ON THE ALGORITHMIC ASPECTS OF DISCRETE AND LEXICOGRAPHIC HELLY-TYPE THEOREMS AND THE DISCRETE LP-TYPE MODEL*

NIR HALMAN†

Abstract. Helly's theorem says that, if every $d+1$ elements of a given finite set of convex objects in $\mathbb{R}^d$ have a common point, there is a point common to all of the objects in the set. In discrete Helly theorems the common point should belong to an a priori given set. In lexicographic Helly theorems the common point should not be lexicographically greater than a given point. Using discrete and lexicographic Helly theorems we get linear time solutions for various optimization problems. For this, we introduce the *DLP-type* (discrete linear programming–type) model, and provide new algorithms that solve in randomized linear time fixed-dimensional DLP-type problems. For variable-dimensional DLP-type problems, our algorithms run in time subexponential in the combinatorial dimension. Finally, we use our results in order to solve in randomized linear time problems such as the discrete p-center on the real line, the discrete weighted 1-center problem in $\mathbb{R}^d$ with either l_1 or l_∞ norm, the standard (continuous) problem of finding a line transversal for a totally separable set of planar convex objects, a discrete version of the problem of finding a line transversal for a set of axis-parallel planar rectangles, and the (planar) lexicographic rectilinear p-center problem for $p = 1, 2, 3$. These are the first known linear time algorithms for these problems. Moreover, we use our algorithms to solve in randomized subexponential time various problems in game theory, improving upon the best known algorithms for these problems.

1. Introduction.

1.1. Helly-type theorems.

The classical theorem of Helly stands at the origin of what is known today as the combinatorial geometry of convex sets. It was discovered in 1913 and may be formulated as follows.

THEOREM 1.1 (Helly's theorem). *Let H be a family of closed convex sets in $\mathbb{R}^d$, and suppose either H is finite or at least one member of H is compact. If every $d+1$ or fewer members of H have a common point, then there is a point common to all members of H.*

A possible generalization of Helly's theorem is as follows. Let H be a family of objects, and let $\mathcal{P}$ be a predicate on subsets of H. A *Helly-type theorem* for H is of the form:

There is a constant k such that for every finite set G, $G \subseteq H$, $\mathcal{P}(G)$, if and only if, for every $F \subseteq G$ with $|F| \leq k$, $\mathcal{P}(F)$.

The minimal such constant k is called the *Helly number* of H with respect to the predicate $\mathcal{P}$. If no such constant exists, we say that the Helly number of H with

*Received by the editors April 5, 2006; accepted for publication (in revised form) August 21, 2007; published electronically March 28, 2008. An extended abstract containing parts of this work appeared in *Proceedings of the Forty-Fifth Annual IEEE Symposium on Foundations of Computer Science (FOCS)*, 2004 [18]. This work is part of the author's Ph.D. thesis, prepared at the School of Mathematical Sciences at Tel Aviv University, Tel Aviv, Israel, under the supervision of Professor Arie Tamir [17].

†Department of Civil and Environmental Engineering, Massachusetts Institute of Technology, 77 Massachusetts Avenue, Cambridge, MA 02139 (halman@mit.edu).

respect to $\mathcal{P}$ is *unbounded* or *infinite* (∞). In Helly's theorem, the Helly number is $d+1$, and $\mathcal{P}$ is the predicate of having a nonempty intersection.

Over the years, a vast body of application analogues and far-reaching generalizations of Helly's theorem has been assembled in the literature (see, for instance, the excellent surveys of [10, 12, 16]).

It is possible to give lexicographic versions to some of the Helly theorems. For instance, the following theorem is a lexicographic version of Helly's theorem. (Recall that, for every $x = (x_1, \ldots, x_d), y = (y_1, \ldots, y_d) \in \mathbb{R}^d$, x is said to be *lexicographically* smaller than y (*lsmaller*, in short, or $x <_L y$) if either $x_1 < y_1$ or there exists $d \geq k > 1$ such that $x_i = y_i$ for $i = 1, 2, \ldots, k-1$ and $x_k < y_k$.)

THEOREM 1.2 (lexicographic Helly's theorem [26, 20]). *Let H be a finite family of convex sets in $\mathbb{R}^d$. For every $x \in \mathbb{R}^d$, if every $d+1$ or fewer members of H have a common point which is not lexicographically greater than x, then there is a point common to all members of H which is also not lexicographically greater than x.*

This theorem is folklore. It derives directly from Helly's theorem and Lemma 8.1.2 in [26] and is proved independently in [20]. $d+1$ is called the *lexicographic Helly number* of H with respect to intersection (*lex-Helly number*, in short). The following theorem is a discrete version of Helly's theorem, due to Doignon.

THEOREM 1.3 (see [11]). *Let H be a finite family of at least 2^d convex sets in $\mathbb{R}^d$. If every 2^d or fewer members of H have a common point with integer coordinates, then there is a point with integer coordinates common to all members of H.*

2^d is called the *discrete Helly number* of H with respect to intersection. Halman [20] provides discrete versions to numerous known Helly theorems. For instance, a special case of Helly's theorems is when the given convex sets are axis-parallel boxes in $\mathbb{R}^d$. In this case the Helly number is just 2 [9]. A discrete version of this Helly theorem is as follows.

THEOREM 1.4 (Theorem 2.10 in [20]). *Let S be a finite set of points in $\mathbb{R}^d$, and let D be a finite family of closed boxes in $\mathbb{R}^d$ with edges parallel to the axes. If every $2d$ or fewer members of D have a common point in S, then there is a point in S common to all members of D.*

A combined discrete-lexicographic version of this Helly theorem is as follows.

THEOREM 1.5 (Theorem 2.10 in [20]). *Let S be a finite set of points in $\mathbb{R}^d$, and let D be a finite family of closed boxes in $\mathbb{R}^d$ with edges parallel to the axes. For every $x \in \mathbb{R}^d$, if every $2d$ or fewer members of D have a common point $x' \in S$, with $x' \leq_L x$, then there is a point $x^* \in S$ common to all members of D with $x^* \leq_L x$.*

1.2. Algorithmic aspects of finite Helly numbers. In this section we discuss two optimization models and show their relations to Helly numbers.

The LP-type model. Matoušek, Sharir, and Welzl [28] defined a model which generalizes linear programming (LP) and called it the LP-type model (see definitions in section 2). Fixed-dimensional LP-type problems can be solved efficiently by *LP-type algorithms* such as the ones of Matoušek, Sharir, and Welzl [28] or Kalai [22]. The algorithm of Clarkson [8], which was originally formulated to solve LP, fits the LP-type model as well [31, 7, 15]. This provides a tool for obtaining linear time algorithms to various (continuous) optimization problems, mainly in computational geometry and location theory, as shown in [2, 28].

The DLP-type model. In *continuous* optimization models related to LP-type problems, the feasible set is defined by a finite set of constraints. In the *discrete* versions, in addition to the above, there is also a prespecified set of *relaxations*. A

feasible solution is restricted to be in the set of relaxations as well as to satisfy the constraints. *Integer programming* (IP) is an example of a discrete optimization problem where the set of relaxations is the integer lattice. Another example for a discrete optimization problem is the *discrete point set width problem*, where we are given a finite set of points in the plane (i.e., constraints) and a finite set of permissible directions (i.e., relaxations). The goal is to find the minimal width of a band with a permissible direction which contains all of the points (see more detail about this problem in section 4). Many times discrete optimization problems are proved to be computationally harder to solve than their corresponding continuous versions (e.g., LP vs. IP and continuous planar Euclidean 1-center vs. the discrete version as proved in section 9). In this paper we propose the following framework for solving discrete optimization problems: We generalize integer programming by introducing the *discrete* LP-type (*DLP-type*) model. We provide randomized linear time algorithms to solve fixed-dimensional DLP-type problems satisfying a condition we call the violation condition (VC).

Helly numbers and the two optimization models. In [20] Halman defines the notion of discrete and lexicographic Helly theorems, provides lexicographic and discrete versions to numerous known Helly theorems, and studies the relations between the different types of Helly theorems. In this paper we show that discrete and lexicographic Helly theorems have interesting algorithmic aspects as well. In 1994, Amenta [2] showed that every *parameterized Helly system* satisfying a condition called the unique minimum condition (UMC) results in a fixed-dimensional LP-type problem (see definitions of the terms parameterized Helly theorems and UMC in section 2.3). In this paper we define lexicographic parameterized Helly systems and show that *every* such system results in a fixed-dimensional LP-type problem. Unlike in [2], no additional conditions are needed. Similarly to [2], this provides a framework for obtaining linear time algorithms (i.e., the LP-type algorithms mentioned above) for the optimization problems related to these Helly numbers. In this way the *existence* of finite lexicographic Helly numbers implies the *solvability* of their corresponding optimization problems by the linear time LP-type algorithms. Similarly to the above, we show that *every* lexicographic-discrete parameterized Helly system can be formulated as a fixed-dimensional DLP-type problem.

1.3. Applications. We improve upon the best known algorithms for the seven problems listed below. The problems differ in the way we solve them. The first three are solved by using the LP-type model and its connection to lexicographic Helly theorems. The next four problems are solved via the DLP-type model. While the first three of them are solved via lexicographic-discrete Helly theorems, the fourth is not. We solve in this paper the first five problems in linear time. Due to its length, we refer the reader to [17] for details of the solution of the sixth problem. The first six problems lie in the fields of research of either computational geometry or location theory. The seventh problem is solved in [19] and is different, since it lies in game theory and is solved in strongly subexponential time. We summarize the solutions we give to each of these problems in Table 1.1.

1. Planar lexicographic weighted rectilinear p-center optimization problem ($p = 1, 2, 3$). Given a finite set $H = \{h_1, \ldots, h_n\}$ of reference points in the plane and a set $W = \{w_1, \ldots, w_n\}$ of weights in $\mathbb{R}^+$, find the lexicographically smallest vector $(\lambda_1, x_1, y_1, x_2, y_2, \ldots, x_p, y_p) \in \mathbb{R}^+ \times \mathbb{R}^{2p}$ such that for every scaled square $\frac{\lambda_1}{w_i} h_i$, $h_i \in H$, centered at h_i with radius $\frac{\lambda_1}{w_i}$, there exists $1 \leq j \leq p$

TABLE 1.1
A comparison between the various problems solved.

such that $\frac{\lambda_1}{w_i}h$ contains (i.e., is pierced by) point (x_j, y_j) (we call λ_1 the *radius* and $(x_1, y_1, \ldots, x_p, y_p)$ the *centers vector*).

For $p > 3$ [32] showed a lower bound of $\Omega(n \log n)$. [32, 21] solve the corresponding nonlexicographic problem in linear time.

2. Line transversal of axis-parallel rectangles optimization problem. Given a set B of axis-parallel rectangles, find the minimal scaling factor λ^* such that the set of scaled rectangles λ^* admits a line transversal.

For the next problem we use the following definitions. A set H of convex objects is called *totally separable* if there exists a direction such that each line in this direction intersects at most one convex object from H. We call the objects in H *simple* if they have a constant size storage description, the intersections and common tangents between any two objects can be found in constant time, and the minimal scaling factor for any 3 objects to admit a line transversal can be found in constant time.

3. Line transversal of totally separable set of convex planar objects decision problem. Given is a totally separable finite family H of simple convex objects (the direction of separation is not given). Decide whether H admits a line that intersects all of the objects in H.

Given the order in which any line transversal should meet the objects in H, the problem is solvable in linear time [13].

4. Lexicographic discrete line transversal of axis-parallel rectangles problem. Given a finite family D of axis-parallel rectangles and a finite set S of line *directions*, find a line transversal for D, $y = ax + b$, with the lexicographically smallest vector (a, b) satisfying $a \in S$.

We show in section 10 that a similar problem, where, instead of a finite family S of line directions, we are given a finite family S' of lines, and the goal is find the lexicographically smallest vector $(a, b) \in S'$ such that $y = ax + b$ is a line transversal for D, has a lower bound of $\Omega(n \log n)$ under the algebraic computation tree model.

5. Discrete weighted 1-center problem in $\mathbb{R}^d$ with an l_∞ norm. Given are sets $D = \{d_1, \ldots, d_n\}$ and $S = \{s_1, \ldots, s_m\}$ of *points* in $\mathbb{R}^d$ and a set $W = \{w_1, \ldots, w_n\}$ of *weights* in $\mathbb{R}^+$. Find a point $s \in S$ (*center*) which minimizes the real function $r(D, S) = \min_{s \in S} \max_i w_i \|s - d_i\|_\infty$ (the *optimal radius*). We solve the corresponding rectilinear problem (i.e., with an l_1 norm) in linear time as well.

It is folklore that the latter problem restricted to the case $S = D$ is solvable in $O(n \log n)$ time.

6. Discrete p-center problem on the real line. Given a finite set D of real numbers (*points*) and a finite set S of real numbers (*center locations*), find a subset $C \subseteq S$ of p points (*centers*) which minimizes the real function $r_p(D, S) = \min_{C \subseteq S, |C| \leq p} \max_{h \in D} dist(h, C)$ (the *optimal radius*). For every finite set of real numbers C and real h, $dist(h, C) = \min_{c \in C} |h - c|$. Due to space limitations we refer the

interested reader to Chapter 9 in [17] for a detailed description of our linear time solution for this problem.

Assuming the order of the points on the line is given, the discrete p-center problem on the real line is solvable in linear time by the fairly involved technique of Frederickson [14].

7. Simple stochastic games and infinite games. The first strongly subexponential algorithm for binary simple stochastic games (SSGs) was given by Ludwig [25] in 1995 by using ideas from the algorithms of [22] and [31] for LP-type problems. Halman [19] gives the first strongly subexponential solution for (nonbinary) SSGs by formulating the SSG as an LP-type problem and then calculating optimal strategies for both players by the LP-type algorithm of [31]. Since several infinite games are linearly reducible to nonbinary SSGs, this gives strongly subexponential algorithms to parity games (PGs) and the first strongly subexponential algorithms to mean payoff games (MPGs) and discounted payoff games. Halman notes in [19] that nonbinary SSGs can most naturally be formulated as discrete LP-type problems, because of the essentially primal-dual nature of the two-player game. We note that, independently, Björklund, Sandberg, and Vorobyovn [6] developed a (nonstrongly) subexponential algorithm for MPGs, a strongly subexponential algorithm for PGs [5], and a (nonstrongly) subexponential algorithm to nonbinary SSGs [4]. All of their algorithms are "tailored" to the specific game solved and "adapt" ideas from the algorithms of [25, 22, 31] (see formal definitions of all of these games in [19]).

Our contribution. In this paper we define a new model for solving discrete optimization problems, the DLP-type model. We develop for it several linear time (randomized) algorithms. We study the relations between discrete Helly theorems and the DLP-type model. We study also the relations between (nondiscrete) lexicographic Helly theorems and the LP-type model. We show that *every* lexicographic parameterized Helly system results in a fixed-dimensional LP-type problem. In this case the UMC stated in the main theorem of [2] is not needed. By incorporating these "ingredients" together we provide the first linear time algorithms for the first six problems defined above. All of these problems are related to computational geometry and location theory. By solving the seventh problem we show (for the first time, to the best of our knowledge) that the LP-type and DLP-type models have applications in other fields of research, such as game theory. Moreover, we show that these two models are also useful for solving non-fixed-dimensional problems in subexponential time.

Organization of the paper. In this paper we extensively use terms which are defined in [2], two tools for establishing linear time algorithms: the LP-type framework and Helly-type results, which are reviewed in [2, 32], and the two LP-type algorithms in [8, 32]. In order to make the paper self-contained we review these terms, models, and algorithms in section 2. In section 3 we define a dual version of the LP-type model, which we use in order to define the DLP-type model in section 4. In section 5 we develop algorithms which solve (fixed-dimensional) DLP-type problems in (randomized) linear time. The rest of the paper is dedicated to show the interrelations between discrete and lexicographic Helly theorems and DLP-type and LP-type models. In section 6 we study the relations between lexicographic Helly theorems and the LP-type model. By showing that every lexicographic parameterized Helly system results in a fixed-dimensional LP-type problem, we give a partial solution for the main open problem raised by Amenta [2], who asked to characterize the parameterized Helly systems which result in fixed-dimensional LP-type problems. In section 7

we demonstrate the applicability of these relations by solving the first problem discussed in this section—the planar lexicographic weighted rectilinear p-center problem ($p = 1, 2, 3$) in linear time. In section 8 we study the relations between discrete and lex-discrete Helly theorems and the DLP-type model. In sections 9 and 10 we solve in linear time the next four problems discussed in this section.

2. Literature review. In this section we review some of the definitions and results given in Amenta [1, 2], Sharir and Welzl [31], Matoušek, Sharir, and Welzl [28], and Clarkson [8]. The term used in the first two papers is GLP (general linear programming) rather than LP-type.

2.1. LP-type problems.

DEFINITION 2.1. *An* abstract problem *is a tuple (H, ω), where H is a finite set of elements (which we call* constraints*) and ω is an* objective function *from 2^H to some totally ordered set Λ which contains a special maximal (minimal) element ∞ ($-\infty$), respectively. The goal is to compute $\omega(H)$.*

DEFINITION 2.2. *Let (H, ω) be an abstract problem. For any subset $G \subseteq H$ we say that $F \subseteq G$* defines *the solution on G (F is a* solution-defining set *of G) if $\omega(F) = \omega(G)$.*

Clearly, for every $G \subset H$, G is a defining set for itself.

DEFINITION 2.3. *An* LP-type problem *is an abstract problem (H, ω) that obeys the following conditions (when we write $<$, $\leq$, $=$ etc., we mean under the ordered set Λ):*

1. Monotonicity: *For all $F \subseteq G \subseteq H : \omega(F) \leq \omega(G)$ (so the special element $-\infty$ is such that $\omega(\emptyset) = -\infty$).*
2. Locality: *For all $F \subseteq G \subseteq H$, with $\omega(G) = \omega(F) \neq -\infty$, and for each $h \in H$, if $\omega(G \cup \{h\}) > \omega(G)$ then $\omega(F \cup \{h\}) > \omega(F)$.*

Note that *lexicographic linear programming*, where the input is a finite set of closed half-planes in $\mathbb{R}^d$ and the output is the lsmallest point which lies in all half-planes, is an LP-type problem: H is the finite set consisting of these closed half-spaces, and the function $\omega(G)$ returns the coefficients of the lexicographic minimum point in $\bigcap G$. Adding half-planes to H cannot decrease the value of ω, so the monotonicity condition is satisfied. As for the locality condition, note that if $\omega(G) = \omega(F) \neq -\infty$, then $\omega(G)$ is realized in a single point $x^* \in \mathbb{R}^d$. The fact that $\omega(G \cup \{h\}) > \omega(G)$ implies that $x^* \notin h$. Therefore, $\omega(F \cup \{h\}) > \omega(F)$ as needed. An immediate consequence of the monotonicity and locality conditions is the following.

COROLLARY 2.4. *Let (H, ω) be an LP-type problem. For all $F \subseteq G \subseteq H$, with $\omega(G) = \omega(F) \neq -\infty$, and for each $h \in H$, $\omega(G \cup \{h\}) > \omega(G)$ if and only if $\omega(F \cup \{h\}) > \omega(F)$.*

We give now several definitions for every abstract problem (H, ω) which meets the monotonicity condition. Let $G \subseteq H$ be arbitrary, and let $n = |H|$. If $\omega(G) = \infty$, we say G is *infeasible*; otherwise we call G *feasible*. If $\omega(G) = -\infty$, we say G is *unbounded*; otherwise we call G *bounded*. We say a constraint $h \in H$ *violates* G when $\omega(G \cup \{h\}) > \omega(G)$. (Using this definition we note that the locality condition says that, for every bounded subset $G \subseteq H$, defining set F for G, and $h \notin G$, if h violates G, then h must violate the defining set F. Corollary 2.4 says that, for any such G, F, h, h violates G if and only if it violates its defining set F.) A *basis* B is a set $B \subseteq H$, with $\omega(B') < \omega(B)$ for all proper subsets B' of B. A *basis for* G is a basis $B \subseteq G$, with $\omega(B) = \omega(G)$. (In other words, a basis for G is a minimal (by inclusion) defining set of G.) We note that due to the monotonicity condition a basis for G, for any $G \subseteq H$, always exists. The basis for any unbounded set is the empty set.

Observation 2.5. Let (H, ω) be an LP-type problem, let $G \subset H$, and let $B \subseteq G$ be such that $\omega(B) = \omega(G)$. If $\omega(G) < \omega(H)$, then there exists a constraint $h \in H \setminus G$ which violates B.

To see this, it is sufficient to show that if no $h \in H \setminus G$ violates B, then $\omega(G) = \omega(H)$. We add to B and G an arbitrary constraint $h \in H \setminus G$. Since h does not violate B, the locality condition implies that h does not violate G and that $\omega(B) = \omega(G \cup \{h\})$. Repeating this argument $|H \setminus G|$ times, we get that $\omega(G) = \omega(H)$ as needed.

So B is a basis for G if and only if $B \subseteq G$ is a basis and no element in G violates it. We say that $h \in G$ is *extreme* in G if $\omega(G \setminus \{h\}) < \omega(G)$. Thus $h \in G$ is extreme in G if and only if h violates $G \setminus \{h\}$. From the minimality of a basis, every h in a basis B is extreme in B. From the monotonicity condition we get the following.

Observation 2.6. Let (H, ω) be an LP-type problem. Every $h \in G$ which is extreme in $G \subseteq H$ is contained in every basis B for G.

In other words, a basis B for G contains all of the constraints which are extreme in G. We note that not all of the elements in B are extreme in G as seen in Figure 2.1. Let G be the set of 5 lines. The two thick lines form a basis B for G, and each one of them is extreme in B. We note that the line with negative slope is extreme in G.

The terms "violates" and "extreme" are somewhat complementary: For $h \in G$ we may ask whether h is extreme in G (or, equivalently, whether it violates $G \setminus \{h\}$). Similarly, for $h \notin G$ we may test whether h violates G (or, equivalently, whether it is extreme in $G \cup \{h\}$). Using the monotonicity condition and the observation above we get the following.

Observation 2.7. Let (H, ω) be an LP-type problem. Let B be a basis for $G \subseteq H$. If $h \notin G$ violates B, then h is extreme in $G \cup \{h\}$ and is a member of every basis for $G \cup \{h\}$.

The *combinatorial dimension* d of (H, ω) is the maximum size of every basis for any feasible subset G. An abstract problem which meets the monotonicity condition and is of combinatorial dimension d, where d is independent of $|H|$, is called *fixed-dimensional*. A d-dimensional LP-type problem where the cardinality of every basis is exactly d is called a d-dimensional *basis-regular* LP-type problem. Note that if such a problem is feasible and bounded, then $\omega(H) = \max_{G \subset H,\, |G|=d} \omega(G)$.

For instance, in lexicographic linear programming, if $\bigcap G \neq \emptyset$, the lexicographically smallest point in $\bigcap G$ is determined by a basis of cardinality at most d (if G is unbounded, its basis is $\emptyset$). Notice that, although more than d half-spaces may have the minimum point on their boundary, a subfamily of at most d of them is sufficient to determine the minimum. In Figure 2.1 below, the thick two lines are a basis. Notice also that a subfamily G may have more than one basis.

2.2. LP-type algorithms. An LP-type algorithm takes a d-dimensional LP-type problem (H, ω) and returns a basis B for H. Several efficient randomized LP-type algorithms are known such as the ones of Clarkson [8], Matoušek, Sharir, and Welzl [28], or Kalai [22]. In the following two sections we review the first two algorithms. We develop in section 5 a DLP-type algorithm by combining these two algorithms together.

It is not clear, of course, what computational operations are possible on an abstract object such as (H, ω). We assume two computational primitives and analyze the various algorithms by counting the number of calls to these primitives. The running time for a specific LP-type problem then depends on how efficiently the primitives can be implemented. Let us now define the two primitive operations. A *basis computation* Basis(G) takes a family G of at most $d + 1$ constraints and finds a basis for

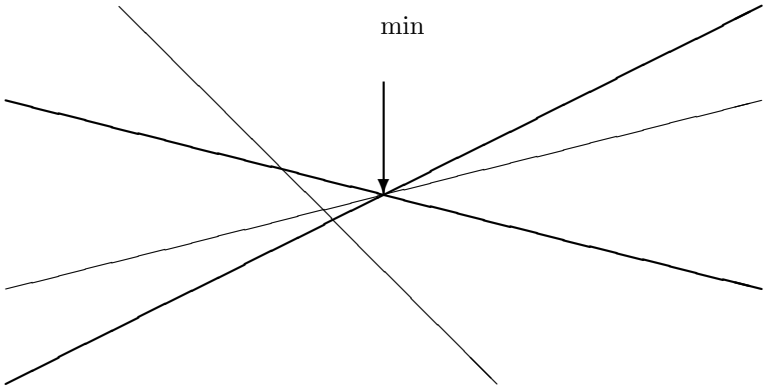

FIG. 2.1. *A basis for LP.*

G. A *violation test* Violation(B, h) takes a basis B and a constraint h and returns true if and only if h violates B (i.e., B is not a basis of $B \cup \{h\}$). Let t_b be the time required for a basis computation and t_v be the time required for a violation test.

2.2.1. Clarkson's algorithm. As originally presented, Clarkson's algorithm is aimed for linear programming. As Sharir and Welzl [31] note, the algorithm solves LP-type problems in the same time bound. We review the algorithm in the context of linear programming. Given a lexicographic linear programming problem in d variables with a set of constraints H ($|H| = n$) and objective function ω, we view it as the d-dimensional LP-type problem (ω, H).

Let x_s^* be an algorithm which gets input of size up to $9d^2$ (d is the dimension of the problem) and outputs a basis for H. The algorithm of Clarkson [8] is as follows:

Function $x_m^*(H)$ (Returns a basis for H)
1. Let $V^* := \emptyset$, let $V := H$
2. If $|H| \leq 9d^2$, then return $x_s^*(H)$
3. Else repeat the following until $V = \emptyset$:
   (a) Choose $R \subset H \setminus V^*$ uniformly at random, $|R| = d\sqrt{|H|}$
   (b) Let $B := x_i^*(R \cup V^*)$, and let $V := \{h \in H \mid \text{Violation}(B, h) = \text{TRUE}\}$
   (c) If $|V| \leq 2\sqrt{|H|}$, then let $V^* := V^* \cup V$
4. Return B

Function $x_i^*(H)$
1. Let $V := H$. For every $h \in H$ let $\nu_h := 1$
2. If $|H| \leq 9d^2$, then return $x_s^*(H)$
3. Else repeat the following until $V = \emptyset$:
   (a) Choose $R \subset H$ at random according to weights ν_h, $|R| = 9d^2$
   (b) Let $B := x_s^*(R)$.
   (c) Let $V := \{h \in H \mid \text{Violation}(B, h) = \text{TRUE}\}$
   (d) If $\nu(V) \leq 2\nu(H)/(9d - 1)$, then for every $h \in V$ let $\nu_h =: 2\nu_h$
4. Return B

As Amenta notes in [1], Clarkson's randomized algorithm for solving an LP-type problem (H, ω) improves the running time by separating the dependence on d and on n. He uses a three-level algorithm, with a "base-case" algorithm at the lowest level (x_s^*) solving subproblems of size up to $9d^2$.

The higher two levels x_m^* and x_i^* reduce the problem to smaller problems using the following idea. Take a sample $R \subseteq H$, find a basis B for R by calling the next lower level algorithm, and then find the subset $V \subseteq H$ of all of the constraints which violate B. If V is empty, Observation 2.5 tells us that B is a basis for H as well. Otherwise, by the monotonicity condition $\omega(H) > \omega(B)$. Let B' be a basis for H, and let $H' = B \cup B'$. Clearly $\omega(H) = \omega(H')$, so B' is a basis for H' as well. Applying Observation 2.5 for H' and B we get that there exists a constraint in B' which violates B. We've just proved the following lemma.

LEMMA 2.8 (Lemma 3.1 in [8]). *If the set V is nonempty, then it contains at least one constraint from every basis B for H.*

The purpose of the top level x_m^* is to get the number of constraints down so we can apply the second level (x_i^*), which is more efficient in d but less efficient in n. In the top level we take a random sample R, with $|R| = d\sqrt{n}$ so that $E[|V|] = O(\sqrt{n})$; that is, we take a big random sample which gives an expected small set of violators. This is a consequence from the following lemma.

LEMMA 2.9 (Lemma 3.2 in [8]). *Let $V^* \subset H$, and let $R \subset H \setminus V^*$ be a random subset of size r, with $|H \setminus V^*| = n$. Let $V \subset H$ be the set of constraints which violate $R \cup V^*$. Then the expected size of V is no more than $d(n - r + 1)/(r - d)$.*

We iterate, keeping the violators in a set V^* and finding a basis B' for $R \cup V^*$. At every iteration in the "repeat-until" loop of x_m^*, we add the violators to V^*, so that after d iterations V^* contains a basis B for H and $E[|V^*|] = d\sqrt{n}$. Solving the subproblem on V^* then gives the answer.

All recursive calls from the first level x_m^* call the second level algorithm x_i^*, which uses small random samples of size $9d^2$. Initially the sample R is chosen using the uniform distribution, but then we double the weights of elements in V and iterate. Since at least one basis element always ends up in V, eventually they all become so heavy that we get $B \subseteq R$. The analysis shows that the expected number of samples before $B \subseteq R$ is $O(d \log n)$. Since we need $O(n)$ work at each iteration to compare each constraint with the basis B' of R, without the first phase this algorithm alone would be $O(n \log n)$. All of the recursive calls from this reweighting algorithm are made to some "base-case" algorithm x_s^*.

Recall that t_v is the time required for a violation test, and let $t_s(n)$ be the time required for function x_s^* to run on n constraints. In his paper, Clarkson chooses x_s^* to be the simplex algorithm for linear programming on sets of $9d^2$ elements and estimates its running time by $t_s(9d^2) = d^{\frac{d}{2}+O(1)}$, using Stirling's approximation. Given a set H of n elements and a basis B (which in linear programming is equivalent to a point in $\mathbb{R}^d$), the time needed for a single call to function Violation(B, h) is d. Thus the time needed to execute the line

$$V \leftarrow \{h \in H \mid \text{Violation}(B, h) = \text{TRUE}\}$$

in the algorithm is dn, or nt_v.

In his time complexity analysis, Clarkson also uses a lemma to show that progress will be made during the execution of the algorithm. We say that an execution of the loop in x_m^* (x_i^*) is *successful* if the test $|V| \leq 2\sqrt{|H|}$ $(\nu(V) \leq 2\nu(H)/(9d-1))$ returns "true."

LEMMA 2.10 (Lemma 3.3 in [8]). *The probability that any given execution of a loop body is successful is at least* $1/2$*, and so on average two executions are required to obtain a successful one.*

Let $T_i(n)$ ($T_m(n)$) be the expected time required by x_i^* (x_m^*) for a problem with n constraints.

THEOREM 2.11 (Theorem 3.4 in [8]). *Given an LP-type problem, the iterative algorithm* x_i^* *requires*

$$T_i(n) = O(d \log n(nt_v + t_s(9d^2)))$$

expected time, where the constant factors do not depend on d*.*

THEOREM 2.12 (Theorem 3.5 in [8]). *Given an LP-type problem, algorithm* x_m^* *requires*

$$T_m(n) = O(d(T_i(d\sqrt{n}) + nt_v)) = O(d^2 \log n(\sqrt{n}t_v + t_s(9d^2)) + dnt_v)$$

expected time, where the constant factors do not depend on d*.*

We can see Clarkson's algorithm as a tool for reducing an LP-type problem with many constraints to a collection of small problems with a few constraints.

2.2.2. Sharir and Welzl's algorithm. As Amenta notes in [1], the algorithm of Sharir and Welzl [31] for solving an LP-type problem (H, ω) is a *monotone algorithm*; i.e., the sequence of values resulted by the calls the algorithm makes to the basis calculation primitive is monotone increasing. The idea is to select a random constraint $h \in H$ and recursively find a basis B for $H \setminus \{h\}$. If h doesn't violate B, then output B; otherwise solve the problem recursively starting from a basis for $B \cup \{h\}$. Although the statement of the algorithm does not include a set of tight constraints (i.e., the set of constraints which the current minimum must satisfy), Observation 2.7 demonstrates that every basis found in the recursive call will include h. So the dimension of the problem is effectively reduced. They show that the algorithm requires expected $O(n)$ calls to the Basis primitive on subproblems with $d+1$ constraints and $O(n)$ calls to the Violation primitive, when the constant depends exponentially on d.

For the sake of completeness we state their algorithm. Function lptype is called with an initial basis C which they call a *candidate basis*. C is not necessarily a basis for H. It can be viewed as some auxiliary information one gets for the computation of the solution. Note that C can have influence on the running time and output of the algorithm (e.g., when there are several optimal bases).

Function lptype(H, C)
1. If $H = C$, then return C
2. Else
   (a) Choose $h \in H \setminus C$ uniformly at random
   (b) Let $B :=$ lptype$(H \setminus \{h\}, C)$
   (c) If Violation$(B, h) =$ TRUE, then return lptype$(H,$ Basis$(B \cup \{h\}))$
   (d) Else return B

Matoušek, Sharir, and Welzl [28] cite explicitly all of the properties which are needed for the correctness and time analysis of their algorithm

LEMMA 2.13 (see [28]). *Let* (H, ω) *be an abstract problem. The correctness and time analysis of algorithm lptype applied on* (H, ω) *as described in* [28] *are valid, if for all* $F, G \subseteq H$*,* $F \subseteq G$*, and* $h \in H$*:*

1. $\omega(G) \geq \omega(F)$.
2. *If* $\omega(G) = \omega(F) > -\infty$, *then* h *violates* G *if and only if* h *violates* F.
3. *If* $\omega(G) < \infty$, *then any* $F \subseteq G$ *has at most* d *extreme constraints.*
4. *If* $\omega(G) < \infty$, *then every basis* $B \subseteq G$ *for* G *has exactly* d *constraints.*

We note that a d-dimensional basis-regular LP-type problem (H, ω) satisfies all of the above properties: The monotonicity condition yields property 1. Corollary 2.4 yields property 2, the d-dimensionality of the (H, ω) together with Observation 2.6 yield property 3, and property 4 (which is needed only for the time analysis) results because (H, ω) is basis-regular.

A simple inductive argument shows that the procedure returns the required answer. This happens after a finite number of steps, since the first recursive call decreases the number of constraints, while the second call increases the value of the candidate basis (and there are only finitely many different bases).

Recall that t_v denotes the time required for a violation test and t_b denotes the time required for the Basis primitive on subproblems with $d + 1$ constraints. Let n_v (n_b) be the number of violation tests (basis computations) performed throughout the execution of the algorithm. Matoušek, Sharir, and Welzl (see section 4 in [28]) show that $n_v \leq n_b n$, which implies a crude upper bound of $O(n_b(t_v n + t_b))$ for the running time of the algorithm. They [28] give a careful and complicated analysis of this algorithm for the case where n is not much larger than d (e.g., $d \leq n \leq \sqrt{d}e^{d/4}$) and show that $n_b = e^{O(\sqrt{d \ln d})}$. Hence, for this case, the algorithm of [31] runs in randomized $O(e^{O(\sqrt{d \ln d})}(t_v n + t_b))$ time, i.e., subexponential in the dimension d of the problem. (Actually they use property 4 only for showing the subexponential bound in d.) Since, for linear programming, both the violation test and the basis calculation can be performed in time polynomial in both n and d, this gives a subexponential randomized algorithm for linear programming. Using this as the base-case algorithm at the third level of Clarkson's algorithm (i.e., x_s^*) gives expected $O(e^{O(\sqrt{d \ln d})} \log n)$ basis computations and expected $O(dn + d^2 \log n e^{O(\sqrt{d \ln d})}))$ violation tests. When d is constant, the running time of the combined algorithm is $O(t_v n + t_b \log n)$. We will use this expression in the analysis of the running times of many of our applications.

2.3. Helly-type theorems and their relations to LP-type problems. The first works to systematically study the relations between Helly-type theorems and LP-type problem were those of Amenta [1, 2]. In this subsection we summarize her results.

An LP-type problem (H, ω) with combinatorial dimension k is an abstract problem with combinatorial dimension k such that ω obeys monotonicity. Therefore the theorem below implies that there is a Helly-type theorem corresponding to the constraint set of every fixed-dimensional LP-type problem.

THEOREM 2.14 (see [2]). *Let* (H, ω) *be an abstract problem with combinatorial dimension* k *such that* ω *obeys monotonicity, and let* $\lambda \in \Lambda$ *be arbitrary.* H *has the property* $\omega(H) \leq \lambda$ *if and only if every* $G \subseteq H$ *with* $|G| \leq k + 1$ *has the property* $\omega(G) \leq \lambda$.

The main theorem in [2] goes in the other direction. Before stating it we need some definitions.

A *set system* is a pair (X, H), where X is a set and H is a set consisting of subsets of X. We say (X, H) is a *Helly system* if there exists a finite integer k such that H has Helly number k with respect to the intersection predicate. Most Helly theorems can be restated in terms of the intersection predicate. For example, let us consider the following Helly-type theorem.

THEOREM 2.15 (radius theorem). *A family H of points in the Euclidean d-dimensional space E^d is contained in a unit ball if and only if every $d+1$ or fewer points from H are contained in a unit ball.*

Here the family of objects is the set of points in E^d, the predicate is that a subfamily is contained in a (closed) unit ball, and the Helly number is $d+1$. In order to restate this theorem in terms of the intersection predicate, we apply the following duality transformation. We transform every point $h \in H$ into the set $\mathcal{D}(h)$ of centers of unit balls containing h. In this way $\mathcal{D}(h)$ is a unit ball centered at h. Let $\mathcal{D}(H) = \{\mathcal{D}(h) \mid h \in H\}$. From the definition of this duality transformation we get that the points in H are contained in a unit ball if and only if the unit balls in $\mathcal{D}(H)$ have a nonempty intersection (see Figure 2.2). Since balls are a special case of convex sets, the radius theorem derives directly from Helly's theorem.

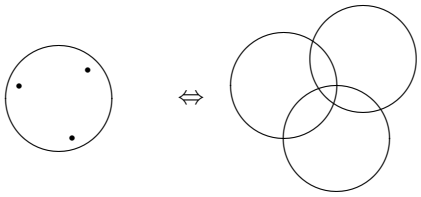

FIG. 2.2. *The 3 points on the left side are contained in a unit ball if and only if the 3 unit balls on the right side intersect.*

Recall that the range Λ of an LP-type problem can be any totally ordered set, and let (X, H) be a set system. We call $\omega' : X \to \Lambda$ a *ground set objective function*. We call $\omega : 2^H \to \Lambda$ the objective function *induced by* ω' on (X, H) if, for every $G \subseteq H$, $\omega(G)$ is the least value $\lambda^* \in \Lambda$ for which there exists $x^* \in \bigcap G$ such that $\omega'(x^*) = \lambda^*$, i.e., $\omega(G) = \min\{\omega'(x) \mid x \in \bigcap G\}$. If $\bigcap G = \emptyset$, we define $\omega(G) = \infty$. For example, when formulating lexicographic linear programming in the LP-type framework, the value of ω on a subset G of constraints is the minimum value that the ground set objective function ω' achieves on the points that are feasible with respect to G.

A *mathematical programming problem* is a triple (X, H, ω'), where X is a ground set, H is a set of subsets of X, and ω' is a ground set objective function to a totally ordered set Λ. We call the pair (H, ω), where ω is the objective function induced by ω' on (X, H), the *induced abstract problem*. If $|\{t \in \bigcap G \mid \omega'(t) = \omega(G)\}| = 1$ for all $G \subseteq H$, then we say that ω' satisfies the unique minimum condition (UMC).

Let $(X \times \Lambda, \bar{H})$ be a set system where Λ is a totally ordered set which contains a maximal element ∞. We call a ground set objective function ω' a *natural ground set objective function* if, for all $(x, \lambda) \in X \times \Lambda$, $\omega'(x, \lambda) = \lambda$. We call an objective function ω *natural* if it is induced by a natural ground set objective function. For every particular constraint $\bar{h} \in \bar{H}$ and $\lambda \in \Lambda$ we write $h_\lambda = \{x \in X \mid \exists \nu \leq \lambda \text{ s.t. } (x, \nu) \in \bar{h}\}$ for the projection into X of the part of $\bar{h}$ with Λ-coordinate no greater than λ. Also, for a subfamily of constraints $\bar{G} \subseteq \bar{H}$, we write G_λ as shorthand for $\{h_\lambda \mid \bar{h} \in \bar{G}\}$. We call an indexed family of subsets $\{h_\lambda \mid \bar{h} \in \bar{G}\}$, such that $h_\alpha \subseteq h_\beta$, for all $\alpha, \beta \in \Lambda$ with $\alpha < \beta$, a *nested family*.

Figure 2.3 (based upon Figure 1 in [2]) is a schematic diagram of a parameterized Helly system. The whole stack represents $X \times \Lambda$, and each of the cones represents a set $\bar{h} \in \bar{H}$. Each $\bar{h}$ is a subset of $X \times \Lambda$. Since all of the $\bar{h}$ are indexed with respect to Λ, the cross section at λ (represented by one of the planes) is equivalent to the Helly system (X, H_λ). Notice that if $\bar{G} \subseteq \bar{H}$ does not intersect at some value λ_2, then

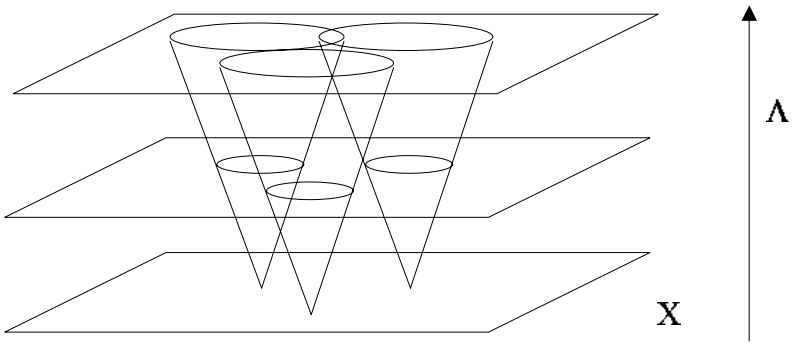

FIG. 2.3. *A parameterized Helly system.*

$\bar{G}$ also fails to intersects at all $\lambda_1 < \lambda_2$, and if $\bar{G} \subseteq \bar{H}$ intersects at λ_1, then $\bar{G}$ also intersects at all $\lambda_2 > \lambda_1$.

In her paper, Amenta [2] relates Helly-type theorems and LP-type problems by parameterization (a similar parameterization appears in [27] under the name "concrete LP-type problem").

DEFINITION 2.16. *A set system* $(X \times \Lambda, \bar{H})$ *is a* parameterized Helly system *with Helly number* k*, when*

1. $\{h_\lambda \mid \lambda \in \Lambda\}$ *is a nested family for all* $\bar{h} \in \bar{H}$*;*
2. (X, H_λ) *is a Helly system, with Helly number* k *for all* λ*.*

So the function ω' is just the projection into the Λ coordinate, and, for $\bar{G} \subseteq \bar{H}$, $\omega(\bar{G}) = \min\{\lambda \mid \bigcap G_\lambda \neq \emptyset\}$, or $\omega(\bar{G}) = \infty$ if $\bar{G}$ does not intersect at any value of λ.

Amenta [1] notes that it is almost always useful to think of Λ as time, so that a subfamily G_λ is a "snapshot" of the situation at time λ. Usually we can think of some initial time 0 at which G_0 does not intersect and then envision the h_λ growing greater with time, so that $\lambda^* = \omega(\bar{G})$ is the first "moment" at which G_λ intersects.

As an example, let us consider how the Helly system (X, H) for the radius theorem can be extended to a parameterized Helly system. (Recall that the ground set X of the Helly system representing the radius theorem is the set of centers of unit balls in E^d (which is equivalent to $\mathbb{R}^d$) and that each $h = h(p) \in H$ is the set of centers of unit balls which contain point p; i.e., $h(p)$ is a unit ball centered at p.) We define a parameterized Helly system $(X \times \Lambda, \bar{H})$, where $\Lambda = \mathbb{R}^+$ is the set radii, and each $h_\lambda = h(p)_\lambda \in H_\lambda$ is the set of centers at which a ball of radius at most λ contains a particular point p. The nested family $\bar{h} = \bar{h}(p)$ is the set of *all* balls containing p. The ground set $X \times \Lambda$ is the set of all balls in E^d, and $\bar{H}$ is the family of nested families for all points (see Figure 2.3).

The natural objective function for this parameterized Helly system $\omega(\bar{G})$ returns the smallest radius at which there is a ball containing all of the points corresponding to constraints $\bar{h} \in \bar{G}$. So $(X \times \Lambda, \bar{H}, \omega')$ is the following mathematical programming problem:

Problem: Smallest enclosing ball
Input: *A finite family* H *of points in* E^d*.*
Output: *The smallest ball enclosing* H*.*

In Figure 2.3 we see the parameterized Helly system corresponding to an instance H of the smallest enclosing ball problem consisting of 3 points. Each nested family $\bar{h}$ is a cone whose base is a point from H.

We say a ball is *realized* by points of H if it is the smallest volume ball enclosing

the points on its boundary. Assuming that the points in H are at general positions, such that no two different congruent balls are realized by points of H, the theorem below implies that the smallest enclosing ball in E^d problem can be formulated as a d-dimensional LP-type problem $(\bar{H}, \omega)$.

THEOREM 2.17 (main theorem in [2]). *Let $(X \times \Lambda, \bar{H})$ be a parameterized Helly system with Helly number k, natural ground set function ω', and natural objective function ω. If ω' meets the UMC, then $(\bar{H}, \omega)$ is an LP-type problem of combinatorial dimension k.*

Amenta showed that, without requiring the UMC, the theorem is not correct by giving an example of a Helly system with no fixed combinatorial dimension [2]. The theorem above is applied in [2] to get linear time solution algorithms for various geometric problems.

In her paper [2], Amenta investigates lexicographic objective functions. Let $(X \times \Lambda, \bar{H})$ be a parameterized Helly system with Helly number k and natural objective function ω. For all $\lambda \in \Lambda$, we assume a function $\nu_\lambda : 2^{H_\lambda} \to \Lambda'$, where Λ' is a totally ordered set containing a maximal element ∞, such that (H_λ, ν_λ) is an LP-type problem of combinatorial dimension at most d. The functions ν_λ may themselves be lexicographic. Amenta [2] imposes a lexicographic order on $\Lambda \times \Lambda'$ with $(\lambda, \kappa) > (\lambda', \kappa')$ if $\lambda > \lambda'$ or if $\lambda = \lambda'$ and $\kappa > \kappa'$. She defines a lexicographic objective function $\nu : 2^{\bar{H}} \to \Lambda \times \Lambda'$ in terms of ω and the functions ν_λ as seen in the following.

THEOREM 2.18 (see [2]). *Let Λ' be a totally ordered set. If $(X \times \Lambda, \bar{H})$ is a parameterized Helly system with Helly number k and natural objective function ω, and if, for every λ, (H_λ, ν_λ) is an LP-type problem of combinatorial dimension d, where $\nu_\lambda : 2^{H_\lambda} \to \Lambda'$, then $(\bar{H}, \nu)$ is an LP-type problem of combinatorial dimension $\leq k+d$, where $\nu : 2^{\bar{H}} \to \Lambda \times \Lambda'$ is defined as $\nu(\bar{G}) = (\omega(\bar{G}), \nu_{\omega(\bar{G})}(G_{\omega(\bar{G})}))$ for all $\bar{G} \subseteq \bar{H}$.*

Certainly, this bound on the combinatorial dimension is not always tight. For d-dimensional linear programming, for instance, this theorem gives an upper bound of $2d-1$ on the combinatorial dimension, since each H_λ is the constraint set of a $(d-1)$-dimensional linear program, and $(E^d, \bar{H})$ is a parameterized Helly system with Helly number d. Nonetheless, the theorem provides the best general bound as shown in [2].

3. Dual LP-type problems.

DEFINITION 3.1. *A* dual LP-type problem *is an abstract problem (H, ω) that obeys the following conditions (when we write $<$, $\leq$, $=$ etc., we mean under the totally ordered set Λ):*

1. Monotonicity: *For all $F \subseteq G \subseteq H : \omega(F) \geq \omega(G)$ (so the special element ∞ is such that $\omega(\emptyset) = \infty$).*
2. Locality: *For all $F \subseteq G \subseteq H$, with $\omega(G) = \omega(F) \neq \infty$, and for each $h \in H$, if $\omega(G \cup \{h\}) < \omega(G)$, then $\omega(F \cup \{h\}) < \omega(F)$.*

Let $G \subseteq H$ be arbitrary. If $\omega(G) = \infty$, we say G is *infeasible*; otherwise we call G *feasible*. If $\omega(G) = -\infty$, we say G is *unbounded*; otherwise we call G *bounded*. A *basis* B is a set $B \subseteq H$, with $\omega(B') > \omega(B)$ for all proper subsets B' of B. A *basis for* G is a basis $B \subseteq G$, with $\omega(B) = \omega(G)$. We note that due to the monotonicity condition a basis for G, for every $G \subseteq H$, always exists.

The *combinatorial dimension* d of a dual LP-type problem is the maximum cardinality of every basis for any *bounded* subfamily G. We note that the basis for every infeasible set is the empty set. A dual LP-type problem of combinatorial dimension d, where d is independent of $|H|$, is called *fixed-dimensional*. We choose the term dual LP-type (which should not be confused with the term dual in linear programming) because of the following.

Observation 3.2. The abstract problem (H, ω) is a dual LP-type problem if and only if $(H, -\omega)$ is an LP-type problem.

Looking at (H, ω), in order to prevent confusion between LP-type problems and their dual versions, we will denote by (D, ω) LP-type problems and by (S, ω) dual LP-type problems. The motivation for the choice of the letters "D" and "S" is as follows. We use the letter "D" in the LP-type problem (D, ω) since we look at D as a set of *demand elements (d-elements)*, or constraints on the feasible region, on which the minimum value is $\omega(D)$. Adding demand elements to D may increase the minimum solution of the problem and will never decrease its value. We use the letter "S" in the dual LP-type problem (S, ω) since we look at S as a set of *supply elements (s-elements)*, or relaxations on the feasible region, on which the minimum value is $\omega(S)$. Adding supply elements to S may decrease the minimum solution of the problem and will never increase its value. In the next section we define *discrete LP-type problems* by using the *same* ω in a primal and a dual LP-type problem.

4. Discrete LP-type problems.

DEFINITION 4.1. *A* discrete abstract problem *is a triple (D, S, ω), where D and S are finite sets of elements and ω is an* objective function *from $2^D \times 2^S \setminus \{(\emptyset, \emptyset)\}$ to some totally ordered set Λ which contains a special maximal (minimal) elements ∞ ($-\infty$). The goal is to compute $\omega(D, S)$.*

DEFINITION 4.2. *Let (D, S, ω) be a discrete abstract problem. For every $D', D'' \subseteq D$ and $S', S'' \subseteq S$ let $\alpha_{S'}(D'') = \omega(D'', S')$, and let $\beta_{D'}(S'') = \omega(D', S'')$. We say that (D, S, ω) is a* discrete LP-type problem *(DLP-type, in short) when $(D, \alpha_{S'})$ is an LP-type problem and $(S, \beta_{D'})$ is a dual LP-type problem for all $D' \subseteq D$ and $S' \subseteq S$. We say that $(D, \alpha_{S'})$ ($(S, \beta_{D'})$) is an* induced *LP-type (dual LP-type) problem of (D, S, ω).*

We note that we do not include $(\emptyset, \emptyset)$ in the domain of ω since this will result in the trivial ordered set $\Lambda = \{-\infty, \infty\}$, where $-\infty = \infty$: To see this, recall that the definition of LP-type problems implies that $\alpha_\emptyset(\emptyset) = -\infty$, the definition of dual LP-type problems implies that $\beta_\emptyset(\emptyset) = \infty$, and the definition of DLP-type problems implies that $\alpha_\emptyset(\emptyset) = \omega(\emptyset, \emptyset) = \beta_\emptyset(\emptyset)$.

Throughout this paper, whenever we call (D, α) $((S, \beta))$ *the induced* LP-type (dual LP-type) problem of (D, S, ω), we mean that $\alpha = \alpha_S$ ($\beta = \beta_D$). It is easy to see that the following definition for a DLP-type problem is equivalent to the former one.

DEFINITION 4.3. *A* DLP-type problem *is a discrete abstract problem (D, S, ω) which for all $S' \subseteq S$ and for all $D' \subseteq D$ obeys the following conditions (when we write $<$, $\leq$, $=$, etc., we mean under the ordered set Λ):*

1. Monotonicity of demand: *For all $D'' \subseteq D' \subseteq D : \omega((D'', S')) \leq \omega((D', S'))$.*
2. Monotonicity of supply: *For all $S'' \subseteq S' \subseteq S : \omega((D', S'')) \geq \omega((D', S'))$.*
3. Locality of demand: *For all $D'' \subseteq D' \subseteq D$ such that $\omega((D', S')) = \omega((D'', S')) > -\infty$ and for each $h \in D$, if $\omega((D' \cup \{h\}, S')) > \omega((D', S'))$, then $\omega((D'' \cup \{h\}, S')) > \omega((D'', S'))$.*
4. Locality of supply: *For all $S'' \subseteq S' \subseteq S$ such that $\omega((D', S')) = \omega((D', S'')) < \infty$ and for each $h \in S$, if $\omega((D', S' \cup \{h\})) < \omega((D', S'))$, then $\omega((D', S'' \cup \{h\})) < \omega((D', S''))$.*

Before continuing any further, we give an example of a DLP-type problem.

Problem: Discrete point set width

Input: *A finite set D of points in E^d and a finite set S of permissible directions.*

Output: *The minimal width of the set in the permissible directions (i.e., the minimal width of a band with a permissible direction which contains all the points in D).*

We assume general positions of the points and directions; that is, all $|S|\ \binom{|D|}{2}$ distances (in each one of the $|S|$ permissible directions) between pairs of points are different. For every set D of points and set S of permissible directions we define $\omega(D,S)$ to be the minimal width of the points in D in the permissible directions from S. Clearly (D,S,ω) is a discrete abstract problem. Let $S' \subseteq S$. We show now that $(D,\alpha_{S'})$ is an LP-type problem for every choice of S'. Since adding points to a set can only increase its width, $(D,\alpha_{S'})$ meets the monotonicity condition. Let $D'' \subset D' \subseteq D$ be such that $\alpha_{S'}(D'') = \alpha_{S'}(D')$. Due to the general position assumption there are unique $d_1, d_2 \in D''$ and $s \in S'$ such that the width of (D'',S') and of (D',S') is the distance between d_1 and d_2 in direction s. (In other words, the width of (D',S') and of (D'',S') is the width of the band in direction s between d_1 and d_2 in which all of the points of D' lie.) If for $h \notin D'$ $\alpha_{S'}(D' \cup \{h\}) > \alpha_{S'}(D')$, then point h is not inside this band, so there must be another triple of two points and one direction which realizes the width $\alpha_{S'}(D'' \cup \{h\})$. Due to the monotonicity condition, $\alpha_{S'}(D'' \cup \{h\}) \geq \alpha_{S'}(D'')$, and from the general position assumption we get that $\alpha_{S'}(D'' \cup \{h\}) > \alpha_{S'}(D'')$, so $(D,\alpha_{S'})$ meets the locality condition as well and thus is an LP-type problem.

Let $D' \subseteq D$. It remains to show that $(S,\beta_{D'})$ is a dual LP-type problem for every choice of D'. $(S,\beta_{D'})$ satisfies the monotonicity condition since adding directions to the set of permissible directions can only decrease the width. Let $S'' \subset S' \subseteq S$ be such that $\beta_{D'}(S'') = \beta_{D'}(S')$, and let $h \notin S'$. If $\beta_{D'}(S' \cup \{h\}) < \beta_{D'}(S')$, then the width $\beta_{D'}(S' \cup \{h\})$ must be realized by a band in direction h, that is, $\beta_{D'}(S' \cup \{h\}) = \beta_{D'}(\{h\})$. Hence we must have $\beta_{D'}(S'' \cup \{h\}) = \beta_{D'}(\{h\}) < \beta_{D'}(S') = \beta_{D'}(S'')$, so $(S,\beta_{D'})$ satisfies the locality condition as well and thus is a dual LP-type problem.

We now give more definitions. Let $G = (D',S') \in 2^D \times 2^S$ be arbitrary. Throughout this paper, if not explicitly specified otherwise, we choose G such that ω is defined on G, i.e., $G \neq (\emptyset,\emptyset)$. If $\omega(G) = \infty$, we say G is *infeasible*; otherwise we call G *feasible*. If $\omega(G) = -\infty$, we say G is *unbounded*; otherwise we call G *bounded*. We extend the terms "violates" and "extreme" in a natural way: We say that a d-element $h \in D \setminus D'$ (s-element $h \in S \setminus S'$) *violates* G if h violates D' (S') in the induced LP-type problem $(D,\alpha_{S'})$ (induced dual LP-type problem $(S,\beta_{D'})$). A d-element $h \in D'$ (s-element $h \in S'$) is *extreme* in G if h is extreme in D' (in S') in its induced LP-type problem $(D',\alpha_{S'})$ (induced dual LP-type problem $(S',\beta_{D'})$). We define bases in the following natural way.

DEFINITION 4.4. *Let (D,S,ω) be a DLP-type problem, let α and β be as defined in Definition* 4.2*, and let $G = (D',S') \in 2^D \times 2^S$. $B = (B_D,B_S) \in 2^{D'} \times 2^{S'}$ is a* basis for G in (D,S,ω) *if B_D is a basis for D' in its induced LP-type problem $(D,\alpha_{S'})$, and B_S is a basis for S' in its induced dual LP-type problem $(S,\beta_{D'})$.*

We note that there always exists a basis $B = (B_D,B_S)$ for any G.

Observation 4.5. Let (D,S,ω) be a DLP-type problem, and let $G = (D',S') \in 2^D \times 2^S$. If B is a basis for G, then $\omega(B) = \omega(G)$, and no $h \in D' \cup S'$ violates B.

This follows from both monotonicity conditions. $\omega(B) = \omega(G)$ since $\omega(G) = \omega(B_D,S') \leq \omega(B_D,B_S) \leq \omega(D',B_S) = \omega(G)$. $h \in D'$ doesn't violate B since $\omega(G) = \omega(B_D,B_S) \leq \omega(B_D \cup \{h\},B_S) \leq \omega(D',B_S) = \omega(G)$, and in a similar way $h \in S'$ doesn't violate B. In order to illustrate the term "basis" let us consider the following instance of the discrete point set width problem.

Example 4.6. Let $G = (D,S)$, where $D = \{(0,0);(2,1);(1,5)\}$ and $S = \{\text{horizontal, vertical}\}$, be an instance of the discrete point set width problem. The

minimal width is achieved by a vertical strip of width 2. Let (D, α) and (S, β) be its induced LP-type and induced dual LP-type problems, respectively. At first glance one may be tempted to suggest $B = (B_D, B_S) = (\{(0,0);(2,1)\}, \{\text{vertical}\})$ as a basis for G, since $\omega(B) = \omega(G)$. This B is not a basis for G, since B_D is not a basis for (D, α) (because of the horizontal direction: $\alpha(B_D) = \omega(B_D, \{\text{horizontal}\}) = 1 \neq \omega(B_D \cup \{(1,5)\}, \{\text{horizontal, vertical}\})$). The other subsets of (D, S) on which the value of ω is 2 are (D, S) and $(D, \{\text{vertical}\})$. (D, S) fails to be a basis for G because S is not a basis in (S, β) ($\beta(S \setminus \{\text{horizontal}\}) = \beta(S)$). It is easy to verify that D is a basis for D in (D, α) and $\{\text{vertical}\}$ is a basis for S in (S, β). Thus, $(D, \{\text{vertical}\})$ is a basis for G.

A "discrete" version of Observation 2.5 is as follows.

Observation 4.7. Let (D, S, ω) be a DLP-type problem. Let $G = (D', S') \in 2^D \times 2^S$, and let $B = (B_D, B_S) \in 2^{D'} \times 2^{S'}$ be such that $\omega(B) = \omega(G)$. If $\omega(B) \neq \omega(D, S)$, then there exists an element in either $D \setminus D'$ or $S \setminus S'$ which violates B.

To see this suppose first that the inequality is $\omega(B) < \omega(D, S)$. Considering the induced LP-type problem (D, α_{B_S}), and since $\omega(D, S) \leq \omega(D, B_S)$, this implies that $\alpha_{B_S}(B_D) < \alpha_{B_S}(D)$. Applying Observation 2.5 on (D, α_{B_S}), D', and B_D, we get that there exists $h \in D \setminus D'$ that violates B_D in (D, α_{B_S}). Hence h violates B. The case where the inequality is $\omega(B) > \omega(D, S)$ is treated similarly by considering the induced LP-type problem (S, β_{B_D}).

Corollary 4.8. *Let (D, S, ω) be a DLP-type problem. Let $G = (D', S') \in 2^D \times 2^S$, and let $B \in 2^{D'} \times 2^{S'}$ be a basis for G. If no $h \in (D \setminus D') \cup (S \setminus S')$ violates B, then B is a basis for (D, S) as well.*

Proof. We need to prove that B_D is a basis for D in the induced problem (D, α) and that B_S is a basis for S in the induced problem (S, β). We prove the first part. The proof of the second part is similar. We first show that B_D is a basis in (D, α). Let B'_D be a proper subset of B_D.

(4.1)
$$\alpha(B'_D) = \omega(B'_D, S) \leq \omega(B'_D, S') < \omega(B_D, S') = \omega(B_D, B_S) = \omega(B_D, S) = \alpha(B_D).$$

The first inequality follows from monotonicity of supply, the second (strict) inequality follows from the fact that B is a basis for G, and therefore B_D is a basis in $(D', \alpha_{S'})$, the following equality is due to the fact that B is a basis for G, and the next equality is due to Observation 2.5 applied on (S, β_{B_D}) (B_S is a basis for S' in this dual LP-type problem). It remains to show that $\alpha(B_D) = \alpha(D)$. From (4.1) we have $\alpha(B_D) = \omega(B_D, S) = \omega(B_D, B_S)$. We conclude by deriving from Observation 4.7 that $\omega(B_D, B_S) = \omega(D, S) = \alpha(D)$. □

We now define a condition sufficient for a DLP-type problem (D, S, ω) to satisfy a discrete version of Observation 2.7. This condition is used in the proof of correctness of our DLP-type algorithms.

Definition 4.9. *We say that the DLP-type problem (D, S, ω) satisfies the violation condition (VC) if for every $(D', S') \in 2^D \times 2^S$ and $(D'', S'') \in 2^{D'} \times 2^{S'}$ with $\omega(D', S') = \omega(D'', S'')$ the following properties hold:*

1. *For every $h \in D$, if $\omega(D'' \cup \{h\}, S'') > \omega(D'', S'')$, then $\omega(D' \cup \{h\}, S') > \omega(D', S')$;*
2. *for every $h \in S$, if $\omega(D'', S'' \cup \{h\}) < \omega(D'', S'')$, then $\omega(D', S' \cup \{h\}) < \omega(D', S')$.*

Note that due to Corollary 2.4 this condition is always satisfied whenever either $S' = S''$ or $D' = D''$. The lemma below is a discrete version of Observation 2.7.

LEMMA 4.10. *Let (D, S, ω) be a DLP-type problem which satisfies the violation condition. Let $G = (D', S') \in 2^D \times 2^S$, and let $B = (B_D, B_S) \in 2^{D'} \times 2^{S'}$ be a basis for G. If $h \in D$ ($h \in S$) violates B, then h is extreme in $(D' \cup \{h\}, S')$ ($(D', S' \cup \{h\})$) and is a member of every basis for this set.*

Proof. We will prove the case where $h \in D$. The proof for $h \in S$ is similar. If $h \in D$ violates B, i.e., $\omega(B_D \cup \{h\}, B_S) > \omega(B)$, then due to the VC

$$\omega(D' \cup \{h\}, S') > \omega(B) = \omega(D', S'), \tag{4.2}$$

so h is extreme in $(D' \cup \{h\}, S')$. To see that h is a member for every basis $B' = (B'_D, B'_S)$ for $(D' \cup \{h\}, S')$, we use the fact that B'_D is a basis for the induced LP-type problem of $(D' \cup \{h\}, S')$ (so $\omega(B') = \omega(B'_D, S')$) and (4.2) to get

$$\omega(B'_D, S') = \omega(D' \cup \{h\}, S') > \omega(D', S'). \tag{4.3}$$

We conclude the proof by noting that if h is not a member in B'_D, then $B'_D \subseteq D'$ and due to monotonicity of demand $\omega(B'_D, S') \leq \omega(D', S')$, in contradiction to (4.3). ∎

The *demand combinatorial dimension* k_D (d-dimension, in short) of (D, S, ω) is the combinatorial dimension of its induced LP-type problem. A DLP-type problem of d-dimension k_D, where k_D is independent of $|D| + |S|$, is called *fixed d-dimensional*. We define the terms *supply combinatorial dimension* (s-dimension, in short) and *fixed s-dimensionality* analogously. We call a DLP-type problem which is both fixed s-dimensional (of dimension k_S) and fixed d-dimensional (of dimension k_D) (k_D, k_S)-dimensional. A (k_D, k_S)-dimensional DLP-type problem where both its induced LP-type problem and induced dual LP-type problem are basis regular is called a (k_D, k_S)-dimensional *basis-regular* DLP-type problem.

We note that the discrete point set width problem is not fixed-dimensional. To see this, suppose by negation that it is k-d-dimensional. Consider an instance of the problem with $n = 2k$ d-elements, consisting of k pairs of antipodal points which are located on a unit circle. Let the s-elements be the n directions perpendicular to the one-unit length segments connecting the antipodal points. Clearly, each proper subset of the d-elements admits a width of less than one unit, whereas the width of the whole set is one unit. Therefore, the number of d-elements in any basis is at least $2k$, in contradiction to our assumption that the problem is k-d-dimensional.

If the problem were fixed-dimensional, the DLP algorithms stated in the next section would solve the problem in (randomized) linear time. The variable dimensionality of the problem is not surprising, since the problem admits an $\Omega(n \log n)$ (deterministic) lower bound under the algebraic computation tree model due to a linear time reduction from:

Problem: Set equality
Input: *Sets A and B of n real numbers each.*
Output: *"true" if and only if $A = B$.*

LEMMA 4.11 (see [3]). *Solving set equality requires $\Omega(n \log n)$ operations under the algebraic computation tree model.*

LEMMA 4.12. *Solving discrete point set width requires $\Omega(n \log n)$ operations under the algebraic computation tree model.*

Proof. Consider without loss of generality two sets A and B of n positive numbers each and a unit circle with center at the origin. We construct from A and B an instance (D, S) of discrete point set width. The numbers of A are transformed into points in D, and the numbers of B are transformed into directions in S as follows. We transform each number $a \in A$ into the two intersection points of the unit circle with the line

with slope a that passes through the origin. We transform each number $b \in B$ into the direction vertical to a line with slope b. It is easy to see that the solution of the instance (D, S) of the discrete point set width is 1 if and only if $A \equiv B$. □

We now define a condition sufficient for a DLP-type problem (D, S, ω) to be fixed s-dimensional.

DEFINITION 4.13. *Let (D, S, ω) be a discrete abstract problem, and let $p \in \mathbb{N}$. We say that (D, S, ω) is a* p-supply problem *if for every $G = (D', S') \in 2^D \times 2^S$ there exists $S'' \subseteq S'$ such that $|S''| \leq p$ and $\omega(D', S'') = \omega(G)$.*

LEMMA 4.14. *A DLP-type problem (D, S, ω) which is a p-supply problem is p-s-dimensional.*

Proof. Let (S, β) be its induced dual LP-type problem. Suppose by negation that there exists a bounded $S' \in 2^S$ and a basis B for S' with $|B| > p$. From the definition of a basis in dual LP-type problems, for every proper subset $B' \subset B$, $\beta(B') > \beta(B) = \beta(S')$. This contradicts the fact that (D, S, ω) is a p-supply problem. □

Integer programming can be formulated as a DLP-type problem where D is a set of half-hyperplanes and $S = \mathbb{Z}^k$. There is one problem with this formulation: The set S is not finite. We can overcome this by noting that, when given an instance of an IP problem, it is always possible to bound the integer lattice by a big box (whose radius depends exponentially on the input size), such that the solution of the IP problem, if it exists, is found inside the bounding box (see, for example, Theorem 17.2 in [30]). Because of the above, solving IP by the DLP-type model is not efficient.

5. DLP-type algorithms. Given an instance (D, S, ω) of a (k_D, k_S)-dimensional DLP-type problem, let $n = |D|$ and $m = |S|$. Similarly to the assumptions made with the LP-type model, we assume two primitive operations. A *basis computation* Basis(D', S') takes an ordered pair $G = (D', S')$, with $|D'| \leq k_D + 1$ and $|S'| \leq 9k_S^2$, and finds a basis for G. A *violation test* Violation(B, h) takes a basis B and a constraint h and returns true if and only if h violates B. Let t_b be the time required for a basis computation and t_v be the time required for a violation test.

We observe that, when changing (by deleting or adding elements) the set D (S) while keeping the set S (D) unchanged, the problem behaves like an LP-type (dual LP-type) problem. Thus, while "fixing" the set S (D) one can use LP-type algorithms in order to solve the induced LP-type (dual LP-type) problem on D (S).

In Chapter 6 in [17] we have developed several randomized algorithms that solve fixed-dimensional DLP-type problems that satisfy the VC in linear time. The algorithms differ in the choice of the LP-type algorithms used to solve the induced LP-type and dual LP-type problems and in the decision rules when and with which input to call these algorithms.

The 4-layer algorithm given below uses this observation. In the first layer, i.e., in Function DLP, the set of s-elements does not change, so Function DLP resembles Function x_m^* in Clarkson's algorithm [8] applied on the induced LP-type problem. In the second layer, i.e., in Function M, the set of d-elements does not change, so Function M (as well as its name) resembles Function x_m^* in Clarkson's algorithm [8] applied on the induced dual LP-type problem. The purpose of Function DLP (Function M) is to get the number of constraints (relaxations) down, so we can apply the third level Function I, which resembles (as well as its name) Function x_i^* in [8] and is more efficient in k_S but less efficient in $|D|$ and $|S|$. The fourth layer Function Demand is called only when the cardinality of the s-element set is bounded by $9k_S^2$ and it behaves similarly to Sharir and Welzl's algorithm [31], applied on the induced LP-type problem.

Function DLP(D, S)

1. Let $V^* := \emptyset$, let $V := D$, and find a candidate basis C_D for D in the induced LP-type problem of (D, S, ω)
2. If $|D| \leq 9k_D^2$, then return $\mathrm{M}(D, S, C_D)$
3. Else repeat the following until $V = \emptyset$:
   (a) Choose $R \subset D \setminus V^*$ uniformly at random, $|R| = k_D\sqrt{|D|}$
   (b) Find a candidate basis C_D for $R \cup V^*$ in the induced LP-type problem of $(R \cup V^*, S, \omega)$
   (c) Let $B := \mathrm{M}(R \cup V^*, S, C_D)$, and let $V := \{d \in D \mid \text{Violation}(B, d) = \text{TRUE}\}$
   (d) If $|V| \leq 2\sqrt{|D|}$, then let $V^* := V^* \cup V$
4. Return B

Function M(D, S, C_D)

1. Let $V^* := \emptyset$, let $V := S$
2. If $|S| \leq 9k_S^2$, then return $\text{Demand}(D, S, C_D)$
3. Else repeat the following until $V = \emptyset$:
   (a) Choose $R \subset S \setminus V^*$ uniformly at random, $|R| = k_S\sqrt{|S|}$
   (b) Let $B := \mathrm{I}(D, R \cup V^*, C_D)$, and let $V := \{s \in S \mid \text{Violation}(B, s) = \text{TRUE}\}$
   (c) If $|V| \leq 2\sqrt{|S|}$, then let $V^* := V^* \cup V$
4. Return B

Function I(D, S, C_D)

1. For every $s \in S$ let $\nu_s := 1$
2. If $|S| \leq 9k_S^2$, then return $\text{Demand}(D, S, C_D)$
3. Else repeat the following until $V = \emptyset$:
   (a) Choose $R \subset S$ at random according to weights ν_s, $|R| = 9k_S^2$
   (b) Let $B := \text{Demand}(D, R, C_D)$
   (c) Let $V := \{s \in S \mid \text{Violation}(B, s) = \text{TRUE}\}$
   (d) If $\nu(V) \leq 2\nu(S)/(9k_S - 1)$, then for every $s \in V$ let $\nu_s =: 2\nu_s$
4. Return B

Function Demand(D, S, C_D)

1. If $D = C_D$, then return $\text{Basis}(C_D, S)$
2. Else
   (a) Choose a random $d \in D \setminus C_D$
   (b) Let $B = (B_D, B_S) := \text{Demand}(D \setminus \{d\}, S, C_D)$
   (c) If $\text{Violation}(B, d) = \text{TRUE}$, then return $\text{Demand}(D, S,$ the first coordinate of $\text{Basis}(B_D \cup \{d\}, S))$
   (d) Else return B

We will first show that Function Demand returns the required answer by showing that all of the arguments of [28] apply here as well. We can view Function Demand applied on the DLP-type problem (D, S, ω) as a function applied on its induced LP-type problem (D, α). This is true since the s-elements set S does not change throughout the execution of Function Demand. In this way all of the conditions stated in Lemma 2.13 are satisfied.

Function Demand is similar, but not identical, to Function lptype of Sharir and Welzl, only because of line 2(c). Due to Corollary 2.4, the violation test in Function lptype, Violation(B, h), returns true if and only if B is not a basis for H. If in Function Demand we called Function Violation$((B_D, S), d)$ instead of calling Function Violation(B, d), then we would get *exactly* Function lptype applied on the induced LP-type problem (D, α) (but the running time would increase by a big constant depending on k_S). Because of this difference we need to prove Lemma 5.1.

LEMMA 5.1. *Let (D, S, ω) be a (k_D, k_S)-dimensional DLP-type problem which meets the VC, and suppose $\omega(D, S) = \omega(B) > -\infty$. Let $B = (B_D, B_S)$ be a basis for $(D \setminus \{d\}, S)$. Let (D, α) be the induced LP-type problem of (D, S, ω). The violation test Violation(B, d) in Function Demand applied on (D, S, ω) returns true if and only if B_D is not a basis for D in (D, α).*

Proof. If d does not violate B, then, due to Corollary 4.8, B is a basis for (D, S). Hence, B_D is a basis for D in (D, α). If d does violate B, then due to the VC we get that $\alpha(D) > \alpha(D \setminus \{d\}) = \alpha(B_D)$, which implies that B_D is not a basis for D. □

So this lemma implies that Function Demand correctly computes a basis for (D, S) whenever (D, S, ω) meets the VC. We now compute t_D, the time needed for Function Demand to run. Let t_{vD} (t_{bDS}) be the time required for the violation test Violation(B, d) (the basis calculation Basis$_{DS}$). Using the analysis in [28], Function Demand calls Functions Basis$_{DS}$ and Violation $O(|D|)$ times where the constant depends (exponentially) on k_D, so the running time of Function Demand is

$$t_D = O(|D|(t_{vD} + t_{bDS})). \tag{5.1}$$

If the violation test and basis calculation are done in constant time, Function Demand runs in $O(n)$ time.

We next show that Functions M and I return the required value. In order to prove this we need to show that Lemmas 2.8, 2.9, and 2.10 and Theorem 2.11 can be modified for the DLP-type framework. We also rely, of course, on the correctness of Function Demand. Lemma 2.10 and Theorem 2.11 are straightforwardly adapted to the DLP-type case. We provide proofs for the first 2 lemmas.

LEMMA 5.2 (adaptation of Lemma 3.1 in [8]). *In Functions M and I, if the set V is nonempty, and if (D, S, ω) satisfies the VC, then V contains an element from B'_S, where $B' = (B'_D, B'_S)$ is any basis of (D, S).*

Proof. We prove the correctness of Function M. The proof for Function I is similar. Let $S^* = R \cup V^*$, and let $B = (B_D, B_S)$ be a basis for (D, S^*). Let NV be the set of s-elements in $S \setminus S^*$ that do not violate B; i.e., S decomposes into $S = S^* \uplus NV \uplus V$. If V is not empty, then there exists $s \in V$ such that $\omega(B_D, B_S \cup \{s\}) < \omega(B)$. Hence, since (D, S, ω) satisfies the VC and s violates B, it also violates (D, S^*), that is, $\omega(D, S^* \cup \{s\}) < \omega(B)$. From the monotonicity of supply condition we get

$$\omega(D, S) < \omega(B). \tag{5.2}$$

None of $s \in NV$ violates B, so, by Corollary 4.8, B is a basis for $(D, S^* \cup NV)$. Let us consider an arbitrary basis $B' = (B'_D, B'_S)$ for (D, S). If B'_S does not contain an

element from V, then $B'_S \subseteq S^* \cup NV$, so by the monotonicity of supply condition we get

$$\omega(D,S) = \omega(B') = \omega(D,B'_S) \geq \omega(D, S^* \cup NV) = \omega(B),$$

in contradiction to (5.2). □

Note that the above lemma is the sole reason for which the VC is required to derive a linear time solution. (The discussion in the paragraph preceding Lemma 5.1 implies that, if the VC were not satisfied, it would still be possible to modify Function Demand to work correctly at an additional constant cost.)

LEMMA 5.3 (adaptation of Lemma 3.2 in [8]). *Let $R \subset S$ be a random subset of size r, where $|S| = m$. If $V \subset S$ is the set of elements violating a basis of (D,R), then its expected size is no more than $k_S(m-r)/(r+1)$.*

Proof. The probability that a random element $s \in S \setminus R$ violates a basis of (D,R) is not more than $k_S/(r+1)$, since $|B_S| \leq k_S$ for every basis (B_D, B_S) and the total size of the sample R with the element s is $r+1$. From the linearity of expectation the expected size of V is not more than $k_S(m-r)/(r+1)$. □

We now compute the complexity of Functions M and I. Theorem 2.12 tells us that Function M calls Function I $O(k_S)$ times (with an s-element set of size $O(\sqrt{|S|})$) and calls Function Violation $O(k_S|S|)$ times. Function I (when called with $|S|$ elements) calls Function Demand $O(k_S \log |S|)$ times and calls Function Violation $O(k_S|S| \log |S|)$ times.

If Function Demand runs in t_D time, then the total running time of Function M is $O(k_S|S|t_{vS} + k_S^2 \log |S| t_D))$, where the constant factors do not depend on k_D and k_S. Using (5.1), we get that the total running time of Function M is $O(k_S|S|t_{vS} + k_S^2(\log |S|)|D|(t_{vD} + t_{bDS}))$, where the constant depends exponentially on k_D.

After proving that Functions M, I, and Demand are correct and calculating their running times, it remains to consider Function DLP. In order to prove that Function DLP works correctly, we need to show that Lemmas 2.8, 2.9, and 2.10 and Theorem 2.11 can be modified for the DLP-type framework. This is done similarly to the way it was proved for Functions M and I.

It remains to consider the running time of Function DLP. Due to Theorem 2.12, Function DLP calls Function M (with a d-element set of size $k_D\sqrt{|D|}$) $O(k_D)$ times and calls Function Violation $O(k_D|D|)$ times. In this way Function Demand is called $O(k_D k_S^2 \log |S|)$ times, with an s-element set of constant size C and a d-element set of size $O(k_D\sqrt{|D|})$. If Function Demand is implemented in t_D time, then the total running time of Function DLP is $O(k_D(|D|t_{vD} + k_S|S|t_{vS} + k_S^2 \log |S| t_D))$, where the constant factors do not depend on k_D and k_S. Using (5.1), we get that the total running time of Function DLP is $O(k_D(|D|t_{vD} + k_S|S|t_{vS} + k_S^2 \log |S|\sqrt{|D|}(t_{vD} + t_{bDS})))$, where the constant depends exponentially on k_D. If the violation tests and basis calculations are done in constant time, this algorithm runs in $O(|D|+|S|)$ time. We have proved the following.

THEOREM 5.4. *Let (D,S,ω) be a (k_D,k_S)-dimensional DLP-type problem which meets the VC. Function DLP solves it in $O((|S|+|D|)t_v + \sqrt{|D|}\log|S| t_b)$ randomized time, where t_v (t_b) is the time needed for the violation test (basis calculation of a set consisting of k_D+1 d-elements and $9k_S^2$ s-elements) primitive.*

We summarize the structure of our algorithm in the following table (recall that $|D| = n$ and $|S| = m$):

The constants in the above algorithm may depend exponentially on k_D and k_S. We can get a linear time algorithm where the constants depend subexponentially on k_D

Function	*Input* $\lvert D\rvert$	*Input* $\lvert S\rvert$	*# iterations*	*Sample from*	*Sample size*
DLP	n	m	k_d	D	$\sqrt{n}$
M	$\sqrt{n}$	m	k_s	S	$\sqrt{m}$
I	$\sqrt{n}$	$\sqrt{m}$	$\log m$	S	const
Demand	$\sqrt{n}$	const	$\sqrt{n}$	D	1

and k_S when (D, S, ω) is basis regular. The idea is to call the modified algorithm of Sharir and Welzl only after the sizes of both the d-element set and the s-element set are reduced to constants and use the fact that this algorithm runs in linear time where the constants depend subexponentially on the dimension of the problem, when the problem is basis regular. Recall that Function I is a modified version of Function x_i^* in [8], applied on the s-element set. Instead of calling Function Demand in lines 2 and 3(b), we change it to call a new and similar Function I', which is a modified version of Function x_i^* in [8], applied on the d-element set. Function I' will call Function Demand in the lines corresponding to lines 2 and 3(b) in Function I. Thus Function Demand is called with both d-element and s-element sets of constant size. Recall that Function Demand is a modified version of Function lptype in [31], applied on the d-elements set. Instead of calling Function Basis in lines 1 and 2(c), we change it to call a new and similar Function Supply, which is a modified version of Function lptype in [31], applied on the s-element set. Function Supply will call Function Basis in the lines corresponding to lines 1 and 2(c) in Function Demand. Using similar arguments to the ones mentioned earlier in this section, we get that the resulting 6-layer algorithm proves the following theorem.

THEOREM 5.5. *Let (D, S, ω) be a (k_D, k_S)-dimensional DLP-type problem which meets the VC. (D, S, ω) is solved in $O((|S| + |D|)t_v + \sqrt{|D||S|}\log|D|\log|S|t_b)$ randomized time, where t_v (t_b) is the time needed for the violation test (basis calculation of a set consisting of at most $k_D + 1$ d-elements and $k_S + 1$ s-elements) primitive. If (D, S, ω) is basis regular, then the constants depend subexponentially on k_D and k_S.*

6. Continuous lexicographic Helly-type theorems and their relations to the LP-type model. Amenta [2] concludes her paper with "The major open problem is to characterize the Helly systems (X, H) for which there is an objective function ω that gives a fixed-dimensional LP-type[1] problem (H, ω)." We give a partial answer for her question in this section, by showing that *every* lexicographic Helly system (to be defined below) admits an objective function ω that gives a fixed-dimensional LP-type problem (H, ω).

Let $(X \times \Lambda, \bar{H})$ be a parameterized Helly system with Helly number k and ω be a natural objective function. If ω meets the UMC, then, by Theorem 2.17, $(\bar{H}, \omega)$ is an LP-type problem of combinatorial dimension k. If ω does not satisfy the UMC, in order to get a fixed-dimensional LP-type problem, one normally uses the following two "tricks." If possible, assume that the input is in such a general position that ω satisfies the UMC. Alternatively, explicitly change ω to be a lexicographic function ν whose first parameter is ω. The resulting LP-type problem $(\bar{H}, \nu)$ has usually combinatorial dimension greater than k (see [2, 32]).

Consider, for instance, LP. As noted in section 3 in [2], the parameterized Helly system corresponding to LP does not generally satisfy the UMC, but by using a lexicographic objective function, it does. As an additional example, consider the smallest

[1] Amenta uses the term GLP rather than LP-type.

enclosing ball problem defined in section 2.3. This problem does not necessarily satisfy the UMC. When we assume that the points in H are in general positions, such that no two different congruent balls are realized by points of H, this problem does satisfy the UMC.

Our approach is different. We provide a machinery which converts any parameterized lexicographic Helly system (to be defined below) into an LP-type problem. In this way, instead of extending the objective function, using (standard) Helly theorems, assuming UMC, and applying Theorem 2.17, we use lexicographic objective functions, lexicographic Helly theorems, and our framework. Unlike Theorem 2.17, this machinery does not require that the natural objective function meets the UMC.

We give some definitions first. For every totally ordered set Λ and $d \in \mathbb{N}$ we impose a lexicographic order on Λ^d such that for any $x = (x_1, \ldots, x_d), y = (y_1, \ldots, y_d) \in \Lambda^d$ we say that $x <_L y$ (x is lexicographically smaller than y (*lsmaller*, in short)) if $x_1 < y_1$ or there exists $d \geq k > 1$ such that $x_i = y_i$ for $i = 1, 2, \ldots, k-1$, and $x_k < y_k$. We say that $x \geq_L y$ if $x <_L y$ does not hold. For every $X \subseteq \Lambda^d$ and $x \in \Lambda^d$ we let $X_x = \{x' \in X \mid x' \leq_L x\}$ and let $X^x = \{x' \in X \mid x' \geq_L x\}$. We note that if X is a convex set, then for every $x \in X$, X_x and X^x are convex sets as well.

DEFINITION 6.1. *Let Λ be a totally ordered set. A* Helly system with lexicographic Helly number l *is a set system (X, H), where $X \subseteq \Lambda^d$ for some positive integer d, such that, for any $x \in X$, $(X, \{h \cap X_x \mid h \in H\})$ is a Helly system with Helly number l.*

This means that for any $x \in X$, whenever every l or less elements of H have a common point which is not lgreater than x, we get that all elements of H have a common point which is not lgreater than x.

In order to get LP-type problems from lexicographic Helly theorems, we impose a lexicographic order on the ground set X and parameterize the Helly system (X, H) with lexicographic Helly number l.

DEFINITION 6.2. *A set system $(X \times X, \bar{H})$ is a* parameterized Helly system with lexicographic Helly number l *if there exists a Helly system with lexicographic Helly number l, (X, H), such that, for all $h \in H$, $\bar{h} = \{(y, x) \mid x \in X,\ y \in h \cap X_x\}$ and $\bar{H} = \{\bar{h} \mid h \in H\}$.*

From the definitions it is easy to verify the following.

Observation 6.3. Let $(X \times X, \bar{H})$ be a parameterized Helly system with lexicographic Helly number l. For every $x, y \in X$ and $\bar{h} \in \bar{H}$ the following attributes hold:

1. $\{h_x \mid x \in X\}$ is a nested family for all $\bar{h} \in \bar{H}$.
2. (X, H_x) is a Helly system with lexicographic Helly number l.
3. $(X \times X, \bar{H})$ is a parameterized Helly system with Helly number l.
4. $(y, x) \in \bar{h} \rightarrow (y, y) \in \bar{h}$.
5. $(y, x) \in \bar{h} \rightarrow y \leq_L x$.

The importance of lexicographic Helly theorems follows partly from the following two results.

THEOREM 6.4. *Let $(X \times X, \bar{H})$ be a parameterized Helly system with lexicographic Helly number l. If ω is its natural objective function, then $(\bar{H}, \omega)$ is an LP-type problem of combinatorial dimension l.*

Proof. We show that all of the conditions of Theorem 2.17 are satisfied. Due to attribute 3 in Observation 6.3, $(X \times X, \bar{H})$ is a parameterized Helly system with Helly number at most l. It remains to show that the natural objective function ω meets the UMC. Suppose on the contrary that there is $\bar{G} \subseteq \bar{H}$, with $\omega(\bar{G}) = x$, such that there are two different points $x', x'' \in X$ such that both $(x', x), (x'', x) \in \bigcap \bar{G}$ realize $\omega(\bar{G})$. Due to attribute 5 in Observation 6.3, $x', x'' \leq_L x$. Without loss of

generality $x'' <_L x'$. Hence $x'' <_L x$, and from attribute 4 in Observation 6.3 we get that $(x'', x'') \in \bigcap \bar{G}$, so $\omega(\bar{G}) \leq_L x'' <_L x$ in contradiction. □

THEOREM 6.5. *Let $(X \times \Lambda, \bar{H})$ be a parameterized Helly system with Helly number k and natural objective function ω. If, for every $\lambda \in \Lambda$, (X, H_λ) is a Helly system with lexicographic Helly number l, then there is a function $\nu : 2^{\bar{H}} \to \Lambda \times X$ such that for all $\bar{G} \subseteq \bar{H}$ the first part of $\nu(\bar{G})$ is $\omega(\bar{G})$ and $(\bar{H}, \nu)$ is an LP-type problem of combinatorial dimension $\leq k + l$.*

Proof. For every $\lambda \in \Lambda$ we parameterize the Helly system (X, H_λ) such that $(X \times X, \bar{H_\lambda})$ is a parameterized Helly system with lexicographic Helly number l. If its natural objective function ν_λ is not well-defined, we symbolically compactify the space X by representing points at infinity. Due to Theorem 6.4 the resultant abstract problem (H_λ, ν_λ) is an LP-type problem of combinatorial dimension l. We conclude our proof by using Theorem 2.18. □

This theorem is useful when we want to omit general position assumptions. For instance, we reconsider the smallest enclosing ball problem. In the beginning of this section we represented this problem on the set H of points in $\mathbb{R}^d$ as a parameterized Helly system with Helly number $d+1$, $(X \times \Lambda, \bar{H})$, where $\Lambda = \mathbb{R}^+$ is the set of radii, and each $h_\lambda \in H_\lambda$ is the set of centers at which a ball of radius at most λ contains a particular point $h \in H$. The natural objective function ω is just the minimal radius of a ball which encloses all of the points in H. By assuming that the input points are in general positions, we caused the natural ground set function ω' to meet the UMC. In this way all of the conditions of Theorem 2.17 are met, and $(\bar{H}, \omega)$ is a d-dimensional LP-type problem.

Using the lexicographic version of Helly's theorem, Theorem 1.2, we note that the Helly system (X, H) representing the radius theorem (i.e., the ground set $X = \mathbb{R}^d$ is the set of centers of unit balls in E^d, and H is a family of unit balls) has lexicographic Helly number $d+1$. In this way we get that, for every $\lambda \in \Lambda = \mathbb{R}^+$, (X, H_λ) (i.e., $X = \mathbb{R}^d$ and H_λ is a family of balls of radius at most λ) is a Helly system with lexicographic Helly number $d+1$. Applying Theorem 6.5, we get that $(\bar{H}, \nu)$ is an LP-type problem of combinatorial dimension $\leq 2(d+1)$, where the first parameter of the objective function ν is the radius of the smallest enclosing ball of H.

It is possible to bound the combinatorial dimension of the resulting LP-type problem even further. We give some more definitions first. In the Helly system (X, H) representing the radius theorem, every $h = h(p) \in H$ is a unit ball centered at p. We call such p a *reference point*. For every positive *scaling factor* $\lambda \in \mathbb{R}^+$ we let $\lambda h = \lambda h(p)$ be the λ-units ball centered at p and $\lambda H = \{\lambda h \mid h \in H\}$ be the set of λ-units balls with the same centers as the balls in H.

THEOREM 6.6. *Let $d \in \mathbb{N}$, and let H be a finite family of compact subsets in $\mathbb{R}^d$ with a reference point for each one of them. If, for every scaling factor $\lambda_0 \in \mathbb{R}^+$, $(\mathbb{R}^d, \lambda_0 H)$ is a Helly system with lexicographic Helly number l, and $(\mathbb{R}^d, \lambda_0\, Int(H))$ is a Helly system with Helly number k, where $Int(H) = \{Int(h) \mid h \in H\}$ is the family of the interiors of the sets in H, then $(\mathbb{R}^d \times \mathbb{R}^+ \times \mathbb{R}^d, \bar{H})$ is a parameterized Helly system with Helly number $m = \max\{k, l\}$, where, for all $h \in H$ and for all $\lambda = (\lambda_0, x) \in \mathbb{R}^+ \times \mathbb{R}^d$, $h_\lambda = (\lambda_0 h \cap X_x) \cup (\lambda_0\, Int(h))$. Moreover, if ω is its natural objective function, then $(\bar{H}, \omega)$ is an LP-type problem of combinatorial dimension $m = \max\{k, l\}$.*

In Figure 6.1 below, $d = 2$, h is a rectangle of length 2 and width 1 centered at the origin, and $\lambda = (1, 0, 0)$. $h_{(1,0,0)}$ is a rectangle whose closure is h itself. The dashed line and the open circles do not belong to $h_{(1,0,0)} = (h \cap \mathbb{R}^2_{(0,0)}) \cup Int(h)$, while the solid line and the black point do.

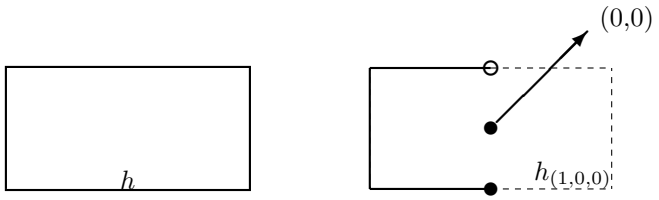

FIG. 6.1. *h and $h_{(1,0,0)}$.*

Proof. In order to prove that $(\mathbb{R}^d \times \mathbb{R}^+ \times \mathbb{R}^d, \bar{H})$ is a parameterized Helly system with Helly number $m = \max\{k, l\}$, we need to show that $\{h_\lambda \mid \lambda \in \mathbb{R}^+ \times \mathbb{R}^d\}$ is a nested family and, for every $\lambda \in \mathbb{R}^+ \times \mathbb{R}^d$, $(\mathbb{R}^d, H_\lambda)$ is a Helly system with Helly number m.

Let $\alpha = (\lambda_0, x)$, $\beta = (\lambda_0', x') \in \mathbb{R}^+ \times \mathbb{R}^d$ be such that $\alpha <_L \beta$. If $\lambda_0 = \lambda_0'$, then $x <_L x'$, so $X_x \subset X_{x'}$, and, from the definition of h_λ, $h_\alpha \subseteq h_\beta$. Otherwise ($\lambda_0 < \lambda_0'$), $\lambda_0 h \subset \lambda_0' \, Int(h)$, so again $h_\alpha \subseteq h_\beta$. Hence $\{h_\lambda \mid \lambda \in \mathbb{R}^+ \times \mathbb{R}^d\}$ is a nested family.

We show now that, for every $\lambda = (\lambda_0, x) \in \mathbb{R}^+ \times \mathbb{R}^d$, $(\mathbb{R}^d, H_\lambda)$ is a Helly system with Helly number $m = \max\{k, l\}$. If every m elements in H_λ intersect in X_x, since $(\mathbb{R}^d, \lambda_0 H)$ is a Helly system with lexicographic Helly number $l \leq m$, then there is a point $x' \in X_x$ common to all of the sets in λH. Hence x' is common to all $h_\lambda \in H_\lambda$. If every m elements in H_λ intersect in $\mathbb{R}^d \setminus X_x$, then from the definition of h_λ every m elements in $\lambda_0 \, Int(H)$ intersect. Since $(\mathbb{R}^d, \lambda_0 \, Int(H))$ is a Helly system with Helly number $k \leq m$, all of the sets in $\lambda \, Int(H)$ have a point in common. Hence there is a point common to all $h_\lambda \in H_\lambda$. In this way we get that $(\mathbb{R}^d, H_\lambda)$ is a Helly system with Helly number m and $(\mathbb{R}^d \times \mathbb{R}^+ \times \mathbb{R}^d, \bar{H})$ is a parameterized Helly system with Helly number m.

We will now apply Theorem 2.17 on the parameterized Helly system with Helly number m, $(\mathbb{R}^d \times \mathbb{R}^+ \times \mathbb{R}^d, \bar{H})$. For this we need to show that the natural ground set objective function ω' meets the UMC. We observe that, due to the definition of h_λ, for every $\lambda_0 \in \mathbb{R}^+$, $\bar{h} \in \bar{H}$, and $x, y \in \mathbb{R}^d$

$$(y, \lambda_0, x) \in \bar{h} \rightarrow (y, \lambda_0, y) \in \bar{h} \tag{6.1}$$

holds. Second, we note that if $\lambda^* = (\lambda_0^*, x^*)$ is the value of the optimal solution over $\bar{G} \subseteq \bar{H}$, that is, $\omega(\bar{G}) = \omega'(x, \lambda^*) = \lambda^*$, then, for every point $(y, \lambda^*) \in \mathbb{R}^d \times \mathbb{R}^+ \times \mathbb{R}^d$ realizing this value, there exists $h' \in H$ such that y lies on the boundary of $\lambda_0^* h' \cap X_x^*$. (Otherwise, y must be in $\cap_{h \in H} \lambda_0^* \, Int(h)$, and we can decrease λ_0^* slightly, say, to λ_0', and still have a nonempty intersection $(y, \lambda_0', x^*) \in \bigcap \bar{G}$, so $\omega(\bar{G}) \leq_L \omega'(y, \lambda_0', x^*) = (\lambda_0', x^*) <_L \lambda^*$ in contradiction to the optimality of λ^*.) Thus we have for every $y \in \mathbb{R}^d$

$$(y, \lambda_0^*, x^*) \in \bigcap \bar{G} \rightarrow y \leq_L x^*. \tag{6.2}$$

Suppose on the contrary that there exists $\bar{G} \subseteq \bar{H}$, with $\omega(\bar{G}) = \lambda^* = (\lambda_0^*, x^*)$, and there are two different points $y', y'' \in \mathbb{R}^d$ such that both $(y', \lambda^*), (y'', \lambda^*) \in \bigcap \bar{G}$ realize $\omega(\bar{G})$. Due to (6.2), $y', y'' \leq_L x^*$. Without loss of generality $y'' <_L y'$. Hence $y'' <_L x^*$, and (6.1) implies that $(y'', \lambda_0^*, y'') \in \bigcap \bar{G}$, so $\omega(\bar{G}) \leq_L (\lambda_0^*, y'') <_L (\lambda_0^*, x) = \lambda^*$ in contradiction to the optimality of λ^*. Hence ω' satisfies the UMC on $(\mathbb{R}^d \times \mathbb{R}^+ \times \mathbb{R}^d, \bar{H})$, and, by Theorem 2.17, $(\bar{H}, \omega)$ is an LP-type problem of combinatorial dimension m. ∎

Considering once again the smallest enclosing ball problem, we note that, for every $\lambda_0 \in \mathbb{R}^+$, $(X, \lambda_0 H)$ ($X = \mathbb{R}^d$ and $\lambda_0 H$ is a family of balls of radius λ_0) is a Helly system with lexicographic Helly number $d+1$. Since Helly's theorem is valid for finite families of open convex sets, $(X, \lambda_0\, Int(H))$ is a Helly system with Helly number $d+1$. Applying the theorem above, we get that $(\bar{H}, \omega)$ is an LP-type problem of combinatorial dimension $d+1$, where the first coordinate (parameter) of ω is the radius of the smallest enclosing ball of the points in H, and the remaining parameters are its center location. We demonstrate the usage of Theorem 6.6 in the next section.

7. Solving the planar lexicographic rectilinear *p*-center problem. In the lexicographic rectilinear p-piercing *decision* problem (p-*lpiercing* decision problem, in short) we are given a finite set B of closed axis-parallel boxes in $\mathbb{R}^d$ and a p-tuple $A = (a_1, \ldots, a_p)$ of p points in $\mathbb{R}^d$, with $a_i \leq_L a_j$ for all $i < j$. We need to decide whether there exists a p-tuple $A' = (a'_1, a'_2, \ldots, a'_p)$ such that $\{a'_1, a'_2, \ldots, a'_p\}$ p-pierces B and $A' \leq_L A$. If such a p-tuple A' exists, we say that B is *A-p-pierceable* and call A' a *p-piercing vector of B*.

In the lexicographic rectilinear p-piercing *optimization* problem (p-*lpiercing* optimization problem, in short) we are given a finite set B of closed boxes in $\mathbb{R}^d$ with edges parallel to the coordinate axes and need to find the lexicographically least p-tuple A such that A p-pierces B. If no such p-tuple exists, we return a special symbol ∞.

The Helly-type theorem related to these problems is about the least $h_L(p)$ such that, for all A, B is A-p-pierceable if each $B' \subseteq B$, with $|B'| \leq h_L$, is A-p-pierceable.

THEOREM 7.1 (Theorem 2.7 in [20]). *Let B be a finite set of axis-parallel closed rectangles in the plane and $A = (a_1, \ldots, a_p)$ be a p-tuple of p points in $\mathbb{R}^d$, with $a_i \leq_L a_j$ for all $i < j$. For $p = 1, 2, 3$ the rectangles in B are A-p-pierceable if every subfamily $G \subset B$ of size at most $h_L(p)$ is A-p-pierceable, where $h_L(1) = 2$, $h_L(2) = 6$, and $16 \leq h_L(3) \leq 34$.*

Its corresponding nonlexicographic Helly-type theorem is the following.

THEOREM 7.2 (see [9]). *Let B be a finite set of axis-parallel rectangles in the plane such that all of the rectangles are either closed or open. For $p = 1, 2, 3$ the rectangles in B are p-pierceable if every subfamily $G \subset H$ of size at most $h(p)$ is p-pierceable, where $h(1) = 2$, $h(2) = 5$, and $h(3) = 16$.*

In this section we solve the planar lexicographic weighted p-center problem for $p = 1, 2, 3$ in randomized linear time by applying Theorem 7.2 on open rectangles, using its corresponding lexicographic version Theorem 7.1, and Theorem 6.6.

We start by defining the parameterized Helly system corresponding to our problem. Let the ground set of all possible p-centers be

$$X_p = \{(x_1, y_1, \ldots, x_p, y_p) \mid x_1, y_1, \ldots, x_p, y_p \in \mathbb{R}\} = \mathbb{R}^{2p},$$

where $(x_1, y_1), \ldots, (x_p, y_p)$ are the p centers. Let the range of the objective function be the radius, so $\Lambda = \mathbb{R}^+$.

We consider the $2p$-dimensional space X_p. For each reference point $h = h_j = (x_0, y_0) \in H$ we define $h_p = \cup_{i=1}^{p} h_p^i$, where

$$h_p^i = \left\{ (x_1, y_1, \ldots, x_p, y_p) \;\middle|\; |x_i - x_0| \leq \frac{1}{w_j};\ |y_i - y_0| \leq \frac{1}{w_j} \right\} \tag{7.1}$$

is the set of all points in X_p such that the ith center is at weighted distance at most 1 from h. We let $H_p = \{h_p \mid h \in H\}$. For every $\lambda_1 \in \mathbb{R}^+$ and $h = h_j \in H$ we define

$\lambda_1 h_p$ as h_p scaled by λ_1, that is, $\lambda_1 h_p = \cup_{i=1}^{p} \lambda_1 h_p^i$, where $\lambda_1 h_p^i = \{(x_1, y_1, \ldots, x_p, y_p) \mid |x_i - x_0| \leq \frac{\lambda_1}{w_j}; |y_i - y_0| \leq \frac{\lambda_1}{w_j}\}$.

Due to Theorem 7.1, for every scaling factor $\lambda_0 \in \mathbb{R}^+$, the set system $(X_p, \lambda_0 H_p)$ is a Helly system with lexicographic Helly number 2 (6, a constant bounded by 34) for $p = 1$ ($p = 2, 3$). Due to Theorem 7.2 (applied on open rectangles) $(X_p, \lambda_0\, Int(H_p))$ is a Helly system with Helly number 2 (5, 16) for $p = 1$ ($p = 2, 3$). Theorem 6.6 implies that $(X_p \times \mathbb{R}^+ \times X_p, \bar{H}_p)$, where for all $h_p \in H_p$ and for all $\lambda = (\lambda_0, x) \in \mathbb{R}^{2p+1}$, $h_{p\lambda} = (\lambda_0 h_p \cap X_x) \cup (\lambda_0\, Int(h_p))$ is a parameterized Helly system with Helly number 2 (6, a constant bounded by 34) for $p = 1$ ($p = 2, 3$). Moreover, if ω_p is its natural objective function, the theorem says that $(\bar{H}_p, \omega)$ is an LP-type problem of combinatorial dimension 2 (6, 34) for $p = 1$ ($p = 2, 3$).

THEOREM 7.3. *The lexicographic weighted planar p-center problem with an l_∞ norm is solvable in (randomized) linear time for $p = 1, 2, 3$.*

Proof. Until now we have shown that the lexicographic planar p-center problem with an l_∞ norm is an LP-type problem of dimension at most 2 (6, 34) for $p = 1$ ($p = 2, 3$). We solve this problem by using the LP-type randomized algorithms, such as the one of Sharir and Welzl (see section 2.2.2). In order to obtain a linear running time it remains to show how to implement the violation test and basis calculation primitives such that they run in constant time. We slightly change the structure of these two primitives: We implement the basis calculation primitives such that when called with input (B, h) it returns, in addition to a basis $B(B \cup \{h\})$ for $B \cup \{h\}$, also the value $\omega(B \cup \{h\})$ of the objective function on $B \cup \{h\}$ and the point $x(B \cup \{h\})$ which realizes this value (there is only such a point since the objective function is lexicographic). The input for the violation tests consists of $x(B)$ in addition to B (i.e., we call Violation$(B, h, x(B))$). The violation test primitive checks whether $x(B) \in \bar{h}_p(h)$. This is done in constant time since $\bar{h}_p(h)$ is of constant complexity. We implement the basis calculation primitive Basis(B, h) in constant time as follows. For any proper subset $B' \subset B \cup \{h\}$ we calculate explicitly $\omega(B')$ and the point $x(B')$ realizing this value. Then for every $h \in B \cup \{h\} \setminus B'$ we call Violation$(B', h, x(B'))$. B' is a basis for $B \cup \{h\}$ if and only if all of these calls return "false." ∎

We note that, since the optimal solution for the lexicographic planar p-center problem is an optimal solution for the nonlexicographic problem, we get an alternative solution to the one of [32]. We summarize as follows.

COROLLARY 7.4. *The planar p-center problem with an l_∞ norm is solvable in (randomized) linear time for $p = 1, 2, 3$.*

We note that the combinatorial dimension of the lexicographic problem is smaller than the combinatorial dimension given by [32] for the corresponding nonlexicographic problems (6 instead of 13 for the case $p = 2$ and 34 instead of 43 for the case $p = 3$).

8. Discrete Helly-type theorems and their relations to the DLP-type model.

8.1. DLP-type problems specialized to mathematical programming. In the DLP-type framework both D and S are sets of abstract objects, and the objective function applies to elements of $2^D \times 2^S$. We consider an extended version of mathematical programming which is a quadruple (X, D, S, ω'), where X is a *ground set* (usually $\mathbb{R}^d$), D is a set of d-elements, S is a set of s-elements (both of which are subsets of the ground set), and ω' is an objective function from X to some totally ordered set Λ. We call the elements of X points. For $G = (D', S') \in 2^D \times 2^S$ we write $\bigcap G$ for $(\bigcap D) \cap (\bigcup S)$. The points in $\bigcap (D, S)$ are called *feasible*. The goal is

to minimize ω' over the set of feasible points.

One can think of a discrete mathematical programming problem (X, D, S, ω') as a mathematical programming problem on a grid made by $\bigcup S$, that is, the mathematical programming problem $(X \cap (\bigcup S), D \cap (\bigcup S), \omega')$. However, our definition of a discrete mathematical programming problem enables us to solve fixed-dimensional DLP-type problems efficiently, as explained later.

To simplify our proofs later, we will make a few observations about the DLP-type framework specialized to mathematical programming.

DEFINITION 8.1. *Let (X, D, S, ω') be a discrete mathematical programming problem. For $G = (D', S') \in 2^D \times 2^S$, let $\omega(G) = \infty$ when $\bigcap G = \emptyset$ and $\omega(G) = \min\{\omega'(m) \mid m \in \bigcap G\}$ elsewhere. We call $\omega : 2^D \times 2^S \to \Lambda$ the* induced *subfamily objective function of (X, D, S, ω') and call the triple (D, S, ω) the* induced discrete abstract problem.

For instance, in the discrete 1-center problem on the real line we are given two finite sets of real numbers H_1 and H_2. We need to find a point $h \in H_2$ which minimizes the maximum distance between points in H_1 and h. We call this point a *center* and call the distance it realizes the *radius*. We formulate this problem as a discrete mathematical programming problem (X, D, S, ω'), where $X = \mathbb{R}^2$, D is the set of $\frac{\pi}{4}$ radians cones whose origins are the points of H_1, S is a set of vertical rays whose origins are the points of H_2, and, for all $(x, y) \in \mathbb{R}^2$, $\omega'(x, y) = y$. In Figure 8.1 we have an instance of the problem where $H_1 = \{5, 9\}$ (the black points) and $H_2 = \{4, 8\}$ (the white points). In the solution of this problem the center is 8, and the radius is 3. If the center is not restricted to be a point of H_2, the radius realized by choosing a center at 7 will be 2. In the next section we will discuss in detail other p-center problems such as the 1-center problem in $\mathbb{R}^d$ with either l_1 or l_∞ norm.

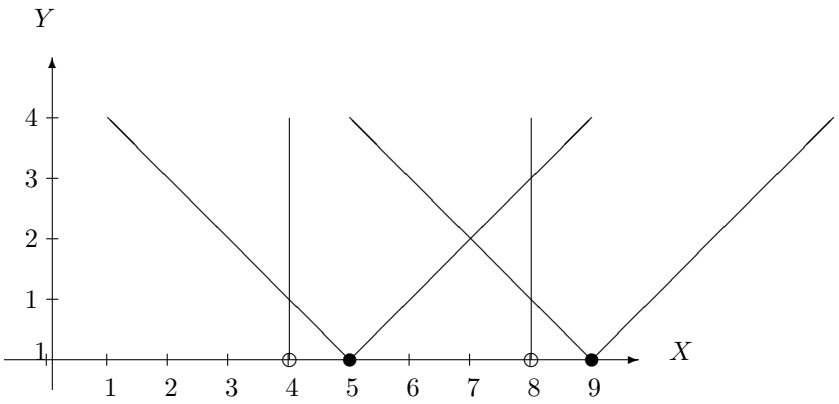

FIG. 8.1. *An instance of the general 1-center problem.*

Observation 8.2. Let (X, D, S, ω') be a discrete mathematical programming problem. The induced discrete abstract problem (D, S, ω) satisfies both monotonicity conditions of the DLP-type framework.

This follows from the fact that adding a d-element (i.e., a constraint) eliminates only feasible points, so the value of the minimum on the remaining feasible points cannot decrease. Adding an s-element (i.e., a relaxation) increases the set of feasible points, so the value of the minimum on the new enlarged set of feasible points cannot

increase.

Observation 8.3. Let (X, D, S, ω') be a discrete mathematical programming problem. Its induced discrete abstract problem (D, S, ω) is a 1-supply problem which satisfies both monotonicity conditions and the locality of supply condition.

Proof. In order to show that (D, S, ω) is a 1-supply problem, it is sufficient to show that for every feasible $G = (D', S') \in 2^D \times 2^S$ there exists $S'' \subseteq S$, with $|S''| = 1$ such that $\omega(G) = \omega(D', S'')$. Since (D, S, ω) is an induced discrete abstract problem, there exists $x \in \bigcap G$ such that $\omega(G) = \omega'(x)$. From the definition of $\bigcap G$, there is $h \in S'$ such that $x \in h$ so $x \in \bigcap(D', \{h\})$ and $\omega(D', \{h\}) = \omega(G)$. Hence we choose $S'' = \{h\}$.

By Observation 8.2, (D, S, ω) obeys both monotonicity conditions.

We now show that (D, S, ω) satisfies the locality of supply condition. Let $G = (D', S') \in 2^D \times 2^S$ be feasible, and let $S'' \subseteq S'$ such that $\omega(D', S') = \omega(D', S'')$. We need to show that, for every $h \in S$, $\omega(D', S' \cup \{h\}) < \omega(G)$ implies $\omega(D', S'' \cup \{h\}) < \omega(G)$. Since (D, S, ω) is a 1-supply problem, $\omega(D', S' \cup \{h\}) < \omega(G)$ only if $\omega(D', \{h\}) < \omega(G)$. From the monotonicity of supply condition we conclude that $\omega(D', S'' \cup \{h\}) \leq \omega(D', \{h\}) < \omega(G)$. ∎

Definition 8.4. *Let (X, D, S, ω') be a discrete mathematical programming problem, and let (D, S, ω) be a discrete abstract problem, where ω is the objective function induced by ω'. If, for all $G = (D', S') \in 2^D \times 2^S$, $|\{x \in \bigcap G \mid \omega'(x) = \omega(G)\}| = 1$, we say that ω' satisfies the* UMC.

This definition says that every subfamily not only has a minimum but that this minimum is achieved by a unique point. There is one simple sufficient condition to satisfy the UMC.

Observation 8.5. If $\omega'(x) \neq \omega'(y)$ for any two distinct points $x, y \in X$, then ω' satisfies the UMC.

Lemma 8.6. *Let (X, D, S, ω') be a discrete mathematical programming problem. If its ground set function ω' meets the UMC on (X, D, S), then its induced abstract problem (D, S, ω) is a 1 s-dimensional DLP-type problem.*

Proof. By Observation 8.3, (X, D, S) is a 1-supply problem which satisfies both monotonicity conditions as well as the locality of supply condition.

We prove now that the locality of demand condition is satisfied. Let $G = (D', S') \in 2^D \times 2^S$ be bounded, and let $D'' \subseteq D'$ such that $\omega(G) = \omega(D'', S')$. We need to show that for all $h \in D$, $\omega(D' \cup \{h\}, S') > \omega(G) \rightarrow \omega(D'' \cup \{h\}, S') > \omega(G)$. Due to the UMC, the value $\omega(D', S') = \omega(D'', S')$ is achieved at a single point $x \in X$. This means that $\omega(D' \cup \{h\}, S') > \omega(G)$ only if $x \notin h$, in which case $\omega(D'' \cup \{h\}, S') > \omega(G)$, so the locality of demand condition is satisfied, and (D, S, ω) is a DLP-type problem. By Lemma 4.14 it is 1 s-dimensional. ∎

We concentrate for a moment on lexicographic integer programming (lex IP, for short) in $\mathbb{Z}^d$. The corresponding discrete mathematical programming formulation is $(\mathbb{Z}^d, D, S, \omega')$, where D is a finite set of half-spaces in $\mathbb{Z}^d$, S is the (exponentially large) set of the integer lattice points inside a "bounding box" around the problem, and ω' is defined for every $x \in \mathbb{Z}^d$ as $\omega'(x) = x$. Since S is finite and ω' satisfies the UMC, we get from Lemma 8.6 that (D, S, ω) is a 1 s-dimensional DLP-type problem. It remains to consider its d-dimension. Alternatively, we consider the combinatorial dimension of its induced LP-type problem (D, α). Suppose its combinatorial dimension is k and that the optimal value is $\alpha(D) = x^*$. We will first show that $k \leq 2^d$. Suppose on the contrary that $k > 2^d$. This means that if B is a basis for D, then every proper subset of B, $B' \subset B$ has $\alpha(B') <_L x^*$. Let $x^{\max} = \max\{\alpha(B') \mid B' \subset B\}$ be the maximal value of α on proper subsets of B. Since B is finite, $x^{\max}$ is well-defined, and

$x^{\max} <_L x^*$. Since the lexicographic version of Theorem 1.3 has Helly number 2^d (see Theorem 2.5 in [20]), applying it on B and $x^{\max}$ implies that the half-spaces in B have a common point which is not lexicographically greater than $x^{\max}$, in contradiction.

We now give a lower bound of $2^d - 1$ on the combinatorial dimension k of lex IP. Theorem 8.7 below applied on lex IP tells us that the special case of the lexicographic version of Theorem 1.3 over half-spaces has a Helly number of at most $k + 1$. Since it is known (see section 2 in [20]) that this special case has Helly number 2^d, we get that $2^d \leq k + 1$ as needed.

8.2. (Nonlexicographic) discrete case. We first show that there is a discrete Helly theorem corresponding to the constraint set of every fixed-dimensional DLP-type problem.

THEOREM 8.7. *Let (D, S, ω) be a (k_D, k_S)-dimensional DLP-type problem. For every $\lambda \in \Lambda$, $H = (D, S)$ has the property $\omega(H) \leq \lambda$ if and only if every $B_D \subseteq D$, with $|B_D| \leq k_D + 1$, has the property $\omega(B_D, S) \leq \lambda$. Moreover, H has the property $\omega(H) \geq \lambda$ if and only if every $B_S \subseteq S$, with $|B_S| \leq k_S + 1$, has the property $\omega(D, B_S) \geq \lambda$.*

Proof. We prove the first part of the theorem. The proof of the second part of the theorem is analogous. Let $\omega(H) \leq \lambda$. By the monotonicity of demand condition, $\omega(B_D, S) \leq \omega(H) \leq \lambda$. Going in the other direction, H must contain a basis $B = (B_D, B_S)$, with $|B_D| \leq k_D + 1$, and $\omega(B_D, S) = \omega(H)$ (if H is feasible, $|B_D| \leq k_D$; otherwise, every subset of B_D is feasible, so $|B_D| \leq k_D + 1$). So if every subfamily (B_D, S), with $|B_D| \leq k_D + 1$, has $\omega(B_D, S) \leq \lambda$, then $\omega(H) = \omega(B_D, S) \leq \lambda$. ∎

We next show how to get fixed-dimensional DLP-type problems from discrete Helly-type problems.

We first "discretize" set systems and Helly systems. A *discrete set system* is a triple (X, D, S), where X is a set and D, S are families of subsets of X. A discrete set system (X, D, S) is a *discrete Helly system* if there exists a finite integer k such that the intersection of every k or less d-elements of D has a common element in $\bigcup S$ implies that $\bigcap D \cap (\bigcup S) \neq \emptyset$. Let $(X \times \Lambda, \bar{D}, \bar{S})$ be a discrete set system, where Λ is a totally ordered set which contains a maximal element ∞. For every $\lambda \in \Lambda$ and $\bar{h} \in \bar{D} \cup \bar{S}$, we write $h_\lambda = \{x \in X \mid \exists \nu \leq \lambda \text{ s.t. } (x, \nu) \in \bar{h}\}$ for the projection into X of the part of $\bar{h}$ with Λ-coordinate no greater than λ. Also, for $G \in 2^D \times 2^S$, we write G_λ as a shorthand for $\{h_\lambda \mid \bar{h} \in \bar{G}\}$.

We next discretize parameterized Helly systems.

DEFINITION 8.8. *A discrete set system $(X \times \Lambda, \bar{D}, \bar{S})$ is a* discrete parameterized Helly system *with Helly number k, when*

1. *$\{h_\lambda \mid \lambda \in \Lambda\}$ is a nested family for all $\bar{h} \in \bar{D} \cup \bar{S}$, and*
2. *$(X, D_\lambda, S_\lambda)$ is a discrete Helly system, with Helly number k for all λ.*

We say that $\bar{G} = (\bar{D}', \bar{S}') \in 2^{\bar{D}} \times 2^{\bar{S}}$ *intersects at* λ if $\bigcap D'_\lambda \cap (\bigcup S'_\lambda) \neq \emptyset$. $\omega(\bar{D}', \bar{S}')$ is then the least value in Λ at which $\bar{G} = (\bar{D}', \bar{S}')$ intersects, i.e., $\omega(\bar{D}', \bar{S}') = \lambda^* = \inf\{\lambda \mid \bigcap D'_\lambda \cap (\bigcup S'_\lambda) \neq \emptyset\}$, and $\omega(\bar{D}', \bar{S}') = \infty$ if $\bar{G}$ fails to intersect at all $\lambda \in \Lambda$.

Figure 8.2 is a schematic diagram of a discrete parameterized Helly system. The whole stack represents $X \times \Lambda$, each of the pyramids represents a set $\bar{h} \in \bar{D}$, and each of the vertical lines represents a set $\bar{h} \in \bar{S}$. Each $\bar{h}$ is a subset of $X \times \Lambda$. Since all of the $\bar{h}$ are indexed with respect to Λ, the cross section at λ (represented by one of the planes) is equivalent to the discrete Helly system $(X, D_\lambda, S_\lambda)$ corresponding to Theorem 1.4. The discrete parameterized Helly system drawn in this figure is related to the discrete weighted 1-center problem with an l_∞ norm, which we solve in the next section. $\omega(\bar{D}, \bar{S})$ is the smallest value in Λ at which the intersection of the pyramids

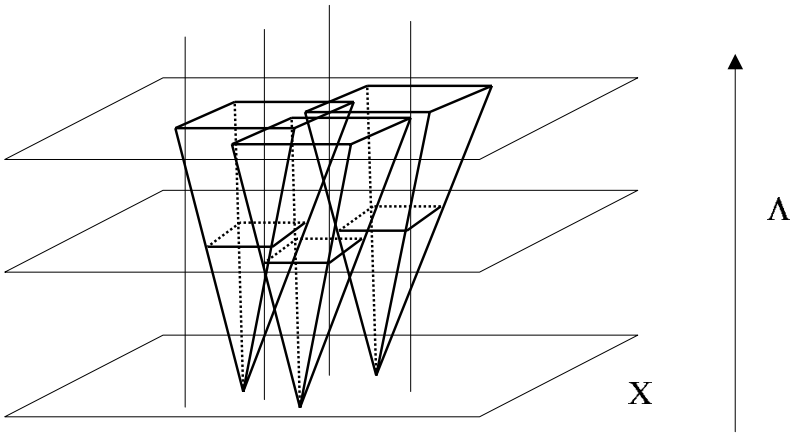

FIG. 8.2. *A discrete parameterized Helly system.*

in $\bar{D}$ "touches" a vertical line from $\bar{S}$.

We extend the main theorem in [2] to the discrete case and get the following.

THEOREM 8.9. *Let $(X \times \Lambda, \bar{D}, \bar{S})$ be a parameterized discrete Helly system with Helly number k, a natural ground set function ω', and a natural objective function ω. If ω' meets the UMC, then $(\bar{D}, \bar{S}, \omega)$ is a DLP-type problem of combinatorial dimension $(k, 1)$.*

Proof. Since ω is induced by the natural ground set objective function ω' on the space $X \times \Lambda$, and since ω' meets the UMC on $(X \times \Lambda, \bar{D}, \bar{S}, \omega')$ (Definition 8.4), by Lemma 8.6 $(\bar{D}, \bar{S}, \omega)$ is a 1 s-dimensional DLP-type problem.

It remains to prove that $(\bar{D}, \bar{S}, \omega)$ is k-d-dimensional. Consider any feasible $\bar{G} = (\bar{D}', \bar{S}') \in 2^{\bar{D}} \times 2^{\bar{S}}$ and a basis $\bar{B} = (\bar{B}_D, \bar{B}_S)$ for $\bar{G}$. Let $(\bar{D}', \alpha_{S'})$ be the induced LP-type problem of $(\bar{D}', \bar{S}', \omega)$. $\bar{B}_D$ is then a basis for $\bar{D}'$. We need to prove that $|\bar{B}_D| \leq k$. From the minimality of a basis we get that, for any $\bar{h} \in \bar{B}_D$, $\alpha_{S'}(\bar{B}_D \setminus \{\bar{h}\}) < \alpha_{S'}(\bar{B}_D)$. Let $\lambda^{\max} = \max\{\alpha_{S'}(\bar{B}_D \setminus \{\bar{h}\}) \mid \bar{h} \in \bar{B}_D\}$. Since $\bar{D}'$ is finite, so is $\bar{B}_D$, and this maximum is guaranteed to exist.

The basis $\bar{B}$ does not intersect at $\lambda^{\max}$, but for any $\bar{h} \in \bar{B}_D$, $\alpha_{S'}(\bar{B}_D \setminus \{\bar{h}\}) \leq \lambda^{\max}$, which means that $(\bar{B}_D \setminus \{\bar{h}\}, \bar{S}')$ intersects at $\lambda^{\max}$. Since $(X, D_{\lambda^{\max}}, S_{\lambda^{\max}})$ is a discrete Helly system with Helly number k, $\bar{B}_D$ must contain some subfamily $\bar{A}$, with $|\bar{A}| \leq k$, such that $(\bar{A}, \bar{S}')$ does not intersect at $\lambda^{\max}$. Every $\bar{h} \in \bar{B}_D$ must be in $\bar{A}$, since otherwise it would be the case that $\bar{A} \in (\bar{B}_D \setminus \{\bar{h}\})$ for some $\bar{h}$. This cannot be, because $(\bar{A}, \bar{S}')$ does not intersect at $\lambda^{\max}$, while every $(\bar{B}_D \setminus \{\bar{h}\}, \bar{S}')$ does. Therefore $\bar{B}_D = \bar{A}$ and $|\bar{B}_D| \leq k$. ∎

8.3. Lexicographic-discrete case. In this rather technical section we discretize the results in section 6. We start by "lexifying" discrete Helly systems.

DEFINITION 8.10. *A discrete Helly system with lexicographic Helly number ld is a discrete set system (X, D, S) such that, for every $x \in X$, $(X, \{d \cap X_x \mid d \in D\}, \{s \cap X_x \mid s \in S\})$ is a discrete Helly system with Helly number ld.*

This means that for every $x \in X$, whenever every ld or less elements of D have a common point in S which is not lgreater than x, we get that all elements of D have a common point in S which is not lgreater than x.

We next discretize Theorem 2.18. Let $(X \times \Lambda, \bar{D}, \bar{S})$ be a parameterized discrete Helly system with Helly number k and natural objective function ω. For all $\lambda \in \Lambda$, we assume a function $\nu_\lambda : 2^{D_\lambda} \times 2^{D_\lambda} \to \Lambda'$, where Λ' is a totally ordered set containing

a maximal element ∞ such that $(D_\lambda, S_\lambda, \nu_\lambda)$ is a DLP-type problem of d-dimension at most d and s-dimension 1. The functions ν_λ may themselves be lexicographic. Similarly to [2], we impose a lexicographic order on $\Lambda \times \Lambda'$ with $(\lambda, \kappa) > (\lambda', \kappa')$ if $\lambda > \lambda'$ or if $\lambda = \lambda'$ and $\kappa > \kappa'$. We define a lexicographic objective function $\nu : 2^{\bar{D}} \times 2^{\bar{S}} \to \Lambda \times \Lambda'$ in terms of ω and the functions ν_λ as seen in the following.

THEOREM 8.11. *Let Λ' be a totally ordered set. Let $(X \times \Lambda, \bar{D}, \bar{S})$ be a parameterized discrete Helly system with Helly number k and natural objective function ω. If, for all λ, $(D_\lambda, S_\lambda, \nu_\lambda)$ is a DLP-type problem of combinatorial dimension $(d, 1)$, where $\nu_\lambda : 2^{D_\lambda} \times 2^{S_\lambda} \to \Lambda'$, then $(\bar{D}, \bar{S}, \nu)$ is a DLP-type problem of d-dimension $\leq k+d$ and s-dimension 1, where $\nu : 2^{\bar{D}} \times 2^{\bar{S}} \to \Lambda \times \Lambda'$ is defined as $\nu(\bar{G}) = (\omega(\bar{G}), \nu_{\omega(\bar{G})}(G_{\omega(\bar{G})}))$ for all $\bar{G} \subseteq \bar{D} \times \bar{S}$.*

Proof. Due to Observation 8.2, $(\bar{D}, \bar{S}, \omega)$ obeys both monotonicity conditions. For every λ, $(D_\lambda, S_\lambda, \nu_\lambda)$ obeys both monotonicity conditions. Hence, since ν is a composition of monotone functions, we get that $(\bar{D}, \bar{S}, \nu)$ obeys both monotonicity conditions as well. We next show that $(\bar{D}, \bar{S}, \nu)$ obeys both locality conditions.

Consider $\bar{D}'' \subseteq \bar{D}' \subseteq \bar{D}$ and $\bar{S}' \subseteq \bar{S}$, with $\nu(\bar{D}'', \bar{S}') = \nu(\bar{D}', \bar{S}') = (\lambda^*, \kappa^*)$ and $\nu(\bar{D}' \cup \{\bar{h}\}, \bar{S}') = (\lambda, \kappa) > \nu(\bar{D}', \bar{S}')$. We must have either $\lambda > \lambda^*$ or $\kappa > \kappa^*$. If $\lambda > \lambda^*$, by the definition of ω, $\nu_{\lambda^*}(D'_{\lambda^*} \cup \{h_{\lambda^*}\}, S'_{\lambda^*}) = \infty$, so $\nu_{\lambda^*}(D'_{\lambda^*} \cup \{h_{\lambda^*}\}, S'_{\lambda^*}) > \nu_{\lambda^*}(D'_{\lambda^*}, S'_{\lambda^*})$. Otherwise, $\kappa > \kappa^*$, that is, $\nu_{\lambda^*}(D'_{\lambda^*} \cup \{h_{\lambda^*}\}, S'_{\lambda^*}) > \nu_{\lambda^*}(D'_{\lambda^*}, S'_{\lambda^*})$. In either case, by the locality of demand condition on ν_{λ^*}, $\nu_{\lambda^*}(D''_{\lambda^*} \cup \{h_{\lambda^*}\}, S'_{\lambda^*}) > \nu_{\lambda^*}(D''_{\lambda^*}, S'_{\lambda^*})$ and $\nu(\bar{D}'' \cup \{\bar{h}\}, \bar{S}') > \nu(\bar{D}'', \bar{S}')$. So the lexicographic function ν also satisfies the locality of demand condition.

We now consider the locality of supply condition. We note that, due to Observation 8.3, $(\bar{D}, \bar{S}, \omega)$ is a 1-supply problem which meets the locality of supply condition. For every λ, $(D_\lambda, S_\lambda, \nu_\lambda)$ obeys both locality conditions. We will show that, since ν is a composition of functions satisfying the locality of supply condition, $(\bar{D}, \bar{S}, \nu)$ meets the locality of supply condition. Let $\bar{S}'' \subseteq \bar{S}' \subseteq \bar{S}$ and $\bar{D}' \subseteq \bar{D}$, with $\nu(\bar{D}', \bar{S}'') = \nu(\bar{D}', \bar{S}') = (\lambda^*, \kappa^*)$ and $\nu(\bar{D}', \bar{S}' \cup \{\bar{h}\}) = (\lambda, \kappa) < \nu(\bar{D}', \bar{S}')$. We need to show that $\nu(\bar{D}', \bar{S}'' \cup \{\bar{h}\}) < (\lambda^*, \kappa^*)$. Clearly, we must have either $\lambda < \lambda^*$ or $\kappa < \kappa^*$. If $\lambda < \lambda^*$, since $(\bar{D}, \bar{S}, \omega)$ obeys the locality condition of supply, $\omega(\bar{D}', \bar{S}'' \cup \{\bar{h}\}) < \lambda^*$, so $\nu(\bar{D}', \bar{S}'' \cup \{\bar{h}\}) < (\lambda^*, \kappa^*)$, as needed. Otherwise, $\kappa < \kappa^*$, that is, $\nu_{\lambda^*}(D'_{\lambda^*}, S'_{\lambda^*} \cup \{h_{\lambda^*}\}) < \nu_{\lambda^*}(D'_{\lambda^*}, S'_{\lambda^*})$. In this case, by the locality of supply condition on ν_{λ^*}, $\nu_{\lambda^*}(D'_{\lambda^*}, S''_{\lambda^*} \cup \{h_{\lambda^*}\}) < \nu_{\lambda^*}(D'_{\lambda^*}, S''_{\lambda^*})$ and again $\nu(\bar{D}', \bar{S}'' \cup \{\bar{h}\}) < \nu(\bar{D}', \bar{S}'')$, as needed.

We now consider the combinatorial s-dimension. It is sufficient to show that, for every feasible $(\bar{D}', \bar{S}') \in 2^{\bar{D}} \times 2^{\bar{S}}$ and every basis $\bar{B} = (\bar{BD}, \bar{BS})$ for $(\bar{D}', \bar{S}')$, $|\bar{BS}| = 1$. Since $\bar{B}$ is a basis for $(\bar{D}', \bar{S}')$, we have $\nu(\bar{B}) = \nu(\bar{D}', \bar{S}') = (\lambda^*, \kappa^*)$. Let $B_{\lambda^*} = (BD'_{\lambda^*}, BS'_{\lambda^*})$ be a basis for $(D'_{\lambda^*}, S'_{\lambda^*})$ in the DLP-type problem $(D'_{\lambda^*}, S'_{\lambda^*}, \nu_{\lambda^*})$. Since the s-dimension of $(D'_{\lambda^*}, S'_{\lambda^*}, \nu_{\lambda^*})$ is 1, there is $\bar{h}' \in \bar{S}'$ such that $BS'_{\lambda^*} = \{h'_{\lambda^*}\}$. Let $\bar{S}'' \subseteq \bar{S}'$ be the set of all such $\bar{h}'$. Since $(\bar{D}', \bar{S}', \omega)$ is an induced discrete abstract problem, there is a feasible point $x \in \bigcap(\bar{D}', \bar{S}')$ such that $\omega(\bar{D}', \bar{S}') = \omega'(x) = \lambda^*$, $x \in h'_{\lambda^*}$ (so $x \in \bar{h}'$), and

$$\nu(\bar{D}', \bar{S}') = \nu(\bar{D}', \{\bar{h}'\}). \tag{8.1}$$

Let BD''_{λ^*} be a basis for D_{λ^*} in the induced LP-type problem of $(D_{\lambda^*}, S_{\lambda^*}, \nu_{\lambda^*})$ such that $BD''_{\lambda^*} \subseteq BD_{\lambda^*}$. It is possible to choose such a basis since $\nu_{\lambda^*}(BD_{\lambda^*}, S'_{\lambda^*}) = \kappa^*$. Similarly, let BS''_{λ^*} be a basis for S_{λ^*} in the induced dual LP-type problem of $(D_{\lambda^*}, S_{\lambda^*}, \nu_{\lambda^*})$ such that $BS''_{\lambda^*} \subseteq BS_{\lambda^*}$. It is possible to choose such a basis since $\nu_{\lambda^*}(D'_{\lambda^*}, BS_{\lambda^*}) = \kappa^*$. Due to the definition of a basis (Definition 4.4), $(BD''_{\lambda^*}, BS''_{\lambda^*})$

is a basis for $(D'_{\lambda^*}, S'_{\lambda^*})$. Hence $\bar{S}'' \cap \bar{BS}'' \neq \emptyset$, and consequently $\bar{S}'' \cap \bar{BS} \neq \emptyset$, so there exists

$$\bar{h}' \in \bar{S}'' \cap \bar{BS}. \tag{8.2}$$

We claim that $\bar{BS} = \{\bar{h}'\}$. Since $(\bar{BD}, \bar{BS})$ is a basis for $(\bar{D}', \bar{S}')$ we get

$$\nu(\bar{D}', \bar{S}') = \nu(\bar{D}', \bar{BS}). \tag{8.3}$$

Combining (8.1) and (8.3) together implies that $\nu(\bar{D}', \bar{BS}) = \nu(\bar{D}', \{\bar{h}'\})$. Since $\bar{BS}$ is a basis for the induced dual LP-type problem $(\bar{S}', \beta)$, the last equality implies that $\bar{BS} = \{\bar{h}'\}$, so $(\bar{D}, \bar{S}, \nu)$ has s-dimension 1.

Finally, we consider the combinatorial d-dimension. We note that, since $\bar{B}$ is a basis, $\nu(\bar{BD} \setminus \{h\}, \bar{S}') = (\lambda, \kappa) < \nu(\bar{B}) = (\lambda^*, \kappa^*)$ for any $\bar{h} \in \bar{BD}$. Let the subset $\bar{B}_1 = \{\bar{h} \in \bar{BD} \mid \nu(\bar{BD} \setminus \{\bar{h}\}, \bar{S}') = (\lambda, \kappa) \text{ and } \lambda < \lambda^*\}$. Since the d-dimension of $(B_{\lambda^*}, \nu_{\lambda^*})$ is d, $\bar{BD} \setminus \bar{B}_1$ contains at most d constraints. If $\bar{B}_1 = \emptyset$, we are done. Otherwise, we let

$$\lambda^{\max} = \max\{\lambda \mid \nu(\bar{BD} \setminus \{\bar{h}\}, \bar{S}') = (\lambda, \kappa),\ \bar{h} \in \bar{B}_1\}.$$

Since $\lambda^{\max} < \lambda^*$, $\bar{BD}$ fails to intersect with S' at $\lambda^{\max}$ and hence must contain a set $\bar{A}$ of size $\leq k$ that also fails to intersect. Every $\bar{h} \in \bar{B}_1$ must also be in $\bar{A}$, since $\bar{BD} \setminus \{\bar{h}\}$ intersects with S' at $\lambda^{\max}$ and $\bar{A}$ does not, so $\bar{A} \not\subseteq \bar{BD} \setminus \{\bar{h}\}$. So $|\bar{B}_1| \leq |\bar{A}| \leq k$ and $|\bar{BD}| \leq k + d$. □

In order to get DLP-type problems from lexicographic-discrete Helly theorems, we impose lexicographic order on the ground set X and parameterize the discrete Helly system (X, D, S) with lexicographic Helly number ld (see Definition 8.10) in the following way (recall that $X_x = \{x' \in X \mid x' \leq_L x\}$).

Definition 8.12. *A discrete set system $(X \times X, \bar{D}, \bar{S})$ is a* parameterized discrete Helly system with lexicographic Helly number *ld if there exists a discrete Helly system with lexicographic Helly number ld, (X, D, S), such that for all $h \in D$, $\bar{h} = \{(y, x) \mid x \in X,\ y \in h \cap X_x\}$, $\bar{D} = \{\bar{h} \mid h \in D\}$, and for all $h \in S$, $\bar{h} = \{(y, x) \mid x \in X,\ y \in h\}$, $\bar{S} = \{\bar{h} \mid h \in S\}$.*

From the definitions it is easy to verify the following.

Observation 8.13. Let $(X \times X, \bar{D}, \bar{S})$ be a parameterized discrete Helly system with lexicographic Helly number ld. For every $x, y \in X$ and $\bar{h} \in \bar{D} \cup \bar{S}$ the following attributes hold:

1. $\{h_x \mid x \in X\}$ is a nested family for all $\bar{h} \in \bar{D} \cup \bar{S}$.
2. (X, D_x, S_x) is a discrete Helly system with lexicographic Helly number ld.
3. $(X \times X, \bar{D}, \bar{S})$ is a parameterized discrete Helly system with Helly number ld.
4. $(y, x) \in \bar{h} \rightarrow (y, y) \in \bar{h}$.
5. $(y, x) \in \bar{h} \rightarrow y \leq_L x$.

We give the discrete versions of Theorems 6.4 and 6.5 and prove them similarly to the way we proved the continuous versions.

Theorem 8.14. *Let $(X \times X, \bar{D}, \bar{S})$ be a parameterized discrete Helly system with lexicographic Helly number ld and ω be its natural objective function. Then $(\bar{D}, \bar{S}, \omega)$ is a DLP-type problem of combinatorial dimension $(ld, 1)$.*

Proof. We show that all of the conditions of Theorem 8.9 are satisfied. Due to attribute 3 in Observation 8.13, $(X \times X, \bar{D}, \bar{S})$ is a parameterized discrete Helly system with Helly number at most ld. It remains to show that the natural objective function ω meets the UMC. Suppose on the contrary that there is $\bar{G} = (\bar{D}', \bar{S}') \in 2^{\bar{D}} \times 2^{\bar{S}}$,

with $\omega(\bar{G}) = x$, such that there are two different points $x', x'' \in X \cap (\bigcup S')$ so that both $(x', x), (x'', x) \in \bigcap \bar{G}$ realize $\omega(\bar{G})$. Due to attribute 5 in Observation 8.13, $x', x'' \leq_L x$. Without loss of generality $x'' <_L x'$. Hence $x'' <_L x$, and from attribute 4 in Observation 8.13 we get that $(x'', x'') \in \bigcap \bar{G}$, so $\omega(\bar{G}) \leq_L x'' <_L x$ in contradiction. □

THEOREM 8.15. *Let $(X \times \Lambda, \bar{D}, \bar{S})$ be a parameterized discrete Helly system with Helly number k and natural objective function ω. If, for every $\lambda \in \Lambda$, $(X, D_\lambda, S_\lambda)$ is a discrete Helly system with lexicographic Helly number ld, then there is a function $\nu : 2^{\bar{D}} \times 2^{\bar{S}} \to \Lambda \times X$ such that for all $\bar{G} \in 2^{\bar{D}} \times 2^{\bar{S}}$ the first part of $\nu(\bar{G})$ is $\omega(\bar{G})$ and $(\bar{D}, \bar{S}, \nu)$ is a DLP-type problem of d-dimension $\leq k + l$ and s-dimension 1.*

Proof. For every $\lambda \in \Lambda$ we parameterize the discrete Helly system $(X, D_\lambda, S_\lambda)$ such that $(X \times X, \bar{D_\lambda}, \bar{S_\lambda})$ is a parameterized discrete Helly system with lexicographic Helly number ld. If its natural objective function ν_λ is not well-defined, we symbolically compactify the space X by representing points at infinity. Due to Theorem 8.14 the resulted discrete abstract problem $(D_\lambda, S_\lambda, \nu_\lambda)$ is a DLP-type problem of combinatorial dimension $(ld, 1)$. We conclude our proof by using Theorem 8.11. □

It is possible to bound the combinatorial dimension of the resulting LP-type problem further by using the following discrete version of Theorem 6.6 (whose proof is similar to the one of Theorem 6.6).

THEOREM 8.16. *Let $d \in \mathbb{N}$, D be a finite family of compact subsets in $\mathbb{R}^d$ and S be a finite family of closed subsets in $\mathbb{R}^d$. If, for every scaling factor $\lambda_0 \in \mathbb{R}^+$, $(\mathbb{R}^d, \lambda_0 D, S)$ is a discrete Helly system with lexicographic Helly number l, and $(\mathbb{R}^d, \lambda_0\, Int(D), S)$ is a discrete Helly system with Helly number k, where $Int(D) = \{Int(h) \mid h \in D\}$ is the family of the interiors of the sets in D, then $(\mathbb{R}^d \times \mathbb{R}^+ \times \mathbb{R}^d, \bar{D}, \bar{S})$ is a parameterized discrete Helly system with Helly number $m = \max\{k, l\}$, where, for all $h \in D$ and for all $\lambda = (\lambda_0, x) \in \mathbb{R}^+ \times \mathbb{R}^d$, $h_\lambda = (\lambda_0 h \cap X_x) \cup (\lambda_0\, Int(h))$, and for all $h \in S$ and for all $\lambda = (\lambda_0, x) \in \mathbb{R}^{d+1}$, $h_\lambda = h$. Moreover, if ω is its natural objective function, then $(\bar{D}, \bar{S}, \omega)$ is a DLP-type problem of combinatorial dimension $(m, 1)$.*

9. Solving the discrete weighted 1-center problem in $\mathbb{R}^d$ with either l_1 or l_∞ norm. In this section we show how to solve the discrete weighted 1-center problem in $\mathbb{R}^d$ with an l_∞ norm (1-center problem, in short) in linear time by formulating it as a fixed-dimensional DLP-type problem which satisfies the VC.

Given an instance D, S, W of the 1-center problem, for every $G = (D', S') \in 2^D \times 2^S$ let $r(D', S')$ be the optimal radius of the 1-center problem on D', S', W, realized by making $s^*(D', S') \in S'$ the center.

Considering the set of boxes $r(D', S')D' = \{r(D', S')d_i \mid d_i \in D'\}$, where $r(D', S')d_i$ is the box with center at d_i and radius $\frac{r(D', S')}{w_i}$, we note that $s^*(D', S')$ intersects all of the boxes of $r(D', S')D'$. The proof of Theorem 1.5 applied on the set of boxes $r(D', S')D'$ and the set of points S' tells us that the following $2d$ boxes "define" the optimal solution:

For every $i = 1, \ldots, d$, let $L_i(D', S') \in D'$ be a d-element $d_{j(i)} \in D'$ such that the projection of box $r(D', S')d_{j(i)}$ on the ith coordinate results in an interval $[l_i, r_i]$ with the smallest r_i. Let $l_i(D', S') \in \mathbb{R}$ be the right end point of the projection of $r(D', S')d_{j(i)}$ on the ith coordinate.

For every $i = 1, \ldots, d$, let $G_i(D', S') \in D'$ be a d-element $d_{j(i)} \in D'$ such that the projection of box $r(D', S')d_{j(i)}$ on the ith coordinate results in an interval $[l'_i, r'_i]$ with the greatest l'_i. Let $g_i(D', S') \in \mathbb{R}$ be the left end point of the projection of $r(D', S')d_{j(i)}$ on the ith coordinate.

We also define $C(D', S') \in S'$ to be the lexicographically smallest optimal center. We let the range of the objective function be $\mathbb{R}^+ \times \mathbb{R}^{3d}$ and define the objective function to be

$$\omega(D', S') = (r(D', S'), C(D', S'), l_1(D', S'), -g_1(D', S'), \ldots, l_d(D', S'), -g_d(D', S')).$$

Clearly (D, S, ω) is a discrete abstract problem.

For every $(D', S') \in 2^D \times 2^S$ we let *Feasible*(D', S') denote the set of points that intersect all of the boxes $r(D', S')D'$. From the definitions of the variables and the optimality of the solution we get the following.

Observation 9.1. Let D, S, W be an instance of the discrete weighted 1-center problem in $\mathbb{R}^d$ with an l_∞ norm. For every $(D', S') \in 2^D \times 2^S$, *Feasible*$(D', S')$ is the minimal axis-parallel box containing the 2 points $(g_1(D', S'), \ldots, g_d(D', S'))$ and $(l_1(D', S'), \ldots, l_d(D', S'))$. Furthermore, $C(D', S')$ lies on its boundary.

We show now that (D, S, ω) is a $(2d, 1)$-dimensional DLP-type problem. (D, S, ω) obeys the monotonicity of demand condition since adding a new element h to D' cannot lexicographically decrease the value, i.e., $\omega(D', S') \leq_L \omega(D' \cup \{h\}, S)$. Similarly, (D, S, ω) obeys the monotonicity of supply condition since adding a new point h cannot lexicographically increase the objective function value.

We now show that (D, S, ω) obeys both locality conditions and that it obeys the VC. Let $G = (D', S') \in 2^D \times 2^S$ and $F = (D'', S'') \in 2^{D'} \times 2^{S'}$ be such that $\omega(G) =_L \omega(F)$ (so due to Observation 9.1 *Feasible*(G) = *Feasible*(F)). It suffices to show that the following 3 properties hold:

1. For all $h \in S$, $\omega(D', S' \cup \{h\}) <_L \omega(G)$ if and only if $\omega(D'', S'' \cup \{h\}) <_L \omega(F)$.
2. For all $h \in D$, $\omega(D' \cup \{h\}, S') >_L \omega(G) \rightarrow \omega(D'' \cup \{h\}, S') >_L \omega(F)$.
3. For all $h \in D$, $\omega(D'' \cup \{h\}, S'') >_L \omega(G) \rightarrow \omega(D' \cup \{h\}, S') >_L \omega(F)$.

Regarding the first property we note (for every set $X \in \mathbb{R}^d$, let *Int*(X) denote its interior, and let $\partial(X)$ denote its boundary) that

$$\begin{aligned}
\omega(D'', S'' \cup \{h\}) <_L \omega(F) &\iff C(D'', S'' \cup \{h\}) = h \\
&\iff (h \in \mathit{Int}(\mathit{Feasible}(F))) \vee ((h \in \partial(\mathit{Feasible}(F))) \\
&\qquad\qquad \wedge (h <_L C(F))) \\
&\iff (h \in \mathit{Int}(\mathit{Feasible}(G))) \vee ((h \in \partial(\mathit{Feasible}(G))) \\
&\qquad\qquad \wedge (h <_L C(G))) \\
&\iff C(D', S' \cup \{h\}) = h \\
&\iff \omega(D', S' \cup \{h\}) <_L \omega(G).
\end{aligned}$$

We now consider the remaining two properties. Let $d_i \in D$. $\omega(D'' \cup \{d_i\}, S'') >_L \omega(F)$ if and only if one of the following cases occurs:

1. $r(D'' \cup \{d_i\}, S'') > r(F)$, or
2. $r(D'' \cup \{d_i\}, S'') = r(F)$ and $C(D'' \cup \{d_i\}, S'') >_L C(F)$, or
3. $r(D'' \cup \{d_i\}, S'') = r(F)$, $C(D'' \cup \{d_i\}, S'') =_L C(F)$, and $(l_1(D'' \cup \{d_i\}, S''), -g_1(D'' \cup \{d_i\}, S''), \ldots, l_d(D'' \cup \{d_i\}, S''), -g_d(D'' \cup \{d_i\}, S'')) >_L (l_1(F), -g_1(F), \ldots, l_d(F), -g_d(F))$.

Regarding case 1, we have

$$\begin{aligned}
&r(D'' \cup \{d_i\}, S'') > r(F) \iff r(F)d_i \cap \mathit{Feasible}(F) \cap S'' = \emptyset \\
&\iff (r(G)d_i \cap \mathit{Feasible}(G) \cap S' = \emptyset) \vee ((r(G)d_i \cap \partial(\mathit{Feasible}(G) \cap (S' \setminus S'')) \neq \emptyset) \\
&\qquad\qquad \wedge C(G) \notin r(G)d_i) \\
&\iff (r(D' \cup \{d_i\}, S') > r(G)) \vee ((r(D' \cup \{d_i\}, S') = r(G)) \\
&\qquad\qquad \wedge (C(D' \cup \{d_i\}, S') >_L C(G))).
\end{aligned}$$

We now consider case 2.

$$\begin{aligned}
&(r(D'' \cup \{d_i\}, S'') = r(F)) \wedge (C(D'' \cup \{d_i\}, S'') >_L C(F)) \\
&\iff (C(F) \notin r(F)d_i) \wedge (r(F)d_i \cap \partial(\mathit{Feasible}(F)) \cap S'' \neq \emptyset) \\
&\Rightarrow (C(G) \notin r(G)d_i) \wedge (r(G)d_i \cap \partial(\mathit{Feasible}(G)) \cap S' \neq \emptyset) \\
&\iff (r(D' \cup \{d_i\}, S') = r(D', S')) \wedge (C(D' \cup \{d_i\}, S') >_L C(D', S')).
\end{aligned}$$

When $S' = S''$, the other direction of implications is also correct.

Case 3 occurs if and only $C(F) \in r(F)d_i$ and there exists j such that, among the projections of the boxes in $r(F)D'' \cup \{r(F)d_i\}$ on the jth coordinate, the projection of $r(F)d_i$ results in an interval $[l, r]$ with either the smallest r or the greatest l. This happens if and only if $C(G) \in r(G)d_i$, and among the projections of the boxes in $r(G)D' \cup \{r(G)d_i\}$ on the jth coordinate, the projection of $r(G)d_i$ results in an interval $[l, r]$ with either the smallest r or the greatest l. This occurs if and only if $r(D' \cup \{d_i\}, S') = r(G)$, $C(D' \cup \{d_i\}, S') =_L C(G)$, and $(l_1(D' \cup \{d_i\}, S'), -g_1(D' \cup \{d_i\}, S'), \ldots, l_d(D' \cup \{d_i\}, S'), -g_d(D' \cup \{d_i\}, S')) >_L (l_1(G), -g_1(G), \ldots, l_d(G), -g_d(G))$.

From the above analysis we get that the last two properties are indeed satisfied. Hence (D, S, ω) is a DLP-type problem which satisfies the VC.

It is easy to verify that $B(D, S) = (\{L_1(D, S), G_1(D, S), \ldots, L_d(D, S), G_d(D, S)\}, \{C(D, S)\})$ is a basis of a feasible and bounded (D, S) and that the problem is of d-dimension $2d$ and s-dimension 1.

The violation test can easily be implemented in constant time. For a basis $B = (B_D, B_S)$ and a d-element d_i, $\omega(B_D \cup \{d_i\}, B_S) > \omega(B)$ if and only if either $r(B)d_i$ does not contain $C(B)$ or there exists j such that, among the projections of the boxes in $r(B)D'' \cup \{r(B)d_i\}$ on the jth coordinate, the projection of $r(B)d_i$ results in an interval $[l, r]$ with either the smallest r or the greatest l. For an s-element h, $\omega(B_D, B_S \cup \{h\}) < \omega(B)$ if and only if either h lies in the interior of $\mathit{Feasible}(B)$ or h lies on the boundary of $\mathit{Feasible}(B)$ and $h \leq_L C(B)$. The basis calculation can be implemented in constant time by calling the violation test a constant number of times. Using a DLP algorithm such as the one stated in section 5, we conclude as follows.

THEOREM 9.2. *The discrete weighted* 1*-center problem in* $\mathbb{R}^d$ *with an* l_∞ *norm is solvable in (randomized) linear time for every fixed* d.

The rectilinear 1-center problem in $\mathbb{R}^d$ (i.e., with an l_1 norm) is solved similarly by using the rectilinear Helly-type versions of Theorems 1.4 and 1.5 (i.e., with rectilinear "balls" instead of axis-parallel boxes), which have Helly number 2^d instead of $2d$. We get the following theorem.

THEOREM 9.3. *The discrete weighted rectilinear* 1*-center problem in* $\mathbb{R}^d$ *is solvable in (randomized) linear time for every fixed* d.

We note that, while the Euclidean 1-center problem in $\mathbb{R}^d$ can be formulated as a $(d+1)$-dimensional LP-type problem and thus is solved in randomized linear time [31], the corresponding discrete problem admits an $\Omega(n \log n)$ lower bound under the algebraic computation tree model and is solved in the same time bound [24]. This demonstrates that sometimes the complexity of a discrete optimization version of a continuous optimization problem is strictly harder, as discussed also in the introduction.

10. Solving problems related to line transversals in the plane.

10.1. Continuous case. We first consider the *lexicographic (continuous) line transversal of axis-parallel rectangles problem.* The input is a family $D = \{d_1, \ldots, d_n\}$ of axis-parallel (closed) rectangles in the plane, together with a set of their reference points $C = \{c_1, \ldots, c_n\}$ such that c_i lies in the interior of d_i for every $i = 1, \ldots, n$. For a particular rectangle $d_i \in D$, let λd_i be the homothet of d_i that results from scaling d_i by a factor of λ, relatively to c_i (i.e., while keeping the point c_i fixed in the plane). Let $\lambda D = \{\lambda d \mid d \in D\}$. In the lexicographic (continuous) line transversal of axis-parallel rectangles *optimization* problem, we are interested in the smallest scaling factor λ^* and lexicographically smallest vector (a'', b'') such that the line $y = a''x + b''$ intersects each of the scaled rectangles in $\lambda^* D$. In the corresponding (nonlexicographic) *decision* problem (i.e., no scaling is allowed), we ask whether there exists a line transversal which intersects all of the rectangles in D. We note that this decision problem is solved in linear time via LP-type algorithms or by reducing it to linear programming [1, 2]. We are unaware of any linear time algorithms for the (nonlexicographic) optimization problem. We solve this problem by solving the (more general) lexicographic problem in linear time and noting that the optimal scaling factors of the lexicographic and nonlexicographic problems are equal. We solve the lexicographic problem by using the LP-type framework and the following two Helly-type theorems.

THEOREM 10.1 (see [29]). *Let D be a family of parallel open rectangles in the plane. If every subset of at most 6 rectangles admits a line transversal, then H does as well.*

THEOREM 10.2 (Theorem 2.12 in [20]). *Let D be a family of axis-parallel (closed) rectangles in the plane. For every pair of reals a' and b', if every subfamily of at most 6 rectangles admits a line transversal $y = ax + b$, with $(a, b) \leq_L (a', b')$, then D does as well.*

We note that, for every line direction (e.g., vertical to the x-axis), the restricted problem of finding the smallest scaling factor λ^*, such that there exists a line transversal for $\lambda^* D$ in this direction, is solvable in linear time by projecting the problem on the vertical direction (e.g., on the x-axis) and formulating it as a 2-dimensional LP problem. Hence it is enough to solve in linear time the problem where the line transversal must not be vertical to the x-axis.

We show that this problem is a 6-dimensional LP-type problem by formulating it as a parameterized Helly system with lexicographic Helly number 6 and using Theorem 6.6. Let the ground set $X = \mathbb{R}^2$ be the set of lines in the plane which are not vertical to the x-axis (i.e., $(a, b) \in X$ is the line $Y = aX + b$), and let $\Lambda = \mathbb{R}^+$. For every $d \in D$, let $t(d)$ be the set of lines intersecting d, let $\bar{d} = \{t(\lambda d) \mid \lambda \in \mathbb{R}^+\}$, and let $\bar{D} = \{\bar{d} \mid d \in D\}$.

Every line that intersects the homothet $\lambda_1 d$ also intersects $\lambda_2 d$ for any $\lambda_2 > \lambda_1$, so each $\bar{d}$ is a nested family of lines. Due to Theorem 10.2 every $(X, \lambda D)$ is a Helly system with lexicographic Helly number 6. Due to Theorem 10.1 every $(X, \lambda\, Int(D))$ is a Helly system with Helly number 6. Hence, Theorem 6.6 implies that $(\mathbb{R}^2 \times \mathbb{R}^+ \times \mathbb{R}^2, \bar{D})$ is a

parameterized Helly system with Helly number 6 and that $(\bar{D}, \omega)$ is a 6-dimensional LP-type problem. The natural objective function $\omega(\bar{D})$ is the lsmallest vector $\lambda = (\lambda_0, a, b)$ such that D_λ intersects at the point (a, b) (i.e., the line $aX + b$ intersects each of the scaled rectangles in $\lambda_0 D$). Recall that the algorithm in [28] runs in $O(t_v n + t_b \log n)$ time, where t_v is the time needed for a violation test and t_b is the time required for a basis calculation. Since both violation test and basis calculation primitives can easily be implemented in constant time, we have just proved the following theorem.

THEOREM 10.3. *The line transversal of axis-parallel rectangles optimization problem is solvable in (randomized) linear time.*

We conclude this section by considering several variants of the line transversal of a totally separable set of convex planar objects problem (problem 3 in the introduction). The input for the *lexicographic* version of this problem is a totally separable family $D = \{d_1, \ldots, d_n\}$ of simple convex objects, a family $C = \{c_1, \ldots, c_n\}$ of reference points such that c_i lies in the interior of d_i for every $i = 1, \ldots, n$, and a vector (a', b'). In the *decision problem* we want to decide whether there exists a line $Y = aX + b$, with $(a, b) \leq_L (a', b')$, which intersects all of the objects in D. In the *optimization problem* we are interested in the smallest scaling factor λ^* and lexicographically smallest vector (a, b) such that the line $y = ax + b$ intersects each of the scaled objects in $\lambda^* D$. Clearly, the answer for the decision problem is positive if and only if the solution of the optimization problem is at most $(1, a', b')$. We solve this problem in linear time using the LP-type framework and the following two Helly-type theorems.

THEOREM 10.4 (see [23]). *Let D be a totally separable finite family of open convex sets. If every subset of at most 3 sets admits a line transversal, then D does as well.*

THEOREM 10.5 (Corollary 2.20 in [20]). *Let D be a totally separable family of (closed) convex sets. For every pair of reals a' and b', if every subfamily of at most 3 sets admits a line transversal $y = ax + b$, with $(a, b) \leq_L (a', b')$, then H does as well.*

It is easy to show, using similar arguments to the ones mentioned earlier in this section, that the optimization problem is indeed a 3-dimensional LP-type problem and that it is solved in linear time. We thus have just proved the following theorem.

THEOREM 10.6. *The line transversal of totally separable set of convex planar objects decision problem is solvable in (randomized) linear time.*

10.2. Discrete case I—A finite number of permissible directions of line transversals. In this section we define a discrete version for the line transversal of axis-parallel rectangles optimization problem. We solve it in randomized linear time by using the DLP-type framework.

Problem 10.7. Given are a set $D = \{d_1, \ldots, d_n\}$ of (not necessarily pairwise disjoint) axis-parallel compact rectangles in the plane, together with a set of their reference points $C = \{c_1, \ldots, c_n\}$, such that c_i lies in the interior of d_i, for every $i = 1, \ldots, n$, and a set $S = \{s_1, \ldots, s_m\}$ of permissible line directions. Find the minimal scaling factor $\lambda_1^* = \lambda_1(D, S) \in \mathbb{R}^+$ such that $\lambda_1^* D$ admits a line transversal whose direction is in S.

If we choose S to be the (infinite) set of all possible directions, this problem coincides with the continuous one. We can assume that S does not contain the vertical direction and that the directions in S are such that the permissible lines are $\{y = ax + b \mid a \in S\}$. (If S does contain a vertical direction, we will take the minimal solution (i.e., scaling factor) among the ones of Problem 10.7 on S without

the vertical direction and on the vertical direction alone. As already mentioned in the previous section, the latter problem is solved in linear time by formulating it as an LP problem.)

A special case of Problem 10.7 is when the line transversal must be nondescending.

Problem 10.8. Given are a set $D = \{d_1, \ldots, d_n\}$ of (not necessarily pairwise disjoint) axis-parallel compact rectangles, together with a set of their reference points $C = \{c_1, \ldots, c_n\}$, such that c_i lies in the interior of d_i for every $i = 1, \ldots, n$, and a set $S = \{s_1, \ldots, s_m\}$ of permissible line directions. Find the minimal scaling factor $\lambda_1^* = \lambda_1(D, S) \in \mathbb{R}^+$ such that $\lambda_1^* D$ admits a nondescending line transversal whose direction is in S.

The solution of Problem 10.7 is the minimum scaling factor between the solution of Problem 10.8 and the analog problem where the line transversal must be nonascending.

10.2.1. A formulation as a discrete LP-type problem. In this section we formulate Problem 10.8 as a fixed-dimensional DLP-type problem by using Theorem 8.16 and the following Helly-type theorems.

THEOREM 10.9 (Theorem 2.13 in [20]). *Let D be a family of open rectangles in the plane with edges parallel to the axes, and let S be a set of nonnegative reals (line directions). If every subfamily of at most 4 rectangles admits a line transversal with a slope from S, then D does as well.*

THEOREM 10.10 (Theorem 5.8 in [20]). *Let D be a family of rectangles in the plane with edges parallel to the axes, and let S be a set of nonnegative reals (line directions). For every pair of reals $a' \geq 0$ and b', and a pair of nonnegative reals $sl_{\min} \leq sl_{\max}$, if every subfamily of at most 5 rectangles admits a line transversal $y = ax + b$, with $a \in S$, $sl_{\min} \leq a \leq sl_{\max}$, and $(a, b) \leq_L (a', b')$, then D does as well.*

Let $G = (D', S') \in 2^D \times 2^S$ be an arbitrary set such that $G \neq (\emptyset, \emptyset)$. We first look closely at an optimal solution for Problem 10.8 on G. Let λ_1^* be the optimal scaling factor. Due to Theorem 10.9 there is a direction $s^* \in S'$ and a set $D'' \subseteq D'$ of at most 4 rectangles such that the solution of Problem 10.8 on $(D'', \{s^*\})$ is λ_1^*. For this solution we define the following variables:

- $\lambda_1(D', S') \in \mathbb{R}^+$ is λ_1^*, the optimal scaling factor.
- $DIR(D', S') \in S$ is s^*, the minimal direction in S' in which there exists a nondecreasing line transversal for $\lambda_1(D', S')D'$.
- $LINE(D', S') = (DIR(D', S'), b(D', S'))$ is the line $y = DIR(D', S')x + b(D', S')$, which intersects every $\lambda_1(D', S')d \in \lambda_1(D', S')D$.

We note that, due to the optimality of λ_1^*, there exists only one line transversal to D' with direction s^*, and this line is tangent to at least 2 rectangles in $\lambda_1^* D'$.

In order to solve Problem 10.8, we first define and solve a lexicographic version of it, containing 4 more parameters. Let us consider the dual space $\mathbb{R}^2$ of all possible line transversals for $\lambda_1^* D'$. In this dual space, each nonvertical line $y = ax + b$ is represented by the point (a, b). We will use the following observation.

Observation 10.11 (Observation 5.7 in [20]). Let D be a family of axis-parallel rectangles in the plane, and, for every $d \in D$, let $\mathcal{L}(d)$ be the set of line transversals which d admits in the dual space of line transversals. Let $P(D) = \cap_{d \in D} \mathcal{L}(d)$ be the set of line transversals which D admits. The intersection of $P(D)$ with either the x nonnegative or x nonpositive half-planes is a convex polygon. The slopes of line transversals with nonnegative (nonpositive) slopes for D generate a slope range interval $[sl^{\min}, sl^{\max}]$ ($[sl_{\min}, sl_{\max}]$) resulted by the projection of $P(D)$ on the nonnegative (nonpositive) part of the x-axis, respectively. Each of the 4 end points of these two

intervals is determined by two rectangles.

Due to this observation, the range of slopes of the possible nondecreasing line transversals is a closed interval contained in $\mathbb{R}^+$. We call this interval the *slope range* corresponding to $\lambda_1^* D'$ and denote it by $[SL^{\min}(D', S'), SL^{\max}(D', S')]$, where

- $SL^{\min}(D', S')$ is the slope of the line transversal for $\lambda_1^* D'$ with a minimal nonnegative slope, and
- $SL^{\max}(D', S')$ is the slope of the line transversal for $\lambda_1^* D'$ with a maximal nonnegative slope.

(Due to the optimality of the scaling factor, the slope range does not contain any direction from S' in its interior.) We are ready to define a lexicographic version for Problem 10.8.

Problem 10.12. Given are a set $D = \{d_1, \ldots, d_n\}$ of (not necessarily pairwise disjoint) axis-parallel rectangles, together with a set of their reference points $C = \{c_1, \ldots, c_n\}$, such that c_i lies in the interior of d_i for every $i = 1, \ldots, n$, and a set $S = \{s_1, \ldots, s_m\}$ of permissible line directions. Find the lexicographically minimal vector $\lambda = (\lambda_1, s, b, sl^{\min}, -sl^{\max})$ such that the line $y = sx + b$ ($s \in S$) is nondescending, intersects all of the rectangles in $\lambda_1 D$, and the slope range corresponding to $\lambda_1 D$ is $[sl^{\min}, sl^{\max}]$.

Clearly, the optimal solution of Problem 10.12 is an optimal solution for Problem 10.8.

We now apply Theorem 10.10 in order to construct a parameterized discrete Helly system. Let the ground set be $X = \mathbb{R}^+ \times \mathbb{R} \times \mathbb{R}^+ \times \mathbb{R}^-$, the space of all nondecreasing lines and slope ranges. In this space, each point represents a line by the geometric duality transformation mentioned above and a slope range, as shown below. Let the range of the objective function be $\Lambda = \mathbb{R}^+$. For every $h \in D$ and $\lambda \in \mathbb{R}^+$ we define

(10.1)
$$h_\lambda = \left\{ x = (a, b, sl^{\min}, -sl^{\max}) \in X \;\middle|\; \begin{array}{l} y = ax + b \text{ is a line transversal for } \lambda h \text{ and} \\ a \in [sl^{\min}, sl^{\max}]. \end{array} \right\}.$$

As usual, we let $\bar{h} = \{h_\lambda \mid \lambda \in \Lambda\}$.

LEMMA 10.13. *For all $h \in D$, $\bar{h}$ is a nested family.*

Proof. We need to show that for all $\alpha, \beta \in \Lambda$, with $\alpha < \beta$, $h_\alpha \subseteq h_\beta$, i.e., for all $x \in h_\alpha$, x is also in h_β. This is true by monotonicity: A line transversal for αh is also a line transversal for βh. □

For every $h \in S$ and $\lambda \in \Lambda$ we let

$$h_\lambda = \{x \mid x \text{ is a line with direction } s\}.$$

Obviously, for every $h \in S$, $\bar{h} = \{h_\lambda \mid \lambda \in \Lambda\}$ is a nested family as well, and h_λ does not depend on λ.

From the definitions and Theorem 10.9 we get that, for all $\lambda \in \Lambda$, $(X, D_\lambda, S_\lambda)$ is a discrete Helly system with Helly number 4, and thus $(X \times \Lambda, \bar{D}, \bar{S})$ is a parameterized discrete Helly system with Helly number 4 (see Definition 8.8). From Theorem 10.10, we get that, for all $\lambda \in \Lambda$, $(X, D_\lambda, S_\lambda)$ is a discrete Helly system with lexicographic Helly number 5. Thus all of the conditions in Theorem 8.16 are fulfilled, and (D, S, ν) is a DLP-type problem of d-dimension at most 5 and s-dimension 1, where for all $G = (D', S') \in 2^D \times 2^S$

$$\nu(G) = (\lambda_1(G), DIR(G), b(G), SL^{\min}(G), -SL^{\max}(G)). \tag{10.2}$$

We have just proved the following lemma.

LEMMA 10.14. *(D, S, ν) is a $(5,1)$-dimensional DLP-type problem.*

Before we continue, we explain the values that the decision and optimization problems return. The decision problem returns "yes" if and only if $\lambda_1^* = \lambda_1(D,S) \leq 1$. The optimization problem returns the minimal scaling factor $\lambda_1(D,S)$, the minimal non-negative direction from S such that $\lambda_1(D,S)$ admits a line transversal with direction $DIR(D,S)$ and intersection point $b(D,S)$ with the y-axis, the slope range defined by $SL^{\min}(D,S), SL^{\max}(D,S)$, and a basis $B = (B_D, B_S)$ for (D,S). We note that there exist line transversals for $\lambda_1^* D$ with each of the slopes $SL^{\min}(D,S)$ and $SL^{\max}(D,S)$. We can view B and $LINE(D,S)$ as witnesses for the optimality of the scaling factor $\lambda_1(D,S)$. We need only to check that $\lambda_1(B_D,S) = \lambda_1^*$ (the monotonicity of demand condition implies $\lambda_1^*(D,S) \geq \lambda_1^*$) and that the line transversal $LINE(D,S)$ intersects each one of the rectangles $\lambda_1^* h$, $h \in D$ (the monotonicity of supply condition implies $\lambda_1^*(D,S) \leq \lambda_1^*$). The first test can be executed in $|S|$ time and the second in $|D|$ time.

10.2.2. A linear time algorithm. In this section we apply the linear time algorithm stated in section 5. We need to show that the conditions stated in Theorem 5.4 are satisfied and implement each of the violation test and basis calculation primitives in constant time. In the last section we formulated Problem 10.8 as a $(5,1)$-dimensional DLP-type problem. Thus, it remains to show the following.

LEMMA 10.15. *(D, S, ν) meets the VC (Definition 4.9).*

Proof. We need to show that for every $(D', S') \in 2^D \times 2^S$ and $(D'', S'') \in 2^{D'} \times 2^{S'}$ with $\nu(D', S') = \nu(D'', S'')$ the following properties hold:

1. For every $h \in D$, if $\nu(D'' \cup \{h\}, S'') > \nu(D'', S'')$, then $\nu(D' \cup \{h\}, S') > \nu(D', S')$.
2. For every $h \in S$, if $\nu(D'', S'' \cup \{h\}) < \nu(D'', S'')$, then $\nu(D', S' \cup \{h\}) < \nu(D', S')$.

Let $\lambda_1 = \lambda_1(D', S') = \lambda_1(D'', S'')$. We define the following functions related to $P(\lambda_1 D')$, the set of line transversal which $\lambda_1 D'$ admits (see Observation 10.11 for the definition and structure of $P(\lambda_1 D')$ in the dual space of line transversals). Let $l^{\min}(D', S')$ be the unique line transversal with direction $SL^{\min}(D', S')$ that $\lambda_1(D', S') D'$ admits. Let $b^{\min}(D', S')$ be its intersection point with the y-axis. In this way $(SL^{\min}(D', S'), b^{\min}(D', S'))$ is the leftmost point in $P(\lambda_1 D')$. We define $l^{\max}(D', S')$ and $b^{\max}(D', S')$ similarly, so $(SL^{\max}(D', S'), b^{\max}(D', S'))$ is the rightmost point in $P(\lambda_1 D')$.

The proof of both properties relies on the following observation which is true due to (10.2):

(10.3)

$$\nu(D', S') = \nu(D'', S'') \rightarrow \quad \text{the functions } SL^{\min},\ b^{\min},\ l^{\min},\ SL^{\max},\ b^{\max}, \text{ and } l^{\max} \text{ have the same values on } (D', S') \text{ and on } (D'', S'').$$

We first show that the first property holds. $h \in D$ violates (D'', S'') if and only if the set of line transversals which $\lambda_1 h$ admits does not contain both lines $l^{\min}(D'', S'')$ and $l^{\max}(D'', S'')$ (i.e., $\{(SL^{\min}(D'', S''), b^{\min}(D'', S'')); (SL^{\max}(D'', S''), b^{\max}(D'', S''))\} \not\subset P(\lambda_1 h)$). Using (10.3), the latter condition occurs if and only if the set of line transversals which $\lambda_1 h$ admits does not contain both lines $l^{\min}(D', S')$ and $l^{\max}(D', S')$, which in turn occurs if and only if $h \in D$ violates (D', S').

Regarding the second property, we observe that $h \in S$ violates (D'', S'') if and only if either the slope h lies in the interior of the slope range corresponding to $\lambda_1 D''$ (so the scaling factor decreases) or h is the left end point of the slope range with $h < DIR(D'', S'')$. We conclude the proof by using (10.3) again. ∎

We are ready to make the complexity calculations. Given a basis $B = (B_D, B_S)$ and its optimal scaling factor λ_1, we compute in constant time the functions $SL^{\min}(B)$, $b^{\min}(B), l^{\min}(B), SL^{\max}(B), b^{\max}(B), l^{\max}(B), DIR(B)$, and the set of all line transversals for $\lambda_1 B$, $P(\lambda_1 B_D) = \cap_{h \in B_D} \mathcal{D}(\lambda_1 h)$ (see Observation 10.11 for the notations). The following violation tests are implemented in constant time as follows:

t_{vS}: A new s-element h violates B if and only if either h lies in the interior of the slope domain $(SL^{\min}(B), SL^{\max}(B))$ or $h = SL^{\min}(B)$ and $DIR(B) = SL^{\max}(B)$.

t_{vD}: A new d-element h violates B if and only if $\mathcal{D}(\lambda_1 h)$ does not contain $\{(SL^{\min}(D'', S''), b^{\min}(D'', S'')); (SL^{\max}(D'', S''), b^{\max}(D'', S''))\}$.

Using the violation tests it is easy to see that the basis calculation for (D', S') where both $|D'|, |S'|$ are constants can be implemented in constant time. We have proved the following.

THEOREM 10.16. *Problem* 10.7 *is solvable in (randomized) linear time.*

COROLLARY 10.17. *The lexicographic discrete line transversal of axis-parallel rectangles problem is solvable in (randomized) linear time.*

10.3. Discrete case II—A finite number of permissible line transversals. In this section we show that the problem below has a lower bound of $\Omega(n \log n)$.

Problem 10.18. Given are a set $D = \{d_1, \ldots, d_n\}$ of (not necessarily pairwise disjoint) axis-parallel compact rectangles, together with a set of their reference points $C = \{c_1, \ldots, c_n\}$, such that c_i lies in the interior of d_i for every $i = 1, \ldots, n$, and a set $S = \{s_1, \ldots, s_m\}$ of permissible lines. Find the minimal scaling factor $\lambda_1^* = \lambda_1(D, S) \in \mathbb{R}^+$ such that $\lambda_1^* D$ admits a line transversal from S.

Clearly it is sufficient to show that the corresponding decision problem has that lower bound.

THEOREM 10.19. *Given a set D of axis-parallel rectangles and a set S of lines, deciding whether D admits a line transversal from S requires $\Omega(n \log n)$ time under the algebraic computation tree model (when $m = n$).*

Proof. We reduce in linear time the set equality problem (see definition in section 4) to this decision problem. Given an instance of the set equality problem, i.e., two sets A, B of n real numbers each, we act as follows. We find $\min_A$ and $\max_A$ ($\min_B$ and $\max_B$) the minimal and maximal elements in A (B), respectively. We define two new sets $A' = \{\frac{2(a-\min_A)}{\max_A - \min_A} - 1 \mid a \in A\}$ and $B' = \{\frac{2(b-\min_B)}{\max_B - \min_B} - 1 \mid b \in B\}$. All of the elements in A' and B' are numbers between -1 to 1, and $A = B$ if and only if $A' = B'$. For any $-1 \le r \le 1$ let $p(r)$ be the intersection point of the unit circle and the ray originating at the origin and having an angle of r radians with the positive part of the x-axis. We define two instances for the problem. The first instance, instance I, has a set of lines $S_{\mathrm{I}} = S(A')$ and a set of rectangles (intervals) $D_{\mathrm{I}} = D(B')$ defined as follows. We let $S(A') = \{s(a') \mid a' \in A'\}$, where $s(a')$ is the line tangent to the unit circle at point $p(a')$. We let $D(B') = \{i(b') \mid b' \in B'\}$, where $i(b')$ is a horizontal interval of length M, where M is a large number (e.g., 100), whose left end is slightly to the right of $p(b')$ (from a computation point of view we build the left end of the interval at exactly $p(b)$ but symbolically do not include this point in the interval). From the above construction we get that $D(B')$ admits a line transversal from $S(A')$ if and only if $A \not\subset B$. The second instance, instance II, has the set of lines $S_{\mathrm{II}} = S(B')$ and the set of rectangles $D_{\mathrm{II}} = D(A')$. We get that $D(A')$ admits a line transversal from $S(B')$ if and only if $B \not\subset A$. We conclude the proof by observing that $A = B$ if and only if both instances of the problem return negative responses. ∎

Acknowledgment. The author expresses his sincere gratitude to the referees for their valuable remarks, which helped to improve the exposition of the paper considerably.

LOWER BOUNDS FOR RANDOMIZED AND QUANTUM QUERY COMPLEXITY USING KOLMOGOROV ARGUMENTS*

SOPHIE LAPLANTE† AND FRÉDÉRIC MAGNIEZ†

Abstract. We prove a very general lower bound technique for quantum and randomized query complexity that is easy to prove as well as to apply. To achieve this, we introduce the use of Kolmogorov complexity to query complexity. Our technique generalizes the weighted and unweighted methods of Ambainis and the spectral method of Barnum, Saks, and Szegedy. As an immediate consequence of our main theorem, it can be shown that adversary methods can only prove lower bounds for Boolean functions f in $O(\min(\sqrt{nC_0(f)}, \sqrt{nC_1(f)}))$, where C_0, C_1 is the certificate complexity and n is the size of the input.

Key words. quantum computing, lower bounds, query complexity, adversary method, Kolmogorov complexity

1. Introduction.

1.1. Overview. In this paper, we study lower bounds for randomized and quantum query complexity. In the query model, the input is accessed using oracle queries, and the query complexity of an algorithm is the number of calls to the oracle. Since it is difficult to obtain lower bounds on time directly, the query model is often used to prove concrete lower bounds, in classical as well as quantum computation.

The two main tools for proving lower bounds on randomized query complexity, the polynomial method [7] and the adversary method [2], were successfully extended to quantum computation. In the randomized setting, the adversary method is most often applied using Yao's minimax principle [21]. Using a different approach, which introduces the notion of quantum adversaries, Ambainis developed a general scheme in which it suffices to analyze combinatorial properties of the function in order to obtain a quantum lower bound. Recently, Aaronson [1] brought these combinatorial properties back to randomized computation, using Yao's minimax principle.

The most general method for proving lower bounds in quantum query complexity is the semidefinite programming method of Barnum, Saks, and Szegedy [5]. This method is in fact an exact characterization of the query complexity. However, the method is so general that it is very difficult to apply to obtain concrete lower bounds. Barnum, Saks, and Szegedy gave a weaker method derived from the semidefinite programming approach, using weight matrices and their largest eigenvalue. This spectral method can be thought of as a generalization of Ambainis's unweighted method. Other generalizations of Ambainis's unweighted method have been previously introduced [6, 3]. All of them use a weight function on the instances. The difficulty in applying these methods is finding a good weight function on the instances. Høyer,

Neerbek, and Shi [15] were the first to use such weight assignments to prove lower bounds for searching in ordered lists and sorting.

This paper presents a new, very general adversary technique (Theorem 1.1) to prove lower bounds in quantum and randomized query complexity. We believed that this technique is simpler to prove and to apply. It is based on the framework of Kolmogorov complexity. This framework has proven to be very useful for proving negative results in other models of computation, for example, for the number of rounds and length of advice in random-self-reductions in [13, 4]. The techniques we use here are an adaptation of those techniques to the framework of query complexity. We expect that this framework will prove to be useful for negative results in other quantum models of computation, for instance, communication complexity, where we hope to give lower bounds for bounded round query complexity.

The proof of Theorem 1.1 is in two parts. The first part (divergence lemma) shows how fast the computations can diverge when they start on different inputs. This part depends on the model of computation (randomized or quantum). The quantum case of this lemma was first proven by Ambainis [2]. The second part (query information lemma) does not depend on the model of computation. It establishes the relationship between the Kolmogorov complexity of individual positions of the input and the probability that a given algorithm makes a query to this position. Whereas Aaronson [1] used a different approach to prove a version of Ambainis's method for randomized algorithms, here we use the same framework to establish lower bounds for both quantum and randomized query complexities (QQC and RQC).

We show that our method encompasses all previous adversary methods, including the quantum and randomized weighted methods [3, 1] (Theorem 4.2) and the spectral method [5] (Theorem 4.3). As an immediate consequence of our main theorem (observed by Troy Lee), our method can only prove lower bounds for arbitrary Boolean functions in $O(\min(\sqrt{nC_0(f)}, \sqrt{nC_1(f)}))$, where C_0 and C_1 is the certificate complexity of negative and positive instances, respectively, of f and n is the size of the input (Theorem 5.2). Prior to our work, it was known [3] that the unweighted Ambainis method [2, Theorem 5.1] could not prove bounds better than $\Omega(\sqrt{C_0(f)C_1(f)})$ for total functions; Szegedy [20] also proved independently that the semidefinite programming method could not prove lower bounds better than $O(\min(\sqrt{nC_0(f)}, \sqrt{nC_1(f)}))$, and Zhang [22] proved the same thing for Ambainis's weighted method.

We end the paper by giving some applications of our method to prove lower bounds for some graph properties: bipartiteness (Theorem 5.4) and connectivity (Theorem 5.3). The lower bound on connectivity was proven in [12] and the one on bipartiteness by Dürr and independently in [22]. We reprove it here to illustrate the simplicity of our method.

In recent developments, Špalek and Szegedy [19] showed that our method is equivalent to both the spectral method [5] as well as Ambainis's weighted method [3]. Subsequently, Laplante, Lee, and Szegedy showed that the square of the quantum adversary method was also a lower bound on formula size [16].

1.2. Main result. The conditional Kolmogorov complexity $\mathsf{K}(a|b)$ (defined formally in section 2.1) is the length of the shortest program which prints a given b as input. Our main result relates the query complexity of an algorithm A for f to the quantities $\{\mathsf{K}(i|x, A), \mathsf{K}(i|y, A) : x_i \neq y_i\}$ for any x, y such that $f(x) \neq f(y)$.

THEOREM 1.1. *There exists a constant $C > 0$ such that the following holds. Let Σ be a finite set, let $n \geq 1$ be an integer, and let $S \subseteq \Sigma^n$ and S' be sets. Let $f : S \to S'$. Let A be an algorithm that for all $x \in S$ computes f, with bounded error ε and at most T queries to the input. Then for every $x, y \in S$ with $f(x) \neq f(y)$:*

1. *if A is a quantum algorithm, then*
$$T \geq C \times \frac{1 - 2\sqrt{\varepsilon(1-\varepsilon)}}{\sum_{i:x_i \neq y_i} \sqrt{2^{-\mathsf{K}(i|x,A)-\mathsf{K}(i|y,A)}}};$$
2. *if A is a randomized algorithm, then*
$$T \geq C \times \frac{1 - 2\varepsilon}{\sum_{i:x_i \neq y_i} \min\left(2^{-\mathsf{K}(i|x,A)}, 2^{-\mathsf{K}(i|y,A)}\right)}.$$

We briefly describe the intuition behind the proof of Theorem 1.1. Consider an algorithm that purports to compute f, presented with two inputs x, y that lead to different outputs. The algorithm must query those positions where x and y differ with average probability of the order of $\frac{1}{T}$, or it will not successfully compute the function. On the other hand, the queries that are made with high average probability can be described succinctly given the input and the algorithm, by using the Shannon–Fano code. If we exhibit a pair of strings x, y for which there is no succinct description of any of the positions where x and y differ, then the number of queries must be large.

The same reasoning can be applied to classical and to quantum computing; the only difference is how fast two different input states cause the outputs to diverge to different outcomes.

To conclude the introduction we give a very simple application, for Grover search.

Example 1. Fix n and a quantum algorithm A for a Grover search for instances of length n. Let z be a binary string of length $\log n$, with $\mathsf{K}(z|A) \geq \log n$. Let j be the integer between 0 and $n-1$ whose binary expansion is z. Consider x, the all 0's string, and let y be everywhere 0 except at position $i = j + 1$, where it is 1. Then $\mathsf{K}(i|x, A) \geq \log n - O(1)$ and $\mathsf{K}(i|y, A) \geq 0$; therefore, $\mathsf{QQC}(\textsc{Search}) = \Omega(\sqrt{n})$.

2. Preliminaries.

2.1. Kolmogorov complexity. We use a few standard results in Kolmogorov complexity and information theory in this paper. We briefly review these here. The reader is invited to consult standard textbooks such as [17] for more background on Kolmogorov complexity and [9] for more on information theory. We denote the length of a finite string x by $|x|$. We assume that the Turing machine's alphabet is the same finite alphabet as the alphabet used to encode instances of the function under consideration. Letters x, y typically represent instances; i is an index into the binary representation of the instance; and p, q are probability distributions. Programs are denoted P, and the output of a Turing machine M on input x is written $M(x)$. When there are multiple inputs, we assume that a standard encoding of tuples is used.

Definition 2.1.

1. *A set of strings is* prefix-free *if no string is a prefix of another string in the set.*
2. *A universal Turing machine M is* prefix-free *if the set of programs $\{P : \exists x\, M(P, x) \neq \epsilon\}$, where ϵ is the empty string, is prefix-free.*
3. *Let M be a universal prefix-free Turing machine. Let x and y be finite strings. The* prefix-free Kolmogorov complexity *of x given y with respect to M is denoted $\mathsf{K}_M(x|y)$ and defined as follows:*
$$\mathsf{K}_M(x|y) = \min(|P| \text{ such that } M(P, y) = x).$$

In the rest of the paper M is a fixed universal prefix-free Turing machine, and we will write K instead of K_M. When y is the empty string, we write $\mathsf{K}(x)$ instead of $\mathsf{K}(x|y)$.

We first state standard bounds on conditional Kolmogorov complexity, where the last one is from [17, Theorem 3.9.1, p. 232].

PROPOSITION 2.2. *There exists a constant $c \geq 0$ such that, for every finite string σ,*

$$\mathsf{K}(x|\sigma) \leq \mathsf{K}(x) + c, \tag{2.1}$$

$$\mathsf{K}(x) \leq \mathsf{K}(\sigma) + K(x|\sigma) + c, \tag{2.2}$$

$$|\mathsf{K}(x,y) - \mathsf{K}(x) - \mathsf{K}(y|x,\mathsf{K}(x))| \leq c. \tag{2.3}$$

We shall also use the following bound.

PROPOSITION 2.3. *There is a constant $c \geq 0$ such that, for any three strings x, y, z,*

$$\mathsf{K}(z|x) \geq \mathsf{K}(x,y) - \mathsf{K}(x) - \mathsf{K}(y|z,x) + \mathsf{K}(z|x,y,\mathsf{K}(x,y)) - c.$$

Proof. Using the third bound of Proposition 2.2, there is a constant $c_1 \geq 0$ such that

$$|\mathsf{K}(a,b) - \mathsf{K}(a) - \mathsf{K}(b|a,\mathsf{K}(a))| \leq c_1.$$

Substituting x, y for a and z for b:

$$\mathsf{K}(x,y) + \mathsf{K}(z|x,y,\mathsf{K}(x,y)) - c_1 \leq \mathsf{K}(x,y,z) \leq \mathsf{K}(x) + \mathsf{K}(z|x) + \mathsf{K}(y|z,x) + c_2,$$

which gives the result, where the second inequality follows from the first and third bounds of Proposition 2.2. □

The main motivation for using prefix-free Kolmogrov complexity is the bound known as Kraft's inequality together with the last two bounds of Proposition 2.2.

PROPOSITION 2.4 (Kraft's inequality). *Let T be any prefix-free set of finite strings. Then $\sum_{P \in T} 2^{-|P|} \leq 1$. In particular, for any set of finite strings S and any finite string σ, $\sum_{x \in S} 2^{-\mathsf{K}(x|\sigma)} \leq 1$.*

A *source* $\mathcal{S}$ of finite strings is a pair (S, p), where S is a set of finite strings and p is a probability distribution over S.

PROPOSITION 2.5 (Shannon's coding theorem). *Consider a source $\mathcal{S}$ of finite strings where x occurs with probability $p(x)$. Then for any code for $\mathcal{S}$ the average code length is bounded below by the entropy of the source; that is, if x is encoded by the code word $c(x)$ of length $|c(x)|$, $H(\mathcal{S}) = \sum_{x:p(x)\neq 0} p(x) \log(\frac{1}{p(x)}) \leq \sum_{x:p(x)\neq 0} p(x)|c(x)|$.*

LEMMA 2.6. *Let $\mathcal{S}$ be a source as above. Then for any fixed finite string σ there exists a string x such that $p(x) \neq 0$ and $\mathsf{K}(x|\sigma) \geq \log(\frac{1}{p(x)})$.*

Proof. By Shannon's coding theorem,

$$H(\mathcal{S}) = \sum_{x:p(x)\neq 0} p(x) \log\left(\frac{1}{p(x)}\right) \leq \sum_{x:p(x)\neq 0} p(x)\mathsf{K}(x|\sigma),$$

because $\mathsf{K}(x|\sigma)$ is the length of an encoding of x. Therefore there exists x such that $p(x) \neq 0$ and $\mathsf{K}(x) \geq \log(\frac{1}{p(x)})$. □

The Shannon–Fano code is a prefix-free code that encodes each word x with $p(x) \neq 0$, using $\lceil \log(\frac{1}{p(x)}) \rceil$ bits. We will write $\log(\frac{1}{p(x)})$ to simplify notation. The code can easily be computed given a description of the probability distribution. We formalize this in the following proposition, letting $\mathsf{K}(x|\mathcal{S})$ denote the prefix-free Kolmogorov complexity of x given a finite description of $\mathcal{S}$.

PROPOSITION 2.7 (Shannon–Fano code). *There exists a constant $c \geq 0$ such that, for every source $\mathcal{S}$ as above, for all x such that $p(x) \neq 0$, $\mathsf{K}(x|\mathcal{S}) \leq \log(\frac{1}{p(x)}) + c$.*

2.2. Query models. The quantum query model was implicitly introduced by Deutsch, Jozsa, Simon, Bernstein, Vazirani, and Grover [11, 10, 18, 8, 14] and explicitly by Beals et al. [7]. In this model, as in its classical counterpart, we pay for accessing the oracle, but unlike the classical case, the machine can use the power of quantum parallelism to make queries in superposition. Access to the input $x \in \Sigma^n$, where Σ is a finite set, is achieved by way of a query operator O_x. The *query complexity* of an algorithm is the number of calls to O_x.

The state of a computation is represented by a register R composed of three subregisters: the *query register* $i \in \{0, \ldots, n\}$, the *answer register* $z \in \Sigma$, and the *work register* w. We denote a register using the ket notation $|R\rangle = |i\rangle|z\rangle|w\rangle$, or simply $|i, z, w\rangle$. In the quantum (resp., randomized) setting, the state of the computation is a complex (resp., nonnegative real) combination of all possible values of the registers. Let $\mathcal{H}$ denote the corresponding finite-dimensional vector space. We denote the state of the computation by a vector $|\psi\rangle \in \mathcal{H}$ over the basis $(|i, z, w\rangle)_{i,z,w}$. Furthermore, the state vectors are unit length for the ℓ_2 norm in the quantum setting and for the ℓ_1 norm in the randomized setting.

A *T-query algorithm* A is specified by a $(T+1)$-tuple $(U_0, U_1, \ldots, U_T)$ of matrices. When A is quantum (resp., randomized), the matrices U_i are unitary (resp., stochastic). The computation takes place as follows. The *query operator* is the unitary (resp., stochastic) matrix O_x that satisfies $O_x|i, z, w\rangle = |i, z \oplus x_i, w\rangle$ for every i, z, w, where by convention $x_0 = 0$. Initially the state is set to some fixed value $|0, 0, 0\rangle$. Then the sequence of transformations $U_0, O_x, U_1, O_x, \ldots, U_{T-1}, O_x, U_T$ is applied.

We say that the algorithm A *ε-computes* a function $f : S \to S'$, for some sets $S \subseteq \Sigma^n$ and S', if the observation of the last bits of the work register equals $f(x)$ with probability at least $1 - \varepsilon$ for every $x \in S$. Then $\mathsf{QQC}(f)$ (resp., $\mathsf{RQC}(f)$) is the minimum query complexity of quantum (resp., randomized) query algorithms that ε_0-compute f, where $\varepsilon_0 = 1/3$.

3. Proof of the main theorem. This section is devoted to the proof of the main theorem. We prove Theorem 1.1 in two main steps. Lemma 3.1 shows how fast the computations diverge when they start on different individual inputs, in terms of the query probabilities. This lemma depends on the model of computation. Lemma 3.2 establishes the relationship between the Kolmogorov complexity of individual positions of the input and the probability that a given algorithm makes a query to this position. This lemma is independent of the model of computation. Theorem 1.1 follows immediately by combining these two lemmas.

In the following two lemmas, let A be an ε-bounded error algorithm for f that makes at most T queries to the input. When A is a randomized algorithm, let $p_t^x(i)$ be the probability that A queries x_i at query t on input x. By analogy, when A is a quantum algorithm, the probability $p_t^x(i)$ is interpreted as the probability of observing i if the query register were measured at query t, that is, the square of the norm of the part of the state that queries x_i. Let $\overline{p}^x(i) = \frac{1}{T}\sum_{t=1}^{T} p_t^x(i)$ be the average query probability over all of the time steps up to time T. We assume henceforth without loss of generality that $\overline{p}^x(i) > 0$. (For example, we start by uniformly querying all positions and reverse the process.)

LEMMA 3.1 (divergence lemma). *For every input $x, y \in S$ such that $f(x) \neq f(y)$ the following hold.*

1. *For quantum algorithms:*

$$2T \sum_{i : x_i \neq y_i} \sqrt{\overline{p}^x(i)\overline{p}^y(i)} \geq 1 - 2\sqrt{\varepsilon(1-\varepsilon)}.$$

2. *For randomized algorithms:*

$$2T \sum_{i:x_i \neq y_i} \min\left(\overline{p}^x(i), \overline{p}^y(i)\right) \geq 1 - 2\varepsilon.$$

We defer the proof of Lemma 3.1 to the end of this section.

The next lemma relates the query probabilities to the Kolmogorov complexity of the strings. In this lemma and the results that follow, we assume that a finite description of the algorithm is given. Using the knowledge of A, we may assume without loss of generality that the function f that it computes is also given, as is the length n of the inputs. With additional care, the additive constants in all of the proofs can be made very small by adding to the auxiliary information made available to the description algorithms those constant-size programs that are described within the proofs.

LEMMA 3.2 (query information lemma). *There exists an absolute constant $c \geq 0$ such that, for every input $x \in S$ and position $i \in \{1, \ldots n\}$,*

$$\mathsf{K}(i|x, A) \leq \log\left(\frac{1}{\overline{p}^x(i)}\right) + c.$$

Proof. Let $\mathcal{S}_x$ be the source where i occurs with probability $\overline{p}^x(i)$. By Proposition 2.7, $\mathsf{K}(i|\mathcal{S}_x) \leq \log(\frac{1}{\overline{p}^x(i)}) + c$ for some absolute constant c. To complete the proof, it suffices to show that $\mathsf{K}(\mathcal{S}_x|x, A) = O(1)$ and apply the second bound of Proposition 2.2. Use x and A to compute the probabilities $(\overline{p}^x(i))_{1 \leq i \leq n}$. The probabilities can be computed in a finite number of steps because the dimension is finite, and the number of queries is bounded by T. □

From these two lemmas we derive the main theorem.

Proof of Theorem 1.1. By Lemma 3.2, there is a constant $c \geq 0$ such that, for any algorithm that makes at most T queries and any x, y, i,

$$\overline{p}^x(i) \leq 2^{-\mathsf{K}(i|x,A)+c} \quad \text{and} \quad \overline{p}^y(i) \leq 2^{-\mathsf{K}(i|y,A)+c}.$$

This is true in particular for all those i where $x_i \neq y_i$. Combining this with Lemma 3.1 concludes the proof of the main theorem with $C = 2^{-c-1}$. □

We now give the proof of Lemma 3.1. The proof of the quantum case is very similar to the proofs found in many papers which give quantum lower bounds on query complexity. To our knowledge, the randomized case is new despite the simplicity of its proof. Whereas Aaronson [1] used a different approach to prove a version of Ambainis's method for randomized algorithms, our lemma allows us to use the same framework to establish lower bounds for both quantum and randomized query complexities.

Proof of Lemma 3.1. Let $|\psi_t^x\rangle$ be the state of the ε-bounded error algorithm A just before the tth oracle query, on input x. By convention, $|\psi_{T+1}^x\rangle$ is the final state. When A is a quantum algorithm, $|\psi_t^x\rangle$ is a unit vector for the ℓ_2 norm; otherwise, it is a probabilistic distribution, that is, a nonnegative and unit vector for the ℓ_1 norm. Observe that the ℓ_1 distance is the total variation distance.

First we prove the quantum case. The starting state of A does not depend on the input, and thus before the first question we have $|\psi_1^x\rangle = |\psi_1^y\rangle$, so $\langle\psi_1^x|\psi_1^y\rangle = 1$. At the end of the computation, if the algorithm is correct with probability ϵ, then $|\langle\psi_{T+1}^x|\psi_{T+1}^y\rangle| \leq 2\sqrt{\epsilon(1-\epsilon)}$ [2]. At each time step, we consider how much the two states can diverge in the following claim, which we will prove after the end of this proof.

Claim 1 (quantum divergence).

$$|\langle\psi_t^x|\psi_t^y\rangle - \langle\psi_{t+1}^x|\psi_{t+1}^y\rangle| \leq 2 \sum_{i:x_i\neq y_i} \sqrt{p_t^x(i)p_t^y(i)}.$$

Over T time steps, the two states diverge as follows. The proof uses only Claim 1 and the Cauchy–Schwartz inequality.

$$\begin{aligned}
1 - 2\sqrt{\varepsilon(1-\varepsilon)} &\leq |\langle\psi_1^x|\psi_1^y\rangle - \langle\psi_{T+1}^x|\psi_{T+1}^y\rangle| \\
&\leq \sum_{t=1}^{T} |\langle\psi_t^x|\psi_t^y\rangle - \langle\psi_{t+1}^x|\psi_{t+1}^y\rangle| \\
&\leq \sum_{t=1}^{T} 2 \sum_{i:x_i\neq y_i} \sqrt{p_t^x(i)p_t^y(i)} \\
&\leq 2 \sum_{i:x_i\neq y_i} \sqrt{\sum_{t=0}^{T-1} p_t^x(i) \sum_{t=0}^{T-1} p_t^y(i)} \\
&= 2T \sum_{i:x_i\neq y_i} \sqrt{\overline{p}^x(i)\overline{p}^y(i)}.
\end{aligned}$$

Now we prove the randomized case. We use the ket notation for real-valued normalized vectors, for consistency in notation. Again, initially $|\psi_1^x\rangle = |\psi_1^y\rangle$. At the end of the computation, if the algorithm is correct with probability ϵ, then $\| \, |\psi_{T+1}^x\rangle - |\psi_{T+1}^y\rangle \, \|_1 \geq 1 - 2\epsilon$. At each time step, the distribution states now diverge according to the following claim, which we will prove after the end of this proof.

Claim 2 (randomized divergence).

$$\begin{aligned}
&\| \, |\psi_{t+1}^x\rangle - |\psi_{t+1}^y\rangle \, \|_1 \\
&\leq \| \, |\psi_t^x\rangle - |\psi_t^y\rangle \, \|_1 + 2 \sum_{i:x_i\neq y_i} \min\left(p_t^x(i), p_t^y(i)\right).
\end{aligned}$$

We now conclude the proof.

$$\begin{aligned}
1 - 2\varepsilon &\leq \sum_{t=1}^{T} \| \, |\psi_{t+1}^x\rangle - |\psi_{t+1}^y\rangle \, \|_1 - \| \, |\psi_t^x\rangle - |\psi_t^y\rangle \, \|_1 \\
&\leq \sum_{t=1}^{T} 2 \sum_{i:x_i\neq y_i} \min\left(p_t^x(i), p_t^y(i)\right) \\
&\leq 2T \sum_{i:x_i\neq y_i} \min\left(\overline{p}^x(i), \overline{p}^y(i)\right). \qquad \square
\end{aligned}$$

Proof of Claim 1. Let

$$\begin{aligned}
|\psi_t^x\rangle &= \sum_{i,z,w} \alpha_{i,z,w}|i,z,w\rangle, \text{ and} \\
|\psi_t^y\rangle &= \sum_{i,z,w} \beta_{i,z,w}|i,z,w\rangle.
\end{aligned}$$

After the tth query is made, the states $|\psi_t'^x\rangle = O_x|\psi_t^x\rangle$ and $|\psi_t'^y\rangle = O_y|\psi_t^y\rangle$ are

$$|\psi_t'^x\rangle = \sum_{i,z,w} \alpha_{i,z,w}|i, z \oplus x_i, w\rangle, \text{ and}$$
$$|\psi_t'^y\rangle = \sum_{i,z,w} \beta_{i,z,w}|i, z \oplus y_i, w\rangle.$$

Now, since the inner product is invariant under unitary transformations, we get

$$\langle\psi_{t+1}^x|\psi_{t+1}^y\rangle = \langle\psi_t'^x|\psi_t'^y\rangle,$$

and therefore

$$\begin{aligned}
&|\langle\psi_t^x|\psi_t^y\rangle - \langle\psi_{t+1}^x|\psi_{t+1}^y\rangle| \\
&= \left|\sum_{i,z,w} \overline{\alpha_{i,z,w}}\beta_{i,z,w} - \sum_{i,z,w} \overline{\alpha_{i,z\oplus x_i,w}}\beta_{i,z\oplus y_i,w}\right| \\
&= \left|\sum_{\substack{i,z,w \\ x_i \neq y_i}} \overline{\alpha_{i,z,w}}\beta_{i,z,w} - \overline{\alpha_{i,z\oplus x_i,w}}\beta_{i,z\oplus y_i,w}\right| \\
&\leq \sum_{i:x_i\neq y_i} \left(\left|\sum_{z,w} \overline{\alpha_{i,z,w}}\beta_{i,z,w}\right| + \left|\sum_{z,w} \overline{\alpha_{i,z\oplus x_i,w}}\beta_{i,z\oplus y_i,w}\right|\right) \\
&\leq 2 \sum_{i:x_i\neq y_i} \sqrt{\left(\sum_{z,w}|\alpha_{i,z,w}|^2\right)\left(\sum_{z,w}|\beta_{i,z,w}|^2\right)} \\
&\leq 2 \sum_{i:x_i\neq y_i} \sqrt{p_t^x(i)p_t^y(i)}. \qquad \square
\end{aligned}$$

Proof of Claim 2. Let us write the distributions using the same formalism as above, that is,

$$|\psi_t^x\rangle = \sum_{i,z,w} \alpha_{i,z,w}|i, z, w\rangle, \text{ and}$$
$$|\psi_t^y\rangle = \sum_{i,z,w} \beta_{i,z,w}|i, z, w\rangle.$$

Note that now the vectors are unit for the ℓ_1 norm. After the tth query is made, the states $|\psi_t'^x\rangle = O_x|\psi_t^x\rangle$ and $|\psi_t'^y\rangle = O_y|\psi_t^y\rangle$ are

$$|\psi_t'^x\rangle = \sum_{i,z,w} \alpha_{i,z,w}|i, z \oplus x_i, w\rangle, \text{ and}$$
$$|\psi_t'^y\rangle = \sum_{i,z,w} \beta_{i,z,w}|i, z \oplus y_i, w\rangle.$$

Now, since the ℓ_1 distance does not increase under stochastic matrices, we get

$$\| \, |\psi_{t+1}^x\rangle - |\psi_{t+1}^y\rangle \, \|_1 \leq \| \, |\psi_t'^x\rangle - |\psi_t'^y\rangle \, \|_1,$$

and therefore

$$\begin{aligned}
&\| \, |\psi_{t+1}^x\rangle - |\psi_{t+1}^y\rangle \, \|_1 \\
&= \left\| \sum_{i,z,w} (\alpha_{i,z,w}|i, z \oplus x_i, w\rangle - \beta_{i,z,w}|i, z \oplus y_i, w\rangle) \right\|_1 \\
&= \sum_i \left\| \sum_{z,w} (\alpha_{i,z,w}|i, z \oplus x_i, w\rangle - \beta_{i,z,w}|i, z \oplus y_i, w\rangle) \right\|_1 .
\end{aligned}$$

We now bound each term of the last sum separately. Fix any i. If $x_i = y_i$, then

$$\left\| \sum_{z,w} (\alpha_{i,z,w}|i, z \oplus x_i, w\rangle - \beta_{i,z,w}|i, z \oplus y_i, w\rangle) \right\|_1 = \sum_{z,w} |\alpha_{i,z,w} - \beta_{i,z,w}|.$$

If $x_i \neq y_i$, then

$$\begin{aligned}
&\left\| \sum_{z,w} (\alpha_{i,z,w}|i, z \oplus x_i, w\rangle - \beta_{i,z,w}|i, z \oplus y_i, w\rangle) \right\|_1 \\
&\leq \left\| \sum_{z,w} (\alpha_{i,z,w}|i, z \oplus y_i, w\rangle - \beta_{i,z,w}|i, z \oplus y_i, w\rangle) \right\|_1 \\
&\quad + \left\| \sum_{z,w} (\alpha_{i,z,w}|i, z \oplus x_i, w\rangle - \alpha_{i,z,w}|i, z \oplus y_i, w\rangle) \right\|_1 \\
&\leq \sum_{z,w} |\alpha_{i,z,w} - \beta_{i,z,w}| + 2 \sum_{z,w} |\alpha_{i,z,w}| \\
&= \sum_{z,w} |\alpha_{i,z,w} - \beta_{i,z,w}| + 2p_t^x(i).
\end{aligned}$$

In the same way we can prove that

$$\begin{aligned}
&\left\| \sum_{z,w} (\alpha_{i,z,w}|i, z \oplus x_i, w\rangle - \beta_{i,z,w}|i, z \oplus y_i, w\rangle) \right\|_1 \\
&\leq \sum_{z,w} |\alpha_{i,z,w} - \beta_{i,z,w}| + 2p_t^y(i).
\end{aligned}$$

We group together these upper bounds and conclude that

$$\begin{aligned}
&\| \, |\psi_{t+1}^x\rangle - |\psi_{t+1}^y\rangle \, \|_1 \\
&\leq \sum_{i,z,w} |\alpha_{i,z,w} - \beta_{i,z,w}| + 2 \sum_{i : x_i \neq y_i} \min \left(p_t^x(i), p_t^y(i) \right) \\
&= \| \, |\psi_t^x\rangle - |\psi_t^y\rangle \, \|_1 + 2 \sum_{i : x_i \neq y_i} \min \left(p_t^x(i), p_t^y(i) \right) . \qquad \square
\end{aligned}$$

4. Comparison with previous adversary methods. In this section, we reprove, as a corollary of Theorem 1.1, the previously known adversary lower bounds. Our framework also allows us to obtain somewhat stronger statements for free.

To obtain the previously known adversary methods as a corollary of Theorem 1.1, we must give a lower bound on terms $\mathsf{K}(i|x,A)$ and $\mathsf{K}(i|y,A)$. To this end, we apply Proposition 2.3 and give a lower bound on $\mathsf{K}(x,y)$ and upper bounds on $\mathsf{K}(x|i,y)$ and $\mathsf{K}(y|i,x)$. The lower bound on $\mathsf{K}(x,y)$ is obtained by applying Lemma 2.6, a consequence of Shannon's coding theorem, for an appropriate distribution. The upper bounds on $\mathsf{K}(x|i,y)$ and $\mathsf{K}(y|i,x)$ are obtained using the Shannon–Fano code for appropriate distributions.

The following lemma is the general formulation of the sketch above.

LEMMA 4.1. *There exists a constant $C>0$ such that the following holds. Let Σ be a finite set, let $n\ge 1$ be an integer, and let $S\subseteq\Sigma^n$. Let q be a probability distribution on S^2, let p be a probability distribution on S, and let $\{p'_{x,i} : x\in S, 1\le i\le n\}$ be a family of probability distributions on S. Assume that whenever $q(x,y)\neq 0$, then $p(x)$, $p(y)$, $p'_{y,i}(x)$, and $p'_{x,i}(y)$ are nonzero for every i such that $x_i\neq y_i$. Then for every finite string σ there exist $x,y\in S$, with $q(x,y)\neq 0$, such that*

$$\frac{1}{\sum_{i:x_i\neq y_i}\sqrt{2^{-\mathsf{K}(i|x,\sigma)-\mathsf{K}(i|y,\sigma)}}} \ge C\times\min_{i:x_i\neq y_i}\left(\frac{\sqrt{p(x)p'_{x,i}(y)\ p(y)p'_{y,i}(x)}}{q(x,y)}\right),$$

and (for the same $x,y\in S$)

$$\frac{1}{\sum_{i:x_i\neq y_i}\min\left(2^{-\mathsf{K}(i|x,\sigma)},2^{-\mathsf{K}(i|y,\sigma)}\right)} \ge C\times\min_{i:x_i\neq y_i}\left(\max\left(\frac{p(x)p'_{x,i}(y)}{q(x,y)},\frac{p(y)p'_{y,i}(x)}{q(x,y)}\right)\right).$$

Proof. In this proof, $c_1,\dots,c_5$ are some appropriate nonnegative constants. By Lemma 2.6, there exists a pair (x,y) such that $q(x,y)\neq 0$ and

$$\mathsf{K}(x,y|\sigma,p,p')\ge\log\left(\frac{1}{q(x,y)}\right),$$

where p' stands for a complete description of all of the $p'_{x,i}$.

Fix x and y so that this holds. By using the Shannon–Fano code (Proposition 2.5),

$$\mathsf{K}(x|p)\le\log\left(\frac{1}{p(x)}\right)+c_1$$

and

$$\mathsf{K}(y|x,i,p'_{x,i})\le\log\left(\frac{1}{p'_{x,i}(y)}\right)+c_1$$

for any i such that $x_i \neq y_i$. By Proposition 2.3,

$$\begin{aligned}
&\mathsf{K}(i|x,\sigma)\\
&\geq \mathsf{K}(i|x,\sigma,p,p') - c_3\\
&\geq \mathsf{K}(x,y|\sigma,p,p') - \mathsf{K}(x|p) - \mathsf{K}(y|i,x,p'_{x,i})\\
&\quad + \mathsf{K}(i|x,y,\mathsf{K}(x,y),\sigma,p,p') - c_4\\
&\geq \log\left(\frac{1}{q(x,y)}\right) - \log\left(\frac{1}{p(x)}\right) - \log\left(\frac{1}{p'_{x,i}(y)}\right)\\
&\quad + \mathsf{K}(i|x,y,\mathsf{K}(x,y),\sigma,p,p') - c_5\\
&= \log\left(\frac{p(x)p'_{x,i}(y)}{q(x,y)}\right) + \mathsf{K}(i|x,y,\mathsf{K}(x,y),\sigma,p,p') - c_5.
\end{aligned}$$

Similarly,

$$\begin{aligned}
\mathsf{K}(i|y,\sigma) \geq \log&\left(\frac{p(y)p'_{y,i}(x)}{q(x,y)}\right)\\
&+ \mathsf{K}(i|x,y,\mathsf{K}(x,y),\sigma,p,p') - c_5.
\end{aligned}$$

To conclude, consider the sum

$$\begin{aligned}
&\frac{1}{\sum_{i:x_i\neq y_i}\sqrt{2^{-\mathsf{K}(i|x,\sigma)-\mathsf{K}(i|y,\sigma)}}}\\
&\geq \frac{1}{\sum_{i:x_i\neq y_i}\sqrt{2^{-\log\left(\frac{p(x)p'_{x,i}(y)}{q(x,y)}\right)-\log\left(\frac{p(y)p'_{y,i}(x)}{q(x,y)}\right)-2\mathsf{K}(i|x,y,\mathsf{K}(x,y),\sigma,p,p')+2c_5}}}\\
&\geq \frac{1}{\sum_{i:x_i\neq y_i} 2^{c_5}\sqrt{\frac{q(x,y)}{p(x)p'_{x,i}(y)}\frac{q(x,y)}{p(y)p'_{y,i}(x)}}2^{-\mathsf{K}(i|x,y,\mathsf{K}(x,y),\sigma,p,p')}}\\
&\geq 2^{-c_5}\min_{i:x_i\neq y_i}\left(\frac{\sqrt{p(x)p'_{x,i}(y)p(y)p'_{y,i}(x)}}{q(x,y)}\right)\frac{1}{\sum_{i:x_i\neq y_i}2^{-\mathsf{K}(i|x,y,\mathsf{K}(x,y),\sigma,p,p')}}.
\end{aligned}$$

We apply Kraft's inequality (Proposition 2.4) to show that $\sum_{i:x_i\neq y_i} 2^{-\mathsf{K}(i|x,y,\mathsf{K}(x,y),\sigma,p,p')} \leq 1$. This concludes the proof of the first part of the lemma using Kraft's inequality and letting $C = 2^{-c_5}$. The second part is similar. □

4.1. Ambainis's weighted scheme.

THEOREM 4.2 (Ambainis's weighted method). *Let Σ be a finite set, let $n \geq 1$ be an integer, and let $S \subseteq \Sigma^n$ and S' be sets. Let $f : S \to S'$. Consider a weight scheme as follows:*

- *Every pair $(x,y) \in S^2$ is assigned a nonnegative weight $w(x,y)$ such that $w(x,y) = 0$ whenever $f(x) = f(y)$.*
- *Every triple (x,y,i) is assigned a nonnegative weight $w'(x,y,i)$ such that $w'(x,y,i) = 0$ whenever $x_i = y_i$ or $f(x) = f(y)$.*

For all x, i, let

$$wt(x) = \sum_y w(x,y) \quad \textit{and}$$
$$v(x,i) = \sum_y w'(x,y,i).$$

If $w'(x,y,i)w'(y,x,i) \geq w^2(x,y)$ *for all* x,y,i *such that* $x_i \neq y_i$*, then*

$$\mathsf{QQC}(f) = \Omega\left(\min_{\substack{x,y,i \\ w(x,y)\neq 0, x_i \neq y_i}} \left(\sqrt{\frac{wt(x)wt(y)}{v(x,i)v(y,i)}}\right)\right).$$

Furthermore, if $w'(x,y,i), w'(y,x,i) \geq w(x,y)$ *for all* x,y,i *such that* $x_i \neq y_i$*, then*

$$\mathsf{RQC}(f) = \Omega\left(\min_{\substack{x,y,i \\ w(x,y)\neq 0, x_i \neq y_i}} \left(\max\left(\frac{wt(x)}{v(x,i)}, \frac{wt(y)}{v(y,i)}\right)\right)\right).$$

The relation in Ambainis's original statement is implicit in this formulation, since it corresponds to the nonzero-weight pairs. A weaker version of the randomized case was proven independently by Aaronson [1] using a completely different approach. We show that Theorem 4.2 follows from Theorem 1.1.

Proof. We derive probability distributions q, p, p' from the weight schemes as follows. Let $W = \sum_{x,y} w(x,y)$. Define

$$\begin{aligned} q(x,y) &= \frac{w(x,y)}{W}, \\ p(x) &= \frac{wt(x)}{W}, \\ p'_{x,i}(y) &= \frac{w'(x,y,i)}{v(x,i)} \quad \text{for any } x,y,i. \end{aligned}$$

It is easy to check that, by construction and hypothesis, these distributions satisfy the conditions of Lemma 4.1. We may now rearrange and simplify the terms as follows:

$$\begin{aligned} \frac{\sqrt{p(x)p'_{x,i}(y)\ p(y)p'_{y,i}(x)}}{q(x,y)} &= \frac{\sqrt{\frac{wt(x)}{W}\frac{w'(x,y,i)}{v(x,i)}\ \frac{wt(y)}{W}\frac{w'(y,x,i)}{v(y,i)}}}{\frac{w(x,y)}{W}} \\ &= \frac{\sqrt{\frac{wt(x)}{v(x,i)}\ \frac{wt(y)}{v(y,i)}w'(x,y,i)w'(y,x,i)}}{w(x,y)} \\ &\geq \sqrt{\frac{wt(x)}{v(x,i)}\ \frac{wt(y)}{v(y,i)}}. \end{aligned}$$

The final line follows from the hypothesis $w'(x,y,i)w'(y,x,i) \geq w^2(x,y)$. The second part of the theorem is obtained by similar rearrangement and simplification. ∎

We conclude this section by sketching the proof of the unweighted version of Ambainis's adversary method, as it affords a simpler combinatorial proof that does not require Lemma 4.1. To simplify notation we omit additive constants and the usual auxiliary strings including A.

Let $R \subseteq S \times S$ be a relation on pairs of instances, where $(x,y) \in R \Longrightarrow f(x) \neq f(y)$, and let R_i be the restriction of R to pairs x,y for which $x_i \neq y_i$. Viewing the relation R as a bipartite graph, let l, l', m, m' be as follows:

- m is a lower bound on the degree of all $x \in X$,
- m' is a lower bound on the degree of all $y \in Y$,
- for any fixed x and $i, 1 \leq i \leq n$, the number of y adjacent to x for which $x_i \neq y_i$ is at most l,

- for any fixed y and $i, 1 \leq i \leq n$, the number of x adjacent to y for which $x_i \neq y_i$ is at most l'.

We make the following observations:

1. $|R| \geq \max\{m|X|, m'|Y|\}$, so $\exists x, y \in R$ such that $\mathsf{K}(x,y) \geq \max(\log(m|X|), \log(m'|Y|))$.
2. For all $x \in X, \mathsf{K}(x) \leq \log(|X|)$, and $\mathsf{K}(y) \leq \log(|Y|)$ for all $y \in Y$.
3. For all x, y, i with $(x,y) \in R_i, \mathsf{K}(y|i,x) \leq \log(l)$ and similarly $\mathsf{K}(x|i,y) \leq \log(l')$.

For any i with $x_i \neq y_i$, by Proposition 2.3,

$$\begin{aligned}\mathsf{K}(i|x) &\geq \mathsf{K}(x,y) - \mathsf{K}(x) - \mathsf{K}(y|i,x) \\ &\quad + \mathsf{K}(i|x,y,\mathsf{K}(x,y)) \\ &\geq \log(m|X|) - \log(|X|) - \log(l) \\ &\quad + \mathsf{K}(i|x,y,\mathsf{K}(x,y)) \\ &= \log\left(\frac{m}{l}\right) + \mathsf{K}(i|x,y,\mathsf{K}(x,y)).\end{aligned}$$

The same proof works to show that $\mathsf{K}(i|y) \geq \log(\frac{m'}{l'}) + \mathsf{K}(i|x,y,\mathsf{K}(x,y))$. By Theorem 1.1 and Kraft's inequality,

$$\mathsf{QQC}(f) = \Omega\left(\sqrt{\frac{mm'}{ll'}}\right).$$

4.2. Spectral lower bound. We now show how to prove the spectral lower bound of Barnum, Saks, and Szegedy [5] as a corollary of Theorem 1.1. Recall that for any matrix Γ, $\lambda(\Gamma)$ is the largest eigenvalue of Γ.

THEOREM 4.3 (Barnum–Saks–Szegedy spectral method). *Let Σ be a finite set, let $n \geq 1$ be an integer, and let $S \subseteq \Sigma^n$ and S' be sets. Let $f : S \to S'$. Let Γ be an arbitrary $S \times S$ nonnegative real symmetric matrix that satisfies $\Gamma(x,y) = 0$ whenever $f(x) = f(y)$. For $i = 1, \ldots, n$ let Γ_i be the matrix:*

$$\Gamma_i(x,y) = \begin{cases} 0 & \text{if } x_i = y_i, \\ \Gamma(x,y) & \text{otherwise.} \end{cases}$$

Then

$$\mathsf{QQC}(f) = \Omega\left(\frac{\lambda(\Gamma)}{\max_i \lambda(\Gamma_i)}\right).$$

Proof. Since Γ and Γ_i are nonnegative real symmetric matrices, they have an eigenvector with only nonnegative real entries for their respective largest eigenvalues. Let $|\alpha\rangle$ (resp., $|\alpha_i\rangle$) be this unit eigenvector of Γ (resp., Γ_i). We define the probability distributions q, p, p' as follows:

$$\begin{aligned} q(x,y) &= \frac{\Gamma(x,y)\langle x|\alpha\rangle\langle y|\alpha\rangle}{\langle\alpha|\Gamma|\alpha\rangle}, \\ p(x) &= \langle x|\alpha\rangle^2, \\ p'_{x,i}(y) &= \frac{\Gamma_i(x,y)\langle y|\alpha_i\rangle}{\langle x|\Gamma_i|\alpha_i\rangle}, \quad \text{for any } x, y, i. \end{aligned}$$

First we check that these are probability distributions. Distribution p also has weight 1 because $|\alpha\rangle$ is a unit vector. Since $|\alpha\rangle$ and $|y\rangle$ have real entries, $\langle y|\alpha\rangle = \langle\alpha|y\rangle$.

Then the distribution q has weight $\frac{1}{\langle\alpha|\Gamma|\alpha\rangle}\sum_{x,y}\langle\alpha|y\rangle\Gamma(x,y)\langle x|\alpha\rangle$, which is 1 since $\sum_x \Gamma(x,y)\langle x|\alpha\rangle = \langle y|\Gamma|\alpha\rangle$. Using the same argument, $p'_{x,i}$ also has weight 1.

Now, fix any x, y, i such that $x_i \neq y_i$ and $q(x,y) \neq 0$. Note that $\langle\alpha|\Gamma|\alpha\rangle = \lambda(\Gamma)$, $\Gamma_i|\alpha_i\rangle = \lambda(\Gamma_i)|\alpha_i\rangle$, and $\Gamma(x,y) = \Gamma_i(x,y)$. Then the fractions $\frac{p(x)p'_{x,i}(y)}{q(x,y)}$ and $\frac{p(y)p'_{y,i}(x)}{q(x,y)}$ are, respectively, $\frac{\lambda(\Gamma)}{\lambda(\Gamma_i)}\frac{\langle y|\alpha_i\rangle}{\langle x|\alpha_i\rangle}\frac{\langle x|\alpha\rangle}{\langle y|\alpha\rangle}$ and $\frac{\lambda(\Gamma)}{\lambda(\Gamma_i)}\frac{\langle x|\alpha_i\rangle}{\langle y|\alpha_i\rangle}\frac{\langle y|\alpha\rangle}{\langle x|\alpha\rangle}$. Taking the square root of their product gives the result using Lemma 4.1. □

5. Certificate complexity and adversary techniques. Let f be a Boolean function. For any positive instance $x \in \Sigma^n$ of f ($f(x)$=1), a *positive certificate* for $f(x)$ is the smallest subset of indices $I \subseteq [n]$ of x such that, for any y with $x_i = y_i$ for all $i \in I$, $f(y)$=1.

The 1-*certificate complexity* of f, denoted $C_1(f)$, is the size of the largest positive certificate for $f(x)$, over all positive instances x. The 0-*certificate complexity* is defined similarly for negative instances x of f ($f(x) = 0$).

Prior to our work, it was known that the best possible bound that could be proven using the unweighted adversary technique for total functions [2, Theorem 5.1] is $O(\sqrt{C_0(f)C_1(f)})$. Independently, Szegedy [20] showed that the best possible lower bound using the spectral method is $O(\min(\sqrt{nC_0(f)}, \sqrt{nC_1(f)}))$ for arbitrary functions, and Zhang [22] proved the same for Ambainis's weighted method.

The following lemma, due to Troy Lee, results in a very simple proof of the fact that our method and, hence, all of the known variants of the adversary method have lower bounds larger than $\min(\sqrt{nC_0(f)}, \sqrt{nC_1(f)})$ for arbitrary functions.

LEMMA 5.1. *There exists a constant $c \geq 0$ such that the following holds. Let Σ be a finite set, let $n \geq 1$ be an integer, and let $S \subseteq \Sigma^n$ be a set. Let $f : S \to \{0,1\}$. For every $x, y \in S$ with $f(x) = 0$ and $f(y) = 1$, there is an i_0 with $x_{i_0} \neq y_{i_0}$ for which $\mathsf{K}(i_0|x,f) \leq \log(C_0(f)) + c$, and similarly there is an i_1 with $x_{i_1} \neq y_{i_1}$ such that $\mathsf{K}(i_1|y,f) \leq \log(C_1(f)) + c$.*

Proof. Among the negative certificates for $f(x)$, let I be the lexicographically smallest one. By definition of the 0-certificate complexity, the size of I is at most $C_0(f)$. Since $f(x) \neq f(y)$, x and y must differ on some $i_0 \in I$. To describe i_0 given x, it suffices to give an index into I, which requires at most $\log(C_0(f)) + c$ bits. The same can also be done for y and $C_1(f)$. □

THEOREM 5.2. *Let Σ be a finite set, let $n \geq 1$ be an integer, and let $S \subseteq \Sigma^n$ be a set. Let $f : S \to \{0,1\}$. Then any quantum query lower bound for f given by Theorem* 1.1 *is in $O(\min(\sqrt{nC_0(f)}, \sqrt{nC_1(f)}))$.*

Proof. Let A be a quantum algorithm that computes f with bounded error by making at most T queries to the input and $x, y \in S$ such that $f(x) = 0$ and $f(y) = 1$. Then a description of f can be obtained from a description of A, so $\mathsf{K}(i|x,A) \leq \mathsf{K}(i|x,f) + O(1)$. By Lemma 5.1, there exists i_0 such that $x_{i_0} \neq y_{i_0}$, and $\mathsf{K}(i_0|x,f) \leq \log(C_0(f)) + O(1)$. For any $i, 1 \leq i \leq n$, $\mathsf{K}(i|y,A) \leq \log(n) + O(1)$. Therefore $K(i_0|x,A) + K(i_0|y,A) \leq \log(nC_0(f)) + O(1)$.

The lower bound given by Theorem 1.1 is $O\big(\frac{1}{\sum_{i:x_i\neq y_i}\sqrt{2^{-\mathsf{K}(i|x,A)-\mathsf{K}(i|y,A)}}}\big)$. Since $\sum_{i:x_i\neq y_i}\sqrt{2^{-\mathsf{K}(i|x,A)-\mathsf{K}(i|y,A)}} \geq \sqrt{2^{-\mathsf{K}(i_0|x,A)-\mathsf{K}(i_0|y,A)}}$, the bound is $O(\sqrt{nC_0(f)})$ Similarly, it can be shown that the bound is $O(\sqrt{nC_1(f)})$. □

In recent work, Špalek and Szegedy showed that, for total functions, the best lower bound one can achieve with any of the adversary methods is $\sqrt{C_0(f)C_1(f)}$ for any total function [19].

5.1. Applications to graph properties. Theorem 1.1 provides a simple and intuitive method to prove lower bounds for specific problems. We illustrate this by giving lower bounds for two graph properties: connectivity and bipartiteness. These are direct applications of Theorem 1.1 in that we analyze directly the complexity $\mathsf{K}(i|x, A)$ without defining relations or weights or distributions: We need only to consider a "typical" hard pair of instances. In this section, we omit additive and multiplicative constants that result from using small, constant-size programs, as well as the constant length auxiliary string A to simplify the proofs.

We consider graphs over n vertices $\{0, 1, \ldots, n-1\}$, where the graph is represented as an adjacency matrix.

5.1.1. Graph connectivity.

THEOREM 5.3 (see [12]). $\mathsf{QQC}(\textsc{GraphConnectivity}) = \Omega(n^{3/2})$.

Proof. We construct one negative and one positive instance of graph connectivity, using the incompressibility method, using the ideas of [12]. Let S be an incompressible string of length $\log(n-1)! + \log\binom{n}{2}$, chopped into two pieces S_1 and S_2 of length $\log(n-1)!$ and $\log\binom{n}{2}$, respectively. We think of S_1 as representing a Hamilton cycle $C = (\pi(0), \pi(1) \ldots \pi(n-1), \pi(0))$ through the n vertices, where π is a permutation over $\{0, 1, \ldots, n-1\}$ such that $\pi(0) = 0$. Let G contain the cycle C, so that $\mathsf{K}(G) = \mathsf{K}(\pi)$. We also think of S_2 as representing a pair of distinct vertices s, t. Let H be obtained from G by breaking the cycle into two cycles at s and t, that is, $H = G \setminus \{(\pi(s), \pi(s+1)), (\pi(t), \pi(t+1))\} \cup \{(\pi(s), \pi(t+1)), (\pi(s+1), \pi(t))\}$, where addition is modulo n.

We show that, for the four edges e where G and H differ, $\mathsf{K}(e|G) + \mathsf{K}(e|H) \geq 3\log n - 4$. Let e_-, e'_- be the edges removed from G and e_+, e'_+ be the edges added to G. Observe that, up to an additive constant, $\mathsf{K}(e_+|G) = \mathsf{K}(e'_+|G)$ and $\mathsf{K}(e_-|H) = \mathsf{K}(e'_-|H)$.

Assume without loss of generality that $e_- = (\pi(s), \pi(s+1))$ and that the smallest cycle of H contains $\pi(s)$. Let l be the length of this cycle. Observe that $\mathsf{K}(s|G) = \mathsf{K}(e_-|G)$ and $\mathsf{K}(e_-|H) = \mathsf{K}(\pi, s, t|H)$.

$$\begin{aligned}
\log(n-1)! + \log\binom{n}{2} &\leq \mathsf{K}(S) \\
&\leq \mathsf{K}(G) + \mathsf{K}(s|G) + \mathsf{K}(t|G) \\
&\leq \mathsf{K}(G) + \mathsf{K}(e_-|G) + \log n, \\
\mathsf{K}(e_-|G) &\geq \log\binom{n}{2} - \log n = \log\frac{n-1}{2}.
\end{aligned}$$

Furthermore,

$$\begin{aligned}
\mathsf{K}(H) &\leq \mathsf{K}(l) + \log\frac{(n-1)!}{(n-l)!} + \log(n-l-1)! \\
&\leq \log\left(\frac{n}{2}\right) + \log(n-1)! - \log(n-l) \\
&\leq \log(n-1)!\,.
\end{aligned}$$

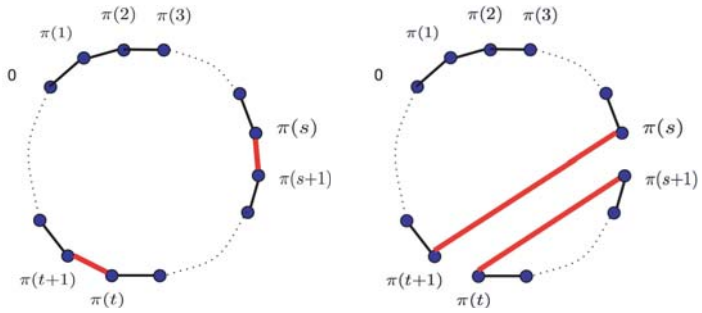

FIG. 5.1. *Graphs G, H for the graph lower bounds.*

Therefore,

$$\begin{aligned}\log(n-1)! + \log\binom{n}{2} &\le \mathsf{K}(S)\\ &\le \mathsf{K}(H) + \mathsf{K}(\pi, s, t|H)\\ &\le \mathsf{K}(H) + \mathsf{K}(e_-|H)\\ &\le \log(n-1)! + \mathsf{K}(e_-|H),\\ \mathsf{K}(e_-|H) &\ge \log\binom{n}{2}.\end{aligned}$$

For the added edges, e_+, e'_+, consider without loss of generality $e_+ = (\pi(s), \pi(t+1))$. Since S is incompressible, $\mathsf{K}(e_+|G) = \mathsf{K}(s,t|G) \ge \log\binom{n}{2}$. Furthermore, $\mathsf{K}(S) \le \mathsf{K}(H) + \mathsf{K}(e_+|H) + \mathsf{K}(e'_+|H)$ and $\mathsf{K}(e'_+|H) \le \log n$, so $\mathsf{K}(e_+|H) \ge \log\binom{n}{2} - \log n = \log\frac{n-1}{2}$. The same proof shows that $\mathsf{K}(e'_+|H) \ge \log\frac{n-1}{2}$. ∎

5.1.2. Bipartiteness. The following lower bound was proven by Dürr and independently in [22].

THEOREM 5.4. $\mathsf{QQC}(\text{BIPARTITENESS}) = \Omega(n^{3/2})$.

Proof. The proof is similar to the one of Theorem 5.3 except that we construct G to be an even cycle on $n = 2m$ vertices and H will be composed of two odd cycles on the same vertex set (see Figure 5.1).

Let S be an incompressible string of length $\log(n-1)! + \log(\binom{n}{2} - 1)$, chopped into two pieces S_1 and S_2 of length $\log(n-1)!$ and $\log(\binom{n}{2} - 1)$, respectively. We think of S_1 as representing a Hamilton cycle $C = (\pi(0) = 0, \pi(1) \dots \pi(n-1), \pi(0))$ through the n vertices and S_2 as representing a pair of distinct vertices s, t, with $s \not\equiv t \pmod 2$. Let G contain the cycle C, and let H be obtained from G by breaking the cycle into two odd cycles at s and t, that is, $H = G \setminus \{(\pi(s), \pi(s+1)), (\pi(t), \pi(t+1))\} \cup \{(\pi(s), \pi(t+1)), (\pi(s+1), \pi(t))\}$.

The same analysis as Theorem 5.3 yields the lower bound $\mathsf{QQC}(\text{BIPARTITENESS}) = \Omega(n^{3/2})$, as claimed. ∎

Acknowledgments. We thank Troy Lee, Christoph Dürr for many useful discussions, and Andris Ambainis for his helpful answers to our questions.

MINIMIZING DISJUNCTIVE NORMAL FORM FORMULAS AND AC^0 CIRCUITS GIVEN A TRUTH TABLE*

ERIC ALLENDER†, LISA HELLERSTEIN‡, PAUL MCCABE§, TONIANN PITASSI§, AND MICHAEL SAKS¶

Abstract. For circuit classes R, the fundamental computational problem *Min-R* asks for the minimum R-size of a Boolean function presented as a truth table. Prominent examples of this problem include *Min-DNF*, which asks whether a given Boolean function presented as a truth table has a k-term disjunctive normal form (DNF), and *Min-Circuit* (also called the minimum circuit size problem (MCSP)), which asks whether a Boolean function presented as a truth table has a size k Boolean circuit. We present a new reduction proving that *Min-DNF* is NP-complete. It is significantly simpler than the known reduction of Masek [*Some NP-Complete Set Covering Problems*, manuscript, 1979], which is from *Circuit-SAT*. We then give a more complex reduction, yielding the result that *Min-DNF* cannot be approximated to within a factor smaller than $(\log N)^\gamma$, for some constant $\gamma > 0$, assuming that NP is not contained in quasi-polynomial time. The standard greedy algorithm for *Set Cover* is often used in practice to approximate *Min-DNF*. The question of whether *Min-DNF* can be approximated to within a factor of $o(\log N)$ remains open, but we construct an instance of *Min-DNF* on which the solution produced by the greedy algorithm is $\Omega(\log N)$ larger than optimal. Finally, we turn to the question of approximating circuit size for slightly more general classes of circuits. DNF formulas are depth-two circuits of AND and OR gates. Depth-d circuits are denoted by AC^0_d. We show that it is hard to approximate the size of AC^0_d circuits (for large enough d) under cryptographic assumptions.

1. Introduction.

A fundamental computational problem is to determine the minimum size of a Boolean function in some representation, given a truth table for the function. Two prominent examples are *Min-DNF*, which asks whether a Boolean function presented as a truth table has a k-term disjunctive normal form (DNF), and *Min-Circuit* (also called the minimum circuit size problem), which asks whether a Boolean function presented as a truth table has a size k Boolean circuit. By varying the representation class, we can obtain a hierarchy of problems between *Min-DNF* and *Min-Circuit*, including such problems as *Min-*AC^0, *Min-*TC^0, and *Min-*NC^1.

The main focus of this paper is the *Min-DNF* problem. *Min-DNF* is the decision version of finding the smallest DNF formula consistent with a truth table, where

the size of a DNF formula is considered to be the number of terms in it. This is a classic problem in computer science and circuit design. Heuristic approaches to solving this problem range from the Karnaugh maps of the 1960s to state-of-the-art software packages (cf. [14]).

Masek proved *Min-DNF* to be NP-complete in the 1970s [30]. This result was cited by Garey and Johnson [21] and is widely known, but Masek never published his proof. More recently, Czort presented a modernized, more readable version of Masek's proof [15] (see also [40]). Masek's proof is by direct reduction from *Circuit-SAT*, using gadget constructions, and even in Czort's version it is long and involved. We present a new, simple NP-completeness proof for *Min-DNF* by reduction from 3-*Partite Set Cover* (or, more particularly, from 3*D-Matching*).

It is well known that *Min-DNF* can be viewed as a special case of *Set Cover* and that the greedy *Set Cover* algorithm can be applied to *Min-DNF* to produce a DNF with $O(\log N)$ times as many terms as the optimal, where N is the size (number of entries) of the input truth table. This prompts the question of whether a better approximation factor can be achieved. Czort considered this question but showed only that, unless P = NP, the size of the smallest DNF cannot be approximated to within an *additive* constant k [15]. We also give a more complicated reduction (again from a restricted version of *Set Cover*) that allows us to prove the following inapproximability result for *Min-DNF*: If NP is not contained in quasi-polynomial time, then *Min-DNF* cannot be approximated to within a factor smaller than $(\log N)^\gamma$ for some constant $\gamma > 0$, where N is the size of the input truth table.

There is a gap between our $\Omega((\log N)^\gamma)$ inapproximability lower bound for *Min-DNF* and the $O(\log N)$ upper bound of the greedy *Set Cover* algorithm. Closing this gap remains an open question. We do, however, construct an instance of *Min-DNF* for which the greedy *Set Cover* algorithm produces a DNF formula that has $\Omega(\log N)$ times as many terms as the optimal. The greedy *Set Cover* algorithm is commonly used as a heuristic for solving *Min-DNF* in practice. We also prove an $\Omega(\sqrt{\log N})$ inapproximability lower bound for *Min-DNF* under the additional assumption that a restriction of *Set Cover* is $\Omega(\log n)$-hard to approximate.

Although the general *Min-DNF* problem is NP-hard, for $k = O(\sqrt{\log N})$ it is tractable [22]. Using a simple padding argument, we show hardness results for *Min-DNF* where $k = \omega(\log N)$. The question of whether *Min-DNF* is tractable for $k = \log N$ remains open. This question was posed in [22]; a negative result would imply that $\log n$-term DNF cannot be learned with membership and proper equivalence queries.

In addition to our results for *Min-DNF*, we also prove a result for *Min-*AC^0_d for all sufficiently large d. Under cryptographic assumptions, it is known that *Min-Circuit*, *Min-*NC^1, and *Min-*TC^0_d are not polynomial-time approximable [4]. (This is stated explicitly for *Min-Circuit* and *Min-*NC^1 in [4], while it is only implicit for *Min-*TC^0_d– because the argument presented in [4] makes use of the TC^0 pseudorandom function generator of [31]. All of this can also be viewed as being implicit in the work of Razborov and Rudich [36], and related results were also presented by Kabanets and Cai [25].) We extend the hardness results for *Min-*TC^0_d to obtain new hardness results for *Min-*AC^0_d, under cryptographic assumptions. This still leaves open the interesting question of whether *Min-Circuit* (or the other problems) are NP-complete. Kabanets and Cai [25] give evidence that such a reduction will not be straightforward.

The organization of this paper is as follows. In section 2 we define the relevant minimization problems and present necessary background. In section 3 we present our new proof that *Min-DNF* is NP-hard. In section 4 we present our hardness results

for approximating *Min-DNF*. In section 5 we give our construction of the instance of *Min-DNF* on which the greedy *Set Cover* algorithm produces an $\Omega(\log N)$ factor approximation. Section 6 concerns the fixed parameter versions of *Min-DNF*. Our hardness results for *Min-*AC^0_d appear in section 8. Conclusions are in section 9.

A preliminary version of this paper appeared in [3]. Feldman independently proved an $\Omega((\log N)^\delta)$ factor inapproximability result for *Min-DNF* [20] using related techniques. Feldman's result is based on the assumption P $\neq$ NP, rather than on the assumption that NP is not contained in quasi-polynomial time. Feldman also proved new results on proper learning of DNF, which are discussed in section 7.

2. Preliminaries. We begin with a few definitions. The set $\{1, \ldots, n\}$ is denoted by $[n]$. We use the bitwise ordering on vectors: For $v, w \in \{0,1\}^n$, we write $v \leq w$ if $v_i \leq w_i$ for all $i \in [n]$. Let $V_n = \{x_1, \ldots, x_n\}$. A *prime implicant* T of a function $f(x_1, \ldots, x_n)$ is a conjunction of literals over the variables V_n such that $T = 1 \Rightarrow f = 1$, and removing any literal from T violates this property. (In the literature, prime implicants are sometimes called *minterms*.) A *DNF formula* over the variables V_n is a formula $\phi = T_1 \vee T_2 \vee \ldots T_k$ for some k, where $T_1, \ldots, T_k$ are each conjunctions of literals over V_n. Each T_i in ϕ is a *term* of ϕ. Every Boolean function f can be expressed by a DNF formula in which every term is a prime implicant of f. The *size* of a DNF formula is the number of terms in it; for a Boolean function or partial function f, *dnf-size*(f) denotes the size of the smallest DNF formula consistent with f. The class of Boolean circuits AC^0_d consists of all depth-d circuits of AND and OR gates with arbitrary fan-in.

The classic *Set Cover* optimization problem is, given input $(\mathcal{S},\mathcal{U})$, where $\mathcal{U}$ is a finite universe and $\mathcal{S}$ is a collection of subsets of $\mathcal{U}$, find a smallest subcollection $\mathcal{C} \subseteq \mathcal{S}$ such that that the union of the sets in $\mathcal{C}$ equals $\mathcal{U}$. It is NP-hard to approximate *Set Cover* to within a factor smaller than $c \log n$, where c is a constant and n is the size of the input (cf. [6]). On the other hand, there is a simple greedy algorithm that achieves an $O(\log n)$ approximation for *Set Cover* [24, 28, 13].

For r a positive integer, the r-*Uniform Set Cover* problem is as follows: On input $(n, k, \mathcal{S})$, where n and k are positive integers and $\mathcal{S}$ is a set of subsets of $[n]$, each subset having size r, determine whether there is a subcollection $\mathcal{C} \subseteq \mathcal{S}$ of size at most k whose union is $[n]$. The r-*Partite Set Cover* problem is a restriction: On input $(n, k, \Pi, \mathcal{S})$, where n and k are positive integers, Π is a partition of $[n]$ into r sets, and $\mathcal{S}$ is a collection of subsets of $[n]$, where every subset contains exactly one element from each of the sets of Π, determine whether there is a subcollection $\mathcal{C} \subseteq \mathcal{S}$ of size at most k whose union is $[n]$. The 3*D-Matching* problem is the NP-complete restriction of 3-*Partite Set Cover* where $k = n/3$ (cf. [21]).

We consider a general family of computational problems of the form *Min-R(S)* where the input is a Boolean function with input representation from S and the output should be a minimum representation of the function from R. For example, *Min-DNF(tt)* is the problem of determining a smallest DNF representation of a Boolean function f on n variables, if f is presented as a truth table of size $N = 2^n$. Our default input representation will be the truth table representation, and when we write *Min-R*, rather than *Min-R(S)*, we will assume the default input representation.

We focus primarily on DNF minimization. We consider the following four variations:

Min-DNF(A): The input is a total Boolean function, specified by explicitly listing all 1's of the function. That is, $A \subseteq \{0,1\}^n$ is the input, and we look for a minimum DNF that realizes the total function f_A, where $f_A(a) = 1$ for $a \in A$ and $f_A(b) = 0$ for $b \in \{0,1\}^n - A$.

Min-DNF: In the full-truth table version, the input is the entire truth table of $f : \{0,1\}^n \to \{0,1\}$, and we look for a minimum DNF that realizes the function f.

Min-DNF(A,B): The input is a partial Boolean function, specified by listing the 1's and 0's of the function, and we look for a minimum DNF that is consistent with the input. That is, $A, B \subseteq \{0,1\}^n$ is the input, and we look for a minimum DNF that realizes a function $f : \{0,1\}^n \to \{0,1\}$, where $f(a) = 1$ for $a \in A$ and $f(b) = 0$ for $b \in B$.

Min-DNF(*): The input is a partial Boolean function, specified by the entire truth table of $f : \{0,1\}^n \to \{0,1,*\}$, where $f(a) = *$ means that the value of f is not defined on a. We look for a minimum DNF that realizes a function $f' : \{0,1\}^n \to \{0,1\}$, where $f'(a) = 1$ for $a \in f^{-1}(1)$ and $f'(b) = 0$ for $b \in f^{-1}(0)$. Note that, as in the (A, B) version, the input here also specifies a partial function, but now the partial function is specified by a 2^n-sized input, regardless of the size of the domain of the partial function.

The decision versions of the above problems ask, given a function f and a natural number k, whether or not there is a DNF formula realizing f that has at most k terms. All decision versions are easily seen to lie in NP. It is also easy to see that *Min-DNF* is a special case of *Min-DNF(*)* and therefore reduces to *Min-DNF(*)*, and *Min-DNF(*)* reduces to *Min-DNF(A,B)*. Also *Min-DNF* reduces to *Min-DNF(A)*. Thus NP-hardness of *Min-DNF* implies NP-hardness of all other versions. The first three of the above problems are covered by Czort [15] in an excellent survey of previous related work. There is a hodgepodge of interesting but incomparable hardness results that are known for versions of DNF minimization, dating back to the 1960s. The simplest of these is the NP-hardness of the (A, B) version due to Pitt and Valiant [34]. As shown by Czort, there is also a clean NP-hardness proof of the A version that follows from a reduction of Gimpel. Masek [30] proved the NP-completeness of *Min-DNF*. In terms of inapproximability, Pitt and Valiant's proof of the (A, B) hardness result preserves solution values and thus shows the NP-hardness of achieving a factor n^ϵ approximation. Neither of the other two NP-hardness proofs (for the A version or for *Min-DNF*) give much in the way of inapproximability results.

A starting point for this paper is the well-known observation that *Min-DNF* easily reduces to *Set Cover* and in fact can be viewed as a special case of *Set Cover*. Given the truth table of a Boolean function f over n variables, all prime implicants of f can be generated in time $2^{O(n)}$. Each prime implicant can then be viewed as a subset of $\{0,1\}^n$ (corresponding to those inputs that satisfy the prime implicant). Thus given all of the prime implicants, finding a smallest DNF is equivalent to finding a smallest cover for these prime implicant sets. Applying the standard greedy algorithm for *Set Cover*, it follows that *Min-DNF* can be approximated to within a factor of $O(\log N)$, where N is the size (number of entries) of the truth table.

For a partial Boolean function f, the prime implicants of f are the prime implicants of the total function f' that satisfies $f'(\vec{x}) = 1$ iff $f(\vec{x}) = 1 \vee f(\vec{x}) = *$. Every partial function f has a smallest consistent DNF whose terms are prime implicants of f. The greedy *Set Cover* algorithm can also be used to approximate *Min-DNF(*)* in the same way that it is applied to *Min-DNF*, except that it chooses sets that cover the maximum number of 1's of the input function (i.e., it ignores $*$'s when greedily choosing sets).

The pseudocode for applying the greedy *Set Cover* algorithm to *Min-DNF* and *Min-DNF(*)* is shown in Figure 2.1. The input is the full truth table of a Boolean function or partial function f.

1: $\mathcal{T} := \{T \mid T \text{ is a prime implicant of } f\}$
2: $\varphi := \bot$
3: **while** φ does not cover all 1's of f **do**
4: let $T \in \mathcal{T}$ cover the most uncovered 1's of f
5: $\varphi := \varphi \vee T$
6: **end while**
7: return φ

FIG. 2.1. *Greedy Min-DNF and Min-DNF(*) algorithm.*

3. Simple proof that *MinDNF* is NP-complete. Our new proof that *Min-DNF* is NP-complete is a modification of the reduction of Gimpel mentioned above, which was was used by Czort to prove the NP-completeness of the A version of DNF minimization [15].

We start by briefly describing Gimpel's reduction. It can be viewed as consisting of two phases. In the first phase, an instance $(\mathcal{S},\mathcal{U})$ of *Set Cover* over the ground set $\mathcal{U} = [n]$ is mapped to a partial function f, as follows. First, both the sets as well as the ground elements are mapped to truth assignments in $\{0,1\}^n$ such that a set covers a ground element in $[n]$ iff the assignment corresponding to the ground element is less than the assignment corresponding to the set (where comparison of assignments is with respect to the bitwise ordering of the vectors). Each ground element $i \in [n]$ is mapped to the assignment that is all zero except for bit i, which is 1. Each set is mapped to the assignment corresponding to the characteristic function of the set. The 1's of f are those assignments corresponding to ground elements; the $*$'s of f are those assignments α such that $\alpha \leq \beta$ for some β corresponding to a set; and the remaining truth assignments are zeros of f. It can be shown that the size of the minimum DNF consistent with the partial function f is equal to the minimum size of the cover for the input instance of *Set Cover*.

In the second phase of Gimpel's reduction, the partial function f is mapped to a total function, g. We give the details of g below in section 3.2. The truth table sizes of f and g are exponential in the size of the *Set Cover* instance from the first phase. Thus Gimpel's reduction does not give a hardness result for *Min-DNF*. As Czort notes, it does, however, give a hardness result for *Min-DNF(A)*, provided that we begin the reduction not from the general *Set Cover* problem but from 3-*Uniform Set Cover*.

Our reduction proving that *Min-DNF* is NP-complete also has two phases. The first phase is similar to that of Gimpel. The main difference is that we need a much more compact mapping from the sets and ground elements of the *Set Cover* instance onto truth assignments, to ensure that the size of the truth table for the resulting function is only polynomial in the size of the input *Set Cover* instance. To do such a compact mapping in a simple way, we reduce from 3-*Partite Set Cover* rather than from 3-*Uniform Set Cover*. The second phase of our reduction is essentially identical to Gimpel's.

3.1. Reducing 3-*Partite Set Cover* to *Min-DNF*(*). In the first phase of our reduction, we reduce 3-*Partite Set Cover* to *Min-DNF(*)*. We note that our reduction from 3-*Partite Set Cover* would also work from 3*D-Matching*. We use the following lemma, which is implicit in Gimpel's reduction.

LEMMA 3.1. *Let $\mathcal{S}$ be a set of subsets of $[n]$. Let $t > 0$, and let $V = \{v^i : i \in [n]\}$ and $W = \{w^A : A \in \mathcal{S}\}$ be sets of vectors from $\{0,1\}^t$ satisfying*

$$(*) \qquad \text{For all } A \in \mathcal{S} \text{ and } i \in [n],\ i \in A \text{ iff } v^i \leq w^A.$$

Let $R = \{x \in \{0,1\}^t \mid x \notin V \text{ and for some } w \in W,\ x \leq w\}$. Let f be a partial

function with domain $\{0,1\}^t$ *such that* $f(x) = 1$ *if* $x \in V$, $f(x) = *$ *if* $x \in R$, *and* $f(x) = 0$ *otherwise. Then* $\mathcal{S}$ *has a cover of size* m *iff there is an* m*-term DNF consistent with* f.

Proof. For $u \in \{0,1\}^t$, let $D(u) = \{w : w \leq u\}$, and let $\tau(u)$ denote the DNF term $\bigwedge_{i:u_i=0} \neg x_i$. Note that $D(u)$ is exactly the set of satisfying assignments of $\tau(u)$. For a set U of vectors $D(U) = \bigcup_{u \in U} D(u)$. By (*), we have that $V \subseteq D(W)$. Also, $f(x) = *$ iff $x \in D(W) - V$.

Given a cover $\mathcal{C} \subseteq \mathcal{S}$ of size m, the m-term DNF whose terms are $\{\tau(w^C) \mid C \in \mathcal{C}\}$ is easily seen to be consistent with f. Conversely, suppose ϕ is an m-term DNF consistent with f. For each term $\tau \in \phi$, let $u(\tau)$ be the maximal vector satisfying τ. Since ϕ is consistent with f, we have that $u(\tau) \in D(W)$, so there must be a set $S(\tau) \in \mathcal{S}$ for which $u(\tau) \leq w^{S(\tau)}$. We claim that $\{S(\tau) : \tau \in \phi\}$ is a cover of $\mathcal{S}$. Let $j \in [n]$. We must show that j is covered. The consistency of ϕ implies that v^j is satisfied by some term $\tau_j \in \phi$. This implies $v^j \leq u(\tau_j)$. Thus $v^j \leq w^{S(\tau_j)}$, which by (*) implies $j \in S(\tau_j)$. ∎

The reduction from 3-*Partite Set Cover* to *Min-DNF(*)* is given in the following lemma.

LEMMA 3.2. *There is an algorithm that takes as input an instance* $(n, k, \Pi, \mathcal{S})$ *of* 3*-Partite Set Cover and outputs an instance of Min-DNF(*). The instance of Min-DNF(*) defines a partial function* f *on* $O(\log n)$ *variables such that the size of the smallest DNF consistent with* f *is equal to the size of the smallest cover for the input* 3*-Partite Set Cover instance. The algorithm runs in time polynomial in* n.

Proof. Given an input instance $(n, k, \Pi, \mathcal{S})$ of 3-*Partite Set Cover*, the algorithm produces an indexed set of vectors $V = \{v^i : i \in [n]\}$ and $W = \{w^A : A \in \mathcal{S}\}$ all of the same (small) length t satisfying the condition (*) of Lemma 3.1. We will specify V and then define W according to the rule that, for $A \in \mathcal{S}$, w^A is the bitwise OR of $\{v^i : i \in A\}$. This guarantees the forward implication of condition (*) for any choice of V; it is the backward implication that requires some care in choosing V.

Let q be the smallest integer such that $\binom{q}{q/2} \geq n$. Thus $q = O(\log n)$. Assign to each $i \in [n]$ a unique q-bit Boolean vector $b(i)$ containing exactly $q/2$ 1's. For $i \in [n]$, write $\Pi(i)$ for the index of the block of Π that contains i. Let $t = 3q$. We will consider the t-bit vectors in V and W as being divided into 3 blocks of size q. For $i \in [n]$, let v^i be equal to 0 on all blocks but block $\Pi(i)$; on block $\Pi(i)$ it is $b(i)$. To see that the backward implication of $(*)$ holds, let $A \in \mathcal{S}$ and $i \in [n]$, and assume that $v^i \leq w^A$. Then A contains one element i' with $\Pi(i') = \Pi(i)$, and so we must have $b(i) \leq b(i')$, which implies $i = i'$.

V and W can be generated in time $n^{O(1)}$. The partial function f will have domain $\{0,1\}^t$. The lemma then follows immediately from Lemma 3.1. ∎

3.2. Reducing *Min-DNF(*)* to *Min-DNF*. As mentioned above, the second phase of our reduction is taken from Gimpel. We describe the phase here and will build on it later in order to prove inapproximability results. The second phase of Gimpel's reduction maps a partial function f to a total function g. The variables underlying g are V (the variables of f) plus two additional variables y_1 and y_2. The total function g is defined as follows:

$$g(\vec{x}\, y_1 y_2) = \begin{cases} 1 & \text{if } f(\vec{x}) = 1 \text{ and } y_1 = y_2 = 1, \\ 1 & \text{if } f(\vec{x}) = * \text{ and } y_1 = y_2 = 1, \\ 1 & \text{if } f(\vec{x}) = *,\ y_1 = p(\vec{x}), \text{ and } y_2 = \neg p(\vec{x}), \\ 0 & \text{otherwise,} \end{cases}$$

where $p(\vec{x}) = 0$ if the parity of $\vec{x}$ is even, and $p(\vec{x}) = 1$ if the parity of $\vec{x}$ is odd. Let $s = |f^{-1}(*)|$. The following lemma is implicit in Gimpel's reduction (cf. [15]).

LEMMA 3.3. *dnf-size*(g) = *dnf-size*$(f) + s$.

Proof. The idea behind the proof is as follows. The key observation is that every DNF for g requires s distinct terms to cover the inputs of the third type in the definition of g above; these terms can simultaneously cover all inputs of the second type but not those of the first type. The remaining terms of the DNF must therefore cover the terms of the first type and may optionally cover the terms of the second type; they thus constitute a solution to the *Min-DNF(*)* problem for f. It follows that *dnf-size*(g) = *dnf-size*$(f) + s$. We now prove this formally.

We first show that *dnf-size*$(g) \leq$ *dnf-size*$(f) + s$. Suppose φ is a minimum-size DNF consistent with f. Define a DNF ψ with terms of two types: First, for every input $\vec{x} \in f^{-1}(*)$, ψ contains the term $\left(\bigwedge_{i:\vec{x}_i=1} x_i\right) \wedge \left(\bigwedge_{i:\vec{x}_i=0} \neg x_i\right) \wedge y_{2-p(\vec{x})}$. These terms cover all inputs of the second and third types in the definition of g. Second, for every term T of φ, ψ contains the term $T \wedge y_1 \wedge y_2$. These terms cover all inputs of the first type in the definition of g.

Finally, suppose that $\vec{x}y_1y_2$ satisfies ψ. Then one of the following three conditions holds: (1) $\vec{x} \in f^{-1}(*)$, $y_1 = p(\vec{x})$, and $y_2 = \neg p(\vec{x})$; (2) $\vec{x} \in f^{-1}(*)$ and $y_1 = y_2 = 1$; (3) $\vec{x}$ satisfies φ (and thus $\vec{x} \in f^{-1}(1) \cup f^{-1}(*)$) and $y_1 = y_2 = 1$. In all three cases we have $g(\vec{x}y_1y_2) = 1$, and thus ψ is consistent with g. The number of terms in ψ is $|f^{-1}(*)| + |\varphi|$ = *dnf-size*$(f) + s$.

We now show that *dnf-size*$(g) \geq$ *dnf-size*$(f) + s$. Suppose that ψ is a smallest DNF for g. We assume without loss of generality that each term of ψ is a prime implicant of g. We begin by proving that, for every $\vec{x} \in f^{-1}(*)$, ψ contains the term $t(\vec{x}) \wedge y_{2-p(\vec{x})}$, where $t(\vec{x}) = \left(\bigwedge_{i:\vec{x}_i=1} x_i\right) \wedge \left(\bigwedge_{i:\vec{x}_i=0} \neg x_i\right)$. The proof is as follows. Let $\vec{x} \in f^{-1}(*)$, and suppose that the parity of $\vec{x}$ is odd: The case of even parity is symmetric. Let T be a term of ψ that is satisfied by $\vec{x}10$ (where 1 and 0 are the values of y_1 and y_2, respectively). If, for some index i, T does not contain the variable x_i, let $\vec{x}'$ be obtained by flipping the ith bit of $\vec{x}$. Then $\vec{x}'10$ falsifies g (since $\vec{x}'$ has even parity) but satisfies T, contradicting the assumption that ψ is consistent with g. Thus T contains each of the variables $x_1, \ldots, x_n$. In addition, T contains the variable y_1, as otherwise $\vec{x}00$ would satisfy T. Finally, since T is a prime implicant of g, we have that $T = t(\vec{x})y_1$.

We now prove that there exists a subformula $\hat{\psi}$ of ψ and a DNF ψ' over the $\vec{x}$ variables that is consistent with f such that $\hat{\psi} = \bigvee_{T \in \psi'} (T \wedge y_1 \wedge y_2)$. Let $\hat{\psi}$ be the subformula of ψ consisting of those terms that are satisfied by $\vec{x}11$ for some $\vec{x} \in f^{-1}(1)$. Each term of $\hat{\psi}$ contains $y_1 \wedge y_2$, since flipping y_1 or y_2 produces an input that falsifies g. It follows that $\hat{\psi} = \bigvee_{T \in \psi'} (T \wedge y_1 \wedge y_2)$, where ψ' is a DNF. It remains to show that ψ' is consistent with f. For every $\vec{x} \in f^{-1}(1)$, there is a term of ψ satisfied by $\vec{x}11$, and thus there is a corresponding term of ψ' satisfied by $\vec{x}$. On the other hand, every $\vec{x} \in f^{-1}(0)$ must falsify ψ', as otherwise $\vec{x}11$ would satisfy ψ.

It follows from the above that ψ consists of the terms $t(\vec{x}) \wedge y_{2-p(\vec{x})}$ for each $\vec{x} \in f^{-1}(*)$, together with the subformula $\hat{\psi}$. These components are pairwise disjoint. Since ψ' is consistent with f, $\hat{\psi}$ contains at least *dnf-size*(f) terms, and thus the size of ψ is at least *dnf-size*$(f) + s$. □

It follows that there is a polynomial-time reduction from *Min-DNF(*)* to *Min-DNF*. Combining this with the previous reduction from 3-*Partite Set Cover* to *Min-DNF(*)*, it follows that *Min-DNF* is NP-complete.

4. On the approximability of *Min-DNF*. Although the two-phase reduction above proves the NP-completeness of *Min-DNF*, it does not give us inapproximability results. There are two problems. First, the reduction begins with an instance of 3-*Partite Set Cover*, a problem that can be approximated in polynomial time to within a factor of 4/3 [18]; to obtain inapproximability results we need to reduce from a problem that is difficult to approximate. Also, the second phase of the reduction, from *Min-DNF(*)* to *Min-DNF*, is not approximation-preserving.

We replace the first phase of the reduction with a reduction that exploits properties of the *Set Cover* instance obtained by the inapproximability results of Lund–Yannakakis [29] that are based on probabilistically-checkable proofs (PCPs). We then modify the second phase to make it approximation-preserving. The final two-phase reduction gives an inapproximability factor of $\Omega((\log N)^{\gamma})$ assuming that NP is not contained in quasi-polynomial time.

In Appendix A we also present a modified version of the first phase of the reduction, which reduces from *r-Uniform Set Cover* rather than from 3-*Partite Set Cover*. This allows us to obtain an inapproximability result for *Min-DNF* by applying known inapproximability results for *r-Uniform Set Cover*. However, the result we obtain for *Min-DNF* is weak (inapproximability to within a factor of $\Omega(\log\log N)$). Nevertheless, the reduction itself may be of independent interest, since it requires a different technique to reduce from *r-Uniform Set Cover* rather than from *r-Partite Set Cover*.

4.1. New reduction to *Min-DNF*(*). In this section we present a reduction that follows the PCP-based inapproximability results for *Set Cover* [29, 19]. We will closely follow the Lund–Yannakakis reduction, as presented by Khot [26].

An instance of *Label Cover* is denoted by $\mathcal{L} = (G, L_1, L_2, \Pi)$, where $G = (V, W, E)$ is a regular bipartite graph, L_1 and L_2 are sets of labels, and $\Pi = \{\pi_{vw}\}_{(v,w)\in E}$ denotes the constraints on each edge. For every edge $(v, w) \in E$ we have a map $\pi_{vw} : L_1 \to L_2$. A labeling $l : V \to L_1$, $W \to L_2$ satisfies the constraint on an edge (v, w) if $\pi_{vw}(l(v)) = l(w)$. Given an instance $\mathcal{L}$, the output should be a labeling that satisfies the maximum fraction $\mathrm{OPT}(\mathcal{L})$ of edge constraints.

THEOREM 4.1 (see [29, 26]). *There is a constant $c < 1$ such that it is NP-hard to solve the following gap version of Label Cover. The input is an instance $\mathcal{L} = (G = (V, W, E), [7], [2], \{\pi_{vw}\}_{(v,w)\in E})$ of Label Cover. The instance should be accepted if $OPT(\mathcal{L}) = 1$, and the instance should be rejected if $OPT(\mathcal{L})$ is at most c.*

Note that the reduction is from *Max3SAT(5)* (the problem of maximizing the number of satisfied clauses in a 3CNF formula where each variable occurs in exactly five clauses). The vertices in V correspond to the m clauses, and the vertices in W correspond to the n variables. Using Raz's parallel repetition theorem [35], we can amplify the gap, obtaining, for any positive integer k, an instance $\mathcal{L}' = (G' = (V', W', E'), [7^k], [2^k], \{\pi_{v'w'}\}_{(v',w')\in E'})$, where $|V'| = |V|^k$ and $|W'| = |W|^k$, such that $\mathrm{OPT}(\mathcal{L}) = 1$ implies $\mathrm{OPT}(\mathcal{L}') = 1$, and $\mathrm{OPT}(\mathcal{L}) \le c$ implies $\mathrm{OPT}(\mathcal{L}') \le 2^{-\gamma k}$, where $\gamma > 0$ is an absolute constant. Note that the sizes of both V' and W' are $n^{O(k)}$, where n is the number of variables in the *Max3SAT(5)* instance.

DEFINITION 4.2. *A partition system $\mathcal{P}(m, h, t)$ consists of t partitions $(A_1, \overline{A_1}), \ldots (A_t, \overline{A_t})$ of $[m]$, with the property that no collection of h sets, with at most one set from each partition, covers all of $[m]$.*

LEMMA 4.3 (see [29]). *For every h and t, there is an efficiently constructible partition system $\mathcal{P}(m, h, t)$, with $m = O(2^h h \log t)$.*

We now review the reduction from the *Label Cover* instance $\mathcal{L}'$ to a *Set Cover* instance $(\mathcal{S}, \mathcal{U})$. First, the universe $\mathcal{U}$ is as follows. Let $t = 2^k$, let h be a parameter to

be determined later, and let $m = m(t,h) = O(2^h h \log t)$ be the parameter specified by Lemma 4.3. For each edge $e \in E'$ we associate a subuniverse $\mathcal{U}_e = \{(e,i) \mid i \in [m]\}$. The entire universe $\mathcal{U}$ is the disjoint union of these $|E'|$ subuniverses. Associated with each edge e is a partition system $\mathcal{P}(m,h,t)$ over $\mathcal{U}_e$, with one partition associated with each of the possible labels in L_2. Thus each label $b \in [t]$ corresponds to a partition $(A_b^e, \overline{A_b^e})$ of $\mathcal{U}_e$. The size of the entire universe is $n^{O(k)}2^{O(h)}$. The set system $\mathcal{S}$ is the union of two collections of sets: $S(v,a)$, for each vertex $v \in V'$ and each label $a \in [7^k]$, and $S(w,b)$, for each $w \in W'$ and each label $b \in [2^k]$. In particular,

$$S(v,a) = \bigcup_{w:(v,w)\in E'} A^{(v,w)}_{\pi_{vw}(a)}, \qquad S(w,b) = \bigcup_{v:(v,w)\in E'} \overline{A_b^{(v,w)}}.$$

The following lemma is implicit in [29, 26].

LEMMA 4.4 (see [29, 26]). *If $OPT(\mathcal{L}') = 1$, then $(\mathcal{S},\mathcal{U})$ has a cover of size $|V'| + |W'|$. If $OPT(\mathcal{L}') \le 1/(2h^2)$, then every cover of $(\mathcal{S},\mathcal{U})$ has size at least $h(|V'| + |W'|)/16$.*

Choosing $h \le 2^{\gamma k/2 - 1/2}$, we obtain a gap of $h/16$ for the *Set Cover* instance from the $2^{\gamma k}$ gap of the *Label Cover* instance. For $k = O(\log\log n)$ sufficiently large, we have $|\mathcal{U}| = 2^{O(h)}$, and thus the gap is $\Omega(\log|\mathcal{U}|)$. The size of the *Set Cover* instance is quasi-polynomial in n. Thus a polynomial-time, $(h/16)$-approximation algorithm for *Set Cover* could distinguish between the cases $\mathrm{OPT}(\mathcal{L}') = 1$ and $\mathrm{OPT}(\mathcal{L}') \le 2^{-\gamma k}$ in time $2^{\mathrm{polylog}(n)}$, implying that NP is contained in $DTIME(2^{\mathrm{polylog}(n)})$.

We now show how to reduce instances of *Set Cover* of the above form to *Min-DNF(*)* instances. By the observations in section 3.1 it suffices to define three sets of vectors $\{u_{e,i} \mid (e,i) \in \mathcal{U}\}$, $\{t_{v,a} \mid v \in V',\ a \in L_1\}$, and $\{t_{w,b} \mid w \in W',\ b \in L_2\}$ such that the following conditions hold: (1) $u_{e,i} \le t_{v,a}$ iff $(e,i) \in S(v,a)$, for all $(e,i) \in \mathcal{U}$, $v \in V$, and $a \in L_1$, and (2) $u_{e,i} \le t_{w,b}$ iff $(e,i) \in S(w,b)$, for all $(e,i) \in \mathcal{U}$, $w \in W$, and $b \in L_2$. Let $r \in O(\log|V'|)$ be such that $\binom{r}{r/2} \ge \max(|V'|,|W'|)$. Our function will have variables $\{x_1,\ldots,x_r\} \cup \{x'_1,\ldots,x'_r\} \cup \{y_a \mid a \in L_1\} \cup \{y'_b \mid b \in L_2\}$. Thus the number of variables is $O(\log|V'| + |L_1| + |L_2|) = O(k\log n + 7^k)$.

We assign to each $v \in V'$ a unique set $S_v \subseteq \{1,\ldots,r\}$ of size $r/2$; similarly each $w \in W'$ is assigned a unique set $S_w \subseteq \{1,\ldots,r\}$ of size $r/2$. For each $v \in V'$ and $a \in L_1$, we define a Boolean vector $t_{v,a}$ as follows. The vector $t_{v,a}$ has zeros corresponding to those variables x_i such that $i \in S_v$, and it has a zero corresponding to y_a. The remaining bits of $t_{v,a}$ are ones. We similarly define, for each $w \in W'$ and $b \in L_2$, a Boolean vector $t_{w,b}$ having zeros corresponding to those variables x'_i such that $i \in S_w$, and a zero corresponding to y'_b and whose remaining bits are ones.

We now describe, for each $(e,i) \in \mathcal{U}$, a Boolean vector $u_{e,i}$. Suppose that $e = (v,w)$, and let $S(v,a_1),\ldots,S(v,a_k)$ and $S(w,b_1),\ldots,S(w,b_\ell)$ be all of the sets in $\mathcal{S}$ containing (e,i). Then $u_{e,i}$ has zeros in the positions corresponding to the following variables: (1) variables x_i, where $i \in S_v$, (2) variables x'_i, where $i \in S_w$, (3) variables y_{a_i}, where $1 \le i \le k$, and (4) variables y'_{b_i}, where $1 \le i \le \ell$. The remaining bits of $u_{e,i}$ are ones.

LEMMA 4.5. *For all $(e,i) \in \mathcal{U}$, $v \in V$, $w \in W$, $a \in L_1$, and $b \in L_2$, the following conditions hold: $u_{e,i} \le t_{v,a}$ iff $(e,i) \in S(v,a)$ and $u_{e,i} \le t_{w,b}$ iff $(e,i) \in S(w,b)$.*

Proof. Suppose first that $(e,i) \in S(v,a)$, where $v \in V'$ and $a \in L_1$. Then $e = (v,w)$ for some vertex $w \in W'$. The zeros of $t_{v,a}$ are in positions corresponding to variables x_i, where $i \in S_v$, and in the position corresponding to y_a. Since $e = (v,w)$, the vector $u_{e,i}$ has zeros in the positions corresponding to variables x_i, where $i \in S_v$, and since $(e,i) \in S(v,a)$ the vector $u_{e,i}$ also has a zero in the position corresponding

to y_a. Thus $u_{e,i} \leq t_{v,a}$. The case where $(e,i) \in S(w,b)$, where $w \in W'$ and $b \in L_2$, is symmetric.

Now suppose that $(e,i) \notin S(v,a)$, where $v \in V'$ and $a \in L_1$. Suppose that $e = (v', w')$. If $v' \neq v$, then there exists an index $j \in S_v \setminus S_{v'}$; $u_{e,i}$ has a one in the position corresponding to x_j, while $t_{v,a}$ has a zero in the same position, and thus $u_{e,i} \not\leq t_{v,a}$. So assume that $v' = v$. By the definition of $t_{v,a}$, we know that $t_{v,a}$ has a zero in the position corresponding to y_a. But since $e = (v, w')$, $u_{e,i}$ has a zero in this position iff $(e,i) \in S(v,a)$; as we have supposed that $(e,i) \notin S(v,a)$, it follows that the position in $u_{e,i}$ corresponding to y_a is set to one. Thus $u_{e,i} \not\leq t_{v,a}$. The case where $(e,i) \notin S(w,b)$, where $w \in W'$ and $b \in L_2$, is symmetric. □

By the results of section 3.1, the vectors $u_{e,i}$, $t_{v,a}$, and $t_{w,b}$ yield an instance of *Min-DNF(*)* on $O(k \log n + 7^k)$ variables whose optimum is equal to the optimum for the instance $(\mathcal{S}, \mathcal{U})$ of *Set Cover*.

THEOREM 4.6. *If NP $\not\subseteq$ DTIME($2^{\text{polylog}(n)}$), then there exists an absolute constant $\delta > 0$ such that no polynomial-time algorithm achieves an approximation ratio better than $(\log N)^{\delta}$ for Min-DNF(*), where N is the size of the input truth table.*

Proof. Let f be the partial function specified by our reduction. Claims 4.4 and 4.5, together with the results of section 3.1, imply that our *Min-DNF(*)* instance has the following properties: If $\text{OPT}(\mathcal{L}') = 1$, then *dnf-size*$(f) \leq |V'| + |W'|$; if $\text{OPT}(\mathcal{L}') \leq 2^{-\gamma k}$, then *dnf-size*$(f) \geq h(|V'| + |W'|)/16$, where $h = \Omega(2^{\gamma k/2})$. Let us take $k = \log\log n$, and thus $h = \Omega((\log n)^{\gamma/2})$. Let N be the size of the truth table for f. The number of variables of f is $\log N = O(k \log n + 7^k) = O((\log n)^{\log 7})$, and thus the gap is $h/16 = \Omega((\log N)^{\gamma/(2\log 7)})$. The truth table has size $2^{\text{polylog}\, n}$ and can be generated in time polynomial in its size. The theorem follows by taking $\delta = \gamma/(2 \log 7)$. □

4.2. Approximation-preserving reduction from *Min-DNF(*)* to *Min-DNF*. We modify the reduction from section 3.2 to make it approximation-preserving. Let f be a partial Boolean function over variables $x_1, \ldots, x_n$. Let $s = |f^{-1}(*)|$. We construct a new total function g' such that *dnf-size*$(g') = s \cdot$ *dnf-size*$(f) + s = s \cdot$ (*dnf-size*$(f) + 1$). Let $t = n + 1$, and let $S \subseteq \{0,1\}^t$ be a collection of s vectors, each containing an odd number of 1's. We add t new variables $z_1, \ldots, z_t$ and define

$$g'(\vec{x}\, y_1 y_2\, \vec{z}) = \begin{cases} 1 & \text{if } f(\vec{x}) = 1,\ y_1 = y_2 = 1, \text{ and } \vec{z} \in S, \\ 1 & \text{if } f(\vec{x}) = * \text{ and } y_1 = y_2 = 1, \\ 1 & \text{if } f(\vec{x}) = *,\ y_1 = p(\vec{x}), \text{ and } y_2 = \neg p(\vec{x}), \\ 0 & \text{otherwise.} \end{cases}$$

LEMMA 4.7. *dnf-size*$(g') = s \cdot$ *dnf-size*$(f) + s$.

Proof. For binary vector $\vec{w}$, we use $t(\vec{w})$ to denote the term $\left(\bigwedge_{i:w_i=1} w_i\right) \wedge \left(\bigwedge_{i:w_i=0} \neg w_i\right)$.

We first show that *dnf-size*$(g') \leq s \cdot$ *dnf-size*$(f) + s$. Suppose that φ is a smallest DNF consistent with f. Define a DNF ψ with terms of the following two types. First, for every input $\vec{x} \in f^{-1}(*)$, ψ contains the term $t(\vec{x}) \wedge y_{2-p(\vec{x})}$. These terms cover all inputs of the second and third types in the definition of g'. Second, for every term T of φ and every vector $\vec{z} \in S$, ψ contains the term $T \wedge y_1 \wedge y_2 \wedge t(\vec{z})$. These terms cover all inputs of the first type in the definition of g'. Finally, suppose that $\vec{x} y_1 y_2 \vec{z}$ satisfies ψ. Then one of the following conditions holds: (1) $\vec{x} \in f^{-1}(*)$, $y_1 = p(\vec{x})$, and $y_2 = \neg p(\vec{x})$; (2) $\vec{x} \in f^{-1}(*)$ and $y_1 = y_2 = 1$; (3) $\vec{x}$ satisfies φ (and thus $\vec{x} \in f^{-1}(1) \cup f^{-1}(*)$), $y_1 = y_2 = 1$, and $\vec{z} \in S$. In all three cases we have $g'(\vec{x} y_1 y_2 \vec{z}) = 1$, and thus ψ is consistent with g'. The number of terms in ψ is $|f^{-1}(*)| + |\varphi| \cdot |S| = s \cdot$ *dnf-size*$(f) + s$.

We next show that *dnf-size*$(g') \geq s \cdot$ *dnf-size*$(f) + s$. Suppose that ψ is a smallest DNF for g'. The same reasoning used in the proof of Lemma 3.3 shows that, for every $\vec{x} \in f^{-1}(*)$, ψ contains the term $t(\vec{x}) \wedge y_{2-p(\vec{x})}$. We now argue that, for each $\vec{z} \in S$, there exists a subformula $\psi_{\vec{z}}$ of ψ and a DNF $\psi'_{\vec{z}}$ over the $\vec{x}$ variables and consistent with f such that $\psi_{\vec{z}} = \bigvee_{T \in \psi'_{\vec{z}}} \big(T \wedge y_1 \wedge y_2 \wedge t(\vec{z})\big)$. Let $\vec{z} \in S$, and let $\psi_{\vec{z}}$ be the subformula of ψ consisting of those terms that are satisfied by $\vec{x}11\vec{z}$ for some $\vec{x} \in f^{-1}(1)$. Each term of $\psi_{\vec{z}}$ contains $y_1 \wedge y_2 \wedge t(\vec{z})$, since flipping either y_1 or y_2, or any bit of $\vec{z}$, produces an input that falsifies g'. It follows that $\psi_{\vec{z}} = \bigvee_{T \in \psi'_{\vec{z}}} (T \wedge y_1 \wedge y_2 \wedge t(\vec{z}))$, where $\psi'_{\vec{z}}$ is a DNF. It remains to show that $\psi'_{\vec{z}}$ is consistent with f. For every $\vec{x} \in f^{-1}(1)$, there is a term of ψ that is satisfied by $\vec{x}11\vec{z}$, and thus there is a corresponding term of $\psi'_{\vec{z}}$ that is satisfied by $\vec{x}$. On the other hand, every $\vec{x} \in f^{-1}(0)$ must falsify $\psi'_{\vec{z}}$, as otherwise $\vec{x}11\vec{z}$ would satisfy ψ.

It follows from the above that ψ consists of the terms $t(\vec{x}) \wedge y_{2-p(\vec{x})}$ for each $\vec{x} \in f^{-1}(*)$ and of the subformulas $\psi_{\vec{z}}$ for each $\vec{z} \in S$. These components are pairwise disjoint. Since $\psi'_{\vec{z}}$ is consistent with f, it follows that $\psi_{\vec{z}}$ contains at least *dnf-size*(f) terms, and thus the size of ψ is at least $s \cdot$ *dnf-size*$(f) + s$. □

The results of section 4.2, together with Theorem 4.6, yield the following hardness result for *Min-DNF*.

THEOREM 4.8. *If NP* $\not\subseteq$ *DTIME*$(2^{\text{polylog}(n)})$, *then there exists a constant* $\gamma > 0$ *such that no polynomial-time algorithm achieves an approximation ratio better than* $(\log N)^{\gamma}$ *for Min-DNF, where* N *is the size of the truth table.*

4.3. An improved hardness result under additional assumptions. In this section, we prove an $\Omega(\sqrt{\log N})$ hardness of approximation result for *Min-DNF* under the additional assumption that a restriction of *Set Cover* is $\Omega(\log n)$-hard to approximate.

DEFINITION 4.9. *The* f*-Frequency Bounded Set Cover problem is the restriction of Set Cover to instances where each element occurs in at most* $f(n)$ *sets, where* n *is the total size of the instance.*

It is well known [23] that a factor f approximation for *f-Frequency Bounded Set Cover* can be obtained in polynomial time. Thus for $f = o(\log n)$, *f-Frequency Bounded Set Cover* is not as hard to approximate as the general *Set Cover* problem. On the other hand, the reduction of Lund and Yannakakis showing an $\Omega(\log n)$ hardness of approximation for *Set Cover* produces an instance of $\Omega((\log n)^c)$-*Frequency-Bounded-Set-Cover*, for some constant c, which implies an $\Omega(\log n)$ hardness result for that problem. We conjecture that *f-Frequency-Bounded-Set-Cover* is NP-hard to approximate within a factor better than $c_2 \ln n$ for $f = c_1 \ln n$ and some constants c_1, c_2. Resolving this conjecture is an interesting question in its own right, since it postulates a frequency threshold (within a constant factor) for hardness. Assuming that the conjecture holds, we can prove an $\Omega(\sqrt{\log N})$ hardness of approximation result for *Min-DNF* using a simple, randomized reduction.

THEOREM 4.10. *If there exist constants* c_1 *and* c_2 *such that it is* ***NP****-hard to approximate* $(c_1 \ln n)$*-Frequency Bounded Set Cover to within* $c_2 \ln n$, *then there exists a constant* c_3 *such that no polynomial-time algorithm for Min-DNF achieves an approximation ratio better than* $c_3\sqrt{\log N}$ *unless* ***NP*** $\subseteq$ *DTIME*$(2^{\text{polylog}(n)})$.

Proof. Assume that there exist constants c_1 and c_2 as in the lemma. We prove an $\Omega(\sqrt{\log N})$ hardness of approximation for *Min-DNF(*)*; the reduction from section 4.2 extends the same result to *Min-DNF*. Let $(\mathcal{S}, \mathcal{U})$ be an instance of $(c_1 \ln n)$-*Frequency Bounded Set Cover* of size n. The idea of the reduction is as follows. First, we will map each set $S \in \mathcal{S}$ to a subset $f(S) \subseteq [b]$, for a suitably chosen parameter

b. Second, we define vectors $w^S \in \{0,1\}^b$ for each $S \in \mathcal{S}$, by letting w^S have zeros in those positions contained in $f(S)$ and ones elsewhere. Finally, we define vectors $u^x \in \{0,1\}^b$ for each $x \in \mathcal{U}$ having zeros in the positions contained in F_x, where

$$F_x = \bigcup_{S \in \mathcal{S}: x \in S} f(S),$$

and ones elsewhere. If the vectors satisfy the condition $u^x \leq w^S \iff x \in S$ for all $x \in \mathcal{U}$ and $S \in \mathcal{S}$, then by Lemma 3.1 we can construct an instance of *Min-DNF(*)* over b variables whose optimum is equal to the optimum for $(\mathcal{S},\mathcal{U})$. Notice that the definition of u^x implies that the "if" part of the condition is always satisfied. For the "only if" part to hold, it is necessary and sufficient that, for every S such that $x \notin S$, u_x has a one in a position where w^S has a zero; that is, $f(S) \not\subseteq F_x$. For $S \in \mathcal{S}$, let $f(S)$ be defined by choosing each $i \in [b]$ independently with probability p. Fix an element $x \in \mathcal{U}$ and a set $S \in \mathcal{S}$ such that $x \notin S$. We will show that the probability that $f(S) \subseteq F_x$ is small. For any choice of p, the probability that $f(S) \subseteq F_x$ is maximized when x occurs in exactly $c_1 \ln n$ sets (since it cannot occur in more than $c_1 \ln n$ sets). As we wish to find an upper bound for the probability that $f(S) \subseteq F_x$, we may therefore assume that x occurs in exactly $c_1 \ln n$ sets. For $1 \leq i \leq b$, let X_i be the indicator variable for the event $i \in F_x$. Then $\mathbf{E}[X_i] = 1 - (1-p)^{c_1 \ln n}$, and by letting $X = \sum_{1 \leq i \leq b} X_i$ be the size of F_x, linearity of expectation implies

$$\begin{aligned}\mathbf{E}[X] &= b(1 - (1-p)^{c_1 \ln n}) \\ &\approx b(1 - e^{-pc_1 \ln n}),\end{aligned}$$

which can be made smaller than $b/4$ by choosing $p \approx \ln(4/3)/(c_1 \ln n)$. The X_i's are independent, and we apply the simplified Chernoff bound $\Pr[X > (1+\delta)\mathbf{E}[X]] < 2^{-\delta \mathbf{E}[X]}$ to obtain

$$\Pr[X > b/2] < 2^{-b/4}.$$

Let us consider the case $|F_x| \leq b/2$. Then the probability that $f(S_j) \subseteq F_x$ is

$$\begin{aligned}\Pr\Big[f(S_j) \subseteq F_x \Big| |F_x| \leq b/2\Big] &\leq (1-p)^{b/2} \\ &\approx \left(1 - \frac{\ln(4/3)}{c_1 \ln n}\right)^{b/2} \\ &< e^{-b \ln(4/3)/(2c_1 \ln n)}.\end{aligned}$$

By choosing $b = 8c_1 \ln^2 n$, we have

$$\begin{aligned}\Pr[f(S_j) \subseteq F_x] &\leq 2^{-b/4} + e^{-4 \ln(4/3) \ln n} \\ &< e^{-3 \ln n} \\ &= 1/n^3.\end{aligned}$$

Applying the union bound, the probability that there exists an element $x \in \mathcal{U}$ and a set $S \in \mathcal{S}$, with $x \notin S$, such that $f(S) \subseteq F_x$, is at most $1/n$. Thus with probability at least $1 - 1/n$, we can apply the construction of Lemma 3.1 to the vectors u^x and w^S, to obtain an instance of *Min-DNF(*)* over $b = O(\log^2 n)$ variables whose

minimum DNF has the same size as the minimum set cover for $(\mathcal{S},\mathcal{U})$. The *Min-DNF(*)* instance has size $N = 2^b = 2^{O(\log^2 n)}$, and the probabilistic construction can be derandomized in quasi-polynomial time using the method of conditional probabilities (see, e.g., [7]). It follows that there is no polynomial-time algorithm for *Min-DNF(*)* which achieves an approximation ratio better than $c_2 \ln n = \Omega(\sqrt{\log N})$ unless $\mathbf{NP} \subseteq \mathrm{DTIME}(2^{\mathrm{polylog}(n)})$. □

Let Hypothesis 1 be the hypothesis that there exists constants c_1, c_2 such that it is **NP**-hard to approximate $(c_1 \ln n)$-*Frequency Bounded Set Cover* to within $(c_2 \ln n)$. We gave a simple argument showing that, under Hypothesis 1, *Min-DNF* cannot be approximated to within a ratio better than some constant times $\sqrt{\log N}$ unless **NP** is in quasi-polynomial time. How believable is Hypothesis 1? A recent paper [16] proves the following related result which gives some evidence that Hypothesis 1 is true.

THEOREM 4.11 (see [16]). *For some constant ϵ, $(\ln n)^\epsilon$-Frequency Bounded Set Cover cannot be approximated to within a factor of 2 unless **NP** is in quasi-polynomial time.*

Hypothesis 1 is stronger than the above theorem in two ways. First, Hypothesis 1 requires that *Frequency Bounded Set Cover* be **NP**-hard instead of quasi-polynomial-hard. The second difference is more substantial. Hypothesis 1 requires that the problem is hard for frequency up to $(\ln n)$ instead of $(\ln n)^\epsilon$. It is possible that the above theorem can be improved to prove Hypothesis 1. In any case, the above theorem gives an alternative proof that *Min-DNF* cannot be approximated to within a ratio better than $(\log N)^\gamma$ for some $\gamma < 1$, unless **NP** is in quasi-polynomial time, where γ is basically $(\epsilon/2)$.

5. A tight example for the greedy algorithm. We show that there exist instances of *Min-DNF* for which the greedy *Set Cover* algorithm achieves an $\Omega(\log N)$ approximation ratio. Our approach is to take a standard worst-case *Set Cover* instance and to apply a version of the reductions of sections 3.1 and 4.2 to obtain first a *Min-DNF(*)* instance and then a *Min-DNF* instance. We then show that the greedy algorithm operates on the resulting *Min-DNF(*)* instance, and on the resulting *Min-DNF* instance, much as it does on the original *Set Cover* instance.

5.1. Tight example for greedy on *Min-DNF*(*). The starting point is the following *Set Cover* instance, on which the greedy *Set Cover* algorithm has worst-case behavior. The instance consists of $m-1$ pairwise disjoint sets $S_1, \ldots, S_{m-1}$ such that $|S_i| = 2^i$ and of two additional sets T_0 and T_1. For each set S_i, the set T_0 contains half of the elements in S_i, while T_1 contains the other half. On this set collection, the greedy algorithm chooses the cover consisting of all of the sets S_i, while the optimal solution consists only of T_0 and T_1.

Let $\mathcal{U}$ be the underlying universe. We define three sets of vectors $\{v^e \mid e \in \mathcal{U}\}$, $\{s^i \mid 1 \le i \le m-1\}$, and $\{t^0, t^1\}$, over $\{0,1\}^{2(m+1)}$, such that the following three conditions hold for all $e \in \mathcal{U}$ and all $1 \le i \le m-1$: (1) $v^e \le s^i$ iff $e \in S_i$; (2) $v^e \le t^0$ iff $e \in T_0$; (3) $v^e \le t^1$ iff $e \in T_1$. The vectors $\{v^e \mid e \in \mathcal{U}\}$ are defined according to the set in which they occur, as follows: Each element $e \in S_i$ is assigned a unique vector v^e from the set $\{x10^{m-i}\overline{x}01^{m-i} \mid x \in \{0,1\}^i\}$. The vectors $\{s^i \mid 1 \le i \le m-1\}$ and $\{t^0, t^1\}$ are defined as follows: $s^i = 1^i10^{m-i}1^i01^{m-i}$, $t^0 = 01^m1^{m+1}$, and $t^1 = 1^{m+1}01^m$. The set T_0 is defined as $\{e \in \mathcal{U} \mid v^e \le t^0\}$, and the set T_1 is defined as $\{e \in \mathcal{U} \mid v^e \le t^1\}$. It is easily verified that the sets $S_1, \ldots, S_{m-1}, T_0, T_1$ have the required structure: Namely, $S_1, \ldots, S_{m-1}$ are pairwise disjoint, S_i has size 2^i, and T_0 and T_1 are disjoint, each consisting of half of the elements from each of the sets

$S_1, \ldots, S_{m-1}$. Conditions (2) and (3) hold by definition, as does the "if" direction of condition (1). For the "only if" direction of (1), note that if $e \in S_j$ for $j \neq i$, then either bit $j+1$ or bit $(m+1)+(i+1)$ witnesses the fact that $v^e \not\leq s^i$.

The partial Boolean function f is defined as in the reduction from section 3.1: The ones of f are the vectors v^e for each $e \in \mathcal{U}$; the stars of f are those remaining inputs $\vec{x}$ such that $\vec{x} \leq s^i$ for some $1 \leq i \leq m-1$, or $\vec{x} \leq t^0$, or $\vec{x} \leq t^1$; and the remaining inputs are zeros. The following general lemma shows that the prime implicants of f, viewed as sets and considering only the ones of f that they cover, have exactly the same structure as the original set system.

LEMMA 5.1. *Let $\mathcal{S}$ be a set system over universe $\mathcal{U}$ such that no set in $\mathcal{S}$ contains another set in $\mathcal{S}$. Let $\{v^e \mid e \in \mathcal{U}\}$ and $\{w^S \mid S \in \mathcal{S}\}$ be sets of Boolean vectors such that the following condition holds for all $e \in \mathcal{U}$ and all $S \in \mathcal{S}$: $v^e \leq w^S$ iff $e \in S$. Let f be the function obtained from $\mathcal{S}$ as in Lemma* 3.1 *using the given vectors. Then the set of prime implicants of f is exactly $\{\tau(w^S) \mid S \in \mathcal{S}\}$.*

Proof. We first show that each term $\tau(w^S)$ is, indeed, a prime implicant of f. Suppose, on the contrary, that there is an implicant τ of f that subsumes $\tau(w^S)$ for some $S \in \mathcal{S}$. Note that all variables in τ are negated. Let $\vec{u}$ be a maximal truth assignment satisfying τ. Since $f(\vec{u}) = 1$, there is a set $S' \in \mathcal{S}$ such that $\vec{u} \leq w^{S'}$; that is, for each index i, if $w_i^{S'} = 0$, then $u_i = 0$. By our choice of $\vec{u}$ we have that $u_i = 0$ iff the literal $\neg x_i$ occurs in τ, and by definition $w_i^{S'} = 0$ iff the literal $\neg x_i$ occurs in $\tau(w_i^{S'})$. Thus for each index i, if the literal $\neg x_i$ occurs in $\tau(w^{S'})$, then it also occurs in τ. As both τ and $\tau(w^{S'})$ consist exclusively of negated literals, we have $\tau \implies \tau(w^{S'})$; since τ subsumes $\tau(w^S)$, we have

$$\tau(w^S) \implies \tau \implies \tau(w^{S'}).$$

For each $e \in U$, $e \in S \iff v^e \leq w^S$, and $v^e \leq w^S$ iff v^e satisfies $\tau(w^S)$. Thus,

$$e \in S \implies v^e \leq w^S \implies v^e \leq w^{S'} \implies e \in S'.$$

That is, $S \subseteq S'$, contradicting the assumption about $\mathcal{S}$.

We now show that every prime implicant of f is equal to $\tau(w^S)$ for some $S \in \mathcal{S}$. Let τ be a prime implicant of f, and let $\vec{u}$ be a maximal truth assignment satisfying τ. Then there exists $S \in \mathcal{S}$ such that $\vec{u} \leq w^S$, and thus $w_i^S = 0$ implies $u_i = 0$, and by the same argument as before we have that each literal $\neg x_i$ occurring in $\tau(w^S)$ also occurs in τ. It follows that $\tau = \tau(w^S)$. □

Lemma 5.1 implies that the prime implicants of f, viewed as sets, have exactly the same structure with respect to the ones of f as the original set collection has with respect to $\mathcal{U}$. It follows that the greedy algorithm finds a solution of size $m-1$, consisting of the terms $\tau(s^1) \wedge \cdots \wedge \tau(s^{m-1})$, while the optimal solution $\tau(t^0) \wedge \tau(t^1)$ has size two. As the instance has $n = 2m+2$ variables, the approximation ratio is $(m-1)/2 = (n-4)/4$.

5.2. Tight example for greedy on *Min-DNF*. We now extend the construction of the previous section to give an instance of *Min-DNF* for which the greedy algorithm achieves an approximation ratio of $\Omega(n) = \Omega(\log N)$. The instance is obtained by applying the reduction of section 4.2 to the function f from section 5.1. As in the proof of Lemma 4.7, we use $t(\vec{w})$ to denote the term $\left(\bigwedge_{i:w_i=1} w_i\right) \wedge \left(\bigwedge_{i:w_i=0} \neg w_i\right)$.

LEMMA 5.2. *Let $\mathcal{S}$ be a set of subsets of $[n]$, and let f be a partial Boolean function, such that $\mathcal{S}$ and f satisfy the conditions of Lemma* 3.1. *Let g be the total Boolean function obtained by applying the reduction from section* 4.2 *to f. Then the*

prime implicants of g consist of exactly the following: $\tau \wedge y_1 \wedge y_2 \wedge t(\vec{z})$, where τ is a prime implicant of f and $\vec{z} \in S$, and $t(\vec{x}) \wedge y_{2-p(\vec{x})}$, where $f(\vec{x}) = *$.

Proof. It is easy to verify that each term in the statement of the lemma is, indeed, a prime implicant of g, noting that every prime implicant τ of f must cover at least one vector in $f^{-1}(1)$, since each set in the original set system is nonempty.

We now argue that all prime implicants of g are of the above types. Let τ be an implicant of g: We will show that τ is subsumed by an implicant of one of the above two types. Let $\vec{x}y_1y_2\vec{z}$ be an assignment that satisfies τ. We first consider the case where $f(\vec{x}) = 1$. From the definition of g, it is clear that τ contains $t(\vec{z})$, y_1, and y_2, as flipping the corresponding bits of the assignment falsifies g. Moreover, the portion τ_x of τ containing x-variables is an implicant of f and is therefore subsumed by a prime implicant τ' of f. Thus $\tau' \wedge y_1 \wedge y_2 \wedge t(\vec{z})$ is an implicant of g and subsumes τ. Now consider the case where $f(\vec{x}) = *$, and assume without loss of generality that $\vec{x}$ has even parity. Then τ must contain y_2 and $t(\vec{x})$, as flipping any of these bits falsifies g, and thus τ is subsumed by $t(\vec{x}) \wedge y_2$. □

The inputs to g are of the form $\vec{x}y_1y_2\vec{z}$, where the length of $\vec{x}$ is n and the length of $\vec{z}$ is $t = n+1$. Each prime implicant of the second type in the statement of Lemma 5.2 covers 2^{t+1} ones of g, and the ones covered by these prime implicants are pairwise disjoint. The prime implicants of the first type each cover at most $2^{n-1} < 2^{t+1}$ ones of g. Thus the greedy algorithm begins by choosing all prime implicants of the second type. At this point, the prime implicants of the first type corresponding to different values of $\vec{z}$ cover disjoint subsets of the ones of g, so let us consider only a particular value of $\vec{z}$: The choices made by the greedy algorithm for other vectors $\vec{z}$ are independent of its behavior on this vector. Now the uncovered ones of g that are covered by a term $\tau \wedge y_1 \wedge y_2 \wedge t(\vec{z})$ are precisely those whose $\vec{x}$-component is a one of f, as the others are already covered by prime implicants of the second type. Thus the prime implicants of this type chosen by the greedy algorithm are exactly the set of prime implicants of the form $\tau \wedge y_1 \wedge y_2 \wedge t(\vec{z})$, where τ is a prime implicant that would be chosen by the greedy algorithm on input f. It follows that the greedy solution has size $s(m-1)+s = sm$, while the optimal solution has size $2s+s = 3s$. As the instance has $n = 2m+4+t$ variables, the approximation ratio is $m/3 = (n-t-4)/6 = \Omega(n)$.

6. Fixed parameter complexity. It is known that the decision problem "Given a truth table of a Boolean function f, and a number k, does f have a DNF with at most k terms?" can be solved in time $p(N, 2^{k^2})$, for some polynomial p, where N is the size of the truth table [22]. (This follows easily from the fact that if f is a Boolean formula that can be represented by a k-term DNF formula, then there exist at most 2^k prime implicants of f [12].) Thus, *Min-DNF* is *fixed parameter tractable* [17]. Moreover, because the size of the input truth table is $N = 2^n$, where n is the number of variables of f, it follows that *Min-DNF* is solvable in polynomial time for any $k = O(\sqrt{n})$.

It is an open question whether *Min-DNF* can be solved in polynomial time for $k = n$. But by applying a simple padding argument, we obtain the following corollary to the NP-completeness result for *Min-DNF*.

COROLLARY 6.1. *If there exists some constant $\epsilon > 0$ such that NP is not contained in DTIME$(2^{O(n^\epsilon)})$, then for some constant $c > 1$, Min-DNF for $k = n^c$ is not solvable in polynomial time (where n is the number of input variables of the Boolean function defined by the Min-DNF instance).*

Proof. Because *Min-DNF* is NP-complete, there exists a polynomial-time reduction from problems Π in NP to *Min-DNF*. If the input to Π is of size n, then the

input to the resulting *Min-DNF* problem will be a truth table of size $s = O(n^b)$ for some constant $b > 1$, defining a Boolean function on $\log s$ variables. The parameter k in the derived *Min-DNF* instance is no more than s, since for any truth table there is always a consistent DNF of size at most the size of the truth table. Let $c > 1$. Let $m = s^{\frac{1}{c}}$. Take the *Min-DNF* instance, and form a new *Min-DNF* instance by padding the function in the truth table with $m - \log s$ new dummy variables. Suppose *Min-DNF* is solvable in polynomial time when $k = n^c$, where n is the number of input variables of the Boolean function defined by the *Min-DNF* instance. Then the padded instance of *Min-DNF* can be solved in time polynomial in 2^m, and Π can be solved in time $2^{O(n^{\frac{b}{c}})}$, where n is the size of input to Π. For $c > \frac{b}{\epsilon}$, this is less than $2^{O(n^\epsilon)}$, a contradiction. □

7. *Min-DNF* and learning. One of the major problems in learning theory is to determine whether DNF formulas can be learned in polynomial time. There are connections between the complexity of *Min-DNF* and its fixed parameter versions, and the complexity of learning DNF formulas. This connection is strongest for "proper" learning models. In such models, any hypotheses used in the learning algorithm must be of the same type as the formulas being learned by the algorithm. Thus if the task is to learn DNF formulas, hypotheses must be DNF formulas. If the task is to learn k-term DNF formulas, then hypotheses must be k-term DNF formulas.

There has been a significant amount of research on learning k-term DNF formulas for small values of k in both proper and improper models (see, e.g., [8, 10, 27, 22, 34]). Pitt and Valiant showed that in the probably approximately correct (PAC) model, unless RP=NP one cannot learn k-term DNF formulas in polynomial time using hypotheses that are k-term DNF formulas (for constant k) [34]. Their proof actually shows that the consistency problem for k-term DNF is hard. This problem takes as input a partial Boolean function, specified by its 1's and 0's, and asks whether there is a k-term DNF formula consistent with those entries. The work of Pitt and Valiant was subsequently extended to obtain significantly stronger results on learning arbitrary length DNF formulas in the PAC learning model [2, 20]. We note that our reduction to *Min-DNF(*)* in fact implies that the consistency problem for k-term DNF is NP-hard for $k = n$, even when the underlying function depends on only $\log n$ of the n input variables (a $\log n$ "junta"); this in turn implies that proper PAC learning of n-term DNF formulas depending on $\log n$ of the n input variables is hard unless RP=NP.

Pillaipakkamnatt and Raghavan [33] showed that, for some $\epsilon < 1$ and some $c > 1$, $\log^c n$-term DNF cannot be learned in the membership and proper equivalence query model unless NP $\subseteq DTIME(2^{O(n^\epsilon)})$. Subsequently, Hellerstein and Raghavan proved that $\Omega(\log^{3+\epsilon} n)$-term DNF formulas cannot be learned in the same model; their proof involves a structural property of DNF formulas, and the result is without any assumptions [22]. (It can be improved to $\Omega(\log^{2+\epsilon})$.) It is open, however, whether $\log n$-term DNF formulas can be learned in polynomial time in this model; $\sqrt{\log n}$-term DNF can be so learned [10].

A polynomial-time algorithm for learning $\log n$-term DNF formulas in the membership and proper equivalence query model (i.e., with hypotheses that are $\log n$-term DNF formulas) would imply a polynomial-time algorithm for *Min-DNF* for $k = n$ [22]. The same proof shows that, for constant c, a polynomial-time algorithm for learning $\log^c n$-term DNF formulas would imply a polynomial-time algorithm for *Min-DNF* for $k = n^c$. It follows that the result of [33] mentioned above can also be derived from Corollary 6.1.

The relation between truth table minimization and learning with membership and equivalence queries relies on the following observation: Given a truth table representing a function f, one can simulate a membership and equivalence query algorithm for learning (a hypothesis representing) f by using the truth table to answer the queries. Feldman observed that one can also use the truth table of f to generate uniformly distributed examples of f. Combining this observation with the hardness of approximating *Min-DNF*, he showed hardness of proper PAC learning of min-DNF under the uniform distribution, with membership queries. More specifically, he showed that for some $\gamma > 0$, unless P=NP, there is no polynomial-time algorithm that PAC learns DNF formulas under the uniform distribution using hypotheses that are DNF formulas of size at most n^γ larger than the function being learned, even if membership queries are allowed [20].

8. Hardness of *Min-*AC^0_d. In this section we consider the problem of estimating *Min-*$AC^0_d(f)$, the size of the smallest AC^0_d circuit for f, given as input its $N(= 2^n)$-bit truth table. In [4] it was shown that neither *Min-Circuit*(f) (the size of the smallest circuit) nor *Min-*$NC^1(f)$ (the size of the smallest NC^1 circuit) can be approximated to within a factor of $N^{1-\epsilon}$ in polynomial time unless Blum integers can be factored in probabilistic polynomial time. Here we prove an analogous result for *Min-*AC^0.

We consider algorithms that produce an estimate that is at least *Min-*$AC^0_d(f)$ (e.g., algorithms that actually produce a circuit C for f and output the size of C). We say that such an algorithm is a $\lambda(N)$-approximation algorithm if the output is no more than $\lambda(N)$ *Min-*$AC^0_d(f)$. Since for each $d \geq 2$, every n-variate Boolean function f satisfies $1 \leq$ *Min-*$AC^0_d(f) \leq nN$, there is a trivial nN-approximation algorithm. In this section, we show that for any $\epsilon > 0$ there is a $d(\epsilon)$ such that there is no polynomial time $O(N^{1-\delta})$-approximation for *Min-*$AC^0_d(f)$ for any $\delta > 0$, unless m-bit Blum integers can be factored in probabilistic time 2^{m^ϵ}. We have not computed the relationship between d and ϵ, but we anticipate that this yields a meaningful inapproximability result for d as small as 10.

The proof of this inapproximability result follows along similar lines as the related results in [4]. In those proofs, the pseudorandom function generator of Naor and Reingold is used, which has the nice property that it can be computed in TC^0_d for some d. Any test that can distinguish random functions from functions generated by this generator can be used to factor Blum integers. A good approximation of TC^0_d circuit size can be used to distinguish pseudorandom and random functions, since random functions require circuits of exponential size, whereas the pseudorandom functions produced by the generator have small TC^0_d circuits. One more ingredient is still needed, in order to obtain inapproximability results for *Min-*AC^0_d. This ingredient is provided by Lemma 8.1, which shows that any function with small TC^0 circuits has "relatively small" AC^0 circuits. (This property extends even to complexity classes seemingly much larger than TC^0.) Taken together, this means that a good approximation to AC^0_d circuit size yields a good enough approximation to $TC^0_{d'}$ circuit size to yield subexponential upper bounds on the complexity of factoring Blum integers.

Because of the way the various parameters involved interact, we see no simple way to present the approximability result by merely appealing to results in [4]. Thus, we present the entire proof below. First, we show that everything in nondeterministic logspace (NL) has AC^0 circuits of subexponential size.

LEMMA 8.1. *For every language $\mathcal{L}$ in NL, and for every ϵ, there exists a d such that there are AC^0_d circuits of size 2^{n^ϵ} that recognize $\mathcal{L}$.*

Proof. Consider an NL machine M running in time $m = n^c$. On input x, we want to find out if M has an accepting path on x. To find an accepting path, it is sufficient to see if there is a sequence of $\sqrt{m}$ configurations of M $C_1, \ldots, C_{\sqrt{m}}$, where C_1 is the initial configuration of M on input x and $C_{\sqrt{m}}$ is the accepting configuration, with the property that for $1 \leq i < \sqrt{m}$ there is a computation path of length $\sqrt{m}$ from C_i to C_{i+1}. We view the configurations C_i as "checkpoints" along the computation path. This approach to finding an accepting path is straightforward to implement using a depth-three AC^0 circuit of size $2^{O(\sqrt{m}\log m)}$.

If the number of checkpoints chosen is $m^{1/3}$ instead of $\sqrt{m}$, then a similar strategy leads to a depth-five circuit of size $2^{O(m^{1/3}\log m)}$. That is, the top level of the depth-five circuit is an OR (over all of the $2^{O(m^{1/3}\log m)}$ sequences S of checkpoints) of the AND that each of the $m^{1/3} - 1$ pairs of adjacent checkpoints in S is connected by a path of length $m^{2/3}$. This latter condition can be checked by an OR over another $2^{O(m^{1/3}\log m)}$ sequences S' of $m^{1/3}$ checkpoints, of an AND that each of the $m^{1/3} - 1$ pairs of adjacent checkpoints in S' is connected by a path of length $m^{1/3}$. Since the input head of M can move only a distance of $m^{1/3}$ in $m^{1/3}$ steps, and each checkpoint specifies the position of the input head, the condition that a given pair of checkpoints is connected by a path of length $m^{1/3}$ depends only on $m^{1/3}$ input variables, namely, those centered around the two input head positions specified by the checkpoints. Thus this condition can be expressed by a CNF formula of size exponential in $m^{1/3}$. (The depth can be optimized somewhat, using closure under complement and merging adjacent layers—but we ignore such issues for now.)

Notice that, by increasing the depth from three to five and decreasing the number of checkpoints from $\sqrt{m}$ to $m^{1/3}$, one is able to obtain smaller circuits. Iterating the above idea gives depth-d AC^0 circuits of size 2^{n^ϵ}. This is basically a strengthening of Nepomnjaščiĭ's theorem [5, 32]. (The same claim, with an identical proof, holds for any language accepted by a nondeterministic machine running in polynomial time and using space $n^{o(1)}$. In particular, it holds for the complexity class LogCFL.) □

DEFINITION 8.2. *An integer M is called a Blum integer if $M = PQ$, where P and Q are two primes such that $P \equiv Q \equiv 3 \mod 4$. The Blum integer factorization problem is as follows. Given a Blum integer M, find the primes P and Q such that $1 < P \leq Q$ and $M = PQ$.*

THEOREM 8.3. *For every $\delta > 0$ and $\epsilon > 0$ there is a depth d such that if $\mathcal{B}$ is an algorithm that approximates Min-AC^0_d to within a factor of $N^{1-\delta}$ (where $N = 2^n$ is the size of the input truth table), then Blum integer factorization is in BPTIME$(2^{m^\epsilon})^{\mathcal{B}}$ (where m is the number of bits of the integer to be factored).*

Proof. We follow the proof given in [4]. In [31] a pseudorandom function ensemble $\{f_{M,r}(x) : \{0,1\}^n \to \{0,1\}\}_{M,r}$ is constructed with the following two properties:

- There is a polynomial size TC^0 circuit computing $f_{M,r}(x)$, given an $m = 2n$ bit integer M, a $4n^2 + 2n$-bit string r, and an n-bit string x. This means that there is a constant d' such that for each n there is a depth-d' threshold circuit of size at most $n^{d'}$ that takes as input M, r, x and outputs $f_{M,r}(x)$.
- For every probabilistic Turing machine $\mathcal{M}$ running in time $t(n)$ with oracle access to $f_{M,r}$ of query length n, there exists a probabilistic Turing machine $\mathcal{A}$ running in time $t(n)n^{O(1)}$ such that for every $2n$-bit Blum integer $M = PQ$, if $|Pr[\mathcal{M}^{f_{M,r}}(M) = 1] - Pr[\mathcal{M}^{R_n}(M) = 1]| > 1/2$, where R_n is a uniformly distributed random function ensemble, and the probability is taken over random r and random bits of $\mathcal{M}$, then $Pr[\mathcal{A}(M) = (P, Q)] > 1/2$. In other words, if $\mathcal{M}$ can distinguish the pseudorandom function ensemble from

a truly random function "efficiently," then Blum integers can be factored "efficiently" on a probabilistic machine.

Let $\delta > 0$ and $\epsilon > 0$ be given as in the theorem. Let $q = n^\epsilon$ and $Q = 2^q$. By the first property of the ensemble together with Lemma 8.1, there is a d such that for each sufficiently large n there is a depth-d AC^0 circuit that takes as input M, r, x and outputs $f_{M,r}(x)$ and has size at most $2^{n^{\epsilon/2}}$; for n sufficiently large this quantity is at most $Q^{\delta/2}$. In particular, for each choice of $M \in \{0,1\}^{2n}$ and $r \in \{0,1\}^{4n^2+2n}$, we can hardwire the values of M and r to get a circuit of size at most $Q^{\delta/2}$ for the function $f_{M,r}$.

For $y \in \{0,1\}^q$ let $\tilde{y} \in \{0,1\}^n$ be the concatentation of y with 0^{n-q}. For any function h defined on $\{0,1\}^n$, let $\tilde{h}$ be the function defined on $\{0,1\}^q$ by $\tilde{h}(y) = h(\tilde{y})$.

Suppose that $\mathcal{B}$ is a function as in the hypothesis of the theorem. We now construct an oracle Turing machine $\mathcal{M}$ which takes as input a $2n$-bit integer M and has oracle access to $\mathcal{B}$ and to an n-variate Boolean function g and reliably distinguishes the case that $g = f_{M,r}$ from the case that g is truly random. By the second property of the pseudorandom function generator $f_{M,r}$, when M is a Blum integer, this will be enough to factor M.

On input N, $\mathcal{M}$ queries $g(\tilde{y})$ for all $y \in \{0,1\}^{n^q}$, thus constructing the truth table for $\tilde{g}$ (of size Q). $\mathcal{M}$ then submits the truth table of $\tilde{g}$ to the approximation algorithm $\mathcal{B}$ and accepts iff the approximate circuit size for $\tilde{g}$ returned by $\mathcal{B}$ is greater than $Q^{1-\delta/2}$.

Now assume that the answer returned by $\mathcal{B}$ is within a $Q^{1-\delta}$ factor of the true answer. If $g = f_{M,r}$, then g (and therefore $\tilde{g}$) has a circuit of size at most $Q^{\delta/2}$, and so $\mathcal{B}$ always returns a value less than $Q^{\delta/2}Q^{1-\delta} = Q^{1-\delta/2}$ and $\mathcal{M}$ rejects. On the other hand, if g is taken uniformly at random from $\mathcal{R}_n$, then the distribution of $\tilde{g}$ is uniformly random from $\mathcal{R}_q$ and thus with extremely high probability requires AC^0_d circuits of size $Q/q > Q^{1-\delta/2}$ (since most functions require circuits of this size), and this condition causes $\mathcal{M}$ to accept. Hence $|Pr[\mathcal{M}^{f_{M,r}(x)}(M) = 1] - Pr[\mathcal{M}^{R_n}(M) = 1]| > 1/2$ for sufficiently large n. Thus, $\mathcal{M}$ can distinguish the pseudorandom function ensemble from a truly random one with probability greater than $1/2$, and thus Blum integers can be efficiently factored probabilistically. □

COROLLARY 8.4. *For all $\delta > 0$ and all $\epsilon > 0$ there exists a d such that Min-AC^0_d cannot be approximated to within a factor $n^{1-\delta}$ in BPP unless Blum integer factorization is in BPTIME(2^{n^ϵ}).*

9. Discussion. There are close connections between the hardness of function minimization problems and related learnability results. In addition to the connections discussed above in section 6, we mention two others: The complexity of *Min-DNF*(DNF) and of approximating *Min-DNF*(DNF) has been shown to be related to the problem of learning DNF with proper membership and equivalence queries [11, 22, 1], and results on learning circuits [9] yield positive results for approximating circuit minimization (cf. [39]). At a basic level, learning a formula or circuit involves gathering information about it and then synthesizing or compressing that information to produce a compact hypothesis. The need for compactness provides the connection to minimization. In many learning problems one can distinguish between informational complexity (the number of queries or sample size needed) and computational complexity (the amount of computation needed to process the information). Information about a formula or circuit typically consists just of input/output pairs. Truth table minimization problems are relevant to the computational hardness of learning; even if you have all input/output pairs, the question is whether you can compact that information in polynomial time.

The NP-hardness of proper PAC learning DNF and of *Min-DNF* are known. On the other hand, very strong inapproximability results are known for both proper PAC learning and the function minimization problem for complexity classes starting at AC^0. However, these latter results rely on cryptographic assumptions and are not known to hold under NP-hardness assumptions. Thus an important open question is to resolve the NP-hardness of both learnability results as well as function minimization results above for classes that are stronger than DNF.

Another open problem is to close the approximability gap for *Min-DNF*.

Appendix A. Reduction from *r-Uniform Set Cover*. The following lemma describes a modified version of the reduction given in section 3.1. Whereas the reduction in that section is from 3-*Partite Set Cover*, the reduction here is from *r-Uniform Set Cover* (all sets in the input set cover instance are of size r). Because the reduction here is not from a partite version of *Set Cover*, it requires different techniques than the reduction in section 3.1.

LEMMA A.1. *There is an algorithm that takes as input an r-uniform collection of subsets $\mathcal{S}$ over $[n]$ and produces the truth table of a partial Boolean function f such that the minimum size of a cover of $[n]$ with $\mathcal{S}$ is equal to the minimum number of terms in a DNF consistent with f. The algorithm runs in time $(n|\mathcal{S}|)^{O(r)}$, and the number of variables of f is $O(r \log(n|\mathcal{S}|))$.*

Proof. Let the r-uniform collection $\mathcal{S}$ over $[n]$ be given.

As in the proof of Lemma 3.2, we produce two indexed sets of vectors $V = \{v^i : i \in [n]\}$ and $W = \{w^A : A \in \mathcal{S}\}$ of length t satisfying the property $(*)$ that, for all $A \in \mathcal{S}$ and $i \in [n]$, $i \in A$ iff $v^i \leq w^A$. Again, we specify V and then define W according to the rule that, for $A \in \mathcal{S}$, w^A is the bitwise OR of $\{v^i : i \in A\}$. The construction of partial function f, given V and W, is then the same as in the proof of Lemma 3.2, and again it follows that the size of the minimum DNF consistent with f is equal to the size of the minimum cover of $[n]$ by $\mathcal{S}$.

We now describe the construction of V. Let P be the set of pairs (j, A), with $A \in \mathcal{S}$ and $j \in [n] - A$. The desired conditions on V can be restated as specifying that for all $(j, A) \in P$:

> $C(j, A)$: There is a bit position $\alpha \in [t]$ such that $v^j_\alpha = 1$ and $v^i_\alpha = 0$ for all $i \in A$.

If we choose $v^1, \ldots, v^n$ of length t at random where each bit is 1 independently with probability $1/r$, then for each $(j, A) \in P$ the probability that $C(j, A)$ does not hold is $(1 - \frac{1}{r}(1 - \frac{1}{r})^r)^t \leq e^{-t/3r}$, so the probability that $v^1, \ldots, v^r$ fails to meet the requirements is at most $|P|e^{-t/3r} \leq |\mathcal{S}|ne^{-t/3r}$. Thus if $t \geq 3r(1 + \ln(|\mathcal{S}|n))$, this random choice succeeds with probability more than $1/2$. This is enough for a randomized reduction. To make it deterministic, we derandomize this construction using the method of conditional probabilities (see, e.g., [7]). This is routine but technical, so we provide only a sketch. Let $X(j, A)$ be the random variable that is 1 if $C(j, A)$ fails. We want to choose $v^1, \ldots, v^r$ so that $X = \sum_{(j,A)\in P} X(j, A) = 0$. The above argument says that under random choice $\mathbf{Exp}[X] \leq 1/2$. The key point for derandomizing is that if we fix any subset of the bits in $v^1, \ldots, v^r$, then it is straightforward to compute the conditional expectation of X given this fixing in time $(|\mathcal{S}|n)^{O(1)})$. We can then use the method of conditional probabilities to fix these bits one at a time by always choosing the value of the bit that does not increase the expectation. Once all bits are fixed, we must have a good choice for V.

Clearly V and W can be constructed in time $(n|\mathcal{S}|)^{O(1)}$, with $t = O(r \log (n|\mathcal{S}|))$. Since the truth table has size 2^t, outputting it takes time $(n|\mathcal{S}|)^{O(r)}$. □

Combining the above reduction with the modified reduction from *Min-DNF(*)* to *Min-DNF* in section 4.2 yields a reduction from *r-Uniform Set Cover* to *Min-DNF*. By setting $r = \log N$, where N is the truth table size, one can then apply inapproximability results for *r-Uniform Set Cover* [19, 38] to show that *Min-DNF* cannot be approximated to within a factor of $\Omega(\log \log N)$ in polynomial time unless NP is in randomized quasi-polynomial time.

Acknowledgments. The authors gratefully acknowledge Uri Feige and Subhash Khot for helpful conversations on the inapproximability of partite restrictions of set cover. We thank the referees for their insightful comments.

UNIFORM HASHING IN CONSTANT TIME AND OPTIMAL SPACE*

ANNA PAGH† AND RASMUS PAGH†

Abstract. Many algorithms and data structures employing hashing have been analyzed under the *uniform hashing* assumption, i.e., the assumption that hash functions behave like truly random functions. Starting with the discovery of universal hash functions, many researchers have studied to what extent this theoretical ideal can be realized by hash functions that do not take up too much space and can be evaluated quickly. In this paper we present an almost ideal solution to this problem: a hash function $h : U \to V$ that, on any set of n inputs, behaves like a truly random function with high probability, can be evaluated in constant time on a RAM and can be stored in $(1+\epsilon)n \lg |V| + O(n + \lg \lg |U|)$ bits. Here ϵ can be chosen to be any positive constant, so this essentially matches the entropy lower bound. For many hashing schemes this is the first hash function that makes their uniform hashing analysis come true, with high probability, without incurring overhead in time or space.

Key words. hash function, uniform hashing, randomized algorithms

1. Introduction.

Hashing is an important tool in randomized algorithms and data structures, with applications in such diverse fields as information retrieval, complexity theory, data mining, cryptology, and parallel algorithms. Many algorithms using hashing have been analyzed under the assumption of *uniform hashing*, i.e., the idealized assumption that the hash function employed is a truly random function. In this paper we present a theoretical justification for such analyses, in the form of the construction of a hash function that makes the uniform hashing assumption "come true" with high probability. Our hash function can be evaluated in constant time on a RAM, and its description uses very close to the minimum possible space.

1.1. History.

According to Knuth [16], the idea of hashing was originated in 1953 by H. P. Luhn. The basic idea is to use a function $h : U \to V$, called a *hash function*, that "mimics" a random function. In this way a "random" value $h(x)$ can be associated with each element from the domain U. In this paper, as in most other hash function constructions, we consider a universe of the form $U = \{0, \ldots, u-1\}$ and a range of the form $V = \{0, \ldots, v-1\}$, where $1 < v \leq u$.

Representation of a random function requires $u \lg v$ bits, so it is usually not feasible to actually store a randomly chosen function. For many years hashing was largely a heuristic, and practitioners used fixed functions that were empirically found to work well in cases where uniform hashing could be shown to work well.

The gap between hashing algorithms and their analysis narrowed with the advent of *universal hashing* [6]. The key insight was that it is often possible to get provable performance guarantees by choosing hash functions at random from a small family of functions (rather than from the family of all functions). The importance of the family being small is, of course, that a function from the family can be stored succinctly.

*Received by the editors April 28, 2006; accepted for publication (in revised form) September 19, 2007; published electronically March 28, 2008. A preliminary version of this paper appeared at Symposium on Theory of Computation (STOC), 2003. This work was completed in part while the authors were at BRICS, Department of Computer Science, University of Aarhus, Denmark.

Hash functions are usually chosen uniformly at random from some *family* $\mathcal{H}$ of hash functions. For example, the family

$$\{x \mapsto ((ax+b) \bmod p) \bmod v \mid 0 < a < p,\, 0 \le b < p\},$$

first studied by Carter and Wegman [6], has many known applications. The family is described by the parameters p and v, while a particular function in the family is given by the values of parameters a and b. In our results, we will distinguish between the space needed to represent the family and the space needed to represent a function in the family.

One property of the choice of hash function that often suffices to give performance guarantees is that it maps each set of k elements in U to uniformly random and independent values, where k is some parameter that depends on the application. If this holds for a random function from a family $\mathcal{H}$, we say that $\mathcal{H}$ is *k-wise independent*. There exist such function families whose functions can be stored in $O(k \lg u)$ bits of space [25]. For many years, all known k-wise independent families with nontrivial space usage required time $\Omega(k)$ for evaluating a hash function. A breakthrough was made by Siegel [23], who showed that high independence is achievable with relatively small families of hash functions that can be evaluated in *constant* time on a RAM.

The *RAM model* used in Siegel's result, as well as in this paper, is a standard unit cost RAM with an instruction set that includes multiplication, and a word size of $\Theta(\lg u)$ bits. The RAM has access to a source of random bits, and in particular we assume that a random value in V and a random word can be generated in constant time.

The two main performance parameters of a hash function family is the space needed to represent a function and the time necessary to compute a given function value from a representation. A tight bound on the number of bits needed to achieve k-wise independence is $\Theta(k \lg u)$ bits [3, 7]. Sometimes there is a trade-off between the space used to represent a function and its evaluation time. For example, Siegel [23] shows that if $u = k^{1+\Omega(1)}$, it is necessary to use $k^{1+\Omega(1)} \lg v$ bits of space to achieve constant evaluation time.

Siegel's construction of a k-wise independent family comes close to this lower bound (see Theorem 3). If one applies this family with $k = n$ to a set S of n elements, it will map these to independent and uniformly random values. We say that it is *uniform on S*. However, the space usage is superlinear meaning that, in many possible applications, the hash function description itself becomes asymptotically larger than all other parts of the data structure.

1.2. Our result. In this paper we present a family of hash functions that has the same performance as Siegel's family on any *particular* set of n elements and space usage close to the lower bound of $n \lg v + \lg \lg_v u$ bits shown in section 5. The previously best construction using $O(n \lg v + \lg \lg u)$ space is based on evaluation of a degree $n-1$ polynomial over a finite field and has $\Omega(n)$ evaluation time.

THEOREM 1. *Let $S \subseteq U = \{0, \ldots, u-1\}$ be a set of $n > 1$ elements. For any constants $c > 0$ and $\epsilon > 0$, and for $1 < v < u$, there is a RAM algorithm that, using time $\lg n (\lg v)^{O(1)}$ and $O(\lg n + \lg \lg u)$ bits of space, selects a family $\mathcal{H}$ of functions from U to $V = \{0, \ldots, v-1\}$ (independent of S) such that*

- *$\mathcal{H}$ is k-wise independent when restricted to S, with probability $1 - O(\frac{1}{n^c})$.*
- *A function in $\mathcal{H}$ can be represented by a RAM data structure using space $(1+\epsilon) n \lg v + O(n)$ bits such that function values can be computed in constant time. The data structure of a random function in $\mathcal{H}$ can be constructed in time $O(n)$.*

As our hash functions are optimal with respect to evaluation time and essentially optimal with respect to space usage, the only possible significant improvement would be an error probability that decreases more rapidly with n. Such a result could possibly be achieved for $u = n^{O(1)}$ by explicit constructions of certain expanders in Siegel's hash function construction.

Techniques. Our main technical ingredient is to use the two-choice paradigm [4] that has recently found a number of applications in load balancing and data structures. The central fact we make use of is that if we associate, using hashing, two memory locations in a linear size array with every element of the set S, then with high probability (whp.) there exists a way of associating keys with unique memory locations [19]. Essentially, each key gets the independence of its hash value from random bits at the memory location with which it is associated. A complication is that one needs to take care of cyclic dependencies that may arise, but this involves only a logarithmic number of elements, whp. The solution is to add a hash function that is independent (whp.) on the set of problematic elements.

Perspective. It should be noted that a data structure with slightly different functionality is very easy to construct: use a high performance dictionary such as the one in [9] to store elements from U and associated "hash values" from V. When a new function value is needed, it is randomly generated "on the fly" and stored with the element in the dictionary. The space needed for this is $O(n(\lg u + \lg v))$ bits, which is a constant factor from the space usage achieved by our data structure if $u = v^{O(1)}$. The main difference between this and the data structure of Theorem 1 is that our hash function can be generated once and for all, after which it may be used without any need for random bits. This also means that our hash function may be distributed and used by many parties without any need for additional communication. Another distinguishing feature is that our hash function will be uniform with high probability on *each* of $n^{O(1)}$ sets of size n. Thus it may be shared among many independently running algorithms or data structures.

1.3. Implications. The fact that the space usage of our hash function is linear in n means that a large class of hashing schemes can be implemented to perform, with high probability, *exactly as if uniform hashing was used*, increasing space by at most a constant factor. This means that our family makes a large number of analyses performed under the uniform hashing assumption come true with high probability.

Two comprehensive surveys of early data structures analyzed under the uniform hashing assumption can be found in the monographs of Gonnet [13] and Knuth [16]. Gonnet provides more than 100 references to books, surveys, and papers dealing with the analysis of classic hashing algorithms. This large body of work has made the characteristics of these schemes very well understood, under the uniform hashing assumption. As the classic hashing algorithms are often very simple to implement, and efficient in practice, they seem to be more commonly used in practice than newer schemes with provably good behavior. While our family may not be of practical importance for these hashing schemes, it does provide a theoretical bridge justifying the uniform hashing assumption for a large class of them. Previously, such justifications have been made for much more narrow classes of hashing schemes and have dealt only with certain performance parameters (see, e.g., [20, 21]). More details on applications of our scheme in hashing data structures can be found in the conference version of this paper [17].

In addition to the classic hashing schemes, our result provides the first provably efficient hashing based implementation of load balancing schemes of Azar et al. [4] and

Vöcking [24]. The fact that hash functions can be used to perform the random choices in these algorithms means that it is possible to retrace any previous load balancing decision by checking a small number of possible choices.

Finally, our construction has an application in cryptography, where it "derandomizes" a construction of Bellare, Goldreich, and Krawczyk [5] for the most important parameters. (See the discussion in section 3.1.1.)

1.4. Overview of the paper. The organization of the paper is as follows. In section 2 we provide the background information necessary to understand our construction. Specifically, we survey Siegel's construction, which will play an important role. Section 3 presents our initial construction, which achieves space that is within a constant factor of optimal. Section 4 shows, by a general reduction, how to reduce the space to (essentially) $1+\epsilon$ times the space lower bound shown in section 5.

2. Background. Theorem 1 can be seen as an improvement of Siegel's family of high performance hash functions [23]. The motivation for Siegel's work was that many algorithms employing hashing can be shown to work well if the hash functions are chosen at random from a *k-wise independent* family of functions, for suitably large k.

DEFINITION 1. *A family $\mathcal{H}$ of functions from U to V is* k-wise independent *if, for any distinct elements $x_1, \ldots, x_k \in U$, and any $y_1, \ldots, y_k \in V$, when $h \in \mathcal{H}$ is chosen uniformly at random,*

$$\Pr[h(x_1) = y_1 \wedge \cdots \wedge h(x_k) = y_k] = |V|^{-k}.$$

In other words, a random function from a k-wise independent family acts like a truly random function on any set of k elements of U. We note that several relaxed notions of k-wise independence exist, e.g., the notion of (c,k)-universality [8]. However, we don't know of any data structures in the literature that allow evaluation of a function from a (c,k)-universal (or similar) family in time $o(k)$, except for those achieving k-wise independence.

Siegel's construction. Siegel showed that for arbitrary constants $c > 0$ and $\epsilon > 0$ it is possible to construct, using $O(u^{\sqrt{\lg k/\lg u}+\epsilon} \lg v)$ bits of space, a family of functions from U to V with the following properties:

- It is k-wise independent with probability at least $1 - u^{-c}$.
- There is a RAM data structure of $O(u^{\sqrt{\lg k/\lg u}+\epsilon} \lg v)$ bits representing its functions such that function values can be computed in constant time.

Siegel mainly considered the case $k = u^{o(1)}$, e.g., $k = O(\lg u)$, where the space usage is dominated by the u^ϵ term. The positive probability that the family is not k-wise independent is due to the fact that Siegel's construction relies on a certain type of expander graph that, in lack of an explicit construction, is found by selecting a graph at random (and storing it). However, there is a small chance that the randomly chosen graph is not the desired expander, in which case there is no guarantee on the performance of the family. Also, there seems to be no known efficient way of generating a graph at random and verifying that it is the desired expander. (However, a slightly different class of expanders can be efficiently generated in this way [2].)

Space lower bound. It is inevitable that the space usage grows with u when constant evaluation time is required. Siegel shows the following trade-off between evaluation time and the size of the data structure.

THEOREM 2 (see Siegel [23]). *Consider any k-wise independent family $\mathcal{H}$ of functions from U to V and any RAM data structure using m words of $O(\lg v)$ bits to*

represent a function from $\mathcal{H}$. Then there exists $h \in \mathcal{H}$ and $x \in U$ such that the data structure for h requires time $\Omega(\min(\lg_{m/k}(u/k), k))$ on input x.

Note that when using optimal space, i.e., $m = O(k)$, the time needed to evaluate a function is $\Omega(\min(\lg(u/k), k))$.

Applying domain reduction. Theorem 2 establishes that high independence requires either high evaluation time or high space usage when u is large. A standard way of getting around problems with hashing from a large domain is to first perform a *domain reduction*, where elements of U are mapped to elements of a smaller domain U' using universal hashing. As this mapping cannot be 1-1, the domain reduction forces some hash function values to be identical. However, for any particular set S of n elements, the probability of two elements in S mapping to the same element of U' is $O(n^{-c})$ if $|U'| \geq n^{c+2}$. One universal family, suggested implicitly in [12] and explicitly in [18], uses primes in a certain range. A function from the family can be generated in expected time $(\lg|U'| + \lg\lg u)^{O(1)}$ and stored in $O(\lg|U'| + \lg\lg u)$ bits. Another universal family [8] has functions that can be generated in constant time and stored in $O(\lg u)$ bits. Both families support constant time evaluation of functions. In the following we will state all results using the former universal family, obtaining the smallest possible space at the cost of a modest amount of precomputation.

Using domain reduction with Siegel's family described above, one gets the following result. For $k = n$ it is similar to our main theorem, the main difference being that the space usage is superlinear.

THEOREM 3 (see Siegel [23]). *Let $S \subseteq U = \{0, \ldots, u-1\}$ be a set of n elements. For any constants $\epsilon > 0$ and $c > 0$ there is a RAM algorithm constructing a random family $\mathcal{SI}(U, V, k, n, c, \epsilon)$ of functions from U to $V = \{0, \ldots, v-1\}$ in expected time $O(s) + (\lg\lg u)^{O(1)}$ and $O(s \lg v + \lg\lg u)$ bits of space, where $s = n^{\sqrt{(c+2)\lg k / \lg n} + \epsilon}$, such that.*

- *With probability $1 - O(\frac{1}{n^c})$ the family is k-wise independent when restricted to S.*
- *There is a RAM data structure of $O(s \lg v + \lg\lg u)$ bits representing its functions such that function values can be computed in constant time. The data structure can be initialized to a random function in time $O(s)$.*

Notice that the space usage is $\omega(k^{\sqrt{2}})$ bits for all parameters, so it is truly superlinear in k. With currently known ways of constructing expanders, Siegel's hash function family exhibits high constant factors.

Other constructions. Other proposals for high-performance hash functions, due to Dietzfelbinger and Meyer auf der Heide [9, 10], appear more practical than Siegel's. However, these families only exhibit $O(1)$-wise independence and are difficult to analyze in general.

Dietzfelbinger and Woelfel [11] have analyzed a family similar to the abovementioned high-performance hash functions and showed that it may be used for hashing schemes whose analysis rests on a bipartite graph defined by a pair of hash functions. In particular, they are able to give an alternative to our initial uniform hashing construction, described in section 3, that is likely to be more practical. However, their construction restricts the size v of the range to be a prime number.

3. Initial hash function construction. In this section we describe a hash function family with properties as stated in Theorem 1 for *some* constant $\epsilon > 0$. In section 4 we will extend this to show Theorem 1 (where ϵ can be any positive constant). We use the notation $T[i]$ to denote the ith entry in an array T. By $[m]$ we denote the set $\{0, \ldots, m-1\}$.

3.1. The hash function family. We start with a definition.

DEFINITION 2. *Let $\mathcal{G}$ be a family of functions from U to V, and consider functions $i_1, i_2 : U \to [m]$. We define the family of functions*

$$\mathcal{H}(i_1, i_2, \mathcal{G}) = \{x \mapsto (T_1[i_1(x)] + T_2[i_2(x)] + g(x)) \bmod v \mid T_1, T_2 \in V^m \text{ and } g \in \mathcal{G}\}.$$

The hash function family considered in this section uses Siegel's construction of function families to get the functions i_1 and i_2, as well as the family $\mathcal{G}$ in the above definition.

DEFINITION 3. *For $n \leq u$ and any constant $c > 0$ we define the random family $\mathcal{H}_{n,c} = \mathcal{H}(i_1, i_2, \mathcal{G})$ of functions as follows. Let $k = \lceil n^{1/(2c+4)} \rceil$ and construct the random families*

$$\mathcal{G} = \mathcal{SI}(U, V, k, n, c, 1/4) \text{ and}$$
$$\mathcal{F} = \mathcal{SI}(U, [4n], k, n, c, 1/4)$$

according to Theorem 3. Pick i_1 and i_2 independently at random from $\mathcal{F}$.

3.1.1. Related constructions. A similar way of constructing a function family was presented in [9]. The essential change in the above definition compared to [9] is that we look up *two* values in tables, rather than just one.

The technique of using multiple lookups in a random (or pseudorandom) table to produce a new random value has previously been used in cryptography by Bellare, Goldreich, and Krawczyk [5] in connection with stateless evaluation of pseudorandom functions. The construction given in this paper is strictly more general that the one in [5] as we get a random *function* rather than just a way of generating random values. Also, function evaluation is deterministic, whereas the generation procedure in [5] is randomized. Our analysis is completely different from the one in [5].

On the other hand, our analysis shares some features with the analysis of cuckoo hashing in [19], as it rests on the analysis of the same random bipartite graph (generated by Siegel's hash functions). In fact, Dietzfelbinger and Woelfel show in [11] how to base uniform hashing (with range of size that is a prime number) on any hash function that works with cuckoo hashing.

3.2. Properties of the family. For two functions $i_1, i_2 : U \to [m]$ and a set $S \subseteq U$, let $G(i_1, i_2, S) = (A, B, E)$ be the bipartite graph that has left vertex set $A = \{a_1, \ldots, a_m\}$, right vertex set $B = \{b_1, \ldots, b_m\}$, and edge set

$$E = \{e_x \mid x \in S\}, \text{ where } e_x = (a_{i_1(x)}, b_{i_2(x)}).$$

We consider the edge e_x to be labeled by x. Note that there may be parallel edges with different labels.

We define a *leafless subgraph* $E' \subseteq E$ of a graph as a subset of the edges such that there is no vertex incident to exactly one edge in E'. A graph's *leafless part* $C \subseteq E$ consists of the edges that are on a cycle and the edges that are on a path connecting two cycles. (This is also known as the 2-core.)

LEMMA 1. *Let $S \subseteq U$ be a set of n elements and let $\mathcal{G}$ be a family of functions from U to V that is k-wise independent on S. If the total number of edges in the leafless part of $G(i_1, i_2, S) = (A, B, E)$ is at most k, then $\mathcal{H}(i_1, i_2, \mathcal{G})$ is uniform when restricted to S.*

Proof. Let S' be the set of all elements $x \in S$, where the edge e_x with label x is in the leafless part C of $G(i_1, i_2, S)$.

The proof is by induction on $|E \setminus C|$. In the base case we assume that $|E \setminus C| = 0$, i.e., that $S' = S$. Since $|S| \leq k$ it holds for any function h that the function family $x \mapsto (h(x) + g(x)) \bmod v$, where g is chosen from a k-wise independent family, is uniform on S. In particular, $\mathcal{H}(i_1, i_2, \mathcal{G})$ has this property.

For the inductive step, note that among the edges in $E \setminus C$ there has to be at least one edge with one unique endpoint. Let $e_{x^*} = (a_{i_1(x^*)}, b_{i_2(x^*)})$ be such an edge, $x^* \in S \setminus S'$. By symmetry we may assume that $a_{i_1(x^*)}$ is the unique endpoint. The induction hypothesis says that $\mathcal{H}(i_1, i_2, \mathcal{G})$ is uniform on $S \setminus \{x^*\}$, and for $h \in \mathcal{H}(i_1, i_2, \mathcal{G})$ chosen at random, all values $h(x)$ for $x \in S \setminus \{x^*\}$ are independent of the value $T_1[i_1(x^*)]$. These facts mean that given $g \in \mathcal{G}$ and all entries in vectors T_1 and T_2 except $T_1[i_1(x^*)]$, $h(x^*)$ is uniformly distributed when choosing $T_1[i_1(x^*)]$ at random. Hence $\mathcal{H}(i_1, i_2, \mathcal{G})$ is uniform on S. □

LEMMA 2. *For each set S of size n, and for $i_1, i_2 : U \to [4n]$ chosen at random from a family that is k-wise independent on S, $k \geq 32$, the probability that the leafless part C of the graph $G(i_1, i_2, S)$ has size at least k is $n/2^{\Omega(k)}$.*

Proof. Assume that $|C| \geq k$ and that $k \leq n$ is even (this may be assumed without loss of generality). Either there is a *connected* leafless subgraph in $G(i_1, i_2, S)$ of size at least $k/2$ or there is a leafless subgraph of size k', where $k/2 < k' \leq k$. In the first case there is a connected subgraph in $G(i_1, i_2, S)$ with exactly $k/2$ edges and at most $k/2 + 1$ vertices. In the second case there is a subgraph with k' edges and at most k' vertices in $G(i_1, i_2, S)$.

In the following we will count the number of different edge-labeled subgraphs with k' edges and at most $k' + 1$ vertices for $k/2 \leq k' \leq k$ to bound the probability of such a subgraph to appear in $G(i_1, i_2, S)$. Hence, we also get an upper bound on the probability that $|C|$ is at least k. Note that since i_1 and i_2 are chosen from a k-wise independent family, each subset of at most k elements of S will map to to random and independent edges. We will only consider subgraphs corresponding to at most k elements of S.

To count the number of different subgraphs with k' edges and at most $k' + 1$ vertices, for $k/2 \leq k' \leq k$, in a bipartite graph $G = (A, B, E)$ with $|A| = |B| = 4n$ and $|E| = n$, we count the number of ways to choose the edge labels, the vertices, and the endpoints of the edges such that they are among the chosen vertices. The k' edge labels can be chosen in $\binom{n}{k'} \leq (en/k')^{k'}$ ways. Since the number of vertices in the subgraph is at most $k' + 1$, and they are chosen from $8n$ vertices in G, the total number of ways in which they can be chosen is bounded by

$$\sum_{i=1}^{k'+1} \tbinom{8n}{i} \leq (8en/(k'+1))^{k'+1}.$$

Let k_a and k_b be the number of vertices chosen from A and B, respectively. The number of ways to choose an edge such that it has both its endpoints among the chosen vertices is $k_a k_b \leq ((k'+1)/2)^{2k'}$. In total, the number of different subgraphs with k' edges and up to $k' + 1$ vertices is at most

$$\begin{aligned}
&(en/k')^{k'} \cdot (8en/(k'+1))^{k'+1} \cdot ((k'+1)/2)^{2k'} \\
&= \tfrac{8en}{k'+1} \cdot (2e^2 \cdot n^2 \cdot \tfrac{k'+1}{k'})^{k'} \\
&\leq \tfrac{8en}{k'+1} \cdot (\tfrac{63}{4} \cdot n^2)^{k'},
\end{aligned}$$

using $k' \geq k/2 \geq 16$.

There are in total $(4n)^{2k'}$ graphs with k' specific edges. In particular, the probability that k' specific edges form a particular graph is $(4n)^{-2k'}$, using k'-wise independence. To get an upper bound on the probability that there is some subgraph with k' edges and at most $k'+1$ vertices, where $k/2 \leq k' \leq k$, we sum over all possible values of k':

$$\begin{aligned}\sum_{k/2\leq k'\leq k} & \tfrac{8en}{k'+1}\cdot(\tfrac{63}{4}\cdot n^2)^{k'}\cdot(4n)^{-2k'} \\ &= \sum_{k/2\leq k'\leq k} \tfrac{8en}{k'+1}\cdot(\tfrac{63}{64})^{k'} \\ &\leq (k/2+1)\cdot\tfrac{8en}{k/2+1}\cdot(\tfrac{63}{64})^{k/2} \\ &= n/2^{\Omega(k)}. \qquad \square\end{aligned}$$

We now proceed to show Theorem 1 for *some* constant $\epsilon > 0$. More precisely, we will show that the random family $\mathcal{H}_{n,c}$ of Definition 3 fulfills the requirements in the theorem. The families $\mathcal{G} = \mathcal{SI}(U, V, k, n, c, 1/4)$ and $\mathcal{F} = \mathcal{SI}(U, [4n], k, n, c, 1/4)$ are both k-wise independent with probability $1 - n^{-c}$ for sets of size up to n according to Theorem 3. If $\mathcal{F}$ is k-wise independent, then by Lemma 2 the probability that the leafless part of graph $G(i_1, i_2, S)$ has size at most k is at least $1 - n^{-\Omega(k)}$ if $k \geq 32$. We can assume without loss of generality that $k \geq 32$, since otherwise the theorem follows directly from Theorem 3. When the leafless part of graph $G(i_1, i_2, S)$ has size at most k, then, by Lemma 1, $\mathcal{H}_{n,c}$ is uniform on S if $\mathcal{G}$ is k-wise independent. The probability that $\mathcal{G}$ is k-wise independent, that $\mathcal{F}$ is k-wise independent, and that the leafless part of the graph $G(i_1, i_2, S)$ has size at most k is altogether $(1 - n^{-c})^2(1 - 2^{-\Omega(k)}) = 1 - O(n^{-c})$.

The construction of $\mathcal{H}_{n,c}$, i.e., constructing $\mathcal{F}$ and $\mathcal{G}$ and choosing i_1 and i_2, can according to Theorem 3 be done in expected $O(s)+(\lg\lg u)^{O(1)}$ time and $O(s \lg v)$ bits of space, where $s = n^{\sqrt{(c+2)\lg k/\lg n}+1/4} = O(n^{0.96})$. The space usage of a data structure representing a function from $\mathcal{H}_{n,c}$ is $O(n \lg v)$ bits for T_1 and T_2 and $O(s \lg v + \lg\lg u)$ bits for storing i_1, i_2, and g. The initialization time is dominated by the time used for initializing T_1 and T_2 to random arrays and the $(\lg\lg u)^{O(1)}$ term from Siegel's construction. Function values can clearly be computed in constant time.

4. Achieving near-optimal space. In this section we present a general reduction for decreasing the space used by a uniform hashing construction. Together with section 3 this will show Theorem 1. The idea of the reduction is the following. We construct a data structure of $(1+\epsilon/2)n \lg v + O(n)$ bits representing a function f such that for any set $S \subseteq U$ of n elements there exists, with probability $1 - O(n^{-c})$, a set $S' \subseteq S$, where $|S'| \geq (1 - \epsilon/16)\, n$, such that the following independence property holds:

- The values $(f(x))_{x\in S'}$ are independent and uniform in $[v]$, even when conditioned on particular f-values for elements in $S \backslash S'$.

To be precise, we associate with each possible choice of f a unique set S'. The uniformity property above holds when restricting f to the subset of functions associated with any particular set S'. (The probability space may be empty for some choices of S'.)

Now choose a function h according to a uniform hashing construction for sets of size $(\epsilon/16)\, n$, and error probability $O(n^{-c})$. We consider the function

$$x \mapsto (f(x) + h(x)) \bmod v.$$

For a given set $S \subseteq U$ of size n, there exists with probability $1 - O(n^{-c})$ a set S' with properties as stated above. With probability $1 - O(n^{-c})$ the function h then maps the elements of $S \backslash S'$ to uniformly distributed and independent values. Hence, using the independence property of f, the function $x \mapsto (f(x) + h(x)) \bmod v$ must be uniform on the set S with probability $1 - O(n^{-c})$.

Using the uniform hashing construction of section 3, the space to represent h is $(8\epsilon/16)\, n\lceil \lg v \rceil + o(n) + O(\lg \lg u) = (\epsilon/2) n \lg v + O(n + \lg \lg u)$ bits, so the total space for storing f and h is as required in Theorem 1.

4.1. Details of the reduction. It remains to see how to construct f in the desired space bound, with the desired preprocessing time, and such that function values can be computed in constant time. Below we will several times refer to a constant ℓ, which is assumed to be "sufficiently large." That is, the arguments are valid if ℓ is set to a sufficiently large constant. We first notice that for the case where $v \leq \ell$, Theorem 1 was already shown in section 3. Thus, in the following we may assume that $v > \ell$. Let $p \geq v$ be a prime in the range v to $v + O(v^{2/3})$. We know from [14] that there are $\Omega(v^{2/3}/\lg v)$ such primes, so p can be found in time $\lg n (\lg v)^{O(1)}$ with high probability by sampling [1].

Let $d = \lceil \ell/\epsilon^2 \rceil$, $k = \lceil n^{1/(2c+4)} \rceil$, $r_1 = \lceil (1 + \epsilon/2) n/d \rceil$, and let $r_2 > 9d^3/\epsilon$ be a constant. Since v can be assumed to be sufficiently large, we have that $p - v < \epsilon v/(9d)$. Now pick the following functions uniformly at random:

$$\rho_1 : U \to \{0, \ldots, r_1 - 1\} \text{ from } \mathcal{SI}(U, [r_1], k, n, c, 1/4),$$
$$\rho_2 : U \to \{0, \ldots, r_2 - 1\} \text{ from } \mathcal{SI}(U, [r_2], k, n, c, 1/4).$$

Also, pick functions $f_1, \ldots, f_{r_1}$ independently at random from the family of degree $d-1$ polynomials in the field of size p, which is known to be d-wise independent. Note that such a polynomial can be stored in $d\lceil \lg p \rceil = d \lg v + O(d)$ bits and evaluated in $O(d)$ time using arithmetic modulo p. Without loss of generality we may assume that $\epsilon < 1$ and $p \geq r_2$. Thus we may interpret a value of ρ_2 as an input to $f_1, \ldots, f_{r_1}$, and the following is well -defined:

$$f(x) = f_{\rho_1(x)}(\rho_2(x)).$$

Observe that f may have function values up to $p - 1$, i.e., not in $[v]$. However, we will define S' such that the function values of elements in S' are uniform in $[v]$, and this suffices for the reduction to work.

4.2. Analysis.

Time and space usage. We first argue that f has the desired properties with respect to storage, preprocessing time, and evaluation time. The storage required for ρ_1 and ρ_2 is bounded by the storage used in the construction of section 3, so it can be ignored in this context. The functions $f_1, \ldots, f_{r_1}$ require space $r_1(d \lg v + O(d)) = (1 + \epsilon/2) n \lg v + O(n)$ bits, and a function can be evaluated in $O(1)$ time, since d is a constant. Selection of ρ_1 and ρ_2 can be done in $o(n)$ time, while construction of $f_1, \ldots, f_{r_1}$ requires expected time $w^{O(1)}$ to find the prime p, and $O(n)$ time to choose the random polynomials.

Independence. To argue that f has the desired independence property, we let $S_i = \{x \in S \mid \rho_1(x) = i\}$ and define S' to be the union of the sets S_i for which

- $|S_i| \leq d$,
- $|\rho_2(S_i)| = |S_i|$, i.e., ρ_2 is 1-1 on S_i, and
- $f_i(\rho_2(S_i)) \subseteq [v]$.

In other words, if we think of ρ_1 as hashing into buckets of capacity d, the set S' consists of those elements that are hashed to a bucket i that does not overflow, whose elements have no collisions under ρ_2, and where f_i produces values in the right range for all elements in the bucket.

Consider a nonempty part of the probability space where f is associated with a particular set S' and has a specific, fixed value on each of the elements in $S\backslash S'$. We will argue that if f is chosen in this part of the probability space, we get a uniform function on S'. First, function values of elements hashing to different buckets are completely independent as $f_1, \ldots, f_{r_1}$ are chosen independently. If S_i is part of S', then $|S_i| \leq d$ by definition of S'. Since f_i is d-wise independent and there is no collision among elements in S_i under ρ_2, the f-values of elements in S_i are independent and uniformly random in $[v]$ (because of the requirement $f_i(\rho_2(S_i)) \subseteq [v]$). This concludes the argument for uniformity on S'.

Size of S'. Finally, we need to show that $|S'| \geq (1 - \epsilon/16)\, n$ with probability $1 - O(n^{-c})$. For this we split $[r_1]$ into blocks of at most 2^z consecutive integers $I_j = \{2^z j, \ldots, 2^z(j+1) - 1\}$, $j = 0, 1, 2, \ldots$, where $z = \Omega(\lg n)$ is the highest integer for which $2^z d < k$. If 2^z does not divide r_1, there will be one block of size less than 2^z. If we conservatively assume that all elements of S having a ρ_1-value in this final block will be part of S', it will follow from the arguments below that this will contribute only negligibly to S'. Thus we simply assume that 2^z divides r_1.

First we observe that for all j, $|\cup_{i\in I_j} S_i| < (1-\epsilon/4)2^z d$ with probability $1-n^{-\omega(1)}$. This follows from Chernoff bounds for random variables with limited dependence [22, Theorem 5.I.b]. On the condition that $|\cup_{i\in I_j} S_i| < (1 - \epsilon/4)2^z d$ (which is assumed in the following) the z least significant bits of the ρ_1-values of elements in $\cup_{i\in I_j} S_i$ will be random and independent for any particular j. We conclude the argument by proving that for any j, $|S' \cap (\cup_{i\in I_j} S_i)| \geq (1 - \epsilon/16)|\cup_{i\in I_j} S_i|$ with probability $1 - O(n^{-\omega(1)})$. By the union bound this will imply that S' has the desired size with probability $1 - O(n^{-\omega(1)})$.

Consider the indicator random variables Y_x, $x \in \cup_{i\in I_j} S_i$, where $Y_x = 1$ if and only if x has the same value under ρ_1 as at least d other elements in $\cup_{i\in I_j} S_i$. Observe that if $Y_x = 1$, then x is not included in S' due to the first requirement in the definition of S. By uniformity of ρ_1 in the z least-significant bits, and since the expected number of elements colliding with x is bounded by $(1 - \epsilon/4)d$, it follows from classical Chernoff bounds that $\Pr(Y_x = 1) \leq \epsilon/6$. The random variables Y_x are not independent; however, they are *negatively related* [15], which means that we can apply a Chernoff bound on the sum of the Y_xs to show that it is bounded by $(\epsilon/4)|\cup_{i\in I_j} S_i|$ with probability $1 - n^{\omega(1)}$ [15].

Finally, consider the indicator random variables X_i, $i \in I_j$, where $X_i = 1$ if and only if $|S_i| \leq d$ and either $|\rho_2(S_i)| < |S_i|$ or $f_i(\rho_2(S_i)) \not\subseteq [v]$. That is, X_i indicates whether the set S_i fails to be included in S' because of at least one of the two last requirements in the definition of S'. For each variable X_i equal to 1 we have at most d elements (those in S_i) that are not part of S'. We next show that with probability $1 - n^{\omega(1)}$ the sum $\sum_{i\in I_j} X_i$ is bounded by $2^z\epsilon/(4d)$, which means that the number of elements not included in S' due to requirements two and three is at most $(\epsilon/4)|\cup_{i\in I_j} S_i|$. Since ρ_2 is independent on all elements in $\cup_{i\in I_j} S_i$, the X_i are independent. By the choice of p and r_2 we have that for all i, $\Pr(X_i = 1) \leq \frac{p-v}{v} + \binom{d}{2}/r_2 < 2\epsilon/(9d)$. Hence by Chernoff bounds $\sum_{i\in I_j} X_i < 2^z\epsilon/(4d)$ with probability $1-n^{\omega(1)}$. Together with the similar bound above for the first requirement, this shows that S' has the desired size with high probability.

The combined construction. For ease of reference we state the full uniform hashing construction used to show Theorem 1:

$$x \mapsto (f_{\rho_1(x)}(\rho_2(x)) + T_1[i_1(x)] + T_2[i_2(x)] + g(x)) \bmod v.$$

5. Space lower bound. We now show that our space usage in bits is close to the best possible. To this end, note that any data structure achieving n-wise independence on a set S of n elements, with nonzero probability, must be able to represent every function from S to V.

THEOREM 4. *For integers $u \geq n \geq 2$ and $v \geq 2$, let $U = \{0, \ldots, u-1\}$ and $V = \{0, \ldots, v-1\}$. Any data structure representing functions $h : U \to V$ such that the restriction $h|_S$ to any set $S \subseteq U$ of n elements can be an arbitrary function from S to V must use space $\max(n \lg v, \lg \lg_v u)$ bits.*

Proof. Even for fixed S, $n \lg v$ bits are necessary to be able to represent all functions from S to V. Second, if the data structure can represent fewer than $\lg_v u$ different functions, there will be elements $x_1, x_2 \in U$ such that all functions map x_1 and x_2 to the same value, contradicting the assumptions of the theorem. Thus the data structure must have at least $\lg \lg_v u$ bits. □

Note that when $\lg v < \lg \lg u$, the second term in the lower bound is $\Omega(\lg \lg u)$, so the lower bound is $\Omega(n \lg v + \lg \lg u)$ bits.

Acknowledgments. We would like to thank Martin Dietzfelbinger for enlightening discussions and in particular for pointing out an error in the quotation of Siegel's result in the conference version of this paper. Also, we thank an anonymous reviewer for help on improving the presentation.

FUZZY EXTRACTORS: HOW TO GENERATE STRONG KEYS FROM BIOMETRICS AND OTHER NOISY DATA*

YEVGENIY DODIS†, RAFAIL OSTROVSKY‡, LEONID REYZIN§, AND ADAM SMITH¶

Abstract. We provide formal definitions and efficient secure techniques for turning noisy information into keys usable for *any* cryptographic application, and, in particular, reliably and securely authenticating biometric data. Our techniques apply not just to biometric information, but to any keying material that, unlike traditional cryptographic keys, is (1) not reproducible precisely and (2) not distributed uniformly. We propose two primitives: a *fuzzy extractor* reliably extracts nearly uniform randomness R from its input; the extraction is error-tolerant in the sense that R will be the same even if the input changes, as long as it remains reasonably close to the original. Thus, R can be used as a key in a cryptographic application. A *secure sketch* produces public information about its input w that does not reveal w and yet allows exact recovery of w given another value that is close to w. Thus, it can be used to reliably reproduce error-prone biometric inputs without incurring the security risk inherent in storing them. We define the primitives to be both formally secure and versatile, generalizing much prior work. In addition, we provide nearly optimal constructions of both primitives for various measures of "closeness" of input data, such as Hamming distance, edit distance, and set difference.

1. Introduction.

Cryptography traditionally relies on uniformly distributed and precisely reproducible random strings for its secrets. Reality, however, makes it difficult to create, store, and reliably retrieve such strings. Strings that are neither uniformly random nor reliably reproducible seem to be more plentiful. For example, a random person's fingerprint or iris scan is clearly not a uniform random string, nor does it get reproduced precisely each time it is measured. Similarly, a long pass-phrase (or answers to 15 questions [31] or a list of favorite movies [38]) is not uniformly random and is difficult to remember for a human user. This work is about using such

nonuniform and unreliable secrets in cryptographic applications. Our approach is rigorous and general, and our results have both theoretical and practical value.

To illustrate the use of random strings on a simple example, let us consider the task of password authentication. A user Alice has a password w and wants to gain access to her account. A trusted server stores some information $y = f(w)$ about the password. When Alice enters w, the server lets Alice in only if $f(w) = y$. In this simple application, we assume that it is safe for Alice to enter the password for the verification. However, the server's long-term storage is not assumed to be secure (e.g., y is stored in a publicly readable `/etc/passwd` file in UNIX [55]). The goal, then, is to design an efficient f that is hard to invert (i.e., given y it is hard to find w' such that $f(w') = y$) so that no one can figure out Alice's password from y. Recall that such functions f are called *one-way functions*.

Unfortunately, the solution above has several problems when used with passwords w available in real life. First, the definition of a one-way function assumes that w is *truly uniform* and guarantees nothing if this is not the case. However, human-generated and biometric passwords are far from uniform, although they do have some unpredictability in them. Second, Alice has to reproduce her password *exactly* each time she authenticates herself. This restriction severely limits the kinds of passwords that can be used. Indeed, a human can precisely memorize and reliably type in only relatively short passwords, which do not provide an adequate level of security. Greater levels of security are achieved by longer human-generated and biometric passwords, such as pass-phrases, answers to questionnaires, handwritten signatures, fingerprints, retina scans, voice commands, and other values selected by humans or provided by nature, possibly in combination (see [30] for a survey). These measurements seem to contain much more entropy than human-memorizable passwords. However, two biometric readings are rarely identical, even though they are likely to be close; similarly, humans are unlikely to precisely remember their answers to multiple questions from time to time, though such answers will likely be similar. In other words, the ability to tolerate a (limited) number of errors in the password while retaining security is crucial if we are to obtain greater security than provided by typical user-chosen short passwords.

The password authentication described above is just one example of a cryptographic application where the issues of nonuniformity and error-tolerance naturally come up. Other examples include any cryptographic application, such as encryption, signatures, or identification, where the secret key comes in the form of noisy nonuniform data.

Our definitions. As discussed above, an important general problem is to convert noisy nonuniform inputs into reliably reproducible, uniformly random strings. To this end, we propose a new primitive, termed *fuzzy extractor*. It extracts a uniformly random string R from its input w in a noise-tolerant way. Noise-tolerance means that if the input changes to some w' but remains close, the string R can be reproduced exactly. To assist in reproducing R from w', the fuzzy extractor outputs a non-secret string P. It is important to note that R remains uniformly random even given P. (Strictly speaking, R will be ϵ-close to uniform rather than uniform; ϵ can be made exponentially small, which makes R as good as uniform for the usual applications.)

Our approach is general: R extracted from w can be used as a key in a cryptographic application but, unlike traditional keys, need not be stored (because it can be recovered from any w' that is close to w). We define fuzzy extractors to be *information-theoretically* secure, thus allowing them to be used in cryptographic systems without introducing additional assumptions (of course, the cryptographic ap-

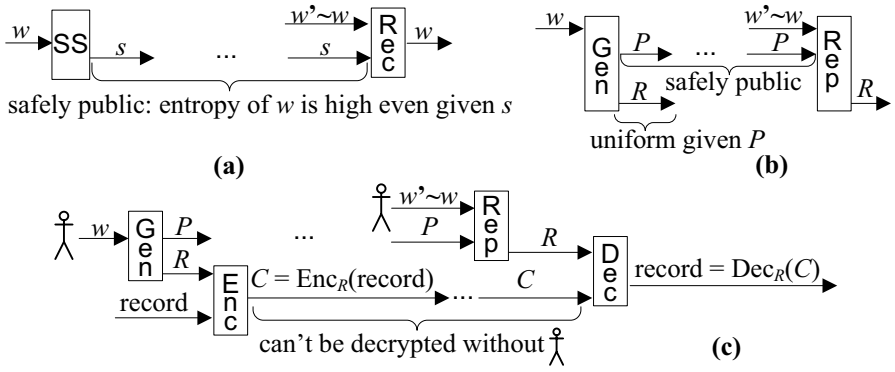

FIG. 1. (a) *Secure sketch.* (b) *Fuzzy extractor.* (c) *A sample application: User who encrypts a sensitive record using a cryptographically strong, uniform key R extracted from biometric w via a fuzzy extractor; both P and the encrypted record need not be kept secret, because no one can decrypt the record without a w' that is close.*

plication itself will typically have computational, rather than information-theoretic, security).

For a concrete example of how to use fuzzy extractors, in the password authentication case, the server can store $(P, f(R))$. When the user inputs w' close to w, the server reproduces the actual R using P and checks if $f(R)$ matches what it stores. The presence of P will help the adversary invert $f(R)$ only by the additive amount of ϵ, because R is ϵ-close to uniform even given P.[1] Similarly, R can be used for symmetric encryption, for generating a public-secret key pair, or for other applications that utilize uniformly random secrets.[2]

As a step in constructing fuzzy extractors, and as an interesting object in its own right, we propose another primitive, termed *secure sketch*. It allows precise reconstruction of a noisy input as follows: on input w, a procedure outputs a sketch s. Then, given s and a value w' close to w, it is possible to recover w. The sketch is secure in the sense that it does not reveal much about w: w retains much of its entropy even if s is known. Thus, instead of storing w for fear that later readings will be noisy, it is possible to store s instead, without compromising the privacy of w. A secure sketch, unlike a fuzzy extractor, allows for the precise reproduction of the original input but does not address nonuniformity.

Secure sketches, fuzzy extractors, and a sample encryption application are illustrated in Figure 1.

Secure sketches and extractors can be viewed as providing fuzzy key storage: they allow recovery of the secret key (w or R) from a faulty reading w' of the password w by using some public information (s or P). In particular, fuzzy extractors can be viewed as error- and nonuniformity-tolerant secret key *key-encapsulation mechanisms* [65].

Because different biometric information has different error patterns, we do not

[1] To be precise, we should note that because we do not require w, or hence P, to be efficiently samplable, we need f to be a one-way function even in the presence of samples from w; this is implied by security against circuit families.

[2] Naturally, the security of the resulting system should be properly defined and proven and will depend on the possible adversarial attacks. In particular, in this work we do not consider active attacks on P or scenarios in which the adversary can force multiple invocations of the extractor with related w and get to observe the different P values. See [8, 9, 23] for follow-up work that considers attacks on the fuzzy extractor itself.

assume any particular notion of closeness between w' and w. Rather, in defining our primitives, we simply assume that w comes from some metric space and that w' is no more than a certain distance from w in that space. We consider particular metrics only when building concrete constructions.

General results. Before proceeding to construct our primitives for concrete metrics, we make some observations about our definitions. We demonstrate that fuzzy extractors can be built out of secure sketches by utilizing strong *randomness extractors* [56], such as, for example, universal hash functions [12, 75] (randomness extractors, defined more precisely below, are families of hash which "convert" a high entropy input into a shorter, uniformly distributed output). We also provide a general technique for constructing secure sketches from transitive families of isometries, which is instantiated in concrete constructions later in the paper. Finally, we define a notion of a *biometric embedding* of one metric space into another and show that the existence of a fuzzy extractor in the target space, combined with a biometric embedding of the source into the target, implies the existence of a fuzzy extractor in the source space.

These general results help us in building and analyzing our constructions.

Our constructions. We provide constructions of secure sketches and fuzzy extractors in three metrics: Hamming distance, set difference, and edit distance. Unless stated otherwise, all the constructions are new.

Hamming distance (i.e., the number of symbol positions that differ between w and w') is perhaps the most natural metric to consider. We observe that the "fuzzy-commitment" construction of Juels and Wattenberg [39] based on error-correcting codes can be viewed as a (nearly optimal) secure sketch. We then apply our general result to convert it into a nearly optimal fuzzy extractor. While our results on the Hamming distance essentially use previously known constructions, they serve as an important stepping stone for the rest of the work.

The set difference metric (i.e., the size of the symmetric difference of two input sets w and w') is appropriate whenever the noisy input is represented as a subset of features from a universe of possible features.[3] We demonstrate the existence of optimal (with respect to entropy loss) secure sketches and fuzzy extractors for this metric. However, this result is mainly of theoretical interest, because (1) it relies on optimal constant-weight codes, which we do not know how to construct, and (2) it produces sketches of length proportional to the universe size. We then turn our attention to more efficient constructions for this metric in order to handle exponentially large universes. We provide two such constructions.

First, we observe that the "fuzzy vault" construction of Juels and Sudan [38] can be viewed as a secure sketch in this metric (and then converted to a fuzzy extractor using our general result). We provide a new, simpler analysis for this construction, which bounds the entropy lost from w given s. This bound is quite high unless one makes the size of the output s very large. We then improve the Juels–Sudan construction to reduce the entropy loss and the length of s to near optimal. Our improvement in the running time and in the length of s is exponential for large universe sizes. However, this improved Juels–Sudan construction retains a drawback of the original: it is able to handle only sets of the same fixed size (in particular, $|w'|$ must equal $|w|$).

[3] A perhaps unexpected application of the set difference metric was explored in [38]: A user would like to encrypt a file (e.g., her phone number) using a small subset of values from a large universe (e.g., her favorite movies) in such a way that those and only those with a similar subset (e.g., similar taste in movies) can decrypt it.

Second, we provide an entirely different construction, called PinSketch, that maintains the exponential improvements in sketch size and running time and also handles variable set size. To obtain it, we note that in the case of a small universe, a set can be simply encoded as its characteristic vector (1 if an element is in the set, 0 if it is not), and set difference becomes Hamming distance. Even though the length of such a vector becomes unmanageable as the universe size grows, we demonstrate that this approach can be made to work quite efficiently even for exponentially large universes (in particular, because it is not necessary to ever actually write down the vector). This involves a result that may be of independent interest: we show that BCH codes can be decoded in time polynomial in the *weight* of the received corrupted word (i.e., in *sublinear* time if the weight is small).

Finally, edit distance (i.e., the number of insertions and deletions needed to convert one string into the other) comes up, for example, when the password is entered as a string, due to typing errors or mistakes made in handwriting recognition. We discuss two approaches for secure sketches and fuzzy extractors for this metric. First, we observe that a recent low-distortion embedding of Ostrovsky and Rabani [57] immediately gives a construction for edit distance. The construction performs well when the number of errors to be corrected is very small (say, n^α for $\alpha < 1$) but cannot tolerate a large number of errors. Second, we give a biometric embedding (which is less demanding than a low-distortion embedding but suffices for obtaining fuzzy extractors) from the edit distance metric into the set difference metric. Composing it with a fuzzy extractor for set difference gives a different construction for edit distance, which does better when t is large; it can handle as many as $O(n/\log^2 n)$ errors with meaningful entropy loss.

Most of the above constructions are quite practical; some implementations are available [36].

Extending results for probabilistic notions of correctness. The definitions and constructions just described use a very strong error model: we require that secure sketches and fuzzy extractors accept *every* secret w' which is sufficiently close to the original secret w, with probability 1. Such a stringent model is useful, as it makes no assumptions on the stochastic and computational properties of the error process. However, slightly relaxing the error conditions allows constructions which tolerate a (provably) much larger number of errors, at the price of restricting the settings in which the constructions can be applied. In section 8, we extend the definitions and constructions of earlier sections to several relaxed error models.

It is well known that in the standard setting of error-correction for a binary communication channel, one can tolerate many more errors when the errors are random and independent than when the errors are determined adversarially. In contrast, we present fuzzy extractors that meet Shannon's bounds for correcting random errors and, moreover, can correct the same number of errors even when errors are adversarial. In our setting, therefore, under a proper relaxation of the correctness condition, adversarial errors are no stronger than random ones. The constructions are quite simple and draw on existing techniques from the coding literature [4, 22, 33, 43, 48].

Relation to previous work. Since our work combines elements of error-correction, randomness extraction, and password authentication, there has been a lot of related work.

The need to deal with nonuniform and low-entropy passwords has long been realized in the security community, and many approaches have been proposed. For example, Kelsey et al. [42] suggested using $f(w, r)$ in place of w for the password authentication scenario, where r is a public random "salt," to make a brute-force at-

tacker's life harder. While practically useful, this approach does not add any entropy to the password and does not formally address the needed properties of f. Another approach, more closely related to ours, is to add biometric features to the password. For example, Ellison et al. [28] proposed asking the user a series of n personalized questions and using these answers to encrypt the "actual" truly random secret R. A similar approach using the user's keyboard dynamics (and, subsequently, voice [52, 53]) was proposed by Monrose, Reiter, and Wetzel [54]. These approaches require the design of a secure "fuzzy encryption." The above works proposed heuristic designs (using various forms of Shamir's secret sharing) but gave no formal analysis. Additionally, error tolerance was addressed only by brute-force search.

A formal approach to error tolerance in biometrics was taken by Juels and Wattenberg [39] (for less formal solutions, see [20, 54, 28]), who provided a simple way to tolerate errors in *uniformly distributed* passwords. Frykholm and Juels [31] extended this solution and provided entropy analysis to which ours is similar. Similar approaches have been explored earlier in seemingly unrelated literature on cryptographic information reconciliation, often in the context of quantum cryptography (where Alice and Bob wish to derive a secret key from secrets that have small Hamming distance), particularly [4, 6]. Our construction for the Hamming distance is essentially the same as a component of the quantum oblivious transfer protocol of [6].

Juels and Sudan [38] provided the first construction for a metric other than Hamming: they constructed a "fuzzy vault" scheme for the set difference metric. The main difference is that [38] lacks a cryptographically strong definition of the object constructed. In particular, their construction leaks a significant amount of information about their analogue of R, even though it leaves the adversary with provably "many valid choices" for R. In retrospect, their informal notion is closely related to our secure sketches. Our constructions in section 6 improve exponentially over the construction of [38] for storage and computation costs, in the setting when the set elements come from a large universe.

Linnartz and Tuyls [45] defined and constructed a primitive very similar to a fuzzy extractor (that line of work was continued in [73].) The definition of [45] focuses on the continuous space $\mathbb{R}^n$ and assumes a particular input distribution (typically a known, multivariate Gaussian). Thus, our definition of a fuzzy extractor can be viewed as a generalization of the notion of a "shielding function" from [45]. However, our constructions focus on discrete metric spaces.

Other approaches have also been taken for guaranteeing the privacy of noisy data. Csirmaz and Katona [19] considered quantization for correcting errors in "physical random functions." (This corresponds roughly to secure sketches with no public storage.) Barral, Coron, and Naccache [3] proposed a system for offline, private comparison of fingerprints. Although seemingly similar, the problem they study is complementary to ours, and the two solutions can be combined to yield systems which enjoy the benefits of both.

Work on privacy amplification, e.g., [4, 5], as well as work on derandomization and hardness amplification, e.g., [37, 56], also addressed the need to extract uniform randomness from a random variable about which some information has been leaked. A major focus of follow-up research has been the development of (ordinary, not fuzzy) extractors with short seeds (see [63] for a survey). We use extractors in this work (though for our purposes, universal hashing is sufficient). Conversely, our work has been applied recently to privacy amplification: Ding [21] used fuzzy extractors for noise tolerance in Maurer's bounded storage model [47].

Independently of our work, similar techniques appeared in the literature on non-

cryptographic information reconciliation [51, 15] (where the goal is communication efficiency rather than secrecy). The relationship between secure sketches and efficient information reconciliation is explored further in section 9, which discusses, in particular, how our secure sketches for set differences provide more efficient solutions to the set and string reconciliation problems.

Follow-up work. Since the original presentation of this paper [25], several follow-up works have appeared (e.g., [8, 9, 27, 24, 67, 14, 44, 13]). We refer the reader to a recent survey about fuzzy extractors [26] for more information.

2. Preliminaries. Unless explicitly stated otherwise, all logarithms below are base 2. The *Hamming weight* (or just *weight*) of a string is the number of nonzero characters in it. We use U_ℓ to denote the uniform distribution on ℓ-bit binary strings. If an algorithm (or a function) f is randomized, we use the semicolon when we wish to make the randomness explicit; i.e., we denote by $f(x;r)$ the result of computing f on input x with randomness r. If X is a probability distribution, then $f(X)$ is the distribution induced on the image of f by applying the (possibly probabilistic) function f. If X is a random variable, we will (slightly) abuse notation and also denote by X the probability distribution on the range of the variable.

2.1. Metric spaces. A metric space is a set $\mathcal{M}$ with a distance function $\mathsf{dis} : \mathcal{M} \times \mathcal{M} \to \mathbb{R}^+ = [0, \infty)$. For the purposes of this work, $\mathcal{M}$ will always be a finite set, and the distance function will take on only integer values (with $\mathsf{dis}(x, y) = 0$ if and only if $x = y$) and will obey symmetry $\mathsf{dis}(x, y) = \mathsf{dis}(y, x)$ and the triangle inequality $\mathsf{dis}(x, z) \le \mathsf{dis}(x, y) + \mathsf{dis}(y, z)$ (we adopt these requirements for simplicity of exposition, even though the definitions and most of the results below can be generalized to remove these restrictions).

We will concentrate on the following metrics.

1. *Hamming metric.* Here $\mathcal{M} = \mathcal{F}^n$ for some alphabet $\mathcal{F}$, and $\mathsf{dis}(w, w')$ is the number of positions in which the strings w and w' differ.

2. *Set difference metric.* Here $\mathcal{M}$ consists of all subsets of a universe $\mathcal{U}$. For two sets w, w', their symmetric difference $w \triangle w' \stackrel{\text{def}}{=} \{x \in w \cup w' \mid x \notin w \cap w'\}$. The distance between two sets w, w' is $|w \triangle w'|$.[4] We will sometimes restrict $\mathcal{M}$ to contain only s-element subsets for some s.

3. *Edit metric.* Here $\mathcal{M} = \mathcal{F}^*$, and the distance between w and w' is defined to be the smallest number of character insertions and deletions needed to transform w into w'.[5] (This is different from the Hamming metric because insertions and deletions shift the characters that are to the right of the insertion/deletion point.)

As already mentioned, all three metrics seem natural for biometric data.

2.2. Codes and syndromes. Since we want to achieve error-tolerance in various metric spaces, we will use *error-correcting codes* for a particular metric. A code C is a subset $\{w_0, \ldots, w_{K-1}\}$ of K elements of $\mathcal{M}$. The map from i to w_i, which we will also sometimes denote by C, is called *encoding*. The *minimum distance* of C is the smallest $d > 0$ such that for all $i \neq j$ we have $\mathsf{dis}(w_i, w_j) \ge d$. In our case of integer metrics, this means that one can detect up to $(d - 1)$ "errors" in an element

[4] In the preliminary version of this work [25], we worked with this metric scaled by $\frac{1}{2}$; that is, the distance was $\frac{1}{2}|w \triangle w'|$. Not scaling makes more sense, particularly when w and w' are of potentially different sizes since $|w \triangle w'|$ may be odd. It also agrees with the Hamming distance of characteristic vectors; see section 6.

[5] Again, in [25], we worked with this metric scaled by $\frac{1}{2}$. Likewise, this makes little sense when strings can be of different lengths, and we avoid it here.

of $\mathcal{M}$. The *error-correcting distance* of C is the largest number $t > 0$ such that for every $w \in \mathcal{M}$ there exists at most one codeword c in the ball of radius t around w: $\mathsf{dis}(w, c) \leq t$ for at most one $c \in C$. This means that one can correct up to t errors in an element w of $\mathcal{M}$; we will use the term *decoding* for the map that finds, given w, the $c \in C$ such that $\mathsf{dis}(w, c) \leq t$ (note that for some w, such c may not exist, but if it exists, it will be unique; note also that decoding is not the inverse of encoding in our terminology). For integer metrics by triangle inequality we are guaranteed that $t \geq \lfloor (d-1)/2 \rfloor$. Since error correction will be more important than error detection in our applications, we denote the corresponding codes as $(\mathcal{M}, K, t)$-codes. For efficiency purposes, we will often want encoding and decoding to be polynomial-time.

For the Hamming metric over $\mathcal{F}^n$, we will sometimes call $k = \log_{|\mathcal{F}|} K$ the *dimension* of the code and denote the code itself as an $[n, k, d = 2t + 1]_{\mathcal{F}}$-code, following the standard notation in the literature. We will denote by $A_{|\mathcal{F}|}(n, d)$ the maximum K possible in such a code (omitting the subscript when $|\mathcal{F}| = 2$), and by $A(n, d, s)$ the maximum K for such a code over $\{0,1\}^n$ with the additional restriction that all codewords have exactly s ones.

If the code is linear (i.e., $\mathcal{F}$ is a field, $\mathcal{F}^n$ is a vector space over $\mathcal{F}$, and C is a linear subspace), then one can fix a parity-check matrix H as any matrix whose rows generate the orthogonal space $C^{\perp}$. Then for any $v \in \mathcal{F}^n$, the syndrome $\mathsf{syn}(v) \stackrel{\text{def}}{=} Hv$. The syndrome of a vector is its projection onto subspace that is orthogonal to the code and can thus be intuitively viewed as the vector modulo the code. Note that $v \in C \Leftrightarrow \mathsf{syn}(v) = 0$. Note also that H is an $(n-k) \times n$ matrix and that $\mathsf{syn}(v)$ is $n - k$ bits long.

The syndrome captures all the information necessary for decoding. That is, suppose a codeword c is sent through a channel and the word $w = c + e$ is received. First, the syndrome of w is the syndrome of e: $\mathsf{syn}(w) = \mathsf{syn}(c) + \mathsf{syn}(e) = 0 + \mathsf{syn}(e) = \mathsf{syn}(e)$. Moreover, for any value u, there is at most one word e of weight less than $d/2$ such that $\mathsf{syn}(e) = u$ (because the existence of a pair of distinct words e_1, e_2 would mean that $e_1 - e_2$ is a codeword of weight less than d, but since 0^n is also a codeword and the minimum distance of the code is d, this is impossible). Thus, knowing syndrome $\mathsf{syn}(w)$ is enough to determine the error pattern e if not too many errors occurred.

2.3. Min-entropy, statistical distance, universal hashing, and strong extractors. When discussing security, one is often interested in the probability that the adversary predicts a random value (e.g., guesses a secret key). The adversary's best strategy, of course, is to guess the most likely value. Thus, the *predictability* of a random variable A is $\max_a \Pr[A = a]$, and, correspondingly, the *min-entropy* $\mathbf{H}_\infty(A)$ is $-\log(\max_a \Pr[A = a])$ (min-entropy can thus be viewed as the "worst-case" entropy [16]; see also section 2.4).

The min-entropy of a distribution tells us how many nearly uniform random bits can be extracted from it. The notion of "nearly" is defined as follows. The *statistical distance between* two probability distributions A and B is $\mathbf{SD}(A, B) = \frac{1}{2} \sum_v |\Pr(A = v) - \Pr(B = v)|$.

Recall the definition of *strong randomness extractors* [56].

DEFINITION 1. *Let* $\mathsf{Ext} : \{0,1\}^n \to \{0,1\}^\ell$ *be a polynomial time probabilistic function which uses* r *bits of randomness. We say that* Ext *is an efficient* (n, m, ℓ, ϵ)-strong extractor *if for all min-entropy* m *distributions* W *on* $\{0,1\}^n$

$$\mathbf{SD}\left((\mathsf{Ext}(W; X), X), (U_\ell, X)\right) \leq \epsilon\,,$$

where X *is uniform on* $\{0,1\}^r$.

Strong extractors can extract at most $\ell = m - 2\log\left(\frac{1}{\epsilon}\right) + O(1)$ nearly random bits [59]. Many constructions match this bound (see Shaltiel's survey [63] for references). Extractor constructions are often complex since they seek to minimize the length of the seed X. For our purposes, the length of X will be less important, so universal hash functions [12, 75] (defined in the lemma below) will already give us the optimal $\ell = m - 2\log\left(\frac{1}{\epsilon}\right) + 2$, as given by the *leftover hash lemma* below (see [37, Lemma 4.8] as well as references therein for earlier versions).

LEMMA 2.1 (universal hash functions and the leftover hash/privacy-amplification lemma). *Assume a family of functions* $\{H_x : \{0,1\}^n \to \{0,1\}^\ell\}_{x \in X}$ *is* universal*: for all* $a \neq b \in \{0,1\}^n$, $\Pr_{x \in X}[H_x(a) = H_x(b)] = 2^{-\ell}$. *Then, for any random variable* W,[6]

$$\mathbf{SD}\left((H_X(W), X)\ ,\ (U_\ell, X)\right) \leq \frac{1}{2}\sqrt{2^{-\mathbf{H}_\infty(W)} 2^\ell}. \tag{2.1}$$

In particular, universal hash functions are (n, m, ℓ, ϵ)*-strong extractors whenever* $\ell \leq m - 2\log\left(\frac{1}{\epsilon}\right) + 2$.

2.4. Average min-entropy. Recall that *predictability* of a random variable A is $\max_a \Pr[A = a]$, and its *min-entropy* $\mathbf{H}_\infty(A)$ is $-\log(\max_a \Pr[A = a])$. Consider now a pair of (possibly correlated) random variables A, B. If the adversary finds out the value b of B, then predictability of A becomes $\max_a \Pr[A = a \mid B = b]$. On average, the adversary's chance of success in predicting A is then $\mathbb{E}_{b \leftarrow B}\left[\max_a \Pr[A = a \mid B = b]\right]$. Note that we are taking the *average* over B (which is not under adversarial control) but the *worst case* over A (because prediction of A is adversarial once b is known). Again, it is convenient to talk about security in log-scale, which is why we define the *average min-entropy* of A given B as simply the logarithm of the above:

$$\tilde{\mathbf{H}}_\infty(A \mid B) \stackrel{\text{def}}{=} -\log\left(\mathop{\mathbb{E}}_{b \leftarrow B}\left[\max_a \Pr[A = a \mid B = b]\right]\right) = -\log\left(\mathop{\mathbb{E}}_{b \leftarrow B}\left[2^{-\mathbf{H}_\infty(A|B=b)}\right]\right).$$

Because other notions of entropy have been studied in cryptographic literature, a few words are in order to explain why this definition is useful. Note the importance of taking the logarithm *after* taking the average (in contrast, for instance, to conditional Shannon entropy). One may think it more natural to define average min-entropy as $\mathbb{E}_{b \leftarrow B}\left[\mathbf{H}_\infty(A \mid B = b)\right]$, thus reversing the order of log and $\mathbb{E}$. However, this notion is unlikely to be useful in a security application. For a simple example, consider the case when A and B are 1000-bit strings distributed as follows: $B = U_{1000}$ and A is equal to the value b of B if the first bit of b is 0, and U_{1000} (independent of B) otherwise. Then for half of the values of b, $\mathbf{H}_\infty(A \mid B = b) = 0$, while for the other half, $\mathbf{H}_\infty(A \mid B = b) = 1000$, so $\mathbb{E}_{b \leftarrow B}\left[\mathbf{H}_\infty(A \mid B = b)\right] = 500$. However, it would be obviously incorrect to say that A has 500 bits of security. In fact, an adversary who knows the value b of B has a slightly greater than 50% chance of predicting the value of A by outputting b. Our definition correctly captures this 50% chance of prediction, because $\tilde{\mathbf{H}}_\infty(A \mid B)$ is slightly less than 1. In fact, our definition of average min-entropy is simply the logarithm of predictability.

The following useful properties of average min-entropy are proven in Appendix A. We also refer the reader to Appendix B for a generalization of average min-entropy and a discussion of the relationship between this notion and other notions of entropy.

[6] In [37], this inequality is formulated in terms of Rényi entropy of order two of W; the change to $\mathbf{H}_\infty(C)$ is allowed because the latter is no greater than the former.

LEMMA 2.2. *Let A, B, C be random variables. Then the following hold.*

(a) *For any $\delta > 0$, the conditional entropy $\mathbf{H}_\infty(A|B = b)$ is at least $\tilde{\mathbf{H}}_\infty(A|B) - \log(1/\delta)$ with probability at least $1 - \delta$ over the choice of b.*

(b) *If B has at most 2^λ possible values, then $\tilde{\mathbf{H}}_\infty(A \mid (B, C)) \geq \tilde{\mathbf{H}}_\infty((A, B) \mid C) - \lambda \geq \tilde{\mathbf{H}}_\infty(A \mid C) - \lambda$. In particular, $\tilde{\mathbf{H}}_\infty(A \mid B) \geq \mathbf{H}_\infty((A, B)) - \lambda \geq \mathbf{H}_\infty(A) - \lambda$.*

2.5. Average-case extractors. Recall from Definition 1 that a strong extractor allows one to extract almost all the min-entropy from some nonuniform random variable W. In many situations, W represents the adversary's uncertainty about some secret w conditioned on some side information i. Since this side information i is often probabilistic, we shall find the following generalization of a strong extractor useful (see Lemma 4.1).

DEFINITION 2. *Let $\mathsf{Ext} : \{0,1\}^n \to \{0,1\}^\ell$ be a polynomial time probabilistic function which uses r bits of randomness. We say that Ext is an efficient* average-case *(n, m, ℓ, ϵ)-strong extractor if, for all pairs of random variables (W, I) such that W is an n-bit string satisfying $\tilde{\mathbf{H}}_\infty(W \mid I) \geq m$, we have $\mathbf{SD}\left((\mathsf{Ext}(W; X), X, I), (U_\ell, X, I)\right) \leq \epsilon$, where X is uniform on $\{0,1\}^r$.*

To distinguish the strong extractors of Definition 1 from average-case strong extractors, we will sometimes call the former *worst-case* strong extractors. The two notions are closely related, as can be seen from the following simple application of Lemma 2.2(a).

LEMMA 2.3. *For any $\delta > 0$, if Ext is a (worst-case) $(n, m - \log\left(\frac{1}{\delta}\right), \ell, \epsilon)$-strong extractor, then Ext is also an average-case $(n, m, \ell, \epsilon + \delta)$-strong extractor.*

Proof. Assume (W, I) are such that $\tilde{\mathbf{H}}_\infty(W \mid I) \geq m$. Let $W_i = (W \mid I = i)$ and let us call the value i "bad" if $\mathbf{H}_\infty(W_i) < m - \log\left(\frac{1}{\delta}\right)$. Otherwise, we say that i is "good." By Lemma 2.2(a), $\Pr(i \text{ is bad}) \leq \delta$. Also, for any good i, we have that Ext extracts ℓ bits that are ϵ-close to uniform from W_i. Thus, by conditioning on the "goodness" of I, we get

$$\begin{aligned}
\mathbf{SD}\left((\mathsf{Ext}(W; X), X, I), (U_\ell, X, I)\right) &= \sum_i \Pr(i) \cdot \mathbf{SD}\left((\mathsf{Ext}(W_i; X), X), (U_\ell, X)\right) \\
&\leq \Pr(i \text{ is bad}) \cdot 1 \\
&\quad + \sum_{\text{good } i} \Pr(i) \cdot \mathbf{SD}\left((\mathsf{Ext}(W_i; X), X), (U_\ell, X)\right) \\
&\leq \delta + \epsilon. \qquad \square
\end{aligned}$$

However, for many strong extractors we do not have to suffer this additional dependence on δ, because the strong extractor may already be average-case. In particular, this holds for extractors obtained via universal hashing.

LEMMA 2.4 (generalized leftover hash lemma). *Assume $\{H_x : \{0,1\}^n \to \{0,1\}^\ell\}_{x \in X}$ is a family of universal hash functions. Then, for any random variables W and I,*

$$\mathbf{SD}\left((H_X(W), X, I)\ ,\ (U_\ell, X, I)\right) \leq \frac{1}{2}\sqrt{2^{-\tilde{\mathbf{H}}_\infty(W|I)} 2^\ell}. \tag{2.2}$$

In particular, universal hash functions are average-case *(n, m, ℓ, ϵ)-strong extractors whenever $\ell \leq m - 2\log\left(\frac{1}{\epsilon}\right) + 2$.*

Proof. Let $W_i = (W \mid I = i)$. Then

$$\begin{aligned}\mathbf{SD}\left((H_X(W), X, I)\ ,\ (U_\ell, X, I)\right) &= \mathop{\mathbb{E}}_i\left[\mathbf{SD}\left((H_X(W_i), X)\ ,\ (U_\ell, X)\right)\right] \\ &\le \frac{1}{2}\mathop{\mathbb{E}}_i\left[\sqrt{2^{-\mathbf{H}_\infty(W_i)}2^\ell}\right] \\ &\le \frac{1}{2}\sqrt{\mathop{\mathbb{E}}_i\left[2^{-\mathbf{H}_\infty(W_i)}2^\ell\right]} \\ &= \frac{1}{2}\sqrt{2^{-\tilde{\mathbf{H}}_\infty(W|I)}2^\ell}\,.\end{aligned}$$

In the above derivation, the first inequality follows from the standard leftover hash lemma (Lemma 2.1), and the second inequality follows from Jensen's inequality (namely, $\mathbb{E}[\sqrt{Z}] \le \sqrt{\mathbb{E}\,[Z]}$). □

3. New definitions.

3.1. Secure sketches. Let $\mathcal{M}$ be a metric space with distance function dis.

DEFINITION 3. *An* $(\mathcal{M}, m, \tilde{m}, t)$-secure sketch *is a pair of randomized procedures, "sketch" (*SS*) and "recover" (*Rec*), with the following properties:*

1. *The sketching procedure* SS *on input* $w \in \mathcal{M}$ *returns a bit string* $s \in \{0,1\}^*$.
2. *The recovery procedure* Rec *takes an element* $w' \in M$ *and a bit string* $s \in \{0,1\}^*$. *The* correctness *property of secure sketches guarantees that if* $\mathsf{dis}(w, w') \le t$, *then* $\mathsf{Rec}(w', \mathsf{SS}(w)) = w$. *If* $\mathsf{dis}(w, w') > t$, *then no guarantee is provided about the output of* Rec.
3. *The* security *property guarantees that for any distribution* W *over* $\mathcal{M}$ *with min-entropy* m, *the value of* W *can be recovered by the adversary who observes* s *with probability no greater than* $2^{-\tilde{m}}$. *That is,* $\tilde{\mathbf{H}}_\infty(W \mid \mathsf{SS}(W)) \ge \tilde{m}$.

A secure sketch is efficient *if* SS *and* Rec *run in expected polynomial time.*

Average-case secure sketches. In many situations, it may well be that the adversary's information i about the password w is probabilistic, so that sometimes i reveals a lot about w, but most of the time w stays hard to predict even given i. In this case, the previous definition of a secure sketch is hard to apply: it provides no guarantee if $\mathbf{H}_\infty(W|i)$ is not fixed to at least m for some bad (but infrequent) values of i. A more robust definition would provide the same guarantee for all pairs of variables (W, I) such that predicting the value of W given the value of I is hard. We therefore define an *average-case* secure sketch as follows.

DEFINITION 4. *An* average-case $(\mathcal{M}, m, \tilde{m}, t)$-secure sketch *is a secure sketch (as defined in Definition* 3*) whose security property is strengthened as follows: for any random variables* W *over* $\mathcal{M}$ *and* I *over* $\{0,1\}^*$ *such that* $\tilde{\mathbf{H}}_\infty(W \mid I) \ge m$, *we have* $\tilde{\mathbf{H}}_\infty(W \mid (\mathsf{SS}(W), I)) \ge \tilde{m}$. *Note that an average-case secure sketch is also a secure sketch (take* I *to be empty).*

This definition has the advantage that it composes naturally, as Lemma 4.7 shows. All of our constructions will in fact be average-case secure sketches. However, we will often omit the term "average-case" for simplicity of exposition.

Entropy loss. The quantity $\tilde{m}$ is called the *residual (min-)entropy* of the secure sketch, and the quantity $\lambda = m - \tilde{m}$ is called the *entropy loss* of a secure sketch. In analyzing the security of our secure sketch constructions below, we will typically bound the entropy loss regardless of m, thus obtaining families of secure sketches that work for all m (in general, [62] shows that the entropy loss of a secure sketch is upperbounded by its entropy loss on the uniform distribution of inputs). Specifically, for a given construction of SS, Rec, and a given value t, we will get a value λ for the

entropy loss, such that, for *any* m, $(\mathsf{SS}, \mathsf{Rec})$ is an $(\mathcal{M}, m, m-\lambda, t)$-secure sketch. In fact, the most common way to obtain such secure sketches would be to bound the entropy loss by the length of the secure sketch $\mathsf{SS}(w)$, as given in the following simple lemma.

LEMMA 3.1. *Assume some algorithms* SS *and* Rec *satisfy the correctness property of a secure sketch for some value of* t *and that the output range of* SS *has size at most* 2^λ *(this holds, in particular, if the length of the sketch is bounded by* λ*). Then, for any min-entropy threshold* m, $(\mathsf{SS}, \mathsf{Rec})$ *form an average-case* $(\mathcal{M}, m, m-\lambda, t)$*-secure sketch for* $\mathcal{M}$*. In particular, for any* m*, the entropy loss of this construction is at most* λ*.*

Proof. The result follows immediately from Lemma 2.2(b), since $\mathsf{SS}(W)$ has at most 2^λ values: for any (W, I), $\tilde{\mathbf{H}}_\infty(W \mid (\mathsf{SS}(W), I)) \geq \tilde{\mathbf{H}}_\infty(W \mid I) - \lambda$. □

The above observation formalizes the intuition that a good secure sketch should be as short as possible. In particular, a short secure sketch will likely result in a better entropy loss. More discussion about this relation can be found in section 9.

3.2. Fuzzy extractors.

DEFINITION 5. *An* $(\mathcal{M}, m, \ell, t, \epsilon)$-fuzzy extractor *is a pair of randomized procedures, "generate" (*Gen*) and "reproduce" (*Rep*), with the following properties:*

1. *The generation procedure* Gen *on input* $w \in \mathcal{M}$ *outputs an extracted string* $R \in \{0,1\}^\ell$ *and a helper string* $P \in \{0,1\}^*$.
2. *The reproduction procedure* Rep *takes an element* $w' \in M$ *and a bit string* $P \in \{0,1\}^*$ *as inputs. The* correctness *property of fuzzy extractors guarantees that if* $\mathsf{dis}(w, w') \leq t$ *and* R, P *were generated by* $(R, P) \leftarrow \mathsf{Gen}(w)$*, then* $\mathsf{Rep}(w', P) = R$*. If* $\mathsf{dis}(w, w') > t$*, then no guarantee is provided about the output of* Rep.
3. *The* security *property guarantees that for any distribution* W *on* $\mathcal{M}$ *of min-entropy* m*, the string* R *is nearly uniform even for those who observe* P*: if* $(R, P) \leftarrow \mathsf{Gen}(W)$*, then* $\mathbf{SD}((R, P), (U_\ell, P)) \leq \epsilon$.

A fuzzy extractor is efficient *if* Gen *and* Rep *run in expected polynomial time.*

In other words, fuzzy extractors allow one to extract some randomness R from w and then successfully reproduce R from any string w' that is close to w. The reproduction uses the helper string P produced during the initial extraction; yet P need not remain secret, because R looks truly random even given P. To justify our terminology, notice that strong extractors (as defined in section 2) can indeed be seen as "nonfuzzy" analogues of fuzzy extractors, corresponding to $t = 0$, $P = X$, and $\mathcal{M} = \{0,1\}^n$.

We reiterate that the nearly uniform random bits output by a fuzzy extractor can be used in any cryptographic context that requires uniform random bits (e.g., for secret keys). The slight nonuniformity of the bits may decrease security, but by no more than their distance ϵ from uniform. By choosing ϵ negligibly small (e.g., 2^{-80} should be enough in practice), one can make the decrease in security irrelevant.

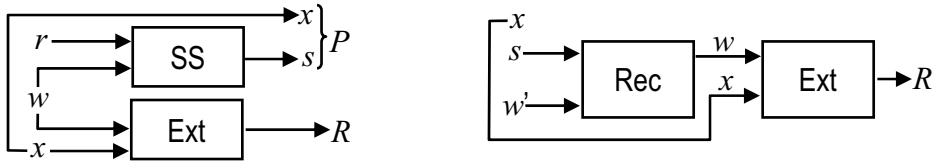
Similarly to secure sketches, the quantity $m - \ell$ is called the *entropy loss* of a fuzzy extractor. Also similarly, a more robust definition is that of an *average-case* fuzzy extractor, which requires that if $\tilde{\mathbf{H}}_\infty(W \mid I) \geq m$, then $\mathbf{SD}((R, P, I), (U_\ell, P, I)) \leq \epsilon$ for any auxiliary random variable I.

4. Metric-independent results.

In this section we demonstrate some general results that do not depend on specific metric spaces. They will be helpful in obtaining specific results for particular metric spaces below. In addition to the results in this section, some generic combinatorial lower bounds on secure sketches and fuzzy

extractors are contained in Appendix C. We will later use these bounds to show the near-optimality of some of our constructions for the case of uniform inputs.[7]

4.1. Construction of fuzzy extractors from secure sketches. Not surprisingly, secure sketches are quite useful in constructing fuzzy extractors. Specifically, we construct fuzzy extractors from secure sketches and strong extractors as follows: apply SS to w to obtain s, and a strong extractor Ext with randomness x to w to obtain R. Store (s, x) as the helper string P. To reproduce R from w' and $P = (s, x)$, first use $\mathsf{Rec}(w', s)$ to recover w and then $\mathsf{Ext}(w, x)$ to get R.



A few details need to be filled in. First, in order to apply Ext to w, we will assume that one can represent elements of $\mathcal{M}$ using n bits. Second, since after leaking the secure sketch value s, the password w has only *conditional* min-entropy, technically we need to use the *average-case* strong extractor, as defined in Definition 2. The formal statement is given below.

LEMMA 4.1 (fuzzy extractors from sketches). *Assume* $(\mathsf{SS}, \mathsf{Rec})$ *is an* $(\mathcal{M}, m, \tilde{m}, t)$*-secure sketch, and let* Ext *be an* average-case $(n, \tilde{m}, \ell, \epsilon)$*-strong extractor. Then the following* $(\mathsf{Gen}, \mathsf{Rep})$ *is an* $(\mathcal{M}, m, \ell, t, \epsilon)$*-fuzzy extractor:*

- $\mathsf{Gen}(w; r, x)$*: set* $P = (\mathsf{SS}(w; r), x)$ *and* $R = \mathsf{Ext}(w; x)$*, and output* (R, P)*.*
- $\mathsf{Rep}(w', (s, x))$*: recover* $w = \mathsf{Rec}(w', s)$*, and output* $R = \mathsf{Ext}(w; x)$*.*

Proof. From the definition of a secure sketch (Definition 3), we know that $\tilde{\mathbf{H}}_\infty(W \mid \mathsf{SS}(W)) \geq \tilde{m}$. And since Ext is an average-case $(n, \tilde{m}, \ell, \epsilon)$-strong extractor,

$$\mathbf{SD}\left((\mathsf{Ext}(W; X), \mathsf{SS}(W), X), (U_\ell, \mathsf{SS}(W), X)\right) = \mathbf{SD}\left((R, P), (U_\ell, P)\right) \leq \epsilon\,. \qquad \square$$

On the other hand, if one would like to use a worst-case strong extractor, we can apply Lemma 2.3 to get the following corollary.

COROLLARY 4.2. *If* $(\mathsf{SS}, \mathsf{Rec})$ *is an* $(\mathcal{M}, m, \tilde{m}, t)$*-secure sketch and* Ext *is an* $(n, \tilde{m} - \log\left(\frac{1}{\delta}\right), \ell, \epsilon)$*-strong extractor, then the above construction* $(\mathsf{Gen}, \mathsf{Rep})$ *is a* $(\mathcal{M}, m, \ell, t, \epsilon + \delta)$*-fuzzy extractor.*

Both Lemma 4.1 and Corollary 4.2 hold (with the same proofs) for building *average-case* fuzzy extractors from *average-case* secure sketches.

While the above statements work for general extractors, for our purposes we can simply use universal hashing, since it is an average-case strong extractor that achieves the optimal [59] entropy loss of $2\log\left(\frac{1}{\epsilon}\right)$. In particular, the lemma below is an immediate corollary of Lemmas 2.4 and 4.1.

LEMMA 4.3. *If* $(\mathsf{SS}, \mathsf{Rec})$ *is an* $(\mathcal{M}, m, \tilde{m}, t)$*-secure sketch and* Ext *is an* $(n, \tilde{m}, \ell, \epsilon)$*-strong extractor given by universal hashing (in particular, any* $\ell \leq \tilde{m} - 2\log\left(\frac{1}{\epsilon}\right) + 2$ *can be achieved), then the above construction* $(\mathsf{Gen}, \mathsf{Rep})$ *is an* $(\mathcal{M}, m, \ell, t, \epsilon)$*-fuzzy extractor. In particular, one can extract up to* $(\tilde{m} - 2\log\left(\frac{1}{\epsilon}\right) + 2)$ *nearly uniform bits from a secure sketch with residual min-entropy* $\tilde{m}$*.*

[7] Although we believe our constructions to be near optimal for nonuniform inputs as well, and our combinatorial bounds in Appendix C are also meaningful for such inputs, at this time we can use these bounds effectively only for uniform inputs.

Again, if the above secure sketch is average-case secure, then so is the resulting fuzzy extractor. In fact, combining the above result with Lemma 3.1, we get the following general construction of average-case fuzzy extractors.

LEMMA 4.4. *Assume some algorithms* SS *and* Rec *satisfy the correctness property of a secure sketch for some value of* t*, and that the output range of* SS *has size at most* 2^λ *(this holds, in particular, if the length of the sketch is bounded by* λ*). Then, for any min-entropy threshold* m*, there exists an average-case* $(\mathcal{M}, m, m-\lambda-2\log\left(\frac{1}{\epsilon}\right)+2, t, \epsilon)$*-fuzzy extractor for* $\mathcal{M}$*. In particular, for any* m*, the entropy loss of the fuzzy extractor is at most* $\lambda + 2\log\left(\frac{1}{\epsilon}\right) - 2$*.*

4.2. Secure sketches for transitive metric spaces. We give a general technique for building secure sketches in *transitive* metric spaces, which we now define. A permutation π on a metric space $\mathcal{M}$ is an *isometry* if it preserves distances, i.e., $\mathsf{dis}(a,b) = \mathsf{dis}(\pi(a), \pi(b))$. A family of permutations $\Pi = \{\pi_i\}_{i\in\mathcal{I}}$ acts *transitively* on $\mathcal{M}$ if, for any two elements $a, b \in \mathcal{M}$, there exists $\pi_i \in \Pi$ such that $\pi_i(a) = b$. Suppose we have a family Π of transitive isometries for $\mathcal{M}$ (we will call such $\mathcal{M}$ *transitive*). For example, in the Hamming space, the set of all shifts $\pi_x(w) = w \oplus x$ is such a family (see section 5 for more details on this example).

Construction 1 (secure sketch for transitive metric spaces). Let C be an $(\mathcal{M}, K, t)$-code. Then the general sketching scheme SS is the following: given an input $w \in \mathcal{M}$, pick uniformly at random a codeword $b \in C$, pick uniformly at random a permutation $\pi \in \Pi$ such that $\pi(w) = b$, and output $\mathsf{SS}(w) = \pi$ (it is crucial that each $\pi \in \Pi$ should have a canonical description that is independent of how π was chosen and, in particular, independent of b and w; the number of possible outputs of SS should thus be $|\Pi|$). The recovery procedure Rec to find w given w' and the sketch π is as follows: find the closest codeword b' to $\pi(w')$, and output $\pi^{-1}(b')$.

Let Γ be the number of elements $\pi \in \Pi$ such that $\min_{w,b} |\{\pi | \pi(w) = b\}| \geq \Gamma$. That is, for each w and b, there are at least Γ choices for π. Then we obtain the following lemma.

LEMMA 4.5. $(\mathsf{SS}, \mathsf{Rec})$ *is an average-case* $(\mathcal{M}, m, m - \log|\Pi| + \log\Gamma + \log K, t)$*-secure sketch. It is efficient if operations on the code, as well as* π *and* π^{-1}*, can be implemented efficiently.*

Proof. Correctness is clear: when $\mathsf{dis}(w, w') \leq t$, then $\mathsf{dis}(b, \pi(w')) \leq t$, so decoding $\pi(w')$ will result in $b' = b$, which in turn means that $\pi^{-1}(b') = w$. The intuitive argument for security is as follows: we add $\log K + \log\Gamma$ bits of entropy by choosing b and π, and we subtract $\log|\Pi|$ by publishing π. Since, given π, w and b determine each other, the total entropy loss is $\log|\Pi| - \log K - \log\Gamma$. More formally, $\tilde{\mathbf{H}}_\infty(W \mid \mathsf{SS}(W), I) = \tilde{\mathbf{H}}_\infty((W, \mathsf{SS}(W)) \mid I) - \log|\Pi|$ by Lemma 2.2(b). Given a particular value of w, there are K equiprobable choices for b and, further, at least Γ equiprobable choices for π once b is picked, and hence any given permutation π is chosen with probability at most $1/(K\Gamma)$ (because different choices for b result in different choices for π). Therefore, for all i, w, and π, $\Pr[W = w \wedge \mathsf{SS}(w) = \pi \mid I = i] \leq \Pr[W = w \mid I = i]/(K\Gamma)$; hence $\tilde{\mathbf{H}}_\infty((W, \mathsf{SS}(W)) \mid I) \geq \tilde{\mathbf{H}}_\infty(W \mid I) + \log K + \log\Gamma$. □

Naturally, security loss will be smaller if the code C is denser.

We will discuss concrete instantiations of this approach in sections 5 and 6.1.

4.3. Changing metric spaces via biometric embeddings. We now introduce a general technique that allows one to build fuzzy extractors and secure sketches in some metric space $\mathcal{M}_1$ from fuzzy extractors and secure sketches in some other metric space $\mathcal{M}_2$. Below, we let $\mathsf{dis}(\cdot,\cdot)_i$ denote the distance function in $\mathcal{M}_i$. The

technique is to *embed* $\mathcal{M}_1$ into $\mathcal{M}_2$ so as to "preserve" relevant parameters for fuzzy extraction.

DEFINITION 6. *A function $f : \mathcal{M}_1 \to \mathcal{M}_2$ is called a (t_1, t_2, m_1, m_2)-biometric embedding if the following two conditions hold:*

- *For any $w_1, w_1' \in \mathcal{M}_1$ such that $\mathsf{dis}(w_1, w_1')_1 \le t_1$, we have $\mathsf{dis}(f(w_1), f(w_2))_2 \le t_2$.*
- *For any distribution W_1 on $\mathcal{M}_1$ of min-entropy at least m_1, $f(W_1)$ has min-entropy at least m_2.*

The following lemma is immediate (correctness of the resulting fuzzy extractor follows from the first condition, and security follows from the second).

LEMMA 4.6. *If f is a (t_1, t_2, m_1, m_2)-biometric embedding of $\mathcal{M}_1$ into $\mathcal{M}_2$ and $(\mathsf{Gen}(\cdot), \mathsf{Rep}(\cdot,\cdot))$ is an $(\mathcal{M}_2, m_2, \ell, t_2, \epsilon)$-fuzzy extractor, then $(\mathsf{Gen}(f(\cdot)), \mathsf{Rep}(f(\cdot), \cdot))$ is an $(\mathcal{M}_1, m_1, \ell, t_1, \epsilon)$-fuzzy extractor.*

It is easy to define *average-case* biometric embeddings (in which $\tilde{\mathbf{H}}_\infty(W_1 \mid I) \ge m_1 \Rightarrow \tilde{\mathbf{H}}_\infty(f(W_1) \mid I) \ge m_2$) which would result in an analogous lemma for average-case fuzzy extractors.

For a similar result to hold for secure sketches, we need biometric embeddings with an additional property.

DEFINITION 7. *A function $f : \mathcal{M}_1 \to \mathcal{M}_2$ is called a* (t_1, t_2, λ)-biometric embedding with recovery information g *if the following hold:*

- *For any $w_1, w_1' \in \mathcal{M}_1$ such that $\mathsf{dis}(w_1, w_1')_1 \le t_1$, we have $\mathsf{dis}(f(w_1), f(w_2))_2 \le t_2$.*
- *$g : M_1 \to \{0,1\}^*$ is a function with range size at most 2^λ, and $w_1 \in M_1$ is uniquely determined by $(f(w_1), g(w_1))$.*

With this definition, we get the following analogue of Lemma 4.6.

LEMMA 4.7. *Let f be a (t_1, t_2, λ)-biometric embedding with recovery information g. Let $(\mathsf{SS}, \mathsf{Rec})$ be an $(\mathcal{M}_2, m_1 - \lambda, \tilde{m}_2, t_2)$ average-case secure sketch. Let $\mathsf{SS}'(w) = (\mathsf{SS}(f(w)), g(w))$. Let $\mathsf{Rec}'(w', (s, r))$ be the function obtained by computing $\mathsf{Rec}(w', s)$ to get $f(w)$ and then inverting $(f(w), r)$ to get w. Then $(\mathsf{SS}', \mathsf{Rec}')$ is an $(\mathcal{M}_1, m_1, \tilde{m}_2, t_1)$ average-case secure sketch.*

Proof. The correctness of this construction follows immediately from the two properties given in Definition 7. As for security, using Lemma 2.2(b) and the fact that the range of g has size at most 2^λ, we get that $\tilde{\mathbf{H}}_\infty(W \mid g(W)) \ge m_1 - \lambda$ whenever $\mathbf{H}_\infty(W) \ge m_1$. Moreover, since W is uniquely recoverable from $f(W)$ and $g(W)$, it follows that $\tilde{\mathbf{H}}_\infty(f(W) \mid g(W)) \ge m_1 - \lambda$ as well whenever $\mathbf{H}_\infty(W) \ge m_1$. Using the fact that $(\mathsf{SS}, \mathsf{Rec})$ is an *average-case* $(\mathcal{M}_2, m_1 - \lambda, \tilde{m}_2, t_2)$-secure sketch, we get that $\tilde{\mathbf{H}}_\infty(f(W) \mid (\mathsf{SS}(W), g(W))) = \tilde{\mathbf{H}}_\infty(f(W) \mid \mathsf{SS}'(W)) \ge \tilde{m}_2$. Finally, since the application of f can only reduce min-entropy, $\tilde{\mathbf{H}}_\infty(W \mid \mathsf{SS}'(W)) \ge \tilde{m}_2$ whenever $\mathbf{H}_\infty(W) \ge m_1$. □

As we saw, the proof above critically used the notion of average-case secure sketches. Luckily, all our constructions (for example, those obtained via Lemma 3.1) are average-case, so this subtlety will not matter too much.

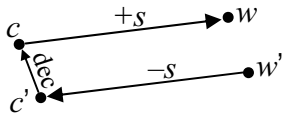
We will see the utility of this novel type of embedding in section 7.

5. Constructions for Hamming distance. In this section we consider constructions for the space $\mathcal{M} = \mathcal{F}^n$ under the Hamming distance metric. Let $F = |\mathcal{F}|$ and $f = \log_2 F$.

Secure sketches: The code-offset construction. For the case of $\mathcal{F} = \{0,1\}$, Juels and Wattenberg [39] considered a notion of "fuzzy commitment."[8] Given an $[n, k, 2t+1]_2$ error-correcting code C (not necessarily linear), they fuzzy-commit to x by publishing $w \oplus C(x)$. Their construction can be rephrased in our language to give a very simple construction of secure sketches for general $\mathcal{F}$.

We start with an $[n, k, 2t+1]_{\mathcal{F}}$ error-correcting code C (not necessarily linear). The idea is to use C to correct errors in w even though w may not be in C. This is accomplished by shifting the code so that a codeword matches up with w and storing the shift as the sketch. To do so, we need to view $\mathcal{F}$ as an additive cyclic group of order $\mathcal{F}$ (in the case of most common error-correcting codes, F will already be a field).

Construction 2 (code-offset construction). On input w, select a random codeword c (this is equivalent to choosing a random $x \in \mathcal{F}^k$ and computing $C(x)$), and set $\mathsf{SS}(w)$ to be the shift needed to get from c to w: $\mathsf{SS}(w) = w - c$. Then $\mathsf{Rec}(w', s)$ is computed by subtracting the shift s from w' to get $c' = w' - s$, decoding c' to get c (note that because $\mathsf{dis}(w', w) \le t$, so is $\mathsf{dis}(c', c)$), and computing w by shifting back to get $w = c + s$.



In the case of $\mathcal{F} = \{0,1\}$, addition and subtraction are the same, and we get that computation of the sketch is the same as the Juels–Wattenberg commitment: $\mathsf{SS}(w) = w \oplus C(x)$. In this case, to recover w given w' and $s = \mathsf{SS}(w)$, compute $c' = w' \oplus s$, decode c' to get c, and compute $w = c \oplus s$.

When the code C is linear, this scheme can be simplified as follows.

Construction 3 (syndrome construction). Set $\mathsf{SS}(w) = \mathsf{syn}(w)$. To compute $\mathsf{Rec}(w', s)$, find the unique vector $e \in \mathcal{F}^n$ of Hamming weight $\le t$ such that $\mathsf{syn}(e) = \mathsf{syn}(w') - s$, and output $w = w' - e$.

As explained in section 2, finding the short error-vector e from its syndrome is the same as decoding the code. It is easy to see that two constructions above are equivalent: given $\mathsf{syn}(w)$ one can sample from $w - c$ by choosing a random string v with $\mathsf{syn}(v) = \mathsf{syn}(w)$; conversely, $\mathsf{syn}(w - c) = \mathsf{syn}(w)$. To show that Rec finds the correct w, observe that $\mathsf{dis}(w' - e, w') \le t$ by the constraint on the weight of e, and $\mathsf{syn}(w' - e) = \mathsf{syn}(w') - \mathsf{syn}(e) = \mathsf{syn}(w') - (\mathsf{syn}(w') - s) = s$. There can be only one value within distance t of w' whose syndrome is s (else by subtracting two such values we get a codeword that is closer than $2t+1$ to 0, but 0 is also a codeword), so $w' - e$ must be equal to w.

As mentioned in the introduction, the syndrome construction has appeared before as a component of some cryptographic protocols over quantum and other noisy channels [6, 18], though it has not been analyzed the same way.

Both schemes are $(\mathcal{F}^n, m, m - (n-k)f, t)$-secure sketches. For the randomized scheme, the intuition for understanding the entropy loss is as follows: we add k random elements of $\mathcal{F}$ and publish n elements of $\mathcal{F}$. The formal proof is simply Lemma 4.5, because addition in $\mathcal{F}^n$ is a family of transitive isometries. For the syndrome scheme, this follows from Lemma 3.1, because the syndrome is $(n-k)$ elements of $\mathcal{F}$.

We thus obtain the following theorem.

[8] In their interpretation, one commits to x by picking a random w and publishing $\mathsf{SS}(w; x)$.

THEOREM 5.1. *Given an $[n, k, 2t+1]_{\mathcal{F}}$ error-correcting code, one can construct an average-case $(\mathcal{F}^n, m, m-(n-k)f, t)$-secure sketch, which is efficient if encoding and decoding are efficient. Furthermore, if the code is linear, then the sketch is deterministic, and its output is $(n-k)$ symbols long.*

In Appendix C we present some generic lower bounds on secure sketches and fuzzy extractors. Recall that $A_F(n,d)$ denotes the maximum number K of codewords possible in a code of distance d over n-character words from an alphabet of size F. Then by Lemma C.1, we obtain that the entropy loss of a secure sketch for the Hamming metric is at least $nf - \log_2 A_F(n, 2t+1)$ when the input is uniform (that is, when $m = nf$), because $K(\mathcal{M}, t)$ from Lemma C.1 is in this case equal to $A_F(n, 2t+1)$ (since a code that corrects t Hamming errors must have minimum distance at least $2t+1$). This means that if the underlying code is optimal (i.e., $K = A_F(n, 2t+1)$), then the code-offset construction above is optimal for the case of uniform inputs, because its entropy loss is $nf - \log_F K \log_2 F = nf - \log_2 K$. Of course, we do not know the exact value of $A_F(n,d)$, let alone any efficiently decodable codes which meet the bound, for many settings of F, n, and d. Nonetheless, the code-offset scheme gets as close to optimality as possible given the coding constraints. If better efficient codes are invented, then better (i.e., lower loss or higher error-tolerance) secure sketches will result.

Fuzzy extractors. As a warm-up, consider the case when W is uniform ($m = n$), and look at the code-offset sketch construction: $v = w - C(x)$. For $\mathsf{Gen}(w)$, output $R = x$, $P = v$. For $\mathsf{Rep}(w', P)$, decode $w' - P$ to obtain $C(x)$, and apply C^{-1} to obtain x. The result, quite clearly, is an $(\mathcal{F}^n, nf, kf, t, 0)$-fuzzy extractor, since v is truly random and independent of x when w is random. In fact, this is exactly the usage proposed by Juels and Wattenberg [39], except they viewed the above fuzzy extractor as a way to use w to "fuzzy commit" to x, without revealing information about x.

Unfortunately, the above construction setting $R = x$ works only for uniform W, since otherwise v would leak information about x.

In general, we use the construction in Lemma 4.3 combined with Theorem 5.1 to obtain the following theorem.

THEOREM 5.2. *Given any $[n, k, 2t+1]_{\mathcal{F}}$ code C and any m, ϵ, there exists an average-case $(\mathcal{M}, m, \ell, t, \epsilon)$-fuzzy extractor, where $\ell = m + kf - nf - 2\log\left(\frac{1}{\epsilon}\right) + 2$. The generation Gen and recovery Rep are efficient if C has efficient encoding and decoding.*

6. Constructions for set difference. We now turn to inputs that are subsets of a universe $\mathcal{U}$; let $n = |\mathcal{U}|$. This corresponds to representing an object by a list of its features. Examples include "minutiae" (ridge meetings and endings) in a fingerprint, short strings which occur in a long document, or lists of favorite movies.

Recall that the distance between two sets w, w' is the size of their symmetric difference: $\mathsf{dis}(w, w') = |w \triangle w'|$. We will denote this metric space by $\mathsf{SDif}(\mathcal{U})$. A set w can be viewed as its *characteristic vector* in $\{0,1\}^n$, with 1 at position $x \in \mathcal{U}$ if $x \in w$, and 0 otherwise. Such representation of sets makes set difference the same as the Hamming metric. However, we will mostly focus on settings where n is much larger than the size of w, so that representing a set w by n bits is much less efficient than, say, writing down a list of elements in w, which requires only $|w| \log n$ bits.

Large versus small universes. More specifically, we will distinguish two broad categories of settings. Let s denote the size of the sets that are given as inputs to the secure sketch (or fuzzy extractor) algorithms. Most of this section studies situations

where the universe size n is superpolynomial in the set size s. We call this the "large universe" setting. In contrast, the "small universe" setting refers to situations in which $n = poly(s)$. We want our various constructions to run in polynomial time and use polynomial storage space. In the large universe setting, the n-bit string representation of a set becomes too large to be usable—we will strive for solutions that are polynomial in s and $\log n$.

In fact, in many applications—for example, when the input is a list of book titles—it is possible that the actual universe is not only large, but also difficult to enumerate, making it difficult to even find the position in the characteristic vector corresponding to $x \in w$. In that case, it is natural to enlarge the universe to a well-understood class—for example, to include all possible strings of a certain length, whether or not they are actual book titles. This has the advantage that the position of x in the characteristic vector is simply x itself; however, because the universe is now even larger, the dependence of running time on n becomes even more important.

Fixed versus flexible set size. In some situations, all objects are represented by feature sets of exactly the same size s, while in others the sets may be of arbitrary size. In particular, the original set w and the corrupted set w' from which we would like to recover the original need not be of the same size. We refer to these two settings as *fixed* and *flexible* set size, respectively. When the set size is fixed, the distance $\mathsf{dis}(w, w')$ is always even: $\mathsf{dis}(w, w') = t$ if and only if w and w' agree on exactly $s - \frac{t}{2}$ points. We will denote the restriction of $\mathsf{SDif}(\mathcal{U})$ to s-element subsets by $\mathsf{SDif}_s(\mathcal{U})$.

Summary. As a point of reference, we will see below that $\log \binom{n}{s} - \log A(n, 2t+1, s)$ is a lower bound on the entropy loss of any secure sketch for set difference (whether or not the set size is fixed). Recall that $A(n, 2t + 1, s)$ represents the size of the largest code for Hamming space with minimum distance $2t + 1$, in which every word has weight exactly s. In the large universe setting, where $t \ll n$, the lower bound is approximately $t \log n$. The relevant lower bounds are discussed at the end of sections 6.1 and 6.2.

In the following sections we will present several schemes which meet this lower bound. The setting of small universes is discussed in section 6.1. We discuss the code-offset construction (from section 5), as well as a permutation-based scheme which is tailored to a fixed set size. The latter scheme is optimal for this metric but impractical.

In the remainder of the section, we discuss schemes for the large universe setting. In section 6.2 we give an improved version of the scheme of Juels and Sudan [38]. Our version achieves optimal entropy loss and storage $t \log n$ for fixed set size (notice the entropy loss does not depend on the set size s, although the running time does). The new scheme provides an exponential improvement over the original parameters (which are analyzed in Appendix D). Finally, in section 6.3 we describe how to adapt syndrome decoding algorithms for BCH codes to our application. The resulting scheme, called PinSketch, has optimal storage and entropy loss $t \log(n + 1)$, handles flexible set sizes, and is probably the most practical of the schemes presented here. Another scheme achieving similar parameters (but less efficiently) can be adapted from information reconciliation literature [51]; see section 9 for more details.

We do not discuss fuzzy extractors beyond mentioning here that each secure sketch presented in this section can be converted to a fuzzy extractor using Lemma 4.3. We have already seen an example of such a conversion in section 5.

Table 1 summarizes the constructions discussed in this section.

6.1. Small universes. When the universe size is polynomial in s, there are a number of natural constructions. The most direct one, given previous work, is the

TABLE 1

Summary of secure sketches for set difference. Notes: In the Juels–Sudan (JS) scheme, r is a parameter, $s \le r \le n$; generic syndrome and permutation-based schemes achieve entropy loss similar to that of the improved Juels–Sudan scheme and PinSketch, $\approx t \log n$, when $t \ll n$; see section 6.3 for running time of PinSketch.

	Entropy loss	Storage	Time	Set size
Juels–Sudan [38]	$t \log n + \log \left(\binom{n}{r} / \binom{n-s}{r-s} \right) + 2$	$r \log n$	$poly(r \log(n))$	Fixed
Generic syndrome	$n - \log A(n, 2t+1)$	$n - \log A(n, 2t+1)$ (for linear codes)	$poly(n)$	Flexible
Permutation-based	$\log \binom{n}{s} - \log A(n, 2t+1, s)$	$O(n \log n)$	$poly(n)$	Fixed
Improved JS	$t \log n$	$t \log n$	$poly(s \log n)$	Fixed
PinSketch	$t \log(n+1)$	$t \log(n+1)$	$poly(s \log n)$	Flexible

construction of Juels and Sudan [38]. Unfortunately, that scheme requires a fixed set size and achieves relatively poor parameters (see Appendix D).

We suggest two possible constructions. The first involves representing sets as n-bit strings and using the constructions of section 5. The second construction, presented below, requires a fixed set size but achieves slightly improved parameters by going through "constant-weight" codes.

Permutation-based sketch. Recall the general construction of section 4.2 for transitive metric spaces. Let Π be a set of all permutations on $\mathcal{U}$. Given $\pi \in \Pi$, make it a permutation on $\mathsf{SDif}_s(\mathcal{U})$ naturally: $\pi(w) = \{\pi(x) | x \in w\}$. This makes Π into a family of transitive isometries on $\mathsf{SDif}_s(\mathcal{U})$, and thus the results of section 4.2 apply.

Let $C \subseteq \{0,1\}^n$ be any $[n, k, 2t+1]$ binary code in which all words have weight exactly s. Such codes have been studied extensively (see, e.g., [1, 11] for a summary of known upper and lower bounds). View elements of the code as sets of size s. We obtain the following scheme, which produces a sketch of length $O(n \log n)$.

Construction 4 (permutation-based sketch). On input $w \subseteq \mathcal{U}$ of size s, choose $b \subseteq \mathcal{U}$ at random from the code C, and choose a random permutation $\pi : \mathcal{U} \to \mathcal{U}$ such that $\pi(w) = b$ (that is, choose a random matching between w and b and a random matching between $\mathcal{U} - w$ and $\mathcal{U} - b$). Output $\mathsf{SS}(w) = \pi$ (say, by listing $\pi(1), \ldots, \pi(n)$). To recover w from w' such that $\mathsf{dis}(w, w') \le t$ and π, compute $b' = \pi^{-1}(w')$, decode the characteristic vector of b' to obtain b, and output $w = \pi(b)$.

This construction is efficient as long as decoding is efficient (everything else takes time $O(n \log n)$). By Lemma 4.5, its entropy loss is $\log \binom{n}{s} - k$: here $|\Pi| = n!$ and $\Gamma = s!(n-s)!$, so $\log |\Pi| - \log \Gamma = \log n!/(s!(n-s)!)$.

Comparing the Hamming scheme with the permutation scheme. The code-offset construction was shown to have entropy loss $n - \log A(n, 2t+1)$ if an optimal code is used; the random permutation scheme has entropy loss $\log \binom{n}{s} - \log A(n, 2t+1, s)$ for an optimal code. The Bassalygo–Elias inequality (see [72]) shows that the bound on the random permutation scheme is always at least as good as the bound on the code offset scheme: $A(n, d) \cdot 2^{-n} \le A(n, d, s) \cdot \binom{n}{s}^{-1}$. This implies that $n - \log A(n, d) \ge \log \binom{n}{s} - \log A(n, d, s)$. Moreover, standard packing arguments give better constructions of constant-weight codes than they do of ordinary codes.[9] In fact, the random

[9] This comes from the fact that the intersection of a ball of radius d with the set of all words of weight s is much smaller than the ball of radius d itself.

permutations scheme is optimal for this metric, just as the code-offset scheme is optimal for the Hamming metric.

We show this as follows. Restrict t to be even, because $\mathsf{dis}(w, w')$ is always even if $|w| = |w'|$. Then the minimum distance of a code over $\mathsf{SDif}_s(\mathcal{U})$ that corrects up to t errors must be at least $2t + 1$. Indeed, suppose not. Then take two codewords, c_1 and c_2, such that $\mathsf{dis}(c_1, c_2) \le 2t$. There are k elements in c_1 that are not in c_2 (call their set $c_1 - c_2$), and k elements in c_2 that are not in c_1 (call their set $c_2 - c_1$) with $k \le t$. Starting with c_1, remove $t/2$ elements of $c_1 - c_2$ and add $t/2$ elements of $c_2 - c_1$ to obtain a set w (note that here we are using that t is even; if $k < t/2$, then use k elements). Then $\mathsf{dis}(c_1, w) \le t$ and $\mathsf{dis}(c_2, w) \le t$, and so if the received word is w, the receiver cannot be certain whether the sent word was c_1 or c_2 and hence cannot correct t errors.

Therefore, by Lemma C.1, we get that the entropy loss of a secure sketch must be at least $\log \binom{n}{s} - \log A(n, 2t + 1, s)$ in the case of a uniform input w. Thus in principle, it is better to use the random permutation scheme. Nonetheless, there are caveats. First, we do not know of *explicitly* constructed constant-weight codes that beat the Elias–Bassalygo inequality and would thus lead to better entropy loss for the random permutation scheme than for the Hamming scheme (see [11] for more on constructions of constant-weight codes and [1] for upper bounds). Second, much more is known about efficient implementation of decoding for ordinary codes than for constant-weight codes; for example, one can find off-the-shelf hardware and software for decoding many binary codes. In practice, the Hamming-based scheme is likely to be more useful.

6.2. Improving the construction of Juels and Sudan. We now turn to the large universe setting, where n is superpolynomial in the set size s, and we would like operations to be polynomial in s and $\log n$.

Juels and Sudan [38] proposed a secure sketch for the set difference metric with fixed set size (called a "fuzzy vault" in that paper). We present their original scheme here with an analysis of the entropy loss in Appendix D. In particular, our analysis shows that the original scheme has good entropy loss only when the storage space is very large.

We suggest an improved version of the Juels–Sudan scheme which is simpler and achieves much better parameters. The entropy loss and storage space of the new scheme are both $t \log n$, which is optimal. (The same parameters are also achieved by the BCH-based construction PinSketch in section 6.3.) Our scheme has the advantage of being even simpler to analyze, and the computations are simpler. As with the original Juels–Sudan scheme, we assume $n = |\mathcal{U}|$ is a prime power and work over $\mathcal{F} = GF(n)$.

An intuition for the scheme is that the numbers $y_{s+1}, \ldots, y_r$ from the Juels–Sudan scheme need not be chosen at random. One can instead evaluate them as $y_i = p'(x_i)$ for some polynomial p'. One can then represent the entire list of pairs (x_i, y_i) implicitly, using only a few of the coefficients of p'. The new sketch is deterministic (this was not the case for our preliminary version in [25]). Its implementation is available [36].

Construction 5 (improved Juels–Sudan secure sketch for sets of size s). To compute $\mathsf{SS}(w)$, do the following:

1. Let $p'()$ be the unique monic polynomial of degree exactly s such that $p'(x) = 0$ for all $x \in w$. (That is, let $p'(z) \stackrel{\text{def}}{=} \prod_{x \in w}(z - x)$.)
2. Output the coefficients of $p'()$ of degree $s - 1$ down to $s - t$.

This is equivalent to computing and outputting the first t symmetric polynomials of the values in A; i.e., if $w = \{x_1, \ldots, x_s\}$, then output

$$\sum_i x_i,\ \sum_{i \neq j} x_i x_j, \ldots,\ \sum_{S \subseteq [s], |S| = t} \left(\prod_{i \in S} x_i \right).$$

To compute $\mathsf{Rec}(w', p')$, where $w' = \{a_1, a_2, \ldots, a_s\}$, do the following:

1. Create a new polynomial p_{high}, of degree s which shares the top $t+1$ coefficients of p'; that is, let $p_{\text{high}}(z) \stackrel{\text{def}}{=} z^s + \sum_{i=s-t}^{s-1} a_i z^i$.
2. Evaluate p_{high} on all points in w' to obtain s pairs (a_i, b_i).
3. Use $[s, s-t, t+1]_{\mathcal{U}}$ Reed–Solomon decoding (see, e.g., [7, 72]) to search for a polynomial p_{low} of degree $s-t-1$ such that $p_{\text{low}}(a_i) = b_i$ for at least $s - t/2$ of the a_i values. If no such polynomial exists, then stop and output "fail."
4. Output the list of zeros (roots) of the polynomial $p_{\text{high}} - p_{\text{low}}$ (see, e.g., [66] for root-finding algorithms; they can be sped up by first factoring out the known roots—namely, $(z - a_i)$ for the $s - t/2$ values of a_i that were not deemed erroneous in the previous step).

To see that this secure sketch can tolerate t set difference errors, suppose that $\mathsf{dis}(w, w') \leq t$. Let p' be as in the sketch algorithm; that is, $p'(z) = \prod_{x \in w}(z - x)$. The polynomial p' is monic; that is, its leading term is z^s. We can divide the remaining coefficients into two groups: the high coefficients, denoted $a_{s-t}, \ldots, a_{s-1}$, and the low coefficients, denoted $b_1, \ldots, b_{s-t-1}$:

$$p'(z) = \underbrace{z^s + \sum_{i=s-t}^{s-1} a_i z^i}_{p_{\text{high}}(z)} + \underbrace{\sum_{i=0}^{s-t-1} b_i z^i}_{q(z)}.$$

We can write p' as $p_{\text{high}} + q$, where q has degree $s - t - 1$. The recovery algorithm gets the coefficients of p_{high} as input. For any point x in w, we have $0 = p'(x) = p_{\text{high}}(x) + q(x)$. Thus, p_{high} and $-q$ agree at all points in w. Since the set w intersects w' in at least $s - t/2$ points, the polynomial $-q$ satisfies the conditions of step 3 in Rec. That polynomial is unique, since no two distinct polynomials of degree $s - t - 1$ can get the correct b_i on more than $s - t/2$ a_is (else, they agree on at least $s - t$ points, which is impossible). Therefore, the recovered polynomial p_{low} must be $-q$; hence $p_{\text{high}}(x) - p_{\text{low}}(x) = p'(x)$. Thus, Rec computes the correct p' and therefore correctly finds the set w, which consists of the roots of p'.

Since the output of SS is t field elements, the entropy loss of the scheme is at most $t \log n$ by Lemma 3.1. (We will see below that this bound is tight, since any sketch must lose at least $t \log n$ in some situations.) We have proven the following theorem.

THEOREM 6.1 (analysis of improved Juels–Sudan). *Construction* 5 *is an average-case* $(\mathsf{SDif}_s(\mathcal{U}), m, m - t \log n, t)$ *secure sketch. The entropy loss and storage of the scheme are at most* $t \log n$*, and both the sketch generation* $\mathsf{SS}()$ *and the recovery procedure* $\mathsf{Rec}()$ *run in time polynomial in* s*,* t*, and* $\log n$*.*

Lower bounds for fixed set size in a large universe. The short length of the sketch makes this scheme feasible for essentially any ratio of set size to universe size (we only need $\log n$ to be polynomial in s). Moreover, for large universes the entropy loss $t \log n$ is essentially optimal for uniform inputs (i.e., when $m = \log \binom{n}{s}$). We show this as follows. As already mentioned in section 6.1, Lemma C.1 shows that for a uniformly distributed input, the best possible entropy loss is $m - m' \geq \log \binom{n}{s} - \log A(n, 2t+1, s)$.

By Theorem 12 of Agrell, Vardy, and Zeger [1],

$$A(n, 2t+2, s) \le \frac{\binom{n}{s-t}}{\binom{s}{s-t}}.$$

Noting that $A(n, 2t+1, s) = A(n, 2t+2, s)$ because distances in $\mathsf{SDif}_s(\mathcal{U})$ are even, the entropy loss is at least

$$\begin{aligned} m - m' &\ge \log \binom{n}{s} - \log A(n, 2t+1, s) \\ &\ge \log \binom{n}{s} - \log \left(\binom{n}{s-t} \Big/ \binom{s}{s-t} \right) \\ &= \log \binom{n-s+t}{t}. \end{aligned}$$

When $n \gg s$, this last quantity is roughly $t \log n$, as desired.

6.3. Large universes via the Hamming metric: Sublinear-time decoding. In this section, we show that the syndrome construction of section 5 can in fact be adapted for small sets in a large universe, using specific properties of algebraic codes. We will show that BCH codes, which contain Hamming and Reed–Solomon codes as special cases, have these properties. As opposed to the constructions of the previous section, the construction of this section is flexible and can accept input sets of any size.

Thus we obtain a sketch for sets of flexible size, with entropy loss and storage $t \log(n+1)$. We will assume that n is one less than a power of 2: $n = 2^m - 1$ for some integer m, and will identify $\mathcal{U}$ with the nonzero elements of the binary finite field of degree m: $\mathcal{U} = GF(2^m)^*$.

Syndrome manipulation for small-weight words. Suppose now that we have a small set $w \subseteq \mathcal{U}$ of size s, where $n \gg s$. Let x_w denote the characteristic vector of w (see the beginning of section 6). Then the syndrome construction says that $\mathsf{SS}(w) = \mathsf{syn}(x_w)$. This is an $(n-k)$-bit quantity. Note that the syndrome construction gives us no special advantage over the code-offset construction when the universe is small: storing the n-bit $x_w + C(r)$ for a random k-bit r is not a problem. However, it is a substantial improvement when $n \gg n - k$.

If we want to use $\mathsf{syn}(x_w)$ as the sketch of w, then we must choose a code with $n - k$ very small. In particular, the entropy of w is at most $\log \binom{n}{s} \approx s \log n$, and so the entropy loss $n - k$ had better be at most $s \log n$. Binary BCH codes are suitable for our purposes: they are a family of $[n, k, \delta]_2$ linear codes with $\delta = 2t + 1$ and $k = n - tm$ (assuming $n = 2^m - 1$) (see, e.g., [72]). These codes are optimal for $t \ll n$ by the Hamming bound, which implies that $k \le n - \log \binom{n}{t}$ [72].[10] Using the syndrome sketch with a BCH code C, we get entropy loss $n - k = t \log(n+1)$, which is essentially the same as the $t \log n$ of the improved Juels–Sudan scheme (recall that $\delta \ge 2t + 1$ allows us to correct t set difference errors).

The only problem is that the scheme appears to require computation time $\Omega(n)$, since we must compute $\mathsf{syn}(x_w) = Hx_w$ and, later, run a decoding algorithm to recover

[10] The Hamming bound is based on the observation that for any code of distance δ, the balls of radius $\lfloor (\delta - 1)/2 \rfloor$ centered at various codewords must be disjoint. Each such ball contains $\binom{n}{\lfloor (\delta-1)/2 \rfloor}$ points, and so $2^k \binom{n}{\lfloor (\delta-1)/2 \rfloor} \le 2^n$. In our case $\delta = 2t + 1$, and so the bound yields $k \le n - \log \binom{n}{t}$.

x_w. For BCH codes, this difficulty can be overcome. A word of small weight w can be described by listing the positions on which it is nonzero. We call this description the *support* of x_w and write $\mathrm{supp}(x_w)$ (note that $\mathrm{supp}(x_w) = w$; see the discussion of enlarging the universe appropriately at the beginning of section 6).

The following lemma holds for general BCH codes (which include binary BCH codes and Reed–Solomon codes as special cases). We state it for binary codes since that is most relevant to the application.

LEMMA 6.2. *For a $[n, k, \delta]$ binary BCH code C one can compute*

- $\mathsf{syn}(x)$*, given* $\mathrm{supp}(x)$*, in time polynomial in* δ*,* $\log n$*, and* $|\mathrm{supp}(x)|$*,*
- $\mathrm{supp}(x)$*, given* $\mathsf{syn}(x)$ *(when x has weight at most $(\delta - 1)/2$), in time polynomial in δ and* $\log n$*.*

The proof of Lemma 6.2 requires a careful reworking of the standard BCH decoding algorithm. The details are presented in Appendix E. For now, we present the resulting secure sketch for set difference.

Construction 6 (PinSketch). To compute $\mathsf{SS}(w) = \mathsf{syn}(x_w)$, do the following:

1. Let $s_i = \sum_{x \in w} x^i$ (computations in $GF(2^m)$).
2. Output $\mathsf{SS}(w) = (s_1, s_3, s_5, \ldots, s_{2t-1})$.

To recover $\mathsf{Rec}(w', (s_1, s_3, \ldots, s_{2t-1}))$, do the following:

1. Compute $(s'_1, s'_3, \ldots, s'_{2t-1}) = \mathsf{SS}(w') = \mathsf{syn}(x_{w'})$.
2. Let $\sigma_i = s'_i - s_i$ (in $GF(2^m)$, so "$-$" is the same as "$+$").
3. Compute $\mathrm{supp}(v)$ such that $\mathsf{syn}(v) = (\sigma_1, \sigma_3, \ldots, \sigma_{2t-1})$ and $|\mathrm{supp}(v)| \le t$ by Lemma 6.2.
4. If $\mathsf{dis}(w, w') \le t$, then $\mathrm{supp}(v) = w \triangle w'$. Thus, output $w = w' \triangle \mathrm{supp}(v)$.

An implementation of this construction, including the reworked BCH decoding algorithm, is available [36].

The bound on entropy loss is easy to see: the output is $t \log(n+1)$ bits long, and hence the entropy loss is at most $t \log(n+1)$ by Lemma 3.1. We obtain the following theorem.

THEOREM 6.3. *PinSketch is an average-case* $(\mathsf{SDif}(\mathcal{U}), m, m - t\log(n+1), t)$*-secure sketch for set difference with storage* $t \log(n+1)$*. The algorithms* SS *and* Rec *both run in time polynomial in t and* $\log n$*.*

7. Constructions for edit distance. The space of interest in this section is the space $\mathcal{F}^*$ for some alphabet $\mathcal{F}$, with distance between two strings defined as the number of character insertions and deletions needed to get from one string to the other. Denote this space by $\mathsf{Edit}_{\mathcal{F}}(n)$. Let $F = |\mathcal{F}|$.

First, note that applying the generic approach for transitive metric spaces (as with the Hamming space and the set difference space for small universe sizes) does not work here, because the edit metric is not known to be transitive. Instead, we consider embeddings of the edit metric on $\{0,1\}^n$ into the Hamming or set difference metric of much larger dimension. We look at two types: standard low-distortion embeddings and "biometric" embeddings as defined in section 4.3.

For the binary edit distance space of dimension n, we obtain secure sketches and fuzzy extractors correcting t errors with entropy loss roughly $tn^{o(1)}$, using a standard embedding, and $2.38\sqrt[3]{tn \log n}$, using a relaxed embedding. The first technique works better when t is small, say, $n^{1-\gamma}$ for a constant $\gamma > 0$. The second technique is better when t is large; it is meaningful roughly as long as $t < \frac{n}{15 \log^2 n}$.

7.1. Low-distortion embeddings. A (standard) embedding with distortion D is an injection $\psi : \mathcal{M}_1 \hookrightarrow \mathcal{M}_2$ such that for any two points $x, y \in \mathcal{M}_1$, the ratio

$\frac{\mathsf{dis}(\psi(x),\psi(y))}{\mathsf{dis}(x,y)}$ is at least 1 and at most D.

When the preliminary version of this paper appeared [25], no nontrivial embeddings were known mapping edit distance into ℓ_1 or the Hamming metric (i.e., known embeddings had distortion $O(n)$). Recently, Ostrovsky and Rabani [57] gave an embedding of the edit metric over $\mathcal{F} = \{0,1\}$ into ℓ_1 with subpolynomial distortion. It is an injective, polynomial time computable embedding which can be interpreted as mapping to the Hamming space $\{0,1\}^d$, where $d = \mathrm{poly}(n)$.[11]

FACT 7.1 (see [57]). *There is a polynomial time computable embedding denoted* $\psi_{\mathrm{ed}} : \mathsf{Edit}_{\{0,1\}}(n) \hookrightarrow \{0,1\}^{\mathrm{poly}(n)}$ *with distortion* $D_{\mathrm{ed}}(n) \stackrel{\mathrm{def}}{=} 2^{O(\sqrt{\log n \log\log n})}$.

We can compose this embedding with the fuzzy extractor constructions for the Hamming distance to obtain a fuzzy-extractor for edit distance which will be good when t, the number of errors to be corrected, is quite small. Recall that instantiating the syndrome fuzzy-extractor construction (Theorem 5.2) with a BCH code allows one to correct t' errors out of d at the cost of $t' \log d + 2\log\left(\frac{1}{\epsilon}\right) - 2$ bits of entropy.

Construction 7. For any length n and error threshold t, let ψ_{ed} be the embedding given by Fact 7.1 from $\mathsf{Edit}_{\{0,1\}}(n)$ into $\{0,1\}^d$ (where $d = \mathrm{poly}(n)$), and let syn be the syndrome of a BCH code correcting $t' = tD_{\mathrm{ed}}(n)$ errors in $\{0,1\}^d$. Let $\{H_x\}_{x\in X}$ be a family of universal hash functions from $\{0,1\}^d$ to $\{0,1\}^\ell$ for some ℓ. To compute Gen on input $w \in \mathsf{Edit}_{\{0,1\}}(n)$, pick a random x and output

$$R = H_x(\psi_{\mathrm{ed}}(w)) \ , P = (\mathsf{syn}(\psi_{\mathrm{ed}}(w)), x)\,.$$

To compute Rep on inputs w' and $P = (s, x)$, compute $y = \mathsf{Rec}(\psi_{\mathrm{ed}}(w'), s)$, where Rec is from Construction 3, and output $R = H_x(y)$.

Because ψ_{ed} is injective, a secure sketch can be constructed similarly: $\mathsf{SS}(w) = \mathsf{syn}(\psi(w))$. To recover w from w' and s, compute $\psi_{\mathrm{ed}}^{-1}(\mathsf{Rec}(\psi_{\mathrm{ed}}(w')))$. However, this secure sketch is not known to be efficient, because it is not known how to compute ψ_{ed}^{-1} efficiently.

PROPOSITION 7.2. *For any* n, t, m, *there is an average-case* $(\mathsf{Edit}_{\{0,1\}}(n), m, m', t)$*-secure sketch and an efficient average-case* $(\mathsf{Edit}_{\{0,1\}}(n), m, \ell, t, \epsilon)$*-fuzzy extractor where* $m' = m - t2^{O(\sqrt{\log n \log\log n})}$ *and* $\ell = m' - 2\log\left(\frac{1}{\epsilon}\right) + 2$. *In particular, for any* $\alpha < 1$, *there exists an efficient fuzzy extractor tolerating* n^α *errors with entropy loss* $n^{\alpha+o(1)} + 2\log\left(\frac{1}{\epsilon}\right)$.

Proof. Construction 7 is the same as the construction of Theorem 5.2 (instantiated with a BCH-code-based syndrome construction) acting on $\psi_{\mathrm{ed}}(w)$. Because ψ_{ed} is injective, the min-entropy of $\psi_{\mathrm{ed}}(w)$ is the same as the min-entropy m of w. The entropy loss in Construction 3 instantiated with BCH codes is $t' \log d = t2^{O(\sqrt{\log n \log\log n})} \log \mathrm{poly}(n)$. Because $2^{O(\sqrt{\log n \log\log n})}$ grows faster than $\log n$, this is the same as $t2^{O(\sqrt{\log n \log\log n})}$. □

Note that the peculiar-looking distortion function from Fact 7.1 increases more slowly than any polynomial in n, but still faster than any polynomial in $\log n$. In sharp contrast, the best lower bound states that any embedding of $\mathsf{Edit}_{\{0,1\}}(n)$ into ℓ_1 (and hence Hamming) must have distortion at least $\Omega(\log n / \log\log n)$ [2]. Closing the gap between the two bounds remains an open problem.

General alphabets. To extend the above construction to general $\mathcal{F}$, we represent each character of $\mathcal{F}$ as a string of $\log F$ bits. This is an embedding $\mathcal{F}^n$ into $\{0,1\}^{n\log F}$,

[11] The embedding of [57] produces strings of integers in the space $\{1,\ldots,O(\log n)\}^{\mathrm{poly}(n)}$, equipped with ℓ_1 distance. One can convert this into the Hamming metric with only a logarithmic blowup in length by representing each integer in unary.

which increases edit distance by a factor of at most $\log F$. Then $t' = t(\log F)D_{\mathrm{ed}}(n)$ and $d = \mathrm{poly}(n, \log F)$. Using these quantities, we get the generalization of Proposition 7.2 for larger alphabets (again, by the same embedding) by changing the formula for m' to $m' = m - t(\log F)2^{O(\sqrt{\log(n \log F) \log\log(n \log F)})}$.

7.2. Relaxed embeddings for the edit metric. In this section, we show that a relaxed notion of embedding, called a *biometric embedding* in section 4.3, can produce fuzzy extractors and secure sketches that are better than what one can get from the embedding of [57] when t is large (they are also much simpler algorithmically, which makes them more practical). We first discuss fuzzy extractors and later extend the technique to secure sketches.

Fuzzy extractors. Recall that unlike low-distortion embeddings, biometric embeddings do not care about relative distances, as long as points that were "close" (closer than t_1) do not become "distant" (farther apart than t_2). The only additional requirement of a biometric embedding is that it preserve some min-entropy: we do not want too many points to collide together. We now describe such an embedding from the edit distance to the set difference.

A *c-shingle* is a length-c consecutive substring of a given string w. A *c-shingling* [10] of a string w of length n is the set (ignoring order or repetition) of all $(n-c+1)$ c-shingles of w. (For instance, a 3-shingling of "abcdecdeah" is {abc, bcd, cde, dec, ecd, dea, eah}.) Thus, the range of the c-shingling operation consists of all nonempty subsets of size at most $n-c+1$ of $\mathcal{F}^c$. Let $\mathsf{SDif}(\mathcal{F}^c)$ stand for the set difference metric over subsets of $\mathcal{F}^c$ and SH_c stand for the c-shingling map from $\mathsf{Edit}_{\mathcal{F}}(n)$ to $\mathsf{SDif}(\mathcal{F}^c)$. We now show that SH_c is a good biometric embedding.

LEMMA 7.3. *For any c, SH_c is an average-case $(t_1, t_2 = (2c-1)t_1, m_1, m_2 = m_1 - \lceil \frac{n}{c} \rceil \log_2(n-c+1))$-biometric embedding of $\mathsf{Edit}_{\mathcal{F}}(n)$ into $\mathsf{SDif}(\mathcal{F}^c)$.*

Proof. Let $w, w' \in \mathsf{Edit}_{\mathcal{F}}(n)$ be such that $\mathsf{dis}(w, w') \le t_1$ and I be the sequence of at most t_1 insertions and deletions that transforms w into w'. It is easy to see that each character deletion or insertion adds at most $(2c-1)$ to the symmetric difference between $\mathsf{SH}_c(w)$ and $\mathsf{SH}_c(w')$, which implies that $\mathsf{dis}(\mathsf{SH}_c(w), \mathsf{SH}_c(w')) \le (2c-1)t_1$, as needed.

For $w \in \mathcal{F}^n$, define $g_c(w)$ as follows. Compute $\mathsf{SH}_c(w)$ and store the resulting shingles in lexicographic order $h_1 \dots h_k$ $(k \le n-c+1)$. Next, naturally partition w into $\lceil n/c \rceil$ c-shingles $s_1 \dots s_{\lceil n/c \rceil}$, all disjoint except for (possibly) the last two, which overlap by $c\lceil n/c \rceil - n$ characters. Next, for $1 \le j \le \lceil n/c \rceil$, set p_j to be the index $i \in \{0 \dots k\}$ such that $s_j = h_i$. In other words, p_j tells the index of the jth disjoint shingle of w in the alphabetically ordered k-set $\mathsf{SH}_c(w)$. Set $g_c(w) = (p_1, \dots, p_{\lceil n/c \rceil})$. (For instance, g_3("abcdecdeah") $= (1, 5, 4, 6)$, representing the alphabetical order of "abc", "dec", "dea", and "eah" in SH_3("abcdecdeah").) The number of possible values for $g_c(w)$ is at most $(n-c+1)^{\lceil \frac{n}{c} \rceil}$, and w can be completely recovered from $\mathsf{SH}_c(w)$ and $g_c(w)$.

Now, assume W is any distribution of min-entropy at least m_1 on $\mathsf{Edit}_{\mathcal{F}}(n)$. Applying Lemma 2.2(b), we get $\tilde{\mathbf{H}}_\infty(W \mid g_c(W)) \ge m_1 - \lceil \frac{n}{c} \rceil \log_2(n-c+1)$. Since $\Pr(W = w \mid g_c(W) = g) = \Pr(\mathsf{SH}_c(W) = \mathsf{SH}_c(w) \mid g_c(W) = g)$ (because given $g_c(w)$, $\mathsf{SH}_c(w)$ uniquely determines w and vice versa), by applying the definition of $\tilde{\mathbf{H}}_\infty$, we obtain $\mathbf{H}_\infty(\mathsf{SH}_c(W)) \ge \tilde{\mathbf{H}}_\infty(\mathsf{SH}_c(W) \mid g_c(W)) = \tilde{\mathbf{H}}_\infty(W \mid g_c(W))$. The same proof holds for average min-entropy, conditioned on some auxiliary information I. ∎

By Theorem 6.3, for universe $\mathcal{F}^c$ of size F^c and distance threshold $t_2 = (2c-1)t_1$, we can construct a secure sketch for the set difference metric with entropy loss $t_2\lceil \log(F^c + 1) \rceil$ ($\lceil \cdot \rceil$ because Theorem 6.3 requires the universe size to be one less

than a power of 2). By Lemma 4.3, we can obtain a fuzzy extractor from such a sketch, with additional entropy loss $2\log\left(\frac{1}{\epsilon}\right) - 2$. Applying Lemma 4.6 to the above embedding and this fuzzy extractor, we obtain a fuzzy extractor for $\mathsf{Edit}_{\mathcal{F}}(n)$, any input entropy m, any distance t, and any security parameter ϵ, with the following entropy loss:

$$\left\lceil \frac{n}{c} \right\rceil \cdot \log_2(n-c+1) + (2c-1)t\lceil \log(F^c+1)\rceil + 2\log\left(\frac{1}{\epsilon}\right) - 2$$

(the first component of the entropy loss comes from the embedding, the second from the secure sketch for set difference, and the third from the extractor). The above sequence of lemmas results in the following construction, parameterized by shingle length c and a family of universal hash functions $\mathcal{H} = \{\mathsf{SDif}(\mathcal{F}^c) \to \{0,1\}^l\}_{x\in X}$, where l is equal to the input entropy m minus the entropy loss above.

Construction 8 (fuzzy extractor for edit distance). To compute $\mathsf{Gen}(w)$ for $|w| = n$:

1. Compute $\mathsf{SH}_c(w)$ by computing $n-c+1$ shingles $(v_1, v_2, \ldots, v_{n-c+1})$ and removing duplicates to form the shingle set v from w.
2. Compute $s = \mathsf{syn}(x_v)$ as in Construction 6.
3. Select a hash function $H_x \in \mathcal{H}$ and output $(R = H_x(v), P = (s, x))$.

To compute $\mathsf{Rep}(w', (s, x))$:

1. Compute $\mathsf{SH}_c(w')$ as above to get v'.
2. Use $\mathsf{Rec}(v', s)$ from in Construction 6 to recover v.
3. Output $R = H_x(v)$.

We thus obtain the following theorem.

THEOREM 7.4. *For any n, m, c, and $0 < \epsilon \le 1$, there is an efficient average-case $(\mathsf{Edit}_{\mathcal{F}}(n), m, m - \lceil \frac{n}{c} \rceil \log_2(n-c+1) - (2c-1)t\lceil \log(F^c+1)\rceil - 2\log\left(\frac{1}{\epsilon}\right) + 2, t, \epsilon)$-fuzzy extractor.*

Note that the choice of c is a parameter; by ignoring $\lceil\cdot\rceil$ and replacing $n-c+1$ with n, $2c-1$ with $2c$, and F^c+1 with F^c, we get that the minimum entropy loss occurs near

$$c = \left(\frac{n\log n}{4t\log F}\right)^{1/3}$$

and is about $2.38\,(t\log F)^{1/3}\,(n\log n)^{2/3}$ (2.38 is really $\sqrt[3]{4} + 1/\sqrt[3]{2}$). In particular, if the original string has a linear amount of entropy $\theta(n\log F)$, then we can tolerate $t = \Omega(n\log^2 F/\log^2 n)$ insertions and deletions while extracting $\theta(n\log F) - 2\log\left(\frac{1}{\epsilon}\right)$ bits. The number of bits extracted is linear; if the string length n is polynomial in the alphabet size F, then the number of errors tolerated is linear also.

Secure sketches. Observe that the proof of Lemma 7.3 actually demonstrates that our biometric embedding based on shingling is an embedding with recovery information g_c. Observe also that it is easy to reconstruct w from $\mathsf{SH}_c(w)$ and $g_c(w)$. Finally, note that PinSketch (Construction 6) is an average-case secure sketch (as are all secure sketches in this work). Thus, combining Theorem 6.3 with Lemma 4.7, we obtain the following theorem.

Construction 9 (secure sketch for edit distance). For $\mathsf{SS}(w)$, compute $v = \mathsf{SH}_c(w)$ and $s_1 = \mathsf{syn}(x_v)$ as in Construction 8. Compute $s_2 = g_c(w)$, writing each p_j as a string of $\lceil \log n \rceil$ bits. Output $s = (s_1, s_2)$. For $\mathsf{Rec}(w', (s_1, s_2))$, recover v as in Construction 8, sort it in alphabetical order, and recover w by stringing along elements of v according to indices in s_2.

THEOREM 7.5. *For any n, m, c, and $0 < \epsilon \leq 1$, there is an efficient average-case $(\mathsf{Edit}_{\mathcal{F}}(n), m, m - \lceil \frac{n}{c} \rceil \log_2(n - c + 1) - (2c - 1)t\lceil \log(F^c + 1) \rceil, t)$-secure sketch.*

The discussion about optimal values of c from above applies equally here.

Remark. In our definitions of secure sketches and fuzzy extractors, we required the original w and the (potentially) modified w' to come from the same space $\mathcal{M}$. This requirement was for simplicity of exposition. We can allow w' to come from a larger set, as long as distance from w is well defined. In the case of edit distance, for instance, w' can be shorter or longer than w; all the above results will apply as long as it is still within t insertions and deletions.

8. Probabilistic notions of correctness. The error model considered so far in this work is very strong: we required that secure sketches and fuzzy extractors accept *every* secret w' within distance t of the original input w, with no probability of error.

Such a stringent model is useful as it makes no assumptions on either the exact stochastic properties of the error process or the adversary's computational limits. However, Lemma C.1 shows that secure sketches (and fuzzy extractors) correcting t errors can only be as "good" as error-correcting codes with minimum distance $2t + 1$. By slightly relaxing the correctness condition, we will see that one can tolerate many more errors. For example, there is no good code which can correct $n/4$ errors in the binary Hamming metric: by the Plotkin bound (see, e.g., [69, Lecture 8]) a code with minimum distance greater than $n/2$ has at most $2n$ codewords. Thus, there is no secure sketch with residual entropy $m' \geq \log n$ which can correct $n/4$ errors with probability 1. However, with the relaxed notions of correctness below, one can tolerate arbitrarily close to $n/2$ errors, i.e., correct $n(\frac{1}{2} - \gamma)$ errors for any constant $\gamma > 0$, and still have residual entropy $\Omega(n)$.

In this section, we discuss three relaxed error models and show how the constructions of the previous sections can be modified to gain greater error-correction in these models. We will focus on secure sketches for the binary Hamming metric. The same constructions yield fuzzy extractors (by Lemma 4.1). Many of the observations here also apply to metrics other than Hamming.

A common point is that we will require only that the a corrupted input w' be recovered with probability at least $1 - \alpha < 1$ (the probability space varies). We describe each model in terms of the additional assumptions made on the error process. We describe constructions for each model in the subsequent sections.

Random errors (section 8.1). Assume there is a *known* distribution on the errors which occur in the data. For the Hamming metric, the most common distribution is the binary symmetric channel BSC_p: each bit of the input is flipped with probability p and left untouched with probability $1 - p$. We require that for any input w, $\mathsf{Rec}(W', \mathsf{SS}(w)) = w$ with probability at least $1 - \alpha$ over the coins of SS and over W' drawn applying the noise distribution to w.

In that case, one can correct an error rate up to Shannon's bound on noisy channel coding. This bound is tight. Unfortunately, the assumption of a known noise process is too strong for most applications: there is no reason to believe we understand the exact distribution on errors which occur in complex data such as biometrics.[12] However, it provides a useful baseline by which to measure results for other models.

[12]Since the assumption here plays a role only in correctness, it is still more reasonable than assuming that we know exact distributions on the data in proofs of *secrecy*. However, in both cases, we would like to enlarge the class of distributions for which we can provably satisfy the definition of security.

Input-dependent errors (section 8.2). The errors are adversarial, subject only to the conditions that (a) the error magnitude $\mathsf{dis}(w, w')$ is bounded to a maximum of t, and (b) the corrupted word *depends only on the input* w, and not on the secure sketch $\mathsf{SS}(w)$. Here we require that for any pair w, w' at distance at most t, we have $\mathsf{Rec}(w', \mathsf{SS}(w)) = w$ with probability at least $1 - \alpha$ over the coins of SS.

This model encompasses any complex noise process which has been observed to never introduce more than t errors. Unlike the assumption of a particular distribution on the noise, the bound on magnitude can be checked experimentally. Perhaps surprisingly, in this model we can tolerate just as large an error rate as in the model of random errors. That is, we can tolerate an error rate up to Shannon's coding bound and no more.

Computationally bounded errors (section 8.3). The errors are adversarial and may depend on both w and the publicly stored information $\mathsf{SS}(w)$. However, we assume that the errors are introduced by a process of bounded computational power. That is, there is a probabilistic circuit of polynomial size (in the length n) which computes w' from w. The adversary cannot, for example, forge a digital signature and base the error pattern on the signature.

It is not clear whether this model allows correcting errors up to the Shannon bound, as in the two models above. The question is related to open questions on the construction of efficiently list-decodable codes. However, when the error rate is either very high or very low, then the appropriate list-decodable codes exist, and we can indeed match the Shannon bound.

Analogues for noisy channels and the Hamming metric. Models analogous to those above have been studied in the literature on codes for noisy binary channels (with the Hamming metric). Random errors and computationally bounded errors both make obvious sense in the coding context [64, 48]. The second model—input-dependent errors—does not immediately make sense in a coding situation, since there is no data other than the transmitted codeword on which errors could depend. Nonetheless, there is a natural, analogous model for noisy channels: one can allow the sender and receiver to share either (1) common, secret random coins (see [22, 43] and references therein) or (2) a side channel with which they can communicate a small number of noise-free, secret bits [33].

Existing results on these three models for the Hamming metric can be transported to our context using the code-offset construction:

$$\mathsf{SS}(w; x) = w \oplus C(x)\,.$$

Roughly, any code which corrects errors in the models above will lead to a secure sketch (respectively, fuzzy extractor) which corrects errors in the model. We explore the consequences for each of the three models in the next sections.

8.1. Random errors. The random error model was famously considered by Shannon [64]. He showed that for any discrete, memoryless channel, the rate at which information can be reliably transmitted is characterized by the maximum mutual information between the inputs and outputs of the channel. For the binary symmetric channel with crossover probability p, this means that there exist codes encoding k bits into n bits, tolerating error probability p in each bit if and only if

$$\frac{k}{n} < 1 - h(p) - \delta(n),$$

where $h(p) = -p \log p - (1-p)\log(1-p)$ and $\delta(n) = o(1)$. Computationally efficient codes achieving this bound were found later, most notably by Forney [29]. We can use

the code-offset construction $\mathsf{SS}(w; x) = w \oplus C(x)$ with an appropriate concatenated code [29] or, equivalently, $\mathsf{SS}(w) = \mathsf{syn}_C(w)$ since the codes can be linear. We obtain the following proposition.

PROPOSITION 8.1. *For any error rate $0 < p < 1/2$ and constant $\delta > 0$, for large enough n there exist secure sketches with entropy loss $(h(p) + \delta)n$ which correct the error rate of p in the data with high probability (roughly $2^{-c_\delta n}$ for a constant $c_\delta > 0$).*

The probability here is taken over the errors *only (the distribution on input strings w can be arbitrary).*

The quantity $h(p)$ is less than 1 for any p in the range $(0, 1/2)$. In particular, one can get nontrivial secure sketches even for a very high error rate p as long as it is less than $1/2$; in contrast, no secure sketch which corrects errors with probability 1 can tolerate $t \geq n/4$. Note that several other works on biometric cryptosystems consider the model of randomized errors and obtain similar results, though the analyses assume that the distribution on inputs is uniform [71, 17].

A matching impossibility result. The bound above is tight. The matching impossibility result also applies to input-dependent and computationally bounded errors, since random errors are a special case of both more complex models.

We start with an intuitive argument: If a secure sketch allows recovering from random errors with high probability, then it must contain enough information about w to describe the error pattern (since given w' and $\mathsf{SS}(w)$, one can recover the error pattern with high probability). Describing the outcome of n independent coin flips with probability p of heads requires $nh(p)$ bits, and so the sketch must reveal $nh(p)$ bits about w.

In fact, that argument simply shows that $nh(p)$ bits of Shannon information are leaked about w, whereas we are concerned with min-entropy loss as defined in section 3. To make the argument more formal, let W be uniform over $\{0,1\}^n$ and observe that with high probability over the output of the sketching algorithm, $v = \mathsf{SS}(w)$, the conditional distribution $W_v = W|_{\mathsf{SS}(W)=v}$ forms a good code for the binary symmetric channel. That is, for most values v, if we sample a random string w from $W|_{\mathsf{SS}(W)=v}$ and send it through a binary symmetric channel, we will be able to recover the correct value w. That means there exists some v such that (a) W_v is a good code and (b) $\mathbf{H}_\infty(W_v)$ is close to $\tilde{\mathbf{H}}_\infty(W|\mathsf{SS}(W))$. Shannon's noisy coding theorem says that such a code can have entropy at most $n(1 - h(p) + o(1))$. Thus the construction above is optimal.

PROPOSITION 8.2. *For any error rate $0 < p < 1/2$, any secure sketch SS which corrects random errors (with rate p) with probability at least $2/3$ has entropy loss at least $n(h(p) - o(1))$; that is, $\tilde{\mathbf{H}}_\infty(W|\mathsf{SS}(W)) \leq n(1 - h(p) - o(1))$ when W is drawn uniformly from $\{0,1\}^n$.*

8.2. Randomizing input-dependent errors. Assuming errors distributed randomly according to a known distribution seems very limiting. In the Hamming metric, one can construct a secure sketch which achieves the same result as with random errors for every error process where the magnitude of the error is bounded, as long as the errors are independent of the output of $\mathsf{SS}(W)$. The same technique was used previously by Bennett et al. [4, p. 216] and, in a slightly different context, Lipton [46, 22].

The idea is to choose a random permutation $\pi : [n] \to [n]$, permute the bits of w before applying the sketch, and store the permutation π along with $\mathsf{SS}(\pi(w))$. Specifically, let C be a linear code tolerating a p fraction of random errors with

redundancy $n - k \approx nh(p)$. Let

$$\mathsf{SS}(w;\pi) = (\pi,\ \mathsf{syn}_C(\pi(w)))\,,$$

where $\pi : [n] \to [n]$ is a random permutation and, for $w = w_1 \cdots w_n \in \{0,1\}^n$, $\pi(w)$ denotes the permuted string $w_{\pi(1)}w_{\pi(2)}\cdots w_{\pi(n)}$. The recovery algorithm operates in the obvious way: it first permutes the input w' according to π and then runs the usual syndrome recovery algorithm to recover $\pi(w)$.

For any particular pair w, w', the difference $w \oplus w'$ will be mapped to a random vector of the same weight by π, and any code for the binary symmetric channel (with rate $p \approx t/n$) will correct such an error with high probability.

Thus we can construct a sketch with entropy loss $n(h(t/n) - o(1))$ which corrects any t flipped bits with high probability. This is optimal by the lower bound for random errors (Proposition 8.2), since a sketch for data-dependent errors will also correct random errors. It is also possible to reduce the amount of randomness, so that the *size* of the sketch meets the same optimal bound [67].

An alternative approach to input-dependent errors is discussed in the last paragraph of section 8.3.

8.3. Handling computationally bounded errors via list decoding. As mentioned above, many results on noisy coding for other error models in Hamming space extend to secure sketches. The previous sections discussed random, and randomized, errors. In this section, we discuss constructions [33, 43, 48] which transform a *list-decodable* code, defined below, into uniquely decodable codes for a particular error model. These transformations can also be used in the setting of secure sketches, leading to better tolerance of computationally bounded errors. For some ranges of parameters, this yields optimal sketches, that is, sketches which meet the Shannon bound on the fraction of tolerated errors.

List-decodable codes. A code C in a metric space $\mathcal{M}$ is called *list-decodable* with list size L and distance t if for every point $x \in \mathcal{M}$, there are at most L codewords within distance t of $\mathcal{M}$. A list-decoding algorithm takes as input a word x and returns the corresponding list $c_1, c_2, \ldots$ of codewords. The most interesting setting is when L is a small polynomial (in the description size $\log |\mathcal{M}|$), and there exists an efficient list-decoding algorithm. It is then feasible for an algorithm to go over each word in the list and accept if it has some desirable property. There are many examples of such codes for the Hamming space; for a survey see Guruswami's thesis [32]. Recently there has been significant progress in constructing list-decodable codes for large alphabets, e.g., [58, 34].

Similarly, we can define a *list-decodable secure sketch* with size L and distance t as follows: for any pair of words $w, w' \in \mathcal{M}$ at distance at most t, the algorithm $\mathsf{Rec}(w', \mathsf{SS}(w))$ returns a list of at most L points in $\mathcal{M}$; if $\mathsf{dis}(w, w') \le t$, then one of the words in the list must be w itself. The simplest way to obtain a list-decodable secure sketch is to use the code-offset construction of section 5 with a list-decodable code for the Hamming space. One obtains a different example by running the improved Juels–Sudan scheme for set difference (Construction 5), replacing ordinary decoding of Reed–Solomon codes with list decoding. This yields a significant improvement in the number of errors tolerated at the price of returning a list of possible candidates for the original secret.

Sieving the list. Given a list-decodable secure sketch SS, all that is needed is to store some additional information which allows the receiver to disambiguate w from the list. Let us suggestively name the additional information $Tag(w;R)$, where R

is some additional randomness (perhaps a key). Given a list-decodable code C, the sketch will typically look like

$$\mathsf{SS}(w; x) = (\ w \oplus C(x),\ Tag(w)\ ).$$

On inputs w' and (Δ, tag), the recovery algorithm consists of running the list-decoding algorithm on $w' \oplus \Delta$ to obtain a list of possible codewords $C(x_1), \ldots, C(x_L)$. There is a corresponding list of candidate inputs $w_1, \ldots, w_L$, where $w_i = C(x_i) \oplus \Delta$, and the algorithm outputs the first w_i in the list such that $Tag(w_i) = tag$. We will choose the function $Tag()$ so that the adversary cannot arrange to have two values in the list with valid tags.

We consider two $Tag()$ functions, inspired by [33, 43, 48].

1. Recall that for computationally bounded errors, the corrupted string w' depends on *both* w and $\mathsf{SS}(w)$, but w' is computed by a probabilistic circuit of size polynomial in n.

Consider $Tag(w) = \mathsf{hash}(w)$, where hash is drawn from a collision-resistant function family. More specifically, we will use some extra randomness r to choose a key *key* for a collision-resistant hash family. The output of the sketch is then

$$\mathsf{SS}(w; x, r) = (\ w \oplus C(x),\ key(r),\ \mathsf{hash}_{key(r)}(w)\ ).$$

If the list-decoding algorithm for the code C runs in polynomial time, then the adversary succeeds only if he can find a value $w_i \neq w$ such that $\mathsf{hash}_{key}(w_i) = \mathsf{hash}_{key}(w)$, that is, only by finding a collision for the hash function. By assumption, a polynomially bounded adversary succeeds only with negligible probability.

The additional entropy loss, beyond that of the code-offset part of the sketch, is bounded above by the output length of the hash function. If α is the desired bound on the adversary's success probability, then for standard assumptions on hash functions this loss will be polynomial in $\log(1/\alpha)$.

In principle this transformation can yield sketches which achieve the optimal entropy loss $n(h(t/n) - o(1))$, since codes with polynomial list size L are known to exist for error rates approaching the Shannon bound. However, in order to use the construction the code must also be equipped with a reasonably efficient algorithm for finding such a list. This is necessary both so that recovery will be efficient and, more subtly, for the proof of security to go through (that way we can assume that the polynomial time adversary knows the list of words generated during the recovery procedure). We do not know of *efficient* (i.e., polynomial time constructible and decodable) binary list-decodable codes which meet the Shannon bound for all choices of parameters. However, when the error rate is near $\frac{1}{2}$ such codes are known [35]. Thus, this type of construction yields essentially optimal sketches when the error rate is near 1/2. This is quite similar to analogous results on channel coding [48]. Relatively little is known about the performance of efficiently list-decodable codes in other parameter ranges for binary alphabets [32].

2. A similar, even simpler, transformation can be used in the setting of input-dependent errors (i.e., when the errors depend only on the input and not on the sketch, but the adversary is not assumed to be computationally bounded). One can store $Tag(w) = (I, h_I(w))$, where $\{h_i\}_{i \in \mathcal{I}}$ comes from a universal hash family mapping from $\mathcal{M}$ to $\{0,1\}^\ell$, where $\ell = \log\left(\frac{1}{\alpha}\right) + \log L$, and α is the probability of an incorrect decoding.

The proof is simple: the values $w_1, \ldots, w_L$ do not depend on I, and so for any value $w_i \neq w$, the probability that $h_I(w_i) = h_I(w)$ is $2^{-\ell}$. There are at most L

possible candidates, and so the probability that any one of the elements in the list is accepted is at most $L \cdot 2^{-\ell} = \alpha$. The additional entropy loss incurred is at most $\ell = \log\left(\frac{1}{\alpha}\right) + \log(L)$.

In principle, this transformation can do as well as the randomization approach of the previous section. However, we do not know of efficient binary list-decodable codes meeting the Shannon bound for most parameter ranges. Thus, in general, randomizing the errors (as in the previous section) works better in the input-dependent setting.

9. Secure sketches and efficient information reconciliation. Suppose Alice holds a set w and Bob holds a set w' that are close to each other. They wish to reconcile the sets, i.e., to discover the symmetric difference $w \triangle w'$ so that they can take whatever appropriate (application-dependent) action to make their two sets agree. Moreover, they wish to do this communication-efficiently, without having to transmit entire sets to each other. This problem is known as set reconciliation and naturally arises in various settings.

Let $(\mathsf{SS}, \mathsf{Rec})$ be a secure sketch for set difference that can handle distance up to t; furthermore, suppose that $|w \triangle w'| \leq t$. Then if Bob receives $s = \mathsf{SS}(w)$ from Alice, he will be able to recover w, and therefore $w \triangle w'$, from s and w'. Similarly, Alice will be able find $w \triangle w'$ upon receiving $s' = \mathsf{SS}(w')$ from Bob. This will be communication-efficient if $|s|$ is small. Note that our secure sketches for set difference of sections 6.2 and 6.3 are indeed short—in fact, they are secure precisely because they are short. Thus, they also make good set reconciliation schemes.

Conversely, a good (single-message) set reconciliation scheme makes a good secure sketch: simply make the message the sketch. The entropy loss will be at most the length of the message, which is short in a communication-efficient scheme. Thus, the set reconciliation scheme CPISync of [51] makes a good secure sketch. In fact, it is quite similar to the secure sketch of section 6.2, except instead of the top t coefficients of the characteristic polynomial it uses the values of the polynomial at t points.

PinSketch of section 6.3, when used for set reconciliation, achieves the same parameters as CPISync of [51], except decoding is faster, because instead of spending t^3 time to solve a system of linear equations, it spends t^2 time for Euclid's algorithm. Thus, it can be substituted wherever CPISync is used, such as PDA synchronization [68] and PGP key server updates [49]. Furthermore, optimizations that improve computational complexity of CPISync through the use of interaction [50] can also be applied to PinSketch.

Of course, secure sketches for other metrics are similarly related to information reconciliation for those metrics. In particular, ideas for edit distance very similar to ours were independently considered in the context of information reconciliation by [15].

Appendix A. Proof of Lemma 2.2. Recall that Lemma 2.2 considered random variables A, B, C and consisted of two parts, which we prove one after the other.

Part (a) stated that for any $\delta > 0$, the conditional entropy $\mathbf{H}_\infty(A|B = b)$ is at least $\tilde{\mathbf{H}}_\infty(A|B) - \log(1/\delta)$ with probability at least $1 - \delta$ (the probability here is taken over the choice of b). Let $p = 2^{-\tilde{\mathbf{H}}_\infty(A|B)} = \mathbb{E}_b\left[2^{-\mathbf{H}_\infty(A|B=b)}\right]$. By the Markov inequality, $2^{-\mathbf{H}_\infty(A|B=b)} \leq p/\delta$ with probability at least $1 - \delta$. Taking logarithms, part (a) follows.

Part (b) stated that if B has at most 2^λ possible values, then $\tilde{\mathbf{H}}_\infty(A \mid (B, C)) \geq \tilde{\mathbf{H}}_\infty((A, B) \mid C) - \lambda \geq \tilde{\mathbf{H}}_\infty(A \mid C) - \lambda$. In particular, $\tilde{\mathbf{H}}_\infty(A \mid B) \geq \mathbf{H}_\infty((A, B)) - \lambda \geq \mathbf{H}_\infty(A) - \lambda$. Clearly, it suffices to prove the first assertion (the second follows from

taking C to be constant). Moreover, the second inequality of the first assertion follows from the fact that $\Pr[A = a \wedge B = b \mid C = c] \le \Pr[A = a \mid C = c]$ for any c. Thus, we prove only that $\tilde{\mathbf{H}}_\infty(A \mid (B, C)) \ge \tilde{\mathbf{H}}_\infty((A, B) \mid C) - \lambda$:

$$\begin{aligned}
\tilde{\mathbf{H}}_\infty(A \mid (B,C)) &= -\log \mathop{\mathbb{E}}_{(b,c)\leftarrow(B,C)} \left[\max_a \Pr[A = a \mid B = b \wedge C = c]\right] \\
&= -\log \sum_{(b,c)} \max_a \Pr[A = a \mid B = b \wedge C = c] \Pr[B = b \wedge C = c] \\
&= -\log \sum_{(b,c)} \max_a \Pr[A = a \wedge B = b \mid C = c] \Pr[C = c] \\
&= -\log \sum_b \mathop{\mathbb{E}}_{c\leftarrow C} \left[\max_a \Pr[A = a \wedge B = b \mid C = c]\right] \\
&\ge -\log \sum_b \mathop{\mathbb{E}}_{c\leftarrow C} \left[\max_{a,b'} \Pr[A = a \wedge B = b' \mid C = c]\right] \\
&= -\log \sum_b 2^{-\tilde{\mathbf{H}}_\infty((A,B)|C)} \ge -\log 2^{\lambda} 2^{-\tilde{\mathbf{H}}_\infty((A,B)|C)} \\
&= \tilde{\mathbf{H}}_\infty((A,B) \mid C) - \lambda\,.
\end{aligned}$$

The first inequality in the above derivation holds since taking the maximum over all pairs (a, b') (instead of over pairs (a, b) where b is fixed) increases the terms of the sum and hence decreases the negative log of the sum.

Appendix B. On smooth variants of average min-entropy and the relationship to smooth Rényi entropy. Min-entropy is a rather fragile measure; a single high-probability element can ruin the min-entropy of an otherwise good distribution. This is often circumvented within proofs by considering a distribution which is close to the distribution of interest, but which has higher entropy. Renner and Wolf [60] systematized this approach with the notion of ϵ-*smooth* min-entropy (they use the term "Rényi entropy of order ∞" instead of "min-entropy"), which considers all distributions that are ϵ-close:

$$\mathbf{H}^\epsilon_\infty(A) = \max_{B:\ \mathbf{SD}(A,B)\le\epsilon} \mathbf{H}_\infty(B)\,.$$

Smooth min-entropy very closely relates to the amount of extractable nearly uniform randomness: if one can map A to a distribution that is ϵ-close to U_m, then $\mathbf{H}^\epsilon_\infty(A) \ge m$; conversely, from any A such that $\mathbf{H}^\epsilon_\infty(A) \ge m$, and for any ϵ_2, one can extract $m - 2\log(\frac{1}{\epsilon_2})$ bits that are $\epsilon+\epsilon_2$-close to uniform (see [60] for a more precise statement; the proof of the first statement follows by considering the inverse map, and the proof of the second follows from the leftover hash lemma, which is discussed in more detail in Lemma 2.4). For some distributions, considering the smooth min-entropy will improve the number and quality of extractable random bits.

A smooth version of average min-entropy can also be considered, defined as

$$\tilde{\mathbf{H}}^\epsilon_\infty(A \mid B) = \max_{(C,D):\ \mathbf{SD}((A,B),(C,D))\le\epsilon} \tilde{\mathbf{H}}_\infty(C \mid D)\,.$$

It similarly relates very closely to the number of extractable bits that look nearly uniform to the adversary who knows the value of B and is therefore perhaps a better measure for the quality of a secure sketch that is used to obtain a fuzzy extractor.

All our results can be cast in terms of smooth entropies throughout, with appropriate modifications (if input entropy is ϵ-smooth, then output entropy will also be ϵ-smooth, and extracted random strings will be ϵ further away from uniform). We avoid doing so for simplicity of exposition. However, for some input distributions, particularly ones with few elements of relatively high probability, this will improve the result by giving more secure sketches or longer-output fuzzy extractors.

Finally, a word is in order on the relation of average min-entropy to conditional min-entropy, introduced by Renner and Wolf in [61], and defined as $\mathbf{H}_\infty(A \mid B) = -\log \max_{a,b} \Pr(A = a \mid B = b) = \min_b \mathbf{H}_\infty(A \mid B = b)$ (an ϵ-smooth version is defined analogously by considering all distributions (C, D) that are within ϵ of (A, B) and taking the maximum among them). This definition is too strict: it takes the worst-case b, while for randomness extraction (and many other settings, such as predictability by an adversary), average-case b suffices. Average min-entropy leads to more extractable bits. Nevertheless, after smoothing, the two notions are equivalent up to an additive $\log(\frac{1}{\epsilon})$ term: $\tilde{\mathbf{H}}^\epsilon_\infty(A \mid B) \geq \mathbf{H}^\epsilon_\infty(A \mid B)$ and $\mathbf{H}_\infty{}^{\epsilon+\epsilon_2}(A \mid B) \geq \tilde{\mathbf{H}}^\epsilon_\infty(A \mid B) - \log(\frac{1}{\epsilon_2})$ (for the case of $\epsilon = 0$, this follows by constructing a new distribution that eliminates all b for which $\mathbf{H}_\infty(A \mid B = b) < \tilde{\mathbf{H}}_\infty(A \mid B) - \log(\frac{1}{\epsilon_2})$, which will be within ϵ_2 of the (A, B) by Markov's inequality; for $\epsilon > 0$, an analogous proof works). Note that by Lemma 2.2(b), this implies a simple chain rule for $\mathbf{H}^\epsilon_\infty$ (a more general one is given in [61, section 2.4]): $\mathbf{H}_\infty{}^{\epsilon+\epsilon_2}(A \mid B) \geq \tilde{\mathbf{H}}^\epsilon_\infty((A, B)) - H_0(B) - \log(\frac{1}{\epsilon_2})$, where $H_0(B)$ is the logarithm of the number of possible values of B.

Appendix C. Lower bounds from coding. Recall that an $(\mathcal{M}, K, t)$-code is a subset of the metric space $\mathcal{M}$ which can *correct* t errors (this is slightly different from the usual notation of coding theory literature).

Let $K(\mathcal{M}, t)$ be the largest K for which there exists an $(\mathcal{M}, K, t)$-code. Given any set S of 2^m points in $\mathcal{M}$, we let $K(\mathcal{M}, t, S)$ be the largest K such that there exists an $(\mathcal{M}, K, t)$-code all of whose K points belong to S. Finally, we let $L(\mathcal{M}, t, m) = \log(\min_{|S|=2^m} K(n, t, S))$. Of course, when $m = \log|\mathcal{M}|$, we get that $L(\mathcal{M}, t, n) = \log K(\mathcal{M}, t)$. The exact determination of quantities $K(\mathcal{M}, t)$ and $K(\mathcal{M}, t, S)$ is a central problem of coding theory and is typically very hard. To the best of our knowledge, the quantity $L(\mathcal{M}, t, m)$ was not explicitly studied in any of three metrics that we study, and its exact determination seems hard as well.

We give two simple lower bounds on the entropy loss (one for secure sketches and the other for fuzzy extractors) which show that our constructions for the Hamming and set difference metrics output as much entropy m' as possible when the original input distribution is uniform. In particular, because the constructions have the same entropy loss regardless of m, they are optimal in terms of the entropy loss $m - m'$. We conjecture that the constructions also have the highest possible value m' for all values of m, but we do not have a good enough understanding of $L(\mathcal{M}, t, m)$ (where $\mathcal{M}$ is the Hamming metric) to substantiate the conjecture.

LEMMA C.1. *The existence of an $(\mathcal{M}, m, m', t)$-secure sketch implies that $m' \leq L(\mathcal{M}, t, m)$. In particular, when $m = \log|\mathcal{M}|$ (i.e., when the password is truly uniform), $m' \leq \log K(\mathcal{M}, t)$.*

Proof. Assume that SS is such a secure sketch. Let S be any set of size 2^m in $\mathcal{M}$, and let W be uniform over S. Then we must have $\tilde{\mathbf{H}}_\infty(W \mid \mathsf{SS}(W)) \geq m'$. In particular, there must be some value v such that $\mathbf{H}_\infty(W \mid \mathsf{SS}(W) = v) \geq m'$. But this means that conditioned on $\mathsf{SS}(W) = v$, there are at least $2^{m'}$ points w in S (call this set T) which could produce $\mathsf{SS}(W) = v$. We claim that these $2^{m'}$ values of w form a code of error-correcting distance t. Indeed, otherwise there would be a point $w' \in \mathcal{M}$

such that $\mathsf{dis}(w_0, w') \le t$ and $\mathsf{dis}(w_1, w') \le t$ for some $w_0, w_1 \in T$. But then we must have that $\mathsf{Rec}(w', v)$ is equal to both w_0 and w_1, which is impossible. Thus, the set T above must form an $(\mathcal{M}, 2^{m'}, t)$-code inside S, which means that $m' \le \log K(\mathcal{M}, t, S)$. Since S was arbitrary, the bound follows. □

LEMMA C.2. *The existence of $(\mathcal{M}, m, \ell, t, \epsilon)$-fuzzy extractors implies that $\ell \le L(\mathcal{M}, t, m) - \log(1-\epsilon)$. In particular, when $m = \log|\mathcal{M}|$ (i.e., when the password is truly uniform), $\ell \le \log K(\mathcal{M}, t) - \log(1-\epsilon)$.*

Proof. Assume that $(\mathsf{Gen}, \mathsf{Rep})$ is such a fuzzy extractor. Let S be any set of size 2^m in $\mathcal{M}$, let W be uniform over S, and let $(R, P) \leftarrow \mathsf{Gen}(W)$. Then we must have that $\mathbf{SD}((R, P), (U_\ell, P)) \le \epsilon$. In particular, there must be some value p of P such that R is ϵ-close to U_ℓ conditioned on $P = p$. In particular, this means that conditioned on $P = p$, there are at least $(1-\epsilon)2^\ell$ points $r \in \{0,1\}^\ell$ (call this set T) which could be extracted with $P = p$. Now, map every $r \in T$ to some arbitrary $w \in S$ which could have produced r with nonzero probability given $P = p$, and call this map C. C must define a code with error-correcting distance t by the same reasoning as in Lemma C.1. □

Observe that, as long as $\epsilon < 1/2$, we have $0 < -\log(1-\epsilon) < 1$, so the lower bounds on secure sketches and fuzzy extractors differ by less than a bit.

Appendix D. Analysis of the original Juels–Sudan construction. In this section we present a new analysis for the Juels–Sudan secure sketch for set difference. We will assume that $n = |\mathcal{U}|$ is a prime power and work over the field $\mathcal{F} = GF(n)$. On input set w, the original Juels–Sudan sketch is a list of r pairs of points (x_i, y_i) in $\mathcal{F}$, for some parameter r, $s < r \le n$. It is computed as follows.

Construction 10 (original Juels–Sudan secure sketch [38]). Input: a set $w \subseteq \mathcal{F}$ of size s and parameters $r \in \{s+1, \dots, n\}$, $t \in \{1, \dots, s\}$.

1. Choose $p()$ at random from the set of polynomials of degree at most $k = s - t - 1$ over $\mathcal{F}$.

Write $w = \{x_1, \dots, x_s\}$, and let $y_i = p(x_i)$ for $i = 1, \dots, s$.

2. Choose $r - s$ distinct points $x_{s+1}, \dots, x_r$ at random from $\mathcal{F} - w$.
3. For $i = s+1, \dots, r$, choose $y_i \in \mathcal{F}$ at random such that $y_i \ne p(x_i)$.
4. Output $\mathsf{SS}(w) = \{(x_1, y_1), \dots, (x_r, y_r)\}$ (in lexicographic order of x_i).

The parameter t measures the error-tolerance of the scheme: given $\mathsf{SS}(w)$ and a set w' such that $w \triangle w' \le t$, one can recover w by considering the pairs (x_i, y_i) for $x_i \in w'$ and running Reed–Solomon decoding to recover the low-degree polynomial $p(\cdot)$. When the parameter r is very small, the scheme corrects approximately twice as many errors with good probability (in the "input-dependent" sense from section 8). When r is low, however, we show here that the bound on the entropy loss becomes very weak.

The parameter r dictates the amount of storage necessary, one on hand, and also the security of the scheme (that is, for $r = s$ the scheme leaks all information and for larger and larger r there is less information about w). Juels and Sudan actually propose two analyses for the scheme. First, they analyze the case where the secret w is distributed uniformly over all subsets of size s. Second, they provide an analysis of a nonuniform password distribution, but only for the case $r = n$ (that is, their analysis applies only in the small universe setting, where $\Omega(n)$ storage is acceptable). Here we give a simpler analysis which handles nonuniformity and any $r \le n$. We get the same results for a broader set of parameters.

LEMMA D.1. *The entropy loss of the Juels–Sudan scheme is at most $t \log n + \log\binom{n}{r} - \log\binom{n-s}{r-s} + 2$.*

Proof. This is a simple application of Lemma 2.2(b). $\mathbf{H}_\infty((W, \mathsf{SS}(W)))$ can be computed as follows. Choosing the polynomial p (which can be uniquely recovered from w and $\mathsf{SS}(w)$) requires $s - t$ random choices from $\mathcal{F}$. The choice of the remaining x_i's requires $\log \binom{n-s}{r-s}$ bits, and choosing the $y_i's$ requires $r - s$ random choices from $\mathcal{F} - \{p(x_i)\}$. Thus, $\mathbf{H}_\infty((W, \mathsf{SS}(W))) = \mathbf{H}_\infty(W) + (s-t)\log n + \log \binom{n-s}{r-s} + (r-s)\log(n-1)$. The output can be described in $\log \left(\binom{n}{r} n^r\right)$ bits. The result follows by Lemma 2.2(b) after observing that $(r-s)\log \frac{n}{n-1} < n \log \frac{n}{n-1} \le 2$. □

In the large universe setting, we will have $r \ll n$ (since we wish to have storage polynomial in s). In that setting, the bound on the entropy loss of the Juels–Sudan scheme is in fact very large. We can rewrite the entropy loss as $t \log n - \log \binom{r}{s} + \log \binom{n}{s} + 2$, using the identity $\binom{n}{r}\binom{r}{s} = \binom{n}{s}\binom{n-s}{r-s}$. Now the entropy of W is at most $\binom{n}{s}$, and so our lower bound on the remaining entropy is $(\log \binom{r}{s} - t \log n - 2)$. To make this quantity large requires making r very large.

Appendix E. BCH syndrome decoding in sublinear time. We show that the standard decoding algorithm for BCH codes can be modified to run in time polynomial in the length of the syndrome. This works for BCH codes over any field $GF(q)$, which include Hamming codes in the binary case and Reed–Solomon for the case $n = q - 1$. BCH codes are handled in detail in many textbooks (e.g., [72]); our presentation here is quite concise. For simplicity, we discuss only primitive, narrow-sense BCH codes here; the discussion extends easily to the general case.

The algorithm discussed here has been revised due to an error pointed out by Ari Trachtenberg. Its implementation is available [36].

We will use a slightly nonstandard formulation of BCH codes. Let $n = q^m - 1$ (in the binary case of interest in section 6.3, $q = 2$). We will work in two finite fields: $GF(q)$ and a larger extension field $\mathcal{F} = GF(q^m)$. BCH codewords, formally defined below, are then vectors in $GF(q)^n$. In most common presentations, one indexes the n positions of these vectors by discrete logarithms of the elements of $\mathcal{F}^*$: position i, for $1 \le i \le n$, corresponds to α^i, where α generates the multiplicative group $\mathcal{F}^*$. However, there is no inherent reason to do so: they can be indexed by elements of $\mathcal{F}$ directly rather than by their discrete logarithms. Thus, we say that a word has value p_x at position x, where $x \in \mathcal{F}^*$. If one ever needs to write down the entire n-character word in an ordered fashion, one can arbitrarily choose a convenient ordering of the elements of $\mathcal{F}$ (e.g., by using some standard binary representation of field elements); for our purposes this is not necessary, as we do not store entire n-bit words explicitly, but rather represent them by their supports: $\mathrm{supp}(v) = \{(x, p_x) \mid p_x \neq 0\}$. Note that for the binary case of interest in section 6.3, we can define $\mathrm{supp}(v) = \{x \mid p_x \neq 0\}$, because p_x can take only two values: 0 or 1.

Our choice of representation will be crucial for efficient decoding: in the more common representation, the last step of the decoding algorithm requires one to find the position i of the error from the field element α^i. However, no efficient algorithms for computing the discrete logarithm are known if q^m is large (indeed, a lot of cryptography is based on the assumption that such an efficient algorithm does not exist). In our representation, the field element α^i will in fact be the position of the error.

Definition 8. *The (narrow-sense, primitive) BCH code of designed distance δ over $GF(q)$ (of length $n \ge \delta$) is given by the set of vectors of the form $(c_x)_{x \in \mathcal{F}^*}$ such that each c_x is in the smaller field $GF(q)$, and the vector satisfies the constraints $\sum_{x \in \mathcal{F}^*} c_x x^i = 0$ for $i = 1, \ldots, \delta - 1$, with arithmetic done in the larger field $\mathcal{F}$.*

To explain this definition, let us fix a generator α of the multiplicative group of

the large field $\mathcal{F}^*$. For any vector of coefficients $\left(c_x\right)_{x\in\mathcal{F}^*}$, we can define a polynomial

$$c(z) = \sum_{x\in GF(q^m)^*} c_x z^{\mathsf{dlog}(x)},$$

where $\mathsf{dlog}(x)$ is the discrete logarithm of x with respect to α. The conditions of the definition are then equivalent to the requirement (more commonly seen in presentations of BCH codes) that $c(\alpha^i) = 0$ for $i = 1, \ldots, \delta - 1$, because $(\alpha^i)^{\mathsf{dlog}(x)} = (\alpha^{\mathsf{dlog}(x)})^i = x^i$.

We can simplify this somewhat. Because the coefficients c_x are in $GF(q)$, they satisfy $c_x^q = c_x$. Using the identity $(x + y)^q = x^q + y^q$, which holds even in the large field $\mathcal{F}$, we have $c(\alpha^i)^q = \sum_{x\neq 0} c_x^q x^{iq} = c(\alpha^{iq})$. Thus, roughly a $1/q$ fraction of the conditions in the definition are redundant: we need only to check that they hold for $i \in \{1, \ldots, \delta - 1\}$ such that $q \not| i$.

The syndrome of a word (not necessarily a codeword) $(p_x)_{x\in\mathcal{F}^*} \in GF(q)^n$ with respect to the BCH code above is the vector

$$\mathsf{syn}(p) = p(\alpha^1), \ldots, p(\alpha^{\delta-1}), \quad \text{where} \quad p(\alpha^i) = \sum_{x\in\mathcal{F}^*} p_x x^i.$$

As mentioned above, we do not in fact have to include the values $p(\alpha^i)$ such that $q|i$.

Computing with low-weight words. A low-weight word $p \in GF(q)^n$ can be represented either as a long string or, more compactly, as a list of positions where it is nonzero and its values at those points. We call this representation the support list of p and denote it $\mathrm{supp}(p) = \{(x, p_x)\}_{x:p_x\neq 0}$.

LEMMA E.1. *For a q-ary BCH code C of designed distance δ, one can compute*

(1) $\mathsf{syn}(p)$ *from* $\mathrm{supp}(p)$ *in time polynomial in* δ, $\log n$, *and* $|\mathrm{supp}(p)|$, *and*

(2) $\mathrm{supp}(p)$ *from* $\mathsf{syn}(p)$ *(when p has weight at most $(\delta-1)/2$) in time polynomial in δ and* $\log n$.

Proof. Recall that $\mathsf{syn}(p) = (p(\alpha), \ldots, p(\alpha^{\delta-1}))$, where $p(\alpha^i) = \sum_{x\neq 0} p_x x^i$. Part (1) is easy, since to compute the syndrome we need only to compute the powers of x. This requires about $\delta \cdot \mathsf{weight}(p)$ multiplications in $\mathcal{F}$. For part (2), we adapt Berlekamp's BCH decoding algorithm, based on its presentation in [72]. Let $M = \{x \in \mathcal{F}^* | p_x \neq 0\}$, and define

$$\sigma(z) \stackrel{\text{def}}{=} \prod_{x\in M} (1 - xz) \quad \text{and} \quad \omega(z) \stackrel{\text{def}}{=} \sigma(z) \sum_{x\in M} \frac{p_x xz}{(1 - xz)}.$$

Since $(1 - xz)$ divides $\sigma(z)$ for $x \in M$, we see that $\omega(z)$ is in fact a polynomial of degree at most $|M| = \mathsf{weight}(p) \leq (\delta - 1)/2$. The polynomials $\sigma(z)$ and $\omega(z)$ are known as the error locator polynomial and evaluator polynomial, respectively; observe that $\gcd(\sigma(z), \omega(z)) = 1$.

We will in fact work with our polynomials modulo z^δ. In this arithmetic the inverse of $(1 - xz)$ is $\sum_{\ell=1}^{\delta} (xz)^{\ell-1}$; that is,

$$(1 - xz) \sum_{\ell=1}^{\delta} (xz)^{\ell-1} \equiv 1 \mod z^\delta.$$

We are given $p(\alpha^\ell)$ for $\ell = 1, \ldots, \delta$. Let $S(z) = \sum_{\ell=1}^{\delta-1} p(\alpha^\ell) z^\ell$. Note that $S(z) \equiv \sum_{x\in M} p_x \frac{xz}{(1-xz)} \mod z^\delta$. This implies that

$$S(z)\sigma(z) \equiv \omega(z) \mod z^\delta.$$

The polynomials $\sigma(z)$ and $\omega(z)$ satisfy the following four conditions: they are of degree at most $(\delta-1)/2$ each, they are relatively prime, the constant coefficient of σ is 1, and they satisfy this congruence. In fact, let $w'(z), \sigma'(z)$ be any nonzero solution to this congruence, where degrees of $w'(z)$ and $\sigma'(z)$ are at most $(\delta-1)/2$. Then $w'(z)/\sigma'(z) = \omega(z)/\sigma(z)$. (To see why this is so, multiply the initial congruence by $\sigma'()$ to get $\omega(z)\sigma'(z) \equiv \sigma(z)\omega'(z) \mod z^{\delta}$. Since both sides of the congruence have degree at most $\delta-1$, they are in fact equal as polynomials.) Thus, there is at most one solution $\sigma(z), \omega(z)$ satisfying all four conditions, which can be obtained from any $\sigma'(z), \omega'(z)$ by reducing the resulting fraction $\omega'(z)/\sigma'(z)$ to obtain the solution of minimal degree with the constant term of σ equal to 1.

Finally, the roots of $\sigma(z)$ are the points x^{-1} for $x \in M$, and the exact value of p_x can be recovered from $\omega(x^{-1}) = p_x \prod_{y \in M, y \neq x}(1 - yx^{-1})$ (this is needed only for $q > 2$, because for $q = 2$, $p_x = 1$). Note that it is possible that a solution to the congruence will be found even if the input syndrome is not a syndrome of any p with $\mathsf{weight}(p) > (\delta-1)/2$ (it is also possible that a solution to the congruence will not be found at all, or that the resulting $\sigma(z)$ will not split into distinct nonzero roots). Such a solution will not give the correct p. Thus, if there is no guarantee that $\mathsf{weight}(p)$ is actually at most $(\delta-1)/2$, it is necessary to recompute $\mathsf{syn}(p)$ after finding the solution, in order to verify that p is indeed correct.

Representing coefficients of $\sigma'(z)$ and $\omega'(z)$ as unknowns, we see that solving the congruence requires only solving a system of δ linear equations (one for each degree of z, from 0 to $\delta-1$) involving $\delta+1$ variables over $\mathcal{F}$, which can be done in $O(\delta^3)$ operations in $\mathcal{F}$ using, e.g., Gaussian elimination. The reduction of the fraction $\omega'(z)/\sigma'(z)$ requires simply running Euclid's algorithm for finding the gcd of two polynomials of degree less than δ, which takes $O(\delta^2)$ operations in $\mathcal{F}$. Suppose the resulting σ has degree e. Then one can find the roots of σ as follows. First test that σ indeed has e distinct roots by testing that $\sigma(z) | z^{q^m} - z$ (this is a necessary and sufficient condition, because every element of $\mathcal{F}$ is a root of $z^{q^m} - z$ exactly once). This can be done by computing $(z^{q^m} \mod \sigma(z))$ and testing if it equals $z \bmod \sigma$; it takes m exponentiations of a polynomial to the power q, i.e., $O((m \log q)e^2)$ operations in $\mathcal{F}$. Then apply an equal-degree-factorization algorithm (e.g., as described in [66]), which also takes $O((m \log q)e^2)$ operations in $\mathcal{F}$. Finally, after taking inverses of the roots of $\mathcal{F}$ and finding p_x (which takes $O(e^2)$ operations in $\mathcal{F}$), recompute $\mathsf{syn}(p)$ to verify that it is equal to the input value.

Because $m \log q = \log(n+1)$ and $e \leq (\delta-1)/2$, the total running time is $O(\delta^3 + \delta^2 \log n)$ operations in $\mathcal{F}$; each operation in $\mathcal{F}$ can done in time $O(\log^2 n)$, or faster using advanced techniques.

One can improve this running time substantially. The error locator polynomial $\sigma()$ can be found in $O(\log \delta)$ convolutions (multiplications) of polynomials over $\mathcal{F}$ of degree $(\delta-1)/2$ each [7, section 11.7] by exploiting the special structure of the system of linear equations being solved. Each convolution can be performed asymptotically in time $O(\delta \log \delta \log\log \delta)$ (see, e.g., [74]), and the total time required to find σ gets reduced to $O(\delta \log^2 \delta \log\log \delta)$ operation in $\mathcal{F}$. This replaces the δ^3 term in the above running time.

While this is asymptotically very good, Euclidean-algorithm-based decoding [70], which runs in $O(\delta^2)$ operations in $\mathcal{F}$, will find $\sigma(z)$ faster for reasonable values of δ (certainly for $\delta < 1000$). The algorithm finds σ as follows:

```
set R_old(z) ← z^{δ-1}, R_cur(z) ← S(z)/z, V_old(z) ← 0, V_cur(z) ← 1.
while deg(R_cur(z)) ≥ (δ-1)/2:
     divide R_old(z) by R_cur(z) to get quotient q(z) and remainder
```

$R_{\text{new}}(z)$;
set $V_{\text{new}}(z) \leftarrow V_{\text{old}}(z) - q(z)V_{\text{cur}}(z)$;
set $R_{\text{old}}(z) \leftarrow R_{\text{cur}}(z)$, $R_{\text{cur}}(z) \leftarrow R_{\text{new}}(z)$, $V_{\text{old}}(z) \leftarrow V_{\text{cur}}(z)$, $V_{\text{cur}}(z) \leftarrow V_{\text{new}}(z)$.
set $c \leftarrow V_{\text{cur}}(0)$; set $\sigma(z) \leftarrow V_{\text{cur}}(z)/c$ and $\omega(z) \leftarrow z \cdot R_{\text{cur}}(z)/c$

In the above algorithm, if $c = 0$, then the correct $\sigma(z)$ does not exist, i.e., $\mathsf{weight}(p) > (\delta-1)/2$. The correctness of this algorithm can be seen by observing that the congruence $S(z)\sigma(z) \equiv \omega(z) \pmod{z^\delta}$ can have z factored out of it (because $S(z)$, $\omega(z)$, and z^δ are all divisible by z) and rewritten as $(S(z)/z)\sigma(z) + u(z)z^{\delta-1} = \omega(z)/z$ for some $u(z)$. The obtained σ is easily shown to be the correct one (if one exists at all) by applying [66, Theorem 18.7] (to use the notation of that theorem, set $n = z^{\delta-1}$, $y = S(z)/z$, $t^* = r^* = (\delta-1)/2$, $r' = \omega(z)/z$, $s' = u(z)$, $t' = \sigma(z)$).

The root finding of σ can also be sped up. Asymptotically, detecting if a polynomial over $\mathcal{F} = GF(q^m) = GF(n+1)$ of degree e has e distinct roots and finding these roots can be performed in time $O(e^{1.815}(\log n)^{0.407})$ operations in $\mathcal{F}$ using the algorithm of Kaltofen and Shoup [40], or in time $O(e^2 + (\log n)e \log e \log\log e)$ operations in $\mathcal{F}$ using the EDF algorithm of Cantor and Zassenhaus.[13] For reasonable values of e, the Cantor–Zassenhaus EDF algorithm with Karatsuba's multiplication algorithm [41] for polynomials will be faster, giving root-finding running time of $O(e^2 + e^{\log_2 3} \log n)$ operations in $\mathcal{F}$. Note that if the actual weight e of p is close to the maximum tolerated $(\delta-1)/2$, then finding the roots of σ will actually take longer than finding σ. □

A dual view of the algorithm. Readers may be more familiar with a different, evaluation-based formulation of BCH codes, in which codewords are generated as follows. Let $\mathcal{F}$ again be an extension of $GF(q)$, and let n be the length of the code (note that $|\mathcal{F}^*|$ is not necessarily equal to n in this formulation). Fix distinct $x_1, x_2, \ldots, x_n \in \mathcal{F}$. For every polynomial c over the large field $\mathcal{F}$ of degree at most $n - \delta$, the vector $(c(x_1), c(x_2), \ldots c(x_n))$ is a codeword if and only if every coordinate of the vector happens to be in the smaller field: $c(x_i) \in GF(q)$ for all i. In particular, when $\mathcal{F} = GF(q)$, then every polynomial leads to a codeword, thus giving Reed–Solomon codes.

The syndrome in this formulation can be computed as follows: given a vector $y = (y_1, y_2, \ldots, y_n)$ find the interpolating polynomial $P = p_{n-1}x^{n-1} + p_{n-2}x^{n-2} + \cdots + p_0$ over $\mathcal{F}$ of degree at most $n-1$ such that $P(x_i) = y_i$ for all i. The syndrome is then the negative top $\delta - 1$ coefficients of P: $\mathsf{syn}(y) = (-p_{n-1}, -p_{n-2}, \ldots, -p_{n-(\delta-1)})$. (It is easy to see that this is a syndrome: it is a linear function that is zero exactly on the codewords.)

When $n = |\mathcal{F}| - 1$, we can index the n-component vectors by elements of $\mathcal{F}^*$, writing codewords as $(c(x))_{x\in\mathcal{F}^*}$. In this case, the syndrome of $(y_x)_{x\in\mathcal{F}^*}$ defined as the negative top $\delta - 1$ coefficients of P such that for all $x \in F^*$, $P(x) = y_x$ is equal to the syndrome defined following Definition 8 as $\sum_{x\in\mathcal{F}} y_x x^i$ for $i = 1, 2, \ldots, \delta - 1$.[14] Thus, when $n = |\mathcal{F}| - 1$, the codewords obtained via the evaluation-based definition are *identical* to the codewords obtain via Definition 8, because codewords are simply

[13] See [66, section 21.3], and substitute the most efficient known polynomial arithmetic. For example, the procedures described in [74] take time $O(e \log e \log\log e)$ instead of time $O(e^2)$ to perform modular arithmetic operations with degree-e polynomials.

[14] This statement can be shown as follows: because both maps are linear, it is sufficient to prove that they agree on a vector $(y_x)_{x\in\mathcal{F}^*}$ such that $y_a = 1$ for some $a \in \mathcal{F}^*$ and $y_x = 0$ for $x \neq a$. For such a vector, $\sum_{x\in\mathcal{F}} y_x x^i = a^i$. On the other hand, the interpolating polynomial $P(x)$ such that $P(x) = y_x$ is $-ax^{n-1} - a^2x^{n-2} - \cdots - a^{n-1}x - 1$ (indeed, $P(a) = -n = 1$; furthermore, multiplying $P(x)$ by $x - a$ gives $a(x^n - 1)$, which is zero on all of $\mathcal{F}^*$; hence $P(x)$ is zero for every $x \neq a$).

elements with the zero syndrome, and the syndrome maps agree.

This is an example of a remarkable duality between evaluations of polynomials and their coefficients: the syndrome can be viewed either as the evaluation of a polynomial whose coefficients are given by the vector, or as the coefficients of the polynomial whose evaluations are given by a vector.

The syndrome decoding algorithm above has a natural interpretation in the evaluation-based view. Our presentation is an adaptation of Welch–Berlekamp decoding as presented in, e.g., [69, Chapter 10].

Suppose $n = |F| - 1$ and $x_1, \ldots, x_n$ are the nonzero elements of the field. Let $y = (y_1, y_2, \ldots, y_n)$ be a vector. We are given its syndrome $\mathsf{syn}(y) = (-p_{n-1}, -p_{n-2}, \ldots, -p_{n-(\delta-1)})$, where $p_{n-1}, \ldots, p_{n-(\delta-1)}$ are the top coefficients of the interpolating polynomial P. Knowing only $\mathsf{syn}(y)$, we need to find at most $(\delta-1)/2$ locations x_i such that correcting all the corresponding y_i will result in a codeword. Suppose that codeword is given by a degree-$(n-\delta)$ polynomial c. Note that c agrees with P on all but the error locations. Let $\rho(z)$ be the polynomial of degree at most $(\delta-1)/2$ whose roots are exactly the error locations. (Note that $\sigma(z)$ from the decoding algorithm above is the same $\rho(z)$ but with coefficients in reverse order, because the roots of σ are the inverses of the roots of ρ.) Then $\rho(z) \cdot P(z) = \rho(z) \cdot c(z)$ for $z = x_1, x_2, \ldots, x_n$. Since $x_1, \ldots, x_n$ are all the nonzero field elements, $\prod_{i=1}^{n}(z - x_i) = z^n - 1$. Thus,

$$\rho(z) \cdot c(z) \;=\; \rho(z) \cdot P(z) \bmod \prod_{i=1}^{n}(z - x_i) \;=\; \rho(z) \cdot P(z) \bmod (z^n - 1)\,.$$

If we write the left-hand side as $\alpha_{n-1}x^{n-1} + \alpha_{n-2}x^{n-2} + \cdots + \alpha_0$, then the above equation implies that $\alpha_{n-1} = \cdots = \alpha_{n-(\delta-1)/2} = 0$ (because the degree if $\rho(z) \cdot c(z)$ is at most $n - (\delta+1)/2$). Because $\alpha_{n-1}, \ldots, \alpha_{n-(\delta-1)/2}$ depend on the coefficients of ρ as well as on $p_{n-1}, \ldots, p_{n-(\delta-1)}$, but not on lower coefficients of P, we obtain a system of $(\delta-1)/2$ equations for $(\delta-1)/2$ unknown coefficients of ρ. A careful examination shows that it is essentially the same system we had for $\sigma(z)$ in the algorithm above. The lowest-degree solution to this system is indeed the correct ρ, by the same argument which was used to prove the correctness of σ in Lemma E.1. The roots of ρ are the error locations. For $q > 2$, the actual corrections that are needed at the error locations (in other words, the light vector corresponding to the given syndrome) can then be recovered by solving the linear system of equations implied by the value of the syndrome.

Acknowledgments. This work evolved over several years, and discussions with many people enriched our understanding of the material at hand. In roughly chronological order, we thank Piotr Indyk for discussions about embeddings and for his help in the proof of Lemma 7.3; Madhu Sudan for helpful discussions about the construction of [38] and the uses of error-correcting codes; Venkat Guruswami for enlightenment about list decoding; Pim Tuyls for pointing out relevant previous work; Chris Peikert for pointing out the model of computationally bounded adversaries from [48]; Ari Trachtenberg for finding an error in the preliminary version of Appendix E; Ronny Roth for discussions about efficient BCH decoding; Kevin Harmon and Soren Johnson for their implementation work; and Silvio Micali and anonymous referees for suggestions on presenting our results.

SUB-CONSTANT ERROR LOW DEGREE TEST OF ALMOST-LINEAR SIZE*

DANA MOSHKOVITZ† AND RAN RAZ†

Abstract. Given (the table of) a function $f : \mathbb{F}^m \to \mathbb{F}$ over a finite field $\mathbb{F}$, a *low degree tester* tests its agreement with an m-variate polynomial of total degree at most d over $\mathbb{F}$. The tester is usually given access to an oracle $\mathcal{A}$ providing the *supposed* restrictions of f to affine subspaces of constant dimension (e.g., lines, planes, etc.). The tester makes very few (probabilistic) queries to f and to $\mathcal{A}$ (say, one query to f and one query to $\mathcal{A}$) and decides whether to accept or reject based on the replies. We wish to minimize two parameters of the tester: its *error* and its *size*. The error bounds the probability that the tester accepts although the function is far from a low degree polynomial. The size is the number of bits required to write the oracle replies on all possible tester queries. Low degree testing is a central ingredient in most constructions of probabilistically checkable proofs (PCPs). The error of the low degree tester is related to the error of the PCP, and its size is related to the size of the PCP. We design and analyze new low degree testers that have both *subconstant error* $o(1)$ and *almost-linear size* $n^{1+o(1)}$ (where $n = |\mathbb{F}|^m$). Previous constructions of subconstant error testers had *polynomial size*. These testers enabled the construction of PCPs with subconstant error, but polynomial size. Previous constructions of almost-linear size testers obtained only *constant error*. These testers were used to construct almost-linear size PCPs with constant error. The testers we present in this work enabled the construction of PCPs with both subconstant error and almost-linear size.

Key words. low degree testing, plane vs. point test, sampling, probabilistically checkable proofs

1. Introduction.

1.1. Low degree testing. Let $\mathbb{F}$ be a finite field, and let m and d be two positive integers. [A particular setting of parameters to have in mind is the one used in constructions of probabilistically checkable proofs: a large field $\mathbb{F}$, a smaller m, and a fairly large d that satisfy $m^{O(1)}d \leq o(|\mathbb{F}|)$.]

Define $\mathcal{P}$ to be the set of all m-variate polynomials of total degree at most d over $\mathbb{F}$. The *agreement* of a function $f : \mathbb{F}^m \to \mathbb{F}$ with a low degree polynomial is

$$\mathsf{agr}(f, \mathcal{P}) \stackrel{def}{=} \max_{Q \in \mathcal{P}} \left\{ \Pr_{\vec{x} \in \mathbb{F}^m} [f(\vec{x}) = Q(\vec{x})] \right\}.$$

Note that $\mathsf{agr}(f, \mathcal{P})$ is simply $1 - \Delta(f, \mathcal{P})$, where Δ denotes the (normalized) Hamming distance between functions that are given by their tables.

A *low degree tester* is a probabilistic procedure M that is meant to check the agreement of a function f with a low degree polynomial by making as few *queries* to f as possible. If $f \in \mathcal{P}$, M should always accept, while if f is far from $\mathcal{P}$ (i.e., $\mathsf{agr}(f, \mathcal{P})$ is small), M should reject with significant probability.

It is easy to see that, when having oracle access only to f, any low degree tester must make more than d queries. To break this degree barrier, the low degree tester

is usually given access to an additional oracle $\mathcal{A}$ providing the *supposed* restrictions of f to affine subspaces of constant dimension (e.g., lines, planes, etc.). We assume, without loss of generality, that these restrictions in themselves are polynomials of total degree at most d over the subspaces.

The tester is required to satisfy:

- *Completeness*: If $f \in \mathcal{P}$, then there is an oracle $\mathcal{A}$ that makes the tester accept with probability 1.
- *Soundness*: If $\mathsf{agr}(f, \mathcal{P})$ is small, then for any oracle $\mathcal{A}$ the tester may accept only with a small probability.

Rubinfeld and Sudan [18] designed the line vs. point tester that makes only two probabilistic queries. This tester picks independently at random a line l in $\mathbb{F}^m$ and a point $\vec{x} \in l$, queries the oracle $\mathcal{A}$ for the (supposed) restriction of f to l (which is simply a univariate polynomial of degree at most d over $\mathbb{F}$), queries f at $\vec{x}$, and checks whether the two restrictions are consistent on $\vec{x}$, i.e., $\mathcal{A}(l)(\vec{x}) = f(\vec{x})$.

The importance of low degree testers comes from the key role they play in the construction of *probabilistically checkable proofs* (PCPs), which are proofs for NP statements that can be probabilistically verified by making only a constant number of queries to the proof [4, 10, 2, 1]. This motivated further improvements to low degree testing.

Specifically, the following parameters were of interest:

1. *Queries.* How many queries does the tester make?
2. *Error.* How sound is the tester?
3. *Size.* How many bits are needed to write the oracle replies on all possible queries?

Henceforth, the number of queries will always be 2. The two other parameters are discussed next.

1.1.1. Error. To prove that a low degree tester is sound, most results address contrapositive arguments of the following type: assume that the tester accepts with probability $\gamma \geq \gamma_0$, and show the existence of a low degree polynomial that agrees with f on at least $\approx \gamma$ of the points. In this case, we say that γ_0 bounds the *error* of the tester, since the probability that the tester accepts although the function is very far from a low degree polynomial is at most γ_0.

The first analyses of the line vs. point tester [18, 2, 12] showed only that the error of the tester is bounded away from 1. The error can be amplified to any *constant*, by a constant number of repetitions. Nevertheless, to keep the total number of queries constant, one cannot perform more than a constant number of repetitions.

Only a later, more careful, inspection [3, 17] revealed that there are low degree testers with a *subconstant error*. Specifically, [3, 17] proved claims of the following type for various low degree testers: there exist (large enough) constants $C \geq 1$, $a, b \geq 0$, and a (small enough) constant $0 < c \leq 1$ such that the error is at most $Cm^a d^b / |\mathbb{F}|^c$. In other words, the error can be made arbitrarily small by taking m and d to be small enough with respect to $|\mathbb{F}|$. The number of queries remains 2.

Arora and Sudan [3] proved that the error of the line vs. point tester is in fact subconstant. Their proof was algebraic in nature. Raz and Safra [17] proved a subconstant error for a slightly different tester, by considering planes that intersect on a line or a plane and a point within it. Their proof was more combinatorial in nature. The two proofs led to the construction of PCPs with subconstant error [3, 17, 9].

1.1.2. Size. Let us represent the set of honest oracles by a code. That is, for every polynomial $Q : \mathbb{F}^m \to \mathbb{F}$ of degree at most d, we have a code word. The code

word has an entry for every affine subspace s that the tester may query. This entry contains the oracle's reply when it is queried regarding s, i.e., the restriction of Q to s. The *size* of a tester is the length (in bits) of a code word.

For instance, the size of Rubinfeld and Sudan's line vs. point tester [18] is roughly $|\mathbb{F}|^{2m}(d+1)\log|\mathbb{F}|$: for every line (defined by two points), the oracle should provide a univariate polynomial of degree at most d over $\mathbb{F}$. The size of a tester is measured with respect to $n = |\mathbb{F}^m|$. The size of the line vs. point tester [18] is quadratic $n^{2+o(1)}$.

Alternatively, we refer to the *randomness* of the tester, which is the amount of random bits that the tester requires. Note that the size of a tester that uses r random bits to make q queries to a proof over alphabet Σ is bounded by $2^r \cdot q \log|\Sigma|$. Thus, when the number of queries q is constant and the alphabet Σ is relatively small, 2^r is a good estimate on the size.

For instance, to pick a random line and a random point within it, we merely have to pick a random point $\vec{x} \in \mathbb{F}^m$ and a random direction $\vec{y} \in \mathbb{F}^m$. The line is $\vec{x} + t \cdot \vec{y}$ for $t \in \mathbb{F}$. Hence, the randomness of the line vs. point tester [18] is $2m \log|\mathbb{F}| = \log(|\mathbb{F}|^{2m})$.

The size of a tester is related to the size of probabilistically checkable proofs and locally testable codes constructed by using it. Hence, Goldreich and Sudan [13] suggested to improve the line vs. point tester by considering a relatively small subset of lines (instead of all lines). Goldreich and Sudan achieved *nonexplicit* constant error tester of *almost-linear* size $n^{1+o(1)}$ instead of quadratic size $n^{2+o(1)}$.

Shortly afterwards, Ben-Sasson et al. [7] gave an explicit construction of a constant error line vs. point tester of almost-linear size. Their idea was to choose a line by picking a uniformly distributed point over $\mathbb{F}^m$ (as before) and a direction that is uniformly distributed over a small ϵ-biased set $S \subseteq \mathbb{F}^m$. They showed that the error of this tester is bounded away from 1. Unfortunately, their analysis is inherently able to show only error larger than $\frac{1}{2}$. It is possible that their tester has smaller error, but proving it would require a substantially different analysis.

The work of [13, 7] gave rise to explicit constructions of almost-linear size PCPs with constant error [13, 7, 5]. The recent work of Dinur [8] also constructs almost-linear size PCPs with constant error, based on the PCP theorem of [2, 1] and the work of Ben-Sasson and Sudan [6]. Both use low degree testers with constant error. Dinur's work [8] also gives new constructions of PCPs without low degree testers. However, at this point, these constructions achieve neither subconstant error nor almost-linear size.

1.2. Our contribution: Randomness-efficient subconstant error testers. We design and analyze two low degree testers that have both subconstant error and almost-linear size. Subsequent to this work and by using it, we showed a construction of a PCP with both subconstant error and almost-linear size [15].

Before we present our testers, let us revisit the construction of Ben-Sasson et al. [7] for constant error and point out the most severe difficulty one encounters when trying to argue it has error smaller than $\frac{1}{2}$. The reader who is not familiar with the work of Ben-Sasson et al. may skip this and move directly to the text after Remark 1.1.

Assume a line vs. point tester that inspects only lines whose directions are taken from a small *random* set $S \subseteq \mathbb{F}^m$. Recall that Ben-Sasson et al. used a small ϵ-biased set because of its *pseudorandom* properties [7].

Consider two linearly independent directions $\vec{y}_1, \vec{y}_2 \in S$. With high probability, the set S does not contain any additional vector from the linear span of $\vec{y}_1$ and $\vec{y}_2$ (since the fractional size of the linear span is merely $|\mathbb{F}|^2 / |\mathbb{F}|^m$). Thus, the only lines inside this two-dimensional linear subspace that get inspected by the tester are

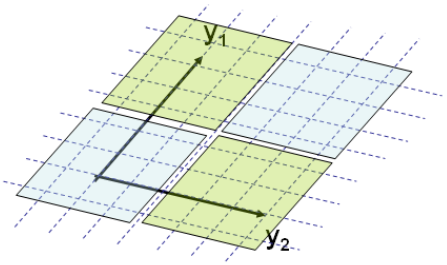

FIG. 1.1. *Acceptance probability* $\frac{1}{2}$ *inside a plane does not necessarily imply agreement with a low degree polynomial.*

those that are parallel to either $\vec{y}_1$ or $\vec{y}_2$. It is known by a lemma of Polishchuk and Spielman [16] that if the acceptance probability of the line vs. point test in this setting approaches 1, then there exists a low degree polynomial for the entire subspace that agrees with almost all lines. However, it may be the case that the acceptance probability is as large as $\frac{1}{2}$, although the agreement of those lines with any low degree polynomial is very small.

Let us demonstrate this in Figure 1.1.

Note that each of the $|\mathbb{F}|^2$ points on the plane spanned by $\vec{y}_1$ and $\vec{y}_2$ can be uniquely represented as $\alpha_1\vec{y}_1 + \alpha_2\vec{y}_2$, where $\vec{\alpha} = (\alpha_1, \alpha_2) \in \mathbb{F}^2$.

Let $d \ll d' \ll \frac{|\mathbb{F}|}{4}$. Define polynomials $C, R \in \mathbb{F}[\alpha_1, \alpha_2]$ (for *columns* and *rows*, respectively) as follows. The degree of C in α_1 is d, and the degree in α_2 is d'. The degree of R in α_1 is d', and the degree in α_2 is d. Let the $|\mathbb{F}|$ columns, i.e., lines parallel to $\vec{y}_1$, agree with C. Let the $|\mathbb{F}|$ rows, i.e., lines parallel to $\vec{y}_2$, agree with R. Note that all lines, columns and rows, are assigned (univariate) polynomials of degree at most d.

Let points in the dark region agree with columns and points in the bright region agree with rows. Both R and C are polynomials of degree *at least* $d' \gg d$ for the plane that agree with at least $\frac{1}{2}$ of the points. However, no polynomial of degree *at most* d for the plane agrees with a fraction of more than $\frac{4d'}{|\mathbb{F}|} = o(1)$ of the points. On the other hand, the acceptance probability of the line vs. point tester on this plane (where all lines are assigned polynomials of degree at most d) is at least $\frac{1}{2}$.

Remark 1.1. One may consider other low degree testers, such as the *line vs. line* tester, in order to solve the problem we described. However, it is not known whether or not the line vs. line tester (on the plane) with lines parallel to the axes gives a probability of error lower than $\frac{1}{2}$.

We manage to overcome this difficulty by considering sets that are *not pseudo-random*. Our key idea is to consider a subfield $\mathbb{H} \subseteq \mathbb{F}$ and generate subspaces by picking directions uniformly over $\mathbb{H}^m$ instead of over $\mathbb{F}^m$. Note that this eliminates the problem we described: for every two $\vec{y}_1, \vec{y}_2 \in \mathbb{H}^m$, for every two scalars $\alpha_1, \alpha_2 \in \mathbb{H}$, we have $\alpha_1\vec{y}_1 + \alpha_2\vec{y}_2 \in \mathbb{H}^m$.

Moreover, the field structure of $\mathbb{H}$ allows us to use the combinatorial approach of Raz and Safra [17], and, more importantly, it allows us to use induction: the structure of the problem when restricted to affine subspaces of dimension $k \leq m$ is the same as its structure in $\mathbb{F}^m$.

As in the analysis of Raz and Safra [17], we abandon the line vs. point test and address subspaces of dimension larger than 1 rather than lines. Specifically, given

1. Pick uniformly and independently at random $\vec{z} \in \mathbb{F}^m$, $\vec{y}_1, \vec{y}_2 \in \mathbb{H}^m$.
2. Accept if either $\vec{y}_1, \vec{y}_2$ are linearly dependent or if the plane p through $\vec{z}$ in directions $\vec{y}_1, \vec{y}_2$ satisfies $\mathcal{A}(p)(\vec{z}) = f(\vec{z})$.

FIG. 1.2. *Randomness-efficient plane vs. point tester.*

access to f and to an oracle $\mathcal{A}$, our *randomness-efficient plane vs. point* tester chooses a plane and a point within it and checks that they are consistent as shown in Figure 1.2.

Note that the same plane p goes through many points $\vec{z} \in \mathbb{F}^m$ and in many directions $\vec{y}_1, \vec{y}_2 \in \mathbb{H}^m$. However, the oracle's reply $\mathcal{A}(p)$ depends on the plane p and not on its representation given by $\vec{z}$ and $\vec{y}_1, \vec{y}_2$.

For $\mathbb{H} = \mathbb{F}$, the randomness-efficient plane vs. point tester is exactly the plane vs. point tester of Raz and Safra [17]. However, in our work the more interesting case is $|\mathbb{H}| \leq |\mathbb{F}|^{o(1)}$. In this case, the tester requires only $m \log |\mathbb{F}| + 2m \log |\mathbb{H}| = m \log |\mathbb{F}| (1 + o(1))$ bits of randomness. This corresponds to an almost-linear size $n^{1+o(1)}$ (recall that $n = |\mathbb{F}^m|$). The tester is randomness efficient in comparison to all known testers with subconstant error, such as the tester of Arora and Sudan [3] that requires $2m \log |\mathbb{F}|$ bits of randomness and the tester of Raz and Safra [17] that requires $3m \log |\mathbb{F}|$ bits of randomness. As to testers with constant error: that of Ben-Sasson et al. [7] requires $m \log |\mathbb{F}| + O(\log \log |\mathbb{F}^m|)$ bits of randomness, which is (usually) less than the randomness of our tester, but the difference is only in the dependence of the *low order term* in m.

The tester is clearly *complete*; namely, if there exists a polynomial $Q : \mathbb{F}^m \to \mathbb{F}$ of degree at most d such that for every $\vec{x} \in \mathbb{F}^m$, $f(\vec{x}) = Q(\vec{x})$ and for every affine subspace s the oracle $\mathcal{A}$ replies $\mathcal{A}(s) = Q_{|s}$, then the tester accepts with probability 1. We show that the tester is also *sound*: if the tester accepts with probability γ, then f agrees with a polynomial of total degree at most md on a fraction of at least $\gamma - \varepsilon$ of the points in $\mathbb{F}^m$, where $\varepsilon \leq \text{const} \cdot m(\sqrt[8]{\frac{1}{|\mathbb{H}|}} + \sqrt[4]{\frac{md}{|\mathbb{F}|}})$. Note that the analysis works for any acceptance probability γ. In particular, this means that, when γ is significantly larger than ε, say, $\gamma \geq 100\varepsilon$, f agrees with a polynomial of total degree at most md on at least $\approx \gamma$ of the points. [Even if $\mathbb{H} = \mathbb{F}$, the constants 4 and 8 in the error expression appear to improve on the results of [3, 17], where unspecified constants were given.]

The downside of the randomness-efficient plane vs. point tester is that it allows us only to argue something about the agreement of the oracle with a polynomial of degree md rather than d. Hence, we design another tester that has essentially the same parameters but ensures agreement with a polynomial of degree at most d.

The additional consideration that comes into play when designing the new tester is *degree preservation*. We want the total degree of a polynomial not to decrease when restricted to most of the subspaces queried by the tester. We achieve this by picking one of the *directions* for the subspace (rather than the base point) uniformly from $\mathbb{F}^m$. In order to keep the size almost linear, this tester considers linear subspaces (i.e., affine subspaces through the origin) rather than general affine subspaces. A related technique was previously used in [7].

Specifically, given access to f and to an oracle $\mathcal{A}$, the *randomness-efficient subspace vs. point* tester chooses a three-dimensional subspace and a point within it and checks that they are consistent as shown in Figure 1.3.

1. Pick uniformly and independently at random $\vec{z} \in \mathbb{F}^m$, $\vec{y}_1, \vec{y}_2 \in \mathbb{H}^m$.
2. Accept if either $\vec{z}, \vec{y}_1, \vec{y}_2$ are linearly dependent or if the linear subspace s spanned by $\vec{z}, \vec{y}_1, \vec{y}_2$ satisfies $\mathcal{A}(s)(\vec{z}) = f(\vec{z})$.

FIG. 1.3. *Randomness-efficient subspace vs. point tester.*

This tester uses the same number of random bits as the randomness-efficient plane vs. point tester $m \log |\mathbb{F}| + 2m \log |\mathbb{H}|$, and its size is only slightly larger (as the answer size is larger: the oracle should provide polynomials over three-dimensional subspaces rather than two-dimensional subspaces). For this small price, we manage to prove a stronger soundness claim: if the randomness-efficient subspace vs. point tester accepts with probability γ, then f agrees with a polynomial of total degree at most d (rather than md) on a fraction of at least $\gamma - \varepsilon$ of the points in $\mathbb{F}^m$, where $\varepsilon \leq \text{const} \cdot m(\sqrt[8]{\frac{1}{|\mathbb{H}|}} + \sqrt[4]{\frac{md}{|\mathbb{F}|}})$. This follows rather easily from the soundness of the randomness-efficient plane vs. point tester together with an argument showing that the degree of the recovered polynomials must in fact be at most d.

There is a trade-off between the size of the testers and their error. To make the size as small as possible, one wishes to minimize $|\mathbb{H}|$. In particular, to get an almost-linear size, one needs to take $|\mathbb{H}| \leq |\mathbb{F}|^{o(1)}$. On the other hand, to make the error as small as possible, one wishes to maximize $|\mathbb{H}|$. In particular, to get a subconstant error, one needs to take $|\mathbb{H}| \geq \omega(m^8)$.

All finite fields are isomorphic to $GF(p^k)$ for a prime p and a natural number k. All subfields of $GF(p^k)$ are isomorphic to $GF(p^r)$ for $r|k$. For a wide family of finite fields $GF(p^k)$ there are subfields of suitable sizes (see [14, 11] for analysis of the distribution of k's with suitable divisors). Though, indeed, not every finite field is such. We wish to emphasize that, in the settings that interest us (e.g., construction of PCPs), *we get to choose the field*. For instance, we can take $\mathbb{F} = GF(2^{r_1 \cdot r_2})$ for appropriate r_1, r_2.

1.3. Sampling. A basic step in our proof is the analysis of the sampling properties of affine subspaces with directions over a subfield. This analysis may be of independent interest.

By *sampling* we refer to assertions of the following nature: if one colors a large enough fraction of the points in $\mathbb{F}^m$ green, then a subspace (e.g., a line) picked at random is likely to hit the green points in almost their true fraction.

First, let us consider the non-randomness-efficient setting. For instance, consider choosing a line by picking a point and a direction independently at random from $\mathbb{F}^m$. The indicator variables "is the ith point on the line green?" for $i = 1, \ldots, |\mathbb{F}|$ are *pairwise independent*. Thus, one can easily bound the variance of the number of green points on a line. This yields a sampling property by Chebyshev's inequality (see, e.g., [3]).

In the randomness-efficient setting, more subtle arguments are needed. For instance, consider the work of Ben-Sasson et al. [7]. They use an ϵ-biased set $S \subseteq \mathbb{F}^m$ and choose a line by independently picking a uniformly distributed base point in $\mathbb{F}^m$ and a uniformly distributed direction in S. They show that *almost-pairwise independence* still holds, and this allows them to bound the variance, by bounding the covariances.

Our set of directions is $\mathbb{H}^m$, which does not have a small bias (when $\mathbb{H} \subsetneq \mathbb{F}$). Nevertheless, we are still able to prove a sampling property. We observe that we

can directly bound the variance of the number of green points on a line by analyzing the convolution of two relatively simple functions. We do this by means of Fourier analysis. The difference between the previous approaches and our approach is that, instead of giving one bound for the probability that two points $i \neq j$ on a line are green *for every* $i \neq j$, we directly bound the *average* probability over all pairs $i \neq j$.

The extension to higher-dimensional subspaces is a relatively simple consequence of the analysis for lines.

1.4. More randomness-efficient line samplers. Ariel Gabizon has noted that our analysis implies numerous randomness-efficient line samplers.

Recall that the set $\mathbb{H}^m$ for a subfield $\mathbb{H} \subseteq \mathbb{F}$—in addition to implying a sampling property—also has an algebraic structure that is essential for our analysis. However, if one is interested only in the sampling property, more randomness-efficient constructions may be obtained.

Jointly with Ariel we arrived at the following corollaries to our analysis.

Direct product construction. Our sampling lemma holds for any field $\mathbb{F} = GF(p^k)$ and a subset of it $H \subseteq \mathbb{F}$ (not necessarily a subfield). Formally we state the following.

COROLLARY 1.2. *For any subset* $A \subseteq \mathbb{F}^m$ *of density* $\mu = |A| / |\mathbb{F}^m|$, *for any* $\varepsilon > 0$,

$$\Pr_{\vec{x} \in \mathbb{F}^m, \vec{y} \in H^m} \left[\left| \frac{|l_{\vec{x},\vec{y}} \cap A|}{|l_{\vec{x},\vec{y}}|} - \mu \right| \geq \varepsilon \right] \leq \frac{1}{|H|} \cdot \frac{\mu}{\varepsilon^2},$$

where $l_{\vec{x},\vec{y}} \stackrel{def}{=} \{\vec{x} + t \cdot \vec{y} \mid t \in \mathbb{F}\}$.

Linear code construction. Assume a linear code of length k, dimension m, and relative distance $1 - \delta$ over alphabet $\mathbb{F} = GF(p)$, given by its generating matrix

$$\begin{pmatrix} - & \vec{y}_1 & - \\ & \vdots & \\ - & \vec{y}_k & - \end{pmatrix}.$$

Let $S = \{\vec{y}_1, \ldots, \vec{y}_k\} \subseteq \mathbb{F}^m$ be the set of rows of the generating matrix. Then our analysis actually implies the following.

COROLLARY 1.3. *For any subset* $A \subseteq \mathbb{F}^m$ *of density* $\mu = |A| / |\mathbb{F}^m|$, *for any* $\varepsilon > 0$,

$$\Pr_{\vec{x} \in \mathbb{F}^m, \vec{y} \in S} \left[\left| \frac{|l_{\vec{x},\vec{y}} \cap A|}{|l_{\vec{x},\vec{y}}|} - \mu \right| \geq \varepsilon \right] \leq \delta \cdot \frac{\mu}{\varepsilon^2},$$

where $l_{\vec{x},\vec{y}} \stackrel{def}{=} \{\vec{x} + t \cdot \vec{y} \mid t \in \mathbb{F}\}$.

Note that every $S \subseteq \mathbb{F}^m$ that is ϵ-biased forms a generating matrix of a linear code with distance $1 - (\frac{1}{|\mathbb{F}|} + \epsilon \cdot \frac{|\mathbb{F}|-1}{|\mathbb{F}|})$. Yet, the converse does not necessarily hold, and the corollary is a strengthening of the sampling lemma of [7] for the case $\mathbb{F} = GF(p)$.

A randomness-efficient line sampler can be constructed by using an efficient linear code. For instance, we can use the Reed–Solomon code that corresponds to $S = \{(1, t, t^2, \ldots, t^{m-1}) \mid t \in \mathbb{F}\}$. This code has relative distance $1 - \delta$ for $\delta = \frac{m-1}{|\mathbb{F}|}$. It gives a line sampler that has randomness complexity $(m + 1) \log |\mathbb{F}|$ and query complexity $|\mathbb{F}|$.

1.5. Proof outline. We first prove the soundness of the randomness-efficient plane vs. point tester and then deduce the soundness of the randomness-efficient subspace vs. point tester from it. For the purpose of this outline we consider only the first. Assume that the randomness-efficient plane vs. point tester, given access to an input function $f : \mathbb{F}^m \to \mathbb{F}$ and oracle $\mathcal{A}$, accepts with probability γ. Let us prove the existence of a polynomial over $\mathbb{F}^m$ of degree at most md that agrees with f on at least $\gamma - \varepsilon$ fraction of the points, for $\varepsilon \leq \text{const} \cdot m(\sqrt[8]{\frac{1}{|\mathbb{H}|}} + \sqrt[4]{\frac{md}{|\mathbb{F}|}})$.

1.5.1. Reformulating our goal. First, let us reformulate the problem in a more convenient manner. For dimensions k, m, where $k \leq m$, let $\mathcal{S}_k^m$ be the family of all affine subspaces of dimension k in $\mathbb{F}^m$ that are of the type in which we are interested. Namely, a k-dimensional affine subspace $s \subseteq \mathbb{F}^m$ is in $\mathcal{S}_k^m$ if it can be written as $s = \{\vec{z} + \sum_{i=1}^k \alpha_i \vec{y}_i \mid (\alpha_1, \ldots, \alpha_k) \in \mathbb{F}^k\}$ for some point $\vec{z} \in \mathbb{F}^m$ and some linearly independent directions $\vec{y}_1, \ldots, \vec{y}_k \in \mathbb{H}^m$ (where the linear independence is over $\mathbb{F}$).

We can express (up to very small additive errors) the acceptance probability of the tester given access to $f : \mathbb{F}^m \to \mathbb{F}$ and $\mathcal{A}$ as follows:

$$\begin{aligned}\Pr\left[\text{tester accepts}\right] &\approx \Pr_{s \in \mathcal{S}_2^m, \vec{x} \in s}\left[\mathcal{A}(s)(\vec{x}) = f(\vec{x})\right] \\ &= \mathop{\mathbf{E}}_{s \in \mathcal{S}_2^m}\left[\Pr_{\vec{x} \in s}\left[\mathcal{A}(s)(\vec{x}) = f(\vec{x})\right]\right].\end{aligned}$$

For an affine subspace s and a degree d, let $\mathcal{Q}_{s,d}$ be the set of polynomials of degree at most d over s. It is evident from the last expression that an oracle $\mathcal{A}$ that optimizes the acceptance probability of the tester on input f assigns each subspace $s \in \mathcal{S}_2^m$ a polynomial $Q \in \mathcal{Q}_{s,d}$ that maximizes the agreement $Q(\vec{x}) = f(\vec{x})$ on points $\vec{x} \in s$. Hence, for every dimension m, function $f : \mathbb{F}^m \to \mathbb{F}$, dimension k, and degree d, consider the *average agreement* of f with polynomial of degree at most d over subspaces $s \in \mathcal{S}_k^m$:

$$\mathsf{agr}_d^{k,m}(f) \stackrel{def}{=} \mathop{\mathbf{E}}_{s \in \mathcal{S}_k^m}\left[\max_{Q \in \mathcal{Q}_{s,d}}\left\{\Pr_{\vec{x} \in s}\left[Q(\vec{x}) = f(\vec{x})\right]\right\}\right].$$

Then

$$\gamma = \Pr\left[\text{tester accepts}\right] \lesssim \mathsf{agr}_d^{2,m}(f).$$

For every m, the space $\mathbb{F}^m$ is the only affine subspace of dimension m in $\mathbb{F}^m$, and $\mathbb{H}^m$ contains a basis for $\mathbb{F}^m$, so $\mathcal{S}_m^m = \{\mathbb{F}^m\}$. Thus, for every dimension m, function $f : \mathbb{F}^m \to \mathbb{F}$, degree d, and fraction γ, $\mathsf{agr}_d^{m,m}(f) \geq \gamma$ means that there exists $Q : \mathbb{F}^m \to \mathbb{F}$ of degree at most d such that $\Pr_{\vec{x} \in \mathbb{F}^m}\left[Q(\vec{x}) = f(\vec{x})\right] \geq \gamma$.

We conclude that our goal can be reformulated as showing that a large average agreement over planes implies a large average agreement over $\mathbb{F}^m$. More accurately, for every function $f : \mathbb{F}^m \to \mathbb{F}$ and fraction $0 \leq \gamma \leq 1$,

$$\mathsf{agr}_d^{2,m}(f) \geq \gamma \quad \Rightarrow \quad \mathsf{agr}_{md}^{m,m}(f) \geq \gamma - \varepsilon.$$

1.5.2. Main idea. We fix a dimension m, and our proof is by induction on the dimension k of the affine subspaces within $\mathbb{F}^m$. We assume that $\mathsf{agr}_d^{2,m}(f) \geq \gamma$ and show that, for every dimension $2 \leq k \leq m$,

$$\mathsf{agr}_{kd}^{k,m}(f) \geq \gamma - \frac{k}{m} \cdot \varepsilon.$$

Fix a dimension k such that $\mathsf{agr}^{k-1,m}_{(k-1)d}(f) \geq \gamma - \frac{k-1}{m} \cdot \varepsilon$, and let us outline how the induction step is done.

Consider *any* affine subspace $s \in \mathcal{S}^m_k$. Assume that s contains the point $\vec{z} \in \mathbb{F}^m$ and is in directions $\vec{y}_1, \ldots, \vec{y}_k \in \mathbb{H}^m$, where $\vec{y}_1, \ldots, \vec{y}_k$ are linearly independent over $\mathbb{F}$. The directions within s, $\{\vec{x}_1 - \vec{x}_2 \mid \vec{x}_1, \vec{x}_2 \in s\}$, are precisely $\sum_{i=1}^k \alpha_i \vec{y}_i$ for $\vec{\alpha} = (\alpha_1, \ldots, \alpha_k) \in \mathbb{F}^k$. Moreover, *since* $\mathbb{H}$ *is a subfield of* $\mathbb{F}$,

$$\vec{\alpha} \in \mathbb{H}^k \quad \Leftrightarrow \quad \sum_{i=1}^k \alpha_i \vec{y}_i \in \mathbb{H}^m.$$

Therefore (unlike the construction of [7] via ϵ-biased sets), the families of affine subspaces we consider preserve the following two properties enabling induction:

1. *Self-similarity.* Every affine subspace $s \in \mathcal{S}^m_k$ is mapped onto $\mathbb{F}^k$ (via the natural bijection $\vec{z} + \sum_{i=1}^k \alpha_i \vec{y}_i \in s \;\leftrightarrow\; \vec{\alpha} \in \mathbb{F}^k$) such that the directions the tester considers (namely, the vectors in $\mathbb{H}^m$) that are also in s are mapped onto $\mathbb{H}^k$.
2. *Uniformity.* For every dimension $k' \leq k$, each subspace $s \in \mathcal{S}^m_k$ contains exactly the same number of subspaces $s' \in \mathcal{S}^m_{k'}$, and each subspace $s' \in \mathcal{S}^m_{k'}$ is contained in exactly the same number of subspaces $s \in \mathcal{S}^m_k$.

Let $f_{|s} : \mathbb{F}^k \to \mathbb{F}$ denote the restriction of f to s; namely, for every $(\alpha_1, \ldots, \alpha_k) \in \mathbb{F}^k$, let $f_{|s}(\alpha_1, \ldots, \alpha_k) = f(\vec{z} + \sum_{i=1}^k \alpha_i \vec{y}_i)$.

Consider some degree d' and dimension $k' \leq k$. By *self-similarity* and *uniformity*,

$$\mathsf{agr}^{k',m}_{d'}(f) = \mathop{\mathbf{E}}_{s \in \mathcal{S}^m_k} \left[\mathsf{agr}^{k',k}_{d'}(f_{|s}) \right]. \tag{1.1}$$

Thus, it is sufficient (as we will see shortly) to show that, for every function $f : \mathbb{F}^k \to \mathbb{F}$ and every fraction $0 \leq \gamma \leq 1$,

$$\mathsf{agr}^{k-1,k}_{(k-1)d}(f) \geq \gamma \quad \Rightarrow \quad \mathsf{agr}^{k,k}_{kd}(f) \geq \gamma - \frac{\varepsilon}{m}. \tag{1.2}$$

The inductive step is then completed by applying the induction hypothesis as well as (1.1) and (1.2) above:

$$\begin{aligned}
\mathsf{agr}^{k,m}_{kd}(f) &= \mathop{\mathbf{E}}_{s \in \mathcal{S}^m_k} \left[\mathsf{agr}^{k,k}_{kd}(f_{|s}) \right] \\
&\geq \mathop{\mathbf{E}}_{s \in \mathcal{S}^m_k} \left[\mathsf{agr}^{k-1,k}_{(k-1)d}(f_{|s}) - \frac{\varepsilon}{m} \right] \\
&= \mathsf{agr}^{k-1,m}_{(k-1)d}(f) - \frac{\varepsilon}{m} \\
&\geq \gamma - \frac{k}{m} \cdot \varepsilon.
\end{aligned}$$

1.5.3. Proving (1.2). By an adaptation of an idea by Raz and Safra [17], we can prove that there exists a small error $\delta \ll \varepsilon/m$ such that, for every function $f : \mathbb{F}^k \to \mathbb{F}$ and every fraction $0 \leq \gamma \leq 1$,

$$\mathsf{agr}^{k-1,k}_{(k-1)d}(f) \geq \gamma \quad \Rightarrow \quad \mathsf{agr}^{k,k}_{2(k-1)d}(f) \geq \gamma^2 - \delta.$$

The idea of Raz and Safra [17] centers around a construction of a *consistency graph*. The vertices of the graph are the affine subspaces of dimension $(k-1)$ within $\mathbb{F}^k$

(namely, *hyperplanes*). The edges of the graph indicate whether there is an agreement between assignments of degree $(k-1)d$ polynomials to the hyperplanes. Due to its algebraic structure, the graph has a combinatorial property called *almost-transitivity*. It allows us to use a graph-theoretic lemma originally proven in [17] and go up from dimension $(k-1)$ to dimension k.

The reduction to the graph-theoretic setting introduces a certain deterioration of the degree and agreement parameters. The degree doubles (from $(k-1)d$ to $2(k-1)d$ rather than to kd), and the agreement is raised to the power of two (from γ to $\gamma^2-\delta$ rather than to $\gamma-\varepsilon/m$). We cannot tolerate either deterioration, since they ultimately cause an exponential decay in k. Hence, we apply steps of what we call *consolidation* to retain the desired parameters. Similar techniques were already used in previous work, and they rely on the sampling properties we discussed above.

1.6. Organization. We state the main theorems regarding the soundness of our testers in section 2. The rest of the paper is devoted to proving these theorems. We start with some preliminary definitions and propositions in section 3. We discuss basic properties of affine subspaces with directions over a subfield in section 4. We prove sampling properties in section 5. This allows us to prove consolidation claims in section 6. We present and analyze the consistency graph in section 7 and use it for going up one dimension in section 8. The soundness of the randomness-efficient plane vs. point tester is proven via induction in section 9. We show that the soundness of the randomness-efficient subspace vs. point tester follows in section 10. We give the proof of the combinatorial lemma of [17] in the appendix.

2. Our results.

2.1. Notation. In all that follows, we consider a finite field $\mathbb{F}$, a subfield $\mathbb{H} \subseteq \mathbb{F}$, a dimension m, and a degree d.

Given vectors $\vec{y}_1, \ldots, \vec{y}_k \in \mathbb{F}^m$, we define the *linear subspace* they span by

$$span\{\vec{y}_1, \ldots, \vec{y}_k\} \stackrel{def}{=} \{a_1\vec{y}_1 + \cdots + a_k\vec{y}_k \mid a_1, \ldots, a_k \in \mathbb{F}\}.$$

We say that $\vec{y}_1, \ldots, \vec{y}_k$ are *linearly independent* and denote $\mathsf{ind}(\vec{y}_1, \ldots, \vec{y}_k)$ if for every $a_1, \ldots, a_k \in \mathbb{F}$, if $\sum_{i=1}^k a_i\vec{y}_i = 0$, then $a_1 = \cdots = a_k = 0$. Throughout the paper we will refer to a span over $\mathbb{F}$ (and not over a subfield, even if the vectors are over a subfield). Note that vectors $\vec{y}_1, \ldots, \vec{y}_k \in \mathbb{H}^m$ are linearly independent over $\mathbb{H}$ if and only if $\vec{y}_1, \ldots, \vec{y}_k \in \mathbb{H}^m$ are linearly independent over $\mathbb{F}$.

Given two sets $A, B \subseteq \mathbb{F}^m$, we define $A + B \stackrel{def}{=} \{\vec{x} + \vec{y} \mid \vec{x} \in A, \vec{y} \in B\}$. Given a point $\vec{x} \in \mathbb{F}^m$ and a set $A \subseteq \mathbb{F}^m$, define $\vec{x} + A \stackrel{def}{=} \{\vec{x}\} + A$. A k-dimensional *affine subspace* in the vector space $\mathbb{F}^m$ is defined by a base point $\vec{x} \in \mathbb{F}^m$ and k linearly independent directions $\vec{y}_1, \ldots, \vec{y}_k \in \mathbb{F}^m$ as

$$\text{affine}(\vec{x}; \vec{y}_1, \ldots, \vec{y}_k) \stackrel{def}{=} \vec{x} + span\{\vec{y}_1, \ldots, \vec{y}_k\}.$$

Points are 0-dimensional affine subspaces. *Lines* are 1-dimensional affine subspaces. *Planes* are 2-dimensional affine subspaces. Every affine subspace can be equivalently represented by many choices of vectors $\vec{x}; \vec{y}_1, \ldots, \vec{y}_k$, but, clearly, there is an affine transformation between every two representations of the same affine subspace.

An *m-variate polynomial* over a field $\mathbb{F}$ is a function $Q : \mathbb{F}^m \to \mathbb{F}$ of the form

$$Q(x_1, \ldots, x_m) = \sum_{i_1, \ldots, i_m} a_{i_1, \ldots, i_m} x_1^{i_1} \ldots x_m^{i_m},$$

where all of the *coefficients* $a_{i_1,\ldots,i_m}$ are in $\mathbb{F}$. The *degree* of Q is

$$\deg Q \stackrel{def}{=} \max\left\{\sum_{j=1}^{m} i_j \mid a_{i_1,\ldots,i_m} \neq 0\right\},$$

where the degree of the *identically zero* polynomial is defined to be 0.

The restriction of a polynomial $Q : \mathbb{F}^m \to \mathbb{F}$ to an affine subspace s represented as $s = \text{affine}(\vec{x}; \vec{y}_1, \ldots, \vec{y}_k)$ is a polynomial in k variables: $Q_{|s}(\alpha_1, \ldots, \alpha_k) \stackrel{def}{=} Q(\vec{x} + \alpha_1\vec{y}_1 + \ldots + \alpha_k\vec{y}_k)$. We will sometimes wish to refer to a polynomial Q defined over an affine subspace s without specifying the subspace's representation, in which case we will use the notation $Q(\vec{x})$ for a point $\vec{x} \in s$. Note that the degree of the polynomial does not depend on the representation of s.

2.2. Oracles. We assume an oracle $\mathcal{A}$ that, given any affine subspace s in $\mathbb{F}^m$, provides a polynomial $\mathcal{A}(s)$ of degree at most d defined over s. For the sake of simplicity, we do not refer to both an oracle $\mathcal{A}$ and a function $f : \mathbb{F}^m \to \mathbb{F}$ as in the introduction. Instead, we assume that f's values on points $\vec{x}$ are given by $\mathcal{A}(\vec{x})$. Our testers query $\mathcal{A}$ only on affine subspaces of constant dimension. However, for the analysis, it will be convenient to consider oracles queried regarding higher-dimensional affine subspaces as well. Hence, an oracle $\mathcal{A}$ is defined to provide a value for any affine subspace.

For a polynomial $Q : \mathbb{F}^m \to \mathbb{F}$, we will use the notation $(Q \equiv \mathcal{A})(s)$ to indicate that Q and $\mathcal{A}$ agree on a subspace s, i.e., for every $\vec{x} \in s$, $Q(\vec{x}) = \mathcal{A}(s)(\vec{x})$.

2.3. Low degree testers. Define two predicates for our two testers: for $\vec{z} \in \mathbb{F}^m$ and $\vec{y}_1, \vec{y}_2 \in \mathbb{H}^m$, let the following apply:

1. $PlanePoint^{\mathcal{A}}(\vec{z}, \vec{y}_1, \vec{y}_2)$: $\vec{y}_1, \vec{y}_2$ are linearly dependent or
$$\mathcal{A}(\text{affine}(\vec{z}; \vec{y}_1, \vec{y}_2))(\vec{z}) = \mathcal{A}(\vec{z});$$
2. $SpacePoint^{\mathcal{A}}(\vec{z}, \vec{y}_1, \vec{y}_2)$: $\vec{z}, \vec{y}_1, \vec{y}_2$ are linearly dependent or
$$\mathcal{A}(\text{affine}(\vec{0}; \vec{z}, \vec{y}_1, \vec{y}_2))(\vec{z}) = \mathcal{A}(\vec{z}).$$

2.4. Soundness. To prove that a tester is sound we assume that it accepts with probability γ when given access to an oracle $\mathcal{A}$ and show the agreement of $\mathcal{A}$ with a low degree polynomial. Specifically, for a subconstant ε, we prove two claims, which we argue to be essentially equivalent:

1. *(Decoding)* There exists a low degree polynomial that is consistent with the oracle $\mathcal{A}$ on at least a $\gamma - \varepsilon$ fraction of the points.
2. *(List decoding)* For every $0 < \delta < 1$, there exists a short list of $t = t(\delta)$ low degree polynomials that *explains* all of the tester's acceptance but a $\delta + \varepsilon$ fraction of the probability (explanation follows).

When saying that a list of polynomials explains almost all of the success, we mean that, with high probability over the random bits of the tester (i.e., over the choice of a subspace and a point within it), either the tester rejects or one of the polynomials agrees with the oracle on the subspace and on the point. There is a trade-off between the amount of success explained and the length of the list: the more one wishes to explain, the longer the list is.

We wish ε to be as small as possible. The parameter ε we achieve depends on $\frac{md}{|\mathbb{F}|}$. This comes from the use of the Schwartz–Zippel lemma. It also depends on $\frac{1}{|\mathbb{H}|}$, which is the price we pay for considering the subfield $\mathbb{H}$ instead of the entire field $\mathbb{F}$.

The statement for the randomness-efficient plane vs. point tester is as follows. Note that we make no effort to optimize the constants.

THEOREM 1 (plane vs. point soundness). *Fix a dimension $m \geq 2$, a field $\mathbb{F}$, a subfield $\mathbb{H} \subseteq \mathbb{F}$, and a degree d. Denote $\varepsilon \stackrel{def}{=} 2^7 m \left(\sqrt[8]{\frac{1}{|\mathbb{H}|}} + \sqrt[4]{\frac{md}{|\mathbb{F}|}}\right)$. For every oracle $\mathcal{A}$:*

1. (Decoding) *There exists a polynomial $Q : \mathbb{F}^m \to \mathbb{F}$, with $\deg Q \leq md$, such that*

$$\Pr_{\vec{x} \in \mathbb{F}^m} [Q(\vec{x}) = \mathcal{A}(\vec{x})] \geq \Pr_{\vec{z} \in \mathbb{F}^m, \vec{y}_1, \vec{y}_2 \in \mathbb{H}^m} \left[PlanePoint^{\mathcal{A}}(\vec{z}, \vec{y}_1, \vec{y}_2)\right] - \varepsilon;$$

2. (List decoding) *For every $\delta > 2\varepsilon$, there exist $t \leq 2/\delta$ polynomials $Q_1, \ldots, Q_t : \mathbb{F}^m \to \mathbb{F}$, with $\deg Q_i \leq md$, such that*

$$\Pr_{\vec{z} \in \mathbb{F}^m, \vec{y}_1, \vec{y}_2 \in \mathbb{H}^m} \left[\neg PlanePoint^{\mathcal{A}}(\vec{z}, \vec{y}_1, \vec{y}_2) \ \vee \ \exists i \ (Q_i \equiv \mathcal{A})(\text{affine}(\vec{z}; \vec{y}_1, \vec{y}_2))\right]$$
$$\geq \quad 1 - \delta - 2\varepsilon.$$

We prove a similar theorem for the randomness-efficient subspace vs. point tester. Note that for this tester we manage to show agreement with polynomials of degree at most d rather than md.

THEOREM 2 (subspace vs. point soundness). *Fix a dimension $m \geq 3$, a field $\mathbb{F}$, a subfield $\mathbb{H} \subseteq \mathbb{F}$, and a degree d. Denote $\varepsilon \stackrel{def}{=} 2^7 m \left(\sqrt[8]{\frac{1}{|\mathbb{H}|}} + \sqrt[4]{\frac{md}{|\mathbb{F}|}}\right)$. For every oracle $\mathcal{A}$:*

1. (Decoding) *There exists a polynomial $Q : \mathbb{F}^m \to \mathbb{F}$, with $\deg Q \leq d$, such that*

$$\Pr_{\vec{x} \in \mathbb{F}^m} [Q(\vec{x}) = \mathcal{A}(\vec{x})] \geq \Pr_{\vec{z} \in \mathbb{F}^m, \vec{y}_1, \vec{y}_2 \in \mathbb{H}^m} \left[SpacePoint^{\mathcal{A}}(\vec{z}, \vec{y}_1, \vec{y}_2)\right] - 3\varepsilon;$$

2. (List decoding) *For every $\delta > 3\varepsilon$, there exist $t \leq 2/\delta$ polynomials $Q_1, \ldots, Q_t : \mathbb{F}^m \to \mathbb{F}$, with $\deg Q_i \leq d$, such that*

$$\Pr_{\vec{z} \in \mathbb{F}^m, \vec{y}_1, \vec{y}_2 \in \mathbb{H}^m} \left[\neg SpacePoint^{\mathcal{A}}(\vec{z}, \vec{y}_1, \vec{y}_2) \ \vee \ \exists i \ (Q_i \equiv \mathcal{A})(\text{affine}(\vec{0}; \vec{z}, \vec{y}_1, \vec{y}_2))\right]$$
$$\geq 1 - \delta - 3\varepsilon.$$

It is interesting to note that our sampling arguments also imply a converse to the above theorems: for any polynomial $Q : \mathbb{F}^m \to \mathbb{F}$, with $\deg Q \leq d$, there exists an oracle $\mathcal{A}'$ agreeing with $\mathcal{A}$ on the points and assigning affine subspaces polynomials of degree at most d such that both of our testers accept with probability at least $\Pr_{\vec{x} \in \mathbb{F}^m} [Q(\vec{x}) = \mathcal{A}(\vec{x})] - \varepsilon$ when given access to $\mathcal{A}'$.

3. Preliminaries.

3.1. Orthogonality and vector spaces. Given a vector $\vec{y} \in \mathbb{F}^m$, we write $\vec{y} = (y_1, \ldots, y_m)$. For a sequence of vectors $\vec{y}_1, \ldots, \vec{y}_k$, we write, for every $1 \leq i \leq k$, $\vec{y}_i = (y_{i,1}, \ldots, y_{i,m})$.

We define an *inner product* between two vectors $\vec{x}, \vec{y} \in \mathbb{F}^m$ as $(\vec{x}, \vec{y}) \stackrel{def}{=} \sum_{i=1}^m x_i \cdot y_i$. We say that $\vec{x}, \vec{y}$ are *orthogonal* if $(\vec{x}, \vec{y}) = 0$.

PROPOSITION 3.1. *For every $\vec{y} \neq \vec{0} \in \mathbb{F}^m$, for every $c \in \mathbb{F}$,*

$$\Pr_{\vec{z} \in \mathbb{H}^m} [(\vec{z}, \vec{y}) = c] \leq \frac{1}{|\mathbb{H}|}.$$

Proof. As $\vec{y} \neq \vec{0} \in \mathbb{F}^m$, there exists $1 \leq i \leq m$ such that $y_i \neq 0$. For every fixing of all $\vec{z}$'s coordinates but the ith, the condition $(\vec{z}, \vec{y}) = c$ uniquely determines z_i to

some scalar in $\mathbb{F}$. This scalar may or may not be in the subfield $\mathbb{H}$, but, in any case, there exists at most one possibility for $z_i \in \mathbb{H}$. ∎

PROPOSITION 3.2. *For every $\vec{y} \neq \vec{0} \in \mathbb{F}^m$, for every $k < m$,*

$$\Pr_{\vec{y}_1,\ldots,\vec{y}_k \in \mathbb{H}^m} [\vec{y} \in span\{\vec{y}_1,\ldots,\vec{y}_k\} \mid \mathit{ind}(\vec{y}_1,\ldots,\vec{y}_k)] \leq \frac{1}{|\mathbb{H}|}.$$

Proof. Consider uniformly distributed linearly independent $\vec{y}_1,\ldots,\vec{y}_k \in \mathbb{H}^m$. Pick uniformly and independently at random a vector $\vec{z} \neq \vec{0} \in \mathbb{H}^m$ that is orthogonal to $\vec{y}_1,\ldots,\vec{y}_k$ (there exist such vectors since $k < m$). Note that for every $\vec{y} \in span\{\vec{y}_1,\ldots,\vec{y}_k\}$ it holds that $(\vec{z},\vec{y}) = 0$. By Proposition 3.1, since $\vec{z}$ is uniformly distributed over $\mathbb{H}^m \setminus \{\vec{0}\}$, this happens with probability at most $\frac{1}{|\mathbb{H}|}$. ∎

PROPOSITION 3.3. *For every subset $A \subseteq \mathbb{F}^m$ with $|A| > |\mathbb{F}|^{m-1}$, there exist linearly independent $\vec{y}_1,\ldots,\vec{y}_m \in \mathbb{F}^m$ such that, for every $1 \leq i \leq m$, $\vec{y}_i \in A$.*

Proof. We have

$$|span(A)| \geq |A| > |\mathbb{F}|^{m-1}.$$

Since $span(A)$ is a linear subspace in $\mathbb{F}^m$, we must have $|span(A)| = |\mathbb{F}|^m$. Thus, $span(A) = \mathbb{F}^m$, and so A contains a basis for $\mathbb{F}^m$. ∎

3.2. Polynomials. The Schwartz–Zippel lemma shows that different low degree polynomials differ on most points,

PROPOSITION 3.4 (Schwartz–Zippel). *For two different polynomials $Q, P : \mathbb{F}^m \to \mathbb{F}$ with $\deg Q, \deg P \leq d$,*

$$\Pr_{\vec{x} \in \mathbb{F}^m} [Q(\vec{x}) = P(\vec{x})] \leq \frac{d}{|\mathbb{F}|}.$$

The Schwartz–Zippel lemma can be viewed as showing the unique-decoding property of the Reed–Muller code. This immediately implies a list-decoding property, namely, that only a few polynomials can agree with a function on many of the points.

We include a simple proof of this property.

PROPOSITION 3.5 (list decoding). *Fix a finite field $\mathbb{F}$ and a dimension m. Let $f : \mathbb{F}^m \to \mathbb{F}$ be some function, and consider some degree $d \leq |\mathbb{F}|$. Then, for any $\delta \geq 2\sqrt{\frac{d}{|\mathbb{F}|}}$, if $Q_1,\ldots,Q_l : \mathbb{F}^m \to \mathbb{F}$ are* different *polynomials of degree at most d, and for every $1 \leq i \leq l$, the polynomial Q_i agrees with f on at least a δ fraction of the points, i.e., $\Pr_{\vec{x} \in \mathbb{F}^m} [Q_i(\vec{x}) = f(\vec{x})] \geq \delta$, then $l \leq \frac{2}{\delta}$.*

Proof. Let $\delta \geq 2\sqrt{\frac{d}{|\mathbb{F}|}}$, and assume by way of contradiction that there exist $l = \lfloor \frac{2}{\delta} \rfloor + 1$ different polynomials $Q_1,\ldots,Q_l : \mathbb{F}^m \to \mathbb{F}$ as stated.

For every $1 \leq i \leq l$, let $A_i \stackrel{def}{=} \{\vec{x} \in \mathbb{F}^m \mid Q_i(\vec{x}) = f(\vec{x})\}$. By inclusion-exclusion,

$$|\mathbb{F}^m| \geq \left|\bigcup_{i=1}^{l} A_i\right| \geq \sum_{i=1}^{l} |A_i| - \sum_{i \neq j} |A_i \cap A_j|.$$

By Schwartz–Zippel, for every $1 \leq i \neq j \leq l$, $|A_i \cap A_j| \leq \frac{d}{|\mathbb{F}|} \cdot |\mathbb{F}^m|$. Therefore, by the premise,

$$|\mathbb{F}^m| \geq l\delta\,|\mathbb{F}^m| - \binom{l}{2} \frac{d}{|\mathbb{F}|}\,|\mathbb{F}^m|.$$

On one hand, since $l > \frac{2}{\delta}$, we get $l\delta > 2$. On the other hand, since $\frac{2}{\delta} \leq \sqrt{\frac{|\mathbb{F}|}{d}}$ and $d \leq |\mathbb{F}|$, we get $\binom{l}{2} \leq \frac{|\mathbb{F}|}{d}$. This results in a contradiction. ∎

4. Affine subspaces with directions over a subfield. In this section we prove basic facts regarding affine subspaces in $\mathbb{F}^m$ that are spanned by directions over a subfield $\mathbb{H} \subseteq \mathbb{F}$. All of the properties we prove for such subspaces are well known when $\mathbb{H} = \mathbb{F}$.

For $0 \leq k \leq m$, consider the set of representations of affine subspaces with directions over a subfield

$$\mathcal{R}_k^m \stackrel{def}{=} \{(\vec{z}; \vec{y}_1, \ldots, \vec{y}_k) \mid \vec{z} \in \mathbb{F}^m, \vec{y}_1, \ldots, \vec{y}_k \in \mathbb{H}^m, \mathsf{ind}(\vec{y}_1, \ldots, \vec{y}_k)\}.$$

The corresponding set of affine subspaces is

$$\mathcal{S}_k^m \stackrel{def}{=} \{\text{affine}(r) \mid r \in \mathcal{R}_k^m\}.$$

First we would like to assert that every subspace in $\mathcal{S}_k^m$ is associated with the same number of tuples in $\mathcal{R}_k^m$ and that every subspace in $\mathcal{S}_k^m$ contains the same number of subspaces in $\mathcal{S}_{k'}^m$ for $k' \leq k$.

PROPOSITION 4.1 (uniformity). *For every dimension k, there is a number $T = T(k)$ such that, for every $s \in \mathcal{S}_k^m$, $|\{r \in \mathcal{R}_k^m \mid s = \text{affine}(r)\}| = T$.*

PROPOSITION 4.2 (uniformity downwards). *For every dimension $k' \leq k$, there is a number $T = T(k, k')$ such that, for every $s \in \mathcal{S}_k^m$, $|\{s' \in \mathcal{S}_{k'}^m \mid s' \subseteq s\}| = T$.*

To prove both assertions we introduce an additional notation allowing us to refer to affine subspaces in $\mathcal{S}_k^m$ as isomorphic copies of $\mathbb{F}^k$. Fix an affine subspace together with a representation for it: $s = \text{affine}(\vec{z}; \vec{y}_1, \ldots, \vec{y}_k)$. For a representation $r = (\vec{\alpha}_0; \vec{\alpha}_1, \ldots, \vec{\alpha}_{k'})$ of a k'-dimensional affine subspace within $\mathbb{F}^k$, we define the representation r *relative to* (the representation of) the space s by

$$r_s \stackrel{def}{=} \left(\vec{z} + \sum_{i=1}^{k} \vec{\alpha}_{0,i} \vec{y}_i \;;\; \sum_{i=1}^{k} \vec{\alpha}_{1,i} \vec{y}_i, \ldots, \sum_{i=1}^{k} \vec{\alpha}_{k',i} \vec{y}_i \right).$$

Note that, since $\vec{y}_1, \ldots, \vec{y}_k$ are linearly independent, if two representations r, r' are the same relative to a subspace s, $r_s = r'_s$, then they are the same representation $r = r'$.

Denote the corresponding relative affine subspace:

$$\text{affine}_s(r) \stackrel{def}{=} \text{affine}(r_s).$$

Note that, for every r, $\text{affine}_s(r) \subseteq s$. Moreover, if $\text{affine}(r) = \text{affine}(r')$, then $\text{affine}_s(r) = \text{affine}_s(r')$. Now the above two propositions follow from the following proposition.

PROPOSITION 4.3. *For every subspace $s \in \mathcal{S}_k^m$, for every dimension $k' \leq k$,*

$$S_1 \stackrel{def}{=} |\{r \in \mathcal{R}_{k'}^m \mid \text{affine}(r) \subseteq s\}| = \left|\mathcal{R}_{k'}^k\right| \stackrel{def}{=} S_2.$$

Proof. Fix a subspace $s \in \mathcal{S}_k^m$, and fix a tuple $(\vec{z}; \vec{y}_1, \ldots, \vec{y}_k) \in \mathcal{R}_k^m$, with $s = \text{affine}(\vec{z}; \vec{y}_1, \ldots, \vec{y}_k)$.

1. $S_1 \geq S_2$: For every tuple $r = (\vec{\alpha}_0; \vec{\alpha}_1, \ldots, \vec{\alpha}_{k'}) \in \mathcal{R}_{k'}^k$, the tuple r_s satisfies $r_s \in \mathcal{R}_{k'}^m$ and $\text{affine}(r_s) \subseteq s$.
2. $S_1 \leq S_2$: For every tuple $r \in \mathcal{R}_{k'}^m$ satisfying $\text{affine}(r) \subseteq s$, there exists exactly one $\alpha = (\vec{\alpha}_0; \vec{\alpha}_1, \ldots, \vec{\alpha}_{k'})$, $\vec{\alpha}_0, \vec{\alpha}_1, \ldots, \vec{\alpha}_{k'} \in \mathbb{F}^k$, $\mathsf{ind}(\vec{\alpha}_1, \ldots, \vec{\alpha}_{k'})$, such that $r = \alpha_s$. Since $r \in \mathcal{R}_{k'}^m$ and $\vec{y}_1, \ldots, \vec{y}_k \in \mathbb{H}^m$, also $\vec{\alpha}_1, \ldots, \vec{\alpha}_{k'} \in \mathbb{H}^k$. ∎

Every subspace in $\mathcal{S}_k^m$ is contained in the same number of subspaces in $\mathcal{S}_{k'}^m$ for $k' \geq k$.

PROPOSITION 4.4 (uniformity upwards). *For every dimension $k \leq k' \leq m$, there is a number $T = T(m,k,k')$ such that, for every subspace $s \in \mathcal{S}_k^m$,*

$$|\{s' \in \mathcal{S}_{k'}^m \mid s' \supseteq s\}| = T.$$

Proof. Let us introduce an additional piece of notation: $\mathcal{L}_{k'}^m$ is the set of all linear subspaces of dimension k' in $\mathbb{F}^m$ spanned by vectors from $\mathbb{H}^m$.

Fix $s = \text{affine}(\vec{z}; \vec{y}_1, \ldots, \vec{y}_k) \in \mathcal{S}_k^m$. Since $\vec{y}_1, \ldots, \vec{y}_k \in \mathbb{H}^m$ are linearly independent, the proposition will clearly follow if we prove the following:

$$S_1 \stackrel{def}{=} |\{s' \in \mathcal{S}_{k'}^m \mid s' \supseteq s\}| = |\{Y' \in \mathcal{L}_{k'}^m \mid Y' \supseteq \{\vec{y}_1, \ldots, \vec{y}_k\}\}| \stackrel{def}{=} S_2.$$

1. $S_1 \leq S_2$: Let $s' = \text{affine}(\vec{z}'; \vec{y}'_1, \ldots, \vec{y}'_{k'}) \in \mathcal{S}_{k'}^m$, $(\vec{z}'; \vec{y}'_1, \ldots, \vec{y}'_{k'}) \in \mathcal{R}_{k'}^m$, $s' \supseteq s$. Let $Y' = span\{\vec{y}'_1, \ldots, \vec{y}'_{k'}\}$. Clearly, Y' is in $\mathcal{L}_{k'}^m$, and Y' is uniquely defined by s', $s' = \vec{z}' + Y'$. It holds that $\vec{z} \in s \subseteq s' = \vec{z}' + Y'$; thus $\vec{z}' \in \vec{z} + Y'$, and, hence, $s' = \vec{z} + Y'$. Let $1 \leq i \leq k$. It holds that $\vec{z} + \vec{y}_i \in s \subseteq s'$. This implies that $\vec{z} + \vec{y}_i \in \vec{z} + Y'$. Hence, $\vec{y}_i \in Y'$. Therefore, $\{\vec{y}_1, \ldots, \vec{y}_k\} \subseteq Y'$.
2. $S_1 \geq S_2$: Let $Y' \in \mathcal{L}_{k'}^m$, $Y' \supseteq \{\vec{y}_1, \ldots, \vec{y}_k\}$. Clearly, $\vec{z} + Y' \in \mathcal{S}_{k'}^m$ and $s \subseteq \vec{z} + Y'$. ∎

Uniformity is so important because it allows us to count in several ways. A simple argument of this nature is that the fraction of affine subspaces $s \in \mathcal{S}_k^m$ satisfying some condition is exactly the same as the fraction of $r \in \mathcal{R}_k^m$ such that affine(r) satisfies the condition. Let us demonstrate a more sophisticated argument of this nature. Fix $k' \leq k$. Suppose that we have a predicate R indicating whether an affine subspace $s \in \mathcal{S}_k^m$ and an affine subspace $s' \in \mathcal{S}_{k'}^m$ *contained in it*, $s' \subseteq s$, satisfy some relation. Then

$$\mathop{\mathbf{E}}_{s}\left[\Pr_{s' \subseteq s}[R(s,s')]\right] = \mathop{\mathbf{E}}_{s'}\left[\Pr_{s \supseteq s'}[R(s,s')]\right].$$

The intersection between two subspaces $s_1 \in \mathcal{S}_{k^{(1)}}^m$ and $s_2 \in \mathcal{S}_{k^{(2)}}^m$ is again (provided it is not empty) a subspace in $\mathcal{S}_{k^{(3)}}^m$ for some $k^{(3)}$.

PROPOSITION 4.5 (closure under intersection). *If $s_1 \in \mathcal{S}_{k^{(1)}}^m$ and $s_2 \in \mathcal{S}_{k^{(2)}}^m$, where $s_1 \cap s_2 \neq \phi$, then there exists $k^{(3)}$ such that $s_1 \cap s_2 \in \mathcal{S}_{k^{(3)}}^m$.*

Proof. Write $s_1 = \vec{z}_1 + V_1$ and $s_2 = \vec{z}_2 + V_2$, where $\vec{z}_1, \vec{z}_2 \in \mathbb{F}^m$ and $V_1, V_2 \subseteq \mathbb{F}^m$ are linear subspaces spanned by vectors in $\mathbb{H}^m$. Assume that $\vec{x} \in s_1 \cap s_2$. Then we can alternatively write $s_1 = \vec{x} + V_1$ and $s_2 = \vec{x} + V_2$. Thus, $s_1 \cap s_2 = \vec{x} + (V_1 \cap V_2)$. The proposition follows by noticing that $V_1 \cap V_2$ can be spanned by vectors in $\mathbb{H}^m$. ∎

A useful representation of affine subspaces is given in the following proposition.

PROPOSITION 4.6 (affine subspaces as solutions of linear equations). *Let $s = \text{affine}(\vec{z}; \vec{y}_1, \ldots, \vec{y}_k) \in \mathcal{S}_k^m$, and let $\vec{\alpha}_1, \ldots, \vec{\alpha}_{m-k} \in \mathbb{H}^m$ be $(m-k)$ linearly independent vectors orthogonal to $\vec{y}_1, \ldots, \vec{y}_k \in \mathbb{H}^m$. Then*

$$s = \{\vec{x} \in \mathbb{F}^m \mid \forall 1 \leq j \leq m-k,\ (\vec{x}, \vec{\alpha}_j) = (\vec{z}, \vec{\alpha}_j)\}.$$

Proof. Fix $\vec{x} \in s$. Hence, there exists $\vec{c} \in \mathbb{F}^k$ such that $\vec{x} = \vec{z} + \sum_{i=1}^k c_i \vec{y}_i$. For every $1 \leq j \leq m-k$,

$$(\vec{x}, \vec{\alpha}_j) = \left(\vec{z} + \sum_{i=1}^k c_i \vec{y}_i, \vec{\alpha}_j\right) = (\vec{z}, \vec{\alpha}_j) + \sum_{i=1}^k c_i \cdot (\vec{y}_i, \vec{\alpha}_j) = (\vec{z}, \vec{\alpha}_j).$$

Thus, $s \subseteq \{\vec{x} \in \mathbb{F}^m \mid \forall 1 \leq j \leq m-k,\ (\vec{x}, \vec{\alpha}_j) = (\vec{z}, \vec{\alpha}_j)\}$. The proposition follows by noticing that, in addition, the two sets are of size $\left|\mathbb{F}^k\right|$. □

5. Affine subspaces with directions over a subfield sample well. We say that an affine subspace s in $\mathbb{F}^m$ samples a set $A \subseteq \mathbb{F}^m$ well if the fraction of points from A contained in it, i.e., $\frac{|s \cap A|}{|s|}$, is approximately $\frac{|A|}{|\mathbb{F}^m|}$. We say that a distribution $\mathcal{D}$ on affine subspaces in $\mathbb{F}^m$ samples well if, no matter how one fixes a large enough subset $A \subseteq \mathbb{F}^m$, a random subspace $s \sim \mathcal{D}$ samples A well with high probability. In this section we use Fourier analysis to show that the distributions induced by our testers sample well.

5.1. Fourier transform. Let $(G, +)$ be a finite Abelian group. Consider functions from the group to the complex numbers $f : G \to \mathbb{C}$. One example for such a function is the indicator function of a multiset $A \subseteq G$, i.e., the function $\mathcal{I}_A$ that assigns every $\vec{x} \in G$ its multiplicity in A.

We define an inner product between functions $f, g : G \to \mathbb{C}$ as

$$\langle f, g \rangle \stackrel{def}{=} \frac{1}{|G|} \sum_{x \in G} f(x)\overline{g(x)}.$$

A *character* of G is a homomorphism $\chi : G \to \mathbb{C}^*$, where $\mathbb{C}^*$ is the multiplicative group of the complex numbers. Namely, for every $x, y \in G$,

$$\chi(x + y) = \chi(x) \cdot \chi(y).$$

Every group G trivially has identically 1 function as a character.

It can be shown that the set of all characters of G forms an orthonormal basis for the space of all functions $f : G \to \mathbb{C}$ under the inner product defined above. Hence, every function $f : G \to \mathbb{C}$ can be equivalently represented as $f(x) = \sum_\chi \hat{f}(\chi) \cdot \chi(x)$, where $\hat{f}(\chi) \stackrel{def}{=} \langle f, \chi \rangle$ is called the *Fourier coefficient* of f corresponding to the character χ. The linear transformation from f to $\hat{f}$ is called the *Fourier transform* of f.

We will need two basic facts regarding the Fourier transform.

PROPOSITION 5.1 (Parseval's identity). *For two functions $f, g : G \to \mathbb{C}$, $\langle f, g \rangle = |G| \cdot \langle \hat{f}, \hat{g} \rangle = \sum_\chi \hat{f}(\chi)\overline{\hat{g}(\chi)}$.*

Define the *convolution* of two functions $f, g : G \to \mathbb{C}$, denoted $(f * g) : G \to \mathbb{C}$, as $(f * g)(x) \stackrel{def}{=} \frac{1}{|G|} \sum_{y \in G} f(y)g(x - y)$.

PROPOSITION 5.2 (convolution formula). *Fix two functions $f, g : G \to \mathbb{C}$. For every character χ of G, $\widehat{(f * g)}(\chi) = \hat{f}(\chi) \cdot \hat{g}(\chi)$.*

We focus on the additive group $G = \mathbb{F}^m$ for some finite field $\mathbb{F} = GF(p^k)$. The field $\mathbb{F}$ is also viewed as a vector space of dimension k over the field $GF(p)$.

Denote $\omega_p = e^{2\pi i/p}$ the pth *primitive root of unity* in $\mathbb{C}$. For every $\alpha \in \mathbb{F}^m$, there is a character $\chi_\alpha : \mathbb{F}^m \to \mathbb{C}$,

$$\chi_\alpha(x) \stackrel{def}{=} \omega_p^{\sum_{i=1}^m (\alpha_i, x_i)}.$$

Note that we view α_i, x_i as vectors in $GF(p)^k$. Their inner product is in $GF(p)$ and so is the sum in the above expression.

For a function $f : \mathbb{F}^m \to \mathbb{C}$, we denote its Fourier coefficient corresponding to the character χ_α by $\hat{f}(\alpha)$.

5.2. Sampling lemma. In this subsection we prove our basic lemma via Fourier analysis. Given $z, y \in \mathbb{F}^m$ and a subset $A \subseteq \mathbb{F}^m$, define $X_{z,y}$ to be the number of $c \in \mathbb{F}$ satisfying $z + c \cdot y \in A$. Clearly, the expectation of $X_{z,y}$ when picking independently at random $z \in \mathbb{F}^m$ and $y \in \mathbb{H}^m$ is $|\mathbb{F}| \cdot \frac{|A|}{|\mathbb{F}^m|}$. We bound the variance of $X_{z,y}$, implying that it is concentrated around its expectation.

LEMMA 5.3. *For any subset $A \subseteq \mathbb{F}^m$ of density $\mu = |A|/|\mathbb{F}^m|$,*

$$\mathop{\mathbf{Var}}_{z \in \mathbb{F}^m, y \in \mathbb{H}^m}[X_{z,y}] \leq |\mathbb{F}|^2 \frac{\mu}{|\mathbb{H}|}.$$

Proof. If we denote the indicator function of A by $\mathcal{I}_A$, and the indicator function of the multiset $\{c \cdot y \mid c \in \mathbb{F}\}$ by $\mathcal{I}_{\mathbb{F}y}$, we can express:

$$X_{z,y} = \sum_{x \in \mathbb{F}^m} \mathcal{I}_A(x)\mathcal{I}_{\mathbb{F}y}(z-x) = |\mathbb{F}^m| \cdot (\mathcal{I}_A * \mathcal{I}_{\mathbb{F}y})(z).$$

Hence, by Parseval's identity and the convolution formula,

$$\begin{aligned}
\mathop{\mathbf{E}}_{z \in \mathbb{F}^m, y \in \mathbb{H}^m}\left[X_{z,y}^2\right] &= \frac{1}{|\mathbb{F}^m|\,|\mathbb{H}^m|} \cdot \sum_{y \in \mathbb{H}^m} \sum_{z \in \mathbb{F}^m} \left(|\mathbb{F}^m|\,(\mathcal{I}_A * \mathcal{I}_{\mathbb{F}y})(z)\right)^2 \\
&= \frac{|\mathbb{F}^m|^2}{|\mathbb{H}^m|} \cdot \sum_{y \in \mathbb{H}^m} \sum_{\alpha \in \mathbb{F}^m} \left|\widehat{(\mathcal{I}_A * \mathcal{I}_{\mathbb{F}y})}(\alpha)\right|^2 \\
&= \frac{|\mathbb{F}^m|^2}{|\mathbb{H}^m|} \cdot \sum_{y \in \mathbb{H}^m} \sum_{\alpha \in \mathbb{F}^m} \left|\hat{\mathcal{I}}_A(\alpha)\right|^2 \cdot \left|\hat{\mathcal{I}}_{\mathbb{F}y}(\alpha)\right|^2.
\end{aligned}$$

By definition, for any multiset $S \subseteq \mathbb{F}^m$, $\hat{\mathcal{I}}_S(\vec{0}) = \frac{|S|}{|\mathbb{F}^m|}$ (where $|S| = \sum_{\vec{x} \in \mathbb{F}^m} \mathcal{I}_S(\vec{x})$), and hence

$$\begin{aligned}
\mathop{\mathbf{E}}_{z \in \mathbb{F}^m, y \in \mathbb{H}^m}\left[X_{z,y}^2\right] &= \frac{|\mathbb{F}^m|^2}{|\mathbb{H}^m|} \cdot \sum_{y \in \mathbb{H}^m} \left(\left|\hat{\mathcal{I}}_A(\vec{0})\right|^2 \cdot \left|\hat{\mathcal{I}}_{\mathbb{F}y}(\vec{0})\right|^2 + \sum_{\alpha \neq \vec{0} \in \mathbb{F}^m} \left|\hat{\mathcal{I}}_A(\alpha)\right|^2 \cdot \left|\hat{\mathcal{I}}_{\mathbb{F}y}(\alpha)\right|^2\right) \\
&= \left(\frac{|\mathbb{F}|\,|A|}{|\mathbb{F}^m|}\right)^2 + \sum_{\alpha \neq \vec{0} \in \mathbb{F}^m} \left(\left|\hat{\mathcal{I}}_A(\alpha)\right|^2 \cdot \frac{|\mathbb{F}^m|^2}{|\mathbb{H}^m|} \sum_{y \in \mathbb{H}^m} \left|\hat{\mathcal{I}}_{\mathbb{F}y}(\alpha)\right|^2\right).
\end{aligned}$$

We will show that $\frac{|\mathbb{F}^m|^2}{|\mathbb{H}^m|} \cdot \sum_{y \in \mathbb{H}^m} |\hat{\mathcal{I}}_{\mathbb{F}y}(\alpha)|^2 \leq \frac{|\mathbb{F}|^2}{|\mathbb{H}|}$. Let us see how the lemma follows. Bu using this bound and applying Parseval's identity again, we get

$$\begin{aligned}
\mathop{\mathbf{E}}_{z \in \mathbb{F}^m, y \in \mathbb{H}^m}\left[X_{z,y}^2\right] &\leq \left(\frac{|\mathbb{F}|\,|A|}{|\mathbb{F}^m|}\right)^2 + \frac{|\mathbb{F}|^2}{|\mathbb{H}|} \cdot \sum_{\alpha \neq \vec{0} \in \mathbb{F}^m} \left|\hat{\mathcal{I}}_A(\alpha)\right|^2 \\
&\leq \left(\frac{|\mathbb{F}|\,|A|}{|\mathbb{F}^m|}\right)^2 + \frac{|\mathbb{F}|^2}{|\mathbb{H}|} \cdot \frac{1}{|\mathbb{F}^m|} \cdot \sum_{z \in \mathbb{F}^m} |\mathcal{I}_A(z)|^2 \\
&= \left(\frac{|\mathbb{F}|\,|A|}{|\mathbb{F}^m|}\right)^2 + \frac{|\mathbb{F}|^2}{|\mathbb{H}|} \cdot \frac{|A|}{|\mathbb{F}^m|}.
\end{aligned}$$

By linearity of expectations,

$$\mathop{\mathbf{E}}_{z \in \mathbb{F}^m, y \in \mathbb{H}^m}[X_{z,y}] = \frac{|\mathbb{F}|\,|A|}{|\mathbb{F}^m|}.$$

Therefore,

$$\begin{aligned}\operatorname*{\mathbf{Var}}_{z\in\mathbb{F}^m,y\in\mathbb{H}^m}[X_{z,y}] &= \operatorname*{\mathbf{E}}_{z,y}\left[X_{z,y}^2\right] - \operatorname*{\mathbf{E}}_{z,y}[X_{z,y}]^2 \\ &\le \left(\frac{|\mathbb{F}|\,|A|}{|\mathbb{F}^m|}\right)^2 + \frac{|\mathbb{F}|^2}{|\mathbb{H}|}\cdot\frac{|A|}{|\mathbb{F}^m|} - \left(\frac{|\mathbb{F}|\,|A|}{|\mathbb{F}^m|}\right)^2 \\ &= |\mathbb{F}|^2\,\frac{\mu}{|\mathbb{H}|}.\end{aligned}$$

We conclude that proving the lemma boils down to proving the following.

CLAIM 5.3.1. *For every $\alpha \neq \vec{0} \in \mathbb{F}^m$,*

$$\frac{1}{|\mathbb{H}^m|}\cdot\sum_{y\in\mathbb{H}^m}\left|\hat{\mathcal{I}}_{\mathbb{F}y}(\alpha)\right|^2 \le \frac{|\mathbb{F}|^2}{|\mathbb{F}^m|^2}\cdot\frac{1}{|\mathbb{H}|}.$$

Proof. Assume that $\mathbb{F} = GF(p^k)$. Fix some $\alpha \neq \vec{0} \in \mathbb{F}^m$.

$$\left|\hat{\mathcal{I}}_{\mathbb{F}y}(\alpha)\right| = |\langle \mathcal{I}_{\mathbb{F}y}, \chi_\alpha\rangle| = \left|\frac{1}{|\mathbb{F}^m|}\cdot\sum_{z\in\mathbb{F}^m}\mathcal{I}_{\mathbb{F}y}(z)\omega_p^{-\sum_{i=1}^m(\alpha_i,z_i)}\right| = \left|\frac{1}{|\mathbb{F}^m|}\cdot\sum_{c\in\mathbb{F}}\omega_p^{-\sum_{i=1}^m(\alpha_i,c\cdot y_i)}\right|.$$

Multiplication by a field element $a \in \mathbb{F}$ in the field $\mathbb{F} = GF(p^k)$ corresponds to a linear transformation in the vector space $GF(p)^k$. That is, for every $a \in \mathbb{F}$, there exists a $k \times k$ matrix M_a over $GF(p)$ such that, for every $b \in \mathbb{F} = GF(p)^k$, $a \cdot b = M_a b$. Hence,

$$\begin{aligned}\sum_{i=1}^m(\alpha_i, c\cdot y_i) &= \sum_{i=1}^m(\alpha_i, M_{y_i}c) \\ &= \sum_{i=1}^m(M_{y_i}^T\alpha_i, c) \\ &= \sum_{i=1}^m(M_{y_i}^T\alpha_i, c).\end{aligned}$$

Thus, for every $y \in \mathbb{H}^m$,

$$\left|\hat{\mathcal{I}}_{\mathbb{F}y}(\alpha)\right| = \begin{cases} 0 & \sum_{i=1}^m M_{y_i}^T\alpha_i \neq \vec{0}, \\ \frac{|\mathbb{F}|}{|\mathbb{F}^m|} & \text{otherwise.}\end{cases}$$

Assume that $1 \le i \le m$ is such that $\alpha_i \neq \vec{0} \in GF(p)^k$. Note that, for every $a_1 \neq a_2 \in \mathbb{F}$, we know that $M_{a_1}^T\alpha_i \neq M_{a_2}^T\alpha_i$. (For every $b \neq 0 \in \mathbb{F}$, $a_1 \cdot b \neq a_2 \cdot b$. Thus, for every $b \neq \vec{0} \in GF(p)^k$, $(M_{a_1} - M_{a_2})b \neq \vec{0}$ and for every $b \neq \vec{0} \in GF(p)^k$, $M_{a_1}^T b - M_{a_2}^T b = (M_{a_1} - M_{a_2})^T b \neq \vec{0}$.) Hence, for every $v \in GF(p)^k$, there exists at most one $a \in \mathbb{H}$ for which $M_a^T\alpha_i = v$. In particular,

$$\Pr_{\vec{y}\in\mathbb{H}^m}\left[M_{y_i}^T\alpha_i = -\sum_{j\neq i}M_{y_j}^T\alpha_j\right] \le \frac{1}{|\mathbb{H}|}.$$

The claim follows. □

Remark 5.4. To get the corollaries stated in the introduction, note the following:

1. Only Claim 5.3.1 uses the nature/structure of $\mathbb{H}^m$.
2. Claim 5.3.1 does not require $\mathbb{H}$ to be a subfield of $\mathbb{F}$. Its proof holds for any subset $H \subseteq \mathbb{F}$.
3. If $\mathbb{F} = GF(p)$, then for any subset $S \subseteq \mathbb{F}^m$, for any $\vec{\alpha} \neq \vec{0} \in \mathbb{F}^m$,

$$\Pr_{\vec{y}\in S}\left[\sum_{i=1}^{m} M_{y_i}^T \alpha_i \neq \vec{0}\right] = \Pr_{\vec{y}\in S}\left[\sum_{i=1}^{m} y_i \cdot \alpha_i \neq 0\right] = \Pr_{\vec{y}\in S}\left[(\vec{y},\vec{\alpha}) \neq 0\right].$$

We have that $\min_{\vec{\alpha}\neq\vec{0}\in\mathbb{F}^m} \Pr_{\vec{y}\in S}\left[(\vec{y},\vec{\alpha}) \neq 0\right]$ is the relative distance of the linear code obtained when using the vectors of S as the rows of a generating matrix.

5.3. Affine subspaces sample well. By using the sampling lemma (Lemma 5.3), we can prove that the uniform distribution over lines in $\mathcal{S}_1^m$ samples well. Note that the sampling lemma does not show exactly this, as it considers y uniformly distributed over $\mathbb{H}^m$ instead of over $\mathbb{H}^m \setminus \{\vec{0}\}$.

LEMMA 5.5. *For any $A \subseteq \mathbb{F}^m$ of density $\mu = |A|/|\mathbb{F}^m|$,*

$$\operatorname*{\mathbf{Var}}_{l\in\mathcal{S}_1^m}\left[\frac{|l\cap A|}{|l|}\right] \leq \frac{\mu}{|\mathbb{H}|}.$$

Proof. Note that the probability that a random point in $\mathbb{F}^m$ is in A is the same as the expected fraction of points in A on a random line in $\mathcal{S}_1^m$:

$$\operatorname*{\mathbf{E}}_{p\in\mathcal{S}_0^m}\left[\frac{|p\cap A|}{|p|}\right] = \operatorname*{\mathbf{E}}_{l\in\mathcal{S}_1^m}\left[\frac{|l\cap A|}{|l|}\right] = \mu,$$

but the variance may only decrease when considering lines rather than points:

$$\operatorname*{\mathbf{Var}}_{p\in\mathcal{S}_0^m}\left[\frac{|p\cap A|}{|p|}\right] \geq \operatorname*{\mathbf{Var}}_{l\in\mathcal{S}_1^m}\left[\frac{|l\cap A|}{|l|}\right].$$

Hence, since $\mathbf{Var}[X] = \mathbf{E}\left[(X - \mathbf{E}[X])^2\right]$ and expectations satisfy that, for every random variable Y and set A, $\mathbf{E}[Y] = \Pr[Y \in A]\cdot\mathbf{E}[Y|Y\in A] + \Pr[Y\notin A]\cdot\mathbf{E}[Y|Y\notin A]$,

$$\begin{aligned}
\operatorname*{\mathbf{Var}}_{z\in\mathbb{F}^m, y\in\mathbb{H}^m}\left[\frac{1}{|\mathbb{F}|}\cdot X_{z,y}\right] &= \frac{1}{|\mathbb{H}|^m}\cdot\operatorname*{\mathbf{Var}}_{p\in\mathcal{S}_0^m}\left[\frac{|p\cap A|}{|p|}\right] + \left(1-\frac{1}{|\mathbb{H}|^m}\right)\cdot\operatorname*{\mathbf{Var}}_{l\in\mathcal{S}_1^m}\left[\frac{|l\cap A|}{|l|}\right] \\
&\geq \frac{1}{|\mathbb{H}|^m}\cdot\operatorname*{\mathbf{Var}}_{l\in\mathcal{S}_1^m}\left[\frac{|l\cap A|}{|l|}\right] + \left(1-\frac{1}{|\mathbb{H}|^m}\right)\cdot\operatorname*{\mathbf{Var}}_{l\in\mathcal{S}_1^m}\left[\frac{|l\cap A|}{|l|}\right] \\
&= \operatorname*{\mathbf{Var}}_{l\in\mathcal{S}_1^m}\left[\frac{|l\cap A|}{|l|}\right].
\end{aligned}$$

The lemma follows from Lemma 5.3. □

By using the analysis for dimension 1, we can bound the variance of the hitting rate for any larger dimension,

LEMMA 5.6. *Fix dimensions k and m, $1 \leq k \leq m$. For any $A \subseteq \mathbb{F}^m$ of density $\mu = |A|/|\mathbb{F}^m|$,*

$$\operatorname*{\mathbf{Var}}_{s\in\mathcal{S}_k^m}\left[\frac{|s\cap A|}{|s|}\right] \leq \frac{\mu}{|\mathbb{H}|}.$$

Proof. Pick $s \in \mathcal{S}_k^m$ and additional $r \in \mathcal{R}_1^k$ independently at random. Denote by $l = \text{affine}_s(r)$ the line within s corresponding to r (the notation affine_s was introduced in section 4). By uniformity, l is uniformly distributed in $\mathcal{S}_1^m$. Hence, by Lemma 5.5 and uniformity,

$$\begin{aligned}\mathop{\mathbf{Var}}_{s}\left[\frac{|s\cap A|}{|s|}\right] &= \mathop{\mathbf{Var}}_{s}\left[\mathop{\mathbf{E}}_{r}\left[\frac{|l\cap A|}{|l|}\right]\right]\\ &\le \mathop{\mathbf{Var}}_{s,r}\left[\frac{|l\cap A|}{|l|}\right]\\ &\le \frac{\mu}{|\mathbb{H}|}. \qquad \square\end{aligned}$$

We can now bound the deviation of the hitting rate from its expected value.

COROLLARY 5.7 (sampling). *Fix dimensions k and m, $1 \le k \le m$. Fix $A \subseteq \mathbb{F}^m$ of density $\mu = |A| / |\mathbb{F}^m|$. Then, for any $\varepsilon > 0$,*

$$\Pr_{s\in\mathcal{S}_k^m}\left[\left|\frac{|s\cap A|}{|s|} - \mu\right| \ge \varepsilon\right] \le \frac{\mu}{\varepsilon^2\,|\mathbb{H}|}.$$

Proof. Apply Lemma 5.6 and then Chebyshev's inequality. $\square$

5.4. Linear subspaces sample well. We can similarly prove that linear subspaces with one direction chosen from $\mathbb{F}^m$ and all other directions chosen from $\mathbb{H}^m$ sample well. We will need this lemma to analyze the randomness-efficient subspace vs. point tester.

LEMMA 5.8. *Fix dimensions k and m, $1 \le k < m$. Fix a set $A \subseteq \mathbb{F}^m$ of density $\mu = |A|/|\mathbb{F}^m|$. Pick uniformly $\vec{z} \in \mathbb{F}^m$, $\vec{y}_1, \ldots, \vec{y}_k \in \mathbb{H}^m$, such that $\vec{z}, \vec{y}_1, \ldots, \vec{y}_k$ are linearly independent. Denote $s = \text{affine}(\vec{0}; \vec{z}, \vec{y}_1, \ldots, \vec{y}_k)$. Then*

$$\mathop{\mathbf{E}}_{s}\left[\left(\frac{|s\cap A|}{|s|} - \mu\right)^2\right] \le \frac{\mu}{|\mathbb{H}|} + \frac{1}{|\mathbb{F}|}.$$

Proof. Pick an additional scalar $\alpha \in \mathbb{F}$ independently at random. Let $s_\alpha = \text{affine}(\alpha\vec{z}; \vec{y}_1, \ldots, \vec{y}_k)$. Note that s_α is distributed in $\mathcal{S}_k^m$ as follows: with probability $\frac{1}{|\mathbb{F}|}$, s_α is uniformly distributed in the set of affine subspaces in $\mathcal{S}_k^m$ through the origin; with probability $1 - \frac{1}{|\mathbb{F}|}$, s_α is uniformly distributed in the set of affine subspaces in $\mathcal{S}_k^m$ that do not contain the origin. Therefore,

$$\begin{aligned}\mathop{\mathbf{E}}_{s,\alpha}\left[\left(\frac{|s_\alpha\cap A|}{|s_\alpha|} - \mu\right)^2\right] &\le 1 \cdot \mathop{\mathbf{E}}_{s'\in\mathcal{S}_k^m}\left[\left(\frac{|s'\cap A|}{|s'|} - \mu\right)^2\right] + \frac{1}{|\mathbb{F}|}\cdot 1\\ &= \mathop{\mathbf{Var}}_{s'\in\mathcal{S}_k^m}\left[\frac{|s'\cap A|}{|s'|}\right] + \frac{1}{|\mathbb{F}|}.\end{aligned}$$

By Lemma 5.6,

$$\mathop{\mathbf{E}}_{s,\alpha}\left[\left(\frac{|s_\alpha\cap A|}{|s_\alpha|} - \mu\right)^2\right] \le \frac{\mu}{|\mathbb{H}|} + \frac{1}{|\mathbb{F}|}.$$

By Jensen inequality,

$$\mathop{\mathbf{E}}_{s}\left[\left(\frac{|s\cap A|}{|s|} - \mu\right)^2\right] \le \mathop{\mathbf{E}}_{s,\alpha}\left[\left(\frac{|s_\alpha\cap A|}{|s_\alpha|} - \mu\right)^2\right].$$

The lemma follows. $\square$

We can now bound the deviation of the hitting rate from its expected value.

COROLLARY 5.9 (sampling). *Fix dimensions k and m, $1 \le k < m$. Fix a set $A \subseteq \mathbb{F}^m$ of density $\mu = |A|/|\mathbb{F}^m|$. Pick uniformly $\vec{z} \in \mathbb{F}^m$, $\vec{y}_1, \ldots, \vec{y}_k \in \mathbb{H}^m$, such that $\vec{z}, \vec{y}_1, \ldots, \vec{y}_k$ are linearly independent. Denote $s = \text{affine}(\vec{0}; \vec{z}, \vec{y}_1, \ldots, \vec{y}_k)$. Then, for any $\varepsilon > 0$,*

$$\Pr_s \left[\left| \frac{|s \cap A|}{|s|} - \mu \right| \ge \varepsilon \right] \le \frac{1}{\varepsilon^2} \cdot \left(\frac{\mu}{|\mathbb{H}|} + \frac{1}{|\mathbb{F}|} \right).$$

Proof. Apply Markov inequality on Lemma 5.8. □

6. Consolidation. In this section we show that *weak* low degree testing claims imply *strong* low degree testing claims. Specifically, we are interested in the following (for exact definitions, see the next subsections):

1. *Decoding/list decoding*: By decoding we refer to finding a single polynomial $Q : \mathbb{F}^m \to \mathbb{F}$ agreeing with the oracle on many of the points. By list decoding we refer to finding a short list of polynomials $Q_1, \ldots, Q_t : \mathbb{F}^m \to \mathbb{F}$ explaining almost all of the acceptance probability of a tester.
2. *Consistency consolidation*: We are able to construct polynomials $Q : \mathbb{F}^m \to \mathbb{F}$ agreeing with the oracle on some fraction of the points and wish to find polynomials agreeing with the oracle on a larger fraction of the points.
3. *Degree consolidation*: We are able to construct polynomials $Q : \mathbb{F}^m \to \mathbb{F}$ of degree at most $d' \ge d$ and wish to find polynomials of degree at most d.

We call such arguments *consolidating arguments*. They are standard in the low degree testing literature (see, e.g., [3, 17, 9]); however, they require some adaptation to our new setting. In the following subsections we provide the statements and the proofs of the exact claims we need.

6.1. From decoding to list decoding. If we have a way to decode, then we can list decode by repeatedly applying decoding. In our setting, it is easy to force the decoding process to output a polynomial that differs from existing polynomials by modifying the oracle.

LEMMA 6.1 (from decoding to list decoding). *Assume that $|\mathbb{F}| \ge 4$. Fix a distribution $\mathcal{D}$ over affine subspaces of dimension $k > 0$ in $\mathbb{F}^m$. Fix a function $f : \mathbb{R} \to \mathbb{R}$ and a degree d' such that $d \le d' \le |\mathbb{F}| - 3$. If*
(decoding):
for every success probability $0 < \gamma \le 1$ *and oracle $\mathcal{A}$,*
(much consistency)

$$\mathop{\mathbf{E}}_{s \sim \mathcal{D}} \left[\Pr_{\vec{x} \in s} [\mathcal{A}(s)(\vec{x}) = \mathcal{A}(\vec{x})] \right] \ge \gamma$$

implies
(a relatively low degree polynomial that slightly agrees with the oracle),
there exists a polynomial $Q : \mathbb{F}^m \to \mathbb{F}$, with $\deg Q \le d'$, such that

$$\Pr_{\vec{x} \in \mathbb{F}^m} [Q(\vec{x}) = \mathcal{A}(\vec{x})] \ge f(\gamma).$$

Then
(list-decoding):
for every oracle $\mathcal{A}$,

(almost all consistency is explained by a relatively short list),
fix $\epsilon_0 \stackrel{def}{=} \sqrt{\frac{d'}{|\mathbb{F}|}}$. *For every* $\epsilon_0 < \delta < 1$ *such that* $\delta' \stackrel{def}{=} f(\delta - \epsilon_0) - \epsilon_0 \geq 2\epsilon_0$, *there exists a list of* $t \leq 2/\delta'$ *polynomials* $Q_1, \ldots, Q_t : \mathbb{F}^m \to \mathbb{F}$, *with* $\deg Q_i \leq d'$, *such that*

$$\mathop{\mathbf{E}}_{s \sim \mathcal{D}} \left[\Pr_{\vec{x} \in s} \left[\mathcal{A}(s)(\vec{x}) \neq \mathcal{A}(\vec{x}) \ \vee \ \exists i \ (Q_i \equiv \mathcal{A})(s) \right] \right] \geq 1 - \delta.$$

Proof. Assume by way of contradiction that decoding holds and there exists an oracle $\mathcal{A}$ for which there exists $\epsilon_0 < \delta < 1$ satisfying $f(\delta - \epsilon_0) - \epsilon_0 \geq 2\epsilon_0$ such that there is no list decoding for δ.

Let $Q_1, \ldots, Q_t : \mathbb{F}^m \to \mathbb{F}$ be all polynomials of degree at most d' for which

$$\Pr_{\vec{x} \in \mathbb{F}^m} [Q_i(\vec{x}) = \mathcal{A}(\vec{x})] \geq \delta'.$$

By Proposition 3.5, $t \leq 2/\delta'$. By our assumption, $Q_1, \ldots, Q_t$ is not a list decoding for δ. Note that $t \leq 1/\epsilon_0$.

When picking a subspace $s \sim \mathcal{D}$ and a point $\vec{x}$ uniformly distributed in s, define the following events:

1. C: $\mathcal{A}(s)(\vec{x}) = \mathcal{A}(\vec{x})$ *(consistent).*
2. P: $\exists i \in [t]$, $\mathcal{A}(\vec{x}) = Q_i(\vec{x})$ *(point explained).*
3. S: $\exists i \in [t]$, $(Q_i \equiv \mathcal{A})(s)$ *(subspace explained).*

By using this notation, the contradicting assumption implies that there is much consistency within unexplained subspaces:

$$\Pr_{s,\vec{x}}[C \wedge \neg S] = 1 - \Pr_{s,\vec{x}}[\neg C \vee S] = 1 - \mathop{\mathbf{E}}_{s} \left[\Pr_{\vec{x}} [\neg C \vee S] \right] > \delta.$$

When C and P both happen, the polynomial $\mathcal{A}(s)$ agrees with a polynomial Q_i for some $i \in [t]$ on the point $\vec{x}$. Hence, by a union bound over the $i \in [t]$ and by the Schwartz–Zippel lemma, an unexplained subspace is rarely consistent with explained points:

$$\Pr_{s,\vec{x}}[C \wedge P | \neg S] \leq \frac{td'}{|\mathbb{F}|} \leq \frac{1}{\epsilon_0} \cdot \epsilon_0^2 = \epsilon_0.$$

Thus, there is much consistency on unexplained points:

$$\begin{aligned}
\Pr_{s,\vec{x}}[C \wedge \neg P] &\geq \Pr_{s,\vec{x}}[C \wedge \neg P \wedge \neg S] \\
&= \Pr_{s,\vec{x}}[C \wedge \neg S] - \Pr_{s,\vec{x}}[C \wedge P \wedge \neg S] \\
&\geq \Pr_{s,\vec{x}}[C \wedge \neg S] - \Pr_{s,\vec{x}}[C \wedge P | \neg S] \\
&> \delta - \epsilon_0.
\end{aligned}$$

Pick an arbitrary polynomial $Q' : \mathbb{F}^m \to \mathbb{F}$, with $\deg Q' = d' + 1$. Define a new oracle $\mathcal{A}'$ as follows: $\mathcal{A}'$ assigns $Q'(\vec{x})$ to all explained points $\vec{x}$ and agrees with $\mathcal{A}$ on all other affine subspaces (recall that points are affine subspaces of dimension 0). Hence,

$$\begin{aligned}
\mathop{\mathbf{E}}_{s \sim \mathcal{D}} \left[\Pr_{\vec{x} \in s} [\mathcal{A}'(s)(\vec{x}) = \mathcal{A}'(\vec{x})] \right] &\geq \Pr_{s \sim \mathcal{D}, \vec{x} \in s} [\mathcal{A}(s)(\vec{x}) = \mathcal{A}(\vec{x}) \wedge \mathcal{A}(\vec{x}) = \mathcal{A}'(\vec{x})] \\
&\geq \Pr_{s,\vec{x}}[C \wedge \neg P] \\
&> \delta - \epsilon_0.
\end{aligned}$$

Thus, by decoding, there exists a polynomial Q, $\deg Q \le d'$, agreeing with $\mathcal{A}'$ on many of the points

$$\Pr_{\vec{x}\in\mathbb{F}^m}[\mathcal{A}'(\vec{x}) = Q(\vec{x})] \ge f(\delta - \epsilon_0).$$

The polynomials Q and Q' are necessarily distinct (they do not have the same degree). Thus, by the Schwartz–Zippel lemma,

$$\Pr_{\vec{x}\in\mathbb{F}^m}[\mathcal{A}'(\vec{x}) = Q(\vec{x}) \wedge \mathcal{A}'(\vec{x}) \ne \mathcal{A}(\vec{x})] \le \Pr_{\vec{x}\in\mathbb{F}^m}[Q'(\vec{x}) = Q(\vec{x})] \le \frac{d'+1}{|\mathbb{F}|} \le \epsilon_0.$$

Hence,

$$\begin{aligned}\Pr_{\vec{x}\in\mathbb{F}^m}[\mathcal{A}(\vec{x}) = Q(\vec{x}) = \mathcal{A}'(\vec{x})] &= \Pr_{\vec{x}\in\mathbb{F}^m}[\mathcal{A}'(\vec{x}) = Q(\vec{x})] \\ &\quad - \Pr_{\vec{x}\in\mathbb{F}^m}[\mathcal{A}'(\vec{x}) = Q(\vec{x}) \wedge \mathcal{A}'(\vec{x}) \ne \mathcal{A}(\vec{x})] \\ &\ge f(\delta - \epsilon_0) - \epsilon_0 \\ &= \delta'.\end{aligned}$$

Therefore,

$$\Pr_{\vec{x}\in\mathbb{F}^m}[\mathcal{A}(\vec{x}) = Q(\vec{x})] \ge \Pr_{\vec{x}\in\mathbb{F}^m}[\mathcal{A}(\vec{x}) = Q(\vec{x}) = \mathcal{A}'(\vec{x})] \ge \delta'.$$

Hence, there exists $i \in [t]$ such that $Q = Q_i$. However, if this is the case, by the definition of $\mathcal{A}'$,

$$\delta' \le \Pr_{\vec{x}\in\mathbb{F}^m}[\mathcal{A}(\vec{x}) = Q_i(\vec{x}) = \mathcal{A}'(\vec{x})] \le \Pr_{\vec{x}\in\mathbb{F}^m}[Q'(\vec{x}) = Q(\vec{x})] \le \epsilon_0,$$

which is a contradiction. □

We can additionally demand that each member of the list decoding agrees with the oracle on many of the subspaces, i.e., there are no nonuseful members in the list.

LEMMA 6.2 (pruning the list). *Fix a distribution $\mathcal{D}$ over affine subspaces in $\mathbb{F}^m$. For every $0 < \epsilon < 1$ and oracle $\mathcal{A}$, if $Q_1, \ldots, Q_t : \mathbb{F}^m \to \mathbb{F}$ are $t > 0$ polynomials satisfying*

(almost all consistency is explained by the list)

$$\mathop{\mathbf{E}}_{s\sim\mathcal{D}}\left[\Pr_{\vec{x}\in s}[\mathcal{A}(s)(\vec{x}) \ne \mathcal{A}(\vec{x}) \ \vee \ \exists i \ (Q_i \equiv \mathcal{A})(s)]\right] \ge 1 - \delta,$$

then there exists a sublist $T \subseteq [t]$ such that

1. (each polynomial agrees with the oracle on many of the subspaces) *for every $i \in T$,*

$$\Pr_{s\sim\mathcal{D}}[(Q_i \equiv \mathcal{A})(s)] > \frac{\epsilon}{t};$$

2. (still almost all consistency is explained by the list)

$$\mathop{\mathbf{E}}_{s\sim\mathcal{D}}\left[\Pr_{\vec{x}\in s}[\mathcal{A}(s)(\vec{x}) \ne \mathcal{A}(\vec{x}) \ \vee \ \exists i \in T \ (Q_i \equiv \mathcal{A})(s)]\right] \ge 1 - \delta - \epsilon.$$

Proof. We prune the given list $Q_1, \ldots, Q_t$ by throwing away any polynomial Q_i, for which the first item does not hold. In other words,

$$T \stackrel{def}{=} \left\{ i \in [t] \;\middle|\; \Pr_{s \sim \mathcal{D}} \left[(Q_i \equiv \mathcal{A})(s) \right] > \frac{\epsilon}{t} \right\}.$$

By the union bound, $\Pr_{s \sim \mathcal{D}} \left[\exists i \in [t] \setminus T,\ (Q_i \equiv \mathcal{A})(s) \right] \leq t \cdot \frac{\epsilon}{t} = \epsilon$. For a subspace $s \sim \mathcal{D}$ and a point $\vec{x}$ uniformly distributed in s, define the following events:

1. C: $\mathcal{A}(s)(\vec{x}) = \mathcal{A}(\vec{x})$ *(consistent).*
2. B: $\exists i \in [t]$, $(Q_i \equiv \mathcal{A})(s)$ *(explained before).*
3. N: $\exists i \in T$, $(Q_i \equiv \mathcal{A})(s)$ *(explained now).*

By using this notation, we have (e.g., by observing the appropriate Venn diagram)

$$\begin{aligned} \mathop{\mathbf{E}}_{s} \left[\Pr_{\vec{x}} \left[\neg C \vee N \right] \right] &= \Pr_{s,\vec{x}} \left[\neg C \vee N \right] \\ &\geq \Pr_{s,\vec{x}} \left[\neg C \vee B \right] - \Pr_{s,\vec{x}} \left[B \wedge \neg N \right] \\ &\geq 1 - \delta - \epsilon. \qquad \square \end{aligned}$$

6.2. Consistency consolidation. In this subsection, we prove a lemma allowing us to deduce that a *significant consistency* γ together with a list decoding for it imply that at least one of the polynomials in the list agrees with the oracle on almost a γ fraction of the points. The lemma requires that the distribution over affine subspaces samples well (see section 5). Together with Lemma 6.1 that transforms decoding into list decoding, this lemma allows us to improve the consistency we manage to recover.

We phrase a rather general lemma addressing *distributional oracles* instead of oracles. We say that $\widetilde{\mathcal{A}}$ is a *distributional oracle* if it assigns each affine subspace s a *distribution* over functions $s \to \mathbb{F}$ (not necessarily a *single* polynomial of degree at most d over s). Our semantic even permits the distribution to produce a *null* function $\perp$ with some probability. The null function satisfies that, for every subspace s, point $\vec{x} \in s$, and scalar $a \in \mathbb{F}$, the probability (over $\widetilde{\mathcal{A}}$, namely, over the randomness in choosing $\widetilde{\mathcal{A}}(s)$) that $\widetilde{\mathcal{A}}(s)(\vec{x}) = a$, when $\widetilde{\mathcal{A}}(s)$ evaluates to $\perp$, is 0.

LEMMA 6.3 (from list decoding to decoding). *Fix a distribution $\mathcal{D}$ over affine subspaces that sample well; i.e., there exists $\Delta : [0,1] \to [0,1]$ such that, for every set $A \subseteq \mathbb{F}^m$, for every $0 < \varepsilon < 1$,*

$$\Pr_{s \sim \mathcal{D}} \left[\left| \frac{|s \cap A|}{|s|} - \frac{|A|}{|\mathbb{F}^m|} \right| \geq \varepsilon \right] \leq \Delta(\varepsilon).$$

Let $\mathcal{A}$ denote an oracle, and let $\widetilde{\mathcal{A}}$ denote a distributional oracle. Assume that

1. (the oracles are γ-consistent)

$$\mathop{\mathbf{E}}_{\widetilde{\mathcal{A}}} \left[\mathop{\mathbf{E}}_{s \sim \mathcal{D}} \left[\Pr_{\vec{x} \in s} \left[\widetilde{\mathcal{A}}(s)(\vec{x}) = \mathcal{A}(\vec{x}) \right] \right] \right] \geq \gamma.$$

2. (most consistency is explained by a relatively short list)
   There exist t functions $f_1, \ldots, f_t : \mathbb{F}^m \to \mathbb{F}$ such that

$$\mathop{\mathbf{E}}_{\widetilde{\mathcal{A}}} \left[\mathop{\mathbf{E}}_{s \sim \mathcal{D}} \left[\Pr_{\vec{x} \in s} \left[\widetilde{\mathcal{A}}(s)(\vec{x}) \neq \mathcal{A}(\vec{x}) \ \vee\ \exists i\ (f_i \equiv \widetilde{\mathcal{A}})(s) \right] \right] \right] \geq 1 - \delta.$$

Then, for any $0 < \varepsilon < 1$ *such that* $\varepsilon \geq t \cdot \Delta(\varepsilon)$*, there exists* $1 \leq i \leq t$ *such that*

$$\Pr_{\vec{x} \in \mathbb{F}^m} [f_i(\vec{x}) = \mathcal{A}(\vec{x})] \geq \gamma - \delta - 2\varepsilon.$$

Proof. Assume, by way of contradiction, that for every $1 \leq i \leq t$, $\Pr_{\vec{x} \in \mathbb{F}^m}[f_i(\vec{x}) = \mathcal{A}(\vec{x})] < \gamma - \delta - 2\varepsilon$. Let us bound the consistency towards a contradiction to the first item of the premise. For every $1 \leq i \leq t$, define the set of points explained by f_i:

$$A_i \stackrel{def}{=} \{\vec{x} \in \mathbb{F}^m \mid f_i(\vec{x}) = \mathcal{A}(\vec{x})\}.$$

For every $1 \leq i \leq t$, note that $\mu_i \stackrel{def}{=} \frac{|A_i|}{|\mathbb{F}^m|} < \gamma - \delta - 2\varepsilon$.

As $\mathcal{D}$ samples well, for every $1 \leq i \leq t$, a random subspace $s \sim \mathcal{D}$ is not likely to hit A_i much more than it is expected:

$$\Pr_{s \sim \mathcal{D}} \left[\frac{|s \cap A_i|}{|s|} \geq \mu_i + \varepsilon \right] \leq \Delta(\varepsilon) \leq \frac{\varepsilon}{t}.$$

By the union bound,

$$\Pr_{s \sim \mathcal{D}} \left[\exists i \in [t],\ \frac{|s \cap A_i|}{|s|} \geq \gamma - \delta - \varepsilon \right] \leq \varepsilon.$$

For a random oracle assignment $\widetilde{\mathcal{A}}$, a subspace $s \sim \mathcal{D}$, and a uniformly distributed point $\vec{x} \in s$ chosen independently at random, define the following events:

1. B: $\exists i \in [t]$, $|s \cap A_i| \geq (\gamma - \delta - \varepsilon) \cdot |s|$ *(bad subspace).*
2. C: $\widetilde{\mathcal{A}}(s)(\vec{x}) = \mathcal{A}(\vec{x})$ *(consistent).*
3. E: $\exists i \in [t]$, $(f_i \equiv \widetilde{\mathcal{A}})(s)$ *(explained).*

By using this notation, we have established that

$$\begin{aligned}
\Pr_{\widetilde{\mathcal{A}},s,\vec{x}} [C \wedge E] &= \Pr_{\widetilde{\mathcal{A}},s,\vec{x}} [C \wedge E \wedge \neg B] + \Pr_{\widetilde{\mathcal{A}},s,\vec{x}} [C \wedge E \wedge B] \\
&\leq \Pr_{\widetilde{\mathcal{A}},s,\vec{x}} [C | E \wedge \neg B] + \Pr_{s} [B] \\
&< (\gamma - \delta - \varepsilon) + \varepsilon \\
&= \gamma - \delta.
\end{aligned}$$

The second item of the premise implies that

$$\begin{aligned}
\Pr_{\widetilde{\mathcal{A}},s,\vec{x}} [C] &= \Pr_{\widetilde{\mathcal{A}},s,\vec{x}} [C \wedge \neg E] + \Pr_{\widetilde{\mathcal{A}},s,\vec{x}} [C \wedge E] \\
&< \delta + (\gamma - \delta) \\
&= \gamma.
\end{aligned}$$

This contradicts the first item of the premise. ∎

6.3. Degree consolidation. *Degree consolidation* shows that, if one reconstructs a polynomial of not too large degree that agrees with the oracle on many of our subspaces, the polynomial's true degree is, in fact, low. The reason is that the polynomial's degree does not decrease much when restricted to almost all of our subspaces.

First we prove a lemma allowing us to deduce degree d if one of the *directions* of our subspaces is distributed over $\mathbb{F}^m$ (rather than $\mathbb{H}^m$). This is used only in the analysis of the randomness-efficient subspace vs. point tester.

LEMMA 6.4 (degree d consolidation). *Fix dimensions k and m, $0 \le k < m$. Fix an oracle $\mathcal{A}$ assigning polynomials of degree at most d to all affine subspaces. Suppose that a polynomial $Q : \mathbb{F}^m \to \mathbb{F}$ satisfies the following for some $0 \le \delta \le 1$:*

1. $\deg Q \le \delta\,|\mathbb{F}|$.
2. *Q and $\mathcal{A}$ agree on a linear subspace chosen at random:*

$$\Pr_{\vec{z}\in\mathbb{F}^m,\vec{y}_1,\ldots,\vec{y}_k\in\mathbb{H}^m}\Big[(Q\equiv\mathcal{A})(\mathrm{affine}(\vec{0};\vec{z},\vec{y}_1,\ldots,\vec{y}_k))\,|\,\mathit{ind}(\vec{z},\vec{y}_1,\ldots,\vec{y}_k)\Big] > \delta+\frac{1}{|\mathbb{F}|}.$$

Then $\deg Q \le d$.

Proof. Assume by way of contradiction that $\deg Q > d$. Consider linearly independent $\vec{z}\in\mathbb{F}^m$ and $\vec{y}_1,\ldots,\vec{y}_k\in\mathbb{H}^m$. Denote $s = \mathrm{affine}(\vec{0};\vec{z},\vec{y}_1,\ldots,\vec{y}_k)$, and observe the polynomial

$$Q_{|s}(\alpha_0,\alpha_1,\ldots,\alpha_k) = Q(\alpha_0\vec{z}+\alpha_1\vec{y}_1+\cdots+\alpha_k\vec{y}_k).$$

Note that each of the coefficients of this polynomial can be viewed as a polynomial in $z_1,\ldots,z_m$ and $y_{1,1},\ldots,y_{1,m},\ldots,y_{k,1},\ldots,y_{k,m}$ of total degree at most $\deg Q$. In particular, consider the coefficient of the degree $\deg Q$ monomial $\alpha_0^{\deg Q}$ in $Q_{|s}$. Note that it depends solely on $z_1,\ldots,z_m$ (and not on $y_{1,1},\ldots,y_{1,m},\ldots,y_{k,1},\ldots,y_{k,m}$). Hence, let us denote it by $P(z_1,\ldots,z_m)$.

To analyze P we will need more notation. Denote

$$Q(x_1,\ldots,x_m) = \sum_{i_1\cdots i_m} a_{i_1\cdots i_m} x_1^{i_1}\cdots x_m^{i_m}.$$

Define $I \stackrel{def}{=} \{(i_1,\ldots,i_m) \mid \sum_j i_j = \deg Q\}$. Now,

$$P(z_1,\ldots,z_m) = \sum_{(i_1\ldots i_m)\in I} a_{i_1\cdots i_m} z_1^{i_1}\cdots z_m^{i_m}.$$

Thus, by definition, $\deg P = \deg Q$, and P is not identically zero.

Clearly,

$$\begin{aligned}\Pr_{\vec{z}\in\mathbb{F}^m,\vec{y}_1,\ldots,\vec{y}_k\in\mathbb{H}^m}&\Big[\deg Q_{|\mathrm{affine}(\vec{0};\vec{z},\vec{y}_1,\ldots,\vec{y}_k)} > d\,|\mathsf{ind}(\vec{z},\vec{y}_1,\ldots,\vec{y}_k)\Big]\\ &\ge \Pr_{\vec{z}\in\mathbb{F}^m,\vec{y}_1,\ldots,\vec{y}_k\in\mathbb{H}^m}[P(\vec{z})\ne 0\,|\mathsf{ind}(\vec{z},\vec{y}_1,\ldots,\vec{y}_k)].\end{aligned}$$

By the Schwartz–Zippel lemma, we have

$$\Pr_{\vec{z}\in\mathbb{F}^m,\vec{y}_1,\ldots,\vec{y}_k\in\mathbb{H}^m}[P(\vec{z})\ne 0] \ge 1-\frac{\deg Q}{|\mathbb{F}|} \ge 1-\delta.$$

For any linearly independent $\vec{y}_1,\ldots,\vec{y}_k$, the probability that a uniformly distributed $\vec{z}\in\mathbb{F}^m$ satisfies $\neg\mathsf{ind}(\vec{z},\vec{y}_1,\ldots,\vec{y}_k)$ is at most $\frac{1}{|\mathbb{F}|}$. Therefore,

$$\Pr_{\vec{z}\in\mathbb{F}^m,\vec{y}_1,\ldots,\vec{y}_k\in\mathbb{H}^m}\Big[\deg Q_{|\mathrm{affine}(\vec{0};\vec{z},\vec{y}_1,\ldots,\vec{y}_k)} > d \mid \mathsf{ind}(\vec{z},\vec{y}_1,\ldots,\vec{y}_k)\Big] \ge 1-\delta-\frac{1}{|\mathbb{F}|}.$$

However, $\Pr_{\vec{z}\in\mathbb{F}^m,\vec{y}_1,\ldots,\vec{y}_k\in\mathbb{H}^m}[\deg Q_{|\mathrm{affine}(\vec{0};\vec{z},\vec{y}_1,\ldots,\vec{y}_k)} \le d \mid \mathsf{ind}(\vec{z},\vec{y}_1,\ldots,\vec{y}_k)] > \delta + \frac{1}{|\mathbb{F}|}$. ∎

Next we prove a lemma allowing us to deduce degree md (rather than d), even if we observe only affine subspaces in $\mathcal{S}_k^m$. This lemma will be used in the analysis of the randomness-efficient plane vs. point tester.

LEMMA 6.5 (degree md consolidation). *Fix dimensions k and m, $1 \le k \le m$. Fix an oracle $\mathcal{A}$ assigning polynomials of degree at most d to all affine subspaces. Suppose that a polynomial $Q : \mathbb{F}^m \to \mathbb{F}$ satisfies the following for some $0 \le \delta \le 1$:*

1. $\deg Q \le \delta\,|\mathbb{F}|$.
2. $\Pr_{s \in \mathcal{S}_k^m}\left[(Q \equiv \mathcal{A})(s)\right] > \delta + \frac{1}{|\mathbb{H}|}$.

Then $\deg Q \le md$.

Proof. By the premise and uniformity,

$$\Pr_{\vec{y}_1,\ldots,\vec{y}_k \in \mathbb{H}^m}\left[\Pr_{\vec{z}\in\mathbb{F}^m}\left[(Q \equiv \mathcal{A})(\mathrm{affine}(\vec{z};\vec{y}_1,\ldots,\vec{y}_k))\right] > \delta \;\middle|\; \mathsf{ind}(\vec{y}_1,\ldots,\vec{y}_k)\right] > \frac{1}{|\mathbb{H}|}.$$

Thus,

$$\Pr_{\vec{y}\neq\vec{0}\in\mathbb{H}^m}\left[\Pr_{\vec{z}\in\mathbb{F}^m}\left[\deg Q_{|\mathrm{affine}(\vec{z};\vec{y})} \le d\right] > \delta\right] > \frac{1}{|\mathbb{H}|}.$$

By Proposition 3.3, there exist linearly independent $\vec{y}_1,\ldots,\vec{y}_m \in \mathbb{H}^m$ such that, for every $1 \le i \le m$,

$$\Pr_{\vec{z}\in\mathbb{F}^m}\left[\deg Q_{|\mathrm{affine}(\vec{z};\vec{y}_i)} \le d\right] > \delta.$$

$\vec{y}_1,\ldots,\vec{y}_m$ is a basis for $\mathbb{F}^m$. Thus, every point $\vec{x} \in \mathbb{F}^m$ can be represented as $\vec{x} = \sum_{i=1}^m \alpha_i \vec{y}_i$ for some $\alpha_1,\ldots,\alpha_m \in \mathbb{F}$. Hence, view Q as a polynomial in variables $\alpha_1,\ldots,\alpha_m$. Assume by way of contradiction that $\deg Q > md$. Hence, there exists $1 \le i \le m$ such that the degree of Q in the variable α_i, which we will denote by D, is larger than d. The coefficient of α_i^D in the polynomial $Q_{|\mathrm{affine}(\vec{z};\vec{y}_i)}$ is a nonzero polynomial $P(z_1,\ldots,z_m)$ of degree at most $\deg Q$. Hence, by the Schwartz–Zippel lemma,

$$\Pr_{\vec{z}\in\mathbb{F}^m}\left[P(z_1,\ldots,z_m) = 0\right] \le \frac{\deg Q}{|\mathbb{F}|} \le \delta.$$

Thus, $\Pr_{\vec{z}\in\mathbb{F}^m}\left[\deg Q_{|\mathrm{affine}(\vec{z};\vec{y}_i)} \le d\right] \le \delta$, which is a contradiction. ∎

7. Consistency graph. Fix a dimension $k \ge 3$. In this section we define and analyze a *graph* that captures the consistency among hyperplanes in $\mathbb{F}^k$, i.e., affine subspaces of dimension $(k-1)$. By using the graph we prove a list decoding lemma (Lemma 7.4). This lemma is used in the analysis of the randomness-efficient plane vs. point tester to go up one dimension (see section 8). Lemma 7.4 is also the only lemma in this section that is used outside it.

The idea is a variation of the analysis of Raz and Safra for the non-randomness-efficient setting [17]. Our crucial observation is that we can essentially still apply their analysis *when considering only directions with coordinates in a subfield* $\mathbb{H} \subseteq \mathbb{F}$ instead of the entire field $\mathbb{F}$.

7.1. Graph construction. Given an oracle $\mathcal{A}$ assigning affine subspaces polynomials of degree at most d, define a simple undirected graph $G_{\mathcal{A}} = (V, E_{\mathcal{A}})$ that captures the consistency among affine subspaces in $\mathcal{S}_{k-1}^k$ as follows. Let the vertices be the set of affine subspaces $V \stackrel{def}{=} \mathcal{S}_{k-1}^k$. Let the edges indicate whether two

affine subspaces are assigned polynomials that are consistent on the intersection of the subspaces:

$$E_{\mathcal{A}} \stackrel{def}{=} \{(s_1, s_2) \mid \forall \vec{x} \in s_1 \cap s_2,\ \mathcal{A}(s_1)(\vec{x}) = \mathcal{A}(s_2)(\vec{x})\}.$$

Note that every two subspaces in $\mathcal{S}^k_{k-1}$ are either parallel (i.e., identify or do not intersect) or intersect by an affine subspace from $\mathcal{S}^k_{k-2}$ (see closedness under intersection; Proposition 4.5).

7.2. Graph is almost transitive. A graph $G = (V, E)$ is said to be *transitive* if, for every three vertices $u, v, w \in V$, if $(u, v) \in E$ and $(v, w) \in E$, then $(u, w) \in E$. In other words, a graph is transitive if and only if for every two vertices $u, w \in V$, $u \neq w$, they are not neighbors, namely, $(u, w) \notin E$, no vertex $v \in V$ neighbors both u and w, i.e., for every $v \in V$, either $(u, v) \notin E$ or $(v, w) \notin E$.

We first wish to establish that the graph is *almost transitive* in the sense that every two vertices that are not neighbors do not have too many common neighbors (whereas, if the graph had been transitive, they would not have had common neighbors at all).

LEMMA 7.1 (almost-transitivity). *Fix an oracle $\mathcal{A}$ assigning affine subspaces polynomials of degree at most d. Let $G_{\mathcal{A}} = (V, E_{\mathcal{A}})$ be its corresponding consistency graph for affine subspaces of dimension $k \geq 3$. Then, for every two different affine subspaces $s_1, s_2 \in V$,*

$$(s_1, s_2) \notin E_{\mathcal{A}} \quad \Rightarrow \quad \Pr_{s_3 \in V}[(s_1, s_3) \in E_{\mathcal{A}} \ \wedge\ (s_3, s_2) \in E_{\mathcal{A}}] \leq \frac{1}{|\mathbb{H}|} + \frac{d}{|\mathbb{F}|}.$$

Proof. Assume that $(s_1, s_2) \notin E_{\mathcal{A}}$. By definition, there exists $\vec{x} \in s_1 \cap s_2$, for which $\mathcal{A}(s_1)(\vec{x}) \neq \mathcal{A}(s_2)(\vec{x})$. Hence, $a \stackrel{def}{=} s_1 \cap s_2 \in \mathcal{S}^k_{k-2}$, and $\mathcal{A}(s_1)$ and $\mathcal{A}(s_2)$ induce two different polynomials of degree at most d on a. Let us denote these polynomials by P_1 and P_2, respectively. Fix a representation in $\mathcal{R}^k_{k-2}$ for a. We say that a vertex $s_3 \in V$ *spots inconsistency* if there exists $\vec{x} \in s_3 \cap a$ such that $P_1(\vec{x}) \neq P_2(\vec{x})$. We wish to argue that a random vertex $s_3 \in V$ is likely to spot inconsistency.

Pick uniformly $r = (\vec{z}; \vec{y}_1, \ldots, \vec{y}_{k-1}) \in \mathcal{R}^k_{k-1}$. Let us say that $s_3 = \text{affine}(r)$ is *bad* if s_3 either contains a or does not intersect it. Since $(k-2)+(k-1) \geq k$, for s_3 to be bad, a's directions must be linearly dependent on $\vec{y}_1, \ldots, \vec{y}_{k-1}$. Hence, by uniformity and by Proposition 3.2,

$$\Pr_{s_3 \in V}[s_3 \text{ is bad}] \leq \frac{1}{|\mathbb{H}|}. \tag{7.1}$$

By the Schwartz–Zippel lemma, $\Pr_{\vec{x} \in a}[P_1(\vec{x}) \neq P_2(\vec{x})] \geq 1 - \frac{d}{|\mathbb{F}|}$. For all of the hyperplanes s that do not contain a but do intersect it, the dimension of their intersection with a is $(k-1)+(k-2)-k = k-3$. Let $I \stackrel{def}{=} \{s \cap a \mid s \in V; a \nsubseteq s \wedge s \cap a \neq \phi\}$. By closedness under intersection and uniformity, $\mathbf{E}_{a' \in I}[\Pr_{\vec{x} \in a'}[P_1(\vec{x}) \neq P_2(\vec{x})]] = \Pr_{\vec{x} \in a}[P_1(\vec{x}) \neq P_2(\vec{x})] \geq 1 - \frac{d}{|\mathbb{F}|}$. By uniformity,

$$\Pr_{s_3 \in V}[s_3 \text{ spots inconsistency} \,|\, s_3 \text{ is not bad}] \geq 1 - \frac{d}{|\mathbb{F}|}. \tag{7.2}$$

By combining inequalities (7.1) and (7.2), we get

$$\Pr_{s_3}[s_3 \text{ spots inconsistency}] \geq 1 - \frac{1}{|\mathbb{H}|} - \frac{d}{|\mathbb{F}|}.$$

If s_3 spots inconsistency, then either $(s_1, s_3) \notin E_{\mathcal{A}}$ or $(s_3, s_2) \notin E_{\mathcal{A}}$. Thus, $(s_1, s_3) \in E_{\mathcal{A}}$ and $(s_3, s_2) \in E_{\mathcal{A}}$ with probability at most $\frac{1}{|\mathbb{H}|} + \frac{d}{|\mathbb{F}|}$. □

7.3. Graph-based list decoding. The almost-transitivity of the graph $G_{\mathcal{A}}$ can be used to prove that, other than relatively few edges, the graph is truly transitive, i.e., composed of disjoint cliques. Moreover, these cliques are relatively large. This was shown by Raz and Safra [17].

LEMMA 7.2 (graph partition). *Fix $\epsilon = \frac{1}{|\mathbb{H}|} + \frac{d}{|\mathbb{F}|}$. Fix an oracle $\mathcal{A}$ assigning affine subspaces polynomials of degree at most d. Let $G_{\mathcal{A}} = (V, E_{\mathcal{A}})$ be its corresponding consistency graph for affine subspaces of dimension $k \geq 3$. Then there exists a partition of the vertices of $G_{\mathcal{A}}$ into cliques $V = \biguplus_{i=1}^{t} V_i$, such that the following apply:*

1. (All nontrivial cliques are large) *For every $1 \leq i \leq t$, either $|V_i| = 1$ or $|V_i| > 2\sqrt{\epsilon}\,|V|$.*
2. (Almost all edges are within cliques)

$$\Pr_{s_1, s_2 \in V}\left[(s_1, s_2) \notin E_{\mathcal{A}} \ \vee \ \exists i \ s_1, s_2 \in V_i\right] \geq 1 - 5\sqrt{\epsilon}.$$

Proof. The proof follows by Lemma 7.1 and the combinatorial lemma of Raz and Safra [17] (for completeness we include a proof for this lemma; see Lemma A.1 in the appendix). □

A large clique in $G_{\mathcal{A}}$ corresponds to a single relatively low degree polynomial agreeing with the oracle $\mathcal{A}$ on all affine subspaces associated with the vertices in the clique.

LEMMA 7.3 (from large clique to polynomial). *Fix an oracle $\mathcal{A}$ assigning affine subspaces polynomials of degree at most d. Let $G_{\mathcal{A}} = (V, E_{\mathcal{A}})$ be its corresponding consistency graph for affine subspaces of dimension $k \geq 3$. Then, for every large clique $U \subseteq V$, $|U| > (\frac{2d}{|\mathbb{F}|} + \frac{1}{|\mathbb{H}|}) \cdot |V|$, there exists a polynomial $Q : \mathbb{F}^k \to \mathbb{F}$, with $\deg Q \leq 2d$, such that, for every $s \in U$, $(Q \equiv \mathcal{A})(s)$.*

Proof. For linearly independent $\vec{y}_1, \ldots, \vec{y}_{k-1} \in \mathbb{F}^k$, there are exactly $|\mathbb{F}|$ different hyperplanes of the form $\vec{z} + span\{\vec{y}_1, \ldots, \vec{y}_{k-1}\}$ for some $\vec{z} \in \mathbb{F}^k$. Let us denote their set by $\mathcal{H}[\vec{y}_1, \ldots, \vec{y}_{k-1}]$.

Pick uniformly at random linearly independent $\vec{y}_1, \ldots, \vec{y}_{k-1} \in \mathbb{H}^k$, and consider the random variable X denoting the fraction of hyperplanes in $\mathcal{H}[\vec{y}_1, \ldots, \vec{y}_{k-1}]$ that land in U.

By linearity of expectations,

$$\mathop{\mathbf{E}}_{\vec{y}_1, \ldots, \vec{y}_{k-1} \in \mathbb{H}^k \ : \ \mathsf{ind}(\vec{y}_1, \ldots, \vec{y}_{k-1})}[X] = \frac{|U|}{|V|} > \frac{2d}{|\mathbb{F}|} + \frac{1}{|\mathbb{H}|}.$$

Hence, since $0 \leq X \leq 1$,

$$\Pr_{\vec{y}_1, \ldots, \vec{y}_{k-1} \in \mathbb{H}^k}\left[X > \frac{2d}{|\mathbb{F}|} \ \middle| \ \mathsf{ind}(\vec{y}_1, \ldots, \vec{y}_{k-1})\right] > \frac{1}{|\mathbb{H}|}.$$

Let us say that linearly independent directions $\vec{y}_1, \ldots, \vec{y}_{k-1} \in \mathbb{H}^k$ are *good* if the number of hyperplanes in $\mathcal{H}[\vec{y}_1, \ldots, \vec{y}_{k-1}]$ that land in U is more than $2d$.

It follows from our calculations that there are good linearly independent directions $\vec{y}^1_1, \ldots, \vec{y}^1_{k-1} \in \mathbb{H}^k$. Fix any $\vec{y}^1_k \in \mathbb{H}^k$ that is not spanned by $\vec{y}^1_1, \ldots, \vec{y}^1_{k-1}$ (such necessarily exists since $k-1 < k$). Then there exist at least $(2d+1)$ scalars $c_0, \ldots, c_{2d} \in \mathbb{F}$ such that for every $0 \leq i \leq 2d$ we have $\mathrm{affine}(c_i \vec{y}^1_k; \vec{y}^1_1, \ldots, \vec{y}^1_{k-1}) \in U$.

But recall that we in fact established that, for uniformly distributed linearly independent $\vec{y}_1, \ldots, \vec{y}_{k-1} \in \mathbb{H}^k$, the probability that $\vec{y}_1, \ldots, \vec{y}_{k-1}$ are good is larger than $\frac{1}{|\mathbb{H}|}$. Thus (by using Proposition 3.2), for uniformly distributed linearly independent $\vec{y}^2_1, \ldots, \vec{y}^2_{k-1} \in \mathbb{H}^k$, the probability that $\vec{y}^2_1, \ldots, \vec{y}^2_{k-1}$ are good and $\vec{y}^1_1 \notin span\{\vec{y}^2_1, \ldots, \vec{y}^2_{k-1}\}$ is also positive.

Therefore, there necessarily exists a basis $\vec{y}_1, \ldots, \vec{y}_k \in \mathbb{H}^k$ for $\mathbb{F}^k$ as well as $2 \cdot (2d+1)$ scalars $c_0, \ldots, c_{2d}, c'_0, \ldots, c'_{2d} \in \mathbb{F}$ such that

$$\begin{aligned} s_0 &= \text{affine}(c_0\vec{y}_k; \vec{y}_1, \ldots, \vec{y}_{k-1}) \in U, \\ &\vdots \\ s_{2d} &= \text{affine}(c_{2d}\vec{y}_k; \vec{y}_1, \ldots, \vec{y}_{k-1}) \in U, \\ s'_0 &= \text{affine}(c'_0\vec{y}_1; \vec{y}_2, \ldots, \vec{y}_k) \in U, \\ &\vdots \\ s'_{2d} &= \text{affine}(c'_{2d}\vec{y}_1; \vec{y}_2, \ldots, \vec{y}_k) \in U. \end{aligned}$$

Let us define a polynomial $Q : \mathbb{F}^k \to \mathbb{F}$ such that, for every $0 \le i \le d$, $(Q \equiv \mathcal{A})(s_i)$. This is done by using Lagrange's interpolation formula:

$$Q\left(\sum_{i=1}^{k} \alpha_i \vec{y}_i\right) = \sum_{i=0}^{d} \frac{\prod_{j \in \{0,\ldots,d\}-\{i\}} (\alpha_k - c_j)}{\prod_{j \in \{0,\ldots,d\}-\{i\}} (c_i - c_j)} \cdot \mathcal{A}(s_i) \left(c_i \vec{y}_k + \sum_{j=1}^{k-1} \alpha_j \vec{y}_j\right).$$

The degree of Q in α_k is at most d, and its total degree is $\deg Q \le 2d$.

We would like to argue that, for every $s \in U$, $(Q \equiv \mathcal{A})(s)$. Let $0 \le j \le 2d$. For every line of the form $l = \text{affine}(\sum_{i=1}^{k-1} a_i \vec{y}_i; \vec{y}_k)$ contained in s'_j, the polynomial $Q_{|l}$ has degree at most d. Moreover, for every $0 \le i \le d$, $Q_{|l}$ and $\mathcal{A}(s'_j)$ identify on $l \cap s_i$. By the Schwartz–Zippel lemma, $Q_{|l}$ and $\mathcal{A}(s'_j)$ identify on the entire line l. Thus, for every $0 \le j \le 2d$, Q and $\mathcal{A}$ identify on s'_j. Hence, by the Schwartz–Zippel lemma, for every $0 \le j \le 2d$ (and not only for every $0 \le j \le d$), the polynomial Q (of degree at most $2d$) and $\mathcal{A}$ identify on s_j.

Let $s \in U$. Necessarily, s intersects the s_j's or the s'_j's (or both). Hence, $Q_{|s}$ and $\mathcal{A}(s)$ identify on more than $\frac{2d}{|\mathbb{F}|}$ of the points on s. $Q_{|s}$ is of degree at most $2d$. Thus, by the Schwartz–Zippel lemma, Q and $\mathcal{A}$ identify on s. □

The partition of $G_{\mathcal{A}}$ into cliques yields list decoding,

LEMMA 7.4 (hyperplane vs. hyperplane). *Fix an oracle $\mathcal{A}$ assigning affine subspaces polynomials of degree at most d. Let $G_{\mathcal{A}} = (V, E_{\mathcal{A}})$ be its corresponding consistency graph for affine subspaces of dimension $k \ge 3$. Then for any $\delta \ge 8\sqrt{\frac{d}{|\mathbb{F}|} + \frac{1}{|\mathbb{H}|}}$ there exists a list of polynomials $Q_1, \ldots, Q_t : \mathbb{F}^k \to \mathbb{F}$, $t \le \frac{4}{\delta}$, with $\deg Q_i \le 2d$, such that*

$$\Pr_{s_1, s_2 \in V}\left[(s_1, s_2) \notin E_{\mathcal{A}} \ \vee \ \exists i, \ (Q_i \equiv \mathcal{A})(s_1) \wedge (Q_i \equiv \mathcal{A})(s_2)\right] > 1 - \delta.$$

Proof. Consider the partition of Lemma 7.2. Let $S_1, \ldots, S_l$ denote the small cliques in this partition, i.e., cliques whose size is $|S_i| < \frac{\delta}{4}|V|$. Clearly,

$$\sum_{i=1}^{l} |S_i|^2 < \frac{\delta}{4}|V| \cdot \sum_{i=1}^{l} |S_i| \le \frac{\delta}{4}|V|^2.$$

Hence, $\Pr_{s_1,s_2\in V}[\exists i,\ s_1,s_2\in S_i] < \frac{\delta}{4}$. Let $L_1,\ldots,L_t$ be the set of all large cliques $|L_i| \geq \frac{\delta}{4}|V|$. We have $t \leq \frac{4}{\delta}$. Moreover,

$$\Pr_{s_1,s_2\in V}[(s_1,s_2)\notin E_{\mathcal{A}} \ \vee\ \exists i,\ s_1,s_2\in L_i] > 1-\frac{5}{8}\delta-\frac{1}{4}\delta > 1-\delta.$$

For every $1\leq i\leq t$, let $Q_i:\mathbb{F}^k\to\mathbb{F}$ be the polynomial associated with L_i according to Lemma 7.3. We have $\deg Q_i \leq 2d$ and

$$\Pr_{s_1,s_2\in V}[(s_1,s_2)\notin E_{\mathcal{A}} \ \vee\ \exists i,\ (Q_i\equiv\mathcal{A})(s_1)\wedge(Q_i\equiv\mathcal{A})(s_2)] > 1-\delta. \qquad \square$$

Note that the lemma is meaningful only when the *density* of the graph $|E_{\mathcal{A}}|/|V|^2$ is large enough with respect to δ; otherwise, the list might be empty. This corresponds to the fact that the oracle must assign the affine subspaces somewhat consistent polynomials if we wish to (list) decode.

8. Going up one dimension. Let $\mathcal{A}$ be an oracle assigning polynomials of degree at most d to affine subspaces in $\mathbb{F}^m$. Let us say that $\mathcal{A}$ is γ-*consistent* over subspaces of dimension k (we usually omit the dimensions when they are clear from the context) if

$$\mathop{\mathbf{E}}_{s\in\mathcal{S}_k^m}\left[\Pr_{\vec{x}\in s}[\mathcal{A}(s)(\vec{x})=\mathcal{A}(\vec{x})]\right]\geq\gamma.$$

Fix a dimension $k\geq 3$. Let $\mathcal{A}$ be an oracle assigning polynomials of degree at most d to affine subspaces in $\mathbb{F}^k$. In this section we prove that, if $\mathcal{A}$ is γ-consistent over affine subspaces of dimension $(k-1)$ in $\mathbb{F}^k$, there exists a polynomial $Q:\mathbb{F}^k\to\mathbb{F}$ of degree at most $2d$ that agrees with the oracle on almost γ of the points. This is done in three steps:

1. We use an argument of counting in several ways to transform our setting to one that resembles that of the consistency graph of section 7.
2. We use the analysis of the consistency graph to prove the claim we want while losing in the consistency parameter.
3. We fix the consistency parameter via the consistency consolidation of section 6.

The final result of this section is given in Lemma 8.3. This is also the only lemma in this section that is used outside it. Note that the degree parameter grows from d to $2d$, and we need to take care of that when we use this lemma.

8.1. From hyperplane vs. point to hyperplane vs. hyperplane. We start by showing that γ-consistency over hyperplanes implies that, for an average pair (s_1,s_2) of intersecting hyperplanes, $\mathcal{A}(s_1)$ and $\mathcal{A}(s_2)$ agree (with each other and with $\mathcal{A}$) on at least a γ^2 fraction of the points in the intersection of s_1 and s_2.

The proof uses repeatedly the trick of counting in several ways, which is made possible due to uniformity considerations (see section 4).

For an affine subspace $a\in\mathcal{S}_{k-2}^k$, denote the set of hyperplane pairs that intersect in a by $S_a \stackrel{def}{=} \left\{(s_1,s_2)\ \middle|\ s_1,s_2\in\mathcal{S}_{k-1}^k, s_1\cap s_2 = a\right\}$.

LEMMA 8.1 (counting in several ways). *If, for an oracle $\mathcal{A}$,*

$$\mathop{\mathbf{E}}_{s\in\mathcal{S}_{k-1}^k}\left[\Pr_{\vec{x}\in s}[\mathcal{A}(s)(\vec{x})=\mathcal{A}(\vec{x})]\right]\geq\gamma,$$

then

$$\mathop{\mathbf{E}}_{a\in\mathcal{S}^k_{k-2}}\left[\mathop{\mathbf{E}}_{(s_1,s_2)\in S_a}\left[\Pr_{\vec{x}\in a}\left[\mathcal{A}(s_1)(\vec{x})=\mathcal{A}(\vec{x})=\mathcal{A}(s_2)(\vec{x})\right]\right]\right]\geq\gamma^2-\frac{1}{|\mathbb{H}|}.$$

Proof. For an affine subspace $s\in\mathcal{S}^k_{k-1}$, an affine subspace of it $a\subset s$, $a\in\mathcal{S}^k_{k-2}$, and a point $\vec{x}\in a$, let $I_{s,a,\vec{x}}$ be the indicator variable of the event $\mathcal{A}(s)(\vec{x})=\mathcal{A}(\vec{x})$. By the premise and uniformity,

$$\mathop{\mathbf{E}}_{s}\left[\mathop{\mathbf{E}}_{a\subset s}\left[\mathop{\mathbf{E}}_{\vec{x}\in a}\left[I_{s,a,\vec{x}}\right]\right]\right]\geq\gamma.$$

By uniformity, we can also count in a different way and obtain

$$\mathop{\mathbf{E}}_{a}\left[\mathop{\mathbf{E}}_{\vec{x}\in a}\left[\mathop{\mathbf{E}}_{s\supset a}\left[I_{s,a,\vec{x}}\right]\right]\right]\geq\gamma.$$

By convexity considerations,

$$\mathop{\mathbf{E}}_{a}\left[\mathop{\mathbf{E}}_{\vec{x}\in a}\left[\left(\mathop{\mathbf{E}}_{s\supset a}\left[I_{s,a,\vec{x}}\right]\right)^2\right]\right]\geq\gamma^2,$$

or, in other words,

$$\mathop{\mathbf{E}}_{a}\left[\mathop{\mathbf{E}}_{\vec{x}\in a}\left[\mathop{\mathbf{E}}_{s_1,s_2\supset a}\left[I_{s_1,a,\vec{x}}I_{s_2,a,\vec{x}}\right]\right]\right]\geq\gamma^2.$$

We can change the order of summation once again, and get

$$\mathop{\mathbf{E}}_{a}\left[\mathop{\mathbf{E}}_{s_1,s_2\supset a}\left[\mathop{\mathbf{E}}_{\vec{x}\in a}\left[I_{s_1,a,\vec{x}}I_{s_2,a,\vec{x}}\right]\right]\right]\geq\gamma^2.$$

The lemma follows by using uniformity and noticing that the probability that $s_1=s_2$ given that $s_1,s_2\supset a$ is at most $\frac{1}{|\mathbb{H}|}$. □

8.2. Hyperplane vs. point lemma. Next, we show that considerable consistency between $(k-1)$-dimensional affine subspaces and points implies a significant correspondence of the values assigned to points with a relatively low degree polynomial over $\mathbb{F}^k$. The heart of the proof is the analysis of the consistency graph (Lemma 7.4).

LEMMA 8.2 (hyperplane vs. point). *Assume that $\mathcal{A}$ assigns polynomials of degree at most d to affine subspaces. Fix $\delta\stackrel{def}{=}16\max\{\sqrt{\frac{d}{|\mathbb{F}|}},\sqrt[4]{\frac{1}{|\mathbb{H}|}}\}$. Assume that*

$$\mathop{\mathbf{E}}_{s\in\mathcal{S}^k_{k-1}}\left[\Pr_{\vec{x}\in s}\left[\mathcal{A}(s)(\vec{x})=\mathcal{A}(\vec{x})\right]\right]\geq\gamma.$$

Then there exists a polynomial $Q:\mathbb{F}^k\to\mathbb{F}$, with $\deg Q\leq 2d$, such that

$$\Pr_{\vec{x}\in\mathbb{F}^k}\left[Q(\vec{x})=\mathcal{A}(\vec{x})\right]\geq\gamma^2-3\delta.$$

Proof. Lemma 8.1 allows us to translate the consistency given in this lemma to consistency between pairs of hyperplanes on points:

$$\mathop{\mathbf{E}}_{a\in\mathcal{S}^k_{k-2}}\left[\mathop{\mathbf{E}}_{(s_1,s_2)\in S_a}\left[\Pr_{\vec{x}\in a}\left[\mathcal{A}(s_1)(\vec{x})=\mathcal{A}(\vec{x})=\mathcal{A}(s_2)(\vec{x})\right]\right]\right]\geq\gamma^2-\frac{1}{|\mathbb{H}|}.$$

Lemma 7.4 gives list decoding $Q_1, \ldots, Q_t : \mathbb{F}^k \to \mathbb{F}$, $\deg Q_i \leq 2d$, $t \leq \frac{4}{\delta}$, for consistency among pairs of hyperplanes. We wish to argue that at least one of these polynomials also agrees with the oracle on many of the points.

Let us define an appropriate notation. Choose independently and uniformly at random a subspace $a \in \mathcal{S}^k_{k-2}$, hyperplanes that intersect on a, $(s_1, s_2) \in S_a$, and a point $\vec{x} \in a$. Define the following events:

1. X: $\mathcal{A}(s_1)(\vec{x}) = \mathcal{A}(\vec{x}) = \mathcal{A}(s_2)(\vec{x})$ *(hyperplanes are consistent on (and with) a point).*
2. C: $(s_1, s_2) \in E_{\mathcal{A}}$ *(hyperplanes are consistent).*
3. E: $\exists i\ (Q_i \equiv \mathcal{A})(s_1) \wedge (Q_i \equiv \mathcal{A})(s_2)$ *(hyperplanes are explained).*

By using this notation we have $\Pr_{a,s_1,s_2,\vec{x}}[X] \geq \gamma^2 - \frac{1}{|\mathbb{H}|}$. By uniformity, s_1, s_2 are uniformly distributed over the set of all pairs with $s_1 \cap s_2 \in \mathcal{S}^k_{k-2}$. Since for a uniformly distributed pair $s_1, s_2 \in V$, the probability that $s_1 \cap s_2 \notin \mathcal{S}^k_{k-2}$ is bounded by $\frac{1}{|\mathbb{H}|}$ (see Proposition 3.2), the list decoding translates into

$$\Pr_{s_1,s_2}[\neg C \vee E] \geq 1 - \delta - \frac{1}{|\mathbb{H}|}.$$

$\vec{x}$ is uniformly distributed within $s_1 \cap s_2$. Hence, by the Schwartz–Zippel lemma, $\Pr_{a,s_1,s_2,\vec{x}}[X|\neg C] \leq \frac{d}{|\mathbb{F}|}$. Therefore, the probability that s_1, s_2 are consistent on $\vec{x}$ but not explained is small:

$$\begin{aligned}
\Pr_{a,s_1,s_2,\vec{x}}[X \wedge \neg E] &= \Pr_{a,s_1,s_2,\vec{x}}[C \wedge X \wedge \neg E] + \Pr_{a,s_1,s_2,\vec{x}}[\neg C \wedge X \wedge \neg E] \\
&\leq \Pr_{s_1,s_2}[C \wedge \neg E] + \Pr_{a,s_1,s_2,\vec{x}}[\neg C \wedge X] \\
&\leq 1 - \Pr_{s_1,s_2}[\neg C \vee E] + \Pr_{a,s_1,s_2,\vec{x}}[X|\neg C] \\
&\leq \delta + \frac{1}{|\mathbb{H}|} + \frac{d}{|\mathbb{F}|}.
\end{aligned}$$

Thus, the probability that s_1, s_2 are consistent on $\vec{x}$ and are explained is large:

$$\begin{aligned}
\Pr_{a,s_1,s_2,\vec{x}}[X \wedge E] &\geq \Pr_{a,s_1,s_2,\vec{x}}[X] - \Pr_{a,s_1,s_2,\vec{x}}[X \wedge \neg E] \\
&\geq \gamma^2 - \frac{1}{|\mathbb{H}|} - \delta - \frac{1}{|\mathbb{H}|} - \frac{d}{|\mathbb{F}|} \\
&\geq \gamma^2 - 2\delta. \qquad (8.1)
\end{aligned}$$

Let us define a *distributional oracle* $\widetilde{\mathcal{A}}$, assigning each affine subspace $a \in \mathcal{S}^k_{k-2}$, a distribution over polynomials of degree at most d over a (for clarification of our notion of distributional oracles, see the discussion before Lemma 6.3). To define the distribution $\widetilde{\mathcal{A}}(a)$, we indicate how to sample a polynomial accordingly:

- Pick uniformly at random hyperplanes that intersect on a, $(s_1, s_2) \in S_a$.
- If there is i such that $(Q_i \equiv \mathcal{A})(s_1)$ and $(Q_i \equiv \mathcal{A})(s_2)$, output the restriction of Q_i to a (note that if there are two (or more) such polynomials, they must identify on a).
- Otherwise, output a *null* polynomial.

If $\widetilde{\mathcal{A}}(a)$ is not null, then there exists i such that $(Q_i \equiv \widetilde{\mathcal{A}})(a)$, while if $\widetilde{\mathcal{A}}(a)$ is null, $\widetilde{\mathcal{A}}(a)(\vec{x}) \neq \mathcal{A}(\vec{x})$ for every $\vec{x} \in a$. Thus,

$$\mathop{\mathbf{E}}_{\widetilde{\mathcal{A}}}\left[\mathop{\mathbf{E}}_{a \in \mathcal{S}^k_{k-2}}\left[\Pr_{\vec{x} \in a}\left[\widetilde{\mathcal{A}}(a)(\vec{x}) \neq \mathcal{A}(\vec{x}) \vee\ \exists i\ (Q_i \equiv \widetilde{\mathcal{A}})(a)\right]\right]\right] = 1.$$

By the construction of $\widetilde{\mathcal{A}}$ and inequality (8.1), $\widetilde{\mathcal{A}}$ is $(\gamma^2 - 2\delta)$-consistent with $\mathcal{A}$:

$$\mathop{\mathbf{E}}_{\widetilde{\mathcal{A}}}\left[\mathop{\mathbf{E}}_{a\in\mathcal{S}^k_{k-2}}\left[\Pr_{\vec{x}\in a}\left[\widetilde{\mathcal{A}}(a)(\vec{x}) = \mathcal{A}(\vec{x})\right]\right]\right] \geq \gamma^2 - 2\delta.$$

By Corollary 5.7, the uniform distribution on $\mathcal{S}^k_{k-2}$ samples well: for every set $A \subseteq \mathbb{F}^k$, for every $0 < \varepsilon < 1$,

$$\Pr_{a\in\mathcal{S}^k_{k-2}}\left[\left|\frac{|a\cap A|}{|a|} - \frac{|A|}{|\mathbb{F}^k|}\right| \geq \varepsilon\right] \leq \frac{1}{\varepsilon^2\,|\mathbb{H}|}.$$

Thus, by Lemma 6.3, since $\frac{\delta}{2} \geq t\cdot\frac{4}{\delta^2|\mathbb{H}|}$, there exists $1 \leq i \leq t$ such that

$$\Pr_{\vec{x}\in\mathbb{F}^k}[Q_i(\vec{x}) = \mathcal{A}(\vec{x})] \geq \gamma^2 - 3\delta. \qquad \square$$

8.3. Consolidating. We can apply consistency consolidation to improve the result of the last subsection. The following summarizes what we establish in this section.

LEMMA 8.3 (consistency consolidated). *Denote* $\theta_0 \stackrel{def}{=} 2^4\cdot(\sqrt[8]{\frac{1}{|\mathbb{H}|}} + \sqrt[4]{\frac{d}{|\mathbb{F}|}})$. *Fix* $k \geq 3$. *Fix an oracle* $\mathcal{A}$ *assigning polynomials of degree at most* d *to all affine subspaces. Assume that*

$$\mathop{\mathbf{E}}_{s\in\mathcal{S}^k_{k-1}}\left[\Pr_{\vec{x}\in s}[\mathcal{A}(s)(\vec{x}) = \mathcal{A}(\vec{x})]\right] \geq \gamma.$$

Then there exists a polynomial $Q : \mathbb{F}^k \to \mathbb{F}$, *with* $\deg Q \leq 2d$, *such that*

$$\Pr_{\vec{x}\in\mathbb{F}^k}[Q(\vec{x}) = \mathcal{A}(\vec{x})] \geq \gamma - 2\theta_0.$$

Proof. Assume that $\theta_0 \leq 1$ (otherwise, the claim trivially holds). Denote $\epsilon_0 = \sqrt{\frac{2d}{|\mathbb{F}|}}$ and $\delta_0 = 16\max\{\sqrt{\frac{d}{|\mathbb{F}|}}, \sqrt[4]{\frac{1}{|\mathbb{H}|}}\}$. Define $f(\gamma) \stackrel{def}{=} \gamma^2 - 3\delta_0$. It holds that

$$f(\theta_0 - \epsilon_0) - \epsilon_0 = (\theta_0 - \epsilon_0)^2 - 3\delta_0 - \epsilon_0 \geq \theta_0^2/2,$$

where $\theta_0^2/2 \geq 2\epsilon_0$. Apply Lemma 6.1 on Lemma 8.2 to deduce the existence of $t \leq 4/\theta_0^2$ polynomials $Q_1, \ldots, Q_t : \mathbb{F}^k \to \mathbb{F}$, with $\deg Q_i \leq 2d$, such that

$$\mathop{\mathbf{E}}_{s\in\mathcal{S}^k_{k-1}}\left[\Pr_{\vec{x}\in s}[\mathcal{A}(s)(\vec{x}) \neq \mathcal{A}(\vec{x}) \ \vee\ \exists i(Q_i \equiv \mathcal{A})(s)]\right] \geq 1 - \theta_0.$$

For $\varepsilon = \frac{\theta_0}{2}$, we have $\varepsilon \geq \frac{t}{\varepsilon^2|\mathbb{H}|}$. Thus, by Lemma 6.3 (by using sampling Corollary 5.7), there exists $1 \leq i \leq t$ such that

$$\Pr_{\vec{x}\in\mathbb{F}^k}[Q_i(\vec{x}) = \mathcal{A}(\vec{x})] \geq \gamma - 2\theta_0. \qquad \square$$

9. The randomness-efficient plane vs. point tester is sound. We wish to show that, if the average consistency between planes and points is large, the oracle assigns points values that are close to a low degree polynomial. Theorem 1 will follow.

LEMMA 9.1 (from dimension 2 to dimension k). *Denote* $\theta_k \stackrel{def}{=} 2^4(\sqrt[4]{\frac{kd}{|\mathbb{F}|}} + \sqrt[8]{\frac{1}{|\mathbb{H}|}})$. *For every dimension* $k \geq 2$, *for every* $0 < \gamma \leq 1$ *and oracle* $\mathcal{A}$, *if*

$$\mathop{\mathbf{E}}_{s \in \mathcal{S}_2^k} \left[\Pr_{\vec{x} \in s} [\mathcal{A}(s)(\vec{x}) = \mathcal{A}(\vec{x})] \right] \geq \gamma,$$

then there exists a polynomial $Q : \mathbb{F}^k \to \mathbb{F}$ *with* $\deg Q \leq kd$ *such that*

$$\Pr_{\vec{x} \in \mathbb{F}^k} [Q(\vec{x}) = \mathcal{A}(\vec{x})] \geq \gamma - (8k-10)\theta_k.$$

Proof. We prove the lemma by induction on k. Let us formulate two inductive claims. The second argues what we wish to show. The first argues slightly better consistency but worse degree.

$Claim_1[k]$. For every $0 < \gamma \leq 1$ and oracle $\mathcal{A}$, if

$$\mathop{\mathbf{E}}_{s \in \mathcal{S}_2^k} \left[\Pr_{\vec{x} \in s} [\mathcal{A}(s)(\vec{x}) = \mathcal{A}(\vec{x})] \right] \geq \gamma,$$

then there exists a polynomial $Q : \mathbb{F}^k \to \mathbb{F}$, with $\deg Q \leq 2(k-1)d$, such that

$$\Pr_{\vec{x} \in \mathbb{F}^k} [Q(\vec{x}) = \mathcal{A}(\vec{x})] \geq \gamma - (8k-16)\theta_k.$$

$Claim_2[k]$. For every $0 < \gamma \leq 1$ and oracle $\mathcal{A}$, if

$$\mathop{\mathbf{E}}_{s \in \mathcal{S}_2^k} \left[\Pr_{\vec{x} \in s} [\mathcal{A}(s)(\vec{x}) = \mathcal{A}(\vec{x})] \right] \geq \gamma,$$

then there exists a polynomial $Q : \mathbb{F}^k \to \mathbb{F}$, with $\deg Q \leq kd$, such that

$$\Pr_{\vec{x} \in \mathbb{F}^k} [Q(\vec{x}) = \mathcal{A}(\vec{x})] \geq \gamma - (8k-10)\theta_k.$$

$Claim_1[2]$ holds by taking Q to be $\mathcal{A}(s)$ for the only plane s. Hence, the lemma will follow if we prove that, for every $k \geq 2$,

$$Claim_1[k] \;\Rightarrow\; Claim_2[k] \;\Rightarrow\; Claim_1[k+1].$$

CLAIM 9.1.1. $Claim_1[k] \Rightarrow Claim_2[k]$.

Proof. Fix $0 < \gamma \leq 1$ and oracle $\mathcal{A}$ such that

$$\mathop{\mathbf{E}}_{s \in \mathcal{S}_2^k} \left[\Pr_{\vec{x} \in s} [\mathcal{A}(s)(\vec{x}) = \mathcal{A}(\vec{x})] \right] \geq \gamma.$$

Assume that $(8k-10)\theta_k \leq 1$ (otherwise, we are done). Denote $\epsilon_0 = \sqrt{2(k-1)d/|\mathbb{F}|}$. Define $f(\gamma) \stackrel{def}{=} \gamma - (8k-16)\theta_k$. Let $\delta = (8k-14)\theta_k$. It holds that

$$f(\delta - \epsilon_0) - \epsilon_0 = (8k-14)\theta_k - \epsilon_0 - (8k-16)\theta_k - \epsilon_0 \geq \theta_k,$$

where $\theta_k \geq 2\epsilon_0$. By Lemmas 6.1 and 6.2 applied on $Claim_1[k]$, there exist $t \leq 2/\theta_k$ polynomials $Q_1, \ldots, Q_t : \mathbb{F}^k \to \mathbb{F}$, $\deg Q_i \leq 2(k-1)d$, such that

1. *(each agrees with many planes)* for every $1 \le i \le t$,

$$\Pr_{s \in \mathcal{S}_2^k}[(Q_i \equiv \mathcal{A})(s)] \ge \frac{\theta_k}{t} > \frac{2(k-1)d}{|\mathbb{F}|} + \frac{1}{|\mathbb{H}|};$$

2. *(all explain almost all of the consistency)*

$$\mathop{\mathbf{E}}_{s \in \mathcal{S}_2^k}\left[\Pr_{\vec{x} \in s}[\mathcal{A}(s)(\vec{x}) \neq \mathcal{A}(\vec{x}) \vee \exists i\ (Q_i \equiv \mathcal{A})(s)]\right] \ge 1 - \delta - \theta_k.$$

By Lemma 6.5, for every $1 \le i \le t$, $\deg Q_i \le kd$. By Lemma 6.3 (by using sampling Corollary 5.7), there exists $1 \le i \le t$ such that

$$\Pr_{\vec{x} \in \mathbb{F}^k}[Q_i(\vec{x}) = \mathcal{A}(\vec{x})] \ge \gamma - (8k-10)\theta_k. \qquad \square$$

CLAIM 9.1.2. *$Claim_2[k] \Rightarrow Claim_1[k+1]$.*

Proof. Fix $0 < \gamma \le 1$ and oracle $\mathcal{A}$ such that

$$\mathop{\mathbf{E}}_{s \in \mathcal{S}_2^{k+1}}\left[\Pr_{\vec{x} \in s}[\mathcal{A}(s)(\vec{x}) = \mathcal{A}(\vec{x})]\right] \ge \gamma.$$

Let $s \in \mathcal{S}_k^{k+1}$. Define an oracle relative to s, $\mathcal{A}_s$, as follows: for every affine subspace $s' = \mathrm{affine}(r)$ in $\mathbb{F}^k$ (this includes the points in $\mathbb{F}^k$), let $\mathcal{A}_s(s') \stackrel{def}{=} \mathcal{A}(\mathrm{affine}_s(r))$ (the notation affine_s was introduced in section 4). Let the *consistency within s* be

$$\gamma_s \stackrel{def}{=} \mathop{\mathbf{E}}_{s' \in \mathcal{S}_2^k}\left[\Pr_{\vec{x} \in s'}[\mathcal{A}_s(s')(\vec{x}) = \mathcal{A}_s(\vec{x})]\right].$$

By uniformity, the *average* consistency within $s \in \mathcal{S}_k^{k+1}$ is large:

$$\mathop{\mathbf{E}}_{s \in \mathcal{S}_k^{k+1}}[\gamma_s] = \mathop{\mathbf{E}}_{s' \in \mathcal{S}_2^{k+1}}\left[\Pr_{\vec{x} \in s'}[\mathcal{A}(s')(\vec{x}) = \mathcal{A}(\vec{x})]\right] \ge \gamma.$$

$Claim_2[k]$ implies the existence of a new oracle $\mathcal{A}'$ that assigns each hyperplane $s \in \mathcal{S}_k^{k+1}$ a polynomial of degree at most kd that agrees with $\mathcal{A}$ on at least $\gamma_s - (8k-10)\theta_k$ of its points. It holds that

$$\mathop{\mathbf{E}}_{s \in \mathcal{S}_k^{k+1}}\left[\Pr_{\vec{x} \in s}[\mathcal{A}'(s)(\vec{x}) = \mathcal{A}(\vec{x})]\right] \ge \mathop{\mathbf{E}}_{s \in \mathcal{S}_k^{k+1}}[\gamma_s - (8k-10)\theta_k] \ge \gamma - (8k-10)\theta_k.$$

By Lemma 8.3, there exists a polynomial $Q : \mathbb{F}^{k+1} \to \mathbb{F}$, with $\deg Q \le 2kd$, such that

$$\Pr_{\vec{x} \in \mathbb{F}^{k+1}}[Q(\vec{x}) = \mathcal{A}(\vec{x})] \ge \gamma - (8(k+1)-16)\theta_{k+1}. \qquad \square$$

Lemma 9.1 follows by induction. $\square$

The soundness of the randomness-efficient plane vs. point tester easily follows.

Proof (of Theorem 1). Assume that

$$\Pr_{\vec{z} \in \mathbb{F}^m, \vec{y}_1, \vec{y}_2 \in \mathbb{H}^m}\left[PlanePoint^{\mathcal{A}}(\vec{z}, \vec{y}_1, \vec{y}_2)\right] = \gamma.$$

The probability that $\vec{y}_1, \vec{y}_2$ are linearly dependent is at most $\frac{1}{|\mathbb{H}|^m} + \frac{1}{|\mathbb{H}|^{m-1}} \leq \frac{2}{|\mathbb{H}|}$. Thus,

$$\mathop{\mathbf{E}}_{s \in \mathcal{S}_2^m} \left[\Pr_{\vec{x} \in s} \left[\mathcal{A}(s)(\vec{x}) = \mathcal{A}(\vec{x}) \right] \right] \geq \gamma - \frac{2}{|\mathbb{H}|}.$$

By Lemma 9.1, we have decoding: there exists a polynomial $Q : \mathbb{F}^m \to \mathbb{F}$, with $\deg Q \leq md$, such that

$$\Pr_{\vec{x} \in \mathbb{F}^m} \left[Q(\vec{x}) = \mathcal{A}(\vec{x}) \right] \geq \gamma - \varepsilon.$$

By Lemma 6.1, we have list decoding: for every δ, $\delta > 2\varepsilon$, there exist $t \leq 2/\delta$ polynomials $Q_1, \ldots, Q_t : \mathbb{F}^m \to \mathbb{F}$, with $\deg Q_i \leq md$, such that

$$\mathop{\mathbf{E}}_{s \in \mathcal{S}_2^m} \left[\Pr_{\vec{x} \in s} \left[\mathcal{A}(s)(\vec{x}) \neq \mathcal{A}(\vec{x}) \ \vee \ \exists i \ (Q_i \equiv \mathcal{A})(s) \right] \right] \geq 1 - \delta - 2\varepsilon + \frac{2}{|\mathbb{H}|}.$$

Therefore,

$$\Pr_{\vec{z} \in \mathbb{F}^m, \vec{y}_1, \vec{y}_2 \in \mathbb{H}^m} \left[\neg PlanePoint^{\mathcal{A}}(\vec{z}, \vec{y}_1, \vec{y}_2) \ \vee \ \exists i \ (Q_i \equiv \mathcal{A})(\mathrm{affine}(\vec{z}; \vec{y}_1, \vec{y}_2)) \right] \geq 1 - \delta - 2\varepsilon.$$

The proof is complete. □

10. The randomness-efficient subspace vs. point tester is sound. In this section we use the result from the previous section, namely, the soundness of the randomness-efficient plane vs. point tester, to prove the soundness of the subspace vs. point tester.

Consider the distribution $\mathcal{D}$ over three-dimensional affine subspaces induced by the tester: pick uniformly $\vec{z} \in \mathbb{F}^m, \vec{y}_1, \vec{y}_2 \in \mathbb{H}^m$ such that $\vec{z}, \vec{y}_1, \vec{y}_2$ are linearly independent, and output $\mathrm{affine}(\vec{0}; \vec{z}, \vec{y}_1, \vec{y}_2)$.

LEMMA 10.1 (from plane vs. point to subspace vs. point). *Fix dimension $m \geq 3$. Fix $\varepsilon \stackrel{def}{=} 2^7 m(\sqrt[4]{\frac{md}{|\mathbb{F}|}} + \sqrt[8]{\frac{1}{|\mathbb{H}|}})$. If an oracle $\mathcal{A}$ assigning polynomials of degree at most d to affine subspaces satisfies*

$$\mathop{\mathbf{E}}_{s \sim \mathcal{D}} \left[\Pr_{\vec{x} \in s} \left[\mathcal{A}(s)(\vec{x}) = \mathcal{A}(\vec{x}) \right] \right] \geq \gamma,$$

then there exists a polynomial $Q : \mathbb{F}^m \to \mathbb{F}$, with $\deg Q \leq md$, such that

$$\Pr_{\vec{x} \in \mathbb{F}^m} \left[Q(\vec{x}) = \mathcal{A}(\vec{x}) \right] \geq \gamma - \varepsilon.$$

Proof. Let us construct a new oracle $\mathcal{A}'$. For every plane $p \in \mathcal{S}_2^m$ that does not contain the origin, let $\mathcal{A}'(p)$ be the restriction of $\mathcal{A}(s)$ to p, where s is the unique three-dimensional linear subspace that contains p. Let $\mathcal{A}'$ identify with $\mathcal{A}$ on all other affine subspaces.

For a subspace $s \sim \mathcal{D}$, $s = \mathrm{affine}(\vec{0}; \vec{z}, \vec{y}_1, \vec{y}_2)$, and a random scalar $\alpha \in \mathbb{F}$, let $s_\alpha = \mathrm{affine}(\alpha\vec{z}; \vec{y}_1, \vec{y}_2)$. Clearly, the premise implies that

$$\mathop{\mathbf{E}}_{s, \alpha} \left[\Pr_{\vec{x} \in s_\alpha} \left[\mathcal{A}(s)(\vec{x}) = \mathcal{A}(\vec{x}) \right] \right] \geq \gamma.$$

The plane s_α is distributed as follows: with probability $\frac{1}{|\mathbb{F}|}$, s_α is uniformly distributed within the planes in $\mathcal{S}_2^m$ that contain the origin; with probability $1-\frac{1}{|\mathbb{F}|}$, s_α is uniformly distributed within the planes in $\mathcal{S}_2^m$ that do not contain the origin.

Hence, by noticing that a uniformly distributed plane in $\mathcal{S}_2^m$ contains the origin with probability $\frac{|\mathbb{F}|^2}{|\mathbb{F}|^m} \leq \frac{1}{|\mathbb{F}|}$,

$$\mathop{\mathbf{E}}_{p\in\mathcal{S}_2^m}\left[\Pr_{\vec{x}\in p}\left[\mathcal{A}'(p)(\vec{x})=\mathcal{A}(\vec{x})\right]\right] \geq \gamma - \frac{1}{|\mathbb{F}|}.$$

By Lemma 9.1, there exists a polynomial $Q:\mathbb{F}^m\to\mathbb{F}$, with $\deg Q \leq md$, such that

$$\Pr_{\vec{x}\in\mathbb{F}^m}\left[Q(\vec{x})=\mathcal{A}(\vec{x})\right] \geq \gamma-\varepsilon. \qquad \square$$

Now we can apply degree consolidation and get the following.

LEMMA 10.2 (degree consolidated). *Fix dimension $m \geq 3$. Fix $\varepsilon \stackrel{def}{=} 2^7 m(\sqrt[4]{\frac{md}{|\mathbb{F}|}} + \sqrt[8]{\frac{1}{|\mathbb{H}|}})$. If an oracle $\mathcal{A}$ assigning polynomials of degree at most d to affine subspaces satisfies*

$$\mathop{\mathbf{E}}_{s\sim\mathcal{D}}\left[\Pr_{\vec{x}\in s}\left[\mathcal{A}(s)(\vec{x})=\mathcal{A}(\vec{x})\right]\right] \geq \gamma,$$

then there exists a polynomial $Q:\mathbb{F}^m\to\mathbb{F}$, with $\deg Q \leq d$, such that

$$\Pr_{\vec{x}\in\mathbb{F}^m}\left[Q(\vec{x})=\mathcal{A}(\vec{x})\right] \geq \gamma - 2\varepsilon.$$

Proof. Assume that $\varepsilon \leq \frac{1}{2}$ (otherwise, we are done). Denote $\epsilon_0 = \sqrt{\frac{md}{|\mathbb{F}|}}$, $\delta = 1.5\varepsilon - \epsilon_0$. By applying Lemmas 6.1 and 6.2 on Lemma 10.1, we know that there exist $t \leq 8/\varepsilon$ polynomials $Q_1,\ldots,Q_t:\mathbb{F}^m\to\mathbb{F}$, with $\deg Q_i \leq md$, such that

1. *(each agrees with many planes)* for every $1\leq i\leq t$,

$$\Pr_{s\sim\mathcal{D}}\left[(Q_i\equiv\mathcal{A})(s)\right] > \frac{\epsilon_0}{t} \geq \frac{md}{|\mathbb{F}|}+\frac{1}{|\mathbb{F}|};$$

2. *(all explain almost all of the consistency)*

$$\mathop{\mathbf{E}}_{s\sim\mathcal{D}}\left[\Pr_{\vec{x}\in s}\left[\mathcal{A}(s)(\vec{x})\neq\mathcal{A}(\vec{x})\vee\exists i(Q_i\equiv\mathcal{A})(s)\right]\right] \geq 1-\delta-\epsilon_0.$$

By Lemma 6.4, for every $1\leq i\leq t$, $\deg Q_i \leq d$. By Corollary 5.9, $\mathcal{D}$ samples well: for every set $A\subseteq\mathbb{F}^m$, for every $0<\epsilon<1$,

$$\Pr_{s\sim\mathcal{D}}\left[\left|\frac{|s\cap A|}{|s|}-\frac{|A|}{|\mathbb{F}^m|}\right|\geq\epsilon\right] \leq \frac{1}{\epsilon^2}\cdot\left(\frac{1}{|\mathbb{H}|}+\frac{1}{|\mathbb{F}|}\right).$$

Hence, by Lemma 6.3, there exists $1\leq i\leq t$ such that

$$\Pr_{\vec{x}\in\mathbb{F}^m}\left[Q_i(\vec{x})=\mathcal{A}(\vec{x})\right] \geq \gamma-2\varepsilon. \qquad \square$$

Our main theorem stating the soundness of the randomness efficient subspace vs. point tester follows.

Proof (of Theorem 2). Assume that

$$\Pr_{\vec{z}\in\mathbb{F}^m,\vec{y}_1,\vec{y}_2\in\mathbb{H}^m}\left[SpacePoint^{\mathcal{A}}(\vec{z},\vec{y}_1,\vec{y}_2)\right]=\gamma.$$

The probability that $\vec{z},\vec{y}_1,\vec{y}_2$ are linearly dependent is very small:

$$\Pr_{\vec{z}\in\mathbb{F}^m,\vec{y}_1,\vec{y}_2\in\mathbb{H}^m}\left[\neg\mathsf{ind}(\vec{z},\vec{y}_1,\vec{y}_2)\right]\le\frac{1}{|\mathbb{H}|^m}+\frac{1}{|\mathbb{H}|^{m-1}}+\frac{1}{|\mathbb{F}|^{m-2}}\le\frac{2}{|\mathbb{H}|}+\frac{1}{|\mathbb{F}|}.$$

Hence,

$$\mathop{\mathbf{E}}_{s\sim\mathcal{D}}\left[\Pr_{\vec{x}\in s}\left[\mathcal{A}(s)(\vec{x})=\mathcal{A}(\vec{x})\right]\right]\ge\gamma-\frac{2}{|\mathbb{H}|}-\frac{2}{|\mathbb{F}|}.$$

By Lemma 10.2 we have decoding: there exists a polynomial $Q:\mathbb{F}^m\to\mathbb{F}$, with $\deg Q\le d$, such that

$$\Pr_{\vec{x}\in\mathbb{F}^m}\left[Q(\vec{x})=\mathcal{A}(\vec{x})\right]\ge\gamma-2.5\varepsilon.$$

Lemma 6.1 applied on Lemma 10.2 gives list decoding: there exist $t\le 2/\delta$ polynomials $Q_1,\ldots,Q_t:\mathbb{F}^m\to\mathbb{F}$, with $\deg Q_i\le d$, such that

$$\mathop{\mathbf{E}}_{s\sim\mathcal{D}}\left[\Pr_{\vec{x}\in s}\left[\mathcal{A}(s)(\vec{x})\ne\mathcal{A}(\vec{x})\ \vee\ \exists i\ (Q_i\equiv\mathcal{A})(s)\right]\right]\ge 1-\delta-2.75\varepsilon.$$

Therefore,

$$\Pr_{\vec{z}\in\mathbb{F}^m,\vec{y}_1,\vec{y}_2\in\mathbb{H}^m}\left[\neg SpacePoint^{\mathcal{A}}(\vec{z},\vec{y}_1,\vec{y}_2)\ \vee\ \exists i\ (Q_i\equiv\mathcal{A})(\mathrm{affine}(\vec{0};\vec{z},\vec{y}_1,\vec{y}_2))\right]\ge 1-\delta-3\varepsilon.$$

The proof is complete. □

Appendix A. Combinatorial lemma. Let us prove the lemma of Raz and Safra [17] that we use. First, let us introduce several notations. Given a graph $G=(V,E)$ and a vertex $v\in V$, the *neighbors* of v are $\mathcal{N}_G(v)\stackrel{def}{=}\{u\in V\mid(v,u)\in E\}$. The *degree* of v is $d_G(v)\stackrel{def}{=}|\mathcal{N}_G(v)|$. The *connected component* of v is $C_G(v)\stackrel{def}{=}\{u\in V\mid u\text{ is reachable from }v\}$. The nonneighbors of v within its connected component are denoted by $\mathcal{D}_G(v)\stackrel{def}{=}C_G(v)\setminus(\{v\}\cup\mathcal{N}_G(v))$.

Lemma A.1 (graph partition [17]). *Let $G=(V,E)$ be an undirected graph in which every two nonneighbors $u,v\in V$, $(u,v)\notin E$, have at most $\epsilon|V|$ common neighbors. Then there exists a partition of the vertices into cliques $V=\biguplus_{i=1}^{t}V_i$ such that the following apply:*

1. (All nontrivial cliques are large) *For every $1\le i\le t$, either $|V_i|=1$, or $|V_i|>2\sqrt{\epsilon}\,|V|$.*
2. (Almost all edges are within cliques)

$$\Pr_{u,v\in V}\left[(u,v)\notin E\ \vee\ \exists i\ u,v\in V_i\right]\ge 1-5\sqrt{\epsilon}.$$

Proof. Consider the following operation on graphs, meant to improve transitivity by removing some edges: Pick a vertex $v\in V$.

1. If $d_G(v)\le 2\sqrt{\epsilon}\,|V|$, remove all of the edges that touch v.

2. If $d_G(v) > 2\sqrt{\epsilon}\,|V|$, remove all edges between neighbors of v and nonneighbors of v (these edges are necessarily within v's connected component).

If there is no vertex for which this operation causes removal of edges, then the graph is necessarily transitive, and, moreover, all of its nontrivial cliques are of size more than $2\sqrt{\epsilon}\,|V|$.

Hence, iteratively perform this operation, picking each time an arbitrary vertex for which edges would be removed, until this is no longer possible. Let $v_1, v_2, \ldots, v_l$ denote the picked (not necessarily distinct) vertices. Let $G_1, G_2, \ldots, G_l$ denote the subgraphs obtained in the l iterations. Let I_1 be the set of all indices $1 \le i \le l$ in which step 1 was performed. Let I_2 be the set of all indices $1 \le i \le l$ in which step 2 was performed.

We will bound the total number of edges removed. Observe that, if step 1 is performed for a vertex v_i, its connected component becomes a singleton. Thus, $|I_1| \le |V|$, and we have

$$\sum_{i \in I_1} |\mathcal{N}_{G_i}(v_i)| \le \sum_{i \in I_1} 2\sqrt{\epsilon}\,|V| = |I_1| \cdot 2\sqrt{\epsilon}\,|V| \le 2\sqrt{\epsilon}\,|V|^2 .$$

Observe that, if step 2 is performed for a vertex v_i, after the ith operation, the vertices of $\mathcal{N}_{G_i}(v_i)$ and the vertices of $\mathcal{D}_{G_i}(v_i)$ do not belong to the same connected component. Thus, $\sum_{i \in I_2} |\mathcal{D}_{G_i}(v_i)| \cdot |\mathcal{N}_{G_i}(v_i)| \le |V|^2$ (no pair of vertices appears twice in this sum). By the almost-transitivity, for every $i \in I_2$, every vertex $u \in \mathcal{D}_{G_i}(v_i)$ has at most $\epsilon\,|V|$ neighbors in $\mathcal{N}_{G_i}(v_i)$ (each is a common neighbor of u and v_i). Therefore, we can bound the total number of edges removed in step 2 by

$$\sum_{i \in I_2} |\mathcal{D}_{G_i}(v_i)| \cdot \epsilon\,|V| < \sum_{i \in I_2} |\mathcal{D}_{G_i}(v_i)| \cdot \epsilon \cdot \frac{|\mathcal{N}_{G_i}(v_i)|}{2\sqrt{\epsilon}} \le \frac{\sqrt{\epsilon}}{2} \cdot \sum_{i \in I_2} |\mathcal{D}_{G_i}(v_i)| \cdot |\mathcal{N}_{G_i}(v_i)| \le \frac{\sqrt{\epsilon}}{2}\,|V|^2 .$$

Therefore, the total number of edges removed is at most $2.5\sqrt{\epsilon}\,|V|^2$, and the total number of pairs $u, v \in V$ for which $(u, v) \in E$ but u and v are not in the same clique is at most $5\sqrt{\epsilon}\,|V|^2$. □

Acknowledgments. We are grateful to Muli Safra for many discussions. We also thank Ariel Gabizon, Amir Yehudayoff, and Igor Shparlinski for their suggestions. We thank Ariel Gabizon for allowing us to include his observations regarding our sampling lemma. We also thank the anonymous referees for faithfully doing their job.

ON APPROXIMATING RESTRICTED CYCLE COVERS*

BODO MANTHEY†

Abstract. A cycle cover of a graph is a set of cycles such that every vertex is part of exactly one cycle. An L-cycle cover is a cycle cover in which the length of every cycle is in the set L. The weight of a cycle cover of an edge-weighted graph is the sum of the weights of its edges. We come close to settling the complexity and approximability of computing L-cycle covers. On the one hand, we show that, for almost all L, computing L-cycle covers of maximum weight in directed and undirected graphs is APX-hard. Most of our hardness results hold even if the edge weights are restricted to zero and one. On the other hand, we show that the problem of computing L-cycle covers of maximum weight can be approximated within a factor of 2 for undirected graphs and within a factor of 8/3 in the case of directed graphs. This holds for arbitrary sets L.

Key words. approximation algorithms, inapproximability, cycle covers, two-factors

1. Introduction.

A cycle cover of a graph is a spanning subgraph that consists solely of cycles such that every vertex is part of exactly one cycle. Cycle covers play an important role in the design of approximation algorithms for the traveling salesman problem [4, 6, 7, 10, 11, 12, 13, 23], the shortest common superstring problem [9, 28], and vehicle routing problems [19].

In contrast to Hamiltonian cycles, which are special cases of cycle covers, cycle covers of maximum weight can be computed efficiently. This is exploited in the aforementioned approximation algorithms, which usually start by computing an initial cycle cover and then join cycles to obtain a Hamiltonian cycle. This technique is called *subtour patching* [16].

Short cycles in a cycle cover limit the approximation ratios achieved by such algorithms. In general, the longer the cycles in the initial cover, the better the approximation ratio. Thus, we are interested in computing cycle covers that do not contain short cycles. Moreover, there are approximation algorithms that perform particularly well if the cycle covers computed do not contain cycles of odd length [6]. Finally, some vehicle routing problems [19] require covering vertices with cycles of bounded length.

Therefore, we consider *restricted cycle covers*, where cycles of certain lengths are ruled out a priori: For $L \subseteq \mathbb{N}$, an *L-cycle cover* is a cycle cover in which the length of each cycle is in L. To fathom the possibility of designing approximation algorithms based on computing cycle covers, we aim to characterize the sets L for which L-cycle covers of maximum weight can be computed, or at least well approximated, efficiently.

Beyond being a basic tool for approximation algorithms, cycle covers are interesting in their own right. Matching theory and graph factorization are important topics in graph theory. The classical matching problem is the problem of finding one-factors, i.e., spanning subgraphs each vertex of which is incident to exactly one edge. Cycle covers of undirected graphs are also known as two-factors because every vertex is incident to exactly two edges. A considerable amount of research has been done on structural properties of graph factors and on the complexity of finding graph factors (cf. Lovász and Plummer [24] and Schrijver [27]). In particular, the complexity of finding restricted two-factors, i.e., L-cycle covers in undirected graphs, has been investigated, and Hell et al. [22] showed that finding L-cycle covers in undirected graphs is NP-hard for almost all L. However, almost nothing is known so far about the complexity of finding directed L-cycle covers.

1.1. Preliminaries. Let $G = (V, E)$ be a graph with vertex set V and edge set E. If G is undirected, then a *cycle cover* of G is a subset $C \subseteq E$ of the edges of G such that all vertices in V are incident to exactly two edges in C. If G is a directed graph, then a cycle cover of G is a subset $C \subseteq E$ such that all vertices are incident to exactly one incoming and one outgoing edge in C. Thus, the graph (V, C) consists solely of vertex-disjoint cycles. The length of a cycle is the number of edges of which it consists. Since we do not allow self-loops or multiple edges, the shortest cycles of undirected and directed graphs are of length three and two, respectively.

We call a cycle of length λ a λ-cycle for short. Cycles of even or odd length will simply be called even or odd cycles, respectively.

An *L-cycle cover* of an undirected graph is a cycle cover in which the length of every cycle is in $L \subseteq \mathcal{U} = \{3, 4, 5, \dots\}$. An L-cycle cover of a directed graph is analogously defined except that $L \subseteq \mathcal{D} = \{2, 3, 4, \dots\}$. A *$k$-cycle cover* is a $\{k, k+1, \dots\}$-cycle cover. In the following, let $\overline{L} = \mathcal{U} \setminus L$ in the case of undirected graphs and $\overline{L} = \mathcal{D} \setminus L$ in the case of directed graphs (whether we consider undirected or directed cycle covers will be clear from the context).

Given edge weights $w : E \to \mathbb{N}$, the *weight* $w(C)$ of a subset $C \subseteq E$ of the edges of G is $w(C) = \sum_{e \in C} w(e)$. In particular, this defines the weight of a cycle cover since we view cycle covers as sets of edges. Let $U \subseteq V$ be any subset of the vertices of G. The *internal edges of U* are all edges of G that have both vertices in U. We denote by $w_U(C)$ the sum of the weights of all internal edges of U that are also contained in C. The *external edges at U* are all edges of G with exactly one vertex in U.

For $L \subseteq \mathcal{U}$, L-UCC is the decision problem whether an undirected graph contains an L-cycle cover as a spanning subgraph.

Max-L-UCC(0,1) is the following optimization problem: Given an undirected complete graph with edge weights zero and one, find an L-cycle cover of maximum weight. We can also consider the graph as being not complete and without edge weights. Then we try to find an L-cycle cover with a minimum number of "nonedges" (nonedges correspond to weight zero edges, edges to weight one edges); i.e., the L-cycle cover should contain as many edges as possible. Thus, Max-L-UCC(0,1) generalizes L-UCC.

Max-L-UCC is the problem of finding L-cycle covers of maximum weight in graphs with arbitrary nonnegative edge weights.

For $k \in \mathcal{U}$, k-UCC, Max-k-UCC(0,1), and Max-k-UCC are defined like L-UCC, Max-L-UCC(0,1), and Max-L-UCC except that k-cycle covers rather than L-cycle covers are sought.

The problems L-DCC, Max-L-DCC(0,1), and Max-L-DCC as well as k-DCC, Max-k-DCC(0,1), and Max-k-DCC are defined for directed graphs like their undirected counterparts except that $L \subseteq \mathcal{D}$ and $k \in \mathcal{D}$.

An instance of Min-Vertex-Cover(λ)is an undirected λ-regular graph $H = (X, F)$; i.e., every vertex in X is incident to exactly λ edges. A vertex cover of H is a subset $\tilde{X} \subseteq X$ such that at least one vertex of every edge in F is in $\tilde{X}$. The aim is to find a subset $\tilde{X} \subseteq X$ of minimum cardinality. Min-Vertex-Cover(λ) is APX-complete for $\lambda \geq 3$ as follows from results by Alimonti and Kann [2] as well as Chlebík and Chlebíková [14].

An instance of λ-XC (exact cover by λ-sets) is a tuple (X, F), where X is a finite set and F is a collection of subsets of X, each of cardinality λ. The question is whether there exists a subcollection $\tilde{F} \subseteq F$ such that for every $x \in X$ there is a unique $a \in \tilde{F}$ with $x \in a$. For $\lambda \geq 3$, λ-XC is NP-complete [15, Problem SP2].

Let Π be an optimization problem, and let I be its set of instances. For an instance $X \in I$, let $\mathrm{opt}(X)$ denote the weight of an optimum solution. We say that Π can be approximated with an approximation ratio of $\alpha \geq 1$ if there exists a polynomial-time algorithm that, for every instance $X \in I$, computes a solution Y of X whose weight $w(Y, X)$ is at most a factor of α away from $\mathrm{opt}(X)$. This means that $w(Y, X) \leq \alpha \cdot \mathrm{opt}(X)$ if Π is a minimization problem and $w(Y, X) \geq \mathrm{opt}(X)/\alpha$ if Π is a maximization problem [3, Definition 3.6].

1.2. Previous results. Max-$\mathcal{U}$-UCC, and thus $\mathcal{U}$-UCC and Max-$\mathcal{U}$-UCC(0,1), can be solved in polynomial time via Tutte's reduction to the classical perfect matching problem [24, section 10.1]. Hartvigsen presented a polynomial-time algorithm that can be used to decide 4-UCC in polynomial time [17]. Furthermore, it can be adapted to solve Max-4-UCC(0,1) as well.

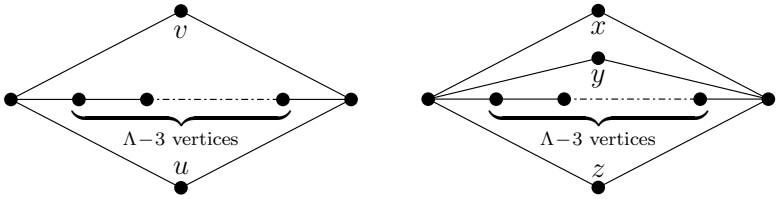
Max-k-UCC admits a simple factor 3/2 approximation for all k: Compute a maximum weight cycle cover, break the lightest edge of each cycle, and join the paths thus obtained to a Hamiltonian cycle. Unfortunately, this algorithm cannot be generalized to work for Max-L-UCC for general L. For the problem of computing k-cycle covers of minimum weight in graphs with edge weights one and two, there exists a factor 7/6 approximation algorithm for all k [8]. Hassin and Rubinstein [20, 21] devised a randomized approximation algorithm for Max-{3}-UCC that achieves an approximation ratio of $83/43 + \epsilon$.

Hell et al. [22] proved that L-UCC is NP-hard for $\overline{L} \not\subseteq \{3, 4\}$. For $k \geq 7$, Max-k-UCC(0,1) and Max-k-UCC are APX-complete [5]. Vornberger showed that Max-5-UCC is NP-hard [29].

The directed cycle cover problems $\mathcal{D}$-DCC, Max-$\mathcal{D}$-DCC(0,1), and Max-$\mathcal{D}$-DCC can be solved in polynomial time by reduction to the maximum weight perfect matching problem in bipartite graphs [1, Chapter 12]. But already 3-DCC is NP-complete [15]. Max-k-DCC(0,1) and Max-k-DCC are APX-complete for all $k \geq 3$ [5].

Similar to the factor 3/2 approximation algorithm for undirected cycle covers, Max-k-DCC has a simple factor 2 approximation algorithm for all k: Compute a maximum weight cycle cover, break the lightest edge of every cycle, and join the cycles to obtain a Hamiltonian cycle. Again, this algorithm cannot be generalized to work for arbitrary L. There is a factor 4/3 approximation algorithm for Max-3-DCC [7] and a factor 3/2 approximation algorithm for Max-k-DCC(0,1) for $k \geq 3$ [5].

The complexity of finding L-cycle covers in undirected graphs seems to be well understood. However, hardly anything is known about the complexity of L-cycle covers in directed graphs and about the approximability of L-cycle covers in both undirected and directed graphs.



(a) L-clamp. (b) L-gadget.

FIG. 1. *An L-clamp and an L-gadget for a set L with* $\max(L) = \Lambda$.

1.3. Our results. We prove that Max-L-UCC(0,1) is APX-hard for all L with $\overline{L} \not\subseteq \{3, 4\}$ (section 2.2) and that Max-L-UCC is APX-hard if $\overline{L} \not\subseteq \{3\}$ (section 2.3). The hardness results for Max-L-UCC hold even if we allow only the edge weights zero, one, and two.

We show a dichotomy for directed graphs: For all L with $L \neq \{2\}$ and $L \neq \mathcal{D}$, L-DCC is NP-hard and Max-L-DCC(0,1) and Max-L-DCC are APX-hard (section 2.5), while all three problems are solvable in polynomial time if $L = \{2\}$ or $L = \mathcal{D}$.

The hardness results for Max-L-UCC(0,1) and Max-L-DCC(0,1) carry over to the problem of computing L-cycle covers of minimum weight in graphs restricted to edge weights one and two. The hardness results for Max-L-UCC for $\overline{L} = \{3, 4\}$ and $\overline{L} = \{4\}$ carry over to the problem of computing L-cycle covers of minimum weight where the edge weights are required to fulfill the triangle inequality.

To show the hardness of directed cycle covers, we show that certain kinds of graphs, called *L-clamps*, exist for nonempty $L \subseteq \mathcal{D}$ if and only if $L \neq \mathcal{D}$ (Theorem 2.10). This graph-theoretical result might be of independent interest.

Finally, we devise approximation algorithms for Max-L-UCC and Max-L-DCC that achieve ratios of 2 and 8/3, respectively (section 3). Both algorithms work for all sets L.

2. The hardness of approximating L-cycle covers.

2.1. Clamps and gadgets. To begin the hardness proofs, we introduce *clamps*, which were defined by Hell et al. [22]. Clamps are crucial for our hardness proof.

Let $K = (U, E)$ be an undirected graph, and let $u, v \in U$ be two vertices of K, which we call the *connectors* of K. We denote by K_{-u} and K_{-v} the graphs obtained from K by deleting u and v, respectively, and their incident edges. K_{-u-v} is obtained from K by deleting both u and v. For $k \in \mathbb{N}$, K^k is the following graph: Let $y_1, \ldots, y_k \notin U$ be new vertices, and add edges $\{u, y_1\}$, $\{y_i, y_{i+1}\}$ for $1 \leq i \leq k-1$, and $\{y_k, v\}$. For $k = 0$, we directly connect u to v.

Let $L \subseteq \mathcal{U}$. The graph K is called an *L-clamp* if the following properties hold:

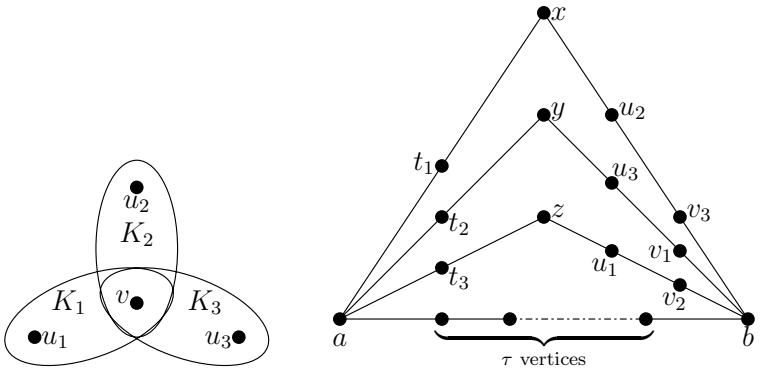
1. Both K_{-u} and K_{-v} contain an L-cycle cover.
2. Neither K nor K_{-u-v} nor K^k for any $k \in \mathbb{N}$ contains an L-cycle cover.

Figure 1(a) shows an example of an L-clamp for a set L with $\Lambda = \max(L)$. Hell et al. [22] proved the following result which we will exploit for our reduction.

LEMMA 2.1 (Hell et al. [22]). *Let $L \subseteq \mathcal{U}$ be nonempty. Then there exists an L-clamp if and only if $\overline{L} \not\subseteq \{3, 4\}$.*

Let G be a graph with vertex set V and $U \subseteq V$. We say that the vertex set U is an L-clamp with connectors $u, v \in U$ in G if the subgraph of G induced by U is an L-clamp and the only external edges of U are incident to u or v.

Let us fix some technical terms. For this purpose, let C be a subset of the edges of G. (In particular, C can be a cycle cover of G.) For any $V' \subseteq V$, we say that V' *is*



(a) A triple L-clamp with connectors u_1, u_2, u_3. The connectors of L-clamp K_i are u_i and v.

(b) An L-gadget with connectors x, y, z. The connectors of triple L-clamps T_i are t_i, u_i, v_i. For legibility, the triple L-clamps are not shown explicitly but only their connectors.

FIG. 2. *A triple L-clamp and an L-gadget.*

isolated in C if there is no edge in C connecting V' to $V \setminus V'$. If C is a cycle cover, then this means that all cycles of C traverse either only nodes of V' or only nodes of $V \setminus V'$. We say that the L-clamp U *absorbs* u *and expels* v if $U \setminus \{v\}$ is isolated in C. This means that each cycle of C traverses either only vertices in $(V \setminus U) \cup \{v\}$ or only vertices in $U \setminus \{v\}$ (which includes u). Analogously, U *absorbs* v *and expels* u if $U \setminus \{u\}$ is isolated in C.

An L-clamp implements an exclusive-or of u and v: In every L-cycle cover, exactly one of them is absorbed, and the other one is expelled. For our purpose of reducing from Min-Vertex-Cover(λ), we need a one-out-of-three behavior. A graph K is called an *L-gadget with connectors* x, y, z if the following property is fulfilled: Let G be an arbitrary graph that contains K as a subgraph such that only x, y, and z are incident to external edges. Then in all L-cycle covers C of G, exactly two of K's connectors are expelled while the third one is absorbed. To put it another way, either K_{-x-y} or K_{-x-z} or K_{-y-z} is isolated in C.

For finite sets L, we obtain an L-gadget, shown in Figure 1(b), by equipping the L-clamp of Figure 1(a) with an additional connector.

For infinite sets L, we first build an intermediate subgraph. A *triple L-clamp* is built from three L-clamps and has three connectors u_1, u_2, u_3. Figure 2(a) shows the construction. Triple L-clamps show a two-out-of-three behavior: Only one connector will be expelled, and the other two will be absorbed. More precisely, one of the three clamps has to absorb v. The other two absorb their connectors u_i, which are also connectors of the triple clamp.

Now we are prepared to build L-gadgets for infinite sets L. These graphs are built from three triple L-clamps T_1, T_2, and T_3, where T_i has connectors u_i, v_i, t_i. Figure 2(b) shows the L-gadget. Since L is infinite, there exists a $\tau \geq 1$, with $\tau + 6 \in L$. Let us argue why the L-gadget behaves as claimed. For this purpose, let C be an arbitrary L-cycle cover of G, where G contains the L-gadget as a subgraph. First, we observe that all $\tau + 2$ vertices of the path connecting a to b must be on the same cycle c in C. The only other vertices to which a is incident are t_1, t_2, and t_3. By symmetry, we assume that t_1 lies also in c. Therefore, T_1 absorbs u_1 and v_1. Hence,

v_2 and u_3 are absorbed by T_2 and T_3, respectively, and c runs through x, u_2, v_3 back to b to form a $(\tau + 6)$-cycle. Thus, x is absorbed by the gadget. T_2 expels u_2 and absorbs u_3, while T_3 expels v_3 and absorbs v_2. Hence, the gadget expels y and z as claimed. The other two cases are symmetric.

To conclude this section about clamps, we transfer the notion of L-gadgets to complete graphs with edge weights zero and one and prove some properties. In section 2.3, we will generalize the notion of L-gadgets to graphs with arbitrary edge weights.

The transformation to graphs with edge weights zero and one is made in the obvious way: Let G be an undirected complete graph with vertex set V and edge weights zero and one. Let $U \subseteq V$. We say that U is an L-gadget with connectors $x, y, z \in U$ if the subgraph of G induced by U restricted to the edges of weight one is an L-gadget with connectors x, y, z.

Let σ be the number of vertices of an L-gadget U with connectors x, y, and z. Let C be a subset of the edges of G (in particular, C can be a cycle cover). We call U *healthy in* C if U absorbs x, y, or z, expels the other two connectors, and $w_U(C) = \sigma - 2$. Since the edge weighted graph is complete, the L-cycle may traverse L-gadgets arbitrarily. The following lemma shows that we cannot gain weight by not traversing them healthily.

LEMMA 2.2. *Let G be an undirected graph with vertex set V and edge weights zero and one, and let $U \subseteq V$ be an L-gadget with connectors x, y, z. Let C be an arbitrary L-cycle cover of G and $|U| = \sigma$. Then the following properties hold:*

1. *$w_U(C) \leq \sigma - 1$.*
2. *If there are 2α external edges at U in C, i.e., edges with exactly one end point in U, then $w_U(C) \leq \sigma - \alpha$.*
3. *Assume that U absorbs exactly one of x, y, or z. Then there exists an L-cycle cover $\tilde{C}$ that differs from C only in the internal edges of U and has $w_U(\tilde{C}) = \sigma - 2$.*
4. *Assume that there are two external edges at U in C that are incident to two different connectors. Then $w_U(C) \leq \sigma - 2$.*

Proof. If $w_U(C) = \sigma$ was true, then U would contain an L-cycle cover consisting solely of weight one edges since $|U| = \sigma$. This would contradict U being an L-gadget.

The second claim follows immediately from $|U| = \sigma$ and the fact that every vertex is incident to exactly two edges in a cycle cover.

Assume without loss of generality that U absorbs x and expels y and z. Since U is an L-gadget, $U \setminus \{y, z\}$ contains an L-cycle cover consisting of $\sigma - 1$ weight one edges, which proves the third claim.

The fourth claim remains to be proved. If there are more than two external edges at U in C, we have at least four external edges and thus $w_U(C) \leq \sigma - 2$. So assume that there are exactly two external edges at U in C incident to, say, x and y. We have $\sigma - 1$ internal edges of U in C. If all of them had weight one, this would contradict the property that in an unweighted L-gadget always $U \setminus \{x, y\}$, $U \setminus \{x, z\}$, or $U \setminus \{y, z\}$ is isolated. □

2.2. The reduction for undirected graphs. The notion of L-reductions was introduced by Papadimitriou and Yannakakis [25] (cf. Ausiello et al. [3, Definition 8.4]). L-reductions can be used to show the APX-hardness of optimization problems. We present an L-reduction from Min-Vertex-Cover(λ) to show the inapproximability of Max-L-UCC(0,1) for $\overline{L} \not\subseteq \{3, 4\}$. The inapproximability of Max-L-UCC for $\overline{L} \not\subseteq \{3\}$ and Max-L-DCC(0,1) for $L \neq \{2\}$ and $L \neq \mathcal{D}$ will be shown in subsequent sections.

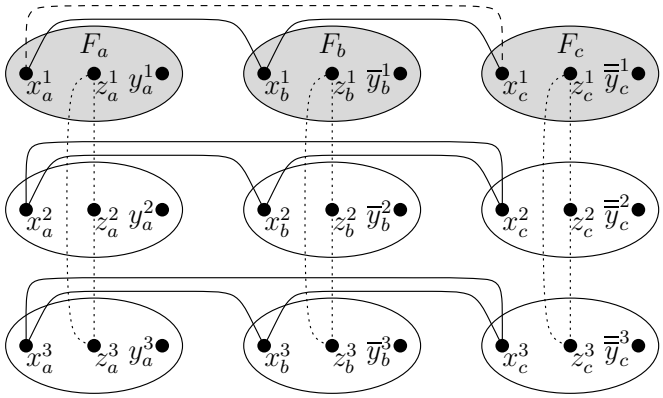


FIG. 3. *The construction for $x \in X$ incident to $a = \{x, y\}, b = \{x, \overline{y}\}, c = \{x, \overline{\overline{y}}\} \in F$ for $\lambda = 3$. F_a, F_b, and F_c are gray. The three ellipses in the second and third rows build G_2 and G_3, respectively. The cycles connecting the z-vertices are dotted. The junctions of x and their copies are solid, except for $\{x_c^1, x_a^1\}$, which has weight zero and is dashed.*

Let $L \subseteq \mathcal{U}$ be nonempty with $\overline{L} \not\subseteq \{3, 4\}$. Thus, L-gadgets exist, and we fix one as in the previous section. Let $\lambda = \min(L)$. (This choice is arbitrary. We could choose any number in L.) We will reduce Min-Vertex-Cover(λ) to Max-L-UCC(0,1). Min-Vertex-Cover(λ) is APX-complete since $\lambda \geq 3$.

Let $H = (X, F)$ be an instance of Min-Vertex-Cover(λ) with $|X| = n$ vertices and $|F| = m = \lambda n/2$ edges. Our instance G for Max-L-UCC(0,1) consists of λ subgraphs $G_1, \ldots, G_\lambda$, each containing σm vertices, where σ is the number of vertices of the L-gadget. We start by describing G_1. Then we state the differences between G_1 and $G_2, \ldots, G_\lambda$ and say to which external edges of $G_1, \ldots, G_\lambda$ weight one is assigned.

Let $a = \{x, y\} \in F$ be any edge of H. We construct an L-gadget F_a for a that has connectors x_a^1, y_a^1, and z_a^1. We call F_a an *edge gadget*.

Now let $x \in X$ be any vertex of H, and let $a_1, \ldots, a_\lambda \in F$ be the λ edges that are incident to x. We connect the vertices $x_{a_1}^1, \ldots, x_{a_\lambda}^1$ to form a path by assigning weight one to the edges $\{x_{a_\eta}^1, x_{a_{\eta+1}}^1\}$ for $\eta \in \{1, \ldots, \lambda - 1\}$. Together with edge $\{x_{a_\lambda}^1, x_{a_1}^1\}$, these edges form a cycle of length $\lambda \in L$, but note that $w(\{x_{a_\lambda}^1, x_{a_1}^1\}) = 0$. These λ edges are called the *junctions of x*. The *junctions at F_a* for some $a = \{x, y\} \in F$ are the junctions of x and y that are incident to F_a. Overall, the graph G_1 consists of σm vertices since every edge gadget consists of σ vertices.

The graphs $G_2, \ldots, G_\lambda$ are almost exact copies of G_1. The graph G_ξ ($\xi \in \{2, \ldots, \lambda\}$) consists of L-gadgets with connectors x_a^ξ, y_a^ξ, and z_a^ξ for each edge $a = \{x, y\} \in F$, just as above. The edge weights are also identical with the single exception that the edge $\{x_{a_\lambda}^\xi, x_{a_1}^\xi\}$ also has weight one. Note that we use the term "edge gadget" only for the subgraphs F_a of G_1 defined above although almost the same subgraphs occur in $G_2, \ldots, G_\lambda$ as well. Similarly, the term "junction" refers only to edges in G_1.

Finally, we describe how to connect $G_1, \ldots, G_\lambda$ with each other. For every edge $a \in F$, there are λ vertices $z_a^1, \ldots, z_a^\lambda$. These are connected to form a cycle consisting solely of weight one edges; i.e., we assign weight one to all edges $\{z_a^\xi, z_a^{\xi+1}\}$ for $\xi \in \{1, \ldots, \lambda - 1\}$ and to $\{z_a^\lambda, z_a^1\}$. Figure 3 shows an example of the whole construction from the viewpoint of a single vertex.

Edges with both vertices in the same gadget are called *internal edges*. Besides junctions and internal edges, the third kind of edges are the *z-edges* of F_a for $a \in F$,

which are the two edges $\{z_a^1, z_a^2\}$ and $\{z_a^1, z_a^\lambda\}$. The fourth kind of edges are *illegal edges*, which are edges that are not junctions but connect any two vertices of two different gadgets. The z-edges, however, are not illegal. Edges within $G_2, \ldots, G_\lambda$ as well as edges connecting G_ξ to $G_{\xi'}$ for $\xi, \xi' \geq 2$ have no special name.

We define the following terms for arbitrary subsets C of the edges of the graph G thus constructed, which includes the case of C being a cycle cover. Let $a = \{x, y\} \in F$ be an arbitrary edge of H. We say that C *legally connects* F_a if the following properties are fulfilled:

(i) C contains either two or four of the junctions at F_a and no illegal edges incident to F_a.
(ii) If C contains exactly two junctions at F_a, then these belong to the same vertex, and the two z-edges at F_a are contained in C.
(iii) If C contains four junctions at F_a, then C does not contain the z-edges at F_a.

We call C *legal* if C legally connects all gadgets. If $\tilde{C}$ is a legal L-cycle cover, then for all $x \in X$ either all junctions of x or no junction of x is in $\tilde{C}$. From a legal L-cycle cover $\tilde{C}$, we obtain the subset $\tilde{X} = \{x \mid \text{the junctions of } x \text{ are in } \tilde{C}\} \subseteq X$. Since at least two junctions at F_a are in $\tilde{C}$ for every $a \in F$, the set $\tilde{X}$ is a vertex cover of H.

The idea behind the reduction is as follows: Consider an edge $a = \{x, y\} \in F$. We interpret x_a^1 being expelled to mean that x is in the vertex cover. (In this case, the junctions of x are in the cycle cover.) Analogously, y is in the vertex cover if y_a^1 is expelled. The vertex z_a^1 is absorbed only if both x and y are in the vertex cover. If only one of x and y is in the vertex cover, z_a^1 forms a λ-cycle together with $z_a^2, \ldots, z_a^\lambda$.

We considered only G_1 when defining the terms "legally connected" and "legal." This is because in G_1 we lose weight one for putting x into the vertex cover since the junction $\{x_{a_\lambda}^1, x_{a_1}^1\}$ weighs zero. The other $\lambda - 1$ copies of the construction are needed only because z_a^1 must be part of some cycle if z_a^1 is not absorbed.

LEMMA 2.3. *Let $\tilde{X}$ be a vertex cover of size $\tilde{n}$ of H. Then G contains an L-cycle cover $\tilde{C}$, with $w(\tilde{C}) = \sigma\lambda m - \tilde{n}$.*

Proof. We start by describing $\tilde{C}$ in G_1. For every vertex $x \in \tilde{X}$, the cycle consisting of all λ junctions is in $\tilde{C}$. Let $a = \{x, y\} \in F$ be any edge. Then either x or y or both are in $\tilde{X}$. If only x is in $\tilde{X}$, we let F_a absorb y_a^1 while z_a^1 is expelled. If only y is in $\tilde{X}$, we let F_a absorb x_a^1 while z_a^1 is again expelled. If both x and y are in $\tilde{X}$, then we let x_a^1 and y_a^1 be expelled while z_a^1 is absorbed.

We perform the same construction as for G_1 for all copies $G_2, \ldots, G_\lambda$. If z_a^1 is expelled, then $z_a^2, \ldots, z_a^\lambda$ are expelled as well. We let them form a λ-cycle in $\tilde{C}$.

Clearly, $\tilde{C}$ is legal. Furthermore, $\tilde{C}$ is an L-cycle cover: Every cycle either has a length of $\lambda \in L$ or lies totally inside a single L-gadget. All L-gadgets are healthy in $\tilde{C}$, and thus $\tilde{C}$ is an L-cycle cover.

All edges of $\tilde{C}$ within $G_2, \ldots, G_\lambda$ have weight one. The only edges that connect different copies G_ξ and $G_{\xi'}$ are edges $\{z_a^\xi, z_a^{\xi+1}\}$ and $\{z_a^\lambda, x_a^1\}$, which have weight one as well. Almost all edges used in G_1 also have weight one; the only exception is one junction of weight zero for each $x \in \tilde{X}$. Since $|\tilde{X}| = \tilde{n}$, there are $\tilde{n}$ edges of weight zero in $\tilde{C}$. The graph G contains $\sigma\lambda m$ vertices, and thus $\tilde{C}$ contains $\sigma\lambda m$ edges, $\sigma\lambda m - \tilde{n}$ of which have weight one. ∎

Let C be an L-cycle cover of G, and let $a \in F$. We define $W_{F_a}(C)$ as the sum of the weights of all internal edges of F_a plus half the number of z-edges in C at F_a. Analogously, $W_{G_\xi}(C)$ is the number of weight one edges with both vertices in G_ξ plus half the number of weight one edges with exactly one vertex in G_ξ.

LEMMA 2.4. *Let C be an L-cycle cover, and let j be the number of weight one junctions in C. Then $w(C) = j + \sum_{a \in F} W_{F_a}(C) + \sum_{\xi=2}^{\lambda} W_{G_\xi}(C)$.*

Proof. Every edge with both vertices in the same G_ξ is counted once. The only edges of weight one between different G_ξ are the edges $\{z_a^\xi, z_a^{\xi+1}\}$ and $\{z_a^\lambda, z_a^1\}$. These are counted with one-half in both $W_{G_\xi}(C)$ and $W_{G_{\xi+1}}(C)$ for $2 \le \xi \le \lambda-1$ or one-half in both $W_{G_\xi}(C)$ and $W_{F_a}(C)$ for $\xi \in \{2, \lambda\}$. □

In a legal L-cycle cover $\tilde{C}$ as described in Lemma 2.3, we have $W_{G_\xi}(\tilde{C}) = \sigma m$ for all $\xi \in \{2, \dots, \lambda\}$ since every vertex in G_ξ is incident only to edges of weight one in $\tilde{C}$ by construction. Now we show that it is always best to traverse the gadgets legally and to keep the gadgets healthy.

LEMMA 2.5. *Given an arbitrary L-cycle cover C, we can compute a legal L-cycle cover $\tilde{C}$ with $w(\tilde{C}) \ge w(C)$ in polynomial time.*

Proof. We proceed as follows to obtain $\tilde{C}$:

1. Let C' be C with all illegal edges removed.
2. For all $x \in X$ in arbitrary order: If at least one junction of x is in C, then put all junctions of x into C'.
3. For all $a = \{x, y\} \in F$ in arbitrary order: If neither the junctions of x nor the junctions of y are in C', choose arbitrarily one vertex of a, say, x, and add all junctions of x to C'.
4. Rearrange C' within G_1 such that all clamps are healthy in C'.
5. Rearrange C' such that all $G_2, \dots, G_\lambda$ are traversed exactly like G_1.
6. For all $a \in F$: If $z_a^1, \dots, z_a^\xi$ are not absorbed, let them form a λ-cycle. Call the result $\tilde{C}$.

The running time of the algorithm is polynomial. Moreover, $\tilde{C}$ is a legal L-cycle cover by construction. What remains is to prove $w(\tilde{C}) \ge w(C)$.

Let $w(C) = j + \sum_{a \in F} W_{F_a}(C) + \sum_{\xi=2}^{\lambda} W_{G_\xi}(C)$ be the weight of C according to Lemma 2.4; i.e., C contains j junctions of weight one. Analogously, let $w(\tilde{C}) = \tilde{j} + \sum_{a \in F} W_{F_a}(\tilde{C}) + \sum_{\xi=2}^{\lambda} W_{G_\xi}(\tilde{C})$; i.e., $\tilde{j}$ is the number of junctions of weight one in $\tilde{C}$.

All illegal edges have weight zero, and we do not remove any junctions. We have $W_{G_\xi}(\tilde{C}) = \sigma m$ for all ξ, which is maximal. Thus, no weight is lost in this way. What remains is to consider the internal edges of the gadgets and the z-edges.

Let $a = \{x, y\}$ be an arbitrary edge of H. If $W_{F_a}(C) \le W_{F_a}(\tilde{C})$, then nothing has to be shown. Those gadgets F_a with $W_{F_a}(C) > W_{F_a}(\tilde{C})$ remain to be considered. We have $W_{F_a}(\tilde{C}) \ge \sigma - 2$ and $W_{F_a}(C) \le \sigma - 1$ according to Lemma 2.2. Thus, $W_{F_a}(C) = \sigma - 1$ and $W_{F_a}(\tilde{C}) = \sigma - 2 = W_{F_a}(C) - 1$ for all $a \in F$ with $W_{F_a}(C) > W_{F_a}(\tilde{C})$. What remains to be proved is that, for all such gadgets, there is a junction of weight one in $\tilde{C}$ that is not in C and can thus compensate for the loss of weight one in F_a. This means that we have to show that $\tilde{j}$ is at least j plus the number of edges a with $W_{F_a}(C) > W_{F_a}(\tilde{C})$.

If $W_{F_a}(C) = \sigma - 1$, then according to Lemma 2.2(4) the junctions at F_a in C (if there are any) belong to the same vertex. Since $W_{F_a}(\tilde{C}) = \sigma - 2$, all four junctions at F_a are in $\tilde{C}$. Thus, while executing the above algorithm, there is a moment at which at least one of, say, y's junctions at F_a is in C', and the junctions of x are added in the next step. We say that a vertex x *compensates* F_a if

1. $\tilde{C}$ contains x's junctions,
2. no junction of x at F_a is in C, and
3. at the moment at which x's junctions are added, C' already contains at least one junction of y at F_a.

Thus, every gadget F_a with $W_{F_a}(\tilde{C}) < W_{F_a}(C)$ is compensated by some vertex $x \in a$.

It remains to be shown that the number of gadgets that are compensated by some vertex is at most equal to the number of weight one junctions added to C'.

Let $\eta \in \{0, \ldots, \lambda\}$ be the number of junctions of x in C. If $\eta = \lambda$, then x does not compensate any gadget. If $\eta = 0$, i.e., C does not contain any of x's junctions, then the junctions of x are added during step 3 of the algorithm because there is some edge $a \in F$ with $x \in a$ such that there is no junction at all in C' at F_a before adding x's junctions. Thus, x does not compensate F_a. At most $\lambda - 1$ gadgets are compensated by x, and $\lambda - 1$ junctions of x have weight one. The case that remains is $\eta \in \{1, \ldots, \lambda - 1\}$. Then $\lambda - \eta$ junctions of x are added, and at least $\lambda - \eta - 1$ of them have weight one. On the other hand, there are at least $\eta + 1$ gadgets F_a such that at least one junction of x at F_a is already in C: Every junction is at two gadgets, and thus η junctions are at $\eta + 1$ or more gadgets. Thus, at most $\lambda - \eta - 1$ gadgets are compensated by x. □

Finally, we prove the following counterpart to Lemma 2.3.

LEMMA 2.6. *Let $\tilde{C}$ be the L-cycle cover constructed as described in the proof of Lemma 2.5, and let $\tilde{X} = \{x \mid x$'s junctions are in $\tilde{C}\}$ be the subset of X obtained from $\tilde{C}$. Choose $\tilde{n}$ such that $w(\tilde{C}) = \sigma\lambda m - \tilde{n}$. Then $|\tilde{X}| = \tilde{n}$.*

Proof. The proof is similar to the proof of Lemma 2.3. We set the weight of all junctions to one. With respect to the modified edge weights, the weight of $\tilde{C}$ is $\sigma\lambda m$. Thus, $\tilde{n}$ is the number of weight zero junctions in $\tilde{C}$, which is just $|\tilde{X}|$. □

Now we are prepared to prove the main theorem of this section.

THEOREM 2.7. *For all $L \subseteq \mathcal{U}$ with $\overline{L} \not\subseteq \{3, 4\}$,* Max-$L$-UCC(0,1) *is* APX*-hard.*

Proof. We show that the reduction presented is an L-reduction. Then the result follows from the APX-hardness of Min-Vertex-Cover(λ). Let $\mathrm{opt}(H)$ be the size of a minimum vertex cover of H and $\mathrm{opt}(G)$ be the weight of a maximum weight L-cycle cover of G. From Lemmas 2.3, 2.5, and 2.6, we obtain that $\mathrm{opt}(G) = \sigma\lambda m - \mathrm{opt}(H) \leq \sigma\lambda m$. Since H is λ-regular, we have $\mathrm{opt}(H) \geq n/2$. Thus,

$$\mathrm{opt}(G) \leq \sigma\lambda m = \sigma\lambda \cdot (\lambda n/2) \leq (\sigma\lambda^2) \cdot \mathrm{opt}(H).$$

Let C be an arbitrary L-cycle cover of G, $\tilde{C}$ be a legal L-cycle cover obtained from C as in Lemma 2.5, and $\tilde{X} \subseteq X$ be obtained from $\tilde{C}$. Then

$$\big||\tilde{X}| - \mathrm{opt}(H)\big| = \big|w(\tilde{C}) - \mathrm{opt}(G)\big| \leq \big|w(C) - \mathrm{opt}(G)\big|,$$

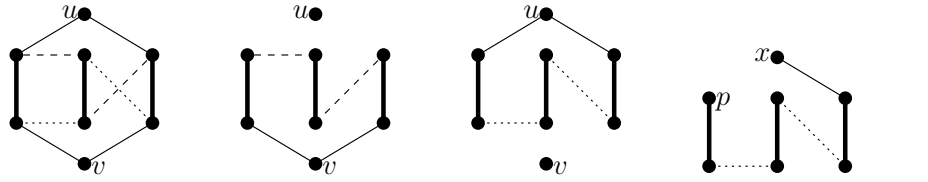
which completes the proof. □

2.3. Adaption of the reduction to Max-*L*-UCC. To prove the APX-hardness of Max-L-UCC for $\overline{L} \not\subseteq \{3\}$, all we have to do is to deal with $\overline{L} = \{4\}$ and $\overline{L} = \{3, 4\}$. For all other sets L, the inapproximability follows from Theorem 2.7. We will adapt the reduction presented in the previous section.

To do this, we have to find an edge weighted analogue of an L-clamp. We do not explicitly define the properties a weighted L-clamp has to fulfill. Instead, we just call the graph shown in Figure 4(a) a *weighted L-clamp* for $\overline{L} = \{3, 4\}$ and $\overline{L} = \{4\}$.

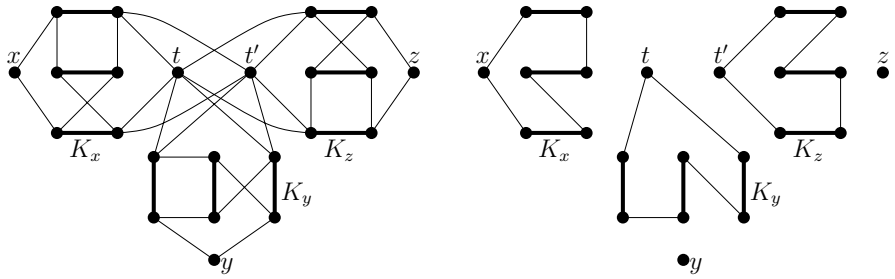
The basic idea is that all three edges of weight two of the weighted clamp have to be traversed in a cycle cover. Since 4-cycles are forbidden, we have to take either the two dotted edges or the two dashed edges. Otherwise, we would have to take an edge of weight zero. Furthermore, if we take the dashed edges, we have to absorb v and to expel u, and if we take the dotted edges, we have to absorb u and to expel v (Figures 4(b) and 4(c)). Again, we would have to take edges of weight zero otherwise.

Using three weighted L-clamps K_x, K_y, K_z, we build an L-gadget as shown in Figure 5(a). Note that both t and t' can serve as a connector for each of the clamps. This weighted L-gadget has essentially the same properties as the L-gadgets of section 2.1,



(a) The clamp. (b) Absorbing v. (c) Absorbing u. (d) Illegal traversal of K_x.

FIG. 4. *A weighted L-clamp for* $\{4\} \subseteq \overline{L} \subseteq \{3,4\}$ *and how to traverse it. Bold edges have weight two; solid, dashed, and dotted edges have weight one.*



(a) The weighted L-gadget. (b) How to absorb x.

FIG. 5. *A weighted L-gadget and how to use it.*

which were stated as Lemma 2.2. The difference is that $\sigma = 32$ is no longer the number of vertices, but the number of vertices plus the number of edges of weight two.

LEMMA 2.8. *Let G be an undirected graph with vertex set V and edge weights zero and one, and let $U \subseteq V$ be a weighted L-gadget with connectors x, y, z in G. Let C be an arbitrary L-cycle cover of G. Then the following properties hold:*

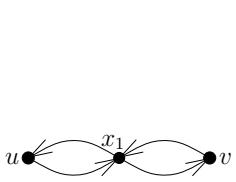
1. $w_U(C) \leq 31$.
2. *If there are 2α external edges at U in C, then $w_U(C) \leq 32 - \alpha$.*
3. *If U absorbs x, then there exists an L-cycle cover $\tilde{C}$ that differs from C only in the internal edges of U and has $w_U(\tilde{C}) = 30$. The same holds if U absorbs y or z.*
4. *Assume that there are two external edges at U in C that are incident to two different connectors. Then $w_U(C) \leq 30$.*

Proof. The only way to achieve $w_U(C) > 31$ is $w_U(C) = 32$, which requires that we have 23 internal edges including all nine edges of weight two. Since 4-cycles are forbidden, such an L-cycle cover does not exist.

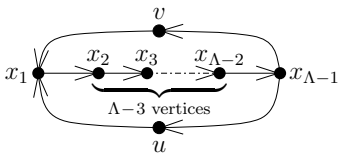
If we have 2α external edges, then we have $23 - \alpha$ internal edges. At most nine of them are of weight two.

If U absorbs x, then we can achieve a weight of 30 by letting K_y and K_z absorb t_1 and t_2, respectively (Figure 5(b)). (We can also connect K_y and K_z via t and t' to obtain a 14-cycle. The weight would be the same.) In the same way, we can achieve weight 30 if U absorbs y or z.

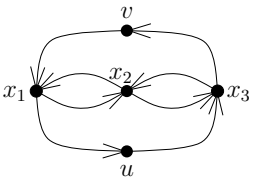
The fourth claim remains to be proved. We have $w_U(C) \leq 31$ and 22 internal edges. If $w_U(C) > 30$, then $w_U(C) = 31$, and C contains all nine edges of weight two and no internal edge of weight zero of U. By symmetry, it suffices to consider the case that x is incident to one external edge. Figure 4(d) shows which edges are mandatory in order to keep all three edges of weight two. Since the cycle that contains x must



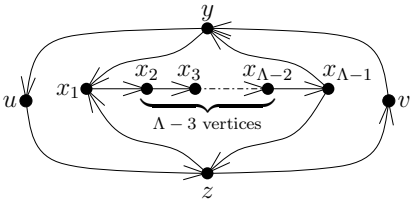
(a) A $\{2\}$-clamp.



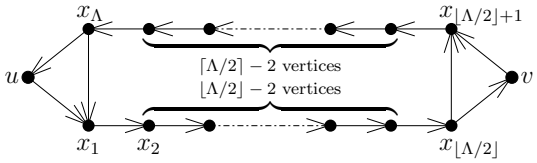
(b) An L-clamp for finite sets L with $\max(L) = \Lambda \geq 3$.



(c) A $\overline{\{2\}}$-clamp.



(d) An L-clamp for $\Lambda \notin L$ and $\Lambda + 2 \in L$ with $\Lambda \geq 3$.



(e) An L-clamp for $\Lambda, \Lambda + 2 \notin L$, and $\Lambda + 1 \in L$ with $\Lambda \geq 4$.

FIG. 6. *Directed L-clamps. The connectors are u and v; the internal vertices are $x_1, x_2, \ldots$ and y, z.*

be continued at p, vertex p is incident to an edge of weight zero in C, which proves the claim. □

Given these properties, we can plug the L-gadget into the reduction described in the previous section to obtain the APX-hardness of Max-L-UCC for $\overline{L} = \{4\}$ and $\overline{L} = \{3, 4\}$. Together with Theorem 2.7, we obtain the following result.

THEOREM 2.9. Max-L-UCC *is* APX*-hard for all L with $\overline{L} \not\subseteq \{3\}$ even if the edge weights are restricted to be zero, one, or two.*

2.4. Clamps in directed graphs. The aim of this section is to prove a counterpart to Lemma 2.1 (for the existence of L-clamps) for directed graphs. Let $K = (V, E)$ be a directed graph and $u, v \in V$. Again, K_{-u}, K_{-v}, and K_{-u-v} denote the graphs obtained by deleting u, v, and both u and v, respectively. For $k \in \mathbb{N}$, K_u^k denotes the following graph: Let $y_1, \ldots, y_k \notin V$ be new vertices, and add edges $(u, y_1), (y_1, y_2), \ldots, (y_k, v)$. For $k = 0$, we add the edge (u, v). The graph K_v^k is similarly defined, except that we now start at v; i.e., we add the edges (v, y_1), $(y_1, y_2), \ldots, (y_k, u)$. K_v^0 is K with the additional edge (v, u).

Now we can define clamps for directed graphs: Let $L \subseteq \mathcal{D}$. A directed graph $K = (V, E)$ with $u, v \in V$ is a *directed L-clamp* with connectors u and v if the following properties hold:

(i) Both K_{-u} and K_{-v} contain an L-cycle cover.

(ii) Neither K, K_{-u-v}, K_u^k, nor K_v^k for any $k \in \mathbb{N}$ contains an L-cycle cover.

Let us now prove that directed L-clamps exist for almost all L.

THEOREM 2.10. *Let $L \subseteq \mathcal{D}$ be nonempty. Then there exists a directed L-clamp if and only if $L \neq \mathcal{D}$.*

Proof. We first prove that directed L-clamps exist for all nonempty sets $L \subseteq \mathcal{D}$ with $L \neq \mathcal{D}$. We start by considering finite L. If L is finite, $\max(L) = \Lambda$ exists. For $L = \{2\}$, the graph shown in Figure 6(a) is a directed L-clamp: Either u or v forms a 2-cycle with x_1, and there are no other possibilities. Otherwise, we have $\Lambda \geq 3$. Figure 6(b) shows a directed L-clamp for this case, which is a directed variant of the undirected clamp shown in Figure 1(a).

Now we consider finite $\overline{L}$. Figure 6(c) shows an L-clamp for $\overline{L} = \{2\}$: x_1, x_2, and x_3 must be on the same path since length two is forbidden. This cycle must include u or v but cannot include both of them.

Otherwise, $\max(\overline{L}) = \Lambda \geq 3$, $\Lambda + 2 \in L$, and the graph shown in Figure 6(d) is an L-clamp: The vertices $x_1, \ldots, x_{\Lambda-1}$ must all be on the same cycle. Thus, either (y, x_1) or (z, x_1) is in the cycle cover. By symmetry, it suffices to consider the first case. Since $\Lambda \notin L$, the edge $(x_{\Lambda-1}, y)$ cannot be in the cycle cover. Thus, (v, y), $(x_{\Lambda-1}, z)$, and hence (z, v) are in the cycle cover.

The case that remains to be considered is that both L and $\overline{L}$ are infinite. We distinguish two subcases. First, there exists a $\Lambda \geq 4$ with $\Lambda, \Lambda+2 \notin L$ and $\Lambda+1 \in L$. In this case, the graph shown in Figure 6(e) is an L-clamp: $x_1, \ldots, x_\Lambda$ must be on the same cycle. Since the lengths Λ and $\Lambda + 2$ are not allowed, either v or u is expelled and the other vertex is absorbed.

Second, if no Λ exists with $\Lambda, \Lambda+2 \notin L$ and $\Lambda+1 \in L$ (but L and $\overline{L}$ are infinite), then there exists a $\Lambda \geq 3$ with $\Lambda \notin L$ and $\Lambda+2 \in L$, and we can use the graph already used for finite $\overline{L}$ (Figure 6(d)) as a directed L-clamp.

Lemma 2.11 below shows that $\mathcal{D}$-clamps do not exist, which completes the proof. □

LEMMA 2.11. *Let $G = (V, E)$ be a directed graph, and let $u, v \in V$. If G_{-u} and G_{-v} both contain a cycle cover, then*

(i) *both G and G_{-u-v} contain cycle covers or*
(ii) *all G_u^k and G_v^k for $k \in \mathbb{N}$ contain cycle covers.*

Proof. Let E_{-u} and E_{-v} be the sets of edges of the cycle covers of G_{-u} and G_{-v}, respectively. We construct two sequences of edges $P = (e_1, e_2, \ldots)$ and $P' = (e'_1, e'_2, \ldots)$. These sequences can be viewed as augmenting paths, and we use them to construct cycle covers of G_{-u-v} and G or G_u^k and G_v^k. The sequence P is given uniquely by traversing edges of E_{-v} forwards and edges of E_{-u} backwards:

(i) $e_1 = (u, x_1)$ is the unique outgoing edge of $u = x_0$ in E_{-v}.
(ii) If $e_i = (x_{i-1}, x_i) \in E_{-v}$, i.e., if i is odd, then $e_{i+1} = (x_{i+1}, x_i) \in E_{-u}$ is the unique incoming edge of x_i in E_{-u}.
(iii) If $e_i = (x_i, x_{i-1}) \in E_{-u}$, i.e., if i is even, then $e_{i+1} = (x_i, x_{i+1}) \in E_{-v}$ is the unique outgoing edge of x_i in E_{-v}.
(iv) If in any of the above steps no extension of P is possible, then stop.

Let $P = (e_1, \ldots, e_\ell)$. We observe two properties of the sequence P.

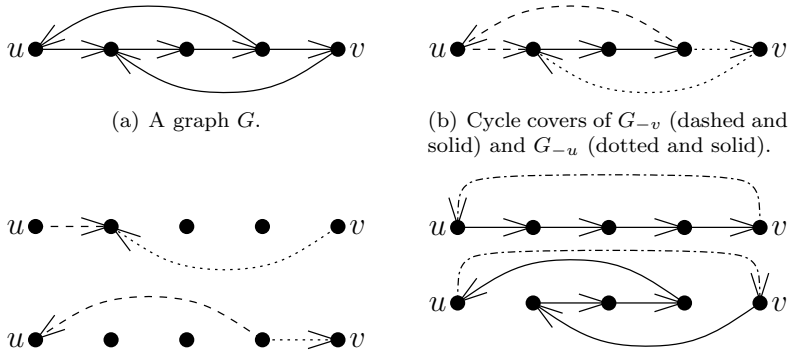
LEMMA 2.12. 1. *No edge appears more than once in P.*

2. *If ℓ is odd, i.e., $e_\ell \in E_{-v}$, then $e_\ell = (x_{\ell-1}, u)$. If ℓ is even, i.e., $e_\ell \in E_{-u}$, then $e_\ell = (v, x_{\ell-1})$.*

Proof. Assume the contrary of the first claim, and let $e_i = e_j$ $(i \neq j)$ be an edge that appears at least twice in P such that i is minimal. If $i = 1$, then $e_j = (u, x_1) \in E_{-v}$. This would imply that $e_{j-1} = (u, x_{j-2}) \in E_{-u}$, a contradiction. If $i > 1$, then assume $e_i = (x_{i-1}, x_i) \in E_{-v}$ without loss of generality. Since exactly one edge leaves x_{i-1} in E_{-u}, the edge $e_{i-1} = e_{j-1}$ is uniquely determined, which contradicts the assumption that i be minimal.

Let us now prove the second claim. Without loss of generality, we assume that the last edge e_ℓ belongs to E_{-v}. Let $e_\ell = (x_{\ell-1}, x_\ell)$. The path P cannot be extended, which implies that there does not exist an edge $(x_{\ell+1}, x_\ell) \in E_{-u}$. Since E_{-u} is a cycle cover of G_{-u}, this implies that $x_\ell = u$ and completes the proof. □

We build the sequence P' analogously, except that we start with the edge $e'_1 = (x'_1, v) \in E_{-u}$. Again, we traverse edges of E_{-v} forwards and edges of E_{-u} backwards. Let $P' = (e'_1, \ldots, e'_{\ell'})$.



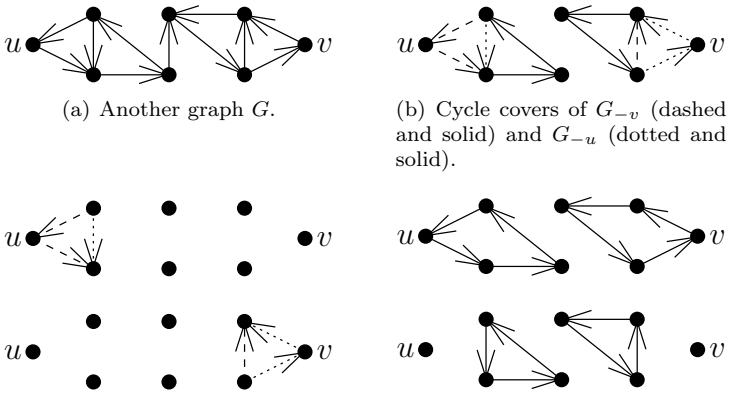
(a) A graph G.

(b) Cycle covers of G_{-v} (dashed and solid) and G_{-u} (dotted and solid).

(c) P (top) and P' (bottom). Dashed and dotted edges belong to the cycle covers of G_{-v} and G_{-u}, respectively.

(d) Cycle covers of G_v^0 (top) and G_u^0 (bottom).

FIG. 7. *Constructing cycle covers of G_v^0 and G_u^0 from the sequences P and P'.*



(a) Another graph G.

(b) Cycle covers of G_{-v} (dashed and solid) and G_{-u} (dotted and solid).

(c) P (top) and P' (bottom).

(d) Cycle covers of G (top) and G_{-u-v} (bottom).

FIG. 8. *Constructing cycle covers of G and G_{-u-v} from the sequences P and P'.*

No edge appears in both P and P' as can be proved similarly to the first claim of Lemma 2.12. Moreover, either P ends at u and P' ends at v or vice versa: We have $e_\ell = (x_{\ell-1}, u)$ if and only if $e'_{\ell'} = (v, x_{\ell'-1})$, and we have $e_\ell = (v, x_{\ell-1})$ if and only if $e'_{\ell'} = (x_{\ell'-1}, u)$. Let $P_{-u} \subseteq E_{-u}$ denote the set of edges of E_{-u} that are part of P. The sets P_{-v}, P'_{-u}, P'_{-v} are defined similarly.

Two examples are shown in Figures 7 and 8: Figures 7(a) and 7(b) show a graph with its cycle covers, while Figure 7(c) depicts P and P', the former starting at u and ending at v and the latter starting at v and ending at u. Figures 8(a), 8(b), and 8(c) show another example graph; this time P starts and ends at u and P' starts and ends at v.

Our aim is now to construct cycle covers of G and G_{-u-v} or of G_u^k and G_v^k. We distinguish two cases. Let us start with the case that P starts at u and ends at v and, consequently, P' starts at v and ends at u. Then

$$E_u^0 = (E_{-v} \setminus P_{-v}) \cup P_{-u} \cup \{(u, v)\}$$

is a cycle cover of G_u^0. To prove this, we have to show $\text{indeg}_{E_u^0}(x) = \text{outdeg}_{E_u^0}(x) = 1$ for all $x \in V$:

(i) We removed the outgoing edge of u in E_{-v}, which is in P_{-v}. The incoming edge of u in E_{-v} is left. P_{-u} does not contain any edge incident to u, and (u, v) is an outgoing edge of u. Thus, $\text{indeg}_{E_u^0}(u) = \text{outdeg}_{E_u^0}(u) = 1$.

(ii) There is no edge incident to v in E_{-v}. P_{-u} contains an outgoing edge of v, and (u, v) is an incoming edge of v. Thus, $\text{indeg}_{E_u^0}(v) = \text{outdeg}_{E_u^0}(v) = 1$.

(iii) For all $x \in V \setminus \{u, v\}$, either both P_{-v} and P_{-u} contain an incoming edge of x or neither of them does. Analogously, either both P_{-v} and P_{-u} contain an outgoing edge of x or neither of them does. Thus, replacing P_{-v} by P_{-u} changes neither $\text{indeg}(x)$ nor $\text{outdeg}(x)$.

By replacing the edge (u, v) by a path $(u, y_1), \ldots, (y_k, v)$, we obtain a cycle cover of G_u^k for all $k \in \mathbb{N}$. A cycle cover of G_v^0 is obtained similarly:

$$E_v^0 = (E_{-u} \setminus P_{-u}) \cup P_{-v} \cup \{(v, u)\}.$$

As above, we get cycle covers of G_v^k by replacing (v, u) by a path $(v, y_1), \ldots, (y_k, u)$. Figure 7(d) shows an example of how the new cycle covers are obtained.

The second case is that P starts and ends at u and P' starts and ends at v. Then

$$(E_{-v} \setminus P_{-u}) \cup P_{-v} \text{ and } (E_{-u} \setminus P'_{-v}) \cup P'_{-u}$$

are cycle covers of G, and

$$(E_{-v} \setminus P_{-v}) \cup P_{-u} \text{ and } (E_{-u} \setminus P'_{-u}) \cup P'_{-v}$$

are cycle covers of G_{-u-v}. The proof is similar to the first case. Figure 8(d) shows an example. □

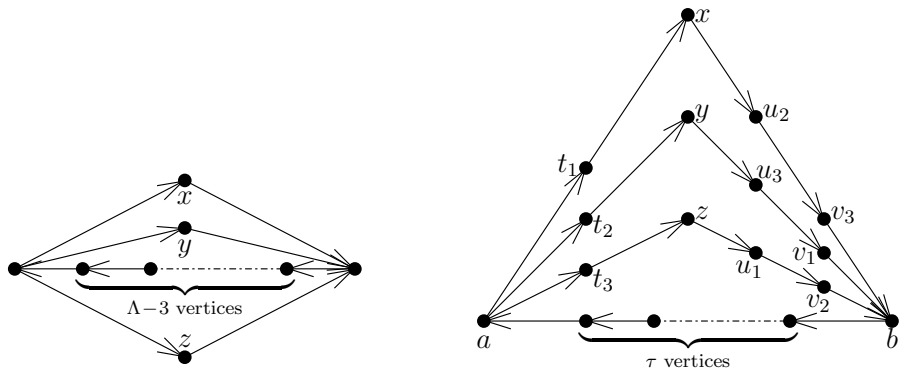
2.5. Intractability for directed graphs. From the hardness results in the previous sections and the work by Hell et al. [22], we obtain the NP-hardness and APX-hardness of L-DCC and Max-L-DCC(0,1), respectively, for all L with $2 \notin L$ and $\overline{L} \not\subseteq \{2, 3, 4\}$: We use the same reduction as for undirected cycle covers and replace every undirected edge $\{u, v\}$ by a pair of directed edges (u, v) and (v, u). However, this does not work if $2 \in L$ and also leaves open the cases when $\overline{L} \subsetneq \{2, 3, 4\}$. $\mathcal{D}$-DCC, Max-$\mathcal{D}$-DCC(0,1), and Max-$\mathcal{D}$-DCC can be solved in polynomial time, but the case $L = \{2\}$ is also easy: Replace two opposite edges (u, v) and (v, u) by an edge $\{u, v\}$ of weight $w(u, v) + w(v, u)$, and compute a matching of maximum weight on the undirected graph thus obtained.

We will settle the complexity of the directed cycle cover problems by showing that $L = \{2\}$ and $L = \mathcal{D}$ are the only tractable cases. For all other L, L-DCC is NP-hard, and Max-L-DCC(0,1) and Max-L-DCC are APX-hard. Let us start by proving the APX-hardness.

THEOREM 2.13. *Let $L \subseteq \mathcal{D}$ be a nonempty set. If $L \notin \{\{2\}, \mathcal{D}\}$, then* Max-$L$-DCC(0,1) *is* APX*-hard.*

Proof. We adapt the proof presented in section 2.2. Since $L \neq \{2\}$, there exists a $\lambda \in L$, with $\lambda \geq 3$. Thus, Min-Vertex-Cover(λ) is APX-complete. All we need is such a λ and a directed L-clamp. Then we can reduce Min-Vertex-Cover(λ) to Max-L-DCC(0,1).

We use the L-clamps to build L-gadgets, which again should have the property that they absorb one of their connectors and expel the other two. In the case of L being finite, the graph shown in Figure 9(a) is a directed L-gadget. In the case of



(a) L-gadget for finite L.

(b) L-gadget for infinite L with $\tau + 6 \in L$. The triple clamps are represented by their connectors t_i, u_i, v_i.

FIG. 9. *Directed L-gadgets with connectors x, y, z.*

infinite L, we can build directed triple L-clamps exactly as for undirected graphs. By using these, we can build directed L-gadgets, which are simply directed variants of their undirected counterparts (Figure 9(b)).

The edge gadgets build the graph G_1: Let $x \in X$ be a vertex of H and $a_1, \ldots, a_\lambda \in F$ be the edges incident to x in H (in arbitrary order). Then we assign weight one to the edges $(x^1_{a_\xi}, x^1_{a_{\xi+1}})$ for all $\xi \in \{1, \ldots, \lambda - 1\}$. The edge $(x^1_{a_\lambda}, x^1_{a_1})$ has weight zero. These λ edges are called the junctions of x.

Again, $G_2, \ldots, G_\lambda$ are exact copies of G_1 except that weight one is assigned also to $(x^\xi_{a_\lambda}, x^\xi_{a_1})$ for all $\xi \in \{2, 3, \ldots, \lambda\}$.

Again, we let the z-vertices form λ-cycles: For all edges $a \in F$, we assign weight one to $(z^\xi_a, z^{\xi+1}_a)$ for $\xi \in \{1, 2, \ldots, \lambda - 1\}$ and to (z^λ_a, z^1_a).

Weight zero is assigned to all edges that are not mentioned.

The remainder of the proof goes along the same lines as the APX-hardness proof for undirected L-cycle covers. □

Note that the NP-hardness of L-DCC for $L \notin \{\{2\}, \mathcal{D}\}$ does not follow directly from the APX-hardness of Max-L-DCC(0,1): A famous counterexample is 2SAT, for which it is APX-hard to maximize the number of simultaneously satisfied clauses [25], although testing whether a 2CNF formula is satisfiable takes only linear time.

THEOREM 2.14. *Let $L \subseteq \mathcal{D}$ be a nonempty set. If $L \notin \{\{2\}, \mathcal{D}\}$, then* L-DCC *is* NP*-hard.*

Proof. All we need is an L-clamp and some $\lambda \in L$, with $\lambda \geq 3$. We present a reduction from λ-XC (which is NP-complete since $\lambda \geq 3$) that is similar to the reduction of Hell et al. [22] used to prove the NP-hardness of L-UCC for $\overline{L} \not\subseteq \{3, 4\}$.

Let (X, F) be an instance of λ-XC. Note that we will construct a directed graph G as an instance of L-DCC; i.e., G is neither complete nor edge-weighted. For each $x \in X$, we have a vertex in G that we again call x. For $a = \{x_1, \ldots, x_\lambda\} \in F$, we construct a λ-cycle consisting of the vertices $a_1, \ldots, a_\lambda$. Then we add λ L-clamps $K^{x_\eta}_a$, with a_η and x_η as connectors for all $\eta \in \{1, \ldots, \lambda\}$. See Figure 10 for an example.

What remains to be shown is that G contains an L-cycle cover if and only if F is a "yes" instance of λ-XC. Assume first that there exists a subset $\tilde{F} \subseteq F$ such that $\bigcup_{a \in \tilde{F}} a = X$ and every element $x \in X$ is contained in exactly one set of $\tilde{F}$. We construct an L-cycle cover of G in which all clamps are healthy: Let $a = \{x_1, \ldots, x_\lambda\} \in F$. If $a \in \tilde{F}$, then let $K^{x_\eta}_a$ expel a_η and absorb x_η for all $\eta \in \{1, \ldots, \lambda\}$, and

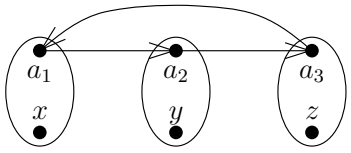


FIG. 10. *The construction for the* NP*-hardness of* L-DCC *from the viewpoint of* $a = \{x, y, z\} \in F$. *Each ellipse represents an* L*-clamp.*

let $a_1, a_2, \ldots, a_\lambda$ form a λ-cycle. If $a \notin \tilde{F}$, let $K_a^{x_\eta}$ expel x_η and absorb a_η for all $\eta \in \{1, \ldots, \lambda\}$. All connectors are absorbed by exactly one clamp or are covered by a λ-cycle since $\tilde{F}$ is an exact cover.

Now we prove the reverse direction. Let C be an L-cycle cover of G. Then every clamp of G is healthy in C; i.e., it absorbs one of its connectors and expels the other one. Let $a = \{x_1, \ldots, x_\lambda\} \in F$, and assume that $K_a^{x_\eta}$ expels a_η. Since a_η must be part of a cycle in C, $(a_{\eta-1}, a_\eta)$ and $(a_\eta, a_{\eta+1})$ must be in C. We obtain either that all $a_1, \ldots, a_\lambda$ are absorbed by $K_a^{x_1}, \ldots, K_a^{x_\lambda}$ or that all are expelled by $K_a^{x_1}, \ldots, K_a^{x_\lambda}$. Now consider any $x \in X$, and let $a_1, a_2, \ldots, a_\ell \in F$ be all of the sets that contain x. All clamps $K_{a_1}^x, \ldots, K_{a_\ell}^x$ are healthy, C is an L-cycle cover of G, and x is not incident to any further edges. Hence, there must be a unique a_i such that $K_{a_i}^x$ absorbs x. Thus,

$$\tilde{F} = \left\{a = \{x_1, \ldots, x_\lambda\} \in F \mid K_a^{x_\eta} \text{ absorbs } x_\eta \text{ for all } \eta \in \{1, \ldots, \lambda\}\right\}$$

is an exact cover of (X, F). □

If the language $\{1^\lambda \mid \lambda \in L\}$ is in NP, then L-DCC is also in NP and therefore NP-complete if $L \notin \{\{2\}, \mathcal{D}\}$: We can nondeterministically guess a cycle cover and then check if $\lambda \in L$ for every cycle length λ occurring in that cover. Conversely, if $\{1^\lambda \mid \lambda \in L\}$ is not in NP, then L-DCC is not in NP either since there is a reduction of $\{1^\lambda \mid \lambda \in L\}$ to L-DCC: On input $x = 1^\lambda$, construct a graph G on λ vertices that consists solely of a Hamiltonian cycle. Then $x \in L$ if and only if G contains an L-cycle cover.

3. Approximation algorithms. The goal of this section is to devise approximation algorithms for Max-L-UCC and Max-L-DCC that work for arbitrary L. The catch is that we have an uncountable number of problems Max-L-UCC and Max-L-DCC, and for most L it is impossible to decide whether some cycle length is in L or not.

Assume, for instance, that we have an algorithm that solves Max-L-UCC for some set L that is not recursively enumerable. We enumerate all instances of Max-L-UCC and run the algorithm on these instances. This yields an enumeration of a subset of L. Since L is not recursively enumerable, there exist $\lambda \in L$ such that the algorithm never outputs λ-cycles. Now consider a graph with λ vertices where all edges have weight zero except for a Hamiltonian cycle of weight one edges. Then the Hamiltonian cycle is the unique optimum solution, but our algorithm does not output the λ-cycle, contradicting the assumption that it solves Max-L-UCC.

One possibility to circumvent this problem would be to restrict ourselves to sets L such that $\{1^\lambda \mid \lambda \in L\}$ is in P. Another possibility to cope with this problem is to include the permitted cycle lengths in the input. However, while such restrictions are necessary for finding optimum solutions, it turns out that they are unnecessary for designing approximation algorithms.

A necessary and sufficient condition for a complete graph with n vertices to have an L-cycle cover is that there exist (not necessarily distinct) lengths $\lambda_1, \ldots, \lambda_k \in L$ for some $k \in \mathbb{N}$ with $\sum_{i=1}^{k} \lambda_i = n$. We call such an n *L-admissible* and define $\langle L \rangle = \{n \mid n \text{ is } L\text{-admissible}\}$. Although L can be arbitrarily complicated, $\langle L \rangle$ always allows efficient membership testing.

LEMMA 3.1. *For all $L \subseteq \mathbb{N}$, there exists a finite set $L' \subseteq L$ with $\langle L' \rangle = \langle L \rangle$.*

Proof. Let $L_{\leq \ell} = \{n \in L \mid n \leq \ell\} \subseteq L$. Let $g_L \in \mathbb{N}$ be the greatest common divisor of all numbers in L. There exists an $\ell_0 \in L$ such that g_L is also the greatest common divisor of $L_{\leq \ell_0}$.

If $g_L \in L$, then $\langle \{g_L\} \rangle = \langle L \rangle$, and we are done. Thus, we assume that $g_L \notin L$. There exist $\xi_1, \ldots, \xi_k \in \mathbb{Z}$ and $\lambda_1, \ldots, \lambda_k \in L_{\leq \ell_0}$ for some $k \in \mathbb{N}$ with $\sum_{i=1}^{k} \xi_i \lambda_i = g_L$. Let $\xi = \min_{1 \leq i \leq k} \xi_i$. We have $\xi < 0$ since $g_L \notin L$. Choose any $\lambda \in L_{\leq \ell_0}$, and let $\ell = -\xi\lambda \cdot \sum_{i=1}^{k} \lambda_i$. Let $n \in \langle L \rangle$ with $n \geq \ell$, let $m = \bmod(n - \ell, \lambda)$, and let $s = \left\lfloor \frac{n-\ell}{\lambda} \right\rfloor$. We can write n as

$$n = \lambda s + m + \ell = \lambda s + \frac{m}{g_L} \cdot \sum_{i=1}^{k} \xi_i \lambda_i - \lambda\xi \cdot \sum_{i=1}^{k} \lambda_i = \lambda s + \sum_{i=1}^{k} (m\xi_i - \lambda\xi) \cdot \lambda_i.$$

Since $m < \lambda$ and $\xi_i \geq \xi < 0$, we have $(m\xi_i - \lambda\xi) \geq 0$ for all i. Hence, $\langle L_{\leq \ell_0} \rangle$ contains all elements $n \in \langle L \rangle$, with $n \geq \ell$. Elements of $\langle L \rangle$ smaller than ℓ are contained in $\langle L_{\leq \ell} \rangle \supseteq \langle L_{\leq \ell_0} \rangle$. Hence, $\langle L_{\leq \ell} \rangle = \langle L \rangle$, and $L' = L_{\leq \ell}$ is the finite set for which we are looking. □

For every fixed L, we can not only test in time polynomial in n whether n is L-admissible, but we can, provided that $n \in \langle L \rangle$, also find numbers $\lambda_1, \ldots, \lambda_k \in L'$ that add up to n, where $L' \subseteq L$ denotes a finite set with $\langle L \rangle = \langle L' \rangle$. This can be done via dynamic programming in time $O(n \cdot |L'|)$, which is $O(n)$ for fixed L.

Although $\langle L \rangle = \langle L' \rangle$, there are clearly graphs for which the weights of an optimal L-cycle cover and an optimal L'-cycle cover differ: Let $\lambda \in L \setminus L'$, and consider a λ-vertex graph where all edge weights are zero except for one Hamiltonian cycle of weight one edges. However, this does not matter for our approximation algorithms.

The two approximation algorithms presented in sections 3.2 and 3.3 are based on a decomposition technique for cycle covers presented in section 3.1.

3.1. Decomposing cycle covers. In this section, we present a decomposition technique for cycle covers. The technique can be applied to cycle covers of undirected graphs but also to directed cycle covers that do not contain 2-cycles.

A *single* is a single edge (or a path of length one) in a graph, while a *double* is a path of length two. Our aim is to decompose a cycle cover C on n vertices into roughly $n/6$ singles, $n/6$ doubles, and $n/6$ isolated vertices. If n is not divisible by six, we replace $n/6$ by $\lfloor n/6 \rfloor$ or $\lceil n/6 \rceil$: If $n = 6k + \ell$ for $k, \ell \in \mathbb{N}$ and $\ell \leq 5$, then we take $k + \alpha_\ell$ singles and $k + \beta_\ell$ doubles, where α_ℓ and β_ℓ are given in Table 1. Thus, we retain half of the edges of C. We aim to decompose the cycle covers such that at least half of the weight of the cycle cover is preserved.

The reason why we decompose cycle covers into singles and doubles is the following: We cannot decompose them into longer paths in general since this does not work for $\{3\}$-cycle covers. If we restricted ourselves to decomposing the cycle covers into singles only, then 3-cycles would limit the weight preserved: We would retain only one-third of the edges of the 3-cycles and thus at most one-third of their weight in general. Finally, if we restricted ourselves to doubles, then 5-cycles would limit the weight we could obtain since we would retain only two of their five edges.

TABLE 1
A cycle cover on $n = 6k + \ell$ vertices will be decomposed into $k + \alpha_\ell$ singles and $k + \beta_\ell$ doubles.

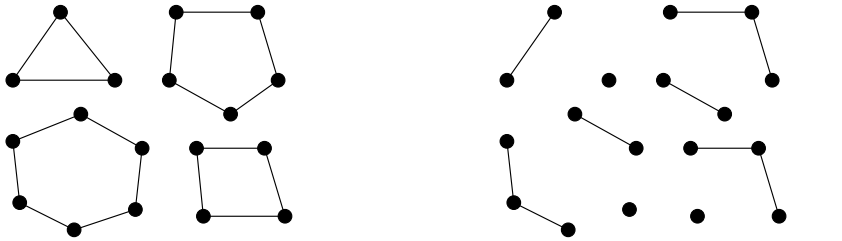
β_ℓ	0	0	0	1	1	1



(a) A cycle cover. (b) A decomposition of the cycle cover.

FIG. 11. *An example of a decomposition according to Lemma* 3.2.

In our approximation algorithms, we exploit the following observation: If every cycle cover on n vertices can be decomposed into α singles and β doubles, then, for every L, every L-cycle cover on n vertices can be decomposed in the same way. This implies that we can build cycle covers from such a decomposition: Given α singles and β doubles, and $n - 2\alpha - 3\beta$ isolated vertices, we can join them to form an L-cycle cover. (The only restriction is that n must be L-admissible.)

Let us now state the decomposition lemma.

LEMMA 3.2. *Let $C = (V, E)$ be a cycle cover on $n = 6k + \ell$ vertices such that the length of each cycle is at least three. Let $w : E \to \mathbb{N}$ be an edge weight function.*

Then there exists a decomposition $D \subseteq E$ of C such that (V, D) consists of vertex-disjoint $k + \alpha_\ell$ singles, $k + \beta_\ell$ doubles, and $n - 5k - 3\beta_\ell - 2\alpha_\ell$ isolated vertices and $w(D) \geq w(E)/2$, where α_ℓ and β_ℓ are given in Table 1.

The decomposition can be done in polynomial time.

Figure 11 illustrates how a cycle cover is decomposed into singles and doubles.

Let us first prove some helpful lemmas.

LEMMA 3.3. *Let $\lambda, \alpha, \beta \in \mathbb{N}$, with $\alpha + 2\beta \geq \lambda/2$ and $2\alpha + 3\beta \leq \lambda$. Then every cycle c of length λ can be decomposed into α singles and β doubles such that the weight of the decomposition is at least $w(c)/2$.*

Proof. Every single involves two vertices of c, while every double involves three vertices. Thus, $2\alpha + 3\beta \leq \lambda$ is a necessary condition for c being decomposable into α singles and β doubles. It is also a sufficient condition.

We assign an arbitrary orientation to c. Let $e_0, \ldots, e_{\lambda-1}$ be the consecutive edges of c, where e_0 is chosen uniformly at random among the edges of c. We take α singles $e_0, e_2, \ldots, e_{2\alpha-2}$ and β doubles $(e_{2\alpha}, e_{2\alpha+1}), (e_{2\alpha+3}, e_{2\alpha+4}), \ldots, (e_{2\alpha+3\beta-3}, e_{2\alpha+3\beta-2})$. Since $2\alpha + 3\beta \leq \lambda$, this is a feasible decomposition. The probability that any fixed edge of c is included in the decomposition is $\frac{\alpha+2\beta}{\lambda}$. Thus, the expected weight of the decomposition is $\frac{\alpha+2\beta}{\lambda} \cdot w(c) \geq w(c)/2$. ∎

LEMMA 3.4. *Let $\lambda \in \mathbb{N}$. Suppose that every cycle c of length λ can be decomposed into α singles and β doubles of weight at least $w(c)/2$. Then every cycle c' of length $\lambda + 6$ can be decomposed into $\alpha + 1$ singles and $\beta + 1$ doubles of weight at least $w(c')/2$.*

TABLE 2

The induction basis. The columns α and β show the number of singles and doubles needed, respectively. We denote by $\lambda \rightsquigarrow (\alpha, \beta)$ that a λ-cycle is decomposed into α singles and β doubles. If there are two lines for a case, then the option that yields more weight is chosen.

(b) Removing two odd cycles.

Proof. We have $\alpha+2\beta \geq \lambda/2$ and $2\alpha+3\beta \leq \lambda$. Thus, $\alpha+1+2(\beta+1) \geq (\lambda+6)/2$ and $2(\alpha+1)+3(\beta+1) \leq \lambda+6$. The lemma follows from Lemma 3.3. □

Lemma 3.4 also holds if we consider more than one cycle: Assume that every collection of k cycles of lengths $\lambda_1, \ldots, \lambda_k$ can be decomposed into α singles and β doubles such that the weight of the decomposition is at least half the weight of the cycles. Then k cycles of lengths $\lambda_1+6, \lambda_2, \ldots, \lambda_k$ can be decomposed into $\alpha+1$ singles and $\beta+1$ doubles such that also at least half of the weight of the cycles is preserved. Due to Lemma 3.4, we can restrict ourselves to cycles of length at most eight in the following. The reason for this is the following: If we know how to decompose cycles of length λ, then we also know how to decompose cycles of length $\lambda+6, \lambda+12, \ldots$ from Lemma 3.4.

We are now prepared to prove Lemma 3.2.

Proof of Lemma 3.2. We prove the lemma by induction on the number of cycles. As the induction basis, we consider a cycle cover consisting of either a single cycle or of two odd cycles. See Table 2. Due to Lemma 3.4, we can restrict ourselves to considering cycles of length at most eight. Tables 3(a) and 3(b) show how to decompose a single cycle and two odd cycles, respectively. We always perform the decomposition such that the weight preserved is maximized. In particular, if there are two odd cycles of different length, we have two options in how to decompose these cycles, and we choose the one that yields the larger weight. Overall, we obtain a decomposition with an appropriate number of singles and doubles that preserves at least one half of the weight.

$L \notin \{\{2\}, \mathcal{D}\}$	NP-hard	APX-hard	APX-hard

(b) Directed cycle covers.

As the induction hypothesis, we assume that the lemma holds if the number of cycles is less than r. Assume that we have a cycle cover C consisting of r cycles. Let $n = 6k + \ell$ for the number of its vertices for $k, \ell \in \mathbb{N}$ and $\ell \leq 5$. We remove either an even cycle or two odd cycles. In the following, let C' be the new cycle cover obtained by removing one or two cycles from C. A little more care is needed than in the induction basis: Consider, for instance, the case of removing a 4-cycle. If $\ell = 4$, then C has to be decomposed into k singles and $k+1$ doubles, while we have to take k singles and k doubles from C'. Thus, the 4-cycle has to be decomposed into a double. But if $\ell = 1$, then we need $k + 1$ singles and k doubles from C and $k - 1$ singles and k doubles from C'. Thus, the 4-cycle has to be decomposed into two singles. Overall, the 4-cycle has to be decomposed into a double if $\ell \in \{0, 3, 4, 5\}$ and into two singles if $\ell \in \{1, 2\}$. Similar case distinctions hold for all other cases. How to remove one even or two odd cycles is shown in Tables 4(a) and 4(b), respectively.

To complete the proof, we have to deal with the cases of a 3- and a 5-cycle, which are slightly more complicated and not covered by Table 4(b). We run into trouble if, for instance, $\ell = 3$. In this case, we have to take two doubles. If the 5-cycle is much heavier than the 3-cycle, then it is impossible to preserve half of the weight of the two cycles. But we can avoid this problem: As long as there is an even cycle, we decompose this one. After that, as long as there are at least three odd cycles, we can choose two of them such that we do not have a pair of one $(3 + 6\xi)$-cycle and one $(5 + 6\xi')$-cycle for some $\xi, \xi' \in \mathbb{N}$. The only situation in which it can happen that we cannot avoid decomposing a $(3+6\xi)$-cycle and a $(5+6\xi')$-cycle is when there are only two cycles left. In this case, we have $\ell = 2$, and we have treated this case already in the induction basis. □

If we consider directed graphs where 2-cycles can also occur, only one-third of the weight can be preserved. This can be done by decomposing the cycle cover into a matching of cardinality $\lceil n/3 \rceil$. (Every λ-cycle can be decomposed into a matching of size up to $\lfloor \lambda/2 \rfloor \geq \lceil \lambda/3 \rceil$. The bottleneck is 3-cycles, which yield only one edge.)

An obvious question is whether the decomposition lemma can be improved in order to preserve more than half of the weight or more than one-third of the weight if we additionally allow 2-cycles. Unfortunately, this is not the case.

A generic decomposition lemma states the following: For every $n \in \mathbb{N}$, every k-cycle cover (for $k \in \{2, 3\}$) on n vertices can be decomposed into α singles and β doubles such that at least a fraction r of the weight of the cycle cover is preserved. (As already mentioned, longer paths are impossible due to 3-cycles.) Lemma 3.2 instantiates this generic lemma with $\alpha \approx n/6$, $\beta \approx n/6$, and $r = 1/2$. In case of the

Input: undirected complete graph $G = (V, E)$, $|V| = n$; edge weights $w : E \to \mathbb{N}$
Output: an L-cycle cover C^{apx} of G if n is L-admissible, $\perp$ otherwise
1: **if** $n \notin \langle L \rangle$ **then**
2: **return** $\perp$
3: compute a cycle cover C^{init} in G of maximum weight
4: decompose C^{init} into a set $D \subseteq C^{\text{init}}$ of edges according to Lemma 3.2
5: join the singles and doubles in D to obtain an L-cycle cover C^{apx}
6: **return** C^{apx}

Algorithm 1: A 2 approximation algorithm for Max-L-UCC.

presence of 2-cycles, we have sketched a decomposition with $\alpha \approx n/3$, $\beta = 0$, and $r = 1/3$.

LEMMA 3.5. *No decomposition technique for* 3*-cycle covers can in general preserve more than one-half of the weight of the* 3*-cycle covers.*

Furthermore, no decomposition technique for 2*-cycle covers can in general preserve more than one-third of the weight of the* 2*-cycle covers.*

Proof. We exploit the fact that the fraction of edges that are preserved in a cycle cover decomposition is a lower bound for the fraction of the weight that can be preserved.

Since, in particular, $\{3\}$-cycle covers have to be decomposed, we cannot decompose the cycle cover into paths of length more than two. Now consider decomposing a $\{4\}$-cycle cover. Since paths of length 3 are not allowed, we have to discard two edges of every 4-cycle. Thus, at most two edges of every 4-cycle are preserved, which proves the first part of the lemma.

The second part follows analogously by considering 3-cycles and observing that paths of length two or more are not allowed. ∎

Overall, Lemma 3.5 shows that every approximation algorithm for Max-L-UCC or Max-L-DCC that works for arbitrary sets L and is purely decomposition-based achieves approximation ratios of at best 2 or 3, respectively. We achieve an approximation ratio of $8/3 < 3$ for Max-L-DCC by paying special attention to 2-cycles (section 3.3).

3.2. Undirected cycle covers. Our approximation algorithm for Max-L-UCC (Algorithm 1) directly exploits Lemma 3.2.

THEOREM 3.6. *Algorithm* 1 *is a factor* 2 *approximation algorithm for* Max-L-UCC *for all* $L \subseteq \mathcal{U}$*. Its running time is* $O(n^3)$*.*

Proof. If L is infinite, we replace L by a finite set $L' \subseteq L$, with $\langle L' \rangle = \langle L \rangle$ according to Lemma 3.1. Algorithm 1 returns $\perp$ if and only if $n \notin \langle L \rangle$. Otherwise, an L-cycle cover C^{apx} is returned. Let $C^\star$ denote an L-cycle cover of maximum weight of G. We have $w(C^\star) \leq w(C^{\text{init}}) \leq 2 \cdot w(D) \leq 2 \cdot w(C^{\text{apx}})$. The first inequality holds because L-cycle covers are special cases of cycle covers. The second inequality holds due to the decomposition lemma (Lemma 3.2). The last inequality holds since no weight is lost during the joining. Overall, the algorithm achieves an approximation ratio of 2.

The running time of the algorithm is dominated by the time needed to compute the initial cycle cover, which is $O(n^3)$ [1, Chapter 12]. ∎

3.3. Directed cycle covers. In the following, let C^{opt} be an L-cycle cover of maximum weight. Let w_λ denote the weight of the λ-cycles in C^{opt}; i.e., $w(C^{\text{opt}}) = \sum_{\lambda \geq 2} w_\lambda$.

We distinguish three cases: First, $2 \notin L$; second, $2 \in L$ and $3 \notin L$; and third, $2, 3 \in L$.

We use the decomposition lemma (Lemma 3.2) only if $2 \notin L$. In this case, the weight of an optimal L-cycle cover is at most the weight of an optimal 3-cycle cover C_3^{opt}. Thus, we proceed as follows: First, we compute a 4/3 approximation C_3^{init} for Max-3-DCC, which can be done by using the algorithm of Bläser, Ram, and Sviridenko [7]. We have $w(C_3^{\text{init}}) \geq \frac{3}{4} \cdot w(C_3^{\text{opt}}) \geq \frac{3}{4} \cdot w(C^{\text{opt}})$. Now we decompose C_3^{init} into a collection D of singles and doubles according to Lemma 3.2. Finally, we join the singles, doubles, and isolated vertices of D to form an L-cycle cover C^{apx}. We obtain a factor 8/3 approximation for the case that $2 \notin L$:

$$w(C^{\text{apx}}) \geq w(D) \geq \frac{1}{2} \cdot w(C_3^{\text{init}}) \geq \frac{3}{8} \cdot w(C^{\text{opt}}).$$

Now we consider the case that $2 \in L$ and $3 \notin L$. In this case, a matching-based algorithm achieves an approximation ratio of 5/2: We compute a matching of a certain cardinality, which we will specify in a moment, and then we join the edges of the matching to obtain an L-cycle cover. The cardinality of the matching is chosen such that an L-cycle cover can be built from such a matching. A λ-cycle yields a matching of cardinality $\lfloor \lambda/2 \rfloor$. Thus, a matching of cardinality d in a graph of n vertices can be extended to form an L-cycle cover if and only if $d \leq D(n, L)$, where

$$D(n, L) = \max \left\{ \sum_{i=1}^{k} \lfloor \lambda_i/2 \rfloor \mid k \in \mathbb{N}, \sum_{i=1}^{k} \lambda_i = n, \text{ and } \lambda_i \in L \text{ for } 1 \leq i \leq k \right\} \leq \frac{n}{2}.$$

Given L, we can compute $D(n, L)$ by using dynamic programming. Let us now estimate the weight of a matching of cardinality at most $D(n, L)$ that has maximum weight among all such matchings. From C^{opt}, we obtain a matching with a weight of at least

$$\sum_{\lambda \geq 2} \frac{1}{\lambda} \cdot \left\lfloor \frac{\lambda}{2} \right\rfloor \cdot w_\lambda \geq \sum_{\lambda \geq 2} \frac{2}{5} \cdot w_\lambda = \frac{2}{5} \cdot w(C^{\text{opt}}).$$

The reason is that $w_3 = 0$ because $3 \notin L$ and that $\min_{\lambda \in \{2,4,5,6,7,\dots\}} \frac{1}{\lambda} \cdot \lfloor \lambda/2 \rfloor \geq 2/5$. Thus, by computing a maximum-weight matching M of cardinality at most $D(n, L) \geq 2n/5$ and joining the edges to form an L-cycle cover C^{apx}, we obtain a factor 5/2 approximation.

What remains to be considered is the case that $2, 3 \in L$. In this case, we start by computing an initial cycle cover C^{init} (without any restrictions). Then we do the following: For every even cycle, we take every other edge such that at least one-half of its weight is preserved. For every edge thus obtained, we add the converse edge to obtain a collection of 2-cycles. For every odd cycle, we take every other edge and one path of length two such that at least half of the weight is preserved. Then we add edges to obtain 2-cycles and one 3-cycle. In this way, we obtain a $\{2, 3\}$-cycle cover C^{apx}, which is also an L-cycle cover. We have $w(C^{\text{apx}}) \geq \frac{1}{2} \cdot w(C^{\text{init}}) \geq \frac{1}{2} \cdot w(C^{\text{opt}})$. Figure 12 shows an example.

Our approximation algorithm is summarized as Algorithm 2. The running time of the algorithm of Bläser, Ram, and Sviridenko is polynomial [7], and all other steps can be executed in polynomial time as well. Thus, the running time of Algorithm 2 is also polynomial.

THEOREM 3.7. *Algorithm* 2 *is a factor* 8/3 *approximation algorithm for* Max-L-UCC *for all nonempty sets* $L \subseteq \mathcal{D}$. *Its running time is polynomial.*

FIG. 12. *Sketch of the algorithm for* $\{2,3\} \subseteq L$.

Input: directed complete graph $G = (V, E)$, $|V| = n$; edge weights $w : E \to \mathbb{N}$
Output: an L-cycle cover C^{apx} of G if n is L-admissible, $\perp$ otherwise

if $n \notin \langle L \rangle$ **then**
    return $\perp$
if $2 \in L$ and $3 \in L$ **then**
    compute a cycle cover C^{init} (without restrictions)
    for all even cycles c of C^{init} **do**
        take every other edge of c such that at least one-half of c's weight is preserved
        add the converse edges to obtain 2-cycles; add these cycles to C^{apx}
    for all odd cycles c of C^{init} **do**
        take every other edge and one path of length two of c such that at least one-half of c's weight is preserved
        add edges to obtain 2-cycles plus one 3-cycle; add these cycles to C^{apx}
else if $2 \in L$, $3 \notin L$ **then**
    compute a matching M of maximum weight of cardinality at most $D(n, L)$
    join the edges of M to form an L-cycle cover C^{apx}
else $(2 \notin L)$
    compute a 4/3 approximation C_3^{init} to an optimal 3-cycle cover
    decompose C_3^{init} into a set $D \subseteq C_3^{\text{init}}$ of edges according to Lemma 3.2
    join the singles and doubles in D to obtain an L-cycle C^{apx}
return C^{apx}

Algorithm 2: A factor 8/3 approximation algorithm for Max-L-DCC.

4. Conclusions. For almost all L, finding L-cycle covers is NP-hard, and finding L-cycle covers of maximum weight is APX-hard. Table 4 shows an overview. Although this shows that computing restricted cycle covers is generally very hard, we have proved that L-cycle covers of maximum weight can be approximated within a constant factor in polynomial time for all L.

For directed graphs, we have settled the complexity: If $L = \{2\}$ or $L = \mathcal{D}$, then L-DCC, Max-L-DCC(0,1), and Max-L-DCC are solvable in polynomial time; otherwise, they are intractable. For undirected graphs, the status of only five cycle cover problems remains open: L-UCC and Max-L-UCC(0,1) for $\overline{L} = \{4\}, \{3,4\}$ and Max-4-UCC.

There are some reasons for optimism that L-UCC and Max-L-UCC(0,1) for $\overline{L} = \{4\}, \{3,4\}$ are solvable in polynomial time: Hartvigsen [18] devised a polynomial-time algorithm for finding $\overline{\{4\}}$-cycle covers in bipartite graphs (forbidding 3-cycles does not change the problem for bipartite graphs). Moreover, there are augmenting path theorems for L-cycle covers for all L with $\overline{L} \subseteq \{3,4\}$ [26], which includes the two cases that are known to be polynomial-time solvable. Augmenting path theorems are often a building block for matching algorithms. But there are also augmenting path theorems for $L \subseteq \{3,4\}$ [26], even though these L-cycle cover problems are intractable.

TESTING GRAPH ISOMORPHISM*

ELDAR FISCHER† AND ARIE MATSLIAH†

Abstract. Two graphs G and H on n vertices are ϵ-far from being isomorphic if at least $\epsilon\binom{n}{2}$ edges must be added or removed from $E(G)$ in order to make G and H isomorphic. In this paper we deal with the question of how many queries are required to distinguish between the case that two graphs are isomorphic and the case that they are ϵ-far from being isomorphic. A query is defined as probing the adjacency matrix of any one of the two graphs, i.e., asking if a pair of vertices forms an edge of the graph or not. We investigate both one-sided and two-sided error testers under two possible settings: The first setting is where both graphs need to be queried, and the second setting is where one of the graphs is fully known to the algorithm in advance. We prove that the query complexity of the best one-sided error testing algorithm is $\widetilde{\Theta}(n^{3/2})$ if both graphs need to be queried, and that it is $\widetilde{\Theta}(n)$ if one of the graphs is known in advance (where the $\widetilde{\Theta}$ notation hides polylogarithmic factors in the upper bounds). For two-sided error testers, we prove that the query complexity of the best tester is $\widetilde{\Theta}(\sqrt{n})$ when one of the graphs is known in advance, and we show that the query complexity lies between $\Omega(n)$ and $\widetilde{O}(n^{5/4})$ if both G and H need to be queried. All of our algorithms are additionally nonadaptive, while all of our lower bounds apply for adaptive testers as well as nonadaptive ones.

1. Introduction.

Combinatorial property testing deals with the following task: For a fixed $\epsilon > 0$ and a fixed property P, distinguish using as few queries as possible (and with probability at least $\frac{2}{3}$) between the case that an input of length m satisfies P and the case that the input is ϵ-far (with respect to an appropriate metric) from satisfying P. The first time a question formulated in terms of property testing was considered was in the work of Blum, Luby, and Rubinfeld [8]. The general notion of property testing was first formally defined by Rubinfeld and Sudan [16], mainly for the context of the algebraic properties (such as linearity) of functions over finite fields and vector spaces. The first investigation in the combinatorial context is that of Goldreich, Goldwasser, and Ron [13], where testing of combinatorial graph properties was first formalized. The "dense" graph testing model that was defined in [13] is also the one that will serve us here. In recent years the field of property testing has enjoyed rapid growth, as witnessed in the surveys [15] and [9].

Formally, our inputs are two functions $g : \{1, 2, \ldots, \binom{n}{2}\} \to \{0, 1\}$ and $h : \{1, 2, \ldots, \binom{n}{2}\} \to \{0, 1\}$, which represent the edge sets of two corresponding graphs G and H over the vertex set $V = \{1, \ldots, n\}$. The *distance* of a graph from a property P is measured by the minimum number of bits that have to be modified in the input in order to make it satisfy P, divided by the input length m, which in our case is taken to be $\binom{n}{2}$. For the question of testing graphs with a constant number of queries, there are many recent advances, such as [4], [11], [3], and [2]. For the properties that we

consider here the number of required queries is of the form n^α for some $\alpha > 0$, and our interest will be to find bounds as tight as possible on α. We consider the following questions:

1. Given two input graphs G and H, how many queries to G and H are required to test that the two graphs are isomorphic? This property was already used in [1] for proving lower bounds on property testing, and a lower bound of the form n^α was known for quite a while (see, e.g., [9]).
2. Given a graph G_k, which is known in advance (and for which any amount of preprocessing is allowed), and an input graph G_u, how many queries to G_u are required to test that G_u is isomorphic to G_k? Some motivation for this question comes from [10], where upper and lower bounds that correlate this question with the "inherent complexity" of the provided G_k are proved. In this paper, our interest is in finding the bounds for the "worst possible" G_k.

For the case where the testers must have one-sided error, our results show tight (up to logarithmic factors) upper and lower bounds of $\widetilde{\Theta}(n^{3/2})$ for the setting where both graphs need to be queried, and of $\widetilde{\Theta}(n)$ for the setting where one graph is given in advance. The upper bounds are achieved by trivial algorithms of edge sampling and exhaustive search. As we are interested in the number of queries, we make no attempt to optimize the running time. The main work here lies in proving a matching lower bound for the first setting where both graphs need to be queried, as the lower bound for the second setting is nearly trivial.

Unusually for graph properties that involve no explicit counting in their definition, we can do significantly better if we allow our algorithms to have two-sided error. When one graph is given in advance, we show $\widetilde{\Theta}(n^{1/2})$ upper and lower bounds. The upper bound algorithm uses a technique that allows us to greatly reduce the number of candidate bijections that need to be checked, while assuring that for isomorphic graphs one of them will still be close to an isomorphism. For this to work we need to combine it with a distribution testing algorithm from [7], whose lower bound is in some sense the true cause of the matching lower bound here.

For two-sided error testers where the two graphs need to be queried, a gap in the bounds remains. We present here a lower bound proof of $\Omega(n)$ on the query complexity—it is in fact the lower bound proof already known from the literature, only here we analyze it to its fullest potential. The upper bound of $\widetilde{O}(n^{5/4})$ uses the ideas of the algorithm above for the setting where one of the graphs is known, with an additional mechanism to compensate for having to query from both graphs to find matching vertices.

To our knowledge, the best known algorithm for deciding this promise problem in the classical sense (i.e., given two graphs, distinguish whether they are isomorphic or ϵ-far from being isomorphic) requires quasi-polynomial running time [6]. Both our two-sided error testers have the additional property of a quasi-polynomial running time (similarly to the algorithm in [6]) even with the restriction on the number of queries.

Table 1.1 summarizes our results for the query complexity in various settings. We made no effort to optimize the logarithmic factors in the upper bounds, as well as the exact dependence on ϵ (which is at most polynomial).

The rest of the paper is organized as follows. We provide some preliminaries and definitions in section 2. Upper and lower bounds for the one-sided algorithms are proved in section 3, and the upper and lower bounds for the two-sided algorithms are proved in section 4. The final section 5 contains some discussion and concluding comments.

TABLE 1.1

	Upper bound	Lower bound
One-sided error, one graph known	$\widetilde{O}(n)$	$\Omega(n)$
One-sided error, both graphs unknown	$\widetilde{O}(n^{3/2})$	$\Omega(n^{3/2})$
Two-sided error, one graph known	$\widetilde{O}(n^{1/2})$	$\Omega(n^{1/2})$
Two-sided error, both graphs unknown	$\widetilde{O}(n^{5/4})$	$\Omega(n)$

2. Notation and preliminaries. All graphs considered here are undirected and with neither loops nor parallel edges. We also assume (even where not explicitly stated) that the number of vertices of the input graph is large enough, as a function of the other parameters. We denote by $[n]$ the set $\{1, 2, \ldots, n\}$. For a vertex v, $N(v)$ denotes the set of v's neighbors. For a pair of vertices u, v we denote by $N(u) \triangle N(v)$ the symmetric difference between $N(u)$ and $N(v)$. Given a permutation $\sigma : [n] \to [n]$ and a subset U of $[n]$, we denote by $\sigma(U)$ the set $\{\sigma(i) : i \in U\}$. Given a subset U of the vertices of a graph G, we denote by $G(U)$ the induced subgraph of G on U. We denote by $G(n, p)$ the random graph where each pair of vertices forms an edge with probability p, independently of each other.

DEFINITION 2.1. *Given two labeled graphs G and H on the same vertex set V, the* distance *between G and H is the size of the symmetric difference between the edge sets of G and H, divided by $\binom{|V|}{2}$.*

Given a graph G and a graph H on the same vertex set V, we say that H and G are ϵ-far *if the distance between G and any permutation of H is at least ϵ.*

Given a graph G and a graph property (a set of graphs that is closed under graph isomorphisms) P, we say that G is ϵ-far *from satisfying the property P if G is ϵ-far from any graph H on the same vertex set which satisfies P.*

Using this definition of the distance, we give a formal definition of a graph testing algorithm.

DEFINITION 2.2. *An* ϵ-testing algorithm with q queries *for a property P is a probabilistic algorithm that for any input graph G makes up to q queries (a query consisting of finding whether two vertices u, v of G form an edge of G or not) and satisfies the following.*

- *If G satisfies P, then the algorithm accepts G with probability at least $\frac{2}{3}$.*
- *If G is ϵ-far from P, then the algorithm rejects G with probability at least $\frac{2}{3}$.*

A property testing algorithm has one-sided error probability *if it accepts inputs that satisfy the property with probability* 1. *We also call such testers* one-sided error testers.

A property testing algorithm is nonadaptive *if the outcomes of its queries do not affect the choice of the following queries but only the decision of whether to reject or accept the input in the end.*

The following is just an extension of the above definition to properties of pairs of graphs. In our case, we will be interested in the property of two graphs being isomorphic.

DEFINITION 2.3. *An* ϵ-testing algorithm with q queries *for a property P of pairs of graphs is a probabilistic algorithm that for any input pair G, H makes up to q queries in G and H (a query consisting of finding whether two vertices u, v of G (H) form an edge of G (H) or not) and satisfies the following.*

- *If the pair G, H satisfies P, then the algorithm accepts with probability at least $\frac{2}{3}$.*

- *If the pair G, H is ϵ-far from P, then the algorithm rejects with probability at least $\frac{2}{3}$.*

To simplify the arguments when discussing the properties of the query sets, we define *knowledge charts*.

DEFINITION 2.4. *Given a query set Q to the adjacency matrix A of the graph $G = (V, E)$ on n vertices, we define the* knowledge chart *$I_{G,Q}$ of G as the subgraph of G known after making the set Q of queries to A. We partition the pairs of vertices of $I_{G,Q}$ into three classes: Q^1, Q^0, and Q^*. The pairs in Q^1 are those known to be edges of G, the pairs in Q^0 are those that are known not to be edges of G, and all unknown (unqueried) pairs are in Q^*. In other words, $Q^1 = E(G) \cap Q$, $Q^0 = Q \setminus E(G)$, and $Q^* = [V(G)]^2 \setminus Q$. For a fixed q, $0 \leq q \leq n$, and G, we define $I_{G,q}$ as the set of knowledge charts $\{I_{G,Q} : |Q| = q\}$. For example, note that $|I_{G,0}| = |I_{G,\binom{n}{2}}| = 1$.*

We will ask the question of whether two query sets are consistent, i.e., do they provide any evidence for the two graphs being nonisomorphic? We say that the knowledge charts are *knowledge-packable* if the query sets that they represent are consistent. Formally, we have the following definition.

DEFINITION 2.5. *A* knowledge-packing *of two knowledge charts I_{G_1,Q_1}, I_{G_2,Q_2}, where G_1 and G_2 are graphs with n vertices, is a bijection π of the vertices of G_1 into the vertices of G_2 such that for all $v, u \in V(G_1)$, if $\{v, u\} \in E(G_1) \cap Q_1$, then $\{\pi(v), \pi(u)\} \notin Q_2 \setminus E(G_2)$, and if $\{v, u\} \in Q_1 \setminus E(G_1)$, then $\{\pi(v), \pi(u)\} \notin E(G_2) \cap Q_2$.*

In particular, if G_1 is isomorphic to G_2, then for all $0 \leq q_1, q_2 \leq \binom{n}{2}$, every member of I_{G_1,q_1} is knowledge-packable with every member of I_{G_2,q_2}. In other words, if G_1 is isomorphic to G_2, then there is a knowledge-packing of I_{G_1,Q_1} and I_{G_2,Q_2} for any possible query sets Q_1 and Q_2.

LEMMA 2.6. *Any one-sided error isomorphism tester, after completing its queries Q_1, Q_2, must always accept G_1 and G_2 if the corresponding knowledge charts I_{G_1,Q_1} and I_{G_2,Q_2} on which the decision is based are knowledge-packable. In particular, if for some G_1, G_2 and $0 \leq q \leq \binom{n}{2}$, any $I_{G_1,Q_1} \in I_{G_1,q}$ and $I_{G_2,Q_2} \in I_{G_2,q}$ are knowledge-packable, then every one-sided error isomorphism tester which is allowed to ask at most q queries must always accept G_1 and G_2.*

Proof. This is true, since if the knowledge charts I_{G_1,Q_1} and I_{G_2,Q_2} are packable, it means that there is an extension G_1' of G_1's restriction to Q_1 to a graph that is isomorphic to G_2. In other words, given G_1' and G_2 as inputs, there is a positive probability that the isomorphism tester obtained $I_{G_1',Q_1} = I_{G_1,Q_1}$ and I_{G_2,Q_2} after completing its queries, and hence, a one-sided error tester must always accept in this case. □

Proving lower bounds for the two-sided error testers involves Yao's method [17], which for our context informally says that if there is a small enough statistical distance between the distributions of q query results, from two distributions over inputs that satisfy the property and inputs that are far from satisfying the property, then there is no tester for that property which makes at most q queries. We start with definitions that are adapted to property testing lower bounds.

DEFINITION 2.7 (restriction, variation distance). *For a distribution D over inputs, where each input is a function $f : \mathcal{D} \to \{0, 1\}$, and for a subset $\mathcal{Q}$ of the domain $\mathcal{D}$, we define the* restriction *$D|_{\mathcal{Q}}$ of D to $\mathcal{Q}$ to be the distribution over functions of the type $g : \mathcal{Q} \to \{0, 1\}$ that results from choosing a random function $f : \mathcal{D} \to \{0, 1\}$ according to the distribution D and then setting g to be $f|_{\mathcal{Q}}$, the restriction of f to $\mathcal{Q}$.*

Given two distributions D_1 and D_2 of binary functions from $\mathcal{Q}$, we define the variation distance *between D_1 and D_2 as follows: $d(D_1, D_2) = \frac{1}{2} \sum_{g:\mathcal{Q}\to\{0,1\}} |\Pr_{D_1}[g] -$*

$\Pr_{D_2}[g]|$, *where* $\Pr_D[g]$ *denotes the probability that a random function chosen according to* D *is identical to* g.

The next lemma follows from [17] (see, e.g., [9]).

LEMMA 2.8 (see [9]). *Suppose that there exist a distribution* D_P *on inputs over* $\mathcal{D}$ *that satisfy a given property* P *and a distribution* D_N *on inputs that are* ϵ*-far from satisfying the property, and suppose further that for any* $\mathcal{Q} \subset \mathcal{D}$ *of size* q*, the variation distance between* $D_P|_{\mathcal{Q}}$ *and* $D_N|_{\mathcal{Q}}$ *is less than* $\frac{1}{3}$*. Then it is not possible for a nonadaptive algorithm making* q *(or less) queries to* ϵ*-test for* P.

An additional lemma for adaptive testers is proved implicitly in [12], and a detailed proof appears in [9]. Here we strengthen it somewhat, but exactly the same proof still works in our case, too.

LEMMA 2.9 (Fischer, Newman, and Sgall [12]; see [9]). *Suppose that there exists a distribution* D_P *on inputs over* $\mathcal{D}$ *that satisfy a given property* P *and a distribution* D_N *on inputs that are* ϵ*-far from satisfying the property. Suppose further that for any* $\mathcal{Q} \subset \mathcal{D}$ *of size* q *and any* $g : \mathcal{Q} \to \{0,1\}$*, we have* $\Pr_{D_P|_{\mathcal{Q}}}[g] < \frac{3}{2}\Pr_{D_N|_{\mathcal{Q}}}[g]$*. Then it is not possible for any algorithm making* q *(or less) queries to* ϵ*-test for* P*. The conclusion also holds if instead of the above, for any* $\mathcal{Q} \subset \mathcal{D}$ *of size* q *and any* $g : \mathcal{Q} \to \{0,1\}$*, we have* $\Pr_{D_N|_{\mathcal{Q}}}[g] < \frac{3}{2}\Pr_{D_P|_{\mathcal{Q}}}[g]$.

Often, given two isomorphic graphs G, H on n vertices, we want to estimate how many vertices from both graphs need to be randomly chosen in order to get an intersection set of size k with high probability.

LEMMA 2.10. *Given two graphs* G, H *on* n *vertices, a bijection* σ *of their vertices, and two uniformly random subsets* $C_G \subset V(G)$*,* $C_H \subset V(H)$*, the following holds: For any* $0 < \alpha < 1$ *and any positive integers* c, k*, if* $|C_G| = kn^{\alpha}\log^c n$ *and* $|C_H| = n^{1-\alpha}\log^c n$*, then with probability* $1 - o(2^{-\log^c n})$ *the size of* $C_G \cap \sigma(C_H)$ *is greater than* k.

Proof sketch. By the linearity of expectation, the expected size of the intersection set is $\frac{|C_G||C_H|}{n} = k\log^{2c} n$. Using large deviation inequalities, $C_G \cap \sigma(C_H) > k$ with probability $1 - o(2^{-\log^c n})$. □

3. One-sided testers. By Lemma 2.6, one-sided testers for isomorphism look at some query set Q of the input and accept if and only if the restriction of the input to Q is extensible to some input satisfying the property. The main idea is to prove that if the input is far from satisfying the property, then with high probability its restriction Q will provide the evidence for it. To prove lower bounds for one-sided testers, it is sufficient to find an input that is ϵ-far from satisfying the property, but for which the restriction of the input to any possible set Q is extensible to some alternative input that satisfies the property. In this section we prove the following.

THEOREM 3.1. *The query complexity of the best one-sided isomorphism tester is* $\widetilde{\Theta}(n^{3/2})$ *(up to coefficients depending only on the distance parameter* ϵ*) if both graphs are unknown, and it is* $\widetilde{\Theta}(n)$ *if one of the graphs is known in advance.*

We first prove Theorem 3.1 for the case where both graphs are unknown and then move to the proof of the simpler second case where one of the graphs is known in advance.

3.1. One-sided testing of two unknown graphs.

The upper bound.

ALGORITHM 1.

1. For both graphs G_1, G_2 construct the query sets Q_1, Q_2 respectively, by choosing every possible query with probability $\sqrt{\frac{\ln n}{\epsilon n}}$, independently of other queries.

2. If $|Q_1|$ or $|Q_2|$ is larger than $1000n^{3/2}\sqrt{\frac{\ln n}{\epsilon}}$, accept without making the queries. Otherwise make the chosen queries.
3. If there is a knowledge-packing of I_{G_1,Q_1} and I_{G_2,Q_2}, accept. Otherwise reject.

Clearly, the query complexity of Algorithm 1 is $O(n^{3/2}\sqrt{\log n})$ for every fixed ϵ.

LEMMA 3.2. *Algorithm* 1 *accepts with probability* 1 *if* G_1 *and* G_2 *are isomorphic, and if* G_1 *and* G_2 *are* ϵ*-far from being isomorphic, Algorithm* 1 *rejects with probability* $1 - o(1)$.

Proof. Assume first that G_1 and G_2 are isomorphic, and let π be an isomorphism between them. Obviously π is also a knowledge-packing for any pair of knowledge charts of G_1 and G_2. Hence, if the algorithm did not accept in the second stage, then it will accept in the third stage.

Now we turn to the case where G_1 and G_2 are ϵ-far from being isomorphic. Due to large deviation inequalities, the probability that Algorithm 1 terminates in step 2 is $o(1)$, and therefore we can assume in the proof that it reaches step 3 without harming the correctness. Since G_1 and G_2 are ϵ-far from being isomorphic, every possible bijection π of their vertices has a set E_π of at least ϵn^2 pairs of G_1's vertices such that for every $\{u, v\} \in E_\pi$, either $\{u, v\}$ is an edge in G_1 or $\{\pi(u), \pi(v)\}$ is an edge in G_2, but not both. Now we fix π and let $\{u, v\} \in E_\pi$ be one such pair. The probability that $\{u, v\}$ was not queried in G_1 or $\{\pi(u), \pi(v)\}$ was not queried in G_2 is $1 - \frac{\ln n}{\epsilon n}$. Since the queries were chosen independently, the probability that for all $\{u, v\} \in E_\pi$ either $\{u, v\}$ was not queried in G_1 or $\{\pi(u), \pi(v)\}$ was not queried in G_2 is at most $(1 - \frac{\ln n}{\epsilon n})^{\epsilon n^2}$. Using the union bound, we bound the probability of not revealing at least one such pair in both graphs for all possible bijections by $n!(1 - \frac{\ln n}{\epsilon n})^{\epsilon n^2}$. This bound satisfies

$$n! \left(1 - \frac{\ln n}{\epsilon n}\right)^{\epsilon n^2} \leq n! \left(e^{-\frac{\ln n}{\epsilon n}}\right)^{\epsilon n^2} = n! \frac{1}{n^n} = o(1);$$

thus the algorithm rejects graphs that are ϵ-far from being isomorphic with probability $1 - o(1)$. ∎

The lower bound. Here we construct a pair G, H of 1/100-far graphs on n vertices such that every knowledge chart from $I_{G,n^{3/2}/200}$ can be packed with every knowledge chart from $I_{H,n^{3/2}/200}$, and hence by Lemma 2.6, any one-sided algorithm which is allowed to use at most $n^{3/2}/200$ queries must always accept G and H. Note that this holds for nonadaptive as well as adaptive algorithms, since we actually prove that there is no certificate of size $n^{3/2}/200$ for the nonisomorphism of these graphs.

LEMMA 3.3. *For every large enough* n*, there are two graphs* G *and* H *on* n *vertices such that*

1. G *is* 1/100*-far from being isomorphic to* H*;*
2. *every knowledge chart from* $I_{G,n^{3/2}/200}$ *can be knowledge-packed with any knowledge chart from* $I_{H,n^{3/2}/200}$

Proof. We set both G and H to be the union of a complete bipartite graph with a set of isolated vertices. Formally, G has three vertex sets L, R_f, R_e, where $|L| = n/2$, $|R_f| = 26n/100$ and $|R_e| = 24n/100$, and it has the following edges: $\{\{u, v\} : u \in L \wedge v \in R_f\}$. H has the same structure, but with $|R_f| = 24n/100$ and $|R_e| = 26n/100$, as illustrated in Figure 3.1. Clearly, just by the difference in the edge count, G is 1/100-far from being isomorphic to H, so G and H satisfy the first part of Lemma 3.3.

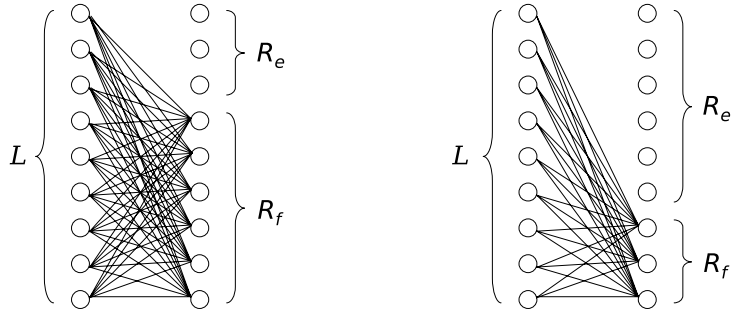

FIG. 3.1. *The graphs G and H (with the difference between them exaggerated).*

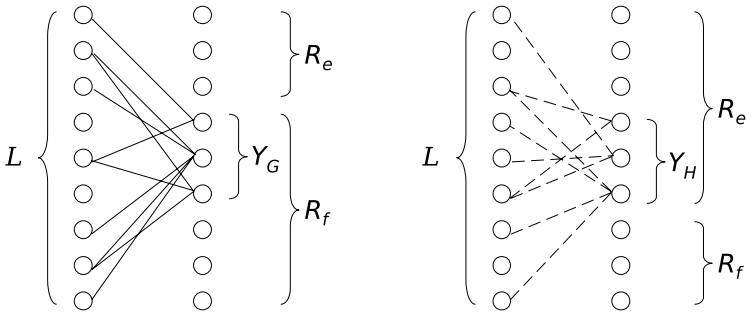

FIG. 3.2. *Finding Y_G and Y_H.*

To prove that the second condition of Lemma 3.3 holds, we will show that for all possible query sets Q_G, Q_H of size $n^{3/2}/200$ there exist sets $Y_G \in R_f(G)$ and $Y_H \in R_e(H)$ that satisfy the following:

- $|Y_G| = |Y_H| = n/50$.
- The knowledge charts I_{G,Q_G} and I_{H,Q_H} restricted to $L(G) \cup Y_G$ and $L(H) \cup Y_H$ can be packed in a way that pairs vertices from $L(G)$ with vertices from $L(H)$.

In Figure 3.2 we illustrate these restricted knowledge charts, where solid lines are known (queried) edges and dashed lines are known (queried) "nonedges." The existence of such Y_G and Y_H implies the desired knowledge-packing, since we can complete the partial packing from the second item by arbitrarily pairing vertices from $R_f(G) \setminus Y_G$ with vertices from $R_f(H)$ and pairing vertices from $R_e(G)$ with vertices from $R_e(H) \setminus Y_H$.

Remark 3.4. Note that there is a trivial algorithm that distinguishes between the two graphs in $O(n)$ queries by sampling vertices and checking their degrees. However, such an algorithm has two-sided error. Any one-sided error algorithm must find evidence of the nonisomorphism of the graphs, i.e., two knowledge charts that cannot be packed (in the sense that there is no isomorphism consistent with them).

Proving the existence of Y_G and Y_H. For every vertex $v \in V(G)$, we define its query degree as

$$d_Q(v) = |\{\{v, u\} : u \in V(G) \wedge \{v, u\} \in Q_G\}|.$$

We also denote by $N_Q(v)$ the set $\{u : \{v, u\} \in E(G) \cap Q_G\}$ and denote by $\overline{N}_Q(v)$ the set $\{u : \{v, u\} \in Q_G \setminus E(G)\}$. In other words, $N_Q(v)$ is the set of known neighbors of

v, $\overline{N}_Q(v)$ is the set of known nonneighbors of v, and $d_Q(v) = |\overline{N}_Q(v)| + |N_Q(v)|$. We define $d_Q(v)$, $N_Q(v)$, and $\overline{N}_Q(v)$ for H's vertices similarly.

Since $|Q_G|, |Q_H| \leq n^{3/2}/200$, there must be two sets of vertices $D_G \in R_f(G)$ and $D_H \in R_e(H)$, both of size $n/10$, such that $\forall_{v \in D_G} : d_Q(v) \leq n^{1/2}/2$ and $\forall_{v \in D_H} : d_Q(v) \leq n^{1/2}/2$.

Now we prove the existence of Y_G and Y_H (as defined above) using a simple probabilistic argument. First we set an arbitrary pairing

$$B_D = \{\{v_G^1, u_H^1\}, \{v_G^2, u_H^2\}, \ldots, \{v_G^{n/10}, u_H^{n/10}\}\}$$

of D_G's and D_H's elements. Then we choose a bijection $B_L : L(G) \to L(H)$ uniformly at random and show that with some positive probability, there are at least $n/50$ consistent (packable) pairs in B_D. Formally, we define

$$Y = \left\{\{v_G, u_H\} \in B_D : B_L(N_Q(v_G)) \cap \overline{N}_Q(u_H) = \emptyset\right\}$$

as the set of consistent pairs and show that $\Pr[|Y| \geq n/50] > 0$.

For a specific pair $\{v \in D_G, u \in D_H\}$, we have

$$\begin{aligned}\Pr_{B_L}[B_L(N_Q(v)) \cap \overline{N}_Q(u) = \emptyset] &\geq \prod_{i=0}^{n^{1/2}/2-1} \left(1 - \frac{n^{1/2}/2}{n/2 - i}\right) \\ &\geq \left(1 - \frac{2n^{1/2}}{n}\right)^{n^{1/2}/2} \geq (e + 0.001)^{-1} \geq 1/3,\end{aligned}$$

and by the linearity of expectation, $\mathrm{E}[|Y|] \geq |D_G|/3 > n/50$. Therefore, there is at least one bijection B_L for which the size of Y is no less than its expectation. We can now set

$$Y_G = \{u : \exists v \in V(H) \text{ such that } \{u, v\} \in Y\}$$

and

$$Y_H = \{v : \exists u \in V(G) \text{ such that } \{u, v\} \in Y\},$$

concluding the proof. □

3.2. One-sided testing where one of the graphs is known in advance. The algorithm for testing isomorphism between an unknown graph and a graph that is known in advance is similar to Algorithm 1. In this case the algorithm makes a quasi-linear number of queries, to accept with probability 1 if the graphs are isomorphic and reject with probability $1 - o(1)$ if they are ϵ-far from being isomorphic. We also prove an almost matching nearly trivial lower bound for this problem.

The upper bound. Denote by G_k and G_u the known and the unknown graphs, respectively.

ALGORITHM 2.

1. Construct a query set Q by choosing every possible query from G_u with probability $\frac{\ln n}{\epsilon n}$, independently at random.
2. If $|Q|$ is larger than $\frac{10n \ln n}{\epsilon}$, accept without making the queries. Otherwise make the chosen queries.

3. If there is a knowledge-packing of $I_{G_u,Q}$ and $I_{G_k,[V(G_k)]^2}$, accept. Otherwise reject.

Clearly the query complexity of Algorithm 2 is $O(n \log n)$, and it rejects in step 2 with probability $o(1)$.

LEMMA 3.5. *Algorithm* 2 *always accepts isomorphic graphs, and it rejects* ϵ*-far graphs with probability* $1 - o(1)$.

Proof. The proof is almost identical to that of Lemma 3.2. It is clear that isomorphic graphs are always accepted by Algorithm 2. Now we assume that the graphs G_k and G_u are ϵ-far and that the algorithm reached step 3 (as it stops at step 2 with probability $o(1)$). Given a bijection π, the probability that no violating pair $\{u, v\} \in E_\pi$ was queried is at most $(1 - \frac{\ln n}{\epsilon n})^{\epsilon n^2} \leq e^{-n \ln n} = n^{-n}$. Applying the union bound over all $n!$ possible bijections, the acceptance probability is bounded by $n!/n^n = o(1)$. ∎

The lower bound. As before, to give a lower bound on one-sided error algorithms it is sufficient to show that for some G_k and G_u that are far, no "proof" of their nonisomorphism can be provided with $\Omega(n)$ queries. First we formulate the second part of Lemma 2.6 for the special case where one of the graphs is known in advance.

LEMMA 3.6. *If for some* G_k, G_u*, where* G_k *is known in advance, and some fixed* $0 \leq q \leq \binom{n}{2}$*,* $I_{G_k,[v(G_k)]^2}$ *is knowledge-packable with every* $I_{G_u,Q} \in I_{G_u,q}$*, then every one-sided error isomorphism tester which is allowed to ask at most* q *queries must always accept* G_k *and* G_u*.*

We set G_k to be a disjoint union of $K_{n/2}$ and $n/2$ isolated vertices and set G_u to be a completely edgeless graph.

OBSERVATION 3.7. G_k *and* G_u *are* 1/4*-far, and every* $I_{G_u,Q} \in I_{G_u,\frac{n}{4}}$ *is knowledge-packable with* $I_{G_k,[V(G_k)]^2}$*.*

Proof. Clearly, just by the difference in the edge count, G_k is 1/4 far from being isomorphic to G_u. But since $n/4$ queries cannot involve more than $n/2$ vertices from G_u (all isolated), and G_k has $n/2$ isolated vertices, the knowledge charts are packable. ∎

Together with Lemma 3.6, we get the desired lower bound. This concludes the proof of the last part of Theorem 3.1.

4. Two-sided testers. In the context of graph properties, two-sided error testers are usually not known to achieve significantly lower query complexity than the one-sided error testers, apart from the properties that explicitly involve counting, such as *Max-Cut* and *Max-Clique* [13]. However, in our case two-sided error isomorphism testers have substantially lower query complexity than their one-sided error counterparts.

4.1. Two-sided testing where one of the graphs is known in advance.

THEOREM 4.1. *The query complexity of two-sided error isomorphism testers is* $\widetilde{\Theta}(\sqrt{n})$ *if one of the graphs is known in advance and the other needs to be queried.*

We prove the lower bound first. This way it will be easier to understand why certain stages of the upper bound testing algorithm are necessary.

The lower bound.

LEMMA 4.2. *Any isomorphism tester that makes at most* $\frac{\sqrt{n}}{4}$ *queries to* G_u *cannot distinguish between the case that* G_k *and* G_u *are isomorphic and the case that they are* 1/32*-far from being isomorphic, where* G_k *is known in advance.*

We begin with a few definitions.

DEFINITION 4.3. *Given a graph G and a set W of $\frac{n}{2}$ vertices of G, we define the* clone $G^{(W)}$ *of G in the following way:*

- *The vertex set of $G^{(W)}$ is defined as $V(G^{(W)}) = W \cup \{w' : w \in W\}$*
- *The edge set of $G^{(W)}$ is defined as*

$$\begin{aligned} E(G^{(W)}) = &\Big\{\{v,u\} : \{v,u\} \in E(G)\Big\} \\ \cup &\Big\{\{v',u\} : \{v,u\} \in E(G)\Big\} \\ \cup &\Big\{\{v',u'\} : \{v,u\} \in E(G)\Big\}. \end{aligned}$$

In other words, $G^{(W)}$ is the product of the subgraph of G induced on W with the graph K_2.

For the two copies $v, v' \in V(G^{(W)})$ of $v \in W$, we say that v is the source *of both v and v'.*

LEMMA 4.4. *Let $G \sim G(n, 1/2)$ be a random graph. With probability $1 - o(1)$ the graph G is such that for every subset $W \subset V(G)$ of size $n/2$, the clone $G^{(W)}$ of G is $1/32$-far from being isomorphic to G.*

Proof. Let G be a random graph according to $G(n, 1/2)$, and let $W \subset V(G)$ be an arbitrary subset of G's vertices of size $n/2$. First we show that for an arbitrary bijection $\sigma : V(G^{(W)}) \to V(G)$ the graphs $G^{(W)}$ and G are $1/32$-close under σ with probability at most $2^{-\Omega(n^2)}$, and then we apply the union bound on all bijections and every possible subset W.

We split the bijection $\sigma : V(G^{(W)}) \to V(G)$ into two injections $\sigma_1 : W \to V(G)$ and $\sigma_2 : V(G^{(W)}) \setminus W \to V(G) \setminus \sigma_1(W)$. Note that either $|W \setminus \sigma_1(W)| \geq n/4$ or $|W \setminus \sigma_2(W)| \geq n/4$. Assume without loss of generality that the first case holds, and let U denote the set $W \setminus \sigma_1(W)$. Since every edge in G is chosen at random with probability $1/2$, the probability that for some pair $u, v \in U$ either $\{u, v\}$ is an edge in G and $\{\sigma(u), \sigma(v)\}$ is not an edge in G or $\{u, v\}$ is not an edge in G and $\{\sigma(u), \sigma(v)\}$ is an edge in G is exactly $1/2$. Therefore, using large deviation inequalities, the probability that in the set U there are less than $\binom{n}{2}/32$ such pairs is at most $2^{-\Omega(n^2)}$ (as these events are all independent). There are at most $n!$ possible bijections and $\binom{n}{n/2}$ possible choices for W, so using the union bound, the probability that for some W the graph $G \sim G(n, 1/2)$ is not $1/32$-far from being isomorphic to $G^{(W)}$ is at most $2^{-\Omega(n^2)}\binom{n}{n/2}n! = o(1)$. ∎

Given a graph G satisfying the assertion of Lemma 4.4, we set $G_k = G$ and define two distributions over graphs, from which we choose the unknown graph G_u:

- D_P: A permutation of G_k, chosen uniformly at random.
- D_N: A permutation of $G_k^{(W)}$, where both W and the permutation are chosen uniformly at random.

According to Lemmas 4.4 and 2.9, it is sufficient to show that the distributions D_P and D_N restricted to a set of $\sqrt{n}/4$ queries are close. In particular, we intend to show that for any $\mathcal{Q} \subset \mathcal{D} = V^2$ of size $\sqrt{n}/4$ and any $Q : \mathcal{Q} \to \{0, 1\}$, we have $\Pr_{D_P|_{\mathcal{Q}}}[Q] < \frac{3}{2}\Pr_{D_N|_{\mathcal{Q}}}[Q]$. This will imply a lower bound for adaptive (as well as nonadaptive) testing algorithms.

OBSERVATION 4.5. *For a set U of $G^{(W)}$'s vertices, define the event E_U as the event that there is no pair of copies w, w' of any one of G's vertices in U. For a given set Q of pairs of vertices, let U_Q be the set of all vertices that belong to some pair in*

Q. Then the distribution $D_N|_{\mathcal{Q}}$ conditioned on the event E_{U_Q} (defined above) and the unconditioned distribution $D_P|_{\mathcal{Q}}$ are identical.

Proof. In D_N, if no two copies of any vertex were involved in the queries, then the source vertices of the queries to G_u are in fact a uniformly random sequence (with no repetition) of the vertices of G_k, and this (together with G_k) completely determines the distribution of the answers to the queries. This is the same as the unconditioned distribution induced by D_P. □

Intuitively, the next lemma states that picking two copies of the same vertex in a randomly permuted $G^{(W)}$ requires many samples, as per the well-known birthday problem.

LEMMA 4.6. *For a fixed set Q of at most $\sqrt{n}/4$ queries and the corresponding set $U = U_Q$ of vertices, the probability that the event E_U did not happen is at most $1/4$.*

Proof. The bound on $|Q|$ implies that $|U| \leq \sqrt{n}/2$. Now we examine the vertices in U as if we add them one by one. The probability that a vertex v that is added to U is a copy (with respect to the original graph G) of some vertex u that was already inserted into U (or vice versa) is at most $\frac{\sqrt{n}}{2n}$. Hence, the probability that eventually (after $\sqrt{n}/2$ insertions) we have two copies of the same vertex in U is at most $\frac{\sqrt{n}}{2n} \cdot \sqrt{n}/2 = 1/4$. □

From Observation 4.5, the distribution $D_N|_{\mathcal{Q}}$ conditioned on the event E_U and the unconditioned distribution $D_P|_{\mathcal{Q}}$ are identical. By Lemma 4.6 it follows that $\Pr[E_U] > 2/3$. Therefore, for any $g : \mathcal{Q} \to \{0,1\}$ we have

$$\begin{aligned}\Pr_{D_N|_{\mathcal{Q}}}[g] &= \Pr[E_U] \cdot \Pr_{D_P|_{\mathcal{Q}}}[g] + (1 - \Pr[E_U]) \cdot \Pr_{D_N|_{\mathcal{Q}}}[g] \\ &\geq \Pr[E_U] \cdot \Pr_{D_P|_{\mathcal{Q}}}[g] > \frac{2}{3} \cdot \Pr_{D_P|_{\mathcal{Q}}}[g]\end{aligned}$$

or, equivalently,

$$\Pr_{D_P|_{\mathcal{Q}}}[g] < \frac{3}{2}\Pr_{D_N|_{\mathcal{Q}}}[g];$$

hence the distributions D_P and D_N satisfy the conditions of Lemma 2.9. The following corollary completes the proof of Lemma 4.2.

COROLLARY 4.7. *It is not possible for any algorithm (adaptive or not) making $\sqrt{n}/4$ (or less) queries to test for isomorphism between a known graph and a graph that needs to be queried.*

The upper bound. We start with a few definitions. Given a graph G and a subset C of $V(G)$, we define the *C-labeling* of G's vertices as follows: Every vertex $v \in V(G)$ gets a label according to the set of its neighbors in C. Note that there are $2^{|C|}$ possible labels for a set C, but even if $2^{|C|} > n$, still at most n of the labels occur, since there are only n vertices in the graph. On the other hand, it is possible that several vertices will have the same label according to C. Such a labeling implies the following distribution over the vertices of G.

DEFINITION 4.8. *Given a graph G and a C-labeling of its vertices (according to some $C \subset V(G)$), we denote by D_C the distribution over the actual labels of the C-labeling (at most n labels), in which the probability of a certain label γ is calculated from the number of vertices from $V(G)$ having the label γ under the C-labeling, divided by n.*

Given a graph G on n vertices and a graph C on $k < n$ vertices, we say that a one-to-one function $\eta : V(C) \to V(G)$ is an *embedding* of C in G. We also call

$\eta(V(C))$ the *placement* of C in G. With a slight abuse of notation, from now on by a placement $\eta(V(C))$ we mean also the correspondence given by η and not just the set.

Given graphs G, H on n vertices, a subset C_G of $V(G)$ and a placement C_H of C_G in H under an embedding η, we define the *distance* between the C_G-labeling of G and the C_H-labeling of H as

$$\frac{1}{2}\sum_{\gamma\in 2^{C_G}} \big|\,|\{u\in V(G): N(u)\cap C_G=\gamma\}| - |\{v\in V(H): N(v)\cap \eta(C_G)=\gamma\}|\,\big|.$$

This distance measure is equal to the usual variation distance between D_{C_G} and D_{C_H} multiplied by n. We are now ready to prove the upper bound.

LEMMA 4.9. *Given an input graph G_u and a known graph G_k (both of order n), there is a property tester A_{ku} that accepts with probability at least $2/3$ if G_u is isomorphic to G_k and rejects with probability at least $2/3$ if G_u is ϵ-far from G_k. Furthermore, A_{ku} makes $\widetilde{O}(\sqrt{n})$ queries to G_u.*

We first outline the algorithm: The test is performed in two main phases. In Phase 1 we randomly choose a small subset C_u of G_u's vertices, and try all possible placements of C_u in the known graph G_k. The placements that imply a large distance between the labeling of G_u and G_k are discarded. After filtering the good placements of C_u in G_k, we move to Phase 2. In Phase 2 every one of the good placements is tested separately, by defining a random bijection $\pi : V(G_u) \to V(G_k)$ and testing whether π is close to being an isomorphism. Finally, if one of the placements passed both Phase 1 and Phase 2, the graphs are accepted. Otherwise they are rejected.

Phase 1. In the first phase we choose at random a core set C_u of $\log^2 n$ vertices from G_u (the unknown graph). For every embedding η of C_u in G_k and the corresponding placement $C_k \in G_k$, we examine the distributions D_{C_u} and D_{C_k} as in Definition 4.8. Since the graph G_k is known in advance, we know exactly which are the actual labels according to C_k (in total no more than n labels), so from now on we will consider the restriction of both distributions to these actual labels only. Next we test for every embedding of C_u whether D_{C_u} is statistically close to D_{C_k}. Note that the distribution D_{C_k} is explicitly given, and the distribution D_{C_u} can be sampled by choosing a vertex v from $V(G_u)$ uniformly at random and making all queries $\{v\} \times C_u$. If the label of some $v \in V(G_u)$ does not exist in the C_k-labeling of G_k, we immediately reject this placement and move to the next one. Now we use the following lemma from [7], which states that $\widetilde{O}(\sqrt{n})$ samples are sufficient for testing if the sampled distribution is close to the explicitly given distribution.

LEMMA 4.10. *There is an algorithm that given two distributions D_K, D_U over n elements and a distance parameter ϵ, where D_K is given explicitly and D_U is given as a black box that allows sampling according to the distribution, satisfies the following: If the distributions D_K and D_U are identical, then the algorithm accepts with probability at least $1 - 2^{-\log^7 n}$, and if the variation distance between D_K and D_U is larger than $\epsilon/10$, then the algorithm accepts with probability at most $2^{-\log^7 n}$. For a fixed ϵ, the algorithm uses $\widetilde{O}(\sqrt{n})$ many samples.*

Actually, this is an amplified version of the lemma from [7], which can be achieved by independently repeating the algorithm provided there polylog(n) many times and taking the majority vote. This amplification allows us to reuse the same $\widetilde{O}(\sqrt{n})$ samples for all possible placements of the core set. As a conclusion of Phase 1, the algorithm rejects the placements of C_u that imply a large variation distance between the above distributions and passes all other placements of C_u to Phase 2. Naturally,

if Phase 1 rejects all placements of C_k due to distribution test failures or due to the existence of labels in G_u that do not exist in G_k, then G_u is rejected without moving to Phase 2 at all. First we observe the following.

OBSERVATION 4.11. *With probability* $1 - o(1)$*, all of the placements that passed Phase* 1 *imply* $\epsilon/10$*-close distributions, and all placements that imply identical distributions passed Phase* 1*. In other words, the distribution test did not err on any of the placements.*

Proof. There are at most $2^{\log^3 n}$ possible placements of C_u. Using the union bound with Lemma 4.10, we conclude that Phase 1 will not err with probability $1-o(1)$. ∎

Phase 2. Following Observation 4.11, we need to design a test such that given a placement C_k of C_u in G_k that implies close distributions, the test satisfies the following conditions:

1. If the graphs are isomorphic and the embedding of C_u is expandable to some isomorphism, then the test accepts with probability at least 3/4.
2. If the graphs G_u and G_k are ϵ-far, then the test accepts with probability at most $o(2^{-\log^3 n})$.

If our test in Phase 2 satisfies these conditions, then we get the desired isomorphism tester. From now on, when we refer to some placement of C_u we assume that it has passed Phase 1 and hence implies close distributions.

In Phase 2 we choose a set W_u of $\log^4 n$ vertices from $V(G_u)$ and retrieve their labels according to C_u by making the queries $W_u \times C_u$. Additionally, we split W_u into $\frac{1}{2}\log^4 n$ pairs $\{\{u_1, v_1\}, \ldots, \{u_{\frac{1}{2}\log^4 n}, v_{\frac{1}{2}\log^4 n}\}\}$ randomly and make all $\frac{1}{2}\log^4 n$ queries according to these pairs. This is done once, and the same set W_u is used for all the placements of C_u that are tested in Phase 2. Then, for every placement C_k of C_u, we would like to define a random bijection $\pi_{C_u,C_k} : V(G_u) \to V(G_k)$ as follows. For every label γ, the bijection π_{C_u,C_k} pairs the vertices of G_u having label γ with the vertices of G_k having label γ uniformly at random. There might be labels for which one of the graphs has more vertices than the other. We call these remaining vertices *leftovers*. Note that the amount of leftovers from each graph is equal to the distance between the C_k-labeling and the C_u-labeling. Finally, after π_{C_u,C_k} pairs all matching vertices, the leftover vertices are paired arbitrarily. In practice, since we do not know the labels of G_u's vertices, we instead define a partial bijection $\widetilde{\pi}_{C_u,C_k}(W_u) \to V(G_k)$ as follows. Every vertex $v \in W_u$ that has the label γ_v is paired uniformly at random with one of the vertices of G_k which has the same label γ_v and was not paired yet. If this is impossible, we reject the current placement of C_u and move to the next one.

Denote by δ_{C_u,C_k} the fraction of the queried pairs from W_u for which exactly one of $\{u_i, v_i\}$ and $\{\widetilde{\pi}_{C_u,C_k}(u_i), \widetilde{\pi}_{C_u,C_k}(v_i)\}$ is an edge. If $\delta_{C_u,C_k} \le \epsilon/2$, then G_u is accepted. Otherwise we move to the next placement of C_u. If none of the placements was accepted, G_u is rejected.

Correctness. A crucial observation in our proof is that with high probability, any two vertices that have many distinct neighbors in the whole graph will also have distinct neighbors within a "large enough" random core set.

Formally, given a graph G and a subset C of its vertices, we say that C is β-*separating* if for every pair of vertices $u, v \in V(G)$ such that $d_{uv} \triangleq \frac{1}{n}|\{N(u) \triangle N(v)\}| \ge \beta$ the vertices u and v have different labels under the C-labeling of G.

CLAIM 4.12. *Let* $\beta > 0$ *be fixed, let* G *be a graph of order* n*, and let* $C \subset V(G)$ *be a uniformly chosen random subset of size* $\log^2 n$*. Then* C *is* β*-separating with probability* $1 - o(1)$*.*

Proof. Fix a pair $u, v \in V(G)$. If u, v are such that $d_{uv} > \beta$, then the probability that they share exactly the same neighbors in C is bounded by $(1-\beta)^{\log^2 n} \leq e^{-\beta \log^2 n} = n^{-\beta \log n}$. Using the union bound, with probability $1 - o(1)$ every pair u, v of vertices with $d_{uv} > \beta$ will not have exactly the same neighbors in C; i.e., the vertices will have different labels under the C-labeling. □

LEMMA 4.13 (completeness). *Conditioned over the event that C_u is $\epsilon/8$-separating, if the graphs G_u and G_k are isomorphic and the placement C_k of C_u is expandable to some isomorphism, then $\Pr[\delta_{C_u,C_k} \leq \epsilon/2] = 1 - o(1)$, and hence C_k is accepted in Phase 2 with probability $1 - o(1)$.*

Proof. Let $\phi : V(G_u) \to V(G_k)$ be an isomorphism to which the placement of C_u is expandable. By definition, for every pair v_1, v_2 of G_u's vertices, $\{v_1, v_2\}$ is an edge in G_u if and only if $\{\phi(v_1), \phi(v_2)\}$ is an edge in G_k. In addition, for every vertex $v \in V(G_u)$, the vertices v and $\phi(v)$ have exactly the same labels. Let σ be the permutation such that π_{C_u,C_k} is the composition of σ and the isomorphism ϕ. In the rest of this proof, by distance we mean the absolute distance between two labeled graphs (which is between 0 and $\binom{n}{2}$).

First we show that the distance from $\sigma(G_u)$ to G_k is almost the same as the distance from $\phi(G_u)$ to G_k (which is zero since ϕ is an isomorphism), and then we apply large deviation inequalities to conclude that $\Pr[\delta_{C_u,C_k} \leq \epsilon/2] = 1 - o(1)$.

To prove that the distance from $\sigma(G_u)$ to G_k is close to zero we show a transformation of ϕ into π_{C_u,C_k} by performing "swaps" between vertices that have the same label. Namely, we define a sequence of permutations ϕ_i, starting from $\phi_0 = \phi$ and ending with $\phi_t = \pi_{C_u,C_k}$. In each step, if there is some vertex v_0 such that $\phi_i(v_0) = u_1$ while $\pi_{C_u,C_k}(v_0) = u_0$, then we find a vertex v_1 such that $\phi_i(v_1) = u_0$, and set $\phi_{i+1}(v_0) = u_0$ and $\phi_{i+1}(v_1) = u_1$. The rest of the vertices are mapped by ϕ_{i+1} as they were mapped by ϕ_i.

Since in each step we swap only between vertices with the same label, and since the core set C_u is $\epsilon/8$-separating, every such swap can increase the distance by at most $\epsilon n/8$, so eventually the distance between $\sigma(G_u)$ and G_k is at most $\epsilon n^2/8$. Therefore, by large deviation inequalities, δ_{C_u,C_k} as defined in Phase 2 is at most $\epsilon/2$ with probability $1 - o(1)$, and so the placement C_k is accepted. □

We now turn to the case where G_u and G_k are ϵ-far. Note that until now we did not use the fact that C_u and C_k imply close distributions. To understand why this closeness is important, recall the pairs of graphs from the lower bound proof. If we give up the distribution test in Phase 1, then these graphs will be accepted with high probability, since the algorithm cannot reveal two copies of the same vertex when sampling $o(\sqrt{n})$ vertices (recall that $|W_u| = O(\log^4 n)$). Intuitively, the problem is that in these pairs of graphs, the partial random bijection $\widetilde{\pi}_{C_u,C_k}$ will not simulate a restriction of the random bijection π_{C_u,C_k} to a set of $\log^4 n$ vertices. In the lower bound example, $\widetilde{\pi}_{C_u,C_k}$ will have no leftovers with high probability, even though π_{C_u,C_k} will always have $\Omega(n)$ leftovers. The reason is that in the cloned graph G_u, for each of about half of the labels from C_k there are two times more vertices, while for the second half there are no vertices at all. The distribution test in Phase 1 actually checks whether the clustering of the vertices according to the labels is into subsets of almost equal sizes in both G_u and G_k. If it is so, then the partial random bijection $\widetilde{\pi}_{C_u,C_k}$ is indeed similar to the restriction of a bijection π_{C_u,C_k} to a set of $\log^4 n$ vertices.

LEMMA 4.14 (soundness). *If the graphs G_u and G_k are ϵ-far, and the placement C_k implies $\epsilon/10$-close distributions, then $\Pr[\delta_{C_u,C_k} \leq \epsilon/2] \leq o(2^{-\log^3 n})$, and hence*

C_k is accepted in Phase 2 with probability at most $o(2^{-\log^3 n})$.

Proof. Assume that for a fixed C_k the random bijection π_{C_u,C_k} is ϵ-far from isomorphism. We then need to show that δ_{C_u,C_k} as defined in Phase 2 is larger than $\epsilon/2$ with probability $1 - o(2^{-\log^3 n})$.

Since the variation distance between the distributions D_{C_u} and D_{C_k} is at most $\epsilon/10$, the amount of leftovers (which is exactly the distance between the C_u-labeling of G_u and the C_k-labeling of G_k) is at most $\epsilon n/10$. Therefore, even if we first remove those $\epsilon n/10$ (or less) leftovers, the fraction of pairs u, v for which exactly one of $\{u, v\}$ and $\{\widetilde{\pi}_{C_u,C_k}(u), \widetilde{\pi}_{C_u,C_k}(v)\}$ is an edge is not smaller by more than $4\epsilon/10$ from that of π_{C_u,C_k}.

Let $\widetilde{\pi}_{C_u,C_k}$ be the random partial bijection as defined above. The distribution test of Phase 1 guarantees that $\widetilde{\pi}_{C_u,C_k}$ is a random restriction of a function that is $\epsilon/10$-close to some bijection π_{C_u,C_k}. Since G_u is ϵ-far from G_k, the bijection π_{C_u,C_k} must be ϵ-far from being an isomorphism, and hence $\widetilde{\pi}_{C_u,C_k}$ must exhibit a $6\epsilon/10$-fraction of mismatching edges. Note that the acceptance probability of C_k given $\widetilde{\pi}_{C_u,C_k}$ is equal to the probability that δ_{C_u,C_k} as defined in Phase 2 is at most $\epsilon/2$. Large deviation inequalities show that this probability is at most $2^{-\Omega(\log^4 n)} = o(2^{-\log^3 n})$. □

In conclusion, if G_k and G_u are isomorphic, then the probability that C_u is not $\epsilon/8$-separating is at most $o(1)$, and for a correct (under some isomorphism) embedding of C_u in G_k, the probability that the distribution test will fail is also $o(1)$; thus in summary algorithm A_{ku} accepts with probability greater than $2/3$. In the case that G_k and G_u are ϵ-far from being isomorphic, with probability $1 - o(1)$ all placements that are passed to Phase 2 imply close label distributions. Then each such placement is rejected in Phase 2 with probability $1 - o(2^{-\log^3 n})$, and by the union bound over all possible placements the graphs are accepted with probability less than $1/3$. Algorithm A_{ku} makes $\widetilde{O}(\sqrt{n})$ queries in Phase 1 and $\widetilde{O}(n^{1/4})$ queries in Phase 2. This completes the proof of Lemma 4.9 and thus of Theorem 4.1.

4.2. Two-sided testing of two unknown graphs.

THEOREM 4.15. *The query complexity of two-sided error isomorphism testers is between $\Omega(n)$ and $\widetilde{O}(n^{5/4})$ if both graphs need to be queried.*

The upper bound.

LEMMA 4.16. *Given two unknown graphs G and H on n vertices, there is a property tester A_{uu} that accepts with probability at least $2/3$ if G is isomorphic to H, and rejects with probability at least $2/3$ if G is ϵ-far from H. Furthermore, A_{uu} makes $\widetilde{O}(n^{5/4})$ queries to G and H.*

We use here ideas similar to those used in the upper bound proof of Lemma 4.9, but with several modifications. The main difference between this case and the case where one of the graphs is known in advance is that here we cannot write all label distributions with all possible core sets in either one of the unknown graphs (because doing that would require $\Omega(n^2)$ queries). We overcome this difficulty by sampling from both graphs in a way that with high probability will make it possible to essentially simulate the test for isomorphism where one of the graphs is known in advance.

Phase 1. First we randomly pick a set U_G of $n^{1/4}\log^3(n)$ vertices from G and a set U_H of $n^{3/4}\log^3(n)$ vertices from H. Then we make all $n^{5/4}\log^3(n)$ possible queries in $U_G \times V(G)$. Note that if G and H have an isomorphism σ, then according to Lemma 2.10 with probability $1 - o(1)$ the size of $U_G \cap \sigma(U_H)$ will exceed $\log^2(n)$.

For all subsets C_G of U_G of size $\log^2 n$ we try every possible placement $C_H \subset U_H$ of C_G. There are at most $2^{\log^3 n}$ subsets C_G, and at most $2^{\log^3 n}$ possible ways to

embed each C_G in U_H. Since we made all $n^{5/4}\log^3(n)$ possible queries in $U_G \times V(G)$, for every $C_G \subset U_G$ the corresponding distribution D_{C_G} is entirely known.

So now for every possible placement of C_G in U_H we test if the variation distance between the distributions D_{C_G} and D_{C_H} is at most $\epsilon/10$. Since we know the entire distributions D_{C_G}, we need only sample the distribution D_{C_H}; therefore we can still use the amplified distribution test of Lemma 4.10. The test there requires $\widetilde{O}(\sqrt{n})$ samples, so similarly to the proof of Lemma 4.9, we take a random set S of $\widetilde{O}(\sqrt{n})$ vertices from H and make all $n^{5/4}\text{polylog}(n)$ queries in $S \times U_H$.

We reject the pairs of a set C_G and a placement C_H that were rejected by the distribution test for D_{C_G} and D_{C_H}, and pass all other pairs to Phase 2. If Phase 1 rejects all possible pairs, then the graphs G and H are rejected without moving to Phase 2. The following observation is similar to the one we used in the case where one of the graphs is known in advance.

OBSERVATION 4.17. *With probability* $1 - o(1)$*, all of the placements that passed Phase* 1 *imply* $\epsilon/10$*-close distributions, and all placements that imply identical distributions passed Phase* 1*. In other words, the distribution test did not err on any of the placements.*

Phase 2. As in Lemma 4.9, we need to design a test which, given a placement C_H of C_G in H that implies close distributions, satisfies the following conditions:

1. If the graphs are isomorphic and the embedding of C_H is expandable to some isomorphism, then the test accepts with probability at least 3/4.
2. If the graphs G and H are ϵ-far, then the test accepts with probability at most $o(2^{-2\log^3 n})$.

In Phase 2 we choose at random a set W_G of $n^{1/2}\log^{13} n$ vertices from $V(G)$, and a set W_H of $n^{1/2}\log^6 n$ vertices from $V(H)$. We retrieve the labels in W_H according to any C_H by making the queries $W_H \times U_H$. Additionally, we make all queries inside W_H and all queries inside W_G. This is done once, and the same sets W_G, W_H are used for all of the pairs C_G, C_H that are tested in Phase 2. According to Lemma 2.10, if the graphs are isomorphic under some isomorphism σ, then $|W_H \cap \sigma(W_G)| > \log^7 n$ with probability $1 - o(1)$.

Then, similarly to what is done in Lemma 4.9, for every pair C_G, C_H, we would like to define a random bijection $\pi_{C_G,C_H} : V(G) \to V(H)$ as follows. For every label γ, π_{C_G,C_H} pairs the vertices of G having label γ with the vertices of H having label γ uniformly at random. After π_{C_G,C_H} pairs all matching vertices, the leftover vertices are paired arbitrarily. Then again, since we do not know the labels of H's vertices, we define a partial bijection $\widetilde{\pi}_{C_G,C_H}(W_H) \to V(G)$ instead, in which every vertex $v \in W_H$ that has the label γ_v is paired uniformly at random with one of the vertices of G which has the same label γ_v and is not paired yet. If this is impossible, we reject the current pair C_G, C_H and move to the next one.

Denote by I_H the set $\widetilde{\pi}_{C_G,C_H}(W_H) \cap W_G$, and denote by S_H the set $\widetilde{\pi}^{-1}_{C_G,C_H}(I_H)$. According to Lemma 2.10, $|I_H| > \log^7 n$ with probability $1 - o(2^{-\log^6 n})$; that is, with probability $1 - o(1)$ we have $|I_H| > \log^7 n$ for every pair C_G, C_H (if this is not the case, we terminate the algorithm and answer arbitrarily). Next we take $\frac{1}{2}\log^7 n$ pairs $\{\{u_1, v_1\}, \ldots, \{u_{\frac{1}{2}\log^7 n}, v_{\frac{1}{2}\log^7 n}\}\}$ randomly from S_H, and denote by δ_{C_G,C_H} the fraction of S_H's pairs for which exactly one of $\{u_i, v_i\}$ and $\{\widetilde{\pi}_{C_G,C_H}(u_i), \widetilde{\pi}_{C_G,C_H}(v_i)\}$ is an edge. If $\delta_{C_G,C_H} \leq \epsilon/2$, then the graphs are accepted. Otherwise we move to the next pair C_G, C_H. If none of the pairs accepted, then the graphs are rejected.

As noted above, if G and H are isomorphic, then according to Lemma 2.10 with probability $1 - o(1)$, the size of $U_G \cap \sigma(U_H)$ is at least $\log^2(n)$. Therefore with probability $1 - o(1)$ for some pair C_H, C_G, the placement C_H of C_G is expandable to an isomorphism. We now need to show that in this case the pair C_H, C_G is accepted with sufficient probability.

LEMMA 4.18 (completeness). *If the graphs G and H are isomorphic and σ is an isomorphism between them, then with probability at least $3/4$ there exists $C_G \subset U_G$ with a placement $C_H \subset U_H$ which is expandable to σ, and for which $\delta_{C_G,C_H} \leq \epsilon/2$.*

Proof sketch. First we look at the set $\Delta = U_G \cap \sigma^{-1}(U_H)$. By Lemma 2.10 the size of Δ is at least $\log^2 n$ with probability $1-o(1)$. Conditioned on this event, we pick $C_G \subseteq \Delta \subseteq U_G$ uniformly from all subsets of Δ with size $\log^2 n$, and set $C_H = \sigma(C_G)$ to be its placement in U_H. We now prove that, conditioned on the event that Δ is large enough, C_G and C_H will be as required with probability $1 - o(1)$.

Our main observation is that if we condition only on the event that Δ is large enough, then C_G is distributed uniformly among all subsets with this size of $V(G)$, so we proceed similarly to the case where one of the graphs is known in advance. We observe that if two vertices have many distinct neighbors, then with high probability they will not share exactly the same neighbors within a random core set of size $\log^2 n$ (see Lemma 4.12), so C_G has a separating property. When this happens, it is possible to switch between the vertices with identical labels and still retain a small enough bound on δ_{C_G,C_H}. □

LEMMA 4.19 (soundness). *If the graphs G and H are ϵ-far, and the pair C_G, C_H implies close distributions, then $\Pr[\delta_{C_G,C_H} \leq \epsilon/2] \leq o(2^{-\log^6 n})$, and hence the pair C_G, C_H is accepted in Phase 2 with probability at most $o(2^{-\log^6 n})$.*

Proof sketch. As before, assume that for a fixed pair C_G, C_H the random bijection π_{C_G,C_H} is ϵ-far from isomorphism. We then need to show that δ_{C_G,C_H} as defined in Phase 2 is at most $\epsilon/2$ with probability only $o(2^{-\log^6 n})$.

Since the variation distance between the distributions D_{C_G} and D_{C_H} is at most $\epsilon/10$, the amount of leftovers (which is exactly the distance between the C_G-labeling and the C_H-labeling) is at most $\epsilon n/10$. After removing those $\epsilon n/10$ (or less) leftovers, the fraction of pairs u, v for which exactly one of $\{u, v\}$ and $\{\widetilde{\pi}_{C_G,C_H}(u), \widetilde{\pi}_{C_G,C_H}(v)\}$ is an edge is still not smaller than that of π_{C_G,C_H} by more than $4\epsilon/10$. Now the distribution test of Phase 1 guarantees that $\widetilde{\pi}_{C_G,C_H}$ is $\epsilon/10$-close to the restriction of some random bijection π_{C_G,C_H}. Since the graph G is ϵ-far from being isomorphic to the graph H, the bijection π_{C_G,C_H} must be ϵ-far from an isomorphism. Hence $\widetilde{\pi}_{C_G,C_H}$ must exhibit a $6\epsilon/10$-fraction of incompatible edges, and the acceptance probability of the pair C_G, C_H given $\widetilde{\pi}_{C_G,C_H}$ is equal to the probability that δ_{C_G,C_H} as defined in Phase 2 is at most $\epsilon/2$. Applying large deviation inequalities shows that this probability is at most $2^{-\Omega(\log^7 n)} = o(2^{-\log^6 n})$. □

The isomorphism testing algorithm A_{uu} makes $\widetilde{O}(n^{5/4})$ queries in total, completing the proof of Theorem 4.15.

The lower bound. A lower bound of $\Omega(n)$ queries is implicitly stated in [9] following [1]. Here we provide the detailed proof for completeness.

LEMMA 4.20. *Any adaptive (as well as nonadaptive) testing algorithm that makes at most $\frac{n}{4}$ queries cannot distinguish between the case that the unknown input graphs G and H are isomorphic and the case that they are $\frac{1}{8}$-far from being isomorphic.*

Proof. We construct two distributions over pairs of graphs. The distribution D_P is constructed by letting the pair of graphs consist of a random graph $G \sim G(n, 1/2)$ and

a graph H that is a random permutation of G. The distribution D_N is constructed by letting the pair of graphs consist of two independently chosen random graphs $G, H \sim G(n, 1/2)$.

Clearly D_P satisfies the property with probability 1. By large deviation inequalities, it is also clear that in an input chosen according to D_N, the graphs G and H are $\frac{1}{8}$-far with probability $1 - 2^{\Omega(n^2)}$. The next step is to replace D_N with D'_N, in which the graphs are $\frac{1}{8}$-far from being isomorphic with probability 1. We just set D'_N to be the distribution that results from conditioning D_N on the event that G is indeed $\frac{1}{8}$-far from H.

We now consider any fixed set $Q = \{p_1, \ldots, p_{\frac{n}{4}}\}$ of vertex pairs, some from the first graph, and others from the second graph. For an input chosen according to the distribution D_N, the values of these pairs (the answers for corresponding queries) are $\frac{n}{4}$ uniformly and independently chosen random bits. We now analyze the distribution D_P. Let $e_1, \ldots, e_k$ and $f_1, \ldots, f_l$ be all vertex pairs of the first and the second graph, respectively, that appear in Q. Clearly $k, l \leq |Q| = \frac{n}{4}$. Let $\sigma : \{1, \ldots, n\} \to \{1, \ldots, n\}$ be the permutation according to which the second graph is chosen in D_P. Let E denote the event that $\sigma(e_i) \neq f_j$ for every $1 \leq i \leq k$ and $1 \leq j \leq l$, where for $e = \{u, v\}$ we denote by $\sigma(e)$ the pair $\{\sigma(u), \sigma(v)\}$. Clearly, if E occurs, then $\{p_1, \ldots, p_{\frac{n}{4}}\}$ will be a set of $\frac{n}{4}$ uniformly and independently chosen random bits.

CLAIM 4.21. *The event E as defined above occurs with probability at least $3/4$.*

Proof. For a single pair e_i and a random permutation σ, the probability that $e_i = \sigma(f_j)$ for some $1 \leq j \leq l$ is bounded by $\frac{n}{2\binom{n}{2}}$. Hence by the union bound,

$$\Pr[E] \geq 1 - \frac{kn}{2\binom{n}{2}} > 3/4. \qquad \square$$

Since E occurs with probability at least $3/4$ and since the event upon which we conditioned D_N to get D'_N occurs with probability $1 - 2^{-\Omega(n^2)} = 1 - o(2^{-|Q|})$, we get that for any $g : \mathcal{Q} \to \{0, 1\}$, $\Pr_{D'_N|_Q}[g] < \frac{3}{2}\Pr_{D_P|_Q}[g]$, and therefore the distributions D_P and D'_N satisfy the conditions of Lemma 2.9. $\square$

5. Concluding remarks. While our two-sided error algorithms run in time quasi-polynomial in n (like the general approximation algorithm of [6]), the one-sided algorithms presented here require an exponential running time. It would be interesting to reduce the running time of the one-sided algorithms to be quasi-polynomial while still keeping them one-sided.

Another issue goes back to [1]. There, the graph isomorphism question was used to prove that certain first order graph properties are impossible to test with a constant number of queries. However, in view of the situation with graph isomorphism, the question now is whether every first order graph property is testable with $O(n^{2-\alpha})$ many queries for some $\alpha > 0$ that depends on the property to be tested.

Finally, it would be interesting to close the remaining gap between $\Omega(n)$ and $\widetilde{O}(n^{5/4})$ in the setting of two graphs that need to be queried and a two-sided error algorithm. It appears (with the aid of martingale analysis on the same distributions D_P, D_N as above) that at least for nonadaptive algorithms the lower bound can be increased a little to a bound of the form $\Omega(n \log^{\alpha} n)$, but we are currently unable to give tighter bounds on the power of n.

Acknowledgments. We would like to thank Salil Vadhan and two anonymous referees for their useful comments.

IMPROVING THE STRETCH FACTOR OF A GEOMETRIC NETWORK BY EDGE AUGMENTATION*

MOHAMMAD FARSHI†, PANOS GIANNOPOULOS‡, AND JOACHIM GUDMUNDSSON§

Abstract. Given a Euclidean graph G in $\mathbb{R}^d$ with n vertices and m edges, we consider the problem of adding an edge to G such that the stretch factor of the resulting graph is minimized. Currently, the fastest algorithm for computing the stretch factor of a graph with positive edge weights runs in $\mathcal{O}(nm+n^2\log n)$ time, resulting in a trivial $\mathcal{O}(n^3m+n^4\log n)$-time algorithm for computing the optimal edge. First, we show that a simple modification yields the optimal solution in $\mathcal{O}(n^4)$ time using $\mathcal{O}(n^2)$ space. To reduce the running time we consider several approximation algorithms.

1. Introduction.

Consider a set V of n points in $\mathbb{R}^d$. A network on V can be modeled as an undirected graph G with vertex set V of size n and an edge set E of size m where every edge (u, v) has a positive weight $w(u, v)$. A Euclidean network is a geometric network where the weight of the edge (u, v) is equal to the Euclidean distance $|uv|$ between its two endpoints u and v.

For two vertices u, v in a weighted graph G we use $\delta_G(u, v)$ to denote a shortest path between u and v in G, and the length of the path is denoted by $d_G(u, v)$. Consider a weighted graph $G = (V, E)$ and a graph $G' = (V, E')$ on the same vertex set but with edge set $E' \subseteq E$. We say that G' is a *t-spanner* of G if for each pair of vertices $u, v \in V$ we have that $d_{G'}(u, v) \leq t \cdot d_G(u, v)$. The minimum t such that G is a t-spanner for V is called the stretch factor, or dilation, of G.

We say that a Euclidean network $G = (V, E)$ is a *t-spanner* if $G = (V, E)$ is a t-spanner of the complete network on V. In other words, for any two points $p, q \in V$ the graph distance in G is at most t times the Euclidean distance between the two points.

Complete graphs represent ideal communication networks, but they are expensive to build; sparse spanners represent low-cost alternatives. The weight of the spanner network is a measure of its sparseness; other sparseness measures include the number of edges, the maximum degree, and the number of Steiner points. Spanners for complete Euclidean graphs as well as for arbitrary weighted graphs find applications in robotics, network topology design, distributed systems, design of parallel machines, and many other areas. Recently spanners found interesting practical applications

in areas such as metric space searching [29, 30] and broadcasting in communication networks [2, 14, 25].

Several well-known theoretical results also use the construction of t-spanners as a building block; for example, Rao and Smith [32] made a breakthrough by showing an optimal $\mathcal{O}(n \log n)$-time approximation scheme for the well-known Euclidean *traveling salesperson problem*, using t-spanners (or banyans). Similarly, Czumaj and Lingas [7] showed approximation schemes for minimum-cost multiconnectivity problems in geometric graphs. The problem of constructing geometric spanners has received considerable attention from a theoretical perspective; see [1, 3, 4, 5, 8, 9, 10, 17, 20, 21, 23, 24, 33, 36], the surveys [12, 16, 34], and the book by Narasimhan and Smid [28]. Note that considerable research has also been done in the construction of spanners for general graphs; see, for example, the book by Peleg [31] or the recent work by Elkin and Peleg [11] and Thorup and Zwick [35].

All the existing algorithms construct a network from scratch, but in many applications the network is already given, and the problem at hand is to extend the network with an additional edge, or edges, while minimizing the stretch factor of the resulting graph. The problem was first stated by Narasimhan [26] and, surprisingly, it had not been studied earlier, to the best of the authors' knowledge. In this paper we study the following problem.

Problem. Given a graph G, construct a graph G' by adding an edge to G such that the stretch factor of G' is minimized.

The results presented in this paper are summarized in Table 1. Note that some of the presented bounds hold for any graph with positive edge weights (*weighted graphs*), while some hold only for Euclidean graphs.

Finally, throughout this paper we will use $G_{\mathcal{P}}$ to denote the optimal solution, while $t_{\mathcal{P}}$ and t denote the stretch factor of $G_{\mathcal{P}}$ and the input graph G, respectively.

2. Three simple algorithms. A naive approach to deciding which edge to add is to test every possible candidate edge. The number of such edges is obviously $(\frac{n(n-1)}{2} - m) = \mathcal{O}(n^2)$. Testing a candidate edge e entails computing the stretch factor of the graph $G' = (V, E \cup \{e\})$, denoted the candidate graph. Therefore we briefly consider the problem of computing the stretch factor of a given graph with

positive edge weights. This problem has recently received considerable attention; see, for example, [13, 22, 27].

2.1. Exact algorithms. We consider the problem of computing an optimal solution $G_{\mathcal{P}}$. That is, we are given a t-spanner $G = (V, E)$, and the aim is to compute a $t_{\mathcal{P}}$-spanner $G_{\mathcal{P}} = (V, E \cup \{e\})$.

A trivial upper bound is obtained by computing the length of the shortest paths between every pair of vertices in G'. This can be done by running Dijkstra's algorithm —implemented using Fibonacci heaps—n times, resulting in an $\mathcal{O}(mn+n^2 \log n)$-time algorithm using linear space. This approach is quite slow, and we would like to be able to compute the stretch factor more efficiently, but no faster algorithm is known for any graphs except planar graphs, paths, cycles, stars, and trees [13, 22, 27]. Applying the stated bound to the problem of computing the exact stretch factor of G' gives that $G_{\mathcal{P}}$ can be computed in time $\mathcal{O}(n^3(m + n \log n))$ using linear space.

A small improvement can be obtained by observing that when an edge (u, v) is about to be tested, we do not have to check all possible shortest paths between two vertices $x, y \in V$ again; it suffices to check whether there is a shorter path using the edge (u, v). That is, we only have to compute $d_G(x, u) + w(u, v) + d_G(v, y)$, $d_G(x, v) + w(v, u) + d_G(u, y)$, and $d_G(x, y)$, which can be done in constant time since the length of a shortest path between every pair of vertices in G has already been computed (provided that we store this information). Hence, by first computing all-pair-shortest paths of G we obtain the following lemma.

LEMMA 1. *Given a graph G with positive edge weights, an optimal solution $G_{\mathcal{P}}$ can be computed in time $\mathcal{O}(n^4)$ using $\mathcal{O}(n^2)$ space.*

Proof. Computing the all-pair-shortest path requires cubic time, and all the distances are stored in an $n \times n$ matrix. The $\mathcal{O}(n^2)$ edges are tested for insertion: for each candidate edge compute the length of the shortest path between every pair of points in G, each of which can be done in constant time as described above. □

2.2. A $(1+\varepsilon)$-approximation for Euclidean graphs. In the previous section we showed that an optimal solution can be obtained by testing a quadratic number of candidate edges. Testing each candidate edge entails $\mathcal{O}(n^2)$ distance queries, where a distance query asks for the length of a shortest path in the graph between two query points. One way to speed up the computation is to compute an approximate stretch factor. t' is said to be a β-approximate stretch factor of G if $t_G \leq t' \leq \beta \cdot t_G$, where t_G is the stretch factor of G. The problem of computing an approximate stretch factor of a geometric graph was considered by Narasimhan and Smid in [27]. They showed the following fact.

Fact 1 (Narasimhan and Smid [27]). Given a Euclidean graph G and a real value $\tau > 0$, a $(1 + \tau)^2$-approximative stretch factor of G can be computed by performing $\mathcal{O}(n/\tau^d)$ many $(1 + \gamma)$-approximate distance queries, where γ is a positive constant smaller than τ.

The algorithm is almost as stated in the previous section with the exception that when the stretch factor of the candidate graph is computed we approximate it by only performing $\mathcal{O}(n/\tau^d)$ shortest path queries as stated in Fact 1. As a result the time to compute the stretch factor decreases from $\mathcal{O}(n^2)$ to $\mathcal{O}(n/\tau^d)$; thus the total running time decreases from $\mathcal{O}(n^4)$ to $\mathcal{O}(n^3/\tau^d)$.

THEOREM 2. *Given a Euclidean graph $G = (V, E)$ and a real constant $\varepsilon > 0$, one can in $\mathcal{O}(n^3/\varepsilon^d)$ time, using $\mathcal{O}(n^2)$ space, compute a t'-spanner $G' = (V, E \cup \{e\})$ such that $t' \leq (1 + \varepsilon) \cdot t_{\mathcal{P}}$.*

Proof. The time bound follows from the above discussion setting $\tau = \sqrt{1+\varepsilon} - 1$, where τ is as stated in Fact 1. It remains to prove that G' has stretch factor $((1+\varepsilon)\cdot t_{\mathcal{P}})$.

For each candidate graph G'_i, let t'_i be its approximate stretch factor as computed by the algorithm, and let t_i be its exact stretch factor. From Fact 1 it follows that for each candidate graph G'_i, $t'_i \leq (1+\tau)^2 \cdot t_i$. Assume that $t_{\mathcal{P}} = t_j$ and that $t' = t'_k = \min_i t'_i$, for some indices j and k. As a result we have

$$t' = t'_k \leq t'_j \leq (1+\tau)^2 \cdot t_j = (1+\tau)^2 \cdot t_{\mathcal{P}} = (1+\varepsilon)\cdot t_{\mathcal{P}} \quad \text{and} \quad t_{\mathcal{P}} \leq t_k \leq t'_k = t'.$$

Thus, $t_{\mathcal{P}} \leq t' \leq (1+\varepsilon)\cdot t_{\mathcal{P}}$. □

3. Adding a bottleneck edge. Consider a graph $G = (V, E)$ with positive edge weights and stretch factor t. In this section we analyze the following simple algorithm: Add an edge between a pair of vertices in G with stretch factor t; this edge is called a *bottleneck edge* of G.

Let $G_{\mathcal{B}}$ be a graph obtained from G by adding a bottleneck edge, and let $t_{\mathcal{B}}$ be the stretch factor of $G_{\mathcal{B}}$. Note that $G_{\mathcal{B}}$ can be computed in the same time as the stretch factor of G can be decided, i.e., in $\mathcal{O}(mn + n^2 \log n)$ time for graphs with positive edge weights.

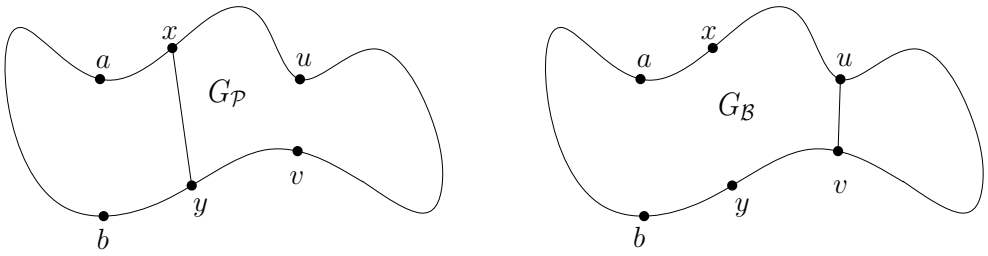

FIG. 1. (x, y) *is the optimal edge added to* G, *and* (u, v) *is a bottleneck edge.*

LEMMA 3. *Given a graph* G *with positive edge weights, it holds that* $t_{\mathcal{B}} < 3t_{\mathcal{P}}$.

Proof. Recall that t denotes the stretch factor of G and that $G_{\mathcal{P}}$ denotes the optimal graph. Let (x, y) be the edge added to G to obtain $G_{\mathcal{P}}$, and let (u, v) be the edge added to G to obtain $G_{\mathcal{B}}$; i.e., (u, v) is a bottleneck edge of G, as illustrated in Figure 1.

First note that if $t_{\mathcal{P}} > t/3$, then the lemma holds and we are done. Thus we may assume that $t_{\mathcal{P}} \leq t/3$. The proof of the lemma is done by considering a pair of vertices, denoted (a, b), that are endpoints of a bottleneck edge of $G_{\mathcal{B}}$. Fix a path $\delta_{G_{\mathcal{P}}}(a, b)$. If this path does not include the edge (x, y), then $d_{G_{\mathcal{P}}}(a, b) = d_G(a, b) \geq d_{G_{\mathcal{B}}}(a, b)$ and we are done. Therefore, we may assume that the path $\delta_{G_{\mathcal{P}}}(a, b)$ includes (x, y). Also, we will assume without loss of generality that a shortest path in $G_{\mathcal{P}}$ from a to b goes from a to x and then to b via y; otherwise the labels a and b may be switched. Note that $\delta_{G_{\mathcal{P}}}(u, v)$ must pass through (x, y); otherwise we have $t_{\mathcal{P}} \geq d_{G_{\mathcal{P}}}(u, v)/|uv| = d_G(u, v)/|uv| = t$, which means that $t = t_{\mathcal{P}}$, which contradicts the assumption that $t_{\mathcal{P}} \leq t/3$. Furthermore, we assume that a shortest path in $G_{\mathcal{P}}$ from u to v goes from u to x and then to v via y; otherwise the labels u and v may be switched.

As a first step we bound the distance between the endpoints of the bottleneck edge u and v. This is done by bounding the length of the path in G between x and y

as follows (see Figure 1):

$$\begin{aligned} d_G(u,v) &\le d_{G_{\mathcal{P}}}(u,v) - |xy| + d_G(x,y) \\ &\le t_{\mathcal{P}} \cdot |uv| - |xy| + t \cdot |xy| \\ &\le \frac{t}{3} \cdot |uv| - |xy| + t \cdot |xy| \\ &< \frac{t}{3} \cdot |uv| + t \cdot |xy|. \end{aligned}$$

Since $d_G(u,v) = t \cdot |uv|$ it follows that

$$|uv| < 3/2 \cdot |xy|. \tag{1}$$

Also,

$$\begin{aligned} t \cdot |uv| &= d_G(u,v) \\ &\le d_G(u,a) + d_G(a,b) + d_G(b,v) \\ &\le d_G(u,a) + t \cdot |ab| + d_G(b,v), \end{aligned}$$

which implies that

$$t \cdot (|uv| - |ab|) \le d_G(u,a) + d_G(b,v), \tag{2}$$

and

$$\begin{aligned} d_G(a,u) + 2|xy| + d_G(v,b) &\le d_G(a,x) + d_G(x,u) + 2|xy| + d_G(v,y) + d_G(y,b) \\ &= d_{G_{\mathcal{P}}}(a,b) + d_{G_{\mathcal{P}}}(u,v) \\ &\le t_{\mathcal{P}}(|ab| + |uv|), \end{aligned} \tag{3}$$

which gives that

$$d_G(a,u) + d_G(v,b) \le t_{\mathcal{P}}(|ab| + |uv|) - 2|xy|. \tag{4}$$

By putting together (2) and (4) we have

$$\begin{aligned} t(|uv| - |ab|) &\le d_G(a,u) + d_G(v,b) \\ &\le t_{\mathcal{P}}(|ab| + |uv|) - 2|xy| \\ &< t_{\mathcal{P}}(|ab| + |uv|), \end{aligned}$$

which implies that

$$|ab|(t_{\mathcal{P}} + t) > |uv|(t - t_{\mathcal{P}})$$

and

$$|ab| > \frac{t - t_{\mathcal{P}}}{t_{\mathcal{P}} + t} \cdot |uv| > \frac{t - \frac{t}{3}}{\frac{t}{3} + t} \cdot |uv| = \frac{1}{2} \cdot |uv|. \tag{5}$$

Now we are ready to put together the results:

$$\begin{aligned} t_{\mathcal{B}} \cdot |ab| &= d_{G_{\mathcal{B}}}(a,b) \\ &\le d_G(a,u) + |uv| + d_G(v,b) \\ &< d_G(a,u) + \frac{3}{2}|xy| + d_G(v,b) && \text{(from (1))} \\ &< d_G(a,u) + 2|xy| + d_G(v,b) \\ &\le t_{\mathcal{P}}\,(|ab| + |uv|) && \text{(from (3))} \\ &< 3t_{\mathcal{P}} \cdot |ab| && \text{(from (5))}. \end{aligned}$$

This completes the proof of the lemma since $t_{\mathcal{B}} < 3t_{\mathcal{P}}$. ∎

We conclude by stating the main result of this section followed by a lower bound for the bottleneck approach.

THEOREM 4. *Given a graph $G = (V, E)$ with positive edge weights, a $t_{\mathcal{B}}$-spanner $G' = (V, E \cup \{e\})$ with $t_{\mathcal{B}} < 3t_{\mathcal{P}}$ can be computed in $\mathcal{O}(mn + n^2 \log n)$ time using $\mathcal{O}(m)$ space.*

OBSERVATION 1. *There exists a Euclidean graph G such that $(2-\varepsilon)\cdot t_{\mathcal{P}} \leq t_{\mathcal{B}}$ for any $0 < \varepsilon < 1$.*

Proof. Consider the graph G, as in Figure 2(a). More specifically, G is a graph with ten vertices $p_i = ((i-1) \mod 5, \lfloor (i-1)/5 \rfloor \cdot \delta)$, $1 \leq i \leq 10$, and nine edges (p_5, p_{10}) and (p_j, p_{j+1}) for $1 \leq j \leq 4$ and $6 \leq j \leq 9$. For any value $\delta \leq 1$, (p_1, p_6) is a bottleneck edge in G and $t_{\mathcal{B}} = \frac{4+\delta}{\delta}$; see Figure 2(b).

In the case where edge (p_2, p_7) is added to G, as shown in Figure 2(c), the resulting graph has stretch factor $(2+\delta)/\delta$. Combining the upper and lower bounds gives $\frac{t_{\mathcal{B}}}{t_{\mathcal{P}}} \geq \frac{4+\delta}{2+\delta} = (2-\varepsilon)$, where the last equality follows if we set $\delta = \min\{1, \frac{2\varepsilon}{1-\varepsilon}\}$. ∎

Grüne [15] improved the lower bound in Observation 1 to $(3-\varepsilon)$, so the upper bound stated in Lemma 3 is tight.

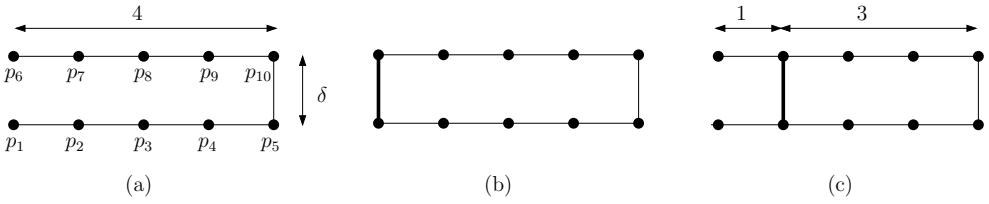

FIG. 2. (a) *The input graph G,* (b) *the graph $G_{\mathcal{B}}$, and* (c) *the graph $G_{\mathcal{P}}$.*

4. A $(2+\varepsilon)$-approximation for Euclidean graphs. In the remainder of the paper we will develop approximation algorithms for Euclidean graphs. In this section we present a fast approximation algorithm which guarantees an approximation factor of $(2+\varepsilon)$. The algorithm is similar to the algorithms presented in section 2 in the sense that it tests candidate edges. Testing a candidate edge entails computing the stretch factor of the input graph augmented with the candidate edge. The main difference is that we will show, in section 4.2, that only a linear number of candidate edges need to be tested to obtain a solution that gives a $(2+\varepsilon)$-approximation, instead of a quadratic number of edges.

Moreover, in section 4.3 we show that the same approximation bound can be achieved by performing only a linear number of shortest path queries for each candidate edge. The candidate edges are selected by using the well-separated pair decomposition, which we briefly define below.

4.1. Well-separated pair decomposition. Our algorithm uses the well-separated pair decomposition defined by Callahan and Kosaraju [6]. We briefly review this decomposition before we state the algorithms.

DEFINITION 5 (see [6]). *Let $s > 0$ be a real number, and let A and B be two finite sets of points in $\mathbb{R}^d$. We say that A and B are* well separated *with respect to s if there are two disjoint d-dimensional balls C_A and C_B, having the same radius, such that* (i) *C_A contains the bounding box $R(A)$ of A,* (ii) *C_B contains the bounding box $R(B)$ of B, and* (iii) *the minimum distance between C_A and C_B is at least s times the radius of C_A.*

The parameter s will be referred to as the *separation constant*. The next lemma follows easily from Definition 5.

LEMMA 6 (see [6]). *Let A and B be two finite sets of points that are well separated with respect to s, let x and p be points of A, and let y and q be points of B. Then* (i) $|xy| \leq (1 + 4/s) \cdot |pq|$, *and* (ii) $|px| \leq (2/s) \cdot |pq|$.

DEFINITION 7 (see [6]). *Let S be a set of n points in $\mathbb{R}^d$, and let $s > 0$ be a real number. A* well-separated pair decomposition *(WSPD) for S with respect to s is a sequence of pairs of nonempty subsets of S, $(A_1, B_1), \ldots, (A_m, B_m)$, such that*

1. *$A_i \cap B_i = \emptyset$ for all $i = 1, \ldots, m$,*
2. *for any two distinct points p and q of S, there is exactly one pair (A_i, B_i) in the sequence, such that* (i) *$p \in A_i$ and $q \in B_i$, or* (ii) *$q \in A_i$ and $p \in B_i$,*
3. *A_i and B_i are well separated with respect to s for $1 \leq i \leq m$.*

The integer m is called the size *of the WSPD.*

Callahan and Kosaraju showed that a WSPD of size $m = \mathcal{O}(s^d n)$ can be computed in $\mathcal{O}(s^d n + n \log n)$ time.

4.2. Linear number of candidate edges. In this section we show how to obtain a $(2 + \varepsilon)$-approximation in cubic time. As mentioned above, the algorithm is similar to the algorithm presented in section 2 in the sense that it tests candidate edges. Here we will show that only a linear number of candidate edges need to be tested to obtain a solution that gives a $(2 + \varepsilon)$-approximation.

The approach is straightforward. First the algorithm computes the length of the shortest path in G between every pair of points in V. The distances are saved in a matrix M. Next, the WSPD is computed. Note that, in step 5, the candidate edges will be chosen using the WSPD. In step 6, the function StretchFactor returns the stretch factor of the graph on V with edge set $E \cup (a_i, b_i)$; i.e., in steps 5–8, a candidate edge is tested by computing the stretch factor of G with the candidate edge (a_i, b_i) added to G.

ALGORITHM ExpandGraph(G, ε)
Input: Euclidean graph $G = (V, E)$ and a real constant $\varepsilon > 0$.
Output: Euclidean graph $G' = (V, E \cup \{e\})$.
1. $M \leftarrow$All-Pairs-Shortest-Path distance matrix of G.
2. $\{(A_i, B_i)\}_{i=1}^{k} \leftarrow$WSPD of the set V with respect to separation constant $s = \frac{256}{\varepsilon^2}$.
3. $t' \leftarrow \infty$.
4. **for** $i \leftarrow 1$ to k
5. Select arbitrary points $a_i \in A_i$ and $b_i \in B_i$.
6. $t_i \leftarrow$StretchFactor(a_i, b_i, M).
7. **if** $t_i < t'$
8. **then** $t' \leftarrow t_i$ and $e \leftarrow (a_i, b_i)$
9. **return** $G' = (V, E \cup \{e\})$.

Next, we bound the running time of the approximation algorithm and then prove the approximation bound.

LEMMA 8. *Algorithm* ExpandGraph *requires $\mathcal{O}(n^3/\varepsilon^{2d})$ time and $\mathcal{O}(n^2)$ space.*

Proof. The complexity of all steps of the algorithm, except step 6, is straightforward to calculate. Recall that step 1 requires $\mathcal{O}(mn + n^2 \log n)$ time and quadratic space, and step 2 requires $\mathcal{O}(n/\varepsilon^{2d} + n \log n)$ time according to section 4.1. Thus, it remains to consider step 6 of the algorithm. Note that the number of times step 6 is executed is $\mathcal{O}(n/\varepsilon^{2d})$.

Let $G_i = (V, E \cup \{(a_i, b_i)\})$. Since we computed the all-pair-shortest distances of G and stored the results in a matrix M, it holds that shortest path distance queries in G_i can be computed in constant time. That is, for a query (p, q) return $\min\{M[p,q], M[p,a_i]+|a_ib_i|+M[b_i,q], M[p,b_i]+|b_ia_i|+M[a_i,q]\}$. For each candidate edge, a quadratic number of queries are performed; thus summing up we get $\mathcal{O}(\frac{n}{\varepsilon^{2d}} \cdot n^2)$, as stated in the lemma. □

It remains to analyze the quality of the solution obtained from Algorithm ExpandGraph. We need to compare the graph resulting from adding an optimal edge to G and the graph G' resulting from ExpandGraph. Let $e = (a, b)$ be an optimal edge, and let (A_i, B_i) be the well-separated pair such that $a \in A_i$ and $b \in B_i$. At first sight, it seems that the edge (a_i, b_i) tested by the algorithm should be a good candidate. However, the separation constant of our WSPD depends only on ε, which implies that the shortest path between a and a_i, and between b and b_i, could be very long compared to the distance between a and b. In Lemma 9, we show the existence of a "short" edge e' that is a good approximation of the optimal edge and then, in Lemma 10, we show that ExpandGraph computes a good approximation of e'.

Let $\Delta(p, q)$ denote the set of point pairs in V such that the point pair (u, v) belongs to $\Delta(p, q)$ if and only if $(p, q) \in \delta_{G\cup\{(p,q)\}}(u, v)$. That is, $\Delta(p, q)$ is the set of point pairs for which a shortest path between them in $G \cup \{(p, q)\}$ passes through (p, q).

Lemma 9. *For any given constant $0 < \lambda \leq 1$, there exists a point pair $p, q \in V$ such that*

(I) $|uv| \geq \frac{\lambda}{2}|pq|$ *for every pair* $(u, v) \in \Delta(p, q)$, *and*

(II) *the stretch factor of* $G \cup \{(p, q)\}$ *is bounded by* $(2 + \lambda) \cdot t_{\mathcal{P}}$.

Proof. The proof is done in two steps. First a point pair $p_j, q_j \in V$ is selected that fulfills (I). Then we prove that this pair will also fulfill (II), i.e., that the stretch factor of $G \cup \{(p_j, q_j)\}$ is bounded by $(2 + \lambda) \cdot t_{\mathcal{P}}$.

Consider an optimal solution $G_1 = G \cup \{(p_1, q_1)\}$. If (p_1, q_1) fulfills (I), then we are done; i.e., we have found the point pair $(p = p_1, q = q_1)$ we are searching for. Otherwise, let $e_2 = (p_2, q_2)$ denote the closest pair in $\Delta(p_1, q_1)$. Since there exists a pair $(u, v) \in \Delta(p_1, q_1)$ such that $|uv| < \frac{\lambda}{2} \cdot |p_1q_1|$ and since (p_2, q_2) is the closest pair in $\Delta(p_1, q_1)$ we have $|p_2q_2| < \frac{\lambda}{2} \cdot |p_1q_1|$, as illustrated in Figure 3(a).

If (p_2, q_2) fulfills (I), then $(p = p_2, q = q_2)$ and we are done. Otherwise, let $e_3 = (p_3, q_3)$ denote the closest pair in $\Delta(p_2, q_2)$. We continue this procedure until we find a point pair (p_j, q_j) that satisfies (I). Since, for each $i > 0$, $|p_{i+1}q_{i+1}| < \frac{\lambda}{2} \cdot |p_iq_i|$, the process must terminate.

Now for each $1 \leq i \leq j$, let $G_i = G \cup \{(p_i, q_i)\}$ where (p_i, q_i) are the point pairs constructed above. We claim that G_j has stretch factor at most $(2 + \lambda) \cdot t_{\mathcal{P}}$. Before we continue we need to prove

$$d_{G_i}(p_{i+1}, q_{i+1}) \leq t_{\mathcal{P}} \cdot |p_{i+1}q_{i+1}|. \tag{6}$$

The inequality is obviously true for $i = 1$. For $i > 1$ it holds that $|p_{i+1}q_{i+1}| < |p_2q_2|$ which implies that $(p_{i+1}, q_{i+1}) \notin \Delta(p_1, q_1)$ since (p_2, q_2) is the closest pair in $\Delta(p_1, q_1)$. This, in turn, implies that $d_G(p_{i+1}, q_{i+1}) = d_{G_1}(p_{i+1}, q_{i+1}) \leq t_{\mathcal{P}} \cdot |p_{i+1}, q_{i+1}|$. Since G is a subgraph of G_i, the length of the shortest path in G_i between p_{i+1} and q_{i+1} must be bounded by the length of the shortest path in G between p_{i+1} and q_{i+1}, which is bounded by $t_{\mathcal{P}} \cdot |p_{i+1}q_{i+1}|$. Thus, inequality (6) holds.

We continue with the second part of the proof. If $(u, v) \notin \Delta(p_1, q_1)$, then we are done since $d_{G_j}(u, v) \leq d_G(u, v) = d_{G_1}(u, v)$. Otherwise, if $(u, v) \in \Delta(p_1, q_1)$, the

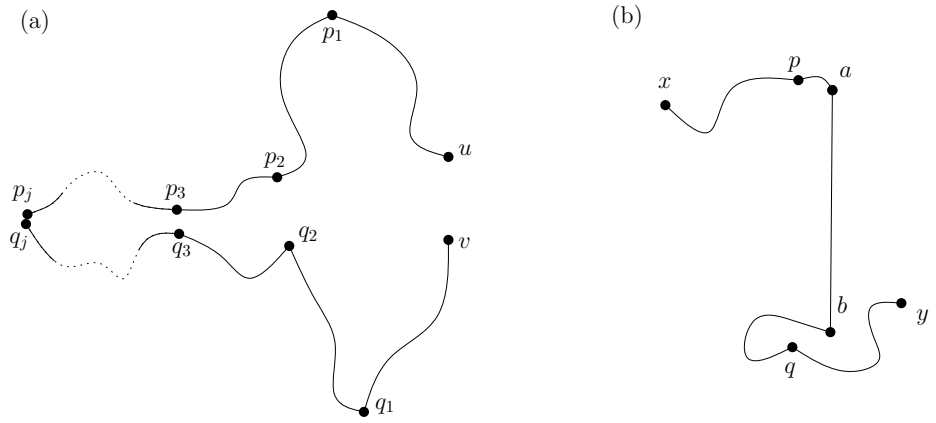

FIG. 3. (a) *Illustrating the proof of Lemma* 9. (b) *Illustrating the proof of Lemma* 10.

following holds (see Figure 3(a) for an illustration):

$$\begin{aligned}
d_{G_j}(u,v) &\le d_{G_1}(u,v) - |p_1q_1| + (d_{G_1}(p_2,q_2) - |p_1q_1|) + \cdots \\
&\quad + (d_{G_{j-1}}(p_j,q_j) - |p_{j-1}q_{j-1}|) + |p_jq_j| \\
&< t_{\mathcal{P}} \cdot |uv| - |p_1q_1| + (t_{\mathcal{P}} \cdot |p_2q_2| - |p_1q_1|) + \cdots \\
&\quad + (t_{\mathcal{P}} \cdot |p_jq_j| - |p_{j-1}q_{j-1}|) + |p_jq_j| && \text{(cf. (6))} \\
&= t_{\mathcal{P}} \cdot |uv| - 2|p_1q_1| + ((t_{\mathcal{P}}-1) \cdot |p_2q_2|) + \cdots + ((t_{\mathcal{P}}-1) \cdot |p_jq_j|) + 2|p_jq_j| \\
&< t_{\mathcal{P}} \cdot |uv| + (t_{\mathcal{P}}-1)(|p_2q_2| + \cdots + |p_jq_j|) && \text{(since } |p_jq_j| < |p_1q_1|\text{)} \\
&< t_{\mathcal{P}} \cdot |uv| + t_{\mathcal{P}} \cdot \sum_{i=2}^{j} \left(\frac{\lambda}{2}\right)^{i-2} |p_2q_2| && \text{(since } |p_{i+1}q_{i+1}| \le (\lambda/2) \cdot |p_iq_i|\text{)} \\
&\le t_{\mathcal{P}} \cdot |uv| + t_{\mathcal{P}} \cdot |uv| \cdot \sum_{i=0}^{j-2} \left(\frac{\lambda}{2}\right)^{i} && \text{(since } |p_2q_2| \le |uv|\text{)} \\
&= 2t_{\mathcal{P}} \cdot |uv| + t_{\mathcal{P}} \cdot |uv| \cdot \sum_{i=1}^{j-2} \left(\frac{\lambda}{2}\right)^{i} \\
&\le 2t_{\mathcal{P}} \cdot |uv| + t_{\mathcal{P}} \cdot |uv| \cdot \lambda \cdot \sum_{i=1}^{j-2} \frac{1}{2^i} && \text{(since } \lambda \le 1\text{)} \\
&< (2+\lambda) \cdot t_{\mathcal{P}} \cdot |uv|.
\end{aligned}$$

Thus, $t_j < (2+\lambda) \cdot t_{\mathcal{P}}$, which concludes the lemma. □

In the previous lemma we showed the existence of a "short" candidate edge (p,q) for which the resulting graph has small stretch factor. Note that Algorithm EXPAND-GRAPH might not test (p,q). However, in the following lemma it will be shown that Algorithm EXPANDGRAPH will test an edge (a,b) that is almost as good as (p,q).

LEMMA 10. *For any given constant* $0 < \varepsilon \le 1$ *it holds that the graph* G' *returned by Algorithm* EXPANDGRAPH *has stretch factor at most* $(2+\varepsilon) \cdot t_{\mathcal{P}}$.

Proof. According to Lemma 9, there exists an edge (p,q) such that for every pair $(u,v) \in \Delta(p,q)$ it holds that $|uv| \ge \frac{\lambda}{2}|pq|$, and the stretch factor t_H of $H = G \cup \{(p,q)\}$ is bounded by $(2+\lambda) \cdot t_{\mathcal{P}}$. Let (A_i, B_i) be the well-separated pair computed in step 2 of the algorithm such that $p \in A_i$ and $q \in B_i$. According to Definition 7 such a

well-separated pair must exist. Next, consider the candidate edge (a_i, b_i) tested by the algorithm, such that $a_i, p \in A_i$ and $b_i, q \in B_i$. For simplicity of writing we will use a and b to denote a_i and b_i, respectively.

Our claim is that the stretch factor t' of $G' = G \cup \{(a, b)\}$ is bounded by $(1+\varepsilon/4) \cdot t_H$. Thus, setting $\lambda = \varepsilon/4$ would then prove the lemma since $(2+\varepsilon/4)(1+\varepsilon/4) < (2+\varepsilon)$ for $\varepsilon \leq 1$.

Now we are ready to prove the claim. To compute the stretch factor of G' the algorithm performs a shortest path distance query between each pair of points in V. If it holds that $(x, y) \notin \Delta(p, q)$ for every pair of points $x, y \in V$, then the claim is obviously true; thus we have to consider only the pairs x, y for which it holds that $(x, y) \in \Delta(p, q)$; see Figure 3(b). Now the claim is

$$d_G(a, p) = d_H(a, p) \quad \text{and} \quad d_G(b, q) = d_H(b, q). \tag{7}$$

Lemma 9 states that if $(x', y') \in \Delta(p, q)$, then $|x'y'| \geq \frac{\varepsilon}{8}|pq|$. But by Lemma 6 the distances $|ap|$ and $|bq|$ are less than $\frac{2}{s}|pq| = \frac{\varepsilon^2}{128}|pq|$, which is less than $\frac{\varepsilon}{8}|pq|$ since $\varepsilon \leq 1$. As a consequence, $(a, p) \notin \Delta(p, q)$ and $(b, q) \notin \Delta(p, q)$; thus $(p, q) \notin \delta_H(a, p)$ and $(p, q) \notin \delta_H(b, q)$. Hence, claim (7) holds, which we will need below.

Next, we consider the length of the path in G' between x and y as illustrated in Figure 3(b). Recall that x and y are two arbitrary points of V for which it holds that $(x, y) \in \Delta(p, q)$. Without loss of generality we have

$$\begin{aligned}
d_{G'}(x, y) &\leq d_G(x, p) + d_G(p, a) + |ab| + d_G(b, q) + d_G(q, y) \\
&\leq d_G(x, p) + d_H(p, a) + |ab| + d_H(b, q) + d_G(q, y) && \text{(cf. (7))} \\
&\leq d_G(x, p) + |ab| + d_G(q, y) + t_H \cdot (|pa| + |bq|) \\
&\leq d_G(x, p) + (1 + 4/s) \cdot |pq| + d_G(q, y) + \frac{4t_H}{s} \cdot |pq| && \text{(Lemma 6)} \\
&\leq d_H(x, y) + \frac{8t_H}{s} \cdot |pq| \\
&\leq d_H(x, y) + \frac{64t_H}{\varepsilon s} \cdot |xy| && \text{(Lemma 9)} \\
&= d_H(x, y) + \frac{\varepsilon}{4} \cdot t_H \cdot |xy|.
\end{aligned}$$

The stretch factor of the path in G' between x and y is

$$\frac{d_{G'}(x, y)}{|xy|} \leq \frac{d_H(x, y)}{|xy|} + \frac{\frac{\varepsilon}{4} t_H |xy|}{|xy|} \leq \left(1 + \frac{\varepsilon}{4}\right) \cdot t_H.$$

Finally, according to Lemma 9 and the fact that $\lambda = \varepsilon/4$, it holds that $t_H \leq (2 + \varepsilon/4) \cdot t_{\mathcal{P}}$. This completes the lemma since $(2 + \varepsilon/4)(1 + \varepsilon/4) < (2 + \varepsilon)$. □

We may now conclude this section with the following theorem.

THEOREM 11. *Given a Euclidean graph $G = (V, E)$ in $\mathbb{R}^d$ one can in time $\mathcal{O}(n^3/\varepsilon^{2d})$, using $\mathcal{O}(n^2)$ space, compute a t'-spanner $G' = (V, E \cup \{e\})$, where $t' \leq (2 + \varepsilon) \cdot t_{\mathcal{P}}$.*

4.3. Speeding up Algorithm ExpandGraph. In the previous section we showed that a $(2+\varepsilon)$-approximate solution can be obtained by testing a linear number of candidate edges. Testing each candidate edge entails $\mathcal{O}(n^2)$ shortest path queries. One way to speed up the computation is to compute an approximate stretch factor. As in section 2.2 we will use Fact 1 by Narasimhan and Smid [27].

Their idea is to compute a WSPD of size $\mathcal{O}(s^d n)$ with respect to $s = 4(1+\tau)/\tau$, and then for each well-separated pair (A_i, B_i) select an arbitrary pair $a_i \in A_i$ and $b_i \in B_i$. They prove that these are the only pairs for which the $(1+\tau)^2$-approximate stretch factor needs to be computed.

We will use their idea to speed up step 6 of ExpandGraph from $\mathcal{O}(n^2)$ to $\mathcal{O}(n/\varepsilon^d)$; i.e., we check a linear number of pairs in order to compute an approximate stretch factor using Fact 1. However, we will not use the fact that only approximate distance queries are needed; instead the exact shortest distance will be computed, and thus $\gamma = 0$ where γ is as stated in Fact 1. There will be two main changes in the ExpandGraph algorithm; two WSPDs will be computed, and the computation of the stretch factor will be different. Instead of computing the exact stretch factor of G with the candidate edge (a_i, b_i) added to G, we compute the approximate stretch factor. This is done by a call to ApproximateStretchFactor, or ASF for short, with parameters (a_i, b_i), M, and $\mathcal{S}$. The ASF algorithm is stated in more detail below. Note that the number of point pairs in $\mathcal{S}$ is bounded by $\mathcal{O}(n/\varepsilon^d)$.

Algorithm ExpandGraph2(G, ε)
Input: Euclidean graph $G = (V, E)$ and a real constant $\varepsilon > 0$.
Output: Euclidean graph $G' = (V, E \cup \{e\})$.
1. $M \leftarrow$All-Pairs-Shortest-Path distance matrix of G.
2. $\{(A_i, B_i)\}_{i=1}^{k} \leftarrow$WSPD of the set V with respect to $s = 256/\varepsilon^2$.
3. $\{(C_j, D_j)\}_{j=1}^{\ell} \leftarrow$WSPD of the set V with respect to $s' = 4(1+\varepsilon)/\varepsilon$.
4. **for** $j \leftarrow 1$ **to** ℓ
5. Select an arbitrary point c_j of C_j and an arbitrary point d_j of D_j.
6. $\mathcal{S} = \{(c_1, d_1), \ldots, (c_\ell, d_\ell)\}$.
7. $t' \leftarrow \infty$.
8. **for** $i \leftarrow 1$ to k
9. Select an arbitrary point a_i of A_i and an arbitrary point b_i of B_i.
10. $t_i \leftarrow \mathrm{ASF}((a_i, b_i), M, \mathcal{S})$.
11. **if** $t_i < t'$
12. **then** $t' \leftarrow t_i$ and $e \leftarrow (a_i, b_i)$
13. **return** $G' = (V, E \cup \{e\})$.

For completeness we also state the ASF algorithm.

Algorithm ASF$((a, b), M, \mathcal{S})$
Input: Vertex pair $(a, b) \in V^2$, distance matrix M, and a set of point pairs $\mathcal{S}$.
Output: A real value $\mathcal{D}$.
1. $\mathcal{D} \leftarrow 1$
2. **for** each point pair (c_j, d_j) in $\mathcal{S}$
3. dist $\leftarrow \min\{M[c_j, d_j],\ \ M[c_j, a] + |ab| + M[b, d_j],\ \ M[c_j, b] + |ba| + M[a, d_j]\}$
4. $\mathcal{D} \leftarrow \max\{\mathcal{D}, \text{dist}/|c_j d_j|\}$
5. **return** $\mathcal{D}$.

Theorem 12. *Given a Euclidean graph $G = (V, E)$ and a real constant $\epsilon > 0$, one can in $\mathcal{O}(nm + n^2(\log n + 1/\epsilon^{3d}))$ time, using $\mathcal{O}(n^2)$ space, compute a t'-spanner $G' = (V, E \cup \{e\})$ such that $t' \leq (2+\epsilon) \cdot t_{\mathcal{P}}$.*

Proof. The complexity of all steps of the algorithm, except step 10, is as in Lemma 8. Steps 1–7 require $\mathcal{O}(mn + n^2 \log n + n/\varepsilon^{2d})$ time. It remains to consider

step 10 of the algorithm. Note that the number of times step 10 is executed is $\mathcal{O}(n/\varepsilon^{2d})$. Procedure ASF performs $\mathcal{O}(n/\varepsilon^d)$ shortest path queries, instead of $\mathcal{O}(n^2)$, thus the total time needed by step 10 is $\mathcal{O}(\frac{n}{\varepsilon^{2d}} \cdot \frac{n}{\varepsilon^d})$. Summing up the running times gives the stated time complexity.

In Lemma 10 it was proven that the solution returned by algorithm ExpandGraph had a stretch factor that was at most a factor $(2+\varepsilon)$ worse than the stretch factor of an optimal solution. Since the modified algorithm does not compute the exact stretch factor of a candidate graph, but instead computes a $(1+\varepsilon)^2$-approximate stretch factor it is not hard to verify that the same arguments as in Lemma 10 can be applied to prove that the algorithm ExpandGraph2 returns a graph with stretch factor at most $(1+\varepsilon)^2 \cdot (2+\varepsilon) \cdot t_{\mathcal{P}}$. Setting $\varepsilon = \min\{\epsilon/10, 1\}$ concludes the proof of the theorem. □

5. A special case: G has constant stretch factor. In the special case when the stretch factor of a graph G is known to be constant there are well-known tools that we can use to decrease both the time complexity and the space complexity of the algorithms and improve the approximation factor.

Fact 2 (see [18]). Let V be a set of n points in $\mathbb{R}^d$, let $t > 1$ and $0 < \varepsilon \leq 1$ be real numbers, and let $G = (V, E)$ be a t-spanner for V. In $\mathcal{O}(m + \frac{nt^{5d}}{\varepsilon^{2d}}(\log n + (t/\varepsilon)^d))$ time, we can preprocess G into a data structure of size $\mathcal{O}(\frac{t^{3d}}{\varepsilon^{2d}} n \log tn)$ such that for any two distinct points p and q in V, a $(1+\varepsilon)$-approximation to the shortest path distance between p and q in G can be computed in time $\mathcal{O}\big((t^5/\varepsilon^2)^d\big)$.

The query structure in Fact 2 is denoted M' and is constructed by algorithm QueryStructure. We have to use a modified version of ASF, denoted ASF′, that takes the query structure M' as input instead of the matrix M. The shortest path distance queries using M in ASF are replaced in ASF′ by performing approximate shortest path distance queries using M'.

Next we state the main algorithm. Recall that the parameter t is a constant and an upper bound on the stretch factor of the input graph G. Also note that this algorithm only needs one WSPD.

Algorithm ExpandGraph3(G, t, ε)
Input: Euclidean t-spanner $G = (V, E)$ and two real constants $t > 1$ and $\varepsilon > 0$.
Output: Euclidean graph $G' = (V, E \cup \{e\})$.
1. $M' \leftarrow$QueryStructure(G, t, ε) using Fact 2.
2. $\{(A_i, B_i)\}_{i=1}^k \leftarrow$WSPD of V with respect to the separation constant $s = 8(t+1)/\varepsilon$.
3. **for** $j \leftarrow 1$ **to** k
4. Select an arbitrary point a_j of A_j and an arbitrary point b_j of B_j.
5. $\mathcal{S} = \{(a_1, b_1), \ldots, (a_k, b_k)\}$.
6. $t_{\mathcal{C}} \leftarrow \infty$.
7. **for** $i \leftarrow 1$ **to** k
8. $t_i \leftarrow$ASF′$((a_i, b_i), M', \mathcal{S})$.
9. **if** $t_i < t_{\mathcal{C}}$
10. **then** $t_{\mathcal{C}} \leftarrow t_i$ and $e_C \leftarrow (a_i, b_i)$
11. **return** $G' = (V, E \cup \{e_C\})$.

Lemma 13. *Algorithm* ExpandGraph3 *runs in* $\mathcal{O}((t^7/\varepsilon^4)^d \cdot n^2)$ *time and uses* $\mathcal{O}((t^3/\varepsilon^2)^d\, n \log(tn))$ *space.*

Proof. The time complexity of steps 1–3 is dominated by step 1; thus $\mathcal{O}(m + n(t^5/\varepsilon^2)^d(\log n+(t/\varepsilon)^d))$ time. Step 8 is executed $\mathcal{O}((t/\varepsilon)^d n)$ times, and each iteration requires $\mathcal{O}((t/\varepsilon)^d n \cdot (t^{5d}/\varepsilon^{2d}))$ time according to Facts 1 and 2. Summing up the time bounds gives the time bound stated in the algorithm.

The space bound follows since the approximate distance oracle stated in Fact 2 uses only $\mathcal{O}((t^3/\varepsilon^2)^d\, n \log tn)$ space instead of the quadratic space needed earlier. ∎

Now, we show that this algorithm computes a $(1+\varepsilon)$-approximation of the optimal solution. Note that in ExpandGraph3 the separation constant depends on both ε and t, which is the main difference compared to the previous algorithms. This allows us to improve the approximation factor.

Lemma 14. *Let $G = (V, E)$ be a Euclidean graph with constant stretch factor t and a positive real constant ε, and let $\{(A_i, B_i)\}_{i=1}^k$ be a WSPD of V with respect to $s = \frac{8(t+1)}{\varepsilon}$. For every pair (A_i, B_i) and any elements $a_1, a_2 \in A_i$ and $b_1, b_2 \in B_i$, let $G_1 = (V, E \cup \{(a_1, b_1)\})$ and $G_2 = (V, E \cup \{(a_2, b_2)\})$, and let t_1 and t_2 denote the stretch factor of G_1 and G_2, respectively. It holds that $t_1 \leq (1 + \varepsilon)t_2$.*

Proof. It suffices to prove that for every pair of points $(u, v) \in \Delta(a_2, b_2)$ there exists a path in G_1 of length at most $(1 + \varepsilon) \cdot d_{G_2}(u, v)$. Without loss of generality we may assume that the shortest path between u and v in G_2 goes from u to a_2 and to v via b_2. We have

$$\begin{aligned}
d_{G_1}(u, v) &\leq d_G(u, a_2) + d_G(a_2, a_1) + |a_1b_1| + d_G(b_1, b_2) + d_G(b_2, v) \\
&\leq d_G(u, a_2) + t|a_1a_2| + |a_1b_1| + t|b_1b_2| + d_G(b_2, v) \\
&\leq d_G(u, a_2) + \frac{4t}{s}|a_2b_2| + (1 + 4/s) \cdot |a_2b_2| + d_G(b_2, v) \\
&< d_G(u, a_2) + |a_2b_2| + d_G(b_2, v) + \frac{8t}{s}|a_2b_2| \\
&= d_{G_2}(u, v) + \frac{t\varepsilon}{t+1}|a_2b_2| \\
&< (1 + \varepsilon) \cdot d_{G_2}(u, v).
\end{aligned}$$

In the second inequality we used Lemma 6, in the fifth inequality we used the fact that $s = 8(t + 1)/\varepsilon$, and in the final step we used that $d_{G_2}(u, v) \geq |a_2b_2|$ since $(u, v) \in \Delta(a_2, b_2)$. The lemma follows. ∎

Lemma 15. *Algorithm* ExpandGraph3 *returns a graph with stretch factor at most $(1 + \varepsilon)^3 \cdot t_{\mathcal{P}}$.*

Proof. Assume that $t_{\mathcal{P}}$ is the stretch factor of an optimal solution $G \cup \{(p, q)\}$, and let G' with stretch factor $t_{\mathcal{C}}$ be the output of the above algorithm.

We will use the same notation as in the algorithm. For each i let t_i^* be the stretch factor of $G_i = G \cup \{(a_i, b_i)\}$. According to Fact 1 we have $t_i^* \leq t_i \leq (1 + \varepsilon)^2 \cdot t_i^*$ for each i.

Let (A_j, B_j) be the pair in the WSPD such that $p \in A_j$ and $q \in B_j$, or $p \in B_j$ and $q \in A_j$. From Lemma 14 it follows that $t_j^* \leq (1 + \varepsilon) \cdot t_{\mathcal{P}}$. As a result it follows that $t_{\mathcal{C}} \leq t_j \leq (1 + \varepsilon)^2 \cdot t_j^* \leq (1 + \varepsilon)^3 \cdot t_{\mathcal{P}}$. Therefore $t_{\mathcal{P}} \leq t_{\mathcal{C}} \leq (1 + \varepsilon)^3 \cdot t_{\mathcal{P}}$, which completes the lemma. ∎

The following theorem follows by setting $\varepsilon = \min\{\varphi/15, 1\}$ and combining Lemmas 13 and 15.

Theorem 16. *Let V be a set of n points in $\mathbb{R}^d$, let $t > 1$ and $\varphi > 0$ be real numbers, and let $G = (V, E)$ be a t-spanner of V. One can in $\mathcal{O}((t^7/\varphi^4)^d \cdot n^2)$ time, using $\mathcal{O}((t^3/\varphi)^d\, n \log tn)$ space, compute a t'-spanner $G' = (V, E \cup \{e\})$ such that $t' \leq (1 + \varphi) \cdot t_{\mathcal{P}}$.*

6. Concluding remarks. We considered the problem of adding an edge to a Euclidean graph such that the stretch factor of the resulting graph is minimized and gave several algorithms. Our main result is a $(2+\varepsilon)$-approximation algorithm with running time $\mathcal{O}(nm + n^2(\log n + 1/\varepsilon^{3d}))$ using $\mathcal{O}(n^2)$ space. Several problems remain open:

1. Is there an exact algorithm with running time $o(n^4)$ using linear space?
2. Can we achieve a $(1+\varepsilon)$-approximation within the same time bound as in Theorem 12?
3. A natural extension is to allow more than one edge to be added. Can we generalize our results to this case?

Acknowledgments. The authors would like to thank René van Oostrum for fruitful discussions during the early stages of this work, Mohammad Ali Abam for discussions about section 2.2, and Sergio Cabello for simplifying the algorithm in section 5. Finally, we thank the anonymous referees for many insightful comments and suggestions on how to improve the paper.

EQUITABLE COST ALLOCATIONS VIA PRIMAL–DUAL-TYPE ALGORITHMS*

KAMAL JAIN† AND VIJAY V. VAZIRANI‡

Abstract. Perhaps the strongest notion of truth-revealing in a cost sharing mechanism is group strategyproofness. However, matters are not so clear-cut on fairness, and many different, sometimes even conflicting, notions of fairness have been proposed which have relevance in different situations. We present a large class of group strategyproof cost sharing methods, for submodular cost functions, satisfying a wide range of fairness criteria, thereby allowing the service provider to choose a method that best satisfies the notion of fairness that is most relevant to its application. Our class includes the Dutta–Ray egalitarian method as a special case. It also includes a new cost sharing method, which we call the *opportunity egalitarian method*.

Key words. cost sharing methods, submodular cost functions, fairness in cost sharing, group strategyproof mechanism, opportunity egalitarian method

DOI. 10.1137/060658448

1. Introduction.

Distributing the cost of a shared resource in a fair and truth-revealing manner is a central problem in cooperative game theory. Perhaps the strongest notion of truth-revealing is *group strategyproofness*, under which the dominant strategy of users is to reveal their true utility, even if they collude. However, matters are not so clear-cut on fairness—many different, sometimes conflicting, notions have been proposed which have relevance in different situations. Let us clarify that we are not necessarily postulating a service provider who is inherently "fair," but that in the long run, it is in the best interest of the service provider to subscribe to some form of fairness in choosing its cost allocations. We will assume that the cost function is submodular, a natural economies-of-scale condition. Equivalently, these results also apply to the situation of profit sharing under a convex transferable utility game; e.g., see [23]. In this paper, we will be concerned with fully budget-balanced methods; i.e., the total amount accrued from the users should be exactly equal to the cost of the shared resource.

As shown by Moulin [23], a *cross-monotone cost sharing method* for the given cost function gives rise to a group strategyproof mechanism, and for submodular cost functions, essentially the converse holds as well. Informally, a cost sharing method is cross-monotone, also called population monotone, if the cost share of any user can only decrease if a superset is being served.

Two well-known cross-monotone cost sharing methods for submodular cost functions are the Shapley value and the egalitarian method of Dutta and Ray [6] (the former requires that the cost function be *nondecreasing* as well; i.e., the cost of serving a set should not be larger than the cost of serving any of its supersets). Both these methods have been extensively studied; for the latter, see [12, 11, 13, 16, 21, 3, 2, 5, 7].

These two methods satisfy different fairness criteria. The Shapley value charges higher amounts from users who are more expensive to serve. The egalitarian method attempts to charge equal amounts from all users subject to the coalition participation constraint that the method lies in the core of the game; i.e., no subset is charged more than its stand-alone cost (thereby precluding the possibility of its seceding).

Consider the following situation in which neither of these criteria appears to be fair. Suppose that two users, Fred Smith and Gill Bates, are proximally located so that they are equally expensive to serve. For concreteness, assume that the service provider is transmitting valuable financial data and needs to recover a cost of $2000, regardless of whether it serves one or both users. Fred Smith and Gill Bates derive widely different utilities on receiving this data—the former is a man of modest means, and the latter is a multimillionaire. Hence, they are also willing to pay different amounts for this data. In this situation, the Shapley value as well as the egalitarian method will assign cost shares of $1000 each for the service, an amount that is not acceptable to Fred Smith. However, Gill Bates considers this data useful for wisely managing his vast acquisitions and ends up paying the entire $2000 for the service. If, instead, the cost sharing method were to take into consideration the relative paying powers of the two users and charge differentially, it may be able to find an outcome that Pareto dominates the previous outcome. For instance, if it charges Fred Smith $100 and Gill Bates $1900, both accept the service and both are better off. In addition, the service provider is also better off since it has a larger and more satisfied pool of customers.

This form of differential pricing, sometimes also called price discrimination, is widely resorted to and is in fact crucial to the survival of many industries [25, 27, 28, 29]. For instance, it provides mechanisms to the airline industry to charge higher fares from business travelers, who can afford to pay higher fares, than from casual travelers. Clearly, the fate of the airline industry, which has been on the brink of bankruptcy numerous times, would be dire without such a mechanism. Another common example is differential subscription rates for journals charged from students, professionals, and institutions.

Can the service provider resort to differential pricing and still ensure that the mechanism is strategyproof or, better, group strategyproof? In this paper, we provide a formal setting to accomplish this. We present a large class of group strategyproof mechanisms for submodular cost functions, satisfying a wide range of fairness criteria—hence the name "equitable." Our class includes the Dutta–Ray egalitarian method as a special case. It also includes a new cost sharing method, which we call the *opportunity egalitarian method*. Assuming that individual utilities are drawn from probability distributions which are known to the service provider, this method finds cost shares that attempt to equalize the users' probabilities of accepting the service, subject to core constraints. The above-stated examples of differential cost shares can be viewed as approximations of the opportunity egalitarian method.

Each equitable cost sharing method is parameterized by n *equalizing functions* which encode the fairness criterion chosen. The method ensures that w.r.t. the chosen criterion, the cost shares satisfy min-max as well as max-min fairness; i.e., no one underpays, and no one overpays. Thus, in the case of the egalitarian method (opportunity egalitarian method), among all cost allocations in the core, the chosen allocation minimizes the maximum cost shares (probability of accepting service) as well as maximizes the minimum cost shares (for fairness). Precise definitions appear in sections 3, 5.1, and 6. Max-min fairness has been used in the networking community for tackling issues of bandwidth allocation [4, 15] and has also been algorithmically studied in the context of routing in networks [22, 1, 20]. Approximate versions of this

notion have also been studied [9].

Our algorithms are inspired by the primal-dual schema from the field of approximation algorithms (see [30]). In the latter setting, it is natural to view the dual program as "paying" for the primal, and the algorithm as progressive bidding to get access to a shared resource (this viewpoint is particularly clear in the primal-dual algorithm presented in [18]). The equalizing functions determine the rates at which individual users increase their "bids." Each iteration of our algorithm runs in polynomial time. We utilize recently discovered polynomial time algorithms for the minimization of a submodular function [14, 26]. The precise number of iterations depends upon the accuracy needed.

We have recently found some rather unexpected applications of the results of this paper. The cross-monotonic cost sharing method developed in this paper for submodular cost functions has been used for proving competition monotonicity for submodular utility allocation markets in [19]. Our max-min and min-max fairness results for these cost sharing methods have also been used in [19] for establishing that the equilibrium allocations for submodular utility allocation markets are max-min fair.

It is interesting to note that independently, though somewhat preceding our work, Hokari [11] generalized Dutta–Ray solutions to give a class of cost sharing methods that turns out to be identical to ours. He calls his methods *monotone path cost allocations*. Hokari's formalization and point of view are quite different from ours—the definitions of the cost sharing methods are strikingly different,[1] and so are the algorithms for computing them (Hokari does not address issues of algorithmic efficiency). We believe that this class deserves further study—in the past, notions derived from diverse considerations have turned out to be particularly robust and canonical.

Mutuswami [24] proved the following interesting fact about the Dutta–Ray egalitarian method. If the utilities of individual users are independently and identically distributed (i.i.d.) (and the distribution satisfies the monotone hazard rate condition; see section 7 for a formal definition), then for every set S of users, the egalitarian method maximizes the probability that all members of S accept the service, among all cost sharing methods in the core. We generalize this result by removing the restriction that all utilities come from the *same* distribution. We show that for each choice of distributions from which the utilities are picked (provided they satisfy the strict monotone hazard rate condition), there is an equitable cost sharing method that maximizes, for every set $S \subseteq U$, the probability that all members of S accept the service, among all cost sharing methods for S in the core.

2. Basic definitions. Let $U = \{1, \ldots, n\}$ denote the set of users and cost : $2^U \to \mathbf{R}^+$ denote the function that gives the cost of serving any subset of the users. We will assume that this function is *submodular*; i.e.,

$$\forall S, T \subseteq U, \quad \text{cost}(S) + \text{cost}(T) \geq \text{cost}(S \cup T) + \text{cost}(S \cap T).$$

Following is an equivalent definition that makes it clear that such cost functions satisfy a natural economies-of-scale condition. The marginal cost of including a new user can only be smaller if a superset is being served:

$$\forall S \subset T \subset U,\ i \notin T, \quad \text{cost}(S + i) - \text{cost}(S) \geq \text{cost}(T + i) - \text{cost}(T).$$

[1] See section 8 for an implication that is easier to derive from our formulation.

We consider the following game. The service provider picks a *mechanism* for deciding the set $S \subseteq U$ of users that get the service and the individual cost shares of users in S so as to retrieve the cost of serving them, $\text{cost}(S)$. It obtains from the users their utilities for receiving the service. Thus each user's strategy is simply the utility he reports. The service provider is not allowed to charge a user more than his reported utility (otherwise, the user will refuse the service).

We will say that the service provider's mechanism is *strategyproof* if the dominant strategy of each user is to report his true utility. It is *group strategyproof* if the above holds despite collusions among users. Let us make this precise. Consider a coalition C of users. Let $\boldsymbol{u}$ and $\boldsymbol{u}'$ be two vectors of bids (we will think of the former as agents' true values and $\boldsymbol{u}'$ as strategically chosen bids). Assume that $\boldsymbol{u}_j = \boldsymbol{u}'_j$ for all $j \notin C$. Let $(\boldsymbol{q}, \boldsymbol{x})$ and $(\boldsymbol{q}', \boldsymbol{x}')$ denote the users served and costs at $\boldsymbol{u}$ and $\boldsymbol{u}'$, respectively. Now, group strategyproofness requires that if the inequality

$$\boldsymbol{u}'_i \boldsymbol{q}_i - \boldsymbol{x}_i \geq \boldsymbol{u}'_i \boldsymbol{q}'_i - \boldsymbol{x}'_i$$

holds for all $i \in C$, then it must hold with equality for all $i \in C$ as well; i.e., if no member of C is made worse off by misreporting of their utility values, then no member of C is made better off either. Moulin [23] showed that it is sufficient for the service provider to pick a cross-monotone cost sharing method in order to obtain a group strategyproof mechanism. His procedure for obtaining such a mechanism from the method is recapitulated below.

A *cost sharing method*, ξ, specifies how to distribute, for any set $S \subseteq U$, $\text{cost}(S)$ among the users in S. It satisfies the following:

1. Users will not be paid for receiving service; i.e.,

$$\forall S \subseteq U,\ i \in S, \quad \xi(S, i) \geq 0.$$

2. Budget balance

$$\forall S \subseteq U, \quad \sum_{i \in S} \xi(S, i) = \text{cost}(S).$$

3. Users not being served will not be charged; i.e.,

$$\forall S \subseteq U,\ i \notin S, \quad \xi(S, i) = 0.$$

For any set $S \subseteq U$, the slice of ξ at S, i.e., $\xi(S, \cdot)$, will be denoted by ξ^S. Thus, $\xi^S : S \to \mathbf{R}^+$ specifies the cost shares of users in S, assuming that S is the set being served. We will say that ξ is *cross-monotonic* if it satisfies the following economies of scale condition:

$$\forall S \subset T \subseteq U,\ \forall i \in S, \quad \xi^S(i) \geq \xi^T(i);$$

i.e., the cost share of a user can only be smaller if a superset is being served.

Let ξ be a cross-monotone cost sharing method. Consider the following mechanism. Initialize $S \leftarrow U$. If for each user $i \in S$, his cost share $\xi(S, i)$ is at most his utility, HALT. Else, drop users whose utilities are smaller than their cost shares, update S, and repeat.

THEOREM 1 (Moulin [23]). *If ξ is a cross-monotone cost sharing method, then the mechanism specified above is group strategyproof.*

A cost allocation for set $S \subseteq U$, $\alpha : S \to \mathbf{R}^+$ is said to satisfy the *coalition participation constraint* if it satisfies the following:

1. Budget balance, i.e.,

$$\sum_{i \in S} \alpha(i) = \text{cost}(S).$$

2. No subset $S' \subset S$ is charged more than the stand-alone cost of serving S'; i.e.,

$$\forall S' \subset S, \quad \sum_{i \in S'} \alpha(i) \leq \text{cost}(S').$$

The core is usually defined as the set of all cost allocations for U (i.e., the grand coalition) satisfying the coalition participation constraint. In this paper, we will define the *core* to consist of all cost allocations satisfying the coalition participation constraint for all sets $S \subseteq U$, rather than only U. We will say that *a cost sharing method ξ is in the core* if for all $S \subseteq U$, ξ^S is in the core.

3. Equitable cost sharing methods. Let $\boldsymbol{q}$ and $\boldsymbol{r}$ be n-dimensional vectors with nonnegative coordinates. We will denote by $\boldsymbol{q}_{INC}$ the vector obtained by sorting the components of $\boldsymbol{q}$ in increasing order. Thus $\boldsymbol{q}_{INC}(i) \leq \boldsymbol{q}_{INC}(i+1)$ for $1 \leq i \leq n-1$. Define a partial order as follows: say that $\boldsymbol{q}$ *max-min dominates* $\boldsymbol{r}$ if $\boldsymbol{q}_{INC}$ is lexicographically larger than $\boldsymbol{r}_{INC}$, i.e., if there is an i such that $\boldsymbol{q}_{INC}(i) > \boldsymbol{r}_{INC}(i)$ and $\boldsymbol{q}_{INC}(j) = \boldsymbol{r}_{INC}(j)$ for $j < i$. Clearly, $\boldsymbol{q}_{INC} = \boldsymbol{r}_{INC}$ may hold even though $\boldsymbol{q} \neq \boldsymbol{r}$.

An equitable cost sharing method is parameterized by n strictly increasing, continuous, and unbounded functions from $\mathbf{R}^+$ to $\mathbf{R}^+$, $f_1, \ldots, f_n$ satisfying further that $f_i(0) = 0$. These will be called *equalizing functions*. The *equitable cost sharing method* corresponding to this set of equalizing functions, say ξ, is defined as follows. We will specify ξ^S for each set $S \subseteq U$. Without loss of generality assume that S consists of users $1, \ldots, s$. Let α be a cost allocation for S that lies in the core. Let $\boldsymbol{t}(\alpha)$ denote the s-dimensional vector whose ith component is $f_i^{-1}(\alpha(i))$. We will show in Theorem 6 that there is a unique cost allocation for set S in the core, say β, such that $\boldsymbol{t}(\beta)$ max-min dominates $\boldsymbol{t}(\alpha)$ for all other allocations, α, for S in the core. We will define $\xi^S = \beta$.

If all n equalizing functions are picked to be the identity function, the resulting cost sharing method will be the egalitarian method of Dutta and Ray (strictly speaking, this is not the way they defined their method; see section 5.2). The egalitarian method maximizes the minimum cost shares, i.e., ensures that no one underpays, subject to core constraints—in that sense, it tries to make the cost shares of individual users as equal as possible. Our generalization optimizes the max-min objective function relative to the equalizing functions $f_1, \ldots, f_n$, which encode the particular fairness criterion chosen. As shown in Theorem 10, equitable methods (including the egalitarian method) optimize the min-max objective as well, ensuring that no one overpays.

4. The algorithm. We now present a primal–dual-type algorithm for obtaining ξ^S for any set S. First we give some definitions. Let $x : S \to \mathbf{R}^+$ be a function assigning costs to users in S. Set $A \subseteq S$ will be said to be *tight* if $\sum_{i \in A} x_i = \text{cost}(A)$. It will be said to be *overtight* if $\sum_{i \in A} x_i > \text{cost}(A)$. We will say that x is *feasible* if no subset of S is overtight. Note that we have not imposed the condition that $\sum_{i \in S} x_i = \text{cost}(S)$. The algorithm will utilize the following properties.

LEMMA 2. *Let* cost *be submodular and x be feasible for S. If $A, B \subseteq S$ are both tight, then $A \cup B$ is also tight.*

Proof. By submodularity,

$$\text{cost}(A \cup B) \leq \text{cost}(A) + \text{cost}(B) - \text{cost}(A \cap B).$$

Since x is feasible for S,

$$\sum_{i \in (A \cap B)} x_i \leq \text{cost}(A \cap B).$$

Combining this with the fact that A and B are both tight, we get

$$\text{cost}(A \cup B) \leq \sum_{i \in A} x_i + \sum_{i \in B} x_i - \sum_{i \in (A \cap B)} x_i = \sum_{i \in (A \cup B)} x_i.$$

Therefore, $A \cup B$ must also be tight. □

COROLLARY 3. *If* cost *is submodular and x is feasible for S, then there is a unique maximal tight set. It is given by $\{i \in S \mid i$ belongs to some tight set$\}$.*

For each set $S \subseteq U$, the algorithm below computes a cost allocation for S.

ALGORITHM 1. We will associate a notion of time with our algorithm. Initially, the time t is set to zero. As the algorithm proceeds, we raise cost shares of users in S in proportion to their respective functions f_i; thus, at time t, the cost share of a user i is $f_i(t)$. Whenever a set $A \subseteq S$ goes tight, the cost shares of all users in A are frozen at the current value. The cost shares of the remaining users keep increasing with time as before. The algorithm terminates when the cost shares of all users are frozen. For each user $i \in S$, define $\xi^S(i)$ to be i's cost share at termination.

By Corollary 3, at any time, there is a unique maximal tight set. This tight set can be found in polynomial time using a submodular function minimization algorithm [14, 26] as follows. The difference of a submodular function and a modular function is a submodular function. Hence, the following function, defined on 2^S, is submodular:

$$\text{cost}'(A) = \text{cost}(A) - \sum_{i \in A} f_i(t_i)$$

for $A \subseteq S$, where t_i's are fixed for each element $i \in S$. For an element i that is already frozen, fix t_i to be the time at which i froze. For an element i that is not yet frozen, let $t_i = t$. Now we will do a binary search on t to find the smallest time at which there is a set $A \subseteq S$ such that $\text{cost}'(A)$ is a small negative number. At that value of time, the set whose cost$'$ is minimum will clearly be the maximal set to go tight next.

REMARK 4. *Observe that $\boldsymbol{t}(\xi^S)$ is precisely the vector of times at which individual elements went tight ($\boldsymbol{t}$ is defined at the beginning of section 3).*

LEMMA 5. *For each set $S \subseteq U$, the cost allocation given by ξ^S lies in the core.*

Proof. Clearly, ξ^S is feasible for S and no subset of S is overtight. Furthermore, by Corollary 3, at termination, set S must be tight. □

THEOREM 6. *For any set $S \subseteq U$, the cost allocation, ξ^S, found by Algorithm 1 is such that $\boldsymbol{t}(\xi^S)$ max-min dominates $\boldsymbol{t}(\alpha)$ for all other cost allocations, α, for S in the core.*

Proof. Let α be an allocation for set S that lies in the core. Suppose that $\boldsymbol{t}(\xi^S)$ does not max-min dominate $\boldsymbol{t}(\alpha)$. Then we will show that ξ^S and α are in fact the same allocation, hence proving the theorem.

Let $A_1 \subset A_2 \subset \cdots \subset S$ be the sequence of maximal sets that go tight when the algorithm is run on set S. We will show by induction on i that all users in A_i must have the same cost allocation in α and ξ^S. Observe that all elements in $A_i - A_{i-1}$ go tight at the same time, and hence the components corresponding to them in $\boldsymbol{t}(\xi^S)$ are identical.

Clearly,

$$\sum_{i \in A_1} \alpha(i) \leq \sum_{i \in A_1} \xi^S(i) = \text{cost}(A_1).$$

If this inequality is strict, there exists $i \in A_1$ such that $\alpha(i) < \xi^S(i)$. Since users $i \in A_1$ give rise to the smallest entries of $\boldsymbol{t}_{INC}(\xi^S)$, $\boldsymbol{t}(\xi^S)$ max-min dominates $\boldsymbol{t}(\alpha)$, leading to a contradiction. Therefore, this inequality must hold with equality. If for some user $i \in A_1$, $\alpha(i) > \xi^S(i)$, then for some other user $j \in A_1$, $\alpha(j) < \xi^S(j)$, and again $\boldsymbol{t}(\xi^S)$ max-min dominates $\boldsymbol{t}(\alpha)$, leading to a contradiction. Therefore,

$$\forall i \in A_1, \quad \alpha(i) = \xi^S(i).$$

The idea for the induction step is the same as for the basis. □

REMARK 7. *Observe that the precise manner of "dual" increase in the algorithm was essential for proving Theorem* 6.

For a definition of equitable cost sharing method, see the beginning of section 3.

COROLLARY 8. *The cost sharing method, ξ, found by Algorithm* 1 *is the equitable cost sharing method for equalizing functions $f_1, \ldots, f_n$.*

THEOREM 9. *The cost sharing method ξ is cross-monotonic.*

Proof. Suppose that $S \subset T \subseteq U$. Let us call the two runs of the algorithm S-run and T-run, respectively. It suffices to prove that at each time t, the tight set in the T-run is a superset of the tight set in the S-run, because then each user $i \in S$ can be frozen only at an earlier time in the T-run and hence can have only a smaller cost share under the T-run.

Consider time t, and let A and B be the tight sets in the S- and T-runs, respectively. Let x_i denote the cost share of $i \in S$ at time t under the S-run, and let x'_i denote the cost share of $i \in T$ at time t under the T-run.

By submodularity,

$$\text{cost}(A \cup B) + \text{cost}(A \cap B) \leq \text{cost}(A) + \text{cost}(B).$$

Since x is feasible for S, we have

$$\sum_{i \in (A \cap B)} x_i \leq \text{cost}(A \cap B).$$

Using the additional fact that A and B are tight in the S- and T-runs, respectively, we get

$$\text{cost}(A \cup B) + \sum_{i \in (A \cap B)} x_i \leq \sum_{i \in A} x_i + \sum_{i \in B} x'_i.$$

Therefore,

$$\text{cost}(A \cup B) \leq \sum_{i \in (A - B)} x_i + \sum_{i \in B} x'_i.$$

Observe that at time t, the users in $A - B$ are frozen in the S-run but not in the T-run. Therefore for each $i \in A - B$, $x_i \leq x'_i$. Therefore,

$$\text{cost}(A \cup B) \leq \sum_{i \in (A \cup B)} x'_i.$$

Therefore, $A \cup B$ is tight at time t in the T-run. Hence $A \subseteq B$, and the theorem follows. □

5. Alternative characterizations of equitable methods. In this section, we will give two alternative characterizations of equitable methods. The proofs of both characterizations appeal to Algorithm 1, and we do not know of direct proofs. These alternative characterizations are as basic as the definition of equitable methods and could have been taken as alternative definitions of these methods.

5.1. Min-max domination. Let $\boldsymbol{q}$ and $\boldsymbol{r}$ be n-dimensional vectors with nonnegative coordinates. We will denote by $\boldsymbol{q}_{DEC}$ the vector obtained by sorting the components of $\boldsymbol{q}$ in decreasing order and will say that $\boldsymbol{q}$ *min-max dominates* $\boldsymbol{r}$ if $\boldsymbol{q}_{DEC}$ is lexicographically smaller than $\boldsymbol{r}_{DEC}$, i.e., if there is an i such that $\boldsymbol{q}_{DEC}(i) < \boldsymbol{r}_{DEC}(i)$ and $\boldsymbol{q}_{DEC}(j) = \boldsymbol{r}_{DEC}(j)$ for $j < i$.

THEOREM 10. *For any set $S \subseteq U$, the cost allocation, ξ^S, found by Algorithm 1 is such that $\boldsymbol{t}(\xi^S)$ min-max dominates $\boldsymbol{t}(\alpha)$ for all other cost allocations, α, for S in the core.*

Proof. The proof is similar to that of Theorem 6. Let α be an allocation for set S that lies in the core. Suppose that $\boldsymbol{t}(\xi^S)$ does not min-max dominate $\boldsymbol{t}(\alpha)$. Then we will show that ξ^S and α are in fact the same allocation, hence proving the theorem.

Let $S = A_1 \supset A_2 \supset \cdots \supset \emptyset$ be the *reverse* order in which sets go tight when the algorithm is run on set S. We will show by induction on i that all users in $A_i - A_{i+1}$ must have the same cost allocation in α and ξ^S. Observe that all elements in $A_i - A_{i+1}$ go tight at the same time, and hence the components corresponding to them in $\boldsymbol{t}(\xi^S)$ are identical.

Clearly,

$$\sum_{i \in A_2} \alpha(i) \leq \sum_{i \in A_2} \xi^S(i) = \text{cost}(A_2).$$

Therefore,

$$\sum_{i \in A_1 - A_2} \alpha(i) \geq \sum_{i \in A_1 - A_2} \xi^S(i).$$

If this inequality is strict, there exists $i \in A_1 - A_2$ such that $\alpha(i) > \xi^S(i)$. Since users $i \in A_1 - A_2$ give rise to the largest entries in $\boldsymbol{t}_{INC}(\xi^S)$, $\boldsymbol{t}(\xi^S)$ min-max dominates $\boldsymbol{t}(\alpha)$, leading to a contradiction. Therefore, this inequality must hold with equality. If for some user $i \in A_1 - A_2$, $\alpha(i) < \xi^S(i)$, then for some other user $j \in A_1 - A_2$, $\alpha(j) > \xi^S(j)$, and again $\boldsymbol{t}(\xi^S)$ min-max dominates $\boldsymbol{t}(\alpha)$, leading to a contradiction. Therefore,

$$\forall i \in A_1 - A_2, \quad \alpha(i) = \xi^S(i).$$

The idea for the induction step is the same as for the basis. □

5.2. *L*-domination. The next characterization is along the lines of Dutta and Ray's definition of the egalitarian method which uses the notion of Lorentz orderings. Following is their definition when applied to the case of a submodular cost function (for the complete definition, which involves a recursive construct, see [6]).

Let $\alpha_1 \leq \cdots \leq \alpha_n$ and $\beta_1 \leq \cdots \leq \beta_n$ be such that $\alpha_1 + \cdots + \alpha_n = \beta_1 + \cdots + \beta_n$. We will say that $(\alpha_1, \ldots, \alpha_n)$ *Lorentz dominates* $(\beta_1, \ldots, \beta_n)$ if for $1 \leq k \leq n$, we have

$$\alpha_1 + \cdots + \alpha_k \geq \beta_1 + \cdots + \beta_k,$$

and the inequality is strict for at least one k.

Dutta and Ray [6] showed that if the underlying cost function is submodular, there is a core cost allocation for S, say $\boldsymbol{q}$, such that $\boldsymbol{q}_{INC}$ Lorentz dominates $\boldsymbol{r}_{INC}$ for all other cost allocations, $\boldsymbol{r}$, for S in the core. $\boldsymbol{q}$ is the egalitarian cost allocation for S.

Note that the definition of Lorentz ordering may compare cost shares of different users, since $\boldsymbol{q}_{INC}(i)$ and $\boldsymbol{r}_{INC}(i)$ may be cost shares of different users. In our setting, the equalizing functions for different users may be very different, thus making such comparisons meaningless. We give below an ordering that takes this into consideration. This ordering is not a generalization of Lorentz ordering—if all f_i's are the identity function, it does not necessarily reduce to the Lorentz ordering, but it does preserve the property established in Lemma 11.

Let V be the set of all nonnegative s-dimensional vectors $\boldsymbol{q}$ such that $f_1(\boldsymbol{q}(1)) + \cdots + f_s(\boldsymbol{q}(s)) = \text{cost}(S)$. Let $V_c \subseteq V$ be the set of vectors $\boldsymbol{q}$ such that $(f_1(\boldsymbol{q}(1)), \ldots, f_s(\boldsymbol{q}(s)))$ forms a cost allocation for S lying in the core. For $\boldsymbol{q}, \boldsymbol{r} \in V$, say that $\boldsymbol{q}$ *L-dominates* $\boldsymbol{r}$ if there exists a permutation π such that

1. $\boldsymbol{q}(\pi(1)) \leq \cdots \leq \boldsymbol{q}(\pi(s))$,
2. for $1 \leq i \leq s$, we have

$$\sum_{k=1}^{i} f_{\pi(k)}(\boldsymbol{q}(\pi(k))) \geq \sum_{k=1}^{i} f_{\pi(k)}(\boldsymbol{r}(\pi(k))),$$

and the inequality is strict for at least one i.

It is easy to construct examples showing that the relation defined above is not necessarily transitive. However, it is *acyclic* in the following sense: if $\boldsymbol{q}_1, \ldots, \boldsymbol{q}_k \in V$, then it cannot be the case that $\boldsymbol{q}_i$ L-dominates $\boldsymbol{q}_{i+1}$, for $1 \leq i \leq k$, and $\boldsymbol{q}_k$ L-dominates $\boldsymbol{q}_1$. The definition of L-dominates requires that vectors $\boldsymbol{q}$ and $\boldsymbol{r}$ be ordered according to the *same* permutation—it is for this reason that this notion does not generalize the notion of Lorentz ordering.

LEMMA 11. *Let $\boldsymbol{q}, \boldsymbol{r} \in V$, and suppose that $\boldsymbol{q}$ L-dominates $\boldsymbol{r}$. Then $\boldsymbol{q}_{INC}$ is lexicographically larger than $\boldsymbol{r}_{INC}$.*

Proof. Without loss of generality, assume that the permutation π showing that $\boldsymbol{q}$ L-dominates $\boldsymbol{r}$ is the identity permutation. Let i be the smallest index, $1 \leq i \leq s$, such that $\sum_{k=1}^{i} f_k(\boldsymbol{q}(k)) > \sum_{k=1}^{i} f_k(\boldsymbol{r}(k))$. Clearly, $\boldsymbol{q}(k) = \boldsymbol{r}(k)$, for $k < i$, and $\boldsymbol{q}(i) > \boldsymbol{r}(i)$. Therefore, $\boldsymbol{r}(1) \leq \cdots \leq \boldsymbol{r}(i)$. By assumption, $\boldsymbol{q} = \boldsymbol{q}_{INC}$. On the other hand, the first i components of $\boldsymbol{r}_{INC}$ can be only smaller than the corresponding components of $\boldsymbol{r}$. Hence $\boldsymbol{q}_{INC}$ is lexicographically larger than $\boldsymbol{r}_{INC}$. □

Since lexicographic domination is acyclic, we get the following corollary.

COROLLARY 12. *The relation of L-domination is acyclic.*

We will need the following technical lemma for the main result.

LEMMA 13. *Let $M, a_1, \ldots, a_l, m, b_1, \ldots, b_l$ be nonnegative real numbers satisfying*

- $M \geq m$,
- $M + a_1 + \cdots + a_l \geq m + b_1 + \cdots + b_l$.

Then, there is a permutation π over $[1, \ldots, l]$ such that for $1 \leq i \leq l$,

$$M + \sum_{k=1}^{i} a_{\pi(k)} \geq m + \sum_{k=1}^{i} b_{\pi(k)}.$$

Proof. Let us show how to construct π. Let us first determine $\pi(1)$. We claim that there exists k, $1 \leq k \leq l$, such that

$$M + a_k \geq m + b_k.$$

Suppose not. Then, for $1 \leq k \leq l$,

$$M + a_k < m + b_k.$$

Adding these l inequalities, we get

$$(l-1)M + (M + a_1 + \cdots + a_l) < (l-1)m + (m + b_1 + \cdots + b_l).$$

But this contradicts the assumptions made on these numbers, proving existence of k satisfying the inequality above. Set $\pi(1) = k$. The idea for constructing the rest of π is the same. □

THEOREM 14. *Let $\boldsymbol{q} \in V_c$ correspond to the equitable cost allocation χ^S, and let $\boldsymbol{r} \in V_c$ be any other vector. Then $\boldsymbol{q}$ L-dominates $\boldsymbol{r}$.*

Proof. We need to construct permutation π that shows that $\boldsymbol{q}$ L-dominates $\boldsymbol{r}$. Let $A_1 \subset A_2 \subset \cdots \subset S$ be the sequence in which sets go tight when Algorithm 1 computes cost shares for S. In the simple case that each of $A_{i+1} - A_i$ is a singleton, let π be the order in which elements go tight. Then, for $1 \leq i \leq s$,

$$\sum_{k=1}^{i} f_{\pi(k)}(\boldsymbol{q}(\pi(k))) = \text{cost}(A_i) \geq \sum_{k=1}^{i} f_{\pi(k)}(\boldsymbol{r}(\pi(k))).$$

The inequality holds because the cost allocation corresponding to $\boldsymbol{r}$ lies in the core. Since $\boldsymbol{q} \neq \boldsymbol{r}$, one of these inequalities must be strict, thereby showing that $\boldsymbol{q}$ L-dominates $\boldsymbol{r}$.

In the general case, we will order elements of A_1 first, the elements of $A_2 - A_1$ next, and so on. This ensures that

$$\sum_{k \in A_i} f_k(\boldsymbol{q}(k)) = \text{cost}(A_i) \geq \sum_{k \in A_i} f_k(\boldsymbol{r}(k)).$$

Next, let us specify the precise order given to elements of $A_{i+1} - A_i = \{j_1, \ldots, j_l\}$. For this, we will use Lemma 13 with

$$M = \sum_{k \in A_i} f_k(\boldsymbol{q}(k)) = \text{cost}(A_i), \quad m = \sum_{k \in A_i} f_k(\boldsymbol{r}(k))$$

and for $1 \leq k \leq l$,

$$a_k = f_{j_k}(\boldsymbol{q}(j_k)) \quad \text{and} \quad b_k = f_{j_k}(\boldsymbol{r}(j_k)). \qquad \square$$

Observe that the proof given above uses the fact that the functions f_j are *strictly* increasing.

6. The opportunity egalitarian method. For each user $i \in U$, let $G_i : \mathbf{R}^+ \to [0,1]$ be the cumulative probability distribution function from which i's utility is drawn; assume that these distributions are independent. Assume that G_i is monotonically increasing.

Let α be any cost allocation for $S \subseteq U$ that lies in the core. User i will accept the service only if his utility turns out to be at least $\alpha(i)$, his cost share. The probability of this event is $1 - G_i(\alpha(i))$. Let $\boldsymbol{p}(\alpha)$ denote the vector whose ith component is this probability. We will say that a cost sharing method ξ is the *opportunity egalitarian method* for cumulative distribution functions $G_1, \ldots, G_n$ if for each set $S \subseteq U$, ξ^S is the cost allocation in the core such that

1. $\boldsymbol{p}(\xi^S)$ max-min dominates $\boldsymbol{p}(\alpha)$ and
2. $\boldsymbol{p}(\xi^S)$ min-max dominates $\boldsymbol{p}(\alpha)$

for all other cost allocations, α, for S in the core. Theorem 15 shows that there is a unique such cost allocation. Observe that ξ is attempting to equalize the probabilities of users receiving the service, subject to core constraints. The two characterizations, min-max and max-min, ensure that both extremes are avoided.

Let $f_i : [0,1] \to \mathbf{R}^+$ denote the inverse of G_i. Let ξ be the equitable cost sharing method for functions $f_1, \ldots, f_n$.

THEOREM 15. *ξ is the opportunity egalitarian method for probability density functions $G_1, \ldots, G_n$.*

Proof. Consider any set $S \subseteq U$, and let α be a cost allocation for S lying in the core. Clearly, for $i \in S$,

$$\boldsymbol{t}(\alpha)(i) = f_i^{-1}(\alpha(i)) = G_i(\alpha(i)) = 1 - \boldsymbol{p}(\alpha)(i);$$

i.e., this is the probability that user i does not accept service under cost allocation α. Since ξ is the equitable method for $f_1, \ldots, f_n$, $\boldsymbol{t}(\xi^S)$ max-min dominates $\boldsymbol{t}(\alpha)$ for all cost allocations, α, for S in the core. Equivalently, $\boldsymbol{p}(\xi^S)$ min-max dominates $\boldsymbol{p}(\alpha)$ for all core cost allocations for S. Its uniqueness follows from Theorem 6. By Theorem 10, $\boldsymbol{p}(\xi^S)$ max-min dominates $\boldsymbol{p}(\alpha)$ for all other cost allocations, α, for S in the core. Hence, ξ is the opportunity egalitarian method for cumulative distribution functions $G_1, \ldots, G_n$. □

By Theorem 9, the opportunity egalitarian method is cross-monotone.

7. Maximizing acceptance probability. As in the last section, for each user $i \in U$, let $G_i : \mathbf{R}^+ \to [0,1]$ be the cumulative probability distribution function from which i's utility is drawn; assume that these distributions are independent. Let g_i be the corresponding probability density function, i.e., $g_i(x) = \frac{\partial G_i(x)}{\partial x}$. Assume that $g_i(0) = 0$. We further assume that G_i satisfies the *strict monotone hazard rate condition*, i.e.,

$$\frac{\partial}{\partial x}\left[\frac{g_i(x)}{1 - G_i(x)}\right] > 0.$$

If g_i represents the failure probability of a component as a function of time, the above condition says that the failure rate, conditioned on the component still being intact, strictly increases with age. The monotone hazard rate condition is satisfied by most standard probability distributions and is a standard assumption in the Bayesian mechanism design literature [8].

Let $\lambda_i : \mathbf{R}^+ \to \mathbf{R}^+$ be the function

$$\lambda_i(x) = \frac{g_i(x)}{1 - G_i(x)}.$$

Observe that under the assumption of strict monotone rate hazard rate condition, λ_i is an invertible function. Let f_i be the inverse of this function, and let χ be the equitable method corresponding to equalizing functions $f_1, f_2, \ldots, f_n$.

Let ξ be any cost sharing method in the core. Let $P(\xi^S)$ denote the probability that all users in S accept service when it is offered at cost shares ξ^S. Clearly,

$$P(\xi^S) = \prod_{i \in S} [1 - G_i(\xi_i^S)].$$

THEOREM 16. *Let χ be the equitable cost sharing method defined above, and ξ be any cost sharing method in the core. Then, for each set of users $S \subseteq U$, $P(\chi^S) \geq P(\xi^S)$.*

This is a generalization of Mutuswami's result [24], which deals with the case that G_i's are i.i.d. (on the other hand, he requires only monotone hazard rate condition—not necessarily *strict*). In this case, χ is the Dutta–Ray egalitarian method. Mutuswami's proof uses the original definition of Dutta and Ray, in terms of Lorentz orderings, and a theorem of Hardy, Littlewood, and Polya [10], giving a condition that is equivalent to Lorentz domination. To prove the generalization, we prove a characterization for L-domination, in Lemma 18, in the style of the Hardy–Littlewood–Polya theorem. The proof of Theorem 16 is given below.

By Theorem 16, χ *simultaneously* maximizes the probability of all users accepting service, for each set S of users, among all cost sharing methods in the core. One may be led to believe that if the mechanism of Theorem 1 is run with χ, then the expected size of the set served is maximized, over all cost sharing methods in the core. However, this is not true, as shown in the example below.

Example. Let $U = \{a, b\}$ and the cost function be $\text{cost}(a, b) = 10$, $\text{cost}(a) = 8$, $\text{cost}(b) = 6$, $\text{cost}(\emptyset) = 0$. Suppose the utilities of a and b are picked from the uniform distribution over the interval $[0, 20]$. In this case, χ will be the egalitarian method:

$$\chi(\{a, b\}, a) = \chi(\{a, b\}, b) = 5, \quad \chi(\{a\}, a) = 8, \quad \chi(\{b\}, b) = 6.$$

The expected size of set picked by the mechanism is 1.45. However, using the following cross-monotonic cost sharing method, ξ, the expected size of set picked is 1.45125:

$$\xi(\{a, b\}, a) = 5.5, \quad \xi(\{a, b\}, b) = 4.5, \quad \xi(\{a\}, a) = 8, \quad \xi(\{b\}, b) = 6.$$

For completeness, we first state the following theorem.

THEOREM 17 (Hardy, Littlewood, and Polya [10]). *Let $\alpha_1 \leq \cdots \leq \alpha_n$ and $\beta_1 \leq \cdots \leq \beta_n$ be such that $\alpha_1 + \cdots + \alpha_n = \beta_1 + \cdots + \beta_n$. The following two statements are equivalent.*

1. *$(\alpha_1, \ldots, \alpha_n)$ Lorentz dominates $(\beta_1, \ldots, \beta_n)$.*
2. *$(\alpha_1, \ldots, \alpha_n)$ can be obtained from $(\beta_1, \ldots, \beta_n)$ by applying the following transformations to $(\beta_1, \ldots, \beta_n)$ a finite number of times:*
   (a) *Find $i < j$ such that $\beta_i < \beta_j$ and the next step can be performed.*
   (b) *Increase β_i and decrease β_j by a small $\epsilon > 0$.*

Following is an analogous fact for L-domination. As defined in section 5.2, let V be the set of all nonnegative s-dimensional vectors $\boldsymbol{q}$ such that $f_1(\boldsymbol{q}(1)) + \cdots + f_s(\boldsymbol{q}(s)) = \text{cost}(S)$.

LEMMA 18. *Let $\boldsymbol{q}, \boldsymbol{r} \in V$. The following two statements are equivalent.*

1. *$\boldsymbol{q}$ L-dominates $\boldsymbol{r}$, with π being the identity permutation.*
2. *$\boldsymbol{q}$ can be obtained from $\boldsymbol{r}$ by applying the following transformations to $\boldsymbol{r}$ a nonzero number of times:*

(a) *Find $i < j$ such that $\boldsymbol{r}(i) < \boldsymbol{r}(j)$ and the next step can be performed.*
(b) *Increase $\boldsymbol{r}(i)$ and decrease $\boldsymbol{r}(j)$ by small positive amounts such that*
- *$f_i(\boldsymbol{r}(i)) + f_j(\boldsymbol{r}(j))$ is preserved,*
- *$\boldsymbol{r}(i) \le \boldsymbol{r}(j)$ is preserved.*

Proof. We will prove the forward direction only; the reverse direction is straightforward. Let i be the smallest index such that $\boldsymbol{q}(i) \neq \boldsymbol{r}(i)$ (if such an index i does not exist, then $\boldsymbol{q}$ and $\boldsymbol{r}$ are identical). Since $\boldsymbol{q}$ L-dominates $\boldsymbol{r}$, $\boldsymbol{q}(i) > \boldsymbol{r}(i)$. By definition,

$$f_1(\boldsymbol{q}(1)) + \cdots + f_s(\boldsymbol{q}(s)) = f_1(\boldsymbol{r}(1)) + \cdots + f_s(\boldsymbol{r}(s)).$$

Let j be the smallest index $> i$ such that

$$f_1(\boldsymbol{q}(1)) + \cdots + f_j(\boldsymbol{q}(j)) = f_1(\boldsymbol{r}(1)) + \cdots + f_j(\boldsymbol{r}(j)).$$

By the choice of j, it must be the case that

$$f_1(\boldsymbol{q}(1)) + \cdots + f_{j-1}(\boldsymbol{q}(j-1)) > f_1(\boldsymbol{r}(1)) + \cdots + f_{j-1}(\boldsymbol{r}(j-1));$$

therefore $\boldsymbol{q}(j) < \boldsymbol{r}(j)$. Since $i < j$, $\boldsymbol{q}(i) \le \boldsymbol{q}(j)$. Now we have $\boldsymbol{r}(i) < \boldsymbol{q}(i) \le \boldsymbol{q}(j) < \boldsymbol{r}(j)$. Increase $\boldsymbol{r}(i)$ and decrease $\boldsymbol{r}(j)$ as much as possible so that the following are preserved:

1. $f_i(\boldsymbol{r}(i)) + f_j(\boldsymbol{r}(j))$.
2. $\boldsymbol{r}(i) \le \boldsymbol{r}(j)$.
3. For $1 \le k \le s$,

$$f_1(\boldsymbol{q}(1)) + \cdots + f_k(\boldsymbol{q}(k)) \ge f_1(\boldsymbol{r}(1)) + \cdots + f_k(\boldsymbol{r}(k)).$$

Clearly, $\boldsymbol{r}(i)$ must increase by a positive amount, and $\boldsymbol{r}(j)$ must decrease by a positive amount. Therefore, in the limit, $\boldsymbol{q}$ can be obtained from $\boldsymbol{r}$ by applying such steps. □

Proof of Theorem 16. Consider any set of users $S \subseteq U$. Let $\boldsymbol{q}, \boldsymbol{r} \in V_c$ correspond to χ^S and ξ^S, respectively. By Theorem 14, $\boldsymbol{q}$ L-dominates $\boldsymbol{r}$. Now, $\boldsymbol{q}$ can be obtained from $\boldsymbol{r}$ by steps specified in Lemma 18. Finally, by Lemma 19 given below, each of these steps will only increase the probability that all users accept service. Hence $P(\chi^S) \ge P(\xi^S)$. □

LEMMA 19. *Let $f_1, \ldots, f_s$ be the equalizing functions specified above. Let $x_i \ge 0$, $1 \le i \le s$, and define $\boldsymbol{v} = (f_1(x_1), \ldots, f_s(x_s))$. Define $P(\boldsymbol{v}) = \prod_{i=1}^{s}[1 - G_i(f_i(x_i))]$. Suppose there exist i and j such that $x_i < x_j$. Then,*

$$dP(\boldsymbol{v}) = \sum_{k=1}^{s} \frac{\partial P(\boldsymbol{v})}{\partial f_k(x_k)} df_k(x_k) \ge 0,$$

where $0 < df_i(x_i) = -df_j(x_j)$ and $df_k(x_k) = 0$ if $k \neq i, j$.

Proof.

$$dP(\boldsymbol{v}) = \sum_{k=1}^{s} \frac{\partial P(\boldsymbol{v})}{\partial f_k(x_k)} df_k(x_k)$$

$$= \sum_{k=1}^{s} \frac{P(\boldsymbol{v})}{1 - G(f_k(x_k))} \times (-g(f_k(x_k))) \times df_k(x_k)$$

$$= P(\boldsymbol{v}) \left[\frac{g_j(f_j(x_j))}{1 - G_j(f_j(x_j))} - \frac{g_i(f_i(x_i))}{1 - G_i(f_i(x_i))} \right] dx$$

$$= P(\boldsymbol{v})[\lambda_j(f_j(x_j)) - \lambda_i(f_i(x_i))]dx$$

$$= P(\boldsymbol{v})[x_j - x_i]dx \geq 0,$$

where $dx = df_i(x_i) = -df_j(x_j)$.

The second-to-last step uses the fact that f_i is the inverse of λ_i and the last step follows from the assumption that $x_i < x_j$. □

8. Discussion. Submodular cost functions admit a rich class of cross-monotone cost sharing methods. Of these, equitable methods capture a large subclass, though not all, as evidenced by the example below. Our definition as well as Hokari's [11] appears quite natural, and despite differences, they lead to the same class of cost sharing methods. This raises the following question: how to impose an economic criterion on cross-monotone methods so as to obtain precisely the class of equitable methods.

Example. Consider the following cross-monotone cost sharing method (the costs of individual sets are simply the sum of cost shares of their elements).
$\xi(\{a,b,c,d\},a) = 2$,
$\xi(\{a,b,c,d\},b) = 2$, $\xi(\{a,b,c,d\},c) = 1$, $\xi(\{a,b,c,d\},d) = 1$,
$\xi(\{a,b,c\},a) = 2$, $\xi(\{a,b,c\},b) = 3$, $\xi(\{a,b,c\},c) = 1$,
$\xi(\{a,b,d\},a) = 3$, $\xi(\{a,b,d\},b) = 2$, $\xi(\{a,b,d\},d) = 1$,
$\xi(\{a,c,d\},a) = 2$, $\xi(\{a,c,d\},c) = 2$, $\xi(\{a,c,d\},d) = 2$,
$\xi(\{b,c,d\},b) = 2$, $\xi(\{b,c,d\},c) = 2$, $\xi(\{b,c,d\},d) = 2$,
$\xi(\{a,b\},a) = 3$, $\xi(\{a,b\},b) = 3$,
$\xi(\{a,c\},a) = 3$, $\xi(\{a,c\},c) = 3$,
$\xi(\{a,d\},a) = 3$, $\xi(\{a,d\},d) = 3$,
$\xi(\{b,c\},b) = 3$, $\xi(\{b,c\},c) = 3$,
$\xi(\{b,d\},b) = 3$, $\xi(\{b,d\},d) = 3$,
$\xi(\{c,d\},c) = 3$, $\xi(\{c,d\},d) = 3$,
$\xi(\{a\},a) = 5$, $\xi(\{b\},b) = 5$, $\xi(\{c\},c) = 5$, $\xi(\{d\},d) = 5$.
We will show, by contradiction, that this is not an equitable cost sharing method. First run Algorithm 1 on $S = \{a,b,c\}$. In order to produce the above method, S must be the first set to go tight. Suppose this happens at time t. Clearly, none of the proper subsets of S is tight at time t. Therefore, $f_a(t) = 2$, and $f_b(t) = 3$. Next, run Algorithm 1 on set $S' = \{a,b,d\}$. The first set to go tight must be the entire set S', at time t', say. Therefore, $f_a(t') = 3$, and $f_b(t') = 2$. But then at least one of f_a or f_b is not monotonically increasing.

Observe that Algorithm 1 is very explicitly trying to impose equality among users, as specified by the equalizing functions. Of course, the precise notion of "equality" or "fairness" imposed depends on these functions. An exciting research direction is to characterize the notions of fairness captured by particular choices of the equalizing functions.

This very explicit seeking of "equality" is also the chief difference between our definition and Hokari's definition and algorithm. Hokari defines *sequential monotone path* cost sharing methods by partitioning the set of users, ordering the partitions sequentially, and applying monotone path methods within each partition, with an incremental method applied on the ordered list of partitions. In our setting it is easy

to see that the resulting method is also equitable, and so this operation does not lead to new cost sharing methods.

Considering the fact that for submodular cost functions, our definition is a natural generalization of the Dutta–Ray egalitarian method, one wonders whether there is a similar generalization for nonsubmodular cost functions as well. L-orderings, presented in section 5.2, may lead to such a definition. At present it is not clear how to generalize Algorithm 1 to this setting—if the cost function is not submodular, then every element may be in a tight set, without the entire set being tight. Algorithm 1 will halt at this point, and the resulting cost allocation will not be budget balanced.

Next, assume that the cost function is nondecreasing and submodular. Let σ be a permutation on $1, \ldots, n$. The *incremental cost sharing method*, ξ_σ, corresponding to permutation σ is defined as follows. Let $S \subseteq U$, $|S| = k$, and let $i_1, \ldots, i_k$ be the users in S ordered according to σ. Then, $\xi_\sigma(S, i_1) = \text{cost}(i_1)$, and for $2 \leq j \leq k$, $\xi_\sigma(S, i_j) = \text{cost}(\{i_1, \ldots, i_j\}) - \text{cost}(\{i_1, \ldots, i_{j-1}\})$.

In [17] we showed that the class of cross-monotone methods for a nondecreasing submodular cost function form a polytope and that incremental cost sharing methods form corner points of this polytope. We also gave an example of a cross-monotone method that is not in the convex hull of these corner points (corresponding to incremental cost sharing methods) and left the open problem of characterizing the rest of the corner points. We show below that this example is in fact an equitable method. It is easy to see that all incremental methods are also equitable. Do equitable methods capture all corner points of this polytope? Are equitable methods closed under convex combinations? Since not all cost sharing methods are equitable, the answers to both these questions cannot be "Yes."

Example. Consider the following cost sharing method:
$\xi(\{a, b, c\}, a) = 2$, $\xi(\{a, b, c\}, b) = 3$, $\xi(\{a, b, c\}, c) = 4$,
$\xi(\{a, b\}, a) = 4$, $\xi(\{a, b\}, b) = 3$,
$\xi(\{a, c\}, a) = 3$, $\xi(\{a, c\}, c) = 4$,
$\xi(\{b, c\}, b) = 3$, $\xi(\{b, c\}, c) = 4$,
$\xi(\{a\}, a) = 4$, $\xi(\{b\}, b) = 4$, $\xi(\{c\}, c) = 4$.
In [17] we showed that this cross-monotone method is not a convex combination of incremental cost sharing methods. However, it is an equitable cost sharing method corresponding to equalizing functions f_a, f_b, f_c satisfying

$$f_a(2) = 0, \quad f_b(1) = 0, \quad f_b(2) = 3, \quad f_b(3) = 3, \quad f_b(4) = 4, \quad \text{and } f_c(1) = 4.$$

Finally, the example given in section 7 raises the question of identifying the cost sharing method that maximizes the expected size of the set served.

Acknowledgments. We wish to thank Bhaskar Dutta, Suresh Mutuswami, and Christos Papadimitriou for valuable comments and for providing references to the literature. Thanks also go to the anonymous STOC referee for valuable suggestions on the paper.

VERTICAL RAY SHOOTING AND COMPUTING DEPTH ORDERS FOR FAT OBJECTS*

MARK DE BERG† AND CHRIS GRAY†

Abstract. We present new results for three problems dealing with a set $\mathcal{P}$ of n convex constant-complexity fat polyhedra in 3-space. (i) We describe a data structure for vertical ray shooting in $\mathcal{P}$ that has $O(\log^2 n)$ query time and uses $O(n \log^2 n)$ storage. (ii) We give an algorithm to compute in $O(n \log^3 n)$ time a depth order on $\mathcal{P}$ if it exists. (iii) We give an algorithm to verify in $O(n \log^3 n)$ time whether a given order on $\mathcal{P}$ is a valid depth order. All three results improve on previous results.

Key words. computational geometry, depth orders, fat objects, ray shooting

AMS subject classification. 68U05

DOI. 10.1137/060672261

1. Introduction.

Motivation. Many algorithms and data structures developed in computational geometry have a rather poor worst-case performance. This behavior is often caused by sets of objects in very intricate configurations, such as many long and thin objects packed closely together. For example, the worst-case running time of the best known general motion-planning algorithm is $\Theta(n^f)$, where f is the number of degrees of freedom of the robot, because for certain configurations of obstacles the free space has complexity $\Theta(n^f)$. The configurations that determine the worst-case behavior, however, are usually rather artificial constructions; one would expect that in practice the input is much more well behaved, and that better performance is possible than the worst-case analysis suggests.

These considerations have led to the study of geometric problems in so-called *realistic input models* [9]. Here one places certain restrictions on the shape and/or distribution of the input objects, so that hypothetical worst-case examples are excluded. The hope is that this will enable proving much stronger theoretical results than are possible for arbitrary inputs, while the results are still general enough for practical applications. One of the most widely studied realistic input models assumes that the input objects are *fat*, that is, they are not arbitrarily long and skinny—see the next section for a formal definition. For motion planning this has proved to be quite successful: the free space for a not-too-large robot moving amidst a set of fat obstacles has only linear complexity [26], which has enabled the development of motion-planning algorithms with near-linear running times in this setting [25].

In this paper we study two problems arising in computer graphics in the context of realistic input models: the vertical ray-shooting problem and the depth-order problem for fat polytopes in $\mathbb{R}^3$.

Problem statement and previous results. Let $\mathcal{P}$ be a set of n disjoint objects in $\mathbb{R}^3$.

†Department of Computing Science, TU Eindhoven, P.O. Box 513, 5600 MB Eindhoven, The Netherlands (mdberg@win.tue.nl, cgray@win.tue.nl).

The first problem we study is the *ray-shooting problem*: preprocess the set $\mathcal{P}$ such that ray-shooting queries (i.e., what is the first object in $\mathcal{P}$ hit by a query ray?) can be answered efficiently. Ray-shooting queries are important for realistic image synthesis: they form the basis of ray-tracing algorithms and can be used in radiosity methods to approximate form factors. Hence, data structures for ray shooting have received ample attention, in both computer graphics and computational geometry; the book by De Berg [5] and the survey by Pellegrini [24] discuss many of the (computational geometry) solutions. As for the motion-planning problem, the worst-case bounds that have been obtained for the general ray-shooting problem are rather disappointing. For ray-shooting queries with arbitrary rays in a collection of n disjoint triangles, for example, the best known structures that achieve $O(\log n)$ query time use $O(n^{4+\epsilon})$ storage [5, 23], and the best structures with near-linear storage have roughly $O(n^{3/4})$ query time [3]. For vertical ray shooting in a collection of disjoint triangles the situation is still not very rosy: to obtain $O(\log n)$ query time one needs $O(n^{2+\epsilon})$ storage, and with near-linear storage the query time becomes roughly $O(\sqrt{n})$ [5].

Given the prominence of the ray-shooting problem in computational geometry and the fact that general inputs do not seem to admit very efficient (near-linear) solutions, it is not surprising that ray shooting has already been studied from the perspective of realistic input models. In particular, the vertical ray-shooting problem—here the query ray is required to be vertical—has been studied for fat convex polyhedra. For this case Katz [19] presented a data structure that uses $O(n \log^3 n)$ storage and has $O(\log^4 n)$ query time. (In fact, Katz's solution works for polygons whose projections onto the xy-plane are fat, but it is not difficult to see that it works for fat three-dimensional polytopes as well.) Using the techniques of Efrat et al. [17], it is possible to improve the storage bound to $O(n \log^2 n)$ and the query time to $O(\log^3 n)$ [20]. Recently De Berg [6] presented a structure with $O(\log^2 n)$ query time; his structure uses $O(n \log^3 n (\log \log n)^2)$ storage.

The second problem we study is the *depth-order problem*: compute a depth order for the set $\mathcal{P}$, that is, an ordering $P_1, \ldots, P_n$ of the objects in $\mathcal{P}$ such that if P_i is below P_j, then $i < j$. Here we say that P_i is below P_j, denoted by $P_i \prec P_j$, if there are points $(x, y, z_i) \in P_i$ and $(x, y, z_j) \in P_j$ with $z_i < z_j$. In other words, a depth order is a linear extension of the $\prec$-relation. Since there can be cycles in the $\prec$-relation—we then say there is *cyclic overlap* among the objects—a depth order does not always exist. In that case the algorithm should report that there is cyclic overlap. Depth orders are useful in several applications. For example, they can be used to render scenes with the Painter's algorithm [18] or to do hidden-surface removal with the algorithm of Katz, Overmars, and Sharir [21]. Depth orders also play a role in assembly planning [1].

The depth-order problem for arbitrary sets of triangles in 3-space does not seem to admit a near-linear solution; the best known algorithm runs in $O(n^{4/3+\varepsilon})$ time [11]. This has led researchers to also study this problem for fat objects. Agarwal, Katz, and Sharir [2] gave an algorithm for computing the depth order of a set of triangles whose projections onto the xy-plane are fat; their algorithm runs in $O(n \log^5 n)$ time. However, their algorithm cannot detect cycles—when there are cycles it reports an incorrect order. A subsequent result by Katz [19] produced an algorithm that runs in $O(n \log^5 n)$ time and that can detect cycles. In this case though, the constant of proportionality depends on the minimum overlap of the projections of the objects that do overlap. If there is a pair of objects whose projections barely overlap, then the running time of the algorithm increases greatly. One advantage that this algorithm has is that it can deal with convex curved objects.

Our results. First, we present a new data structure for vertical ray shooting in a collection of n convex constant-complexity fat polyhedra[1] in $\mathbb{R}^3$. Our structure uses $O((1/\beta)n\log^2 n)$ storage and has $O((1/\beta^2)\log^2 n)$ query time. Compared to Katz's structure [20] it has a better query time (while the storage is the same) and compared to De Berg's structure [6] it has a better storage bound (while keeping the same query time).

Second, we present a new algorithm for computing a depth order on a collection of n convex constant-complexity fat polyhedra in $\mathbb{R}^3$. Our algorithm runs in $O((1/\beta^3)n\log^3 n)$ time, improving the result of Agarwal, Katz, and Sharir [2] by two logarithmic factors. Like their algorithm, our algorithm unfortunately does not detect cyclic overlap. Hence, we also study the problem of verifying a given depth order. We give an algorithm that checks in $O((1/\beta^2)n\log^3 n)$ time[2] whether a given ordering for a set of fat convex polyhedra is a valid depth order. This is the first result for this problem. Until now, the only algorithm for verifying a given depth order was an algorithm for arbitrary triangles [11], which runs in $O(n^{4/3+\varepsilon})$ time.

2. Preliminaries. In this section we introduce some basic definitions and terminology.

For a three-dimensional object o, we use $vol(o)$ to denote the volume of o and we use $proj(o)$ to denote the vertical projection of o onto the xy-plane. For a two-dimensional object, we use $area(o)$ to denote its area. We use the following definition of fatness [9].

DEFINITION 1. *An object o in $\mathbb{R}^d$ is defined to be β-fat if for any ball b whose center lies in o and that does not fully contain o, we have $vol(b\cap o)\geq\beta\cdot vol(b)$.*

(For convex objects—the case considered in this paper—this definition is equivalent, up to constant factors, to other definitions of fatness that have been proposed.) It is not hard to show that the projection of a fat object is also fat, as proved by De Berg [6] and made precise in the following lemma.

LEMMA 1 (see [6]). *If an object P is a β-fat object in three dimensions, then $proj(P)$ has fatness $\Omega(\beta)$ in two dimensions.*

Define the *size* of an object o, denoted by $size(o)$ to be the radius of its smallest enclosing ball. Note that the size of a ball is simply its radius.

Finally, we need a result that will allow us to stab a set of relatively large fat objects that all intersect some region R using only a few points. Similar results have been proved earlier [7].

LEMMA 2. *Let R be a bounded region in the plane, and let c be a constant with $0<c\leq 1$. Then there is a collection Q of $O(1/(c\beta)^2)$ points with the following property: any β-fat object o with $size(o)\geq c\cdot size(R)$ that intersects R contains at least one point from Q.*

Proof. Let U be a bounding square of R, and let $\widehat{U}$ be the square twice the size of U and with the same center. Consider a β-fat object o with $size(o)\geq c\cdot size(R)$ that intersects R. Then $area(o\cap\widehat{U})\geq c'c\beta\cdot area(\widehat{U})$ for a suitable constant c' (cf. Van der Stappen's thesis [25, Theorem 2.9]). Hence, a regular grid on $\widehat{U}$ with $\lceil M\rceil^2$ cells, where $M=2/(c'c\beta)$, must have at least one grid point inside P, because the area of any convex object missing all grid points is less than $2\cdot area(\widehat{U})/M$. □

The following lemma was proved in a more general setting by Van Kreveld [22].

[1] Though results are presented in terms of fat polyhedra, all our results also work in the more general setting of objects that project to fat polygons.

[2] This is an improvement over the $O(n\log^4 n)$ bound that we had in the preliminary version of the paper [8], which was published in SODA 2006.

However, his definition of fatness is different from ours. Therefore we have proved it independently using our definition. The proof can be found in the appendix. In the lemma below, an α-fat triangle refers to a triangle all of whose angles are at least α. (Such a triangle is α'-fat, according to Definition 1, for some $\alpha' = \Omega(\alpha)$.)

LEMMA 3. *Let P be a β-fat convex polygon with n vertices. There is a set T of α-fat triangles that cover P, where $|T| = O(n)$ and $\alpha = \Theta(\beta)$.*

We will also need the following lemma.

LEMMA 4. *Let P_1 and P_2 be simple polygons. Let e_1 be an edge of P_1 and e_2 be an edge of P_2. If P_1 intersects P_2 so that there is no vertex of P_1 inside P_2 and no vertex of P_2 inside P_1, then there is an intersection of edges e_3 of P_1 and e_4 of P_2 such that $e_3 \neq e_1$ and $e_4 \neq e_2$.*

Proof. Let e of P_1 and e' of P_2 be edges that intersect. If $e \neq e_1$ and $e' \neq e_2$, then we are done. If $e \neq e_1$ and $e' = e_2$, then there must be an intersection between e and a different edge of P_2 (since there are no vertices of P_1 inside P_2), meaning that we have found an intersection between e and some edge $e'' \neq e_2$, and we are done. Similarly, we are done if $e = e_1$ and $e' \neq e_2$. Finally, suppose $e = e_1$ and $e' = e_2$. Since e_1 enters P_2, it must exit it, and that implies that there must be an intersection between e_1 and some edge $e'' \neq e_2$. This puts us in the previous case, so we are done. ∎

3. Vertical ray shooting. Let $\mathcal{P} = \{P_1, \ldots, P_n\}$ be a collection of n constant-complexity convex β-fat polyhedra that we wish to preprocess for vertical ray shooting. We start by studying the simpler case where all the objects are intersected by a common vertical line. After that we will show how to use this structure to obtain an efficient solution to the general problem.

Agarwal, Katz, and Sharir [2] already described a data structure for the case where all objects are intersected by a common vertical line and project to triangles. We observe that it is possible to apply fractional cascading to their structure to obtain the following result.

LEMMA 5. *Let $\mathcal{P} = \{P_1, \ldots, P_n\}$ be a set of n disjoint convex constant-complexity β-fat polyhedra that are all stabbed by a vertical line ℓ and that all project to fat triangles. Then there is a data structure such that vertical ray shooting queries on $\mathcal{P}$ can be answered in $O(\log n)$ time. The structure uses $O((1/\beta)n \log n)$ storage and can be built in $O((1/\beta)n \log n)$ time.*

Proof. As stated above, all we need to do is apply fractional cascading to the structure of Agarwal, Katz, and Sharir [2]. For completeness, we briefly describe their solution and explain how to apply fractional cascading.

The structure is a balanced binary tree $\mathcal{T}$ with the objects in the leaves, sorted by their position along ℓ; the lowest object is in the leftmost leaf, the second lowest object in the next leaf, and so on. Since the objects are nonintersecting and convex, this ordering is well defined.

For a node ν, let $\mathcal{P}(\nu)$ denote the set of objects stored in the leaves of the subtree rooted at ν. At each nonleaf node ν of $\mathcal{T}$, we store the union $U(\nu)$ of the projections of the objects in $\mathcal{P}(\nu)$. We preprocess $U(\nu)$ for point-enclosure queries, that is, queries that ask whether a point q in the xy-plane lies inside $U(\nu)$, as follows. Let p_ℓ be the point where ℓ intersects the xy-plane. Then all projections contain p_ℓ, and since they are convex, $U(\nu)$ is star-shaped with p_ℓ in the kernel. Hence, if we partition the plane into cones by drawing half-lines from p_ℓ through all breakpoints on the boundary of $U(\nu)$, then a point-enclosure query can be answered in $O(1)$ time after we have determined in which cone the query point lies.

To perform a query with a vertical ray starting above all objects, we walk down the tree as follows. Suppose we reach a node ν. When the point p where the ray hits

the xy-plane lies inside the union of the right child of ν, we proceed to the right child; otherwise we proceed to the left child. The leaf we reach must store the first object hit (if any object is hit at all). When the starting point of the ray does not lie above all objects, things are more complicated. However, Agarwal, Katz, and Sharir have shown that a query can still be answered by walking down the tree, although now up to four nodes per level may be visited. In any case, we visit $O(\log n)$ nodes in total, and at each node we have to do a point-enclosure query. As explained above, a point-enclosure query can be answered in $O(1)$ time after we have determined in which cone the query point lies. Finding the right cone can be done in $O(\log n)$ time by binary search, but this can be made faster: using fractional cascading [13, 14], finding the cones can be done in $O(1)$ time, except for the search at the root. Since the application of fractional cascading is completely standard in this setting, we omit further details.

To build the structure, we sort the objects along ℓ in $O(n \log n)$ time, and then we construct the unions to be stored at each node in a bottom-up fashion. Hence, when we arrive at a node ν, we have to merge the two unions of the children of ν. Because the unions are star-shaped with respect to the same point, computing the union of these unions boils down to merging the two circularly sorted lists of breakpoints. Hence, this can be done in linear time. The total time to construct all unions is therefore equal to the total size of the data structure, which is $\sum_\nu O(|\mathcal{P}(\nu)|) = O(n \log n)$. Adding the additional pointers for the fractional cascading does not increase the preprocessing time or the amount of storage asymptotically. □

Now consider the general case, where the objects in $\mathcal{P}$ are not necessarily stabbed by a vertical line. We can cover each object by $O(1)$ subobjects whose projections are fat triangles using the technique of Lemma 3, so we can assume without loss of generality that all objects project to fat triangles. We shall make use of balanced aspect ratio trees (BAR-trees). *BAR-trees* are a special type of binary space partition (BSP) trees for point sets. They were introduced by Duncan, Goodrich, and Kobourov [15, 16], who showed that BAR-trees have excellent performance for approximate range searching and approximate nearest-neighbor searching. A BSP tree $\mathcal{T}$ for a set S of points contained in some bounding square σ is a recursive partitioning of σ by splitting lines, such that the final cells of the subdivision do not contain any points in their interior. Each node ν of $\mathcal{T}$ corresponds to a region $\mathit{region}(\nu) \subset \sigma$, which is defined recursively as follows. The region $\mathit{region}(\mathit{root}(\mathcal{T}))$ is the whole square σ. Furthermore, if the splitting line stored at a node ν is $\ell(\nu)$, then $\mathit{region}(\mathit{leftchild}(\nu)) = \mathit{region}(\nu) \cap \ell(\nu)^-$, where $\ell(\nu)^-$ is the half-plane below $\ell(\nu)$. Similarly, $\mathit{region}(\mathit{rightchild}(\nu)) = \mathit{region}(\nu) \cap \ell(\nu)^+$, where $\ell(\nu)^+$ is the half-plane above $\ell(\nu)$.

The special properties of BAR-trees that are relevant for us are the following. First, a BAR-tree on a set S of points has depth $O(\log |S|)$ and size $O(|S|)$. Furthermore, the regions corresponding to a node in a BAR-tree have bounded aspect ratio, which implies they are c-fat for some constant c. It has been shown by De Berg and Streppel [12] that this implies the following.

LEMMA 6 (see [12]). *Let o be a β-fat object. Then there is a set $G(o)$ of 12 points—we call these points* guards*—such that for any BAR-tree region R that intersects o but does not contain a guard from $G(o)$ in its interior we have $\mathit{size}(o) = \Omega(\mathit{size}(R))$.*

De Berg and Streppel [12] used this to design a so-called object BAR-tree: this is a BAR-tree that can be used for approximate range searching in a set of objects rather than in a point set. Our ray-shooting structure combines BAR-trees and the lemma above in a different way, as described next.

Let $\mathcal{P} = \{P_1, \ldots, P_n\}$ be a set of n constant-complexity β-fat polyhedra. Let $G_i = G(proj(P_i))$ be a set of guards for the projection of P_i, as in Lemma 6. Our data structure for vertical ray shooting on $\mathcal{P}$ is defined as follows.

- The main tree $\mathcal{T}$ is a BAR-tree for the set $G = G_1 \cup \cdots \cup G_n$.
- Let ν be a node in $\mathcal{T}$. We say that an object P_i is *large* at ν if (i) $proj(P_i)$ intersects $region(\nu)$, and (ii) $region(parent(\nu))$ contains a guard from G_i in its interior, but $region(\nu)$ does not. Note that Lemma 6 implies that $size(P_i) = \Omega(size(region(\nu)))$ if P_i is large at ν. Let $\mathcal{P}(\nu) \subset \mathcal{P}$ be the subset of objects that are large at ν.
  Let $Q(\nu)$ be a set of points such that for any $P_i \in \mathcal{P}(\nu)$, there is a point $q \in Q(\nu)$ with $q \in proj(P_i)$. By Lemma 2 there exists such a set $Q(\nu)$ of size $O(1/\beta^2)$. Assign each object $P_i \in \mathcal{P}(\nu)$ arbitrarily to one of the points $q \in Q(\nu)$ contained in its projection. Let $\mathcal{P}(q)$ denote the set of objects assigned to q. We store the set $\mathcal{P}(q)$ in a data structure $\mathcal{T}(q)$ for vertical ray shooting according to Lemma 5. Thus each node ν has $|Q(\nu)|$ associated structures.

Let us first see how to answer a vertical ray shooting query with this structure.

LEMMA 7. *A vertical ray-shooting query can be answered in $O((1/\beta^2)\log^2 n)$ time.*

Proof. Let p be the point where the line through the query ray intersects the xy-plane. Search with p down the tree $\mathcal{T}$. At every node ν on the search path, perform a query in the associated structure $\mathcal{T}(q)$ of each $q \in Q(\nu)$. A query thus takes $O(\log n \cdot \log n \cdot (1/\beta^2))$ time, that is, the length of every search path, times the query time in the associated data structures along the search path, times the size of $Q(\nu)$.

To prove the correctness, it suffices to argue that any object P_i whose projection contains p must be large at one of the nodes on the search path of p. To see this, we observe that $region(root(\mathcal{T}))$ contains all guards from G_i, while the leaf regions do not contain any guards in their interior. It follows that when we follow the path of p, the object P_i must become large at some node. □

We can now prove our final result on vertical ray shooting.

THEOREM 1. *Let $\mathcal{P}$ be a collection of n convex disjoint constant-complexity β-fat polyhedra in $\mathbb{R}^3$. Then there is a data structure such that vertical ray-shooting queries on $\mathcal{P}$ can be answered in $O((1/\beta^2)\log^2 n)$ time. The structure uses $O((1/\beta)n\log^2 n)$ storage and can be built in $O((1/\beta)n\log^2 n)$ time.*

Proof. The correctness of the query procedure and the query time have been shown in Lemma 7.

It remains to prove the bound on the construction time; the storage bound then follows trivially. Computing the guards for each object takes constant time per object, and constructing the BAR-tree takes $O(n\log n)$ time [16]. We claim that an object P_i is large at $O(\log n)$ nodes. Indeed, any guard is contained in the regions of the nodes on a single path down the tree, and an object can be large at a node only if the parent region contains one of its guards. Hence, $\sum_\nu |\mathcal{P}(\nu)| = O(n\log n)$. We can generate the sets $\mathcal{P}(\nu)$ in $O(n\log n)$ time by filtering the objects down the tree $\mathcal{T}$. The set $Q(\nu)$ can be constructed in $O(|Q(\nu)|)$ time, and associating the objects with the points in $Q(\nu)$ can be done in a brute-force way in $O(|Q(\nu)| \cdot |\mathcal{P}(\nu)|)$. Finally, constructing the associated structures of ν takes time

$$\sum_{q \in Q(\nu)} O((1/\beta)|\mathcal{P}(q)|\log|\mathcal{P}(q)|) \;=\; O((1/\beta)|\mathcal{P}(\nu)|\log|\mathcal{P}(\nu)|)$$

by Lemma 5. Hence, the overall construction time is

$$\begin{aligned}&\textstyle\sum_\nu O(|\mathcal{P}(\nu)| \cdot (|Q(\nu)| + (1/\beta)\log|\mathcal{P}(\nu)|))\\ =\ & O((1/\beta)n\log^2 n + (1/\beta^2)n\log n)\\ =\ & O((1/\beta)n\log^2 n). \qquad \square\end{aligned}$$

4. The size of the transitive reduction of depth-order graphs. Let $\mathcal{P} = \{P_1, \ldots, P_n\}$ be a set of disjoint objects in $\mathbb{R}^3$. Recall that we say that P_i is below P_j, denoted by $P_i \prec P_j$, if there are points $(x, y, z_i) \in P_i$ and $(x, y, z_j) \in P_j$ with $z_i < z_j$. We define the *depth-order graph of* $\mathcal{P}$ to be the graph $\mathcal{G}(\mathcal{P}) = (\mathcal{P}, E)$, where $(P_i, P_j) \in E$ if and only if $P_i \prec P_j$. Hence, a depth order for $\mathcal{P}$ corresponds to a topological order on $\mathcal{G}(\mathcal{P})$.

In general it is too costly to compute $\mathcal{G}(\mathcal{P})$ explicitly, since it can have $\Omega(n^2)$ arcs. When computing depth orders for segments in the plane, this can be circumvented by looking only at pairs of segments that "see" each other, that is, that can be connected vertically without crossing another segment. For objects in 3-space, however, the number of pairs that see each other can be quadratic, even when the objects are fat. In this section we therefore study the size of the transitive reduction of depth-order graphs, since the transitive reduction is the smallest subgraph that is sufficient to topologically sort a graph. The main result is that the number of arcs in the transitive reduction of the depth-order graph of a set of fat objects is linear. Then in the next section we will compute a superset of the arcs in the transitive reduction.

We define the *separation* of two nodes in the depth-order graph, denoted $sep(P_i, P_j)$, to be the length of the longest path from P_i to P_j. Notice that if the graph contains cycles, $sep(P_i, P_j)$ can be infinite. We define $\mathcal{G}^{(1)}(\mathcal{P}) = (\mathcal{P}, E^{(1)})$ to be the subgraph of the depth-order graph $\mathcal{G}(\mathcal{P})$, where $(P_i, P_j) \in E^{(1)}$, if and only if $sep(P_i, P_j) = 1$ in $\mathcal{G}(\mathcal{P})$. In other words, $(P_i, P_j) \in E^{(1)}$ if there exists a vertical line that intersects both objects, and every such line does not intersect any other object between P_i and P_j.

LEMMA 8. *If $\mathcal{G}(\mathcal{P})$ is acyclic, the transitive closure of $\mathcal{G}^{(1)}(\mathcal{P})$ is the transitive closure of $\mathcal{G}(\mathcal{P})$.*

Proof. We have to prove that there is a path $P_i \rightsquigarrow P_j$ in $\mathcal{G}(\mathcal{P})$ if and only if there is a path $P_i \rightsquigarrow P_j$ in $\mathcal{G}^{(1)}(\mathcal{P})$. The "if" part is obvious since $\mathcal{G}^{(1)}(\mathcal{P})$ is a subgraph of $\mathcal{G}(\mathcal{P})$. We prove the "only if" part by induction on $sep(P_i, P_j)$.

If $sep(P_i, P_j) = 1$, the arc (P_i, P_j) exists in $\mathcal{G}^{(1)}(\mathcal{P})$ by construction. Now assume there is a path in $\mathcal{G}^{(1)}(\mathcal{P})$ between all nodes with separation m. Take P_i and P_j in $\mathcal{G}(\mathcal{P})$ which have separation $m + 1$. Then there is a node x such that $sep(P_i, x) = 1$ and $sep(x, P_j) = m$. By the induction hypothesis, we then have a path $P_i \rightarrow x \rightsquigarrow P_j$ in $\mathcal{G}^{(1)}(\mathcal{P})$. $\square$

For arbitrary triangles in 3-space, the number of arcs in $\mathcal{G}^{(1)}(\mathcal{P})$ can still be $\Theta(n^2)$. For some special classes of objects, however, the number of arcs is linear. For example, one can show that this number is linear for a set of disjoint polyhedra whose projections form a set of polygonal pseudodisks [10]. Here we concentrate on the case where the objects in the given set $\mathcal{P}$ project onto fat convex objects. We show that in this case the number of arcs is also linear. Since fat convex objects project to fat objects, showing this also shows that the number of arcs in $\mathcal{G}^{(1)}(\mathcal{P})$ is small if the input is a set of fat objects. We start with an auxiliary lemma.

LEMMA 9. *Let $P_i \in \mathcal{P}$ be an object and let $\mathcal{P}^+(i)$ be the subset of objects $P_j \in \mathcal{P}$ that are above P_i and where $sep(P_i, P_j) = 1$. Then the projections $proj(P_j)$ of the objects $P_j \in \mathcal{P}^+(i)$ are pairwise disjoint.*

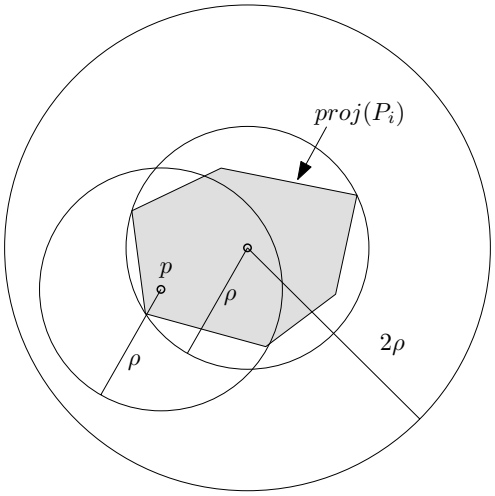

FIG. 1. *Illustration of the packing argument.*

Proof. Suppose the projections are not pairwise disjoint. Then there are objects $P_j, P_k \in \mathcal{P}^+(i)$ such that $proj(P_j) \cap proj(P_k) \neq \emptyset$ and $sep(P_i, P_j) = 1$ and $sep(P_i, P_k) = 1$. Since $proj(P_j)$ and $proj(P_k)$ intersect, they must share at least one point, so there must be an arc between P_j and P_k in $\mathcal{G}(\mathcal{P})$. Therefore, either $sep(P_i, P_j) > 1$ or $sep(P_i, P_k) > 1$, either case being a contradiction. □

THEOREM 2. *Let $\mathcal{P}$ be a collection of n disjoint objects in $\mathbb{R}^3$ that project to convex β-fat objects. Then the number of edges in $\mathcal{G}^{(1)}(\mathcal{P})$ is $O(n/\beta)$.*

Proof. We will charge each arc in $\mathcal{G}^{(1)}(\mathcal{P})$ to an object and then use a packing argument to show that the number of arcs in $\mathcal{G}^{(1)}(\mathcal{P})$ charged to each object is $O(1/\beta)$.

We project all objects onto the xy-plane, making them convex fat objects. In this setting, we say that one object is above another if the original objects satisfy this relationship.

Recall that for a planar object o, its size is defined as the radius of its smallest enclosing disk. Consider an arc (P_i, P_j) in $\mathcal{G}^{(1)}(\mathcal{P})$. We charge the arc to the smaller of the two objects. That is, we charge the arc to P_i if $size(proj(P_i)) < size(proj(P_j))$ and to P_j otherwise. We claim that any object is charged $O(1/\beta)$ arcs. To prove this, take an arbitrary object P_j such that (P_i, P_j) is charged to P_i. Let $\rho = size(proj(P_i))$. If there is an arc in $\mathcal{G}^{(1)}(\mathcal{P})$ between P_i and P_j, then $proj(P_j)$ intersects $proj(P_i)$. Let p be a point in this intersection. Then a circle centered at p with radius ρ is centered in $proj(P_j)$ and does not fully enclose $proj(P_j)$, or else $proj(P_j)$ would have a smallest enclosing circle that is smaller than or equal to that of $proj(P_i)$. Thus, this circle contains at least $\beta\pi\rho^2$ units of area of $proj(P_j)$ by the definition of fatness. Also, this circle is completely enclosed in a circle of radius 2ρ centered at the center of the smallest enclosing disk of $proj(P_i)$. This is illustrated in Figure 1.

Since all objects $proj(P_j)$ where P_j is above P_i and $sep(P_i, P_j) = 1$ must be disjoint by Lemma 9, and because each must have at least $\beta\pi\rho^2$ units of area inside a disk that has $4\pi\rho^2$ units of area, there can be only $4/\beta$ edges of $\mathcal{G}^{(1)}(\mathcal{P})$ charged to P_i. We must double this number to account for objects P_j below P_i such that (P_j, P_i) is charged to P_i. Therefore, we get an upper bound on the number of arcs charged to P_i of $8/\beta$. Finally, since there are n objects, $\mathcal{G}^{(1)}(\mathcal{P})$ can have at most $8n/\beta$ edges, which is $O(n/\beta)$. □

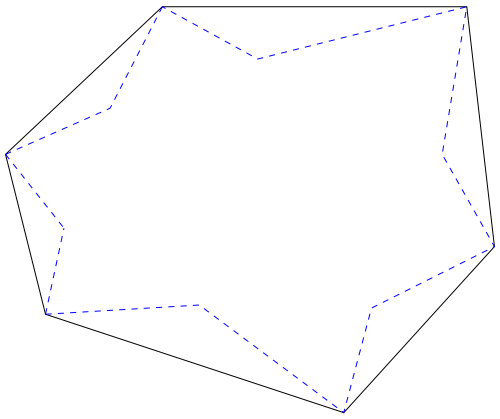

FIG. 2. *A projection of a polyhedron with witness edges added.*

5. Computing depth orders. We now present the algorithm for finding the depth order of a set $\mathcal{P} = \{P_1, \ldots, P_n\}$ of n disjoint β-fat convex polyhedra. In contrast to the proof of Theorem 2, we require the complexity of the projection of each object to be constant.

Witness edges. One of the basic steps that we need to perform repeatedly in our algorithm will be to find polyhedra that are above a query polyhedron. To facilitate this, we will add so-called *witness edges* inside the projection of each P_i. They are defined as follows.

Let β' be defined so that each member of $\{proj(P_i)|P_i \in \mathcal{P}\}$ is β'-fat. By Lemma 1 we know that $\beta' = \Omega(\beta)$. Also let $\mathcal{C} = \{0, \alpha, 2\alpha, \ldots, c\alpha\}$, where $\alpha = (\beta'\pi)/8$ and $c = \lfloor 2\pi/\alpha \rfloor$. We call the directions in $\mathcal{C}$ *canonical directions*. We require the witness edges to have the following properties. Let W_i and W_j be the sets of witness edges constructed for P_i and P_j, respectively.

(i) Each witness edge has one of the canonical directions.

(ii) For any pair of polyhedra P_i and P_j, we have that $proj(P_i)$ intersects $proj(P_j)$ if and only if at least one of the following is true:

- A vertex of $proj(P_i)$ is inside $proj(P_j)$, or a vertex of $proj(P_j)$ is inside $proj(P_i)$.
- A witness edge in W_i crosses a witness edge in W_j.

The construction of the set W_i of witness edges for P_i is done as follows. For each edge $e = vw$ of $proj(P_i)$ we add to W_i two witness edges e' and e'' that are incident to v and w, respectively, extend into the interior of P_i, and form a triangle with e. The directions of the witness are chosen from the canonical directions, such that the angles that e' and e'' make with e are minimal; see Figure 2. We claim that if we add the witness edges in this manner, they have the required properties. The first property holds by construction, so it remains to prove the second property. We first argue that the witness edges lie completely inside $proj(P_i)$, which implies that the "if" part of the second property holds.

LEMMA 10. *The witness edges in W_i lie completely inside $proj(P_i)$.*

Proof. Let e be the edge for which we are adding witness edges. Let p be the midpoint of e and consider the circle C with center p and diameter equal to the length of e. Suppose an edge of $proj(P_i)$ intersects the region bounded by e' and e''. Note that this region must be inside the lighter region in Figure 3 by the minimal-angle

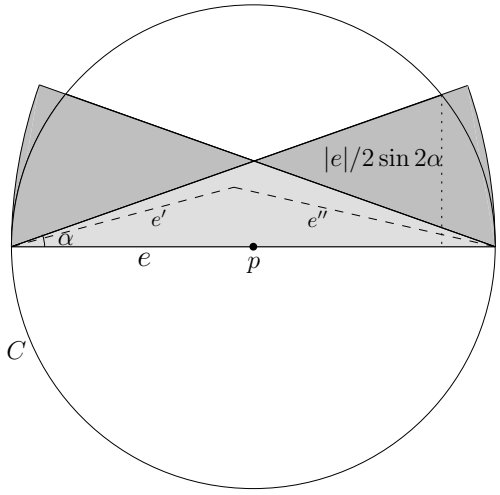

FIG. 3. *No edge of the polygon may enter the light gray region.*

condition which implies that the angles that e makes with e' and e'' are at most α. Then, by convexity of $proj(P_i)$, we know that $proj(P_i) \cap C$ must be completely inside the union of the triangular wedges in Figure 3. These wedges have area at most $\beta'\pi|e|^2/8$ inside C. Hence, $area(proj(P_i) \cap C) < \beta'\pi|e|^2/4$, contradicting our assumption that $proj(P_i)$ is β'-fat. □

The following lemma, which follows directly from Lemma 4, finishes the proof that the witness edges have the required properties.

LEMMA 11. *If $proj(P_i)$ intersects $proj(P_j)$ and $proj(P_i)$ does not contain a vertex of $proj(P_j)$ or vice versa, then a witness edge from P_i intersects a witness edge from P_j.*

The algorithm. The general idea of our algorithm is as follows. By Lemma 8 it is sufficient to find all pairs of objects P_i, P_j of separation 1 in the depth-order graph. Such a pair of objects must, of course, intersect in the projection. Thus, ideally we would like to find among all pairs P_i, P_j whose projections intersect the pairs of separation 1. Our algorithm does not quite achieve this—it will find more pairs, but the number of extra pairs we find will be small. Lemma 11 suggests that the task of finding the intersecting pairs of projections can be broken into two parts: finding pairs for which there is a vertex of the projection of one polyhedron inside the projection of another and finding crossing pairs of witness edges.

Below we give a more detailed description of the algorithm. The algorithm will find a set A of arcs—a superset of the arcs (P_i, P_j) for objects of separation 1—and then topologically sort the graph $\mathcal{G}^* = (\mathcal{P}, A)$. Initially A is empty.

1. For every vertex v of each object $P_i \in \mathcal{P}$, find the objects $P^b(v)$ and $P^a(v)$ that are directly below and above v, respectively, and add the arcs $(P^b(v), P_i)$ and $(P_i, P^a(v))$ to A.
2. Sort the objects by decreasing size so that $size(proj(P_1)) \geq \cdots \geq size(proj(P_n))$, and define $\mathcal{S}_i = \{P_1, \ldots, P_i\}$.
3. For every witness edge e associated with each P_i, find a set $\mathcal{P}(e)$ consisting of objects $P_j \in \mathcal{S}_{i-1}$ with the following properties:
   (P1) Each $P_j \in \mathcal{P}(e)$ has a witness edge that intersects e.
   (P2) Each $P_j \in \mathcal{P}(e)$ is above P_i.

(P3) Each $P_j \in \mathcal{S}_{i-1}$ with $sep(P_i, P_j) = 1$ that satisfies (P1) and (P2) is a member of $\mathcal{P}(e)$.

For each P_i, add the set of arcs $\{(P_i, P_j) : P_j \in \mathcal{P}(e)$ and e is a witness edge of $P_i\}$ to A.

4. Repeat step 3 with "below" substituted for "above" and the directions of the arcs added reversed.
5. Topologically sort the graph $\mathcal{G}^* = (\mathcal{P}, A)$ and report the order.

LEMMA 12. *The order reported by the algorithm is a valid depth order for $\mathcal{P}$ if a depth order exists.*

Proof. Assume a depth order exists for $\mathcal{P}$. It follows directly from the construction that every arc added to the set A is also an arc in the depth-order graph $\mathcal{G}(\mathcal{P})$. It remains to argue that A is a superset of the set of arcs in the graph $\mathcal{G}^{(1)}(\mathcal{P})$.

Consider an arc (P_i, P_j) in $\mathcal{G}^{(1)}(\mathcal{P})$. If there is a vertex of $proj(P_i)$ in $proj(P_j)$ (or vice versa) then, because $sep(P_i, P_j) = 1$, that vertex is directly below P_j (resp., above P_i). Hence, the arc is found in step 1. By Lemma 11, the remaining case is that a witness edge of $proj(P_i)$ intersects a witness edge from $proj(P_j)$. Without loss of generality, assume P_i is smaller than P_j. Hence, $P_j \in \mathcal{S}_{i-1}$. Since (P_i, P_j) is an arc in $\mathcal{G}^{(1)}(\mathcal{P})$, $sep(P_i, P_j) = 1$. By condition (P3), the arc will be found in step 3 or 4, depending on whether P_j is above or below P_i. □

Step 1 can be carried out efficiently using the ray-shooting data structure presented in the previous section. Hence, it remains to describe step 3 in more detail. This step will be performed as follows. We will treat each $P_2, \ldots, P_n$ in order. When we have to handle P_i, we will make sure we have a data structure available that we can query with each witness edge e of P_i and that will then report the set $\mathcal{P}(e)$. After having queried with all witness edges of P_i, we insert P_i into the data structure and proceed with P_{i+1}. Next we describe this data structure.

The witness-edge-intersection data structure. Consider the set of all witness edges of the objects in $\mathcal{P}_{i-1}$. These witness edges have canonical directions, so we can partition them into $|\mathcal{C}|$ subsets depending on their directions. The query segment e has one of the canonical directions as well. Hence, we construct for each subset $|\mathcal{C}|$ different data structures, one for each query direction. We now describe the structure for one such subset, call it W, and a fixed query direction.

Assume without loss of generality that the witness edges in W are all horizontal, and that the query edge e is vertical. The structure is a multilevel data structure defined as follows.

- The top level of the data structure is a segment tree $\mathcal{T}$ on the projections of the edges in W onto the x-axis. Note that each node ν in $\mathcal{T}$ corresponds to a vertical slab in the plane.
- Let $W(\nu)$ denote the edges in W whose projection is in the canonical subset of ν. Such an edge crosses the slab of ν but not the slab of the parent of ν. We store the edges in $W(\nu)$ in a balanced binary tree $\mathcal{T}(\nu)$, ordered according to their y-coordinates. We call this the "slab tree." So far our structure is just a standard two-level tree to perform intersection queries with vertical segments in a set of horizontal segments in the plane [10].
- Let μ be a node in $\mathcal{T}(\nu)$. Let $\mathcal{P}(\mu)$ denote the subset of objects that have a witness edge in the subtree rooted at μ. The node μ represents a rectangular[3] region $R(\mu)$ that is bounded by two slab boundaries and the topmost and

[3]This is only true because we assumed the edges in W are horizontal and the query edge is vertical. In general, μ will represent a parallelogram, but this does not influence the arguments.

bottommost edge stored in the subtree rooted at μ. We associate with μ a reduced subset $\overline{\mathcal{P}(\mu)} \subset \mathcal{P}(\mu)$ of the objects, in the following way: $P_j \in \overline{\mathcal{P}(\mu)}$ if and only if $P_j \in \mathcal{P}(\mu)$ and $size(proj(P_j)) \geq size(R(\mu))/2\sqrt{2}$.

By Lemma 2 we can find a set $Q(\mu)$ consisting of $O(1/\beta^2)$ points such that the projection of any object $P_j \in \overline{\mathcal{P}(\mu)}$ is stabbed. We arbitrarily assign each $P_j \in \overline{\mathcal{P}(\mu)}$ to one of the points q it contains, and we associate a balanced binary search tree $\mathcal{T}(q)$ with each point q on the associated objects, where the sorting order is defined by the height of the objects along the vertical line through q.

This finishes the description of the data structure. Next we describe the algorithms to query the structure and to insert an object.

LEMMA 13. *With the structure described above, we can find the set $\mathcal{P}(e)$ referred to in Step 3 of the depth-order algorithm in $O((1/\beta^3)\log^3 n)$ time. Furthermore, the set $\mathcal{P}(e)$ contains $O((1/\beta^3)\log^2 n)$ objects.*

Proof. Recall that we actually have to query $|\mathcal{C}| = O(1/\beta)$ different versions of the structure. We focus on the time spent in one of these structures.

To perform a query with a witness edge e belonging to an object P_i, we search with e in the first two levels of the tree in the standard way. This gives us $O(\log^2 n)$ nodes μ whose subtrees contain exactly those edges that intersect e. At each node μ, we use the trees $\mathcal{T}(q)$ for $q \in Q(\mu)$ to find the lowest object that is above P_i. We can search in $\mathcal{T}(q)$ since P_i is known to intersect all objects in $\mathcal{P}(q)$ in the projection. Hence, at μ, we find $|Q(\mu)|$ objects in $O(|Q(\mu)|\log n)$ time in total. The query time and the bound on the size of $\mathcal{P}(e)$ follow.

It remains to argue that the reported set has the required properties. Properties (P1) and (P2) follow immediately from the definition of the data structure and query algorithm. Furthermore, when we query a tree $\mathcal{T}(q)$ we can indeed restrict our attention to the lowest object that is above P_i, because the other objects P_j will either be below P_i or have $sep(P_i, P_j) > 1$. Hence, to prove (P3) it is sufficient to argue that any P_j satisfying (P1) and (P2) and with $sep(P_i, P_j) = 1$ will be a member of one of the sets $\overline{\mathcal{P}(\mu)}$. We know that the object will be a member of $\mathcal{P}(\mu)$ for a visited node μ.

Suppose for a contradiction that $P_j \notin \overline{\mathcal{P}(\mu)}$. This means that we must have $size(proj(P_j)) < size(R(\mu))/2\sqrt{2}$. This can happen only when $size(proj(P_j))$ is less than $d/2$, where d is the distance between the top and bottom edges of $R(\mu)$, because P_j crosses the slab of which $R(\mu)$ is a part. On the other hand, when we reach a node μ in the slab tree by querying with a witness edge e of $\mathcal{P}_i$, we have $size(proj(P_i)) \geq \text{length}(e)/2 \geq d/2$. This contradicts that when we query with a witness edge e of P_i, all objects P_j in the data structure have $size(proj(P_j)) \geq size(proj(P_i))$. □

LEMMA 14. *An object P_i can be inserted in $O((1/\beta)\log^2 n(\log n + 1/\beta^2))$ time into the structure.*

Proof. Each of the $O(1)$ witness edges of P_i has to be inserted into $|\mathcal{C}| = O(1/\beta)$ structures. To insert a witness edge, we first find each node μ in a slab tree whose canonical subset contains the witness edge. We test if $size(P_j) \geq size(R(\mu))/2$ and, if so, find a point $q \in Q(\mu)$ that is contained in $proj(P_i)$ and insert P_i into the tree $\mathcal{T}(q)$. This takes $O(\log^2 n(\log n + 1/\beta^2))$ time per structure, thus $O((1/\beta)\log^2 n(\log n + 1/\beta^2))$ time in total. □

From Lemmas 13 and 14, we see that steps 3 and 4 of the depth-order algorithm can be performed in $O((1/\beta^3)n\log^3 n)$ time in total. We get the following theorem.

THEOREM 3. *Let $\mathcal{P}$ be a collection of n disjoint constant-complexity β-fat convex polyhedra in $\mathbb{R}^3$. Then we can compute a depth order for $\mathcal{P}$ in time $O((1/\beta^3)n\log^3 n)$ if it exists.*

6. Verifying depth orders. In order for our algorithm to be complete, it should output the correct depth order if one exists, but it should also not output an incorrect depth order if no depth order exists. Unfortunately the algorithm of the previous section does not necessarily detect cycles in the $\prec$-relation. Hence, we present an algorithm for checking whether a given order is correct.

We use the general approach by De Berg, Overmars, and Schwarzkopf [11] for verifying depth orders. Let $L = P_1, \ldots, P_n$ be the given order. Define $L_1 = \{P_1, \ldots, P_{\lfloor n/2 \rfloor}\}$ and $L_2 = \{P_{\lfloor n/2 \rfloor + 1}, \ldots, P_n\}$. We first check if any object in L_1 is above any object in L_2. Clearly, if the answer is "yes," then the given ordering is not valid. Otherwise, we verify the lists L_1 and L_2 recursively. If $T(\beta, n)$ is the amount of time to check the objects in L_1 against those in L_2, then the overall algorithm takes $O(T(\beta, n)\log n)$ time. We shall see that $T(\beta, n) = O((1/\beta^2)n\log^2 n)$, so the algorithm for verifying the depth order takes $O((1/\beta^2)n\log^3 n)$ time. Next we describe how to check the objects in L_1 against those in L_2.

First we introduce a new type of witness edge. The difference from the witness edges in section 5 is that the new witness edges will have canonical directions in three dimensions, rather than in the projection. In order to achieve this we need the following lemma from Aronov, De Berg, and Gray [4].

LEMMA 15 (see [4]). *Let $\sigma := \lceil 54\sqrt{3}/\beta \rceil$. For any convex β-fat object o in $\mathbb{R}^3$, there exist concentric axis-aligned cubes $C^-(o)$ and $C^+(o)$ with $C^-(o) \subseteq o \subseteq C^+(o)$ such that*

$$\frac{size(C^+(o))}{size(C^-(o))} = \sigma\,.$$

Assume we are given $C^-(o)$ and $C^+(o)$ for object o. We partition each face of $C^+(o)$ into squares with side length equal to the side length of $C^-(o)$. For each facet f of $C^-(o)$ and each square on the corresponding facet of $C^+(o)$, we sweep f so that it coincides with the square; see Figure 4(i). The sweeping directions form the set of canonical directions. There are at most σ^2 different directions that a facet of $C^-(o)$ can be swept in, so we have $O(1/\beta^2)$ canonical directions. We denote an arbitrary member of this set of directions by $\vec{d}$. Note that the set of canonical directions thus obtained does not depend on o, only on the value σ, which is specified by the fatness factor β.

For each P_i we construct a set W_i of witness edges as follows. First, we add the edges of $C^-(P_i)$ to W_i. Second, for each silhouette vertex v of P_i (a silhouette vertex is a vertex whose projection is a boundary vertex of the projection of P_i), we add an edge e_v that connects v to one of the facets of $C^-(P_i)$. This edge is allowed to be in any of the canonical directions as long as it reaches a facet of $C^-(P_i)$. We can be certain that at least one direction works for v since there must be at least one pair consisting of a facet f of $C^-(P_i)$ and a square on a facet of $C^+(P_i)$ such that v is hit when sweeping f to that square.

We also add some vertices to P_i that we call *witness vertices* as follows (see Figure 4(ii)). For each witness edge e, we add the intersection point of $proj(e)$ and $\partial\, proj(C^-(P_i))$, lifted back to e, to the set of witness vertices for P_i. Moreover, if the projected witness edges of two consecutive silhouette vertices intersect, then we lift

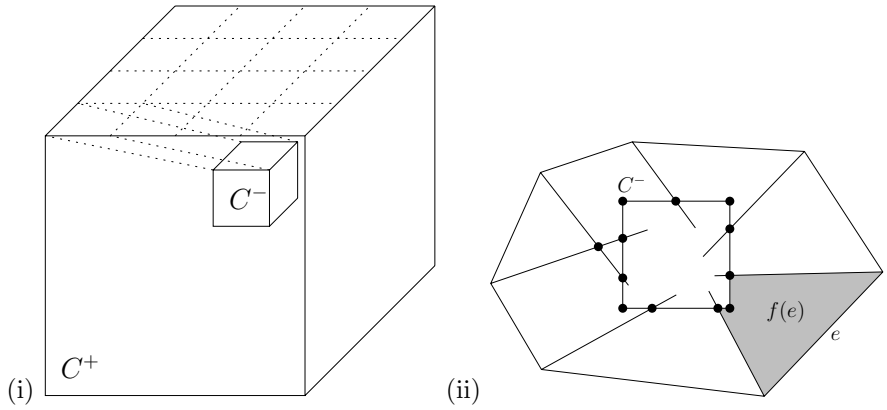

FIG. 4. (i) *One of the canonical directions.* (ii) *Projection of the new witness edges and witness vertices.*

those intersection points to either of the witness edges and make the resulting point a witness vertex. Finally, we add the vertices of $C^-(P_i)$ to the set of witness vertices.

LEMMA 16. *The witness edges satisfy the following properties.*

(i) *Each witness edge has one of the canonical directions.*

(ii) *For any pair of polyhedra P_i and P_j, we have that $proj(P_i)$ intersects $proj(P_j)$ if and only if at least one of the following is true:*

- *A projected witness or silhouette vertex of P_i is inside $proj(P_j)$, or a projected witness or silhouette vertex of P_j is inside $proj(P_i)$.*
- *A projected witness edge in W_i crosses a projected witness edge in W_j.*

Proof. Property (i) is satisfied by construction. Also, if one of the two conditions in property (ii) is satisfied, then the projections of P_i and P_j must intersect since they share a point. Therefore, we will concentrate on proving that a projected witness edge in W_i crosses a projected witness edge in W_j assuming that $proj(P_i) \cap proj(P_j) \neq \emptyset$, and that no projected witness or silhouette vertex of P_i is contained in $proj(P_j)$ (or vice versa).

Since $proj(P_i)$ intersects $proj(P_j)$ and no projected silhouette vertex of one is inside the projection of the other, there must be silhouette edges of $proj(P_i)$ and $proj(P_j)$ that cross. Take one such pair of edges and call them e_i and e_j. Consider the arrangement induced by the projections of the silhouette edges and the witness edges of P_i, and let $f(e_i)$ denote the (bounded) face in this arrangement with e_i on its boundary; see Figure 4(ii). Define $f(e_j)$ similarly for the arrangement induced by the projections of the silhouette edges and the witness edges of P_j. By Lemma 4, there must be an intersection between a pair of edges from $f(e_i)$ and $f(e_j)$, neither of which is $proj(e_i)$ or $proj(e_j)$. Hence, there must be an intersection between two projected witness edges. □

It follows from Lemma 16 that there is an object from L_1 below an object from L_2 when at least one of the following conditions holds for some pair P_i, P_j with $P_i \in L_1$ and $P_j \in L_2$: a witness or silhouette vertex of P_i is below P_j, or a witness or silhouette vertex of P_j is above P_i, or a witness edge of P_i is below a witness edge of P_j. To test for the first condition, we construct a data structure for vertical ray shooting on the objects in L_2 and query it with upward rays from the witness and silhouette vertices of the objects in L_1. The second condition can be tested similarly, namely, by constructing a data structure for vertical ray shooting on the objects in L_1 and

querying it with downward rays from the witness and silhouette vertices of the objects in L_2. By Theorem 1 and the fact that the total number of witness and silhouette vertices is $O(n)$, this will take $O((1/\beta^2)\log^2 n)$ in total. To test the third condition we proceed as follows. Let $W(L_1)$ and $W(L_2)$ denote the set of all witness edges defined for the objects in L_1 and L_2, respectively. We will preprocess $W(L_2)$ into a data structure for querying with witness edges from $W(L_1)$, according to the following lemma.

LEMMA 17. *We can preprocess the set $W(L_2)$ in $O((1/\beta^2)n\log n)$ time into a data structure of size $O((1/\beta^2)n\log n)$ such that, for any witness edge $e \in W(L_1)$, we can determine in $O((1/\beta^2)\log^2 n)$ time whether any witness edge from $W(L_2)$ is above e.*

Proof. Let $W_{\vec{d}}(L_2) \subset W(L_2)$ denote the subset of witness edges of canonical direction $\vec{d}$. Note that

$$\sum_{\vec{d}} |W_{\vec{d}}(L_2)| = |W(L_2)| = O(n).$$

Define $W_{\vec{d}}(L_1)$ similarly. For each pair of directions $\vec{d}_1, \vec{d}_2$ we build a data structure on $W_{\vec{d}_1}(L_2)$ for querying with edges from $W_{\vec{d}_2}(L_1)$. (In fact, the structure can be queried with any segment with direction $\vec{d}_2$.) Assume without loss of generality that $\vec{d}_1$ is parallel to the x-axis and $\vec{d}_2$ is parallel to the y-axis. The structure is a multi-level data structure similar to the structure of section 5. The first two levels are exactly the same as for the structure in section 5: the first level is a segment tree on the x-ranges of the witness edges, and the second level is a balanced binary search tree on their y-values (in section 5 this was called the slab tree). For each canonical subset of a node in the slab tree, we store its highest witness edge. Note that the concept of "highest" is well defined since the witness edges in the canonical subset all have the same direction and the query edge will have a fixed direction as well.

A query with a witness edge $e \in W_{\vec{d}_2}(L_1)$ can be answered in $O(\log^2 n)$ time, as follows: query with the x-coordinate of e in the segment tree; for each node ν on the path, query with the y-range of e in the associated slab tree $\mathcal{T}(\nu)$; and for each selected node μ in $\mathcal{T}(\nu)$, check if the witness stored there is above e.

When we are querying with an edge e, we actually have to query in the sets $W_{\vec{d}}(L_2)$ for each canonical direction $\vec{d}$. Since there are $O(1/\beta^2)$ canonical directions, this means that the total query time is $O((1/\beta^2)\log^2 n)$.

Building the structure on $W_{\vec{d}_1}(L_2)$ for a given query direction $\vec{d}_2$ can be done in $O(|W_{\vec{d}_1}(L_2)|\log|W_{\vec{d}_1}(L_2)|)$ time. This is because the associated structures of the segment tree (the slab trees) can be built in linear time if we presort the witness edges by y-coordinate. After that we compute the highest edge for each node in a slab tree in a bottom-up fashion (the highest edge for a node is the higher of the highest edges of its two children) in linear time. Hence, the overall preprocessing time is the same as the amount of storage, which is $O(|W_{\vec{d}_1}(L_2)|\log|W_{\vec{d}_1}(L_2)|)$. Overall, the preprocessing is therefore

$$\begin{aligned}
&\textstyle\sum_{\vec{d}_1,\vec{d}_2} O(|W_{\vec{d}_1}(L_2)|\log|W_{\vec{d}_1}(L_2)|)\\
&= O(1/\beta^2)\cdot\textstyle\sum_{\vec{d}_1} O(|W_{\vec{d}_1}(L_2)|\log|W_{\vec{d}_1}(L_2)|)\\
&= O((1/\beta^2)n\log n). \qquad \square
\end{aligned}$$

Putting everything together, we get the following theorem.

THEOREM 4. *We can verify whether a given order on a set of n disjoint convex constant-complexity β-fat polyhedra in $\mathbb{R}^3$ is a valid depth order in $O((1/\beta^2)n\log^3 n)$ time.*

7. Concluding remarks. We have presented new and improved solutions to three problems on fat convex polyhedra in 3-space: vertical ray shooting, computing depth orders, and verifying depth orders. One open problem is to see if the results can be extended to fat nonconvex polyhedra or fat curved objects.

Our algorithm for verifying depth orders uses a collection of witness edges that have canonical directions in three dimensions and allow us to capture (together with a certain set of points in the objects) the above-below relation between the objects. It would be interesting to investigate if these witness edges can be useful for other problems on convex fat objects as well.

Appendix. This appendix contains a proof that was omitted.

LEMMA 3. *Let P be a β-fat convex polygon with n vertices. There is a set T of α-fat triangles that cover P where $|T| = O(n)$ and $\alpha \geq \beta/128$.*

Proof. Recall that for triangles, we use the definition that the fatness is given by the smallest angle in the triangle.

Let S be the largest possible square contained in P. Any convex subset of P that contains all of S is at least β'-fat, where $\beta' = \Theta(\beta)$, by Lemma 19 below.

We extend the edges of S until they intersect P and add vertices to P at the intersection points (see Figure 5). We let P_a denote the part of P above the (extended) top edge of S, let P_b denote the part below the bottom edge of S, let P_c denote the part to the right of the right edge of S, and let P_d denote the part to the left of the left edge of S. We will show how to cover P_a. The three other parts of P are covered similarly, and S is covered with two triangles that each have a fatness of 45°.

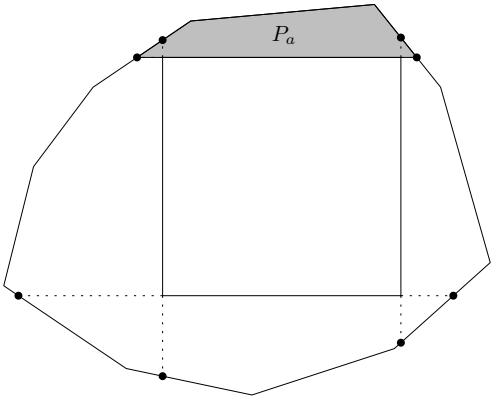

FIG. 5. *One of the subpolygons of P induced by S.*

An ear of a polygon P consists of two consecutive edges of P that have the property that a straight edge connecting the first and last vertex of the edges stays completely inside the polygon. In a convex polygon, any two consecutive edges are ears.

We cover P_a by choosing an arbitrary ear from it (except any ear that also contains the top edge of S), covering it using Lemma 18, and then replacing P by P with that ear removed. Since no part of S is ever removed, P remains fat. Thus we keep removing ears from P_a until it exactly coincides with the extended edge of S.

Since we cover the ears that we remove using the procedure from Lemma 18, we add a constant number of triangles to T per vertex, implying that $|T| = O(n)$. The exact bound on α is given by combining Lemmas 18 and 19. ∎

LEMMA 18. *An ear of a β-fat polygon P can be covered with at most four α-fat triangles that all stay inside P where $\alpha = (\beta\pi)/16$.*

Proof. In a convex polygon, an ear is a triangle formed by three consecutive vertices. Consider the ear defined by vertices v_{i-1}, v_i, and v_{i+1}. Let ϕ_{i-1}, ϕ_i, and ϕ_{i+1} be the angles at the respective vertices—see Figure 6(i). Because P is β-fat, we know that the angle between any two adjacent edges of P, and in particular the angle ϕ_i, is at least $\beta/(2\pi)$. There are three possibilities for the other two angles, ϕ_{i-1} and ϕ_{i+1}: either they are both at least α, they are both less than 2α, or one is larger than 2α and one is smaller than α. Note that these cases overlap.

Case (i). $\phi_{i-1} \geq \alpha$ and $\phi_{i+1} \geq \alpha$. In this case, the ear is trivial to cover: it is already an α-fat triangle that can be covered by a copy of itself.

Case (ii). $\phi_{i-1} < 2\alpha$ and $\phi_{i+1} < 2\alpha$. First, we add triangles to the edges $v_{i-1}v_i$ and v_iv_{i+1} where the angles of the edges of the triangles with respect to the boundary edges are at least 2α. By Lemma 10, these triangles must stay inside P as long as $\alpha \leq (\beta\pi)/16$. However, it is clear that the nonboundary vertex of these triangles must be outside the ear that we are covering. Therefore, we can place a triangle at the middle vertex of the ear with two sides that correspond to the sides of the two triangles that we just added and whose third side is the edge of the ear that goes between these two edges. This triangle completes the covering of the ear.

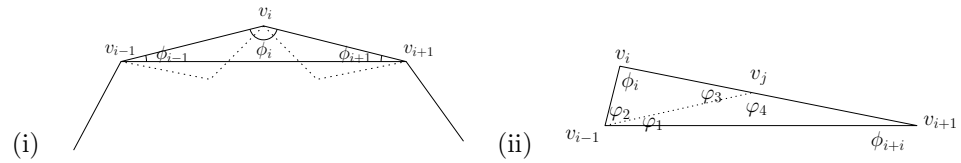

FIG. 6. (i) *Case* (ii). (ii) *Case* (iii).

Case (iii). $\phi_{i-1} > 2\alpha$ and $\phi_{i+1} < \alpha$ (or the symmetric case). See Figure 6(ii). In this case, we add an edge between the vertex that is at the large angle (v_{i-1}, without loss of generality) and the edge across from it, making vertex v_j. This splits ϕ_i into two angles φ_1 and φ_2. We place v_j such that φ_1 is exactly α. Thus, $\varphi_3 = \alpha + \phi_{i+1} > \alpha$. By assumption, $\varphi_2 > \alpha$. Thus, we can cover the triangle $v_{i-1}v_iv_j$ with a copy of itself. Triangle $v_{i-1}v_jv_{i+1}$ can be covered according to the procedure outlined for Case (ii) above. Note that in all cases, we have covered the ear with at most four α-fat triangles. ∎

LEMMA 19. *Let P be a convex β-fat polygon in $\mathbb{R}^2$ and S be the largest square contained in P. Then any convex subset P' such that $S \subseteq P' \subseteq P$ is β'-fat where $\beta' \geq \beta/(8\pi)$.*

Proof. By the results of section 3.2.1 of Van der Stappen's thesis [25], the side length of S is at least $\beta\rho/(2\sqrt{2})$, where ρ is the diameter of P.

Let $d = \overline{p_1p_2}$ be the diameter of P'. Let $S' \subseteq S$ be the largest square contained in S that has an edge parallel to d. The side length of S' is at least $\sqrt{2}/2$ times the side length of S. Let p_3 and p_4 denote the midpoints of the sides of S' parallel to d; see Figure 7.

We will make two triangles: $p_1p_3p_4$ and $p_2p_3p_4$. By convexity, both of these triangles must be completely inside P'. The sum of the area of these triangles is not

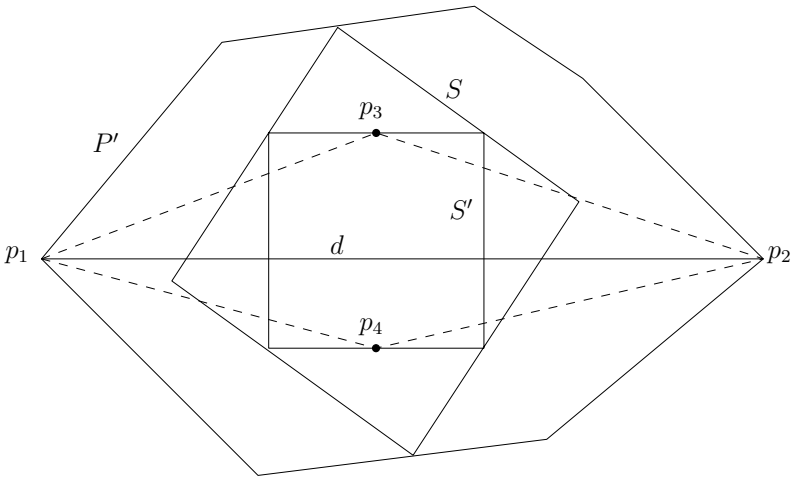

FIG. 7. *P' must be fat.*

dependent on the placement of S'—it is always $d \cdot s/2$, where s is the side length of S'.

Since P' is convex, the fatness of P' is determined by a circle placed at p_1 with radius d [25]. The area of that circle is πd^2. Thus the fatness of P' is

$$\beta' = \frac{\frac{d \cdot s}{2}}{\pi d^2} = \frac{s}{2d\pi} \geq \frac{\beta\rho}{8d\pi} \geq \frac{\beta}{8\pi}$$

since $d \leq \rho$. □

CONVERGENCE OF AUTONOMOUS MOBILE ROBOTS WITH INACCURATE SENSORS AND MOVEMENTS*

REUVEN COHEN† AND DAVID PELEG‡

Abstract. A number of recent studies concern algorithms for distributed control and coordination in systems of autonomous mobile robots. The common theoretical model adopted in these studies assumes that the positional input of the robots is obtained by perfectly accurate visual sensors, that robot movements are accurate, and that internal calculations performed by the robots on (real) coordinates are perfectly accurate as well. The current paper concentrates on the effect of weakening this rather strong set of assumptions and replacing it with the more realistic assumption that the robot sensors, movement, and internal calculations may have slight inaccuracies. Specifically, the paper concentrates on the ability of robot systems with inaccurate sensors, movements, and calculations to carry out the task of convergence. The paper presents several impossibility theorems, limiting the inaccuracy levels that still allow convergence, and prohibiting a general algorithm for gathering, namely, meeting at a point, in a finite number of steps. The main positive result is an algorithm for convergence under bounded measurement, movement, and calculation errors.

Key words. autonomous robots, fault tolerance, inaccurate sensors

1. Introduction: Background.

Distributed systems consisting of autonomous mobile robots (also known as *robot swarms*) are motivated by the idea that instead of using a single, highly sophisticated and expensive robot, it may be advantageous in certain situations to employ a group of small, simple, and relatively cheap robots. This approach is of interest for a number of reasons. Multiple robot systems may be used to accomplish tasks that *cannot* be achieved by a single robot. Such systems usually have decreased cost due to the simpler individual robot structure. These systems can be used in a variety of environments where the acting (human or artificial) agents may be at risk, such as military operations, exploratory space missions, cleanups of toxic spills, fire fighting, search and rescue missions, and other hazardous tasks. In such situations, a multiple robot system has a better chance of successfully carrying out its mission (while possibly accepting the loss or destruction of some of its robots) than a single irreplaceable robot. Such systems may also be useful for carrying out simple repetitive tasks that humans may find extremely boring or tiresome.

Subsequently, studies of autonomous mobile robot systems can be found in different disciplines, from engineering to artificial intelligence (e.g., [17, 23, 24]). Notable engineering efforts in these directions include the cellular robotic system [18],

swarm intelligence [5], and the self-assembly machine [20]. Relevant studies in the realm of artificial intelligence include social interaction and intelligent behavior [19], behavior-based robot systems [4, 21, 22], multirobot learning [23, 24], and ant robotics [30]. (A survey on this area is presented in [6].)

A number of recent studies on autonomous mobile robot systems focus on algorithms for distributed control and coordination. Most of the studies mentioned above handled control and coordination issues following experimental, empirical, or architectural approaches, which resulted in the design of heuristic protocols. Algorithmic aspects were handled implicitly, with little or no emphasis on formal analysis of the correctness, termination, or complexity properties of the algorithms. During the last decade, various coordination related issues have been studied from a distributed computing point of view (cf. [2, 15, 26, 27, 28]). The approach is to propose suitable computational models and analyze the minimal capabilities the robots must possess in order to achieve their common goals. The basic model studied in these papers can be summarized as follows. The robots execute a given algorithm in order to achieve a prespecified task. Each robot in the system is assumed to operate individually in simple cycles consisting of three steps:

(1) *Look*. Determine the current configuration by identifying the locations of all visible robots and marking them on your private coordinate system (the model may assume perfect or limited visibility range);

(2) *Compute*. Execute the given algorithm, resulting in a goal point p_G; and

(3) *Move*. Travel towards the point p_G.

Weak and strong model assumptions. Due to the focus on cheap robot design and the minimal capabilities allowing the robots to perform some tasks, most papers in this area (cf. [8, 14, 15, 27]) assume the robots to be rather limited. Specifically, the robots are assumed to be indistinguishable, so when looking at the current configuration, a robot cannot tell the identity of the robots at each of the points (apart from itself). Furthermore, the robots are assumed to have no means of direct communication. This gives rise to challenging "distributed coordination" problems since the only permissible communication is based on "positional" or "geometric" information exchange, yielding an interesting variant of the classical (direct communication-based) distributed model.

Moreover, the robots are also assumed to be *oblivious* (or memoryless); namely, they cannot remember their previous states, their previous actions, or the previous positions of the other robots. Hence the algorithm employed by the robots for the Compute step cannot rely on information from previous cycles, and its only input is the current configuration. While this is admittedly an overrestrictive and unrealistic assumption, developing algorithms for the oblivious model still makes sense in various settings, for two reasons. First, solutions that rely on nonobliviousness, namely, storing information regarding history, become more complex when they need to be applied in a dynamic environment where the robots have different start times, i.e., they are activated in different cycles, or robots might be added to or removed from the system dynamically. In dynamic environments an algorithm relying on the outcome of previous rounds may enter an inconsistent state and fail to reach the desired result. In contrast, oblivious solutions are insensitive to changing conditions and thus require no modification in dynamic settings. Second, any algorithm that works correctly for oblivious robots is inherently self-stabilizing; i.e., it withstands transient errors that alter the robots' local states.

On the other hand, the robot model studied in the literature includes the following *overly strong* assumptions:

- when a robot observes its surroundings, it obtains a perfect map of the locations of the other robots relative to itself;
- when a robot performs internal calculations on (real) coordinates, the outcome is exact (infinite precision) and suffers no numerical errors; and
- when a robot decides to move to a point p, it progresses on the straight line connecting its current location to p, stopping either precisely at p or at some earlier point on the straight line segment leading to it.

All of these assumptions are unrealistic. In practice, the robot measurements suffer from nonnegligible inaccuracies in both distance and angle estimations. (The most common range sensors in mobile robots are sonar sensors. The accuracy in range estimation of the common models is about $\pm 1\%$, and the angular separation is about 3°; see, e.g., [25]. Other possible range detectors are based on laser range detection, which is usually more accurate than the sonar, and on stereoscopic vision, which is usually less accurate.) The same applies to the precision of robot movements. Due to various mechanical factors such as unstable power supply, friction, and force control, the exact distance a robot traverses in a single cycle is hard to control or to even predict to a high degree of accuracy. This makes most previous algorithms proposed in the literature inapplicable in most practical settings. Finally, the robots' internal calculations cannot be assumed precise, for a variety of well-understood reasons such as convergence rates of numerical procedures, truncated numeric representations, rounding errors, and more.

In this paper we address the issue of imperfections in robot measurements, calculations, and movements. Specifically, we replace the unrealistic assumptions described above with more appropriate ones, allowing for measurement, calculation, and movement inaccuracies, and show that efficient algorithmic solutions can still be obtained in the resulting model.

We focus on the *gathering* and *convergence* problems, which have been extensively studied in the common (fully accurate) model (cf. [7, 8, 15, 27, 28]). The *gathering* problem is defined as follows. Starting from any initial configuration, the robots should occupy a single point within a finite number of steps. The closely related *convergence* problem requires the robots to converge to a single point, rather than reach it (namely, for every $c > 0$ there must be a time t_c by which all robots are within a distance of at most c of each other).

It is important to note that analyzing the effect of errors is not merely of theoretical value. In section 3.1 we show that gathering cannot be guaranteed in environments with errors. In section 3.2 we illustrate how certain existing geometric algorithms, including ones designed for fault tolerance, fail to guarantee even convergence in the presence of small errors. We also show (in Theorem 6.10) that the standard center-of-gravity algorithm may also fail to converge when errors occur.

Related work. A number of problems concerning coordination in autonomous mobile robot systems have been considered so far in the literature. The gathering problem was first discussed in [27, 28] in the semisynchronous model. It was proved that it is impossible to achieve gathering of *two* oblivious autonomous mobile robots that have no common sense of orientation under the semisynchronous model. Also, an algorithm was presented in [28] for gathering $N \geq 3$ robots in the semisynchronous model. In the asynchronous model, an algorithm for gathering $N = 3, 4$ robots is brought in [8, 15], and an algorithm for gathering $N \geq 5$ robots has recently been described in [7]. Fault tolerant gathering algorithms (in the crash and Byzantine fault models) were studied in [1]. The gathering problem was also studied in a system where the robots have limited visibility. The visibility conditions are modeled by means of

a *visibility graph*, representing the (symmetric) visibility relation of the robots with respect to one another; i.e., an edge exists between robots i and j if and only if i and j are visible to each other. (Note that in this model visibility is a boolean predicate and does not involve imprecisions; namely, if robot j is visible to robot i, then its precise coordinates are measured accurately.) It was shown that the problem is unsolvable in the case that the visibility graph is not connected [14]. In [2] a convergence algorithm was provided for any N in limited visibility systems. The effect of sensor and control errors was also studied numerically in [2]. The natural gravitational algorithm based on going to the center of gravity and its convergence properties were studied in [10, 11] in the semisynchronous and asynchronous models, respectively.

Another class of problems studied, e.g., in [12, 13, 26, 27, 28], concerns the formation of geometric patterns. The robots are required to arrange themselves (approximately) in a simple geometric form (such as a circle, a simple polygon, or a line segment) within a finite number of cycles. Algorithms were presented for enabling a group of robots to achieve such self-arrangement and even spread itself nearly evenly along the form shaped. Flocking (or "following the leader") is yet another task studied in the literature, where the robots are required to follow the movements of a predefined leader [15]. Distributed *search* by a group of robots after a (static or moving) target in a specified region is a potentially useful application for mobile robot systems. An important subtask in this context is achieving an *even distribution* of the robots, namely, requiring the robots to spread out uniformly over a specified region of a simple geometric shape. This problem has been studied in [26]. A related task of interest is *partitioning*, where the robots are required to organize themselves into a number of groups. An algorithm for this problem was also presented in [26]. A final example is the *wake-up* task, where a single initially awake robot must wake up all the others (with the help of those already wakened). The *freeze-tag* problem, which is a paradigm for the distributed wakeup of a group of robots, was presented in [3, 29] and given a number of approximation algorithms.

Our results. In this paper we study the convergence problem in the common semisynchronous model where the robots' only inputs are obtained by inaccurate visual sensors, and their movements and internal calculations may be inaccurate as well. In section 3 we present several impossibility theorems in a model allowing measurement errors, limiting the inaccuracy allowing convergence, and prohibiting a general algorithm for gathering in a finite number of steps. In section 4 we present an algorithm for convergence under bounded measurement error and prove its correctness, first in the fully synchronous model and then in the semisynchronous model. In section 5 we describe how movement and calculation errors can be treated. In section 6 we consider the fully asynchronous model, where we analyze our algorithm in the one-dimensional case and compare it with the ordinary center-of-gravity algorithm. The main contributions are summarized in Table 1. We remark that the paper does not explicitly concern the question of establishing the convergence rate of our algorithm. Note, however, that our convergence proofs do imply certain lower bounds on the convergence rate (that is, upper bounds on the time to halve some measure of the dispersion). Some additional comments on this issue are deferred to the conclusions section.

2. The model. Robot operation cycle. Each of the N robots i in the system is assumed to operate individually in simple cycles. Every cycle consists of three steps, Look, Compute, and Move.

- *Look*. Identify the locations of all robots in i's private coordinate system;

TABLE 1
The contribution of this paper. Results of convergence or divergence for the `Go_to_COG` *and* `RCG` *algorithms under different timing models for robots with inaccurate sensors.*

Algorithm	`Go_to_COG`	`RCG`
$\mathcal{FSYNC}$	converges (Lemma 4.2)	converges (Thm. 4.8)
$\mathcal{SSYNC}$	?	converges (Thm. 4.10)
$\mathcal{ASYNC}$	diverges (Thm. 6.10)	converges in 1 dim (Thm. 6.8)

the result of this step is a multiset of points $P = \{p_1, \ldots, p_N\}$ defining the current *configuration*. The robots are indistinguishable, so each robot i knows its own location p_i, but does not know the identity of the robots at each of the other points.

- *Compute*. Execute the given algorithm, resulting in a goal point p_G.
- *Move*. Move towards the point p_G.

A common assumption made in a number of papers dealing with this model, known as *premature stopping*, is that the robot might stop before reaching its goal point p_G, but is guaranteed to traverse at least some minimal distance s (unless it has reached the goal first). For ease of presentation, we assume throughout most of this paper (particularly, in sections 3 and 4, which deal with measurement errors), a slightly simpler model where the Move step of a robot is ensured to bring it to its goal point p_G. We handle premature stopping in section 5, when we discuss movement errors.

Note that the Look and Move steps are carried out identically in every cycle, independently of the algorithm used. The differences between different algorithms occur in the Compute step. Moreover, the procedure carried out in the Compute step is identical for all robots. If the robots are oblivious, then the algorithm cannot rely on information from previous cycles; thus the procedure can be fully specified by describing a single Compute step, and its only input is the current configuration P, giving the locations of the robots.

The synchronization model. As mentioned earlier, our computational model for studying and analyzing problems of coordinating and controlling a set of autonomous mobile robots follows the well-studied *semisynchronous* ($\mathcal{SSYNC}$) model. This model is partially synchronous in the sense that all robots operate according to the same clock cycles, but not all robots are necessarily active in all cycles. Those robots which are awake at a given cycle take a measurement of the positions of all other robots. Then they may make a computation and move instantaneously accordingly. The activation of the different robots can be thought of as managed by a hypothetical scheduler, whose only fairness obligation is that each robot must be activated and given a chance to operate infinitely often in any infinite execution. On the way to establishing the result on the $\mathcal{SSYNC}$ model, we prove it first in the fully synchronous ($\mathcal{FSYNC}$) model, where each robot moves at each cycle. In section 6.2 we also discuss its performance in the fully asynchronous ($\mathcal{ASYNC}$) model, in which there is no global clock and the robots operate independently of each other, at arbitrary and possibly nonuniform rates.

Modeling measurement imprecisions. Our model assumes that the robot's location estimation is imprecise, where, in general, this imprecision can affect both distance and angle estimations. However, we make the following restrictive assumption.

Bounded imprecision assumption. The distance imprecision is bounded by some accuracy parameter ε_{d} known at the robot's design. Similarly, the imprecision in angle measurements is bounded by an accuracy parameter ε_θ (where it can always be assumed that $\varepsilon_\theta \leq \pi$).

Formally, the bound on distance imprecision means that if the true location of an observed point in i's coordinate system is $\overline{V}$ and the measurement taken by i is $\bar{v}$, then this measurement will satisfy $(1-\varepsilon_{\mathrm{d}})V < v < (1+\varepsilon_{\mathrm{d}})V$. (Throughout, for a vector $\bar{v}$, we denote by v its scalar length, $v = |\bar{v}|$. Also, capital letters are used for exact quantities, whereas lowercase letters denote the robots' views.) Similarly, the bound on angle imprecision means that the angle θ between the actual distance vector $\overline{V}$ and the measured distance vector $\bar{v}$ satisfies $\theta \leq \varepsilon_\theta$, or, alternatively, $\cos\theta = \frac{\overline{V}\bar{v}}{Vv} \geq \cos\varepsilon_\theta$.

In what follows, we consider the model $\mathcal{ERR}$, in which both types of imprecision are possible, and the model $\mathcal{ERR}^-$, where only distance estimates are inaccurate. This gives rise to six composite timing/error models, denoted $\langle \mathcal{T}, \mathcal{E} \rangle$, where $\mathcal{T}$ is the timing model under consideration ($\mathcal{FSYNC}$, $\mathcal{SSYNC}$, or $\mathcal{ASYNC}$) and $\mathcal{E}$ is the error model ($\mathcal{ERR}$ or $\mathcal{ERR}^-$).

While in reality each robot uses its own private coordinate system, for simplicity of presentation it is convenient to assume the existence of a global coordinate system (which is unknown to the robots) and use it for our notation. Throughout, we denote by $\bar{R}_j$ the location of robot j in the global coordinate system. In addition, for every two robots i and j, denote by $\overline{V}^i_j = \bar{R}_j - \bar{R}_i$ the true location of robot j from the position of robot i (i.e., the true vector from i to j), and by $\bar{v}^i_j$ the location of robot j as measured by i, *translated* to the global coordinate system. Likewise, our algorithm and its analysis will be described in the global coordinate system, although each of the robots will apply it in its own local coordinate system. As the functions computed by the algorithm are all invariant under translations and rotations, this representation does not violate the correctness of our analysis.

If the robots may have inaccuracies in distance estimation but not in directions, then i will measure $\overline{V}^i_j$ as $\bar{v}^i_j = (1+\sigma^i_j)\overline{V}^i_j$, where $-\varepsilon_{\mathrm{d}} < \sigma^i_j < \varepsilon_{\mathrm{d}}$ is the actual local error factor in distance estimation at robot i. For robots with inaccuracy in angle measurement as well, if the true distance is V^i_j, then i will measure it as $v^i_j = (1+\sigma^i_j)V^i_j$, where $-\varepsilon_{\mathrm{d}} < \sigma^i_j < \varepsilon_{\mathrm{d}}$ and the angle θ between $\overline{V}^i_j$ and $\bar{v}^i_j$ will satisfy $|\theta| \leq \varepsilon_\theta$.

Throughout, values computed at time slot t are denoted by a parameter $[t]$. Also, the actual error factor is time dependent, and its value at time t is denoted by $\sigma^i_j[t]$. The parameter t is omitted whenever it is clear from the context.

Modeling movement and calculation imprecisions. Other than inaccuracies in measurements, inaccuracies in movement and calculations should also be taken into account. For movement, we may assume that if the robot wants to move from its current location $\bar{R}_i$ to some goal point p_G, then it will move on a vector in angle of at most $\varepsilon^{\mathrm{mv}}_\theta$ from the vector $\overline{r_i p_G}$ and to any distance d in the interval $d \in [1-\varepsilon^{\mathrm{mv}}_{\mathrm{d}}, 1+\varepsilon^{\mathrm{mv}}_{\mathrm{d}}]|\overline{r_i p_G}|$. When it calculates a goal point $p_G = (x, y)$, it will have a multiplicative error of up to ε_{c}. Since in the center-of-gravity algorithms presented below, the calculation error is bounded linearly in the calculated terms, these inaccuracies can be treated as global inaccuracies in the measurement instead with the same effect. It can be seen that relative movement and calculation errors can be replaced with errors in measurement causing the same effect, so these errors can be treated using the same algorithm by recalibrating ε_{d}. Absolute errors in movement or calculation cannot be treated, since even if the robots have almost converged, they

may lead to wider spreading. Therefore, throughout most of the ensuing technical development, we will assume only measurement inaccuracies, where the treatment of movement and calculation inaccuracies can be conducted by assimilating them into the measurement errors.

Another often ignored aspect of robot motion is the existence of a consistent sense of direction. As mentioned earlier, following the commonly used model of [27, 28], it is assumed in this paper that the robots do not share a common sense of orientation. Let us remark, however, that this is an expected feature of real robots, since the robot's body is positioned in an angle dependent on the previous movement direction. Hence in practice, this feature may allow the usage of the robot's direction as a finite state memory between robot movements. The algorithms presented herein do not rely on sense of direction. However, one of the impossibility results presented below (Theorem 3.5) relies on the inability to use sense of direction.

Technical lemmas. We make use of the following technical lemmas. The first lemma says that if a point $\bar{b}$ outside the unit circle moves towards the center of the circle and stops at its boundary, then it gets closer to any point $\bar{a}$ inside the circle. (See Figure 1.)

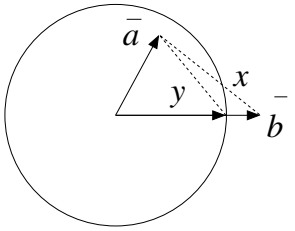

FIG. 1. *Illustration for Lemma* 2.1.

LEMMA 2.1. *For two vectors* $\bar{a}$ *and* $\bar{b}$ *with* $a \leq 1 \leq b$, *let* $x = |\bar{a} - \bar{b}|$ *and* $y = |\bar{a} - \bar{b}/b|$. *Then*

(1) $x^2 - y^2 \geq (b-1)^2 + 2(1-a)(b-1) \geq (b-1)^2$,

(2) $y \leq x$.

Proof. Note that $|\bar{a} - \bar{b}|^2 = a^2 + b^2 - 2\bar{a}\bar{b}$ and $|\bar{a} - \bar{b}/b|^2 = a^2 + 1 - 2\bar{a}\bar{b}/b$. Thus

$$\begin{aligned} |\bar{a} - \bar{b}|^2 - |\bar{a} - \bar{b}/b|^2 &= b^2 - 1 - 2\bar{a}\bar{b}(1 - 1/b) \\ &\geq b^2 - 1 - 2a(b-1) \;=\; (b-1)^2 + 2(1-a)(b-1) \\ &\geq b^2 - 1 - 2(b-1) \;=\; (b-1)^2 \,, \end{aligned}$$

and part (1) of the lemma follows. Part (2) follows from part (1), as $(b-1)^2 \geq 0$. □

LEMMA 2.2. *For vectors* $\overline{V}$ *and* $\bar{v}$, *if* $(1-\varepsilon_d)V < v < (1+\varepsilon_d)V$ *and* $\frac{\overline{V}\bar{v}}{Vv} \geq \cos(\varepsilon_\theta)$, *then* $|\overline{V} - \bar{v}| < V\sqrt{2(1+\varepsilon_d)(1-\cos\varepsilon_\theta) + {\varepsilon_d}^2}$.

Proof. Let $A = v/V$. Then $\bar{v}\overline{V} = AV^2\cos\theta$, where θ is the angle between the vectors; hence $(\bar{v} - \overline{V})^2 = \bar{v}^2 + \overline{V}^2 - 2\bar{v}\overline{V} = (1 + A^2)V^2 - 2AV^2\cos\theta$. In the range $A \in [1 - \varepsilon_{\rm d}, 1 + \varepsilon_{\rm d}]$ and $\theta \leq \varepsilon_\theta$, this function attains its maximum for $\theta = \varepsilon_\theta$ and $A = 1 + \varepsilon_{\rm d}$, whereby $(\bar{v} - \overline{V})^2 = \left(1 + (1+\varepsilon_{\rm d})^2 - 2(1+\varepsilon_{\rm d})\cos\varepsilon_\theta\right)V^2$, implying the lemma. □

The following lemma is used in conjunction with Lemma 2.1 to show that moving some fraction of the distance to the circle perimeter will reduce the squared distance by at least the same fraction of the total improvement.

LEMMA 2.3. *For any two vectors $\bar{A}$ and $\bar{B}$ satisfying $A^2 - B^2 \geq c$, for some constant c, and for any $0 \leq \mu \leq 1$, the parameterized difference $X(\mu) = A^2 - |\mu\bar{B} + (1-\mu)\bar{A}|^2$ satisfies $X(\mu) \geq \mu c$.*

Proof.

$$\begin{aligned} X(\mu) &= A^2 - |\mu\bar{B} + (1-\mu)\bar{A}|^2 \;\geq\; A^2 - (1-\mu)^2A^2 - \mu^2B^2 - 2\mu(1-\mu)AB \\ &= \mu(A^2 - B^2) + (\mu - \mu^2)(A-B)^2 \;\geq\; \mu(A^2 - B^2) \;=\; \mu c. \qquad \square \end{aligned}$$

3. The effect of measurement errors. To appreciate the importance of error analysis one must realize two facts. First, computers are limited in their computational power and therefore cannot perform perfect precision calculations. This may seem insignificant, since floating point arithmetic can be made to very high accuracy with modern computers. However, this may prove to be a practical problem. For instance, the point that minimizes the sum of distances to the robots' locations, also known as the Weber point [31], may be used to achieve gathering. However, this point is not computable, due to its infinite sensitivity to location errors [9].

Second, the correctness of algorithms that use geometric properties of the plane is usually proved using theorems from Euclidean geometry. However, these theorems are, in many cases, no longer applicable when measurement or calculation errors occur.

3.1. Impossibility results. We start with some impossibility results. The proofs of these results are based on the ability of the adversary to partition the space of possible initial configurations into countably many regions, each of uncountably many configurations (say, on the basis of the initial distance between the robots), such that within each region, the outcome of the algorithm (i.e., the instructions to the robots on how far to move in each round) is the same. Note that our impossibility proofs for gathering (Theorems 3.1 and 3.3) exploit the requirement of meeting at a point, and do not preclude the possibility of convergence. In contrast, Theorem 3.5 shows that assuming sufficiently large inaccuracies in angle measurement, and in the absence of consistent sense of direction, even convergence is impossible, and the adversary can cause the robots to diverge under any algorithm.

Although this paper does not concern the issue of memory complexity and all the algorithms presented hereafter are deterministic, it may be of interest to note that the following two impossibility theorems hold even in a rather strong setting where the timing model is fully synchronous and the robots have unlimited memory and are allowed to use randomness. The main idea of the proof is to divide the line into a set of segments, where each segment is small enough such that each robot may see each of its points as the location of the other robot due to measurement errors. Since the algorithm must perform the same movement (or a random movement chosen from the same distribution), it will fail to meet the other robot, or reach the next landmark for the algorithm, starting from almost any point in the segment.

THEOREM 3.1. *Gathering is impossible for two robots on the line with inexact distance measurements even in the strong setting outlined above.*

Proof. Consider two robots 1 and 2 on the line in the $\mathcal{FSYNC}$ model and a potential gathering algorithm `ALG`. At each round t, the algorithm `ALG` at robot j has only one input $v^j_{j'}[t]$, namely, the result of the distance measurement taken by j to the other robot j'. Assuming the adversary ensures that in each round t the two robots obtain the same measurement result, i.e., $v^{j'}_j[t] = v^j_{j'}[t] = m[t]$, the inter-robot distance change $o(t)$ (namely, the distance reduction between the two robots) on round t becomes some function of $m[t]$, i.e., $o[t] = \varphi(m[t])$, and hence the total inter-robot

distance change $L(n)$ after n cycles is the sum of n outputs of the algorithm, $L(n) = \sum_{t \le n} o[t]$.

The adversary policy exploits this observation as follows. Partition the positive reals into infinitely many disjoint segments $(a_i, b_i]$, for $i \ge 1$, such that $b_i/a_i < (1+\varepsilon_{\mathrm{d}})/(1-\varepsilon_{\mathrm{d}})$ for each i. The adversary initially selects for every i a single possible measurement result m_i in the range $(1-\varepsilon_{\mathrm{d}})b_i < m_i < (1+\varepsilon_{\mathrm{d}})a_i$. During the execution of the algorithm, whenever a robot j takes a measurement where the true inter-robot distance $V^j_{j'}$ falls in the ith segment, $V^j_{j'} \in (a_i, b_i]$, the (inaccurate) measurement result will be $v^j_{j'} = m_i$.

This policy allows the introduction of only countably many distinct measurement results. Hence the total inter-robot distance change $L[t]$ after n cycles is the sum of a finite number of reals from a countable basis. The set of possible inter-robot distance changes is therefore still countable. As the set of possible initial inter-distances between the robots in the starting configuration is uncountable, it follows that gathering is never achieved from almost every starting configuration.

Observe that adding memory (allowing robots to store their previous measurements) or allowing the use of randomness will not help, since now the output of the algorithm on round t is a function of a finite number of variables, $o[t] = \varphi(\langle m(t'), \rho(1,t'), \rho(2,t')\rangle_{t' \le t})$, representing the entire history of the execution till this round, where $\rho(j,t')$ is the random number drawn by robot j on round t'. The results of each measurement are again taken from a countable set, and the values of ρ for each run form a countable set. It follows that, fixing the sequence of random number pairs $\langle \rho(1,t'), \rho(2,t')\rangle$ drawn in the execution and considering all uncountably many possible starting configurations, the robots will achieve gathering only from a countable number of starting configurations, which are of zero measure. Therefore, the robots cannot gather even with constant probability. ∎

In the case of $N > 2$ robots on the line it is presumable that a similar construction can apply. However, in the plane, assuming exact angle measurements, there is a continuum of possible measurements, and therefore gathering may be possible, using some method to estimate the distance using the angles (and possibly memory of several angles). We make the conjecture that (possibly with some limitations on the model) this does not help to achieve gathering.

CONJECTURE 3.2. *$N > 2$ robots with inaccurate distance measurements and accurate angle measurements in the $\mathcal{FSYNC}$ model cannot achieve convergence in the plane.*

In the case of angle and distance errors in the plane, gathering is impossible for any number of robots.

THEOREM 3.3. *Gathering in the plane is impossible for any number of robots assuming inaccuracies in both the distance* and *angle measurements even in the strong setting outlined above.*

Proof. Consider N robots in the plane in the $\mathcal{FSYNC}$ model and a potential gathering algorithm `ALG`. At each round t, the algorithm `ALG` at robot j has only $N-1$ inputs $\bar{v}^j_{j'}(t)$, namely, the result of the measurement taken by j to any other robot $1 \ge j' \ne j \le N$. Assuming the adversary ensures that the robot j obtains the distance measurement results $m^j_{j'}[t]$ and angle measurements $\alpha^j_{j'}$ for the distance and angle to the j' robot, respectively, in each round t, the robot configuration $\bar{R}_j$ in round t becomes $\bar{R}_j[t+1] = \bar{R}_j[t] + \Delta\bar{R}_j[t]$, where $\Delta\bar{R}_j[t]$ is some function $\varphi(\{m^j_{j'}, \alpha^j_{j'}\})$ of $m^j_{j'}[t]$ and $\alpha^j_{j'}[t]$, and hence the total change $\bar{L}^j(n)$ in each robot j after n cycles is the sum of n outputs of the algorithm, $\bar{L}^j(n) = \sum_{t \le n} \Delta\bar{R}_j[t]$.

The adversary policy exploits this observation as follows. Partition the positive reals into infinitely many disjoint segments $(a_i, b_i]$, for $i \geq 1$, such that $b_i/a_i < (1+\varepsilon_{\mathrm{d}})/(1-\varepsilon_{\mathrm{d}})$ for each i. Partition the range $[0, 2\pi)$ into the $n > 2\pi/\varepsilon_\theta$ segments $[0, 2\pi/n), \ldots, [k\pi/n, (k+1)\pi/n), \ldots, [(n-1)\pi/n, 2\pi)$. The adversary initially selects for every i a single possible measurement result m_i in the range $(1-\varepsilon_{\mathrm{d}})b_i < m_i < (1+\varepsilon_{\mathrm{d}})a_i$, and for every k the adversary selects an angle θ_k such that $(k+1)\pi/n - \varepsilon_\theta < \theta_k < k\pi/n + \varepsilon_\theta$. During the execution of the algorithm, whenever a robot j takes a measurement where the true inter-robot distance $V^j_{j'}$ falls in the ith segment, $V^j_{j'} \in (a_i, b_i]$, the (inaccurate) measurement result will be $v^j_{j'} = m_i$. Whenever the angle between a robot i and a robot j falls in the range $[k\pi/n, (k+1)\pi/n)$ the angle will be measured as θ_k.

This policy allows the introduction of only countably many distinct measurement results. Hence each of the changes $\bar{L}^j(t)$ after n cycles is the sum of a finite number of real vectors from a countable basis. The set of possible robot location changes is therefore still countable. As the set of possible initial inter-distances between the robots in the starting configuration is uncountable, it follows that gathering is never achieved from almost every starting configuration.

Observe that adding memory (allowing robots to store their previous measurements) or allowing the use of randomness will not help, since now the output of the algorithm on round t is a function of a finite number of variables, $\bar{L}^j(t) = \varphi(\langle m^j_{j'}(t'), \theta^j_{j'}, \rho(j,t')\rangle_{t' \leq t})$, representing the entire history of the execution till this round, where $\rho(j,t')$ is the random number drawn by robot j on round t'. The results of each measurement are again taken from a countable set, and the values of ρ for each run form a countable set. It follows that, fixing the sequence of random number lists $\langle(\rho(j,t'))\rangle$ drawn in the execution and considering all uncountably many possible starting configurations, the robots will achieve gathering only from a countable number of starting configurations, which are of zero measure. Therefore, the robots cannot gather even with constant probability. □

It seems reasonable to conjecture that even convergence is impossible for robots with large measurement errors. The exact limits are not completely clear. The following theorem gives some rather weak limits on the possibility of convergence. We start with a technical lemma.

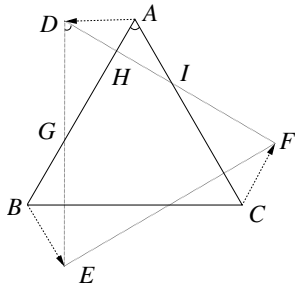

FIG. 2. *Illustration for Lemma* 3.4.

LEMMA 3.4. *If three robots are positioned in an equilateral triangular configuration and every robot moves the same distance counterclockwise parallel to the line formed by the locations of the other two robots, then the distances between the robots increase.*

Proof. A movement as in the lemma is illustrated in Figure 2, where the robots

move from the triangle $\triangle ABC$ to $\triangle DEF$, which by symmetry is also equilateral. Therefore $\angle BAC = 60°$ and $\angle EDF = 60°$. Now $\angle GHD = \angle FHA$. Thus, $\triangle HDG \sim \triangle HAI$. Since $DA \parallel BC$, also $\angle HAD = 60°$. Since $\angle HAI = 60°$, it follows that $\angle AHI < 120°$, and since it is external to $\triangle AHD$, $\angle HDA < 60° = \angle HAD$. This implies that $HD > HA$ and thus also $area(\triangle HDG) > area(\triangle HAI)$. By similar considerations on the other two corners, it follows that $area(\triangle DEF) > area(\triangle ABC)$. □

In the theorem we assume that the robot has no sense of direction in a strong way; i.e., at every cycle the adversary can choose each robot's axes independent of previous cycles.

THEOREM 3.5. *For a configuration of $N = 3$ robots having an error parameter $\varepsilon_\theta \geq \pi/3$ in angle measurement, there is no deterministic algorithm for convergence even assuming* exact *distance estimation, fully synchronous model, and unlimited memory.*

Proof. Start with a configuration with the robots positioned at the vertices of an equilateral triangle. The adversary can distort the measurements of each robot in such a way that it sees the locations of the other two robots as if its own location were exactly at the center of the line segment connecting them. This situation is symmetric under 180° rotation around the robot. Therefore, assuming a deterministic algorithm, the output vector $\bar{v}$ depends only on the robot's coordinate system. By rotating the coordinate system by 180°, the adversary can always ensure that the vector of movement is in the half-plane external to the triangle. By symmetry, the adversary can enforce a similar movement vector (rotated by 120°) for each of the three robots. In the resulting configuration, the robots will again be positioned at the vertices of an equilateral triangle (see Figure 3). Moreover, each of these movement vectors can be split into two movements: a movement away from the center, which will trivially increase the distances, and movement perpendicular to the line connecting the robot to the center, which by Lemma 3.4 will also increase the distances. Hence, the adversary can cause the algorithm to diverge. □

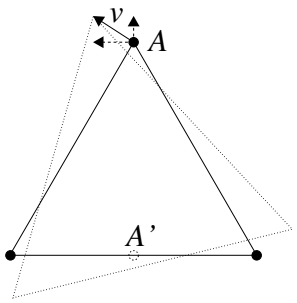

FIG. 3. *Illustration for Theorem* 3.5. *Robot A observes its environment and deduces that it is in location A'. It applies the algorithm and moves by vector v (whose projections are dashed). By symmetry the final configuration is the (larger) dotted triangle.*

3.2. Problems with existing algorithms. To illustrate the second point raised in the beginning of this section, consider the algorithm `3-Gather` presented in [1]. This algorithm achieves gathering of three robots using the following three simple rules:

(1) If two robots already reside in the same point, then the third should go to that point.

(2) If the robots form an obtuse triangle, they move towards the obtuse angled vertex.

(3) If the robots form an acute triangle, they move towards the intersection point of the angle bisectors.

As shown above, no algorithm can guarantee gathering when measurement errors occur. Furthermore, by Theorem 3.5, no algorithm can guarantee even convergence when angle measurement errors of $\varepsilon_\theta \geq 60^\circ$ might occur. We now show that even though Algorithm `3-Gather` is designed to robustness and achieves gathering even if one of the robots fails, we have the following.

OBSERVATION 3.6. *Algorithm* `3-Gather` *might fail to achieve convergence in the presence of angle measurement errors of at least* $\varepsilon_\theta \geq 15^\circ$.

Proof. Suppose the three robots form an equilateral triangle. Due to measurement errors of 15° to each of its neighbors, each robot may think its corner of the triangle forms a 90° angle and subsequently conclude that it need not move. Thus, a deadlock occurs. ∎

Likewise, for a group of $N > 3$ robots, the algorithm `N-Gather` is presented in [1]. In this algorithm (which is more complex and will not be described here), the smallest enclosing circle of the robot group is calculated, and in case there is a single robot inside this circle, it does not move. In the presence of measurement inaccuracies, this rule can potentially cause deadlock, implying the following.

OBSERVATION 3.7. *Algorithm* `N-Gather` *might fail to achieve even convergence in the presence of angle and distance measurement errors of* $\varepsilon_d > 0$.

Proof. Suppose the $N > 3$ robots form a regular N-gon. All robots are on the smallest enclosing circle. Any $\varepsilon_{\mathrm{d}} > 0$ error in the measurements taken by each of the robots may cause it to believe it is located inside the circle while all others are on the circle. Therefore, a deadlock can occur. ∎

4. The convergence algorithm.

4.1. Algorithm `Go_to_COG`. Arguably, the most natural algorithm for autonomous robot convergence is the gravitational algorithm, where each robot computes the average position (center of gravity) of the group as perceived by it,

$$\bar{v}^i_{cog} \;=\; \frac{1}{N}\sum_j \bar{v}^i_j \;,$$

and moves towards it. A formal definition of this algorithm follows.

Algorithm `Go_to_COG` (code for robot i):

1. Estimate the measured center of gravity, $\bar{v}^i_{cog} = \frac{1}{N}\sum_j \bar{v}^i_j$.
2. Move to the point $\bar{v}^i_{cog}$.

The properties of Algorithm `Go_to_COG` in a model with fully accurate measurements have been studied in [11]. In particular, the following theorem has been proved therein.

THEOREM 4.1 (see [11]). *A group of N robots executing Algorithm* `Go_to_COG` *will converge in the $\mathcal{ASYNC}$ model with no measurement errors.*

If distance measurements are not guaranteed to be accurate (but angle measurements are accurate, i.e., $\varepsilon_\theta = 0$), Algorithm `Go_to_COG` may not guarantee convergence. Nevertheless, as shown next, convergence *is* guaranteed in the fully synchronous model.

Denote the true center of gravity of the robots in the global coordinate system by

$$\bar{R}_{cog} \;=\; \frac{1}{N}\sum_j \bar{R}_j$$

and the vector from robot i to the center of gravity by

$$\overline{V}^i_{cog} \;=\; \bar{R}_{cog} - \bar{R}_i \;=\; \frac{1}{N}\sum_j \overline{V}^i_j \;,$$

recalling that $\overline{V}^i_j = \bar{R}_j - \bar{R}_i$. Denote the distance from the true center of gravity of the robots to the robot farthest from it by $D_{cog} = \max_i\{V^i_{cog}\}$. Also, denote the true distance from i to the robot farthest from it by $D^i_{max} = \max_j\{V^i_j\}$.

We have the following.

LEMMA 4.2. *In the $\langle \mathcal{FSYNC}, \mathcal{ERR}^- \rangle$ model with $\varepsilon_d < \frac{1}{2}$, a group of N robots performing Algorithm* `Go_to_COG` *converge.*

Proof. At every time step, each robot moves to its perceived center of gravity, $\bar{v}^i_{cog}$. For every robot, the perceived center of gravity satisfies $|\bar{v}^i_{cog} - \overline{V}^i_{cog}| \leq \varepsilon_{\mathrm{d}} D_{cog}$. Therefore, after step t, all robots are concentrated in a circle of radius $\varepsilon_{\mathrm{d}} D_{cog}[t]$ around $\bar{R}_{cog}[t]$. By convexity, the new center of gravity $\bar{R}_{cog}[t+1]$ also falls in this circle; hence the maximum distance between a robot and the new center of gravity is at most $D_{cog}[t+1] \leq 2\varepsilon_{\mathrm{d}} D_{cog}[t]$. Hence as long as $\varepsilon_{\mathrm{d}} < \frac{1}{2}$, $D_{cog}[t+1] \leq (1-\eta) D_{cog}[t]$ for some constant $\eta > 0$. Thus, the robots converge. □

The convergence of Algorithm `Go_to_COG` in the $\mathcal{SSYNC}$ model is not clear at the moment. However, as shown in section 6.2, in the $\mathcal{ASYNC}$ model there are scenarios where robots executing Algorithm `Go_to_COG` fail to converge. This leads us to propose the following slightly more involved algorithm.

4.2. Algorithm `RCG`. Our algorithm, named `Restricted_Go_to_COG`, or `RCG` for short, is based on calculating the center of gravity of the group of robots and also estimating the maximum possible error in the center-of-gravity calculation. The robot makes no movement if it is within the maximum possible error from the center of gravity. If it is outside the circle of error, it moves towards the center of gravity but only up to the bounds of the circle of error. We fix a conservative error estimate parameter, $\epsilon_0 > \varepsilon_{\mathrm{d}}$. We also fix a parameter $0 < \beta \leq 1$, controlling the rate of convergence. In subsection 4.4, dealing only with measurement inaccuracies, we assume $\beta = 1$. Later on, in section 5, this parameter needs to be adjusted.

Following is a more detailed explanation of the algorithm. In step 1, the measured center of gravity is estimated using the conducted measurements. In step 2 the distance to the farthest robot is found. Notice that this distance may not be accurate and that this might not even be the real farthest robot. The result of step 2 is used in step 3 to give an estimate of the possible error in the center-of-gravity calculation. In step 4 the robot decides to stay in place if it is within the circle of error or calculates its destination point, which is on the boundary of the error circle centered at the calculated center of gravity, as illustrated in Figure 4.

A formal description of the algorithm is given next. Note that Algorithm `Go_to_COG` is identical to Algorithm `RCG` with parameter $\epsilon_0 = 0$.

4.3. Analysis of `RCG` for measurement errors in the $\mathcal{FSYNC}$ model. We first prove the convergence of Algorithm `RCG` in the $\langle \mathcal{FSYNC}, \mathcal{ERR}^- \rangle$ model. We use the following two properties of D^i_{max}.

Algorithm RCG (code for robot i):

1. Estimate the measured center of gravity, $\bar{v}^i_{cog} = \frac{1}{N}\sum_j \bar{v}^i_j$.
2. Let $d^i_{max} = \max_j\{v^i_j\}$
   /* max distance measured to another robot */
3. Let $\rho^i = \dfrac{\epsilon_0}{1-\epsilon_0} \cdot d^i_{max}$
   /* estimate for max error between calculated and actual CoG */
   and $\mathcal{F} = 1 - \rho^i / v^i_{cog}$
   /* safe movement fraction */
4. If $\mathcal{F} > 0$, then move to the point $\bar{c}_i = \beta \cdot \mathcal{F} \cdot \bar{v}^i_{cog}$.
   Otherwise do not move.

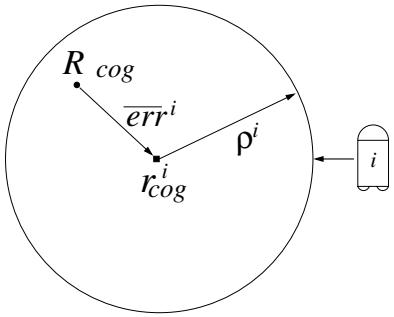

FIG. 4. *Illustration of the Algorithm* RCG.

FACT 4.3. *For every i, the true and perceived maximum distances satisfy*
(a) $(1-\epsilon_0)D^i_{max} < (1-\varepsilon_d)D^i_{max} \le d^i_{max} \le (1+\varepsilon_d)D^i_{max} < (1+\epsilon_0)D^i_{max}$,
(b) $D_{cog} \le D^i_{max} \le 2D_{cog}$.

Proof. The first property is immediate from the definition of D^i_{max}, the choice of d^i_{max}, and the assumption. For the lower bound in the second property notice that the center of gravity is in the convex hull of the robot group. For the upper bound in the second property, let $\ell = \arg\max_j\{V^i_j\}$. By the triangle inequality for each j, we have

$$D^i_{max} = V^i_\ell \le \frac{1}{N}\sum_j (V^i_j + V^\ell_j) = V^i_{cog} + V^\ell_{cog} \le 2D_{cog}. \qquad \square$$

For the synchronous model, we define the tth round to begin at time t and end at time $t+1$. The robots all perform their Look phase simultaneously. The robots' *moment of inertia* at time t is defined as

$$I[t] = \frac{1}{N}\sum_j \left(\overline{V}^j_{cog}[t]\right)^2 = \frac{1}{N}\sum_j \left(\bar{R}_j[t] - \bar{R}_{cog}[t]\right)^2.$$

Defining the function $I_{\bar{x}}[t] \equiv \frac{1}{N}\sum_j (\bar{R}_j[t] - \bar{x})^2$, we notice the following fact (cf. [16]).

FACT 4.4. *$I_{\bar{x}}[t]$ attains its minimum on $\bar{x} = \bar{R}_{cog}[t]$.*

We now identify a key property required to ensure convergence of Algorithm RCG. For some time t, denote the *error component* in the center-of-gravity calculation by robot i by

$$\overline{err}^i = \frac{1}{N}\sum_j \sigma^i_j \overline{V}^i_j \ .$$

We refer to the ratio err^i/D_{cog} at time t as the *error ratio* of the algorithm at t. Algorithm RCG is said to have *bounded error ratio* if

$$\frac{err^i}{D_{cog}} \;<\; 2\epsilon_0 \quad \text{at any time } t. \tag{1}$$

Our two main lemmas, presented next, relate the bounded error ratio property to convergence.

LEMMA 4.5. *In the $\langle \mathcal{FSYNC}, \mathcal{ERR} \rangle$ model, if $\epsilon_0 < 0.2$ and Algorithm* RCG *has bounded error ratio, then the algorithm guarantees that at every round t*

1. *at least one robot can move,*
2. *every robot i that makes a move decreases its distance from the true center of gravity at time t, i.e., $|\bar{R}_i[t+1] - \bar{R}_{cog}[t]| < |\bar{R}_i[t] - \bar{R}_{cog}[t]|$,*
3. *the robots' moment of inertia decreases, i.e., $I[t+1] < I[t]$.*

Proof. Consider some time t. By assumption, the algorithm satisfies inequality (1) at time t, and by the two parts of Fact 4.3, the calculated value ρ^i is bounded by

$$\rho^i \;\le\; \frac{\epsilon_0(1+\epsilon_0)}{1-\epsilon_0} \cdot D^i_{max} \;\le\; \frac{\epsilon_0(1+\epsilon_0)}{1-\epsilon_0} \cdot 2D_{cog}.$$

By assumption (1), we have for each i

$$err^i + \rho^i \;\le\; f(\epsilon_0) \cdot D_{cog} \;<\; D_{cog}\ , \tag{2}$$

where $f(\epsilon_0) = 4\epsilon_0/(1-\epsilon_0)$, and the last inequality follows from the assumption that $\epsilon_0 < 0.2$.

For $k = \arg\max_j \{V^j_{cog}\}$, the robot farthest from the center of gravity, we have $V^k_{cog} = D_{cog}$ and $\bar{v}^k_{cog} = \overline{V}^k_{cog} + \overline{err}^k$; hence by inequality (2) and the triangle inequality,

$$\rho^k \;<\; V^k_{cog} - err^k \;\le\; v^k_{cog}\ .$$

This implies that at round t, robot k is allowed to move in step 4 of the algorithm, proving part 1 of the Lemma.

To prove part 2, consider a round t and a robot i which moved in round t. Fix $\bar{x} = \bar{R}_{cog}[t]$ and take $\bar{a} = \overline{err}^i[t]/\rho^i[t]$ and $\bar{b} = \bar{v}^i_{cog}[t]/\rho^i[t]$. Note that by (1) and Fact 4.3(a),

$$err^i[t] \;\le\; \frac{\varepsilon_{\mathrm{d}}}{1-\varepsilon_{\mathrm{d}}} \cdot d^i_{max}[t] \;<\; \frac{\epsilon_0}{1-\epsilon_0} \cdot d^i_{max}[t] \;=\; \rho^i[t];$$

hence $a \le 1$. Also, at round $t+1$, robot i moves if and only if $v^i_{cog}[t] > \rho^i[t]$; hence if i moved, then $b = v^i_{cog}[t]/\rho^i[t] > 1$. Hence Lemma 2.1(1) can be applied. Noting that $\bar{b}/b = (\bar{R}_i[t+1] - \bar{R}_{cog}[t])/\rho^i[t]$, we get

$$|\bar{R}_i[t+1] - \bar{x}| < |\bar{R}_i[t] - \bar{x}|\ ,$$

yielding part 2 of the Lemma. It remains to prove part 3. Note that for a robot that did not move, $|\bar{R}_i[t+1] - \bar{x}| = |\bar{R}_i[t] - \bar{x}|$. Using this fact and part 2, we have that

$$I_{\bar{x}}[t+1] < I_{\bar{x}}[t] = I[t]\ .$$

Finally, by Fact 4.4 we get $I[t+1] \;\le\; I_{\bar{x}}[t+1]$, yielding part 3 of Lemma 4.5. ∎

LEMMA 4.6. *In the $\langle \mathcal{FSYNC}, \mathcal{ERR} \rangle$ model, if $\epsilon_0 < 0.2$ and Algorithm* RCG *has bounded error ratio, then in every execution of the algorithm, the robots converge.*

Proof. By part 1 of Lemma 4.5, the robot k most distant from the center of gravity can always move if Algorithm Go_to_COG is applied. By part 2 of Lemma 4.5, in round t every robot decreases its distance from the old center of gravity, $\bar{x} = \bar{R}_{cog}[t]$. Therefore, to bound from below the decrease in I, we are required only to examine the behavior of the most distant robot. By Lemma 2.1(1) with $a = \bar{R}_k[t+1] - \bar{R}_{cog}[t]$ and $b = \bar{R}_k[t] - \bar{R}_{cog}[t]$, for $\epsilon_0 < 0.2$ we have $v^k_{cog} > \rho^k$ and

$$(\bar{R}_k[t] - \bar{R}_{cog}[t])^2 - (\bar{R}_k[t+1] - \bar{R}_{cog}[t])^2 \;\geq\; (v^k_{cog} - \rho^k)^2 \;.$$

Since $\bar{v}^k_{cog} = \overline{V}^k_{cog} + \overline{err}^k$, and using the triangle inequality,

$$(\bar{R}_k[t] - \bar{R}_{cog}[t])^2 - (\bar{R}_k[t+1] - \bar{R}_{cog}[t])^2 \geq \left(V^k_{cog} - (\rho^k + err^k)\right)^2 \;. \tag{3}$$

Recall that since k is the most distant robot, $V^k_{cog} = D_{cog}$. Denoting $\gamma = 1 - f(\epsilon_0)$, we have by (2) that

$$V^k_{cog} - (\rho^k + err^k) \;\geq\; \gamma \cdot D_{cog} \;. \tag{4}$$

As mentioned above, if $\epsilon_0 < 0.2$, then $\gamma > 0$. We also use the fact that

$$I[t] = I_{\bar{x}}[t] \leq D^2_{cog}. \tag{5}$$

Using Fact 4.4 and inequalities (3), (4), and (5), we have that

$$\begin{aligned}
I[t+1] \leq I_{\bar{x}}[t+1] \;&=\; \frac{1}{N}\left((\bar{R}_k[t+1] - \bar{R}_{cog}[t])^2 + \sum_{j \neq k}(\bar{R}_j[t+1] - \bar{R}_{cog}[t])^2\right) \\
&\leq \frac{1}{N}(\bar{R}_k[t+1] - \bar{R}_{cog}[t])^2 + \frac{1}{N}\sum_{j \neq k}(\bar{R}_j[t] - \bar{R}_{cog}[t])^2 \\
&\leq \frac{1}{N}(\bar{R}_k[t+1] - \bar{R}_{cog}[t])^2 - \frac{1}{N}(\bar{R}_k[t] - \bar{R}_{cog}[t])^2 + I[t] \\
&\leq I[t] - \frac{1}{N}\left(V^k_{cog} - (\rho^k + err^k)\right)^2 \;\leq\; I[t] - \frac{\gamma^2}{N} \cdot D^2_{cog} \\
&\leq I[t]\left(1 - \frac{\gamma^2}{N}\right),
\end{aligned}$$

and therefore the system converges, proving the theorem. □

Next, our two main theorems, stating the convergence of Algorithm RCG in the $\mathcal{ERR}^-$ and $\mathcal{ERR}$ models, respectively, are established by showing that a suitable selection of ϵ_0 ensures that the algorithm has bounded error ratio.

THEOREM 4.7. *In the $\langle \mathcal{FSYNC}, \mathcal{ERR}^- \rangle$ model, if there exists a fixed ϵ_0 such that $\varepsilon_d < \epsilon_0 < 0.2$, then in every execution of Algorithm* RCG*, the robots converge.*

Proof. The center of gravity computed by robot i can be expressed as

$$\bar{v}^i_{cog} \;=\; \frac{1}{N}\sum_j \bar{r}^i_j \;=\; \frac{1}{N}\sum_j (\bar{R}_j + \sigma^i_j \overline{V}^i_j) \;=\; \overline{V}^i_{cog} + \overline{err}^i \;.$$

By the bounded imprecision assumption and Fact 4.3(b),

$$(6)\quad err^i \;=\; \frac{1}{N}\left|\sum_j \sigma_j^i \cdot V_j^i\right| \;\le\; \frac{1}{N}\sum_j |\sigma_j^i|\cdot V_j^i \;\le\; \varepsilon_{\rm d} D_{max}^i \;\le\; 2\varepsilon_{\rm d} D_{cog} \;<\; 2\epsilon_0 D_{cog}.$$

The claim now follows from Lemma 4.6. □

We now turn to the $\mathcal{ERR}$ model, also allowing inaccuracies in angle measurements.

THEOREM 4.8. *In the $\langle \mathcal{FSYNC}, \mathcal{ERR}\rangle$ model, if there exists a fixed ϵ_0 such that $\sqrt{2(1+\varepsilon_d)(1-\cos\varepsilon_\theta)+{\varepsilon_d}^2} < \epsilon_0 < 0.2$, then in every execution of Algorithm* RCG*, the robots converge.*

Proof. Recall that $\bar v_{cog}^i = \overline{V}^i_{cog} + \overline{err}^i$. By Lemma 2.2

$$\begin{aligned} err^i \;&=\; |\bar v_{cog}^i - \overline{V}^i_{cog}| < V_{cog}^i\sqrt{2(1+\varepsilon_{\rm d})(1-\cos\varepsilon_\theta)+{\varepsilon_{\rm d}}^2} \\ &\le \sqrt{2(1+\varepsilon_{\rm d})(1-\cos\varepsilon_\theta)+{\varepsilon_{\rm d}}^2}\, D_{max}^i \\ &\le 2\sqrt{2(1+\varepsilon_{\rm d})(1-\cos\varepsilon_\theta)+{\varepsilon_{\rm d}}^2}\, D_{cog} \;<\; 2\epsilon_0 D_{cog}\ . \end{aligned}$$

Lemma 4.6 can thus be applied, completing the proof. □

4.4. Analysis of RCG for measurement errors in the $\mathcal{SSYNC}$ model. Turning to the semisynchronous model, we observe that the results of Theorem 4.8 also hold true for the $\langle \mathcal{SSYNC}, \mathcal{ERR}\rangle$ model. We start with a lemma aiming to show that in any execution of Algorithm RCG, for any move of a group of robots that produces a shift of the center of gravity, the moment of inertia decreases.

LEMMA 4.9. *For a group of N robots performing Algorithm* RCG *in the $\mathcal{SSYNC}$ model, if at time step t the center of gravity has moved such that $|\bar R_{cog}[t+1]-\bar R_{cog}[t]| \ge \Delta x$ for some Δx, then $I[t]-I[t+1] \ge 2\epsilon_0(1-a)\Delta x D_{cog}[t]$ for some constant $a<1$.*

Proof. Consider a robot i moving along a vector $\bar y^i$ (of size y^i) at time t, and let $\rho^i[t]$ be the calculated maximum error for this robot at time t. Fix

$$\bar a \;=\; \overline{err}^i[t]/\rho^i[t] \qquad \text{and} \qquad \bar b \;=\; \bar v_{cog}^i/\rho^i[t]\ .$$

We therefore have that $a = err^i[t]/\rho^i[t]$ and, since we know that the motion of the robot is of size y^i, it follows that $|\bar b - \bar b/b| = y^i/\rho^i[t]$. Thus, $b = 1 + y^i/\rho^i[t]$. By (6), $err^i \le \varepsilon_{\rm d} D_{max}^i \le \varepsilon_{\rm d} d_{max}^i/(1-\varepsilon_{\rm d})$ (with $\varepsilon' \equiv \sqrt{2(1+\varepsilon_{\rm d})(1-\cos\varepsilon_\theta)+{\varepsilon_{\rm d}}^2}$ replacing $\varepsilon_{\rm d}$ for the $\mathcal{ERR}$ model), while $\rho^i = \epsilon_0 d_{max}^i/(1-\epsilon_0)$. This implies that $a \le \frac{\varepsilon_{\rm d}(1-\epsilon_0)}{\epsilon_0(1-\varepsilon_{\rm d})} < 1$ (where we use the fact that $\epsilon_0 > \varepsilon_{\rm d}$). Also, clearly $b \ge 1$. Hence Lemma 2.1(1) can be applied, yielding

$$(\bar a - \bar b)^2 - (\bar a - \bar b/b)^2 \ge (b-1)^2 + 2(1-a)(b-1) \ge 2(1-a)(b-1) = 2(1-a)y^i/\rho^i[t].$$

Now, $\bar a - \bar b = (\bar R_i[t] - \bar R_{cog}[t])/\rho^i[t]$, and $\bar a - \bar b/b = (\bar R_i[t+1] - \bar R_{cog}[t])/\rho^i[t]$. Thus,

$$(\bar R_i[t] - \bar R_{cog}[t])^2 - (\bar R_i[t+1] - \bar R_{cog}[t])^2 \;\ge\; 2(1-a)y^i\rho^i[t]\ .$$

Note that

$$(7)\qquad \rho^i[t] \;=\; \frac{\epsilon_0}{1-\epsilon_0} d_{max}^i[t] \;\ge\; \epsilon_0 D_{max}^i[t] \;\ge\; \epsilon_0 D_{cog}[t]\ ,$$

and therefore $(\bar{R}_i[t]-\bar{R}_{cog}[t])^2-(\bar{R}_i[t+1]-\bar{R}_{cog}[t])^2 \geq 2(1-a)y^i\epsilon_0 D_{cog}[t]$. The total decrease in I is therefore

$$I[t]-I[t+1] \geq I[t]-I_{\bar{x}}[t] \geq \frac{1}{N}\sum_i 2(1-a)y^i\epsilon_0 D_{cog}[t], \tag{8}$$

with $\bar{x}=\bar{R}_{cog}[t]$.

Now, we know that the center of gravity has moved by at least Δx, and, therefore,

$$\Delta x \leq |\bar{R}_{cog}[t+1]-\bar{R}_{cog}[t]| = \frac{1}{N}\left|\sum_i y^i\right| \leq \frac{1}{N}\sum_i |y^i| \ .$$

Thus, using (8), one obtains $I[t]-I[t+1] \geq 2(1-a)\Delta x\epsilon_0 D_{cog}[t]$. □

We now turn to prove the main theorem for the $\mathcal{SSYNC}$ model.

THEOREM 4.10. *In every execution of Algorithm* RCG *(with ϵ_0 as in Theorem* 4.8*) in the $\langle \mathcal{SSYNC}, \mathcal{ERR}\rangle$ model, the robots converge.*

Proof. The proof of Lemma 4.5 holds for any movement of any robot, and therefore also for any partial robot group making a move. Thus, it also applies to the semi-synchronous model. In Lemma 4.6, it may happen that the robot most distant from the center of gravity is inactive and does not make a move for a number of steps, during which the situation changes and the center of gravity approaches it due to movements taken by the other robots. Hence, we have to deal with the complication arising from the possibility that the most distant robot at some time t' is no longer the most distant when its turn to move arrives at some later time t.

Suppose at time t' this robot, k, was at distance $D_{cog}[t']$ from the center of gravity. Now take $t>t'$ as the time of its next activation. Take $\delta=\frac{1}{3}[1-f(\epsilon_0)]$. If $V^k_{cog}[t] > (1-\delta)D_{cog}[t']$ and $D_{cog}[t] < (1+\delta)D_{cog}[t']$, then $V^k_{cog}[t]/D_{cog}[t] > 1-2\delta$. This implies that robot k can still make a move at time t, since

$$\rho^k[t] \ = \ \frac{\epsilon_0}{1-\epsilon_0}\cdot d^k_{max}[t] \ \leq \ 2\frac{\epsilon_0}{1-\epsilon_0}(1+\varepsilon_{\mathrm{d}})D_{cog}[t] \ < \ \frac{f(\epsilon_0)}{1-2\delta}V^k_{cog}[t] \ < \ V^k_{cog}[t] \ , \tag{9}$$

where the last inequality holds as long as $f(\epsilon_0)<1$. We may now use Lemma 2.1(1), with $b=V^k_{cog}[t]/\rho^k[t] > (1-2\delta)/f(\epsilon_0)$, leading to

$$(\bar{R}_k[t]-\bar{R}_{cog}[t])^2-(\bar{R}_k[t+1]-\bar{R}_{cog}[t])^2 \ \geq \ (v^k_{cog}[t]-\rho^k)^2 \geq \left(\frac{1-2\delta}{f(\epsilon_0)}-1\right)^2\rho^k[t] \ .$$

Equation (7) implies that $\rho^k[t] \geq \epsilon_0 D_{cog}[t] \geq (1-2\delta)\epsilon_0 D^k_{cog}[t']$, and thus

$$I[t+1] \ \leq \ \left[1-\frac{1}{N}\left(\frac{1-2\delta}{f(\epsilon_0)}-1\right)^2[(1-2\delta)\epsilon_0]^{-2}\right]I[t'].$$

If one of the requirements is violated, this means that the center of gravity has moved at least a distance of $\delta D_{cog}[t']$ in some time interval $[t',t_1]\subset[t',t]$. Choose t_1 to be the first time at which the center of gravity has moved at least $\delta D_{cog}[t']$. Then, for every time $t^*\in[t',t_1-1]$, $D_{cog}[t^*]\geq(1-\delta)D_{cog}[t']$. Denote by $\overline{\Delta x}[t^*]$ the change in the center of gravity between cycles t^* and t^*+1. We have

$$\sum_{t^*\in[t',t_1-1]}\Delta x[t^*] \ \geq \ \left|\sum_{t^*\in[t',t_1-1]}\overline{\Delta x}[t^*]\right| \ \geq \ \delta D_{cog}[t'] \ .$$

By Lemma 4.9 we have that for all t^*,

$$I[t^*] - I[t^*+1] \geq 2(1-a)\Delta x[t^*]\epsilon_0 D_{cog}[t^*] \geq 2(1-a)\Delta x[t^*]\epsilon_0(1-\delta)D_{cog}[t'].$$

Therefore, the total improvement in I is

$$\begin{aligned} I[t'] - I[t] \;&\geq\; I[t'] - I[t_1] \;\geq \sum_{t^* \in [t', t_1 - 1]} 2(1-a)\Delta x[t^*]\epsilon_0(1-\delta)D_{cog}[t'] \\ &\geq\; 2(1-a)\delta D_{cog}[t']\epsilon_0(1-\delta)D_{cog}[t'] \;\geq\; 2(1-a)\delta\epsilon_0(1-\delta)I[t']; \end{aligned}$$

hence $I[t] \leq (1-\eta)I[t']$ for some constant $\eta > 0$. Thus, the robots converge. □

5. Handling movement and calculation errors. We now turn to treat the case of movement errors. Assume the robots' motion is inaccurate, where the robot aiming to move a distance d_0 at an angle α_0 will actually move a distance d satisfying $ad_0 < d < bd_0$ at an angle α satisfying $|\alpha - \alpha_0| < \delta$, for constants $0 < a < 1$, $b > 1$, and $\delta > 0$.

As mentioned earlier, another possible type of movement error discussed in the literature is that the robot might halt its movement prematurely (it is commonly assumed that the robot's movement is guaranteed to traverse at least some constant distance s).

Movement distance errors may be readily treated as measurement errors. In fact, movement distance errors are somewhat less severe, as they may not cause the robot to move in the wrong direction but only move an inaccurate distance in the correct direction. Therefore, no limit on the size of the error is needed (other than b being finite and $a > 0$), and the only requirement necessary for ensuring convergence of the algorithm is to set the calibration parameter β to $\beta = 1/b$. We have the following.

THEOREM 5.1. *Robots having movement errors performing Algorithm* `RCG` *will converge to a point.*

Proof. A robot having an angular movement error of $\alpha - \alpha_0 = \theta$ performing algorithm `RCG` will make exactly the same movement as a robot having accurate movement and viewing all other robots with an error of θ in the angle measurement (possibly in addition to any measurement errors included in the model). Therefore, a model with motion angle errors is reducible to a model with $\varepsilon_\theta = \varepsilon_\theta^{\mathrm{mv}}$. In general, if both measurement and movement errors occur, then the model is reducible (for Algorithm `RCG`) to a model with total angle measurement inaccuracy of $\varepsilon_\theta + \varepsilon_\theta^{\mathrm{mv}}$.

To adjust for the motion distance error, the parameter β is modified to $\beta = 1/b$ (or any lower value). Thus, every robot attempts to move to the point $\bar{c}_i = \frac{1}{b}(1 - \rho^i/v^i_{cog}) \cdot \bar{v}^i_{cog}$. This guarantees that the distance travelled is always less than $b\bar{c}_i = (1 - \rho^i/v^i_{cog}) \cdot \bar{v}^i_{cog}$ and at least $a\bar{c}_i = \frac{a}{b}(1 - \rho^i/v^i_{cog}) \cdot \bar{v}^i_{cog}$, a constant multiple of the distance travelled in the original algorithm. Furthermore, since the calculation of ρ^i is not influenced by β, it is guaranteed that any robot that can move in the original (accurate movement) model can also move in the inaccurate movement model. Therefore, using Lemma 2.3, one determines that whenever in the accurate movement model a robot decreases its squared distance from the center of gravity by some amount c, in the inaccurate movement model its squared distance from the center of gravity will decrease by at least ca/b, guaranteeing a constant factor improvement in I. The case presented above in the model definition is equivalent to the case $b \equiv 1 + \varepsilon_{\mathrm{d}}^{\mathrm{mv}}$, $a \equiv 1 - \varepsilon_{\mathrm{d}}^{\mathrm{mv}}$. □

The second possible form of movement inaccuracies is the "premature stopping" model, presented above, in which the robot may fail to move the full distance determined by the algorithm and stop prematurely. This model guarantees, however,

that the robot will complete a movement of at least some constant distance, s, unless the distance determined by the algorithm is less than s, in which case the robot is guaranteed to complete its movement.

THEOREM 5.2. *In the $\mathcal{FSYNC}$ and $\mathcal{SSYNC}$ models, a group of N robots performing algorithm* `RCG` *with premature stopping will converge to a point.*

Proof. We start with the $\mathcal{FSYNC}$ model. Take the robot k farthest from the center of gravity. There are two possibilities for this robot's movement.

1. Robot k completes its movement. This case is analyzed exactly the same as in Theorem 4.7 or Theorem 4.8 (depending on the error model), and I can be shown to decrease by a constant multiplicative factor.
2. Robot k travels some distance $s^* \geq s$ at time t. Assume the robot would have completed the move determined by the algorithm, of some distance $d \leq D_{cog}[t]$. Then, by Theorem 4.7 or Theorem 4.8, $I[t] - I[t+1] \geq \eta(N) I[t]$ for some $\eta(N)$. The ratio μ between the distance travelled by the robot and the distance determined by the algorithm satisfies

$$\mu \;=\; \frac{s^*}{d} \;\geq\; \frac{s}{d} \;\geq\; \frac{s}{D_{cog}[t]} \;.$$

By Lemma 2.3 the decrease in robot k's distance to the center of gravity by the actual movement is at least μ times the decrease due to the desired movement. Thus

$$I[t] - I[t-1] \;\geq\; \mu^2 \eta(N) I \;\geq\; \frac{s^2}{D_{cog}[t]^2} \eta(N) I[t] \;.$$

Since $I[t] \leq D_{cog}[t]^2$, it follows that $I[t] - I[t-1] \geq \eta(N) s^2$.

Thus, at every time step, I is decreased by either a multiplicative or an additive constant. The theorem follows.

In the case of the $\mathcal{SSYNC}$ model, as in the proof of Theorem 4.10, either the farthest robot k is at a distance at least $(1-\delta) D_{cog}[t']$ from the center of gravity when it performs its next move after time t', in which case it induces a multiplicative or an additive constant improvement in I (as in the $\mathcal{FSYNC}$ model above), or the center of gravity has moved a distance of at least $\delta D_{cog}[t']$, in which case I has improved by a multiplicative factor. ∎

Calculation errors and limited accuracy can be modeled in several ways. The most commonly used model assumes that each operand, x_i, in each operation can include an additional error term, ε_{ci}, which satisfies $|\varepsilon_{ci}| \leq \varepsilon_c x_i$ for some ε_c.

We begin with a technical lemma relating inaccuracies in a vector's component with angle inaccuracies.

LEMMA 5.3. *Let $\bar{a}$ be a vector with components (x, y), and $\bar{b}$ be a vector with components (x', y'), where $(1-\varepsilon)x < x' < (1+\varepsilon)x$ and $(1-\varepsilon)y < y' < (1+\varepsilon)y$ for some $0 < \varepsilon < 1$. The angle between $\bar{a}$ and $\bar{b}$ is at most $(\ln(1+\epsilon) - \ln(1-\epsilon))/2$ radians.*

Proof. If $x = 0$ or $y = 0$, then $x' = 0$ or $y' = 0$, respectively, so the angle between $\bar{a}$ and $\bar{b}$ is 0 and the theorem follows immediately. Assume now that $x \neq 0$ and $y \neq 0$ and denote $x' = (1+\alpha)x$ and $y' = (1+\beta)y$, where $-\epsilon < \alpha, \beta < \epsilon$. Notice that $\bar{a}$ and $\bar{b}$ are in the same quadrant. Now choose θ as the angle between $\bar{a}$ and the appropriate axis by the rule

$$\tan\theta = \begin{cases} |x|/|y|, & \alpha > \beta, \\ |y|/|x|, & \alpha \leq \beta, \end{cases}$$

and set θ' to be the angle between the same axis and $\bar{b}$ defined by

$$\tan\theta' = \begin{cases} |x'|/|y'|, & \alpha > \beta, \\ |y'|/|x'|, & \alpha \le \beta. \end{cases}$$

Thus, $\tan\theta' = \frac{1+\alpha}{1+\beta}\tan\theta$ if $\alpha > \beta$ and $\tan\theta' = \frac{1+\beta}{1+\alpha}\tan\theta$ otherwise. Either way, we have $\tan\theta \le \tan\theta' \le \frac{1+\epsilon}{1-\epsilon}\tan\theta$ or

$$\ln\tan\theta \le \ln\tan\theta' \le \ln\tan\theta + \ln(1+\epsilon) - \ln(1-\epsilon). \tag{10}$$

Denote $\theta' = \theta + \Delta\theta$. Since tan is a continuous function with continuous derivative inside each quadrant, we have

$$\begin{aligned} \ln\tan(\theta+\Delta\theta) &= \ln\tan\theta + \left(\frac{d\ln\tan\theta}{d\theta}\right)_{\theta=\theta^*} \cdot \Delta\theta = \ln\tan\theta + \frac{1}{|\cos^2\theta|\tan\theta}\ \Delta\theta \\ &= \ln\tan\theta + \frac{2}{|\sin 2\theta|}\Delta\theta \ \ge\ \ln\tan\theta + 2\Delta\theta, \end{aligned} \tag{11}$$

for some $\theta \le \theta^* \le \theta + \Delta\theta$. From (10) and (11) it follows that the angle $\Delta\theta$ between $\bar{a}$ and $\bar{b}$ satisfies $|\Delta\theta| \le (\ln(1+\epsilon) - \ln(1-\epsilon))/2$. □

THEOREM 5.4. *A group of robots having inaccurate or limited accuracy calculations with $\varepsilon_c < 0.125$ (assuming accurate measurement and movement) executing Algorithm* `RCG` *will converge to a point.*

Proof. We use uppercase letters to represent real quantities and lowercase to represent calculated quantities. For simplicity of notation we assume exact measurements and inaccurate calculations. A combination of the two with limited errors is expected to behave similarly using the same lines of argument.

In step 1 of the calculation in Algorithm `RCG`, the additional errors are equivalent to inaccurate measurements, since each $\bar{v}_j^i$ is augmented with an error term of at most $\varepsilon_c \bar{v}_j^i$. To bound the error, we notice that the calculated $\bar{v}_{cog}^i$ for each robot i is

$$\bar{v}_{cog}^i \ = \ \frac{1}{N}\sum_j (\bar{v}_j^i + \bar{\sigma}_j^i) \ = \ \frac{1}{N}\sum_j (\overline{V}_j^i + \overline{err}^i + \bar{\sigma}_j^i)\ .$$

It is known that $\sigma_j^i \le \varepsilon_c v_j^i \le (1+\varepsilon_d)\varepsilon_c V_j^i$. Defining $\varepsilon_t = (1+\varepsilon_c)(1+\varepsilon_d) - 1$ and assuming the calculation is done by components (so the error bound holds for each component and therefore also for the vector size), it follows that

$$\left|\bar{v}_{cog}^i - \overline{V}_{cog}^i\right| \ = \ \frac{1}{N}\left|\sum_j (\overline{err}^i + \bar{\sigma}_j^i)\right| \ \le \ \frac{1}{N}\sum_j (|\overline{err}^i| + |\bar{\sigma}_j^i|) \ \le \ \frac{1}{N}\sum_j \varepsilon_t V_j^i \ \le \ \varepsilon_t D_{max}\ .$$

This implies that the inaccuracy in the calculated center of gravity appears in exactly the same form as in inaccurate measurements.

Step 2 of Algorithm `RCG` involves a comparison between vectors, which may be considered accurate up to the limited accuracy in the calculation of the vector sizes. This may lead to the calculated d_{max}^i having a relative error of at most ε_c. In the calculation performed in step 3 of the algorithm, another relative error of ε_c may be introduced, and yet another may occur in the calculation of ρ^i/v_{cog}^i in step 4. Therefore, it can be concluded that

$$\frac{\epsilon_0}{1-\epsilon_0}(1-\varepsilon_c)^3 d_{max}^i \ \le \ \rho^i \ \le \ \frac{\epsilon_0}{1-\epsilon_0}(1+\varepsilon_c)^3 d_{max}^i\ .$$

The choice of ϵ_0 should be large enough to ensure that the value of ρ^i resulting from the calculation of step 3 will always be greater than the total error in the target location (discussed below) but small enough to ensure that at least one robot can move at every configuration, i.e., such that the calculated ρ^i satisfies $\rho^i < D_{cog}$. This imposes the conditions $\frac{\epsilon_0}{1-\epsilon_0}(1-\varepsilon_c)^3 > \frac{\varepsilon_c}{1-\varepsilon_c}$ and $\frac{\epsilon_0}{1-\epsilon_0}(1+\varepsilon_c)^3 d^i_{max} < D_{cog}$ for at least one i. Since for at least one robot $d^i_{max} \geq 2(1-\varepsilon_d)D_{cog}$, it follows that we require $\frac{\epsilon_0}{1-\epsilon_0}(1+\varepsilon_c)^3(1-\varepsilon_d) < [2(1-\varepsilon_d)]^{-1}$. That is, we must choose ϵ_0 such that this condition holds.

Errors in step 4 of the algorithm are relative errors in the motion vector and therefore are identical to movement errors, treated in Theorem 5.1. Since the calculated motion vector may contain a relative error of ε_c, leading to a factor of $1+\varepsilon_c$ in the motion vector size, β should be chosen such that $\beta < (1+\varepsilon_c)^{-1}$. By Lemma 5.3, an error of at most $\theta_c = (\ln(1+\varepsilon_c) - \ln(1-\varepsilon_c))/2$ may occur in the angle of motion, which is similar to the error in Theorem 5.1.

The total error in the aimed location of the center of gravity, using Lemma 2.2, is therefore

$$\sqrt{2(1+\varepsilon_t)(1-\cos(\theta_c+\varepsilon_\theta)) + {\varepsilon_t}^2}\; D_{max}\ .$$

In the case of exact measurements, $\varepsilon_d = 0$, ϵ_0 should satisfy

$$\frac{\sqrt{2(1+\varepsilon_c)(1-\cos\theta_c) + {\varepsilon_c}^2}}{(1-\varepsilon_c)^3} \;<\; \frac{\epsilon_0}{1-\epsilon_0} \;<\; \frac{1}{2(1+\varepsilon_c)^3}\ .$$

For these inequalities to allow a solution, the upper bound should be higher than the lower bound. Thus, ε_c should satisfy $\varepsilon_c < 0.126\ldots$. When $\varepsilon_d > 0$, the maximum value of ε_c should be lower accordingly. □

It should be noted that unlike the measurement and movement inaccuracies discussed earlier, calculation errors are rather negligible. In particular, commercially available processors, even low-end ones, can be assumed to introduce very small numerical errors; hence it is safe to assume that for any practical purpose $\varepsilon_c < 10^{-3}$ in any real system. Consequently, the limit above poses no problem in practical applications.

6. Analysis of RCG in the fully asynchronous model.

6.1. Convergence in the one-dimensional case. So far, we have not been able to establish the convergence of Algorithm RCG in the fully asynchronous model. In this section we prove its convergence in the restricted one-dimensional case and with no angle inaccuracies, i.e., in the $\langle \mathcal{ASYNC}, \mathcal{ERR}^- \rangle$ model.

Denote by $\bar{c}_i[t]$ the calculated destination of robot i at time t. If robot i has not gone through a Look yet, or has reached its previous destination, then, by definition, $\bar{c}_i[t] = \bar{R}_i[t]$. Notice that we set $\bar{c}_i[t]$ to be the destination of the robot's motion after the Look phase even if the robot has not yet completed its computation and is still unaware of this destination.

Following are some technical lemmas and definitions used to prove the result when the robots are on a straight line. Define $H[t]$ as the minimum segment containing all robots and destinations at time t.

LEMMA 6.1. *In the $\langle \mathcal{ASYNC}, \mathcal{ERR}^- \rangle$ model, $H[t] \subseteq H[t_0]$ for all times $t \geq t_0$.*

Proof. By the proof of part 2 of Lemma 4.5 it follows that every robot approaches the true center of gravity; i.e., in the one-dimensional case, it always moves in the correct direction towards the center of gravity. Furthermore, the size of its motion is

always an underestimation to the true distance. Therefore, the calculated destination resides between the current location of the robot and the real center of gravity, which is always in the segment. Thus no destination is calculated outside the segment. Therefore, no robot leaves the segment either. ∎

Next, we define the following quantities:

$$\begin{aligned}
\phi_1[t] &= \sum_{i=1}^{N} |\bar{R}_{cog}[t] - \bar{c}_i[t]| \ , \\
\phi_2[t] &= \sum_{i=1}^{N} |\bar{c}_i[t] - \bar{R}_i[t]| \ , \\
\phi[t] &= \phi_1[t] + \phi_2[t] \ , \\
h[t] &= |H[t]| \ , \\
\psi[t] &= \frac{\phi[t]}{2N} + h[t] \ .
\end{aligned}$$

We now claim that ϕ, h, and ψ are nonincreasing functions of time.

LEMMA 6.2. *For every $t_1 > t_0$, $\phi[t_1] \leq \phi[t_0]$.*

Proof. Examine the change in ϕ due to the various robot actions. If a Look operation is performed by robot i at time t, then the destination $\bar{c}_i[t]$ is between the robot and the real center of gravity. Therefore $|\bar{R}_{cog}[t] - \bar{c}_i[t]| + |\bar{c}_i[t] - \bar{c}_i[t]| = |\bar{c}_i[t^*] - \bar{R}_{cog}[t]|$ for any $t^* \in [t', t]$, where t' is the end of the last move performed by robot i. Therefore, ϕ is unchanged by the Look performed.

Now consider some time interval $[t'_0, t'_1] \subseteq [t_0, t_1]$, such that no Look operations were performed during $[t'_0, t'_1]$. Suppose that during this interval each robot i moved a distance Δ_i (where some of these distances may be 0). Then ϕ_2 decreased by $\sum_i \Delta_i$, the maximum change in the center of gravity is $|\bar{R}_{cog}[t_1] - \bar{R}_{cog}[t_0]| \leq \sum_i \Delta_i / N$, and the robots' calculated centers of gravity have not changed. Therefore, the change in ϕ_1 is at most $\phi_1[t_1] - \phi_1[t] \leq \sum_i \Delta_i$. Hence, the sum $\phi = \phi_1 + \phi_2$ cannot increase. ∎

LEMMA 6.3. *ψ is a nonincreasing function of time.*

Proof. By Lemma 6.2, ϕ is nonincreasing. By Corollary 6.1, h is nonincreasing. Therefore their sum is also nonincreasing. ∎

LEMMA 6.4. *$h \leq \psi \leq 2h$.*

Proof. The lower bound is trivial. For the upper bound, notice that ϕ is the sum of $2N$ summands, each of which is at most h (since they all reside in the segment). ∎

We now state a lemma which allows the analysis of the change in ϕ (and therefore also ψ) in terms of the contributions of individual robots.

LEMMA 6.5. *If by the individual action of a robot i alone, in the time interval $[t_0, t_1]$ its contribution to ϕ is δ_i, then $\phi[t_1] \leq \phi[t_0] + \delta_i$.*

Proof. Lemma 6.2 implies that Look actions have no effect on ϕ and therefore can be disregarded. A robot moving a distance Δ_i will always decrease its term in ϕ_2 by Δ_i, and the motions of other robots have no effect on this term. Denote by Δ_j the motions of the other robots. Notice that

$$\left| \bar{R}_{cog} + \frac{\Delta_i}{N} + \frac{1}{N} \sum_{j \neq i} \Delta_j - \bar{c}_k \right| \ \leq \ \left| \bar{R}_{cog} + \frac{\Delta_i}{N} - \bar{c}_k \right| + \frac{1}{N} \sum_{j \neq i} |\Delta_j|.$$

The function ϕ_1 contains N summands, each of which contains a contribution of at most $\frac{1}{N}|\Delta_j|$ from every robot $j \neq i$. Therefore, the total contribution of each robot to ϕ_1 is at most $|\Delta_j|$, which is canceled by the negative contribution of $|\Delta_j|$ to ϕ_2. ∎

LEMMA 6.6. *If at some time t_0, for some $0 < A < 1$, the convex hull of the robot group $H'[t]$ satisfies $|H'[t_0]| \leq (1-A)h[t_0]$, then there exists a time $t > t_0$ such that $\psi[t] \leq (1 - \frac{A}{4N^2})\psi[t_0]$.*

Proof. Take t^* to be the time after t_0 where all robots finished a complete Look-Compute-Move cycle. If for some time $t_1 \in [t_0, t]$ it held that $h[t_1] \leq (1 - \frac{A}{2})h[t_0]$, then $\psi[t_1] < (1 - \frac{A}{4N^2})\psi[t_0]$, and we are done. If no such time (t_1) existed, then at time t_0 at least one robot had its calculated destination at a distance $\frac{A}{4}h[t_0]$ from the convex hull of the robot group. Suppose robot k had the most distant destination from the group, $\Delta_k \geq \frac{A}{4}h[t_0]$. By the movement of robot k alone, the real center of gravity moves a distance $\frac{\Delta_k}{N}$ towards robot k's perceived center of gravity. Therefore, by its motion ψ decreases by $\frac{2\Delta_k}{N^2}$. By Lemma 6.5 the decrease of ψ by the motion of all robots is at least the same, thus proving the claim. ∎

We now proceed to prove the main theorem regarding convergence in the asynchronous model.

LEMMA 6.7. *For all times t_0 there exist a time $t_1 > t_0$ and a constant δ such that $\psi[t_1] \leq (1 - \frac{\delta}{16N^2})\psi[t_0]$.*

Proof. We have established that ψ is a nonincreasing function of time. Now assume that at time t_0, $H[t_0]$ is the convex hull of the locations of the robots and their destinations. Without loss of generality we assume $H[t_0] = [0, 1]$. Take $t^* > t_0$ to be the time when all robots completed at least one full cycle. If at some time $t \in (t_0, t^*]$ the size of the interval occupied by the robots is $h[t^*] \leq 1 - \delta$, we are done by Lemma 6.6.

Suppose now that at all times $t \in (t_0, t^*]$ the robots' interval never shrinks to $1-\delta$. This implies that there exist robots in the intervals $[0, \delta]$ and $[1-\delta, 1]$. Now, for each robot, i, there exists at least one robot, j, with distance at least $V_j^i \geq \frac{1-\delta}{2}$ from it, and this robot is viewed at a distance at least $v_j^i \geq (1-\varepsilon_c)\frac{1-\delta}{2} \geq (1-\epsilon_0)\frac{1-\delta}{2}$. Therefore, it follows that $\rho^i \geq \frac{\epsilon_0(1-\delta)}{2} \geq \frac{\epsilon_0}{2}$, and thus no robot calculates its destination to within $\frac{\epsilon_0}{2}$ of $\{0, 1\}$. If we take $\delta < \frac{\epsilon_0}{2}$, then no robot approaches a distance δ from the boundary.

Now take the leftmost and rightmost robots $k_l = \arg\min_i \bar{R}_i$ and $k_r = \arg\max_i \bar{R}_i$ and take $t_l > t^*$ and $t_r > t^*$ to be their next Look times. By assumption $\bar{R}_{k_l}[t^*] \in [0, \delta]$ and $\bar{R}_{k_r}[t^*] \in [1-\delta, 1]$. Assume, without loss of generality, that $t_l \leq t_r$. Then, for robot k_l, either $\bar{c}_{k_l}[t^*] \geq \delta$ or $\bar{c}_{k_l}[t_l] \geq \delta$, or otherwise robot k_l decided to maintain its position. This means that the real center of gravity at time t_l was within a distance $\rho_{k_l} + err_{k_l}$ of $\bar{R}_{k_l}$. For $\epsilon_0 < 0.2$, $\rho_{k_l} + err_{k_l} \leq (\epsilon_0 + \epsilon_0\frac{1+\epsilon_0}{1-\epsilon_0})D_{max} < \frac{1}{2}$. Take $2\delta < \frac{1}{2} - \epsilon_0 - \epsilon_0\frac{1+\epsilon_0}{1-\epsilon_0}$. Since $\bar{R}_{k_l} \in [0, \delta]$, it follows that the center of gravity at time t_l was in the interval $\bar{R}_{cog}[t_l] \in [0, \frac{1}{2} - \delta]$. Now again for k_r, either $\bar{c}_{k_r}[t^*] \leq 1 - \delta$ or $\bar{c}_{k_r}[t_r] \leq 1 - \delta$ or the center of gravity has moved to the interval $[\frac{1}{2} + \delta, 1]$, in which case the center of gravity moved by at least 2δ approaching $\bar{c}_{k_r}\bar{R}_{k_r}$, leading to the desired decrease in ψ. Thus, no robot enters the δ environment of the boundary, and either one of the robots in this environment has left or ψ decreased by the desired amount. Since the number of robots is finite, after a finite number of such steps it is guaranteed that either ψ decreased by the desired amount or the interval shrunk by at least δ, leading again to the desired decrease in ψ. ∎

Lemma 6.7 yields the following theorem.

THEOREM 6.8. *In the $\langle \mathcal{ASYNC}, \mathcal{ERR}^- \rangle$ model, N robots performing Algorithm* `RCG` *converge on the line.*

We make the following more general conjecture.

CONJECTURE 6.9. *Algorithm* `RCG` *converges in the $\langle \mathcal{ASYNC}, \mathcal{ERR} \rangle$ model for sufficiently small error in the angle and distance measurements.*

6.2. Separating Go_to_COG from RCG in the $\mathcal{ASYNC}$ model. This section establishes the advantage of Algorithm RCG over the basic Algorithm Go_to_COG. In the fully synchronous case there is no justification for using the more involved Algorithm RCG, since the simpler Algorithm Go_to_COG also guarantees convergence as shown above in Lemma 4.2.

However, a gap between the two algorithms can be established in the fully asynchronous model. Specifically, we now show that the ordinary center-of-gravity algorithm Go_to_COG does not converge in the $\langle \mathcal{ASYNC}, \mathcal{ERR}^- \rangle$ model, even when the robots are positioned on a straight line. Contrasting this result with Theorem 6.8 yields the claimed separation between the two algorithms.

THEOREM 6.10. *In the $\langle \mathcal{ASYNC}, \mathcal{ERR}^- \rangle$ model, for every ε_d and $N > 1/\varepsilon_d$ there exists an activation schedule for which Algorithm* Go_to_COG *does not converge, even when the robots are restricted to a line.*

Proof. Start with a configuration in which the first robot is at $\bar{R}_1 = 0$ and the other $N-1$ robots are located at $\bar{R}_i = 1$ for $i = 2, \ldots, N$. Robot 1 makes a Look, and sees the other robots at location $1 + \varepsilon_{\mathrm{d}}$. While robot 1 is at its Compute phase, the other robots go through a long sequence of cycles, leading them to a distance $\delta \ll \varepsilon_{\mathrm{d}}$ from robot 1. Robot 1 now finishes its Compute phase, concludes that the center of gravity is at location $\frac{N-1}{N}(1+\varepsilon_{\mathrm{d}})$, and moves to this location. The robots are now at a setup similar to the initial setup but with a distance of $1 - \frac{1}{N} + \frac{N-1}{N}\varepsilon_{\mathrm{d}} - \delta > 1$ between robot 1 and the rest of the robots. Repeating this process leads to the divergence of the algorithm. ∎

7. Conclusions. We have discussed the feasibility of robot swarm convergence under conditions of inaccuracy in the robots' sensors, calculations, and movements. We have presented several impossibility results under various conditions and have discussed the inadequacy of existing algorithms. We then presented an algorithm based on restricted movement to the center of gravity of the robot swarm and have proved its correctness under a range of the inaccuracy parameters.

We have also shown that in the case of the one-dimensional asynchronous model the restricted center-of-gravity algorithm guarantees convergence, while the standard center-of-gravity algorithm fails to converge under certain circumstances.

Establishing tight bounds for the convergence rate remains an open problem for future study. Our proofs provide only some trivial bounds stemming from the time required to traverse the distance between the two farthest robots. In the model allowing possible premature stopping of a robot after traversing a distance of at least S, this time (in terms of number of steps) is at least the distance between the two farthest robots divided by $2S$. Another trivial bound on the convergence rate of the center-of-gravity algorithm Go_to_COG follows from the ability of the adversary to increase or decrease the distance viewed from a robot to all other robots by a factor of $1 \pm \varepsilon_{\mathrm{d}}$. This implies that even in the fully synchronous model, instead of meeting at the center of gravity, after every step the robots may reach a configuration similar to their previous one, except with all distances multiplied by ε_{d}.

PLOTTABLE REAL NUMBER FUNCTIONS AND THE COMPUTABLE GRAPH THEOREM*

VASCO BRATTKA†

Abstract. The Graph Theorem of classical recursion theory states that a total function on the natural numbers is computable if and only if its graph is recursive. It is known that this result can be generalized to real number functions where it has an important practical interpretation: the total computable real number functions are precisely those which can be effectively plotted with any given resolution. We generalize the Graph Theorem to appropriate partial real number functions and even further to functions defined on certain computable metric spaces. Besides the nonuniform version of the Graph Theorem which logically relates computability properties of the function and computability properties of its graph, we also discuss the uniform version: given a program of a function, can we algorithmically derive a description of its graph? And, vice versa, given a description of the graph, can we derive a program of the function? While the passage from functions to graphs is always computable, the inverse direction from graphs to functions is problematic, and it turns out that the answers to the uniform and the nonuniform questions do not coincide. We prove that in both cases certain topological and computational properties (such as compactness or effective local connectedness) are sufficient for a positive answer, and we provide counterexamples which show that the corresponding properties are not superfluous. Additionally, we briefly discuss the special situation of the linear case.

Key words. computable real number functions, recursive graphs

1. Introduction.

The Graph Theorem of classical recursion theory states that a total function $f : \mathbb{N} \to \mathbb{N}$ on the natural numbers $\mathbb{N} := \{0, 1, 2, \ldots\}$ is computable if and only if its graph, i.e., the set $\text{graph}(f) := \{(n, f(n)) : n \in \mathbb{N}\} \subseteq \mathbb{N} \times \mathbb{N}$, is recursive [17]. In particular, this result shows that the notions of a computable function and of a recursive subset are logically equivalent (in the sense that one could be derived from the other).

We will investigate generalizations of the Graph Theorem from the point of view of computable analysis, which is the Turing machine based theory of computability on real numbers and other topological spaces. Pioneering work on this theory has been presented by Turing [19], Banach and Mazur [1], Lacombe [14, 15], and Grzegorczyk [12]. Recent monographs have been published by Pour-El and Richards [18], Ko [13], and Weihrauch [20].

Roughly speaking, a real number function $f : \mathbb{R}^n \to \mathbb{R}$ is computable in the sense of computable analysis if and only if there exists a Turing machine that transforms better and better rational approximations of x into corresponding approximations of $f(x)$. Based on the well-known physical Church–Turing thesis [17] one might derive a thesis that underlines that this notion has a direct relation to the abilities of physical computers.

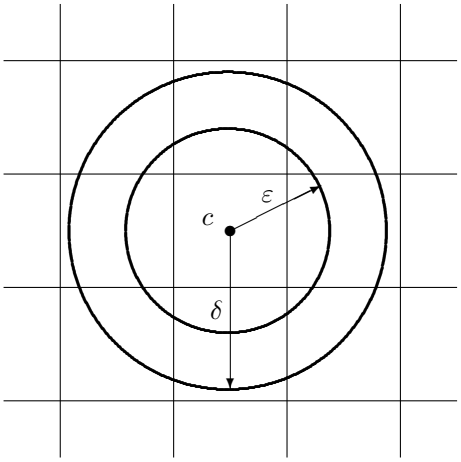

FIG. 1.1. *Determination of a pixel color.*

THESIS 1.1. *A function $f : \mathbb{R}^n \to \mathbb{R}$ is computable if and only if it can be evaluated on a physical computer with arbitrary given precision.*

It is an important feature of computable analysis that the Graph Theorem can be generalized to continuous real number functions $f : \mathbb{R} \to \mathbb{R}$ (as discussed in [20], this fact was first proved for continuous functions $f : [0,1] \to \mathbb{R}$ by Zhou [23]).[1] Thus, a continuous function $f : \mathbb{R} \to \mathbb{R}$ is computable if and only if its graph $\text{graph}(f) := \{(x, f(x)) : x \in \mathbb{R}\} \subseteq \mathbb{R} \times \mathbb{R}$ is recursive.

Here, a closed subset $A \subseteq \mathbb{R} \times \mathbb{R}$ is called *recursive* if and only if its distance function $d_A : \mathbb{R} \times \mathbb{R} \to \mathbb{R}, (x,y) \mapsto \inf_{(a,b)\in A} ||(x,y) - (a,b)||$ is computable (where $||(x,y)|| := \max\{|x|, |y|\}$ denotes the maximum norm). Similarly to the computable functions, the recursive subsets also have a very practical meaning: these are exactly those subsets that can be effectively displayed.

This is easy to see since, given a screen with pixels of a certain size, the color of any given pixel can be determined by computing the distance $d_A(c)$ from the center c of the pixel to the set A (cf. the discussions in [8, 20] or in [9]). If ε is the radius of a ball with center c that completely contains the pixel and if $\delta > \varepsilon$ is the radius of such a ball that is completely contained in the pixel and its immediate eight neighbor pixels, then $d_A(c) < \delta$ could lead to a black pixel and $d_A(c) > \varepsilon$ to a white pixel (depending on which inequality can be verified first; see Figure 1.1). Since in principle the decision cannot be made with infinite precision, there will always remain a certain area of indetermination (in our case the values in the interval $\varepsilon < d_A(c) < \delta$) where the pixel might be white as well as black. However, this procedure guarantees that, on the one hand, the pixel will be black if the set hits the pixel and that, if the pixel is black, then the set does hit at least one of the neighbor pixels or the pixel itself. Altogether, this justifies the derivation of the following thesis.

THESIS 1.2. *A closed subset $A \subseteq \mathbb{R}^2$ is recursive if and only if it can be displayed by a physical computer for an arbitrary given resolution.*

If we apply these considerations to functions $f : \mathbb{R} \to \mathbb{R}$ with a recursive graph, then we obtain that these functions are *plottable* in the sense that there exists an

[1] The Graph Theorem does not hold for real number functions in the so-called BSS model, where it holds only for algebraically closed fields [11].

algorithm that can display any part of the graph for any given resolution. Thus, in particular, any computable function f is plottable.

Unfortunately, this pleasant property does not hold true for partial functions. Topologically, $\mathrm{graph}(f) := \{(x, f(x)) : x \in \mathrm{dom}(f)\} \subseteq \mathbb{R} \times \mathbb{R}$ is not even closed in general if $f :\subseteq \mathbb{R} \to \mathbb{R}$ is a partial computable function. And even if the graph is closed, it is not necessarily recursive, as the following counterexample shows.

Example 1.3. There exists a partial computable function $f :\subseteq \mathbb{R} \to \mathbb{R}$ with $\mathrm{dom}(f) = \mathbb{R} \setminus \mathbb{N}$ such that $\mathrm{graph}(f) \subseteq \mathbb{R} \times \mathbb{R}$ is closed but not recursive closed.

Proof. Let $a : \mathbb{N} \to \mathbb{N}$ be some computable and injective enumeration of a non-recursive set $K = \mathrm{range}(a)$. Let the partial function $t :\subseteq \mathbb{R} \to \mathbb{R}$ be defined by $t(x) := \tan(\pi(x - \frac{1}{2}))$. Then t is a computable function with $\mathrm{dom}(t) = \mathbb{R} \setminus \mathbb{N}$. We will define $f :\subseteq \mathbb{R} \to \mathbb{R}$ by modifying t. Therefore, for any $n \in K = \mathrm{range}(a)$ let $p_n : [n + 2^{-a^{-1}(n)-4}, n + 2^{-a^{-1}(n)-2}] \to \mathbb{R}$ be the polygon defined by the vertices

$$\left(n + 2^{-a^{-1}(n)-4}, t(n + 2^{-a^{-1}(n)-4})\right),$$

$$\left(n + 2^{-a^{-1}(n)-3}, 0\right),$$

$$\left(n + 2^{-a^{-1}(n)-2}, t(n + 2^{-a^{-1}(n)-2})\right).$$

Now we define $f :\subseteq \mathbb{R} \to \mathbb{R}$ by

$$f(x) := \begin{cases} p_n(x) & \text{if } (\exists n \in K)\ x \in [n + 2^{-a^{-1}(n)-4}, n + 2^{-a^{-1}(n)-2}] \\ t(x) & \text{otherwise} \end{cases},$$

for all $x \in \mathbb{R}$. Figure 1.2 displays the graph of f on some interval $[n, n + 1]$ with the graph of t and the alternative part p_n as a dotted line. Then f with $\mathrm{dom}(f) = \mathbb{R} \setminus \mathbb{N}$ is computable since a is computable. On the other hand, $\mathrm{graph}(f) \subseteq \mathbb{R} \times \mathbb{R}$ is obviously closed but not recursive closed, since $K = \mathrm{range}(a)$ is not co–recursively enumerable (co-r.e.) and

$$n \notin K \iff d_{\mathrm{graph}(f)}\left(n + \frac{1}{8}, 0\right) > \frac{1}{8}. \qquad \square$$

The intuitive reason for this inconsistency between computability of partial functions and plottability of their graphs is the following: the computation of a function might take longer when we approach the singularities, while the decision for any pixel in a plot of its graph has to be made after finite time. In other words, the topology of the display does not take care of the singularities. It is worth mentioning that such pathologies are well known in practice. Figure 1.3 shows a standard plot of the tangent function (produced by gnuplot 3.7.3 with default options).

Of course, Example 1.3 exploits the fact that the domain of the function has countably many singularities. However, if one is prepared to accept a counterexample with a graph that is not closed (in $\mathbb{R} \times \mathbb{R}$), then there is such an example even for the domain $(0, 1)$.

Example 1.4. Let $X = (0, 1)$ and $Y = \mathbb{R}$. There exists a continuous and computable function $f : X \to Y$ such that $\overline{\mathrm{graph}(f)} \subseteq \mathbb{R} \times \mathbb{R}$ is not recursive closed. The same holds true for $Y = [0, 1]$.

Proof. Let $(a_i)_{i \in \mathbb{N}}$ be an increasing sequence of positive real numbers that converges to a left but not right computable real number $a < 1$. We define a function

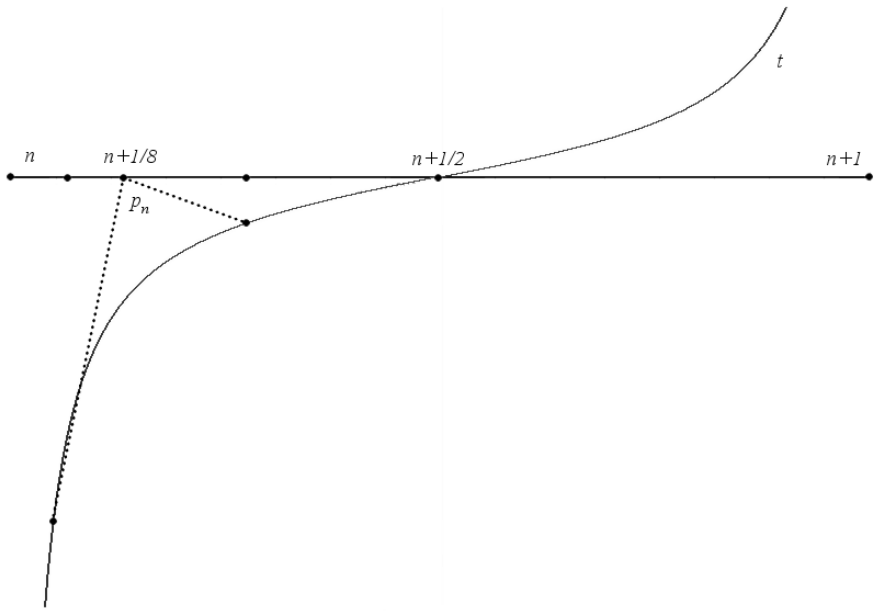

FIG. 1.2. *The function f on $[n, n+1]$ in case of $a^{-1}(n) = 0$.*

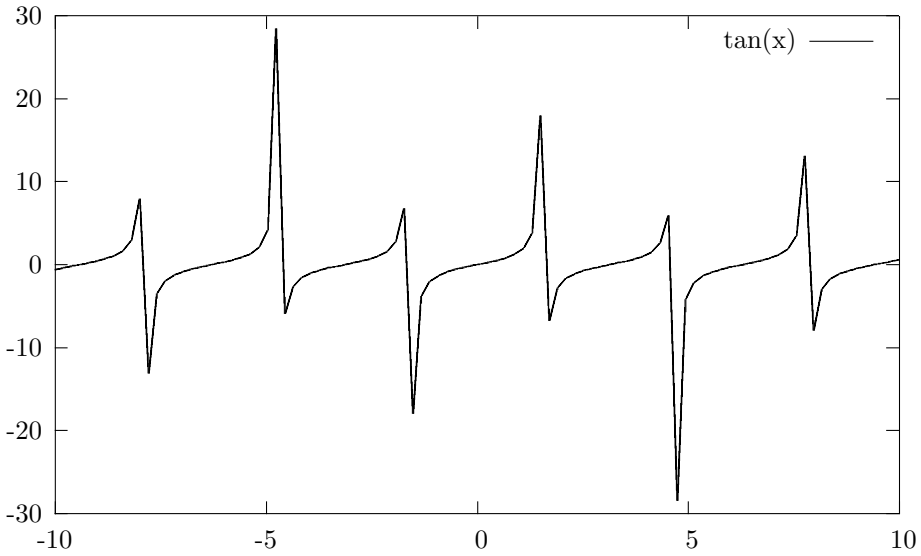

FIG. 1.3. *An unsatisfactory standard plot of the tangent function.*

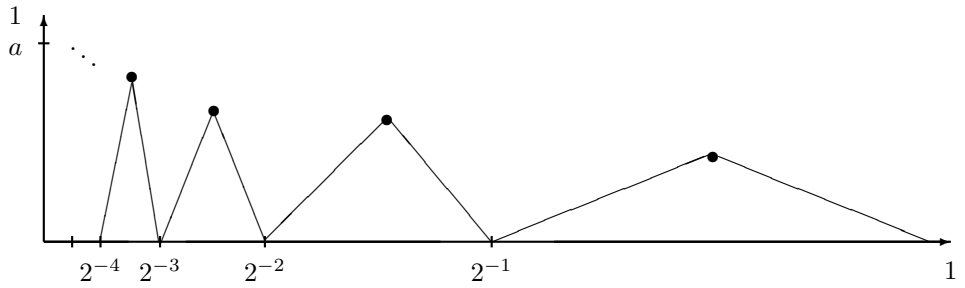

FIG. 1.4. *The function f.*

$f : (0,1) \to \mathbb{R}$ as follows. For any $n \in \mathbb{N}$ let $p_n : [2^{-n-1}, 2^{-n}] \to \mathbb{R}$ be the rational polygon with vertices

$$\left(2^{-n-1}, 0\right), \left(2^{-n-1} + 2^{-n-2}, a_n\right), \left(2^{-n}, 0\right),$$

and let $f(x) := p_n(x)$ for any $x \in [2^{-n-1}, 2^{-n})$ and $n \in \mathbb{N}$. The function f is displayed in Figure 1.4. The function $f : (0,1) \to \mathbb{R}$ defined in this way is obviously computable. However, $\overline{\text{graph}(f)} \cap (\{0\} \times \mathbb{R}) = \{0\} \times [0, a]$, and hence the distance function $\text{dist}_{\overline{\text{graph}(f)}} : \mathbb{R}^2 \to \mathbb{R}$ of $\overline{\text{graph}(f)} \subseteq \mathbb{R}^2$ is not computable. □

These examples show that even for very simple domains $X \subseteq \mathbb{R}$ it is no longer true that the graph of a computable function $f : X \to \mathbb{R}$ is recursive as a subset of $\mathbb{R} \times \mathbb{R}$, and thus it is not necessarily plottable. However, as we will see, it is always true and a property of interest that the graph is recursive, considered as a subset of $X \times \mathbb{R}$. This change of the topology has a practical interpretation in our examples above: when we approach the singularities the resolution has to be increased correspondingly.

Actually, we will even address a slightly more general question in the following (without much extra costs) where we consider as domain of our functions f certain metric spaces X (and in some cases we will consider metric spaces Y for the images as well). In this general case the intuitive notion of plottability is no longer meaningful. However, our formal notion of recursiveness is still available and has important applications in theory. Altogether, we arrive at the following problem.

Nonuniform graph problem. Which computable metric spaces X and Y have the property that for all continuous functions $f : X \to Y$ it holds that f is computable if and only if $\text{graph}(f) = \{(x, f(x)) : x \in X\} \subseteq X \times Y$ is recursive?

This nonuniform question relates a computability property of f just logically to a computability property of $\text{graph}(f)$. But given f, can we effectively compute $\text{graph}(f)$ from f? And, vice versa, given $\text{graph}(f)$, can we effectively compute f? This uniform question can be formulated as follows.

Uniform graph problem. Which computable metric spaces X and Y have the property that the mapping $\text{graph} : \mathcal{C}(X,Y) \to \mathcal{A}(X \times Y), f \mapsto \text{graph}(f)$ and its inverse are computable?

Here, by $\mathcal{C}(X,Y)$ we denote the set of continuous functions $f : X \to Y$ and by $\mathcal{A}(X \times Y)$ the set of closed subsets of $X \times Y$.

We are far from presenting a complete solution of the above questions, and we will mainly concentrate on the case $Y = \mathbb{R}^n$. Even in this special case it appears that the answers to these questions sensitively rely on topological and computational properties of the space X, and even in case of important and well-understood concrete spaces X we obtain a somewhat surprising variety of answers (see Figure 10.1).

We close this introduction with a short survey on the organization of this paper. In section 2 we will provide some basic concepts of computable analysis, and section 3 is devoted to computable metric spaces. To make all the above problems precise, we have, for instance, to define computability on the hyperspace $\mathcal{A}(X \times Y)$ of closed subsets, and we have to define an appropriate notion of recursiveness. The corresponding definitions will be presented in section 4. In section 5 we discuss one direction of the Graph Theorem that we will call the weak Graph Theorem: any total computable function $f : X \to Y$ has a recursive graph, and this holds even uniformly. In sections 6, 7, 8, and 9, we discuss different properties on computable metric spaces that guarantee that the inverse direction of the Graph Theorem holds as well. Such conditions are recursive compactness of the target space or different effective connectedness properties of the source space. Finally, in section 10 we give a survey of our results.

2. Preliminaries from computable analysis. In this section we briefly summarize some notions from computable analysis. For details the reader is referred to [20]. The basic idea of the representation based approach to computable analysis is to represent infinite objects like real numbers, functions, or sets by infinite strings over some alphabet Σ (which should contain at least the symbols 0 and 1). Thus, a *representation* of a set X is a surjective mapping $\delta :\subseteq \Sigma^\omega \to X$, and in this situation we will call (X, δ) a *represented space*. Here Σ^ω denotes the set of infinite sequences over Σ, and the inclusion symbol is used to indicate that the mapping might be partial. If we have two represented spaces, then we can define the notion of a computable function.

DEFINITION 2.1 (computable function). *Let (X, δ) and (Y, δ') be represented spaces. A function $f :\subseteq X \to Y$ is called* (δ, δ')-computable *if there exists some computable function $F :\subseteq \Sigma^\omega \to \Sigma^\omega$ such that $\delta' F(p) = f\delta(p)$ for all $p \in \mathrm{dom}(f\delta)$.*

Of course, we have to define computability of functions $F :\subseteq \Sigma^\omega \to \Sigma^\omega$ to make this definition complete, but this can be done via Turing machines: F is *computable* if there exists some Turing machine which computes for an infinitely long time and transforms each sequence p, written on the input tape, into the corresponding sequence $F(p)$, written on the one-way output tape. Later, we will also need computable multivalued operations $f :\subseteq X \rightrightarrows Y$, which are defined analogously to computable functions by substituting $\delta' F(p) \in f\delta(p)$ for the equation in Definition 2.1 above. The intuition behind the concept of computable multivalued operations f is that a computable realization F selects upon input of a name of x one of the possible values in $f(x)$. In some application $f(x)$ could be, for instance, the set of solutions of some equation with parameter x. This set could have continuum cardinality, but in practice we might just be interested in finding one arbitrary solution $y \in f(x)$. If the represented spaces are fixed or clear from the context, then we will simply call a function or operation f *computable*.

Analogously to the notion of computability we can define the notion of (δ, δ')-*continuity* for single- and multivalued operations by substituting a continuous function $F :\subseteq \Sigma^\omega \to \Sigma^\omega$ for the computable function F in the definitions above. On Σ^ω we use the *Cantor topology*, which is simply the product topology of the discrete topology on Σ. Again we will simply say that the corresponding function is *continuous* if the representations are fixed or clear from the context. If not mentioned otherwise, we will always assume that a represented space is endowed with the final topology induced by its representation.

This will lead to no confusion with the ordinary topological notion of continuity, as long as we are dealing with *admissible* representations. A representation δ of a topological space X is called *admissible* if δ is maximal among all continuous repre-

sentations δ' of X in the sense that the identity $\mathrm{id} : X \to X$ is (δ', δ)-continuous for all such δ'. If δ, δ' are admissible representations of T_0-spaces with countable bases, X, Y, then a function $f :\subseteq X \to Y$ is (δ, δ')-continuous if and only if it is continuous in the ordinary topological sense [20].

Given a represented space (X, δ), we will occasionally use the notions of a *computable sequence* and a *computable point*. A *computable sequence* is a computable function $f : \mathbb{N} \to X$, where we assume that $\mathbb{N} = \{0, 1, 2, \ldots\}$ is represented by $\delta_{\mathbb{N}}(1^n 0^\omega) := n$, and a point $x \in X$ is called *computable* if there is a constant computable function with value x.

Given two represented spaces (X, δ) and (Y, δ'), there is a canonical representation $[\delta, \delta']$ of $X \times Y$ and a representation $[\delta \to \delta']$ of certain functions $f : X \to Y$. If δ, δ' are *admissible* representations of T_0-spaces with countable bases, then $[\delta \to \delta']$ is actually a representation of the set $\mathcal{C}(X, Y)$ of continuous functions $f : X \to Y$. If $Y = \mathbb{R}$, then we write for short $\mathcal{C}(X) := \mathcal{C}(X, \mathbb{R})$. The function space representation can be characterized by the fact that it admits evaluation and type conversion.

PROPOSITION 2.2 (evaluation and type conversion). *Let $(X, \delta), (Y, \delta')$ be admissibly represented T_0-spaces with countable bases, and let (Z, δ'') be a represented space. Then the following hold:*

1. (Evaluation) $\mathrm{ev} : \mathcal{C}(X, Y) \times X \to Y, (f, x) \mapsto f(x)$ *is* $([[\delta \to \delta'], \delta], \delta')$*-computable.*
2. (Type conversion) $f : Z \times X \to Y$, *is* $([\delta'', \delta], \delta')$*-computable, if and only if the function $\check{f} : Z \to \mathcal{C}(X, Y)$, defined by $\check{f}(z)(x) := f(z, x)$, is $(\delta'', [\delta \to \delta'])$-computable.*

The proof of this proposition is based on a version of smn and utm theorems and can be found in [20]. If (X, δ), (Y, δ') are admissibly represented T_0-spaces with countable bases, then in the following we will always assume that $\mathcal{C}(X, Y)$ is represented by $[\delta \to \delta']$. It is known that the computable points in $(\mathcal{C}(X, Y), [\delta \to \delta'])$ are just the (δ, δ')-computable functions $f : X \to Y$ [20]. If (X, δ) is a represented space, then we will always assume that the set of sequences $X^{\mathbb{N}}$ is represented by $\delta^{\mathbb{N}} := [\delta_{\mathbb{N}} \to \delta]$. The computable points in $(X^{\mathbb{N}}, \delta^{\mathbb{N}})$ are just the computable sequences in (X, δ). Moreover, we assume that X^n is always represented by δ^n, which can be defined inductively by $\delta^1 := \delta$ and $\delta^{n+1} := [\delta^n, \delta]$.

3. Computable metric spaces. In this section we will briefly discuss computable metric spaces; see also [4] for further details. First, we just mention that we will denote the *open balls* of a metric space (X, d) by $B(x, \varepsilon) := \{y \in X : d(x, y) < \varepsilon\}$ for all $x \in X$, $\varepsilon > 0$ and correspondingly the *closed balls* by $\overline{B}(x, \varepsilon) := \{y \in X : d(x, y) \leq \varepsilon\}$. Occasionally, we denote complements of sets $A \subseteq X$ by $A^c := X \setminus A$.

DEFINITION 3.1 (computable metric space). *A tuple (X, d, α) is called a* computable metric space *if*

1. *$d : X \times X \to \mathbb{R}$ is a metric on X,*
2. *$\alpha : \mathbb{N} \to X$ is a sequence that is dense in X, and*
3. *$d \circ (\alpha \times \alpha) : \mathbb{N}^2 \to \mathbb{R}$ is a computable (double) sequence in $\mathbb{R}$.*

Here, we tacitly assume that the reader is familiar with the notion of a computable sequence of reals, but we will come back to that point below. Occasionally, we will say for short that X is a *computable metric space*. Obviously, a computable metric space is in particular separable. Given a computable metric space (X, d, α), its *Cauchy representation* $\delta_X :\subseteq \Sigma^\omega \to X$ can be defined by

$$\delta_X(01^{n_0+1}01^{n_1+1}01^{n_2+1}\ldots) := \lim_{i \to \infty} \alpha(n_i)$$

for all n_i such that $(\alpha(n_i))_{i\in\mathbb{N}}$ converges and $d(\alpha(n_i),\alpha(n_j)) \leq 2^{-i}$ for all $j > i$ (and undefined for all other input sequences). In the following we tacitly assume that computable metric spaces are represented by their Cauchy representations. If X is a computable metric space, then it is easy to see that $d : X \times X \to \mathbb{R}$ is computable (see Proposition 5.3 in [4]). All Cauchy representations are admissible with respect to the corresponding metric topology.

An important computable metric space is $(\mathbb{R}, d_{\mathbb{R}}, \alpha_{\mathbb{R}})$ with the Euclidean metric $d_{\mathbb{R}}(x,y) := |x-y|$ and some numbering $\alpha_{\mathbb{R}}\langle i,j,k\rangle := (i-j)/(k+1)$ of the rational numbers $\mathbb{Q}$. Here, $\langle i,j\rangle := \frac{1}{2}(i+j)(i+j+1)+j$ denotes *Cantor pairs* and this definition is extended inductively to finite tuples. For short we will occasionally write $\overline{k} := \alpha_{\mathbb{R}}(k)$. In the following we assume that $\mathbb{R}$ is endowed with the Cauchy representation $\delta_{\mathbb{R}}$ induced by the computable metric space given above. This representation of $\mathbb{R}$ can also be defined if $(\mathbb{R}, d_{\mathbb{R}}, \alpha_{\mathbb{R}})$ just fulfills (1) and (2) of the definition above, and this leads to a definition of computable real number sequences without circularity. Occasionally, we will also use the represented space $(\mathbb{Q}, \delta_{\mathbb{Q}})$ of rational numbers with $\delta_{\mathbb{Q}}(1^n0^\omega) := \alpha_{\mathbb{R}}(n) = \overline{n}$. We close this section with a brief discussion of metric product spaces.

PROPOSITION 3.2 (product spaces). *If (X,d,α), (Y,d',α') are computable metric spaces, then the product space $(X\times Y, d'', \alpha'')$, defined by*

$$d''((x,y),(x',y')) := \max\{d(x,x'),d'(y,y')\} \text{ and } \alpha''\langle i,j\rangle := (\alpha(i),\alpha'(j)),$$

is a computable metric space, too, and the canonical projections of the product space $\mathrm{pr}_1 : X\times Y \to X$ and $\mathrm{pr}_2 : X\times Y \to Y$ are computable.

Particularly, the corresponding Cauchy representations $\delta_{X\times Y}$ and $[\delta_X,\delta_Y]$ are computably equivalent. In the following we will tacitly use the computable metric spaces $\mathbb{R}^n$, $\{0,1\}^{\mathbb{N}}$, and $\mathbb{N}^{\mathbb{N}}$, defined in the standard way.

4. Hyperspaces of closed subsets. In this section we want to introduce computability on the hyperspace of closed subsets of computable metric spaces. At this point we have to carefully consider the fact that different equivalent characterizations of the notion of a recursive closed subset $A \subseteq \mathbb{R}^n$ split into inequivalent notions if we generalize them to computable metric spaces. The logical relation between several notions of effectivity of closed subsets of metric spaces is illustrated in Figure 4.1.

The displayed results have been obtained in [7] from a very uniform point of view and each arrow in the diagram indicates not only an implication but also an effective reducibility. Below, we will precisely define the notions that are relevant for the present paper. In case of Euclidean space (and certain other computable metric spaces) the vertical arrows can be reversed, and thus the three horizontal layers of the diagram collapse [8]. However, some examples prove that these notions have to be distinguished in the general case of computable metric spaces [7, 3]. If we consider a subset $A \subseteq \mathbb{N}$ as a closed subset of $\mathbb{R}$ (embedded in the canonical way), then the set is recursively enumerable (r.e.), co-r.e., and recursive in the classical sense if and

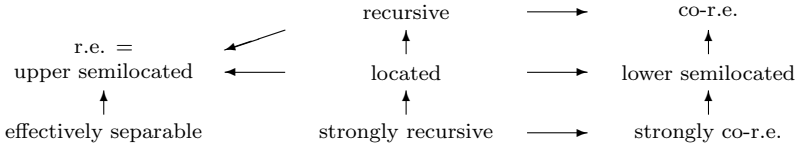

FIG. 4.1. *Notions of effectivity for closed subsets of computable metric spaces.*

only if it is r.e., co-r.e., and recursive in the metric sense, respectively. Thus, all the displayed notions can be considered as formal generalizations of the corresponding classical notions of r.e., co-r.e., and recursive sets.

Now the following question appears: Which of these notions fit together with the Graph Theorem? It could happen, for instance, that the graph of a computable function is recursive (but not strongly recursive in general), while only continuous functions with a strongly recursive graph are computable in general. However, our results show that this does not happen and actually the notion of "recursive" is the one which optimally fits the Graph Theorem. In the following definition we start to define corresponding hyperspace representations. Such representations have been studied in the Euclidean case in [8, 20] and for the metric case in [7].

DEFINITION 4.1 (hyperspace of closed subsets). *Let (X, d, α) be a computable metric space. We endow the hyperspace $\mathcal{A}(X) := \{A \subseteq X : A \text{ closed}\}$ of closed subsets with the representation $\delta^<_{\mathcal{A}(X)}$, defined by*

$$\delta^<_{\mathcal{A}(X)}(01^{\langle n_0,k_0\rangle+1}01^{\langle n_1,k_1\rangle+1}01^{\langle n_2,k_2\rangle+1}\ldots) = A$$

$$:\iff \{(n,k) : A \cap B(\alpha(n),\overline{k}) \neq \emptyset\} = \{(n_i,k_i) \in \mathbb{N}^2 : i \in \mathbb{N}\},$$

and with the representation $\delta^>_{\mathcal{A}(X)}$, defined by

$$\delta^>_{\mathcal{A}(X)}(01^{\langle n_0,k_0\rangle+1}01^{\langle n_1,k_1\rangle+1}01^{\langle n_2,k_2\rangle+1}\ldots) := X \setminus \bigcup_{i=0}^{\infty} B(\alpha(n_i),\overline{k_i}).$$

The intuition behind the representation $\delta^<_{\mathcal{A}(X)}$ is that a closed set A is represented by a list of positive information on the set A. Such positive pieces of information are just open rational balls. Analogously, $\delta^>_{\mathcal{A}(X)}$ represents closed sets A by negative information. A name of A is just a list of open rational balls whose union exhausts the complement of A. Whenever we have two representations δ, δ' of some set, we can define the *infimum* $\delta \sqcap \delta'$ of δ and δ' by $(\delta \sqcap \delta')\langle p,q\rangle = x :\iff \delta(p) = x$ and $\delta'(q) = x$. We use the short notation $\mathcal{A}_< = \mathcal{A}_<(X) = (\mathcal{A}_<(X), \delta^<_{\mathcal{A}(X)})$, $\mathcal{A}_> = \mathcal{A}_>(X) = (\mathcal{A}_>(X), \delta^>_{\mathcal{A}(X)})$, and $\mathcal{A} = \mathcal{A}(X) = (\mathcal{A}(X), \delta^<_{\mathcal{A}(X)} \sqcap \delta^>_{\mathcal{A}(X)})$ for the corresponding represented spaces. For the computable points of these spaces special names are used.

DEFINITION 4.2 (r.e. and recursive sets). *Let X be a computable metric space and let $A \subseteq X$ be a closed subset.*

(1) *A is called* r.e. closed *if A is a computable point in $\mathcal{A}_<(X)$.*
(2) *A is called* co-r.e. closed *if A is a computable point in $\mathcal{A}_>(X)$.*
(3) *A is called* recursive closed *if A is a computable point in $\mathcal{A}(X)$.*

Intuitively, a set A is r.e. closed if we can effectively enumerate all rational open balls that intersect the set, and A is called co-r.e. closed if we can enumerate sufficiently many open rational balls whose union is the complement of A. Finally, A is called recursive closed if it has both properties. We continue this section with some helpful results on hyperspaces, which follow directly from results in [7]. The first result states that we can represent closed subsets by preimages of continuous functions. It is an effective version of the statement that closed subsets of metric spaces coincide with the functional closed subsets.

PROPOSITION 4.3 (functional closed subsets). *Let X be a computable metric space. The map $Z : \mathcal{C}(X,\mathbb{R}) \to \mathcal{A}_>(X), f \mapsto f^{-1}\{0\}$ is computable and admits a computable right-inverse $\mathcal{A}_>(X) \rightrightarrows \mathcal{C}(X,\mathbb{R})$.*

The second result can be considered as an effective version of the statement that closed subsets of separable metric spaces are separable. Here and in the following $\overline{A}$ denotes the topological closure of a subset $A \subseteq X$ of some topological space X.

PROPOSITION 4.4 (separable closed subsets). *Let X be a computable metric space. The mapping $\overline{\text{range}} : X^{\mathbb{N}} \to \mathcal{A}_<(X), (x_n)_{n\in\mathbb{N}} \mapsto \overline{\{x_n : n \in \mathbb{N}\}}$ is computable and if X is complete, then it admits a computable multivalued partial right-inverse $\subseteq \mathcal{A}_<(X) \rightrightarrows X^{\mathbb{N}}$, defined for all nonempty closed subsets.*

We close this section with the definition of the remaining notions of effectivity for closed subsets that we are going to use in this paper.

DEFINITION 4.5 (strongly recursive and located subsets). *Let (X, d, α) be a computable metric space and let $A \subseteq X$ be a closed subset. Then the following hold:*

1. *A is called* strongly co-r.e. closed *if $\{\langle n, k\rangle \in \mathbb{N} : A \cap \overline{B}(\alpha(n), \overline{k}) = \emptyset\}$ is r.e.*
2. *A is called* strongly recursive closed *if A is r.e. closed and strongly co-r.e. closed.*
3. *A is called* located *if $A = \emptyset$ or the distance function $d_A : X \to \mathbb{R}, x \mapsto \inf_{y\in X} d(x, y)$ of A is computable.*

The definition of locatedness can even be applied to sets that are not closed.

5. The weak Graph Theorem. In this section we will study the easy direction of the Graph Theorem, and we will discuss a number of counterexamples that limit the possibilities for the problematic direction. We immediately obtain the following positive result, which is based on Propositions 4.4 and 4.3.

THEOREM 5.1 (weak Graph Theorem). *Let X and Y be computable metric spaces. The mapping $\text{graph} : \mathcal{C}(X, Y) \to \mathcal{A}(X \times Y), f \mapsto \text{graph}(f)$ is computable.*

Proof. We consider the computable metric spaces (X, d, α), (Y, d', β). Then, $\alpha : \mathbb{N} \to X$ is a computable function such that $\overline{\text{range}(\alpha)} = X$. If $f : X \to Y$ is continuous, then $S : X \to X \times Y, x \mapsto (x, f(x))$ is continuous, too, and because of continuity of S we obtain that $\text{range}(S\alpha)$ is dense in $\text{range}(S) = \text{graph}(f)$. Using evaluation and type conversion as well as Proposition 4.4, it follows that $\text{graph} : \mathcal{C}(X, Y) \to \mathcal{A}_<(X \times Y)$ is computable.

Now $U : X \times Y \to \mathbb{R}, (x, y) \mapsto d'(f(x), y)$ is continuous, since $f : X \to Y$ and the metric $d' : Y \times Y \to \mathbb{R}$ are continuous, and we obtain

$$U(x, y) = 0 \iff d'(f(x), y) = 0 \iff f(x) = y \iff (x, y) \in \text{graph}(f).$$

Thus $U^{-1}\{0\} = \text{graph}(f)$ and evaluation together with type conversion and Proposition 4.3 allow us to conclude that $\text{graph} : \mathcal{C}(X, Y) \to \mathcal{A}_>(X \times Y)$ is computable. Altogether, this shows that $\text{graph} : \mathcal{C}(X, Y) \to \mathcal{A}(X \times Y)$ is computable. □

Unfortunately, the partial inverse graph^{-1} is not continuous in general, as the following result shows. Here and in the following we write $w \sqsubseteq p$ if w is a finite *prefix* of p.

PROPOSITION 5.2. *The function $\text{graph}^{-1} :\subseteq \mathcal{A}(X \times \mathbb{R}) \to \mathcal{C}(X)$ is discontinuous in case of Cantor space $X = \{0, 1\}^{\mathbb{N}}$.*

Proof. Let $f_n : \{0, 1\}^{\mathbb{N}} \to \mathbb{R}$ be defined by

$$f_n(p) := \begin{cases} n + 1 & \text{if } 0^n \sqsubseteq p, \\ 0 & \text{otherwise} \end{cases}$$

for all $n \in \mathbb{N}$ and $p \in \{0, 1\}^{\mathbb{N}}$. Then $(f_n)_{n\in\mathbb{N}}$ is a sequence in $\mathcal{C}(\{0, 1\}^{\mathbb{N}})$ that does not converge, but $(\text{graph}(f_n))_{n\in\mathbb{N}}$ converges in $\mathcal{A}(\{0, 1\}^{\mathbb{N}} \times \mathbb{R})$ to $A := \{0, 1\}^{\mathbb{N}} \times \{0\}$ (recall that $\mathcal{A}(\{0, 1\}^{\mathbb{N}} \times \mathbb{R})$ is endowed with the final topology induced by the representation

$\delta^{<}_{\mathcal{A}(\{0,1\}^{\mathbb{N}}\times\mathbb{R})} \sqcap \delta^{>}_{\mathcal{A}(\{0,1\}^{\mathbb{N}}\times\mathbb{R})}$, which means that a sequence $(A_n)_{n\in\mathbb{N}}$ converges in this space to A if and only if for any rational ball $B(x,r)$ with $A \cap B(x,r) \neq \emptyset$ it follows that $A_n \cap B(x,r) \neq \emptyset$ for almost all n and for any closed rational ball $\overline{B}(x,r)$ with $A \cap \overline{B}(x,r) = \emptyset$ it follows that $A_n \cap \overline{B}(x,r) = \emptyset$ for almost all n; in other words, $(A_n)_{n\in\mathbb{N}}$ converges to A if any positive or negative information on A is shared by almost all sets in the sequence). □

Thus, the uniform version of the Graph Theorem does not hold true in general, not even for compact computable metric spaces X. However, as Corollary 7.3 will show, this fact cannot be used to construct a computable counterexample for the nonuniform case. Such a nonuniform counterexample can be obtained if we omit compactness, as the following example shows.

Example 5.3. Let $X = \mathbb{N}^{\mathbb{N}}$ be the Baire space. There exists a continuous but noncomputable function $f : X \to \mathbb{R}$ such that $\mathrm{graph}(f) \subseteq X \times \mathbb{R}$ is strongly recursive closed. The same holds in case of $X = \mathbb{N}\{0,1\}^{\mathbb{N}}$.

Proof. Let $a : \mathbb{N} \to \mathbb{N}$ be some computable and injective enumeration of a nonrecursive set $K = \mathrm{range}(a)$. Define $f : \mathbb{N}^{\mathbb{N}} \to \mathbb{R}$ by

$$f(np) := \begin{cases} k+1 & \text{if there exists some } k \text{ with } a(k) = n \text{ and } 0^k \sqsubseteq p, \\ 0 & \text{otherwise} \end{cases}$$

for all $p \in \mathbb{N}^{\mathbb{N}}$ and $n \in \mathbb{N}$. Then f is continuous but noncomputable since $K = \mathrm{range}(a)$ is not co-r.e. and

$$n \notin K \iff f(n0^\omega) < 1.$$

Moreover,

$$\begin{aligned} &\Big(w\mathbb{N}^{\mathbb{N}} \times (r,s)\Big) \cap \mathrm{graph}(f) \neq \emptyset \\ \iff &(\exists n,k \geq 0, j \geq 1)\Big(\Big((w \sqsubseteq n0^k \text{ or } n0^k \sqsubseteq w) \text{ and } a(k) = n \text{ and } k+1 \in (r,s)\Big) \text{ or} \\ &\qquad \Big((w = n0^k \text{ or } n0^k j \sqsubseteq w) \text{ and } n \notin \{a(0),\ldots,a(k)\} \text{ and } 0 \in (r,s)\Big)\Big) \end{aligned}$$

for all $w \in \mathbb{N}^*$ and $r,s \in \mathbb{Q}$ with $r \leq s$. Since a is computable and only finitely many values n,k,j have to be checked, it follows that the stated property is recursive in r,s, and w. Particularly, $\mathrm{graph}(f)$ is r.e. closed. Analogously, the equivalence also holds with $[r,s]$ substituted for (r,s) in all of its three incidences. As the property is recursive, its negation is in particular r.e. Thus, $\mathrm{graph}(f)$ is also strongly co-r.e. closed. Altogether, $\mathrm{graph}(f)$ is strongly recursive closed. The proof for the case $X = \mathbb{N}\{0,1\}^{\mathbb{N}}$ is the same. □

Altogether, this shows that the problematic direction of the Graph Theorem does not hold in general—neither in the uniform case nor in the nonuniform case. The previous example additionally shows that in general it does not help to use the stronger notion of "strongly recursive closed subsets" for the problematic direction (not even in the nonuniform case).

Finally, we ask whether the positive result of this section could be improved by obtaining a stronger computability property of the graph. On the one hand, results of Cenzer and Remmel show that there is a computable function $f : \mathbb{N}^{\mathbb{N}} \to \mathbb{N}^{\mathbb{N}}$ such that $\mathrm{graph}(f)$ is not strongly recursive (see Corollary 4.6 in [10]). On the other hand, a reinterpretation of Examples 1.3 and 1.4 shows that the graph of a computable

function is not located in general. For the reformulation we consider $X := \mathbb{R} \setminus \mathbb{N}$ or $X = (0,1)$ as a computable metric subspace of $\mathbb{R}$, endowed with the restriction of the Euclidean metric to $X \times X$.

Example 5.4. Consider $X = \mathbb{R} \setminus \mathbb{N}$ or $X = (0,1)$ as a computable metric subspace of $\mathbb{R}$ endowed with the restriction of the Euclidean metric. There exists a computable function $f : X \to \mathbb{R}$ such that $\mathrm{graph}(f) \subseteq X \times \mathbb{R}$ is not located.

Since $\mathrm{graph}(f)$ need not be closed as a subset of $\mathbb{R} \times \mathbb{R}$, we could even obtain the same result with $[0,1]$ as the target space instead of $\mathbb{R}$ (as Example 1.4 shows). The reader should notice the fine distinctions: $\mathrm{graph}(f)$ is recursive as a closed subset of $X \times \mathbb{R}$ by Theorem 5.1, but it is not recursive as a closed subset of $\mathbb{R} \times \mathbb{R}$ in Example 1.3. Moreover, it is not located as a subset of $X \times \mathbb{R}$ and thus, in particular, not strongly recursive in the same sense (however, there is a different but equivalent metric on X that yields the aforementioned properties). Therefore, Theorem 5.1 formulates the best possible general result (with respect to the computability properties of subsets given in Figure 4.1).

6. Compact target spaces. In this section we want to prove that the inverse graph^{-1} of the graph mapping becomes computable if the target space is effectively compact in a certain sense. We start with the definition of some effectiveness notions for compact subsets (see [7]).

Definition 6.1 (recursive compact sets). *Let (X, d, α) be a computable metric space. A subset $K \subseteq X$ is called* co-r.e. compact *if it is compact and the set*

$$\left\{ \langle \langle n_0, k_0 \rangle, \langle n_1, k_1 \rangle, \ldots, \langle n_j, k_j \rangle, j \rangle \in \mathbb{N} : K \subseteq \bigcup_{i=0}^{j} B(\alpha(n_i), \overline{k_i}) \right\}$$

is r.e. Moreover, a subset $K \subseteq X$ is called recursive compact *if it is both r.e. closed and co-r.e. compact.*

One can prove that, for computable metric spaces that fulfill certain additional properties, a compact subset $K \subseteq X$ is co-r.e. compact if and only if it is co-r.e. closed [7]. We will call a computable metric space Y *recursive compact* if it is recursive compact as a subset of itself. Any computable metric space Y that is co-r.e. compact as a subset of itself is automatically recursive compact, since any computable metric space is r.e. closed as a subset of itself. To prepare for the main result of this section, we prove two lemmas.

Lemma 6.2. *Let X, Y be computable metric spaces. Then the section map*

$$\mathrm{sec} : \mathcal{A}_>(X \times Y) \times X \to \mathcal{A}_>(Y), (A, x) \mapsto A_x := \{y \in Y : (x, y) \in A\}$$

is computable.

Proof. Let $A \subseteq X \times Y$ be a closed subset, and let $(x_i, y_i) \in X \times Y$ and $r_i \in \mathbb{Q}$ for all $i \in \mathbb{N}$ be points such that $\bigcup_{i=0}^{\infty} B((x_i, y_i), r_i) = (X \times Y) \setminus A$. Then one directly obtains $\bigcup \{B(y_i, r_i) : i \in \mathbb{N} \text{ and } x \in B(x_i, r_i)\} = Y \setminus A_x$. Since the property "$x \in B(x_i, r_i)$" is r.e., the claim follows. □

The following lemma will be formulated slightly more generally than necessary for the proof of Theorem 6.4 (the case $Z \neq Y$ will be used in order to prove Proposition 7.2 in the next section).

Lemma 6.3. *Let Y be a computable metric space, and let $Z \subseteq Y$ be recursive compact. The injection map $\mathrm{in}_Z : Z \to \mathcal{A}_>(Y), y \mapsto \{y\}$ and its partial inverse $\mathrm{in}_Z^{-1} :\subseteq \mathcal{A}_>(Y) \to Z$ are computable.*

Proof. Consider the computable metric space (Y, d, α). Since Z is r.e. closed we can consider it as a computable metric subspace $(Z, d|_{Z\times Z}, \beta)$ of Y. Without loss of generality we can assume $\text{range}(\beta) \subseteq \text{range}(\alpha)$. Computability of the injection map in_Z follows directly since

$$Y \setminus \{y\} = \bigcup \{B(\alpha(n), \overline{k}) : n, k \in \mathbb{N}, \text{ and } d(y, \alpha(n)) > \overline{k}\}$$

for all $y \in Y$. Now let $y \in Z$ and assume that $x_i \in \text{range}(\alpha)$ and $r_i \in \mathbb{Q}$ for all $i \in \mathbb{N}$ are points such that $Y \setminus \{y\} = \bigcup_{i=0}^{\infty} B(x_i, r_i)$. Then

$$y \in B(x, r) \iff Z \subseteq B(x, r) \cup \bigcup_{i=0}^{\infty} B(x_i, r_i)$$

$$\iff (\exists j) Z \subseteq B(x, r) \cup \bigcup_{i=0}^{j} B(x_i, r_i)$$

for all $x \in \text{range}(\beta)$ and $r \in \mathbb{Q}$ with $r > 0$, where the last equivalence holds since Z is compact. Since Z is even co-r.e. compact, it follows that in_Z^{-1} is computable. □

Using the previous two lemmas we can now prove the main result of this section.

THEOREM 6.4 (compact Graph Theorem). *Let X and Y be computable metric spaces and let Y be co-r.e. compact. The graph map* $\text{graph} : \mathcal{C}(X, Y) \to \mathcal{A}_>(X \times Y)$, $f \mapsto \text{graph}(f)$ *as well as its partial inverse*

$$\text{graph}^{-1} :\subseteq \mathcal{A}_>(X \times Y) \to \mathcal{C}(X, Y)$$

are computable.

Proof. The first part of the claim follows from the weak Graph Theorem, Theorem 5.1. Now any continuous function $f : X \to Y$ can be represented as

$$f(x) = \text{in}_Y^{-1} \circ \text{sec}(\text{graph}(f), x)$$

for any $x \in X$, where $\text{sec} : \mathcal{A}_>(X \times Y) \times X \to \mathcal{A}_>(Y)$ and $\text{in}_Y : Y \to \mathcal{A}_>(Y)$ are the mappings defined in Lemmas 6.2 and 6.3. Since sec and in_Y^{-1} are computable, it follows by type conversion that graph^{-1} is computable. □

As a corollary of Theorems 5.1 and 6.4 we immediately obtain the following nonuniform version of the Graph Theorem.

COROLLARY 6.5. *Let X, Y be computable metric spaces, let Y be co-r.e. compact, and let $f : X \to Y$ be a (continuous) function. Then f is computable if and only if* $\text{graph}(f)$ *is co-r.e. closed and if and only if* $\text{graph}(f)$ *is recursive closed.*

The formula in the proof of Theorem 6.4 additionally shows that f is automatically continuous whenever $\text{graph}(f)$ is closed (under the assumptions of the previous corollary). Hence, the corollary remains true without the word "continuous." The previous corollary has been proved directly in case of $X = Y = [0, 1]$ and $X = Y = \{0, 1\}^{\mathbb{N}}$ by Cenzer and Remmel (see Theorem 4.7 in [10]). In these cases one can even replace co-r.e. by strongly co-r.e. Proposition 5.2 and Example 5.3 show that the compactness conditions are not superfluous in the previous results. The following example shows that co-r.e. closed graphs cannot be replaced by r.e. closed graphs in the previous corollary.

Example 6.6. Let $X = Y = [0, 1]$. There exists a continuous but noncomputable function $f : X \to Y$ such that $\text{graph}(f) \subseteq X \times Y$ is r.e. closed. The same holds in case of $X = Y = \mathbb{R}$.

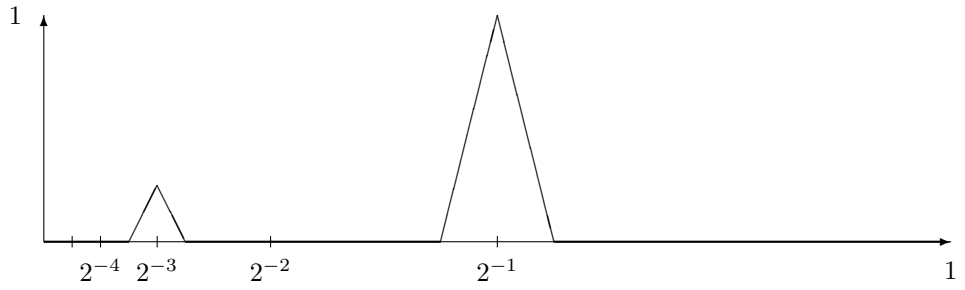

FIG. 6.1. *The function f in case of $a(0) = 2$, $a(1) = 0$ and $1, 3, 4, 5, 6, \ldots \notin K$.*

Proof. Let $a : \mathbb{N} \to \mathbb{N}$ be some computable and injective enumeration of a non-recursive set $K = \text{range}(a)$. We define a function $f : [0,1] \to [0,1]$ as follows. For any $n \in K = \text{range}(a)$ let $p_n : [2^{-n-1} - 2^{-n-3}, 2^{-n-1} + 2^{-n-3}] \to \mathbb{R}$ be the rational polygon with vertices

$$\left(2^{-n-1} - 2^{-n-3}, 0\right), \left(2^{-n-1} - 2^{-n-3-a^{-1}(n)}, 0\right), \left(2^{-n-1}, 2^{-n}\right),$$
$$\left(2^{-n-1} + 2^{-n-3-a^{-1}(n)}, 0\right), \left(2^{-n-1} + 2^{-n-3}, 0\right),$$

and let

$$f(x) := \begin{cases} p_n(x) & \text{if there exists some } n \in \text{range}(a) = K \text{ with} \\ & x \in [2^{-n-1} - 2^{-n-3}, 2^{-n-1} + 2^{-n-3}], \\ 0 & \text{otherwise} \end{cases}$$

for all $x \in [0,1]$; see Figure 6.1.

It is easy to see that f is continuous and $\text{graph}(f) \subseteq [0,1] \times [0,1]$ is r.e. closed since a is computable. On the other hand, f is not computable, since $K = \text{range}(a)$ is not co-r.e. and

$$n \notin K \iff f\left(2^{-n-1}\right) < 2^{-n}. \qquad \square$$

Similar counterexamples have been presented by Cenzer and Remmel (also for the case $X = Y = \mathbb{N}^{\mathbb{N}}$; see Theorem 4.8 in [10]). As a further corollary of Theorems 5.1 and 6.4, we can formulate a uniform version of the statement that negative information on the graph of a continuous function with compact target can be translated into positive information.

COROLLARY 6.7. *Let X, Y be computable metric spaces and let Y be co-r.e. compact. Then the identity* $\text{id} : \mathcal{A}_>(X \times Y) \to \mathcal{A}(X \times Y), A \mapsto A$, *restricted to such subsets $A \subseteq X \times Y$ that are graphs of (continuous) functions $f : X \to Y$, is computable.*

The following proposition shows that this does not hold in the general case of arbitrary computable metric spaces Y.

PROPOSITION 6.8. *The function* $\text{graph}^{-1} :\subseteq \mathcal{A}_>(X \times Y) \to \mathcal{C}(X, Y)$ *is discontinuous in case of the unit interval $X = [0,1]$ and $Y = \mathbb{R}$. The same holds true with $\mathcal{A}_<$ instead of $\mathcal{A}_>$ (and in this case one can even choose $Y = [0,1]$).*

Proof. Now let $f_n : [0,1] \to \mathbb{R}$ be defined by $f_n(x) := n$ for all $x \in [0,1]$ and $n \in \mathbb{N}$. Then $(f_n)_{n \in \mathbb{N}}$ is a sequence in $\mathcal{C}[0,1]$ that does not converge, but $(\text{graph}(f_n))_{n \in \mathbb{N}}$

converges in $\mathcal{A}_>([0,1]\times\mathbb{R})$ to $A := [0,1]\times\{0\}$ (since any negative information on A is shared by almost all sets in the sequence; we mention that $\mathcal{A}_>([0,1]\times\mathbb{R})$ is not a Hausdorff space, and hence limits of converging sequences are not uniquely determined, and the given limit A is just one of many possible limits). This proves the claim for $\mathcal{A}_>$.

Let $f_n : [0,1] \to \mathbb{R}$ be defined by

$$\operatorname{graph}(f_n) := \Big\{(x, 2^{n+1}x) : x \in [0, 2^{-n-1}]\Big\}$$
$$\cup\ \Big\{(x, 2 - 2^{n+1}x) : x \in [2^{-n-1}, 2^{-n}]\Big\} \cup \Big([2^{-n}, 1]\times\{0\}\Big).$$

Then $(f_n)_{n\in\mathbb{N}}$ is a sequence of continuous functions in $\mathcal{C}[0,1]$ that does not converge, but the sequence $(\operatorname{graph}(f_n))_{n\in\mathbb{N}}$ converges in $\mathcal{A}_<([0,1]\times\mathbb{R})$ to $A := [0,1]\times\{0\}$ (since any positive information on A is shared by almost all sets in the sequence). This proves the claim for $\mathcal{A}_<$. Since $\operatorname{range}(f_n) \subseteq [0,1]$, the same holds true in case of $Y = [0,1]$. □

The second part of the previous proposition shows that the previous corollary does not hold true if we replace $\mathcal{A}_>$ by $\mathcal{A}_<$—not even if both X and Y are recursive compact.

7. Locally compact target spaces. In this section we will show that the nonuniform version of the compact Graph Theorem, i.e., Corollary 6.5, can be transferred to the case that the source space X is compact and the target space Y is effectively locally compact. Up to now different notions of "effective local compactness" have been used (see, for instance, [22, 7]), and the terminology is not stable yet. In the next definition we do not want to propose a new version, but we just formulate a very weak property that should be met by most of the reasonable definitions of effective local compactness and which is sufficient for our proofs.

DEFINITION 7.1 (locally computable). *A computable metric space X is called* locally computable *if for any compact subset $A \subseteq X$ there exists a recursive compact subset $K \subseteq X$ such that $A \subseteq K$.*

It is obvious that, for instance, the Euclidean space $\mathbb{R}^n$ is locally computable in this sense (since any closed ball is recursive compact). Next we will show that if the target space is locally computable, then we can deduce that any continuous function with co-r.e. graph-maps computable points to computable points. Furthermore, it is computable restricted to any r.e. compact subset. If $f : X \to Y$ is a total function and $A \subseteq X$, then we denote by $f|_A :\subseteq X \to Y$ the *restriction* of f to A, defined by $f|_A(x) := f(x)$ and $\operatorname{dom}(f) := A$.

PROPOSITION 7.2. *Let X, Y be computable metric spaces, let Y be locally computable, and let $f : X \to Y$ be a continuous function. If* $\operatorname{graph}(f)$ *is co-r.e. closed, then $f|_K$ is computable for any compact subset $K \subseteq X$. Particularly, f maps computable points to computable points.*

Proof. Since f is continuous, it follows that $f(K)$ is compact for any compact set $K \subseteq X$. Since Y is locally computable, there is a recursive compact set $L \subseteq Y$ such that $f(K) \subseteq L$. Particularly, L can be considered as a computable metric subspace of Y, and thus the injection $L \hookrightarrow Y$ is computable. Now f can be represented as

$$f(x) = \mathrm{in}_L^{-1} \circ \operatorname{sec}(\operatorname{graph}(f), x)$$

for any $x \in K$, where $\operatorname{sec} : \mathcal{A}_>(X\times Y)\times X \to \mathcal{A}_>(Y)$ and $\mathrm{in}_L : L \to \mathcal{A}_>(Y)$ are the functions defined in Lemmas 6.2 and 6.3. Since sec, in_L^{-1} and $L \hookrightarrow Y$ are computable,

the partial function $f|_K :\subseteq X \to Y$ is computable. The last part of the claim holds since $K := \{x\}$ is a compact subset for any $x \in X$. □

We obtain the following corollary of the previous result and the weak Graph Theorem (Theorem 5.1) for compact source spaces and locally computable target spaces.

COROLLARY 7.3. *Let X, Y be computable metric spaces, let X be compact, let Y be locally computable, and let $f : X \to Y$ be a continuous function. Then f is computable if and only if* graph(f) *is co-r.e. closed and if and only if* graph(f) *is recursive closed.*

This corollary in particular applies to continuous functions $f : [0,1] \to \mathbb{R}$. Proposition 6.8 shows that the uniform version of the first equivalence of the previous corollary does not hold true in general. Here, continuity of f does not automatically follow if graph(f) is closed (see Example 4.3 in [10]). Finally, Example 5.3 shows that the previous corollary does not hold true for locally compact source spaces X. The next example proves that local computability of the target space is not a superfluous property in the previous corollary. The example is a modified version of Example 6.6, and as target space we will use the computable metric space (see, e.g., [6] for details)

$$\ell_2 := \{x \in \mathbb{R}^{\mathbb{N}} : ||x||_2 < \infty\} \text{ with } ||(x_k)_{k\in\mathbb{N}}||_2 := \sqrt{\sum_{k=0}^{\infty} |x_k|^2}.$$

Example 7.4. Let $X = [0,1]$ and $Y = \ell_2$. There exists a continuous but noncomputable function $f : X \to Y$ such that graph$(f) \subseteq X \times Y$ is recursive closed.

Proof. Let $a : \mathbb{N} \to \mathbb{N}$ be some computable and injective enumeration of a nonrecursive set $K = \text{range}(a)$. We define a function $f : [0,1] \to \ell_2$ using the polygons p_n as defined in Example 6.6 as follows:

$$f(x)(k) := \begin{cases} p_n(x) & \text{if } a(k) = n \text{ and } x \in [2^{-n-1} - 2^{-n-3}, 2^{-n-1} + 2^{-n-3}] =: I_n, \\ 0 & \text{otherwise} \end{cases}$$

for all $x \in [0,1]$ and $k \in \mathbb{N}$.

It is easy to see that f is continuous and graph$(f) \subseteq [0,1] \times \ell_2$ is r.e. closed since a is computable. One can also show that graph(f) is co-r.e. In case that $x \in I_n$ and we already know that $n \notin a(\{0,\ldots,k\})$, we obtain $B((x,y),r) \subseteq \text{graph}(f)^c$ for any $y = (y_0, y_1, \ldots, y_k, 0, 0, \ldots) \in \ell_2$ with $||y|| > 0$ and $0 < r < \min\{||y||, 2^{-n-4}\}$. Exploiting this idea, one can exhaust graph$(f)^c$ effectively by open balls, and thus graph(f) is co-r.e.

On the other hand, f is not computable, since $K = \text{range}(a)$ is not co-r.e. and

$$n \notin K \iff ||f\left(2^{-n-1}\right)||_2 < 2^{-n}. \qquad \square$$

In the previous example $f : [0,1] \to \ell_2$ is continuous and thus $K := f[0,1]$ is compact. However, K cannot be co-r.e. compact by Corollary 6.5, and by Corollary 7.3 ℓ_2 is not locally computable. In particular, there is no recursive compact set $K' \subseteq \ell_2$ such that $K \subseteq K'$. This observation in particular proves that pure compactness of Y is not sufficient in Theorem 6.4 (and correspondingly for Corollary 6.5). Moreover, local computability of Y cannot be replaced by compactness in Corollary 7.3.

8. Locally connected source spaces. In this section we will discuss another property of the source space that guarantees that the uniform inverse direction of

the Graph Theorem becomes computable. We will call a computable metric space X effectively locally connected (cf. [16]) if for any point $x \in X$ and any open ball $B(x,r)$ we can effectively find some connected neighborhood U of x that is contained in $B(x,r)$. For the precise formulation we employ the hyperspace $\mathcal{O}(X)$ of open subsets of X, represented by $\delta_{\mathcal{O}(X)}(p) = X \setminus \delta_{\mathcal{A}_>(X)}(p)$.

DEFINITION 8.1 (effective local connectedness). *A computable metric space X is called* effectively locally connected *if there exists a computable multivalued function $C :\subseteq X \times \mathbb{R} \rightrightarrows \mathcal{O}(X)$ such that for any $x \in X$ and $r > 0$ there exists some $U \in C(x,r)$ and any such U is connected and fulfills $x \in U \subseteq B(x,r)$.*

One should mention that it would not suffice to consider balls $U = B(x,s)$ with some $s \leq r$ because it might happen that any such ball is not connected although there exists some connected (more complicated) U (consider an appropriate spiral line in $\mathbb{R}^2$ such that any box with the same center as the spiral cuts the spiral into several distinct connectedness components).

The main result of this section will be based on the following lemma, which employs the hyperspace $\mathcal{K}(X) := \{K \subseteq X : K \text{ nonempty and compact}\}$ of nonempty compact subsets of a metric space X, endowed with the *Hausdorff metric* $d_{\mathcal{K}} : \mathcal{K}(X) \times \mathcal{K}(X) \to \mathbb{R}$, defined by

$$d_{\mathcal{K}}(A,B) := \max\left\{\sup_{a\in A} d_B(a), \sup_{b\in B} d_A(b)\right\}.$$

If (X,d,α) is a computable metric space, then a standard numbering $\alpha_{\mathcal{K}}$ of the set $\mathcal{Q}$ of finite subsets of range(α) can be defined by $\alpha_{\mathcal{K}}\langle k, \langle n_0, \ldots, n_k\rangle\rangle := \{\alpha(n_0), \ldots, \alpha(n_k)\}$. It is easy to see that under these assumptions $(\mathcal{K}(X), d_{\mathcal{K}}, \alpha_{\mathcal{K}})$ is a computable metric space, too. In the following we assume that $\mathcal{K}(X)$ is endowed with the corresponding Cauchy representation $\delta_{\mathcal{K}}$. It is easy to prove that the canonical injection $\mathcal{K}(X) \hookrightarrow \mathcal{A}(X)$ is computable [7]. To prepare for our main result, we formulate a lemma. Here, ∂A denotes the *boundary* of a subset $A \subseteq X$ of a metric space X.

LEMMA 8.2. *Let $n \geq 1$ a natural number. The function*

$$I :\subseteq \mathbb{R}^n \times \mathbb{R} \to \mathcal{K}(\mathbb{R}^n), (y,\varepsilon) \mapsto \partial B(y,\varepsilon),$$

defined for all $(y,\varepsilon) \in \mathbb{R}^n \times \mathbb{R}$ with $\varepsilon > 0$, is computable.

The proof is straightforward. The fact that the target space $\mathbb{R}^n$ is locally compact and has balls whose boundaries are compact is essential for the following result. Proposition 8.6 will show that the same result does not hold true in case of the Hilbert space ℓ_2 as target space. Now we are prepared to prove the following theorem.

THEOREM 8.3 (locally connected Graph Theorem). *Let X be an effectively locally connected computable metric space and let $n \geq 1$ be a natural number. The graph mapping* $\mathrm{graph} : \mathcal{C}(X, \mathbb{R}^n) \to \mathcal{A}(X \times \mathbb{R}^n), f \mapsto \mathrm{graph}(f)$ *as well as its partial inverse*

$$\mathrm{graph}^{-1} :\subseteq \mathcal{A}(X \times \mathbb{R}^n) \to \mathcal{C}(X, \mathbb{R}^n)$$

are computable.

Proof. We consider the computable metric space (X,d,α). Computability of the map graph follows from Theorem 5.1. We investigate the mapping graph^{-1}. Thus, let $f : X \to \mathbb{R}^n$ be a continuous function. We can assume that $\mathrm{graph}(f) \in \mathcal{A}(X \times \mathbb{R}^n)$ is given. Furthermore, let $x \in X$ and a precision $k \in \mathbb{N}$ be given. We prove that we can effectively evaluate $f(x)$ up to precision 2^{-k}, which implies by type conversion the desired result. Since $\mathrm{graph}(f)$ is given as a point of $\mathcal{A}(X \times \mathbb{R}^n)$, we can, on the

one hand, find points $(x_i, y_i) \in \text{range}(\alpha) \times \mathbb{Q}^n$ and rational numbers $r_i > 0$ such that

$$\text{graph}(f)^c = (X \times \mathbb{R}^n) \setminus \text{graph}(f) = \bigcup_{i=0}^{\infty} B((x_i, y_i), r_i) = \bigcup_{i=0}^{\infty} (B(x_i, r_i) \times B(y_i, r_i)),$$

and, on the other hand, given some open set $U \in \mathcal{O}(X \times \mathbb{R}^n)$, we can effectively recognize that $U \cap \text{graph}(f) \neq \emptyset$ if this is the case. Given a compact subset $K \in \mathcal{K}(\mathbb{R}^n)$ such that $K \subseteq \bigcup_{i=0}^{\infty} B(y_i, r_i)$, the computable Heine–Borel theorem (cf. Theorems 4.6 and 4.10 in [8]) ensures that we can effectively find a natural number $m \in \mathbb{N}$ such that $K \subseteq \bigcup_{i=0}^{m} B(y_i, r_i)$. Now the evaluation of $f(x)$ up to precision 2^{-k} works as follows: we systematically search for some $y \in \mathbb{Q}^n$, some rational numbers $r > 0$, $t \geq 1$, and natural numbers $n_0, \ldots, n_m \in \mathbb{N}$ such that for some arbitrary determined $W \in C(x, r)$ the following conditions are satisfied (where (1) holds automatically):

(1) $x \in W \subseteq B(x, r)$ and W is connected and open,
(2) $U \cap \text{graph}(f) \neq \emptyset$ with $U := W \times B(y, r)$,
(3) $d(x_{n_i}, x) + r < r_{n_i}$ for all $i = 0, \ldots, m$,
(4) $\partial B(y, tr) \subseteq \bigcup_{i=0}^{m} B(y_{n_i}, r_{n_i})$, and
(5) $tr < 2^{-k}$.

Figure 8.1 illustrates the situation. If for certain values $y, r, t, n_0, \ldots, n_m$ and $W \in C(x, r)$ the conditions (2)–(5) are fulfilled, then we can eventually recognize this by the previous considerations and the previous lemma and since X is effectively locally connected. Now we claim that such values always exist and $||f(x) - y|| < 2^{-k}$ if (1)–(5) are fulfilled.

Thus, let us first assume that (1)–(5) hold. It is obvious that (3) implies $B(x, r) \subseteq \bigcap_{i=0}^{m} B(x_{n_i}, r_{n_i})$ and thus by (4) it follows that

$$B(x, r) \times \partial B(y, tr) \subseteq \bigcup_{i=0}^{m} (B(x_{n_i}, r_{n_i}) \times B(y_{n_i}, r_{n_i})) \subseteq \text{graph}(f)^c.$$

Thus, by (1) we obtain $f(W) \subseteq B(y, tr) \cup (\mathbb{R}^n \setminus \overline{B}(y, tr))$, and hence $f(W)$ is covered by a disjoint union of open subsets. Since W is connected and f is continuous, it follows that $f(W)$ is connected, too, and thus $f(W)$ has empty intersection with either $B(y, tr)$ or $\mathbb{R}^n \setminus \overline{B}(y, tr)$. By (2) there is some $z \in W$ such that $f(z) \in B(y, r) \subseteq B(y, tr)$ and hence $f(W) \cap \overline{B}(y, tr)^c = \emptyset$. This implies $f(x) \in B(y, tr)$ by (1) and hence $||f(x) - y|| < tr < 2^{-k}$ by (5).

Now we still have to prove that there are always values $y, r, t, n_0, \ldots, n_m$ such that (1)–(5) are fulfilled with arbitrary $W \in C(x, r)$. Therefore, let $0 < s < 2^{-k}$ be a

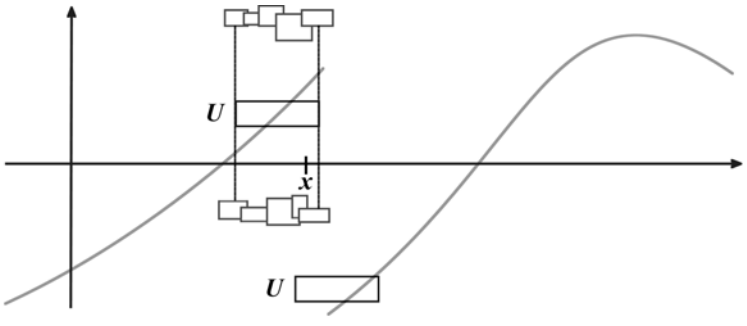

FIG. 8.1. *A graph of some function f with two potential sets U.*

rational number. Then $\partial B(f(x),s) \subseteq \bigcup\{B(y_i,r_i) : i \in \mathbb{N} \text{ and } x \in B(x_i,r_i)\}$ and by compactness there exist $n_0,\dots,n_m \in \mathbb{N}$ such that $\partial B(f(x),s) \subseteq \bigcup_{i=0}^m B(y_{n_i},r_{n_i})$ and $x \in \bigcap_{i=0}^m B(x_{n_i},r_{n_i}) =: V$. Thus, V is an open neighborhood of x and we can choose some rational r with $0 < r < s$ such that $d(x_{n_i},x) + r < r_{n_i}$ for all $i = 0,\dots,m$, in particular, $B(x,r) \subseteq V$. Now there exists some $y \in \mathbb{Q}^n$ such that $||f(x) - y|| < r$ and still $\partial B(y,s) \subseteq \bigcup_{i=0}^m B(y_{n_i},r_{n_i})$. For this choice of $y, r, n_0,\dots,n_m$, $t := \frac{s}{r}$, and $W \in C(x,r)$, conditions (1)–(5) are fulfilled: (1) holds since $W \in C(x,r)$. (2) holds since by definition $x \in W$ and $f(x) \in B(y,r)$, and thus $(x,f(x)) \in \text{graph}(f) \cap U$. (4) holds by choice of y and t and (3) by choice of r. (5) holds since $tr = s < 2^{-k}$ by choice of s and definition of t. □

This result in particular applies to computable normed spaces X and other spaces with connected balls (such as locally convex spaces). We directly obtain the following nonuniform corollary.

COROLLARY 8.4. *Let X be an effectively locally connected computable metric space and let $f : X \to \mathbb{R}^n$ be a continuous function. Then f is computable if and only if* graph(f) *is recursive closed.*

Example 5.3 already showed that "effective local connectedness" is not a superfluous condition—neither in the previous result nor in its uniform version. The following proposition shows that in the uniform case the target space $Y = \mathbb{R}^n$ cannot be replaced by an arbitrary computable metric space (not even if we restrict ourselves to linear operators). The result is based on the following easy lemma and results from [6].

LEMMA 8.5. *Let X, Y be computable metric spaces. The "swap map"*

$$S : \mathcal{A}(X \times Y) \to \mathcal{A}(Y \times X), A \mapsto \{(y,x) \in Y \times X : (x,y) \in A\}$$

is computable.

The proof follows from the fact that the pointwise "swap function" $s : X \times Y \to Y \times X, (x,y) \mapsto (y,x)$ operates on centers of balls, i.e.,

$$sB((x,y),r) = B((y,x),r) = B(s(x,y),r)$$

for all $(x,y) \in X \times Y$ and $r > 0$ provided that $X \times Y$ and $Y \times X$ are endowed with the product space structure according to Proposition 3.2.

PROPOSITION 8.6. *The mapping* $\text{graph}^{-1} :\subseteq \mathcal{A}(\ell_2 \times \ell_2) \to \mathcal{C}(\ell_2,\ell_2)$*, defined for all closed subsets $A \subseteq \ell_2 \times \ell_2$ such that $A =$* graph(T) *for some linear bounded and bijective operator $T : \ell_2 \to \ell_2$ with $||T|| = 1$, is discontinuous.*

Proof. Let us assume that $\text{graph}^{-1} :\subseteq \mathcal{A}(\ell_2 \times \ell_2) \to \mathcal{C}(\ell_2,\ell_2)$ would be continuous in the stated sense. By the previous lemma and the weak Graph Theorem (Theorem 5.1) it follows that the inversion $I :\subseteq \mathcal{C}(\ell_2,\ell_2) \to \mathcal{C}(\ell_2,\ell_2), T \mapsto T^{-1}$, restricted to linear bounded and bijective operators $T : \ell_2 \to \ell_2$ with $||T|| = 1$, would be continuous, too, since $I = \text{graph}^{-1} \circ S \circ \text{graph}$. This contradicts Example 17 in [6]. □

Finally, we want to prove that with the same assumptions on the spaces Theorem 8.3 cannot be strengthened in the way that only negative information on the graph is required in order to determine the function. In the following example we consider $\mathbb{R} \setminus \mathbb{N}$ as a computable metric subspace of $\mathbb{R}$, endowed with the restriction of the Euclidean metric.

Example 8.7. Consider $X = \mathbb{R} \setminus \mathbb{N}$ as a computable metric subspace of $\mathbb{R}$ endowed with the restriction of the Euclidean metric. There exists a continuous but noncomputable function $f : X \to \mathbb{R}$ such that graph$(f) \subseteq X \times \mathbb{R}$ is strongly co-r.e. closed.

Proof. Let $a : \mathbb{N} \to \mathbb{N}$ be some computable and injective enumeration of a nonrecursive set $K = \text{range}(a)$. Define $f : \mathbb{R} \setminus \mathbb{N} \to \mathbb{R}$ by

$$f(x) := \begin{cases} n+1 & \text{if } (\exists n, k)\ x \in (k, k+1) \text{ and } a(n) = k, \\ 0 & \text{otherwise} \end{cases}$$

for all $x \in \mathbb{R} \setminus \mathbb{N}$. Then f is continuous but noncomputable since $K = \text{range}(a)$ is not co-r.e. and

$$k \notin K \iff f\left(k + \frac{1}{2}\right) < 1.$$

Moreover, $\text{graph}(f)$ is strongly co-r.e. closed since a is computable and

$$\begin{aligned} & ([c,d] \times [r,s]) \cap \text{graph}(f) = \emptyset \\ \iff & (\exists k)\Big(\Big(k < c \le d < k+1 \text{ and } (\forall n+1 \in [r,s])(a(n) \ne k)\Big) \\ & \text{and } \Big(0 \in [r,s] \implies (\exists n)(a(n) = k)\Big)\Big) \end{aligned}$$

for all $c, d, r, s \in \mathbb{Q}$ such that $r \le s$ and there exists some k with $k < c \le d < k+1$. The general case of those $c \le d$ that are not subject to the previous inequality can easily be reduced to the presented special case. □

9. Pathwise connected source spaces. In this section we will discuss another connectedness property of the source space which guarantees that the uniform inverse direction of the Graph Theorem becomes computable, even if essentially only negative information on the graph is available. The only positive information that we will require is a single point $(a, b) \in \text{graph}(f)$.

We will call a computable metric space X effectively pathwise connected if for all points $x, y \in X$ we can effectively find some continuous function $p : [0,1] \to X$ such that $p(0) = x$ and $p(1) = y$. More precisely, we have the following definition.

DEFINITION 9.1 (effective pathwise connectedness). *A computable metric space X is called* effectively pathwise connected *if there exists a computable multivalued function $P : X \times X \rightrightarrows \mathcal{C}([0,1], X)$ such that for all $x, y \in X$ and $p \in P(x, y)$ it holds that $p(0) = x$ and $p(1) = y$.*

It is easy to see that the Euclidean space $\mathbb{R}^n$ and computable normed spaces X are effectively pathwise connected (a path $p : [0,1] \to X$ can simply be obtained by $p(r) := x + r(y - x)$ in these cases). Now we are prepared to prove the following theorem. The proof is a modified version of the proof of Theorem 8.3.

THEOREM 9.2 (pathwise connected Graph Theorem). *Let X be an effectively pathwise connected computable metric space and let $n \ge 1$ be a natural number. The mapping*

$$F :\subseteq \mathcal{A}_>(X \times \mathbb{R}^n) \times X \times \mathbb{R}^n \to \mathcal{C}(X, \mathbb{R}^n), (A, a, b) \mapsto \text{graph}^{-1}(A),$$

which is defined for all (A, a, b) such that $A = \text{graph}(f)$ and $f(a) = b$ for some $f \in \mathcal{C}(X, \mathbb{R}^n)$, is computable.

Proof. We consider the computable metric space (X, d, α). Let $f : X \to \mathbb{R}^n$ be a continuous function and let $(a, b) \in X \times \mathbb{R}^n$ with $f(a) = b$. Furthermore, let $x \in X$ and a precision $k \in \mathbb{N}$ be given. We prove that we can effectively evaluate $f(x)$ up

to precision 2^{-k}, which implies by type conversion the desired result. We can assume that graph(f) is given as point graph$(f) \in \mathcal{A}_>(X \times \mathbb{R}^n)$, and thus we can find points $(x_i, y_i) \in \text{range}(\alpha) \times \mathbb{Q}^n$ and rational numbers $r_i > 0$ such that

$$\text{graph}(f)^c = (X \times \mathbb{R}^n) \setminus \text{graph}(f) = \bigcup_{i=0}^{\infty} (B(x_i, r_i) \times B(y_i, r_i)) .$$

Since X is effectively pathwise connected, we can effectively find a continuous function $p : [0,1] \to X$ such that $p(0) = a$ and $p(1) = x$. The strategy of the proof is to follow the graph along the path p from a to x in order to evaluate f at x. Therefore, we systematically search for values $m \in \mathbb{N}$ and a partition $0 = a_0 < a_1 < a_2 < \cdots < a_m = 1$ with $a_j \in \mathbb{Q}$, and we guess possible function values $b_0 := b$, $b_{j+1} \in B(b_j, 2^{-k}) \cap \mathbb{Q}^n$ for $j = 0, \ldots, m-1$ such that we obtain

$$p[a_j, a_{j+1}] \times \partial B(b_j, 2^{-k}) \subseteq \bigcup_{i=0}^{\infty} (B(x_i, r_i) \times B(y_i, r_i)) \tag{9.1}$$

and such that we obtain for all $j = 0, \ldots, m-2$

$$\{p(a_{j+1})\} \times \overline{(\overline{B}(b_j, 2^{-k}) \Delta \overline{B}(b_{j+1}, 2^{-k}))} \subseteq \bigcup_{i=0}^{\infty} (B(x_i, r_i) \times B(y_i, r_i)) . \tag{9.2}$$

Here $C \Delta D := C \setminus D \cup D \setminus C$ denotes the symmetric difference. Figure 9.1 illustrates the situation. We first mention that the inclusions in (9.1) and (9.2) are r.e. in all parameters by the computable Heine–Borel theorem (cf. Theorems 4.6 and 4.10 in [8]). This follows from Lemma 8.2 together with the fact that the mapping $C([0,1], X) \times \mathcal{K}[0,1] \to \mathcal{K}(X), (p, A) \mapsto p(A)$ is computable (see Theorem 3.3 in [21] and Theorem 4.12 in [7]) and since $x \mapsto \{x\}$ and $(x, y, k) \mapsto \overline{(\overline{B}(x, 2^{-k}) \Delta \overline{B}(y, 2^{-k}))}$ are both computable with respect to $\delta_{\mathcal{K}}$ on the output.

Now we claim that always appropriate values m, a_j, b_j exist such that (9.1) and (9.2) are fulfilled, and we claim that $||f(x) - y|| < 2^{-k}$ holds for $y := b_m$ in this case.

Thus, let us first assume that (9.1) and (9.2) hold. Since the composition $fp : [0,1] \to \mathbb{R}^n$ is continuous, it follows that graph(fp) is connected, and since $fp(a_0) = fp(0) = f(a) = b = b_0$, it follows that

$$\text{graph}(fp) \subseteq \bigcup_{j=0}^{m-1} \left([a_j, a_{j+1}] \times B(b_j, 2^{-k}) \right) .$$

In particular, $f(x) = fp(1) = fp(a_m) \in B(b_m, 2^{-k})$, and thus $||f(x) - y|| < 2^{-k}$, as we have claimed.

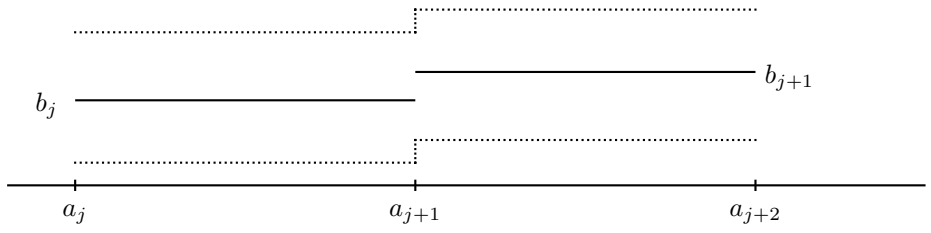

FIG. 9.1. *The tube constructed around the path p.*

Now we still have to prove that there always exist appropriate values m, a_j, b_j such that (9.1) and (9.2) are fulfilled. Since $fp : [0,1] \to \mathbb{R}^n$ is continuous and $[0,1]$ is compact, it follows that fp is even uniformly continuous and there exists some value $l \in \mathbb{N}$ such that $fp[a_j, a_{j+1}] \subseteq B(fp(a_j), 2^{-k-2})$ for all $j = 0, \ldots, m-1$ with $m := 2^l$ and $a_j := j \cdot 2^{-l}$. Thus, if we choose $b_j \in \mathbb{Q}^n$ such that $||fp(a_j) - b_j|| \leq 2^{-k-2}$, then (9.1) and (9.2) are fulfilled. □

Since in case of complete spaces X positive information on the graph allows us to find some x and y with $f(x) = y$ (which follows from Proposition 4.4), we obtain the following corollary.

COROLLARY 9.3. *Let X be an effectively pathwise connected and complete computable metric space. The mapping* $\text{graph} : \mathcal{C}(X, \mathbb{R}^n) \to \mathcal{A}(X \times \mathbb{R}^n), f \mapsto \text{graph}(f)$ *as well as its inverse* $\text{graph}^{-1} :\subseteq \mathcal{A}(X \times \mathbb{R}^n) \to \mathcal{C}(X, \mathbb{R}^n)$ *are computable.*

We do not know whether completeness is a superfluous property in this case. In the nonuniform case we have learned by Proposition 7.2 that a continuous function $f : X \to \mathbb{R}^n$ with a co-r.e. graph always maps computable inputs to computable outputs. Therefore, we obtain the following corollary of Theorem 9.2.

COROLLARY 9.4. *Let X be an effectively pathwise connected computable metric space and let $f : X \to \mathbb{R}^n$ be a continuous function. Then f is computable if and only if* $\text{graph}(f)$ *is recursive closed and if and only if* $\text{graph}(f)$ *is co-r.e. closed.*

Moreover, we can easily conclude a linear version of the previous theorem (where we consider only negative information on the graph) since in the linear case $f(0) = 0$ and thus the additional input information (a pair from the graph of f) is automatically available. Here, a *computable normed* space is a computable metric space with an additional vector space structure such that the algebraic operations are computable (see, e.g., [6] for details).

COROLLARY 9.5. *Let X be a computable normed space and let $n \geq 1$ be a natural number. The mapping* $\text{graph} :\subseteq \mathcal{C}(X, \mathbb{R}^n) \to \mathcal{A}_>(X \times \mathbb{R}^n), f \mapsto \text{graph}(f)$*, defined for linear mappings $f : X \to \mathbb{R}^n$, as well as its partial inverse* $\text{graph}^{-1} :\subseteq \mathcal{A}_>(X \times \mathbb{R}^n) \to \mathcal{C}(X, \mathbb{R}^n)$ *are computable.*

We close this section with an example that shows that in general a linear function $f : X \to Y$ with a co-r.e. closed graph need not be computable. For any $x = (x_i)_{i \in \mathbb{N}} \in \mathbb{R}^{\mathbb{N}}$ we denote by $x[j] := (x_0, x_1, \ldots, x_j, 0, 0, \ldots) \in \mathbb{R}^{\mathbb{N}}$ the sequence up to element j and filled up with zeros.

Example 9.6. There exists a linear and continuous but noncomputable map $f : \ell_2 \to \ell_2$ with a co-r.e. closed $\text{graph}(f) \subseteq \ell_2 \times \ell_2$.

Proof. Let $a : \mathbb{N} \to \mathbb{N}$ be an injective computable function such that $\text{range}(a) = K$ is r.e. but not recursive. We define a linear map $f : \ell_2 \to \ell_2$ by $f(e_j) := a_{ij} e_i$, where

$$a_{ij} := \begin{cases} 1 & \text{if } a(i) = j, \\ 0 & \text{otherwise} \end{cases}$$

for all $i, j \in \mathbb{N}$. Then $||f|| \leq 1$ and f is obviously not computable, as

$$||f(e_j)||_2 = \begin{cases} 1 & \text{if } j \in K, \\ 0 & \text{otherwise} \end{cases}$$

for all $j \in \mathbb{N}$. However, $\text{graph}(f)$ is co-r.e. closed, as we will prove now. Therefore, let $(x, y) = ((x_i)_{i \in \mathbb{N}}, (y_i)_{i \in \mathbb{N}}) \in (\ell_2 \times \ell_2) \setminus \text{graph}(f)$. Then there is some $m \in \mathbb{N}$ such that $B((x, y), 2^{-m}) \subseteq (\ell_2 \times \ell_2) \setminus \text{graph}(f)$ and, in particular, $||f(x) - y||_2 \geq 2^{-m}$. For this

m there exist $n, k \in \mathbb{N}$ and $q = (q_0, \ldots, q_n, 0, 0, \ldots)$, $r = (r_0, \ldots, r_k, 0, 0, \ldots) \in \mathbb{Q}^{\mathbb{N}}$ such that

$$||q - x||_2 < 2^{-m-2} \text{ and } ||r - y||_2 < 2^{-m-2}. \tag{9.3}$$

Due to the definition of f, k can even be chosen large enough such that $f(q) = f(q)[k]$. Equation (9.3) implies $||f(q) - f(x)||_2 < ||f|| \cdot 2^{-m-2} \leq 2^{-m-2}$, and we obtain

$$\begin{aligned} ||f(q)[k] - r||_2 &\geq ||f(x) - y||_2 - ||f(q) - f(x)||_2 - ||r - y||_2 \\ &> 2^{-m} - 2^{-m-2} - 2^{-m-2} = 2^{-m-1}. \end{aligned}$$

Thus, given some arbitrary $(x, y) \in \ell_2 \times \ell_2$, we can systematically search for $n, k, m \in \mathbb{N}$ such that (9.3) and

$$||f(q)[k] - r||_2 > 2^{-m-1} \tag{9.4}$$

hold. Due to the definition of f this condition is decidable for q, r of the particular form. In the case that both conditions are satisfied, it follows that

$$\begin{aligned} ||f(x) - y||_2 &\geq ||f(q) - r||_2 - ||f(q) - f(x)||_2 - ||y - r||_2 \\ &\geq ||f(q)[k] - r||_2 - ||f(q) - f(x)||_2 - ||y - r||_2 \\ &> 2^{-m-1} - 2^{-m-2} - 2^{-m-2} = 0 \end{aligned}$$

and, in particular, $(x, y) \notin \text{graph}(f)$. Altogether, the proof shows that the algorithm finds suitable n, k, m for given (x, y) if and only if $(x, y) \notin \text{graph}(f)$. But this means that $\text{graph}(f)$ is co-r.e. closed. □

10. Conclusions. The table in Figure 10.1 gives a survey of our results. We assume that X, Y are computable metric spaces and $f : X \to Y$ is a continuous function. Each double row lists a certain version of the Graph Theorem (where the first row of any double row contains a nonuniform version and the second row the corresponding uniform version). The first double row treats the easy direction of the Graph Theorem, the remaining double rows of the table consider the problematic direction, and they are split into three cases where positive, negative, and both types of information on graphs are considered (in reverse order). The columns correspond to different additional conditions on the spaces X and Y (and on the functions f in the second half, which is devoted to the linear case). Any symbol "+" indicates that the statement of the corresponding row holds in general under the assumptions of the corresponding column. Any "−" indicates that there are counterexamples of spaces (and functions) that fulfill the assumptions of the corresponding column, but the statement of the corresponding row does not hold in case of the counterexample (in the uniform case it typically indicates that the corresponding mapping is not even continuous). Finally, the bottom of the columns contains examples of functionalities $X \to Y$ that simultaneously meet all indicated properties of the corresponding column.

The results of the first double row follow directly from Theorem 5.1, the weak version of the Graph Theorem. The positive results in the second column follow from Theorem 8.3, the Graph Theorem for locally connected source spaces. The additional positive results in the third column follow from Corollary 7.3, the Graph Theorem

FIG. 10.1. *Survey of different versions of the Graph Theorem.*

for compact source spaces and locally computable target spaces. The positive results in the fourth column follow from Corollaries 9.3 and 9.4, the Graph Theorem for pathwise connected source spaces. The positive results in the fifth column follow from Theorem 6.4, the Graph Theorem for compact target spaces. All positive results in the first row of the second and fourth double row concerning the linear case follow from the effective version of the closed Graph Theorem [2]. The remaining positive results in the second double row are implied by the corresponding positive results of the second column. The remaining positive results in the third double row follow from Corollary 9.5. The remaining positive result of the fourth double row is a consequence of Theorem 4.7 in [5]. All negative results in the first column follow from Example 5.3 for the space $X = \mathbb{N}^{\mathbb{N}}$ and Proposition 5.2. The negative results in the second column of the third double row follow from Example 8.7 for the space $X = \mathbb{R} \setminus \mathbb{N}$. The negative results in the third column and second and third double rows follow from Proposition 5.2 for the space $X = \{0,1\}^{\mathbb{N}}$. The negative results in the second, third, fourth, and fifth columns of the fourth double row follow from Example 6.6 for the spaces $X = Y = [0,1]$ or $X = Y = \mathbb{R}$. This example can easily be modified in order to obtain the negative results concerning the third column for the space $X = \{0,1\}^{\mathbb{N}}$. The remaining negative result in the fourth column is a consequence of Proposition 6.8 for the spaces $X = Y = \mathbb{R}$. The negative results in the sixth column are consequences of Proposition 8.6 for the spaces $X = Y = \ell_2$ and of Example 9.6. The negative result in the seventh column is a consequence of Theorem 4.5 in [5]. It should be mentioned that completeness in the fourth column has been used only for the positive result of the third row.

Of course the table leaves open many further questions. We just formulate one example.

Open problem. Is there an effectively pathwise connected computable metric space X such that $\text{graph}^{-1} :\subseteq \mathcal{A}(X \times \mathbb{R}^n) \to \mathcal{C}(X, \mathbb{R}^n)$ is not computable?

By the known results it follows that such a space X can be neither effectively locally connected nor complete. The space $X = (\mathbb{R} \times \{0\}) \cup (\mathbb{Q} \times \mathbb{R})$, endowed with the subtopology of the Euclidean topology, is an example of an effectively pathwise connected computable metric space that is neither locally connected nor complete and thus a potential candidate.

One interesting consequence of the Graph Theorem is that it allows certain conclusions with respect to the inversion problem: spaces X, Y such that the mapping from $\text{graph}(f)$ to $f : X \to Y$ is computable also have the property that the mapping from any homeomorphism $g : Y \to X$ to its inverse $g^{-1} : X \to Y$ is computable (in the uniform case as well as in the nonuniform case). This follows since information on the graph is symmetric (this is made precise by Lemma 8.5). Thus, in all those cases where the second double row in Figure 10.1 carries a plus, it follows that inversion is effective. However, the negative results cannot be transferred that easily (since it might happen that inversion can be established without using the graph as an intermediate step). This interesting problem deserves further investigation.

Acknowledgments. The author would like to express his gratitude to the anonymous referees who made a number of very valuable comments that helped to clarify and improve the presentation. One referee pointed out an omission in the proof of Theorem 9.2 that led to the introduction of (9.2).

MAX ONES GENERALIZED TO LARGER DOMAINS*

PETER JONSSON†, FREDRIK KUIVINEN†, AND GUSTAV NORDH‡

Abstract. We study a family of problems, called MAXIMUM SOLUTION, where the objective is to maximize a linear goal function over the feasible integer assignments to a set of variables subject to a set of constraints. When the domain is Boolean (i.e., restricted to $\{0,1\}$), the maximum solution problem is identical to the well-studied MAX ONES problem, and the approximability is completely understood for all restrictions on the underlying constraints [S. Khanna, M. Sudan, L. Trevisan, and D. P. Williamson, *SIAM J. Comput.*, 30 (2001), pp. 1863–1920]. We continue this line of research by considering domains containing more than two elements. We present two main results: a complete classification for the approximability of all maximal constraint languages over domains of cardinality at most 4, and a complete classification of the approximability of the problem when the set of allowed constraints contains all permutation constraints. Under the assumption that a conjecture due to Szczepara [*Minimal Clones Generated by Groupoids*, Ph.D. thesis, Université de Móntreal, Montreal, QC, 1996] holds, we give a complete classification for all maximal constraint languages. These classes of languages are well studied in universal algebra and computer science; they have, for instance, been considered in connection with machine learning and constraint satisfaction. Our results are proved by using algebraic results from clone theory, and the results indicate that this approach is very powerful for classifying the approximability of certain optimization problems.

Key words. combinatorial optimization, constraint satisfaction, approximability, universal algebra

1. Introduction.

Our starting point is the general combinatorial optimization problem MAX ONES(Γ), where Γ (known as the *constraint language*) is a finite set of finitary relations over $\{0,1\}$. An instance of this problem consists of constraints from Γ applied to a number of Boolean variables, and the goal is to find an assignment that satisfies all constraints while maximizing the number of variables set to 1. It is easy to see that by choosing the constraint language appropriately, MAX ONES(Γ) captures a number of well-known problems, for instance, MAX INDEPENDENT SET (problem GT23 in [2]) and certain variants of MAX 0/1 PROGRAMMING (problem MP2 in [2]). Many other problems are equivalent to MAX ONES under different reductions: for instance, MAX SET PACKING (also known as MAX HYPERGRAPH MATCHING) and MAX ONES are equivalent under PTAS-reductions [3].

The approximability (and thus the computational complexity) is known for all choices of Γ [37]. For any Boolean constraint language Γ, MAX ONES(Γ) is either in **PO** or is **APX**-complete or **poly-APX**-complete, or finding a solution of nonzero value is **NP**-hard or finding any solution is **NP**-hard. The exact borderlines between

the different cases are given in [37]. Actually, two different problems are studied in [37]: the *weighted* problem (where each variable is assigned a nonnegative weight and the objective is to find a solution of maximum total weight) and the *unweighted* problem (where each variable is assigned the weight 1). They prove that the approximabilities for the weighted and unweighted versions of the problem coincide.

We will study a generalization of MAX ONES where variable domains are different from $\{0,1\}$: this allows us to capture more problems than with MAX ONES. For instance, this enables the study of certain problems in integer linear programming [28], problems in multiple-valued logic [36], and in equation solving over Abelian groups [38]. For larger domains, it seems significantly harder to obtain an exact characterization of approximability than in the Boolean case. Such a characterization would, for instance, show whether the dichotomy conjecture for constraint satisfaction problems is true or not—a famous open question which is believed to be difficult [25]. Hence, we exhibit restricted (but still fairly general) families of constraint languages where the approximability can be determined.

Let us now formally define the problem that we will study: let $D \subset \mathbb{N}$ (*the domain*) be a finite set. The set of all n-tuples of elements from D is denoted by D^n. Any subset of D^n is called an n-ary relation on D. The set of all finitary relations over D is denoted by R_D. A *constraint language* over a finite set, D, is a finite set $\Gamma \subseteq R_D$. Constraint languages are the way in which we specify restrictions on our problems. The constraint satisfaction problem over the constraint language Γ, denoted $\textsc{Csp}(\Gamma)$, is defined to be the decision problem with instance (V, D, C), where

- V is a set of variables,
- D is a finite set of values (sometimes called a domain), and
- C is a set of constraints $\{C_1, \ldots, C_q\}$, in which each constraint C_i is a pair (s_i, R_i), where s_i is a list of variables of length m_i, called the constraint scope, and R_i is an m_i-ary relation over the set D, belonging to Γ, called the constraint relation.

The question is whether there exists a solution to (V, D, C) or not, that is, a function from V to D such that, for each constraint in C, the image of the constraint scope is a member of the constraint relation. To exemplify this definition, let NAE be the following ternary relation on $\{0,1\}$: $NAE = \{0,1\}^3 \setminus \{(0,0,0),(1,1,1)\}$. It is easy to see that the well-known **NP**-complete problem NOT-ALL-EQUAL SAT can be expressed as $\textsc{Csp}(\{NAE\})$.

The optimization problem that we are going to study, WEIGHTED MAXIMUM SOLUTION(Γ) (which we abbreviate W-MAX SOL(Γ)), is defined as follows:

Instance: Tuple (V, D, C, w), where D is a finite subset of $\mathbb{N}$, (V, D, C) is a $\textsc{Csp}(\Gamma)$ instance, and $w : V \to \mathbb{N}$ is a weight function.

Solution: An assignment $f : V \to D$ to the variables such that all constraints are satisfied.

Measure: $\sum_{v \in V} w(v) \cdot f(v)$.

EXAMPLE 1.1. *Consider the domain $D = \{0,1\}$ and the binary relation $R = \{(0,0),(1,0),(0,1)\}$. Then,* W-MAX SOL($\{R\}$) *is exactly the weighted* MAXIMUM INDEPENDENT SET *problem.*

Although the W-MAX SOL(Γ) problem is defined only for finite constraint languages, we will, in order to simplify the presentation, sometimes deal with sets of relations which are infinite. For a (possible infinite) set of relations X we will say that W-MAX SOL(X) is tractable if W-MAX SOL(Y) is tractable for every finite subset Y of X. Here "tractable" may be containment in one of **PO**, **APX**, or **poly-**

APX. Similarly, we say that W-MAX SOL(X) is hard if there is a finite subset Y of X such that W-MAX SOL(Y) is hard. Here "hard" will be one of **APX**-hard, **poly-APX**-hard, or that it is **NP**-hard to find feasible solutions.

Note that our choice of measure function in the definition of W-MAX SOL(Γ) is just one of several reasonable choices. Another reasonable alternative, used in [38], would be to let the domain D be any finite set and introduce an additional function $g : D \to \mathbb{N}$ mapping elements from the domain to natural numbers. The measure could then be defined as $\sum_{v \in V} w(v) \cdot g(f(v))$. This would result in a parameterized problem W-MAX SOL(Γ, g) where the goal is to classify the complexity of W-MAX SOL(Γ, g) for all combinations of constraint languages Γ and functions g. Note that our definition of W-MAX SOL(Γ) is equivalent to the definition of W-MAX SOL(Γ, g) if, in addition, g is required to be injective. One of our motivations for the choice of measure function in the definition of W-MAX SOL(Γ) is to stay closer to the definition of integer programming.

Considering only finite constraint language is in many cases not very restrictive. Consider, for instance, integer programming over the bounded domain $\{0, \ldots, d-1\}$. Each row in the constraint matrix can be viewed as an inequality

$$a_1 x_1 + a_2 x_2 + \cdots + a_k x_k \geq b.$$

Obviously, such an inequality is equivalent to the following three inequalities:

$$\begin{gathered} a_1 x_1 + a_2 x_2 + \cdots + a_{\lfloor k/2 \rfloor} x_{\lfloor k/2 \rfloor} - z \geq 0, \\ -a_1 x_1 - a_2 x_2 - \cdots - a_{\lfloor k/2 \rfloor} x_{\lfloor k/2 \rfloor} + z \geq 0, \\ z + a_{\lfloor k/2 \rfloor + 1} + \cdots + a_k x_k \geq b, \end{gathered}$$

where z denotes a fresh variable that is given the weight 0 in the objective function. By repeating this process, one ends up with a set of inequalities where each inequality contains at most three variables, and the optimal solution to this instance has the same measure as the original instance. There are at most $2^d + 2^{d^2} + 2^{d^3}$ different inequalities of length ≤ 3 since the domain contains d elements; that is, we have reduced the problem to one with a finite constraint language. Finally, this reduction is polynomial-time: each inequality of length k in the original instance gives rise to at most $3^{\lceil \log_2 k \rceil} = O(k^2)$ inequalities and at most $O(k^2)$ new variables.

While the approximability of W-MAX SOL is well understood for the Boolean domain, this is not the case for larger domains. For larger domains we are aware of three results, the first one being a tight (in)approximability result for W-MAX SOL(Γ) when Γ is the set of relations that can be expressed as linear equations over $\mathbb{Z}_p$ [38] (see also section 6.3.1 where we define the problem formally). The second result is due to Hochbaum and Naor [28] who study integer programming with monotone constraints, i.e., every constraint is of the form $ax - by \leq c$, where x and y are variables and $a, b \in \mathbb{N}$ and $c \in \mathbb{Z}$. In our setting, their result is a polynomial-time algorithm for certain constraint languages. The third result is a study of the approximability of certain logically defined constraint languages [36]. The main goal of this article is to gain a better understanding of non-Boolean W-MAX SOL—for doing so, we will adapt the algebraic approach for CSPs [13, 32] for studying the approximability of W-MAX SOL.

When the algebraic approach is applicable to a certain problem, there is an equivalence relation on the constraint languages such that two constraint languages which are equivalent under this relation have the same complexity. More specifically, two constraint languages are in the same equivalence class if they generate the same *relational clone*. The relational clone generated by Γ captures the expressive power of Γ

and is denoted by $\langle\Gamma\rangle$. Hence, instead of studying every possible finite set of relations it is enough to study the relational clones. Thus, given two constraint languages Γ_1 and Γ_2 such that $\langle\Gamma_1\rangle = \langle\Gamma_2\rangle$, it follows that W-MAX SOL(Γ_1) and W-MAX SOL(Γ_2) are equivalent under polynomial-time reductions.

The clone-theoretic approach for studying the complexity of CSPs has been very successful: it has, for instance, made it possible to design new efficient algorithms and to clarify the borderline between tractability and intractability in many important cases. In particular the complexity of the CSP problem over three-element domains is now completely understood [10]. In addition to the CSP problem it is possible to use the tools from universal algebra to prove complexity results in many other CSP-like problems. One example of such a problem is the quantified constraint satisfaction problem (QCSP), where variables can not only be existentially quantified but also universally quantified. The complexity of QCSP has been successfully attacked with the clone-theoretic approach [7, 17]. Furthermore, the #CSP problem [11] (where the number of solutions to a CSP is counted) has also benefitted from this approach. However, it seems that this technique cannot be used for some other CSP-like problems: notable exceptions are MAX CSP [34] and the problem of enumerating all solutions to a CSP instance [46]. For some problems it is the case that the relational clones are a useable tool in the Boolean domain but not in larger domains. The enumeration problem is one such case [46].

We begin by proving that the algebraic approach is applicable to W-MAX SOL, and this result can be found in Theorem 3.3.[1] In fact, we show that, given two constraint languages Γ_1 and Γ_2 such that $\langle\Gamma_1\rangle = \langle\Gamma_2\rangle$, W-MAX SOL($\Gamma_1$) S-reduces to W-MAX SOL(Γ_2), and vice versa. An *S-reduction* is a certain strong approximation-preserving reduction: if $\langle\Gamma_1\rangle = \langle\Gamma_2\rangle$, then Γ_1 and Γ_2 are very similar with respect to approximability. For instance, if W-MAX SOL(Γ_1) is **NP**-hard to approximate within some constant c, then W-MAX SOL(Γ_2) is **NP**-hard to approximate within c, too. The proof is accompanied by an example of how the approach can be used "in practice" for proving approximability results. We note that the clone-theoretic approach was not used in the original classification of MAX ONES and, consequently, the technique we use differs substantially from those used in [37]. The results that we prove with the aid of Theorem 3.3 are the following.

Result 1. Our first result concerns the complexity of W-MAX SOL for *maximal* constraint languages. A constraint language Γ is maximal if, for any $R \notin \langle\Gamma\rangle$, $\Gamma \cup \{R\}$ has the ability to express (in a sense to be formally defined later) every relation in R_D. Such languages have attracted much attention lately: for instance, the complexity of the corresponding CSP problems has been completely classified. In [14] the complexity was classified for domains $|D| \leq 3$, and necessary conditions for tractability were proved for the general case. More recently, in [8], it was proved that those necessary conditions also are sufficient for tractability. Maximal constraint languages have also been studied in the context of machine learning [24] and quantified CSPs [18], and they attract a great deal of attention in universal algebra; cf. the survey by Quackenbush [44].

Our results show that if Γ is maximal and $|D| \leq 4$, then W-MAX SOL(Γ) is tractable, or **APX**-complete, or **poly-APX**-complete, or finding any solution with nonzero measure is **NP**-hard, or CSP(Γ) is not tractable. Moreover, we prove that

[1] The proof is easy to adapt to other problems such as W-MIN SOL (the minimization version of W-MAX SOL) and AW-MAX SOL (where both positive and negative weights are allowed).

under a conjecture by Szczepara [47] our classification of maximal constraint languages extends to arbitrary finite domains. In the conference version [35] of this article we claimed that we had characterized the complexity of MAX SOL for all maximal constraint languages. Unfortunately, there was a flaw in one of the proofs. We have managed to repair some of it by proving the weaker results as stated above, but the general case, when $|D| > 4$ and Szczepara's conjecture is not assumed to hold, remains open. We also note that the different cases can be efficiently recognized; i.e., the approximability of a maximal constraint language Γ can be decided in polynomial time (in the size of Γ).

When proving this result, we identified a new large tractable class of W-MAX SOL(Γ): *generalized* max-*closed* constraints. This class (which may be of independent interest) significantly extends some of the tractable classes of MAX ONES that were identified by Khanna et al. [37]. It is also related to *monotone* constraints which have been studied in mathematical programming and computer science [27, 28, 51]. In fact, generalized max-closed constraints generalize monotone constraints over finite domains. A certain kind of generalized max-closed constraints is relevant in constraint programming languages such as CHIP [50], as is pointed out in [33]. It may thus be possible to extend such languages with optimization capabilities by using the techniques presented in this article.

Result 2. We completely characterize the approximability of W-MAX SOL(Γ) when Γ contains all permutation constraints. Such languages are known as *homogeneous* languages, and Dalmau [23] has determined the complexity of CSP(Γ) for all such languages, while the complexity of the corresponding quantified CSPs has been studied by Börner et al. [6]. Szendrei [48] provides a compact presentation of algebraic results on homogeneous algebras and languages.

We show that W-MAX SOL(Γ) is either tractable, **APX**-complete, or **poly-APX**-complete, or that CSP(Γ) is not tractable. The four different cases can, just as in Result 1, be efficiently recognized. The proof is based on the characterization of homogeneous algebras by Marczewski [40] and Marchenkov [39]. For each domain D, there exists a set of relations Q_D such that every tractable homogeneous constraint language on D is a subset of Q_D. The relations in Q_D are invariant under a certain operation $t : D^3 \to D$ (known as the *discriminator* on D), and the algebra $(D; t)$ is an example of a *quasi-primal* algebra in the sense of Pixley [41]. We note that the tractable homogeneous constraint languages have been considered earlier in connection with *soft constraints* [21], i.e., constraints which allow different levels of "desirability" to be associated with different value assignments [5]. In the terminology of [21], these languages are invariant under a $\langle \mathsf{Mjrty}_1, \mathsf{Mjrty}_2, \mathsf{Mnrty}_3 \rangle$ multimorphism. We also note that the tractable homogeneous languages extend the *width*-2 *affine* class of MAX ONES that was identified by Khanna et al. [37].

We remark that we do not deal explicitly with the unweighted version of the problem (denoted MAX SOL(Γ)), where all variables have weight 1. The reason for this is that the approximability classifications for MAX SOL(Γ) can be deduced from the classifications for W-MAX SOL(Γ) (for all constraint languages Γ considered in this paper). In fact, as we explain in section 8, MAX SOL(Γ) has the same approximability as W-MAX SOL(Γ) when Γ is one of the constraint languages considered in this article.

The article is structured as follows: we begin by presenting some basics on approximability in section 2. The algebraic approach for studying W-MAX SOL is presented in section 3, section 4 identifies certain hard constraint languages, and section 5 contains some tractability results. We continue with section 6 that contains

Result 1 and section 7 that contains Result 2. Finally, section 8 contains some final remarks.

2. Approximability, reductions, and completeness. A *combinatorial optimization problem* is defined over a set of *instances* (admissible input data); each instance I has a finite set $\mathsf{sol}(I)$ of *feasible solutions* associated with it. Given an instance I and a feasible solution s of I, $m(I,s)$ denotes the positive integer *measure* of s. The objective is, given an instance I, to find a feasible solution of *optimum* value with respect to the measure m. The optimal value is the largest one for *maximization* problems and the smallest one for *minimization* problems. A combinatorial optimization problem is said to be an **NPO** problem if its instances and solutions can be recognized in polynomial time, the solutions are polynomially bounded in the input size, and the objective function can be computed in polynomial time (see, e.g., [2]).

We say that a solution $s \in \mathsf{sol}(I)$ to an instance I of an **NPO** problem Π is *r-approximate* if it satisfies

$$\max\left\{\frac{m(I,s)}{\text{OPT}(I)}, \frac{\text{OPT}(I)}{m(I,s)}\right\} \leq r,$$

where $\text{OPT}(I)$ is the optimal value for a solution to I. An approximation algorithm for an **NPO** problem Π has *performance ratio* $\mathcal{R}(n)$ if, given any instance I of Π with $|I| = n$, it outputs an $\mathcal{R}(n)$-approximate solution.

We define **PO** to be the class of **NPO** problems that can be solved (to optimality) in polynomial time. An **NPO** problem Π is in the class **APX** if there is a polynomial-time approximation algorithm for Π whose performance ratio is bounded by a constant. Similarly, Π is in the class **poly-APX** if there is a polynomial-time approximation algorithm for Π whose performance ratio is bounded by a polynomial in the size of the input. Completeness in **APX** and **poly-APX** is defined using appropriate reductions, called AP-reductions and A-reductions, respectively [22, 37]. AP-reductions are more sensitive than A-reductions, and every AP-reduction is also an A-reduction [37]. In this paper we will not need the added flexibility of A-reductions for proving our **poly-APX**-completeness results. Hence, we need only the definition of AP-reductions.

DEFINITION 2.1. *An* **NPO** *problem* Π_1 *is said to be* AP-reducible *to an* **NPO** *problem* Π_2 *if two polynomial-time computable functions* F *and* G *and a constant* α *exist such that*

(a) *for any instance* I *of* Π_1, $F(I)$ *is an instance of* Π_2*;*
(b) *for any instance* I *of* Π_1 *and any feasible solution* s' *of* $F(I)$, $G(I,s')$ *is a feasible solution of* I*;*
(c) *for any instance* I *of* Π_1 *and any* $r \geq 1$, *if* s' *is an* r*-approximate solution of* $F(I)$, *then* $G(I,s')$ *is an* $(1+(r-1)\alpha+o(1))$*-approximate solution of* I, *where the o-notation is with respect to* $|I|$.

An **NPO** *problem* Π *is* **APX**-hard *(***poly-APX**-hard*) if every problem in* **APX** *(***poly-APX***) is AP-reducible (A-reducible) to it. If, in addition,* Π *is in* **APX** *(***poly-APX***), then* Π *is called* **APX**-complete *(***poly-APX**-complete*).* It is a well-known fact (see, e.g., section 8.2.1 in [2]) that AP-reductions compose. In some proofs we will use another kind of reduction, S-reductions. They are defined as follows.

DEFINITION 2.2. *An* **NPO** *problem* Π_1 *is said to be* S-reducible *to an* **NPO** *problem* Π_2 *if two polynomial-time computable functions* F *and* G *exist such that the following hold:*

(a) *Given any instance* I *of* Π_1, *algorithm* F *produces an instance* $I' = F(I)$ *of*

Π_2, *such that the measure of an optimal solution for* I', $\text{OPT}(I')$, *is exactly* $\text{OPT}(I)$.

(b) *Given* $I' = F(I)$ *and any solution* s' *to* I', *algorithm* G *produces a solution* s *to* I *such that* $m_1(I, G(s')) = m_2(I', s')$, *where* m_1 *is the measure for* Π_1 *and* m_2 *is the measure for* Π_2.

Obviously, the existence of an S-reduction from Π_1 to Π_2 implies the existence of an AP-reduction from Π_1 to Π_2. The reason why we need S-reductions is that AP-reductions do not (generally) preserve membership in **PO** [37]. We also note that S-reductions preserve approximation thresholds exactly for problems in **APX**: letting Π_1, Π_2 be problems in **APX**, assume that it is **NP**-hard to approximate Π_1 within c, and that there exists an S-reduction from Π_1 to Π_2. Then, it is **NP**-hard to approximate Π_2 within c, too.

In some of our hardness proofs, it will be convenient for us to use a type of approximation-preserving reduction called L-reduction [2].

DEFINITION 2.3. *An* **NPO** *maximization problem* Π_1 *is said to be* L-reducible *to an* **NPO** *maximization problem* Π_2 *if two polynomial-time computable functions* F *and* G *and positive constants* β *and* γ *exist such that*

(a) *given any instance* I *of* Π_1, *algorithm* F *produces an instance* $I' = F(I)$ *of* Π_2 *such that the measure of an optimal solution for* I', $\text{OPT}(I')$, *is at most* $\beta \cdot \text{OPT}(I)$;

(b) *given* $I' = F(I)$ *and any solution* s' *to* I', *algorithm* G *produces a solution* s *to* I *such that* $|m_1(I, s) - \text{OPT}(I)| \leq \gamma \cdot |m_2(I', s') - \text{OPT}(I')|$, *where* m_1 *is the measure for* Π_1 *and* m_2 *is the measure for* Π_2.

It is well known (see, e.g., Lemma 8.2 in [2]) that, if Π_1 is L-reducible to Π_2 and $\Pi_1 \in$ **APX**, then there is an AP-reduction from Π_1 to Π_2.

3. Algebraic approach. We sometimes need to define relations in terms of other relations, using certain logical formulas. In these definitions we use the standard correspondence between constraints and relations: a relation consists of all tuples of values satisfying the corresponding constraint. Although we sometimes use the same symbol for a constraint and its corresponding relation, the meaning will always be clear from the context. More specifically, for a relation R with arity a we will sometimes write $R(x_1, \ldots, x_a)$ with the meaning $(x_1, \ldots, x_a) \in R$, and the constraint $((x_1, \ldots, x_a), R)$ will sometimes be written as $R(x_1, \ldots, x_a)$.

An *operation* on a finite set D (the domain) is an arbitrary function $f : D^k \to D$. Any operation on D can be extended in a standard way to an operation on tuples over D as follows: let f be a k-ary operation on D and let R be an n-ary relation over D. For any collection of k tuples, $\boldsymbol{t_1}, \boldsymbol{t_2}, \ldots, \boldsymbol{t_k} \in R$, the n-tuple $f(\boldsymbol{t_1}, \boldsymbol{t_2}, \ldots, \boldsymbol{t_k})$ is defined as follows: $f(\boldsymbol{t_1}, \boldsymbol{t_2}, \ldots, \boldsymbol{t_k}) = (f(\boldsymbol{t_1}[1], \boldsymbol{t_2}[1], \ldots, \boldsymbol{t_k}[1]),\ f(\boldsymbol{t_1}[2], \boldsymbol{t_2}[2], \ldots, \boldsymbol{t_k}[2]), \ldots, f(\boldsymbol{t_1}[n], \boldsymbol{t_2}[n], \ldots, \boldsymbol{t_k}[n]))$, where $\boldsymbol{t_j}[i]$ is the ith component in tuple $\boldsymbol{t_j}$. A technique that has shown to be useful in determining the computational complexity of $\text{CSP}(\Gamma)$ is that of investigating whether the constraint language Γ is invariant under certain families of operations [32].

Now, let $R_i \in \Gamma$. If f is an operation such that for all $\boldsymbol{t_1}, \boldsymbol{t_2}, \ldots, \boldsymbol{t_k} \in R_i$, $f(\boldsymbol{t_1}, \boldsymbol{t_2}, \ldots, \boldsymbol{t_k}) \in R_i$, then R_i is *invariant* (or, in other words, *closed*) under f. If all constraint relations in Γ are invariant under f, then Γ is invariant under f. An operation f such that Γ is invariant under f is called a *polymorphism* of Γ. The set of all polymorphisms of Γ is denoted $Pol(\Gamma)$. Given a set of operations F, the set of all relations that are invariant under all the operations in F is denoted $Inv(F)$. Whenever there is only one operation under consideration, we write $Inv(f)$ instead of $Inv(\{f\})$.

We will need a number of operations in what follows: an operation f over D is said to be

- a *constant* operation if f is unary and $f(a) = c$ for all $a \in D$ and some $c \in D$;
- a *majority* operation if f is ternary and $f(a,a,b) = f(a,b,a) = f(b,a,a) = a$ for all $a, b \in D$;
- a *binary commutative idempotent* operation if f is binary, $f(a,a) = a$ for all $a \in D$, and $f(a,b) = f(b,a)$ for all $a, b \in D$;
- an *affine* operation if f is ternary and $f(a,b,c) = a - b + c$ for all $a, b, c \in D$, where $+$ and $-$ are the binary operations of an Abelian group $(D, +, -)$.

EXAMPLE 3.1. *Let $D = \{0,1,2\}$ and let f be the majority operation on D where $f(a,b,c) = a$ if a, b, and c are all distinct. Furthermore, let*

$$R = \{(0,0,1), (1,0,0), (2,1,1), (2,0,1), (1,0,1)\}.$$

It is then easy to verify that for every triple of tuples, $\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z} \in R$, we have $f(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z}) \in R$. For example, if $\boldsymbol{x} = (0,0,1)$, $\boldsymbol{y} = (2,1,1)$, and $\boldsymbol{z} = (1,0,1)$, then

$$\begin{aligned} f(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z}) &= (f(\boldsymbol{x}[1], \boldsymbol{y}[1], \boldsymbol{z}[1]), f(\boldsymbol{x}[2], \boldsymbol{y}[2], \boldsymbol{z}[2]), f(\boldsymbol{x}[3], \boldsymbol{y}[3], \boldsymbol{z}[3])) \\ &= (f(0,2,1), f(0,1,0), f(1,1,1)) = (0,0,1) \in R. \end{aligned}$$

We can conclude that R is invariant under f or, equivalently, that f is a polymorphism of R.

We continue by defining a closure operation $\langle \cdot \rangle$ on sets of relations: for any set $\Gamma \subseteq R_D$ the set $\langle \Gamma \rangle$ consists of all relations that can be expressed using relations from $\Gamma \cup \{=_D\}$ ($=_D$ is the equality relation on D), conjunction, and existential quantification. Intuitively, constraints using relations from $\langle \Gamma \rangle$ are exactly those which can be simulated by constraints using relations from Γ. The sets of relations of the form $\langle \Gamma \rangle$ are referred to as *relational clones*. An alternative characterization of relational clones is given in the following theorem.

THEOREM 3.2 (see [43]). *For every set $\Gamma \subseteq R_D$, $\langle \Gamma \rangle = Inv(Pol(\Gamma))$.*

The following theorem states that when we are studying the approximability of W-MAX SOL(Γ), it is sufficient to consider constraint languages that are relational clones.

THEOREM 3.3. *Let Γ be a constraint language and let $\Gamma' \subseteq \langle \Gamma \rangle$ be finite. Then* W-MAX SOL(Γ') *is S-reducible to* W-MAX SOL(Γ).

Proof. Consider an instance $I = (V, D, C, w)$ of W-MAX SOL(Γ'). We transform I into an instance $F(I) = (V', D, C', w')$ of W-MAX SOL(Γ).

For every constraint $C = ((v_1, \ldots, v_m), R)$ in I, R can be represented as

$$\exists_{v_{m+1}}, \ldots, \exists_{v_n} R_1(v_{11}, \ldots, v_{1n_1}) \wedge \cdots \wedge R_k(v_{k1}, \ldots, v_{kn_k}),$$

where $R_1, \ldots, R_k \in \Gamma \cup \{=_D\}$, $v_{m+1}, \ldots, v_n$ are fresh variables, and $v_{11}, \ldots, v_{1n_1}$, $v_{21}, \ldots, v_{kn_k} \in \{v_1, \ldots, v_n\}$. Replace the constraint C with the constraints

$$((v_{11}, \ldots, v_{1n_1}), R_1), \ldots, ((v_{k1}, \ldots, v_{kn_k}), R_k),$$

add $v_{m+1}, \ldots, v_n$ to V, and extend w so that $v_{m+1}, \ldots, v_n$ are given weight 0. If we repeat the same reduction for every constraint in C, then it results in an equivalent instance of W-MAX SOL($\Gamma_1 \cup \{=_D\}$).

For each equality constraint $((v_i, v_j), =_D)$, we do the following:

- replace all occurrences of v_j with v_i, update w' so that the weight of v_j is added to the weight of v_i, remove v_j from V, and remove the weight corresponding to v_j from w'; and

- remove $((v_i, v_j), =_D)$ from C.

The resulting instance $F(I) = (V', D, C', w')$ of W-MAX SOL(Γ) has the same optimum as I (i.e., $\text{OPT}(I) = \text{OPT}(F(I))$) and has been obtained in polynomial time.

Now, given a feasible solution S' for $F(I)$, let $G(I, S')$ be the feasible solution for I where the following hold:

- The variables in I assigned by S' inherit their value from S'.
- The variables in I which are still unassigned all occur in equality constraints, and their values can be found by simply propagating the values of the variables which have already been assigned.

It should be clear that $m(I, G(I, S')) = m(F(I), S')$ for any feasible solution S' for $F(I)$. Hence, the functions F and G, as described above, are the two parts of an S-reduction from W-MAX SOL(Γ') to W-MAX SOL(Γ). □

To exemplify the use of the results in this section, we prove the following tight approximability result.

LEMMA 3.4. *Let Γ be a finite constraint language over the domain $\{0, 1\}$. If* MAX ONES(Γ) *is in* **APX** *and not in* **PO**, *then there is a polynomial-time approximation algorithm for* MAX ONES(Γ) *with performance ratio 2, and it is* **NP***-hard to approximate* MAX ONES(Γ) *within $2 - \epsilon$, for any $\epsilon > 0$.*

Proof sketch. It follows from the classification results in [37] that if MAX ONES(Γ) is in **APX** and not in **PO**, then Γ is closed under the affine function $f(x, y, z) = x - y + z \pmod 2$. It also follows from [37, Lemma 6.6] that MAX ONES(Γ) is approximable within 2.

In the Boolean domain, the structure of all relational clones is known. This classification was made by Post in [42] and is often referred to as Post's lattice. A gentle introduction to Boolean relations and Post's lattice can be found in [15, 16].

By Theorem 3.3, it is enough to study the relational clones. By studying Post's lattice and the results for MAX ONES in [37], one can conclude that there are three relational clones which are interesting in our case (i.e., there are three relational clones such that MAX ONES(Γ) is in **APX** but not in **PO**). Those relational clones are called IL_0, IL_2, and IL_3 and can be defined as follows [16]:

$$IL_0 = \{x_1 + \cdots + x_k = 0 \pmod 2 \mid k \in \mathbb{N}\},$$
$$IL_2 = \{x_1 + \cdots + x_k = c \pmod 2 \mid k \in \mathbb{N},\ c \in \{0, 1\}\},$$
$$IL_3 = \{x_1 + \cdots + x_k = c \pmod 2 \mid k \text{ even},\ c \in \{0, 1\}\}.$$

We get the following inclusions from Post's lattice: $IL_0 \subset IL_2$ and $IL_3 \subset IL_2$.

It is proved in [38] that for a certain finite subset Γ of IL_3, MAX ONES(Γ) is **NP**-hard to approximate within $2 - \epsilon$ for all $\epsilon > 0$. As $IL_3 \subset IL_2$ we get that MAX ONES(Γ) is **NP**-hard to approximate within $2 - \epsilon$ for all $\epsilon > 0$ if $\langle\Gamma\rangle = IL_2$.

What remains to be done is to prove **NP**-hardness for approximating MAX ONES(Γ) within $2 - \epsilon$ if $\langle\Gamma\rangle = IL_0$. We do this with a reduction from MAX-E3-LIN-2 which is the following problem: given a set of equations over $\mathbb{Z}_2$ with exactly three variables per equation, satisfy as many equations as possible. It is proved in [29] that it is **NP**-hard to approximate MAX-E3-LIN-2 within $2 - \epsilon$ for any $\epsilon > 0$.

Let I be an instance of MAX-E3-LIN-2. We will construct an instance I' of MAX ONES(Γ) for a subset Γ of IL_0. Given an equation $x_1 + x_2 + x_3 = 1 \pmod 2$ in I (we can assume that all equations have 1 on the right-hand side [29]), we add the equation $x_1 + x_2 + x_3 = z$ (where z is a fresh variable that occurs only in one equation) to I'. Furthermore, we assign the weight 0 to x_1, x_2, and x_3 and the weight 1 to z. It is

not hard to see that a solution with measure m to I can easily be transformed into a solution with measure m for I'. It is also the case that a solution of measure m for I' can be seen as a solution with measure m for I. ∎

4. Hardness and membership results. In this section, we first prove some general **APX** and **poly-APX** membership results for W-MAX SOL(Γ). We also prove **APX**-completeness and **poly-APX**-completeness for some particular constraint languages. Most of our hardness results in subsequent sections are based on these results.

We begin by making the following easy but interesting observation: we know from the classification of W-MAX SOL(Γ) over the Boolean domain $\{0,1\}$ that there exist many constraint languages Γ for which W-MAX SOL(Γ) is **poly-APX**-complete. However, if 0 is not in the domain, then there are no constraint languages Γ such that W-MAX SOL(Γ) is **poly-APX**-complete.

PROPOSITION 4.1. *If* CSP(Γ) *is in* **P** *and* $0 \notin D$, *then* W-MAX SOL(Γ) *is in* **APX**.

Proof. It is proved in [19] that if CSP(Γ) is in **P**, then we can also find a solution in polynomial time. It should be clear that this solution is a $\frac{\max(D)}{\min(D)}$-approximate solution. Hence, we have a trivial approximation algorithm with performance ratio $\frac{\max(D)}{\min(D)}$. ∎

Next, we present a general membership result for W-MAX SOL(Γ). The proof is similar to the proof of the corresponding result for the Boolean domain in [37, Lemma 6.2] so we omit the proof.

LEMMA 4.2. *Let* $\Gamma^c = \Gamma \cup \{\{(d_1)\}, \ldots, \{(d_n)\}\}$, *where* $D = \{d_1, \ldots, d_n\}$ *(i.e.,* Γ^c *is the constraint language corresponding to* Γ *where we can force variables to take any given value in the domain). If* CSP(Γ^c) *is in* **P**, *then* W-MAX SOL(Γ) *is in* **poly-APX**.

We continue by proving the **APX**-completeness of some constraint languages.

LEMMA 4.3. *Let* $R = \{(a,a),(a,b),(b,a)\}$ *and* $a, b \in D$ *such that* $0 < a < b$. *Then,* W-MAX SOL($\{R\}$) *is* **APX**-*complete.*

Proof. Containment in **APX** follows from Proposition 4.1. To prove the hardness result we give an L-reduction (with parameters $\beta = 4b$ and $\gamma = \frac{1}{b-a}$) from the **APX**-complete problem INDEPENDENT SET restricted to degree 3 graphs [1] to MAX SOL($\{R\}$). Given an instance $I = (V, E)$ of INDEPENDENT SET (restricted to graphs of degree at most 3 and containing no isolated vertices), let $F(I) = (V, D, C)$ be the instance of MAX SOL($\{R\}$) where, for each edge $(v_i, v_j) \in E$, we add the constraint $R(x_i, x_j)$ to C. For any feasible solution S' for $F(I)$, let $G(I, S')$ be the solution for I where all vertices corresponding to variables assigned b in S' form the independent set. We have $|V|/4 \leq \text{OPT}(I)$ and $\text{OPT}(F(I)) \leq b|V|$, so $\text{OPT}(F(I)) \leq 4b\text{OPT}(I)$. Thus, $\beta = 4b$ is an appropriate parameter.

Let K be the number of variables being set to b in an arbitrary solution S' for $F(I)$. Then,

$$|\text{OPT}(I) - m(I, G(I, S'))| = \text{OPT}(I) - K \quad \text{and}$$
$$|\text{OPT}(F(I)) - m(F(I), S')| = (b-a)(\text{OPT}(I) - K).$$

Hence,

$$|\text{OPT}(I) - m(I, G(I, S'))| = \frac{1}{b-a}|\text{OPT}(F(I)) - m(F(I), S')|,$$

and $\gamma = \frac{1}{b-a}$ is an appropriate parameter. ∎

The generic **poly-APX**-complete constraint languages are presented in the following lemma.

LEMMA 4.4. *Let* $R = \{(0,0),(0,b),(b,0)\}$ *and* $b \in D$ *such that* $0 < b$. *Then,* W-MAX SOL($\{R\}$) *is* **poly-APX**-*complete.*

Proof. It is proved in [37, Lemma 6.15] that for $Q = \{(0,0),(0,1),(1,0)\}$, it is the case that W-MAX SOL($\{Q\}$) is **poly-APX**-complete. To prove the **poly-APX**-hardness we give an *AP*-reduction from W-MAX SOL($\{Q\}$) to W-MAX SOL($\{R\}$). Given an instance I of W-MAX SOL($\{Q\}$), let $F(I)$ be the instance of W-MAX SOL($\{R\}$) where all occurrences of Q have been replaced by R. For any feasible solution S' for $F(I)$, let $G(I,S')$ be the solution for I where all variables assigned b in S' are instead assigned 1. It should be clear that this is an *AP*-reduction, since if S' is an α-approximate solution to $F(I)$, then $G(I,S')$ is an α-approximate solution for I.

To see that W-MAX SOL($\{R\}$) is in **poly-APX**, let $D = \{d_1,\ldots,d_n\}$ and note that $\Gamma^c = \{R,\{(d_1)\},\ldots,\{(d_n)\}\}$ is invariant under the min function. As the min function is associative, commutative, and idempotent, CSP(Γ^c) is solvable in polynomial time [32]. Hence, W-MAX SOL($\{R\}$) is in **poly-APX** due to Lemma 4.2. ∎

5. Tractable constraint languages. In this section, we present tractability results for two classes of constraint languages: *injective* constraint languages and *generalized* max-*closed* constraint languages. The tractability of injective constraints follows from Cohen et al. [21, sect. 4.4], but we present a simple proof for increased readability. The tractability result for generalized max-closed constraints is new, and its proof constitutes the main part of this section.

These two classes can be seen as substantial and nontrivial generalizations of the tractable classes known for the corresponding (WEIGHTED) MAX ONES problem over the Boolean domain. There are only three tractable classes of constraint languages over the Boolean domain, namely, width-2 affine, 1-valid, and weakly positive [37]. Width-2 affine constraint languages are examples of injective constraint languages, and the classes of 1-valid and weakly positive constraint languages are examples of generalized max-closed constraint languages. The monotone constraints which are, for instance, studied by Hochbaum et al. [27] and Hochbaum and Naor [28] (in relation to integer programming) and Woeginger [51] (in relation to constraint satisfaction) are also related to generalized max-closed constraints. Hochbaum and Naor [28] show that monotone constraints can be characterized as those constraints that are simultaneously invariant under the max and min operators. Hence, monotone constraints are also generalized max-closed constraints as long as the underlying domain is finite.

5.1. Injective relations. We begin by formally defining *injective relations.*

DEFINITION 5.1. *A relation* $R \in R_D$ *is called* injective *if there exists a subset* $D' \subseteq D$ *and an injective function* $\pi : D' \to D$ *such that*

$$R = \{(x,\pi(x)) \mid x \in D'\}.$$

It is important to note that the function π is *not* assumed to be total on D. Let I^D denote the set of all injective relations on the domain D and let $\Gamma_I^D = \langle I^D \rangle$.

EXAMPLE 5.2. *Let* $D = \{0,1\}$ *and let* $R = \{(x,y) \mid x,y \in D,\ x+y \equiv 1 \pmod 2\}$. *The relation* R *is injective because the function* $f : D \to D$ *defined as* $f(0) = 1$ *and* $f(1) = 0$ *is injective. More generally, let* $G = (D',+,-)$ *be an arbitrary Abelian group and let* $c \in D'$ *be an arbitrary group element. It is easy to see that the relation* $\{(x,y) \mid x,y \in D',\ x+y = c\}$ *is injective.*

R is an example of a relation which is invariant under an affine operation. Such relations have previously been studied in relation to the MAX ONES problem in [37, 38]. We will give some additional results for such constraints in section 6.3. With the terminology used in [37, 38], R is said to be *width-2 affine*. The relations which can be expressed as the set of solutions to an equation with two variables over an Abelian group are exactly the width-2 affine relations, so the injective relations are a superset of the width-2 affine relations.

To see that W-MAX SOL(Γ) is in **PO** for every finite constraint language $\Gamma \subseteq \langle I^D \rangle$, it is sufficient to prove that W-MAX SOL(I^D) is in **PO** by Theorem 3.3. Given an instance of W-MAX SOL(I^D), consider the graph having the variables as vertices and edges between the vertices/variables occurring together in the same constraint. Each connected component of this graph represents an independent subproblem that can be solved separately. If a value is assigned to a variable/vertex, all variables/vertices in the same component will be forced to take a value by propagating this assignment. Hence, each connected component has at most $|D|$ different solutions (that can be easily enumerated), and an optimal one can be found in polynomial time.

5.2. Generalized max-closed relations. We begin by giving the following basic definition.

DEFINITION 5.3. *A constraint language Γ over a domain $D \subset \mathbb{N}$ is* generalized max-closed *if and only if there exists a binary operation $f \in Pol(\Gamma)$ such that for all $a, b \in D$,*

1. *if $a \neq b$ and $f(a,b) \leq \min(a,b)$, then $f(b,a) > \max(a,b)$; and*
2. *$f(a,a) \geq a$.*

In the conference version of this article [35], the definition of generalized max-closed constraint languages was slightly more restrictive. The following two examples will clarify the definition above.

EXAMPLE 5.4. *Assume that the domain D is $\{0,1,2,3\}$. As an example of a generalized* max*-closed relation consider*

$$R = \{(0,0),(1,0),(0,2),(1,2)\}.$$

R is invariant under max *and is therefore generalized* max*-closed since* max *satisfies the properties of Definition* 5.3*. Now, consider the relation Q defined as*

$$Q = \{(0,1),(1,0),(2,1),(2,2),(2,3)\}.$$

Q is not invariant under max *because*

$$\max((0,1),(1,0)) = (\max(0,1),\max(1,0)) = (1,1) \notin Q.$$

Let the operation $\circ : D^2 \to D$ be defined by the following Cayley table:[2]

$\circ$	0	1	2	3
0	0	2	2	3
1	2	1	2	2
2	2	2	2	3
3	3	2	3	3

Now, it is easy to verify that $Inv(\circ)$ is a set of generalized max*-closed relations and that $Q \in Inv(\circ)$.*

[2]Note that we write $x \circ y$ instead of $\circ(x,y)$.

EXAMPLE 5.5. *Consider the relations R_1 and R_2 defined as*

$$R_1 = \{(1,1,1),(1,0,0),(0,0,1),(1,0,1)\}$$

and $R_2 = R_1 \setminus \{(1,1,1)\}$. The relation R_1 is 1*-valid because the all-*1 *tuple is in R_1, i.e., $(1,1,1) \in R_1$. R_2, on the other hand, is not* 1*-valid but is weakly positive*[3] *because it is invariant under* max*. Note that both R_1 and R_2 are generalized* max*-closed since R_1 is invariant under $f(x,y) = 1$ and R_2 is invariant under $f(x,y) = \max(x,y)$. It is in fact the case that every weakly positive relation is invariant under* max *(more is true in the Boolean domain: a relation is weakly positive if and only if it is invariant under* max*), so the* 1*-valid and weakly positive relations are subsets of the generalized* max*-closed relations.*

The tractability of generalized max-closed constraint languages crucially depends on the following lemma.

LEMMA 5.6. *If Γ is generalized* max*-closed, then all relations*

$$R = \{(d_{11}, d_{12}, \ldots, d_{1m}), \ldots, (d_{t1}, d_{t2}, \ldots, d_{tm})\}$$

in Γ have the property that the tuple

$$\boldsymbol{t_{\max}} = (\max\{d_{11}, \ldots, d_{t1}\}, \ldots, \max\{d_{1m}, \ldots, d_{tm}\})$$

is in R, too.

Proof. Assume that there is a relation R in Γ such that the tuple

$$\boldsymbol{t_{\max}} = (\max\{d_{11}, \ldots, d_{t1}\}, \ldots, \max\{d_{1m}, \ldots, d_{tm}\})$$

is not in R. Define the distance between two tuples to be the number of coordinates where they disagree (i.e., the Hamming distance). Let $\boldsymbol{a}$ be a tuple in R with minimal distance from $\boldsymbol{t_{\max}}$ and let I denote the set of coordinates where $\boldsymbol{a}$ agrees with $\boldsymbol{t_{\max}}$. By the assumption that $\boldsymbol{t_{\max}}$ is not in R, we know that the distance between $\boldsymbol{a}$ and $\boldsymbol{t_{\max}}$ is at least 1. Hence, without loss of generality, assume that $\boldsymbol{a}[1] \neq \boldsymbol{t_{\max}}[1]$ and that $\boldsymbol{a}[1]$ is maximal for all tuples in R agreeing with $\boldsymbol{t_{\max}}$ on the coordinates in I. Let $\boldsymbol{b}$ be a tuple in R such that $\boldsymbol{b}[1] = \boldsymbol{t_{\max}}[1]$.

Since Γ is generalized max-closed, there exists an operation $f \in Pol(\Gamma)$ such that for all $a, b \in D$ $(a \neq b)$, it holds that $f(a,b) > \max(a,b)$ whenever $f(b,a) \leq \min(a,b)$. Furthermore, for all $a \in D$ it holds that $f(a,a) \geq a$. Now consider the tuple $\boldsymbol{x^n}$ $(n = |D|)$ defined as follows: $\boldsymbol{x^1} = f(\boldsymbol{a}, \boldsymbol{b})$ and

$$\boldsymbol{x^{i+1}} = \begin{cases} f(\boldsymbol{x^i}, \boldsymbol{a}) & \text{if } f(\boldsymbol{x^i}[1], \boldsymbol{a}[1]) > \boldsymbol{a}[1], \\ f(\boldsymbol{a}, \boldsymbol{x^i}) & \text{otherwise.} \end{cases}$$

We begin by proving that $\boldsymbol{x^n}$ agrees with $\boldsymbol{a}$ on all coordinates in I. Let $\boldsymbol{z}$ be an arbitrary tuple in R. Note that for each $i \in I$ such that $\boldsymbol{z}[i] \neq \boldsymbol{a}[i]$, it is the case that $f(\boldsymbol{a}[i], \boldsymbol{z}[i]) \leq \min(\boldsymbol{a}[i], \boldsymbol{z}[i])$ implies that $f(\boldsymbol{z}[i], \boldsymbol{a}[i]) > \max(\boldsymbol{a}[i], \boldsymbol{z}[i])$. Hence, as $\boldsymbol{a}[i] = \boldsymbol{t_{\max}}[i]$, we cannot have that $f(\boldsymbol{a}[i], \boldsymbol{z}[i]) \leq \min(\boldsymbol{a}[i], \boldsymbol{z}[i])$. So, for each $\boldsymbol{z} \in R$ and $i \in I$, we must have $f(\boldsymbol{a}[i], \boldsymbol{z}[i]) > \min(\boldsymbol{a}[i], \boldsymbol{z}[i])$ whenever $\boldsymbol{a}[i] \neq \boldsymbol{z}[i]$. By an analogous argument, it follows that for each $\boldsymbol{z} \in R$ and $i \in I$ we must have $f(\boldsymbol{z}[i], \boldsymbol{a}[i]) > \min(\boldsymbol{a}[i], \boldsymbol{z}[i])$ whenever $\boldsymbol{a}[i] \neq \boldsymbol{z}[i]$.

[3] A relation is weakly positive if it can be expressed as a formula in conjunctive normal form having at most one negated variable in each clause.

This together with the fact that $f(d,d) \geq d$ for all $d \in D$ and that $\boldsymbol{a}$ agrees with $\boldsymbol{t_{\max}}$ on I implies that $f(\boldsymbol{a}, \boldsymbol{x^n})$ agrees with $\boldsymbol{a}$ on I.

We now show that $\boldsymbol{x^n}[1] > \boldsymbol{a}[1]$. This follows from essentially the same argument as above. First note that $f(\boldsymbol{a}[1], \boldsymbol{b}[1]) = \boldsymbol{x^1}[1] > \boldsymbol{a}[1]$. If $f(\boldsymbol{a}[1], \boldsymbol{b}[1]) \leq \min(\boldsymbol{a}[1], \boldsymbol{b}[1])$, then $f(\boldsymbol{b}[1], \boldsymbol{a}[1]) > \boldsymbol{b}[1]$ which is not possible since $\boldsymbol{b}[1] = \boldsymbol{t_{\max}}[1]$. Hence, we must have $f(\boldsymbol{a}[1], \boldsymbol{b}[1]) = \boldsymbol{x^1}[1] > \min(\boldsymbol{a}[1], \boldsymbol{b}[1])$. Now, by the definition of $\boldsymbol{x}^{i+1}$, it follows that if $\boldsymbol{x^i}[1] > \boldsymbol{a}[1]$, then $\boldsymbol{x}^{i+1}[1] > \min(\boldsymbol{x^i}[1], \boldsymbol{a}[1]) = \boldsymbol{a}[1]$ (just note that at least one of $f(\boldsymbol{x^i}[1], \boldsymbol{a}[1])$ and $f(\boldsymbol{a}[1], \boldsymbol{x^i}[1])$ is strictly larger than $\min(\boldsymbol{x^i}[1], \boldsymbol{a}[1]) = \boldsymbol{a}[1]$). Hence, it follows by induction that $\boldsymbol{x^n}[1] > \boldsymbol{a}[1]$.

Thus, we have a contradiction with the fact that $a[1]$ is maximal for all tuples in R agreeing with $\boldsymbol{t_{\max}}$ on the coordinates in I. Hence, our assumption was wrong and $\boldsymbol{t_{\max}}$ is in R. □

The algorithm for solving W-Max Sol(Γ) when Γ is generalized max-closed is a simple consistency-based algorithm. The algorithm, which is based on pairwise consistency, closely follows the algorithm for Csps over max-closed constraint languages from [33].

We first need to introduce some terminology.

Definition 5.7. *Given a constraint $C_i = (s_i, R_i)$ and an (ordered) subset s_i' of the variables in s_i, where $(i_1, i_2, \ldots, i_k)$ are the indices in s_i of the elements in s_i', the* projection *of C_i onto the variables in s_i' is denoted by $\pi_{s_i'} C_i$ and defined as $\pi_{s_i'} C_i = C_i' = (s_i', R_i')$, where R_i' is the relation $\{(\boldsymbol{a}[i_1], \boldsymbol{a}[i_2], \ldots, \boldsymbol{a}[i_k]) \mid \boldsymbol{a} \in R_i\}$.*

Definition 5.8. *For any pair of constraints $C_i = (s_i, R_i)$, $C_j = (s_j, R_j)$, the* join *of C_i and C_j, denoted $C_i \bowtie C_j$, is the constraint on $s_i \cup s_j$ containing all tuples $\boldsymbol{t}$ such that $\pi_{s_i}\{\boldsymbol{t}\} \in R_i$ and $\pi_{s_j}\{\boldsymbol{t}\} \in R_j$.*

Definition 5.9 (see [30]). *An instance of a constraint satisfaction problem $I = (V, D, C)$ is* pairwise consistent *if and only if for any pair of constraints $C_i = (s_i, R_i)$, $C_j = (s_j, R_j)$ in C, it holds that the constraint resulting from projecting C_i onto the variables in $s_i \cap s_j$ equals the constraint resulting from projecting C_j onto the variables in $s_i \cap s_j$; i.e., $\pi_{s_i \cap s_j} C_i = \pi_{s_i \cap s_j} C_j$.*

We are now ready to prove the tractability of generalized max-closed constraint languages.

Theorem 5.10. *If Γ is generalized* max*-closed, then* W-Max Sol(Γ) *is in* **PO**.

Proof. Since $Inv(f)$ is a relational clone, constraints built over $Inv(f)$ are invariant when taking joins and projections [31, Lemma 2.8] (i.e., the underlying relations are still invariant under f). It was proved in [30] that any set of constraints can be reduced to an equivalent set of pairwise consistent constraints in polynomial time. Since the set of pairwise consistent constraints can be obtained by repeated application of the join and projection operations, the underlying relations in the resulting constraints are still in $Inv(f)$.

Hence, given an instance $I = (V, D, C, w)$ of W-Max Sol($Inv(f)$), we can assume that the constraints in C are pairwise consistent. We prove that for pairwise consistent C, either C has a constraint with a constraint relation that does not contain any tuples (i.e., no assignment satisfies the constraint and there is no solution) or we can find the optimal solution in polynomial time.

Assume that C has no empty constraints. For each variable x_i, let d_i be the maximum value allowed for that variable by some constraint C_j (where x_i is in the constraint scope of C_j). We will prove that $(d_1, \ldots, d_n)$ is an optimal solution to I. Obviously, if $(d_1, \ldots, d_n)$ is a solution to I, then it is the optimal solution. Hence, it is sufficient to prove that $(d_1, \ldots, d_n)$ is a solution to I.

Assume, with the aim of reaching a contradiction, that $(d_1, \ldots, d_n)$ is not a solution to I. Then, there exists a constraint C_j in C not satisfied by $(d_1, \ldots, d_n)$. Since the constraint relation corresponding to C_j is generalized max-closed, there exists a variable x_i in the constraint scope of C_j such that C_j has no solution where d_i is assigned to x_i. Note that it is essential that C_j is generalized max-closed to rule out the possibility that there exist two variables x_i and x_j in the constraint scope of C_j such that C_j has two solutions t, u where $t(x_i) = d_i$ and $u(x_j) = d_j$, but C_j has no solution s where $s(x_i) = d_i$ and $s(x_j) = d_j$. We know that there exists a constraint C_i in C having x_i in its constraint scope and d_i an allowed value for x_i. This contradicts the fact that C is pairwise consistent. Thus, $(d_1, \ldots, d_n)$ is a solution to I. □

6. Maximal constraint languages. A *maximal constraint language* Γ is a constraint language such that $\langle\Gamma\rangle \subset R_D$, and if $R \notin \langle\Gamma\rangle$, then $\langle\Gamma \cup \{R\}\rangle = R_D$. That is, the maximal constraint languages are the largest constraint languages that are not able to express all finitary relations over D. This implies, among other things, that there exists an operation f such that $\langle\Gamma\rangle = Inv(f)$ whenever Γ is a maximal constraint language [45]. Relational clones $\langle\Gamma\rangle$ such that Γ is a maximal constraint language are called maximal relational clones. The complexity of the Csp(Γ) problem for all maximal constraint languages on domains $|D| \leq 3$ was determined in [14]. Moreover, it was shown in [14] that the only case that remained to be classified in order to extend the classification to all maximal constraint languages over a finite domain was the case where $\langle\Gamma\rangle = Inv(f)$ for binary commutative idempotent operations f. These constraint languages were finally classified by Bulatov in [8].

Theorem 6.1 (see [8, 14]). *Let Γ be a maximal constraint language on an arbitrary finite domain D. Then,* Csp(Γ) *is in* **P** *if $\langle\Gamma\rangle = Inv(f)$ where f is a constant operation, a majority operation, a binary commutative idempotent operation, or an affine operation. Otherwise,* Csp(Γ) *is* **NP***-complete.*

In this section, we classify the approximability of W-Max Sol(Γ) for all maximal constraint languages Γ over $|D| \leq 4$. Moreover, we prove that the only cases that remain to be classified, in order to extend the classification to all maximal constraint languages over finite domains, are constraint languages Γ such that $\langle\Gamma\rangle$ is invariant under a binary commutative idempotent operation. We also prove that if a certain conjecture regarding minimal clones generated by binary operations, due to Szczepara [47], holds, then our classification can be extended to also capture these last cases.

Theorem 6.2. *Let Γ be maximal constraint language on a finite domain D, with $|D| \leq 4$, and $\langle\Gamma\rangle = Inv(f)$.*

1. *If Γ is generalized* max*-closed or an injective constraint language, then* W-Max Sol(Γ) *is in* **PO***;*
2. *else if f is an affine operation, a constant operation different from the constant 0 operation, or a binary commutative idempotent operation satisfying $f(0, b) > 0$ for all $b \in D \setminus \{0\}$ (assuming $0 \in D$), or if $0 \notin D$ and f is a binary commutative idempotent operation or a majority operation, then* W-Max Sol(Γ) *is* **APX***-complete;*
3. *else if f is a binary commutative idempotent operation or a majority operation, then* W-Max Sol(Γ) *is* **poly-APX***-complete;*
4. *else if f is the constant 0 operation, then finding a solution with nonzero measure is* **NP***-hard;*
5. *otherwise, finding a feasible solution is* **NP***-hard.*

Moreover, if Conjecture 131 *from* [47] *holds, then the results above hold for arbitrary finite domains D.*

The proof of the preceding theorem consists of a careful analysis of the approximability of W-MAX SOL(Γ) for all maximal constraint languages Γ such that $\langle\Gamma\rangle = Inv(f)$, where f is one of the types of operations in Theorem 6.1. These results are presented below.

6.1. Constant operation. We begin by considering maximal constraint languages that are invariant under constant operations. Given an instance $I = (V, D, C)$ of a CSP problem, we define the *constraint graph* of I to be $G = (V, E)$, where $\{v, v'\} \in E$ if there is at least one constraint $c \in C$ which has both v and v' in its constraint scope.

LEMMA 6.3. *Let $d^* = \max(D)$ and let C_d be a constraint language such that $\langle C_d\rangle = Inv(f_d)$, where $f_d : D \to D$ satisfies $f_d(x) = d$ for all $x \in D$. Then,* W-MAX SOL(C_{d^*}) *is in* **PO**, W-MAX SOL(C_d) *is* **APX**-*complete if $d \in D\backslash\{d^*, 0\}$, and it is* **NP**-*hard to find a solution with nonzero measure for* W-MAX SOL(C_0).

Proof. The tractability of W-MAX SOL(C_{d^*}) is trivial, since the optimum solution is obtained by assigning d^* to all variables.

For the **APX**-hardness of W-MAX SOL(C_d) ($d \in D\backslash\{d^*, 0\}$), it is sufficient to note that $\{(d, d), (d, d^*), (d^*, d)\}$ is in $\langle C_d\rangle$, and since $0 < d < d^*$ it follows from Lemma 4.3 that W-MAX SOL(C_d) is **APX**-hard. It is easy to realize that W-MAX SOL(C_d) is in **APX**, since we can obtain a $\frac{d^*}{d}$-approximate solution by assigning the value d to all variables.

The fact that it is **NP**-hard to find a solution with nonzero measure for W-MAX SOL(C_0) over the Boolean domain $\{0, 1\}$ is proved in [37, Lemma 6.23]. To prove that it is **NP**-hard to find a solution with nonzero measure for W-MAX SOL(C_0) over a domain D of size ≥ 3, we give a reduction from the well-known **NP**-complete problem POSITIVE-1-IN-3-SAT [26], i.e., CSP($\{R\}$) with $R = \{(1, 0, 0), (0, 1, 0), (0, 0, 1)\}$. It is easy to see that POSITIVE-1-IN-3-SAT restricted to instances where the constraint graph is connected is still **NP**-complete.

Now, let $R' = \{(b, a, a), (a, b, a), (a, a, b), (0, 0, 0)\}$, where $0 < a < b$ and $a, b, 0 \in D$. For an instance $I = (V, D, C)$ of CSP($\{R\}$) where the constraint graph of I is connected, create an instance I' of W-MAX SOL($\{R'\}$) by replacing all occurrences of R by R' and giving all variables weight 1. Since the constraint graph is connected, I has a solution if and only if I' has a solution with nonzero measure, and since $R' \in C_0$, it follows that it is **NP**-hard to find a solution with nonzero measure for W-MAX SOL(C_0). □

6.2. Majority operation. Maximal constraint languages based on majority operations are fairly easy to analyze due to the results in section 4.

LEMMA 6.4. *Let m be an arbitrary majority operation on D. Then,* W-MAX SOL($Inv(m)$) *is* **APX**-*complete if $0 \notin D$ and* **poly-APX**-*complete if $0 \in D$.*

Proof. Arbitrarily choose elements $a, b \in D$ such that $a < b$. Then, it is easy to see that $\{(a, a), (a, b), (b, a)\}$ is in $Inv(m)$. Thus, by Proposition 4.1 and Lemmas 4.3 and 4.4, it follows that W-MAX SOL($Inv(m)$) is **APX**-complete or **poly-APX**-complete depending on whether 0 is in D or not. □

6.3. Affine operation. We split the proof of this result into two parts. The first part, section 6.3.1, contains the hardness result: for every affine operation $a : D^3 \to D$, W-MAX SOL($Inv(a)$) is **APX**-hard. The proof is based on a reduction from MAX-p-CUT which is a well-known **APX**-complete problem [2]. Membership in **APX** is proved in section 6.3.2 by presenting an approximation algorithm with constant performance ratio.

We will denote the affine operation on the group G by a_G; i.e., if $G = (D, +_G, -_G)$, then $a_G(x, y, z) = x -_G y +_G z$.

6.3.1. APX-hardness. In this section we will prove Theorem 6.11, which states that relations invariant under an affine operation give rise to **APX**-hard W-Max Sol-problems. We need a number of lemmas before we can prove this result. We begin by giving an L-reduction from Max-p-Cut to W-Max Sol Eqn$(\mathbb{Z}_p, g)$, where p is prime. Max-p-Cut and W-Max Sol Eqn are defined as follows.

Definition 6.5 (see [2]). Max-p-Cut *is an optimization problem with the following:*

Instance: *A graph $G = (V, E)$.*
Solution: *A partition of V into p disjoint sets $C_1, C_2, \ldots, C_p$.*
Measure: *The number of edges between the disjoint sets, i.e.,*

$$\sum_{i=1}^{p-1} \sum_{j=i+1}^{p} |\{\{v, v'\} \in E \mid v \in C_i \text{ and } v' \in C_j\}|.$$

Definition 6.6 (see [38]). *Let $G = (D, +_G, -_G)$ be a group and $g : D \to \mathbb{N}$ a function.* W-Max Sol Eqn(G, g) *is an optimization problem with the following:*

Instance: *A triple (V, E, w), where $V = \{v_1, v_2, \ldots, v_n\}$ is a set of variables, E is a set of equations of the form $u_1 +_G \ldots +_G u_k = 0_G$, where each u_i is either a variable (e.g., "v_4"), an inverted variable (e.g., "$-_G v_7$"), or a group constant, and w is a weight function $w : V \to \mathbb{N}$.*
Solution: *An assignment $f : V \to D$ to the variables such that all equations are satisfied.*
Measure: $\sum_{v \in V} w(v) g(f(v))$.

We do not require the group G to be Abelian in the definition of W-Max Sol Eqn, but this will always be the case in this article. Note that the function g and the group G are not parts of the input so W-Max Sol Eqn(G, g) is a problem parameterized by G and g. We refer the reader to [38] for more information on the problem W-Max Sol Eqn$(\mathbb{Z}_p, g)$.

The following lemma follows from the proof of Proposition 2.3 in [20].

Lemma 6.7. *For any instance $I = (V, E)$ of* Max-p-Cut, *we have* opt$(I) \geq |E|(1 - 1/p)$.

We can now prove the **APX**-hardness of W-Max Sol Eqn.

Lemma 6.8. *For every prime p and every nonconstant function $g : \mathbb{Z}_p \to \mathbb{N}$,* W-Max Sol Eqn$(\mathbb{Z}_p, g)$ *is* **APX**-*hard.*

Proof. Given an instance $I = (V, E)$ of Max-p-Cut, we construct an instance $F(I)$ of W-Max Sol Eqn$(\mathbb{Z}_p, g)$, where, for every vertex $v_i \in V$, we create a variable x_i and give it weight 0 and, for every edge $\{v_i, v_j\} \in E$, we create p variables $z_{ij}^{(k)}$ for $k = 0, \ldots, p-1$ and give them weight 1. Let $g_{\min}$ denote an element in $\mathbb{Z}_p$ that minimizes g, i.e.,

$$\min_{x \in \mathbb{Z}_p} g(x) = g(g_{\min}),$$

and let g_s denote the sum

$$\sum_{k=0}^{p-1} g(k).$$

For every edge $\{v_i, v_j\} \in E$, we introduce the equations

$$k(x_i - x_j) + g_{\min} = z_{ij}^{(k)}$$

for $k = 0, \ldots, p-1$. If $x_i = x_j$, then the p equations for the edge $\{v_i, v_j\}$ will contribute $pg(g_{\min})$ to the measure of the solution. On the other hand, if $x_i \neq x_j$, then the p equations will contribute g_s to the measure.

Given a solution s' to $F(I)$, we can construct a solution s to I in the following way: let $s(v_i) = s'(x_i)$; i.e., for every vertex v_i, place this vertex in partition $s'(x_i)$. The measures of the solutions s and s' are related to each other by the equality

$$m'(F(I), s') = |E| \cdot p \cdot g(g_{\min}) + (g_s - p \cdot g(g_{\min})) \cdot m(I, s). \tag{6.1}$$

From (6.1), we get

$$\textsc{opt}(F(I)) = |E| \cdot p \cdot g(g_{\min}) + (g_s - p \cdot g(g_{\min})) \cdot \textsc{opt}(I) \tag{6.2}$$

and from Lemma 6.7, we have that $\textsc{opt}(I) \geq |E| \cdot (1 - 1/p)$, which implies $\textsc{opt}(I) \geq |E|/p$. By combining this with (6.2), we can conclude that

$$\begin{aligned}\textsc{opt}(F(I)) &= \textsc{opt}(I)\left(\frac{|E| \cdot p \cdot g(g_{\min})}{\textsc{opt}(I)} + g_s - p \cdot g(g_{\min})\right) \\ &\leq \textsc{opt}(I)\Big(p^2 \cdot g(g_{\min}) + g_s - p \cdot g(g_{\min})\Big).\end{aligned}$$

Hence, $\beta = p(p-1) \cdot g(g_{min}) + g_s$ is an appropriate parameter for the L-reduction.

We will now deduce an appropriate γ-parameter for the L-reduction: from (6.1) and (6.2) we get

$$|\textsc{opt}(F(I)) - m'(F(I), s')| = (g_s - p \cdot g(g_{\min})) \cdot |\textsc{opt}(I) - m(I, s)|;$$

thus, $\gamma = 1/(g_s - p \cdot g(g_{\min}))$ is sufficient (γ is well defined because a nonconstant g implies $g_s > p \cdot g_{\min}$). □

We need two lemmas before we can prove the **APX**-hardness of affine relations. Let $v_1, v_2, \ldots, v_k$ be a collection of variables, $G = (D, +_G, -_G)$ an Abelian group, and E an equation of the form $x_1 +_G x_2 +_G \ldots +_G x_n = c$, where each x_i is a (possibly inverted) variable and $c \in D$. Note that each variable may occur several times in E. The set of all solutions to E may be seen as a k-ary relation R_E on D^k. The following two lemmas are well known [32].

LEMMA 6.9. *The relation R_E is invariant under a_G.*

LEMMA 6.10. *If P is a coset of G, then P is invariant under a_G.*

We now have all results needed to prove the main theorem of this section.

THEOREM 6.11. W-MAX SOL($Inv(a_G)$) *is* **APX***-hard for every affine operation a_G.*

Proof. We show that there exists a prime p and a nonconstant function $h : \mathbb{Z}_p \to \mathbb{N}$ such that W-MAX SOL EQN($\mathbb{Z}_p, h$) can be S-reduced to W-MAX SOL($Inv(a_G)$). The result will then follow from Lemma 6.8.

Let p be a prime such that $\mathbb{Z}_p$ is isomorphic to a subgroup H of G. We know that such a p always exists by the fundamental theorem of finitely generated Abelian groups. Let α be the isomorphism which maps elements of $\mathbb{Z}_p$ to elements of H and let $h = \alpha$. (Note that $H \subset \mathbb{N}$ since the domain is a subset of $\mathbb{N}$. Consequently, h may be viewed as a function from $\mathbb{Z}_p$ to $\mathbb{N}$.)

Let $I = (V, E, w)$ be an instance of W-MAX SOL EQN$(\mathbb{Z}_p, h)$ with variables $V = \{v_1, \ldots, v_n\}$ and equations $E = \{e_1, \ldots, e_m\}$. We will construct an instance $I' = (V, D, C, w)$ of W-MAX SOL$(Inv(a_G))$.

Let U be the unary relation for which $x \in U \iff x \in H$; this relation is in $Inv(a_G)$ by Lemma 6.10. For every equation $E_i \in E$, there is a corresponding pair (s_i, R_i), where s_i is a list of variables and R_i is a relation in $Inv(a_G)$ such that the set of solutions to E_i contains exactly the tuples which satisfy (s_i, R_i) by Lemma 6.9. We can now construct C:

$$C = \{(v_i, U) \mid 1 \leq i \leq n\} \cup \{(s_i, R_i) \mid 1 \leq i \leq m\}.$$

It is easy to see that I and I' are essentially the same in the sense that every feasible solution to I is also a feasible solution to I', and that they have the same measure. The converse is also true: every feasible solution to I' is also a feasible solution to I. Hence, we have given an S-reduction from W-MAX SOL EQN$(\mathbb{Z}_p, h)$ to W-MAX SOL$(Inv(a_G))$. As h is not constant (it is in fact injective), it follows from Lemma 6.8 that W-MAX SOL EQN$(\mathbb{Z}_p, h)$ is **APX**-hard. This S-reduction implies that W-MAX SOL$(Inv(a_G))$ is **APX**-hard. □

6.3.2. Membership in APX. We will now prove that relations that are invariant under an affine operation give rise to problems which are in **APX**. It has been proved that a relation which is invariant under an affine operation is a coset of a subgroup of some Abelian group [32]. We will give an approximation algorithm for the more general problem when the relations are cosets of subgroups of a finite group.

Our algorithm is based on an algorithm by Bulatov and Dalmau [12] for deciding the satisfiability of *Mal'tsev constraints*. A *Mal'tsev operation* is a ternary operation m such that $m(x, y, y) = m(y, y, x) = x$ for all $x, y \in D$. If a constraint language Γ is invariant under a Mal'tsev operation, then Bulatov and Dalmau have proved that CSP(Γ) is solvable in polynomial time. We note that every affine operation is a Mal'tsev operation since $x -_G y +_G y = x$ and $y -_G y +_G x = x$.

Let G^k denote the direct product of k copies of G. We are now ready to prove containment in **APX**.

THEOREM 6.12. *Let $G = (D; +_G, -_G)$ be a finite group and let Γ be a constraint language such that for each $R \in \Gamma$ there is an integer k such that R is a coset of some subgroup of G^k. Then* W-MAX SOL(Γ) *is in* **APX**.

Proof. Let $I = (V, D, C, w)$ be an arbitrary instance of W-MAX SOL(Γ), where $V = \{v_1, \ldots, v_n\}$. Feasible solutions to our optimization problem can be viewed as certain elements in $H = G^n$. Each constraint $C_i \in C$ defines a coset $a_i +_G J_i$ of H with representative $a_i \in H$, for some subgroup J_i of H. The set of solutions to the problem is the intersection of all those cosets. Thus, $S = \bigcap_{i=1}^{|C|} a_i +_G J_i$ denotes the set of all solutions.

Since Γ is invariant under the affine operation $a_G(x, y, z) = x -_G y +_G z$ and a_G is a Mal'tsev operation, we can decide if there are any solutions to I in polynomial time [12]. Clearly, S is empty if and only if there are no solutions. It is well known that an intersection of a set of cosets is either empty or a coset so if $S \neq \emptyset$, then S is a coset.

We will represent the elements of G^n by vectors $\boldsymbol{x} = (x_1, \ldots, x_n)$ where each x_i is an element of G. For any instance I, we define $\mathcal{R}(I)$ to be the random variable which is uniformly distributed over the set of solutions to I. Let V_i denote the random variable which corresponds to the value which will be assigned to v_i by $\mathcal{R}(I)$. We claim that V_i is uniformly distributed over some subset of G. As S is a coset, there

are a subgroup S' of G^n and an element $\boldsymbol{s} \in S$ such that $S = \boldsymbol{s} +_G S'$. Assume, for the sake of contradiction, that V_i is not uniformly distributed. Then, there are group elements $a, b \in G$ such that the sets

$$X_a = \{\boldsymbol{x} \in S' \mid x_i = a\} \quad \text{and} \quad X_b = \{\boldsymbol{x} \in S' \mid x_i = b\}$$

have different cardinality. Assume that $|X_a| > |X_b|$. Arbitrarily pick $\boldsymbol{y} \in X_a, \boldsymbol{z} \in X_b$ and construct the set $Z = \{\boldsymbol{x} -_G \boldsymbol{y} +_G \boldsymbol{z} \mid \boldsymbol{x} \in X_a\}$. From the definition of Z and the fact that S' is invariant under a_G, it follows that $Z \subseteq S'$. For each $\boldsymbol{x} \in Z$ we have $x_1 = b$; hence $Z \subseteq X_b$. However, we also have $|Z| = |X_a|$, which contradicts the assumption that $|X_a| > |X_b|$. We conclude that this cannot hold, and thus V_i is uniformly distributed. Hence, for each $1 \leq i \leq n$, V_i is uniformly distributed.

Now, let A denote the set of indices such that for every $i \in A$, $\Pr[V_i = c_i] = 1$ for some $c_i \in G$. That is, A contains the indices of the variables V_i which are constant in every feasible solution. Let B contain the indices for the variables which are not constant in every solution, i.e., $B = [n] \setminus A$.

Let $S^* = \sum_{i \in B} w(v_i) \max(D) + \sum_{i \in A} w(v_i) c_i$ and note that $S^* \geq \text{OPT}$. Furthermore, let

$$E_{\min} = \min_{X \subseteq G, |X| > 1} \frac{1}{|X|} \cdot \sum_{x \in X} x$$

and note that $\max(D) > E_{\min} > 0$.

The expected value of the measure of $\mathcal{R}(I)$ can now be estimated as

$$\begin{aligned} \text{(6.3)} \quad \mathrm{E}\left[\sum_{i=1}^{n} w(v_i) V_i\right] &= \sum_{i \in A} w(v_i) \mathrm{E}[V_i] + \sum_{i \in B} w(v_i) \mathrm{E}[V_i] \\ &\geq \sum_{i \in A} w(v_i) c_i + E_{\min} \sum_{i \in B} w(v_i) \geq \frac{E_{\min}}{\max(D)} S^* \geq \frac{E_{\min}}{\max(D)} \text{OPT}. \end{aligned}$$

Since $E_{\min} / \max(D) > 0$, it follows that the measure of $\mathcal{R}(I)$ has, in expectation, a constant performance ratio. We will denote $\frac{E_{\min}}{\max(D)} \cdot \text{OPT}$ by E.

To get a deterministic polynomial-time algorithm, note that for any instance I we can use the algorithm by Bulatov and Dalmau [12] to compute the two sums in (6.3) in polynomial time. Hence, we can compute the expected measure of $\mathcal{R}(I)$ in polynomial time. Our algorithm is presented in Figure 6.1.

We claim that the following loop invariant holds in the algorithm: before line 4 is executed it is always the case that the expected measure of $\mathcal{R}(I_i)$ is at least E.

We first prove the correctness of the algorithm assuming that the loop invariant holds. From the loop invariant it follows that the expected measure of $\mathcal{R}(I_{|V|+1})$ is at least E. In $I_{|V|+1}$ there is, for each variable $v_i \in V$, a constraint of the form $v_i = x_i$; therefore there is only one solution to $I_{|V|+1}$. This solution will be returned by the algorithm.

We now prove that the loop invariant holds. The first time line 4 is reached the expected performance ratio of $\mathcal{R}(I_1)$ is at least E, per the calculations above. Now assume that the loop invariant holds in iteration $i = k \leq |V|$; we will prove that it also holds in iteration $i = k + 1$. Since the performance ratio of $\mathcal{R}(I_k)$ is at least E, there must be some value $x \in D$ such that when v_i is fixed to x, the performance ratio of $\mathcal{R}(I_{k+1})$ is at least E. This element will be found by the algorithm as it maximizes the expected performance ratio $\mathcal{R}(I_{k+1})$. Hence, the loop invariant holds for $i = k + 1$. ∎

Input: An instance $I = (V, D, C, w)$ of W-Max Sol(Γ).
Output: A solution with performance ratio at least $E_{\min}/\max(D)$, or "no solution" if there are no solutions.

1. Return "no solution" if there are no solutions (use Bulatov and Dalmau's algorithm to check this).
2. Let $I_1 = I$.
3. For each i from 1 to $|V|$:
4. For each $x \in D$:
5. Let $I_i = I$ and add the constraint $v_i = x$ to I_i.
6. If there is no solution to I_i, then go to 8.
7. Compute the expected measure of $\mathcal{R}(I_i)$.
8. Remove the constraint $v_i = x$ from I_i.
9. Let $x_i \in D$ be the value which maximizes the expected measure of $\mathcal{R}(I_i)$ in the computations in 4–8. Create a new instance, I_{i+1}, which is identical to I_i except for the addition of the constraint $v_i = x_i$.
10. Return the unique solution to $I_{|V|+1}$.

Fig. 6.1. *The algorithm in Theorem* 6.12.

6.4. Binary commutative idempotent operation. We now investigate the complexity of W-Max Sol(Γ) for maximal constraint languages Γ satisfying $\langle\Gamma\rangle = Inv(f)$ where f is a binary commutative idempotent operation.

Let $(F; +_F, -_F, \cdot_F, 1_F)$ be a finite field of prime order p, where $+_F$, $-_F$, $\cdot_F$, and 1_F denote addition, subtraction, multiplication, and multiplicative identity, respectively (we refrain from defining a notation for multiplicative inverses, as we do not need it). Furthermore, let z_F be the unique element in F such that $z_F + z_F = 1_F$. Note that for $F = \mathbb{Z}_p$ we get $1_F = 1$ and $z_F = \frac{p+1}{2}$.

Let $\mathcal{A}$ denote the set of operations $f(x, y) = z_F \cdot_F (x +_F y)$, where F is a finite field of prime order $p = |D|$ and $p > 2$. The proof will be partitioned into two main cases due to the following result.

Lemma 6.13 (see [14, 49]). *If $Inv(f)$ is a maximal relational clone and f is a binary idempotent operation, then either*

1. *$Inv(f) = Inv(g)$, where $g \in \mathcal{A}$, or*
2. *$B \in Inv(f)$ for some two-element $B \subseteq D$.*

The classification result is given in the next lemma together with a proof outline. Full proofs concerning the case when $Inv(f) = Inv(g)$ and $g \in \mathcal{A}$ can be found in section 6.4.1. In section 6.4.2 we give a complete characterization of the complexity for the second case for domains D such that $|D| \leq 4$. Finally, in section 6.4.3 we extend the classification to general domains under the assumption of a conjecture due to Szczepara (Conjecture 6.18).

Lemma 6.14. *Let f be a binary commutative idempotent operation on D such that $Inv(f)$ is a maximal relational clone, and let Γ be a constraint language such that $\langle\Gamma\rangle = Inv(f)$.*

- *If $Inv(f) = Inv(g)$ for some $g \in \mathcal{A}$, then* W-Max Sol(Γ) *is* **APX***-complete.*
- *Else if $|D| \leq 4$ and there exist $a, b \in D$ such that $a < b$ and $f(a, b) = a$, then let a_* be the minimal such element (according to $<$). Then*
  - W-Max Sol(Γ) *is* **poly-APX***-complete if $a_* = 0$, and*
  - **APX***-complete if $a_* > 0$.*
- *Otherwise, if $|D| \leq 4$, then* W-Max Sol(Γ) *is in* **PO**.

Proof. If $Inv(f) = Inv(g)$ and $g \in \mathcal{A}$, then the result follows from section 6.4.1.

If there exist $a, b \in D$ such that $a < b$ and $f(a, b) = a$, then we need to consider two cases depending on a_*. If $a_* = 0$, then W-MAX SOL(Γ) is **poly-APX**-hard by Lemma 4.4 and a member of **poly-APX** by Lemma 4.2 since CSP is in **P** [14]. If $a_* > 0$, then W-MAX SOL(Γ) is **APX**-complete by Lemma 6.25 in section 6.4.2.

Finally, if there do not exist any $a, b \in D$ such that $a < b$ and $f(a, b) = a$, then f acts as the max operation on every two-element $B \subseteq D$ such that $B \in Inv(f)$. Lemma 6.26 shows that f is a generalized max operation in this case, and W-MAX SOL(Γ) is in **PO** by Theorem 5.10. □

6.4.1. f is contained in $\mathcal{A}$. We will now prove that W-MAX SOL(Γ) is **APX**-complete whenever $f \in \mathcal{A}$ and $\langle\Gamma\rangle = Inv(f)$.

LEMMA 6.15. *Let $f(x, y) = z_F \cdot_F (x +_F y)$, where F is a finite field of prime order $p = |D| > 2$ and $Inv(f)$ is a maximal relational clone. Then,* W-MAX SOL(Γ) *is* **APX***-complete if $\langle\Gamma\rangle = Inv(f)$.*

Proof. We will give the proof for $F = \mathbb{Z}_p$ and after that we will argue that the proof can easily be adapted to the general case.

Let $q = \frac{p+1}{2}$ and f be the function $f(x, y) = q(x+y) \pmod p$. We will show that we can express $x - y + z$ through f.

Note that

$$\sum_{i=1}^{p-1} q^i = \frac{1 - q^p}{1 - q} - 1 = 0 \pmod p. \tag{6.4}$$

(The second equality follows from Fermat's little theorem: $a^{p-1} = 1 \pmod p$ for any prime p and integer a not divisible by p.) By using (6.4) and Fermat's little theorem again, we get

$$\sum_{i=1}^{p-2} q^i = -1 \pmod p. \tag{6.5}$$

We can now express $x - y + z$ as follows:

$$\begin{aligned}
&\underbrace{f(f(f(\dots f(f(f(}_{p-1 \text{ times}} x, z), y), y) \dots), y), y) \\
&\quad = q(q(q(\dots q(q(q(x + z) + y) + y) + \cdots) + y) + y) \\
&\quad = q^{p-1}x + q^{p-1}z + \sum_{i=1}^{p-2} q^i y \\
&\quad = x - y + z \pmod p,
\end{aligned}$$

where the final equality follows from (6.4), (6.5), and Fermat's little theorem.

As any finite field F of prime order is isomorphic to $\mathbb{Z}_p$, it is not hard to see that $x -_F y +_F z$ can be expressed through f for any such field. Since $Inv(f)$ is a maximal relational clone, $x -_F y +_F z$ can be expressed through f, and $x -_F y +_F z$ is not a projection, it follows that $Inv(f) = Inv(x -_F y +_F z)$. We now get containment in **APX** from Theorem 6.12 and **APX**-hardness from Theorem 6.11. □

6.4.2. f is not contained in $\mathcal{A}$. In the first part of this section we classify the complexity of W-MAX SOL(Γ) when $\langle\Gamma\rangle = Inv(f)$ for all 2-semilattice operations f. Recall that a 2-semilattice operation f is an operation satisfying the conditions $f(x,x) = x$, $f(x,y) = f(y,x)$, and $f(x, f(x,y)) = f(x,y)$. It is noted in [9] that binary operations f such that $Inv(f)$ is a maximal constraint language on $|D| \leq 4$ are either 2-semilattices or otherwise CSP(Γ) is **NP**-complete. Hence, we get a classification of the complexity of W-MAX SOL(Γ) when $\langle\Gamma\rangle = Inv(f)$ is a maximal constraint language over $|D| \leq 4$ and f is a binary operation.

The second result in this section is a complete complexity classification of W-MAX SOL(Γ) for maximal constraint languages Γ, such that $\langle\Gamma\rangle = Inv(f)$ where f is a binary operation, under the condition that Conjecture 131 from [47] holds.

LEMMA 6.16. *Let f be a 2-semilattice operation on D and let $\langle\Gamma\rangle = Inv(f)$. If there exist $a, b \in D$ such that $a < b$, $f(a,b) = a$, and $a^* > 0$, where a^* is the minimal element such that there is b^* with $f(a^*, b^*) = a^*$, then* W-MAX SOL(Γ) *is* **APX**-*complete.*

Proof. The **APX**-hardness part is clear. What remains is to show that the problem is in **APX**. We can assume, without loss of generality, that $a = a^*$ and $b = b^*$. We begin by proving that $U = D \setminus \{0\}$ is in $Inv(f)$. Assume that $f(a,b) = 0$ and $a, b > 0$; then $f(a, f(a,b)) = f(a,b) = 0$ and, consequently, $f(a,0) = 0$, contradicting the assumption that $a > 0$ was the minimal such element. Hence, $f(a,b) = 0$ if and only if $a = b = 0$. In particular U is in $Inv(f)$.

We continue with the actual proof of the lemma. Let $I = (V, D, C, w)$ be an arbitrary instance of W-MAX SOL(Γ). Define $V' \subseteq V$ such that

$$V' = \{v \in V \mid S(v) = 0 \text{ for every solution } S \text{ of } I\}.$$

We see that V' can be computed in polynomial time: a variable v is in V' if and only if the CSP instance $(V, D, C \cup \{((v), U)\})$ is not satisfiable.

Given two assignments $A, B : V \to D$, we define the assignment $f(A,B)$ such that $f(A,B)(v) = f(A(v), B(v))$. We note that if A and B are solutions of I, then $f(A,B)$ is a solution to I, too: indeed, arbitrarily choose one constraint $((x_1, \ldots, x_k), r) \in C$. Then, $(A(x_1), \ldots, A(x_k)) \in r$ and $(B(x_1), \ldots, B(x_k)) \in r$, which implies that $(f(A(x_1), B(x_1)), \ldots, f(A(x_k), B(x_k))) \in r$, too.

Let $S_1, \ldots, S_m$ be an enumeration of all solutions of I and define

$$S^+ = f(S_1, f(S_2, f(S_3 \ldots f(S_{m-1}, S_m) \ldots))).$$

By the choice of V' and the fact that $f(c,d) = 0$ if and only if $c = d = 0$, we see that the solution S^+ has the following property: $S^+(v) = 0$ if and only if $v \in V'$. Let p denote the second least element in D, and note that $\text{OPT}(I) \geq \sum_{v \in V \setminus V'} w(v)p = c$. Thus, by finding a solution with measure $\geq c$, we have approximated I within $(\max D)/p$, and W-MAX SOL(Γ) is in **APX**. To find such a solution, we consider the instance $I' = (V, D, C', w)$, where $C' = C \cup \{((v), u) \mid v \in V \setminus V'\}$. This instance has feasible solutions (since S^+ is a solution), and every solution has measure $\geq c$. Finally, a concrete solution can be found in polynomial time by the result in [19]. □

LEMMA 6.17. *If f is a 2-semilattice operation such that $f \notin \mathcal{A}$, Γ is a maximal constraint language satisfying $\langle\Gamma\rangle = Inv(f)$, and for all two-element $B \in Inv(f)$ the operation f acts as the* max *operation on B, then* W-MAX SOL(Γ) *is in* **PO**.

Proof. What we will prove is that if f acts as max on all two-element $B \in Inv(f)$, then f is a generalized max operation and consequently W-MAX SOL(Γ) is in **PO**.

First note that if $a \neq b$ and $f(a,b) = a$, then by assumption $a > b$ and $f(a,b) > \min\{a,b\}$. Now, if $f(a,b) \neq a$, then $f(a, f(a,b)) = f(a,b)$ and by assumption f

is max on $\{a, f(a,b)\}$. As a consequence of this we get $f(a,b) > \min\{a,b\}$. Now, $f(a,b) > \min\{a,b\}$ for all $a \neq b$. Moreover, f is idempotent, so f is a generalized max operation and tractability follows from Theorem 5.10. □

We have now completely classified the complexity of W-MAX SOL(Γ) for all constraint languages Γ such that $\langle\Gamma\rangle$ is maximal and $|D| \leq 4$.

6.4.3. Complete classification under a conjecture. In this section we will prove that the validity of Conjecture 131 from [47] implies a complete complexity classification of W-MAX SOL(Γ) for all constraint languages Γ such that $\langle\Gamma\rangle$ is maximal. Given a binary operation f on D, the *fixity* of f is denoted $\mathcal{F}(f)$ and is defined by

$$\mathcal{F}(f) = \{(x,y) \in D^2 \mid f(x,y) \in \{x,y\}\}.$$

The *fixity-count* of f is defined to be the cardinality of $\mathcal{F}(f)$ and is denoted $|\mathcal{F}(f)|$.

CONJECTURE 6.18 (see Conjecture 131). *If $Inv(f)$ is a maximal relational clone and $Inv(f') = Inv(f)$, then $|\mathcal{F}(f)| = |\mathcal{F}(f')|$.*

Although Conjecture 6.18 is not known to hold in the general case, it has been verified for small domains. In particular, it was shown in [47] that for domains D such that $|D| \leq 4$ the conjecture holds. Our proof builds on a construction that facilitates the study of operation f—the details are collected in Lemma 6.19. The underlying idea and the proof of Lemma 6.19 are inspired by Lemma 3 in [14].

Let f be a binary operation on D and define operations $f_1, f_2, \ldots : D^2 \to D$ inductively:

$$f_1(x,y) = f(x,y),$$

$$f_{n+1}(x,y) = f(x, f_n(x,y)).$$

LEMMA 6.19. *Assume f to be a binary commutative idempotent operation on D such that $Inv(f)$ is a maximal relational clone and $Inv(f) \neq Inv(g)$ for every $g \in \mathcal{A}$. The following hold:*

1. *$f|_B = f_n|_B$ for every $n \geq 1$ and every two-element $B \subseteq D$ in $Inv(f)$; and*
2. *$Inv(f) = Inv(f_n)$, $n \geq 1$.*

Proof. 1. Arbitrarily choose a two-element $\{a,b\} = B \subseteq D$ in $Inv(f)$. There are two possible binary commutative idempotent operations on B, namely, max and min. We assume without loss of generality that $f|_B = \max$ and prove the result by induction over n. Since $f_1 = f$, the claim holds for $n = 1$. Assume it holds for $n = k$ and consider f_{k+1}. We see that $f_{k+1}(a,b) = f(a, f_k(a,b))$ and, by the induction hypothesis, $f_k(a,b) = \max(a,b)$. Hence, $f_{k+1}(a,b) = \max(a, \max(a,b)) = \max(a,b)$.

2. Obviously, $f_n \in Pol(Inv(f))$, and, thus, $Inv(f) \subseteq Inv(f_n) \subseteq R_D$. Since $Inv(f) \neq Inv(g)$ for every $g \in \mathcal{A}$, we know from Lemma 6.13 that there is some two-element $B \in Inv(f)$. By the proof above, we also know that $f|_B = f_n|_B$ so $f_n|_B$ (and consequently f_n) is not a projection. Thus, $Inv(f_n) \neq R_D$, since $Inv(f') = R_D$ if and only if f' is a projection. By the assumption that $Inv(f)$ is a maximal relational clone and the fact that $Inv(f) \subseteq Inv(f_n) \subsetneq R_D$, we can draw the conclusion that $Inv(f) = Inv(f_n)$. □

We will now present some technical machinery that is needed for proving Lemmas 6.25 and 6.26.

LEMMA 6.20 (see [47, Lemma 28]). *Let f be an idempotent binary operation and let $n \in \mathbb{N}$. Then, $\mathcal{F}(f) \subseteq \mathcal{F}(f_n)$.*

Proof. Let $(x, y) \in \mathcal{F}(f)$. Then, either $f(x, y) = x$ or $f(x, y) = y$. Now

$$f(x,y) = x \Longrightarrow f_n(x,y) = \underbrace{f(x, f(x, \ldots, f(x,y)\ldots))}_{n \text{ times}}$$

$$= \underbrace{f(x, f(x, \ldots, f(x,x)\ldots))}_{n-1 \text{ times}} = x \Longrightarrow f_n(x,y) = x,$$

while

$$f(x,y) = y \Longrightarrow f_n(x,y) = \underbrace{f(x, f(x, \ldots, f(x,y)\ldots))}_{n \text{ times}}$$

$$= \underbrace{f(x, f(x, \ldots, f(x,y)\ldots))}_{n-1 \text{ times}} \Longrightarrow f_n(x,y) = y. \qquad \square$$

Assuming that Conjecture 6.18 holds, we get the following corollary as a consequence of Lemma 6.20.

COROLLARY 6.21. *If $Inv(f)$ is a maximal relational clone such that f is commutative and idempotent, and $(x, y) \in \mathcal{F}(f_k)$ (i.e., $f_k(x, y) \in \{x, y\}$), then $\{x, y\} \in Inv(f)$.*

Proof. By Lemma 6.20, we have $\mathcal{F}(f) \subseteq \mathcal{F}(f_k)$, and if Conjecture 6.18 holds, then $|\mathcal{F}(f)| = |\mathcal{F}(f_k)|$, which implies that $\mathcal{F}(f) = \mathcal{F}(f_k)$. Now, if $f_k(x, y) \in \{x, y\}$, then $f(x, y) \in \{x, y\}$, and by the commutativity of f we have $f(y, x) \in \{x, y\}$. Since f is idempotent, it is clear that $\{x, y\} \in Inv(f)$. $\square$

We continue by introducing a digraph associated with the binary operation f. This digraph enables us to make efficient use of Lemma 6.19. Given a binary operation $f : D^2 \to D$, we define $G_f = (V, E)$ such that $V = D \times D$ and $E = \{((a, b), (a, f(a, b))) \mid a, b \in D\}$. We make the following observations about G_f:

(1) an edge $((a, b), (a, c))$ implies that $f(a, b) = c$;
(2) every vertex has out-degree 1; and
(3) there is no edge $((a, b), (c, d))$ with $a \neq c$.

We extract some more information about G_f in the next three lemmas.

LEMMA 6.22. *The digraph G_f contains no directed cycle.*

Proof. Assume G_f contains a directed cycle. Fact (3) allows us to assume (without loss of generality) that the cycle is $(0, 1), (0, 2), \ldots, (0, k), (0, 1)$ for some $k \geq 2$. Fact (1) tells us that $f(0, 1) = 2$, $f(0, 2) = 3, \ldots$, $f(0, k - 1) = k$, and $f(0, k) = 1$. Furthermore, one can see that $f_2(0, 1) = 3$, $f_2(0, 2) = 4, \ldots$, and inductively $f_p(0, i) = i + p \pmod{k}$. This implies that $f_k(0, 1) = 1 + k \pmod{k} = 1$. By Corollary 6.21, $\{0, 1\}$ is a subalgebra of $Inv(f)$, which contradicts the fact that $f(0, 1) = 2$. $\square$

LEMMA 6.23. *Every path in G_f of length $n \geq |D|$ ends in a reflexive vertex; i.e., $f_n(a, b) = c$ implies that (a, c) is a reflexive vertex.*

Proof. Assume that G_f contains a path P of length $n \geq |D|$. This path can contain at most $|D|$ distinct vertices by fact (3). Fact (2) together with the acyclicity of G_f implies that at least one vertex v on P is reflexive; by using fact (2) once again, we see that there exists exactly one reflexive vertex on P and that it must be the last vertex. $\square$

LEMMA 6.24. *If $f_n(a, b) = c$, then (a, c) is a reflexive vertex in G_f.*

Proof. By Lemma 6.23, every path in G_f of length $n \geq |D|$ ends in a reflexive vertex. Hence, $(a, f_n(a, b)) = (a, c)$ is a reflexive vertex. $\square$

LEMMA 6.25. *Let f be a binary commutative idempotent operation on D such that Γ is a maximal constraint language satisfying $\langle\Gamma\rangle = Inv(f)$. If there exist $a, b \in D$ such that $a < b$, $f(a,b) = a$, and $a^* > 0$, where a^* is the minimal element such that there is b^* with $f(a^*, b^*) = a^*$, then (assuming Conjecture* 6.18*)* W-MAX SOL(Γ) *is* **APX***-complete.*

Proof. We can assume, without loss of generality, that $a = a^*$ and $b = b^*$. The **APX**-hardness part follows from Lemma 4.3. What remains is to show that the problem is in **APX**. We begin the proof by proving that the unary relation $U = D\backslash\{0\}$ is a member of $Inv(f)$. Consider the digraph G_f. As we have already observed in Lemma 6.22, there are no cycles $(a,b_1),\ldots,(a,b_k),(a,b_1)$, $k \geq 2$, in G_f, and every path of length $n \geq |D|$ ends in a reflexive vertex (by Lemma 6.23). Obviously, no vertex $(a,0)$ $(a > 0)$ in G_f is reflexive since this implies that $f(a,0) = 0$ which is a contradiction. In particular, there exists no path in G_f of length $n \geq |D|$ starting in a vertex (a,b) $(a > 0)$ and ending in a vertex $(a,0)$, since this implies that $(a,0)$ is reflexive by Lemma 6.23.

We can now conclude that $f_n(a,b) > 0$ when $a > 0$: if $f_n(a,b) = 0$, then $(a,0)$ is reflexive by Lemma 6.24, which would lead to a contradiction. Hence, $f_n(a,b) > 0$ whenever $a, b \in D \setminus \{0\} = U$ so U is in $Inv(f_n)$, and, by Lemma 6.19(2), U is in $Inv(f)$, too. We also note that $U \in Inv(f)$ together with the assumption that $f(0,b) > 0$ for all $b > 0$ implies that $f(c,d) = 0$ if and only if $c = d = 0$. The rest of the proof is identical to the second part of the proof of Lemma 6.16. ∎

LEMMA 6.26. *If f is a binary commutative idempotent operation such that $f \notin \mathcal{A}$, Γ is a maximal constraint language satisfying $\langle\Gamma\rangle = Inv(f)$, and for all two-element $B \in Inv(f)$ the operation f acts as the* max *operation on B, then (assuming Conjecture* 6.18*)* W-MAX SOL(Γ) *is in* **PO***.*

Proof. What we will prove is that if $f \notin \mathcal{A}$ and f acts as max on all two-element $B \in Inv(f)$, then there exists a generalized max function f' such that $Inv(f') = Inv(f)$ and, hence, W-MAX SOL(Γ) is in **PO**.

Recall that there are no cycles in G_f and every path of length $n = |D|$ must end in a reflexive vertex by Lemmas 6.22 and 6.23. We also note that if G_f contains a reflexive vertex (a,c) with $a \neq c$, then $f(a,c) = c$ and $c > a$ since f is assumed to act as the max operation on all two-element $B \in Inv(f)$.

We now claim that f_n is a generalized max operation. Arbitrarily choose $a, b \in D$. If $f_n(a,b) = c$ $(a \neq c)$, then there is a path in G_f from (a,b) to a reflexive vertex (a,c), and $c > a$ as explained above. If $f_n(a,b) = a$, then $\{a,b\} \in Inv(f)$ by Corollary 6.21. Since $f(a,b) = \max(a,b)$, Lemma 6.19(1) implies that $f_n(a,b) = \max(a,b)$. Thus, f_n is a generalized max-operation. ∎

7. Homogeneous constraint languages. In this section, we will classify the complexity of MAX SOL when the constraint language is *homogeneous*. A constraint language is called homogeneous if every *permutation relation* is contained in the language.

DEFINITION 7.1. *A relation R is a* permutation relation *if there is a permutation $\pi : D \to D$ such that*

$$R = \{(x, \pi(x)) \mid x \in D\}.$$

Let Q denote the set of all permutation relations on D. The main result of this section is Theorem 7.16 which gives a complete classification of the complexity of W-MAX SOL(Γ) when $Q \subseteq \Gamma$. The theorem provides the exact borderlines between tractability, **APX**-completeness, **poly-APX**-completeness, and **NP**-hardness of finding a feasible solution.

As a direct consequence of Theorem 7.16, we get that the class of injective relations is a maximal tractable class for W-MAX SOL(Γ). That is, if we add a single relation which is not an injective relation to the class of all injective relations, then the problem is no longer in **PO** (unless **P** = **NP**).

Dalmau has completely classified the complexity of CSP(Γ) when Γ is a homogeneous constraint language [23], and this classification relies heavily on the structure of homogeneous algebras. An algebra is called *homogeneous* if and only if every permutation on its universe is an automorphism of the algebra. We will not need a formal definition of homogeneous algebras and refer the reader to [39, 40, 48] for further information on their properties. All homogeneous algebras have been completely classified by Marczewski [40] and Marchenkov [39].

Our classification for the approximability of W-MAX SOL(Γ) when Γ is a homogeneous constraint language uses the same approach as in [23], namely, we exploit the inclusion structure of homogeneous algebras (as proved in [39, 40]). By Theorem 3.3, it is sufficient to consider constraint languages Γ that are relational clones. This is where the homogeneous algebras comes in: the classification of homogeneous algebras gives us a classification of all homogeneous relational clones and, in particular, their inclusion structure (lattice) under set inclusion. We refer the reader to [48] for a deeper treatment of homogeneous algebras and their inclusion structure.

The lattice of all homogeneous relational clones on a domain D having n (≥ 5) elements is given in Figure 7.1. The lattices for the corresponding relational clones over smaller domains (i.e., $2 \leq |D| \leq 4$) contain some exceptional relational clones and are presented separately in Figures 7.2–7.4. Note that the corresponding lattices presented in [23] and [48] are the duals of ours, since they instead consider the inclusion structure among the corresponding clones of operations (but the two approaches are in fact equivalent as shown in [43, Satz 3.1.2]). To understand the lattices we first need some definitions.

Throughout this section n denotes the size of the domain D, i.e., $n = |D|$.

DEFINITION 7.2.

- *The* switching operation s *is defined by*

$$s(a,b,c) = \begin{cases} c & \text{if } a = b, \\ b & \text{if } a = c, \\ a & \text{otherwise.} \end{cases}$$

- *The* discriminator operation t *is defined by*

$$t(a,b,c) = \begin{cases} c & \text{if } a = b, \\ a & \text{otherwise.} \end{cases}$$

- *The* dual discriminator operation d *is defined by*

$$d(a,b,c) = \begin{cases} a & \text{if } a = b, \\ c & \text{otherwise.} \end{cases}$$

- *The* k*-ary* near projection operation l_k $(3 \leq k \leq n)$ *is defined by*

$$l_k(a_1,\ldots,a_k) = \begin{cases} a_1 & \text{if } |\{a_1,\ldots,a_k\}| < k, \\ a_k & \text{otherwise.} \end{cases}$$

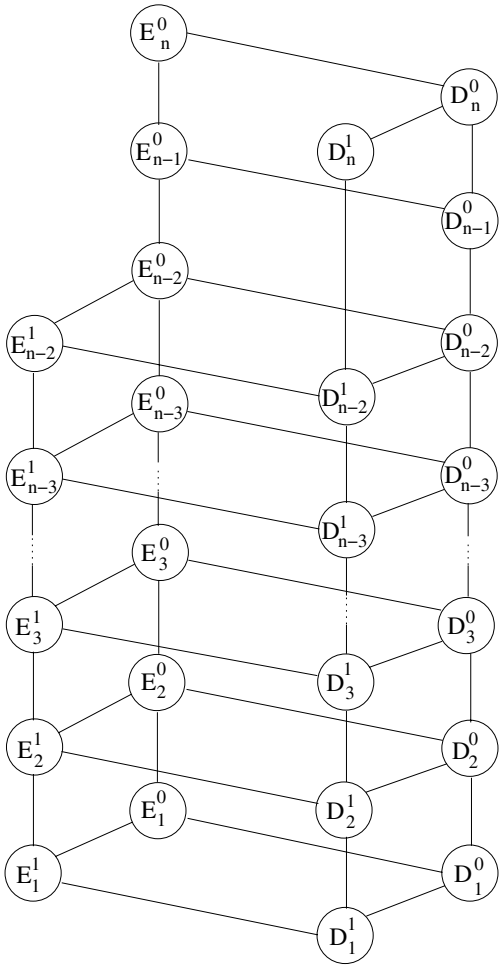

FIG. 7.1. *Lattice of all homogeneous relational clones over domain size $n \geq 5$.*

- *The $(n-1)$-ary operation r_n is defined by*

$$r_n(a_1, \ldots, a_{n-1}) = \begin{cases} a_1 & \text{if } |\{a_1, \ldots, a_{n-1}\}| < n-1, \\ a_n & \text{otherwise.} \end{cases}$$

  In the second case we have $\{a_n\} = D \setminus \{a_1, \ldots, a_{n-1}\}$.
- *The $(n-1)$-ary operation d_n (where $n \geq 4$) is defined by*

$$d_n(a_1, \ldots, a_{n-1}) = \begin{cases} d(a_1, a_2, a_3) & \text{if } |\{a_1, \ldots, a_{n-1}\}| < n-1, \\ a_n & \text{otherwise.} \end{cases}$$

  In the second case we have $\{a_n\} = D \setminus \{a_1, \ldots, a_{n-1}\}$.
- *The operation $[x+y+z]$ is defined by $x+y+z$ where $(D, +, -)$ is a four-element group of exponent 2.*

The notation in the lattices in Figures 7.1–7.4 is explained below.

- $D^0_1 = Inv(t)$;
- $D^0_i = Inv(\{d, l_{i+1}\})$ for $2 \leq i \leq n-1$;

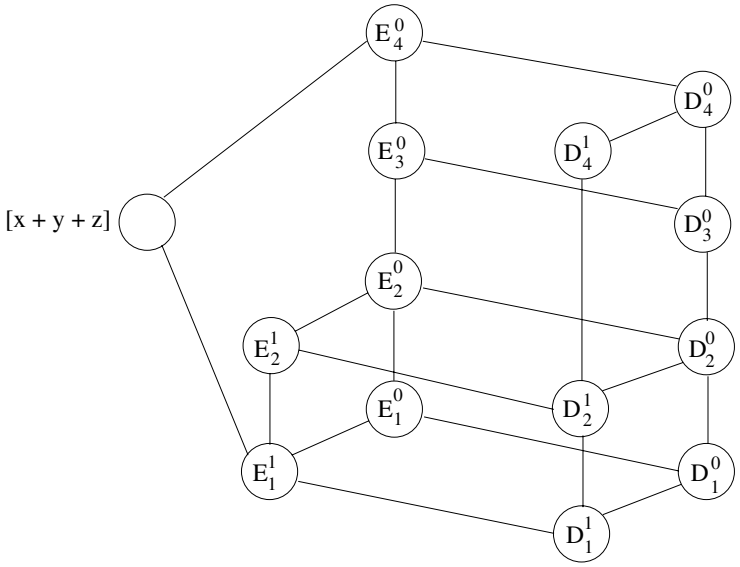

FIG. 7.2. *Lattice of all homogeneous relational clones over domain size* $n = 4$.

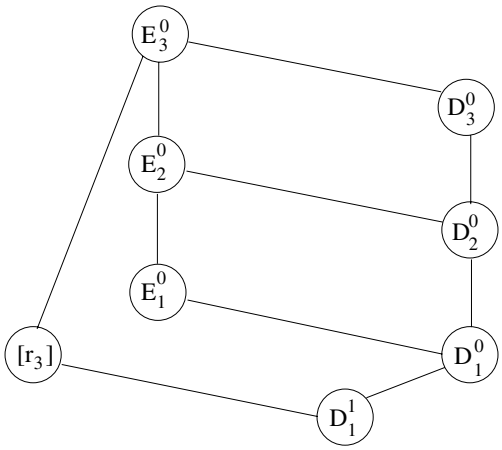

FIG. 7.3. *Lattice of all homogeneous relational clones over domain size* $n = 3$.

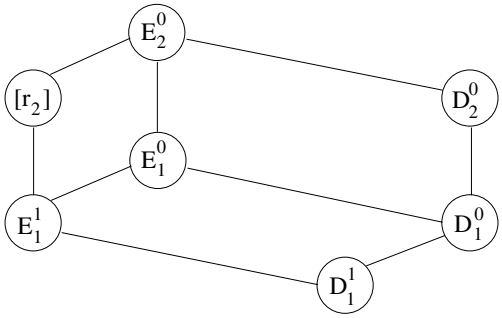

FIG. 7.4. *Lattice of all homogeneous relational clones over domain size* $n = 2$.

- $D_n^0 = Inv(d)$;
- $D_1^1 = Inv(\{t, r_n\})$;
- $D_i^1 = Inv(\{d, l_{i+1}, r_n\})$ for $2 \leq i \leq n-2$;
- $D_n^1 = Inv(d_n)$;
- $E_1^0 = Inv(s)$;
- $E_i^0 = Inv(l_{i+1})$ for $2 \leq i \leq n-1$;
- $E_n^0 = R_D$, i.e., all finitary relations over D;
- $E_1^1 = Inv(\{s, r_n\})$ for $n \neq 3$;
- $E_i^1 = Inv(\{l_{i+1}, r_n\})$ for $2 \leq i \leq n-3$;
- $E_{n-2}^1 = Inv(r_n)$ for $n \geq 4$.

Note that the relational clones described above depend on the size of the domain $|D| = n$. Hence, E_2^0 in Figure 7.3 ($|D| = 3$) is not the same relational clone as E_2^0 ($|D| = 4$) in Figure 7.2. Also note that when we state our (in)approximability results by saying, for example, that W-MAX SOL(E_1^1) is **APX**-complete, we mean that W-MAX SOL(E_1^1) is **APX**-complete for all sizes of the domain where E_1^1 is defined (e.g., E_1^1 is not defined for $n = 3$). We always assume that $n = |D| \geq 2$.

We now state Dalmau's classification for the complexity of CSP(Γ) for homogeneous constraint languages Γ.

THEOREM 7.3 (see [23]). *Let Γ be a homogeneous constraint language. Then,* CSP(Γ) *is in* **P** *if $Pol(\Gamma)$ contains the dual discriminator operation d, the switching operation s, or an affine operation. Otherwise,* CSP(Γ) *is* **NP***-complete.*

We have the following corollary of Dalmau's classification.

COROLLARY 7.4. *Let Γ be a homogeneous constraint language. Then,* W-MAX SOL(Γ) *is in* **poly-APX** *if $Pol(\Gamma)$ contains the dual discriminator operation d, the switching operation s, or an affine operation. Otherwise, it is* **NP***-hard to find a feasible solution to* W-MAX SOL(Γ).

Proof. All dual discriminator operations, switching operations, and affine operations are idempotent (i.e., $f(x, x, x) = x$ for all $x \in D$). Hence, Γ is invariant under a dual discriminator operation, switching operation, or an affine operation if and only if $\Gamma^c = \{\Gamma \cup \{\{(d_1)\}, \ldots, \{(d_n)\}\}$ is invariant under the corresponding operation. Thus, it follows from Theorem 7.3 that CSP(Γ^c) is in **P** if $Pol(\Gamma)$ contains the dual discriminator operation d, the switching operation s, or an affine operation. This together with Lemma 4.2 gives us that W-MAX SOL(Γ) is in **poly-APX** if $Pol(\Gamma)$ contains the dual discriminator operation d, the switching operation s, or an affine operation.

The **NP**-hardness part follows immediately from Theorem 7.3. □

We begin by investigating the approximability of W-MAX SOL(Γ) for some particular homogeneous constraint languages Γ.

LEMMA 7.5. W-MAX SOL(D_n^0) *is in* **APX** *if $0 \notin D$ and in* **poly-APX** *otherwise.*

Proof. Remember that $D_n^0 = Inv(d)$. Hence, membership in **poly-APX** follows directly from Corollary 7.4. It is known from Dalmau's classification that CSP(D_n^0) is in **P**. Thus, by Proposition 4.1, it follows that W-MAX SOL(D_n^0) is in **APX** when $0 \notin D$. □

LEMMA 7.6. W-MAX SOL(D_2^1) *is* **APX***-complete if $0 \notin D$ and* **poly-APX***-complete if $0 \in D$.*

Proof. Choose any $a, b \in D$ such that $a < b$. The relation $r = \{(a, a), (a, b), (b, a)\}$ is in $D_i^1 = Inv(\{d, l_{i+1}, r_n\})$ for $2 \leq i \leq n-2$. Hence, by Lemmas 4.3 and 4.4, it

follows that W-MAX SOL(D_2^1) is **APX**-hard if $0 \notin D$ and **poly-APX**-hard if $0 \in D$. This together with Lemma 7.5 and the fact that $D_i^1 \subseteq D_n^0$ gives us that W-MAX SOL(D_2^1) is **APX**-complete if $0 \notin D$ and **poly-APX**-complete if $0 \in D$. □

LEMMA 7.7. *Finding a feasible solution to* W-MAX SOL(E_2^1) *is* **NP***-hard.*

Proof. Remember that $E_2^1 = Inv(\{l_3, r_n\})$ when $n > 4$ and $E_2^1 = Inv(r_n)$ when $n = 4$, so it follows from Dalmau's classification that CSP(E_2^1) is **NP**-complete. □

LEMMA 7.8. W-MAX SOL(D_1^0) *is in* **PO**.

Proof. It is well known that $D_1^0 = Inv(t) = \langle I^D \rangle$; for instance, it is a direct consequence of Theorem 4.2 in [48]. Hence, W-MAX SOL(D_1^0) is in **PO** by the results in section 5.1. □

LEMMA 7.9. W-MAX SOL(E_1^0) *is in* **APX**.

Proof. Remember that $E_1^0 = Inv(s)$. Dalmau gives a polynomial-time algorithm for CSP($Inv(s)$) in [23] (he actually gives a polynomial-time algorithm for the more general class of paraprimal problems). Dalmau's algorithm exploits in a clever way the internal structure of paraprimal algebras to show that any instance I of CSP($Inv(s)$) can be split into independent subproblems $I_1, \ldots, I_j$, such that

- the set of solutions is preserved (i.e., any solution to I is also a solution to each of the independent subproblems, and any solution to all of the independent subproblems is also a solution to I); and
- each I_i $(1 \leq i \leq j)$ is either an instance of CSP($Inv(t)$) or an instance of CSP($Inv(a)$), where t is the discriminator operation and a is an affine operation.

Hence, to show that W-MAX SOL(E_1^0) is in **APX**, we first use Dalmau's algorithm to reduce the problem (in a solution preserving manner) to a set of independent W-MAX SOL(Γ) problems where Γ is either invariant under an affine operation or the discriminator operation. We know from Lemma 7.8 that W-MAX SOL(Γ) is in **PO** when Γ is invariant under the discriminator operation, and from Theorem 6.12 we know that W-MAX SOL(Γ) is in **APX** when Γ is invariant under an affine operation. Since all the independent subproblems are in **APX**, we get that the original W-MAX SOL(E_1^0) problem is also in **APX**. □

LEMMA 7.10. W-MAX SOL(E_1^1) *is* **APX***-complete.*

Proof. Remember that $E_1^1 = Inv(\{s, r_n\})$. Note that $E_1^1 \subseteq E_1^0$; thus membership in **APX** follows from Lemma 7.9.

For the hardness part, we begin by considering the general case when $n = |D| \geq 4$. Choose an arbitrary two-element subset $\{a, b\}$ of D (without loss of generality assume that $a < b$) and let $(G, +, -)$ be the two-element group on $G = \{a, b\}$ defined by $a + a = a$, $a + b = b + a = b$, and $b + b = a$. Let Γ be the set of all relations expressible as the set of solutions to equations over $(G, +, -)$. It is easy to realize that Γ is invariant under r_n (since r_n $(n \geq 4)$ acts as a projection on $\{a, b\}$). Furthermore Γ is invariant under s since $s(x, y, z)$ acts as the affine operation $x + y + z$ on $\{a, b\}$. It is proved in Lemma 6.8 that W-MAX SOL EQN($\mathbb{Z}_2, g$) is **APX**-hard, so W-MAX SOL(Γ) is **APX**-complete. For $n = |D| = 3$ there is no relational clone of the type $E_1^1 = Inv(\{s, r_n\})$, so the only case that remains to be dealt with is the case where $n = |D| = 2$.

Without loss of generality assume that $D = \{a, b\}$, where $a < b$. Again consider the group $(G, +, -)$ on $\{a, b\}$. Let $\Gamma = \{R_1, R_2\}$, where R_1 is the (4-ary) relation on D which is the set of solutions to the equation $x_1 + x_2 + x_3 + x_4 = a$ and R_2 is the (binary) relation representing the set of solutions to the equation $y_1 + y_2 = b$. Furthermore, let $\Gamma_{0,1} = \{R_1, R_2\}$ denote the special case where $a = 0, b = 1$ (i.e.,

$D = \{0, 1\}$). It has been proved in [37, Lemma 6.9] that MAX SOL($\Gamma_{0,1}$) is **APX**-complete. Let I be an instance of MAX SOL($\Gamma_{0,1}$) containing k variables. It is easy to realize that if I has a solution, then $\text{OPT}(I) \geq k/2$ (just note that the complement of any solution to I is also a solution to I). We give an L-reduction from MAX SOL($\Gamma_{0,1}$) to MAX SOL($\Gamma_{a,b}$). Let $F(I)$ be the instance of MAX SOL($\Gamma_{a,b}$) where all occurrences of 0 have been replaced by a and all occurrences of 1 have been replaced by b. Since $\text{OPT}(I) \geq k/2$, we get that $\text{OPT}(F(I)) \leq bk \leq 2b \cdot \text{OPT}(I)$ and $\beta = 2b$ is a valid parameter in the L-reduction. Let s be an arbitrary solution to $F(I)$ and define $G(F(I), s)$ to be the corresponding solution to I, where a is replaced by 0 and b is replaced by 1. Then,

$$|m(I, G(F(I), s)) - \text{OPT}(I)| \leq \frac{1}{b-a} |m(F(I), s) - \text{OPT}(F(I))|,$$

and $\gamma = \frac{1}{b-a}$ is a valid parameter in the L-reduction. This completes the **APX**-hardness proof for MAX SOL($\Gamma_{a,b}$). Now, the unary operation r_2 acts as the non-identity permutation on $\{a, b\}$ (i.e., $r_2(a) = b$, and $r_2(b) = a$) so both R_1 and R_2 are invariant under r_2. As we have already observed, s acts as the affine operation on $\{a, b\}$ and R_1 and R_2 are invariant under s, too. Hence, $\Gamma_{a,b} \subseteq Inv(\{s, r_2\})$, which concludes the proof. □

We have now proved all the results needed to give a complete classification for the approximability of W-MAX SOL(Γ) for all homogeneous relational clones Γ over domains D of size at least 5. In order to complete the classification also for domains of sizes 2, 3, and 4, we need to consider some exceptional homogeneous relational clones. For domains of size 4, we need to consider the homogeneous relational clone $Inv(x+y+z)$, where $+$ is the operation of a four-element group $(D, +, -)$ of exponent 2 (i.e., a four-element group such that, for all $a \in D$, $a + a = e$, where e is the identity element in $(D, +, -)$).

LEMMA 7.11. *Let $f(x, y, z) = x + y + z$, where $(D, +, -)$ is a group of exponent 2. Then,* W-MAX SOL($Inv(f)$) *is* **APX**-*complete.*

Proof. The operation $x + y + x$ is the affine operation on $(D, +, -)$ (since $-y = y$ in $(D, +, -)$), and it follows directly from Theorems 6.11 and 6.12 that W-MAX SOL($Inv(x + y + z)$) is **APX**-complete. □

For three-element domains, it remains to classify the approximability of W-MAX SOL($Inv(r_3)$), where r_3 is the binary operation defined as follows:

$$r(a_1, a_2) = \begin{cases} a_1 & \text{if } a_1 = a_2, \\ a_3 & \text{where } \{a_3\} = D \setminus \{a_1, a_2\} \text{ otherwise.} \end{cases}$$

LEMMA 7.12. W-MAX SOL($Inv(r_3)$) *is* **APX**-*complete.*

Proof. The operation $r_3(x, y)$ is actually an example of an operation of the type $\frac{p+1}{2}(x + y)$ (where $+$ is the operation of an Abelian group of order $|D| = p$) from Lemma 6.15. In our case $p = 3$ and $r_3(x, y) = 2x + 2y$, where $+$ is the operation of the Abelian group $(D, +, -)$ isomorphic to $\mathbb{Z}_3$. Hence, it follows from Lemma 6.15 that W-MAX SOL($Inv(r_3)$) is **APX**-complete. □

For three-element domains we also need to classify the approximability of W-MAX SOL(E_2^0) since hardness no longer follows from the hardness of W-MAX SOL(E_2^1) (there is no relational clone E_2^1 over three-element domains).

LEMMA 7.13. *It is* **NP**-*hard to find a feasible solution to* W-MAX SOL(E_2^0).

Proof. The proof is an immediate consequence of Theorem 7.3. □

Similarly, we also need to classify the approximability of W-MAX SOL(D_2^0) since hardness no longer follows from the hardness of W-MAX SOL(D_2^1) (there is no relational clone D_2^1 over three-element domains).

LEMMA 7.14. W-MAX SOL(D_2^0) *is* **APX**-*complete if* $0 \notin D$ *and* **poly-APX**-*complete if* $0 \in D$.

Proof. Remember that $D_2^0 = Inv(\{d, l_3\})$. It follows from the proof of Lemma 7.6 that W-MAX SOL(D_2^0) is **APX**-complete if $0 \notin D$ and **poly-APX**-complete if $0 \in D$. □

For two-element domains $\{a, b\}$, we need to classify the unary operation r_2 which acts as the nonidentity permutation (i.e., $r_2(a) = b$ and $r_2(b) = a$).

LEMMA 7.15. *Finding a feasible solution to* W-MAX SOL($Inv(r_2)$) *is* **NP**-*hard.*

Proof. The proof follows from Dalmau's classification. □

Finally, we are in a position to present the complete classification for the approximability of all homogeneous constraint languages.

THEOREM 7.16. *Let* Γ *be a homogeneous constraint language.*

1. *If* $\langle\Gamma\rangle \in \{E_j^i \mid i \in \{0,1\}, j \geq 2\}$ *or* $\langle\Gamma\rangle = Inv(r_2)$*, then it is* **NP**-*hard to find a feasible solution to* W-MAX SOL(Γ)*;*
2. *else, if* $0 \in D$ *and* $\langle\Gamma\rangle \in \{D_j^i \mid i \in \{0,1\}, j \geq 2\}$*, then* W-MAX SOL($\Gamma$) *is* **poly-APX**-*complete;*
3. *else, if*

$$\langle\Gamma\rangle \in \{E_1^1, E_1^0, Inv(x+y+z), Inv(r_3)\} \quad \text{or}$$
$$\langle\Gamma\rangle \in \{D_j^i \mid i \in \{0,1\}, j \geq 2\} \quad \text{and} \quad 0 \notin D,$$

   then W-MAX SOL(Γ) *is* **APX**-*complete;*
4. *otherwise,* $\langle\Gamma\rangle \in \{D_1^1, D_1^0\}$ *and* W-MAX SOL(Γ) *is in* **PO**.

Proof. We know from Theorem 3.3 that it is sufficient to consider constraint languages that are relational clones.

1. It is proved in Lemmas 7.7 and 7.13 that it is **NP**-hard to find a feasible solution to W-MAX SOL(E_2^1) and W-MAX SOL(E_2^0). **NP**-hardness of finding a feasible solution to W-MAX SOL($Inv(r_2)$) was proved in Lemma 7.15. The result follows from the fact that $E_2^1 \subseteq E_j^1$ and $E_2^0 \subseteq E_j^0$ $(2 \leq j \leq n)$.
2. Membership in **poly-APX** is proved in Lemma 7.5, and **poly-APX**-hardness of W-MAX SOL(D_2^1) and W-MAX SOL(D_2^0) when $0 \in D$ is proved in Lemmas 7.6 and 7.14. The result follows from the fact that $D_2^1 \subseteq D_j^1 \subseteq D_n^0$ and $D_2^0 \subseteq D_j^0 \subseteq D_n^0$ $(2 \leq j \leq n)$.
3. It is proved in Lemmas 7.11 and 7.12 that W-MAX SOL($Inv(x+y+z)$) and W-MAX SOL($Inv(r_3)$) are **APX**-complete. It is proved in Lemma 7.9 that W-MAX SOL(E_1^0) is in **APX**. **APX**-hardness for W-MAX SOL(E_1^1) is proved in Lemma 7.10. For $n \geq 4$ or $n = 2$ we have that $E_1^1 \subseteq E_1^0$, and it follows that W-MAX SOL(E_1^0) and W-MAX SOL(E_1^1) are **APX**-complete. For $n = 3$, there exists no E_1^1 so **APX**-hardness for W-MAX SOL(E_1^0) must be proved separately. Since $E_1^0 = Inv(s)$ it is easy to see that the proof of Lemma 7.10 gives **APX**-hardness for W-MAX SOL(E_1^0).
   Membership in **APX** for W-MAX SOL(D_n^0) when $0 \notin D$ is proved in the first part of Lemma 7.5. **APX**-hardness of W-MAX SOL(D_2^1) and W-MAX SOL(D_2^0) is proved in Lemmas 7.6 and 7.14, respectively. Hence, **APX**-completeness of W-MAX SOL(D_j^0) and W-MAX SOL(D_j^1) $(2 \leq j \leq n)$ when $0 \notin D$ follows from the fact that $D_2^1 \subseteq D_j^1 \subseteq D_n^0$, $D_2^0 \subseteq D_j^0 \subseteq D_n^0$ $(2 \leq j \leq n)$.
4. It is proved in Lemma 7.8 that W-MAX SOL(D_1^0) is in **PO**, and the result follows from the fact that $D_1^1 \subseteq D_1^0$. □

As a direct consequence of the preceding theorem, we get that the class of injective relations is a maximal tractable class for W-MAX SOL(Γ). That is, if we add a single relation which is not an injective relation to the class of all injective relations, then the problem is no longer in **PO** (unless **P** = **NP**).

COROLLARY 7.17. *Let Γ_I^D be the class of injective relations and let R be an arbitrary relation which is not in Γ_I^D. Then,* W-MAX SOL($\Gamma_I^D \cup \{R\}$) *is not in* **PO** *(unless* **P** = **NP***).*

Proof. We know from the proof of Lemma 7.8 that $D_1^0 = Inv(t) = \Gamma_I^D = \langle I^D \rangle$. It follows from the lattices of homogeneous relational clones that either $E_1^0 \subseteq \langle D_1^0 \cup \{R\} \rangle$ or $D_2^0 \subseteq \langle D_1^0 \cup \{R\} \rangle$. We know from Lemmas 7.10 and 7.6 that both W-MAX SOL(E_1^0) and W-MAX SOL(D_2^0) are **APX**-hard. Thus, W-MAX SOL($D_1^0 \cup \{R\}$) is **APX**-hard, and it follows that W-MAX SOL($\Gamma_I^D \cup \{R\}$) is not in **PO** (unless **P** = **NP**). □

8. Conclusions. We view this article as a first step toward a better understanding of the approximability of non-Boolean W-MAX SOL. The ultimate long-term goal for this research is, of course, to completely classify the approximability for all finite constraint languages. However, we expect this to be a hard problem since not even a complete classification for the corresponding decision problem CSP is known. A more manageable task would be to completely classify W-MAX SOL for constraint languages over small domains (say, of size 3 or 4). For size 3, this has already been accomplished for CSP [10] and MAX CSP [34]. Another obvious way to extend the results of this paper would be to complete the classification of maximal constraint languages over arbitrary finite domains, perhaps by proving Conjecture 131 from [47].

Our results combined with the results of Khanna et al. [37] for Boolean domains suggest the following conjecture.

CONJECTURE 8.1. *For every constraint language Γ, one of the following holds:*

1. W-MAX SOL(Γ) *is in* **PO**;
2. W-MAX SOL(Γ) *is* **APX***-complete;*
3. W-MAX SOL(Γ) **poly-APX***-complete;*
4. *it is* **NP***-hard to find a nonzero solution to* W-MAX SOL(Γ); *or*
5. *it is* **NP***-hard to find any solution to* W-MAX SOL(Γ).

If this conjecture is true, then there does not exist any constraint language Γ_1 such that W-MAX SOL(Γ_1) has a polynomial-time approximation scheme (PTAS) but W-MAX SOL(Γ_1) is not in **PO**. Such natural classes exist, however, if one restricts the way constraints are applied to variables (instead of restricting the allowed constraint types). MAXIMUM INDEPENDENT SET (and, equivalently, MAX ONES($\{(0,0),(1,0),(0,1)\}$)) is one example: the unrestricted problem is **poly-APX**-complete and not approximable within $O(n^{1-\epsilon})$, $\epsilon > 0$ (unless **P**=**NP**) [52], but the problem restricted to planar instances admits a PTAS [4]. One may ask several questions in connection with this: is there a constraint language with the properties of Γ_1 above? For which constraint languages does W-MAX SOL admit a PTAS on planar instances? Or more generally: under which restrictions on variable scopes does W-MAX SOL(Γ) admit a PTAS?

It is interesting to note that the applicability of the algebraic approach to W-MAX SOL demonstrated in this article also holds for the corresponding minimization problem W-MIN SOL; that is, Theorem 3.3 still holds. The question of whether the algebraic approach can shed some new light on the intriguing approximability of minimization problems (as manifested, e.g., in [37]) is an interesting open question.

As mentioned in the introduction, it is known from [37] that the approximability of the weighted and unweighted versions of (W)-MAX SOL coincide for all Boolean

constraint languages. We remark that the same result holds for all constraint languages considered in this article. This can be readily verified by observing that the AP-reduction from W-Max Ones to Max Ones in the proof of Lemma 3.11 in [37] easily generalizes to arbitrary finite domains. Hence, we get an AP-reduction from W-Max Sol to Max Sol. Furthermore, our tractability proofs are given for the weighted version of the problem. In general, it is still an open problem if tractability (i.e., membership in **PO**) of Max Sol(Γ) implies tractability of W-Max Sol(Γ) for every constraint language Γ (the AP-reduction used above does not give us this result, as AP-reductions do not, in general, preserve membership in **PO**).

Acknowledgment. The authors would like to thank the anonymous referees for many valuable comments and in particular for pointing out a serious flaw in the (previous) proof of Lemma 6.14.

EXPONENTIAL SEPARATION OF QUANTUM AND CLASSICAL ONE-WAY COMMUNICATION COMPLEXITY*

ZIV BAR-YOSSEF†, T. S. JAYRAM‡, AND IORDANIS KERENIDIS§

Abstract. We give the first exponential separation between quantum and bounded-error randomized one-way communication complexity. Specifically, we define the Hidden Matching Problem HM_n: Alice gets as input a string $\mathbf{x} \in \{0,1\}^n$, and Bob gets a perfect matching M on the n coordinates. Bob's goal is to output a tuple $\langle i, j, b\rangle$ such that the edge (i, j) belongs to the matching M and $b = x_i \oplus x_j$. We prove that the quantum one-way communication complexity of HM_n is $O(\log n)$, yet any randomized one-way protocol with bounded error must use $\Omega(\sqrt{n})$ bits of communication. No asymptotic gap for one-way communication was previously known. Our bounds also hold in the model of Simultaneous Messages (SM), and hence we provide the first exponential separation between quantum SM and randomized SM with public coins. For a Boolean decision version of HM_n, we show that the quantum one-way communication complexity remains $O(\log n)$ and that the 0-error randomized one-way communication complexity is $\Omega(n)$. We prove that any randomized *linear* one-way protocol with bounded error for this problem requires $\Omega(\sqrt[3]{n \log n})$ bits of communication.

Key words. communication complexity, quantum computation, separation, hidden matching

1. Introduction.

The investigation of the strength and limitations of quantum computing has become an important field of study in theoretical computer science. The celebrated algorithm of Shor [22] for factoring numbers in polynomial time on a quantum computer gives strong evidence that quantum computers are more powerful than classical ones. The further study of the relationship between quantum and classical computing in models like black-box computation, communication complexity, and interactive proof systems contributes to a better understanding of quantum and classical computing.

In this paper we answer an open question about the relative power of quantum *one-way communication protocols*. We describe a problem which can be solved by a quantum one-way communication protocol exponentially faster than any classical one. No asymptotic gap was previously known. We prove a similar result in the model of Simultaneous Messages.

Communication complexity, defined by Yao [23] in 1979, is a central model of computation with numerous applications. It has been used for proving lower bounds

in many areas including Boolean circuits, time-space tradeoffs, data structures, automata, and formula size. Examples of these applications can be found in the textbook of Kushilevitz and Nisan [15]. A communication complexity problem is defined by three sets X, Y, Z and a relation $\mathcal{R} \subseteq X \times Y \times Z$. Two computationally all-powerful players, Alice and Bob, are given inputs $x \in X$ and $y \in Y$, respectively. Neither of the players has any information about the other player's input. Alice and Bob exchange messages according to a shared *protocol*, until Bob has sufficient information to announce an output $z \in Z$ such that $(x, y, z) \in \mathcal{R}$. The *communication cost* of a protocol is the sum of the lengths of messages (in bits) that Alice and Bob exchange on the worst-case choice of inputs x and y. The *communication complexity* of the problem $\mathcal{R}$ is the cost of the best protocol that computes $\mathcal{R}$ correctly.

One important special case of the above model is *one-way communication complexity* [19, 2, 14], where Alice is allowed to send only one message to Bob, after which Bob announces the output. *Simultaneous Messages (SM)* is a variant in which Alice and Bob cannot communicate directly with each other; instead, each of them sends a single message to a third party, the "referee," who announces the output based on the two messages.

Depending on the kind of allowed protocols, we can define different measures of communication complexity for a problem $\mathcal{R}$. The classical *deterministic* communication complexity of $\mathcal{R}$ is the one described above. In a *bounded-error randomized* protocol with error probability $\delta > 0$, both players have access to *public* random coins, and for any inputs x, y, the output z announced should be correct (i.e., should satisfy $(x, y, z) \in \mathcal{R}$) with probability at least $1 - \delta$ (the probability is over the public random coins). The cost of such a protocol is the number of bits that Alice and Bob exchange on the worst-case choice of inputs and values for the random coins. The randomized communication complexity of $\mathcal{R}$ (w.r.t. δ) is the cost of the optimal randomized protocol for $\mathcal{R}$. In a 0-*error randomized* protocol (also known as Las Vegas protocol) the output announced should be correct with probability 1. The cost of such a protocol is the *expected* number of bits that Alice and Bob exchange on the worst-case choice of inputs. These complexity measures can also be specialized by restricting the communication model to be SM or one-way communication. An interesting variant for randomized protocols in the SM model is when the random coins are restricted to be *private* (i.e., each player has access to his/her own private random coins, and these coins are independent of each other).[1]

Quantum communication complexity, also introduced by Yao [25], apart from being of interest in itself, has been used to prove bounds on quantum formula size, automata, data structures, etc. (e.g., [25, 12, 21]). In this setting, Alice and Bob hold qubits, some of which are initialized to the input. In a communication round, each player can perform some arbitrary unitary operation on his/her part of the qubits and send some of them to the other player. At the end of the protocol they perform a measurement and decide on an outcome. The output of the protocol is required to be correct with probability $1 - \delta$ for some $\delta > 0$. The quantum communication complexity of $\mathcal{R}$ is the number of qubits exchanged in the optimal bounded-error quantum protocol for $\mathcal{R}$. It can be shown that the quantum communication is as powerful as bounded-error randomized communication with private coins,[2] even when

[1] The difference in complexity between public and private coins for the other models is only $O(\log\log(|X||Y|) + \log(1/\delta))$ [16].

[2] As noted earlier, the distinction between public and private coins is significant only for the SM model.

restricted to variants such as one-way communication and SM. It is a natural and important question to ask whether quantum channels can significantly reduce the amount of communication necessary to solve certain problems.

It is known that randomized one-way communication protocols can be much more efficient than deterministic protocols. For example, the equality function on bitstrings of length n can be solved by an $O(1)$ randomized one-way protocol, though its deterministic one-way communication complexity is $\Omega(n)$ (cf. [15]). However, the question of whether quantum one-way communication protocols could be exponentially more efficient than randomized one-way communication protocols remained open. We resolve this in the affirmative, by exhibiting a problem for which the quantum complexity is exponentially smaller than the randomized one.

1.1. Related work. The area of quantum communication complexity was introduced by Yao [25]. Since then, a series of papers have investigated the power and limitations of quantum communication complexity. Buhrman, Cleve, and Wigderson [7] described a relation $\mathcal{R}$ with deterministic communication complexity of $\Theta(n)$ and 0-error quantum communication complexity of $\Theta(\log n)$. However, the bounded-error randomized communication complexity of this problem is $O(1)$. An exponential separation w.r.t. bounded-error randomized protocols was given by Ambainis et al. [4] in the so-called sampling model. However, the separation does not hold in the presence of public coins. Buhrman et al. [6] were able to solve the equality problem in the SM model with a quantum protocol of complexity $O(\log n)$ rather than the $\Theta(\sqrt{n})$ bits necessary in any bounded-error randomized SM protocol with private coins [17, 5]. Again, if we allow the players to share random coins, then equality can be solved classically with $O(1)$ communication.

Raz [20] was the first to show an exponential gap between the quantum and the bounded-error public-coin randomized communication complexity models. He described a relation $\mathcal{P}_1$ with an efficient quantum protocol of complexity $O(\log n)$. He then proved a lower bound of $\Omega(n^{1/4})$ on the classical randomized communication complexity of $\mathcal{P}_1$. Since the quantum protocol given for $\mathcal{P}_1$ uses two rounds, the separation holds only for protocols that use two rounds or more. The definition of $\mathcal{P}_1$ was motivated, in part, by another relation $\mathcal{P}_0$. The latter was first introduced by Kremer [13], who showed that $\mathcal{P}_0$ is a complete problem for quantum one-way communication complexity (in particular, it has an $O(\log n)$ quantum one-way protocol). However, no lower bound is given for the one-way randomized communication complexity of $\mathcal{P}_0$. Proving an exponential separation of classical and quantum one-way communication complexity has been an open question ever since.

Klauck [12] proved that the 0-error quantum one-way communication complexity of *total* functions (i.e., problems $\mathcal{R} \subseteq X \times Y \times Z$, for which *every* $x \in X$ and $y \in Y$ have exactly *one* $z \in Z$ with $(x, y, z) \in \mathcal{R}$) is equal to the classical deterministic one. It is still an open question whether, for total functions, quantum and bounded-error randomized one-way communication complexity are polynomially related.

Subsequent to our work, Aaronson [1] showed that for any Boolean function f, the deterministic one-way communication complexity of f is $O(\log |Y| \cdot Q^1(f) \cdot \log Q^1(f))$, where $Q^1(f)$ is the bounded-error quantum one-way communication complexity of f; namely, if the given communication problem is a Boolean function in which Bob's domain is small, then deterministic one-way communication complexity is almost as efficient as bounded-error quantum one-way communication complexity. Moreover, Gavinsky et al. [10] described a relation which has randomized communication complexity $O(\log n)$ in the SM with public coins model, though its quantum SM commu-

nication complexity is $\Omega(\sqrt{n})$. This separation in the opposite direction from ours shows that the two models are incomparable.

1.2. Our results. Our main result is the definition and analysis of the communication complexity of the Hidden Matching Problem. This provides the first exponential separation between quantum and classical one-way communication complexity.

The HIDDEN MATCHING PROBLEM. Let n be a positive even integer. In the Hidden Matching Problem, denoted HM_n, Alice is given $\mathbf{x} \in \{0,1\}^n$ and Bob is given $M \in \mathcal{M}_n$ ($\mathcal{M}_n$ denotes the family of all possible perfect matchings on n nodes). Their goal is to output a tuple $\langle i, j, b\rangle$ such that the edge (i, j) belongs to the matching M and $b = x_i \oplus x_j$.

This problem is new, and we believe that its definition plays the major role in obtaining our result. The inspiration comes from the work by Kerenidis and de Wolf on Locally Decodable Codes [11]. Let us give the intuition for why this problem is hard for classical communication complexity protocols. Suppose (to make the problem even easier) that Bob's matching M is restricted to be one of n fixed disjoint matchings on $\mathbf{x}$. Bob's goal is to find the value of $x_i \oplus x_j$ for some $(i, j) \in M$. However, since Alice has no information about which matching Bob has, her message needs to contain information about the parity of at least one pair from each matching. Hence, she needs to communicate parities of $\Omega(n)$ different pairs to Bob. It can be shown that such message must be of size $\Omega(\sqrt{n})$. In section 4 we turn this intuition into a proof for the randomized one-way communication complexity of HM_n. We also show that our lower bound is tight by describing a randomized one-way protocol with communication $O(\sqrt{n})$. In this protocol, Alice just sends $O(\sqrt{n})$ random bits of her input. By the birthday paradox, with high probability, Bob can recover the value of at least one of his matching pairs from Alice's message.

Remarkably, this problem remains easy for quantum one-way communication. Alice only needs to send a uniform superposition of her string $\mathbf{x}$, hence communicating only $O(\log n)$ qubits. Bob can perform a measurement on this superposition which depends on the matching M and then output the parity of some pair in M. In section 3 we describe the quantum protocol in more detail.

In section 5 we show that HM_n also provides the first exponential separation between quantum SM and randomized SM with public coins. Previously such a bound was known only in the private-coin model. This result, together with the exponential separation in the opposite direction proved by Gavinsky et al. [10], shows that, in fact, the models of quantum SM and public-coin randomized SM are incomparable.

Our main result exhibits a separation between quantum and classical one-way communication complexity for a relation. Ideally, one would like to prove such a separation for the most basic type of problems—total Boolean functions. The best-known separation between quantum and classical communication complexity (even for an arbitrary number of rounds) for such functions is only quadratic [7]. It is still conceivable that for total functions, the two models are polynomially related. Raz's result [20] shows an exponential gap for a partial Boolean function (i.e., a Boolean function that is defined only on a subset of the domain $\mathcal{X} \times \mathcal{Y}$) and for two-way communication protocols.

We consider a partial Boolean function induced by the Hidden Matching Problem, defined below. In the definition we view each matching $M \in \mathcal{M}_n$ as an $\frac{n}{2} \times n$ edge-vertex incidence matrix. For two Boolean vectors $\mathbf{v}, \mathbf{w}$, we denote by $\mathbf{v} \oplus \mathbf{w}$ the vector obtained by taking the XOR $\mathbf{v}$ and $\mathbf{w}$ coordinatewise. For a bit $b \in \{0,1\}$, we denote by $\mathbf{b}$ the vector all of whose entries are b.

The Boolean Hidden Matching Problem. Let n be a positive integer multiple of 4. In the Boolean Hidden Matching Problem, denoted BHM_n, Alice is given $\mathbf{x} \in \{0,1\}^n$ and Bob is given $M \in \mathcal{M}_n$ and $\mathbf{w} \in \{0,1\}^{n/2}$, which satisfy the following promise: either $M\mathbf{x} \oplus \mathbf{w} = \mathbf{1}$ (a Yes instance) or $M\mathbf{x} \oplus \mathbf{w} = \mathbf{0}$ (a No instance). Their goal is to decide which of the two cases holds.

With a slight modification, the quantum protocol for HM_n also solves BHM_n using $O(\log n)$ qubits. We believe that BHM_n should also exhibit an exponential gap in its quantum and classical one-way communication complexity.

Conjecture 1. *The one-way randomized communication complexity of the Boolean Hidden Matching Problem is* $n^{\Omega(1)}$.

Although we were unable to resolve the above conjecture, we give a strong indication for our belief with two lower bounds. First, we prove an $\Omega(n)$ lower bound on the 0-error randomized one-way communication complexity of BHM_n. We then show that a natural class of randomized bounded-error protocols require $\widetilde{\Omega}(\sqrt[3]{n})$ bits of communication to compute BHM_n. The protocols we refer to are *linear*; that is, Alice and Bob use the public coins to choose a random matrix $\mathbf{A}$, and Alice's message on input $\mathbf{x}$ is simply $\mathbf{Ax}$. These protocols are natural for our problem, because Bob needs to compute a linear transformation of Alice's input. In particular, the $O(\sqrt{n})$ communication protocol that we described earlier is trivially a linear protocol. We note that the study of linear protocols is not unique to our problem. For example, one-way linear protocols for the indexing function can be viewed as linear *random access codes* [3]. Thus, lower bounds for linear protocols preclude the feasibility of a natural class of protocols. Generalizing this lower bound to the case of nonlinear randomized protocols still remains an open problem. These results are described in section 6.

2. Preliminaries.

2.1. Information theory. Throughout the paper we use basic notions and facts from information theory, which we briefly review next. We refer the reader to the textbook of Cover and Thomas [8] for details and proofs.

We deal only with finite discrete probability spaces. The distribution of a random variable X is denoted by μ_X, and we let $\mu_X(x) \stackrel{\text{def}}{=} \Pr[X = x]$. The *entropy* of X (or, equivalently, of μ_X) is $\mathrm{H}(X) \stackrel{\text{def}}{=} \sum_{x \in \mathcal{X}} \mu_X(x) \log \frac{1}{\mu_X(x)}$, where $\mathcal{X}$ is the domain of X. The entropy of a Bernoulli random variable with probability of success p is called the *binary entropy function* of p and is denoted $H_2(p)$. The *joint entropy* of X and Y is the entropy of the joint distribution μ_{XY} of X and Y. The *conditional entropy* of X given an event A, denoted $\mathrm{H}(X|A)$, is the entropy of the conditional distribution of μ_X given A. The *conditional entropy* of X given Y is $\mathrm{H}(X|Y) \stackrel{\text{def}}{=} \sum_{y \in \mathcal{Y}} \mu_Y(y)\, \mathrm{H}(X|Y = y)$, where $\mathcal{Y}$ is the domain of Y. The *mutual information* between X and Y is $\mathrm{I}(X;Y) \stackrel{\text{def}}{=} \mathrm{H}(X) - \mathrm{H}(X|Y) = \mathrm{H}(Y) - \mathrm{H}(Y|X)$. The *conditional mutual information* between X and Y given Z is $\mathrm{I}(X;Y|Z) = \mathrm{H}(X|Z) - \mathrm{H}(X|Y,Z) = \mathrm{H}(Y|Z) - \mathrm{H}(Y|X,Z)$.

Some basic properties of entropy and mutual information we are using in this paper are given in the following theorem.

Theorem 2.1. *Let X, Y, Z be random variables.*

1. $\mathrm{H}(X) \le \log |\mathit{supp}(X)|$, *where $\mathit{supp}(X)$ is the support of X. Equality holds if and only if X is uniform on $\mathit{supp}(X)$.*
2. *Conditioning reduces entropy:* $\mathrm{H}(X|Y) \le \mathrm{H}(X)$. *Equality holds if and only if X, Y are independent.*

3. *Entropy subadditivity:* $\mathrm{H}(X,Y) \le \mathrm{H}(X) + \mathrm{H}(Y)$. *Equality holds if and only if* X, Y *are independent.*
4. *Data processing inequality* I: *for any* k*-to-*1 *function* f, $\mathrm{H}(X) \le \mathrm{H}(f(X)) + \log k$.
5. *Data processing inequality* II: *for any function* f, $\mathrm{I}(X; f(Y)) \le \mathrm{I}(X;Y)$. *Equality holds if* f *is* 1-1.
6. *Chain rule for mutual information:* $\mathrm{I}(X; Y, Z) = \mathrm{I}(X;Y) + \mathrm{I}(X; Z|Y)$.
7. $\mathrm{I}(X;Y) = 0$ *if and only if* X, Y *are independent.*
8. *If* X, Y *are jointly independent of* Z, *then* $\mathrm{I}(X; Y|Z) = \mathrm{I}(X;Y)$.
9. *For any positive integers* n *and* $m \le n/2$, $\sum_{i=0}^{m} \binom{n}{i} \le 2^{nH_2(m/n)}$.

We will also use the following theorems.

THEOREM 2.2 (Fano's inequality). *Let* X *be a binary random variable, and let* Y *be any random variable on a domain* $\mathcal{Y}$. *Let* $f : \mathcal{Y} \to \{0,1\}$ *be a prediction function, which tries to predict the value of* X *based on an observation of* Y. *Let* $\delta \stackrel{\text{def}}{=} \Pr(f(Y) \neq X)$ *be the error probability of the prediction function. Then,* $H_2(\delta) \ge \mathrm{H}(X|Y)$.

THEOREM 2.3. *Let* $C \subseteq \{0,1\}^*$ *be a finite prefix-free code (i.e., no codeword in* C *is a prefix of any other codeword in* C*). Let* X *be a random variable corresponding to a uniformly chosen codeword in* C. *Then,* $\mathrm{H}(X) \le E(|X|)$.

2.2. Quantum computation. We explain the standard notation of quantum computing and describe the basic notions that will be useful in this paper. For more details we refer the reader to the textbook of Nielsen and Chuang [18].

Let H denote a 2-dimensional complex vector space, equipped with the standard inner product. We pick an orthonormal basis for this space, label the two basis vectors $|0\rangle$ and $|1\rangle$, and for simplicity identify them with the vectors $\binom{1}{0}$ and $\binom{0}{1}$, respectively. A *qubit* is a unit length vector in this space and thus can be expressed as a linear combination of the basis states:

$$\alpha_0|0\rangle + \alpha_1|1\rangle = \begin{pmatrix} \alpha_0 \\ \alpha_1 \end{pmatrix}.$$

Here α_0, α_1 are complex *amplitudes*, and $|\alpha_0|^2 + |\alpha_1|^2 = 1$.

An m*-qubit system* is a unit vector in the m-fold tensor space $H \otimes \cdots \otimes H$. The 2^m basis states of this space are the m-fold tensor products of the states $|0\rangle$ and $|1\rangle$. For example, the basis states of a 2-qubit system are the four 4-dimensional unit vectors $|0\rangle \otimes |0\rangle$, $|0\rangle \otimes |1\rangle$, $|1\rangle \otimes |0\rangle$, and $|1\rangle \otimes |1\rangle$. We abbreviate, e.g., $|1\rangle \otimes |0\rangle$ to $|1\rangle|0\rangle$, or $|1,0\rangle$, or $|10\rangle$, or even $|2\rangle$ (since 2 is 10 in binary). With these basis states, an m-qubit state $|\phi\rangle$ is a 2^m-dimensional complex unit vector

$$|\phi\rangle = \sum_{i \in \{0,1\}^m} \alpha_i |i\rangle.$$

We use $\langle\phi| = |\phi\rangle^*$ to denote the conjugate transpose of the vector $|\phi\rangle$, and $\langle\phi|\psi\rangle = \langle\phi| \cdot |\psi\rangle$ for the inner product between states $|\phi\rangle$ and $|\psi\rangle$. These two states are *orthogonal* if $\langle\phi|\psi\rangle = 0$. The *norm* of $|\phi\rangle$ is $\|\phi\| = \sqrt{\langle\phi|\phi\rangle}$.

Let $|\phi\rangle$ be an m-qubit state and $B = \{|b_1\rangle, \ldots, |b_{2^m}\rangle\}$ an orthonormal basis of the m-qubit space. A measurement of the state $|\phi\rangle$ in the B basis means that we apply the projection operators $P_i = |b_i\rangle\langle b_i|$ to $|\phi\rangle$. The resulting quantum state is $|b_i\rangle$ with probability $p_i = |\langle\phi|b_i\rangle|^2$.

3. The quantum upper bound. We present a quantum protocol for the Hidden Matching Problem with communication complexity of $O(\log n)$ qubits. Let $\mathbf{x} = x_1 \ldots x_n$ be Alice's input and $M \in \mathcal{M}_n$ be Bob's input.

QUANTUM PROTOCOL FOR HM_n.

1. Alice sends the state $|\psi\rangle = \frac{1}{\sqrt{n}} \sum_{i=1}^{n} (-1)^{x_i} |i\rangle$.
2. Bob performs a measurement on the state $|\psi\rangle$ in the orthonormal basis $B = \{\frac{1}{\sqrt{2}}(|k\rangle \pm |\ell\rangle) \mid (k,\ell) \in M\}$.

The probability that the outcome of the measurement is a basis state $\frac{1}{\sqrt{2}}(|k\rangle + |\ell\rangle)$ is

$$\left| \langle \psi | \frac{1}{\sqrt{2}} (|k\rangle + |\ell\rangle) \rangle \right|^2 = \frac{1}{2n} ((-1)^{x_k} + (-1)^{x_\ell})^2.$$

This equals $2/n$ if $x_k \oplus x_\ell = 0$, and 0 otherwise. Similarly for the states $\frac{1}{\sqrt{2}}(|k\rangle - |\ell\rangle)$ we have that $|\langle \psi | \frac{1}{\sqrt{2}}(|k\rangle - |\ell\rangle)\rangle|^2$ equals 0 if $x_k \oplus x_\ell = 0$ and $2/n$ if $x_k \oplus x_\ell = 1$. Hence, if the outcome of the measurement is a state $\frac{1}{\sqrt{2}}(|k\rangle + |\ell\rangle)$, then Bob knows with certainty that $x_k \oplus x_\ell = 0$ and outputs $\langle k, \ell, 0 \rangle$. If the outcome is a state $\frac{1}{\sqrt{2}}(|k\rangle - |\ell\rangle)$, then Bob knows with certainty that $x_k \oplus x_\ell = 1$ and hence outputs $\langle k, \ell, 1 \rangle$. Note that the measurement depends only on Bob's input and that the algorithm is 0-error.

This protocol can be tweaked to also solve BHM_n: after obtaining the value $\langle k, \ell, c \rangle$ from that protocol, where (k, ℓ) is the ith pair in Bob's input matching M, Bob outputs $w_i \oplus c$. Note that if $c = x_k \oplus x_\ell$, then $w_i \oplus c$ equals the desired bit b.

Remark. As mentioned above, the inspiration for this problem comes from Locally Decodable Codes. We can think of a 2-query Locally Decodable Code as a code $C : \{0,1\}^n \to \{0,1\}^m$ with the property that for every index $k \in [n]$ there exists a matching M_k on the coordinates of $C(\mathbf{x})$, such that for every pair $(i,j) \in M_k$, $x_k = C(\mathbf{x})_i \oplus C(\mathbf{x})_j$. We can cast this problem as a communication problem, by letting Alice have the codeword $C(\mathbf{x})$, letting Bob have the index k and the corresponding matching M_k, and setting the goal for Bob to output $C(\mathbf{x})_i \oplus C(\mathbf{x})_j$ for some $(i,j) \in M_k$. This gives rise to our Hidden Matching Problem. The fact that a uniform superposition of $C(\mathbf{x})$ is sufficient to compute the parity of some pair in each matching was used by Kerenidis and de Wolf [11] to prove a lower bound on the length of classical 2-query Locally Decodable Codes.

4. The randomized lower bound. We prove an $\Omega(\sqrt{n})$ lower bound on the one-way communication complexity of the Hidden Matching Problem.

THEOREM 4.1. *Any one-way randomized protocol for computing* HM_n *with error probability less than* $1/8$ *requires* $\Omega(\sqrt{n})$ *bits of communication.*

Proof. Using Yao's lemma [24], in order to prove the lower bound, it suffices to construct a "hard" distribution μ over instances of HM_n and prove a lower bound for deterministic one-way protocols whose distributional error w.r.t. μ is at most δ, where $\delta < 1/8$. This is accomplished as follows.

For a deterministic one-way protocol Π and for inputs $\mathbf{x}$ and M to Alice and Bob, respectively, we denote by $\Pi(\mathbf{x}, M)$ the output of the protocol on $\mathbf{x}$ and M. This output is a triple (i,j,b), where $i,j \in [n]$ and b is a bit. The protocol is correct on $(\mathbf{x}, M)$ if $(i,j,b) \in \mathrm{HM}_n(\mathbf{x}, M)$. That is, (i,j) is an edge in M and $b = \mathbf{x}_i \oplus \mathbf{x}_j$. Since Bob knows the matching M and also is the one who announces the output $\Pi(\mathbf{x}, M)$, we can assume without loss of generality that the pair (i,j) is always an edge in M. Therefore, an error can occur only if $b \neq \mathbf{x}_i \oplus \mathbf{x}_j$.

The following notation will be used in the proof. For a pair of random inputs U and V to Alice and Bob, respectively, let $\mathcal{E}rr_\Pi(U,V)$ denote the distributional error of Π when the inputs are drawn according to the joint distribution μ of U and V.

That is,

$$\mathcal{E}rr_{\Pi}(U,V) = \Pr_{(U,V)\sim\mu}(\Pi(U,V) \notin \mathrm{HM}_n(U,V)).$$

We define the hard distribution μ as follows: let $\mathbf{X}$ be a uniformly chosen bitstring in $\{0,1\}^n$; let $\mathbf{M}$ be an independent and uniformly chosen perfect matching in $\mathcal{M}$, where $\mathcal{M}$ is any set of $m = \Omega(n)$ pairwise edge-disjoint matchings. (For example, let $m = n/2$ and $\mathcal{M} = \{M_1, M_2, \ldots, M_m\}$, where M_i is defined by the edge set $\{(j, m + (j + i) \bmod m) \mid j = 0, \ldots, m-1\}$.) Fix any deterministic protocol Π whose distributional error on μ is at most δ, i.e., $\mathcal{E}rr_{\Pi}(\mathbf{X}, \mathbf{M}) \leq \delta$.

For each $\mathbf{x}$, let $\hat{e}_{\mathbf{x}} = \mathcal{E}rr_{\Pi}(\mathbf{x}, \mathbf{M})$ denote the distributional error of Π on the fixed input $\mathbf{x}$ to Alice and a random input $\mathbf{M}$ to Bob. Note that $\mathbb{E}[\hat{e}_{\mathbf{X}}] = \mathcal{E}rr_{\Pi}(\mathbf{X}, \mathbf{M}) \leq \delta$. By Markov's inequality, $\Pr[\hat{e}_{\mathbf{X}} \geq 2\delta] \leq 1/2$. Since $\mathbf{X}$ is uniformly distributed, this means that $\hat{e}_{\mathbf{x}} \leq 2\delta$ for at least half of the individual $\mathbf{x}$'s.

Let $A(\mathbf{x})$ denote the message that Alice sends on input $\mathbf{x}$ in the protocol Π. For every message τ, define

$$S_\tau = \{\mathbf{x} \mid A(\mathbf{x}) = \tau \text{ and } \hat{e}_{\mathbf{x}} \leq 2\delta\}.$$

Since $\hat{e}_{\mathbf{x}} \leq 2\delta$ for at least half of the $\mathbf{x}$'s, we have

$$\sum_{\tau} |S_\tau| \geq 2^{n-1}. \tag{1}$$

On the other hand, we will prove the following upper bound on the size of S_τ.

LEMMA 4.2. *For every message τ,*

$$|S_\tau| \leq 2^{n - \Omega(\sqrt{n})}.$$

Before we prove the lemma observe that (1) and Lemma 4.2 imply that the number of distinct τ's is at least $2^{\Omega(\sqrt{n})}$. Thus, the communication cost of Π is $\Omega(\sqrt{n})$, proving the theorem. □

Proof of Lemma 4.2. Fix a message τ of Alice, and let $\mathbf{X}_\tau$ be uniformly distributed in S_τ. Define $e_\tau = \mathcal{E}rr_{\Pi}(\mathbf{X}_\tau, \mathbf{M})$ to be the distributional error of Π on the random inputs $(\mathbf{X}_\tau, \mathbf{M})$. By the definition of S_τ, $\hat{e}_{\mathbf{x}} \leq 2\delta$ for every input $\mathbf{x}$ in S_τ. It follows that $e_\tau \leq 2\delta$ as well.

For each matching $M \in \mathcal{M}$, let $e_{\tau,M} = \mathcal{E}rr_{\Pi}(\mathbf{X}_\tau, M)$. Note that $\mathbb{E}[e_{\tau,\mathbf{M}}] = e_\tau$. By Markov's inequality,

$$\Pr(e_{\tau,\mathbf{M}} \geq 2e_\tau) \leq \frac{1}{2}.$$

Therefore, for at least half of the matchings M, $e_{\tau,M} \leq 2e_\tau \leq 4\delta$ (recall that $\mathbf{M}$ is uniform on the matchings). Let $\mathcal{M}'$ be the set of matchings M for which $e_{\tau,M} \leq 2e_\tau$. By the above, $|\mathcal{M}'| \geq |\mathcal{M}|/2 = m/2 = \Omega(n)$.

The output of Π depends only on τ and on the input to Bob. Therefore, for each fixed matching M, the output of the protocol on inputs $\mathbf{X}_\tau$ and M is a constant triple (i_M, j_M, b_M), where (i_M, j_M) is an edge in M and b_M is a bit. Let G_τ be the graph defined by the set of edges $\{(i_M, j_M) | M \in \mathcal{M}'\}$. The graph has n nodes and $|\mathcal{M}'| \geq \Omega(n)$ edges. (Note that here we use the fact the matchings are pairwise disjoint; hence edges corresponding to different matchings must be distinct.) Let $\mathbf{u} \in \{0,1\}^{|\mathcal{M}'|}$ be the sequence of bits b_M for $M \in \mathcal{M}'$.

We will use the following proposition to extract an acyclic subgraph of G_τ.

PROPOSITION 4.3. *Every graph G with t edges has an acyclic subgraph with $\Omega(\sqrt{t})$ edges.*

The proof of the proposition is given below. Then let F be an acyclic subgraph of G_τ with $|F| = \Omega(\sqrt{n})$ (here, $|F|$ denotes the number of edges in F). Let N denote the $n \times |F|$ vertex-edge incidence matrix of F, and let $\mathbf{v} \in \{0,1\}^{|F|}$ denote the projection of $\mathbf{u}$ on F. For any $\mathbf{x} \in \{0,1\}^n$, the vector $\mathbf{x}N$ taken over $GF[2]$ is of length $|F|$.

Since F is a subgraph of G_τ and each edge of G_τ is associated with a unique matching $M \in \mathcal{M}'$, we can label the coordinates of the vectors $\mathbf{x}N$ and $\mathbf{v}$ by matchings. Let $\mathcal{M}_F$ be the set of matchings $M \in \mathcal{M}'$, for which $(i_M, j_M) \in F$. For a matching $M \in \mathcal{M}_F$, we know $\mathbf{v}_M = b_M$. On the other hand, $(\mathbf{x}N)_M = \mathbf{x}_{i_M} \oplus \mathbf{x}_{j_M}$. Thus, disagreements of the vectors $\mathbf{v}$ and $\mathbf{x}N$ correspond to errors of Π on the input $\mathbf{x}$. In fact, the number of errors of Π on inputs of the form $(\mathbf{x}, M)$, where M varies over $\mathcal{M}_F$, is exactly the *Hamming distance* between the vectors $\mathbf{x}N$ and $\mathbf{v}$.

Let $\mathbf{F}$ be a uniformly chosen matching from $\mathcal{M}_F$ and consider $\mathcal{E}rr_\Pi(\mathbf{X}_\tau, \mathbf{F})$—the distributional error of Π on inputs drawn from $\mathbf{X}_\tau$ and $\mathbf{F}$ independently. Let $h(\mathbf{x}N, \mathbf{v})$ denote the *relative Hamming distance* between the vectors $\mathbf{x}N$ and $\mathbf{v}$. (That is, $h(\mathbf{x}N, \mathbf{v}) = (1/|F|) \cdot |\{M \in \mathcal{M}_F | (\mathbf{x}N)_M \neq \mathbf{v}_M\}|$.) By the above observation, $\mathcal{E}rr_\Pi(\mathbf{X}_\tau, \mathbf{F}) = \mathbb{E}[h(\mathbf{X}_\tau N, \mathbf{v})]$.

There is another way to look at $\mathcal{E}rr_\Pi(\mathbf{X}_\tau, \mathbf{F})$. Recall that for a fixed matching M, $e_{\tau,M} = \mathcal{E}rr_\Pi(\mathbf{X}_\tau, M)$. Recall also that for every matching $M \in \mathcal{M}'$, $e_{\tau,M} \leq 2e_\tau$. Hence, $\mathcal{E}rr_\Pi(\mathbf{X}_\tau, \mathbf{F}) = \mathbb{E}[e_{\tau,\mathbf{F}}] \leq 2e_\tau$. We conclude that $\mathbb{E}[h(\mathbf{X}_\tau N, \mathbf{v})] \leq 2e_\tau$.

Next, we resort to another proposition, whose proof appears below.

PROPOSITION 4.4. *Let Z be a random variable on $\{0,1\}^k$ and suppose there exists a vector $\mathbf{v} \in \{0,1\}^k$ such that $\mathbb{E}[h(Z, \mathbf{v})] \leq \epsilon$ with $0 \leq \epsilon \leq 1/2$. Then,* $\mathrm{H}(Z) \leq k \cdot H_2(\epsilon)$.

It follows from the above proposition and the fact $\mathbb{E}[h(\mathbf{X}_\tau N, \mathbf{v})] \leq 2e_\tau$ that $\mathrm{H}(\mathbf{X}_\tau N) \leq |F| \cdot H_2(2e_\tau)$. Note that $2e_\tau \leq 4\delta < 1/2$ as required by the proposition.

The matrix N has full rank, because it is the vertex-edge incidence matrix of an acyclic graph. It follows that the dimension of the null space of N is $n - \mathrm{rank}(N) = n - |F|$. Hence, the mapping $\mathbf{x} \mapsto \mathbf{x}N$ is a $2^{n-|F|}$-to-1 mapping. By the first data processing inequality (Theorem 2.1, part 4), since $\mathrm{H}(\mathbf{X}_\tau N) \leq |F| \cdot H_2(2e_\tau)$,

$$\mathrm{H}(\mathbf{X}_\tau) \leq |F| \cdot H_2(2e_\tau) + \log(2^{n-|F|}) = n - |F| \cdot (1 - H_2(2e_\tau)) = n - \Omega(\sqrt{n}),$$

since $H_2(2e_\tau) \leq H_2(4\delta) < 1$ when $2e_\tau \leq 4\delta < 1/2$. This completes the proof of the lemma. □

Proof of Proposition 4.3. Let $C_1, C_2, \ldots, C_s$ be the connected components of G, and let $b_1, b_2, \ldots, b_s$ be the number of edges they have ($b_1 + b_2 + \cdots + b_s = t$). C_i has $\Omega(\sqrt{b_i})$ nodes and thus has a spanning tree with $\Omega(\sqrt{b_i})$ edges. Therefore, G contains a forest F with at least $\sum_i \Omega(\sqrt{b_i}) = \Omega(\sqrt{t})$ edges, using the fact that $\sqrt{u} + \sqrt{v} \geq \sqrt{u+v}$. F is the desired acyclic subgraph. □

Proof of Proposition 4.4. We will prove the proposition for the case $\mathbf{v} = 0^k$. The generalization to other $\mathbf{v}$'s is straightforward.

Let $(Z_1, \ldots, Z_k)$ be the coordinates of Z. Each Z_i is a Bernoulli random variable, and we let $\alpha_i = \Pr[Z_i = 1]$. We have

$$\mathbb{E}[h(Z, 0^k)] = \frac{1}{k} \sum_{i=1}^{k} \mathbb{E}[Z_i] = \frac{1}{k} \sum_{i=1}^{k} \Pr(Z_i = 1) = \frac{1}{k} \sum_{i=1}^{k} \alpha_i. \tag{2}$$

Applying the subadditivity of entropy (Theorem 2.1, part 3) and the concavity of the binary entropy function,

$$\mathrm{H}(Z) \le \sum_{i=1}^{k} \mathrm{H}(Z_i) = \sum_{i=1}^{k} H_2(\alpha_i) \le k \cdot H_2\left(\frac{1}{k}\sum_{i=1}^{k}\alpha_i\right). \tag{3}$$

Combining (2) and (3), we obtain

$$\mathrm{H}(Z) \le k \cdot H_2(\mathbb{E}[h(Z, 0^k)]) \le k \cdot H_2(\epsilon),$$

since $\mathbb{E}[h(Z, 0^k)] \le \epsilon \le 1/2$ and $H_2(\cdot)$ is nondecreasing in $[0, 1/2]$. □

Next, we describe a public-coin randomized protocol of complexity $O(\sqrt{n})$ for HM_n. Alice uses the shared random string to pick $O(\sqrt{n})$ locations in $[n]$ and sends the corresponding bits to Bob. A standard birthday paradox argument shows that these bits include the end-points of at least one edge of the matching with constant probability. This shows that our lower bound is tight, and thus we have the following theorem.

THEOREM 4.5. *The randomized one-way communication complexity of* HM_n *is* $\Theta(\sqrt{n})$.

5. An exponential separation for Simultaneous Messages. Recall that in the model of SM, Alice and Bob both send a single message to a referee, after which he computes the output. We prove an exponential separation in this model between quantum and public-coin randomized communication complexity. To this end, we use a restricted version of the Hidden Matching Problem.

The RESTRICTED HIDDEN MATCHING PROBLEM (RHM_n).

Let n be a positive even integer. In the Restricted Hidden Matching Problem, fix $\mathcal{M}$ to be any set of $m = \Omega(n)$ pairwise edge-disjoint matchings. Alice is given $\mathbf{x} \in \{0,1\}^n$, and Bob is given $M \in \mathcal{M}$. Their goal is to output a tuple $\langle i, j, b\rangle$ such that the edge (i, j) belongs to the matching M and $b = x_i \oplus x_j$.

The lower bound we proved for HM_n in the model of one-way communication (Theorem 4.1) is in fact a lower bound for RHM_n. This lower bound holds also in the SM model since this model is no more powerful than one-way communication (cf. [14]). Hence, we have the following theorem.

THEOREM 5.1. *Any public-coin SM protocol for computing* RHM_n *with error probability at most* $1/8$ *requires* $\Omega(\sqrt{n})$ *bits of communication.*

On the other hand, the Restricted Hidden Matching Problem can be solved by a quantum protocol with only $O(\log n)$ communication. Bob sends the index of his matching to the referee using $O(\log n)$ bits, and Alice sends a superposition of her input string using $O(\log n)$ qubits, similarly to the one-way protocol. Since the referee knows Bob's input matching M, he can perform the same measurement Bob performed in the one-way protocol and compute the XOR of some pair in the matching.

6. The complexity of Boolean Hidden Matching.

6.1. Lower bound for 0-error protocols. In order to prove the lower bound for 0-error randomized one-way protocols, we note the following characterization of such protocols for partial functions. Let $f : \mathcal{X} \times \mathcal{Y} \to \{0, 1, *\}$ be a partial Boolean function. We say that the input (x, y) is *legal* if $f(x, y) \ne *$. A protocol for f is required to be correct only on legal inputs; it is allowed to output arbitrary answers on illegal inputs. The *confusion graph* G_f of f is a graph whose vertex set is $\mathcal{X}$; (x, x') is an edge in G_f if and only if there exists a y such that both (x, y) and (x', y) are legal inputs and $f(x, y) \ne f(x', y)$.

It is known [15] that the deterministic one-way communication complexity of f is $\log \chi(G_f) + O(1)$, where $\chi(G_f)$ is the chromatic number of the graph G_f. We will obtain a lower bound on the 0-error randomized one-way communication complexity via another measure on G_f. For any graph $G = (V, E)$, let

$$\theta(G) = \max_{W \subseteq V} \frac{|W|}{\alpha(G_W)},$$

where G_W is the subgraph of G induced on W and $\alpha(G_W)$ is the independence number of G_W. It is easy to see that $\chi(G) \geq \theta(G)$. The following theorem gives a lower bound on the 0-error communication complexity of f in terms of $\theta(G_f)$.

THEOREM 6.1. *The 0-error randomized one-way communication complexity of any partial Boolean function f is at least $\Omega(\log \theta(G_f))$.*

Proof. Let $G_f = (V, E)$ and let $W \subseteq V$ achieve the maximum for $\theta(G_f)$. Define μ to be the uniform distribution on W.

Suppose Π is a randomized 0-error one-way protocol for f with public randomness R, and whose cost is $c+1$ (Bob just outputs a bit which is the last bit of the transcript). Let $A(\mathbf{x}, R)$ be the message sent by Alice on input $\mathbf{x}$, and let $B(\tau, y, R)$ be the output of the protocol given by Bob on input y when the message sent by Alice is τ. For any legal input (x, y), we have $\mathbb{E}[|A(x, R)|] \leq c$, and $\Pr[B(A(x, R), y, R) = f(x, y)] = 1$.

Let X be a random input for Alice whose distribution is μ. Then $\mathbb{E}[|A(X, R)|] \leq c$, where the randomness is now over both X and R. Therefore, there exists a choice r^* for R such that $\mathbb{E}[|A(X, r^*)|] \leq c$. Define a deterministic protocol where $A'(x) = A(x, r^*)$ and $B'(\tau, y) = B(\tau, y, r^*)$. Note that this protocol correctly computes f and $\mathbb{E}[|A'(X)|] \leq c$. Let T be the set of messages sent by Alice in this new protocol. For any message $\tau \in T$, define $S_\tau = \{x \in W : A'(x) = \tau\}$. By the definition of G_f, it follows that S_τ is an independent set, so $|S_\tau| \leq \alpha(G_W)$. Therefore, the entropy of the random variable $A'(X)$ satisfies

$$\begin{aligned} \mathrm{H}(A'(X)) &= \sum_{\tau \in T} \frac{|S_\tau|}{|W|} \log\left(\frac{|W|}{|S_\tau|}\right) \\ &\geq \sum_{\tau \in T} \frac{|S_\tau|}{|W|} \log\left(\frac{|W|}{\alpha(G_W)}\right) = \log \theta(G_f), \end{aligned} \tag{4}$$

because the S_τ's partition W.

Finally, if we assume that the messages are prefix-free (which can be achieved with a constant factor blow-up in the communication cost), then $\mathbb{E}[|A'(X)|] \geq \mathrm{H}(A'(X))$ (Theorem 2.3). It follows from (4) that $c = \Omega(\log \theta(G_f))$. ∎

We use this characterization to prove the lower bound for BHM_n.

THEOREM 6.2. *Let $n = 4p$, where p is prime. Then, the 0-error randomized one-way communication complexity of* BHM_n *is $\Omega(n)$.*

Proof. Let f denote the partial function BHM_n. The vertex set of the confusion graph G_f is $\{0,1\}^n$. We next show that $(\mathbf{x}, \mathbf{x}')$ is an edge in G_f if and only if the Hamming distance between $\mathbf{x}$ and $\mathbf{x}'$ is exactly $n/2$.

Suppose $(\mathbf{x}, \mathbf{x}')$ is an edge in G_f. Therefore, there exist a matching M and a vector $\mathbf{w}$, so that $M\mathbf{x} \oplus \mathbf{w} = \mathbf{0}$ and $M\mathbf{x}' \oplus \mathbf{w} = \mathbf{1}$, or vice versa. That means that for every edge $(i, j) \in M$, $x_i \oplus x_j \neq x'_i \oplus x'_j$, and thus $\mathbf{x}, \mathbf{x}'$ agree on one of the position i, j and disagree on the other. Hence, the Hamming distance between $\mathbf{x}$ and $\mathbf{x}'$ is exactly $n/2$. Conversely, given two strings $\mathbf{x}, \mathbf{x}'$ of Hamming distance $n/2$, let M be

any matching between the positions on which $\mathbf{x}, \mathbf{x}'$ agree and the positions on which they disagree. Let $\mathbf{w} = M\mathbf{x}$. Clearly, $M\mathbf{x} \oplus \mathbf{w} = \mathbf{0}$. For each edge (i, j) in M we have $x_i \oplus x_j \neq x'_i \oplus x'_j$, and therefore $M\mathbf{x}' \oplus \mathbf{w} = \mathbf{1}$, implying that $(\mathbf{x}, \mathbf{x}')$ is an edge in G_f.

If $n/2$ is odd, G_f is the bipartite graph between the even and odd parity vertices. Therefore, G_f is 2-colorable, implying that f has a $O(1)$ protocol (Alice just sends the parity of her input). We will show that the situation changes dramatically when n is a prime multiple of 4.

PROPOSITION 6.3 (Frankl and Wilson [9]). *Let $m = 4p - 1$, where p is prime. Define the graph $G = (V, E)$ where $V = \{A \subseteq [m] : |A| = 2p - 1\}$, and $(A, B) \in E$ if and only if $|A \cap B| = p - 1$. Then,*

$$\alpha(G) \leq \sum_{i=0}^{p-1} \binom{m}{i}.$$

Let $m = 4p - 1 = n - 1$, and let G be the graph defined by Proposition 6.3. We claim that G is isomorphic to a vertex-induced subgraph of the confusion graph G_f: for every vertex A in G, the corresponding vertex in G_f is the characteristic vector of the set $A \cup \{4p\}$. Let V denote the vertex set of G; it follows that $\theta(G_f) \geq |V|/\alpha(G)$.

We have $|V| = \binom{m}{2p-1} \approx 2^m/\sqrt{m}$, and by Proposition 6.3 and Theorem 2.1, part 9, $\alpha(G) \leq 2^{mH_2(\gamma)}$, where H_2 is the binary entropy function and $\gamma = (p-1)/(4p-1) \leq 1/4$. The result now follows from Theorem 6.1. □

6.2. Lower bound for linear randomized protocols. In this section, we study a natural class of randomized bounded-error protocols for BHM_n and show a $\tilde{\Omega}(\sqrt[3]{n})$ communication lower bound for them.

DEFINITION 6.4 (linear protocols). *A deterministic one-way communication complexity protocol is called* linear *if for any input $\mathbf{x} \in \{0,1\}^n$, Alice's message on $\mathbf{x}$ is of the form $A\mathbf{x}$, where A is a fixed $c \times n$ Boolean matrix.*

A public-coin one-way protocol is linear *if for any input $\mathbf{x} \in \{0,1\}^n$, Alice's message on $\mathbf{x}$ is of the form $\mathbf{Ax}$, where $\mathbf{A}$ is a random $c \times n$ Boolean matrix chosen using the public random bits.*

THEOREM 6.5. *Let n be a positive integer multiple of 4 and let $0 < \delta < 1/2$ be a constant bounded away from $1/2$. Then, any δ-error public-coin one-way linear protocol for BHM_n requires $\Omega(\sqrt[3]{n \log n})$ bits of communication.*

Proof. Using Yao's lemma [24], to prove the lower bound, it suffices to construct a "hard" distribution μ over instances of BHM_n and prove a distributional lower bound w.r.t. deterministic one-way linear protocols. We define μ as follows: let $\mathbf{X}$ be a uniformly chosen bitstring in $\{0,1\}^n$; let $\mathbf{M}$ be a uniformly chosen perfect matching in $\mathcal{M}_n$; and let B be a uniformly chosen bit. $\mathbf{W}$ is a random bitstring in $\{0,1\}^{n/2}$, defined as $\mathbf{W} \stackrel{\text{def}}{=} \mathbf{MX} \oplus \mathbf{B}$ (recall that $\mathbf{B}$ is the vector all of whose entries are B).

Let Π be any deterministic one-way linear protocol that has error probability of at most δ when solving BHM_n on inputs drawn according to μ. Let c be the communication cost of Π.

Since Π is deterministic, one-way, and linear, there exists a fixed $c \times n$ Boolean matrix A, such that the message of Π on any input $\mathbf{x}$ is $A\mathbf{x}$. By adding at most one bit to the communication cost of Π, we can assume $\mathbf{1}$ is one of the rows of A. We also assume, without loss of generality, that A has a full row rank, because otherwise Alice sends redundant information, which Bob can figure out by himself.

We assume c satisfies $c^3/\log c \leq 3n/4$, since, otherwise, $c \geq \Omega(\sqrt[3]{n \log n})$, and we are done.

For a matrix T, we denote by $\mathrm{sp}(T)$ the span of the row vectors of T over the field $GF(2)$. Clearly, for any matrix T, $\mathbf{0} \in \mathrm{sp}(T)$. In particular, $\mathbf{0} \in \mathrm{sp}(M) \cap \mathrm{sp}(A)$ for any matching $M \in \mathcal{M}_n$ (recall that we view a matching M as an $\frac{n}{2} \times n$ edge-vertex incidence matrix). By our assumption about A, $\mathbf{1} \in \mathrm{sp}(A)$. Since M is a perfect matching, the sum of its rows is $\mathbf{1}$; thus $\mathbf{1} \in \mathrm{sp}(M)$. We conclude that for any M, $\{\mathbf{0}, \mathbf{1}\} \subseteq \mathrm{sp}(M) \cap \mathrm{sp}(A)$. Let Z be an indicator random variable of the event $\{\mathrm{sp}(\mathbf{M}) \cap \mathrm{sp}(A) = \{\mathbf{0}, \mathbf{1}\}\}$, meaning that $\mathbf{0}$ and $\mathbf{1}$ are the only vectors in the intersection of the spans.

At a high level, our plan for the rest of the proof is as follows. Loosely speaking, for any matching M belonging to the above event (i.e., $\mathrm{sp}\, M \cap \mathrm{sp}(A) = \{\mathbf{0}, \mathbf{1}\}$) and for any possible input $\mathbf{x} \neq \mathbf{0}, \mathbf{1}$, the vectors $M\mathbf{x}$ and $A\mathbf{x}$ are linearly independent. This linear independence also implies *statistical* independence of the random variables $M\mathbf{X}$ and $A\mathbf{X}$. In particular, it means that Alice's message, $A\mathbf{X}$, has no information about $M\mathbf{X}$, and thus Bob cannot determine whether $M\mathbf{X} \oplus \mathbf{W} = \mathbf{1}$ or $M\mathbf{X} \oplus \mathbf{W} = \mathbf{0}$. We conclude that the protocol can succeed only when the event does not happen. We will prove that the probability of this event not happening is $\tilde{O}(c^3/n)$, and thus only when $c \geq \tilde{\Omega}(\sqrt[3]{n})$, is the success probability of the protocol sufficiently high. The formal argument follows.

In the protocol Π, Bob observes values of the random variables $A\mathbf{X}, \mathbf{M}$, and $\mathbf{W}$ and uses them to predict the random variable B with error probability δ. Therefore, by Fano's inequality (Theorem 2.2),

$$H_2(\delta) \geq \mathrm{H}(B \mid A\mathbf{X}, \mathbf{M}, \mathbf{W}). \tag{5}$$

Since conditioning reduces entropy,

$$\begin{aligned} \mathrm{H}(B \mid A\mathbf{X}, \mathbf{M}, \mathbf{W}) &\geq \mathrm{H}(B \mid A\mathbf{X}, \mathbf{M}, \mathbf{W}, Z) \\ &= \mathrm{H}(B \mid A\mathbf{X}, \mathbf{M}, \mathbf{W}, Z = 1) \cdot \Pr(Z = 1) \\ &\quad + \mathrm{H}(B \mid A\mathbf{X}, \mathbf{M}, \mathbf{W}, Z = 0) \cdot \Pr(Z = 0) \\ &\geq \mathrm{H}(B \mid A\mathbf{X}, \mathbf{M}, \mathbf{W}, Z = 1) \cdot \Pr(Z = 1). \qquad (6) \end{aligned}$$

The following two lemmas bound the two factors in the last expression.

LEMMA 6.6. $\mathrm{H}(B \mid A\mathbf{X}, \mathbf{M}, \mathbf{W}, Z = 1) = 1$.

LEMMA 6.7. $\Pr(Z = 1) \geq 1 - O(\frac{c^3}{n \log c})$.

The proofs of Lemmas 6.6 and 6.7 are provided below. Let us first show how the two lemmas derive the theorem. By combining (5) and (6), and Lemmas 6.6 and 6.7, we have

$$H_2(\delta) \geq 1 - O\left(\frac{c^3}{n \log c}\right).$$

Therefore,

$$\begin{aligned} c &\geq \Omega(\sqrt[3]{n(1 - H_2(\delta)) \cdot \log(n(1 - H_2(\delta)))}) \\ &= \Omega(\sqrt[3]{n \log n}), \end{aligned}$$

since $H_2(\delta)$ is a constant bounded away from 1. This completes the proof of the theorem. □

Proof of Lemma 6.6. Recall that we assume that $\mathbf{1}$ is one of the rows of A and that A has a full row rank. Let A' be the submatrix of A consisting of all the rows

of A, except $\mathbf{1}$. Clearly, $\mathrm{sp}(A') \subseteq \mathrm{sp}(A)$ and $\mathbf{1} \notin \mathrm{sp}(A')$. It follows that the event $\{\mathrm{sp}(\mathbf{M}) \cap \mathrm{sp}(A) = \{\mathbf{0}, \mathbf{1}\}\}$ is the same as the event $\{\mathrm{sp}(\mathbf{M}) \cap \mathrm{sp}(A') = \{\mathbf{0}\}\}$. Thus, from now on we will think of Z as an indicator random variable of the latter.

Observe that since n is a multiple of 4, the parity of the bits of $\mathbf{w}$ is always equal to the parity of the bits of $\mathbf{x}$. The parity of the bits of $\mathbf{x}$ is exactly the inner product $\mathbf{1}^t \cdot \mathbf{x}$, which is one of the bits in the vector $A\mathbf{x}$. It follows that there is a 1-1 mapping f such that $f(A(\mathbf{x}), \mathbf{w}) = (A'(\mathbf{x}), \mathbf{w})$. By the second data processing inequality (Theorem 2.1, part 5), we can therefore rewrite $\mathrm{H}(B \mid A\mathbf{X}, \mathbf{M}, \mathbf{W}, Z = 1)$ as $\mathrm{H}(B \mid A'\mathbf{X}, \mathbf{M}, \mathbf{W}, Z = 1)$.

By the definition of mutual information,

$$\begin{aligned}&\mathrm{H}(B \mid A'\mathbf{X}, \mathbf{M}, \mathbf{W}, Z = 1)\\ &= \mathrm{H}(B \mid \mathbf{M}, \mathbf{W}, Z = 1) - \mathrm{I}(B\ ;\ A'\mathbf{X} \mid \mathbf{M}, \mathbf{W}, Z = 1).\end{aligned}$$

The next proposition shows that the random variables $B, \mathbf{M}$, and $\mathbf{W}$ are mutually independent given the event $\{Z = 1\}$, which together with Theorem 2.1, part 2, implies that $\mathrm{H}(B \mid \mathbf{M}, \mathbf{W}, Z = 1) = \mathrm{H}(B|Z = 1)$. Since B and Z are independent (Z is a function of $\mathbf{M}$ only), $\mathrm{H}(B|Z = 1) = \mathrm{H}(B) = 1$. Thus, in order to prove the lemma it would suffice to show that $\mathrm{I}(B\ ;\ A'\mathbf{X} \mid \mathbf{M}, \mathbf{W}, Z = 1) = 0$.

PROPOSITION 6.8. *The random variables $B, \mathbf{M}$, and $\mathbf{W}$ are mutually independent, given the event $\{Z = 1\}$.*

Proof. We will show that the random variables $B, \mathbf{M}$, and $\mathbf{W}$ are mutually independent unconditionally. This independence would then hold even given the event $\{Z = 1\}$, because this event is a function of $\mathbf{M}$ only.

The random variables B and $\mathbf{M}$ are independent, by definition. Let M be any value of the random variable $\mathbf{M}$, and let b be any value of the random variable B. In order to show the desired independence, we need to prove that for any possible value $\mathbf{w}$ of $\mathbf{W}$, $\Pr(\mathbf{W} = \mathbf{w} \mid \mathbf{M} = M, B = b) = \Pr(\mathbf{W} = \mathbf{w})$.

Using conditional probability, we can rewrite $\Pr(\mathbf{W} = \mathbf{w} \mid \mathbf{M} = M, B = b)$ as follows:

$$\begin{aligned}&\Pr(\mathbf{W} = \mathbf{w} \mid \mathbf{M} = M, B = b)\\ &= \sum_{\mathbf{x} \in \{0,1\}^n} \Pr(\mathbf{W} = \mathbf{w} \mid \mathbf{M} = M, B = b, \mathbf{X} = \mathbf{x})\\ &\qquad \cdot \Pr(\mathbf{X} = \mathbf{x} \mid \mathbf{M} = M, B = b).\end{aligned}$$

Since $\mathbf{X}, \mathbf{M}$, and B are mutually independent by definition, $\Pr(\mathbf{X} = \mathbf{x} \mid \mathbf{M} = M, B = b) = \Pr(\mathbf{X} = \mathbf{x}) = 1/2^n$. $\Pr(\mathbf{W} = \mathbf{w} \mid \mathbf{M} = M, B = b, \mathbf{X} = \mathbf{x}) = 1$ only if $\mathbf{w} = M\mathbf{x} \oplus \mathbf{b}$, and it is 0 otherwise. The number of $\mathbf{x}$'s that satisfy this condition is the number of solutions to the linear system $M\mathbf{x} = \mathbf{w} \oplus \mathbf{b}$ over Z_2^n. Since M is an $\frac{n}{2} \times n$ matrix that has a full row rank, this number is $2^{n/2}$. Therefore, $\Pr(\mathbf{W} = \mathbf{w} \mid \mathbf{M} = M, B = b) = 2^{n/2}/2^n = 1/2^{n/2}$.

Consider now the quantity $\Pr(\mathbf{W} = \mathbf{w})$. Using conditional probability we can rewrite it as

$$\begin{aligned}&\Pr(\mathbf{W} = \mathbf{w})\\ &= \sum_{M,b} \Pr(\mathbf{W} = \mathbf{w} \mid \mathbf{M} = M, B = b) \cdot \Pr(\mathbf{M} = M, B = b).\end{aligned}$$

We already proved that for all M and b, $\Pr(\mathbf{W} = \mathbf{w} \mid \mathbf{M} = M, B = b) = 1/2^{n/2}$. Therefore, also $\Pr(\mathbf{W} = \mathbf{w}) = 1/2^{n/2}$, completing the proof. ∎

Next we prove $\mathrm{I}(B\ ;\ A'\mathbf{X} \mid \mathbf{M}, \mathbf{W}, Z = 1) = 0$. By the chain rule for mutual information,

$$\begin{aligned}&\mathrm{I}(B, \mathbf{M}, \mathbf{W}\ ;\ A'\mathbf{X} \mid Z = 1)\\ &= \mathrm{I}(\mathbf{M}, \mathbf{W}\ ;\ A'\mathbf{X} \mid Z = 1) + \mathrm{I}(B\ ;\ A'\mathbf{X} \mid \mathbf{M}, \mathbf{W}, Z = 1).\end{aligned}$$

Since mutual information is always a nonnegative quantity, it would thus suffice to show that $\mathrm{I}(B, \mathbf{M}, \mathbf{W}\ ;\ A'\mathbf{X} \mid Z = 1) = 0$.

The function $f(b, M, \mathbf{w}) = (b, M, \mathbf{w} \oplus \mathbf{b})$ is a 1-1 function. Note that $f(B, \mathbf{M}, \mathbf{W}) = (B, \mathbf{M}, \mathbf{W} \oplus \mathbf{B}) = (B, \mathbf{M}, \mathbf{MX})$. Therefore, by the second data processing inequality (Theorem 2.1, part 5), we have

$$\mathrm{I}(B, \mathbf{M}, \mathbf{W}\ ;\ A'\mathbf{X} \mid Z = 1) = \mathrm{I}(B, \mathbf{M}, \mathbf{MX}\ ;\ A'\mathbf{X} \mid Z = 1).$$

Using again the chain rule for mutual information we have

$$\begin{aligned}&\mathrm{I}(B, \mathbf{M}, \mathbf{MX}\ ;\ A'\mathbf{X} \mid Z = 1)\\ &= \mathrm{I}(B, \mathbf{M}\ ;\ A'\mathbf{X} \mid Z = 1) + \mathrm{I}(\mathbf{MX}\ ;\ A'\mathbf{X} \mid B, \mathbf{M}, Z = 1).\end{aligned} \tag{7}$$

We next show that each of the above mutual information quantities is 0. By the definition of the input distribution μ, the random variables $B, \mathbf{M}$, and $\mathbf{X}$ are mutually independent. This holds even given the event $\{Z = 1\}$, because the latter is a function of $\mathbf{M}$ only. It follows that $B, \mathbf{M}$, $A'\mathbf{X}$ are also mutually independent given the event $\{Z = 1\}$, and thus $\mathrm{I}(B, \mathbf{M}\ ;\ A'\mathbf{X} \mid Z = 1) = 0$ (Theorem 2.1, part 7).

As for the second mutual information quantity on the right-hand side of (7), we use again the independence of $B, \mathbf{M}$, and $A'\mathbf{X}$ given $\{Z = 1\}$ as well as Theorem 2.1, part 8, to derive $\mathrm{I}(\mathbf{MX}\ ;\ A'\mathbf{X} \mid B, \mathbf{M}, Z = 1) = \mathrm{I}(\mathbf{MX}\ ;\ A'\mathbf{X} \mid \mathbf{M}, Z = 1)$. The following proposition proves that for any matching M satisfying the condition indicated by the event $\{Z = 1\}$, the random variables $M\mathbf{X}$ and $A'\mathbf{X}$ are independent. It then follows that $\mathrm{I}(\mathbf{MX}\ ;\ A'\mathbf{X} \mid \mathbf{M}, Z = 1) = 0$.

PROPOSITION 6.9. *For any matching $M \in \mathcal{M}_n$ satisfying the condition $\mathrm{sp}(M) \cap \mathrm{sp}(A') = \{\mathbf{0}\}$, the random variables $M\mathbf{X}$ and $A'\mathbf{X}$ are independent.*

Proof. Let $\mathbf{z}$ be any possible value for the random variable $M\mathbf{X}$, and let $\mathbf{y}$ be any possible value for the random variable $A'\mathbf{X}$. In order to prove the independence, we need to show that $\Pr(M\mathbf{X} = \mathbf{z} \mid A'\mathbf{X} = \mathbf{y}) = \Pr(M\mathbf{X} = \mathbf{z})$.

M is an $\frac{n}{2} \times n$ Boolean matrix that has a full row rank. Therefore, the number of solutions to the linear system $M\mathbf{x} = \mathbf{z}$ over Z_2^n is exactly $2^{n/2}$. Recall that $\mathbf{X}$ was chosen uniformly at random from Z_2^n. Therefore, $\Pr(M\mathbf{X} = \mathbf{z}) = 1/2^{n/2}$.

By the definition of conditional probability, $\Pr(M\mathbf{X} = \mathbf{z} \mid A'\mathbf{X} = \mathbf{y}) = \Pr(M\mathbf{X} = \mathbf{z}, A'\mathbf{X} = \mathbf{y}) / \Pr(A'\mathbf{X} = \mathbf{y})$. Since A' is a $(c-1) \times n$ Boolean matrix and has a full row rank, the same argument as above shows that $\Pr(A'\mathbf{X} = \mathbf{y}) = 1/2^{n-c+1}$. Let D be an $(\frac{n}{2} + c - 1) \times n$ matrix, which is created by putting M on top of A'. Since $\mathrm{sp}(M) \cap \mathrm{sp}(A') = \{\mathbf{0}\}$, D has a full row rank. We thus obtain $\Pr(M\mathbf{X} = \mathbf{z}, A'\mathbf{X} = \mathbf{y}) = \Pr(D\mathbf{X} = (\mathbf{z}, \mathbf{y})) = 1/2^{n/2-c+1}$. Hence, $\Pr(M\mathbf{X} = \mathbf{z} \mid A'\mathbf{X} = \mathbf{y}) = 2^{n/2-c+1}/2^{n-c+1} = 1/2^{n/2} = \Pr(M\mathbf{X} = \mathbf{z})$. The proposition follows. □

This completes the proof of Lemma 6.6. □

We now turn to the proof of Lemma 6.7.

Proof of Lemma 6.7. Denote the event $\{\mathrm{sp}(\mathbf{M}) \cap \mathrm{sp}(A) \neq \{\mathbf{0}, \mathbf{1}\}\}$ by E. We would like to prove $\Pr(E) \leq O(c^3/(n \log c))$. For $0 \leq k \leq n$, define $\mathrm{sp}_k(A)$ to be the vectors in $\mathrm{sp}(A)$ whose Hamming weight is k. Define E_k to be the event $\{\mathrm{sp}(\mathbf{M}) \cap \mathrm{sp}_k(A) \neq \emptyset\}$.

Since $\mathrm{sp}_0(A) = \{\mathbf{0}\}$ and $\mathrm{sp}_n(A) = \{\mathbf{1}\}$, the event E can be rewritten as $\bigvee_{k=1}^{n-1} E_k$. Thus, using the union bound, we can bound the probability of E as follows:

$$\Pr(E) \leq \sum_{k=1}^{n-1} \Pr(\mathrm{sp}(\mathbf{M}) \cap \mathrm{sp}_k(A) \neq \emptyset). \tag{8}$$

Let M be any matching in $\mathcal{M}_n$. Any vector $\mathbf{v}$ in $\mathrm{sp}(M)$, when viewed as a set $S_{\mathbf{v}}$ (i.e., $\mathbf{v}$ is the characteristic vector of $S_{\mathbf{v}}$), is a disjoint union of edges from M. We thus immediately conclude that $\mathbf{v}$ has to have an even Hamming weight. This implies that for all odd $1 \leq k \leq n-1$,

$$\Pr(\mathrm{sp}(\mathbf{M}) \cap \mathrm{sp}_k(A) \neq \emptyset) = 0. \tag{9}$$

Consider then an even k, and let $\mathbf{v}$ be any vector in $\mathrm{sp}_k(A)$. If $\mathbf{v}$ belongs to $\mathrm{sp}(M)$, then M can be partitioned into two perfect "submatchings": a perfect matching on $S_{\mathbf{v}}$ and perfect matching on $[n] \setminus S_{\mathbf{v}}$. We conclude that the number of matchings M in $\mathcal{M}_n$, for which $\mathbf{v} \in \mathrm{sp}(M)$, is exactly $m_k \cdot m_{n-k}$, where m_ℓ is the number of perfect matchings on ℓ nodes. Note that $m_\ell = \frac{\ell!}{(\ell/2)!2^{\ell/2}}$, and thus,

$$\Pr(\mathbf{v} \in \mathrm{sp}(\mathbf{M})) = \frac{m_k \cdot m_{n-k}}{m_n} = \frac{\binom{\frac{n}{2}}{\frac{k}{2}}}{\binom{n}{k}}.$$

It follows, by the union bound, that for any even k,

$$\Pr(\mathrm{sp}(\mathbf{M}) \cap \mathrm{sp}_k(A) \neq \emptyset) \leq |\mathrm{sp}_k(A)| \cdot \frac{\binom{\frac{n}{2}}{\frac{k}{2}}}{\binom{n}{k}}. \tag{10}$$

Since $\mathbf{1} \in \mathrm{sp}(A)$, $|\mathrm{sp}_k(A)| = |\mathrm{sp}_{n-k}(A)|$ for all $0 \leq k \leq n$. Combining this and (8), (9), and (10), it would thus suffice to prove the following:

$$\sum_{j=1}^{n/4} |\mathrm{sp}_{2j}(A)| \cdot \frac{\binom{\frac{n}{2}}{j}}{\binom{n}{2j}} \leq O\left(\frac{c^3}{n \log c}\right). \tag{11}$$

We start by bounding the ratio in each of the terms:

$$\begin{aligned} \frac{\binom{\frac{n}{2}}{j}}{\binom{n}{2j}} &= \frac{(\frac{n}{2})! \cdot (2j)! \cdot (n-2j)!}{(\frac{n}{2}-j)! \cdot j! \cdot n!} \\ &= \frac{\frac{n}{2} \cdots (\frac{n}{2}-j+1) \cdot (2j) \cdots (j+1)}{n \cdots (n-2j+1)} \\ &\leq \left(\frac{1}{2}\right)^j \cdot \left(\frac{2j}{n-j}\right)^j = \left(\frac{j}{n-j}\right)^j \leq \left(\frac{4j}{3n}\right)^j. \end{aligned} \tag{12}$$

The last inequality follows from the fact $j \leq n/4$. We next bound $|\mathrm{sp}_{2j}(A)|$ for small values of j.

PROPOSITION 6.10. *For every* $1 \leq j \leq \lfloor c/2 \rfloor$, $|\mathrm{sp}_{2j}(A)| \leq \sum_{i=1}^{2j} \binom{c}{i}$.

Proof. Using just the elementary row operations of Gaussian elimination, we can transform A into a matrix A' which has exactly the same span as A and has the $c \times c$ identity matrix as a submatrix. (Recall that A has a full row rank of c.) It follows

that any linear combination of t rows of A' results in a vector of Hamming weight at least t. Therefore, the only linear combinations to give vectors in $\mathrm{sp}_{2j}(A)$ are ones that use at most $2j$ rows of A'. The proposition follows, since the number of the latter is $\sum_{i=1}^{2j} \binom{c}{i}$. ∎

We conclude that for $1 \le j \le \lfloor c/2 \rfloor$, $|\mathrm{sp}_{2j}(A)| \le \sum_{i=1}^{2j} c^i = \frac{c^{2j}-1}{c-1} \cdot c \le 2c^{2j}$ (assuming $c \ge 2$). On the other hand, we have for all $1 \le j \le n/4$, $|\mathrm{sp}_{2j}(A)| \le |\mathrm{sp}(A)| \le 2^c$. Note that the quantity $2c^{2j}$ exceeds 2^c, when $j \ge \frac{c-1}{2\log c}$. We thus define $\ell \stackrel{\text{def}}{=} \lfloor \frac{c-1}{2\log c} \rfloor$ and break the sum on the right-hand side of (11), which we need to bound, into two parts as follows:

$$\begin{aligned}
&\sum_{j=1}^{n/4} |\mathrm{sp}_{2j}(A)| \cdot \frac{\binom{\frac{n}{2}}{j}}{\binom{n}{2j}} \\
&= \sum_{j=1}^{\ell} |\mathrm{sp}_{2j}(A)| \cdot \frac{\binom{\frac{n}{2}}{j}}{\binom{n}{2j}} + \sum_{j=\ell+1}^{n/4} |\mathrm{sp}_{2j}(A)| \cdot \frac{\binom{\frac{n}{2}}{j}}{\binom{n}{2j}} \\
&\le \sum_{j=1}^{\ell} (2c^{2j}) \cdot \left(\frac{4j}{3n}\right)^j + 2^c \cdot \max_{\ell < j \le n/4} \left(\frac{4j}{3n}\right)^j. \qquad (13)
\end{aligned}$$

The last inequality follows from (12), from Proposition 6.10, and from the fact that $\sum_{j=\ell+1}^{n/4} |\mathrm{sp}_{2j}(A)| \le |\mathrm{sp}(A)| \le 2^c$. We bound each of the terms on the right-hand side of (13) separately. We start with the first one:

$$\sum_{j=1}^{\ell} (2c^{2j}) \cdot \left(\frac{4j}{3n}\right)^j = 2 \cdot \sum_{j=1}^{\ell} \left(\frac{4c^2 j}{3n}\right)^j \le 2 \cdot \sum_{j=1}^{\ell} \left(\frac{4c^2 \ell}{3n}\right)^j.$$

Recall that we assumed $c^3/\log c \le 3n/4$. Hence, $4c^2\ell/(3n) \le 2c^3/(3n \log c) \le 1/2$. We can thus bound the geometric series as follows:

$$\begin{aligned}
2 \cdot \sum_{j=1}^{\ell} \left(\frac{4c^2\ell}{3n}\right)^j &\le 2 \cdot \frac{4c^2\ell}{3n} \cdot \frac{1}{1 - \frac{4c^2\ell}{3n}} \le \frac{16c^2\ell}{3n} \\
&\le \frac{8c^3}{3n \log c}. \qquad (14)
\end{aligned}$$

We now turn to bounding the second term on the right-hand side of (13).

PROPOSITION 6.11. *The function $g(j) = (aj)^j$, where $a > 0$, has a local minimum at $j^* = \frac{1}{ae}$ in the interval $(0, \infty)$.*

Proof. We rewrite g as follows: $g(j) = e^{j \ln(aj)}$. The derivative of g is the following:

$$g'(j) = e^{j \ln(aj)} \cdot (\ln(aj) + 1).$$

Thus, g has a local extremum at $j^* = \frac{1}{ae}$. We next verify that it is a local minimum. The second derivative of g is the following:

$$g''(j) = g'(j) \cdot (\ln(aj) + 1) + g(j) \cdot \frac{1}{j} = g(j) \cdot \left((\ln(aj) + 1)^2 + \frac{1}{j}\right).$$

Since g is positive in the interval $(0, \infty)$, $g''(j) > 0$ for all j in this interval. In particular, $g''(j^*) > 0$, implying that j^* is a local minimum. ∎

Proposition 6.11 shows that the function $g(j) = (aj)^j$ has a local minimum at $j^* = \frac{1}{ae}$ in the interval $(0, \infty)$. In our case $a = \frac{4}{3n}$, and thus $j^* = 3n/(4e) \geq n/4$. Therefore the maximum of $(\frac{4j}{3n})^j$ in the interval $[\ell, n/4]$ is obtained at $j = \ell$. We conclude that

$$\begin{aligned} 2^c \cdot \max_{\ell < j \leq n/4} \left(\frac{4j}{3n}\right)^j &\leq 2^c \cdot \left(\frac{4\ell}{3n}\right)^\ell \leq 2^c \cdot \left(\frac{2c}{3n \log c}\right)^{\frac{c}{2 \log c}} \\ &\leq \left(\frac{4c}{3n \log c}\right)^c \leq \left(\frac{2c}{n}\right)^c \leq \frac{c}{n} \\ &\leq \frac{c^3}{n \log c}. \end{aligned} \tag{15}$$

In the next-to-last inequality we used the fact $2 \leq c \leq n/4$. Combining (13), (14), and (15), we have

$$\sum_{j=1}^{n/4} |\operatorname{sp}_{2j}(A)| \cdot \frac{\binom{\frac{n}{2}}{j}}{\binom{n}{2j}} \leq \frac{8c^3}{3n \log c} + \frac{c^3}{n \log c} \leq O\left(\frac{c^3}{n \log c}\right).$$

This completes the proof of Lemma 6.7. □

Remark. As mentioned previously, the randomized lower bound for HM_n also holds for a restricted version of the Hidden Matching Problem (which we denoted by RHM_n), in which Bob's input is a matching M taken from a small set $\mathcal{M}$ of $\Theta(n)$ disjoint matchings only. One can define an analogous restricted version of BHM_n, denoted RBHM_n. However, in this case the complexities of BHM_n and RBHM_n are entirely different. By Aaronson's result [1], and by our $O(\log n)$-bit quantum upper bound for BHM_n (which, of course, also works for RBHM_n), the deterministic one-way communication complexity of RBHM_n is only $O(\log^2 n \cdot \log \log n)$. On the other hand, the deterministic (and even 0-error randomized) one-way communication complexity of BHM_n is $\Omega(n)$ (Theorem 6.2). Hence, there is an exponential gap between the two.

7. Open problems. The main question in quantum communication complexity is to characterize its power in relation to classical communication complexity. For partial Boolean functions it was known that quantum two-way communication complexity could be exponentially lower than the classical complexity [20]. Here we prove a similar result for a relation for one-way communication complexity and SM. The main open question is to find the relation between quantum and classical communication complexity for total functions. Are they polynomially related for all total functions? Is this relationship even tighter in the case of one-way communication complexity? Moreover, can we show an exponential separation between quantum one-way communication complexity and randomized two-way communication complexity?

Acknowledgments. We would like to thank Umesh Vazirani, Ashwin Nayak, and Kunal Talwar for helpful discussions.

THE EUCLIDEAN ORIENTEERING PROBLEM REVISITED*

KE CHEN† AND SARIEL HAR-PELED†

Abstract. We consider the *rooted orienteering problem*: Given a set P of n points in the plane, a starting point $r \in P$, and a length constraint $\mathcal{B}$, one needs to find a path starting from r that visits as many points of P as possible and of length not exceeding $\mathcal{B}$. We present a $(1-\varepsilon)$-approximation algorithm for this problem that runs in $n^{O(1/\varepsilon)}$ time; the computed path visits at least $(1-\varepsilon)k_{\text{opt}}$ points of P, where k_{opt} is the number of points visited by an optimal solution. This is the first polynomial time approximation scheme for this problem. The algorithm also works in higher dimensions.

1. Introduction.

Consider a traveling salesperson who has a fixed amount of gasoline and wants to maximize the number of customers visited under this constraint. This is an instance of the *orienteering problem* that requires us to design a network that visits a maximum number of points, subject to an upper bound on the total length of the network. This problem is "dual" to the classical *k-TSP problem* [3, 10, 9], which asks for a minimum length path visiting at least k points.

In this paper, we consider the *rooted path orienteering problem* in the plane, specified by P, r, and $\mathcal{B}$, where P is a set of n points in the plane, r is the starting point, and $\mathcal{B} > 0$ is the maximum length allowed. The solution to this problem is a path that starts at r and visits as many points of P as possible, such that the path length does not exceed $\mathcal{B}$. The effect of fixing the starting point is significant as far as approximation algorithms are concerned. Indeed, approximation algorithms for k-TSP extend easily to the *unrooted orienteering problem*, where there is no fixed starting point, while the approximation algorithm for the rooted orienteering problem is more challenging. The difficulty stems from the fact that an optimal path may visit a large number of points that lie in a small cluster at a distance nearly $\mathcal{B}$ from r, thus making it difficult to visit at least a large fraction of these points unless the path is very efficient [2].

Some related problems include the *prize-collecting traveling salesman problem* and the *vehicle routing problem*. They arise from real world applications such as delivering goods to locations or assigning technicians to maintenance service jobs. A substantial amount of work on heuristics for these problems can be found in the operations research literature [12].

Arkin, Mitchell, and Narasimhan [2] were the first to design approximation algorithms for the rooted orienteering problem. They considered the rooted orienteering problem for points in the plane when the underlying network is a path, a cycle, or

a tree. Their algorithms provide a 2-approximation for the rooted path orienteering problem, and a 2- (resp., 3-) approximation when the networks considered are cycles (resp., trees). Blum et al. [6] proposed the first constant-factor approximation algorithm for the rooted path orienteering problem when the points lie in a general metric space. Bansal et al. [5] improved the approximation factor to 3. Arkin, Mitchell, and Narasimhan [2] asked whether a better approximation is possible in Euclidean spaces.

One difficulty in assailing this problem is the relative lack of algorithmic tools to handle rigid budget constraints. Since the development of $(1+\varepsilon)$-approximation algorithms for TSP [3, 10], a large class of the problems that aim to minimize the tour length, subject to certain constraints on the points visited by the tour, have been resolved. See the surveys by Mitchell [11] and Arora [4] for further information. In contrast, the behavior of the optimization problems that seek to maximize some function on the points visited, subject to constraints on the length of the path used or the timespans the points are being visited [7, 5, 8], are not as well understood.

The main idea in the previous approximation algorithms for the orienteering problem [2, 6, 5] was to transform an approximation algorithm for the *rooted k-TSP problem* into an approximation algorithm for the orienteering problem. In particular, Blum et al. [6] formulated the notion of the *excess* for a path (which is defined to be the difference between the length of a path and the distance between the endpoints of the path) and then combined dynamic programming with the use of k-TSP to obtain an algorithm for orienteering in a metric space. These techniques were also implicitly used in the work of Arkin, Mitchell, and Narasimhan [2].

Our results. To obtain a polynomial time approximation scheme (PTAS) for the orienteering problem, we extend the concept of the excess of a path into the $\mathfrak{u}$-*excess* of a path, which is (loosely) the difference in lengths between π and the best approximation to π by a polygonal line having $\mathfrak{u}$ vertices; see Figure 1. (Therefore, the previous notion of excess is 2-excess in our notation.)

To this end, we revisit the rooted k-TSP problem in the plane and show that Mitchell's algorithm [10] computes an $(\varepsilon, \mathfrak{u})$-approximation for rooted k-TSP; that is, the algorithm outputs a rooted path of length $\leq \|\pi\| + \varepsilon \cdot \mathcal{E}_{\pi,\mathfrak{u}}$, where π is any path that starts from the root and visits k points, $\|\pi\|$ denotes the length of π, and $\mathcal{E}_{\pi,\mathfrak{u}}$ is the $\mathfrak{u}$-excess of π. Note that the quantity $\mathcal{E}_{\pi,\mathfrak{u}}$ might be smaller than $\|\pi\|$ by several orders of magnitude. Therefore, we show that Mitchell's algorithm provides a much tighter approximation for k-TSP than what was previously known. See section 3.

Armed with the new approximation algorithm for k-TSP, it is now possible to reduce the orienteering problem to an instance of k-TSP. The PTAS for orienteering is presented in section 5.

The rest of the paper is organized as follows. Section 2 defines the problem. Section 3 presents the new analysis of Mitchell's algorithm. Section 4 extends the new k-TSP algorithm into higher dimensions by combining Mitchell's technique and Arora's k-TSP algorithm. Section 5 gives the PTAS for the orienteering problem. We conclude in section 6.

2. Problem statement and definitions. Let $\pi = \langle p_1, p_2, \ldots, p_k \rangle$ be a path that visits k points of P, starting at p_1 and ending at p_k. The *length* of π is denoted by $\|\pi\| = \sum_{i=1}^{k-1} \|p_{i+1} - p_i\|$. More generally, for a collection S of segments, $\|S\|$ denotes the total length of segments in S. Let $1 = i_1 < \cdots < i_{\mathfrak{u}} = k$ be a sequence of $\mathfrak{u} \leq k$ integers. The path $\langle p_{i_1}, p_{i_2}, \ldots, p_{i_{\mathfrak{u}}} \rangle$ is a $\mathfrak{u}$-*skeleton* of π. The *optimal* $\mathfrak{u}$-*skeleton* of π is the $\mathfrak{u}$-skeleton of π with maximum total length, denoted by $\mathcal{S}^{\mathfrak{u}}_{\mathrm{opt}}(\pi)$. See Figure 1.

The $\mathfrak{u}$-*excess* of a path π is the difference between the length of π and its optimal

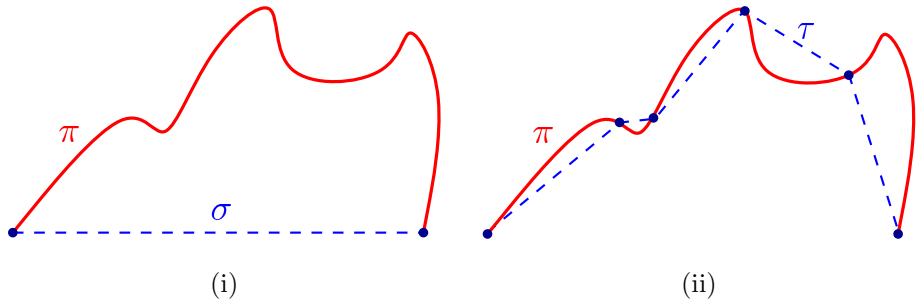

FIG. 1. (i) *The segment σ is the 2-skeleton of the path π. The 2-excess of π, namely, $\mathcal{E}_{\pi,2}$, is the difference between the length of π and the length of σ.* (ii) *The polygonal line τ forms a 6-skeleton of π. The 6-excess of π, namely, $\mathcal{E}_{\pi,6}$, is at most $\|\pi\|-\|\tau\|$.*

$\mathfrak{u}$-skeleton, that is, $\mathcal{E}_{\pi,\mathfrak{u}} = \|\pi\| - \left\|\mathcal{S}^{\mathfrak{u}}_{\text{opt}}(\pi)\right\|$. Note that the $\mathfrak{u}$-excess of π may be considerably smaller than the length of π.

Given a set P of n points and a starting point $r \in P$, the *rooted k-TSP problem* is to find a shortest path that visits k points of P starting at r. An $(\varepsilon, \mathfrak{u})$-*approximation* to the rooted k-TSP is a path ϕ that visits k points of P starting at r, such that the length of ϕ is no more than $\|\mathcal{T}\| + \varepsilon \cdot \mathcal{E}_{\mathcal{T},\mathfrak{u}}$, for any path $\mathcal{T}$ that visits k points of P starting at r.

DEFINITION 2.1 (the rooted orienteering problem). *Given a set P of n points, a budget $\mathcal{B}$, and a starting point $r \in P$, the* rooted orienteering problem *is to find a path ω_{opt} that visits as many points of P as possible, under the constraint that the length of ω_{opt} is at most $\mathcal{B}$. Let k_{opt} denote the number of points visited by ω_{opt}. A* $(1-\varepsilon)$-approximation *to the rooted orienteering problem is a path ω (starting at r) that visits at least $(1-\varepsilon)k_{\text{opt}}$ points of P, such that the length of ω is at most $\mathcal{B}$.*

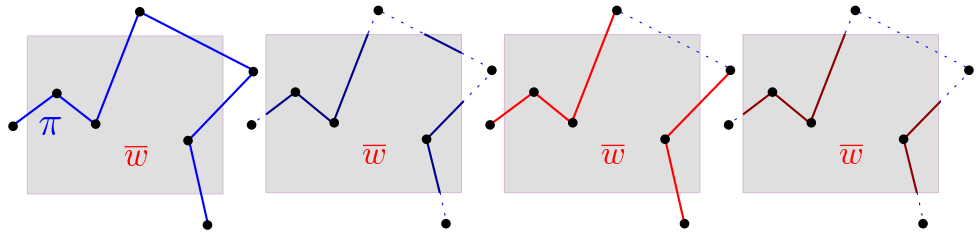
3. An $(\varepsilon, \mathfrak{u})$-approximation algorithm for k-TSP. In this section, we present an $(\varepsilon, \mathfrak{u})$-approximation algorithm for k-TSP. The algorithm is the k-TSP algorithm of Mitchell [10], and our contribution is the new tighter analysis of its performance (see section 3.3). In the following, we first review Mitchell's algorithm and then present our new improved analysis.

3.1. Preliminaries. In the following, m is a fixed constant. We assume, without loss of generality, that the points of P all have distinct x and y coordinates and that P is contained in an axis-parallel square $\mathcal{Q}$. Let π be a given path visiting k points of P.

DEFINITION 3.1. *A closed, axis-parallel rectangle $\overline{w}$ is a* window *if $\overline{w} \subseteq \mathcal{Q}$. The* extent *of a window $\overline{w}$ is the larger of the width and height of $\overline{w}$ and is denoted by $\Delta_{\overline{w}}$. Let $\pi(\overline{w})$ denote the subset of π consisting of the union of segments of π having at least one endpoint inside (or on the boundary of) $\overline{w}$. Given a collection S of segments, we slightly abuse notation and denote the set of segments of S clipped to $\overline{w}$ by $S \cap \overline{w}$. See Figure 2.*

A line ℓ is a cut *for π, with respect to $\overline{w}$, if ℓ is a horizontal or vertical line and ℓ intersects $\overline{w}$; ℓ is an m-*perfect cut *for π, with respect to $\overline{w}$, if ℓ intersects the segments of $\pi(\overline{w}) \cap \overline{w}$ at most m times.*

DEFINITION 3.2. *The combinatorial type of a window $\overline{w}$ with respect to π is the subset of P inside (or on the boundary of) $\overline{w}$ and a listing, for each of the four sides of $\overline{w}$, of the identities of the line segments of $\pi(\overline{w})$ that intersect it. (In particular, if a segment of π intersects $\overline{w}$, but both its endpoints are outside $\overline{w}$, then the segment is*



(i) π (ii) $\pi \cap \overline{w}$ (iii) $\pi(\overline{w})$ (iv) $\pi(\overline{w}) \cap \overline{w}$

FIG. 2. *The different ways of clipping a path π to a window $\overline{w}$.*

not considered in the combinatorial type of $\overline{w}$.) We say that $\overline{w}$ is a minimal window *if there is no window $\overline{w}'$ that is strictly contained in $\overline{w}$ with the same combinatorial type as $\overline{w}$.*

For a minimal window $\overline{w}$, if there is no m-perfect cut for π, with respect to $\overline{w}$, then it is m-dense. *Namely, any horizontal or vertical line that intersects $\overline{w}$ has more than m intersection points with $\pi(\overline{w}) \cap \overline{w}$.*

Given a window $\overline{w}$, Mitchell [10] described how to "shrink" $\overline{w}$ into a minimal window by "pinning" all four sides of $\overline{w}$. It is not hard to see that the number of all possible minimal windows is $O(n^4)$, since (intuitively) it has four degrees of freedom.

CLAIM 3.3. *If a window $\overline{w}$ is m-dense, then $\|\pi(\overline{w}) \cap \overline{w}\| \geq m \cdot \Delta_{\overline{w}}$.*

Proof. Assume, without loss of generality, that the width of $\overline{w}$ is greater than the height of $\overline{w}$, and the interval $[x_1, x_2]$ is the projection of $\overline{w}$ onto the x-axis. Let $f(\alpha)$ denote the number of segments of $\pi(\overline{w})$ within $\overline{w}$ that intersect the vertical line $x = \alpha$. By the density of $\overline{w}$, $f(x) > m$ for $x \in [x_1, x_2]$. The total length of the segments of $\pi(\overline{w}) \cap \overline{w}$ is lower bounded by the integral of $f(x)$ over $[x_1, x_2]$, which in turn is lower bounded by $m(x_2 - x_1) = m \cdot \Delta_{\overline{w}}$. ∎

3.2. Review of the *k*-TSP algorithm. The "new" $(\varepsilon, \mathfrak{u})$-approximation algorithm for k-TSP is the algorithm of Mitchell [10] for k-TSP, and we review it here only for the sake of completeness. We remind the reader that m is a fixed (constant) number.

A problem instance of **WindowTSP** consists of (i) a (minimal) window $\overline{w}$ that contains at least one point of P, with its boundaries determined by (up to) four points of P, (ii) an integer $h \geq 0$, indicating how many points interior to $\overline{w}$ should be visited, (iii) boundary information specifying at most m crossing segments (each determined by a pair of points of P, one interior to or on the boundary of $\overline{w}$, and another outside $\overline{w}$) for each side of the boundary of $\overline{w}$, and (iv) connectivity constraints, indicating which pairs of crossing segments are required to be connected within $\overline{w}$. The solution to the **WindowTSP** problem is a set of (hopefully short) paths inside window $\overline{w}$ such that (i) all of the boundary constraints are satisfied, (ii) all of the connectivity constraints within $\overline{w}$ are satisfied, and (iii) h points of P are visited by the paths inside $\overline{w}$. See Figure 3.

Clearly, the rooted k-TSP problem can be formulated as a **WindowTSP** instance consisting of a bounding box $\mathcal{Q}$ of P, a parameter k, empty boundary information, and connectivity constraints requiring that k points of P inside $\mathcal{Q}$ must be connected by a single path, with r as an endpoint of the path.

The recursive algorithm for **WindowTSP** works as follows. If the window $\overline{w}$ has at most m points of P in its interior, then the problem is solved by enumeration of

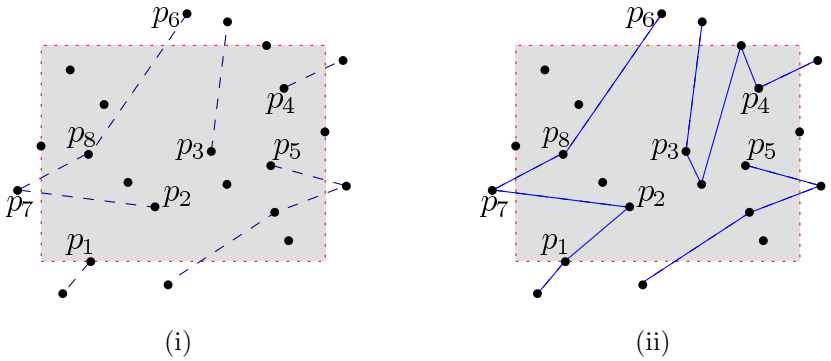


FIG. 3. (i) *An instance of the* **WindowTSP** *problem. The segments specify how the solution crosses the boundary of* $\overline{w}$. *The connectivity constraints are as follows:* p_1 *is required to connect to* p_2 *(possibly via other points within* $\overline{w}$*),* p_3 *is required to connect to* p_4 *(possibly via other points within* $\overline{w}$*), and* p_5 *is the starting point* r *of the path (namely, the degree of* p_5 *is* 1*). The multipaths are required to visit nine points in the window.* (ii) *A possible solution.*

all possible solutions. Otherwise, the algorithm tries all possible cuts for the current window recursively, enumerating over all the possible choices of valid boundary information along this cut and computing the cheapest option. If there is no m-perfect cut, then the algorithm performs a cut and reduces the intersection by introducing bridges; see Remark 1 below. For our analysis, we care only whether a cut used by the algorithm is an m-perfect cut or a more complicated cut.

When a cut divides a window into two smaller windows, we need to "shrink" those two windows into minimal windows. In particular, segments that just pass through a window are ignored during the shrinking. This is a small but important technicality. See Figure 4.

Remark 1. The algorithm of Mitchell [10] also introduces bridges (close to, or) on the boundary of the window $\overline{w}$, where a bridge is a vertical or horizontal segment. To simplify our exposition, we ignored those bridges in describing the algorithm. Of course, for a correct working implementation those bridges are necessary. See [10] for full details. See also Remark 2 below.

3.3. Analysis of the algorithm. The key observation in our analysis is that the approximation algorithm does not introduce any error when a cut is m-perfect. Thus, the error is introduced only when the algorithm works inside an m-dense window, but such windows have high "excess."

DEFINITION 3.4. *For a set* S *of segments, let* $I_x(S)$ *denote the projection of* S *onto the* x*-axis; namely,* $I_x(S)$ *is the set of all points* α *(on the* x*-axis), such that the vertical line* $x = \alpha$ *intersects the segments of* S. *Let* $\mathrm{len}_x(S)$ *denote the total length of* $I_x(S)$. *Note that* $I_x(S)$ *is a set of (disjoint) intervals on the real line, and* $\mathrm{len}_x(S)$ *is the total length of these intervals. We define* $I_y(S)$ *and* $\mathrm{len}_y(S)$ *in a similar fashion.*

DEFINITION 3.5. *For a window* $\overline{w}$ *and a path* π, *the* surplus *of* π *in* $\overline{w}$ *is*

$$\rho(\overline{w}, \pi) = \|\pi \cap \overline{w}\| - \sqrt{(\mathrm{len}_x(\pi \cap \overline{w}))^2 + (\mathrm{len}_y(\pi \cap \overline{w}))^2}.$$

It is easy to verify that the surplus is always nonnegative. See Figure 5.

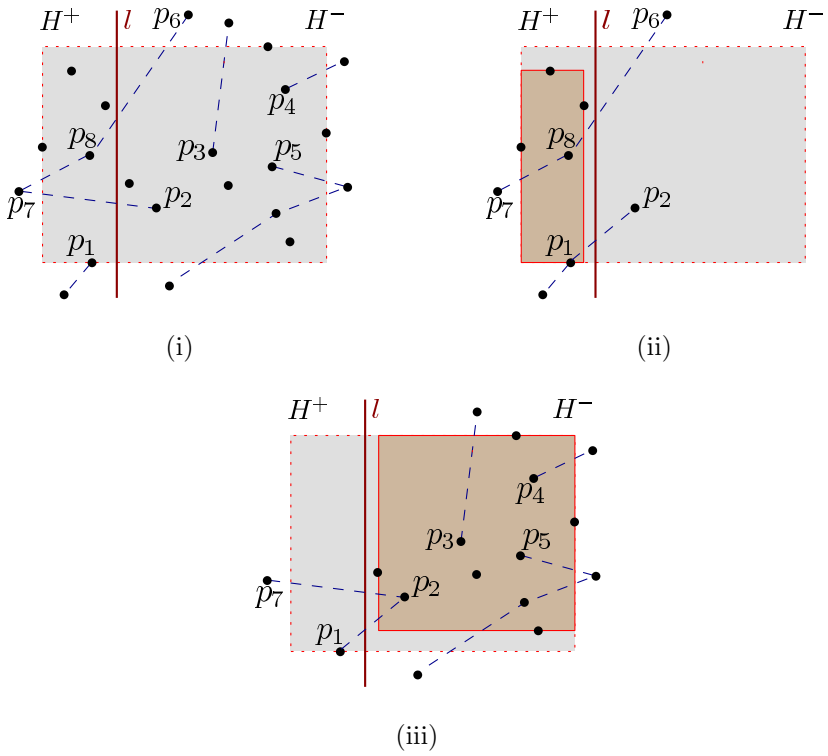

FIG. 4. *Performing a cut on the* **WindowTSP** *instance of Figure* 3. (i) *A cut l divides the window $\overline{w}$ into smaller windows $\overline{w} \cap H^+$ and $\overline{w} \cap H^-$.* (ii) *The minimal window for $\overline{w} \cap H^+$. The segments represent the crossing boundary information for the new window. In particular, the segment p_1p_2 is introduced when "guessing" the boundary information along the cut l before the recursive call. The other segments intersecting the boundary are inherited from the original instance.* (iii) *The minimal window for $\overline{w} \cap H^-$.*

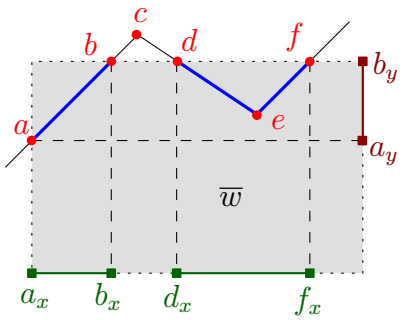

FIG. 5. *Illustrating the intersection of a polygonal line $\pi = \langle a, b, c, d, e, f \rangle$ with a window $\overline{w}$. The set $I_x(\pi \cap \overline{w})$ consists of the segments a_xb_x and d_xf_x; the set $I_y(\pi \cap \overline{w})$ consists of segment a_yb_y. The surplus of π in $\overline{w}$ is $\|a-b\| + \|d-e\| + \|e-f\| - \sqrt{(\|a_x - b_x\| + \|d_x - f_x\|)^2 + \|a_y - b_y\|^2}$.*

LEMMA 3.6. *If $X, Y, X_1, \ldots, X_n, Y_1, \ldots, Y_n$ are nonnegative real numbers such that*

$$\sum_{i=1}^{n} X_i \geq X \quad \text{and} \quad \sum_{i=1}^{n} Y_i \geq Y,$$

then $\sum_{i=1}^{n} \sqrt{X_i^2 + Y_i^2} \geq \sqrt{X^2 + Y^2}$.

Proof. This is an easy application of the triangle inequality. Indeed, let q_i be the point $(\sum_{j=1}^{i} X_j, \sum_{j=1}^{i} Y_j)$ in the plane for $1 \leq i \leq n$, and let $q_0 = (0,0)$. Consider the path $\pi = \langle q_0, q_1, \ldots, q_n \rangle$. Clearly, we have that

$$\|\pi\| = \sum_{i=1}^{n} \sqrt{X_i^2 + Y_i^2} = \sum_{i=1}^{n} \|q_i - q_{i-1}\| \geq \|q_n - q_0\|$$
$$= \sqrt{\left(\sum_{i=1}^{n} X_i\right)^2 + \left(\sum_{i=1}^{n} Y_i\right)^2} \geq \sqrt{X^2 + Y^2},$$

as required. □

LEMMA 3.7. *Let $\overline{\mathsf{D}}$ be a set of interior disjoint windows (inside $\mathcal{Q}$), and let π be a polygonal path inside $\mathcal{Q}$. We have that $\mathcal{E}_{\pi,2} \geq \sum_{\overline{w} \in \overline{\mathsf{D}}} \big(\|\pi \cap \overline{w}\| - \sqrt{2}\Delta_{\overline{w}} \big)$.*

Proof. Let Ψ be a decomposition of $\mathcal{Q}$ into interior disjoint axis-parallel rectangles such that Ψ contains all of the rectangles of $\overline{\mathsf{D}}$. Let $X = \operatorname{len}_x(\pi \cap \mathcal{Q})$ and $Y = \operatorname{len}_y(\pi \cap \mathcal{Q})$. For a window $\overline{w}$, let $X_{\overline{w}} = \operatorname{len}_x(\pi \cap \overline{w})$ and $Y_{\overline{w}} = \operatorname{len}_y(\pi \cap \overline{w})$. Clearly, $X \leq \sum_{\overline{w} \in \Psi} X_{\overline{w}}$ and $Y \leq \sum_{\overline{w} \in \Psi} Y_{\overline{w}}$, since $I_x(\pi) = \bigcup_{\overline{w} \in \Psi} I_x(\pi \cap \overline{w})$ and $I_y(\pi) = \bigcup_{\overline{w} \in \Psi} I_y(\pi \cap \overline{w})$. Let s and t be the two endpoints of π. We have that

$$\mathcal{E}_{\pi,2} = \|\pi\| - \|s - t\| = \|\pi\| - \sqrt{\operatorname{len}_x(st)^2 + \operatorname{len}_y(st)^2} \geq \|\pi\| - \sqrt{X^2 + Y^2},$$

since $\operatorname{len}_x(st) \leq X$ and $\operatorname{len}_y(st) \leq Y$. On the other hand, by Lemma 3.6, we get $\sqrt{X^2 + Y^2} \leq \sum_{\overline{w} \in \Psi} \sqrt{X_{\overline{w}}^2 + Y_{\overline{w}}^2}$, since $\sum_{\overline{w} \in \Psi} X_{\overline{w}} \geq X$ and $\sum_{\overline{w} \in \Psi} Y_{\overline{w}} \geq Y$. Therefore,

$$\mathcal{E}_{\pi,2} \geq \|\pi\| - \sqrt{X^2 + Y^2} \geq \|\pi\| - \sum_{\overline{w} \in \Psi} \sqrt{X_{\overline{w}}^2 + Y_{\overline{w}}^2} = \sum_{\overline{w} \in \Psi} \left(\|\pi \cap \overline{w}\| - \sqrt{X_{\overline{w}}^2 + Y_{\overline{w}}^2} \right)$$
$$= \sum_{\overline{w} \in \Psi} \rho(\overline{w}, \pi) = \sum_{\overline{w} \in \overline{\mathsf{D}}} \rho(\overline{w}, \pi) + \sum_{\overline{w} \in \Psi \setminus \overline{\mathsf{D}}} \rho(\overline{w}, \pi) \geq \sum_{\overline{w} \in \overline{\mathsf{D}}} \rho(\overline{w}, \pi),$$

because the surplus $\rho(\overline{w}, \pi)$ is always nonnegative. Now, since

$$\rho(\overline{w}, \pi) = \|\pi \cap \overline{w}\| - \sqrt{X_{\overline{w}}^2 + Y_{\overline{w}}^2} \geq \|\pi \cap \overline{w}\| - \sqrt{\Delta_{\overline{w}}^2 + \Delta_{\overline{w}}^2} = \|\pi \cap \overline{w}\| - \sqrt{2}\Delta_{\overline{w}},$$

we obtain $\mathcal{E}_{\pi,2} \geq \sum_{\overline{w} \in \overline{\mathsf{D}}} \rho(\overline{w}, \pi) \geq \sum_{\overline{w} \in \overline{\mathsf{D}}} \big(\|\pi \cap \overline{w}\| - \sqrt{2}\Delta_{\overline{w}} \big)$, as claimed. □

THEOREM 3.8. *Let $\pi = \langle p_1, p_2, \ldots, p_k \rangle$ be an arbitrary path that visits k points of P, and let $\mathfrak{u} \geq 2$ be an arbitrary fixed integer. One can compute, in $n^{O(\mathfrak{u})}$ time, a path that starts at p_1 and visits k points of P, with length at most $\|\pi\| + \mathcal{E}_{\pi,\mathfrak{u}}/\mathfrak{u}$.*

Proof. Set $m = \lceil 2\sqrt{2}\mathfrak{u} \rceil$, and use the algorithm presented above. The running time bound follows readily. Thus, we need only argue that the path computed is indeed within the claimed bound on the length.

Thus, consider the (conceptual) execution of the recursive algorithm over the path π, performing the recursive calls according to π. Specifically, let $\overline{w}$ be a *minimal* window that is visited by the recursive algorithm when applied to π. If an m-perfect cut (for π) exists with respect to $\overline{w}$, then we use it to cut the window $\overline{w}$ into two parts and proceed recursively on each side of the cut. If such an m-perfect cut does not exist for $\overline{w}$ (that is, $\overline{w}$ is m-dense), then we (conceptually) stop, and use the results returned by the recursive call on this window. We claim that for these specific choices, the recursive algorithm computes a path σ, such that $\|\sigma\|$ is as required. Since the recursive algorithm returns a path no longer than σ, this would imply the theorem.

Let $\overline{\mathsf{D}}$ be the set of m-dense windows (which by the algorithm execution are minimal windows) visited by the algorithm when applied to π. Let $\mathcal{S} = \mathcal{S}^{\mathfrak{u}}_{\mathrm{opt}}(\pi)$ be an optimal $\mathfrak{u}$-skeleton for π, and let $\pi_1, \ldots, \pi_{\mathfrak{u}-1}$ be the breakup of π into subpaths by the vertices of $\mathcal{S}$. By Lemma 3.7, we have that

$$\begin{aligned}\mathcal{E}_{\pi,\mathfrak{u}} &= \sum_{j=1}^{\mathfrak{u}-1} \mathcal{E}_{\pi_j,2} \geq \sum_{j=1}^{\mathfrak{u}-1} \sum_{\overline{w}\in\overline{\mathsf{D}}} \Big(\|\pi_j \cap \overline{w}\| - \sqrt{2}\Delta_{\overline{w}} \Big) = \sum_{\overline{w}\in\overline{\mathsf{D}}} \sum_{j=1}^{\mathfrak{u}-1} \Big(\|\pi_j \cap \overline{w}\| - \sqrt{2}\Delta_{\overline{w}} \Big) \\ &= \sum_{\overline{w}\in\overline{\mathsf{D}}} \Big(\|\pi \cap \overline{w}\| - \sqrt{2}(\mathfrak{u}-1)\Delta_{\overline{w}} \Big) \geq \sum_{\overline{w}\in\overline{\mathsf{D}}} \frac{\|\pi \cap \overline{w}\|}{2},\end{aligned}$$

since $\|\pi \cap \overline{w}\| \geq m\Delta_{\overline{w}}$, for each $\overline{w} \in \overline{\mathsf{D}}$ (by Claim 3.3), and $m = \lceil 2\sqrt{2}\mathfrak{u} \rceil \geq 2\sqrt{2}\mathfrak{u}$. Now, note that $\pi(\overline{w}) \cap \overline{w}$ is a subset of $\pi \cap \overline{w}$, and henceforth it holds that

$$\mathcal{E}_{\pi,\mathfrak{u}} \geq \sum_{\overline{w}\in\overline{\mathsf{D}}} \frac{\|\pi \cap \overline{w}\|}{2} \geq \sum_{\overline{w}\in\overline{\mathsf{D}}} \frac{\|\pi(\overline{w}) \cap \overline{w}\|}{2}. \tag{1}$$

For an m-dense window $\overline{w} \in \overline{\mathsf{D}}$, the path σ output by the algorithm (when applied to π) inside $\overline{w}$ is of length $\leq (1 + 1/m) \cdot \|\pi(\overline{w}) \cap \overline{w}\|$, as this is the performance guarantee provided by Mitchell's analysis [10]. Namely, the error introduced by the approximation inside $\overline{w}$ is bounded by $\|\pi(\overline{w}) \cap \overline{w}\| / m$. For windows (visited by the algorithm when applied to π) that are not m-dense, the path σ within them is identical to the path π. Thus, for the path σ, it follows from (1) that

$$\|\sigma\| - \|\pi\| \leq \sum_{\overline{w}\in\overline{\mathsf{D}}} \frac{\|\pi(\overline{w}) \cap \overline{w}\|}{m} = \frac{2}{m} \sum_{\overline{w}\in\overline{\mathsf{D}}} \frac{\|\pi(\overline{w}) \cap \overline{w}\|}{2} \leq \frac{2\mathcal{E}_{\pi,\mathfrak{u}}}{m} < \frac{\mathcal{E}_{\pi,\mathfrak{u}}}{\mathfrak{u}},$$

since $m \geq 2\sqrt{2}\mathfrak{u}$. ∎

It is possible to prove Lemma 3.7 and Theorem 3.8 directly, by arguing that the skeleton can be replaced by an alternative skeleton that is longer and is still shorter, by the excess in the dense windows, than an optimal path. (Since excess is a global property that is not directly defined for windows, the resulting argument is somewhat more complicated.) We provide the more technical proof above, since it brings to the forefront the notion of surplus. Note that the surplus is decomposition sensitive; as such, it might be much smaller than the excess. Therefore, the analysis of Theorem 3.8 is probably loose, as the bound on the error depends solely on the surplus in the dense windows.

Remark 2. As mentioned in Remark 1, we ignored the use of bridges in describing Mitchell's algorithm [10]. Our analysis implies that the use of those bridges is restricted only to dense windows, where all we need is the performance guarantees

already provided by Mitchell's analysis. In particular, for those dense windows, we can also use Arora's algorithm. This is the main insight we use in extending our algorithm to higher dimensions.

4. An $(\varepsilon, \mathfrak{u})$-approximation algorithm for k-TSP in $\mathbf{R}^d$. In this section, we present an $(\varepsilon, \mathfrak{u})$-approximation algorithm for k-TSP in higher dimensions, by combining Mitchell's methods together with Arora's k-TSP algorithm [3]. Throughout the section, we are concerned with $\mathbb{R}^d$, where $d > 2$ is a fixed constant.

Let $\mathcal{Q}$ be an axis-parallel d-dimensional hypercube that contains the point set P. In the following, m is a fixed constant, and π is a given path visiting k points of P. The following definitions are analogous to the ones in section 3.

DEFINITION 4.1. *A closed, axis-parallel d-dimensional box $\overline{w}$ is a* window *if $\overline{w} \subseteq \mathcal{Q}$. The* extent *of a window $\overline{w}$ is the largest side length of $\overline{w}$ and is denoted by $\Delta_{\overline{w}}$.*

A $(d-1)$-dimensional hyperplane ℓ is a cut *for π, with respect to $\overline{w}$, if ℓ is axis-parallel and ℓ intersects $\overline{w}$; ℓ is an m-*perfect cut *for π, with respect to $\overline{w}$, if ℓ intersects the segments of $\pi(\overline{w}) \cap \overline{w}$ at most m times.*

DEFINITION 4.2. *The combinatorial type of a window $\overline{w}$ with respect to π is the subset of P inside (or on the boundary of) $\overline{w}$ and a listing, for each facet of $\overline{w}$, of the identities of the line segments of $\pi(\overline{w})$ that intersect it. We say that $\overline{w}$ is a* minimal window *if there is no window $\overline{w}'$ that is strictly contained in $\overline{w}$ with the same combinatorial type as $\overline{w}$.*

*For a minimal window $\overline{w}$, if there is no m-perfect cut for π, with respect to $\overline{w}$, then it is m-*dense*. Namely, any axis-parallel $(d-1)$-dimensional hyperplane that intersects $\overline{w}$ has more than m intersection points with $\pi(\overline{w}) \cap \overline{w}$.*

The following claim is an immediate extension of Claim 3.3.

CLAIM 4.3. *If a window $\overline{w}$ is m-dense, then $\|\overline{w} \cap \pi\| \geq m \cdot \Delta_{\overline{w}}$.*

To bootstrap our algorithm, we need a $(1+\varepsilon)$-approximation algorithm for the **WindowTSP** problem in $\mathbb{R}^d$. To this end, note that the **WindowTSP** problem seeks a set of $O(md)$ paths (with prespecified endpoints) that collectively visits a prespecified number of points inside the given window; it is not hard to adapt Arora's technique to solve the **WindowTSP** problem in $n^{O(md)} \cdot O(m \log n)^{(m\sqrt{d})^{O(d)}}$ time, such that the solution has a total length $\leq (1 + 1/m)L(\overline{w})$, where $L(\overline{w})$ denotes the length of an optimal solution inside the specified window $\overline{w}$. (This problem can be solved even faster, but it has no impact on the overall performance of our algorithm.) The required adaption is straightforward, and we omit the tedious but easy details; see [3, 1]. We denote this subroutine by k**DenseAprxTSP**.

For an instance of the **WindowTSP** problem, the algorithm works as follows. If $\overline{w}$ has at most m points of P in its interior, then the subproblem is solved by brute force. Otherwise, the algorithm chooses the smaller value returned by the following two options.

(a) Use k**DenseAprxTSP** to solve this problem, providing a solution with total length at most $(1 + 1/m)L(\overline{w})$, where $L(\overline{w})$ denotes the length of an optimal solution inside $\overline{w}$.

(b) Solve the problem recursively, optimizing over all choices associated with an m-perfect cut of window $\overline{w}$. (As in the $\mathbb{R}^2$ case, before performing the recursive calls, we need to shrink the windows formed by the cut into minimal windows.)

  (i) There are $O(d \cdot n^2)$ choices for a cut. More specifically, there are d choices of (axial) directions, and we can always let the cut pass through either

a point of P or an intersection point between $\pi(\overline{w})$ and the boundary of $\overline{w}$. Since $\pi(\overline{w})$ is a subset of the set of $\binom{n}{2}$ possible segments (namely, all segments connecting a pair of points of P), it follows that there are $O(n^2)$ possible intersection points between $\pi(\overline{w})$ and the boundary of $\overline{w}$.

(ii) There are $O(k)$ choices of the number of points visited in new subproblems, subject to the requirement that the total number of points visited within the two subproblems is equal to the number specified in the given instance.

(iii) There are $O(n^{2m})$ choices of new boundary information on the cut. Specifically, we select $\leq m$ segments (each determined by a pair of points of P) that cross the cut. We require that the boundary information of the new subproblems be consistent with the boundary information of the given instance.

(iv) There are a constant number of choices (since m and d are fixed constants) of connectivity constraints for the two new subproblems determined by the cut, subject to the requirement that these constraints be consistent with the constraints of the given instance.

Let k**TSPAprxAlg** denote this recursive algorithm. One can easily use memoization to turn it into an efficient dynamic programming algorithm. There are $O\big(k \cdot n^{2d} \cdot (n^{2m})^{2d}\big) = O\big(k\, n^{(4m+2)d}\big)$ possible subproblems, since there are $O(k)$ choices for the number of points that should be visited within $\overline{w}$, $O(n^{2d})$ choices of $\overline{w}$, and $O(n^{2m})$ choices of crossing segments on each of the $2d$ facets of $\overline{w}$. (The number of possible connectivity constraints is a constant since m and d are fixed constants.)

Remark 3. Before analyzing this algorithm, observe that it can be viewed as the combination of Mitchell's method [10] with Arora's k-TSP algorithm [3]. Specifically, the algorithm's top structure follows Mitchell's method. However, conceptually, whenever the algorithm "encounters" a dense window, it uses k**DenseAprxTSP** (which is an easy extension of Arora's k-TSP algorithm).

To see why we had to modify Mitchell's algorithm, observe that the algorithm in section 3 cannot be used in higher dimensions directly, because part of Mitchell's k-TSP algorithm relies on a crucial property of m-guillotine subdivisions in the plane. Namely, it introduces (and accounts for the additional length of) bridges on the path to decrease the interaction of the path with the outside world when considering dense windows. It is not known how to extend this directly to higher dimensions. However, the need for bridges arises only when a window is dense. In a dense window (in higher dimensions) we can circumvent this issue altogether by using Arora's algorithm (namely k**DenseAprxTSP**). Similarly, using Arora's algorithm on its own does not suffice here, since it introduces errors (by deflecting paths through "portals") even in windows which are not dense.

Analysis. To analyze the algorithm, we extend the definition of surplus (see Definition 3.5) to higher dimensions in a natural way. The following lemma is the analogue of Lemma 3.7.

LEMMA 4.4. *Let $\overline{\mathsf{D}}$ be a set of interior disjoint windows (inside $\mathcal{Q}$), and let π be a polygonal path inside $\mathcal{Q}$. We have that $\mathcal{E}_{\pi,2} \geq \sum_{\overline{w} \in \overline{\mathsf{D}}} (\|\pi \cap \overline{w}\| - \sqrt{d}\Delta_{\overline{w}})$.*

The following theorem is similar to Theorem 3.8.

THEOREM 4.5. *Let $\pi = \langle p_1, p_2, \ldots, p_k \rangle$ be an arbitrary path that visits k points of P, and let $\mathfrak{u} \geq 2$ be an arbitrary fixed integer. One can compute, in $n^{O(\mathfrak{u}d\sqrt{d})} \cdot (\mathfrak{u}\sqrt{d}\log n)^{(\mathfrak{u}d)^{O(d)}}$ time, a path that starts at p_1 and visits k points of P, with length at most $\|\pi\| + \mathcal{E}_{\pi,\mathfrak{u}}/\mathfrak{u}$.*

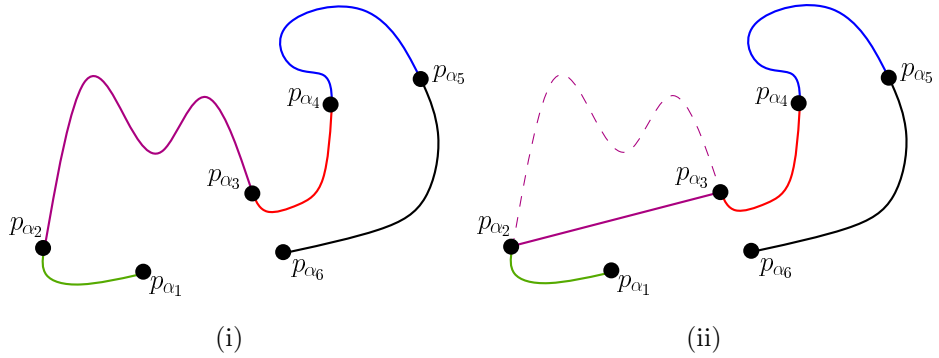

FIG. 6. (i) *The path* π^*_{opt} *is divided into* $\mathfrak{u} = 5$ *subpaths, each of which visits a (roughly) equal number of points.* (ii) *Since* $\mathcal{E}_2 \geq \sum_{i=1}^{\mathfrak{u}} \mathcal{E}_i/\mathfrak{u}$, *we obtain the desired path* π' *by connecting* p_{α_2} *to* p_{α_3}.

Proof. Set $m = \left\lceil 2\sqrt{d} \cdot \mathfrak{u} \right\rceil$. Observe that the algorithm k**TSPAprxAlg** uses the algorithm k**DenseAprxTSP** inside the dense windows, which provides the required approximation guarantee. The argument now follows the proof of Theorem 3.8 (almost) verbatim, and is thus omitted. □

Note that the algorithm in this section also works for the planar case (namely, $d = 2$).

5. A PTAS for orienteering. Next, we apply the algorithm of Theorem 4.5 to the rooted orienteering problem.

LEMMA 5.1. *Given a set* P *of* n *points in* $\mathbb{R}^d$, *a budget* $\mathcal{B}$, *and a root* $r = p_1$, *let* $\pi^*_{\mathrm{opt}} = \langle p_1, p_2, \ldots, p_k \rangle$ *be an optimal rooted orienteering path starting at* r *with budget* $\mathcal{B}$. *One can compute, in* $n^{O(d\sqrt{d}/\varepsilon)} \cdot (\sqrt{d} \log n/\varepsilon)^{(d/\varepsilon)^{O(d)}}$ *time, a path such that it starts at* r *and visits at least* $(1-\varepsilon)k$ *points of* P, *with length at most* $\mathcal{B}$.

Proof. Set $\mathfrak{u} = \lceil 2/\varepsilon \rceil$. Let $\pi^*_{\mathrm{opt}}(i,j) = \langle p_i, p_{i+1}, \ldots, p_j \rangle$ denote the portion of the path π^*_{opt} from p_i to p_j, and let $\mathcal{E}(i,j) = \left\|\pi^*_{\mathrm{opt}}(i,j)\right\| - \|p_i - p_j\|$ denote its 2-excess. Let $\alpha_i = \lceil (i-1)(k-1)/\mathfrak{u} \rceil + 1$. By the definition, we have $\alpha_1 = 1$ and $\alpha_{\mathfrak{u}+1} = k$, and furthermore, each subpath $\pi^*_{\mathrm{opt}}(\alpha_i, \alpha_{i+1})$ visits

$$(2) \quad \alpha_{i+1} - \alpha_i - 1 = \left(\left\lceil \frac{i(k-1)}{\mathfrak{u}} \right\rceil + 1 \right) - \left(\left\lceil \frac{(i-1)(k-1)}{\mathfrak{u}} \right\rceil + 1 \right) - 1 \leq \left\lfloor \frac{k-1}{\mathfrak{u}} \right\rfloor$$

points (excluding the endpoints p_{α_i} and $p_{\alpha_{i+1}}$).

Consider the subpaths $\pi^*_{\mathrm{opt}}(\alpha_1, \alpha_2), \ldots, \pi^*_{\mathrm{opt}}(\alpha_{\mathfrak{u}}, \alpha_{\mathfrak{u}+1})$ of π^*_{opt} and their 2-excesses $\mathcal{E}_1 = \mathcal{E}(\alpha_1, \alpha_2), \ldots, \mathcal{E}_{\mathfrak{u}} = \mathcal{E}(\alpha_{\mathfrak{u}}, \alpha_{\mathfrak{u}+1})$, respectively. Clearly, there exists an index ν, $1 \leq \nu \leq \mathfrak{u}$, such that $\mathcal{E}_\nu \geq (\sum_{i=1}^{\mathfrak{u}} \mathcal{E}_i)/\mathfrak{u}$.

By connecting the vertex p_{α_ν} directly to the vertex $p_{\alpha_{\nu+1}}$ in π^*_{opt}, we obtain a new path $\pi' = \langle p_1, p_2, \ldots, p_{\alpha_\nu}, p_{\alpha_{\nu+1}}, p_{\alpha_{\nu+1}+1}, \ldots, p_k \rangle$. Observe that $\|\pi'\| = \left\|\pi^*_{\mathrm{opt}}\right\| - \mathcal{E}_\nu$, and by (2), π' visits at least $k - (\alpha_{\nu+1} - \alpha_\nu - 1) \geq k - \lfloor (k-1)/\mathfrak{u} \rfloor \geq (1 - 1/\mathfrak{u})k$ points of P. See Figure 6.

Consider the $(\mathfrak{u}+1)$-skeleton $\mathcal{S}' = \langle p_{\alpha_1}, p_{\alpha_2}, \ldots, p_{\alpha_{\mathfrak{u}+1}} \rangle$ of π'. By the definition of $\mathcal{E}_i$, we have that $\|\mathcal{S}'\| = \left\|\pi^*_{\mathrm{opt}}\right\| - \sum_{i=1}^{\mathfrak{u}} \mathcal{E}_i$. Therefore, by the definition of $\mathcal{E}_{\pi',\mathfrak{u}+1}$, we have that

$$\mathcal{E}_{\pi',\mathfrak{u}+1} \leq \|\pi'\| - \|\mathcal{S}'\| = \left(\left\|\pi^*_{\mathrm{opt}}\right\| - \mathcal{E}_\nu \right) - \left(\left\|\pi^*_{\mathrm{opt}}\right\| - \sum_{i=1}^{\mathfrak{u}} \mathcal{E}_i \right) = \sum_{i=1}^{\mathfrak{u}} \mathcal{E}_i - \mathcal{E}_\nu.$$

By applying Theorem 4.5 to the path π', one can compute a path ξ that visits $(1-1/\mathfrak{u})k \geq (1-\varepsilon)k$ points of P, of length

$$\|\xi\| \leq \|\pi'\| + \frac{\mathcal{E}_{\pi',\mathfrak{u}+1}}{\mathfrak{u}+1} \leq \left(\left\|\pi^*_{\mathrm{opt}}\right\| - \mathcal{E}_\nu\right) + \frac{1}{\mathfrak{u}+1}\left(\sum_{i=1}^{\mathfrak{u}} \mathcal{E}_i - \mathcal{E}_\nu\right)$$
$$= \left\|\pi^*_{\mathrm{opt}}\right\| + \frac{1}{\mathfrak{u}+1}\left(\sum_{i=1}^{\mathfrak{u}} \mathcal{E}_i - (\mathfrak{u}+2)\mathcal{E}_\nu\right) \leq \left\|\pi^*_{\mathrm{opt}}\right\| \leq \mathcal{B},$$

since $\sum_{i=1}^{\mathfrak{u}} \mathcal{E}_i - (\mathfrak{u}+2)\mathcal{E}_\nu \leq 0$, implied by $\mathcal{E}_\nu \geq (\sum_{i=1}^{\mathfrak{u}} \mathcal{E}_i)/\mathfrak{u}$. □

Of course, the value of k is not known in advance. Therefore, the algorithm tries all possible values of k from 1 to n and returns the maximum value such that k points of P can be visited within the budget $\mathcal{B}$.

THEOREM 5.2. *Given a set P of n points in $\mathbb{R}^d$, a budget $\mathcal{B}$, and a root r, let k_{opt} be the number of points of P visited by an optimal orienteering path starting at r with budget $\mathcal{B}$. One can compute, in $n^{O(d\sqrt{d}/\varepsilon)} \cdot (\sqrt{d}\log n/\varepsilon)^{(d/\varepsilon)^{O(d)}}$ time, a path that starts at r and visits at least $(1-\varepsilon)k_{\mathrm{opt}}$ points of P, with length at most $\mathcal{B}$.*

6. Conclusions. In this paper, we defined the notion of $(\varepsilon, \mathfrak{u})$-approximation to k-TSP, and showed that Mitchell's k-TSP algorithm [10] actually works as an $(\varepsilon, \mathfrak{u})$-approximation algorithm for the k-TSP problem in the plane. We used it to develop a $(1-\varepsilon)$-approximation algorithm for the orienteering problem. The analysis easily extends to handling the case where both the starting and ending vertices of the orienteering problem are specified. In particular, the algorithm can approximate the best orienteering cycle rooted at a point r.

Our algorithm sheds a light on the power of Mitchell's approach [10], which has the advantage that it introduces errors only when the underlying path is "dense." This is in contrast to Arora's technique [3], which inherently introduces error in the approximation generated.

In the new analysis of the k-TSP algorithm the notion of surplus emerges naturally. We expect it to be much smaller than the excess in a lot of cases, and it might be of independent interest and useful in analyzing other algorithms.

There are numerous problems for further research, including the following:

- Can the running time be significantly improved?
- Can one extend the algorithms presented here to the problem of visiting points with time window constraints [7, 5, 8], where one has to visit a point inside a prespecified time window? This problem seems to be more challenging. Currently, even a constant-factor approximation algorithm is not known for the simple case of visiting points on the line.

Acknowledgment. The authors would like to thank the anonymous referees for their useful comments.

LOWER BOUND FOR THE ONLINE BIN PACKING PROBLEM WITH RESTRICTED REPACKING*

JÁNOS BALOGH†, JÓZSEF BÉKÉSI†, GÁBOR GALAMBOS†, AND GERHARD REINELT‡

Abstract. In 1996 Ivkovič and Lloyd [*A fundamental restriction on fully dynamic maintenance of bin packing*, Inform. Process. Lett., 59 (1996), pp. 229–232] gave the lower bound $\frac{4}{3}$ on the asymptotic worst-case ratio for so-called fully dynamic bin packing algorithms, where the number of repackable items in each step is restricted by a constant. In this paper we improve this result to about 1.3871. We present our proof for a semionline case of the classical bin packing, but it works for fully dynamic bin packing as well. We prove the lower bound by analyzing and solving a specific optimization problem. The bound can be expressed exactly using the Lambert W function.

Key words. bin packing, semionline algorithm, worst-case behavior, lower bound

1. Introduction.

The classical one-dimensional bin packing problem is among the most frequently studied combinatorial optimization problems. In its traditional definition a list $L = \{x_1, x_2, \ldots, x_n\}$ of elements (also called items) with sizes in the interval $(0, 1]$ and an infinite list of unit capacity bins are given. Each element x_i from the list L has to be assigned to a unique bin such that the sum of the sizes of the elements in a bin does not exceed the bin capacity. The size of an element will also be denoted by x_i. The *bin packing problem* consists of packing the items into the bins in such a way that as few bins as possible are used.

It is well known that finding an optimal packing is *NP-hard* [8]. Consequently, a large number of papers have been published which look for polynomial time algorithms that find feasible solutions with an acceptable approximation quality.

For measuring the efficiency of algorithms there are two general methods: the investigation of the worst-case behavior or—assuming some probability distribution of the elements—a probabilistic analysis. In this paper we will concentrate on the asymptotic worst-case ratio of an algorithm. For a given list L, denote by $A(L)$ and $OPT(L)$ the number of bins used by algorithm A and the number of bins used in an optimal packing, respectively. Then the *asymptotic worst-case ratio (AWR)* of algorithm A is

$$R_A := \limsup_{k\to\infty} \left\{ \max_L \left\{ \frac{A(L)}{k} \,\middle|\, OPT(L) = k \right\} \right\}.$$

If an algorithm has an AWR of R_A, we also say that it is R_A*-competitive*.

In recent decades many different types of algorithms have been proposed and also several variants of the classical problem have been introduced and studied [2]. Since the terminology used for classifying algorithms or problems is not unique, we start the paper with a proposal for a new classification based on a different view of the problem. To this end, we distinguish two contributors: the *scheduler*, who provides information on the problem data, and the *loader*, who packs the items. The actual problem then depends on how the scheduler gives the data and which strategies the loader uses for packing.

We suppose that the scheduler reveals information about the items at subsequent discrete time steps. The information consists of messages that certain elements (with respective sizes) arrive and/or that certain elements can be deleted. The total number of such time steps is at most n because information about several items can be given in the same step. If the element x_i appears in step j to be added to the list, then we say that its arrival time a_i is j. In some step k, the scheduler may also inform about the fact that the item x_i can be deleted. We say that the deletion time d_i of x_i is k. From this time the item may be deleted from the bin into which it was packed earlier. Of course, $a_i < d_i$, for $1 \leq i \leq n$. By setting $d_i = \infty$ we indicate that no deletion time for item x_i has been given.

At every time step the loader decides on its actions for packing the items. If some elements are packed and some others are deleted, we assume that first the deletion operations are performed.

In short, the scheduler decides on how the problem data is given, and the loader finds a feasible packing of all items depending on arrival and deletion times. Special strategies now lead to different variants of bin packing.

If $a_i = 1$ and $d_i = \infty$ for every i, $1 \leq i \leq n$, then the loader immediately receives complete knowledge about the list. In this case the scheduler produces an *offline problem* and the loader applies an *offline algorithm*.

If $a_i = i$ and $d_i = \infty$ and the loader packs the items one by one in each step without knowing anything about subsequent elements (neither the sizes nor the number of the elements), and the packed items may not be repacked anymore during the algorithm, then we speak about an *online problem* and an *online algorithm*.

In the case of *semionline (SOL) algorithms* the scheduler specifies the problem online as above, but the loader is allowed to apply at least one of the following operations: a repacking of some items, a lookahead into the next several elements, or some kind of preordering. SOL algorithms allowing only a restricted number of elements to be repacked in each step are called *c-repacking SOL algorithms*.

If the scheduler also allows the deletion of elements, then we speak about a *dynamic bin packing problem (DBP)*, and if the loader exploits this additional information for deleting items then his algorithm is a *dynamic bin-packing algorithm*. In this case $A(L)$ is considered as the maximum number of used bins during the packing. An offline DBP basically would be a special type of scheduling problem. Therefore, in the context of bin packing, only *online and SOL dynamic problems* are investigated.

If, in the SOL case, only repacking is allowed for the loader, and the scheduler may specify some elements to be deleted, then Ivkovič and Lloyd in [12] use the terms *fully dynamic bin packing problem (FDBP)* and *fully dynamic bin packing algorithm*. The c-repacking FDBP can be defined similarly to the definition of c-repacking SOL problems.

For offline bin packing algorithms the best results were achieved in [5] and [13], where the authors proved that for any $\varepsilon > 0$, there are algorithms which can solve

the bin packing problem in linear time, while their AWR is $1+\varepsilon$. Recently, the best online algorithm was given by Seiden in [15] and its AWR is 1.58889. The best-known lower bound 1.5401 is due to van Vliet [16].

SOL algorithms were investigated in [9], [10], and [6]. The first and the second references use different types of lookaheads, and the last one allows repacking. Gambosi, Postiglione, and Talamo [7] also analyzed certain SOL algorithms. In their algorithms repacking was allowed in a special way: those elements which were "large enough" were repacked one by one, while the "small" elements were moved together in a bundle between the bins. In this sense these algorithms can repack even $O(n)$ elements in one step. They analyzed two algorithms. The faster one has linear time and is $\frac{3}{2}$-competitive, and the other one runs in $O(n \log n)$ time and is $\frac{4}{3}$-competitive. Recently, except for trivial results, no good lower bound has been found for the efficiency of SOL algorithms.

Various dynamic approximation algorithms were investigated in [3].

Ivkovič and Lloyd constructed an approximation algorithm to solve the FDBP (see [12]). Similar to the technique used in [7], they also repacked the small elements using a "bundle technique." The competitive ratio of their algorithm is $\frac{5}{4}$ and requires $\Theta(\log n)$ time per step; i.e., its running time is $\Theta(n \log n)$. Investigating the lower bounds, they proved that there is no FDBP algorithm with deletions and where only a constant number of elements may be repacked with a better competitive ratio than $\frac{4}{3}$ [11] (i.e., for the c-repacking FDBP for any c). Using a similar construction in the proof, we can apply this bound to SOL algorithms as well. This fact was also mentioned by Csirik and Woeginger in [4].

In this paper we improve the lower bound to 1.3871 for the c-repacking SOL algorithms, but it follows from the construction that this lower bound is also valid for c-repacking fully dynamic bin packing algorithms. This last fact is coming from the following observation. While we try to construct lower bounds either for the c-repacking SOL problem or the c-repacking FDBP, we realize that the two constructions differ slightly from each other: to allow some deletions will not spoil the c-repacking SOL lower-bound construction for the c-repacking FDBP case.

During our analysis we will use different instruments: LP techniques will be combined with results from linear algebra, and finally we will solve a nonlinear optimization problem.

2. Construction of the linear program. For $k \geq 1$, $n \geq 1$, let $x_1, x_2, \ldots, x_k$ $\left(\frac{1}{2} \leq x_1 < x_2 < \cdots < x_k < 1\right)$ be fixed real numbers and $c \geq 1$ be an arbitrary integer. Define $y_i = 1 - x_i \, (i = 1, \ldots, k)$ and $y_{k+1} = 0$. Furthermore, let $\varepsilon < \min_{j=1,\ldots,k} \{y_j - y_{j+1}\}$ be an arbitrary positive number and $\varepsilon_j := \frac{\varepsilon}{\lceil \frac{n}{2y_j} \rceil}$.

Denote the first list by L_0. Define L_0 as a list of N items of size a, where $a < \frac{\varepsilon_k}{\lceil \frac{n}{y_k} \rceil c}$ and $N := \lfloor \frac{\frac{n}{2} - \varepsilon}{a} \rfloor$. We can see that L_0 contains very small elements with equal, suitably chosen size. The cumulative size of the small items converges to $\frac{n}{2}$ from below if $n \to \infty$. Denote by L_i $(1 \leq i \leq k, k \geq 2)$ the lists containing big elements. Define L_i as a list of $\lceil \frac{n}{2y_i} \rceil$ items of size $x_i + \varepsilon_i$. This means that the sizes of the elements are equal in list L_i. Suppose we need to pack the elements of the lists $L_0, L_1, \ldots, L_k$ with an SOL algorithm which can repack only a constant number of elements. We call these kinds of algorithms c-repacking algorithms. We analyze the behavior of an arbitrary c-repacking algorithm for the lists L_0 and $L_0 L_i$ $(1 \leq i \leq k)$. In our analysis $size(B)$ denotes the total size of items in bin B. We present the lower bound as a solution of a linear programming problem.

LEMMA 1.

$$\limsup_{n\to\infty}\frac{A(L_0)}{OPT(L_0)} \geq 1+\sum_{j=1}^{k}2z_j\left(\frac{1}{y_j}-1\right).$$

Proof. Consider an arbitrary c-repacking algorithm A that has to pack list L_0 first. It is clear that the above-defined a is a very small number, and the total size of the repackable items in $\lceil\frac{n}{2y_j}\rceil$ $(j=1,\ldots,k)$ steps is less than ε_k, which is the smallest among $\varepsilon_1,\ldots,\varepsilon_k$. We want to give a lower bound on $A(L_0)$. Denote by z_in the cumulative size of the items that have been packed in y_i-type bins $(i=1,\ldots,k)$. Bin B is called a y_i-type bin if $size(B)\in(y_{i+1},y_i]$. It is easy to see that the total number of y_i-type bins is at least $\frac{z_in}{y_i}$. The cumulative size of the items that have not been packed in any y_i-type bin is $Na-n\sum_{j=1}^{k}z_j$. So we get that

$$A(L_0)\geq\sum_{j=1}^{k}\frac{z_jn}{y_j}+Na-n\sum_{j=1}^{k}z_j=Na+n\sum_{j=1}^{k}z_j\left(\frac{1}{y_j}-1\right).$$

Because of the definition of N we have $Na\geq\frac{n}{2}-\varepsilon-a$. This means that

$$A(L_0)\geq n\left(\frac{1}{2}+\sum_{j=1}^{k}z_j\left(\frac{1}{y_j}-1\right)\right)-\varepsilon-a. \tag{1}$$

In the following we investigate the behavior of the optimal algorithm on L_0. In the optimal packing each bin B is loaded such that $size(B)>1-a$. So we get

$$OPT(L_0)\leq\frac{Na}{1-a}+1\leq\frac{\frac{n}{2}-\varepsilon}{1-a}+1\leq\frac{\frac{n}{2}}{1-a}+1. \tag{2}$$

From (1) and (2) it follows that

$$\limsup_{n\to\infty}\frac{A(L_0)}{OPT(L_0)}\geq 1+\sum_{j=1}^{k}2z_j\left(\frac{1}{y_j}-1\right). \tag{3}$$ □

LEMMA 2. *For $i=1,\ldots,k$,*

$$\limsup_{n\to\infty}\frac{A(L_0L_i)}{OPT(L_0L_i)}\geq 1+y_i+2y_i\left(\sum_{j=1}^{i-1}z_j\left(\frac{1}{y_j}-1\right)-\sum_{j=i}^{k}z_j\right).$$

Proof. Consider now the packing of the concatenated list L_0L_i $(1\leq i\leq k)$ for fixed i. Let B be a bin which contains an element from L_i. Because the size of the big item is $x_i+\varepsilon_i$, the total size of the small elements in the bin is at most $y_i-\varepsilon_i$. This can also happen in such a way that, after L_0 has been packed, the bin contains more items, but during the processing of L_i, some of them have been repacked to other bins. Since the list L_i has exactly $\lceil\frac{n}{2y_i}\rceil$ elements, at most $c\lceil\frac{n}{2y_i}\rceil$ elements could have been repacked. The size of each small item is a, so from the definition of a and ε_i we get that A can repack small items with at most ε_i cumulative size. So we can say that after packing L_0 $size(B)\leq y_i$ must hold for B. From this it follows that the cumulative size of the small items packed together with an item from L_i is $\sum_{j=i}^{k}z_jn$.

Other small items from L_0 can be packed in y_j-type bins, where $j = 1, \dots, i-1$. The total size of the remaining elements of L_0 is $Na - n\sum_{j=1}^{k} z_j$. So we can estimate the number of bins used by A in the following way:

$$A(L_0L_i) \geq \frac{n}{2y_i} + n\sum_{j=1}^{i-1}\frac{z_j}{y_j} + Na - n\sum_{j=1}^{k} z_j \quad (i = 1, \dots, k). \tag{4}$$

For the optimal packing of L_0L_i $(1 \leq i \leq k)$ we get that

$$OPT(L_0L_i) \leq \left\lceil \frac{n}{2y_i} \right\rceil + S_i \leq \frac{n}{2y_i} + S_i + 1, \tag{5}$$

where S_i is the total number of bins which contain only items from L_0 in an optimal packing. A bin containing an L_i-element will be denoted by B_i. We obtain for the cumulative size $small(B_i)$ of the small elements in B_i that

$$small(B_i) \geq \left\lceil \frac{n}{2y_i} \right\rceil (y_i - \varepsilon_i - a) \geq \frac{n}{2} - \left\lceil \frac{n}{2y_i} \right\rceil \varepsilon_i - \left\lceil \frac{n}{2y_i} \right\rceil a$$

$$\geq Na - \left\lceil \frac{n}{2y_i} \right\rceil a \geq Na - \varepsilon,$$

because $a < \frac{\varepsilon}{\left\lceil \frac{n}{2y_i} \right\rceil}$. So

$$S_i \leq 1. \tag{6}$$

From (5) and (6)

$$OPT(L_0L_i) \leq \frac{n}{2y_i} + 2. \tag{7}$$

Combining (4) and (7) we get that

$$\limsup_{n\to\infty} \frac{A(L_0L_i)}{OPT(L_0L_i)} \geq 1 + y_i + 2y_i \left(\sum_{j=1}^{i-1} z_j \left(\frac{1}{y_j} - 1 \right) - \sum_{j=i}^{k} z_j \right) \tag{8}$$

$$(i = 1, \dots, k). \qquad \square$$

THEOREM 3. *The solution of the following linear programming problem is a lower bound for any SOL c-repacking algorithm:*

$$\min b$$

$$b \geq 1 + y_i + 2y_i \left(\sum_{j=1}^{i-1} z_j \left(\frac{1}{y_j} - 1 \right) - \sum_{j=i}^{k} z_j \right) \quad (i = 1, \dots, k),$$

$$b \geq 1 + \sum_{j=1}^{k} 2z_j \left(\frac{1}{y_j} - 1 \right), \tag{9}$$

$$z_i \geq 0 \ (i = 1, \dots, k),$$

$$\sum_{j=1}^{k} z_j < \frac{1}{2}.$$

Proof. The definition of z_j $(j = 1, \ldots, k)$ obviously implies that $\sum_{j=1}^{k} z_j < \frac{1}{2}$. The statement of the theorem then follows from Lemmas 1 and 2. □

3. Solution of the linear program. To simplify our model we introduce a new variable z, which is the sum of all z_j's, i.e., $z = \sum_{j=1}^{k} z_j$. Using this substitution and some reordering, we can rewrite (9) in the following form:

$$\begin{aligned} &\min\ b \\ -2y_i z + 2y_i \sum_{j=1}^{i-1} \frac{z_j}{y_j} - b &\le -(1+y_i) \quad (i = 1, \ldots, k), \\ -2z + 2\sum_{j=1}^{k} \frac{z_j}{y_j} - b &\le -1, \\ -z + \sum_{j=1}^{k} z_j &= 0, \\ z_i &\ge 0 \ \ (i = 1, \ldots, k), \\ z &< \frac{1}{2}. \end{aligned} \tag{10}$$

Instead of (10) we first solve a linear system of equations related to our problem. The number of equations is $k + 2$. The variables of the system are $z, z_1, \ldots, z_k, b$, while $y_1, \ldots, y_k$ are some fixed parameters, satisfying the conditions of Theorem 3.

$$\begin{aligned} -2y_i z + 2y_i \sum_{j=1}^{i-1} \frac{z_j}{y_j} - b &= -(1+y_i) \quad (i = 1, \ldots, k), \\ -2z + 2\sum_{j=1}^{k} \frac{z_j}{y_j} - b &= -1, \\ -z + \sum_{j=1}^{k} z_j &= 0. \end{aligned} \tag{11}$$

LEMMA 4. *The system* (11) *has a unique solution.*

Proof. Let M be the matrix of (11). Then

$$M = \begin{bmatrix} -2y_1 & 0 & \ldots & 0 & 0 & -1 \\ -2y_2 & 2\frac{y_2}{y_1} & \ldots & 0 & 0 & -1 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ -2y_k & 2\frac{y_k}{y_1} & \ldots & 2\frac{y_k}{y_{k-1}} & 0 & -1 \\ -2 & \frac{2}{y_1} & \ldots & \frac{2}{y_{k-1}} & \frac{2}{y_k} & -1 \\ -1 & 1 & \ldots & 1 & 1 & 0 \end{bmatrix}. \tag{12}$$

Denote by $\det(M)$ the determinant of M. We prove that $\det(M) < 0$, and so from Cramer's rule the statement of the lemma follows. Let us expand $\det(M)$ using the last column of M. So we obtain

$$\det(M) = \sum_{i=1}^{k+1} -1\,(-1)^{k+2+i} \det(M_i) = \sum_{i=1}^{k+1} (-1)^{k+1+i} \det(M_i), \tag{13}$$

where M_i is a $(k+1) \times (k+1)$ matrix, which is obtained from M by deleting its last column and ith row. Expand $\det(M_i)$ by its last row. So

$$\det(M_i) = (-1)(-1)^{k+2} \det(M_{i1}) + \sum_{j=2}^{k+1} (-1)^{k+1+j} \det(M_{ij}), \tag{14}$$

where M_{ij} is a $k \times k$ matrix, which is obtained from M_i by deleting its last row and jth column. Now we investigate how M_{ij} looks:

$$M_{ij} = \begin{bmatrix} -2y_1 & 0 & \dots & 0 & 0 & \dots & 0 & 0 \\ -2y_2 & 2\frac{y_2}{y_1} & \dots & 0 & 0 & \dots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \vdots \\ -2y_{i-1} & 2\frac{y_{i-1}}{y_1} & \dots & 2\frac{y_{i-1}}{y_{j-2}} & 2\frac{y_{i-1}}{y_j} & \dots & 0 & 0 \\ -2y_{i+1} & 2\frac{y_{i+1}}{y_1} & \dots & 2\frac{y_{i+1}}{y_{j-2}} & 2\frac{y_{i+1}}{y_j} & \ddots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \ddots & \vdots \\ -2y_k & 2\frac{y_k}{y_1} & \dots & 2\frac{y_k}{y_{j-2}} & 2\frac{y_k}{y_j} & \dots & 2\frac{y_k}{y_{k-1}} & 0 \\ -2 & \frac{2}{y_1} & \dots & \frac{2}{y_{j-2}} & \frac{2}{y_j} & \dots & \frac{2}{y_{k-1}} & \frac{2}{y_k} \end{bmatrix}.$$

Case A. Suppose that $j \neq i$ and $j \neq i+1$ and consider only the ith and $(i+1)$th columns of M_{ij}. The two columns are the following:

$$\begin{bmatrix} 0 & 0 \\ \vdots & \vdots \\ 0 & 0 \\ 2\frac{y_{i+1}}{y_{i-1}} & 2\frac{y_{i+1}}{y_i} \\ \vdots & \vdots \\ 2\frac{y_k}{y_{i-1}} & 2\frac{y_k}{y_i} \\ \frac{2}{y_{i-1}} & \frac{2}{y_i} \end{bmatrix}.$$

It is easy to see that these columns are not independent, so we obtain that $\det(M_{ij}) = 0$ if $j \neq i$ and $j \neq i+1$.

Case B. If $j = i$, then M_{ii} is a lower triangular matrix of the form

$$M_{ii} = \begin{bmatrix} -2y_1 & 0 & \dots & 0 & 0 & \dots & 0 & 0 \\ -2y_2 & 2\frac{y_2}{y_1} & \dots & 0 & 0 & \dots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \vdots \\ -2y_{i-1} & 2\frac{y_{i-1}}{y_1} & \dots & 2\frac{y_{i-1}}{y_{i-2}} & 0 & \dots & 0 & 0 \\ -2y_{i+1} & 2\frac{y_{i+1}}{y_1} & \dots & 2\frac{y_{i+1}}{y_{i-2}} & 2\frac{y_{i+1}}{y_i} & \ddots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \ddots & \vdots \\ -2y_k & 2\frac{y_k}{y_1} & \dots & 2\frac{y_k}{y_{i-2}} & 2\frac{y_k}{y_i} & \dots & 2\frac{y_k}{y_{k-1}} & 0 \\ -2 & \frac{2}{y_1} & \dots & \frac{2}{y_{i-2}} & \frac{2}{y_i} & \dots & \frac{2}{y_{k-1}} & \frac{2}{y_k} \end{bmatrix}.$$

From this we get that $\det(M_{11}) = 2^k \frac{1}{y_1}$, $\det(M_{(k+1)(k+1)}) = -2^k y_k$, and that for $2 \le i \le k$, $\det(M_{ii}) = -2^k \frac{y_{i-1}}{y_i}$.

Case C. Similarly, if $j = i + 1$, then $M_{i(i+1)}$ is also a lower triangular matrix:

$$M_{i(i+1)} = \begin{bmatrix} -2y_1 & 0 & \dots & 0 & 0 & \dots & 0 & 0 \\ -2y_2 & 2\frac{y_2}{y_1} & \dots & 0 & 0 & \dots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \vdots \\ -2y_{i-1} & 2\frac{y_{i-1}}{y_1} & \dots & 2\frac{y_{i-1}}{y_{i-2}} & 0 & \dots & 0 & 0 \\ -2y_{i+1} & 2\frac{y_{i+1}}{y_1} & \dots & 2\frac{y_{i+1}}{y_{i-2}} & 2\frac{y_{i+1}}{y_{i-1}} & \ddots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \ddots & \vdots \\ -2y_k & 2\frac{y_k}{y_1} & \dots & 2\frac{y_k}{y_{i-2}} & 2\frac{y_k}{y_{i-1}} & \dots & 2\frac{y_k}{y_{k-1}} & 0 \\ -2 & \frac{2}{y_1} & \dots & \frac{2}{y_{i-2}} & \frac{2}{y_{i-1}} & \dots & \frac{2}{y_{k-1}} & \frac{2}{y_k} \end{bmatrix}.$$

It is easy to see that $\det(M_{i(i+1)}) = -2^k$ if $i \neq 1$ and $\det(M_{12}) = 2^k$.

Using these results, we get from (14) that

$$\det(M_1) = -2^k \left((-1)^{k+2} \frac{1}{y_1} + (-1)^{k+3} \right),$$

$$\det(M_i) = -2^k \left((-1)^{k+1+i} \frac{y_{i-1}}{y_i} + (-1)^{k+1+i+1} \right), \quad i = 2, \dots, k,$$

$$\det(M_{k+1}) = -2^k y_k.$$

So from (13) we obtain

$$\begin{aligned}\det(M) &= -2^k\left((-1)^{2(k+1)}\,\frac{1}{y_1}+(-1)^{2(k+1)+1}\right)\\ &\quad + -2^k\left(\sum_{i=2}^{k}\left((-1)^{2(k+1+i)}\,\frac{y_{i-1}}{y_i}+(-1)^{2(k+1+i)+1}\right)+(-1)^{2(k+1)}\,y_k\right)\\ &= -2^k\left(\frac{1}{y_1}+\sum_{i=2}^{k}\frac{y_{i-1}}{y_i}+y_k-k\right).\end{aligned}$$

Since $y_{i-1} > y_i$ $(i = 2,\dots,k)$ and $\frac{1}{2} \geq y_1$ we get $\frac{1}{y_1}+\sum_{i=2}^{k}\frac{y_{i-1}}{y_i} > k$, and so $\det(M) < 0$. □

LEMMA 5. *The solution of system* (11) *satisfies the conditions of the linear program* (10) *and*

$$b = 1 + \frac{1-y_k}{\frac{1}{y_1}+\sum\limits_{i=2}^{k}\frac{y_{i-1}}{y_i}+y_k-k}.$$

Proof. By substituting the right-hand side of (11) into M, we obtain the matrix M_b,

$$M_b = \begin{bmatrix} -2y_1 & 0 & \dots & 0 & 0 & -1-y_1\\ -2y_2 & 2\frac{y_2}{y_1} & \dots & 0 & 0 & -1-y_2\\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots\\ -2y_k & 2\frac{y_k}{y_1} & \dots & 2\frac{y_k}{y_{k-1}} & 0 & -1-y_k\\ -2 & \frac{2}{y_1} & \dots & \frac{2}{y_{k-1}} & \frac{2}{y_k} & -1\\ -1 & 1 & \dots & 1 & 1 & 0 \end{bmatrix},$$

and

$$\det(M_b) = \det(M) + \sum_{i=1}^{k} y_i\,(-1)^{k+1+i}\det(M_i) = \det(M) - 2^k\,(1-y_k).$$

Using again Cramer's rule,

$$b = \frac{\det(M_b)}{\det(M)} = 1 + \frac{1-y_k}{\frac{1}{y_1}+\sum\limits_{i=2}^{k}\frac{y_{i-1}}{y_i}+y_k-k}.$$

By a similar analysis we can prove that the other conditions of (10) also hold. As an example we present only the inequality

$$z = \frac{\det(M_z)}{\det(M)} = \frac{\frac{1}{2}\det(M) - 2^{k-1}\frac{y_k-1}{y_1}}{\det(M)} = \frac{1}{2} + \frac{y_k-1}{2y_1\left(\frac{1}{y_1}+\sum\limits_{i=2}^{k}\frac{y_{i-1}}{y_i}+y_k-k\right)} < \frac{1}{2},$$

where

$$M_z = \begin{bmatrix} -1-y_1 & 0 & \dots & 0 & 0 & -1-y_1 \\ -1-y_2 & 2\frac{y_2}{y_1} & \dots & 0 & 0 & -1-y_2 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ -1-y_k & 2\frac{y_k}{y_1} & \dots & 2\frac{y_k}{y_{k-1}} & 0 & -1-y_k \\ -1 & \frac{2}{y_1} & \dots & \frac{2}{y_{k-1}} & \frac{2}{y_k} & -1 \\ 0 & 1 & \dots & 1 & 1 & 0 \end{bmatrix}.$$

The validity of the other inequalities can be shown easily. □

LEMMA 6. *The solution of system* (11) *is an optimal solution of the linear program* (10).

Proof. Consider the solution vector v of (11). Because of Lemma 5 it is a feasible solution of (10). Let v be a basis solution. The objective function contains only b, which has a positive coefficient, satisfying the optimum criterion. So we get the statement of the lemma. □

4. Getting the lower bound. In this section we deal with the optimal choice of the variables $y_1, y_2, \dots, y_k$. To choose them in an optimal way, we have to solve the following nonlinear optimization problem:

$$\max\left\{1 + \frac{1-y_k}{\frac{1}{y_1} + \sum_{i=2}^{k} \frac{y_{i-1}}{y_i} + y_k - k}\right\} \tag{15}$$

$$\text{subject to } \frac{1}{2} \geq y_1 > \dots > y_k > 0.$$

It does not seem to be easy to solve (15) analytically for arbitrary fixed k, but it can be done numerically by global optimization tools. Details can be found in [1]. In this paper we analyze (15) for the case when $k \to \infty$.

LEMMA 7. *The optimal solution of* (15) *converges to the maximum of the function*

$$f(x) := 1 + \frac{1-x}{x + 1 + \ln\left(\frac{1}{x}\right) - \ln(2)}$$

in the interval $\left(0, \frac{1}{2}\right]$ *if* $k \to \infty$.

Proof. We distinguish two cases.

Case 1. In this case we assume that $y_2 \leq \frac{y_1}{2}$. Then $2 \leq \frac{y_1}{y_2}$. Using $y_1 \leq \frac{1}{2}, y_2 \leq \frac{1}{4}, y_k \leq y_2$, $4 \geq 2 + y_k$, and applying the inequality between the arithmetic and geometric means for the numbers $\frac{y_2}{y_3}, \frac{y_3}{y_4}, \dots, \frac{y_{k-1}}{y_k}, y_k$ in the denominator of (15), we obtain the upper approximation (see [14])

$$1 + \frac{1-y_k}{\frac{1}{y_1} + \sum_{i=2}^{k} \frac{y_{i-1}}{y_i} + y_k - k} \leq 1 + \frac{1-y_k}{4 + \sum_{i=3}^{k} \frac{y_{i-1}}{y_i} + y_k - k}$$

$$\leq 1 + \frac{1-y_k}{2 + y_k - k + (k-1)\sqrt[k-1]{y_k}}.$$

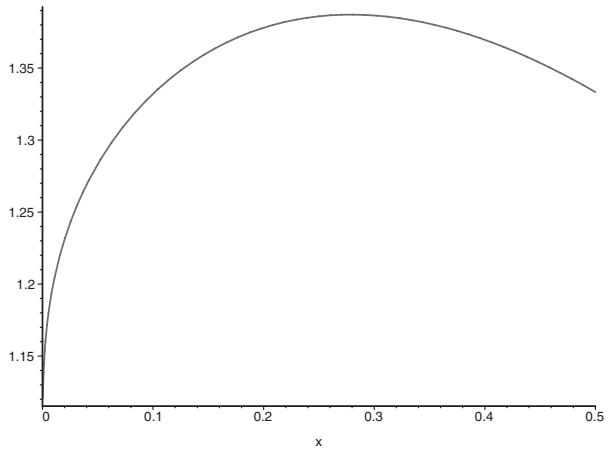

FIG. 1. *Graph of the function $f(x)$ in the interval $\left(0, \frac{1}{2}\right]$.*

Using that $\lim_{k\to\infty} (k-1)\ \sqrt[k-1]{x} - k = \ln(x) - 1$ and $\ln(x) < -\frac{5}{4}$ if $x \le \frac{1}{4}$, we obtain that

$$\lim_{k\to\infty} 1 + \frac{1-y_k}{\frac{1}{y_1} + \sum_{i=2}^{k} \frac{y_{i-1}}{y_i} + y_k - k} \le 1 + \frac{1-y_k}{y_k + 1 + \ln(y_k)} < 1.$$

Case 2. Suppose that $y_2 > \frac{y_1}{2}$. From this we get $2y_2(1-2y_1) \ge y_1(1-2y_1)$, and so

$$\frac{1}{y_1} + \frac{y_1}{y_2} \ge 2 + \frac{1}{2y_2}. \tag{16}$$

Using (16) and $y_1 \le \frac{1}{2}$ and then applying again the inequality between the arithmetic and geometric means for the numbers $\frac{1}{2y_2}, \frac{y_2}{y_3}, \ldots, \frac{y_{k-1}}{y_k}$ in the denominator of (15), we obtain the upper approximation

$$\begin{aligned} 1 + \frac{1-y_k}{\frac{1}{y_1} + \sum_{i=2}^{k} \frac{y_{i-1}}{y_i} + y_k - k} &\le 1 + \frac{1-y_k}{2 + \frac{1}{2y_2} + \sum_{i=3}^{k} \frac{y_{i-1}}{y_i} + y_k - k} \\ &\le 1 + \frac{1-y_k}{2 + y_k - k + (k-1)\ \sqrt[k-1]{\frac{1}{2y_k}}}. \end{aligned}$$

Since $\lim_{k\to\infty} (k-1)\ \sqrt[k-1]{\frac{1}{2x}} - k = \ln\left(\frac{1}{x}\right) - \ln(2) - 1$, we get that

$$\lim_{k\to\infty} 1 + \frac{1-y_k}{\frac{1}{y_1} + \sum_{i=2}^{k} \frac{y_{i-1}}{y_i} + y_k - k} \le 1 + \frac{1-y_k}{y_k + 1 + \ln\left(\frac{1}{y_k}\right) - \ln(2)}.$$

Since $\frac{1-x}{x+1+\ln(\frac{1}{x})-\ln(2)} \ge 0$ if $x \in (0, \frac{1}{2}]$, we get that the maximum of the limit comes from Case 2, which proves the statement of the lemma. The graph of function $f(x)$ of Case 2 can be seen in Figure 1.

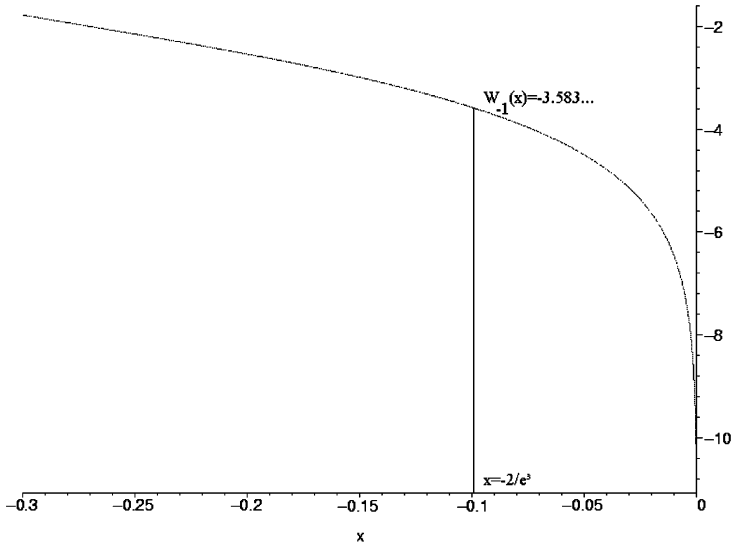

FIG. 2. *Graph of the function* $W_{-1}(x)$ *in the interval* $[-0.3, 0)$.

Here we used the fact that, if we compute the maximum of $f(x)$ in the given interval, then we can construct a series of values $y_1, y_2, \ldots, y_k$ which gives an optimal solution for (15). The construction sets y_1 to $\frac{1}{2}$ and defines the geometrical series $y_i = \frac{1}{2}(2y_k)^{\frac{i-1}{k-1}}$, $i = 2, \ldots, k$, which ends with y_k. □

LEMMA 8. *The maximum of the function* $f(x)$ *is* $1 - \frac{1}{W_{-1}\left(\frac{-2}{e^3}\right)+1} \approx 1.3871$ *in the interval* $\left(0, \frac{1}{2}\right]$, *where* $W_{-1}(x)$ *is the real branch of the Lambert* W *function for which* $W(x) \leq -1$ *holds.*

Proof. The proof is straightforward by taking the derivative of $f(x)$ and investigating the function analytically. Figure 2 displays the graph of the function $W_{-1}(x)$ in the interval $[-0.3, 0)$. □

5. Conclusions. In this paper we discussed improved lower bounds for the c-repacking version of the classical online bin packing problem. Note, however, that these bounds are valid for c-repacking fully dynamic bin packing algorithms as well. Namely, when deletions are allowed, our construction can be applied in the following way. We first give the list L_0, then insert L_1, and after deleting this, we insert L_2, etc. By examining the list L_0 and the L_0L_1, $L_0L_2, \ldots, L_0L_k$ configurations, we obtain the same lower bound with similar arguments as above.

AN APTAS FOR GENERALIZED COST VARIABLE-SIZED BIN PACKING*

LEAH EPSTEIN† AND ASAF LEVIN‡

Abstract. Bin packing is a well-known problem which has a large number of applications. Classical bin packing is a simple model in which all bins are identical. In the bin packing problem with variable-sized bins, we are given a supply of a variety of sizes. This latter model assumes, however, that the cost of a bin is always defined to be its exact size. In this paper we study the more general problem where an available bin size is associated with a fixed cost, which may be smaller or larger than its size. The costs of different bin sizes are unrelated. This generalized problem has various applications in storage and scheduling. In order to generalize previous work, we design new rounding and allocation methods. Our main result is an asymptotic polynomial time approximation scheme for the generalized problem.

1. Introduction.

Bin packing is a natural and well-studied problem which has applications in computer storage, bandwidth allocation, stock cutting, transportation, and many other important fields. The study of bin packing started more than 30 years ago [5, 7]. Since then, a large amount of research has been dedicated to this problem and its variants (see, e.g., [1, 3, 10]).

An interesting variant of this problem is variable-sized bin packing, in which a supply of containers of some fixed (finite) number of given sizes is available, instead of just a supply of a single bin type. The cost of using a bin is simply its size. The first to investigate the variable-sized bin packing problem were Friesen and Langston [4]. Several papers studied this problem in offline and online environments [12, 2, 13, 14].

We consider the following variant of one-dimensional bin packing, which is a natural generalization of both classical bin packing and variable-sized bin packing. We are given an infinite supply of bins of r types whose sizes are denoted by $b_r < \cdots < b_1 = 1$. We denote $B = \{b_1, \ldots, b_r\}$. Items of sizes in $(0, 1]$ are to be partitioned into subsets. The set of items is denoted S, and the items have indices in the set $\{1, 2, \ldots, n\}$. The size of item j is denoted by s_j. Each subset J in the partition has to be assigned (packed) to some bin type i, such that the set of items fits into an instance of this bin type, i.e., $\sum_{j \in J} s_j \leq b_i$. A bin type i is associated with a cost c_i. We assume $c_1 = 1$. Thus, the cost of a solution is the sum of costs of the bins used, taking multiple subsets which are using the same bin type into account. That is, if the subsets are $J_1, \ldots, J_k$, and subset ℓ is packed into a bin of type i_ℓ (for $1 \leq \ell \leq k$), we get the cost $\sum_{\ell=1}^{k} c_{i_\ell}$. The goal is to find a feasible solution whose total cost is minimized. Without loss of generality we let $b_{r+1} = c_{r+1} = 0$. We call this problem generalized cost variable-sized bin packing (GCVS).

This problem clearly generalizes the classical bin packing problem (where $B = \{b_1\}$) and variable-sized bin packing (where $c_i = b_i$ for $1 \leq i \leq r$). Classical bin

packing assumes a very simple model with uniform bin sizes. Although a large number of real-world problems can indeed be defined as such a problem, an even larger number of problems involve bins of various sizes. This started the study of variable-sized bin packing. To simplify reality, such models usually assume that the cost per unit of storage area is constant. Once again, this is not always the case in real life, as can be easily seen from prices of memory sticks and portable hard disks. Moreover, typically a smaller container has a larger cost per unit of storage, as is the case with various current storage devices. On the other hand, we sometimes encounter a phenomenon where we find that due to technological barriers, the cost of a memory storage device with a capacity twice as large is more than twice the cost of the more modest device.

These are just examples that in reality the cost of storage containers just cannot be assumed to be linear in their sizes. Previous studies of generalized costs functions assumed that the price per unit decreases as the bin size grows. Kang and Park [9], who studied a generalized problem with cost functions satisfying $\frac{c_i}{b_i} \leq \frac{c_j}{b_j}$ for $i > j$, suggested an algorithm of asymptotic approximation ratio $\frac{3}{2}$. Another possibly reasonable assumption is a concave cost function (see [11]). From the scenarios stated above, showing that pricing policies can be arbitrary, we deduce that neither option describes the typical real situation. This leads to the study of general cost functions.

It is known that no approximation algorithm for the classical bin packing problem can have a cost within a constant factor r of the minimum number of required bins for $r < \frac{3}{2}$ unless $\mathcal{P} = \mathcal{NP}$. This leads to the usage of the standard quality measure for the performance of bin packing algorithms which is the *asymptotic approximation ratio* or *asymptotic performance guarantee*. For an algorithm $\mathcal{A}$, we denote its cost on an input $\mathcal{X}$ by $\mathcal{A}(\mathcal{X})$. An optimal algorithm is denoted by OPT, and its cost of input $\mathcal{X}$ is denoted by $\text{OPT}(\mathcal{X})$.

The asymptotic approximation ratio for an algorithm $\mathcal{A}$ is defined to be

$$\mathcal{R}(\mathcal{A}) = \limsup_{n\to\infty} \sup_{\mathcal{X}} \left\{ \frac{\mathcal{A}(\mathcal{X})}{\text{OPT}(\mathcal{X})} \middle| \text{OPT}(\mathcal{X}) = n \right\}.$$

The natural question, which was whether this measure allows one to find an approximation scheme for classical bin packing, was answered affirmatively by Fernandez de la Vega and Lueker [3]. They designed an algorithm whose output never exceeds $(1+\varepsilon)\text{OPT}(I) + f(\varepsilon)$ bins for an input I and a given $\varepsilon > 0$. The running time was linear in n but depended exponentially on ε. Such a class of algorithms is considered to be an asymptotic polynomial time approximation scheme (APTAS).

Karmarkar and Karp [10] developed an asymptotic fully polynomial time approximation scheme (AFPTAS) for the same problem. This means that using a similar (but much more complex) algorithm, it is possible to achieve a running time which depends on $\frac{1}{\varepsilon}$ polynomially, without any loss in the approximation ratio. Karmarkar and Karp [10] also designed an algorithm which uses at most $\text{OPT}(I) + \log^2[\text{OPT}(I)]$ bins for an input I.

Murgolo [12] designed an APTAS and an AFPTAS for the bin packing problem with variable-sized bins. These results are relatively similar to those of [3, 10] and rely heavily on the fact that the cost of a bin equals its size.

Outline. In this paper, we design an APTAS for GCVS. In section 2 we state and prove some reductions which allow us to seek a slightly simpler structure of solution. These reductions need to be handled carefully to enable the usage of some simplifying assumptions later. In particular, we define a structure for optimal packings, which

turns out to give a solution which is not very different from an overall optimal solution but allows one to simplify the search for optimal solutions. Such a solution allows one to pack an item into a bin that is much larger than the smallest bin that can contain this item or whose cost is not more than a constant multiplicative factor (in terms of ε) away from the cost of such a minimal bin. Before describing the scheme in full detail, we present an outline in section 3. In section 4 we show how to apply grouping and rounding procedures on the input. We partition the input into sets as a function of the smallest bin they can fit into. To be able to apply rounding techniques on each set, we show that the largest items of every group can be packed according to one of two very different packing rules. We note that the number of item sizes resulting from the rounding procedure is not a constant. Therefore, many of the known methods for solving such rounded problems cannot be applied to solve our rounded problem. One example of a standard approach which fails is to formulate an integer programming formulation for the rounded problem. However, in our case its dimension is not constant, and therefore we cannot simply use Lenstra's algorithm [8] to solve the rounded instance and find an optimal packing for it. Despite these difficulties, we show in section 5 that we can get a near-optimal solution to the original problem using a shortest path computation. We use the properties proved in section 2 to reduce to a polynomial size the size of the graph in which we look for the shortest path. Our shortest path computation allocates items to bins, where bin sizes are considered along the path in an increasing order of costs, starting with the cheapest bins. We prove the correctness of our scheme in section 6. We conclude this paper with some remarks in section 7.

This algorithm uses methods of rounding and grouping that are based on ideas from [3] and [12]. However, as the adaptation of these ideas into a scheme with general costs requires a treatment of the bin types in a sorted order, we apply a layered graph based scheme for this. Such a scheme (for a scheduling problem) was given by Hochbaum and Shmoys [6]. To be able to design a solution for the most general problem with no assumptions on the cost function, we additionally apply some novel methods. Note that the running time of our APTAS depends on the number of bin types, r, polynomially (i.e., r is seen as a part of the input). Throughout this paper we denote by ε a fixed positive constant such that $\varepsilon < \frac{1}{100}$ and $\frac{1}{\varepsilon}$ is an integer.

2. Some reductions. In this section we show a series of modifications on B and restrictions on the optimal solution. We do not apply any modifications on the input items at this time. In the following sections we will compute a solution that uses only the modified set of bins and approximates an optimal solution among the possible solutions under the specified restrictions. The first reduction keeps at least one optimal solution unaffected, whereas the other reductions change the optimal solutions and moreover result in an increase in the total cost of an optimal solution. However, we will show that this increase is bounded by a (multiplicative) factor of $1 + \varepsilon$.

LEMMA 1. *Without loss of generality we assume that the values c_i are monotonically decreasing (i.e., for $i < j$, $c_i > c_j$).*

Proof. To achieve this we show that, given a set of bin types and a solution, we can omit some bins from B and change any solution (to a given input) into a solution that does not use bins removed from B and whose cost is not larger than the cost of the original solution. To achieve this, we apply the following process on B. While there exist i, j such that $i < j$ but $c_i \leq c_j$, remove bin type j from B. Note that since $b_i > b_j$, we can move the contents of every bin of size b_j into a bin of size b_i

without increasing the cost of a given solution. This is done until no such pair i, j exists and thus results in a set B' where the sequence of values c_i is monotonically decreasing. □

Since the process described in Lemma 1 can be applied to B without changing the cost of optimal solutions, we use the notation B for the set of bin type to which the process was already applied. We assume in the remainder of the paper that the values c_i are monotonically decreasing.

The following reductions increase the cost of an optimal solution by a factor of at most $1+\varepsilon$. In our analysis, we compare the cost of our approximation algorithm to the cost of an optimal solution for the instance resulting from the reductions and prove an approximation ratio of $1+O(\varepsilon)$. We get that even though the "real" approximation ratio (i.e., the approximation ratio with respect to an optimal solution of the original problem) may be slightly larger, it is at most $1+\varepsilon$ times the approximation ratio that we prove, and thus our analysis results in an approximation factor of $1+O(\varepsilon)$. Therefore, since we are interested in designing an APTAS for the problem, the reductions are harmless from our point of view. The next lemma shows that we can assume that the sequence of bin costs decreases geometrically or faster.

LEMMA 2. *Without loss of generality we may assume that for all i, $\frac{c_i}{c_{i+1}} \geq 1+\varepsilon$.*

Proof. If the claim does not already hold for the input bin types, we apply the following process on the bin types of the input. Traverse the list of bin types from the largest bin (i.e., $j=1$) to the smallest bin ($j=r$). During the traversal keep only a subset of the types, and remove the other types from B. We keep the first bin type ($j=1$) and recursively assume that the last bin type that is kept has index j. Then, given the value j for $i=j+1, j+2, \ldots$, as long as $\frac{c_j}{c_i} < 1+\varepsilon$ and $i > j$ we remove the ith type from the list of bin types. We always keep the bin type with smallest index i such that $\frac{c_j}{c_i} \geq 1+\varepsilon$ and i becomes the new value of j. If there is no such value of i, we remove all bin types $j+1, j+2, \ldots, r$ from B.

Consider a feasible solution that packs the set of items S using a bin of type i that is removed during this process. Then, the set of resulting bins contains a bin type j such that $\frac{c_j}{1+\varepsilon} < c_i < c_j$. Then, we modify the solution by using a bin of type j to pack all the items in S. Applying this procedure on all bins of types that were removed from B results in a feasible solution to the new instance, whose total cost is at most $1+\varepsilon$ times the cost of the original solution. Therefore, the cost of an optimal solution for the new instance is at most $1+\varepsilon$ times the cost of an optimal solution for the original instance. Thus, if we design APTAS for instances satisfying the assumption of the lemma, then the resulting solution will also be an APTAS for the original instances. We conclude that it suffices to consider instances satisfying the property. □

We say that a feasible solution is *nice* if it satisfies the following condition for every pair of a bin and an item. Assume that the solution uses a bin of type i to pack a set of items S. For a given $j \in S$, let k_j be the maximum index such that $b_{k_j} \geq s_j$ (i.e., b_{k_j} is the smallest bin size where j can be packed). Then, either $b_{k_j} \leq \varepsilon^6 b_i$ or $c_{k_j} \geq \varepsilon^8 c_i$ (or both). This means either that an item packed in a bin can fit into a much smaller bin or that the smallest (and thus cheapest) bin that can accommodate this item has a cost which differs from the cost of the current bin by a constant factor. Note that an item that does not fit into any bin of index strictly larger than i immediately satisfies the second condition.

The next lemma shows that we can restrict ourselves to looking for an approximated nice solution.

LEMMA 3. *Given an instance of the GCVS problem, denote by* OPT_n *the minimum cost of a nice solution and by* OPT *the cost of an optimal solution (which is not necessarily nice). Then,* $\text{OPT}_n \leq (1+3\varepsilon)\text{OPT}$.

Proof. Fix an optimal solution O whose cost is OPT. It suffices to show how to transform it into a nice solution whose cost is at most $(1+3\varepsilon)$OPT. We do the transformation for each packed bin in O separately. Assume that O uses a bin of type i to pack the item set which is denoted by C. We use a set of bins to pack C in order to convert the packing of C into a nice packing. To do so, we first identify the sequence $i_1, i_2, \ldots$. This sequence is independent of C and can be computed as a function of i as follows. Let i_ℓ be the smallest value of an index q such that $c_q \leq \varepsilon^{\ell+6} \cdot c_i$. Then, instead of using just one bin (of type i) to pack the items in C, we use one bin of type i and in addition, for each $\ell = 1, 2, \ldots$, we use $\frac{2}{\varepsilon^6}$ bins of type i_ℓ. This set of bins is used to pack C as follows. We use the single bin of type i to pack two sets of items. The first set consists of all items of C with size larger than b_{i_1}. The second set consists of all items j such that $b_{k_j} \leq \varepsilon^6 b_i$ (where k_j is as defined above, the index of a smallest type of bin into which item j can fit). Note that for such items it holds that $s_j \leq \varepsilon^6 b_i$. Denote the set of items that we pack using this unique bin of type i by C_0. The rest of the items from C is partitioned into classes, where the ℓth class, denoted by C_ℓ, contains all items whose size is between $b_{i_{\ell+1}}$ and b_{i_ℓ}. That is, $C_\ell = \{a \in C \setminus C_0 : b_{i_{\ell+1}} < s_a \leq b_{i_\ell}\}$.

Then, the items of set C_0 clearly fit into the bin of type i, since C was originally packed into this bin and $C_0 \subseteq C$. The items of C_ℓ for $\ell \geq 1$ are packed using the first-fit algorithm into at most $\frac{2}{\varepsilon^6}$ bins of type i_ℓ. To see this last claim, note that if $C_\ell \neq \emptyset$, then $b_{i_\ell} \geq \varepsilon^6 b_i$. Therefore, the total size of the items in C_ℓ is at most $\frac{b_{i_\ell}}{\varepsilon^6}$ (as they are packed into a single bin of type i). Since first-fit opens a new bin only if the total size of the items in the previous bin and the new item is at least the capacity of the bin, it has at most one bin with a total size of less than half the size of the bin, and therefore we conclude that first-fit, when applied to C_ℓ and bins of type i_ℓ, will use at most $\frac{2}{\varepsilon^6}$ bins.

Therefore, instead of using one bin of type i whose cost is c_i, we use a set of bins whose total cost is at most $c_i + \sum_{\ell=1}^{\infty} \frac{2}{\varepsilon^6} \cdot c_{i_\ell} \leq c_i + \sum_{\ell=1}^{\infty} \frac{2}{\varepsilon^6} \cdot \varepsilon^{\ell+6} \cdot c_i = c_i \cdot (1 + 2\sum_{\ell=1}^{\infty} \varepsilon^\ell) = c_i(1 + \frac{2\varepsilon}{1-\varepsilon}) \leq c_i(1+3\varepsilon)$, where the last inequality holds since $\varepsilon \leq \frac{1}{3}$.

It is clear that the resulting packing of C_0 into the bin of type i satisfies the conditions of a nice packing since all items violating the condition were removed from this bin. We next prove that the packing of every newly created bin satisfies the conditions of a nice packing as well. Consider an item $j \in C_\ell$ (which is packed into a bin of type i_ℓ). We show that this item satisfies the second condition of nice packings. By definition, $c_{i_\ell} \leq \varepsilon^{\ell+6} c_i$. Note that $i_{\ell+1}$ must exist since $c_{r+1} = 0$. Consider the bin type k_j. By definition of C_ℓ, $s_j > b_{i_{\ell+1}}$, and thus $k_j < i_{\ell+1}$. However, $i_{\ell+1}$ is the smallest index q for which $c_q \leq \varepsilon^{\ell+7} \cdot c_i$, and thus $c_{k_j} > \varepsilon^{\ell+7} \cdot c_i \geq \varepsilon c_{i_\ell} \geq \varepsilon^8 c_{i_\ell}$.

Application of the above transformation on all the bins of O results in a feasible solution that is also nice (as shown above, by the definition of the sets C_ℓ for $\ell \geq 0$) whose cost is at most $(1+3\varepsilon)$OPT. ∎

In what follows we assume that the instance satisfies the assumptions of Lemma 2. We approximate the minimum cost nice solution whose cost is denoted by OPT_n, and we construct a feasible solution whose cost is at most $(1+O(\varepsilon)) \cdot \text{OPT}_n + f(\frac{1}{\varepsilon})$, where f is some function (which will turn out to be polynomial). Note that the solution that we obtain is not necessarily nice, since the original problem does not require this. (It is possible, however, to convert it into a nice solution in polynomial time by applying a construction as above.)

3. Outline of the scheme. In this section we provide the outline of the scheme. The complete details will be given in the following sections.

The first step of the scheme is to preprocess the list of bin sizes so that this list will satisfy the properties of Lemmas 1 and 2.

We next partition the set of items into types. For a bin of type i, we say that an item of size s_j is *large for a bin of type* i if $\varepsilon^6 b_i \le s_j \le b_i$. It is *small for a bin of type* i if $s_j < \varepsilon^6 b_i$, and otherwise it is *huge for a bin of type* i. An item j is *large* if there is a type i such that it is large for a bin of type i. We denote by $\mathcal{L}$ the set of large items. We partition $\mathcal{L}$ into sets: for all i, $\mathcal{L}_i$ consists of all the large items for a bin of type i that are huge for a bin of type $i+1$, and $\mathcal{L}_r$ consists of all the large items for a bin of type r.

The next step of the scheme is to apply linear grouping for each $\mathcal{L}_i$ separately. We denote by S_1^i the set of the largest items resulting from the linear grouping of $\mathcal{L}_i$.

Our scheme looks for solutions that satisfy an additional property. That is, for each i we consider only two possibilities for packing S_1^i: either we have $|S_1^i|$ dedicated bins of size b_i, each of which contains exactly one item from the set S_1^i and no other item is packed into such a special bin, or the items of S_1^i are packed as small items in much larger bins. (Note that we do not allow mixtures of the two options for a given value of i.) We will show that there exists such a solution that does not cost much more than an optimal nice solution.

To find our solution we construct a layered graph. The graph is split into levels, where each level i corresponds to decisions regarding the packing of bins of type i. Each level consists of $3n+1$ layers, where each layer is associated with packing at most one bin of the corresponding type. At the entry for each level we decide whether S_1^i is packed in dedicated bins or the items of S_1^i are packed as small items in much larger bins (the graph contains edges of both possibilities). Each vertex encodes the number of (large) items of each rounded size that still needs to be packed. A vertex encodes also the rounded total size of the small items (i.e., small for the bin type of its level) that still need to be packed. Each vertex needs to recall the subset of the indices i such that S_1^i is packed as small items only if for the current level the items of S_1^i are still large items (and not small items).

We then look for a shortest path in this (very large but still polynomial size) layered graph. This shortest path corresponds to a well-defined packing of the items that are packed as large items. Afterwards, the remaining items need to be distributed to the empty slots in the resulting packing. To this end, additional bins (of each size) are used, if the process of packing small items as indicated by our path did not result in packing a large enough total size of small items. We show that these additional bins have a small cost and do not hurt the returned solution too much. Thus we show that the resulting solution is a good approximation of an optimal solution.

4. Linear grouping. Recall that for a bin of type i, we say that an item of size s_j is *large for a bin of type* i if $\varepsilon^6 b_i \le s_j \le b_i$. It is *small for a bin of type* i if $s_j < \varepsilon^6 b_i$, and otherwise it is *huge for a bin of type* i. An item j is *large* if there is a type i such that it is large for a bin of type i. We denote by $\mathcal{L}$ the set of large items.

We next partition $\mathcal{L}$ into subsets according to the size of the items. $\mathcal{L}_r$ is the set of large items for a bin of type r. If we defined $\mathcal{L}_{j+1}, \ldots, \mathcal{L}_r$, then $\mathcal{L}_j$ is defined as the intersection of the set of large items for a bin of type j and the set $\mathcal{L} \setminus (\mathcal{L}_{j+1} \cup \cdots \cup \mathcal{L}_r)$.

For each i such that $|\mathcal{L}_i| \le \frac{1}{\varepsilon^{16}}$ we pack each item of $\mathcal{L}_i$ in a bin of type i by itself. (Such a bin is called a dedicated bin.) Such a class $\mathcal{L}_i$ with at most $\frac{1}{\varepsilon^{16}}$ elements is called *thin*.

LEMMA 4. *The total cost of packing each item of a thin class into a dedicated bin is at most* $\frac{1+\varepsilon}{\varepsilon^{17}}$.

Proof. Since each bin type is used to pack at most $\frac{1}{\varepsilon^{16}}$ items, the total cost of these bins is at most the total cost of using $\frac{1}{\varepsilon^{16}}$ copies of every bin in the input sequence; i.e., it is at most $\frac{1}{\varepsilon^{16}} \cdot \sum_{i=1}^{r} c_i \leq \frac{1}{\varepsilon^{16}} \cdot c_1 \cdot \sum_{i=0}^{r-1} (\frac{1}{1+\varepsilon})^i \leq \frac{1}{\varepsilon^{16}} \cdot c_1 \cdot \sum_{i=0}^{\infty} (\frac{1}{1+\varepsilon})^i = \frac{1+\varepsilon}{\varepsilon^{17}}$, where the first inequality holds by Lemma 2. ∎

By Lemma 4, we can assume without loss of generality that for each nonempty class of large items, the class has at least $\frac{1}{\varepsilon^{16}}$ elements.

Next, we perform a linear grouping of each class $\mathcal{L}_i$ separately. More precisely, let $|\mathcal{L}_i| = n_i$ (recall that we assume that $n_i \geq \frac{1}{\varepsilon^{16}}$). We sort the elements $a_1^i, a_2^i, \ldots a_{n_i}^i$ of $\mathcal{L}_i$ according to their size. That is, we denote the size of the element a_j^i by s_j^i, and we assume without loss of generality that $s_1^i \geq s_2^i \geq \cdots \geq s_{n_i}^i$. We partition $\mathcal{L}_i$ into $\frac{1}{\varepsilon^{16}}$ subclasses denoted by $\bar{S}_1^i, \bar{S}_2^i, \ldots, \bar{S}_{1/\varepsilon^{16}}^i$. The partition is defined by the following two conditions: $|\bar{S}_p^i| = \lfloor n_i \varepsilon^{16} \rfloor$ or $|\bar{S}_p^i| = \lceil n_i \varepsilon^{16} \rceil$ for all $p \geq 1$, and if $p < q$, then $|\bar{S}_p^i| \geq |\bar{S}_q^i|$ (thus we always have $|\bar{S}_1^i| = \lceil n_i \varepsilon^{16} \rceil$). Moreover, we require that if $a_j^i \in \bar{S}_p^i$ and $a_k^i \in \bar{S}_q^i$ such that $p < q$, then $s_j^i \geq s_k^i$. Thus $\bar{S}_1^i$ is a set which contains the largest $\lceil n_i \varepsilon^{16} \rceil$ elements of $\mathcal{L}_i$ (breaking ties arbitrarily). In general, we partition $\mathcal{L}_i$ to approximately equal-size sets (sets of lower indices may have one additional item compared to sets of higher indices) so that $\bar{S}_j^i$ contains the largest elements from $\mathcal{L}_i \setminus (\bar{S}_1^i \cup \cdots \cup \bar{S}_{j-1}^i)$. We note that $n_i \varepsilon^{16} \leq |\bar{S}_1^i| \leq \lfloor n_i \varepsilon^{16} \rfloor + 1 \leq 3|\mathcal{L}_i \setminus \bar{S}_1^i| \cdot \varepsilon^{16}$, where the last inequality can be proved using simple algebra and the properties $|\mathcal{L}_i \setminus \bar{S}_1^i| = n_i - |\bar{S}_1^i| \geq n_i - (n_i \varepsilon^{16} + 1)$, $\varepsilon < \frac{1}{3}$, and $n_i \geq \frac{1}{\varepsilon^{16}}$.

For all i and all $j \geq 2$, we round up the size of all the elements of $\bar{S}_j^i$ to the size of the largest element of $\bar{S}_j^i$, the set of rounded items is denoted by S_j^i, and we denote by σ_j^i the rounded up size of an item in S_j^i. We also define $S_1^i = \bar{S}_1^i$. The set of rounded (large) items, resulting from $\mathcal{L}_i$ is denoted by $\mathcal{L}_i'$, and the set of all rounded (large) items is denoted by $\mathcal{L}'$. In the APTAS of [3] for the classical bin packing problem, the set of the largest elements in the linear grouping is packed using a separate bin for each such item. This packing is applied also for the later APTAS of Murgolo [12] for the variable-sized bin packing problem. In both cases, such a packing increases the cost of a packing only by an arbitrarily small factor. In the generalized problem, the important property that a small number of items of $\mathcal{L}_i$ can be packed into separate bins of size b_i does not hold, since an optimal packing may pack many items of $\mathcal{L}_i$ into larger bins. Instead, for each i, we allow the algorithm to choose between two possibilities: in the first possibility the algorithm packs S_1^i using a separate bin of size b_i for each item in S_1^i. This is the typical packing of the set of largest items of the linear grouping, and it is useful (by the analysis of the algorithm) in cases where most of the items of $\mathcal{L}_i$ are packed in OPT_n into bins of size smaller than $\frac{b_i}{\varepsilon^6}$. For other cases, we allow the algorithm to pack the set S_1^i, seeing them as a part of the set of small items of larger bins. In this case the algorithm will pack the elements of S_1^i using bins of size at least $\frac{b_i}{\varepsilon^6}$. That is, in our scheme the total size of elements of S_1^i will be added to the total size of small elements that the algorithm needs to pack using bins whose size is at least $\frac{b_i}{\varepsilon^6}$. To state the next lemma we consider a fixed optimal nice solution (the optimum among the nice solutions) denoted by OPT_n. We use $\mathcal{A}_i$ to denote the subset of elements of $\mathcal{L}_i \setminus \bar{S}_1^i$ which OPT_n packs into bins of size smaller than $\frac{b_i}{\varepsilon^6}$. If $|\mathcal{A}_i| \geq \frac{1}{2}|\mathcal{L}_i \setminus \bar{S}_1^i|$, we say that $\mathcal{L}_i$ is *good*.

LEMMA 5. *Assume that $\mathcal{L}_i$ is good. Consider a packing where each item of S_1^i is packed into a separate bin of size b_i. In this case, the total cost of bins containing*

the items of S_1^i is at most $6 \cdot \varepsilon^4 \cdot \psi_i$, where ψ_i is the total cost of the subset of bins in OPT_n, that consists of all bins that contain at least one item of $\mathcal{A}_i$.

Proof. We first argue that each bin that is used to pack an element of $\mathcal{A}_i$ has size of at least b_i. Since $\mathcal{A}_i \subset \mathcal{L}_i$, such an item is not large for b_{i+1}, and since $b_{i+1} < b_i$ this means that it is huge for it and does not fit into smaller-size bins. Therefore, the cost for such a bin is at least c_i. Next note that each bin that is used to pack an element of $\mathcal{A}_i$ packs at most $\frac{1}{\varepsilon^{12}}$ such elements. This follows since each such element has size of at least $\varepsilon^6 b_i$, and the size of such bin is smaller than $\frac{b_i}{\varepsilon^6}$ (due to the definition of $\mathcal{A}_i$). Therefore, there exist at least $\frac{|\mathcal{L}_i \setminus \bar{S}_1^i|}{2}\varepsilon^{12}$ bins of OPT_n, where each one of them costs at least c_i, and each one of them contains at least one element of $\mathcal{A}_i$. So $\psi_i \geq \frac{|\mathcal{L}_i \setminus \bar{S}_1^i|}{2}\varepsilon^{12} c_i$. As already stated in the proof of Lemma 4, $|S_1^i| = |\bar{S}_1^i| \leq 3|\mathcal{L}_i \setminus \bar{S}_1^i|\varepsilon^{16}$, and therefore $|S_1^i|$ is at most $6 \cdot \varepsilon^4$ times the number of bins that are used by OPT_n to pack the elements of $\mathcal{A}_i$. The claim follows since each bin used to pack an element of $\mathcal{L}_i$ costs at least c_i which is exactly the cost of the bins used to pack each element of S_1^i. ∎

LEMMA 6. *The total cost of assigning each element of S_1^i a separate bin, for all values of i such that $\mathcal{L}_i$ is good, is at most $3\varepsilon^2 \cdot \text{OPT}_n$.*

Proof. By Lemma 5, the total cost incurred by S_1^i for a value of i such that $\mathcal{L}_i$ is good is at most $6\varepsilon^4$ times the total cost of the bins that OPT_n uses to pack elements of $\mathcal{A}_i$. Since OPT_n is nice, and the first property of nice packings does not hold for the bin sizes that we consider here, we conclude that each of these bins has a cost of at least c_i and at most $\frac{c_i}{\varepsilon^8}$. By Lemma 2, there are at most $\left\lceil \log_{1+\varepsilon} \frac{1}{\varepsilon^8} \right\rceil$ bin types with cost in the interval $\left[c_i, \frac{c_i}{\varepsilon^8}\right]$. Therefore, a specific bin can be used by OPT_n to pack elements from at most $\left\lceil \log_{1+\varepsilon} \frac{1}{\varepsilon^8} \right\rceil$ different sets $\mathcal{A}_i$. Thus, the total cost of assigning each element of S_1^i a separate bin for all i such that $\mathcal{L}_i$ is good is at most $6\varepsilon^4 \cdot \left\lceil \log_{1+\varepsilon} \frac{1}{\varepsilon^8} \right\rceil \cdot \text{OPT}_n \leq 3\varepsilon^2 \text{OPT}_n$, where the last inequality can be easily verified and holds since $\varepsilon < \frac{1}{100}$. ∎

By Lemma 6, if we allow our scheme to choose one of the two possibilities described above for each i, then the cost of the largest sets in the linear groupings can be disregarded if the class is good. We argue in the next lemma that if the class $\mathcal{L}_i$ is not good, then by deciding to pack S_1^i in bins of size at least $\frac{b_i}{\varepsilon^6}$, we increase the space demand for such bins by a multiplicative factor of at most $(1 + 6\varepsilon^{10})$. This increase does not cause any harm, since in any case we will have more dominant rounding errors (that will still lead to an $(1 + O(\varepsilon))$-approximate solution with respect to the asymptotic approximation ratio).

LEMMA 7. *If $\mathcal{L}_i$ is not good, then the total size of the elements of S_1^i is at most $6\varepsilon^{10}$ times the total size of elements of $\mathcal{L}_i \setminus \bar{S}_1^i$ that are packed in OPT_n into bins which are of size at least $\frac{b_i}{\varepsilon^6}$.*

Proof. Using $\mathcal{A}_i < \frac{1}{2}|\mathcal{L}_i \setminus \bar{S}_1^i|$, we get $|\mathcal{L}_i \setminus (\bar{S}_1^i \cup \mathcal{A}_i)| \geq \frac{1}{2}|\mathcal{L}_i \setminus \bar{S}_1^i|$ and thus $\frac{|S_1^i|}{|\mathcal{L}_i \setminus (\bar{S}_1^i \cup \mathcal{A}_i)|} \leq \frac{3|\mathcal{L}_i \setminus \bar{S}_1^i|\varepsilon^{16}}{\frac{1}{2}|\mathcal{L}_i \setminus \bar{S}_1^i|} \leq 6\varepsilon^{16}$. Since $\varepsilon^6 b_i \leq s_j^i \leq b_i$ for all j, the claim follows. ∎

The next lemma holds by a similar argument to the arguments of [3]. Namely, using the fact that if the items of S_1^i are removed for all i, the rounded input can be mapped back into the original input, so that every item is mapped to an item that is no smaller than it.

LEMMA 8. *Given an instance of the GCVS problem, the optimal solution cost of the instance after applying the linear grouping step as described above (with rounded-up sizes), and removing all items in S_1^i for all i, is at most the cost of the optimal solution to the original instance.*

5. The main scheme. In this section we show how to use the linear grouping, as it is described in the previous section, to compute an approximated nice solution. Our method is based on constructing a layered graph and then computing a shortest path in this graph. This shortest path is then used to construct a feasible solution of the GCVS problem.

For $i = 1, 2, \ldots, r$ we denote by d_i the total size of elements whose individual sizes are in the interval $(b_{i+1}, \varepsilon^6 b_i)$. Such elements are huge with respect to bin types $i+1, i+2, \ldots, r$ and small with respect to bin type i. They are not large with respect to any type of bin. If $b_{i+1} \geq \varepsilon^6 b_i$, then $d_i = 0$.

A level in a layered graph is defined as a consecutive set of layers. Our layered directed graph $G = (V, E)$ is composed of $r+1$ levels, where the ith level corresponds to decisions regarding the packing of elements into bins of type i. (Recall that $b_{r+1} = 0$ and hence there are no elements packed into bins of type $r+1$. We add this level to unify the presentation of our scheme.) Each level consists of $3n+1$ layers, where n is the total number of items in the input. Each edge connects a vertex of one layer with a vertex of the consecutive layer, where the layers are ordered so that first there are the $3n+1$ layers of level $r+1$, then the layers of level r, and so on up to the layers of level 1. We add to G one additional vertex denoted by t, which is defined to be the very last layer. We partition the levels into phases as follows. A level i is a *phase p level* if $b_i \in \left(\varepsilon^p, \varepsilon^{p-1}\right]$. For a bin type i, we denote by $B_i = \{k : b_k \in \left[\varepsilon^6 b_i, b_i\right] \text{ and } c_k \in \left[\varepsilon^8 c_i, c_i\right]\}$.

For a phase p level i, a *pattern of level i* corresponds to a packing of a bin of size b_i with elements resulting from the linear grouping, which are of size in the interval $[\varepsilon^6 b_i, b_i]$. These are elements in $\bigcup_{\substack{k \in B_i \\ j \geq 2}} S_j^k \cap \{a \in S : \sigma_a \in [\varepsilon^6 b_i, b_i]\}$. Each such bin can contain space for smaller items as well, where the space defined by the pattern is an integer multiple of $\varepsilon^6 b_i$. This integer is called *the number of slots for small items of the pattern* and is denoted by n_{slot}. Formally, a pattern of level i is $(n_{slot}, (n_j^k)_{\substack{k \in B_i \\ j \geq 2}})$, where n_j^k is the number of items from S_j^k that are packed into this bin. In this notation we assume that $n_j^k = 0$ if $\sigma_j^k < \varepsilon^6 b_i$.

LEMMA 9. *The number of possible patterns of level i is $O((n\varepsilon^{16}+2)^{\frac{8\log_{1+\varepsilon}\frac{1}{\varepsilon}+1}{\varepsilon^{16}}} \cdot (\frac{1}{\varepsilon^6}+1))$; i.e., it is bounded by a polynomial in the input size.*

Proof. The number n_{slot} is an integer in the interval $[0, \frac{1}{\varepsilon^6}]$. The number n_j^k is an integer in the interval $[0, \lceil n\varepsilon^{16} \rceil]$. By Lemma 2, $|B_i|$ is at most $\log_{1+\varepsilon}\frac{1}{\varepsilon^8}+1$. Since each such class (whose index belong to B_i) has at most $\frac{1}{\varepsilon^{16}}$ different values of element size, we conclude that the number of possible patterns of level i is at most $O((n\varepsilon^{16}+2)^{\frac{8\log_{1+\varepsilon}\frac{1}{\varepsilon}+1}{\varepsilon^{16}}} \cdot (\frac{1}{\varepsilon^6}+1))$. ∎

We next describe the vertex set of our layered graph G. A vertex u of the ith level, which is a phase p level, is associated with a label consisting of the following information, which has four parts. The first part contains information on the number $n_j^k(u)$ of items from S_j^k that still needs to be packed, for relevant values of k and j, if the current vertex is reached. That is, for every $k \in B_i$ and for all $j \geq 2$, the label contains the number $n_j^k(u)$ of remaining such elements. The second part of the label contains information on the total size D of small elements for a bin of type i that needs to be packed. This information in the label is $n_{slot}(u) = \lfloor \frac{D}{b_i \varepsilon^6} \rfloor$. Note that D is an approximated sum of such items, which never exceeds the real amount to be packed. The third part of the label contains approximated sums of items that we decided to pack as small items but that are still considered to be large items for bins

of type i, and thus this information should be carried over to future phases. To be more precise, if level i is a phase p level, then the label contains six integer numbers $n^p_{slot}(u)$, $n^{p+1}_{slot}(u), \ldots, n^{p+5}_{slot}(u)$, where $n^q_{slot}(u) \cdot b_i\varepsilon^6$ (for $q = p, p+1, \ldots, p+5$) is an approximated sum of the sizes of all items whose sizes are in $\left(\varepsilon^q, \varepsilon^{q-1}\right]$, and the smallest bin that is large enough to contain such items is of type k for some $k > i$ such that $c_k < \varepsilon^8 c_i$ (and therefore $k \notin B_i$). Note that such items are packed as small items in a nice solution; however, they are still large items for a bin of type i (this is so since for an item x we have $\varepsilon^q < s_x \leq b_k < b_i \leq \varepsilon^{p-1} \leq \varepsilon^{q-6}$ and therefore $s_x \geq \varepsilon^6 b_i$). The fourth part of the label is described next. For all $k \in B_i$, the label contains the information regarding whether we decide to pack each member of S^k_1 using its own bin of size b_k, or all elements of S^k_1 are packed as small items in bins of size at least $\frac{b_k}{\varepsilon^6}$. Therefore, the label encodes a subset $I(u)$ of the index set B_i and if k belongs to this subset, we decide to pack each element of S^k_1 using a dedicated bin of size b_k.

LEMMA 10. *The number of vertices in the graph is polynomial in the input size.*

Proof. Consider a phase p level i and a given layer of this level. In this layer there is a vertex for each possible value of the label. Since the number of levels is $r+1$ and the number of layers in each level is $3n+1$ (plus one last layer which consists of a single vertex), in order to prove the claim it suffices to show that the number of possible labels for level i is polynomial. The number $n^k_j(u)$ is an integer in the range $[0, n_i]$, and therefore there are at most $n+1$ such possibilities. We have to identify this number for the pairs of indices k and j such that $b_k \in [\varepsilon^6 b_i, b_i]$, $c_k \in [\varepsilon^8 c_i, c_i]$ and $j = 2, 3, \ldots, \frac{1}{\varepsilon^{16}}$, and by Lemma 2 there are at most $1 + \log_{1+\varepsilon} \frac{1}{\varepsilon^8}$ values that k can have. Therefore, the number of possibilities for the first part of the label is at most $(n+1)^{(1+\log_{1+\varepsilon} \frac{1}{\varepsilon^8}) \cdot \frac{1}{\varepsilon^{16}}}$ and since ε is a fixed constant, this number is polynomial in the input size. Next, consider the number of possibilities for $n_{slot}(u)$. Note that the number of small elements for a bin of type i is at most n, and each one of them has size less than $\varepsilon^6 b_i$. Therefore, $D < nb_i\varepsilon^6$, and we conclude that $n_{slot}(u) = \lfloor \frac{D}{b_i\varepsilon^6} \rfloor$ is an integer in the interval $[0, n-1]$. Hence, the number of possibilities for $n_{slot}(u)$ is at most n. We next bound the value of $n^q_{slot}(u)$ for $q = p, p+1, \ldots, p+5$. Note that each item considered so far has a size smaller than b_i, and there are at most n such items. Therefore, the total size of these items (that still needs to be packed) is less than nb_i. Hence, $n^q_{slot}(u) \in [0, \frac{nb_i}{b_i\varepsilon^6})$. Since this is an integer, we get that the number of possibilities for this value is polynomial (for a fixed value of ε). It remains to bound the number of possibilities for $I(u)$. By Lemma 2, $|B_i| = \log_{1+\varepsilon} \frac{1}{\varepsilon^8} + O(1)$, and the number of possibilities for $I(u)$ is the number of subsets of B_i that is $O(2^{\log_{1+\varepsilon} \frac{1}{\varepsilon^8}})$ that is a constant (for a fixed value of ε). ∎

We define five types of edges. The first two types are edges connecting two vertices from a common level (and consecutive layers). The last three types of edges connect vertices from consecutive levels. The first type has the purpose of assigning a set of items into a bin. The second type allows us to bypass a bin and not use it. The next two types translate configurations of different levels. The last type allows us to terminate all paths in the target vertex t.

1. The first type of an edge connects two vertices from two consecutive layers of a common level i, where i is a phase p level. It corresponds to a packing of a single bin of size b_i according to a pattern of level i denoted by $(n_{slot}, (n^k_j)_{\substack{k \in B_i \\ j \geq 2}})$. The two vertices connected by such an edge (u, v) have labels that differ only in the first and second part of the label (so $I(u) = I(v)$ and $n^q_{slot}(u) = n^q_{slot}(v)$ for $q = p, p+1, \ldots, p+5$). The first part of the label changes according to $n^k_j(v) = \left(n^k_j(u) - n^k_j\right)^+$ for all $k \in B_i$ and for all

$j \geq 2$ (where for a real number a we let $a^+ = \max\{a, 0\}$). That is, the first part of the the label of v results from the label of u by decreasing the number of items that need to be packed from the set S_j^k by exactly the number of elements from S_j^k that are packed by the pattern corresponding to this edge. Similarly, $n_{slot}(v) = (n_{slot}(u) - n_{slot})^+$. Such an edge has a cost of c_i.

2. The second type of an edge is an edge connecting two vertices in consecutive layers of a common level with equal labels. Such an edge has a zero cost. Such an edge corresponds to the decision not to pack an additional bin of the corresponding size.

3. The third type of an edge connects a vertex u that belongs to the last layer of phase p level $i+1$ to a vertex v that belongs to the first layer of level i, where level i is also a phase p level. In order to obtain the label of v from the label of u we need to apply the following changes. For each value of $k \in B_{i+1} \setminus B_i$, we remove the entries $n_j^k(u)$, for all $j \geq 2$, from the first part of the label of u. These are items that lost their opportunity to be packed as large items and must be packed as small items to maintain the properties of a nice packing. Out of these elements, we compute the total size of elements that need to be packed as small elements according to u and they are already small elements for bin of type i. We need to add to this total size the value of d_i, which are items that are immediately small without being large for any previous bin. However, since the two levels are of the same phase, b_i and b_{i+1} are within a factor of $\frac{1}{\varepsilon}$, which implies that such items do not exist and so $d_i = 0$. Denote the resulting value, which is the sum of all items that became small, by T. Then, the second part of the label of v is exactly $n_{slot}(v) = \lfloor \frac{T}{\varepsilon^6 b_i} + \frac{n_{slot}(u) \cdot b_{i+1}}{b_i} \rfloor$. The first part of the label of v is augmented with new entries for the number of elements of S_j^i that need to be packed for $j \geq 2$; we showed how to compute this number earlier, and it is either $n_j^i = \lfloor n_i \varepsilon^{16} \rfloor$ or $n_j^i = \lceil n_i \varepsilon^{16} \rceil$ for all $j \geq 2$. Note that $B_i \setminus B_{i+1} = \{i\}$; thus these are the only new entries. For $q = p, p+1, \ldots, p+5$, we define $n_{slot}^q(v)$ as follows: for each $k \in B_{i+1}$ such that $c_k < \varepsilon^8 c_i$, we compute $\text{Size}_k^q(u) = \sum_{j \geq 2 : \sigma_j^k \in (\varepsilon^q, \varepsilon^{q-1}]} n_j^k(u) \cdot \sigma_j^k$. We sum up all the values $\text{Size}_k^q(u)$ for all k such that $k \in B_{i+1}$ and $c_k < \varepsilon^8 c_i$, and we denote this sum by $E_q(u)$. That is, $E_q(u) = \sum_{k \in B_{i+1} : c_k < \varepsilon^8 c_i} Size_k^q(u)$. Then we let $n_{slot}^q(v) = \lfloor \frac{n_{slot}^q(u) \cdot b_{i+1}}{b_i} + \frac{E_q(u)}{b_i \varepsilon^6} \rfloor$. We finish the definition of the label of v by setting either $I(v) = I(u) \cap B_{i+1} \cap B_i$ or $I(v) = (I(u) \cap B_{i+1} \cap B_i) \cup \{i\}$ (both edges are constructed, having the exact same cost). The cost of the edge (u, v) is $\sum_{k \in I(u) \setminus I(v)} |S_1^k| \cdot c_k$, and this cost reflects the cost of packing each element of S_1^k in a separate bin of type k if $k \in I(u)$. We charge this packing of the S_1^k to an edge of type 3 or 4, which is a transition between levels, at the time that the packing of S_1^k stops being indicated in the label.

4. The fourth type of edge connects a vertex u that belongs to the last layer of phase p level $i+1$ to a vertex v that belongs to the first layer of level i, where level i is a phase p' level for $p' \leq p-1$. In order to obtain the label of v from the label of u we need to apply the following changes. For each value of $k \in B_{i+1} \setminus B_i$, we remove from the first part of the label of u the entries $n_j^k(u)$ for all $j \geq 2$. Out of these items, we compute the total size of such elements that need to be packed according to u and that are already small for a bin of type i, and we add to this total size the value of d_i. We denote the resulting value by T. We need to take into account the term $Y = \sum_{q=\max\{p, p'+6\}}^{p+5} n_{slot}^q(u)$. The last term corresponds to items that we previously decided to pack as small items but that were still large for bins of type $i+1$, and now such an item x satisfies $s_x < \varepsilon^5 b_i$, as $s_x \leq \varepsilon^{q-1}$ and

$b_i > \varepsilon^{p'} \geq \varepsilon^{q-6}$. Note that we slightly relax the condition of packing items as small and sometimes allow items that are smaller than a bin by a factor of at least ε^5 (instead of ε^6) to be packed as small items in this bin. Then, the second part of the label of v is exactly $n_{slot}(v) = \lfloor \frac{T}{\varepsilon^6 b_i} + \frac{(n_{slot}(u)+Y)\cdot b_{i+1}}{b_i} \rfloor$. The first part of the label of v is augmented with new entries for the number of elements of S_j^i that needs to be packed for $j \geq 2$, and this number is either $n_j^i = \lfloor n_i \varepsilon^{16} \rfloor$ or $n_j^i = \lceil n_i \varepsilon^{16} \rceil$ for all $j \geq 2$. For $q = p', p'+1, \ldots, p'+5$, we define $n_{slot}^q(v)$ as follows. For a given value of q, denote by Y_q the set of pairs (k,j) such that $(k,j) \in Y_q$ if and only if $k \in B_{i+1} \setminus B_i$ and $\sigma_j^k \in (\varepsilon^q, \varepsilon^{q-1}]$. We compute $E_q(u) = \sum_{(k,j)\in Y_q} n_j^k(u) \cdot \sigma_j^k$. For $q \notin \{p, p+1, \ldots, p+5\}$, we denote $n_{slot}^q(u) = 0$. Then, for $q = p', p'+1, \ldots, p'+5$, we let $n_{slot}^q(v) = \lfloor \frac{n_{slot}^q(u)\cdot b_{i+1}}{b_i} + \frac{E_q(u)}{\varepsilon^6 b_i} \rfloor$. Note that every entry $n_{slot}^q(u)$ was translated either into a part of the small jobs or into a part of an entry $n_{slot}^q(v)$ but not to both.

We finish the definition of the label of v by setting either $I(v) = I(u) \cap B_{i+1} \cap B_i$ or $I(v) = (I(u) \cap B_{i+1} \cap B_i) \cup \{i\}$ (again, both edges exist with the same cost). The cost of the edge (u,v) is $\sum_{k \in I(u)\setminus I(v)} |S_1^k| \cdot c_k$ and this cost reflects the cost of packing each element of S_1^k in a separate bin of type k if $k \in I(u)$. As in the previous type of edge, we charge this packing of the S_1^k items to the edges the level transition, where the packing of S_1^k stops being indicated in the label.

5. The last type of edge connects vertices u of the last layer of level 1 to t. Such a vertex u is adjacent to t only if all parts of the label of u except for the last one are either empty sets or are equal to zero. The cost of such an edge if it exists is $\sum_{k \in I(u)} |S_1^k| \cdot c_k$.

Note that $b_{r+1} = 0$ and thus no items can fit into this bin (which was created so that the levels of the graph can be created uniformly). Let a be the vertex of the first layer of level $r+1$ whose label is defined as follows. The first part, which indicates the number of items in S_k^j for $2 \leq j \leq \frac{1}{\varepsilon^{16}}$ and $k \in B_{r+1}$, is empty as $B_{r+1} = \emptyset$. The second part is zero and so are the six amounts in the third part. Finally, $I(a) = \emptyset$. Our scheme finds the minimum cost path $\mathcal{P}$ from a to t. Note that items to be packed are added to the graph as soon as the first level of any bin that can accommodate them is reached.

We next construct a feasible solution based on the path found by the algorithm. If the path uses an edge connecting (u,v), where both of them belong to a common level i and the label of u differs from the label of v, then this edge corresponds to a pattern $(n_{slot}, (n_j^k)_{\substack{k\in B_i \\ j\geq 2}})$. We open a bin of type i and allocate it exactly n_j^k items of S_j^k for all $k \in B_i$ and $j \geq 2$. (The actual allocation is of the $\bar{S}_j^k$ items, but we may assume that each of them occupies the same space which is the size of an S_j^k item.) We also reserve a space of size $n_{slot}\varepsilon^6 b_i$ for small items (which will be allocated later to these spaces). We apply this for all edges of the first type that $\mathcal{P}$ uses. Edges of the second type in $\mathcal{P}$ do not affect the solution (they have cost zero with an empty configuration and are associated with bins that are bypassed). Next assume that $\mathcal{P}$ uses an edge (u,v) of the third or fourth type, where u belongs to the $(i+1)$th level (and v to level i). The effect of such an edge except for translation between levels is to assign large items from a set S_1^k such that $k \in B_{i+1}$ and $k \notin B_i$, which are supposed to be packed in their own bins, one item per bin. In this case for all $k \in I(u) \setminus I(v)$ we open $|S_1^k|$ bins of size b_k and allocate them the items of S_1^k. It remains to consider the edge of the last type that $\mathcal{P}$ uses. Assume that this edge is (u,t); then for all $k \in I(u)$ we open $|S_1^k|$ bins of size b_k and allocate them the items of S_1^k. Note that the total cost of the bins that we open is exactly the cost of $\mathcal{P}$.

We next consider the nonallocated items (which are supposed to be packed as small items as implied by the chosen path). We sort the nonallocated items in a nonincreasing size order. We start to allocate them into the space kept for small items as follows.

Let μ_i be the number of slots for small items in bins of level i in the solution as implied by the sum of values n_{slot} in the patterns. Let R_i be the number of edges of the first type in the path (inside level i) that contain at least one slot for small items. We would like to allow a total size of at least $\varepsilon^6 b_i(\mu_i + 37)$ that will be allocated to items to be packed, and for that we open $R_i\varepsilon^5(1+\varepsilon)+2$ new bins of type i for small items.

We start to allocate the largest remaining item to the space in the smallest-type bin (the largest bin) and keep allocating items according to the sorted list into the space in the bins. While allocating items into bins of level i, if there is not enough room for the current item in the current space we move to the next space. We do this as long as there are free slots in the bins that correspond to edges of the first type. We use the new bins of size b_i and assign small items into them until either we run out of small items to be packed completely or we have used all new bins that were opened for level i as stated above. A new bin that is opened in this step is called a *small item bin of type i*. We later show that our bound (i.e., the number of new bins per level) is large enough, and we bound the additional cost caused by the new bins.

We conclude this section by noting that since the layered graph has polynomial size, and its construction takes polynomial time, finding the shortest path in G takes a polynomial time and constructing the solution based on this path is also polynomial. Therefore, our scheme (for a fixed value of ε) is a polynomial time algorithm. Hence we establish the following corollary.

COROLLARY 11. *Given a fixed value of ε, the time complexity of the scheme is polynomial.*

6. Analysis. In this section we prove that our algorithm is an APTAS for GCVS. We first bound the cost of $\mathcal{P}$. To do so, we present a path from a to t in G whose cost is $(1+3\varepsilon^2+2\varepsilon^6)\text{OPT}_n + \frac{1+\varepsilon}{\varepsilon}$.

LEMMA 12. *There exists a path $\tilde{\mathcal{P}}$ from a to t whose cost is at most* $(1+3\varepsilon^2+2\varepsilon^6)\text{OPT}_n + \frac{1+\varepsilon}{\varepsilon}$.

Proof. Consider an optimal solution OPT_n. From this solution, remove all items which belong to thin classes, as such items do not exist in the layered graph.

Before we can define a path in the graph, we make some adaptations to the solution, and, specifically, we convert it into a packing of the rounded items, where some of the items that are packed as small items are converted into tiny items in the packing.

This packing is later translated into a path in the graph, where items that are packed as small need to be considered carefully. We are going to use the space allocated in the solution to the items of $\bar{S}_j^k$ to accommodate the items of S_{j+1}^k, which are (by definition) no larger of items of $\bar{S}_j^k$. This leaves the items of $\bar{S}_1^k$ unpacked. Thus we create a new instance of each item of $\bar{S}_1^k = S_1^k$, the additional set with the new instances of these items is denoted by $\mathcal{S}^k$. The room taken by each item of the original set $\bar{S}_1^k$ will be used later for items of S_2^k. No adaptations are performed on the placement of a new set $\mathcal{S}^k$. The replacement of $\bar{S}_j^k$ items into the S_{j+1}^k items is done after a packing for the new set $\mathcal{S}^k$ is created.

We next define a packing of the items in $\mathcal{S}^i$ for $1 \le i \le r$. For every such i such

that $\mathcal{L}_i$ is good, i.e., if OPT_n packs at least half of the elements of $\mathcal{L}_i$ using bins of size smaller than $\frac{b_i}{\varepsilon^6}$, we put each item of $\mathcal{S}^i$ into a bin of size b_i. We earlier showed in Lemma 6 that this transformation increases the cost of the solution by at most an additive factor of $3\varepsilon^2\text{OPT}_n$.

We would like to pack the items of $\mathcal{S}^i$ for values of i such that $\mathcal{L}_i$ is not good. This packing is composed of several steps. These items are converted into "sand," which are infinitely small items. We insert a set of empty bins into the packing and bound the resulting increase in the cost. Next, we show that these bins are sufficient to accommodate all sand resulting from items of the sets $\mathcal{S}^i$ for values of i, such that $\mathcal{L}_i$ is not good. We do not convert the items into their original sizes since these items are small for the bins into which they are packed, and the graph takes into account only an approximated sum of sizes of such items rather than the specific sizes. Given the list of bins used by OPT_n we do the following. Let N_i be the number of bins of type i used by OPT_n. We open another $\lceil 2N_i\varepsilon^6 \rceil \leq 2N_i\varepsilon^6 + 1$ bins of type i. This increases the cost of the solution by an additive factor of at most $2\varepsilon^6\text{OPT}_n + \frac{1+\varepsilon}{\varepsilon}$. (The last term is found by summing up on the costs of all types, similar to the summation in the proof of Lemma 4.)

By Lemma 7, the space required for the sand resulting from a set $\mathcal{S}^i$ (where $\mathcal{L}_i$ is not good) is at most $6\varepsilon^{10}$ times the total size of items in $\mathcal{L}_i \setminus \bar{S}_1^i$ that are packed into bins of size at least $\frac{b_i}{\varepsilon^6}$. The value $D_{i,k}$ is now defined for values of i, k such that $\mathcal{L}_i$ is not good, and $b_k \geq b_i$. We let $D_{i,k}$ be the sum of sizes of the items of $\mathcal{L}_i \setminus \bar{S}_1^i$ that are packed into bins of type k as small items for these bins. For other values of i, k we let $D_{i,k} = 0$. We associate a total size of (at most) $6\varepsilon^{10}D_{i,k}$ of sand created from items of $\mathcal{S}^i$ with these items and, specifically, for every item in $\mathcal{L}_i \setminus \bar{S}_1^i$ packed in a bin of type k such that $D_{i,k} > 0$, which has size x, we associate a total size of sand of $6\varepsilon^{10}x$, which is a part of the sand resulting from $\mathcal{S}^i$. This is done unless the amount of sand that is not associated with any items is smaller, and in this case we associate the remainder and stop. Due to Lemma 7, every portion of the sand is associated with some item. For every bin size b_i, the total size of sand associated with items packed in these bins is therefore at most $6\varepsilon^{10}N_ib_i$. Thus this sand can be packed into the new bins.

We now replace the $\bar{S}_j^k$ items by S_{j+1}^k items. We have a solution for the rounded items, where all items are packed, but some items that are packed as small (not all of them) are seen as sand. We say that an item j is *tiny* for bin i if the smallest bin that can be used for packing j has size b_k such that $b_k < \varepsilon^6 b_i$. We next convert all items that are packed as tiny items for their bins into sand. We would like to convert the total amount of sand in a bin of type k to be an integer multiple of $\varepsilon^6 b_k$. Given a bin with a total amount of sand which is Δ, we keep an amount of $\Delta' = \lfloor \frac{\Delta}{\varepsilon^6 b_k} \rfloor \varepsilon^6 b_k$ and move the remainder of total size $\Delta - \Delta'$ to the new bins of this type. The total size of sand that these new bins need to accommodate increases to at most $6\varepsilon^{10}N_kb_k + \varepsilon^6 b_k N_k \leq 2N_k\varepsilon^6 b_k$. Thus the new bins have enough space to accommodate these items. Empty bins are removed from the solution.

The cost of the current solution is at most $(1 + 3\varepsilon^2 + 2\varepsilon^6)\text{OPT}_n + \frac{1+\varepsilon}{\varepsilon}$. We show a path in the graph with at most the cost of the current solution.

In order to proceed, we identify a subset of the vertex set U as follows. Consider a vertex u of level i. We define a set of indices $J(u) \subseteq B_i$ as follows. For every $k \in B_i$, $k \in J(u)$ if and only if the items of $\mathcal{S}^k$ are packed in separate bins, i.e., if $\mathcal{L}_k$ is good. The set U is defined to contain the vertex u if and only if $I(u) = J(u)$. We also define $t \in U$.

Then, $a \in U$ by definition, we start the path in a and proceed to define the path edge by edge until t is reached. We show a path in the induced subgraph of G over U whose cost is at most the cost of the current solution.

Since the number of layers in a level of the graph is $3n + 1$ (corresponds to the packing of at most $3n$ bins), we show that for all values of k, the number of bins of type k in the current solution never exceeds $3n$. Clearly, $N_k \leq n$, since OPT_n packs at least one item in every bin. Therefore, we get $N_k + \lceil 2N_k\varepsilon^6 \rceil \leq N_k(1 + 2\varepsilon^6) + 1 \leq 3n$.

We are ready to construct the path. The first vertex in the path is a. At each step, we need to show which edges are traversed inside levels and which edges are used between levels.

When we reach a first vertex of a level, we traverse an edge for every bin, except for bins of the solution that contain single items of $\mathcal{S}_i$. The cost of these bins is added to the cost of the path in the edges of the third, fourth, and fifth type. For a given bin f, denote by Δ the total size of the items that are tiny items for a bin of type i, which are packed into this bin. Recall that Δ is an integer multiple of $\varepsilon^6 b_i$, unless this is the last bin of sand. If there is at least one item in the bin that is not sand, we further calculate the number ν_j^k of items from S_j^k for all $k \in B_i$ and for all $j \geq 1$. Then we use in our path an edge of pattern $(n_{slot} = \frac{\Delta}{\varepsilon^6 b_i}, (n_j^k = \nu_j^k))$. For every bin which contains only sand, we traverse an edge of pattern $(n_{slot} = \frac{1}{\varepsilon^6}, (n_j^k = 0))$. The edges that are traversed are those that decrease n_{slot} by the largest possible value (i.e., by $\frac{1}{\varepsilon^6}$, unless n_{slot} is smaller than this value at some point, and then it becomes zero in the next vertex).

The remaining edges connecting vertices inside level i will be the zero cost edges.

Next, we need to define the edges we traverse that connect levels. However, since we use only the subset U of vertices, there is a unique edge connecting the last vertex we reached in a level to a vertex of the next level. For an outgoing edge (u, v) the label of v is defined by the label of u and the vertex set U. Therefore, there is a unique edge left for every u.

Therefore, this identifies a path in the network. The cost of the path up to the last layer of level 1 is identical to the cost of the adapted solution.

Finally, we need to show that the path reaches vertex t. Since there is one-to-one correspondence between the location of items, which are defined to be packed not as tiny items, in the packing and in the path, we need to consider items that are packed as tiny. That is, we need to show that in the last vertex of the last level which we defined for the path, the value of n_{slot} is zero.

Since the sum of items that are to be packed as tiny in the graph is only rounded down and never rounded up, the space in the solution that is used for sand is large enough to pack these items. In the packing, the total size of sand in a bin of type k is always an integer multiple of $\varepsilon^6 b_k$, except for possibly the last bin, which contains only sand. However, we allow the edge of the graph that corresponds to this bin to use the complete bin for sand, which may only result in allocation of additional space for items that are packed as tiny.

Denote by $\mathcal{G}$ the set of indices i such that $\mathcal{L}_i$ is good. Then, we note that nontiny items in OPT_n that are not in $\cup_{i \notin \mathcal{G}} \mathcal{S}^i$ are transformed to sand if and only if they are tiny, and the items in $\cup_{i \notin \mathcal{G}} \mathcal{S}^i$ are transformed to sand (items in $\cup_{i \in \mathcal{G}} \mathcal{S}^i$ are not transformed to sand). □

We next need to consider the path $\mathcal{P}$ that the algorithm finds. For this path we show how a packing is created and bound its cost.

Clearly, the cost of $\mathcal{P}$ is at most the cost of $\tilde{\mathcal{P}}$.

Since the total cost of the bins corresponding to the patterns that belong to $\mathcal{P}$ is at most the total cost of $\tilde{\mathcal{P}}$, we conclude that the total cost of $\mathcal{P}$ is at most $(1+3\varepsilon^2+2\varepsilon^6)\text{OPT}_n + \frac{1+\varepsilon}{\varepsilon}$. We denote the total cost of $\mathcal{P}$ by $c(\mathcal{P})$. Since the total cost of the solution is partitioned into the total cost of the path $\mathcal{P}$ and the total cost of the small item bins of type i for all i, in order to prove that our scheme is an APTAS, it suffices to show that the total cost of the small item bins is at most $\varepsilon^4 c(\mathcal{P}) + \frac{2}{\varepsilon}$.

LEMMA 13. *The total cost of the small item bins is at most* $\varepsilon^4 c(\mathcal{P}) + \frac{2(1+\varepsilon)}{\varepsilon}$.

Proof. We first prove that items packed as tiny items of bins of type i are of size at most $\varepsilon^5 b_i$. To prove this it is enough to show by induction that for every level i, the items that were supposed to be packed as tiny in levels $1,\ldots,i$ as implied by the selected path can indeed be packed in such bins. These are items that are large for bins $i+1,\ldots,r$ but are not packed as large items there according to the path, and items that belong to some set S_1^ℓ that are supposed to be packed as tiny in bins of types $1,\ldots,i$. The claim must hold for $i=0$ before any tiny items are packed, since no such items exist. Assume that the claim holds for a level $k-1$. This means that the items that need to be packed in level k or in smaller bins are no larger than $\varepsilon^5 b_k$. The loss of a factor of ε (i.e., the reason that we consider $\varepsilon^5 b_k$ and not $\varepsilon^6 b_k$) is due to the fact that levels are partitioned into phases and we may allow a large item for a bin of type k to be packed in bin of type k as tiny, if its size is at most $\varepsilon^5 b_k$ and it is supposed to be packed as tiny in a bin. This happens only if it belongs to some set S_1^ℓ where $c_\ell < \varepsilon^8 c_k$.

The edges of the path assign spaces for the sum of all items (in terms of sand) except an amount that was lost when rounding down was applied. Such rounding for the current level was applied at most 37 times; one such time is in the calculation of the total number of slots needed for the tiny items. The other times were applied on the information on items that had to be packed as tiny, but were not small enough just yet, which were kept in six components. Each such component is updated at most six times (it is changed only between phases and not between every pair of levels) before it is added to the total number of tiny items.

Thus by increasing the space, reserved for items which are packed as tiny in this level, to $\varepsilon^6 b_k(\mu_k+37)$, the allocated space is large enough for the items if they are packed as sand.

We conclude that here may be an additional amount of sand at most $37\varepsilon^6 b_k$. Thus, if we make sure that at least this total sum of items can always be packed in bins of level $k+1$ (unless all tiny items are packed, and no additional tiny items remain to be packed into smaller bins), the inductive claim is proved. We need to take into account that the real items are not sand but are of size at most $\varepsilon^5 b_k$.

If no new bins for small items are opened in level k we are done, since this means that all remaining unpacked items are packed. Assume therefore that in level k, at least one bin for small items was opened. When the items are packed greedily into the existing bins, the space that is reserved in each bin is filled except for possibly a remainder of size at most $\varepsilon^5 b_i$ in a bin of size b_i. The reason is that some item of size at most $\varepsilon^5 b_i$ did not fit in it. This is true for the original bins as well as for the new bins.

The total size of tiny items that can be packed into the original bins of this level is therefore at least $\varepsilon^6 b_k \mu_k - \varepsilon^5 b_k R_k$, where R_k is the number of edges in the path which belong to level k and correspond to nonempty patterns. After the original bins are used, new ones are opened, where each new one is opened only after a previous bin is full up to a level of at least $b_k - \varepsilon^5 b_k$. Thus, if we keep opening

bins until all required items are packed, the number of additional bins is at most $\lceil \frac{\varepsilon^5 b_k R_k + 37\varepsilon^6 b_k}{b_k - \varepsilon^5 b_k} \rceil \leq \varepsilon^5(1+\varepsilon)(R_k + 37\varepsilon) + 1 \leq R_k\varepsilon^5(1+\varepsilon) + 2$. The inequalities hold since $\varepsilon < \frac{1}{100}$. Since the algorithm opens this number of bins, we can conclude that it succeeds to pack all required items. The claim is therefore proved for level k.

We next calculate the additional cost, on top of the cost of the path. Since $\sum_{i=1}^{r} c_i \leq \sum_{i=1}^{r} \frac{1}{(1+\varepsilon)^i} \leq \frac{1+\varepsilon}{\varepsilon}$, we conclude that if we ignore the last two *small item bins* of each type i and consider only the remaining small item bins, it suffices to show that the total cost of these bins is at most $\varepsilon^4 c(\mathcal{P})$. However, this holds since the original cost is at least $\sum_{i=1}^{r} R_i c_i$ (recall that R_i is the number of edges of the first type inside level i that contain some tiny items), and the additional cost is $\sum_{i=1}^{r} \varepsilon^5(1+\varepsilon)(R_i c_i) \leq \sum_{i=1}^{r} \varepsilon^4(R_i c_i)$ (since $\varepsilon(1+\varepsilon) < 1$). ∎

We next show our main result of this paper, i.e., that our scheme is an APTAS for GCVS.

THEOREM 14. *The main scheme is an APTAS for GCVS.*

Proof. Recall that ε is a fixed positive constant. Then, by Corollary 11, finding a feasible solution based on our scheme can be done in polynomial time. It remains to bound the performance guarantee of our algorithm.

By Lemmas 4, 12, and 13, we conclude that the total cost of the solution is at most $(1+\varepsilon^4)((1+3\varepsilon^2+2\varepsilon^6)\text{OPT}_n + \frac{1+\varepsilon}{\varepsilon}) + \frac{(1+\varepsilon)}{\varepsilon^{17}} + \frac{2(1+\varepsilon)}{\varepsilon} \leq (1+4\varepsilon^2)\text{OPT}_n + \frac{8}{\varepsilon^{17}}$ (since $\varepsilon < \frac{1}{100}$). By Lemma 3, $\text{OPT}_n \leq (1+3\varepsilon)\text{OPT}$, and, therefore, the cost of the solution returned by the scheme is at most $(1+4\varepsilon^2)(1+3\varepsilon)\text{OPT} + \frac{8}{\varepsilon^{17}}$. Taking the value of OPT before applying Lemma 2 the performance guarantee increases to $(1+4\varepsilon^2)(1+3\varepsilon)(1+\varepsilon)\text{OPT} + \frac{8}{\varepsilon^{17}}$. The claim follows from $(1+\varepsilon)(1+4\varepsilon^2)(1+3\varepsilon) \leq 1+6\varepsilon = 1+O(\varepsilon)$ (since $\varepsilon < \frac{1}{100}$) and from $\frac{8}{\varepsilon^{17}} = O(1)$. ∎

7. Concluding remarks. We showed how to obtain an APTAS for the variant of variable-sized bin packing where the cost of a bin of size b_i is a general cost and not necessarily b_i. In order to establish our scheme we needed to reduce the problem using Lemmas 2 and 3. We note that even though the reduction in Lemma 2 uses standard tricks, the property of the nice solution is a novel method and is the crucial tool in the construction of our scheme. It is clear that the notion of a nice solution is the main combinatorial structure that allowed us to reduce the time complexity of the scheme into a polynomial scheme. We argue that similar approaches can provide generalizations of approximation results for unweighted problems into approximations for weighted variants (using different notions of nice solutions that would be tailored per problem).

BINARY SPACE PARTITIONS FOR AXIS-ALIGNED FAT RECTANGLES*

CSABA D. TÓTH†

Abstract. It is shown that for any n disjoint axis-aligned fat rectangles in three-space there is a *binary space partition* (BSP) of $O(n \log^8 n)$ size and $O(\log^5 n)$ height and it can be constructed in $O(n \operatorname{polylog} n)$ time. This improves earlier bounds of Agarwal et al. [*SIAM J. Comput.*, 29 (2000), pp. 1422–1448]. On the other hand, for every $n \in \mathbb{N}$, there are n disjoint axis-aligned fat rectangles in $\mathbb{R}^3$ such that their smallest axis-aligned BSP has $\Omega(n \log n)$ size.

Key words. binary space partition, convex partition, fat objects, axis-aligned rectangles

1. Introduction.

For a set of input objects in the Euclidean space, a *binary space partition* (BSP) is a recursive cutting scheme that dissects the space along hyperplanes into convex cells and, in the meantime, dissects the input objects as well. A BSP corresponds to a data structure, called a *BSP tree*, that stores all cutting hyperplanes and the final fragments of the input objects. Initially, the BSP tree data structure was designed for efficient hidden-surface removal from a moving viewpoint by Fuchs, Kedem, and Naylor [16] based on ideas of Schumacker et al. [22] in the computer graphics community. Ever since, BSPs have found innumerable applications in robotics [7], shadow generation [8, 9], solid modeling [23], graph drawing [6], network design [18], collision detection [2, 3], range counting [13], point location [5, 10], and in many other fields.

The efficiency of most applications depends crucially on the space complexity of the underlying BSP tree. The *size* of a BSP is the total number of fragments into which the input objects are partitioned. The BSP size gives an upper bound on the number of leaf nodes in the BSP tree if the BSP does not make redundant cuts; i.e., the cutting hyperplane always partitions the convex hull of the objects. Ideally, none of the input objects are cut during the partitioning, and the BSP size equals the number of input objects. In many cases, however, it is inevitable that input objects are also fragmented, and the size of the BSP becomes superlinear. There are configurations where the smallest BSP for n disjoint convex objects (for instance, line segments in three-space [14]) has $\Theta(n^2)$ size, which is often prohibitive for applications. The *height* of a BSP is the height of the corresponding BSP tree. *Balanced* BSP trees are important for some applications, such as ray tracing and solid modeling, and for the efficient construction of the BSPs [4].

After numerous heuristic algorithms constructing small size BSPs [16, 19, 23], Paterson and Yao [20] were the first to study their combinatorial properties. They showed that for any n disjoint line segments in the plane there is a BSP of $O(n \log n)$ size and $O(\log n)$ height. The currently known best lower bound is $\Omega(n \log n / \log \log n)$ [24].

Paterson and Yao [20] showed that n disjoint triangles in three-space always have a BSP of $O(n^2)$ size and $O(n)$ height. There is a set of n disjoint triangles (each having one side along a hyperbolic paraboloid) for which every BSP has $\Omega(n^2)$ size [14]. The best currently known upper bound for the BSP size of disjoint $(d-1)$-dimensional simplices in $\mathbb{R}^d$, $d \geq 3$, is $O(n^d)$.

Theoretical research focused on object classes where near linear size BSP is possible. There is an $O(n)$ size BSP for n disjoint segments in the plane if they have a constant number of distinct orientations [25], if the ratio of the longest and the shortest segment is bounded by a constant [12], or if they are convexly independent (every line segment has an end point along the convex hull) [12].

Paterson and Yao [21] constructed a BSP of $O(n^{3/2})$ size and $O(\log n)$ height for n disjoint *axis-aligned* objects in $\mathbb{R}^3$. They also showed that this bound is tight in the worst case apart from a constant factor. Dumitrescu, Mitchell, and Sharir [15] extended this result and proved an upper bound of $O(n^{d/(d-k)})$ on the BSP size of n disjoint axis-aligned k-dimensional boxes in $\mathbb{R}^d$, $1 \leq k \leq d-1$. This bound is tight for $k < d/2$. For $d/2 \leq k < d-1$, only one tight bound is known currently: there is an $O(n^{5/3})$ size an $O(\log n)$ height BSP for n disjoint axis-aligned (2-dimensional) rectangles in four-space [15]. Results of Dumitrescu, Mitchell, and Sharir, combined with ideas of Paterson and Yao, imply an $O(n^{d/2})$ upper bound on the minimal size of a BSP for disjoint axis-aligned boxes in d-space [17].

Disjoint fat objects also have small size BSPs in some cases. We say that a k-dimensional object r is *fat* if the ratio of side length of the smallest enclosing cube and the largest inscribed cube in the affine k-dimensional space spanned by r is at most a constant.[1] If this constant is $\alpha \geq 1$, then r is said to be *α-fat*. Specifically, every line segment is 1-fat, and the aspect ratio of every α-fat rectangle is at most α. De Berg [10] constructed an $O(n)$ size BSP for n *full-dimensional* fat objects of constant combinatorial complexity (e.g., fat boxes) in $\mathbb{R}^d$ for any dimension $d \in \mathbb{N}$. This technique can be generalized, and it leads to linear size BSPs for a wider class of input sets, such as *uncluttered scenes* [10] and *guardable scenes* [11]. None of these results gives a bound for $(d-1)$-dimensional or lower-dimensional fat polygonal objects in $\mathbb{R}^d$, $d \geq 3$.

Agarwal et al. [1] studied BSPs for n disjoint *axis-aligned* fat rectangles in three-space. They have constructed a BSP of $n2^{O(\sqrt{\log n})}$ size and $O(\log n)$ height in $n2^{O(\sqrt{\log n})}$ time. Our main result improves upon this bound.

THEOREM 1. *For every set of n disjoint axis-aligned fat rectangles in $\mathbb{R}^3$, there is a BSP of $O(n \log^8 n)$ size and $O(\log^5 n)$ height. Such a BSP can be computed in $O(n \log^{12} n)$ time and $O(n \log^8 n)$ space.*

If the input rectangles are α-fat, $1 \leq \alpha \leq n$, then our proof gives a BSP of $O(n\alpha^4 \log^8 n)$ size and $O(\log^5 n)$ height. Our proof is constructive; we present an explicit algorithm to compute a BSP for fat rectangles. In our algorithm, every partition hyperplane is axis-aligned (i.e., parallel to $(d-1)$ coordinate axes). Such a BSP is called an *axis-aligned BSP*. We complement our upper bound with a lower bound construction and present a set of n disjoint axis-aligned fat rectangles in $\mathbb{R}^3$ that requires a $\Omega(n \log n)$ size axis-aligned BSP.

THEOREM 2. *For every $n \in \mathbb{N}$, there are n pairwise disjoint axis-aligned squares in $\mathbb{R}^3$ such that any axis-aligned BSP for them has $\Omega(n \log n)$ size.*

[1] Fat objects are usually defined in terms of enclosing and inscribed *disks*. Our definition, in terms of *cubes*, is more convenient for our analysis of axis-aligned objects, and it is equivalent to the usual definition (with a possibly different constant).

That is, the minimal size of an axis-aligned BSP for n disjoint axis-aligned fat rectangles in $\mathbb{R}^3$ is always $O(n \log^8 n)$ and it is sometimes $\Omega(n \log n)$. No attempts were made to optimize the degree of the polylogarithmic factors; it is left open for future research.

The and remainder of the paper is organized as follows. In section 2, we define several BSP schemes. We distinguish between different types of axis-aligned rectangles with respect to an axis-aligned box in section 3. We present a hierarchy of recursive partition schemes for special classes of axis-aligned fat rectangles in section 4. Based on these building blocks, we prove Theorem 1 in section 5. We present our lower bound construction and prove Theorem 2 in section 6. Finally, we conclude with some conjectures in section 7.

2. Preliminaries: BSP schemes and BSPs. We start with defining a slightly more general partitioning procedure than the classical BSP. A *binary space partition scheme* (*BSP scheme*) is a recursive partitioning algorithm for a pair (R, C) of an input set R of objects lying in an open bounding volume C. The volume C is called the *cell* associated with the input. (If C is not given with the input set R, then C may be considered as the entire space, a convex hull, or a bounding box of the input.) Unless the input satisfies an *end condition*, the cell C is split along a hyperplane h into two open subcells C_1 and C_2, and then a BSP scheme is applied recursively for (R_1, C_2) and (R_2, C_2), where $R_i = \{r \cap C_i : r \in R\}$, $i = 1, 2$, is the set of object fragments clipped to the subcell C_i. (Notice that the fragments lying *in* the hyperplane h are not fragmented any further.)

A classical BSP is, in our terminology, a BSP scheme with a specific end condition. A cell C is partitioned until the input consists of at most one full-dimensional and no lower-dimensional input object. Specifically, for rectangles in three-space, the end condition requires that the input is *empty*.

Every BSP scheme naturally corresponds to a binary tree. Every node v of the tree corresponds to a subproblem (R_v, C_v): the root corresponds to the initial input $R = R_0$ and its bounding volume C_0. The two children of a nonleaf node v correspond to the two subproblems in the two open subcells of the spitting hyperplane h_v. The BSP scheme can be encoded (or stored) in a data structure, called a *BSP tree*, based on this binary tree: every nonleaf node stores a splitting hyperplane and all fragments of k-dimensional input objects, $k < d$, lying on the splitting plane. Every leaf node stores at most one fragment of a full-dimensional input object, which is the input of the corresponding subproblem (for an input of rectangles in three-space, the leaf nodes do not store any fragment).

The size of a BSP scheme is the total number of fragments of input objects stored in the corresponding BSP tree. If the BSP scheme does not make *redundant cuts*, i.e., if every splitting plane partitions the convex hull of the input objects, then the size of the BSP scheme is an upper bound on the number of nonleaf nodes of the BSP tree. Our explicit algorithms can be implemented with no redundant cuts (cf., Lemma 4), and so our bounds on the size of various BSP schemes lead to the same asymptotic bounds on the size of a corresponding BSP trees.

Every BSP scheme defines a *subdivision* of the input volume C. The subdivision of a BSP scheme is the collection of nonoverlapping cells corresponding to the leaf nodes of the BSP tree. The cells in the subdivision jointly tile the volume C.

Colorful BSPs. We have defined the classical BSP as a BSP scheme with a specific end condition. The (classical) BSP terminates when every subproblem consists of at most one full-dimensional object. In our algorithms, we use another

BSP scheme: a *colorful binary space partition* is defined as a BSP scheme where some input object is colored, each object with at most one color, and the end condition is satisfied if and only if in each subproblem no two objects have different colors. A (classical) BSP for the complete input is, of course, a colorful BSP. A colorful BSP, however, may have a smaller size than a BSP (i.e., it may dissect the input into much fewer fragments).

Overlays of BSPs. We define a powerful tool to concatenate several BSP schemes while keeping the total size small. Consider two BSP schemes P_1 and P_2 (their inputs (R_1, C_1) and (R_2, C_2) may be different, and their end conditions may also be different). For $i = 1, 2$, let $T(P_i)$ denote the BSP tree of P_i, and let $\mathcal{L}_i$ denote the subdivision of P_i. Assume C_2 can be tiled with cells of $\mathcal{L}_1$ (i.e., the closure of C_2 is the union of the closures of some cells of $\mathcal{L}_1$).

The *overlay* BSP scheme $P_1 \circ P_2$ is defined for the input $(R_1 \cup R_2, C_1)$ as follows. First $P_1 \circ P_2$ performs P_1; then in each cell $L \in \mathcal{L}_1$, independently, it performs P_2 restricted to L. Technically, in each cell $L \in \mathcal{L}_1$, we run P_2 on the input set $(\{r \cap L : r \in R_2\}, L)$ and partition L with the splitting planes of P_2 recursively. See Figure 1 for an example in the plane.

For a set A of objects, we also define the *restricted overlay* BSP scheme $P_1 \circ_A P_2$, which first performs P_1; then in each cell $L \in \mathcal{L}_1$ that contains a portion of some object in A, it performs P_2 restricted to L (while cells $L \in \mathcal{L}_1$ that are disjoint from A are not partitioned any further).

We obtain the BSP tree $T(P_1 \circ P_2)$ by appending to every leaf node $v \in T(P_1)$ the BSP tree obtained when we perform the binary partition P_2 restricted to the tile $C_v \in \mathcal{L}_1$ until the end condition of P_2 is satisfied in each subproblem. Notice that the subdivision corresponding to the overlay BSP scheme $P_1 \circ P_2$ satisfies the end conditions of both P_1 and P_2. More importantly, if P_1 is a (classical) BSP *for a set R_1 of $(d-1)$-dimensional objects*, then P_2 does not partition any object in R_1 because they all lie on the boundaries of the tiling $\mathcal{L}_1$. Intuitively, P_1 *eliminates* the objects in R_1 from further fragmentation. Similarly, if P_1 is a colorful BSP for a set A of red objects and a set B of blue objects, and P_2 is a (classical) BSP for A, then the splitting planes of P_2 cannot partition any blue objects in $P_1 \circ_A P_2$. We will use these properties in our algorithms.

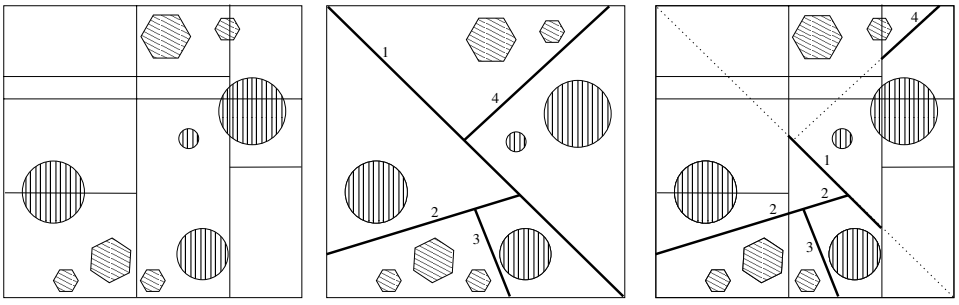

FIG. 1. *An example with an axis-aligned BSP scheme P_1 (whose input objects are not shown in the figure) and a colorful BSP P_2 for a set of disks and hexagons (shown in the figure). (Left) The axis-aligned subdivision $\mathcal{L}_1$ and the input objects of R_2 in their common bounding box $C_1 = C_2$. (Middle) The subdivision $\mathcal{L}_2$ produced by P_2. (Right) The subdivision produced by the overlay BSP scheme $P_1 \circ P_2$. Redundant cuts made by the overlay BSP scheme are drawn with dotted lines.*

The overlay $\bigcirc_{i=1}^{k} P_i = P_1 \circ P_2 \circ \cdots \circ P_k = (\ldots((P_1 \circ P_2) \circ P_3) \circ \cdots \circ P_k)$ of k BSP schemes is obtained by successively overlaying the partition schemes $P_1, P_2, \ldots, P_k$. Let us point out an immediate consequence of our definition.

PROPOSITION 3. *Consider k BSP schemes $P_1, P_2, \ldots, P_k$. The height of the overlay $\bigcirc_{i=1}^{k} P_i$ is no more than the sum of the heights of $P_1, P_2, \ldots, P_k$.*

Redundant cuts of overlays. Even if neither of the BSP schemes P_1 and P_2 makes redundant cuts, the overlay $P_1 \circ P_2$ may perform redundant cuts (e.g., along the dotted lines in Figure 1, right).

Recall that the number of nodes in the BSP tree is proportional to the number of fragments of the input objects only if the BSP makes no redundant cuts. Since we want to use the fragmentation of the objects to measure the size of our data structure, we need to filter out all redundant cuts. This can be easily done by simply skipping all redundant cuts.

LEMMA 4. *Given a BSP scheme P for an input (R, C) that partitions R into a set F of fragments and has height H (but possibly makes redundant cuts), we can construct a BSP scheme P' for (R, C) that has the same end condition as P, partitions R into the same set F of fragments, has height at most H, and makes no redundant cuts.*

Proof. We construct P' by performing the cuts made by P but skipping redundant cuts. We use the following auxiliary data structure: for every intermediate cell C of P, we create an open convex volume $\hat{C} \subseteq C$ that contains all portions of the input objects clipped to C (i.e., $\{r \cap C : r \in R\} \subset \hat{C}$). We construct the cells $\hat{C}$ and the BSP scheme P' as the partitioning algorithm P progresses. If P performs a redundant cut that splits a cell C into subcells C_1 and C_2 such that $\{r \cap C : r \in R\} \subset C_1$, then P' does nothing, but we put $\hat{C}_1 := \hat{C} \cap C_1$ and $\hat{C}_2 = \emptyset$ (in fact, we can remove C_2 from further consideration). If P performs a nonredundant cut that splits a cell C into subcells C_1 and C_2 along a hyperplane h, then we look up the (unique) cell C' at the current level of partition of P' that contains $\hat{C}$ and make P' partition C' along h into subcells C'_1 and C'_2, and we put $\hat{C}_1 := \hat{C} \cap C_1$ and $\hat{C}_2 := \hat{C} \cap C_2$.

Note that by skipping redundant cuts, the cell C' of P' may be much larger than the corresponding cell C of P. Hence, the cut along h can extend beyond the cell C (in Figure 1, e.g., the cut along 3 would extend above 2). This, however, has no effect on the number of fragments of the input objects in R or whether the end condition is reached: P and P' differ only in the way they partition $C' \setminus \hat{C}$ and $C \setminus \hat{C}$ which are empty of input objects. □

In our algorithms, we sometimes overlay several BSP schemes whose input objects are the same (namely, the set of axis-aligned fat rectangles) but whose input cells are different. In this case, a *redundant cut* has the same meaning for each BSP scheme: it is a splitting hyperplane for a cell C that is disjoint from the convex hull of $\{r \cap C : r \in R\}$. In the following sections, we present explicit algorithms that may perform redundant cuts (due to overlaying several BSP schemes). These BSP schemes together with the filtering done by Lemma 4 lead to BSP trees of size proportional to the number of fragments into which the input objects are partitioned.

3. Basic properties of axis-aligned objects. An *axis-aligned box* in $\mathbb{R}^3$ is the cross product of three nonempty intervals, which we call the *extents* of the box. The lengths of the x-, y-, and z-extent of a box B are denoted by $x(B)$, $y(B)$, and $z(B)$, respectively. A box is *full-dimensional* if all three extents have nonzero length. An *axis-aligned rectangle* is a box where exactly two extents have positive lengths and one extent has zero length (i.e., it is a point). Finally, an axis-aligned rectangle is

α-*fat* (or *fat* if α is clear from the context) if its aspect ratio (the ratio of its longer and shorter positive extents) is at most a constant $\alpha \geq 1$.

If all input objects of a BSP scheme are axis-aligned, then we assume that the initial cell C_0 is the axis-aligned bounding box of the input. If C_0 is axis-aligned and every splitting plane is orthogonal to a coordinate axis, then the cell of every subproblem is an open axis-aligned box.

Shelves and bridges. The input of a subproblem (R_v, C_v) is the set of rectangles clipped to the cell C_v. Even if a rectangle r of the initial input is fat, the fragment $r \cap C_v$ clipped to C_v is not necessarily fat. In the following definition, we describe the possible positions of a fat rectangle relative to an axis-aligned cell C.

DEFINITION 5. *Consider an axis-aligned full-dimensional open box C and an axis-aligned closed rectangle r such that $r \cap C$ is nonempty. We say that r is* pass-through *for C, if an extent of r contains the corresponding extent of C. We distinguish three classes of pass-through rectangles for C (see Figure 2):*

- *r is* free *for C if both positive extents of r contain the corresponding extents of C;*
- *r is a* shelf *for C if one extent of r contains the corresponding extent of C and the other positive extent of r contains an end point of the corresponding extent of C;*
- *r is a* bridge *for C if one extent of r contains the corresponding extent of C and the other positive extent of r lies in the interior of the corresponding extent of C.*

Each type of pass-through rectangle has a specific role in our algorithms. Whenever an input rectangle r is free for an intermediate cell C of the partitioning, we split C along $r \cap C$. This partition step is called a *free cut*. It is always a nonredundant cut and it does not increase the number of fragments of the input objects.

The fragment $r \cap C$ of a fat *shelf* r can have an arbitrary aspect ratio, but we can construct an $O(n \log n)$ size BSP for any n shelves in a cell C (cf., Lemma 10). The fragment $r \cap C$ of a *fat bridge* r is not necessarily fat, either, but it preserves some properties of the fatness of r: if r is α-fat, then the extent of $r \cap C$ which is the same as the corresponding extent of C is at most α times as long as the other positive extent (which lies in the interior of that of C).

Agarwal et al. [1] proved that for n disjoint axis-aligned fat rectangles, all of which are pass-through for their bounding box C_0, there is a BSP of $O(n)$ size and $O(n)$ height. (They also give an $O(n \log n)$ size and $O(\log n)$ height BSP for such an input.) These BSPs, however, do not provide a good partitioning for a set of fat axis-aligned rectangles, in general, because they may partition a rectangle lying in the interior of C into $O(n)$ fragments, resulting in a BSP of size $O(n^2)$. We can improve

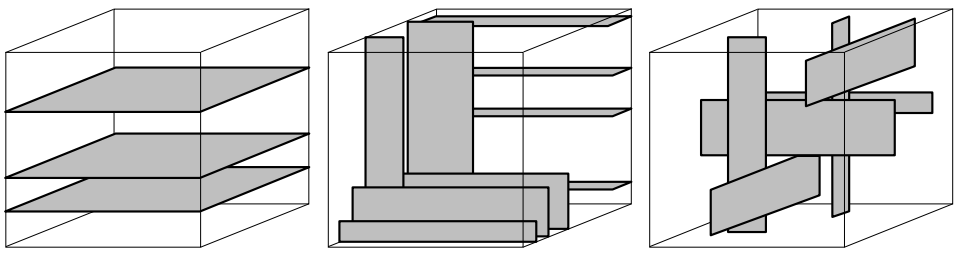

FIG. 2. *Free rectangles, shelves, and bridges clipped to an axis-aligned box.*

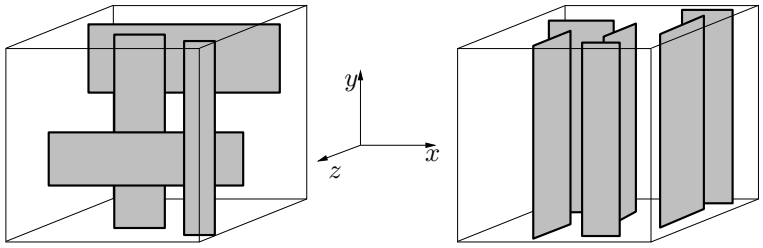

FIG. 3. *Pass-through xy-rectangles (left) and y-class pass-through rectangles (right).*

upon the upper bound $n2^{O(\sqrt{n})}$ of Agarwal et al. because we distinguish shelves and bridges. This allows us to better exploit the particular geometric properties of these objects.

Orientation of edges and rectangles. A line segment (or an edge of a rectangle) is called an x-, y-, or z-segment (x-, y-, or z-edge) if it is parallel to the x-, y-, or z-coordinate axis, respectively. The *orientation* of an axis-aligned rectangle is the pair of orientations of its edges; thus we can talk about xy-, yz-, and xz-rectangles (Figure 3). The *base* of a shelf r for a cell C is a side s of C such that the segment $r \cap s$ is the common extent of C and $r \cap C$. Every shelf for C has a unique base. All shelves based at the same side s of a cell C must have the same orientation: the orientation of every shelf based at s is different from that of s, and if two shelves r_1 and r_2 based at s had the remaining two distinct orientations, then the segments $s \cap r_1$ and $s \cap r_2$ would intersect.

For pass-through (but not free) rectangles with respect to a cell C, we distinguish three *classes* depending on their extent dimension covering that of C: a pass-through rectangle r is in the x-class for C (resp., y-class and z-class) if $x(r \cap C) = x(C)$ (resp., $y(r \cap C) = y(C)$ and $z(r \cap C) = z(C)$), i.e., the x-extent of r contains the corresponding extent of C. (Agarwal et al. [1] also distinguished these classes and called them *front*, *right*, and *top*.)

Computation of BSP size. We do not count directly the number of fragments of input rectangles in the analyses of our algorithms. Instead, we deduce a bound on the BSP size from the number of fragments of segments clipped to the input rectangles.

DEFINITION 6. *Consider a set R of disjoint axis-aligned rectangles in $\mathbb{R}^3$. For every rectangle $r \in R$ and every axis-parallel line ℓ, the line segment $\ell \cap r$ is called a* mast *of R.*

PROPOSITION 7. *Assume that we are given a set R of axis-aligned rectangles in $\mathbb{R}^3$ and an axis-aligned BSP scheme P that applies every possible free cut. If P partitions any* mast *of R into at most k pieces, then it partitions every rectangle of R into $O(k^2)$ fragments.*

Proof. The BSP scheme P restricted to an axis-aligned rectangle $r \in R$ is a 2-dimensional BSP-scheme. During the partition algorithm, only the fragments of r adjacent to the boundary ∂r may be further partitioned: if a fragment of r is not adjacent to any edge of r (see Figure 4(a)), then it is free for the cell in which it is contained, and we assume that P makes a (free) cut along every free fragment of the input.

Consider the steps of the BSP scheme that partition a fragment r' of r. Each of these steps increases the number of fragments of r by one. We distinguish two types of splitting planes: (i) The splitting plane $h \cap r'$ subdivides the common boundary

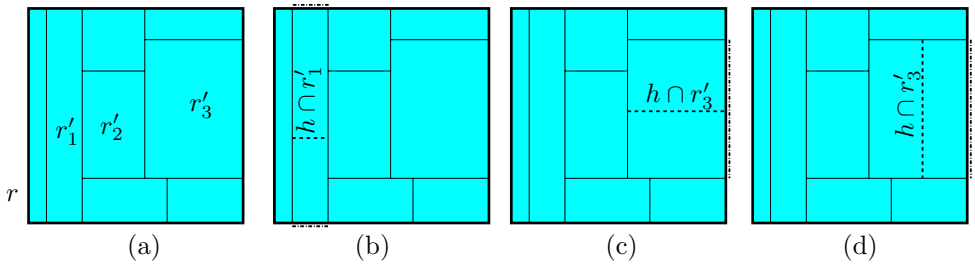

FIG. 4. *The subdivision of a rectangle r after a few steps of a partition algorithm. Fragment r'_2 of r is free* (a). *The splitting plane $h \cap r'$ subdivides the set $\partial r \cap r'$* (b) *and* (c). *The splitting plane $h \cap r'$ does not subdivide $\partial r \cap r'$* (d).

$\partial r \cap r'$ (i.e., $\partial r \cap r'$ has points on both sides of h; see Figures 4(b),(c)). Since every edge of r is subdivided into at most k fragments, at most $4k-4$ steps can partition ∂r this way. (ii) The splitting plane $h \cap r'$ partitions the fragment $r' \subset r$ but does not subdivide the set $\partial r \cap r'$ (see Figure 4(d)). In this case, $h \cap r'$ is parallel to a portion of $\partial R \cap r'$, which is part of an edge e of r. Let us project $h \cap r'$ orthogonally to such an edge e. The projections of all splitting segments of type (ii) give a multiple coverage of e. Consider a final fragment e' of an edge e of r. Note that the projection of every splitting segment either contains e' or is disjoint from e'. If e' is ℓ-fold covered, then any mast of r orthogonal to e' and having an end point on e' is partitioned into at least $\ell + 1$ pieces. Each final fragment of the four edges along ∂r is covered at most $k-1$ times, and so the number of splitting segments of type (ii) is no more than $(4k-4)(k-1)$. □

The upper bound $O(k^2)$ of Proposition 7 is optimal apart from a constant factor. An xy-rectangle might be split along x-lines into k slabs, and then each slab can be split along y-lines into k pieces, which gives a total of k^2 fragments.

4. Building blocks. We present our BSP scheme for fat axis-aligned rectangles in $\mathbb{R}^3$ in the next section. It is composed of several layers of recursive BSP schemes. In this section, we build up these layers gradually, starting with simple BSP schemes and culminating with a BSP for pass-through rectangles for a cell C. We discuss each level in a separate subsection below. In subsection 4.1, we describe how the free cuts are performed. In subsection 4.2, we present a BSP for shelves such that every mast of an input rectangle is partitioned into $O(\log n)$ pieces. In subsections 4.3 and 4.4, we present a colorful BSP separating pass-through rectangles of different classes. Finally, in subsection 4.5, we describe a BSP for z-class pass-through rectangles. All our BSP schemes and their analyses are similar; they apply recursion and partition a cell along some kind of median plane in each recursive step.

4.1. Free cuts. We construct our BSP schemes recursively, and we often have to partition every cell along all free cuts. A free cut does not increase the total number of fragments of input objects, but it increases the height of the corresponding BSP tree. Since several input rectangles may be free for the same cell, it *does* matter how we perform the free cuts.

Consider a set of n disjoint axis-aligned rectangles, and let P be an axis-aligned BSP scheme. For each cell C of the subdivision defined by P, we partition C recursively along all free rectangles of C. Since the input rectangles are disjoint, all free rectangles for C are parallel. In one recursive step, we split C along the *median* free rectangle. Therefore in $O(\log n)$ recursive calls, we eliminate all free cuts.

Let $P \triangleleft \texttt{FreeCut}(R)$ denote the BSP scheme obtained by performing the recursive free cuts described above in each cell of the subdivision of P. The BSP tree $T(P \triangleleft \texttt{FreeCut}(R))$ can be obtained from $T(P)$ by appending a binary tree of height $O(\log f(C))$ to each leaf node of $T(P)$ that corresponds to a cell with $f(C)$ free rectangles.

PROPOSITION 8. *The operation $P \leftarrow P \triangleleft \texttt{FreeCut}(R)$ does not increase the size of P, but it increases its height by $O(\log n)$.*

4.2. BSP for shelves. Given a set R of disjoint axis-aligned rectangles and an axis-aligned cell C, we present the BSP scheme $\texttt{Shelf}(R, C)$, which is a classical BSP for the set $S = \{r \cap C : r \in R \text{ is a shelf for } C\}$. That is, $\texttt{Shelf}(R, C)$ partitions the cell C recursively until every (open) subcell is disjoint from elements of S. A rectangle $r \in R$ may be a shelf for a resulting subcell $C' \subset C$, but $\texttt{Shelf}(R, C)$ eliminates all fragments of $r \cap C$ if r is a shelf *for the input cell* C.

We construct $\texttt{Shelf}(R, C)$ as an overlay of six BSPs for shelves with a common base side. Let s be a side of cell C. We may assume without loss of generality (w.l.o.g.) that s is the lower xz-side of C and the orientation of every shelf with base s is yz (see Figure 5, left). Notice that the x-coordinates of shelves with base s are distinct.

ALGORITHM 1 ($\texttt{OneShelf}_s(R, C)$).

Input: R is a set of disjoint axis-aligned fat rectangles, C is an axis-aligned cell, and s is a side of C. $S_s(C) = \{r \cap C : r \in R \text{ is a shelf for } C \text{ with base side } s\} \neq \emptyset$.

1. Permute the coordinate axes (temporarily, for the sake of this algorithm only) such that s is the lower xz-side of C and every shelf based at s is a yz-rectangle.
2. Let P be a BSP scheme that partitions C along an xz-plane h through an edge of a shelf of $S_s(C)$ with a maximum y coordinate, and then P partitions the subcell between h and s by a yz-plane along the median shelf into two cells C_1 and C_2. (See an example in Figure 5, middle.)
3. $P \leftarrow P \triangleleft \texttt{FreeCut}(R)$.
4. For $i = 1, 2$ do: If a rectangle of $S_s(C)$ intersects C_i, then $P \leftarrow P \circ \texttt{OneShelf}_{s \cap C_i}(R, C_i)$.
5. Return P.

Rounds. We analyze Algorithm 1 (and other recursive BSP schemes) in increments of work done in one level of the recursion, which we call a *round*. In the first round, the algorithm is called for the initial input cell C; the second round calls the algorithm for the cells C_1 and C_2 independently. In round i, in general, Algorithm 1 is called for up to 2^i disjoint cells, in parallel. The work done in round i includes a

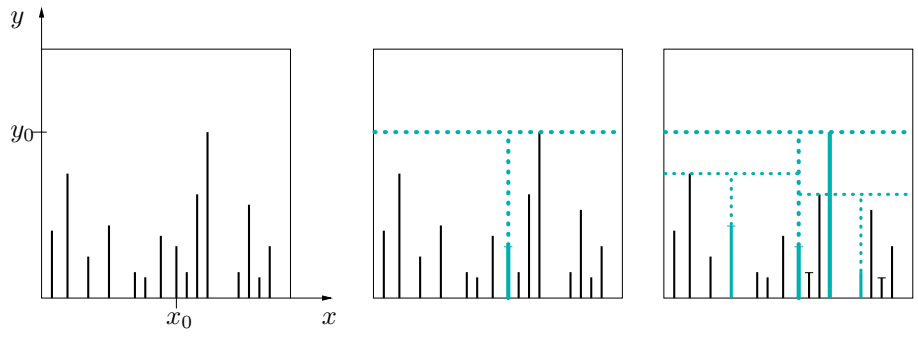

FIG. 5. *The partition done in two consecutive rounds of Algorithm* 2.

median cut and the free cuts performed in each of these cells. (Note that free cuts may partition C_1 and C_2 into several smaller subcells, yet the recursive calls are applied for C_1 and C_2.)

LEMMA 9. *If R is a set of n disjoint axis-aligned rectangles and $S_s = \{r \cap C : r \in R$ is a shelf for C with base side $s\}$ is nonempty, then $\texttt{OneShelf}_s(R, C)$ is a BSP for S_s. It partitions every mast of R into $O(\log(|S_s| + 1))$ fragments, and its height is $O(\log(|S_s| + 1) \cdot \log n) = O(\log^2 n)$.*

Proof. We analyze Algorithm 1 in rounds (increments of work done in one level of the recursion). In each round, the number of elements of $S_s(C_i)$ in a cell C_i (for which the $\texttt{OneShelf}_{s\cap C_i}(R, C_i)$ is applied) decreases by a factor of at least two. After $O(\log(|S_s(C)| + 1))$ rounds, no cell contains any fragment of $S_s(C)$ in its interior. It follows that $\texttt{OneShelf}_s(R, C)$ is a BSP for $S_s(C)$ and it terminates in $O(\log(|S_s(C)| + 1))$ rounds. By Proposition 8, its height increases by $O(\log n)$ in every round, and so its total height is $O(\log n \cdot \log(|S_s(C)| + 1)) = O(\log^2 n)$.

Consider a mast along a rectangle $r \in R$. We assume w.l.o.g. that s is the lower xz-side of C and every shelf based at s is a yz-rectangle. Since we split the cells by xz- and yz-planes in step 2, no z-segment is ever cut. Every y-mast is dissected into $O(\log(|S_s| + 1))$ fragments because it can be cut at most once in every round. Now let e be an x-mast. Consider a fragment $e \cap C_i$ in a cell C_i for which $\texttt{OneShelf}_{s\cap C_i}(R, C_i)$ is called in round j. Observe that $e \cap C_i$ can only be cut if C_i contains an end point of e in its interior: otherwise e is pass-through for C_i, and since e is disjoint from all the shelves of $S_s(C_i)$, it must lie above the highest shelf of $S_s(C_i)$. This implies that e is cut at most twice in every round, and so it is partitioned into $O(\log(|S_s(C)| + 1)) = O(\log n)$ fragments during the entire algorithm. □

By overlaying the BSP scheme $\texttt{OneShelf}_s(R, C)$ for the six sides of a cell C, we obtain a BSP for all portions of shelves for C that lie in cell C.

ALGORITHM 2 ($\texttt{Shelf}(R, C)$).

Input: R is a set of disjoint axis-aligned fat rectangles, and C is an axis-aligned cell.

1. Let J be the set of (at most six) sides of C such that $S_s(C) \neq \emptyset$ for $s \in J$.
2. Return $\bigcirc_{s\in J} \texttt{OneShelf}_s(R, C)$.

By combining Lemma 9 with Proposition 3, we obtain the following result.

LEMMA 10. *If R is a set of n disjoint axis-aligned rectangles, then $\texttt{Shelf}(R, C)$ is a BSP for the set $S = \{r \cap C : r \in R$ is a shelf for $C\}$. It partitions every mast of R into $O(\log n)$ fragments, and its height is $O(\log^2 n)$.*

4.3. A colorful BSP to separate xy-oriented y-class rectangles from the z-class. Next, we present a colorful BSP that separates the y- and z-class pass-through rectangles in a cell C under certain conditions. Consider a set R of n disjoint α-fat axis-aligned rectangles in $\mathbb{R}^3$. Let C be an axis-aligned cell such that the lengths of its three extents are ordered as $x(C) \geq y(C) \geq z(C)$.

We distinguish a *red set* $A = \{r \cap C : r \in R$ is a z-class bridge for $C\}$ and a *blue set* $B = \{r \cap C : r \in R$ is a y-class bridge for C of orientation $xy\}$ (see Figure 6). Project every rectangle $r \in A \cup B$ to the x-axis. Since the projections of red and blue pass-through rectangles do not overlap, we can subdivide the x-extent of C into intervals $x_0x_1, x_1x_2, \ldots, x_kx_{k+1}$ for some $k \in \mathbb{N}$, $0 \leq k \leq n$, such that each interval contains projections of rectangles from one color class only and any two consecutive intervals contain projections of different color classes. We define $X(R, C) = (x_1, x_2, \ldots, x_k)$ to be a sequence of such interval end points.

If we partition C by yz-planes through $x_1, x_2, \ldots, x_k$, then we separate the red and blue rectangles within C. These k yz-planes, however, might partition other

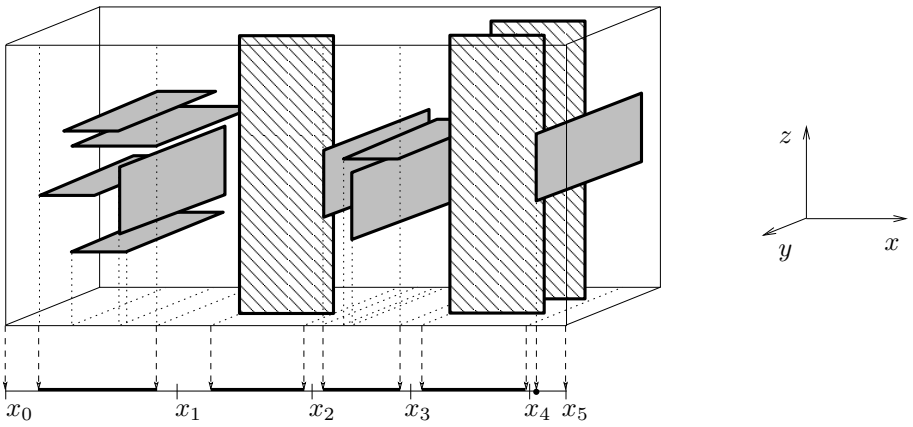

FIG. 6. *Bridges from two classes and a subdivision of the extent $x(C)$ into five intervals.*

rectangles of R into too many fragments. We can show, however, that all α-fat rectangles that intersect more than $2\alpha^2$ such yz-planes must intersect the boundary of the cell C.

PROPOSITION 11. *Consider a cell C such that $x(C) \geq y(C) \geq z(C)$. An α-fat rectangle whose y- and z-extents lie in the interior of the corresponding extents of C intersects at most $2\alpha^2$ yz-planes through points of $X(R, C)$.*

Proof. We have assumed that every *blue* bridge is an α-fat xy-rectangle. The length of the interval $x_i x_{i+1}$ corresponding to projections of blue bridges is at least $y(C)/\alpha$. The x-extent of an α-fat rectangle r whose y- and z-extents lie in the interior of the corresponding extents of C is less than $\alpha \cdot y(C)$ independently of the orientation of r because $y(C) \geq z(C)$. Therefore, r intersects fewer than α^2 intervals corresponding to blue bridges. Since the intervals correspond to red and blue bridges alternately, we conclude that r intersects less than $2\alpha^2$ yz-planes through points of $X(R, C)$. □

Based on the above observations, we may now present a colorful BSP for A and B.

ALGORITHM 3 ($\texttt{Sep2}(R, C)$).

Input: R is a set of disjoint axis-aligned rectangles, and C is an axis-aligned cell such that $x(C) \geq y(C) \geq z(C)$ and $X(R, C)$ is nonempty.

Let P be the trivial BSP scheme for (R, C) (its BSP tree $T(P)$ consists of the root only).

1. If R contains shelves for C, then $P \leftarrow P \circ \texttt{Shelf}(R, C)$.
2. $P \leftarrow P \circ M_{yz}(R, C)$, where $M_{yz}(R, C)$ is a BSP scheme that partitions C into two cells C_1 and C_2 along the yz-plane through the median element of the sequence $X(R, C)$.
3. $P \leftarrow P \triangleleft \texttt{FreeCut}(R)$.
4. For $i = 1, 2$ do: If the sequence $X(R, C_i)$ is nonempty, then $P \leftarrow P \circ \texttt{Sep2}(R, C_i)$.
5. **Return** P.

LEMMA 12. *If R is a set of n disjoint α-fat axis-aligned rectangles and $x(C) \geq y(C) \geq z(C)$, then $\texttt{Sep2}(R, C)$ is a colorful BSP for the red set $A = \{r \cap C : r \in R$ is a z-class bridge for $C\}$ and the blue set $B = \{r \cap C : r \in R$ is a y-class bridge for C of orientation $xy\}$. It partitions every x-mast of R into $O(\alpha^2 \log^2 n)$ fragments, every y- or z-mast of R into $O(\log^2 n)$ fragments, and its height is $O(\log^3 n)$.*

Proof. We analyze Algorithm 3 in rounds (increments of work done in one level

of the recursion). Since the y- and z-extents of C_1 and C_2 are the same as that of C, and $M_{yz}(R, C)$ does not partition any y- or z-bridges for C, we have $X(R, C_1) \cup X(R, C_2) \subset X(R, C)$. Since $M_{yz}(R, C)$ cuts along a median element of $X(R, C)$, we have $|X(R, C_1)| \leq |X(R, C)|/2$ and $|X(R, C_2)| \leq |X(R, C)|/2$. After $\log(|X(R, C)| + 1) \leq O(\log n)$ rounds, Algorithm 3 partitions C along yz-planes through all points of $X(R, C)$. It follows that $\texttt{Sep2}(R, C)$ is a colorful BSP for A and B and it terminates in $O(\log n)$ rounds. Every round may call $\texttt{Shelf}(R, C)$, which produces a BSP-scheme of height $O(\log^2 n)$, so the total height of P amounts to $O(\log^3 n)$.

A y- or z-mast e is never cut by a splitting yz-plane of $M_{yz}(R, C)$, and so it is in the interior of at most one cell C for which $\texttt{Sep2}(R, C)$ is called. In each round, $\texttt{Shelf}(R, C)$ is called for a cell C containing e. By Lemma 10, e is partitioned into $O(\log n)$ fragments in each round. In $O(\log n)$ rounds, the overlay of $O(\log n)$ algorithms $\texttt{Shelf}(R, C_i)$ dissects e into $O(\log^2 n)$ fragments.

Now consider an x-mast f along an input rectangle $r \in R$. First, suppose that the y- and z-extents of r lie in the interior of the corresponding extents of C. By Proposition 11, yz-planes through points of $X(R, C)$ can dissect r into at most $2\alpha^2$ pieces. Each piece is dissected into $O(\log^2 n)$ fragments by the overlay of $O(\log n)$ calls to $\texttt{Shelf}(R, C_i)$, one in each round, which gives a total of $O(\alpha^2 \log^2 n)$ fragments. Next, suppose that the y- or z-extent of r contains an end point of the corresponding extent of C. A cut $M_{yz}(R, C)$ can partition a fragment $f \cap C$ only if C contains one end point of f. If f is pass-through for C, then r is a *shelf* for C and $r \cap C$ has been eliminated by a call to $\texttt{Shelf}(R, C)$ in step 1 of the same round. In each round, $M_{yz}(R, C)$ partitions at most two fragments of f (those incident to the end points of f). In the next round, the resulting four or fewer fragments of f may be partitioned by calls to $\texttt{Shelf}(R, C)$ in step 1. So the mast f is cut $O(\log n)$ times in each round. In a total of $O(\log n)$ rounds, f is partitioned into $O(\log^2 n)$ fragments. □

4.4. A colorful BSP to separate y- and z-class rectangles. In the previous subsection, we separated y- and z-class pass-through rectangles under certain conditions. In this section, we create an environment where those conditions are satisfied, and we separate *all* y- and z-class pass-through rectangles.

We define the BSP scheme $P(\alpha, C)$ that splits C into $(\lfloor \alpha \rfloor + 1)^2$ congruent cells by $\lfloor \alpha \rfloor$ equally spaced xy-planes and by $\lfloor \alpha \rfloor$ equally spaced xz-planes (i.e., $P(\alpha, C)$ splits the y- and z-extents of C while keeping the x-extent). This can be accomplished by a BSP scheme of height $2 \log \lfloor \alpha \rfloor = O(\log \alpha)$. We denote by $\Pi(\alpha, C)$ the resulting set of $(\lfloor \alpha \rfloor + 1)^2$ cells.

PROPOSITION 13. *Consider a cell C such that $x(C) \geq y(C) \geq z(C)$. Every α-fat pass-through rectangle* for *C satisfies one of the following four conditions for every $C_i \in \Pi(\alpha, C)$:*

(i) *it is free for C_i;*
(ii) *it is a shelf for C_i;*
(iii) *it is a z-class bridge for C_i;*
(iv) *it is a y-class bridge for C_i with orientation xy.*

Proof. Consider a subcell $C_i \in \Pi(\alpha, C)$. Since the x-edge of C_i is more than α times as long as its y- and z-edges, there is no bridge for C_i in the x-class. Similarly, the y-edge of the initial cell C is more than α times as long as the z-edge of C_i; therefore, a y-class bridge for C with orientation yz cannot be a bridge for C_i. □

We partition every cell $C_i \in \Pi(\alpha, C)$ so that the x-, y-, and z-class pass-through rectangles are separated. Free rectangles can be eliminated by free cuts. By Lemma 10, the BSP scheme $\texttt{Shelf}(R, C_i)$ can eliminate shelves. By Lemma 12, the *colorful BSP*

$\texttt{Sep2}(R, C_i)$ can separate pass-through rectangles of types (iii) and (iv). We combine these algorithms to separate x-, y-, and z-class bridges, independently of the length of the three extents of the cell C. Since we use the next algorithm as a subroutine of another BSP scheme, it rotates its input cell C in a position where $x(C) \geq y(C) \geq z(C)$.

ALGORITHM 4 ($\texttt{Sep3}(R, C)$).

Input: R is a set of disjoint axis-aligned fat rectangles, and C is an axis-aligned cell.

1. Permute the coordinate axes (temporarily for this algorithm) such that $x(C) \geq y(C) \geq z(C)$.
2. $P \leftarrow P(\alpha, C)$.
3. $P \leftarrow P \triangleleft \texttt{FreeCut}(R)$.
4. For every $C_i \in \Pi(\alpha, C)$ do: If there are shelves for C_i, then $P \leftarrow P \circ \texttt{Shelf}(R, C_i)$.
5. For $C_i \in \Pi(\alpha, C)$ do: If the sequence $X(R, C_i)$ is nonempty, then $P \leftarrow P \circ \texttt{Sep2}(R, C_i)$.
6. **Return** P.

LEMMA 14. *Assume that R is a set of n disjoint α-fat axis-aligned rectangles, $1 \leq \alpha \leq n$, and C is an axis-aligned cell with $x(C) \geq y(C) \geq z(C)$. Then the BSP scheme $\texttt{Sep3}(R, C)$ is a colorful BSP for the red set $A = \{r \cap C : r \in R$ is a y-class bridge for $C\}$ and the blue set $B = \{r \cap C : r \in R$ is a z-class bridge for $C\}$; it is also a (classical) BSP for the set $\{r \cap C : r \in R$ is an x-class bridge for $C\}$. It partitions every mast of R into $O(\alpha^2 \log^2 n)$ fragments, and its height is $O(\log^3 n)$.*

Proof. By Proposition 13, a pass-through α-fat rectangle for C can have four different positions in a subcell $C_i \in \Pi(\alpha, C)$. Free rectangles are eliminated in step 3, and the shelves are eliminated in step 4. Finally, $\texttt{Sep2}(R, C_i)$ separates z-class bridges of C from y-class bridges of C with orientation xy in each subcell $C_i \in \Pi(\alpha, C)$.

The height of the BSP scheme $P(\alpha, C)$ is $O(\log \alpha)$. By Proposition 8, step 3 increases the height by $O(\log n)$. Finally, by Lemma 12 and Proposition 3, the height increases by $O(\log^3 n)$ in step 5.

Step 2 of Algorithm 4 cuts every y- and z-mast into $O(\alpha)$ fragments but does not partition any x-mast. By Lemma 12, $\texttt{Sep2}(R, C_i)$ partitions every x-mast into $O(\alpha^2 \log^2 n)$ fragments and any y- or z-mast into $O(\log^2 n)$ fragments in each $C_i \in \Pi(R, C)$. Altogether, Algorithm 4 partitions every mast (of any orientation) into $O(\alpha^2 \log^2 n) \subset O(\log^2 n)$ fragments. ∎

4.5. BSP for one class of pass-through rectangles. We are now ready to present a (classical) BSP for z-class pass-through rectangles for a cell C. Our algorithm is based on a simple intuition: we partition C recursively along xz-medians of the vertex set of the z-class pass-through rectangles. (The *xz-median* of a set of m points is an xz-plane h with a minimal y-coordinate such that the open half-space behind h contains fewer than $m/2$ points.) In order to avoid the possibility that pass-through rectangles of the y-class are fragmented into too many pieces, we separate z-class pass-through rectangles from any other classes by applying $\texttt{Sep3}(R, C_i)$ in each subcell in every round of the recursion.

ALGORITHM 5 ($\texttt{Long}(R, C)$).

Input: R is a set of disjoint axis-aligned fat rectangles, and C is an axis-aligned cell.

Let $L(R, C) = \{r \cap C : r \in R$ is pass-through for C in class $z\} \neq \emptyset$ and $V(R, C) = \{v \in \mathbb{R}^3 : v$ is a vertex of a $r \in L(R, C)$, v lies on the boundary of C but not on any xz-side of $C\}$. Let P be the trivial BSP scheme for the input (R, C).

1. If the sequence $X(R, C)$ is nonempty, then $P \leftarrow \texttt{Sep3}(R, C)$.

2. $P \leftarrow P \circ_{L(R,C)} N_{xz}(R, C)$, where $N_{xz}(R, C)$ is a BSP scheme that partitions C into two cells C_1 and C_2 along the median xz-plane of the point set $V(R, C)$.
3. $P \leftarrow P \triangleleft \texttt{FreeCut}(R)$.
4. For $i = 1, 2$, do: If $V(R, C_i) \neq \emptyset$, then $P \leftarrow P \circ_{L(R,C)} \texttt{Long}(R, C_i)$.
5. **Return** P.

LEMMA 15. *If R is a set of n disjoint α-fat axis-aligned rectangles, $1 \leq \alpha \leq n$, then the BSP scheme* $\texttt{Long}(R, C)$ *is a BSP for the set $L(R, C) = \{r \cap C : r \in R$ is pass-through for C in class $z\}$. It partitions every mast of R into $O(\alpha^2 \log^3 n)$ fragments, and its height is $O(\log^4 n)$.*

Proof. We analyze Algorithm 5 in rounds (increments of work done in one level of the recursion). Since the z-extents of C_1 and C_2 are the same as that of C, we have $L(R, C_1) \cup L(R, C_2) \subset L(R, C)$. In every round, $N_{xy}(R, C)$ decreases the number of vertices in $V(R, C)$. If $V(R, C) = \emptyset$, then every element of $L(R, C)$ is free for C, which is eliminated in step 3. It follows that Algorithm 5 is a BSP for $L(R, C)$ and it terminates in $O(\log(|V(R, C)| + 1)) = O(\log n)$ rounds. Every round may call $\texttt{Sep3}(R, C)$, which has height $O(\log^3 n)$, so the total height of P is $O(\log^4 n)$.

It remains to show that Algorithm 5 dissects every mast e into $O(\alpha^2 \log^3 n)$ fragments. First, consider an x- or z-mast e. Note that $N_{xz}(R, C_i)$ in step 2 cannot cut e, and so in every round e lies in the interior of at most one cell C_i for which $\texttt{Long}(R, C_i)$ is applied. By Lemma 14, $\texttt{Sep3}(R, C_i)$ can dissect e into $O(\alpha^2 \log^2 n)$ fragments, and so e is partitioned into $O(\alpha^2 \log^3 n)$ fragments in total.

Now consider a y-mast f. A fragment $f \cap C_i$ can be cut if C_i contains an end point of f in its interior. Otherwise f lies along a rectangle r, where $r \cap C_i$ is y-class pass-through for the cell C_i. Therefore $\texttt{Sep3}(R, C_i)$ in step 1 separated $r \cap C_i$ from elements of $L(R, C)$ (i.e., partitioned C_i into subcells whose interiors do not contain fragments of both $r \cap C_i$ and $L(R, C)$). By the definition of restricted overlay BSPs, that means that $N_{xz}(R, C_i)$ does not partition $f \cap C_i$ (in this and all recursive calls). Hence, the cuts $N_{xz}(R, C_i)$ can successively dissect f into at most $O(\log n)$ pieces. In each round, at most four pieces are partitioned by $\texttt{Sep3}(R, C_i)$ in step 2. So the mast f is cut $O(\alpha^2 \log^2 n)$ times in each round. In a total of $O(\log n)$ rounds, f is partitioned into $O(\alpha^2 \log^3 n)$ fragments. ∎

5. Binary space partition algorithm for fat rectangles. In this section we present our main algorithm, a BSP for n disjoint axis-aligned fat rectangles in three-space, and its analysis. The algorithm is based on a simple heuristic: we split the space recursively along the median xy-plane of the clipped rectangles. After each cut, fragments of input rectangles may become pass-through with respect to the resulting cells. All new pass-through rectangles belong to the z-class. In order to prevent subsequent xy-median cuts from further partitioning a pass-through rectangle, we *eliminate* all z-class pass-through rectangles. By Lemma 15, we can remove the set $L(R, C)$ of z-class pass-through rectangles by overlaying the current BSP scheme with $\texttt{Long}(R, C)$.

ALGORITHM 6 ($\texttt{Main}(R, C)$).

Input: R is a set of disjoint axis-aligned fat rectangles, and C is an axis-aligned cell. $R(C) = \{r \cap C : r \in R, r \cap C \neq \emptyset\}$ is nonempty. Initially, let P denote the trivial BSP scheme for the input (R, C).

1. If $L(R, C) \neq \emptyset$, then $P \leftarrow P \circ \texttt{Long}(R, C)$.
2. $P \leftarrow P \circ Q_{xy}(R, C)$, where $Q_{xy}(R, C)$ is a BSP scheme that partitions C into two cells C_1 and C_2 along the median xy-plane of the point set $\{v \in \mathbb{R}^3 : v$ is

a vertex of a rectangle $r \in R(C)$, and v does not lie on any xy-side of $C\}$.

3. $P \leftarrow P \triangleleft \texttt{FreeCut}(R)$.
4. For $i = 1, 2$, do: If $R(C_i) \neq \emptyset$, then $P \leftarrow P \circ \texttt{Main}(R, C_i)$.
5. `Return` P.

LEMMA 16. *If R is a set of n disjoint α-fat axis-aligned rectangles, $1 \leq \alpha \leq n$, then the BSP scheme* $\texttt{Main}(R, C)$ *is a BSP for $R(C) = \{r \cap C : r \in R, r \cap C \neq \emptyset\}$. It partitions every mast of R into $O(\alpha^2 \log^4 n)$ fragments, and its height is $O(\log^5 n)$.*

Proof. We analyze Algorithm 6 in rounds (increments of work done in one level of the recursion). In step 2, $Q_{xy}(R, C)$ decreases the number of rectangle vertices that do not lie on either xy-side of a cell by a factor of at least two. If a clipped rectangle $r \cap C$ intersects C but all its vertices lie on xy-sides of C, then r is pass-through for C in the z-class, and $\texttt{Long}(R, C)$ in step 1 eliminates it. It follows that Algorithm 6 is a BSP for $R(C)$ and it terminates in $O(\log n)$ rounds. Since $\texttt{Main}(R, C)$ calls $\texttt{Long}(R, C)$ in every round, its height is $O(\log n) \cdot O(\log^4 n) = O(\log^5 n)$.

It remains to show that Algorithm 6 partitions every mast into $O(\alpha^2 \log^4 n)$ fragments. Consider an x- or y-mast e. In step 2, $Q_{xy}(R, C)$ does not cut e. Therefore, in each round e is in the interior of at most one cell C_i for which $\texttt{Main}(R, C_i)$ is applied. By Lemma 15, each call to $\texttt{Long}(R, C_i)$ can partition e into $O(\alpha^2 \log^3 n)$ fragments. In a total of $O(\log n)$ rounds, e is partitioned into $O(\alpha^2 \log^4 n)$ fragments.

Now, consider a z-mast f along an input rectangle r. Both $\texttt{Long}(R, C_i)$ and $Q_{xy}(R, C_i)$ can dissect f, and so its fragments may lie in several cells for which $\texttt{Main}(R, C_i)$ is called in a round. A fragment $f \cap C_i$ may be dissected only if an end point of f is in the interior of C_i; otherwise, r is a z-class pass-through rectangle for C_i and was eliminated by $\texttt{Long}(R, C_i)$ in step 1. Thus in each round, step 2 may cut f twice, and $\texttt{Long}(R, C_i)$ may cut it $O(\alpha^2 \log^3 n)$ times. In a total of $O(\log n)$ rounds, f may be partitioned into $O(\alpha^2 \log^4 n)$ fragments. ∎

We are now ready to prove our main result, which we reiterate here.

THEOREM 1. *For every set of n disjoint axis-aligned fat rectangles in $\mathbb{R}^3$, there is a BSP of $O(n \log^8 n)$ size and $O(\log^5 n)$ height. Such a BSP can be computed in $O(n \log^{12} n)$ time and $O(n \log^8 n)$ space.*

Proof. Consider a set R of n disjoint α-fat axis-aligned rectangles, and let C be their axis-aligned bounding box. By Lemma 16, $\texttt{Main}(R, C)$ is a BSP for R. It partitions every mast into $O(\alpha^2 \log^4 n)$ fragments. By Proposition 7, it partitions every rectangle $r \in R$ into $O(\alpha^4 \log^8 n)$ fragments. In particular, for $\alpha = O(1)$, every rectangle $r \in R$ is partitioned into $O(\log^8 n)$ fragments, and the size of the BSP is $O(n \log^8 n)$.

Computational complexity. Our algorithm relies heavily on overlaying several simple BSP schemes. We present a simple data structure that leads to straightforward implementation of Algorithm 6 in $O(n \log^{12} n)$ time and $O(n \log^8 n)$ space. For an input of n disjoint axis-aligned rectangles, Algorithm 6 constructs a BSP tree P starting from a single root node by repeating the following operation: choose a leaf node v (corresponding to a cell C), store a splitting hyperplane h at v, and append two new leaf nodes to v (corresponding to the subcells of C on the two sides of h). In order to keep the size of the BSP tree proportional to the number of fragments of R, we also construct the variant of the main BSP algorithm that skips all redundant cuts, as described in Lemma 4.

Our data structure maintains several subdivisions of the bounding box C of the input rectangles. We maintain the subdivision of the current BSP scheme P. Besides the main BSP scheme P, we have several algorithms (namely, $\texttt{Main}(R, C)$, $\texttt{Long}(R, C)$, $\texttt{Sep3}(R, C)$, $\texttt{Sep2}(R, C)$, $\texttt{Shelf}(R, C)$, and $\texttt{OneShelf}(R, C)$), which are applied in

each round to a family of disjoint cells. Initially all of these algorithms are applied in the bounding box C of the input R, but later they are applied in cells of different subdivisions. For each of these algorithms, we maintain the set of cells in which these algorithms are applied in the current level of recursion and which contain some portions of input objects. Since R is partitioned into $O(n \log^8 n)$ fragments, this is an upper bound on the number of cells that we need to store at any point in our algorithm for each subdivision.

For every cell C in every subdivision that contains any fragment of an input object, we maintain the set $R(C) = \{r \cap C : r \in R, r \cap C \neq \emptyset\}$ of clipped rectangles and the axis-aligned bounding box $\hat{C}$ of $R(C)$. Empty cells are discarded from any further consideration. For each clipped rectangle $r \cap C$, we store its status with respect to C (orientation; pass-through or not; if pass-through then free, shelf, or bridge; x-, y-, or z-class). We maintain a vector for C indicating if $R(C)$ contains any pass-through rectangles; x-, y-, or z-class rectangles; or shelves. From the sorted list of m clipped rectangles we can extract the sorted list of vertices of clipped pass-through rectangles, bridges, and shelves in $O(m)$ time, and so we can quickly find the median planes for the steps $M_{yz}(R, C)$, $N_{xz}(R, C)$, and $Q_{xy}(R, C)$.

Assume that the input rectangles are partitioned into N fragments in the current BSP scheme P. There are two types of operations we apply. The first type is operation $P \leftarrow P \triangleleft \texttt{FreeCut}(R)$, which partitions every cell along all free cuts. We can scan each cell C for free rectangles and partition C along all of them at once. If $R(C)$ contained m fragments, then we can extract the data structure for all of the resulting subcells in $O(m)$ time. Operation $P \leftarrow P \triangleleft \texttt{FreeCut}(R)$ can be done in $O(N)$ time.

The second type of operation corresponds to the median cuts of one round of an algorithm $\texttt{Main}(R, C)$, $\texttt{Long}(R, C)$, $\texttt{Sep3}(R, C)$, $\texttt{Sep2}(R, C)$, $\texttt{Shelf}(R, C)$, or $\texttt{OneShelf}(R, C)$. We are given a family $\mathcal{C}$ of disjoint cells, each cell $C \in \mathcal{C}$ may contain several cells of the subdivision $\mathcal{L}$ of the current BSP scheme P, and we overlay some kind of median cut $h(C)$ for each $C \in \mathcal{C}$ with P. For each cell $C \in \mathcal{C}$ and its splitting plane $h(C)$, we identify all cells in $\mathcal{L}$ that lie in C and intersect $h(C)$. For each such cell $L \in \mathcal{L}$, we decide in $O(1)$ time whether L should be partitioned along $h(C)$ or not. Since each cell of $\mathcal{L}$ is partitioned into at most two subcells, we can update the data structure in $O(N)$ time.

In total, our algorithm has $O(\log^4 n)$ rounds (the height of the BSP tree is $O(\log^5 n)$, where one $O(\log n)$ factor corresponds to the free cuts). Each round can be performed in $O(N) = O(n \log^8 n)$ time, so the total time complexity amounts to $O(n \log^{12} n)$. □

6. Lower bound. We present a set of $3n$ disjoint axis-aligned squares in $\mathbb{R}^3$ such that any axis-aligned BSP for them has $\Omega(n \log n)$ size. The $3n$ squares are grouped into three families, each of size n, as follows (refer to Figure 7):

$$A(n) = \{a_i = [3i, 3i + 3n] \times [3i - 3n, 3i] \times [3i] : i = 0, 1, \ldots, n - 1\},$$
$$B(n) = \{b_i = [3i + 1] \times [3i + 1, 3i + 1 + 3n] \times [3i + 1 - 3n, 3i + 1] : i = 0, 1, \ldots, n - 1\},$$
$$C(n) = \{c_i = [3i + 2 - 3n, 3i + 2] \times [3i + 2] \times [3i + 2, 3i + 2 + 3n] : i = 0, 1, \ldots, n - 1\}.$$

Each of the families $A(n)$, $B(n)$, and $C(n)$ consists of n parallel and pairwise disjoint axis-aligned squares. Every square has a vertex along the line $x = y = z$. Squares of different families are disjoint because any two families are separated by a plane. $A(n)$ and $B(n)$ are separated by the plane $x = y$. Similarly, $A(n)$ and $C(n)$ lie on different sides of $x = z$, while $B(n)$ and $C(n)$ are separated by $y = z$.

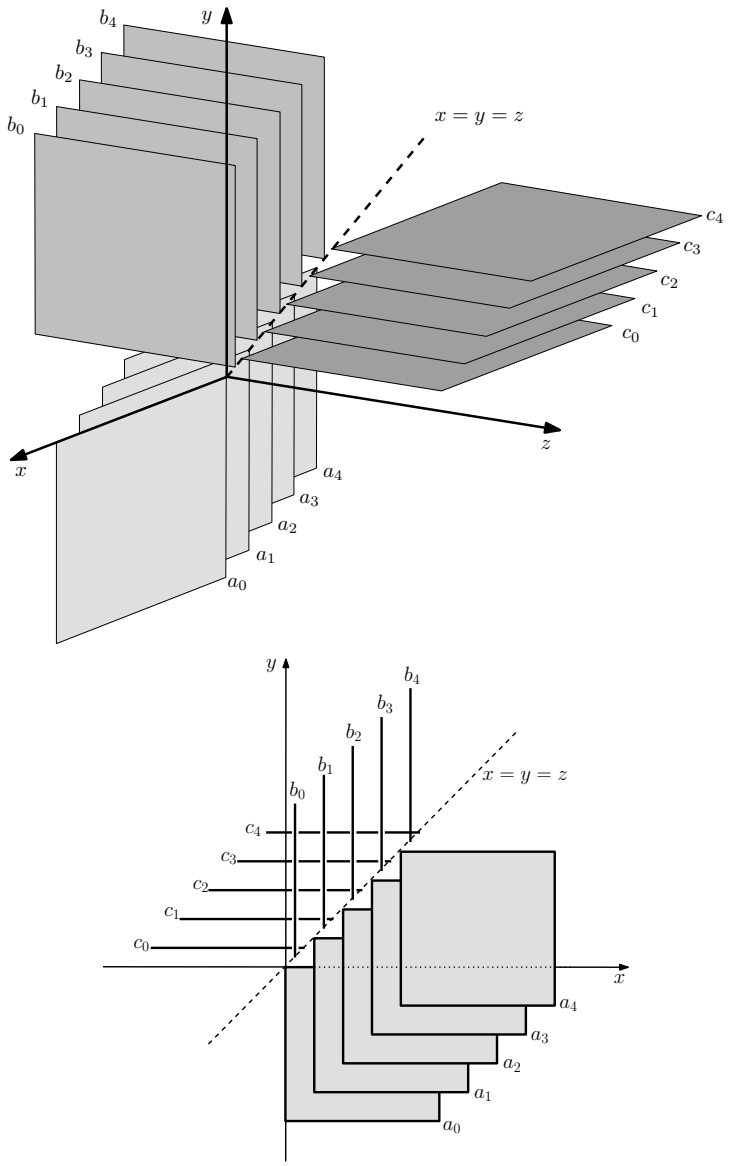

FIG. 7. *The lower bound construction for $n = 5$. View of 15 squares from the negative octant, where the dashed segment lies in the positive octant (top), and a projection to the xy-plane (bottom).*

For every $k = 1, 2, \ldots, n$, let $F(k)$ denote the set of fragments of input squares clipped in the cube $Q(k) = [0, 3k] \times [0, 3k] \times [0, 3k]$. Let $f(k)$ denote the minimum size of an axis-aligned BSP for $F(k)$. We show that the following recursion relations hold:

$$f(0) = 0, \tag{1}$$

$$f(1) \geq 1, \tag{2}$$

$$f(k) \geq k - 1 + \min_{0 \leq i \leq k-1} (f(i) + f(k - 1 - i)) \quad \text{for} \quad 2 \leq k \leq n. \tag{3}$$

The solution to this recursion is $f(n) = \Omega(n \log n)$, and so Theorem 2 follows immediately.

Inequalities (1) and (2) are obvious. For inequality (3), consider a configuration $F(k)$, $1 < k \leq n$, and suppose that an axis-aligned splitting plane h cuts the cube $Q(k)$. Suppose that h cuts the diagonal $[(0,0,0),(3k,3k,3k)]$ of $Q(k)$ at a point on the segment $[(3i,3i,3i),(3i+3,3i+3,3i+3)]$ for some $i \in \{0,1,\ldots,n-1\}$. First, we show that h cuts at least $k-1$ elements of $F(k)$. If h is an xy-plane, then it cuts $c_0, c_1, \ldots, c_{i-1}$ and $b_{i+1}, b_{i+2}, \ldots, b_{k-1}$. If h is an xz-plane, then it cuts $b_0, b_1, \ldots, b_{i-1}$ and $a_{i+1}, a_{i+2}, \ldots, a_{k-1}$. If h is an yz-plane, then it cuts $a_0, a_2, \ldots, a_{i-1}$ and $c_{i+1}, c_{i+2}, \ldots, c_{k-1}$.

Let us denote by Q_1 and Q_2 the cubes spanned by the segments $[(0,0,0),(3i,3i,3i)]$ and $[(3i+3,3i+3,3i+3),(3k,3k,3k)]$, respectively. The set of rectangles of $F(k)$ clipped in Q_1 is $F(i)$, and the set of rectangles of $F(k)$ clipped in Q_2 is a configuration congruent to $F(k-i-1)$. The cubes Q_1 and Q_2 are disjoint from h, and so the subconfigurations $F(i)$ and $F(k-i-1)$ are intact. Hence the size of the axis-aligned BSP $F(k)$ is at least $k-1+f(i)+f(k-i-1)$. This confirms inequality (3) and completes our proof.

7. Conclusion. Let $f(F_n(k,d))$ denote the minimum size of an axis-aligned BSP for a set $F_n(k,d)$ of n disjoint fat axis-aligned k-flats in $\mathbb{R}^d$, and let $f_n(k,d) = \max_{F_n(k,d)}\{f(F_n(k,d))\}$. We have shown that $f_n(2,3) = O(n\log^8 n)$ and $f_n(2,3) = \Omega(n\log n)$. Moreover, there is an $O(n\log^8 n)$ size and $O(\log^5 n)$ height BSP for any $F_n(2,3)$ such that every input rectangle is partitioned into $O(\log^8 n)$ fragments.

In general we would like to determine the asymptotic behavior of $f_n(k,d)$ for every $k,d \in N$, $1 < k < d$, when $n \to \infty$. It is easy to see that we cannot hope for anything better than $f_n(k,d) = \Theta(f_n(1,d-k+1))$. Indeed, consider a worst case construction $F_n(1,d-k+1)$ for n axis-parallel line segments in $\mathbb{R}^{d-k+1}$. Embed $F_n(1,d-k+1)$ into a $(d-k+1)$-dimensional affine subspace H of $\mathbb{R}^d$, and draw a k-dimensional square above every line segment orthogonally to H. We obtain n disjoint k-dimensional squares in $\mathbb{R}^d$. The size of an axis-aligned BSP for this set $F_n(k,d)$ cannot be smaller than $f_n(1,d-k+1)$. We conjecture that this bound can be attained apart from a polylogarithmic factor, i.e., k-dimensional axis-aligned fat rectangles allow (in some sense) for reducing the dimension of the space by $k-1$.

CONJECTURE 1. *For any $d \in \mathbb{N}$, $4 \leq d$, there is a BSP of $O(n\,\mathrm{polylog}\,n)$ size and $O(\mathrm{polylog}\,n)$ height for any set $F_n(d-1,d)$.*

CONJECTURE 2. *For any $k,d \in \mathbb{N}$, where $1 < k$ and $k+1 < d$, there is a BSP of $O(n^{\frac{d-k+1}{d-k}}\,\mathrm{polylog}\,n)$ size and $O(\mathrm{polylog}\,n)$ height for any set $F_n(k,d)$.*

SPECIAL ISSUE DEDICATED TO THE THIRTY-SEVENTH ANNUAL ACM SYMPOSIUM ON THEORY OF COMPUTING (STOC 2005)

This volume comprises the polished and fully refereed versions of a selection of papers presented at the Thirty-Seventh Annual ACM Symposium on Theory of Computing (STOC 2005), held in Baltimore, Maryland, May 22–24, 2005. Unrefereed preliminary versions of the papers presented at the symposium appeared in the proceedings of the meeting, published by ACM. The symposium was sponsored by the ACM Special Interest Group on Algorithms and Computation Theory (SIGACT).

The STOC 2005 Program Committee consisted of Gerth Stølting Brodal, Harry Buhrman, Jin-Yi Cai, Cynthia Dwork, Ronald Fagin (chair), Martin Farach-Colton, Anupam Gupta, Sariel Har-Peled, Russell Impagliazzo, Kamal Jain, Adam Tauman Kalai, David Karger, Claire Kenyon, Subhash Khot, Ravi Kumar, Moni Naor, Ryan O'Donnell, Toniann Pitassi, Tim Roughgarden, Alistair Sinclair, and Amnon Ta-Shma.

Out of 290 "Extended Abstracts" submitted to the STOC 2005 Program Committee, 84 were selected for presentation at the symposium. The present volume includes 9 of these papers that were invited to this volume. All papers were refereed in accordance with the *SIAM Journal on Computing*'s stringent standards, and these papers were substantially updated in the process. We take this opportunity to thank all the referees whose anonymous work has significantly contributed to the value of this volume.

Ronald Fagin, the Program Chair of the 2005 STOC Conference, invited three other members of the Program Committee (Anupam Gupta, Ravi Kumar, and Ryan O'Donnell) to assist in editing this special issue of the of the *SIAM Journal on Computing*, and all agreed. We feel that it was an honor to edit this issue.

AN $O(\log n \log\log n)$ SPACE ALGORITHM FOR UNDIRECTED ST-CONNECTIVITY*

VLADIMIR TRIFONOV†

Abstract. We present a deterministic $O(\log n \log\log n)$ space algorithm for undirected st-connectivity. It is based on a space-efficient simulation of the deterministic EREW algorithm of Chong and Lam [*J. Algorithms*, 18 (1995), pp. 378–402], an approach suggested by Prof. Vijaya Ramachandran, and uses the universal exploration sequences for trees constructed by Koucký in [*Proceedings of the* 16*th Annual IEEE Conference on Computational Complexity*, 2001, pp. 21–27]. Our result improves the $O(\log^{4/3} n)$ bound of Armoni et al. in [*Proceedings of the* 20*th Annual ACM Symposium on Theory of Computing*, 1997, pp. 230–239] and is a big step towards the optimal $O(\log n)$. Independently of our result and using a different set of techniques, the optimal bound was achieved by Reingold in [*Proceedings of the* 37*th Annual ACM Symposium on Theory of Computing*, 2005, pp. 376–385].

Key words. undirected st-connectivity, space-bounded computation

1. Introduction.

The problem we are concerned with is st-connectivity in an undirected graph G with n vertices (USTCONN); i.e., given two vertices s and t of G, we want to answer the question whether there is a path between s and t. This is one of the most basic graph problems with applications ranging from image processing and VLSI design to solving more complex graph problems. Furthermore, st-connectivity plays an important role in complexity theory because directed st-connectivity (STCONN) is **NL**-complete [20] and USTCONN is **SL**-complete [14].

Linear time and space sequential algorithms for solving even the harder STCONN problem have been known for a long time [22]. The problem of developing more efficient space and parallel algorithms was posed. The result of Aleliunas et al. [1] shows that USTCONN can be solved in $O(\log n)$ space with a randomized algorithm with one-sided error, i.e., an algorithm which produces an answer in polynomial time, and, if the two vertices are not connected, then the algorithm is correct; otherwise, it answers incorrectly with probability at most 1/2. The starting point of deterministic space-efficient sequential algorithms is the $O(\log^2 n)$ space algorithm for STCONN of Savitch [20]. For a long time, this was the best result even for USTCONN. The space bound for undirected graphs was first improved by Nisan, Szemerédi, and Wigderson [16] to $O(\log^{3/2} n)$ and then to $O(\log^{4/3} n)$ by Armoni et al. [2]. Both of these results depend on the efficient construction of universal traversal sequences by Nisan [15]. Finally, simultaneous to our result and using different set of techniques, the space complexity of USTCONN was shown by Reingold [18] to be $O(\log n)$.

Developing efficient parallel algorithms for USTCONN has a very rich history. The situation here is complicated further by the existence of multiple models of parallel computation. The models from the PRAM family are generally considered to be of great theoretical value. The results of [10, 19, 4, 11, 12] are concerned with the

CREW PRAM model, [21, 3, 7, 8] with the CRCW PRAM model, and [9, 6, 5, 17] with the EREW PRAM. The state of the art in parallel algorithms for USTCONN are the results of Chong, Han, and Lam [5], which shows that the problem can be solved on the EREW PRAM in $O(\log n)$ time with $O(m+n)$ processors, and Pettie and Ramachandran [17], which demonstrates a randomized EREW PRAM algorithm running in time $O(\log n)$ with optimal number of processors. The algorithms of [5] and [17] actually solve the harder problem of finding the minimum spanning tree of a weighted graph.

The starting point of our algorithm is the $O(\log n \log\log n)$ time deterministic EREW PRAM algorithm with $O(m+n)$ processors of Chong and Lam [6], which we call the CL algorithm. This parallel algorithm can be trivially simulated sequentially in linear space. We use the sequential algorithm to define a mathematical structure called configuration, which captures the state of the algorithm. We define also a sequence of configurations, such that every element of this sequence corresponds to the state of the sequential algorithm at a certain point of its execution. We use the sequence of configurations to trivially define an $O(\log^2 n)$ space algorithm, which instead of storing all of its current state recomputes parts of it when it needs them. This technique is standard for designing space-efficient algorithms. Finally, we modify the $O(\log^2 n)$ space algorithm into an algorithm which uses $O(\log n \log\log n)$ space.

The possibility of simulating parallel algorithms for USTCONN space-efficiently was suggested to the author by Prof. Vijaya Ramachandran in 2000. She conjectured an $O(\log n \log\log n)$ space algorithm derived from the CL algorithm and an alternate simple $O(\log^{3/2} n)$ space algorithm derived from the algorithm of Johnson and Metaxas [11], by using the max-degree hooking scheme of [6]. She observed that the step needing derandomization in [16] is not necessary in a tree-based hook and contract approach, because the trees automatically give rise to disjoint clusters of vertices. The max-degree hooking scheme employed by [6] gives the additional benefit that small trees have small neighborhoods. The main challenge was to implement the levels of recursion, so that they process small trees in $o(\log n)$ space. Solving this problem is the main contribution of this paper.

In the algorithm presented here the space of a level of recursion is between $\Omega(\log\log n)$ and $\Theta(\log n)$, depending on the level. A key tool for our method are the exploration walks on trees defined by Koucký [13]. Exploration walks on trees are similar to the Euler tour technique used by Tarjan and Vishkin [23] in the parallel context. These walks play the role of the edge-list plugging technique and pointer jumping employed by the CL algorithm, because they allow us to traverse trees very efficiently.

Section 2 contains a high-level overview of the CL algorithm. Section 3 defines formally a labeled multigraph and operations on it. Furthermore, it provides a complete description of the sequential version of the CL algorithm. Section 4 gives a detailed description of the space-efficient implementation of the CL algorithm. Section 5 proves the correctness of the sequential CL algorithm. The proofs in section 5 are from [6] and for completeness are adapted here to our framework. Although we make frequent references to [6], the exposition in this paper is self-contained, except for Proposition 3.4, whose proof is not too difficult.

Define $[k] = \{1, \ldots, k\}$ and the double exponential function $\operatorname{dexp}(x) = 2^{2^x}$. All logarithms in the paper are of base 2.

2. The Chong–Lam algorithm. This section gives a high-level overview of the Chong–Lam (CL) algorithm [6] to motivate the definitions in the next section. The CL algorithm uses a hook and contract approach. There are several phases of

hooking and contraction. Before every phase, every vertex of the current graph is in exactly one of three states—active, inactive, and done; all active and inactive vertices have nonzero degree, the done vertices have zero degree, and there are no multiedges between active vertices; the inactive vertices are organized in a set of hooking trees. A hooking tree is a subgraph of the current graph, which is a tree and whose internal edges, which we call hooking edges, are obtained as described below. Initially all vertices with nonzero degree are active, and the rest are done.

In a hooking phase the active vertices in parallel choose to hook to one of their current neighbors, establishing their hooking edges, and thus either become part of existing hooking trees or form new ones. The fact that the connected components formed by the hooking of vertices are trees is ensured by the hooking scheme of the CL algorithm. This hooking scheme uses an ordering $<_d$ of the vertices such that $u <_d v$ iff the degree of u is less than the degree of v or they are the same, but u is less than v, thinking of the vertices as elements of $\mathbb{N}$. To choose their hooking edges, the active vertices of the graph perform in parallel two consecutive, synchronized steps. First, if a vertex v has a neighbor larger according to $<_d$ than itself, then v hooks to the largest such neighbor. Second, if after the first step all neighbors of v are hooked to it, then v hooks to itself; i.e., it does not choose a hooking edge. Otherwise, if after the first step a neighbor u of v is hooked to a vertex different from v, then v hooks to u.

In a contraction phase some of the current hooking trees are contracted to a representative vertex. The representative vertex is the only vertex in the tree which is hooked to itself. Which trees are contracted is determined by a parameter, which depends on the phase and sets an upper bound on the total degree, i.e., the sum of the degrees of the vertices, of the trees which are contracted. For every contracted tree, its representative becomes a new active vertex and the rest of its vertices become done. Also all multiedges between new active vertices are cleaned up. Finally, the vertices of every uncontracted tree become inactive.

The processing required by a hooking phase is performed in parallel time $O(\log d)$, where d is the degree of the active vertex, using pointer jumping. The important part of a contraction phase is checking the degree of a hooking tree. In parallel this could be done in $O(\log c)$ time, where c is the contraction parameter, by using pointer jumping and a constant time edge-list plugging technique.

Finally, the CL algorithm is given by the following recursive procedure. Here `MaxHook` and `Contract`(c) denote correspondingly a hooking and a contracting phase with parameter c.

```
procedure Connect(k)
    MaxHook;
    if k > 0 then
        Contract(dexp(k));
        Connect(k − 1);
        Connect(k − 1);
    Contract(dexp(k+1));
```

The correctness of the CL algorithm ensures that a call to `Connect`$(\lceil \log \log n \rceil)$ contracts every connected component of the graph to a single vertex and all the other vertices are organized in a set of rooted parent trees such that the root of the tree of a vertex u is the vertex to which the connected component of u contracted.

We simulate the CL algorithm trivially with a sequential algorithm using linear space. We fix an ordering on the edges incident to a vertex, and instead of performing the hooking in parallel for all active vertices, we do it sequentially for each of them.

This is possible, because by changing the hooking scheme of CL slightly we can ensure that the hooking of an active vertex does not depend on the hooking of the other active vertices. The new hooking strategy gives preference to neighbors which are inactive or have an inactive neighbor, but it still ensures that small trees composed of active vertices have small degree. The details of the sequential algorithm are given in the following section, and space-efficient versions of the same algorithm are given in section 4.

3. Definitions.

3.1. Multigraphs and exploration walks. An undirected multigraph is a graph with possibly multiple edges between two vertices and such that every edge has a label on each side, where the labels of the edges incident to a vertex v have distinct labels on the side of v. We also have a single self-loop with label 0 at every vertex. Formally, we have the following.

DEFINITION 3.1. *An* undirected multigraph G *is a triple* $\langle V, \delta, \mu\rangle$*, where* V *is a set,* $\delta : V \to \mathbb{N}$*, and* $\mu : E \to E$ *is a bijection such that* $\mu(\mu(e)) = e$ *and* $\mu(v, 0) = (v, 0)$*, where* $E = \{(v, i) : v \in V \text{ and } 0 \le i \le \delta(v)\}$*.*

V *is the* set of vertices *of* G*,* E *is the* set of edges *of* G*,* $\delta(v)$ *is the* degree *of* v*, and* $\mu(e)$ *is the* reverse edge *of* e*. For an edge* e*, call the set* $\{e, \mu(e)\}$ *an* undirected edge*.*

Let $\eta : E \to V$ *and* $\beta : E \to \mathbb{N}$ *be the first and the second component of* μ*, respectively. Then* $\eta(v, i)$ *is the* ith neighbor *of* v*,* i *is the* label *of the edge* (v, i)*, and* $\beta(v, i)$ *is its* back-label*.*

Define the size *of* G*,* $\text{size}(G)$*, to be* $|V|$*.*

In the following a graph means undirected multigraph.

DEFINITION 3.2. *A graph* $G' = \langle V', \delta', \mu'\rangle$ *is a subgraph of a graph* $G = \langle V, \delta, \mu\rangle$ *if* $V' \subseteq V$ *and for every* $u, v \in V'$*,*

$$|\{i : \eta'(u, i) = v\}| \le |\{i : \eta(u, i) = v\}|.$$

Define (simple) path, connected vertices, forest, and tree in the usual way.

DEFINITION 3.3. *Let* G *be a graph. Let* $\Delta : E \times \mathbb{Z} \to E$ *be such that* $\Delta((v, i), j)$ *changes by* j *the label of the edge* (v, i)*. More precisely, for* $i \ne 0$*,*

$$\Delta((v, i), j) = (v, 1 + (i - 1 + j \bmod \delta(v))).$$

Define $\Gamma_{G,k}, \Gamma'_{G,k} : E \to E$ *inductively on* $k \ge 0$*. First,* $\Gamma_{G,0}(e) = \Gamma'_{G,0}(e) = e$*. Now let*

$$\Gamma_{G,k+1}(e) = \Delta(\mu(\Gamma_{G,k}(e)), 1),$$
$$\Gamma'_{G,k+1}(e) = \mu(\Delta(\Gamma'_{G,k}(e), -1)).$$

The sequence $\Gamma_{G,\le l}(e) = \langle \Gamma_{G,0}(e), \Gamma_{G,1}(e), \dots, \Gamma_{G,l}(e)\rangle$ *is called the* exploration walk *of length* $l + 1$ *starting from the edge* e*. We will also refer to the corresponding infinite sequence as* the exploration walk*. Let* $e_k = (v_k, i_k) = \Gamma_{G,k}(e)$*. Then* v_k *and* e_k *are correspondingly the* k*th vertex and the* k*th edge visited by the exploration walk starting from* e*. We have the equivalent notions for the reverse exploration walk, where* Γ *is replaced with* Γ'*.*

Exploration walks were introduced by Koucký [13]. We define them only for the exploration sequence which always changes by one the label of the current edge because this is the case of interest to us. The fact that exploration walks are reversible,

i.e., $\Gamma'_{G,l}(\Gamma_{G,l}(e)) = e$, was noticed by Koucký and is what makes them important to us. We will use the following property of exploration walks on trees.

PROPOSITION 3.4 (see [13]). *Let G be a tree with at most one undirected edge between any two vertices, let $e = (v, i) \in E$, $i \neq 0$, be an edge of G, and let $l = 2(\text{size}(G) - 1)$. Then the exploration walk $\Gamma_{G,\leq l-1}(e)$ of length l starting from e visits every edge of G which is not a self-loop exactly once. Furthermore, this is the shortest exploration walk which visits v exactly $\delta(v) + 1$ times.*

3.2. Operations on graphs.

3.2.1. Configuration. A configuration is the state of the sequential algorithm outlined at the end of section 2. Formally, we have the following.

DEFINITION 3.5. *A* configuration *is a tuple $\mathcal{C} = \langle G, A, I, D, H, R\rangle$, where G is a graph with $V = [n]$, for some $n \in \mathbb{N}$. A, I, and D form a partition of V. $v \in D$ iff $\delta(v) = 0$. $H : V \to \mathbb{N}$ and $R : V \to V$ are such that $H(v) \leq \delta(v)$, and if $R(v) \neq v$, then $v \in D$.*

The elements of A, I, and D are called correspondingly the active, *the* inactive, *and the* done *vertices of G. For $u \in V$, $(u, H(u))$ is the* hooking edge *of u, and $R(u)$ is the* immediate representative *of u.*

We require that H and R do not have nontrivial cycles in the following sense. Let $v_1, \ldots, v_k \in V$, $k \geq 2$. Then

(i) *if $v_{i+1} = \eta(v_i, H(v_i))$, $i \in [k-1]$, and $v_1 = \eta(v_k, H(v_k))$, then $H(v_1) = 0$;*
(ii) *if $v_{i+1} = R(v_i)$, $i \in [k-1]$, and $v_1 = R(v_k)$, then $R(v_1) = v_1$.*

We also require that there is at most one undirected edge between any two active vertices, i.e., if $u, v \in A$, then $|\{i : \eta(v, i) = u\}| \leq 1$, and that there is no hooking edge from an inactive to an active vertex, i.e., if $u \in I$, then $\eta(u, H(u)) \in I$.

Define the representative of v according to R to be

$$\text{rep}_R(v) = \begin{cases} v, & R(v) = v, \\ \text{rep}_R(R(v)) & \text{otherwise.} \end{cases}$$

Definition 3.5(ii) ensures the correctness of this definition.

DEFINITION 3.6. *Let $\mathcal{C} = \langle G, A, I, D, H, R\rangle$ be a configuration. H defines a subforest $F = \langle V, \delta_F, \mu_F\rangle$ of G, called the* hooking forest *of $\mathcal{C}$, with at most one undirected edge between any two vertices in the following way. Fix $v \in V$. Let ε be 1, if $H(v) \neq 0$, and 0 otherwise. Let $0 < i_1 < \cdots < i_k$ be such that*

$$\{i_1, \ldots, i_k\} = \{i : \exists u \in V \text{ such that } \mu(u, H(u)) = (v, i)\}.$$

First, define $\delta_F(v) = k + \varepsilon$. Now define $\eta_F(v, j) = \eta(v, i_j)$, for $1 \leq j \leq k$, and, if $\varepsilon = 1$, $\eta_F(v, k + \varepsilon) = \eta(v, H(v))$. Finally, define $\beta_F(v, j) = i$, where $\eta_F(v, j) = u$ and $\eta_F(u, i) = v$.

Let T be a maximal connected subtree of the forest F. We call T a hooking tree *in $\mathcal{C}$. The* root *of T,* root(T), *is the only vertex v in T such that $H(v) = 0$. The* degree *of T,* deg(T), *is $\sum_{v \in V_T} \delta(v)$. For a vertex $v \in V$, we denote with T_v the subtree of F which contains v.*

The correctness of this definition and the fact that F is a forest with at most one undirected edge between any two vertices follow from Definition 3.5(i).

3.2.2. Hooking. We will define Hook$(\mathcal{C})$ so that if $\mathcal{C}$ describes the state of the sequential algorithm, then Hook$(\mathcal{C})$ is its state after a hooking phase.

Being elements of $\mathbb{N}$, the elements of V are ordered. Define the linear ordering $<_d$ on V so that

$$u <_d v \quad \text{iff} \quad \delta(u) < \delta(v) \quad \text{or} \quad \delta(u) = \delta(v) \quad \text{and} \quad u < v.$$

The hooking operation $\mathrm{Hook}(\mathcal{C})$ produces the configuration $\langle G, A, I, D, H', R\rangle$ defined in the following way. If v is inactive, then $H'(v) = H(v)$. If v is active, let $v_1, \dots, v_{\delta(v)}$ be the neighbors of v, i.e., $v_i = \eta(v, i)$. For the rest of the definition when we have to choose an index i, we always pick the smallest one with the corresponding property. If v has an inactive neighbor v_i, let $H'(v) = i$. If all neighbors of v are active, let v_i be the largest according to $<_d$ amongst the neighbors of v. If $v <_d v_i$, let $H'(v) = i$. If all neighbors of v are active and smaller than v according to $<_d$, then if v has a neighbor v_i which has an inactive neighbor, let $H'(v) = i$. If all neighbors of v and their neighbors are active, then if v has a neighbor v_i which has a neighbor larger than v according to $<_d$, let $H'(v) = i$. Finally, if all neighbors of v and their neighbors are active and smaller than v according to $<_d$, define $H'(v) = 0$.

The hooking strategy described above differs from the hooking strategy of the CL algorithm because it gives preference to neighbors which are inactive or have an inactive neighbor. For example, in our hooking strategy a vertex hooks to an inactive neighbor, if it has one, regardless of its degree. In the hooking strategy of the CL algorithm, a vertex hooks to its largest according to $<_d$ neighbor, regardless of its state. The new hooking strategy does not change the correctness of the CL algorithm because first an active vertex still hooks to itself iff all of its neighbors are active and hooked to it, and second along a sequence of hooking edges of active vertices the vertices increase according to $<_d$ the same way as in the CL algorithm. The reason we chose the new strategy is to ensure that we do not look up the degree of an inactive vertex. The essential properties of the hooking operation are given by the following lemmas. The proofs are the same as in [6].

LEMMA 3.7. *Let $k \geq 3$ and $v_i \in A$, $i \in [k]$, be distinct and such that $v_{i+1} = \eta(v_i, H'(v_i))$, $i \in [k-1]$. Then $v_1 <_d \max_d\{v_{k-1}, v_k\}$.*

Proof. The proof is by induction on k. For $k = 3$, the statement holds, because v_1 is hooked to v_2, either because $v_2 >_d v_1$ or because $v_2 <_d v_1$, but v_2 had an inactive neighbor or an active neighbor larger than v_1. Since v_2 is hooked to v_3, the latter must be the case. So $v_1 <_d \max_d\{v_2, v_3\}$. For the inductive step, we have that $v_{k-1} <_d \max_d\{v_k, v_{k+1}\}$ and $v_1 <_d \max_d\{v_{k-1}, v_k\}$, and so $v_1 <_d \max_d\{v_k, v_{k+1}\}$. □

COROLLARY 3.8. $\mathrm{Hook}(\mathcal{C})$ *is a configuration.*

Proof. Since Hook changes only the hooking edges of active vertices, the only thing we have to check is that it does not create nontrivial cycles of active vertices. Assume that there is $k \geq 2$, and $v_i \in A$, $i \in [k]$, distinct and such that $v_{i+1} = \eta(v_i, H'(v_i))$ and $v_1 = \eta(v_k, H'(v_k))$. The case $k = 2$ is impossible because we must have either $v_1 <_d v_2$ or $v_1 >_d v_2$. In the first case v_2 will hook to v_1 only if v_1 is hooked to a vertex different from v_2. The second case is also impossible, and hence $k \geq 3$. By Lemma 3.7, $v_1 <_d \max_d\{v_{k-1}, v_k\}$ and $v_2 <_d \max_d\{v_k, v_1\}$. If $v_{k-1} <_d v_k$, then $v_1, v_2 <_d v_k$, a contradiction with Lemma 3.7 for v_k, v_1, and v_2. If $v_k <_d v_{k-1}$, then $v_1, v_k <_d v_{k-1}$, a contradiction with Lemma 3.7 for v_{k-1}, v_k, and v_1. Thus we must have that $H'(v_1) = 0$. □

LEMMA 3.9. *Let T be a hooking tree in* $\mathrm{Hook}(\mathcal{C})$ *composed of active vertices. Then* $\mathrm{size}(T) \geq 2$ *and* $\deg(T) < \mathrm{size}^2(T)$.

Proof. Let $r = \mathrm{root}(T)$. r hooks to itself, i.e., $H'(r) = 0$, iff all of its neighbors are active and hooked to it. So T must contain at least two vertices—r and its neighbors.

Let us see now that for $v \in V_T$,

$$\delta(v) \le \delta(r). \tag{3.1}$$

If v is a neighbor of r in T, then since r is hooked to itself, we must have that $v <_d r$ and hence that $\delta(v) \le \delta(r)$. Otherwise, let u be the neighbor of r on the path in T from v to r. Then, by Lemma 3.7, $v <_d \max_d\{u, r\}$, and so again $\delta(v) \le \delta(r)$.

We have that

$$\deg(T) = \sum_{v \in V_T} \delta(v) \le \text{size}(T)\delta(r) < \text{size}^2(T),$$

where in the first inequality we use (3.1), and the second follows because, as explained earlier, T must contain all neighbors of r. $\delta(r)$ is exactly the number of distinct neighbors of r, since there are no multiple edges between active vertices. □

3.2.3. Contraction. We will define Contract$(\mathcal{C}, d)$ so that if $\mathcal{C}$ describes the state of the sequential algorithm, then Contract$(\mathcal{C}, d)$ is its state after a contraction phase with parameter d. A hooking tree T in $\mathcal{C}$ is *d-contractable* if $\deg(T) \le d$.

The result of Contract$(\mathcal{C}, d)$ is the configuration $\mathcal{C}' = \langle G', A', I', D', H', R' \rangle$ defined in the following way. First, define

$$\begin{aligned} A'' &= \{v : v \notin D \text{ and } \deg(T_v) \le d \text{ and } \text{root}(T_v) = v\}, \\ I' &= \{v : v \notin D \text{ and } \deg(T_v) > d\}, \\ D'' &= \{v : v \in D \text{ or } \deg(T_v) \le d \text{ and } \text{root}(T_v) \ne v\}. \end{aligned}$$

Now define

$$H'(v) = \begin{cases} H(v), & v \in I', \\ 0 & \text{otherwise} \end{cases}$$

and

$$R'(v) = \begin{cases} R(v), & v \in D, \\ \text{root}(T_v), & v \in D'' - D, \\ v & \text{otherwise.} \end{cases}$$

Let T be a hooking tree in $\mathcal{C}$ and $s = \text{size}(T)$. Let $\langle v_1, \ldots, v_s \rangle$ be the sequence of the vertices of T in the order in which they are visited by the exploration walk on T of length $2(s-1)$ starting from the edge $(\text{root}(T), 1)$ of T, where we include a vertex only the first time it is visited by the exploration walk. Let $\langle e_1, \ldots, e_k \rangle$ be the sequence of the edges of G incident to the vertices of T defined in the following way—list in order of their labels all edges incident to v_1, then all edges incident to v_2, and so on. Obviously, $k = \deg(T)$.

Let us now define G'. For $u \in A''$, define $l_u \ge 0$ and the sequence of edges $\langle e_{u,1}, \ldots, e_{u,l_u} \rangle$. First, consider the sequence $\langle e_1, \ldots, e_k \rangle$ of the edges of G incident to the vertices of T_u from the previous paragraph. Remove from this sequence all edges which are internal to T_u, i.e., such that $\eta(e_i) \in V_{T_u}$. From every subsequence of edges whose other end belongs to the same d-contractable hooking tree, leave only the first edge; i.e., for every d-contractable hooking tree $T \ne T_u$ of $\mathcal{C}$, if the sequence $\langle e_{i_1}, \ldots, e_{i_h} \rangle$, $i_1 < \cdots < i_h$, contains all the edges from the sequence $\langle e_1, \ldots, e_k \rangle$ such that $\eta(e_{i_j}) \in V_T$, then remove e_{i_j}, $j > 1$. Let l_u be the number of remaining edges

in the sequence and $\langle e_{u,1}, \dots, e_{u,l_u} \rangle$ be the resulting sequence. Naturally, we call the edges $e_{u,j}$ the *remaining edges of* T_u.

Define

$$A' = A'' - \{v \in A'' : l_v = 0\},$$
$$D' = D'' \cup \{v \in A'' : l_v = 0\}$$

and

$$\delta'(v) = \begin{cases} l_v, & v \in A', \\ \delta(v), & v \in I', \\ 0, & v \in D'. \end{cases}$$

We are left to define $\mu'(v,i)$. First, assume $v \in A'$. Let $(u,j) = \mu(e_{v,i})$. If T_u is not d-contractable, then define $\mu'(v,i) = (u,j)$. If T_u is d-contractable, then define $\mu'(v,i) = (w,k)$, where $w = \mathrm{root}(T_u)$ and k is the only index such that $\eta(e_{w,k}) \in V_{T_v}$. Now assume $v \in I'$. Let $(u,j) = \mu(v,i)$. If T_u is not d-contractable, then define $\mu'(v,i) = (u,j)$. If T_u is d-contractable, let $\mu'(v,i) = (w,k)$, where $w = \mathrm{root}(T_u)$ and k is the only index such that $e_{w,k} = (u,j)$.

LEMMA 3.10. *Let* $\mathcal{C}' = \mathrm{Contract}(\mathcal{C}, d)$. *Then* $\mathcal{C}'$ *is a configuration such that* $\delta'(v) \le d$ *for* $v \in A'$, *and* $\deg(T_v) > d$ *for* $v \in I'$. *Furthermore, in the hooking forest of* $\mathcal{C}'$ *every* $v \in A' \cup D'$ *is in a hooking tree which contains only* v.

Proof. The proof is immediate from the definition of $\mathrm{Contract}(\mathcal{C}, d)$. □

3.3. Sequential version of the CL algorithm. For every $k \in \mathbb{N}$, we will define a sequence of configurations $\mathcal{C}_l = \langle G_l, A_l, I_l, D_l, H_l, R_l \rangle$, $0 \le l \le r(k)$, where $r(k) = 5 \cdot 2^k - 3$.

First, define recursively a sequence of pairs, the first element of which is always either *Hook* or *Contract*, and the second is a natural number, in the following way:

$$S_k = \begin{cases} (\langle Hook, 0 \rangle, \langle Contract, 1 \rangle), & k = 0, \\ (\langle Hook, k \rangle, \langle Contract, k \rangle, S_{k-1}, S_{k-1}, \langle Contract, k+1 \rangle), & k > 0. \end{cases}$$

The definition of S_k is obtained by "linearizing" the recursive definition of `Connect`(k).

By induction, S_k has $r(k)$ elements $P_1, \dots, P_{r(k)}$. Let $P_l = \langle Op_l, Arg_l \rangle$, $1 \le l \le r(k)$. Let $\mathcal{C}_0$ be some configuration. Assume that we have already defined $\mathcal{C}_0, \dots, \mathcal{C}_{l-1}$ for $1 \le l \le r(k)$. Define

$$\mathcal{C}_l = \begin{cases} \mathrm{Hook}(\mathcal{C}_{l-1}), & Op_l = Hook, \\ \mathrm{Contract}(\mathcal{C}_{l-1}, \mathrm{dexp}(Arg_l + 1)) & \text{otherwise.} \end{cases}$$

The sequential version of the CL algorithm for testing whether two vertices u and v are connected in a graph G consists of computing the sequence of configurations $\mathcal{C}_0, \dots, \mathcal{C}_{r(k)}$, where $\mathcal{C}_0$ is initialized according to G and $k = \lceil \log \log n \rceil$, and checking whether u and v have the same representative in $C_{r(k)}$: the two vertices are connected iff they have the same representative. The correctness of this algorithm follows from the statements below (see section 5 for their proofs). We make the following definition first.

DEFINITION 3.11. *A configuration* $\mathcal{C}_l$, $0 \le l < r(k)$, *is* nice *if the following hold:*

(i) *if* $Op_{l+1} = Hook$, *then for every* $v \in I_l$, $\mathrm{size}(T_v) > \mathrm{dexp}(Arg_{l+1} + 1)$ *and* $\deg(T_v) > \mathrm{dexp}(Arg_{l+1} + 2)$; *and*

(ii) *for every* $v \in A_l$, $\delta_l(v) \le \mathrm{dexp}(Arg_{l+1} + 2)$.

By definition, if $Op_{l+1} = Hook$, then $\mathcal{C}_l$ is nice iff the state described by it fulfills the preconditions given in [6] for executing $\texttt{Connect}(Arg_{l+1})$. These preconditions ensure the correctness of the algorithm and that it can be executed efficiently in parallel. Considering the correspondence between the sequence $\mathcal{C}_0, \ldots, \mathcal{C}_{r(k)}$ and the $\texttt{Connect}(k)$ procedure of the CL algorithm, the following theorem is a consequence of the results in [6].

THEOREM 3.12. *If $\mathcal{C}_0$ is a nice configuration, then $\mathcal{C}_l$ is nice, for every $1 \leq l < r(k)$, $|A_{r(k)}| \leq \max\{|A_0|/\mathrm{dexp}(k), 1\}$, and $\mathrm{size}(T_v) > \mathrm{dexp}(k+1)$ for $v \in I_{r(k)}$.*

Finally, again similarly to [6], we have the following corollary, which says that if we initialize $\mathcal{C}_0$ according to some undirected graph G, then in $\mathcal{C}_r$ all components of G are contracted.

COROLLARY 3.13. *Let G be a graph with at most one undirected edge between any two vertices and $V = [n]$. Let $k = \lceil \log \log n \rceil$ and $\mathcal{C}_0 = \langle G, A, I, D, H, R \rangle$, where $A = \{v : \delta(v) \neq 0\}$, $I = \emptyset$, $D = V - A$, $H(v) = 0$, and $R(v) = v$, for $v \in V$. Then u and v are connected in G iff $\mathrm{rep}_{R_{r(k)}}(u) = \mathrm{rep}_{R_{r(k)}}(v)$.*

4. Space-efficient algorithm. Since giving directly the Turing machine which solves the problem and reasoning about its space complexity is rather cumbersome, we define the algorithms outlined in sections 4.1 and 4.2 using pseudocode and then explain how to translate the pseudocode to a Turing machine. The algorithms, as given by the pseudocode, are almost a literal rephrasing of the definitions given in sections 3.2 and 3.3 into a precise language in which analyzing space complexity is possible. The deviations from a literal rephrasing exist only to decrease the space requirements of the algorithms. Besides that, the correctness of the algorithms follows essentially from Corollary 3.13. In fact, the algorithm in section 4.1 can be thought of as a literal $O(\log^2 n)$ space implementation of the sequential algorithm described in section 3.3.

In section 4.1 we outline an $O(\log^2 n)$ space implementation of the sequential algorithm derived from the definitions in sections 3.2 and 3.3, which instead of storing all of the current configuration recomputes parts of it when it needs them. In section 4.2 we describe the changes we make to the algorithm from section 4.1 to reduce its space complexity to $O(\log n \log \log n)$. Section 4.4 discusses in detail the pseudocode for the algorithm from section 4.2.

4.1. An $O(\log^2 n)$ space algorithm. Let G be a graph with $V = [n]$ and with at most one undirected edge between any two vertices. Let

$$r = 5 \cdot 2^{\lceil \log \log n \rceil} - 3.$$

Consider the sequence of configurations $\mathcal{C}_0, \ldots, \mathcal{C}_r$ from Corollary 3.13 for k equal to $\lceil \log \log n \rceil$. The starting point for a space-efficient algorithm comes directly from the definition of this sequence. More precisely, we define functions $\texttt{Active}(l, v)$, $\texttt{Inactive}(l, v)$, $\texttt{Done}(l, v)$, $\texttt{Degree}(l, v)$, $\texttt{Neighbor}(l, v, i)$, $\texttt{BackLabel}(l, v, i)$, $\texttt{Rep}(l, v)$, and $\texttt{Hook}(l, v)$, where $0 \leq l \leq r$, v is a vertex, and i is the label of an edge incident to v, which return the corresponding component of $\mathcal{C}_l$. Namely, $\texttt{Active}(l, v)$, $\texttt{Inactive}(l, v)$, and $\texttt{Done}(l, v)$ check, correspondingly, whether v is active, inactive, or done in $\mathcal{C}_l$, i.e., whether it belongs to A_l, I_l, or D_l; $\texttt{Degree}(l, v)$ returns $\delta_l(v)$, the degree of v in G_l; $\texttt{Neighbor}(l, v, i)$ returns $\eta_l(v, i)$, the ith neighbor of v in G_l; $\texttt{BackLabel}(l, v, i)$ returns $\beta_l(v, i)$, the back-label of the ith edge of v; $\texttt{Hook}(l, v)$ returns $H_l(v)$, the label of the hooking edge of v in $\mathcal{C}_l$; $\texttt{Rep}(l, v)$ returns $R_l(v)$, the immediate representative of v in $\mathcal{C}_l$.

Call the parameter l of the above functions the *level of recursion*. Thus the levels of recursion of our algorithm correspond to the elements of the sequence $\mathcal{C}_0, \ldots, \mathcal{C}_r$. For $l = 0$, the bottom of the recursion, all of these functions just use the input graph G (see Corollary 3.13). According to the definitions in section 3.3, $\mathcal{C}_{l+1}$ is derived from $\mathcal{C}_l$, and thus the outputs of the functions mentioned in the previous paragraph for level $l + 1$ is determined recursively from their output for level l. Using these functions, we apply Corollary 3.13 to solve undirected st-connectivity.

If $Op_l = \mathit{Contract}$, then $\mathcal{C}_l$ is obtained from $\mathcal{C}_{l-1}$ by contracting some of its hooking trees as defined in section 3.2.3. In this case for a hooking tree T in $\mathcal{C}_{l-1}$, we must determine $\deg(T)$ and be able to enumerate the vertices of T as they are visited by the exploration walk on T starting from $(v, 1)$ for $v \in V_T$. For these purposes, we define $\texttt{TreeSize}(l, v)$ and $\texttt{TreeWalk}(l, v, i)$. Let T be the hooking tree in $\mathcal{C}_{l-1}$ containing v. If s is the size of T, $\texttt{TreeSize}(l, v)$ returns $2(s-1)$. Notice that $2(s-1)$ is the length of the exploration walk on T given in Proposition 3.4. $\texttt{TreeWalk}(l, v, i)$ returns $\Gamma_{T,i}(v, 1)$.

Going over the details of the definitions of each of the functions mentioned above, it is not hard to see that each level of recursion can be implemented in $O(\log n)$ space, and since we have $r = O(\log n)$ levels of recursion, this results in an $O(\log^2 n)$ algorithm for USTCONN. We omit those details, because they are rather immediate and are superceded by the discussion in the next section and the precise definitions in section 4.4.

4.2. The $O(\log n \log\log n)$ space algorithm. The $O(\log n)$ space per level of recursion in the algorithm outlined in the previous section comes mainly from having to store vertices in the local variables of the functions, since each vertex takes $\Theta(\log n)$ space. To see more precisely what is going on, consider the following. The definition of $H_l(v)$ contains a comparison of the ith neighbor of v in $\mathcal{C}_{l-1}$ with its jth neighbor; i.e., the definition of $\texttt{Hook}(l, v)$ contains a comparison $\texttt{Neighbor}(l-1, v, i) = \texttt{Neighbor}(l-1, v, j)$. Let us say that v is passed to `Hook` through a global variable. Obviously, this global variable must be stored locally before the execution of such comparison, because otherwise its value might be overwritten during the two calls to `Neighbor`. To take care of this bottleneck, we define the functions so that they never store a vertex in their local variables.

The first step towards such definitions is to remove the vertex v from the argument list of the functions. Instead of this argument, we maintain one current vertex in a global variable, and all functions return information about this vertex. A function which otherwise must return a vertex is defined so that after its execution the current vertex is its result (in this case we say that the function moves the current vertex). It is a responsibility of the calling function to keep enough information locally to restore the original current vertex if it needs to. Denote the current vertex with cv.

To implement this, first we change the definitions of some of our functions. Instead of $\texttt{Neighbor}(l, v, i)$, we have $\texttt{Neighbor}(l, i)$, which moves the current vertex to $\eta_l(cv, i)$, its ith neighbor in $\mathcal{C}_l$. Let T be the hooking tree of cv in $\mathcal{C}_{l-1}$. Instead of $\texttt{TreeWalk}(l, v, i)$ we have $\texttt{TreeForward}(l, i)$, which returns j and moves the current vertex to u, where $(u, j) = \Gamma_{T,i}(cv, 1)$. Similarly, we have $\texttt{TreeBack}(l, i, j)$, which moves the current vertex to the vertex of $\Gamma'_{T,i}(cv, j)$.

The most important part of our idea to avoid storing vertices locally is to be able to move the current vertex temporarily, perform something at the new current vertex, and then return to the original current vertex. For this, define $\texttt{Move}(l, i)$ to return $\beta_{l-1}(cv, i)$, i.e., $\texttt{BackLabel}(l-1, i)$, and move the current vertex to $\eta_{l-1}(cv, i)$,

i.e., a call to `Neighbor`$(l-1,i)$. Call `Move`(l,i) and `TreeForward`(l,i) *forward moves*. For a forward move M, let `Reverse`(M,j) be its reverse, i.e., it is correspondingly `Move`(l,j) or `TreeBack`(l,i,j), where j is the result of M. We use the reversibility of exploration walks here, so that `TreeBack` reverts `TreeForward`. Finally, we have a "dummy" forward move `Current` which does not change the current vertex and whose purpose is to address the current vertex. The reverse of `Current` is `Current` again.

We use forward moves to change the current vertex and their reverses to restore it. Call a sequence of forward moves *path description relative to the current vertex*. If `P` is a path description relative to the current vertex and `B` is some instruction(s), then define **after** `P` **do** `B` to change the current vertex according to `P`, perform `B`, and then use the reverses of the moves in `P` to restore the current vertex.

A simple example of the use of **after** is the comparison operator `=`, which compares two vertices given their path descriptions relative to the current vertex and returns true iff they are the same. Using **after**, we can move to the first vertex and store it in a local variable, and then go to the second vertex and compare the two. This takes $\Theta(\log n)$ space. Instead of this, going back and forth between the two vertices, using the reversibility of the moves along the edges and the exploration walks on the trees, we perform the comparison bit by bit. Aside from the information stored for the ways back, this takes only the $\Theta(\log\log n)$ space necessary to store the index of a bit. This way the bottleneck of $\Omega(\log n)$ space is reduced to $\Omega(\log\log n)$.

For example, the `=` operator is used in the definition of `TreeSize`(l), which determines the size of the hooking tree T of cv in $\mathcal{C}_{l-1}$, in the following way. Starting at cv and using Proposition 3.4, we can make steps from the exploration walk on T until we go back to cv sufficiently many times. For this, we can store cv, so that we can compare it with each new vertex of the walk. This takes $\Theta(\log n)$ space, independent of the size of T. Instead, we incrementally find i with properties as in Proposition 3.4, where to check if the ith vertex of the walk is equal to cv we keep the current vertex at cv and use the `=` operator, as defined above, to compare it to the vertex with path description `TreeForward`(l,i). More precisely, we use the comparison `Current=TreeForward`(l,i) to check whether the ith vertex of the walk is equal to cv, where the semantics of the comparison in this case is explained in the previous paragraph. Thus, if $\text{size}(T) \le s$, then we can find its size in space $O(\log s + \log\log n)$ (the $\log\log n$ appears because of counters used during comparison of vertices). Alternatively, if $\text{size}(T) > s$, we can still use only $O(\log s + \log\log n)$ space to learn this without actually computing $\text{size}(T)$, because it is enough to stop the exploration walk on T as soon as we learn that $\text{size}(T) > s$.

The second part of our idea to reduce the space of the algorithm is to have an upper bound $v(l)$ on the values which variables can take at level l; i.e., during the execution of all functions at level l, the values of their local variables are at most $v(l)$. We set

$$v(l) = 2 \cdot \text{dexp}(Arg_l + 2).$$

Call a number x *valid* for level l if it is at most $v(l)$. A vertex v is *valid* for level l if its degree $\delta_{l-1}(v)$ is valid for level l.

Using the concept of a current vertex, we can eliminate the need to store a vertex in a local variable, and thus our local variables contain essentially only degrees of vertices, labels and back-labels of edges, and lengths of exploration walks on hooking trees. For example, the information stored for reversing a forward move is a back-label (for `Move`) or a tree-edge label (for `TreeForward`). We still have to make sure

that every time we store a value in a local variable it is valid. For this the following observation is helpful.

OBSERVATION 4.1.

(i) *The labels of the edges incident to vertex v valid for level l are valid for level l. This is not necessarily true for their back-labels.*

(ii) *All vertices which are active in $\mathcal{C}_{l-1}$ are valid for level l.*

(iii) *If $Op_l = Contract$, then if a hooking tree T in $\mathcal{C}_{l-1}$ has degree at most $\operatorname{dexp}(Arg_l + 1)$, then all of its vertices are valid for level l.*

The first item of the observation is trivial, the second follows from Theorem 3.12, because all $\mathcal{C}_l$ are nice, and the third follows because $\operatorname{dexp}(Arg_l + 1) < v(l)$.

Our goal has become to prove the following lemma. The functions mentioned in the lemma are the ones outlined previously in this section. Their precise definitions are given in section 4.4. Let T be a hooking tree in $\mathcal{C}_{l-1}$. T is *contractable for level l* if $\deg(T) \le \operatorname{dexp}(Arg_l + 1)$. Let (v, i) be an edge of T and $u = \eta_T(v, i)$. A move along (v, i) is *possible for level l* if u is valid for level l.

LEMMA 4.2. *Let T be the hooking tree in $\mathcal{C}_{l-1}$ of the current vertex cv.*

(i) `Active`(l), `Inactive`(l), `Done`(l), `Hook`(l), *and* `Degree`(l) *correctly return the value of the corresponding component of $\mathcal{C}_l$ for cv.*

(ii) *If T is uncontractable for level l or $cv \in D_{l-1}$, then* `Root`(l) *returns* 0*; otherwise, it returns the index of the first occurrence of* $\operatorname{root}(T)$ *in the exploration walk on T starting from $(cv, 1)$.*
`TreeSize`(l) *returns* $2(\texttt{size}(T) - 1)$*, if T is contractable for level l, and* `null` *otherwise.*
Assume that cv is valid for level l. If all moves of $\Gamma_{T,\le i}(cv, 1)$ are possible for level l and it ends in (v, j), then `TreeForward`(l, i) *moves the current vertex to v and returns j. If all moves of $\Gamma'_{T,\le i}(cv, j)$ are possible for level l and it ends in v, then* `TreeBack`(l, i, j) *moves the current vertex to v.*

(iii) *Let $(v, j) = \mu_l(cv, i)$.*
`Neighbor`(l, i) *moves the current vertex to v.*
`BackLabel`(l, i) *returns j, if j is valid for the level at which* `BackLabel`(l, i) *was called (see the discussion on returning values in section* 4.4.2*), and* `null` *otherwise.*

All local variables are valid.

The proof of the lemma is done by induction on the level of recursion. For this, we need the correctness of the functions which a given function calls. Sometimes we have to use correctness for the same level of recursion, but this does not result in a circular reasoning because for any two functions `F` and `G`, there are no chains of function calls within the same level of recursion both from `F` to `G` and from `G` to `F`.

The correctness essentially follows from the correctness of the CL algorithm (Corollary 3.13). It can be easily seen that the introduction of one global current vertex and always returning information about this vertex maintains the faithfulness of our implementation to the CL algorithm—the current vertex is an implicit argument to all functions describing a configuration, and calling it "current" just facilitates our intuition about how the algorithm proceeds.

The only real deviation from the definitions given in section 3.2 is that we have an upper bound on the numerical values which can be stored at a level, and so we might be unable to process the result of a function if it is invalid for the current level of recursion. Actually, as can be seen from Lemma 4.2, some functions are specified to return `null` if their result is invalid for the level requesting it. By Observation 4.1, the only information we can derive from an invalid or `null` result is that either the

current vertex is invalid (if `Degree`(l) is invalid), a neighbor of the current vertex is invalid (if `BackLabel`(l, i) is `null`), or the current vertex is part of an uncontractable tree (if `TreeSize` is `null`). This information is enough to define the functions as in Lemma 4.2. First, we never move to a vertex from which we cannot return, i.e., along an edge with an invalid back-label, so that we never have to store an invalid back-label locally. Second, during contraction, vertices which are either invalid or part of an uncontractable tree will become inactive and thus, by definition, will inherit their properties, e.g., degree and hooking edge, from the previous level. In a hooking operation (section 3.2.2), we do not need to look up the degree of an invalid (and even inactive) vertex. In a contraction operation (section 3.2.3), we can stop the exploration walk on a tree as soon as the walk runs into an invalid vertex, because then the tree is clearly uncontractable.

To ensure that all local variables are valid for the current level of recursion, we use Observation 4.1 in the following way. First, notice that since the value returned from a function resides in a global variable we can check whether it is valid by simply inspecting this global variable. Furthermore, some functions (e.g., `TreeSize` and `BackLabel`) return `null` if their result is invalid for the current level of recursion. In any case, we can easily learn when the return value of a function is invalid without having to store it locally. According to Observation 4.1(i), if the result of `BackLabel` is `null`, then the corresponding neighbor is invalid and we never move the current vertex along such edges. Also, Observation 4.1(ii) ensures that we can always process locally active vertices. Finally, according to Observation 4.1(iii), if the result of `TreeSize` is `null`, then the hooking tree of the current vertex is uncontractable.

4.3. Solving undirected st-connectivity. Using Lemma 4.2, we can prove the main theorem of this paper.

THEOREM 4.3. *USTCONN on a graph with n vertices can be solved in space $O(\log n \log\log n)$.*

Let $m = \lceil \log\log n \rceil$. Recall that $r = 5 \cdot 2^m - 3 = O(\log n)$. By Corollary 3.13, s and t are connected iff $\mathrm{rep}_{R_r}(s) = \mathrm{rep}_{R_r}(t)$. Thus to solve USTCONN it is enough to define a function `MoveToRep`(l) which moves the current vertex cv to its representative $\mathrm{rep}_{R_l}(cv)$ in $\mathcal{C}_l$. Then, to check whether s and t are connected, we call `MoveToRep`(r) twice, once from s and once from t, and compare the two resulting final current vertices (see the defintion of `Connected` in section 4.4.10). `MoveToRep` is defined by first calling itself recursively. This moves the current vertex cv to its representative $v = \mathrm{rep}_{R_{l-1}}(cv)$ in $\mathcal{C}_{l-1}$. Then, if $Op_l = Contract$ and the hooking tree T in $\mathcal{C}_l$ of the new current vertex v is contractable for level l, `MoveToRep` moves v to the root of T. We use here that the root of T will be the immediate representative of v after contracting T. See section 4.4.10 for a precise definition of `MoveToRep`.

The space complexity of the algorithm is dominated by the space taken by the execution stack. From Lemma 4.2, it follows that each local variable at level l is at most $v(l)$. Since there are a constant number of local variables per function and the length of every chain of function calls within the same level of recursion is bounded by a constant, the space taken by level l is $O(\log v(l) + m)$ (the additional $O(m)$ space appears because of the counters used during comparison of vertices). Since $\log v(l) = 4 \cdot 2^{Arg_l} + 1$, $1 \le l \le r$, and $r \cdot m = O(\log n \log\log n)$, we have to prove that

$$\sum_{l=1}^{r} 2^{Arg_l} = O(\log n \log\log n).$$

Consider the recurrence given by

$$S(k) = \begin{cases} 3, & k = 0, \\ 2S(k-1) + 2 \cdot 2^k + 2^{k+1}, & k > 0. \end{cases}$$

From the recursive definition of S_m given in section 3.3, it follows that the left-hand side of the equation which we want to prove is exactly $S(m)$. Finally, it is not hard to prove by induction on k that $S(k) = 2^k(4k + 3)$. Hence $S(m) = O(\log n \log\log n)$.

4.4. Pseudocode. The language of the pseudocode is self-explanatory. The difference between a function and a procedure, marked with **function** and **procedure** correspondingly, is that the first returns a value and the second does not. In the following we will refer to both as functions. Operators, marked with **operator**, are functions for which a more traditional in-fix position of their usage is emphasized. The semantics of statements, marked with **statement**, is closer to what is traditionally known as macroses than to procedures and functions; namely, they do not allocate a new stack frame. Blocks are marked by indentation, **break** exits the closest surrounding loop, **continue** continues with the next cycle of the execution of the closest surrounding loop, and **return** exits the current function, returning a value, if necessary. We use a fixed width font to denote the names of functions and variables from the pseudocode, e.g., `F` and `i`, and a roman italics font for mathematical functions and variables, e.g., f and i.

4.4.1. Execution of the pseudocode. The variable usage and execution of the pseudocode is standard. During its execution, a function can use only its own local variables and the global variables. For the execution of the functions, we use a stack which contains the local variables of the functions executed at the moment. The part of the stack devoted to the execution of a function is called the *stack frame of the function*. Statements use the stack frame of their surrounding function. The top of this stack contains the stack frame of the function being executed at the moment. When the current function calls another function, first a new stack frame is allocated on the top of the stack and then the new function is executed. Part of the stack frame of a function contains information about the address (the place in the program) from which the function was called. Once the current function is finished, its stack frame is removed from the top of the stack, and the execution resumes from the address from which the current function was called.

In addition to functions which are executed using the stack, we have *global functions*, which do not use the stack for their execution. Such functions use only global variables for their execution; i.e., their "local" variables are in fact global variables which are visible only from the particular global function. Since in what follows we are concerned only with the contents of the stack, we will concentrate on functions which use the stack.

The execution of the pseudocode proceeds in the following way. Every function is executed at some level of recursion. Every function has an argument l, which contains the current level of recursion. During its execution, a function can either call other functions on the same level of recursion, i.e., calls like $\mathtt{F}(l, \ldots)$, or make calls to the previous level of recursion, i.e., calls like $\mathtt{F}(l-1, \ldots)$. There is a constant c such that the length of a chain of function calls within the same level of recursion is at most c. The stack frames of functions executed in the same level of recursion are consecutive on the stack. We call such a sequence of stack frames the *stack frame for the level*. From the fact that any stack frame for a level contains at most c stack frames for functions and that each function uses a constant number of variables, it follows that there is a constant d such that the stack frame of every level contains a total of at

most d variables.

The local and global variables contain only numerical and boolean values, and a special value `null`, different from any other value. For every level of recursion l, we have an upper bound $v(l)$, computed by a global function, on the numerical values which are valid for this level; i.e., all numerical values at level l are at most $v(l)$. Boolean values and `null` are always valid. The counters used for comparison of vertices are at most $\lceil \log n \rceil$.

4.4.2. Passing arguments and returning values. We have two methods of passing arguments to a function and returning a value. The first is through global variables, and the second is through global arrays which contain an entry for every level of recursion.

The method which uses global variables is straightforward. We have global variables which are set to the arguments of the function before it is called. We denote the global variables for the arguments of a function `F` with `arg1F`, `arg2F`, and so on. During its execution, a function can look up its arguments from these global variables. It might decide to store them as local variables, but this might not always be possible, because the arguments might be invalid for the current level of recursion.

To return a value a function sets a global variable. After a return from a call of a function, the calling function decides whether it wants to store the returned value locally. We have a special assignment operator, `::=`, which assigns the return value r of a function returning through a global variable to a local variable in the following way: if r is valid for the current level of recursion, the result of the assignment is r; otherwise, it is `null`.

The method which uses arrays is more subtle. Let `F` be a function which uses this method of passing arguments and returning values. This method can be used only if all calls to `F` at the current level of recursion l are recursive; i.e., all calls to `F` look like `F`$(l-1,\ldots)$. We have two global arrays—one, `argF`, for passing arguments to `F` and one, `retF`, for returning a value from it. Those arrays contain exactly one entry for every possible level of recursion, and each entry could be marked. Also each entry holds values which are valid for the corresponding level of recursion, so that the space taken by each such array is the same as the space taken by the execution stack.

Let `H` call `F`. If `H` uses the value returned by `F`, then before the call to `F` the entry of `retF` for the current level of recursion is marked; otherwise, it is left unmarked. When `F` produces a result at level l, it finds the smallest index $i > l$ such that the ith entry of `retF` is marked and tries to store its result there. If the value produced is too large for the corresponding entry, `F` writes `null`. After the call to `F` returns, `H` unmarks the entry of `retF` for the current level of recursion. The only time when `H` does not use the value returned by `F` is when `H` is actually `F` and the call to `F` is a recursive call whose result is passed back without modification, e.g., a call like **return** `F`$(l-1,\ldots)$ in the definition of `F`.

Similarly, if `H` provides arguments to `F`, then before the call to `F`, `H` marks the entry of `argF` for the current level of recursion and provides values for it. When `F` wants to access its arguments at level l, it finds the smallest index $i > l$ such that the ith entry of `argF` is marked and uses the values stored in the entry as its arguments. After the call to `F` returns, `H` unmarks the entry of `argF` for the current level of recursion. Again we have that the only time when `H` does not provide arguments to `F` is when `H` is `F` and the call to `F` is a recursive call whose arguments are the same as for the current call to `F`, e.g., a call like `F`$(l-1,y)$ in the definition of `F`(l,x) at a place where it is always true that $x = y$.

Since this method is used only if all calls to `F` are recursive, there is no danger of overwriting `F`'s arguments or returned value. For passing arguments, this method helps when we need to store an argument only at the level which generates it, where it is valid, but still allow for lower levels of recursion to access it, where it might be invalid. For returning values, this method helps when we want to return a value exactly at the level which requested it originally. This method allows for nested calls from different levels of recursion to the same function, which the ordinary method of passing variables through global variables does not always allow.

The restriction we have on the space of a level is the reason why we chose those methods of passing arguments and returning value. The method using arrays is more unusual, and it is used only in two functions, `BackLabel` and `BackLabelAux`. The reason why we introduced it is explained in the notes for those functions.

In the code, we use $\texttt{F}(l, x_1, \ldots, x_k)$ to call a function `F` at level l with arguments $x_1, \ldots, x_k$. If a function `F` takes arguments, but is called without ones, it uses the values currently located in the global variables (or the arrays) for `F`.

4.4.3. Translation of the pseudocode to a Turing machine. Let us address now the issue of translating the pseudocode to a Turing machine with a binary alphabet. Most of the details, like doing arithmetic and performing conditionals, are rather straightforward, and so we skip them and concentrate only on variable usage. Numerical values are represented in binary. To represent the `null` value, we use one additional bit to designate whether or not the value is `null`. We have a separate tape for each global variable (there are only a constant number of them). The space taken by each global variable is $O(\log n)$.

There is a tape assigned for the stack, and the head of this tape is positioned at the stack frame of the current function, i.e., at the top of the stack. The stack frame of a function contains the state to which the Turing machine must return after the execution of the function (this takes a constant number of bits depending only on the Turing machine) and the values of the local variables of the function.

The space taken by each local variable depends on the level of recursion at which the stack frame occurs. Since at a level l the value of every valid local variable is at most $v(l)$, the space $s(l)$ taken by such a variable at level l is $O(\log v(l))$. This space is known to the current function, because it can be computed by a global function from the current level of recursion. So to use the ith local variable the current function must move the head of the stack tape to the place where the variable is located. This place can be computed by the current function from i and $s(l)$. As discussed earlier, there is a constant d such that the stack frame of the lth level of recursion contains at most d variables. Thus the space taken by the stack frame of level l is $O(\log v(l) + \log\log n)$. The $O(\log\log n)$ appears because of comparison of vertices, as explained in section 4.2.

After the execution of the current function, the state of the Turing machine is restored to the value stored on the stack, and the head of the stack tape is moved to the stack frame of the caller.

4.4.4. Preliminaries. To simplify the exposition of the algorithm, we remove the level of recursion from the argument lists of the functions. Instead we have one global variable, `level`, which contains the current level of recursion. `level` is set to $5 \cdot 2^{\lceil \log\log n \rceil} - 3$ initially. Let `F` be a function which calls a function `G` on the previous level of recursion. This task is performed by `Prev`; namely, `Prev`(`G`(...)) passes arguments to `G`, decreases the current level of recursion, calls `G`, and upon return from `G` increases the current level of recursion. This is the only way that the

current level of recursion is changed—all functions can look up the value of `level`, but none of them changes it. We denote the current level of recursion with cl.

The global variable `currvertex` contains the current vertex cv.

In the following, T denotes the hooking tree of the current vertex in $\mathcal{C}_{cl-1}$. Unless specified otherwise, the exploration walk refers to the exploration walk on T starting from $(cv, 1)$. A hooking tree in $\mathcal{C}_{cl-1}$ is called contractable if its degree is at most $\mathrm{dexp}(Arg_{cl} + 1)$. A value is valid if it is at most $v(cl)$.

We use the following observation. It follows from Observation 4.1 and the correctness of the functions mentioned in it. `MoveValid`(i) checks whether the back-label $\beta_{cl-1}(cv, i)$ of the ith edge of cv in $\mathcal{C}_{cl-1}$ is valid, i.e., whether $\beta_{cl-1}(cv, i) \leq v(cl)$.

OBSERVATION 4.4.

(i) *If* `TreeSize` $\neq$ `null`*, then all moves of* `TreeForward`(i) *are possible for level* cl*.*

(ii) *If* `MoveValid`(i) *is true, then the result of* `Move`(i) *is not* `null` *and valid for level* cl*; otherwise,* $\beta_{cl-1}(cv, i)$ *is invalid for level* cl*.*

By this observation, `TreeSize` and `MoveValid` serve as "safeguard" checks for forward moves. Thus, before making a forward move to change the current vertex, if we want to be able to return, e.g., in an **after** statement, we always first make sure that the forward move returns a valid result. In this case we say that the forward move is valid.

All functions, except `BackLabel` and `BackLabelAux`, take arguments and return values through global variables.

Every function is preceded by paragraphs which give its specification. Also notes are made on the definition and correctness of the function, and on the validity of its local variables. In the notes we use interchangeably the name of a local variable, given in fixed font, and its value at a particular point of the execution of the function. To facilitate the reading of the pseudocode, we have annotated the meaning of the local variables of the nonglobal functions.

4.4.5. Important functions. Global function `ArgOp`. **Input** l. **Output** $2 \cdot Arg_l + \varepsilon_l$, where ε_l is 0, if $Op_l = Hook$, and 1 otherwise. **Assumes** $1 \leq l \leq 5 \cdot 2^{\lceil \log\log n \rceil} - 3$.

```
global function ArgOp
    l := argArgOp;
    k := ⌈log log n⌉;
    while true
        if k = 0 then return 2·(l − 1) + (l − 1);
        else
            if l ≤ 2 then return 2·k + (l − 1);
            else
                if l = 5·2^k − 3 then return 2·(k + 1) + 1;
                else
                    if l ≥ 5·2^(k−1) then l := l − 5·2^(k−1) + 1;
                    else l := l − 2;
                    k := k − 1;
```

Global functions `Valid`, `ContractDegree`, and `Contraction`. **Input** None. **Output** Correspondingly $2 \cdot \mathrm{dexp}(Arg_{cl} + 2)$, $\mathrm{dexp}(Arg_{cl} + 1)$, and whether $Op_{cl} = Contract$.

```
global function Valid
    return 2·dexp(2 + ArgOp(level) div 2);
```

```
global function ContractDegree
    return dexp(1 + ArgOp(level) div 2);

global function Contraction
    return ArgOp(level) mod 2 = 1;
```

Statement "**after** $M_1, M_2, \ldots, M_k$ **do** B." **Input** $M_1, \ldots, M_k$—path description relative to the current vertex, B some instruction(s). **Output** Moves the current vertex according to the forward moves in $M_1, \ldots, M_k$, executes B, and finally restores the original current vertex. **Assumes** All forward moves are valid. **Local variables** $l_1, \ldots, l_k$ (results of the forward moves).

```
statement after M1, M2, ..., Mk do B
    l1 := M1; l2 := M2; ...; lk := Mk;
    B;
    Reverse(Mk, lk); ...; Reverse(M2, l2); Reverse(M1, l1);
```

Operators <, =, and $<_d$. **Input** P_1 and P_2—path descriptions relative to the current vertex. **Output** Let v_1 and v_2 be the end vertex of P_1 and P_2, correspondingly. The three operators check correspondingly, whether $v_1 < v_2$, $v_1 = v_2$, and $v_1 <_d v_2$. **Assumes** All forward moves are valid. $<_d$ assumes also that v_1 and v_2 are valid. **Local variables** i (counter for indices of bits), b_1 (ith bit of v_1), and b_2 (ith bit of v_2) for < and =. d_1 (degree of v_1) and d_2 (degree of v_2) for $<_d$. **Notes** Bit(s, t) returns the sth most significant bit of t. b_1 and b_2 are single bits.

```
operator P1 < P2
    for i := 1 to ⌈log n⌉ do
        after P1 do b1 := Bit(i, currvertex);
        after P2 do b2 := Bit(i, currvertex);
        if b1 ≠ b2 then return b1 < b2;
    return false;
operator P1 = P2
    for i := 1 to ⌈log n⌉ do
        after P1 do b1 := Bit(i, currvertex);
        after P2 do b2 := Bit(i, currvertex);
        if b1 ≠ b2 then return false;
    return true;
operator P1 <d P2
    after P1 do d1 ::= Prev(Degree);
    after P2 do d2 ::= Prev(Degree);
    return (d1 < d2) or (d1 = d2 and P1 < P2);
```

4.4.6. State functions. Functions Done, Active, and Inactive. **Input** None. **Output** Correspondingly whether $cv \in D_{cl}$, $cv \in A_{cl}$, and $cv \in I_{cl}$. **Assumes** None. **Local variables** None.

```
function Done
    return (level = 0 and Degree = 0) or
        (level > 0 and not Contraction and Prev(Done)) or
        (level > 0 and Contraction and
            (Prev(Done) or Root ≠ 0 or Degree = 0));
function Active
    return (level = 0 and Degree ≠ 0) or
        (level > 0 and not Contraction and Prev(Active)) or
        (level > 0 and Contraction and
```

```
            not Done and TreeSize ≠ null);
function Inactive
    return (level > 0 and not Contraction and Prev(Inactive)) or
        (level > 0 and Contraction and
            not Done and TreeSize = null);
```

4.4.7. Hooking. Function Hook. **Input** None. **Output** $H_{cl}(cv)$. **Assumes** None. **Local variables** $\mathtt{d}_1$ (degree of cv), i (counter for neighbors of cv), $\mathtt{d}_2$ (degree of the ith neighbor of cv), j (counter for neighbors of the ith neighbor of cv), and m (current candidate neighbor for hooking). **Notes** Hook is defined as given in section 3.2.2. In line 9 we use Observation 4.1(i) to deduce that $\eta_{cl-1}(cv, \mathtt{i}) \in I_{cl-1}$. At line 5 $cv \in A_{cl-1}$, and hence $\mathtt{d}_1$ is valid and non-null. So i and m are also valid. At line 12 we have that $\eta_{cl-1}(cv, \mathtt{i}), \eta_{cl-1}(cv, \mathtt{m}) \in A_{cl-1}$. At line 14 all neighbors of cv are in A_{cl-1}. Hence $\mathtt{d}_2$ and j are valid.

```
   function Hook
 1     if level = 0 then return 0;
 2     if not Contraction and Prev(Inactive) then return Prev(Hook);
 3     if Contraction and Inactive then return Prev(Hook);
 4     if Prev(Done) or Contraction then return 0;

 5     d1 ::= Prev(Degree);
 6     m := 0;
 7     for i := 1 to d1 do
 8         // if the ith neighbor is inactive, then hook to it
 9         if not MoveValid(i) then return i;
10         after Move(i) do fl := Prev(Inactive);
11         if fl then return i;

           // otherwise, check if it is bigger than the current biggest
           // active neighbor
12         if Move(m) <d Move(i) then m := i;
13     if m > 0 then return m;

14     for i := 1 to d1 do
15         after Move(i) do d2 ::= Prev(Degree);
16         for j := 1 to d2 do
               // if the jth neighbor of the ith neighbor
               // is inactive, then hook to the ith neighbor
17             after Move(i) do fl := MoveValid(j);
18             if not fl then return i;
19             after Move(i), Move(j) do fl := Prev(Inactive);
20             if fl then return i;

               // otherwise, hook to the ith neighbor
               // if its jth neighbor is bigger than currvertex
21             if Current <d (Move(i), Move(j)) then m := i;
22     return m;
```

Function IsHooked. **Input** i. **Output** Let $(v, j) = \mu_{cl-1}(cv, i)$ and $h = H_{cl-1}(v)$. IsHooked is true iff $h = j$. **Assumes** $cl \geq 1$, $0 \leq i \leq \delta_{cl-1}(cv)$, and cv is valid or $\delta_{cl-1}(cv) \leq \delta_{cl-1}(v)$. **Local variables** i, j, and h (contain their equiv-

alents from the definition of the output). **Notes** `i` is valid because of line 2, `j` is valid because of the assignment in line 5, and `h` is valid because of the assignment in line 9.

```
   function IsHooked
 1     if argIsHooked = 0 then return Prev(Hook) = 0;
 2     if argIsHooked > Valid then return Prev(IsHooked);
 3     i := argIsHooked;
 4     if Prev(Degree) > Valid then return Prev(IsHooked(i));

 5     j := Prev(BackLabel(i));
 6     if j = null then
 7         if Prev(Active) then return false;
 8         return Prev(IsHooked(i));
 9     after Move(i) do h ::= Prev(Hook);
10     return h = j;
```

Correctness We will prove the correctness of `IsHooked` by induction on cl. Notice that for $cl = 1$, the checks in lines 2, 4, and 6 all fail because at level 1 all vertices are valid, and we compare `h` and `j` in line 10.

First, consider the case when $cv \in A_{cl-1}$. In this case cv is valid by Observation 4.1(ii). If `j` is invalid, then $v \in I_{cl-1}$, and it is not hooked to cv (otherwise, $cv \in I_{cl-1}$ by Definition 3.5). We catch this in line 7. If `j` is valid, then in line 10 we check whether it is equal to `h`.

Now let $cv \in I_{cl-1}$ and $v \in A_{cl-1}$. Since v is valid, cv is valid also, because this follows from v being valid, and cv being valid or $\delta_{cl-1}(cv) \le \delta_{cl-1}(v)$. So `i`, `j`, and `h` are valid, and we can compare `h` and `j` in line 10.

Assume now that $cv, v \in I_{cl-1}$. In this case the only way `IsHooked` returns an answer without calling recursively is in line 10; then `j` is valid, and we have compared it to `h`. Notice now that if `IsHooked` calls itself recursively, then $\delta_{cl-1}(cv) \le \delta_{cl-1}(v)$. This is true for the calls in lines 2 and 4, because then cv is invalid. For the call in line 8, this is true, because cv is valid and v is invalid. Since $cv, v \in I_{cl-1}$, we have that $cl \ge 2$, $\delta_{cl-2}(cv) = \delta_{cl-1}(cv)$, $\delta_{cl-2}(v) = \delta_{cl-1}(v)$, $(v, \mathtt{j}) = \mu_{cl-2}(cv, \mathtt{i})$, and $\mathtt{h} = H_{cl-2}(v)$. Thus the correctness in this case is ensured by the inductive hypothesis.

4.4.8. Exploration walk. The functions in this section come from the definition of a hooking forest of a configuration given in section 3.2.1. Throughout, it is assumed that $cl \ge 1$ and $Op_{cl} = Contract$.

Function `TreeDegree`. **Input** None. **Output** If cv is valid, `TreeDegree` returns $\delta_T(cv)$; otherwise, it returns `null`. **Assumes** None. **Local variables** `i` (counter for steps of the exploration walk), `d` (degree of cv), and `td` (output). **Notes** In line 5 we use that cv is valid to apply the correctness of `IsHooked`. `d` is valid because of the assignment in line 1, and `i` and `td` are valid because at line 3 cv is valid.

```
   function TreeDegree
       // if currvertex is invalid, return null
 1     d ::= Prev(Degree);
 2     if d = null then return null;

 3     td := 0;
       // count the number of neighbors which are hooked to currvertex
 4     for i := 1 to d do
 5         if IsHooked(i) then td := td + 1;
       // add 1 if currvertex did not hook to itself
```

```
6       if Prev(Hook) ≠ 0 then td := td + 1;
7       return td
```

Function `TreeMove`. **Input** i. **Output** Let $(v, r) = \mu_T(cv, i)$. If a move along (cv, i) is possible, i.e., v is valid, `TreeMove` returns r and moves the current vertex to v; otherwise, it does not change the current vertex and returns `null`. **Assumes** $0 \le i \le \delta_T(cv)$, cv is valid. **Local variables** `i` (input), `j` (graph-edge label of the `i`th T-edge of cv), `k` (counter for the neighbors of v), `l` (counter for vertices which are hooked to cv), `d` (degree of cv), $\mathtt{d}_1$ (degree of v), and `r` (back-label of the `i`th T-edge of cv).

Notes Lines 2–7 convert from the label `i` of a T-edge $e = (v, \mathtt{i})$ to a label `j` of an edge in the graph. In line 5 we use that cv is valid to apply `IsHooked`. Lines 8–10 handle the case when v is invalid. Lines 11–26 compute the tree back-label `r` of e and move the current vertex to v. Lines 11–13 handle the case when v is hooked to the current vertex. Lines 14–26 handle the case when e is the hooking edge of the current vertex. In lines 19–21 we use that if the `k`th neighbor of v is invalid, then it is not cv, because cv is valid.

`i`, `j`, `l`, and `d` are valid, because cv is valid (the assignments in lines 3 and 7 are non-`null`). $\mathtt{d}_1$ is valid because of the assignment in line 9. `k` and `r` are valid because at line 14 v is valid.

```
   function TreeMove
        i := argTreeMove;
1       if i = 0 then return 0;

        // convert from T-edge label to graph-edge label
2       l := i;
3       d ::= Prev(Degree);
4       for j := 1 to d do
5           if IsHooked(j) then l := l - 1;
6           if l = 0 then break;
7       if j > d then j ::= Prev(Hook);

        // if the new vertex is invalid, return null
8       if not MoveValid(j) then return null;
9       after Move(j) do d1 ::= Prev(Degree);
10      if d1 = null then return null;

11      if i < TreeDegree or (i = TreeDegree and Prev(Hook) = 0) then
            // e goes to a neighbor which is hooked to currvertex
12          Move(j);
13          return TreeDegree;

        // e is the hooking edge of currvertex

        // compute the tree back-label
14      r := 1;
15      for k := 1 to d1 do
16          after Move(j) do fl := IsHooked(k);
17          if not fl then continue;
            // enumerate all the edges with which neighbors
            // of the new vertex hooked to it
```

```
18          after Move(j) do fl := MoveValid(k);
19          if not fl then
20              // the kth neighbor of the new vertex is invalid
21              r := r + 1;
22              continue;

            // check if this is the edge with which currvertex
            // is hooked to the new vertex
23          if (Move(j), Move(k)) = Current then break;
24          r := r + 1;

        // move to the new vertex
25      Move(j);
        // return the tree back-label
26      return r;
```

Function `TreeForwardStep`. **Input** i. **Output** Let $(v, j) = \Gamma_{T,1}(cv, i)$. If a move along (cv, i) is possible, i.e., v is valid, then `TreeForwardStep` returns j and moves the current vertex to v; otherwise, it returns `null` and does not change the current vertex. **Assumes** $0 \le i \le \delta_T(cv)$, cv is valid. **Local variables** `j` (back-label of the ith T-edge of cv).

```
function TreeForwardStep
    j := TreeMove(argTreeForwardStep);
    if j = null then return null;
    j := j + 1;
    if j > TreeDegree then j := 1;
    return j;
```

Function `TreeForward`. **Input** i. **Output** If $(v, j) = \Gamma_{T,i}(cv, 1)$, then the function `TreeForward` returns j and moves the current vertex to v. **Assumes** cv and i are valid, all moves of $\Gamma_{T,\le i}(v, 1)$ are possible. **Local variables** `i` (input), `j` (output), and `k` (counter for steps of the exploration walk).

```
function TreeForward
    i := argTreeForward;
    j := 1;
    for k := 1 to i do
        j := TreeForwardStep(j);
    return j;
```

Function `TreeBack`. **Input** i, j. **Output** If v is the vertex of $\Gamma'_{T,i}(cv, j)$, then `TreeBack` moves the current vertex to v. **Assumes** $0 \le j \le \delta_T(cv)$, cv and i are valid, all moves of $\Gamma'_{T,\le i}(v, j)$ are possible. **Local variables** `i` (input), `j` (input), and `k` (counter for steps of the exploration walk). **Notes** `TreeBack` is defined in a way similar to `TreeForward` using a function `TreeBackStep`.

```
function TreeBackStep
    j := argTreeBackStep - 1;
    if j = 0 then j := TreeDegree;
    return TreeMove(j);

procedure TreeBack
    i := arg1TreeBack; j := arg2TreeBack;
    for k := 1 to i do
        j := TreeBackStep(j);
```

Function `TreeSize`. **Input** None. **Output** $2(\texttt{size}(T)-1)$, if T is contractable, and `null` otherwise. **Assumes** None. **Local variables** `i` (length of the exploration walk), $\texttt{i}_1$ (counter for steps of the exploration walk), $\texttt{k}_1$ (T-edge label of the $(\texttt{i}-1)$st edge of the exploration walk), $\texttt{k}_2$ (T-edge label of the `i`th edge of the exploration walk), `d` (T-degree of cv), $\texttt{d}_1$ (T-degree of the `i`th vertex of the exploration walk), and `td` (degree of T).

Notes $2(\texttt{size}(T)-1)$ is the length of the exploration walk given in Proposition 3.4. The method to compute it is provided by the same proposition; i.e., `TreeSize` incrementally finds (lines 6–22) the length of a walk which visits the current vertex exactly the number of times equal to its tree-degree plus 1 (the check is done in lines 13 and 14). Before increasing the length of the walk, we first make sure that the next move is possible (lines 7–12). If it is not, `TreeSize` returns `null`. This is correct, because if T has an invalid vertex, it is not contractable (`Valid` > `ContractDegree`). Otherwise, it checks, if the walk went back to the starting vertex and returns, if the starting vertex was visited sufficiently many times. Also when `TreeSize` visits a vertex for the first time (lines 15–17), it adds its degree to the current total degree of T and returns `null` if the total degree becomes larger than `ContractDegree` (lines 18–21).

The condition of the loop in line 6 makes sure that the current length `i` of the exploration walk is valid. If it is not, line 23 returns `null` because T is uncontractable. This is correct because, on one hand, $\text{size}(T) \le \deg(T)$ (at line 6 T has at least one edge) and, on the other, by Proposition 3.4, exploration walk of length $2(\text{size}(T)-1)$ visits all vertices of a tree of size $\text{size}(T)$ and returns to the starting vertex sufficiently many times. Since `Valid` $\ge$ 2 `ContractDegree`, if the length of the exploration walk becomes bigger than `Valid`, then $\text{size}(T) >$ `ContractDegree`, so that $\deg(T) >$ `ContractDegree` and T is uncontractable.

`i` and $\texttt{i}_1$ are valid because of the condition of the loop in line 6. $\texttt{k}_1$ is valid because of the assumption that all vertices visited by the exploration walk of length $\texttt{i}-1$ in line 7 are valid. $\texttt{k}_2$ is valid because of the condition on the output of `TreeForwardStep` in line 8. `d` is valid because of the condition on the output of `TreeDegree` in line 1. `td` is valid because at line 20 both `td` and $\texttt{d}_1$ are at most `ContractDegree`, and since `Valid` $\ge$ 2 `ContractDegree`, the addition in line 20 produces a valid result.

```
   function TreeSize
 1     d := TreeDegree;
       // if currvertex is invalid, then the tree is uncontractable
 2     if d = null then return null;
 3     if d = 0 then return 0;

 4     i := 1;
 5     td := 0;
 6     while i ≤ Valid do
           // check if we can make one more step
           // from the exploration walk
 7         k1 := TreeForward(i-1);
 8         k2 := TreeForwardStep(k1);
 9         if k2 = null then
               // if we cannot, then the tree is uncontractable
10             TreeBack(i-1, k1);
11             return null;
12         TreeBack(i, k2);
```

```
          // check if we have visited the starting vertex
          // sufficiently many times
13        if TreeForward(i) = Current then d := d - 1;
          // if yes, then return the current length of
          // the exploration walk
14        if d = 0 then return i;

          // check if the end of the current exploration walk
          // is visited for the first time
15        for i1 := 0 to i - 1 do
16            if TreeForward(i) = TreeForward(i1) then break;
17        if i1 = i then
              // if it is, add its degree to the total degree
18            after TreeForward(i) do d1 ::= Prev(Degree)
              // if the total degree becomes too large,
              // then the tree is uncontractable
19            if d1 > ContractDegree then return null;
20            td := td + d1;
21            if td > ContractDegree then return null;

          // increase the length of the exploration walk by 1
22        i := i + 1;
23    return null;
```

Function `Root`. **Input** None. **Output** If T is uncontractable or $cv \in D_{cl-1}$, then `Root` returns 0; otherwise, it returns the index of the first occurrence of root(T) in the exploration walk. **Assumes** None. **Local variables** `d` ($2(\text{size}(T) - 1)$) and `i` (counter for steps of the exploration walk).

Notes According to the definition of root(T) given in section 3.2.1, `Root` enumerates the vertices of T using the exploration walk starting from $(cv, 1)$ (lines 3–5) and finds the first vertex which is hooked to itself (line 4). `d` is valid because of the assignment in line 1, and `i` is valid because at line 3 T is contractable.

```
  function Root
      // check if T is contractable
1     d := TreeSize;
2     if d = null or Prev(Done) then return 0;

      // if it is, find the first vertex in it which is hooked
      // to itself
3     for i := 0 to d-1 do
4         after TreeForward(i) do fl := (Prev(Hook) = 0);
5         if fl then return i;
```

4.4.9. Contraction. The definitions of the functions in this section come from the definition of the contraction operation given in section 3.2.3.

Function `IsEdge`. **Input** i and j. **Output** If v is the vertex of $\Gamma_{T,i}(cv, 1)$, then `IsEdge` returns true iff (v, j) is a remaining edge of T (see the definition in section 3.2.3). **Assumes** i is valid, $0 \le j \le \delta_{cl-1}(v)$, $cv = \text{root}(T)$, and T is contractable. **Local variables** `i` (input), `j` (input), `k` (counter for steps of the exploration walk), $\texttt{j}_1$ (counter for neighbors of the `k`th vertex of the exploration walk), $\texttt{k}_1$ (counter for steps of the exploration walk on the tree of the `j`th neighbor of v), `d` ($2(\text{size}(T) - 1)$),

$\mathtt{d}_1$ (degree of the kth vertex of the exploration walk), and $\mathtt{d}_2$ ($2(s-1)$, where s is the size of the tree of the jth neighbor of v).

Notes The definition of `IsEdge` follows exactly the definition of the remaining edges of T given in section 3.2.3. Let $e = (v, j)$, $w = \eta_{cl-1}(e)$, and T' be the hooking tree of w in $\mathcal{C}_{cl-1}$. Lines 2–5 check if T' is contractable. Line 7 checks if e is internal. Let u be the kth vertex in the exploration walk of T starting from cv. Because of lines 9 and 10, at line 12 $(u, \mathtt{j}_1)$ is an edge before e in the sequence of the remaining edges of T given in section 3.2.3. Let $u' = \eta_{cl-1}(u, \mathtt{j}_1)$. Lines 14–16 check whether u' is in T'. In line 13 we use that if the hooking tree of u' in $\mathcal{C}_{cl-1}$ is uncontractable, then u' is not from T', because at this point T' is contractable.

i, j, and d are valid because T is contractable. $\mathtt{d}_2$ and $\mathtt{k}_1$ are valid, because at line 6 T' is contractable. Lines 9 and 10 ensure the validity of $\mathtt{d}_1$ and $\mathtt{j}_1$.

```
   function IsEdge
        i := arg1IsEdge; j := arg2IsEdge;
 1      d := TreeSize;
        // if T' is uncontractable, then e remains
 2      after TreeForward(i) do fl := MoveValid(j);
 3      if not fl then return true;
 4      after TreeForward(i), Move(j) do d2 := TreeSize;
 5      if d2 = null then return true;

        // T' is contractable
 6      for k := 0 to d-1 do
            // e does not remain if it is an internal edge
 7          if TreeForward(k) = (TreeForward(i), Move(j)) then
                return false;
 8          if k > i then continue;

 9          if k = i then d1 := j - 1;
            else
10              after TreeForward(k) do d1 ::= Prev(Degree);

            // e does not remain if it is not the first edge
            // from T to T'
11          for j1 := 1 to d1 do
12              after TreeForward(k) do fl := MoveValid(j1);
13              if not fl then continue;

14              for k1 := 0 to d2-1 do
15                  if (Treeforward(i), Move(j), TreeForward(k1)) =
                            (TreeForward(k), Move(j1)) then
16                      return false;
17      return true;
```

Statement "**after** P **for every edge** (i, j) **do** B." **Input** P a path description relative to the current vertex, i and j names of local variables using this statement, B instruction(s) which might depend on the variables i and j. **Output** Let v be the vertex with path description P, and T' is its hooking tree in $\mathcal{C}_{cl-1}$. This statement executes B for all possible values of (i, j) such that $(u, \mathtt{j})$ is a remaining edge of T', where u is the vertex of $\Gamma_{T',\mathtt{i}}(v, 1)$. **Assumes** $cl \geq 1$, all forward moves in P are valid, T' is contractable and $v = \mathrm{root}(T')$. **Local variables** $\mathtt{i}_1$ (counter for steps of the

exploration walk on T' starting from $(v,1)$), $\mathtt{d}_1$ ($2(\text{size}(T')-1)$), and $\mathtt{d}_2$ (degree of the $\mathtt{i}$th vertex of the exploration walk on T' starting from $(v,1)$).

Notes Lines 3–5 check if this is the first time the exploration walk on T' starting from $(v,1)$ visits the $\mathtt{i}$th vertex v. If so, lines 7–9 enumerate the remaining edges of T' incident to v. All local variables, and `i` and `j`, are valid because T' is contractable.

```
  statement after P for every edge (i, j) do B
1     after P do d1 := TreeSize;
2     for i := 0 to d1 - 1 do
          // visit only once every vertex of T'
3         for i1 := 0 to i - 1 do
4             if (P, TreeForward(i)) = (P, TreeForward(i1)) then
                  break;
5         if i1 < i then continue;

6         after P, TreeForward(i) do d2 ::= Prev(Degree);
7         for j := 1 to d2 do
8             after P do fl := IsEdge(i, j);
9             if not fl then continue;

              // if (i, j) is a remaining edge, then execute B
10            B;
```

Function `Degree`. **Input** None. **Output** $\delta_{cl}(cv)$. **Assumes** None. **Local variables** `i` (counter for steps of the exploration walk), `j` (counter for neighbors of the $\mathtt{i}$th vertex of the exploration walk), and `d` (degree of cv). **Notes** To obtain the degree of the current vertex, we just enumerate all remaining edges of T. If T is not contractable, then, by definition, the degree comes from a previous level (line 2). Line 2 handles the case when $cv \in I_{cl}$ and line 3 the case when $cv \in D_{cl}$. All local variables are valid because at line 3 T is contractable.

`GraphDegree` returns the degree of the current vertex in the input graph G.

```
  function Degree
1     if level = 0 then return GraphDegree;
2     if not Contraction or TreeSize = null then return Prev(Degree);
3     if Prev(Done) or Root ≠ 0 then return 0;

4     d := 0;
5     after Current for every edge (i,j) do d := d + 1;
6     return d;
```

Procedure `Neighbor`. **Input** i. **Output** Moves the current vertex to $\eta_{cl}(cv,i)$. **Assumes** $0 \le i \le \delta_{cl}(cv)$. **Local variables** `i` (input), `l` (counter for steps of the exploration walk), `j` (counter for neighbors of the $\mathtt{l}$th vertex of the exploration walk), and `d` ($2(\text{size}(T)-1)$).

Notes The definition of `Neighbor` follows the definitions in section 3.2.3. First, we make sure that T is contractable (lines 4 and 10). If not, then we call recursively. Otherwise, i is the index of a remaining edge e of T, and we locate e and move along it (lines 14–20). Once we move along e, we move the current vertex to the representative of the new current vertex, i.e., the root of the new current hooking tree T', if it is contractable (lines 6, 12, and 19).

`i` is valid because at line 8 `argNeighbor` is valid, and the other local variables are valid because at line 14 T is contractable.

`GraphNeighbor`(i) moves the current vertex to its ith neighbor in the input

graph G.

```
   procedure Neighbor
 1     if level = 0 then GraphNeighbor(argNeighbor);
       if not Contraction then Prev(Neighbor);
 2     // handle the self-loop case
 3     if argNeighbor = 0 then return;

 4     if argNeighbor > Valid then
           // if T is uncontractable, call recursively
 5         Prev(Neighbor);
           // if T' is contractable, move to its root
 6         if TreeSize ≠ null then TreeForward(Root);
 7         return;
 8     i := argNeighbor;

 9     d := TreeSize;
10     if d = null then
           // T is uncontractable
11         Prev(Neighbor(i));
12         if TreeSize ≠ null then TreeForward(Root);
13         return;

       // T is contractable
14     after Current for every edge (l, j) do
15         i := i - 1;
           // check if (l, j) is e
16         if i > 0 then continue;

           // move to e and then along e
17         TreeForward(l);
18         Prev(Neighbor(j));
           // move to the root of T'
19         if TreeSize ≠ null then TreeForward(Root);
20         return;
```

Function `BackLabel`. **Input** i. **Output** $\beta_{cl}(cv, i)$. Uses the array method described in section 4.4.2 of taking arguments and returning values. **Assumes** $0 \leq i \leq \delta_{cl}(cv)$. **Local variables** `i` (input), `l` (counter for steps of the exploration walk), $\mathtt{k}_1$ (same as `l`), `j` (counter for the neighbors of the `l`th vertex of the exploration walk), `d` ($2(\text{size}(T) - 1)$), `nd` (output), `k` (counter for steps of the exploration walk on T' starting from $(u, 1)$), $\mathtt{j}_1$ (counter for neighbors of the `k`th vertex of the exploration walk on T' starting from $(u, 1)$), and `r` (index of the first occurrence of the root of T' in the exploration walk on T' starting from $(u, 1)$), where u is the `j`th neighbor of the `l`th vertex of the exploration walk and T' is the hooking tree of u.

Notes The first case of `BackLabel` is when T is contractable. In this case we find the remaining edge e of T with index i (lines 12–14). Let $v = \eta_{cl-1}(e)$ and T' be the hooking tree of v in $\mathcal{C}_{cl-1}$. If T' is uncontractable, then we call recursively, because in this case the back-label comes from the previous level of recursion (line 22). Otherwise, we have to find the index `nd` of the first remaining edge e' of T' which goes from T' to T (lines 24–32). This is the new back-label. To find the index of e', first we find the root of T' (line 20) and then enumerate all remaining edges of T' (lines

25–32). For each remaining edge of T', we check if it goes to T (line 30–32). In lines 27–29, we use that if a remaining edge of T' goes to an uncontractable hooking tree, then it does not go to T, because at this point T is contractable. The case when T is uncontractable is handled by `BackLabelAux` (lines 5 and 10).

`i` is valid because of line 4. `d` is valid because of the assignment in line 8. `l`, `j`, and $\texttt{k}_1$ are valid because at line 12 T is contractable. `r` is valid because of line 20. $\texttt{j}_1$, `k`, and `nd` are valid because at line 24 T' is contractable.

The recursive call in line 22 does not assign the returned value to a local variable; i.e., this call returns a value at some higher level of recursion, depending on the array for returning values of `BackLabel`. This call is the reason why `BackLabel` returns through an array instead of a global variable. The conventional thing to do is to store the result of this call locally, and once the **after** statement has restored the original current vertex, return the stored value. This will not work for us, because the value returned from the recursive call might be invalid. Instead, using that the only reason why we store the returned value is to pass it back, when `BackLabel` produces a result we let it store the result at the level at which it is requested. This works because `BackLabel` is always called on the previous level of recursion.

`GraphBackLabel`(i) returns the back-label of the ith edge incident to cv in the input graph G.

```
   function BackLabel
 1     if level = 0 then return GraphBackLabel(argBackLabel);
 2     if not Contraction then return Prev(BackLabel);
 3     if argBackLabel = 0 then return 0;

       // if currvertex is invalid, call BackLabelAux
 4     if argBackLabel > Valid then
 5         BackLabelAux;
 6         return;
 7     i := argBackLabel;

       // if T is uncontractable, call BackLabelAux
 8     d := TreeSize;
 9     if d = null then
10         BackLabelAux;
11         return;

       // T is contractable
12     after Current for every edge (l, j) do
13         i := i - 1;
           // find e
14         if i > 0 then continue;

15         after TreeForward(l) do
16             fl := MoveValid(j);
17             if fl then
18                 after Move(j) do
19                     fl := (TreeSize ≠ null);
20                     if fl then r := Root;

21         if not fl then
```

```
            // if T' is uncontractable, call recursively
22          after TreeForward(l) do Prev(BackLabel(j));
23          return;

    // T' is contractable
24      nd := 0;
        // find the first edge of T' which goes to T and
        // return its index
25      after TreeForward(l), Move(j), TreeForward(r)
                for every edge (k, j_1) do
26          nd := nd + 1;
27          after TreeForward(l), Move(j),
                        TreeForward(r), TreeForward(k) do
28              fl := MoveValid(j_1);
29          if not fl then continue;

30          for k_1 := 0 to d-1 do
31              if (TreeForward(l), Move(j),
                      TreeForward(r), TreeForward(k), Move(j_1)) =
                    TreeForward(k_1) then
32                  return nd;
```

Function `BackLabelAux`. **Input** i. **Output** $\beta_{cl}(cv)$. To take argument and return value, `BackLabelAux` uses the arrays of `BackLabel`. **Assumes** $0 \le i \le \delta_{cl}(cv)$, T is uncontractable. **Local variables** `l` (counter for steps of the exploration walk on T' starting from $(v, 1)$), `j` (counter for neighbors of the `l`th vertex of the exploration walk on T' starting from $(v, 1)$), `k` (same as `l`), `bl` ($\beta_{cl-1}(cv, i)$), `nbl` (output), `r` (index of the first occurrence of the root of T' in the exploration walk on T' starting from $(v, 1)$), and `d` ($2(\text{size}(T') - 1)$), where T' and v are as in the note for `BackLabel`.

Notes The definition of `BackLabelAux` follows the definitions given in section 3.2.3 when T is uncontractable. Let v and T' be as in the note for `BackLabel`. If T' is uncontractable, the back-label is inherited from the previous level of recursion, and so we call `BackLabel` recursively (lines 3 and 10). Otherwise, at line 12 T' is contractable, the current vertex is v (because of line 5), and `bl` is the back-label of e (because of line 1). So we have to find the index of $(v, \texttt{bl})$ in T' ($(v, \texttt{bl})$ is a remaining edge of T' because T is uncontractable). Line 12 finds the root of T', and lines 13 and 14 find the index `k` of the first occurrence of v in the exploration walk of T' starting from its root. Lines 16–20 enumerate the remaining edges of T' until we find $(v, \texttt{bl})$.

`bl` is valid by the assumption for the return convention of `BackLabel` for line 1. `d` is valid because of the assignment in line 6. `r`, `l`, `j`, `k`, and `nbl` are valid because at line 12 T' is contractable.

Just like for `BackLabel`, the calls to `BackLabel` in lines 3 and 10 return values at some higher level of recursion. The calls to `BackLabel` in lines 1, 3, and 10 do not have arguments—by convention this means that the argument to `BackLabel` comes from a higher level of recursion.

The case when T is uncontractable is the reason why the argument to `BackLabel` is passed through an array instead of a global variable. More precisely, the problem is when the current vertex is invalid; then the argument i to `BackLabel`, which is the label of an edge incident to cv, might be invalid and storing it locally will be impossible. In this case we still want to be able to use the value of i after calling

functions which can potentially change the value of a global argument to `BackLabel`. The decision is to let the value of the argument stay at the level which produced it, because it certainly is valid for this level. For this to work, it is important that the value of the argument stored in the array is not changed while processing the call to `BackLabel`. Fortunately, this does not happen, because `BackLabel` is always called on the previous level of recursion.

```
   function BackLabelAux
 1     bl := Prev(BackLabel);
 2     if bl = null then
           // if T' is uncontractable, call recursively
 3         Prev(BackLabel);
 4         return;

       // move along e
 5     Prev(Neighbor(argBackLabel));

 6     d := TreeSize;
 7     if d = null then
 8         // if T' is uncontractable, go back and call recursively
 9         Prev(Neighbor(bl));
10         Prev(BackLabel);
11         return;

       // T' is contractable
12     r := Root;
       // find the index of the first occurrence of v in
       // the exploration walk on T' starting from (r,1)
13     for k := 0 to d - 1 do
14         if TreeForward(r), TreeForward(k) = Current then break;

       // compute the new back-label
15     nbl := 0;
16     after TreeForward(r) for every edge (l, j) do
           // increase the new back-label by one for every edge
           // that happens before e
17         nbl := nbl + 1;

18         if l = k and j = bl then
               // if we are at (v,bl), move back and return
               // the new back-label
19             Prev(Neighbor(bl));
20             return nbl;
```

Function `Move`. **Input** i. **Output** Let $(v, j) = \mu_{cl-1}(cv, i)$. `Move` returns j and moves the current vertex to v. **Assumes** $cl \geq 1$, $0 \leq i \leq \delta_{cl-1}(cv)$, i and j valid. **Local variables** `i` (input) and `j` (output), which are valid by the assumption about the argument of `Move`.

```
function Move
    i := argMove;
    j := Prev(BackLabel(i));
    Prev(Neighbor(i));
```

```
    return j;
```

Function `MoveValid`. **Input** i. **Output** True iff $\beta_{cl-1}(cv, i)$ is valid. **Assumes** $cl \geq 1$, $0 \leq i \leq \delta_{cl-1}(cv)$, i valid. **Local variables** None.

```
function MoveValid
    return Prev(BackLabel(argMoveValid)) ≠ null;
```

4.4.10. Solving undirected st-connectivity. Procedure `MoveToRep`. **Input** None. **Output** Moves the current vertex to $\mathrm{rep}_{R_{cl}}(cv)$. **Assumes** None. **Local variables** None.

```
procedure MoveToRep
    if level > 0 then
        Prev(MoveToRep);
        if Contraction and TreeSize ≠ null then TreeForward(Root);
```

Global function `Connected`. **Input** s and t. **Output** True iff s and t are connected in G.

```
global function Connected
    level := 5 · 2^⌈log log n⌉ − 3;
    currvertex := arg1Connected; MoveToRep;
    v := currvertex;
    currvertex := arg2Connected; MoveToRep;
    return v = currvertex;
```

5. Proofs of Theorem 3.12 and Corollary 3.13. The proofs in this section are a direct translation into our notation of equivalent statements from [6] and are given here only for completeness. We use the notation of section 3.3.

LEMMA 5.1. *Assume that $\mathcal{C}_l$ is nice and $P_{l+1} = \langle Hook, k\rangle$.*

(i) *If $v \in I_l$, then $v \in I_{l+r(k)}$, $\delta_{l+r(k)}(v) = \delta_l(v)$, and $H_{l+r(k)}(v) = H_l(v)$.*

(ii) *If $v \in I_{l+r(k)} - I_l$, then $\delta_{l+r(k)}(v) \leq \mathrm{dexp}(k+2)$.*

(iii) *$\mathcal{C}_{l+1}$ is nice. If $k > 0$, then $\mathcal{C}_{l+2}$ is nice.*

Proof. (i) The state and degree of a vertex change only during a contraction operation. The same holds for the hooking edges of inactive vertices. Let T be the hooking tree of v in $\mathcal{C}_l$. Since $\mathcal{C}_l$ is nice, $\deg(T) > \mathrm{dexp}(k+2)$. For $l+1 \leq i \leq l+r(k)$, we have that $Arg_i \leq k+1$, so that trees of degree more than $\mathrm{dexp}(k+2)$ are never contracted. Therefore the status, degree, and hooking edge of v are never changed.

(ii) Since $v \in I_{l+r(k)} - I_l$ and because a done vertex stays done, we have that $v \in A_l$, and so $\delta_l(v) \leq \mathrm{dexp}(k+2)$, because $\mathcal{C}_l$ is nice. Hooking does not change degrees. For $l+1 \leq i \leq l+r(k)$, we have that $Arg_i \leq k+1$, so that any active vertex appearing after a contraction must have degree at most $\mathrm{dexp}(k+2)$. Let i be the largest $l \leq i < l+r(k)$ such that $v \in A_i$. Then $\delta_i(v) \leq \mathrm{dexp}(k+2)$, and its degree does not change afterwards. Hence $\delta_{l+r(k)}(v) \leq \mathrm{dexp}(k+2)$.

(iii) We have that $P_{l+2} = \langle Contract, k\rangle$ or $P_{l+2} = \langle Contract, 1\rangle$, if $k = 0$. Since a hooking operation changes only the hooking edges of active vertices, $\mathcal{C}_{l+1}$ is nice. Furthermore, for a hooking tree T' in $\mathcal{C}_{l+1}$ which contains an inactive vertex, we have that $\mathrm{size}(T') > \mathrm{dexp}(k+1)$

If $k > 0$, then $P_{l+3} = \langle Hook, k-1\rangle$. Let T be a hooking tree in $\mathcal{C}_{l+2}$ composed of inactive vertices. Because $P_{l+2} = \langle Contract, k\rangle$, we have that $\delta_{l+2}(v) \leq \mathrm{dexp}(k+1)$, for $v \in A_{l+2}$, and $\deg(T) > \mathrm{dexp}(k+1)$. There are two possibilities for T—either it was a hooking tree in $\mathcal{C}_{l+1}$ composed of active vertices or it contains a hooking tree T' of $\mathcal{C}_{l+1}$ which contained an inactive vertex. In the first case by Lemma 3.9, $\mathrm{size}(T) > \mathrm{dexp}(k)$. This is also true in the second case because, as mentioned at the

end of the previous paragraph, $\text{size}(T) > \text{dexp}(k+1) > \text{dexp}(k)$. Therefore $\mathcal{C}_{l+2}$ is nice. □

LEMMA 5.2. *Assume that $\mathcal{C}_l$ is nice and $P_{l+1} = \langle Hook, k\rangle$.*

(i) *If T is a hooking tree in $\mathcal{C}_{l+r(k)}$ composed of inactive vertices, then* $\text{size}(T) > \text{dexp}(k+1)$ *and* $\deg(T) > \text{dexp}(k+2)$.

(ii) *If $k > 0$, then $\mathcal{C}_{l+2+r(k-1)}$ and $\mathcal{C}_{l+2+2r(k-1)}$ are nice.*

Proof. Let $l_0 = l+2$, $l_1 = l_0 + r(k-1)$, $l_2 = l_1 + r(k-1)$, and $l_3 = l_2 + 1$ $(= l + r(k))$.

(i) Let T be a hooking tree of $\mathcal{C}_{l_3}$ composed of inactive vertices, i.e., $V_T \subseteq I_{l_3}$. Since $P_{l_3} = \langle Contract, k+1\rangle$, we have that

$$\deg(T) > \text{dexp}(k+2), \tag{5.1}$$

which ensures the degree part of the first item of the lemma. We are left with proving the size part.

Case 1: $V_T \cap I_l \neq \emptyset$. By Lemma 5.1(i), the vertices in $V_T \cap I_l$ form a hooking tree T' of $\mathcal{C}_l$ composed of inactive vertices. Since $\mathcal{C}_l$ is nice, $\text{size}(T') > \text{dexp}(k+1)$, and hence $\text{size}(T) > \text{dexp}(k+1)$.

Case 2: $V_T \cap I_l = \emptyset$. We do induction on k. If $k = 0$, then by Lemma 3.9 and (5.1), $\text{size}(T) > \text{dexp}(1)$.

Assume that $k > 0$.

From $\mathcal{C}_l$ nice and $P_{l_0} = \langle Contract, k\rangle$, it follows that $I_l \subseteq I_{l_0}$. Also by Lemma 5.1(i), $I_{l_0} \subseteq I_{l_1} \subseteq I_{l_2}$. Finally, $I_{l_3} \subseteq I_{l_2}$, because $Op_{l_3} = Contract$. Hence $V_T \subseteq I_{l_2}$.

For $l_0 + 1 \leq i \leq l_2$, we have that $Arg_i \leq k$. Therefore we can use the same argument as in the proof of Lemma 5.1(ii) to see that for every $v \in I_{l_2} - I_{l_0}$,

$$\delta_{l_2}(v) \leq \text{dexp}(k+1). \tag{5.2}$$

Case 1.1: $V_T \cap I_{l_0} = \emptyset$. By (5.2), $\delta_{l_2}(v) \leq \text{dexp}(k+1)$ for every $v \in V_T$. Hence $\deg(T) \leq \text{size}(T)\,\text{dexp}(k+1)$. Thus, from (5.1), it follows that $\text{size}(T) > \text{dexp}(k+1)$.

Case 1.2: $V_T \cap I_{l_0} \neq \emptyset$. From Lemma 5.1(i), it follows that $V_T \cap I_{l_0}$ form a hooking tree T' in $\mathcal{C}_{l_0}$. Let $d = \deg(T')/\text{size}(T')$, the average degree of a vertex of T'.

Case 1.2.1: $d \leq \text{dexp}(k+1)$. We have that $\deg(T') \leq \text{dexp}(k+1)\,\text{size}(T')$. Also for every $v \in V_T - V_{T'} \subseteq I_{l_2} - I_{l_0}$, by (5.2), $\delta_{l_2}(v) \leq \text{dexp}(k+1)$. Hence

$$\deg(T) = \sum_{v \in V_{T'}} \delta_{l_2}(v) + \sum_{v \in V_T - V_{T'}} \delta_{l_2}(v) \leq \text{dexp}(k+1)\,\text{size}(T),$$

and so $\text{size}(T) > \text{dexp}(k+1)$, because of (5.1).

Case 1.2.2: $d > \text{dexp}(k+1)$. Since $V_{T'} \subseteq V_T$, we have that $V_{T'} \cap I_l = \emptyset$. Hence $V_{T'} \subseteq A_l$, and so, by Lemma 3.9, $\text{size}(T') > \deg(T')/\text{size}(T') = d > \text{dexp}(k+1)$. Therefore, by (5.2),

$$\begin{aligned}\deg(T) &\leq \deg(T') + \text{dexp}(k+1)(\text{size}(T) - \text{size}(T')) \\ &< \text{size}^2(T') + \text{size}(T')(\text{size}(T) - \text{size}(T')) = \text{size}(T')\,\text{size}(T) \leq \text{size}^2(T).\end{aligned}$$

Hence in this last case and using (5.1) again, $\text{size}(T) > \text{dexp}(k+1)$ as well.

(ii) By Lemma 5.1(iii), $\mathcal{C}_{l_0}$ is nice. Hence, by the first item of the lemma (notice that $P_{l_0+1} = \langle Hook, k-1\rangle$), for any hooking tree T in $\mathcal{C}_{l_1}$ composed of inactive vertices, we have that $\text{size}(T) > \text{dexp}(k)$ and $\deg(T) > \text{dexp}(k+1)$. Furthermore,

since $P_{l_1} = \langle Contract, k\rangle$, for any $v \in A_{l_1}$, $\delta_{l_1}(v) \le \mathrm{dexp}(k+1)$. Therefore $\mathcal{C}_{l_1}$ is nice. $\mathcal{C}_{l_2}$ is nice for similar reasons. ∎

LEMMA 5.3. *Assume that $\mathcal{C}_l$ is nice and $P_{l+1} = \langle Hook, k\rangle$. Then for every $v \in A_{l+r(k)}$,*

$$|\{u \in A_l : \mathrm{rep}_{l+r(k)}(u) = v\}| \ge \mathrm{dexp}(k).$$

Proof. We do induction on k. Let $k = 0$. Consider $v \in A_{l+2}$. v must be a root of a hooking tree T in $\mathcal{C}_{l+1}$ and $V_T \subseteq A_{l+1}$, because $\mathcal{C}_l$ is nice and $P_{l+2} = \langle Contract, 1\rangle$. Hooking does not change the states of vertices, and so $A_l = A_{l+1}$. By Lemma 3.9, T has at least two vertices, and therefore v represents at least two vertices from A_l.

Assume that $k > 0$. Let $l_0 = l + 2$, $l_1 = l_0 + r(k-1)$, $l_2 = l_1 + r(k-1)$, and $l_3 = l_2 + 1$ $(= l + r(k))$. As can be seen in the proof of Lemma 5.2, we have that $A_{l_2} \subseteq A_{l_1} \subseteq A_{l_0} \subseteq A_l$ and $A_{l_2} \subseteq A_{l_3}$. Let $v \in A_{l_3}$. We have that v is in either A_{l_2} or in I_{l_2}.

Assume first that $v \in I_{l_2}$. Since $v \in A_{l_3}$ and $P_{l_3} = \langle Contract, k+1\rangle$, v is a root of a hooking tree T of $\mathcal{C}_{l_2}$ composed of inactive vertices which contracts to v. $V_T \subseteq A_l$, because if there exists $u \in V_T \cap I_l$, then by Lemma 5.1(i), $u \in I_{l_3}$, but we have that $V_T \cap I_{l_3} = \emptyset$. By Lemma 5.2(ii), $\mathcal{C}_{l_1}$ is nice, and therefore by Lemma 5.2(i), $\mathrm{size}(T) > \mathrm{dexp}(k)$. Thus v represents at least $\mathrm{dexp}(k)$ vertices from A_l.

Assume now that $v \in A_{l_2}$. Let

$$U_v = \{u \in A_{l_1} : \mathrm{rep}_{l_2}(u) = v\}.$$

By the inductive hypothesis, $|U_v| \ge \mathrm{dexp}(k-1)$. Let $u \in U_v$. Again by the inductive hypothesis, $|\{w \in A_{l_0} : \mathrm{rep}_{l_1}(w) = u\}| \ge \mathrm{dexp}(k-1)$. Hence

$$|\{w \in A_{l_0} : \mathrm{rep}_{l_2}(w) = v\}| \ge \mathrm{dexp}(k-1)\,\mathrm{dexp}(k-1) = \mathrm{dexp}(k).$$

Since $A_{l_0} \subseteq A_l$, the statement follows in this case as well. ∎

We are ready to prove Theorem 3.12.

Proof of Theorem 3.12. $|A_{r(k)}| \le \max\{|A_0|/\mathrm{dexp}(k), 1\}$ follows from Lemma 5.3 and the fact that the sets of vertices represented by different vertices from $A_{r(k)}$ are disjoint. $\mathrm{size}(T_v) > \mathrm{dexp}(k+1)$, for $v \in I_{r(k)}$, follows from Lemma 5.2(i).

We have to prove now that $\mathcal{C}_l$ is nice for $1 \le l < r(k)$. We prove by induction on t that if $\mathcal{C}_l$ is nice and $P_{l+1} = \langle Hook, t\rangle$, then $\mathcal{C}_i$ is nice for $l+1 \le i < l + r(t)$, and if $0 < t < k$, then $\mathcal{C}_{l+r(t)}$ is also nice.

By Lemma 5.1(iii), $\mathcal{C}_{l+1}$ is nice. This takes care of $t = 0$. Assume that $t > 0$. By Lemma 5.1(iii) and Lemma 5.2(ii), $\mathcal{C}_{l+2}$, $\mathcal{C}_{l+2+r(t-1)}$, and $\mathcal{C}_{l+2+2r(t-1)}$ are nice. By the inductive hypothesis applied twice, $\mathcal{C}_i$ is nice for $l+3 \le i < l+2+r(t-1)$ and $l+3+r(t-1) \le i < l+2+2r(t-1)$. Since $P_{l+r(t)} = \langle Contract, t+1\rangle$, we have that $\delta_{l+r(t)}(v) \le \mathrm{dexp}(t+2)$ for $v \in A_{l+r(t)}$. By Lemma 5.2(i), for any hooking tree of $\mathcal{C}_{l+r(t)}$ composed of inactive vertices, $\mathrm{size}(T) > \mathrm{dexp}(t+1)$ and $\deg(T) > \mathrm{dexp}(t+2)$. If $t < k$, then $P_{l+r(t)+1}$ is either $\langle Contract, t+2\rangle$ or $\langle Hook, t\rangle$, and in both cases $\mathcal{C}_{l+r(t)}$ is nice. ∎

Finally, let us prove Corollary 3.13.

Proof of Corollary 3.13. Let $k = \lceil \log\log n \rceil$. By Theorem 3.12,

$$|A_{r(k)}| \le \max\{n/\mathrm{dexp}(k), 1\} = 1.$$

On the other hand, again by Theorem 3.12, every hooking tree in $\mathcal{C}_{r(k)}$ composed of inactive vertices has size more than $\mathrm{dexp}(k+2) \ge n^2$. Therefore $I_{r(k)} = \emptyset$.

Suppose that u and v are connected in G, but $r_1 = \mathrm{rep}_{r(k)}(u) \neq \mathrm{rep}_{r(k)}(v) = r_2$. As we saw, $|A_{r(k)}| \leq 1$ and $I_{r(k)} = \emptyset$, and so without loss of generality we can assume that $r_1 \in D_{r(k)}$. Let l be the largest such that $r_1 \notin D_l$. $\delta_{l+1}(r_1) > 0$, because $r_1 \neq r_2$, r_1 and r_2 are connected in G, and r_1 inherits the neighbors of the vertices it represents. This contradicts the fact that r_1 becomes done if it is a root of a hooking tree and its degree is 0 (it can also become done if it is a nonroot of a hooking tree which is contracted, but then it would not be a representative). □

Acknowledgments. The author is grateful to Prof. Anna Gál for help in the preparation of this paper and Prof. Vijaya Ramachandran for pointing out the problem and many helpful discussions.

THE MIXING TIME OF THE THORP SHUFFLE*

BEN MORRIS†

Abstract. The Thorp shuffle is defined as follows. Cut a deck of cards into two equal piles. Drop the first card from the left pile or the right pile according to the outcome of a fair coin flip, then drop from the other pile. Continue this way until both piles are empty. We show that the mixing time for the Thorp shuffle with 2^d cards is polynomial in d.

Key words. mixing time, Markow chain, card shuffling

AMS subject classification. 60J10

DOI. 10.1137/050636231

1. Introduction.

1.1. The Thorp shuffle. How many shuffles are necessary to mix up a deck of cards? (see section 1.2 for a precise definition). The mathematics of card shuffling has been studied extensively over the past several decades and many of the problems have been solved. Most famously, Bayer and Diaconis [2] (in one of the few mathematical results to have made the front page of the New York Times) gave very precise bounds for the Gilbert–Shannon–Reeds (riffle) shuffle model. Their bounds were correct even up to the constant factors. For many other natural shuffles matching upper and lower bounds are known. However, despite Bayer and Diaconis's definitive analysis of the Gilbert–Shannon–Reeds shuffle, little is known about any variation of this model, and one problem, in particular, has stood out for its resistance to attack.

In 1973, Thorp [11] introduced the following shuffling procedure. Assume that the number of cards, n, is even. Cut the deck into two equal piles. Drop the first card from the left pile or the right pile according to the outcome of a fair coin flip, then drop from the other pile. Continue this way, with independent coin flips deciding whether to drop LEFT-RIGHT or RIGHT-LEFT each time, until both piles are empty.

The Thorp shuffle, despite its simple description, has been hard to analyze. The problem of determining its mixing time (see [1, 4, 9]) is, according to Diaconis [3], the "longest-standing open card shuffling problem." It has long been conjectured that the mixing time is $O(\log^c n)$ for some constant c. However, despite much effort the only known upper bounds are trivial ones of the form $O(n^c)$ that have circulated in the folklore. The main contribution of this paper is to give the first poly log upper bound for the mixing time.

We shall assume that the number of cards is 2^d for a positive integer d. (Thus, our aim is to prove that the mixing time is polynomial in d.) In this case the Thorp shuffle has a very appealing alternative description. By writing the position of each card, from the bottom card (0) to the top card $(2^d - 1)$, in binary, we can view the cards as occupying the vertices of the d-dimensional unit hypercube $\{0, 1\}^d$. The Thorp shuffle proceeds in two stages. In the first stage, an independent coin is flipped for each edge e in direction 1 (i.e., each edge in the cube that connects two vertices that differ in

only the first coordinate). If the coin lands heads, the cards at the endpoints of e are interchanged; otherwise the cards remain in place. In the second stage, a "cyclic left bit shift" is performed for each card, where the card in position $(x_1, \ldots, x_d)$ is moved to $(x_2, \ldots, x_d, x_1)$.

We will actually use a slightly modified definition of the Thorp shuffle. Say that an edge in the hypercube *rings* if its endpoints are switched with probability $\frac{1}{2}$. For $j = 1, \ldots, d$, let K_j be the transition kernel for the process in which every edge e in direction j rings. This leads us to the following definition.

Definition: Thorp shuffle. The *Thorp shuffle* is the Markov chain whose transition kernel at time n is K_{j+1} if $j \equiv n \bmod d$.

Note that if X_n is the shuffle described in [11], then this modified process can be written as $\theta^n X_n$, where θ denotes the operation that executes a cyclic right bit shift. Thus d iterations of our shuffle is equivalent to d iterations of the shuffle described in [11], so it is enough to prove a poly(d) mixing time bound for this new model.

It is natural to consider the change in the deck after d shuffles have been performed. (This represents one complete "cycle.") We will call this a *round*. Using the language of network computing, a round of the Thorp shuffle is like passing the cards through d levels of a butterfly network (see, e.g., Knuth's book [6]), where at each stage neighboring cards are interchanged with probability $\frac{1}{2}$.

The main result of this paper is that indeed the mixing time is polynomial in d. Our proof uses *evolving sets*, a technique for bounding mixing times that was introduced by the author and Peres in [8]. Another paper that uses some of the same ideas is [7], in which a variant of evolving sets is used to analyze the exclusion process. Evolving sets are related to the notion of strong stationary duality due to Diaconis and Fill [5].

1.2. Statement of main result. For a Markov chain on state space V with uniform stationary distribution, define the *(uniform) mixing time* by

$$\tau_{\text{mix}} = \min\Big\{n : \Big|p^n(x,y)|V| - 1\Big| \le \tfrac{1}{4} \ \ \forall\, x, y \in V\Big\},$$

where $p^n(x,y)$ is the n-step transition probability from x to y. (This is a stricter definition of mixing time than the usual one involving total variation distance.)

Our main result is the following theorem.

THEOREM 1.1. *The mixing time for the Thorp shuffle is* $O(d^{44})$.

Our approach will be to start by proving a "local" mixing property (i.e., a property involving a limited number of cards) and then build up to a global one. In section 2, we show that the Thorp shuffle (more precisely, a "reversibilized" version of the Thorp shuffle) has the following local property: Let $k > 2^{d-1}$. There is a constant b such that if every set of cards S with $|S| = k$ is almost uniformly distributed after bd^5 steps, then for any such set S, any card $x \in S$ will be roughly mixed within S after bd^5 steps. In section 3, we use this property to show that any collection of cards, if viewed as indistinguishable, mixes in $O(d^5)$ time. Later, we go on to prove that the Thorp shuffle satisfies a global mixing property that relates to an l^2 norm on the transition kernel; a precise statement of this property can be found in section 8. Before we get to the global property, we give some necessary background on evolving sets. Following [8], our mixing time bounds are achieved using an isoperimetric function called the root profile, which is connected to evolving sets. In section 4 we give a brief introduction to evolving sets and show how l^2 techniques can be used to give a bound on the root profile. Next, in section 5 we state the main technical result of this

paper (proved in section 8), which is the global property; then we use this to obtain our bound on the root profile. Next, armed with a good bound on the root profile we prove Theorem 1.1 in section 6. We conclude with proofs of technical lemmas in sections 7 and 8.

2. First step: A local mixing property. The basic aim of this section is to show that the following holds for some constant b: if $k > 2^{d-1}$ and every set of cards S with $|S| = k$ is almost uniformly distributed after bd^5 steps, then for any such set S, any card $x \in S$ will be roughly mixed within S after bd^5 steps. We will actually work with the following reversibilized version of the Thorp shuffle: the shuffle that behaves like the Thorp shuffle for the first d steps $(K_1, \dots, K_d)$, and then like a "reverse Thorp shuffle" for the next d steps $(K_d, \dots, K_1)$. We will call this the zigzag shuffle. Every $2d$ steps of the zigzag shuffle will be called a round. (So a round of the zigzag shuffle is a round of the Thorp shuffle followed by a round of a time-reversed Thorp shuffle.)

2.1. Chameleon process. We would like to have a technique to analyze, for a set S of cards, how a particular card $x \in S$ gets mixed within S. For this reason we will consider an auxiliary process called the *chameleon process*. In the chameleon process the cards move in the same way as in the zigzag shuffle, but they also have colors, which can be red, white, black, or pink. Fix $b > 2^{d-1}$ and let $S = \{x_1, \dots, x_b\}$ be a set of cards. Then the initial colors of the chameleon process are as follows: Cards $x_1, \dots, x_{b-1}$ are colored white, card x_b is colored red, and the remaining cards are colored black. The cards can change color in two ways. The first way is called *pinkening*, which takes place when an edge connecting a red card to a white card rings; in this case both cards are recolored pink. The second way is called *depinking*, which takes place at the end of every $64cd$ rounds of shuffling (where the constant c is specified in the next paragraph); in this case all of the pink cards are collectively recolored red or white, with probability $\frac{1}{2}$ each. (A process of this type was first used in [7] to analyze the exclusion process.) Note that black cards can never change color.

We now specify the constant c that appears above. If α is large enough so that $4\alpha^{-d} \le 2^{-d-1}4^{-d}$ for all $d \ge 1$ and $\beta = 8224 \cdot 64 \cdot 5$, then let c be an integer large enough so that $[4e^{-c}]^d \lceil \beta \log \alpha\, c \rceil d^5 \le \alpha^{-d}$ for all $d \ge 1$.

Let X_n be the zigzag shuffle. For $j = 1, \dots, 2^d$, we will write $X_n(j)$ for the position of card j at time n. If $\Lambda = \{z_1, \dots, z_k\}$ is a set of cards, define $X_n(\Lambda) = \{X_n(z_1), \dots, X_n(z_k)\}$. Let $W_n = X_n(S)$ be the *unordered* set of locations of nonblack cards (i.e., cards that are white, red, or pink in the chameleon process) at time n. For vertices x in the hypercube, define

$$\rho_n(x) = \mathbf{1}(\text{there is a red card at } x \text{ at time } n) + \tfrac{1}{2}\mathbf{1}(\text{there is a pink card at } x \text{ at time } n).$$

The following lemma indicates the fundamental relationship between the chameleon process and the zigzag shuffle.

LEMMA 2.1. *Consider the chameleon process with b nonblack cards. Then*

$$\mathbf{P}\Big(X_n(x_b) = x \,\Big|\, W_1, W_2, \dots\Big) = \mathbf{E}\Big(\rho_n(x) \,\Big|\, W_1, W_2, \dots\Big).$$

Proof. We will use induction on n. The base case $n = 0$ is trivial because there is initially only one red ball which is located at the position of card x_b. Now assume that the result holds for n. Let e be the edge incident to x that rings at time n and let x' be the neighbor of x across e. Let A_1, A_2, and A_3 be the events corresponding to the following three possible values of $(W_n \cap \{x, x'\}, W_{n+1} \cap \{x, x'\})$ when $x \in W_{n+1}$:

1. $(\{x, x'\}, \{x, x'\})$,
2. $(\{x'\}, \{x\})$,
3. $(\{x\}, \{x\})$.

Let $\mathcal{F}_n = \sigma(\rho_n(x), \rho_n(x'))$. Note that

$$\mathbf{E}\Big(\rho_{n+1}(x) \;\Big|\; \mathcal{F}_n, W_1, W_2, \dots\Big) = \Big(\tfrac{1}{2}\rho_n(x) + \tfrac{1}{2}\rho_n(x')\Big)\mathbf{1}(A_1) + \rho_n(x')\mathbf{1}(A_2) + \rho_n(x)\mathbf{1}(A_3). \tag{1}$$

Define $\mu_n(\cdot) = \mathbf{P}\Big(X_n(x_b) = \cdot \;\Big|\; W_1, W_2, \dots\Big)$. Then

$$\mu_{n+1}(x) = \Big(\tfrac{1}{2}\mu_n(x) + \tfrac{1}{2}\mu_n(x')\Big)\mathbf{1}(A_1) + \mu_n(x')\mathbf{1}(A_2) + \mu_n(x)\mathbf{1}(A_3). \tag{2}$$

But by induction we have

$$\mu_n(x) = \mathbf{E}\Big(\rho_n(x) \;\Big|\; W_1, W_2, \dots\Big), \qquad \mu_n(x') = \mathbf{E}\Big(\rho_n(x') \;\Big|\; W_1, W_2, \dots\Big).$$

To complete the proof, take the conditional expectation given $W_1, W_2, \dots$ of both sides of (1) and combine with (2). □

Remark. Note that

$$\mathbf{E}\Big(\sum_x \rho_n(x) \;\Big|\; W_1, W_2, \dots\Big) = \sum_x \mathbf{P}\Big(X_n(b) = x \;\Big|\; W_1, W_2, \dots\Big) = 1. \tag{3}$$

2.2. A useful lemma. Let A and B be disjoint sets of cards. For $x \in A$, say that x is *antisocial in round j* of the zigzag shuffle if at no point in round j does an edge connecting x to a card in B ring. Let $Z(A, B, j)$ denote the number of cards that are antisocial in round j. We say that A *avoids* B if $Z(A, B, j) > \frac{7}{8}|A|$ for $64cd$ consecutive rounds j before time m. If S is a set of cards, say that S *circulates* if there do not exist disjoint sets A, B of cards with $|A| \le \frac{1}{2}|S|$ and $A \cup B = S$ such that A avoids B.

Fix a set of cards $S = \{x_1, \dots, x_k\}$ and consider the corresponding chameleon process. Let $\mathcal{F} = \sigma(X_n(S) : n \ge 0)$. Let $Z_n = \sum_x \rho_{128cd^2 n}(x)$ be the total amount of "red paint" in the system after $64cdn$ rounds of the chameleon process. (Recall that a round is defined as $2d$ steps.) Define $Z_n^\sharp = \min(Z_n, k - Z_n)$. Note that $\lim_{n\to\infty} Z_n^\sharp = 0$ almost surely.

We will need the following lemma.

LEMMA 2.2. *We have*

$$\mathbf{E}\Big(\sqrt{Z_n^\sharp} \;\Big|\; \mathcal{F}, S \text{ circulates}\Big) \le \exp\Big[-\frac{n}{8224d^2}\Big] \tag{4}$$

for all n.

Proof. Fix n such that $64cd^2 n \le m$, and let A_n be either the set of cards that are red or the set of cards that are white at the start of round $64cdn$, according to whether $Z_n \le k/2$ or $Z_n > k/2$, respectively. Let P denote the number of cards pinkened during the next $64cd$ rounds. Let $B_n = S - A_n$. When S circulates, A_n doesn't avoid B_n. We claim that this ensures that $P \ge \frac{|A_n|}{8d}$. Consider a round j such that $Z(A_n, B_n, j) \le \frac{7}{8}|A_n|$. Note that after an edge connecting a card x in A_n to a card y in B_n rings, at least one of the resulting cards is pink. Let us associate that

pink card with x. (If both endpoints are pink, then choose one of them arbitrarily.) Since at least a fraction $1/8$ of the cards in A_n will have a pink card associated to them in this round, and since any given pink card can be associated to at most $2d$ cards in A_n in this round, the number of pink cards at the end of this round must be at least $\frac{|A_n|}{16d}$. It follows that $P \geq \frac{|A_n|}{16d}$.

Note that Z_{n+1} is either $Z_n + \frac{1}{2}P$ or $Z_n - \frac{1}{2}P$, with probability $\frac{1}{2}$ each. Thus, if we write E for the event that S does not circulate, then

$$\mathbf{E}\Big(\sqrt{Z^\sharp_{n+1}}\,\Big|\,P, Z_n, \mathcal{F}, E^c\Big) = \mathbf{E}\Big(\tfrac{1}{2}\sqrt{(Z_n + \tfrac{1}{2}P)^\sharp} + \tfrac{1}{2}\sqrt{(Z_n - \tfrac{1}{2}P)^\sharp}\,\Big|\,Z_n, \mathcal{F}, E^c\Big) \tag{5}$$

$$\leq \sqrt{Z^\sharp_n}\,\frac{\sqrt{1+\frac{1}{32d}} + \sqrt{1-\frac{1}{32d}}}{2} \tag{6}$$

$$\leq \sqrt{Z^\sharp_n}\,\exp\Big[-\frac{1}{8224d^2}\Big], \tag{7}$$

where the first inequality follows from the concavity of the square root, and the second inequality follows from the fact that $\frac{1}{2}\sqrt{1+u} + \frac{1}{2}\sqrt{1-u} \leq \exp(-u^2/8)$ whenever $u \in [0,1]$ (see [8, Lemma 9]). The lemma now follows from (7) and the fact that $Z_0 = 1$. □

2.3. Proof of a local mixing property. If S is a set of cards and S' is a set of locations, then we will write $S \to_m S'$ for the event that $X_m(S) = S'$. For $j \in \{1, \dots, 2^d\}$ define

$$\lambda(j) = \max_{|S|=j} \max_{|S'|=j} \Big|\tbinom{2^d}{j}\mathbf{P}(S \to_m S') - 1\Big|.$$

The following is the principal result of this section.

LEMMA 2.3. *Let $S = \{x_1, \dots, x_k\}$ be a set of cards and suppose that $\lambda(k) \leq \frac{1}{2}$. Then for any set S' of locations and $y \in S'$, we have*

$$\Big|\mathbf{P}\Big(X_m(x_k) = y\,\Big|\,S \to_m S'\Big) - \tfrac{1}{k}\Big| \leq 4\alpha^{-d}. \tag{8}$$

Proof. Define $Z_\infty = \lim_{n\to\infty} Z_n$. (Note that for any S' we have $\mathbf{E}(Z_\infty \,|\, S \to_m S') = 1$; see the remark immediately following Lemma 2.1.) Let $\rho_m = \sum_x \rho_m(x) = Z_{m/128cd^2}$. Lemma 2.1 implies that for all $y \in S'$ we have

$$\Big|\mathbf{P}\Big(X_m(x_k) = y\,\Big|\,S \to_m S'\Big) - \tfrac{1}{k}\Big| = \Big|\mathbf{E}\Big(\rho_m(y) - \tfrac{1}{k}Z_\infty\,\Big|\,S \to_m S'\Big)\Big| \tag{9}$$

$$\leq \mathbf{E}\Big(|\rho_m(y) - \tfrac{1}{k}Z_\infty|\,\Big|\,S \to_m S'\Big) \tag{10}$$

$$\leq \mathbf{P}(\rho_m \notin \{0,k\} \,|\, S \to_m S'). \tag{11}$$

Let E be the event that S does not circulate. Since $\lambda(k) \leq \frac{1}{2}$, Lemma 7.1 in Appendix A gives $\mathbf{P}(E \,|\, S \to_m S') \leq 3\alpha^{-d}$. Hence

$$\mathbf{P}\Big(\rho_m \notin \{0,k\}\,\Big|\,S \to_m S'\Big) \leq \mathbf{P}\Big(E\,\Big|\,S \to_m S'\Big) + \mathbf{P}\Big(\rho_m \notin \{0,k\}\,\Big|\,S \to_m S', E^c\Big) \tag{12}$$

$$\leq 3\alpha^{-d} + \mathbf{P}\Big(\rho_m \notin \{0,k\}\,\Big|\,S \to_m S', E^c\Big). \tag{13}$$

But

$$\mathbf{P}\Big(\rho_m \notin \{0,k\}\,\Big|\,S \to_m S', E^c\Big) \leq \mathbf{E}\Big(\sqrt{Z^\sharp_{m/64cd^2}}\,\Big|\,S \to_m S', E^c\Big) \tag{14}$$

$$\leq \exp\Big[-\frac{m}{8224 \cdot 64 \cdot cd^4}\Big] \leq \alpha^{-d}, \tag{15}$$

where the second inequality follows from Lemma 2.2. Combining (11), (13), and (15) yields the lemma. □

3. Indistinguishable cards mix in poly time. Let Λ be a set of cards. In this section we show that the uniform mixing time for the Markov chain $\{X_n(\Lambda) : n \geq 0\}$ is $O(d^5)$.

Recall that in the previous section we showed that if $k > 2^{d-1}$ and every set S with $|S| = k$ is roughly uniformly distributed after bd^5 steps, then for any such set S, any card $x \in S$ will be roughly mixed after bd^5 steps. But note that if a set of cards S is mixed and $x \in S$ is mixed within S, then $S - \{x\}$ must also be mixed. Iterating this (starting with S being the set of all cards) gives the main result of this section.

LEMMA 3.1. *There is a positive integer constant b such that if $m = bd^5$, then*

$$\max_{\Lambda,\Lambda'} \left| \tbinom{2^d}{|\Lambda|} \mathbf{P}(\Lambda \to_m \Lambda') - 1 \right| \leq \tfrac{1}{4}. \tag{16}$$

Proof. It is enough to consider sets Λ with $|\Lambda| \geq 2^{d-1}$. (Otherwise, consider Λ^c.) Let α, β, and c be defined as in section 2, let $b = \lceil \beta \log \alpha \, c \rceil$, and let $m = bd^5$. Let $\lambda(\cdot)$ be defined as in the previous section. We will show that for all $k \geq 2^{d-1}$, we have

$$\lambda(k) \leq k^\star 4^{-d}, \tag{17}$$

where $k^\star = 2^d - k$. This yields the lemma because the RHS of (17) is at most $\frac{1}{4}$ for all $d \geq 1$.

We will verify (17) by induction on $k^\star$. The base case $k^\star = 0$ ($k = 2^d$) is trivial. Suppose it is true for k, where $k > 2^{d-1}$, and consider $k - 1$. Fix a set of cards Λ with $|\Lambda| = k - 1$ and let $z \notin \Lambda$. Define $\Lambda_z = \Lambda \cup \{z\}$. Fix a set Λ' of vertices of the hypercube with $|\Lambda'| = k - 1$. For $w \notin \Lambda'$, let $\Lambda'_w = \Lambda' \cup \{w\}$, and define

$$x_w = \mathbf{P}(\Lambda_z \to_m \Lambda'_w), \qquad \Delta x_w = x_w - \tbinom{2^d}{k}^{-1}, \tag{18}$$

$$y_w = \mathbf{P}(z \to_m w \,|\, \Lambda_z \to_m \Lambda'_w), \qquad \Delta y_w = y_w - 1/k. \tag{19}$$

Note that $\left|\{w : w \notin \Lambda'\}\right| = k^\star + 1$, and $\frac{k^\star+1}{k}\tbinom{2^d}{k}^{-1} = \tbinom{2^d}{k-1}^{-1}$. It follows that

$$\left|\mathbf{P}(\Lambda \to_m \Lambda') - \tbinom{2^d}{k-1}^{-1}\right| = \left| \sum_{w \notin \Lambda'} \mathbf{P}\Big(\Lambda_z \to_m \Lambda'_w, \{z\} \to_m \{w\}\Big) - \tfrac{1}{k}\tbinom{2^d}{k}^{-1} \right| \tag{20}$$

$$= \left| \sum_{w \notin \Lambda'} x_w y_w - \tfrac{1}{k}\tbinom{2^d}{k}^{-1} \right| \tag{21}$$

$$= \left| \sum_{w \notin \Lambda'} \Delta x_w \tfrac{1}{k} + \Delta y_w \tbinom{2^d}{k}^{-1} + \Delta x_w \Delta y_w \right|. \tag{22}$$

Note that

$$|\Delta x_w| \leq k^\star 4^{-d} \tbinom{2^d}{k}^{-1} \leq \tbinom{2^d}{k}^{-1}, \tag{23}$$

where the first inequality is induction and the second inequality holds because $k^\star \leq 2^d$. Induction also implies that $\lambda(k) \leq \frac{1}{2}$, hence Lemma 2.3 implies that

$$|\Delta y_w| \leq 4\alpha^{-d} \leq \tfrac{1}{2k} 4^{-d} \tag{24}$$

for all $d \geq 1$, where the second inequality follows from the definition of α. Thus, using (23), (24), and the triangle inequality, (22) becomes

$$\begin{aligned}\left|\mathbf{P}(\Lambda \to_m \Lambda') - \tbinom{2^d}{k-1}^{-1}\right| &\leq \frac{k^\star + 1}{k}\left[k^\star 4^{-d}\tbinom{2^d}{k}^{-1} + 4^{-d}\tbinom{2^d}{k}^{-1}\right] \\ &= \frac{1}{k}(k^\star+1)^2 4^{-d}\tbinom{2^d}{k}^{-1} \\ &= (k^\star+1)4^{-d}\tbinom{2^d}{k-1}^{-1} = (k-1)^\star 4^{-d}\tbinom{2^d}{k-1}^{-1}.\end{aligned}$$

Since this is true for all Λ with $|\Lambda| = k-1$, the proof is complete. □

Let K be the transition kernel for one *round* of the Thorp shuffle (i.e., d steps), and let K^t be the transpose of K, defined by $K^t(x,y) = K(y,x)$. Note that K^t is the time-reversal of K. Let $\hat{K} := KK^t$ be the transition kernel for one round of the zigzag shuffle. Let $\{Z_n : n \geq 0\}$ be a Markov chain with transition kernel $\hat{K}$. Then Lemma 3.1 implies that for any set of cards B, the uniform mixing time for the process $\{Z_n(B) : n \geq 0\}$ is at most bd^4. Thus, using standard facts about geometric convergence and the uniform mixing time, we can conclude that for a universal constant C we have

$$\max_{B'} \tbinom{2^d}{|B|}\mathbf{P}(Z_{kCd^4}(B) = B') \leq 1 + e^{-k} \tag{25}$$

for all $k \geq 1$.

Definition: Truncated Thorp shuffle. Fix $d_\star \leq d$. Define the *$d_\star$-truncated Thorp shuffle* as the Markov chain with transition kernel $K_\star = K_1, \ldots, K_{d_\star}$. This is a "partial round" of the Thorp shuffle, with steps $d_\star + 1$ through d censored. To make things irreducible, we define the state space as the set of states reachable from an (arbitrary) fixed starting state.

Define the $d_\star$-truncated zigzag shuffle as the Markov chain with transition kernel $K_\star K_\star^t$. Note that we can think of this shuffle as a product of $2^{d-d_\star}$ copies of a "$d_\star$-dimensional" zigzag shuffle, where the cards occupy $2^{d-d_\star}$ (disconnected) hypercubes of dimension $d_\star$. Combining this observation with (25) yields the following corollary to Lemma 3.1.

COROLLARY 3.2. *Fix $d_\star \geq 2$, let $\{Z_n : n \geq 0\}$ be the $d_\star$-truncated zigzag shuffle, and let $\mathcal{S}$ denote the state space of $\{Z_n\}$. There is a universal constant c such that if $l = kcd(d_\star - 1)^4$, then*

$$|\mathcal{S}| \max_{B'} \mathbf{P}(Z_l(B) = B') \leq \exp(\exp(-k)). \tag{26}$$

Proof. Let $c = 2^5 C$. Then $l \geq 2kdCd_\star^4$, so (25) implies that

$$\begin{aligned}|\mathcal{S}| \max_{B'} \mathbf{P}(Z_l(B) = B') &\leq (1 + e^{-2kd})^{2^{d-d_\star}} \\ &\leq \exp(2^d \exp(-2dk)) \\ &\leq \exp(\exp(-k))\end{aligned}$$

for all $d \geq 1$. □

4. Evolving sets and ℓ^2 techniques. In previous sections we have found that after $O(d^5)$ steps (of the zigzag shuffle), subsets of the deck are fairly well mixed. We would like to show that the Thorp shuffle mixes the deck in the sense of the global

property that every ordering of cards is roughly equally likely. In order to do this, we need to find the best global property of random permutations (and the effect of a Thorp shuffle) to study. In this section we introduce the notion of evolving sets, and proceed to find that the global property of interest will be an ℓ^2 norm on the transition kernel.

4.1. Evolving sets. We will now give a brief overview of evolving sets (see [8] for a more detailed account). Let $\{p(x,y)\}$ be transition probabilities for an irreducible a periodic Markov chain on a finite state space V. Assume that the chain has a uniform stationary distribution (which means that p is doubly stochastic: $\sum_{x\in V} p(x,y) = 1$ for all $y \in V$). For subsets $S \subset V$, define $p(S,y) := \sum_{x\in S} p(x,y)$.

Definition: Evolving sets. The *evolving set* process is the Markov chain $\{S_n\}$ on *subsets* of V with the following transition rule. If the current state S_n is $S \subset V$, choose U uniformly from $[0,1]$ and let the next state S_{n+1} be

$$\widetilde{S} = \{y : p(S,y) \geq U\}.$$

Write $\mathbf{P}_S(\,\cdot\,) := \mathbf{P}(\,\cdot\,|\,S_0 = S)$ and similarly for $\mathbf{E}_S(\,\cdot\,)$. Evolving sets have the following properties (see [8]):

1. The sequence $\{|S_n|\}_{n\geq 0}$ forms a martingale.
2. For all $n \geq 0$ and $x, y \in V$ we have
$$p^n(x,y) = \mathbf{P}_{\{x\}}(y \in S_n).$$
3. The sequence of complements $\{S_n^c\}_{n\geq 0}$ is also an evolving set process, with the same transition probabilities.

As in [8], we will prove our mixing time bound using an isoperimetric quantity that we denote by ψ, which is defined as follows. For $S \subset V$, define

$$\psi(S) := 1 - \mathbf{E}_S\sqrt{\frac{|\widetilde{S}|}{|S|}}.$$

Define $\psi(x)$ for $x \in [0, 1/2]$ by

$$\psi(x) = \inf\{\psi(S) : |S| \leq x|V|\}, \tag{27}$$

and for $x > 1/2$, let $\psi(x) := \psi_* = \psi(\frac{1}{2})$. Observe that ψ is nonnegative and (weakly) decreasing on $[0,\infty)$. We will call the function ψ the *root profile.*

4.2. From ℓ^2 bounds to a bound on ψ. In this section, we show how to use l^2 techniques to obtain a bound on the root profile.

For functions $f : V \to [0,1]$, define $||f||_1 := \frac{1}{|V|}\sum_{x\in V} f(x)$ and $||f||_2 := (\frac{1}{|V|}\sum_{x\in V} f(x)^2)^{1/2}$. For $S \subset V$, define $\mathbf{1}_S : V \to [0,1]$ by

$$\mathbf{1}_S(x) = \begin{cases} 1 & \text{if } x \in S, \\ 0 & \text{otherwise.} \end{cases}$$

LEMMA 4.1. *Let $\widetilde{S}$ be the next step in the evolving set process starting from S, i.e., $\widetilde{S} = \{y : p(S,y) > U\}$, where U is uniform. Let $\alpha = \frac{||p(S,\cdot)||_2^2}{||\mathbf{1}_S||_1}$. Then*

$$\mathbf{E}\left(\sqrt{\frac{|\widetilde{S}|}{|S|}}\right) \leq [\alpha(2-\alpha)]^{\frac{1}{4}}.$$

Proof. Let Λ be an independent copy of $\widetilde{S}$, i.e., $\Lambda = \{y : p(S,y) > U'\}$, for an independent uniform random variable U'. Note that either $\widetilde{S} \subseteq \Lambda$ or $\Lambda \subseteq \widetilde{S}$ (depending on which of the uniform variables U, U' is larger). Let $X = |\widetilde{S} \cap \Lambda|$ and $Y = |\widetilde{S} \cup \Lambda|$. Then

$$\left[\mathbf{E}\left(\sqrt{|\widetilde{S}|}\right)\right]^2 = \mathbf{E}\left(\sqrt{|\widetilde{S}||\Lambda|}\right) \tag{28}$$

$$= \mathbf{E}(\sqrt{XY}) \tag{29}$$

$$\leq \sqrt{\mathbf{E}(X)\mathbf{E}(Y)} \tag{30}$$

$$= \sqrt{\mathbf{E}(X)(2|S| - \mathbf{E}(X))}, \tag{31}$$

where the first inequality is Cauchy Schwarz and the second inequality follows from the fact that $\mathbf{E}(X+Y) = 2\mathbf{E}(\widetilde{S}) = 2|S|$. But

$$\mathbf{E}(X) = \sum_{y \in V} \mathbf{P}(y \in \widetilde{S} \cap \Lambda) \tag{32}$$

$$= \sum_{y \in V} \mathbf{P}(y \in \widetilde{S})^2 \tag{33}$$

$$= \sum_{y \in V} p(S,y)^2 = |V| \cdot ||p(S,\cdot)||_2^2, \tag{34}$$

so dividing the LHS of (28) and the RHS of (31) by $|S| = |V| \cdot ||\mathbf{1}_S||_1$ and then taking a square root yields the lemma. □

Remark. If we define $\Delta := 1 - \alpha$, then

$$\left[\alpha(2-\alpha)\right]^{\frac{1}{4}} = (1-\Delta^2)^{\frac{1}{4}} \leq 1 - \frac{\Delta^2}{4}.$$

5. A bound on the root profile. We will need the following technical result, which is proved in Appendix B.

Corollary 8.5. *Fix $S \subset V$ and let $x = \frac{|S|}{(2^d)!} = ||\mathbf{1}_S||_1$. Let $p(\,\cdot\,,\,\cdot\,)$ be the transition kernel for one round of the Thorp shuffle. Then there is a universal constant $C > 0$ such that*

$$||p(S,\cdot)||_2^2 \leq x^{1+C/d^{14}}.$$

We are now ready to obtain a bound on the root profile of the Thorp shuffle.

LEMMA 5.1. *Let ψ be the root profile of the Markov chain that each step performs a round of the Thorp shuffle ($K_1 K_2 \cdots K_d$). There is a universal constant $\gamma > 0$ such that*

$$\psi(x) \geq \max\left(1 - x^{\gamma/2d^{42}}, \gamma d^{-28}\right). \tag{35}$$

Proof. Let C be the constant appearing in Corollary 8.5. We will show that there is a universal constant $B > 0$ such that

$$\psi(x) \geq \max\left(1 - x^{CB/2d^{42}}, Bd^{-28}\right). \tag{36}$$

Setting $\gamma = \min(BC, B)$ will then yield the lemma. First, we show that $\psi_* \geq Bd^{-28}$. Fix S with $\frac{|S|}{(2^d)!} = x \leq \frac{1}{2}$ and let

$$\widetilde{S} = \{y : p(S,y) > U\},$$

where $\{p(x,y)\}$ are the transition probabilities for one round of the Thorp shuffle. The remark following Lemma 4.1 implies that

$$\mathbf{E}\sqrt{\frac{|\widetilde{S}|}{|S|}} \le 1 - \frac{\Delta^2}{4},$$

where $\Delta = 1 - \frac{||p(S,\cdot)||_2^2}{||\mathbf{1}_S||_1}$, and Corollary 8.5 implies that $||p(S,\cdot)||_2^2 \le x^{C/d^{14}}||\mathbf{1}_S||_1 \le 2^{-C/d^{14}}||\mathbf{1}_S||_1$. Thus

$$\Delta \ge 1 - 2^{-Cd^{-14}} \tag{37}$$

$$= 1 - e^{-C\log 2\, d^{-14}} \tag{38}$$

$$\ge Ad^{-14} \tag{39}$$

for a universal constant $A > 0$, and hence $1 - \frac{\Delta^2}{4} \le 1 - Bd^{-28}$ for a universal constant $B \in (0, \frac{1}{4})$. (The fact that we can take $B < \frac{1}{4}$ will be used later on.) Since this holds for all S with $|S| \le \frac{1}{2}(2^d)!$, we conclude that $\psi_* \ge Bd^{-28}$. To complete the proof of Lemma 5.1, we must show that (36) holds when the max is achieved by the first term. Suppose that $1 - x^{CB/2d^{42}} \ge Bd^{-28}$. Then

$$x \le (1 - Bd^{-28})^{2d^{42}/CB} \le \exp(-2C^{-1}d^{14}). \tag{40}$$

Recall that Lemma 4.1 gives

$$\mathbf{E}\sqrt{\frac{|\widetilde{S}|}{|S|}} \le (\alpha(2-\alpha))^{\frac{1}{4}} \le (2\alpha)^{\frac{1}{4}}, \tag{41}$$

where $\alpha = \frac{||p(S,\cdot)||_2^2}{||\mathbf{1}_S||_1}$. Thus, (40) implies that

$$x^{C/2d^{14}} \le e^{-1} < \tfrac{1}{2},$$

and hence

$$2 \le x^{-C/2d^{14}}. \tag{42}$$

Furthermore, Corollary 8.5 implies that $\alpha \le x^{C/d^{14}}$. Plugging this and (42) into (41) gives

$$\mathbf{E}\sqrt{\frac{|\widetilde{S}|}{|S|}} \le (x^{-C/2d^{14}}x^{C/d^{14}})^{\frac{1}{4}} = x^{C/8d^{14}} \le x^{CB/2d^{42}}, \tag{43}$$

since $B < \frac{1}{4}$ (and $x \le 1$). □

6. Proof of main result. *Proof of Theorem* 1.1. We shall start by bounding the mixing time of the Markov chain that does an entire round of the Thorp shuffle each step. Recall that the root profile $\psi : [0,\infty) \to \mathbf{R}$ is defined by

$$\psi(x) = \begin{cases} \inf\{\psi(S) : |S| \le x|V|\} & \text{if } x \in [0, \frac{1}{2}], \\ \psi_* & \text{if } x > \frac{1}{2}, \end{cases}$$

where $\psi_* = \psi(\frac{1}{2})$. Thus ψ is (weakly) decreasing on $[0,\infty)$.

Let $h(z) := 1 - \psi(1/z^2)$. Since $\psi(x) = \psi_*$ for all real numbers $x \geq \frac{1}{2}$, the function h is well defined even for $z \leq 1$. Note that h is nonincreasing. In [8] it is shown (see section 5 and the part of section 3 entitled "Derivation of Theorem 1 from Lemma 3 and Theorem 4") that there is a sequence of random variables $\{Z_n : n \geq 0\}$ that satisfies $Z_0 = \sqrt{|V|}$ and

$$\mathbf{E}\left(\frac{Z_{n+1}}{Z_n}\Big| Z_n\right) \leq h(Z_n) \tag{44}$$

such that

$$\tau_{\text{mix}} \leq 2 \min\{n : \mathbf{E}(Z_n) \leq \tfrac{1}{2}\}. \tag{45}$$

Lemma 5.1 gave the following bound on the root profile:

$$\psi(x) \geq \max\Big(1 - x^{\gamma/2d^{42}}, \gamma d^{-28}\Big) \tag{46}$$

for a universal constant $\gamma > 0$. Thus $h \leq g$, where g is defined by

$$g(z) = \min\Big(z^{-\gamma/d^{42}}, 1 - \gamma d^{-28}\Big),$$

and hence $\mathbf{E}(Z_{n+1}|Z_n) \leq g(Z_n)Z_n$. Let $f(z) = zg(z) = \min(z^{1-\gamma/d^{42}}, z(1 - \gamma d^{-28}))$. Note that f is increasing and, as the minimum of two concave functions, is concave. We claim that $\mathbf{E}(Z_n) \leq f^n(Z_0)$, where f^n is the n-fold iterate of f. We verify this by induction. The base case $n = 0$ is immediate. Suppose that the claim holds for n. Then

$$\mathbf{E}(Z_{n+1}) = \mathbf{E}(\mathbf{E}(Z_{n+1}|Z_n)) \tag{47}$$
$$\leq \mathbf{E}(f(Z_n)) \tag{48}$$
$$\leq f(\mathbf{E}(Z_n)) \tag{49}$$
$$\leq f(f^n(Z_0)) = f^{n+1}(Z_0), \tag{50}$$

where the third line follows from concavity and the last line is the induction hypothesis. Let

$$f_1 = z^{1-\gamma/d^{42}}, \qquad f_2 = z(1 - \gamma d^{-28}),$$

so that $f = \min(f_1, f_2)$. Then for all m, n we have

$$\mathbf{E}(Z_{m+n}) \leq f^{m+n}(\sqrt{Z_0}) \leq f_2^m(f_1^n(Z_0)).$$

But $f_1^n(z) = z^{(1-\gamma/d^{42})^n} \leq z^{\exp(-\gamma n/d^{42})}$, and $Z_0 = \sqrt{|V|} \leq (2^d)^{2^d} = 2^{d2^d}$. Thus, choosing $n \geq \gamma^{-1}d^{43}$ gives

$$f_1^n(Z_0) \leq 2^{d2^d e^{-d}},$$

which is at most 4 for all $d \geq 1$. Finally, since

$$f_2^m(z) = z\Big(1 - \gamma d^{-28}\Big)^m \leq ze^{-\gamma m/d^{28}},$$

we have $f_2^m(4) \leq 4e^{-\gamma m/d^{28}}$, which is at most $\frac{1}{2}$ whenever $m \geq \gamma^{-1}d^{28}\log 8$. Putting this together, we conclude that $\tau_{\text{mix}} \leq 2\gamma^{-1}(d^{43} + d^{28}\log 8) = O(d^{43})$. Since each round corresponds to d Thorp shuffles we conclude that the mixing time for the original model is $O(d^{44})$. □

7. Appendix A. In this section we prove some technical results needed in section 3. We will adopt the notation of that section; for the convenience of the reader, we now give a brief recap. Let A and B be disjoint sets of cards. For $x \in A$, say that x is *antisocial in round* j of the zigzag shuffle if at no point in round j does an edge connecting x to a card in B ring. Let $Z(A, B, j)$ denote the number of cards that are antisocial in round j. We say that A *avoids* B if $Z(A, B, j) > \frac{7}{8}|A|$ for $64cd$ consecutive rounds j before time m. If S is a set of cards, say that S *circulates* if there do not exist disjoint sets A, B of cards with $|A| \le \frac{1}{2}|S|$ and $A \cup B = S$ such that A avoids B.

The main purpose of this section is to prove Lemma 7.1, which was used in the proof of Lemma 2.3 in section 3. The proof of Lemma 7.1 uses some fairly technical large deviation results. For the convenience of the reader, we shall prove Lemma 7.1 first, and the large deviation results second.

LEMMA 7.1. *Fix a set of cards S with $|S| \ge 2^{d-1}$. Then for any set S' of vertices of the hypercube we have*

$$\mathbf{P}\Big(S \text{ does not circulate} \,\Big|\, S \to_m S'\Big) \le \alpha^{-d} \frac{1 + \lambda(|S|)}{1 - \lambda(|S|)}.$$

Proof. Let E be the event that S does not circulate. We have

$$\begin{aligned}\mathbf{P}\Big(E, S \to_m S'\Big) &\le \sum_{k \le \frac{1}{2}|S|} \sum_{A:|A|=k} \mathbf{P}\Big(A \text{ avoids } B, S \to_m S'\Big) \\ &\le 2^{d-1} \max_k \Big[2^{dk} \max_{A:|A|=k} \mathbf{P}\Big(A \text{ avoids } B, S \to_m S'\Big)\Big],\end{aligned}$$

where in the summations we write B for $S - A$, the 2^{d-1} is an upper bound on the number of $k \le \frac{1}{2}|S|$, and the 2^{dk} is an upper bound on the number of sets A with $|A| = k$. Since $|A| \le \frac{1}{2}|S|$ and $A \cup B = S$, we must have $|B| \ge \frac{1}{4}2^d$. Hence if $|A| = k$, then

$$\mathbf{P}\Big(A \text{ avoids } B, S \to_m S'\Big) \le \sum_{B' \subset S'} \mathbf{P}\Big(A \text{ avoids } B, B \to_m B', A \to_m S' - B'\Big) \tag{51}$$

$$\le \sum_{B' \subset S'} \mathbf{P}(B \to_m B') \mathbf{P}\Big(A \text{ avoids } B \,\Big|\, B \to_m B'\Big). \tag{52}$$

But

$$\begin{aligned}&\mathbf{P}\Big(A \text{ avoids } B \;\Big|\; B \to_m B'\Big) \\ &\le \sum_{i=0}^{m} \prod_{j=i}^{i+64cd-1} \mathbf{P}\Big(Z(A, B, j) > \tfrac{7k}{8} \,\Big|\, B \to_m B'\Big) \le m\Big(e^{-k/64}\Big)^{64cd},\end{aligned} \tag{53}$$

where the last inequality follows from Corollary 7.3 below. (See Lemma 7.2 and Corollary 7.3 immediately following the present proof.) Hence

$$\begin{aligned}\mathbf{P}\Big(A \text{ avoids } B, S \to_m S'\Big) &\le \sum_{B' \subset S'} \mathbf{P}(B \to_m B') m e^{-ckd} \\ &\le 2^{dk} m e^{-ckd} \max_{B'} \mathbf{P}(B \to_m B'),\end{aligned}$$

where the 2^{dk} is an upper bound on the number of subsets $B' \subset S'$. But for any B' we have

$$\mathbf{P}(B \to_m B') \le \sum_{\hat{S}:\hat{S}\supset B'} \mathbf{P}(S \to_m \hat{S}) \le 2^{dk} \tbinom{2^d}{|S|}^{-1} (1 + \lambda(|S|)).$$

It follows that

$$\mathbf{P}\Big(A \text{ avoids } B, S \to_m S'\Big) \le 4^{dk} m e^{-cdk} \tbinom{2^d}{|S|}^{-1} (1 + \lambda(|S|)) \tag{54}$$

$$= [4e^{-c}]^d \lceil \beta \log \alpha\, c \rceil d^5 \tbinom{2^d}{|S|}^{-1} (1 + \lambda(|S|)) \tag{55}$$

$$\le \alpha^{-d} \tbinom{2^d}{|S|}^{-1} (1 + \lambda(|S|)), \tag{56}$$

where the second inequality follows from the definition of c. Finally, since $\mathbf{P}(S \to_m S') \ge \binom{2^d}{|S|}^{-1}(1 - \lambda(|S|))$, we get $\mathbf{P}(A \text{ avoids } B \,|\, S \to_m S') \le \alpha^{-d} \frac{1+\lambda(|S|)}{1-\lambda(|S|)}$. □

Lemma 7.1 used a corollary to the following lemma.

LEMMA 7.2. *Let $\{X_n : n \ge 0\}$ be the zigzag shuffle. Let $Z = Z(A, B, 1)$ be the number of cards that are antisocial in the first round. Define $\mathcal{F}_B = \sigma(X_1(B), \dots, X_d(B))$. Let $p = 1 - \frac{|B|}{2^d}$ and let $k = |A|$. For $\theta \ge 0$ define $\Phi_p(\theta) = 1 - p + pe^\theta$. Then for all $\theta \ge 0$ we have*

$$\mathbf{E}\Big(e^{\theta Z} \,\Big|\, \mathcal{F}_B\Big) \le \Phi_p(\theta)^k. \tag{57}$$

Proof. We verify this by induction on d. If $d = 1$, then the LHS of (57) is 1 if $p < 1$, and $e^{\theta k}$ otherwise, so (57) holds. Now suppose that $d > 1$. Let A' be the set of cards in A not adjacent to B in direction 1, and let $k' = |A'|$. Let l be half the number of cards in A' adjacent to another card in A' in direction 1. (Note that l is an integer.) Let k_0 and k_1 be the number of cards in A' that end up with a leading 0 and 1, respectively, after the first step of the round (i.e., after the edges in direction 1 ring). Of those in the first group, let Z_0 be the number that are antisocial, with a similar definition for Z_1. Note that given $\mathcal{F}_B$, the random variables k_0 and k_1 are both distributed like $W + l$, where $W \sim \text{Binomial}(k' - 2l, \frac{1}{2})$, and note that $Z = Z_0 + Z_1$. By induction, we have

$$\begin{aligned}\mathbf{E}\Big(e^{\theta Z} \,\Big|\, \mathcal{F}_B, X_1(A)\Big) &= \mathbf{E}\Big(e^{\theta Z_0} \,\Big|\, \mathcal{F}_B, X_1(A)\Big)\mathbf{E}\Big(e^{\theta Z_1} \,\Big|\, \mathcal{F}_B, X_1(A)\Big) \\ &\le \Phi_{p_0}(\theta)^{k_0} \Phi_{p_1}(\theta)^{k_1},\end{aligned}$$

where p_0 is the fraction of locations of the part of the hypercube with a leading 0 not occupied by a card in B after the first step, with a similar definition for p_1. It follows that $\mathbf{E}(e^{\theta Z} \,|\, \mathcal{F}_B, k_0, k_1) \le \Phi_{p_0}(\theta)^{k_0} \Phi_{p_1}(\theta)^{k_1}$. Hence

$$\begin{aligned}\mathbf{E}\Big(e^{\theta Z} \,\Big|\, \mathcal{F}_B\Big) &\le \sum_{i=0}^{k'-2l} (\tfrac{1}{2})^{k'-2l} \binom{k'-2l}{i} \Phi_{p_0}^i(\theta) \Phi_{p_1}^{k'-2l-i}(\theta) \Phi_{p_0}^l(\theta) \Phi_{p_1}^l(\theta) \\ &= \Big[\tfrac{1}{2}\Phi_{p_0}(\theta) + \tfrac{1}{2}\Phi_{p_1}(\theta)\Big]^{k'-2l} \Phi_{p_0}^l(\theta) \Phi_{p_1}^l(\theta) \\ &\le \Big[\tfrac{1}{2}\Phi_{p_0}(\theta) + \tfrac{1}{2}\Phi_{p_1}(\theta)\Big]^{k'} = \Phi_p(\theta)^{k'},\end{aligned}$$

where the last inequality follows from the AM-GM inequality and the final equality holds because $p = \frac{1}{2}(p_0 + p_1)$. This yields the lemma because $k' \le k$. ∎

Lemma 7.2 easily gives the following large deviation inequality, which was used in the proof of Lemma 7.1.

COROLLARY 7.3. *Suppose that $p \le 3/4$. Then*

$$\mathbf{P}\Big(Z > \tfrac{7}{8}k \,\Big|\, \mathcal{F}_B\Big) < e^{-k/64}.$$

Proof. We have

$$\mathbf{E}(e^{\theta(Z-pk)} \mid \mathcal{F}_B) = e^{-pk\theta}\mathbf{E}(e^{\theta Z} \mid \mathcal{F}_B) \tag{58}$$

$$\le \Big[(1-p)e^{-p\theta} + pe^{\theta(1-p)}\Big]^k, \tag{59}$$

by Lemma 7.2. The quantity inside the square brackets is $\mathbf{E}(e^{\theta(Y-p)})$, for a Bernoulli($p$) random variable Y. The inequality $\mathbf{E}(e^W) \le e^{\mathrm{var}(W)}$, valid when $\mathbf{E}(W) = 0$ and $W \le 1$ (see, e.g., [10]), implies that the quantity (59) is at most $\exp(\frac{1}{4}\theta^2 k)$ if $\theta \le 1$. Letting $\theta = \frac{1}{4}$ gives

$$\mathbf{E}\Big(\exp[\tfrac{1}{4}(Z-pk)] \,\Big|\, \mathcal{F}_B\Big) \le e^{k/64}, \tag{60}$$

and hence

$$\mathbf{P}\Big(Z > \tfrac{7}{8}k \,\Big|\, \mathcal{F}_B\Big) = \mathbf{P}\Big(\exp[\tfrac{1}{4}(Z-pk)] > \exp\Big[\tfrac{7k}{32} - \tfrac{pk}{4}\Big] \mid \mathcal{F}_B\Big) \tag{61}$$

$$\le \exp\Big[-\tfrac{7k}{32} + \tfrac{pk}{4}\Big] \exp\Big[\tfrac{k}{64}\Big], \tag{62}$$

by Markov's inequality. Finally, since $p \le 3/4$, the quantity (62) is at most $e^{-k/64}$. ∎

8. Appendix B. The purpose of this section is to prove Corollary 8.5, which is used to bound the root profile. If K is the transition kernel for a Markov chain on the state space V, we will consider K as an operator acting on the space of functions $f : V \to \mathbf{R}$ by

$$Kf(x) = \sum_{y \in V} K(x,y) f(y). \tag{63}$$

We will need the following lemma, which is well known.

LEMMA 8.1. *Let K be a doubly stochastic transition kernel and define $\hat{K} = KK^t$. For any function $g : V \to [0,1]$ and $n \ge 1$ we have*

$$||K^t g||_2^2 \le \langle g, g\rangle^{1-\frac{1}{n}} \langle \hat{K}^n g, g\rangle^{\frac{1}{n}}.$$

Proof. Since $\hat{K}$ is symmetric it is diagonalizable. Thus we can write $g = \sum_i \alpha_i g^i$, where the g^i are orthonormal eigenfunctions of $\hat{K}$ with corresponding eigenvalues λ_i. We have

$$\frac{||K^t g||_2^2}{\langle g, g\rangle} = \frac{\langle \hat{K} g, g\rangle}{\langle g, g\rangle} \tag{64}$$

$$= \frac{\sum_i \alpha_i^2 \lambda_i}{\sum_i \alpha_i^2} \tag{65}$$

$$\le \Big(\frac{\sum_i \alpha_i^2 \lambda_i^n}{\sum_i \alpha_i^2}\Big)^{1/n} = \Big(\frac{\langle \hat{K}^n g, g\rangle}{\langle g, g\rangle}\Big)^{1/n}, \tag{66}$$

by Jensen's inequality. Multiplying both sides by $\langle g, g\rangle$ yields the lemma. □

We will also need the following lemma, which was proved by Keith Ball.

LEMMA 8.2. *Let X be a random variable taking values in $[0,1]$ and suppose that $\mathbf{E}(X) = \mu \leq \frac{1}{2}$. Then for any $p > 1$ we have*

$$\frac{\mathbf{E}(X^p)}{\mu^p} - 1 \leq (\mu^{1-p} - 1)\mathbf{E}\Big|\frac{X-\mu}{\mu}\Big|. \tag{67}$$

Proof. Let $l = \frac{1}{2}\mathbf{E}(|X-\mu|)$. For a given value of l, the LHS of (67) is maximized when X is concentrated on the three values 0, μ, and 1 (because it is a convex function of X). Let p_0, p_μ, and p_1 be the respective probabilities. Then $l = p_1(1-\mu) = p_0\mu$, and hence $p_\mu = 1 - p_0 - p_1 = 1 - \frac{l}{\mu(1-\mu)}$. It follows that

$$\begin{aligned}\frac{\mathbf{E}(X^p)}{\mu^p} - 1 &= \frac{p_1 + p_\mu\mu^p}{\mu^p} - 1 \\ &= l\Big[\frac{1}{\mu^p(1-\mu)} - \frac{1}{\mu(1-\mu)}\Big] \\ &\leq \frac{2l}{\mu}(\mu^{1-p} - 1),\end{aligned}$$

since $1 - \mu \geq \frac{1}{2}$, and the proof is complete. □

Fix $d_\star \leq d$. Recall that the $d_\star$-truncated Thorp shuffle is the Markov chain with transition kernel $K_\star = K_1 \cdots K_{d_\star}$. Let V denote the state space of this chain. We will need the following technical lemma.

LEMMA 8.3. *Fix $f : V \to [0,1]$ and suppose that $||f||_1 \leq 6^{-cdd_\star^6}$. Then*

$$||K_\star^t f||_2^2 \leq ||f||_1^{1+1/cdd_\star^5},$$

where c is the constant appearing in Corollary 3.2.

Proof. We will prove the lemma by induction on $d_\star$. Suppose that $d_\star = 1$. Then the truncated Thorp shuffle makes the distribution uniform over V in one step. Thus,

$$||K_\star^t f||_2^2 = \sum_{x\in V} ||f||_1^2 \frac{1}{|V|} \tag{68}$$

$$= ||f||_1^2 \tag{69}$$

$$\leq ||f||_1^p, \tag{70}$$

for any $p \in [1,2]$, since $||f||_1 \leq 1$. Suppose now that $d_\star \geq 2$ and assume that the result holds for $d_\star - 1$. Define $\mathcal{L}_\star$ as the set of vertices in the cube whose $d_\star^{th}$ coordinate is 0. Let $\mathcal{B}$ denote the collection of subsets b of $\{1,\ldots,2^d\}$ such that $X(b) = \mathcal{L}_\star$ for some $X \in V$ (i.e., there is a configuration $X \in V$ such that the set of cards occupying $\mathcal{L}_\star$ is b). For $b \in \mathcal{B}$, define $V_b = \{X \in V : X(b) = \mathcal{L}_\star\}$. Let $r = ||f||_1$ and for $\Lambda \subset \mathcal{B}$, define

$$V_\Lambda = \cup_{b\in\Lambda} V_b.$$

Let

$$H = \left\{ b \in \mathcal{B} : \frac{||f\mathbf{1}_{V_b}||_1}{||f||_1} \geq \frac{r^{-1/d_\star}}{|\mathcal{B}|} \right\}.$$

Since $\sum_{b\in\mathcal{B}} \frac{||f\mathbf{1}_{V_b}||_1}{||f||_1} = \frac{||f||_1}{||f||_1} = 1$, Markov's inequality implies that

$$\frac{|H|}{|\mathcal{B}|} \leq r^{1/d_\star}. \tag{71}$$

Let $A = V_H$ and let $f_1 = f\mathbf{1}_A$ and $f_2 = f\mathbf{1}_{A^c}$. Then

$$||K_\star^t f||_2^2 = ||K_\star^t f_1 + K_\star^t f_2||_2^2 \leq 2||K_\star^t f_1||_2^2 + 2||K_\star^t f_2||_2^2. \tag{72}$$

We will bound each term on the RHS separately. First, consider $||K_\star^t f_1||_2^2$. Let $\hat{K}$ be the transition kernel for the $d_\star$-truncated zigzag shuffle, i.e, $\hat{K} = K_1 \cdots K_{d_\star} \cdots K_1$. Let $n = cd(d_\star - 1)^4$. Using Corollary 3.2 (with $k = 1$) and combining this with (71) gives $\hat{K}^n(x, V_H) \leq \exp(\exp(-1))r^{1/d_\star}$ for all x. Hence

$$\langle \hat{K}^n f_1, \mathbf{1}_A\rangle = |V|^{-1} \sum_x f_1(x)\hat{K}^n(x, V_H) \tag{73}$$

$$\leq ||f_1||_1 \exp(\exp(-1))r^{1/d_\star}. \tag{74}$$

Finally, Lemma 8.1 gives

$$||K_\star^t f_1||_2^2 \leq \langle f_1, f_1\rangle^{1-1/n}\langle \hat{K}^n f_1, f_1\rangle^{1/n} \tag{75}$$

$$\leq \langle f_1, f_1\rangle^{1-1/n}\langle \hat{K}^n f_1, \mathbf{1}_A\rangle^{1/n}, \tag{76}$$

where the second inequality holds because $f_1 \leq \mathbf{1}_A$. Putting this all together, we get

$$||K_\star^t f_1||_2^2 \leq \langle f_1, f_1\rangle^{1-1/n}\left[||f_1||_1(\exp(\exp(-1)))r^{1/d_\star}\right]^{1/n} \tag{77}$$

$$\leq 2\left(\frac{\langle f_1, f_1\rangle}{||f_1||_1}\right)^{1-1/n} \times ||f_1||_1 \times r^{1/d_\star n}, \tag{78}$$

since $\exp(\frac{1}{n}\exp(-1)) \leq 2$ for all n. Since $n = cd(d_\star - 1)^4$, and $\frac{\langle f_1, f_1\rangle}{||f_1||_1} \leq 1$, we have

$$||K_\star^t f_1||_2^2 \leq 2r^{1/cdd_\star(d_\star-1)^4}||f||_1. \tag{79}$$

Next we bound $||K_\star^t f_2||_2^2$. Since $K_{d_\star}$ is symmetric it contracts l^2. Hence

$$||K_\star^t f_2||_2^2 \leq ||K_{(d_\star-1)} \cdots K_1 f_2||_2^2 \tag{80}$$

$$= \sum_{b\in\mathcal{B}} ||K_{(d_\star-1)} \cdots K_1 f_2 \mathbf{1}_{V_b}||_2^2. \tag{81}$$

Note that $K_1 \cdots K_{(d_\star-1)}$ is just the transition kernel for a $(d_\star - 1)$-truncated Thorp shuffle and that the V_b are communicating classes for this process. Thus, we can use the induction hypothesis to bound each $||K_{(d_\star-1)} \cdots K_1 f_2 \mathbf{1}_{V_b}||_2^2$, provided that the corresponding normalized l^1 norm $\frac{||f_2\mathbf{1}_{V_b}||_1}{||\mathbf{1}_{V_b}||_1}$ is sufficiently small. Define $r_b := \frac{||f_2\mathbf{1}_{V_b}||_1}{||\mathbf{1}_{V_b}||_1}$. We claim that for every $b \in \mathcal{B}$ we have $r_b \leq r^{\frac{d_\star-1}{d_\star}}$. To see this, note that if $b \in H$, then $||f_2\mathbf{1}_{V_b}||_1 = 0$ and the claim holds trivially, so assume $b \notin H$. Then

$$\frac{||f_2\mathbf{1}_{V_b}||_1}{||\mathbf{1}_{V_b}||_1} = ||f_2\mathbf{1}_{V_b}||_1|\mathcal{B}| \tag{82}$$

$$\leq ||f\mathbf{1}_{V_b}||_1|\mathcal{B}| \tag{83}$$

$$\leq r^{\frac{-1}{d_\star}}||f||_1 = r^{\frac{d_\star-1}{d_\star}}, \tag{84}$$

where the first equality holds because $||\mathbf{1}_{V_b}||_1 = |\mathcal{B}|^{-1}$, the second inequality holds because $b \notin H$ (and by the definition of H), and the last equality holds because $||f||_1 = r$. It follows that

$$r_b \leq r^{\frac{d_\star - 1}{d_\star}} \leq 6^{-c(d_\star - 1)d_\star{}^5} \leq 6^{-c(d_\star-1)^6}. \tag{85}$$

Since r_b is the norm of $f_2\mathbf{1}_{V_b}$ when restricted to the smaller state space accessible via $K_1 \cdots K_{d_\star - 1}$, the induction hypothesis gives

$$||K_{(d_\star-1)} \cdots K_1 f_2 \mathbf{1}_{V_b}||_2^2 \leq r_b^{1/cd(d_\star-1)^5} ||f_2\mathbf{1}_{V_b}||_1 \tag{86}$$

$$\leq r^{1/cdd_\star(d_\star-1)^4} ||f_2\mathbf{1}_{V_b}||_1, \tag{87}$$

where the second inequality follows from the first inequality in (85). Combining this with (81) and using the fact that $f_2 \leq f$ gives

$$||K_\star^t f_2||_2^2 \leq r^{1/cdd_\star(d_\star-1)^4} ||f||_1. \tag{88}$$

We are now ready to bound $||K^t f||_2^2$. Combining (88), (79), and (72), we get

$$||K_\star^t f||_2^2 \leq \left(6r^{1/cdd_\star(d_\star-1)^4}\right)||f||_1. \tag{89}$$

Since $(k-1)^{-4} - k^{-4} \geq k^{-5}$ for integers $k \geq 2$, the quantity (89) is at most

$$6r^{1/cdd_\star^5 + 1/cdd_\star^6}||f||_1 \leq r^{1/cdd_\star^5}||f||_1,$$

since $r \leq 6^{-cdd_\star^6}$. This concludes the proof. □

Corollary 8.5 is a consequence of the following lemma, which extends Lemma 8.3 by removing the assumption on $||f||_1$.

LEMMA 8.4. *Let $C = \lceil 2^{15}c^2 15 \log 2 \log 6 \rceil$. Then for any $f : V \to [0,1]$ we have*

$$||K_\star^t f||_2^2 \leq ||f||_1^{1+1/Cd^2 d_\star^{12}}.$$

Proof. Again, our proof will be by induction on $d_\star$. The base case $d_\star = 1$ can be handled identically as in the proof of Lemma 8.3, so assume that $d_\star \geq 2$ and suppose that the result holds for $d_\star - 1$. Define $r = ||f||_1$. We may assume that $r > 6^{-cdd_\star^6}$, since otherwise we can invoke Lemma 8.3.

We can also assume w.l.o.g. that $r \leq \frac{1}{2}$. Otherwise, let $h = 1 - f$, and suppose that the result holds for h, i.e., for $q = 1/Cd^2 d_\star^{12}$ we have

$$||K_\star^t h||_2^2 \leq ||h||_1^{1+q},$$

or equivalently,

$$||h||_1 - ||K_\star^t h||_2^2 \geq \left[1 - ||h||_1^q\right]||h||_1. \tag{90}$$

Note that

$$||K_\star^t h||_2^2 = \langle K_\star^t(1-f), K_\star^t(1-f)\rangle \tag{91}$$

$$= \langle K_\star^t \mathbf{1}, K_\star^t \mathbf{1}\rangle - 2\langle K_\star^t \mathbf{1}, K_\star^t f\rangle + \langle K_\star^t f, K_\star^t f\rangle \tag{92}$$

$$= 1 - 2||f||_1 + ||K_\star^t f||_2^2 \tag{93}$$

$$= ||h||_1 - ||f||_1 + ||K_\star^t f||_2^2, \tag{94}$$

where the third equality holds because $K_\star^t$ is doubly stochastic and hence $K_\star^t \mathbf{1} = \mathbf{1}$. Thus

$$||h||_1 - ||K^t h||_2^2 = ||f||_1 - ||K^t f||_2^2. \tag{95}$$

Define $u : [0,1] \to \mathbf{R}$ by

$$u(x) = (1 - x^q)x = \frac{x(1-x)}{1 + x^q + \cdots + x^{1-q}}, \tag{96}$$

so the RHS of (90) is $u(||h||_1)$. Since the numerator on the RHS of (96) is symmetric about $\frac{1}{2}$ and the denominator is increasing, we have $u(x) \geq u(1-x)$ if $x \leq \frac{1}{2}$. This, combined with (95), shows that (90) is still true if we replace the h by f. Thus we can assume henceforth that $r \leq \frac{1}{2}$.

Let $\mathcal{B}$ and V_b be defined as in the proof of Lemma 8.3. Then

$$||K_\star^t f||_2^2 \leq ||K_{(d_\star - 1)} \cdots K_1 f||_2^2 \tag{97}$$

$$= \sum_{b \in \mathcal{B}} ||K_{(d_\star - 1)} \cdots K_1 f \mathbf{1}_{V_b}||_2^2. \tag{98}$$

For $b \in \mathcal{B}$, define $r_b = \frac{||f\mathbf{1}_{V_b}||_1}{||\mathbf{1}_{V_b}||_1} = ||f\mathbf{1}_{V_b}||_1 \, |\mathcal{B}|$. Then induction gives

$$||K_{(d_\star - 1)} \cdots K_1 f \mathbf{1}_{V_b}||_2^2 \leq r_b^{1/Cd^2(d_\star - 1)^{12}} ||f\mathbf{1}_{V_b}||_1.$$

Combining this with (98) gives

$$||K_\star^t f||_2^2 \leq \sum_{b \in \mathcal{B}} r_b^{1/Cd^2(d_\star - 1)^{12}} ||f\mathbf{1}_{V_b}||_1 = |\mathcal{B}|^{-1} \sum_{b \in \mathcal{B}} r_b^{1 + 1/Cd^2(d_\star - 1)^{12}}.$$

Thus, unless

$$|\mathcal{B}|^{-1} \sum_{b \in \mathcal{B}} r_b^{1 + 1/Cd^2(d_\star - 1)^{12}} \geq r^{1 + 1/Cd^2 d_\star^{12}}, \tag{99}$$

the result is immediate. So assume that (99) holds. For $b \in \mathcal{B}$, define $w_b = \frac{||f\mathbf{1}_{V_b}||_1}{||f||_1}$. Note that $\sum_{b \in \mathcal{B}} w_b = 1$. Let U be chosen uniformly at random from $\mathcal{B}$, and let $p = 1 + 1/Cd^2(d_\star - 1)^{12}$. Dividing both sides of (99) by r^p gives

$$\frac{\mathbf{E}(r_U^p)}{r^p} \geq r^{1/Cd^2 d_\star^{12} - 1/Cd^2(d_\star - 1)^{12}}. \tag{100}$$

Using the inequality $k^{-12} - (k-1)^{-12} \leq -k^{-13}$, valid for integers $k \geq 2$, and subtracting 1 from both sides of (100) gives

$$\frac{\mathbf{E}(r_U^p)}{r^p} - 1 \geq r^{-1/Cd^2 d_\star^{13}} - 1. \tag{101}$$

Let π be the uniform probability measure on $\mathcal{B}$ and let ν be the measure on $\mathcal{B}$ defined by the w_b. Define

$$\|\pi - \nu\|_{TV} = \tfrac{1}{2} \sum_{b \in \mathcal{B}} \Big| w_b - |\mathcal{B}|^{-1} \Big| = \tfrac{1}{2} \mathbf{E} \Big| \frac{r_U - r}{r} \Big|.$$

Note that $\mathbf{E}(r_U) = |\mathcal{B}|^{-1} \sum_{b \in \mathcal{B}} r_b = r$. Plugging $X = r_U$ and $\mu = r$ into Lemma 8.2 and combining with (101) gives

$$2\|\pi - \nu\|_{TV} \geq \frac{r^{-1/Cd^2 d_\star^{13}} - 1}{r^{-1/Cd^2 (d_\star - 1)^{12}} - 1} \tag{102}$$

$$= \frac{\exp\Big(\frac{-\log r}{Cd^2 d_\star^{13}}\Big) - 1}{\exp\Big(\frac{-\log r}{Cd^2 (d_\star - 1)^{12}}\Big) - 1}. \tag{103}$$

Since $r > 6^{-cdd_\star^6}$, the quantities in the exponents in (103) are in $(0, \frac{1}{2}]$. (Recall that C is much larger than c.) Hence, the fact that $\frac{e^t - 1}{t} \in [1, 2]$ whenever $t \in (0, \frac{1}{2}]$ implies that the quantity in (103) is at least

$$\frac{(d_\star - 1)^{12}}{2 d_\star^{13}} \geq \frac{d_\star^{-1}}{2^{13}},$$

where the inequality holds because $d_\star \geq 2$ and hence $\frac{d_\star - 1}{d_\star} \geq \frac{1}{2}$. It follows that $\|\pi - \nu\|_{TV} \geq 2^{-14} d_\star^{-1}$. Note that

$$2\|\pi - \nu\|_{TV} = \sum_{b \in \mathcal{B}} \max(\nu(b), \pi(b)) - \min(\nu(b), \pi(b)), \tag{104}$$

$$2 = \sum_{b \in \mathcal{B}} \max(\nu(b), \pi(b)) + \min(\nu(b), \pi(b)). \tag{105}$$

Subtracting the first equation from the second and dividing by 2 gives

$$1 - \|\pi - \nu\|_{TV} = \sum_{b \in \mathcal{B}} \min(\nu(b), \pi(b)). \tag{106}$$

Let $\hat{K}$ be the transition kernel for the $d_\star$-truncated zigzag shuffle. Note that

$$\langle f, \hat{K}^n f \rangle = \sum_{b \in \mathcal{B}} \langle f \mathbf{1}_{V_b}, (\hat{K}^n f) \mathbf{1}_{V_b} \rangle \tag{107}$$

$$\leq \sum_{b \in \mathcal{B}} \min\Big(||f \mathbf{1}_{V_b}||_1, ||(\hat{K}^n f) \mathbf{1}_{V_b}||_1 \Big) \tag{108}$$

$$= ||f||_1 \sum_{b \in \mathcal{B}} \min\Big(w_b, \frac{||(\hat{K}^n f) \mathbf{1}_{V_b}||_1}{||f||_1} \Big), \tag{109}$$

where the inequality holds because $f \mathbf{1}_{V_b} \leq 1$ and $(\hat{K}^n f) \mathbf{1}_{V_b} \leq 1$. Let $n = 15cdd_\star^5 \log 2$. Corollary 3.2 implies that $\frac{||(\hat{K}^n f) \mathbf{1}_{V_b}||_1}{||f||_1} \leq \alpha(d_\star) |\mathcal{B}|^{-1}$, where $\alpha(k) := \exp(2^{-15k})$. Hence,

$$\langle f, \hat{K}^n f \rangle \leq ||f||_1 \, \alpha(d_\star) \sum_{b \in \mathcal{B}} \min\big(w_b, \tfrac{1}{|\mathcal{B}|} \big) \tag{110}$$

$$= ||f||_1 \, \alpha(d_\star) (1 - \|\nu - \pi\|_{TV}) \tag{111}$$

$$\leq ||f||_1 \, \alpha(d_\star) \left[1 - 2^{-14} d_\star^{-1} \right]. \tag{112}$$

Hence Lemma 8.1 gives

$$||K_\star^t f||_2^2 \le \langle f,f\rangle^{1-1/n}\left[||f||_1\,\alpha(d_\star)(1-2^{-14}d_\star^{-1})\right]^{1/n} \tag{113}$$

$$= \Big(\frac{\langle f,f\rangle}{||f||_1}\Big)^{1-1/n} \times ||f||_1 \times \alpha(d_\star)^{1/n} \times (1-2^{-14}d_\star^{-1})^{1/n} \tag{114}$$

$$\le ||f||_1 \exp\Big(\frac{1}{n}\Big[2^{-15d_\star} - d_\star^{-1}2^{-14}\Big]\Big) \tag{115}$$

$$\le ||f||_1 \exp\Big(-1/2^{15}cdd_\star^6 15\log 2\Big), \tag{116}$$

since $\frac{\langle f,f\rangle}{||f||_1} \le 1$ and $2^{-15k} \le 2^{-15}k^{-1}$ for all positive integers k. Finally, since $r > 6^{-cdd_\star^6} = \exp(-cdd_\star^6 \log 6)$, we have $r^{1/Cd^2d_\star^{12}} \ge \exp(-1/2^{15}cdd_\star^6 15\log 2)$. (Recall that $C \ge 2^{15}c^2 15\log 2\log 6$.) It follows that $||K_\star^t f||_2^2 \le r^{1/Cd^2d_\star^{12}}||f||_1$. This completes the proof. ∎

To bound the root profile, we used the following corollary.

COROLLARY 8.5. *Fix $S \subset V$ and let*

$$x = \frac{|S|}{(2^d)!}.$$

Let $\{p(x,y)\}$ be the transition probabilities for a round of the Thorp shuffle. Then there is a universal constant $C > 0$ such that

$$||p(S,\cdot)||_2^2 \le x^{1+C/d^{14}}.$$

Proof. Let $f = \mathbf{1}_S$ and $d_\star = d$ and apply Lemma 8.4. (Note that if K is the transition kernel for a round of the Thorp shuffle, then $p(S,\cdot) = K^t f$.) ∎

Acknowledgments. I am grateful to K. Ball, T. Coulhon, E. Mossel, C. Nair, Y. Peres, A. Sinclair, D. Wilson, and P. Winkler for invaluable discussions. Keith Ball proved Lemma 8.2. I want to thank the referees for carefully reading the paper and suggesting some significant improvements.

I am grateful to Laurent Saloff-Coste and Jessica Zuniga for pointing out an error in an earlier version of the paper.

I also want to thank Christian Borgs and Jennifer Chayes for giving me the opportunity to spend a year at the Theory Group of Microsoft Research, where I did much of this research.

EVERY MONOTONE GRAPH PROPERTY IS TESTABLE*

NOGA ALON† AND ASAF SHAPIRA‡

Abstract. A graph property is called *monotone* if it is closed under removal of edges and vertices. Many monotone graph properties are some of the most well-studied properties in graph theory, and the abstract family of all monotone graph properties was also extensively studied. Our main result in this paper is that any monotone graph property can be tested with one-sided error, and with query complexity depending only on ϵ. This result unifies several previous results in the area of property testing and also implies the testability of well-studied graph properties that were previously not known to be testable. At the heart of the proof is an application of a variant of Szemerédi's regularity lemma. The main ideas behind this application may be useful in characterizing all testable graph properties and in generally studying graph property testing. As a byproduct of our techniques we also obtain additional results in graph theory and property testing, which are of independent interest. One of these results is that the query complexity of testing testable graph properties with one-sided error may be arbitrarily large. Another result, which significantly extends previous results in extremal graph theory, is that for any monotone graph property $\mathcal{P}$, any graph that is ϵ-far from satisfying $\mathcal{P}$ contains a subgraph of size depending on ϵ only, which does not satisfy $\mathcal{P}$. Finally, we prove the following compactness statement: If a graph G is ϵ-far from satisfying a (possibly infinite) set of monotone graph properties $\mathcal{P}$, then it is at least $\delta_{\mathcal{P}}(\epsilon)$-far from satisfying one of the properties.

Key words. property testing, monotone properties, regularity lemma, graphs

1. Introduction.

1.1. Definitions and background. All graphs considered here are finite and undirected and have neither loops nor parallel edges. Let $\mathcal{P}$ be a property of graphs, namely, a family of graphs closed under isomorphism. All graph properties discussed in this paper are assumed to be decidable; that is, we disregard properties for which it is not possible to tell whether a given graph satisfies them. A graph G with n vertices is said to be *ϵ-far from satisfying $\mathcal{P}$* if one must add or delete at least ϵn^2 edges in order to turn G into a graph satisfying $\mathcal{P}$. A *tester* for $\mathcal{P}$ is a randomized algorithm which, given the quantity n and the ability to query whether a desired pair of vertices of an input graph G with n vertices are adjacent or not, distinguishes with high probability (say, 2/3) between the case of G satisfying $\mathcal{P}$ and the case of G being ϵ-far from satisfying $\mathcal{P}$. One of the striking results in the area of property testing is that many natural graph properties have a tester, whose total number of queries is bounded only by a function of ϵ, which is independent of the size of the input graph.

A property having such a tester is called *testable*. Note, that if the number of queries performed by the tester is bounded by a function of ϵ only, then so is its running time. A tester is said to have *one-sided error* if whenever G satisfies $\mathcal{P}$, the algorithm declares that this is the case with probability 1. Throughout the paper, we assume that a tester first samples a set of vertices S, queries all the pairs $(i,j) \in S$, and then accepts or rejects by considering the graph spanned by the set. As observed in [3] and formally proved in [23], this can be assumed with no loss of generality, as this assumption at most squares the query complexity (and we will not care about such factors in this paper).

The general notion of property testing was first formulated by Rubinfeld and Sudan [33], who were motivated mainly by its connection to the study of program checking. The study of the notion of testability for combinatorial structures, and mainly for labeled graphs, was introduced in the seminal paper of Goldreich, Goldwasser, and Ron [22], who showed that several natural graph properties are testable. In the wake of [22], many other graph properties were shown to be testable, while others were shown to be nontestable. See [18], [32], and [31] for additional results and references on graph property testing as well as on testing properties of other combinatorial structures.

1.2. Related work. The most interesting results in property testing are those that show that large families of problems are testable. The main result of [22] states that a certain abstract graph partition problem, which includes as a special case k-colorability, having a large cut and having a large clique, is testable. The authors of [23] gave a characterization of the partition problems discussed in [22] that are testable with one-sided error. In [3], a logical characterization of a family of testable graph properties was obtained. According to this characterization, every first order graph property of type $\exists\forall$ is testable, while there are first order graph properties of type $\forall\exists$ that are not testable. These results were extended in [17].

There are also several general testability and nontestability results in other areas besides testing graph properties. In [4] it is proved that every regular language is testable. This result was extended to any read-once branching program in [29]. On the other hand, it was proved in [20] that there are read-twice branching programs that are not testable. The main result of [6] states that any constraint satisfaction problem is testable.

With this abundance of general testability results, a natural question is what makes a combinatorial property testable. As graphs are the most well-studied combinatorial structures in the theory of computation, it is natural to consider the problem of characterizing the testable graph properties as the most important open problem in the area of property testing. Regretfully, though, finding such a characterization seems to be a very challenging endeavor, which is still open. Therefore, a natural line of research is to find large families of testable graph properties.

1.3. The main new result. Our main goal in this paper is to show that all the graph properties that belong to a large, natural, and well-studied family of graph properties are testable. In fact, we even show that these properties are testable with one-sided error. A graph property $\mathcal{P}$ is said to be *monotone* if it is closed under removal of edges and vertices. In other words, if a graph G does not satisfy $\mathcal{P}$, then any graph that contains G as a (not necessarily induced) subgraph does not satisfy $\mathcal{P}$ as well. Various monotone graph properties were extensively studied in graph theory. As examples of monotone properties one can consider the property of having a homomorphism to a fixed graph H (which includes as a special case the

property of being k-colorable; see Definition 2.2) and the property of not containing a (not necessarily induced) copy of some fixed graph H. Another set of well-studied monotone properties are those defined by having a *fractional chromatic number*, *vector chromatic number*, and *Lovász theta function* bounded by some constant c, which need not be an integer (see [25] and [27]). Another monotone property is being $(k, \mathcal{H})$-*Ramsey*: For a (possibly infinite) family of graphs $\mathcal{H}$, a graph is said to be $(k, \mathcal{H})$-Ramsey if one can color its edges using k colors, such that no color class contains a copy of a graph $H \in \mathcal{H}$. This property is the main focus of Ramsey theory; see [24] and its references. As another example, one can consider the property of being $(k, \mathcal{H}, f)$-multicolorable; for a (possibly infinite) family of graphs $\mathcal{H}$ and a function f from $\mathcal{H}$ to the positive integers, a graph is said to be $(k, \mathcal{H}, f)$-multicolorable if one can color its edges using k colors, such that every copy of a graph $H \in \mathcal{H}$ receives at least $f(H)$ colors. See [16], [14], and their references for a discussion of some special cases. The abstract family of monotone graph properties has also been extensively studied in graph theory. See [21], [13], [11], and their references. Our main result is the following.

THEOREM 1 (main result). *Every monotone graph property is testable with one-sided error.*

We stress that we actually prove a slightly weaker statement than the one given above, as the monotone property has to satisfy some technical conditions (which cannot be avoided). However, as the cases where the actual result is weaker than what is stated in Theorem 1 deal with extremely unnatural properties, and even in these cases the actual result is roughly the same, we postpone the precise statement to section 5 (see Theorem 6). Another important note is that in [23], Goldreich and Trevisan define a monotone graph property to be one that is closed under removal of edges, and not necessarily under removal of vertices. They show that there are such properties that are not testable even with two-sided error. In fact, their result is stronger as the property they define belongs to NP and requires query complexity $\Omega(n^2)$. This means that Theorem 1 cannot be extended, in a strong sense, to properties that are only closed under removal of edges.

As we have mentioned above, having a homomorphism to a fixed graph H, k-colorability, and the property of not containing a copy of a fixed graph H are monotone properties and are thus testable with one-sided error by Theorem 1. These properties were known to be testable before, and as Theorem 1 applies to general monotone properties, the bounds it supplies for these properties are inferior compared to the ones proved by the ad hoc arguments (see [5], [22], [23], and [7]). In Theorem 4 we prove that this is unavoidable. The main importance of Theorem 1 thus lies in its generality. However, as described in the beginning of this subsection, there are additional natural and well-studied monotone graph properties that prior to this work were not known to be testable, and we may thus use Theorem 1 to conclude that these properties are testable with one-sided error. We also believe that Theorem 1 and its proof may be an important step toward a combinatorial characterization of the graph properties that are testable with one-sided error. Another important aspect of Theorem 1 is that it can be used to prove general results on graph property testing. Two examples are Theorems 4 and 5, which we describe in the next subsection. Another result appears in a related subsequent paper [8] and is discussed in section 5. We believe that Theorem 1 will be useful for proving other consequences as well. See section 7 for more details and possible natural lines of research suggested by the results of this paper.

1.4. Techniques and additional results. The first technical ingredient in the proof of Theorem 1 is the proof of an (almost) equivalent formulation of it. For a (possibly infinite) family of graphs $\mathcal{F}$ we say that a graph is $\mathcal{F}$-free if it contains no member from $\mathcal{F}$ as a (not necessarily induced) subgraph. Clearly, being $\mathcal{F}$-free is a monotone property. It is well known (see, e.g., [2]) that for any *finite* family of graphs $\mathcal{F}$, the property of being $\mathcal{F}$-free is testable. This follows from a standard application of Szemerédi's regularity lemma. As we discuss in section 2, this lemma is inadequate for obtaining a similar result for infinite families of graphs. The main technical step in the proof of Theorem 1 is the following theorem, which is the main technical contribution of this paper.

THEOREM 2. *For every (possibly infinite) family of graphs $\mathcal{F}$, there are functions $N_{\mathcal{F}}(\epsilon)$ and $Q_{\mathcal{F}}(\epsilon)$ with the following properties: If G is a graph on $n \geq N_{\mathcal{F}}(\epsilon)$ vertices which is ϵ-far from being $\mathcal{F}$-free, then a random subset of $Q_{\mathcal{F}}(\epsilon)$ vertices of G spans a member of $\mathcal{F}$ with probability at least $2/3$.*

Note that Theorem 2 immediately implies that for every family of graphs $\mathcal{F}$, the property of being $\mathcal{F}$-free is testable. In order to prove Theorem 2 we apply a strong version of the regularity lemma, proved by Alon et al. [3]. We believe that our application of this lemma may be useful for attacking other problems. As a byproduct of our argument we obtain the following graph theoretic result.

THEOREM 3. *For every monotone graph property $\mathcal{P}$, there is a function $W_{\mathcal{P}}(\epsilon)$ with the following property: If G is ϵ-far from satisfying $\mathcal{P}$, then G contains a subgraph of size at most $W_{\mathcal{P}}(\epsilon)$ which does not satisfy $\mathcal{P}$.*

The above theorem significantly extends a result of Rödl and Duke [30], conjectured by Erdős, which asserts that the above statement holds for the k-colorability property. Theorem 3 applies to any monotone property and, in particular, to all the properties discussed in the beginning of the previous subsection.

As will become evident from the proof of Theorem 1 (which is based on Theorem 2), the upper bounds for testing a monotone property depend on the property being tested. In other words, what we prove is that for every property $\mathcal{P}$, there is a function $Q_{\mathcal{P}}(\epsilon)$ such that $\mathcal{P}$ can be tested with query complexity $Q_{\mathcal{P}}(\epsilon)$. A natural question one may ask is if the dependency on the specific property being tested can be removed. We rule out this possibility by proving the following.

THEOREM 4. *For any function $Q : (0,1) \mapsto \mathbb{N}$, there is a monotone graph property $\mathcal{P}$ which has no one-sided error property tester with query complexity bounded by $o(Q(\epsilon))$.*

Prior to this work, the best lower bound proved for testing a testable graph property with one-sided error was obtained in [1], where it is shown that for every nonbipartite graph H, the query complexity of testing whether a graph does not contain a copy of H is at least $(1/\epsilon)^{\Omega(\log 1/\epsilon)}$. The fact that for every H this property is testable with one-sided error follows from [2] and [3] and also as a special case from Theorem 1. As by Theorem 1 every monotone graph property is testable with one-sided error, Theorem 4 establishes that the one-sided error query complexity of testing testable graph properties, even those that are testable with one-sided error, may be *arbitrarily large*.

Our next result can be considered a compactness-type result in property testing. Suppose $\mathcal{P}_1, \ldots, \mathcal{P}_k$ are k graph properties that are closed under removal of edges. It is clear that if a graph G is ϵ-far from satisfying these k properties then it is at least ϵ/k-far from satisfying at least one of them. However, it is not clear that there is a fixed $\delta > 0$ such that even if $k \to \infty$, G must be δ-far from satisfying one of these properties. By using Theorem 2 we can prove that if these properties are monotone

then such a δ exists. We also show that in general there is no such δ.

THEOREM 5. *For any (possibly infinite) set of monotone graph properties $\mathcal{P} = \{\mathcal{P}_1, \mathcal{P}_2, \dots\}$, there is a function $\delta_{\mathcal{P}} : (0,1) \mapsto (0,1)$ with the following property: If a graph G is ϵ-far from satisfying all the properties of $\mathcal{P}$, then for some i, the graph G is $\delta_{\mathcal{P}}(\epsilon)$-far from satisfying $\mathcal{P}_i$. Furthermore, there are properties $\mathcal{P} = \{\mathcal{P}_1, \mathcal{P}_2, \dots\}$, which are closed under removal of edges, for which no such $\delta_{\mathcal{P}}$ exists.*

1.5. Recent results. By applying the techniques of this paper along with several additional ideas we have managed to extend Theorem 1 by showing that any hereditary graph property is testable with one-sided error (a graph property is hereditary if it is closed under removal of vertices, and not necessarily under removal of edges). Besides implying that many additional graph properties are testable, we can also use this result to obtain a precise characterization of the graph properties, which can be tested with one-sided error by testers with a certain natural restriction (essentially all the testers that have been designed thus far in the literature satisfy this restriction). These results, which appear in a subsequent paper [9], demonstrate the relevance of the techniques developed in this paper to the problem of characterizing the testable graph properties. Also, in a joint work with Benny Sudakov [10], we have obtained approximation algorithms for the edit distance of a given graph from satisfying an arbitrary monotone graph property. We also obtained nearly matching hardness of approximation results. Some of the results of [10] also apply the main technique developed in this paper. In a recent paper, Avart, Rödl, and Schacht [12] extended our main result to the case of 3-uniform hypergraphs, which applies the main ideas of this paper along with the hypergraph regularity lemma. Finally, Lovász and Szegedy [28] recently gave an alterative proof of the main result of [9] on testing hereditary properties using the notion of convergent graph sequences.

1.6. Organization. The rest of the paper is organized as follows. In section 2 we introduce the basic notions of regularity and state the regularity lemmas that we use and some of their standard consequences. We also (do our best to) explain why the standard regularity lemma and its applications seem inadequate for proving Theorem 2. In section 3 we give a high level description of the proof of Theorem 2 as well as the main ideas behind it. The full proof of Theorem 2 appears in section 4. In section 5 we give the precise statement of Theorem 1 and use Theorem 2 in order to prove it. In section 7, we describe several possible extensions and open problems that this paper suggests. The proofs of Theorems 3 and 5 appear in section 4 and the proof of Theorem 4 appears in section 6. Throughout the paper, whenever we relate, for example, to a function $f_{3.1}$, we mean the function f defined in Lemma/Claim/Theorem 3.1.

2. Regularity lemmas: Definitions, statements, and applications. In this section we discuss the basic notions of regularity and some of the basic applications of regular partitions and state the regularity lemmas that we use in the proof of Theorem 2. For a comprehensive survey on the regularity lemma the reader is referred to [26]. We start with some basic definitions. For every two nonempty disjoint vertex sets A and B of a graph G, we define $e(A,B)$ to be the number of edges of G between A and B. The *edge density* of the pair is defined by $d(A,B) = e(A,B)/|A||B|$.

DEFINITION 2.1 (γ-regular pair). *A pair (A,B) is* γ-regular *if for any two subsets $A' \subseteq A$ and $B' \subseteq B$, satisfying $|A'| \geq \gamma|A|$ and $|B'| \geq \gamma|B|$, the inequality $|d(A',B') - d(A,B)| \leq \gamma$ holds.*

Note that a sufficiently large random bipartite graph, where each edge is chosen independently with probability d, is very likely to be a γ-regular pair with density

roughly d for any $\gamma > 0$. Thus, in some sense, the smaller γ is, the closer a γ-regular pair is to looking like a random bipartite graph. For this reason, the reader who is unfamiliar with the regularity lemma and its applications should try to compare the statements given in this section to analogous statements about random graphs. Throughout the paper we will make extensive use of the notion of graph homomorphism, which we now formally define.

DEFINITION 2.2 (homomorphism). *A homomorphism from a graph F to a graph K is a mapping $\varphi : V(F) \mapsto V(K)$ that maps edges to edges; namely, $(v,u) \in E(F)$ implies $(\varphi(v), \varphi(u)) \in E(K)$.*

Observe that a graph F has a homomorphism into the complete graph of size k if and only if F is k-colorable. In what follows, $F \mapsto K$ denotes the fact that there is a homomorphism from F to K. Let F be a graph on f vertices and K a graph on k vertices, and suppose $F \mapsto K$. Let G be a graph obtained by taking a copy of K, replacing every vertex with a sufficiently large independent set, and replacing every edge with a random bipartite graph of edge density d. It is easy to show that with high probability, G contains many copies of F. The following lemma shows that in order to infer that G contains many copies of F, it is enough to replace every edge with a "regular enough" pair. Intuitively, the larger f and k are, and the sparser the regular pairs are, the more regular we need each pair to be, because we need the graph to be "closer" to a random graph. This is formulated in Lemma 2.3 below. Several versions of this lemma were previously proved in papers using the regularity lemma. See, e.g., [26]. The reader should think of the mapping φ in the statement of the lemma as defining the homomorphism from F to the (implicit) graph K.

LEMMA 2.3. *For every real $0 < \eta < 1$, and integers $k, f \geq 1$ there exist $\gamma = \gamma_{2.3}(\eta, k, f)$, $\delta = \delta_{2.3}(\eta, k, f)$, and $M = M_{2.3}(\eta, k, f)$ with the following property. Let F be any graph on f vertices, and let $U_1, \ldots, U_k$ be k pairwise disjoint sets of vertices in a graph G, where $|U_1| = \cdots = |U_k| = m \geq M$. Suppose there is a mapping $\varphi : V(F) \mapsto \{1, \ldots, k\}$ such that the following holds: If (i,j) is an edge of F then $(U_{\varphi(i)}, U_{\varphi(j)})$ is γ-regular with density at least η. Then, the sets $U_1, \ldots, U_k$ span at least δm^f copies of F.*

COMMENT 2.4. *Note that the functions $\gamma_{2.3}(\eta, k, f)$ and $\delta_{2.3}(\eta, k, f)$ may and will be assumed to be monotone nonincreasing in k and f. Similarly, we will assume that the function $M_{2.3}(\eta, k, f)$ is monotone nondecreasing in k and f. Also, for ease of future definitions (particularly the one given in (4)) we set $\gamma_{2.3}(\eta, k, 0) = \delta_{2.3}(\eta, k, 0) = M_{2.3}(\eta, k, 0) = 1$ for any $k \geq 1$ and $0 < \eta < 1$.*

A partition $\mathcal{A} = \{V_i \mid 1 \leq i \leq k\}$ of the vertex set of a graph is called an *equipartition* if $|V_i|$ and $|V_j|$ differ by no more than 1 for all $1 \leq i < j \leq k$ (so, in particular, each V_i has one of two possible sizes). When we refer to the size of such an equipartition, we mean the number of partition classes of the equipartition (k above). The regularity lemma of Szemerédi can be formulated as follows.

LEMMA 2.5 (see [34]). *For every m and $\gamma > 0$ there exists a number $T = T_{2.5}(m, \gamma)$ with the following property: Any graph G on $n \geq T$ vertices has an equipartition $\mathcal{A} = \{V_i \mid 1 \leq i \leq k\}$ of $V(G)$ with $m \leq k \leq T$, for which all pairs (V_i, V_j), but at most $\gamma\binom{k}{2}$ of them, are γ-regular.*

The original formulation of the lemma also allows for an exceptional set with up to γn vertices outside of this equipartition, but one can first apply the original formulation with a somewhat smaller parameter instead of γ and then evenly distribute the exceptional vertices among the sets of the partition to obtain this formulation. $T_{2.5}(m, \gamma)$ may and is assumed to be monotone nondecreasing in m and monotone

nonincreasing in γ.

A standard application of Lemmas 2.3 and 2.5 shows that for any *finite* set of graphs $\mathcal{F}$, the property of not containing a member of $\mathcal{F}$, that is, being $\mathcal{F}$-free, is testable. We first use Lemma 2.3 by setting f and k to be the size of the largest graph in $\mathcal{F}$ and letting $\eta = \epsilon$. Lemma 2.3 gives a $\gamma_{2.3}$, which tells us how regular an equipartition should be (that is, how small should γ be) in order to find many copies of a member of $\mathcal{F}$ in it, assuming the input graph is ϵ-far from being $\mathcal{F}$-free. We then apply Lemma 2.5, with $\gamma = \gamma_{2.3}$. The main difficulty with applying this strategy when $\mathcal{F}$ is infinite is that we do not know a priori the size of the member of $\mathcal{F}$ that we will eventually find in the equipartition that Lemma 2.5 returns. After finding $F \in \mathcal{F}$ in an equipartition, we may find out that F is too large for Lemma 2.3 to be applied, because Lemma 2.5 was not used with a small enough γ. One may then try to find a new equipartition based on the size of F. However, that requires using a smaller γ, and thus the new equipartition may be larger (that is, contain more partition classes) and thus contain only larger members of $\mathcal{F}$. Hence, even the new γ is not good enough in order to apply Lemma 2.3. This leads to a circular definition of constants, which seems unbreakable. Our main tool in the proof of Theorem 2 is Lemma 2.7 below, proved in [3] for a different reason, which enables us to break this circular chain of definitions. This lemma can be considered a variant of the standard regularity lemma, where one can use a function that defines γ as a function of the size of the equipartition[1] rather than having to use a fixed γ as in Lemma 2.5. To state the lemma we need the following definition.

DEFINITION 2.6 (the function $W_{\mathcal{E},m}$). *Let $\mathcal{E}(r) : \mathbb{N} \mapsto (0,1)$ be an arbitrary monotone nonincreasing function. Let also m be an arbitrary positive integer. We define the function $W_{\mathcal{E},m} : \mathbb{N} \mapsto (0,1)$ inductively as follows: $W_{\mathcal{E},m}(1) = T_{2.5}(m, \mathcal{E}(0))$. For any integer $i > 1$ put $R = W_{\mathcal{E},m}(i-1)$ and define*

$$W_{\mathcal{E},m}(i) = T_{2.5}(R, \mathcal{E}(R)/R^2). \tag{1}$$

LEMMA 2.7 (see [3]). *For every integer m and monotone nonincreasing function $\mathcal{E}(r) : \mathbb{N} \mapsto (0,1)$ define*

$$S = S_{2.7}(m, \mathcal{E}) = W_{\mathcal{E},m}(100/\mathcal{E}(0)^4).$$

For any graph G on $n \geq S$ vertices, there exist an equipartition $\mathcal{A} = \{V_i \mid 1 \leq i \leq k\}$ of $V(G)$ and an induced subgraph U of G, with an equipartition $\mathcal{B} = \{U_i \mid 1 \leq i \leq k\}$ of the vertices of U, that satisfy the following:

1. *$m \leq k \leq S$.*
2. *$U_i \subseteq V_i$ for all $i \geq 1$, and $|U_i| \geq n/S$.*
3. *In the equipartition $\mathcal{B}$,* all *pairs are $\mathcal{E}(k)$-regular.*
4. *All but at most $\mathcal{E}(0)\binom{k}{2}$ of the pairs $1 \leq i < j \leq k$ are such that $|d(V_i, V_j) - d(U_i, U_j)| < \mathcal{E}(0)$.*

COMMENT 2.8. *For technical reasons (see the proof in* [3]*), Lemma* 2.7 *requires that for any $r > 0$ the function $\mathcal{E}(r)$ will satisfy*

$$\mathcal{E}(r) \leq \min\{\mathcal{E}(0)/4, 1/4r^2\}. \tag{2}$$

One of the difficulties in the proof of Theorem 2 is in showing that all the constants that are used in the course of the proof can be upper bounded by functions depending on ϵ only. The following observation will thus be useful.

[1] This is a simplification of the actual statement; see item (3) in the statement of Lemma 2.7.

PROPOSITION 2.9. *If m is bounded by a function of ϵ only and $\mathcal{E}(r)$ satisfies (2), then the integer $S = S_{2.7}(m, \mathcal{E})$ can be upper bounded by a function of ϵ only.*[2]

The dependency of the function $T_{2.5}(m, \gamma)$ on γ is a tower of exponents of height polynomial in $1/\gamma$ (see the proof in [26]). Thus, even for moderate functions $\mathcal{E}$ the integer S has a huge dependency on ϵ, which is a tower of towers of exponents of height polynomial in $1/\epsilon$.

3. Overview of the proof of Theorem 2. Though we believe that the proof of Theorem 2 is not harder than several other proofs applying the regularity lemma, we could not avoid the usage of a hefty number of constants that may hide the main ideas of the proof. We thus give in this section a general overview of the proof and the way we overcome the difficulties described in section 2. The complete proof is given in section 4.

For an equipartition of a graph G, let the *regularity graph* of G, denoted $R = R(G)$, be the following graph: We first use Lemma 2.5 in order to obtain the equipartition satisfying the assertions of the lemma. Let k be the size of the equipartition. Then, R is a graph on k vertices, where vertices i and j are connected if and only if (V_i, V_j) is a dense regular pair (with the appropriate parameters). In some sense, the regularity graph is an approximation of the original graph, up to γn^2 modifications. One of the main (implicit) implications of the regularity lemma is the following: Suppose we consider two graphs to be *similar* if their regularity graphs are identical. It thus follows from Lemma 2.5 that for every $\gamma > 0$, the number of graphs that are pairwise nonsimilar is bounded by a function of γ only ($2^{\binom{T}{2}}$, where $T = T_{2.5}(1/\gamma, \gamma)$). Namely, up to γn^2 modifications, all the graphs can be approximated using a set of equipartitions of size bounded by a function of γ only. The reader is referred to [15], where this interpretation of the regularity lemma is also (implicitly) used. This leads us to the key definitions of the proof of Theorem 2. The reader should think of the graphs R considered below as the set of regularity graphs discussed above, and the parameter r as representing the size of R.

DEFINITION 3.1 (the family $\mathcal{F}_r$). *For any (possibly infinite) family of graphs $\mathcal{F}$, and any integer r, let $\mathcal{F}_r$ be the following set of graphs: A graph R belongs to $\mathcal{F}_r$ if it has at most r vertices and there is at least one $F \in \mathcal{F}$ such that $F \mapsto R$.*

Practicing definitions, observe that if $\mathcal{F}$ is the family of odd cycles, then $\mathcal{F}_r$ is precisely the family of nonbipartite graphs of size at most r. In the proof of Theorem 2, the set $\mathcal{F}_r$, defined above, will represent a subset of the regularity graphs of size at most r—namely, those R for which there is at least one $F \in \mathcal{F}$ such that $F \mapsto R$. As r will be a function of ϵ only, and thus finite, we can take the maximum over all the graphs $R \in \mathcal{F}_r$ of the size of the smallest $F \in \mathcal{F}$ such that $F \mapsto R$. We thus define the following.

DEFINITION 3.2 (the function $\Psi_{\mathcal{F}}$). *For any family of graphs $\mathcal{F}$ and integer r for which $\mathcal{F}_r \neq \emptyset$, define*

$$\Psi_{\mathcal{F}}(r) = \max_{R \in \mathcal{F}_r} \min_{\{F \in \mathcal{F} : F \mapsto R\}} |V(F)|. \tag{3}$$

Define $\Psi_{\mathcal{F}}(r) = 0$ if $\mathcal{F}_r = \emptyset$. Therefore, $\Psi_{\mathcal{F}}(r)$ is monotone nondecreasing in r.

Practicing definitions again, note that if $\mathcal{F}$ is the family of odd cycles, then $\Psi_{\mathcal{F}}(r) = r$ when r is odd, and $\Psi_{\mathcal{F}}(r) = r - 1$ when r is even. The "right" way to

[2] In our application of Lemma 2.7 the function $\mathcal{E}$ will (implicitly) depend on ϵ. For example, it will be convenient to set $\mathcal{E}(0) = \epsilon$. However, note that even in this case $S_{2.7}(m, \mathcal{E})$ can be upper bounded by a function of ϵ only.

think of the function $\Psi_{\mathcal{F}}$ is the following: Let R be a graph of size at most r and suppose we are guaranteed that there is a graph $F' \in \mathcal{F}$ such that $F' \mapsto R$ (thus $R \in \mathcal{F}_r$). Then by this information only and *without* having to know the structure of R itself, the definition of $\Psi_{\mathcal{F}}$ implies that there is a graph $F \in \mathcal{F}$ of size at most $\Psi_{\mathcal{F}}(r)$, such that $F \mapsto R$.

The function $\Psi_{\mathcal{F}}$ has a critical role in the proof of Theorem 2. The first usage of this function is that, as by Lemma 2.5 we can upper bound the size of the regularity graph R, we can also upper bound the size of the smallest graph $F \in \mathcal{F}$ for which $F \mapsto R$. A second important property of $\Psi_{\mathcal{F}}$ is discussed in section 5. A natural question one may ask is whether there is a function Ψ that can upper bound $\Psi_{\mathcal{F}}$ for all families $\mathcal{F}$. As it turns out, this is impossible; namely, the dependency on the specific family $\mathcal{F}$ is unavoidable. See the discussion following the proof of Theorem 4 in section 6. As we have mentioned in the previous section, the main difficulty that prevents one from proving Theorem 2 using Lemma 2.3 is that one does not know a priori the size of the graph that one may expect to find in the equipartition. This leads us to define the following function, where $0 < \epsilon < 1$ is an arbitrary real.

$$\mathcal{E}'(r) = \begin{cases} \epsilon/8, & r = 0, \\ \gamma_{2.3}(\epsilon/8,\ r,\ \Psi_{\mathcal{F}}(r)), & r \geq 1. \end{cases} \tag{4}$$

In simple words, given r, which will represent the size of the equipartition and thus also the size of the regularity graph which it defines, $\mathcal{E}'(r)$ returns "how regular" this equipartition should be in order to allow one to find many copies of the *largest* graph one may possibly have to work with. Note that we obtain the upper bound on the size of this largest possible graph by invoking $\Psi_{\mathcal{F}}(r)$. As for different families of graphs $\mathcal{F}$, the function $\Psi_{\mathcal{F}}(r)$ may behave differently; $\mathcal{E}'(r)$ may also behave differently for different families $\mathcal{F}$, as it is defined in terms of $\Psi_{\mathcal{F}}(r)$. However, and this is one of the key points of the proof, as we are fixing the family of graphs $\mathcal{F}$, the function $\mathcal{E}'(r)$ depends only on r.

Given the above definitions we apply Lemma 2.7 with a slight modification of $\mathcal{E}'(r)$ in order to obtain an equipartition of G. We then throw away edges that reside inside the sets V_i and between (V_i, V_j), whose edge density differs significantly from that of (U_i, U_j). We then argue that we thus throw away less than ϵn^2 edges. As G is by assumption ϵ-far from not containing a member of $\mathcal{F}$, the new graph still contains a copy of $F \in \mathcal{F}$. By the definition of the new graph, it thus means that there is a (natural) homomorphism from F to the regularity graph of G. We then arrive at the main step of the proof, where we use the key property of Lemma 2.7, item (3), and the definition of $\mathcal{E}'(r)$ to get that the sets U_i are regular enough to let us use Lemma 2.3 on them and to infer that they span many copies of F. It thus follows that a large enough sample of vertices spans a copy of F with high probability. The complete details appear in section 4.

4. Proofs of Theorems 2, 3, and 5. We start with the proof of Theorem 2. We assume the reader is familiar with the overview of its proof given in section 3.

Proof of Theorem 2. Fix any family of graphs $\mathcal{F}$. Our goal is to show the existence of functions $N_{\mathcal{F}}(\epsilon)$ and $Q_{\mathcal{F}}(\epsilon)$ with the following properties: If a graph G on $n \geq N_{\mathcal{F}}(\epsilon)$ vertices is ϵ-far from being $\mathcal{F}$-free, then a random subset of $Q_{\mathcal{F}}(\epsilon)$ vertices of $V(G)$ spans a member of $\mathcal{F}$ with probability at least $2/3$. For the rest of the proof, let $\mathcal{E}'(r) : N \mapsto (0, 1)$ be as defined in (4). In order to apply Lemma 2.7, we need to define a function $\mathcal{E}$, based on $\mathcal{E}'$, which will satisfy the technical condition (2)

in Comment 2.8. We thus set $\mathcal{E}(0) = \mathcal{E}'(0)$ $(= \epsilon/8)$ and define for any $r > 0$

$$\mathcal{E}(r) = \min\{\mathcal{E}'(r),\ \mathcal{E}(0)/4,\ 1/4r^2\}. \tag{5}$$

For the rest of the proof set

$$S(\epsilon) = S_{2.7}(8/\epsilon, \mathcal{E}).$$

We may indeed define $S(\epsilon)$ using $\mathcal{E}$ as it satisfies (2). Furthermore, as we define $S(\epsilon)$ using $m = 8/\epsilon$ we get by Proposition 2.9 that $S(\epsilon)$ is indeed a function of ϵ only. We now set

$$N = N_{\mathcal{F}}(\epsilon) = S(\epsilon) \cdot M_{2.3}(\epsilon/8, S(\epsilon), \Psi_{\mathcal{F}}(S(\epsilon))) \tag{6}$$

to be an integer bounded by a function of ϵ as well. We postpone the definition of $Q_{\mathcal{F}}(\epsilon)$ till the end of the proof.

Given a graph G on n vertices, with $n \geq N \geq S(\epsilon)$, we can use Lemma 2.7 with $m = 8/\epsilon$ and $\mathcal{E}(r)$ as defined in (5) in order to obtain an equipartition of $V(G)$ into $8/\epsilon \leq k \leq S(\epsilon)$ clusters $V_1, \ldots, V_k$ (this is possible by item 1 in Lemma 2.7). By item 2 of Lemma 2.7, for every $1 \leq i \leq k$ we have sets $U_i \subseteq V_i$ each of size at least $n/S(\epsilon)$. Remove from G the following edges according to the following order:

1. Any edge (u, v) for which both u and v belong to the same cluster V_i. As each of the clusters contains at most $n/k + 1$ vertices, the total number of edges removed is at most $k(n/k)^2$. As $k \geq 8/\epsilon$ we have $k(n/k)^2 < \frac{\epsilon}{8}n^2$.
2. If for some $i < j$ we have $|d(V_i, V_j) - d(U_i, U_j)| > \frac{\epsilon}{8} = \mathcal{E}(0)$, remove all the edges connecting vertices that belong to V_i to vertices that belong to V_j. By item 4 of Lemma 2.7, there are at most $\frac{\epsilon}{8}k^2$ such pairs i, j. As V_i and V_j contain at most $(n/k+1)$ vertices, we remove at most $\frac{\epsilon}{8}k^2 \cdot (n/k+1)^2 \leq \frac{\epsilon}{7}n^2$ edges in this step.
3. If for some $i < j$ we have $d(U_i, U_j) < \frac{\epsilon}{8}$, remove all the edges connecting vertices that belong to V_i to vertices that belong to V_j. As we have already removed in the previous step all the edges between pairs (V_i, V_j) for which $|d(V_i, V_j) - d(U_i, U_j)| > \frac{\epsilon}{8}$, we may conclude that if $d(U_i, U_j) < \frac{\epsilon}{8}$ then we also have $d(V_i, V_j) < \frac{\epsilon}{8} + \mathcal{E}(0) = \frac{\epsilon}{4}$. As V_i and V_j contain at most $(n/k + 1)$ vertices, we thus remove at most $k^2 \cdot \frac{\epsilon}{4}(n/k + 1)^2 \leq \frac{\epsilon}{3}n^2$ edges.

Call the graph obtained after removing the above edges G', and observe that G' is obtained from G by removing less than ϵn^2 edges. By item 3 of Lemma 2.7, in G all the pairs (U_i, U_j) are $\mathcal{E}(k)$-regular. Thus, by the third step of obtaining G' we get the following property.

PROPOSITION 4.1. *If $v_i \in V_i$ is connected to $v_j \in V_j$ in G', then (U_i, U_j) is an $\mathcal{E}(k)$-regular pair with density at least $\frac{\epsilon}{8}$ in G.*

Consider a graph R on k vertices $r_1, \ldots, r_k$, where vertices r_i and r_j are connected if and only if (U_i, U_j) is an $\mathcal{E}(k)$-regular pair in G with density at least $\frac{\epsilon}{8}$. This is the regularity graph, which we have mentioned in section 3, of the graph induced by the sets $U_1, \ldots, U_k$. As G is by assumption ϵ-far from being $\mathcal{F}$-free, and G' is obtained from G by removing less than ϵn^2 edges, G' must contain a copy of a graph $F' \in \mathcal{F}$. Let R_i contain all the vertices of F' that belong to cluster V_i and note that by Proposition 4.1, there is a natural homomorphism $\varphi : V(F') \mapsto V(R)$ which maps all the vertices of $R_i \subseteq V(F')$ to r_i. As $|V(R)| = k$ and F' is a graph in $\mathcal{F}$ such that $F' \mapsto R$, we conclude that $R \in \mathcal{F}_k$ (recall Definition 3.1). Therefore, there is a graph $F \in \mathcal{F}$ of size at most $\Psi_{\mathcal{F}}(k)$ such that $V(F) \mapsto V(R)$ (recall Definition 3.2). Let

$\varphi : V(F) \mapsto V(R)$ be the homomorphism mapping the vertices of F to the vertices of R. By definition, we have that whenever (i,j) is an edge of F their image $(\varphi(i),\varphi(j))$ is an edge of R. Furthermore, by definition of R we know that if $(\varphi(i),\varphi(j))$ is an edge of R then $(U_{\varphi(i)}, U_{\varphi(j)})$ is an $\mathcal{E}(k)$-regular pair with density at least $\frac{\epsilon}{8}$.

We have thus arrived at the following situation: We have k clusters of vertices $U_1,\ldots,U_k$ of the same size. We also have a graph F of size at most $\Psi_{\mathcal{F}}(k)$, and a mapping $\varphi : V(H) \mapsto \{1,\ldots,k\}$ that satisfies the condition; if $(i,j) \in E(F)$ then $(U_{\varphi(i)}, U_{\varphi(j)})$ is an $\mathcal{E}(k)$-regular pair with density $\epsilon/8$. This, together with the definition of $\mathcal{E}(k)$, implies that we can use Lemma 2.3 on the graph U spanned by $U_1,\ldots,U_k$. Let $f \leq \Psi_{\mathcal{F}}(k)$ denote the size of F. Item 4 in Lemma 2.7 states that each U_i contains at least $n/S(\epsilon)$ vertices. Also, by (6), and by the monotonicity properties of $M_{2.3}$ discussed in Comment 2.4, we have for any $1 \leq i \leq k$

$$|U_i| \geq n/S(\epsilon) \geq M_{2.3}(\epsilon/8, S(\epsilon), \Psi_{\mathcal{F}}(S(\epsilon))) \geq M_{2.3}(\epsilon/8, k, \Psi_{\mathcal{F}}(k)).$$

Therefore, we may apply Lemma 2.3 on the sets $U_1,\ldots,U_k$ to conclude that U spans at least

$$\delta \prod_{i=1}^{f} |U_i| \geq \delta(n/S(\epsilon))^f \geq \delta n^f / S(\epsilon)^{\Psi_{\mathcal{F}}(k)} \geq \delta n^f / S(\epsilon)^{\Psi_{\mathcal{F}}(S(\epsilon))} \tag{7}$$

copies of F, where $\delta = \delta_{2.3}(\epsilon/8, k, \Psi_{\mathcal{F}}(k))$. By Comment 2.4, the function $\delta_{2.3}(\eta,k,f)$ is monotone nonincreasing in k and f. Also, $\Psi_{\mathcal{F}}(k)$ is monotone nondecreasing in k. Hence, as $k \leq S(\epsilon)$ we have that $\delta \geq \delta_{2.3}(\epsilon/8, S(\epsilon), \Psi_{\mathcal{F}}(S(\epsilon)))$, and, in particular, $1/\delta$ is upper bounded by a function of ϵ only. As U is a subgraph of G, we may conclude that G contains at least as many copies of F as (7). Thus, if we independently sample $2S(\epsilon)^{\Psi_{\mathcal{F}}(S(\epsilon))}/\delta$ sets of $\Psi_{\mathcal{F}}(S(\epsilon))$ $(\geq f)$ vertices (which is a total of $2\Psi_{\mathcal{F}}(S(\epsilon)) \cdot S(\epsilon)^{\Psi_{\mathcal{F}}(S(\epsilon))}/\delta$ vertices) we have probability at least $2/3$ of finding a copy of $F \in \mathcal{F}$.

We can now give the formal definition of $Q_{\mathcal{F}}(\epsilon)$. Given a family of graphs $\mathcal{F}$ let $\Psi_{\mathcal{F}}(r)$ be the function from Definition 3.2. We note that the only place where $Q_{\mathcal{F}}(\epsilon)$ depends on $\mathcal{F}$ is in the function $\Psi_{\mathcal{F}}(r)$. Using $\Psi_{\mathcal{F}}(r)$ define the function $\mathcal{E}(r)$ as in (5). Given $\epsilon > 0$ define the function $W_{\mathcal{E},8/\epsilon}$ as in Definition 2.6 and put $S(\epsilon) = W_{\mathcal{E},8/\epsilon}(100/(\epsilon/8)^4)$. Finally, we can set

$$Q_{\mathcal{F}}(\epsilon) = \frac{2\Psi_{\mathcal{F}}(S(\epsilon)) \cdot S(\epsilon)^{\Psi_{\mathcal{F}}(S(\epsilon))}}{\delta_{2.3}(\epsilon/8, S(\epsilon), \Psi_{\mathcal{F}}(S(\epsilon)))} \tag{8}$$

to be a function of ϵ only. This completes the proof of the theorem. □

From the definition of $\mathcal{E}'(r)$ in (4) it is clear that if the function $\Psi_{\mathcal{F}}(r)$ is recursive, then so is $\mathcal{E}'(r)$ and therefore also $\mathcal{E}(r)$ (for this we also need the fact that $\gamma_{2.3}(\eta,k,f)$ is recursive, which follows from the standard proofs of Lemma 2.3; see [26]). In this case the function $W_{\mathcal{E},m}(i)$ is also recursive (see Definition 2.6), and therefore so is the function $S_{2.7}(8/\epsilon, \mathcal{E})$. Finally, this means that the integer $S(\epsilon)$, used in the above proof, can also be computed. Now, given $S(\epsilon)$ and the fact that $\Psi_{\mathcal{F}}(r)$ is recursive, one can use (6) and (8) as well as the fact that $\delta_{2.3}(\eta,k,f)$ and $M_{2.3}(\eta,k,f)$ are recursive (see the proof in [26]) in order to compute $N_{\mathcal{F}}(\epsilon)$ and $Q_{\mathcal{F}}(\epsilon)$.

We finish this section with the proofs of Theorems 3 and 5.

Proof of Theorem 3. We claim that we can set $W_{\mathcal{P}}(\epsilon) = \max\{N_{\mathcal{F}}(\epsilon), Q_{\mathcal{F}}(\epsilon)\}$ with $\mathcal{F} = \mathcal{F}_{\mathcal{P}}$ as in the proof of Theorem 1, and $N_{\mathcal{F}}(\epsilon)$, $Q_{\mathcal{F}}(\epsilon)$ are the functions from Theorem 2. Indeed, If G is ϵ-far from satisfying $\mathcal{P}$, and G has less than $N_{\mathcal{F}}(\epsilon)$

vertices, we can take G itself to be a subgraph of G not satisfying $\mathcal{P}$. Suppose now that G has more than $N_{\mathcal{F}}(\epsilon)$ vertices. As G is also ϵ-far from being $\mathcal{F}$-free, we get from Theorem 2 that G contains a subgraph (in fact, many) of size $Q_{\mathcal{F}}(\epsilon)$, which is not $\mathcal{F}$-free and therefore does not satisfy $\mathcal{P}$. □

Proof of Theorem 5. For each of the monotone properties $\mathcal{P}_i$, let $\mathcal{F}_i$ be the family of graphs, which do not satisfy $\mathcal{P}_i$, and let $\mathcal{F} = \mathcal{F}_1 \bigcup \mathcal{F}_2 \bigcup \mathcal{F}_3 \bigcup \dots$. Clearly, a graph G satisfies all the properties of $\mathcal{P}$ if and only if it is $\mathcal{F}$-free. Consider a graph G, which is ϵ-far from satisfying all the properties of $\mathcal{P}$. In this case G is also ϵ-far from being $\mathcal{F}$-free. The proof of Theorem 2 establishes that there is a graph $F \in \mathcal{F}$ of size at most $f = f_{\mathcal{F}}(\epsilon)$ such that G contains $\delta_{\mathcal{F}}(\epsilon)n^f$ copies of F. Note that removing an edge from G destroys at most $\binom{n}{f-2} \leq n^{f-2}$ copies of F. Thus, one must remove at least $\delta_{\mathcal{F}}(\epsilon)n^2$ edges from G in order to make it F-free. Let i be such that $F \in \mathcal{F}_i$. We may now infer that G is $\delta_{\mathcal{F}}(\epsilon)$-far from satisfying $\mathcal{P}_i$. Finally, note that as $\mathcal{F}$ is determined by $\mathcal{P}$, we can also say that G is $\delta_{\mathcal{P}}(\epsilon)$-far from satisfying $\mathcal{P}_i$.

To show that in case the properties $\mathcal{P}_i$ are just closed under removal of edges the above does not hold, consider the following: For any integer n, let $H_1, H_2, \dots$ be some ordering of the graphs on n vertices, which contain precisely $n^{3/2}$ edges. A graph of size n is said to satisfy property $\mathcal{P}_i$ if it contains no copy of H_i. Clearly, any property $\mathcal{P}_i$ is closed under removal of edges but not necessarily under removal of vertices. Observe that any graph with at least $n^{3/2}$ edges does not satisfy one of the properties $\mathcal{P}_i$. Therefore, any graph G of size n which contains $2\epsilon n^2$ edges is ϵ-far from satisfying all the properties $\mathcal{P}_i$. We claim that any such G is not $\frac{\log n}{\sqrt{n}}$-far from satisfying any one of these properties. To this end, it is enough to show that for any graph H_i, we can remove at most $n^{3/2} \log n$ edges from G and thus make it H_i-free. To see this, note that as G and H_i are both of size n, G spans at most $n!$ copies of H_i. As H_i contains $n^{3/2}$ edges a randomly chosen edge of G is spanned by H_i with probability at least $n^{3/2}/\binom{n}{2} > 1/\sqrt{n}$. Thus, if we remove from G a set of $n^{3/2} \log n$ edges, where each edge is randomly and uniformly chosen from the edges of G (with repetitions), the probability that none of the edges of one of the copies of H_i in G were removed is at most $(1 - 1/\sqrt{n})^{n^{3/2} \log n} < 1/n!$. By the union bound, the probability that for *some* copy of H_i in G, none of its edges were removed is strictly smaller than 1. Thus, there exists a choice of $n^{3/2} \log n$ edges, whose removal from G makes the graph H_i-free. □

5. Proof of Theorem 1. For a monotone graph property $\mathcal{P}$, define $\mathcal{F} = \mathcal{F}_{\mathcal{P}}$ to be the set of graphs which are minimal with respect to not satisfying property $\mathcal{P}$. In other words, a graph F belongs to $\mathcal{F}$ if it does not satisfy $\mathcal{P}$, but any graph obtained from F by removing an edge or a vertex satisfies $\mathcal{P}$. Thus, for example, if $\mathcal{P}$ is the property of being 2-colorable, then $\mathcal{F}$ is the set of odd cycles. Clearly, a graph satisfies $\mathcal{P}$ if and only if it contains no member of $\mathcal{F}$ as a (not necessarily induced) subgraph.

As we have mentioned in section 1, we will prove a slightly different version of Theorem 1. In order to precisely restate Theorem 1 we need two definitions. Note that in defining a tester in section 1, we did not mention whether the error parameter ϵ is given as part of the input, or whether the tester is designed to distinguish between graphs that satisfy $\mathcal{P}$ from those that are ϵ-far from satisfying it, when ϵ is a known fixed constant. In fact, the literature about property testing is not clear about this issue as in some papers ϵ is assumed to be a part of the input while in others it is not. We define a property to be *uniformly* testable if there is a tester for it that receives ϵ as part of the input. We define a property to be *nonuniformly* testable if for every

fixed ϵ, there is a tester that can distinguish between graphs that satisfy $\mathcal{P}$ from those ϵ-far from satisfying it (which may not work properly for other values of ϵ). We are now ready to restate Theorem 1.

THEOREM 6 (Theorem 1 restated). *Every monotone graph property $\mathcal{P}$ is nonuniformly testable with one-sided error. Moreover, if the function $\Psi_{\mathcal{F}}$ is recursive (where $\mathcal{F} = \mathcal{F}_{\mathcal{P}}$) then $\mathcal{P}$ is also uniformly testable with one-sided error.*

We stress that all reasonable graph properties $\mathcal{P}$, in particular, those that were discussed in section 1, are such that $\Psi_{\mathcal{F}}$ is recursive (a function is recursive if there is an algorithm that computes it in finite time). In particular, all the monotone properties mentioned in section 1 are uniformly testable with one-sided error. We thus bother to define uniformly and nonuniformly testing as well as discuss $\Psi_{\mathcal{F}}$ because it has the following interesting property: Not only is it sufficient to require $\Psi_{\mathcal{F}}$ to be recursive in order to infer that $\mathcal{P}$ can be tested uniformly with one-sided error, but this is also *necessary*. In other words, the recursiveness of $\Psi_{\mathcal{F}}$ determines whether $\mathcal{P}$ can be tested uniformly.[3] This is somewhat surprising as $\Psi_{\mathcal{F}}$ has little to do with property testing. Using this necessary condition, it is possible to show that there are graph properties that can be *nonuniformly* tested with one-sided error but cannot be *uniformly* tested, even with two-sided error. In fact, there are such graph properties, which are monotone and belong to $coNP$. The proofs of the necessity of $\Psi_{\mathcal{F}}$ being recursive in order to obtain a uniform tester, as well as the existence of a property that cannot be tested uniformly, are rather involved and significantly deviate from the main topic of this paper. Hence, we refrain from describing them here. These results will appear in a subsequent paper [8].

Proof of Theorem 6. Let $\mathcal{F} = \mathcal{F}_{\mathcal{P}}$ be as defined above, and let $N_{\mathcal{F}}(\epsilon)$ and $Q_{\mathcal{F}}(\epsilon)$ be the functions of Theorem 2. As satisfying $\mathcal{P}$ is equivalent to being $\mathcal{F}$-free, we focus on testing the property of being $\mathcal{F}$-free. We first show that every monotone property is nonuniformly testable. In this case we may design a tester for every given error parameter ϵ (but one that can handle *any* graph as an input). In this case, for every fixed ϵ, the tester knows the values of $N_{\mathcal{F}}(\epsilon)$ and $Q_{\mathcal{F}}(\epsilon)$ in advance (i.e., they are part of its description). If the size of the input graph is less than $N_{\mathcal{F}}(\epsilon)$, the algorithm queries about all edges of the graph and accepts if and only if the graph is $\mathcal{F}$-free (obviously, in this case the algorithm always answers correctly). If the size of the input graph is larger than $N_{\mathcal{F}}(\epsilon)$, it samples $Q_{\mathcal{F}}(\epsilon)$ random vertices and accepts if and only if the graph spanned by this set of vertices is $\mathcal{F}$-free. Clearly, if G is $\mathcal{F}$-free the algorithm declares that this is the case with probability 1. On the other hand, if it is ϵ-far from being $\mathcal{F}$-free then by Theorem 2 the sample of size $Q_{\mathcal{F}}(\epsilon)$ will contain $F \in \mathcal{F}$ with probability at least 2/3, and thus the algorithm will reject the input with this probability. In any case, the query complexity, which is $\max\{N_{\mathcal{F}}(\epsilon), Q_{\mathcal{F}}(\epsilon)\}$, is bounded by a function of ϵ only.

We now turn to uniform testers. In this case, we can imitate the proof of the case where ϵ is given in advance, which was described above. The only technical obstacle that may prevent us from carrying out the same testing algorithm is that the algorithm should be able to compute $N_{\mathcal{F}}(\epsilon)$ and $Q_{\mathcal{F}}(\epsilon)$. As the details of the proof of Theorem 2 reveal (see the discussion following the proof of Theorem 2 in section 4), the only step in computing $N_{\mathcal{F}}(\epsilon)$ and $Q_{\mathcal{F}}(\epsilon)$ which is not well defined (i.e., that depends on $\mathcal{F}$) is the computation of the function $\Psi_{\mathcal{F}}(r)$ (see Definition 3.2). In other words, if $\Psi_{\mathcal{F}}$ is recursive, then so are $N_{\mathcal{F}}(\epsilon)$ and $Q_{\mathcal{F}}(\epsilon)$. We thus get that if $\Psi_{\mathcal{F}}$ is

[3] This is in fact a simplification of the actual result that we can show. See [8] for the precise statement.

recursive, we can uniformly test the property of being $\mathcal{F}$-free. □

6. Proof of Theorem 4. In this section we describe the proof of Theorem 4. We remind the reader that we denote by $F \mapsto K$ the fact that there is a homomorphism from F to K (see Definition 2.2). In what follows, an s-blowup of a graph K is the graph obtained from K by replacing every vertex $v_i \in V(K)$ with an independent set I_i, of size s, and replacing every edge $(v_i, v_j) \in E(K)$ with a complete bipartite graph whose partition classes are I_i and I_j. It is easy to see that a blowup of K is far from being K-free (K-free is the property of not containing a copy of K). It is also easy to see that if $F \mapsto K$, then a blowup of K is far from being F-free (see [1, Lemma 3.3]). However, in this case the farness of the blowup from being F-free is a function of the size of F. As it turns out, for the proof of Theorem 4 we need a stronger assertion where the farness is only a function of k. This is given in Lemma 6.1 below, which is proved in [8].

LEMMA 6.1 (see [8]). *Let F be a graph on f vertices with at least one edge, let K be a graph on k vertices, and suppose $F \mapsto K$ (thus, $k \geq 2$). Then, for every sufficiently large $n \geq n(f)$, an n/k-blowup of K, is $\frac{1}{2k^2}$-far from being F-free.*

For the proof of Theorem 4 we also need the following simple observation. Recall that by the results of [3] and [23] we may assume that a tester first picks a set of vertices S, and then accepts or rejects according to the graph induced by S. We also comment on the following subtle point: when defining a testable graph property we require the query complexity to be *upper bounded* by a function of ϵ. This, however, does not imply that it is *independent* of n. Therefore, when considering arbitrary testers we have to consider testers whose query complexity and decisions may depend on the size of the input, which we denote by n.

CLAIM 6.2. *Let $\mathcal{F}$ be a family of graphs, such that no $F \in \mathcal{F}$ has isolated vertices and let T be a one-sided error tester for the property of being $\mathcal{F}$-free with query complexity $Q(\epsilon, n)$. If for some $\epsilon_0 > 0$ and n, after T samples a set of vertices S of size $Q(\epsilon_0, n)$, the graph induced by S is $\mathcal{F}$-free, then T must accept the input.*

Proof. Fix any n and $\epsilon_0 > 0$ and suppose that when we execute T on a graph G of size n with $\epsilon = \epsilon_0$, and the sample of vertices S spans a graph H that is $\mathcal{F}$-free, the algorithm still rejects the input. Consider a graph G' of size n, which contains a graph isomorphic to H on some of its $|S|$ vertices. Other than the edges of the copy of H, the graph G' has no other edges. As $\mathcal{F}$ contains no graph with isolated vertices and H is $\mathcal{F}$-free we infer that G' is $\mathcal{F}$-free. Suppose we execute T on G' with $\epsilon = \epsilon_0$. As G and G' are of the same size n, when given G' as input the algorithm samples a set of vertices of size $Q(\epsilon_0, n) = |V(H)|$. As we assume that when given H the algorithm rejects, we get that there is a nonzero probability that T will reject G', contradicting the assumption that it has one-sided error. □

As our goal is to prove a lower bound on the query complexity we may and will assume that Q is monotone nonincreasing (hence, monotone nondecreasing in $1/\epsilon$). For every such function Q we will define a property $\mathcal{P} = \mathcal{P}(Q)$ needed in order to prove Theorem 4. These properties can be thought of as *sparse bipartiteness* as they will be defined in terms of not containing a certain subset of the set of odd cycles.

Let $Q : (0,1) \mapsto \mathbb{N}$ be an arbitrary monotone nonincreasing function. For such a function, let Q^i be the following i times iterated version of Q. We put $Q^1(x) = Q(x)$ and for any $i \geq 1$ define

$$Q^{i+1}(x) = 2Q\left(\frac{1}{2(Q^i(x)+2)^2}\right) + 1. \tag{9}$$

Define $I(Q) = \{Q^i(1/2) : i \in N\}$ and note that $I(Q)$ contains only odd integers. For a function as above, let $C(Q) = \{C_i : i \in I(Q)\}$; that is, $C(Q)$ is the set of odd cycles whose lengths are the integers of the set $I(Q)$. Finally, let $\mathcal{P} = \mathcal{P}(Q)$ denote the property of not containing any of the odd cycles of $C(Q)$ as a (not necessarily induced) subgraph.

Proof of Theorem 4. Given a monotone nonincreasing function Q, let $\mathcal{P} = \mathcal{P}(Q)$ be the property defined above. We show that for any positive integer k for which $k-2 \in I(Q)$, any one-sided error tester that distinguishes between graphs of sufficiently large n that satisfy $\mathcal{P}$ from those that are $\frac{1}{2k^2}$-far from satisfying it has query complexity at least $Q(1/2k^2)$. As Q is by assumption monotone nonincreasing, $I(Q)$ contains infinitely many integers. Hence, for infinitely many values of ϵ, and for all large enough n, the query complexity of such a one-sided error tester is at least $Q(\epsilon)$. Note also that the set of these ϵ's approaches zero.

Fix any integer k for which $k-2 \in I(Q)$ and assume $k-2 = Q^i(1/2)$. As $I(Q)$ contains only odd integers, k is also odd. Define $\ell = Q^{i+1}(1/2)$ and recall that by (9), we have $\ell = 2Q(1/2k^2) + 1$. As it is clear that there is a homomorphism from C_ℓ to C_k, we get by Lemma 6.1 that for any $n \geq N(\ell)$, an n/k-blowup of C_k is $\frac{1}{2k^2}$-far from being C_ℓ-free. Denote such a blowup by G. As by definition $C_\ell \in C(Q)$, the graph G is also $\frac{1}{2k^2}$-far from satisfying $\mathcal{P}$. Also, as $k-2$ is odd, G contains no copy of C_{k-2}. In particular, G contains no member of $C(Q)$ of length less than ℓ. As property $\mathcal{P}$ is determined in terms of not containing a certain set of odd cycles, none of which has isolated vertices, we get from Claim 6.2 that a one-sided error tester must find a copy of a graph not satisfying $\mathcal{P}$ in order to determine that it does not satisfy $\mathcal{P}$. Therefore, for any $n \geq N(\ell)$ the query complexity of any tester for distinguishing between graphs of size n satisfying $\mathcal{P}$ from graphs of size n that are $\frac{1}{2k^2}$-far from satisfying it is at least ℓ. As $\ell = 2Q(1/2k^2) + 1 \geq Q(1/2k^2)$ the proof is complete. □

An immediate consequence of Theorem 4 is that there is no function $Q(\epsilon)$ that upper bounds the query complexity $Q_{\mathcal{F}}(\epsilon)$ of testing the property of being $\mathcal{F}$-free for all families of graphs, $\mathcal{F}$. In other words, the dependence on the specific family of graph is unavoidable. By the same reasoning, the dependence on $\mathcal{P}$ in Theorem 3 is also unavoidable. As we have commented after the proof of Theorem 2 in section 4, the only dependence of the function $Q_{\mathcal{F}}(\epsilon)$ defined in the proof of Theorem 1 (see (8)) on $\mathcal{P}$ is due to the function $\Psi_{\mathcal{F}}$ from Definition 3.2 (where $\mathcal{F} = \mathcal{F}_{\mathcal{P}}$ is the set of minimal graphs with respect to not satisfying $\mathcal{F}$). This implies that the function $\Psi_{\mathcal{F}}$ must depend on $\mathcal{F}$ and thus also on $\mathcal{P}$, as otherwise we could obtain an upper bound on $Q_{\mathcal{F}}(\epsilon)$ which would apply to all families of graphs, thus contradicting Theorem 4. We conjecture that Theorem 4 can be extended to two-sided error testers; see section 7.

As we have commented at the beginning of this section, the proof of Theorem 4 heavily relies on the fact that the farness of the graph considered in Lemma 6.1 from being F-free is only a function of k. From the proof of Theorem 4 it should indeed be clear that if this farness had been a function of the size of F, then the length of each cycle of the family would have depended on its own size, which would result in a cycle of definitions.

7. Concluding remarks and open problems. Besides proving that a large family of graph properties are all testable, and that specific properties that were previously not known to be testable are in fact testable, another important aspect of Theorem 1 is that it can be used to prove general results on testing graph properties. Two such results are Theorems 4 and 5. Another result, discussed in section 5, is that there are graph properties that can be nonuniformly tested but cannot be uniformly

tested [8]. We believe that Theorem 1 will be useful for proving other results as well.

Our main result gives that the natural family of monotone graph properties are all testable with one-sided error. This gives rise to several questions. For example, one can study the relation between testing with one-sided and two-sided error by considering how large the gap between the query complexity of testing a monotone graph property with one-sided and two-sided error can be. Specifically, it will be interesting to investigate whether there is a monotone property for which there is a superpolynomial gap between the two tasks. It will also be interesting to strengthen Theorem 4 by proving that for any function $Q : (0, 1) \mapsto \mathbb{N}$, there is a monotone graph property that cannot be tested with $o(Q(\epsilon))$ queries, even with two-sided error. Currently, the best lower bound on the *two-sided* error query complexity of a monotone graph property is a $(1/\epsilon)^{\Omega(\log 1/\epsilon)}$ lower bound for testing the property of not containing a copy of a graph H for any nonbipartite H [7].

A particularly interesting problem to study regarding the family of monotone graph properties is to obtain a characterization of the monotone properties, which are testable with $poly(1/\epsilon)$ queries. For some properties, such as k-colorability, it is known that $poly(1/\epsilon)$ queries suffice (see [22] and [5]). For others, such as being H-free for any nonbipartite H, it is known that $poly(1/\epsilon)$ are not sufficient (see [1] and [7]).

Even a special case of this problem seems hard to resolve. While it is known that the property of not containing an odd cycle, namely, being bipartite, can be tested with $\tilde{O}(1/\epsilon)$ queries (see [5]), Theorem 4 establishes that testing the property of being $\mathcal{F}$-free, where $\mathcal{F}$ is a subset of the family of odd cycles, may be arbitrarily hard (at least with one-sided error). It is interesting to check if one can at least characterize the families of odd cycles $\mathcal{F}$, for which one can test the property of being $\mathcal{F}$-free with $poly(1/\epsilon)$ queries.

As was mentioned in the introduction, a result of Goldreich and Trevisan [23] rules out the possibility of extending Theorem 2 to graph properties that are only closed under removal of edges. It seems interesting to bridge the gap between their result and the main result of this paper by characterizing the testable graph properties that are closed under edge removal.

Two graph properties $\mathcal{P}_1$ and $\mathcal{P}_2$ are defined in [3] to be *indistinguishable* if for every $\epsilon > 0$ and large enough n, any graph on n vertices satisfying one property is never ϵ-far from satisfying the other. It is shown in [3] that in this case, $\mathcal{P}_1$ is testable if and only if $\mathcal{P}_2$ is testable. It is first proved in [3] that certain colorability properties are testable with one-sided error. It is then shown that every first order graph property of type $\exists\forall$ is indistinguishable from some colorability property, thus obtaining that these properties are also testable. It would be interesting to characterize (combinatorially, logically, or by other means) the graph properties that are indistinguishable from some monotone property. By Theorem 1, this will immediately imply that these properties are testable, possibly with two-sided error.

Fischer and Newman [19] have recently shown that if a graph property $\mathcal{P}$ is testable, then it is also estimable; that is, it is possible to estimate how far a given graph is from satisfying $\mathcal{P}$, within an error $\delta > 0$ in time depending only on δ. Combining Theorem 1 and the result of [19] gives that any monotone property is estimable. We further note that this result (in fact, a stronger one) follows directly from the main result of [10], which was obtained independently of [19].

The proof of Theorem 5 gives weak lower bounds for the function $\delta_{\mathcal{P}}(\epsilon)$. It may be interesting to check if this dependency can be linear or polynomial for some natural

families $\mathcal{P}$.

Acknowledgments. We would like to thank Eldar Fischer and Oded Goldreich for their very helpful suggestions regarding the presentation of our results.

THE ROUND COMPLEXITY OF TWO-PARTY RANDOM SELECTION*

SAURABH SANGHVI† AND SALIL VADHAN†

Abstract. We study the round complexity of two-party protocols for generating a random n-bit string such that the output is guaranteed to have bounded "bias," even if one of the two parties deviates from the protocol (possibly using unlimited computational resources). Specifically, we require that the output's statistical difference from the uniform distribution on $\{0,1\}^n$ is bounded by a constant less than 1. We present a protocol for the above problem that has $2\log^* n + O(1)$ rounds, improving a previous $2n$-round protocol of Goldreich, Goldwasser, and Linial (FOCS '91). Like the GGL Protocol, our protocol actually provides a stronger guarantee, ensuring that the output lands in any set $T \subseteq \{0,1\}^n$ of density μ with probability at most $O(\sqrt{\mu + \delta})$, where δ may be an arbitrarily small constant. We then prove a nearly matching lower bound, showing that any protocol guaranteeing bounded statistical difference requires at least $\log^* n - \log^* \log^* n - O(1)$ rounds. We also prove several results for the case when the output's bias is measured by the maximum *multiplicative* factor by which a party can increase the probability of a set $T \subseteq \{0,1\}^n$.

1. Introduction.

One of the most basic protocol problems in cryptography and distributed computing is that of *random selection*, in which several mutually distrusting parties aim to generate an n-bit random string jointly. The goal is to design a protocol such that even if a party cheats, the outcome will still not be too "biased." (There are many different choices for how to measure the "bias" of the output; the one we use will be specified later.) Random selection protocols can dramatically simplify the design of protocols for other tasks via the following common methodology: first, design a protocol in a model where truly random strings are provided by a trusted third party (generally a much easier task), and then use the random selection protocol to eliminate the trusted third party. Specific applications of this paradigm often require random selection protocols with specific additional properties (such as "simulatability"), but the basic requirement of bounded "bias" in the face of adversarial behavior is always present in some form and thus merits study on its own.

Because of their wide applicability, there is a large literature on random selection protocols, both in the computational setting, where cheating parties are restricted to polynomial time (starting with Blum's "coin flipping by telephone" [Blu82]), and in the information-theoretic setting, where security is provided even against computationally unbounded adversaries. There has also been a significant amount of recent work on random selection in the quantum setting, where the communication

consists of quantum bits (qubits) and security is provided against a computationally unbounded quantum adversary; see [Amb04] and the references therein.

In this paper, we focus on *two-party* protocols in the (classical) *information-theoretic setting* (also known as the "full information model"). In addition to its stronger security guarantees, the information-theoretic setting has the advantage that protocols typically do not require complexity-theoretic assumptions (such as the existence of one-way functions). Various such random selection protocols have been used to construct perfectly hiding bit-commitment schemes [NOVY98], to convert honest-verifier zero-knowledge proofs into general zero-knowledge proofs [Dam94, DGW94, GSV98], to construct oblivious transfer protocols in the bounded storage model [CCM98, DHRS04], and to perform general fault-tolerant computation [GGL98]. There has also been substantial work in the k-party case for $k \geq 3$, where the goal is to tolerate coalitions of a minority of cheating players. This body of work includes the well-studied "collective coin-flipping" problem [BL89, Sak89, AN93, BN00, ORV94, RZ01, Fei99] (closely related to the "leader-election" problem) and again the use of random selection as a tool for general fault-tolerant computation [GGL98].

In most of the lines of work mentioned above (computational and information-theoretic, two-party and k-party), the *round complexity* has been a major parameter of interest. For some forms of random selection and their applications, constant-round protocols have been found (e.g., [DGW94, GSV98] improving [Dam94], [DHRS04] improving [CCM98], and [Lin01, KO04] improving [Blu82, Yao86]), but for others the best known protocols have a nonconstant number of rounds, e.g., [Cle86, NOVY98, GGL98, RZ01]. Lower bounds on round complexity, however, have proven much more difficult to obtain. In the computational setting, Cleve [Cle86] proved that for two-party random selection protocols, the number of rounds must grow linearly as the bias of the output tends to zero. (See also [CI93].) Ambainis [Amb04] gave a similar kind of result for two-party quantum protocols for leader election, a.k.a. weak coin flipping. As far as we know, all other previous round complexity lower bounds impose additional constraints on the protocol (beyond the basic security guarantee of bounded bias). For example, in the computational setting, it has been recently shown that five rounds are necessary and sufficient for random selection protocols satisfying a certain "black-box simulation" condition [KO04]. In the information-theoretic setting, a long line of work on the collective coin-flipping problem has culminated in the $(\log^* n + O(1))$-round protocol of Russell and Zuckerman [RZ01] (see also Feige [Fei99]), but the only known lower bound (of $\Omega(\log^* n)$ rounds), due to Russell, Saks, and Zuckerman [RSZ02], is restricted to protocols where each party can communicate only a small number of bits per round. Without this restriction, it is not even known how to prove that one round is impossible.

The problem and main results. As mentioned above, previous works on random selection have considered a number of different measures of the bias of the output, typically motivated by particular applications. Here we focus on what we consider to be the most natural measure—the statistical difference (i.e., total variation distance) of the output from the uniform distribution. The *statistical difference* between two random variables X and Y taking values in a universe $\mathcal{U}$ is defined to be $\max_{S \subseteq \mathcal{U}} |\Pr[X \in S] - \Pr[Y \in S]|$. We call the maximum statistical difference of the output from uniform when a player is honest (but when the other may deviate arbitrarily from the protocol) that player's *statistical guarantee*. We seek a two-party protocol that produces an output in $\{0,1\}^n$ such that both players' statistical guarantees are constant (i.e., bounded away from 1). Equivalently (see Lemma 2.4), we

want to satisfy the following criterion.

Statistical Criterion: There are fixed constants $\mu > 0$ and $\epsilon > 0$ such that for every n and every subset $T \subseteq \{0,1\}^n$ of density at most μ, the probability that the output lands in T is at most $1-\epsilon$, even if one party deviates arbitrarily from the specified protocol.

In addition to being a natural choice, this criterion is closely related to others considered in the literature. In particular, the standard criterion for the "collective coin-flipping" problem is that output bit $B \in \{0,1\}$ satisfies $\max\{\Pr[B=0], \Pr[B=1]\} < p$, where p is a constant less than 1; this is equivalent to B's statistical difference from uniform being bounded away from 1. (Here we see that the problem we consider is in some sense "dual" to collective coin flipping—we restrict ourselves to two players, but the output comes from a large set, whereas in collective coin flipping there are many players, but the output has only two possibilities.)

Of course, the first question is whether or not the Statistical Criterion can be met at all, regardless of round complexity. Indeed, being able to tolerate computationally unbounded cheating strategies is a strong requirement. In fact, when $n = 1$ (i.e., the output is a single bit), it turns out that one of the two parties can always force the outcome to be constant [Sak89]. This implies that the Statistical Criterion is impossible to meet for $\mu = 1/2$. Surprisingly, the criterion is achievable, however, for some smaller constant $\mu > 0$. This is implied by the following result of Goldreich, Goldwasser, and Linial [GGL98].

THEOREM 1.1 (see [GGL98]). *For every n, there is a two-party protocol producing output in $\{0,1\}^n$ such that, as long as one party plays honestly, the probability that the output lands in any set $T \subseteq \{0,1\}^n$ of density μ is at most $p = O(\sqrt{\mu})$. The protocol has $2n$ rounds.*

Notice that for sufficiently small μ, the probability p is indeed a constant less than 1. This implies that the Statistical Criterion is achievable with a *linear* number of rounds. Our goal is to determine the minimal round complexity of this problem.

First, we give a protocol achieving the Statistical Criterion with substantially fewer rounds than the above.

THEOREM 1.2. *For every constant $\delta > 0$, there is an efficient two-party protocol producing output in $\{0,1\}^n$ with $2\log^* n + O(1)$ rounds such that, as long as one party plays honestly, the probability that the output lands in any set T of density μ is at most $p = O(\sqrt{\mu + \delta})$.*

Our protocol is inspired by the $\log^* n$-round protocols for leader election [RZ01, Fei99] and Lautemann's proof that **BPP** is contained in the polynomial hierarchy [Lau83]. Specifically, we exhibit a two-round protocol that reduces the universe of size $N = 2^n$ to a universe of size polylog(N), while approximately preserving the density of the set T with high probability. Repeating this protocol $\log^* n$ times reduces the universe size to a constant, after which point we apply the GGL Protocol.

Second, we prove a lower bound that matches the above up to a factor of $2 + o(1)$.

THEOREM 1.3. *Any two-party protocol producing output in $\{0,1\}^n$ that satisfies the Statistical Criterion must have at least $\log^* n - \log^* \log^* n - O(1)$ rounds.*

Our proof of this theorem is a technically intricate induction on the game tree of the protocol. Roughly speaking, we associate with each node z of the game tree a collection $\mathcal{H}$ of very small sets such that if the protocol is started at z and R is a random subset of the universe of density $o(1)$, then one of the players X can force the outcome of the protocol to land in $R \cup S$ with probability $1 - o(1)$ for any $S \in \mathcal{H}$. The challenge is to keep the size of the sets in the collections $\mathcal{H}$ small as we induct up the game tree (so that they remain of density $o(1)$ when z is the root, which yields the

desired lower bound). In particular, a node can have an arbitrary number of children, and so we cannot afford to take unions of sets S occurring across all children. The key idea that allows us to keep the sets small is the following: We consider two cases: If we have a collection of sets that contains a large disjoint subcollection, then the random set R will contain one of the sets with high probability, and so we do not need to carry the set through the recursion. On the other hand, if the collection of sets has no large disjoint subcollection, then we show how we can use this fact to construct a successful strategy for the *other* player (based on how we inductively construct the collections $\mathcal{H}$).

We stress that our lower bound does not impose any additional constraint on the protocol, such as the number of bits sent per round. Thus, we hope that our techniques can help in establishing unrestricted lower bounds on round complexity for other problems, in particular for the collective coin-flipping (and leader-election) problem.

Results on multiplicative guarantees. A different measure of the quality of random selection protocol is a *multiplicative guarantee* ρ, whereby we require that even if one player cheats, the probability that the outcome lands in any set T of density μ is at most $\rho \cdot \mu$. The goal, naturally, is for ρ to be as small as possible (ideally a constant independent of n). Previous protocols, e.g., the one in [DGW94], have given a multiplicative guarantee to one player, while the other has a statistical guarantee (i.e., a bound on the output's statistical difference from uniform if the other cheats). Our observations and results on multiplicative guarantees are the following:

- If both parties have multiplicative guarantees ρ_A and ρ_B, then an argument of [GGL98] implies $\rho_A \cdot \rho_B \geq 2^n$, regardless of the number of rounds. On the other hand, for any desired ρ_A, there is a simple two-round protocol with multiplicative guarantees of ρ_A and $2^n/\rho_A$ for the two players.
- If one party has a multiplicative guarantee ρ and the other has a statistical guarantee ε, then $\varepsilon \geq 1/\rho - 1/2^n$. This explains inverse relationships in existing protocols of [DGW94] (where $\varepsilon = 1/\mathrm{poly}(n)$ and $\rho = \mathrm{poly}(n)$) and [GSV98] (where $\varepsilon = \mathrm{poly}(n) \cdot 2^{-k}$ and $\rho = 2^k$ for any k).[1]
- There is a protocol with $2\log^* n + O(1)$ rounds that provides a constant statistical guarantee to one player and a $1+\delta$ multiplicative guarantee to the other, for an arbitrarily small constant δ. Theorem 1.3 implies that this round complexity is tight up to a constant factor, because a constant multiplicative guarantee implies a constant statistical guarantee.

Notation for logarithms. As in other work [RZ01], for the purposes of this paper, we define $\log_b^{(k)} n$ to be k base-b iterated logarithms of n, with 1 being a minimum value:

$$\log_b^{(k)} n = \begin{cases} 1 & : \text{ if } \log_b^{(k-1)} n < b, \\ \log_b \left(\log_b^{(k-1)} n \right) & : \text{ otherwise,} \end{cases}$$

with $\log_b^{(0)} n = n$. Moreover, for $n \geq 1$, we define $\log_b^* n$ to be the least natural number k such that $\log_b^{(k)} n = 1$. Throughout the paper, we take the base of the logarithms to be $b = 2$ unless otherwise specified.

[1] Actually, the protocol of [GSV98] does not provide a multiplicative guarantee of 2^k but rather ensures that the probability that the output lands in any set T of density μ is at most $2^k \cdot \mu + o(1)$. Our lower bound also applies to this more general type of guarantee.

2. Defining random selection protocols. Although we introduced the problem for a universe $\{0,1\}^n$, for the rest of the paper we assume we have an arbitrary universe $\mathcal{U}$. We can formally characterize a random selection protocol as follows.

DEFINITION 2.1. *A* random selection protocol $\Pi = (A, B, f)$ *over a universe* $\mathcal{U}$ *consists of a pair of programs* A *and* B *and a function* f *such that we have the following:*

- *Both* A *(Alice) and* B *(Bob) alternately output strings ("messages")* m_i *of arbitrary length that are a function of the conversation thus far and their sequences of random coin tosses* r_A *and* r_B*, respectively. That is,* $m_1 = A(r_A)$*,* $m_2 = B(r_B, m_1)$*,* $m_3 = A(r_A, m_1 m_2)$*, etc.*
- *The* conversation *between Alice and Bob is the transcript* $(A, B) = (m_1, m_2, \ldots, m_r)$*, where* r *is a parameter defining the number of messages (also called the number of "rounds" or "turns") of the protocol.*
- *The* output *of the protocol is* $f((m_1, m_2, \ldots, m_r))$*, which is some element of* $\mathcal{U}$*.*

We are interested in the behavior of the protocol when one of these programs is replaced with an arbitrary "cheating" program A^* or B^*, which may send its messages as an arbitrary function of the conversation and input length. If the cheating program "aborts" or sends an irregular message (too long, ill-formed, etc.), the protocol can assume it has sent the empty string.

Although the formulation we have provided assumes a protocol operates over a single fixed universe, in general we will be interested in studying asymptotic behavior of protocols as the universe size increases. Thus, we define a *random selection protocol ensemble* to be a sequence $(\Pi^{(1)}, \Pi^{(2)}, \ldots)$ where each $\Pi^{(N)}$ is a protocol over $\mathcal{U} = \{1, \ldots, N\}$. From now on, we blur the distinction between random selection protocols over a fixed universe and random selection protocol ensembles.

Two additional desirable properties of random selection protocols are the following: (a) the output is uniformly distributed in $\mathcal{U}$ assuming honest players; (b) in a protocol ensemble, honest strategies can be computed in time polynomial in the output length, $\log N$. Our protocols will have these properties, but our lower bounds will apply even to protocols without them.

We now introduce a formalism that will be essential in the proofs in this paper.

DEFINITION 2.2. *Given a protocol* Π *over universe* $\mathcal{U}$*, define the* game tree T *as follows:*

- *A set of nodes* V*, each representing a partial transcript of messages,* $(m_1, \ldots, m_i)$*.*
- *A set of edges* E*, defined by* $(u, v) \in E$ *if and only if* $u = (m_1, \ldots, m_i)$ *and (abusing notation)* $v = (u, m_{i+1})$*, for some message* m_{i+1}*. That is,* u *has* v *as a* child *if* v *is a potential protocol state one message after state* u*. Note that this makes* T *a tree, rooted at the empty transcript.*
- *For each node* z*, a distribution* $\mathcal{D}_z$ *over the children* z_i *whereby* A *or* B *chooses the next message (where the children are all nodes* z_i *such that* $(z, z_i) \in E$*).*
- *For every leaf* $z = (m_1, \ldots, m_r)$*, a label equal to* $f((m_1, \ldots, m_r))$*, the output of the protocol ending at node* z*.*

One can verify that this formalism produces an equivalent specification to Definition 2.1 of a random selection protocol.

Just as any node of a tree can be viewed as the root of another tree, any node of a protocol's game tree induces its own random selection protocol starting from that state. We simply fix the messages leading to that node and have the players choose the remaining messages as in the original protocol. This observation is one of the

main reasons that the abstraction of a random selection protocol as a tree will prove useful.

Evaluating a random selection protocol. We evaluate random selection protocols with metrics measuring how "close" the output is to the uniform distribution on $\mathcal{U}$. The primary metric we use is the following.

DEFINITION 2.3. *The* statistical difference from uniform *of a distribution X over universe $\mathcal{U}$ is defined to be*

$$\max_T \left| \Pr_{x \leftarrow X}[x \in T] - \mu(T) \right| = \max_T \left(\Pr_{x \leftarrow X}[x \in T] - \mu(T) \right),$$

where $T \subseteq \mathcal{U}$ and $\mu(T)$ is the density of T in $\mathcal{U}$, $|T|/|\mathcal{U}|$.

It can be verified that this distance is in the interval $[0, 1 - 1/N]$, where N is the size of the universe $\mathcal{U}$. A statistical difference of 0 implies that X is uniform, and $1 - 1/N$ implies X is concentrated on a single point. It is equal to one-half of the ℓ_1 distance between X and the uniform distribution, where we view each as a vector in $[0, 1]^N$.

We will want to avoid output distributions X whose statistical difference from uniform is very close to 1. The following lemma demonstrates that this (undesirable) property is equivalent to X landing in a small set with high probability.

LEMMA 2.4. *If X has statistical difference at least $1 - \epsilon$ from uniform, then there exists a set T such that $\mu(T) \leq \epsilon$ and $\Pr_{x \leftarrow X}[x \in T] \geq 1 - \epsilon$. Conversely, if there exists such a set T, then X has statistical difference at least $1 - 2\epsilon$ from uniform.*

Proof. If X has statistical difference at least $1 - \epsilon$ from uniform, then there exists a set T such that $\Pr[x \in T] - \mu(T) \geq 1 - \epsilon$. Since $\Pr[x \in T] \leq 1$, we can conclude that $\mu(T) \leq \epsilon$, and since $\mu(T) \geq 0$, we can conclude that $\Pr[x \in T] \geq 1 - \epsilon$. The second statement follows directly from the definition of statistical difference. ∎

Given these metrics, we can define the following.

DEFINITION 2.5. *Let $\Pi = (A, B, f)$ be a random selection protocol. The* statistical guarantee *for Alice playing honest strategy A in Π, denoted ϵ_A, is the maximum over all B^* of the statistical difference between the distribution of $f((A, B^*))$ and the uniform distribution over $\mathcal{U}$. The guarantee for Bob is defined analogously.*

Intuitively, the guarantee of a protocol for a player bounds the damage that the opponent can effect on the distribution by deviating from the protocol. Unfortunately, the terminology here is a bit counterintuitive—the lower the number, the better the guarantee. We will try to avoid confusion by saying a guarantee is "at best x," rather than "at least x."

Armed with this notion of a guarantee, we can state the following important equivalence, following directly from Lemma 2.4.

PROPOSITION 2.6. *The Statistical Criterion is equivalent to both of the statistical guarantees of a protocol being bounded away from* 1.

Later on, we will prove the following proposition, which lower bounds the ability of any protocol to provide strong statistical guarantees to both players simultaneously.

PROPOSITION 2.7. *In any random selection protocol Π over universe $\mathcal{U}$ achieving statistical guarantees ϵ_A and ϵ_B, $\epsilon_A + \epsilon_B \geq 1 - 1/N$, where $N = |\mathcal{U}|$.*

In addition to statistical guarantees, we also consider multiplicative guarantees, which come from bounds on multiplicative difference.

DEFINITION 2.8. *The* multiplicative ratio *of a distribution X is*

$$\max_T \Pr_{x \leftarrow X}[x \in T]/\mu(T),$$

where T ranges over all nonempty subsets of $\mathcal{U}$. Similarly to Definition 2.5*, for a random selection protocol $\Pi = (A, B, f)$, we define the* multiplicative guarantee *ρ_A (resp., ρ_B) for Alice (resp., Bob) by taking the maximum multiplicative ratio over all cheating strategies B^* (resp., A^*).*

The multiplicative ratio is always a rational in $[1, N]$, where 1 implies the uniform distribution, and N implies one element is chosen with probability 1. The multiplicative ratio of a distribution is actually equal to the factor by which a single element's probability of being the protocol's output can be increased from uniform. Formally, we have the following lemma.

LEMMA 2.9. *The multiplicative ratio of a distribution X is equal to*

$$\max_{s \in \mathcal{U}} \left(N \cdot \Pr_{x \leftarrow X}[x = s] \right).$$

Later on, we will prove the following result from [GGL98].

THEOREM 2.10 (see [GGL98]). *For any protocol Π, we have $\rho_A \cdot \rho_B \geq N$.*

When the universe is $\{0,1\}^n$ (i.e., $N = 2^n$), this theorem implies that one player can always increase the probability that a single element is chosen by an exponential factor—namely, $2^{n/2}$.

While both measures bound the deviation of a distribution from uniform, multiplicative ratio tends to focus on the concentration of probability into small sets (indeed, by Lemma 2.9, sets of size 1), while statistical difference will prove more useful when considering larger subsets (e.g., a constant fraction of the universe).

This said, we can prove some basic relationships between the two metrics that will prove useful.

LEMMA 2.11. *Let X be an arbitrary distribution over universe $\mathcal{U}$, with $N = |\mathcal{U}|$. Denote by ϵ the statistical difference of X from uniform and by ρ the multiplicative difference from uniform. Then*

1. $\rho \leq N\epsilon + 1$,
2. $\epsilon \leq 1 - 1/\rho$.

Part 2 of Lemma 2.11 implies that a distribution with a constant multiplicative ratio will have a constant statistical difference, though the converse is not necessarily true. Put another way, a strong multiplicative guarantee is harder to achieve than a strong statistical guarantee.

Proof of Lemma 2.11. By Lemma 2.9, we have $\rho = N \cdot \max_{s \in \mathcal{U}} \Pr_{x \leftarrow X}[x = s]$. But by the definition of statistical difference, we have for any $x \in \mathcal{U}$, $\Pr_{x \leftarrow X}[x = s] \leq \epsilon + 1/N$, by setting $T = \{s\}$. Part 1 of the lemma follows.

For part 2, it suffices to show that for all T, $\Pr_{x \leftarrow X}[x \in T] - \mu(T) \leq 1 - 1/\rho$. If $\mu(T) \geq 1/\rho$, then this certainly holds. Otherwise, $\Pr_{x \leftarrow X}[x \in T] \leq |T| \cdot (\rho/N) = \mu(T)\rho$, which implies that $\Pr_{x \leftarrow X}[x \in T] - \mu(T) \leq \Pr_{x \leftarrow X}[x \in T](1 - 1/\rho) \leq 1 - 1/\rho$. ∎

3. The Iterated Random Shift Protocol. In this section, we describe the main protocol of this paper, the Iterated Random Shift Protocol, and prove its main properties. That is, we show that for any constant δ, Iterated Random Shift is a $(2\log^* N + O(1))$-round protocol where the probability that the output falls in a set of density μ is at most $O(\sqrt{\mu + \delta})$. It follows that the protocol satisfies the Statistical Criterion given above.

3.1. The GGL Protocol. We begin by briefly describing the $2\log N$-round protocol satisfying the Statistical Criterion given by Goldreich, Goldwasser, and Linial [GGL98], which we will use in the construction of our protocol.

The GGL Protocol (idealized). Let $\mathcal{U}$ be a universe of size N, where N is a power of 2.

1. Alice randomly divides $\mathcal{U}$ into two equal-sized halves and sends this partition to Bob.
2. Bob randomly selects one of the halves, randomly divides it, and sends the resulting partition to Alice.
3. This process continues until one element remains: this element is the output of the protocol.

Actually, to obtain a protocol with computation time polylogarthmic in N, the authors use pairwise independent partitions of the universe. They first prove that this protocol achieves that, as long as one party plays honestly, the probability that the output lands in any set $T \subseteq \mathcal{U}$ of density μ is at most $p = O(\mu^{1/4})$.

They go on to improve this result by using a slightly different protocol to achieve Theorem 1.1 (Theorem 23 in [GGL98]), which improves the bound to $p = O(\sqrt{\mu})$.

3.2. The Random Shift Protocol. The Iterated Random Shift Protocol is inspired by the $\log^* n$-round protocols for leader election [RZ01, Fei99] and Lautemann's proof that **BPP** is contained in the polynomial hierarchy [Lau83]. It is built by iteration of the following two-round protocol, which we will call the Random Shift Protocol.

The Random Shift Protocol. Given a universe $\mathcal{U}$ of size N and $m \in \mathbb{N}$,

1. Alice uniformly randomly selects and sends a sequence of elements $a_1, \ldots, a_m \in \mathcal{U}$;
2. Bob uniformly randomly selects and sends a sequence of elements $b_1, \ldots, b_m \in \mathcal{U}$;
3. output the sequence $(a_i + b_j)_{1 \le i,j \le m}$, where $+$ is a group operation over $\mathcal{U}$.

Note that the Random Shift Protocol is not, strictly speaking, a random selection protocol over $\mathcal{U}$: its output is a *sequence* of elements from the universe. In using it, we will typically choose the parameter m so that the number of output elements, m^2, is much smaller than N (e.g., $m = \text{polylog}(N)$) and recursively use our random selection protocol to select one of the m^2 output elements. To show that this approach yields a protocol with bounded statistical guarantees, we argue that even if one of the players cheats, any subset T of the universe is unlikely to appear in much more than a $\mu(T)$ fraction of the outputs of the Random Shift Protocol. This is formalized by the following lemma.

LEMMA 3.1. *Let T be an arbitrary subset of $\mathcal{U}$. Let $\mu(T) = |T|/N$, and let $\mu'(T)$ denote the density of T in the sequence output by the Random Shift Protocol: $\mu'(T) = \#\{(i,j) : a_i + b_j \in T\}/m^2$. Then as long as one player plays honestly (i.e., chooses elements uniformly at random) and $m \ge (1/2\delta^2) \cdot \log(N/\epsilon)$, we have*

$$\Pr[\mu'(T) \ge \mu(T) + \delta] \le \epsilon.$$

That is, when one player is honest, the sequence $(a_i + b_j)_{ij}$ will be sufficiently random so that it is very unlikely that the density of T in the output sequence will increase substantially.

Proof. Suppose Alice plays honestly and chooses her elements $a_1, \ldots, a_m$ uniformly at random from $\mathcal{U}$. The lemma certainly holds a fortiori for an honest Alice, as a cheating Bob can see what elements Alice has selected.

For each element $b \in \mathcal{U}$, define the random variables

$$X_i^{(b)} = \begin{cases} 1 & \text{if } (a_i + b) \in T, \\ 0 & \text{otherwise.} \end{cases}$$

Then define $X^{(b)} = (1/m)\sum_{i=1}^{m} X_i^{(b)}$. Notice that $\mathrm{E}[X_i^{(b)}] = \mu(T)$ and, for each b, the random variables $X_1^{(b)}, \ldots, X_m^{(b)}$ are mutually independent.

By a Chernoff bound, we may conclude the following for any δ:

$$\Pr[X^{(b)} \geq \mu(T) + \delta] \leq e^{-2\delta^2 m} \leq 2^{-2\delta^2 m} \leq \epsilon/N.$$

Using a union bound, we conclude that

$$\Pr[\exists b \in \mathcal{U} \text{ such that } X^{(b)} \geq \mu(T) + \delta] \leq N \cdot \epsilon/N = \epsilon.$$

But if for all b we have $X^{(b)} < \mu(T) + \delta$, then no matter what elements $b_1, \ldots, b_m$ Bob chooses, we have

$$\mu'(T) = (1/m)\sum_{j=1}^{m} X^{(b_j)} < \mu(T) + \delta.$$

It follows that $\Pr[\mu'(T) \geq \mu(T) + \delta] \leq \epsilon$ as desired. □

Remark 3.2. We note that the number of elements sent by Bob need only be $(1/2\delta^2) \cdot \log(1/\epsilon)$ (i.e., the $\log N$ factor can be eliminated), since there is no need to do a union bound as in the above proof when proving Bob's guarantee. However, the symmetry of the protocol as presented above has the advantage that it can actually be implemented in *one* round in a model of simultaneous communication (where honest parties can send messages at the same time, but a cheating party may wait to see the other party's message before sending its own message), as is typically used in many-party protocols (e.g., leader election and collective coin flipping). This reduces the round complexity of our Iterated Random Shift Protocol below to $\log^* N + O(1)$ in the simultaneous communication model. It is interesting to know whether our lower bound of $\log^* N - \log^* \log^* N - O(1)$ rounds (in section 4.2) can be extended to the simultaneous communication model (without paying the factor of 2 in the trivial reduction to our nonsimultaneous model), since we would then have bounds in that model that are tight up to a factor of $1 + o(1)$.

3.3. The Iterated Random Shift Protocol. We now describe our Iterated Random Shift Protocol satisfying Theorem 1.2, which consists of recursively applying the Random Shift Protocol until the universe size is small (say, less than a fixed constant), after which we apply the GGL Protocol from [GGL98] discussed in section 3.1. Formally, we have the following.

The Iterated Random Shift Protocol. Given a universe $\mathcal{U}$ of size N and $M \in \mathbb{N}$ being a sufficiently large "cutoff parameter" that is a power of 2, we have the following three cases:

1. If $N > M^2$, then letting $m = \max\{M, \lceil \log^3 N \rceil\}$, execute the following:
   (a) Alice uniformly randomly selects and sends a sequence of elements $a_1, \ldots, a_m \in \mathcal{U}$.
   (b) Bob uniformly randomly selects and sends a sequence of elements $b_1, \ldots, b_m \in \mathcal{U}$.
   (c) Recursively execute the protocol on universe $\mathcal{U}' = [m] \times [m]$ to obtain result (i, j) and output $a_i + b_j$.
2. If $N = M^2$, run the GGL Protocol on $\mathcal{U}$ and output its result.
3. If $N < M^2$, recursively use the protocol on universe $\mathcal{U}' = \mathcal{U} \times [M^2]$ to obtain result (x, y) and output x.

First, we observe that, assuming M is chosen sufficiently large, the recursion will always terminate with an application of case 2 (the GGL Protocol): When we run case 1, we have $|\mathcal{U}'| = m^2 = \max\{M^2, \lceil \log^3 N \rceil\} \leq \max\{M^2, N-1\}$ for sufficiently large N, and so eventually the universe size will equal M^2, provided M is large enough. Case 3 will be executed at most once and is present only to avoid running the GGL Protocol immediately if the universe size is not a power of 2.

Observe that the output of this protocol is uniform if both players are playing honestly—by symmetry, all elements of the universe are equally likely to be selected. We note also that, by inspection, the honest players' strategies and the output of the protocol can certainly be computed in polynomial time.

We now analyze the round complexity of the Iterated Random Shift Protocol.

PROPOSITION 3.3. *For all sufficiently large M and all N, the Iterated Random Shift Protocol over a universe $\mathcal{U}$ of size N with parameter M takes $2\log^* N + O(\log M)$ rounds. Moreover, the strategies of the players are computable in time $\mathrm{poly}(\log N, \log M)$.*

Proof. Each application of the Random Shift Protocol (except for the last) reduces the universe size from N to $\lceil \log^3 N \rceil^2 < \log^7 N$ for sufficiently large N and takes two rounds. A lemma proven in [RZ01] states that if $f(n) \leq \log^a n$ for some constant a, then $f^{(\log^* n)}(n) \leq b$ for some constant b depending only on a, where $f^{(k)}$ represents k repeated applications of f. This implies that if M is sufficiently large and the initial universe size is $N \geq M^2$, the Random Shift Protocol is applied at most $\log^* N$ times. (If $N < M^2$, then we apply the Random Shift Protocol at most $\log^*(NM^2) = \log^* N + O(\log M)$ times.) By Theorem 1.1, the GGL Protocol on a universe of size at most M^2 takes at most $4\log M$ rounds.

As for the efficiency of the protocol, note that the players need only generate in each round a number of random bits that is polylogarithmic in the size of the universe. ∎

3.4. The statistical guarantees of the Iterated Random Shift Protocol.

THEOREM 3.4. *If $M \geq 1/\delta^3$, then for any set $T \subseteq \mathcal{U}$, the probability that the output of the Iterated Random Shift Protocol lands in T is $O(\sqrt{\mu + \delta})$, where $\mu = \mu(T)$, assuming at least one player plays honestly.*

COROLLARY 3.5. *For a sufficiently large constant M, the Iterated Random Shift Protocol satisfies the Statistical Criterion. Equivalently, there exists a constant $\epsilon > 0$ such that the Iterated Random Shift Protocol achieves $\max\{\epsilon_A, \epsilon_B\} \leq 1 - \epsilon$.*

Observe that Theorem 3.4 is much stronger than what we need to show Corollary 3.5. Using Theorem 3.4, we know that when one player is honest, for any "small" set T, the probability that the output falls in T is close to zero. The Statistical Criterion requires only that this probability is not arbitrarily close to 1.

Proof of Theorem 3.4. The key idea is that in the ith application of the Random Shift Protocol, we can bound the increase in density of any particular set T by at most some small δ_i (with high probability) and these δ_i's can be chosen so that $\sum_i \delta_i \leq \delta$. The Iterated Random Shift Protocol concludes by applying the GGL Protocol to this small universe, and then Theorem 1.1 gives us the result.

We first note that the modification of the protocol in case $N < M^2$, selecting from $\mathcal{U} \times [M^2]$ and taking the first component, does not affect the property claimed in the theorem (because the density of $T \times [M^2]$ in $\mathcal{U} \times [M^2]$ equals the density of T in $\mathcal{U}$). Thus we assume that $N \geq M^2$, and let $N_0, N_1, \ldots, N_{k^*}$ be the universe sizes in an execution of the Iterated Random Shift Protocol, where k^* is the first value of k such that $N_k = M^2$. That is,

$$N_0 = N,$$
$$N_k = m_k^2 \quad \text{for } m_k = \max\{M, \lceil \log^3 N_{k-1} \rceil\}.$$

Note that for sufficiently large M, the sequence of N_i's is strictly decreasing, and there exists a finite k^* such that $N_{k^*} = M^2$.

Given a subset $T \subseteq \mathcal{U}$, we track how T evolves through an execution of the Iterated Random Shift Protocol using the following notation for $k = 0, \ldots, k^*$:

$$\begin{aligned} &\mathcal{U}_0 = \mathcal{U}, && \mathcal{U}_k = [m_k] \times [m_k], \\ &T_0 = T, && T_k = \{(i,j) \in \mathcal{U}_k : (a_i + b_j) \in T_{k-1},\ 1 \le i, j \le m_k\}, \\ &\mu(T_k) = |T_k|/|\mathcal{U}_k|, \end{aligned}$$

where in the definition of T_k, (a_i) and (b_j) are the sequences of elements of $\mathcal{U}_{k-1}$ chosen by Alice and Bob in the kth application of the Random Shift Protocol, and $+$ is the group operation over $\mathcal{U}_{k-1}$ used in the protocol.

Intuitively, $\mathcal{U}_k$ is the remaining universe (of size N_k) after k iterations, and T_k represents the portion of the remaining universe such that choosing $(i,j) \in T_k$ will lead to an element of T being the output of the whole protocol. We call $\mu(T_k)$ the "effective density" of T in the kth iteration.

CLAIM 3.6. *There is a finite constant C independent of N and M such that we have*

$$\Pr\left[\mu(T_{k^*}) \ge \mu(T) + C \cdot M^{-1/3}\right] \le C \cdot 2^{-M^{1/3}},$$

provided at least one party plays honestly.

Proof. Recall that in the kth iteration, we are applying the Random Shift Protocol with parameter $m = m_k = \max\{M, \lceil \log^3 N_{k-1} \rceil\}$. Define $\epsilon_k = 2^{-m_k^{1/3}}$, and $\delta_k = 1/m_k^{1/3}$. Notice that $m_k \ge (1/2\delta_k^2) \cdot \log(N_{k-1}/\epsilon_k)$.

Using Lemma 3.1 repeatedly in an induction and using a union bound, we have that for any k,

$$\Pr\left[\mu(T_k) \ge \mu(T) + \sum_{i=1}^{k} \delta_i\right] \le \sum_{i=1}^{k} \epsilon_i.$$

Since the N_k's are decreasing exponentially fast, we have

$$\begin{aligned} \sum_{i=0}^{k^*} \delta_i &= O(\delta_{k^*}) \\ &= O(1/m_{k^*}^{1/3}) \\ &= O(1/M^{1/3}). \end{aligned}$$

Similarly,

$$\sum_{i=1}^{k^*} \epsilon_i = O(2^{-m_{k^*}^{1/3}}) = O(2^{-M^{1/3}}).$$

This completes the proof. ∎

Applying Claim 3.6 and using Theorem 1.1, we deduce that the probability that the output lands in T is at most

$$O\left(\sqrt{\mu(T) + C \cdot M^{-1/3}}\right) + C \cdot 2^{-M^{1/3}} = O\left(\sqrt{\mu(T) + M^{-1/3}}\right) = O\left(\sqrt{\mu(T) + \delta}\right),$$

using $M \geq 1/\delta^3$. Theorem 3.4 is proven. □

Recalling Proposition 3.3, and taking M to be a sufficiently large constant, we obtain a protocol with $2\log^* N + O(1)$ rounds satisfying the Statistical Criterion, thereby proving Theorem 1.2. More generally, we obtain a protocol of $2\log^* N + O(\log(1/\delta))$ rounds such that the output lands in a sets of density μ with probability at most $O(\sqrt{\mu + \delta})$. Note that we can take δ to be a slowly vanishing function of N and still have $O(\log^* N)$ rounds.

3.5. The multiplicative guarantees of the Iterated Random Shift Protocol. In this section, we discuss the multiplicative guarantees provided by the Iterated Random Shift Protocol. Later, we will see how lower bounds require that one of the players (in this case, Alice) receives a very poor multiplicative guarantee; however, we will see that Bob receives a very strong guarantee. In this way, we can say something about the ability of a protocol to provide a strong multiplicative guarantee to one player, while providing a strong statistical guarantee to the other. Specifically, we establish the following theorem.

THEOREM 3.7. *There exist constants $\epsilon < 1$ and ρ such that the Iterated Random Shift Protocol with the cutoff parameter M taken to be a sufficiently large constant achieves guarantees $\rho_B \leq \rho$ and $\epsilon_A \leq \epsilon$.*

This is the first protocol achieving constant statistical and multiplicative guarantees that we know of, and later we will prove Theorem 1.3, which, together with Lemma 2.11, implies that it has optimal round complexity (up to a factor of $2+o(1)$). (See Corollary 5.2.)

Given Corollary 3.5, to prove Theorem 3.7, it suffices to show the following.

PROPOSITION 3.8. *Let Π be a Iterated Random Shift Protocol defined with constant cutoff parameter M. Then Π provides a constant multiplicative guarantee to Bob: there exists constant ρ such that, as long as Bob plays honestly, the output of the Iterated Random Shift Protocol will fall in a set T with probability at most $M^2 \cdot \mu(T)$, for any set T.*

Proof of Proposition 3.8. Fix an arbitrary set $T \subseteq \mathcal{U}$. We use the notation from the proof of Theorem 1.2; in particular, $\mathcal{U}_k$ is the remaining universe after k iterations, and T_k is the set of elements of $\mathcal{U}_k$ corresponding to elements of T. The following is the key lemma.

LEMMA 3.9. *Assuming Bob plays honestly,* $\mathrm{E}[\mu(T_k)] = \mathrm{E}[\mu(T_{k-1})]$ *for all* $k = 1, \ldots, k^*$.

Proof. Consider the Random Shift Protocol. Let $a_1, \ldots, a_m$ be given. Then if $b_1, \ldots, b_m$ are chosen uniformly at random, it follows that for each i, j, the element $a_i + b_j$ is uniform over $\mathcal{U}$ (since $+$ is a group operation), and thus $\Pr[a_i + b_j \in T] = \mu(T)$. By linearity of expectations, we can conclude that $\mathrm{E}[\#(a_i + b_j) \in T] = \mu(T) \cdot m^2$ (where m^2 is the size of the new universe), and thus $\mathrm{E}[\mu(T')] = \mu(T)$, where $\mu(T')$ is the residual density of T in the resulting universe.

Applying this logic within the Iterated Random Shift Protocol, the lemma is proven (since for given $\mu(T_{k-1})$, we know $\mathrm{E}[\mu(T_k)] = \mu(T_{k-1})$). □

By induction, we then have that for all k, $\mathrm{E}[\mu(T_k)] = \mu(T)$. In particular, this is true for $k = k^*$. We can then derive

$$\begin{aligned}\mu(T) &= \mathrm{E}[\mu(T_{k^*})] \\ &\geq (1/M^2) \cdot \mathrm{E}[|T_{k^*}|] \\ &\geq (1/M^2) \cdot \Pr[|T_{k^*}| > 0].\end{aligned}$$

Since if $|T_{k^*}| = 0$, the protocol's output cannot possibly fall in T, we conclude that the probability the output falls in T is at most $M^2 \cdot \mu(T)$. This proves the proposition and thus Theorem 3.7. □

As an aside, notice that by using Lemma 2.11, Proposition 3.8 allows us to conclude one half of Theorem 1.2: the Iterated Random Shift Protocol provides a constant statistical guarantee to Bob.

We can conclude that the Iterated Random Shift Protocol has the following properties:

- It has only $2\log^* N + O(1)$ rounds.
- It provides both Alice and Bob with constant statistical guarantees (equivalently, it satisfies the Statistical Criterion).
- It provides Bob with a constant multiplicative guarantee.

Notice that in the above proof, we never used the multiplicative guarantee properties of the GGL Protocol—we simply relied on the initial recursions of Random Shift to provide the strong guarantee to Bob.

In fact, by changing the protocol used when the universe size becomes of size M^2 in the definition of the Iterated Random Shift Protocol, we can improve even further the multiplicative guarantee given to Bob. The current protocol implies only that Bob gets *some* constant multiplicative guarantee. Specifically, consider the following simple two-round protocol.

The Random Set Protocol. Given universe $\mathcal{U}$ of size N and parameter K,

1. Alice selects a subset S of $\mathcal{U}$ of size K, uniformly at random, and sends S to Bob;
2. Bob selects an element $x \in S$, uniformly at random;
3. the output is x.

It is straightforward to prove the following.

PROPOSITION 3.10. *For all positive integers $N \geq K$, the Random Set Protocol provides multiplicative guarantees $\rho_A = K$ and $\rho_B = N/K$.*

Thus, by using the Random Set Protocol on the universe of size M^2 with parameter $K = M^2/(1+\gamma)$ instead of GGL, Bob can achieve a multiplicative guarantee $1+\gamma$, while still keeping Alice's statistical guarantee constant (when γ is constant—if the residual density of Bob's target set T is smaller than $1 - 1/(1+\gamma)$, there is a nonzero probability that Alice will choose a set S disjoint from T).

In the next section, we will prove that the Iterated Random Shift Protocol has optimal round complexity, up to a factor of $2 + o(1)$, among protocols achieving the Statistical Criterion.

4. Lower bounds on statistical guarantees.

4.1. Tradeoffs between statistical guarantees. As a warmup to our main lower bound, in this section we present a tradeoff between the statistical guarantees ϵ_A and ϵ_B of Alice and Bob, respectively.

PROPOSITION 4.1 (Proposition 2.7, restated). *In any random selection protocol* Π *over universe* $\mathcal{U}$ *achieving statistical guarantees* ϵ_A *and* ϵ_B, $\epsilon_A + \epsilon_B \geq 1 - 1/N$, *where* $N = |\mathcal{U}|$.

COROLLARY 4.2. *In any random selection protocol* Π, $\max\{\epsilon_A, \epsilon_B\} \geq 1/2 - 1/(2N)$.

Proof. Suppose we have a protocol (A, B, f), where $\epsilon_A + \epsilon_B < 1 - 1/N$. Then we can partition the universe into two sets, S and $\mathcal{U} \setminus S$, where $|S| > \epsilon_A N$ and $|\mathcal{U} \setminus S| > \epsilon_B N$. Now, the argument follows logic similar to the impossibility result of Saks [Sak89] for collective coin flipping when at least half of the players are dishonest (where we think of outcomes in S as "heads" and $\mathcal{U} \setminus S$ as "tails").

Specifically, we view the protocol as a game where Alice wins if the output lands in S and Bob wins if the output lands in $\mathcal{U} \setminus S$. A well-known result in game theory is Zermelo's theorem: it implies that one of the players will have a winning strategy (one that wins regardless of how the other player plays). The basic reasoning is *backwards induction* on the game tree: every leaf node can be labeled A-WIN or B-WIN, depending on whether the output is in S or $\mathcal{U} \setminus S$, respectively, and then we can inductively label the remaining nodes depending on whether there exists a winning child for the current player to select. If there is, the current player can choose that child and will thus have a winning strategy from the current node. If there is not, then the opposing player can certainly win from the current node, as he or she has a winning strategy from all the children of the node.

This result implies one of the following:

- There exists strategy A^* where $\Pr[f((A^*, B^*)) \in S] = 1$, for any B^*. Taking $B^* = B$ (Bob's honest strategy), we have $\Pr[f((A^*, B)) \in S] - \mu(S) = 1 - \mu(S) > \epsilon_B$. This contradicts the guarantee of ϵ_B for Bob.
- There exists strategy B^* where $\Pr[f((A^*, B^*)) \in \mathcal{U} \setminus S] = 1$, for any A^*. This similarly contradicts guarantee ϵ_A. ∎

The main intuition behind the above proof is that, at every stage, either there exists a move that is good for the current player or all moves are good for the other player. In either case, the result is good for one of the two players. All that is needed is a way to make sure that every node on the bottom level can be defined as "winning" for someone and that this notion can propagate up the tree. As we will see, this type of reasoning will figure strongly in the proof of our main lower bound. There, the primary challenge will be to handle the cases when some nodes do not appear to be "winning" for either player.

4.2. The main lower bound. In this section, we prove Theorem 1.3, giving a lower bound on round complexity matching the Iterated Random Shift Protocol up to a factor of $2 + o(1)$.

THEOREM 4.3 (Theorem 1.3, strengthened). *For any* $\epsilon, \mu > 0$ *and* $N \in \mathbb{N}$, *any random selection protocol on a universe of size* N *satisfying the Statistical Criterion with parameters* ϵ *and* μ *requires at least* $\log^* N - \log^*(\max\{\log^* N, 1/\epsilon, 1/\mu\}) - O(1)$ *rounds.*

COROLLARY 4.4. *For every constant* $\delta > 0$, *there exists a constant* C *such that if a protocol* Π *achieves* $\epsilon_A, \epsilon_B \leq 1 - \delta$, *then* Π *has at least* $\log^* N - \log^* \log^* N - C$ *rounds.*

To prove this theorem, we must show that in a protocol with "few" rounds, one of the two players will be able to find a set of small size that will contain the output with high probability. We will refer to such a set (into which the cheating player is trying to make the output fall) as a *cheating set*. The proof will rely to some degree on the

probabilistic method: we will show the existence of such a cheating set by choosing it *randomly*, at least in part. The distribution on sets we will use is the following.

DEFINITION 4.5. *For a universe $\mathcal{U}$ and a parameter $\mu \in [0,1]$, we define* "a random subset of $\mathcal{U}$ of expected density μ" *to be a set $S \subseteq \mathcal{U}$ obtained by including each element $x \in \mathcal{U}$ in S independently with probability μ.*

Notice that the expected density of sets S chosen in this way is μ (and with high probability the density will not deviate significantly from μ).

We now can state the main helper theorem that will allow us to prove Theorem 4.3.

THEOREM 4.6. *There exists a function h such that for any $\mu, \epsilon > 0$, $r \in \mathbb{N}$, and protocol Π with r rounds, one of the following three cases holds:*

1. *(*A-EASY-WIN*) When R is a randomly chosen set of expected density μ, and Alice plays a strategy maximizing the probability that the output of the protocol falls in R assuming that Bob plays honestly, she will succeed with probability $1-\epsilon$, on average over all possible R. Formally,*

$$\mathop{\mathrm{E}}_{R}\left[\max_{A^*}\left\{\Pr_{B}[\Pi(A^*,B)\in R]\right\}\right] \geq 1-\epsilon.$$

2. *(*B-EASY-WIN*)*

$$\mathop{\mathrm{E}}_{R}\left[\max_{B^*}\left\{\Pr_{A}[\Pi(A,B^*)\in R]\right\}\right] \geq 1-\epsilon.$$

3. *(*DIFFICULT-WIN-WIN*) When R is a randomly chosen set of expected density μ, both Alice and Bob can force the output into R plus an additional $h(r,\epsilon,\mu)$ elements with high probability. That is, the following two conditions hold:*
   (a) *$\exists\, T$, $|T| \leq h(r,\epsilon,\mu)$, such that*

$$\mathop{\mathrm{E}}_{R}\left[\max_{A^*}\left\{\Pr_{B}[\Pi(A^*,B)\in R\cup T]\right\}\right] \geq 1-\epsilon.$$

   (b) *$\exists\, S$, $|S| \leq h(r,\epsilon,\mu)$, such that*

$$\mathop{\mathrm{E}}_{R}\left[\max_{B^*}\left\{\Pr_{A}[\Pi(A,B^*)\in R\cup S]\right\}\right] \geq 1-\epsilon.$$

Moreover, h does not grow too fast in r. Specifically, there is a constant C such that $h(r,\epsilon,\mu) \leq \mu N$ for all $r \leq \log^* N - \log^*(\max\{\log^* N, 1/\epsilon, 1/\mu\}) - C$.

Putting the three conditions together, this theorem says that either one player can make the output fall into a random set of a certain expected density with high probability (EASY-WIN), or *both* players can make the output fall into a set consisting of a randomly chosen set of a certain expected density and a certain bounded number of (nonrandom) elements (DIFFICULT-WIN-WIN).

Proof of Theorem 4.3. Let μ and ϵ be given and set $\mu' = \mu/4$, $\epsilon' = \epsilon/4$. By Theorem 4.6, we know that one of the players can force the output into a set $R \cup X$, where $|X| = h(r,\epsilon',\mu')$, with probability $1-\epsilon'$ in expectation over selecting R of expected density μ', for any protocol using r rounds. Suppose, without loss of generality, that the cheating player is Alice, playing with strategy A^*. Then we have

$$\mathop{\mathrm{E}}_{R}\left[\max_{A^*}\left\{\Pr_{B}[\Pi(A^*,B)\in R\cup X]\right\}\right] \geq 1-\epsilon',$$

where R is a random set of expected density μ'. By a Chernoff bound, we have that

$$\Pr_{R}[\mu(R) \geq 2\mu'] \leq e^{-2(\mu')^2 N} = e^{-\mu^2 N/8} \leq \epsilon',$$

where we may assume the last inequality holds because otherwise

$$\log^* N - \log^*(\max\{\log^* N, 1/\epsilon, 1/\mu\}) - C \leq 0$$

for a constant C and the lower bound to be proven is trivial. But then it follows that

$$\mathop{\mathrm{E}}_{R}\left[\max_{A^*}\left\{\Pr_{B}[\Pi(A^*, B) \in R \cup X]\right\} \cdot I(\mu(R) < 2\mu')\right] \geq 1 - 2\epsilon',$$

where $I(\mu(R) < 2\mu')$ is the indicator random variable for the event $\mu(R) < 2\mu'$. By averaging, we can find a particular set R^*, $\mu(R^*) < 2\mu'$, such that

$$\max_{A^*}\left\{\Pr_{B}[\Pi(A^*, B) \in R^* \cup X]\right\} \geq 1 - 2\epsilon' > 1 - \epsilon.$$

Assuming for contradiction that

$$\begin{aligned} r &\leq \log^* N - \log^*(\max\{\log^* N, 1/\epsilon', 1/\mu'\}) - C \\ &= \log^* N - \log^*(\max\{\log^* N, 1/\epsilon, 1/\mu\}) - O(1), \end{aligned}$$

we have $h(r, \epsilon', \mu')/N < \mu' N$, and so $|R^* \cup X| \leq 3\mu' N < \mu N$, violating the Statistical Criterion. □

4.2.1. Proof outline. In this section, we give an overview of the proof of Theorem 4.6. A detailed implementation is contained in section 4.2.2. A pictorial depiction of the proof for protocols with up to three rounds can be found in [San05].

Proving Theorem 4.6 will require an intricate analysis of the game tree using backwards induction. Like the proof of Proposition 4.1, we will show how to "label" the nodes of the game tree, where each label corresponds to a power of a player to force a particular outcome.

The labels. We will use three labels, corresponding precisely to the three cases of a protocol in Theorem 4.6. Specifically, the labels for a node on level k of the game tree will correspond to the following (where the leaves are at level 0):

- A-EASY-WIN: Alice could from that point choose a cheating set of small (say, constant) density at random and "win"—that is, make the output fall in that set with high probability.
- B-EASY-WIN: Bob could choose a cheating set at random and win.
- DIFFICULT-WIN-WIN: Neither player can win easily by choosing a totally random set, but *both* can win by choosing a set partly at random but also including a small (e.g., constant or very slowly growing) number of nonrandom elements (what we call a "helper set").

A node z labeled as DIFFICULT-WIN-WIN will have two collections of sets associated with it: $A\text{-}\mathcal{H}_z$ and $B\text{-}\mathcal{H}_z$. If the node is on level k of the game tree and it is Alice's turn to act, then $A\text{-}\mathcal{H}_z$ consists of sets of size s_{k-1} and $B\text{-}\mathcal{H}_z$ consists of sets of size s_k, where $s_1, \ldots, s_r$ will be an ascending sequence of appropriately defined constants (where r is the number of rounds of the protocol).[2] Each set $H \in A\text{-}\mathcal{H}_z$ is a set Alice can use as a "helper"—after choosing a cheating set at random and then adding the helper set, Alice can win from the given node with high probability. Similarly every set in $B\text{-}\mathcal{H}_z$ can be used by Bob as a "helper."

[2] In the actual proof, they will be very slowly growing functions of N, but for this outline one may think of them as constants.

Our main challenge is to show that every node can be given a label as above. Once we do that, Theorem 4.6 and thus Theorem 4.3 would follow readily. As a start, notice that the leaves of the tree (the base case of our induction) can certainly be labeled DIFFICULT-WIN-WIN, simply by setting $A\text{-}\mathcal{H}_z = B\text{-}\mathcal{H}_z = \{\{x\}\}$, where x is the output of the protocol at leaf z.

Piths. Before demonstrating how the internal nodes will be labeled, we define the following key concept.

DEFINITION 4.7. *Given a collection $\mathcal{H}$ of nonempty subsets of a universe $\mathcal{U}$, the* s-pith *of $\mathcal{H}$ is the collection of all sets $S \subseteq \mathcal{U}$, $|S| \leq s$, that intersect every $H \in \mathcal{H}$ (that is, $S \cap H \neq \emptyset$). We call each such S in the pith an* intersect-set *of $\mathcal{H}$.*

Three combinatorial facts about piths and collections of disjoint sets will prove useful.

FACT 4.8. *Suppose $\mathcal{H}$ consists of nonempty sets of size at most s. Then for any s', either $\mathcal{H}$ has a disjoint subcollection of size at least s'/s or it has a nonempty s'-pith.*

Proof. Take a maximal disjoint subcollection $\mathcal{P}$ of $\mathcal{H}$. If it is not of size at least s'/s, then the union of all sets in $\mathcal{P}$ will be a set of size at most s' intersecting every set in $\mathcal{H}$ (because $\mathcal{P}$ is maximal). □

FACT 4.9. *Suppose $\mathcal{H}$ consists of m disjoint sets of size at most s and $m \geq (1/\mu)^s \cdot \ln(1/\epsilon)$. Then the probability that a random set R of expected density μ will encompass a set in $\mathcal{H}$ (i.e., there exists $H_i \in \mathcal{H}$ with $H_i \subseteq R$) is at least $1 - \epsilon$.*

Proof. The probability of failure is at most $(1 - \mu^s)^m \leq e^{-\mu^s m}$. The result follows. □

Putting these two facts together, note that either a set in $\mathcal{H}$ is encompassed by a random set with probability $1 - \epsilon$, or $\mathcal{H}$ has a nonempty s'-pith, as long as $s' \geq (1/\mu)^s \cdot \ln(1/\epsilon) \cdot s$. Finally, we have the third fact.

FACT 4.10. *Suppose $\mathcal{H}$ consists of sets of size at most s, and a set S intersects every set in the s'-pith of $\mathcal{H}$. Then either S encompasses a set in $\mathcal{H}$ or $\mathcal{H}' = \{H \backslash S : H \in \mathcal{H}\}$ has a disjoint subcollection of size at least s'/s.*

Proof. Say S does not encompass a set in $\mathcal{H}$. Then every set in $\mathcal{H}'$ is nonempty. If $\mathcal{H}'$ does not have a disjoint subcollection of size s'/s, then by Fact 4.8 $\mathcal{H}'$ has a nonempty s'-pith. But if a set T is in the s'-pith of $\mathcal{H}'$, then $T \backslash S$ is in the s'-pith of $\mathcal{H}$, contradicting the definition of S. □

This strange last fact is actually an important key to the whole proof.

Labeling the nodes. We now can describe how we will inductively label a node z on level k of the game tree, assuming it is Alice's turn at that node. First, we define the constants s_k to obey $s_k \geq (1/\mu)^{s_{k-1}} \cdot \ln(1/\epsilon) \cdot s_{k-1}$. Next, we assign labels as follows:

- If all children of z are labeled B-EASY-WIN, then certainly we can give z the label B-EASY-WIN.
- If there exists a child of z that is labeled A-EASY-WIN, then we can give z the label A-EASY-WIN (Alice would just choose that child on her turn).

If neither of these cases occur, then we know that all of the children of z are either labeled DIFFICULT-WIN-WIN or B-EASY-WIN (with at least one labeled DIFFICULT-WIN-WIN). Let $\mathcal{X}$ be the union of all the collections $A\text{-}\mathcal{H}_{z_i}$, over all children z_i labeled DIFFICULT-WIN-WIN. $\mathcal{X}$ contains the helper sets that we know Alice can use to win from any such child. There are two cases:

- Suppose $\mathcal{X}$ has a large disjoint subcollection (specifically, of size at least s_k/s_{k-1}). Then label z as A-EASY-WIN.

- Else, label z as DIFFICULT-WIN-WIN, letting $A\text{-}\mathcal{H}_z$ equal $\mathcal{X}$ and letting $B\text{-}\mathcal{H}_z$ equal the s_k-pith of $\mathcal{X}$.

The correctness of the first bullet follows quickly from Fact 4.9—with high probability a random cheating set R chosen by Alice will encompass one of the sets $X \in \mathcal{X}$, and Alice can then choose the child z_i associated with X (i.e., $X \in A\text{-}\mathcal{H}_{z_i}$) and force the output into $X \cup R = R$ with high probability.

As for the second bullet, Alice certainly has a difficult win (that is, she can win with any helper set $X \in \mathcal{X}$) because she can choose the child associated with X.

The crux of the proof is showing that Bob has a difficult win from this point, using any helper set S from the pith of $\mathcal{X}$. Note first that by Fact 4.8 and the fact that we did not fall into the first bullet, we know this pith is nonempty.

It suffices to show that no matter what child Alice chooses, Bob can win using S—that is, force the output into $R \cup S$ with high probability, where R is a random set. Certainly, if she chooses a B-EASY-WIN node, Bob can win, even without S. So suppose she chooses a child node z_i labeled DIFFICULT-WIN-WIN. Inductively, we know Bob could win from this node z_i using any of the helper sets in $B\text{-}\mathcal{H}_{z_i}$ and that the pith of $B\text{-}\mathcal{H}_{z_i}$ is $A\text{-}\mathcal{H}_{z_i} \subseteq \mathcal{X}$. Since S is in the pith of $\mathcal{X}$, we know in particular that it intersects every set in $A\text{-}\mathcal{H}_{z_i}$.

Applying Fact 4.10, we then have two cases, both of which ensure Bob has some $T \in B\text{-}\mathcal{H}_{z_i}$ encompassed by his cheating set $R \cup S$, allowing him to win:

- S encompasses a set T in $B\text{-}\mathcal{H}_{z_i}$.
- $T' = \{T \backslash S : T \in B\text{-}\mathcal{H}_{z_i}\}$ has a large disjoint subcollection (i.e., of size s_{k-1}/s_{k-2}), in which case the random set will encompass one of these sets $T \backslash S$ with high probability (by Fact 4.9), and thus $T \subseteq R \cup S$.

This completes the induction and the proof sketch. The bulk of the ideas in the main proof were demonstrated above. What remains to flesh out is proper bookkeeping of parameters, namely the randomly chosen set and the sizes of the helper sets $A\text{-}\mathcal{H}_z$ and $B\text{-}\mathcal{H}_z$, to derive the precise round complexity bound. Jumping ahead, notice that the induction will stop at $\log^* N$ rounds because the sizes of these helper sets grow as tower in the number of rounds—each s_{k+1} is exponential in s_k. Thus, if there are more than $\log^* N$ rounds, the helper sets could contain all of the elements of the universe, rendering them useless for violating the Statistical Criterion.

4.2.2. Proof of Theorem 4.6. We proceed by backwards induction on the game tree of the protocol.

DEFINITION 4.11. *Given a protocol* Π *with* r *rounds and constants* ϵ *and* μ*, let* $h(r, \epsilon, \mu) = g(r, r, \epsilon, \mu)$*, where*

$$g(0, r, \epsilon, \mu) = 1,$$
$$g(k, r, \epsilon, \mu) = \ln(r/\epsilon) \cdot (r/\mu)^{g(k-1, r, \epsilon, \mu)} \cdot g(k-1, r, \epsilon, \mu).$$

For readability, we write s_k for $g(k, r, \epsilon, \mu)$, as r, ϵ, and μ will remain fixed throughout the proof. So

$$s_0 = 1,$$
$$s_k = \ln(r/\epsilon) \cdot (r/\mu)^{s_{k-1}} \cdot s_{k-1}.$$

Now, fix a protocol Π with r rounds, and consider the game tree T it induces (see Definition 2.2).

We inductively label the nodes of the tree as either A-EASY-WIN, B-EASY-WIN, or DIFFICULT-WIN-WIN. For each of the DIFFICULT-WIN-WIN nodes, we will also associate

two collections of sets (which are subsets of $\mathcal{U}$), $A\text{-}\mathcal{H}_z$ and $B\text{-}\mathcal{H}_z$, as defined below. The sets in these collections will correspond to the sets S and T of case 3 of Theorem 4.6. As we will see, the labels have been chosen to indicate the power of one or both of the players to manipulate the output effectively from that point in the tree.

DEFINITION 4.12. *Fix a protocol Π. Let z be a node on its game tree at level k (where leaves are at level 0). Assume it is Alice's turn at this node. (If it is Bob's turn, swap "A"/"A" with "B"/"B" everywhere in the description below.)*

If $k = 0$ (i.e., z is a leaf of the tree), then label z as DIFFICULT-WIN-WIN. *Moreover, let $B\text{-}\mathcal{H}_z = A\text{-}\mathcal{H}_z = \{\{x\}\}$, where x is the output of the protocol ending at node z.*

If $k > 0$, consider the children $z_1, \ldots, z_\ell$ of z. Use the following rules to label the nodes:

1. *If there exists $1 \le i \le \ell$ such that z_i is in case* A-EASY-WIN, *then label z as* A-EASY-WIN.
2. *If, for all $1 \le i \le \ell$, z_i is in case* B-EASY-WIN, *then label z as* B-EASY-WIN.
3. *Otherwise, denote $\bigcup_{z_i} A\text{-}\mathcal{H}_{z_i} = \{S : z_i$ is* DIFFICULT-WIN-WIN *and $S \in A\text{-}\mathcal{H}_{z_i}\}$. That is, $\bigcup_{z_i} A\text{-}\mathcal{H}_{z_i}$ is the union of the collections of sets associated with all children of z that are labeled* DIFFICULT-WIN-WIN. *Now, let $\mathcal{P}$ denote the largest disjoint subcollection of $\bigcup_{z_i} A\text{-}\mathcal{H}_{z_i}$ (break ties arbitrarily), and let s_k, s_{k-1} be defined as in Definition* 4.11.
   There are two cases:
   (a) $|\mathcal{P}| \ge s_k/s_{k-1} \Rightarrow$ *label z as* A-EASY-WIN.
   (b) $|\mathcal{P}| < s_k/s_{k-1} \Rightarrow$ *label z as* DIFFICULT-WIN-WIN, *and define $A\text{-}\mathcal{H}_z$ to be $\bigcup_{z_i} A\text{-}\mathcal{H}_{z_i}$, and $B\text{-}\mathcal{H}_z$ to be the s_k-pith of $A\text{-}\mathcal{H}_z$ (i.e., all sets of size at most s_k intersecting all sets in $A\text{-}\mathcal{H}_z$).*

Intuitively, this structure defines the power of the players at various stages of the protocol. The A-EASY-WIN, B-EASY-WIN, and DIFFICULT-WIN-WIN nodes refer to cases 1, 2, and 3 of Theorem 4.6, respectively. Moreover, the sets in the collections $B\text{-}\mathcal{H}_z$ and $A\text{-}\mathcal{H}_z$ will correspond to S and T in case 3 of Theorem 4.6.

We will codify this power in Lemma 4.14. Before stating it, it will help to define the following.

DEFINITION 4.13. *Let $\Pi = (A, B, f)$ be a protocol, and let T be its equivalent game tree (see Definition* 2.2*). For any node $z = (m_1, \ldots, m_{r-k})$ on level k of the tree T, let $\Pi_z = (A_z, B_z, f_z)$ be a protocol of k rounds, where $f_z((m'_1, \ldots, m'_k)) = f((m_1, \ldots, m_{r-k}, m'_1, \ldots, m'_k))$, and where A_z and B_z denote the strategies of A and B conditioned on history z (i.e., we choose their coin tosses r_A and r_B uniformly from those consistent with the history).*

Intuitively, Π_z is the protocol induced by starting the protocol at node z (i.e., assuming all messages leading to z are fixed in advance).

LEMMA 4.14. *Fix ϵ and μ, and suppose the protocol has r turns. Let z be some node on the tree at level k, at which it is Alice's turn to play. Throughout, let R be a random subset of $\mathcal{U}$ of expected density $k\mu/r$.*

1. *If z is in case* A-EASY-WIN, *then*

$$\mathop{\mathrm{E}}_{R}\left[\max_{A^*}\left\{\Pr_{B}\left[\Pi_z(A^*, B) \in R\right]\right\}\right] \ge 1 - k\epsilon/r,$$

where Π_z is the protocol induced by beginning at node z, as defined in Definition 4.13. *(We say Alice can "win" from node z.)*

2. *If z is in case* B-EASY-WIN*, then, similarly,*

$$\mathop{\mathrm{E}}_{R}\left[\max_{B^*}\left\{\Pr_{A}\left[\Pi_z(A,B^*)\in R\right]\right\}\right]\geq 1-k\epsilon/r.$$

(We say Bob can "win" from node z.)

3. *If z is in case* DIFFICULT-WIN-WIN*, then*
   (a) *B-$\mathcal{H}_z$ and A-$\mathcal{H}_z$ are nonempty;*
   (b) *for any $T\in A$-$\mathcal{H}_z$,*

$$\mathop{\mathrm{E}}_{R}\left[\max_{A^*}\left\{\Pr_{B}\left[\Pi_z(A^*,B)\in R\cup T\right]\right\}\right]\geq 1-k\epsilon/r;$$

   (c) *for any $S\in B$-$\mathcal{H}_z$,*

$$\mathop{\mathrm{E}}_{R}\left[\max_{B^*}\left\{\Pr_{A}\left[\Pi_z(A,B^*)\in R\cup S\right]\right\}\right]\geq 1-k\epsilon/r.$$

(We say both Alice and Bob "win" from node z, with "helper sets" T and S, respectively.)

*Moreover, the same (with "Alice"/"A"/"*A*" exchanged for "Bob"/"B"/"*B*," respectively) holds for all nodes for which it is Bob's turn.*

Lemma 4.14 more precisely asserts Theorem 4.6 at each level of the game tree. To use this lemma to prove Theorem 4.6, we simply need to apply it with $k=r$ and z being the root of the game tree. Certainly, if z_r is in case 1 or 2 of Lemma 4.14, it is in case 1 or 2 of Theorem 4.6, respectively. If z_r is in case 3 of Lemma 4.14, then subcases 3(b) and 3(c) directly prove subcases 3(a) and 3(b), respectively, where the sets in A-$\mathcal{H}_z$ and B-$\mathcal{H}_z$ of 3(a) and 3(b) correspond precisely to the sets T and S we need in those subcases of the theorem. The existence of such sets is guaranteed by subcase 3(a) of the lemma.

Thus, after proving Lemma 4.14, all that will remain will be to bound the function $h(r,\epsilon,\mu)$ to prove Theorem 4.6, which we will do in Lemma 4.20.

We prove Lemma 4.14 by induction on the levels of the tree.

Base case: $k=0$. So z is a leaf node, and the output of Π_z is just deterministically fixed at, say, x. According to Definition 4.12, A-$\mathcal{H}_z = B$-$\mathcal{H}_z = \{\{x\}\}$, and we are in case DIFFICULT-WIN-WIN. Since the density of R is chosen to be zero (it is $k\mu/r$), $R=\emptyset$, and so we need to show that

$$\max_{B^*}\left\{\Pr_{A}\left[\Pi_z(A,B^*)\in\{x\}\right]\right\}=1,$$

and similarly with A and B swapped. This, of course, holds because the output is fixed at x.

Inductive step. Suppose Lemma 4.14 holds for nodes on all levels up to level $k-1$. We will show that it holds for an arbitrary node z on level k. Assume it is Alice's turn at z. There are several possibilities.

CLAIM 4.15. *If z is in case* B-EASY-WIN*, then*

$$\mathop{\mathrm{E}}_{R}\left[\max_{B^*}\left\{\Pr_{A}\left[\Pi_z(A,B^*)\in R\right]\right\}\right]\geq 1-k\epsilon/r,$$

where R is a random subset of expected density $k\mu/r$.

Proof. We will use Definition 4.12 and the inductive hypothesis to show that every child node z_i is "good" for Bob—that is, on average over R, B^* can make the

outcome land in R with probability at least $1-(k-1)\epsilon/r$. Then certainly the same holds for node z, since Alice cannot help but move to such a node.

Formally, we first notice that it suffices to show

$$\mathop{\mathrm{E}}_{R'}\left[\max_{B^*}\left\{\Pr_{A}\left[\Pi_z(A,B^*)\in R'\right]\right\}\right]\geq 1-(k-1)\epsilon/r,$$

where R' is a random subset of expected density $\mu'=(k-1)\mu/r$, since a random set R of expected density $k\mu/r$ "contains" such an R'. (Formally, R can be obtained by first picking R' and then adding each element $x\notin R'$ to R with probability $(\mu/r)/(1-(k-1)\mu/r)$.)

Now, for z to be labeled B-EASY-WIN, we must have used rule 2 of Definition 4.12. Thus, all of the children of z are in case B-EASY-WIN. By the inductive hypothesis,

$$\mathop{\mathrm{E}}_{R'}\left[\max_{B^*}\left\{\Pr_{A}\left[\Pi_{z_i}(A,B^*)\in R'\right]\right\}\right]\geq 1-(k-1)\epsilon/r \tag{4.1}$$

for each child z_i of z. Since at node z it is Alice's turn, we have

$$\begin{aligned}\mathop{\mathrm{E}}_{R'}\left[\max_{B^*}\left\{\Pr_{A}\left[\Pi_z(A,B^*)\in R'\right]\right\}\right]&=\mathop{\mathrm{E}}_{R',\,z_i\leftarrow\mathcal{Z}}\left[\max_{B^*}\left\{\Pr_{A}\left[\Pi_{z_i}(A,B^*)\in R'\right]\right\}\right]\\&\geq 1-(k-1)\epsilon/r,\end{aligned}$$

where $\mathcal{Z}$ is the distribution according to which Alice chooses child z_i of z when playing honestly, and the last inequality is by (4.1).

CLAIM 4.16. *If z is in case* A-EASY-WIN*, then*

$$\mathop{\mathrm{E}}_{R}\left[\max_{A^*}\left\{\Pr_{B}\left[\Pi_z\left(A^*,B\right)\in R\right]\right\}\right]\geq 1-k\epsilon/r,$$

where R is a random subset of expected density $k\mu/r$.

Proof. By Definition 4.12, z could have been labeled A-EASY-WIN by either rule 1 or rule 3(a).

In rule 1, z has a child z_j that is in case A-EASY-WIN. Since it is Alice's turn at node z, if she can choose a node z_j "good" for her, then node z will be "good" for her too. Formally, by the inductive hypothesis applied to z_j, and again noting that a random set of expected density $k\mu/r$ "contains" a random set of expected density $(k-1)\mu/r$, we have that

$$\mathop{\mathrm{E}}_{R}\left[\max_{A^*}\left\{\Pr_{B}\left[\Pi_{z_j}(A^*,B)\in R\right]\right\}\right]\geq 1-(k-1)\epsilon/r.$$

But $\max_{A^*}\{\Pr_B[\Pi_z(A^*,B)\in R]\}$ is at least $\max_{A^*}\{\Pr_B[\Pi_{z_j}(A^*,B)\in R]\}$, since node z is Alice's turn and she can always choose z_j. Taking expectations of both sides, the claim is proven for this case.

The alternative possibility is that z is in A-EASY-WIN because of rule 3(a). So among the sets $\bigcup_{z_i} A\text{-}\mathcal{H}_{z_i}$ (for all children z_i in DIFFICULT-WIN-WIN), we can find a disjoint subcollection $\mathcal{P}$, where $|\mathcal{P}|\geq s_k/s_{k-1}$.

Intuitively, since no A-EASY-WIN nodes are available among the children of z, Alice cannot simply choose such a branch as above. However, we know that from the DIFFICULT-WIN-WIN nodes, Alice can ensure the output lands in $S\cup R$ for any $S\in A\text{-}\mathcal{H}_{z_i}$, with high probability over the choice of a random set R. But this is true for many possible sets S—not only at a given child but also across all the potential children that are in case DIFFICULT-WIN-WIN (i.e., any $S\in\bigcup_{z_i} A\text{-}\mathcal{H}_{z_i}$). Thus, we can

expect that with sufficiently many disjoint sets in $\bigcup_{z_i} A\text{-}\mathcal{H}_{z_i}$, the random set R will encompass some $S \in \bigcup_{z_i} A\text{-}\mathcal{H}_{z_i}$ with high probability. The inductive hypothesis will then give the desired result.

Formally, since $\mathcal{P} \subseteq \bigcup_{z_i} A\text{-}\mathcal{H}_{z_i}$ consists of at least $s_k/s_{k-1} = \ln(r/\epsilon)(r/\mu)^{s_{k-1}}$ (disjoint) sets of size at most s_{k-1}, Fact 4.9 tells us that

$$\mathop{\mathrm{E}}_{R_1}\left[\exists S \in \bigcup_{z_i} A\text{-}H_{z_i},\ S \subseteq R_1\right] \geq 1 - \epsilon/r, \tag{4.2}$$

where R_1 is a random subset of expected density μ/r.

For any $S \in \bigcup_{z_i} A\text{-}\mathcal{H}_{z_i}$, we can then assert

$$\mathop{\mathrm{E}}_{R_2}\left[\max_{A^*}\left\{\Pr_B[\Pi_z(A^*, B) \in R_2 \cup S]\right\}\right] \geq 1 - (k-1)\epsilon/r, \tag{4.3}$$

where R_2 is a random subset of expected density $(k-1)\mu/r$. This comes from applying the inductive hypothesis to the child z_j such that $S \in A\text{-}\mathcal{H}_{z_j}$ and noting that $\max_{A^*}\{\Pr_B[\Pi_z(A^*, B) \in R_2 \cup S]\}$ is at least $\max_{A^*}\{\Pr_B[\Pi_{z_j}(A^*, B) \in R_2 \cup S]\}$ (because at node z it is Alice's turn).

Now, since a random subset R of expected density $k\mu/r$ "contains" $R_1 \cup R_2$, where R_1 and R_2 are independent random subsets of expected densities μ/r and $(k-1)\mu/r$, respectively,[3] we can combine (4.2) and (4.3) to derive

$$\begin{aligned}\mathop{\mathrm{E}}_{R}\left[\max_{A^*}\left\{\Pr_B[\Pi_z(A^*, B) \in R]\right\}\right] &\geq (1 - \epsilon/r) \cdot (1 - (k-1)\epsilon/r) \\ &\geq 1 - k\epsilon/r.\end{aligned}$$

The claim follows. ∎

The final possibility is that z is in case DIFFICULT-WIN-WIN. Since z is not a leaf, this can come about only by rule 3(b) from Definition 4.12. That is, no children of z are in case A-EASY-WIN, and at least some are in DIFFICULT-WIN-WIN. Moreover, among $\bigcup_{z_i} A\text{-}\mathcal{H}_{z_i} = A\text{-}\mathcal{H}_z$ the largest (maximal) disjoint subcollection $\mathcal{P}$ has fewer than s_k/s_{k-1} elements.

We must prove the following: $B\text{-}\mathcal{H}_z$ is nonempty, $A\text{-}\mathcal{H}_z$ is nonempty, Alice can win from this node with a helper set from $A\text{-}\mathcal{H}_z$, and Bob can win from this node with a helper set from $B\text{-}\mathcal{H}_z$ (see Lemma 4.14).

CLAIM 4.17. *$B\text{-}\mathcal{H}_z \neq \emptyset$ and $A\text{-}\mathcal{H}_z \neq \emptyset$.*

Proof. We have already established that z has children in case DIFFICULT-WIN-WIN (this follows from Definition 4.12 and from our assumption that $z \in$ DIFFICULT-WIN-WIN). By the inductive hypothesis on such a child z_i, $A\text{-}\mathcal{H}_{z_i}$, and thus $A\text{-}\mathcal{H}_z$ is nonempty. Since the largest disjoint subcollection $\mathcal{P}$ of $A\text{-}\mathcal{H}_z$ has size less than s_k/s_{k-1} and since all $S \in \mathcal{P}$ have size at most s_{k-1}, Fact 4.8 tells us that the s_k-pith of $A\text{-}\mathcal{H}_z$—namely, $B\text{-}\mathcal{H}_z$—is nonempty. ∎

CLAIM 4.18. *For any $S \in A\text{-}\mathcal{H}_z$, $\mathrm{E}_R[\max_{A^*}\{\Pr_B[\Pi_z(A^*, B) \in S \cup R]\}] \geq 1 - k\epsilon/r$, where R is a random subset of expected density $k\mu/r$.*

The proof of this claim is identical to the proof of (4.3) in the proof of Claim 4.16, noting also that a random set R of expected density $k\mu/r$ contains a random set R_2 of expected density $(k-1)\mu/r$.

[3] Formally, R can be obtained by first picking R_1 and R_2 and adding each element $x \notin R_1 \cup R_2$ to $R_1 \cup R_2$ with probability $(\mu/r) \cdot ((k-1)\mu/r)/[(1-\mu/r) \cdot (1-(k-1)\mu)/r]$.

The final claim required to prove Lemma 4.14 is the following.

CLAIM 4.19. *For any $S \in B\text{-}\mathcal{H}_z$, $\mathrm{E}_R[\max_{B^*}\{\Pr_A[\Pi_z(A, B^*) \in S \cup R]\}] \geq 1 - k\epsilon/r$, where R is a random subset of expected density $k\mu/r$.*

This claim is the heart of the entire proof. All we know now is that there is at least one DIFFICULT-WIN-WIN node that is a child of the current node z and that among the corresponding sets in $A\text{-}\mathcal{H}_z$, the largest disjoint subcollection $\mathcal{P} \subseteq A\text{-}\mathcal{H}_z$ contains fewer than s_k/s_{k-1} sets. That $\mathcal{P}$ is so small is a limitation on the power of Alice, who would like there to be enough such disjoint sets in $\mathcal{P}$ that she could choose randomly and encompass a set in $\mathcal{P}$ with high probability. The key to this proof is converting this *limitation* on Alice into an *ability* for Bob to cheat.

Proof. Fix a set $S \in B\text{-}\mathcal{H}_z$, which recall is the s_k-pith of $A\text{-}\mathcal{H}_z$. Since an honest Alice will choose a child z_i at random, it suffices to prove the following for each child z_i:

$$\mathop{\mathrm{E}}_{R}\left[\max_{B^*}\left\{\Pr_{A}\left[\Pi_{z_i}(A, B^*) \in S \cup R\right]\right\}\right] \geq 1 - k\epsilon/r, \tag{4.4}$$

where R is a random subset of expected density $k\mu/r$. So fix an arbitrary child z_i. Looking to Definition 4.12, the only way we could have defined z to be in case DIFFICULT-WIN-WIN is if all children z_i are in either case B-EASY-WIN or case DIFFICULT-WIN-WIN. So z_i is in one of these two cases.

If z_i is in case B-EASY-WIN, then we are done by the inductive hypothesis. So suppose z_i is in case DIFFICULT-WIN-WIN. Applying the inductive hypothesis to z_i, we know that $B\text{-}\mathcal{H}_{z_i}$ is nonempty. Moreover, for any $T \in B\text{-}\mathcal{H}_{z_i}$,

$$\mathop{\mathrm{E}}_{R_1}\left[\max_{B^*}\left\{\Pr_{A}\left[\Pi_{z_i}(A, B^*) \in T \cup R_1\right]\right\}\right] \geq 1 - (k-1)\epsilon/r, \tag{4.5}$$

where R_1 is a random subset of expected density $(k-1)\mu/r$.

We have that S is in the s_k-pith of $A\text{-}\mathcal{H}_z$, which means in particular that it intersects every set in $A\text{-}\mathcal{H}_{z_i}$, which in turn is the s_{k-1}-pith of $B\text{-}\mathcal{H}_{z_i}$ (whose sets are of size s_{k-2}, when $k > 1$). By Fact 4.10, either there exists a set T in $B\text{-}\mathcal{H}_{z_i}$ such that $T \subseteq S$ (in which case (4.4) follows immediately from (4.5)), or else $\mathcal{T} = \{T \backslash S : T \in B\text{-}\mathcal{H}_{z_i}\}$ has a disjoint subcollection of size s_{k-1}/s_{k-2}. (When $k = 1$, $B\text{-}\mathcal{H}_{z_i}$ contains only the set $T = \{x\}$, where x is the output of the protocol at leaf z_i, and we also have $x \in S$ because S intersects every set in $A\text{-}\mathcal{H}_{z_i} = \{\{x\}\}$. So we have $T \subseteq S$, and (4.4) follows immediately from (4.5).)

Informally, there are not many disjoint sets in $B\text{-}\mathcal{H}_{z_i}$—if there were, we would have labeled z_i as a case B-EASY-WIN node for Bob. That said, by intersecting every (small) set that intersected every set in $B\text{-}\mathcal{H}_{z_i}$, S captures the lack of disjointness of $B\text{-}\mathcal{H}_{z_i}$ in the first place. Once the elements of S are removed from consideration, the result has a large number of disjoint sets.

Returning to the proof of Claim 4.19, by Fact 4.9 we may conclude the following:

$$\Pr_{R_2}[\exists T' \in \mathcal{T},\, T' \subseteq R_2] \geq 1 - \epsilon/r,$$

where R_2 is a random subset of expected density μ/r. By the definition of $\mathcal{T}$, this in turn implies

$$\Pr_{R_2}[\exists T \in B\text{-}H_{z_i},\, T \subseteq S \cup R_2] \geq 1 - \epsilon/r.$$

Using (4.5) and choosing R through independent choices of R_1 and R_2 as in the proof of Claim 4.16, we are done. ∎

Taking together Claims 4.15, 4.16, 4.17, 4.18, and 4.19, the proof of Lemma 4.14 is complete.

To conclude Theorem 4.6, it remains to prove that the function h defining the set sizes s_k does not grow too fast in the number of rounds. Intuitively, the reason the lower bound holds only for protocols with fewer than $\log^* N - \log^* \log^* N - O(1)$ rounds is that these "helper sets" must have much fewer than N elements to be useful, but this function h grows as a tower—where the height (and base) of the tower grow with the number of rounds. Our challenge is to lower bound the number of rounds that keep this tower of size $o(N)$.

LEMMA 4.20. *Recall the definition $h(r, \epsilon, \mu) = g(r, r, \epsilon, \mu)$, where we define*

$$g(0, r, \epsilon, \mu) = 1,$$
$$g(k, r, \epsilon, \mu) = \ln(r/\epsilon) \cdot (r/\mu)^{g(k-1,r,\epsilon,\mu)} \cdot g(k-1, r, \epsilon, \mu).$$

There exists a constant C such that when $r < \log^* N - \log^*(\max\{\log^* N, 1/\epsilon, 1/\mu\}) - C$, we have $h(r, \epsilon, \mu) \le \mu N$.

Proof. First, bound r by $\log^* N$. Again, for shorthand we will write s_k for $g(k, r, \epsilon, \mu)$. Thus, we have that

$$s_k = \ln(r/\epsilon) \cdot (r/\mu)^{s_{k-1}} \cdot s_{k-1}.$$

Notice that this is no more than $(r \ln(r/\epsilon)/\mu)^{s_{k-1}}$. ($xy \le x^y$ if $x \ge 2$ and $y \ge 1$.) Letting $d = (r \ln(r/\epsilon)/\mu)$, we can then bound s_k by t_k, where t_k is defined by $t_0 = 1$ and $t_k = d^{t_{k-1}}$.

This means that we can set $k = \log_d^* N - 1$ (recall that by our definition, $\log_b^* N$ is always an integer, for any b or N) and still have $s_k \le t_k \le \log N \le \mu N$, where we may assume that the last inequality holds, because otherwise $\log^* N - \log^*(1/\mu) - C < 0$ and the lemma is vacuously true. It remains only to relate this to a base 2 logarithm.

CLAIM 4.21. *If $d \ge 4$, then $\log_d^* N \ge \log^* N - \log^*(2 \log d)$.*

Proof. Recall that $\log^{(k)} N$ is k iterated logarithms of N. We claim the following.

CLAIM 4.22. *For $k \le \log_d^* N$, $d \ge 4$, $\log^{(k)} N \le (2 \log d) \log_d^{(k)} N$.*

Proof. The base case $k = 0$ is clear. Assume, then, that

$$\log^{(k-1)} N \le (2 \log d) \log_d^{(k-1)} N.$$

Applying log to both sides, we have that

$$\begin{aligned} \log^{(k)} N &\le \log(2 \log d) + \log(\log_d^{(k-1)} N) \\ &\le \log(2 \log d) + (\log_d^{(k)} N)(\log d) \\ &\le (2 \log d)(\log_d^{(k)} N), \end{aligned}$$

where the last line follows because for $d \ge 4$, $d \ge 2 \log d$ and for $k \le \log_d^* N$, $\log_d^{(k)} N \ge 1$. ∎

Plugging in $k = \log_d^* N$, then we have that $\log^{(\log_d^* N)} N \le 2 \log d$. Applying $\log^*(2 \log d)$ logarithms to both sides, we have $\log^{(\log_d^* N + \log^*(2 \log d))} N \le 1$. Since $\log^* N$ is defined to be the least k such that $\log^{(k)} N \le 1$, it follows that $\log^* N \le \log_d^* N + \log^*(2 \log d)$. ∎

Thus we have that we can set k to be at least $\log_d^* N - 1$ and s_k will be no more than $\log N$. Moreover,

$$\begin{aligned}\log_d^* N - 1 &\geq \log^* N - \log^*(2\log d) - 1 \\ &= \log^* N - \log^*(2\log((r\ln(r/\epsilon))/\mu)) - 1 \\ &\geq \log^* N - \log^*(\max\{\log^* N, 1/\epsilon, 1/\mu\}) - O(1). \qquad \square\end{aligned}$$

By applying Lemma 4.14 to the root of the tree and using Lemma 4.20, we prove Theorem 4.6 and thus Theorem 4.3.

5. Multiplicative lower bounds. In this section, we concentrate on lower bounds regarding multiplicative guarantees—and indeed show that no protocol exists that provides constant multiplicative guarantees to both players. This is a very strong limitation on the ability of protocols to limit a cheating player's power in this regard.

An initial lower bound. Proposition 4.1 can be adapted to provide a quick lower bound for multiplicative guarantees.

PROPOSITION 5.1. *In any random selection protocol,* $(\rho_A - 1)/\rho_A + (\rho_B - 1)/\rho_B \geq 1 - 1/N$. *Moreover,* $\epsilon_A + (\rho_B - 1)/\rho_B \geq 1 - 1/N$ *(or equivalently,* $\epsilon_A \geq 1/\rho_B - 1/N$*).*

Proof. The results follow immediately from Proposition 4.1 and from the second part of Lemma 2.11. $\square$

This lower bound for multiplicative guarantees is not very strong—ρ is a number from 1 to N, but this lower bound is satisfied (for instance) as long as both ρ_A and ρ_B are at least 2. In Theorem 5.3, we will prove that $\rho_A \rho_B \geq N$, which is a substantially stronger result.

On the other hand, when looking at one player getting a statistical guarantee and the other player getting a multiplicative guarantee, Proposition 5.1 does provide some useful information. Specifically, it tells us that (minus a small $1/N$ term) we can always expect the statistical guarantee for one player to be worse than the reciprocal of the multiplicative guarantee to the other player. This explains inverse relationships in existing protocols of [DGW94] (where $\varepsilon = 1/\text{poly}(n)$ and $\rho = \text{poly}(n)$) and [GSV98] (where $\varepsilon = \text{poly}(n) \cdot 2^{-k}$ and $\rho = 2^k$ for any k).[4] Notice that these earlier works focus on the case of nonconstant guarantees ($\varepsilon \to 0$ and $\rho \to \infty$). Earlier, we showed that the Iterated Random Shift Protocol achieves simultaneous *constant* statistical and multiplicative guarantees. From Theorem 4.3 and Lemma 2.11, it follows that our protocol has optimal round complexity up to a factor of $2 + o(1)$ among those achieving simultaneous constant statistical and multiplicative guarantees.

COROLLARY 5.2. *For every two constants* $\epsilon_A < 1$ *and* ρ_B*, there exists a constant* C *such that any protocol* Π *selecting from a universe of size* N *and achieving statistical guarantee* ϵ_A *and multiplicative guarantee* ρ_B *will have at least* $\log^* N - \log^* \log^* N - C$ *rounds.*

A tight lower bound. Despite the inability of the above to give a strong lower bound for simultaneous multiplicative guarantees, in this section we present a tight lower bound in this setting, which follows from the work of Goldreich, Goldwasser, and Linial [GGL98].

THEOREM 5.3 (Theorem 2.10, restated; see [GGL98]). *For any protocol* Π*,* $\rho_A \cdot \rho_B \geq N$.

[4] Actually, the protocol of [GSV98] does not provide a multiplicative guarantee of 2^k but rather ensures that the probability that the output lands in any set T of density μ is at most $2^k \cdot \mu + o(1)$. Our lower bound also applies to this more general type of guarantee.

COROLLARY 5.4. *In any protocol* Π, $\max\{\rho_A, \rho_B\} \geq \sqrt{N}$.

Recalling that the multiplicative guarantee ρ_A is the greatest factor by which Bob can improve the probability that a single element is chosen over uniform, we conclude the following.

In any random selection protocol, at least one of the players can improve the probability that a single element is chosen by a factor *exponential* in the length of the output (which equals $\log N$).

Goldreich, Goldwasser, and Linial [GGL98] showed a more general result than Theorem 5.3 (for multiparty protocols) using different language and a moderately involved proof. We include below the simplification of their proof for the two-party case.

Proof of Theorem 5.3. Fix some element v of the universe. Now, consider the game tree T of the protocol (see Definition 2.2). At each node z of the tree, denote the protocol induced by beginning at node z to be Π_z. Then define

$$\begin{aligned}
\phi_A^z &= \max_{A^*} \Pr_B[\Pi_z((A^*, B)) = v], \\
\phi_B^z &= \max_{B^*} \Pr_A[\Pi_z((A, B^*)) = v], \\
p_z &= \Pr_{A,B}[\Pi_z((A, B)) = v].
\end{aligned}$$

That is, ϕ_A^z (resp., ϕ_B^z) is the highest probability Alice (resp., Bob) can make the output to be v, given that the protocol is now at node z and that Bob (resp., Alice) is playing honestly. p_z is the probability that v is chosen starting from z and assuming both players play honestly.

To prove the theorem, we will show that for every node z on T, $\phi_A^z \cdot \phi_B^z \geq p_z$. Applying this fact to the root r of the tree r and noting that we can choose v so that $p_r \geq 1/N$, the theorem follows easily.

We will prove $\phi_A^z \cdot \phi_B^z \geq p_z$ by backwards induction on the levels of the tree.

When z is a leaf, the protocol is complete. If v is the output of the protocol at leaf z, then $\phi_A^z = \phi_B^z = p_z = 1$. Otherwise, $\phi_A^z = \phi_B^z = p_z = 0$.

Now, suppose that the lemma holds for all children of z—denote them $z_1, \ldots, z_m$. Thus, we know $\phi_A^{z_i} \phi_B^{z_i} \geq p_{z_i}$ for all children z_i. Suppose also, without loss of generality, that at node z it is Alice's turn.

Suppose an honest Alice chooses child node z_i with probability λ_i. Then $p_z = \sum \lambda_i p_{z_i}$, and $\phi_B^z = \sum \lambda_i \phi_B^{z_i}$. When considering ϕ_A^z, however, Alice will cheat and choose the best child available. Thus, $\phi_A^z = \max_{z_i} \phi_A^{z_i}$, and so in particular for all i, $\phi_A^z \geq \phi_A^{z_i}$.

Now, just compute

$$\phi_A^z \phi_B^z = \phi_A^z \sum \lambda_i \phi_B^{z_i} \geq \sum \lambda_i \phi_A^{z_i} \phi_B^{z_i} \geq \sum \lambda_i p_{z_i} = p_z. \qquad \square$$

To understand this result intuitively, suppose that there were only one path down the tree that led to v being chosen as the output. At each node along that path, starting from the root, there is a certain probability that an honest player will choose the (unique) next node in the path. So the probability that v is chosen is the product of these probabilities when both players play honestly. If Alice (resp., Bob) is cheating, then the probability that v will be chosen is the product of the probabilities at nodes where it is Bob's (resp., Alice's) turn. In this case, $\phi_A^z \cdot \phi_B^z = p_z$. More paths yielding v merely provide more options to the cheating player, and so $\phi_A^z \cdot \phi_B^z \geq p_z$.

Note that, unlike Proposition 4.1, this result relies centrally on the assumption that, when one player is cheating, the other player is playing *honestly*.

Theorem 5.3 is, in fact, tight. In Proposition 3.10, we noted that the Random Set Protocol—in which Alice chooses a uniformly random subset of fixed size K and Bob chooses a random element of this set—achieves multiplicative guarantees of K and N/K for the two players.

Note that one negative aspect of the Random Set Protocol is that it is not efficient—sending a description of the random subset requires communication linear in N (rather than polylog(N)). This is certainly not necessary to achieve $\rho_A \rho_B = N$, however: other very simple and efficient protocols achieve this tradeoff. Specifically, instead of using all sets of size K, we can use any subcollection such that every element of $[N]$ is contained in the same number of sets. For example, if $N = K \cdot L$ for an integer L, then we can view the universe as $[K] \times [L]$ and use only the sets of the form $S_a = [K] \times \{a\}$ for each $a \in [L]$, and so the communication becomes $\log L + \log K = \log N$. The optimality of such a trivial protocol suggests that, ultimately, multiplicative guarantees are not by themselves likely to be sufficient metrics of study for two-party random selection protocols.

Acknowledgments. We thank Oded Goldreich, Grant Schoenebeck, and Alexander Healy for several helpful discussions. We are also grateful to anonymous reviewers for suggestions that greatly improved the presentation.

SHORT PCPS WITH POLYLOG QUERY COMPLEXITY*

ELI BEN-SASSON† AND MADHU SUDAN‡

Abstract. We give constructions of probabilistically checkable proofs (PCPs) of length $n \cdot \text{polylog}\, n$ proving satisfiability of circuits of size n that can be verified by querying $\text{polylog}\, n$ bits of the proof. We also give analogous constructions of locally testable codes (LTCs) mapping n information bits to $n \cdot \text{polylog}\, n$ bit long codewords that are testable with $\text{polylog}\, n$ queries. Our constructions rely on new techniques revolving around properties of codes based on relatively *high*-degree polynomials in *one* variable, i.e., Reed–Solomon codes. In contrast, previous constructions of short PCPs, beginning with [L. Babai, L. Fortnow, L. Levin, and M. Szegedy, *Checking computations in polylogarithmic time*, in Proceedings of the 23rd ACM Symposium on Theory of Computing, ACM, New York, 1991, pp. 21–31] and until the recent [E. Ben-Sasson, O. Goldreich, P. Harsha, M. Sudan, and S. Vadhan, *Robust PCPs of proximity, shorter PCPs, and applications to coding*, in Proceedings of the 36th ACM Symposium on Theory of Computing, ACM, New York, 2004, pp. 13–15], relied extensively on properties of *low*-degree polynomials in *many* variables. We show how to convert the problem of verifying the satisfaction of a circuit by a given assignment to the task of verifying that a given function is close to being a Reed–Solomon codeword, i.e., a univariate polynomial of specified degree. This reduction also gives an alternative to using the "sumcheck protocol" [C. Lund, L. Fortnow, H. Karloff, and N. Nisan, *J. ACM*, 39 (1992), pp. 859–868]. We then give a new PCP for the special task of proving that a function is close to being a Reed–Solomon codeword. The resulting PCPs are not only shorter than previous ones but also arguably simpler. In fact, our constructions are also more natural in that they yield locally testable codes first, which are then converted to PCPs. In contrast, most recent constructions go in the opposite direction of getting locally testable codes from PCPs.

Key words. probabilistically checkable proofs (PCPs), PCPs of proximity, locally testable codes, Reed–Solomon codes

1. Introduction.

Probabilistically checkable proof (PCP) systems as formulated in [20, 3, 2] are proof systems that allow efficient probabilistic verification based on querying a few bits of a proof. Formally, a PCP system is given by a PCP-verifier that probabilistically queries a few bits of a purported proof of a claimed theorem and accepts valid proofs of true theorems with probability 1, while accepting any claimed proof of false assertions with low probability, say, at most 1/2. The celebrated PCP theorem [3, 2] asserts that for any language in NP there exists a PCP-verifier that reads just a constant number of bits from a proof of polynomial length. Subsequently, it was shown in [28, 26] that the number of queries can be made as small as *three* bits, while rejecting proofs of false assertions with probability arbitrarily close to (but

larger than) 1/2. Such query-efficient proofs translate to strong inapproximability results for many combinatorial optimization problems; see [7, 8, 26, 28, 38].

Somewhat surprisingly, PCPs are rarely appreciated for their positive properties, i.e., as methods of transforming proofs into extremely efficiently verifiable formats. Instead their negative implications for combinatorial optimization dominate their study. In principle, PCPs could form the semantic analogue of error-correcting codes: Error-correcting codes are used to preserve data for long periods of time; PCPs may be used to preserve data, with a promise of integrity with respect to any fixed Boolean property, for long periods of time. However such uses seemed infeasible using current PCP constructions, which are *too long* and *too complex*. This forms the motivation of our work, which tries to find *shorter and simpler PCPs*.

A number of works [5, 37, 27, 24, 11, 9] have been focused on optimizing the length of the PCP. In addition to the inherent motivation mentioned above, the length of PCPs also plays an important role in their use in cryptography (e.g., in CS proofs [30, 35] and their applications [6, 13]) and is closely related to the construction of locally testable codes [24, 11, 9]. Simplifying PCP constructions has long been a goal within the study of PCPs, though little progress had been achieved in this direction until Dinur's recent surprising proof of the PCP theorem by gap amplification [18] continuing the combinatorial approach taken in [19]. Although we also construct simpler PCPs, our approach by contrast relies on adding algebraic structure instead of combinatorics.

PCPs. Our main result, Theorem 2.2, is a PCP construction that blows up the proof length by only a polylogarithmic factor resulting in a PCP of *quasilinear* length. (Throughout this paper, a function $f : \mathbb{N}^+ \to \mathbb{N}^+$ is said to be *quasilinear* if $f(n) = n \cdot \text{polylog}\, n$.) These short proofs can be verified by querying a polylogarithmic number of bits of the proof. By way of comparison, the recent results of Ben-Sasson et al. [9] give proofs of length $n \cdot \exp(\text{poly}\log\log n)$ with a query complexity of $\text{poly}\log\log n$. Thus, while the query complexity of our PCPs is higher than that of most recent results, the proof size is smaller.

PCPs of proximity. The results of [9] are actually for a stronger notion of PCPs, called *PCPs of proximity* (PCPPs). This notion was simultaneously introduced (under the name *assignment testers*) in [19] and a similar notion also appeared earlier in [40]. Informally, a PCPP-verifier's input includes two oracles, a "claimed theorem" and the "proof," and the verifier confirms that the claimed theorem is *close* in, say, Hamming distance, to a true theorem. It does so by making few oracle queries into the theorem and the proof. In contrast, recall that a PCP-verifier had unlimited access to the "claimed theorem" but verified that it was true *exactly* as stated. Theorem 2.10 gives a construction of PCPPs for all languages in NP with shorter proofs of proximity, though with larger query complexity than that of [9].

Locally testable codes. PCPs typically go hand-in-hand with *locally testable codes* (LTCs); for a detailed discussion of LTCs, see [24, 23] and references therein. Briefly, LTCs are error-correcting codes with relatively large rate and distance. Additionally, the amount of noise in a received word can be bounded from above by querying only a sublinear number of positions of the received word. Specifically, these codes have an associated tester that reads very few symbols of a received word and accepts codewords with probability 1, while rejecting words that are far from all codewords with constant probability (say, 1/2). Theorem 2.13 constructs LTCs with parameters similar to those of our PCPs. Namely, the codes have linear distance while the codeword to message ratio and the query complexity of the tester are polylogarithmic.

We highlight the fact that our work first constructs LTCs with polylogarithmic rate and query complexity, after which PCPs with the same parameters are derived as a consequence. While the early work of Babai et al. [5] also had this feature, constructions of smaller LTCs (in particular, those in [24, 11, 9]) reverse this direction, getting PCPs first and then deriving LTCs as a consequence. Our work thus achieves one of the goals associated with LTCs, namely, offering benefits and insights into PCPs via direct construction of LTCs.

Our techniques. Although our construction is algebraic as in prior PCP constructions, our techniques are significantly different and thus interesting in their own right. All previous algebraic PCPs (i.e., those excluding the combinatorial construction of [19]) start with a PCP based on the properties of multivariate polynomials over some finite field. Some key ingredients in such constructions are the following: (1) a *low-degree test*, i.e., a method to test if a function given by an oracle is close to being a low-degree multivariate polynomial, (2) a *self-corrector*, i.e., a procedure to compute the value of a multivariate polynomial at a given point, given oracle access to a polynomial that is close to this polynomial, (3) a *zero-tester*, i.e., an efficient procedure to verify if a function given by an oracle is close to a multivariate polynomial that is zero on every point in a prespecified subset of its domain, and (4) a reduction from verifying satisfiability to zero-testing. Typical solutions to the above problems yield a query complexity that is polynomial in the number of variables and the degree of the multivariate polynomial. This query complexity can then be reduced using a set of techniques referred to as *proof composition*.

Our solution follows a similar outline (though we do not need a self-corrector) except that, for the most part, we work only with univariate polynomials. This forms the essence of our technical advantage, giving PCPs with smaller proof length. The length of PCPs is well known to grow with the number of variables in the polynomials used to construct them, and reducing this number was an obvious way to try to reduce PCP length. However, reducing the number of variables increases the degree of the associated polynomials, and since solutions to steps (1)–(3) above had query complexity polynomial in the degree, previous solutions needed to use a large number of variables to significantly reduce the number of queries. In our case, we propose analogous questions for *univariate* polynomials and give query-efficient solutions for them, leading to short PCPs. We describe our solutions to the steps (1)–(4) in reverse order.

We start with the reduction from satisfiability to testing zero polynomials, which is step (4) above. The usual reduction is a transformation from a Boolean formula ϕ to a constraint C on pairs of polynomials along with subsets S_1 and S_2 of the multivariate domains with the following property: ϕ is satisfiable iff there exist polynomials P_1, P_2 that are zero on S_1, S_2, respectively, and furthermore $C(P_1, P_2)$ holds. (To enable "easy verification," $C(P_1, P_2)$ needs to be of a special form, but we will not get into this now.) In general, these reductions are simple, and our version of the reduction is as well. However in our case, the reductions appear particularly natural since we deal with a very small number of variables. In section 5 we describe our natural way of reducing NP-complete problems to problems about testing zeros of polynomials. In the end we use a somewhat more complex solution due only to our goal of extreme length efficiency; even in this case the full proof is only a few pages long.

Next we move to the zero-testing problem, which is step (3) above. We reduce this to two univariate low-degree testing questions, along with a natural consistency test between the two polynomials. The query complexity is a *constant* independent of

the degrees of the polynomials we are working with. Furthermore, it directly reduces zero-testing to low-degree testing while most previous solutions relied on some form or other of the self-correcting question. Put together, our solutions for steps (3) and (4) give a short and simple reduction from verifying NP statements to testing the degree of a univariate function. Furthermore, these reductions add only a *constant* number of queries to the query complexity of the low-degree testing protocol. This highlights the importance of the low-degree testing problem for univariate polynomials, which we describe below.

Reed–Solomon codes and proofs of proximity. The problem at the heart of our PCPs is the following: Given a finite field $\mathbb{F}$, a degree bound d, and oracle access to a function $f : \mathbb{F} \to \mathbb{F}$, test if f is close to a polynomial of degree at most d. Specifically, if f is a degree-d polynomial, then the test must always accept. On the other hand, if f is δ-far from every degree-d polynomial, i.e., the value of f needs to be changed on at least δ-fraction of the points in $\mathbb{F}$ to get a degree-d polynomial, then the test must reject with high probability. The objective is to do this while querying the oracle for f as few times as possible. The functions derived by evaluating polynomials of a specified degree over a field are known as *Reed–Solomon codes*, which we sometimes refer to by the name *RS-codes*. Our goal is thus to provide an efficient test for membership in these codes.

It is easy to see that, as such, the problem above allows no very efficient solutions: A tester that accepts all degree-d polynomials with probability 1 must probe the value of f in at least $d+2$ places before it can reject any function. This is too many queries for our purpose. This is where the notion of PCPPs comes to the rescue. Whereas it is hard to test if function f described by the oracle represents a degree-d polynomial with fewer than $\Omega(d)$ queries, it is conceivable (and indeed implied by previous works, for example, by [9]) that one can use an auxiliary proof oracle π to "prove" that f is close to the evaluations of a degree-d polynomial. More formally, our new task is thus to design a PCPP-verifier that makes a few queries to a pair of oracles (f, π), where we allow π to return elements of $\mathbb{F}$ as answers, and the following holds: If f is a degree-d polynomial, there exists a valid proof π so that (f, π) is always accepted by the tester. If f is δ-far from every degree-d polynomial, then for every π, the pair (f, π) must be rejected with high probability.

Since the property of being a degree-d polynomial over $\mathbb{F}$ can be efficiently verified (in time $|\mathbb{F}| \cdot \operatorname{polylog} |\mathbb{F}|$), we can apply the final theorem of Ben-Sasson et al. [9], which gives length-efficient proofs for any property relative to the time it takes to verify the property deterministically, to get moderately efficient solutions to this problem. Unfortunately, such a solution would involve proof oracles of length $|\mathbb{F}| \cdot \exp(\operatorname{poly} \log \log |\mathbb{F}|)$, which is longer than we can allow. Their solution would also not satisfy our (subjective) simplicity requirement. However it does confirm that our goal of making $o(d)$ queries is attainable.

Our main technical result is a PCPP for Reed–Solomon codes. This proof of proximity has length $O(n \cdot \operatorname{polylog} n)$ and query complexity $\operatorname{polylog} n$ for RS-codes over a field $\mathbb{F}$ of cardinality n and characteristic 2. We also describe some variations, such as PCPPs for RS-codes over certain prime fields, but these are not needed for our final PCP results. Our proof of proximity consists of an encoding of an efficient FFT-like evaluation of the low-degree polynomial. Our analysis makes crucial (black-box) use of Polishchuk and Spielman's [37] analysis of a natural low-degree test for bivariate polynomials.

We remark that almost all ingredients in the construction of our PCPs, including

the PCPPs for RS-codes, are simple. The simplicity of the PCP also means that the "hidden constants" in the construction are relatively small and the building blocks we use can be implemented with relative ease. In fact, our main building blocks, namely, the PCP of proximity for Reed–Solomon codes and its verifier described in Theorem 3.2, have been recently implemented successfully in code [12], resulting in PCPPs of length $\approx \frac{1}{4}n \cdot \log^4 n$ for RS-codes over binary fields of size n.

Recent developments. One of the main problems left open by this work was obtaining quasilinear PCPs and PCPPs with *constant* query complexity. This was recently solved by Dinur in [18] by applying her novel proof of the PCP theorem by gap amplification to our Theorem 2.2. Dinur provides a general transformation that takes any PCP of length $\ell(n)$ where the verifier makes $q(n)$ queries and converts it into a PCP of length $\ell(n) \cdot q(n)^{O(1)}$ where the verifier makes $O(1)$ queries. Applying this to the trivial PCP that makes $O(n)$ queries yields a simple proof of the PCP theorem, though with long proofs. On the other hand, applying this transformation to our PCP yields a quasilinear PCP with constant query complexity.

With the exception of [5], the running time of all previously known PCP- and PCPP-verifiers, including ours, is polynomial in the size of the input. Recently, it was shown in [10] that the running time of our PCPP-verifier can be reduced to be polylogarithmic, maintaining the query complexity and proof length of our PCPP construction in Theorem 2.10.

Organization of this paper. In section 2 we present formal definitions of the notions of PCPs, LTCs, and PCPPs, and we present the formal statements of our main theorems about these concepts. In section 3 we introduce the main technical notions used in this paper, namely, Reed–Solomon codes, some computationally important subclasses of Reed–Solomon codes, and algebraic satisfiability problems. We state our technical results about these problems and then show how our main theorems (i.e., the ones stated in section 2) follow from these technical results. In sections 4–7, we prove our technical results. A more detailed breakdown of these results is given at the end of section 3.

2. Definitions and main results.

Preliminaries. Unless specified otherwise, our alphabet of choice is $\Sigma = \{0, 1\}$ and all logarithms are taken to base 2. For a function $t : \mathbb{N}^+ \to \mathbb{N}^+$, recall that NTIME($t(n)$) is the class of languages $L \subseteq \Sigma^*$ decidable in nondeterministic time $t(n)$ on inputs of length n.

2.1. PCPs.

The following is a variant of the standard definition of PCPs [3], where the running time of the verifier is allowed to grow exponentially with the randomness. This is done following [10] to allow a statement of results about languages whose nondeterministic decision time is superpolynomial. Recall that an oracle machine is said to be *nonadaptive* if its queries do not depend on previous oracle answers. We stress that all oracle machines considered in this paper, and, in particular, the following PCP-verifier and the PCPP-verifier of Definition 2.4, are nonadaptive.

DEFINITION 2.1 (PCP). *For functions $r, q : \mathbb{N}^+ \to \mathbb{N}^+$ an $(r(n), q(n))$-*PCP-verifier *is a probabilistic machine V with oracle access to a* probabilistically checkable proof*, or simply, a* proof*, denoted π. On input x of length n, V runs in time $2^{O(r(n))}$, tosses $r(n)$ coins, makes $q(n)$ nonadaptive queries to the proof, and outputs either* `accept` *or* `reject`*. We denote by $V^{\pi}[x; R]$ the output of V on input x, proof π, and random coins R.*

For constant $s \in [0, 1]$, a language $L \subseteq \Sigma^*$ is said to belong to the class of

languages

$$\mathbf{PCP}_s[\mathsf{randomness}\ r(n), \mathsf{query}\ q(n)]$$

if there exists an $(r(n), q(n))$-PCP-verifier V_L such that the following hold:

- Perfect completeness: *If $x \in L$ then $\exists \pi$ such that* $\Pr_R[V_L^{\pi}[x; R] = \texttt{accept}] = 1$.
- Soundness: *If $x \notin L$ then $\forall \pi$ we have* $\Pr_R[V_L^{\pi}[x; R] = \texttt{accept}] \leq s$.

Our first main result is the following. Recall the definition of a *proper complexity function* from [36, Definition 7.1], where a function $f(n)$ is proper if it can be computed in time $\text{polylog}\, n$.

THEOREM 2.2 (quasilinear PCPs). *For any proper complexity function $t : \mathbb{N}^+ \to \mathbb{N}^+$,*

$$\text{NTIME}(t(n)) \subseteq \mathbf{PCP}_{\frac{1}{2}}\mathsf{randomness}\ \log(t(n) \cdot \text{polylog}\, t(n)), \mathsf{query}\ \text{polylog}\, t(n)].$$

Remark 2.3. The parameters of Theorem 2.2 have been recently improved. In particular, [18] reduced the query complexity to $O(1)$ and [10] reduced the verifier's running time to $\text{poly}\, n + \text{polylog}\, t(n)$ (as opposed to $t(n) \cdot \text{polylog}\, t(n)$). In both cases all other parameters remain unchanged.

Since without loss of generality the proof is of size at most $2^{\mathsf{randomness}} \times \mathsf{query}$ the previous theorem implies that the probabilistically checkable proof for $x \in L$ is quasilinear in the running time of the nondeterministic machine deciding L.

In contrast, the recent results of [9] give proofs of length $n \cdot \exp(\text{poly}\log\log n)$ with a query complexity of $\text{poly}\log\log n$ and slightly longer proofs with constant query complexity. Thus, while the query complexity of our PCPs is higher than that of the previous state of the art, their length is shorter.

2.2. Proximity and proofs of proximity. We now formalize the notion of verifying proofs of theorems where even the theorem is not known but rather is provided as an oracle to the verifier. The verifier, in such a case, can hope only to certify that the theorem is "close" to one that is true. To define this notion we first need to formalize the notion of "closeness," or proximity.

We will work with a variety of distance measures $\Delta : \Sigma^N \times \Sigma^N \to [0, 1]$, where a distance measure satisfies the properties (1) $\Delta(x, x) = 0$, (2) $\Delta(x, y) = \Delta(y, x)$, and (3) $\Delta(x, z) \leq \Delta(x, y) + \Delta(y, z)$. The most common/natural one, and the target of most of our theorems, will be *relativized Hamming distance* over the alphabet Σ, denoted $\mathsf{Hamming}_{\Sigma}(\cdot, \cdot)$. Formally, for $y = (y_1, \ldots, y_N), y' = (y'_1, \ldots, y'_N) \in \Sigma^N$,

$$\mathsf{Hamming}_{\Sigma}(y, y') = |\{i : y_i \neq y'_i\}|/N.$$

For our proofs we use other distance measures on strings which may weigh different coordinates differently. For example, given a set $I \subseteq [N]$ we may consider the distance $\mathsf{Hamming}_{\Sigma,I}(y, y') = |\{i \in I : y_i \neq y'_i\}|/|I|$. Note that a convex combination of distance measures is also a distance measure, and this describes many other distance measures we use later.

Given a distance measure $\Delta : \Sigma^N \times \Sigma^N \to [0, 1]$ and a set $S \subseteq \Sigma^N$ we define the distance of an element $y \in \Sigma^N$ from S to be

$$\Delta(y, S) = \begin{cases} \min_{s \in S} \Delta(y, s), & S \neq \emptyset, \\ 1, & S = \emptyset. \end{cases}$$

We are now ready to describe PCPs of proximity (PCPPs)/assignment testers [9, 19]. We follow the general formulation as appearing in [9]. In this formulation, the input comes in two parts (x, y), where $x \in \Sigma^*$ is given explicitly to the verifier and $y \in \Sigma^*$ is given as oracle. In addition, the verifier is given oracle access to a proof. The verifier is allowed to read x in its entirety, but its queries to y are counted as part of its query complexity, i.e., together with the queries to the proof. Throughout this paper we assume without loss of generality the explicit input of a pair instance includes a specification of the length of the implicit input. If unspecified we set the length to be $t(|x|)$. Formally, we assume the explicit input is of the form $x = (x', N)$, where $N = |y|$. The size of the explicit input is the size of x'.

DEFINITION 2.4 (PCPP-verifier). *For functions $r, q : \mathbb{N}^+ \to \mathbb{N}^+$ an $(r(n), q(n))$-*PCPP-verifier *is a probabilistic machine V with oracle access to an* implicit input y *and a* proof of proximity*, or simply, a* proof*, denoted π. On explicit input $x = (x', N)$ with $|x'| = n$, and N an integer, verifier V runs in time $2^{O(r(n))}$, tosses $r(n)$ coins, makes at most $q(n)$ nonadaptive queries in total to the two oracles, y of size N and π, and outputs either* `accept` *or* `reject`*. We denote by $V^{(y,\pi)}[x; R]$ the output of the PCPP-verifier on input x and random coins R.*

PCPPs refer to languages consisting of pairs of strings where the elements in these pairs refer to the two parts of the input in Definition 2.4. Thus, we define a *pair language* to be subset of $\Sigma^* \times \Sigma^*$. It is useful for us to measure the complexity of a pair language as a function of its first input. So PAIR-TIME$(t(n))$ is the set of languages L such that there exists a machine M that takes time $t(|x|)$ on input (x, y) such that $L = \{(x, y) : M(x, y) = \texttt{accept}\}$. One notable pair language in PAIR-TIME$(n \cdot \operatorname{polylog} n)$ is CKTVAL, the language of pairs (C, w), where C is a Boolean circuit with N inputs and w is an assignment satisfying C. PAIR-NTIME$(t(n))$ is defined similarly, this time allowing M to be a nondeterministic machine.

For a pair language L and $x \in \Sigma^*$, $x = (x', N)$, let

$$L_x \triangleq \{y \in \Sigma^N : (x, y) \in L\}.$$

PCPP-verifiers are intended to accept implicit inputs in L_x and reject implicit inputs that are far from being in L_x. This gives rise to classes of pair languages defined in terms of PCPPs.

DEFINITION 2.5 (PCPP). *For functions $r, q : \mathbb{N}^+ \to \mathbb{N}^+$,* soundness parameter *$s \in [0, 1]$, family of* distance measures *$\Delta = \{\Delta_N : \Sigma^N \times \Sigma^N \to [0, 1]\}_{N \in \mathbb{N}^+}$, and* proximity parameter *$\delta \in [0, 1]$ we say the pair language L belongs to the class of languages*

$$\mathbf{PCPP}_{s,\delta}\left[\begin{array}{l}\mathsf{randomness}\ r(n),\\ \mathsf{query}\ q(n),\\ \mathsf{distance}\ \Delta\end{array}\right]$$

if there exists an $(r(n), q(n))$-PCPP-verifier V_L such that the following hold for all $(x, y), |y| = N$:

- Perfect completeness: *If $(x, y) \in L$ then $\exists \pi$ such that* $\Pr_R[V_L^{(y,\pi)}[x; R] = \texttt{accept}] = 1$.
- Soundness: *If $\Delta_N(y, L_x) \geq \delta$, then $\forall \pi$* $\Pr_R[V_L^{(y,\pi)}[x; R] = \texttt{accept}] \leq 1 - s$.

Remark 2.6. As mentioned earlier, our main results (for example, Theorem 2.10) target the relative Hamming distance. However, to prove these we shall need to use PCPPs with different distance measures (see subsection 3.4).

Our constructions of PCPPs come naturally with a somewhat different soundness condition than the one required in Definition 2.5. On the one hand, they do not achieve a soundness error of an absolute constant. On the other hand, they satisfy the additional property that a PCPP-verifier for L_x rejects *every* string y with probability proportional to the distance of y from L_x. We formalize this "strong" soundness condition below and then state a general transformation from PCPPs with strong soundness to the weaker version above. (The term "strong" is derived from the analogous definition of *strong locally testable codes* [24, Definition 2.1].)

DEFINITION 2.7 (strong PCPP). *For r, q, Δ as in Definition 2.5 and* soundness function $s : (0,1] \times \mathbb{N}^+ \to (0,1]$*, we say language L belongs to the class*

$$\mathbf{Strong\text{-}PCPP}_{s(\delta,n)} \left[\begin{array}{l} \mathsf{randomness}\ r(n), \\ \mathsf{query}\ q(n), \\ \mathsf{distance}\ \Delta \end{array} \right]$$

if there exists an $(r(n), q(n))$-PCPP-verifier V_L with perfect completeness as in Definition 2.5 and for all (x, y), $|y| = N$, the following holds:

- Strong soundness: $\forall \pi \quad \Pr_R[V_L^{(y,\pi)}[x; R] = \mathtt{accept}] \leq 1 - s(\Delta_N(y, L_x), n)$.

Remark 2.8. Naturally, one expects the soundness function to be nondecreasing. Formally, we say $s : (0,1] \times \mathbb{N}^+ \to [0,1]$ is *nondecreasing* if for all $n \in \mathbb{N}^+$ the function $s(\cdot, n) : (0,1] \to (0,1]$ is nondecreasing. This implies that the farther y is from L_x, the higher the rejection probability or soundness. Indeed, all soundness functions considered in this paper are nondecreasing.

Notice that a "weak" PCPP, with soundness parameter s_0 and distance parameter s_0, is also a "strong" PCPP with a threshold soundness function $s(\delta, n)$ that evaluates to 0 on $\delta' < \delta_0$ and to s_0 on $\delta' \geq \delta_0$. A converse of this is also true. To see this one needs only to amplify the soundness error from $s(\delta, n)$ to some fixed desired constant s'. The now standard application of randomness efficient sampling allows such amplification with little additional cost in randomness. Indeed, using the expander-neighborhood sampler of [25] (see also [22, section C.4]) we get the following proposition, given here without proof. (For a proof see [9, Lemma 2.11].)

PROPOSITION 2.9 (strong PCPPs imply "weak" ones). *Let $s : (0,1] \times \mathbb{N}^+ \to (0,1]$ be a nondecreasing soundness function as defined in Remark 2.8. If a pair language L belongs to*

$$\mathbf{Strong\text{-}PCPP}_{s(\delta,n)} \left[\begin{array}{l} \mathsf{randomness}\ r(n), \\ \mathsf{query}\ q(n), \\ \mathsf{distance}\ \Delta \end{array} \right],$$

then, for every $s', \delta \in (0,1)$, the language L belongs to

$$\mathbf{PCPP}_{s',\delta} \left[\begin{array}{l} \mathsf{randomness}\ r(n) + O(\frac{1}{s(\delta,n)} \cdot \log \frac{1}{s'}), \\ \mathsf{query}\ O\left(\frac{q(n) \cdot \log 1/s'}{s(\delta,n)}\right), \\ \mathsf{distance}\ \Delta \end{array} \right].$$

Furthermore, the proof queried by the "weak" PCPP-verifier is of the same length as that queried by the "strong" one.

We are now ready to state our main result for PCPPs.

THEOREM 2.10 (quasilinear PCPPs). *For any proper complexity function t :*

$\mathbb{N}^+ \to \mathbb{N}^+$,

$$\text{PAIR-NTIME}(t(n)) \subseteq \mathbf{Strong\text{-}PCPP}_{\delta/\operatorname{polylog} t(n)} \left[\begin{array}{l} \mathsf{randomness}\ \log(t(n) \cdot \operatorname{polylog} t(n)), \\ \mathsf{query}\ \operatorname{polylog} t(n), \\ \mathsf{distance}\ \mathsf{Hamming}_\Sigma \end{array} \right].$$

Consequently, as implied by Proposition 2.9*, for any* $s, \delta \in (0,1)$*,*

$$\text{PAIR-NTIME}(t(n)) \subseteq \mathbf{PCPP}_{s,\delta} \left[\begin{array}{l} \mathsf{randomness}\ \log(t(n) \cdot \operatorname{polylog} t(n)), \\ \mathsf{query}\ \operatorname{polylog} t(n), \\ \mathsf{distance}\ \mathsf{Hamming}_\Sigma \end{array} \right].$$

Furthermore, the length of the proof queried by the PCPP-verifier (in both the strong and weak cases) is $t(n) \cdot \operatorname{polylog} t(n)$*.*

Remark 2.11. As in the case of Theorem 2.2, the parameters of Theorem 2.10 have been recently improved. In particular, [18] reduced the query complexity to $O(1)$ and [10] reduced the verifier running time to $\operatorname{poly} n + \operatorname{polylog} t(n)$. In both cases all other parameters remain unchanged.

The previous state of the art with respect to PCPPs [9] gave proofs of length $n \cdot \exp(\operatorname{poly}\log\log n)$ with a query complexity of $\operatorname{poly}\log\log n$ (and slightly longer proofs with constant query complexity). Once again, our query complexity is somewhat higher but our proofs are somewhat shorter.

2.3. Locally testable codes. We now move to the third notion addressed by this paper—that of LTCs.

For field $\mathbb{F}$ and integers n, k, d, a linear $[n,k,d]_{\mathbb{F}}$-code is an injective linear map $C : \mathbb{F}^k \to \mathbb{F}^n$ such that for every pair $x \neq y \in \mathbb{F}^k$, $\mathsf{Hamming}_{\mathbb{F}}(C(x), C(y)) \geq d/n$. We point out that all codes considered in this paper are linear. The *alphabet* of C is $\mathbb{F}$, the *blocklength* is n, the *dimension* is k, the *rate* is k/n, and the *distance* is d. The *image* of C is the linear space $\text{Image}(C) = \{C(a) : a \in \mathbb{F}^k\}$. Often a code is identified with its image.

Loosely speaking, a linear $[n,k,d]_{\mathbb{F}}$-code is said to be *locally testable* if a *tester*, i.e., a randomized machine with oracle access to the supposed codeword, can distinguish with high probability between words in the code and words that are far from it, while making only $o(k)$ random queries into a purported codeword. The following is essentially Definition 2.1 from [24].

DEFINITION 2.12 (locally testable codes). *A randomized polynomial time oracle machine* T *is called a* (δ, q, γ)-tester *for the linear* $[n,k,d]_{\mathbb{F}}$ *code* C *if it satisfies the following two conditions:*

- *For any* $w \in \text{Image}(C)$*,*

$$\Pr[T^w[R] = \texttt{accept}] = 1,$$

  where $T^w[R]$ *denotes the output of the tester on oracle* w *and random coins* R*.*
- *For any* $w \in \mathbb{F}^n$ *such that* $\mathsf{Hamming}_{\mathbb{F}}(w, \text{Image}(C)) \geq \delta$*,*

$$\Pr[T^w[R] = \texttt{reject}] \geq \gamma.$$

A code is said to be (δ, q, γ)-locally testable *if it has a* (δ, q, γ)*-tester.*

THEOREM 2.13 (locally testable codes with polylogarithmic rate). *Let $\delta, \gamma \in (0,1)$, $\Sigma = \mathbb{F}_2$ be the field of two elements and let n be any power of 2. Then, there exists a linear $[N = n \cdot \text{polylog}\, n, K = n/8, D = N/8]_\Sigma$-code that is $(\delta, \text{polylog}\, n, \gamma)$-locally testable. Furthermore, encoding, decoding, and testing can be performed in time polynomial in n.*

Remark 2.14. As with Theorems 2.2 and 2.10, the query complexity of Theorem 2.13 has been recently improved in [18] to $O(1)$, leaving all other parameters unchanged.

We remark that we also give LTCs over a variety of other fields and other choices of n (see Theorems 3.2 and 3.4 for details). Also if we relax the requirement that the code be linear, then the theorem above follows immediately from Theorem 2.10 (and [9, section 4.1]) without any restrictions on the choice of n.

3. Technical ingredients of our constructions. In this section we introduce the main technical ingredients of our paper and prove the three main theorems (Theorems 2.2, 2.10, and 2.13) of our paper, assuming these ingredients. Recall that these theorems promise short PCPs, PCPPs, and LTCs. We stress that while the construction of PCPs and LTCs follows easily from the PCPP construction, this is not the approach in our paper.

We start by constructing an LTC, based on one of the most popular codes, namely, the Reed–Solomon code. We give a PCPP for a language whose elements are essentially Reed–Solomon codewords. Recalling the fact that Reed–Solomon codes are evaluations of univariate polynomials of bounded degree, this result shows how it is possible to prove that a function given as an oracle is close to some polynomial of bounded degree. Subsection 3.1 below describes the actual language based on Reed–Solomon codes and states the PCPP construction that we obtain for this language. This immediately leads to a proof of Theorem 2.13.

We then move to the constructions of PCPs and PCPPs for general NTIME languages. These constructions are obtained by first reducing the NTIME language under consideration to an algebraic version of SAT that we call an algebraic constraint satisfaction problem, and then giving PCPs (and PCPPs) for algebraic constraint satisfaction problems. We define algebraic constraint satisfaction problems and state their completeness for NTIME in subsection 3.2.
