}(X_0) \cup \cdots \cup \mathcal{F}(X_p)$ is at most $8h/t = 2\sqrt{2C(G)/t}$.

Let S_2 be the set of vertices on the fundamental cycles in $\mathcal{F}(X_0) \cup \cdots \cup \mathcal{F}(X_p)$. The final separator $S = S_1 \cup S_2$ partitions G into subgraphs of weight at most $tw(G)$ and has cost $c(S_1) + c(S_2) \leq 4\sqrt{2C(G)/t}$.

Aleksandrov et al. [3] showed how to implement this procedure in linear time. In the next section, we show how to carry out the three steps of the algorithm in O(sort(N)) I/Os.

6.2. An I/O-efficient algorithm.

6.2.1. Computing T. In order to compute the shortest-path tree T, we need to compute a planar embedding of G, triangulate G, add a new vertex of cost and weight 0 inside one of its faces, assign weights $w'(e)$ to the edges of G, and finally, compute single-source shortest paths w.r.t. these edge weights.

A planar embedding of G can be computed in O(sort(N)) I/Os [33]; an embedded planar graph can be triangulated in the same I/O-bound [25]. Next, we extract a description of the faces of the triangulation as lists of vertices, each containing the boundary vertices of one face sorted clockwise around that face; this can also be done in O(sort(N)) I/Os. We add a vertex s to G and traverse the vertex list representing one of the faces of G to add edges between s and the vertices on the boundary of this face to G. Now it takes O(sort(N)) I/Os to label every edge of G with the costs of its endpoints, replace every edge of G with its corresponding directed edges, and assign weights as defined in section 6.1.1 to these edges (see section 2.4). The shortest-path tree T can now be computed in O(sort(N)) I/Os using the shortest-path algorithm of [8].

This procedure for computing T is where we depend on Theorems 4.1 and 5.1. The embedding algorithm of [33] relies on a proper B^2-partition of G; the shortest-path algorithm of [8] requires a regular proper B^2-partition.

6.2.2. Cutting T into layers. To compute the levels $L(\ell_1), \ldots, L(\ell_p)$ used to partition G into layers $G_0, \ldots, G_p$, we first need to compute the values $\ell_1, \ldots, \ell_p$ and then extract the vertices belonging to $S_1 = L(\ell_1) \cup \cdots \cup L(\ell_p)$.

To compute values $\ell_1, \ldots, \ell_p$, we label both endpoints of every edge in T with their costs and their distances from s. Then we sort the edges of T by the distances of their tails from s and scan the sorted edge list to simulate a sweep from $\ell = -\infty$ to $\ell = +\infty$. During this sweep, we maintain the cost $c(L(\ell))$ of the current level $L(\ell)$ and keep track of the value i such that $(i-1)h < \ell \leq ih$. We also maintain the minimum cost $c_{\min}(i)$ of all levels $L(\ell')$ with $(i-1)h < \ell' \leq ih$ we have seen so far, as well as the level ℓ_i such that $(i-1)h < \ell_i \leq ih$ and $c(L(\ell_i)) = c_{\min}(i)$. When $\ell = d(x_j)$, for some vertex x_j, we perform the following operations: First, we test whether $d(x_{j+1}) > ih$. If so, we have finished processing all levels $L(\ell')$ with $(i-1)h < \ell' \leq ih$, so we report ℓ_i, increase i by one, and initialize $c_{\min}(i) = +\infty$. Then we decrease $c(L(\ell))$ by $c(x_j)$ and increase $c(L(\ell))$ by the total cost of the heads of all edges having x_j as their tail. This produces $c(L(d(x_{j+1})))$. If $c(L(d(x_{j+1}))) < c_{\min}(i)$, we set $c_{\min}(i) = c(L(d(x_{j+1})))$ and $\ell_i = d(x_{j+1})$.

Given values $\ell_1, \ldots, \ell_p$ and the edge set of T as sorted above, the set $S_1 = L(\ell_1) \cup \cdots \cup L(\ell_p)$ can be extracted as follows: We scan the list of values $\ell_1, \ldots, \ell_p$ and the edge set of T, again to simulate a sweep from $\ell = -\infty$ to $\ell = +\infty$. During the sweep we maintain the index i of the next level ℓ_i to be passed by the sweep; initially, $i = 1$. When the sweep passes the tail of an edge xy, its tail is at a depth less than ℓ_i. Thus, we add its head y to $L(\ell_i)$ if $d(y) \geq \ell_i$. When the sweep passes level ℓ_i, we increase i by one and, thus, start constructing the next level $L(\ell_{i+1})$. Since this computation of set S_1 requires sorting and scanning the edge set of T a constant number of times, its I/O-complexity is $\mathrm{O}(\mathrm{sort}(N))$.

6.2.3. Partitioning the layers. The final step of the algorithm extracts graphs $G_0, \ldots, G_p$, computes shortest-path trees $T_0, \ldots, T_p$ for these graphs, and partitions each graph G_i, $0 \leq i \leq p$, into subgraphs of weight at most $tw(G)$ using fundamental cycles w.r.t. T_i.

Computing the layers. To compute graphs $G_0, \ldots, G_p$, we first compute the set $V - S_1$ and sort the vertices in $V - S_1$ by their distances from s. We scan the vertices in $V - S_1$ and the values $-\infty = \ell_0, \ldots, \ell_{p+1} = r(T)$ to partition $V - S_1$ into sets $V_0, \ldots, V_p$, where $V_i = \{x \in V - S_1 : \ell_i < d(x) \leq \ell_{i+1}\}$. For $1 \leq i \leq p$, we add a new vertex s_i to V_i. This produces the vertex sets of graphs $G_0, \ldots, G_p$.

Next we partition E into sets $E_0, \ldots, E_p$, $E_1^-, \ldots, E_p^-$, and E^+ such that every edge in E_i has both endpoints in V_i; every edge xy in E_i^- has one endpoint, say y, in V_i, and the other endpoint, x, satisfies $x \in S_1$ and $d(x) < d(y)$; and set E^+ contains the remaining edges. This partition is easily computed in $\mathrm{O}(\mathrm{sort}(N))$ I/Os: We label every edge with the membership of its endpoints in $V_0, \ldots, V_p$ or S_1 and with their distances from s. Every edge can then determine its membership in one of the sets based on its local information, and we can sort E to obtain the desired partition. Graph G_i is now defined as $G_i = (V_i, E_i \cup E_i')$, where $E_i' = \{s_i y, y s_i : xy \in E_i^- \text{ and } d(x) < d(y)\}$. Finally, we triangulate G_i using the algorithm of [25].

This procedure requires sorting and scanning the vertex and edge sets of G a constant number of times. In addition, we invoke the $\mathrm{O}(\mathrm{sort}(N))$-I/O triangulation algorithm of [25] on graphs $G_0, \ldots, G_p$, whose total size is $\mathrm{O}(N)$. Hence, the construction of graphs $G_0, \ldots, G_p$ takes $\mathrm{O}(\mathrm{sort}(N))$ I/Os.

Computing shortest-path trees and their duals. Each shortest-path tree T_i can be computed in $\mathrm{O}(\mathrm{sort}(|G_i|))$ I/Os using the procedure described in section 6.2.1.

To construct T_i^*, we compute the dual $G_i^* = (F_i, E_i^*)$ of G_i, which can be done in $O(\text{sort}(|G_i|))$ I/Os [25]. Then we remove all edges dual to edges in T_i from E_i^*. This takes another $O(\text{sort}(|G_i|))$ I/Os (see section 2.4). Thus, in total, the construction of trees $T_0, \ldots, T_p$ and $T_0^*, \ldots, T_p^*$ takes $O(\text{sort}(N))$ I/Os.

Computing dual edge weights. Before computing an edge separator of T_i^* and the corresponding set of fundamental cycles, we have to assign weights $w^*(e^*)$ as defined in section 6.1.3 to the edges of T_i^*. We do this in two phases. First, we partition V_i into two sets V_i' and V_i'' such that every vertex in V_i' has an incident nontree edge, while all edges incident to a vertex in V_i'' are tree edges. While doing this, we also identify a nontree edge e incident to each vertex $x \in V_i'$ and add $w(x)$ to $w^*(e^*)$. In the second phase, we find a nontree edge e for every vertex $x \in V_i''$ such that both endpoints of e are neighbors of x in T_i; we add $w(x)$ to $w^*(e^*)$. The details follow.

To implement the first phase, we create a list Y_i of nontree edges of G_i. More precisely, Y_i contains directed edges xy and yx for every nontree edge xy of G_i. We sort the edges in Y_i by their tails and sort the vertices in V_i by their IDs. Now a single scan of lists V_i and Y_i suffices to identify all vertices x in V_i such that Y_i contains at least one edge with tail x. These are the vertices in V_i'; all other vertices belong to V_i''. During this scan, we also extract, for every vertex $x \in V_i'$, the first edge e with tail x from Y_i and add a pair $(e^*, w(x))$ to a list W. This list will be used after the second phase to compute the weights of the edges in T_i^*.

To implement the second phase, we observe that, for every vertex $x \in V_i''$ and every nontree edge yz such that y and z are both neighbors of x in T_i, one endpoint of yz, say y, must be a child of x in T_i, and the other, z, must be x's parent in T_i or another child of x. This implies in particular that, for every nontree edge yz, there exists at most one vertex $x \in V_i''$ such that y and z are both neighbors of x in T_i. Our goal, therefore, is to partition the nontree edges of G_i into sets $E(x)$ such that both endpoints of each edge in $E(x)$ are neighbors of x in T_i; for every vertex $x \in V_i''$, we then choose one edge from $E(x)$ and add the pair $(e^*, w(x))$ to W. To obtain the partition into sets $E(x)$, we first label every vertex $x \in T_i$ with its grandparent in T_i: We create a second copy P_i of V_i, sort the vertices in P_i by their IDs, and sort the vertices in V_i by the IDs of their parents. This ensures that the vertices in V_i are stored in the same order as their parents in P_i. Since each vertex in P_i also stores the ID of its parent, a single scan of V_i and P_i now suffices to label every vertex in V_i with the ID of its grandparent. Now we label every nontree edge of G_i with the parents and grandparents of its endpoints. A nontree edge yz belongs to $E(x)$ if and only if x is the parent of both y and z or, w.l.o.g., x is the parent of y and z is the grandparent of y. This can now be tested based on the local information stored with edge yz. If edge yz satisfies this condition, we label it as belonging to $E(x)$. We sort the nontree edges by their membership in sets $E(x)$ and scan V_i'' and the sorted edge list to add a pair $(e^*, w(x))$ to W for every vertex $x \in V_i''$ and the first edge $e \in E(x)$.

To finish the computation of the weights of the edges in T_i^*, we sort the edges of T_i^* by their IDs and the pairs in W by their first components. A single scan of these two sorted lists now suffices to add $w(x)$ to $w^*(e^*)$, for every pair $(e^*, w(x)) \in W$.

Since this procedure sorts and scans lists of size $O(|G_i|)$ a constant number of times, the assignment of weights to the edges of T_i^* takes $O(\text{sort}(|G_i|))$ I/Os. The total cost for all graphs $G_0, \ldots, G_p$ is therefore $O(\text{sort}(N))$.

Computing the edge separator and fundamental cycles. To obtain the edge separator X_i of T_i^*, we root T_i^* in an arbitrary leaf, compute a preorder numbering of T_i^* w.r.t. the chosen root, and direct all edges in T_i^* from children to parents. This

can be done using the Euler tour technique and list ranking [14]. The construction of the edge separator X_i as described in section 6.1.3 can now be implemented using the time-forward processing technique of [14]. Given the edge separator X_i of T_i^* produced by this procedure, we mark the endpoints of all edges $e \in G_i$ such that $e^* \in X_i$ and then process T_i from the bottom up (using time-forward processing again) to identify all vertices of G_i that belong to the fundamental cycles defined by the edges in X_i. We add these vertices to S_2.

This procedure applies the Euler tour technique, list ranking, and time-forward processing to T_i and T_i^*, both of which have size $O(|G_i|)$. Hence, this takes $O(\text{sort}(|G_i|))$ I/Os. Apart from this, we sort and scan lists of size $O(|G_i|)$. Thus, partitioning each graph G_i takes $O(\text{sort}(|G_i|))$ I/Os, and the computation of the whole separator S_2 takes $O(\text{sort}(N))$ I/Os.

6.2.4. Final remarks. Since we have shown that the computation of both S_1 and S_2 takes $O(\text{sort}(N))$ I/Os, Theorem 6.2 is proved. Since the algorithm relies on the separator algorithm of section 4 and the shortest-path algorithm of [8], it inherits their memory requirements. In particular, the latter requires a proper $\Theta\big(B^2\big)$-partition as part of the input and uses $\Theta\big(B^2\big)$ main memory to carry out its computation. The algorithm from section 4 can be used to produce the desired partition in $O(\text{sort}(N))$ I/Os, provided that $M = \Omega\big(B^2 \log^2 B\big)$.

As a final comment, note that the shortest-path algorithm of [8] relies on a *regular* proper $\Theta\big(B^2\big)$-partition, which is guaranteed to exist only if the graph has bounded degree. The triangulations in which we need to compute shortest paths may not satisfy this constraint, but given an embedding, each planar graph G can be transformed into a planar graph G' of size $O(|G|)$ such that every vertex in G' has degree at most three. This is done by replacing every vertex x of degree $\deg(x) > 3$ with a cycle of $\deg(x)$ vertices and making every edge incident to x incident to a different vertex on this cycle. This takes $O(\text{sort}(|G|))$ I/Os. Moreover, if the edges in each cycle replacing a high-degree vertex are given weight 0, this transformation preserves the distances between vertices. Thus, the algorithm of [8] can be used to compute shortest paths in G and in the layers $G_0, \ldots, G_p$.

6.3. Edge separators. The final result of this section is an I/O-efficient edge separator algorithm. Aleksandrov et al. [3] showed that Theorem 6.1 can also be used to compute optimal edge separators of planar graphs as follows: Define the cost of each vertex to be equal to its degree. Then compute a vertex separator S of cost at most $4\sqrt{2(\sum_{x \in V}(\deg(x))^2)/t}$ and add all edges incident to a vertex in S to the edge separator.

It is easy to verify that the computation of the vertex costs and the extraction of the edge separator from the computed vertex separator can be carried out in $O(\text{sort}(N))$ I/Os. Hence, the following result is an immediate consequence of Theorem 6.2.

THEOREM 6.3. *Let $G = (V, E)$ be a planar graph, let $0 < t < 1$ be a real number, and let $w : V \to \mathbb{R}^+$ be a weight function so that $w(x) \leq tw(G)$ for all $x \in V$. Then there exists a set S of at most $4\sqrt{2(\sum_{v \in V}(\deg(v))^2)/t}$ edges so that no connected component of $G - S$ has weight exceeding $tw(G)$. Such an edge separator S can be found in $O(\text{sort}(N))$ I/Os, provided that $M = \Omega\big(B^2 \log^2 B\big)$.*

7. Improving the memory requirements. In this final section of the paper, we show how to reduce the memory requirements of our algorithm from section 4 to $M \geq \max\big(196B^2, 7r\big)$. The resulting algorithm also produces a separator significantly

smaller than the one produced by the algorithm in section 4. However, these two improvements come at the expense of increasing the internal-memory computation of the algorithm from $O(N \log N)$ to $O(N \log N + NB)$.

Recall the reason why $M \geq 56r \log^2 B$ is required for the algorithm in section 4: If we choose to compute an r'-partition of each graph G_i in the graph hierarchy, then the separator vertices introduced at each level correspond to $O\big(N/\sqrt{r'}\big)$ vertices in G; no better upper bound is known. Since there are $\lfloor \log B \rfloor$ levels in the hierarchy, and we want a separator of size $O(N/\sqrt{r})$, we have to ensure that $O\big(\big(N/\sqrt{r'}\big) \log B\big) = O(N/\sqrt{r})$, which we achieve by choosing $r' = r \log^2 B$. This now forces us to use $56r \log^2 B$ main memory because, as argued in section 4, every piece of $G_i - S'_i$ has size at most $56r' = 56r \log^2 B$, and we need to load each such piece into memory to partition it into smaller pieces.

So the central problem is that, if we were to choose $r' = r$, then every level in the hierarchy adds $O(N/\sqrt{r})$ vertices to the final separator of G, that is, we would obtain a separator that is too big by a factor of $\log B$. Next we explain how to avoid this problem by using a recursive bootstrapping approach.

The centerpiece of the algorithm is the separator algorithm from section 6, but now using vertex costs and weights equal to 1. This algorithm takes $O(\mathrm{sort}(N))$ I/Os using only $\Theta(B)$ main memory if we ignore the costs and memory requirements of computing an embedding of G, computing the shortest-path tree T of G, and computing the shortest-path trees $T_0, \ldots, T_p$ for layers $G_0, \ldots, G_p$. Given appropriate separator decompositions, the computation of the embedding and the shortest-path computations take $O(\mathrm{sort}(N))$ I/Os and require $\Theta\big(B^2\big)$ main memory [5, 33]. Our strategy is to obtain these separator decompositions by recursive application of our algorithm.

Embedding G. To compute a planar embedding of G, we require a proper $\Theta\big(B^2\big)$-partition $\mathcal{P} = (S, \{G_1, \ldots, G_q\})$ of G. We obtain this partition as follows: First, we apply the uniform graph contraction procedure to G and recursively compute a proper B^2-partition $\tilde{\mathcal{P}} = \big(\tilde{S}, \big\{\tilde{G}_1, \ldots, \tilde{G}_q\big\}\big)$ of the resulting graph $\tilde{G}$. Then we choose S to be the set of vertices in G represented by the vertices in $\tilde{S}$, and each graph G_i in $\mathcal{P}$ to be the subgraph of G represented by the vertices in $\tilde{G}_i$. To bound the number of vertices in G represented by each vertex in $\tilde{G}$, we assign weight 1 to every vertex in G and provide a weight threshold u, to be specified later, to the uniform graph contraction procedure. This guarantees that $|S| \leq u\big|\tilde{S}\big| = O(N/B)$, $|G_i| \leq u\big|\tilde{G}_i\big| = O\big(B^2\big)$, and $|\mathcal{N}(G_i)| = O(B)$ for all $1 \leq i \leq q$. It also ensures that $\sum_{i=1}^{q} |\mathcal{N}(G_i)| \leq u \sum_{i=1}^{q} \big|\mathcal{N}\big(\tilde{G}_i\big)\big| = O(N/B)$. Thus, $\mathcal{P}$ is a proper $\Theta\big(B^2\big)$-partition of G. An embedding of G can now be obtained from $\mathcal{P}$ in $O(\mathrm{sort}(N))$ I/Os [33]. In total, the cost of computing a planar embedding of G is $O(\mathrm{sort}(N))$ I/Os plus the cost of the recursive call on $\tilde{G}$.

Computing $T, T_0, \ldots, T_p$. Given a planar embedding of G, we use the procedure from section 6.2.4 to transform G into a planar graph G' of degree at most three and so that the distances between vertices in G are the same as the distances between their representatives in G'. This takes $O(\mathrm{sort}(N))$ I/Os. Now we apply the procedure from the previous paragraph to obtain a proper $\Theta\big(B^2\big)$-partition of G' and then use the procedures from sections 4.3 and 5 to augment this partition to obtain a regular proper B^2-partition of G'. The construction of G' takes $O(\mathrm{sort}(N))$ I/Os and, as discussed in the previous paragraph, the cost of computing a proper $\Theta(B^2)$-partition of G' is $O(\mathrm{sort}(|G'|))$ plus the cost of the recursive call on a compressed version $\tilde{G}'$ of G'. As discussed in sections 4.3 and 5, augmenting the computed partition to a regular proper

$\Theta(B^2)$-partition also takes $\mathrm{O}(\mathrm{sort}(|G'|))$ I/Os. Given such a partition, we use the single-source shortest-path algorithm of [8] to obtain a shortest-path tree T' of G' in $\mathrm{O}(\mathrm{sort}(|G'|))$ I/Os, which is easily transformed into a shortest-path tree T of G in the same number of I/Os. Thus, the total cost of computing T is $\mathrm{O}(\mathrm{sort}(N) + \mathrm{sort}(|G'|))$ plus the cost of the recursive call on $\tilde{G}'$.

The shortest-path trees $T_0, \ldots, T_p$ are obtained by applying the same procedure to graphs $G_0, \ldots, G_p$. We denote the degree-3 graphs obtained from $G_0, \ldots, G_p$ by $G'_0, \ldots, G'_p$ and the compressed versions of $G'_0, \ldots, G'_p$ for which we recursively compute proper B^2-partitions by $\tilde{G}'_0, \ldots, G'_p$. Using this notation, our discussion above implies that the computation of each tree T_i takes $\mathrm{O}(\mathrm{sort}(|G_i|) + \mathrm{sort}(|G'_i|))$ I/Os plus the cost of a recursive call on $\tilde{G}'_i$.

Analysis. Summing up the costs of the individual steps of our algorithm, the cost of computing a proper B^2-partition of G is

$$T(N) = \mathrm{O}(\mathrm{sort}(N)) + \mathrm{O}\big(\mathrm{sort}\big(\big|G'\big|\big)\big) + T\big(\big|\tilde{G}\big|\big) + T\big(\big|\tilde{G}'\big|\big) + \sum_{i=0}^{q} \Big(\mathrm{sort}(|G_i|) + \mathrm{sort}\big(\big|G'_i\big|\big) + T\big(\big|\tilde{G}'_i\big|\big)\Big).$$

The first $\mathrm{O}(\mathrm{sort}(N))$ term includes the cost of computing the separator once the trees $T, T_0, \ldots, T_p$ have been computed.

To bound this recurrence by $\mathrm{O}(\mathrm{sort}(N))$, we first bound the sizes of the different graphs involved in the computation as follows: Graph G has N vertices. Graph G' has at most $6N$ vertices, at most two per edge in G. Graphs $G_0, \ldots, G_p$ contain at most N vertices, as they are vertex-disjoint subgraphs of G. Thus, graphs $G'_0, \ldots, G'_p$ also contain at most $6N$ vertices. The total size of graphs $G, G', G_0, \ldots, G_p, G'_0, \ldots, G'_p$ is therefore $\mathrm{O}(N)$, which implies that the sort$(\cdot)$-terms in the above recurrence sum to $\mathrm{O}(\mathrm{sort}(N))$, simplifying the recurrence to

$$T(N) = \mathrm{O}(\mathrm{sort}(N)) + T\big(\big|\tilde{G}\big|\big) + T\big(\big|\tilde{G}'\big|\big) + \sum_{i=0}^{p} T\big(\big|\tilde{G}'_i\big|\big).$$

Now, if we choose $u = 196$, graph $\tilde{G}$ contains at most $|G|/98$ heavy vertices and, by Theorem 3.1, has size at most $|G|/14$. Similarly, $\big|\tilde{G}'\big| \le |G'|/14$ and, for $0 \le i \le p$, $\big|\tilde{G}'_i\big| \le |G'_i|/14$. Thus, we have

$$\begin{aligned}\big|\tilde{G}\big| + \big|\tilde{G}'\big| + \sum_{i=0}^{p}\big|\tilde{G}'_i\big| &\le \frac{|G|}{14} + \frac{|G'|}{14} + \sum_{i=0}^{p}\frac{|G'_i|}{14} \\ &\le \frac{N}{14} + \frac{6N}{14} + \frac{6N}{14} \\ &= \frac{13N}{14},\end{aligned}$$

and the recurrence solves to $T(N) = \mathrm{O}(\mathrm{sort}(N))$. The memory requirements of the embedding and shortest-path algorithms are at most $uB^2 = 196B^2$, as we provide them with uB^2-partitions. This proves that we can compute a t-vertex separator and, thus, a t-edge separator, for any $0 < t < 1$, in $\mathrm{O}(\mathrm{sort}(N))$ I/Os, provided that $M \ge 196B^2$. In order to obtain a (regular) proper r-partition from an (r/N)-separator, we still have to be able to load subgraphs of size at most $7r$ into internal memory. This leads to the following result.

THEOREM 7.1. *The partitions in Theorems* 4.1 *and* 5.1 *can be computed in* $O(\mathrm{sort}(N))$ *I/Os, provided that* $M \geq \max\bigl(196B^2, 7r\bigr)$. *The separators in Theorems* 6.2 *and* 6.3 *can be computed in* $O(\mathrm{sort}(N))$ *I/Os, provided that* $M \geq 196B^2$.

The memory requirements in Theorem 7.1 can be reduced further to $M \geq \max\bigl(cB^2, 7r\bigr)$ and $M \geq cB^2$, for an arbitrarily small constant $c > 0$. Indeed, $196B^2$ memory is required because we recursively compute B^2-partitions of the compressed graphs, which correspond to $\bigl(196B^2\bigr)$-partitions in the uncompressed graphs. Instead, we can compute $\bigl(cB^2/196\bigr)$-partitions of the compressed graphs, thereby obtaining $\bigl(cB^2\bigr)$-partitions of the uncompressed graphs. This affects the sizes of the produced separators—and, thus, the performance of the embedding and shortest-path algorithms—by only a constant factor but reduces the memory requirements.

8. Conclusions. In this paper, we have demonstrated that different types of separator decompositions of planar graphs can be computed I/O-efficiently. Using these partitions, a wide variety of fundamental problems on planar graphs can be solved I/O-efficiently.

A number of open questions remain, however. The constant factors in our algorithms—in terms of the size of the produced separator, the memory requirements, and the efficiency—are big. In order for the algorithms to be of practical value, these constant factors have to be reduced. Furthermore, even though the individual steps of the algorithm are fairly simple, the algorithm consists of too many of them. This makes the algorithm tedious to implement and impacts the efficiency of the algorithm; for example, only a small number of sorting steps is affordable in practice. From a practical point of view, it would therefore be desirable to have a simpler—even possibly a theoretically suboptimal—algorithm for computing separators I/O-efficiently. On the theoretical side, the most important open questions are whether separators can be computed in $O(\mathrm{sort}(N))$ I/Os using $o\bigl(B^2\bigr)$ main memory and whether they can be computed in $O(\mathrm{sort}(N))$ I/Os cache-obliviously. See [20] for a discussion of cache-obliviousness.

Acknowledgments. We would like to thank Richard Cole and the anonymous referees for helpful comments on how to improve the presentation of the results in this paper.

APPROXIMATE SHORTEST PATHS IN ANISOTROPIC REGIONS*

SIU-WING CHENG†, HYEON-SUK NA‡, ANTOINE VIGNERON§, AND YAJUN WANG†

Abstract. Our goal is to find an approximate shortest path for a point robot moving in a planar subdivision with n vertices. Let $\rho \geqslant 1$ be a real number. Distances in each face of this subdivision are measured by a convex distance function whose unit disk is contained in a concentric unit Euclidean disk and contains a concentric Euclidean disk with radius $1/\rho$. Different convex distance functions may be used for different faces, and obstacles are allowed. These convex distance functions may be asymmetric. For any $\varepsilon \in (0,1)$ and for any two points v_s and v_d, we give an algorithm that finds a path from v_s to v_d whose cost is at most $(1+\varepsilon)$ times the optimal. Our algorithm runs in $O(\frac{\rho^2 \log \rho}{\varepsilon^2} n^3 \log(\frac{\rho n}{\varepsilon}))$ time. This bound does not depend on any other parameters; in particular it does not depend on the minimum angle in the subdivision. We give applications to two special cases that have been considered before: the weighted region problem and motion planning in the presence of uniform flows. For the weighted region problem with weights in $[1,\rho] \cup \{\infty\}$, the time bound of our algorithm improves to $O(\frac{\rho \log \rho}{\varepsilon} n^3 \log(\frac{\rho n}{\varepsilon}))$.

1. Introduction.

The problem of computing a shortest path between two points arises naturally in geographic information systems, VLSI design, logistics, and motion planning. Another area of application for shortest path algorithms is computer graphics, where the geometric properties of shortest paths along a surface can be exploited for mesh cutting and editing. (See the article by V. Surazhsky et al. [20].) The path lies in a geometric environment in all of these applications. This environment is usually represented by a polygonal (or polyhedral) subdivision. Different metrics may be used in different regions of the subdivision in order to model friction, wind, steepness, or any other mechanical constraint.

Due to these applications and to the variety of possible geometric environments and metrics, algorithms for geometric shortest path problems have been extensively studied. We mention the most relevant work here and refer the interested reader to the survey by Mitchell [12] for more details.

In the weighted region problem [13], a point robot moves within a planar subdivision $\mathcal{T}$, each face f of $\mathcal{T}$ being associated with a weight $w_f > 0$. The cost of a path within a face f is the length of this path multiplied by w_f. Assume that the faces of the subdivision $\mathcal{T}$ are all triangular. (We can make this assumption as any planar subdivision can be triangulated by introducing a linear number of edges.) We denote

by n the number of vertices of $\mathcal{T}$. The first approximation scheme for the weighted region problem was given by Mitchell and Papadimitriou [13]. It runs in $O(n^8 L)$ time, where L represents the maximum number of bits of the input numbers (such as the integer coordinates of the vertices of the subdivision, and the weights). This algorithm is a continuous version of Dijkstra's algorithm for finding shortest paths in a graph. Other algorithms for the weighted region problem discretize the search space by placing Steiner points and by finding a shortest path in a graph whose nodes are Steiner points or input vertices and whose edges are line segments. In particular, Aleksandrov, Maheshwari, and Sack [2] and Sun and Reif [19] gave algorithms that have linear dependency in n. However, their time bounds depend on the minimum angle in $\mathcal{T}$ (and the weights, too, in the algorithm by Aleksandrov, Maheshwari, and Sack [2]).

The main limitation of the weighted region model is that it models only situations where the metrics are isotropic. It cannot account for the effect of wind, current, or any other force field that favors some directions of travel. A more general model was introduced by Reif and Sun for motion planning in the presence of uniform flows [16]. In each face f of $\mathcal{T}$, the velocity of the robot is the sum of a flow $\vec{v}_f$ and a control velocity chosen by the robot. It allows one to model friction and a uniform flow within each region. Reif and Sun [16] showed that this problem is PSPACE hard in three dimensions and gave an FPTAS for the two-dimensional (2D) case. (Some geometric parameters were treated as constant, such as the minimum angle in $\mathcal{T}$.)

As pointed out by Aleksandrov, Maheshwari, and Sack [2], one challenge is to remove the dependence on parameters other than n and ε in the running time. It is also desirable to handle more general types of metrics in order to model a larger class of problems that arise in applications. (See the article by Sellen [17] on the direction-weighted problem, where the cost is proportional to a continuous function of the direction.) We make progress in both aspects in this paper.

1.1. Our results. We consider a generalization of Reif and Sun's model for motion planning in the presence of uniform flows [16]. A point robot moves within a planar subdivision from a source point v_s to a target point v_d. The planar subdivision $\mathcal{T}$ may have holes in order to model obstacles. The distance within each face f of the subdivision is measured according to a possibly asymmetric convex distance function [4]. (See section 2.2 for a definition of convex distance functions.) Different convex distance functions may be used for different faces. The cost of a path is measured according to these distance functions. (See section 2 for the case of a polygonal path and section 6 for the case of a rectifiable path.) Let B_f denote the unit "disk" of the distance function of a face f. We assume that B_f is contained in a concentric unit Euclidean disk and that B_f contains a concentric Euclidean disk with radius $1/\rho$. In other words, there exists $\rho \geqslant 1$ such that the speed of the robot in any direction and within any face of $\mathcal{T}$ is in the interval $[1/\rho, 1]$. The weighted region problem and the problem of path planning in the presence of uniform flows are special cases in our model.

We assume that the distance between two points under any of the convex distance functions can be computed in $O(1)$ time. Our model of computation is the standard real-RAM model [15] in which the operations $(+, -, \times, /)$ can be performed in constant time.

Our main results include an algorithm that computes in time $O(\frac{\rho^2 \log \rho}{\varepsilon^2} n^3 \log(\frac{\rho n}{\varepsilon}))$ a polygonal path whose cost is at most $(1 + \varepsilon)$ times the optimal. This is the first algorithm that can handle general convex distance functions. For the weighted region problem, the time bound improves to $O(\frac{\rho \log \rho}{\varepsilon} n^3 \log(\frac{n\rho}{\varepsilon}))$. Our time bounds have the

nice feature that they do not depend on the geometry of $\mathcal{T}$. It is not obvious that an optimal path exists in our model. Indeed, we give an example in which no polygonal path is optimal. Nevertheless, using the theory of length spaces [3, 10], we can prove that there exists an optimal *rectifiable* path. (A rectifiable path is a path with finite Euclidean length.) Furthermore, we show that there exists a $(1+\varepsilon)$-approximate shortest path that is polygonal and has $O(\rho n^2/\varepsilon)$ links. This is instrumental to establishing the correctness and the complexity of our algorithm.

Our approach is the following. We define a k-link path to be a polygonal path with at most k edges, each edge being contained in a face of $\mathcal{T}$ and having its endpoints on the boundary of this face. (Our definition is different from the one given by Daescu et al. [5].) We first give approximation algorithms that return a polygonal path with cost at most $(1+\varepsilon)$ times the cost of any k-link path (see section 3). In the weighted region problem, Mitchell and Papadimitriou [13] showed that there exists a shortest path that is a k-link path with $k = \Theta(n^2)$, so we apply our algorithm with $k = \Theta(n^2)$ and obtain the result stated above. In the general case, we show that for any polygonal path P, there exists a $(21\rho n^2/\varepsilon)$-link path with cost at most $(1+\varepsilon)$ times the cost of P (see sections 4 and 5). Thus, by choosing $k = 21\rho n^2/\varepsilon$, our algorithm returns a path with cost at most $(1+\varepsilon)$ times the cost of any polygonal path. Then, in section 6, we prove that there exists an optimal rectifiable path and show that there exists a polygonal path with cost arbitrarily close to the optimal. It follows that our algorithm returns a $(1+\varepsilon)$-approximate shortest path within the class of rectifiable paths.

1.2. Comparison with previous work. A direct comparison cannot be made with any previous result because our algorithm is the first that can handle general convex distance functions. Anisotropic shortest path problems have been studied on terrains [11, 18] in a special case that models some common mechanical constraints on a mobile robot. This model cannot account for the presence of flows (even uniform flows), so it is not more general than ours. On the other hand, our algorithm applies to planar subdivisions, not terrains. The problems of navigating through weighted regions and in the presence of uniform flows are special cases in our model. So we compare them with the previous results for these problems.

Weighted region problem. In this case, ρ is equal to the ratio of the maximum weight to the minimum weight. Other than the dependence on n and ε, there is a factor of $\Omega(1/\theta_{\min})$ in the worst-case running times of the algorithms by Aleksandrov, Maheshwari, and Sack [1, 2] and Sun and Reif [19], where $\theta_{\min}$ is the minimum angle in $\mathcal{T}$. The worst-case running time of the algorithms by Aleksandrov, Maheshwari, and Sack [1, 2] depend on ρ, too. Our running time is independent of the geometry of $\mathcal{T}$, although it has a higher dependence on n, ε, and ρ. The algorithm of Mitchell and Papadimitriou [13] has a running time of $O(n^8 \log \frac{nN\rho}{\varepsilon})$, where the input vertices have integer coordinates in $[0, N]$. In comparison, our algorithm works in the standard real RAM model, and our algorithm has a smaller dependence on n but a higher dependence on ε and ρ.

Movement in the presence of uniform flows. Assume that there is a uniform flow of velocity $\vec{v}_f$ in each face f of $\mathcal{T}$. The robot can apply a control velocity $\vec{v}_r$ in any direction such that $\|\vec{v}_r\|$ is at most some constant c_f. For each face f, we define a convex distance function whose unit "disk" B_f is a Euclidean disk with radius c_f and centered at $O + \vec{v}_f$, where O is the origin. Thus, B_f is contained in a disk with radius $c_f + \|\vec{v}_f\|$ and centered at O, and B_f contains a disk with radius $c_f - \|\vec{v}_f\|$ and centered at O. Let $v_{\min} = \min\{c_f - \|\vec{v}_f\| : f \in \mathcal{T}\}$. Let $v_{\max} = \max\{c_f + \|\vec{v}_f\| : f \in \mathcal{T}\}$. Assuming that $v_{\min} > 0$, we can model the problem with $\rho = v_{\max}/v_{\min}$ and find an

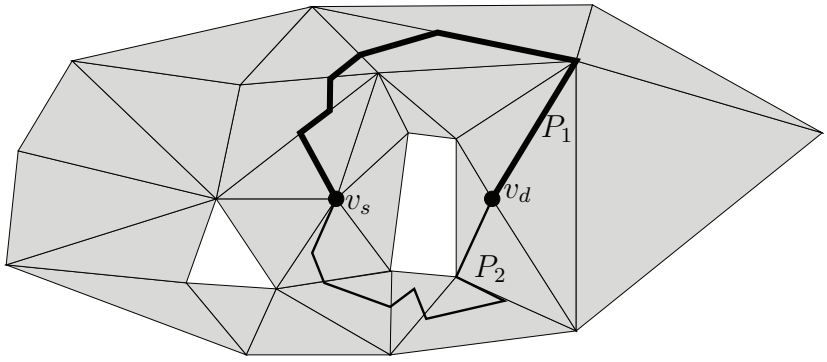

FIG. 1. *The underlying space $|\mathcal{T}|$ is shaded. The path P_1 is a 7-link path, and thus it is $\mathcal{T}$-respecting. The path P_2 is a $\mathcal{T}$-respecting path with 8 links, but it is not an 8-link path.*

approximate shortest path in time $O(\frac{\rho^2 \log \rho}{\varepsilon^2} n^3 \log(\frac{\rho n}{\varepsilon}))$. An algorithm by Reif and Sun runs in $O\left(\frac{nC_{\text{skew}}}{\varepsilon}(\log \frac{C_{\text{skew}}}{\varepsilon})(\log \frac{C_{\text{skew}}}{\varepsilon} + \log n)\right)$ time [16], where C_{skew} is defined as follows. Let $\lambda = \max\{c_f/c_{f'} : \text{adjacent faces } f \text{ and } f'\}$. Let $\rho_{\min} = \min\{c_f/\|\vec{v}_f\| : f \in \mathcal{T}\}$. Let $\theta_{\min}$ be the minimum angle in $\mathcal{T}$. Then $C_{\text{skew}} = \Theta(\frac{\lambda(\rho_{\min}+1)}{\theta_{\min}(\rho_{\min}-1)})$. Reif and Sun's algorithm requires $\rho_{\min} > 1$, which is equivalent to our condition of $v_{\min} > 0$. Our running time does not depend on $\theta_{\min}$, but Reif and Sun's running time has a better dependence on n, ε, and ρ.

2. Notation and preliminaries.

2.1. Environment. We model the environment $\mathcal{T}$ in which the point robot can move by a *simplicial complex* [6]: it is a collection of triangles such that any two triangles can intersect only along a common edge or vertex or not at all. A *face* of $\mathcal{T}$ is a triangle in $\mathcal{T}$. We consider faces to be closed subsets of $\mathbb{R}^2$. A *vertex* (resp., an *edge*) of $\mathcal{T}$ is a vertex (resp., an edge) of some face of $\mathcal{T}$. (We do not allow dangling edges or vertices; that is, all edges and vertices must be edges or vertices of a face of $\mathcal{T}$.) The *underlying space* $|\mathcal{T}| \subset \mathbb{R}^2$ of $\mathcal{T}$ is the union of its faces (see Figure 1). We assume that $|\mathcal{T}|$ is connected, but we allow $|\mathcal{T}|$ to have holes. The point robot is free to move inside $|\mathcal{T}|$, but it cannot move outside $|\mathcal{T}|$. We use n to denote the number of vertices in $\mathcal{T}$, and we assume that n is finite.

For any two points $p, q \in \mathbb{R}^2$, we denote by $\overline{pq}$ the closed, oriented line segment from p to q. In particular, when $p \neq q$, we have $\overline{pq} \neq \overline{qp}$. We denote by $\|pq\|$ the Euclidean distance between p and q. For any two points $p, q \in |\mathcal{T}|$, the *geodesic distance* between p and q is the Euclidean length of the shortest polyline in $|\mathcal{T}|$ with endpoints p and q. We use $\|pq\|_{\mathcal{T}}$ to denote this geodesic distance.

For each face f of $\mathcal{T}$, we denote by $\text{int}(f)$ (resp., $\text{bd}(f)$) the interior (resp., boundary) of f according to the usual topology of $\mathbb{R}^2$. For a segment $\overline{pq}$, we use $\text{int}(\overline{pq})$ to denote the open line segment from p to q. When X is a polyline with endpoints p, q, we use $\text{int}(X)$ to denote $X \setminus \{p, q\}$. A *chord* of a face f of $\mathcal{T}$ is an oriented line segment $\overline{pq}$ such that $\text{int}(\overline{pq}) \subset \text{int}(f)$ and $\{p, q\} \subset \text{bd}(f)$. If $\overline{pq} \subset \text{bd}(f)$, we say that $\overline{pq}$ is a *boundary segment*.

2.2. Convex distance functions. Each face f of $\mathcal{T}$ is associated with a compact convex set $B_f \subset \mathbb{R}^2$ that contains the origin O in its interior. The *convex distance*

function associated with f is defined by

$$\forall\, x, y \in f,\ d_f(x,y) = \min\{\lambda \in [0,+\infty) : y \in x + \lambda B_f\}.$$

This type of distance function has been studied before [4, 7] in the context of Voronoi diagrams. A convex distance function is not necessarily a metric as it may be asymmetric. Still, d_f satisfies the triangle inequality, and the shortest path from p to q is the oriented line segment $\overline{pq}$.

If $\mathrm{int}(\overline{pq}) \subset \mathrm{int}(f)$ for some face f, the cost of $\overline{pq}$ is defined as $\mathrm{cost}(\overline{pq}) = d_f(p,q)$. If $\overline{pq}$ is contained in an edge e of $\mathcal{T}$ that is adjacent to exactly one face f, we also define $\mathrm{cost}(\overline{pq})$ to be $d_f(p,q)$. On the other hand, if e is adjacent to two faces f_1 and f_2, we define $\mathrm{cost}(\overline{pq})$ to be $\min(d_{f_1}(p,q), d_{f_2}(p,q))$.

We assume that there exists $\rho \geqslant 1$ such that, for any face f, the set B_f contains a Euclidean disk with radius $1/\rho$ centered at the origin, and B_f is contained in the unit Euclidean disk centered at the origin. Intuitively, it means that the speed allowed in any direction is always in the interval $[1/\rho, 1]$. It implies that, for any face f and for any points $p, q \in f$, we have $\|pq\| \leqslant \mathrm{cost}(\overline{pq}) \leqslant \rho\,\|pq\|$. Another useful consequence is that for any two chords $\overline{ps}$ and $\overline{qr}$ of the same face f, we have

$$\begin{aligned} \mathrm{cost}(\overline{ps}) = d_f(p,s) &\leqslant d_f(p,q) + d_f(q,r) + d_f(r,s) \\ &= d_f(p,q) + \mathrm{cost}(\overline{qr}) + d_f(r,s) \\ &\leqslant \rho\,\|pq\| + \mathrm{cost}(\overline{qr}) + \rho\,\|rs\|. \end{aligned} \tag{1}$$

A similar derivation shows that the above inequality also holds when $\overline{ps}$ and $\overline{qr}$ are boundary segments contained in the same edge of $\mathcal{T}$. (If the edge containing $\overline{ps}$ and $\overline{qr}$ is incident to two faces f_1 and f_2, one needs to replace $d_f(x,y)$ by $\min(d_{f_1}(x,y), d_{f_2}(x,y))$ for any x and y in the above derivation.)

2.3. Polygonal paths. We consider paths from a point v_s to a point v_d in $|\mathcal{T}|$. Without loss of generality, we can assume that v_s and v_d are vertices of $\mathcal{T}$. If not, we can force v_s and v_d to be vertices by splitting the triangle(s) containing them into smaller triangles. (These smaller triangles inherit their convex distance functions from the triangles containing them.)

A *polygonal path* is a polyline in $|\mathcal{T}|$ with endpoints v_s and v_d. A *link* is an edge of a polygonal path, and a *node* is a vertex of a polygonal path—we use this terminology to avoid confusion with edges and vertices of $\mathcal{T}$. We identify a polygonal path with its sequence of nodes. Thus if a polygonal path P has the node sequence $(v_s = p_0, p_1, \ldots, p_m = v_d)$, we write $P = (p_0, p_1, \ldots, p_m)$. We do not require the nodes of P to be distinct. The *length* of P is defined as $\mathrm{length}(P) = \sum_{i=1}^{m} \|p_{i-1}p_i\|$.

A *$\mathcal{T}$-respecting path* is a polygonal path P such that each link of P is contained in a face of $\mathcal{T}$ (see Figure 1). The cost of a $\mathcal{T}$-respecting path P is simply the sum of the costs of its links when P is traversed from v_s to v_d. Therefore, we have $\mathrm{cost}(P) = \sum_{i=1}^{m} \mathrm{cost}(\overline{p_{i-1}p_i})$. It implies that $\mathrm{cost}(P)/\rho \leqslant \mathrm{length}(P) \leqslant \mathrm{cost}(P)$. We also define $\mathrm{cost}(P)$ when P is an arbitrary polygonal path. We first obtain a $\mathcal{T}$-respecting path P' by introducing new nodes at the intersections between the links of P and the edges of $\mathcal{T}$. We then define $\mathrm{cost}(P) = \mathrm{cost}(P')$.

For any integer k, a *k-link path* is a polygonal path with at most k links, and whose links are either chords or boundary segments (see Figure 1). In particular, a k-link path is $\mathcal{T}$-respecting, and none of its nodes lies in the interior of a face. Our definition is different from previous work [5] on k-link paths, where the path is not required to be $\mathcal{T}$-respecting. By our definitions, a $\mathcal{T}$-respecting path can have a node in the interior of a face of $\mathcal{T}$, but a k-link path cannot.

3. Approximation algorithms. We present algorithms for approximating a shortest k-link path for some given $\varepsilon \in (0,1)$ and k. The cost of the output polygonal path is less than $(1+\varepsilon)$ times the cost of any k-link path, but the output path is allowed to have more than k links. After showing the existence of an approximate shortest path with few links, we can use these algorithms to find $(1+\varepsilon)$-approximate shortest paths.

We first present a simple algorithm in section 3.1, which discretizes the environment with a graph and then computes a shortest path in the graph. Unlike the previous discretization schemes [1, 2], our discretization makes use of the global geodesic distance $\|v_s v_d\|_{\mathcal{T}}$. In section 3.2, we show another simple idea to space out the graph vertices that are far away from v_s and v_d. It results in a reduction of the graph size and hence an improvement of the running time. We show that it is possible to improve the running time further by working with the graph vertices alone (without computing the graph edges), by employing the algorithm BUSHWHACK [19].

3.1. A simple algorithm. In this section we present a simple algorithm that computes an approximate k-link shortest path. It is based on two ideas. First, we observe that any $\frac{4}{3}$-approximate shortest path lies in a region delimited by an ellipse with diameter $\frac{4}{3}\rho\|v_s v_d\|_{\mathcal{T}}$. Second, we discretize the problem by placing Steiner points uniformly along the portion of each edge of $\mathcal{T}$ that lies inside this ellipse. With an appropriate spacing of the Steiner points, we show that there is an approximate shortest path whose nodes are all Steiner points or vertices of $\mathcal{T}$. We find one such path by computing a shortest path in a graph whose nodes are the Steiner points and the vertices of $\mathcal{T}$, using Dijkstra's algorithm.

Let $k \geqslant 2n-4$ denote an integer. Because $\mathcal{T}$ is a planar graph with n vertices, it has at most $2n-4$ faces [14]. It implies that there exists a k-link path from v_s to v_d. Therefore, for any $\varepsilon > 0$, there exists a k-link path P_k^{ε} such that

$$\operatorname{cost}(P_k^{\varepsilon}) \leqslant \left(1+\frac{\varepsilon}{3}\right) \inf\{\operatorname{cost}(P_k) : P_k \text{ is a } k\text{-link path}\}.$$

This path has the following property.

LEMMA 1. *If $k \geqslant 2n-4$ and $\varepsilon \in (0,1)$, then $\operatorname{cost}(P_k^{\varepsilon}) \leqslant \frac{4\rho}{3}\|v_s v_d\|_{\mathcal{T}}$.*

Proof. Let $G = (g_0, g_1, \ldots, g_m)$ be a $\mathcal{T}$-respecting path with length $\|v_s v_d\|_{\mathcal{T}}$ and such that m is minimum. The path G cannot have two links inside the same face of $\mathcal{T}$: if there were two such links, say $\overline{g_{i-1}g_i}$ and $\overline{g_j g_{j+1}}$ with $i \leqslant j$, we could remove from G the nodes $(g_i, \ldots, g_j)$. It would yield a polygonal path with at most the same length but fewer nodes. As we noted above, $\mathcal{T}$ has at most $2n-4$ faces. Therefore, G is a $(2n-4)$-link path and hence a k-link path. We conclude that $\operatorname{cost}(P_k^{\varepsilon}) \leqslant \left(1+\frac{\varepsilon}{3}\right)\operatorname{cost}(G) \leqslant \frac{4}{3}\operatorname{cost}(G) = \frac{4}{3}\sum_{i=1}^{m}\operatorname{cost}(\overline{g_{i-1}g_i}) \leqslant \frac{4}{3}\sum_{i=1}^{m}\rho\|g_{i-1}g_i\| \leqslant \frac{4\rho}{3}\operatorname{length}(G) = \frac{4\rho}{3}\|v_s v_d\|_{\mathcal{T}}$. ∎

Let $\mathbb{E}$ denote the following elliptic region:

$$\mathbb{E} = \left\{ x \in \mathbb{R}^2 : \|v_s x\| + \|v_d x\| \leqslant \frac{4\rho}{3}\|v_s v_d\|_{\mathcal{T}} \right\}.$$

Since $\operatorname{length}(P_k^{\varepsilon}) \leqslant \operatorname{cost}(P_k^{\varepsilon})$, we know by Lemma 1 that $P_k^{\varepsilon} \subset \mathbb{E}$. For each edge e of $\mathcal{T}$, we place a maximal set of equally spaced points on $\operatorname{int}(e \cap \mathbb{E})$ (see Figure 2). The spacing is $\delta = \frac{\varepsilon}{6\rho k}\|v_s v_d\|_{\mathcal{T}}$. The following lemma shows that our Steiner points give an accurate discretization.

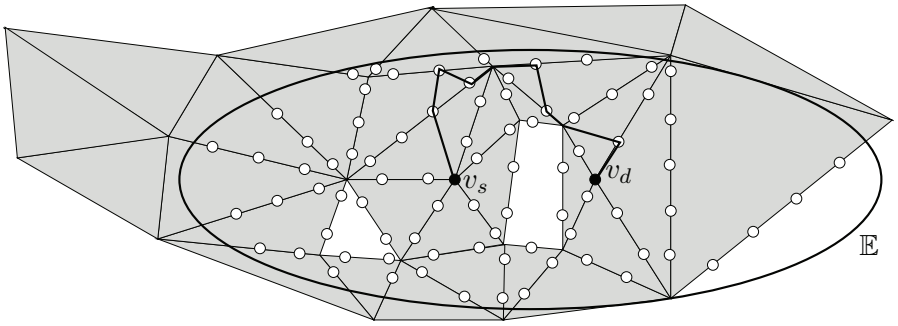

FIG. 2. *The white points are the Steiner points. The polygonal path is a 9-link path whose nodes are all Steiner points or vertices of $\mathcal{T}$.*

LEMMA 2. *If $k \geqslant 2n-4$ and $\varepsilon \in (0,1)$, there exists a k-link path S_k such that $\operatorname{cost}(S_k) \leqslant (1+\varepsilon)\operatorname{cost}(P_k)$ for any k-link path P_k, and all the nodes of S_k are Steiner points or vertices of $\mathcal{T}$.*

Proof. Let $(p_0, p_1, \ldots, p_m)$ be the node sequence of P_k^ε. For any $i \in [0,m]$, we associate a point s_i to p_i as follows. If p_i is a vertex of $\mathcal{T}$, we set $s_i = p_i$. Otherwise, since P_k^ε is a k-link path, p_i lies in the interior of some edge e of $\mathcal{T}$. Thus, there is a Steiner point $x \in \operatorname{int}(e)$ such that $\|xp_i\| \leqslant \delta$. We set $s_i = x$. We denote $S_k = (s_0, s_1, \ldots, s_m)$. (It is possible that $s_{i-1} = s_i$ for some i, in which case the link $\overline{s_{i-1}s_i}$ degenerates to a point.) By construction, for any $i \in [1,m]$, the links $\overline{p_{i-1}p_i}$ and $\overline{s_{i-1}s_i}$ either are chords of the same face of $\mathcal{T}$ or are contained in the same edge of $\mathcal{T}$. Therefore, S_k is a k-link path, and inequality (1) implies that

$$\operatorname{cost}(S_k) \leqslant \sum_{i=1}^{m} \rho\,\|s_{i-1}p_{i-1}\| + \operatorname{cost}(\overline{p_{i-1}p_i}) + \rho\,\|s_ip_i\| \tag{2}$$

$$\leqslant \operatorname{cost}(P_k^\varepsilon) + 2\rho m\delta \tag{3}$$

$$= \operatorname{cost}(P_k^\varepsilon) + \frac{m\varepsilon}{3k}\,\|v_sv_d\|_{\mathcal{T}}. \tag{4}$$

By definition, P_k^ε is a k-link path. So $m \leqslant k$, and thus $\operatorname{cost}(S_k) \leqslant \operatorname{cost}(P_k^\varepsilon) + \frac{\varepsilon}{3}\,\|v_sv_d\|_{\mathcal{T}}$. Since $\|v_sv_d\|_{\mathcal{T}} \leqslant \operatorname{length}(P_k^\varepsilon) \leqslant \operatorname{cost}(P_k^\varepsilon)$, we have $\operatorname{cost}(S_k) \leqslant (1+\varepsilon/3)\operatorname{cost}(P_k^\varepsilon)$. Thus, for any k-link path P_k, $\operatorname{cost}(S_k) \leqslant (1+\varepsilon/3)^2\operatorname{cost}(P_k) \leqslant (1+\varepsilon)\operatorname{cost}(P_k)$. ∎

The *Steiner graph* is the directed weighted graph defined as follows. Its nodes are the Steiner points and the vertices of $\mathcal{T}$. There is a directed edge (p,q) between any two nodes p and q that lie on the boundary of the same face of $\mathcal{T}$. The edge (p,q) is assigned the weight $\operatorname{cost}(\overline{pq})$.

Here is the pseudocode of our approximation algorithm.

Approximate$(\mathcal{T}, k, \varepsilon)$

1. Compute $\|v_sv_d\|_{\mathcal{T}}$.
2. Compute the Steiner graph.
3. Compute a weighted shortest path S in the Steiner graph.
4. Output S.

In the analysis of this algorithm, we use the standard real-RAM model [15] and assume that, for any points p and q in the same face of $\mathcal{T}$, we can compute $\operatorname{cost}(\overline{pq})$ in $O(1)$ time. We obtain the following result.

LEMMA 3. *If $k \geqslant 2n-4$ and $\varepsilon \in (0,1)$, then* Approximate$(\mathcal{T}, k, \varepsilon)$ *computes a polygonal path S such that* $\operatorname{cost}(S) \leqslant (1+\varepsilon)\operatorname{cost}(P_k)$ *for any k-link path P_k. The algorithm can be implemented to run in $O\left(nk^2\rho^4/\varepsilon^2\right)$ time.*

Proof. Correctness follows from Lemma 2. The geodesic distance computation in line 1 can be performed in $O(n^2) = O(nk)$ time [12]. The diameter of $\mathbb{E}$ is $\frac{4}{3}\rho\,\|v_s v_d\|_{\mathcal{T}}$, so each edge e of $\mathcal{T}$ contains $O(k\rho^2/\varepsilon)$ Steiner points. Therefore, the Steiner graph has $O(nk\rho^2/\varepsilon)$ nodes and $O(nk^2\rho^4/\varepsilon^2)$ edges. Using a Fibonacci heap, Dijkstra's algorithm can be implemented to compute single-source shortest paths in $O(|E| + |V|\log|V|)$ time for a graph with $|V|$ nodes and $|E|$ edges [8]. We use this method to implement step 4 and, thus, we obtain the desired running time. ∎

3.2. A sparser Steiner graph. We can speed up the above algorithm by reducing the number of Steiner points. The idea is to place Steiner points more sparsely on portions of edges that are far from v_s and v_d. So we introduce a family of elliptic regions. For $0 \leqslant i \leqslant \lceil \log\rho \rceil$, each region is defined as

$$\mathbb{E}_i = \left\{ x \in \mathbb{R}^2 : \|v_s x\| + \|v_d x\| \leqslant \frac{4\rho}{2^i\,3}\,\|v_s v_d\|_{\mathcal{T}} \right\}.$$

For convenience, we take $\mathbb{E}_{\lceil \log\rho \rceil + 1}$ to denote the empty set.

We construct a set of Steiner points as follows. For each edge e of $\mathcal{T}$ and for any integer i such that $0 \leqslant i \leqslant \lceil \log\rho \rceil$, we insert the intersection points between e and the boundary of $\mathbb{E}_i$, and then we place a maximal set of points on $\operatorname{int}(e \cap (\mathbb{E}_i \setminus \mathbb{E}_{i+1}))$ with uniform spacing $\delta_i = \frac{\varepsilon}{2^{i+1}\,6k}\,\|v_s v_d\|_{\mathcal{T}}$. After obtaining the new set of Steiner points, the Steiner graph is constructed as before. Observe that now, the number of Steiner graph nodes per edge is $O((k\rho\log\rho)/\varepsilon)$ instead of $O(k\rho^2/\varepsilon)$. Therefore, the size of the Steiner graph is $O((nk^2\rho^2\log^2\rho)/\varepsilon^2)$, and the running time improves to $O((nk^2\rho^2\log^2\rho)/\varepsilon^2)$.

It remains to prove that this new algorithm is correct. Let j denote the largest integer such that $P_k^\varepsilon \subset E_j$. (There is such an integer because $P_k^\varepsilon \subset \mathbb{E}_0 = \mathbb{E}$ by Lemma 1.) For every edge e of $\mathcal{T}$, the distance between two consecutive Steiner points along $e \cap E_j$ is at most δ_j. Thus, using the derivation in inequalities (2) and (3) in the proof of Lemma 2, we can show that $\operatorname{cost}(S_k) \leqslant \operatorname{cost}(P_k^\varepsilon) + \rho\varepsilon\,\|v_s v_d\|_{\mathcal{T}}/(2^{j+1}\,3)$. As P_k^ε is not contained in $\mathbb{E}_{j+1}$, we have

$$\operatorname{length}(P_k^\varepsilon) \geqslant 4\rho\,\|v_s v_d\|_{\mathcal{T}}/(2^{j+1}\,3)$$

and thus $\operatorname{cost}(S_k) \leqslant (1+\varepsilon/4)\operatorname{cost}(P_k^\varepsilon)$. Recall that $\operatorname{cost}(P_k^\varepsilon) \leqslant (1+\varepsilon/3)\operatorname{cost}(P_k)$ for any k-link path P_k. It follows that $\operatorname{cost}(S_k) \leqslant (1+\varepsilon)\operatorname{cost}(P_k)$. Therefore, we have proved the following result.

LEMMA 4. *If $k \geqslant 2n-4$ and $\varepsilon \in (0,1)$, we can compute in $O((nk^2\rho^2\log^2\rho)/\varepsilon^2)$ time a polygonal path S such that* $\operatorname{cost}(S) \leqslant (1+\varepsilon)\operatorname{cost}(P_k)$ *for any k-link path P_k.*

3.3. Further improvement. We can improve the running time further if we can avoid computing explicitly the edges of the Steiner graph. This means that, instead of using Dijkstra's algorithm, we need to use an algorithm that does not require these edges to produce a shortest path. BUSHWHACK, an algorithm by Sun and Reif [19], does exactly this, provided that the cost function is *pseudo-Euclidean*.

The cost function is pseudo-Euclidean if it meets the following two conditions. First, it obeys the triangle inequality in the interior of each face (in other words, a shortest path in the interior of a face is a line segment). Second, let p be a point inside a face f and let e be an edge of f such that $p \notin e$. Let $\varphi_{p,e} : e \to \mathbb{R}$ be the

function defined by $\varphi_{p,e}(x) = \mathrm{cost}(\overline{px})$. For any p and e, this function is required to have the following property: we can compute in $O(1)$ time a partition of e into $O(1)$ subsegments such that $\varphi_{p,e}$ is monotone along each such subsegment.

The convexity of the distance functions in $\mathcal{T}$ implies that $\varphi_{p,e}$ has only one local extremum, which is a global minimum. (In degenerate cases, when B_f is not strictly convex, this minimum can be achieved over a closed segment and not just at a single point.) So if we assume that this minimum can be computed in $O(1)$ time, our metric is pseudo-Euclidean.

When there are m Steiner points per edge, the BUSHWHACK algorithm runs in time $O(mn\log(mn))$ instead of $O(m^2n + mn\log(mn))$ for Dijkstra's algorithm. The algorithm presented in section 3.2 uses $m = O((k\rho\log\rho)/\varepsilon)$ Steiner points per edge. Thus, we obtain the following improved algorithm.

THEOREM 5. *If $k \geqslant 2n-4$ and $\varepsilon \in (0,1)$, we can compute in time*

$$O\left(\frac{nk\rho\log\rho}{\varepsilon}\log\left(\frac{k\rho}{\varepsilon}\right)\right)$$

a polygonal path S such that $\mathrm{cost}(S) \leqslant (1+\varepsilon)\,\mathrm{cost}(P_k)$ for any k-link path P_k.

3.4. Applications. In the weighted region problem, each face f is associated with a weight $w_f \in [1,\rho]$ (assuming that the minimum weight is scaled to 1). According to our terminology, for each face f, the set B_f is the Euclidean disk centered at the origin with radius $1/w_f$. Obstacles (holes in $|\mathcal{T}|$) are still allowed; in other words, we allow weights to be in $[1,\rho]\cup\{+\infty\}$. Mitchell and Papadimitriou [12, 13] proved that, in the weighted region problem, the shortest path is an $O(n^2)$-link path. Substituting this bound for k into Theorem 5 yields the following result.

COROLLARY 6. *Consider the weighted region problem in a planar subdivision with n vertices and with weights in $[1,\rho]\cup\{+\infty\}$. For any $\varepsilon \in (0,1)$, we can compute a $(1+\varepsilon)$-approximate shortest path in time $O(\frac{\rho\log\rho}{\varepsilon}n^3\log(\frac{n\rho}{\varepsilon}))$.*

To realize the $(1+\varepsilon)$-approximation bound in Corollary 6, one would need to extract from [13] the constant c_0 hidden in the $O(n^2)$ bound on the number of links. Nevertheless, the proof of Lemma 2 reveals that even if k is set to be c_1n^2 for some constant $c_1 < c_0$, the approximation ratio is still $1+O(\varepsilon)$.

In the anisotropic setting where each face f is associated with a convex distance function d_f, no bound on the number of links in the shortest path was known before. In Theorem 16 in section 5 and Corollary 23 in section 6, for any $\varepsilon \in (0,1)$, we prove a bound of $21\rho n^2/\varepsilon$ on the number of links in a polygonal path whose cost is at most $(1+\varepsilon)$ times the optimal. Substituting this bound for k into Theorem 5 yields the following result.

COROLLARY 7. *Consider the anisotropic shortest path problem in a planar subdivision with n vertices. For any $\varepsilon \in (0,1)$, we can compute a $(1+\varepsilon)$-approximate shortest path in time $O(\frac{\rho^2\log\rho}{\varepsilon^2}n^3\log(\frac{\rho n}{\varepsilon}))$.*

As we mentioned in the introduction (section 1.2), the shortest path problem in the presence of uniform flows can be solved using Corollary 7.

COROLLARY 8. *Consider the shortest path problem in the presence of uniform flows as defined in section 1.2. Assume that $v_{\min} > 0$. For any $\varepsilon \in (0,1)$, we can compute a $(1+\varepsilon)$-approximate shortest path in time $O(\frac{\rho^2\log\rho}{\varepsilon^2}n^3\log(\frac{\rho n}{\varepsilon}))$, where $\rho = v_{\max}/v_{\min}$.*

4. Cost-preserving path transformations. In this section we show how to transform a $\mathcal{T}$-respecting path into another $\mathcal{T}$-respecting path that has at most the same cost and is free of some undesirable features. This result is used in section 5 to show that any polygonal path can be converted into a polygonal path with $O(\rho n^2/\varepsilon)$ links such that the cost increases by a factor of at most $1+\varepsilon$.

4.1. Preliminaries. Let $P = (v_s = p_0, \ldots, p_m = v_d)$ be a polygonal path. We allow $p_i = p_{i+1}$; in this case, we call $\overline{p_i p_{i+1}} = \{p_i\}$ a *degenerate link*. The path P is *self-intersecting* if

- there exist $i < j$ such that $\overline{p_{i-1}p_i} \cap \overline{p_j p_{j+1}} \neq \emptyset$, or
- there exists i such that $p_{i-1} \in \overline{p_i p_{i+1}}$ or $p_{i+1} \in \overline{p_{i-1}p_i}$.

The path P is *simple* if it is not self-intersecting. The points in which P self-intersects are not necessarily nodes of P.

To describe the cost-preserving transformations, we give a classification of nodes in P. The vertices of $\mathcal{T}$ that are nodes of P are called the nodes of P *inherited* from $\mathcal{T}$. The endpoints of degenerate links are called *degenerate nodes*. The other nodes are classified as follows (Figure 3 shows some examples).

- *Transversal node*: $p_i \in \mathrm{int}(e)$ for some edge e, and $\overline{p_{i-1}p_i} \cap \mathrm{int}(f) \neq \emptyset$ and $\overline{p_i p_{i+1}} \cap \mathrm{int}(g) \neq \emptyset$, where f and g are the two faces incident to e.
- *Critical node of entry*: $p_i \in \mathrm{int}(e)$ and $\mathrm{int}(\overline{p_i p_{i+1}}) \cap e \neq \emptyset$ for some edge e, and $\overline{p_{i-1}p_i} \cap \mathrm{int}(f) \neq \emptyset$ for a face f incident to e.
- *Critical node of exit*: $p_i \in \mathrm{int}(e)$ and $\mathrm{int}(\overline{p_{i-1}p_i}) \cap e \neq \emptyset$ for some edge e, and $\overline{p_i p_{i+1}} \cap \mathrm{int}(f) \neq \emptyset$ for a face f incident to e.
- *Reflective node*: $p_i \in \mathrm{int}(e)$ for some edge e, and $\overline{p_{i-1}p_i} \cap \mathrm{int}(f) \neq \emptyset$ and $\overline{p_i p_{i+1}} \cap \mathrm{int}(f) \neq \emptyset$ for a face f incident to e.
- *Interior node*: $p_i \in \mathrm{int}(f)$ for some face f.
- *Linear node*: $p_i \in \mathrm{int}(e)$, $\mathrm{int}(\overline{p_{i-1}p_i}) \cap e \neq \emptyset$, and $\mathrm{int}(\overline{p_i p_{i+1}}) \cap e \neq \emptyset$ for some edge e.

In the definition of a linear, interior, or reflective node p_i, we allow $\overline{p_{i-1}p_i}$ and $\overline{p_i p_{i+1}}$ to overlap. We call a polygonal path *nonredundant* if it does not contain any degenerate, reflective, interior, or linear node. Some intermediate results of the cost-preserving transformations may be self-intersecting paths, so our classification of nodes does not assume simplicity. Our classification does not assume paths to be $\mathcal{T}$-respecting either.

Our cost-preserving transformations manipulate polygonal paths by modifying subpaths and concatenating polygonal paths. Recall that, for convenience, we use the same notation for a polygonal path and its sequence of nodes. For any integers i, j such that $0 \leqslant i \leqslant j \leqslant m$, we use $P[i,j]$ to denote the subpath $(p_i, \ldots, p_j)$. Given two subpaths $A = (a_1, \ldots, a_{m'})$ and $B = (b_1, \ldots, b_{m''})$, we denote by $A \cdot B = (a_1, \ldots, a_{m'}, b_1, \ldots, b_{m''})$ the concatenation of A and B.

4.2. Splitting a path. Let $P = (p_0, \ldots, p_m)$ be a polygonal path. The procedure Split converts P into a $\mathcal{T}$-respecting path with the same cost. This procedure operates as follows. For each vertex v that lies in the interior of a link of P, it splits this link at v and makes v a node of P. For each crossing point x between an edge of $\mathcal{T}$ and a link of P, it splits the link at point x and introduces the node x.

Split(Polygonal path P)

1. If there exist a vertex v of $\mathcal{T}$ and a link $\overline{p_i p_{i+1}}$ of P such that $v \in \mathrm{int}(\overline{p_i p_{i+1}})$, then return Split$(P[0,i] \cdot (v) \cdot P[i+1,m])$.
2. If there exist an edge e of $\mathcal{T}$, a link $\overline{p_i p_{i+1}}$ of P, and a point x such that $x = \mathrm{int}(e) \cap \mathrm{int}(\overline{p_i p_{i+1}})$, then return Split$(P[0,i] \cdot (x) \cdot P[i+1,m])$.
3. Return P.

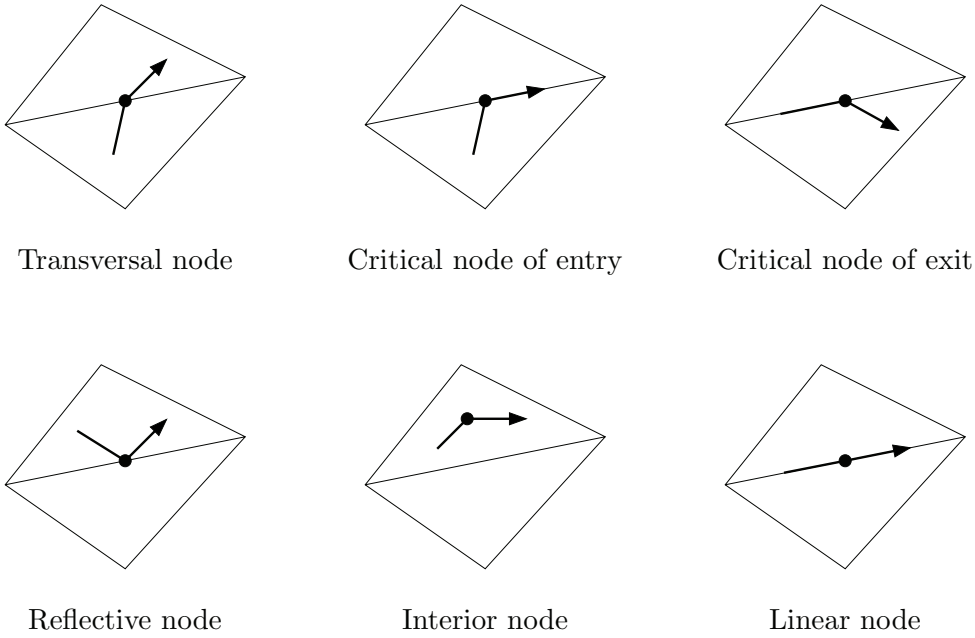

FIG. 3. *Different types of nodes of P other than degenerate nodes and nodes inherited from $\mathcal{T}$.*

The following lemma describes the effect of Split.

LEMMA 9. *For any polygonal path P, the path P' returned by* Split(P) *is $\mathcal{T}$-respecting, and* $\text{cost}(P') = \text{cost}(P)$.

4.3. Reducing a path. Let $P = (p_0, \ldots, p_m)$ be a $\mathcal{T}$-respecting path. The procedure Reduce eliminates some locally nonoptimal features in P, including degenerate, reflective, interior, and linear nodes, as well as self-intersections.

Reduce($\mathcal{T}$-respecting path $P = (p_0, \ldots, p_m)$)

1. If there exists i such that $p_i = p_{i+1}$,
   then return Reduce$(P[0, i-1] \cdot P[i+1, m])$.
2. If a node p_i is a reflective, interior, or linear node,
   then return Reduce$(P[0, i-1] \cdot P[i+1, m])$.
3. If P self-intersects, then we are in one of the following two cases:
   (a) There exist $i < j$ and $x \in |\mathcal{T}|$ such that $x \in \overline{p_{i-1}p_i} \cap \overline{p_j p_{j+1}}$.
   Then return Reduce$(P[0, i-1] \cdot (x) \cdot P[j+1, m])$.
   (b) There exists i such that $p_{i-1} \in \overline{p_i p_{i+1}}$ or $p_{i+1} \in \overline{p_{i-1}p_i}$.
   Then return Reduce$(P[0, i-1] \cdot P[i+1, m])$.
4. Return P.

It is clear that the number of nodes in P decreases after one application of step 1, 2, or 3. It implies that Reduce terminates.

Recall that the input path is assumed to be $\mathcal{T}$-respecting. Clearly, this condition continues to hold after applying step 1, 2, or 3 any number of times. In addition, when Reduce terminates, the output path P' returned by Reduce(P) is simple and nonredundant.

LEMMA 10. *Let P be a $\mathcal{T}$-respecting path. The path P' returned by* Reduce(P) *is simple, nonredundant, and $\mathcal{T}$-respecting. If $P' \neq P$, then P' has fewer links than P, and* $\text{cost}(P') \leqslant \text{cost}(P)$.

4.4. Sliding subpaths. We call (i, j) a *critical pair* if p_i is a critical node of exit, p_j is a critical node of entry, $i < j$, and all of the nodes in the interior of the subpath $P[i, j]$ are transversal nodes (see Figure 4). We introduce a procedure Slide to remove a critical pair in P if there is one. The same technique of sliding subpaths was used by Mitchell and Papadimitriou [13]. Because Reduce will be applied before applying Slide, we assume that P is a simple, nonredundant, $\mathcal{T}$-respecting path.

Slide(simple, nonredundant, $\mathcal{T}$-respecting path P)

1. Look for a critical pair (i, j) in P.
2. If no critical pair is found, return P.
3. Slide $P[i, j]$ in a direction such that $\text{cost}(P)$ does not increase, until one of the following situations occurs:
   (a) $p_{i-1} = p_i$. Then return $P[0, i-1] \cdot P[i+1, m]$.
   (b) $p_j = p_{j+1}$. Then return $P[0, j-1] \cdot P[j+1, m]$.
   (c) P self-intersects or $P[i, j]$ hits a vertex of $\mathcal{T}$. Then return P.

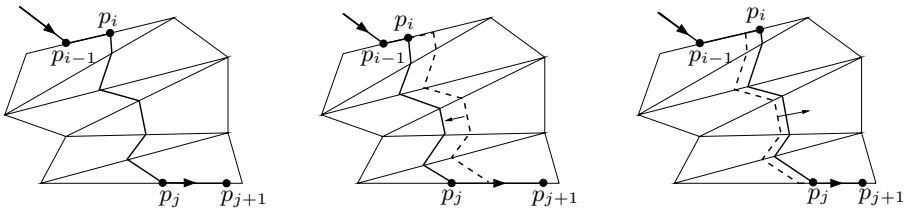

FIG. 4. *A critical pair (i, j). The subpath $P[i, j]$ can slide to the left or to the right.*

We explain the sliding operation in step 3 in more detail. Refer to Figure 4. Sliding $P[i, j]$ means shifting p_i, all of the transversal nodes on $P[i, j]$, and p_j along the corresponding edges in such a way that the links in $P[i, j]$ remain parallel to their original positions. The links $\overline{p_{i-1}p_i}$, $\overline{p_jp_{j+1}}$, and those in $P[i, j]$ may lengthen or shrink. Let Δ be the signed distance of the sliding of p_i from its original position. We take Δ to be positive (resp., negative) if p_i slides to the right (resp., left). Take a sliding link $\overline{p_ap_{a+1}}$. As the slope of $\overline{p_ap_{a+1}}$ is kept constant, the cost of $\overline{p_ap_{a+1}}$ is an affine function of Δ. Clearly, the costs of $\overline{p_{i-1}p_i}$ and $\overline{p_jp_{j+1}}$ are also affine functions of Δ. Thus, the total change in $\text{cost}(P)$ is an affine function of Δ. Since the value of an affine function is minimized at the boundary of its domain, we conclude that there is a direction in which we can slide $P[i, j]$ without increasing $\text{cost}(P)$. The stopping criteria in step 3 exhausts all of the possibilities in which (i, j) no longer satisfies the criteria of being a critical pair or P ceases to be simple. The following lemma describes the effect of Slide.

LEMMA 11. *Let P be a simple, nonredundant, $\mathcal{T}$-respecting path. The path P' returned by* Slide(P) *satisfies the following properties:*

(i) *P' is a $\mathcal{T}$-respecting path.*
(ii) $\text{cost}(P') \leqslant \text{cost}(P)$*, and P' has no more links than P.*
(iii) *If $P' \neq P$ and P' has as many links as P, then P' is self-intersecting or P' has more nodes inherited from $\mathcal{T}$ than P does.*

4.5. Combining the transformations. We define a procedure Simplify that makes use of the previous procedures. The input is a polygonal path P.

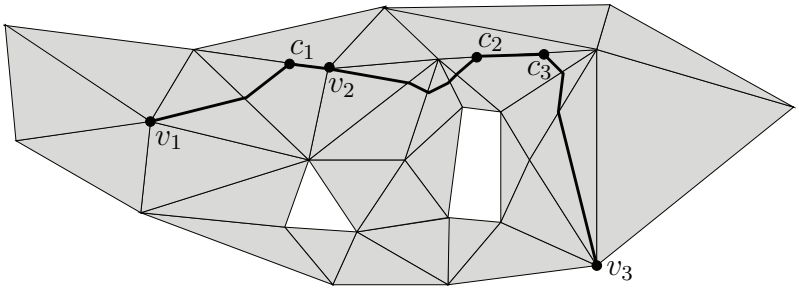

FIG. 5. *An example of a simplified path Q_0. There are two critical nodes c_2 and c_3 between vertices v_2 and v_3.*

Simplify(Polygonal path P)

1. $Q_1 :=$ Split(P).
2. $Q_2 :=$ Reduce(Q_1).
3. $Q_0 :=$ Slide(Q_2). If $Q_0 \neq Q_2$, set $Q_1 := Q_0$ and go back to step 2.
4. Return Q_0.

LEMMA 12. *Let P be a polygonal path. The path Q_0 returned by* Simplify(P) *has the following properties:*

(i) $\text{cost}(Q_0) \leqslant \text{cost}(P)$.

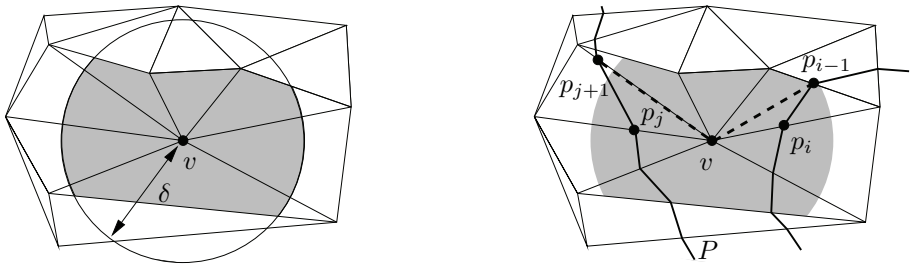
(ii) *Q_0 is a simple, nonredundant, $\mathcal{T}$-respecting path.*

(iii) *Q_0 has no critical pair and has at most $2n$ critical vertices of entry or exit.*

Proof. We first show the termination of Simplify. By Lemmas 10 and 11, the number of links in the path never increases at steps 2 and 3. If the number of links stays the same in step 3, then Lemma 11 says that Q_0 is self-intersecting or it has more nodes inherited from $\mathcal{T}$ than Q_2 does. If Q_0 is self-intersecting, the number of links in the path decreases when Reduce is called in the next step. So if steps 2 and 3 iterate without decreasing the number of links in the path, it means that the path remains simple and the number of nodes inherited from $\mathcal{T}$ increases from iteration to iteration. But this can happen at most $n-2$ times before all vertices of $\mathcal{T}$ lie on the path. Therefore, the number of links in the path must decrease after at most $n-1$ iterations of steps 2 and 3. Clearly, the number of links cannot decrease below one, so Simplify must terminate.

Let $(q_0, \ldots, q_m)$ be the node sequence of Q_0. Property (i) follows from the fact that Split, Reduce, and Slide do not increase the cost. Property (ii) follows from Lemma 10. The termination of Simplify implies that no critical pair is detected by Slide. So if we walk along Q_0 from v_s to v_d and encounter a critical node of exit q_i, we will see a node $q_{i'}$ inherited from $\mathcal{T}$ before encountering any critical node of entry or exit. We charge q_i to $q_{i'}$. The node $q_{i'}$ can only be charged once, so there are at most n critical nodes of exit in Q_0. By a symmetric argument (following Q_0 backward from v_d to v_s), we can show that there are at most n critical nodes of entry. Hence, the total number of critical nodes is at most $2n$. ∎

In fact, the proof of Lemma 12 shows even more. Between any two consecutive nodes of Q_0 inherited from $\mathcal{T}$, there is at most one critical node of entry and one critical node of exit. In case these two critical nodes are present, they lie on the same edge e, and the path enters and exits e from the same side (see Figure 5). All of the other nodes (between these two consecutive inherited nodes) are transversal nodes.



(a) (b)

FIG. 6. (a) *The δ-neighborhood of v is shaded.* (b) *The effect of* Shortcut*(P, δ, v). The subpath $P[i-1, j+1]$ is replaced by the dashed subpath (p_{i-1}, v, p_{j+1}).*

5. Path complexity. In this section we show that any polygonal path P can be approximated by a $(21\rho n^2/\varepsilon)$-link path with cost at most $(1+\varepsilon)\,\mathrm{cost}(P)$. This result, combined with the algorithms for approximating k-link shortest paths that we presented in section 3, allows us to compute a polygonal path with cost at most $(1+\varepsilon)\,\mathrm{cost}(P)$ in time $O(\frac{\rho^2 \log \rho}{\varepsilon^2} n^3 \log(\frac{\rho n}{\varepsilon}))$.

5.1. Shortcut near vertices. We introduce a procedure Shortcut that removes nodes in the vicinity of vertices of $\mathcal{T}$. Shortcut takes as input a polygonal path P, a real number $\delta > 0$, and a vertex v of $\mathcal{T}$. Shortcut will be invoked repeatedly, starting with the output of Simplify. The path may no longer be simple or nonredundant after several applications of Shortcut.

Let v be a vertex of $\mathcal{T}$. The *δ-neighborhood* of v is the intersection of the δ-radius Euclidean disk centered at v with the union of the faces that contain v (see Figure 6(a)). Shortcut(P, δ, v) checks if P has a node in the interior of the δ-neighborhood of v. If so, let p_i and p_j be the first and last nodes of P, respectively, in the interior of the δ-neighborhood of v—here the interior is taken in the topological sense. Then Shortcut replaces $P[i-1, j+1]$ with the subpath (p_{i-1}, v, p_{j+1}) (see Figure 6(b)). The nodes p_{i-1} and p_{j+1} lie on the boundary of a face incident to v, so the new path is still inside $|\mathcal{T}|$. The links $\overline{p_{i-1}v}$ and $\overline{vp_{j+1}}$ introduced by Shortcut may make the path redundant or self-intersecting. Here is the pseudocode of Shortcut.

Shortcut(Polygonal path P, $\delta > 0$, vertex v)

1. If no node of P is in the interior of the δ-neighborhood of v, return P.
2. Let p_i and p_j be the first and last nodes along P, respectively, that lie in the interior of the δ-neighborhood of v. Let p_0 and p_m be the first and last nodes of P.
3. If $v = p_0$, return $(v) \cdot P[j+1, m]$.
4. If $v = p_m$, return $P[0, i-1] \cdot (v)$.
5. Return $P[0, i-1] \cdot (v) \cdot P[j+1, m]$.

The following lemma gives a bound on the cost of the path obtained by applying Shortcut.

LEMMA 13. *Let P be a $\mathcal{T}$-respecting path. Then the path returned by* Shortcut(P, δ, v) *has cost less than* $\mathrm{cost}(P) + 2\rho\delta$.

Proof. Either $\overline{p_{i-1}p_i}$ is a chord of a face incident to v or it is contained in an edge incident to v. In any case, as $\|p_i v\| < \delta$, we have $\mathrm{cost}(\overline{p_{i-1}v}) < \mathrm{cost}(\overline{p_{i-1}p_i}) + \rho\delta$.

Similarly, we can prove that $\text{cost}(\overline{vp_{j+1}}) < \text{cost}(\overline{p_jp_{j+1}}) + \rho\delta$. ∎

Remark. Reif and Sun [19] also used a disk neighborhood. Their disk radius is related to the local geometry around the vertex v, and the disk is completely contained in the union of the faces incident to v. In our construction, the disk radius will be set to be proportional to the global path cost. (See the procedure Convert in section 5.2.) As shown in Figure 6, our disk may not be contained in the union of faces incident to v.

5.2. Path conversion. The pseudocode below describes a procedure Convert that transforms a polygonal path P into another polygonal path R. We show that R has at most $21\rho n^2/\varepsilon$ links and its cost is at most $(1+\varepsilon)\,\text{cost}(P)$. We denote by $\{v_1, v_2, \ldots, v_n\}$ the vertices of $\mathcal{T}$ in the following pseudocode.

Convert(Polygonal path P, $\varepsilon \in (0,1)$)
1. $Q_0 :=$ Simplify(P).
2. $\delta := \varepsilon\,\text{cost}(P)/(2\rho n)$.
3. For $i = 1$ to n, $Q_i :=$ Shortcut(Q_{i-1}, δ, v_i).
4. $R := Q_n$.
5. Return R.

The procedure Convert has the following properties.

LEMMA 14. *Let $R = (r_1, \ldots, r_\ell)$ be the path returned by* Convert(P, ε).

(i) $\text{cost}(R) \leqslant (1+\varepsilon)\ \text{cost}(P)$.
(ii) *R is a $\mathcal{T}$-respecting path with distinct nodes.*
(iii) *If $\{r_i, r_{i+1}\}$ contains no vertex of $\mathcal{T}$, then $\overline{r_ir_{i+1}}$ is a link of Q_0.*
(iv) *If v is a vertex of $\mathcal{T}$ and r_i lies in the interior of an edge incident to v, then $\|r_iv\| \geqslant \delta$.*

Proof. By Lemma 13, the path cost increases by at most $2\rho\delta = \varepsilon\,\text{cost}(P)/n$ for each call to Shortcut. By Lemma 12, $\text{cost}(Q_0) \leqslant \text{cost}(P)$; thus $\text{cost}(R) \leqslant \text{cost}(Q_0) + \varepsilon\ \text{cost}(P) \leqslant (1+\varepsilon)\ \text{cost}(P)$. By Lemma 12 again, Q_0 is a $\mathcal{T}$-respecting path with distinct nodes. Each call to Shortcut preserves these two properties. This proves (ii). Properties (iii) and (iv) follow from the working of Shortcut. ∎

We prove a technical lemma which essentially says that, for any edge e, the transversal nodes in the output of Convert(P, ε) that lie on e are sparse.

LEMMA 15. *Let $R = (r_1, \ldots, r_\ell)$ be the path returned by* Convert(P, ε). *Consider an edge e of $\mathcal{T}$ and a node $r_i \in \text{int}(e)$. Suppose that the following conditions hold:*

- *There exists a node $r_j \in \text{int}(e)$ with $j > i+1$. If there are several such nodes we choose j to be the minimum.*
- *All nodes in $\text{int}(R[i,j])$ are transversal nodes.*

Then $\text{cost}(R[i,j]) > \delta$.

Proof. We denote by ℓ_e the support line of e, and we denote by x the first intersection point between $R[i,j]$ and ℓ_e. If $x \neq r_j$, then $x \notin \text{int}(e)$ as R is $\mathcal{T}$-respecting (see Figure 7(a)). By Lemma 14(iv), we know that $\|r_ix\| > \delta$ and thus $\text{cost}(R[i,j]) \geqslant \|r_ix\| > \delta$.

We now assume that $x = r_j$, and thus $\text{int}(R[i,j])$ lies entirely on one side of ℓ_e. We denote by R_i the region delimited by $R[i,j]$ and $\overline{r_ir_j}$ (see Figure 7(b)). We first prove that there exists an edge e' of $\mathcal{T}$ with one endpoint v' inside R_i. Let E denote the set of edges of $\mathcal{T}$ that contain a node of $R[i,j]$. Pick an edge of E. If this edge has an endpoint inside R_i, we are done. Otherwise, this edge crosses $\text{int}(R[i,j])$ transversally, so it separates a portion of R_i away from e. By recursively applying the argument on this portion of R_i, we must find an edge $e' \in E$ that has an endpoint inside R_i.

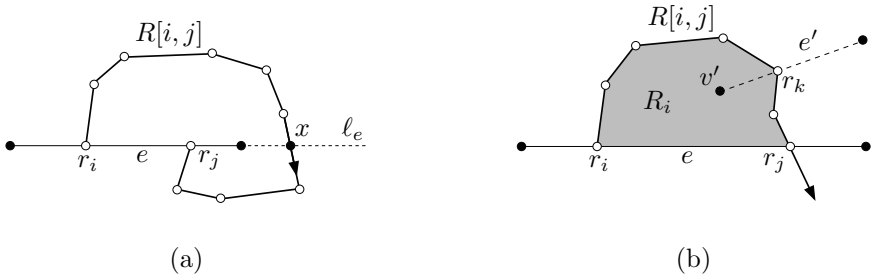


FIG. 7. *In* (a)*, the subpath* $R[i,j]$ *intersects* ℓ_e *outside* e *at point* x*. In* (b)*, the node* v' *is in the interior of the region* R_i *delimited by* $R[i,j]$ *and* $\overline{r_i r_j}$*.*

Let r_k denote a node of $R[i,j]$ that lies on e'. Because no vertex of $\mathcal{T}$ lies on $R[i,j]$, Lemma 14(iv) implies that $\|r_k v'\| \geqslant \delta$. It follows that $\text{length}(R[i,j]) > \|r_k v'\| \geqslant \delta$. Hence, $\text{cost}(R[i,j]) \geqslant \text{length}(R[i,j]) > \delta$. ∎

We are now ready to derive a pseudopolynomial bound on the path complexity.

THEOREM 16. *For any* $\varepsilon \in (0,1)$ *and for any polygonal path* P*, there exists a path* P^ε *with at most* $21\rho n^2/\varepsilon$ *links such that* $\text{cost}(P^\varepsilon) \leqslant (1+\varepsilon)\,\text{cost}(P)$*. In addition,* P^ε *can be chosen to be simple and nonredundant.*

Proof. Let $Q_0 = \mathsf{Simplify}(P)$, $R = \mathsf{Convert}(P,\varepsilon)$, and $P^\varepsilon = \mathsf{Reduce}(R)$. By Lemmas 10, 12, and 14, we know that

- P^ε is simple, nonredundant, and $\mathcal{T}$-respecting;
- $\text{cost}(P^\varepsilon) \leqslant \text{cost}(R) \leqslant (1+\varepsilon)\ \text{cost}(P)$.

Reduce does not increase the number of links. Hence, it suffices to prove that R has $21\rho n^2/\varepsilon$ nodes. By Lemma 14(ii), R is a $\mathcal{T}$-respecting path with distinct nodes.

Take an edge e of $\mathcal{T}$. We denote by N_e the set of nodes $r_i \in \text{int}(e)$. We show below that $|N_e| \leqslant 4\rho n/\varepsilon + 3n + 4$. We assume that $|N_e| \geqslant 2$; otherwise, we are done. Let r_i and r_j, $i < j$, be two nodes in N_e that are consecutive in the order along R.

Case 1. r_{i-1} is a vertex of $\mathcal{T}$. Because $r_i \in \text{int}(e)$, r_{i-1} must be one of the four vertices of the two triangles incident to e. So there are at most four such r_i's in N_e.

Case 2. There is a vertex v of $\mathcal{T}$ in $R[i,j]$. We charge r_i to v; thus there are at most n such r_i's in N_e.

Case 3. $j = i+1$. As $r_i, r_{i+1} \in \text{int}(e)$, r_i and r_{i+1} are not vertices of $\mathcal{T}$. Neither is r_{i-1} as Case 1 does not apply. By Lemma 14(iii), (r_{i-1}, r_i, r_{i+1}) is a subpath of Q_0. We have $\overline{r_i r_{i+1}} \subset \text{int}(e)$ as $r_i, r_{i+1} \in \text{int}(e)$. It follows that r_i is a critical node in Q_0 because Q_0 is nonredundant and $\mathcal{T}$-respecting.

Case 4. There is no vertex of $\mathcal{T}$ in $R[i,j]$, but there is a critical node r_k in $\text{int}(R[i,j])$. We charge r_i to r_k. Lemma 14(iii) implies that $R[i,j]$ is a subpath of Q_0. Thus r_k is also a critical node in Q_0.

Case 5. There is no vertex of $\mathcal{T}$ in $R[i,j]$ and no critical node in $\text{int}(R[i,j])$. Again, Lemma 14(iii) implies that $R[i,j]$ is a subpath of Q_0. Because Q_0 is $\mathcal{T}$-respecting and nonredundant, all of the nodes in $\text{int}(R[i,j])$ are transversal nodes. By Lemma 15, we have $\text{cost}(R[i,j]) > \delta$. Because $\text{cost}(R) \leqslant (1+\varepsilon)\,\text{cost}(P) < 2\,\text{cost}(P)$ and $\delta = \frac{\varepsilon}{2\rho n}\,\text{cost}(P)$, we get $\text{cost}(R[i,j]) > \frac{\varepsilon}{4\rho n}\,\text{cost}(R)$. So there are at most $4\rho n/\varepsilon$ such r_i's in N_e.

Cases 1, 2, and 5 contribute at most $4\rho n/\varepsilon + n + 4$ nodes to N_e. The nodes in Cases 3 and 4 are critical nodes in Q_0. By Lemma 12(iii), there are at most $2n$

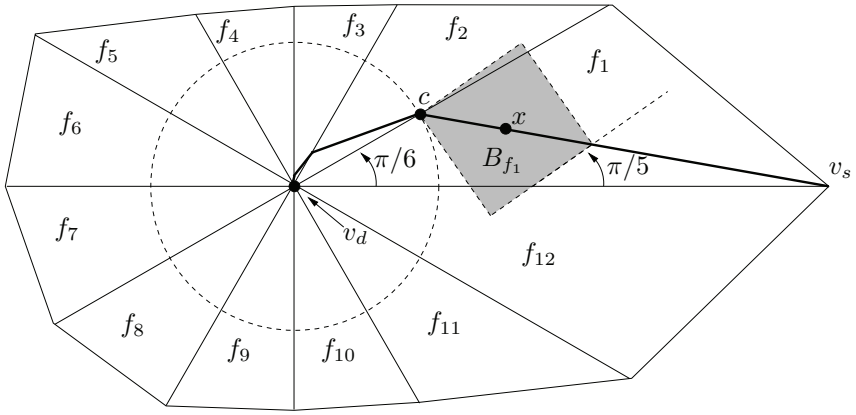

FIG. 8. *B_{f_1} is a square centered at the origin and with edge length $\sqrt{2}$. B_{f_i} is obtained by rotating B_{f_1} by an angle $(i-1)\pi/6$. We know that the shortest path from v_s to v_d is not polygonal. We conjecture that the shortest path from v_s to v_d is an infinite sequence of line segments, forming a spiral around v_d.*

critical nodes in Q_0, so Cases 3 and 4 contribute at most $2n$ nodes to N_e. In all, $|N_e| \leqslant 4\rho n/\varepsilon + 3n + 4$. The number of edges is at most $3n-6$ for a planar graph with n vertices. Summing over all edges of $\mathcal{T}$ and including the vertices of $\mathcal{T}$, the number of nodes in R is at most $n + (3n-6)(4\rho n/\varepsilon + 3n + 4) \leqslant 21\rho n^2/\varepsilon$. □

6. General paths. The statement of Theorem 16 is not entirely satisfactory. For instance, it does not tell us whether there exists a shortest path and if so, whether it is a polygonal path. We give an example in section 6.1 in which the shortest path cannot be polygonal. Nonetheless, we show that there exists a shortest rectifiable path. Intuitively, a path is rectifiable if its length is finite; for example, the class of rectifiable paths includes piecewise C^1 paths. Furthermore, we show that for any $\alpha > 1$, there exists a polygonal path with cost at most α times the optimal. These results imply Corollary 7 in section 3.4.

Throughout this section we do not require the endpoints of a path to be v_s and v_d. Also, we do not require paths to be polygonal unless stated explicitly otherwise.

6.1. Example of a nonpolygonal shortest path. There may not be any (exact) shortest polygonal path. We give an example in Figure 8 in which $\rho = \sqrt{2}$ and there is no shortest polygonal path.

We prove it by contradiction. Consider the points x and c in Figure 8. Assume that the last link of a polygonal path P is $\overline{xv_d}$. Then, if we insert the node c between x and v_d in P (thus replacing the subpath (x, v_d) by (x, c, v_d)), we obtain a polygonal path with strictly smaller cost than P. The same argument shows that the shortest path intersects some edge an infinite number of times.

A similar example can be constructed for any $\rho > 1$ by changing B_{f_i} into a regular polygon with enough edges and by placing a larger number of faces around v_d.

6.2. Rectifiable paths. Intuitively, a path is rectifiable if it has finite length. The length of a path can be defined as the supremum of the length of the polygonal paths inscribed in this path. This definition is a common way of introducing the length of a curve; for instance, see Guggenheimer's book [9]. It allows one to define the length of a curve that is not necessarily piecewise C^1. It can also be proved

that, for a C^1 curve, the length defined in this way coincides with the other usual definition through calculus, where the length is obtained by integrating the norm of the derivative of the curve [9, Theorem 2-3].

We do not require paths to be polygonal, so a path is a continuous function $\pi : [a, b] \to |\mathcal{T}|$ where $a < b \in \mathbb{R}$. We use $\pi[a, b]$ to denote $\{\pi(t) : a \leqslant t \leqslant b\}$ and $\pi(a, b)$ to denote $\{\pi(t) : a < t < b\}$. We say that π is a path from x to y if $\pi(a) = x$ and $\pi(b) = y$.

An $[a, b]$-*sequence* is a finite increasing sequence $\sigma = (t_0, t_1, \ldots, t_m)$ such that $a = t_0 < t_1 < \cdots < t_m = b$. A polygonal path *inscribed in* π is a polyline $\pi_\sigma = (\pi(t_0), \pi(t_1), \ldots, \pi(t_m))$ such that σ is an $[a, b]$-sequence for some $a < b$. When there is no ambiguity, we abuse notation and use π_σ to denote $\bigcup_{i=1}^{m} \overline{\pi(t_{i-1})\pi(t_i)}$.

The *length* of a path $\pi : [a, b] \to |\mathcal{T}|$ is defined as

$$\text{length}(\pi) = \sup\{\, \text{length}(\pi_\sigma) : \sigma \text{ is an } [a, b]\text{-sequence}\,\}.$$

The path π is *rectifiable* if length(π) is finite.

An inscribed polygonal path π_σ is not necessarily contained in $|\mathcal{T}|$. However, there always exists an inscribed polygonal path contained in $|\mathcal{T}|$.

LEMMA 17. *For any path $\pi : [a, b] \to |\mathcal{T}|$, there exists an $[a, b]$-sequence σ such that $\pi_\sigma \subset |\mathcal{T}|$.*

Proof. Let F denote the set of edges e of $\mathcal{T}$ such that $e \cap \pi(a, b) \neq \emptyset$. We prove the lemma by induction on $|F|$. If $F = \emptyset$, then $\pi(a, b)$ lies in a face of $\mathcal{T}$ and we are done. Otherwise, let S denote the union of the faces that contain $\pi(a)$. Note that S is star-shaped around a; i.e., for any $x \in S$, we have $\overline{ax} \subset S$. If $\pi(b) \in S$, we are done (choose $\sigma = (a, b)$). Otherwise, let $c = \max\{t : \pi(t) \in S\}$. Then $\pi(c, b)$ does not intersect any edge e in F such that $e \subset S$. Thus, by our induction hypothesis, there is a $[c, b]$-sequence σ' such that $\pi_{\sigma'} \subset |\mathcal{T}|$. Choosing σ as the concatenation of (a) and σ', we conclude that $\pi_\sigma \subset |\mathcal{T}|$. ∎

6.3. Cost distance. We introduce a new distance function and prove some of its properties. This distance function yields a measure of the cost of a path. We prove that this new cost measure coincides with the path cost defined in section 2 in the case of polygonal paths. We also prove the existence of an optimal rectifiable path under this cost measure, and so the optimal path can be approximated using our algorithmic result in section 3.

Let x, y be two points in $|\mathcal{T}|$. The *cost distance* from x to y, denoted by $\mathrm{d}(x, y)$, is defined as follows:

$$\mathrm{d}(x, y) = \inf\{\text{cost}(P) : P \text{ is a polygonal path from } x \text{ to } y \text{ and } P \subset |\mathcal{T}|\}.$$

The distance function $\mathrm{d}(\cdot, \cdot)$ is well defined, as the cost of a polygonal path is well defined and positive. It has several useful properties, listed in the following lemma. In particular, it is continuous. On the contrary, $\text{cost}(\overline{xy})$ may not be continuous in (x, y), for instance, when we move $\overline{xy}$ from the interior of a face to its boundary.

LEMMA 18. *The cost distance has the following properties.*

(i) *For any $x, y \in |\mathcal{T}|$, $x = y$ if and only if $\mathrm{d}(x, y) = 0$.*
(ii) *For any $x, y, z \in |\mathcal{T}|$, $\mathrm{d}(x, z) \leqslant \mathrm{d}(x, y) + \mathrm{d}(y, z)$.*
(iii) *For any $x, y \in |\mathcal{T}|$, $\|xy\| \leqslant \mathrm{d}(x, y)$.*
(iv) *$\mathrm{d}(\cdot, \cdot)$ is continuous over $|\mathcal{T}|^2$.*
(v) *For any $x, z \in |\mathcal{T}|$, there exists $y \in |\mathcal{T}|$ such that $\mathrm{d}(x, y) = \mathrm{d}(y, z) = \mathrm{d}(x, z)/2$.*

Proof. The correctness of (i), (ii), and (iii) follow from the definition of $\mathrm{d}(\cdot,\cdot)$ and the triangle inequality.

We now prove (iv). Let x_0 and y_0 be two points in $|\mathcal{T}|$. Let D_δ and D'_δ denote the disks centered at x_0 and y_0 with radius δ, respectively. We assume that $\delta > 0$ is sufficiently small so that $D_\delta \cap |\mathcal{T}|$ and $D'_\delta \cap |\mathcal{T}|$ are star-shaped around x_0 and y_0, respectively. So, for any $x \in D_\delta \cap |\mathcal{T}|$ and for any $y \in D'_\delta \cap |\mathcal{T}|$, we have $|\mathrm{d}(x,y) - \mathrm{d}(x_0,y_0)| \leqslant \mathrm{d}(x,x_0) + \mathrm{d}(y_0,y) \leqslant \rho\,\|x_0x\| + \rho\,\|y_0y\|$. It follows that $\lim_{(x,y)\to(x_0,y_0)} \mathrm{d}(x,y) = \mathrm{d}(x_0,y_0)$. Thus $\mathrm{d}(\cdot,\cdot)$ is continuous over $|\mathcal{T}|^2$.

We now prove (v). By definition, for any $n \in \mathbb{N}$, there exists a polygonal path $A_n \subset |\mathcal{T}|$ from x to z such that $\mathrm{cost}(A_n) \leqslant \mathrm{d}(x,z) + 2/n$. There is a point y_n on A_n such that the cost of the subpath from x to y_n is $\mathrm{cost}(A_n)/2$. Then $\mathrm{d}(x,y_n) \leqslant \mathrm{d}(x,z)/2 + 1/n$ and $\mathrm{d}(y_n,z) \leqslant \mathrm{d}(x,z)/2 + 1/n$. Since $|\mathcal{T}|$ is compact, $\{y_n\}$ has a limit point, which we denote by y. By (iv), the cost distance $\mathrm{d}(\cdot,\cdot)$ is continuous; thus $\mathrm{d}(x,y) \leqslant \lim_{n\to\infty} \mathrm{d}(x,z)/2 + 1/n = \mathrm{d}(x,z)/2$. Similarly, $\mathrm{d}(y,z) \leqslant \mathrm{d}(x,z)/2$. We complete the proof using (ii). ∎

Properties (i) and (ii) show that $\mathrm{d}(\cdot,\cdot)$ is a quasi metric: it is similar to a metric, except that it is not symmetric.

6.4. Cost of a rectifiable path. We define a measure of path cost using the distance function $\mathrm{d}(\cdot,\cdot)$. Our definition is similar to the definition of the length of a rectifiable path. The exposition of this section follows the lecture notes by Lang [10] on metric geometry and the book by D. Burago, Y. Burago, and Ivanov [3]. The results in these notes and this book do not apply to our problem directly, because $\mathrm{d}(\cdot,\cdot)$ is not a metric, so we reprove the results we need.

The d-*cost* of a path $\pi : [a,b] \to |\mathcal{T}|$ is defined as

$$C(\pi) = \sup\left\{ \sum_{i=1}^{m} \mathrm{d}(\pi(t_{i-1}),\pi(t_i)) : \sigma = (t_0,\ldots,t_m) \text{ is an } [a,b]\text{-sequence such that } \pi_\sigma \subset |\mathcal{T}| \right\}.$$

By Lemma 17, the above supremum is well defined. We say that π is $\mathcal{T}$-*rectifiable* if $C(\pi)$ is finite.

The above definition of the d-cost works for paths specified as maps. We can extend it to polygonal paths as follows. Let $P = (p_0,\ldots,p_m)$ be a polygonal path. Construct the map $\pi : [0,1] \to |\mathcal{T}|$ such that $\pi(i/m) = p_i$ for any integer $i \in [0,m]$, and π is affine over $[(i-1)/m, i/m]$ for any integer $i \in [1,m]$. Then we define $C(P) = C(\pi)$. The following lemma shows that $C(P)$ coincides with $\mathrm{cost}(P)$ as defined in section 2.

LEMMA 19. *For any polygonal path P, we have $C(P) = \mathrm{cost}(P)$.*

Proof. We associate P with a function $\pi : [0,1] \to |\mathcal{T}|$ as explained earlier. Since $\pi[t,t']$ is a polygonal path from $\pi(t)$ to $\pi(t')$, by the definition of $\mathrm{d}(\cdot,\cdot)$, we know that for any $t < t'$ in $[0,1]$, $\mathrm{d}(\pi(t),\pi(t')) \leqslant \mathrm{cost}(\pi[t,t'])$. It follows that $C(P) \leqslant \mathrm{cost}(P)$.

We now prove that $C(P) \geqslant \mathrm{cost}(P)$. We put a ball with radius δ centered at each node of P, each crossing between P and the edges of $\mathcal{T}$, each crossing between links of P, and each vertex of $\mathcal{T}$ lying on P. We make δ sufficiently small so that the balls are mutually disjoint, each ball intersects only the link(s) of P that contain the ball center, and each ball intersects only the edge(s) and face(s) of $\mathcal{T}$ that contain the ball center.

Assume that there are k links in P. Since $\mathcal{T}$ has $O(n)$ vertices and edges, there are $O(k^2 + kn)$ balls. We denote by $\mathcal{B}$ the set of points in these balls. Clearly, $P \setminus \mathcal{B}$ is a collection of disjoint line segments, each lying in the interior of an edge or a face of $\mathcal{T}$.

Pick a line segment $\overline{xy}$ in $P \setminus \mathcal{B}$. First, assume that $\overline{xy}$ lies in the interior of a face f of $\mathcal{T}$. Let ε be the Euclidean distance between $\overline{xy}$ and $\mathrm{bd}(f)$. Let $[a, b]$ be the subinterval of $[0, 1]$ such that $\pi[a, b] = \overline{xy}$. Consider any $[a, b]$-sequence $(s_0, \ldots, s_\ell)$ such that $\|\overline{\pi(s_{i-1})\pi(s_i)}\| < \varepsilon/\rho$ for any i. So $\mathrm{cost}(\overline{\pi(s_{i-1})\pi(s_i)}) < \varepsilon$ for any i. Consider any polygonal path from $\pi(s_{i-1})$ to $\pi(s_i)$. If the path stays in $\mathrm{int}(f)$, its cost is no less than $\mathrm{cost}(\overline{\pi(s_{i-1})\pi(s_i)})$. If the path reaches $\mathrm{bd}(f)$, then the path cost is at least $\varepsilon > \mathrm{cost}(\overline{\pi(s_{i-1})\pi(s_i)})$. It follows that $\mathrm{d}(\pi(s_{i-1}), \pi(s_i)) = \mathrm{cost}(\overline{\pi(s_{i-1})\pi(s_i)})$ for any i. If $\overline{xy}$ lies in the interior of an edge of $\mathcal{T}$, let F be the union of the face(s) incident to e and let ε be the distance between $\overline{xy}$ and $\mathrm{bd}(F) \setminus \mathrm{int}(e)$. Again, we obtain $\mathrm{d}(\pi(s_{i-1}), \pi(s_i)) = \mathrm{cost}(\overline{\pi(s_{i-1})\pi(s_i)})$ by considering separately polygonal paths that stay in $\mathrm{int}(F) \cup \mathrm{int}(e)$ and polygonal paths that reach $\mathrm{bd}(F) \setminus \mathrm{int}(e)$.

Consider any $[0, 1]$-sequence $\sigma = (t_0, \ldots, t_m)$ such that $\pi_\sigma \subset |\mathcal{T}|$ and for each endpoint x of a segment in $P \setminus \mathcal{B}$, there exists $i \in [0, m]$ such that $\pi(t_i) = x$. This implies that if $[a, b]$ is a subinterval of $[0, 1]$ such that $\pi[a, b] = \overline{xy}$ for a segment $\overline{xy}$ in $P \setminus \mathcal{B}$, then σ contains a $[a, b]$-sequence. Then the result in the previous paragraph implies that $\sum_{i=1}^{m} \mathrm{d}(\pi(t_{i-1}), \pi(t_i)) \geqslant \sum_{\overline{xy}} \mathrm{cost}(\overline{xy})$, where the second sum runs over all segments $\overline{xy}$ in $P \setminus \mathcal{B}$. Since $C(P) = C(\pi)$ is the supremum over all $[0, 1]$-sequences that yields a polygonal path in $|\mathcal{T}|$, we conclude that $C(P) = C(\pi) \geqslant \sum_{\overline{xy}} \mathrm{cost}(\overline{xy})$.

The intersection $P \cap \mathcal{B}$ has a total length of $O(\delta(k^2 + kn))$. Therefore, $\mathrm{cost}(P \cap \mathcal{B}) \leqslant c\rho\delta(k^2 + kn)$ for some constant $c > 0$. By the triangle inequality, $\sum_{\overline{xy}} \mathrm{cost}\,\overline{xy} \geqslant \mathrm{cost}(P) - c\rho\delta(k^2 + kn)$, which tends to $\mathrm{cost}(P)$ as $\delta \to 0$. Hence, $C(P) \geqslant \mathrm{cost}(P)$. ∎

Consider the infimum of $C(\pi)$ over all rectifiable paths π from a point x to another point y in $|\mathcal{T}|$. Our goal is to show that some rectifiable path from x to y achieves this infimum and hence this path is shortest. First, we show that this infimum is equal to $\mathrm{d}(x, y)$.

LEMMA 20. *For any $x, y \in |\mathcal{T}|$,*

$$\mathrm{d}(x, y) = \inf\{C(\pi) : \pi \text{ is a rectifiable path from } x \text{ to } y\}.$$

Proof. By definition, $\mathrm{d}(x, y)$ is the infimum of $\mathrm{cost}(P)$ over all polygonal paths P from x to y in $|\mathcal{T}|$. A polygonal path P is rectifiable and $C(P) = \mathrm{cost}(P)$ by Lemma 19. Therefore, $\mathrm{d}(x, y) \geqslant \inf\{C(\pi) : \pi \text{ is a rectifiable path from } x \text{ to } y\}$. Assume to the contrary that $\mathrm{d}(x, y) > \inf\{C(\pi) : \pi \text{ is a rectifiable path from } x \text{ to } y\}$. Then there exists a rectifiable path $\pi' : [a, b] \to |\mathcal{T}|$ from x to y such that $\mathrm{d}(x, y) > C(\pi')$. It follows from the definition of $C(\pi')$ that there exists an $[a, b]$-sequence $\sigma = (t_0, \ldots, t_m)$ such that

$$\mathrm{d}(x, y) > \sum_{i=1}^{m} \mathrm{d}(\pi'(t_{i-1}), \pi'(t_i)).$$

However, this is impossible by Lemma 18(ii). ∎

Next, we show that $\mathcal{T}$-rectifiability is equivalent to rectifiability. It follows that any rectifiable path has a finite d-cost (in particular, any piecewise C^1 path).

LEMMA 21. *A path π in $|\mathcal{T}|$ is rectifiable if and only if π is $\mathcal{T}$-rectifiable.*

Proof. Suppose that a path $\pi : [a, b] \to |\mathcal{T}|$ is rectifiable. By definition, $C(\pi)$ is equal to the supremum of $\sum_{i=1}^{m} \mathrm{d}(\pi(t_{i-1}), \pi(t_i))$ over all $[a, b]$-sequences $\sigma = (t_0, \ldots, t_m)$

such that $\pi_\sigma \subset |\mathcal{T}|$. By Lemmas 19 and 20, we have

$$\mathrm{d}(\pi(t_{i-1}), \pi(t_i)) \leqslant C\left(\overline{\pi(t_{i-1})\pi(t_i)}\right) = \mathrm{cost}\left(\overline{\pi(t_{i-1})\pi(t_i)}\right).$$

Thus, $C(\pi) \leqslant \sup_\sigma \mathrm{cost}(\pi_\sigma) \leqslant \sup_\sigma \rho\ \mathrm{length}(\pi_\sigma)$. By definition,

$$\mathrm{length}(\pi) \geqslant \mathrm{length}(\pi_\sigma).$$

Therefore, $C(\pi) \leqslant \rho\ \mathrm{length}(\pi)$ which is finite as π is rectifiable. So π is $\mathcal{T}$-rectifiable.

Suppose that a path $\pi : [a, b] \to |\mathcal{T}|$ is $\mathcal{T}$-rectifiable. By definition, $\mathrm{length}(\pi) = \sup_\sigma \mathrm{length}(\pi_\sigma)$, where the supremum is taken over all $[a, b]$-sequences. For each such σ, by applying Lemma 17 to successive numbers in σ, we can find an $[a, b]$-sequence σ' such that σ is a subsequence of σ' (and thus $\mathrm{length}(\pi_\sigma) \leqslant \mathrm{length}(\pi_{\sigma'})$) and $\pi_{\sigma'} \subset |\mathcal{T}|$. Therefore, it is also true that $\mathrm{length}(\pi) = \sup_\sigma \mathrm{length}(\pi_\sigma)$ over all $[a, b]$-sequences σ such that $\pi_\sigma \subset |\mathcal{T}|$. By Lemma 18(iii), we have $\mathrm{length}(\pi_\sigma) \leqslant \sum_{i=1}^{m} \mathrm{d}(\pi(t_{i-1}), \pi(t_i))$ for any $\sigma = (t_0, \ldots, t_m)$. Therefore,

$$\mathrm{length}(\pi) = \sup_\sigma \mathrm{length}(\pi_\sigma) \leqslant \sup_\sigma \left\{ \sum_{i=1}^{m} \mathrm{d}(\pi(t_{i-1}), \pi(t_i)) \right\}$$

over all $[a, b]$-sequences $\sigma = (t_0, \ldots, t_m)$ such that $\pi_\sigma \subset |\mathcal{T}|$. By definition, the right-hand side is equal to $C(\pi)$, which is finite as π is $\mathcal{T}$-rectifiable. So $\mathrm{length}(\pi)$ is finite and π is rectifiable. □

We are ready to show that there exists a shortest rectifiable path from x to y. The proof is analogous to the proof of the midpoint lemma in the lecture notes by Lang [10] and the proof in the book by D. Burago, Y. Burago, and Ivanov [3, Theorem 2.4.16].

THEOREM 22. *For any $x, y \in |\mathcal{T}|$, there exists a rectifiable path π^* from x to y such that*

$$C(\pi^*) = \inf\{C(\pi) : \pi \text{ is a rectifiable path from } x \text{ to } y\}.$$

Proof. We claim that it suffices to prove the existence of a path $\pi^* : [0, 1] \to |\mathcal{T}|$ from x to y such that $C(\pi^*) \leqslant \mathrm{d}(x, y)$. Notice that, if this is true, π^* is $\mathcal{T}$-rectifiable and hence rectifiable by Lemma 21. Then $\mathrm{d}(x, y) \leqslant C(\pi^*)$ by Lemma 20 and so $C(\pi^*) = d(x, y)$. We assume, without loss of generality, that $\mathrm{d}(x, y) = 1$.

Let $U = \{i/2^j : i, j \in \mathbb{N} \text{ and } 0 \leqslant i/2^j \leqslant 1\}$. First, we recursively define π^* over U, starting with $\pi^*(0) = x$ and $\pi^*(1) = y$. By Lemma 18(v), we can choose $\pi^*(1/2)$ such that $\mathrm{d}(\pi^*(0), \pi^*(1/2)) = \mathrm{d}(\pi^*(1/2), \pi^*(1)) = 1/2$. We repeat this process recursively: we choose $\pi^*(3/4)$ such that $\mathrm{d}(\pi^*(1/2), \pi^*(3/4)) = \mathrm{d}(\pi^*(3/4), \pi^*(1)) = 1/4$, and so on. This completes the definition of π^* over U.

With this construction, for any $r < r' \in U$, we have $\mathrm{d}(\pi^*(r), \pi^*(r')) \leqslant r' - r$. Thus, by Lemma 18(iii), we have $\|\pi^*(r)\pi^*(r')\| \leqslant r' - r$. In other words, π^* is Lipschitz over U. As U is dense in $[0, 1]$, we can extend π^* to a Lipschitz (and thus continuous) function over $[0, 1]$, by taking

$$\forall t \in [0, 1], \pi^*(t) = \lim_{\substack{r \in U \\ r \to t}} \pi^*(r).$$

By Lemma 18(iv), we know that $\mathrm{d}(\cdot, \cdot)$ is continuous. Thus, as $\mathrm{d}(\pi^*(r), \pi^*(r')) \leqslant r' - r$ for any $r < r' \in U$, we conclude that $\mathrm{d}(\pi^*(t), \pi^*(t')) \leqslant t' - t$ for any $t < t' \in [0, 1]$.

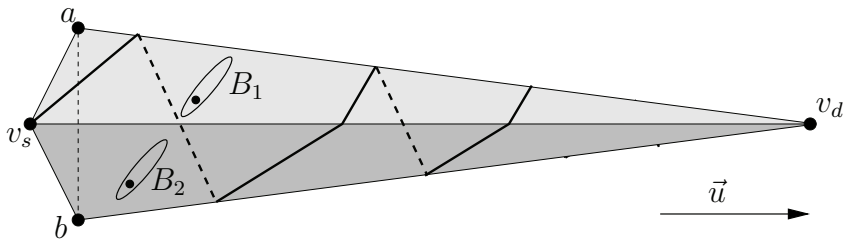

FIG. 9. *The terrain is formed by triangles abv_d, av_sv_d, and bv_sv_d. The ellipses B_1 and B_2 are the unit balls of faces av_sv_d and bv_sv_d, respectively. The vertices a, b, and v_s are fixed, and the convex distance functions are fixed. When v_d goes to infinity in direction $\vec{u}$, the number of times a* 1.01*-approximate shortest path has to turn around the axis $(v_d, \vec{u})$ goes to infinity.*

Finally, by definition, $C(\pi^*) = \sup_\sigma\{\sum_{i=1}^m \mathrm{d}(\pi^*(t_{i-1}), \pi^*(t_i))\}$ over all $[0,1]$-sequences $\sigma = (t_0, \ldots, t_m)$ such that $\pi_\sigma \subset |\mathcal{T}|$. We have proved that

$$\mathrm{d}(\pi^*(t_{i-1}), \pi^*(t_i)) \leqslant t_i - t_{i-1}.$$

So $\sum_{i=1}^m \mathrm{d}(\pi^*(t_{i-1}), \pi^*(t_i)) \leqslant 1$. Hence, $C(\pi^*) \leqslant 1 = \mathrm{d}(x, y)$. □

By the definition of a $\mathcal{T}$-rectifiable path, the following corollary holds.

COROLLARY 23. *For any $\alpha > 1$ and for any $x, y \in |\mathcal{T}|$, there exists a polygonal path S^α from x to y such that $\mathrm{cost}(S^\alpha) = C(S^\alpha) \leqslant \alpha\, C(\pi^*)$, where π^* is a shortest rectifiable path from x to y.*

Theorem 22 and Corollary 23 allow us to apply the results in sections 3 and 5 to approximate the shortest rectifiable path. We summarize our main results in the following.

- Theorem 22 shows that there is a shortest rectifiable path. Furthermore, Corollary 23 shows that, for any $\alpha > 1$, there exists a polygonal path with cost at most α times the optimal.
- Corollary 23 and Theorem 16 imply that, for any $\varepsilon \in (0,1)$, there exists a $(21\rho n^2/\varepsilon)$-link path with cost at most $(1+\varepsilon)$ times the optimal.
- Corollary 23 and Theorem 16 allow us to apply Theorem 5 to approximate shortest paths in anisotropic regions. As stated in Corollary 7, for any $\varepsilon \in (0,1)$, we can compute in time $O(\frac{\rho^2 \log \rho}{\varepsilon^2} n^3 \log(\frac{\rho n}{\varepsilon}))$ a polygonal path S with cost at most $(1+\varepsilon)$ times the optimal.

7. Conclusion. We have given algorithms for shortest path problems in planar subdivisions. A natural question is whether our results can be generalized to higher dimensions. The algorithms for k-link paths that we presented in section 3, as well as the proof of the existence of a shortest rectifiable path (section 6), generalize directly to the case where $\mathcal{T}$ is a 2D simplicial complex properly embedded in $\mathbb{R}^d$ (for any integer d).

However, our bound $O(\rho n^2/\varepsilon)$ on the number of links of an approximate shortest path (Theorem 16) does not generalize to higher dimensions. It does not even generalize to the case of a terrain. See the example shown in Figure 9, where $n = 4$ and ρ is fixed. The number of edges in a 1.01-approximate shortest path goes to infinity when v_d goes to infinity in direction $\vec{u}$.

A PRIMAL-DUAL BICRITERIA DISTRIBUTED ALGORITHM FOR CAPACITATED VERTEX COVER*

F. GRANDONI†, J. KÖNEMANN‡, A. PANCONESI§, AND M. SOZIO¶

Abstract. In this paper we consider the capacitated vertex cover problem, which is the variant of vertex cover where each node is allowed to cover a limited number of edges. We present an efficient, deterministic, distributed approximation algorithm for the problem. Our algorithm computes a $(2+\epsilon)$-approximate solution which violates the capacity constraints by a factor of $(4+\epsilon)$ in a polylogarithmic number of communication rounds. On the other hand, we also show that every efficient distributed approximation algorithm for this problem must violate the capacity constraints. Our result is achieved in two steps. We first develop a 2-approximate, sequential primal-dual algorithm that violates the capacity constraints by a factor of 2. Subsequently, we present a distributed version of this algorithm. We demonstrate that the sequential algorithm has an inherent need for synchronization which forces any naive distributed implementation to use a linear number of communication rounds. The challenge in this step is therefore to achieve a reduction of the communication complexity to a polylogarithmic number of rounds without worsening the approximation guarantee.

Key words. vertex cover, approximation algorithms, distributed algorithms, primal-dual algorithms

1. Introduction.

The *capacitated vertex cover* problem (capVC) is the variant of vertex cover in which there is a limit on the number of edges that a vertex can cover. A precise formulation of the problem is as follows. We are given an n-vertex undirected graph $G=(V,E)$, nonnegative weights wt_v, and vertex capacities $B_v \geq 1$ for all vertices $v \in V$. A solution to a given capVC instance consists of a subset $C \subseteq V$ and an assignment $\pi : E \to C$ of edges to vertices such that

1. $\pi(e) \in \{u,v\} \cap C \ \forall$ edges $e=(u,v) \in E$, and
2. $|\pi^{-1}(v)| \leq B_v \ \forall\ v \in C$.

The first set of constraints says that every edge must be covered by some vertex in the cover C. The second condition limits the number of edges that can be assigned to any cover vertex v to B_v. The goal is to find a feasible solution that has minimum total weight

$$\mathrm{wt}(C) := \sum_{v \in C} \mathrm{wt}_v.$$

We emphasize the difference between the above *hard-capacity* version of capVC and its *soft-capacity* counterpart (capVC$_s$): in capVC$_s$, each vertex $v \in V$ may be included $x_v \geq 0$ times in a cover. Vertex v then contributes $x_v \mathrm{wt}_v$ to the weight of the cover, and the maximum number of edges that can be assigned to v is $x_v B_v$.

In this paper we present *bicriteria* sequential and distributed approximation algorithms for the (hard) capacitated vertex cover problem. Given a feasible instance of the problem of optimal weight opt, our sequential primal-dual algorithm computes a vertex cover C of weight $\sum_{v \in C} \mathrm{wt}_v \leq 2\mathrm{opt}$, which assigns at most $2B_v$ edges to each cover vertex $v \in C$. Note that, differently from the hard-capacity case, capacities might be violated. However, the amount of the violation is bounded, which is not the case for capVC$_s$. We also remark that, unlike capVC$_s$, every $v \in C$ contributes wt_v to the weight of the cover even when its capacity B_v is exceeded.

The distributed implementation of our method has an additional input parameter $\epsilon > 0$ and computes a cover of weight at most $(2+\epsilon)\mathrm{opt}$ that violates the capacity bound of each cover vertex by a factor of at most $(4+\epsilon)$. In the synchronous, message-passing model of computation, the distributed algorithm takes $O(\log(nW)/\epsilon)$ many rounds, where

$$W = \mathrm{wt}_{max}/\mathrm{wt}_{min}$$

is the ratio of largest to smallest vertex weight in the given instance. This reduces to $O(\log n/\epsilon)$ for the interesting case of unit weights. We remark that our algorithm is deterministic, while typically efficient distributed algorithms for graph problems require randomization (see [11, 20, 22, 23, 26, 27] among others).

Observe that any sublinear distributed algorithm for capVC must violate the capacity constraints. Consider for instance a ring where every vertex has unit capacity. A feasible solution provides a consistent orientation of the ring, something that requires a linear number of communication rounds. Therefore a bicriteria solution is the best one can hope for in a distributed setting. In this paper we show that indeed every efficient distributed approximation algorithm for capVC must violate the capacity constraints by a large additive term.

In our opinion the most interesting aspect of our work is that the distributed algorithm is derived in a systematic fashion from a sequential primal-dual algorithm. To our knowledge, the first result of this kind is the $(2+\epsilon)$-approximate vertex cover algorithm described in [16]. Although described for the PRAM setting, the algorithm can be easily adapted to the distributed case. Our paper takes the primal-dual approach pioneered in [16] one step further, giving a new and considerably more sophisticated example. Chudak, Erlebach, and Panconesi [4] recently showed that the techniques introduced in this paper can be extended to yield efficient distributed primal-dual algorithms for vertex cover with soft capacities and for the facility location problem. The power of the primal-dual method in the design of approximation algorithms is well established. In this paper we provide further evidence to the fact that it is also a valuable tool in the design of distributed algorithms.

Capacity constraints arise naturally in distributed computing and computer networking; e.g., the scatternet-formation problem of ad hoc Bluetooth networks asks for a small dominating set where each vertex in the set dominates at most 7 vertices [6]. More generally, a small dominating set can act as the backbone of the routing infrastructure of an ad hoc network (see [28, 30] and the references therein). Capacities model computational and energy limitations and provide effective means to enforce load distribution among the vertices of the backbone. To the best of our knowledge,

our paper is the first result that considers a capacitated network design problem from the distributed computing point of view. Recently, Moscibroda and Kuhn gave an LP-based, bicriteria distributed solution to the capacitated dominating set problem [17].

Related work. Vertex covers with capacities has received considerable attention in recent years in the sequential setting, while our main motivation is to study it from a distributed point of view. The capacitated vertex-cover problem was first introduced by Guha et al. [12], who presented a simple 4-approximate LP-rounding based algorithm for capVC$_s$. Later on, the authors showed a 2-approximate primal-dual algorithm. Subsequently, Gandhi et al. [10] presented a 2-approximate LP-rounding algorithm for capVC$_s$.

The hard-capacitated vertex-cover problem is significantly harder than its soft-capacitated variant. Chuzhoy and Naor [5] first gave a sophisticated 3-approximate LP-rounding algorithm for the special case of capVC with uniform vertex weights. Finally, in [9], Gandhi et al. presented an LP-rounding-based 2-approximation algorithm for capVC with uniform weights.

In [5], Chuzhoy and Naor also showed that capVC in the presence of nonuniform vertex weights is as hard to approximate as set-cover. Lund and Yannakakis [24] proved that there is no $o(\log n)$-approximation for the latter problem unless NP $\subseteq$ DTIME($n^{O(\log\log n)}$) (see also [8] for a refined result). Based on work by Bellare et al. [3] and Raz and Safra [29], Alon, Moshkovitz, and Safra [1] recently improved upon this result and showed that no $o(\log n)$-approximation for the set-cover problem is possible unless P = NP. Chuzhoy and Naor's work implies that these hardness bounds translate to the capVC problem.

The best known approximation algorithm for the vertex-cover problem without capacity constraints is due to Karakostas [15], who presented a $2 - \Theta(1/\sqrt{\log(n)})$-approximation for the problem. This improves upon earlier $(2 - o(1))$-approximation algorithms due to Halperin [13], Bar-Yehuda and Even [2], and Hochbaum [14]. As mentioned, the same bound is essentially achievable in the distributed setting [16].

Unconditional lower-bounds based on communication constraints, as opposed to unproven complexity theoretic assumptions, have been proved since the early stages [21, 25]. For more recent work, see [18]. Also, Elkin [7] recently established trade-offs between the performance guarantee of a distributed approximation algorithm for the minimum-cost spanning tree problem and the number of communication rounds it needs.

Finally, we mention that LP-duality has been previously used to design distributed algorithms for the dominating set problem [19, 27].

Our contribution. The first result we give is a bicriteria primal-dual approximation algorithm for capVC.

THEOREM 1. *Given a feasible* capVC *instance with capacities* $B_v \geq 1$ *for all* $v \in V$*, there is a polynomial-time primal-dual algorithm that computes a vertex cover* (C, π) *of weight at most* $2opt$ *that assigns at most* $2B_v$ *edges to each vertex* $v \in C$*.*

We remark that if the input instance does not have a feasible solution, then our algorithm either computes a feasible solution for the (capacity) relaxed version of the problem or it terminates with a certificate of infeasibility.

Theorem 1 is a natural step toward proving the main result of this paper.

THEOREM 2. *Given a feasible instance of* capVC *with capacities* $B_v \geq 1$ *for all* $v \in V$*, and let* $\epsilon \in (0, 1]$ *be an input parameter. There is a distributed deterministic algorithm that computes a vertex cover* (C, π) *of weight at most* $(2+\epsilon)$opt *that assigns at most* $(4+\epsilon)B_v$ *edges to each vertex* $v \in C$*. The algorithm needs* $O(\log(nW)/\epsilon)$ *rounds.*

We remark that the message-size of our algorithm is $O(\log n + \log \mathrm{wt}_{max})$.

Note that the running time is strongly polylogarithmic for polynomially large weights only. This includes the important special case of unit weights. Obtaining a strongly polylogarithmic algorithm in general is a challenging open problem.

Similar to the sequential case, if the input instance does not have a feasible solution the algorithm either computes a feasible solution for the relaxed version of the problem, or terminates with a certificate of infeasibility. The latter, however, is necessarily local in nature. That is, some vertices will know that the algorithm has failed, but it requires a linear number of communication rounds to distribute this information across the network in general.

These theorems are complemented by the following lower-bound on the communication complexity of any algorithm for the weighted capVC problem with hard capacities.

THEOREM 3. *Let $B, k \geq 1$ be integer parameters. There is a* capVC *instance with uniform vertex capacities B, for which any distributed approximation algorithm that assigns less than $(1+1/k) \cdot B$ edges to all vertices must take at least k communication rounds.*

This result shows in particular that violating the capacity constraints is necessary and provides a trade-off between violation of capacities and running time.

Organization of this paper. In section 2 we describe a sequential algorithm for the capacitated vertex-cover problem and give a proof of Theorem 1. Section 3 shows how to turn the sequential algorithm into a distributed one. This is done in two steps. First, we show how to convert the sequential algorithm into a distributed one that computes a vertex cover that satisfies the approximation requirement. In this step we assign only a subset of the edges. In the second and final step we assign all of the remaining edges. The proof of Theorem 4 is given in section 4.

2. A sequential primal-dual algorithm. We present a so called *primal-dual* algorithm for the capVC problem. The algorithm and its analysis are based on linear programming duality. In section 3 we therefore introduce a linear programming formulation of the problem together with its dual. Following that we describe our sequential algorithm and conclude this section with an analysis of the presented method.

2.1. A linear programming formulation. The problem can be formulated as an integer program where we introduce a binary indicator variable x_v for each $v \in V$. We let $x_v = 1$ if $v \in C$ and $x_v = 0$ otherwise. For each edge $e = (u, v) \in E$ we introduce two binary variables $y_{e,v}$ and $y_{e,u}$. For $w \in \{u, v\}$ we let $y_{e,w} = 1$ if and only if $\pi(e) = w$. In the following, let $\delta(v)$ be the set of edges incident to vertex $v \in V$ in G:

$$
\begin{aligned}
&\text{(IP)} && \min \quad \sum_{v \in V} \mathrm{wt}_v \cdot x_v && \\
&\text{(1)} && \text{s.t.} \quad y_{e,v} + y_{e,u} \geq 1 && \forall e = (u, v) \in E, \\
& && \quad\ y_{e,w} \leq x_w && \forall e = (u, v) \in E, \\
&\text{(2)} && && \forall w \in \{u, v\} \\
&\text{(3)} && \quad \sum_{e=(v,u) \in \delta(v)} y_{e,v} \leq B_v \cdot x_v && \forall v \in V, \\
&\text{(4)} && \quad\ y_{e,v}, x_v \in \{0, 1\} && \forall e \in E, v \in V.
\end{aligned}
$$

We now let (LP) be the standard LP relaxation obtained from (IP) by replacing the constraints (4) by

$$\begin{aligned} y_{e,v} &\geq 0 && \forall e = (u,v) \in E, \\ 0 \leq x_v &\leq 1 && \forall v \in V. \end{aligned} \tag{5}$$

In the following we use $(i)_v$, $(i)_e$, and $(i)_{e,v}$ to denote constraint (i) for vertex $v \in V$, edge $e \in E$, and pair $(e,v) \in E \times V$, respectively. In the linear-programming dual of (LP) we associate variables $\alpha_e, \beta_{e,w}, \gamma_v$ and ω_v with constraints $(1)_e$, $(2)_{e,w}$, $(3)_v$, and $(5)_v$, respectively. The linear programming (LP) dual of is then

$$\text{(D)} \qquad \max \quad \sum_{e \in E} \alpha_e - \sum_{v \in V} \omega_v$$

$$\text{s.t.} \quad \alpha_e \leq \beta_{e,w} + \gamma_w \qquad \forall e = (u,v) \in E, \ \forall w \in \{u,v\} \tag{6}$$

$$\sum_{e=(u,v) \in E} \beta_{e,v} \leq \mathrm{wt}_v + (\omega_v - B_v \cdot \gamma_v) \qquad \forall v \in V, \tag{7}$$

$$\alpha, \beta, \gamma, \omega \geq 0.$$

2.2. The algorithm. We remark that the following simple LP rounding scheme, similar to that proposed by Guha et al. [12], yields a 2-approximate vertex cover in which each vertex v covers at most $2B_v$ edges: Solve the LP relaxation (LP) and let (x,y) be its optimal solution. The cover set C consists of all vertices v with $x_v \geq 1/2$. For $e = (u,v) \in E$, constraint $(1)_e$ implies that there is $w \in \{u,v\}$ such that $y_{e,w} \geq 1/2$. We assign edge e to vertex w in this case. Clearly, the weight of the vertices in C is at most twice the optimal LP value. Moreover, each vertex $v \in C$ has at most $2B_v$ assigned edges.

We provide an alternate primal-dual algorithm in this section. As we shall see later, this algorithm possesses an efficient distributed implementation.

The high-level idea in primal-dual algorithms is to find a pair of feasible solutions for (D) and (IP). Subsequently, we upper-bound the performance ratio of the algorithm by bounding the multiplicative gap between the objective values of the two solutions. Thus, our goal is to find a primal-dual pair of solutions whose objective functions values are within a small multiplicative constant of each other. Primal-dual algorithms typically construct such a primal-dual pair in an iterative manner: Starting from a trivial feasible dual solution and an infeasible primal one, the algorithm continuously raises the objective value of the dual solution while maintaining its feasibility, and it changes the partial primal solution in order to attain feasibility.

Our primal-dual capVC algorithm starts with the dual feasible solution $\alpha = \beta = \gamma = \omega = 0$ and the infeasible primal solution $x = y = 0$. In order to obtain a feasible vertex cover, we have to a) select a set of cover vertices, and b) assign each edge $e \in E$ to one of its endpoints (which must be in the cover). As is typical in primal-dual approximation algorithms, these decisions are governed by *primal complementary slackness*.

In the following we say that a vertex $v \in V$ is *tight* for a current dual solution $(\alpha, \beta, \gamma, \omega)$ if constraint $(7)_v$ holds with equality. Similarly, a pair $(e,w) \in E \times V$ is tight if constraint $(6)_{e,w}$ is satisfied with equality. Our algorithm will now increase the value of some of the dual variables and, as a consequence, create tight vertices and tight edge-vertex pairs. Tight vertices are candidates for our final cover and we

will eventually choose a subset of these. Each edge e will eventually be assigned to one of its tight endpoints. In particular, edge $e = (u, v) \in E$ will only be assigned to endpoint $w \in \{u, v\}$ if (e, w) is tight. Once an edge is assigned to a vertex, we will remove it from the graph and continue. Similarly, once all edges incident to a certain vertex $v \in V$ have been decided, the vertex is removed from the graph. The algorithm terminates, when the graph is empty and, hence, when all edges have been assigned.

We now describe the algorithm. As customary with primal-dual algorithms, we describe it as a continuous process that can be implemented in polynomial-time by standard techniques. Initially all edges are unassigned. At any given point, the algorithm increases the value of dual variables α_e of all unassigned edges uniformly at the same (unit) rate. Increasing variables α_e for unassigned edges increases the left-hand side of constraints of type (6) and we will have to also increase some of the β and γ variables in order to maintain dual feasibility. We describe the update process for these variables for each vertex $v \in V$ depending on its tightness.

v is nontight. In this case, we increase $\beta_{e,v}$ for all $e \in \delta(v)$ uniformly. Thus, the left- and right-hand side of constraint $(6)_{e,v}$ for all $e \in \delta(v)$ increase at the same rate and feasibility is maintained.

v is tight. If v has at most $2B_v$ incident edges, we add v to the cover, assign all edges in $\delta(v)$ to v, and delete v and the newly assigned edges from G. Otherwise v has more than $2B_v$ incident edges. In this case, we increase ω_v at rate B_v, γ_v at unit rate, and we leave $\beta_{e,v}$ as is for all $e \in \delta(v)$. As a consequence, the left- and right-hand sides of $(7)_v$ remain unchanged, and the left- and right-hand sides of $(6)_{e,v}$ for all $e \in \delta(v)$ change at the same (unit) rate. Feasibility is therefore also maintained in this case.

We emphasize that our algorithm maintains a feasible dual solution for (D) for the original instance. In particular, deleting a vertex v and an edge $e \in \delta(v)$ means that the values of variables $\alpha_e, \beta_{e,v}, \omega_v$, and γ_v are frozen at their current state from this point on in the algorithm. The algorithm terminates when all edges have been assigned.

We demonstrate the algorithm using the example instance in Figure 1(i), where we let $B_u = 2$, $B_v = 3$, and $B_w = \infty$ for all other vertices w. We also choose $\mathrm{wt}_a = 2$, $\mathrm{wt}_u = 5$, $\mathrm{wt}_v = 6$, and all other vertices which have infinite weight. In the following we use V and E to refer to the vertex and edge sets of the given instance.

Running our algorithm for one time unit results in $\alpha_e = 1$ for all $e \in E$ and $\beta_{e,w} = 1$ for all $w \in V$ and for all $e \in \delta(w)$. At this point, constraint $(7)_u$ is tight. As u has $5 > 2 \cdot B_u = 4$ unassigned incident edges, we cannot assign any edge at

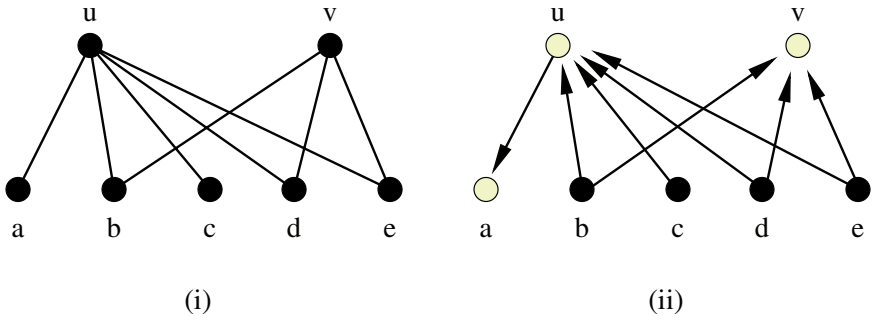

FIG. 1. *An example instance for the primal-dual capVC algorithm.*

this point. Thus, we continue to increase α_e for all edges $e \in E$. Simultaneously, we increase $\beta_{e,w}$ for all $w \in V \setminus \{u\}$ and for all $e \in \delta(w)$ at unit rate, increase ω_u at rate $B_u = 2$, and increase γ_u at unit rate.

After one more time unit, the positive dual variable values are

$$\begin{aligned} \alpha_e &= 2 \quad \forall e \in E, \\ \beta_{e,u} &= 1 \quad \forall e \in \delta(u), \\ \beta_{e,w} &= 2 \quad \forall w \in V \setminus \{u\}, \forall e \in \delta(w), \\ \omega_u &= 2, \\ \gamma_u &= 1. \end{aligned}$$

At this point, vertices a, u, and v are tight. Vertices a and v have one and three incident edges, respectively, and we can hence add both vertices to the cover and delete them and their incident edges from the graph. The number of remaining edges all of which are incident to u is now $4 = 2B_u$. We can assign all of them to u.

Figure 1(ii) shows the computed primal solution; cover vertices are shaded and arc directions indicate edge assignment. We note that the primal solution is feasible for (IP) only if we relax the capacity constraint of vertex u. In fact, it is not hard to see that any feasible solution to (IP) for this instance must have infinite weight.

2.3. Analysis. In this section we present a proof of Theorem 1.

Assume first that the algorithm from section 2.2 does not terminate for a given input instance. It is then not hard to see that the algorithm must reach a point in the execution, where each tight vertex $v \in V$ has a degree of more than $2B_v$ and where each remaining edge is incident to tight vertices on both ends. Using the pigeon-hole principle, it follows that, in any assignment of edges to vertices, there must be at least one tight vertex v that is assigned more than B_v edges. Thus the given input instance is infeasible, and the set of tight vertices together with the set of unassigned edges certifies this fact.

In the following we focus on feasible capVC instances. For such instances our algorithm terminates with a cover $\mathcal{C}$, an assignment $\{y_{e,v}\}_{e \in E, v \in V}$ of edges to vertices in the cover, and a corresponding dual solution $(\alpha, \beta, \omega, \gamma)$. We first show that the dual is feasible for (D).

LEMMA 1. *The dual solution* $(\alpha, \beta, \omega, \gamma)$ *is feasible for* (D).

Proof. We can think of the execution of the algorithm as a process over time: The algorithm starts at time zero and then raises α_e by one for all edges per unit of time. We prove the lemma by induction on (appropriately discretized) time.

Our initial dual solution is clearly feasible. Now consider a later time in the algorithm. Let $\mathcal{O}$ be the set of tight vertices at that time.

For a vertex $v \in V \setminus \mathcal{O}$ and for an edge $e \in \delta(v)$ we raise α_e and $\beta_{e,v}$ simultaneously and hence maintain dual feasibility. For a vertex $v \in \mathcal{O}$ we raise ω_v at a rate of B_v per time unit and raise γ_v at unit rate. For all edges $e \in \delta(v)$ we raise α_e at unit rate as well. It is not hard to see that we maintain dual feasibility this way. ∎

We are ready to prove that our algorithm computes a 2-approximate primal solution.

LEMMA 2. *Our algorithm terminates with a vertex cover* $\mathcal{C}$ *and a corresponding feasible dual solution* $(\alpha, \beta, \gamma, \omega)$ *whenever there exists a feasible solution* (x, y) *for*

(LP). In particular, we must have

$$\sum_{v\in\mathcal{C}} \mathrm{wt}_v \le 2\left(\sum_{e\in E}\alpha_e - \sum_{v\in V}\omega_v\right).$$

Proof. Let $v \in \mathcal{C}$ be a vertex in the computed vertex cover, and let $e \in \delta(v)$ be an edge that is incident to v. Notice that our algorithm always maintains

$$\alpha_e \ge \beta_{e,v} \tag{8}$$

since α_e is raised whenever $\beta_{e,v}$ increases and the rate of increase is the same.

Observe also that γ_v is only increased if the degree $\deg(v)$ of vertex v exceeds $2B_v$. Let $\delta_1(v) \subseteq \delta(v)$ be the set of edges that are incident to v when γ_v is increased for the last time in the algorithm and notice that we must have $|\delta_1(v)| > 2B_v$.

Consider an edge $e \in \delta_1(v)$ and note that γ_v and α_e increase at the same rate after the point of time where v becomes tight. Notice also that the algorithm increases α_e and $\beta_{e,v}$ at the same rate before v becomes tight. Variable $\beta_{e,v}$ is not increased after v becomes tight, and γ_v is not increased before v becomes tight. Therefore, for all $e \in \delta_1(v)$ we must have

$$\alpha_e = \beta_{e,v} + \gamma_v. \tag{9}$$

Since v is tight when the algorithm adds it to the cover and deletes it from the graph, it must also be the case that

$$\sum_{e\in\delta(v)} \beta_{e,v} = \mathrm{wt}_v + \omega_v - B_v\cdot\gamma_v = \mathrm{wt}_v, \tag{10}$$

where the last equality follows from the fact that we raise ω_v at a rate of B_v if and only if we raise γ_v at a rate of 1.

We use $\delta_2(v) = \delta(v) \setminus \delta_1(v)$ and obtain

$$\mathrm{wt}_v \le \sum_{e\in\delta(v)} \beta_{e,v} \le \sum_{e\in\delta_1(v)} (\alpha_e - \gamma_v) + \sum_{e\in\delta_2(v)} \alpha_e \le \sum_{e\in\delta(v)} \alpha_e - 2B_v\gamma_v, \tag{11}$$

where the first inequality uses (10), the second inequality uses (8) and (9), and the last inequality follows from the fact that v is incident to at least $2B_v$ edges whenever γ_v is increased.

Summing (11) over all $v \in \mathcal{C}$ gives

$$\sum_{v\in\mathcal{C}} \mathrm{wt}_v \le \sum_{e\in E} |e\cap\mathcal{C}|\cdot\alpha_e - 2\cdot\sum_{v\in\mathcal{C}} B_v\gamma_v. \tag{12}$$

Now observe that we raise γ_v and ω_v only for tight vertices in our algorithm. Given that the input instance is feasible, the degree of any tight vertex v will eventually drop below $2B_v$. It therefore follows from the algorithm description that any vertex that becomes tight during the execution of the algorithm is eventually included in the vertex cover $\mathcal{C}$. Hence (12) implies

$$\sum_{v\in\mathcal{C}} \mathrm{wt}_v \le \sum_{e\in E} |e\cap\mathcal{C}|\cdot\alpha_e - 2\cdot\sum_{v\in V} B_v\gamma_v.$$

The lemma follows from $B_v\gamma_v = \omega_v$ for all $v \in V$ and from the fact that $|e \cap \mathcal{C}| \le 2$. ∎

Lemmas 1 and 2 complete the proof of Theorem 1.

3. A distributed algorithm. In this section we will describe a distributed primal-dual algorithm for capVC which uses the ideas developed in section 2. As before, the algorithm maintains a pair of (infeasible) primal and (feasible) dual solutions at all times. However, these solutions need to be stored in a distributed fashion: each vertex $v \in V$ stores and manipulates

(a) primal variables x_v and $y_{e,v}$ for all $e \in \delta(v)$, and

(b) dual variables γ_v, ω_v, α_e, and $\beta_{e,v}$ for all $e \in \delta(v)$.

Note that, for every edge $e = (u, v)$, both u and v store a copy of α_e. The algorithm guarantees the consistency of the two copies.

Observe that a naive distributed implementation of the method described in section 2 yields an algorithm that needs a linear number of communication rounds in the worst case. In order to illustrate this, consider a graph G with vertex set $\{v_1, \ldots, v_n, u_1, \ldots, u_{2B}\}$ for some $n, B \geq 1$. Let the edge-set of G be

$$E = \{(v_i, v_{i+1}) : 1 \leq i \leq n-1\} \cup \{(v_i, u_j) : 1 \leq i \leq n, 1 \leq j \leq 2B-1\} \cup \{(v_n, u_{2B})\}$$

and notice that vertex v_1 has a degree of $2B$ while vertices $v_2, \ldots, v_n$ have a degree of $2B + 1$. Let the cost of vertices $v_1, \ldots, v_n$ be 0 and assign a unit cost to all other vertices in G. In the execution of the sequential primal-dual algorithm, all vertices $v_1, \ldots, v_n$ are tight immediately and all other vertices are nontight. Vertex v_1 is the only tight vertex with a degree of at most $2B$. After assigning the $2B$ edges in $\delta(v_1)$ to v_1, the degree of vertex v_2 drops to $2B$. In general, the degree of vertex v_i drops to $2B$ after assigning edges to vertices $v_1, \ldots, v_{i-1}$ for all $1 \leq i \leq n$. Doing this in a distributed fashion takes n communication rounds.

Adapting the algorithm in order to cope with the above synchronization problem is not an easy task. In fact it can be seen that synchronous increase of the duals is at the heart of Lemma 2, where it is used to argue that the dual constraints of type (6) are satisfied with equality at all times.

The distributed algorithm has two main phases.

Vertex-selection. In this phase we compute a vertex cover $\mathcal{C} \subseteq V$ that is $(2 + \epsilon)$-approximate. It is here that we solve the above mentioned synchronization problem. While computing an approximate cover, we also assign part of the edges to the vertices in $\mathcal{C}$. At most $2B_v$ edges are assigned to each $v \in \mathcal{C}$.

Edge-assignment. Here, we assign all of the remaining edges to the vertices in $\mathcal{C}$. This time, at most $(2 + \epsilon)B_v$ edges are assigned to each $v \in \mathcal{C}$.

For ease of presentation we assume from now on that the given capVC instance is feasible.

3.1. Vertex-selection phase. As said, the distributed algorithm mimics the primal-dual algorithm from section 2. Each vertex $v \in V$ stores part of the dual solution and it initially sets $\gamma_v = \omega_v = 0$ and it also lets $\alpha_e = \beta_{e,v} = 0$ for all edges $e \in \delta(v)$.

The distributed algorithm works in rounds. At the beginning of any given round i, we let the *residual weight* wt_v^i of vertex v be the difference between the right- and left-hand sides of $(7)_v$ for the current feasible dual solution. Thus, we initialize wt_v^0 to wt_v for all $v \in V$. A vertex $v \in V$ is either *active* or *inactive* in any given round i. An active vertex v can be in one of two states:

nontight Vertex v is nontight whenever the slack in constraint $(7)_v$ is more than $\theta \cdot \mathrm{wt}_v$ for a parameter $\theta \geq 0$ whose exact value will be determined later.

tight We let the state of vertex v be tight if $\mathrm{wt}_v^i \leq \theta \cdot \mathrm{wt}_v$ and if v has

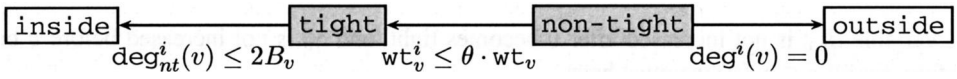

FIG. 2. *The figure shows the possible states of vertex $v \in V$ in the vertex-selection phase. The arrows indicate the possible transitions between the states. Shaded states are active while others are inactive states.*

more than $2B_v$ nontight neighbors. Intuitively, a tight vertex v will eventually be part of the computed cover. It will be assigned a subset of at most $2B_v$ of the edges to its nontight neighbors.

We will say that an edge $(u, v) \in E$ is active in round i if both u and v are active in that round. For any vertex $v \in V$, we let $\deg^i_t(v)$ and $\deg^i_{nt}(v)$ be the number of its tight and nontight neighbors in round i. We also let $\deg^i(v) = \deg^i_t(v) + \deg^i_{nt}(v)$ be the active neighbors of v in round i. An inactive vertex v can be in one of two states:

inside — A tight vertex switches its state to inside if the number $\deg^i_{nt}(v)$ of nontight neighbors is at most $2B_v$. Vertex v will be part of the final cover, and we assign all edges between v and any of its nontight neighbors to vertex v.

outside — We switch the state of a nontight vertex v to outside if it has no tight or nontight neighbors. We will later argue that all neighbors of v in G are inside in this case.

The vertex-selection phase terminates when no active vertices remain. The resulting vertex cover $\mathcal{C}$ consists of all vertices whose final state is inside. Figure 2 illustrates all possible transitions between states in the vertex-selection phase.

We proceed with a detailed description of round i of the distributed algorithm. The round has two steps.

Step 1. All nontight vertices are dormant. Each tight vertex $v \in V$ counts the number of active nontight neighbors. If this number is at most $2B_v$, then we assign all edges connecting v to nontight neighbors to v. We also switch vs state to inside and let v communicate its state-switch to all active neighbors. At this point each active vertex $v \in V$ knows the number $\deg^i(v)$ of active neighbors in G.

Step 2. The behavior of an active vertex $v \in V$ depends on its current state.

v is nontight: If $\deg^i(v)$ is 0, then we know that all edges incident to v have been assigned to other vertices. Therefore, we can switch the state of v to outside.

On the other hand, assume that v has active neighbors. Raising α_e and $\beta_{e,v}$ uniformly by $\mathrm{wt}^i_v/\deg^i(v)$ for all active edges $e \in \delta(v)$ decreases the residual weight of v to 0. Vertex v *strives* for tightness and therefore proposes to any active neighbor u to raise $\alpha_{(u,v)}$ and also $\beta_{(u,v),v}$ by its *proposal*

$$p_v = \frac{\mathrm{wt}^i_v}{\deg^i(v)}.$$

Consider an active edge $e = (u, v) \in \delta(v)$. We raise α_e and $\beta_{e,v}$ by $\min\{p_u, p_v\}$ and decrease the residual weight wt^i_v of v by the same amount.

v is tight: Notice that step 1 guarantees that v has more than $2B_v$ nontight neighbors. Vertex v receives proposals from all such neighbors and lets p_v be their minimum. Vertex v then sends p_v to all such neighbors.

For all nontight neighbors u of v we increase $\alpha_{(u,v)}$ by p_v. In order to maintain dual feasibility, we cannot increase $\beta_{(u,v),v}$ since v is tight. Hence we increase ω_v by $B_v p_v$ and γ_v by p_v.

Observe that tight vertices have to wait for the proposals of their nontight neighbors before making their own proposal. Hence two communication rounds are needed to update all of the variables.

We can show that the number of communication rounds needed to complete the vertex-selection phase is small. Recall that W denotes the ratio of largest to smallest vertex weights.

LEMMA 3. *The vertex-selection phase ends in $O(\log(nW)/\theta)$ rounds.*

Proof. We use a potential function argument in order to show the bound on the number of communication rounds. For round $j \geq 0$ we define the potential of each vertex $v \in V$ as $\Phi_v^j = \mathrm{wt}_v/\deg^j(v)$ if $\deg^j(v) > 0$ and we let $\Phi_v^j = \mathrm{wt}_{max}$ otherwise. Then let

$$\Phi^j = \min_{v \text{ nontight}} \Phi_v^j.$$

Note that Φ^j is a nondecreasing function of j. In fact, we will show that Φ^j doubles at least every $\lceil 2/\theta \rceil$ rounds. The lemma then follows since $\frac{\mathrm{wt}_{min}}{n} \leq \Phi^j \leq \mathrm{wt}_{max}$ for all rounds j.

Consider any given round i. Let V_i^j be the set of nontight vertices at the beginning of round j, $j \geq i$, with $\Phi_v^j \leq 2\Phi^i$, i.e.,

$$V_i^j = \{v \in V \,:\, \deg^j(v) > 0, \mathrm{wt}_v^j > \theta \cdot \mathrm{wt}_v, \Phi_v^j \leq 2\Phi^i\}.$$

Observe that $V_i^{j+1} \subseteq V_i^j$, since the wt_v^js and $\deg^j(v)$s are nonincreasing, while the Φ_v^js are nondecreasing. Consider any vertex $v \in V_i^i$. We will show that $v \notin V_i^{j'}$ for $j' \geq i + \lceil 2/\theta \rceil$. As a consequence, for any nontight vertex v, $\Phi_v^{j'} > 2\Phi^i$, and, hence, $\Phi^{j'} > 2\Phi^i$.

Assume by contradiction that $v \in V_i^{j'}$. Then, by the observation above, $v \in V_i^j$ for any $j \in \{i, i+1, \ldots, j'\}$. Suppose that $w \in V$ is a nontight vertex with the smallest proposal p_w in round j. Recall that $\mathrm{wt}_w^j \geq \theta\, \mathrm{wt}_w$ for nontight vertices. We then have

$$p_{\min,j} = p_w = \frac{\mathrm{wt}_w^j}{\deg^j(w)} \geq \frac{\theta \cdot \mathrm{wt}_w}{\deg^j(w)} \geq \theta \cdot \Phi^j. \tag{13}$$

It follows that the reduction of the residual weight of v in round j is at least

$$\deg^j(v) \cdot p_{\min,j} \geq \deg^j(v) \cdot \theta \cdot \Phi^j \geq \deg^j(v) \cdot \theta \cdot \Phi^i \geq \deg^j(v) \cdot \theta \cdot \Phi_v^j/2 = \theta \cdot \mathrm{wt}_v/2,$$

where the first inequality uses (13) and the third inequality uses the definition of the set V_i^j. Hence

$$\mathrm{wt}_v^{j'} \leq \mathrm{wt}_v - \frac{\theta\, \mathrm{wt}_v}{2} \lceil 2/\theta \rceil \leq 0 \leq \theta \cdot \mathrm{wt}_v,$$

which contradicts the assumption that $v \in V_i^{j'}$. ∎

We now prove that the weight of the vertices in $\mathcal{C}$ is small.

LEMMA 4. *The total weight of the vertices in $\mathcal{C}$ is at most $\frac{2}{1-\theta}$ times the optimum.*

Proof. Assume that the distributed algorithm finishes after $t \geq 0$ rounds, and let $(\alpha, \beta, \gamma, \omega)$ be the final dual. A proof very similar to that of Lemma 1 shows that the dual is indeed feasible. We proceed as in the proof of Lemma 2.

Consider a vertex $v \in \mathcal{C}$ and observe that v must have been tight before switching to the inside state. Thus $\mathrm{wt}_v^t \leq \theta \mathrm{wt}_v$ and

$$\sum_{e \in \delta(v)} \beta_{e,v} \geq \mathrm{wt}_v(1-\theta). \tag{14}$$

We will now show that

$$\sum_{e \in \delta(v)} \beta_{e,v} \leq \sum_{e \in \delta(v)} \alpha_e - 2\omega_v. \tag{15}$$

Equation (15) is trivially satisfied if we consider only the steps in which v is nontight. In fact, in these steps $\omega_v = 0$ and $\beta_{e,v} = \alpha_e$, for all $e \in \delta(v)$.

Consider now a step in which v is tight. The value of the left-hand side of (15) does not change. If ω_v increases by a quantity $B_v \cdot p_v$, then γ_v increases by a quantity p_v. It follows that, for all edges $e = (v, u)$ between v and a nontight neighbor u of v in the current step, the value of α_e also increases by at least p_v. Since there are at least $2B_v$ such neighbors, the right-hand side of (15) cannot decrease.

Let apx denote the weight of $\mathcal{C}$. Hence,

$$\mathrm{apx} = \sum_{v \in \mathcal{C}} \mathrm{wt}_v \leq \frac{1}{1-\theta} \sum_{v \in C} \sum_{e \in \delta(v)} \beta_{e,v} \leq \frac{1}{1-\theta} \sum_{v \in C} \sum_{e \in \delta(v)} (\alpha_e - 2\omega_v),$$

where the first inequality uses (14) and the second inequality (15). Since every edge is incident to at most two vertices from $\mathcal{C}$ we have that the right-hand side of the last inequality is bounded by

$$\frac{2}{1-\theta} \left(\sum_{e \in E} \alpha_e - \sum_{v \in V} \omega_v \right).$$

The claim follows by weak duality. □

For a given accuracy parameter $\epsilon \geq 0$ we now let $\theta = 1 - 2/(2+\epsilon)$. Note that this choice implies that $1/\theta = O(1/\epsilon)$ for $\epsilon \in (0, 1]$. Hence, given a feasible instance of capVC our distributed algorithm terminates within $O(\log(nW)/\epsilon)$ communication rounds with a cover of weight at most $(2+\epsilon)$opt as was claimed in Theorem 2.

3.2. Edge-assignment phase. At the end of the vertex-selection phase we are left with a subset $\mathcal{C}' \subseteq \mathcal{C}$ of the tight vertices such that all unassigned edges have both of their endpoints in $\mathcal{C}'$. In the following we let $G^0 = G[\mathcal{C}'] = (V, E)$ be the graph induced by the vertices in $\mathcal{C}'$. Assuming that the given capVC instance is feasible, there must be an assignment of the edges in G^0 to the vertices in $\mathcal{C}'$ that obeys the original capacity bounds. We describe a deterministic distributed algorithm which assigns at most $(2+\epsilon)B_v$ edges to each $v \in \mathcal{C}'$ in $O(\log n/\epsilon)$ rounds.

Our algorithm starts with all edges unassigned and computes a final assignment iteratively. In each round t we consider all vertices $v \in V$ with at most $(2+\epsilon)B_v$ incident unassigned edges, and we assign all such edges $(u, v) \in \delta(v)$ to v. We continue until no unassigned edges remain.

To prove that the number of rounds is polylogarithmic we need the following lemma. Let H be the set of vertices with a degree of more than $(2+\epsilon)B_v$, and let $E(H)$ be the set of those edges that have both of their endpoints in H. Finally use $\overline{E(H)}$ as an abbreviation for the set $E \setminus E(H)$ of edges that have at most one endpoint in H.

LEMMA 5. *If there is a feasible assignment, then we must have* $|\overline{E(H)}| \geq \epsilon|E(H)|$.

Proof. Let $\pi : E \to V$ be a feasible assignment of edges to vertices. We have that

$$\sum_{v \in H} |\delta(v)| \leq 2|E(H)| + |\overline{E(H)}| \tag{16}$$

as every edge in $E(H)$ is counted exactly twice in the sum on the left-hand side while an edge in $\overline{E(H)}$ is counted at most once. Moreover,

$$|E(H)| \leq \sum_{v \in H} |\pi^{-1}(v)| \tag{17}$$

since every edge in $E(H)$ must be assigned to some vertex in H. From (16) and (17) it follows that

$$(2+\epsilon) \sum_{v \in H} B_v \leq \sum_{v \in H} |\delta(v)| \leq 2 \sum_{v \in H} |\pi^{-1}(v)| + |\overline{E(H)}| \leq 2 \sum_{v \in H} B_v + |\overline{E(H)}|.$$

Hence

$$|\overline{E(H)}| \geq \epsilon \sum_{v \in H} B_v \geq \epsilon |E(H)|$$

which proves the lemma. ∎

LEMMA 6. *If there is a feasible assignment, then the algorithm above assigns at most* $(2+\epsilon)B_v$ *edges to each* $v \in V$. *The number of rounds required is* $O(\log n/\epsilon)$.

Proof. The capacity bound in the theorem follows immediately since for each vertex v in V there is at most one round t in which we assign at most $(2+\epsilon)B_v$ edges to it.

Let E^t be the set of unassigned edges at the beginning of iteration t, and let $G^t = G[E^t]$ be the subgraph of G induced by E^t. We also use H^t to denote the set of vertices $v \in V$ whose degree is more than $(2+\epsilon)B_v$ in G^t. Note that for any t, there must exist a feasible assignment in G^t as G^t is a subgraph of the initial graph G where a feasible assignment exists. So we can apply Lemma 5 and conclude that

$$|E^t| = |\overline{E(H^t)}| + |E(H^t)| \geq (1+\epsilon)|E(H^t)|.$$

In round t all of the edges in $\overline{E(H^t)}$ are assigned to some vertex and so $|E^{t+1}| \leq |E(H^t)|$. Hence, $|E^{t+1}| \leq \frac{1}{1+\epsilon}|E^t|$ and the number of unassigned edges decreases by a factor of $(1+\epsilon)$ in every round. ∎

Since at most $2B_u$ edges are assigned to each u during the vertex-selection phase, this concludes the proof of Theorem 2.

4. A lower bound. In this section we show that every efficient distributed approximation algorithm for capVC needs to violate the capacity constraints by a large additive term.

Consider the following two families of graphs $G^0_{B,k}$ and $G^1_{B,k}$, where $B, k \geq 1$. Graph $G^0_{B,k}$ has $k+1$ levels $L_0, L_1, \ldots, L_k$, each one containing $2B+1$ vertices. Each vertex in level L_i, $i = 0, 1, \ldots, k-1$, is adjacent to exactly B vertices in level L_{i+1}. Symmetrically, each vertex in level L_i, $i = 1, 2, \ldots, k$, is adjacent to exactly B vertices in level L_{i-1}. There are no other edges in the graph. In particular, each level L_i induces an independent set. Graph $G^1_{B,k}$ is obtained from $G^0_{B,k}$ by adding an edge between each pair of vertices in L_0. Let the capacity of all vertices in both graphs

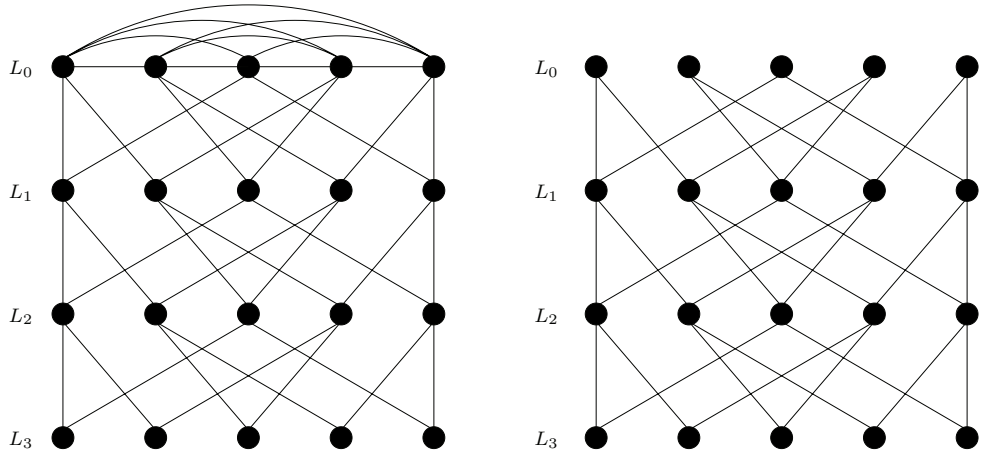

FIG. 3. *The figure shows graphs $G^1_{B,k}$ (on the left) and $G^0_{B,k}$ for $B = 2$ and $k = 3$ (on the right).*

be B. Moreover, all vertices have cost zero, except for the vertices in level L_k, which have cost one. Figure 3 shows an instance of the two graphs.

For $0 \le i \le k-1$, let δ_i be the set of edges that connect vertices in L_i to those in L_{i+1}. We obtain a feasible solution for $G^0_{B,k}$ as follows: Let

$$C = L_0 \cup L_1 \cup \cdots \cup L_{k-1}$$

and assign all edges in δ_i to the vertices in L_i for $0 \le i \le k-1$.

Graph $G^1_{B,k}$ has $n = (k+1)(2B+1)$ vertices and Bn edges. Thus, any feasible capacitated vertex cover must contain all vertices. Moreover, the edges belonging to the clique on L_0 clearly have to be assigned to the vertices in L_0. Thus, the unique feasible capVC solution for $G^0_{B,k}$ assigns all edges in δ_i to the vertices in L_{i+1} for all $0 \le i \le k-1$.

The following lemma turns out to be useful in the proof of the lower bound.

LEMMA 7. *Consider a solution for $G^1_{B,k}$ that assigns at most $(B+c)$ edges to each vertex, for some $c \ge 1$. For $0 \le i \le k-1$, let A_i be the number of edges in δ_i that are assigned to vertices in L_i. Then*

$$A_i \le (2B+1)(i+1)c$$

for all $0 \le i \le k-1$.

Proof. The proof is by induction on i. For $i = 0$, all clique edges need to be assigned to vertices in L_0. The spare capacity of the vertices in L_0 is thus $(2B+1)c$ which is the maximum number of edges in δ_0 that can be assigned to the vertices in L_0.

Now assume that the claim is true for all $0 \le i < k$. Using the induction hypothesis, at most $(2B+1)(i+1)c$ edges in δ_i are assigned to the vertices in L_i. Therefore, the remaining $(2B+1)(B-(i+1)c)$ edges need to be assigned to vertices in L_{i+1}. The remaining capacity of the vertices in L_{i+1} is thus

$$(2B+1)(B+c) - (2B+1)(B-(i+1)c) = (2B+1)(i+2)c$$

which is the maximum number of edges in δ_{i+1} that can be assigned to vertices in L_{i+1}. ∎

Armed with Lemma 7 we are now ready to provide a proof of Theorem 4. We restate it here for completeness.

THEOREM 4. *Let $B, k \geq 1$ be integer parameters. There is a* capVC *instance with uniform vertex capacities B, for which any distributed approximation algorithm that assigns less than $(1+1/k) \cdot B$ edges to all vertices must take at least k communication rounds.*

Proof. The proof is by contradiction. Let $c < B/k$ and consider a distributed approximation algorithm for capVC that assigns at most $(B+c)$ edges to each vertex for any given (uniform capacity) instance whose running time is less than k.

We first execute this algorithm on graph $G^1_{B,k}$. Lemma 7 shows that at most $(2B+1) \cdot kc$ of the edges in δ_{k-1} are assigned to the vertices in L_{k-1}. The number of edges that need to be assigned to vertices in L_k is therefore at least

$$(2B+1)(B-kc) > 0,$$

where the inequality uses our assumption on c. Hence at least one vertex in L_k needs to be in any cover of $G^1_{B,k}$ that assigns at most $B+c$ edges to each vertex. Let u be this vertex.

We now run the algorithm again on $G^0_{B,k}$. Since the graphs $G^0_{B,k}$ and $G^1_{B,k}$ are identical up to distance k from u, this vertex will be included in the cover in this case too. On the other hand, no vertex in L_k can be part of any approximate solution for $G^0_{B,k}$. ∎

For instance, consider an (efficient) distributed approximation algorithm for capVC with running time $O(\log^d n)$, where d is a positive constant. Theorem 4 then shows that there is a family of (uniform capacity) capVC instances for which this algorithm must assign at least $B + \Omega(\frac{B}{\log^d B})$ edges to some vertex.

We observe that graphs $G^0_{B,k}$ and $G^1_{B,k}$ have $n = (2B+1)(k+1)$ vertices. This implies that $B = \Theta\left(\frac{n}{k}\right)$, which is large in the interesting case when k is polylogarithmic. However, this *hitch* is easily removed by defining a graph G_0 (resp., G_1) consisting of t disjoint copies of the main building block $G^0_{B,k}$ (resp., $G^1_{B,k}$). Using the new parameter t we can now produce instances in which B is arbitrarily small in comparison to n while our proof argument goes through unchanged.

Acknowledgment. We would like to thank Volker Kaibel for pointing out a much simplified proof of Lemma 5.

ON THE COMPLEXITY OF VERIFYING CONSISTENCY OF XML SPECIFICATIONS*

MARCELO ARENAS†, WENFEI FAN‡, AND LEONID LIBKIN‡

Abstract. XML specifications often consist of a type definition (typically, a document type definition (DTD)) and a set of integrity constraints. It has been shown previously that such specifications can be inconsistent, and thus it is often desirable to check consistency at compile time. It is known [W. Fan and L. Libkin, *J. ACM*, 49 (2002), pp. 368–406] that for general keys, foreign keys, and DTDs the consistency problem is undecidable; however, it becomes NP-complete when all keys are one-attribute (unary) and tractable, if no foreign keys are used. In this paper, we consider a variety of previously studied constraints for XML data and investigate the complexity of the consistency problem. Our main conclusion is that, in the presence of foreign key constraints, compile-time verification of consistency is infeasible. We look at absolute constraints that hold in the entire document and relative constraints that hold only in a part of the document. For absolute constraints, we prove decidability and establish complexity bounds for primary multiattribute keys and unary foreign keys and study unary constraints that involve regular expressions. For relative constraints, we prove that even for unary constraints the consistency problem is undecidable. We also show that results continue to hold for extended DTDs, a more expressive typing mechanism for XML.

1. Introduction.

XML data, just like relational and object-oriented data, can be specified in a certain data definition language. While the exact details of XML data definition languages are still being worked out, it is clear that all of them would contain a form of document description, as well as integrity constraints. Constraints are naturally introduced when one considers transformations between XML and relational databases [10, 12, 18, 19, 23, 30, 31], as well as integrating several XML documents [2, 3, 4, 15].

Document descriptions usually come in the form of DTDs (document type definitions), and constraints are typically natural analogues of the most common relational integrity constraints: keys and foreign keys. Indeed, a large number of proposals (e.g., [35, 38, 36, 5]) support specifications for keys and foreign keys.

We investigate XML specifications with DTDs and keys and foreign keys. We study the *consistency*, or *satisfiability*, of such specifications: given a DTD and a set of constraints, whether there are XML documents conforming to the DTD and satisfying the constraints. In other words, we want to validate XML specifications statically, at compile time. Invalid XML specifications are likely to be more common than invalid

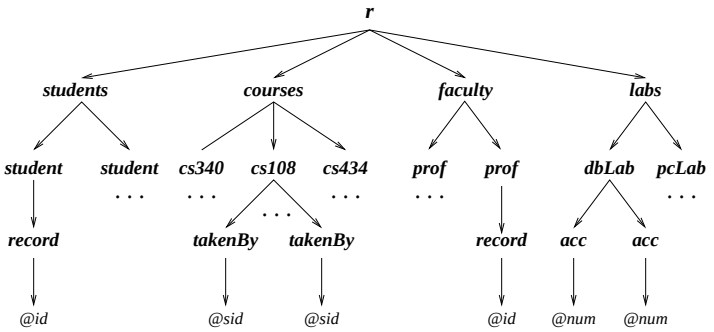

FIG. 1.1. *An XML document.*

specifications of other kinds of data, due to the rather complex interaction of DTDs and constraints. Furthermore, many specifications are not written at once, but rather in stages: as new requirements are discovered, they are added to the constraints, and thus it is quite possible that at some point they may be contradictory.

An alternative to the static validation would be a dynamic approach: simply attempt to validate a document with respect to a DTD and a set of constraints. This, however, would not tell us whether repeated failures are due to a bad specification or problems with the documents.

The consistency analysis for XML specifications is not nearly as easy as for relational data (any set of keys and foreign keys can be declared on a set of relational attributes). Indeed, [16] showed that, for DTDs and arbitrary keys and foreign keys, the consistency problem is undecidable. Furthermore, under the restriction that all keys and foreign keys are unary (single-attribute), the problem is NP-complete.

These results revealed only the tip of the iceberg, as many other flavors of XML constraints exist, and are likely to be added to future standards for XML such as XML Schema [38]. One of our goals is to study such constraints. In particular, we concentrate on constraints with regular expressions and relative constraints that hold only in a part of the document. We now give examples of new kinds of constraints considered here and explain their consistency problem.

Constraints with regular expressions. As XML data are hierarchically structured, one is often interested in constraints specified by regular expressions. For example, consider an XML document (represented as a node-labeled tree) in Figure 1.1, which conforms to the following DTD for schools:

```
<!ELEMENT  r  (students, courses, faculty, labs)>
<!ELEMENT  students   (student+)>
<!ELEMENT  courses    (cs340, cs108, cs434)>
<!ELEMENT  faculty    (prof+)>
<!ELEMENT  labs       (dbLab, pcLab)>
<!ELEMENT  student    (record)>          /* similarly for prof
<!ELEMENT  cs434      (takenBy+)         /* similarly for cs340, cs108
<!ELEMENT  dbLab      (acc+)             /* similarly for pcLab
```

Here we omit the descriptions of elements whose type is string (PCDATA). Assume that each *record* element has an attribute @*id*, each *takenBy* has an attribute @*sid* (for student id), and each *acc* has an attribute @*num*. One may impose the following

constraints over the DTD of that document:

$$r._{-}^{*}.(student \cup prof).record.@id \;\rightarrow\; r._{-}^{*}.(student \cup prof).record,$$
$$r._{-}^{*}.cs434.takenBy.@sid \subseteq_{FK} r._{-}^{*}.student.record.@id,$$
$$r._{-}^{*}.dbLab.acc.@num \subseteq_{FK} r._{-}^{*}.cs434.takenBy.@sid.$$

Here "_" is a wild card that matches any label (tag), and "_*" is its Kleene closure that matches any path. The first constraint says that *@id* is a key for all records of students and professors. The other constraints specify foreign keys, which assert that cs434 can be taken only by students and only students who are taking cs434 can have an account in the database lab. Recall that a foreign key also imposes a key constraint on the target elements; e.g., the last foreign key above also says that *@sid* is a key for students taking cs434.

Clearly, there is an XML tree satisfying both the DTD and the constraints. As was mentioned earlier, specifications are rarely written at once. Now suppose a new requirement is discovered: all faculty members must have a dbLab account. Consequently, one adds a new foreign key:

$$r.faculty.prof.record.@id \subseteq_{FK} r._{-}^{*}.dbLab.acc.@num.$$

However, this addition makes the whole specification inconsistent. This is because previous constraints postulate that *dbLab* users are students taking cs434, and no professor can be a student since *@id* is a key for both students and professors, while the new foreign key insists upon professors also being *dbLab* users and the DTD enforces the requirement that at least one professor be present in the document. Thus no XML document both conforms to the DTD and satisfies all of the constraints.

The consistency problem for regular expression constraints is at least as hard as for constraints specified for element types with simple attributes: NP-hard in the unary case and undecidable in general [16]. We use results from [1, 16, 27] to show that, in the unary case, the problem remains decidable, but the lower bound becomes PSPACE.

Relative integrity constraints. Many types of constraints are specified for an entire document. A different kind of constraints, called *relative*, was proposed in [5]—those constraints hold only in a part of a document. As an example, consider an XML document that for each country lists its administrative subdivisions (e.g., into provinces or states) as well as capitals of provinces. A DTD is given below, and an XML document conforming to it is depicted in Figure 1.2:

```
<!ELEMENT  db       (country+)>
<!ELEMENT  country  (province+, capital+)>
<!ELEMENT  province (capital, city*)>
```

Each country has a nonempty sequence of provinces and a nonempty sequence of province capitals, and for each province we specify its capital and perhaps other cities. Each country and province has an attribute *@name*, and each capital has an attribute *@inProvince*.

Now suppose that we want to define keys for countries and provinces. One can state that country *@name* is a key for *country* elements. It is also tempting to say that *@name* is a key for *province*, but this may not be the case. The example in Figure 1.2 clearly shows that which *Limburg* one is interested in probably depends on whether one's interests are in database theory or in the history of the European

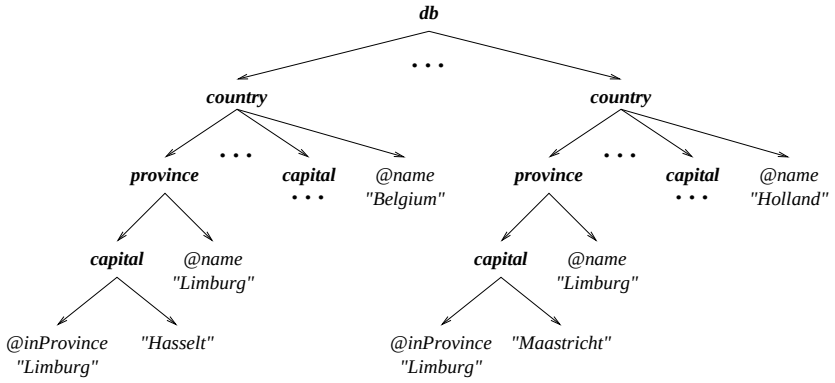

FIG. 1.2. *An XML document storing information about countries and their administrative subdivisions.*

Union. To overcome this problem, we define *@name* to be a key for *province relative* to a country; indeed, it is extremely unlikely that two provinces of the same country would have the same name. Thus, our constraints are

$$\begin{aligned} country.@name &\rightarrow country, \\ country(province.@name &\rightarrow province), \\ country(\_^*.capital.@inProvince &\rightarrow \_^*.capital), \\ country(\_^*.capital.@inProvince &\subseteq_{FK} \_^*.province.@name). \end{aligned}$$

The first constraint is like those we have encountered before: it is an *absolute* key, which applies to the entire document. The rest are *relative constraints* which are specified for subdocuments rooted at *country* elements. They assert that for each country *@name* is a key of all *province* descendants of the country element and *@inProvince* is a key of all *capital* descendants of the country element and a foreign key referring to *@name* of *province* elements in the same subdocument. The foreign keys assure that for each *capital* element in a *country* element (subdocument) its *@inProvince* attribute refers to a *province* in the same country (recall that *capital* elements immediately below *country* also denote *province* capitals). Note that these constraints are somewhat related to the notion of keys for weak entities in relational databases (cf. [33]). In contrast to regular expression constraints given earlier, these constraints are defined for element types; e.g., the first constraint is a key for all *country* elements in the entire document, and the second constraint is a (relative) key for all *capital* elements in a subdocument rooted at a *country* node.

To illustrate the interaction between constraints and DTDs, observe that the above specification—which might look reasonable at first—is actually inconsistent! To see this, let T be a tree that satisfies the specification. The constraints say that for any subdocument rooted at a country c the number of its *capital* elements is at most the number of *province* elements among c's descendants. The DTD says that each *province* has a *capital* element as a child and that each *country* element has at least one *capital* child. Thus, the number of *capital* descendants of c is larger than the number of *province* descendants of c, which contradicts the previous bound. Hence, the specification is inconsistent. We note that one can make the specification consistent by replacing $country(\_^*.capital.@inProvince \rightarrow \_^*.capital)$ with two keys: $country(capital.@inProvince \rightarrow capital)$ and $country(province.capital.@inProvince \rightarrow$

province.capital), which allow *capital.@inProvince* and *province.capital.@inProvince* to share the same value.

Relative constraints appear to be quite useful for capturing information about XML documents that cannot possibly be specified by absolute constraints. It turns out, however, that the consistency problem is much harder for them: it is undecidable even for single-attribute keys and foreign keys.

Decidable restrictions. Since expensive lower bounds, and even undecidability, were established for most versions of the consistency problem, we would like to see some interesting tractable, or decidable, restrictions. In the case of absolute constraints, the results of [16] consider either single attributes or multiattribute sets for both keys and foreign keys and thus say nothing about the intermediate case in which only keys are allowed to be multiattribute. This class of constraints is rather common and arises when relational data is translated into XML. While often identifiers are used as single-attribute keys, other sets of attributes can form a key as well (e.g., via SQL `unique` declaration), and those typically contain more than one attribute. We show that the consistency problem for this class of constraints, when every key is primary (i.e., at most one key is defined for each element type), remains decidable.

The main conclusion of this paper is that, while many proposals such as XML Schema [38] and XML Data [36] support the facilities provided by the DTDs as well as integrity constraints, and while it is possible to write inconsistent specifications, checking consistency at compile time appears to be infeasible, even for fairly small specifications.

Related work. Consistency was studied for other data models, such as object-oriented and extended relational (e.g., with support for cardinality constraints); see [8, 9, 22].

A number of specifications for XML keys and foreign keys have been proposed, e.g., XML Schema [38] and XML Data [36]. A recent proposal [5] introduced relative constraints. To the best of our knowledge, consistency of XML constraints in the presence of schema specifications was investigated only in [16]. However, [16] did not consider relative constraints, constraints defined with regular expressions, and the class of multiattribute keys and unary foreign keys. Other constraints for semistructured data, different from those considered here, were studied in, e.g., [1, 6, 17]. The latter also studies the consistency problem; the special form of constraints used there makes it possible to encode consistency as an instance of conjunctive query containment. Application of constraints in data transformations was studied in [23, 12]; usefulness of keys and foreign keys in query optimization has also been recognized [13, 14].

Organization. Section 2 defines DTDs, absolute keys, and foreign keys for XML. Section 3 studies the class of absolute multiattribute keys and unary foreign keys and the class of regular expression constraints which is an extension of absolute constraints with regular path expressions. Section 4 defines and investigates relative keys and foreign keys. Section 5 provides lower and upper bounds for the consistency problem for extended DTDs, a slight extension of DTDs which captures unranked tree automata, and several different classes of keys and foreign keys. Section 6 summarizes the main results of the paper.

2. Notations.

2.1. DTDs, XML trees, and paths. Assume that we have the following disjoint sets: *El* of element names, *Att* of attribute names, *S* of possible values of attributes and raw text, and *Vert* of node identifiers. All attribute names start with

the symbol @, and these are the only ones starting with this symbol. We let S be a reserved symbol not in any of those sets.

We formalize the notion of DTDs as follows (cf. [35, 7, 25, 16]).

DEFINITION 2.1. *A* DTD *is defined to be* $D = (E, A, P, R, r)$*, where:*

- $E \subseteq El$ *is a finite set of* element types*;*
- $A \subseteq Att$ *is a finite set of* attributes*;*
- P *is a mapping from* E *to* element type definitions*: Given* $\tau \in E$*,* $P(\tau) = \mathtt{S}$ *or* $P(\tau)$ *is a regular expression* α *defined as follows:*

$$\alpha ::= \epsilon \mid \tau' \mid \alpha|\alpha \mid \alpha,\alpha \mid \alpha^*,$$

  where S *denotes the* string *type,* $\tau' \in E$*,* ϵ *is the empty word, and "*$|$*", ",", and "*$*$*" denote union, concatenation, and the Kleene closure, respectively;*
- R *is a mapping from* E *to the powerset of* A*. If* $@l \in R(\tau)$*, we say that* $@l$ *is* defined for τ*;*
- $r \in E$ *and is called* the element type of the root*.*

We normally denote element types by τ and assume that $R(r) = \emptyset$ and r does not appear in $P(\tau)$ for any $\tau \in E$. We also assume that each τ in $E \setminus \{r\}$ is *connected to* r; i.e., either τ appears in $P(r)$, or it appears in $P(\tau')$ for some τ' that is connected to r. In this paper we also use the following shorthand for regular expressions: α^+ for (α, α^*) and $\alpha?$ for $(\epsilon|\alpha)$. Finally, notice that mixed content is not allowed in XML trees; for every $\tau \in E$, $P(\tau)$ is either S or a regular expression over E.

Example 2.2. Let us consider the DTD D given in section 1 for storing information about countries and their administrative subdivisions. In our formalism, D can be represented as (E, A, P, R, r), where $E = \{db, country, province, capital, city\}$, $A = \{@name, @inProvince\}$, $r = db$, and P, R are as follows:

$P(db)$	$=$	$country^+$,	$R(db)$	$=$	$\emptyset$,
$P(country)$	$=$	$(province^+, capital^+)$,	$R(country)$	$=$	$\{@name\}$,
$P(province)$	$=$	$(capital, city^*)$,	$R(province)$	$=$	$\{@name\}$,
$P(capital)$	$=$	S,	$R(capital)$	$=$	$\{@inProvince\}$,
$P(city)$	$=$	S,	$R(city)$	$=$	$\emptyset$.

An XML document is typically modeled as a node-labeled tree. Below we describe valid XML documents w.r.t. a DTD, along the same lines as XQuery [39], XML Schema [38], and DOM [34].

DEFINITION 2.3. *Let* $D = (E, A, P, R, r)$ *be a DTD. An* XML tree T conforming to D*, written* $T \models D$*, is defined to be* $(V, lab, ele, att, root)$*, where*

- $V \subseteq Vert$ *is a finite set of* nodes*;*
- $lab : V \to E$*; if* $lab(v) = \tau$ $(v \in V)$*,* τ *is said to be the* element type *of* v*;*
- $ele : V \to S \cup V^*$*, where* V^* *is the set of all of the finite sequences of values from* V*, such that, for every* $v \in V$*, if* $P(lab(v)) = \mathtt{S}$*, then* $ele(v) = [s]$*, where* $s \in S$*; otherwise,* $ele(v) = [v_1, \ldots, v_n]$*, and the string* $lab(v_1) \ldots lab(v_n)$ *is in the regular language defined by* $P(lab(v))$*;*
- att *is a partial function from* $V \times A$ *to* S *such that, for any* $v \in V$ *and* $@l \in A$*,* $att(v, @l)$ *is defined iff* $@l \in R(lab(v))$*;*
- $root$ *is the root of* T*:* $root \in V$ *and* $lab(root) = r$*.*

The parent-child edge relation on V*,* $\{(v_1, v_2) \mid v_2$ *occurs in* $ele(v_1)\}$*, is required to form a rooted tree.*

In an XML tree T, for each $v \in V$, there is a unique path of parent-child edges from the root to v, and each node has at most one incoming edge. The root is a

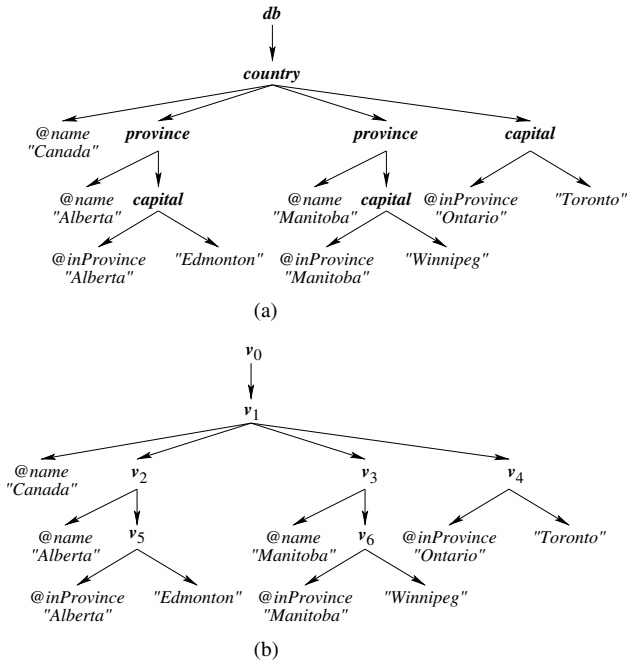

FIG. 2.1. *An XML document represented as a tree.*

unique node labeled with r. If a node x is labeled τ in E, then function ele defines the children of x and function att defines the attributes of x. The children of x are ordered, and their labels observe the regular expression $P(\tau)$. In contrast, its attributes are unordered and are identified by their labels (names).

Example 2.4. Figure 2.1(a) shows an XML document storing information about provinces in Canada and conforming to the DTD shown in Example 2.2. Figure 2.1(b) shows an XML tree $T = (V, lab, ele, att, v_0)$ representing this document. In this tree, $V = \{v_i \mid i \in [0, 6]\}$ and lab is defined as:

$$lab(v_0) = db, \quad lab(v_2) = province, \quad lab(v_4) = capital, \quad lab(v_6) = capital.$$
$$lab(v_1) = country, \quad lab(v_3) = province, \quad lab(v_5) = capital,$$

Furthermore, function ele is defined as:

$$ele(v_0) = [v_1], \quad ele(v_2) = [v_5], \quad ele(v_4) = [\text{Toronto}], \quad ele(v_6) = [\text{Winnipeg}].$$
$$ele(v_1) = [v_2, v_3, v_4], \quad ele(v_3) = [v_6], \quad ele(v_5) = [\text{Edmonton}],$$

Finally, function att is defined as:

$$att(v_1, @name) = \text{Canada}, \quad att(v_4, @inProvince) = \text{Ontario},$$
$$att(v_2, @name) = \text{Alberta}, \quad att(v_5, @inProvince) = \text{Alberta},$$
$$att(v_3, @name) = \text{Manitoba}, \quad att(v_6, @inProvince) = \text{Manitoba}.$$

Our model is simpler than the models of XQuery and XML Schema, as DTDs support only one basic type (PCDATA or string) and do not have complex type constructs. Unlike the data model of XQuery, we do not consider nodes representing namespaces, processing instructions, and references. These simplifications do not affect the lower bounds, however.

We also use the following notations. Referring to an XML tree T, if x is a τ-element in T and $@l$ is an attribute in $R(\tau)$, then $x.@l$ denotes the $@l$-attribute value

of x, i.e., $x.@l = att(x, @l)$. If X is a list $[@l_1, \ldots, @l_n]$ of attributes in $R(\tau)$, then $x[X] = [x.@l_1, \ldots, x.@l_n]$. For any element type $\tau \in E$, $ext(\tau)$ denotes the set of all of the τ-elements in T. For any $@l \in R(\tau)$, $values(\tau.@l)$ denotes $\{x.@l \mid x \in ext(\tau)\}$, the set of all of the $@l$-attribute values of τ-nodes. We write $|S|$ for the cardinality of a set S. Given a DTD D and a set Σ of constraints, we also use $|D|$ and $|\Sigma|$ to denote their sizes, respectively.

Given a DTD $D = (E, A, P, R, r)$ and element types $\tau, \tau' \in E$, a string $\tau_1.\tau_2.\ldots.\tau_n$ over E is a *path in D from τ to τ'* if $\tau_1 = \tau$, $\tau_n = \tau'$, and for each $i \in [2, n]$, τ_i is a symbol in the alphabet of $P(\tau_{i-1})$. Moreover, $paths(D) = \{p \mid$ there is $\tau \in E$ such that p is a path in D from r to $\tau\}$. We say that a DTD is *nonrecursive* if $paths(D)$ is finite and recursive otherwise. We also say that D is a *no-star* DTD if the Kleene star does not occur in any regular expression $P(\tau)$ (note that this is a stronger restriction than being $*$-free: a regular expression without the Kleene star yields a finite language, while the language of a $*$-free regular expression may still be infinite as it allows boolean operators including complement).

2.2. Keys and foreign keys. We consider two forms of constraints for XML: *absolute constraints* that hold on the entire document, denoted by $\mathcal{AC}$, and *relative constraints* that hold on certain subdocuments, denoted by $\mathcal{RC}$. Below we define absolute keys and foreign keys, and we shall define relative constraints in section 4. The constraints given in section 1 are instances of absolute constraints and relative constraints.

Regular expression constraints. To capture the hierarchical nature of XML data, absolute constraints, in their general form, are defined on a collection of elements identified by a regular path expression. It is common to find path expressions in specification and query languages for XML (e.g., XML Schema [38], XQuery [39], and XSL [40]). We define a *regular (path) expression* over a set of element types E as follows:

$$\beta \quad ::= \quad \epsilon \quad | \quad \tau \quad | \quad \beta.\beta \quad | \quad \beta \cup \beta \quad | \quad \beta^*,$$

where ϵ denotes the empty word, τ is an element type in E, and "$.$", "$\cup$", and "$*$" denote concatenation, union, and Kleene closure, respectively. A regular expression defines a language over the alphabet E, which will be denoted by β as well. Given a DTD $D = (E, A, P, R, r)$ and a regular expression β over E, we say that β is a *regular (path) expression over D* if β is of the form $r.\beta'$, where β' does not include r. In this section, we use "$\_$" as shorthand for $E \setminus \{r\}$.

Recall that a path in a DTD is a list of E symbols, that is, a string in E^*. Given an XML tree $T = (V, lab, ele, att, root)$, a pair of nodes x, y in T, with y a descendant of x, and a path $w = \tau_1.\ldots.\tau_n$ over E, we say that *w is a path from x to y* if there exists a sequence of nodes $v_1, \ldots, v_n$ in T such that (1) $v_1 = x$ and $v_n = y$, (2) v_{i+1} is a child of v_i in T, for every $i \in [1, n-1]$, and (3) $lab(v_i) = \tau_i$, for every $i \in [1, n]$. Any pair of nodes x, y in an XML tree T with y a descendant of x uniquely determines the path, denoted by $\rho(x, y)$, from x to y. We say that y is *reachable* from x by following a regular expression β over D, denoted by $T \models \beta(x,\ y)$, iff $\rho(x, y) \in \beta$. For any fixed T, let $nodes(\beta)$ stand for the set of nodes reachable from the root by following the regular expression β: $nodes(\beta) = \{y \mid T \models \beta(root,\ y)\}$. Note that, for any element type $\tau \in E \setminus \{r\}$, $nodes(r.\_^*.\tau) = ext(\tau)$.

We now define unary XML keys and foreign keys with regular path expressions. Let DTD $D = (E, A, P, R, r)$.

- A *key* over D is an expression φ of the form $\beta.\tau[X] \rightarrow \beta.\tau$, where

– $\tau \in E$;
– X is a nonempty set of attributes in $R(\tau)$; and
– β is a regular expression over D.

For any XML tree T that conforms to D, the tree T satisfies φ, denoted by $T \models \varphi$, if

$$\forall\, x, y \in nodes(\beta.\tau),\ x[X] = y[X] \rightarrow x = y.$$

- A *foreign key* over D is an expression φ of the form $\beta_1.\tau_1[X] \subseteq_{FK} \beta_2.\tau_2[Y]$, where
  – $\tau_i \in E$ for $i = 1, 2$;
  – β_i is a regular expression over D, for $i = 1, 2$; and
  – X, Y are nonempty lists of attributes in $R(\tau_1)$, $R(\tau_2)$ of the same length.

  Here $T \models \varphi$ if $T \models \beta_2.\tau_2[Y] \rightarrow \beta_2.\tau_2$, and

$$\forall\, x \in nodes(\beta_1.\tau_1)\ \exists\, y \in nodes(\beta_2.\tau_2)\ \big(x[X] = y[Y]\big).$$

We use two notions of equality to define keys: value equality is assumed when comparing attributes, and node identity is used when comparing elements. We shall use the same symbol "=" for both, as it will never lead to ambiguity.

The above constraints are generally referred to as *multiattribute* regular expression constraints as they may be defined with multiple attributes. A regular expression key (foreign key) is said to be *unary* if it is defined in terms of a single attribute; that is, $|X| = 1$ ($|X| = |Y| = 1$) in the above definition. In that case, we write $\beta.\tau.@l \rightarrow \beta.\tau$ for regular expression unary keys and $\beta_1.\tau_1.@l_1 \subseteq_{FK} \beta_2.\tau_2.@l_2$ for regular expression unary foreign keys.

From [16], we immediately obtain that the consistency problem for regular expression constraints is undecidable. Thus, in this paper we study only the consistency problem for unary constraints defined with regular expressions. We denote this class of constraints by $\mathcal{AC}^{reg}_{K,FK}$, where subscripts K and FK stand for keys and foreign keys, respectively. For example, the constraints over the school DTD that we have seen in section 1 are instances of $\mathcal{AC}^{reg}_{K,FK}$.

Constraints associated with element types. A class of absolute keys and foreign keys, denoted by $\mathcal{AC}^{*,*}_{K,FK}$ (we shall explain the notation shortly), has been studied in [16]. It is a special case of regular-expression constraints and is defined for element types as follows. An $\mathcal{AC}^{*,*}_{K,FK}$-constraint φ over a DTD $D = (E, A, P, R, r)$ has one of the following forms:

- *Key.* $\tau[X] \rightarrow \tau$, where $\tau \in E$ and X is a nonempty set of attributes in $R(\tau)$. An XML tree T satisfies φ, denoted by $T \models \varphi$, if

$$\forall\, x, y \in ext(\tau)\ \big(x[X] = y[X] \rightarrow x = y\big).$$

- *Foreign key.* $\tau_1[X] \subseteq_{FK} \tau_2[Y]$, where $\tau_1, \tau_2 \in E$ and X, Y are nonempty lists of attributes in $R(\tau_1)$, $R(\tau_2)$ of the same length. It is satisfied by a tree T if $T \models \tau_2[Y] \rightarrow \tau_2$, and in addition

$$\forall\, x \in ext(\tau_1)\ \exists\, y \in ext(\tau_2)\ \big(x[X] = y[Y]\big).$$

That is, $\tau[X] \rightarrow \tau$ says that the X-attribute values of a τ-element uniquely identify the element in $ext(\tau)$. Furthermore, $\tau_1[X] \subseteq_{FK} \tau_2[Y]$ says that the list of X-attribute values of every τ_1-node in T must match the list of Y-attribute values of some τ_2-node in T and the Y-attribute values of a τ_2-element uniquely identify the element in $ext(\tau_2)$.

TABLE 2.1
Notation summary.

Notation	Meaning
$\mathcal{AC}^{*,*}_{K,FK}$	Multiattribute keys and foreign keys
$\mathcal{AC}^{*,1}_{PK,FK}$	Multiattribute primary keys, unary foreign keys
$\mathcal{AC}_{K,FK}$	Unary keys and foreign keys
$\mathcal{AC}_{PK,FK}$	Primary unary keys and unary foreign keys
$\mathcal{AC}^{reg}_{K,FK}$	Regular expression unary keys and foreign keys

Note that an $\mathcal{AC}^{*,*}_{K,FK}$-constraint can be readily expressed as a regular expression constraint, by using $r._^*.\tau$ for τ.

As for the case of regular expression constraints, an $\mathcal{AC}^{*,*}_{K,FK}$-constraint is generally referred to as a *multiattribute* constraint as it may be defined with multiple attributes. An $\mathcal{AC}^{*,*}_{K,FK}$-constraint is said to be *unary* if it is defined in terms of a single attribute; that is, $\mid X \mid = \mid Y \mid = 1$ in the above definition. In that case, we write $\tau.@l \rightarrow \tau$ for unary keys and $\tau_1.@l_1 \subseteq_{FK} \tau_2.@l_2$ for unary foreign keys. As in relational databases, we also consider *primary keys*: for each element type, at most one key can be defined.

We shall use the following notations for subclasses of $\mathcal{AC}^{*,*}_{K,FK}$: subscripts K and FK denote keys and foreign keys, respectively. When the primary key restriction is imposed, we use subscript PK instead of K. The superscript "$*$" denotes multiattribute, and "1" means unary. When both superscripts are left out, we mean that both keys and foreign keys are unary. We shall be dealing with the following subclasses of $\mathcal{AC}^{*,*}_{K,FK}$: $\mathcal{AC}^{*,1}_{K,FK}$ denotes the class of multiattribute keys and unary foreign keys; $\mathcal{AC}^{*,1}_{PK,FK}$ is the class of primary multiattribute keys and unary foreign keys; $\mathcal{AC}_{K,FK}$ is the class of unary keys and unary foreign keys; and $\mathcal{AC}_{PK,FK}$ is the class of primary unary keys and unary foreign keys. We note that, since a key is part of a foreign key, the restriction of $\mathcal{AC}^{*,*}_{K,FK}$ to unary keys and multiattribute foreign keys ($\mathcal{AC}^{1,*}_{K,FK}$) does not make sense.

For easy reference, in Table 2.1 we summarize our notation for absolute constraints.

2.3. The consistency problem. We are interested in the consistency or satisfiability problem for XML constraints considered together with DTDs: that is, whether a given set of constraints and a DTD are satisfiable by an XML tree. Formally, for a class $\mathcal{C}$ of integrity constraints we define the *XML specification consistency problem* $\mathsf{SAT}(\mathcal{C})$ as follows:

PROBLEM:	$\mathsf{SAT}(\mathcal{C})$
INPUT:	A DTD D, a finite set Σ of $\mathcal{C}$-constraints.
QUESTION:	Is there an XML tree T such that $T \models D$ and $T \models \Sigma$?

It is known [16] that $\mathsf{SAT}(\mathcal{AC}^{*,*}_{K,FK})$ is undecidable, but $\mathsf{SAT}(\mathcal{AC}_{K,FK})$ and $\mathsf{SAT}(\mathcal{AC}_{PK,FK})$ are NP-complete. Nothing was known, however, about $\mathsf{SAT}(\mathcal{AC}^{*,1}_{K,FK})$, where only keys are allowed to be multiattribute, or about $\mathsf{SAT}(\mathcal{AC}^{reg}_{K,FK})$, where regular expressions are used to define unary keys and foreign keys. These problems will be studied in section 3.

In what follows, we write $T \models (D, \Sigma)$ instead of $T \models D$ and $T \models \Sigma$.

3. Absolute integrity constraints. In this section, we establish the decidability and lower bounds for $\mathsf{SAT}(\mathcal{AC}^{*,1}_{PK,FK})$ and $\mathsf{SAT}(\mathcal{AC}^{reg}_{K,FK})$ and the consistency problems for absolute primary multiattribute keys and unary foreign keys and for regular expression unary keys and unary foreign keys.

3.1. Consistency of multiattribute keys. We know that $\mathsf{SAT}(\mathcal{AC}_{K,FK})$, the consistency problem for unary absolute keys and foreign keys, is NP-complete [16]. In contrast, $\mathsf{SAT}(\mathcal{AC}^{*,*}_{K,FK})$ is undecidable [16]. This leaves a large gap: namely, $\mathsf{SAT}(\mathcal{AC}^{*,1}_{K,FK})$, where only keys are allowed to be multiattribute.

The reason for the undecidability of $\mathsf{SAT}(\mathcal{AC}^{*,*}_{K,FK})$ is that the implication problem for functional and inclusion dependencies can be reduced to it [16]. However, this implication problem is known to be decidable—in fact, in cubic time—for single-attribute inclusion dependencies [11], thus giving us hope to get decidability for multiattribute keys and unary foreign keys.

The problem we resolve here is $\mathsf{SAT}(\mathcal{AC}^{*,1}_{PK,FK})$: the consistency problem for *primary* multiattribute keys and unary foreign keys. Recall that a set Σ of $\mathcal{AC}^{*,1}_{K,FK}$-constraints is said to be *primary* if for each element type τ there is at most one key in Σ defined for τ-elements (including key dependencies defined by foreign key constraints). Even dealing with this version of $\mathsf{SAT}(\mathcal{AC}^{*,1}_{K,FK})$ one encounters considerable difficulties: with a rather involved proof, we manage to show that this problem is equivalent to a certain decidable version of Diophantine equations problem whose exact complexity has been an open problem for a while [21]:

PROBLEM:	PDE (prequadratic Diophantine equations).
INPUT:	An integer $n \times m$ matrix A, a vector $\vec{b} \in \mathbb{Z}^n$, and a set $E \subseteq \{1, \ldots, m\}^3$.
QUESTION:	Is there a vector $\vec{x} \in \mathbb{N}^m$ such that $A\vec{x} \leq \vec{b}$ and $x_i \leq x_j \cdot x_k$ for all $(i, j, k) \in E$?

Note that for $E = \emptyset$ this is exactly the integer linear programming problem [27]. Thus, PDE can be thought of as integer linear programming extended with inequalities of the form $x \leq y \cdot z$ among variables. It is therefore NP-hard, and [21] proved an NEXPTIME upper bound for PDE. The exact complexity of the problem remains unknown.

Recall that two problems P_1 and P_2 are *polynomially equivalent* if there are PTIME reductions from P_1 to P_2 and from P_2 to P_1. We now show the following.

THEOREM 3.1. $\mathsf{SAT}(\mathcal{AC}^{*,1}_{PK,FK})$ *and PDE are polynomially equivalent.*

Proof. The proof consists of two PTIME reductions, one for each direction.

(a) *A reduction from* $\mathsf{SAT}(\mathcal{AC}^{*,1}_{PK,FK})$ *to PDE.* We first define a class of simplified DTDs called *narrow DTDs*, and we explain how to reduce the consistency problem for $\mathcal{AC}^{*,1}_{PK,FK}$-constraints over arbitrary DTDs to that over narrow DTDs. Then we show how to encode the consistency problem for narrow DTDs and $\mathcal{AC}^{*,1}_{PK,FK}$-constraints by a prequadratic Diophantine system.

We start by explaining the process of narrowing the DTDs. Intuitively, we replace long "horizontal" regular expressions in $P(\tau)$ by shorter ones. Formally, consider a DTD $D = (E, A, P, R, r)$. D is basically an extended regular grammar (cf. [7, 25]); for each $\tau \in E$, $P(\tau)$ is a regular expression α, and, thus, $\tau \to \alpha$ can be viewed as the production rule for τ. We rewrite the regular expression by introducing a set N of new element types (nonterminals) such that the production rules of the new DTD

have one of the following forms:

$$\tau \to \tau_1,\ \tau_2, \qquad \tau \to \tau_1 \mid \tau_2, \qquad \tau \to \tau_1^*, \qquad \tau \to \tau', \qquad \tau \to\ \mathtt{S}, \qquad \tau \to \epsilon,$$

where τ, τ_1, τ_2 are element types in $E \cup N$, $\tau' \in E$, $\mathtt{S}$ is the string type, and ϵ denotes the empty word. More specifically, we conduct the following "narrowing" process on the production rule $\tau \to \alpha$:

- If $\alpha = (\alpha_1, \alpha_2)$, then we introduce two new element types τ_1 and τ_2 and replace $\tau \to \alpha$ with a new rule $\tau \to \tau_1, \tau_2$. We proceed to process $\tau_1 \to \alpha_1$ and $\tau_2 \to \alpha_2$ in the same way.
- If $\alpha = (\alpha_1 | \alpha_2)$, then we introduce two new element types τ_1 and τ_2 and replace $\tau \to \alpha$ with a new rule $\tau \to \tau_1 \mid \tau_2$. We proceed to process $\tau_1 \to \alpha_1$ and $\tau_2 \to \alpha_2$ in the same way.
- If $\alpha = \alpha_1^*$, then we introduce a new element type τ_1 and replace $\tau \to \alpha$ with $\tau \to \tau_1^*$. We proceed to process $\tau_1 \to \alpha_1$ in the same way.
- If α is one of $\tau' \in E$, $\mathtt{S}$, or ϵ, then the rule for τ remains unchanged.

We refer to the set of new element types introduced when processing $\tau \to P(\tau)$ as N_τ and the set of production rules generated/revised as P_τ. Observe that $N_\tau \cap E = \emptyset$ for any $\tau \in E$. We define a new DTD $D_N = (E_N, A, P_N, R_N, r)$, referred to as the *narrowed DTD of* D (or just a narrow DTD if D is clear from the context), where

- $E_N = E \cup \cup_{\tau \in E} N_\tau$, i.e., all element types of E and new element types introduced in the narrowing process;
- $P_N = \cup_{\tau \in E} P_\tau$, i.e., production rules generated/revised in the narrowing process;
- $R_N(\tau) = R(\tau)$ for each $\tau \in E$, and $R_N(\tau) = \emptyset$ for each $\tau \in E_N \setminus E$.

Note that the root element type r and the set A of attributes remain unchanged. Moreover, elements of any type in $E_N \setminus E$ do not have any attribute. The only kind of P_N production rules whose right-hand side contains element type E are of the form $\tau \to \tau'$, where $\tau' \in E$. It is easy to see that D_N is computable in polynomial time.

Obviously, any set Σ of $\mathcal{AC}^{*,1}_{PK,FK}$-constraints over D is also a set of $\mathcal{AC}^{*,1}_{PK,FK}$-constraints over the narrow DTD D_N of D. The next lemma establishes the connection between D and D_N, which allows us to consider only narrow DTDs from now on.

LEMMA 3.2. *Let D be a DTD, D_N the narrowed DTD of D, and Σ a set of $\mathcal{AC}^{*,1}_{PK,FK}$-constraints over D. Then there exists an XML tree T_1 such that $T_1 \models (D, \Sigma)$ iff there exists an XML tree T_2 such that $T_2 \models (D_N, \Sigma)$.*

Proof. Given an element type τ and a sequence of attributes $@l_1, \ldots, @l_n \in R(\tau)$, define $values(\tau[@l_1, \ldots, @l_n])$ as $\{(x.@l_1, \ldots, x.@l_n) \mid x \in ext(\tau)\}$.

To prove the lemma, it suffices to show the following.

Claim. Given any XML tree $T_1 \models D$ one can construct an XML tree T_2 by modifying T_1 such that $T_2 \models D_N$, and vice versa. Furthermore, for every element type τ in D and $@l_1, \ldots, @l_n \in R(\tau)$, $|ext(\tau)|$ in T_2 equals $|ext(\tau)|$ in T_1, and $values(\tau[@l_1, \ldots, @l_n])$ in T_2 equals $values(\tau[@l_1, \ldots, @l_n])$ in T_1.

If the claim holds, we can show the lemma as follows. Assume that there exists an XML tree T_1 such that $T_1 \models D$ and $T_1 \models \Sigma$. By the claim, there is T_2 such that $T_2 \models D_N$. Suppose, by contradiction, that there is $\varphi \in \Sigma$ such that $T_2 \not\models \varphi$. (1) If φ is a key $\tau[@l_1, \ldots, @l_n] \to \tau$, then there exist two distinct nodes $x, y \in ext(\tau)$ in T_2 such that $x.@l_i = y.@l_i$ for every $i \in [1, n]$. In other words, $|values(\tau[@l_1, \ldots, @l_n])| < |ext(\tau)|$ in T_2. Since $T_1 \models \varphi$, it must be the case that $|values(\tau[@l_1, \ldots, @l_n])| = |ext(\tau)|$ in T_1 because the tuple $(x.@l_1, \ldots, x.@l_n)$ of each $x \in ext(\tau)$ uniquely identifies x

among $ext(\tau)$. This contradicts the claim that $|ext(\tau)|$ in T_2 equals $|ext(\tau)|$ in T_1 and $values(\tau[@l_1, \ldots, @l_n])$ in T_2 equals $values(\tau[@l_1, \ldots, @l_n])$ in T_1. (2) If φ is a unary foreign key $\tau_1.@l_1 \subseteq_{FK} \tau_2.@l_2$, then either $T_2 \not\models \tau_2.@l_2 \rightarrow \tau_2$ or there is $x \in ext(\tau_1)$ in T_2 such that, for all $y \in ext(\tau_2)$ in T_2, $x.@l_1 \neq y.@l_2$. In the first case, we reach a contradiction as in (1). In the second case, we have $x.@l_1 \notin values(\tau_2.@l_2)$ in T_2. By the claim, $x.@l_1 \in values(\tau_1.@l_1)$ in T_1. Since $T_1 \models \varphi$, $x.@l_1 \in values(\tau_2.@l_2)$ in T_1. Again by the claim, we have $x.@l_1 \in values(\tau_2.@l_2)$ in T_2, which contradicts the assumption. The proof for the other direction is similar.

We next verify the claim. Given an XML tree $T_1 = (V_1, lab_1, ele_1, att, root)$ such that $T_1 \models D$, we construct an XML tree T_2 by modifying T_1 such that $T_2 \models D_N$. Consider a τ-element v in T_1. Let $ele_1(v) = [v_1, \ldots, v_n]$ and $w = lab_1(v_1) \ldots lab_1(v_n)$. Recall N_τ and P_τ, the set of nonterminals and the set of production rules generated when narrowing $\tau \rightarrow P(\tau)$. Let Q_τ be the set of E symbols that appears in P_τ plus S. We can view $G = (Q_\tau, N_\tau \cup \{\tau\}, P_\tau, \tau)$ as an extended context free grammar, where Q_τ is the set of terminals, $N_\tau \cup \{\tau\}$ the set of nonterminals, P_τ the set of production rules, and τ the start symbol.[1] Since $T_1 \models D$, we have $w \in P(\tau)$. By a straightforward induction on the structure of $P_N(\tau)$, it can be verified that w is in the language defined by G. Thus there is a parse tree $T(w)$ w.r.t. the grammar G for w, and w is the frontier (the list of leaves from left to right) of $T(w)$. Without loss of generality, assume that the root of $T(w)$ is v, and the leaves are $v_1, \ldots, v_n$. Observe that the internal nodes of $T(w)$ are labeled with element types in N_τ except that the root v is labeled τ. Intuitively, we construct T_2 by replacing each element v in T_1 by such a parse tree. More specifically, let $T_2 = (V_2, lab_2, ele_2, att, root)$. Here V_2 consists of nodes in V_1 and the internal nodes introduced in the parse trees. For each x in V_2, let $lab_2(x) = lab_1(x)$ if $x \in V_1$, and otherwise let $lab_2(x)$ be the node label of x in the parse tree where x belongs. Note that nodes in $V_2 \setminus V_1$ are elements of some type in $E_N \setminus E$. For every $x \in V_1$, let $ele_2(x)$ be the list of its children in the parse tree having x as root. For every $x \in V_2 \setminus V_1$, let $ele_2(x)$ be the list of its children in the parse tree of an element in V_1 that contains x. Note that att and $root$ remain unchanged. By the construction of T_2 it can be verified that $T_2 \models D_N$; moreover, for every element type τ in D and $@l_1, \ldots, @l_n \in R(\tau)$, $|ext(\tau)|$ in T_2 equals $|ext(\tau)|$ in T_1 and $values(\tau[@l_1, \ldots, @l_n])$ in T_2 equals $values(\tau[@l_1, \ldots, @l_n])$ in T_1 because, among other things, (1) none of the new nodes, i.e., nodes in $V_2 \setminus V_1$, is labeled with an E-type; (2) no new attributes are defined; and (3) the attribute function att is unchanged.

Conversely, assume that there is $T_2 = (V_2, lab_2, ele_2, att, root)$ such that $T_2 \models D_N$. We construct an XML tree T_1 by modifying T_2 such that $T_1 \models D$. For every node $v \in V_2$ with $lab(v) = \tau$ and $\tau \in E_N \setminus E$, we substitute v in $ele_2(v')$ by the children of v, where v' is the parent of v. In addition, we remove v from V_2, $lab_2(v)$ from lab_2, and $ele_2(v)$ from ele_2. Observe that, by the definition of D_N, no attributes are defined for elements of any type in $E_N \setminus E$. We repeat the process until there is no node labeled with element type in $E_N \setminus E$. Now let $T_1 = (V_1, lab_1, ele_1, att, root)$, where V_1, lab_1, and ele_1 are V_2, lab_2, and ele_2 at the end of the process, respectively. Notice that att and $root$ remain unchanged. By the definition of T_1 it can be verified that $T_1 \models D$; and in addition, for every element type τ in D and $@l_1, \ldots, @l_n \in R(\tau)$, $|ext(\tau)|$ in T_2 equals $|ext(\tau)|$ in T_1 and $values(\tau[@l_1, \ldots, @l_n])$ in T_2 equals $values(\tau[@l_1, \ldots, @l_n])$ in T_1 because, among other things, none of the nodes removed is labeled with a type of E and the attribute function att is unchanged.

[1] If τ is in $P(\tau)$, i.e., if τ is recursively defined, we need to rename τ in Q_τ to ensure that Q_τ and $N_\tau \cup \{\tau\}$ are disjoint. It is straightforward to handle that case.

By Lemma 3.2, in the rest of this proof we consider only narrow DTDs. Next we show how to encode $\mathcal{AC}^{*,1}_{PK,FK}$-constraints by a prequadratic Diophantine system. Let $D = (E, A, P, R, r)$ be a narrow DTD and Σ be a set of $\mathcal{AC}^{*,1}_{PK,FK}$-constraints, i.e., primary $\mathcal{AC}^{*,1}_{K,FK}$-constraints. We encode Σ with a set C_Σ of integer constraints, referred to as *the cardinality constraints determined by* Σ. For every $\varphi \in \Sigma$,

- if φ is a key constraint $\tau[@l_1, \ldots, @l_k] \to \tau$, then C_Σ contains $|ext(\tau)| \leq |values(\tau.@l_1)| \cdot \ldots \cdot |values(\tau.@l_k)|$;
- if φ is a unary foreign key $\tau_1.@l_1 \subseteq_{FK} \tau_2.@l_2$, then C_Σ contains $|values(\tau_1.@l_1)| \leq |values(\tau_2.@l_2)|$ and $|ext(\tau_2)| \leq |values(\tau_2.@l_2)|$;
- furthermore, for any $\tau \in E$, if $R(\tau) = \emptyset$, then $0 \leq |ext(\tau)|$ is in C_Σ. Otherwise, for every $@l \in R(\tau)$, $|values(\tau.@l)| \leq |ext(\tau)|$ and $0 \leq |values(\tau.@l)|$ are in C_Σ.

Observe that for a unary key $\tau.@l \to \tau$ we have both $|values(\tau.@l)| \leq |ext(\tau)|$ and $|ext(\tau)| \leq |values(\tau.@l)|$ in C_Σ. Thus C_Σ assures $|ext(\tau)| = |values(\tau.@l)|$.

We write $T \models C_\Sigma$ if T satisfies all of the constraints of C_Σ, and we write $T \models (D, C_\Sigma)$ if T conforms to a narrow DTD D and satisfies C_Σ. Note that C_Σ is equivalent (in fact, can be converted in polynomial time) to a prequadratic Diophantine system since $x \leq x_1 \cdot \ldots \cdot x_k$ can be written as constraints of the form $x \leq y \cdot z$ by introducing $k-2$ fresh variables; e.g., $x \leq x_1 \cdot x_2 \cdot x_3 \cdot x_4$ is equivalent to $x \leq x_1 \cdot z_1$, $z_1 \leq x_2 \cdot z_2$, and $z_2 \leq x_3 \cdot x_4$ (in the sense that the former is satisfiable iff the latter is). Thus, without loss of generality, assume that C_Σ consists of linear and prequadratic integer constraints only. It should be noted that C_Σ can be computed in time polynomial in the size of Σ and D. The lemma below shows that C_Σ characterizes the consistency of Σ if keys in Σ are primary.

LEMMA 3.3. *Let D be a narrow DTD and Σ a set of $\mathcal{AC}^{*,1}_{PK,FK}$-constraints over D. Then every XML tree conforming to D and satisfying Σ also satisfies C_Σ. In addition, if there exists an XML tree T_2 such that $T_2 \models (D, C_\Sigma)$, then there exists an XML tree T_1 such that $T_1 \models (D, \Sigma)$.*

Proof. It is easy to see that, for every XML tree T_1 that satisfies Σ, it must be the case that $T_1 \models C_\Sigma$.

Conversely, we show that if there exists an XML tree $T_2 = (V, lab, ele, att_2, root)$ such that $T_2 \models (D, C_\Sigma)$, then we can construct an XML tree $T_1 = (V, lab, ele, att_1, root)$ such that $T_1 \models (D, \Sigma)$. We construct T_1 from T_2 by modifying the function att_2 while leaving V, lab, ele, and $root$ unchanged. More specifically, let $S = \{\tau.@l \mid \tau \in E, @l \in R(\tau)\}$. To define the new function, denoted by att_1, we first associate a set of string values with each $\tau.@l$ in S. Let N be the maximum cardinality of $values(\tau.@l)$ in T_2, i.e., $N \geq |values(\tau.@l)|$ in T_2 for all $\tau.@l \in S$. Let $V_S = \{a_i \mid i \in [1, N]\}$ be a set of distinct string values. For each $\tau.@l \in S$, let $V_{\tau.@l} = \{a_i \mid i \in [1, |values(\tau.@l)|]\}$, and for each $x \in ext(\tau)$, let $att_1(x, @l)$ be a string value in $V_{\tau.@l}$ such that, in T_1, $values(\tau.@l) = V_{\tau.@l}$. The value $att_1(x, @l)$ can be selected in such a way that, for each key $\varphi = \tau[@l_1, \ldots, @l_k] \to \tau$ in Σ, $x[@l_1, \ldots, @l_k]$ is a distinct list of string values from $V_{\tau.@l_1} \times \cdots \times V_{\tau.@l_k}$. This is possible because by the definition of T_1, (1) $ext(\tau)$ in T_1 equals $ext(\tau)$ in T_2; (2) $|values(\tau.@l)|$ in T_1 equals $|values(\tau.@l)|$ in T_2; (3) $T_2 \models C_\Sigma$ and $|ext(\tau)| \leq |values(\tau.@l_1)| \cdot \ldots \cdot |values(\tau.@l_k)|$ is in C_Σ; and (4) since φ is the only key defined for τ-elements, when we populate attributes $@l_1, \ldots, l_k$ of x, we need only to select the value of $att_1(x, @l_i)$ from $V_{\tau.@l_i}$ such that $x[@l_1, \ldots, @l_k]$ is distinct, without worrying about whether the population may hamper "other keys" defined on x (note that, in the absence of the primary key assumption, the populations of different keys may interact with each other, and, as a result, the

simple population strategy given above may no longer work; this is why we assume primary keys). It should be noted that it may be the case that $V_{\tau_1.@l_1} \subseteq V_{\tau_2.@l_2}$ even if Σ does not imply $\tau_1.@l_1 \subseteq_{FK} \tau_2.@l_2$. This does not lose generality as we do not intend to capture negation of foreign keys. We next show that T_1 is indeed what we want.

It is easy to verify that $T_1 \models D$ given the construction of T_1 from T_2 and the assumption that $T_2 \models D$. To show that $T_1 \models \Sigma$, we consider $\varphi \in \Sigma$ in the following cases. (1) If φ is a key $\tau[@l_1, \ldots, @l_k] \rightarrow \tau$, it is immediate from the definition of T_1 that $T_1 \models \varphi$ since for any $x \in ext(\tau)$, $x[@l_1, \ldots, @l_k]$ is a distinct list of string values from $V_{\tau.@l_1} \times \cdots \times V_{\tau.@l_k}$. (2) If φ is $\tau_1.@l_1 \subseteq_{FK} \tau_2.@l_2$, then $T_2 \models |values(\tau_1.@l_1)| \leq |values(\tau_2.@l_2)|$ by $T_2 \models C_\Sigma$. By the definition of att_1, for $i = 1, 2$, $V_{\tau_i.@l_i} = \{a_i \mid i \in [1, |values(\tau_i.@l_i)|]\}$ and in T_1, $values(\tau_i.@l_i) = V_{\tau_i.@l_i}$. Thus $values(\tau_1.@l_1) \subseteq values(\tau_2.@l_2)$ in T_1. Furthermore, given that $|ext(\tau_2)| \leq |values(\tau_2.@l_2)|$ and $|values(\tau_2.@l_2)| \leq |ext(\tau_2)|$ are both in C_Σ, $T_2 \models C_\Sigma$, $|ext(\tau_2)|$ in T_2 is equal to $|ext(\tau_2)|$ in T_1, and $|values(\tau_2.@l_2)|$ in T_2 is equal to $|values(\tau_2.@l_2)|$ in T_1, we conclude that $|ext(\tau_2)|$ is equal to $|values(\tau_2.@l_2)|$ in T_1 and, hence, $T_1 \models \tau_2.@l_2 \rightarrow \tau_2$ since each $x \in ext(\tau_2)$ in T_1 has a distinct $@l_2$-attribute value and thus the value of its $@l_2$-attribute uniquely identifies x among nodes in $ext(\tau_2)$. Therefore, $T_1 \models \varphi$ and, thus, $T_1 \models (D, \Sigma)$. This concludes the proof of the lemma. □

The above lemma takes care of coding the constraints; the next step is to code DTDs. For that, we use the technique developed in [16]: for each narrow DTD D, one can compute in polynomial time in the size of D a set Ψ_D of linear inequalities on nonnegative integers, referred to as the set of cardinality constraints determined by D, which includes $|ext(\tau)|$ as a variable for each element type τ in D, but it does not have $|values(\tau.@l)|$ as a variable for any attribute $@l$ of τ. More specifically, for each symbol $\tau \in E \cup \{\mathtt{S}\}$, $|ext(\tau)|$ is treated as a distinct variable, which keeps track of the number of all τ elements in an XML tree T conforming to D. In addition, for each occurrence of τ in the definition $P(\tau')$ of some element type τ', we also create distinct variables as follows: if $P(\tau') = \tau_1$ for $\tau_1 \in E \cup \{\mathtt{S}\}$, then we create a distinct variable $x^1_{\tau_1,\tau'}$; if $P(\tau') = (\tau_1, \tau_2)$ or $P(\tau') = (\tau_1|\tau_2)$, then we create two distinct variables $x^1_{\tau_1,\tau'}$ and $x^2_{\tau_2,\tau'}$. Intuitively, for $i \in [1, 2]$, $x^i_{\tau_i,\tau'}$ keeps track of the number of τ_i subelements at position i under all τ' elements in T. Let X_τ be the set of all variables of the form $x^i_{\tau,\tau'}$. By using these variables, for each $\tau \in E$, we define a set ψ_τ of linear integer constraints that characterizes $P(\tau)$ quantitatively, as follows:

- If $P(\tau) = \tau_1$ for $\tau_1 \in E \cup \{\mathtt{S}\}$, then ψ_τ includes $|ext(\tau)| = x^1_{\tau_1,\tau}$. Referring to an XML tree T that conforms to D, this assures that each τ element has a unique τ_1 subelement.
- If $P(\tau') = (\tau_1, \tau_2)$, then ψ_τ includes $|ext(\tau)| = x^1_{\tau_1,\tau}$ and $|ext(\tau)| = x^2_{\tau_2,\tau}$. These assure that each τ element in T must have a unique τ_1 subelement and a unique τ_2 subelement.
- If $P(\tau') = (\tau_1|\tau_2)$, then ψ_τ includes $|ext(\tau)| = x^1_{\tau_1,\tau} + x^2_{\tau_2,\tau}$. These assure that each τ element in T must have either a τ_1 subelement or a τ_2 subelement, and thus the sum of the numbers of these τ_1 and τ_2 subelements equals the number of τ elements in T.

The set Ψ_D of cardinality constraints determined by DTD D consists of the following:

- $|ext(r)| = 1$; i.e., there is a unique root in any XML tree valid w.r.t. D;
- constraints of ψ_τ for each $\tau \in E$; these assure that $P(\tau)$ is satisfied;
- $|ext(\tau)| = \sum_{x^i_{\tau,\tau'} \in X_\tau} x^i_{\tau,\tau'}$ for each $\tau \in (E \setminus \{r\}) \cup \{\mathtt{S}\}$; this indicates that the set $ext(\tau)$ includes all τ elements no matter where they occur in an XML tree;

- $x \geq 0$ for any variable x used above; i.e., the number of elements (subelements) is nonnegative.

It has been shown [16] that Ψ_D has a nonnegative integer solution iff there exists an XML tree T conforming to D such that the cardinality of $ext(\tau)$ in T equals the value of the variable $|ext(\tau)|$ in the solution for each element type τ in D.

We now combine this coding with the coding for $\mathcal{AC}^{*,1}_{PK,FK}$-constraints. Given a narrow DTD D and a set Σ of $\mathcal{AC}^{*,1}_{PK,FK}$-constraints over D, we define *the set of cardinality constraints determined by* D *and* Σ to be

$$\Psi(D, \Sigma) \;=\; \Psi_D \cup C_\Sigma \cup \{(|ext(\tau)| > 0) \rightarrow (|values(\tau.@l)| > 0) \mid \tau \in E,\ @l \in R(\tau)\},$$

where C_Σ is the set of cardinality constraints determined by Σ, Ψ_D is the set of cardinality constraints determined by D, and constraints $(|ext(\tau)| > 0) \rightarrow (|values(\tau.@l)| > 0)$ are to ensure that every τ-element has an $@l$-attribute (note that $|values(\tau.@l)| \leq |ext(\tau)|$ is already in C_Σ). Constraints in $\Psi(D, \Sigma)$ are either linear integer constraints, or inequalities of the form $x \leq y \cdot z$, which come from C_Σ, or constraints of the form $x > 0 \rightarrow y > 0$. Note that, if we leave out constraints of the form $x > 0 \rightarrow y > 0$, $\Psi(D, \Sigma)$ is a prequadratic Diophantine system. Also note that $\Psi(D, \Sigma)$ can be computed in polynomial time in the size of D and Σ.

We say that $\Psi(D, \Sigma)$ is *consistent* iff $\Psi(D, \Sigma)$ admits a nonnegative integer solution. That is, there is a nonnegative integer assignment to the variables in $\Psi(D, \Sigma)$ such that all of the constraints in $\Psi(D, \Sigma)$ are satisfied.

LEMMA 3.4. *Let D be a narrow DTD and Σ a set of $\mathcal{AC}^{*,1}_{PK,FK}$-constraints over D. Then $\Psi(D, \Sigma)$ is consistent iff there is an XML tree T such that $T \models (D, \Sigma)$.*

Proof. Suppose that there exists an XML tree T such that $T \models (D, \Sigma)$. Then there is a nonnegative integer solution to Ψ_D such that for each element type τ in D, the value of the variable $|ext(\tau)|$ equals the number of τ-elements in T [16]. By Lemma 3.3 and $T \models \Sigma$, we have $T \models C_\Sigma$. We extend the solution of Ψ_D to be one to $\Psi(D, \Sigma)$ by letting the variable $|values(\tau.@l)|$ equal the number of distinct $@l$-attribute values of all τ-elements in T, for each element type τ and attribute $@l$ of τ in D. Since $T \models C_\Sigma$, this extended assignment satisfies all of the constraints in C_Σ. In addition, if $|ext(\tau)| > 0$, then $|values(\tau.@l)| > 0$ since every τ-element in T has an $@l$-attribute. Hence the assignment is indeed a nonnegative solution to $\Psi(D, \Sigma)$, and, therefore, $\Psi(D, \Sigma)$ is consistent.

Conversely, suppose that $\Psi(D, \Sigma)$ admits a nonnegative integer solution. Then there exists an XML tree T such that $T \models D$, and, moreover, for each element type τ in D, the cardinality of $ext(\tau)$ in T equals the value of the variable $|ext(\tau)|$ in the solution [16]. We construct a new tree T' from T by modifying the definition of the function att such that in T', for each element type τ and attribute $@l$ of τ, the number of distinct $@l$-attribute values of all τ-elements equals the value of the variable $|values(\tau.@l)|$ in the solution. This is possible since $|values(\tau.@l)| \leq |ext(\tau)|$ and $(|ext(\tau)| > 0) \rightarrow (|values(\tau.@l)| > 0)$ are in $\Psi(D, \Sigma)$. The assignment is also a solution to C_Σ. Thus $T' \models D$ and $T' \models C_\Sigma$. Hence by Lemma 3.3, there exists an XML tree T'' such that $T'' \models (D, \Sigma)$. This concludes the proof of the lemma. □

We now conclude the proof of reduction from $\mathsf{SAT}(\mathcal{AC}^{*,1}_{PK,FK})$ to PDE. By Lemma 3.2, given an arbitrary DTD D and a set Σ of $\mathcal{AC}^{*,1}_{PK,FK}$-constraints, one can compute a narrow DTD D_N such that (D, Σ) is consistent iff (D_N, Σ) is consistent. By Lemma 3.4, (D_N, Σ) is consistent iff $\Psi(D_N, \Sigma)$ has a nonnegative integer solution. Such a solution requires $|values(\tau.@l)| > 0$ if $|ext(\tau)| > 0$. To ensure this, let $\Phi(D_N, \Sigma)$ be a system that includes all linear integer constraints and pre-

quadratic constraints in $\Psi(D_N, \Sigma)$ and, moreover, $|ext(\tau)| \leq |values(\tau.@l)| \cdot |ext(\tau)|$ for each $(|ext(\tau)| > 0) \rightarrow (|values(\tau.@l)| > 0)$ in $\Psi(D_N, \Sigma)$. Now $\Phi(D_N, \Sigma)$ is a prequadratic Diophantine system. In addition, $\Psi(D_N, \Sigma)$ has a nonnegative integer solution iff $\Phi(D_N, \Sigma)$ has a nonnegative integer solution. To see this, observe that, for any nonnegative integer assignment to $|ext(\tau)|$ and $|values(\tau.@l)|$, $(|ext(\tau)| > 0) \rightarrow (|values(\tau.@l)| > 0)$ iff $|ext(\tau)| \leq |values(\tau.@l)| \cdot |ext(\tau)|$. Thus, (D, Σ) is consistent iff the prequadratic Diophantine system $\Phi(D_N, \Sigma)$ has a nonnegative integer solution. Note that D_N can be computed in polynomial time in the size of D, $\Psi(D_N, \Sigma)$ can be computed in polynomial time in the size of D_N and Σ, and $\Phi(D_N, \Sigma)$ can be computed in polynomial time in the size of $\Psi(D_N, \Sigma)$. Hence, it takes polynomial time to compute $\Phi(D_N, \Sigma)$ from D and Σ. Therefore, there is a PTIME reduction from $\mathsf{SAT}(\mathcal{AC}^{*,1}_{PK,FK})$ to PDE.

(b) *A reduction from PDE to* $\mathsf{SAT}(\mathcal{AC}^{*,1}_{PK,FK})$. We now move to the other direction. Given an instance of PDE, i.e., a system S consisting of a set S_L of linear equations/inequalities on integers and a set S_P of prequadratic constraints of the form $x \leq y \cdot z$, we define a DTD D and a set Σ of $\mathcal{AC}^{*,1}_{PK,FK}$-constraints such that S has a nonnegative solution iff there is an XML tree T satisfying Σ and conforming to D. We use $X = \{x_i \mid i \in [1, n]\}$ to denote the set of all of the variables in S. Assume that $S_L = \{e_j \mid j \in [1, m]\}$ and e_j is of the form: $a^j_1\ x_1 + \cdots + a^j_n\ x_n + c_j \leq b^j_1\ x_1 + \cdots + b^j_n\ x_n + d_j$, where a^j_i $(i \in [1, n])$, b^j_i $(i \in [1, n])$, c_j, and d_j are nonnegative integers.[2] Also, assume that $S_P = \{p_j \mid j \in [1, l]\}$, where p_j is a prequadratic equation of the form $x \leq y \cdot z$. Then we define DTD $D = (E,\ A,\ P,\ R,\ r)$ as follows:

(1) For each variable x_i, we define an element type X_i. In addition, for each $p_s \in S_P$ of the form $x_i \leq x_j \cdot x_k$, we define an element type U^s_i. For each linear constraint e_j, we define distinct element types E_j, A^j_1, …, A^j_n, C_j, F_j, B^j_1, …, B^j_n, D_j. We use r to denote the root element type. That is,

$$E\ =\ \{r\} \cup \{X_i \mid i \in [1, n]\} \cup$$
$$\{E_j, A^j_1, \ldots, A^j_n, C_j, F_j, B^j_1, \ldots, B^j_n, D_j \mid j \in [1, m]\} \cup \{U^s_i \mid p_s = x_i \leq x_j \cdot x_k \in S_P\}.$$

Intuitively, referring to an XML tree conforming to D, we use $|ext(X_i)|$ to code the value of the variable x_i in S. For every equation e_j, we use $|ext(A^j_1)|$, …, $|ext(A^j_n)|$, $|ext(C_j)|$ to code the values of constants a^j_1, …, a^j_n, c_j; $|ext(E_j)|$ to code the value of the expression $a^j_1 x_1 + \cdots + a^j_n x_n + c_j$; $|ext(B^j_1)|$, …, $|ext(B^j_n)|$, $|ext(D_j)|$ to code the values of constants b^j_1, …, b^j_n, d_j; and $|ext(F_j)|$ to code the value of the expression $b^j_1 x_1 + \cdots + b^j_n x_n + d_j$. Furthermore, for each prequadratic equation $p_s = x_i \leq x_j \cdot x_k$ in S_P, we create a distinct copy U^s_i of X_i. The reason to use U^s_i instead of X_i is to ensure that the set Σ of $\mathcal{AC}^{*,1}_{K,FK}$-constraints defined below is primary.

(2) $A = \{@c, @d, @e\}$. Intuitively, we shall define $@e$ as a key and use $@c$ and $@d$ to code prequadratic constraints of the form $x \leq y \cdot z$.

(3) We define production rules as follows. For the root of the DTD:

$$P(r)\ =\ (X_1, U^{s_{1,1}}_1, \ldots, U^{s_{1,j_1}}_1)^*, \ldots, (X_n, U^{s_{n,1}}_n, \ldots, U^{s_{n,j_n}}_n)^*,$$
$$\underbrace{C_1, \ldots, C_1}_{c_1 \text{ times}}, \ldots, \underbrace{C_m, \ldots, C_m}_{c_m \text{ times}}, \underbrace{D_1, \ldots, D_1}_{d_1 \text{ times}}, \ldots, \underbrace{D_m, \ldots, D_m}_{d_m \text{ times}},$$

where $\{s_{i,1}, \ldots, s_{i,j_i}\}$ $(i \in [1, n])$ is the set of indexes $\{s \mid p_s = x_i \leq x_j \cdot x_k \in S_P\}$.

[2] For example, we represent the equation $-3x + 5y \leq -7$ as $0x + 5y + 7 \leq 3x + 0y + 0$.

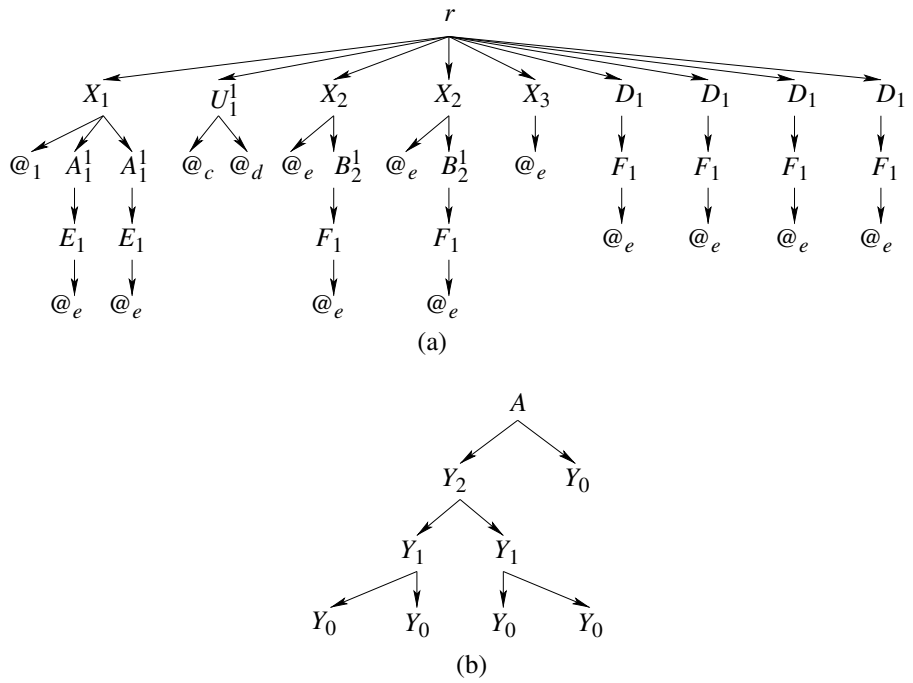

FIG. 3.1. *Trees used in the proof of Theorem* 3.1.

Furthermore, for every $i \in [1,n]$ and every $j \in [1,m]$:

$$\begin{array}{lcl} P(A_i^j) & = & E_j, \\ P(C_j) & = & E_j, \\ P(B_i^j) & = & F_j, \\ P(D_j) & = & F_j, \\ P(X_i) & = & \underbrace{A_i^1,\ldots,A_i^1}_{a_i^1 \text{ times}},\ldots,\underbrace{A_i^m,\ldots,A_i^m}_{a_i^m \text{ times}},\underbrace{B_i^1,\ldots,B_i^1}_{b_i^1 \text{ times}},\ldots,\underbrace{B_i^m,\ldots,B_i^m}_{b_i^m \text{ times}}. \end{array}$$

Finally, for every $i \in [1,n]$ and every $s \in [1,l]$ such that $p_s = x_i \le x_j \cdot x_k \in S_P$, $P(U_i^s) = \epsilon$.

(4) We define the attribute function R as follows: for every $j \in [1,m]$, $R(E_j) = R(F_j) = \{@e\}$. In addition, for every $i \in [1,n]$, $R(X_i) = \{@e\}$, and for every $s \in [1,l]$ such that $p_s = x_i \le x_j \cdot x_k \in S_P$, $R(U_i^s) = \{@c, @d\}$. For all other element types τ, let $R(\tau)$ be empty.

For example, Figure 3.1(a) shows an XML tree conforming to the DTD constructed from the set of equations $S_L = \{2x_1 \le x_2 + 4\}$ and $S_P = \{x_1 \le x_2 \cdot x_3\}$. We note that this tree codes the solution $x_1 = 1$, $x_2 = 2$, $x_3 = 1$ for this system of equations.

Given DTD D, we define a set Σ of $\mathcal{AC}^{*,1}_{PK,FK}$-constraints over D. For each $j \in [1,m]$, Σ includes keys $E_j.@e \to E_j$ and $F_j.@e \to F_j$ and foreign key $E_j.@e \subseteq_{FK} F_j.@e$. Furthermore, for every $i,j,k \in [1,n]$ and $s \in [1,l]$ such that $p_s = x_i \le x_j \cdot x_k \in S_P$, Σ includes the following constraints:

$$U_i^s[@c, @d] \to U_i^s, \qquad U_i^s.@c \subseteq_{FK} X_j.@e, \qquad U_i^s.@d \subseteq_{FK} X_k.@e.$$

Clearly, the set Σ is primary; i.e., for any element type τ there is at most one key defined. In fact, we use copies U_i^s of X_i just to ensure that Σ is primary.

We next show that the encoding is indeed a reduction from PDE to $\mathsf{SAT}(\mathcal{AC}^{*,1}_{PK,FK})$. Suppose that S has a nonnegative solution. Then we construct an XML tree T conforming to D as shown in Figure 3.1(a). That is, for each $i \in [1,n]$ we let $|ext(X_i)|$ be the value of the variable x_i in the solution. We note that, by the definition of D, this implies that, for every $s \in [1,l]$ such that $p_s = x_i \le x_j \cdot x_k \in S_P$, $|ext(U_i^s)|$ is also equal to the value of x_i in the solution. For every $i \in [1,n]$ and every X_i-element x in T, we let $x.@e$ be a distinct value such that, in T, $|values(X_i.@e)| = |ext(X_i)|$. For every $j \in [1,m]$ and every E_j-element x in T, we let $x.@e$ be a distinct value such that, in T, $|values(E_j.@e)| = |ext(E_j)|$. Likewise, we assign values to the $@e$-attribute of the nodes in $ext(F_j)$ in such a way that $|values(F_j.@e)| = |ext(F_j)|$ in T. Finally, for every $i,j,k \in [1,n]$ and $s \in [1,l]$ such that $p_s = x_i \le x_j \cdot x_k \in S_P$, and for every node x in T of type U_i^s, we let $x[@c,@d]$ be a distinct list of string values from $values(X_j.@e) \times values(X_k.@e)$. This is possible since $x_i \le x_j \cdot x_k \in S_P$ and by the definition of T, $|ext(U_i^s)| = |ext(X_i)| = x_i$, $|values(X_j.@e)| = |ext(X_j)| = x_j$, and $|values(X_k.@e)| = |ext(X_k)| = x_k$. Since T codes a solution of S, it is straightforward to prove that $T \models C_\Sigma$, the set of cardinality constraints determined by Σ. Thus, by Lemma 3.3 we conclude that there exists an XML tree T' such that $T' \models (D,\Sigma)$, and, hence, (D,Σ) is consistent. Conversely, suppose that there exists an XML tree T such that $T \models (D,\Sigma)$. We construct a solution of S by letting variable x_i equal $|ext(X_i)|$ in T. By the definitions of D and Σ, it is easy to verify that this is indeed a nonnegative integer solution for S. In particular, each $p_s = x_i \le x_j \cdot x_k$ in S_P holds because $T \models (D,\Sigma)$, and, thus, $|ext(X_i)| = |ext(U_i^s)| \le |values(U_i^s.@c)| \cdot |values(U_i^s.@d)| \le |values(X_j.@e)| \cdot |values(X_k.@e)| \le |ext(X_j)| \cdot |ext(X_k)|$.

We observe that the previous reduction is not polynomial since constants a_i^j, b_i^j ($i \in [1,n]$, $j \in [1,m]$) and c_j, d_j ($j \in [1,m]$) are coded in unary. To overcome this problem, next we show how to code in a DTD the binary representation of a number. We introduce this coding separately to simplify the presentation of this proof.

Assume that $a = \sum_{i=0}^{k} a_i \cdot 2^i$, where each a_i ($i \in [0,k-1]$) is either 0 or 1 and $a_k = 1$; that is, the binary representation of a is $a_k a_{k-1} \dots a_1 a_0$. To code a in a DTD we include element types $A, Y_0, \dots, Y_k$, and we define P on these elements as follows:

$$P(Y_i) = \begin{cases} \epsilon & i = 0, \\ Y_{i-1}, Y_{i-1} & \text{otherwise}, \end{cases}$$

and $P(A) = Y_{i_1}, \dots, Y_{i_l}$, where $i_1 > \dots > i_l \ge 0$ and $\{i_1, \dots, i_l\}$ is the set of indexes $\{j \in [0,k] \mid a_j = 1\}$. We note that the size of this set of rules is polynomial in the size of a. Furthermore, if an XML tree T conforms to this DTD, then $|ext(Y_0)| = a$ in T. For example, if $a = 5$, then $P(A) = Y_2, Y_0$, $P(Y_2) = Y_1, Y_1$, $P(Y_1) = Y_0, Y_0$, and $P(Y_0) = \epsilon$, and an XML tree conforming to these rules is of the form shown in Figure 3.1(b).

Thus, by using this coding in our original reduction of PDE to $\mathsf{SAT}(\mathcal{AC}^{*,1}_{PK,FK})$, we can show that there is a PTIME reduction from PDE to $\mathsf{SAT}(\mathcal{AC}^{*,1}_{PK,FK})$. This completes the proof of Theorem 3.1. □

It is known that the linear integer programming problem is NP-hard and PDE is in NEXPTIME. Thus from Theorem 3.1 follows immediately the corollary below.

COROLLARY 3.5. *$\mathsf{SAT}(\mathcal{AC}^{*,1}_{PK,FK})$ is NP-hard and can be solved in NEXPTIME.*

Obviously we cannot obtain the exact complexity of $\mathsf{SAT}(\mathcal{AC}^{*,1}_{PK,FK})$ without resolving the corresponding question for PDE, which appears to be quite hard [21]. The

result of Theorem 3.1 can be generalized to *disjoint* $\mathcal{AC}^{*,1}_{K,FK}$-constraints: that is, a set Σ of $\mathcal{AC}^{*,1}_{K,FK}$-constraints in which, for every element type τ and every two distinct keys $\tau[X] \to \tau$ and $\tau[Y] \to \tau$ in Σ (including key dependencies defined by foreign key constraints), $X \cap Y = \emptyset$. The proof of Theorem 3.1 applies almost verbatim to show the following.

COROLLARY 3.6. *The restriction of* $\mathsf{SAT}(\mathcal{AC}^{*,1}_{K,FK})$ *to disjoint constraints is polynomially equivalent to PDE, and, thus, it is NP-hard and can be solved in NEXPTIME.*

3.2. Consistency of regular expression constraints. Specifications of $\mathcal{AC}^{*,*}_{K,FK}$-constraints are associated with element types. We next consider $\mathcal{AC}^{reg}_{K,FK}$, the class of unary keys and foreign keys defined in terms of regular path expressions. For $\mathsf{SAT}(\mathcal{AC}^{reg}_{K,FK})$, we are able to establish both an upper and a lower bound. The lower bound already indicates that the problem is perhaps infeasible in practice, even for very simple DTDs. Finding the precise complexity of the problem remains open and does not appear to be easy. In fact, even the current proof of the upper bound is quite involved and relies on combining the techniques from [16] for coding DTDs and constraints with integer linear inequalities and from [1] for reasoning about constraints given by regular expressions by using the product automaton for all of the expressions involved in the constraints.

THEOREM 3.7.

(a) $\mathsf{SAT}(\mathcal{AC}^{reg}_{K,FK})$ *can be solved in* 2*-NEXPTIME.*

(b) $\mathsf{SAT}(\mathcal{AC}^{reg}_{K,FK})$ *is PSPACE-hard, even for nonrecursive no-star DTDs.*

Proof. We reduce $\mathsf{SAT}(\mathcal{AC}^{reg}_{K,FK})$ to the existence of solution of an (almost) instance of linear integer programming, which happens to be of double-exponential size; hence the 2-NEXPTIME bound. For the lower bound, we encode the quantified boolean formula problem (QBF) as an instance of $\mathsf{SAT}(\mathcal{AC}^{reg}_{K,FK})$.

Proof of (a). The proof is a bit long, so we first give a rough outline. The idea is similar to the proof of the NP membership for $\mathsf{SAT}(\mathcal{AC}_{K,FK})$ [16]: we code both the DTD and the constraints with linear inequalities over integers. However, compared to the proof of [16], the current proof is considerably harder due to the following. First, regular expressions in DTDs ("horizontal" regular expressions) interact in a certain way with regular expressions in integrity constraints (those correspond to "vertical" paths through the trees). To eliminate this interaction, we first show how to reduce the problem to that over *narrow* DTDs, in which no wide horizontal regular expressions are allowed. The next problem is that regular expressions in constraints can interact with each other. Thus, to model them with linear inequalities, we extend the approach of [16] by taking into account all possible boolean combinations of regular languages given by expressions used in constraints. The last problem is coding the DTDs in such a way that variables corresponding to each node have the information about the path leading to the node and its relationship with the regular expressions used in constraints. For that, we adopt the technique of [1], and tag all of the variables in the coding of DTDs with states of a certain automaton (the product automaton for all of the automata corresponding to the regular expressions used in constraints).

Now it is time to fill in all of the details. First, we need some additional notation. For every regular expression β and every attribute $@l$, we write $values(\beta.@l)$ to denote the set $\{y.@l \mid y \in nodes(\beta) \text{ and } y.@l \text{ is defined}\}$. Observe that, for any $\tau \in E \setminus \{r\}$ and $@l \in R(\tau)$, $values(r.\_^*.\tau.@l)$ corresponds to our original definition of $values(\tau.@l)$.

We say that a DTD D is *one-attribute* if D contains only one attribute and no element type τ such that $P(\tau) = \mathsf{S}$. We start by showing that $\mathsf{SAT}(\mathcal{AC}^{reg}_{K,FK})$

can be reduced to the consistency problem for regular expression constraints over one-attribute DTDs. Let $D = (E, A, P, R, r)$ be a DTD and Σ a set of $\mathcal{AC}^{reg}_{K,FK}$-constraints over D. First, define DTD $D_U = (E_U, A_U, P_U, R_U, r)$ as follows. For every $\tau \in E$ and $@l \in R(\tau)$, assume that $\tau_{@l}$ is a fresh element type symbol. Then define E_U as $E \cup \{\tau_{@l} \mid \tau \in E \text{ and } @l \in R(\tau)\}$ and $A_U = \{@e\}$, where $@e$ is a fresh attribute symbol. Furthermore, define functions P_U and R_U as follows:

- For every $\tau \in E$ such that $P(\tau) = \mathtt{S}$, if $R(\tau) = \{@l_1, \ldots, @l_n\}$, where $n \geq 0$, then $P_U(\tau) = \tau_{@l_1}, \ldots, \tau_{@l_n}$ and $R_U(\tau) = \emptyset$.
- For every $\tau \in E$ such that $P(\tau)$ is a regular expression over E, if $R(\tau) = \{@l_1, \ldots, @l_n\}$, where $n \geq 0$, then $P_U(\tau) = P(\tau), \tau_{@l_1}, \ldots, \tau_{@l_n}$ and $R_U(\tau) = \emptyset$.
- For every $\tau \in E$ and $@l \in R(\tau)$, $P_U(\tau_{@l}) = \epsilon$ and $R_U(\tau_{@l}) = \{@e\}$.

We note that if $P(\tau) = \mathtt{S}$ and $R(\tau) = \emptyset$, then $P_U(\tau) = \epsilon$.

Second, define the set Σ_U of $\mathcal{AC}^{reg}_{K,FK}$-constraints over D_U as follows. For every key constraint $\beta.\tau.@l \rightarrow \beta.\tau$ in Σ, we include $\beta.\tau.\tau_{@l}.@e \rightarrow \beta.\tau.\tau_{@l}$ in Σ_U, and, for every foreign key constraint $\beta.\tau.@l \subseteq_{FK} \beta'.\tau'.@l'$ in Σ, we add $\beta.\tau.\tau_{@l}.@e \subseteq_{FK} \beta'.\tau'.\tau'_{@l'}.@e$ to Σ_U.

LEMMA 3.8. *Let D be a DTD, Σ be a set of $\mathcal{AC}^{reg}_{K,FK}$-constraints over D, and D_U, Σ_U be as defined above. Then there exists an XML tree T_1 such that $T_1 \models (D, \Sigma)$ iff there exists an XML tree T_2 such that $T_2 \models (D_U, \Sigma_U)$.*

Proof. ($\Rightarrow$) Let $T_1 = (V_1, lab_1, ele_1, att_1, root)$ be an XML tree such that $T_1 \models (D, \Sigma)$. We define an XML tree T_2 from T_1 such that $T_2 \models (D_U, \Sigma_U)$. More specifically, $T_2 = (V_2, lab_2, ele_2, att_2, root)$, where V_2, lab_2, ele_2, and att_2 are defined as follows. Let v be a node in T_1 such that $lab_1(v) = \tau \in E$ and $R(\tau) = \{@l_1, \ldots, @l_k\}$. Then V_2 contains node v and fresh nodes $v_{@l_1}, \ldots, v_{@l_k}$ such that $lab_2(v) = \tau$ and $lab_2(v_{@l_i}) = \tau_{@l_i}$, for every $i \in [1, k]$. Furthermore, if $ele_1(v) = [s]$, where $s \in \mathtt{S}$, then $ele_2(v) = [v_{@l_1}, \ldots, v_{@l_k}]$. Otherwise, $ele_1(v) = [v_1, \ldots, v_n]$, where $n \geq 0$ and each v_i is an element node, and $ele_2(v) = [v_1, \ldots, v_n, v_{@l_1}, \ldots, v_{@l_k}]$. Finally, $att_2(v, @e)$ is not defined and $att_2(v_{@l_i}, @e) = att_1(v, @l_i)$ for every $i \in [1, k]$. Next we show that $T_2 \models (D_U, \Sigma_U)$.

By the definition of D_U and given that $T_1 \models D$, it is easy to see that $T_2 \models D_U$. Assume that $T_2 \not\models \Sigma_U$. Then there exist $\varphi \in \Sigma_U$ such that $T_2 \not\models \varphi$. (1) If φ is a key $\beta.\tau.\tau_{@l}.@e \rightarrow \beta.\tau.\tau_{@l}$, then there exist distinct $v_1, v_2 \in nodes(\beta.\tau.\tau_{@l})$ in T_2 such that $att_2(v_1, @e) = att_2(v_2, @e)$. Let u_1 and u_2 be the parents of v_1 and v_2 in T_2, respectively. By the definition of D_U and given that $v_1 \neq v_2$, we have $u_1 \neq u_2$. Thus, by the definition of T_2, u_1 and u_2 are nodes in T_1 such that $u_1, u_2 \in nodes(\beta.\tau)$ and $att_1(u_1, @l) = att_1(u_2, @l) = att_2(v_1, @e)$. Therefore, $T_1 \not\models \beta.\tau.@l \rightarrow \beta.\tau$, which contradicts the assumption that $T_1 \models \Sigma$. (2) If φ is a foreign key $\beta.\tau.\tau_{@l}.@e \subseteq_{FK} \beta'.\tau'.\tau'_{@l'}.@e$, then either $T_2 \not\models \beta'.\tau'.\tau'_{@l'}.@e \rightarrow \beta'.\tau'.\tau'_{@l'}$ or there exists $v \in nodes(\beta.\tau.\tau_{@l})$ such that $att_2(v, @e) \notin values(\beta'.\tau'.\tau'_{@l'}.@e)$ in T_2. In the former case, we reach a contradiction as in (1). In the latter case, assume that u is the parent of v in T_2. By the definition of T_2, we have that u is a node in T_1 such that $u \in nodes(\beta.\tau)$ and $att_1(u, @l) = att_2(v, @e)$. Thus, given that $values(\beta'.\tau'.\tau'_{@l'}.@e)$ in T_2 is equal to $values(\beta'.\tau'.@l')$ in T_1, we conclude that $att_1(u, @l) \notin values(\beta'.\tau'.@l')$ in T_1. Therefore, $T_1 \not\models \beta.\tau.@l \subseteq_{FK} \beta'.\tau'.@l'$, which contradicts the assumption that $T_1 \models \Sigma$.

($\Leftarrow$) Let $T_2 = (V_2, lab_2, ele_2, att_2, root)$ be an XML tree such that $T_2 \models (D_U, \Sigma_U)$. We define an XML tree T_1 from T_2 such that $T_1 \models (D, \Sigma)$. More specifically, $T_1 = (V_1, lab_1, ele_1, att_1, root)$, where V_1, lab_1, ele_1, and att_1 are defined as follows. Let v be a node in T_2 such that $lab_2(v) = \tau$, $\tau \in E$, and $R(\tau) = \{@l_1, \ldots, @l_k\}$.

Then V_1 also contains node v with $lab_1(v) = \tau$. Furthermore, if $P(\tau) = \mathtt{S}$, then $ele_2(v) = [v_{@l_1}, \ldots, v_{@l_k}]$, where $lab(v_{@l_j}) = \tau_{@l_j}$ $(j \in [1,k])$, and we define $ele_1(v)$ as $[s]$, where s is an arbitrary string in S, and we define $att_1(v, @l_i)$ as $att_2(v_{@l_i}, @e)$ for every $i \in [1,k]$. Otherwise, $P(\tau)$ is a regular expression over E and $ele_2(v) = [v_1, \ldots, v_n, v_{@l_1}, \ldots, v_{@l_k}]$, where $lab(v_i) \in E$ $(i \in [1,n])$ and $lab(v_{@l_j}) = \tau_{@l_j}$ $(j \in [1,k])$, and we define $ele_1(v)$ as $[v_1, \ldots, v_n]$ and $att_1(v, @l_i)$ as $att_2(v_{@l_i}, @e)$ for every $i \in [1,k]$. Next we show that $T_1 \models (D, \Sigma)$.

By the definition of D_U and given that $T_2 \models D_U$, it is easy to see that $T_1 \models D$. Assume that $T_1 \not\models \Sigma$. Then there exists $\varphi \in \Sigma$ such that $T_1 \not\models \varphi$. (1) If φ is a key $\beta.\tau.@l \rightarrow \beta.\tau$, then there exist distinct $u_1, u_2 \in nodes(\beta.\tau)$ in T_1 such that $att_1(u_1, @l) = att_1(u_2, @l)$. By the definition of T_1, u_1 and u_2 are also in $nodes(\beta.\tau)$ in T_2. Let v_1 and v_2 be the children of u_1 and u_2 in T_2 of type $\tau_{@l}$, respectively. Given that $u_1 \neq u_2$, we have $v_1 \neq v_2$. Thus, by the definition of T_1, v_1 and v_2 are nodes in T_2 such that $v_1, v_2 \in nodes(\beta.\tau.\tau_{@l})$ and $att_2(v_1, @e) = att_2(v_2, @e) = att_1(u_1, @l)$. Therefore, $T_2 \not\models \beta.\tau.\tau_{@l}.@e \rightarrow \beta.\tau.\tau_{@l}$, which contradicts the assumption that $T_2 \models \Sigma_U$. (2) If φ is a foreign key $\beta.\tau.@l \subseteq_{FK} \beta'.\tau'.@l'$, then either $T_1 \not\models \beta'.\tau'.@l' \rightarrow \beta'.\tau'$ or there exists $u \in nodes(\beta.\tau)$ such that $att_1(u, @l) \notin values(\beta'.\tau'.@l')$ in T_1. In the former case, we reach a contradiction as in (1). In the latter case, assume that v is the child of u in T_2 of type $\tau_{@l}$ (u is a node of T_2 by the definition of T_1). By the definition of T_1, we have $v \in nodes(\beta.\tau.\tau_{@l})$ and $att_2(v, @e) = att_1(u, @l)$. Thus, given that $values(\beta'.\tau'.\tau'_{@l'}.@e)$ in T_2 is equal to $values(\beta'.\tau'.@l')$ in T_1, we conclude that $att_2(v, @e) \notin values(\beta'.\tau'.\tau'_{@l'}.@e)$ in T_2. Therefore, $T_2 \not\models \beta.\tau.\tau_{@l}.@e \subseteq_{FK} \beta'.\tau'.\tau'_{@l'}.@e$, which contradicts the assumption that $T_2 \models \Sigma_U$. This concludes the proof of the lemma. □

By Lemma 3.8, from now on we consider only one-attribute DTDs. Let $D = (E, \{@l\}, P, R, r)$ be a one-attribute DTD and $D_N = (E_N, \{@l\}, P_N, R_N, r)$ be the narrow DTD of D (defined in the proof of Theorem 3.1). Observe that D_N is also one-attribute. Furthermore, observe that an XML tree T valid w.r.t. D may not conform to D_N and vice versa. In addition, an $\mathcal{AC}^{reg}_{K,FK}$-constraint φ over D may be satisfied by T, but it may not be satisfied by any XML tree conforming to D_N. To explore the connection between XML trees conforming to D and those conforming to D_N, we replace $\mathcal{AC}^{reg}_{K,FK}$-constraints over D by new $\mathcal{AC}^{reg}_{K,FK}$-constraints over D_N. More precisely, given a set Σ of $\mathcal{AC}^{reg}_{K,FK}$-constraints over D, we define a set Σ_N of $\mathcal{AC}^{reg}_{K,FK}$-constraints over D_N, referred to as the *narrowed set of constraints of* Σ, as follows. Let f be a substitution for the element types in E defined as $f(\tau) = \tau.(E_N \setminus E)^*$ for every $\tau \in E$. Then for every key constraint $\beta.\tau.@l \rightarrow \beta.\tau$ in Σ, $f(\beta).\tau.@l \rightarrow f(\beta).\tau$ is in Σ_N, and, for every foreign key constraint $\beta_1.\tau_1.@l \subseteq_{FK} \beta_2.\tau_2.@l$ in Σ (recall that $@l$ is the only attribute of D), $f(\beta_1).\tau_1.@l \subseteq_{FK} f(\beta_2).\tau_2.@l$ is in Σ_N.

We are now ready to establish the connection between D and D_N, which allows us to consider only narrow DTDs from now on.

LEMMA 3.9. *Let D be a one-attribute DTD, D_N the narrowed DTD of D, Σ a set of $\mathcal{AC}^{reg}_{K,FK}$-constraints over D, and Σ_N the narrowed set of constraints of Σ. Then there exists an XML tree T_1 such that $T_1 \models (D, \Sigma)$ iff there exists an XML tree T_2 such that $T_2 \models (D_N, \Sigma_N)$.*

Proof. It suffices to show the following.

Claim. Given any XML tree $T_1 \models D$, one can construct an XML tree T_2 by modifying T_1 such that $T_2 \models D_N$, and vice versa. Furthermore, for any regular expression $\beta.\tau$ over D and $@l \in R(\tau)$, $|nodes(f(\beta).\tau)|$ in T_2 equals $|nodes(\beta.\tau)|$ in T_1, and $values(f(\beta).\tau.@l)$ in T_2 equals $values(\beta.\tau.@l)$ in T_1, where f is the substitution defined above.

If the claim holds, we can show the lemma as follows. Assume that there exists an XML tree T_1 such that $T_1 \models (D, \Sigma)$. By the claim, there is T_2 such that $T_2 \models D_N$. Suppose, by contradiction, that there is $\varphi \in \Sigma_N$ such that $T_2 \not\models \varphi$. (1) If φ is a key $f(\beta).\tau.@l \rightarrow f(\beta).\tau$, then there exist two distinct nodes $x, y \in nodes(f(\beta).\tau)$ in T_2 such that $x.@l = y.@l$. In other words, $|values(f(\beta).\tau.@l)| < |nodes(f(\beta).\tau)|$ in T_2. Since $T_1 \models \varphi$, it must be the case that $|values(\beta.\tau.@l)| = |nodes(\beta.\tau)|$ in T_1 because the value $x.@l$ of each $x \in nodes(\beta.\tau)$ uniquely identifies x among $nodes(\beta.\tau)$. This contradicts the claim that $|nodes(f(\beta).\tau)|$ in T_2 equals $|nodes(\beta.\tau)|$ in T_1 and $values(f(\beta).\tau.@l)$ in T_2 equals $values(\beta.\tau.@l)$ in T_1. (2) If φ is a foreign key $f(\beta_1).\tau_1.@l \subseteq_{FK} f(\beta_2).\tau_2.@l$, then either $T_2 \not\models f(\beta_2).\tau_2.@l \rightarrow f(\beta_2).\tau_2$ or there is $x \in nodes(f(\beta_1).\tau_1)$ such that, for all $y \in nodes(f(\beta_2).\tau_2)$ in T_2, $x.@l \neq y.@l$. In the first case, we reach a contradiction as in (1). In the second case, we have $x.@l \notin values(f(\beta_2).\tau_2.@l)$ in T_2. By the claim, $x.@l \in values(\beta_1.\tau_1.@l)$ in T_1. Since $T_1 \models \varphi$, $x.@l \in values(\beta_2.\tau_2.@l)$ in T_1. Again by the claim, we have $x.@l \in values(f(\beta_2).\tau_2.@l)$ in T_2, which contradicts the assumption. The proof for the other direction is similar.

We next verify the claim. Given an XML tree $T_1 = (V_1, lab_1, ele_1, att, root)$ such that $T_1 \models D$, we construct an XML tree T_2 by modifying T_1 such that $T_2 \models D_N$. Consider a τ-element v in T_1. Let $ele_1(v) = [v_1, \ldots, v_n]$ and $w = lab_1(v_1) \ldots lab_1(v_n)$. Recall N_τ and P_τ, the set of nonterminals and the set of production rules generated when narrowing $\tau \rightarrow P(\tau)$ (see proof of Theorem 3.1), respectively. Let Q_τ be the set of E symbols that appears in P_τ. We can view $G = (Q_\tau, N_\tau \cup \{\tau\}, P_\tau, \tau)$ as an extended context free grammar, where Q_τ is the set of terminals, $N_\tau \cup \{\tau\}$ the set of nonterminals, P_τ the set of production rules, and τ the start symbol.[3] Since $T_1 \models D$, we have $w \in P(\tau)$. By a straightforward induction on the structure of $P_N(\tau)$ it can be verified that w is in the language defined by G. Thus there is a parse tree $T(w)$ w.r.t. the grammar G for w, and w is the frontier (the list of leaves from left to right) of $T(w)$. Without loss of generality, assume that the root of $T(w)$ is v and the leaves are $v_1, \ldots, v_n$. Observe that the internal nodes of $T(w)$ are labeled with element types in N_τ except that the root v is labeled τ. Intuitively, we construct T_2 by replacing each element v in T_1 by such a parse tree. More specifically, let $T_2 = (V_2, lab_2, ele_2, att, root)$. Here V_2 consists of nodes in V_1 and the internal nodes introduced in the parse trees. For each x in V_2, let $lab_2(x) = lab_1(x)$ if $x \in V_1$, and otherwise let $lab_2(x)$ be the node label of x in the parse tree where x belongs. Note that nodes in $V_2 \setminus V_1$ are elements of some type in $E_N \setminus E$. For every $x \in V_1$, let $ele_2(x)$ be the list of its children in the parse tree having x as the root. For every $x \in V_2 \setminus V_1$, let $ele_2(x)$ be the list of its children in the parse tree of an element in V_1 that contains x. Note that att remains unchanged. By the construction of T_2 it can be verified that $T_2 \models D_N$; and moreover, for every regular expression $\beta.\tau$ over D and $@l \in R(\tau)$, $|nodes(f(\beta).\tau)|$ in T_2 equals $|nodes(\beta.\tau)|$ in T_1 and $values(f(\beta).\tau.@l)$ in T_2 equals $values(\beta.\tau.@l)$ in T_1 because, among other things, (1) if a string $r.\tau_1.\ldots.\tau_n.\tau$ over E is in $\beta.\tau$, then for every sequence of strings $w_0, \ldots, w_n$ in $(E_N \setminus E)^*$, $r.w_0.\tau_1.w_1.\ldots.\tau_n.w_n.\tau$ is in $f(\beta).\tau$; (2) if a string $r.w_0.\tau_1.w_1.\ldots.\tau_n.w_n.\tau$ is in $f(\beta).\tau$, where τ_1, ..., τ_n, τ are element types in E and w_0, ..., w_n are strings in $(E_N \setminus E)^*$, then $r.\tau_1.\ldots.\tau_n.\tau$ is in $\beta.\tau$; (3) none of the new nodes, i.e., nodes in $V_2 \setminus V_1$, is labeled with an E type; (4) no new attributes are defined; and (5) the ancestor-descendant relation on T_1-elements is not changed in T_2.

[3] As in the proof of Lemma 3.2, if τ is in $P(\tau)$, then we need to rename τ in Q_τ to ensure that Q_τ and $N_\tau \cup \{\tau\}$ are disjoint. It is straightforward to handle that case.

Conversely, assume that there is $T_2 = (V_2, lab_2, ele_2, att, root)$ such that $T_2 \models D_N$. We construct an XML tree T_1 by modifying T_2 such that $T_1 \models D$. For any node $v \in V_2$ with $lab(v) = \tau$ and $\tau \in E_N \setminus E$, we replace v in $ele_2(v')$ by the children of v, where v' is the parent of v. In addition, we remove v from V_2, $lab_2(v)$ from lab_2, and $ele_2(v)$ from ele_2. Observe that, by the definition of D_N, no attributes are defined for elements of any type in $E_N \setminus E$. We repeat the process until there is no node labeled with an element type in $E_N \setminus E$. Now let $T_1 = (V_1, lab_1, ele_1, att, root)$, where V_1, lab_1, and ele_1 are V_2, lab_2, and ele_2 at the end of the process, respectively. Observe that att and $root$ remain unchanged. By the definition of T_1 it can be verified that $T_1 \models D$; in addition, for any regular expression $\beta.\tau$ over D and $@l \in R(\tau)$, $|nodes(\beta.\tau)|$ in T_1 equals $|nodes(f(\beta).\tau)|$ in T_2, and $values(\beta.\tau.@l)$ in T_1 equals $values(f(\beta).\tau.@l)$ in T_2, because of (1) and (2) above and, among other things, the fact that none of the nodes removed is labeled with a type of E and the attribute function att is unchanged.

We now move to encoding of DTDs, more specifically, narrow one-attribute DTDs. Let $D = (E, \{@l\}, P, R, r)$ be a narrow one-attribute DTD and Σ a set of $\mathcal{AC}^{reg}_{K,FK}$-constraints over D. We encode D with a system Ψ^{Σ}_{D} of integer constraints such that there exists an XML tree conforming to D iff Ψ^{Σ}_{D} admits a nonnegative solution. The coding is developed w.r.t. Σ. More specifically, assume that $\beta_1.\tau_1.@l, \ldots, \beta_k.\tau_k.@l$ is an enumeration of all regular expressions and attributes that appear in Σ and Θ is the set of functions $\theta : \{1, \ldots, k\} \to \{0, 1\}$ which are not identically 0. For every $\theta \in \Theta$, define a regular expression:

$$r_\theta = \left(\bigcap_{i\,:\,\theta(i)=1} \beta_i.\tau_i \right) \cap \left(\bigcap_{j\,:\,\theta(j)=0} \overline{\beta_j.\tau_j} \right), \tag{3.1}$$

where $\overline{\beta_j.\tau_j}$ is the complement $\beta_j.\tau_j$. We allow intersection and complement operators only in regular expressions r_θ. We note that, for every $i \in [1, k]$,[4]

$$\beta_i.\tau_i = \bigcup_{\theta\,:\,\theta(i)=1} r_\theta.$$

Then to capture the interaction between D and constraints of Σ, the system Ψ^{Σ}_{D} has a variable $|nodes(\beta_i.\tau_i)|$, for every $i \in [1, k]$, and $|nodes(r_\theta)|$, for every $\theta \in \Theta$. In other words, Ψ^{Σ}_{D} specifies the dependencies imposed by D on the number of elements reachable by following $\beta_i.\tau_i$ ($i \in [1, k]$) and r_θ ($\theta \in \Theta$).

To capture $\beta_i.\tau_i$ ($i \in [1, k]$) and r_θ ($\theta \in \Theta$) in Ψ^{Σ}_{D}, consider, for each regular expression $\beta_i.\tau_i$ ($i \in [1, k]$), a deterministic automaton that recognizes that expression. Let M be the deterministic automaton equivalent to the product of all of these automata. We refer to M as the DFA for Σ. Let s_M be the start state of M and δ be its transition function. Given an XML tree T conforming to D, for each node x in T we define $state(x)$ as s, if there is a simple path ρ over D such that $T \models \rho(root, x)$ and $s = \delta(s_M, \rho)$. The connection between M and T w.r.t. $\beta_i.\tau_i$ ($i \in [1, k]$) is described by the following lemma.

LEMMA 3.10. *Let D be a narrow one-attribute DTD, Σ a set of $\mathcal{AC}^{reg}_{K,FK}$-constraints over D, M the DFA for Σ, and $\beta_i.\tau_i$ a regular expression in Σ. Then for every XML tree T conforming to D and every τ_i-element x in T, $x \in nodes(\beta_i.\tau_i)$ in T iff $state(x)$ contains some final state $f_{\beta_i.\tau_i}$ of the automaton for $\beta_i.\tau_i$.*

[4]Recall that the regular language defined by a regular expression β is denoted by β as well.

In other words, $nodes(\beta_i.\tau_i)$ in T consists of all τ_i-elements x such that $state(x)$ (which is a tuple of states of automata corresponding to regular expressions in Σ) contains some final state $f_{\beta_i.\tau_i}$ of the automaton for $\beta_i.\tau_i$. A similar idea was exploited in [1].

Proof. Since T is a tree, there exists a unique simple path ρ over D such that $T \models \rho.\tau_i(root,\ x)$. Thus $x \in nodes(\beta.\tau_i)$ in T iff $\rho.\tau_i \in \beta.\tau_i$. If $x \in nodes(\beta.\tau_i)$ in T, then $\rho.\tau_i \in \beta.\tau_i$, and, therefore, there must be a final state $f_{\beta.\tau_i}$ in the automaton for $\beta.\tau_i$ and a state s in M such that $s = \delta(s_M, \rho.\tau_i)$ and s contains $f_{\beta_i.\tau_i}$. Thus $state(x) = s$ contains some final state $f_{\beta_i.\tau_i}$ of the automaton for $\beta_i.\tau_i$. Conversely, if $state(x)$ contains a final state $f_{\beta_i.\tau_i}$ in the automaton for $\beta_i.\tau_i$, then $\rho.\tau_i \in \beta.\tau_i$ since $s = \delta(s_M, \rho.\tau_i)$. Therefore, $x \in nodes(\beta_i.\tau_i)$ in T.

We next define a system Ψ_D^Σ of integer constraints. The variables used in the constraints of Ψ_D^Σ are as follows. Let $\tau \in E$ be an element type and $s = \delta(s_M, \rho.\tau)$ for some simple path $\rho.\tau \in E^*$. For each such pair we create a distinct variable x_τ^s. Intuitively, in an XML tree T conforming to D, we use x_τ^s to keep track of the number of τ-elements with state s. Furthermore, define Y_τ^s as the set of pairs (τ', s') such that $\tau' \in E$, $s' = \delta(s_M, \rho.\tau')$ for some simple path $\rho.\tau' \in E^*$, τ is mentioned in $P(\tau')$, and $s = \delta(s', \tau)$. For each such pair (τ', s'), we create a variable $x_{\tau,\tau'}^{s,s'}$. Intuitively, in an XML tree T conforming to D, we use $x_{\tau,\tau'}^{s,s'}$ to keep track of the number of τ-elements with state s that are children of a node of type τ' with state s'. There are exponentially many variables (in the size of D and Σ) in total since M is a DFA. By using these, we define an integer constraint to specify $\tau \to P(\tau)$ at state s as follows. Let us use Ψ_τ^s to denote the set of integer constraints defined for τ at s.

- If $P(\tau) = \tau_1$, then Ψ_τ^s includes $x_\tau^s = x_{\tau_1,\tau}^{s_1,s}$, where $s_1 = \delta(s, \tau_1)$.
- If $P(\tau) = (\tau_1, \tau_2)$, then Ψ_τ^s includes $x_\tau^s = x_{\tau_1,\tau}^{s_1,s}$ and $x_\tau^s = x_{\tau_2,\tau}^{s_2,s}$, where $s_i = \delta(s, \tau_i)$ for $i = 1, 2$. Referring to the XML tree T, these assure that each τ-element in T must have a τ_1-subelement and a τ_2-subelement.
- If $P(\tau) = (\tau_1|\tau_2)$, then Ψ_τ^s includes $x_\tau^s = x_{\tau_1,\tau}^{s_1,s} + x_{\tau_2,\tau}^{s_2,s}$, where $s_i = \delta(s, \tau_i)$ for $i = 1, 2$. This assures that each τ-element in T must have either a τ_1-subelement or a τ_2-subelement, and thus the sum of the number of these τ_1-subelements and the number of τ_2-subelements equals the number of τ-elements.
- If $P(\tau) = \tau_1^*$, then Ψ_τ^s includes $(x_{\tau_1,\tau}^{s_1,s} > 0) \to (x_\tau^s > 0)$, where $s_1 = \delta(s, \tau_1)$.

In addition, Ψ_τ^s includes $x_\tau^s = \sum_{(\tau',s') \in Y_\tau^s} x_{\tau,\tau'}^{s,s'}$.

Recall that $\beta_1.\tau_1.@l, \ldots, \beta_k.\tau_k.@l$ is an enumeration of all regular expressions and attributes that appear in Σ, that Θ is the set of functions $\theta : \{1, \ldots, k\} \to \{0, 1\}$ which are not identically 0, and that, for each such function θ, r_θ is a regular expression defined as in (3.1). For each $i \in [1, k]$, we define $F_{\beta_i.\tau_i}$ as the set of states $s = (s_1, \ldots, s_k)$ of the DFA for Σ such that s_i is a final state of the DFA for $\beta_i.\tau_i$. Notice that by Lemma 3.10, for every XML tree T conforming to D and every node x of T, $x \in nodes(\beta_i.\tau_i)$ in T iff $state(x) \in F_{\beta_i.\tau_i}$. Furthermore, for each $\theta \in \Theta$, we define F_θ as the set of states $s = (s_1, \ldots, s_k)$ of the DFA for Σ such that for every $i \in [1, k]$, s_i is a final state of the DFA for $\beta_i.\tau_i$ iff $\theta(i) = 1$. Notice that by Lemma 3.10, for every XML tree T conforming to D and every node x of T, $x \in nodes(r_\theta)$ in T iff $state(x) \in F_\theta$. Finally, for each $r_\theta \neq \emptyset$, we have that, for every $i, j \in [1, k]$, if $\theta(i) = \theta(j) = 1$, then $\tau_i = \tau_j$. In this case, we define τ_θ as τ_i, for an arbitrary $i \in [1, k]$ such that $\theta(i) = 1$.

By our restriction on regular expressions regarding element type r, there is a unique variable x_r^s associated with r, where $s = \delta(s_M, r)$. We write x_r for x_r^s. Then

we define *the set of cardinality constraints determined by DTD D* w.r.t. a set Σ of $\mathcal{AC}^{reg}_{K,FK}$-constraints over D, denoted by Ψ^{Σ}_{D}, as follows:

- For each $\tau \in E$ and each state s given above, Ψ^{Σ}_{D} contains all of the constraints in Ψ^{s}_{τ}.
- Ψ^{Σ}_{D} contains constraint $x_r = 1$; i.e., there is a unique root in each XML tree conforming to D.
- For every $i \in [1,k]$, Ψ^{Σ}_{D} contains constraint $|nodes(\beta_i.\tau_i)| = \sum_{s\,:\,s\in F_{\beta_i.\tau_i}} x^{s}_{\tau_i}$.
- For every $\theta \in \Theta$ such that $r_\theta \neq \emptyset$, Ψ^{Σ}_{D} contains constraint $|nodes(r_\theta)| = \sum_{s\,:\,s\in F_\theta} x^{s}_{\tau_\theta}$.
- For every $\theta \in \Theta$ such that $r_\theta = \emptyset$, Ψ^{Σ}_{D} contains constraint $|nodes(r_\theta)| = 0$.

Note that Ψ^{Σ}_{D} can be computed in EXPTIME in the size of D and Σ. We say that Ψ^{Σ}_{D} is *consistent* iff it has a nonnegative solution. We next show that Ψ^{Σ}_{D} indeed characterizes the narrow one-attribute DTD D. □

LEMMA 3.11. *Let D be a narrow one-attribute DTD, Σ a set of $\mathcal{AC}^{reg}_{K,FK}$-constraints over D, and Ψ^{Σ}_{D} the set of cardinality constraints determined by D w.r.t. Σ. Then Ψ^{Σ}_{D} is consistent iff there is an XML tree T such that $T \models D$. In addition, for every $i \in [1,k]$ and $\theta \in \Theta$, $|nodes(\beta_i.\tau_i)|$ and $|nodes(r_\theta)|$ in T equal the value of variables $|nodes(\beta_i.\tau_i)|$ and $|nodes(r_\theta)|$ given by the solution to Ψ^{Σ}_{D}.*

Proof. First, assume that there is an XML tree $T = (V, lab, ele, att, root)$ conforming to D. We define a nonnegative solution of Ψ^{Σ}_{D} as follows. For each variable $x^{s,s'}_{\tau,\tau'}$ in Ψ^{Σ}_{D}, let its value be the number of τ-elements x in T such that x is a child of a node y of type τ' with $state(x) = s$ and $state(y) = s'$. Furthermore, let x_r be 1, and, for every variable x^{s}_{τ} in Ψ^{Σ}_{D}, let x^{s}_{τ} be the sum of the variables $x^{s,s'}_{\tau,\tau'}$ where $(\tau', s') \in Y^{s}_{\tau}$. Finally, for every $i \in [1,k]$ and every $\theta \in \Theta$, let $|nodes(\beta_i.\tau_i)|$ and $|nodes(r_\theta)|$ be $\sum_{s\,:\,s\in F_{\beta_i.\tau_i}} x^{s}_{\tau_i}$ and $\sum_{s\,:\,s\in F_\theta} x^{s}_{\tau_\theta}$, respectively. This defines a nonnegative assignment since T is finite. It can be verified that the assignment is a solution of Ψ^{Σ}_{D}. Indeed, it satisfies the constraint $x_r = 1$ and constraints of the form $x^{s}_{\tau} = \sum_{(\tau',s')\in Y^{s}_{\tau}} x^{s,s'}_{\tau,\tau'}$, $|nodes(\beta_i.\tau_i)| = \sum_{s\,:\,s\in F_{\beta_i.\tau_i}} x^{s}_{\tau_i}$, and $|nodes(r_\theta)| = \sum_{s\,:\,s\in F_\theta} x^{s}_{\tau_\theta}$ by the definition of the assignment. Moreover, one can verify that it also satisfies the constraints of each Ψ^{s}_{τ}, by considering four different cases corresponding to the four different types of regular expressions in D. In particular, it satisfies constraints of the form $(x^{s_1,s}_{\tau_1,\tau} > 0) \rightarrow (x^{s}_{\tau} > 0)$ for each $\tau \rightarrow \tau_1^*$ in P, since if $x^{s_1,s}_{\tau_1,\tau} > 0$, then there exists a τ_1-node in T having as its parent a τ-node y with $state(y) = s$. Thus, $x^{s}_{\tau} > 0$ by the definition of the assignment. Therefore, Ψ^{Σ}_{D} is consistent. Moreover, by Lemma 3.10, for every $i \in [1,k]$ and $\theta \in \Theta$, the values of variables $|nodes(\beta_i.\tau_i)|$ and $|nodes(r_\theta)|$ in the solution are indeed $|nodes(\beta_i.\tau_i)|$ and $|nodes(r_\theta)|$ in T.

Conversely, assume that Ψ^{Σ}_{D} admits a nonnegative solution. We show that there exists an XML tree $T = (V, lab, ele, att, root)$ such that $T \models D$. To do so, for each element type τ and state s for τ, we create x^{s}_{τ} many distinct τ-elements. Let $ext(\tau)$ denote the set of all τ-elements created above and

$$V = \bigcup_{\tau\in E} ext(\tau).$$

Then function lab is defined as $lab(v) = \tau$ if $v \in ext(\tau)$, and function att is defined as follows:

$$att(v, @l) = \begin{cases} \text{empty string} & \text{if } @l \in R(lab(v)), \\ \text{undefined} & \text{otherwise.} \end{cases}$$

It is easy to verify that these functions are well defined. Let *root* be the node labeled r, which is unique since $x_r = 1$ is in Ψ_D^Σ. Finally, to define function *ele*, we do the following. For each $x_{\tau,\tau'}^{s,s'}$ in Ψ_D^Σ, we choose $x_{\tau,\tau'}^{s,s'}$ many distinct vertices labeled τ and mark them with $x_{\tau,\tau'}^{s,s'}$. Note that every τ-element in V can be marked once and only once. Starting at *root*, for each τ-element x marked with $x_{\tau,\tau'}^{s,s'}$ for some $(\tau', s') \in Y_\tau^s$, consider $P(\tau)$ and constraints of Ψ_D^Σ.[5] If $P(\tau)$ is $\tau_1 \in E$, then we choose a distinct τ_1-element y marked with $x_{\tau_1,\tau}^{s_1,s}$ and let $ele(x) = [y]$, where $x_\tau^s = x_{\tau_1,\tau}^{s_1,s}$ is in Ψ_D^Σ. If $P(\tau) = (\tau_1, \tau_2)$, then we choose a τ_1-element y_1 marked with $x_{\tau_1,\tau}^{s_1,s}$ and a τ_2-element y_2 marked with $x_{\tau_2,\tau}^{s_2,s}$ and let $ele(x) = [y_1, y_2]$, where $x_\tau^s = x_{\tau_1,\tau}^{s_1,s}$ and $x_\tau^s = x_{\tau_2,\tau}^{s_2,s}$ are in Ψ_D^Σ. If $P(\tau) = (\tau_1|\tau_2)$, then we choose an element y marked with either $x_{\tau_1,\tau}^{s_1,s}$ or $x_{\tau_2,\tau}^{s_2,s}$ and let $ele(x) = [y]$, where $x_\tau^s = x_{\tau_1,\tau}^{s_1,s} + x_{\tau_2,\tau}^{s_2,s}$ is in Ψ_D^Σ. If $P(\tau) = \tau_1^*$, then we choose a list $[y_1, \ldots, y_n]$ $(n \geq 0)$ of τ_1-elements marked with $x_{\tau_1,\tau}^{s_1,s}$ and let $ele(x) = [y_1, \ldots, y_n]$, where $(x_{\tau_1,\tau}^{s_1,s} > 0) \rightarrow (x_\tau^s > 0)$ is in Ψ_D^Σ. By the constraints in Ψ_D^Σ, each element of V can be chosen once and only once. One can verify that T defined in this way is indeed an XML tree and $T \models D$. Hence, there exists an XML tree conforming to D.

Finally, to see that, for every $i \in [1, k]$ and $\theta \in \Theta$, $|nodes(\beta_i.\tau_i)|$ and $|nodes(r_\theta)|$ in T equal the values of variables $|nodes(\beta.\tau)|$ and $|nodes(r_\theta)|$ in the solution, respectively, it suffices to show, by Lemma 3.10, that for each node x in T, if x is marked with $x_{\tau,\tau'}^{s,s'}$ in the construction, then $state(x) = s$. Since T is a tree, there is a unique simple path $\rho \in E^*$ such that $T \models \rho(root, x)$. We show the claim by induction on the length $|\rho|$ of ρ. If $|\rho| = 1$, i.e., $\rho = r$, then x is the root and, obviously, $state(x) = \delta(s_M, r)$. Assume the claim for ρ, and we show that the claim holds for $\rho.\tau$. Let y be the τ'-element in T such that $T \models \rho(root, y)$ and y is the parent of x. Suppose that y is marked with $x_{\tau',\tau''}^{s',s''}$ in the construction. By the induction hypothesis, $state(y) = s'$. It is easy to see that $state(x) = \delta(s', \tau)$. By the definition of $\Psi_{\tau'}^{s'}$, we have that s is precisely the state $\delta(s', \tau)$. Thus $state(x) = s$. This proves the claim and thus the lemma. □

We now move to encoding $\mathcal{AC}_{K,FK}^{reg}$-constraints in terms of integer constraints. Let D be a DTD $(E, \{@l\}, P, R, r)$ and Σ a set of $\mathcal{AC}_{K,FK}^{reg}$-constraints over D. By Lemmas 3.8 and 3.9, we assume, without loss of generality, that D is a narrow one-attribute DTD. To encode Σ, let $\beta_1.\tau_1.@l, \ldots, \beta_k.\tau_k.@l$ be an enumeration of all regular expressions and attributes that appear in Σ, and, for every function $\theta : \{1, \ldots, k\} \rightarrow \{0, 1\}$ which is not identically 0, let regular expression r_θ be defined as in (3.1). Then for every nonempty $\Omega \subseteq \Theta$, we introduce a new variable z_Ω. In any XML tree conforming to D, the intended interpretation of z_Ω is the cardinality of

$$\left(\bigcap_{\theta\,:\,\theta \in \Omega} values(r_\theta.@l) \right) \setminus \left(\bigcup_{\theta\,:\,\theta \in \Theta \setminus \Omega} values(r_\theta.@l) \right). \tag{3.2}$$

Note that the number of new variables is double-exponential in the number of regular expression in Σ. By using these variables, we define the set of *the cardinality constraints determined by* Σ, denoted by C_Σ, which consists of the following:

[5] We assume that *root* is marked with x_r^s, where $s = \delta(s_M, r)$ and s_M is the initial state of the DFA for Σ.

$$\sum_{\Omega\,:\,\theta\in\Omega} z_\Omega = |values(r_\theta.@l)| \quad \text{for every } \theta\in\Theta,$$

$$\sum_{\Omega\,:\,\Omega\cap\{\theta|\theta(i)=1\}\neq\emptyset} z_\Omega = |values(\beta_i.\tau_i.@l)| \quad \text{for every } i\in[1,k],$$

$$|values(\beta_i.\tau_i.@l)| = |nodes(\beta_i.\tau_i)| \quad \text{for every } \beta_i.\tau_i.@l\to\beta_i.\tau_i \text{ in } \Sigma,$$

$$|values(\beta_j.\tau_j.@l)| = |nodes(\beta_j.\tau_j)| \quad \text{for every } \beta_i.\tau_i.@l\subseteq_{FK}\beta_j.\tau_j.@l \text{ in } \Sigma,$$

$$\sum_{\substack{\Omega\,:\,\Omega\cap\{\theta|\theta(i)=1\}\neq\emptyset,\\ \Omega\cap\{\theta'|\theta'(j)=1\}=\emptyset}} z_\Omega = 0 \quad \text{for every } \beta_i.\tau_i.@l\subseteq_{FK}\beta_j.\tau_j.@l \text{ in } \Sigma,$$

$$|values(\beta_i.\tau_i.@l)| \le |nodes(\beta_i.\tau_i)| \quad \text{for every } i\in[1,k],$$

$$|values(r_\theta.@l)| \le |nodes(r_\theta)| \quad \text{for every } \theta\in\Theta.$$

Note that the size of C_Σ is double-exponential in the size of Σ.

We now combine the encodings for constraints and the DTDs and present a system $\Psi(D,\Sigma)$ of linear integer constraints for a DTD D and a set Σ of $\mathcal{AC}^{reg}_{K,FK}$-constraints. Assuming that D and Σ are as above, the set $\Psi(D,\Sigma)$, called the *set of cardinality constraints determined by D and Σ*, is defined to be:

$$\Psi_D^\Sigma \cup C_\Sigma \cup \{(|nodes(\beta_i.\tau_i)|>0)\to(|values(\beta_i.\tau_i.@l)|>0) \mid i\in[1,k]\} \cup \{(|nodes(r_\theta)|>0)\to(|values(r_\theta.@l)|>0)\mid\theta\in\Theta\},$$

where C_Σ is the set of cardinality constraints determined by Σ and Ψ_D^Σ is the set of cardinality constraints determined by D w.r.t. Σ. The system $\Psi(D,\Sigma)$ is said to be *consistent* iff it has a nonnegative solution that satisfies all of its constraints. Observe that $\Psi(D,\Sigma)$ can be partitioned into two sets: $\Psi(D,\Sigma)=\Psi^l(D,\Sigma)\cup\Psi^d(D,\Sigma)$, where $\Psi^l(D,\Sigma)$ consists of linear integer constraints and $\Psi^d(D,\Sigma)$ consists of constraints of the form $(x>0\to y>0)$. Also note that the size of $\Psi(D,\Sigma)$ is double-exponential in the size of D and Σ.

We next show that $\Psi(D,\Sigma)$ indeed characterizes the consistency of D and Σ.

LEMMA 3.12. *Let D be a narrow one-attribute DTD, Σ a finite set of $\mathcal{AC}^{reg}_{K,FK}$-constraints over D, and $\Psi(D,\Sigma)$ the set of cardinality constraints determined by D and Σ. Then $\Psi(D,\Sigma)$ is consistent iff there is an XML tree T such that $T\models(D,\Sigma)$.*

Proof. Suppose that there exists an XML tree T such that $T\models(D,\Sigma)$. Then by Lemma 3.11, there exists a nonnegative solution for Ψ_D^Σ such that, for every $i\in[1,k]$ and $\theta\in\Theta$, the values of variables $|nodes(r_\theta)|$ and $|nodes(\beta_i.\tau_i)|$ in this solution coincide with $|nodes(r_\theta)|$ and $|nodes(\beta_i.\tau_i)|$ in T, respectively. From this solution, it is easy to generate a solution to $\Psi(D,\Sigma)$ by assigning to variable $|values(r_\theta.@l)|$ the size of $values(r_\theta.@l)$ in T, for every $\theta\in\Theta$, assigning to variable $|values(\beta_i.\tau_i.@l)|$ the size of $values(\beta_i.\tau_i.@l)$ in T, for every $i\in[1,k]$, and then assigning to each variable z_Ω the cardinality of set (3.2) above. It is straightforward to verify that this assignment is a solution to $\Psi(D,\Sigma)$.

Conversely, suppose that $\Psi(D,\Sigma)$ has an integer solution. We show that there is an XML tree T such that $T\models(D,\Sigma)$. By Lemma 3.11, given an integer solution to $\Psi(D,\Sigma)$, we can construct an XML tree $T'=(V,lab,ele,att',root)$ such that

$T' \models D$. Moreover, for every $i \in [1,k]$, there are exactly $n_{\beta_i.\tau_i}$ elements in T' reachable by following $\beta_i.\tau_i$, where $n_{\beta_i.\tau_i}$ is the value of the variable $|nodes(\beta_i.\tau_i)|$ in $\Psi(D, \Sigma)$, and, for every $\theta \in \Theta$, there are exactly n_{r_θ} elements in T' reachable by following r_θ, where n_{r_θ} is the value of the variable $|nodes(r_\theta)|$ in $\Psi(D, \Sigma)$. We modify the definition of the function att', while leaving V, lab, ele, and $root$ unchanged, to generate a tree $T = (V, lab, ele, att, root)$ such that $T \models (D, \Sigma)$. More specifically, we modify $att'(v, @l)$ if v is in $nodes(\beta.\tau)$ for some regular expression $\beta.\tau$ mentioned in Σ and leave $att'(v, @l)$ unchanged otherwise. To do this, for each variable z_Ω we create a set s_Ω of distinct string values such that $|s_\Omega| = z_\Omega$ and $s_\Omega \cap s_{\Omega'} = \emptyset$ if $\Omega \neq \Omega'$. Then for every $\Omega \subseteq \Theta$, we let $values(r_\theta.@l)$ in T contain s_Ω iff $\theta \in \Omega$. This is possible because (1) $\sum_{\Omega\,:\,\theta\in\Omega} z_\Omega = |values(r_\theta.@l)|$ is in C_Σ for every $\theta \in \Theta$; (2) $\sum_{\Omega\,:\,\Omega\cap\{\theta|\theta(i)=1\}\neq\emptyset} z_\Omega = |values(\beta_i.\tau_i.@l)|$ is in C_Σ for every $i \in [1,k]$; (3) if $r_\theta = \emptyset$, then $|nodes(r_\theta)| = 0$ is in Ψ_D^Σ for every $\theta \in \Theta$; (4) $|values(\beta_i.\tau_i.@l)| \leq |nodes(\beta_i.\tau_i)|$ is in C_Σ for every $i \in [1,k]$; (5) $|values(r_\theta.@l)| \leq |nodes(r_\theta)|$ is in C_Σ for every $\theta \in \Theta$; and (6) $nodes(\beta)$ in T equals $nodes(\beta)$ in T' for every regular expression β over D.

We next show that T has the desired properties. It is easy to verify $T \models D$ given the construction of T from T' and the assumption $T' \models D$. By the definition of T, we have that, for every $i \in [1,k]$ and $\theta \in \Theta$, $|nodes(\beta_i.\tau_i)|$, $|values(\beta_i.\tau_i.@l)|$, $|nodes(r_\theta)|$, and $|values(r_\theta.@l)|$ in T equal the value of variables $|nodes(\beta_i.\tau_i)|$, $|values(\beta_i.\tau_i.@l)|$, $|nodes(r_\theta)|$, and $|values(r_\theta.@l)|$, respectively, given by the solution to $\Psi(D, \Sigma)$. We use this property to show that $T \models \Sigma$. Let φ be a constraint in Σ. (1) If φ is a key $\beta_i.\tau_i.@l \rightarrow \beta_i.@l$, it is immediate from the definition of T that $T \models \varphi$ since $|values(\beta_i.\tau_i.@l)| = |nodes(\beta_i.\tau_i)|$ is a constraint in C_Σ and, hence, $|values(\beta_i.\tau_i.@l)| = |nodes(\beta_i.\tau_i)|$ in T. That is, each $x \in nodes(\beta_i.\tau_i)$ in T has a distinct $@l$-attribute value, and thus the value of its $@l$-attribute uniquely identifies x among nodes in $nodes(\beta_i.\tau_i)$. (2) If φ is $\beta_i.\tau_i.@l \subseteq_{FK} \beta_j.\tau_j.@l$, it is easy to see that in T:

$$values(\beta_i.\tau_i.@l) \setminus values(\beta_j.\tau_j.@l) = \bigcup_{\Omega\,:\,\Omega\cap\{\theta|\theta(i)=1\}\neq\emptyset,\,\Omega\cap\{\theta'|\theta'(j)=1\}=\emptyset} s_\Omega.$$

Since $s_\Omega \cap s_{\Omega'} = \emptyset$ if $\Omega \neq \Omega'$,

$$|values(\beta_i.\tau_i.@l) \setminus values(\beta_j.\tau_j.@l)| = \sum_{\Omega\,:\,\Omega\cap\{\theta|\theta(i)=1\}\neq\emptyset,\,\Omega\cap\{\theta'|\theta'(j)=1\}=\emptyset} z_\Omega.$$

Thus, given that

$$\sum_{\Omega\,:\,\Omega\cap\{\theta|\theta(i)=1\}\neq\emptyset,\,\Omega\cap\{\theta'|\theta'(j)=1\}=\emptyset} z_\Omega = 0$$

is in C_Σ (since $\beta_i.\tau_i.@l \subseteq_{FK} \beta_j.\tau_j.@l \in \Sigma$), we have $|values(\beta_i.\tau_i.@l) \setminus values(\beta_j.\tau_j.@l)| = 0$ in T, that is, $values(\beta_i.\tau_i.@l) \subseteq values(\beta_j.\tau_j.@l)$ in T. Furthermore, $T \models \beta_j.\tau_j.@l \rightarrow \beta_j.\tau_j$ since $|values(\beta_j.\tau_j.@l)| = |nodes(\beta_j.\tau_j)|$ is a constraint in C_Σ. Thus $T \models \varphi$. This concludes the proof of the lemma. □

We need another lemma for a mild generalization of linear integer constraints.

LEMMA 3.13. *Given a system $A\vec{x} \leq \vec{b}$ of linear integer constraints together with conditions of the form $(x_i > 0) \rightarrow (x_j > 0)$, where A is an $n \times m$ matrix on integers, $\vec{b}$ is an n-vector on integers, and $1 \leq i, j \leq m$, the problem of determining whether the system admits a nonnegative integer solution is in NP.*

Proof. Let $c_1, \ldots, c_p$ enumerate the conditions of the form $(x > 0) \rightarrow (y > 0)$, c_k being $(x_k^1 > 0) \rightarrow (x_k^2 > 0)$. Consider 2^p instances $\mathcal{I}_j$ of integer linear programming

obtained by adding, for each $k \leq p$, either $x_k^1 = 0$ or $x_k^2 > 0$ to $A\vec{x} \leq \vec{b}$. Clearly, the original system of constraints has a solution iff some $\mathcal{I}_j$ has a solution. By [27], $\mathcal{I}_j$ has a solution iff it has a solution whose size is polynomial in A, $\vec{b}$, and p. Hence, to check if the original system of constraints has a solution, it suffices to guess a system $\mathcal{I}_j$ and then guess a polynomial size solution for it; thus, the problem is in NP.

We now conclude the proof of the first part of the theorem. By Lemma 3.8, given an arbitrary DTD D and a set Σ of $\mathcal{AC}^{reg}_{K,FK}$-constraints over D, it is possible to compute a one-attribute DTD D' and a set Σ' of $\mathcal{AC}^{reg}_{K,FK}$-constraints over D' such that (D, Σ) is consistent iff (D', Σ') is consistent. By Lemma 3.9, one can compute a narrow one-attribute DTD D'_N and a set Σ'_N of $\mathcal{AC}^{reg}_{K,FK}$-constraints over D'_N such that (D', Σ') is consistent iff (D'_N, Σ'_N) is consistent. By Lemma 3.12, (D'_N, Σ'_N) is consistent iff $\Psi(D'_N, \Sigma'_N)$ has a nonnegative integer solution. Thus, (D, Σ) is consistent iff $\Psi(D'_N, \Sigma'_N)$ has a nonnegative integer solution. Note that (D', Σ') can be computed in polynomial time on $|D| + |\Sigma|$, (D'_N, Σ'_N) can be computed in polynomial time on $|D'|+|\Sigma'|$, and $\Psi(D'_N, \Sigma'_N)$ can be computed in double-exponential time on $|D'_N|+|\Sigma'_N|$. Thus, by Lemma 3.13, one can check in 2-NEXPTIME whether there exists an XML tree T such that $T \models (D, \Sigma)$. □

Proof of (b). We establish the PSPACE-hardness by reduction from the QBF-CNF problem. An instance of QBF-CNF is a quantified boolean formula in prenex conjunctive normal form. The problem is to determine whether this formula is valid. QBF-CNF is known to be PSPACE-complete [20, 28].

Let θ be a formula of the form

$$Q_1 x_1 \dots Q_m x_m \psi, \tag{3.3}$$

where each $Q_i \in \{\forall, \exists\}$ $(1 \leq i \leq m)$ and ψ is a propositional formula in conjunctive normal form, say, $C_1 \wedge \dots \wedge C_n$, that mentions variables $x_1, \dots, x_m$. We construct a DTD D_θ and a set Σ_θ of $\mathcal{AC}^{reg}_{K,FK}$-constraint such that θ is valid iff there is an XML tree conforming to D_θ and satisfying Σ_θ.

We construct a DTD $D_\theta = (E, A, P, R, r)$ as follows. $E = \{r, C\} \cup \bigcup_{i=1}^{m} \{x_i, \bar{x}_i, N_{x_i}, P_{x_i}\}$, $A = \{@l\}$, and P is defined by considering the quantifiers of θ. We use Q_1 to define P on the root:

$$P(r) = \begin{cases} (N_{x_1}|P_{x_1}), C & Q_1 = \exists, \\ (N_{x_1}, P_{x_1}), C & Q_1 = \forall. \end{cases}$$

In general, for each $1 \leq i \leq m-1$, we consider quantifier Q_{i+1} to define $P(N_{x_i})$ and $P(P_{x_i})$:

$$P(N_{x_i}) = P(P_{x_i}) = \begin{cases} N_{x_{i+1}}|P_{x_{i+1}} & Q_{i+1} = \exists, \\ N_{x_{i+1}}, P_{x_{i+1}} & Q_{i+1} = \forall. \end{cases}$$

We represent formula ψ as a regular expression. Given a clause $C_j = \bigvee_{i=1}^{p} y_i \vee \bigvee_{i=1}^{q} \neg z_i$ $(j \in [1, n])$, $tr(C_j)$ is defined to be the regular expression $y_1| \dots |y_p|\bar{z}_1| \dots |\bar{z}_q$. We define P on element types N_{x_m} and P_{x_m} as $P(N_{x_m}) = P(P_{x_m}) = tr(C_1), \dots, tr(C_n)$. For the remaining elements of E, we define P as ϵ. We define function R as follows:

$$\begin{array}{lllllll} R(r) & = & R(P_{x_i}) & = & R(N_{x_i}) & = & \emptyset, \quad 1 \leq i \leq m, \\ R(C) & = & R(x_i) & = & R(\bar{x}_i) & = & \{@l\}, \quad 1 \leq i \leq m. \end{array}$$

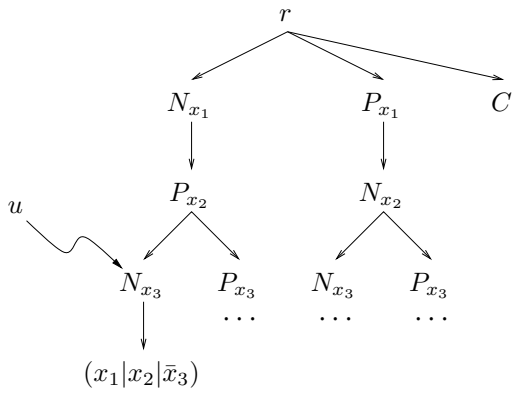

FIG. 3.2. *An XML tree conforming to the DTD constructed from* $\forall x_1 \exists x_2 \forall x_3 (x_1 \vee x_2 \vee \neg x_3)$.

Finally, Σ_θ contains the following foreign keys:

$$r._^*.N_{x_i}._^*.x_i.@l \subseteq_{FK} r.C.C.@l, \qquad r._^*.P_{x_i}._^*.\bar{x}_i.@l \subseteq_{FK} r.C.C.@l, \qquad i \in [1,m].$$

For instance, for the formula $\forall x_1 \exists x_2 \forall x_3 (x_1 \vee x_2 \vee \neg x_3)$, an XML tree conforming to D is shown in Figure 3.2. In this tree, a node of type N_{x_i} represents a negative value (0) for the variable x_i, and a node of type P_{x_i} represents a positive value (1) for this variable. Thus, given that the root has two children of types N_{x_1} and P_{x_1}, the values 0 and 1 are assigned to x_1 (representing the quantifier $\forall x_1$). Nodes of type N_{x_1} have one child of type either N_{x_2} or P_{x_2}, and, therefore, either 0 or 1 is assigned to x_2 (representing the quantifier $\exists x_2$). The same holds for nodes of type P_{x_2}. The fourth level of the tree represents the quantifier $\forall x_3$. Note that, in any XML tree T conforming to D, there is *no* node in T reachable by following the path $r.C.C$.

In Figure 3.2, every path from the root r to a node of type either N_{x_3} or P_{x_3} represents a truth assignment for the variables x_1, x_2, x_3. For example, the path from the root to the node u represents the truth assignment σ_u: $\sigma_u(x_1) = 0$, $\sigma_u(x_2) = 1$, and $\sigma_u(x_3) = 0$. To verify that all of these assignments satisfy the formula $x_1 \vee x_2 \vee \neg x_3$ we use the set of constraints Σ_θ.

Next we prove that θ, defined in (3.3), is valid iff there is an XML tree T conforming to D_θ and satisfying Σ_θ. We show only the "if" direction. The "only if" direction is similar.

Suppose that there is an XML tree T such that $T \models (D_\theta, \Sigma_\theta)$. To prove that θ is valid, it suffices to prove that each path from the root r to a node of type either N_{x_m} or P_{x_m} represents a truth assignment satisfying ψ. Let p be one of these paths, and let v be the node of type either N_{x_m} or P_{x_m} reachable from the root by following p. We define the truth assignment σ_p as follows:

$$\sigma_p(x_i) = \begin{cases} 1 & \text{if } p \text{ contains a node of type } P_{x_i}, \\ 0 & \text{otherwise.} \end{cases}$$

We have to prove that $\sigma_p(C_i) = 1$ for each $i \in [1,n]$. Given that $T \models D_\theta$, v has as a child a node v' whose type is in $tr(C_i)$. If the type of v' is x_j, then, given that $T \models r._^*.N_{x_j}._^*.x_j.@l \subseteq_{FK} r.C.C.@l$ and that there exists no node in T reachable by following the path $r.C.C$, p contains a node of type P_{x_j}, and, therefore, $\sigma_p(C_i) = 1$ since $\sigma_p(x_j) = 1$. If the type of v' is $\bar{x}_j$, then, given that $T \models r._^*.P_{x_j}._^*.\bar{x}_j.@l \subseteq_{FK} r.C.C.@l$, p contains a node of type N_{x_j} and it does not contain a node of type P_{x_j},

and, therefore, $\sigma_p(C_i) = 1$ since $\sigma_p(\neg x_j) = 1$. Thus, we conclude that θ is valid. This concludes the proof of part (b) of the theorem. □

4. Relative integrity constraints. Since XML documents are hierarchically structured, one may be interested in the entire document as well as in its subdocuments. The latter gives rise to *relative integrity constraints* [5] that hold only on certain subdocuments. Below we define relative keys and foreign keys. Recall that we use $\mathcal{RC}$ to denote various classes of such constraints. We use the notation $x \prec y$ when x and y are two nodes in an XML tree and y is a descendant of x.

We first define unary relative keys and foreign keys associated with element types. Let $D = (E, A, P, R, r)$ be a DTD. A *relative key* is an expression φ of the form $\tau(\tau_1.@l \rightarrow \tau_1)$, where $@l \in R(\tau_1)$. It says that, relative to each node x of element type τ, $@l$ is a key for all of the τ_1-nodes that are descendants of x. That is, if a tree T conforms to D, then $T \models \varphi$ if

$$\forall x \in ext(\tau)\ \forall y, z \in ext(\tau_1)\ \big((x \prec y) \wedge (x \prec z) \wedge (y.@l = z.@l) \rightarrow y = z\big).$$

A *relative foreign key* is an expression φ of the form $\tau(\tau_1.@l_1 \subseteq_{FK} \tau_2.@l_2)$, where $@l_i \in R(\tau_i), i = 1, 2$. It indicates that, for each x in $ext(\tau)$, $@l_1$ is a foreign key of descendants of x of type τ_1 that references a key $@l_2$ of τ_2-descendants of x. That is, $T \models \varphi$ if $T \models \tau(\tau_2.@l_2 \rightarrow \tau_2)$ and T satisfies

$$\forall x \in ext(\tau)\ \forall y_1 \in ext(\tau_1)\ \big((x \prec y_1) \rightarrow \exists y_2 \in ext(\tau_2)\ \ ((x \prec y_2) \wedge y_1.@l_1 = y_2.@l_2)\big).$$

Here τ is called the *context type* of φ. Note that absolute constraints are a special case of relative constraints when $\tau = r$: i.e., $r(\tau.@l \rightarrow \tau)$ is the usual absolute key. Thus, the consistency problem for multiattribute relative constraints is undecidable [16], and hence we consider only unary relative constraints here.

Following the notations for $\mathcal{AC}$, we use $\mathcal{RC}_{K,FK}$ to denote the class of all unary relative keys and foreign keys defined for element types; $\mathcal{RC}_{PK,FK}$ means the primary key restriction. For example, the constraints given in section 1 over the country/province/capital DTD can be expressed in $\mathcal{RC}_{K,FK}$ as follows:

$$\begin{aligned} country.@name &\rightarrow country, \\ country(province.@name &\rightarrow province), \\ country(capital.@inProvince &\rightarrow capital), \\ country(capital.@inProvince &\subseteq_{FK} province.@name). \end{aligned}$$

A more general form of unary relative constraints is defined in terms of regular path expressions, along the same lines as $\mathcal{AC}^{reg}_{K,FK}$. For example, the constraints given in section 1 over the country/province/capital DTD are instances of this general form of relative constraints. Since $\mathcal{RC}_{K,FK}$ constraints are a special case of the general regular-expression relative constraints (by substituting $\_^*.\tau$ for τ), the lower bound for $\mathsf{SAT}(\mathcal{RC}_{K,FK})$ carries over to the consistency problem for unary relative constraints defined in terms of regular path expressions.

Recall that $\mathsf{SAT}(\mathcal{AC}_{K,FK})$, the consistency problem for absolute unary constraints, is NP-complete. One would be tempted to think that $\mathsf{SAT}(\mathcal{RC}_{K,FK})$, the consistency problems for relative unary constraints, is decidable as well. We next show, however, that there is an enormous difference between unary absolute constraints and unary relative constraints: while clearly $\mathsf{SAT}(\mathcal{RC}_{K,FK})$ is recursively enumerable, it turns out that one cannot lower this bound.

THEOREM 4.1. $\mathsf{SAT}(\mathcal{RC}_{K,FK})$ *is undecidable.*

Proof. We establish the undecidability of the consistency problem for unary relative keys and foreign keys by reduction from the Hilbert's 10th problem [24]. To do this, we consider a variation of the Diophantine problem, referred to as the *positive Diophantine quadratic system problem*. An instance of the problem is

$$\begin{aligned} P_1(x_1,\ldots,x_k) &= Q_1(x_1,\ldots,x_k) + c_1,\\ P_2(x_1,\ldots,x_k) &= Q_2(x_1,\ldots,x_k) + c_2,\\ &\cdots\\ P_n(x_1,\ldots,x_k) &= Q_n(x_1,\ldots,x_k) + c_n, \end{aligned}$$

where, for $1 \le i \le n$, P_i and Q_i are polynomials in which all coefficients are positive integers; the degree of P_i is at most 2, and the degree of each of its monomials is at least 1; each polynomial Q_i satisfies the same condition, and each c_i is a nonnegative integer constant. The problem is to determine, given any positive Diophantine quadratic system, whether it has a nonnegative integer solution.

The positive Diophantine quadratic system problem is undecidable. To prove this, it is straightforward to reduce to it another variation of the Diophantine problem, the *positive Diophantine equation problem*, which is known to be undecidable. An instance of this problem is $R(\bar{y}) = S(\bar{y})$, where R and S are polynomials in which all coefficients are positive integers, and the problem is to determine whether it has a nonnegative integer solution.

In what follows, we show a reduction from the positive Diophantine quadratic system problem to $\mathsf{SAT}(\mathcal{RC}_{K,FK})$. More precisely, given a quadratic equation we show how to represent it by using a DTD and a set of constraints. It is straightforward to extend this representation to consider an arbitrary number of quadratic equations.

Consider the following equation:

$$\sum_{i=1}^{m} a_i x_{\alpha_i} + \sum_{i=m+1}^{n} a_i x_{\alpha_i} x_{\beta_i} = \sum_{i=1}^{p} b_i x_{\gamma_i} + \sum_{i=p+1}^{q} b_i x_{\gamma_i} x_{\delta_i} + o. \tag{4.1}$$

In this equation, for every $i \in [1,n]$ and $j \in [m+1,n]$, a_i is a positive integer and x_{α_i} and x_{β_j} represent variables, where $\alpha_i, \beta_j \in [1,k]$. Furthermore, for every $i \in [1,q]$ and $j \in [p+1,q]$, b_i is a positive integer and x_{γ_i} and x_{δ_j} are variables, where $\gamma_i, \delta_j \in [1,k]$. Finally, o is a nonnegative integer.

To code the previous equation, we need to define a DTD $D = (E, A, P, R, r)$ and a set of $\mathcal{RC}_{K,FK}$-constraints Σ. Here D includes the following elements and attributes:

$$\begin{aligned} E = {} & \{r, X, Y\} \cup \bigcup_{i=1}^{k} \{n_i\} \cup \bigcup_{i=1}^{n} \{\alpha_i\} \cup \bigcup_{i=m+1}^{n} \{\alpha_i', \beta_i, c_i, d_i, e_i\}\\ & \cup \bigcup_{i=1}^{q} \{\gamma_i\} \cup \bigcup_{i=p+1}^{q} \{\gamma_i', \delta_i, f_i, g_i, h_i\},\\ A = {} & \{@v\}. \end{aligned}$$

In this DTD, r is the root. Intuitively, by referring to an XML tree conforming to D, we use $|ext(n_i)|$ to code the value of the variable x_i, and we use $|ext(X)|$ and $|ext(Y)|$ to code the values of the left- and the right-hand sides of (4.1), respectively.

We define $P(r)$ as follows:

$$P(r) = n_1^*, \ldots, n_k^*, \alpha_1^*, \ldots, \alpha_m^*, (\epsilon|\alpha_{m+1}), \ldots, (\epsilon|\alpha_n), \\ \gamma_1^*, \ldots, \gamma_p^*, (\epsilon|\gamma_{p+1}), \ldots, (\epsilon|\gamma_q), \underbrace{Y, \ldots, Y}_{o \text{ times}}.$$

We define the function P on α_i and β_i as follows:

$$\begin{aligned}
P(\alpha_i) &= \underbrace{X, \ldots, X}_{a_i \text{ times}}, && 1 \le i \le m,\\
P(\alpha_i) &= (\beta_i, c_i, c_i, \underbrace{X, \ldots, X}_{a_i \text{ times}})^*, \alpha_i', && m+1 \le i \le n,\\
P(\gamma_i) &= \underbrace{Y, \ldots, Y}_{b_i \text{ times}}, && 1 \le i \le p,\\
P(\gamma_i) &= (\delta_i, f_i, f_i, \underbrace{Y, \ldots, Y}_{b_i \text{ times}})^*, \gamma_i', && p+1 \le i \le q.
\end{aligned}$$

To code (4.1) we need to capture the multiplication operator. To do this, we use α_i' and γ_i':

$$\begin{aligned}
P(\alpha_i') &= (\beta_i, d_i, d_i)^*, (\alpha_i|(c_i, e_i)^*), && m+1 \le i \le n,\\
P(\gamma_i') &= (\delta_i, g_i, g_i)^*, (\gamma_i|(f_i, h_i)^*), && p+1 \le i \le q.
\end{aligned}$$

For all of the other element types τ in D, $P(\tau)$ is defined as ϵ:

$$\begin{array}{llllll}
P(\beta_i) = \epsilon, & m+1 \le i \le n, & P(\delta_i) = \epsilon, & p+1 \le i \le q, & P(X) = \epsilon, & \\
P(c_i) = \epsilon, & m+1 \le i \le n, & P(f_i) = \epsilon, & p+1 \le i \le q, & P(Y) = \epsilon, & \\
P(d_i) = \epsilon, & m+1 \le i \le n, & P(g_i) = \epsilon, & p+1 \le i \le q, & P(n_i) = \epsilon, & 1 \le i \le k,\\
P(e_i) = \epsilon, & m+1 \le i \le n, & P(h_i) = \epsilon, & p+1 \le i \le q. &&
\end{array}$$

Finally, we include the following attributes:

$$\begin{aligned}
&R(r) = \emptyset,\\
&R(n_i) = \{@v\}, && 1 \le i \le k,\\
&R(X) = R(Y) = \{@v\},\\
&R(\alpha_i) = \{@v\}, && 1 \le i \le n,\\
&R(\gamma_i) = \{@v\}, && 1 \le i \le q,\\
&R(\beta_i) = R(c_i) = R(d_i) = R(e_i) = \{@v\}, && m+1 \le i \le n,\\
&R(\delta_i) = R(f_i) = R(g_i) = R(h_i) = \{@v\}, && p+1 \le i \le q,\\
&R(\alpha_i') = \emptyset, && m+1 \le i \le n,\\
&R(\gamma_i') = \emptyset, && p+1 \le i \le q.
\end{aligned}$$

To ensure that XML documents that conform to D indeed code (4.1), we need to define a set of $\mathcal{RC}_{K,FK}$-constraints Σ. This set contains the following absolute keys:

$$\begin{aligned}
&r(X.@v \to X),\\
&r(\alpha_i.@v \to \alpha_i) && \text{for every } 1 \le i \le n,\\
&r(\beta_i.@v \to \beta_i) && \text{for every } m+1 \le i \le n,\\
&r(c_i.@v \to c_i) && \text{for every } m+1 \le i \le n,\\
&r(d_i.@v \to d_i) && \text{for every } m+1 \le i \le n,\\
&r(e_i.@v \to e_i) && \text{for every } m+1 \le i \le n,\\
&r(n_i.@v \to n_i) && \text{for every } 1 \le i \le k,\\
&r(Y.@v \to Y),\\
&r(\gamma_i.@v \to \gamma_i) && \text{for every } 1 \le i \le q,
\end{aligned}$$

$$\begin{array}{ll} r(\delta_i.@v \to \delta_i) & \text{for every } p+1 \le i \le q, \\ r(f_i.@v \to f_i) & \text{for every } p+1 \le i \le q, \\ r(g_i.@v \to g_i) & \text{for every } p+1 \le i \le q, \\ r(h_i.@v \to h_i) & \text{for every } p+1 \le i \le q. \end{array}$$

Σ contains the following absolute foreign keys:

$$\begin{array}{lll} r(X.@v \subseteq_{FK} Y.@v), & r(Y.@v \subseteq_{FK} X.@v), & \\ r(n_s.@v \subseteq_{FK} \alpha_i.@v), & r(\alpha_i.@v \subseteq_{FK} n_s.@v), & 1 \le i \le n \text{ and the value of } \alpha_i \text{ in (4.1) is equal to } s, \\ r(n_s.@v \subseteq_{FK} e_i.@v), & r(e_i.@v \subseteq_{FK} n_s.@v), & m+1 \le i \le n \text{ and the value of } \beta_i \text{ in (4.1) is equal to } s, \\ r(n_s.@v \subseteq_{FK} \gamma_i.@v), & r(\gamma_i.@v \subseteq_{FK} n_s.@v), & 1 \le i \le q \text{ and the value of } \gamma_i \text{ in (4.1) is equal to } s, \\ r(n_s.@v \subseteq_{FK} h_i.@v), & r(h_i.@v \subseteq_{FK} n_s.@v), & p+1 \le i \le q \text{ and the value of } \delta_i \text{ in (4.1) is equal to } s. \end{array}$$

Finally, Σ contains the following relative foreign keys:

$$\begin{array}{lll} \alpha_i(\beta_i.@v \subseteq_{FK} d_i.@v), & \alpha_i(d_i.@v \subseteq_{FK} \beta_i.@v), & m+1 \le i \le n, \\ \alpha'_i(\beta_i.@v \subseteq_{FK} c_i.@v), & \alpha'_i(c_i.@v \subseteq_{FK} \beta_i.@v), & m+1 \le i \le n, \\ \gamma_i(\delta_i.@v \subseteq_{FK} g_i.@v), & \gamma_i(g_i.@v \subseteq_{FK} \delta_i.@v), & p+1 \le i \le q, \\ \gamma'_i(\delta_i.@v \subseteq_{FK} f_i.@v), & \gamma'_i(f_i.@v \subseteq_{FK} \delta_i.@v), & p+1 \le i \le q. \end{array}$$

We show next that there is an XML tree T such that $T \models (D, \Sigma)$ iff there exists a nonnegative integer solution for (4.1). To do this, we prove that every XML tree T satisfying D and Σ codifies (4.1). More precisely, if the value of every variable x_i is v_i and $|ext(n_i)| = v_i$, for $i \in [1, k]$, then

$$|ext(X)| = \sum_{i=1}^{m} a_i v_{\alpha_i} + \sum_{i=m+1}^{n} a_i v_{\alpha_i} v_{\beta_i}, \tag{4.2}$$

$$|ext(Y)| = \sum_{i=1}^{p} b_i v_{\gamma_i} + \sum_{i=p+1}^{q} b_i v_{\gamma_i} v_{\delta_i} + o. \tag{4.3}$$

Let T be an XML tree conforming to D. Then every node of type X in T appears as a child of some node of type α_i ($i \in [1, n]$). Thus, to prove (4.2) it suffices to show that the number of X-nodes that are children of some node of type α_i ($i \in [1, n]$) is equal to the ith term of (4.2), that is,

$$\begin{array}{l} |\{x \mid x \text{ is an } X\text{-node in } T \text{ and } x \text{ is a child of a node of type } \alpha_i\}| \\ \quad = a_i v_{\alpha_i}, \quad 1 \le i \le m, \\ |\{x \mid x \text{ is an } X\text{-node in } T \text{ and } x \text{ is a child of a node of type } \alpha_i\}| \\ \quad = a_i v_{\alpha_i} v_{\beta_i}, \quad m+1 \le i \le n. \end{array}$$

Analogously, to show that (4.3) holds, we have to prove that the number of Y-nodes that are children of some node of type γ_i ($i \in [1, q]$) is equal to the ith term of (4.3). We will consider here only the case of X-nodes, the other case being similar.

First, let $i \in [1, m]$ and s be the value of α_i in (4.2). Given that $r(n_s.@v \subseteq_{FK} \alpha_i.@v)$ and $r(\alpha_i.@v \subseteq_{FK} n_s.@v)$ are in Σ, by the definition of $P(\alpha_i)$ the total number of X-nodes that are children of a node of type α_i is equal to $a_i v_{\alpha_i}$. Second, let $i \in [m+1, n]$ and s and t be the values of α_i and β_i in (4.1), respectively. Next we prove that $|\{x \mid x \text{ is an } X\text{-node in } T \text{ and } x \text{ is a child of a node of type } \alpha_i\}| = a_i v_s v_t$.

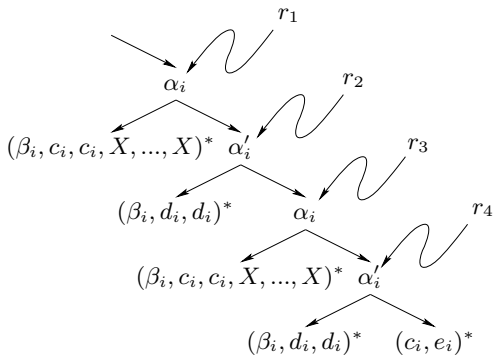

FIG. 4.1. *Part of the XML tree used in the proof of Theorem* 4.1.

Given that $r(n_s.@v \subseteq_{FK} \alpha_i.@v)$ and $r(\alpha_i.@v \subseteq_{FK} n_s.@v)$ are in Σ, $|ext(\alpha_i)|$ in T is equal to $|ext(n_s)| = v_s$. Thus, in T there are exactly v_s nodes of type α_i, each of them having exactly one child of type α_i'. Hence, there are exactly v_s nodes of type α_i', the last one being of the form shown in Figure 4.1 (see node r_4). By the definition of $P(\alpha_i')$, $|\{x \mid x \text{ is a child of } r_4 \text{ of type } c_i\}| = |\{x \mid x \text{ is a child of } r_4 \text{ of type } e_i\}|$. Given that $r(n_t.@v \subseteq_{FK} e_i.@v)$ and $r(e_i.@v \subseteq_{FK} n_t.@v)$ are in Σ and that every node of type e_i in T is a child of r_4, $|\{x \mid x \text{ is a child of } r_4 \text{ of type } c_i\}| = |ext(n_t)|$. Thus, since r_4 is a node of type α_i' and $\alpha_i'(\beta_i.@v \subseteq_{FK} c_i.@v)$ and $\alpha_i'(c_i.@v \subseteq_{FK} \beta_i.@v)$ are in Σ, $|\{x \mid x \text{ is a child of } r_4 \text{ of type } \beta_i\}| = |ext(n_t)| = v_t$. In addition, by the definition of $P(\alpha_i')$, the number of children of r_4 of type d_i is $2v_t$.

Given that r_3 is a node of type α_i and $\alpha_i(\beta_i.@v \subseteq_{FK} d_i.@v)$ and $\alpha_i(d_i.@v \subseteq_{FK} \beta_i.@v)$ are in Σ, $|\{x \mid x \text{ is a child of } r_3 \text{ of type } \beta_i\}| = v_t$, since there are $2v_t$ descendants of r_3 of type d_i and v_t children of r_4 of type β_i. Furthermore, by the definition of $P(\alpha_i)$, the number of children of r_3 of type X is $a_i v_t$, and the number of children of r_3 of type c_i is $2v_t$. We can use the same argument to prove that the number of children of r_2 of types β_i and d_i are v_t and $2v_t$, respectively. Thus, the number of children of r_1 of type X is $a_i v_t$, and the number of descendants of r_1 of type X is $2a_i v_t$. If we continue with this process, we can prove, by induction, that the number of X-nodes in T that are children of some node of type α_i is $v_s a_i v_t$, since there are v_s nodes of type α_i in T. This concludes the proof, since $|\{x \mid x \text{ is an } X\text{-node in } T \text{ and } x \text{ is a child of a node of type } \alpha_i\}| = a_i v_s v_t$. □

In the proof of Theorem 4.1, all relative keys are primary. Thus, we obtain the following.

COROLLARY 4.2. $\mathsf{SAT}(\mathcal{RC}_{PK,FK})$, *the restriction of* $\mathsf{SAT}(\mathcal{RC}_{K,FK})$ *to primary keys, is undecidable.*

5. Extended DTDs. In this section, we consider a slight extension of DTDs which captures unranked tree automata. An *extended DTD* [32, 29] *ED* is a tuple (D', f, E), where $D' = (E', A', P', R', r')$ is a DTD, E is a finite set of element types such that $E \cap E' = \emptyset$, and f is a surjective mapping $f : E' \to E$ such that, for every $\tau_1, \tau_2 \in E'$, we have $R'(\tau_1) = R'(\tau_2)$ if $f(\tau_1) = f(\tau_2)$. We say that a tree T conforms to *ED* if there exists a tree T' that conforms to D' such that $T = f(T')$; that is, T can be obtained by replacing each label τ in T' by $f(\tau)$. Extended DTDs support a subtyping mechanism (specialization) and have proven useful in data migration and integration, among other things (see, e.g., [29] for examples of extended DTDs and their applications in data integration). It is also known that extended DTDs

capture precisely MSO (monadic second-order logic) definable trees and the regular tree languages of finite unranked trees [26, 29].

A constraint φ is said to be defined over extended DTD ED if every element type τ mentioned in φ is in E.

The consistency problem for extended DTDs is defined exactly as in the case of DTDs: given a specification (ED, Σ), the problem is to verify whether there exists a tree T conforming to ED and satisfying Σ. Next we show that the consistency problem for extended DTDs can be efficiently reduced to the consistency problem for DTDs.

Let $ED = (D', f, E)$ be an extended DTD, where $D' = (E', A', P', R', r')$, and Σ be either a set of $\mathcal{AC}^{*,*}_{K,FK}$-constraints over ED or a set of $\mathcal{AC}^{reg}_{K,FK}$-constraints over ED. We consider here only absolute constraints since, by Theorem 4.1, the consistency problem for extended DTDs and relative constraints is already undecidable for unary keys and foreign keys without regular expressions. We define DTD $D(ED) = (E_{ED}, A', P_{ED}, R_{ED}, r')$ as follows. Let $E_{ED} = E' \cup E$ and

$$P_{ED}(\tau) = \begin{cases} f(\tau), P'(\tau), & \tau \in E', \\ \epsilon, & \tau \in E, \end{cases} \qquad R_{ED}(\tau) = \begin{cases} \emptyset, & \tau \in E', \\ R'(\tau'), & \tau \in E \text{ and } f(\tau') = \tau. \end{cases}$$

Notice that R_{ED} is well defined since f is a surjective mapping such that $R'(\tau_1) = R'(\tau_2)$ whenever $f(\tau_1) = f(\tau_2)$. Moreover, we define a set of keys and foreign keys $\Gamma(ED, \Sigma)$ over DTD $D(ED)$ as follows. If Σ is a set of $\mathcal{AC}^{*,*}_{K,FK}$-constraints, then $\Gamma(ED, \Sigma) = \Sigma$. Otherwise, Σ is a set of $\mathcal{AC}^{reg}_{K,FK}$-constraints, and for every $\varphi \in \Sigma$ we have the following constraint ψ in $\Gamma(ED, \Sigma)$. For every element type $\tau \in E$, define the image of substitution h on τ as $h(\tau) = (\tau_1 \cup \cdots \cup \tau_n)$, where $\{\tau_1, \ldots, \tau_n\}$ is the set of element types $\tau' \in E'$ such that $f(\tau') = \tau$. If φ is a key $\beta.\tau.@l \to \beta.\tau$, then $\psi = h(\beta.\tau).\tau.@l \to h(\beta.\tau).\tau$. If φ is a foreign key $\beta_1.\tau_1.@l_1 \subseteq_{FK} \beta_2.\tau_2.@l_2$, then $\psi = h(\beta_1.\tau_1).\tau_1.@l_1 \subseteq_{FK} h(\beta_2.\tau_2).\tau_2.@l_2$. The following simple lemma shows that the consistency problems for (ED, Σ) and $(D(ED), \Gamma(ED, \Sigma))$ are equivalent.

LEMMA 5.1. *Let $ED = (D', f, E)$ be an extended DTD and Σ be either a set of $\mathcal{AC}^{*,*}_{K,FK}$-constraints over ED or a set of $\mathcal{AC}^{reg}_{K,FK}$-constraints over ED. Then (ED, Σ) is consistent iff $(D(ED), \Gamma(ED, \Sigma))$ is consistent.*

We note that if $\mathcal{C}$ is one of $\mathcal{AC}_{PK,FK}$, $\mathcal{AC}_{K,FK}$, $\mathcal{AC}^{*,1}_{PK,FK}$, and $\mathcal{AC}^{reg}_{K,FK}$ and Σ is a set of $\mathcal{C}$-constraints over an extended DTD ED, then $\Gamma(ED, \Sigma)$ is a set of $\mathcal{C}$-constraints over $D(ED)$. Thus, given that $D(ED)$ and $\Gamma(ED, \Sigma)$ can be constructed in polynomial time from (ED, Σ), we obtain the following corollary from the previous lemma, Theorem 4.7 and Corollary 4.8 in [16], Corollary 3.5, and Theorem 3.7.

COROLLARY 5.2.

(a) *The consistency problem for extended DTDs and $\mathcal{AC}_{K,FK}$-constraints ($\mathcal{AC}_{PK,FK}$-constraints) is NP-complete.*
(b) *The consistency problem for extended DTDs and $\mathcal{AC}^{*,1}_{PK,FK}$-constraints is NP-hard and can be solved in NEXPTIME.*
(c) *The consistency problem for extended DTDs and $\mathcal{AC}^{reg}_{K,FK}$-constraints is PSPACE-hard and can be solved in 2-NEXPTIME.*

6. Conclusion. We have studied the problem of statically checking XML specifications, which may include various schema definitions as well as integrity constraints. As observed earlier, such static validation is quite desirable as an alternative to dynamic checking, which would attempt to validate each document; indeed, in the case of repeated failures, one does not know whether the problems lies in the documents or in the specification. Our main conclusion is that, however desirable, the static

Description	Multiattribute keys and foreign keys	Unary keys and foreign keys	Primary unary keys and foreign keys
Lower bound	Undecidable	Undecidable	Undecidable

checking is hard: even with very simple document definitions given by DTDs, and (foreign) keys as constraints, the complexity ranges from NP-hard to undecidable.

The main results are summarized in Tables 6.1 and 6.2 (we also included the main results from [16] in those tables for completeness). When one deals with absolute constraints, which hold in an entire document, the general consistency problem is undecidable. It is solvable in NEXPTIME if foreign keys are single-attribute and is NP-complete if so are all of the keys as well. However, if regular expressions are allowed in single-attribute constraints, the lower bounds become at least PSPACE. For relative constraints, which are required to hold only in a part of a document, the situation is quite bleak, as even the very simple case of single-attribute constraints is undecidable.

Although most of the results of the paper are negative, the techniques developed in the paper help study consistency of individual XML specification with type and constraints. These techniques include, e.g., the connection between regular expression constraints and integer linear programming and automata.

One open problem is to close the complexity gaps. However, these are by no means trivial: for example, $\mathsf{SAT}(\mathcal{AC}^{*,1}_{PK,FK})$ was proved to be equivalent to a problem related to Diophantine equations whose exact complexity remains unknown. In the case of $\mathsf{SAT}(\mathcal{AC}^{reg}_{K,FK})$, we think that it is more likely that our lower bounds correspond to the exact complexity of those problems. However, the algorithms are quite involved, and we do not yet see a way to simplify them to prove the matching upper bounds.

Another topic for future work is to study the interaction between more complex XML constraints, e.g., those defined in terms of XPath [37], and more complex schema specifications such as XML Schema [38] and the type system of XQuery [39]. Our lower bounds apply to those settings, but it is open whether upper bounds remain intact.

Acknowledgments. We are grateful to anonymous referees for their comments. Most of this work was done while Arenas and Libkin were at the University of Toronto.

COMPETITIVE ONLINE APPROXIMATION OF THE OPTIMAL SEARCH RATIO*

RUDOLF FLEISCHER†, TOM KAMPHANS‡, ROLF KLEIN§, ELMAR LANGETEPE§, AND GERHARD TRIPPEN¶

Abstract. How efficiently can we search an unknown environment for a goal in an unknown position? How much would it help if the environment were known? We answer these questions for simple polygons and for undirected graphs by providing online search strategies that are as good as the best offline search algorithms, up to a constant factor. For other settings we prove that no such online algorithms exist. We introduce a natural measure which gives reasonable results and is more realistic than pure pessimistic competitive analysis.

Key words. online motion planning, competitive ratio, searching, exploration, natural measure

DOI. 10.1137/060662204

1. Introduction.

One of the recurring tasks in life is to search one's environment for an object whose location is—at least temporarily—unknown. This problem comes in different variations. The searcher may have vision, or be limited to sensing by touch. The environment may be a simple polygon, for example, an apartment, or a graph, like a street network. Finally, the environment may be known to the searcher or be unknown.

Such search problems have attracted a lot of interest in online motion planning; see, for example, the survey by Berman [5]. Usually the cost of a search is measured by the length of the search path traversed; this, in turn, is compared against the length of the shortest path from the start position to the point where the goal is reached. The maximum quotient of these values, taken over all environments and all goal positions within an environment, is the *competitive ratio* of the search algorithm.

Most prominent is the problem of searching two half-lines emanating from a common start point. The "doubling" strategy visits the half-lines alternatingly, each time doubling the depth of exploration. This way, the goal point is reached after traversing a path at most 9 times as long as its distance from the start, and the competitive ratio of 9 is optimal for this problem; see Baeza-Yates, Culberson, and Rawlins [4] and Alpern and Gal [2]. This doubling approach frequently appears as a subroutine

in more complex navigation strategies.

In searching $m > 2$ half-lines, a constant ratio with respect to the distance from the start can no longer be achieved. Indeed, even if the half-lines were replaced by segments of the same finite length, the goal could be placed at the end of the segment visited last, causing the ratio to be at least $2m - 1$. Exponentially increasing the exploration depth by $m/m-1$ is known [4, 2] to lead to an optimal competitive ratio of

$$C(m) = 1 + 2m\left(\frac{m}{m-1}\right)^{m-1} \leq 1 + 2me.$$

Much less is known about more realistic settings. Suppose a searcher with vision wants to search an unknown simple polygon for a goal in unknown position. He could employ the m-way technique from above: By exploring the shortest paths from the start to the m reflex vertices of the polygon—ignoring their tree structure—a competitive ratio of $C(m)$ can easily be achieved [23]. Schuierer [27] has refined this method and obtained a ratio of $C(2k)$, where k denotes the smallest number of convex and concave chains into which the polygon's boundary can be decomposed.

But these results do not completely settle the problem. For one, it is not clear why the numbers m or k should measure the difficulty of searching a polygon. Also, human searchers can often outperform m-way search, because they make educated guesses about the shape of those parts of the polygon not yet visited.

In this paper we take the following approach: Let π be a *search path* for a fixed polygon P, i.e., a path from the start point, s, through P from which each point p inside P will eventually be visible. Let p_π be the first point on π where this happens for a point p. The cost of getting to p via π is equal to the length of π from s to p_π, plus the Euclidean distance from p_π to p. We divide this value by the length of the shortest s-to-p path in P. The supremum of these ratios, over all $p \in P$, is the *search ratio* of π. The lowest search ratio possible, over all search paths, is the *optimum search ratio* of P; it measures the "searchability" of P.

Apparently, this definition was first given by Koutsoupias, Papadimitriou, and Yannakakis [24]. They studied graphs with unit length edges where the goal can be located only at vertices, and they studied only the offline case where the graph is completely known a priori. They showed that computing the optimal search ratio offline is an NP-complete problem, and gave a polynomial time 8-approximation algorithm based on the doubling heuristic.

The crucial question we are considering in this paper is the following: Is it possible to design an *online* search strategy whose search ratio stays within a constant factor of the optimum search ratio for arbitrary instances of the environment? Surprisingly, the answer is positive for simple polygons as well as for undirected graphs. (However, for polygons with holes, and for graphs with unit edge length, where the goal positions are restricted to the vertices, no such online strategy exists.)

Observe that this way of measuring performance is one step beyond competitivity. Although the definitions of the search ratio and the competitive factor are quite similar, the concepts are different. In the competitive framework, we simply compare the online path from the start to the goal to the shortest s-to-t path. For an approximation of the optimal search ratio, we compare the online path to the best possible offline path, which, in turn, may already have a bad competitive ratio.

To exemplify the given concept let us consider another simple environment: arbitrary trees with a common root as a starting point. For a fixed tree, T, there will be

a strategy $S(T)$ which attains the best competitive search performance $C(T)$ among all possible goals on T. We know that an optimal strategy $S(T)$ exists, but we do not know what it looks like. Furthermore, for arbitrary trees it can be shown that the performance $C(T)$ of $S(T)$ can increase arbitrarily, though $S(T)$ is not known. Therefore, constant competitive searching is impossible for arbitrary trees T. But we can try to approximate the strategy $S(T)$ for any tree T by a simple strategy $A(T)$. In this paper we will show that we can design an approximation strategy $A(T)$ so that $A(T)$ is only a constant time worse than $S(T)$. This means that the competitive ratio of $A(T)$ is smaller than $c \cdot C(T)$ for every T and a fixed constant c. Note that $c = 4$ will be shown for this example in section 4.2.1. Thus, although the best search strategy is not known, we can approximate it efficiently. If the environment is known (but the goal is still unknown), sometimes the factor c can be slightly improved.

The idea of considering realistic ratios rather than pure pessimistic competitive ratios was also examined in the field of scheduling; see, for example, Edmonds et al. [13], Kalyanasundaram and Pruhs [22], or Berman and Coulston [6]. To compete with the optimal offline algorithm in a constant competitive sense, the online scheduler is allowed to have more power in speed or number of processors (or whatever). The increase of power is mainly represented by a parameter which, in turn, influences the competitive ratio. In our framework we increase the power of the agent only in the *offline* setting where the environment is known but the goal still has to be found. In the *online* setting we do not change the power balance between agent and adversary at all.

The *search* strategies we will present use, as building blocks, modified versions of constant-competitive strategies for online *exploration*, namely, the exploration strategy by Hoffmann et al. [21] for simple polygons and the tethered graph exploration strategy by Duncan, Kobourov, and Kumar [12].

At first glance it seems quite natural to employ an exploration strategy in searching—after all, either task involves looking at each point of the environment. But there is a serious difference in performance evaluation! In searching an environment, we compete against shortest start-to-goal paths, so we have to proceed in a breadth first search (BFS) manner.[1] In exploration, we are up against the shortest round trip from which each point is visible; this means that once we have entered some remote part of the environment we should finish it, in a depth first search (DFS) manner, before moving on.[2] However, we can fit these exploration strategies to our search problem by restricting them to a bounded part of the environment. This will be shown in section 3, where we present our general framework, which turns out to be quite elegant despite the complex definitions. The framework can be applied to both online and offline search ratio approximations. In section 2 we review basic definitions and notation. Our framework will then be applied to searching in various environments like trees, (planar) graphs, and (rectilinear) polygonal environments with and without holes in sections 4 and 5. In section 6 we give a construction scheme for lower bounds on the search ratio. Finally, in section 7, we conclude with a summary of our results.

2. Definitions. We want to find a good search path in some given environment $\mathcal{E}$. This may be a tree, a (planar) graph, or a (rectangular) polygon with or without

[1] But, as opposed to searching a data structure, we do not have pointers that allow us to jump to a different location for free.

[2] Observe, however, that neither plain BFS nor DFS would work! BFS is lacking the doubling element, and DFS, in a simple polygon, would tend to follow a long convex chain even though a small step to the side could be sufficient to see its endpoint.

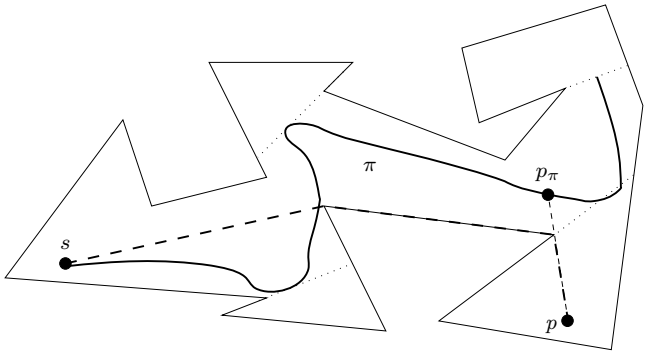

FIG. 2.1. *A search path π in a polygon, visiting all essential cuts (the dotted lines). The dashed path is the shortest path $sp(p)$ from s to the goal p. Moving along π, p can first be seen from p_π.*

holes. In a graph environment, the edges may have either unit length or arbitrary length. Edge lengths do not necessarily represent Euclidean distances, not even in embedded planar graphs. In particular, we do not assume that the triangle inequality holds. The only restriction to the type of environments required by our framework in section 3 is that there is a shortest path from every point, p, in $\mathcal{E}$ back to the start point, s, that is of the same length as a shortest path from s to p;[3] that is, for all p in $\mathcal{E}$ it holds that $|\mathrm{sp}(s,p)| = |\mathrm{sp}(p,s)|$.

In most cases, we want to search the whole environment, but there are special kinds of search problems where we know that the goal may be hidden only in some parts of the scene. Let the *goal set* $\mathcal{G} \subseteq \mathcal{E}$ denote the part of the environment where the stationary goal may be located. For example, if we search in a graph, $G = (V, E)$, the goal may be located anywhere along the edges of the graph; we call this setting *geometric search* and set $\mathcal{G} := V \cup E$. On the other hand, we may consider a *vertex search*, where the goal is restricted to be hidden in a vertex; in this case, we set $\mathcal{G} := V$. Now, *exploring* $\mathcal{E}$ means to move around in $\mathcal{E}$ until all potential goal positions $\mathcal{G}$ have been seen, whereas *searching* in $\mathcal{E}$ means to follow some exploration path in $\mathcal{E}$, until the goal has been seen. We require—as usual—that the distance to the goal is at least 1; otherwise, no search strategy is able to achieve a bounded competitive factor. Further, we assume that agents have perfect localization abilities; that is, they always know a map of the already explored part of $\mathcal{E}$, and they can always recognize when they visit some point for the second time (the robot localization problem is actually a difficult problem by itself; see, for example, [16]).

The searcher either can be *blind* (i.e., it can sense only its very close neighborhood) or can have *vision*; that is, it can see objects far away from its current position if the line of sight is not blocked by an obstacle. The model of visibility depends on the type of environment; see sections 4 and 5 for more details.

We now introduce some notation: Given a start point, $s \in \mathcal{E}$, let π be a path in the environment $\mathcal{E}$ starting in s. For a given point $q \in \pi$ let $\pi(q)$ denote the part of π from s to q. For an arbitrary point $p \in \mathcal{E}$ let $\mathrm{sp}(p)$ denote a shortest path from s to p in the given environment, and let $p_\pi \in \pi$ denote the point from which a searcher following π sees p for the first time; see Figure 2.1. We denote the length of a path

[3]Note that this is not the case for directed graphs, but it holds for undirected graphs and polygonal environments. We will see later that there is no constant-competitive online search algorithm for directed graphs.

segment $\pi(p)$ by $|\pi(p)|$. Paths computed by some algorithm $\mathcal{A}$ will be named $\mathcal{A}$, too. In particular, we write $|\mathcal{A}|$ for the length of the tour computed by $\mathcal{A}$. The main concept in our paper is the following.

DEFINITION 2.1. *Let $\mathcal{E}$ be an environment, $\mathcal{G} \subseteq \mathcal{E}$ a goal set, and $s \in \mathcal{E}$ a point in the environment. A* search path*, π, with start point s is a path which starts in s and allows a searcher following π to see every goal position in $\mathcal{G}$ from at least one point on π. The* search ratio*, $\mathrm{sr}(\pi)$, is defined as*

$$\mathrm{sr}(\pi) := \sup_{p \in \mathcal{G}} \frac{|\pi(p_\pi)| + |p_\pi p|}{|\mathrm{sp}(p)|}\,.$$

In other words, we compare the path walked by a searcher to the shortest path and take the worst ratio among all possible targets as the search ratio of our search path.

An optimal search path*, π_{opt}, is a search path with a minimum search ratio among all possible paths in the environment. We denote the* optimal search ratio *by sr_{opt}; that is, $\mathrm{sr}_{opt} := \mathrm{sr}(\pi_{opt})$. For blind agents, $p = p_\pi$ holds for every $p \in \mathcal{E}$; therefore, the search ratio can be computed as $\mathrm{sr}(\pi) := \sup_{p \in \mathcal{G}} \frac{|\pi(p)|}{|\mathrm{sp}(p)|}$.*

As the optimal search path seems hard to compute [24], we are interested in finding good approximations of the optimal search path in offline and online scenarios. We say a search algorithm $\mathcal{A}$ is *search-competitive* with factor C—or C–search-competitive for short—if there are constants $C \geq 1$ and $B \geq 0$, so that $\mathrm{sr}(\pi_\mathcal{A}) \leq C \cdot \mathrm{sr}_{\mathrm{opt}} + B$ holds for every path $\pi_\mathcal{A}$ computed by $\mathcal{A}$. Note that $\pi_\mathcal{A}$ is then a $C \cdot \mathrm{sr}(\pi_{\mathrm{opt}})$-competitive search path in the usual competitive sense. We use the term C–search-competitive also for the approximation factor of offline approximation algorithms. If there is no C–search-competitive algorithm for any constant C, we call this type of environment *hard-searchable*.

In the following, we want to use existing exploration algorithms to approximate the optimal search path. We assume that every exploration algorithm returns to the start point when the whole environment is explored.

DEFINITION 2.2. *For a given environment $\mathcal{E}$ and $d \geq 1$, let $\mathcal{E}(d)$ denote the part of $\mathcal{E}$ within distance at most d from s, and $\mathrm{OPT}(d)$ the optimal exploration for $\mathcal{E}(d)$. Further, let* Expl *be an—online or offline—algorithm for the exploration of environments of the given type.* Expl *is called* depth-restrictable *if for every $d \geq 1$ it is possible to modify the algorithm* Expl *to an algorithm* Expl(d) *that explores $\mathcal{E}(d)$ (i.e., the algorithm sees at least all potential goal positions of distance at most d—and maybe some more—before it returns to the start point), and there are constants $\beta > 0$ and $C_\beta \geq 1$, so that*

$$|\mathrm{Expl}(d)| \leq C_\beta \cdot |\mathrm{OPT}(\beta \cdot d)| \tag{2.1}$$

holds for every environment of the given type (i.e., Expl(d) *is C_β-competitive with respect to* $\mathrm{OPT}(\beta \cdot d)$*).*

For example, the DFS traversal for trees is depth-restrictable with $\beta = 1$ and $C_\beta = 1$: In every step we know exactly the distance to the tree's root. Thus, we can decide whether we can explore the children of the current node or cannot explore the tree more deeply, because we have reached depth d. Obviously, DFS is optimal also for depth-restricted exploration.

In the usual competitive framework, we would compare Expl(d) to the optimal algorithm $\mathrm{OPT}(d)$ (i.e., $\beta = 1$). As we will see later, our more general definition sometimes makes it easier to find depth-restrictable exploration algorithms. Usually,

we cannot just take an exploration algorithm Expl for $\mathcal{E}$ and restrict it to points within distance at most d from s. This way, we might miss useful shortcuts outside of $\mathcal{E}(d)$. Even worse, it may not be possible to determine in an online setting which parts of the environment belong to $\mathcal{E}(d)$, making it difficult to explore the right part of $\mathcal{E}$. In sections 4 and 5 we will derive depth-restricted exploration algorithms for graphs and polygons by carefully adapting existing exploration algorithms for the entire environment.

3. A general approximation framework. In this section, we show how to transform a depth-restrictable exploration algorithm, offline or online, into a search algorithm, without losing too much on the approximation factor.

Let $\mathcal{E}$ be the given environment and π_{opt} an optimal search path. Remember that we assume that, for any point p, we can reach s from p on a path of length at most $\text{sp}(p)$.

Let Expl be an exploration algorithm for $\mathcal{E}$, and for $d \geq 1$, let Expl(d) be the corresponding depth-restricted exploration algorithm for $\mathcal{E}(d)$. Let OPT and OPT(d) denote the corresponding optimal offline depth-restricted exploration algorithms. We assume that the exploration strategies will always return to the start.

To obtain a search algorithm for $\mathcal{E}$, we use the well-known *doubling paradigm* and successively apply our given exploration strategy with increasing exploration depth; that is, we successively run Expl(2^i), each iteration starting and ending in the start point, s.

THEOREM 3.1. *The doubling strategy based on a depth-restrictable exploration algorithm with factors C_β and β is a $4\beta C_\beta$–search-competitive search algorithm for blind agents and an $8\beta C_\beta$–search-competitive search algorithm for agents with vision.*

Proof. Consider one iteration of the doubling strategy with search radius $d \geq 1$. The optimal search path π_{opt} for $\mathcal{E}$ must in particular explore all possible goal positions within distance at most d from s. Let $last_d$ be the point on π_{opt} from which we see the last point within distance at most d from s when moving along π_{opt}. Returning from $last_d$ to s closes an exploration tour of $\mathcal{E}(d)$; therefore,

$$|\text{OPT}(d)| \leq |\pi_{\text{opt}}(last_d)| + |\text{sp}(last_d)|\,.$$

In contrast to blind searchers, $last_d$ may be located outside $\mathcal{E}(d)$ for agents with vision; thus, we distinguish between blind agents and agents with vision to bound $|\text{sp}(last_d)|$. A blind agent can detect $last_d$ only by visiting it, so we have $\text{sp}(last_d) \leq d$. Thus,

$$\text{sr}_{\text{opt}} \geq \frac{|\pi_{\text{opt}}(last_d)|}{d} \geq \frac{|\text{OPT}(d)| - d}{d} \iff |\text{OPT}(d)| \leq d \cdot (\text{sr}_{\text{opt}} + 1)\,. \tag{3.1}$$

The worst case for the search ratio of the doubling strategy occurs when we explore the environment up to some distance 2^{j+1} while the goal is within distance $2^j + \epsilon$ for some small $\epsilon > 0$. Thus, the search ratio of the doubling strategy is bounded by

$$\text{sr}(\pi) \leq \frac{\sum_{i=1}^{j+1} |\text{Expl}(2^i)|}{2^j + \epsilon}\,.$$

Expl is depth-restrictable with factor C_β, so we can apply (2.1):

$$\text{sr}(\pi) \leq \frac{C_\beta}{2^j} \cdot \sum_{i=1}^{j+1} |\text{OPT}(\beta \cdot 2^i)|\,.$$

Finally, with (3.1) we get

$$\begin{aligned}\mathrm{sr}(\pi) &\le \frac{C_\beta}{2^j} \cdot \sum_{i=1}^{j+1} \beta \cdot 2^i \cdot (\mathrm{sr}_{\mathrm{opt}} + 1) \\ &\le \beta C_\beta \cdot \left(\frac{2^{j+2} - 2}{2^j} \right) \cdot (\mathrm{sr}_{\mathrm{opt}} + 1) \\ &\le 4\beta\, C_\beta \cdot (\mathrm{sr}_{\mathrm{opt}} + 1)\,.\end{aligned}$$

If the agent has vision, it may see the last point within distance at most d from somewhere else, so we cannot guarantee $\mathrm{sp}(\mathit{last}_d) \le d$. We know only $|\mathrm{sp}(\mathit{last}_d)| \le |\pi_{\mathrm{opt}}(\mathit{last}_d)|$ (i.e., the return path to s cannot be longer than the path the agent traveled along π_{opt}). Thus,

$$\mathrm{sr}_{\mathrm{opt}} \ge \frac{|\pi_{\mathrm{opt}}(\mathit{last}_d)|}{d} \ge \frac{|\mathrm{OPT}(d)|}{2d} \iff |\mathrm{OPT}(d)| \le 2d \cdot \mathrm{sr}_{\mathrm{opt}}\,.$$

Further, we detect the goal by applying the exploration strategy with depth 2^{j+1} and return to the start; then we still have to move to the goal. Similar to the case of blind agents, we obtain for the search ratio an upper bound of

$$\begin{aligned}\frac{2^j + \sum_{i=1}^{j+1} |\mathrm{Expl}(2^i)|}{2^j} &\le 1 + C_\beta \cdot \frac{\sum_{i=1}^{j+1} |\mathrm{OPT}(\beta 2^i)|}{2^j} \le 1 + 2C_\beta \cdot \frac{\sum_{i=1}^{j+1} \beta 2^i\, \mathrm{sr}_{\mathrm{opt}}}{2^j} \\ &\le 1 + 8\beta C_\beta \cdot \mathrm{sr}_{\mathrm{opt}}\,. \qquad \square\end{aligned}$$

In the next two sections we will apply our framework to various types of environments and agents. The difficult part is always to find good depth-restrictable exploration algorithms.

4. Searching graphs. We distinguish between graphs with unit length and arbitrary length edges, planar and nonplanar graphs, directed and undirected graphs, as well as vertex and geometric search. We consider only blind agents: Located at a vertex of a (directed) graph, the agent senses only the number of outgoing edges, but neither their lengths nor the positions of the other vertices are known. Incoming edges cannot be sensed; see Deng and Papadimitriou [10]. Blind agents must eventually visit all points in the goal set. In the vertex search problem, we assume w.l.o.g. that graphs do not have parallel edges. Otherwise, there can be no constant–search-competitive vertex search algorithm: In Figure 4.1(i), the optimal search path $s \to v \to t \to s$ has length 3, whereas any online search path can be forced to cycle often between s and v before traversing the edge $v \to t$. Note that we can also use undirected edges.

4.1. Hard-searchable graphs. First, we show that for many graph classes there is no constant–search-competitive online search algorithm. Incidentally, there is also no constant-competitive online exploration algorithm for these graph classes. Note that we have the following implications for hard-searchable graphs:

- If planar graphs are hard-searchable, then so are nonplanar graphs.
- If graphs with unit length edges are hard-searchable, then so are graphs with arbitrary length edges.
- If undirected graphs are hard-searchable, then so are directed graphs (we can replace each undirected edge with directed edges in both directions).

THEOREM 4.1. *For blind agents, there is no constant–search-competitive online algorithm in the following settings:*

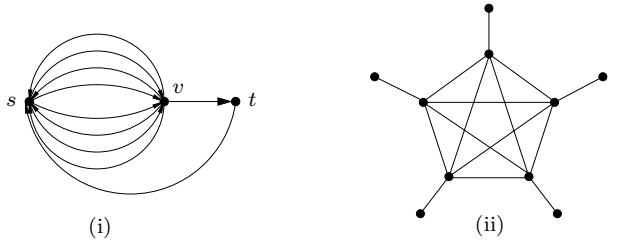

FIG. 4.1. *There is no constant–search-competitive vertex search algorithm for* (i) *graphs with parallel edges,* (ii) *vertex search in nonplanar graphs.*

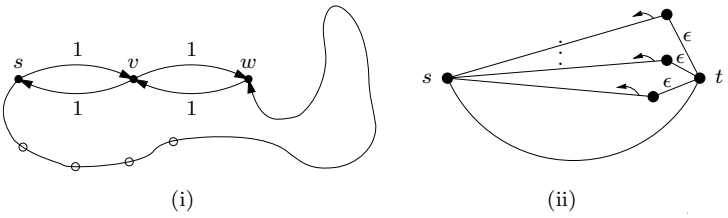

FIG. 4.2. *There is no constant–search-competitive vertex search algorithm for* (i) *vertex search and geometric search in directed graphs (the nodes ∘ occur only in the case of unit-length edges),* (ii) *vertex search in planar graphs with arbitrary edge length (the arrows denote the points on the edges where the searcher decides to return to s).*

1. *Vertex search in nonplanar graphs.*
2. *Vertex search and geometric search in directed planar graphs.*
3. *Vertex search in planar graphs with arbitrary edge lengths.*

Proof.

1. Consider the graph in Figure 4.1(ii) with unit length edges. It is a k-clique, where each vertex has a sibling that has only one connection to the clique. The optimal search ratio is $\Theta(k)$: We successively visit every clique vertex and explore its sibling before proceeding to the next clique vertex. This yields a path of length $3k$. On the other hand, any online search algorithm can be forced to travel $\Omega(k^2)$ before reaching the last vertex, so it has search ratio $\Omega(k^2)$. Thus, it is not better than k-competitive.
   Note that in a k-clique without siblings a BFS traversal achieves the optimal search ratio.
2. For vertex search, consider the planar graph in Figure 4.2(i) with a very long edge from s to w. The optimal search path, $s \to v \to w$, has search ratio 1. However, any online algorithm can be forced to first explore the long edge from s to w, resulting in a very high search ratio.
   If we are restricted to unit length edges, we can add more vertices along the long edge (marked with ∘ in Figure 4.2(i)). Then the optimal search path explores this long path after exploring the short cycle $s \to w \to s$. Because in the worst case the goal is hidden on the first vertex of the long path, this path achieves a search ratio of 5.
   For a geometric search, with unit length edges or arbitrary edges, we can use the same planar graph. Again, we force the online algorithm to explore the long edge at first. In contrast, the optimal strategy visits the cycle $s \to w \to s$ before exploring the long edge. The optimal strategy achieves its worst case

if the goal is hidden within distance 1 on the long edge.

3. For any given online search algorithm, we construct a planar graph as in Figure 4.2(ii) with k outgoing edges at the start vertex, s. An online algorithm visits one of the k edges at first. If the algorithm does not return to s while exploring this edge, the currently visited edge is the only long edge in the graph and all other edges are very short. The optimal strategy visits only short edges; thus, this algorithm can be arbitrarily bad.
   Hence, to achieve a good approximation factor, an online algorithm must at some point decide to stop exploring the first edge and to return to s (the small arrows in the figure indicate this point). We place the endpoint of the currently visited edge immediately behind the last visited point and continue similarly with the next $k-2$ edges. The last edge ends in vertex t, and its length is the minimum length among the first $k-1$ edges. Then we connect the endpoints of the first $k-1$ edges to t by an edge of length ϵ, where $\epsilon > 0$ is some very small number. The optimal search path in this graph first travels the last edge and then visits every other vertex quickly from t. Thus, its search ratio is close to 1. On the other hand, the online algorithm has search ratio at least k. Note that we introduced all the edge endpoints (instead of having the edges ending in t) because we assumed that there are no parallel edges. □

Note that there is an $O(D^8)$-competitive exploration for directed graphs by Fleischer and Trippen [17]. D denotes the *deficiency* of the given graph, that is, the minimum number of edges that must be added to get an Euler graph. This example shows that there are settings where there is no constant–search-competitive online algorithm, although there is an $O(D^8)$–competitive exploration algorithm. The problem is that this algorithm is not depth-restrictable. Besides, directed graphs do not fulfill $|\mathrm{sp}(s,p)| = |\mathrm{sp}(p,s)|$ for all p in $\mathcal{E}$, so we cannot apply our framework to directed graphs, anyway.

4.2. Competitive search in graphs. In this subsection, we present search-competitive online and offline search algorithms for the remaining graph classes. Note that we consider only undirected graphs.

4.2.1. Trees. On trees, DFS is a 1-competitive online exploration algorithm for vertex and geometric search that is depth-restrictable; it is still 1-competitive when restricted to search depth d for any $d \geq 1$. Thus, the doubling strategy gives a polynomial time 4–search-competitive search algorithm for trees—offline as well as online. On the other hand, it is an open problem whether the computation of an optimal vertex or geometric search path in trees with unit length edges is NP-complete [24].

4.2.2. Vertex search in graphs with unit length edges. Now, we give competitive search algorithms for vertex search in planar graphs with unit length edges and—in the next section—for geometric search in undirected graphs with arbitrary length edges. Both algorithms are based on an online algorithm for tethered graph exploration.

In the *tethered exploration* problem the agent is fixed to the start point by a rope of restricted length. An optimal solution to this problem was given by Duncan, Kobourov, and Kumar [12]. Their algorithm, closest first exploration (CFX), explores an unknown graph with unit length edges in $2|E| + (4 + \frac{16}{\alpha})|V|$ edge traversals, using a rope length of $(1+\alpha)d$, where d is the distance of the point farthest away from the

start point and $\alpha > 0$ is some parameter. Note that CFX explores the whole graph in spite of the *tethered* restriction.

CFX explores the graph in a mixture of depth-bounded DFS on G, DFS on spanning trees of parts of G, and recursive calls to explore certain large subgraphs. The basic idea of CFX is to maintain a set, $\mathcal{T}$, of edge-disjoint, partially[4] explored subtrees—more precisely, spanning trees of incomplete graph parts—that fulfill certain conditions on minimum size and maximal depth. Initially, $\mathcal{T}$ consists of one tree containing only the start node, s. The strategy successively selects the subtree nearest to s and walks to its root. Then, CFX traverses the subtree using DFS. For each encountered, incompletely explored vertex, CFX starts a depth-bounded DFS. In this process, new vertices are discovered and new subtrees are added to $\mathcal{T}$, possibly split into several smaller subtrees if they do not fulfill the conditions.

The costs for applying CFX sum up from relocation from s to the roots of the subtrees and back to s, the DFS traversals, and the costs for the depth-bounded DFS starting in unexplored vertices. The latter traverses only unexplored edges; thus, we have costs $2|E|$ for this part. For a subtree, T, with $|T|$ vertices, we have costs $2|T|$ for the DFS traversal. The size restrictions for the subtrees ensure that we can bound the relocation costs by $\frac{8}{\alpha}|T|$. As the subtrees may overlap, we can bound the sum of all vertices in the subtrees by $2|V|$. Altogether, we get

$$2|E| + \left(2 + \frac{8}{\alpha}\right) \sum_T |T| \le 2|E| + \left(2 + \frac{8}{\alpha}\right) \cdot 2|V| = 2|E| + \left(4 + \frac{16}{\alpha}\right) |V| \,.$$

As Duncan, Kobourov, and Kumar pointed out, the algorithm can be used even if the necessary rope length, d, is not known: They explore the whole graph by successively applying CFX and doubling d in every step. The important part is that the analysis still holds in this case. Particularly, we can apply CFX for a depth-restricted exploration (i.e., explore only a subgraph of G). For $d \ge 1$, let $G(d)$ denote the subgraph[5] of $G = (V, E)$ where all points $p \in V \cup E$ have distance at most $(1+\alpha)d$ from s. For convenience, let $G^* = (V^*, E^*) := G((1+\alpha)d)$. To explore all vertices in $G(d)$—and maybe some additional vertices from $G((1+\alpha)d)$—using a rope of length $(1+\alpha)d$, the number of edge traversals is bounded by

$$2|E^*| + \left(4 + \frac{16}{\alpha}\right) |V^*| \,.$$

Let us call this algorithm CFX(d). We have the following lemma.

LEMMA 4.2. *In planar graphs with unit length edges,* CFX *is a depth-restrictable algorithm for online vertex exploration with* $\beta = 1 + \alpha$ *and* $C_\beta = 10 + \frac{16}{\alpha}$.

Proof. As G^* is planar, we have $|E^*| \le 3|V^*| - 6$ by Euler's formula. Thus, the number of edge traversals of CFX(d) is at most

$$2\,|E^*| + \left(4 + \frac{16}{\alpha}\right) |V^*| \le 6\,|V^*| + \left(4 + \frac{16}{\alpha}\right) |V^*| = \left(10 + \frac{16}{\alpha}\right) |V^*| \,.$$

On the other hand, we have $\mathrm{OPT}((1+\alpha)d) \le |V^*|$, because the optimal algorithm must visit each vertex in V^* at least once. □

[4] That is, there are vertices that are already discovered but still have unvisited incident edges.

[5] In the case of unit-length edges, we omit all edges with length < 1 in the subgraph $G(d)$. Such edges occur if d is not an integer value.

Now, we can apply our framework with CFX.

THEOREM 4.3. *The doubling strategy based on* CFX(d) *is a* 206*–search-competitive online vertex search algorithm for blind agents in planar graphs with unit length edges.*

Proof. By Lemma 4.2, CFX(d) is depth-restrictable with $\beta = 1 + \alpha$ and $C_\beta = 10 + \frac{16}{\alpha}$. By Theorem 3.1, the doubling strategy based on CFX is $4\beta C_\beta$-competitive. Altogether, we have

$$4 \cdot \beta \cdot C_\beta = 4 \cdot (1 + \alpha) \cdot \left(10 + \frac{16}{\alpha}\right) = 104 + 40\alpha + \frac{64}{\alpha}\,.$$

By simple analysis, we get the minimal competitive ratio of 205.192... attained for $\alpha = \sqrt{\frac{8}{5}}$. ∎

4.2.3. Geometric search in graphs with arbitrary length edges. We note that CFX(d) can be modified to work on graphs with arbitrary length edges: Instead of counting the number of edge traversals, the algorithm has to track the length of the traversed edges. Now, it may happen that the maximal rope length is reached on an edge somewhere between two vertices. In this case, we interrupt the edge traversal, add an auxiliary vertex, and split the edge into two parts. Note that the added vertex is incompletely explored, so CFX will return to this vertex in a successive stage. Let $\ell(E)$ denote the total length of all edges in E. It is possible to adapt the proofs by Duncan, Kobourov, and Kumar [12] to prove the following lemma.

LEMMA 4.4. *In graphs with arbitrary length edges, CFX*(d) *explores all edges and vertices in* $G(d)$ *using a rope of length* $(1 + \alpha)d$ *at a cost of at most* $(4 + \frac{8}{\alpha}) \cdot \ell(E^*)$.

Proof (sketch). The proof is similar to the unit-length case, but we can no longer use the number of visited vertices to bound the number of traversed edges. Instead, we bound the costs for the depth-bounded DFS by $2\,\ell(E^*)$. As the subtrees are edge disjoint, we can bound the costs for the DFS traversals by $2\,\ell(E^*)$, too. The size restriction on the subtrees still ensures that the relocation costs are bound by $\frac{8}{\alpha}\,\ell(E^*)$. Altogether, we get $(4 + \frac{8}{\alpha}) \cdot \ell(E^*)$. Note that we have no additional costs for the auxiliary vertices, because we count only edge lengths, and by inserting auxiliary vertices we split one edge into two smaller edges whose total length is the same as the original edge. ∎

LEMMA 4.5. *In undirected graphs with arbitrary length edges, CFX is a depth-restrictable online geometric exploration algorithm with* $\beta = 1 + \alpha$ *and* $C_\beta = 4 + \frac{8}{\alpha}$.

Proof. The total cost of CFX(d) is at most $(4 + \frac{8}{\alpha}) \cdot \ell(E^*)$ by Lemma 4.4. On the other hand, OPT($(1 + \alpha)d$) must traverse each edge in E^* at least once. ∎

THEOREM 4.6. *The doubling strategy based on CFX*(d) *is a* 94*–search-competitive online geometric search algorithm for blind agents in undirected graphs with arbitrary length edges.*

Proof. By Lemma 4.5, CFX(d) is depth-restrictable with $\beta = 1+\alpha$ and $C_\beta = 4+\frac{8}{\alpha}$. Thus, by Theorem 3.1 the doubling strategy is $4\beta C_\beta$-competitive, and we have

$$4 \cdot \beta \cdot C_\beta = 4 \cdot (1 + \alpha) \cdot \left(4 + \frac{8}{\alpha}\right) = 48 + 16\alpha + \frac{32}{\alpha}\,.$$

Simple analysis shows that this factor is minimal for $\alpha = \sqrt{2}$, yielding a factor of 93.254.... ∎

4.2.4. Offline searching. In the offline setting, the searcher knows the graph but still does not know the location of the target. Thus, we want to compute (or approximate) an optimal search path in a known graph.

Computing an optimal search path in a known graph is NP-hard [24], but we can use our framework to give an approximation. Given a graph $G = (V, E)$ and an exploration depth $d \geq 1$, we can compute the subgraph $G(d)$. Now, we have to find an appropriate exploration strategy for $G(d)$. In the case of a vertex search, exploring $G(d)$ amounts to finding a traveling salesperson (TSP) tour on $G(d)$. This problem is NP-hard, too, but we can approximate a TSP tour within factor $C_\beta = 2$ using the mimimum–spanning-tree heuristic,[6] or we can use one of the $1+\epsilon$ approximations by Grigni, Koutsoupias, and Papadimitriou [18], Arora [3], or Mitchell [25].

The problem of finding a minimum-length tour that visits every edge of a given graph at least once is known as the Chinese postman problem and can be solved in polynomial time for graphs that are either directed or undirected [14, 26]. In this case, we have $C_\beta = \beta = 1$. Altogether we have the following theorem.

THEOREM 4.7. *There is a* 4*–search-competitive strategy for offline geometric search and an* 8*–search-competitive strategy for offline vertex search.*

5. Searching polygons.

5.1. Simple polygons. A simple polygon, P, is given by a closed, nonintersecting polygonal chain. Our searcher is equipped with ideal, unlimited vision; that is, it is provided with the full *visibility polygon* with respect to the searcher's current position.

To apply our framework, we need a depth-restrictable online exploration algorithm. The best known algorithm, PolyExplore, for the online exploration of a simple polygon by Hoffmann et al. [21] achieves a competitive ratio of 26.5.

Let $P(d) \subseteq P$ denote the part of the polygon P where all points have a distance at most d from the start. We can modify PolyExplore to explore $P(d)$: During the exploration, an unseen part of P always lies behind a *cut* c_v emanating from a reflex vertex, v. These reflex vertices are called *unexplored* as long as we have not visited the corresponding cut c_v. The algorithm maintains a list of unexplored reflex vertices and successively visits the corresponding cuts. While exploring a reflex vertex (along a sequence of line segments and circular arcs), more unexplored reflex vertices may be detected or unexplored reflex vertices may become explored. These vertices are inserted into or deleted from the list, respectively. In PolyExplore(d), unexplored reflex vertices within a distance greater than d from the start are simply ignored; that is, although they may be detected they will not be inserted into the list. Let OPT(d) be the shortest path that sees all points in $P(d)$.

Note that both PolyExplore(d) and OPT(d) may exceed $P(d)$, as shown in Figure 5.1. In (i) PolyExplore(d) successively explores the vertices v_r and v_ℓ, but OPT(d) visits the cuts outside $P(d)$. In (ii) PolyExplore(d) leaves $P(d)$ in e_4. However, we can enlarge $P(d)$ to $P'(d)$ by a well-defined region so that the resulting polygon contains PolyExplore(d) as well as OPT(d); see Figure 5.1.

More precisely, let d' be the maximal distance from PolyExplore(d) *and* OPT(d) to s; then we simply define $P'(d) := P(d')$. Newly inserted reflex vertices in $P'(d)$ cannot influence the paths of OPT(d) and PolyExplore(d) in $P'(d)$. Thus, the analysis of PolyExplore by Hoffmann et al. still holds for OPT(d) and PolyExplore(d) in $P'(d)$, and we have the following lemma.

LEMMA 5.1. *In a simple polygon,* PolyExplore *is a depth-restrictable online exploration algorithm with* $\beta = 1$ *and* $C_\beta = 26.5$.

[6] Note that we cannot apply the Christofides heuristic [8], because the triangle-inequality is not fulfilled in arbitrary graphs.

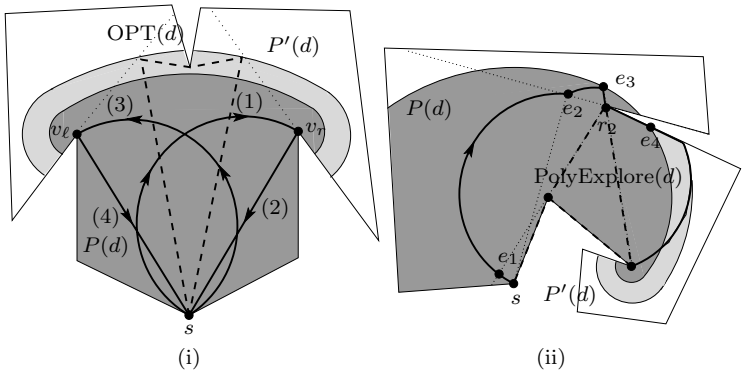

FIG. 5.1. (i) PolyExplore(d) *explores the right reflex vertex* v_r *along a circular arc* (1)*, returns to the start* (2)*, and explores the left reflex vertex* v_ℓ *likewise* (3)–(4). OPT(d) *(dashed line) leaves* $P(d)$. (ii) PolyExplore(d) *leaves* $P(d)$*, whereas the shortest exploration path for* $P(d)$ *lies inside* $P(d)$. *In both cases, we can extend* $P(d)$ *(dark gray) to* $P'(d)$ *(light gray) containing both* PolyExplore(d) *and* OPT(d).

THEOREM 5.2. *The doubling strategy based on* PolyExplore(d) *is a* 212*–search-competitive online search algorithm for an agent with vision in a simple polygon. There is also a polynomial time* 8*–search-competitive offline search algorithm.*

Proof. The online search-competitiveness follows from Lemma 5.1 and Theorem 3.1.

If we know the polygon, we can compute OPT(d) in polynomial time by adapting a corresponding algorithm for P. Every known polynomial time offline exploration algorithm visits the essential cuts in a certain sequence; see, for example, [7, 29, 28, 11]. Any of these algorithms can be used in our framework. As an optimal algorithm has approximation factor $C = 1$, our framework yields an approximation of the optimal search path with a factor of 8.

The overall running time of the algorithm seems to depend on the distance to the farthest reflex vertex of the polygon. However, we skip a step with distance 2^i if there is no reflex vertex within a distance between 2^{i-1} and 2^i. Thus, we always explore at least one new vertex in every iteration of the doubling strategy. Altogether, the total running time is bounded by a polynomial in the number of the vertices of P. ∎

Note that there is a considerable gap between the upper bound given by Hoffmann et al. [21] and the best known lower bound of 1.2825 [20]. The authors conjecture that the actual performance of PolyExplore is below 10 [21]; the worst case known so far is 5 [19]. Under this assumption, the search-competitivity of a doubling strategy based on PolyExplore can be expected to be below 80.

Now the question arises whether there is a polynomial time algorithm that computes the optimal search path in a simple polygon. We have to visit every essential cut, so we can try to visit them in any possible order. Anyway, we do not know exactly which point on the cut we should visit. We are not sure whether there are only a few possibilities as in the shortest watchman route problem. In other words, it is unknown whether this subproblem is discrete at all. So the problem of computing an optimal search path in a polygon is still open.

Even for rectilinear simple polygons no polynomial time algorithm for the optimal search path is known, but we can find better online algorithms.

THEOREM 5.3. *For an agent with vision in a simple rectilinear polygon there is*

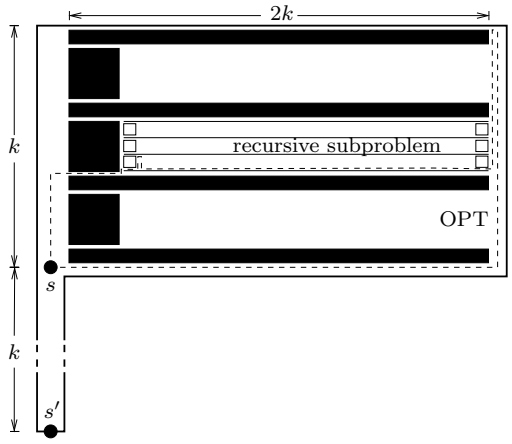

FIG. 5.2. *Lower bound construction for approximating the optimal search path in polygons with holes (start point s'). The upper half shows the lower bound for the exploration task by Albers, Kursawe, and Schuierer (start point s).*

an $8\sqrt{2}$–search-competitive online search algorithm. There is also a polynomial time 8–search-competitive offline search algorithm.

Proof. For a rectilinear simple polygon, P, Deng, Kameda, and Papadimitriou [9] introduced a simple $\sqrt{2}$-competitive online exploration algorithm. Obviously, this algorithm is depth-restrictable—we simply ignore reflex vertices farther away than d—while remaining $\sqrt{2}$-competitive compared to the restricted optimal path $\mathrm{OPT}(d)$. The optimal path never leaves $P(d)$, because we have only 90° reflex vertices. Our framework gives an $8\sqrt{2}$–search-competitive online search algorithm.

In the offline setting, we can obtain a polynomial time 8–search-competitive search algorithm based on an optimal depth-restricted exploration algorithm similar to Theorem 5.2. □

5.2. Polygons with holes. In this section, we show that there is no constant–search-competitive online search algorithm for polygons with (rectangular) holes. Albers, Kursawe, and Schuierer [1] showed that there is no constant-competitive online exploration algorithm for polygons with holes. They filled a rectangle of height k and width $2k$, $k \geq 2$, with $O(k^2)$ rectangular holes such that the optimal exploration tour has a length in $O(k)$, whereas any online exploration algorithm needs to travel a distance within $\Omega(k^2)$. Additionally, every point $p \in \mathcal{E}$ has at most the distance $3k$ from the start point, s; see Figure 5.2 and Albers, Kursawe, and Schuierer [1] for a detailed description.

THEOREM 5.4. *For an agent with vision in a polygon with holes there is no constant–search-competitive online search algorithm.*

Proof. Unfortunately, in the lower bound construction of Albers, Kursawe, and Schuierer the optimal exploration paths yields a bad search ratio. Thus, we enlarge the setting by a thin corridor of length k that leads to the former start point, s. Our new start point, s', is located at the end of the new corridor; see Figure 5.2. Now, every point that is not visible from s' is at least k steps away from s'; that is, $\mathrm{sp}(s', p) \geq k$ holds for such a point p. The optimal exploration path is still never longer than $C \cdot k$ for a constant C; thus, the optimal exploration path is a C-approximation of the optimal search path. In the new scene, every online exploration algorithm is forced to walk

a path of length in $\Omega(k^2)$. Because every online approximation of the optimal search path is also an online exploration algorithm, there are points that are discovered after walking a path length in $\Omega(k^2)$, although their distance to s' is within $O(k)$. Thus, no online approximation is able to achieve a constant approximation factor. □

Since the offline exploration problem is NP-complete (by straightforward reduction from planar TSP) we cannot use our framework to get a polynomial time approximation algorithm of the optimal search path. However, there is an exponential time 8-approximation algorithm. We can list the essential cuts of $\mathrm{OPT}(d)$ in any order to find the best one. Applying our framework gives an approximation factor of 8 for the optimal search ratio.

The results of Koutsoupias, Papadimitriou, and Yannakakis [24] imply that the offline problem of computing an optimal search path in a known polygon with holes is NP-complete.

6. A general lower bound. We have seen that for certain types of environments there exists an approximation for the optimal search path if there exists a depth-restrictable, competitive exploration strategy. Further, we have seen that polygons with holes are hard-searchable. Now, we want to generalize the latter result; that is, we want to show that—under a certain condition—there is no approximation up to a constant factor if there is no competitive exploration strategy for environments of the given type.

Usually, the nonexistence of competitive exploration strategies is shown by giving a lower bound—a scenario in which every exploration strategy is forced to walk a path whose length exceeds the length of the optimal exploration path by more than a constant factor. To transfer such a result to search path approximations, we require that the scenario can be extended around the start point, such that the start point moves further away from the original scenario. We used this technique in section 5.2. One might think of an arbitrary large narrow corridor which is added to a given environment.

DEFINITION 6.1. *Let $\mathcal{E}$ be an environment of arbitrary type and s be a start point in $\mathcal{E}$. We call $\mathcal{E}$ s-*extendable *if we can enlarge $\mathcal{E}$ locally around the start point; that is, it is possible to choose a new start point, s', outside $\mathcal{E}$ and enlarge $\mathcal{E}$ to $\mathcal{E}'$ such that s' is contained in $\mathcal{E}'$ and every path from s' to a point in $\mathcal{E}$ passes s. Additionally, we require that along any path from s' to s all targets in the extension will be (successively) detected—but no target ouside the extension. And we can design $\mathcal{E}'$ so that the shortest path from s to s' has arbitrary length.*

Beyond this rather technical condition some additional properties of a lower bound construction should hold.

We consider environments $\mathcal{E}$ of a given type such that $|\mathrm{sp}(s,p)| = |\mathrm{sp}(p,s)|$ holds. This was already one of our main requirements; see section 2. Let us now assume that there is an optimal exploration strategy OPT for $\mathcal{E}$ but in general there is no constant competitive online exploration strategy. We assume that this is shown by a lower bound construction $L(n)$, where n indicates the *size* of $L(n)$. More precisely, we assume that any online exploration strategy $\mathcal{A}$ has path length $|\mathcal{A}(L(n))| \geq C(n) \cdot |\mathrm{OPT}(L(n))|$ in the environment $L(n)$ and $C(n)$ is unbounded in n.

Furthermore, the length of the shortest path to any goal in $L(n)$ should be bounded by $K \cdot |\mathrm{OPT}(L(n))|$, where K is a constant. Obviously, the last condition always holds for blind agents.

Under the given conditions we can prove the following general result.

THEOREM 6.2. *If there is no constant-competitive online exploration algorithm*

for environments of a given type as indicated above, and the corresponding lower bound is s-extendable and additionally fulfills the properties above, then there is no competitive online approximation of the optimal search path.

Proof. Any online approximation, $\mathcal{A}$, of the optimal search path is also an online exploration strategy; therefore, we have $|\mathcal{A}(L(n))| \geq C(n) \cdot |\mathrm{OPT}(L(n))|$, and $C(n)$ is unbounded in n. We extend $L(n)$ by placing a new start point, s', *outside* $L(n)$ with distance $|\mathrm{OPT}(L(n))|$ and connecting it to the former start point s. Adding the shortest path from s to s' to $\mathrm{OPT}(L(n))$, this offline algorithm obviously has constant search ratio. The targets in the extension are detected optimally, and every target in $L(n)$ has a shortest distance of at least $|\mathrm{OPT}(L(n))|$ from s'. For visiting a detected goal t in $L(n)$ the extended version of $\mathrm{OPT}(L(n))$ might first run to its end and back to the start and then runs along the shortest path to t. This always gives a constant ratio.

On the other hand, for every online approximation, $\mathcal{A}$, there are some goals t which are detected after a path length greater than or equal to $C(n) \cdot |\mathrm{OPT}(L(n))|$, but the shortest path to the goal t is not longer than $(K+1) \cdot |\mathrm{OPT}(L(n))|$ for a constant K. Thus, there is a search ratio of at least $\frac{C(n)}{K+1}$ which is still unbounded in n. ∎

7. Conclusion and open problems. There are environments where no online search strategy can achieve a constant competitive factor. Therefore, we used the *search ratio* as a parameter of a given environment that gives a measure for the environment's searchability. A search strategy is considered "good" if it achieves a good approximation of the optimal search ratio; that is, the search ratio of an online strategy is at most a constant factor worse than the optimal search ratio.

We showed that we can use depth-restrictable exploration strategies—exploration strategies that can be modified to explore the environment only up to a certain depth while they are still competitive—to approximate the optimal search path by successively applying the exploration with exponentially increasing exploration depths. For blind agents we showed that there are $4\beta C_\beta$-approximations and for searchers with vision $8\beta C_\beta$-approximations, where β and C_β are parameters that depend on the modifications to turn an exploration algorithm into a depth-restricted exploration. We applied our results to various types of graphs and polygons; see Table 7.1.

Further, we showed that there is no constant–search-competitive strategy for polygons with holes. The main idea for this proof—enlarging the environment close to the start point—can be generalized for environments that fulfill a certain condition we called s-extendable. We also showed that some graph settings—including directed graphs—are hard-searchable.

Altogether, we showed a close relation between searching and exploring: For environments fulfilling $|\mathrm{sp}(s,p)| = |\mathrm{sp}(p,s)|$ for all p in $\mathcal{E}$ there is some equivalence between constant-competitive exploring and searching if the exploration strategy is depth-restrictable and the lower bounds are s-extendable (among some other natural properties). Naturally, these results lead to the question of whether there is a stronger connection. More precisely, can we omit at least the prerequisites "depth-restrictable" and "s-extendable" and show the following conjecture?

Conjecture 1. *For a given type of environment that fulfills* $\forall p \in \mathcal{E} : |\mathrm{sp}(s,p)| = |\mathrm{sp}(p,s)|$*, there is a constant–search-competitive strategy* if and only if *there exists a constant-competitive online exploration for environments of this type.*

Proving this conjecture would show a closer relation between exploration and searching: We are able to approximate the optimal search path—in other words,

TABLE 7.1

*Summary of our approximation results. The entry marked with * had earlier been proven by Koutsoupias, Papadimitriou, and Yannakakis* [24]. *They had also shown that computing the optimal search path is NP-complete for (planar) graphs. It is also NP-complete for polygons with holes, whereas it is not known to be NP-complete for trees and polygons without holes.*

Environment	Edge length	Goal	Polytime approximation ratio	
			Online	Offline
Tree	unit, arbitrary	vertex, geometric	4	4
Planar graph	arbitrary	vertex	no search-compet. alg.	8
Planar graph	unit	vertex	205.192...	8
Undirected graph	unit, arbitrary	vertex	no search-compet. alg.	8*
Undirected graph	arbitrary	geometric	93.254...	4
Simple polygon			212	8
Rect. simple polygon			$8\sqrt{2}$	8
Polygon with holes			no search-compet. alg.	?

we can find a good search strategy—if there is a constant-competitive exploration strategy. And, vice versa, we have no chance of finding a good search strategy if no constant-competitive exploration is possible. Note that the sp-condition is necessary, anyway, not only because our approximation framework relies on it, but also because it seems to be hard to find depth-restrictable exploration strategies for environments without the sp-condition. For example, there is a competitive exploration strategy for directed graphs (see Fleischer and Trippen [17]) which does not fulfill the sp-condition and is not depth-restrictable.

Acknowledgment. We would like to thank the anonymous referees for helpful comments and suggestions for improvements.

ON APPROXIMATING THE DEPTH AND RELATED PROBLEMS*

BORIS ARONOV† AND SARIEL HAR-PELED‡

Abstract. We study the question of finding a deepest point in an arrangement of regions and provide a fast algorithm for this problem using random sampling, showing it sufficient to solve this problem when the deepest point is shallow. This implies, among other results, a fast algorithm for approximately solving linear programming problems with violations. We also use this technique to approximate the disk covering the largest number of red points, while avoiding all the blue points, given two such sets in the plane. Using similar techniques implies that approximate range counting queries have roughly the same time and space complexity as emptiness range queries.

1. Introduction.

In this paper, we study the problem of efficiently computing the deepest point in a collection of regions. Here, the *depth* of the point is the number of regions containing it. This is a natural problem that arises in optimization, where a constraint induces a region in space where it holds, and we would like to find the point that satisfies all the constraints; see Figure 1. If no such point exists, we would like to find a point that satisfies the maximum number of constraints. As a concrete example, a linear program with n inequalities over d variables induces a set of n halfspaces in $\mathbb{R}^d$. The given linear program is feasible (i.e., it has a feasible solution) if there is a point of depth n in this arrangement of n halfspaces. Furthermore, if the given linear program is not feasible, then a point with maximum depth in the arrangement is a solution violating the least number of constraints.

In this paper, we provide several reductions for the problem of finding the deepest point and show how to solve some depth problems using these techniques.

Computing a point of maximum depth via depth thresholding. In section 3, we present a general reduction that allows one to quickly compute an approximately deepest point in an arrangement of objects given a slower exact procedure for computing the depth exactly. More precisely, suppose we are given a *depth thresholding procedure* that can find, given an integer k, a deepest point for a set of n regions in $T_{\mathrm{DT}}(n,k)$ time, provided the depth does not exceed k; if it does, the procedure outputs "depth $> k$." The resulting approximation algorithm, given a set $\mathcal{S}$ of n regions, can find a point of depth at least $(1-\varepsilon)k_{\mathrm{opt}}$, where k_{opt} is the maximum number of regions covering any point. The running time of this new algorithm is

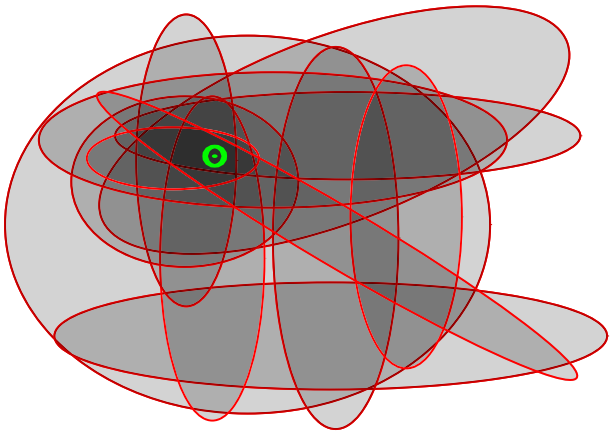

FIG. 1.

$O(T_{\mathrm{DT}}(n, \varepsilon^{-2} \log n) + n)$, assuming $T_{\mathrm{DT}}(n, k) = \Omega(n)$ for any k. This reduction is applicable to any set of "well-behaved" regions in constant dimension.

Unless explicitly stated otherwise, all bounds on running time and space hold with high probability (i.e., at least $1 - 1/n^{O(1)}$) and also in expectation. The results returned by these algorithms are correct with high probability.

Next, in section 4, we present several applications of this reduction. In section 4.1, we show that one can solve linear programming problems with violations approximately in near-linear time. Explicitly, consider a linear program L with n constraints in $\mathbb{R}^d$ and a linear objective function f. Suppose k_{opt} is the minimum number of constraints that have to be violated to make L feasible, and let v be the optimal solution in this case; namely, v is the point minimizing $f(v)$ with exactly k_{opt} violated constraints. Then, one can find a point u that violates at most $(1 + \varepsilon)k_{\mathrm{opt}}$ constraints of L and such that $f(u) \leq f(v)$. The running time of the new algorithm is $O(n(\varepsilon^{-2} \log n)^{d+1})$. This compares favorably with the previous exact algorithm of Matoušek [Mat95] which requires $O(nk^{d+1})$ running time. (In two and three dimensions faster exact algorithms exist [Cha05]. See section 4.1.) To appreciate this result, consider the case where $k = \sqrt{n}$. A natural approach to approximate linear programming problems with violations is to compute a δ-approximation [VC71] to the set of constraints in L and apply the exact algorithm on this sample. However, in this case, $\delta = \varepsilon/\sqrt{n}$, and the required random sample would include (almost) all the constraints of L, thus achieving no speedup.

An application: Finding a disc covering red points, but no blue points. Consider two finite sets of points in the plane, *red* and *blue*. As another application of the aforementioned technique, we investigate the problem of finding a disk containing the largest number of red points, while avoiding all the blue points. This is a natural problem related to learning and clustering [DHS01]. For example, one might try to learn a concept believed to be a disk, from examples, where the red points represent positive examples and the blue ones represent negative ones. A possible criterion to optimize is to say that the best concept (i.e., disk) is the one that classifies the blue points correctly (i.e., avoids them), while minimizing the error on the red points (i.e., the disk covers as many red points as possible).

The corresponding problem, in high dimensions, of computing the best such ball seems to be computationally hard, since computing the separating hyperplane min-

imizing the number of outliers is NP-hard [AK95]. In fact, approximating it within a factor of $2^{\log^{0.5-\varepsilon} n}$, for any fixed $\varepsilon > 0$, is "almost" NP-hard; see [ABSS97] for details. In constant dimension d, this ball can be computed by brute-force enumeration of all possibilities, in $n^{O(d)}$ time. Motivated by this unattractive option, we develop approximation algorithms for this problem, where we look for the ball containing (approximately) the largest number of red points, while avoiding all the blue points. More specifically, we observe that every red point p induces a feasible region which is the locus of the centers of the maximal balls containing p and not containing any blue points in their interior. Thus, the problem reduces to that of finding a point in the plane (or in space) having the largest number of such regions covering it, namely, a *deepest* point in an arrangement of such regions.

In section 4.2, we show that computing the deepest point in an arrangement of disks in the plane is 3SUM-hard [GO95] and present a $(1-\varepsilon)$-approximation algorithm with $O(n\varepsilon^{-2}\log n)$ expected running time. In section 4.3, we investigate the geometry of the problem of, given a set of blue and a set of red points, computing the disk containing the largest number of red points while avoiding all blue points. In particular, we show that this is equivalent to, given a set of red planes and a set of blue planes in three dimensions, computing the point having the largest number of red planes below it, while having all the blue planes above it. The points lying below all blue planes and above a specific red plane form the *feasible region* of that plane. Projecting the feasible regions to the plane, we obtain a set of pseudodisks which can be manipulated efficiently using an implicit representation. Plugging this into the algorithm for computing the depth of an arrangement of pseudodisks results in an approximation algorithm, with $O(n\varepsilon^{-2}\log^2 n)$ expected running time, which returns a disk covering $(1-\varepsilon)k_{\text{opt}}$ points, where k_{opt} is the number of red points covered by the optimal disk. We also study this problem in higher dimensions.

Approximate counting. Given a set of points P in $\mathbb{R}^d$ and a class of ranges, the problem of *range searching* is preprocessing P so that, given a range τ, one can quickly answer (i) *emptiness queries*: test whether $\tau \cap P = \emptyset$; (ii) *counting queries*: report the size of $\tau \cap P$; or (iii) *reporting queries*: report the elements of $\tau \cap P$. This problem and its variants have numerous applications and have received substantial attention. See [AE99] for a survey of the subject.

Interestingly, there is a complexity gap between emptiness queries and counting queries. In the (somewhat reasonable) computation model assumed by Brönnimann, Chazelle, and Pach [BCP93], halfspace counting queries require $\Omega^*(n^{1-2/(d+1)})$ time per query if only linear space is allowed.[1] Matoušek [Mat93] showed how to answer such queries in $O(n^{1-1/d})$ time. On the other hand, halfspace emptiness queries can be answered in logarithmic time in two and three dimensions, and in $O^*(n^{1-1/\lfloor d/2\rfloor})$ time in higher dimensions [Mat92], using near-linear space; this is slightly faster than the aforementioned lower bound for the counting problem. Especially interesting is the situation in dimensions two and three, where the gap is between logarithmic query time for emptiness queries and polynomial query time for counting queries.

In section 5, we show that this gap disappears if one is willing to get an approximate answer to the counting query. In particular, given a prespecified ε, $0 < \varepsilon < 1/2$, we show how to reduce a counting query to a sequence of emptiness queries of length polynomial in $\log n$ and ε^{-1}. For any range τ, this data structure reports a number μ_τ, such that $(1-\varepsilon)\,|\tau \cap P| \le \mu_\tau \le |\tau \cap P|$. Thus, approximate counting and empti-

[1] We use $f(n) = O^*(g(n))$ to express $f(n) = O(g(n)\log^c n)$ and $f(n) = \Omega^*(g(n))$ to mean $f(n) = \Omega(g(n)\log^{-c} n)$ for some constant $c > 0$.

ness range searching are computationally nearly equivalent. Since this circumvents the aforementioned gap, we believe it to be of independent interest.

We contrast our results with the work of Arya and Mount [AM00], which considers a different notion of approximation for the range searching problem. They approximate the range (using a distance which depends on the diameter of the query shape) and return the *exact* count inside this *approximate* shape. In our results, on the other hand, the shape is fixed but the count returned is approximated. In particular, our results apply to halfspace range searching, while Arya–Mount methods cannot be applied here, as a halfspace has infinite diameter.

Our results are based on careful application of random sampling, using several multiresolution samples. By performing the computation at the right resolution, we are able to achieve fast running time. This technique is by now standard in the area of randomized algorithms. Recent results that use similar techniques include [IM98, Ind00, HI00]; this list is by no means exhaustive. In the context of halfspace range searching, Chan [Cha00] used multiresolution random samples to roughly estimate the depth of the query, and speed up halfspace range *reporting* queries, in the expected sense.

2. Preliminaries. Given a set of objects $\mathcal{S}$ in $\mathbb{R}^d$ and a point $q \in \mathbb{R}^d$, let the *depth of q in $\mathcal{S}$*, $\operatorname{depth}(q, \mathcal{S})$, be the number of objects of $\mathcal{S}$ containing q. The *depth of $\mathcal{S}$* is defined as $\max_q \operatorname{depth}(q, \mathcal{S})$, with q ranging over all of $\mathbb{R}^d$. Finally, let $\operatorname{core}(\mathcal{S})$ denote the locus of points realizing $\operatorname{depth}(\mathcal{S})$.

In the remainder of the paper, we assume that the sets $\mathcal{S}$ are well behaved. In particular, we require that the complexity of the arrangement formed by $\mathcal{S}$ be bounded by $|\mathcal{S}|^{O(d)}$. The *arrangement* formed by $\mathcal{S}$ is the decomposition of the plane (or, more generally, $\mathbb{R}^d$) induced by a collection of such shapes [SA95]. The *combinatorial complexity* of an arrangement is the total number of edges, faces, and vertices in the arrangement. A *k-level* in an arrangement of curves is the closure of the set of points on the curves that have exactly k curves below them. For a set of regions R, *the union of R* is the set of points in the plane covered by at least one region of R. For a union of regions, its *complexity* is the number of edges and vertices of the arrangement lying on the boundary of the union (i.e., this is the descriptive complexity of the union). Analogous definitions apply in higher dimensions.

In the following, we need the Chernoff inequality; see [MR95].

THEOREM 2.1 (Chernoff inequality). *Let $X_1, \ldots, X_n$ be n independent Bernoulli trials, where $\mathbf{Pr}[X_i = 1] = p_i$, $\mathbf{Pr}[X_i = 0] = 1 - p_i$, $Y = \sum_i X_i$, and $\mu = \mathbf{E}[Y]$. Then, for any $\delta > 0$,*

$$\mathbf{Pr}[Y > (1+\delta)\mu] < \begin{cases} \exp\left(-\mu\delta^2/4\right), & \delta \le 2e-1 \text{ (case (a))}, \\ 2^{-\mu(1+\delta)}, & \delta \ge 2e-1 \text{ (case (b))}, \end{cases} \tag{1}$$

and

$$\mathbf{Pr}[Y < (1-\delta)\mu] \le \exp\left(-\mu\delta^2/2\right). \tag{2}$$

3. From exact depth to fast approximate depth. Given a set $\mathcal{S}$ of n objects and $\varepsilon > 0$, we consider the following two problems:

Problem 1: Computing $\operatorname{depth}(\mathcal{S})$ exactly, perhaps also producing a *witness point*, i.e., a point in $\operatorname{core}(\mathcal{S})$.

Problem 2: Estimating $\delta = \operatorname{depth}(\mathcal{S})$, i.e., producing an integer k with the $(1-\varepsilon)\delta \le k \le \delta$ together with a witness point of that depth.

We will also need, as a subroutine, a procedure DEPTHTHRESHOLD($\mathcal{S}', k$) with the following behavior: Given a collection $\mathcal{S}' \subset \mathcal{S}$ of n' objects and an integer $k > 0$, determine depth($\mathcal{S}'$) exactly (and produce a witness point of this depth) *if* it does not exceed k; otherwise, just return "depth($\mathcal{S}'$) $> k$." We refer to this as *depth thresholding*. Let $T_{\text{DT}}(n', k)$ be its running time.

Solving Problem 1 seems to require computing the whole arrangement $\mathcal{A}(\mathcal{S})$ (at least in general settings). Therefore, a running time better than $O(n^d)$ for this problem seems unlikely. As such, we will concentrate in this section on the approximation version of this problem, namely, Problem 2. In particular, in this section, we show how to solve Problem 2 by performing a logarithmic number of depth thresholding calls.

3.1. An approximate decision procedure. The intuitive idea behind approximating $\delta := \text{depth}(\mathcal{S})$ for a collection $\mathcal{S}$ of n objects is to perform a binary search on the value of the depth. However, we cannot afford to use an exact decision procedure (i.e., a test comparing δ to a given number k) in each round, as all known methods of computing the depth exactly essentially compute the full arrangement $\mathcal{A} = \mathcal{A}(\mathcal{S})$. (Actually, using the depth thresholding idea, one can test whether $\delta > k$ for any given k, without necessarily computing the whole arrangement, but the cost $T_{\text{DT}}(n, k)$ of doing this usually grows with k, so it is too expensive to perform the test for large values of k. This is precisely the case where the randomized procedure given below is more efficient.) The idea is to first perform a "rough" search for the right depth (up to a constant factor). Once we are in the right range, one can find the approximate depth by applying the depth thresholding procedure to a single random sample, using the relation between the depth of $\mathcal{S}$ and that of the sample.

To this end, we develop an approximate decision procedure, which, given a value k, returns "$k < \delta$" with high probability if k is significantly smaller than δ and "$k > \delta$" with high probability if k is significantly larger than δ. We start by proving the following technical lemma.

LEMMA 3.1. *Let $\mathcal{S}$ be a set of n objects in $\mathbb{R}^d$, ε, $0 < \varepsilon < 1/2$, be fixed, $k > 0$ be an integer, and $R \subseteq \mathcal{S}$ be a random subset formed by picking each object with probability*

$$\psi = \psi(\varepsilon, k) := \min\left(c_1 \frac{\log n}{k\varepsilon^2},\ 1\right)$$

independently, where c_1 is a sufficiently large constant. Then, for a point $p \in \mathbb{R}^d$, we have, with high probability, that

(i) *if* $\text{depth}(p, R) \geq \alpha_+(\varepsilon, k) := 2k\psi$, *then* $\text{depth}(p, \mathcal{S}) \geq (3/2)k$;
(ii) *if* $\text{depth}(p, R) \leq \alpha_-(\varepsilon, k) := (1 - \varepsilon)k\psi$, *then* $\text{depth}(p, \mathcal{S}) \leq k$;
(iii) *if* $\text{depth}(p, R) \geq \alpha_-(\varepsilon, k)$, *then*

$$(1 - \varepsilon)\,\text{depth}(p, \mathcal{S}) \leq \frac{\text{depth}(p, R)}{\psi} \leq (1 + \varepsilon)\,\text{depth}(p, \mathcal{S});$$

namely, the depth of a "deep" point in $\mathcal{A}(R)$ is a good estimate of its depth in $\mathcal{A}(\mathcal{S})$.

Proof. If $\psi = 1$, there is nothing to prove, so we assume $\psi < 1$ in what follows.

(i) Consider a point $p \in \mathcal{A}(\mathcal{S})$ such that $r := \text{depth}(p, \mathcal{S}) < (3/2)k$. We have that

$\mu := \mathbf{E}[\mathrm{depth}(p,R)] = r\psi$ and $r(1+\varepsilon/4) < 2k$. Therefore,

$$\begin{aligned}\nu := \mathbf{Pr}[\mathrm{depth}(p,R) \geq 2k\psi] &= \mathbf{Pr}\left[\mathrm{depth}(p,R) \geq \frac{2k}{r}\mu\right] \\ &= \mathbf{Pr}\left[\mathrm{depth}(p,R) \geq \left(1+\left(\frac{2k}{r}-1\right)\right)\mu\right].\end{aligned}$$

If $\frac{2k}{r} - 1 \leq 2e-1$, i.e., $k/e \leq r$, then, by the Chernoff inequality ((1), case (a)), we have

$$\begin{aligned}\nu &\leq \exp\left(-\mu\left(\frac{2k}{r}-1\right)^2/4\right) = \exp\left(-r\psi\left(\frac{2k}{r}-1\right)^2/4\right) \leq \exp\left(-r\left(c_1\frac{\log n}{k\varepsilon^2}\right)\frac{\varepsilon^2}{36}\right) \\ &\leq \exp\left(-\frac{k}{e}\left(c_1\frac{\log n}{k\varepsilon^2}\right)\frac{\varepsilon^2}{36}\right) = \frac{1}{n^{\Omega(1)}}.\end{aligned}$$

If $r \geq k/e$ then, by the Chernoff inequality ((1), case (b)), we have

$$\nu \leq 2^{-2k\mu/r} = 2^{-2k\psi} \leq \frac{1}{n^{\Omega(1)}}.$$

(ii) Let p be a point of $\mathbb{R}^d$ such that $r = \mathrm{depth}(p,\mathcal{S}) \geq k$. We have that $\mu = \mathbf{E}[\mathrm{depth}(p,R)] = r\psi$. Arguing as above, we have

$$\mathbf{Pr}[\mathrm{depth}(p,R) < (1-\varepsilon)k\psi] \leq \mathbf{Pr}[\mathrm{depth}(p,R) < (1-\varepsilon)r\psi] \leq \exp\left(-\frac{\varepsilon^2}{2}r\psi\right) \leq \frac{1}{n^{\Omega(1)}}.$$

(iii) Arguing as in case (i), we have that if $\mathrm{depth}(p,R) \geq \alpha_-(\varepsilon,k)$, then $\mathrm{depth}(p,\mathcal{S}) \geq k/2$, and this holds with high probability. As such, we have that $\mu = \mathbf{E}[\mathrm{depth}(p,R)] \geq k\psi/2$. This implies, using the Chernoff inequality (Theorem 2.1), that

$$\mathbf{Pr}[\mathrm{depth}(p,R) > (1+\varepsilon)\mu] \leq \exp\left(-\frac{\varepsilon^2}{4}\mu\right) \leq \exp\left(-\frac{\varepsilon^2}{8}k\psi\right) \leq \frac{1}{n^{\Omega(1)}}.$$

Similarly,

$$\mathbf{Pr}[\mathrm{depth}(p,R) < (1-\varepsilon)\mu] \leq \exp\left(-\frac{\varepsilon^2}{2}\mu\right) \leq \frac{1}{n^{\Omega(1)}},$$

implying the claim. □

COROLLARY 3.2. *Let $\mathcal{S}$ be a set of n objects, with $\delta = \mathrm{depth}(\mathcal{S})$. Let ε, $0 < \varepsilon < 1/2$, be fixed, $k \geq \delta/4$ be an integer, and $R \subseteq \mathcal{S}$ be a random subset formed by picking each object with probability*

$$\psi = \psi(\varepsilon,k) := \min\left(c_1\frac{\log n}{k\varepsilon^2},\ 1\right),$$

independently, where c_1 is a sufficiently large constant. Then, we have that

(i) *if $\mathrm{depth}(R) \geq \alpha_+(\varepsilon,k) := 2k\psi$, then with high probability $\delta \geq (3/2)k$;*
(ii) *if $\mathrm{depth}(R) \leq \alpha_-(\varepsilon,k) := (1-\varepsilon)k\psi$, then with high probability $\delta \leq k$; and*
(iii) *for all $p \in \mathbb{R}^d$, such that $\mathrm{depth}(p,R) \geq \alpha_-(\varepsilon,k)$, we have with high probability that*

$$(1-\varepsilon)\,\mathrm{depth}(p,\mathcal{S}) \leq \frac{\mathrm{depth}(p,R)}{\psi} \leq (1+\varepsilon)\,\mathrm{depth}(p,\mathcal{S}).$$

Proof. The proof follows immediately from Lemma 3.1, since the complexity of $\mathcal{A}(\mathcal{S})$ is polynomial. Indeed, place a point inside each face of $\mathcal{A}(\mathcal{S})$, and apply the lemma to all these points. ∎

3.1.1. If we know where to look, we can find it. Assume that we are given an estimate y of $\delta := \operatorname{depth}(\mathcal{S})$, with $y \leq \delta \leq 8y$. Then we can compute approximately the depth of $\mathcal{S}$. Indeed, compute a random sample R of $\mathcal{S}$ as specified by Lemma 3.1 for $k = y/2$. Next, perform depth thresholding on R with threshold $M := 16y\psi = O(\varepsilon^{-2} \log n)$, where $\psi = \psi(\varepsilon/4, k)$. It is easy to verify that, with high probability (by the Chernoff inequality), the depth of R is bounded from above by M (as the expected maximum depth is $M/2$). Furthermore, $\delta > k$, and by Corollary 3.2 (ii), we have $\operatorname{depth}(R) > \alpha_-(\varepsilon/4, k)$ (again, with high probability). Let v be the witness point returned by DepthThreshold(R, M) with the maximum depth in R. The depth of v in $\mathcal{A}(R)$ exceeds $\alpha_-(\varepsilon/4, k)$, and by Corollary 3.2 (iii), $\operatorname{depth}(v, R)/\psi$ is a $(1 \pm \varepsilon/4)$-approximation to $\operatorname{depth}(v, \mathcal{S})$. In particular,

$$\operatorname{depth}(v, R) \leq (1 + \varepsilon/4)\psi \operatorname{depth}(v, \mathcal{S}).$$

Now, consider a point $q \in \operatorname{core}(\mathcal{S})$ that is with $\operatorname{depth}(q, \mathcal{S}) = \operatorname{depth}(\mathcal{S})$. As before, with high probability, $\operatorname{depth}(q, R) \geq \alpha_-(\varepsilon/4, k)$, and we have

$$(1 - \varepsilon/4)\psi \operatorname{depth}(\mathcal{S}) \leq \operatorname{depth}(q, R) \leq \operatorname{depth}(v, R) \leq (1 + \varepsilon/4)\psi \operatorname{depth}(v, \mathcal{S}).$$

Namely, $\operatorname{depth}(v, \mathcal{S}) \geq (1 - \varepsilon) \operatorname{depth}(\mathcal{S})$ and

$$(1 - \varepsilon/4) \operatorname{depth}(\mathcal{S}) \leq \frac{\operatorname{depth}(v, R)}{\psi} \leq (1 + \varepsilon/4) \operatorname{depth}(\mathcal{S}).$$

Computing v takes $O\big(n + T_{\text{DT}}(2n\psi(\varepsilon/4, k), O(\varepsilon^{-2} \log n))\big)$ time and succeeds with high probability, where $2n\psi(\varepsilon/4, k)$ is an upper bound on the size of R that holds with high probability. Let FindDeepPoint$(\mathcal{S}, y)$ denote this algorithm.

3.1.2. Testing the water. It remains to find a good estimate of the maximum depth of $\mathcal{S}$. Assume that we have a guess k such that $\delta \leq 4k$. We construct procedure DepthTest that outputs either "guess too big" or a range $[y, 4y]$ containing δ with high probability.

The procedure DepthTest works by computing the sample R, according to Corollary 3.2, and applying the depth thresholding to R; formally, we execute DepthThreshold$(R, \alpha_+(\varepsilon, k))$. Consider the random variable $X = \operatorname{depth}(R)$.

If $X \geq \alpha_+(\varepsilon, k)$ (i.e., DepthThreshold returned "depth exceeds threshold"), then it follows that $\delta \geq (3/2)k$ by Corollary 3.2(i). In addition, since we assumed that $\delta \leq 4k$, we have that $(3/2)k \leq \delta \leq 4k$, and DepthTest returns $[k, 4k]$ as the range containing δ.

If $X \leq \alpha_-(\varepsilon, k)$, then by Corollary 3.2(ii), with high probability, $\delta \leq k$. Namely, our guess k of the depth is too large, and DepthTest outputs "guess too high."

If $\alpha_-(\varepsilon, k) < X < \alpha_+(\varepsilon, k)$, then, by Lemma 3.1(iii), with high probability, we have that $(1 - \varepsilon)k \leq \delta \leq 2k(1 + \varepsilon)$, so DepthTest returns $[k/2, 4k]$ as the range containing δ.

The running time of DepthTest is dominated by the running time of DepthThreshold.

3.1.3. The algorithm. The procedure DepthTest can tell us if the guess k for the maximum depth is in the right range or, alternatively, that the guess is too large. We use it to perform an exponential decreasing search for the right range, as follows.

Theorem 3.3. *Let $\mathcal{S}$ be a set of n objects in $\mathbb{R}^d$ of depth δ. Suppose there exists an algorithm implementing depth thresholding for depth at most k in a set of m objects in time $T_{\text{DT}}(m,k)$. Then, given a prespecified parameter ε, $0 < \varepsilon < 1/2$, one can compute a point of depth at least $(1-\varepsilon)\delta$ in $O(n + T_{\text{DT}}(r',\delta')\log n)$ expected time, where $\delta' = \min(c_2\varepsilon^{-2}\log n, n)$ and $r' = \min(n, \delta' n/\delta)$. In fact, the running time is $O(n + T_{\text{DT}}(r',\delta'))$ if $T_{\text{DT}}(r',k)$ is $\Omega(r')$ for any k. The output is correct with high probability.*

Proof. Let $k_i = n/2^i$ for $i = 1, \ldots, \lceil \lg n \rceil$. In the ith iteration, we estimate whether $\delta \leq k_i$ using DepthTest. This requires $O(n + T_{\text{DT}}(r_i, \delta_i))$ time, where δ_i and r_i are the depth and the size of the ith random sample, respectively. If k_i is too big according to DepthTest, then we continue to the next iteration.

Otherwise, we know that $k_i \leq \delta \leq 4k_i$. We now use FindDeepPoint$(\mathcal{S}, k_i)$, and this returns the required point and its depth; see section 3.1.1. Note that as for a running time, this invocation of FindDeepPoint takes (asymptotically) the same time as the last call to DepthTest (as both procedures essentially "just" call DepthThreshold).

Since at the last call to FindDeepPoint we have $k_i \leq \delta \leq 4k_i$, it follows that the expected depth of the random sample used is $O(\varepsilon^{-2}\log n)$. Note, that the sizes of the samples used in DepthTest form an increasing geometric sequence. Thus, the last iteration uses the largest sample. Furthermore, the expected depth of the sample increases with each sample. Therefore, using the Chernoff inequality again (we omit the straightforward but tedious details), we deduce that, with high probability, $\delta_i = O(\varepsilon^{-2}\log n)$ for $i \geq 1$.

Since we use $O(\log n)$ calls to DepthTest, the claim follows. As for the improved running time, observe that in those $O(\log n)$ calls, as mentioned above, we use samples of geometrically increasing sizes. Thus the overall running time is dominated by the cost of FindDeepPoint, which results in a call to the depth thresholding algorithm. With high probability, the sample size in the last iteration is $O(c_2(n/\delta)\varepsilon^{-2}\log n)$, as claimed.

To achieve further speedup, observe that we can compute all the random samples in advance. Let $R_1 := \mathcal{S}$, and let R_i be the sample computed from R_{i-1}, by picking each element with probability $1/2$ (this is known as *gradation*). Clearly, this takes $O(n)$ time, with high probability, and we can use the appropriate random sample when needed. Thus the overall time to compute the random samples is linear. (Note that, although the samples are no longer independent, the analysis still works since we have used the union bound to bound the probability of failure.) ∎

In the above algorithm the call to FindDeepPoint can be carried out using the results of the last DepthTest call issued by the algorithm. Therefore, the procedure FindDeepPoint can be merged with DepthTest to create a simpler algorithm. We believe, however, that the current presentation is more intuitive (and we hope that the reader will agree).

3.2. Finding a point of minimum depth. For a set of objects $\mathcal{S}$ in $\mathbb{R}^d$, let $\text{depth}_{\min}(\mathcal{S})$ denote the depth of a point in $\mathbb{R}^d$ covered by the fewest objects in $\mathcal{S}$. An algorithm computes a *minimum depth thresholding* for a set X of objects if it returns a point of minimum depth at most k in $\mathcal{A}(X)$, in time $T_{\text{minDT}}(|X|,k)$, or alternatively

reports that all points in $\mathcal{A}(X)$ are of depth larger than k.

It is easy to verify that the above discussion can be adopted to this "complementary" setting.

THEOREM 3.4. *Let $\mathcal{S}$ be a set of n objects in $\mathbb{R}^d$ of minimum depth $\delta = \mathrm{depth}_{\min}(\mathcal{S})$. Suppose there exists an algorithm implementing depth thresholding for depth at most k in a set of m objects in time $T_{\mathrm{minDT}}(m,k)$. Then, given a prespecified parameter ε, $0 < \varepsilon < 1/2$, one can compute a point of depth at most $(1+\varepsilon)\delta$ in $O(n+T_{\mathrm{minDT}}(r',\delta')\log n)$ expected time, where $\delta' = \min(c_2\varepsilon^{-2}\log n, n)$ and $r' = \min(n, \delta' n/\delta)$. In fact, the running time is $O(n + T_{\mathrm{minDT}}(r',\delta'))$ if $T_{\mathrm{minDT}}(r',k)$ is $\Omega(r')$ for any k. The output is correct with high probability.*

In fact, if we are given a target depth k, there is no need to perform the binary search for the right depth, and we obtain the following theorem.

THEOREM 3.5. *Let $\mathcal{S}$ be a set of n objects in $\mathbb{R}^d$. Let $f(\cdot)$ be a function defined over $\mathbb{R}^d$. Let* `Alg` *be an algorithm that, given $X \subseteq \mathcal{S}$, and a parameter t, can report the point $x \in \mathbb{R}^d$ such that $f(x)$ is the minimum among all points contained in t or fewer regions of X (if no such point exists,* `Alg` *outputs "infeasible"). Suppose that the running time of* `Alg` *is $T_{\mathrm{minDT}}(|X|,t)$. Then, given prespecified parameters $\varepsilon > 0$ and k, one can compute a point $u \in \mathbb{R}^d$ of depth at most $(1+\varepsilon)k$ in $\mathcal{S}$, in $O(n+T_{\mathrm{minDT}}(r',\delta'))$ expected time, where $\delta' = \min(c_2\varepsilon^{-2}\log n, n)$ and $r' = \min(n, \delta' n/k)$. Furthermore, $f(u) \le f(v_k)$, where v_k is a point minimizing f among all points in $\mathbb{R}^d$ of depth k or less in $\mathcal{A}(\mathcal{S})$s. The output is correct with high probability.*

4. Applications.

4.1. Linear programming with violations. Given a linear program L with n constraints in $\mathbb{R}^d$, one can determine whether there exists a point that violates at most k constraints of L in $O(nk^{d+1})$ time [Mat95]. This problem can be solved in $O((n+k^2)\log n)$ time in two dimensions and in $O(n+k^{11/4}n^{1/4})$ time in three dimensions [Cha05]. Using these algorithms to implement depth thresholding in Theorems 3.4 and 3.5 results in the following.

THEOREM 4.1. *Let L be a linear program with n constraints in $\mathbb{R}^d$, and let f be the objective function to be minimized. Let k_{opt} be the minimum number of constraints that must be violated to make L feasible, and let v be the point minimizing $f(v)$ with k_{opt} constraints violated. Then one can output a point $u \in \mathbb{R}^d$ such that u violates at most $(1+\varepsilon)k_{\mathrm{opt}}$ constraints of L, and $f(u) \le f(v)$. The results returned are correct with high probability. The expected running time (which also holds with high probability) of this algorithm is*

- *$O(n\log(\varepsilon^{-1}\log n) + (\varepsilon^{-1}\log n)^{O(1)})$ for $d = 2, 3$ and*
- *$O(n(\varepsilon^{-2}\log n)^{d+1})$ for $d > 3$.*

Remark 4.2. For the algorithm of Theorem 4.1, if k is specified in advance, one can find a point u violating at most $(1+\varepsilon)k$ constraints of L, with $f(u) \le f(v_k)$, where v_k is the optimal solution violating at most k constraints. If L is not feasible when violating only k constraints, the algorithm may output "infeasible."

Note that this observation implies a number of new results; see the introduction of Chan [Cha05] for a list of problems that can be solved approximately using our techniques. For example, in $\mathbb{R}^d$, given n points, an integer k, $0 < k < n$, and $\varepsilon > 0$, one can find a spherical shell containing all but $(1+\varepsilon)k$ points which has a volume smaller than the minimum-volume spherical shell containing all but k points. The resulting running time is $O(n(\varepsilon^{-1}\log n)^{O(d)})$.

Remark 4.3. Observe that if k_{opt} is sufficiently large in Theorem 4.1, then the running time is in fact linear, as the samples used by the algorithm are sufficiently

small. In particular, for $k_{\mathrm{opt}} = \Omega((\varepsilon^{-2}\log n)^{d+2})$, the running time of the algorithm of Theorem 4.1 is $O(n)$.

Remark 4.4 (handling outliers). Using Theorem 3.5 and plugging it into the techniques of Har-Peled and Wang [HW04], one can solve shape fitting problems with outliers in near-linear time. For example, given a set P of n points in the plane and parameters $k, \varepsilon, \delta > 0$, one can compute an annulus A, in expected $O(n+(\varepsilon^{-1}\delta^{-1}\log n)^{O(1)})$ time. With high probability, the annulus A contains all but at most $(1+\varepsilon)k$ points of P and its width is at most $(1+\delta)w_{\mathrm{opt}}(P,k)$, where $w_{\mathrm{opt}}(P,k)$ is the minimum width of an annulus containing all but k points of P. Note that the approximation here is in terms of both the width of the annulus and the number of outliers. This result was known before only for the case when the number of outliers was large (i.e., close to n). Our methods can be applied to all the problems studied by Har-Peled and Wang [HW04]. To prevent this paper from deteriorating into a shopping list, we omit any further details.

4.2. Approximating the deepest point in a pseudodisk arrangement.

LEMMA 4.5. *Determining a point of maximum depth in an arrangement of n disks is* 3SUM*-hard.*

Proof. It is 3SUM-hard to decide, given a set of lines in the plane with integer coefficients, whether any three of the lines have a point in common [GO95]. Consider such a set L of n lines. We assume they are given by equations of the form $ax+by=c$, with $a, b, c \in \mathbb{Z}$.

One can compute in $O(n\log n)$ time an axis-parallel square Q containing all vertices of the arrangement $\mathcal{A}(L)$. Indeed, let M be the coefficient with the largest absolute value appearing in the n given lines. For two lines $ax+by=c$ and $a'x+b'y=c'$, the coordinates of their intersection point is, by Cramer's rule, a ratio of two 2×2 determinants with entries from among these six numbers. So the x coordinate of such an intersection point is in $[-2M^2, 2M^2]$. Arguing similarly for y, we conclude that the square $Q = \left[-2M^2, 2M^2\right]^2$ contains all the intersection points of the lines (and it can be computed in $O(n)$ time). Alternatively, one can compute the leftmost, rightmost, topmost, and bottommost vertices in the arrangement of the lines L in $O(n\log n)$ time [Mat91].

Furthermore, one can compute a lower bound Δ on the distance between a vertex of $\mathcal{A}(L)$ and a line of L not passing through it. Indeed, consider a line $\ell\colon ax+by=c$, where $|a|, |b|, |c| \le M$, and a point $p=(\alpha,\beta)$, which is formed by the intersection of two given lines. The distance of p from ℓ is

$$x = \frac{a\alpha + b\beta - c}{\sqrt{a^2+b^2}}.$$

Now, $a\alpha+b\beta-c$ is a rational number with denominator smaller than $4M^4$, since the denominator of α and β are smaller than $2M^2$ by the above argument, and a, b, c are integers. Thus, if the numerator of x is nonzero, its absolute value is at least $1/(4M^4)$. Therefore, if x is not zero, then

$$|x| = \frac{|a\alpha+b\beta-c|}{\sqrt{a^2+b^2}} \ge \frac{1/4M^4}{\sqrt{2M^2}} > \frac{1}{8M^5} =: \Delta.$$

Next, we replace each line $\ell \in L$ by two sufficiently large disks D_ℓ, D'_ℓ of equal radii such that $\partial D_\ell \cap \partial D'_\ell = \ell \cap \partial Q$ (so that $D_\ell \cap D'_\ell$ is symmetric with respect to ℓ) and $D_\ell \cap D'_\ell$ lies in the strip of half-width $\Delta/4$ centered at ℓ. Namely, we replace the

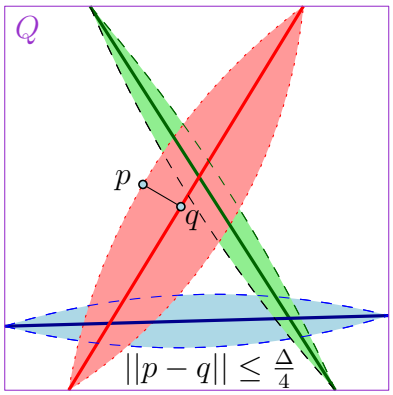

FIG. 2.

segment $\ell \cap Q$ by a lens formed by the intersection of two "large" disks. The union of the two disks that form the lens contains the square Q. By construction, three original lines intersect if and only if the three corresponding lenses share a point. See Figure 2.

Let $\mathcal{D}$ be the resulting set of $2n$ disks. Note that no point outside Q is covered by more than n of the disks. Moreover, there is a point in Q contained in at least $n+3$ disks of $\mathcal{D}$ if and only if some three lines of L share a point. The reduction takes linear time. ∎

Having argued that computing the depth exactly appears difficult, we turn to approximating it. Consider a family $\mathcal{S}$ of n *x-monotone pseudodisks*, i.e., a collection of regions, each bounded by a connected closed curve of constant algebraic complexity, such that any vertical line intersects a region in a connected interval, if at all, and such that the boundaries of any two regions cross at most twice. In the following, we assume that we can perform the geometric primitives on pseudodisks in constant time per operation. We need the following facts:

(i) The complexity of the union $U := \bigcup \mathcal{S}$ of n x-monotone pseudodisks is $O(n)$ [KLPS86].

(ii) Using a randomized incremental construction, one can compute U in $O(n \log n)$ expected time [MMP+94]. Furthermore, in the same amount of time one can preprocess U for $O(\log n)$-time point-location queries.

(iii) For a set $\mathcal{S}$ of n pseudodisks, the total complexity of faces of depth at most k in their arrangement $\mathcal{A} = \mathcal{A}(\mathcal{S})$ is $O(nk)$ [CS89, Sha03, Sha91].

(iv) Using a randomized incremental construction, one can compute all faces at depth at most k in $\mathcal{A}$ in time $O(nk + n \log n)$ [BY98]. (In fact, if we are interested in "depth thresholding" rather than construction of a subset of $\mathcal{A}$, this can be done with a standard plane sweep in $O(nk \log n)$ deterministic time [dBvKOS00].)

THEOREM 4.6. *Given a set $\mathcal{S}$ of n pseudodisks, one can compute a point q of depth at least $(1-\varepsilon)\,\mathrm{depth}(\mathcal{S})$ in $O(n\varepsilon^{-2}\log n)$ expected time. The output is correct with high probability.*

Proof. Given any set X of m pseudodisks, we can compute the deepest point in $\mathcal{A}(X)$, in $T(m,\delta) = O(m\delta + m\log m)$ time, using the algorithm of fact (iv) above, where $\delta := \mathrm{depth}(X)$. The theorem now follows from Theorem 3.3. ∎

4.3. Finding a ball with the maximum number of red points. We consider the following two problems.

Problem 4.7. Given two sets of red and blue points in $\mathbb{R}^d$, denoted by R and B, respectively, with a total of n points, find a ball that contains the maximum number of red points while not containing any blue point in its interior.

Problem 4.8. Given two sets of red and blue hyperplanes in $\mathbb{R}^d$, denoted by R and B, respectively, of total size n, find a point lying below (or on) all blue hyperplanes and below (or on) the maximum number of red hyperplanes.

The second problem appears more abstract and less natural. However, it is more general, as the former reduces to the latter, albeit in one higher dimension. Indeed, if one applies the standard "lifting transformation" [Ede87], which maps balls in $\mathbb{R}^d$ to hyperplanes in $\mathbb{R}^{d+1}$ and points in $\mathbb{R}^d$ to points on the standard paraboloid in $\mathbb{R}^{d+1}$ in such a manner that a point lies within a ball if and only if the corresponding lifted point lies below the corresponding hyperplane, an instance of Problem 4.7 is transformed into that of Problem 4.8. More precisely, we lifted the two points sets by one dimension, such that now we look for a hyperplane lying below all the blue points and that has as many red points below it as possible. Now, using point/hyperplane duality that preserves the above/below relationship between points and hyperplanes, we get Problem 4.8.

We now explain how to solve Problem 4.8 efficiently for $d = 3$ (which corresponds to solving Problem 4.7 for disks in the plane), both exactly and approximately, and later discuss higher-dimensional extensions.

THEOREM 4.9. *Given sets R and B of red and blue planes in $\mathbb{R}^3$, respectively, with a total of n planes, one can compute a point that lies below (or on) all blue planes and above (or on) the maximum number k_{opt} of red planes in time $O(n^2 \log n)$.*

Given in addition a parameter $\varepsilon > 0$, one can compute a point with the property that it lies below (or on) all blue planes and above (or on) $(1-\varepsilon)k_{\text{opt}}$ red planes, in expected time $O(n\varepsilon^{-2} \log^2 n)$.

Proof. We reduce the problem to that of depth in the pseudodisk arrangement. Let $\mathcal{B}$ be the (convex) set of points lying below (or on) all of the blue planes. Without loss of generality, we can restrict our attention to points on $\partial\mathcal{B}$. A point $p \in \partial\mathcal{B}$ lies on or above a plane $\pi \in R$ if and only if its projection p' to the xy-plane lies in the projection of $\pi \cap \mathcal{B}$, which is a convex set in the plane; we denote it by C_π.

We claim that $\{C_\pi \mid \pi \in R\}$ is a family of (convex, and therefore x-monotone) pseudodisks. Indeed, the intersection points of ∂C_π and $\partial C_{\pi'}$ are the projections of the points in $\pi \cap \pi' \cap \partial\mathcal{B}$, which is the intersection of a convex surface with a straight line.

At this point, we observe that $\mathcal{B}$ can be computed in time $O(n \log n)$ time (for example, by computing the convex hull of the dual points; see [Ede87]) and preprocessed into the Dobkin–Kirkpatrick hierarchy [DK90], so that C_π can be manipulated implicitly. More specifically, it is easily checked that the following operations can be performed on the resulting pseudodisks in logarithmic time: computation of boundary intersection points of two pseudodisks, computation of x-extreme points of a pseudodisk, computation of points of intersection of a pseudodisk with a y-vertical line. Armed with these operations, we can compute the entire arrangement and thus its depth in time $O(n^2 \log n)$ as in fact (ii) above. Similarly, Theorem 3.3 together with the implicit representation yields the desired approximation algorithm. □

We now turn to the higher-dimensional version of the problem. Recall that we aim to compute a point above a maximum number of red hyperplanes, while lying below all blue hyperplanes. Check if such a point of depth k exists can be performed

as follows: Compute the $(\leq k)$-levels of the arrangement $\mathcal{A}(R \cup B)$ [AES99, Mul91]. Traverse the 1-skeleton of the resulting structure, clipping away the portions of those levels that lie above the lower envelope of B and record the highest-depth unclipped vertex. This takes time proportional to the time spent on computing the $(\leq k)$-levels of $\mathcal{A}(R \cup B)$, which is $T(n,k) = O\big(n^{\lfloor d/2 \rfloor} k^{\lceil d/2 \rceil}\big)$ [AES99, Mul91]. Using this observation to implement depth thresholding in the algorithm of Theorem 4.6, we obtain the following theorem.

THEOREM 4.10. *Given sets R and B of red and blue hyperplanes in $\mathbb{R}^d$, for $d \geq 4$, $|R| + |B| = n$, and a parameter $\varepsilon > 0$, one can compute a point that lies below (or on) all blue hyperplanes and above (or on) at least $(1-\varepsilon)k_{\mathrm{opt}}$ hyperplanes, where k_{opt} is the maximum number achievable. The running time of the algorithm is $O(n^{\lfloor d/2 \rfloor}(\varepsilon^{-2}\log n)^{\lceil d/2 \rceil})$ with high probability.*

COROLLARY 4.11. *Given sets R and B of red and blue points in $\mathbb{R}^d$ for $d \geq 3$, $|R| + |B| = n$, and a parameter $\varepsilon > 0$, one can compute a ball $\mathcal{B}$ that contains $(1-\varepsilon)k_{\mathrm{opt}}$ red points, while avoiding all blue points, where k_{opt} is the maximum number of red points that can be covered by such a ball. The running time of the algorithm is $O(n^{\lceil d/2 \rceil}(\varepsilon^{-2}\log n)^{\lceil (d+1)/2 \rceil})$.*

Can the algorithm running time in Theorem 4.10 be further improved? We leave this as an open problem for further research.

5. From emptiness to approximate range counting. Assume that there exists an *emptiness testing* data structure that can be constructed in $T(n)$ time for a set $\mathcal{S}$ of n objects such that, given a query range τ, we can check in $Q(n)$ time whether τ intersects any of the objects in $\mathcal{S}$. Let $S(n)$ be the space required to store this data structure. In this section, we show how to build a data structure that quickly returns an approximate number of objects in $\mathcal{S}$ intersecting τ using emptiness testing as a subroutine.

In particular, let μ_τ denote the number of objects of $\mathcal{S}$ intersected by τ. Below we use $\varepsilon > 0$ to denote the required approximation quality; namely, we would like the data structure to output a number α_τ such that $(1-\varepsilon)\mu_\tau \leq \alpha_\tau \leq \mu_\tau$.

5.1. The decision procedure. Given parameters $z \in [1,n]$ and ε, with $1/2 > \varepsilon > 0$, we construct a data structure, such that, for any δ, with $1/2 > \delta \geq \varepsilon$, and a query range τ, we can decide, with high probability, whether $\mu_\tau < z$ or $\mu_\tau \geq z$. The twist that makes it efficiently solvable is that the data structure is allowed to make a mistake if $\mu_\tau \in [(1-\delta)z, (1+\delta)z]$.

The data structure. Let $\mathcal{R}_1, \ldots, \mathcal{R}_M$ be M independent random samples of $\mathcal{S}$, formed by picking every element with probability $1/z$, where $M := N(\varepsilon)$,

$$N(\varepsilon) := \left\lceil c_3 \varepsilon^{-2} \log n \right\rceil,$$

and c_3 is a sufficiently large absolute constant. Build M separate emptiness-query data structures $D_1, \ldots, D_M$ for the sets $\mathcal{R}_1, \ldots, \mathcal{R}_M$, respectively, and put $\mathcal{D} = \mathcal{D}(z,\varepsilon) := \{D_1, \ldots, D_M\}$.

Answering a query. Consider a query range τ and approximation quality δ, $1/2 > \delta \geq \varepsilon$, and let $X_i = 1$ if τ intersects any of the objects of R_i and $X_i = 0$ otherwise for $i = 1, \ldots, N = N(\delta)$; note that we use N rather than all M of the samples R_i in answering the query. The value of X_i can be determined using a single emptiness query in D_i. Compute $Y_\tau := \sum_{1 \leq i \leq N} X_i$.

For a range σ of depth k, the probability that σ does not avoid all the elements

of $\mathcal{R}_i$ is

$$\rho(k) := 1 - \left(1 - \frac{1}{z}\right)^k.$$

If a range σ has depth z, $\mathbf{E}[Y_\sigma] = N\rho(z) =: \Delta$. Our data structure returns "depth$(\tau, \mathcal{S})$ $< z$" if $Y_\tau < \Delta$, and "depth$(\tau, \mathcal{S}) \geq z$" otherwise.

Correctness. In the following, we show that with high probability the data structure indeed returns the correct answer if the depth of the query range is outside the "uncertainty" range $[(1-\delta)z, (1+\delta)z]$. For simplicity of exposition, we assume in the following that $z \geq 10$ (the case $z < 10$ follows by similar arguments). Consider a range τ of depth at most $(1-\delta)z$. The data structure returns a wrong answer if $Y_\tau > \Delta$. We will show that the probability of this event is polynomially small. The other case, where τ has depth at least $(1+\delta)z$ but $Y_\tau < \Delta$, is handled in a similar fashion.

LEMMA 5.1. *The probability* $\mathbf{Pr}[Y_\tau > \Delta \mid \text{depth}(\tau, \mathcal{S}) \leq (1-\delta)z]$ *does not exceed* n^{-c_6}*, where* $c_6 = c_6(c_3) > 0$ *depends only on* c_3 *and can be made arbitrarily large by a choice of a sufficiently large* $c_3 > 0$*.*

The proof of this lemma follows from the Chernoff inequality. It is tedious and not very insightful; thus it is delegated to Appendix A. This implies the following lemma.

LEMMA 5.2. *Given a set* $\mathcal{S}$ *of* n *objects, a parameter* $0 < \varepsilon < 1/2$*, and* $z \in [0, n]$*, one can construct a data structure* $\mathcal{D}(z)$ *which, given a range* τ *and a parameter* $1/2 > \delta \geq \varepsilon$*, returns either* LOW *or* HIGH*. If it returns* LOW*, then* $\mu_\tau \leq (1+\delta)z$*, and if it returns* HIGH*, then* $\mu_\tau \geq (1-\delta)z$*. The data structure might return either answer if* $\mu_\tau \in [(1-\delta)z, (1+\delta)z]$*.*

The data structure $\mathcal{D}$ *consists of* $M = O(\varepsilon^{-2} \log n)$ *emptiness data structures. The space and time needed are* $O(S(2n/z)\varepsilon^{-2} \log n)$ *and* $O(Q(2n/z)\delta^{-2} \log n)$*, where* $S(m)$ *and* $Q(m)$ *are the space needed for a single emptiness data structure storing* m *objects and the time needed for a single query in such a structure, respectively. All bounds hold with high probability.*

Proof. The lemma follows immediately from the above discussion. The only missing part is observing that, by the Chernoff inequality, $|\mathcal{R}_i| \leq 2n/z$, with high probability. □

The path to answering approximate counting query is now clear. We use Lemma 5.2 to perform binary search, repeatedly narrowing the range containing the answer. We stop when the size of the range is within our error tolerances. At the start of the process, this range is large, so we use large values of δ. As the range narrows, δ is reduced. (Recall that δ determines the query cost in Lemma 5.2 by controlling the number of samples whose range emptiness data structures are consulted to answer the query.)

One difficulty is that Lemma 5.2 works only for $\delta < 1/2$. We next strengthen it considerably for much larger values of δ. Intuitively, the number of "experiments" (i.e., emptiness queries) we need to perform is only $\Theta((\log n)/\log \delta)$ to answer a LOW/HIGH query and have a high probability guarantee.

LEMMA 5.3. *Given the data structure of Lemma* 5.2*,* z *a value to compare to, and* $\delta > c_5$*, one can decide for a query range* τ *if* $\mu_\tau < z/(1+\delta)$ *or* $\mu_\tau \geq z(1+\delta)$*. Here* c_5 *is a sufficiently large constant. The data structure is allowed to return any answer if* $\mu_\tau \in [z/(1+\delta), (1+\delta)z]$*. This requires* $N = \lceil c_6(\log n)/\ln \delta \rceil$ *emptiness queries, and the answer returned is correct with high probability, where* c_6 *is an appropriate absolute constant.*

The proof of this lemma is a tedious but careful application of the Chernoff inequality and is deferred to Appendix B.

Remark 5.4. Note, that there is a gap between the ranges of δ to which Lemmas 5.2 and 5.3 are applicable, namely, when δ is between $1/2$ and c_5. If we need to apply either lemma in such a situation, we use Lemma 5.2 with $\delta = 1/4$ a constant number of times.

5.2. The data structure. Lemmas 5.2 and 5.3 provide us with a tool for performing a "binary" search for the count value μ_τ of a range τ. For small values of i, we just build a separate data structure $\mathcal{D}_i = \mathcal{D}(v_i, \varepsilon_i)$ of Lemma 5.3 for depth values $v_i = i/2$ for $i = 1, \ldots, U = O(\varepsilon^{-1})$. For depth i, we use accuracy

$$\varepsilon_i = 1/8i \tag{3}$$

(i.e., this is the value of ε when using Lemma 5.2). Using these data structures, we can decide whether the query range count is at least U or smaller than U. If it is smaller than U, then we can perform a binary search to find its exact value. The result is correct with high probability.

Next, consider the values $v_j = (U/4)(1 + \varepsilon/16)^j$ for $j = U + 1, \ldots, W$, where $W := c \log_{1+\varepsilon/16} n = O(\varepsilon^{-1} \log n)$ for an appropriate choice of an absolute constant $c > 0$, so that $v_W = n$. We build a data structure $\mathcal{D}_j = \mathcal{D}(v_j, \varepsilon/16)$ for each $z = v_j$, using Lemma 5.2.

In the end of this process, we have built $\mathcal{D}_1, \ldots, \mathcal{D}_W$.

Answering a query. Given a range query τ, each data structure in our list returns LOW or HIGH. Moreover, with high probability, if we were to query all the data structures, we would get a sequence of HIGHs, followed by a sequence of LOWs. It is easy to verify that the value associated with the last data structure returning HIGH (rounded to the nearest integer) yields the required approximation. We can use binary search on $\mathcal{D}_1, \ldots, \mathcal{D}_W$ to locate this changeover value using a total of $O(\log W) = O(\log(\varepsilon^{-1} \log n))$ queries in the structures of $\mathcal{D}_1, \ldots, \mathcal{D}_W$. Namely, the overall query time is $O(Q(n)\varepsilon^{-2}(\log n) \log(\varepsilon^{-1} \log n))$.

Answering queries more efficiently. To speed up the query, we organize the search into $O(\log(n/\varepsilon))$ rounds. Treat $\mathcal{D}_1, \ldots, \mathcal{D}_W$ as a linked list L_M, where $M = \lceil \lg W \rceil = O(\log(\varepsilon^{-1} \log n))$. Next, we build a data structure (which is somewhat similar to a skip-list), where L_{i-1} is formed from L_i by picking every other element of L_i, such that the base list L_1 has, say, 4 to 8 elements.

The search now continues in a top-down fashion starting from the list L_1. At the ith stage, we maintain pointers to four consecutive data structures in L_i, such that the left two return HIGH and the right two return LOW. Thus the exact answer μ_τ must lie between the depth associated with the first and the fourth of these data structures in L_i. The corresponding portion of L_{i+1} delimited by these two data structures in L_i is a sublist of (at most) seven data structures in L_{i+1}. We now query the at most three new data structures in the list (i.e., the ones we have not queried on previous rounds) using Lemmas 5.2 and 5.3 to determine the sublist of four consecutive data structures whose range contains the query depth. The key observation, leading to a more efficient query time, is that we answer the queries, on the ith level, using an error parameter δ_i which is as large as possible, such that the error intervals of all these data structures are disjoint.

We continue in this process until we reach the bottom level. Clearly, we have the required approximation and we return the value associated with, say, the leftmost data structure in this sublist as the approximation.

We can set $\delta_1 := n^{1/4}$ and $(1+\delta_i/c)^2 = 1+\delta_{i-1}/c$, where $\delta_{i-1} > 1$ and c is some constant. Therefore, $\delta_i = O(\sqrt{\delta_{i-1}})$ as long as, say, $\delta_i > c^2$. To bound the number of emptiness queries used in this range, where the error is large, we use Lemma 5.3, implying that the number of emptiness queries used is

$$\sum_{i,\delta_i>c^2} O\left(\frac{\log n}{\log \delta_i}\right) = \sum_{i=O(1)}^{\lg\lg n} O\left(\frac{\log n}{\log\left(2^{2^{\lg\lg n - i}}\right)}\right) = \sum_{i=O(1)}^{\lg\lg n} O\left(\frac{\log n}{2^{\lg\lg n - i}}\right) = O(\log n).$$

Next, we bound the number of emptiness queries used when $\delta < 1/2$. In the jth level of this more refined search, we use $\delta'_j = 1/2^j$. Thus, the number of emptiness queries is

$$\sum_{j=2}^{\lg(1/\varepsilon)} O\left(\frac{\log n}{\delta'^2_j}\right) = \sum_{j=2}^{\lg(1/\varepsilon)} O\left(2^{2j}\log n\right) = O(\varepsilon^{-2}\log n),$$

by Lemma 5.2. The number of queries with δ between $1/2$ and c_5 is constant and therefore does not affect our asymptotic analysis; see Remark 5.4.

LEMMA 5.5. *Given a set $\mathcal{S}$ of n objects and a data structure that answers emptiness queries in $Q(n)$ time and can be built in $T(n)$ time, one can construct in $O(T(n)\varepsilon^{-3}\log^2 n)$ time a data structure that, given a range τ, outputs a number α_τ, with $(1-\varepsilon)\mu_\tau \le \alpha_\tau \le \mu_\tau$, where μ_τ is the number of objects in $\mathcal{S}$ intersecting τ. The query time is*

$$O\left(\varepsilon^{-2}Q(n)\log n\right).$$

The output of the query is correct with high probability for all queries, and the running time bounds hold with high probability.

(In the above lemma, we assumed the number of queries is polynomial.)

Space and time requirements. Assume that the emptiness data structure uses $S(n)$ space to store n elements, and it can be constructed in $T(n)$ preprocessing time.

We need a technical definition: If a data structure D can be constructed for n elements using $S(n)$ space in $T(n)$ time, such that $S(n/i) = O(S(n)/i^\lambda)$ and $T(n/i) = O(T(n)/i^\lambda)$, for all n and $1 \le i \le n$, for a constant $\lambda \ge 1$, then the data structure has *degree* λ. (The O notation might hide constants that depend on λ.)

The space requirements to implement the data structure of Lemma 5.5 for the low range $[1, O(1/\varepsilon)]$ can be reduced by using precision $\delta := \varepsilon_i = 1/8i$ (see (3)) when considering numbers in the interval $I_i = [i/4, (i+1)/4]$, which contains only a single integer. Therefore, the data structure returns the exact answer in this case. The space needed is

$$\begin{aligned} S_1 &= \sum_{i=1}^{O(1/\varepsilon)} O\left(i^2 S(n/8i)\log n\right) = \sum_{i=1}^{O(1/\varepsilon)} O\left(i^2\frac{S(n)}{i^\lambda}\log n\right) \\ &= O\left(S(n)\log n \sum_{i=1}^{O(1/\varepsilon)} \frac{1}{i^{\lambda-2}}\right) = O(H_{\lambda-2}(1/\varepsilon)S(n)\log n), \end{aligned}$$

where $H_d(k) = \sum_{i=1}^{k} 1/i^d$. For the intervals $I_{U+1}, \ldots, W$, the space is at most proportional to

$$\sum_{i=1}^{W-U} \frac{S(n/(\varepsilon^{-1}(1+\varepsilon/16)^i))}{\varepsilon^2}\log n \le \sum_{i=1}^{W-U} \frac{(\varepsilon/(1+\varepsilon/16)^i)^\lambda}{\varepsilon^2} O(S(n)\log n)$$

$$\leq \sum_{i=1}^{W-U} \frac{O(S(n)\log n)}{\varepsilon^{2-\lambda}(1+\varepsilon/16)^{i\lambda}}$$
$$\leq \frac{O(S(n)\log n)}{\varepsilon^{2-\lambda}} \sum_{i=1}^{W-U} \frac{1}{(1+\varepsilon/16)^{i\lambda}}$$
$$\leq \frac{O(S(n)\log n)}{\varepsilon^{2-\lambda}} \sum_{i=1}^{\infty} \frac{1}{(1+\varepsilon)^{i}} = \frac{O(S(n)\log n)}{\varepsilon^{3-\lambda}}.$$

Thus, the overall space required is $O((\varepsilon^{\lambda-3} + H_{\lambda-2}(1/\varepsilon))S(n)\log n)$. A similar bound holds on the preprocessing time.

The result. Putting everything together, we have the following result.

THEOREM 5.6. *We are given a set of $\mathcal{S}$ of n objects. Assume that one can construct, in $T(n)$ time, a data structure of degree λ that answers emptiness queries in $Q(n)$ time using $S(n)$ space. Then one can construct a data structure in $O((\varepsilon^{\lambda-3} + H_{\lambda-2}(1/\varepsilon))T(n)\log n)$ time, using $O((\varepsilon^{\lambda-3} + H_{\lambda-2}(1/\varepsilon))S(n)\log n)$ space, such that, given a range τ, it outputs a number α_τ, such that $(1-\varepsilon)\mu_\tau \leq \alpha_\tau \leq \mu_\tau$, and the query time is $O\big(\varepsilon^{-2}Q(n)\log n\big)$, where $H_d(k) := \sum_{i=1}^{k} 1/i^d$ and μ_τ is the exact answer to the counting query. The result returned is correct with high probability for all queries.*

(We assumed in the above theorem that the number of queries is polynomial.)

The number of emptiness queries used by Theorem 5.6 is probably tight. Indeed, just deciding if the query depth lies in the range $[z/(1+\varepsilon),\, z(1+\varepsilon)]$ requires $O(\varepsilon^{-2}\log n)$ emptiness queries by the Chernoff inequality. Since the Chernoff inequality is tight, it seems unlikely that the number of emptiness queries can be improved. Notice that this argument applies only to the case where emptiness queries are treated as "black box" operations. If this assumption is removed, certain improvements are possible [AHS07].

5.3. Applications.

5.3.1. Halfplane and halfspace range counting. Using the data structure of Dobkin and Kirkpatrick [DK85], one can answer emptiness halfspace range searching queries in logarithmic time when $d = 2, 3$. In this case, we have $S(n) = O(n)$, $T(n) = O(n\log n)$, $Q(n) = O(\log n)$, and $\lambda = 1$.

COROLLARY 5.7. *Given a set P of n points in two (resp., three) dimensions and a parameter $\varepsilon > 0$, one can construct in expected $O(n\varepsilon^{-2}\log^2 n)$ time a data structure of size $O(n\varepsilon^{-2}\log n)$, such that, given a halfplane (resp., halfspace) τ, it outputs a number α, such that $(1-\varepsilon)\,|\tau \cap P| \leq \alpha \leq |\tau \cap P|$, and the query time is $O\big(\varepsilon^{-2}\log^2 n\big)$. The result returned is correct with high probability for all queries.*

Using the standard lifting of points in $\mathbb{R}^2$ to the paraboloid in $\mathbb{R}^3$ implies a similar result for approximate range counting for disks, as a disk range query in the plane reduces to a halfspace range query in three dimensions.

COROLLARY 5.8. *Given a set of P of n points in two dimensions and a parameter ε, one can construct a data structure in $O(n\varepsilon^{-2}\log^2 n)$ expected time, using $O(n\varepsilon^{-2}\log n)$ space, such that given a disk τ, it outputs a number α, such that $(1-\varepsilon)\,|\tau \cap P| \leq \alpha \leq |\tau \cap P|$, and the query time is $O\big(\varepsilon^{-2}\log^2 n\big)$. The result returned is correct with high probability for all possible queries.*

These algorithms are faster by a polynomial factor in n than previously known exact procedures for answering the corresponding questions.

Notice that our techniques also apply to the higher dimensions settings in an obvious way. Since the resulting bounds are somewhat less appealing, we refrain from

stating them explicitly.

5.3.2. Depth queries. By computing the union of a set of n pseudodisks in the plane and preprocessing the union for point-location queries, one can perform "emptiness" queries in logarithmic time. This is done by computing the union [EHS04] and then performing a point-location query in it [dBvKOS00]. (Again, we are assuming here that we can implement the geometric primitives on the pseudodisks in constant time.) The space needed is $O(n)$, and it takes $O(n \log n)$ time to construct the data structure. Thus, we get the following result.

COROLLARY 5.9. *A set of $\mathcal{S}$ of n pseudodisks in the plane can be preprocessed in expected $O(n\varepsilon^{-2} \log^2 n)$ time, using $O(n\varepsilon^{-2} \log n)$ space, such that given a query point q one can output a number α, such that $(1-\varepsilon)\operatorname{depth}(p, \mathcal{S}) \leq \alpha \leq \operatorname{depth}(p, \mathcal{S})$, and the query time is $O\bigl(\varepsilon^{-2} \log^2 n\bigr)$. The result returned is correct with high probability for all possible queries.*

6. Conclusions. In this paper, we have shown the connection between depth thresholding, emptiness, and approximate depth computation. Note that Theorem 5.6 is better than the result in the conference version of this paper [AH05].

There are several natural problems for further research:

- Computing a square containing the largest number of red points while avoiding the blue points. Of course, the same question can be asked for other families of shapes, such as rectangles, ellipses, translates, or homothets of a fixed shape.
- Proving a lower bound on the problem of computing the ball containing the largest number of red points while avoiding the blue points. In particular, is this problem 3SUM-hard in two dimensions?

We would also like to point out that the approximate depth computation in the plane does not require "pseudodiskness." Indeed, it is sufficient to have a family of objects with small complexity of the union, such as the one described by [Efr05]. An analogous statement holds in three dimensions, though there are few known classes of objects with small union complexity there for which the computation of the union can be performed efficiently.

6.1. Permutations, emptiness, and randomized incremental construction. In a followup to this work, Haim Kaplan and Micha Sharir [KS06] showed that one can use the "permutations technique" of Cohen [Coh97] to approximate the depth of a query range. The idea is to randomly permute the set of objects $\mathcal{S}$ and compute the first index in the permutation whose corresponding object in $\mathcal{S}$ meets the query range. If the index is i, the estimate of the depth is n/i. Repeating this process a sufficient number of times implies, by the Chernoff inequality, that the estimate is within the acceptable error range. To find the lowest index i where this happens, one can perform the query inside a history graph of a randomized incremental construction algorithm for computing the union of the objects. This yields polylogarithmic improvement over the proceedings version of this paper for some specific applications (but no improvement over the current version). See [KS06] for details.

We observe that up to polylogarithmic factors, the two techniques are equivalent. Indeed, it is sufficient to approximate the first index in the permutation that contains the query range up to a factor of $1+\varepsilon$, which can be reduced to a binary search over emptiness data structures.

The other direction is somewhat more interesting. Our data structure has $O(\varepsilon^{-1} \log n)$ data structures at different resolutions, each comprised of $O(\varepsilon^{-2} \log n)$

emptiness data structures built over random samples. If we were to use instead of independent random subsets of the input in our data structures a gradation (we remind the reader that a gradation is a sequence of random samples, where the ith sample is a random sample of the higher $(i-1)$th-level sample), then the sequence of queries performed along the emptiness data structures associated with this gradation is essentially equivalent to the permutation query. Thus, in some intuitive, rough, and very informal sense, the data structure of Kaplan and Sharir performs the "same" computations as our data structure. The "sameness" here should be taken with several sizeable grains of salt, as everything looks similar from afar. It is interesting and surprising that these two different approaches to the problem are so similar once one inspects the underlying machinery.

Appendix A. Proof of Lemma 5.1.

Proof. The probability $\alpha := \mathbf{Pr}[Y_\tau > \Delta \mid \operatorname{depth}(\tau, \mathcal{S}) \leq (1-\delta)z]$ is maximized when $\operatorname{depth}(\tau, \mathcal{S}) = (1-\delta)z$. Thus

$$\alpha \leq \beta := \mathbf{Pr}[Y_\tau > \Delta \mid \operatorname{depth}(\tau, \mathcal{S}) = (1-\delta)z].$$

We argue that this probability is polynomially small.

Observe that $\mathbf{Pr}[X_i = 1] = \rho((1-\delta)z)$, where $\rho(k) := 1-(1-1/z)^k$. Therefore, we have

$$\mathbf{E}[Y_\tau] = N\rho((1-\delta)z) = N \cdot \left(1 - \left(1 - \frac{1}{z}\right)^{(1-\delta)z}\right) \geq N \cdot \left(1 - e^{-(1-\delta)}\right) \geq \frac{N}{3}, \tag{4}$$

since $1 - 1/z \leq \exp(-1/z)$. The last inequality holds since $\delta \leq 1/2$. By definition, $\Delta = N\rho(z)$; therefore,

$$\begin{aligned}\xi := \frac{\Delta}{\mathbf{E}[Y_\tau]} &= \frac{1-\left(1-\frac{1}{z}\right)^z}{1-\left(1-\frac{1}{z}\right)^{(1-\delta)z}} = 1 + \frac{\left(1-\frac{1}{z}\right)^{(1-\delta)z} - \left(1-\frac{1}{z}\right)^z}{1-\left(1-\frac{1}{z}\right)^{(1-\delta)z}} \\ &= 1 + \left(1-\frac{1}{z}\right)^{(1-\delta)z} \frac{1-\left(1-\frac{1}{z}\right)^{\delta z}}{1-\left(1-\frac{1}{z}\right)^{(1-\delta)z}}.\end{aligned}$$

Since $(1-1/z)/e \leq (1-1/z)^z \leq 1/e$ [MR95], $(1-1/z)^{(1-\delta)z} \geq ((1-1/z)/e)^{1-\delta} \geq (1-1/z)/e$. This implies that

$$\begin{aligned}\xi &\geq 1 + \frac{1}{e}\left(1-\frac{1}{z}\right)\frac{1-\exp(-\delta)}{1-\left(1-\frac{1}{z}\right)\frac{1}{e}} \\ &\geq 1 + \frac{1}{2}\cdot\frac{1}{e}\cdot\frac{1}{1/2}\cdot(1-\exp(-\delta)),\end{aligned}$$

since $(1-1/x)^x \leq 1/e$ (for $x \geq 1$) [MR95] and $z \geq 10$. Observe that $\exp(-\delta) \leq 1 - \delta + \delta^2/2$, using the Taylor expansion of $e^{-\delta}$ for $\delta > 0$. Therefore,

$$\xi \geq 1 + \frac{1}{e}\left(\delta - \delta^2/2\right) \geq 1 + \frac{\delta}{6}.$$

Deploying the Chernoff inequality, we have that if $\operatorname{depth}(\tau, \mathcal{S}) = (1-\delta)z$, then

$$\begin{aligned}\beta = \mathbf{Pr}[Y_\tau > \Delta] &\leq \mathbf{Pr}[Y_\tau > \xi\,\mathbf{E}[Y_\tau]\,] \leq \mathbf{Pr}[Y_\tau > (1+\delta/6)\,\mathbf{E}[Y_\tau]\,] \\ &\leq \exp\left(-\,\mathbf{E}[Y_\tau]\,(\delta/6)^2/4\right) \leq \exp\left(-\frac{N\delta^2}{3\cdot 36\cdot 4}\right) \leq \exp\left(-\frac{\delta^2\left\lceil c_3\delta^{-2}\log n\right\rceil}{432}\right) \leq n^{-c_3/432}\end{aligned}$$

by ((1), case (a)) and (4). ∎

Appendix B. Proof of Lemma 5.3.

Proof. Recall that $Y_\tau = \sum_{i=1}^{N} X_i$. Again, we can assume that $\operatorname{depth}(\tau, \mathcal{S}) = z/(1+\delta)$. We want to bound the probability that this "light" range would be considered to be "heavy" (i.e., $Y_r > N\rho(z)$). We have that

$$\mathbf{E}[Y_\tau] = N\left(1 - \left(1 - \frac{1}{z}\right)^{z/(1+\delta)}\right) \leq N\left(1 - \exp\left(-\frac{2z/(1+\delta)}{z}\right)\right) \leq N\frac{2}{1+\delta}, \tag{5}$$

since $1-1/z \geq \exp(-2/z)$ and $1-x \leq \exp(-x)$ for $0 \leq x \leq 1/2$. By similar reasoning,

$$\mathbf{E}[Y_\tau] \geq N\left(1 - \exp\left(-\frac{z/(1+\delta)}{z}\right)\right) \geq \frac{N}{2(1+\delta)}. \tag{6}$$

Observe that

$$\lim_{z\to\infty} \rho(z) = \lim_{n\to\infty}\left(1 - \left(1 - \frac{1}{z}\right)^{z}\right) = 1 - \frac{1}{e}.$$

Thus $\rho(z) > 1/2$ since z is sufficiently large (we remind the reader that we assumed that $z \geq 10$ for the sake of simplicity of exposition). Thus

$$\begin{aligned}\zeta = \mathbf{Pr}[Y_\tau > N\rho(z)] &\leq \mathbf{Pr}[Y_\tau > N/2] \leq \mathbf{Pr}\left[Y_\tau > \frac{1+\delta}{4}\,\mathbf{E}[Y_\tau]\right] \\ &\leq \mathbf{Pr}\left[Y_\tau > \left(1 + \frac{\delta}{5}\right)\mathbf{E}[Y_\tau]\right]\end{aligned}$$

by (5) and since δ is sufficiently large. Observe that since $\delta \geq c_5$, we have that

$$\frac{e^{\delta/5}}{(1+\delta/5)^{(1+\delta/5)/3}} \leq \frac{1}{e}.$$

Now, by the Chernoff inequality, we have

$$\zeta < \left(\frac{e^{\delta/5}}{(1+\delta/5)^{1+\delta/5}}\right)^{\mathbf{E}[Y_\tau]} \leq \left((1+\delta/5)^{-(1+\delta/5)/2}\right)^{\mathbf{E}[Y_\tau]},$$

since $\delta \geq c_5$. Observe that

$$\frac{(1+\delta/5)\,\mathbf{E}[Y_\tau]}{2} \geq \frac{(1+\delta/5)}{4(1+\delta)}N \geq \frac{1}{20}N$$

by (6). As $\ln(1+\delta/5) \geq (\ln\delta)/2$, we have

$$\zeta \leq (1+\delta/5)^{-N/20} \leq \exp\left(-\frac{N}{40}\ln\delta\right) < \frac{1}{n^{\Omega(1)}}$$

for c_6 sufficiently large, since $N = \lceil c_6(\log n)/\ln\delta \rceil$.

The other direction is slightly more challenging. Assume that $\operatorname{depth}(\tau, \mathcal{S}) = z(1+\delta)$, and let $Z_\tau = N - Y_\tau$. Observe that if $z/(1+\delta) \leq 1$, then any answer returned by the algorithm would be valid in this case (here we are trying to bound

the case that a heavy range is reported as being "light"). Therefore, we assume that $z \geq 1+\delta$. Observe that

$$\mathbf{E}[Z_\tau] = N\left(1-\frac{1}{z}\right)^{z(1+\delta)} \leq N\exp(-(1+\delta)).$$

(Specifically, $\mathbf{E}[Z_\tau] \leq N/10^6$ since $\delta \geq c_5$, and thus $\mathbf{E}[Y_\tau]$ is very close to N in this case.) Now, since z is large enough, we have that $\rho(z) < 1 - 1/10$ as $\rho(z) \approx 1 - 1/e$. Therefore,

$$\begin{aligned}\mathbf{Pr}\Big[Y_\tau < N\rho(z)\Big] &\leq \mathbf{Pr}\left[Y_\tau < \frac{9}{10}N\right] = \mathbf{Pr}\left[N - Z_\tau < \frac{9}{10}N\right] = \mathbf{Pr}\left[Z_\tau > \frac{N}{10}\right] \\ &\leq \mathbf{Pr}\left[Z_\tau > \frac{\mathbf{E}[Z_\tau]}{10\exp(-(1+\delta))}\right] \\ &= \mathbf{Pr}\Big[Z_\tau > (1+\xi)\,\mathbf{E}[Z_\tau]\Big],\end{aligned}$$

where $\xi := (1/10)\exp(1+\delta) - 1 > 10^8$. The variable Z_τ can be interpreted as the sum of N independent 0/1 variables (i.e., it is the complement of the variables forming Y_τ). By applying the Chernoff inequality to Z_τ, we obtain

$$\varrho := \mathbf{Pr}[Y_\tau < N\rho(z)] \leq \mathbf{Pr}\Big[Z_\tau > (1+\xi)\,\mathbf{E}[Z_\tau]\Big] \leq \left(\frac{e^\xi}{(1+\xi)^{(1+\xi)}}\right)^{\mathbf{E}[Z_\tau]}.$$

Now, we have $(1-1/z)^z \geq (1/e)(1-1/z) \geq \exp(-1-2/z) \geq \exp(-(1+2/\delta))$, since $z \geq 1+\delta \geq \delta$. As such,

$$\begin{aligned}\mathbf{E}[Z_\tau] = N\left(1-\frac{1}{z}\right)^{z(1+\delta)} &\geq N\exp(-(1+\delta)(1+2/\delta)) \\ &\geq \frac{N}{\exp(1+\delta+2/\delta+2)} \geq \frac{N}{c_7\xi},\end{aligned}$$

where $c_7 = 20e^3$. Thus, as $\ln(1+\xi) = \ln(1/10) + 1 + \delta \geq \ln\delta$, we have

$$\begin{aligned}\varrho &\leq \Big((1+\xi)^{-(1+\xi)/2}\Big)^{\mathbf{E}[Z_\tau]} \leq (1+\xi)^{-(1+\xi)N/c_7\xi} \leq \exp\left(-\frac{N\ln(1+\xi)}{c_7}\right) \\ &\leq \exp\left(-\frac{N}{c_7}\ln\delta\right) < \frac{1}{n^{\Omega(1)}},\end{aligned}$$

since $N = \lceil c_6(\log n)/\ln\delta \rceil$ and c_6 is sufficiently large. □

Acknowledgments. The authors would like to thank Jeff Erickson and Edgar Ramos for useful discussion on the problems studied in this paper. Haim Kaplan and Micha Sharir have pointed out that the space requirement of depth queries, as described in an earlier version of this paper [AH05] can be improved. We then also improved the query time in Theorem 5.6.

The authors would also like to thank the anonymous referees for their detailed and insightful comments that lead to what we hope are significant improvements in the presentation of this paper.

EFFICIENT ALGORITHMS FOR DESCRIPTION PROBLEMS OVER FINITE TOTALLY ORDERED DOMAINS*

ÁNGEL J. GIL†, MIKI HERMANN‡, GERNOT SALZER§, AND BRUNO ZANUTTINI¶

Dedicated to the memory of Peter Ružička (1947–2003)

Abstract. Given a finite set of vectors over a finite totally ordered domain, we study the problem of computing a constraint in conjunctive normal form such that the set of solutions for the produced constraint is identical to the original set. We develop an efficient polynomial-time algorithm for the general case, followed by specific polynomial-time algorithms producing Horn, dual Horn, and bijunctive formulas for sets of vectors closed under the operations of conjunction, disjunction, and median, respectively. Our results generalize the work of Dechter and Pearl on relational data, as well as the papers by Hébrard and Zanuttini. They complement the results of Hähnle et al. on multivalued logics and Jeavons et al. on the algebraic approach to constraints.

Key words. finite domain, description problems, algorithms, complexity

1. Introduction and summary of results.

Constraint satisfaction problems constitute today a well-studied topic on the frontier of complexity, logic, combinatorics, and artificial intelligence. It is indeed well known that this framework allows us to encode many natural problems or knowledge bases. In principle, an instance of a constraint satisfaction problem is a finite set of variable vectors associated with an allowed set of values. A *model* is an assignment of values to all variables that satisfies every constraint. When a constraint satisfaction problem encodes a decision problem, the models represent its *solutions*. When it encodes some knowledge, the models represent possible combinations that the variables can assume in the described universe.

Constraints can be represented by means of a set of variable vectors associated with an allowed set of values. This representation is not always well suited; therefore, other representations have been introduced. The essence of the most studied alternative is the notion of a *relation*, making it easy to apply it within the database or knowledge base framework. We focus on the representation by formulas in conjunctive normal form with the literals taking the form $(x \leq d)$ and $(x \geq d)$, where x is a variable and d is an element from the given finite domain D, totally ordered by the relation $\leq$ (see Hähnle et al. [5, 6, 16]). We study in this paper the constraint *description* problem, i.e., the problem of converting a set of vectors M to a formula φ

in conjunctive normal form, such that its satisfying assignments $\mathrm{Sol}(\varphi)$ equals the original set M. We consider this problem first in its general setting without any restrictions imposed on the initial set of vectors. We continue by imposing several properties on the initial set, like the closure under the minimum, maximum, and median operations. We subsequently discover that these closure properties induce the description by Horn, dual Horn, and bijunctive constraints, respectively. Moreover, we give an elegant and unified solution to the *structure identification* problem of these three classes, as it was defined by Dechter and Pearl [11]. Given a set of vectors, this problem asks whether it can be represented by a formula of a special type, computing such a formula if the answer is affirmative.

The motivations to study description and identification problems are numerous. From the artificial intelligence point of view, description problems formalize the notion of exact acquisition of knowledge from examples. This means that they formalize situations where a system is given access to a set of examples and it is asked to compute a formula describing it exactly. Moreover, this representation takes usually less space than the original set of examples; thus it can be stored more easily in a knowledge base.

Satisfiability poses a keystone problem in artificial intelligence, automated deduction, databases, and verification. It is well known that the satisfiability problem for arbitrary constraints is an NP-complete problem. Therefore, it is important to look for restricted classes of constraints that admit polynomial algorithms deciding satisfiability. Horn, dual Horn, bijunctive, and affine constraints, in the Boolean case, constitute exactly these tractable classes, as was proved by Schaefer [24]. Thus the description problem for these four classes can be seen as storing specific knowledge into a knowledge base while we are required to respect its format. This problem is also known as *structure identification*, studied by Dechter with Pearl [11] and by Hébrard with Zanuttini [17, 25]. Another motivation for studying description problems comes from combinatorics. Indeed, since finding a solution for an instance of a constraint satisfaction problem is difficult in general but tractable in the four aforementioned cases, it is important to be able to recognize constraints belonging to these tractable cases.

The study of Boolean constraint satisfaction problems, especially their complexity questions, was started by Schaefer in [24], although he did not yet consider constraints explicitly. During the last ten years, constraints gained considerable interest in theoretical computer science. An excellent complexity classification of existing Boolean constraint satisfaction problems can be found in the monograph [10]. Jeavons et al. [9, 19, 20] started to study constraint satisfaction problems from an algebraic viewpoint. Feder, Kolaitis, and Vardi [12, 22] posed a general framework for the study of constraint satisfaction problems. A part of the research in constraint satisfaction problems requires the existence of efficient description and identification methods for special constraint classes.

Recently, there has been much progress on constraint satisfaction problems over domains with larger cardinality. Hell and Nešetřil [18] studied constraint satisfaction problems by means of graph homomorphisms. Bulatov [7] made a significant breakthrough with a generalization of Schaefer's result to three-element domains. He also proved a dichotomy theorem for conservative constraints over arbitrary domains [8]. On the other hand, Hähnle et al. [5, 6, 16] studied the complexity of satisfiability problems for many-valued logics that present yet another viewpoint of constraint satisfaction problems. We realized reading the previous articles on many-valued logics that in the presence of a total order the satisfiability problems for the Horn, dual

Horn, and bijunctive many-valued formulas of signed logic are decidable in polynomial time. We also noticed that Jeavons and Cooper [21] studied some aspects of tractable constraints on finite ordered domains from an algebraic standpoint. This led us to the idea to look more carefully at constraint description problems over finite totally ordered domains, developing a new formalism for constraints based on an already known concept of inequalities.

The purpose of our paper is manifold. We want to generalize the work of Dechter and Pearl [11], based on the more efficient algorithms for Boolean description problems by Hébrard and Zanuttini [17, 25]. We also want to complement the work of Hähnle et al. on many-valued logics. Finally, we want to provide a characterization by closure properties of polynomial-time decidable subcases of constraint satisfaction problems over finite totally ordered domains, which are straightforward generalizations of the known polynomial-time decidable Boolean cases.

2. Preliminaries. Let $D = \{0, \dots, n-1\}$ be a finite, totally ordered domain of cardinality n, and let V be a set of variables. For a variable $x \in V$ and a value $d \in D$, the inequalities $x \geq d$ and $x \leq d$ are called positive and negative *literal*, respectively. The set of *formulas* over D and V is inductively defined as follows:

- the logical constants *false* and *true* are formulas;
- literals are formulas;
- if φ and ψ are formulas, then the expressions $(\varphi \wedge \psi)$ and $(\varphi \vee \psi)$ are formulas.

We write $\varphi(x_1, \dots, x_\ell)$ to indicate that formula φ contains exactly the variables $x_1, \dots, x_\ell$. For convenience, we use the following shorthand notation:

- $x > d$ means $x \geq d+1$ for $d \in \{0, \dots, n-2\}$, and *false* otherwise;
- $x < d$ means $x \leq d-1$ for $d \in \{1, \dots, n-1\}$, and *false* otherwise;
- $x = d$ means $x \geq d \wedge x \leq d$;
- $\neg$*false* and $\neg$*true* mean *true* and *false*, respectively;
- $\neg(x \geq d)$, $\neg(x \leq d)$, $\neg(x > d)$, and $\neg(x < d)$ mean $x < d$, $x > d$, $x \leq d$, and $x \geq d$, respectively;
- $\neg(x = d)$ and $x \neq d$ both mean $x < d \vee x > d$;
- $\neg(\varphi \wedge \psi)$ and $\neg(\varphi \vee \psi)$ mean $\neg\varphi \vee \neg\psi$ and $\neg\varphi \wedge \neg\psi$, respectively.

Note that $x = d$ and $x \neq d$ asymptotically require the same space as their alternative notation, i.e., $O(\log n)$. Indeed, since d is bounded by n, its binary coding has length $O(\log n)$.

A *clause* is a disjunction of literals. It is a *Horn* clause if it contains at most one positive literal, *dual Horn* if it contains at most one negative literal, and *bijunctive* if it contains at most two literals. A formula is in *conjunctive normal form* (CNF) if it is a conjunction of clauses. It is a Horn, a dual Horn, or a bijunctive formula if it is a conjunction of Horn, dual Horn, or bijunctive clauses, respectively. Since the considered formulas in what follows are all in CNF, we will use the expression "formula" with a slight abuse of terminology also for CNF formulas, without explicitly specifying it.

Note that contrary to the Boolean case, a clause in our formalism can contain the same variable twice, in both a negative and a positive literal, without being reducible. However, such a clause can be assumed to contain not more than twice the same variable, since $x \geq d \vee x \geq d'$ can be reduced to $x \geq \min(d, d')$ and, dually, $x \leq d \vee x \leq d'$ can be reduced to $x \leq \max(d, d')$.

Example 2.1. Let $D = \{0, 1, 2, 3, 4\}$ be the domain for our running example. The expressions $x \leq 2$ and $y \geq 4$ are a negative and a positive literal, respectively. Instead of $x \leq 2$ and $y \geq 4$, we can also write $x < 3$ and $y > 3$, respectively. The disjunction

of literals $(x \le 2 \vee x \ge 4 \vee y \le 4)$ is a Horn clause, $(x \le 2 \vee x \ge 4 \vee y \ge 3)$ is a dual Horn clause, and $(x \le 2 \vee x \ge 4)$ is a bijunctive clause. The formula

$$\varphi(x,y) = (x \le 2 \vee x \ge 4 \vee y \le 4) \wedge (x \le 2 \vee x \ge 4 \vee y \ge 4) \wedge (x \le 2 \vee x \ge 3)$$

is in CNF. □

An *assignment* for a formula $\varphi(x_1, \ldots, x_\ell)$ is a mapping $m\colon \{x_1, \ldots, x_\ell\} \to D$ assigning a domain element $m(x)$ to each variable x. The *satisfaction relation* $m \models \varphi$ is inductively defined as follows:

- $m \models \mathit{true}$ and $m \not\models \mathit{false}$;
- $m \models x \le d$ if $m(x) \le d$, and $m \models x \ge d$ if $m(x) \ge d$;
- $m \models \varphi \wedge \psi$ if $m \models \varphi$ and $m \models \psi$;
- $m \models \varphi \vee \psi$ if $m \models \varphi$ or $m \models \psi$.

The set of all assignments satisfying φ is denoted by $\mathrm{Sol}(\varphi)$, also called *models* of φ. If we arrange the variables in some arbitrary but fixed order, say, as a vector $x = (x_1, \ldots, x_\ell)$, then the models can be identified with the vectors in D^ℓ. The jth component of a vector m, denoted by $m[j]$, gives the value of the jth variable, i.e., $m(x_j) = m[j]$. The operations of conjunction, disjunction, addition, and median on vectors $m, m', m'' \in D^\ell$ are defined as follows:

$$\begin{aligned} m \wedge m' &= (\min(m[1], m'[1]), \ldots, \min(m[\ell], m'[\ell])), \\ m \vee m' &= (\max(m[1], m'[1]), \ldots, \max(m[\ell], m'[\ell])), \\ \mathrm{med}(m, m', m'') &= (\mathrm{med}(m[1], m'[1], m''[1]), \ldots, \mathrm{med}(m[\ell], m'[\ell], m''[\ell])). \end{aligned}$$

The ternary *median* operator is defined as follows: for each choice of three values $a, b, c \in D$ such that $a \le b \le c$, we have $\mathrm{med}(a,b,c) = b$. Moreover, median is a permutative operator; i.e., the identity $\mathrm{med}(a,b,c) = \mathrm{med}(\pi(a), \pi(b), \pi(c))$ holds for every permutation π on all domain elements $a, b, c \in D$. Note that the median can also be defined by $\mathrm{med}(a,b,c) = \min(\max(a,b), \max(b,c), \max(c,a))$ as well as by $\mathrm{med}(a,b,c) = \max(\min(a,b), \min(b,c), \min(c,a))$, which implies the identities

$$\begin{aligned} \mathrm{med}(m_1, m_2, m_3) &= (m_1 \vee m_2) \wedge (m_2 \vee m_3) \wedge (m_3 \vee m_1) \\ &= (m_1 \wedge m_2) \vee (m_2 \wedge m_3) \vee (m_3 \wedge m_1) \end{aligned}$$

for all vectors $m_1, m_2, m_3 \in D^\ell$.

Example 2.2. Consider the set of vectors $M = \{010, 013, 220, 440, 444\}$. It is closed under conjunction, since for each pair of vectors $m, m' \in M$ we have $m \wedge m' \in M$. It is *not* closed under disjunction, since $013 \vee 220 = 223 \notin M$. It is also *not* closed under median, since $\mathrm{med}(013, 220, 444) = 223 \notin M$. □

3. Formulas in conjunctive normal form. We investigate first the description problem for arbitrary sets of vectors.

Problem: DESCRIPTION.
Input: A finite set of vectors $M \subseteq D^\ell$ over a finite totally ordered domain D.
Output: A formula $\varphi(x_1, \ldots, x_\ell)$ over D in CNF such that $\mathrm{Sol}(\varphi) = M$.

The naive approach to this problem is to compute first the complement set $\bar{M} = D^\ell \setminus M$, followed by the construction of a clause $c(\bar{m})$ for each vector $\bar{m} \in \bar{M}$ missing from M such that $\bar{m}$ is the unique vector falsifying $c(\bar{m})$. The formula φ is then the conjunction of the clauses $c(\bar{m})$ for all missing vectors $\bar{m} \in \bar{M}$. However, this algorithm is essentially exponential, since the complement set $\bar{M}$ can be exponentially bigger than the original set of vectors M.

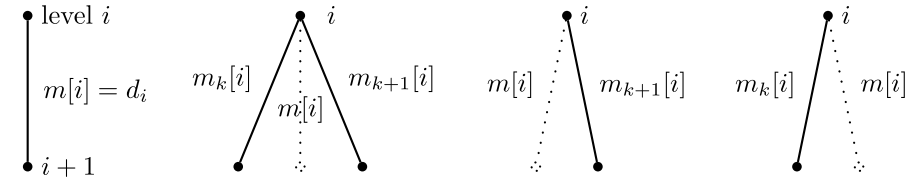
Example 3.1. Consider again the set of vectors $M = \{010, 013, 220, 440, 444\}$ as in Example 2.2. The complement set $\bar{M}$ contains $5^3 - 5 = 120$ vectors, where the lexicographically first ones are $000, 001, \ldots, 004, 011, 012$ and the last ones are $434, 441, 442, 443$. For example, the clause $c(001)$ is $(x_1 \neq 0 \vee x_2 \neq 0 \vee x_3 \neq 1)$, equivalent to $(x_1 \geq 1 \vee x_2 \geq 1 \vee x_3 \leq 0 \vee x_3 \geq 2)$. The only assignment to the variables x_1, x_2, x_3 which does not satisfy the clause $c(001)$ is the vector 001. Similarly, the clause $c(223)$ is $(x_1 \leq 1 \vee x_1 \geq 3 \vee x_2 \leq 1 \vee x_2 \geq 3 \vee x_3 \leq 2 \vee x_3 \geq 4)$. The formula φ describing M and built in this manner contains exactly 120 clauses. ∎

We present a new algorithm running in polynomial time and producing a CNF formula of polynomial length with respect to the cardinality of the set M, the dimension of vectors ℓ, and the size $O(\log |D|)$ of the domain elements in binary notation.

In what follows we assume without loss of generality the set of vectors M to be nonempty, which simplifies the presentation. Note, however, that the empty set $\emptyset$ is easily recognized and described by the formula $(x_1 \leq 0) \wedge (x_1 \geq 1)$, which is logically equivalent to *false*.

To construct the formula φ we proceed in the following way. We arrange the set M into an ordered n-ary semantic tree T_M [14], with branches corresponding to the vectors in M. In case M contains all possible vectors, i.e., $M = D^\ell$, T_M is a complete tree of branching factor $|D|$ and depth ℓ. Otherwise, some branches are missing, leading to gaps in the tree. We characterize these gaps by conjunctions of literals. Their disjunction yields a complete description of all vectors that are *missing* from M. Finally, by negation and de Morgan's laws we obtain φ.

Let T_M be an ordered tree with edges labeled by domain elements such that each path from the root to a leaf corresponds to a vector in M. The tree T_M contains a path labeled $d_1.\cdots.d_i$ from the root to some node if there is a vector $m \in M$ such that $m[j] = d_j$ holds for every $j = 1, \ldots, i$. The level of a node is its distance to the root plus 1; i.e., the root is at level 1 and a node reachable via $d_1.\cdots.d_i$ is at level $i + 1$ (Figure 3.1(a)). Note that all leaves are at level $\ell + 1$. If the edges between a node and its children are sorted in ascending order according to their labels, then traversing the leaves from left to right enumerates the vectors of M in lexicographic order, say, $m_1, \ldots, m_{|M|}$. A vector m is lexicographically smaller than a vector m' if there is a level i such that $m[i] < m'[i]$ holds, and for all $j < i$ we have $m[j] = m'[j]$.



(a) Level i (b) Missing between (c) ... left (d) ... right

FIG. 3.1. *Tree representation of vectors.*

Example 3.2. Let $M = \{m_1 = 010, m_2 = 013, m_3 = 220, m_4 = 440, m_5 = 444\}$ be the set of vectors over the domain $D = \{0, 1, 2, 3, 4\}$ for which we want to construct a formula φ in CNF satisfying the condition $\mathrm{Sol}(\varphi) = M$. The tree T_M is depicted in Figure 3.2 in solid lines. ∎

Suppose that m_k and m_{k+1} are immediate neighbors in the lexicographic enumeration of M, and let m be a vector lexicographically in between, thus missing from M. There are three possibilities for the path corresponding to m. It may leave the tree

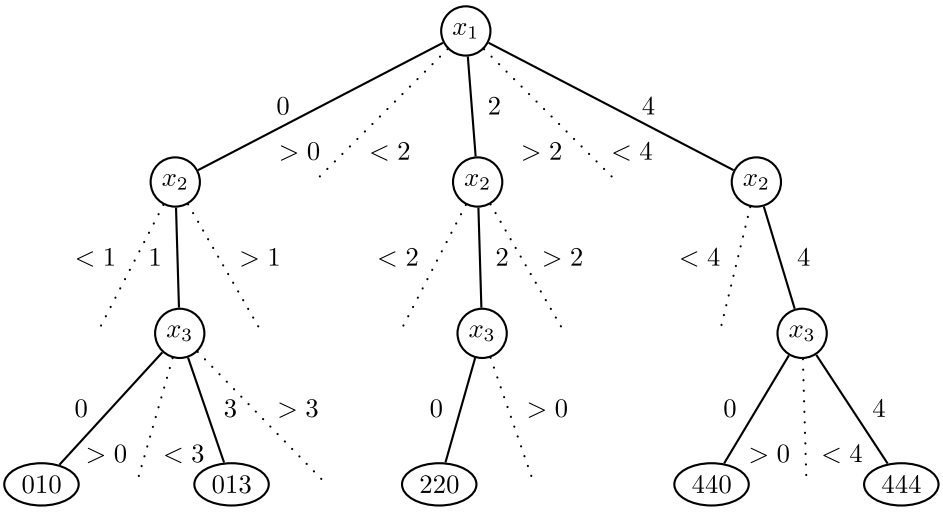


FIG. 3.2. *Tree T_M and the missing parts for the set $M = \{010, 013, 220, 440, 444\}$.*

at the fork *between* m_k and m_{k+1} (Figure 3.1(b)), or at the fork to the *left* of m_{k+1} (Figure 3.1(c)), or at the fork to the *right* of m_k (Figure 3.1(d)). Let i be the least position in which the consecutive vectors m_k and m_{k+1} differ. In other words, we have $m_k[i] \neq m_{k+1}[i]$ and $m_k[j] = m_{k+1}[j]$ for all $j < i$. The set of missing vectors can be characterized by the conjunctions middle(k, i), left$(k + 1, i)$, and right(k, i), defined as follows:

$$\begin{aligned}
\text{middle}(k,i) &= \bigwedge_{j<i}(x_j = m_k[j]) \quad \wedge \quad (x_i > m_k[i]) \ \wedge \ (x_i < m_{k+1}[i]),\\
\text{left}(k+1,i) &= \bigwedge_{j<i}(x_j = m_{k+1}[j]) \quad \wedge \quad (x_i < m_{k+1}[i]),\\
\text{right}(k,i) &= \bigwedge_{j<i}(x_j = m_k[j]) \quad \wedge \quad (x_i > m_k[i]).
\end{aligned}$$

The situation depicted in Figure 3.1 is a snapshot at level i of the tree T_M.

Example 3.3. The missing parts in the tree T_M, displayed in Figure 3.2 by dotted lines, are described by the following conjunctions. First are the parts missing between two vectors,

$$\begin{aligned}
\text{middle}(1,3) &= (x_1 = 0) \wedge (x_2 = 1) \wedge (x_3 > 0) \wedge (x_3 < 3),\\
\text{middle}(2,1) &= (x_1 > 0) \wedge (x_1 < 2),\\
\text{middle}(3,1) &= (x_1 > 2) \wedge (x_1 < 4),\\
\text{middle}(4,3) &= (x_1 = 4) \wedge (x_2 = 4) \wedge (x_3 > 0) \wedge (x_3 < 4),
\end{aligned}$$

followed by the parts missing to the left,

$$\begin{aligned}
\text{left}(1,2) &= (x_1 = 0) \wedge (x_2 < 1),\\
\text{left}(3,2) &= (x_1 = 2) \wedge (x_2 < 2),\\
\text{left}(4,2) &= (x_1 = 4) \wedge (x_2 < 4),
\end{aligned}$$

and finally the parts missing to the right,

$$\begin{aligned}
\mathrm{right}(2,2) &= (x_1 = 0) \wedge (x_2 > 1),\\
\mathrm{right}(2,3) &= (x_1 = 0) \wedge (x_2 = 1) \wedge (x_3 > 3),\\
\mathrm{right}(3,2) &= (x_1 = 2) \wedge (x_2 > 2),\\
\mathrm{right}(3,3) &= (x_1 = 2) \wedge (x_2 = 2) \wedge (x_3 > 0).
\end{aligned}$$

There are no other missing parts in the tree T_M. □

To describe *all* vectors missing from M we form the disjunction of the above conjunctions for appropriate values of k and i. We need to determine the levels at which neighboring models fork by means of the following function:

$$\mathrm{fork}(k) \quad = \quad \begin{cases} 0 & \text{for } k = 0,\\ \min\{i \mid m_k[i] \neq m_{k+1}[i]\} & \text{for } k = 1, \ldots, |M| - 1,\\ 0 & \text{for } k = |M|. \end{cases}$$

The values $\mathrm{fork}(0)$ and $\mathrm{fork}(|M|)$ correspond to imaginary models m_0 and $m_{|M|+1}$ forking at a level above the root. They allow us to write the conditions below in a concise way at the left and right borders of the tree. The three situations in Figure 3.1 can now be specified by the following conditions:

$$\begin{array}{lcll}
i = \mathrm{fork}(k) & \wedge & m_k[i] + 1 < m_{k+1}[i] & \text{(edges missing in between)},\\
\mathrm{fork}(k) < i & \wedge & m_{k+1}[i] > 0 & (\ldots \text{ to the left}),\\
\mathrm{fork}(k) < i & \wedge & m_k[i] < |D| - 1 & (\ldots \text{ to the right}).
\end{array}$$

The second condition in each line ensures that there is at least one missing edge. It avoids the conjunctions $\mathrm{middle}(k,i)$, $\mathrm{left}(k+1,i)$, and $\mathrm{right}(k,i)$ to evaluate to false.

Example 3.4. The function fork for $M = \{m_1 = 010,\ m_2 = 013,\ m_3 = 220,\ m_4 = 440,\ m_5 = 444\}$ is given by the following table:

	0	1	2	3	4	5
fork	0	3	1	1	3	0

The aforementioned fork conditions for missing edges are satisfied in the following cases.

(i) For the first condition, implying edges missing in between, we have four cases where it is satisfied:

$$\begin{array}{lcl}
3 = \mathrm{fork}(1) & \wedge & 1 = m_1[3] + 1 < m_2[3] = 3,\\
1 = \mathrm{fork}(2) & \wedge & 1 = m_2[1] + 1 < m_3[1] = 2,\\
1 = \mathrm{fork}(3) & \wedge & 3 = m_3[1] + 1 < m_4[1] = 4,\\
3 = \mathrm{fork}(4) & \wedge & 1 = m_4[3] + 1 < m_5[3] = 4.
\end{array}$$

(ii) For the second condition, implying edges missing to the left, we have three cases where it is satisfied:

$$\begin{array}{lcl}
\mathrm{fork}(0) < 2 & \wedge & 1 = m_1[2] > 0,\\
\mathrm{fork}(2) < 2 & \wedge & 2 = m_3[2] > 0,\\
\mathrm{fork}(3) < 2 & \wedge & 4 = m_4[2] > 0.
\end{array}$$

(iii) Finally, for the third condition, implying edges missing to the right, we have also three cases where it is satisfied:

$$\begin{aligned}
&\mathrm{fork}(2) < 2 \quad \wedge \quad 1 = m_2[2] < 4,\\
&\mathrm{fork}(2) < 3 \quad \wedge \quad 3 = m_2[3] < 4,\\
&\mathrm{fork}(3) < 2 \quad \wedge \quad 2 = m_3[2] < 4,\\
&\mathrm{fork}(3) < 3 \quad \wedge \quad 0 = m_3[3] < 4.
\end{aligned}$$

It can be easily seen that these conditions trigger the middle, left, and right formulas shown in Example 3.3. □

The disjunction of terms $\mathrm{middle}(k,i)$, $\mathrm{left}(k+1,i)$, and $\mathrm{right}(k,i)$ that satisfy the first, second, and third condition, respectively, for all models and all levels represents a disjunctive formula satisfied by the models *missing* from M. After applying negation and de Morgan's laws, we arrive at the required formula in CNF,

$$\begin{aligned}
\varphi(M) \quad = \quad & \bigwedge\{\, \neg\,\mathrm{middle}(k,i) \mid 0 < k < |M|,\ i = \mathrm{fork}(k),\ m_k[i]+1 < m_{k+1}[i] \,\}\\
\wedge \quad & \bigwedge\{\, \neg\,\mathrm{left}(k+1,i) \mid 0 \le k < |M|,\ \mathrm{fork}(k) < i \le \ell,\ m_{k+1}[i] > 0 \,\}\\
\wedge \quad & \bigwedge\{\, \neg\,\mathrm{right}(k,i) \quad \mid 0 < k \le |M|,\ \mathrm{fork}(k) < i \le \ell,\ m_k[i] < |D|-1 \,\},
\end{aligned}$$

where the condition $\mathrm{Sol}(\varphi) = M$ holds. Note that we use the negation symbol not as an operator on the syntax level but as a metanotation expressing that the formula following the negation sign has to be replaced by its dual. Note also that the conjunct $\mathrm{left}(k+1,i)$ is defined and used with the shifted parameter $k+1$ since it characterizes a gap lexicographically before the vector m_{k+1}.

Example 3.5. The set of vectors $M = \{010, 013, 220, 440, 444\}$ is described by the following CNF formula:

$$\begin{aligned}
\varphi(M) \ = \ & \neg\,\mathrm{middle}(1,3) \ \wedge \ \neg\,\mathrm{middle}(2,1) \ \wedge \ \neg\,\mathrm{middle}(3,1) \ \wedge \ \mathrm{middle}(4,3)\\
& \wedge \ \neg\,\mathrm{left}(1,2) \ \wedge \ \neg\,\mathrm{left}(3,2) \ \wedge \ \neg\,\mathrm{left}(4,2)\\
& \wedge \ \neg\,\mathrm{right}(2,2) \ \wedge \ \neg\,\mathrm{right}(2,3) \ \wedge \ \neg\,\mathrm{right}(3,2) \ \wedge \ \neg\,\mathrm{right}(3,3).
\end{aligned}$$

After substitution and application of de Morgan laws, this amounts to

$$\begin{aligned}
\varphi(M) \ = \ & (x_1 \neq 0 \vee x_2 \neq 1 \vee x_3 \le 0 \vee x_3 \ge 3) \ \wedge \ (x_1 \le 0 \vee x_1 \ge 2)\\
& \wedge \ (x_1 \le 2 \vee x_1 \ge 4) \ \wedge \ (x_1 \neq 4 \vee x_2 \neq 4 \vee x_3 \le 0 \vee x_3 \ge 4)\\
& \wedge \ (x_1 \neq 0 \vee x_2 \ge 1) \ \wedge \ (x_1 \neq 2 \vee x_2 \ge 2) \ \wedge \ (x_1 \neq 4 \vee x_2 \ge 4)\\
& \wedge \ (x_1 \neq 0 \vee x_2 \le 1) \ \wedge \ (x_1 \neq 0 \vee x_2 \neq 1 \vee x_3 \le 3) \ \wedge \ (x_1 \neq 2 \vee x_2 \le 2)\\
& \wedge \ (x_1 \neq 2 \vee x_2 \neq 2 \vee x_3 \le 0).
\end{aligned}$$

Replacing the shorthand notation $\neq$ by proper literals gives the following final formula:

$$\begin{aligned}
\varphi(M) \ = \ & (x_1 \ge 1 \vee x_2 \le 0 \vee x_2 \ge 2 \vee x_3 \le 0 \vee x_3 \ge 3) \ \wedge \ (x_1 \le 0 \vee x_1 \ge 2)\\
& \wedge \ (x_1 \le 2 \vee x_1 \ge 4) \ \wedge \ (x_1 \le 3 \vee x_2 \le 3 \vee x_3 \le 0 \vee x_3 \ge 4)\\
& \wedge \ (x_1 \ge 1 \vee x_2 \ge 1) \ \wedge \ (x_1 \le 1 \vee x_1 \ge 3 \vee x_2 \ge 2) \ \wedge \ (x_1 \le 3 \vee x_2 \ge 4)\\
& \wedge \ (x_1 \ge 1 \vee x_2 \le 1) \ \wedge \ (x_1 \ge 1 \vee x_2 \le 0 \vee x_2 \ge 2 \vee x_3 \le 3)\\
& \wedge \ (x_1 \le 1 \vee x_1 \ge 3 \vee x_2 \le 2) \wedge (x_1 \le 1 \vee x_1 \ge 3 \vee x_2 \le 1 \vee x_2 \ge 3 \vee x_3 \le 0).
\end{aligned}$$

Algorithm: DESCRIPTION
Input: Nonempty set $M \subseteq D^\ell$ of vectors.
Output: Formula $\varphi(M)$ in CNF, satisfying $\mathrm{Sol}(\varphi) = M$.
Method:

```
1: let M = (m_1, ..., m_|M|) be lexicographically sorted
2: φ(M) ← true
3: fork ← FORK(M)
4: for k ← 0 to |M| do
5:     f ← fork[k]
6:     if f > 0 and m_k[f] + 1 < m_{k+1}[f] then
7:         φ(M) ← φ(M) ∧ ¬middle(k, f)
8:     end if
9:     for i ← f + 1 to ℓ do
10:        if k < |M| and m_{k+1}[i] > 0 then
11:            φ(M) ← φ(M) ∧ ¬left(k + 1, i)
12:        end if
13:        if k > 0 and m_k[i] < |D| − 1 then
14:            φ(M) ← φ(M) ∧ ¬right(k, i)
15:        end if
16:    end for
17: end for
18: return φ(M)
```

Algorithm: FORK
Input: Lexicographically sorted nonempty list $M \subseteq D^\ell$ of vectors without duplicates.
Output: Array fork: $[0 \dots |M|]$ containing the fork function for M.
Method:

```
1: fork[0] ← 0
2: fork[|M|] ← 0
3: for k ← 1 to |M| − 1 do
4:     i ← 1
5:     while m_k[i] = m_{k+1}[i] do
6:         i ← i + 1
7:     end while
8:     fork[k] ← i
9: end for
10: return fork
```

FIG. 3.3. *Algorithm for the description problem.*

It can be easily checked that the constructed formula $\varphi(M)$ satisfies the condition $\mathrm{Sol}(\varphi(M)) = M$. □

The main algorithm that implements the construction of a formula φ in CNF for a given set of vectors M over a finite totally ordered domain D, satisfying the condition $\mathrm{Sol}(\varphi) = M$, and the algorithm computing the fork function are displayed in Figure 3.3.

THEOREM 3.6. *For each set of vectors $M \subseteq D^\ell$ over a finite ordered domain D there exists a formula φ in CNF such that $M = \mathrm{Sol}(\varphi)$. It contains at most $2\,|M|\,\ell$ clauses and its length is $O(|M|\,\ell^2 \log |D|)$. The algorithm constructing φ runs in time*

$O(|M|\,\ell^2 \log|D|)$.

Proof. The formula $\varphi(M)$ contains at most $|M|-1$ middle-clauses and at most $\ell + (|M|-1)(\ell-1)$ left/right-clauses. Summing up these partial bounds, we obtain for the total number of clauses the bound

$$|M| - 1 + 2(\ell + (|M|-1)(\ell-1)) = 2\,|M|\,\ell - |M| + 1 \;\le\; 2\,|M|\,\ell \quad (\text{for } M \neq \emptyset).$$

Each clause contains at most 2ℓ literals, namely at most one positive and one negative for each variable. Each literal has length $O(\log|D|)$, since the domain elements are written in binary notation. Hence, the overall length of the formula $\varphi(M)$ is $O(|M|\,\ell^2 \log|D|)$.

The vectors in M can be lexicographically sorted in time $O(|M|\,\ell \log|D|)$ using a decision tree (trie) or a radix sort. The factor $\log|D|$ stems from the comparison of domain elements. The fork levels can also be computed in time $O(|M|\,\ell \log|D|)$, in parallel with sorting the set M. The formula $\varphi(M)$ is produced by two loops, where the outer loop is going through each vector in M and the inner loop through the variables. The three clauses $\neg\,\mathrm{middle}(k,i)$, $\neg\,\mathrm{left}(k+1,i)$, and $\neg\,\mathrm{right}(k,i)$ are potentially written in each step inside the combined loops. This makes an algorithm with time complexity $O(|M|\,\ell^2 \log|D|)$. □

An important property of our algorithm is its linearity with respect to the number of models $|M|$ being the most relevant parameter. In fact, the paper by Amilhastre, Fargier, and Marquis [1] mentions an industrial problem provided by Renault DVI, where the cardinality of the set of vectors is $|M| = 1.5 \cdot 10^{12}$ with the vector arity $\ell = 101$ over a domain of size $|D| = 43$. The complement set $\bar{M}$ contains $43^{101} - 1.5 \cdot 10^{12}$ vectors; therefore, the naive algorithm is inapplicable in this situation.

4. Prime formulas. The formulas in CNF computed by Algorithm DESCRIPTION in section 3 are of a particular form: The variables in each clause form a prefix of the variable vector $(x_1, \ldots, x_\ell)$. As a consequence, although polynomial in the size of the initial relation M, the size of the formulas is not minimal. In Example 3.5, for instance, it can be easily seen that several literals and even clauses can be removed from the formula. We investigate in this section a way to shorten formulas. To this aim we generalize the notion of a *prime* formula in propositional logic to the case of finite domains and show how to obtain such a prime formula in CNF describing the given relation M. Note that although we apply the minimization process to the formulas produced by our algorithm, it can be applied to any formula in CNF.

The notion of primality and prime clauses in many-valued logic was considered for the first time by Murray and Rosenthal in [23].

4.1. Notions of primality. Recall that a clause of a propositional formula φ in CNF is said to be *prime* (with respect to φ) if φ implies none of its proper subclauses. This leads to the following straightforward generalization. Let φ be a CNF formula over some finite totally ordered domain. A clause $c = (l_1 \vee \cdots \vee l_q)$ of φ is said to be *prime* (with respect to φ) if for each $i = 1, \ldots, q$ there exists a model $m_i \in \mathrm{Sol}(\varphi)$ not satisfying the reduced clause $c \setminus l_i = (l_1 \vee \cdots \vee l_{i-1} \vee l_{i+1} \cdots \vee l_q)$. The formula φ is said to be prime if all its clauses are prime.

However, this notion of primality considers each literal as a whole. This is adequate in the case of classical propositional logic but does not meet our requirements in the case of larger domains. The following more sophisticated notion of primality also considers the value d involved in a literal $x \le d$ or $x \ge d$.

DEFINITION 4.1 (primality). *For a variable x and a pair of values $d, d' \in D$ satisfying the relation $d' > d$ (resp., $d' < d$), the literal $x \ge d'$ (resp., $x \le d'$) is said*

to be stronger *than the literal $x \geq d$ (resp., $x \leq d$). The constant false is stronger than any other nonfalse literal. Removal of a literal from a clause is a particular case of strengthening, namely, of this literal to the constant false.*

Let φ be a CNF formula over a finite totally ordered domain D. A clause c in φ is prime *with respect to φ if strengthening any literal in c yields a clause which is not implied by φ. A formula φ is* prime *if all its clauses are prime.*

As in the propositional case, it is easily seen that for a given formula φ there always exists at least one prime formula φ' which is logically equivalent to φ and can be obtained from φ by strengthening and removing some of its literals. If φ is already prime, then φ and φ' are identical.

The interest in this new, stronger notion of primality comes from efficiency requirements. In fact, the presence of a literal $x \leq d$ or $x \geq d$ instead of $x \leq d'$ or $x \geq d''$, respectively, for $d < d'$ or $d > d''$ reduces the search space during a search for a suitable satisfying assignment.

4.2. Algorithm. Given a CNF formula φ, we show how to efficiently compute a prime formula φ' satisfying the equality $\mathrm{Sol}(\varphi) = \mathrm{Sol}(\varphi')$. Our algorithm, specified in Figure 4.1, is inspired by the one presented in [25] for the Boolean domain. The algorithm considers each clause $l_1 \vee \cdots \vee l_q$ of φ separately. First, it determines for each model m_k the last literal satisfied by it and stores the index of the literal in the array $last[k]$ (lines 3–9). Then the literals are strengthened in turn, starting with the first one.

Suppose that the literal is positive; i.e., it is of the form $x_i \geq d$ (lines 12–20). Strengthening means to increase the value of d. Some models that satisfied the literal before might not satisfy the literal after strengthening. This is a problem only for those models for which the literal was the last possibility to make the clause true (remember that for a model to satisfy a clause it suffices to satisfy a single literal). Therefore, we choose the new value d' as the minimum of all such models (lines 14–19) and construct the new literal as $x_i \geq d'$. Negative literals are handled dually by taking the maximum (lines 21–30). If the literal is redundant, i.e., if no model depends on it as its last literal, the minimum (maximum) would have to be taken over the empty set; in this case we set d' to n (resp., -1).

Line 31 checks whether the literal is redundant. If it is not redundant, it is added to the new clause constructed to replace the old one (line 32). Finally, all models m_k satisfying the new literal are marked by setting $last[k]$ to zero (lines 33–37). As a consequence, the minimum/maximum computations for the remaining literals will ignore these models.

Example 4.2. Let $x_1 \leq 3 \vee x_2 \leq 3 \vee x_3 \leq 0 \vee x_3 \geq 4$ be the clause under consideration, and let M be as in Example 3.5. The array *last* is set to the values

	010	013	220	440	444
last	3	2	3	3	4

The first literal is eliminated since there is no model m_k such that $last[k] = 1$. The second literal is strengthened to $x_2 \leq 1$ since $d' = 1$ for $j = 2$. The last two literals remain unchanged, since the maximum for $j = 3$ is $d' = 0$ and the minimum for $j = 4$ is $d' = 4$. Hence the reduced clause is equal to $x_2 \leq 1 \vee x_3 \leq 0 \vee x_3 \geq 4$.

The PRIMALITY algorithm applied to the whole formula $\varphi(M)$ from Example 3.5

Algorithm: PRIMALITY
Input: A formula φ in conjunctive normal form and a nonempty set $M \subseteq D^\ell$ of vectors such that $\mathrm{Sol}(\varphi) = M$.
Output: A reduced prime formula φ' such that $\mathrm{Sol}(\varphi) = \mathrm{Sol}(\varphi')$.
Method:

```
1: φ' ← true
2: for all clauses c = (l_1 ∨ ··· ∨ l_q) ∈ φ do                ▷ compute the vector last
3:     for k ← 1 to |M| do
4:         for j ← 1 to q do
5:             if m_k satisfies l_j then
6:                 last[k] ← j
7:             end if
8:         end for
9:     end for
10:    c' ← false                                              ▷ greedy strengthening of literals
11:    for j ← 1 to q do
12:        if l_j is positive then
13:            let l_j = x_i ≥ d
14:            d' ← n                  ▷ d' = min({n} ∪ {m_k[i] | 1 ≤ k ≤ |M|, last[k] = j})
15:            for k ← 1 to |M| do
16:                if last[k] = j then
17:                    d' ← min(d', m_k[i])
18:                end if
19:            end for
20:            l' ← x_i ≥ d'
21:        else
22:            let l_j = x_i ≤ d
23:            d' ← −1             ▷ d' = max({−1} ∪ {m_k[i] | 1 ≤ k ≤ |M|, last[k] = j})
24:            for k ← 1 to |M| do
25:                if last[k] = j then
26:                    d' ← max(d', m_k[i])
27:                end if
28:            end for
29:            l' ← x_i ≤ d'
30:        end if
31:        if 0 ≤ d' ≤ n − 1 then
32:            c' ← c' ∨ l'
33:            for k ← 1 to |M| do
34:                if m_k satisfies l' then
35:                    last[k] ← 0
36:                end if
37:            end for
38:        end if
39:    end for
40:    φ' ← φ' ∧ c'
41: end for
42: return φ'
```

FIG. 4.1. *Reduction to a prime formula.*

returns the reduced formula

$$\begin{aligned}\varphi'(M) = {} & (x_3 \leq 0 \vee x_3 \geq 3) \wedge (x_1 \leq 0 \vee x_1 \geq 2) \wedge (x_1 \leq 2 \vee x_1 \geq 4) \\ & \wedge (x_2 \leq 1 \vee x_3 \leq 0 \vee x_3 \geq 4) \wedge (x_2 \geq 1) \wedge (x_1 \leq 0 \vee x_2 \geq 2) \\ & \wedge (x_1 \leq 2 \vee x_2 \geq 4) \wedge (x_1 \geq 2 \vee x_2 \leq 1) \wedge (x_2 \geq 4 \vee x_3 \leq 3) \\ & \wedge (x_1 \geq 4 \vee x_2 \leq 2) \wedge (x_2 \leq 1 \vee x_2 \geq 4 \vee x_3 \leq 0)\,.\end{aligned}$$

Note that $\varphi'(M)$ is a Horn formula with at most three literals per clause. □

THEOREM 4.3. *For a formula φ in conjunctive normal form (CNF) there exists a logically equivalent prime formula φ' such that* $\mathrm{Sol}(\varphi) = \mathrm{Sol}(\varphi')$*, which can be computed in time $O(|\varphi|\,|M|\,\ell \log |D|)$, where $|\varphi|$ is the number of clauses in φ.*

Proof. The time complexity directly follows from Figure 4.1. To prove the correctness of the algorithm, let c be a clause of φ and c' be the clause obtained from c by running Algorithm PRIMALITY.

We first show that the models satisfying c are the same as those satisfying c'. The lines 3–9 set $last[k]$ to a value in $\{1, \ldots, q\}$ for every k, since every model in M satisfies at least one literal in c. Moreover, $last[k]$ is set to zero if and only if the corresponding model satisfies the literal added to c'. Obviously every element of *last* will eventually be set to zero: either the model "accidentally" satisfies a new literal before the last one, or otherwise the new literal derived from the literal identified by $last[k]$ is satisfied by m_k. Therefore, we have $\mathrm{Sol}(\varphi) = \mathrm{Sol}(\varphi')$.

It remains to show that c' is prime. According to Definition 4.1 we have to prove that no literal from c' can be removed or strengthened. Consider the start of the jth iteration of the **for**-loop in lines 11–39. Construct the set $M^{(j)} = \{m_k \mid 1 \leq k \leq |M|\,, last[k] = j\}$. The models in $M^{(j)}$ satisfy none of the literals added to c' so far (otherwise their *last*-entry would have been set to zero, preventing their inclusion into the set $M^{(j)}$), nor will they satisfy any future literal since the jth literal is the last one satisfied by the models. Therefore, the literal constructed in this iteration cannot be dropped from c' without changing the set of satisfying models. Now suppose that the literal considered in this round is $l_j = x_i \geq d$ (the other case is dual). Let $m^{(j)}$ be one of the models in $M^{(j)}$ for which the ith component is minimal, i.e., $m^{(j)}[i] = d'$. It satisfies $x_i \geq d'$ but clearly no other literal $x_p \geq d_p$ satisfying $d_p > d'$. We conclude that the literals added to c' can be neither removed nor strengthened, which implies that c' is prime. □

Combining Algorithms DESCRIPTION and PRIMALITY, i.e., first describing M by means of a CNF formula $\varphi(M)$, followed by a reduction of $\varphi(M)$ to a prime formula, we get the following result.

COROLLARY 4.4. *For each set of vectors $M \subseteq D^\ell$ over a finite totally ordered domain D there exists a prime formula φ in CNF such that $M = \mathrm{Sol}(\varphi)$. The algorithm constructs φ in time $O(|M|^2\,\ell^2 \log |D|)$.*

5. Horn formulas. Horn clauses and formulas constitute a frequently studied subclass of propositional formulas. This is due to the fact that there exists a polynomial-time algorithm for deciding their satisfiability problem. It turns out that this is still the case for Horn formulas over finite domains [4], which motivates our study of their description and identification problems. As we will see, the sets of vectors described by Horn formulas are closed under the minimum operation.

A question may arise about the usefulness and practical implications of computing a Horn formula $\varphi(M)$ for a given set of vectors M whenever it is possible. Since the complexity of the description algorithm is determined by the cardinality of the

set of vectors M, it may seem superfluous to compute a Horn formula describing them. However, imagine a two-stage procedure, where first a describing formula φ is computed offline for the set of vectors M, followed by its extensive use during a second stage for online reasoning. It is obvious that we prefer a structurally simpler formula φ for the second stage reasoning process. There exist numerous examples in logic and automated deduction (see, e.g., the survey [3] in case of many-valued logics), like resolution or several tableau methods, where it is more efficient to work with Horn clauses or Horn formulas, compared with general formulas in CNF.

Problem: DESCRIPTION[HORN].

Input: A finite set of vectors $M \subseteq D^\ell$, closed under conjunction, over a finite totally ordered domain D.

Output: A Horn formula φ over D such that $\mathrm{Sol}(\varphi) = M$.

The general construction in section 3 does not guarantee that the final formula is Horn whenever the set M is closed under conjunction. For instance, there exists a Horn formula describing the set M presented in Example 2.2, but the formula $\varphi(M)$ computed by the DESCRIPTION algorithm in Example 3.5 is *not* Horn. Therefore, we must reduce the clauses of the formula φ, produced in section 3, to obtain only Horn clauses. For this, we will modify a construction proposed by Jeavons and Cooper in [21]. Their method is exponential, since it proposes to construct a Horn clause for each vector in the complement set $D^\ell \setminus M$. We will first adapt the method of Jeavons and Cooper to get a polynomial-time algorithm and then propose a more sophisticated implementation of the approach that will guarantee us an algorithm with even lower asymptotic complexity.

Let $\varphi(M)$ be a formula produced by the DESCRIPTION algorithm in section 3, and let c be a clause from $\varphi(M)$. We denote by c^- the disjunction of the negative literals in c. The vectors in M satisfying a negative literal in c also satisfy the restricted clause c^-. Hence we have only to care about the vectors that satisfy a positive literal but no negative literals in c, described by the set

$$M_c \;=\; \{m \in M \mid m \not\models c^-\}.$$

If M_c is empty, we can replace the clause c by $h(c) = c^-$ in the formula $\varphi(M)$ without changing the set of models $\mathrm{Sol}(\varphi)$. Otherwise, note that M_c is closed under conjunction, since M is already closed under this operation. Indeed, if the vectors m and m' falsify every negative literal $x \le d$ of c^-, then the conjunction $m \wedge m'$ falsifies the same negative literals. Hence M_c contains a unique minimal model $m_* = \bigwedge M_c$. Every positive literal in c satisfied by m_* is also satisfied by all vectors in M_c. Let l be a positive literal from c and satisfied by m_*. There exists at least one such literal since otherwise m_* would satisfy neither c^- nor any positive literal in c; hence it would not be in M_c. Then c can be replaced with the Horn clause $h(c) = l \vee c^-$, without changing the set of models $\mathrm{Sol}(\varphi)$. We obtain a Horn formula $h(M)$ for a Horn set M by replacing every non-Horn clause c in $\varphi(M)$ by its Horn restriction $h(c)$.

Example 5.1. Consider again the set of vectors $M = \{010, 013, 220, 440, 444\}$ and the non-Horn clause $c = (x_1 \ge 1 \vee x_2 \le 0 \vee x_2 \ge 2 \vee x_3 \le 0 \vee x_3 \ge 3)$ from Example 3.5. We have $c^- = (x_2 \le 0 \vee x_3 \le 0)$; thus any subclause of c containing c^- is already satisfied by the vectors 010, 220, and 440. We need to keep a positive literal from c in order to satisfy the reduced clause also by the vectors $013, 444 \in M$. In other words, we have $M_c = \{013, 444\}$. The unique minimal model is $m_* = 013 \wedge 444 = 013$. Since the minimal model m_* satisfies the positive literal $(x_3 \ge 3)$ in c, we can reduce the clause c to $h(c) = (x_3 \ge 3 \vee x_2 \le 0 \vee x_3 \le 0)$. ∎

The length of $h(M)$ is basically the same as that of $\varphi(M)$. The number of clauses is the same and the length of clauses is $O(\ell \log |D|)$ in both cases. There are at most 2ℓ literals in each clause of $\varphi(M)$ (one positive and one negative literal per variable) versus $\ell + 1$ literals in each clause of $h(M)$ (one negative literal per variable plus a single positive literal).

The construction of each Horn clause $h(c)$ requires time $O(|M|\,\ell \log |D|)$. Indeed, for every vector $m \in M$ we have to evaluate at most ℓ negative literals in c to find out whether m belongs to M_c. The evaluation of a literal takes time $O(\log |D|)$. Hence the computation of the set M_c takes time $O(|M|\,\ell \log |D|)$. To obtain $m_* = \bigwedge M_c$, we have to compute $|M_c|-1$ conjunctions between vectors of length ℓ, each of the ℓ conjunctions taking time $O(\log |D|)$. Therefore, m_* can also be computed in time $O(|M|\,\ell \log |D|)$. Since there are at most $2\,|M|\,\ell$ clauses in $\varphi(M)$, the transformation of $\varphi(M)$ into $h(M)$ can be done in time $O(|M|^2\,\ell^2 \log |D|)$. Hence, the whole algorithm producing the Horn formula $h(M)$ from the set of vectors M runs in time $O(|M|^2\,\ell^2 \log |D|)$.

Note that we can also use the PRIMALITY algorithm to reduce a CNF formula φ to a Horn formula $h(\varphi)$ whenever there exists a Horn formula logically equivalent to φ. The application of the PRIMALITY algorithm yields the same asymptotic time complexity as the aforementioned method according to Corollary 4.4. However, neither the application of the PRIMALITY algorithm nor the aforementioned method are asymptotically optimal.

Another interest for using the primality algorithm comes from the fact that this method does not need the assumption that M is closed under conjunction. Indeed, once we compute a prime formula describing M, we can conclude that M is Horn if the obtained prime formula is Horn. We will return to this issue in section 6 on bijunctive formulas.

We now describe a new algorithm that significantly outperforms the previous methods in terms of running time. This new algorithm is inspired by the one from [17] for the Boolean case. The basic idea is to describe the set M directly by means of a CNF formula as in section 3, but keeping only one or no positive literal in each obtained clause. For this purpose, we define the terms hmiddle(k, i), hleft$(k+1, i)$, and hright(k, i) that replace the corresponding terms defined in section 3. The replacement of the previous terms by the new ones is based on the following lemma.

LEMMA 5.2. *Let $M \subseteq D^\ell$ be a finite set of vectors closed under conjunction and let c be a clause satisfied by each model $m \in M$. Then there exists a Horn subclause $h(c)$ of c that is satisfied by every model from M.*

Proof. If c contains only one or no positive literals, then we set $h(c)$ equal to c. Otherwise, let $c = (x_i \geq a \vee x_j \geq b \vee c')$ be a clause containing two different positive literals, where $i \neq j$ since otherwise one of the two positive literals would be implied by the other and could therefore be eliminated. Assume that neither $x_i \geq a$ nor $x_j \geq b$ can be removed from c if the truth of c with respect to M has to be preserved. Then there must be two models $m, m' \in M$ satisfying the conditions $m[i] \geq a$, $m[j] < b$ and $m'[i] < a$, $m'[j] \geq b$. Moreover, neither m nor m' satisfy the rest of the clause c'. Then it can be easily seen that $(m \wedge m')[i] < a$, $(m \wedge m')[j] < b$, and that the model $m \wedge m'$ does not satisfy c'. Hence, the model $m \wedge m' \in M$ does not satisfy the clause c. This contradicts the hypothesis because M is closed under conjunction. ∎

We now define the terms for the Horn formulas by distinguishing the cases hmiddle, hleft, and hright. The conditions of their application are inherited from

section 3. The first two cases are relatively easy to determine:

$$\begin{aligned}\text{hmiddle}(k,i) &= \bigwedge_{j<i}(x_j \geq m_k[j]) \ \wedge \ (x_i > m_k[i]) \wedge (x_i < m_{k+1}[i]),\\ \text{hleft}(k+1,i) &= \bigwedge_{j<i}(x_j \geq m_{k+1}[j]) \ \wedge \ (x_i < m_{k+1}[i]).\end{aligned}$$

We can easily see that $\neg\,\text{hmiddle}(k,i)$ and $\neg\,\text{hleft}(k+1,i)$ are Horn clauses. Observe that $\neg\,\text{hleft}(k+1,i)$ implies $\neg\,\text{left}(k+1,i)$. We will show that the rightmost literal cannot be removed from $\neg\,\text{left}(k+1,i)$ when we compute the Horn subclause $\neg\,\text{hleft}(k+1,i)$. From the tree T_M and the term $\text{left}(k+1,i)$ observe that the clause $c = \neg\,\text{left}(k+1,i) \setminus (x_i \geq m_{k+1}[i])$ is falsified by at least one model in M. Therefore, there is no Horn subclause $h(c)$ of c that is satisfied by all models in M. Since M is closed under conjunction, from Lemma 5.2 it follows that there must be a Horn subclause $h(c)$ of c that is satisfied by all models of M. Hence, the clause $h(c)$ must contain the literal $x_i \geq m_{k+1}[i]$ and since it is Horn, it must be a subclause of $\neg\,\text{hleft}(k+1,i)$. Similarly for $\text{hmiddle}(k,i)$, the construction ensures that the rightmost literal cannot be removed from $\neg\,\text{middle}(k,i)$, since otherwise the clause $\neg\,\text{middle}(k,i)$ would be equal to $\neg\,\text{right}(k,i)$. Thus all other positive literals can be removed from $\neg\,\text{middle}(k,i)$ to obtain the Horn subclause $\neg\,\text{hmiddle}(k,i)$.

The construction of the term $\text{hright}(k,i)$ is more involved. Recall that for all convenient parameters k and i we have the clause

$$\neg\,\text{right}(k,i) \ = \ \bigvee_{j<i}(x_j < m_k[j] \ \vee \ x_j > m_k[j]) \ \vee \ (x_i \leq m_k[i]).$$

We look for the positive literals that can be removed from $\neg\,\text{right}(k,i)$ in order to derive the term $\text{hright}(k,i)$. For this purpose, construct the set

$$M(k,i) \ = \ \{m \in M \mid m[i] > m_k[i] \text{ and } \forall j < i, \ m[j] \geq m_k[j]\}$$

for the given parameters k and i. Clearly, $M(k,i)$ is the set of all vectors from M that falsify all negative literals in $\neg\,\text{right}(k,i)$. The set $M(k,i)$ corresponds to the previously defined set M_c for $c = \neg\,\text{right}(k,i)$.

We distinguish the cases $M(k,i) = \emptyset$ and $M(k,i) \neq \emptyset$. When the set $M(k,i)$ is empty, this means that every model $m \in M$ satisfies at least one negative literal in $\neg\,\text{right}(k,i)$. Thus we can construct $\neg\,\text{hright}(k,i)$ from $\neg\,\text{right}(k,i)$ by removing all positive literals. In other words, $\text{hright}(k,i)$ is obtained from $\text{right}(k,i)$ by removing all negative literals.

When the set $M(k,i)$ is nonempty, we know from Lemma 5.2 that there exists a positive literal in $\neg\,\text{right}(k,i)$ which is satisfied by all models in $M(k,i)$. This amounts to the computation of intersection $\bigwedge M(k,i)$ followed by a choice of a model from it, but we need to do it in a more sophisticated way than in the previous Horn method if we wish to obtain an algorithm with lower asymptotic complexity. Let us define a function that will compute the position of the kept literal:

$$\text{pos}(k,i) \ = \ \max_{1\leq j\leq k}\{j \mid \exists m \in M(k,i) \text{ such that } \forall p, \ p < j \text{ implies } m[p] \leq m_k[p]\}.$$

Note that since every model $m \in M(k,i)$ satisfies the clause $\neg\,\text{right}(k,i)$ and thus at least one of its positive literals, the condition $\text{pos}(k,i) < i$ is satisfied.

Algorithm: POS
Input: Nonempty set $M \subseteq D^\ell$ of vectors and a parameter k.
Output: The position function $pos(k)$.
Method:

```
 1: for i ← 1 to ℓ do
 2:     pos(k)[i] ← 0
 3: end for
 4: for k' ← 1 to |M| do
 5:     if k' ≠ k then
 6:         i_0 ← 1
 7:         while i_0 < ℓ and m_{k'}[i_0] ≤ m_k[i_0] do
 8:             i_0 ← i_0 + 1
 9:         end while
10:         i ← 1
11:         while i ≤ ℓ and m_{k'}[i] ≥ m_k[i] do
12:             if i > fork(k) and m_k[i] < |D| − 1 and m_{k'}[i] > m_k[i] then
13:                 pos(k)[i] ← max(pos(k)[i], i_0)
14:             end if
15:             i ← i + 1
16:         end while
17:     end if
18: end for
19: return pos(k)
```

FIG. 5.1. *Position function* $\mathrm{pos}(k,i)$.

The term $\mathrm{hright}(k,i)$ is defined as follows:

$$\mathrm{hright}(k,i) = \begin{cases} \bigwedge_{j<i}(x_j \geq m_k[j]) \ \wedge \ (x_i > m_k[i]) & \text{if } M(k,i) = \emptyset, \\ \bigwedge_{j<i}(x_j \geq m_k[j]) \ \wedge \ (x_i > m_k[i]) \ \wedge \ (x_{\mathrm{pos}(k,i)} \leq m_k[\mathrm{pos}(k,i)]) & \\ \qquad \text{otherwise.} & \end{cases}$$

We can finally present the Horn formula $h(M)$ for a set of vectors M closed under conjunction that satisfies the equality $\mathrm{Sol}(h(M)) = M$. It resembles the formula $\varphi(M)$ from section 3 modulo some syntactic changes.

$$\begin{aligned} h(M) \quad &= \quad \bigwedge\{ \neg\,\mathrm{hmiddle}(k,i) \mid 0 < k < |M|\,,\ i = \mathrm{fork}(k),\ m_k[i]+1 < m_{k+1}[i] \} \\ &\wedge \quad \bigwedge\{ \neg\,\mathrm{hleft}(k+1,i) \mid 0 \leq k < |M|\,,\ \mathrm{fork}(k) < i \leq \ell,\ m_{k+1}[i] > 0 \} \\ &\wedge \quad \bigwedge\{ \neg\,\mathrm{hright}(k,i) \quad \mid 0 < k \leq |M|\,,\ \mathrm{fork}(k) < i \leq \ell,\ m_k[i] < |D|-1 \}. \end{aligned}$$

Our algorithm computing the Horn formula $h(M)$ for a given set of vectors M is equivalent to Algorithm DESCRIPTION, where the terms $\mathrm{middle}(k,i)$, $\mathrm{left}(k+1,i)$, and $\mathrm{right}(k,i)$ are replaced by the terms $\mathrm{hmiddle}(k,i)$, $\mathrm{hleft}(k+1,i)$, and $\mathrm{hright}(k,i)$, respectively. Computing the clauses $\neg\,\mathrm{hmiddle}(k,i)$ and $\neg\,\mathrm{hleft}(k+1,i)$ does not pose any problems, whereas the clause $\neg\,\mathrm{hright}(k,i)$ heavily depends on the position function $\mathrm{pos}(k,i)$ which must be computed efficiently. For a given k, Algorithm POS in Figure 5.1 computes the values of $\mathrm{pos}(k,i)$ for all positions $i = 1,\ldots,\ell$ at the same

time. This is what makes our algorithm efficient. The result is returned in the form of an array $pos(k)$, where the equality $pos(k)[i] = \mathrm{pos}(k, i)$ holds for all positions i.

The algorithm is based on the following principle. Given a vector m_k, it considers every vector $m_{k'} \in M$ different from m_k. For a pair of vectors m_k and $m_{k'}$, the algorithm considers each index i in increasing order. While the condition $m_{k'}[i] \geq m_k[i]$ (line 11) holds, we are sure that the model $m_{k'}$ belongs to $M(k, i)$, and therefore $m_{k'}$ is taken into account for the value of $\mathrm{pos}(k, i)$ (line 13). On the other hand, as soon as the condition does not hold any more, then we are sure that for all $j > i$ the vector $m_{k'}$ does not belong to $M(k, i)$, and therefore $m_{k'}$ does not need to be taken into account for the value of $\mathrm{pos}(k, i)$. Note that the value $pos[k, i]$ has no meaning for a nonconvenient i, and therefore it is set to 0, which also means $M(k, i) = \emptyset$.

Example 5.3. We already know from Example 4.2 that there exists a Horn formula describing the set of vectors $M = \{010, 013, 220, 440, 444\}$. Let us transform the terms middle, left, and right from Example 3.3 to hmiddle, hleft, and hright, respectively. We will get the middle terms

$$\begin{aligned}
\mathrm{hmiddle}(1,3) &= (x_1 \geq 0) \wedge (x_2 \geq 1) \wedge (x_3 > 0) \wedge (x_3 < 3),\\
\mathrm{hmiddle}(2,1) &= (x_1 > 0) \wedge (x_1 < 2),\\
\mathrm{hmiddle}(3,1) &= (x_1 > 2) \wedge (x_1 < 4),\\
\mathrm{hmiddle}(4,3) &= (x_1 \geq 4) \wedge (x_2 \geq 4) \wedge (x_3 > 0) \wedge (x_3 < 4)
\end{aligned}$$

and the left terms

$$\begin{aligned}
\mathrm{hleft}(1,2) &= (x_1 \geq 0) \wedge (x_2 < 1),\\
\mathrm{hleft}(3,2) &= (x_1 \geq 2) \wedge (x_2 < 2),\\
\mathrm{hleft}(4,2) &= (x_1 \geq 4) \wedge (x_2 < 4)
\end{aligned}$$

easily. To transform the terms $\mathrm{right}(2,2)$, $\mathrm{right}(3,2)$, and $\mathrm{right}(3,3)$ to $\mathrm{hright}(2,2)$, $\mathrm{hright}(3,2)$, and $\mathrm{hright}(3,3)$, respectively, we need first to compute the arrays $pos(2)$ and $pos(3)$. We get

pos	1	2	3
2	0	1	1
3	0	1	1

which implies the terms

$$\begin{aligned}
\mathrm{hright}(2,2) &= (x_1 \geq 0) \wedge (x_2 > 1) \wedge (x_1 \leq 0),\\
\mathrm{hright}(2,3) &= (x_1 \geq 0) \wedge (x_2 \geq 1) \wedge (x_3 > 3) \wedge (x_1 \leq 0),\\
\mathrm{hright}(3,2) &= (x_1 \geq 2) \wedge (x_2 > 2) \wedge (x_1 \leq 2),\\
\mathrm{hright}(3,3) &= (x_1 \geq 2) \wedge (x_2 \geq 2) \wedge (x_3 > 0) \wedge (x_1 \leq 2).
\end{aligned}$$

The final Horn formula will be

$$\begin{aligned}
h(M) &= (x_2 \leq 0 \vee x_3 \leq 0 \vee x_3 \geq 3) \wedge (x_1 \leq 0 \vee x_1 \geq 2) \wedge (x_1 \leq 2 \vee x_1 \geq 4)\\
&\wedge\ (x_1 \leq 3 \vee x_2 \leq 3 \vee x_3 \leq 0 \vee x_3 \geq 4) \wedge (x_2 \geq 1) \wedge (x_1 \leq 1 \vee x_2 \geq 2)\\
&\wedge\ (x_1 \leq 3 \vee x_2 \geq 4) \wedge (x_1 \geq 1 \vee x_2 \leq 1) \wedge (x_1 \geq 1 \vee x_2 \leq 0 \vee x_3 \leq 3)\\
&\wedge\ (x_1 \leq 1 \vee x_1 \geq 3 \vee x_2 \leq 2) \wedge (x_1 \leq 1 \vee x_1 \geq 3 \vee x_2 \leq 1 \vee x_3 \leq 0). \qquad \square
\end{aligned}$$

THEOREM 5.4. *For each set of vectors $M \subseteq D^\ell$ over a finite totally ordered domain D that is closed under conjunction, there exists a Horn formula φ such that $M = \mathrm{Sol}(\varphi)$. The formula φ contains at most $2\,|M|\,\ell$ clauses, its length is $O(|M|\,\ell^2 \log |D|)$, and it can be computed in time $O(|M|\,\ell(|M| + \ell) \log |D|)$.*

Proof. Time complexity is straightforward since we essentially run the DESCRIPTION algorithm from section 3 with the computation of $pos(k)$ added. As for correctness, it is a consequence of the previously written reasoning in this section. ∎

Using Theorem 5.4, we are able to prove a generalization of a well-known characterization of the set of models $\mathrm{Sol}(\varphi)$ of a Horn formula φ. We wish to point out that this characterization is not new and was proved before. Indeed, a related characterization in a different setting can be found in [15], and a similar proof can be found in [21]. We mention the result here for completeness.

PROPOSITION 5.5. *A set of vectors M over a finite totally ordered domain is closed under conjunction if and only if there exists a Horn formula φ satisfying the identity $\mathrm{Sol}(\varphi) = M$.*

Proof. Theorem 5.4 shows that there exists a Horn formula φ describing a set of vectors M if M is closed under conjunction. It remains to show the converse, namely, that the set $\mathrm{Sol}(\varphi)$ is closed under conjunction if φ is a Horn formula. We need to show that for any two models m and m' of φ, their conjunction $m \wedge m'$ is also a model of φ. A model satisfies a Horn formula φ if and only if it satisfies every clause of φ. Therefore, we need to show for each clause c that $m \wedge m'$ satisfies c whenever both m and m' satisfy c. We distinguish two cases.

(i) Clause c contains a positive literal $x \geq d$ that is satisfied by both m and m'. Then we have $m(x) \geq d$ and $m'(x) \geq d$, which implies $(m \wedge m')(x) = \min(m(x), m'(x)) \geq d$. This proves that $m \wedge m'$ satisfies the clause c.

(ii) Clause c contains no positive literal satisfied by both m and m'. Then at least one model, say, m, must satisfy a negative literal $x \leq d$ in c, i.e., $m(x) \leq d$. We obtain $(m \wedge m')(x) = \min(m(x), m'(x)) \leq m(x) \leq d$. Hence also $m \wedge m'$ satisfies c. ∎

If we interchange conjunctions with disjunctions of models, as well as positive and negative literals throughout section 5, we obtain identical results for dual Horn formulas.

THEOREM 5.6. *A set of vectors $M \subseteq D^\ell$ over a finite ordered domain D is closed under disjunction if and only if there exists a dual Horn formula φ satisfying the identity $M = \mathrm{Sol}(\varphi)$. Given M closed under disjunction, the dual Horn formula φ contains at most $2\,|M|\,\ell$ clauses, and its length is $O(|M|\,\ell^2 \log |D|)$. It can be constructed in time $O(|M|\,\ell(|M| + \ell) \log |D|)$.*

6. Bijunctive formulas. Bijunctive clauses and formulas present another frequently studied subclass of propositional formulas, once more because there exists a polynomial-time algorithm for deciding their satisfiability which generalizes to the finite-domain case [5]. We investigate in this section the description problem for a generalization of bijunctive formulas to ordered finite domains, namely, for sets of vectors closed under the median operation.

Problem: DESCRIPTION[BIJUNCTIVE].
Input: A finite set of vectors $M \subseteq D^\ell$, closed under median, over a finite totally ordered domain D.
Output: A bijunctive formula φ over D such that $\mathrm{Sol}(\varphi) = M$.

Once again, the general construction in section 3 does not guarantee that the final formula is bijunctive whenever the set M is closed under median. Therefore,

we add a postprocessing step that transforms the formula φ into a bijunctive one $b(\varphi)$. Let $\varphi(M)$ be the formula produced by the method of section 3, and let c be a clause from $\varphi(M)$. We construct a bijunctive restriction $b(\varphi)$ by removing appropriate literals from φ such that no more than two literals remain in each clause. Since φ is a CNF, any model of $b(\varphi)$ is still a model of φ. The converse does not hold in general. However, if $\mathrm{Sol}(\varphi)$ is closed under median, the method presented below preserves the models; i.e., every model of φ remains a model of $b(\varphi)$. In the proof we need the following simple lemma.

LEMMA 6.1. *The model* $\mathrm{med}(m_1, m_2, m_3)$ *satisfies a literal* l *if and only if at least two of the models* m_1*,* m_2*, and* m_3 *satisfy* l*.*

Proof. Recall the identities $\mathrm{med}(m_1, m_2, m_3) = (m_1 \vee m_2) \wedge (m_2 \vee m_3) \wedge (m_3 \vee m_1) = (m_1 \wedge m_2) \vee (m_2 \wedge m_3) \vee (m_3 \wedge m_1)$. Recall also that $m \wedge m'$ and $m \vee m'$ are shorthand for the more cumbersome prefix notation $\min(m, m')$ and $\max(m, m')$, respectively. Let l be satisfied by at least two models, say, m_1 and m_2. If the literal l is positive, then it is also satisfied by the models $m_1 \vee m_2$, $m_2 \vee m_3$, and $m_3 \vee m_1$. If the literal l is negative, then it is also satisfied by the models $m_1 \wedge m_2$, $m_2 \wedge m_3$, and $m_3 \wedge m_1$. Hence, in both cases, l is also satisfied by $\mathrm{med}(m_1, m_2, m_3)$.

Conversely, if l is satisfied only by one model, say, m_1, or if l is not satisfied by any of the three models, then it is falsified by the model $m_2 \vee m_3$ if l is positive and by the model $m_2 \wedge m_3$ if l is negative. Hence, the literal l cannot be satisfied by $\mathrm{med}(m_1, m_2, m_3)$. □

DEFINITION 6.2. *We say that a literal* l *is* essential *for a clause* c *with respect to a set of models* M *if there is a model* $m \in M$ *that satisfies* l*, but no other literal in* c*. We also say that* m *is a* justification *for* l *with respect to* M*.*

Obviously, we may remove nonessential literals from c without losing models. It remains to show that no clause from φ contains more than two essential literals.

To derive a contradiction, suppose that c is a clause from φ containing at least three essential literals, say, l_1, l_2, and l_3. Let m_1, m_2, and m_3 be their justifications; i.e., for each i we have $m_i \models l_i$ and m_i does not satisfy any other literal in c. According to Lemma 6.1, in this case the model $\mathrm{med}(m_1, m_2, m_3)$ satisfies no literal at all. Hence $\mathrm{med}(m_1, m_2, m_3)$ satisfies neither c nor φ, which contradicts the assumption that $\mathrm{Sol}(\varphi)$ is closed under median.

The previous discussion suggests applying the following algorithm to every clause c of φ. For every literal l in $c = c' \vee l$, check whether the remaining clause c' is still satisfied by all models in M. If the answer is yes, the literal is not essential and can be removed. Otherwise, it is one of the (at most) two literals in the final bijunctive clause $b(c)$. As we can easily see, this operation is performed by the PRIMALITY algorithm from section 4.

THEOREM 6.3. *For each set of vectors* $M \subseteq D^\ell$ *over a finite ordered domain* D *that is closed under median, there exists a bijunctive formula* φ *such that* $M = \mathrm{Sol}(\varphi)$*. The length of* φ *is* $O(|M|\,\ell(\log \ell + \log |D|))$*, and it contains at most* $2\,|M|\,\ell$ *clauses. The algorithm constructing* φ *runs in time* $O(|M|^2\,\ell^2 \log |D|)$*.*

Proof. The main part of the result follows from Theorems 3.6 and 4.3. Concerning the length of φ, note that each clause contains at most two literals. Each literal consists of a variable and one domain element. Hence we can represent a literal by the index of its variable and the domain value, both written in binary. Therefore, the length of a literal and subsequently of each bijunctive clause is $O(\log \ell + \log |D|)$. Since there are at most $2\,|M|\,\ell$ clauses, this implies the length of φ. □

Similarly to the Horn and dual Horn formulas, we get a nice relation between bijunctive formulas by means of a closure property.

PROPOSITION 6.4. *A set of vectors M over a finite totally ordered domain is closed under median if and only if there exists a bijunctive formula φ satisfying the identity $M = \mathrm{Sol}(\varphi)$.*

Proof. Theorem 6.3 shows that there exists a bijunctive formula for every set of vectors M closed under median. It remains to show the converse, namely, that $\mathrm{Sol}(\varphi)$ is closed under median if φ is a bijunctive formula. Since φ is a conjunction of clauses, it is sufficient to show the closure property for a bijunctive clause $c = l \vee l'$. Let m_1, m_2, and m_3 be three models of c. From the pigeonhole principle it follows that one of the two literals l or l' of the clause c is satisfied by at least two models. Hence, by Lemma 6.1, at least one of the two literals l and l', and therefore also the clause c, is satisfied by $\mathrm{med}(m_1, m_2, m_3)$. □

We wish to point out that contrary to the Horn case, the most efficient known algorithm for the bijunctive description problem does not seem to lift well from the Boolean to the finite domain. Dechter and Pearl [11] showed that in the Boolean case this problem can be solved in time $O(|M|\,\ell^2)$, which is better than our result even when ignoring the unavoidable factor $\log|D|$. Their algorithm generates first all the $O(\ell^2)$ bijunctive clauses built from the variables of the formula, followed by an elimination of those falsified by a vector from M, where the bijunctive formula is the conjunction of the retained clauses. However, there are $O(\ell^2\,|D|^2)$ bijunctive clauses for a finite domain D yielding an algorithm with time complexity $O(|M|\,\ell^2\,|D|^2)$, which is exponential in the size $O(\log|D|)$ of the domain elements.

Another idea, not applicable more efficiently in the finite domain case, is that of projecting M onto each pair of variables and then computing a bijunctive formula for each projection. This requires time $O(|M|\,\ell^2)$ in the Boolean case, since we need only to compute a CNF for each projection. A CNF for a projection is always bijunctive; thus only the general Algorithm DESCRIPTION has to be used. However, in the finite domain case, computing a formula with Algorithm DESCRIPTION does not necessarily yield a bijunctive CNF. Each clause can contain up to four literals, a positive and a negative one for each variable. Thus we need to use an algorithm for computing a *bijunctive* CNF, like that of Theorem 6.3, yielding an overall time complexity of $O(|M|^2\,\ell^2\log|D|)$.

Finally, let us return to the identification problem. As was mentioned in the introduction, our results present an elegant and unified algorithm for identification of Horn, dual Horn, and bijunctive sets of vectors. Given a set of vectors M, the method presented by the PRIMALITY algorithm computes a prime formula φ satisfying the identity $\mathrm{Sol}(\varphi) = M$. Then we check in linear time whether it is Horn, dual Horn, or bijunctive. The results in sections 5 and 6 ensure that the resulting formula φ is Horn, dual Horn, or bijunctive if and only if M is a Horn, dual Horn, or bijunctive set of vectors, respectively. This generalizes the result presented by Zanuttini and Hébrard in [25].

7. Changing the literals. We finish the paper with a short discussion of the description problems for a slightly different formalism, where only the literals are changed.

If we change the underlying notion of literals, using the expressions $x = d$ and $x \neq d$ as basic building blocks, the situation changes drastically. Former positive literal $x \geq d$ becomes shorthand for the disjunction $(x = d) \vee (x = d+1) \vee \cdots \vee (x = n-1)$, whereas the former negative literal $x \leq d$ now represents the disjunction $(x = 0) \vee (x = 1) \vee \cdots \vee (x = d)$. Even if we compress literals containing the same variable into a bit vector, the new representation still needs n bits; i.e., its size is $O(n)$.

Compared to the former literals of size $O(\log n)$, this amounts to an exponential blow-up. As an immediate consequence, the algorithms given in the preceding sections become exponential, since we have to replace literals like $x_i < m_k[i]$, $x_i > m_k[i]$, and $x_i < m_{k+1}[i]$ by disjunctions of equalities.

The satisfiability problem for formulas in CNF over finite totally ordered domains with basic operators $\leq$ and $\geq$ is defined similarly to Boolean satisfiability. The complexity of these problems was studied for fixed domain cardinalities, from the standpoint of many-valued logics, by Béjar, Hähnle, and Manyà [6] and Hähnle [16]. The NP-completeness proof for Boolean satisfiability generalizes uniformly to finite ordered domains. Béjar, Hähnle, and Manyà [6] and Hähnle [16] proved that the satisfiability problems restricted to Horn, dual Horn, and bijunctive formulas are decidable in polynomial time for a fixed domain cardinality. These algorithms can be generalized to arbitrary domain cardinalities, adding only the unavoidable factor $\log |D|$.

The satisfiability of formulas in CNF is also affected when switching to $=$ and $\neq$ as basic operators. While the satisfiability problem for general formulas remains NP-complete, the restrictions to Horn, dual Horn, and bijunctive formulas change from polynomially solvable to NP-complete for $|D| \geq 3$. This can be shown by encoding, for example, the graph problem of k-COLORING [2, 9]. When we use the Horn and bijunctive clause $(u \neq d \vee v \neq d)$, we can express by $C(u, v) = (u \neq 0 \vee v \neq 0) \wedge \cdots \wedge (u \neq k-1 \vee v \neq k-1)$ that the adjacent vertices of the edge (u, v) are "colored" by different "colors." On the other hand, Beckert, Hähnle, and Manyà [5] proved that bijunctive formulas restricted to positive literals can be solved in linear time.

8. Concluding remarks. The studied formula description problems constitute a generalization of the Boolean structure identification problems, studied by Dechter and Pearl [11], with more efficient algorithms as a byproduct. Our paper presents a complement to the work of Hähnle et al. [5, 6, 16] on the complexity of the satisfiability problems in many-valued logics. It also completes the study of tractable formulas [9, 20, 21] by Jeavons and his group.

We have constructed an efficient polynomial-time algorithm for the formula description problem over a finite totally ordered domain, where the produced formula is in CNF. We have then presented a subsequent algorithm that eliminates in polynomial time redundancies from the previously computed formula, given the original set of vectors, producing in this way the prime formula. The notion of primality that we use is an extension of the same notion used in Boolean formulas. It not only captures irrelevant literals in clauses but also strengthens the value d in the literals $x \leq d$ or $x \geq d$, respectively. If the original set of vectors is closed under the operation of conjunction, disjunction, or median, we have presented specific algorithms that produce a Horn, a dual Horn, or a bijunctive formula, respectively. These algorithms generalize the well-known ones from the Boolean domain. It is interesting to note that they are compatible, with respect to asymptotic complexity, with known algorithms for the Boolean case presented in [17, 25]. This means that the restriction of the new algorithms presented in our paper to domains D with cardinality $|D| = 2$ produces the aforementioned algorithms for the Boolean case. We also found that in the case when the finite domain is totally ordered, the three well-known special cases, namely, Horn, dual Horn, and bijunctive, display the same behavior as in the Boolean case: (1) they have polynomial satisfiability algorithms and (2) they have the same closure properties.

It would be interesting to know if more efficient algorithms exist or whether

our algorithms are asymptotically optimal. Certainly a more involved lower bound analysis is necessary to answer this open question. Another possible extension of our work would be a generalization of our algorithms to partially ordered domains and to domains with a different structure, like lattices. An additional direction for future work is to look at infinite domains. Some related complexity results for satisfiability problems in the infinite domain case can be found in [4].

APPROXIMATING THE SPANNING STAR FOREST PROBLEM AND ITS APPLICATION TO GENOMIC SEQUENCE ALIGNMENT*

C. THACH NGUYEN†, JIAN SHEN‡, MINMEI HOU§, LI SHENG¶, WEBB MILLER‖, AND LOUXIN ZHANG**

Abstract. This paper studies the algorithmic issues of the spanning star forest problem. We prove the following results: (1) There is a polynomial-time approximation scheme for planar graphs; (2) there is a polynomial-time $\frac{3}{5}$-approximation algorithm for graphs; (3) it is NP-hard to approximate the problem within ratio $\frac{259}{260}+\epsilon$ for graphs; (4) there is a linear-time algorithm to compute the maximum star forest of a weighted tree; (5) there is a polynomial-time $\frac{1}{2}$-approximation algorithm for weighted graphs. We also show how to apply this spanning star forest model to aligning multiple genomic sequences over a tandem duplication region.

Key words. dominating set, spanning star forest, approximation algorithm, genomic sequence alignment

1. Introduction.

A star is a tree in which some vertex is incident to each of the edges in the graph. Let G be a graph. A spanning star forest SF_G of a graph G is a spanning subgraph of G in which each connected component is a star. The size of SF_G is defined to be the number of edges in SF_G; if G is weighted, the size of SF_G is defined to be the sum of the weights of all edges in SF_G. Even in a graph, spanning star forests may have different sizes. As in any forest, the size of a spanning star forest of a graph G is equal to the number of vertices of G minus the number of stars in the star forest. We call the vertex that is incident to all edges the center of a star. A subset of vertices dominates G if every other vertex is adjacent to at least one vertex in the subset. It is not hard to see that the centers of the stars in a spanning star forest form a dominating set for G. Hence, finding a maximum spanning star forest of a graph is equivalent to finding a smallest dominating set. The latter is a fundamental problem in algorithmic graph theory.

Although the size of a spanning star forest of a graph and its relationship to the dominating number have been observed [13], the problem of finding a maximum

spanning star forest of a graph has yet to be well studied. Our work focuses on this algorithmic problem.

Our motivation for studying this problem comes from aligning multiple genomic sequences, a basic bioinformatics task in comparative genomics. A speciation is an evolutionary process that creates new species. Two genes from different species are orthologous if they diverged as the result of a speciation event. A duplication is an evolutionary event in which a genomic segment is copied and inserted at a different position. Two related genes could have diverged due to an intraspecies duplication event. To perform comparative genome analysis, it is desirable to produce a multispecies orthologous alignment, in which there is at most one row of sequence from a given species in each alignment block. The many-to-many orthologous relationships among duplicated genes causes a dramatic explosion of the alignment size when the multispecies alignment contains all combinations of pairwise orthologous relationships [16].

Currently, there are no good solutions to aligning duplication-rich genomic regions. The existing threaded blockset aligner (TBA) program screens out duplicated alignments and thus is not able to capture all pairwise orthologous relationships in a duplicated-gene cluster [7]. For example, using TBA, each human alpha-globin gene is aligned to only one rat alpha-globin gene, despite the fact that a human alpha-globin gene is actually orthologous to several rat alpha-globin genes, and those other alignments are lost. To control the size of the computed alignment blocks while guaranteeing the alignment quality, we propose to define a so-called alignment graph using the pairwise similarity of the given sequences and then utilize a maximum spanning star forest of the resulting alignment graph as a guide for building alignment blocks (see section 5 for details).

In addition, the spanning star forest problem has potential application in comparison of phylogenetic trees [6]. A directed star is defined to be outward if all arcs are from the center to a leaf. The directed version of the spanning star forest problem is, given a directed graph, to find a maximum spanning subgraph in which each connected component is an outward star. Such a directed version of the spanning star forest problem arises from the diversity problem in the automobile industry [1].

The dominating set problem is a well-known NP-hard problem. Because of this, the problem of finding a maximum spanning star forest is NP-hard in general but is polynomial-time solvable for trees and has a polynomial-time approximation scheme (PTAS) for planar graphs, as indicated in section 3.1. In section 3.2, we also present a polynomial-time algorithm of approximation ratio $\frac{3}{5}$ for any graph. On the other hand, we prove in section 3.3 that it is NP-hard to approximate the problem within ratio $\frac{259}{260} + \epsilon$ for any small $\epsilon > 0$.

For weighted graphs, the spanning star forest problem is not equivalent to the dominating set problem. In section 4, we present a dynamic programming algorithm for weighted trees; we also give a simple polynomial-time algorithm of approximation ratio $\frac{1}{2}$ for arbitrary weighted graphs.

Finally, in section 5, we show how to apply this spanning star forest model to aligning multiple genomic sequences over a duplicated region.

2. The spanning star forest problem. In this paper, we consider simple graphs that are undirected and connected, weighted or unweighted. We simply say that G is a graph if it is unweighted. A *star* is a tree having a vertex (called the center) incident to each of all edges in the graph. The center of a star S has the maximum degree. If a star has only two vertices, either vertex can be its center. A

star forest is a graph in which each component is a star.

Star forests have previously appeared in the literature on star arboricity [2]. The star arboricity of a graph G is the minimum number of star forests whose union contains all edges of G. Bounds on star arboricity have been established for several classes of graphs including planar graphs [3, 4, 11, 14].

The *size* of a graph G is the number of edges in G, and it is the sum of the edge weights if G is weighted. A *spanning star forest* of a graph G is a star forest that contains all the vertices of G. Different spanning star forests of G may have different sizes. In the rest of paper, we study the following algorithmic problem:

Spanning Star Forest.

INSTANCE: A (unweighted or weighted) graph $G = (V, E)$.

OBJECTIVE: Find a spanning star forest of G that has the largest size.

As we shall prove in the next section, this problem is NP-hard. Hence, we shall focus on developing approximation algorithms for it. An approximation algorithm for the spanning star forest problem has approximation ratio $r < 1$ if it always outputs a spanning star forest of size at least $r \cdot \mathrm{OPT}_{sf}(G)$ given a graph G, where $\mathrm{OPT}_{sf}(G)$ is the maximum size of a spanning star forest of G. We call such an algorithm an r-approximation algorithm.

3. Algorithms for unweighted graphs.

3.1. Spanning star forest and dominating set. The dominating set is one of the most important concepts in graph theory [15]. Given a graph $G = (V, E)$, a subset of vertices $D \subseteq V$ is called a *dominating set* if, for every $v \in V - D$, there is at least one vertex $u \in D$ that is adjacent to it, i.e., $(u, v) \in E$. Assume $D = \{v_1, v_2, \ldots, v_k\}$ is a k-vertex dominating set of G. For each $u \in V - D$, we select a unique vertex $v_u \in D$ such that $(u, v_u) \in E$ and associate the edge (u, v_u) to v_u. For each $d \in D$, all the associated edges of the form (v, d) give rise to a star S_d centered at d. Trivially, $\cup_{d \in D} S_d$ is a spanning star forest of G. As in any spanning forest of d components, there are $n - d$ edges in $\cup_{d \in D} S_d$, where n is the number of vertices in G. Note that from a dominating set, one may construct different spanning star forests with the same size.

Conversely, given a spanning star forest F of size k of G, the centers of the stars in F form a dominating set that contains $n - k$ vertices. In summary, we have the following simple fact.

LEMMA 3.1. *Let the largest size of a spanning star forest of a graph G be denoted by $\alpha(G)$ and the domination number of G be denoted by $\gamma(G)$. Then, $\alpha(G) = n - \gamma(G)$, where n is the order of G.*

This implies that finding a maximum spanning star forest of a graph is equivalent to finding a minimum dominating set. Therefore, as the dominating set problem [10], the spanning star forest problem can be solved in linear time for trees. The lemma also implies the following result.

THEOREM 3.2. *The spanning star forest problem has a PTAS for planar graphs.*

Proof. Recall that $\gamma(G)$ denotes the dominating number of a graph G. Since the dominating set problem has a PTAS for planar graphs [5], for any small $\epsilon > 0$, there is a polynomial-time algorithm $\mathcal{A}_\epsilon$ of approximation ratio $(1+\epsilon)$ for the problem. We first obtain a dominating set D_ϵ of at most $(1+\epsilon)\gamma(G)$ vertices by applying $\mathcal{A}_\epsilon$ to G. Then, we construct a spanning star forest F_ϵ from D_ϵ as described before Lemma 3.1. Since $\gamma(G) \leq \frac{n}{2}$ (Ore theorem; see [15], for example), by Lemma 3.1, F_ϵ has size

$$n - |D_\epsilon| \geq n - (1+\epsilon)\gamma(G) \geq (1-\epsilon)(n - \gamma(G)) = (1-\epsilon)\alpha(G).$$

Thus, F_ϵ is a $(1-\epsilon)$-approximation solution of the spanning star forest problem for G. ∎

3.2. A $\frac{3}{5}$-approximation algorithm. In this subsection, we mainly present a polynomial-time $\frac{3}{5}$-approximation algorithm using a known upper bound on the size of a dominating set in a graph.

THEOREM 3.3. *If there is a polynomial-time algorithm that finds a dominating set of at most $(\frac{1}{2}-\epsilon)n$ vertices given an n-vertex graph of minimum degree at least 2, then there is a polynomial-time $(\frac{1}{2}+\epsilon)$-approximation algorithm for the spanning star forest problem.*

Proof. Let $\mathcal{A}$ be the algorithm that outputs a dominating set of at most $(\frac{1}{2}-\epsilon)n$ vertices given an n-vertex graph of minimum degree 2. Consider a graph G. A vertex is called a support vertex if it is adjacent to some degree-1 vertices. Suppose G contains l degree-1 vertices. For simplicity, we first assume that G contains an even number of support vertices $u_1, u_2, \ldots, u_{2k}$, $k \geq 0$. Obviously, $l \geq 2k$. We first construct a graph H from G by removing all the degree-1 vertices and adding k vertices $v_1, v_2, \ldots, v_k$ and the following $2k$ edges

$$(u_{2i-1}, v_i), (u_{2i}, v_i), \qquad 1 \leq i \leq k.$$

Then, H has $n-l+k$ vertices of degree at least 2. Applying $\mathcal{A}$ to H, we obtain a dominating set D_H of at most $(\frac{1}{2}-\epsilon)(n-l+k)$ vertices. Now we construct a dominating set D_G of G as follows: for each i, if $v_i \in D_H$, we remove v_i from D_H and add u_{2i-1} and u_{2i} into the set; if $v_i \notin D_H$, then at least one of u_{2i-1} and u_{2i} is in D_H, and we add the other into the set. In other words, $D_G = (D_H - \{v_1, v_2, \ldots, v_k\}) \cup \{u_1, u_2, \ldots, u_{2k}\}$. It is easy to verify that D_G is a dominating set. By the construction of D_G, its size is at most

$$|D_H| + k \leq \left(\frac{1}{2}-\epsilon\right)(n-l+k) + k \leq \left(\frac{1}{2}-\epsilon\right)n + \left(\frac{1}{2}+\epsilon\right)k \tag{3.1}$$

since $l \geq 2k$. This implies that a spanning star forest F of G can be obtained from D_G with at least

$$n - |D_G| \geq n - \left[\left(\frac{1}{2}-\epsilon\right)n + \left(\frac{1}{2}+\epsilon\right)k\right] > \left(\frac{1}{2}+\epsilon\right)(n-2k) \tag{3.2}$$

edges. Since any dominating set of G must contain each support vertex or its degree-1 neighbors, $\gamma(G) \geq 2k$, and hence $\alpha(G) \leq n-2k$. Therefore, F contains at least $(\frac{1}{2}+\epsilon)\alpha(G)$ edges. This has proved that $\mathcal{A}$ can be extended into a ratio-$(\frac{1}{2}+\epsilon)$ approximation algorithm for the spanning star forest problem.

When G contains an odd number of support vertices $u_1, u_2, \ldots, u_{2k+1}$, $k \geq 1$, we modify the construction of H presented above by adding two new vertices x_{k+1} and x_{k+2} and three edges (u_{2k+1}, x_{k+1}), (x_{k+1}, x_{k+2}), (x_{k+2}, u_{2k+1}). Now, H has $n-l+k+2$ vertices. We derive dominating set D_G of G from the output dominating set D_H from the algorithm as

$$D_G = (D_H - \{v_1, v_2, \ldots, v_k, x_{k+1}, x_{k+2}\}) \cup \{u_1, u_2, \ldots, u_{2k+1}\}.$$

The size of D_G is at most $|D_H| + k$ and the inequalities (3.1) and (3.2) become

$$|D_H| + k \leq \left(\frac{1}{2}-\epsilon\right)(n-l+k+2) + k \leq \left(\frac{1}{2}-\epsilon\right)(n+1) + \left(\frac{1}{2}+\epsilon\right)k$$

and

$$n - |D_G| \geq n - \left[\left(\frac{1}{2} - \epsilon\right)(n+1) + \left(\frac{1}{2} + \epsilon\right)k\right] > \left(\frac{1}{2} + \epsilon\right)(n - 2k - 1),$$

respectively. Since $\alpha(G) \leq n - 2k - 1$, we have that the corresponding spanning star forest F contains at least $(\frac{1}{2} + \epsilon)\alpha(G)$ edges. Hence, the theorem also holds in this case. □

THEOREM 3.4. *There is a $\frac{3}{5}$-approximation algorithm for the spanning star forest problem.*

Proof. McCuaig and Shepherd proved that any n-vertex graph of minimum degree 2 has a dominating set of size at most $\frac{2}{5}n$ for any $n \geq 8$ (see [18]). We demonstrate that such a dominating set can be found in polynomial time by giving a different constructive proof of their theorem (see Appendix A). Hence, by Theorem 3.3, there is a polynomial-time algorithm of approximation ratio $\frac{1}{2} + \frac{1}{10} = \frac{3}{5}$ for the problem. □

The above result could be improved by using a better upper bound on $\gamma(G)$ for graphs G with large minimum degree $\delta(G)$. If $\delta(G) \geq 7$, $\gamma(G) \leq |V_G|[1 - \delta(G)(\frac{1}{\delta(G)+1})^{1+1/\delta(G)}]$ (Theorem 2.8 in [15]). Although such a bound is not true for $\delta(G) = 3$, $\gamma(G) \leq \frac{3}{8}|V_G|$ if $\delta(G) \geq 3$ (see [19]). If there is a polynomial-time algorithm that, given a graph of minimum degree at least 3, always outputs a dominating set of at most $\alpha|V_G|$, $\frac{3}{8} \leq \alpha < \frac{2}{5}$, the following theorem implies a better approximation algorithm.

THEOREM 3.5. *Let $\frac{3}{8} \leq \alpha < \frac{2}{5}$. If there is a polynomial-time algorithm that finds a dominating set of at most αn vertices given an n-vertex graph of minimum degree at least 3, then there is a polynomial-time $(\frac{4}{5} - \frac{1}{2}\alpha)$-approximation algorithm for the spanning star forest problem.*

Proof. Let $G = (V, E)$ be a graph with n vertices, where $n \geq 8$. We denote the subset of vertices of degree i by V_i, and hence $V = \cup_i V_i$. First, we construct a maximal subset $A_1 \subseteq V_1$ such that the distance between any two vertices in A_1 is at least 3. Recall that a vertex is called a support vertex if it is adjacent to some degree-1 vertices. It is easy to see that each support vertex is adjacent to a unique vertex in A_1. We next construct an $A_2 \subseteq V_2$ having the following property:

(i) Any pair of vertices in $A_1 \cup A_2$ has distance at least 3; and

(ii) A_2 is maximal; i.e., $A_2 \cup \{u\}$ does not satisfy condition (i) for any $u \in V_2 - A_2$.

Such a subset can be constructed recursively in polynomial time. Initially, we set $A_2 = \phi$ and add the vertices in V_2 one by one to A_2 subject to condition (i).

Let a_j denote the number of vertices in A_j, $j = 1, 2$. By condition (i), no vertex in G can dominate more than one vertex in $A_1 \cup A_2$. Thus,

$$\gamma(G) \geq a_1 + a_2. \tag{3.3}$$

For each vertex u, we use $N(u)$ to denote the set of its neighbors. Define $B_j = \cup_{u \in A_j} N(u)$, $j = 1, 2$. By the above observation, B_1 is identical to the set of the support vertices and $|B_1| = |A_1| = a_1$. Hence, for each $u \in V_1 - A_1$, there is a unique $v \in A_1$ such that the distance $d(u, v)$ between u and v is 2.

Since no two vertices in A_2 have a common neighbor, $|B_2| = 2a_2$. By the maximality property of A_2, for each $u \in V_2 - A_2$, there is some $v \in A_1 \cup A_2$ such that $d(u, v) \leq 2$. If $d(u, v)$=1, then $u \in B_1 \cup B_2$. If $d(u, v) = 2$, then u is adjacent to some vertex in $B_1 \cup B_2$. This implies that the disjoint union $B_1 \cup B_2$ dominates $V_1 \cup V_2$.

Now, we construct from G a graph G' such that $\delta(G') \geq 3$ as follows.

Step 1. Delete all the degree-1 vertices. For simplicity, we assume that 3 divides $|B_1|$. Partition B_1 into groups of 3 vertices each. For each group of vertices x, y, z, we add a new vertex u_{xyz} and three edges $u_{xyz}x$, $u_{xyz}y$, and $u_{xyz}z$. We also add edges xy, yz, and zx if any of them is not in G. In this way, x, y, x, u_{xyz} all have degree at least 3. After the completion of step 1, the number of vertices in the resulting graph is

$$n - |V_1| + \frac{|B_1|}{3} \leq n - |B_1| + \frac{|B_1|}{3} = n - \frac{2a_1}{3}.$$

Step 2. Add edge uv if it is not in G for every $u, v \in V_2 - A_2$. This makes each vertex in $V_2 - A$ have degree at least three if $|V_2 - A_2| \geq 4$. (In case $0 \leq |V_2 - A_2| \leq 3$, in the argument below $D \cup B_1 \cup V_2$ would be a dominating set of G, and so the right-hand side of inequality (3.4) would be replaced by $\alpha n + \frac{2}{3}(1-\alpha)a_1 + \frac{1}{3}(1-\alpha)a_2 + 3$.)

Step 3. Delete all vertices in A_2. For simplicity, again, we assume that 3 divides $|B_2|$. Partition B_2 into groups of 3 vertices each. For each group of three vertices x, y, z, add a new vertex u_{xyz} and three edges $u_{xyz}x$, $u_{xyz}y$, and $u_{xyz}z$. We also add edges xy, yz, and zx if any of them is not in G. As a result, x, y, z, u_{xyz} all have degree at least 3. After this step is done, the resulting graph G' has at most

$$n - \frac{2a_1}{3} - a_2 + \frac{|B_2|}{3} = n - \frac{2a_1}{3} - \frac{a_2}{3}$$

vertices and $\delta(G') \geq 3$.

By applying the polynomial-time algorithm to G', we obtain a dominating set D' of size at most $(n - \frac{2a_1}{3} - \frac{a_2}{3})\alpha$. Since $B_1 \cup B_2$ dominates $V_1 \cup V_2$, $D' \cup B_1 \cup B_2$ induces a dominating set D_1 for G: For each group x, y, z in steps 1 and 3, if u_{xyz} is in D', we replace it with x, y, z. The resulting dominating set D_1 is of size at most

$$|D'| + \frac{2(|B_1| + |B_2|)}{3} \leq \alpha n + \frac{2(1-\alpha)}{3}a_1 + \frac{4-\alpha}{3}a_2. \tag{3.4}$$

Notice that B_1 is the set of support vertices and $|B_1| = a_1$. Applying inequality (3.1) with the McCuaig–Shepherd bound ($\frac{1}{2} - \epsilon = \frac{2}{5}$, $k = \frac{a_1}{2}$), we can also obtain a dominating set D_2 of size at most $\frac{2}{5}n + \frac{3}{10}a_1$. By selecting the smaller one between D_1 and D_2, we obtain a dominating set D having size at most

$$\frac{1}{2}(|D_1| + |D_2|) \leq \frac{5\alpha + 2}{10}n + \frac{29 - 20\alpha}{60}a_1 + \frac{4-\alpha}{6}a_2.$$

From D, by inequality (3.2), we construct a desired spanning star forest that has at least

$$\begin{aligned} & n - |D| \\ \geq\ & (\tfrac{4}{5} - \tfrac{1}{2}\alpha)n - \tfrac{29-20\alpha}{60}a_1 - \tfrac{4-\alpha}{6}a_2 \\ \geq\ & (\tfrac{4}{5} - \tfrac{1}{2}\alpha)(n - a_1 - a_2) \\ \geq\ & (\tfrac{4}{5} - \tfrac{1}{2}\alpha)(n - \gamma(G)) \end{aligned} \tag{3.5}$$

edges since $\frac{4}{5} - \frac{1}{2}\alpha \geq \frac{29-20\alpha}{60}$, $\frac{4}{5} - \frac{1}{2}\alpha \geq \frac{4-\alpha}{6}$, and $\gamma(G) \geq a_1 + a_2$. This shows the fact stated in the theorem.

When 3 does not divide $|B_1|$ and $|B_2|$, we can modify the above argument in the same way as we have done in the proof of Theorem 3.4. For $j = 1, 2$, if $|B_j| \equiv 2 \pmod 3$, we add two more vertices to form a 4-vertex clique with the last two

vertices in B_j; if $|B_j| \equiv 1 \pmod 3$, we add three more vertices to form a 4-vertex clique with the last vertex. By this modification, the inequality (3.5) becomes

$$n - |D| \geq \left(\frac{4}{5} - \frac{1}{2}\alpha\right)(n - \gamma(G)) - \frac{6 - r_1 - r_2}{6}(4\alpha - 1),$$

where $r_j \equiv |B_j| \pmod 3$, $j = 1, 2$. Since $n - \gamma(G) \geq n/2$, the fact stated in the theorem remains true. □

3.3. Hardness of approximation. We have shown that the spanning star forest problem can be approximated within a constant ratio in polynomial time. On the other hand, the dominating set problem cannot be approximated within $(1-\epsilon)\ln n$ for any ϵ unless $NP \subset DTIME(n^{\log\log n})$ [17, 12]. Hence, intuitively, the spanning star forest problem should not be approximated within a large constant ratio in polynomial time. Now, we prove this fact rigorously.

THEOREM 3.6. *The spanning star forest problem cannot be approximated within a ratio* $\frac{259}{260} + \epsilon$ *in polynomial time for any* $\epsilon > 0$ *unless* $P = NP$.

Proof. We prove this fact using a reduction from the VERTEX COVER problem. Recall that the VERTEX COVER problem is to find the smallest subset $U \subset V$ such that every edge has at least one endpoint in U given a graph $G = (V, E)$. It is known that this problem cannot be approximated within a ratio $\frac{53}{52} - \epsilon$ for 4 regular graphs unless $P = NP$ [9]. Given a 4-regular graph $G = (V_G, E_G)$, we construct a graph $H = (V_H, E_H)$ from G by adding a length-2 path parallel to each edge in G. Without loss of generality, we assume that G is connected and not a tree. Formally,

$$V_H = V_G \cup \{v_e |\ e \in E_G\},$$
$$E_H = E_G \cup \{(x, v_e), (v_e, y) |\ e = (x, y) \in E_G\}.$$

It is easy to see that the following facts hold:

> ($\star$) For any $V \subset V_G$, if it is a vertex cover set of G, then it is a dominating set of H. Conversely, for each subset $V \subset V_H$, if it is a dominating set of H, then $(V \cap V_G) \cup \{x \in V_G \mid v_e \in V$ and $e = (x, y) \in E$ and $x < y\} \subseteq V_G$ is a vertex cover of G.

Let $\mathrm{OPT}_{vc}(G)$, $\mathrm{OPT}_d(H)$, and $\mathrm{OPT}_{sf}(H)$ denote the minimum size of a vertex cover of G, the minimum size of a dominating set of H, and the maximum size of a spanning star forest of H, respectively. Then, the above facts imply that $\mathrm{OPT}_d(H) = \mathrm{OPT}_{vc}(G)$. Since G is 4-regular and connected,

$$|E_G| \leq 4\mathrm{OPT}_{vc}(G).$$

By the handshaking theorem,

$$|V_G| = \frac{1}{2}|E_G| \leq 2\mathrm{OPT}_{vc}(G).$$

Therefore,

$$\begin{aligned} & \mathrm{OPT}_{sf}(H) \\ = \ & |V_H| - \mathrm{OPT}_d(H) = (|V_G| + |E_G|) - \mathrm{OPT}_d(H) \\ = \ & (|V_G| + |E_G|) - \mathrm{OPT}_{vc}(G) \\ \leq \ & 5\mathrm{OPT}_{vc}(G). \end{aligned}$$

Assume S is a spanning star forest of H. If S contains k stars, then the size $|S|$ of S is $|V_H| - k$. In addition, these k centers of S form a dominating set of H and

hence induce a vertex cover V_S of size at most k of G by the fact $(\star)$. Hence, since $\mathrm{OPT}_d(H) = \mathrm{OPT}_{vc}(G)$,

$$|V_S| - \mathrm{OPT}_{vc}(G) \le k - \mathrm{OPT}_d(H) = k - (|V_H| - \mathrm{OPT}_{sf}(H)) = \mathrm{OPT}_{sf}(H) - |S|.$$

Thus, if $|S|$ is a ratio-$(1 - \frac{1}{5} \cdot \frac{1}{52} + \epsilon)$ approximation of the spanning star forest problem for H, where $\epsilon > 0$, i.e., $|S| \ge (1 - \frac{1}{5} \cdot \frac{1}{52} + \epsilon)\mathrm{OPT}_{sf}(H)$, then the resulting vertex cover set V_S satisfies

$$|V_S| - \mathrm{OPT}_{vc}(G) \le \left(\frac{1}{5} \cdot \frac{1}{53} - \epsilon\right) \mathrm{OPT}_{sf}(H) \le \left(\frac{1}{52} - 5\epsilon\right) \mathrm{OPT}_{vc}(G).$$

In other words, V_S is a ratio-$(\frac{53}{52} - 5\epsilon)$ approximation of the VERTEX COVER problem for G. This implies that the spanning star forest problem cannot be approximated within a ratio $1 - \frac{1}{5} \cdot \frac{1}{52} + \epsilon = \frac{259}{260} + \epsilon$ in polynomial time unless $P = NP$. □

4. Algorithms for weighted graphs.

4.1. A remark on the maximum spanning star forests. In a connected weighted graph, every maximum spanning star forest may contain some isolated vertices. For example, the graph shown in Figure 4.1 has a unique spanning star graph with the maximum weight 7. Therefore, when we design an algorithm for the spanning star forest problem for connected weighted graphs, we have to consider the start forests with isolated vertices.

4.2. A linear-time algorithm for weighted trees. Trees are the simplest connected graphs. In this subsection, we present a linear-time algorithm for finding the maximum spanning star forest of a tree.

Given a tree T, we first root T at an arbitrary vertex r and consider each edge (u, v) as a directed edge from the endpoint closer to the root to the other endpoint. In the rest of this subsection, when we mention that (u, v) is an edge, we mean that u is closer to the root; we say that u is the parent of v or v is a child of u if (u, v) is an edge in the rooted tree. Obviously, in a star forest of T, the root can be a center of a star, a leaf of a star centered at one of its children, or an isolated vertex. For each vertex u of T, we let $T(u)$ be the subtree rooted at u and define the following three numbers:

$\Phi(u)$: The maximum weight of a spanning star forest of $T(u)$ in which u is a center of a multiple-vertex star.
$\Psi(u)$: The maximum weight of a spanning star forest of $T(u)$ in which u is a leaf of a multiple-vertex star.
$\Omega(u)$: The maximum weight of a spanning star forest of $T(u)$ in which u is an isolated node.

First, these three numbers can be computed through recurrence formulas as shown below.

LEMMA 4.1. *Let $C(u)$ be the set of the children of u. Then,*

$$\begin{aligned}
\Phi(u) &= \textstyle\sum_{v \in C(u)} \Delta(v) \\
&\quad - \min_{v \in C(u)} (\Delta(v) - \Omega(v) - w(uv)), \\
\Psi(u) &= \max_{v \in C(u)} [w(uv) + \max\{\Phi(v), \Omega(v)\} \\
&\quad + \textstyle\sum_{x \in C(u) - \{v\}} \max\{\Phi(x), \Psi(x), \Omega(x)\}], \\
\Omega(u) &= \textstyle\sum_{v \in C(u)} \max\{\Phi(v), \Psi(v), \Omega(v)\},
\end{aligned}$$

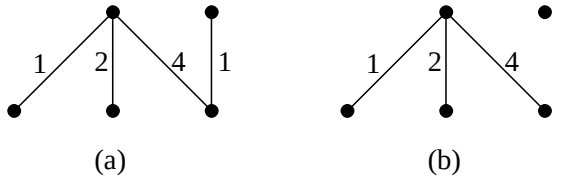

FIG. 4.1. (a) *A weighted graph;* (b) *The unique maximum spanning star forest with an isolated vertex.*

where $\Delta(v) = \max\{\Phi(v), \Psi(v), \Omega(v) + w(uv)\}$.

Proof. For any vertex u of T, let $SFR(u)$ be a star forest of $T(u)$ that has a maximum weight $\Phi(u)$, over all the star forests in which u is a center of a star S_u. For any $v \in C(u)$, we use $SFR(u)|_v$ to denote the restriction of $SFR(u)$ in the subtree $T(v)$ rooted at v and define $\Delta(v) = \max\{\Phi(v), \Psi(v), \Omega(v) + w(uv)\}$. We consider the following cases.

Case 1. *The star S_u centered at u contains at least two leaves.* If v is a leaf of the star S_u centered at u in $SFR(u)$, then $SFR(u)|_v$ must be a star forest of $T(v)$ that has the maximum weight $\Omega(v)$, over all the star forests in which v is an isolated vertex. Moreover, $w(uv) + \Omega(v) \geq \Phi(v), \Psi(v)$. Equivalently, $\Delta(v) = w(uv) + \Omega(v)$. Otherwise, we could obtain a star forest with larger weight from $SFR(u)$ by removing edge uv and replacing $SFR(u)|_v$ by a star forest (of $T(v)$) in which v is not isolated, contradicting our assumption that $SFR(u)$ has the maximum weight.

If v is a not a leaf of the star S_u, then $SFR(u)|_v$ is a star forest (of $T(v)$) with weight $\Delta(v)$, which is $\max\{\Psi(v), \Phi(v)\}$. Otherwise, we can obtain a star forest of $T(u)$ with a larger weight by replacing $SFR(u)|_v$ by another star forest of weight $\Omega(v)$ and adding the edge uv into $T(u)$.

This implies that $\Phi(u) = \sum_{v \in C(u)} \Delta(v) = \sum_{v \in C(u)} \max\{\Phi(v), \Psi(v), \Omega(v) + w(uv)\}$. For any $v \in C(u)$, by definition, $\Delta(v) - w(uv) - \Omega(v) \geq 0$. For any v that is a leaf of the star S_u, by the above argument, $\Delta(v) = w(uv) + \Omega(v)$. Therefore, in this case, $\min_{v \in C(u)}(\Delta(v) - w(uv) - \Omega(v)) = 0$, and hence

$$\begin{aligned} \Phi(u) &= \sum_{v \in C(u)} \max\{\Phi(v), \Psi(v), \Omega(v) + w(uv)\} \\ &\quad - \min_{v \in C(u)}(\Delta(v) - w(uv) - \Omega(v)). \end{aligned}$$

Case 2. *The star S_u centered at u contains only one leaf.* Let v' be the unique leaf in S_u. Then, for any $v \in C(u)$, we have $\Delta(v) - w(uv) - \Omega(v) \geq \Delta(v') - w(uv') - \Omega(v')$. Otherwise, we could obtain a star forest of a larger weight from $SRF(u)$ by the following operations:

(a) add edge uv,
(b) delete uv',
(c) replace $SFR(u)|_v$ by a star forest (of $T(v)$) in which v is isolated, and
(d) replace $SFR(u)|_{v'}$ by the star forest (of $T(v')$ with the maximum weight $\Delta(v')$.

Hence, the weight $\Phi(u)$ of the star forest $SFR(u)$ is equal to

$$\begin{aligned} & \sum_{v \in C(u) - \{v'\}} \Delta(v) + (w(uv') + \Omega(v')) \\ = \; & \sum_{v \in C(u)} \Delta(v) - (\Delta(v') - w(uv') - \Omega(v')) \\ = \; & \sum_{v \in C(u)} \Delta(v) - \min_{v \in C(u)}(\Delta(v) - w(uv) - \Omega(v)). \end{aligned}$$

This proves the recurrence formula for $\Phi(u)$.

Let SFL be a star forest (of $T(u)$) in which u is a leaf of a star S_u centered at one of its children, $v \in C(u)$. Then, $SFL|_v$ is a star forest (of $T(v)$) in which v is isolated or the center of a star. Hence, $SFL|_v$ has weight $\max\{\Phi(v), \Omega(v)\}$. For any other $v' \neq v$ in $C(u)$, $SFL|_{v'}$ is a star forest (of $T(v')$) in which v' can be a center of a star, a leaf of a star, or an isolated vertex, and so $SFL|_{v'}$ has weight $\Delta(v')$. Hence,

$$\begin{aligned}\Psi(u) &= \max_{v\in C(u)}[w(uv) + \max\{\Phi(v), \Omega(v)\} \\ &\quad + \textstyle\sum_{x\in C(u)-\{v\}} \max\{\Phi(x), \Psi(x), \Omega(x)\}].\end{aligned}$$

This proves the recurrence formula for $\Psi(u)$.

Let $SFI(u)$ be the star forest (of $T(u)$) with the maximum weight $\Omega(u)$ in which u is isolated. Then, for each $v \in C(u)$, $SFI(u)|_v$ has to be a star forest of $T(v)$ with the maximum weight $\Delta(v)$. Otherwise, $SFI(u)$ does not have the maximum weight $\Omega(u)$. Therefore, the recurrence formula for $\Omega(u)$ is correct. This finishes the proof of the lemma. □

THEOREM 4.2. *There is a linear-time algorithm that outputs a star forest with the maximum weight given a weighted tree.*

Proof. Lemma 4.1 implies a dynamic programming approach for computing the maximum star forest of a weight tree rooted at r. For each u in the tree, compute $\Psi(u)$, $\Phi(u)$, $\Omega(u)$ from the corresponding numbers at its children according to the recurrence formulas given in the lemma in linear time.

After $\Phi(r)$, $\Psi(r)$, $\Omega(r)$ are computed, the maximum star forest can be found by backtracking along the computation path. We call a star forest $SF(u)$ in which u is a center of a star, a leaf of star, or an isolated vertex a type-1, type-2, or type-3 star forest. The goal of finding the maximum star forest can be achieved by introducing backtracking pointers r-ptr, l-ptr, i-ptr, which are used to construct the maximum star forest of type-1, type-2, and type-3 at each vertex. At each vertex u, r-ptr(u) specifies (a) which child of u is in the star S_u centered at u, and (b) if $v \in C(u)$ is not in the star S_u, the type of the restriction star forest on $T(v)$; l-ptr(u) specifies (a) which child of u is the center of the star containing u, and (b) the type of the restriction star forest on $T(v)$ for each $v \in C(u)$; i-ptr(u) specifies the type of the restriction star forest on $T(v)$ for each $v \in C(u)$. Obviously, with these backtracking pointers, the maximum star forest can be found in linear time. This finishes the proof. □

4.3. A $\frac{1}{2}$-approximation algorithm. For an arbitrary weighted graph, we find a spanning star forest using the following algorithm:

1. Find a maximum spanning tree T_G of the given graph G.
2. Compute a maximum spanning star forest SF_G of T_G.

Given a positively weighted connected graph, its maximum spanning tree can be computed in polynomial time. For example, we can use Kruskal's algorithm for this purpose. Since Step 2 also takes polynomial time, the above method can be executed in polynomial time.

Let $\mathrm{OPT}_{sf}(G)$ and $\mathrm{OPT}_t(G)$ be the maximum weight of a spanning star forest and a spanning tree of G, respectively. Since G is connected, any spanning star forest can be extended into a spanning tree by adding some "bridge" edges between the stars. Hence, $\mathrm{OPT}_{sf}(G) \leq \mathrm{OPT}_t(G)$.

Consider a rooted weighted tree T. We call a node an odd node if the unique path from the root to it has an odd number of edges and an even node otherwise. Deleting from T all edges from an odd node to an even node gives a spanning star forest of T; deleting from T all edges from an even node to an odd node gives another

spanning star forest of T. In addition, these two resulting spanning star forests are edge-disjoint and the weight of one of these two spanning star forests is at least half of the weight of T. Hence,

$$w(SF_G) \geq \frac{1}{2}w(T_G) = \frac{1}{2}\mathrm{OPT}_t(G) \geq \frac{1}{2}\mathrm{OPT}_{sf}(G).$$

Therefore, the above algorithm has approximation ratio $\frac{1}{2}$. This has proved the following theorem.

THEOREM 4.3. *The spanning star forest problem can be approximated within ratio $\frac{1}{2}$ in polynomial time for arbitrary weighted graphs.*

5. Application to aligning genomic sequences. To align multiple genomic sequences from different species, the TBA program [7] works on the phylogenetic tree T over the species in a bottom-up fashion. At each internal node v of T, the program outputs a set of alignments of multiple segments (called blocks) in the given sequences by merging the blocks generated at the left and right children of v through pairwise alignments between sequences contained in left and right children. The program stops and outputs a set of blocks (called a blockset) at the root of T. The output blockset can be considered as a packing of the pairwise alignments between sequence segments generated at each internal node.

Tandem duplication is an evolutionary event in which a genomic segment is duplicated into several adjacent copies. It is believed to be a major mechanism for producing large gene clusters. In the human and mouse genomes, a gene family may have dozens or even hundreds of members due to tandem duplication. Assume we align a set of genomes. Consider a gene family that has multiple homologous genes in each species. At an internal node v of T, in the worst case, an alignment program will generate a pairwise alignment between every pair of the orthologous gene sequences contained in the left and right subtrees, respectively. As a result, every pair of blocks that contain the orthologous gene sequences and that are generated at the left and right children of v, respectively, will be merged into a larger block. Hence, the number of blocks that contain the gene sequences is equal to the product of the numbers of blocks generated in the left and right children of v. When the program stops at the root of T, it will output a blockset of an exponentially large size.

Currently, there are no good solutions to aligning duplication-rich genomic regions. The existing TBA program screens out duplicated alignments and thus is not able to capture all pairwise orthologous relationships in a duplicated-gene cluster. An example of this deficiency, involving the human and rat alpha-globin genes, is described in the introduction.

One way to avoid exponential growth of the number of blocks is to generate a linear number of blocks at each internal node by carefully selecting the blocks to be merged. More specifically, for the node v, we use B_v to denote the blockset generated at v and $|B_v|$ to denote the number of blocks contained in B_v. Obviously, when v is a leaf in T, $B_v = \phi$. Let v' and v'' be the left and right children of v, respectively. A size explosion can be avoided by arranging that the blockset B_v contains at most $|B_{v'}| + |B_{v''}| + c$ blocks, where c is a constant independent of $|B_{v'}|$ and $|B_{v''}|$. In this way, for a gene family having g_i copies in species i of N species, the final output blockset will contain at most $\sum_{i=1}^{N} g_i + cN$ blocks over the gene family.

Let P be the set of pairwise alignments generated at v. We denote an alignment in P with rows a and b by $a.b$, where a and b are segments of sequences in the left

and right subtree, respectively. Define

$$L_P = \{a \mid a.b \in P \text{ for some } b\}$$

and

$$R_P = \{b \mid a.b \in P \text{ for some } a\}.$$

Our method selects blocks in $B_{v'}$ and $B_{v''}$ to merge according to the following theory.

We first define a weighted bipartite graph G_v with vertex bipartition (V', V''). The vertices in V' correspond one-to-one to the blocks in $B_{v'}$ and the rows in L_p that are not contained in any blocks in $B_{v'}$; the vertices in V'' correspond to the blocks in $B_{v''}$ and the rows in R_P in the same way. For simplicity, we considered the rows in L_P and R_P as trivial blocks. For each $x \in V'$, $y \in V''$, there is an edge between x and y if and only if there is a pairwise alignment $a.b \in P$ such that a and b appear in the blocks corresponding to x and y, respectively, called a *reference alignment* of the blocks. In general, there are multiple reference alignments for each pair of blocks. Hence, the weight of the edge (x, y) is then defined to be the maximum alignment score over all the reference alignments of the blocks corresponding to x and y. In practice, the rows in P can partially overlap with some rows of a block in $B_{v'} \cup B_{v''}$. Here, however, we assume a row in P is either contained in or disjoint from any row in $B_{v'} \cup B_{v''}$. Since each genomic sequence may contain many different orthologous sequences, the resulting bipartite graph G_v has more than one connected component in general. By construction, none of the connected components in the graph are singletons.

To control the size of the output blockset, we make use of a maximum spanning star forest of G_v to merge the blocks $B_{v'}$ and $B_{v''}$ as shown in the *Block-Merging Algorithm*. One desired property of a spanning star forest SF of a graph G is that each edge has at least one degree-1 endpoint in SF. Such a property is critical for controlling the size of the output blockset as shown below.

BLOCK-MERGING ALGORITHM

Input: $B_{v'}$, $B_{v''}$, and P.

0. $B_v = \phi$;
1. Construct the graph G_v by using $B_{v'}$, $B_{v''}$, and P;
2. Heuristically compute a maximum spanning star forest SF of G_v;
3. For each edge (x, y) in SF, merge the blocks correspondent to x and y, and add the resulting block into B_v;
4. Output B_v.

THEOREM 5.1. *The Block-Merging Algorithm outputs a blockset satisfying the following properties:*

Full coverage property. *Any position covered by a pairwise alignment produced during the aligning process appears in some block in the output blockset.*

Nonredundancy property. *Each block in the output blockset contains a unique row that does not appear in any other blocks.*

Proof. The full coverage property is obvious. We prove the nonredundancy property by induction on the depth of an internal node. Let v be an internal node. If the children v' and v'' of v are leaves, then $B_{v'}$ and $B_{v''}$ are empty; hence each vertex of the bipartite graph G_v corresponds to a segment in some given sequence. For each edge $e = (x, y)$ in the spanning star forest of G_v computed in step 3 of the algorithm, one of x and y, say, x, is of degree 1 and hence incident only to e. Then, the segment corresponding to x is covered only by the block derived from e through merging the two segments corresponding to x and y, respectively. Therefore, each block in B_v has a unique row.

If at least one of v' and v'' is not a leaf, by induction, we assume that both $B_{v'}$ and $B_{v''}$ satisfy the nonredundancy property if they are not empty. Consider a block $Z \in B_v$ obtained through an edge (x, y) of the spanning star forest found in step 3 of the algorithm. Without loss of generality, we assume that x is of degree 1 in the spanning star forest. If x corresponds to a block in $B_{v'}$, then the unique row in the block corresponding to x appears only in Z among all the blocks in B_v. If x corresponds to a row R_x of a pairwise alignment in P, then, by the definition of G_v, R_x is not contained in any block in $B_{v'}$ and $B_{v''}$ and hence appears uniquely in Z among all the blocks in B_v. This concludes the proof. □

Theorem 5.1 can be used to estimate the base-pair size $||B||$ of the blockset B generated by the algorithm. Let N be the number of sequences in the input genomic sequence set S. Since any pair of orthologous sequence segments s and s' can be assumed to have more than 50% identical bases, they have roughly equal length; i.e., $|s| = \Theta(|s'|)$. For each block $X \in B$, we use $r_{unique}(X)$ to denote the unique row in X. By assumption, the base-pair size $|X|$ of X is at most $N\Theta(|r_{unique}(X)|)$ since X has at most N rows. Therefore, using the fact that $r_{unique}(X)$'s are disjoint segments of the input sequences in S, we have

$$||B|| = \sum_{X \in B} |X| \leq \sum_{X \in B} N\Theta(|r_{unique}(X)|) \leq N\Theta\left(\sum_{s \in S} |s|\right).$$

In other words, the base-pair size of the output blockset is at most N times the base-pair size of the input sequence set.

An initial test shows that our proposed approach is quite promising. For example, we consider the alpha-globin gene cluster that has as many as 91 genes in 20 mammals. Both alpha-related and theta-related genes have clear many-to-many homologous relationships. When aligning the alpha-globin gene cluster region (of total length 3.9 Mbytes) in 20 mammals, a straightforward strategy meeting the two requirements described in the last theorem produced a blockset of size over 900 Mbytes, but the preliminary implementation of our approach can reduce the alignment size to less than 10 Mbytes with little sacrifice of the alignment quality.

6. Conclusions. In this paper, we initiate the algorithmic study of the spanning star forest problem. In particular, we present a $\frac{3}{5}$-approximation algorithm for graphs and a $\frac{1}{2}$-approximation algorithm for weighted graphs. In contrast, we also prove that it is NP-hard to approximate the problem within a ratio $\frac{259}{260}+\epsilon$. This study raises several research questions for future investigation. For example, how to obtain an approximation algorithm with better ratio and how to improve the inapproximability result are two interesting open problems. After this work was submitted, a polynomial-time algorithm with approximation ratio 0.71 was presented in [8]. Another interesting question is how to design approximation algorithms for the spanning star forest problem for directed and weighted graphs.

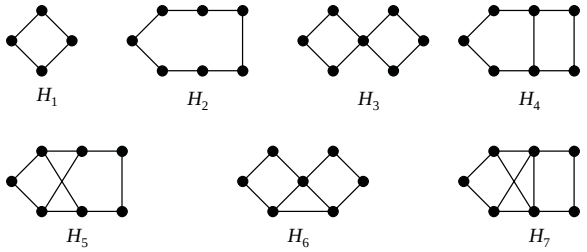

FIG. A.1. *Seven bad graphs whose minimum dominating sets have size larger than* $2n/5$ *(reproduced from* [18]*; reprinted with permission of John Wiley & Sons, Inc.).*

Appendix A. Finding a dominating set of size at most $2n/5$.

THEOREM A.1. *Let* $G = (V, E)$ *be a connected graph such that each vertex has degree at least* 2*. If* G *is not one of the* 7 *graphs in Figure* A.1 *(called* bad graphs*), then* $\gamma(G) \leq \frac{2}{5}|V|$*. Moreover, such a dominating set can be found in* $O(|E|^2|V|)$ *time.*

Proof. We use $\delta(G)$ to denote the minimum degree of a vertex in $G = (V, E)$. We prove by induction on $|V|$. It is easy to check that, for $|V| \leq 15$, we can always find a desired dominating set. Now assume that $|V| > 15$ and that the theorem holds for all graphs G' that have a smaller number of vertices than G and that are not listed in Figure A.1. We show how to construct a dominating set of G whose size is at most $\frac{2}{5}|V|$.

If G is not edge-minimal with respect to connectedness and with a minimum degree of 2, we keep deleting edges. Therefore, in the following, we assume that G is edge-minimal with respect to these conditions.

Let $B(G) = \{u \in V \mid d(u) > 2\}$. If $|B(G)| = 0$, then G is a cycle. In this case, a dominating set of G can be found by numbering its vertices starting from 0 and choosing all the vertices whose indices is divisible by 3. It is readily verified that such a dominating set contains at most $\frac{2}{5}|V|$ vertices for any cycles that are different from H_1 and H_2.

If $|B(G)| = 1$, then G is a union of cycles that intersect at the unique vertex $u \in B(G)$. Let $\mathcal{A}$, $\mathcal{B}$, $\mathcal{C}$ be the sets of cycles of length 4, 7, and another length, respectively. Furthermore, let $\mathcal{C} = \{C_1, C_2, \ldots, C_t\}$. A dominating set of G can be constructed by the following steps: (i) Construct a dominating set of size 2 that contains u for each cycle in $\mathcal{A}$; (ii) construct a dominating set of size 3 that contains u for each cycle in $\mathcal{B}$; (iii) construct a dominating set that contains u and is of size at most $\frac{2}{5}|C_i|$ for each i; (iv) merge all the dominating sets. The size of this dominating set is

$$1 + |\mathcal{A}| + 2|\mathcal{B}| + \sum_{i=1}^{t} \left(\frac{2}{5} n_i - 1 \right) = 1 + |\mathcal{A}| + 2|\mathcal{B}| + \frac{2}{5} \sum_{i=1}^{t} n_i - t,$$

in which n_i denotes the number of vertices in C_i. Noting that $|V| = 3|\mathcal{A}| + 6|\mathcal{B}| + \sum_{i=1}^{t} n_i - t + 1$, we have that the size of the constructed dominating set is larger than $\frac{2}{5}|V|$ only if $G = H_3$, which contains exactly two length-4 cycles.

Now assume that $|B(G)| \geq 2$. In the following, we call G a good graph if it is not listed in Figure A.1. We consider the following cases.

Case 1. *There is an edge* uv *between two vertices* u *and* v *in* $B(G)$. Due to the minimality of G, this edge must be a bridge of G. Let G_u and G_v be the components

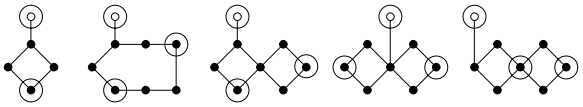

FIG. A.2. *A graph formed by adding a vertex to a bad graph contains one of these graphs. The white vertex is the additional vertex. The circles mark the vertices in a dominating set of each graph.*

of $G - uv$ containing u and v, respectively. Then both G_u and G_v are connected and $\delta(G_u) \geq 2$ and $\delta(G_v) \geq 2$.

Case 1.1. *Both G_u and G_v are good.* By hypothesis, we can find dominating sets D_u and D_v of G_u and G_v such that $D_u \leq \frac{2}{5}|V_u|$ and $D_v \leq \frac{2}{5}|V_v|$. $D_u \cup D_v$ contains at most $\frac{2}{5}|V|$ vertices and dominates G.

Case 1.2. *Only one, say, G_v is a good graph.* Then G_u is a bad graph. Let $G_u = (V_u, E_u)$, and let G_u^* be the graph with vertex set $V_u^* = V_u \cup \{v\}$ and edge set $E_u^* = E_u \cup \{uv\}$. We also let G_v^* be the graph constructed by (i) choosing a neighbor v' of v in G_v; (ii) joining v' with all other neighbors of v in G_v; and (iii) deleting v. Then, G_v^* is connected and $\delta(G_v^*) \geq 2$. Since G_u is a bad graph, G_u^* contains one of the graphs in Figure A.2. Note that H_4, H_5, H_7 in Figure A.1 contain H_2 and H_6 contains H_3, and so we need only to consider the cases in Figure A.2. From this figure, we can see that G_u^* has a dominating set D_u^* that contains v and satisfies that $|D_u^*| \leq \frac{2}{5}|V_u^*|$. Since G_u is bad and $|V| \geq 16$, G_v^* contains at least eight vertices, and so it is good. By induction, it has a dominating set D_v^* of size at most $\frac{2}{5}|V_v^*|$. Then $D_u^* \cup D_v^*$ form a dominating set of G whose size is at most $\frac{2}{5}|V|$.

Case 2. *There is no edge between any two vertices in $B(G)$.* In the following, we will use 2-*cycles* to refer to the cycles that contain exactly one vertex in $B(G)$, and this unique vertex is called the *endpoint* of the cycle. We will also use 2-*paths* to refer to the paths whose endpoints are in $B(G)$ and in which other vertices are of degree 2.

If there is a path $vv_1v_2v_3v'$ in G such that $v \neq v'$ and $d(v_1) = d(v_2) = d(v_3) = 2$, we construct a graph G' by removing v_1, v_2, v_3 and adding the edge vv' if $vv' \notin E(G)$. Clearly G' is connected and $\delta(G') \geq 2$. Since $|V| > 16$, G' must be good. Hence, G' has a dominating set D' of size at most $\frac{2}{5}|V'|$. We construct a dominating set D for G as follows: (i) if $v \in D'$, then $D = D' \cup \{v_3\}$; (ii) if $v' \in D$, then $D = D' \cup \{v_1\}$; and (iii) if neither v nor v' is in D', then $D = D' \cup \{v_2\}$. Then $|D| = |D'| + 1 \leq \frac{2}{5}(|V'| + 3) = \frac{2}{5}|V|$. Now assume that all 2-cycles in G are of length at most 4 and all 2-paths in G are of length at most 3.

Case 2.1. *G contains a 2-cycle of length 4 whose endpoint's degree is larger than 3.* Let this cycle be $vv_1v_2v_3v$, where v is the endpoint. A graph G' is formed by deleting v_1, v_2, and v_3 from G. Since G' contains at least thirteen vertices, it is good and has a dominating set D' of size at most $\frac{2}{5}|V'|$. Then $D' \cup \{v_2\}$ is a dominating set of G whose size is smaller than $\frac{2}{5}(|V'| + 3) = \frac{2}{5}|V|$.

Case 2.2. *Every 2-cycle of length 4 in G has an endpoint of degree 3.* Consider such a cycle $vv_1v_2v_3v$, where v is the endpoint. The other neighbor v' of v has degree 2, since there is no edge between two vertices in $B(G)$. The subgraph of G induced by $\{v, v_1, v_2, v_3, v'\}$ is called a 4-cluster and v' is called the *anchor* of this cluster.

In this case, we assume that G contains a 4-cluster, say, $C = \{v, v_1, v_2, v_3, v'\}$, with anchor v' such that the neighbor u of v' not in C has degree larger than 2 in G, and we define $G' = G - C$. Then G' is a connected graph with $\delta(G) \geq 2$. Since G' contains at least eleven vertices, G' is good, and it has a dominating set D' such that

$|D'| \leq \frac{2}{5}|V'|$. Furthermore, $D = D' \cup \{v, v_2\}$ is a dominating set of G and $|D| \leq \frac{2}{5}|V|$.

Case 2.3. *For every* 4*-cluster, its anchor's neighbor that is not in the cluster is of degree* 2. We define a 2-cycle of length 3 in G to be a 3-cluster, and the anchor of a 3-cluster is the endpoint of the cluster. Note that we define the anchor of a 3-cluster differently. Finally, each vertex u such that $d(u) > 2$ and u is not an endpoint of any 2-cycles is considered as a 1-cluster with u as the anchor.

If there is an edge joining two anchors, the two anchors must be that of two 4-clusters since other cases have been considered in Case 2.2. In this case, this graph has only ten vertices. But we assume G has at least sixteen vertices. Hence, there is no edge joining two anchors in G. A dominating set D of G is formed by collecting all anchors and one vertex in each 4-cluster. Now we prove that $|D| \leq \frac{2}{5}|V|$.

Let m_4, m_3, m_1 be the number of 4-clusters, 3-clusters, and 1-clusters, respectively. Then, there are also m_4, m_3, and m_1 anchors of 4-clusters, 3-clusters, and 1-clusters, respectively. Clearly, $|D| = 2m_4 + m_3 + m_1$.

Now we count the nonanchor vertices. Each 4-cluster, 3-cluster, and 1-cluster contains 4, 2, and 0 nonanchor vertices, respectively. Furthermore, on each 2-path connecting two anchors, there are one or two nonanchor vertices depending on whether it is of length two or three. Therefore, the number of nonanchor vertices on these paths is at least $\frac{1}{2}(m_4 + m_3 + 3m_1)$ since there is at least one nonanchor vertex in the 2-path between two anchors and the degree of the unique vertex in a 1-cluster is at least 3. Hence, the number of nonanchor vertices is at least $\frac{9}{2}m_4 + \frac{5}{2}m_3 + \frac{3}{2}m_1$. Recall that the dominating set D contains one nonanchor vertex in each 4-cluster. This implies $|V| \geq \frac{11}{2}m_4 + \frac{7}{2}m_3 + \frac{5}{2}m_1$. Simple computation shows that $|D| \leq \frac{2}{5}|V|$. □

A recursive algorithm to compute a desired dominating set follows from the above induction proof. To implement this algorithm, we have to compute $d(v)$ for each vertex in G and find (a) an edge between two vertices in $B(G)$, (b) a length-4 path that contains three consecutive degree-2 vertices in the middle, and (c) a 4-cluster with an endpoint of degree larger than 3. Given the adjacent matrix of a graph G as input, we can find the degree of a vertex in $O(|V|)$ time and thus find $B(G)$ in $O(|V|^2)$ time. With $B(G)$, we can find an edge between two vertices in $B(G)$ if any exist in $O(|V|^2)$ time. To compute (b), we just need to check if there is a degree-2 vertex having two degree-2 neighbors and these two neighbors have different neighbors in $O(|E|^2)$ time. The task (c) can be done similarly. Overall, the algorithm finds a dominating set iteratively. The number of vertices decreases by at least 1 after each iteration step, and each iteration step takes $O(|E|^2)$ time and removes three vertices from the graph. Therefore, the running time of the algorithm is $O(|E|^2|V|)$.

SIMULATING QUANTUM COMPUTATION BY CONTRACTING TENSOR NETWORKS*

IGOR L. MARKOV† AND YAOYUN SHI†

Abstract. The treewidth of a graph is a useful combinatorial measure of how close the graph is to a tree. We prove that a quantum circuit with T gates whose underlying graph has a treewidth d can be simulated deterministically in $T^{O(1)}\exp[O(d)]$ time, which, in particular, is polynomial in T if $d = O(\log T)$. Among many implications, we show efficient simulations for log-depth circuits whose gates apply to nearby qubits only, a natural constraint satisfied by most physical implementations. We also show that *one-way quantum computation* of Raussendorf and Briegel (*Phys. Rev. Lett.*, 86 (2001), pp. 5188–5191), a universal quantum computation scheme with promising physical implementations, can be efficiently simulated by a randomized algorithm if its quantum resource is derived from a small-treewidth graph with a constant maximum degree. (The requirement on the maximum degree was removed in [I. L. Markov and Y. Shi, preprint:quant-ph/0511069].)

1. Introduction.

The recent interest in quantum circuits is motivated by several complementary considerations. Quantum information processing is rapidly becoming a reality as it allows the manipulation matter on an unprecedented scale. Such manipulations may create particular entangled states or implement specific quantum evolutions—they find uses in atomic clocks, ultra-precise metrology, high-resolution lithography, optical communication, etc. On the other hand, engineers traditionally simulate new designs before implementing them. Such simulation may identify subtle design flaws and save both costs and effort. It typically uses well-understood host hardware, e.g., one can simulate a quantum circuit on a commonly-used conventional computer.

More ambitiously, quantum circuits compete with conventional computing and communication. Quantum-mechanical effects may potentially lead to computational speed-ups, more secure or more efficient communication, better keeping of secrets, etc. To this end, one seeks new circuits and algorithms with revolutionary behavior as in Shor's work on number-factoring, or provable limits on possible behaviors. While proving abstract limitations on the success of unknown algorithms appears more difficult, a common line of reasoning for such results is based on simulation. For example, if the behavior of a quantum circuit can be faithfully simulated on a conventional computer, then the possible speed-up achieved by the quantum circuit is limited by the cost of simulation. Thus, aside from sanity-checking new designs for quantum information-processing hardware, more efficient simulation can lead to sharper bounds on all possible algorithms.

Since the outcome of a quantum computation is probabilistic, we shall clarify our notion of simulation. By a randomized simulation, we mean a classical randomized algorithm whose output distribution on an input is identical to that of the simulated quantum computation. By a deterministic simulation, we mean a classical deterministic algorithm which, on a given pair of input x and output y of the quantum computation, outputs the probability that y is observed at the end of the quantum computation on x.

To simulate a quantum circuit, one may use a naïve brute-force calculation of quantum amplitudes that has exponential overhead. Achieving significantly smaller overhead in the generic case appears hopeless—in fact, this observation lead Feynman to suggest that quantum computers may outperform conventional ones in some tasks. Therefore, only certain restricted classes of quantum circuits were studied in existing literature on simulation.

Classes of quantum circuits that admit efficient simulation are often distinguished by a restricted "gate library," but do not impose additional restrictions on how gates are interconnected or sequenced. A case in point is the seminal Gottesman–Knill theorem [12] and its recent improvement by Aaronson and Gottesman [1]. These results apply only to circuits with stabilizer gates—controlled-NOT, Hadamard, phase, and single-qubit measurements in the so-called Clifford group. Another example is given by *match gates* defined and studied by Valiant [33], and extended by Terhal and DiVincenzo [31].

A different way to impose a restriction on a class of quantum circuits is to limit the amount of entanglement in intermediate states. Jozsa and Linden [16], as well as Vidal [36], demonstrate efficient classical simulation of such circuits and conclude that achieving quantum speed-ups requires more than a bounded amount of entanglement.

In this work we pursue a different approach to efficient simulation and allow the use of arbitrary gates. More specifically, we assume a general quantum circuit model in which a gate is a general quantum operation (so-called *physically realizable operators*) on a constant number of qubits. This model, proposed and studied by Aharonov, Kitaev, and Nisan [2], generalizes the standard quantum circuit model, defined by Yao [40], where each gate is unitary and measurements are applied at the end of the computation. We also assume that (i) the computation starts with a fixed unentangled state in the computational basis, and (ii) at the end each qubit is either measured or *traced-out*.

Our simulation builds upon the framework of *tensor network contraction*. Being a direct generalization of matrices, tensors capture a wide range of linear phenomena including vectors, operators, multilinear forms, etc. They facilitate convenient and fundamental mathematical tools in many branches of physics such as fluid and solid mechanics, and general relativity [14]. More recently, several methods have been developed to simulate quantum evolution by contracting variants of tensor networks, under the names of *matrix product states (MPS)*, *projected entangled pairs states (PEPS)*, etc. [36, 37, 34, 41, 35, 24]. Under this framework, a quantum circuit is regarded as a network of tensors. The simulation contracts edges one by one and performs the convolution of the corresponding tensors, until there is only one vertex left. Having degree 0, this vertex must be labeled by a single number, which gives the final measurement probability sought by simulation. In contrast with other simulation techniques, we do not necessarily simulate individual gates in their original order—in fact, a given gate may even be simulated *partially* at several stages of the simulation.

While tensor network contraction has been used in previous work, little was known

about optimal contraction orders. We prove that the minimal cost of contraction is determined by the *treewidth* $\mathrm{tw}(G_C)$ of the circuit graph G_C. Moreover, existing constructions that approximate optimal *tree-decompositions* (e.g., [28]) produce near-optimal contraction sequences. We shall define the concepts of treewidth and tree decompositions in section 2. Intuitively, the smaller a graph's treewidth is, the closer it is to a tree, and a tree decomposition is a drawing of the graph to make it look like a tree as much as possible. Our result allows us to leverage the extensive graph-theoretical literature dealing with the properties and computation of treewidth.

THEOREM 1.1. *Let C be a quantum circuit with T gates and whose underlying circuit graph is G_C. Then C can be simulated deterministically in time $T^{O(1)} \exp[O(\mathrm{tw}(G_C))]$.*

A rigorous restatement of the above theorem is Theorem 4.6. By this theorem, given a function computable in polynomial time by a quantum algorithm but not classically, any polynomial-size quantum circuit computing the function must have super-logarithmic treewidth. The following corollary is an immediate consequence.

COROLLARY 1.2. *Any polynomial-size quantum circuit of a logarithmic treewidth can be simulated deterministically in polynomial time.*

Quantum formulas defined and studied by Yao [40] are quantum circuits whose underlying graphs are trees. Roychowdhury and Vatan [30] showed that quantum formulas can be efficiently simulated deterministically. Since every quantum formula has treewidth 1, Corollary 1.2 gives an alternative efficient simulation.

Our focus on the *topology* of the quantum circuit allows us to accommodate arbitrary gates, as long as their qubit-width (number of inputs) is limited by a constant. In particular, Corollary 1.2 implies efficient simulation of some circuits that create the maximum amount of entanglement in a partition of the qubits, e.g., a layer of two-qubit gates. Therefore, our results are not implied by previously published techniques.

We now articulate some implications of our main result to classes of quantum circuits, in terms of properties of their underlying graphs. The following two classes of graphs are well-studied, and their treewidths are known. The class of *series parallel graphs* arises in electric circuits, and such circuits have treewidth ≤ 2. Planar graphs G with n vertices are known to have treewidth $\mathrm{tw}(G) = O(\sqrt{|V(G)|})$ [4].

COROLLARY 1.3. *Any polynomial size parallel serial quantum circuit can be simulated deterministically in polynomial time.*

COROLLARY 1.4. *A size T planar quantum circuit can be simulated deterministically in $\exp[O(\sqrt{T})]$ time.*

Another corollary deals with a topological restriction representative of many physical realizations of quantum circuits. Let $q \geq 1$ be an integer. A circuit is said to be q-local-interacting if under a linear ordering of its qubits, each gate acts only on qubits that are at most q distance apart. A circuit is said to be local-interacting if it is q-local interacting with a constant q independent of the circuit size. Such *local-interaction* circuits generalize the restriction of qubit couplings to nearest-neighbor qubits (e.g., in a spin-chain) commonly appearing in proposals for building quantum computers, where qubits may be stationary and cannot be coupled arbitrarily. To this end, we observe that the treewidth of any local-interaction circuit of logarithmic depth is at most logarithmic.

COROLLARY 1.5. *Let C be a quantum circuit of size T and depth D and q-local-interacting. Then C can be simulated deterministically in $T^{O(1)} \exp[O(qD)]$ time. In particular, if C is a polynomial-size local-interacting circuit with a logarithmic depth,*

then it can be simulated deterministically in polynomial time.

Yet another important application of our approach is the simulation of *one-way quantum computation*. In two influential papers [7, 25], Briegel and Raussendorf introduced the concept of *graph states*—quantum states derived from graphs,—and show that an arbitrary quantum circuit can be simulated by *adaptive*, *single-qubit measurements* on the *graph state* derived from the grid graph. Note that the graph state for a one-way quantum computation does not depend on the quantum circuit to be simulated (except that its size should be large enough) and that for most physical implementations single-qubit measurements are much easier to implement than multiqubit operations. Hence it is conceivable that graph states would be manufactured by a technologically more advanced party, then used by other parties with lesser quantum-computational power in order to facilitate universal quantum computing. This makes one-way quantum computation an attractive scheme for physical implementations of universal quantum computation. An experimental demonstration of one-way quantum computation appeared in a recent Nature article [38].

A natural question about one-way computation is to characterize the class of graphs whose graph states are universal for quantum computation. We call a family of quantum states $\phi = \{|\phi_1\rangle, |\phi_2\rangle, \ldots, |\phi_n\rangle, \ldots\}$ *universal for one-way quantum computation* if (a) the number of qubits in $|\phi_n\rangle$ is bounded by a fixed polynomial in n; (b) any quantum circuit of size n can be simulated by a one-way quantum computation on $|\phi_n\rangle$. On the other hand, ϕ is said to be efficiently simulatable if any one-way quantum computation on $|\phi_n\rangle$ can be efficiently simulated classically for all sufficiently large n. Note that the class of universal families and that of efficiently simulatable families are disjoint if and only if efficient quantum computation is indeed strictly more powerful than efficient classical computation. We show that it is necessary for graphs with a constant maximum degree to have high treewidth so that the corresponding graph states are not efficiently simulatable.

THEOREM 1.6. *Let G be a simple undirected graph with the maximum degree $\Delta(G)$. Then a one-way quantum computation on the respective graph state can be simulated by a randomized algorithm in time $|V(G)|^{O(1)} \exp[O(\Delta(G)\mathrm{tw}(G))]$.*

The above result was improved in [19] so that the simulation time does not depend exponentially in $\Delta(G)$. Our simulation can be made deterministic with a better upper bound on time complexity if the one-way computation satisfies additional constraints, such as those in [25]. We shall elaborate on this improvement in section 6.

An important limitation of our techniques is that a circuit family with sufficiently fast-growing treewidth may require super-polynomial resources for simulation. In particular, this seems to be the case with known circuits for modular exponentiation. Therefore, there is little hope to efficiently simulate number-factoring algorithms using tree decompositions. As an extreme example to illustrate the limitation of our technique, we give a depth-4 circuit—including the final measurement as the fourth layer—that has large treewidth.

THEOREM 1.7. *There exists a depth-4 quantum circuit on n qubits using only one- and two-qubit gates such that its treewidth is $\Omega(n)$.*

Note that a circuit satisfying the assumption in the above theorem must have $O(n)$ size. Our construction is based on expander graphs, whose treewidth must be linear in the number of vertices (Lemma 5.2).

This finding is consistent with the obstacles to efficient simulation that are evident in the results of Terhal and DiVincenzo [32], later extended by Fenner et al. [13]. In contrast, we are able to efficiently simulate any depth-3 circuit *deterministically* while

the simulation in [32] is probabilistic.

THEOREM 1.8. *Assuming that only one- and two-qubit gates are allowed, any polynomial-size depth-3 quantum circuit can be simulated deterministically in polynomial time.*

Our simulation algorithm is related to algorithms for other tasks in that its runtime depends on the treewidth of a graph derived from the input. Bodlaender wrote an excellent survey [8] on this subject. Particularly relevant are algorithms based on "vertex eliminations," e.g., the *bucket elimination* algorithm for Bayesian inference [11]. Another parallel can be made with the work by Broering and Lokam [10], which solves circuit-SAT in time exponential in the treewidth of the graph of the given circuit. However, to the best of our best knowledge, we are the first to relate the treewidth of a quantum circuit to its classical simulation.

Our results are applicable to the simulation of classical probabilistic circuits, which can be modeled by matrices, similarly to quantum circuits. Such simulation has recently gained prominence in the literature on the reliability of digital logic [17], and is particularly relevant to satellite-based and airborne electronics which experience unpredictable particle strikes at higher rates.

The rest of this paper is organized as follows. After introducing notation, we describe how quantum circuits and their simulation can be modeled by tensor networks. The runtime of such simulation depends on the graph parameter that we call the *contraction complexity*. We then relate the contraction complexity to treewidth, and apply the simulation to restricted classes of graphs and to one-way quantum computation. Finally, we discuss possible directions for future investigations with a brief survey on the subsequent development since the announcement of our results.

2. Notation and definitions. For integer $n \geq 1$, define $[n] \stackrel{\text{def}}{=} \{1, 2, \ldots, n\}$. An ordering π of an n-element set is denoted by $\pi(1)$, $\pi(2)$, ..., $\pi(n)$. Unless otherwise stated, graphs in this paper are undirected and may have multiple edges or loops. Edges connecting the same pair of vertices are called parallel edges. If G is a graph, then its vertex set is denoted by $V(G)$ and its edge set by $E(G)$. When it is clear in this context, we use $V = V(G)$ and $E = E(G)$. The *degree* of a vertex v, denoted by $d(v)$, is the number of edges incident to it. In particular, a loop counts as 1 edge. The maximum degree of a vertex in G is denoted by $\Delta(G)$.

Treewidth of a graph. Let G be a graph. A *tree decomposition* of G [27] is a tree $\mathcal{T}$, together with a function that maps each vertex $w \in V(\mathcal{T})$ to a subset $B_w \subseteq V(G)$. These subsets B_w are called *bags* (of vertices). In addition, the following conditions must hold.

(T1) $\bigcup_{v \in V(\mathcal{T})} B_v = V(G)$, i.e., each vertex must appear in at least one bag.
(T2) $\forall\ \{u, v\} \in E(G)$, $\exists w \in V(\mathcal{T})$, $\{u, v\} \subseteq B_w$, i.e., for each edge, at least one bag must contain both of its endvertices.
(T3) $\forall\ u \in V(G)$, the set of vertices $w \in V(\mathcal{T})$ with $u \in B_w$ form a connected subtree, i.e., all bags containing a given vertex must be connected in $\mathcal{T}$.

The *width* of a tree decomposition is defined by $\max_{w \in V(\mathcal{T})} |B_w| - 1$. The *treewidth* of G is the minimum width over its tree decompositions. For example, all trees have treewidth 1 and single cycles of length at least 3 have treewidth 2. Figure 1 shows an example of tree decomposition. Intuitively, a tree decomposition $\mathcal{T}$ is a way of drawing a graph to look like a tree, which may require viewing sets of vertices (bags) as single vertices. The less a graph looks like a tree, the larger the bags become. The notion of tree decomposition has been useful in capturing the complexity of constraint

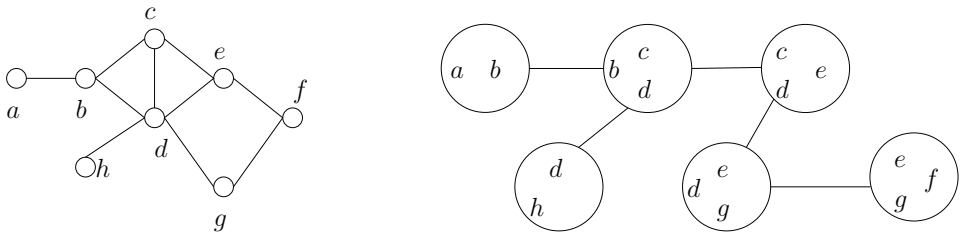

FIG. 1. *A graph and its decomposition of width* 2 *with* 6 *bags.*

satisfaction problems, Bayesian networks, and other combinatorial phenomena represented by graphs. In further writing, we may refer to a vertex in $\mathcal{T}$ by its bag when the context is clear.

Treewidth can be defined in several seemingly unrelated ways, e.g., as the minimum k for which a given graph is a *partial k-tree*, as the *induced width* (also called the *dimension*), or as the *elimination width* [29, 5]. An *elimination ordering* π of a graph G is an ordering of $V(G)$. The *induced width of a vertex* $v \in V(G)$ in the ordering is the number of its neighbors at the time it is being removed in the following process: Start with $\pi(1)$, add an edge for each pair of its neighbors that were previously not adjacent, remove $\pi(1)$, then repeat this procedure with the next vertex in the ordering. The *width of* π is the maximum induced width of a vertex, and the *induced width of* G is the minimum width of an elimination ordering. It is known that the induced width of a graph is precisely its treewidth [5].

It follows straightforwardly from the definition of treewidth that if G is obtained from G' by removing a degree 1 vertex, then $\mathrm{tw}(G) = \mathrm{tw}(G')$, unless G' has only 1 edge, in which case $\mathrm{tw}(G) = 0$ and $\mathrm{tw}(G') = 1$. We will also use the following well-known and simple fact, a proof for which is provided in the appendix.

PROPOSITION 2.1. *Let G be a simple undirected graph, and w be a degree* 2 *vertex. Then removing w and connecting its two adjacent vertices does not change the treewidth.*

Quantum circuits. We review some basic concepts of quantum mechanics and quantum computation. For a more detailed treatment, we refer the readers to the book by Nielsen and Chuang [23].

The state space of one qubit is denoted by $\mathcal{H} \stackrel{\text{def}}{=} \mathbb{C}^2$. We fix an orthonormal basis for $\mathcal{H}$ and label the basis vectors with $|0\rangle$ and $|1\rangle$. The space of operators on a vector space V is denoted by $\mathbf{L}(V)$. The identity operator on V is denoted by I_V, or by I if V is implicit from the context. A density operator, or a mixed state, of n qubits is a positive semidefinite operator $\rho \in \mathbf{L}(\mathcal{H}^{\otimes n})$ with $\mathrm{trace}\rho = 1$. For a binary string $x = x_1 x_2 \cdots x_n \in \{0,1\}^n$, let $\rho_x \stackrel{\text{def}}{=} \bigotimes_{i=1}^n |x_i\rangle\langle x_i|$ be the density operator of the state $|x\rangle \stackrel{\text{def}}{=} \otimes_{i=1}^n |x_i\rangle$.

In this paper, a quantum gate with a input qubits and b output qubits is a superoperator $Q : \mathbf{L}(\mathcal{H}^{\otimes a}) \to \mathbf{L}(\mathcal{H}^{\otimes b})$. There are certain constraints that Q must satisfy in order to represent a physically realizable quantum operation. We need not be concerned about those constraints as our simulation method does not depend on them. In existing applications one typically has $a \geq b$ and often $a = b$, though a density operator can also be regarded as a gate with $a = 0$. The ordering of inputs and outputs is, in general, significant. If Q is a *traced out* operator, then $b = 0$, and $Q(|x\rangle\langle y|) = \langle x|y\rangle$ for all $x, y \in \{0,1\}^a$. We denote by $Q[A]$ the application of Q to an

ordered set A of a qubits.

The information in a quantum state is retrieved through the application of measurements. A POVM (positive operator-valued measure) $\mathcal{M}$ on n qubits is a set $\mathcal{M} = \{M_1, M_2, \ldots, M_k\}$, where each M_i is called a POVM element, and is a positive semidefinite operator in $\mathbf{L}(\mathcal{H}^{\otimes n})$ such that $\sum_{i=1}^{k} M_i = I$. The single-qubit measurement in the computational basis is $\{|0\rangle\langle 0|, |1\rangle\langle 1|\}$.

We assume that the maximum number of qubits on which a quantum gate can act is bounded by a constant (often two or three). A quantum circuit of size T with n input-qubits and m output-qubits consists of the following:

(1) A sequence of n input-wires, each of which represents one input-qubit, i.e., a qubit which is not the output qubit of any gate.
(2) A sequence of T quantum gates g_1, g_2, ..., g_T, each of which is applied to some subset of the wires.
(3) A sequence of m output-wires, each of which represents an output-qubit, i.e., a qubit which is not the input qubit of any gate.

Note that by the above definition, a quantum circuit C defines a function $C : \mathbf{L}(\mathcal{H}^{\otimes n}) \to \mathbf{L}(\mathcal{H}^{\otimes m})$. In most applications, a circuit C is applied to an input state $\rho_x \stackrel{\text{def}}{=} \otimes_{i=1}^{n} |x_i\rangle\langle x_i|$, for some binary string $x = x_1 \cdots x_n \in \{0,1\}^n$, and at the end of the computation, measurements in the computational basis are applied to a subset of the qubits. We shall restrict our discussions to such a case, though our results can be extended to more general cases.

The graph of a quantum circuit C, denoted by G_C, is obtained from C as follows. Regard each gate as a vertex, and for each input/output wire add a new vertex to the open edge of the wire.[1] Each wire segment can now be represented by an edge in the graph.

3. Tensors and tensor networks. Tensors, commonly used in physics, are multidimensional matrices that generalize more traditional tools from linear algebra, such as matrix products. Here we focus on features of tensors that are relevant to our work.

DEFINITION 3.1. *A rank-k tensor in an m-dimension space $g = [g_{i_1,i_2,\ldots,i_k}]_{i_1,i_2,\ldots,i_k}$ is an m^k-dimensional array of complex numbers $g_{i_1,i_2,\ldots,i_k}$, indexed by k indices, i_1, i_2, ..., i_k, each of which takes m values. When the indices are clear we omit them outside the bracket.*

For example, a rank-0 tensor is simply a complex number, and a rank-1 tensor is a dimension-m complex vector. We focus on dimension-4 tensors, and set the range of each index to be $\Pi \stackrel{\text{def}}{=} \{|b_1\rangle\langle b_2| : b_1, b_2 \in \{0,1\}\}$. We fix the following tensor representation of a density operator and a superoperator.

DEFINITION 3.2. *Let ρ be a density operator on a qubits. The tensor of ρ is $[\rho_{\sigma_1,\sigma_2,\ldots,\sigma_a}]_{\sigma_1,\sigma_2,\ldots,\sigma_a \in \Pi}$, where*

$$\rho_{\sigma_1,\ldots,\sigma_a} \stackrel{\text{def}}{=} tr(\rho \cdot (\otimes_{i=1}^{a} \sigma_i)^\dagger).$$

Let Q be a superoperator acting on a input qubits and b output qubits. The tensor of Q is

$$Q_{\sigma_1,\sigma_2,\ldots,\sigma_a,\tau_1,\tau_2,\ldots,\tau_b}]_{\sigma_1,\ldots,\sigma_a,\tau_1,\ldots,\tau_b \in \Pi},$$

[1] These vertices are going to represent input states, as well as measurements and trace-out operators at the end of the computation.

where

$$Q_{\sigma_1,\sigma_2,\ldots,\sigma_a,\tau_1,\tau_2,\ldots,\tau_b} \stackrel{\text{def}}{=} tr(Q(\otimes_{i=1}^{a}\sigma_i)\cdot(\otimes_{j=1}^{b}\tau_j)^\dagger).$$

We shall use the same notation for a density operator (or a superoperator) and its tensor. We now define the central object of this paper.

DEFINITION 3.3. *A* tensor network *is a collection tensors, each index of which may be used by either one or two tensors.*

A rank-k tensor g can be graphically represented as a vertex labeled with g, and connected to k open wires, each of which is labeled with a distinct index. We may represent a tensor network by starting with such graphical representations of its tensors, and then connecting wires corresponding to the same index. Note that now each wire corresponds to a distinct index. Also, an index that appears in one tensor corresponds to an open wire, and an index that appears in two tensors corresponds to an edge connecting two vertices. Parts (a) and (b) in Figure 2 give an example of the graphical representation of a tensor and a tensor network. In the tensor g_Q, we call the σ_i wires, $1 \le i \le a$, input wires, and the τ_j wires, $1 \le j \le b$, the output wires.

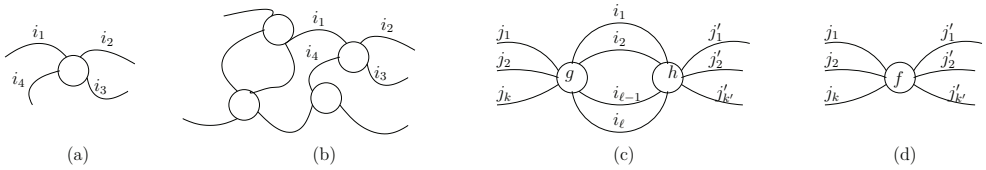

FIG. 2. *A rank-4 tensor is illustrated in* (a)*, and a tensor network with four tensors is shown in* (b)*. Contraction of two tensors is illustrated in* (c) *and* (d)*.*

Suppose in a tensor network there are ℓ parallel edges i_1, i_2, …, i_ℓ between two vertices $g = [g_{i_1,\ldots,i_\ell,j_1,\ldots,j_k}]$ and $h = [h_{i_1,\ldots,i_\ell,j'_1,\ldots,j'_{k'}}]$. We may contract those edges by first removing them, then merging v_g and v_h into a new vertex v_f, whose tensor is $f = [f_{j_1,\ldots,j_k,j'_1,\ldots,j'_{k'}}]$, and

$$f_{j_1,\ldots,j_k,j'_1,\ldots,j'_{k'}} \stackrel{\text{def}}{=} \sum_{i_1,i_2,\ldots,i_\ell} g_{i_1,\ldots,i_\ell,j_1,\ldots,j_k} \cdot h_{i_1,\ldots,i_\ell,j'_1,\ldots,j'_{k'}}. \tag{1}$$

Parts (c) and (d) in Figure 2 illustrate the above contraction. Note that a tensor network with k open wires can be contracted to a single tensor of rank k, and the result does not depend on the order of contractions. The following example is instructive.

Example 1. Let ρ be an a-qubit density operator and Q be a superoperator with a input qubits and b output qubits. Consider the tensor network that connects all wires of the tensor ρ to the input wires of the tensor Q. Then contracting this tensor network gives the tensor of the density operator $Q(\rho)$. Figure 3 illustrates this example.

A quantum circuit C can be naturally regarded as a tensor network $N(C)$: each gate is regarded as the corresponding tensor. The qubit lines are wires connecting the tensors, or open wires that correspond to the input and output qubits. Figure 4 illustrates the concept.

Let C be a quantum circuit with n input qubits and m output qubits. Suppose that C is applied to the initial state ρ_x, for some $x \in \{0,1\}^n$. We are interested in

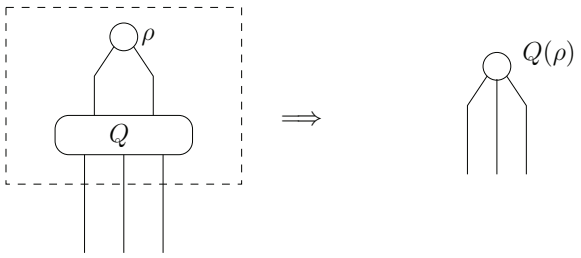

FIG. 3. *Contracting the wires connecting the tensors for a density operator ρ and a gate Q results in the tensor for $Q(\rho)$.*

knowing the probability of observing some particular outcome when some single-qubit measurements are applied to a subset of the qubits. The setting can be described by a measurement scenario defined as follows.

DEFINITION 3.4. *Let $m \geq 1$ be an integer. A* measurement scenario *on m qubits is a function $\tau : [m] \to \mathbf{L}(\mathbb{C}^2)$, such that $\tau(i)$ is a single-qubit POVM measurement element.*

Note that if a qubit i is not to be measured, then we can set $\tau(i) = I$.

To compute the probability that τ is realized on $C(\rho_x)$, we build a tensor network $N(C; x, \tau)$ from $N(C)$ by attaching to each input open wire i the tensor for $|x_i\rangle\langle x_i|$, and attaching to each open wire for the output qubit i the tensor for $\tau(i)$. When $x = 0^n$, we abbreviate $N(C; x, \tau)$ as $N(C; \tau)$. Figure 4 illustrates the concept of $N(C)$ and $N(C; \tau)$.

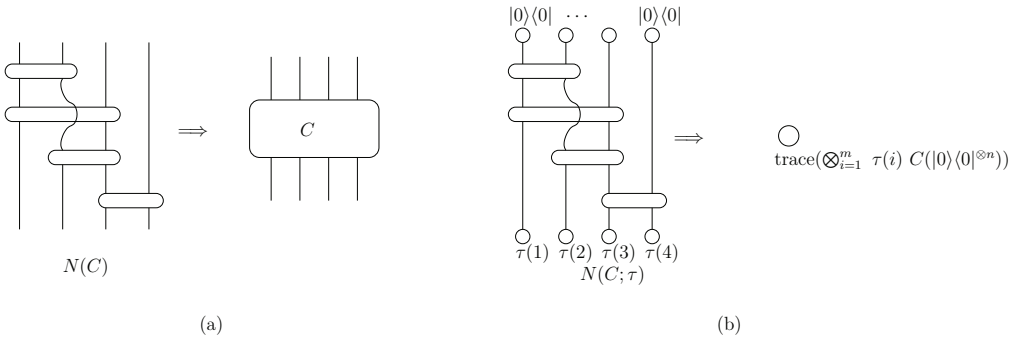

FIG. 4. *In* (a)*, a circuit C can be naturally regarded as a tensor network $N(C)$. Contracting $N(C)$ gives the tensor for the operator that C realizes. Part* (b) *illustrates the tensor network $N(C; \tau)$, contracting which gives the rank-*0 *tensor whose value is precisely the probability that the measurement scenario τ is realized on $C(|0\rangle\langle 0|^{\otimes n})$.*

PROPOSITION 3.5. *Let C be a quantum circuit, x be a binary string, and τ be a measurement scenario. Contracting the tensor network $N(C; x, \tau)$ to a single vertex gives the rank-*0 *tensor which is the probability that τ is realized on $C(\rho_x)$.*

Proof. Let $\rho^t \stackrel{\text{def}}{=} g_t g_{t-1} \cdots g_1(\rho_x)$, $1 \leq t \leq T$, and $\rho^0 = \rho_x$. By the definitions of tensors for density operators and superoperators and tensor contraction, contracting wires connecting the tensor of a superoperator Q and the tensors for a density operator ρ gives the tensor of $Q(\rho)$. Thus sequentially contracting input wires of $g_1, \ldots, g_t$ gives the tensor for ρ^t, and contracting the remaining wires gives the tensor for $\tau(\rho^T)$, which is the probability of realizing τ on $\rho^T = C(\rho_x)$. ∎

We remark that $N(C; x, \tau)$ is not the only tensor network for which the previous proposition holds.

Although the ordering of the edges in the contraction process does not affect the final tensor, it may significantly affect space and time requirements.

PROPOSITION 3.6. *Given a tensor network N of a size T quantum circuit, and a contraction process specified by an ordering of wires in N, let d be the maximum rank of all the tensors that appear in the process. Then the contraction takes $O(T \exp[O(d)])$ time.*

Proof. Note that the size of N is $\Theta(T)$. The algorithm stores the tensors of each vertex. When contracting an edge, it computes the new tensor according to (1) and updates the tensor accordingly. This takes $\exp[O(d)]$ time. Hence the total runtime is $O(T \exp[O(d)])$. □

In the next section we will investigate near-optimal orderings for simulation and ways to find them. While traditional simulation of quantum circuits proceeds in the same order in which the gates are applied, it appears that an optimal ordering may not have any physical meaning. Therefore, we formalize this optimization using abstract graph contractions.

4. Contraction complexity and treewidth. Let G be a graph with vertex set $V(G)$ and edge set $E(G)$. Recall that the contraction process discussed in the previous section removes parallel edges in one step because contracting one edge at a time can create multiple loops. However, for future convenience we prefer the latter simulation and therefore allow loops to remain uncontracted, counting toward the degree of a vertex. Note that if a "parallel" contraction contracts ℓ edges between two vertices u and v of degrees $\ell + k$ and $\ell + k'$, respectively, the corresponding "one-edge-at-a-time" contraction would create vertices of degrees $k+k'+\ell-1$, $k+k'+\ell-2$, ..., $k+k'$, each of which is $\leq d(u) + d(v)$. Thus the one-edge-at-a-time contraction process can emulate the parallel contraction, while increasing the maximum vertex degree observed by no more than twofold. We make the definition of this new contraction process precise below.

DEFINITION 4.1. *The* contraction of an edge *e removes e and replaces its end vertices (or vertex) with a single vertex. A* contraction ordering *π is an ordering of all the edges of G, $\pi(1)$, $\pi(2)$, ..., $\pi(|E(G)|)$. The complexity of π is the maximum degree of a merged vertex during the contraction process. The* contraction complexity *of G, denoted by $\mathrm{cc}(G)$, is the minimum complexity of a contraction ordering.*

Since only the degrees of the merged vertices are considered in defining the contraction complexity, $\mathrm{cc}(G)$ could be strictly larger than $\Delta(G)$. For example, if G is a path, then $\mathrm{cc}(G) = 1$ and $\Delta(G) = 2$.

Note that sequentially contracting all $\pi(i)$, $1 \leq i \leq |E(G)|$, reduces G to a single vertex (or an empty graph of several vertices). Also, for any graph G, $\mathrm{cc}(G) \leq |E(G)| - 1$, since any merged vertex would be incident to no more than $|E(G)| - 1$ number of edges. Furthermore, $\mathrm{cc}(G) \geq \Delta(G) - 1$, since when an edge incident to a vertex of degree $\Delta(G)$ is removed, the resulting merged vertex is incident to at least $\Delta(G) - 1$ edges.

The nature of $\mathrm{cc}(G)$ becomes clearer once we consider the *line graph* of G, denoted by G^*. That is, the vertex set of G^* is $V(G^*) \stackrel{\text{def}}{=} E(G)$, and the edge set is

$$E(G^*) \stackrel{\text{def}}{=} \{e_1, e_2\} \subseteq E(G) : e_1 \neq e_2, \exists v \in V(G)$$

such that e_1 and e_2 are both incident to v.

PROPOSITION 4.2. *For any graph $G = (V, E)$, $\mathrm{cc}(G) = \mathrm{tw}(G^*)$. Furthermore, given a tree decomposition of G^* of width d, there is a deterministic algorithm that outputs a contraction ordering π with $\mathrm{cc}(\pi) \leq d$ in polynomial time.*

Computing the treewidth of an arbitrary graph is NP-hard [6], but we do not know if this remains true for the special class of graphs G^*. Nevertheless, this is not critical in our work since the constant-factor approximation due to Robertson and Seymour [28] suffices for us to prove our key results.

THEOREM 4.3 (see Robertson and Seymour [28]). *There is a deterministic algorithm that, given a graph G, outputs a tree decomposition of G of width $O(\mathrm{tw}(G))$ in time $|V(G)|^{O(1)} \exp[O(\mathrm{tw}(G))]$.*

Proof of Proposition 4.2. There is a one-to-one correspondence of the contraction of an edge in G and the elimination of a vertex in G^*, and the degree of the merged vertex resulting from contracting an edge e in G is the same as the degree of e being eliminated in G^*. Thus $\mathrm{cc}(G) = \mathrm{tw}(G^*)$.

To prove the second part of the statement, denote the tree decomposition by $\mathcal{T}$. Repeat the following until the tree decomposition becomes an empty graph. Choose a leaf ℓ in $\mathcal{T}$. If ℓ is the single vertex of $\mathcal{T}$, then output vertices (of G^*) in B_ℓ in any order. Otherwise, let ℓ' be its parent. If $B_\ell \subseteq B_{\ell'}$, then remove ℓ and repeat this process. Otherwise, let $e \in B_\ell - B_{\ell'}$. Then, output e, remove it from the tree decomposition, and continue the process until all vertices of the tree decomposition are removed. The number of steps in this process is polynomial in the size of the tree decomposition.

Note that each output e appears in only one bag in the tree decomposition. Therefore, all (current) neighbors of e must appear in the same bag. Hence its induced width is at most d, by the one-to-one correspondence of the vertex elimination in G^* and the contraction process in G, $\mathrm{cc}(\pi) \leq d$. □

Before we complete the description of our simulation algorithm, we relate the treewidth of G to that of G^*. This is useful for reasoning about quantum circuits C when the graph G_C is easier to analyze than its line graph G_C^*. In such cases one hopes to bound the runtime of the simulation algorithm in terms of parameters of G rather than G^*. Fortunately, since G_C is of bounded degree, the treewidths of G_C and G_C^* are asymptotically the same.

LEMMA 4.4. *For any graph G of maximum degree $\Delta(G)$,*

$$(\mathrm{tw}(G) - 1)/2 \leq \mathrm{tw}(G^*) \leq \Delta(G)(\mathrm{tw}(G) + 1) - 1.$$

Proof. From a tree decomposition $\mathcal{T}$ of G of width d we obtain a tree decomposition $\mathcal{T}^*$ of G^* of width $(d+1) \cdot \Delta(G) - 1$ by replacing each vertex $v \in V(G)$ with all edges e incident to v. This guarantees that every edge of G^* is in some bag, i.e., (T1) is true. Item (T2) is true since if e_1 and e_2 are both incident to a vertex u in G, then any bag in $\mathcal{T}$ containing u contains both e_1 and e_2 in $\mathcal{T}^*$. To verify item (T3), suppose that e connects u and v in $V(G)$. Take two bags a and b that both contain e. Then, in $\mathcal{T}$, both bags a and b must have either u or v. If they contain the same vertex, then a and b are connected, by (T3). Otherwise, there must be a bag c that contains both u and v, by (T2). So a and b are connected through c. Therefore we have proved that $\mathrm{tw}(G^*) \leq \Delta(G)(\mathrm{tw}(G) + 1) - 1$.

Now to prove $\mathrm{tw}(G) \leq 2\mathrm{tw}(G^*) + 1$, we start with a tree decomposition $\mathcal{T}^*$ of G^* of width d, and replace every e by its two endvertices in $V(G)$. The verification of (T1) through (T3) can be accomplished in a similar way. □

Note that the above bounds are asymptotically tight, since for an m-ary tree (of which each nonroot internal vertex has degree $m + 1$), the treewidth is 1 and the

contraction complexity is m. We summarize the previous finding in the following theorem.

THEOREM 4.5. *Let $d \geq 1$ be an integer. For any family of graphs G_n, $n \in \mathbb{N}$, such that $\Delta(G_n) \leq d$ for all n. Then*

$$(\mathrm{tw}(G_n) - 1)/2 \leq \mathrm{cc}(G_n) = \mathrm{tw}(G_n^*) \leq d(\mathrm{tw}(G_n) + 1) - 1 \quad \forall n \in \mathbb{N}.$$

We are now ready to put everything together to prove the following restatement of Theorem 1.1.

THEOREM 4.6. *Let C be a quantum circuit of size T and with n input and m output qubits, $x \in \{0,1\}^n$ be an input, and $\tau : [m] \to \mathbf{L}(\mathbb{C}^2)$ be a measurement scenario. Denote by G_C the underlying circuit graph of C. Then the probability that τ is realized on $C(\rho_x)$ can be computed deterministically in time $T^{O(1)} \exp[O(\mathrm{cc}(G_C))] = T^{(1)} \exp[O(\mathrm{tw}(G_C))]$.*

Proof. The following algorithm computes the desired probability.

(1) Construct $N = N(C; x, \tau)$.
(2) Apply the Robertson–Seymour algorithm to compute a tree decomposition $\mathcal{T}$ of N^* of width $w = O(\mathrm{tw}(N^*))$ (Theorem 4.3).
(3) Find a contraction ordering π from $\mathcal{T}$ (Proposition 4.2) of width w.
(4) Contract N using π, and output the desired probability from the final (rank-0) tensor (Proposition 3.5).

The runtime bottlenecks are steps (2) and (4), which can be combined, and both take time $T^{O(1)} \exp(O[\mathrm{tw}(N^*)])$, which by Theorem 4.5 is $T^{O(1)} \exp[O(\mathrm{cc}(G_C))] = T^{O(1)} \exp[O(\mathrm{tw}(G_C))]$; for the sake of clarity we separate both steps . ∎

5. Treewidth and quantum circuits. In this section we prove the implications of Theorem 1.1 stated in the introduction. A number of tight bounds for the treewidth of specific families of graphs have been published, including those for planar and series-parallel graphs. However, similar results for graphs derived from quantum circuits are lacking. To this end, we strengthen Corollary 1.5 as follows.

PROPOSITION 5.1. *Let C be a quantum circuit in which each gate has an equal number of input and output qubits, and whose qubits are index by $[n]$, for an integer $n \geq 1$. Suppose that the size of C is T, and r is the minimum integer so that for any i, $1 \leq i \leq n-1$, no more than r gates act on some qubits j and j' with $j \leq i < j'$. Then C can be simulated deterministically in time $T^{O(1)} \exp[O(r)]$.*

Corollary 1.5 follows since $r = O(qD)$ under its assumption.

Proof of Proposition 5.1. Assume without loss of generality that $\mathrm{tw}(G_C) \geq 2$. Let G be the graph obtained from G_C by removing degree 1 vertices and contracting edges incident to degree 2 vertices. Then $\mathrm{tw}(G) = \mathrm{tw}(G_C)$, by Proposition 2.1 and the observation stated before it. Then each vertex in G corresponds to a multiqubit gate in C.

We now construct a tree decomposition $\mathcal{T}$ for G that forms a path of $n-1$ vertices B_1–B_2–$\cdots$–B_{n-1}. The bag B_i of the ith vertex ($1 \leq i \leq n-1$) consists of multiqubit gates (vertices) that act on some qubits j and j' with $j \leq i < j'$. Hence $|B_i| \leq r$ by the assumption. If u acts on qubits $i_1, i_2, \ldots, i_k$, $i_1 < i_2 < \cdots < i_k$, then $u \in B_i$ for all i, $i_1 \leq i \leq i_k$. Thus (T1) and (T3) are true. If a wire segment corresponding to the qubit i connects two gates u and v, then the bag B_i contains both u and v. Thus (T2) is true. Therefore $\mathcal{T}$is a tree decomposition for G with width $r-1$. Hence $\mathrm{tw}(G_C) = \mathrm{tw}(G) = O(r)$, which by Theorem 1.1 implies that C can be simulated in $T^{O(1)} \exp[O(r)]$ time. ∎

We now turn to quantum circuits of bounded depth. To prove Theorem 1.7 we will make use of the following observation that relates expander graphs to contraction complexity. Let d be a constant and $\{G_n\}_{n\in\mathbb{N}}$ be a family of d-regular graphs, and $\epsilon > 0$ be a universal constant. Recall that $\{G_n\}$ is called a family of expander graphs with expansion parameter ϵ if, for any subset $S \subseteq V(G_n)$ with $|S| \le |V(G_n)|/2$, there are no less than $\epsilon|S|$ edges connecting vertices in S with vertices in $V(G) - S$.

LEMMA 5.2. *For an expander graph G_n with the expansion parameter ϵ,* $\mathrm{cc}(G_n) \ge \epsilon|V(G_n)|/4$.

Proof. Fix a contraction ordering of G_n. Let v be the first merged vertex so that k_v, the number of vertices in $V(G_n)$ that were eventually merged to v, is at least $|V(G_n)|/4$. Then $k_v \le |V(G_n)|/2$, and v must have a degree $\epsilon|V(G_n)|/4$. ∎

The following graph is shown to be an expander by Lubotzky, Phillips, and Sarnak [18]. Let $p > 2$ be a prime, and G_n be the graph with $V(G_p) \stackrel{\mathrm{def}}{=} \mathbb{Z}_p \cup \{\infty\}$. Every vertex x is connected to $x+1$, $x-1$, and x^{-1} ($\infty \pm 1$ are defined to be ∞). Note that G_p is a 3-regular graph.

Proof of Theorem 1.7. By Lemma 5.2, $\mathrm{cc}(G_p) = \Omega(p)$. Since G_p is a 3 regular graph, $\mathrm{tw}(G_p) = \Theta(\mathrm{cc}(G_p)) = \Omega(p)$, by Theorem 4.5. Let G'_p be the graph obtained from G_p by removing the vertex ∞ and the edge $\{0, p-1\}$. This would only decrease $\mathrm{tw}(G_p)$ by at most constant. Hence $\mathrm{tw}(G'_p) = \Omega(p)$. Therefore to prove the theorem, it suffices to construct a quantum circuit C on p qubits so that G'_p is a minor of G^*_C.

Each qubit of C corresponds to a distinct vertex in $V(G'_p)$. Observe that edges in $E(G'_p)$ can be partitioned into three vertex-disjoint subsets: (1) $\{x, x^{-1}\}$; (2) $\{x, x+1\}$ for even x, $0 \le x \le p-3$; (3) the remaining edges. Each subset gives a layer of two-qubit gates in C. In G^*_C, contracting all of the vertices that correspond to the same qubit gives a graph of which G'_p is a minor. Hence $\mathrm{tw}(C) = \Theta(\mathrm{tw}(G^*_C)) = \Omega(p)$. ∎

Proof of Theorem 1.8. By Theorem 4.5, it suffices to prove that $\mathrm{cc}(G_C) = O(1)$ for any depth-2 circuit. Observe that for any such circuit, after contracting the input and output vertices (those are of degree 1, hence contracting them will not increase the contraction complexity), every vertex in G_C has degree either 1 or 2. Hence the edges can be decomposed into disjoint paths and cycles, which can be contracted without increasing the degree. Hence $\mathrm{cc}(G_C) \le 2$. ∎

6. Simulating one-way quantum computation. This section revisits the notions of *graph states* and *one-way quantum computation*. We simulate one-way computation with an algorithm whose complexity grows exponentially with the contraction complexity of the underlying graph.

Let $G = (V, E)$ be a simple undirected graph with $|V| = n$. For a subset $V' \subseteq V$, denote by $e(V')$ the number of edges in the subgraph induced by V'. We associate a qubit with each vertex $v \in V$ and refer to it by qubit v. For a subset $V' \subseteq V$, we identify the notation $|V'\rangle$ with the computational basis $|x\rangle$, for $x \in \{0,1\}^n$ being the characteristic vector of V' (i.e., the ith bit of x is 1 if and only if the ith vertex under some fixed ordering is in V'). The graph state $|G\rangle$ is the following n-qubit quantum state [7]

$$|G\rangle \stackrel{\mathrm{def}}{=} \frac{1}{\sqrt{2^n}} \sum_{V' \subseteq V} (-1)^{e(V')} |V'\rangle.$$

Note that $|G\rangle$ can be created from $|0^n\rangle$ by first applying Hadamard gates to all qubits, followed by the controlled-phase gate $\Lambda(\sigma^z) = \sum_{b_1,b_2\in\{0,1\}} (-1)^{b_1 \cdot b_2} |b_1, b_2\rangle\langle b_1, b_2|$ on each pair of qubits u and v with $\{u, v\} \in E$. Since all of the $\Lambda(\sigma^z)$ operators commute, the order of applying them does not affect the result.

A basic building block of our simulation algorithm is the following.

LEMMA 6.1. *Let $G = (V, E)$ be a graph with n vertices, and let τ be a measuring scenario (defined in Definition 3.4) on n qubits. Then the probability p that τ is realized on $|G\rangle$ can be computed deterministically in time $O(|V|^{O(1)} \exp[O(\mathrm{cc}(G))])$.*

Proof. Fix a circuit C_G that creates $|G\rangle$ from $|0\rangle\langle 0|^{\otimes n}$. Let $\{u, v\} \in E$ and $g = g_{u^+,u^-,v^+,v^-}$ be a tensor in $N(C_G; \tau)$ corresponding to $\Lambda(\sigma^z)[u, v]$. The wires representing the qubit u (or v) before and after the gate are labeled u^+ (or v^+) and u^- (or v^-), respectively. We replace g by two tensors $g^u = g^u_{u^+,u^-,t^+,t^-}$ and $g^v = g^v_{v^+,v^-,t^+,t^-}$, which share two labels t^+ and t^- and are defined as follows. For a wire segment with a label a, denote by $\mathbf{L}_a$ the 4-dimensional space of linear operators associated with this wire segment. Set g^u to be the identity superoperator that maps $\mathbf{L}_{u^+} \otimes \mathbf{L}_{t^-} \to \mathbf{L}_{t^+} \otimes \mathbf{L}_{u^-}$, and g^v to be the tensor for a $\Lambda(\sigma^z)$ that maps $\mathbf{L}_{t^+} \otimes \mathbf{L}_{v^+} \to \mathbf{L}_{t^-} \otimes \mathbf{L}_{v^-}$. By their definitions, contracting g^u and g^v gives precisely g. We call the inserted wires labeled with t^+ and t^- *transition wires*. See Figure 5 for an illustration.

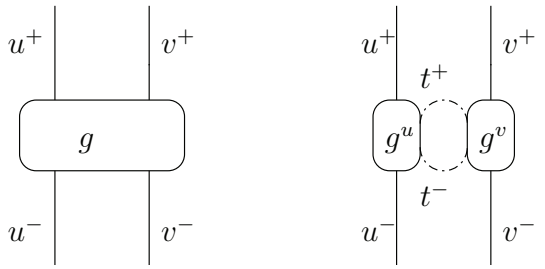

FIG. 5. *Replacing a tensor g corresponding to $\sigma_z[u, v]$ by two tensors g^u and g^v.*

Denote by $N'(C_G; \tau)$ the tensor network obtained from $N(C_G; \tau)$ by applying the above replacement procedure for each edge in E. Let G' be the underlying graph of $N'(C_G; \tau)$. Note that G' has the maximum degree 4 and the number of vertices is $O(|E|)$. See Figure 6 for an illustration. Thus p can be computed by contracting $N'(C_G; \tau)$ in time $O(|V|^{O(1)} \exp[O(\mathrm{cc}(G'))])$, according to Theorem 4.6.

We now prove that $\mathrm{cc}(G') = O(\mathrm{cc}(G))$. This can be seen by contracting all wire segments corresponding to the same qubit in G', while leaving the transition wires untouched. Since contracting the edge incident to an input or output vertex results in a new vertex of degree 3, and contracting the rest of the wires for a qubit v results in a new vertex of degree $2d(v)$, the maximum degree of a merged vertex in this process is $\max\{3, 2\Delta(G)\}$. The one-to-one correspondence between the resulting vertex set and V induces naturally a one-to-one correspondence between the pairs of transition wires and E. Thus a contraction ordering of G gives a contraction ordering of G' (of this stage) with at most twice the contraction complexity. Therefore

$$\mathrm{cc}(G') \le \max\{3, 2\Delta(G), 2\mathrm{cc}(G)\} = O(\mathrm{cc}(G) + 1).$$

Thus p can be computed deterministically in time $O(|V|^{O(1)} \exp[O(\mathrm{cc}(G'))])$ $= O(|V|^{O(1)} \exp[O(\mathrm{cc}(G))])$. ∎

A *one-way* computation on a quantum state $|\phi\rangle$ consists of a sequence of adaptive single-qubit measurements and single-qubit unitary operations applied to $|\phi\rangle$. The description of each measurement or unitary operation, including the index of the qubit that it acts on, can be computed by a deterministic and efficient (polynomial

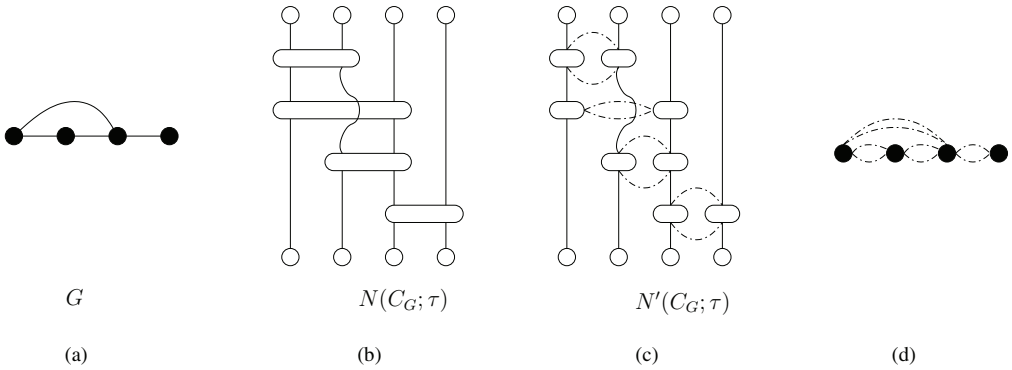

FIG. 6. *For a graph G in* (a)*, the tensor network $N(C_G;\tau)$ is shown in* (b)*. Input vertices are at the top, and output vertices are at the bottom. Each box is a tensor corresponding to a $\Lambda(\sigma_z)$ applied to qubits adjacent in G. In* (c)*, each $\Lambda(\sigma_z)$ tensor is replaced by two tensors and two wires connecting them, as described in Figure* 5*. Contracting all solid lines in* (c) *produces the graph in* (d)*, which is precisely G with each edge doubled.*

time) algorithm from previous operations and their measurement outcomes. In our discussion we treat this computation time as a constant. We call a one-way quantum computation *oblivious* if before the last measurement (which produces the outcome of the computation), different computational paths involve the same number of measurements, take place with the same probability, and result in an identical state. Note that the one-way computation of Raussendorf and Briegel [25] is oblivious.

We point out that allowing single-qubit unitary operations in the definition is for the convenience of discussion only, since each single-qubit unitary can be combined with a future measurement on the same qubit (should there be one). To see this fact, let us call two quantum states *LU-equivalent* (where LU stands for local unitary), if there exists a set of single-qubit unitary operations applying which maps one state to the other. A one-way computation with unitary operators always has an almost identical one-way computation without unitary operations: the measurements are in one-to-one correspondence with identical outcome distributions, and the states after corresponding measurements are LU-equivalent. Therefore, when we are only interested in the distribution of the measurement outcomes, we may assume without loss of generality that a one-way computation does not involve any unitary operation.

We now derive a simulation algorithm whose complexity depends on the contraction complexity.

THEOREM 6.2. *A one-way quantum computation on a graph $G = (V, E)$ can be simulated by a randomized algorithm in time $O(|V|^{O(1)} \exp[O(\mathrm{cc}(G))])$. If the one-way computation is oblivious, then the simulation can be made deterministic.*

Theorem 1.6 follows immediately from the combination of the above theorem with Theorem 4.5.

Proof of Theorem 6.2. Let T be the number of measurements during the one-way computation. Assume without loss of generality that no single-qubit unitary operation is applied. The simulation consists of T steps, one for each single-qubit measurement. It maintains a data structure $r = (\tau, p)$, where τ is a measurement scenario, and p is the probability that τ is realized on $|G\rangle$. Denote by $r_t = (\tau_t, p_t)$ the value of r when t measurements have been simulated. Initially $\tau_0(i) = I$ for all i, $1 \le i \le n$, and $p_0 = 1$.

Suppose we have simulated the first $t-1$ measurements, $1 \le t \le T-1$.

(1) Based on the one-way algorithm, compute from τ_{t-1} the description of the tth measurement $P_t = \{P_t^0, P_t^1\}$ and the qubit a_t that it acts on. Denote by τ_t^0 the measurement scenario identical to τ_{t-1}, except that $\tau_t^0(a_t) = P_t^0$.
(2) Compute p_t^0, the probability of realizing τ_t^0. By Lemma 6.1, this step takes $O(|V|^{O(1)} \exp[O(\mathrm{cc}(G))])$ time.
(3) Flip a coin that produces 0 with probability p_t^0/p_{t-1}, resulting in an outcome $b_t \in \{0,1\}$. Set τ_t to be identical to τ_{t-1}, except that $\tau(a_t) = p_t^{b_t}$. Set $p_t = (1-b_t)p_t^0 + b_t(p_{t-1} - p_t^0)$. Continue the simulation until $t = T$.

By construction, the output distribution is identical to that of the one-way computation. The complexity of the algorithm is $O(|V|^{O(1)} \exp[\mathrm{cc}(G)])$.

If the one-way computation is oblivious, then there is no need to adaptively simulate the first $T-1$ measurements, as all of them lead to the same state with the same probability p_{T-1}. Let τ_{T-1} (τ_T) be the measurement scenario corresponding to the first $T-1$ (T, respectively) measurements giving the outcome 0. We compute the probabilities p_{T-1} and p_T that τ_{T-1} and τ_T are realized. Then the probability that the one-way computation produces 0 is precisely p_T/p_{T-1}. The computation is deterministic and takes $|V|^{O(1)} \exp[O(\mathrm{cc}(G))]$ time by Lemma 6.1. □

7. Discussion. In this work we studied quantum circuits regardless of the types of gates they use, but with a focus on how the gates are connected. We have shown that quantum circuits that look too similar to trees do not offer significant advantage over classical computation. More generally, when solving a difficult classical problem on a quantum computer, one encounters an *inherent* trade-off between the treewidth and the size of quantum circuits for solving it—the smaller the quantum circuit, the more topologically sophisticated it must be. Investigating such trade-offs for specific problems of interest is an entirely open and very attractive avenue for future research. Similar considerations may apply to classical circuits. We conjecture that there are simple functions, such as modular exponentiation, whose circuit realizations require large treewidth.

Furthermore, our work raises an intriguing possibility that the treewidth of some quantum circuits may be systematically reduced by restructuring the circuit, while preserving the final result of the entire computation. Perhaps future research in this direction can clarify the limits to efficient quantum computation, while the tools developed in this context will be useful for practical tasks.

The preprint of this paper [19] has lead to several follow-up results. Jozsa [15] and Aharonov, Landau, and Makowsky [3] gave alternative proofs for some of our theorems. Furthermore, Aharonov, Landau, and Makowsky [3], and Yoran and Short [39] pointed out that quantum Fourier transform (QFT) over $\mathbb{Z}_n$ admits approximate circuit realizations that, viewed as tensor networks, have small treewidth. Given the central role of QFT in known quantum algorithms, their results are somewhat unexpected and their implications are yet to be fully explored. For example, what type of circuits would remain efficiently simulatable when interleaved with QFT circuits? In general, as implied by Theorems 1.7 and 1.8, the treewidth of a circuit may increase dramatically under composition. Yoran and Short [39] have shown that this drawback may be avoided in some cases. Extending their result would deepen our understanding of quantum speed-ups.

As mentioned earlier, Theorem 1.6 was improved in [19] so that any one-way quantum computation on a graph state $|G\rangle$ can be simulated deterministically in $|V(G)|^{O(1)} \exp(\mathrm{tw}(G))$ time. The proof relies on a graph-theoretical result from [20]:

for any graph G there is a graph G' such that $\Delta(G') \leq 3$, $\mathrm{tw}(G') \leq \mathrm{tw}(G) + 1$, and that G can be restored from G' by contracting a subset of edges forming a forest. A small modification turns G' into a graph G'' with $\Delta(G'') \leq 3$, $\mathrm{tw}(G'') \leq \mathrm{tw}(G) + 1$, and $|G\rangle$ can be constructed from $|G''\rangle$ through an efficient one-way computation. Since $\mathrm{cc}(G'') = O(\mathrm{tw}(G'')) = O(\mathrm{tw}(G))$ (Theorem 4.5), this implies, by Theorem 6.2, that any one-way computation on $|G\rangle$ can be simulated deterministically in time $|V(G)|^{O(1)} \exp(O(\mathrm{tw}(G)))$. The interested reader is referred to [19, 20] for details.

The important question of characterizing quantum states that are universal (or efficiently simulatable) for one-way quantum computation remains unsolved. In another follow-up thread, van den Nest et al. [22, 21] defined additional width-based parameters of quantum states and demonstrated results for those parameters similar to Theorem 1.6. It is unlikely that the set of quantum states with small width-based parameters includes all efficiently simulatable states because a set of simulatable states of high widths was identified recently by Bravyi and Raussendorf [9]. Nevertheless, it remains plausible that those width-based results and their further extensions may be part of a classification theorem that gives a complete characterization of efficiently simulatable states.

Appendix. Proof of Proposition 2.1. Recall that a minor of a graph G is a graph obtained from a subgraph of G by contracting edges. A basic property of treewidth is that it does not increase under taking minors [26].

Proof of Proposition 2.1. Let G' be the graph resulting from the contractions. Since G' is a minor of G, $\mathrm{tw}(G') \leq \mathrm{tw}(G)$ [26]. If $\mathrm{tw}(G') = 1$, then G' is a nonempty forest (otherwise, G has a triangle minor, thus $\mathrm{tw}(G) \geq 2$). Thus G is also a nonempty forest and $\mathrm{tw}(G) = 1 = \mathrm{tw}(G')$. Suppose $\mathrm{tw}(G') \geq 2$. Let $\mathcal{T}$ be a tree decomposition for G'. We obtain a tree decomposition $\mathcal{T}'$ for G by inserting a bag containing $\{u, w, v\}$, and connecting it to a bag that contains $\{u, v\}$. One can verify directly that the three conditions $(T_1 - T_3)$ that define tree decompositions hold for $\mathcal{T}'$. Since the width of $\mathcal{T}'$ is no more than that of $\mathcal{T}$, we have $\mathrm{tw}(G) \leq \mathrm{tw}(G')$. Therefore, $\mathrm{tw}(G) = \mathrm{tw}(G')$. □

Acknowledgments. We thank George Viamontes and John Hayes for motivating this study and helpful discussions. We are grateful to Guifré Vidal, Frank Verstraete, Ashwin Nayak, Tzu-Chieh Wei, and the anonymous reviewers for many valuable comments, including pointing out relevant previous works. Yaoyun Shi is grateful to Alexei Kitaev for introducing him to the general concept of tensor networks, and to Peng-Jun Wan for useful comments. Igor Markov is grateful to Ike Chuang for useful discussions.

EFFICIENT COLORED ORTHOGONAL RANGE COUNTING*

HAIM KAPLAN†, NATAN RUBIN†, MICHA SHARIR‡, AND ELAD VERBIN†

Abstract. Let P be a set of n points in $\mathbb{R}^d$, so that each point is colored by one of C given colors. We present algorithms for preprocessing P into a data structure that efficiently supports queries of the following form: Given an axis-parallel box Q, count the number of distinct colors of the points of $P \cap Q$. We present a general and relatively simple solution that has a polylogarithmic query time and worst-case storage about $O(n^d)$. It is based on several interesting structural properties of the problem, which we establish here. We also show that for random inputs, the data structure requires almost linear expected storage. We then present several techniques for achieving space-time tradeoff. In $\mathbb{R}^2$, the most efficient solution uses fast matrix multiplication in the preprocessing stage. In higher dimensions we use simpler tradeoff mechanisms, which behave just as well. We give a reduction from matrix multiplication to the off-line version of problem, which shows that in $\mathbb{R}^2$ our time-space tradeoffs are reasonably sharp, in the sense that improving them substantially would improve the best exponent of matrix multiplication. Finally, we present a generalized matrix multiplication problem and show its intimate relation to counting colors in boxes in higher dimension.

Key words. colored orthogonal range counting, generalized range searching, matrix multiplication, union of orthants, output-sensitive decomposition, time-space tradeoff

1. Introduction.

We consider the following range counting problem. Let P be an input set of n points in $\mathbb{R}^d$, each colored in one of C different colors. Our goal is to preprocess P into a data structure that, for any query axis-parallel box $Q \subset \mathbb{R}^d$, can efficiently count the number of *distinct colors* of points in $Q \cap P$. We call this problem *colored orthogonal range counting*. In this work we deal only with the static setting of the problem, not allowing insertions of points into, or deletions, from the data structure.

The problem arises in many applications. For example, in database applications, a person may be stored in the database as an item with attributes (e.g., the city where the person has been born, the college that she has attended, or even numerical attributes such as her age), and the query may ask for the number of different *attribute values* of all the items in a query box (e.g., How many different cities of birth do the persons in a query box have?). In geometric contexts, the problem arises, e.g., in the following scenario: We are given C rectilinear polygons in the plane with a total of n edges and wish to count the number of distinct polygons that intersect a given query box (which represents, say, a window on the screen). Similar problems arise in higher

dimensions.

1.1. Related work. *Colored intersection range searching.* In colored intersection range searching we are given n colored objects of constant description complexity. We wish to construct a data structure that can report or count the colors of objects in a query range. Colored range searching problems[1] have been extensively studied by Gupta, Janardan, Smid, and others (see a recent survey by Gupta, Janardan, and Smid [12] for a comprehensive review). As has been observed, colored variants of range searching are in general much harder than the standard variants. The reason for this contrast is that colored problems are not *decomposable*. For example, partitioning the query box into two (disjoint) subranges and counting the number of colors in each subrange tells us practically nothing about the number of colors in the full range. Halfspace colored range searching (with halfspaces as queries and points as colored objects) was studied in [15]. Orthogonal colored range searching problems (where queries are axis-parallel boxes) were studied in [4, 5, 13, 16, 19]. Additional colored range searching problems were studied in [4, 5, 14, 15]. Batched colored range intersection problems, where we wish to report all pairs of colors (c_1, c_2) such that an object of color c_1 intersects an object of color c_2, were studied in [6, 20].

Orthogonal colored range reporting. In [16], Gupta, Janardan, and Smid describe solutions for colored range *reporting* in $\mathbb{R}^1$, $\mathbb{R}^2$, and $\mathbb{R}^3$, with polylogarithmic query time and near-linear storage. For $\mathbb{R}^1$, the authors perform orthogonal colored range searching (counting and reporting) in both static and dynamic settings, by a reduction to standard orthogonal range searching in $\mathbb{R}^2$. The authors obtain a dynamic data structure of size $O(n)$, such that the i distinct colors of the points in a query interval can be reported in $O(\log n + i)$ time, while supporting updates (insertions and deletions of points) in $O(\log n)$ time. Specifically, if the points of some color are $\{p_1, p_2, \ldots, p_n\}$, such that $p_1 < p_2 < \cdots < p_n$, then they are mapped to the points $(p_1, -\infty), (p_2, p_1), \ldots, (p_n, p_{n-1})$ in $\mathbb{R}^2$. A query interval $[a, b]$ is mapped to the semiunbounded rectangle $[a, b] \times (-\infty, a]$. It is an easy observation that $[a, b]$ contains at least one (resp., no) point of color c iff the corresponding rectangle contains exactly one (resp., no) transformed point of color c. Hence, counting or reporting colors in intervals in $\mathbb{R}^1$ is equivalent to counting or reporting points in the above kind of semiunbounded rectangles in the transformed set in $\mathbb{R}^2$. See Figure 1.1 for an illustration.

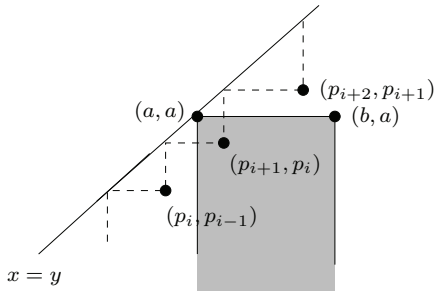

FIG. 1.1. *The transformed point set of color c (points below the line $x = y$). The highlighted semiunbounded rectangle $[a, b] \times (-\infty, a]$ contains exactly one transformed point of color c; the interval $[a, b]$ contains two original points of color c.*

[1] These problems are also referred to in the literature as *generalized range searching* problems; see [12].

In $\mathbb{R}^2$, the static data structure of Janardan and Lopez [19] uses $O(n \log^2 n)$ space and answers reporting queries in time $O(\log n + i)$, where as before, i is the output size. Gupta, Janardan, and Smid [16] obtain a semidynamic solution for the reporting problem by first dealing with the special case, when the queries are quadrants of the form $[a, \infty) \times [b, \infty)$. They reduce this special case to standard ray-segment intersection searching in $\mathbb{R}^2$. In order to process arbitrary rectangular queries, the authors decompose a rectangular query into four quadrant queries, each answered over an appropriate subset of points. The resulting data structure requires $O(n \log^2 n)$ space and allows the reporting of the i distinct colors of points contained in a query rectangle in $O(\log^2 n + i)$ time. A point can be inserted into this data structure in $O(\log^3 n)$ amortized time. Gupta, Janardan, and Smid [16] then give a fully dynamic solution to the reporting problem in $\mathbb{R}^2$. Their solution is based on decomposing the two-dimensional query into $O(\log n)$ one-dimensional queries, each answered over a proper subset of points. This data structure uses $O(n \log n)$ space, supports queries in $O(\log^2 n + i \log n)$ time, and allows insertions and deletions in $O(\log^2 n)$ time.

In $\mathbb{R}^3$, Gupta, Janardan, and Smid [16] extend their two-dimensional semidynamic solution and describe a static data structure of size $O(n \log^4 n)$ with $O(\log^2 n + i)$ query time, where i is the number of reported colors. In [13], Gupta, Janardan, and Smid describe a static data structure for orthogonal colored range reporting in any dimension, which requires storage $O(n^{1+\epsilon})$, such that for any query box in $\mathbb{R}^d$, the i distinct colors of points contained in it are reported in $O(\log n + i)$ time.[2]

These results use the fact that if we decompose the problem into a small (constant or logarithmic) number of subproblems and solve each subproblem separately, then each color is discovered only a small number of times. This still keeps the query time close to $O(\text{polylog}(n) + i)$.

Orthogonal colored range counting. Orthogonal colored range *counting* turns out to be harder than orthogonal colored range reporting. In [16], Gupta, Janardan, and Smid describe solutions for colored range counting in $\mathbb{R}^1$ and $\mathbb{R}^2$. Similarly to the case of reporting, they reduce[3] the one-dimensional problem to standard orthogonal range searching in $\mathbb{R}^2$. The resulting solution has query time $O(\log n)$ and storage and preprocessing cost $O(n \log n)$. Its *dynamic* version also requires $O(n \log n)$ space and supports queries and updates in $O(\log^2 n)$ time. (The storage of the static and the dynamic data structures can be further reduced by a logarithmic factor, as noted in [4].) Using persistence, Gupta, Janardan, and Smid [16] extend their one-dimensional data structure into a static two-dimensional structure which supports queries that involve 3-*sided boxes*, that is, boxes of the form, say, $[a, b] \times (-\infty, c]$. Using a linear number of copies of this structure, they obtain a complete solution in $\mathbb{R}^2$, with query time $O(\log^2 n)$ and storage and preprocessing cost $O(n^2 \log^2 n)$.

Halfspace colored range searching. Efficient static data structures for halfspace colored range searching were described by Gupta, Janardan, and Smid [15]. Their solution in $\mathbb{R}^2$ and $\mathbb{R}^3$ for counting and reporting is based, through duality, on a straightforward reduction to an instance of the *ray-envelope intersection problem*. In this problem, we are given a set of upper envelopes of linear functions (the lines/planes dual to the input points), such that each envelope is computed for the lines/planes of

[2] Bounds of the form $O(f(n, \epsilon))$ hold for any $\epsilon > 0$; the constant of proportionality depends on ϵ and generally tends to ∞ as $\epsilon > 0$ approaches to 0.

[3] In a sense, their reduction is the forefather of the decomposition scheme that we develop for the higher-dimensional cases; see section 3.

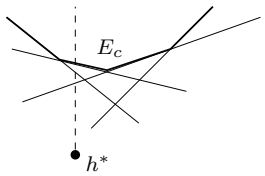

FIG. 1.2. *E_c is the upper envelope of the dual hyperplanes of the input points having color c. h^* is the point dual to the hyperplane h bounding the query halfspace below h. There is an input point below h having color c iff the upward vertical ray emanating from h^* intersects E_c (that is, h^* lies below E_c).*

some fixed color. The overall complexity of the envelopes is $O(n)$. The objective is to preprocess the envelopes into a data structure such that, given an upward vertical ray, we can report (resp., count) the envelopes that it intersects. See Figure 1.2. The solution in $\mathbb{R}^2$ uses $O(n \log n)$ space and answers reporting (resp., counting) queries in $O(\log^2 n + i)$ (resp., $O(n^{1/2})$) time. The solution in $\mathbb{R}^3$ is based on partition trees (see [23]) and uses $O(n \log^2 n)$ space and answers reporting (resp., counting) queries in $O(n^{1/2+\epsilon} + i)$ (resp., $O(n^{2/3+\epsilon})$) time. Using cutting trees instead [24, 25], reporting in $\mathbb{R}^3$ can be solved with $O(n^{2+\epsilon})$ storage, so that a query takes $O(\log^2 n + i)$ time. Note that the time and space bounds for the colored range counting in $\mathbb{R}^2$ and $\mathbb{R}^3$ are close to those achieved for the standard range counting problems in $\mathbb{R}^2$ and $\mathbb{R}^3$, respectively, [23, 24, 25].

This approach does not efficiently generalize to $\mathbb{R}^d$, for $d > 3$. Gupta, Janardan, and Smid [15] solve the reporting problem in $\mathbb{R}^d$, for $d > 3$, using a balanced binary tree CT built over the colors. Each node v in CT points to a halfspace range-emptiness data structure (described in [22]), built over the points, whose colors belong to the subtree of v. The query algorithm starts at the root of CT and continues to the children of a node v only if the query range contains at least one point, whose color belongs to the subtree of v. The resulting data structure requires $O(n^{\lfloor d/2 \rfloor} / \log^{\lfloor d/2 \rfloor - 1 - \epsilon} n)$ storage and can report the i distinct colors of points contained in a query halfspace in time $O(\log n + i \log^2 n)$. Other applications of this approach can be found in [14].

Batched colored intersection searching. In a *batched colored intersection searching problem* we are given a set of colored geometric objects and wish to compute all the pairs of colors (c_1, c_2) such that there are two intersecting input objects, one of color c_1 and one of color c_2. Often a *bipartite* version of the problem is considered, where we are given two sets of objects of two different classes and wish to report all pairs (c_1, c_2) such that an object of the first set having color c_1 intersects an object of the second set having color c_2. Efficient solutions of the colored batched intersection searching problem for line segments in $\mathbb{R}^1$, line segments in $\mathbb{R}^2$, axis-parallel boxes in $\mathbb{R}^d$, points and triangles in $\mathbb{R}^2$, and points and halfspaces in $\mathbb{R}^d$ are given in [6, 20]. For example, in the case of segments in $\mathbb{R}^1$ the problem can be solved in time $O(nc^{0.69})$ if $n \geq c^{1.69}$, and $O(n^{0.7}c^{1.21} + c^2)$ if $n \leq c^{1.69}$, using matrix multiplication techniques [20]. Variants of these techniques will also be used in this paper. See section 4.

1.2. Our contribution. We present a different approach to orthogonal colored range counting, based on a reduction from this problem to standard orthogonal range counting, which works in any dimension. We transform P into a higher-dimensional space, where each query box corresponds to a point, and for each color $c \in C$, the space $Q(c)^+$ of all (points representing) query boxes containing a point with color c is the union of positive orthants.

For each color c, we show how to decompose $Q(c)^+$ into pairwise disjoint boxes. As a consequence, a query box contains a point of color c iff the point corresponding to the query in the transformed space is contained in exactly one of the boxes in the decomposition of $Q(c)^+$. Our algorithm thus collects the decomposition boxes, over all colors c, and stores them in a data structure that supports efficient containment counting queries of the following form: Given a query point x, count the number of boxes that contain x.

A straightforward implementation of this technique yields a solution for the colored orthogonal range counting problem in $\mathbb{R}^d$, having query time $O(\log^{2d-1} n)$, storage complexity $O(n^d \log^{2d-1} n)$, and worst-case deterministic preprocessing time $O(n^d \log^{2d-1} n)$. A simple enhancement of the technique reduces all three performance parameters by a factor of $\log n$, thus matching the performance parameters of the algorithms of Gupta, Janardan, and Smid [12] for $d = 2$. If our queries are orthants, that is, boxes that are semiunbounded in each (say, negative) coordinate direction, then we can do better, obtaining a data structure with a query time of $O(\log^{d-1} n)$ and storage and preprocessing cost $O(n^{\lfloor d/2 \rfloor} \log^{d-1} n)$. For $d \geq 4$ and even, the same enhancement trick mentioned above reduces all three performance parameters by a $\log n$ factor.

In fact, the storage size and preprocessing time of our algorithm depends on the overall number of boxes in the decomposition of $Q(c)^+$, over all colors c. We show that for some sets of points the number of boxes in any such decomposition is $\Omega(n^d)$, but in practice we expect it to be much smaller. To support this statement, we show that, for random point sets (drawn independently and uniformly at random from $[0,1]^d$), the expected number of boxes in our decomposition is only $O(n \log^{d-1} n)$, which leads to algorithms with polylogarithmic query time and near-linear expected storage and preprocessing cost.

Time-space tradeoff. We also consider techniques for reducing the storage (and preprocessing) at the cost of increasing the query time. In $\mathbb{R}^2$, we use a technique of Gupta, Janardan, and Smid [12] to decompose a query $[a,b] \times [c,d]$ into two 3-sided queries $[a,b] \times (-\infty, d]$ and $[a,b] \times [c,\infty)$ on secondary structures stored at the nodes of a binary search tree over the points sorted by their y-coordinates. (This leads to significant gains, because, as we show, the structure for answering 3-sided queries requires only near-linear storage and preprocessing, whereas the structure for 4-sided queries may require near-quadratic storage.) We obtain the solution for each 3-sided query as a collection of pairwise disjoint canonical sets of colors. The difficulty is that a single color may appear in the solutions of the two 3-sided queries but we need to count it only once. To efficiently compute the union of the answers of the two queries, we use the principle of inclusion-exclusion to reduce the problem to computing the sizes of all pairwise intersections of the output canonical subsets. We use sparse matrix multiplication techniques [7, 20, 27] to precompute efficiently some of these intersection sizes and handle others on the fly when processing a query.

We obtain a solution that has query time $O(X \log^7 n)$ and $O\big(\big(\frac{n}{X}\big)^2 \log^6 n + n \log^4 n\big)$ storage, for any tradeoff parameter $1 \leq X \leq n$. The construction time of the data structure is (the $O^*(\cdot)$ notation hides polylogarithmic factors)

$$\begin{cases} O^*\left(\frac{n^{(\omega+1)/2}}{X^{(\omega-1)/2}}\right) = O\left(\frac{n^{1.688}}{X^{0.688}}\right) & \text{when } X \geq n^{\frac{\omega-1}{\omega+1}} \approx n^{0.408}, \\ O^*\left(\frac{n^{\frac{2-\alpha\beta+2\beta}{\beta+1}}}{X^{\frac{2-\alpha\beta}{\beta+1}}}\right) = O\left(\frac{n^{1.898}}{X^{1.203}}\right) & \text{when } n^{\frac{\alpha/2}{\alpha/2+1}} \approx n^{0.128} \leq X \leq n^{\frac{\omega-1}{\omega+1}} \approx n^{0.408}, \\ O^*(\frac{n^2}{X^2}) & \text{when } X \leq n^{\frac{\alpha/2}{\alpha/2+1}} \approx n^{0.128}. \end{cases}$$

Here ω is the smallest number such that two $t \times t$ matrices can be multiplied in time $O(t^\omega)$ (the best known upper bound on ω is roughly 2.376), $\alpha > 0.294$ is another parameter related to matrix multiplication, and $\beta = \frac{\omega-2}{1-\alpha}$; see [10, 11] and section 4. In particular, it follows from these bounds that, for $m \leq n$, we can answer m queries in overall time $O^*(nm^{\frac{\omega-1}{\omega+1}}) = O(nm^{0.408})$ (including preprocessing).

Interestingly, we also show a reduction of a version of sparse matrix multiplication to an off-line version of colored orthogonal range counting in $\mathbb{R}^2$. This reduction implies that if we can answer m queries on a set of n points, for $m^{\frac{1+\omega}{4}} \leq n$, in $o(nm^{\frac{\omega-1}{4}}) = o(n^{1.34})$ time, then we can obtain a better algorithm for sparse multiplication of rectangular zero-one matrices than the best known to date. Furthermore, if we can answer n such queries in $o(n^{\frac{2.376}{2}}) = o(n^{1.188})$ time, we improve the best known bound on ω (restricted to zero-one matrices). This suggests that our bounds, while not claimed to be near optimal, are significant, and that substantial improvements are likely to be quite difficult.

A simple bucketing technique allows us to trade time for space also in dimension $d > 2$. Specifically, for any threshold parameter $1 \leq X \leq n$, we obtain a data structure, having query time $O(X \log^d n + \log^{2d-1} n)$ and preprocessing and storage cost $O(\frac{n^d}{X^{d-1}} \log^{2d-1} n)$. We suggest two additional techniques to improve this tradeoff for $X = \Omega^*(n^{\frac{d-2}{d-1}})$.

Finally, we show that colored orthogonal range counting in dimension $d > 2$ is related to the following generalization of sparse matrix multiplication, which we believe to be of independent interest. One is given a 0-1 matrix A with N nonzero entries in sparse representation and a list O of M d-tuples of indices of rows of A. Let t be the number of columns in A. The goal is to compute for each tuple $(i_1, \ldots, i_d) \in O$ the sum $\sum_{j=1}^{t} \prod_{k=1}^{d} A_{i_k,j}$. We call this problem *$d$-dimensional output restricted sparse matrix multiplication* ($ORSMM_d$). (Note that the case $d = 2$ asks for computing t specified entries in AA^T.) We give a reduction from this problem to colored range counting in boxes in dimension d, showing that the off-line version of the latter problem is at least as hard as this generalized matrix multiplication problem. Finally, we describe reasonably efficient algorithms for $ORSMM_d$.

This paper is organized as follows.

In section 2 we describe the solution to colored orthogonal range counting in $\mathbb{R}^d$, which requires polylogarithmic query time and uses $\tilde{O}(n^d)$ space. The solution is based on a decomposition of the c-positive region $Q^+(c)$ (the union of the positive orthants dual to points with color c), for each of the colors c, into pairwise disjoint boxes.

In section 3 we describe the decomposition of the c-positive region into pairwise disjoint boxes and analyze its complexity and construction time. Next, we analyze, for random point sets (according to a natural model that we detail in section 3.3), the expected number of boxes in our decomposition. This leads to algorithms with polylogarithmic query time and $\tilde{O}(n)$ expected storage and preprocessing cost.

In section 4 we describe efficient methods for achieving time-space tradeoff. We also consider the time required to answer m queries over an input set of n colored points.

In section 5 we consider the relation between colored orthogonal range counting in $\mathbb{R}^d$ and sparse matrix multiplication, or its generalized version $ORSMM_d$, as defined above. In addition, we provide efficient algorithms for solving the generalized $ORSMM_d$.

We conclude this paper in section 6, with a brief discussion and a few open

problems.

2. Reducing to standard orthogonal range counting. We first solve the *semiunbounded colored range counting* problem, in which the query boxes are orthants of the form $\prod_{i=1}^{d}(-\infty, a_i]$. Then we show how to reduce the colored counting problem in general boxes to the semiunbounded case.

Let us represent each query orthant $\prod_{i=1}^{d}(-\infty, a_i]$ by its apex $(a_1, \ldots, a_d) \in \mathbb{R}^d$. Fix a color c, $1 \le c \le C$, and let P_c denote the subset of points of P with color c. For a point $p \in P_c$, denote by $Q_p^+ \subseteq \mathbb{R}^d$ the locus of all points that represent (closed) query orthants containing p. Clearly, if $p = (p_1, \ldots, p_d)$, then Q_p^+ is the positive orthant $\prod_{i=1}^{d}[p_i, \infty) \subseteq \mathbb{R}^d$. We refer to Q_p^+ as the *dual orthant* of p.

The *c-positive region* of color c, denoted $Q(c)^+$, is the region in $\mathbb{R}^d$ of all points representing queries that contain at least one point of P_c. Clearly, $Q(c)^+ = \bigcup_{p \in P_c} Q_p^+$. For any point set $A \subset \mathbb{R}^d$, define $U(A) := \bigcup_{p \in A} Q_p^+$. According to this definition, $Q(c)^+ = U(P_c)$. In section 3 we establish the following theorem.

THEOREM 2.1. *Let A be a set of n points in $\mathbb{R}^d$. We can decompose $U(A)$ into B pairwise disjoint boxes, where B is proportional to the complexity of $U(A)$. Furthermore, we can generate these boxes in $O((B+n)\log^{d-1} n)$ time. Our construction implies that $B = O(n^{\lfloor d/2 \rfloor})$, and we prove that this bound is tight in the worst case.*

In particular, when A is a set of n points in $\mathbb{R}$, $U(A)$ is a (positively oriented) closed orthant, which can be computed in $O(n)$ time.

We remark that Theorem 2.1 can be regarded as a refinement of the result of Boissonnat et al. [3] concerning the complexity of the union of n congruent axis-parallel cubes in $\mathbb{R}^d$ (think of the orthants as very large congruent cubes). As a matter of fact, our constructive proof of the theorem follows similar footsteps to those in the proof of the bound in [3]; see also [8]. In the rest of this paper, unless stated otherwise, decomposition of $U(A)$ means the disjoint decomposition asserted in Theorem 2.1.

We use Theorem 2.1 to solve the semiunbounded colored range counting problem as follows. For each color $1 \le c \le C$, we generate the boxes in the decomposition of $U(P_c) = Q(c)^+$. We build a standard orthogonal range searching data structure for counting the number of boxes containing a query point[4] $q \in \mathbb{R}^d$. By construction (using the fact that the boxes corresponding to any fixed color are pairwise disjoint), this number is equal to the number of distinct colors that appear in the original query orthant.

To implement the data structure, we use a d-dimensional segment tree with fractional cascading at its deepest level. Let B_c be the number of boxes in the decomposition of $Q(c)^+$. Then this structure has a query time $O(\log^{d-1} n)$ and requires $O(\sum_{1 \le c \le C} B_c \log^{d-1} n)$ space and preprocessing time. These improved bounds on the storage and preprocessing time (by a logarithmic factor, as compared with standard d-dimensional segment trees) are based on the fact, established in section 3, that all the decomposition boxes are unbounded in the positive x_1-direction. This allows us to use sorted lists instead of segment trees at the bottom level of the data structure, thereby saving a logarithmic factor in both storage and preprocessing time. Fractional cascading takes care of the corresponding saving in the query time.

Specifically, at the top level we have a segment tree over the x_d-coordinates of the boxes. The boxes assigned to a node v in this top-level tree are stored in a secondary segment tree, associated with v, defined over their x_{d-1}-coordinates. The structure

[4]The problem is called the "stabbing query problem" in [2].

continues this way where each node of a segment tree over the x_j-coordinates of the boxes stores the boxes assigned to it in a segment tree over their x_{j-1}-coordinates for every $3 \le j \le d$. At the bottom-level we have a segment tree over the x_2-coordinate of the boxes. Each node of such a segment tree stores the boxes assigned to it in a list sorted by the left endpoints of their x_1-projections. The sorted lists at the bottom-level of each segment tree are linked together in a fractional cascading data structure (see, e.g., [2]) so once we find the location of the query in the list associated with a node v we can search in the lists associated with the children of v in $O(1)$ time. (We also need a search tree over the list associated with the root of the tree to efficiently search in the first list.) Each node of a bottom-level list stores the number of boxes covering it, that is, the number of elements preceding it in the list. We obtain the following theorem.

THEOREM 2.2. *Let P be a set of n colored points in dimension $d \ge 2$, let B_c be the number of boxes in the decomposition of $Q(c)^+$, for each color $1 \le c \le C$, and let $B = \sum_{1 \le c \le C} B_c$. Then there exists a data structure supporting semiunbounded (orthant) colored range counting queries in $O(\log^{d-1} n)$ time, whose storage is $O(B \log^{d-1} n)$ and which can be constructed in $O((B+n)\log^{d-1} n)$ time.*

Using the bounds of Theorem 2.1, we immediately obtain the following theorem.

THEOREM 2.3. *There exists a data structure for colored semiunbounded (orthant) range counting queries on n colored points in dimension $d \ge 2$, which answers a query in $O(\log^{d-1} n)$ time, requires $O(n^{\lfloor d/2 \rfloor} \log^{d-1} n)$ space, and can be constructed in $O(n^{\lfloor d/2 \rfloor} \log^{d-1} n)$ time.*

General orthogonal range counting. The general colored orthogonal range counting problem, in which queries are arbitrary bounded axis-parallel boxes in $\mathbb{R}^d$, can be reduced to the semiunbounded case in $\mathbb{R}^{2d}$, as follows. We denote the x_i-coordinate of a point p by $x_i(p)$. Double all of the coordinates of each point $p = (x_1(p), \ldots, x_i(p), \ldots, x_d(p)) \in P$, to obtain the point $(x_1(p), -x_1(p), \ldots, x_i(p), -x_i(p), \ldots, x_d(p), -x_d(p))$ in $\mathbb{R}^{2d}$, which is given the same color as the original point p. Now, answering a colored range counting query $\prod_{i=1}^{d} [a_i, b_i]$ on the original point set is equivalent to answering the range counting query $\prod_{i=1}^{d} [a_i, \infty) \times [-b_i, \infty)$ on the transformed point set. Thus we obtain the following theorems.

THEOREM 2.4. *Let P be a set of n colored points in $\mathbb{R}^d$, let $\tilde{P} \subset \mathbb{R}^{2d}$ be the transformed point set of P as defined above, let B_c be the number of boxes in the decomposition of $U(\tilde{P}_c)$, for color $1 \le c \le C$, and let $B = \sum_{1 \le c \le C} B_c$. Then there exists a data structure supporting colored range counting queries in $O(\log^{2d-1} n)$ time, whose storage is $O(B \log^{2d-1} n)$ and which can be constructed in $O((B+n)\log^{2d-1} n)$ time.*

THEOREM 2.5. *There exists a data structure for colored orthogonal range counting queries on n colored points in $\mathbb{R}^d$, which answers a query in $O(\log^{2d-1} n)$ time, requires $O(n^d \log^{2d-1} n)$ space, and can be constructed in $O(n^d \log^{2d-1} n)$ time.*

We can generalize this approach to colored orthogonal range counting queries for boxes with bounded projections on k specific coordinates and semiunbounded projections on the remaining $d-k$ coordinates. In this case we can reduce the problem to a semiunbounded problem in $\mathbb{R}^{d+k}$, by duplicating the k "bounded" coordinates of each point in our input set. A query then takes $O(\log^{d+k-1} n)$ time, and the storage and preprocessing costs are both $O(n^{\lfloor (d+k)/2 \rfloor} \log^{d+k-1} n)$.

As a special case, consider the colored orthogonal range counting problem on n points in the plane, where the queries are 3-sided boxes of the form $[a, b] \times (-\infty, c]$. Here $d = 2$, $k = 1$, and we obtain an algorithm with $O(\log^2 n)$ query time and space

and preprocessing cost $O(n \log^2 n)$. These performance parameters are the same as those obtained by Gupta, Janardan, and Smid [12], using a different approach based on persistence (which, as already noted, does not seem to extend to higher dimensions).

We can then use the same paradigm as in [12] to extend this solution to the general case of bounded box queries. That is, let $(p_1, \ldots, p_n)$ be the sorted sequence of the points of P in their increasing y-order. For each $i = 1, \ldots, n$, construct the above data structure (for 3-sided queries) for the set $P_i^+ = \{p_j \mid j \geq i\}$. Now, given a query box $[a, b] \times [c, d]$, we find, by binary search, the index i satisfying $y(p_{i-1}) < c \leq y(p_i)$ and search with the 3-sided box $[a, b] \times (-\infty, d]$ in the structure of P_i^+. This yields a slightly improved algorithm, in which a query takes $O(\log^2 n)$ time, and the storage and the preprocessing cost are both $O(n^2 \log^2 n)$ (saving a logarithmic factor over the bounds in Theorem 2.5). The same enhancement can be applied in arbitrary dimension $d \geq 2$, leading to the following result.

THEOREM 2.6. *There exists a data structure for colored orthogonal range counting queries on n colored points in dimension $d \geq 2$, which answers a query in $O(\log^{2d-2} n)$ time, requires $O(n^d \log^{2d-2} n)$ space, and can be constructed in $O(n^d \log^{2d-2} n)$ time.*

The same enhancement can save a logarithmic factor for any d and k for which $d + k$ is even and ≥ 4. In particular, for even $d \geq 4$ and $k = 0$, we can improve all three performance parameters in Theorem 2.3 by a logarithmic factor.

In section 4 we present a more sophisticated approach that reduces colored box range counting to colored range counting with boxes unbounded in one direction, so as to obtain a much more significant reduction in storage and preprocessing (at the cost of increasing query time).

3. Decomposing the union of orthants into disjoint boxes. Let A be a set of n points in $\mathbb{R}^d$ in general position, meaning that no two points have the same x_i-coordinate,[5] for any $i = 1, \ldots, d$. In this section we prove Theorem 2.1. We start proving the first part of Theorem 2.1 and show how to decompose $U(A)$ into $B = O(n^{\lfloor d/2 \rfloor})$ pairwise disjoint boxes, where B is proportional to the complexity of $U(A)$. We then show, in section 3.2, that this bound is tight in the worst case.

An open *maximal empty orthant* O (with respect to A) is a region of the form $\prod_{i=1}^d (-\infty, a_i)$, where $a_i \in \mathbb{R} \cup \{+\infty\}$ for each i, which does not contain any point of A, and is maximal with this property under inclusion. That is, any open orthant O' that strictly contains O must also contain a point of A. It follows that each facet of O must contain a distinct point of A in its *relative interior*. Let s_i be the point in the relative interior of the facet of O orthogonal to the x_i-axis, for $1 \leq i \leq d$. Thus $O = \prod_{i=1}^d (-\infty, x_i(s_i))$ (see Figure 3.1). We also include, under this definition, orthants O that are unbounded in the positive direction of some coordinate axes; for each such direction, we replace the corresponding value $x_i(s_i)$ by $+\infty$. As an extreme example, the halfspace $x_1 < \min_{s \in A} x_1(s)$ is such a degenerate maximal empty orthant. Alternatively, for each coordinate x_i in which O is unbounded in both directions, we can define s_i to be the point at infinity whose x_i-coordinate is $+\infty$ and all other coordinates are $-\infty$. We follow the latter convention and say that O is defined by the tuple of points $\langle s_1, \ldots, s_d \rangle$.

[5] We can avoid this assumption by symbolically perturbing the x_i-coordinates of all points for $1 \leq i \leq d$ and constructing the decomposition with respect to the perturbed point set. In terms of the old coordinates, we obtain a legal decomposition of $U(A)$ into pairwise disjoint boxes. The cardinality of this decomposition, however, might be larger than the boundary complexity of $U(A)$, and some of its boxes are possibly empty (redundant). Alternatively, we can apply standard but tedious care of degenerate configurations which we omit here; see [2] for an example of such a treatment.

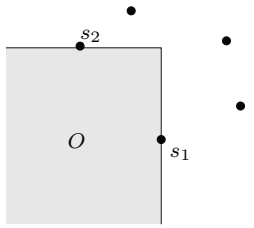

FIG. 3.1. *A maximal empty orthant.*

Our decomposition of $U(A)$ is constructed so that there is a bijection between its boxes and the maximal empty orthants defined by tuples $\langle s_1, \ldots, s_d \rangle$ such that $x_1(s_1) < \infty$. Specifically, let O be such a maximal empty orthant defined by $\langle s_1, \ldots, s_d \rangle$. The box in our decomposition corresponding to O is

$$B(O) = [x_1(s_1), \infty) \times \prod_{i=2}^{d} \Big[\max_{j<i} \{x_i(s_j)\}, x_i(s_i) \Big).$$

Note that each interval in the product is nonempty, which follows from the above general position assumption. See Figure 3.2 for an illustration.

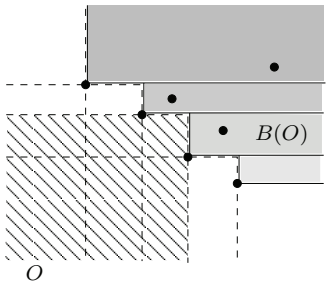

FIG. 3.2. *A maximal empty orthant O and its corresponding box $B(O)$ in the decomposition of $U(A)$. Altogether there are four maximal empty orthants bounded in the $(+x_1)$-direction and four respective boxes in the decomposition of $U(A)$.*

LEMMA 3.1. *Let A be a finite point set in $\mathbb{R}^d$, let $\mathcal{O}$ be the set of all maximal empty orthants with respect to A, which are defined by tuples $\langle s_1, \ldots, s_d \rangle$ satisfying $x_1(s_1) < \infty$, and let $\mathcal{B}$ be the collection of boxes of the form $B(O)$, for $O \in \mathcal{O}$. Then the boxes of $\mathcal{B}$ are pairwise disjoint, and their union is $U(A)$.*

Proof. We establish the lemma by induction on the dimension of the space containing A.

For the induction basis, consider a one-dimensional set of points $A = \{p_1, \ldots, p_n\} \subset \mathbb{R}$, where $p_1 < p_2 < \cdots < p_n$. The orthant $(-\infty, p_1)$, defined by $\langle p_1 \rangle$, is the only maximal empty orthant with respect to A (which clearly satisfies $x_1(p_1) < \infty$). The corresponding box $B = [x_1(s_1), \infty) = [p_1, \infty)$ is indeed equal to $U(A)$, as required.

Assume now that the lemma is true for any finite set of points in $\mathbb{R}^{d-1}$. Sweep $U(A)$ with a hyperplane h orthogonal to the x_d-axis. Let $(p_1, \ldots, p_n)$ be the sequence of the points of A sorted in increasing order of their x_d-coordinates. For $1 \le j \le n$, put $q_j := x_d(p_j)$, let h_j be the hyperplane $x_d = q_j$, and let H_j be the half-closed slab bounded between h_j and h_{j+1} (containing h_j but not h_{j+1}); let H_n be the infinite slab "beyond" h_n, i.e., the slab $x_d \ge x_d(p_n)$.

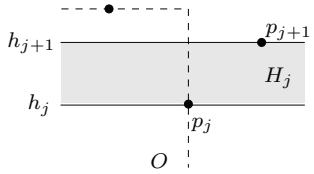

FIG. 3.3. *The proof of Lemma* 3.1.

By definition, the boxes in our decomposition that intersect H_j correspond to maximal empty orthants defined by tuples $\langle s_1, \ldots, s_d \rangle$, such that $q_{j+1} \leq x_d(s_d)$ (or $x_d(s_d) = \infty$ for $j = n$), $\max_{j<d}\{x_d(s_j)\} \leq q_j$, and $x_1(s_1) < \infty$. See Figure 3.3 for an illustration. Denote by $\mathcal{O}_j$ the set of these orthants, and denote by $\mathcal{B}(\mathcal{O}_j)$ the corresponding set of boxes. We claim that the intersections of the boxes in $\mathcal{B}(\mathcal{O}_j)$ with H_j form a pairwise disjoint decomposition of $H_j \cap U(A)$.

Indeed, let $D_j = \{p_i \mid i \leq j\}$, and let D'_j be the orthogonal projection of D_j on the hyperplane h_j. Let $\mathcal{O}'_j$ be the set of maximal empty orthants with respect to D'_j in the $(d-1)$-dimensional space h_j, defined by tuples $\langle s_1, \ldots, s_{d-1} \rangle$ satisfying $x_1(s_1) < \infty$. Let $\mathcal{B}(\mathcal{O}'_j)$ be the corresponding set of boxes within h_j. The following facts are easy to verify.

1. The intersection of $U(A)$ with h_j is equal to the intersection of $U(D_j)$ with h_j, which in turn is equal to $U(D'_j)$.
2. Each maximal empty orthant $O' \in \mathcal{O}'_j$ is the intersection of an orthant $O \in \mathcal{O}_j$ with h_j. Conversely, for each orthant $O \in \mathcal{O}_j$, the $(d-1)$-orthant $O' = O \cap h_j$ is a maximal empty orthant with respect to D'_j.
3. Let $O \in \mathcal{O}_j$, and let $B(O)$ be the corresponding box. The intersection of $B(O)$ with h_j is equal to $B(O')$, where O' is the $(d-1)$-orthant $O \cap h_j$.

See Figure 3.3 for an illustration. By the induction hypothesis, the boxes of $\mathcal{B}(\mathcal{O}'_j)$ form a pairwise disjoint decomposition of $U(D'_j)$. Furthermore, by 2. and 3., each box $B(O)$ in $\mathcal{B}(\mathcal{O}_j)$ corresponds to a box $B(O')$ in $\mathcal{B}(\mathcal{O}'_j)$, where $O' = O \cap h_j$, so that $B(O') \times [q_j, q_{j+1}) \subseteq B(O)$, and vice versa. Thus the boxes in $\mathcal{B}(\mathcal{O}_j)$ are pairwise disjoint within H_j, and by 1. their union is equal to $U(A) \cap H_j$. Repeating this argument for each slab H_j completes the proof. ∎

The number of boxes. Let $A \subset \mathbb{R}^d$ be an arbitrary set of points. As we have seen, the number of cells in the decomposition of $U(A)$ is bounded by the number of maximal empty orthants with respect to A. Hence, it suffices to bound the latter quantity.

Here is a straightforward constructive derivation of the bound $O(n^{\lfloor d/2 \rfloor})$ for this latter quantity, which resembles the analysis of Boissonnat et al. [3]. We have already seen, for dimension $d = 1$, that the decomposition of $U(A)$ consists of a single orthant. Now assume that $d \geq 2$. Note that the number of maximal empty orthants that are halfspaces, and contain only one point of A on their boundary, is $O(n)$. So it remains to count maximal empty orthants with at least two points of A on their boundary. Given any empty orthant O, with at least two points of A on its boundary (possibly on lower-dimensional faces of the boundary), a *shift* of O is the operation of shrinking O by translating a facet of O in the negative direction of the orthogonal coordinate axis. By the general position assumption, when a shift starts, exactly one point leaves the boundary of O. The shift is *legal* if such a point lies in the relative interior of a facet. A legal shift terminates as soon as one of the points of A on ∂O reaches the relative boundary of the face it is currently on, so that it now lies on a lower-dimensional face.

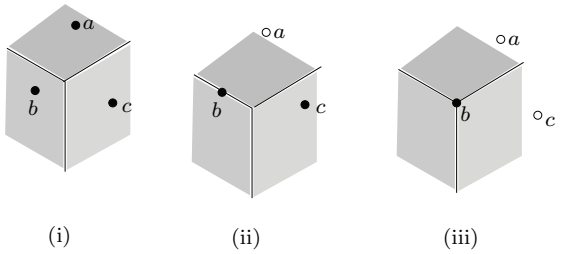

FIG. 3.4. *Three legal shifts that turn a maximal empty orthant into the one that has point b as an apex.*

Note that the orthant reached at the end of a legal shift is contained in the original orthant and is thus also empty.

We start with a maximal empty orthant O, with at least two points of A on its boundary, and apply to it any sequence of legal shifts, until we reach an orthant O' to which no further legal shifts can be applied. See Figure 3.4. Upon termination, no point of A lies in the relative interior of any facet of O'. Hence each point of A on $\partial O'$ determines at least two of the coordinate values that define facets of O', and, since we assume general position, no such coordinate value is determined by more than one point. Hence, the number of points on $\partial O'$ is at most $\lfloor d/2 \rfloor$, which implies that the number of such empty orthants O', which can be obtained from some maximal empty orthant in the manner described above, is $O(n^{\lfloor d/2 \rfloor})$. Moreover, knowing the sequence of directions of the legal shifts that have transformed an original maximal empty orthant O into O', the orthant O can be uniquely reconstructed from O', using a sequence of reverse legal shifts, each stopping when the facet that moves outwards hits a new point. Clearly, the total number of such sequences of shifts is at most $d!$. The bound of $O(n^{\lfloor d/2 \rfloor})$ on the number of maximal empty orthants with respect to A, and therefore on the number of boxes in our decomposition, follows.

We claim that each maximal empty orthant corresponds to a distinct face on the boundary of $U(A)$. This implies that the number of boxes B in our decomposition is at most the number of distinct faces on the boundary of $U(A)$. (Note that not every maximal empty orthant induces a decomposition cell $B(O)$, because O may be unbounded in the positive direction of the x_1-axis, having $x_1(s_1) = \infty$.) On the other hand, it is clear that the number of boxes cannot be smaller by more than a constant factor than the complexity of $U(A)$. So it follows that number of boxes B is proportional to the complexity of $U(A)$ (and to the number of maximal empty orthants) and thereby asymptotically optimal.

To establish the claim, let O be a maximal empty orthant, defined by the d-tuple $\langle s_1, \ldots, s_d \rangle$. Let J denote the (nonempty) set of all indices $1 \leq i \leq d$, such that $x_i(s_i) < \infty$. For each $i \in J$, let F_i denote the (closed) facet of the (positively oriented) dual orthant, $Q^+_{s_i}$, of s_i, that is orthogonal to the x_i-axis. Let F be the set of all points o, such that for $1 \leq i \leq d$, $x_i(o) = x_i(s_i)$ if $i \in J$, and $x_i(o) \geq \max_{j \in J}\{x_i(s_j)\}$, otherwise. We claim that $F = \bigcap_{i \in J} F_i$, and therefore $F \subseteq U(A)$. It is immediate that $\bigcap_{i \in J} F_i \subseteq F$. To show that $F \subseteq \bigcap_{i \in J} F_i$, note that for each $o \in F$ and $i \in J$, the negatively oriented orthant with apex o contains s_i on its facet orthogonal to the x_i-axis, and therefore o is contained in F_i. We next show that F does not intersect the interior of $U(A)$. To see that, note that any negatively oriented orthant O', whose apex belongs to F, does not contain any point of A in its interior. Let k be the number

of indices $1 \leq i \leq d$ such that $x_i(s_i) = \infty$. Then F is a k-dimensional (closed) face, on the boundary of $U(A)$, having nonzero (and unbounded) extent in exactly the k coordinates just defined. Moreover, as is easy to check, O is uniquely defined by F.

3.1. Output-sensitive construction. In order to construct the desired decomposition of $U(A)$, it suffices to enumerate all the maximal empty orthants with respect to A, each with the d-tuple defining it. As mentioned previously, when $d = 1$, $U(A)$ is an orthant which we can compute in $O(n)$ time. Hence, we can assume $d \geq 2$. We have seen that each such maximal empty orthant can be defined (up to a constant number of possibilities) by a t-tuple of points of A, such that $t \leq \lfloor d/2 \rfloor$. The constructive proof of the bound on the number of boxes (or, rather, of maximal open orthants) can be trivially converted into an algorithm that generates $O(n^{\lfloor d/2 \rfloor})$ candidate empty orthants, prunes away those that are not empty (using orthogonal emptiness range queries on the set A), and extends each of them, by some sequence (out of $O(1)$ possible ones) of reverse legal shifts, into a maximal empty orthant.

The running time of this straightforward algorithm is close to $O(n^{\lfloor d/2 \rfloor})$, and is always $\Omega(n^{\lfloor d/2 \rfloor})$, which might be much larger than the actual complexity of the decomposition of $U(A)$. In this section, we present an alternative *output-sensitive* algorithm for constructing all maximal empty orthants with respect to A. This immediately leads to an *output-sensitive* construction of our decomposition of $U(A)$.

We can enumerate all maximal empty orthants with respect to A by implementing the sweep that was used to establish Lemma 3.1. Let $p_1, \ldots, p_n$ be the points in the increasing order of their x_d-coordinates. We sweep $\mathbb{R}^d$ with a hyperplane π orthogonal to the x_d-direction. As above, let $D_j = \{p_i \mid i \leq j\}$, let p'_j be the projection of p_j on π, and let D'_j be the projection of D_j onto π, i.e., $D'_j = \{p'_i \mid i \leq j\}$.

After π passes through p_j, we update the maximal empty ($(d-1)$-dimensional) orthants with respect to D'_j on π. Specifically, we find the set Q of all maximal empty orthants (on π) with respect to D'_{j-1} which are not maximal empty orthants with respect to D'_j (because the projection p'_j of p_j, or rather, p_j itself at this moment, lies in their relative interior). Each such orthant, together with p_j, defines a maximal empty orthant with respect to A, which we output. We delete all orthants in Q and generate a new set N of maximal empty orthants with respect to D'_j which were not maximal empty $(d-1)$-orthants with respect to D'_{j-1} (those have a $(d-2)$-facet containing p_j in its relative interior). See Figure 3.5.

To efficiently identify the set Q when processing p_j, we maintain the maximal empty $(d-1)$-orthants on π in a dynamic $(d-1)$-dimensional range tree, where each orthant is represented by its apex (a point on π). Using this structure, we can find all k orthants containing p'_j in $O(\log^{d-1} n + k)$ time. We can also delete from, or insert into, the dynamic data structure an orthant, in $O(\log^{d-1} n)$ time (see [26] for more details).

To efficiently identify the set N, we make the following observation. Let O be an orthant in N, containing p_j on its facet which is orthogonal to the x_i-axis, for some $i < d$. Ignoring p_j, and shifting the facet containing p_j away from O, we either hit a point of D'_{j-1} or have this facet of O reach infinity. In both cases, we end up with an orthant O' of Q. Hence, each orthant in N can be obtained by taking an orthant O' of Q and by replacing a facet of O' by a parallel facet through p_j. (Not all orthants obtained in this manner are valid: One also needs to ensure that each facet of the shrunk orthant, other than the one through p_j, still contains a point of D'_j in its relative interior.)

It is easily verified that the total number of updates to the dynamic range tree

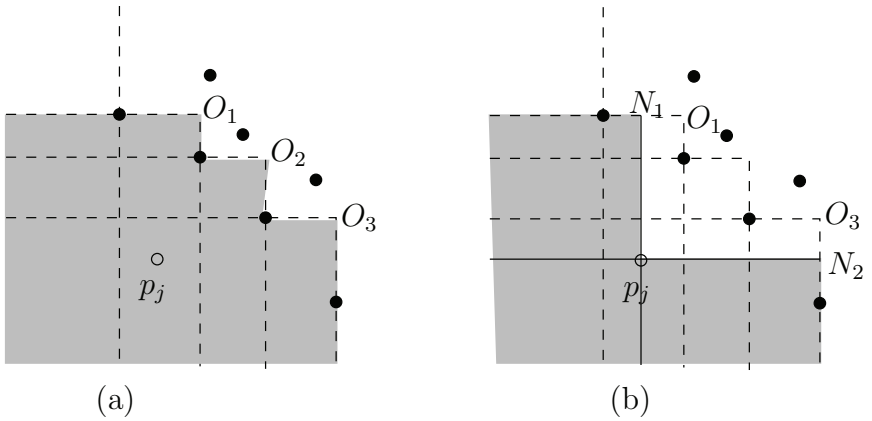

FIG. 3.5. *The sweep procedure in* $\mathbb{R}^3$*:* (a) *The structure on the sweep plane* π *just before reaching* p_j*; the set* Q *of* $(d-1)$*-orthants that are eliminated by* p_j *is shaded.* (b) *The structure on* π *immediately after reaching* p_j*; the set* N *of* $(d-1)$*-orthants that are generated by* p_j *is shaded. In the example,* $|Q| = 3$ *and* $|N| = 2$*. The new orthant* N_1 *is obtained by shrinking* O_1 *to the left, and* N_2 *is obtained by shrinking* O_3 *downwards.*

is bounded by the number H of maximal empty orthants with respect to A. Indeed, this is clear for orthants in Q: each such orthant O corresponds to a unique maximal empty d-orthant that is "completed" when the sweep hyperplane reaches its present position. Each orthant O in N will either be completed into a maximal empty d-orthant when it hits a new point at some future position of the sweep hyperplane, or else survive until the sweep is completed, and then become a degenerate d-orthant, unbounded in both directions of the x_d-axis. Since we argued before that the overall number H of maximal empty orthants with respect to A is proportional to the number B of boxes in our decomposition of $U(A)$, it follows that the decomposition of $U(A)$ can be constructed in $O((B+n)\log^{d-1} n)$ time.

3.2. Lower bounds. We now show that the upper bound in Theorem 2.1 is tight in the worst case. Specifically, we construct, for every dimension $d \geq 2$ and n, a set of n points A in $\mathbb{R}^d$ such that there are $\Omega(n^{\lfloor d/2 \rfloor})$ maximal empty orthants with respect to A. Since each of these orthants corresponds to a distinct face on the boundary of $U(A)$, we obtain that the number of boxes in any decomposition of $U(A)$ is $\Omega(n^{\lfloor d/2 \rfloor})$.

In fact, we prove a more general lower bound on the number of maximal empty boxes with respect to a finite set of points $A \subseteq \mathbb{R}^d$. A *maximal empty box* with respect to a point set A is an open axis-parallel box, which does not contain any point of A in its interior, and is maximal with this property under inclusion (so, as in the case of orthants, each facet of the box contains a point of P in its relative interior). We allow a maximal empty box to be unbounded in certain directions, so every maximal empty orthant with respect to P is also a maximal empty box.

Worst-case tightness of the upper bound in Theorem 2.1 is an easy consequence of the following two lemmas.

LEMMA 3.2. *There exists a set of points* $A = \{p_i^j \mid 1 \leq i \leq n, 1 \leq j \leq d\}$ *in general position in dimension* $d \geq 2$ *such that, for any choice of indices* $1 \leq i_d \leq i_{d-1} \leq \cdots \leq i_1 \leq n$*, there is an (open) empty box* R *whose boundary contains only the points* $p_{i_j}^j$*, for* $1 \leq j \leq d$*.*

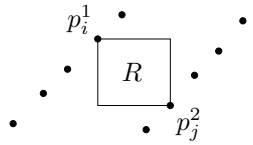

FIG. 3.6. *Illustrating Lemma* 3.2 *in dimension* $d = 2$. *We have* $p_i^1 = (i, i)$ *for* $1 \le i \le n$, *and* $p_j^2 = (n + j, j)$ *for* $1 \le j \le n$. *For any choice of* $1 \le j \le i \le n$, *the rectangle* $(i, j + n) \times (j, i)$ *contains only* p_i^1 *and* p_j^2 *on its boundary.*

Proof. Let $\vec{1} \in \mathbb{R}^d$ be the vector with all components equal to 1. Let $\vec{1}_{<j} \in \mathbb{R}^d$ be the vector whose ℓth component is 1, for $\ell < j$, and 0 for $\ell \ge j$. Let $p_i^j = n\vec{1}_{<j} + i\vec{1}$, for $1 \le i \le n$ and $1 \le j \le d$. We claim that the box $R = (i_1, i_2 + n) \times (i_2, i_3 + n) \times \cdots \times (i_{d-2}, i_{d-1} + n) \times (i_{d-1}, i_d + n) \times (i_d, i_1)$ contains only the points $p_{i_j}^j$. See Figure 3.6 for an illustration in dimension $d = 2$.

To prove the claim, consider a fixed point $p_{i_j}^j$. The first $j - 1$ coordinates of this point are equal to $i_j + n$, and the rest are equal to i_j. It easily follows that this point is on the boundary of R. On the other hand, let p_a^j be a point such that $a \ne i_j$. We argue that p_a^j does not belong to the closure of R.

Case 1a. If $a < i_j$ and $j \ne d$, then the projection of R on the jth coordinate is the interval $(i_j, i_{j+1} + n)$, but the jth coordinate of p_a^j is a, and since $a < i_j$, p_a^j does not belong to the closure of R.

Case 1b. If $a < i_j$ and $j = d$, then the projection of R on the dth coordinate is the interval (i_d, i_1), but the dth coordinate of p_a^j is a, and since $a < i_d$, p_a^j does not belong to the closure of R.

Case 2a. If $a > i_j$ and $j \ne 1$, then the projection of R on the $(j-1)$th coordinate is the interval $(i_{j-1}, i_j + n)$, but the $(j - 1)$th coordinate of p_a^j is $a + n$, since $a > i_j$, p_a^j does not belong to the closure of R.

Case 2b. If $a > i_j$ and $j = 1$, then the projection of R on the dth coordinate is the interval (i_d, i_1), but the dth coordinate of p_a^j is a, since $a > i_1$, p_a^j does not belong to the closure of R.

By symbolically perturbing the points of A, we can ensure that A is a set of points in general position, and the lemma still holds for the perturbed set. □

LEMMA 3.3. *For any dimension* d, *there exists a set* A *of* n *points in* $\mathbb{R}^d$ *in general position, such that there is* $\Omega(n^d)$ *maximal empty boxes with respect to* A.

Proof. If $d = 1$, we can choose A to be any set of points in $\mathbb{R}$ in general position. We thus assume that $d > 1$.

Let A be the point set of Lemma 3.2. Then, for any of the $\Omega(n^d)$ possible choices of indices $1 \le i_d \le i_{d-1} \le \cdots \le i_1 \le n$, there is an empty box R whose boundary contains p_{i_j} for all $1 \le j \le d$. Let $\mathcal{R}$ be this set of empty boxes. For each box $R \in \mathcal{R}$, let $B(R)$ be any maximal empty box containing R. (By the definition of a maximal empty box, $B(R)$ always exists.) Clearly, the boundary of $B(R)$ also contains p_{i_j} for all $1 \le j \le d$. Since A is a set of points in general position, $B(R)$ contains at most $2d$ points on its boundary. It follows that $B(R)$ may be equal to $B(R')$ for at most a constant number of boxes $R' \in \mathcal{R}$. So we obtain $\Omega(n^d)$ distinct maximal empty boxes in this way. □

To see the tightness of the upper bound in Theorem 2.1 for an even $d \ge 2$, take a point set B of n points in $\mathbb{R}^{d/2}$ such that there are $\Omega(n^{d/2})$ maximal empty boxes with respect to B. Such a set exists by Lemma 3.3. Let A be the point set in dimension d obtained from B by applying the transformation of Theorem 2.4. It is

easy to verify that if $\prod_{i=1}^{d}(a_i, b_i)$ is a maximal empty box with respect to B, then $\prod_{i=1}^{d}(-\infty, a_i) \times (-\infty, -b_i)$ is a maximal empty orthant with respect to A and vice versa. So it follows that there are $\Omega(n^{d/2})$ maximal empty orthants with respect to A.

If we embed A in $\mathbb{R}^{d+1}$ by setting coordinate x_{d+1} of all points to 0 (and then symbolically perturb it), we establish the tightness of the bound in Theorem 2.1 also for odd $d \geq 3$.

This, at long last, completes the proof of Theorem 2.1. □

Remark. The storage required by the data-structure of Theorem 2.3 depends on the number of maximal empty orthants with respect to each of the sets of points P_c of color c, for $1 \leq c \leq C$. Since this quantity can be as large as $\Omega(n^{\lfloor d/2 \rfloor})$, we have a lower bound of $\Omega(n^{\lfloor d/2 \rfloor})$ for the storage required by the data structure of Theorem 2.3 in a worst-case scenario.

The storage required by the data-structure of Theorem 2.5 depends on the number of maximal empty orthants with respect to each of the sets $\tilde{P}_c$, for $1 \leq c \leq C$, obtained from P_c by doubling each coordinate in the manner described above. As just noted, the number of maximal empty orthants with respect to each transformed set $\tilde{P}_c$ is equal to the number of maximal empty boxes with respect to the initial set P_c. By Lemma 3.3, a point set of cardinality n in dimension $d \geq 1$ can define $\Omega(n^d)$ maximal empty boxes in the worst-case. So we obtain a lower bound of $\Omega(n^d)$ on the worst-case storage required by the data-structure of Theorem 2.5. Similarly, we can prove a lower bound of $\Omega(n^d)$ for the worst-case storage required by the data-structure of Theorem 2.6.

3.3. Random sets of points. The decomposition-based data structures of Theorems 2.5 and 2.3 are especially efficient, when the number of maximal empty boxes with respect to each of the sets $P_c \subset \mathbb{R}^d$ is small for all $1 \leq c \leq C$. In this subsection we prove that the expected number of maximal empty boxes for a random point-set with n points in $\mathbb{R}^d$ is only $O(n \log^{d-1} n)$. It would be interesting to explore the connection between this result and the known bound of $O(\log^{d-1} n)$ on the expected number of *maximal* points in a set of n random points in $\mathbb{R}^d$; see [1, 17].

We assume that the set P is constructed so that each point is chosen independently and uniformly at random from the uniform distribution on $[0, 1]^d$. Thus, with probability 1, the points of P are in general position, and, for each i, the x_i-coordinates of the sampled points form a random permutation, which are independent of each other. We define a *t-box* to be an axis-parallel box B, that may be unbounded in certain directions, containing t points on its boundary, such that each one of the finite facets of B contains a point of P (possibly on its relative boundary).[6] Let $B_{t,k}(P)$ (resp., $B_{t,\leq k}(P)$), for $1 \leq t \leq 2d$, denote the set of t-boxes containing exactly (resp., at most) k points of P in their interior, and put $N_{t,k}(P) = |B_{t,k}(P)|$ (resp., $N_{t,\leq k}(P) = |B_{t,\leq k}(P)|$). Note that we may have degenerate boxes with identical opposite facets. However, the number of such boxes is at most $O(n)$, due to the general position assumption. Finally, we let $N^{(d)}_{t,k}(n)$ (resp., $N^{(d)}_{t,\leq k}(n)$) denote the expected value of $|B_{t,k}(P)|$ (resp., $|B_{t,\leq k}(P)|$), over the random choice of a set P of n points in $\mathbb{R}^d$. In order to obtain the asserted bound on the expected number of maximal empty boxes with respect to P, it suffices to show that $N^{(d)}_{t,0}(n) = O(n \log^{d-1} n)$ for all $1 \leq t \leq 2d$.

[6] With some abuse of notation, we allow degenerate 1-boxes contained in orthogonal planes. Clearly, there are $O(n)$ such boxes.

We prove the bound by induction on d. The case $d = 1$ is trivial: We clearly have $N^{(1)}_{1,0}(n)$ is 2, since any empty nondegenerate 1-box in $\mathbb{R}^1$ is an empty ray emanating from a point of P. Similarly, $N^{(1)}_{2,0}(n) = n - 1$, since any empty 2-box is a segment bounded by a pair of consecutive points of P.

Assume now that $d > 1$, and that the bound holds for $d - 1$ (and for all $t \leq 2(d-1)$). Assume also (without really changing the model) that we draw each point $p \in P$ by first drawing a point $p' \in [0,1]^{d-1}$, thereby fixing the projection of p on the hyperplane $x_d = 0$ to be p', and then drawing x_d uniformly from $[0,1]$ to be the x_d-coordinate of p.

Let $P' = \{p' \mid p \in P\}$ be the set of projections of all points in P on the hyperplane $x_d = 0$. Let $\hat{B}_{t,0}(P)$ denote the set of empty t-boxes of P whose both facets orthogonal to the x_d-axis contain a point of P on their relative boundary. Set $\hat{N}_{t,0}(P) = |\hat{B}_{t,0}(P)|$ and $\hat{N}_{t,0}(n) = \max_{|P|=n} \hat{N}_{t,0}(P)$. Every t-box B in $\hat{B}_{t,0}(P)$ corresponds to the t-box B' of P', obtained by projecting B onto $x_d = 0$; note, however, that B' is not necessarily empty.

Fix P', and consider the random drawings of the x_d-coordinates of the points of P. What is the probability that a t-box B' in $B_{t,k}(P')$ corresponds to an empty t-box B in $\hat{B}^d_{t,0}(P)$? For this to happen, it is necessary and sufficient that the t boundary points of B' be consecutive in the permutation defined by the $t + k$ boundary and interior points of B' along the x_d-axis (see Figure 3.7). This happens with probability $\frac{t!(k+1)!}{(k+t)!} = \frac{t!}{(k+2)(k+3)\cdots(k+t)}$. So we obtain the following inequality:

$$\mathbb{E}(\hat{N}_{t,0}(P)) \leq \sum_{k=0}^{n-t} \frac{t!}{\prod_{i=2}^{t}(k+i)} |B_{t,k}(P')|.$$

Rearranging this sum, we get

$$\mathbb{E}(\hat{N}_{t,0}(P)) \leq \sum_{k=0}^{n-t-1} \frac{t!(t-1)}{\prod_{i=2}^{t+1}(k+i)} |B_{t,\leq k}(P')| + \frac{t!}{\prod_{i=2}^{t}(n-t+i)} |B_{t,\leq n-t}(P')|.$$

This holds for every choice of P', so if we average over the choices of P', we obtain the following recurrence:

$$\hat{N}^{(d)}_{t,0}(n) \leq \sum_{k=0}^{n-t-1} \frac{t!(t-1)}{\prod_{i=2}^{t+1}(k+i)} N^{(d-1)}_{t,\leq k}(n) + \frac{t!}{\prod_{i=2}^{t}(n-t+i)} N^{(d-1)}_{t,\leq n-t}(n). \tag{3.1}$$

To estimate $N^{(d-1)}_{t,\leq k}(n)$, for $k \geq 1$, we note that if we sample a random subset of P of size n/k, we obtain a random set of n/k points drawn independently from the same uniform distribution as P. Hence, we can apply the Clarkson–Shor probabilistic technique [9] to conclude that

$$N^{(d-1)}_{t,\leq k}(n) = O(k^t N^{(d-1)}_{t,0}(n/k)). \tag{3.2}$$

By the induction hypothesis we have $N^{(d-1)}_{t,0}(n) = O(n \log^{d-2} n)$, for any $1 \leq t \leq 2d$, and for any n. Hence, by (3.2), $N^{(d-1)}_{t,\leq k}(n) = O(nk^{t-1} \log^{d-2} n)$, for any $1 \leq t \leq 2d$. Plugging this into inequality (3.1), we obtain the bound $\hat{N}^{(d)}_{t,0}(n) = O(n \log^{d-1} n)$, for $1 \leq t \leq 2d$.

We next consider empty t-boxes, for which neither of their facets orthogonal to the x_d-axis contains points of P in their relative boundaries. We consider only boxes that are not strips bounded by one or two hyperplanes orthogonal to the x_d-direction (there are $O(n)$ such strips). Any such box B can be charged to a box in $\hat{B}_{t',0}(P)$, for some $t-2 \le t' \le t$, by applying two legal shifts to B (as defined at the beginning of this section), the first of which shifts the top facet down, and the second shifts the bottom facet up. With some care, this also applies to boxes that are unbounded in the x_d-direction. The resulting box $\hat{B}$ is uniquely charged in this manner. Similarly, an empty t-box B, such that one of its facets orthogonal to the x_d-axis does not contain a point in the relative boundary, can be charged to a box $\hat{B}$ in $\hat{B}_{t',0}(P)$, for some $t-1 \le t' \le t$. This can be done by applying just one legal shift that shifts that facet. Such a $\hat{B}$ is charged at most twice. Hence we have

$$N_{t,0}^{(d)}(n) = O(\hat{N}_{t,0}^{(d)}(n) + \hat{N}_{t-1,0}^{(d)}(n) + \hat{N}_{t-2,0}^{(d)}(n) + n). \tag{3.3}$$

Since we have already proved that $\hat{N}_{t,0}^{(d)}(n) = O(n \log^{d-1} n)$, for $1 \le t \le 2d$, the induction step follows from (3.3). The following theorem summarizes what we have shown.

THEOREM 3.4. *Let P be a set of n points in $\mathbb{R}^d$, drawn independently from the uniform distribution on $[0,1]^d$. Then the expected number of maximal empty boxes with respect to P is $O(n \log^{d-1} n)$, where the constant of proportionality depends on d.*

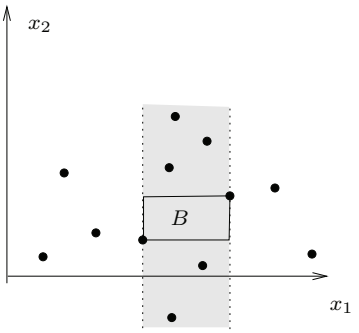

FIG. 3.7. *Bounding the expected number of empty boxes in the plane. The highlighted box B belongs to $\hat{B}_{2,0}(P)$, and its x_1-projection belongs to $B_{2,5}(P')$. The two points defining B must be consecutive in the x_2-order of the points in the shaded strip.*

Semiunbounded colored range counting for random sets. In particular, the bound of Theorem 3.4 also applies to the expected number of maximal empty orthants. Since the storage required by the data-structure of Theorem 2.2 depends on the number of maximal empty orthants with respect to each of the sets P_c, for $1 \le c \le C$, we obtain the following result.

THEOREM 3.5. *Let P be a set of n colored points in dimension $d \ge 2$, such that each point is drawn independently from the uniform distribution on $[0,1]^d$. Then there exists a data structure supporting semiunbounded colored range counting queries in $O(\log^{d-1} n)$ time, whose expected storage is $O(n \log^{2d-2} n)$ and which can be constructed in expected $O(n \log^{2d-2} n)$ time.*

General colored range counting for random sets. Recall that we solve the problem when queries are general bounded boxes by a reduction to the semibounded problem.

However, since this reduction transforms the points by doubling each coordinate, we can no longer assume that the transformed set satisfies our randomness assumption.

We overcome this difficulty using the following observation from section 3.2. Let A be a random point set in $\mathbb{R}^d$ and $\tilde{A}$ the point set in $\mathbb{R}^{2d}$ into which A is mapped; then every maximal empty orthant in $\mathbb{R}^{2d}$ with respect to $\tilde{A}$ corresponds to a maximal empty box in $\mathbb{R}^d$ with respect to A. Hence, we can still apply Theorem 3.4 to the original set A in order to upper-bound the number of maximal empty orthants with respect to $\tilde{A}$. Using the data structure of Theorem 2.4 we obtain the following result.

THEOREM 3.6. *Let P be a random colored point-set of cardinality n in $\mathbb{R}^d$, such that the points of each color are selected as above. Then there exists a data structure supporting colored range counting queries in $O(\log^{2d-1} n)$ time, whose expected storage is $O(n \log^{3d-2} n)$ and which can be constructed in expected $O(n \log^{3d-2} n)$ time.*

Using the same technique, we can build a data structure to answer colored range counting queries for boxes with bounded projections on k specific coordinates, for a random point set, by reducing the problem to a semiunbounded problem in $\mathbb{R}^{d+k}$ and using Theorem 3.4.

Remark. The enhancement that shaves off a logarithmic factor, as provided in Theorem 2.6, does not apply in this case, because it is based on n copies of the structure, and the expected number of maximal empty orthants may be linear in each subproblem, giving rise to an overall data structure of superquadratic size.

4. Achieving time-space tradeoff. In this section we present several techniques for reducing storage at the expense of increasing query time.

4.1. The planar case: Splitting boxes. Our tradeoff technique for the planar case uses the more space efficient data structure of Theorem 2.3 that supports colored range counting queries with 3-sided boxes of the form $[a, b] \times (-\infty, d]$ or $[a, b] \times [c, \infty)$. Recall that we transform this problem into a standard orthogonal containment searching in $\mathbb{R}^3$, and that the resulting data structure requires only $O(n \log^2 n)$ storage and preprocessing cost. (See the discussion preceding Theorem 2.2.) This data structure is a three-level segment tree where each node of a segment tree at the second level stores a linked list of all the boxes associated with it sorted according to their x_1-coordinate.

To obtain Theorem 2.2 we stored at each node of a bottom-level list the number of boxes preceding it in its list. For the present solution, in addition to counting colors, we also want to represent the set of all colors in the query 3-sided box as a disjoint union of canonical sets of colors. This is easy to achieve with our three-level segment tree. We associate a *canonical set of colors* with each node w of a bottom-level list in the three-level segment tree. This is the set of colors of boxes preceding w in the list. (The prefix of the list up to w in fact represents this set.) The representation of the set of all colors in the query 3-sided box consists of the canonical sets of the bottom-level nodes reached by the query. Since the data structure has three levels, the number of such sets in a query output is $O(\log^3 n)$, and each color appears in at most one of these sets (because of the disjointness of the boxes in the decomposition of any single $U(P_c)$).

The full data structure. In order to handle general queries of the form $[a, b] \times [c, d]$, we use the following technique, which has already been used in [12], for solving orthogonal colored range *reporting* problems. We store the points of P, in the increasing order of their y-coordinates, at the leaves of a balanced binary tree T. At each internal node v, we store a pair of auxiliary data structures, one for answering queries of the form $[a, b] \times [c, \infty)$, and one for queries of the form $[a, b] \times (-\infty, d]$. The first (resp., second) structure is built on the points stored at the left (resp., right) subtree of v.

We also store at v a y-coordinate $Y(v)$ that separates the y-coordinates of the points stored at the left subtree from those stored at the right subtree of v. If v is a leaf, we let $Y(v)$ be the y-coordinate of the singleton point stored at v.

For each node w of a bottom-level list of an auxiliary structure we denote by $c(w)$ the canonical set of colors associated with w.

Let $q = [a, b] \times [c, d]$ be a query box. We search down the tree T with $[c, d]$ and denote by v_q the highest node for which $[c, d]$ contains $Y(v_q)$. If v_q is a leaf, we check whether the single point that it stores lies in q, and return 1 if it does and 0 otherwise. If v_q is an internal node, we query the two structures at v_q with $[a, b] \times [c, \infty)$ and with $[a, b] \times (-\infty, d]$, respectively. Let D_q (resp., U_q) denote the set of $O(\log^3 n)$ bottom-level nodes reached by the former (resp., latter) subquery. Observe that the set of colors in q is exactly the union of the canonical sets of colors associated with the nodes in $U_q \cup D_q$. Another crucial property (which follows from the fact that, for each color c, the boxes that represent $U(P_c)$ are pairwise disjoint) is that each color in the output appears in the canonical set of at most one node of U_q and at most one node of D_q (see [12] for more details). Hence, using the exclusion-inclusion principle, the number of colors that appear in q is equal to

$$\sum_{s \in U_q} |c(s)| + \sum_{t \in D_q} |c(t)| - \sum_{s \in U_q,\, t \in D_q} |c(s) \cap c(t)|. \tag{4.1}$$

Ideally, we would like to have for every $s \in U_q$ and $t \in D_q$ the value of $|c(s) \cap c(t)|$ prestored. However, doing this for every possible pair of canonical sets would be too expensive and may result in superquadratic space complexity. Nevertheless, if we did have these values available, answering a query could then be done in $O(\log^6 n)$ time, using (4.1).

Instead, we derive a tradeoff between storage and query time, determined by a threshold parameter X in the range $1 \le X \le n$. Let $\mathcal{D}(v)$ (resp., $\mathcal{U}(v)$) be the set of all bottom-level nodes in the auxiliary structure of a node $v \in T$ used for answering queries of type $[a, b] \times [c, \infty)$ (resp., $[a, b] \times (-\infty, d]$). A node $t \in \mathcal{D}(v) \cup \mathcal{U}(v)$ is called *X-heavy* if $|c(t)| > X$; otherwise it is called *X-light*. For every node $v \in T$ we construct and store, as part of the preprocessing stage, a matrix $M(v)$, whose rows and columns correspond to the X-heavy nodes in $\mathcal{D}(v)$ and $\mathcal{U}(v)$, respectively. For each pair of X-heavy nodes $s \in \mathcal{U}(v)$ and $t \in \mathcal{D}(v)$, we store in $M_{s,t}(v)$ the value of $|c(t) \cap c(s)|$. Let n_v be the number of points stored at the subtree of T rooted at v. The overall size of all the canonical sets associated with the nodes of $\mathcal{U}(v) \cup \mathcal{D}(v)$ is $O(n_v \log^3 n)$. Hence, the number of X-heavy nodes in $\mathcal{D}(v) \cup \mathcal{U}(v)$ is $O\big(\frac{n_v}{X} \log^3 n\big)$, so $M(v)$ has size $O\big(\big(\frac{n_v}{X}\big)^2 \log^6 n\big)$. (The time needed to construct $M(v)$, for all nodes $v \in T$, is discussed later.) Summing this bound over all nodes v of T, we get an overall bound of $O(\big(\frac{n}{X}\big)^2 \log^6 n)$.

For each node $t \in \mathcal{D}(v) \cup \mathcal{U}(v)$, in addition to storing the size $|c(t)|$ of its canonical set, we also store a dictionary data structure on $c(t)$ (implemented as a binary search tree), supporting logarithmic-time searches. Clearly, since $\sum_{t \in \mathcal{D}(v) \cup \mathcal{U}(v)} |c(t)| = O(n_v \log^3 n)$, these additional dictionary structures take a total of $O(n \log^4 n)$ extra storage.

The total space complexity of our solution is thus $O\big(\big(\frac{n}{X}\big)^2 \log^6 n + n \log^4 n\big)$.

Answering queries. It suffices to describe how to compute $|c(s) \cap c(t)|$ efficiently, for each $s \in U_q$ and $t \in D_q$. If both s and t are X-heavy, then this value is stored in $M(v_q)$ and we simply retrieve it. Otherwise, we can assume, without loss of generality,

that $|c(s)| \le X$. In this case we check, for each $c \in c(s)$, whether $c \in c(t)$ and count the number of such colors. Using the dictionary structure over $c(t)$ takes a total of $O(|c(s)| \log n) = O(X \log n)$ time. We repeat this for each pair $(s,t) \in U_q \times D_q$, for a total of $O(X \log^7 n)$ query time.

Preprocessing. It is easy to see that the primary tree T with all its auxiliary data structures can be constructed in $O(n \log^3 n)$ time and the dictionary structures at the nodes of $|\mathcal{U} \cup \mathcal{D}|$ can be constructed in overall time $O(n \log^4 n)$. It remains to describe the construction of matrices M_v.

Denote by $\mathcal{D}$ (resp., $\mathcal{U}$) the set of bottom-level nodes in all of the auxiliary structures used for answering queries of type $[a,b] \times [c,\infty)$ (resp., $[a,b] \times (-\infty,d]$). Let M_D (resp., M_U) denote the matrix whose rows correspond to the X-heavy nodes of $\mathcal{D}$ (resp., of $\mathcal{U}$), and whose columns correspond to the colors $1,\dots,C$, such that, for $t \in \mathcal{D}$ (resp., $t \in \mathcal{U}$) and color c, the (t,c)-entry of the matrix is 1 if $c \in c(t)$ and is 0 otherwise. It follows that $M = M_D {M_U}^T$ contains all the matrices M_v as submatrices.[7]

Using the fact that $\sum_v n_v = O(n \log n)$, we get that each of the matrices M_D and M_U has $t = O\left(\frac{n}{X} \log^4 n\right)$ rows and $N = O(n \log^4 n)$ nonzero entries. Hence, we can construct M using the sparse rectangular matrix multiplication technique of Kaplan, Sharir, and Verbin [20] (which extends a technique of Yuster and Zwick [27] and of Chan [7]). Specifically, for two matrices A, B, each having t rows and at most N nonzero items, these methods construct AB^T in time

$$\begin{cases} O(Nt^{\frac{\omega-1}{2}}) & \text{if } N \ge t^{\frac{\omega+1}{2}}, \\ O(N^{\frac{2\beta}{\beta+1}} t^{\frac{2-\alpha\beta}{\beta+1}}) & \text{if } t^{1+\frac{\alpha}{2}} \le N \le t^{\frac{\omega+1}{2}}, \\ O(t^2) & \text{if } N \le t^{1+\frac{\alpha}{2}}. \end{cases} \tag{4.2}$$

Here (i) ω is the exponent of matrix multiplication; i.e., ω is the smallest number such that two $t \times t$ matrices can be multiplied in time $O(t^\omega)$, (ii) α is the largest value of r for which a $t \times t^r$ matrix and a $t^r \times t$ matrix can be multiplied in time $O(t^2)$, and (iii) $\beta = \frac{\omega-2}{1-\alpha}$. It is known (see, e.g., [18]) that $\omega < 2.376$ and $\alpha > 0.294$; thus we can use $\beta \approx 0.533$.

Hence, the construction time of the data structure is

$$\begin{cases} O^*\left(\frac{n^{(\omega+1)/2}}{X^{(\omega-1)/2}}\right) = O\left(\frac{n^{1.688}}{X^{0.688}}\right) & \text{when } X \ge n^{\frac{\omega-1}{\omega+1}} \approx n^{0.408}, \\ O^*\left(\frac{n^{\frac{2-\alpha\beta+2\beta}{\beta+1}}}{X^{\frac{2-\alpha\beta}{\beta+1}}}\right) = O\left(\frac{n^{1.898}}{X^{1.203}}\right) & \text{when } n^{\frac{\alpha/2}{\alpha/2+1}} \approx n^{0.128} \le X \le n^{\frac{\omega-1}{\omega+1}} \approx n^{0.408}, \\ O^*(\frac{n^2}{X^2}) & \text{when } X \le n^{\frac{\alpha/2}{\alpha/2+1}} \approx n^{0.128}. \end{cases} \tag{4.3}$$

We thus have the following result.

THEOREM 4.1. *Let P be a set of n colored points in the plane, and let $1 \le X \le n$ be a given tradeoff parameter. Then we can preprocess P into a data structure of size $O\left(\left(\frac{n}{X}\right)^2 \log^6 n + n \log^4 n\right)$ so that a colored range counting query can be answered in $O(X \log^7 n)$ time. The preprocessing cost is as given in* (4.3).

[7] We combine all of the matrices M_v into one matrix M to simplify the presentation. In doing so, we lose a polylogarithmic factor in the time bound.

Optimizing for a fixed number of queries. Suppose next that we know (or guess) in advance the number m of queries. We can then optimize the choice of X, so as to minimize the overall time for answering m colored range counting queries, including the time spent at the preprocessing stage. A simple calculation yields the following corollary.

COROLLARY 4.2. *Let P be a set of n colored points in the plane.*

(a) *$m \leq n$ colored range counting queries can be answered in overall time $O^*(nm^{\frac{\omega-1}{\omega+1}}) = O(nm^{0.408})$.*

(b) *$n \leq m \leq n^{\frac{4-\alpha}{\alpha+2}} \approx n^{1.616}$ colored range counting queries can be answered in overall time $O^*(n^{\frac{2-\alpha\beta+2\beta}{3-\alpha\beta+\beta}} m^{\frac{2-\alpha\beta}{3-\alpha\beta+\beta}}) = O(n^{0.862}m^{0.546})$.*

(c) *$m \geq n^{\frac{4-\alpha}{\alpha+2}} \approx n^{1.616}$ colored range counting queries can be answered in overall time $O^*(m^{2/3}n^{2/3})$.*

In particular, n colored range counting queries can be answered in $O(n^{\frac{2\omega}{\omega+1}}) = O(n^{1.408})$ time, including time spent at the preprocessing stage.

4.2. Time-space tradeoff in dimension $d > 2$. In higher dimensions, there are other approaches to achieving a tradeoff between query time and storage.

Bucketing. Partition the set of colors into $O(\log n)$ "buckets" $\mathcal{C}_i$, such that $c \in \mathcal{C}_i$ iff $2^{i-1} \leq |P_c| < 2^i$. Put $C_i := |\mathcal{C}_i|$, and let n_i be the number of points having colors in $\mathcal{C}_i$. Clearly, $n_i = \Theta(2^i C_i)$. We solve the colored range counting problem separately within each $\mathcal{C}_i$ and output the sum of the counts obtained in each of these $O(\log n)$ subproblems.

We use a threshold parameter $1 \leq X \leq n$. Answering a colored range counting query with a box q within $\mathcal{C}_i$ depends on the relationship between X and C_i. If $X \geq C_i$, we simply test, for each color c in $\mathcal{C}_i$, whether $q \cap P_c \neq \emptyset$ and count the number of colors with this property. Using the standard orthogonal range searching machinery [2], this takes $O(\log^{d-1}|P_c|) = O(i^{d-1})$ time per color c, for a total of $O(i^{d-1}C_i) = O(i^{d-1}X)$ time. Summing these bounds over all buckets with $X \geq C_i$, we obtain a total of $O(X \log^d n)$ time.

If $X < C_i$, we use the technique of Theorem 2.5 for answering the query. We use a single colored range counting data structure for all the buckets with $C_i > X$. Let $N = \sum_{\{i|X<C_i\}} n_i \leq n$ be the overall number of points in buckets with $X < C_i$. The query time is $O(\log^{2d-1} N) = O(\log^{2d-1} n)$, and the space and preprocessing cost are both

$$O\left(\sum_i C_i \cdot \left(\frac{n_i}{C_i}\right)^d \log^{2d-1} n\right) = O\left(\sum_i \frac{n_i^d}{X^{d-1}} \log^{2d-1} n\right) = O\left(\sum_i \frac{n^d}{X^{d-1}} \log^{2d-1} n\right),$$

where the summation is over all those "heavy" buckets (we use here the facts that $n_i/C_i = \Theta(2^i)$ and that $X < C_i$). Hence, summing over the buckets, and adding the costs for buckets with $X \geq C_i$, the overall query time is $O(X \log^d n + \log^{2d-1} n)$. The overall preprocessing and space complexity is $O\big(\frac{n^d}{X^{d-1}} \log^{2d-1} n\big)$. Optimizing the choice of X, we can answer m colored range counting queries in time $O(nm^{1-1/d}\log^{d+1-1/d} n + m \log^{2d-1} n)$, including time spent at the preprocessing stage (for this we take $X = \frac{n}{m^{1/d}} \log^{\frac{d-1}{d}}(n)$). We thus have the following result.

THEOREM 4.3. *Let P be a set of n colored points in $\mathbb{R}^d$, $d > 2$, and let $1 \leq X \leq n$ be a tradeoff parameter. We can preprocess P, in time $O\big(\frac{n^d}{X^{d-1}} \log^{2d-1} n\big)$, into a data structure of size $O\big(\frac{n^d}{X^{d-1}} \log^{2d-1} n\big)$, which supports colored range counting queries in time $O(X \log^d n)$. In particular, m such queries can be answered in*

$O(nm^{1-1/d}\log^{d+1-1/d} n + m\log^{2d-1} n)$ *time, including the cost of preprocessing. The storage required in this case is* $O(nm^{1-1/d}\log^{d+1-1/d} n)$.

Two additional methods are presented in section 4.3. They partially improve the upper bounds in the time-space tradeoff for $X = \Omega^*(n^{\frac{d-2}{d-1}})$, but they are more expensive at the preprocessing stage. Ignoring storage, the bucketing method described previously provides the best upper bound so far on the time required to answer any fixed number of queries, if time spent at the preprocessing stage is also included.

4.3. Additional time-space tradeoffs in dimension $d > 2$.

Bucketing with box-splitting. We further improve the tradeoff achieved by bucketing for values of $X = \Omega^*(n^{\frac{d-2}{d-1}})$, by using the box-splitting technique within each bucket, as in the planar case. Specifically, apply bucketing with some threshold value $1 \le X \le n$. Again, if the number of colors within a fixed bucket $\mathcal{C}_i$ is smaller than X, test each of the C_i colors in the bucket for intersection with the query range. This costs $O(X\log^{d-1} n)$ time per bucket, for a total of $O(X\log^d n)$.

Consider then all the "heavy" buckets with $C_i > X$. Apply the box splitting technique for the colors in the corresponding union $\cup_i \mathcal{C}_i$ (using the same threshold parameter X to distinguish between "heavy" and "light" canonical sets; see section 4.1). That is, construct a binary tree on the points sorted by their x_1-coordinates. For each node of the tree we maintain two auxiliary structures for querying with boxes that are semiunbounded in the x_1-direction. As above, the data structure is implemented so that processing a query takes $O(\log^{2d-1} n)$ time, and returns the output as the disjoint union of $O(\log^{2d-1} n)$ canonical sets, each associated with some bottom-level node of the structure. The preprocessing and space complexity of the structure are both

$$O\left(\sum_i C_i \cdot \left(\frac{n_i}{C_i}\right)^{d-1} \log^{2d-1} n_i\right) = O\left(\sum_i \frac{n_i^{d-1}}{X^{d-2}} \log^{2d-1} n\right) = O\left(\frac{n^{d-1}}{X^{d-2}} \log^{2d-1} n\right),$$

where the summation is over all "heavy buckets." Note that this bound holds also if we store a dictionary over each canonical set.

To process a bounded-box query, we proceed as above, finding the highest node in the tree that splits the x_1-span of the query box, performing appropriate queries in the auxiliary data structures with the two corresponding semiunbounded "half-boxes," and combining the solutions, using an appropriate variant of (4.1). The time of the query is then $O(X\log^{4d-1} n)$ by a straightforward extension of the analysis of the planar case.

Since the total size of all the canonical sets of nodes of the respective collections $\mathcal{U}(v)$, $\mathcal{D}(v)$ is now $O\big(\frac{n_v^{d-1}}{X^{d-2}}\log^{2d-1} n\big)$, for a given vertex $v \in T$, the size of the matrix $M(v)$ is

$$O\left(\left(\frac{\frac{n_v^{d-1}}{X^{d-2}}}{X}\right)^2 \log^{4d-2} n\right) = O\left(\left(\frac{n_v}{X}\right)^{2d-2} \log^{4d-2} n\right),$$

and the total storage, over all nodes v and buckets i, is thus

$$O\left(\frac{n^{d-1}}{X^{d-2}}\log^{2d-1} n + \left(\frac{n}{X}\right)^{2d-2} \log^{4d-2} n\right).$$

Comparing this with the bound for the bucketing technique alone, we get an improved tradeoff for $X = \Omega^*(n^{\frac{d-2}{d-1}})$, as asserted.

It remains to bound the preprocessing time, which is dominated by the cost of computing the matrices $M(v)$. As in section 4.1, denote by $\mathcal{D}$ (resp., $\mathcal{U}$) the set of bottom-level nodes in all of the auxiliary structures used for answering queries of type $[a,b]\times[c,\infty)$ (resp., $[a,b]\times(-\infty,d]$). Let M_D (resp., M_U) denote the matrix whose rows correspond to the X-heavy nodes of $\mathcal{D}$ (resp., of $\mathcal{U}$), and whose columns correspond to the colors $1,\dots,C$, such that, for $t\in\mathcal{D}$ (resp., $t\in\mathcal{U}$) and color c, the (t,c)-entry of the matrix is 1 if $c\in c(t)$, the canonical set of t, and is 0 otherwise. We compute the matrix $M=M_D{M_U}^T$ which contains all the matrices M_v as submatrices. Here each of the matrices M_D and M_U has $O\big(\frac{n^{d-1}}{X^{d-2}}\log^{2d-1}n\big)$ nonzero entries, which is the total size of all canonical set, and $O\big(\frac{n^{d-1}}{X^{d-1}}\log^{2d-1}n\big)$ rows, each corresponding to an X-heavy canonical set. Using (4.2) we obtain the following bound on the time to compute M:

$$\text{(4.4)}\qquad \begin{cases} O^*\left(\frac{n^{(d-1)(\omega+1)/2}}{X^{(d-1)(\omega+1)/2-1}}\right) & \text{when } n^{\frac{(d-1)(\omega-1)}{(d-1)(\omega-1)+2}}\le X,\\ O^*\left(\frac{n^{(d-1)\frac{2\beta+2-\alpha\beta}{\beta+1}}}{X^{(d-2)\frac{2\beta}{\beta+1}+(d-1)\frac{2-\alpha\beta}{\beta+1}}}\right) & \text{when } n^{\frac{(d-1)\alpha}{(d-1)\alpha+2}}\le X\le n^{\frac{(d-1)(\omega-1)}{(d-1)(\omega-1)+2}},\\ O^*\left(\frac{n^{2d-2}}{X^{2d-2}}\right) & \text{when } X\le n^{\frac{(d-1)\alpha}{(d-1)\alpha+2}}. \end{cases}$$

That is, we have the following theorem.

THEOREM 4.4. *Let P be a set of n colored points in $\mathbb{R}^d$, $d>2$, and let $1\le X\le n$ be a tradeoff parameter. We can preprocess P, in time as in* (4.4)*, into a data structure of size*

$$O\left(\frac{n^{d-1}}{X^{d-2}}\log^{2d-1}n+\left(\frac{n}{X}\right)^{2d-2}\log^{4d-2}n\right),$$

which supports colored range counting queries in time $O(X\log^{4d-1}n)$.

Grid. Using this method, we achieve additional improvement of the time-space tradeoff for $X=\Omega^*(n^{\frac{d+1}{d+2}})$. Recall that we assume general position of the points of P, in the sense that no two points have the same x_i-coordinate for any $1\le i\le d$. We fix a parameter t, and partition $\mathbb{R}^d$, for each $1\le i\le d$, into t slabs, each containing n/t points of P and bounded by two hyperplanes orthogonal to the x_i-axis. These partitions, when superimposed on each other, induce a nonuniform grid G with t^d cells. There are $O(t^{2d})$ "canonical" boxes, each bounded by $2d$ grid hyperplanes. In the preprocessing stage we compute for each such box the number of colors that it contains, using the bucketing method in $O(nt^{2d-2}\log^{d+1-1/d}n+t^{2d}\log^{2d-1}n)$ time. This bound follows from Theorem 4.3 (with $m=t^{2d}$).

To perform an actual query with some box Q, we find the maximal canonical box Q_0 that it contains and retrieve the number C_0 of colors in Q_0. We then retrieve the $n'\le 2dn/t$ points of P that lie in the "fringe" $Q\setminus Q_0$ of Q, using a standard orthogonal range *reporting* data structure [2]. See Figure 4.1. For each such point p, we check whether its color $c(p)$ is a color that appears in Q_0. For this, we preprocess each of the monochromatic subsets P_c of P, for $c=1,\dots,C$, for d-dimensional orthogonal emptiness range queries. For each $p\in Q\setminus Q_0$, with color $c=c(p)$, such that this is the first fringe point of that color, we test whether $Q_0\cap P_{c(p)}=\emptyset$ using the corresponding structure in $O(\log^{d-1}n)$ time. If this is the case, we add 1 to the color count. In all other cases p is ignored. The overall query time is $O\big(\frac{n}{t}\log^{d-1}n\big)$. The data structure

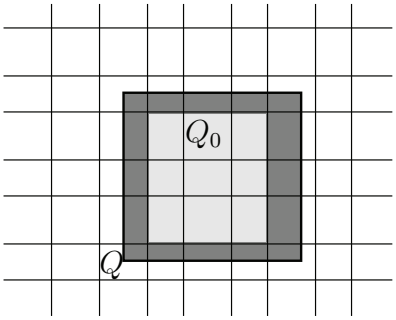

FIG. 4.1. *The grid construction in the plane, a query rectangle Q, its (lightly-shaded) "core" Q_0, and its (darkly-shaded) fringe.*

uses $O(n \log^{d-1} n + t^{2d})$ storage and can be constructed in $O(t^{2d-2} n \log^{d+1-1/d} n + t^{2d} \log^{2d-1} n)$ time. Alternatively, substituting $X := \frac{n}{t}$, we obtain tradeoff bounds that are similar to the previous ones (we leave it to the reader to verify that we get an improvement for $X = \Omega^*(n^{\frac{d+1}{d+2}})$).

THEOREM 4.5. *Let P be a set of n colored points in $\mathbb{R}^d$, $d > 2$, and let $1 \le X \le n$ be a tradeoff parameter. We can preprocess P, in $O\big(\big(\frac{n}{X}\big)^{2d-2} n \log^{d+1-1/d} n + \big(\frac{n}{X}\big)^{2d} \log^{2d-1} n\big)$ time, into a data structure of size $O((\frac{n}{X})^{2d} + n \log^{d-1} n)$, which supports colored range counting queries in $O(X \log^{d-1} n)$ time.*

5. Colored range counting and sparse matrix multiplication. In this section we further elaborate on the relation between sparse matrix multiplication and colored orthogonal range counting. We use this relation to derive lower bounds for the off-line version of the problem in $\mathbb{R}^2$. We also define and analyze a generalized version of sparse matrix multiplication that is related to colored orthogonal range counting in higher dimensions.

5.1. Hardness of orthogonal colored range counting. Consider the following *output restricted sparse matrix multiplication* problem ($ORSMM$). The input is a sparse matrix A with N nonzero entries (and therefore at most N rows and columns), and a set O of M pairs, (i, j), where i and j are indices of two rows of A. The goal is to compute, for each pair $(i, j) \in O$, the (i, j)th entry of the product AA^T. We further assume here that A is zero-one, although AA^T is computed over the integers (or reals).[8]

The off-line version of the colored orthogonal range counting problem with n points and m queries is closely related to the $ORSMM$ problem, as follows from our solution to colored range counting in $\mathbb{R}^2$ in section 4.

THEOREM 5.1. *The 2-dimensional orthogonal colored range counting problem on n points and m query rectangles can be reduced to an $ORSMM$ problem, where the matrix A has $N = O(n \log^4 n)$ nonzero entries and we ask for $M = O(m \log^6 n)$ entries of the matrix AA^T. The reduction takes $O(n \log^4 n)$ time.*

The following theorem shows that a reverse reduction also exists.

THEOREM 5.2. *The $ORSMM$ problem, for a zero-one matrix A with N nonzero entries, where we need to compute M output pairs, can be reduced in linear time to*

[8] We can instead ask for M entries in the product of two arbitrary zero-one matrices A and B with N nonzero items in both. Our results carry over to this generalized version.

a 2-dimensional colored orthogonal range counting problem on $O(N)$ points and M query rectangles.

Proof. We can restate the $ORSMM$ problem as follows. Let Z be the set of columns in the matrix A. For each row i, let $S_i \subseteq Z$ denote the set of columns where row i has ones. Let O be the set of M output pairs to be computed. For each pair $(i,j) \in O$ we have to compute $|S_i \cap S_j|$, which is the (i,j)th entry of AA^T. Since $|S_i \cap S_j| = |S_i| + |S_j| - |S_i \cup S_j|$, this is equivalent to computing, for each pair $(i,j) \in O$, the quantity $|S_i \cup S_j|$.

Let k denote the number of nonempty rows of A. We construct a colored range counting instance with the point set defined in Lemma 3.2; see Figure 3.6. That is, we choose $p_1^1 = (1,1)$, $p_2^1 = (2,2)$, ..., $p_k^1 = (k,k)$ and $p_1^2 = (k+1,1)$, $p_2^2 = (k+2,2)$, ..., $p_k^2 = (2k,k)$. We assign a distinct color to each column of A. We next replace each point p_i^1 by $|S_i|$ points, colored by the colors of the columns in S_i. We place the $|S_i|$ colored points, which correspond to p_i^1, close to each other within distance $\epsilon \ll 1$ of p_i. We do the same for each of the points p_i^2. Let P denote the resulting point set; we have $|P| = 2N$. Clearly, with an appropriate representation of the input, this construction takes $O(N)$ time.

Now, in order to calculate $|S_i \cup S_j|$, for $j \leq i$, we query P with the rectangle $R = [i - \epsilon, k + j + \epsilon] \times [j - \epsilon, i + \epsilon]$ which is slightly larger than the rectangle in the proof of Lemma 3.2 and contains it. Since R contains only the points p_i^1 and p_j^2, it is clear that the number of distinct colors in R is $|S_i \cup S_j|$. ∎

We next describe some observations regarding the complexity of $ORSMM$ and the implications of Theorem 5.2. For any $t \times t$ zero-one matrix A, computing AA^T (over the reals) is a special case of $ORSMM$, with $N = M = t^2$ [11]. The best known algorithm for computing AA^T runs in $O(t^\omega) = O(N^{\omega/2})$ time, for $\omega \simeq 2.376$. So any algorithm for $ORSMM$ whose running time is faster than $O(\min(N,M)^{\omega/2})$ would immediately imply a better algorithm for multiplying zero-one matrices (over the reals), thereby solving a long-standing open problem. Using Theorem 5.2, we obtain that an algorithm for planar colored orthogonal range counting that can answer m box queries with respect to a set of $O(n)$ colored points in $o(\min(n,m)^{\omega/2})$ time would imply an algorithm that can compute AA^T in $o(t^\omega)$ time, for any $t \times t$ zero-one matrix A.

Similarly, consider the problem of computing AA^T, where A is a sparse rectangular zero-one matrix with t rows and N ones such that $N \geq t^{\frac{\omega+1}{2}}$. The best known algorithm for performing this computation runs in $O(Nt^{\frac{\omega-1}{2}})$ time (see section 4). For any such matrix A, computing AA^T is also an instance of $ORSMM$, with N ones and $M = t^2$ pairs. So an algorithm for $ORSMM$ that runs in $o(NM^{\frac{\omega-1}{4}})$ time, for $N \geq M^{\frac{\omega+1}{4}}$, would imply a faster algorithm for sparse rectangular matrix multiplication than the best known to date. Using Theorem 5.2, we obtain that the existence of an algorithm for planar colored orthogonal range counting that can answer m box queries with respect to a set of n colored points in $o(nm^{\frac{\omega-1}{4}}) \approx o(nm^{0.344})$ time, for $n \geq m^{\frac{1+\omega}{4}} \approx m^{0.844}$, would also imply an algorithm that can compute AA^T for any rectangular zero-one matrix A with t rows and N ones, such that $N \geq t^{\frac{\omega+1}{2}}$, faster than what is known to date.

Generalized matrix multiplication and higher-dimensional colored range counting. For $d > 2$, we can show a similar relation between colored orthogonal range counting and a generalization of $ORSMM$. In this generalization, one is given a zero-one matrix A with N nonzero entries in sparse representation and a list O of M d-tuples of indices of rows of A. Let t be the number of columns in A. The goal is to compute,

for each tuple $(i_1, \ldots, i_d) \in O$, the sum $\sum_{j=1}^{t} \prod_{k=1}^{d} A_{i_k,j}$, which is the $ORSMM_d$ problem stated in subsection 1.2, and denote it by $ORSMM_d$. The following theorem generalizes Theorem 5.2 to dimension $d > 2$.

THEOREM 5.3. *Any instance of the $ORSMM_d$ problem, of a zero-one matrix A with N nonzero entries and M output tuples, can be reduced, in linear time, to $O(1)$ instances of d'-dimensional colored orthogonal range counting, for $d' \leq d$, each on $O(N)$ points and M query boxes.*

Proof. Let Z be the set of columns of A. The $ORSMM_d$ problem is equivalent to the following problem if we take S_i to be the set of columns with nonzero entries in row i.

We are given a family of sets $\mathcal{F} = \{S_1, \ldots, S_k\}$, such that $S_i \subseteq Z$ and $\sum_{i=1}^{k} |S_i| = N$, and M d-tuples $\{(i_1, \ldots, i_d)\}_{i=1}^{M}$; the goal is to compute, for each of the tuples, the corresponding quantity $|\bigcap_{j=1}^{d} S_{i_j}|$.

By using the inclusion-exclusion principle, one can easily verify that the above problem is equivalent to computing, for each output tuple $(i_1, \ldots, i_d)$, the quantities $|\bigcup_{j \in J} S_{i_j}|$, for every $J \subseteq \{1, \ldots, d\}$. We first show how to do it for the case where $J = \{1, \ldots, d\}$.

Let k denote the number of nonempty rows of A. We assign to each column of A a distinct color. Let $\{p_i^j \mid 1 \leq i \leq k, 1 \leq j \leq d\}$ be the set of points defined in Lemma 3.2. We define a colored range counting instance composed of dk "point clusters" P_i^j, for $1 \leq i \leq k$ and $1 \leq j \leq d$, as follows. For each i and j, we replace p_i^j by a set P_i^j of $|S_i|$ distinct points placed at distance less than $\epsilon \ll 1$ from p_i^j, each colored by one of the colors of the columns in S_i. Let P be the resulting set of points.

Now, in order to compute $|\bigcup_{j=1}^{d} S_{i_j}|$, where $1 \leq i_d < i_{d-1} < \cdots < i_1 \leq k$, we query P with the box $R = [i_1 - \epsilon, i_2 + k + \epsilon] \times [i_2 - \epsilon, i_3 + k + \epsilon] \times \cdots \times [i_{d-2} - \epsilon, i_{d-1} + k + \epsilon] \times [i_{d-1} - \epsilon, i_d + k + \epsilon] \times [i_d - \epsilon, i_1 + \epsilon]$. (This box is slightly larger than the corresponding box used in Lemma 3.2 and contains it.)

By Lemma 3.2, $R \cap P = \bigcup_{j=1}^{d} P_{i_j}^j$. The number of colors in R is then $|\bigcup_{i=1}^{d} S_{i_j}|$. We have $|P| = dN$, and P can be constructed in $O(N)$ time, assuming an appropriate representation of A.

We find $|\bigcup_{j \in J} S_{i_j}|$, for each tuple $(i_1, \ldots, i_d)$ and some fixed $J \subset \{1, \ldots, d\}$ by a similar reduction obtaining a $|J|$-dimensional colored orthogonal range counting instance with $O(N)$ points and M query boxes. ∎

5.2. Efficient algorithms for $ORSMM_d$. We obtain an efficient algorithm for $ORSMM_d$ in three stages, where each stage uses the previous algorithm as a subroutine.

The case of nonsparse matrices with no output restriction. We start by considering the nonsparse version of the problem where A is any $t \times t$ matrix and we want to compute $\sum_{j=1}^{t} \prod_{k=1}^{d} A_{i_k,j}$ for all d-tuples of rows of A. We refer to this problem as *d-dimensional matrix multiplication.*

Recall that we denote by ω the smallest constant such that standard matrix multiplication of $t \times t$ matrices takes $O(t^\omega)$ time. Let ω_d be a constant such that d-dimensional matrix multiplication takes $O(t^{\omega_d})$ time (in particular, $\omega_2 = \omega$). The output size of the d-dimensional matrix multiplication problem is $\Theta(t^d)$, so $\omega_d \geq d$. On the other hand we can compute each of the $O(t^d)$ sums $\sum_{j=1}^{t} \prod_{k=1}^{d} A_{i_k,j}$ in $O(t)$ time, so $\omega_d \leq d + 1$. In fact it is not hard to obtain a better upper bound on ω_d.

LEMMA 5.4. *For any $d \geq 2$, $\omega_d \leq \omega + d - 2$. Furthermore, if $\omega > 2$ and $d > 2$, then $\omega_d < \omega + d - 2$.*

Proof. For $d = 2$ the lemma obviously holds, so we assume $d \geq 3$. Let A be the input matrix. First compute two matrices B and C, so that B (resp., C) is a $t^{\lceil d/2 \rceil} \times t$ matrix (resp., $t \times t^{\lfloor d/2 \rfloor}$ matrix) whose rows (resp., columns) contain the elementwise products of all sets of $\lceil d/2 \rceil$ rows (resp., $\lfloor d/2 \rfloor$ columns) of A. Both B and C can be computed in time $O(\binom{t}{\lceil d/2 \rceil} \cdot t) = O(t^d)$. By construction, the (usual, two-dimensional) product BC provides a solution to the d-dimensional matrix multiplication for A. By partitioning BC into blocks of size $t \times t$, computing BC can be done in $O(t^{\omega+d-2})$ time. In fact, if $\omega > 2$, then the results of Huang and Pan [18] about rectangular matrix multiplication allows us to improve this, thus establishing the second part of the lemma. □

LEMMA 5.5. *Let A be an $s \times t$ rectangular matrix. Then one can compute $\sum_{j=1}^{t} \prod_{k=1}^{d} A_{i_k,j}$, for all d-tuples of rows of A, in time*

$$\begin{cases} O(s^{\omega+d-3}t) & if\ s \leq t, \\ O(s^{d-\alpha\beta}t^{\beta}) & if\ s^{\alpha} < t < s, \\ O(s^d) & if\ t \leq s^{\alpha}. \end{cases}$$

Proof. As in the proof of Lemma 5.4, we reduce the problem, in $O(\binom{s}{\lceil d/2 \rceil} \cdot t)$ time, to the multiplication of two rectangular matrices B and C of size $s^{\lceil d/2 \rceil} \times t$ and $t \times s^{\lfloor d/2 \rfloor}$, respectively. The multiplication can be done by partitioning B and C into blocks of size $s \times t$ and $t \times s$, respectively. The lemma follows using the upper bound

$$\begin{cases} O(s^{\omega-1}t) & \text{if } s \leq t, \\ O(s^{2-\alpha\beta}t^{\beta}) & \text{if } s^{\alpha} < t < s, \\ O(s^2) & \text{if } t \leq s^{\alpha} \end{cases}$$

on the complexity of multiplication of two rectangular matrices of size $s \times t$ and $t \times s$, respectively (Coppersmith [10], Huang and Pan [18]; see also [7, 20, 27]). □

The case of sparse matrices with no output restriction. We next consider the d-dimensional sparse matrix multiplication problem, where the zero-one input matrix has N ones and s rows, and the goal is to compute $\sum_{j=1}^{t} \prod_{k=1}^{d} A_{i_k,j}$ for all d-tuples of the rows. We already considered this problem for $d = 2$ in section 4.

We solve this problem, for $d > 2$, using the same approach as in [20] (which is built upon the earlier technique of [27]; see also [7]). Let x be a parameter to be determined shortly. We consider separately columns with fewer than x nonzero entries (*light columns*) and columns with at least x nonzero entries (*heavy columns*). A light column with $z \leq x$ nonzero entries contributes a nonzero term to z^d products. So the total time to handle the light columns is at most $O(\sum_i x_i^d)$, where x_i is the number of nonzero items in the ith light column. This expression is maximized and equals $\frac{N}{x}x^d$, if we split the at most N nonzero entries among at most N/x light columns, placing x nonzero entries in each column. We have at most N/x heavy columns and we compute their contribution to the output by the previous algorithm for d-dimensional multiplication of the corresponding rectangular (nonsparse) matrix with s rows and N/x columns, as provided by Lemma 5.5. Optimizing over x, we obtain the following overall bound on the running time:

$$\begin{cases} \left(Ns^{(\omega+d-3)\frac{d-1}{d}}\right) & \text{if } N \geq s^{1+(\omega+d-3)/d}, \\ O\left(N^{\frac{\beta-1}{d+\beta-1}(d-1)+1}s^{\frac{d-\alpha\beta}{d+\beta-1}(d-1)}\right) & \text{if } s^{1+\alpha-\frac{\alpha}{d}} \leq N \leq s^{1+(\omega+d-3)/d}, \\ O(s^d) & \text{if } N \leq s^{1+\alpha-\frac{\alpha}{d}}. \end{cases}$$

The general case: An efficient algorithm for $ORSMM_d$. We fix another threshold parameter y and consider separately the rows with at most y nonzero entries (the *light rows*) and the rows with at least y nonzero entries (the *heavy rows*). We can compute each product in which a light row takes part in $O^*(y)$ time, so all such products can be computed in $O^*(My)$ time. We are left with products that include only heavy rows. Since there are at most N/y heavy rows, we can compute all remaining products by solving a d-dimensional sparse multiplication problem (with no output restriction) with $s = \frac{N}{y}$ rows and N nonzero entries, using the algorithm just described. Optimizing over y in order to minimize the total time complexity of the solution, we obtain the following theorem.

THEOREM 5.6. *For any $d \geq 2$, $ORSMM_d$ with N nonzero entries and M output tuples can be solved in time:*

$$\begin{cases} O^*\left(NM^{\frac{(d-1)(\omega+d-3)}{d+(d-1)(\omega+d-3)}}\right) & if\ M \leq N^{\frac{d+(d-1)(\omega+d-3)}{\omega+2d-3}}, \\ O^*\left(N^{\frac{(d-\alpha\beta+\beta-1)(d-1)+d+\beta-1}{(d-\alpha\beta)(d-1)+d+\beta-1}} M^{\frac{(d-1)(d-\alpha\beta)}{(d-1)(d-\alpha\beta)+d+\beta-1}}\right) & if\ N^{\frac{d+(d-1)(\omega+d-3)}{\omega+2d-3}} \leq M \leq N^{\frac{d-\alpha+\alpha/d}{1+\alpha-\alpha/d}}, \\ O^*\left(N^{\frac{d}{d+1}} M^{\frac{d}{d+1}}\right) & if\ M \geq N^{\frac{d-\alpha+\alpha/d}{1+\alpha-\alpha/d}}. \end{cases}$$

In particular, we get for $d = 2$ a solution for $ORSMM_2$ that takes $O^*\left(NM^{\frac{\omega-1}{\omega+1}}\right)$ time, for $M \leq N$. Note that this solution is inferior to the one given in subsection 4.1 for the case $M = \binom{t}{2}$ (no output restriction): The previous algorithm takes $O\left(Nt^{\frac{\omega-1}{2}}\right)$ time, whereas the new one takes $O\left(Nt^{\frac{2(\omega-1)}{\omega+1}}\right)$ time, which is indeed much larger. It would be interesting to improve the new algorithm for all possible values of M.

6. Conclusion. In this paper we obtain the first nontrivial solution for colored orthogonal range counting in dimension $d \geq 3$. In dimension $d = 2$, we provide an efficient tradeoff scheme between query time and storage. In particular, we show that the off-line version of the problem is nearly equivalent to an output-restricted version of sparse (zero-one) matrix multiplication ($ORSMM$). This suggests that our tradeoff scheme, in dimension $d = 2$, which takes $O^*(n^{1.408})$ time to answer n queries of n points, is fairly efficient. Moreover, its substantial improvement (to $o(n^{1.188})$ for the above off-line version) would immediately reduce the best known bound on the exponent ω of matrix multiplication (for zero-one matrices).

The challenge, however, is to provide a uniform (and efficient) tradeoff scheme in dimension $d \geq 3$. It would be interesting to find a reduction from the off-line version of the problem in dimension $d \geq 3$ to the $ORSMM_d$ problem (which is a straightforward generalization of $ORSMM$), presented in section 5. The reverse reduction is stated (and proven) in Theorem 5.3.

Acknowledgment. We thank three anonymous referees for valuable suggestions that helped us to improve the presentation.

FINDING BRANCH-DECOMPOSITIONS AND RANK-DECOMPOSITIONS*

PETR HLINĚNÝ† AND SANG-IL OUM‡

Abstract. We present a new algorithm that can output the rank-decomposition of width at most k of a graph if such exists. For that we use an algorithm that, for an input matroid represented over a fixed finite field, outputs its branch-decomposition of width at most k if such exists. This algorithm works also for partitioned matroids. Both of these algorithms are fixed-parameter tractable, that is, they run in time $O(n^3)$ where n is the number of vertices / elements of the input, for each constant value of k and any fixed finite field. The previous best algorithm for construction of a branch-decomposition or a rank-decomposition of optimal width due to Oum and Seymour [*J. Combin. Theory Ser. B*, 97 (2007), pp. 385–393] is not fixed-parameter tractable.

Key words. rank-width, clique-width, branch-width, fixed-parameter tractable algorithm, graph, matroid

1. Introduction. Many graph problems are known to be NP-hard in general; however, for practical application we still need to solve them. One method to solve them is to restrict the input graph to have a certain structure. Clique-width, defined by Courcelle and Olariu [4], is very useful for that purpose. Many hard graph problems (in particular all those expressible in monadic second-order logic (MSOL) of adjacency graphs) are solvable in polynomial time as long as the input graph has bounded clique-width and is given in the form of the decomposition for clique-width, called a *k-expression* [3, 24, 6, 15, 10]. A k-expression is an algebraic expression with the following four operations on a vertex-labeled graph with k labels: create a new vertex with label i, take the disjoint union of two labeled graphs, add all edges between vertices of label i and label j, and relabel all vertices with label i to have label j. However, for fixed $k > 3$, it is not known how to find a k-expression of an input graph having clique-width at most k. (If $k \leq 3$, then it has been shown in [2, 1].)

Rank-width is another graph structural invariant introduced by Oum and Seymour [19], aiming at the construction of an $f(k)$-expression of the input graph having clique-width k for some fixed function f in polynomial time. Rank-width is defined (section 7) as the branch-width (see section 2) of the *cut-rank* function of graphs. Rank-width turns out to be very useful for algorithms on graphs of bounded clique-width, since a class of graphs has bounded rank-width if and only if it has bounded clique-width. In fact, if rank-width of a graph is k, then its clique-width lies between

k and $2^{k+1}-1$ [19] and an expression can be constructed from a rank-decomposition of width k.

In this paper, we are mainly interested in the following problem.

> Find a fixed-parameter tractable algorithm that outputs a rank-decomposition of width at most k if the rank-width of an input graph (with more than one vertex) is at most k.

The first rank-width algorithm by Oum and Seymour [19] finds only a rank-decomposition of width at most $3k+1$ for n-vertex graphs of rank-width at most k in time $O(n^9 \log n)$. This algorithm has been improved by Oum [18] to output a rank-decomposition of width at most $3k$ in time $O(n^3)$. Using this approximation algorithm and finiteness of excluded vertex-minors [17], Courcelle and Oum [5] have constructed an $O(n^3)$-time algorithm to decide whether a graph has rank-width at most k. However, this is only a decision algorithm; if the rank-width is at most k, then this algorithm verifies that the input graph contains none of the excluded graphs for rank-width at most k as a vertex-minor. It does *not* output a rank-decomposition showing that the graph indeed has rank-width at most k.

In another paper, Oum and Seymour [20] have constructed a polynomial-time algorithm that can output a rank-decomposition of width at most k for graphs of rank-width at most k. However, it is not fixed-parameter tractable; its running time is $O(n^{8k+12} \log n)$. Obviously, it is very desirable to have a fixed-parameter tractable algorithm to output such an "optimal" rank-decomposition, because most algorithms on graphs of bounded clique-width require a k-expression on their input. So far, the only known efficient way of constructing an expression with bounded number of labels for a given graph of bounded clique-width uses rank-decompositions.

In this paper, we present an affirmative answer to the above problem (Theorem 7.3). An amusing aspect of our solution is that we deeply use submodular functions and matroids to solve the rank-decomposition problem, which shows (somehow unexpectedly) a "truly geometrical" nature of this graph-theoretical problem. In fact we solve the following related problem on matroids, too (Theorem 6.7).

> Find a fixed-parameter tractable algorithm that, given a matroid represented by a matrix over a fixed finite field, outputs a branch-decomposition of width at most k if the branch-width of the input matroid (with more than one element) is at most k.

So to give the final solution of our first problem, Theorem 7.3, we are going to bring together two previously separate lines of research: We will combine Oum and Seymour's above sketched work on rank-width and on branch-width of submodular functions with Hliněný's recent works [13, 14] on parametrized algorithms for matroids over finite fields.

Namely, Hliněný [13] has given a parametrized algorithm which in time $O(n^3)$ either outputs a branch-decomposition of width $\leq 3k+1$ of an input matroid M represented over a fixed finite field or confirms that the branch-width of M is more than $k+1$ (Algorithm 6.1). Using the ideas of [14] and minor-monotonicity of the branch-width parameter, he has concluded with an $O(n^3)$ fixed-parameter tractable algorithm [13] for the (exact value of) branch-width k of an input matroid M represented over a fixed finite field (Theorem 5.1). Similarly as above, this algorithm is only a decision algorithm and does not output a branch-decomposition of width k.

We last remark that the following (indeed widely expected) hardness result has been given only recently by Fellows et al. [7]: It is NP-hard to find graph clique-width. To argue that it is NP-hard to find rank-width, we combine some known

results: Hicks and McMurray Jr. [11] and Mazoit and Thomassé [16] independently proved that the branch-width of the cycle matroid of a graph is equal to the branch-width of the graph if it is 2-connected. Hence, we can reduce (section 7) the problem of finding branch-width of a graph to finding rank-width of a certain bipartite graph, and finding graph branch-width is NP-hard as shown by Seymour and Thomas [23]. Still, the main advantage of rank-width over clique-width is the fact that we currently have a fixed-parameter tractable algorithm for rank-width but not for clique-width.

Our paper is structured as follows: The next section briefly introduces definitions of branch-width, partitions, matroids, and the amalgam operation on matroids. In section 3, we explain the notion of so-called titanic partitions, which we further use in section 4 to "model" partitioned matroids in ordinary matroids. At this point it is worth noting that partitioned matroids present the key tool that allows us to shift from a branch-width-testing algorithm [13] to a construction of an "optimal" branch-decomposition (see Theorem 5.7) and of a rank-decomposition. In section 5, we will discuss a simple but slow algorithm for matroid branch-decompositions. In section 6, we will present a faster algorithm. As the main application, we then use our result to give an algorithm for constructing a rank-decomposition of optimal width of a graph in section 7.

2. Definitions. *Branch-width.* Let $\mathbb{Z}$ be the set of integers. For a finite set V, a function $f : 2^V \to \mathbb{Z}$ is called *symmetric* if $f(X) = f(V \setminus X)$ for all $X \subseteq V$, and is called *submodular* if $f(X) + f(Y) \geq f(X \cap Y) + f(X \cup Y)$ for all subsets X, Y of V. A tree is *subcubic* if all vertices have degree 1 or 3. For a symmetric submodular function $f : 2^V \to \mathbb{Z}$ on a finite set V, the branch-width is defined as follows (see Figure 1).

A *branch-decomposition* of the symmetric submodular function f is a pair (T, μ) of a subcubic tree T and a bijective function $\mu : V \to \{t : t \text{ is a leaf of } T\}$. (If $|V| \leq 1$, then f admits no branch-decomposition.) For an edge e of T, the connected components of $T \setminus e$ induce a partition (X, Y) of the set of leaves of T. (In such a case, we say that $\mu^{-1}(X)$ (or $\mu^{-1}(Y)$) is *displayed* by e in the branch-decomposition (T, μ). We also say that V and $\emptyset$ are displayed by the branch-decomposition.) The *width* of an edge e of a branch-decomposition (T, μ) is $f(\mu^{-1}(X))$. The *width* of (T, μ) is the maximum width of all edges of T. The *branch-width* of f, denoted by $\mathrm{bw}(f)$, is the minimum of the width of all branch-decompositions of f. (If $|V| \leq 1$, we define $\mathrm{bw}(f) = f(\emptyset)$.)

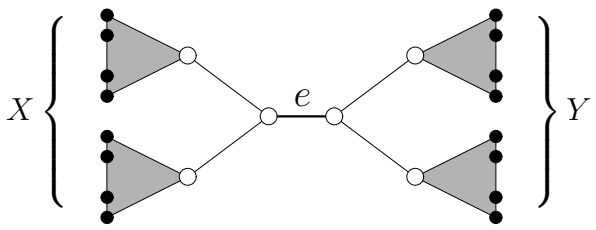

FIG. 1. *An illustration of the definition of a branch-decomposition (T, μ) of f: An edge e of the tree T displays the sets $\mu^{-1}(X)$ and $\mu^{-1}(Y)$, and the width of e is $f(\mu^{-1}(X))$.*

A natural application of this definition is the branch-width of a graph, as introduced by Robertson and Seymour [22] along with better known tree-width, and its direct matroidal counterpart below in this section. We also refer to further formal definition of rank-width in section 7.

Partitions. A *partition* $\mathcal{P}$ of V is a collection of nonempty pairwise disjoint subsets of V whose union is equal to V. Each element of $\mathcal{P}$ is called a *part*. For a symmetric submodular function f on 2^V and a partition $\mathcal{P}$ of V, let $f^{\mathcal{P}}$ be a function on $2^{\mathcal{P}}$ (also symmetric and submodular) such that $f^{\mathcal{P}}(X) = f(\cup_{Y\in X} Y)$. The *width* of a partition $\mathcal{P}$ is $f(\mathcal{P}) = \max\{f(Y) : Y \in \mathcal{P}\}$.

We will often denote a partition by a function as follows. For a function $\pi : V \to W$, let $\pi_y = \{x : \pi(x) = \pi(y)\}$ for $y \in V$, and let $[\pi] = \{\pi_x : x \in V\}$ be the partition of V induced by π.

Matroids. We refer to Oxley [21] in our matroid terminology. A *matroid* is a pair $M = (E, \mathcal{B})$, where $E = E(M)$ is the ground set of M (elements of M), and $\mathcal{B} \subseteq 2^E$ is a nonempty collection of *bases* of M, no two of which are in an inclusion. Moreover, matroid bases satisfy the "exchange axiom": if $B_1, B_2 \in \mathcal{B}$ and $x \in B_1 \setminus B_2$, then there is $y \in B_2 \setminus B_1$ such that $(B_1 \setminus \{x\}) \cup \{y\} \in \mathcal{B}$. We consider only finite matroids. A typical example of a matroid is given by a set of vectors (forming the columns of a matrix $\boldsymbol{A}$) with usual linear independence. The matrix $\boldsymbol{A}$ is then called a *representation* of the matroid.

All matroid bases have the same cardinality called the *rank* $r(M)$ of the matroid. Subsets of bases are called *independent*, and sets that are not independent are *dependent*. A matroid M is *uniform* if all subsets of $E(M)$ of certain size are the bases, and M is *free* if $E(M)$ is a basis. The *rank function* $r_M(X)$ in M is the maximum cardinality of an independent subset of a set $X \subseteq E(M)$. The *dual matroid* M^* is defined on the same ground set with the bases as set-complements of the bases of M. For a subset X of E, the *deletion* $M \setminus X$ of X from M, or the *restriction* $M \restriction (E \setminus X)$ of M to $E \setminus X$, is the matroid on $E \setminus X$ in which $Y \subseteq E \setminus X$ is independent in $M \setminus X$ if and only if Y is an independent set of M. The *contraction* M/X of X in M is the matroid $(M^* \setminus X)^*$. Matroids of the form $M/X \setminus Y$ are called *minors* of M.

To define the branch-width of a matroid, we consider its (symmetric and submodular) connectivity function

$$\lambda_M(X) = r_M(X) + r_M(E \setminus X) - r_M(E) + 1$$

defined for all subsets $X \subseteq E = E(M)$. A "*geometric*" meaning is that the subspaces spanned by X and $E\setminus X$ intersect in a subspace of dimension $\lambda_M(X)-1$. *Branch-width* $\mathrm{bw}(M)$ and *branch-decompositions* of a matroid M are defined as the branch-width and branch-decompositions of λ_M. Notice that $\lambda_{M^*} \equiv \lambda_M$.

Partitioned matroids. A pair $(M, \mathcal{P})$ is called a *partitioned matroid* if M is a matroid and $\mathcal{P}$ is a partition of $E(M)$. A partitioned matroid $(M, \mathcal{P})$ is *representable* if M is representable. A connectivity function of a partitioned matroid $(M, \mathcal{P})$ is defined as $\lambda^{\mathcal{P}}_M$. We note that $\lambda^{\mathcal{P}}_M$ is *symmetric* and *submodular*; in other words,

$$\lambda^{\mathcal{P}}_M(X) = \lambda^{\mathcal{P}}_M(\mathcal{P} \setminus X),$$
$$\lambda^{\mathcal{P}}_M(X) + \lambda^{\mathcal{P}}_M(Y) \geq \lambda^{\mathcal{P}}_M(X \cap Y) + \lambda^{\mathcal{P}}_M(X \cup Y).$$

Branch-width $\mathrm{bw}(M, \mathcal{P})$ and *branch-decompositions* of a partitioned matroid $(M, \mathcal{P})$ are defined as branch-width, branch-decompositions of $\lambda^{\mathcal{P}}_M$.

Amalgams of matroids. Let M_1, M_2 be matroids on E_1, E_2, respectively, and $T = E_1 \cap E_2$. Moreover, let us assume that $M_1 \restriction T = M_2 \restriction T$. If M is a matroid on $E_1 \cup E_2$ such that $M \restriction E_1 = M_1$ and $M \restriction E_2 = M_2$, then M is called an *amalgam* of M_1 and M_2 (see Figure 2).

It is known that an amalgam of two matroids need neither exist nor be unique. However, there are certain interesting cases when an amalgam is known to exist.

We show one such example here, and we use another one in Proposition 5.4 with representable matroids. Let r_1, r_2 be the rank function of M_1, M_2, respectively. Let r be the rank function of $M_1 \restriction T$. Let

$$\eta(X) = r_1(X \cap E_1) + r_2(X \cap E_2) - r(X \cap T)$$

and

$$\zeta(X) = \min\{\eta(Y) : Y \supseteq X\}.$$

PROPOSITION 2.1 (see [21, Proposition 12.4.2]). *If ζ is submodular, then ζ is the rank function of a matroid that is an amalgam of M_1 and M_2.*

If ζ is submodular, then the matroid on $E_1 \cup E_2$ having ζ as its rank function is called the *proper amalgam* of M_1 and M_2.

LEMMA 2.2. *If $M_1 \restriction T$ is free, then ζ is submodular and therefore the proper amalgam of M_1 and M_2 exists.*

Proof. Since $M_1 \restriction T$ is a free matroid, we have $r(X \cap T) = |X \cap T|$ and therefore η is submodular. We will show that this implies that ζ is submodular, that is to show that $\zeta(X_1) + \zeta(X_2) \geq \zeta(X_1 \cap X_2) + \zeta(X_1 \cup X_2)$. For $i \in \{1, 2\}$, let Y_i be a set such that $Y_i \supseteq X_i$ and $\zeta(X_i) = \eta(Y_i)$. Then $\zeta(X_1) + \zeta(X_2) = \eta(Y_1) + \eta(Y_2) \geq \eta(Y_1 \cap Y_2) + \eta(Y_1 \cup Y_2) \geq \zeta(X_1 \cap X_2) + \zeta(X_1 \cup X_2)$. By Proposition 2.1, the proper amalgam of M_1 and M_2 exists. □

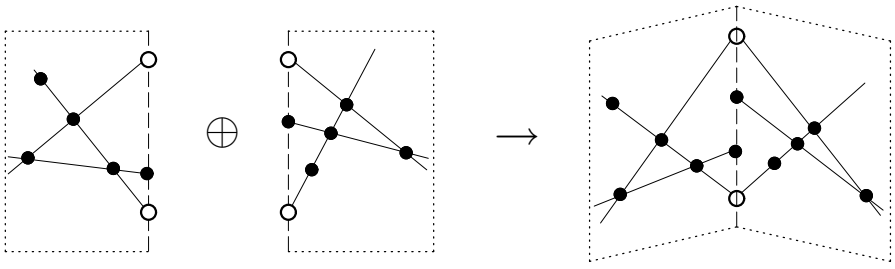

FIG. 2. *A "geometrical" illustration of an amalgam of two matroids, in which hollow points are the shared elements T.*

3. Titanic partitions. This technical section is about general symmetric submodular functions. Let V be a finite set and f be a symmetric submodular function on 2^V.

A set $\mathcal{T} \subset 2^V$ of subsets of V is called an *f-tangle* of order $k+1$ if it satisfies the following three axioms.

(T1) For all $A \subseteq V$, if $f(A) \leq k$, then either $A \in \mathcal{T}$ or $V \setminus A \in \mathcal{T}$.

(T2) If $A, B, C \in \mathcal{T}$, then $A \cup B \cup C \neq V$.

(T3) For all $v \in V$, we have $V \setminus \{v\} \notin \mathcal{T}$. Robertson and Seymour [22] showed that tangles are related to branch-width.

THEOREM 3.1 (Robertson and Seymour [22]). *There is no f-tangle of order $k+1$ if and only if the branch-width of f is at most k.*

A subset X of V is called *titanic* with respect to f if whenever A_1, A_2, A_3 are pairwise disjoint subsets of X such that $A_1 \cup A_2 \cup A_3 = X$, there is $i \in \{1, 2, 3\}$ such that $f(A_i) \geq f(X)$.

LEMMA 3.2. *Let V be a finite set and f be a symmetric submodular function on 2^V. Let X be a titanic set with respect to f. If $X_1 \cup X_2 \cup X_3 = X$, then there exists*

$i \in \{1,2,3\}$ such that $f(X_i) \geq f(X)$. (Note that X_1, X_2, X_3 are not required to be pairwise disjoint.)

Proof. Suppose not. We pick a counterexample with minimum $|X_1|+|X_2|+|X_3|$. If X_1, X_2, X_3 are pairwise disjoint, then by definition the lemma is true.

We may assume that $X_1 \cap X_2 \neq \emptyset$. Let Y_1 be a set minimizing $f(Y_1)$ subject to the condition $X_1 \setminus X_2 \subseteq Y_1 \subseteq X_1$. Then $f(X_1) \geq f(Y_1)$ and $f(X_1 \setminus X_2) \geq f(Y_1)$. Let $Y_2 = X_2 \setminus Y_1$. By the submodular inequality,

$$f(Y_1) + f(X_2) \geq f(X_1 \setminus X_2) + f(Y_2) \geq f(Y_1) + f(Y_2),$$

and therefore $f(X_2) \geq f(Y_2)$. Since $Y_1 \cup Y_2 \cup X_3 = X$, $|Y_1|+|Y_2|+|X_3| < |X_1|+|X_2|+|X_3|$, and $f(X_3) < f(X)$, we conclude that either $f(Y_1) \geq f(X)$ or $f(Y_2) \geq f(X)$. But both cases lead to the conclusion that either $f(X_1) \geq f(X)$ or $f(X_2) \geq f(X)$, a contradiction. □

A partition $\mathcal{P}$ of V is called *titanic* with respect to f if every part of $\mathcal{P}$ is titanic with respect to f. The following lemmas are equivalent to a lemma by Geelen, Gerards, and Whittle [9, Proposition 4.4], which generalizes a result of Robertson and Seymour [22, Proposition (8.3)].

LEMMA 3.3. *Let V be a finite set and f be a symmetric submodular function on 2^V of branch-width k. Let Q be a nonempty titanic set with respect to f. Let $y \in Q$. Let $\pi(x) = x$ if $x \notin Q$ and $\pi(x) = y$ if $x \in Q$. If $f(Q) \leq k$, then the branch-width of $f^{[\pi]}$ is at most k.*

Proof. Suppose that the branch-width of $f^{[\pi]}$ is larger than k. Then by Theorem 3.1, there is an $f^{[\pi]}$-tangle $\mathcal{T}^{[\pi]}$ of order $k+1$. Let $\mathcal{T}' = \{\cup_{Z \in Y} Z : Y \in \mathcal{T}^{[\pi]}\}$.

We would like to construct an f-tangle $\mathcal{T}$ of order $k+1$ as follows:

$$\mathcal{T} = \big\{X \subseteq V : f(X) \leq k \text{ and either } X \cup Q \in \mathcal{T}' \text{ or } X \setminus Q \in \mathcal{T}'\big\}.$$

To show that $\mathcal{T}$ is an f-tangle of order $k+1$, it is enough to verify the three axioms (T1)–(T3).

For (T1), suppose that $f(X) \leq k$ and $X, V \setminus X \notin \mathcal{T}$. Since Q is titanic, either $f(X \cap Q) \geq f(Q)$ or $f(Q \setminus X) \geq f(Q)$. We may assume that $f(X \cap Q) \geq f(Q)$ by replacing X with $V \setminus X$ if necessary. By the submodular inequality,

$$f(X) + f(Q) \geq f(X \cup Q) + f(X \cap Q) \geq f(X \cup Q) + f(Q),$$

and therefore $f(X \cup Q) \leq f(X) \leq k$. Since $\mathcal{T}^{[\pi]}$ is an $f^{[\pi]}$-tangle, we know that either $X \cup Q \in \mathcal{T}'$ or $V \setminus (X \cup Q) \in \mathcal{T}'$. If $X \cup Q \in \mathcal{T}'$, then $X \in \mathcal{T}$. If $V \setminus (X \cup Q) = (V \setminus X) \setminus Q \in \mathcal{T}'$, then $V \setminus X \in \mathcal{T}$. So, (T1) is proved.

To show (T2), suppose that there are $X_1, X_2, X_3 \in \mathcal{T}$ such that $X_1 \cup X_2 \cup X_3 = V$. By Lemma 3.2, there exists $i \in \{1,2,3\}$ such that $f(X_i \cap Q) \geq f(Q)$. We may assume that $i = 1$. By the submodular inequality, we deduce that $f(X_1 \cup Q) \leq f(X_1) \leq k$. Since $\mathcal{T}'$ has no three sets whose union is V, we have $X_1 \cup Q \notin \mathcal{T}'$. Therefore, $X_1 \setminus Q \in \mathcal{T}'$ and $V \setminus (X_1 \cup Q) \in \mathcal{T}'$. By (T3) of $\mathcal{T}^{[\pi]}$, we have $V \setminus Q \notin \mathcal{T}'$. Since $f(Q) \leq k$, we have $Q \in \mathcal{T}'$ by (T1) of $\mathcal{T}^{[\pi]}$. However, $(V \setminus (X_1 \cup Q)) \cup (X_1 \setminus Q) \cup Q = V$, contradictory to the fact that $\mathcal{T}^{[\pi]}$ is an $f^{[\pi]}$-tangle.

To show (T3), suppose that $X = V \setminus \{v\} \in \mathcal{T}$ for some $v \in V$. Since $V, V \setminus Q \notin \mathcal{T}'$ and $V \setminus \{v\} \notin \mathcal{T}'$ when $v \notin Q$, we deduce that $v \notin Q$ and $V \setminus \{v\} \setminus Q \in \mathcal{T}'$. We know that $\{v\}, Q \in \mathcal{T}'$. Then the union of three sets $\{v\}, Q, V \setminus \{v\} \setminus Q$ is equal to V, a contradiction.

Now we conclude that $\mathcal{T}$ is an f-tangle of order $k+1$. However, this is a contradiction to Theorem 3.1, because we assumed that the branch-width of f is k. □

LEMMA 3.4. *Let V be a finite set and f be a symmetric submodular function on 2^V of branch-width at most k. If $\mathcal{P}$ is a titanic partition of width at most k with respect to f, then the branch-width of $f^{\mathcal{P}}$ is at most k.*

Proof. Suppose that there is a counterexample. We pick a counterexample with a minimum number of parts having at least two elements. If all parts have exactly one element, then it is trivial.

Choose one member from each part of $\mathcal{P}$ and consider a function $\pi : V \to V$ that maps each element x of V to a representative of the part containing x. Then $[\pi] = \mathcal{P}$.

Let y be an element of V such that $|\pi_y| \geq 2$. Then let $\pi' : V \to V$ be a function such that

$$\pi'(x) = \begin{cases} \pi(x) & \text{if } x \notin \pi_y, \\ x & \text{if } x \in \pi_y. \end{cases}$$

By definition, $[\pi'] = \{\pi_x : x \notin \pi_y\} \cup \{\{x\} : x \in \pi_y\}$. Since the number of parts in $[\pi']$ having at least two elements is strictly smaller than that of $[\pi] = \mathcal{P}$ and $[\pi']$ is a titanic partition of width at most k, we know that the branch-width of $f^{[\pi']}$ is at most k.

Then $Q = \{\{x\} : x \in \pi_y\}$ is titanic with respect to $f^{[\pi']}$, because $\mathcal{P}$ is a titanic partition and $\pi_y \in \mathcal{P}$. In addition, $f^{[\pi']}(Q) = f(\pi_y) \leq k$. Therefore, by Lemma 3.3, the branch-width of $f^{[\pi']}$ is at most k. This contradicts the assumption that $\mathcal{P}$ is chosen as a counterexample with a minimum number of parts with more than one element. ∎

4. Replacing each part by a gadget. The purpose of this section is to show how a partitioned matroid may be "modeled" by an ordinary matroid having the same branch-width.

LEMMA 4.1. *Let M be a matroid and T be a subset of $E(M)$. If $|T|+1 > \lambda_M(T)$, then there is $e \in T$ such that one of the following is true:*

1. *$\lambda_{M/e}(X) = \lambda_M(X)$ for all $X \subseteq E(M) \setminus T$, or*
2. *$\lambda_{M\setminus e}(X) = \lambda_M(X)$ for all $X \subseteq E(M) \setminus T$.*

Proof. Let X be a subset of $E(M) \setminus T$. If there is an element $e \in T$ that is not spanned by $E(M) \setminus T$, then $\mathrm{r}_{M/e}(X) = \mathrm{r}_M(X)$. Therefore, $\lambda_{M/e}(X) = \mathrm{r}_{M/e}(X) + \mathrm{r}_{M/e}\big(E(M)\setminus(\{e\}\cup X)\big) - \mathrm{r}(M/e) + 1 = \mathrm{r}_M(X) + \mathrm{r}_M\big(E(M)\setminus X\big) - \mathrm{r}_M(\{e\}) - \big(\mathrm{r}(M) - \mathrm{r}_M(\{e\})\big) + 1 = \lambda_M(X)$.

So, we may assume that $E(M) \setminus T$ spans T. Since $|T| + 1 > \lambda_M(T) = \mathrm{r}_M(T) + 1$, T is dependent in M, and hence in the dual matroid M^* the set T is not spanned by $E(M^*) \setminus T$. We apply the previous argument to M^*. (Note that $(M \setminus e)^* = M^*/e$ and $\lambda_{M^*} \equiv \lambda_M$.) ∎

COROLLARY 4.2. *Let M be a matroid, and let T be a subset of $E(M)$. Then there exist disjoint subsets C, D of T such that $\lambda_{M/C\setminus D}(T \setminus (C \cup D)) = |T \setminus (C \cup D)| + 1$, and $\lambda_{M/C\setminus D}(X) = \lambda_M(X)$ for all $X \subseteq E(M) \setminus T$.*

We aim to transform a partitioned matroid $(M, \mathcal{P})$ to another partitioned matroid $(M^\#, \mathcal{P}^\#)$, such that they have the same branch-width and $\mathcal{P}^\#$ is a titanic partition with respect to $\lambda_{M^\#}$. To do so, we use an amalgam operation on matroids, described in section 2.

Let $(M, \mathcal{P})$ be a partitioned matroid. We may assume each part T of $\mathcal{P}$ satisfies $\lambda_M(T) = |T| + 1$ if $|T| > 1$, because otherwise we can contract or delete elements in T while preserving $\mathrm{bw}(M, \mathcal{P})$ by Corollary 4.2. This means that $M \restriction T$ is a free matroid. For each part T of $(M, \mathcal{P})$, if $|T| > 1$, then we define a matroid U_T (a *titanic*

gadget of T) as a rank-$|T|$ uniform matroid on the ground set $E_T = E(U_T)$ such that $|E_T| = 3|T| - 2$, $E(M) \cap E_T = T$, and $E_T \cap E_{T'} = \emptyset$ if $T' \neq T$ is a part of $\mathcal{P}$ and $|T'| > 1$. Since $M \restriction T = U_T \restriction T$ is a free matroid, an amalgam of M and U_T exists by Lemma 2.2.

LEMMA 4.3. *Let M be a matroid and T be a subset of $E(M)$ such that $\lambda_M(T) = |T| + 1$. Let M' be an amalgam of M and U_T. Then the following are true:*

1. *If $T \subseteq X \subseteq E(M')$, then $\mathrm{r}_M(X \cap E(M)) = \mathrm{r}_{M'}(X)$.*
2. *$\lambda_M(X) = \lambda_{M'}(X)$ for all $X \subseteq E(M) \setminus T$.*
3. *The set $E(U_T)$ is titanic in the matroid M'.*

Proof. 1. Because $M' \restriction E(M) = M$, we have $\mathrm{r}_M(X \cap E(M)) = \mathrm{r}_{M'}(X \cap E(M)) \leq \mathrm{r}_{M'}(X)$.

Since T is independent in U_T, we can pick a maximally independent subset I of X in M' such that $T \subseteq I$. Since $M' \restriction E(U_T) = U_T$, the set $I \cap E(U_T)$ is independent in U_T, and therefore $I \cap E(U_T) = T$. So, $I \subseteq E(M)$. Therefore, $\mathrm{r}_M(X \cap E(M)) \geq |I| = \mathrm{r}_{M'}(X)$.

2. Let $Y = E(M') \setminus X$. We note that $E(U_T)$ is a subset of Y. By definition,

$$\lambda_M(X) = \mathrm{r}_M(X) + \mathrm{r}_M(Y \cap E(M)) - \mathrm{r}(M) + 1,$$
$$\lambda_{M'}(X) = \mathrm{r}_{M'}(X) + \mathrm{r}_{M'}(Y) - \mathrm{r}(M') + 1.$$

Since $M' \restriction E(M) = M$, we have $\mathrm{r}_M(X) = \mathrm{r}_{M'}(X)$. By 1, $\mathrm{r}_M(Y \cap E(M)) = \mathrm{r}_{M'}(Y)$ and $\mathrm{r}(M') = \mathrm{r}(M)$. Thus $\lambda_M(X) = \lambda_{M'}(X)$.

3. We claim that if X is a subset of $E(U_T)$ and $|X| \geq |T|$, then $\lambda_{M'}(X) \geq \lambda_{M'}(E(U_T))$. Since U_T is a uniform matroid of rank $|T|$, we have

$$\mathrm{r}_{M'}(X) = |T| = \mathrm{r}_{M'}(E(U_T)),$$
$$\mathrm{r}_{M'}(E(M') \setminus X) \geq \mathrm{r}_{M'}(E(M') \setminus E(U_T)).$$

Therefore, $\lambda_{M'}(X) \geq \lambda_{M'}(E(U_T))$.

Now suppose that X_1, X_2, X_3 are pairwise disjoint subsets of $E(U_T)$. Then there is $i \in \{1, 2, 3\}$ such that $|X_i| \geq \lceil |E(U_T)|/3 \rceil = |T|$ and therefore $\lambda_{M'}(X_i) \geq \lambda_{M'}(E(U_T))$. Therefore, $E(U_T)$ is titanic in M'. □

Using Corollary 4.2, we first obtain a minor M_0 of M such that $\lambda_{M_0}(T \cap E(M_0)) = |T \cap E(M_0)| + 1$ for all parts $T \in \mathcal{P}$, and if a subset X of $E(M)$ satisfies that $X \cap T \in \{\emptyset, T\}$ for all parts $T \in \mathcal{P}$, then $\lambda_{M_0}(X \cap E(M_0)) = \lambda_M(X)$. Let $\mathcal{P}_0$ be the partition of $E(M_0)$ induced by $\mathcal{P}$. Then we deduce from Corollary 4.2 that the branch-width of $(M, \mathcal{P})$ is equal to the branch-width of $(M_0, \mathcal{P}_0)$. However, the branch-width of the matroid M_0 may still be different from the branch-width of the partitioned matroid $(M_0, \mathcal{P}_0)$.

In the following theorem, we will extend $(M_0, \mathcal{P}_0)$ by amalgamating uniform matroids in the fashion of Lemma 4.3 so that the obtained partitioned matroid $(M^\#, \mathcal{P}^\#)$ has the same branch-width as the matroid $M^\#$ itself.

THEOREM 4.4. *Let $(M_0, \mathcal{P}_0)$ be a partitioned matroid, and let $T_1, T_2, \ldots, T_m$ be the parts of $\mathcal{P}_0$ having at least two elements. Assume that $\lambda_{M_0}(T_i) = |T_i| + 1$ for every $i \in \{1, 2, \ldots, m\}$. For all $i = 1, 2, \ldots, m$, let M_i be an amalgam of M_{i-1} and U_{T_i}. Then the branch-width of M_m is equal to the branch-width of the partitioned matroid $(M_0, \mathcal{P}_0)$.*

We call the resulting $M^\# = M_m$ the *normalized matroid* of the partitioned matroid $(M_0, \mathcal{P}_0)$.

Proof. Let $\mathcal{P}_i = (\mathcal{P}_{i-1} \setminus \{T_i\}) \cup \{E(U_{T_i})\}$. By 2. of Lemma 4.3, the branch-width of $(M_i, \mathcal{P}_i)$ is equal to that of $(M_{i-1}, \mathcal{P}_{i-1})$, and therefore the branch-width

of $(M_m, \mathcal{P}_m)$ is equal to the branch-width of $(M_0, \mathcal{P}_0)$. By 3. of Lemma 4.3, $\mathcal{P}_m$ is a titanic partition. Let k be the branch-width of M_m. It is easy to see that the branch-width of the uniform matroid U_{T_i} is $|T_i| + 1 = \lambda_{M_m}(E(U_{T_i}))$. Since U_{T_i} is a minor of M_m, the branch-width of M_m is at least $|T_i| + 1$ for all i, and therefore the width of $\mathcal{P}_m$ is at most k. We conclude that the branch-width of $(M_m, \mathcal{P}_m)$ is at most k by Lemma 3.4.

To finish the proof, we need to show that the branch-width of $(M_m, \mathcal{P}_m)$ is at least k. Let (T, μ) be the branch-decomposition of $(M_m, \mathcal{P}_m)$ of width at most w. From (T, μ), we would like to obtain a branch-decomposition (T', μ') of M_m whose width is at most w as follows. Let v_i be the leaf of T corresponding to $E(U_{T_i})$. We prepare a rooted binary tree with a bijection from its leaves to $E(U_{T_i})$ and then identify the root with v_i. Let T' be the new tree obtained by the above process for all i. A bijection μ' from $E(M_m)$ to leaves of T' is easily obtained from the above process. Since $\lambda_{M_m}(X) = |X| + 1 \leq \lambda_{M_m}(E(U_{T_i})) \leq w$ for all $X \subseteq E(U_{T_i})$, the width of (T', μ') is at most w. □

5. Branch-decompositions of represented partitioned matroids. We now specialize the above ideas to the case of representable matroids. We aim to provide an efficient algorithm for testing small branch-width on such partitioned matroids. For the rest of our paper, a *represented matroid* is the vector matroid of a (given) matrix over a *fixed* finite field. We also write an $\mathbb{F}$-*represented* matroid to explicitly refer to the field $\mathbb{F}$. In other words, an $\mathbb{F}$-represented matroid is a set of points (a *point configuration*) in a (finite) projective geometry over $\mathbb{F}$. To begin, we restate a previous result of Hliněný.

THEOREM 5.1 (see [13, Theorems 4.14 and 5.5]). *Let $k > 1$ be a constant, and let $\mathbb{F}$ be a fixed finite field. There is a parametrized algorithm that, for a given matroid M represented by an $r \times n$ matrix over $\mathbb{F}$ for some $r \leq n$, tests whether the branch-width of M is at most k in time $O(n^3)$.*

We remark that the algorithm for Theorem 5.1 in [13] is purely of theoretical importance. First, it uses the result of Geelen et al. [8] stating that minor-minimal matroids of branch-width larger than k have size at most $(6^k - 1)/5$. Second, it tests whether the input matroid contains such a minor-minimal matroid as a minor by encoding the question in a monadic second-order logic formula on matroids and using a generic algorithm to solve an MSOL formula for $\mathbb{F}$-represented matroids of branch-width at most k. Since our algorithm will use Theorem 5.1, it will be purely theoretical and difficult to implement.

Not all matroids are representable over $\mathbb{F}$. Particularly, in the construction of the normalized matroid (Theorem 4.4) we apply amalgams with uniform matroids which need not be $\mathbb{F}$-representable. To achieve their representability, we extend the field $\mathbb{F}$ in a standard algebraic way.

Remark 5.2. Let $\mathbb{F}$ be a fixed finite field with q elements and d be a fixed positive integer. We assume that one can perform arithmetic operations over $\mathbb{F}$ in time depending only on q. Then, one can construct by brute force an extension (finite) field $\mathbb{F}' = \mathbb{F}(\alpha)$ with q^d elements by searching for a polynomial root α of degree d over $\mathbb{F}$. This can be done by searching through all polynomials in $\mathbb{F}[x]$ of degree d for the irreducible ones.

LEMMA 5.3. *The n-element rank-r uniform matroid $U_{r,n}$ is representable over a (finite) field $\mathbb{F}$ if $|\mathbb{F}| \geq n - 1$.*

Proof. Let $|\mathbb{F}| = q$. It is trivial to represent $U_{0,n}, U_{1,n}, U_{n-1,n}$, or $U_{n,n}$ over every field. Furthermore, standard arguments of projective geometry show that a

so-called normal rational curve in a projective geometry over $\mathbb{F}$ is a representation of the uniform matroid $U_{r,\,q+1}$, for every $1 < r < q$; see, for instance, [12, section 3]. Although it is not useful in our context, it is worth noting that the size bound $q+1$ is almost optimal in most cases. Finally, if $q+1 > n$, then we delete arbitrary $q+1-n$ points from the representation to get $U_{r,n}$. □

Recall the notion of a matroid amalgam from section 2 from the perspective of represented matroids. We shall use the following proposition.

PROPOSITION 5.4. *Let M_1, M_2 be two matroids such that $E(M_1) \cap E(M_2) = T$ and $M_1 \restriction T = M_2 \restriction T$. If both M_1, M_2 are $\mathbb{F}$-represented, and the matroid $M_1 \restriction T$ has a unique $\mathbb{F}$-representation up to linear transformations, then there exists an amalgam of M_1 and M_2 which is also $\mathbb{F}$-represented.*

Proof. We denote by $[\boldsymbol{A}_1 \mid \boldsymbol{A}_T]$ the matrix over $\mathbb{F}$ representing M_1, where the columns of $\boldsymbol{A}_T$ represent the set T. Analogously we denote by $[\boldsymbol{A}_2 \mid \boldsymbol{A}'_T]$ the matrix representing M_2. Since $M_1 \restriction T = M_2 \restriction T$ has a unique $\mathbb{F}$-representation, there is a linear transformation carrying $\boldsymbol{A}'_T$ onto $\boldsymbol{A}_T$. This transformation takes a whole $[\boldsymbol{A}_2 \mid \boldsymbol{A}'_T]$ to an equivalent matrix $[\boldsymbol{A}'_2 \mid \boldsymbol{A}_T]$ representing the same matroid M_2. It is now trivial to verify that the matroid M which is $\mathbb{F}$-represented by the composed matrix $[\boldsymbol{A}_1 \mid \boldsymbol{A}_T \mid \boldsymbol{A}'_2]$ is an amalgam of M_1 and M_2. □

We remark that representable matroids typically do have inequivalent vector representations, but we are using Proposition 5.4 only in the case when $M_1 \restriction T$ is a free matroid which clearly has a unique $\mathbb{F}$-representation for every field $\mathbb{F}$.

We now outline a simple fixed-parameter tractable algorithm for testing branch-width $\leq k$ on $\mathbb{F}$-represented partitioned matroids.

ALGORITHM 5.5. Testing branch-width of a represented partitioned matroid.

Parameters: A finite field $\mathbb{F}$, and a positive integer k.

Input: A rank-r matrix $\boldsymbol{A} \in \mathbb{F}^{r \times n}$ and a partition $\mathcal{P}$ of the columns of $\boldsymbol{A}$. (Assume $n \geq 2$.)

Output: For the vector matroid $M = M(\boldsymbol{A})$ on the columns of $\boldsymbol{A}$ partitioned by $\mathcal{P}$, a correct answer whether the branch-width of $(M, \mathcal{P})$ is at most k.

1. First, we extend $\mathbb{F}$ to a nearest field $\mathbb{F}'$ such that $|\mathbb{F}'| \geq 3k-6$ (Remark 5.2).
2. If the width of the partition $\mathcal{P}$ in given $(M, \mathcal{P})$ is more than k, then we answer NO.
3. Otherwise, we directly construct the normalized matroid $M^{\#}$ (Theorem 4.4), together with its vector representation over $\mathbb{F}'$ (Lemma 5.3 and Proposition 5.4).
4. Finally, we use Theorem 5.1 to test whether the branch-width of $M^{\#}$ is at most k.

Hence, we can conclude with the following theorem.

THEOREM 5.6. *Let $k > 1$ be a constant, and let $\mathbb{F}$ be a fixed finite field. There is a parametrized algorithm that, for a partitioned matroid $(M, \mathcal{P})$ represented over $\mathbb{F}$, tests in time $O(|E(M)|^3)$ whether the branch-width of $(M, \mathcal{P})$ is at most k.*

Proof. We refer to Algorithm 5.5. Denote $n = |E(M)|$. In the first step we find the extension field $\mathbb{F}'$ which takes only constant time by Remark 5.2. Since $\mathbb{F}' \supseteq \mathbb{F}$, we do not need to touch the input vector representation of M. Step 2. of Algorithm 5.5 is trivial.

The technical part comes in step 3. of Algorithm 5.5. For each part $X \in \mathcal{P}$ of more than one element, we compute the intersection of the spans of X and of $E(M) \setminus X$, called the *guts* of the separation $(X, E(M) \setminus X)$, in the representation of M. The reader should understand that we deal with represented matroids, that means we

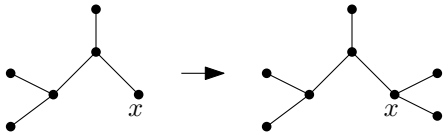

FIG. 3. *Splitting x.*

compute with actual vectors and subspaces in a projective geometry over $\mathbb{F}'$. If the dimension $\lambda_M(X)-1$ of these guts was at least k, then each branch-decomposition of $(M,\mathcal{P})$ should have width at least $\lambda_M(X) > k$, and we have answered NO in step 2. of Algorithm 5.5 in such a case. Therefore, the dimension of the guts of $(X, E(M)\setminus X)$ is bounded by a constant k, and a set T of its independent generator vectors can be easily computed in time $O(n^2)$ (see, e.g., [13, Algorithm 4.4]), per each part of $\mathcal{P}$.

In order to get the situation anticipated in Theorem 4.4—each part representing a free matroid—we replace the vectors of each nonsingleton part $X \in \mathcal{P}$ by the respective vectors T computed in the previous paragraph. Let the resulting represented partitioned matroid be denoted by $(M_0,\mathcal{P}_0)$, and note that $\mathrm{bw}(M_0,\mathcal{P}_0) = \mathrm{bw}(M,\mathcal{P})$. For each $T \in \mathcal{P}_0$ we construct an $\mathbb{F}'$-representation of the titanic gadget (uniform matroid) U_T from section 4 using Lemma 5.3, and then construct an amalgam of M_0 with U_T according to Proposition 5.4. Since U_T is of bounded size, this last step can be computed in time proportional to the vector length $O(n)$, per each part of $\mathcal{P}_0$.

After processing all $O(n)$ nonsingleton parts in $\mathcal{P}_0$ by the previous procedure, we get a vector $\mathbb{F}'$-representation of the normalized matroid $M^\#$ for $(M_0,\mathcal{P}_0)$. By Theorem 4.4, $\mathrm{bw}(M^\#) = \mathrm{bw}(M_0,\mathcal{P}_0) = \mathrm{bw}(M,\mathcal{P})$. So, we call the algorithm of Theorem 5.1 to determine whether the branch-width of $M^\#$ (as well as the branch-width of $(M,\mathcal{P})$) is at most k. This takes only $O(n^3)$ time since both k, $\mathbb{F}'$ are of bounded size here. □

We are now able to test branch-width of partitioned matroids. We show how this result can be extended to finding an appropriate branch-decomposition.

THEOREM 5.7. *Let $\mathcal{K}$ be a class of matroids, and let k be an integer. If there is an $f(|E(M)|,k)$-time algorithm to decide whether a partitioned matroid $(M,\mathcal{P})$ has branch-width at most k for every pair of a matroid $M \in \mathcal{K}$ and a partition $\mathcal{P}$ of $E(M)$, then a branch-decomposition of the partitioned matroid $(M,\mathcal{P})$ of width at most k, if it exists, can be found in time $O\big(|\mathcal{P}|^3 \cdot f(|E(M)|,k)\big)$.*

The idea of the proof is due to Jim Geelen, published by Oum and Seymour in [20]. Details of the algorithm follow. Clearly, we may assume that the branch-width of the partitioned matroid $(M,\mathcal{P})$ in question is at most k, since otherwise there is nothing to compute. A *splitting* of a leaf x of a subcubic tree is an operation that creates two new leaves and makes them adjacent to x (see Figure 3).

ALGORITHM 5.8. Computing a branch-decomposition of a partitioned matroid.
Oracle: A subroutine for testing the branch-width of a partitioned matroid $(M,\mathcal{P})$, where M belongs to a given class $\mathcal{K}$, and $\mathcal{P}$ is a partition of $E(M)$.
Input: A partitioned matroid $(M,\mathcal{P})$ of branch-width at most k, where $M \in \mathcal{K}$.
Output: A branch-decomposition of $(M,\mathcal{P})$ of width at most k.

1. If $|\mathcal{P}| \le 2$, then it is trivial to output a branch-decomposition.
2. We find a pair X,Y of disjoint parts of $\mathcal{P}$ such that a partitioned matroid $(M,(\mathcal{P}\setminus\{X,Y\})\cup\{X\cup Y\})$ has branch-width at most k. Let $\mathcal{P}' = (\mathcal{P}\setminus\{X,Y\})\cup\{X\cup Y\}$.
3. Let (T',μ') be the branch-decomposition of $(M,\mathcal{P}')$ of width at most k ob-

tained by calling this algorithm recursively.

4. Let T be a tree obtained from T' by splitting the leaf $\mu'(X \cup Y)$ into two leaves which we denote by $\mu(X)$ and $\mu(Y)$. Let $\mu(Z) = \mu'(Z)$ for all $Z \in \mathcal{P} \setminus \{X, Y\}$. We output (T, μ) as the resulting branch-decomposition of (M, P) of width at most k.

Proof of Theorem 5.7. We start by estimating the running time of the algorithm. At each level of recursion, we call our oracle (the decision algorithm) at most $\binom{|\mathcal{P}|}{2} = O(|\mathcal{P}|^2)$ times. The depth of recursion is $|\mathcal{P}| - 1$, and therefore the number of calls to the decision algorithm is at most $O(|\mathcal{P}|^3)$. Thus, the running time of the algorithm is $O\big(|\mathcal{P}|^3 \cdot f(|E(M)|, k)\big)$.

It remains to show correctness of the algorithm. It is obvious that in every subcubic tree with at least three leaves, there are two leaves that have a common neighbor. Suppose that (T, μ) is a branch-decomposition of $(M, \mathcal{P})$ of width at most k. Then there are two leaves $\mu(X)$ and $\mu(Y)$ having a common neighbor z in T. It is easy to see that if we remove $\mu(X)$ and $\mu(Y)$ from T and map $X \cup Y$ to z by μ, then (T, μ) is a branch-decomposition of $(M, \mathcal{P}')$ of width at most k. Therefore, the branch-width of $(M, \mathcal{P}')$ is at most k.

Conversely, suppose that (T', μ') is the branch-decomposition of $(M, \mathcal{P}')$. Since $(M, \mathcal{P})$ has a branch-width of at most k, we know that $\lambda_M(X) \leq k$ and $\lambda_M(Y) \leq k$. Thus (T, μ) is a branch-decomposition of $(M, \mathcal{P})$ of width at most k. □

COROLLARY 5.9. *For a constant k and a fixed finite field $\mathbb{F}$, we can find a branch-decomposition of a given $\mathbb{F}$-represented matroid M of branch-width at most k, if it exists, in time $O(|E(M)|^6)$.*

Proof. Let $\mathcal{P} = \{\{x\} : x \in E(M)\}$. Then the branch-decomposition of M is one-to-one correspondent to the branch-decomposition of a partitioned matroid $(M, \mathcal{P})$. By Theorem 5.6, the problem of deciding whether branch-width is at most k can be done in time $O(|E(M)|^3)$, and therefore we can construct the branch-decomposition of width at most k in time $O(|\mathcal{P}|^3 \cdot |E(M)|^3) = O(|E(M)|^6)$ by Theorem 5.7. □

Remark 5.10. One can actually improve the bound in Theorem 5.7 to $O\big(|\mathcal{P}|^2 \cdot f(|E(M)|, k)\big)$ time. The basic idea is the following: At the first level of recursion we find not only one pair of parts but a maximal set of disjoint pairs of parts from $\mathcal{P}$ that can be joined (pairwise) while keeping the branch-width at most k. This again requires $O(|\mathcal{P}|^2)$ calls to the decision algorithm. At the deeper levels of recursion we then use the same approach but process only such pairs of parts that contain one joined at the previous level. An amortized complexity analysis shows that only additional $O(|\mathcal{P}|^2)$ calls to the decision algorithm are necessary at all subsequent levels of recursion together. Detailed arguments of this approach can be found further in Theorem 6.7, part (III) of the proof.

6. Faster algorithm for branch-decompositions. Even with Remark 5.10 in account, the approach of section 5 results in an $O(n^5)$ parametrized algorithm for constructing a branch-decomposition of an n-element matroid represented over a fixed finite field. That is still far from the cubic running time of the decision algorithm in Theorem 5.1. Although not straightforwardly, we are able to improve the running time of our constructive algorithm to asymptotically match cubic time of that and [5].

It is the purpose of this section to present a detailed analysis of such a faster implementation of Algorithm 5.8 using Remark 5.10. For that we have to dive into fine details of the ideas and algorithms in [13]. To be consistent, we also adopt the writing style of [13] for this section and recall a few necessary technical definitions

here. More technical details are given along with a formal setting of Algorithm 6.6. We first give a brief informal outline of our faster algorithm, which seems necessary since Algorithm 6.6 itself is quite long and complex. We also collect formal statements of useful subroutines from [13], and then we conclude with the main algorithm (Algorithm 6.6) and a proof of its correctness.

One key point in the approach of [13, 14] is that a matroid M, which is $\mathbb{F}$-represented by a matrix $\boldsymbol{A}$, is equivalent to a projective point configuration over $\mathbb{F}$, and therefore we can speak about M in schematic geometric terms. Briefly speaking, a *parse tree* [14] of an $\mathbb{F}$-represented matroid M is a rooted tree $\mathcal{T}$, with at most two children per node, such that the leaves of $\mathcal{T}$ hold nonloop elements of M represented by points of a projective geometry over $\mathbb{F}$, or loops of M represented by the empty set. The internal nodes of $\mathcal{T}$, on the other hand, hold suitable "composition operators over $\mathbb{F}$."

Such a *composition operator* $\odot$ is a configuration in the projective geometry over $\mathbb{F}$ such that $\odot$ has three subspaces (possibly empty) distinguished as its *boundaries*; two of which are used to "glue" the matroid elements represented in the left and right subtrees, respectively, together. The third one, *upper boundary*, is then used to "glue" this node further up in the parse tree $\mathcal{T}$. Our "glue" operation, called the boundary sum by Hliněný [14], is analogous to the amalgam of matroids in Proposition 5.4. The ranks of adjacent boundaries of two composition operators in $\mathcal{T}$ must be equal for "gluing." A parse tree $\mathcal{T}$ is $\leq t$*-boundaried* if all composition operators in $\mathcal{T}$ have boundaries of rank at most t. Such a parse tree actually gives a branch-decomposition of width at most $t+1$ and vice versa, by [14, Theorem 3.8]. See [14] for additional details.

We will use the following algorithm shown by Hliněný [13].

ALGORITHM 6.1 (see [13, Algorithm 4.1]). Computing a parse tree of a represented matroid.

Parameters: A finite field $\mathbb{F}$, and a positive integer k.
Input: A rank-r matrix $\boldsymbol{A} \in \mathbb{F}^{r\times n}$ representing a matroid M over $\mathbb{F}$. (Assume $n \geq 2$.)
Output: Computed in time $O(n^3)$; either a $\leq 3k$-boundaried parse tree $\mathcal{T}$ of the matroid M, or a proof that the branch-width of M is more than $k+1$.

The basic idea of Algorithm 6.1 is as follows: We start with a basis $\boldsymbol{I}_r$ of the input matrix $\boldsymbol{A} = [\boldsymbol{I}_r \mid \boldsymbol{A}'] \in \mathbb{F}^{r\times n}$, and assign an arbitrary parse tree $\mathcal{T}$ to $\boldsymbol{I}_r$. Then we are adding, one by one, the remaining elements of $\boldsymbol{A}'$ arbitrarily to $\mathcal{T}$. Whenever the largest boundary rank (the *width*) of $\mathcal{T}$ exceeds certain constant threshold, say $10k$, we "compress" $\mathcal{T}$ into a new parse tree $\mathcal{T}'$ of width at most $3k$ again. However, if the compression step fails, then we have a certificate that the branch-width of $M(\boldsymbol{A})$ is more than $k+1$. The compression routine, [13, Algorithm 4.1, step 3] and [13, Lemma 4.13], is crucial also in our new algorithm, and thus we restate it explicitly here.

ALGORITHM 6.2 (see [13, Algorithm 4.1]). "Compressing" a parse tree of bounded width.

Parameters: A finite field $\mathbb{F}$, and a positive integer k.
Input: A $\leq ck$-boundaried parse tree $\mathcal{T}$ (of an n-element matroid M represented over $\mathbb{F}$), where $c > 3$ is a fixed constant, say $c = 10$.
Output: Computed in time $O(n^2)$; either a $\leq 3k$-boundaried parse tree $\mathcal{T}'$ of the same matroid M, or a proof that the branch-width of M is more than $k+1$.

Outline of the faster algorithm. Before giving full details of our new Algorithm 6.6 for computing a branch-decomposition of a represented partitioned matroid, we sketch

its main ideas with respect to the previous Algorithms 6.2 and 6.1.

Parameters: A finite field $\mathbb{F}$, and a positive integer k.

Input: A rank-r matrix $\boldsymbol{A} \in \mathbb{F}^{r\times n}$ and a partition $\mathcal{P}$ of the columns of $\boldsymbol{A}$. (Assume $n \geq 2$.)

Initial phase. Let $M = M(\boldsymbol{A})$ be the vector matroid on the columns of $\boldsymbol{A}$. We run Algorithm 5.5 to obtain the represented normalized matroid $M^{\#}$ for our M and $\mathcal{P}$, and to decide whether $\mathrm{bw}(M^{\#}) \leq k$. In the positive case, we also call Algorithm 6.1 to obtain a $\leq 3(k-1)$-boundaried parse tree $\mathcal{T}$ for the matroid $M^{\#}$.

Construction phase. We construct a branch-decomposition of $(M, \mathcal{P})$ as a rooted forest D which is initialized to the set of disconnected nodes $\mathcal{P}_1 := \mathcal{P}$. A *rooted forest* is a forest in which every connected component has a specified vertex called a *root*.

In the first iteration, we find an inclusion-wise maximal collection of pairwise disjoint pairs $\{X_i, Y_i\}$, $i = 1, 2, \ldots, c$, of parts of $\mathcal{P}_1$ such that the branch-width of $(M, \mathcal{P}_1')$ is at most k, where $\mathcal{P}_1'$ is obtained from $\mathcal{P}_1$ via replacing parts X_i, Y_i with $X_i \cup Y_i$ for $i = 1, 2, \ldots, c$. The meaning is that these pairs $\{X_i, Y_i\}$ simultaneously correspond to pairs of leaves of distance two in some branch-decomposition of width $\leq k$. We let $\mathcal{Q}_1 = \{X_i \cup Y_i : i = 1, 2, \ldots, c\}$, and add the new nodes from $\mathcal{Q}_1$ to our forest D connected to the appropriate X_i, Y_i's. Then we set $\mathcal{P}_1 := \mathcal{P}_1'$.

In each of the subsequent iterations, we again find an inclusion-wise maximal collection of pairwise disjoint pairs $\{X_i, Y_i\}$, $i = 1, 2, \ldots, c$, of parts of $\mathcal{P}_1$ such that the branch-width of $(M, \mathcal{P}_1')$ is at most k, but now we *restrict* $Y_i \in \mathcal{Q}_1$ (whereas $X_i \in \mathcal{P}_1$). Then we continue analogously to the first iteration, until D becomes a tree.

Output: Either a branch-decomposition D of $(M, \mathcal{P})$ of width at most k, or the answer NO if $\mathrm{bw}(M, \mathcal{P}) > k$.

There are two important points to notice in the above outline, which make the whole algorithm run in time $O(n^3)$. First, we only consider altogether $O(n^2)$ pairs $\{X_i, Y_i\}$ of parts for possible merging, throughout all iterations of the algorithm. A formal proof of this fact in included as part (III) of the proof of Theorem 6.7. Second, to be able to run a quick test whether the branch-width of $(M, \mathcal{P}_1')$ exceeds k or not, we need to maintain a certain "working" parse tree $\mathcal{T}_1$ of bounded width. Then, as noted already after Theorem 5.1, such a test can be done by looking for the excluded minors for branch-width at most k because each excluded minor has size at most $(6^k - 1)/5$, shown by Geelen et al. [8].

THEOREM 6.3 (see [14, Theorem 6.1] and [13, Corollary 5.4]). *Let $t > 1$ be a constant, and let $\mathbb{F}$ be a fixed finite field. There is a parametrized algorithm that, for every $k \leq t$ and for a given $\leq t$-boundaried parse tree $\mathcal{T}$ of an n-element matroid M, decides whether the branch-width of M is at most k in time $O(n)$.*

We have skipped, for simplicity, an explicit reference to the "working" parse tree $\mathcal{T}_1$ in the above outline; however, one can roughly say that $\mathcal{T}_1$ is maintained as a parse tree of the normalization of the current partitioned matroid $(M, \mathcal{P}_1)$. This will be precise in Algorithm 6.6. It is essential that we keep the width of $\mathcal{T}_1$ bounded throughout the computation, for which we use to call Algorithm 6.2 after each of the $O(n)$ major updates to $\mathcal{T}_1$.

Therefore, to quickly test whether merging a pair of parts $X_i, Y_i \in \mathcal{P}_1$ increases the branch-width of $(M, \mathcal{P}_1)$ above k or not, we temporarily modify the parse tree $\mathcal{T}_1$

each time by replacing $W = X_i \cup Y_i$ with the titanic gadget (amalgamated according to section 4). As this (Algorithm 6.4) does not increase the width of $\mathcal{T}_1$ much, we then solve the task in time $O(n)$ using Theorem 6.3.

To make a precise statement of this procedure, we introduce an additional technical definition inspired by section 4: Let M be a matroid and $X \subseteq E(M)$. Let $F = E(M) \setminus X$ and Y be disjoint from $E(M)$. Assume M' is a matroid on $E(M) \cup Y$ such that $M' \restriction F = M \restriction F$, $\mathrm{r}_{M'}(X \cup Y) = \mathrm{r}_M(X)$ (i.e., Y is spanned by X), and $\lambda_{M' \setminus X}(Y) = |Y| + 1 = \lambda_M(X) > 1$. If a matroid N is an amalgam of $M' \setminus X$ and the titanic gadget U_Y, then we say that N is obtained from M by a (titanic) *normalization* of the set X. If, on the other hand, $\lambda_M(X) = 1$, then a normalization of the set X in M results in $M \setminus X$. The point is that, by Lemmas 3.3 and 4.3, part 3., the branch-width of N equals the branch-width of $(M, \mathcal{P}_X)$, where $\mathcal{P}_X = \big\{\{X\}\big\} \cup \big\{\{y\} : y \in E(M) \setminus X\big\}$.

Algorithm 6.4. Computing a titanic normalization of a point set on the parse tree.

Parameters: A finite field $\mathbb{F}$, and an integer $k \geq 1$. (We may assume that $|\mathbb{F}| \geq 3k-6$ as in Remark 5.2.)

Input: A $\leq(3k-1)$-boundaried parse tree $\mathcal{T}_1$ representing a matroid M_1 with n elements, and a set $W \subseteq E(M_1)$ such that $\lambda_{M_1}(W) = \ell \leq k$.

Output: A $\leq(3k+\ell-2)$-boundaried parse tree $\mathcal{T}_2$ of an $\mathbb{F}$-represented matroid M_2 such that M_2 can be obtained from M_1 by the normalization of W.

Algorithm 6.4 is an immediate extension of [13, Algorithm 4.9] for computing $\lambda_{M_1}(W)$. We describe it in terms of a projective geometry and the point configuration representing a matroid M_1 via the parse tree $\mathcal{T}_1$. If $\ell = 1$, then we return $\mathcal{T}_1$ without W, immediately.

At the beginning we make $\mathcal{T}_2$ a copy of $\mathcal{T}_1$. The idea is to "enlarge" all of the composition operators in $\mathcal{T}_2$ to fully contain the guts Γ (a projective subspace of rank $\ell-1$ with a basis Y) of the separation $\big(W, E(M_1) \setminus W\big)$, and then to "glue" or amalgamate a decomposition of the titanic gadget $U_Y \simeq U_{\ell-1,3\ell-5}$ to the root of $\mathcal{T}_2$ so that it matches Y in Γ. For that we apply leaf-to-root dynamic programming on $\mathcal{T}_2$ with constant-time operations at each node.

At a node $x \in V(\mathcal{T}_2)$, we compute the subspace Σ_x of Γ spanned by the elements of W held in the leaves below x. Knowing $\Sigma_{x'}$ and $\Sigma_{x''}$ for the children x', x'' of x in $\mathcal{T}_2$, it is a constant-time manipulation to determine Σ_x using the composition operator $\odot$ at x. Notice that as our algorithm is set up, Σ_x is spanned by $\odot$. If the upper boundary of $\odot$ does not fully contain Σ_x, we enlarge it accordingly and also freely extend the matching boundary at the parent node of x. Note that $\Sigma_r = \Gamma$ will become the upper boundary of the root node r.

After finishing that computation, we take an arbitrary parse tree $\mathcal{T}_3$ of the titanic gadget (i.e., uniform matroid) $U_Y \simeq U_{\ell-1,3\ell-5}$, and add to $\mathcal{T}_2$ a new root node r' adjacent to the former root r of $\mathcal{T}_2$ and to the root of $\mathcal{T}_3$. The composition operator at r' "glues" U_Y directly to Σ_r. Finally, we strip from $\mathcal{T}_2$ all leaves holding the points of W. This is trivial since our definition of a parse tree allows nodes with only one descendant.

Since we use only constant-time operations at each node of $\mathcal{T}_2$, we conclude with the following lemma.

Lemma 6.5. *Algorithm* 6.4 *computes correctly in time* $O(n)$.

We are now ready to restate the above algorithmic outline in a formal setting. Our notation of variables in Algorithm 6.6 essentially follows the outline, but we need

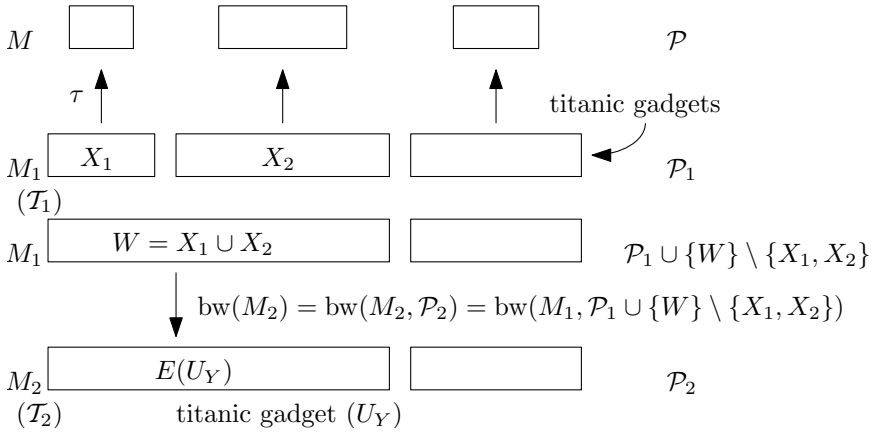

FIG. 4. *An illustration of Algorithm* 6.6.

a few more of them. For instance, $\mathcal{Q}_2$ at each round holds the set of all pairs of parts among which we are looking for the admissible ones. See also an informal hint in Figure 4.

ALGORITHM 6.6. Computing a branch-decomposition of a represented partitioned matroid.

Parameters: A finite field $\mathbb{F}$, and a positive integer k.

Input: A rank-r matrix $\boldsymbol{A} \in \mathbb{F}^{r \times n}$ and a partition $\mathcal{P}$ of the columns of $\boldsymbol{A}$. (Assume $n \geq 2$.)

Output: For the vector matroid $M = M(\boldsymbol{A})$ on the columns of $\boldsymbol{A}$, either a branch-decomposition of the partitioned matroid $(M, \mathcal{P})$ of width at most k, or the answer NO if $\mathrm{bw}(M, \mathcal{P}) > k$.

1. Using brute force, we extend the field $\mathbb{F}$ to a (nearest) finite field $\mathbb{F}'$ such that $|\mathbb{F}'| \geq 3k - 6$ (Remark 5.2 and Lemma 5.3).
2. We check whether $\mathrm{bw}(M, \mathcal{P}) \leq k$, using Algorithm 5.5. If $\mathrm{bw}(M, \mathcal{P}) > k$, then we answer NO. Otherwise we keep the *normalized matroid* $M^{\#}$ and its $\mathbb{F}'$-representation $\boldsymbol{A}^{\#}$ obtained at this step. We denote by $\mathcal{P}_1$ the (titanic) partition of $E(M^{\#})$ corresponding to $\mathcal{P}$, and by $\tau(X) \in \mathcal{P}$ for $X \in \mathcal{P}_1$ the corresponding parts.
3. Calling Algorithm 6.1, we compute a $\leq 3(k-1)$-boundaried parse tree $\mathcal{T}$ for the matroid $M^{\#}$ which is $\mathbb{F}'$-represented by $\boldsymbol{A}^{\#}$ (regardless of $\mathcal{P}_1$).
4. We initially set $\mathcal{T}_1 := \mathcal{T}$, $\mathcal{Q}_1 := \emptyset$, $\mathcal{Q}_2 := \big\{\{X_1, X_2\} : X_1 \neq X_2, X_1, X_2 \in \mathcal{P}_1\big\}$, and create a new rooted forest D consisting so far of the set of disconnected nodes $\mathcal{P}_1$.
   Let M_1 (M_2) denote the matroid represented by $\mathcal{T}_1$ ($\mathcal{T}_2$, respectively) at each step. Then we repeat the following steps (a), (b), until $\mathcal{P}_1$ contains at most two parts:
   (a) While there is $\{X_1, X_2\} \in \mathcal{Q}_2$ such that $X_1, X_2 \in \mathcal{P}_1$, we perform the following steps:
      i. Let $\mathcal{Q}_2 := \mathcal{Q}_2 \setminus \big\{\{X_1, X_2\}\big\}$. Calling [13, Algorithm 4.9] in linear time, we compute connectivity value $\ell = \lambda_{M_1}(X_1 \cup X_2)$ over the parse tree $\mathcal{T}_1$. If $\ell > k$, then we continue this cycle again from (a).
      ii. We call Algorithm 6.4 on $\mathcal{T}_1$ and $W = X_1 \cup X_2$ to compute a $\leq (3k + \ell - 2)$-boundaried parse tree $\mathcal{T}_2$ of a matroid M_2 which is obtained

by a titanic normalization of the part W.
By Lemmas 3.4 and 4.3 we have $\mathrm{bw}\big(M_1,\ \mathcal{P}_1 \cup \{W\} \setminus \{X_1, X_2\}\big) = \mathrm{bw}(M_2)$.

iii. We check whether branch-width $\mathrm{bw}(M_2) \leq k$ by applying Theorem 6.3. If $\mathrm{bw}(M_2) > k$, then we continue this cycle again from (a).

iv. If $\mathrm{bw}\big(M_1,\ \mathcal{P}_1 \cup \{W\} \setminus \{X_1, X_2\}\big) = \mathrm{bw}(M_2) \leq k$, then we add a *new node* $Z = E(U_Y)$ (U_Y given by the normalization of W in Algorithm 6.4) adjacent to X_1 and X_2 in the rooted forest D, and make Z the root for its component. We update $\mathcal{P}_1 := \mathcal{P}_2 = \mathcal{P}_1 \cup \{Z\} \setminus \{X_1, X_2\}$, and $\mathcal{Q}_1 := \mathcal{Q}_1 \cup \{Z\}$.

v. Last, by calling Algorithm 6.2 on $\mathcal{T}_2$, we compute in a *new* $\leq 3(k-1)$-*boundaried parse tree* $\mathcal{T}_3$ for the matroid M_2, and set $\mathcal{T}_1 := \mathcal{T}_3$.

(b) When the "while" cycle (4.a) is finished, we set $\mathcal{Q}_2 := \big\{\{X_1, X_2\} : X_1 \neq X_2,\ X_1 \in \mathcal{P}_1,\ X_2 \in \mathcal{Q}_1\big\}$ and $\mathcal{Q}_1 := \emptyset$, and continue from (4.a).

5. Finally, if $|\mathcal{P}_1| = 2$, then we connect by an edge in D the two nodes $X_1, X_2 \in \mathcal{P}_1$. We output (D, τ) as the branch-decomposition of $(M, \mathcal{P})$.

THEOREM 6.7. *Let k be a fixed integer and $\mathbb{F}$ be a fixed finite field. We assume that a vector matroid $M = M(\boldsymbol{A})$ is given as an input together with a partition $\mathcal{P}$ of $E(M)$, where $n = |E(M)|$ and $|\mathcal{P}| \geq 2$. Algorithm* 6.6 *outputs in time $O(n^3)$ (parametrized by k and $\mathbb{F}$) a branch-decomposition of the partitioned matroid $(M, \mathcal{P})$ of width at most k, or confirms that $\mathrm{bw}(M, \mathcal{P}) > k$.*

Proof. We refer to the above outline. Our proof of the theorem constitutes the following three claims holding true if $\mathrm{bw}(M, \mathcal{P}) \leq k$.

(I) The computation of Algorithm 6.6 maintains invariants, with respect to the actual matroid M_2 of $\mathcal{T}_2$, the rooted forest D, and the current value $\mathcal{P}_2$ of the partition variable $\mathcal{P}_1$ after each call to step (4.a.iv), such that
- $\mathcal{P}_2$ is the set of roots of D, and a titanic partition of M_2 such that $\mathrm{bw}(M_2, \mathcal{P}_2) = \mathrm{bw}(M_2) \leq k$,
- $\lambda_M\big(\tau^D(\mathcal{S})\big) = \lambda_{M_2}^{\mathcal{P}_2}(\mathcal{S})$ for each $\mathcal{S} \subseteq \mathcal{P}_2$, where $\tau^D(\mathcal{S})$ is a shortcut for the union of $\tau(X)$ with X running over all leaves of the connected components of D whose root is in $\mathcal{S}$ (see Algorithm 6.6, step 2. for τ).

(II) Each iteration of the main cycle in Algorithm 6.6 (4.) succeeds to step (4.a.iv) at least once.

(III) The main cycle in Algorithm 6.6 step 4. is repeated $O(n)$ times. Moreover, the total number of calls to the steps in (4.a) is $O(n^2)$ for steps i, ii, iii, and $O(n)$ for steps iv, v.

Having all of these facts at hand, it is now easy to finish the proof. It is immediate from (I) that the resulting (D, τ) is a branch-decomposition of width at most k of $(M, \mathcal{P})$. Note that all parse trees involved in the algorithm have constant width less than $4k$ (see in steps (4.a.ii,v)). The starting steps (1.), (2.), (3.) of the algorithm are already known to run in time $O(n^3)$ (Theorem 5.6 and Algorithm 6.1), and the particular steps in (4.a) need time (III) $O(n^2) \cdot O(n) + O(n) \cdot O(n^2) = O(n^3)$ by Lemma 6.5 and Algorithm 6.2. The size of the matroid M_1 clearly stays linear in n after $O(n)$ constant-size updates. Hence, our Algorithm 6.6 runs correctly in parametrized time $O(n^3)$, provided that (I)–(III) hold true.

The proof of (I) essentially extends the arguments of Theorem 5.7. Initially, with M_1 and $\mathcal{P}_1$ in place of M_2, $\mathcal{P}_2$, all the claims of (I) obviously hold true, analogously to Theorem 5.6. Each call to step (4.a.iv) then adds a new titanic set $E(U_Y)$ to $\mathcal{P}_2$ (see Lemma 4.3 (3)), and hence the partition $\mathcal{P}_2$ remains titanic for M_2 and, subsequently,

$\mathrm{bw}(M_2, \mathcal{P}_2) = \mathrm{bw}\big(M_1, \mathcal{P}_1 \cup \{W\} \setminus \{X_1, X_2\}\big) = \mathrm{bw}(M_2) \le k$ follows from Lemma 3.4. The most complex claim of (I) is the last assertion, that $\lambda_M(\tau^D(\mathcal{S})) = \lambda_{M_2}^{\mathcal{P}_2}(\mathcal{S})$ for each $\mathcal{S} \subseteq \mathcal{P}_2$. By induction, we may assume that $\lambda_M(\tau^D(\mathcal{S}_1)) = \lambda_{M_1}^{\mathcal{P}_1}(\mathcal{S}_1)$ holds for all $\mathcal{S}_1 \subseteq \mathcal{P}_1$ just before this call to (4.a.iv). Now, by Algorithm 6.4, the titanic gadget $E(U_Y)$ in the representation spans exactly the same subspace because it is the guts of the separation $(X_1 \cup X_2,\ E(M_1) \setminus (X_1 \cup X_2))$ in M_1. Therefore, for all $\mathcal{S}_1 \subseteq \mathcal{P}_1$ such that $|\mathcal{S}_1 \cap \{X_1, X_2\}| \neq 1$, the corresponding $\mathcal{S} \subseteq \mathcal{P}_2$ satisfies $\lambda_{M_2}^{\mathcal{P}_2}(\mathcal{S}) = \lambda_{M_1}^{\mathcal{P}_1}(\mathcal{S}_1)$. This proves the assertion.

To prove (II), we use that $\mathrm{bw}(M_1, \mathcal{P}_1) \le k$ at each iteration of the main cycle (4.), which directly follows from above $\mathrm{bw}(M_2, \mathcal{P}_2) \le k$. Then, by the same arguments as in Theorem 5.7, there is a pair $\{X_1, X_2\} \subset \mathcal{P}_1$ for which (4.a) would succeed up to step (4.a.iv), which happens if $\mathrm{bw}\big(M_1, \mathcal{P}_1 \cup \{X_1 \cup X_2\} \setminus \{X_1, X_2\}\big) \le k$. We call such a pair X_1, X_2 *admissible*. It remains to argue that all admissible pairs $\{X_1, X_2\} \subset \mathcal{P}_1$ belong also to $\mathcal{Q}_2$, which is trivial only during the first round of (4.). For a contradiction, assume that $\{X_1, X_2\} \notin \mathcal{Q}_2$ at the least round $i > 1$. Consider now the values of our variables $\mathcal{P}_1, \mathcal{Q}_1, \mathcal{Q}_2$ at the previous round $i - 1$: It was $\{X_1, X_2\} \cap \mathcal{Q}_1 = \emptyset$ by the assignment to $\mathcal{Q}_2$ in (4.b), and so $\{X_1, X_2\} \subset \mathcal{P}_1$ is already there. That means the pair X_1, X_2 has been admissible since round $i - 1$ started, but it has not been processed only due to $\{X_1, X_2\} \notin \mathcal{Q}_2$ at round $i-1$, which contradicts our least choice of i.

Concerning (III), each iteration of (4.) adds at least one new node to the decomposition D by (II), and hence no more than $O(n)$ iterations occur. The same argument also bounds the total number of calls to the crucial steps (4.a.iv–v). The situation with steps i, ii, iii is more versatile, and we bound the total number of calls to them from above by the total number of iterations of the cycle in (4.a): During the initial round of the main cycle (4.), there are clearly at most $|\mathcal{Q}_2| = O(n^2)$ iterations of (4.a). For each subsequent round $i > 1$, the number of iterations is at most $|\mathcal{Q}_2| \le q_i \cdot |\mathcal{P}_1|$, where $q_i = |\mathcal{Q}_1|$ at the end of the previous run $i - 1$. Hence, the total number of iterations of the cycle in (4.a) is at most $O(n^2) + O(n) \cdot \sum_{i=2}^{r} q_i$ since $|\mathcal{P}_1| = O(n)$ always. It remains to argue that $\sum_{i=2}^{r} q_i = O(n)$, which follows from the fact that each element ever assigned to $\mathcal{Q}_1$ in step (4.a.iv) appears as an internal node of the decomposition D, and $|V(D)| = O(n)$.

This also finishes the whole proof of Theorem 6.7. □

7. Finding a rank-decomposition of a graph. In this last section, we present a fixed-parameter tractable algorithm to find a rank-decomposition of width at most k or confirm that the input graph has rank-width larger than k. It is a direct translation of the algorithm of Theorem 6.7. Let us first review necessary definitions from [19] and [17]. We assume that all graphs in this section have no loops and no parallel edges.

We have seen in section 2 that every symmetric submodular function can be used to define branch-width. We define a symmetric submodular function on a graph, called the *cut-rank* function of a graph. For an $X \times Y$ matrix $\boldsymbol{R}$ and $A \subseteq X$, $B \subseteq Y$, let $\boldsymbol{R}[A, B]$ be the $A \times B$ submatrix of $\boldsymbol{R}$. For a graph $G = (V, E)$, let $\boldsymbol{A}(G)$ be the adjacency matrix of G, that is a $V \times V$ matrix over the binary field GF(2) such that an entry is 1 if and only if vertices corresponding to the column and the row are adjacent in G. The cut-rank function $\rho_G(X)$ of a graph $G = (V, E)$ is defined as the rank of the matrix $\boldsymbol{A}(G)[X, V \setminus X]$ for each subset X of V. Then ρ_G is symmetric and submodular; see [19]. *Rank-decomposition* and *rank-width* of a graph G is branch-decomposition

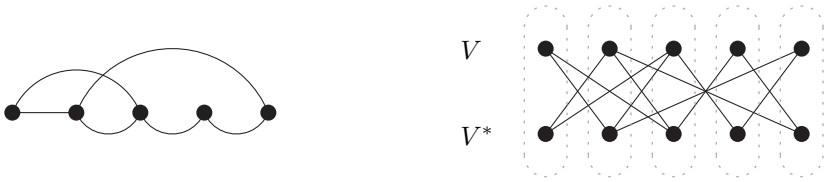

FIG. 5. *Graph G and the associated bipartite graph* $\mathrm{bip}(G)$ *with its canonical partition.*

and branch-width of the cut-rank function ρ_G of the graph G, respectively. So, if the graph has at least two vertices, then the rank-width is at most k if and only if there is a rank-decomposition of width at most k.

Now let us recall why bipartite graphs are essentially binary matroids. Oum [17] showed that the connectivity function of a binary matroid is exactly one more than the cut-rank function of its *fundamental graph*. The fundamental graph of a binary matroid M on $E = E(M)$, with respect to a basis B, is a bipartite graph on E such that two vertices in E are adjacent if and only if one vertex v is in B, another vertex w is not in B, and $(B \setminus \{v\}) \cup \{w\}$ is independent in M. Given a bipartite graph G, we can easily construct a binary matroid having G as a fundamental graph; if (C, D) is a bipartition of $V(G)$, then take the matrix

$$\begin{array}{c} \\ C \end{array} \begin{array}{c} \begin{array}{ccc} C & & D \end{array} \\ \left(\begin{array}{ccc|c} 1 & & 0 & \\ & \ddots & & \boldsymbol{A}(G)[C,D] \\ 0 & & 1 & \begin{array}{c} C \times D \text{ submatrix of} \\ \text{the adjacency matrix} \end{array} \end{array}\right) \end{array}$$

as the representation of a binary matroid. Thus, the column indices are elements of the binary matroid, and a set of columns is independent in the matroid if and only if its vectors are linearly independent. After all, finding the rank-decomposition of a bipartite graph is equivalent to finding the branch-decomposition of the associated binary matroid, that is essentially Theorem 6.7.

To find a rank-decomposition of nonbipartite graphs, we transform the graph into a canonical bipartite graph. For a finite set V, let V^* be a disjoint copy of V, that is, formally speaking, $V^* = \{v^* : v \in V\}$ such that $v^* \neq w$ for all $w \in V$ and $v^* \neq w^*$ for all $w \in V \setminus \{v\}$. For a subset X of V, let $X^* = \{v^* : v \in X\}$. For a graph $G = (V, E)$, let $\mathrm{bip}(G)$ be the bipartite graph on $V \cup V^*$ such that vw^* are adjacent in $\mathrm{bip}(G)$ if and only if v and w are adjacent in G (see Figure 5). Let $P_v = \{v, v^*\}$ for each $v \in V$. Then $\Pi(G) = \{P_v : v \in V\}$ is a canonical partition of $V(\mathrm{bip}(G))$.

LEMMA 7.1. *For every subset X of $V(G)$, $2\rho_G(X) = \rho_{\mathrm{bip}(G)}(X \cup X^*)$.*

Proof. This is clear from the construction of $\mathrm{bip}(G)$. Let $Y = V(G) \setminus X$. Let $N = \boldsymbol{A}(G)[X, Y]$. Since

$$\rho_{\mathrm{bip}(G)}(X \cup X^*) = \operatorname{rank} \begin{array}{c} \\ X \\ X^* \end{array} \begin{array}{c} \begin{array}{cc} Y & Y^* \end{array} \\ \begin{pmatrix} 0 & N \\ N^t & 0 \end{pmatrix} \end{array},$$

we conclude that $\rho_{\mathrm{bip}(G)}(X \cup X^*) = 2 \operatorname{rank} N = 2\rho_G(X)$. ∎

COROLLARY 7.2. *Let $p : V(G) \to \Pi(G)$ be the bijective function such that $p(x) = P_x$. If (T, μ) is a branch-decomposition of $\rho_{\mathrm{bip}(G)}^{\Pi(G)}$ of width k, then $(T, \mu \circ p)$*

is a branch-decomposition of ρ_G of width $k/2$. Conversely, if (T, μ') is a branch-decomposition of ρ_G of width k, then $(T, \mu' \circ p^{-1})$ is a branch-decomposition of $\rho^{\Pi(G)}_{\mathrm{bip}(G)}$ of width $2k$. Therefore, the branch-width of ρ_G is equal to half of the branch-width of $\rho^{\Pi(G)}_{\mathrm{bip}(G)}$.

Let $M = \mathrm{mat}(G)$ be the binary matroid on $V \cup V^*$ represented by the matrix

$$\begin{array}{c} \\ V \end{array} \begin{array}{c} \begin{array}{cc} V & V^* \end{array} \\ \left(\begin{array}{c|c} \text{Identity matrix} & \boldsymbol{A}(G) \end{array}\right) \end{array}.$$

Since the bipartite graph $\mathrm{bip}(G)$ is a fundamental graph of M, we have $\lambda_M(X) = \rho_{\mathrm{bip}(G)}(X) + 1$ for all $X \subseteq V \cup V^*$ (see Oum [17]) and therefore (T, μ) is a branch-decomposition of a partitioned matroid $(M, \Pi(G))$ of width $k+1$ if and only if it is a branch-decomposition of $\rho^{\Pi(G)}_{\mathrm{bip}(G)}$ of width k. Corollary 7.2 implies that a branch-decomposition of $\rho^{\Pi(G)}_{\mathrm{bip}(G)}$ of width k is equivalent to that of ρ_G of width $k/2$. So, we can deduce the following theorem from Theorem 6.7.

THEOREM 7.3. *Let k be a constant. Let $n \geq 2$. For an n-vertex graph G, we can output the rank-decomposition of width at most k or confirm that the rank-width of G is larger than k in time $O(n^3)$.*

Proof. We apply Theorem 6.7 to find a branch-decomposition of a partitioned matroid $(\mathrm{mat}(G), \Pi(G))$ of width at most $2k+1$. If such a branch-decomposition is found, then one can canonically transform it into a rank-decomposition of G of width at most k by Corollary 7.2. If there is no such branch-decomposition, then the rank-width of G is larger than k. □

Acknowledgments. The authors are very grateful to Jim Geelen for his comments on the possible approach to the problem. We would also like to thank the anonymous referees for helpful comments.

QUERY-EFFICIENT ALGORITHMS FOR POLYNOMIAL INTERPOLATION OVER COMPOSITES*

PARIKSHIT GOPALAN†

Abstract. The problem of polynomial interpolation is to reconstruct a polynomial based on its valuations on a set of inputs I. We consider the problem over $\mathbb{Z}_m$ when m is composite. We ask the following question: Given $I \subseteq \mathbb{Z}_m$, how many evaluations of a polynomial at points in I are required to compute its value at every point in I? Surprisingly for composite m, this number can vary exponentially between $\log |I|$ and $|I|$, in contrast to the prime case where $|I|$ evaluations are necessary. While we show this minimization problem to be NP-hard, we give an efficient algorithm of query complexity within a factor t of the optimum, where t is the number of prime factors of m. We use our interpolation algorithm to design algorithms for zero testing and distributional learning of polynomials over $\mathbb{Z}_m$. In some cases, we get an exponential improvement over known algorithms in query complexity and running time. Our main technical contribution is the notion of an interpolating set for I which is a subset S of I such that a polynomial which is 0 over S must be 0 at every point in I. Any interpolation algorithm needs to query an interpolating set for I. Our query-efficient algorithms are obtained by constructing interpolating sets whose size is close to optimal.

1. Introduction.

The problem of polynomial interpolation is to reconstruct a polynomial from its evaluations. This is a fundamental algorithmic question in algebra with numerous applications. The problem is especially well studied when the polynomial is over a field such as $\mathbb{R}$ or $\mathbb{Z}_p$ dating back to Newton and Lagrange. Relatively less is known about interpolation over rings which contain zero divisors, in particular over $\mathbb{Z}_m$ with m composite. The zero-testing problem is a special case of the interpolation problem where we want to know if the polynomial is 0 everywhere. In this paper we study the problem of learning a univariate polynomial in $\mathbb{Z}_m[X]$ based on its evaluations at a set $I \subseteq \mathbb{Z}_m$. We ask the following question: *Given $I \subseteq \mathbb{Z}_m$, how many evaluations of a polynomial at points in I are required to compute its value at every point in I?* Throughout, we will consider a polynomial as a function rather than a formal sum, and our aim will be to correctly predict its values at every point in I.

Polynomials and specifically the problem of interpolation over $\mathbb{Z}_m$ are well studied in mathematics [18, 31]. Dueball (see [31]) shows that when $I = \mathbb{Z}_m$, there is a subset S whose size can lie between $\log m$ and m such that the evaluations at S are sufficient for interpolation. However, this result leaves open the question of whether a similar statement holds for subsets of $\mathbb{Z}_m$. Polynomials over $\mathbb{Z}_m$ have many applications in computer science. They are used in algorithms for primality testing [1, 2], in the construction of explicit Ramsey graphs and extremal set systems [21, 24], and in circuit lower bounds [7, 36]. As we will elaborate shortly, many of these applications

implicitly address questions related to polynomial interpolation. We hope that a better understanding of the interpolation problem will throw new light on these problems.

The polynomial interpolation problem over $\mathbb{Z}_m$ is very different from $\mathbb{Z}_p$, since it is no longer true that a degree d polynomial has at most d zeroes. For instance $X^k \equiv 0 \bmod 2^k$ has 2^{k-1} roots. This implies that even two polynomials of small degree can agree on a large fraction of points in $\mathbb{Z}_m$. Hence, unlike over $\mathbb{Z}_p$ one cannot interpolate even low degree polynomials from their evaluations at a few arbitrarily chosen points. On the other hand, not every function $f : \mathbb{Z}_m \to \mathbb{Z}_m$ is a polynomial, since functions defined by polynomials need to satisfy certain congruences. For instance let $m = pq$ and $x, y \in \mathbb{Z}_m$ such that $x \equiv y \bmod p$. Then $P(x) \equiv P(y) \bmod p$ for any polynomial $P(X) \in \mathbb{Z}_m[X]$. Thus the values of a polynomial at a point give some information about its values at other points. This raises the possibility of learning a polynomial by looking at its evaluations at only a few carefully chosen points.

We give an query-efficient algorithm to solve the following problem.

Problem 1. Generalized Polynomial Interpolation: *Given m, a set $I \subseteq \mathbb{Z}_m$, and black-box access to the values of a polynomial $P(X) \in \mathbb{Z}_m[X]$ at points in I, compute $P(X)$ and minimize the number of black-box queries.*

The query complexity of our algorithm is within a factor t of the optimum, where t is the number of prime divisors of m. One has to settle for approximation, since we prove that the problem of minimizing the number of queries is NP-hard. Our main technical contribution is the notion of *interpolating sets for I* which are subsets of I such that a polynomial which is 0 over that subset must in fact be 0 at every point in I. We show that any interpolation algorithm needs to query an interpolating set for I. Our query-efficient algorithms are obtained by constructing interpolating sets whose size is close to optimal. We use our interpolation algorithm to design algorithms for zero testing and distributional learning of polynomials over $\mathbb{Z}_m$. In some cases, we get an exponential improvement over known algorithms in query complexity and running time. We show some new results about the structure of polynomials over $\mathbb{Z}_m$, which may be useful in other applications.

1.1. History and motivation. Given a commutative ring R, a function $f : R \to R$ which can be computed by a polynomial in $R[X]$ is called a polynomial function. Polynomial functions over various commutative rings are well studied in algebra [15, 31, 18]. The problem of characterizing polynomial functions over $\mathbb{Z}_m$ was first studied by Carlitz and Spira (see [35] and the book by Narkiewicz and the references therein [31]). Kempner gave a canonical polynomial for every polynomial function over $\mathbb{Z}_m$ [30]. Dueball studied the problem of interpolation over $\mathbb{Z}_m$ [31]. He proved that one can solve the interpolation problem over $\mathbb{Z}_m$ with as few as $O(\log m)$ queries for some composites m. More precisely, he showed the following result:

Let $k(m)$ be the smallest integer such that $k(m)! \equiv 0 \bmod m$. Every polynomial function over $\mathbb{Z}_m$ can be learned from its values at $\{0, \ldots, k(m) - 1\}$.

In the zero-testing problem, we are given an implicit representation of a polynomial P, either as a circuit or a black box which returns the value $P(x)$ on query x. We wish to determine if P is the 0 polynomial. The problem of zero testing for polynomials over $\mathbb{Z}_m$ was studied by Agrawal and Biswas [1], motivated by primality testing. They give a randomized algorithm for this problem. However, they view polynomials as formal sums rather than as functions, and this is important for their application. Karpinski, van der Poorten, and Shparlinski [28] give a black-box algorithm for zero testing over $\mathbb{Z}_m$. However, they require that all nonzero coefficients of the polynomial are relatively prime to m. Bshouty, Tamon, and Wilson give a randomized algorithm

for interpolation over $\mathbb{Z}_m$ [14]. However, if the smallest prime dividing m is p, they require the degree to be at most $\frac{p}{2}$. The results of [14, 28] hold for multivariate polynomials, but in the univariate case Dueball's result is stronger.

Interpolation and zero testing for polynomials over $\mathbb{Z}_p$ have been studied extensively in computer science, motivated by applications in coding theory, proof checking, and several other areas (see, for instance, [20]). Most of these applications crucially use the fact that a degree d polynomial over $\mathbb{Z}_p$ has at most d roots, which does not hold for polynomials over $\mathbb{Z}_m$. Nevertheless, polynomials over $\mathbb{Z}_m$ have found surprising applications in algorithms, combinatorics, and complexity, which rely on the fact that they behave differently from polynomials over $\mathbb{Z}_p$.

- *Primality and factoring:* The primality testing algorithms of Agrawal and Biswas and the AKS algorithm reduce testing primality to testing a polynomial identity over $\mathbb{Z}_m[X]$ [1, 2]. They then devise algorithms to solve the problem of zero testing over $\mathbb{Z}_m[X]$. Shamir [33] shows that the problem of factoring polynomials over $\mathbb{Z}_m[X]$ is as hard as integer factoring.
- *Boolean function complexity:* A frontier open problem in complexity theory is to show lower bounds for circuits with Mod-m gates. Strong lower bounds are known when the circuit contains only Mod-p gates for a single prime p [32, 34]. In contrast much less is known if Mod-m gates are allowed with m composite, or Mod-p and Mod-q gates for distinct primes [26, 16]. Motivated by this problem, Barrington, Beigel, and Rudich [7] studied representations of Boolean functions by polynomials over $\mathbb{Z}_m$. They proved that functions like OR can have low degree representations when m is composite, unlike in the prime case. The problem of showing tight bounds for such representations over $\mathbb{Z}_m$ is wide open [4, 13, 36].
- *Extremal set theory:* A set system on $[n]$ is said to have restricted intersections modulo m if there exists $L \subseteq \mathbb{Z}_m$ such that the pairwise intersections mod m lie in L but the set sizes lie outside it [5]. Polynomials over $\mathbb{Z}_m$ have been used to explicitly construct large set systems and also to prove upper bounds on their size. A surprising insight from this area is that when m is a prime or a prime power, the size of such set systems is polynomial in the number of elements in the universe [5, 6, 21]. In contrast, when m has two or more prime divisors, the size can be superpolynomial [24]. These results about set systems have important combinatorial applications [5].
- *Explicit Ramsey constructions:* A Ramsey graph is a graph with no large cliques and independent sets. The problem of explicitly constructing good Ramsey graphs is an important open problem in combinatorics. Recently, the author [21] showed that the algebraic Ramsey graph constructions of Alon [3], Frankl and Wilson [17], and Grolmusz [24, 25] can be derived in a unified manner from low degree polynomials over $\mathbb{Z}_m$. Further, facts about interpolating sets over $\mathbb{Z}_{p^a}$ from this work are used in [21] in order to show that certain approaches (based on symmetric polynomials) cannot yield better Ramsey graphs.

The last three applications deal with whether certain functions can be computed by low degree polynomials over $\mathbb{Z}_m$, and hence they all implicitly address questions related to polynomial interpolation.

1.2. Our results.

The generalized interpolation problem. Our main result is an efficient algorithm to solve the generalized interpolation problem. We prove that minimizing

the number of queries is NP-hard, and hence one can hope only to approximately minimize the query complexity. Our algorithm has query complexity close to optimal.

THEOREM 1. *Let t be the number of distinct prime factors of m. There is an algorithm to solve the general interpolation problem over $\mathbb{Z}_m$, with query complexity within a factor t of the optimum.*

In fact the guarantee is slightly stronger. When the algorithm terminates, it produces a factorization of m into $t' \leq t$ relatively prime factors. The approximation factor is in fact bounded by t'. Thus input sets I which force the algorithm to make several queries must also reveal the factorization of m. The algorithm first computes a set S of queries to ask based on the input set I. Thus the set of queries is chosen nonadaptively. The size of S is within a factor t' of the optimal query complexity. This step takes time proportional to $|S| \cdot |I|$. Once the set S is found, the polynomial can be computed with $|S|$ queries in time $\text{poly}(\log m, |S|)$.

While Dueball's result gives an efficient algorithm for the case when $I = \mathbb{Z}_m$, it does not imply anything for the general interpolation problem. The naive approach for this problem would be to write a linear equation for each point in I. We can replace each equation $\sum_j a_{ij}X_{ij} = b_i \bmod m$ with $\sum_j a_{ij}X_{ij} = b_i + y_i m$, where the y_i's are integer variables, and find integer solutions to the resulting system of equations. This has query complexity $|I|$, which can be exponentially larger than the complexity of our algorithm.

The generalized zero-testing problem is a special case of the interpolation problem, where we wish to know if some identity holds for every point in I. Theorem 1 implies a query-efficient algorithm for this problem. It improves on the algorithms of [14, 28], since there are no restrictions on the degree or coefficients of the polynomial. Our results are incomparable with those of Agrawal and Biswas [1], who view polynomials as formal sums.

Learning under a distribution. We give the first efficient algorithms for learning polynomials over $\mathbb{Z}_m$ under a distribution. Here we are given evaluations of the polynomial at points which are drawn from some distribution, and we are asked to learn the polynomial. See section 5 for precise problem definitions.

THEOREM 2. *Polynomials in $\mathbb{Z}_m[X]$ are exactly learnable under the uniform distribution and PAC learnable under an arbitrary distribution in polynomial time.*

The algorithm for the uniform distribution learns the polynomial exactly, but its running time is a random variable. These algorithms use the algorithm for the general interpolation problem as a subroutine. For distributional learning it is essential that our algorithm solves the general interpolation problem, where inputs come from some subset $I \subseteq \mathbb{Z}_m$ rather than all of $\mathbb{Z}_m$.

Interpolating sets. The crux of our algorithm is the notion of an *interpolating set* which we introduce and study here. A set $S \subseteq I$ is an interpolating set for I if knowing the values of any polynomial at S fixes its value at every point in I. We show that the set of queries of an interpolation algorithm must correspond to an interpolating set for I, and thus the problem of designing query-efficient algorithms reduces to finding small interpolating sets.

Let $k(I)$ denote the size of the smallest interpolating set for I. In general $k(I)$ can lie between $\log |I|$ and $|I|$. However, we prove that the problem of computing a minimum interpolating set for I is NP-hard. We define a related quantity $\bar{k}(I)$, which is the smallest integer such that there is a degree $\bar{k}(I)$ monic polynomial $M(X) \in \mathbb{Z}_m[X]$ which is 0 over I. This quantity can be computed in polynomial time by solving a

system of linear equations. We show that for $I \subseteq \mathbb{Z}_m$, where m has t prime divisors, the following relation holds:

$$\bar{k}(I) \;\leq\; k(I) \;\leq\; t \cdot \bar{k}(I).$$

Thus $\bar{k}(I)$ is a factor t approximation to $k(I)$, where t is the number of prime divisors of m. This is where the approximation factor of t in the query complexity of our algorithm comes from.

We sketch the idea behind the algorithm for computing an interpolating set. For the prime-power case, we use a greedy algorithm. There is a natural metric on the points $I \subseteq \mathbb{Z}_{p^a}$, namely p-adic distance. Our algorithm finds a set of points so that the sum of pairwise distances is maximized; this is done by picking a new point in a natural greedy manner. We show that this in fact gives an interpolating set. For the composite case, we essentially try and repeat this greedy approach. However, this approach might fail: first, we do not know the factorization of m, and, second, distinct prime divisors p and q give different metrics on the set I. However, we show that when it fails, one can get a factorization $m = m_1 \cdot m_2$, where $(m_1, m_2) = 1$. This allows us to use divide and conquer: we find interpolating sets modulo m_1 and m_2 independently and combine the result using the Chinese remainder theorem.

Interpolating sets over $\mathbb{Z}_{p^a}$ have rich algebraic and combinatorial structure which we study in detail; these properties are also useful in analyzing our algorithm. In proving these properties, we make crucial use of the fact that the underlying space is in fact an ultrametric space (metrics where the following strengthening of the triangle inequality holds: $d(x, y) \leq \max(d(x, z), d(y, z))$. Ultrametric spaces are well studied in computer science [8, 9, 10]. We show that many algebraic properties of polynomials can be reinterpreted as geometric properties of ultrametric spaces. Further, the proof of these properties for general ultrametric spaces follows directly from the proof for polynomials over $\mathbb{Z}_{p^a}$. We note that our notion of interpolating sets over $\mathbb{Z}_{p^a}$ is closely related to very well distributed and well-ordered sequences that have been studied in mathematics [15].

1.3. Organization of this paper. In the next section, we give some basic definitions and results about interpolation over $\mathbb{Z}_m$. We study interpolating sets in section 3. We present our algorithms for interpolation in section 4 and learning algorithms in section 5. We present other algebraic and combinatorial characterizations of interpolating sets in section 6. In section 7, we use these characterizations to establish some geometric properties of ultrametric spaces. An extended abstract of this paper appeared in SODA'06 [22].

2. Preliminaries. We will use X to denote a variable and x for a constant. Let (a, b) denote the greatest common divisor of a and b.

Given $x \in \mathbb{Z}_{p^a}$, $x \neq 0$, let its p-adic valuation $\mathrm{val}_p(x)$ be the highest power of p which divides x. Set $\mathrm{val}_p(0) = \infty$. We have the so-called ultrametric inequality, which states that

$$\mathrm{val}_p(x + y) \geq \min(\mathrm{val}_p(x), \mathrm{val}_p(y)).$$

The p-adic norm of x is defined as

$$|x|_p = p^{-\,\mathrm{val}_p(x)}.$$

The p-adic norm satisfies the following condition:

$$|x + y|_p \leq \max(|x|_p, |y|_p).$$

This induces a metric (the p-adic metric) on $\mathbb{Z}_{p^a}$ given by $d(x,y) = |x-y|_p$. This metric satisfies the following strong form of the triangle inequality:

$$d(x,z) \leq \max(d(x,y), d(y,z)). \tag{1}$$

Metrics which satisfy (1) are known as ultrametrics.

We will also define valuations over $\mathbb{Z}_m$, where m is not a prime power. Assume that p divides m, and let p^e be the highest power of p dividing m. For $x \in \mathbb{Z}_m$, we define

$$\mathrm{val}_p(x) \;=\; \mathrm{val}_p(x \bmod p^e).$$

All our results can be stated either in terms of p-adic valuations or norms. For our algorithmic results, it is more natural to work with valuations. For our combinatorial results, we will use p-adic norms, since it is easier to translate these results into general ultrametric spaces.

We start with some basic algebraic facts that will be useful to us.

PROPOSITION 3 (see [27]). *Let $a, b \in \mathbb{Z}_m$ and $a \not\equiv 0$. The equation*

$$aX \;\equiv\; b \bmod m$$

has a solution in $\mathbb{Z}_m$ iff $(a,m)|b$. If this condition holds, there is a unique solution in the interval $\left[0, \ldots, \frac{m}{(a,m)} - 1\right]$.

PROPOSITION 4. *Let $M(X)$ be a monic polynomial in $\mathbb{Z}_m[x]$ of degree k. Given $P(X) \in \mathbb{Z}_m[X]$, we can divide it by $M(X)$ and get a remainder of degree at most $k-1$.*

Proof. This is just Euclidean division. Let $P(X) = \sum_{i \leq d} c_i X^i$, where $d \geq k$. Since $M(X)$ is monic, $P(X) - c_d X^{d-k} M(X)$ has degree $d-1$. Now repeat the same procedure until we are left with a polynomial of degree $\leq k-1$. ∎

PROPOSITION 5. *Let $N_0(X), \ldots, N_k(X)$ be polynomials in $\mathbb{Z}_m[X]$, where $N_i(X)$ is a monic polynomial of degree i. Every polynomial $P(X)$ of degree at most k can be written as*

$$P(X) = \sum_{i=0}^{k} c_i N_i(X).$$

Further, if $P(X)$ is a monic polynomial of degree k, then $c_k = 1$.

Proof. The proof is by induction on k. When $k = 0$, $N_0(X) = 1$, so there is nothing to prove. Assume the claim holds for $k-1$. Let $P(X) = \sum_{i \leq k} a_i X^i$. Since $N_k(X)$ is monic, $P(X) - a_k N_k(X)$ has degree $k-1$, so we can apply induction to it. Note that the leading coefficient in the monomial basis and the $\{N_i(X)\}$ basis is the same. This shows the second part of the claim. ∎

We can use this to give a canonical form for polynomial functions over $\mathbb{Z}_m$ due to Kempner [30]. Let $N_0(X) = 1$, and, for $j \geq 1$, let

$$N_j(X) = \prod_{i=0}^{j-1} (X - i).$$

Let the elements $\{0, \ldots, m-1\}$ of $\mathbb{Z}_m$ be endowed with the ordering $0 < 1 < \cdots < m-1$. Let $k(m)$ be the smallest integer such that $k(m)! \equiv 0 \bmod m$.

LEMMA 6 (see [30]). *Every polynomial function over $\mathbb{Z}_m$ is computed by a unique polynomial of the form*

$$P(X) = \sum_{j=0}^{k(m)-1} c_j N_j(X), \qquad 0 \le c_j < \frac{m}{(m, j!)}. \tag{2}$$

Proof. For any $x \in \mathbb{Z}$,

$$N_j(x) \;=\; \prod_{i=0}^{j-1}(x-i) \;=\; \binom{x}{j} j!.$$

Hence $N_j(x)$ is divisible by $j!$. So the polynomial $\frac{m}{(m,j!)}N_j(X)$ is zero over $\mathbb{Z}_m$. In particular, $N_{k(m)}(X)$ is a degree $k(m)$ monic polynomial which is 0 over $\mathbb{Z}_m$.

Given an arbitrary polynomial $Q(X)$, we first divide by $N_{k(m)}(X)$ to get a polynomial $Q'(X)$ of degree $k(m)-1$. Since the polynomial $N_j(X)$ is monic and of degree j for $j \in \{0, \ldots, k(m)-1\}$, we can write $Q(X)$ as

$$Q'(X) = \sum_{j=0}^{k(m)-1} c_j N_j(X).$$

We can reduce this to the form of (2) by subtracting an appropriate multiple of $\frac{m}{(m,j!)}N_j(X)$ for $j \le k(m)$. Since we are subtracting only polynomials that are 0 over $\mathbb{Z}_m$, the resulting polynomial computes the same function as the polynomial $Q(X)$ that we started with.

To show that this representation is unique, take two polynomials

$$P(X) = \sum_{j=0}^{k(m)-1} c_j N_j(X), \qquad 0 \le c_j < \frac{m}{(m, j!)},$$
$$Q(X) = \sum_{j=0}^{k(m)-1} d_j N_j(X), \qquad 0 \le d_j < \frac{m}{(m, j!)}.$$

Pick the smallest index j so that $c_j \ne d_j$, and assume that $c_j > d_j$. We claim that $P(j) \not\equiv Q(j) \bmod m$. Since $N_i(j) = 0$ for $i > j$ and $c_i = d_i$ for $i < j$, we have

$$P(j) - Q(j) \;=\; (c_j - d_j)N_j(j) \;=\; (c_j - d_j)j! \;\not\equiv\; 0 \bmod m,$$

since

$$0 \;<\; c_j - d_j \;<\; \frac{m}{(m, j!)}. \qquad \square$$

An easy consequence is the following result of Dueball (see [31]).

COROLLARY 7 (see [31]). *Every polynomial function over $\mathbb{Z}_m$ can be interpolated from its evaluations at the points $\{0, \ldots, k(m)-1\}$.*

Proof. Let

$$P(X) = \sum_j c_j N_j(X), \qquad 0 \le c_j < \frac{m}{(m, j!)}.$$

We let $c_0 = P(0)$. Assuming we know $c_0, \ldots, c_{j-1}$, we solve for c_j from the equation

$$c_j j! \equiv P(j) - \sum_{i<j} c_i N_i(j) \bmod m.$$

The coefficients of $P(X)$ in the canonical form are a solution to this equation. Further, the solution must be unique, since the canonical form is unique. □

The following estimates for $k(m)$ show that the number of queries can be significantly smaller than m if m is smooth.

LEMMA 8. *For prime powers,*

$$p(a-1)+1 \;\leq\; k(p^a) \;\leq\; pa.$$

If $m = \prod_j p_j^{a_j}$, *then*

$$k(m) = \max_j k(p_j^{a_j}).$$

Proof. Since $(pa)! \equiv 0 \bmod p^a$, $k(p^a) \leq pa$. Let $k = \sum_i k_i p^i$ be the base-p expansion of k. Using a formula due to Legendre (see [23]),

$$\mathrm{val}_p(k!) \;=\; \sum_i \left\lfloor \frac{k}{p^i} \right\rfloor \;=\; \frac{k - \sum k_i}{p-1}. \tag{3}$$

Hence if $k! \equiv 0 \bmod p^a$, then

$$\frac{k - \sum k_i}{p-1} \geq a \quad\Rightarrow\quad k \;\geq\; (p-1)a + \sum_i k_i \;\geq\; (p-1)a + 1.$$

For $m = \prod_j p_j^{a_j}$, by Chinese remaindering, $k! \equiv 0 \bmod m$ is equivalent to $k! \equiv 0 \bmod p_j^{a_j}$ for all j. So $k(m) = \max_j k(p_j^{a_j})$. □

Next we show that the problem of computing $k(m)$ from m is as hard as factoring m.

LEMMA 9. *The problem of computing* $k(m)$ *given* m *as input is equivalent to factoring* m.

Proof. One can check in polynomial time if m is a prime power [11], so assume it is not. We will show that $(k(m), m)$ gives a nontrivial factor of m. Note that $k(m) = \max_j k(p_j^{a_j})$. Assume this maximum is attained for the prime p_i. Note that $k(p^a) \equiv 0 \bmod p$; else

$$\mathrm{val}_p(k(p^a)!) = \mathrm{val}_p((k(p^a)-1)!),$$

which contradicts the definition of $k(p^a)$. Then $k(m) = k(p_i^{a_i})$ is divisible by p_i. Further,

$$k(p_i^{a_i}) \;\leq\; p_i a_i \;\leq\; p_i^{a_i} \;<\; m,$$

since m is not a prime power. Hence

$$p_i \;\leq\; (k(m), m) \;<\; m.$$

Thus we get a nontrivial factor of m. If $(k(m), m)$ is not a prime power, we can repeat this procedure until we get a prime-power divisor of m. □

3. Interpolating sets. We say that a polynomial $P(X)$ is 0 over set S if it evaluates to 0 at every point in S.

DEFINITION 1. *Given $I \subseteq \mathbb{Z}_m$, $S \subseteq I$ is an interpolating set for I if every polynomial which is 0 over S is 0 over I. Let $k(I)$ denote the size of the smallest interpolating set for I.*

Note that I itself is trivially an interpolating set. However, in general there can be interpolating sets which are significantly smaller than I. Note that two polynomials $P(X)$ and $Q(X)$ that agree at S must in fact agree at every point in I by considering $P(X) - Q(X)$. Thus the values of a polynomial over I are uniquely determined by the values at points in an interpolating set. The next lemma shows that the minimum number of queries to interpolate a polynomial over I is $k(I)$.

LEMMA 10. *The set of black-box queries of any interpolation algorithm is an interpolating set for I.*

Proof. Assume that the set S of queries to the black box is not an interpolating set. Then there exists polynomial $Q(X) \in \mathbb{Z}_m[X]$ such that $Q(x)$ is 0 at all $x \in S$ but nonzero at some point $y \in I$. Hence the algorithm cannot distinguish between polynomials $P(X)$ and $P(X)+Q(X)$ which agree on S but are different at $y \in I$. ∎

Note that this bound holds even if the algorithm chooses its queries adaptively.

DEFINITION 2. *Let $\bar{k}(I)$ be the smallest integer such that there is a degree $\bar{k}(I)$ monic polynomial $M(X) \in \mathbb{Z}_m[X]$ which is 0 over I.*

If S is an interpolating set of size $k(I)$, then the polynomial $\prod_{\alpha \in S}(X - \alpha)$ is a monic polynomial of degree $k(I)$. It is zero over S and hence over I. Hence

$$\bar{k}(I) \leq k(I). \tag{4}$$

This lets us prove lower bounds on $k(I)$ by showing that any polynomial that is 0 over I must have a certain degree.

Example 1. For $I \subseteq \mathbb{Z}_p$, $\bar{k}(I) = k(I) = |I|$. Since $\mathbb{Z}_p$ is a field, the smallest degree monic polynomial which is 0 over I is $M(X) = \prod_{\alpha \in I}(X - \alpha)$, and hence $\bar{k}(I) = |I|$.

Example 2. For $I = \mathbb{Z}_m$, $\bar{k}(I) = k(I) = k(m)$. By Corollary 7, the set $S = \{0, \ldots, k(m) - 1\}$ is an interpolating set, so $k(I) \leq k(m)$. To show that $\bar{k}(I) \geq k(m)$, assume that $M(X)$ is a monic polynomial of degree $d < k(m)$. Writing it in the canonical form, we get $M(X) = \sum_{i \leq d} c_i N_i(X)$, where $c_d = 1$. So $M(X)$ cannot be zero over $\mathbb{Z}_m$ by Lemma 6.

One can use the Chinese remainder theorem to relate the problem of computing $k(I)$ and $\bar{k}(I)$ for $I \subseteq \mathbb{Z}_m$ for composite m to the prime-power case. First, we need to introduce some notation. Let $m = \prod_{j=1}^{t} p_i^{a_i}$. Given a set $L \subseteq \mathbb{Z}_m$ we define the *projection* L_j of L mod $p_j^{a_j}$ as

$$L_j = \{y \in \mathbb{Z}_{p_j{}^{a_j}} | \exists\, x \in L, x \equiv y \bmod p_j^{a_j}\}.$$

For a polynomial $P(X) \in \mathbb{Z}_m[X]$, we define $P_j(X) \in \mathbb{Z}_{p_j{}^{a_j}}[X]$ to be its *projection* modulo $p_j^{a_j}$ obtained by taking each coefficient of $P(X)$ modulo $p_j^{a_j}$. Conversely, given polynomials $P_j(X) \in \mathbb{Z}_{p_j{}^{a_j}}[X]$ we can combine the coefficients using the Chinese remainder theorem to get a unique polynomial $P(X) \in \mathbb{Z}_m[X]$ whose projections are the polynomials $P_j(X)$. We call $P(X)$ the *lift* of the $P_j(X)$'s.

LEMMA 11. *Let $I \subseteq \mathbb{Z}_m$. Then*

$$\bar{k}(I) \quad = \quad \max_j \ \bar{k}(I_j). \tag{5}$$

Proof. It is easy to show using the Chinese remainder theorem that a polynomial $P(X)$ is zero over I iff $P_j(X)$ is zero over I_j for all j. Let $M(X)$ be a monic polynomial which is zero over $I \subseteq \mathbb{Z}_m$. Then, by the Chinese remainder theorem, $M_j(X)$ is a monic polynomial which is 0 over $I_j \subseteq \mathbb{Z}_{p_j{}^{a_j}}$. Hence $k(I) \geq k(I_j)$ for every j.

Conversely let $\max_j \bar{k}(I_j) = d$. For each j, there is a monic polynomial $M_j(X)$ of degree $d_j \leq d$ which is zero over I_j. The polynomial

$$M'_j(X) = X^{d-d_j} M_j(X)$$

is a degree d monic polynomial which is zero over I_j. Let $M'(X) \in \mathbb{Z}_m[X]$ be the lift of the $M'_j(X)$s. It follows that $M'(X)$ is a monic polynomial of degree d and that it is zero over I. □

LEMMA 12. *Let $I \subseteq \mathbb{Z}_m$. The set S is an interpolating set for I iff S_j is an interpolating set for I_j for every j.*

Proof. Assume that S_j is an interpolating set for I_j for every j, but S is not an interpolating set for I. Then there is a polynomial $Q(X) \in \mathbb{Z}_m[X]$ such that at every point $x \in S, Q(x) \equiv 0 \bmod m$, but for some $y \in I,\ Q(y) \not\equiv 0 \bmod m$. But then $Q(y) \not\equiv 0 \bmod p_j^{a_j}$ for some j. Consider the polynomial $Q_j(X)$. Since $Q(X)$ is zero over S, $Q_j(X)$ is zero over S_j. However, there exists $y' \equiv y \bmod p_j^{a_j}$ in I_j such that $Q_j(y') \not\equiv 0 \bmod p_j^{a_j}$. This contradicts the assumption that S_j is an interpolating set for I_j.

In the other direction, assume that S is an interpolating set for I, but S_j is not an interpolating set for I_j. Then there is a polynomial $Q_j(X) \in \mathbb{Z}_{p_j{}^{a_j}}[X]$ such that for every $x \in S_j, Q(x) \equiv 0 \bmod p_j^{a_j}$, but there exists $y \in I_j$ such that $Q(y) \not\equiv 0 \bmod p_j^{a_j}$. Take $Q_i(X) = 0$ for $i \neq j$, and set $Q(X) \in \mathbb{Z}_m[X]$ to be the lift of the $Q_i(X)$'s. Then $Q(X)$ is zero over S, since it is zero over every S_j. But it is not zero at some point in I, since Q_j is not zero over I_j. This contradicts the assumption that S is an interpolating set. □

COROLLARY 13. *Let $I \subseteq \mathbb{Z}_m$. Then*

$$\max_j\ k(I_j) \quad \leq \quad k(I) \quad \leq \quad \sum_{j=1}^{t} k(I_j). \tag{6}$$

Proof. The bound $k(I) \geq k(I_j)$ follows trivially since $|S| \geq |S_j| \geq k(I_j)$. To prove the other direction, let S_j be a minimum interpolating set for I_j. For $y \in S_j$, there exists a preimage $x \in I$ such that $x \equiv y \bmod p_j^{a_j}$. Define $S'_j \subseteq I$ by choosing one preimage for each y. Set $T = \cup_j S'_j$. T is an interpolating set for I, since $S_j \subseteq T_j$ is an interpolating set for I_j. Also $|T| \leq \sum_j k(I_j)$. □

Example 3. We give an example where $\bar{k}(I) < k(I)$ and the upper bound in (6) is (near) tight. Let $m = p_1 p_2$, and let

$$I = \{ap_1 | 1 \leq a \leq p_2 - 1\} \cup \{bp_2 | 1 \leq b \leq p_1 - 1\}.$$

It is easy to see that $\bar{k}(I_1) = k(I_1) = p_1$, $\bar{k}(I_2) = k(I_2) = p_2$, and hence $\bar{k}(I) = \max(p_1, p_2)$. On the other hand, the only interpolating set for I is I itself. Each point of the form ap_1 must be included, since it is the only point in its congruence class modulo p_2. Similarly, every point bp_2 must be included. Thus $k(I) = p_1 + p_2 - 2$.

The following extension of the above lemmas can be proved similarly using the Chinese remainder theorem.

COROLLARY 14. *Let* $m = \prod_{j=1}^{t'} m_j$ *and* $(m_i, m_j) = 1$. *Let* I_j *denote the projection of* I *modulo* m_j*:*

$$\begin{aligned} \bar{k}(I) &= \max_j \bar{k}(I_j), \\ \max_j k(I_j) \leq\ k(I) &\leq \sum_j k(I_j). \end{aligned}$$

THEOREM 15. *The problem of computing* $k(I)$ *given* I *and* m *as input is* NP*-hard.*

Proof. Consider the following decision problem.

PROBLEM 2. MIN-INTERPOLATING-SET: *Given* m *and* $I \subseteq \mathbb{Z}_m$, *is* $k(I) \leq n$*?*

We prove this problem is NP-hard by reduction from 3-dimensional matching [19].

PROBLEM 3. 3-DIMENSIONAL MATCHING: *Given sets* U, V, W *of size* n *and a set of edges* $E \subseteq U \times V \times W$, *is there a subset of* E *of size* n *that covers all the vertices?*

Take p_1, p_2, p_3 to be three distinct primes greater than n. Let $m = p_1 p_2 p_3$. For each triple $(u_i, v_j, w_k) \in E$ with $i, j, k \leq n$, we add a number $x \in \mathbb{Z}_m$ to I, where $x \equiv i \bmod p_1,\ x \equiv j \bmod p_2,\ x \equiv k \bmod p_3$. We claim that there is a matching of size n iff the set I has an interpolating set of size n. We may assume that every vertex occurs in some edge, and hence $|I_1| = |I_2| = |I_3| = n$. Thus S is an interpolating set for I iff $S_j = I_j$ for $1 \leq j \leq 3$. Thus an interpolating set corresponds to a set of edges that cover every vertex. If there is an interpolating set of size n, then there is a cover of size n and vice versa.

In fact, it is possible to show that the MIN-INTERPOLATING-SET problem is NP-complete, so we skip the proof. □

In Theorem 17, we will show that for $I \subseteq \mathbb{Z}_{p^a}$, $\bar{k}(I) = k(I)$. Combining this with (5) and (6),

$$\bar{k}(I) \leq k(I) \leq t\bar{k}(I). \tag{7}$$

Thus $\bar{k}(I)$ is a factor t approximation to $k(I)$, where t is the number of prime divisors of m.

4. Algorithms for interpolation.

4.1. The prime-power case. We give an algorithm to solve the polynomial interpolation problem over $\mathbb{Z}_{p^a}$ using exactly $k(I)$ queries. We first give a (greedy) algorithm to find a minimum interpolating set.

We start by picking an arbitrary element in I. Suppose that we have chosen $\{\alpha_0, \ldots, \alpha_{i-1}\}$ so far. If the polynomial $N_i^S(X) = \prod_{j<i}(X - \alpha_j)$ is 0 over I, we stop. Else we choose the next element $\alpha_i \in I$ so that $\mathrm{val}_p(N_i(\alpha_i))$ is minimized.

ALGORITHM 1. **IntSet**(I, p^a)
Input: Set $I \subseteq \mathbb{Z}_{p^a}$.
Output: Interpolating set S for I.

Pick $\alpha_0 \in I$ arbitrarily. Set $S = \{\alpha_0\}$, $i = 1$.
Repeat
  Let $N_i^S(X) = \prod_{j<i}(X - \alpha_j)$.
  If $N_i^S(x)$ is zero for all $x \in I$,
    Output $S = \{\alpha_0, \ldots, \alpha_{i-1}\}$. Stop.
  Else
    Find $x \in I$ that minimizes $\mathrm{val}_p(N_i^S(x))$.
    Set $\alpha_i = x$, $i = i + 1$.

Assume that the algorithm outputs a set $S = \{\alpha_0, \ldots, \alpha_{k-1}\}$ of size k, and let $e_i = \mathrm{val}_p(N_i^S(\alpha_i)$.

LEMMA 16. *Every polynomial function over I is computed by a unique polynomial of the form*

$$P(X) = \sum_{j=0}^{k-1} c_j N_j^S(X), \qquad 0 \le c_j < p^{a-e_j}. \tag{8}$$

Proof. The proof is similar to that of Lemma 6. Given any polynomial $Q(X)$, we give an algorithmic procedure to construct $P(X)$ with the above form that agrees with $Q(X)$ on I. By the termination condition, the polynomial $N_k^S(X) = \prod_{j<k}(X - \alpha_j)$ is identically zero over I. Dividing $Q(X)$ by $N_k^S(X)$ and taking the remainder, we get $Q'(X)$ of degree $k-1$ that computes the same function on I. Let us set $N_0^S(X) = 1$. Since the polynomial $N_j^S(X)$ is monic and of degree j for $j \in \{0, \ldots, k-1\}$, we can write any polynomial of degree at most $k-1$ as a linear combination of these polynomials. Hence we have

$$Q'(X) = \sum_{j<k} c_j N_j^S(X).$$

Note that, by our choice of α_j,

$$e_j \;=\; \mathrm{val}_p(N_j^S(\alpha_j)) \;\le\; \mathrm{val}_p(N_j^S(x)) \;\text{ for } x \in I.$$

So the polynomials $p^{a-e_j} N_j^S(X)$ are 0 over I. So by subtracting appropriate multiples of these polynomials from $Q'(X)$ we can get a polynomial $P(X)$, where $0 \le c_j < p^{a-e_j}$, that computes the same function as $Q(X)$.

To show uniqueness of this representation, consider two polynomials

$$P(X) = \sum_{j=0}^{k-1} c_j N_j^S(X), \qquad 0 \le c_j < p^{a-e_j},$$

$$Q(X) = \sum_{j=0}^{k-1} d_j N_j^S(X), \qquad 0 \le d_j < p^{a-e_j}$$

with different canonical forms. Pick the smallest j such that $c_j \neq d_j$. We claim that $P(\alpha_j) \neq Q(\alpha_j)$. Note that

$$P(\alpha_j) - Q(\alpha_j) = \sum_i (c_i - d_i) N_i^S(\alpha_j).$$

Since $N_i^S(\alpha_j) = 0$ for $i > j$ and $c_i = d_i$ for $i < j$, we have

$$P(\alpha_j) - Q(\alpha_j) = (c_j - d_j)N_j^S(\alpha_j).$$

Since $\mathrm{val}_p(N_j^S(\alpha_j)) = e_j$ and $\mathrm{val}(c_j - d_j) < a - e_j$, hence

$$P(\alpha_j) - Q(\alpha_j) \not\equiv 0 \bmod p^a. \qquad \square$$

THEOREM 17. *The set S is a minimum interpolating set. In fact, $\bar{k}(I) = k(I) = |S|$.*

Proof. Since S is an interpolating set of size k, $k(I) \le k$, it suffices to show that $\bar{k}(I) \ge k$. Let $M(X)$ be a monic polynomial of degree $d \le k-1$. We can put $M(X)$ in the canonical form using the procedure above to get

$$M(X) = \sum_{j \le d} c_j N_j^S(X), \qquad 0 \le c_j < p^{a-e_j}.$$

Since $M(X)$ is monic, it follows that $c_d = 1$. Thus $M(X)$ does not compute the 0 function by Lemma 16. So $\bar{k}(I) \ge k$. $\square$

Note that Algorithm 1 for picking a minimum interpolating set is essentially a greedy algorithm: at each stage it picks a new element x that minimizes $\sum_{j<i} \mathrm{val}_p(x - \alpha_j)$. One can ask what objective function is being optimized by this greedy algorithm. In Theorem 30 (proved in section 6), we prove that this algorithm minimizes the power of p that divides the Vandermonde determinant of $\prod_{i<j}(\alpha_i - \alpha_j)$. In other words, the minimum interpolating sets of I are all subsets $S = \{\beta_i\}$ of size $k(I)$ that minimize

$$\sum_{i<j \le k(I)} \mathrm{val}_p(\beta_i - \beta_j).$$

This gives a simple algorithm to check if a set $T = \{\beta_i\}$ is a minimum interpolating set for I. We first compute an interpolating set $S = \{\alpha_i\}$ using Algorithm 1 and then check that $|T| = |S|$ and that $\sum \mathrm{val}_p(\beta_i - \beta_j) = \sum \mathrm{val}_p(\alpha_i - \alpha_j)$.

We now give an algorithm for polynomial interpolation over $\mathbb{Z}_{p^a}$ whose query complexity is optimal. One can show that this algorithm computes the canonical form of $P(X)$ using an argument similar to Corollary 7.

ALGORITHM 2. **Interpolate**$(I, \mathbb{Z}_{p^a})$
Input: Set $I \subseteq \mathbb{Z}_{p^a}$, a black box for $P(X)$ evaluated at I.
Output: The polynomial $P(X)$.

Compute $S = \{\alpha_0, \ldots, \alpha_{k-1}\}$ using IntSet(I, p^a).
For $i = 0, \ldots, k-1$,
  Query $P(\alpha_i)$.
  Compute c_i so that $0 \le c_i < p^{a-e_i}$ and

$$P(\alpha_i) \equiv \sum_{j \le i} c_j N_j^S(\alpha_i) \bmod p^a.$$

Output $P(X) = \sum_{i<k} c_i N_i^S(X)$.

4.2. The general interpolation problem. We first give an algorithm to find interpolating sets over $\mathbb{Z}_m$. The algorithm is given I as input; it does not have the factorization of m. It computes an interpolating set for I. We sketch the idea of the algorithm for $m = pq$. The algorithm tries to add elements to S greedily as in the prime-power case. Assume we have picked $\{\alpha_0, \ldots, \alpha_{i-1}\}$, and let $N_i^S(X) = \prod_{j<i}(X - \alpha_i)$. We compute $g(x) = (N_i^S(x), m)$ for every $x \in I$. This quantity plays the role of $\mathrm{val}_p(N_i^S(X))$ in Algorithm 1.

1. If there is an x such that $\mathrm{val}_p(N_i^S(X))$ and $\mathrm{val}_q(N_i^S(X))$ are both minimized at x, then $g(x)|g(y)$ for all $y \in I$. We add x to S and proceed.
2. If $\mathrm{val}_p(N_i^S(X))$ and $\mathrm{val}_q(N_i^S(X))$ are minimized at distinct points x and y, then $g(x) \not| g(y)$ and vice versa. Here the greedy approach fails. But in this case we can efficiently factor $m = pq$ using $g(x)$ and $g(y)$. We then use divide and conquer.

For general m, in case 2 we compute a factorization $m = m_1 m_2$, where $(m_1, m_2) = 1$ using the subroutine Factor, and then use divide and conquer.

ALGORITHM 3. **IntSet(I, m)**
Input: Set $I \subseteq \mathbb{Z}_m$.
Output: A factorization $m = \prod_{j=1}^{t'} m'_j$, where $(m'_i, m'_j) = 1$ and a minimum interpolating set S_j for $I_j = I \bmod m'_j$.

```
Pick α_0 ∈ I arbitrarily. Set S = {α_0}, i = 1.
Repeat
   Let N_i^S(X) = ∏_{j<i}(X − α_j).
   If N_i^S(x) is zero for all x ∈ I,
      Output S = {α_0, ..., α_{i−1}}, m. Stop.
   Else
      For each x ∈ I, set g(x) = (N_i^S(x), m).
      If some g(x) divides g(y) for all y ∈ I,
         Set α_i = x, i = i + 1.
      Else
         Find g(x), g(y) that do not divide each other.
         Factor(m, g(x), g(y)) = m_1 · m_2.
         Return IntSet(I_1, m_1), IntSet(I_2, m_2). Stop.
```

We first analyze the algorithm when Factor is not called. We then present the factoring subroutine. In particular, Lemmas 18, 19, and 20 all assume that Factor was not called. In this case, the behavior of the algorithm is similar to the prime-power case.

Let $m = \prod_{j=1}^{t} p_j^{a_j}$. Let $S = \{\alpha_i\}$ be the set output. Let I_j and S_j be the projections of I and S modulo $p_j^{a_j}$. We show that if Factor is not called, then the algorithm finds a minimum interpolating set by showing $\bar{k}(I) = k(I) = |S|$. This is done by simulating Algorithm 1 on I_j and showing that it would produce the same outcome.

Fix a prime p_j. Let $\alpha'_i \equiv \alpha_i \bmod p_j^{a_j}$. We take T to be the projection of the first $k(I_j)$ elements of I. In other words, let $T = \{\alpha'_1, \ldots, \alpha'_{k(I_j)}\}$. Note that $T \subseteq S_j$.

LEMMA 18. *The set T is a minimum interpolating set for I_j.*

Proof. We will show that $\mathrm{val}_{p_j}(N_i^T(x))$ is minimized over I_j at α'_i. Hence the set T is a possible output when we run Algorithm 1 on the set I_j.

Assume that there is a $y' \in I_j$ such that

$$\mathrm{val}_{p_j}(N_i^T(y')) < \mathrm{val}_{p_j}(N_i^T(\alpha_i')).$$

Choose $y \in I$ so that $y \equiv y' \bmod p_j^{a_j}$. Note that

$$\mathrm{val}_{p_j}(N^T(y')) = \mathrm{val}_{p_j}(g(y)), \qquad \mathrm{val}_{p_j}(N^T(\alpha_i')) = \mathrm{val}_{p_j}(g(\alpha_i));$$

$$\text{hence} \qquad \mathrm{val}_{p_j}(g(y)) < \mathrm{val}_{p_j}(g(\alpha_i)).$$

So $g(\alpha_i)$ cannot divide $g(y)$. But since Factor is not used, α_i satisfies $g(\alpha_i)|g(y)$ for all $y \in I$, which is a contradiction. □

LEMMA 19. *The set S is a minimum interpolating set for I. In fact, $\bar{k}(I) = k(I) = |S|$.*

Proof. By Lemma 18, the set S_j is an interpolating set for I_j, so S is an interpolating set for I. We will show that $\bar{k}(I) = k(I) = |S|$.

For each j, the polynomial $\prod_{i<k(I_j)}(X-\alpha_i)$ is 0 mod $p_j^{a_j}$ over I_j because the first $k(I_j)$ elements are an interpolation set for I_j. Take $k = \max_j k(I_j)$. The polynomial $\prod_{i<k}(X-\alpha_i)$ is 0 mod m over I. Since this is the termination condition for Algorithm 3, it will stop after k steps and output S of size $k = \max_j k(I_j)$. By (6), we have

$$\max_j k(I_j) \;\le\; k(I).$$

Hence the set S is a minimum interpolating set. Further, by (5),

$$\bar{k}(I) \;= \max_j \bar{k}(I_j).$$

But for prime powers, $\bar{k}(I_j) = k(I_j)$. So we conclude that

$$\bar{k}(I) \;=\; \max_j \bar{k}(I_j) \;=\; \max_j k(I_j) \;=\; k(I). \qquad \square$$

$P(X)$ can be computed by a procedure similar to Algorithm 2.

LEMMA 20. *The polynomial $P(X)$ can be computed from the values at points in S.*

Proof. The proof of correctness is similar to Corollary 7. For $i \le k$, the polynomials $\frac{m}{(m,N_i^S(\alpha_i))}N_i^S(X)$ are 0 over I. This is because

$$\frac{m}{(m, N_i^S(\alpha_i))} N_i^S(\alpha_i) \equiv 0 \bmod m$$

and, for every $x \in I$,

$$N_i^S(x) = y \cdot N_i^S(\alpha_i) \bmod m \quad \text{for some } y \in \mathbb{Z}_m.$$

Hence every polynomial function over I can be canonically represented as

$$P(X) = \sum_{i=0}^{k-1} c_i N_i^S(X), \qquad 0 \le c_i < \frac{m}{(m, N_i^S(\alpha_i))}.$$

To compute the canonical form of $P(X)$, we query the value of $P(X)$ at every point in S. For $i \leq k-1$ we solve the equation

$$c_i N_i^S(\alpha_i) \equiv P(\alpha_i) - \sum_{j<i} c_j N_j^S(\alpha_i) \bmod m, \qquad 0 \leq c_i < \frac{m}{(m, N_i^S(\alpha_i))}.$$

The unique solution to this system is the canonical from of $P(X)$. □

We now turn to the subroutine for factoring. The idea is to use $g(x)$ and $g(y)$ to get m_1, m_2, which divide m and are relatively prime. Their product $m_1 m_2$ might be less than m. At each step, we take a nontrivial divisor of $\frac{m}{m_1 m_2}$ and multiply either m_1 or m_2 by it. We do this in such a way that they stay relatively prime.

ALGORITHM 4. **Factor(m,g(x),g(y))**
Input: A number m and $g(x), g(y)$ that divide m but do not divide each other.
Output: $m_1 \cdot m_2 = m$ and $(m_1, m_2) = 1$.

Let $g = (g(x), g(y))$. Let $m_1 = \frac{g(x)}{g}$, $m_2 = \frac{g(y)}{g}$.
Repeat
  Set $c = \frac{m}{m_1 \cdot m_2}$.
  If $(c, m_1) = 1$, Set $m_2 = m_2 \cdot c$.
  Else, Set $m_1 = m_1 \cdot (c, m_1)$.
  If $m_1 \cdot m_2 = m$, Output m_1, m_2. Stop.

LEMMA 21. *Factor(m, g(x), g(y)) returns m_1, m_2 such that $m_1 \cdot m_2 = m$ and $(m_1, m_2) = 1$.*

Proof. At the start of the algorithm,

$$m_1 = \frac{g(x)}{(g(x), g(y))}, \qquad m_2 = \frac{g(y)}{(g(x), g(y))},$$

so $(m_1, m_2) = 1$. Also m_1, m_2 are nontrivial divisors of m, since $g(x)$ and $g(y)$ do not divide each other.

Let

$$c = \frac{m}{m_1 m_2}.$$

If $(m_1, c) = 1$, since $(m_1, m_2) = 1$, we have $(m_1, cm_2) = 1$. So we set $m_2 = cm_2$, and we are done. If $(c, m_1) = d > 1$, then since d divides m_1, we have $(d, m_2) = 1$. So we set $m_1 = dm_1$. In either case, the product $m_1 m_2$ increases by a factor of 2, and hence the algorithm terminates in $O(\log m)$ iterations. □

The subroutine above is somewhat inefficient. The running time can be considerably improved by running the factor refinement algorithm of Bernstein [12] on $g(x), g(y)$, and m. This algorithm gives a factorization into coprimes in near linear time.

If we find factors m_1, m_2 which are relatively prime, then we run IntSet(I_1, m_1) and IntSet(I_2, m_2). In doing so we could find further factors of m_1 and m_2, but these will be relatively prime, since m_1 and m_2 are relatively prime. So finally, the algorithm returns a factorization $m = \prod_{i \leq t'} m_i'$, where the m_i''s are relatively prime. If m has t distinct prime factors, then clearly $t' \leq t$. We now solve the interpolation problem

modulo m'_j using Lemma 20 and combine the results using the Chinese remainder theorem.

ALGORITHM 5. **Interpolate**$(I, \mathbb{Z}_m)$
Input: Set $I \subseteq \mathbb{Z}_m$, a black box for $P(X)$ evaluated at I.
Output: The polynomial $P(X)$.

Using IntSet(I, m), compute $m = \prod_{j=1}^{t'} m'_j$ and interpolating sets S_j for I_j.
For each $j \in 1, \ldots, t'$
  For each $y \in S_j$,
    Query $P(X)$ at $x \in I$ so that $x \equiv y \bmod m'_j$.
  Use these to compute $P_j(X) \bmod m'_j$.
Lift the polynomials $P_j(X)$ to a polynomial $P(X) \in \mathbb{Z}_m[X]$ using Chinese remaindering.

LEMMA 22. *Algorithm* 5 *solves the interpolation problem over* $\mathbb{Z}_m[X]$. *The number of queries is within a factor* t' *of the optimal.*

Proof. The proof that the polynomial $P(X)$ is correct follows by the Chinese remainder theorem. The number of queries is at most $\sum_{j \le t'} |S_j|$. By Lemma 19, since each m_j is not factored further, the set S_j is a minimum interpolating set for I_j. Hence $|S_j| = k(I_j)$. Hence by Corollary 14,

$$\max_j |S_j| \;\le\; k(I) \;\le\; \sum_{j \le t'} |S_j| \;\le\; t' k(I). \qquad \square$$

Also by Corollary 14,

$$\bar{k}(I) \;=\; \max_j \bar{k}(I_j) \;=\; \max_j |S_j|.$$

Hence Algorithm 3 can be used to compute $\bar{k}(I)$ exactly. (Note that this can also be done by solving a system of linear equations.)

5. Learning algorithms. One can use the algorithms in the previous section to design efficient algorithms for interpolation over $\mathbb{Z}_m$ in various learning theoretic settings. We consider the problem of learning under the uniform distribution and PAC learning under an arbitrary distribution. In the uniform distribution problem, we are given evaluations of a polynomial $P(X)$ at points x chosen at random from $\mathbb{Z}_m$. In the PAC-learning problem, the samples are drawn from an unknown distribution $\mathcal{D}$ over $\mathbb{Z}_m$. We are required to output a polynomial that computes $P(X)$ correctly with good probability on points chosen from the same distribution. In this setting, it is necessary to allow some error probability. Consider a distribution D which is concentrated on a set I which does not contain an interpolating set for $\mathbb{Z}_m$. A polynomial time algorithm cannot distinguish between the 0 function and a function which is 0 on I but nonzero elsewhere.

For learning algorithms, the notion of polynomial running time needs to be defined carefully. Let $F(m)$ denote the number of polynomial functions over $\mathbb{Z}_m$. The algorithm is required to output some polynomial function which requires at least $\log F(m)$ bits to represent. Hence we say the algorithm runs in polynomial time if the running time is $\text{poly}(\log F(m))$.

From Lemma 6, we get

$$F(m) = \prod_{0 \le j < k(m)} \frac{m}{(m, j!)}. \tag{9}$$

Note that $\log F(m)$ can vary between $\log m$ and m depending on the prime factorization of m. We compute a rough lower bound on $\log F(m)$ in terms of its factorization. Note that, if $m = p^a$, it follows from Lemma 6 that

$$F(p^a) \ \geq \ (p^a)^p \ = \ p^{ap}.$$

Hence if $m = \prod_{j \le t} p_j^{a_j}$, then

$$F(m) \geq \prod_j p_j^{a_j p_j} \ \Rightarrow \ \log F(m) \geq \sum_{j \le t} a_j p_j \log p_j.$$

5.1. Learning under the uniform distribution. We first consider the problem of learning polynomials from their evaluations at random points in $\mathbb{Z}_m$.

Problem 4. Learning under the Uniform Distribution: *Given samples $(x, f(x))$, where x is drawn uniformly from $\mathbb{Z}_m$ and f is a polynomial function, find a polynomial $P(X)$ that computes f.*

Algorithm 6. **Interpolation under the Uniform Distribution**
Input: Black box for evaluations of $P(X)$ under the uniform distribution.
Output: The polynomial $P(X)$.

Compute the factorization $m = \prod_{j=1}^{t} p_j^{a_j}$.
Draw samples until we have an interpolating set S_j for $\mathbb{Z}_{{p_j}^{a_j}}$.
Compute $P_j(X)$ for each j.
Let $P(X)$ be the lift of the $P_j(X)$'s.

We compute the factorization using brute force which takes time $O(\sum_j p_j a_j) = O(F(m))$. We now bound the number of samples needed until we have an interpolating set modulo p^a. Let p^b be the smallest power of p such that $p^b > k(p^a)$. By Lemma 8, $p^b < p^2 a$. Let $S = \{\alpha_0, \ldots, \alpha_{k(p^a)-1}\}$, where $\alpha_i \equiv i \bmod p^b$.

Lemma 23. *The set S is an interpolating set for $\mathbb{Z}_{p^a}$.*

Proof. By Corollary 7, $T = \{0, \ldots, k(p^a) - 1\}$ is an interpolating set for $\mathbb{Z}_{p^a}$. By the choice of α_i, α_j,

$$\alpha_i - \alpha_j \ \equiv \ i - j + cp^b \bmod p^a.$$

Since $0 \le i \ne j < p^b$, $\mathrm{val}_p(\alpha_i - \alpha_j) = \mathrm{val}_p(i - j)$. Hence

$$\sum_{i < j \le k(p^a)} (\alpha_i - \alpha_j) = \sum_{i < j \le k(p^a)} (i - j).$$

So, by Theorem 30, S is an interpolating set. ∎

Lemma 24. *Algorithm 6 requires $O(\log^2 F(m))$ samples with high probability.*

Proof. The uniform distribution over $\mathbb{Z}_m$ induces the uniform distribution over congruence classes modulo $p_j^{b_j}$, since $b_j < a_j$. By the coupon collector's problem,

in time $O(p_j^{b_j} \log(p_j^{b_j}))$ we will see a sample from each congruence class with high probability. By Lemma 23, this gives an interpolating set modulo $p_j^{a_j}$. Overall the number of samples needed can be bounded by $O(\log^2 F(m))$ with high probability. □

THEOREM 25. *Algorithm* 6 *learns the polynomial* $P(X)$ *exactly under the uniform distribution. It runs in time* $O(\log^2 F(m))$ *with high probability.*

We needed to factor m to check whether the set of points seen so far is an interpolating set for $\mathbb{Z}_m$. Is there an algorithm to check if S is an interpolating set for $\mathbb{Z}_m$ that does not need to factor m?

5.2. PAC learning. Next we consider the problem of PAC-learning polynomials. We refer the reader to the book of Kearns and Vazirani for details of the PAC-learning model [29].

PROBLEM 5. PAC LEARNING: *Given samples* $(x, f(x))$*, where* x *is drawn from an unknown distribution* $\mathcal{D}$ *and* f *is a polynomial function, find a polynomial* $P(X)$ *that computes* f *over* $\mathcal{D}$ *with probability* $1 - \varepsilon$.

We show that polynomial functions are PAC learnable under an arbitrary distribution in polynomial time. Once we have drawn the set of samples, the problem reduces to one of general interpolation. The number of samples to be drawn can be determined from $F(m)$ using Occam's razor [29]. We first compute $F(m)$ using (9). This can be done in time $O(\log F(m))$. We then draw $\frac{1}{\varepsilon} \log \frac{F(m)}{\delta}$ samples from $\mathcal{D}$ and solve the interpolation problem on these inputs using Algorithm 5. The proof that this suffices for PAC learning is standard [29].

THEOREM 26. *Polynomials over* $\mathbb{Z}_m$ *are PAC learnable in polynomial time using* $\frac{1}{\varepsilon} \log \frac{F(m)}{\delta}$ *queries.*

6. Algebraic structure of interpolating sets modulo prime powers. In this section we study the algebraic properties of interpolating sets modulo prime powers. We give alternate algebraic characterizations of such sets (Theorems 29 and 30). In this section and the next, we use p-adic distance as opposed to valuations.

Recall that by the definition of interpolating sets, every polynomial which is nonzero over I is in fact nonzero over some point in S. The next lemma generalizes this to show that, in fact, the norm of every polynomial is maximized over I at some point in S.

LEMMA 27. *A set* S *is an interpolating set iff, for any polynomial* $P(X)$*, there exists* $\alpha \in S$ *such that*

$$|P(\alpha)|_p \geq |P(x)|_p \qquad \forall x \in I. \tag{10}$$

Proof. ($\Rightarrow$) Assume there exists $P(X) \in \mathbb{Z}_{p^a}$ such that $|P(x)|_p > |P(\alpha)|_p$ for all $\alpha \in S$. But then for an appropriately chosen e, $p^e P(X)$ is nonzero at x but 0 everywhere in S. Hence S cannot be an interpolating set.

($\Leftarrow$) Assume that S satisfies (10). There cannot exist a polynomial $P(X)$ which is 0 on S, but $P(x) \neq 0$ for some $x \in \mathbb{Z}_{p^a}$, since this implies that $|P(x)|_p > |P(\alpha)|_p$ for all $\alpha \in S$. Hence S is an interpolating set. □

This property of interpolating sets allows us to order its elements in a natural manner. Given an ordered set $S = \{\alpha_0, \alpha_1, \ldots\}$, let $N_j^S(X) = \prod_{i<j}(X - \alpha_i)$.

ALGORITHM 7. **Ordering an Interpolating Set**
Input: An interpolating set T of I.
Output: An ordered set $S \subseteq T$ which is a (minimal) interpolating set.

Pick $\alpha_0 \in T$ arbitrarily, and put it in S.
Given $S = \{\alpha_0, \ldots, \alpha_{j-1}\}$.
  If $N_j^S(X)$ is 0 over T, stop and output $S = \{\alpha_0, \ldots, \alpha_{j-1}\}$.
  Else pick $\alpha_j \in T$, which maximizes $|N_j^S(\alpha_j)|_p$, and add it to S.

Assume that the above procedure outputs an ordered set $S = \{\alpha_0, \ldots, \alpha_{k-1}\}$ of size k. Let $e_j = \mathrm{val}_p(N_j^S(\alpha_j))$ for $i \le j \le k-1$. Observe that $0 \le e_j < a$. Using the argument of Lemma 16, we can show that every polynomial function over I is computed by a unique polynomial of the form

$$P(X) = \sum_{j=0}^{t} c_j N_j^S(X), \qquad 0 \le c_j < p^{a-e_j}.$$

Using the canonical form above, one can show that all minimal interpolating sets over $\mathbb{Z}_{p^a}$ have the same size. The proof is similar to that of Theorem 17.

COROLLARY 28. *The set $S = \{\alpha_0, \ldots, \alpha_{k-1}\}$ is an interpolating set iff $|N_j^S(\alpha_j)|_p \ge |N_j^S(x)|_p$ for all $x \in I$.*

Proof. Clearly an interpolating set with the canonical ordering has this property. To prove the other direction, simply take $T = I$ in Algorithm 7. Since $|N_j^S(x)|_p$ is maximized at α_j, we can add α_j to S at step j, giving the interpolating set $S = \{\alpha_0, \ldots, \alpha_{k-1}\}$. □

Henceforth we will assume that interpolating sets are canonically ordered and that polynomials are in the canonical form. Lemma 27 states that for any polynomial function $P(X)$, $|P(x)|_p$ is maximized at some point $\alpha \in S$. We strengthen this to show that if the degree of $P(X)$ is d, such an α can be found among the first $d+1$ elements in S.

THEOREM 29. *The set $S = \{\alpha_0, \ldots, \alpha_{k-1}\}$ is an interpolating set iff, for every polynomial $P(X)$ of degree d, there exists $\alpha \in \{\alpha_0, \ldots, \alpha_d\}$ such that $|P(\alpha)|_p \ge |P(x)|_p$ for all $x \in I$.*

Proof. Clearly a set with this property is an interpolating set by Lemma 27. We prove the other direction. The proof is by induction on d. The base case when $d = 0$ is trivial. Assume the claim holds for $d-1$. Let $P(X) = Q(X) + c_d N_k^S(X)$, where $\deg(Q) \le d-1$.

$$|P(x)|_p \le \max(|Q(x)|_p, |c_d N_d^S(x)|_p) \qquad \text{(ultrametric inequality)}. \tag{11}$$

We bound $|Q(x)|_p$ using the inductive hypothesis. Since $Q(X)$ has degree $d-1$,

$$|Q(x)|_p \le \max(|Q(\alpha_0)|_p, \ldots, |Q(\alpha_{d-1})|_p). \tag{12}$$

By our choice of α_d,

$$\begin{aligned} |c_d N_d^S(x)|_p &\le |c_d N_d^S(\alpha_d)| \\ &= |P(\alpha_d) - Q(\alpha_d)|_p \\ &\le \max(|Q(\alpha_d)|_p, |P(\alpha_d)|_p) \\ &\le \max(|Q(\alpha_0)|_p, \ldots, |Q(\alpha_{d-1})|_p, |P(\alpha_d)|_p) \qquad \text{(induction on } Q(X)). \end{aligned} \tag{13}$$

Hence from (11), (12), and (13) we get

$$|P(x)|_p \le \max(|Q(\alpha_0)|_p, \ldots, |Q(\alpha_{d-1})|_p, P(\alpha_d)|_p).$$

Since $N_d^S(\alpha_j) = 0$ for $j < d$, we have $Q(\alpha_j) = P(\alpha_j)$ for $j < d$. Hence

$$|P(x)|_p \le \max(|P(\alpha_0)|_p, \ldots, |P(\alpha_{d-1})|_p, |P(\alpha_d)|_p). \qquad (14)$$ □

We use this to show that interpolating sets are greedy solutions for the problem of maximizing the p-adic norm of the Vandermonde determinant. Since the determinant could vanish mod p^a, we define the norm of the Vandermonde determinant as follows:

$$\text{Let} \quad |V(\alpha_0, \ldots, \alpha_{k-1})|_p \;=\; \prod_{0 \le i < j \le k-1} |(\alpha_i - \alpha_j)|_p \;=\; \prod_{j=1}^{k-1} |N_j^S(\alpha_j)|_p.$$

This is equivalent to regarding the determinant as an integer and taking its norm.

THEOREM 30. *The set $S = \{\alpha_0, \ldots, \alpha_{k-1}\}$ is an interpolating set for I iff, for all subsets $\{x_0, \ldots, x_{k-1}\}$ of I,*

$$|V(\alpha_0, \ldots, \alpha_{k-1})|_p \ge |V(x_0, \ldots, x_{k-1})|_p. \qquad (15)$$

Proof. ($\Rightarrow$). We will show a stronger statement: for $1 \le j \le k-1$, for any subset $\{x_0, \ldots, x_j\}$ of I,

$$|V(\alpha_0, \ldots, \alpha_j)|_p \ge |V(x_0, \ldots, x_j)|_p. \qquad (16)$$

Consider the polynomial $Q(X) = \prod_{i<j}(X - x_i)$. By Theorem 29, there exists $\alpha_i \in \{\alpha_0, \ldots, \alpha_j\}$ such that $|Q(\alpha_i)|_p \ge |Q(x_j)|_p$. Hence one can replace x_j by α_i without decreasing the norm of the Vandermonde determinant. Now repeat the same argument for the set $\{x_0, \ldots, x_{j-1}, \alpha_i\}$ and the element x_{j-1} and so on. We get

$$|V(\alpha_0, \ldots, \alpha_j)|_p \;\ge\; \cdots \;\ge\; |V(x_0, \ldots, x_{j-1}, \alpha_i)|_p \;\ge\; |V(x_0, \ldots, x_j)|_p.$$

($\Leftarrow$). Assume we have a set S satisfying (15). Assume that the α_i's are ordered canonically. We will show that $|N_j^S(\alpha_j)|_p \ge |N_j^S(x)|_p$ for all $x \in I$. This implies S is an interpolating set by Corollary 28.

Assume there exists β such that $|N_j^S(\alpha_j)|_p < |N_j^S(\beta)|_p$. Pick $\alpha_i \in \{\alpha_j, \ldots, \alpha_{k-1}\}$ such that $|\beta - \alpha_i|_p$ is minimized. We will show that replacing α_i by β will increase the norm of the Vandermonde determinant. Observe that, for any $\ell \ne i$ and $\ell \ge j$,

$$\begin{aligned} |\alpha_\ell - \alpha_i|_p &\le \max(|\beta - \alpha_\ell|_p, |\beta - \alpha_i|_p) \\ \text{but} \quad |\alpha_\ell - \beta|_p &\ge |\beta - \alpha_i|_p \qquad \text{by choice of } \alpha_i; \\ \text{hence} \quad |\alpha_i - \alpha_\ell|_p &\le |\beta - \alpha_\ell|_p \\ \Rightarrow \prod_{\ell > j, \ell \ne i} |\alpha_i - \alpha_\ell|_p &\le \prod_{\ell \ge j, \ell \ne i} |\beta - \alpha_\ell|_p. \end{aligned} \qquad (17)$$

We also have

$$|N_j^S(\alpha_i)|_p \;\le\; |N_j^S(\alpha_j)|_p \;<\; |N_j^S(\beta)|_p.$$

The first inequality is because S is ordered canonically, and the second is by the definition of β. Hence, from the definition of $N_j^S(X)$,

$$\left|\prod_{\ell<j}(\alpha_i-\alpha_\ell)\right|_p \;<\; \left|\prod_{\ell<j}(\beta-\alpha_\ell)\right|_p . \tag{18}$$

Combining (17) and (18), we get

$$\left|\prod_{\ell\neq i}(\alpha_i-\alpha_\ell)\right|_p \;<\; \left|\prod_{\ell\neq i}(\beta-\alpha_\ell)\right|_p . \tag{19}$$

Hence replacing α_i with β increases the norm of the Vandermonde determinant, which contradicts the assumption that the norm is maximized at S. □

COROLLARY 31. *The parameters $e_1,\ldots,e_{k-1}$ are independent of the choice of interpolating set.*

Proof. Note that

$$|N_j^S(\alpha_j)| \;=\; p^{-e_j}$$

and

$$|V(\alpha_0,\ldots,\alpha_j)|_p \;=\; \prod_{i\leq j}|N_i^S(\alpha_i)|_p \;=\; p^{-\sum_{i\leq j}e_i}.$$

This quantity is maximized over subsets of I at every interpolating set. So $\sum_{i\leq j}e_i$, and hence e_i is the same for every interpolating set of I. □

7. Some combinatorial properties of ultrametric spaces. We show that many of our results for interpolating sets can be translated into properties of general ultrametric spaces. Further, the proof of these properties for general ultrametric spaces follows directly from the proof for polynomials over $\mathbb{Z}_{p^a}$.

DEFINITION 3. *Let T be a tree rooted at a vertex r such that the distances of all leaves from the root r are equal. The metric space whose points are the leaves of the tree and distance is the shortest path in the tree is called an* equidistant tree *and is denoted by (T,d).*

It is easy to show that (T,d) is an ultrametric . In fact, the converse is also true.

FACT 32. *Every finite ultrametric space embeds isometrically into an equidistant tree.*

Every equidistant tree can in turn be associated with $I\subseteq\mathbb{Z}_{p^a}$ for appropriate choices of p,a, and I.

LEMMA 33. *There is a mapping from any equidistant tree T to $I\subseteq\mathbb{Z}_{p^a}$ for some p,a such that*

$$|x-y|_p = p^{\frac{d(x,y)}{2}-a} \quad \textit{for } x\neq y.$$

Proof. There is a natural way to associate $\mathbb{Z}_{p^a}$ with an equidistant tree of degree p and depth a [6]. The root is at depth 0. The edges from each vertex to its descendants are labeled $\{0,\ldots,p-1\}$. Given a point $x=\sum_i x_ip^i\in\mathbb{Z}_{p^a}$, we associate it with a leaf of the tree as follows: Start from the root. At depth i, follow the edge labeled x_i. Thus the leaf nodes correspond to points in $\mathbb{Z}_{p^a}$, while nodes at depth d correspond

to congruence classes modulo p^d. If $d(x,y)$ is the tree distance between the points, then $|x-y|_p = p^{\frac{d(x_i,x_j)}{2}-a}$.

Given an equidistant tree T, we take p to be a prime larger than the maximum degree of T and a to be the depth of the tree. For any node, we arbitrarily label the edges to its descendants with $\{0,\dots,p-1\}$. This can be done, since there are at most p of them. This will map the leaves of T to $I \subseteq \mathbb{Z}_{p^a}$, and it is easy to verify that the distance satisfies the desired condition. □

Based on this correspondence, we can translate properties of interpolating sets into properties of ultrametric spaces. We consider the following NP-hard optimization problem.

PROBLEM 6. MAX-DIST-K: *Given a metric space (X,d), pick a subset S of k points such that the sum of pairwise distances is maximized.*

For ultrametrics, the problem can be solved greedily.

ALGORITHM 8. **Greedy Algorithm for Max-Dist-k**
Input: An n point ultrametric space (T,d).
Output: A subset S of size k maximizing the sum of pairwise distances.

Pick $\alpha_0 \in T$ arbitrarily.
For $j \le k-1$,
  Pick α_j so that $\sum_{i<j} d(\alpha_j,\alpha_i)$ is minimized.
Output $S = \{\alpha_0,\dots,\alpha_{k-1}\}$.

LEMMA 34. *The greedy algorithm solves Max-Dist-k over ultrametric spaces.*

Proof. Associate T with $I \subseteq \mathbb{Z}_{p^a}$. For any subset $(x_0,\dots,x_{k-1})$ of size k,

$$\prod_{i<j} |x_i - x_j|_p = p^{\sum_{i,j} \frac{d(x_i,x_j)}{2} - \binom{k}{2}a}.$$

Hence MAX-DIST-K on an ultrametric reduces to choosing k points in I such that $|V(x_0,\dots,x_{k-1})|_p$ is maximized; by Theorem 30 this can be done by choosing the points greedily. □

Next we consider the problem of finding a point in a metric space that is farthest from a given set of points.

PROBLEM 7. FARTHEST-POINT: *Given a metric space (X,d) and a set of points $\{y_1,\dots,y_{k-1}\}$ of size $k-1$, find the point $x \in X$ that maximizes $\sum_{i<k} d(x,y_i)$.*

This problem is easy to solve for arbitrary metric spaces; we can just try every point in X and pick the best. However, ultrametric spaces admit a more efficient solution with some preprocessing. In the preprocessing step, we find a solution S to MAX-DIST-K using the greedy algorithm. This step is oblivious of the y_i's. We then return the point $x \in S$ that maximizes $\sum_{i<k} d(x,y_i)$. The running time of this step depends only on k; it is independent of the number of points n.

LEMMA 35. *Let $\{y_1,\dots,y_{k-1}\}$ be any subset of size $k-1$ in X. Let $S = \{\alpha_0,\dots,\alpha_{k-1}\}$ be a greedy solution to Max-Dist-k. The quantity $\sum_{i<k} d(x,y_i)$ is maximized over X at a point $\alpha \in S$.*

Proof. Associate X with $I \subseteq \mathbb{Z}_{p^a}$. Given points y_i, consider the polynomial

$$P(X) = \prod_{i<k} (X - y_i).$$

Note that

$$|P(x)|_p = p^{\sum \frac{d(x,y_i)}{2} - a(k-1)}.$$

Hence, maximizing the distance is equivalent to maximizing $|P(x)|_p$. Since $P(X)$ is of degree $k-1$, by Theorem 29 its norm over I is maximized at some point in $\{\alpha_0, \ldots, \alpha_{k-1}\}$. □

The case $k = 2$ of this lemma is a direct consequence of the ultrametric inequality. We are unaware of a direct combinatorial proof of Lemma 35 for $k \geq 3$ and higher.

Acknowledgments. We thank Sophie Frisch, Igor Shparlinski, and an anonymous referee for many useful references and Saugata Basu and Ernie Croot for helpful discussions. We thank T. S Jayram, Ravi Kumar, and Satyen Kale for their comments, which greatly improved the presentation. We thank Dick Lipton for numerous illuminating discussions on this and related problems.

EXACT ALGORITHMS FOR TREEWIDTH AND MINIMUM FILL-IN*

FEDOR V. FOMIN†, DIETER KRATSCH‡, IOAN TODINCA§, AND YNGVE VILLANGER†

Abstract. We show that the treewidth and the minimum fill-in of an n-vertex graph can be computed in time $\mathcal{O}(1.8899^n)$. Our results are based on combinatorial proofs that an n-vertex graph has $\mathcal{O}(1.7087^n)$ minimal separators and $\mathcal{O}(1.8135^n)$ potential maximal cliques. We also show that for the class of asteroidal triple–free graphs the running time of our algorithms can be reduced to $\mathcal{O}(1.4142^n)$.

Key words. exact exponential algorithm, treewidth, fill-in, minimal separators, potential maximal clique, minimal triangulation

1. Introduction. Exact exponential algorithms.

The interest in exact (fast) exponential algorithms dates back to Held and Karp's paper [28] on the travelling salesman problem in the early 1960s. We mention just a few examples: an $\mathcal{O}(1.4422^n)$ time algorithm for knapsack (Horowitz and Sahni [29]); $\mathcal{O}(1.2600^n)$ and $\mathcal{O}(1.2109^n)$ time algorithms for independent set (Tarjan and Trojanowski [43] and Robson [40]); 3-coloring in time $\mathcal{O}(1.4422^n)$ (Lawler [35]); and 3-SAT in time $\mathcal{O}(1.6181^n)$ (Monien and Speckenmeyer [36]).[1]

Nowadays, it is commonly believed that NP-hard problems cannot be solved in polynomial time. For a number of NP-hard problems, we even have strong evidence that they cannot be solved in subexponential time [30]. In order to obtain exact solutions to these problems, the only hope is to design exact algorithms with good exponential running times. In recent years there has been emerging interest in attacking this question for concrete combinatorial problems: there are, for example, an $\mathcal{O}^*(2^n)$ time algorithm for coloring (Björklund and Husfeldt [5] and Koivisto [34]); an $\mathcal{O}(1.3289^n)$ time algorithm for 3-coloring (Beigel and Eppstein [3]); an $\mathcal{O}(1.7325^n)$ time algorithm for Max-Cut (Williams [45]); an algorithm for 3-SAT in time $\mathcal{O}(1.4726^n)$ (Brueggemann and Kern [15]); and an $\mathcal{O}(1.5129^n)$ time algorithm for dominating set (Fomin, Grandoni, and Kratsch [23]).

There are several explanations for the current revival of interest in fast exponential algorithms within the algorithmic community.

- The design and analysis of exact algorithms leads to a better understanding of NP-hard problems and initiates interesting new combinatorial and algorithmic challenges.

[1] Because $c^n \cdot n^{\mathcal{O}(1)} = \mathcal{O}((c+\epsilon)^n)$ for any $\epsilon > 0$, we omit polynomial factors in the big-Oh notation every time we round the base of the exponent. We also use a modified big-Oh notation that suppresses all other (polynomially bounded) terms. Thus for functions f and g we write $f(n) = \mathcal{O}^*(g(n))$ if $f(n) = \mathcal{O}(g(n) \cdot n^{\mathcal{O}(1)})$.

- For certain applications it is important to find exact solutions. With the increased speed of modern computers, fast algorithms, even though they have exponential running times in the worst case, may actually lead to practical algorithms for certain NP-hard problems, at least for moderate instance sizes.
- Approximation algorithms, randomized algorithms, and different heuristics are not always satisfactory. Each of these approaches has weak points such as the necessity of exact solutions, difficulty of approximation, limited power of the method itself, and many others.
- A reduction of the base of the exponential running time, say from $\mathcal{O}(2^n)$ to $\mathcal{O}(1.8^n)$, increases the size of the instances solvable within a given amount of time by a constant *multiplicative* factor. However, running a given exponential algorithm on a faster computer can enlarge the mentioned size by only a constant *additive* factor.

For overviews and introductions to the field see the recent surveys by Fomin, Grandoni, and Kratsch [24], Iwama [31], Schöning [41], and Woeginger [46, 47].

Treewidth and minimum fill-in. Treewidth is one of the most basic parameters in graph algorithms [7], and it plays an important role in structural graph theory. It serves as one of the main tools in Robertson and Seymour's graph minors project [39]. Treewidth also plays a crucial role in parameterized complexity theory [19]. The minimum fill-in problem (also known as minimum chordal graph completion) has important applications in sparse matrix computations and computational biology.

The problems of computing the treewidth and minimum fill-in of a graph are known to be NP-hard even when the input is restricted to complements of bipartite graphs (so called cobipartite graphs) [2, 48]. Despite the importance of treewidth almost nothing is known about how to cope with its intractability. For a long time the best known approximation algorithm for treewidth had a factor $\log OPT$ [1, 11] (see also [10]). Recently, Feige, Hajiaghayi, and Lee [21] obtained a factor $\sqrt{\log OPT}$ approximation algorithm for treewidth. Furthermore, it is an old open question whether the treewidth can be approximated within a constant factor.

Treewidth is known to be fixed parameter tractable. Moreover, for any fixed k, there is a linear time algorithm to compute the treewidth of graphs of treewidth at most k (unfortunately there is a huge hidden constant in the running time) [6]. There is a number of algorithms that, for a given graph G and integer k, either report that the treewidth of G is at least k or produce a tree decomposition of width at most $c_1 \cdot k$ in time ${c_2}^k \cdot n^{O(1)}$, where c_1, c_2 are some constants (see, e.g., [1]). Fixed parameter algorithms are known for the minimum fill-in problem as well [16, 32].

There exists an exact $\mathcal{O}(2.9512^n)$ time algorithm that computes the treewidth of a graph in polynomial space [9]. We are not aware of any previous work on exact algorithms for the treewidth or minimum fill-in problem that solves the problem in $\mathcal{O}(c^n)$ time where $c < 2$. There are three relatively simple approaches resulting in time $\mathcal{O}^*(2^n)$ algorithms:

- One can reformulate the problems as problems of finding special vertex elimination orderings and then find an optimal permutation by using the dynamic programming based technique as in the article of Held and Karp [28] for the travelling salesman problem. The algorithm of Bodlaender et al. [9] also uses this approach.
- With some modifications, the algorithm of Arnborg, Corneil, and Proskurowski [2] for a given k deciding in time $O(n^{k+1})$ if the treewidth of a graph is at most k can be used to compute the treewidth (and similarly fill-in) in time $\mathcal{O}^*(2^n)$.

- Both problems can be solved by making use of the game theoretic approach, by finding a specific path in the graph of possible states of a cop and robber game [22].

However, it is not clear whether any of the aforementioned approaches can bring us to an $\mathcal{O}(c^n)$ time algorithm for some $c < 2$. Prior to our work, no exact algorithm computing the treewidth or minimum fill-in of a graph in time $\mathcal{O}(c^n)$ for some $c < 2$ was known.

Our results. In this paper we obtain the first exact algorithm computing the treewidth in time $\mathcal{O}(c^n)$ for $c < 2$. Additionally it can be adapted to solve a number of other minimal triangulation problems such as minimum fill-in.

Our main result is an $\mathcal{O}(1.8899^n)$ algorithm computing the treewidth and minimum fill-in of a graph on n vertices. The algorithm can be regarded as dynamic programming across partial solutions and is based on results of Bouchitté and Todinca [13, 14]. The analysis of the running time is difficult and is based on combinatorial properties of special structures in a graph, namely, potential maximal cliques, i.e., vertex subsets in a graph that can be maximal cliques in some minimal triangulation of this graph. (See the next section for the definition.)

More precisely, first we modify the algorithm of Bouchitté and Todinca [13] which computes the treewidth and minimum fill-in of a graph G with the given set Π_G of all potential maximal cliques of G and then improve the analysis of its running time to obtain an $\mathcal{O}^*(|\Pi_G|)$ time complexity. The most technical and difficult part of the paper is the proof that all potential maximal cliques can be listed in time $\mathcal{O}(1.8899^n)$. Very roughly, our listing algorithm is based on the following combinatorial result: every "large" potential maximal clique either is "almost" a minimal separator or can be represented by a "small" vertex subset. The technique developed to prove this combinatorial result can be interesting on its own.

For several special graph classes, for which both problems remain NP-complete, we are able to prove that our approach guarantees significantly better bounds. To exemplify this we show that, for the class of asteroidal triple (AT)-free graphs, the number of minimal separators and the number of potential maximal cliques, and thus the running time of our algorithm, is $\mathcal{O}^*(2^{n/2})$.

This paper is organized as follows. In section 2 we give basic definitions. In section 3 we show how Bouchitté and Todinca's approach can be used to compute the treewidth and fill-in in time linear in the number of potential maximal cliques. In section 4 we prove that every graph on n vertices has $\mathcal{O}(n{\cdot}1.7087^n)$ minimal separators. In section 5 we show that an n-vertex graph contains $\mathcal{O}(1.8135^n)$ potential maximal cliques. This bound is of only combinatorial interest because it is not constructive, in a sense, that we do not know how to use this bound to list all potential maximal cliques in time $\mathcal{O}(1.8135^n)$. In order to obtain a fast algorithm computing the treewidth and the fill-in of a graph, we need an algorithm listing all potential maximal cliques. In the remaining part of section 5 we derive the most difficult and important algorithmic result of this paper, namely, that all potential maximal cliques of a graph can be listed in time $\mathcal{O}(1.8899^n)$. This result is based on a novel characterization of potential maximal cliques. Combined with the results from section 3, this yields the main result of the paper, that the treewidth and minimum fill-in can be computed in time $\mathcal{O}(1.8899^n)$. In section 6 we design a faster $\mathcal{O}^*(2^{n/2})$ time algorithm for AT-free graphs. We conclude with open problems and final remarks in section 7.

2. Basic definitions. We denote by $G = (V, E)$ a finite, undirected, and simple graph with $|V| = n$ vertices and $|E| = m$ edges. For any nonempty subset $W \subseteq V$,

the subgraph of G induced by W is denoted by $G[W]$. For $S \subseteq V$ we often use $G \setminus S$ to denote $G[V \setminus S]$. The *neighborhood* of a vertex v is $N(v) = \{u \in V : \{u, v\} \in E\}$, $N[v] = N(v) \cup \{v\}$, and for a vertex set $S \subseteq V$ we set $N(S) = \bigcup_{v \in S} N(v) \setminus S$, $N[S] = N(S) \cup S$. A *clique* C of a graph G is a subset of V such that all the vertices of C are pairwise adjacent. By $\omega(G)$ we denote the maximum clique-size of a graph G.

Treewidth and minimum fill-in of graphs. The notion of treewidth is due to Robertson and Seymour [38]. A *tree decomposition* of a graph $G = (V, E)$, denoted by $TD(G)$, is a pair (X, T) in which $T = (V_T, E_T)$ is a tree and $X = \{X_i \mid i \in V_T\}$ is a family of subsets of V such that

(i) $\bigcup_{i \in V_T} X_i = V$;
(ii) for each edge $e = \{u, v\} \in E$ there exists an $i \in V_T$ such that both u and v belong to X_i; and
(iii) for all $v \in V$, the set of nodes $\{i \in V_T \mid v \in X_i\}$ induces a connected subtree of T.

The maximum of $|X_i| - 1$, $i \in V_T$, is called the *width* of the tree decomposition. The *treewidth* of a graph G, denoted by $\mathrm{tw}(G)$, is the minimum width taken over all tree decompositions of G.

A graph H is *chordal* (or *triangulated*) if every cycle of length at least four has a chord, i.e., an edge between two nonconsecutive vertices of the cycle. A *triangulation* of a graph $G = (V, E)$ is a chordal graph $H = (V, E')$ such that $E \subseteq E'$. H is a *minimal triangulation* if, for any intermediate set E'' with $E \subseteq E'' \subset E'$, the graph $F = (V, E'')$ is not chordal.

The following result is very useful for our algorithms.

THEOREM 2.1 (folklore). *For any graph G, $\mathrm{tw}(G) \leq k$ if and only if there is a triangulation H of G such that $\omega(H) \leq k + 1$.*

Thus the treewidth of a graph G can be defined as the minimum of $\omega(H) - 1$ taken over all triangulations H of G, of $\omega(H) - 1$.

The *minimum fill-in* of a graph $G = (V, E)$, denoted by $\mathrm{mfi}(G)$, is the smallest value of $|E_H - E|$, where the minimum is taken over all triangulations $H = (V, E_H)$ of G.

In other words, computing the treewidth of G means finding a (minimal) triangulation with the smallest maximum clique-size, while computing the minimum fill-in means finding a (minimal) triangulation with the smallest number of edges. Clearly, in both cases it is sufficient to consider only minimal triangulations of G, which makes minimal separators and potential maximal cliques important tools of our algorithmic approach.

Minimal separators. Minimal separators and potential maximal cliques are the most important tools used in our proofs. Let a and b be two nonadjacent vertices of a graph $G = (V, E)$. A set of vertices $S \subseteq V$ is an *a, b-separator* if a and b are in different connected components of the graph $G \setminus S$. A connected component C of $G \setminus S$ is a *full* component (associated to S) if $N(C) = S$. S is a *minimal a, b-separator* of G if no proper subset of S is an a, b-separator. We say that S is a *minimal separator* of G if there are two vertices a and b such that S is a minimal a, b-separator. Notice that a minimal separator can be strictly included in another one. We denote by Δ_G the set of all minimal separators of G. A set of vertices $\Omega \subseteq V$ of a graph G is called a *potential maximal clique* if there is a minimal triangulation H of G such that Ω is a maximal clique of H. We denote by Π_G the set of all potential maximal cliques of G. Clearly, $|\Delta_G| \leq 2^n$ and $|\Pi_G| \leq 2^n$ for every graph G on n vertices, and no better upper bounds had been known prior to our work.

The following result will be used to list all minimal separators of a graph.

THEOREM 2.2 (see [4]). *There is an algorithm listing all minimal separators of an input graph G in $\mathcal{O}(n^3|\Delta_G|)$ time.*

There is a very useful relationship between the minimal separators of a graph and its minimal triangulations. Two minimal separators S and T of a graph G are said to be *crossing* if S is a minimal u,v-separator for a pair of vertices $u,v \in T$, in which case T is a minimal x,y-separator for a pair $x,y \in S$. (See [33] and [37] for a full proof.)

THEOREM 2.3 (see [37]). *The graph H is a minimal triangulation of the graph G if and only if there is a maximal set of pairwise noncrossing minimal separators $\{S_1, S_2, \ldots, S_p\}$ of G such that H can be obtained from G by completing each S_i, $i \in \{1, 2, \ldots, p\}$, into a clique.*

Although we do not use this characterization explicitly it is fundamental for our paper.

Potential maximal cliques. The following structural characterization of potential maximal cliques is extremely useful for our purposes.

For a set $K \subseteq V$, a connected component C of $G \backslash K$ is a *full component associated to* K if $N(C) = K$.

THEOREM 2.4 (see [13]). *Let $K \subseteq V$ be a set of vertices of the graph $G = (V, E)$. Let $\mathcal{C}(K) = \{C_1(K), \ldots, C_p(K)\}$ be the set of the connected components of $G \setminus K$ and let $\mathcal{S}(K) = \{S_1(K), S_2(K), \ldots, S_p(K)\}$, where $S_i(K)$, $i \in \{1, 2, \ldots, p\}$, is the set of those vertices of K which are adjacent to at least one vertex of the component $C_i(K)$. Then K is a potential maximal clique of G if and only if*

1. *$G \setminus K$ has no full component associated to K, and*
2. *the graph on the vertex set K obtained from $G[K]$ by completing each $S_i \in \mathcal{S}(K)$ into a clique is a complete graph.*

Moreover, if K is a potential maximal clique, then $\mathcal{S}(K)$ is the set of the minimal separators of G contained in K.

Remark 2.5. By Theorem 2.4, for every potential maximal clique Ω of G, the sets $S_i(\Omega)$ are exactly the minimal separators of G contained in Ω. For each minimal separator $S_i = S_i(\Omega)$, all vertices of $\Omega \setminus S_i$ are contained in the same component of $G \setminus S_i$.

The following result is an easy consequence of Theorem 2.4.

THEOREM 2.6 (see [13]). *There is an algorithm that, given a graph $G = (V, E)$ and a set of vertices $K \subseteq V$, verifies if K is a potential maximal clique of G. The time complexity of the algorithm is $\mathcal{O}(nm)$.*

According to [14], the number of potential maximal cliques of a graph G is at least $|\Delta_G|/n$ and at most $n|\Delta_G|^2 + n|\Delta_G| + 1$.

3. Computing treewidth and minimum fill-in. We describe a modification of the algorithm of [13] that, given a graph, all its minimal separators, and all its potential maximal cliques, computes the treewidth and the minimum fill-in of the graph. The running time stated in [13] could be reformulated as $\mathcal{O}(n^2\,|\Delta_G| \cdot |\Pi_G|)$. We show how the algorithm can be implemented to run in time $\mathcal{O}(n^3 \cdot |\Pi_G|)$.

For a minimal separator S and a component $C \in \mathcal{C}(S)$ of $G \backslash S$, we say that (S, C) is a *block* associated to S. We sometimes use the notation (S, C) to denote the set of vertices $S \cup C$ of the block. It is easy to notice that if $X \subseteq V$ corresponds to the set of vertices of a block, then this block (S, C) is unique: indeed, $S = N(V \setminus X)$ and $C = X \setminus S$.

A block (S, C) is called *full* if C is a full component associated to S. The graph $R(S, C) = G_S[S \cup C]$ obtained from $G[S \cup C]$ by completing S into a clique is called the *realization* of the block B.

THEOREM 3.1 (see [33]). *Let G be a noncomplete graph. Then*

$$\mathrm{tw}(G) = \min_{S \in \Delta_G} \max_{C \in \mathcal{C}(S)} \mathrm{tw}(R(S, C)),$$

$$\mathrm{mfi}(G) = \min_{S \in \Delta_G} \left(\mathrm{fill}(S) + \sum_{C \in \mathcal{C}(S)} \mathrm{mfi}(R(S, C)) \right),$$

where $\mathrm{fill}(S)$ *is the number of nonedges of* $G[S]$.

Remark 3.2. In the equations of Theorem 3.1 we may take the minimum only over the inclusion-minimal separators of G. Then all the blocks in the equations are full.

Unfortunately, Theorem 3.1 is not sufficient for computing the treewidth and the minimum fill-in. Therefore we now express the treewidth and the minimum fill-in of realizations of full blocks from realizations of smaller full blocks. Let Ω be a potential maximal clique of G. We say that a block (S', C') is *associated to* Ω if C' is a component of $G \setminus \Omega$ and $S' = N(C')$.

THEOREM 3.3 (see [13]). *Let (S, C) be a full block of G. Then*

$$\mathrm{tw}(R(S, C)) = \min_{S \subset \Omega \subseteq (S,C)} \max(|\Omega| - 1, \mathrm{tw}(R(S_i, C_i))),$$

$$\mathrm{mfi}(R(S, C)) = \min_{S \subset \Omega \subseteq (S,C)} \left(\mathrm{fill}(\Omega) - \mathrm{fill}(S) + \sum \mathrm{mfi}(R(S_i, C_i)) \right),$$

where the minimum is taken over all potential maximal cliques Ω such that $S \subset \Omega \subseteq (S, C)$ and (S_i, C_i) are the blocks associated to Ω in G such that $S_i \cup C_i \subset S \cup C$.

THEOREM 3.4. *There is an algorithm that, given a graph G together with the list of its minimal separators Δ_G and the list of its potential maximal cliques Π_G, computes the treewidth and the minimum fill-in of G in $\mathcal{O}(n^3 |\Pi_G|)$ time. Moreover, the algorithm constructs optimal triangulations for the treewidth and the minimum fill-in.*

Proof. W.l.o.g. we may assume that the input graph G is connected (otherwise we can run the algorithm for each connected component of G).

The algorithm for computing the treewidth and the minimum fill-in of a graph, using its minimal separators and its potential maximal cliques, is given below. It is a slightly different version of the algorithm given in [13].

`Input:` G, all its potential maximal cliques and all its minimal separators
`Output:` $\mathrm{tw}(G)$ and $\mathrm{mfi}(G)$
`begin`
  compute all the full blocks (S, C) and sort them by the number of vertices
  `for` each full block (S, C) taken in increasing order
    $\mathrm{tw}(R(S, C)) := |S \cup C| - 1$ if (S, C) is inclusion-minimal
      and $\mathrm{tw}(R(S, C)) := \infty$ otherwise
    $\mathrm{mfi}(R(S, C)) := \mathrm{fill}(S \cup C)$ if (S, C) is inclusion-minimal
      and $\mathrm{mfi}(R(S, C)) := \infty$ otherwise
    `for` each p.m.c. Ω with $S \subset \Omega \subseteq (S, C)$

compute the blocks (S_i, C_i) associated to Ω s.t. $S_i \cup C_i \subset S \cup C$
$\mathrm{tw}(R(S,C)) := \min(\mathrm{tw}(R(S,C)),$
$\max_i(|\Omega| - 1, \mathrm{tw}(R(S_i, C_i))))$
$\mathrm{mfi}(R(S,C)) := \min(\mathrm{mfi}(R(S,C)),$
$\mathrm{fill}(\Omega) - \mathrm{fill}(S) + \sum_i(\mathrm{mfi}(R(S_i, C_i))))$
`end_for`
`end_for`
let Δ_G^* be the set of inclusion-minimal separators of G
$\mathrm{tw}(G) := \min_{S \in \Delta_G^*} \max_{C \in \mathcal{C}(S)} \mathrm{tw}(R(S,C))$
$\mathrm{mfi}(G) := \min_{S \in \Delta_G^*}(\mathrm{fill}(S) + \sum_{C \in \mathcal{C}(S)} \mathrm{mfi}(R(S,C)))$
`end`

For the sake of completeness we shortly discuss the correctness proof. According to Theorem 3.3, at the end of the outer `for` loop the values of $\mathrm{tw}(R(S,C))$ and $\mathrm{mfi}(R(S,C))$ are correctly computed for each full block (S,C) of G. Then the treewidth and the minimum fill-in of the graph are computed using Theorem 3.1 and the fact that in Theorem 3.1 one can work only with inclusion-minimal separators.

Let us show how the algorithm can be implemented such that its running time is $\mathcal{O}(n^3 \cdot |\Pi_G|)$.

To store and manipulate the minimal separators, potential maximal cliques, and blocks we use data structures that allow us to search, to insert, or to check whether an element is inclusion-minimal in $\mathcal{O}(n)$ time.

During a preprocessing step, we realize the following operations.

- Compute the list of all full blocks and, for each minimal separator S, store a pointer towards each full block of type (S,C). These operations are performed as follows. For each minimal separator S, we compute the connected components of $G \setminus S$. For each such component C, if $N(C) = S$, then the block (S,C) is full, so we add it to the list of full blocks and store the pointer from S to (S,C). Note that this procedure will generate all the full blocks, and each of them is encountered exactly once. For a given minimal separator S, there are at most n full blocks associated to it, and thus at most n pointers to be stored. The insertion of these blocks into the list of full blocks requires $\mathcal{O}(n)$ time for each block. Hence the whole step costs $\mathcal{O}(n^2|\Delta_G|)$ time.
- For each potential maximal clique Ω, store a pointer to each full block associated to it as follows: compute the components C_i of $G \setminus \Omega$, and then $(N(C_i), C_i)$ are precisely the blocks associated to Ω. In particular there are at most n such blocks. This computation can be done in $\mathcal{O}(n^2)$ time for each potential maximal clique, hence globally in $\mathcal{O}(n^2|\Pi_G|)$ time.
- Compute all the *good triples* (S,C,Ω), where (S,C) is a full block and Ω is a potential maximal clique such that $S \subset \Omega \subseteq S \cup C$. Moreover, for each good triple we store a pointer from (S,C) to Ω. By Theorem 2.4, there are at most n minimal separators $S \subset \Omega$, each of them being the neighborhood of a component of $G \setminus \Omega$, and for each such S there is exactly one component $G \setminus S$ intersecting Ω (in particular there are at most $n|\Pi_G|$ good triples). For each component C' of $G \setminus \Omega$ we take $S = N(C')$, find the component C of $G \setminus S$ intersecting Ω, and store the pointer from (S,C) to Ω. Thus this computation takes $\mathcal{O}(nm)$ time for each potential maximal clique, hence $\mathcal{O}(nm|\Pi_G|)$ globally.

Hence this preprocessing step costs $\mathcal{O}(n^2|\Delta_G| + nm|\Pi_G|)$. Sorting the blocks by their size can be done in $\mathcal{O}(n|\Delta_G|)$ time using a bucket sort.

Observe that the cost of one iteration of the inner `for` loop is $\mathcal{O}(n^2)$, by the fact that there are at most n blocks associated to a potential maximal clique. With the data structures obtained during the preprocessing step, each full block (S, C) keeps a pointer towards each potential maximal clique Ω such that (S, C, Ω) form a good triple. Thus the number of iterations of the two nested loops is exactly the number of good triples, that is, at most $n|\Pi_G|$. It follows that the two loops cost $\mathcal{O}(n^3|\Pi_G|)$ time.

After the execution of the loops, computing the set Δ_G^* of inclusion-minimal separators costs $\mathcal{O}(n|\Delta_G|)$ time. Each inclusion-minimal separator S keeps the list of its associated blocks, obtained during the preprocessing step. Computing the maximum required by the two last instructions costs $\mathcal{O}(n)$ time for a given S. This last step costs $\mathcal{O}(n|\Delta_G|)$ time.

Altogether, the algorithm runs in time $\mathcal{O}(n^2 \cdot |\Delta_G| + n^3 \cdot |\Pi_G|)$. It is known [14] that each minimal separator is contained in at least one potential maximal clique. According to Theorem 2.4, each potential maximal clique contains at most n minimal separators. Therefore $|\Pi_G| \geq |\Delta_G|/n$. We conclude that the algorithm runs in $\mathcal{O}(n^3 \cdot |\Pi_G|)$ time.

The algorithm can be easily transformed in order to output not only the treewidth and the minimum fill-in of the graph, but also optimal triangulations with respect to these parameters. It is sufficient to keep, for each full block, the set of potential maximal cliques realizing the minimum treewidth and fill-in of its realization. At the end of the algorithm, the potential maximal cliques of the chosen blocks will be the maximal cliques of the computed optimal triangulation: optimal tree decomposition or minimum triangulation. □

Using Theorem 3.4, the only missing ingredient of our treewidth and minimum fill-in algorithms is an algorithm listing all (minimal separators and) potential maximal cliques of a graph in time $\mathcal{O}^*(c^n)$ for some $c < 2$. This requires exponential upper bounds of the type $\mathcal{O}^*(c^n)$ for some $c < 2$ for the number of minimal separators and for the number of potential maximal cliques in a graph on n vertices. In the next two sections we discuss this issue.

4. The number of minimal separators. In this section we show that any graph with n vertices has $\mathcal{O}(1.7087^n)$ minimal separators. For the main algorithm of this paper the upper bound $\mathcal{O}(1.8899^n)$ would be sufficient. However, bounding the number of minimal separators in a graph is a nice combinatorial problem, and we prefer to give here the best upper bound we were able to find.

Let S be a separator in a graph $G = (V, E)$. For $x \in V \setminus S$, we denote by $C_x(S)$ the component of $G \setminus S$ containing x. The following lemma is an exercise in [27].

LEMMA 4.1 (folklore). *A set S of vertices of G is a minimal a, b-separator if and only if a and b are in different full components associated to S. In particular, S is a minimal separator if and only if there are at least two distinct full components associated to S.*

Here is one of the main combinatorial results of our paper.

THEOREM 4.2. *For any graph G, $|\Delta_G| = \mathcal{O}(1.7087^n)$.*

Proof. For a constant α, $0 < \alpha < 1$, we distinguish two types of minimal separators: *small* separators, of size at most αn, and *big* separators, of size more than αn. We denote the cardinalities of these sets by #`small sep` and #`big sep`. Notice that $|\Delta_G| = \#\texttt{small sep} + \#\texttt{big sep}$.

The number of big separators. Let S be a minimal separator. By Lemma 4.1, there are at least two full components associated to S. Hence at least one of these full

components has at most $n(1-\alpha)/2$ vertices. For every $S \in \Delta_G$ we choose one of these full components and call it the *small* component of S, denoted by $\mathrm{s}(S)$.

By the definition of a full component, $S = N(\mathrm{s}(S))$. In particular, for distinct minimal separators S and T, we have that $\mathrm{s}(S) \neq \mathrm{s}(T)$. Therefore the number #`big sep` of big minimal separators is at most the number of small components, and we conclude that #`big sep` does not exceed the number of subsets of V of cardinality at most $n(1-\alpha)/2$; i.e.,

$$\#\texttt{big sep} \leq \sum_{i=1}^{\lceil n(1-\alpha)/2 \rceil} \binom{n}{i}.$$

By making use of Stirling's formula we deduce that

$$\#\texttt{big sep} \leq \frac{n(1-\alpha)}{2} \left(\pi n(1-\alpha)\frac{(1+\alpha)}{2}\right)^{-\frac{1}{2}} \left[\left(\frac{1-\alpha}{2}\right)^{-\frac{1-\alpha}{2}} \left(\frac{1+\alpha}{2}\right)^{-\frac{1+\alpha}{2}}\right]^n.$$

The number of small separators. To count small separators we use a different technique. Let S be a minimal separator, let x be a vertex of a full component $C_x(S)$ associated to S with minimum number of vertices, and let $X \subset V$ be a vertex subset. We say that (x, X) is a *bad pair* associated to S if $C_x(S) \subseteq X \subseteq V \setminus S$.

Claim 1. *Let $S \neq T$ be two minimal separators and let (x, X) and (y, Y) be two bad pairs associated to S and T, respectively. Then $(x, X) \neq (y, Y)$.*

Proof. Since $C_x(S) \subseteq X$ and $X \cap S = \emptyset$, we have that the connected component of $G[X]$ containing x is $C_x(S)$. Similarly, the connected component of $G[Y]$ containing y is $C_y(T)$.

Thus if $x = y$ and $X = Y$, then $C_x(S) = C_y(T)$. Since $C_x(S)$ is a full component associated to S in G, we have that $S = N(C_x(S))$ and $T = N(C_y(T))$. Therefore $S = T$, which is a contradiction. □

By Lemma 4.1, there are at least two full components associated to every small separator S. For a full component $C_x(S)$ associated to S with the minimum number of vertices, $|V \setminus (S \cup C_x(S))| \geq n \cdot (1-\alpha)/2$. For any $Z \subseteq V \setminus (S \cup C_x(S))$, the pair $(x, Z \cup C_x(S))$ is a bad pair associated to S. Therefore there are at least $2^{n\cdot(1-\alpha)/2}$ distinct bad pairs associated to S. Hence by Claim 1, the total number of bad pairs is at least $\#\texttt{small sep} \cdot 2^{n\cdot(1-\alpha)/2}$. On the other hand, the number of bad pairs is at most $n \cdot 2^n$. We conclude that

$$\#\texttt{small sep} \leq n2^{n\cdot(1+\alpha)/2}.$$

Finally, choosing $\alpha = 0.5456$, we obtain

$$|\Delta_G| = \#\texttt{small sep} + \#\texttt{big sep} = \mathcal{O}(n \cdot 1.7087^n). \qquad \square$$

Let us note that, by Theorem 2.2, Theorem 4.2 yields that all minimal separators of a graph can be listed in time $\mathcal{O}(1.7087^n)$.

5. The number of potential maximal cliques. In this section we prove that the number of potential maximal cliques in a graph with n vertices is $\mathcal{O}(1.8135^n)$ and then show that there exists an algorithm to list all potential maximal cliques of any graph in time $\mathcal{O}(1.8899^n)$.

We bound the number of potential maximal cliques by counting specific potential maximal cliques called nice potential maximal cliques. Later these nice potential maximal cliques are used to generate and to bound the number of all potential maximal cliques.

DEFINITION 5.1. *Let Ω be a potential maximal clique of a graph G, and let $S \subset \Omega$ be a minimal separator of G. We say that S is an* active separator for Ω *if Ω is not a clique in the graph $G_{\mathcal{S}(\Omega)\setminus\{S\}}$, obtained from G by completing all the minimal separators contained in Ω except S. If S is active, a pair of vertices $x, y \in S$ nonadjacent in $G_{\mathcal{S}(\Omega)\setminus\{S\}}$ is called an* active pair. *Otherwise, S is called* inactive for Ω.

DEFINITION 5.2. *We say that a potential maximal clique Ω is* nice *if at least one of the minimal separators contained in Ω is active for Ω.*

We define Π_n as the maximum number of nice potential maximal cliques in a graph on n vertices. By the theorem and lemma below, the number of potential maximal cliques is polynomially bounded by the number of nice potential maximal cliques and minimal separators.

THEOREM 5.3 (see [14]). *Let Ω be a potential maximal clique of G, and let a be a vertex of G and $G' = G \setminus \{a\}$. Then one of the following cases holds:*

1. *either Ω or $\Omega \setminus \{a\}$ is a potential maximal clique of G';*
2. *$\Omega = S \cup \{a\}$, where S is a minimal separator of G;*
3. *Ω is nice.*

LEMMA 5.4. *A graph G on n vertices has at most $n^2|\Delta_G|+n\Pi_n$ potential maximal cliques.*

Proof. Let $x_1, x_2, \ldots, x_n$ be the vertices of G and $G_i = G[\{x_1, \ldots, x_i\}]$ for all $i \in \{1, 2, \ldots, n\}$. By Theorem 5.3, for each $i \in \{2, 3, \ldots, n\}$, $|\Pi_{G_i}| \leq |\Pi_{G_{i-1}}|+n|\Delta_{G_i}|+\Pi_i$. By [14, Corollary 4], $|\Delta_{G_i}| \leq |\Delta_G|$ for any $i \in \{1, \ldots, n\}$. This yields that

$$|\Pi_{G_n}| \leq \sum_{i=1}^{n} n|\Delta_{G_i}| + \Pi_i \leq n^2|\Delta_{G_n}| + n\Pi_n. \qquad \square$$

5.1. Nonconstructive upper bound on the number of potential maximal cliques. We show that the number of potential maximal cliques in a graph is $\mathcal{O}(1.8135^n)$. This bound is obtained by finding an upper bound on the number of nice potential maximal cliques. We do this by computing two numbers (as for the separator bound): the number of nice potential maximal cliques of size less than αn and the number of nice potential maximal cliques of size at least αn for $0 < \alpha < 1$.

DEFINITION 5.5. *We say that the pair (Z, z) is a* vertex representation *of a potential maximal clique Ω in G where $Z \subset V$ and $z \in Z$ if $\Omega = N(Z) \cup \{z\}$ and $G[Z]$ is connected.*

LEMMA 5.6. *Let Ω be a potential maximal clique of G and let $z \in \Omega$. Then (Z, z) is a vertex representation of Ω if and only if Z is the vertex set of the connected component of $G \setminus (\Omega \setminus \{z\})$ containing z.*

Proof. Suppose that (Z, z) is a vertex representation of Ω. Vertex z is contained in Z, and thus every neighbor of z not in Ω has to be contained in Z. By applying this argument recursively, every connected component C of $G \setminus \Omega$, where $z \in N(C)$, is contained in Z. On the other hand, these are the only vertices in Z, because the rest are separated by $\Omega \setminus \{z\}$.

Conversely, let Z be the vertex set of the component of $G \setminus (\Omega \setminus \{z\})$ containing z. Clearly $N(Z) \cup \{z\}$ is contained in Ω, so it remains to prove that any $x \in \Omega \setminus \{z\}$ is contained in $N(Z)$. By Theorem 2.4, x is adjacent to z or there is a component C of $G \setminus \Omega$ such that both x and z are in $N(C)$. Since $C \subset Z$ the conclusion follows. $\square$

LEMMA 5.7. *Let Ω be a nice potential maximal clique of size αn. Then there exists a* vertex representation *(U, u) of Ω such that $|U| \leq 2n(1-\alpha)/3 + 1$.*

Proof. Let S be a minimal separator active for Ω, let $x, y \in S$ be an active pair, and let z be a vertex contained in $\Omega \setminus S$. By Lemma 5.6, every vertex in a potential maximal clique defines a unique vertex representation. Let $(X, x), (Y, y), (Z, z)$ be the unique vertex representations defined by Ω and, respectively, x, y, and z (Lemma 5.6).

Let us now prove that one of the sets X, Y, Z contains at most $2n(1-\alpha)/3 + 1$ vertices. By Lemma 5.6, we can observe that if (U, u) is a vertex representation of Ω, then $G[U \setminus \{u\}]$ is formed exactly by the set of connected components of $G \setminus \Omega$ having u in their neighborhood. We partition the connected components of $G \setminus \Omega$ into three sets:

- $A_1 = (X \setminus \{x\}) \cap (Y \setminus \{y\})$,
- $A_2 = (X \setminus \{x\}) \setminus (Y \setminus \{y\})$, and
- $A_3 = (V \setminus \Omega) \setminus (A_1 \cup A_2)$.

Let us emphasize that

- $|A_1 \cup A_2 \cup A_3| = n(1-\alpha)$ (because $A_1 \cup A_2 \cup A_3 = V \setminus \Omega$ and $|\Omega| = \alpha n$),
- the sets A_1, A_2, A_3 are pairwise disjoint,
- $X \setminus \{x\} = A_1 \cup A_2$,
- $Y \setminus \{y\} \subseteq A_1 \cup A_3$, and
- $Z \setminus \{z\} \subseteq A_2 \cup A_3$ (by construction, $G[A_1]$ is the union of components of $G \setminus \Omega$ that see both x and y; since S is an active separator for Ω, x, y is an active pair, and $z \notin S$, it follows by Definition 5.1 that none of these components can see z; thus $A_1 \cap Z = \emptyset$).

One of the vertex sets A_1, A_2, A_3, say A_1, is of size at least $n(1-\alpha)/3$; then $|A_2| + |A_3| \leq 2n(1-\alpha)/3$. Since $Z \setminus \{z\} \subseteq A_2 \cup A_3$, we have that $|Z \setminus \{z\}| \leq 2n(1-\alpha)/3$, and thus there exists a vertex representation $(U, z) = (Z, z)$ of Ω such that $|U| \leq (2n(1-\alpha)/3) + 1$. □

LEMMA 5.8. *For a constant $0 < \alpha < 1$ and a graph G, the number $\Pi_{\geq \alpha n}$ of nice potential maximal cliques of size at least αn is at most $n \sum_{i=1}^{2n(1-\alpha)/3} \binom{n}{i}$.*

Proof. By Lemma 5.7, every potential maximal clique Ω of size at least αn has a vertex representation (X, x) such that $|X \setminus \{x\}| \leq 2n(1-\alpha)/3$. Thus $\Pi_{\geq \alpha n}$ is at most the number of pairs (X, x), where $|X \setminus \{x\}| \leq 2n(1-\alpha)/3$ and $x \in V \setminus X$, which is at most $n \sum_{i=1}^{2n(1-\alpha)/3} \binom{n}{i}$. □

LEMMA 5.9. *For a constant $0 < \alpha < 1$ and a graph G, the number $\Pi_{<\alpha n}$ of nice potential maximal cliques of size less than αn is at most $n \cdot 2^{n(2+\alpha)/3}$.*

Proof. We say that (x, X) is a *bad pair* associated to Ω if $\Omega = N(C_x) \cup \{x\}$, where C_x is the connected component of $G[X \cup \{x\}]$ containing x.

To prove that a bad pair is unique for a potential maximal clique, we let (x, X) be a bad pair associated to Ω_x, and let (y, Y) be a bad pair associated to Ω_y, where $\Omega_x \neq \Omega_y$. We claim that $(x, X) \neq (y, Y)$. Targeting a contradiction, we assume that $x = y$ and that $X = Y$. From the definition of a bad pair, we know that $N(X) \cup \{x\} = N(Y) \cup \{y\}$. But this is a contradiction because $N(X) \cup \{x\} = \Omega_x$, $N(Y) \cup \{y\} = \Omega_y$, and $\Omega_x \neq \Omega_y$.

By Lemma 5.7, every potential maximal clique Ω of size less than αn has a vertex representation (U, u) such that $|V \setminus (\Omega \cup U)| \geq n(1-\alpha)/3$. Thus we can create $2^{n(1-\alpha)/3}$ unique bad pairs (u, X) for Ω by selecting $X = U \cup Z$, where Z is any of the $2^{n(1-\alpha)/3}$ subsets of $V \setminus N[U]$. The number of bad pairs is at most $n \cdot 2^n$, and we get that $n \cdot 2^n \geq \Pi_{<\alpha n} \cdot 2^{n(1-\alpha)/3}$. □

LEMMA 5.10. *The number of nice potential maximal cliques in a graph G with n vertices is $\mathcal{O}(1.8135^n)$.*

Proof. The number of nice potential maximal cliques Π_n is at most $\Pi_{\geq \alpha n} + \Pi_{<\alpha n}$ for $0 \leq \alpha \leq 1$. By using Lemmas 5.8 and 5.9, we have that $\Pi_n \leq n \cdot \sum_{i=1}^{2n(1-\alpha)/3} \binom{n}{i} +$

$n \cdot 2^{n(2+\alpha)/3}$. By making use of Stirling's formula for $\alpha = 0.5763$, we obtain the bound $\mathcal{O}(1.81349^n)$. □

THEOREM 5.11. *For every graph G on n vertices, $|\Pi_G| = \mathcal{O}(1.8135^n)$.*

Proof. By Lemma 5.4, G has at most $n^2|\Delta_G| + n\Pi_n$ potential maximal cliques. By Theorem 4.2 and Lemma 5.10, this yields that $\Pi_G = \mathcal{O}(n^2 1.7087^n + n1.81349^n) = \mathcal{O}(1.8135^n)$. □

5.2. Listing potential maximal cliques. Notice that the proof of Lemma 5.9 is nonconstructive; i.e., the proof cannot be turned into an algorithm listing potential maximal cliques, which is required by the algorithms computing treewidth and fill-in.

Roughly speaking, the idea of this subsection is to show that each potential maximal clique of a graph can be identified by a set of vertices of size at most $n/3$. The algorithm for generating all the potential maximal cliques of a graph lists all the sets of vertices of size at most $n/3$ and then, by applying a polynomial time procedure for each set, generates all the potential maximal cliques of the input graph. A potential maximal clique can be recognized by the following three representations.

DEFINITION 5.12. *Let Ω be a potential maximal clique of G. The triple (S, a, b) is called a* separator representation *of Ω if S is a minimal separator of G, $a \in S$, $b \in V \setminus S$, and $\Omega = S \cup (N(a) \cap C_b)$, where C_b is the component of $G \setminus S$ containing b.*

The number of all possible separator representations of a graph is at most $n^2|\Delta_G|$. Unfortunately, not every nice potential maximal clique has a separator representation. The two definitions below allow us to represent a potential maximal clique by using a small vertex set.

DEFINITION 5.13. *For a potential maximal clique Ω of G, we say that a pair (X, c), where $X \subset V$ and $c \in X$, is a* partial representation *of Ω if $\Omega = N(C_c) \cup (X \setminus C_c)$, where C_c is the connected component of $G[X]$ containing c.*

DEFINITION 5.14. *For a potential maximal clique Ω of G, we say that a triple (X, x, c), where $X \subset V$ and $x, c \notin X$, is an* indirect representation *of Ω if $\Omega = N(C_c \cup D_x \cup \{x\}) \cup \{x\}$, where*

- *C_c is the connected component of $G \setminus N[X]$ containing c;*
- *D_x is the vertex set of the union of all connected components C' of $G[X]$ such that $x \in N(C')$.*

Let us note that for a given vertex set X and two vertices x, c one can check in polynomial time whether the pair (X, c) is a partial representation or if the triple (X, x, c) is a separator representation or indirect representation of a (unique) potential maximal clique Ω.

The next step is to partition the vertex sets of the graph into smaller sets that can be used to create one of the three representations for the nice potential maximal clique. First the following theorem is required.

THEOREM 5.15 (see [14]). *Let Ω be a potential maximal clique of G and $S \subset \Omega$ a minimal separator, active for Ω. Let (S, C) be the block associated to S containing Ω, and let $x, y \in \Omega$ be an active pair. Then $\Omega \setminus S$ is a minimal x, y-separator in $G[C \cup \{x, y\}]$.*

We are now ready to divide the set of connected components of $G \setminus \Omega$ into subsets.

LEMMA 5.16. *Let Ω be a nice potential maximal clique, S be a minimal separator active for Ω, $x, y \in S$ be an active pair, and C be the component of $G \setminus S$ containing $\Omega \setminus S$. There is a partition (D_x, D_y, D_r) of $C \setminus \Omega$ such that $N(D_x \cup \{x\}) \cap C = N(D_y \cup \{y\}) \cap C = \Omega \setminus S$.*

Proof. By Theorem 5.15, $\Omega \setminus S$ is a minimal x, y-separator in $G[C \cup \{x, y\}]$. Let C_x be the full component associated to $\Omega \setminus S$ in $G[C \cup \{x, y\}]$ containing x, $D_x = C_x \setminus \{x\}$,

and let C_y be the full component associated to $\Omega \setminus S$ in $G[C \cup \{x, y\}]$ containing y, $D_y = C_y \setminus \{y\}$, and $D_r = C \setminus (\Omega \cup D_x \cup D_y)$. Since $D_x \cup \{x\}$ and $D_y \cup \{y\}$ are full components of $\Omega \setminus S$, we have that $N(D_x \cup \{x\}) \cap C = N(D_y \cup \{y\}) \cap C = \Omega \setminus S$. □

By the lemma below we get that every potential maximal clique Ω that is not defined by the closed neighborhood of a vertex or defined by a separator representation has a neighbor outside of Ω in a full connected component of S.

LEMMA 5.17. *Let Ω be a potential maximal clique of G, S be a minimal separator contained in Ω, and C be the component of $G \setminus S$ intersecting Ω. Then one of the following holds:*

1. *there is a vertex a such that $\Omega = N[a]$;*
2. *Ω has a separator representation;*
3. *$\Omega = N(C \setminus \Omega)$.*

Proof. Suppose that there is a vertex $a \in \Omega$ having no neighbor in $C \setminus \Omega$. We consider first the case $a \in \Omega \setminus S$. We claim that in this case $\Omega = N[a]$. Because $a \in \Omega \setminus S \subseteq C$, we conclude that $N[a] \subseteq \Omega$. Thus to prove the claim we need to show that $\Omega \subseteq N[a]$. For sake of contradiction, suppose that there is $b \in \Omega$ which is not adjacent to a. By Theorem 2.4, every two nonadjacent vertices of a potential maximal clique are contained in some minimal separator $S_i(\Omega)$. Thus both a and b should have neighbors in a component $C_i(\Omega)$ of $G \setminus \Omega$. Since $a \in \Omega \setminus S \subseteq C$, we have that $C_i(\Omega) \subseteq C \setminus \Omega$. But this contradicts the assumption that a has no neighbors in $C \setminus \Omega$.

The case $a \in S$ is similar. Suppose that $\Omega \setminus S \neq N(a) \cap C$; i.e., there is a vertex $b \in \Omega \setminus S$ nonadjacent to a. Then again, a and b are contained in some minimal separator and thus should have neighbors in a component $C_i(\Omega) \subseteq C$ of $G \setminus \Omega$ which is a contradiction.

Since C is a component of $G \setminus S$ and S is contained in Ω, we have that $N(C \setminus \Omega) \subseteq \Omega$. If every vertex of Ω is adjacent to a vertex of $C \setminus \Omega$, then $\Omega = N(C \setminus \Omega)$. □

We state now the main tool for upper bounding the time required to list the set of nice potential maximal cliques.

LEMMA 5.18. *Let Ω be a nice potential maximal clique of G. Then one of the following holds:*

1. *there is a vertex a such that $\Omega = N[a]$;*
2. *Ω has a separator representation;*
3. *Ω has a partial representation (X, c) such that $|X| \leq n/3$;*
4. *Ω has a indirect representation (X, x, c) such that $|X| \leq n/3$.*

Proof. Let S be a minimal separator active for Ω, $x, y \in S$ be an active pair, and C be the component of $G \setminus S$ containing $\Omega \setminus S$. By Lemma 5.16, there is a partition (D_x, D_y, D_r) of $C \setminus \Omega$ such that $N(D_x \cup \{x\}) \cap C = N(D_y \cup \{y\}) \cap C = \Omega \setminus S$. If one of the sets D_x, D_y, say D_x, is empty, then $N(D_x \cup \{x\}) \cap C = N(x) \cap C = \Omega \setminus S$, and thus the triple (S, x, z) is a separator representation of Ω.

Suppose that none of the first two conditions of the lemma holds. Then D_x and D_y are nonempty. In order to argue that Ω has a partial representation (X, c) or an indirect representation (X, x, c) such that $|X| \leq n/3$, we partition the graph further. Let $R = \Omega \setminus S$, and let D_S be the union of all full components associated to S in $G \setminus \Omega$. The vertex set D_x is the union of vertex sets of all connected components C' of $G \setminus (\Omega \cup D_S)$ such that x is contained in the neighborhood of C'. Thus a connected component C' of $G \setminus (\Omega \cup D_S)$ is contained in D_x if and only if $x \in N(C')$. Similarly, a connected component C' of $G \setminus (\Omega \cup D_S)$ is contained in D_y if and only if $y \in N(C')$. We also define $D_r = V \setminus (\Omega \cup D_S \cup D_x \cup D_y)$, which is the set of vertices of the components of $G \setminus (\Omega \cup D_S)$ which are not in D_x and D_y.

We partition S in the following sets:

- $S_{\overline{x}} = (S \setminus N(D_x)) \cap N(D_y)$;
- $S_{\overline{y}} = (S \setminus N(D_y)) \cap N(D_x)$;
- $S_{\overline{xy}} = S \setminus (N(D_y) \cup N(D_x))$;
- $S_{xy} = S \cap N(D_y) \cap N(D_x)$.

Thus $S_{\overline{x}}$ is the set of vertices in S with no neighbor in D_x and with at least one neighbor in D_y, $S_{\overline{y}}$ is the set of vertices in S with no neighbor in D_y and with at least one neighbor in D_x, $S_{\overline{xy}}$ is the set of vertices in S with neighbors in neither D_x nor D_y, and, finally, S_{xy} is the set of vertices in S with neighbors in both D_x and D_y. Notice that the vertex sets D_S, D_x, D_y, D_r, R, $S_{\overline{x}}$, $S_{\overline{y}}$, $S_{\overline{xy}}$, and S_{xy} are pairwise disjoint. The set S_{xy} is mentioned only to complete the partition of S and will not be used in the rest of the proof.

Both for size requirements and because of the definition of indirect representation we cannot use the sets $S_{\overline{x}}$, $S_{\overline{y}}$, and $S_{\overline{xy}}$ directly; they have to be represented by the sets $Z_{\overline{x}}$, $Z_{\overline{y}}$, and $Z_{\overline{r}}$, which are subsets of the vertex sets D_y, D_x, and D_r. By the definition of $S_{\overline{x}}$ and $S_{\overline{y}}$ it follows that there exist two vertex sets $Z_{\overline{x}} \subseteq D_y$ and $Z_{\overline{y}} \subseteq D_x$ such that $S_{\overline{x}} \subseteq N(Z_{\overline{x}})$ and $S_{\overline{y}} \subseteq N(Z_{\overline{y}})$. Let Z be such a set of minimum cardinality. By Lemma 5.17, $\Omega = N(D_x \cup D_y \cup D_r)$ since cases 1 and 2 of Lemma 5.17 correspond to cases 1 and 2 of the lemma we are proving. Thus, there exists a vertex set $Z_{\overline{r}} \subseteq D_r$ such that $S_{\overline{xy}} \subseteq N(Z_{\overline{r}})$. Let Z be such a set of minimum cardinality. A sketch of how these vertex sets relate to each other is given in Figure 5.1.

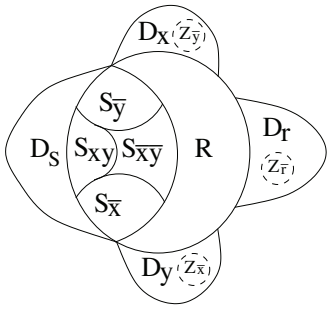

FIG. 5.1. *The figure shows a sketch of how the vertex sets $D_S, D_x, D_y, D_r, R, S_{\overline{x}}, S_{\overline{y}}, S_{\overline{xy}}$, and S_{xy} partition the graph G, and how the sets $Z_{\overline{x}}, Z_{\overline{y}}$, and $Z_{\overline{r}}$ relate to this partition.*

Let C^* be a connected component of $G[D_S]$ (let us remind that $N(C^*) = S$). We define the following sets:

- $X_1 = C^* \cup R$;
- $X_2 = D_x \cup Z_{\overline{x}} \cup Z_{\overline{r}}$;
- $X_3 = D_y \cup Z_{\overline{y}} \cup Z_{\overline{r}}$.

First we claim that

- the pair (X_1, c), where $c \in C^*$, is a partial representation of Ω;
- the triple (X_2, x, c), where $c \in C^*$, is an indirect representation of Ω;
- the triple (X_3, y, c), where $c \in C^*$, is an indirect representation of Ω.

In fact, the pair $(X_1, c) = (C^* \cup R, c)$ is a partial representation of Ω because $N(C^*) \cap R = \emptyset$, C^* induces a connected graph, and $\Omega = N(C^*) \cup R$.

To prove that $(X_2, x, c) = (D_x \cup Z_{\overline{x}} \cup Z_{\overline{r}}, x, c)$ is an indirect representation of Ω, we have to show that $\Omega = N(C_c \cup D'_x \cup \{x\}) \cup \{x\}$, where C_c is the connected component of $G \setminus N[X_2]$ containing c, and D'_x is the vertex set of the union of all connected components C' of $G[X_2]$ such that $x \in N(C')$. Notice that $(S \cup C^*) \cap X_2 = \emptyset$ and

that $S \subseteq N(X_2)$ since $S \subseteq N(D_x \cup Z_{\overline{x}} \cup Z_{\overline{r}})$ and $X_2 = D_x \cup Z_{\overline{x}} \cup Z_{\overline{r}}$. Hence the connected component C_c of $G \setminus N[X_2]$ containing c is C^*.

Every connected component C' of $G[X_2]$ is contained in $D_x, Z_{\overline{x}}$, or $Z_{\overline{r}}$ since $\Omega \cap (D_x \cup Z_{\overline{x}} \cup Z_{\overline{r}}) = \emptyset$ and Ω separates $D_x, Z_{\overline{x}}$, and $Z_{\overline{r}}$. From the definition of D_x it follows that $x \in N(C')$ for every component C' of $G[D_x]$, and from the definition of D_y and D_r it follows that $x \notin N(C')$ for every component C' of $G[Z_{\overline{x}} \cup Z_{\overline{r}}]$. We can now conclude that D_x is the vertex set of the union of all connected components C' of $G[X_2]$ such that $x \in N(C')$. It remains to prove that $\Omega = N(C^* \cup D_x \cup \{x\}) \cup \{x\}$. By Lemma 5.16, we have that $\Omega \setminus S = R$ is a subset of $N(D_x \cup \{x\})$ and $N(D_y \cup \{y\})$, and we remember that $N(C^*) = S$. From this observation it follows that $\Omega = N(C^* \cup D_x \cup \{x\}) \cup \{x\}$ since $N(C^* \cup D_x \cup \{x\}) = (S \cup R) \setminus \{x\}$.

By similar arguments, (X_3, y, c) is an indirect representation of Ω.

To conclude the proof of the lemma, we argue that at least one of the vertex sets X_1, X_2, or X_3 used to represent Ω contains at most $n/3$ vertices.

We partition the graph into the following three sets:

- $V_1 = D_S \cup R$;
- $V_2 = D_x \cup S_{\overline{x}} \cup S_{\overline{xy}}$;
- $V_3 = D_y \cup S_{\overline{y}} \cup D_r$.

These sets are pairwise disjoint, and at least one of them is of size at most $n/3$; to prove the lemma we show that $|X_1| \leq |V_1|$, $|X_2| \leq |V_2|$, and $|X_3| \leq |V_3|$.

$|X_1| \leq |V_1|$. Since $C^* \subseteq D_S$, we have that $X_1 = C^* \cup R \subseteq V_1 = D_S \cup R$.

$|X_2| \leq |V_2|$. To prove the inequality we need the additional result

$$|Z_{\overline{x}}| \leq |S_{\overline{x}}|, \ |Z_{\overline{y}}| \leq |S_{\overline{y}}|, \text{ and } |Z_{\overline{r}}| \leq |S_{\overline{xy}}|. \tag{5.1}$$

In fact, since $Z_{\overline{x}}$ is the smallest subset of D_y such that $S_{\overline{x}} \subseteq N(Z_{\overline{x}})$, we have that for any vertex $u \in Z_{\overline{x}}$, $S_{\overline{x}} \not\subseteq N(Z_{\overline{x}} \setminus \{u\})$. Thus u has a private neighbor in $S_{\overline{x}}$, or in other words there exists $v \in S_{\overline{x}}$ such that $\{u\} = N(v) \cap Z_{\overline{x}}$. Therefore $S_{\overline{x}}$ contains at least one vertex for every vertex in $Z_{\overline{x}}$, which yields $|Z_{\overline{x}}| \leq |S_{\overline{x}}|$. The proofs of inequalities $|Z_{\overline{y}}| \leq |S_{\overline{y}}|$ and $|Z_{\overline{r}}| \leq |S_{\overline{xy}}|$ are similar.

Now the proof of $|X_2| \leq |V_2|$, which is equivalent to $|D_x \cup Z_{\overline{x}} \cup Z_{\overline{r}}| \leq |D_x \cup S_{\overline{x}} \cup S_{\overline{xy}}|$, follows from (5.1) and the fact that all subsets on each side of the inequality are pairwise disjoint.

$|X_3| \leq |V_3|$. This inequality is equivalent to $|D_y \cup Z_{\overline{y}} \cup Z_{\overline{r}}| \leq |D_y \cup S_{\overline{y}} \cup D_r|$. Again, the sets on each side of the inequality are pairwise disjoint. $|Z_{\overline{r}}| \leq |D_r|$ because $Z_{\overline{r}} \subseteq D_r$, and $|Z_{\overline{y}}| \leq |S_{\overline{y}}|$ by (5.1).

Thus $\min\{|X_1|, |X_2|, |X_3|\} \leq n/3$, which concludes the proof of the lemma. ∎

LEMMA 5.19. *The set of nice potential maximal cliques in a graph G on n vertices can be listed in listed in $\mathcal{O}^*(\binom{n}{n/3})$ time.*

Proof. By Lemma 5.18, the number of possible partial representations (X, c) and indirect representations (X, x, c) with $|X| \leq n/3$ is at most $2n^2 \sum_{i=1}^{n/3} \binom{n}{i}$. By Theorem 4.2, the number of all possible separator representations is at most $n^2|\Delta_G| \leq n^2\binom{n}{n/3}$, and we deduce that the number of nice potential maximal cliques is at most $2n^2 \sum_{i=1}^{n/3} \binom{n}{i}$. Moreover, these potential maximal cliques can be computed in $\mathcal{O}^*(\binom{n}{n/3})$ time as follows. We enumerate all the triples (S, a, b) where S is a minimal separator and a, b are vertices, and check if the triple is the separator representation of a potential maximal clique Ω; if so, we store this potential maximal clique. We also enumerate all the potential maximal cliques of type $N[a], a \in V(G)$ in polynomial time. Finally, by listing all the sets X of at most $n/3$ vertices and all the couples

of vertices (x, c), we compute all the nice potential maximal cliques with a partial representation (X, c) or an indirect representation (X, x, c). □

THEOREM 5.20. *There is an algorithm to list all potential maximal cliques of a graph G on n vertices in time $\mathcal{O}(1.8899^n)$.*

Proof. Let $x_1, x_2, \ldots, x_n$ be the vertices of G and $G_i = G[\{x_1, \ldots, x_i\}]$ for all $i \in \{1, 2, \ldots, n\}$. Theorem 5.3 and Lemma 5.19 imply that $|\Pi_{G_i}| \leq |\Pi_{G_{i-1}}| + n|\Delta_{G_i}| + 2n^2 \sum_{i=1}^{n/3} \binom{n}{i}$ for all $i \in \{2, 3, \ldots, n\}$. By Theorem 4.2, $|\Pi_G| \leq 2n^3 \sum_{i=1}^{n/3} \binom{n}{i}$.

Clearly, if we have the potential maximal cliques of G_{i-1}, the potential maximal cliques of G_i can be computed in $\mathcal{O}^*(|\Pi_{G_{i-1}}| + \binom{n}{n/3})$ time by making use of Theorems 5.3 and 4.2 and Lemma 5.19. The graph G_1 has a unique potential maximal clique, namely, $\{x_1\}$. Therefore Π_G can be listed in time $\mathcal{O}^*(\binom{n}{n/3})$ time which is $\mathcal{O}(1.8899^n)$. □

Theorems 3.4 and 5.20 imply the main result of this paper.

THEOREM 5.21. *For a graph G on n vertices, the treewidth and the minimum fill-in of G can be computed in $\mathcal{O}(1.8899^n)$ time.*

6. AT-free graphs. In this section we establish exact algorithms to compute the treewidth and the minimum fill-in of AT-free graphs which are faster than the ones obtained for general graphs in the previous section. Both algorithms are based on new upper bounds on the number of minimal separators and the number of potential maximal cliques in AT-free graphs.

Three pairwise nonadjacent vertices of a graph G form an *asteroidal triple* (AT) if any two of them are connected by a path avoiding the neighborhood of the third vertex. Graphs without asteroidal triples are called *AT-free*.

Corneil, Olariu, and Stewart studied structural properties of AT-free graphs in their fundamental paper [17]. Among other results, they showed that every connected AT-free graph has a dominating pair, where two vertices x and y of G form a *dominating pair* (DP for short) if the vertex set of each x, y-path is a dominating set of G.

AT-free graphs contain cocomparability graphs, permutation graphs, interval graphs, and cobipartite graphs. Thus the treewidth problem and the minimum fill-in problem remain NP-hard when restricted to AT-free graphs [2, 48].

Remark 6.1. There is a well-known cobipartite (and thus AT-free) graph consisting of two cliques of size $n/2$ and a perfect matching between them which has precisely $2^{n/2} - 2$ minimal separators. It is not hard to show that this is indeed the largest number of minimal separators of a cobipartite graph on n vertices.

First we show that $|\Pi_G| = \mathcal{O}^*(|\Delta_G|)$ for AT-free graphs, improving a result in [13, Corollary 5.2]. This also establishes an algorithm to list the potential maximal cliques of an AT-free graph in $\mathcal{O}^*(|\Delta_G|)$ time. Then we prove that an AT-free graph on n vertices has at most $2^{n/2+3}$ minimal separators.

First let us summarize some structural properties of potential maximal cliques in AT-free graphs.

LEMMA 6.2 (Proposition 5.1 of [13]). *Let Ω be a potential maximal clique of an AT-free graph G. Then the set $\mathcal{S}(\Omega)$ of minimal separators contained in Ω has at most two inclusion-maximal elements.*

LEMMA 6.3 (Theorem 3.10 of [13]). *Let G be a graph and Ω be a potential maximal clique of G such that $\mathcal{S}(\Omega)$ has a unique inclusion-maximal element S. Then $\Omega \setminus S$ is a connected component of $G \setminus S$.*

Let S and T be two noncrossing minimal separators of G, incomparable with respect to inclusion. Thus S meets a unique component of $G \setminus T$, say $C_S(T)$, and T

meets a unique component of $G \setminus S$, say $C_T(S)$. We define the *piece between* S and T as $P(S,T) = S \cup T \cup (C_T(S) \cap C_S(T))$.

LEMMA 6.4 (Theorem 3.11 of [13]). *Let G be a graph and Ω be a potential maximal clique of G such that $\mathcal{S}(\Omega)$ has exactly two inclusion-maximal elements S and T. Then $\Omega = P(S,T)$.*

LEMMA 6.5. *Let G be an AT-free graph and Ω be a potential maximal clique of G such that $\mathcal{S}(\Omega)$ has two inclusion-maximal elements S and T. Choose $s \in S \setminus T$. Then $\Omega = S \cup (N(s) \cap C_T(S))$.*

Proof. By Lemma 6.4, $\Omega = P(S,T)$. Clearly s is in the unique component $C_S(T)$ of $G \setminus T$ meeting S, so $N(s) \cap C_T(S) \subseteq P(S,T)$. Consequently, $S \cup (N(s) \cap C_T(S)) \subseteq \Omega$.

Conversely, suppose there is a vertex $t \in \Omega$, not contained in $S \cup (N(s) \cap C_T(S))$. Let $S' = (S \setminus \{s\}) \cup (N(s) \cap C_T(S))$. Clearly S' separates s and any vertex of $C_T(S) \setminus S'$ in G; in particular S' separates s and t. It follows that there is a minimal separator $S'' \subseteq S'$ of G, contained in Ω and separating two vertices of Ω. According to Theorem 2.4, for each minimal separator U contained in Ω, Ω intersects exactly one component of $G \setminus U$, which is a contradiction. □

THEOREM 6.6. *An AT-free graph G has at most $n^2|\Delta_G| + n|\Delta_G| + 1$ potential maximal cliques. Furthermore, there is an algorithm to list the potential maximal cliques of an AT-free graph in $\mathcal{O}^*(|\Delta_G|)$ time.*

Proof. If G has no minimal separator, then G is a complete graph, and its vertex set is the unique potential maximal clique of G.

Suppose now that G is not complete. Fix a minimal separator S of G. By Lemma 6.3, the number of potential maximal cliques Ω such that S is the unique inclusion-maximal element of $\mathcal{S}(\Omega)$ is bounded by the number of connected components of $G \setminus S$. Hence, there are at most n such potential maximal cliques.

Now let us consider the potential maximal cliques Ω for which S is one of the two inclusion-maximal separators contained in $\mathcal{S}(\Omega)$. For any component C of $G \setminus S$, there are, by Lemma 6.5, at most $|S|$ such potential maximal cliques contained in $S \cup C$. It follows that there are at most n^2 potential maximal cliques of this type.

Therefore, G contains at most $(n^2+n)|\Delta_G|+1$ potential maximal cliques. These combinatorial arguments can easily be transformed into an algorithm listing the potential maximal cliques of an AT-free graph in time $\mathcal{O}^*(|\Delta_G|)$. □

Hence Theorem 3.4 implies that to construct an $O(1.4142^n)$ algorithm computing the treewidth and the minimum fill-in of an AT-free graph it is enough to prove that the number of minimal separators in an AT-free graph is $O(1.4142^n)$.

Our proof that the number of minimal separators in an AT-free graph is at most $2^{n/2+3}$ relies on properties of 2LexBFS, i.e., a combination of two runs of lexicographic breadth-first-search (also called 2-sweep LexBFS), on AT-free graphs established by Corneil, Olariu, and Stewart in [18].

DEFINITION 6.7. *A vertex ordering $x_n, x_{n-1}, \ldots, x_1$ is said to be a* 2LexBFS ordering *of G if some* 2LexBFS(G) *returns the vertices in this order (starting with x_n) during the second sweep of LexBFS on G where x_n is supposed to be the last vertex of the first sweep of LexBFS on G.*

We shall write $u \prec v$ if $u = x_i$, $v = x_j$, and $i < j$. A 2LexBFS ordering and the levels $L_0 = \{x_n\}, L_1 = N(x_n), \ldots, L_i = \{x_j : d(x_j, x_n) = i\}, \ldots, L_r$ are called a 2*LexBFS scheme* of G. Consider any 2LexBFS scheme. Clearly all neighbors of a vertex $v \in L_i$ are contained in $L_{i-1} \cup L_i \cup L_{i+1}$. For a vertex $v \in L_i$ we denote $N(v) \cap L_{i-1}$ by $N^{\uparrow}(v)$, and we denote $N(v) \cap L_{i+1}$ by $N_{\downarrow}(v)$.

THEOREM 6.8 (see [18]). *Every 2LexBFS ordering $x_n, x_{n-1}, \ldots, x_1$ of a connected AT-free graph has the* dominating pair-property *(DP-property); i.e., for all*

$i \in \{1, 2, \ldots, n\}$, (x_n, x_i) is a dominating pair of the graph $G[\{x_i, x_{i+1}, \ldots, x_n\}]$.

The following easy consequence of Theorem 6.8 is useful.

LEMMA 6.9. *Let $x_n, x_{n-1}, \ldots, x_1$ be a 2LexBFS ordering of an AT-free graph G, and let $L_0, L_1, \ldots, L_r$ be the corresponding 2LexBFS scheme. Let $s > r$, $x_s, x_r \in L_i$ and $\{x_r, x_s\} \notin E$. Then $N^{\uparrow}(x_r) \subseteq N^{\uparrow}(x_s)$.*

Proof. Let $w \in N^{\uparrow}(x_r) \setminus N^{\uparrow}(x_s)$. Then the path $x_r, w, u_{i-2}, \ldots, u_1, x_n$ with $u_j \in L_j$ and $u_{j-1} \in N^{\uparrow}(u_j)$ for all $j = i-2, \ldots, 1$ contains no neighbor of x_s, contradicting the DP-property of a 2LexBFS scheme of an AT-free graph. ∎

THEOREM 6.10. *An AT-free graph on n vertices has at most $2^{n/2+3}$ minimal separators.*

Proof. Let G be an AT-free graph. Let $x_n, x_{n-1}, \ldots, x_1$ be a 2LexBFS ordering of G, and let $L_0, L_1, \ldots, L_r$ be the levels of the corresponding 2LexBFS scheme.

Let S be any minimal separator of G. Let C and C' be two (not necessarily full) components of $G \setminus S$. We claim that at most one level of the 2LexBFS scheme may contain vertices of C and C'. Suppose not. Let L_i and L_{i+1} be levels containing vertices of C and C'. Then there are edges $\{u, v\}$ in C and $\{w, x\}$ in C' such that $u, w \in L_i$ and $v, x \in L_{i+1}$. W.l.o.g. assume $u \prec w$. Then Lemma 6.9 implies that w and v are adjacent, a contradiction.

Let C and C' be two (not necessarily full) components of $G \setminus S$ such that both contain vertices of some level of the 2LexBFS scheme, say L_i. Furthermore, assume $C \cap L_{i-1} \neq \emptyset$ and $C' \cap L_{i-1} = \emptyset$. Hence there is an edge $\{u, v\}$ in C such that $u \in L_i$ and $v \in L_{i-1}$. Then for each $w \in C'$ holds $w \prec u$. Otherwise $u \prec w$, $w \in L_i$, and Lemma 6.9 would imply that w and v are adjacent, a contradiction.

Finally we claim that in this case $c' \prec c$ for each vertex $c \in C$ and each vertex $c' \in C'$. This is obviously true if one of c and c' is not in L_i. It remains to consider the case $c \in L_i$, $c' \in L_i$. To the contrary assume $c \prec c'$. Since C contains vertices of L_i and L_{i-1}, there is a path in C starting in c passing through vertices of $C \cap L_i$ only until it passes through an edge $\{u, v\}$ in C with $u \in L_i$ and $v \in L_{i-1}$. This path can be extended to a path from c to x_n that does not contain a neighbor of c' although $c \prec c'$, a contradiction to the DP-property.

Now we are able to upper bound the number of those minimal separators in an AT-free graph in which no full component contains only vertices of one level. Simply divide the vertex set into two halves: $A = \{x_n, x_{n-1}, \ldots, x_{\lceil n/2 \rceil + 1}\}$ and $B = \{x_{\lfloor n/2 \rfloor}, \ldots, x_1\}$. Now consider two full components C and C' of a minimal separator S of G, i.e., $S = N(C) = N(C')$. Then either C or C' is a subset of either A or B, and surely each of C and C' uniquely determines S. Hence we simply consider all subsets of A and all subsets of B as possible full components of a minimal separator of G. Consequently, there are at most $2^{n/2+1}$ minimal separators of this type.

It remains to upper bound the number of all those minimal separators S of an AT-free graph G for which each full component is neither a subset of A nor a subset of B. Hence at least one full component of S contains only vertices from one level of the 2LexBFS scheme.

Let S be such a minimal separator of G. Let C and C' be two full components of $G \setminus S$. W.l.o.g. assume $C \subseteq L_i$. Hence $x_{\lfloor n/2 \rfloor} \in L_i$, and thus the level L_i is uniquely determined.

$C' \cap \bigcup_{j=0}^{i-1} L_j = \emptyset$ since otherwise $c \prec c'$ for all $c \in C$ and all $c' \in C'$, and either C or C' is a subset of A or B. Similarly C' must contain vertices of L_i. Consequently, $C' \subseteq \bigcup_{j=i}^{r} L_j$. It is easy to see that $C \subseteq L_i$ and $S = N(C)$ imply $N(C') = S \subseteq \bigcup_{j=i-1}^{i+1} L_j$. Furthermore, $N(C) = N(C') = S$ implies $S \cap L_{i-1} = N^{\uparrow}(C \cap L_i) = N^{\uparrow}(C' \cap L_i)$.

Now let us consider the graph $G' = G \setminus \bigcup_{j=0}^{i-1} L_j$. Then $S' = S \setminus \bigcup_{j=0}^{i-1} L_j$ is

a separator of G'; C and C' are components of $G' \setminus S'$. Furthermore, every vertex of $S' \subseteq S$ has a neighbor in C and C', and thus S' is a minimal separator of G'. Consequently, every minimal separator S of G for which no full component is a subset of A or B corresponds uniquely to a minimal separator of G'. Notice that G' has at most $n-1$ vertices since we remove at least one vertex of L_{i-1} from G to obtain G'.

Let $f(n)$ be a function such that $f(n)$ is an upper bound for the number of minimal separators in an n-vertex AT-free graph. Then we establish the recurrence $f(n) \geq 2^{n/2+1} + f(n-1)$ and conclude with $f(n) = 4 \cdot 2^{n/2+1} = 8 \cdot 2^{n/2}$. □

Combining Theorems 3.4, 6.6, and 6.10, we obtain algorithms for AT-free graphs that are faster than the corresponding ones for general graphs.

THEOREM 6.11. *There are algorithms to compute the treewidth and the minimum fill-in of an AT-free graph in $\mathcal{O}(1.4142^n)$ time.*

7. Open problems and final remarks. Planar graphs. The computational complexity of treewidth restricted to planar graphs is a longstanding open problem in graph algorithms. The treewidth of planar graphs can be approximated within a constant factor of 1.5. More precisely, Seymour and Thomas [42] gave a polynomial algorithm for computing the *branchwidth* of planar graphs, and the latter parameter differs by at most a factor of 1.5 from the treewidth.

In the case of planar graphs with n vertices, the treewidth is at most $\mathcal{O}(\sqrt{n})$.

THEOREM 7.1 (see [26]). *For any planar graph G on n vertices,* $\mathrm{tw}(G) \leq 3.182\sqrt{n} + \mathcal{O}(1)$.

Also, given a graph G and a number k, one can decide if $\mathrm{tw}(G) \leq k$ in $\mathcal{O}^*(n^k)$ time, either using the algorithm of Arnborg Corneil, and Proskurowski [2] or our technique, restricted to potential maximal cliques of size at most $k+1$.

Consequently, the treewidth of planar graphs can be computed in time $\mathcal{O}^*(n^{3.182\sqrt{n}}) = 2^{\mathcal{O}(\sqrt{n}\log n)}$.

Unfortunately, although the structure of potential maximal cliques in planar graphs is very particular [12], our approach cannot be used for obtaining algorithms of running time $2^{\mathcal{O}(\sqrt{n})}$ for planar treewidth. This is because the number of "large" potential maximal cliques in planar graphs can be "large."

CLAIM 2. *For any integer N, there is a planar graph on $n > N$ vertices with at least $2^{0.49\sqrt{n}\log n}$ potential maximal cliques of size at least $2\sqrt{n}+2$.*

Proof. Consider the planar graph G_p depicted in Figure 7.1. It has $n = p^2+p+3$ vertices. The set of vertices $S = \{a_1, b_{1i_1}, a_2, b_{2i_2}, \ldots, a_p, b_{pi_p}, a_{p+1}\}$ forms a c,d-minimal separator for any values $i_1, i_2, \ldots, i_p$ between 1 and p. By making use of Theorem 2.4, it is not hard to see that $S \cup \{c\}$ is a potential maximal clique of size $p+1$ in G_p. Consequently, G has at least p^p potential maximal cliques. If $p \geq 2$, we have $p > \sqrt{n} - 1$; thus the number of potential maximal cliques is at least $(\sqrt{n}-1)^{\sqrt{n}-1}$. □

Since we do not know if the treewidth of a planar graph can be computed in polynomial time, an interesting task is to design an algorithm of running time $2^{\mathcal{O}(\sqrt{n})}$. As we mentioned, this will need new techniques.

Combinatorial bounds. The running time estimation of our algorithms is based on combinatorial upper bounds on the number of minimal separators and an upper bound for the time to list all potential maximal cliques of a graph. Finding better bounds on the number of minimal separators and potential maximal cliques in a graph is an interesting combinatorial challenge.

How many potential maximal cliques can be in a graph? We have shown that the number of potential maximal cliques in a graph on n vertices is at most $\mathcal{O}(1.8135^n)$. Unfortunately, it is not clear if the same bound can be obtained by an algorithm

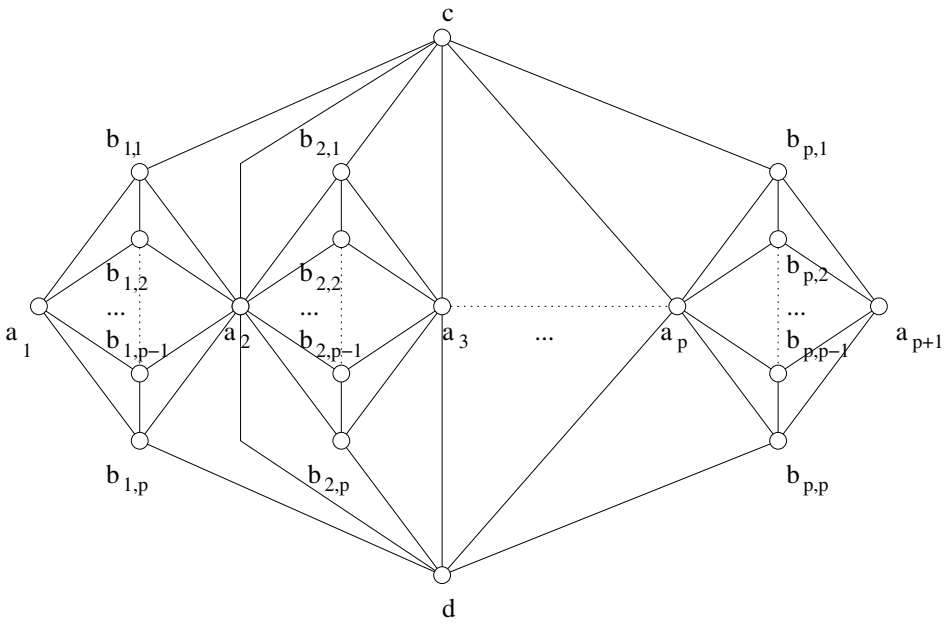

FIG. 7.1. *Planar graphs with many large potential maximal cliques.*

listing potential maximal cliques. Of course, such an algorithm can be used to speed up our algorithm for treewidth and fill-in. A related interesting question is whether it is possible to list potential maximal cliques with polynomial time delay.

How many minimal separators can be in a graph? We are aware of the following construction providing the lower bound $3^{n/3} \approx 1.4422^n$ on the number of minimal separators: Let G be a graph on $n = 3k + 2$ vertices. G has two vertices a, b that are connected by k vertex disjoint paths of length 4. Every minimal a, b-separator in G contains exactly one inner vertex of each a, b-path. Thus the number of minimal separators in G is at least $3^{n/3} \approx 1.4422^n$. However, the gap between the lower bound and the upper bound $\mathcal{O}(1.7087^n)$ from Theorem 4.2 is still big. A related question is whether it is possible to list the minimal separators with polynomial delay.

For some special graph classes, the use of minimal separators can imply faster algorithms for triangulation problems. For example, we have shown that every AT-free graph on n vertices has at most $2^{n/2+3}$ minimal separators and that this upper bound is tight up to a multiplicative constant factor. The interesting question here is whether similar techniques can be used for other graph classes, such as bipartite graphs and graphs of small degree.

Related problems. Our algorithms for treewidth and minimum fill-in can also be used for solving other problems that can be expressed in terms of minimal triangulations such as finding a tree decomposition of minimum cost [8] or computing treewidth of weighted graphs. However, there are two "width" parameters related to treewidth, namely bandwidth and pathwidth, and one parameter called profile, related to minimum fill-in, that do not fit into this framework. Bandwidth can be computed in time $\mathcal{O}^*(10^n)$ [20], and reducing Feige's bounds is a challenging problem. Pathwidth (and profile) can be expressed as vertex ordering problems and thus solved in $\mathcal{O}^*(2^n)$ time by applying a dynamic programming approach similar to Held and Karp's approach [28] for the travelling salesman problem. Let us note that reach-

ing time complexity $\mathcal{O}^*(c^n)$ for any constant $c < 2$, even for the Hamiltonian cycle problem, is a longstanding problem. So it is unlikely that some modification of Held and Karp's approach would provide us with a better exact algorithm for pathwidth or profile. It is tempting to ask if one can reach time complexity $\mathcal{O}^*(c^n)$, for any constant $c < 2$, for these problems.

Acknowledgment. We are grateful to Hans Bodlaender for nice discussions and for pointing out that the algorithm of Arnborg, Corneil, and Proskurowski [2] can be used to compute treewidth and minimum fill-in in time $\mathcal{O}^*(2^n)$.

DIMENSIONS OF POINTS IN SELF-SIMILAR FRACTALS*

JACK H. LUTZ† AND ELVIRA MAYORDOMO‡

Abstract. Self-similar fractals arise as the unique attractors of iterated function systems (IFSs) consisting of finitely many contracting similarities satisfying an open set condition. Each point x in such a fractal F arising from an IFS S is naturally regarded as the "outcome" of an infinite *coding sequence* T (which need not be unique) over the alphabet $\Sigma_k = \{0, \ldots, k-1\}$, where k is the number of contracting similarities in S. A classical theorem of Moran (1946) and Falconer (1989) states that the Hausdorff and packing dimensions of a self-similar fractal coincide with its similarity dimension, which depends only on the contraction ratios of the similarities. The theory of computing has recently been used to provide a meaningful notion of the *dimensions of individual points* in Euclidean space. In this paper, we use (and extend) this theory to analyze the dimensions of individual points in fractals that are *computably self-similar*, meaning that they are unique attractors of IFSs that are computable and satisfy the open set condition. Our main theorem states that, if $F \subseteq \mathbb{R}^n$ is any computably self-similar fractal and S is any IFS testifying to this fact, then the dimension identities $\dim(x) = \mathrm{sdim}(F)\dim^{\pi_S}(T)$ and $\mathrm{Dim}(x) = \mathrm{sdim}(F)\mathrm{Dim}^{\pi_S}(T)$ hold for all $x \in F$ and all coding sequences T for x. In these equations, $\mathrm{sdim}(F)$ denotes the similarity dimension of the fractal F; $\dim(x)$ and $\mathrm{Dim}(x)$ denote the dimension and strong dimension, respectively, of the point x in Euclidean space; and $\dim^{\pi_S}(T)$ and $\mathrm{Dim}^{\pi_S}(T)$ denote the dimension and strong dimension, respectively, of the coding sequence T relative to a probability measure π_S that the IFS S induces on the alphabet Σ_k. The above-mentioned theorem of Moran and Falconer follows easily from our main theorem by relativization. Along the way to our main theorem, we develop the elements of the theory of constructive dimensions relative to general probability measures. The proof of our main theorem uses Kolmogorov complexity characterizations of these dimensions.

1. Introduction.

The theory of computing has recently been used to formulate effective versions of Hausdorff dimension and packing dimension, the two most important dimensions in geometric measure theory [36, 37, 11, 1]. These effective fractal dimensions have already produced quantitative insights into many aspects of algorithmic randomness, Kolmogorov complexity, computational complexity, data compression, and prediction [24]. They are also beginning to yield results in geometric measure theory itself [20].

The most fundamental effective dimensions are the constructive dimension [37] and the constructive strong dimension [1]. These two constructive dimensions (which are defined explicitly in section 3 below) are the constructive versions of the Hausdorff and packing dimensions, respectively. For each set X of (infinite) sequences over a

finite alphabet Σ, the constructive dimension $\mathrm{cdim}(X)$ and the constructive strong dimension $\mathrm{cDim}(X)$ are real numbers satisfying the inequalities

$$\begin{array}{ccccccc} & & \mathrm{cdim}(X) & \leq & \mathrm{cDim}(X) & \leq & 1 \\ & & \vee\mid & & \vee\mid & & \\ 0 & \leq & \dim_{\mathrm{H}}(X) & \leq & \mathrm{Dim}_{\mathrm{P}}(X), & & \end{array}$$

where $\dim_{\mathrm{H}}(X)$ and $\mathrm{Dim}_{\mathrm{P}}(X)$ are the Hausdorff and packing dimensions, respectively, of X. These constructive dimensions are exact analogues of the constructive Lebesgue measure that Martin-Löf used to formulate algorithmic randomness [38]. As such, they are endowed with universality properties that make them especially well behaved. For example, unlike the other effective dimensions, and unlike their classical counterparts, the constructive dimensions are *absolutely stable*, meaning that the dimension of *any* union (countable or otherwise) of sets is the supremum of the dimensions of the individual sets. In particular, this implies that, if we define the dimension and strong dimension of an individual sequence $S \in \Sigma^\infty$ to be

$$\dim(S) = \mathrm{cdim}(\{S\}) \tag{1.1}$$

and

$$\mathrm{Dim}(S) = \mathrm{cDim}(\{S\}), \tag{1.2}$$

respectively, then the constructive dimensions of any set $X \subseteq \Sigma^\infty$ are determined by the equations

$$\mathrm{cdim}(X) = \sup_{S \in X} \dim(S) \tag{1.3}$$

and

$$\mathrm{cDim}(X) = \sup_{S \in X} \mathrm{Dim}(S). \tag{1.4}$$

Constructive dimensions are thus investigated entirely in terms of the dimensions of individual sequences.

The two constructive dimensions also admit precise characterizations in terms of Kolmogorov complexity [39, 1]. Specifically, for any sequence $S \in \Sigma^\infty$,

$$\dim(S) = \liminf_{j \to \infty} \frac{\mathrm{K}(S[0..j-1])}{j \log |\Sigma|} \tag{1.5}$$

and

$$\mathrm{Dim}(S) = \limsup_{j \to \infty} \frac{\mathrm{K}(S[0..j-1])}{j \log |\Sigma|}, \tag{1.6}$$

where $\mathrm{K}(S[0..j-1])$ denotes the Kolmogorov complexity of the j-symbol prefix of S [33] and the logarithm is base-2. Since $\mathrm{K}(w)$ measures the algorithmic information content (in bits) of a string w, (1.5) and (1.6) say that $\dim(S)$ and $\mathrm{Dim}(S)$ are asymptotic measures of the *algorithmic information density* of S.

Although the constructive dimensions have primarily been investigated in sequence spaces Σ^∞, they work equally well in Euclidean spaces $\mathbb{R}^n$. One of several

equivalent ways to achieve this is to fix a base $k \geq 2$ in which to expand the coordinates of each point $x = (x_1, \ldots, x_n) \in \mathbb{R}^n$. If the expansions of the fractional parts of these coordinates are $S_1, \ldots, S_n \in \Sigma_k^\infty$, respectively, where $\Sigma_k = \{0, \ldots, k-1\}$, and if S is the interleaving of these sequences, i.e.,

$$S = S_1[0]S_2[0] \ldots S_n[0]S_1[1]S_2[1] \ldots S_n[1]S_1[2]S_2[2] \ldots,$$

then the *dimension* of the point x is

$$\dim(x) = n \dim(S), \tag{1.7}$$

and the *strong dimension* of x is

$$\mathrm{Dim}(x) = n \mathrm{Dim}(S). \tag{1.8}$$

If one or more of the coordinates of x have two base-k expansions (because they are rationals whose denominators are powers of k), it is easily seen that the numbers $\dim(x)$ and $\mathrm{Dim}(x)$ are unaffected by how we choose between these base-k expansions. Also, a theorem of Staiger [47], in combination with (1.5) and (1.6), implies that $\dim(x)$ and $\mathrm{Dim}(x)$ do not depend on the choice of the base k. The dimension and strong dimension of a point $x \in \mathbb{R}^n$ are properties of the point x itself and not properties of a particular encoding.

Clearly, $0 \leq \dim(x) \leq \mathrm{Dim}(x) \leq n$ for all $x \in \mathbb{R}^n$. In fact, this is the only restriction that holds in general; i.e., for any two real numbers $0 \leq \alpha \leq \beta \leq n$, there is a point x in $\mathbb{R}^n$ with $\dim(x) = \alpha$ and $\mathrm{Dim}(x) = \beta$ [1].

The theory of computing thus assigns a dimension $\dim(x)$ and a strong dimension $\mathrm{Dim}(x)$ to each point x in Euclidean space. This assignment is robust (i.e., several natural approaches all lead to the same assignment), but is it geometrically meaningful? Prior work already indicates an affirmative answer. By Hitchcock's correspondence principle for constructive dimension ([26], extending a result of [46]), together with the absolute stability of constructive dimension [37], if $X \subseteq \mathbb{R}^n$ is any countable (not necessarily effective) union of computably closed, i.e., Π_1^0, sets, then $\mathrm{cdim}(X) = \dim_{\mathrm{H}}(X)$. Putting this together with (1.3) and (1.7), we have

$$\dim_{\mathrm{H}}(X) = \sup_{x \in X} \dim(x) \tag{1.9}$$

for any set X that is a union of computably closed sets. That is, the *classical* Hausdorff dimension [15] of any such set is completely determined by the dimensions of its individual points. Many, perhaps most, of the sets which arise in "standard" mathematical practice are unions of computably closed sets, so (1.9) constitutes strong prima facie evidence that the dimensions of individual points are indeed geometrically meaningful.

This paper analyzes the dimensions of points in the most widely known type of fractals, the self-similar fractals. The class of self-similar fractals includes such famous members as the Cantor set, the von Koch curve, the Sierpinski triangle, and the Menger sponge, along with many more exotic sets in Euclidean space [2, 12, 13, 15]. A self-similar fractal (defined precisely in section 5 below) is constructed from an *iterated function system (IFS)* $S = (S_0, \ldots, S_{k-1})$, which is a list of two or more contracting similarities mapping an initial nonempty, closed set $D \subseteq \mathbb{R}^n$ into itself. Each set $S_i(D)$ is a strictly smaller "copy" of D inside of D, and each set $S_i(S_j(D))$

is a strictly smaller "copy" of $S_j(D)$ inside of $S_i(D)$. Continuing in this way, each sequence $T \in \Sigma_k^\infty$ encodes a nested sequence

$$D \supseteq S_{T[0]}(D) \supseteq S_{T[0]}(S_{T[1]}(D)) \supseteq \dots \tag{1.10}$$

of nonempty, closed sets in $\mathbb{R}^n$. Each of these sets is strictly smaller than the one preceding it, because each similarity S_i has a contraction ratio $c_i \in (0,1)$. Hence there is a unique point $S(T) \in \mathbb{R}^n$ that is an element of all the sets in (1.10). Figure 1 illustrates how a *coding sequence* T represents a point $S(T)$ in the Sierpinski triangle.

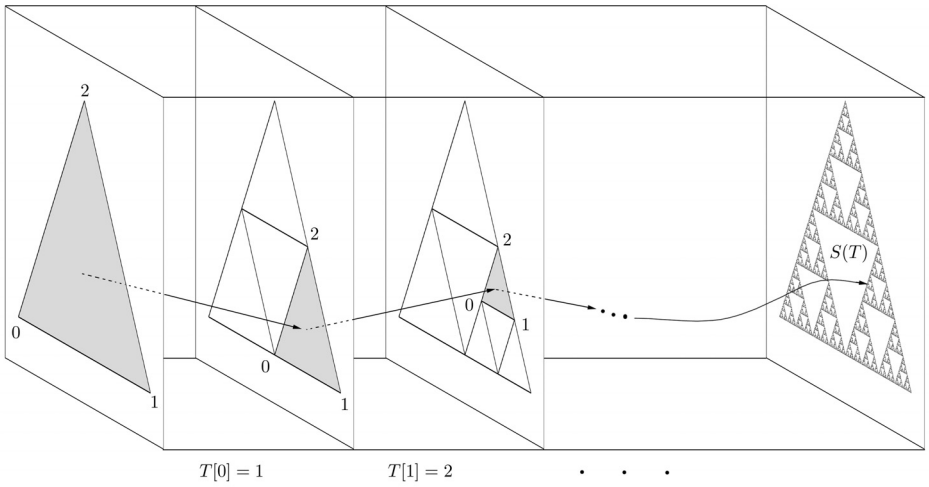

FIG. 1. *A sequence $T \in \{0,1,2\}^\infty$ codes a point $S(T)$ in the Sierpinski triangle.*

The *attractor* of the IFS S is the set

$$F(S) = \{ S(T) \mid T \in \Sigma_k^\infty \}. \tag{1.11}$$

In general, the sets $S_0(D), \dots, S_{k-1}(D)$ need not be disjoint, so a point $x \in F(S)$ may have many *coding sequences*, i.e., many sequences T for which $S(T) = x$. A *self-similar fractal* is a set $F \subseteq \mathbb{R}^n$ that is the attractor of an IFS S that satisfies a technical *open set condition* (defined in section 5), which ensures that the sets $S_0(D), \dots, S_{k-1}(D)$ are "nearly" disjoint.

The *similarity dimension* of an IFS S is the (unique) solution $\mathrm{sdim}(S)$ of the equation

$$\sum_{i=0}^{k-1} c_i^{\mathrm{sdim}(S)} = 1, \tag{1.12}$$

where $c_0, \dots, c_{k-1}$ are the contraction ratios of the similarities $S_0, \dots, S_{k-1}$, respectively. The *similarity dimension* of a self-similar fractal $F = F(S)$ is $\mathrm{sdim}(F) = \mathrm{sdim}(S)$. A classical theorem of Moran [40] and Falconer [14] says that, for any self-similar fractal F,

$$\dim_{\mathrm{H}}(F) = \mathrm{Dim}_{\mathrm{P}}(F) = \mathrm{sdim}(F), \tag{1.13}$$

i.e., the Hausdorff and packing dimensions of F coincide with its similarity dimension. In addition to its theoretical interest, the Moran–Falconer theorem has the pragmatic

consequence that the Hausdorff and packing dimensions of a self-similar fractal are easily computed from the contraction ratios by solving (1.12).

Our main theorem concerns the dimensions of points in fractals that are *computably self-similar*, meaning that they are attractors of *computable* IFSs satisfying the open set condition. (We note that most self-similar fractals occurring in practice—including the four famous examples mentioned above—are, in fact, computably self-similar.) Our main theorem says that, if F is any fractal that is computably self-similar with the IFS S as witness, then, for every point $x \in F$ and every coding sequence T for x, the dimension and strong dimension of the point x are given by the dimension formulas

$$\dim(x) = \mathrm{sdim}(F)\dim^{\pi_S}(T) \tag{1.14}$$

and

$$\mathrm{Dim}(x) = \mathrm{sdim}(F)\mathrm{Dim}^{\pi_S}(T), \tag{1.15}$$

where $\dim^{\pi_S}(T)$ and $\mathrm{Dim}^{\pi_S}(T)$ are the dimension and strong dimension of T *with respect to* the probability measure π_S on the alphabet Σ_k defined by

$$\pi_S(i) = c_i^{\mathrm{sdim}(F)} \tag{1.16}$$

for all $i \in \Sigma_k$. (We note that $\dim^{\pi_S}(T)$ is the constructive analogue of Billingsley dimension [3, 9].) This theorem gives a complete analysis of the dimensions of points in computably self-similar fractals and the manner in which the dimensions of these points arise from the dimensions of their coding sequences.

Although our main theorem applies directly only to computably self-similar fractals, we use relativization to show that the Moran–Falconer theorem (1.13) for arbitrary self-similar fractals is an easy consequence of our main theorem. Hence, as is often the case, a theorem of computable analysis (i.e., the theoretical foundations of scientific computing [6]) has an immediate corollary in classical analysis.

The proof of our main theorem has some geometric and combinatorial similarities with the classical proofs of Moran [40] and Falconer [14], but the argument here is information-theoretic. Specifically, our proof uses Kolmogorov complexity characterizations of dimensions with respect to probability measures. These characterizations (proven in section 4 below) say that, if ν is a suitable probability measure on a sequence space Σ^∞, then, for every sequence $S \in \Sigma^\infty$,

$$\dim^\nu(S) = \liminf_{j\to\infty} \frac{\mathrm{K}(S[0..j-1])}{\mathcal{I}_\nu(S[0..j-1])} \tag{1.17}$$

and

$$\mathrm{Dim}^\nu(S) = \limsup_{j\to\infty} \frac{\mathrm{K}(S[0..j-1])}{\mathcal{I}_\nu(S[0..j-1])}, \tag{1.18}$$

where

$$\mathcal{I}_\nu(w) = \log \frac{1}{\nu(w)}$$

is the Shannon self-information of the string w with respect to the probability measure ν [10]. The older characterizations (1.5) and (1.6) are the special cases of (1.17) and

(1.18) in which $\nu(w) = |\Sigma|^{-|w|}$ for all w in Σ^*. The characterizations (1.17) and (1.18) say that $\dim^\nu(S)$ and $\mathrm{Dim}^\nu(S)$ are asymptotic measures of the algorithmic information density of S, but the "density" here is now an information-to-cost ratio. In this ratio, the "information" is algorithmic information, i.e., Kolmogorov complexity, and the "cost" is the Shannon self-information. To see why this makes sense, consider the case of interest in our main theorem. In this case, (1.16) says that

$$\nu(w) = \prod_{j=0}^{|w|-1} c_{w[j]}^{\mathrm{sdim}(F)},$$

whence the cost of a string $w \in \Sigma_k^*$ is

$$\mathcal{I}_\nu(w) = \mathrm{sdim}(F) \sum_{j=0}^{|w|-1} \log \frac{1}{c_{w[j]}},$$

i.e., the sum of the costs of the symbols in w, where the cost of a symbol $i \in \Sigma_k$ is $\mathrm{sdim}(F)\log(1/c_i)$. These symbol costs are computational and realistic. A symbol i with high cost invokes a similarity S_i with a small contraction ratio c_i, thereby necessitating a high-precision computation.

We briefly mention some other recent research on fractals in theoretical computer science. Braverman and Cook [5, 6] have used computability and complexity of various fractals to explore the relationships between the two main models of real computation. Rettinger and Weihrauch [42], Hertling [23], and Braverman and Yampolsky [7] have investigated computability and complexity properties of Mandelbrot and Julia sets. Gupta, Krauthgamer, and Lee [21] have used fractal geometry to prove lower bounds on the distortions of certain embeddings of metric spaces. Most of the fractals involved in these papers are more exotic than the self-similar fractals that we investigate here. Cai and Hartmanis [8] and Fernau and Staiger [17] have investigated Hausdorff dimension in self-similar fractals and their coding spaces. This work is more closely related to the present paper, but the motivations and results are different. Our focus here is on a *pointwise* analysis of dimensions.

Some of the most difficult open problems in geometric measure theory involve establishing lower bounds on the fractal dimensions of various sets. Kolmogorov complexity has proven to be a powerful tool for lower-bound arguments, leading to the solution of many long-standing open problems in discrete mathematics [33]. There is thus reason to hope that our pointwise approach to fractal dimension, coupled with the introduction of Kolmogorov complexity techniques, will lead to progress in this classical area. In any case, our results extend computable analysis [41, 28, 54] in a new, geometric direction.

The rest of this paper is organized as follows. Section 2 summarizes basic terminology and notation. Section 3 develops the basic theory of constructive dimensions with respect to probability measures. Section 4 establishes the Kolmogorov complexity characterizations of these dimensions. Section 5 is a brief exposition of self-similar fractals for readers who are not familiar with IFSs. Section 6 proves our main theorem and derives the Moran–Falconer theorem from it.

2. Preliminaries. Given a finite alphabet Σ, we write Σ^* for the set of all (finite) *strings* over Σ and Σ^∞ for the set of all (infinite) *sequences* over Σ. If $\psi \in \Sigma^* \cup \Sigma^\infty$ and $0 \le i \le j < |\psi|$, where $|\psi|$ is the length of ψ, then $\psi[i]$ is the ith symbol in ψ (where $\psi[0]$ is the leftmost symbol in ψ), and $\psi[i..j]$ is the string consisting of the ith

through the jth symbols in ψ. If $w \in \Sigma^*$ and $\psi \in \Sigma^* \cup \Sigma^\infty$, then w is a prefix of ψ, and we write $w \sqsubseteq \psi$ if there exists $i \in \mathbb{N}$ such that $w = \psi[0..i-1]$. If $A \subseteq \Sigma^*$, then $A^{=n} = \{x \mid x \in A \wedge |x| = n\}$.

For functions on Euclidean space, we use the computability notion formulated by Grzegorczyk [19] and Lacombe [29, 30, 31] in the 1950's and exposited in the monographs by Pour-El and Richards [41], Ko [28], and Weihrauch [54] and in the recent survey paper by Braverman and Cook [6]. A function $f : \mathbb{R}^n \to \mathbb{R}^n$ is *computable* if there is an oracle Turing machine M with the following property. For all $x \in \mathbb{R}^n$ and $r \in \mathbb{N}$, if M is given a function oracle $\varphi_x : \mathbb{N} \to \mathbb{Q}^n$ such that, for all $k \in \mathbb{N}$, $|\varphi_x(k) - x| \leq 2^{-k}$, then M, with oracle φ_x and input r, outputs a rational point $M^{\varphi_x}(r) \in \mathbb{Q}^n$ such that $|M^{\varphi_x}(r) - f(x)| \leq 2^{-r}$.

A point $x \in \mathbb{R}^n$ is *computable* if there is a computable function $\psi_x : \mathbb{N} \to \mathbb{Q}^n$ such that, for all $r \in \mathbb{N}$, $|\psi_x(r) - x| \leq 2^{-r}$.

For subsets of Euclidean space, we use the computability notion introduced by Brattka and Weihrauch [4] (see also [54, 6]). A set $X \subseteq \mathbb{R}^n$ is computable if there is a computable function $f_X : \mathbb{Q}^n \times \mathbb{N} \to \{0, 1\}$ that satisfies the following two conditions for all $q \in \mathbb{Q}^n$ and $r \in \mathbb{N}$.

(i) If there exists $x \in X$ such that $|x - q| \leq 2^{-r}$, then $f_X(q, r) = 1$.

(ii) If there is no $x \in X$ such that $|x - q| \leq 2^{1-r}$, then $f_X(q, r) = 0$.

The following two observations are well known and easy to verify.

OBSERVATION 2.1. *A nonempty set $X \subseteq \mathbb{R}^n$ is computable if and only if the associated distance function*

$$\rho_X : \mathbb{R}^n \to [0, \infty),$$
$$\rho_X(y) = \inf_{x \in X} |x - y|$$

is computable.

OBSERVATION 2.2. *If $X \subseteq \mathbb{R}^n$ is both computable and closed, then X is a computably closed, i.e., Π^0_1, set.*

All logarithms in this paper are base-2.

3. Dimensions relative to probability measures. Here we develop the basic theory of constructive fractal dimension on a sequence space Σ^∞ with respect to a suitable probability measure on Σ^∞. We first review the classical Hausdorff and packing dimensions.

Let ρ be a metric on a set $\mathcal{X}$. We use the following standard terminology. The *diameter* of a set $X \subseteq \mathcal{X}$ is

$$\operatorname{diam}(X) = \sup \{\rho(x, y) \mid x, y \in X\}$$

(which may be ∞). For each $x \in \mathcal{X}$ and $r \in \mathbb{R}$, the *closed ball* of radius r about x is the set

$$B(x, r) = \{y \in \mathcal{X} \mid \rho(y, x) \leq r\},$$

and the *open ball* of radius r about x is the set

$$B^o(x, r) = \{y \in \mathcal{X} \mid \rho(y, x) < r\}.$$

A *ball* is any set of the form $B(x, r)$ or $B^o(x, r)$. A ball B is *centered* in a set $X \subseteq \mathcal{X}$ if $B = B(x, r)$ or $B = B^o(x, r)$ for some $x \in X$ and $r \geq 0$.

For each $\delta > 0$, we let $\mathcal{C}_\delta$ be the set of all countable collections $\mathcal{B}$ of balls such that $\operatorname{diam}(B) \le \delta$ for all $B \in \mathcal{B}$, and we let $\mathcal{D}_\delta$ be the set of all $\mathcal{B} \in \mathcal{C}_\delta$ such that the balls in $\mathcal{B}$ are pairwise disjoint. For each $X \subseteq \mathcal{X}$ and $\delta > 0$, we define the sets

$$\mathcal{H}_\delta(X) = \left\{ \mathcal{B} \in \mathcal{C}_\delta \;\middle|\; X \subseteq \bigcup_{B \in \mathcal{B}} B \right\},$$
$$\mathcal{P}_\delta(X) = \{ \mathcal{B} \in \mathcal{D}_\delta \mid (\forall B \in \mathcal{B}) B \text{ is centered in } X \}.$$

If $\mathcal{B} \in \mathcal{H}_\delta(X)$, then we call $\mathcal{B}$ a *δ-cover* of X. If $\mathcal{B} \in \mathcal{P}_\delta(X)$, then we call $\mathcal{B}$ a *δ-packing* of X. For $X \subseteq \mathcal{X}$, $\delta > 0$, and $s \ge 0$, we define the quantities

$$H^s_\delta(X) = \inf_{\mathcal{B} \in \mathcal{H}_\delta(X)} \sum_{B \in \mathcal{B}} \operatorname{diam}(B)^s,$$
$$P^s_\delta(X) = \sup_{\mathcal{B} \in \mathcal{P}_\delta(X)} \sum_{B \in \mathcal{B}} \operatorname{diam}(B)^s.$$

Since $H^s_\delta(X)$ and $P^s_\delta(X)$ are monotone as $\delta \to 0$, the limits

$$H^s(X) = \lim_{\delta \to 0} H^s_\delta(X),$$
$$P^s_0(X) = \lim_{\delta \to 0} P^s_\delta(X)$$

exist, though they may be infinite. Let

$$P^s(X) = \inf \left\{ \sum_{i=0}^{\infty} P^s_0(X_i) \;\middle|\; X \subseteq \bigcup_{i=0}^{\infty} X_i \right\}. \tag{3.1}$$

It is routine to verify that the set functions H^s and P^s are outer measures [15]. The quantities $H^s(X)$ and $P^s(X)$—which may be infinite—are called the *s-dimensional Hausdorff (outer) ball measure* and the *s-dimensional packing (outer) ball measure* of X, respectively. The optimization (3.1) over all countable partitions of X is needed because the set function P^s_0 is *not* an outer measure.

DEFINITION 3.1. *Let ρ be a metric on a set $\mathcal{X}$, and let $X \subseteq \mathcal{X}$.*

1. *(Hausdorff* [22]*). The* Hausdorff dimension *of X with respect to ρ is*

$$\dim^{(\rho)}_{\mathrm{H}}(X) = \inf \{ s \in [0, \infty) \mid H^s(X) = 0 \}.$$

2. *(Tricot* [50]*, Sullivan* [49]*). The* packing dimension *of X with respect to ρ is*

$$\operatorname{Dim}^{(\rho)}_{\mathrm{P}}(X) = \inf \{ s \in [0, \infty) \mid P^s(X) = 0 \}.$$

When $\mathcal{X}$ is a Euclidean space $\mathbb{R}^n$ and ρ is the usual Euclidean metric on $\mathbb{R}^n$, $\dim^{(\rho)}_{\mathrm{H}}$ and $\operatorname{Dim}^{(\rho)}_{\mathrm{P}}$ are the ordinary Hausdorff and packing dimensions, also denoted by $\dim_{\mathrm{H}}$ and $\operatorname{Dim}_{\mathrm{P}}$, respectively.

We now focus our attention on sequence spaces. Let Σ be a finite alphabet with $|\Sigma| \ge 2$. A *(Borel) probability measure* on Σ^∞ is a function $\nu : \Sigma^* \to [0, 1]$ such that $\nu(\lambda) = 1$ and $\nu(w) = \sum_{a \in \Sigma} \nu(wa)$ for all $w \in \Sigma^*$. Intuitively, $\nu(w)$ is the probability that $w \sqsubseteq S$ when a sequence $S \in \Sigma^\infty$ is chosen according to the probability measure ν. A probability measure ν on Σ^∞ is *strongly positive* if there exists $\delta > 0$ such that, for all $w \in \Sigma^*$ and $a \in \Sigma$, $\nu(wa) > \delta \nu(w)$.

The following type of probability measure is used in our main theorem.

Example 3.2. Let π be a probability measure on the alphabet Σ, i.e., a function $\pi : \Sigma \to [0,1]$ such that $\sum_{a\in\Sigma} \pi(a) = 1$. Then π induces the *product probability measure* π on Σ^∞ defined by

$$\pi(w) = \prod_{i=0}^{|w|-1} \pi(w[i])$$

for all $w \in \Sigma^*$. If π is *positive* on Σ, i.e., $\pi(a) > 0$ for all $a \in \Sigma$, then the probability measure π on Σ^∞ is strongly positive.

Example 3.3. We reserve the symbol μ for the *uniform probability measure* on Σ^∞, which is the function $\mu : \Sigma^* \to [0,\infty)$ defined by

$$\mu(w) = |\Sigma|^{-|w|}$$

for all $w \in \Sigma^*$. Note that this is the special case of Example 3.2 in which $\pi(a) = 1/|\Sigma|$ for each $a \in \Sigma$.

Definition 3.4. *The* metric induced by *a strongly positive probability measure ν on Σ^∞ is the function $\rho_\nu : \Sigma^\infty \times \Sigma^\infty \to [0,1]$ defined by*

$$\rho_\nu(S,T) = \inf\{\nu(w) \mid w \sqsubseteq S \text{ and } w \sqsubseteq T\}$$

for all $S, T \in \Sigma^\infty$.

The following fact is easily verified.

Observation 3.5. *For every strongly positive probability measure ν on Σ^∞, the function ρ_ν is a metric on Σ^∞.*

Hausdorff and packing dimensions with respect to probability measures on sequence spaces are defined as follows.

Definition 3.6. *Let Σ be a finite alphabet with $|\Sigma| \geq 2$, let ν be a strongly positive probability measure on Σ^∞, and let $X \subseteq \Sigma^\infty$.*

1. *The* Hausdorff dimension *of X with respect to ν (also called the* Billingsley dimension *of X with respect to ν [3, 9]) is*

$$\dim_{\mathrm{H}}^{\nu}(X) = \dim_{\mathrm{H}}^{(\rho_\nu)}(X).$$

2. *The* packing dimension *of X with respect to ν is*

$$\mathrm{Dim}_{\mathrm{P}}^{\nu}(X) = \mathrm{Dim}_{\mathrm{P}}^{(\rho_\nu)}(X).$$

Note. We have assumed strong positivity here for clarity of presentation, but this assumption can be weakened in various ways for various results.

When ν is the probability measure μ, it is generally omitted from the terminology. Thus, the *Hausdorff dimension* of X is $\dim_{\mathrm{H}}(X) = \dim_{\mathrm{H}}^{\mu}(X)$, and the *packing dimension* of X is $\mathrm{Dim}_{\mathrm{P}}(X) = \mathrm{Dim}_{\mathrm{P}}^{\mu}(X)$.

It was apparently Wegmann [53] who first noticed that the metric ρ_ν could be used to make Billingsley dimension a special case of Hausdorff dimension. Fernau and Staiger [17] have also investigated this notion.

We now develop gale characterizations of $\dim_{\mathrm{H}}^{\nu}$ and $\mathrm{Dim}_{\mathrm{P}}^{\nu}$.

Definition 3.7. *Let Σ be a finite alphabet with $|\Sigma| \geq 2$, let ν be a probability measure on Σ^∞, and let $s \in [0,\infty)$.*

1. *A* ν-s-supergale *is a function* $d : \Sigma^* \to [0, \infty)$ *that satisfies the condition*

$$d(w)\nu(w)^s \geq \sum_{a \in \Sigma} d(wa)\nu(wa)^s \tag{3.2}$$

for all $w \in \Sigma^*$.
2. *A* ν-s-gale *is a* ν-s-*supergale that satisfies* (3.2) *with equality for all* $w \in \Sigma^*$.
3. *A* ν-supermartingale *is a* ν-1-*supergale.*
4. *A* ν-martingale *is a* ν-1-*gale.*
5. *An* s-supergale *is a* μ-s-*supergale.*
6. *An* s-gale *is a* μ-s-*gale.*
7. *A* supermartingale *is a* 1-*supergale.*
8. *A* martingale *is a* 1-*gale.*

The following observation shows how gales and supergales are affected by variation of the parameter s.

Observation 3.8 (see[37]). *Let* ν *be a probability measure on* Σ^∞, *let* $s, s' \in [0, \infty)$, *and let* $d, d' : \Sigma^* \to [0, \infty)$. *Assume that*

$$d(w)\nu(w)^s = d'(w)\nu(w)^{s'}$$

holds for all $w \in \Sigma^*$.

1. d *is a* ν-s-*supergale if and only if* d' *is a* ν-s'-*supergale.*
2. d *is a* ν-s-*gale if and only if* d' *is a* ν-s'-*gale.*

For example, if the probability measure ν is positive, then a function $d : \Sigma^* \to [0, \infty)$ is a ν-s-gale if and only if the function $d' : \Sigma^* \to [0, \infty)$ defined by $d'(w) = \nu(w)^{s-1}d(w)$ is a ν-martingale.

Martingales were introduced by Lévy [32] and Ville [52]. They have been used extensively by Schnorr [43, 44, 45] and others in investigations of randomness and by Lutz [34, 35] and others in the development of resource-bounded measure. Gales are a convenient generalization of martingales introduced by Lutz [36, 37] in the development of effective fractal dimensions.

The following generalization of Kraft's inequality [10] is often useful.

Lemma 3.9 (see [37]). *Let* d *be a* ν-s-*supergale, where* ν *is a probability measure on* Σ^∞ *and* $s \in [0, \infty)$. *Then, for all* $w \in \Sigma^*$ *and all prefix sets* $B \subseteq \Sigma^*$,

$$\sum_{u \in B} d(wu)\nu(wu)^s \leq d(w)\nu(w)^s.$$

Intuitively, a ν-s-gale d is a strategy for betting on the successive symbols in a sequence $S \in \Sigma^\infty$. We regard the value $d(w)$ as the amount of money that a gambler using the strategy d will have after betting on the symbols in w if w is a prefix of S. If $s = 1$, then the ν-s-gale identity

$$d(w)\nu(w)^s = \sum_{a \in \Sigma} d(wa)\nu(wa)^s \tag{3.3}$$

ensures that the payoffs are fair in the sense that the conditional ν-expected value of the gambler's capital after the symbol following w, given that w has occurred, is precisely $d(w)$, the gambler's capital after w. If $s < 1$, then (3.3) says that the payoffs are less than fair. If $s > 1$, then (3.3) says that the payoffs are more than fair. Clearly, the smaller s is, the more hostile the betting environment is.

There are two important notions of success for a supergale.

DEFINITION 3.10. *Let d be a ν-s-supergale, where ν is a probability measure on Σ^∞ and $s \in [0,\infty)$, and let $S \in \Sigma^\infty$.*

1. *We say that d* succeeds *on S, and we write $S \in S^\infty[d]$ if* $\limsup_{t\to\infty} d(S[0..t-1]) = \infty$.
2. *We say that d* succeeds strongly *on S and we write $S \in S^\infty_{\mathrm{str}}[d]$ if*

$$\liminf_{t\to\infty} d(S[0..t-1]) = \infty.$$

Notation. Let ν be a probability measure on Σ^∞, and let $X \subseteq \Sigma^\infty$.

1. $\mathcal{G}^\nu(X)$ is the set of all $s \in [0,\infty)$ such that there is a ν-s-gale d for which $X \subseteq S^\infty[d]$.
2. $\mathcal{G}^{\nu,\mathrm{str}}(X)$ is the set of all $s \in [0,\infty)$ such that there is a ν-s-gale d for which $X \subseteq S^\infty_{\mathrm{str}}[d]$.
3. $\widehat{\mathcal{G}}^\nu(X)$ is the set of all $s \in [0,\infty)$ such that there is a ν-s-supergale d for which $X \subseteq S^\infty[d]$.
4. $\widehat{\mathcal{G}}^{\nu,\mathrm{str}}(X)$ is the set of all $s \in [0,\infty)$ such that there is a ν-s-supergale d for which $X \subseteq S^\infty_{\mathrm{str}}[d]$.

The following theorem gives useful characterizations of the classical Hausdorff and packing dimensions with respect to probability measures on sequence spaces.

THEOREM 3.11 (gale characterizations of $\dim^\nu_{\mathrm{H}}(X)$ and $\mathrm{Dim}^\nu_{\mathrm{P}}(X)$). *If ν is a strongly positive probability measure on Σ^∞, then, for all $X \subseteq \Sigma^\infty$,*

$$\dim^\nu_{\mathrm{H}}(X) = \inf \mathcal{G}^\nu(X) = \inf \widehat{\mathcal{G}}^\nu(X) \tag{3.4}$$

and

$$\mathrm{Dim}^\nu_{\mathrm{P}}(X) = \inf \mathcal{G}^{\nu,\mathrm{str}}(X) = \inf \widehat{\mathcal{G}}^{\nu,\mathrm{str}}(X). \tag{3.5}$$

Proof. In this proof we will use the following notation for each $w \in \Sigma^*$, $\mathbf{C}_w = \{S \in \Sigma^\infty \mid w \sqsubseteq S\}$.

Notice that for each $S \in \Sigma^\infty$, $r > 0$, the balls $B(S,r) = \mathbf{C}_v$, $B^o(S,r) = \mathbf{C}_w$ for some $v, w \in \Sigma^*$. Therefore, either two balls $\mathbf{C}_w$, $\mathbf{C}_{w'}$ are disjoint or one is contained in the other.

In order to prove (3.4) it suffices to show that for all $s \in [0,\infty)$,

$$H^s(X) = 0 \implies s \in \mathcal{G}^\nu(X) \implies s \in \widehat{\mathcal{G}}^\nu(X) \implies H^s(X) = 0.$$

First, assume that $H^s(X) = 0$. Then $H^s_1(X) = 0$, which implies that for each $r \in \mathbb{N}$ there is a disjoint cover $\mathcal{B} \in \mathcal{C}_1$ such that $\sum_{B\in\mathcal{B}} \mathrm{diam}(B)^s < 2^{-r}$. Let $A_r = \{w \in \Sigma^* \mid \mathbf{C}_w \in \mathcal{B}\}$.

We define a function $d : \Sigma^* \to [0,\infty)$ as follows. Let $w \in \Sigma^*$. If there exists $v \sqsubseteq w$ such that $v \in A_r$, then

$$d_r(w) = \left(\frac{\nu(w)}{\nu(v)}\right)^{1-s}.$$

Otherwise,

$$d_r(w) = \sum_{\substack{u,\\ wu\in A_r}} \left(\frac{\nu(wu)}{\nu(w)}\right)^s.$$

It is routine to verify that the following conditions hold for all $r \in \mathbb{N}$.

(i) d_r is a ν-s-gale.
(ii) $d_r(\lambda) < 2^{-r}$.
(iii) For all $w \in A_r$, $d_r(w) = 1$.

Let $d = \sum_{r=0}^{\infty} 2^r d_{2r}$. Notice that d is a ν-s-gale. To see that $X \subseteq S^\infty[d]$, let $T \in X$, and let $r \in \mathbb{N}$ be arbitrary. Since $\mathcal{B}$ covers X, there exists $w \in A_{2r}$ such that $w \sqsubseteq T$. Then by (iii) above, $d(w) \geq 2^r d_{2r}(w) = 2^r$. Since $r \in \mathbb{N}$ is arbitrary, this shows that $T \in S^\infty[d]$, confirming that $X \subseteq S^\infty[d]$.

We have now shown that d is a ν-s-gale such that $X \subseteq S^\infty[d]$, whence $s \in \mathcal{G}^\nu(X)$.

Conversely, assume that $s \in \widehat{\mathcal{G}}^\nu(X)$. To see that $H^s(X) = 0$, let $\delta > 0$, $r \in \mathbb{N}$. It suffices to show that $H^s(X) \leq 2^{-r}$. If $X = \emptyset$, this is trivial, so assume that $X \neq \emptyset$.

Since $s \in \widehat{\mathcal{G}}^\nu(X)$, there is a ν-s-supergale d such that $X \subseteq S^\infty[d]$. Note that $d(\lambda) > 0$ because $X \neq \emptyset$. Let

$$A = \{w \in \Sigma^* \mid \nu(w) < \delta, d(w) \geq 2^r d(\lambda) \text{ and } (\forall v)[v \sqsubset w \implies v \notin A]\}.$$

It is clear that A is a prefix set. It is also clear that $\mathcal{B} = \{\mathbf{C}_w \mid w \in A\}$ is a δ-cover of $S^\infty[d]$, and since $X \subseteq S^\infty[d]$, $\mathcal{B}$ is also a δ-cover of X. By Lemma 3.9 and the definition of A, we have

$$d(\lambda) \geq \sum_{w \in A} \nu(w)^s d(w) \geq 2^r d(\lambda) \sum_{w \in A} \nu(w)^s.$$

Since $B \in \mathcal{C}_\delta(X)$ and $d(\lambda) > 0$, it follows that

$$H^s_\delta(X) \leq \sum_{w \in A} \nu(w)^s \leq 2^{-r}.$$

This completes the proof of (3.4).

The proof of (3.5) is based on the following three claims.

Claim 1. *For each family $X_i \subseteq \Sigma^\infty$, $i \in \mathbb{N}$, $\inf \mathcal{G}^{\nu,\mathrm{str}}(\cup_i X_i) = \sup_i \inf \mathcal{G}^{\nu,\mathrm{str}}(X_i)$.*

Claim 2. *For each $X \subseteq \Sigma^\infty$, if $P^s_0(X) < \infty$, then $\inf \mathcal{G}^{\nu,\mathrm{str}}(X) \leq s$.*

Claim 3. *For each $X \subseteq \Sigma^\infty$, if $s > \inf \widehat{\mathcal{G}}^{\nu,\mathrm{str}}(X)$, then $P^s(X) = 0$.*

Proof of Claim 1. The $\geq$ inequality follows from the definition of $\mathcal{G}^{\nu,\mathrm{str}}()$. To prove that $\inf \mathcal{G}^{\nu,\mathrm{str}}(\cup_i X_i) \leq \sup_i \inf \mathcal{G}^{\nu,\mathrm{str}}(X_i)$, let $s > \sup_i \inf \mathcal{G}^{\nu,\mathrm{str}}(X_i)$. Assume that $X_i \neq \emptyset$ for every i, since otherwise the proof is similar taking only nonempty X_i's. Then for each $i \in \mathbb{N}$ there is a ν-s-gale d_i such that $X_i \subseteq S^\infty_{\mathrm{str}}[d_i]$. We define a ν-s-gale d by

$$d(w) = \sum_i \frac{2^{-i}}{d_i(\lambda)} d_i(w)$$

for all $w \in \Sigma^*$. Then for each i, for any $S \in X_i$, we have

$$d(S[0..n-1]) \geq \frac{2^{-i}}{d_i(\lambda)} d_i(S[0..n-1])$$

for all n, so $S \in S^\infty_{\mathrm{str}}[d]$. Therefore, $\cup_i X_i \subseteq S^\infty_{\mathrm{str}}[d]$ and the claim follows. □

Proof of Claim 2. Assume that $P^s_0(X) < \infty$. Let $\epsilon > 0$. Let

$$A = \{w \mid w \in \Sigma^* \text{ and } C_w \cap X \neq \emptyset\}.$$

Notice that there is a constant c such that for every n, $\sum_{w \in A^{=n}} \nu(w)^s < c$ and that for each $T \in X$, for every n, $T[0..n-1] \in A$. For each $n \in \mathbb{N}$ we define $d_n : \Sigma^* \to [0, \infty)$

similarly to the first part of this proof; that is, we let $w \in \Sigma^*$. If there exists $v \sqsubseteq w$ such that $v \in A^{=n}$, then

$$d_n(w) = \left(\frac{\nu(w)}{\nu(v)}\right)^{1-s}.$$

Otherwise,

$$d_n(w) = \sum_{\substack{u,\\ wu \in A^{=n}}} \left(\frac{\nu(wu)}{\nu(w)}\right)^{s}.$$

d_n is a ν-s-gale, $d_n(\lambda) = \sum_{u \in A^{=n}} \nu(u)^s$, and for all $w \in A^{=n}$, $d_n(w) = 1$.

Let $d(w) = \sum_{n=0}^{\infty} \nu(w)^{-\epsilon} d_n(w)$. Notice that d is a ν-$(s+\epsilon)$-gale. To see that $X \subseteq S^{\infty}_{\mathrm{str}}[d]$, let $T \in X$ and let n be arbitrary. Since $T[0..n-1] \in A$,

$$d(T[0..n-1]) \geq \nu(T[0..n-1])^{-\epsilon} d_n(T[0..n-1]) \geq \nu(T[0..n-1])^{-\epsilon}.$$

Since $\nu(T[0..n-1]) \stackrel{n\to\infty}{\longrightarrow} 0$, this shows that $T \in S^{\infty}_{\mathrm{str}}[d]$. Therefore, $X \subseteq S^{\infty}_{\mathrm{str}}[d]$ and $\inf \mathcal{G}^{\nu,\mathrm{str}}(X) \leq s + \epsilon$ for arbitrary ϵ, so the claim follows. □

Proof of Claim 3. Let $s > t > \inf \widehat{\mathcal{G}}^{\nu,\mathrm{str}}(X)$. To see that $P^s(X) = 0$, let d be a ν-t-supergale such that $X \subseteq S^{\infty}_{\mathrm{str}}[d]$. Let $i \in \mathbb{N}$ and

$$X_i = \{T \mid \forall n \geq i, d(T[0..n-1]) > d(\lambda)\}.$$

Then $X \subseteq \cup_i X_i$. For each $i \in \mathbb{N}$ we prove that $P^s_0(X_i) = 0$.

Let $\delta_i = \min_{|w| \leq i} \nu(w)$. Let $\delta < \delta_i$ and B be a δ-packing of X_i; then $B \subseteq \{w \mid d(w) > d(\lambda)\}$ and $\sum_{w \in B} \nu(w)^t \leq 1$. Therefore, $P^t_0(X_i) \leq 1$ and $P^s_0(X_i) = 0$ (since $\sum_{w \in B} \nu(w)^s \leq \delta^{s-t} \stackrel{\delta\to 0}{\longrightarrow} 0$). Therefore $P^s(X) = 0$ and the claim follows. □

We next prove (3.5). $\inf \mathcal{G}^{\nu,\mathrm{str}}(X) \leq \mathrm{Dim}^{\nu}_{\mathrm{P}}(X)$ follows from Claims 1 and 2, and $\mathrm{Dim}^{\nu}_{\mathrm{P}}(X) \leq \widehat{\mathcal{G}}^{\nu,\mathrm{str}}(X)$ from Claim 3. □

We note that the case $\nu = \mu$ of (3.4) was proven by Lutz [36], and the case $\nu = \mu$ of (3.5) was proven by Athreya et al. [1].

Guided by Theorem 3.11, we now develop the constructive fractal ν-dimensions.

DEFINITION 3.12. *A ν-s-supergale d is constructive if it is lower semicomputable, i.e., if there is an exactly computable function $\widehat{d} : \Sigma^* \times \mathbb{N} \to \mathbb{Q}$ with the following two properties.*

(i) *For all $w \in \Sigma^*$ and $t \in \mathbb{N}$, $\widehat{d}(w,t) \leq \widehat{d}(w,t+1) < d(w)$.*

(ii) *For all $w \in \Sigma^*$, $\lim_{t\to\infty} \widehat{d}(w,t) = d(w)$.*

Notation. For each probability measure ν on Σ^∞ and each set $X \subseteq \Sigma^\infty$, we define the sets $\mathcal{G}^{\nu}_{\mathrm{constr}}(X)$, $\mathcal{G}^{\nu,\mathrm{str}}_{\mathrm{constr}}(X)$, $\widehat{\mathcal{G}}^{\nu}_{\mathrm{constr}}(X)$, and $\widehat{\mathcal{G}}^{\nu,\mathrm{str}}_{\mathrm{constr}}(X)$ exactly like the sets $\mathcal{G}^{\nu}(X)$, $\mathcal{G}^{\nu,\mathrm{str}}(X)$, $\widehat{\mathcal{G}}^{\nu}(X)$, and $\widehat{\mathcal{G}}^{\nu,\mathrm{str}}(X)$, respectively, except that the gales and supergales d are now required to be constructive.

DEFINITION 3.13. *Let ν be a probability measure on Σ^∞, and let $X \subseteq \Sigma^\infty$.*

1. *The* constructive ν-dimension *of X is* $\mathrm{cdim}^{\nu}(X) = \inf \widehat{\mathcal{G}}^{\nu}_{\mathrm{constr}}(X)$.
2. *The* constructive strong ν-dimension *of X is* $\mathrm{cDim}^{\nu}(X) = \inf \widehat{\mathcal{G}}^{\nu,\mathrm{str}}_{\mathrm{constr}}(X)$.
3. *The* constructive dimension *of X is* $\mathrm{cdim}(X) = \mathrm{cdim}^{\mu}(X)$.
4. *The* constructive strong dimension *of X is* $\mathrm{cDim}(X) = \mathrm{cDim}^{\mu}(X)$.

The fact that the "unhatted" $\mathcal{G}$-classes can be used in place of the "hatted" $\widehat{\mathcal{G}}$-classes is not as obvious in the constructive case as in the classical case. Nevertheless,

Fenner [16] proved that this is the case for constructive ν-dimension. (Hitchcock [25] proved this independently for the case $\nu = \mu$.) The case of strong ν-dimension also holds with a more careful argument [1].

THEOREM 3.14 (Fenner [16]). *If ν is a strongly positive, computable probability measure on Σ^∞, then, for all $X \subseteq \Sigma^\infty$,*

$$\mathrm{cdim}^\nu(X) = \inf \mathcal{G}^\nu_{\mathrm{constr}}(X)$$

and

$$\mathrm{cDim}^\nu(X) = \inf \mathcal{G}^{\nu,\mathrm{str}}_{\mathrm{constr}}(X).$$

A *correspondence principle* for an effective dimension is a theorem stating that the effective dimension coincides with its classical counterpart on sufficiently "simple" sets. The following such principle, proven by Hitchcock [26], extended a correspondence principle for computable dimension that was implicit in results of Staiger [46].

THEOREM 3.15 (correspondence principle for constructive dimension [26]). *If $X \subseteq \Sigma^\infty$ is any union (not necessarily effective) of computably closed, i.e., Π^0_1, sets, then* $\mathrm{cdim}(X) = \dim_{\mathrm{H}}(X)$.

We now define the constructive dimensions of individual sequences.

DEFINITION 3.16. *Let ν be a probability measure on Σ^∞, and let $S \in \Sigma^\infty$. Then the ν-dimension of S is*

$$\dim^\nu(S) = \mathrm{cdim}^\nu(\{S\}),$$

and the strong ν-dimension of S is

$$\mathrm{Dim}^\nu(S) = \mathrm{cDim}^\nu(\{S\}).$$

4. Kolmogorov complexity characterizations. In this section we prove characterizations of constructive ν-dimension and constructive strong ν-dimension in terms of Kolmogorov complexity. These characterizations are used in the proof of our main theorem in section 6.

Let Σ be a finite alphabet, with $|\Sigma| \geq 2$. The *Kolmogorov complexity* of a string $w \in \Sigma^*$ is the natural number

$$\mathrm{K}(w) = \min\{|\pi| \mid \pi \in \{0,1\}^* \text{ and } U(\pi) = w\},$$

where U is a fixed optimal universal prefix Turing machine. This is a standard notion of (prefix) Kolmogorov complexity. The reader is referred to the standard text by Li and Vitányi [33] for background on prefix Turing machines and Kolmogorov complexity.

If ν is a probability measure on Σ^∞, then the *Shannon self information* of a string $w \in \Sigma^*$ with respect to ν is

$$\mathcal{I}_\nu(w) = \log \frac{1}{\nu(w)}.$$

Note that $0 \leq \mathcal{I}_\nu(w) \leq \infty$. Equality holds on the left here if and only if $\nu(w) = 1$, and equality holds on the right if and only if $\nu(w) = 0$. Since our results here concern strongly positive probability measures, we will have $0 < \mathcal{I}_\nu(w) < \infty$ for all $w \in \Sigma^+$.

The following result is the main theorem of this section. It gives characterizations of the ν-dimensions and the strong ν-dimensions of sequences in terms of Kolmogorov complexity.

THEOREM 4.1. *If ν is a strongly positive, computable probability measure on Σ^∞, then, for all $S \in \Sigma^\infty$,*

$$\dim^\nu(S) = \liminf_{m\to\infty} \frac{\mathrm{K}(S[0..m-1])}{\mathcal{I}_\nu(S[0..m-1])} \tag{4.1}$$

and

$$\mathrm{Dim}^\nu(S) = \limsup_{m\to\infty} \frac{\mathrm{K}(S[0..m-1])}{\mathcal{I}_\nu(S[0..m-1])}. \tag{4.2}$$

Proof. Let $S \in \Sigma^\infty$. Let $s > s' > \liminf_m \frac{\mathrm{K}(S[0..m-1])}{\mathcal{I}_\nu(S[0..m-1])}$. For infinitely many m, $\mathrm{K}(S[0..m-1]) < s'\,\mathcal{I}_\nu(S[0..m-1])$, and so $\nu(S[0..m-1])^{s'} < 2^{-\mathrm{K}(S[0..m-1])}$.

Let $m \in \mathbb{N}$. We define the computably enumerable (c.e.) set

$$A = \{w \mid \mathrm{K}(w) < s'\,\mathcal{I}_\nu(w)\}$$

and the ν-s-constructive supergale d_m as follows. If there exists $v \sqsubseteq w$ such that $v \in A^{=m}$, then

$$d_m(w) = \left(\frac{\nu(w)}{\nu(v)}\right)^{1-s}.$$

Otherwise,

$$d_m(w) = \sum_{\substack{u,\\ wu\in A^{=m}}} \left(\frac{\nu(wu)}{\nu(w)}\right)^{s}.$$

First, notice that d_m is well defined since $d_m(\lambda) < \infty$ and d_m is a supergale,

$$d_m(\lambda) = \sum_{u\in A^{=m}} \nu(u)^s \le \sum_{u\in A^{=m}} 2^{-\mathrm{K}(u)}(1-\delta)^{m(s-s')} \le (1-\delta)^{m(s-s')},$$

for $\delta \in (0,1)$ a constant testifying that ν is strongly positive.

We define the ν-s-constructive supergale

$$d(w) = \sum_m (1-\delta)^{-m(s-s')} d_{2m}(w) + \sum_m (1-\delta)^{-m(s-s')} d_{2m+1}(w).$$

Notice that the fact that A is c.e. is necessary for the constructivity of d. Since for $w \in A$, $d_{|w|}(w) = 1$, we have that $d(w) \ge (1-\delta)^{-|w|(s-s')/2}$ for $w \in A$. Since for infinitely many m, $S[0..m-1] \in A$, we have that $S \in S^\infty[d]$ and $\dim^\nu(S) \le s$. This finishes the proof of the first inequality of (4.1).

For the other direction, let $s > \dim^\nu(S)$. Let d be a ν-s-constructive gale succeeding on S. Let $c \ge d(\lambda)$ be a rational number.

Let $B = \{w \mid d(w) > c\}$, and notice that B is c.e. For every m,

$$\sum_{w\in B^{=m}} \nu(w)^s \le 1.$$

Let $\theta_m : B^{=m} \to \{0,1\}^*$ be the Shannon–Fano–Elias code given by the probability submeasure p defined as $p(w) = \nu(w)^s$ for $w \in B^{=m}$ (this code assigns shorter code

words $\theta_m(w)$ to words with a larger probability $p(w)$; see, for example, [10]). Specifically, for each $w \in B^{=m}$, $\theta_m(w)$ is defined as the most significant $1 + \lceil \log \frac{1}{p(w)} \rceil$ bits of the real number

$$\sum_{\substack{|v|=m,\\ v<_B w}} p(v) + \frac{1}{2}\, p(w),$$

where $<_B$ corresponds to the words in B ordered according to their appearance in the computable enumeration of B.

Then

$$|\theta_m(w)| = 1 + \left\lceil \log \frac{1}{p(w)} \right\rceil = 1 + \lceil s\, \mathcal{I}_\nu(w) \rceil$$

for $w \in B^{=m}$.

Since B is c.e., codification and decodification can be computed given the length; that is, every $w \in B$ can be computed from $|w|$ and $\theta_{|w|}(w)$. Therefore, if $w \in B$, $\mathrm{K}(w) \le 2 + s\, \mathcal{I}_\nu(w) + 2 \log(|w|)$.

Notice that since ν is strongly positive, $\mathcal{I}_\nu(w) = \Omega(|w|)$, and since there exist infinitely many m for which $S[0..m-1] \in B$,

$$\liminf_{m\to\infty} \frac{\mathrm{K}(S[0..m-1])}{\mathcal{I}_\nu(S[0..m-1])} \le s.$$

The proof of (4.2) is analogous. □

If ν is a strongly positive probability measure on Σ^∞, then there is a real constant $\alpha > 0$ such that, for all $w \in \Sigma^*$, $\mathcal{I}_\nu(w) \ge \alpha |w|$. Since other notions of Kolmogorov complexity, such as the plain complexity $\mathrm{C}(w)$ and the monotone complexity $\mathrm{K_m}(w)$ [33], differ from $\mathrm{K}(w)$ by at most $O(\log |w|)$, it follows that Theorem 4.1 also holds with $\mathrm{K}(S[0..m-1])$ replaced by $\mathrm{C}(S[0..m-1])$, $\mathrm{K_m}(S[0..m-1])$, etc.

The following known characterizations of dimension and strong dimension are simply the special case of Theorem 4.1 in which $\Sigma = \{0,1\}$ and $\nu = \mu$.

Corollary 4.2 (see [39, 1]). *For all $S \in \{0,1\}^\infty$,*

$$\dim(S) = \liminf_{m\to\infty} \frac{\mathrm{K}(S[0..m-1])}{m}$$

and

$$\mathrm{Dim}(S) = \limsup_{m\to\infty} \frac{\mathrm{K}(S[0..m-1])}{m}.$$

Later, alternative proofs of Corollary 4.2 appear in [37, 48].

We define the dimension and strong dimension of a point x in Euclidean space as in (1.7) and (1.8). It is convenient to characterize these dimensions in terms of Kolmogorov complexity of rational approximations in Euclidean space. Specifically, for each $x \in \mathbb{R}^n$ and $r \in \mathbb{N}$, we define the *Kolmogorov complexity* of x at *precision* r to be the natural number

$$\mathrm{K}_r(x) = \min\left\{ K(q) \;\middle|\; q \in \mathbb{Q}^n \text{ and } |q - x| \le 2^{-r} \right\}.$$

That is, $\mathrm{K}_r(x)$ is the minimum length of any program $\pi \in \{0,1\}^*$ for which $U(\pi) \in \mathbb{Q}^n \cap B(x, 2^{-r})$. (Related notions of approximate Kolmogorov complexity have recently

been considered by Vereshchagin and Vitányi [51] and Fortnow, Lee, and Vereshchagin [18].) We also mention the quantity

$$\mathrm{K}_r(r,x) = \min\left\{K(r,q) \;\middle|\; q \in \mathbb{Q}^n \text{ and } |q-x| \le 2^{-r}\right\},$$

in which the program π must specify the precision parameter r as well as a rational approximation q of x to within 2^{-r}. The following relationship between these two quantities is easily verified by standard techniques.

OBSERVATION 4.3. *There exist constants $a, b \in \mathbb{N}$ such that, for all $x \in \mathbb{R}^n$ and $r \in \mathbb{N}$,*

$$\mathrm{K}_r(x) - a \le \mathrm{K}_r(r,x) \le \mathrm{K}_r(x) + \mathrm{K}(r) + b.$$

We now show that the quantity $\mathrm{K}_r(r,x)$ is within a constant of the Kolmogorov complexity of the first nr bits of an interleaved binary expansion of the fractional part of the coordinates of x, which was defined in section 1, together with the integer part of x.

LEMMA 4.4. *There is a constant $c \in \mathbb{N}$ such that, for all $x = (x_1, \ldots, x_n) \in \mathbb{R}^n$, all interleaved binary expansions S of the fractional parts of $x_1, \ldots, x_n$, and all $r \in \mathbb{N}$,*

$$|\mathrm{K}_r(r,x) - \mathrm{K}(\lfloor x \rfloor, S[0..nr-1])| \le c, \tag{4.3}$$

where $\lfloor x \rfloor$ is the interleaved binary expansion of $(\lfloor x_1 \rfloor, \ldots, \lfloor x_n \rfloor)$.

Proof. We first consider the case $x \in [0,1]^n$. For convenience, let $l = \lceil \frac{\log n}{2} \rceil$ (notice that both n and l are constants). Let M be a prefix Turing machine such that, if $\pi \in \{0,1\}^*$ is a program such that $U(\pi) = w \in \{0,1\}^*$ and $|w|$ is divisible by n, and if $v \in \{0,1\}^{nl}$, then $M(\pi v) = (|w|/n, q)$, where $q \in \mathbb{Q}^n$ is the dyadic rational point whose interleaved binary expansion is wv. Let $c_1 = nl + c_M$, where c_M is an optimality constant for M. Let $x \in \mathbb{R}^n$, let S be an interleaved binary expansion of x, and let $r \in \mathbb{N}$. Let $\pi \in \{0,1\}^*$ be a witness to the value of $\mathrm{K}_r(S[0..nr-1])$, and let $v = S[nr..n(r+l)-1]$. Then $M(\pi v) = (r,q)$, where q is the dyadic rational point whose interleaved binary expansion is $S[0..n(l+r)-1]$. Since

$$|q-x| = \sqrt{n(2^{-(r+l)})^2} = 2^{-(r+l)}\sqrt{n} \le 2^{-r},$$

it follows that

$$\mathrm{K}_r(r,x) \le |\pi v| + c_M = \mathrm{K}(S[0..nr-1]) + c_1, \tag{4.4}$$

which is one of the inequalities we need to get (4.3).

We now turn to the reverse inequality. For each $r \in \mathbb{N}$ and $q \in \mathbb{Q}^n$, let $A_{r,q}$ be the set of all r-dyadic points within $2^{l-r} + 2^r$ of q. That is, $A_{r,q}$ is the set of all points $q' = (q'_1, \ldots, q'_n) \in \mathbb{Q}^n$ such that $|q-q'| \le 2^{l-r} + 2^r$ and each q'_i is of the form $2^{-r}a'_i$ for some integer a'_i.

Let $q', q'' \in A_{r,q}$. For each $1 \le i \le n$, let $q'_i = 2^{-r}a'_i$ and $q''_i = 2^{-r}a''_i$ be the ith coordinates of q' and q'', respectively. Then, for each $1 \le i \le n$, we have

$$\begin{aligned} |a'_i - a''_i| &= 2^r|q'_i - q''_i| \\ &\le 2^r(|q'-q| + |q''-q|) \\ &\le 2^{r+1}(2^{l-r} + 2^{-r}) \\ &= 2^{l+1} + 2. \end{aligned}$$

This shows that there are at most $2^{l+1}+3$ possible values of a'_i. It follows that

$$|A_{r,q}| \le (2^{l+1}+3)^n. \tag{4.5}$$

Let M' be a prefix Turing machine such that, if $\pi \in \{0,1\}^*$ is a program such that $U(\pi) = (r,q) \in \mathbb{N} \times \mathbb{Q}^n$, $0 \le m < |A_{r,q}|$, and s_m is the mth string in the standard enumeration $s_0, s_1, s_2, \ldots$ of $\{0,1\}^*$, then $M'(\pi 0^{|s_m|}1 s_m)$ is the nr-bit interleaved binary expansion of the fractional points of the coordinates of the mth element of a canonical enumeration of $A_{r,q}$. Let $c_2 = n(2l'+1) + c_{M'}$, where $l' = \lceil \log(2^{l+1}+3) \rceil$ and $c_{M'}$ is an optimality constant for M'.

Let $x \in \mathbb{R}^n$, let S be an interleaved binary expansion of x, and let $r \in \mathbb{N}$. Let q' be the r-dyadic point whose interleaved binary expansion is $S[0..nr-1]$, and let $\pi \in \{0,1\}^*$ be a witness to the value of $\mathrm{K}_r(r,x)$. Then $U(\pi) = (r,q)$ for some $q \in \mathbb{Q}^n \cap B(x, 2^{-r})$. Since

$$\begin{aligned} |q'-q| &\le |q'-x| + |q-x| \\ &\le 2^{-r}\sqrt{n} + 2^{-r} \\ &\le 2^{l-r} + 2^{-r}, \end{aligned}$$

we have $q' \in A_{q,r}$. It follows that there exists $0 \le m < |A_{r,q}|$ such that $M'(\pi 0^{|s_m|}1 s_m) = S[0..nr-1]$. This implies that

$$\begin{aligned} \mathrm{K}(S[0..nr-1]) &\le |\pi 0^{|s_m|}1 s_m| + c_{M'} \\ &= \mathrm{K}_r(r,x) + 2|s_m| + c_{M'} + 1 \\ &\le \mathrm{K}_r(r,x) + 2|s_{|A_{r,q}|-1}| + c_{M'} + 1 \\ &= \mathrm{K}_r(r,x) + 2\lfloor \log |A_{r,q}| \rfloor + c_{M'} + 1 \\ &\le \mathrm{K}_r(r,x) + 2\lfloor n \log(2^{l+1}+3) \rfloor + c_{M'} + 1 \\ &\le \mathrm{K}_r(r,x) + c_2. \end{aligned} \tag{4.6}$$

If we let $c = \max\{c_1, c_2\}$, then (4.4) and (4.6) imply (4.3).

For the general case, notice that $\mathrm{K}_r(r, \lfloor x \rfloor) = \mathrm{K}(\lfloor x \rfloor) + O(1)$. □

We now have the following characterizations of the dimensions and strong dimensions of points in Euclidean space.

THEOREM 4.5. *For all $x \in \mathbb{R}^n$,*

$$\dim(x) = \liminf_{r\to\infty} \frac{\mathrm{K}_r(x)}{r}, \tag{4.7}$$

and

$$\mathrm{Dim}(x) = \limsup_{r\to\infty} \frac{\mathrm{K}_r(x)}{r}. \tag{4.8}$$

Proof. Let $x \in \mathbb{R}^n$, and let S be an interleaved binary expansion of the fractional parts of the coordinates of x. By (1.7) and Corollary 4.2, we have

$$\begin{aligned} \dim(x) &= n \dim(S) \\ &= n \liminf_{m\to\infty} \frac{\mathrm{K}(S[0..m-1])}{m}. \end{aligned}$$

Since all values of $\mathrm{K}(S[0..m-1])$ with $nr \leq m < n(r+1)$ are within a constant (that depends on the constant n) of one another, it follows that

$$\begin{aligned}\dim(x) &= n \liminf_{r\to\infty} \frac{\mathrm{K}(S[0..nr-1])}{nr} \\ &= \liminf_{r\to\infty} \frac{\mathrm{K}(S[0..nr-1])}{r}.\end{aligned}$$

Since $\mathrm{K}(r) = O(\log r)$ [33], it follows by Observation 4.3 and Lemma 4.4 that (4.7) holds. The proof that (4.8) holds is analogous. □

5. Self-similar fractals. This expository section reviews a fragment of the theory of self-similar fractals that is adequate for understanding our main theorem and its proof. Our treatment is self-contained but of course far from complete. The interested reader is referred to any of the standard texts [2, 12, 13, 15] for more extensive discussion.

DEFINITION 5.1. *A* contracting similarity *on a set $D \subseteq \mathbb{R}^n$ is a function $S : D \to D$ for which there exists a real number $c \in (0,1)$, called a* contraction ratio *of S, satisfying $|S(x) - S(y)| = c|x-y|$ for all $x, y \in D$.*

DEFINITION 5.2. *An* iterated function system (IFS) *is a finite sequence $S = (S_0, \ldots, S_{k-1})$ of two or more contracting similarities on a nonempty, closed set $D \subseteq \mathbb{R}^n$. We call D the* domain *of S, writing $D = \mathrm{dom}(S)$.*

We note that IFSs are often defined more generally. For example, IFSs consisting of *contractions*, which merely satisfy inequalities of the form $|S(x)-S(y)| \leq c|x-y|$ for some $c \in (0,1)$, are often considered. Since our results here are confined to self-similar fractals, we have used the more restrictive definition.

We use the standard notation $\mathcal{K}(D)$ for the set of all nonempty compact (i.e., closed and unbounded) subsets of a nonempty closed set $D \subseteq \mathbb{R}^n$. For each IFS S, we write $\mathcal{K}(S) = \mathcal{K}(\mathrm{dom}(S))$.

With each IFS $S = (S_0, \ldots, S_{k-1})$, we define the transformation $S : \mathcal{K}(S) \to \mathcal{K}(S)$ by

$$S(A) = \bigcup_{i=0}^{k-1} S_i(A)$$

for all $A \in \mathcal{K}(S)$, where $S_i(A)$ is the image of A under the contracting similarity S_i.

OBSERVATION 5.3. *For each IFS S, there exists $A \in \mathcal{K}(S)$ such that $S(A) \subseteq A$.*

Proof. Assume the hypothesis, with $S = (S_0, \ldots, S_{k-1})$ and $\mathrm{dom}(S) = D$, and let $c_0, \ldots, c_{k-1}$ be contraction ratios of $S_0, \ldots, S_{k-1}$, respectively. Let $c = \min\{c_0, \ldots, c_{k-1}\}$, noting that $c \in (0,1)$, and fix $z \in D$. Let

$$r = \frac{1}{1-c} \max_{0\leq i<k} |S_i(z) - z|,$$

and let $A = D \cap \mathcal{B}_r(z)$. Then A is a closed subset of the compact set $\mathcal{B}_r(z)$, and $z \in A$, so $A \in \mathcal{K}(S)$. For all $x \in A$ and $0 \leq i < k$, we have

$$\begin{aligned}|S_i(x) - z| &\leq |S_i(x) - S_i(z)| + |S_i(z) - z| \\ &= c|x - z| + |S_i(z) - z| \\ &\leq cr + (1-c)r \\ &= r,\end{aligned}$$

so each $S_i(A) \subseteq A$, and so $S(A) \subseteq A$. □

For each IFS $S = (S_0, \ldots, S_{k-1})$ and each set $A \in \mathcal{K}(S)$ satisfying $S(A) \subseteq A$, we define the function $S_A : \Sigma_k^* \to \mathcal{K}(S)$ by the recursion

$$S_A(\lambda) = A,$$

$$S_A(iw) = S_i(S_A(w))$$

for all $w \in \Sigma_k^*$ and $i \in \Sigma_k$.

If $c = \max\{c_0, \ldots, c_{k-1}\}$, where $c_0, \ldots, c_{k-1}$ are contraction ratios of $S_0, \ldots, S_{k-1}$, respectively, then routine inductions establish that, for all $w \in \Sigma_k^*$ and $i \in \Sigma_k$,

$$S_A(iw) \subseteq S_A(w) \tag{5.1}$$

and

$$\operatorname{diam}(S_A(w)) \leq c^{|w|}\operatorname{diam}(A). \tag{5.2}$$

Since $c \in (0,1)$, it follows that, for each sequence $T \in \Sigma_k^\infty$, there is a unique point $S_A(T) \in \mathbb{R}^n$ such that

$$\bigcap_{w \sqsubseteq T} S_A(w) = \{S_A(T)\}. \tag{5.3}$$

In this manner, we have defined a function $S_A : \Sigma_k^\infty \to \mathbb{R}^n$. The following observation shows that this function does not really depend on the choice of A.

Observation 5.4. *Let S be an IFS. If $A, B \in \mathcal{K}(S)$ satisfy $S(A) \subseteq A$ and $S(B) \subseteq B$, then $S_A = S_B$.*

Our proof of Observation 5.4 uses the *Hausdorff metric* on $\mathcal{K}(\mathbb{R}^n)$, which is the function $\rho_H : \mathcal{K}(\mathbb{R}^n) \times \mathcal{K}(\mathbb{R}^n) \to [0, \infty)$ defined by

$$\rho_H(A, B) = \max\{\sup_{x \in A} \inf_{y \in B} |x - y|, \sup_{y \in B} \inf_{x \in A} |x - y|\}$$

for all $A, B \in \mathcal{K}(\mathbb{R}^n)$. It is easy to see that ρ_H is a *metric* on $\mathcal{K}(\mathbb{R}^n)$. It follows that ρ_H is a metric on $\mathcal{K}(S)$ for every IFS S.

Proof of Observation 5.4. Assume the hypothesis, with $S = (S_0, \ldots, S_{k-1})$, and let $c_0, \ldots, c_{k-1}$ be contraction ratios of $S_0, \ldots, S_{k-1}$, respectively. The definition of ρ_H implies immediately that, for all $E, F \in \mathcal{K}(S)$ and $0 \leq i < k$, $\rho_H(S_i(E), S_i(F)) = c_i \rho_H(E, F)$. It follows by an easy induction that, if we let $c = \max\{c_0, \ldots, c_{k-1}\}$, then, for all $w \in \Sigma_k^*$,

$$\rho_H(S_A(w), S_B(w)) \leq c^{|w|}\rho_H(A, B). \tag{5.4}$$

To see that $S_A = S_B$, let $T \in \Sigma_k^\infty$, and let $\epsilon > 0$. For each $w \sqsubseteq T$, (5.1), (5.2), and (5.3) tell us that

$$\rho_H(\{S_A(T)\}, S_A(w)) \leq \operatorname{diam}(S_A(w)) \leq c^{|w|}\operatorname{diam}(A) \tag{5.5}$$

and

$$\rho_H(\{S_A(T)\}, S_B(w)) \leq \operatorname{diam}(S_B(w)) \leq c^{|w|}\operatorname{diam}(B). \tag{5.6}$$

Since $c \in (0,1)$, (5.4), (5.5), and (5.6) tell us that there is a prefix $w \sqsubseteq T$ such that

$$\begin{aligned}
&\rho_H(\{S_A(T)\},\{S_B(T)\}) \\
&\leq \rho_H(\{S_A(T)\},S_A(w)) + \rho_H(S_A(w),S_B(w)) + \rho_H(\{S_B(T)\},S_B(w)) \\
&< \epsilon/3 + \epsilon/3 + \epsilon/3 \\
&= \epsilon.
\end{aligned}$$

Since this holds for all $\epsilon > 0$, it follows that $\rho_H(\{S_A(T)\},\{S_B(T)\}) = 0$, i.e., that $S_A(T) = S_B(T)$. □

For each IFS S, we define the induced function $S : \Sigma_k^\infty \to \mathbb{R}^n$ by setting $S = S_A$, where A is *any* element of $\mathcal{K}(S)$ satisfying $S(A) \subseteq A$. By Observations 5.3 and 5.4, this induced function S is well defined.

We now have the machinery to define a rich collection of fractals in $\mathbb{R}^n$.

DEFINITION 5.5. *The* attractor *(or* invariant set*) of an IFS $S = (S_0,\ldots,S_{k-1})$ is the set*

$$F(S) = S(\Sigma_k^\infty),$$

i.e., the range of the induced function $S : \Sigma_k^\infty \to \mathbb{R}^n$.

It is well known that the attractor $F(S)$ is the unique fixed point of the induced transformation $S : \mathcal{K}(S) \to \mathcal{K}(S)$, but we do not use this fact here.

For each $T \in \Sigma_k^\infty$, we call T a *coding sequence*, or an *S-code*, of the point $S(T) \in F(S)$.

Example 5.6 (generalized Sierpinski triangles S in $\mathbb{R}^2$). Let D be the set consisting of the triangle in $\mathbb{R}^2$ with vertices $v_0 = (0,0)$, $v_1 = (1,0)$, and $v_2 = (\frac{1}{2}, \frac{\sqrt{3}}{2})$, together with this triangle's interior. Given $c_0, c_1, c_2 \in (0,1)$, define $S_0, S_1, S_2 : D \to D$ by

$$S_i(p) = v_i + c_i(p - v_i)$$

for $i \in \{0,1,2\}$ and $p \in D$. Then S_0, S_1, and S_2 are contracting similarities with contraction ratios c_0, c_1, and c_2, respectively, and so $S = (S_0, S_1, S_2)$ is an IFS with domain D. Intuitively, a coding sequence $T \in \{0,1,2\}^\infty$ can be regarded as an abbreviation of the procedure

$\Delta_0 := D$;
for $j := 0$ to ∞ do
    $\Delta_{j+1} :=$ the $c_{T[j]}$ − reduced copy of Δ_j lying in corner $T[j]$ of Δ_j.

The point $S(T)$ of $F(S)$ is then the unique point of $\mathbb{R}^2$ lying in all the triangles $\Delta_0, \Delta_1, \Delta_2, \ldots$. The attractor $F(S)$ is thus a generalized Sierpinski triangle. Figure 2(a,b) illustrates this construction in the case where $c_0 = \frac{1}{2}$, $c_1 = \frac{1}{4}$, and $c_2 = \frac{1}{3}$. If $c_0 = c_1 = c_2 = 1/2$, then $F(S)$ is the familiar Sierpinski triangle of Figure 2(c).

In general, the attractor of an IFS $S = (S_0,\ldots,S_{k-1})$ is easiest to analyze when the sets $S_0(\mathrm{dom}(S)),\ldots,S_{k-1}(\mathrm{dom}(S))$ are "nearly disjoint." (Intuitively, this prevents each point $x \in F(S)$ from having "too many" coding sequences $T \in \Sigma_k^\infty$.) The following definition makes this notion precise.

DEFINITION 5.7. *An IFS $S = (S_0,\ldots,S_{k-1})$ with domain D satisfies the* open set condition *if there exists a nonempty, bounded, open set $G \subseteq D$ such that $S_0(G),\ldots,S_{k-1}(G)$ are disjoint subsets of G.*

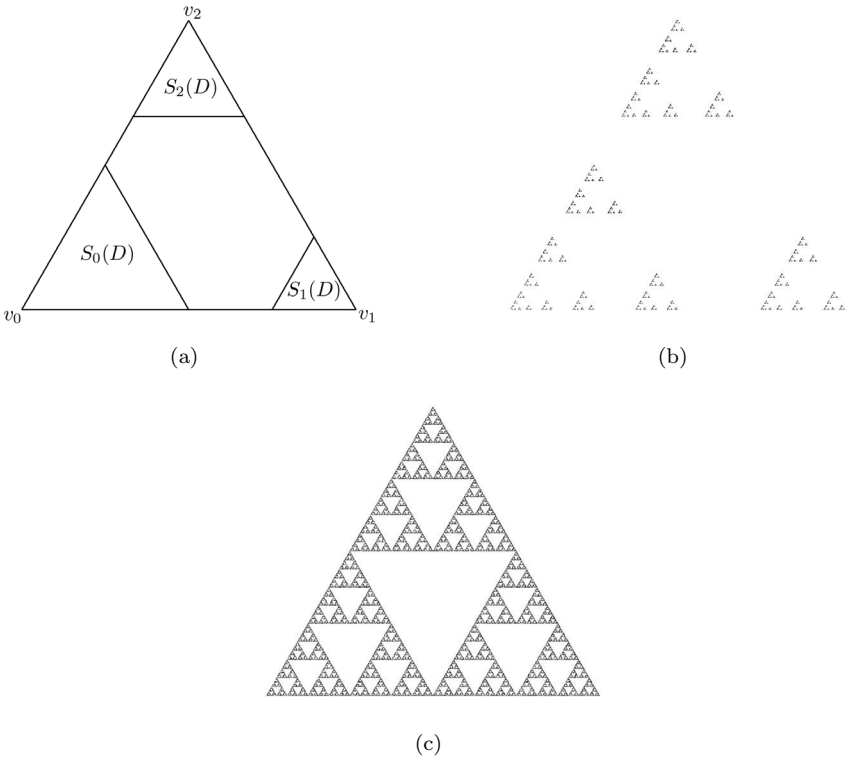

FIG. 2. (a) *The IFS S of Example* 5.6, *with* $c_0 = \frac{1}{2}$, $c_1 = \frac{1}{4}$, *and* $c_2 = \frac{1}{3}$. (b) *The attractor $F(S)$ of this IFS.* (c) *The attractor $F(S)$ when* $c_0 = c_1 = c_2 = \frac{1}{2}$.

We now define the most widely known type of fractal.

DEFINITION 5.8. *A* self-similar fractal *is a set $F \subseteq \mathbb{R}^n$ that is the attractor of an IFS that satisfies the open set condition.*

Example 5.9 (Example 5.6 continued). If $c_0+c_1 \leq 1$, $c_0+c_2 \leq 1$, and $c_1+c_2 \leq 1$, then the set $G = D^o$ (the topological interior of D) testifies that S satisfies the open set condition, whence $F(S)$ is a self-similar fractal. If $c_0 + c_1 > 1$ or $c_0 + c_2 > 1$ or $c_1 + c_2 > 1$, then S does not satisfy the open set condition.

The following quantity plays a central role in the theory of self-similar fractals.

DEFINITION 5.10. *The* similarity dimension *of an IFS $S = (S_0, \ldots, S_{k-1})$ with contraction ratios $c_0, \ldots, c_{k-1}$ is the (unique) solution* $\operatorname{sdim}(S) = s \in [0, \infty)$ *of the equation*

$$\sum_{i=0}^{k-1} c_i^s = 1.$$

If $F = F(S)$ is a self-similar fractal, where S is an IFS satisfying the open set condition, then the classical Hausdorff and packing dimensions of F are known to coincide with the similarity dimension of S. (The fact that this holds for Hausdorff dimension was proven by Moran [40]. The fact that it holds for packing dimension was proven by Falconer [14]. As we shall see, both facts follow from our main theorem.) In particular, this implies that the following definition is unambiguous.

DEFINITION 5.11. *The* similarity dimension *of a self-similar fractal F is the number*

$$\mathrm{sdim}(F) = \mathrm{sdim}(S),$$

where S is an IFS satisfying $F(S) = F$ and the open set condition.

It should be noted that some authors define a fractal to be self-similar if it is the attractor of *any* IFS S. With this terminology, i.e., in the absence of the open set condition, the Hausdorff and packing dimensions may be less than the similarity dimension.

6. Pointwise analysis of dimensions. In this section we prove our main theorem, which gives a precise analysis of the dimensions of individual points in computably self-similar fractals. We first recall the known fact that such fractals are computable.

DEFINITION 6.1. *An IFS $S = (S_0, \ldots, S_{k-1})$ is computable if* $\mathrm{dom}(S)$ *is a computable set and the functions $S_0, \ldots, S_{k-1}$ are computable.*

THEOREM 6.2 (Kamo and Kawamura [27]). *For every computable IFS S, the attractor $F(S)$ is a computable set.*

One consequence of Theorem 6.2 is the following.

COROLLARY 6.3. *For every computable IFS S,* $\mathrm{cdim}(F(S)) = \dim_{\mathrm{H}}(F(S))$.

Proof. Let S be a computable IFS. Then $F(S)$ is compact, hence closed, and is computable by Theorem 6.2, so $F(S)$ is computably closed by Observation 2.2. It follows by the correspondence principle for constructive dimension (Theorem 3.15) that $\mathrm{cdim}(F(S)) = \dim_{\mathrm{H}}(F(S))$. □

We next present three lemmas that we use in the proof of our main theorem. The first is a well-known geometric fact (e.g., it is Lemma 9.2 in [15]) whose proof is short enough to repeat here.

LEMMA 6.4. *Let $\mathcal{G}$ be a collection of disjoint open sets in $\mathbb{R}^n$, and let $r, a, b \in (0, \infty)$. If every element of $\mathcal{G}$ contains a ball of radius ar and is contained in a ball of radius br, then no ball of radius r meets more than $\left(\frac{1+2b}{a}\right)^n$ of the closures of the elements of $\mathcal{G}$.*

Proof. Assume the hypothesis, and let B be a ball of radius r. Let

$$\mathcal{M} = \left\{ G \in \mathcal{G} \;\middle|\; B \cap \overline{G} \neq \emptyset \right\},$$

and let $m = |\mathcal{M}|$. Let B' be a closed ball that is concentric with B and has radius $(1 + 2b)r$. Then B' contains $\overline{G}$ for every $G \in \mathcal{M}$. Since each $G \in \mathcal{M}$ contains a ball B_G of radius ar, and since these balls are disjoint, it follows that

$$\mathrm{volume}(B') \geq \sum_{G \in \mathcal{M}} \mathrm{volume}(B_G).$$

This implies that

$$[(1 + 2b)r]^n \geq m(ar)^n,$$

whence $m \leq \left(\frac{1+2b}{a}\right)^n$. □

Our second lemma gives a computable means of assigning rational "hubs" to the various open sets arising from a computable IFS satisfying the open set condition.

DEFINITION 6.5. *A* hub function *for an IFS $S = (S_0, \ldots, S_{k-1})$ satisfying the open set condition with G as witness is a function $h : \Sigma_k^* \to \mathbb{R}^n$ such that $h(w) \in$*

$S_G(w)$ for all $w \in \Sigma_k^*$. In this case, we call $h(w)$ the hub *that h assigns to the set $S_G(w)$.*

LEMMA 6.6. *If $S = (S_0, \ldots, S_{k-1})$ is a computable IFS satisfying the open set condition with G as witness, then there is an exactly computable, rational-valued hub function $h : \Sigma_k^* \to \mathbb{Q}^n$ for S and G.*

Proof. Assume the hypothesis. From oracle Turing machines computing $S_0, \ldots, S_{k-1}$, it is routine to construct an oracle Turing machine M computing the function

$$\tilde{S} : \mathrm{dom}(S) \times \Sigma_k^* \to \mathrm{dom}(S)$$

defined by the recursion

$$\begin{aligned} \tilde{S}(x, \lambda) &= x, \\ \tilde{S}(x, iw) &= S_i(\tilde{S}(x, w)) \end{aligned}$$

for all $x \in \mathrm{dom}(S)$, $w \in \Sigma_k^*$, and $i \in \Sigma_k$. Fix a rational point $q \in G \cap \mathbb{Q}^n$, and let C_q be the oracle that returns the value q on all queries, noting that

$$|M^{C_q}(w, r) - \tilde{S}(q, w)| \leq 2^{-r} \tag{6.1}$$

holds for all $w \in \Sigma_k^*$ and $r \in \mathbb{N}$. Fix $l \in \mathbb{Z}^+$ large enough to satisfy the following conditions.

(i) G contains the closed ball of radius 2^{-l} about q.

(ii) For each $i \in \Sigma_k$, $2^{-l} \leq c_i$, where c_i is the contraction ratio of S_i.

Then a routine induction shows that, for each $w \in \Sigma_k^*$, $S_G(w)$ contains the closed ball of radius $2^{-l(1+|w|)}$ about $\tilde{S}(q, w)$. It follows by (6.1) that the function $h : \Sigma_k^* \to \mathbb{Q}^n$ defined by

$$h(w) = M^{C_q}(w, l(1 + |w|))$$

is a hub function for S and G. It is clear that h is rational-valued and exactly computable. □

Iterated function systems induce probability measures on alphabets in the following manner.

DEFINITION 6.7. *The* similarity probability measure *of an IFS $S = (S_0, \ldots, S_{k-1})$ with contraction ratios $c_0, \ldots, c_{k-1}$ is the probability measure π_S on the alphabet Σ_k defined by*

$$\pi_S(i) = c_i^{\mathrm{sdim}(S)}$$

for all $i \in \Sigma_k$. For $w \in \Sigma_k^*$, we use the abbreviation $\mathcal{I}_S(w) = \mathcal{I}_{\pi_S}(w)$.

Our third lemma provides a decidable set of well-behaved "canonical prefixes" of sequences in Σ_k^∞.

LEMMA 6.8. *Let $S = (S_0, \ldots, S_{k-1})$ be a computable IFS, and let $c_{\min}$ be the minimum of the contraction ratios of $S = (S_0, \ldots, S_{k-1})$. For any real number*

$$\alpha > \mathrm{sdim}(S) \log \frac{1}{c_{\min}}, \tag{6.2}$$

there exists a decidable set $A \subseteq \mathbb{N} \times \Sigma_k^*$ such that, for each $r \in \mathbb{N}$, the set

$$A_r = \{ w \in \Sigma_k^* \mid (r, w) \in A \}$$

has the following three properties.

(i) *No element of A_r is a proper prefix of any element of $A_{r'}$ for any $r' \leq r$.*
(ii) *Each sequence in Σ_k^∞ has a (unique) prefix in A_r.*
(iii) *For all $w \in A_r$,*

$$r \cdot \mathrm{sdim}(S) < \mathcal{I}_S(w) < r \cdot \mathrm{sdim}(S) + \alpha. \tag{6.3}$$

Proof. Let S, $c_{\min}$, and α be as given, and let $c_0, \ldots, c_{k-1}$ be the contraction ratios of $S_0, \ldots, S_{k-1}$, respectively. Let $c_{\max} = \max\{c_0, \ldots, c_{k-1}\}$, and let $\delta = \frac{1}{2}\min\{c_{\min}, 1 - c_{\max}\}$, noting that $\delta \in (0, \frac{1}{2k}]$. Since S is computable, there is, for each $i \in \Sigma_k$, an exactly computable function

$$\widehat{c}_i : \mathbb{N} \to \mathbb{Q} \cap [\delta, 1 - \delta]$$

such that, for all $t \in \mathbb{N}$,

$$|\widehat{c}_i(t) - c_i| \leq 2^{-t}. \tag{6.4}$$

For all $T \in \Sigma_k^\infty$ and $l, t \in \mathbb{N}$, we have

$$\begin{aligned}
&\prod_{i=0}^{l-1} \widehat{c}_{T[i]}(t+i) - \prod_{i=0}^{l-1} c_{T[i]} \\
&= \sum_{i=0}^{l-1} \left[\left(\prod_{j=0}^{i-1} c_{T[j]} \right) \left(\prod_{j=i}^{l-1} \widehat{c}_{T[j]}(t+j) \right) \right. \\
&\quad \left. - \left(\prod_{j=0}^{i} c_{T[j]} \right) \left(\prod_{j=i+1}^{l-1} \widehat{c}_{T[j]}(t+j) \right) \right] \\
&= \sum_{i=0}^{l-1} (\widehat{c}_{T[i]}(t+i) - c_{T[i]}) p_i,
\end{aligned}$$

where

$$p_i = \left(\prod_{j=0}^{i-1} c_{T[j]} \right) \left(\prod_{j=i+1}^{l-1} \widehat{c}_{T[j]}(t+j) \right).$$

Since each $|p_i| \leq 1$, it follows by (6.4) that

$$\left| \prod_{i=0}^{l-1} \widehat{c}_{T[i]}(t+i) - \prod_{i=0}^{l-1} c_{T[i]} \right| < 2^{1-t} \tag{6.5}$$

holds for all $T \in \Sigma_k^\infty$ and $l, t \in \mathbb{N}$.

By (6.2), we have $2^{-\alpha/\mathrm{sdim}(S)}/c_{\min} < 1$, so we can fix $m \in \mathbb{Z}^+$ such that

$$2^{1-m} < 1 - 2^{-\alpha/\mathrm{sdim}(S)}/c_{\min}. \tag{6.6}$$

For each $T \in \Sigma_k^\infty$ and $r \in \mathbb{N}$, let

$$l_r(T) = \min \left\{ l \in \mathbb{N} \;\middle|\; \prod_{i=0}^{l-1} \widehat{c}_{T[i]}(r+m+i+1) \leq 2^{-r} - 2^{-(r+m)} \right\},$$

and let

$$A = \{(r, T[0..l_r(T)]) \mid T \in \Sigma_k^\infty \text{ and } r \in \mathbb{N}\}.$$

Since the functions $\widehat{c}_0, \ldots, \widehat{c}_{k-1}$ are rational-valued and exactly computable, the set A is decidable. It is clear that each A_r has properties (i) and (ii).

Let $r \in \mathbb{N}$. To see that A_r has property (iii), let $w \in A_r$. Let $l = |w|$, and fix $T \in \Sigma_k^\infty$ such that $l = l_r(T)$ and $w = T[0..l-1]$. By the definition of $l_r(T)$ and (6.5), we have

$$\prod_{i=0}^{l-1} c_{w[i]} < 2^{-r},$$

which implies that

$$\mathcal{I}_S(w) > r \cdot \operatorname{sdim}(S). \tag{6.7}$$

If $l > 0$, then the minimality of $l_r(T)$ tells us that

$$\prod_{i=0}^{l-2} \widehat{c}_{w[i]}(r+m+i+1) > 2^{-r} - 2^{-(r+m)}.$$

It follows by (6.5) and (6.6) that

$$\begin{aligned}\prod_{i=0}^{l-2} c_{w[i]} &> 2^{-r} - 2^{1-(r+m)} \\ &= 2^{-r}(1 - 2^{1-m}) \\ &> 2^{-(r+\alpha/\operatorname{sdim}(S))}/c_{\min},\end{aligned}$$

whence

$$\begin{aligned}\prod_{i=0}^{l-1} c_{w[i]} &> \frac{c_{w[l-1]}}{c_{\min}} 2^{-(r+\alpha/\operatorname{sdim}(S))} \\ &\geq 2^{-(r+\alpha/\operatorname{sdim}(S))}.\end{aligned}$$

This implies that

$$\pi_S(w) > 2^{-(r\cdot\operatorname{sdim}(S)+\alpha)}. \tag{6.8}$$

If $l = 0$, then $\pi_S(w) = 1$, so (6.8) again holds. Hence, in any case, we have

$$\mathcal{I}_S(w) < r \cdot \operatorname{sdim}(S) + \alpha. \tag{6.9}$$

By (6.7) and (6.9), A_r has property (iii). □

Our main theorem concerns the following type of fractal.

DEFINITION 6.9. *A* computably self-similar fractal *is a set $F \subseteq \mathbb{R}^n$ that is the attractor of an IFS that is computable and satisfies the open set condition.*

Most self-similar fractals occurring in the literature are, in fact, computably self-similar. For instance, let F be a generalized Sierpinski triangle with contraction ratios $c_0, c_1, c_2 \in (0,1)$, defined as in Example 5.6. As we have noted, F is self-similar if

$c_0 + c_1 \leq 1$, $c_0 + c_2 \leq 1$, and $c_1 + c_2 \leq 1$. It is easy to see that F is computably self-similar if c_0, c_1, and c_2 are also computable real numbers.

We now have the machinery to give a complete analysis of the dimensions of points in computably self-similar fractals.

THEOREM 6.10 (main theorem). *If $F \subseteq \mathbb{R}^n$ is a computably self-similar fractal and S is an IFS testifying this fact, then, for all points $x \in F$ and all S-codes T of x,*

$$\dim(x) = \mathrm{sdim}(F)\dim^{\pi_S}(T) \tag{6.10}$$

and

$$\mathrm{Dim}(x) = \mathrm{sdim}(F)\mathrm{Dim}^{\pi_S}(T). \tag{6.11}$$

Proof. Assume the hypothesis, with $S = (S_0, \ldots, S_{k-1})$. Let $c_0, \ldots, c_{k-1}$ be the contraction ratios of $S_0, \ldots, S_{k-1}$, respectively, let G be a witness to the fact that S satisfies the open set condition, and let $l = \max\{0, \lceil \log \mathrm{diam}(G) \rceil\}$. Let $h : \Sigma_k^* \to \mathbb{Q}^n$ be an exactly computable, rational-valued hub function for S and G as given by Lemma 6.6. Let $\alpha = 1 + \mathrm{sdim}(F) \log \frac{1}{c_{\min}}$ for $c_{\min} = \min\{c_0, \ldots, c_{k-1}\}$, and choose a decidable set A for S and α as in Lemma 6.8.

For all $w \in \Sigma_k^*$, we have

$$\begin{aligned} \mathrm{diam}(S_G(w)) &= \mathrm{diam}(G) \prod_{i=0}^{|w|-1} c_{w[i]} \\ &= \mathrm{diam}(G)\pi_S(w)^{\frac{1}{\mathrm{sdim}(F)}}. \end{aligned}$$

It follows by (6.3) that, for all $r \in \mathbb{N}$ and $w \in A_{r+l}$,

$$2^{-r} a_1 \leq \mathrm{diam}(S_G(w)) \leq 2^{-r}, \tag{6.12}$$

where $a_1 = 2^{-\left(l + \frac{\alpha}{\mathrm{sdim}(F)}\right)} \mathrm{diam}(G)$.

Let $x \in F$, and let $T \in \Sigma_k^\infty$ be an S-code of x, i.e., $S(T) = x$. For each $r \in \mathbb{N}$, let w_r be the unique element of A_{r+l} that is a prefix of T. Much of this proof is devoted to deriving a close relationship between the Kolmogorov complexities $\mathrm{K}_r(x)$ and $\mathrm{K}(w_r)$. Once we have this relationship, we will use it to prove (6.10) and (6.11).

Since the hub function h is computable, there is a constant a_2 such that, for all $w \in \Sigma_k^*$,

$$\mathrm{K}(h(w)) \leq \mathrm{K}(w) + a_2. \tag{6.13}$$

Since $h(w_r) \in S_G(w_r)$ and $x = S(T) \in S_{\overline{G}}(w_r) = \overline{S_G(w_r)}$, (6.12) tells us that

$$|h(w_r) - x| \leq \mathrm{diam}(S_G(w_r)) \leq 2^{-r},$$

whence

$$\mathrm{K}_r(x) \leq \mathrm{K}(h(w_r))$$

for all $r \in \mathbb{N}$. It follows by (6.13) that

$$\mathrm{K}_r(x) \leq \mathrm{K}(w_r) + a_2 \tag{6.14}$$

for all $r \in \mathbb{N}$. Combining (6.14) and the right-hand inequality in (6.3) gives

$$\frac{\mathrm{K}_r(x)}{r \cdot \mathrm{sdim}(F)} \leq \frac{\mathrm{K}(w_r) + a_2}{\mathcal{I}_S(w_r) - \alpha} \tag{6.15}$$

for all $r \in \mathbb{N}$.

Let E be the set of all triples (q, r, w) such that $q \in \mathbb{Q}^n$, $r \in \mathbb{N}$, $w \in A_{r+l}$, and

$$|q - h(w)| \leq 2^{1-r}. \tag{6.16}$$

Since the set A and the condition (6.16) are decidable, the set E is decidable.

For each $q \in \mathbb{Q}^n$ and $r \in \mathbb{N}$, let

$$E_{q,r} = \{ w \in \Sigma_k^* \mid (q, r, w) \in E \}.$$

We prove two key properties of the sets $E_{q,r}$. First, for all $q \in \mathbb{Q}^n$ and $r \in \mathbb{N}$,

$$|q - x| \leq 2^{-r} \Rightarrow w_r \in E_{q,r}. \tag{6.17}$$

To see that this holds, assume that $|q-x| \leq 2^{-r}$. Since $x = S(T) \in S_{\overline{G}}(w_r) = \overline{S_G(w_r)}$, the right-hand inequality in (6.12) tells us that

$$|q - h(w_r)| \leq |q - x| + |x - h(w_r)| \leq 2^{-r} + \mathrm{diam}(S_G(w_r)) \leq 2^{1-r},$$

confirming (6.17).

The second key property of the sets $E_{q,r}$ is that they are small, namely, that

$$|E_{q,r}| \leq \gamma \tag{6.18}$$

holds for all $q \in \mathbb{Q}^n$ and $r \in \mathbb{N}$, where γ is a constant that does not depend on q or r. To see this, let $w \in E_{q,r}$. Then $w \in A_{r+l}$ and $|q - h(w)| \leq 2^{1-r}$, so $h(w) \in S_G(w) \cap B(q, 2^{1-r})$. This argument establishes that

$$w \in E_{q,r} \Rightarrow B(q, 2^{1-r}) \text{ meets } S_G(w). \tag{6.19}$$

Now let

$$\mathcal{G}_r = \{ S_G(w) \mid w \in A_{r+l} \}.$$

By our choice of G, $\mathcal{G}_r$ is a collection of disjoint open sets in $\mathbb{R}^n$. By the right-hand inequality in (6.12), each element of $\mathcal{G}_r$ is contained in a closed ball of radius 2^{-r}. Since G is open, it contains a closed ball of some radius $a_3 > 0$. It follows by the left-hand inequality in (6.12) that $S_G(w)$, being a contraction of G, contains a closed ball of radius $2^{1-r}a_4$, where $a_4 = \frac{a_1 a_3}{2\mathrm{diam}(G)}$. By Lemma 6.4, this implies that $B(q, 2^{1-r})$ meets no more than γ of the (closures of the) elements of $\mathcal{G}_r$, where $\gamma = (\frac{2}{a_4})^n$. By (6.19), this confirms (6.18).

Now let M be a prefix Turing machine with the following property. If $U(\pi) = q \in \mathbb{Q}^n$ (where U is the universal prefix Turing machine), s_r is the rth string in a standard enumeration $s_0, s_1, \ldots$ of $\{0,1\}^*$, and $0 \leq m < |E_{q,r}|$, then $M(\pi 0^{|s_r|} 1 s_r 0^m 1)$ is the mth element of $E_{q,r}$. There is a constant a_5 such that, for all $w \in \Sigma_k^*$,

$$\mathrm{K}(w) \leq \mathrm{K}_M(w) + a_5. \tag{6.20}$$

Taking π to be a program testifying to the value of $\mathrm{K}_r(x)$ and applying (6.17) and (6.18) shows that

$$\begin{aligned}\mathrm{K}_M(w_r) &\le |\pi 0^{|s_r|}1 s_r 0^m 1| \\ &= \mathrm{K}_r(x) + 2|s_r| + m + 2 \\ &\le \mathrm{K}_r(x) + 2\log(r+1) + |E_{q,r}| + 1 \\ &\le \mathrm{K}_r(x) + 2\log(r+1) + \gamma + 1,\end{aligned}$$

whence (6.20) tells us that

$$\mathrm{K}(w_r) \le \mathrm{K}_r(x) + \epsilon(r) \tag{6.21}$$

for all $r \in \mathbb{N}$, where $\epsilon(r) = 2\log(r+1) + a_5 + \gamma + 1$. Combining (6.21) and the left-hand inequality in (6.3) gives

$$\frac{\mathrm{K}_r(x)}{r \cdot \mathrm{sdim}(F)} \ge \frac{\mathrm{K}(w_r) - \epsilon(r)}{\mathcal{I}_S(w_r)} \tag{6.22}$$

for all $r \in \mathbb{N}$. Note that $\epsilon(r) = o(\mathcal{I}_S(w_r))$ as $r \to \infty$.

By (6.15) and (6.22), we now have

$$\frac{\mathrm{K}(w_r) - \epsilon(r)}{\mathcal{I}_S(w_r)} \le \frac{\mathrm{K}_r(x)}{r \cdot \mathrm{sdim}(F)} \le \frac{\mathrm{K}(w_r) + a_2}{\mathcal{I}_S(w_r) - \alpha} \tag{6.23}$$

for all $r \in \mathbb{N}$. In order to use this relationship between $\mathrm{K}_r(x)$ and $\mathrm{K}(w_r)$, we need to know that the asymptotic behavior of $\frac{\mathrm{K}(w_r)}{\mathcal{I}_S(w_r)}$ for $r \in \mathbb{N}$ is the same as the asymptotic behavior of $\frac{\mathrm{K}(w)}{\mathcal{I}_S(w)}$ for arbitrary prefixes w of T. Our verification of this fact makes repeated use of the *additivity* of $\mathcal{I}_S$, by which we mean that

$$\mathcal{I}_S(uv) = \mathcal{I}_S(u) + \mathcal{I}_S(v) \tag{6.24}$$

holds for all $u, v \in \Sigma_k^*$.

Let $r \in \mathbb{N}$, and let $w_r \sqsubseteq w \sqsubseteq w_{r+1}$, writing $w = w_r u$ and $w_{r+1} = wv$. Then (6.24) tells us that

$$\mathcal{I}_S(w_r) \le \mathcal{I}_S(w) \le \mathcal{I}_S(w_{r+1}),$$

and (6.3) tells us that

$$\mathcal{I}_S(w_{r+1}) - \mathcal{I}_S(w_r) \le \mathrm{sdim}(F) + \alpha,$$

so we have

$$\mathcal{I}_S(w_r) \le \mathcal{I}_S(w) \le \mathcal{I}_S(w_r) + a_6, \tag{6.25}$$

where $a_6 = \mathrm{sdim}(F) + \alpha$. We also have

$$\begin{aligned}a_6 &\ge \mathcal{I}_S(w_{r+1}) - \mathcal{I}_S(w_r) \\ &= \mathcal{I}_S(uv) \\ &= \log \frac{1}{\pi_S(uv)} \\ &\ge \log c_{\min}^{-\mathrm{sdim}(F)|uv|} \\ &= |uv|\mathrm{sdim}(F) \log \frac{1}{c_{\min}},\end{aligned}$$

i.e.,

$$|w_{r+1}| - |w_r| \leq a_7, \tag{6.26}$$

where $a_7 = \frac{a_6}{\mathrm{sdim}(F) \log \frac{1}{c_{\min}}}$.

Since (6.26) holds for all $r \in \mathbb{N}$ and a_7 does not depend on r, there is a constant a_8 such that, for all $r \in \mathbb{N}$ and $w_r \sqsubseteq w \sqsubseteq w_{r+1}$,

$$|\mathrm{K}(w) - \mathrm{K}(w_r)| \leq a_8. \tag{6.27}$$

It follows by (6.25) that

$$\frac{\mathrm{K}(w_r) - a_8}{\mathcal{I}_S(w_r) + a_6} \leq \frac{\mathrm{K}(w)}{\mathcal{I}_S(w)} \leq \frac{\mathrm{K}(w_r) + a_8}{\mathcal{I}_S(w_r)} \tag{6.28}$$

holds for all $r \in \mathbb{N}$ and $w_r \sqsubseteq w \sqsubseteq w_{r+1}$.

By (6.23), (6.28), Theorem 4.5, and Theorem 4.1, we now have

$$\begin{aligned}
\dim(x) &= \liminf_{r\to\infty} \frac{\mathrm{K}_r(x)}{r} \\
&= \mathrm{sdim}(F) \liminf_{r\to\infty} \frac{\mathrm{K}(w_r)}{\mathcal{I}_S(w_r)} \\
&= \mathrm{sdim}(F) \liminf_{j\to\infty} \frac{\mathrm{K}(T[0..j-1])}{\mathcal{I}_S(T[0..j-1])} \\
&= \mathrm{sdim}(F) \dim^{\pi_S}(T)
\end{aligned}$$

and

$$\begin{aligned}
\mathrm{Dim}(x) &= \limsup_{r\to\infty} \frac{\mathrm{K}_r(x)}{r} \\
&= \mathrm{sdim}(F) \limsup_{r\to\infty} \frac{\mathrm{K}(w_r)}{\mathcal{I}_S(w_r)} \\
&= \mathrm{sdim}(F) \limsup_{j\to\infty} \frac{\mathrm{K}(T[0..j-1])}{\mathcal{I}_S(T[0..j-1])} \\
&= \mathrm{sdim}(F) \mathrm{Dim}^{\pi_S}(T);
\end{aligned}$$

i.e., (6.10) and (6.11) hold. □

Finally, we use relativization to derive the following well-known classical theorem from our main theorem.

Corollary 6.11 (Moran [40], Falconer [14]). *For every self-similar fractal $F \subseteq \mathbb{R}^n$,*

$$\dim_{\mathrm{H}}(F) = \mathrm{Dim}_{\mathrm{P}}(F) = \mathrm{sdim}(F).$$

Proof. Let $F \subseteq \mathbb{R}^n$ be self-similar. Then there is an IFS S satisfying $F(S) = F$ and the open set condition. For any such S, there is an oracle $A \subseteq \{0,1\}^*$ relative to

which S is computable. We then have

$$\begin{aligned}
\dim_{\mathrm{H}}(F) &\le \mathrm{Dim}_{\mathrm{P}}(F) \\
&= \mathrm{Dim}_{\mathrm{P}}^{A}(F) \\
&\le \mathrm{cDim}^{A}(F) \\
&= \sup_{x\in F} \mathrm{Dim}^{A}(x) \\
&=^{(a)} \mathrm{sdim}(F) \sup_{T\in\Sigma_k^\infty} \mathrm{Dim}^{\pi_S,A}(T) \\
&= \mathrm{sdim}(F) \\
&= \mathrm{sdim}(F) \sup_{T\in\Sigma_k^\infty} \dim^{\pi_S,A}(T) \\
&=^{(b)} \sup_{x\in F} \dim^{A}(x) \\
&= \mathrm{cdim}^{A}(F) \\
&=^{(c)} \dim_{\mathrm{H}}^{A}(F) \\
&= \dim_{\mathrm{H}}(F),
\end{aligned}$$

which implies the corollary. Equalities (a) and (b) hold by Theorem 6.10, relativized to A. Equality (c) holds by Corollary 6.3, relativized to A. □

7. Conclusion. Our main theorem gives a complete analysis of the dimensions of points in computably self-similar fractals. It will be interesting to see whether larger classes of fractals are also amenable to such pointwise analyses of dimensions.

Acknowledgments. The first author thanks Dan Mauldin for useful discussions. We thank Xiaoyang Gu for pointing out that $\dim_{\mathrm{H}}^{\nu}$ is Billingsley dimension, and we thank the referees for careful reading and several corrections and improvements.

THE COMPLEXITY OF MONADIC SECOND-ORDER UNIFICATION*

JORDI LEVY†, MANFRED SCHMIDT-SCHAUß‡, AND MATEU VILLARET§

Abstract. Monadic second-order unification is second-order unification where all function constants occurring in the equations are unary. Here we prove that the problem of deciding whether a set of monadic equations has a unifier is NP-complete, where we use the technique of compressing solutions using singleton context-free grammars. We prove that monadic second-order matching is also NP-complete.

Key words. second-order unification, theorem proving, lambda calculus, context-free grammars, rewriting systems

1. Introduction.

The solvability of monadic second-order unification problems considered in this paper is a decision problem with many natural relationships with other well-known decision problems (higher-order unification, word unification, context unification and specializations thereof). For various members of this family, the exact complexity is still not known. In this paper we show that solvability of monadic second-order unification problems is NP-complete, thus adding a new piece to the larger puzzle. The techniques we use in our proof turned out to be relevant for other problems as well. Before we describe the organization of the paper we illuminate in more detail the relationship of monadic second-order unification with the above problems, give a brief survey on the techniques used in our proof, and indicate further contributions obtained from our method.

1.1. Monadic second-order unification from a higher-order perspective.

Higher-order unification (HOU) is unification in the simply typed λ-calculus, i.e., the problem of, given two λ-terms with the same type, deciding if there is a substitution (of free variables by equally typed terms) that, applied to both terms, makes them equivalent w.r.t. $\alpha\beta\eta$-equality (see chapter about HOU in [1]).

Second-order unification (SOU) is a restriction of HOU where all variables are at most second-order typed and constants are at most third-order typed. Some authors restrict constants in SOU to also be second-order typed, and it is also common to consider just one base type. Here, we will also make these assumptions. It is well known that the problem of deciding if an SOU problem has a solution is undecidable [5], even

if we impose additional restrictions on the number of second-order variables (just one), their number of occurrences (just four), and their arity (just one) [3, 9, 13]. All these undecidability proofs require a language with at least a binary or higher arity constant. In fact, one single binary constant is enough [3, 14].

Monadic second-order unification (MSOU) is a restriction of SOU where all function constants occurring in the problem are at most unary. Contrary to general SOU, MSOU is decidable [6, 24, 2]. In [23], it is proved that the problem is NP-hard. In this paper, our main contribution is to prove that MSOU is in NP.

Assuming that second-order variables, like constants, are also unary does not affect the decidability of MSOU or its complexity (see Proposition 3.1). Also, the use of a unique first-order constant does not affect the complexity of MSOU. Here we will use a single one called $\flat$. Thus, in instantiations $\lambda y\,.\,t$ for variables X of the problem, the variable y can occur at most once in t. This leads to the specialization where every equation is of the form $f_1(f_2(\dots f_n(\flat)\dots)) \stackrel{?}{=} g_1(g_2(\dots g_n(\flat)\dots))$, where f_i, g_i are unary function symbols or unary variables, and which is rather similar to a word equation.

Example 1. The equation $X(a(X(\flat))) \stackrel{?}{=} a(Y(Y(\flat)))$ has, among others, the solutions $[X \mapsto \lambda x\,.\,a(a(a(x))), Y \mapsto \lambda x\,.\,a(a(a(x)))]$ and $[X \mapsto \lambda x\,.\,a(a(a(\flat))), Y \mapsto \lambda x\,.\,a(x)]$. In the second solution the instantiation of X does not use its argument.

Since all terms are monadic, we will avoid the use of parenthesis in all cases where this is possible and write the terms as words.

1.2. Monadic second-order unification from a word unification perspective. Word unification (WU) is the problem of solving equations on strings. Given a finite alphabet of constants Σ and variables $\mathcal{X}$, a word equation $s \stackrel{?}{=} t$ is defined by a pair of words $s, t \in (\Sigma \cup \mathcal{X})^+$. A solution of $s \stackrel{?}{=} t$ is a substitution of variables by words in Σ^* such that, after replacing, the words obtained from s and t are equal.

In MSOU, apart from Σ and $\mathcal{X}$, we also have a special symbol denoted by $\flat$. A basic MSOU equation $s \stackrel{?}{=} t$ is defined by a pair of words $s, t \in (\Sigma \cup \mathcal{X})^+\flat$. A solution of $s \stackrel{?}{=} t$ is a substitution of variables by either $\lambda x\,.\,w\,x$ or $\lambda x\,.\,w\flat$, where $w \in \Sigma^*$ and where we use β-reduction after the substitution. In the first case we say that the instantiation uses its argument. The substitution of a variable X by $\lambda x\,.\,w\,x$ in $w_1\,X\,w_2$, where w_1, w_2 do not contain X, results in $w_1\,w\,w_2$, as in word unification, whereas the substitution of X by $\lambda x\,.\,w\flat$ in $w_1\,X\,w_2$ results in $w_1\,w\flat$. Therefore, compared to WU in MSOU some part of the original equation can be removed after instantiation. Moreover, the set of solutions of an MSOU equation is wider than the set of solutions of the corresponding WU equation.

Example 2. All solutions of the word equation $X\,a\,X \stackrel{?}{=} a\,Y\,Y$ have the form $[X \mapsto a^n, Y \mapsto a^n]$. The monadic equation $X\,a\,X\flat \stackrel{?}{=} a\,Y\,Y\flat$ has, apart from solutions of the form $[X \mapsto \lambda x\,.\,a^n\,x, Y \mapsto \lambda x\,.\,a^n\,x]$, other solutions of the form $[X \mapsto \lambda x\,.\,a\,w\,w\flat, Y \mapsto \lambda x\,.\,w\,x]$, $[X \mapsto \lambda x\,.\,a\,w\,x, Y \mapsto \lambda x\,.\,w\,a\,a\,w\flat]$, $[X \mapsto \lambda x\,.\,x, Y \mapsto \lambda x\,.\,\flat]$, and $[X \mapsto \lambda x\,.\,a\,w\flat, Y \mapsto \lambda x\,.\,w\flat]$, for any $w \in \Sigma^*$.

MSOU problems can be decided by guessing for every variable whether it uses its argument or not, modifying the equation by dropping symbols to the right of variables that do not use their arguments, and then calling WU (see also Proposition 2.5).

Example 3. The solutions of the MSOU equation $X\,a\,X\flat \stackrel{?}{=} a\,Y\,Y\flat$ can be found by solving the disjunction of the word equations $X\,a\,X \stackrel{?}{=} a\,Y\,Y$, $X \stackrel{?}{=} a\,Y\,Y$, $X\,a\,X \stackrel{?}{=} a\,Y$, and $X \stackrel{?}{=} a\,Y$.

This simple reduction shows that MSOU is decidable, since WU is decidable [16],

and also that MSOU is in PSPACE, since the reduction is in NP and by using the result that WU is in PSPACE [20]. Since this is the best currently known upper bound for WU, our result that MSOU is NP-complete gives a sharp bound that (currently) cannot be obtained from results on WU.

1.3. Techniques. To prove that MSOU is in NP, we first show for any solvable set of equations how we can represent (at least) one of the solutions (unifiers) in polynomial space. Then, we prove that we can check in polynomial time if a substitution (written in such a representation) is a solution.

We combine two key results to obtain this sharp bound: One is the result on the exponential upper bound on the exponent of periodicity of size-minimal unifiers [16, 8, 23] (see Lemma 2.4). This upper bound allows us to represent exponents in linear space. The other key is a result of Plandowski [17, 18] (see Theorem 4.2). He proves that, given two context-free recursion-free grammars with just one rule for every nonterminal symbol (here called *singleton* grammars), we can check if they define the same (singleton) language in polynomial time (in the size of the grammars). This result is used to check that applying a substitution (represented using this kind of grammar) to both sides of an equation will result in the same term. The successful combination requires us to prove a polynomial upper bound for the size increase of the singleton grammars obtained after a series of extensions (see section 4).

1.4. Further contributions. The method presented in this paper appears to be new and powerful for obtaining sharp complexity bounds and efficient algorithms for unification problems.

WU can be seen as a restriction of MSOU with the extra condition that every variable must be instantiated with a λ-term $\lambda x\,.\,t$, where t has exactly one occurrence of the bound variable x. Our results suggests that MSOU is an easier problem—from the complexity point of view—than WU. Moreover, all naive attempts to encode WU as MSOU have failed. The direct application of our method to WU fails, since Lemma 6.8 does not hold for WU; i.e., if all equations are of the form $X \ldots \stackrel{?}{=} Y \ldots$, then there is a trivial solution as MSOU equations, but this syntactic form does not imply any easy solution method for the equations interpreted as word equations.

Context unification (CU) is a variant of SOU where instantiations of second-order variables use their arguments exactly once. Hence, WU is monadic CU. Decidability of CU is currently unknown. During revision of this paper we were able to apply variants of this technique to determine the complexity of a fragment of CU: stratified context unification [12].

Bounded second-order unification (BSOU) is another variant of SOU where, given a positive integer k, instantiations of second-order variables can use their arguments at most k times. Hence, MSOU is also a subproblem of BSOU, because in MSOU instantiations of variables can use their arguments at most once. It is also known that BSOU is decidable [22], which provides another proof of decidability of MSOU, but no tight upper complexity bound. On the other hand, our proof and results suggest an application to BSOU, which has recently (during revision of this paper) resulted in proving a precise upper complexity bound for BSOU [11].
