1.4. Application to zero-knowledge arguments. Barak's construction [6] of non–black-box zero-knowledge arguments (for any set in $\mathcal{NP}$) uses a witness indistinguishable (WI) argument of knowledge for $R_{\mathcal{U}}$.[7] In his protocol, the prover uses this WI argument (of knowledge) to prove that it knows either an NP witness for the original common input or a program that fits the verifier functionality (as reflected in the challenge-respond exchange that follows). Thus, as a first step, we need to transform our universal argument (of knowledge) into a corresponding WI universal argument (of knowledge). The transformation essentially follows Barak's transformation [6], but then we encounter a second place where Barak uses a superpolynomial hardness assumption: Barak uses a collision-resistant hashing function to hash "$S_{\mathcal{U}}$-witnesses" (into fixed-length strings), where the length of these witnesses is bounded by some superpolynomial function (but not by any polynomial). Consequently, a collision on such long strings yields only the violation of a superpolynomial collision-resistant assumption. To avoid superpolynomial hardness assumptions, we hash these witnesses by combining "tree hashing" (as in Kilian's construction [21]) with an error-correcting code. Specifically, first the witness string is encoded using an error-correcting code, and then the tree hashing is applied to the result. Thus, if two different strings are hashed to the same value, then we can form a collision with respect to the basic hashing function (used in the tree hashing) by considering a uniformly selected leaf (which is quite likely to be assigned different values under an error-correction coding of different strings). Combining the foregoing, we obtain the following theorem.

THEOREM 1.2 (our main application). *The existence of* (standard) *collision-resistant hashing functions implies the existence of* (non–black-box) *zero-knowledge arguments for any set in $\mathcal{NP}$ such that these protocols have the following additional properties:*

1. *The protocol has a constant number of rounds and uses only public coins.*
2. *The simulator runs in strict* (rather than expected) *probabilistic polynomial time.*
3. *The protocol remains zero-knowledge when, say, n^2 copies are executed concurrently.*[8]

[6] Specifically, Kilian's construction [21] uses a probabilistic checkable proof (PCP) system, and the hypothetical violation of its computational soundness is shown to yield a (relatively small) collision-forming circuit, but this circuit is bigger than the length of the corresponding PCP oracle (which, in the case of $S_{\mathcal{U}}$, is exponential in the input length). Instead, we show how to obtain a collision-forming circuit that is smaller than the length of the corresponding PCP oracle.

[7] In fact, Barak uses a CS proof (of knowledge) for $R^f_{\mathcal{U}} \subset R_{\mathcal{U}}$, where f is any "nice" superpolynomial function (e.g., $f(n) = n^{\log_2 n}$) and $((M,x,t),w)$ is in $R^f_{\mathcal{U}}$ only if $t \leq f(|x|)$. He constructs such a CS proof assuming the existence of hashing functions that are resilient with respect to f-size circuits (rather than subexponential hardness which would have been required for a CS proof for $R_{\mathcal{U}}$).

[8] In fact, we can tolerate $p(n)$ concurrent copies, where p is an arbitrary polynomial that is fixed a priori; that is, the argument system depends on the polynomial p.

Recall that, assuming $\mathcal{NP} \not\subseteq \mathcal{BPP}$, each of the three extra properties requires a non–black-box simulator (and that such protocols were first presented in [6]).[9] Thus, Theorem 1.2 establishes the main result of [6] *under a weaker assumption*: we only assume the existence of hashing functions that are resilient with respect to polynomial-size circuits (rather than with respect to circuits of some superpolynomial size).

1.5. Organization. In section 2 we define universal arguments, and in section 3 we show how to construct them (using any family of collision-resistant hash functions). The application to the construction of non–black-box zero-knowledge arguments is presented in section 4. Appendix B contains a revised treatment of the notion of a nonoblivious commitment scheme, which may be of independent interest (because it augments the initial treatment provided in [16, section 4.9.2.1] and corrected in [17, section C.3.3]).

Comment. The current version of this paper differs from prior versions mainly in section 4.1. The presentation in prior versions (see [8]) relied on the existence of constant-round, public-coin *strong*-WI proofs of knowledge for any NP set. Unfortunately, contrary to prior misconceptions (cf. [16, section 4.6]), such protocols are not known to exist [17, Appendix C.3]. Indeed, this gap can be bypassed—as done in [7] and in the current version by using a rather ugly patch—but our hope was to bridge the gap (i.e., prove the existence of the said strong-WI protocols) and maintain the original presentation. Having failed to do so for several years, we decided to archive the current version.

2. The definition of universal arguments. Let us start with some general notions. For an integer n, we denote the set $\{1, \ldots, n\}$ by $[n]$. We denote by $\mu : \mathsf{N} \to [0,1]$ an unspecified *negligible function*; that is, for every positive polynomial p and all sufficiently large n, it holds that $\mu(n) < 1/p(n)$. We say that an event occurs with *overwhelmingly high probability* if it occurs with probability at least $1 - \mu(n)$, where n is the relevant security parameter. For a pair of (interactive) strategies denoted by (P, V), we denote by $(P(w), V)(y)$ the output of V when interacting with $P(w)$ on common input y, where $P(w)$ denotes the functionality of P when given auxiliary input w.

In continuation of the discussion in section 1.2, we now define universal argument systems (for $S_{\mathcal{U}}$). Recall that $S_{\mathcal{U}} = \{(M, x, t) : \exists w \text{ s.t. } ((M, x, t), w) \in R_{\mathcal{U}}\}$, where $((M, x, t), w) \in R_{\mathcal{U}}$ if M accepts (x, w) within t steps. Let $T_M(x, w)$ denote the number of steps made by M on input (x, w); indeed, if $((M, x, t), w) \in R_{\mathcal{U}}$, then $T_M(x, w) \leq t$. Recall that $|(M, x, t)| = O(|M| + |x| + \log t)$; that is, t is given in binary. In the following definition, we incorporate a (weak) proof-of-knowledge property (which was mentioned in sections 1.3 and 1.4 but not in section 1.2).[10]

DEFINITION 2.1 (universal argument). *A universal-argument system is a pair of strategies denoted by (P, V) that satisfies the following properties:*

Efficient Verification. There exists a polynomial p such that for any $y = (M, x, t)$, the total time spent by the (probabilistic) *verifier strategy V, on the common input y, is at most $p(|y|)$. In particular, all messages exchanged in the protocol have a length smaller than $p(|y|)$.*

[9] Indeed, see [6, 7] for a discussion of various results regarding the impossibility of achieving the above via a black-box simulator. We stress that the current discussion refers to protocols of negligible soundness error.

[10] Indeed, the (weak) proof-of-knowledge property may be considered an auxiliary feature, which need not be mandated by the basic definition of a "universal argument" (i.e., Definition 2.1). Our choice to include this property in Definition 2.1 is motivated by the specific context and results of the present work.

Completeness via a relatively efficient prover. For every $((M,x,t),w)$ *in* $R_{\mathcal{U}}$,

$$\Pr[(P(w),V)(M,x,t)=1]=1.$$

Furthermore, there exists a polynomial p *such that for every* $((M,x,t),w)\in R_{\mathcal{U}}$ *the total time spent by* $P(w)$*, on the common input* (M,x,t)*, is at most* $p(|M|+T_M(x,w))\le p(|M|+t)$.

Computational Soundness. For every polynomial-size circuit family $\{\widetilde{P}_n\}_{n\in\mathsf{N}}$ *and every* $(M,x,t)\in\{0,1\}^n\setminus S_{\mathcal{U}}$,

$$\Pr\left[\left(\widetilde{P}_n,V\right)(M,x,t)=1\right] \;<\; \mu(n),$$

where $\mu:\mathsf{N}\to[0,1]$ *is a negligible function.*[11]

A weak proof-of-knowledge property. For every positive polynomial p *there exists a positive polynomial* p' *and a probabilistic polynomial-time oracle machine* E *such that the following holds:*[12] *for every polynomial-size circuit family* $\{\widetilde{P}_n\}_{n\in\mathsf{N}}$ *and every sufficiently long* $y=(M,x,t)\in\{0,1\}^*$*, if* $\Pr[(\widetilde{P}_n,V)(y)=1]>1/p(|y|)$*, then*

$$\Pr_r\left[\begin{array}{l}\exists w=w_1\cdots w_t\in R_{\mathcal{U}}(y)\\ \quad(\forall i\in[t])\quad E_r^{\widetilde{P}_n}(y,i)=w_i\end{array}\right] \;>\; \frac{1}{p'(|y|)}, \tag{2.1}$$

where $R_{\mathcal{U}}(y)\stackrel{\text{def}}{=}\{w:(y,w)\in R_{\mathcal{U}}\}$ *and* $E_r^{\widetilde{P}_n}(.,.)$ *denotes the function defined by fixing the random tape of* E *to equal* r *and providing the resulting* E_r *with oracle access to* $\widetilde{P}_n$*. The oracle machine* E *is called a* (knowledge) extractor.

A few comments regarding the weak proof-of-knowledge property are in place. First, note that the condition "$\forall i\in[t]$ it holds that $E_r^{\widetilde{P}_n}(y,i)=w_i$" means that $E_r^{\widetilde{P}_n}(y,.)$ is an *implicit representation* of the string $w=w_1\cdots w_t$ (i.e., any specific bit of w is obtained by instantiating the second input to $E_r^{\widetilde{P}_n}(y,.)$ accordingly). If $\Pr[(\widetilde{P}_n,V)(y)=1]>1/p(|y|)$, then at least an $1/p'(|y|)$ fraction of the possible r's yields such implicit representations of some string in $R_{\mathcal{U}}(y)$, but these strings are not necessarily equal (i.e., different r's may yield different strings in $R_{\mathcal{U}}(y)$). Implicit (rather than explicit) representation is required here because we want the extractor to run in polynomial time, whereas the length of the strings in $R_{\mathcal{U}}(y)$ may not be bounded by any polynomial (in $|y|$). Finally, we note that the weak proof-of-knowledge property is indeed weaker than the standard definition of a proof of knowledge (cf. [9], [16, section 4.7], and Footnote 12), but it suffices for the applications that we have in mind.

3. The construction of universal arguments. As mentioned in section 1.3, by adapting the construction of Kilian [21], one can easily show that the existence of *strong* collision-resistant hashing functions implies the existence of universal arguments (and even CS proofs for $S_{\mathcal{U}}$; cf. Micali [23]). Here we show how a similar adaptation, when using only *standard* collision-resistant hashing functions, yields universal arguments. Our focus is on demonstrating the computational soundness of this construction, which should now be established under a weaker assumption than the one used in [21, 23].

[11] That is, the function μ is fixed depending on $\{\widetilde{P}_n\}_{n\in\mathsf{N}}$ and on an infinite sequence of inputs that contains at most one input per each input length. Equivalently, one may fix the function μ depending only on the polynomial bounding the size of the circuit family.

[12] Indeed, the polynomial p' as well as the (polynomial) running time of E may depend on the polynomial p (which determines the noticeable threshold probability).

3.1. Motivation. In order to explain the difficulty and its resolution, let us recall the basic construction of Kilian [21] (used also by Micali [23]), as adapted to our setting.

Our starting point is a $\mathcal{PCP}[\text{poly}, \text{poly}]$ system for $S_{\mathcal{U}} \in \mathcal{NEXP}$, which is used in the universal-argument system as follows. The verifier starts by sending the prover a hashing function. The prover constructs a PCP proof/oracle (corresponding to the common input and its own auxiliary input), places the bits of this oracle at the leaves of a polynomial-depth full binary tree, and places in each internal node the hash value obtained by applying the hashing function to the labels (i.e., contents) of its children. The prover sends the *label of the root* to the verifier, which responsed by sending a random tape of the type used by the PCP verifier. Both parties determine the queries corresponding to this tape, and the prover responds with the values of the corresponding leaves, along with the labels of the vertices along the paths from these leaves to the root (as well as the labels of the siblings of these vertices). The verifier checks that this sequence of labels matches the corresponding applications of the hashing function and also emulates the PCP verifier. Ignoring (for a moment) the issue of the prover's complexity, the problem we consider next is that of establishing computational soundness.

The naive approach is to consider how the prover responds to each of the possible random tapes sent to it. If the prover answers consistently (i.e., with leaf labels that depend only on the leaf location), then we obtain a PCP oracle, and soundness follows by the soundness of the PCP scheme. On the other hand, inconsistent labels for the same leaf yield a (hashing) collision somewhere along the path to the root. However, in order to find such a collision, we must spend time proportional to the size of the tree, which yields a contradiction only in the case that the hashing function is supposed to withstand adversaries that use that much time. Note that the size of the tree is picked by the (adversarial) prover, and since we wish to handle $S_{\mathcal{U}}$ (or merely "only" all of $\mathcal{NP}$) we do not have an a priori polynomial bound on the size of the tree that the prover is allowed to use (because no such bound exists for the designated prover). But in such a case, if the tree is exponential (or even merely super polynomial) in the security parameter, then we derive a contradiction only when using hashing functions of subexponential (respectively, superpolynomial) security.

In contrast to the (above) naive approach, the approach taken here is to consider each leaf separately rather than all leaves together. That is, the naive analysis distinguishes the case that the prover answers inconsistently on *some* leaf from the case that it answers consistently on *all* leaves. Instead, we consider each leaf separately and distinguish the case that the prover answers inconsistently on *this leaf* from the case that it answers consistently on *this leaf*. Loosely speaking, we call a leaf *good* if the prover answers consistently on it and observe that if a big fraction of the leaves is good, then soundness follows by the soundness of the PCP scheme (regardless of the contents of other leaves). On the other hand, if sufficiently many leaves are not good, then we obtain a collision by picking a random leaf (hoping that it is not good) and obtaining inconsistent labels for it. This requires being able to uniformly select a random tape that causes the PCP verifier to make the corresponding query, a property which is fortunately enjoyed by the relevant PCP systems.

We warn that the above is merely a rough description of the main idea in our analysis. Furthermore, in order to establish the proof-of-knowledge property of our construction, we need to rely on an analogous property of the PCP system (which again happens to be satisfied by the relevant PCP systems).

3.2. The PCP system in use. We first recall the basic definition of a PCP system. Loosely speaking, a probabilistically checkable proof (PCP) system consists of a probabilistic polynomial-time verifier having access to an oracle which represents a proof in redundant form. Typically, the verifier accesses only a few of the oracle bits, and these bit positions are determined by the outcome of the verifier's coin tosses. It is required that if the assertion holds, then the verifier always accepts (i.e., when given access to an adequate oracle); whereas if the assertion is false, then the verifier must reject with high probability (as specified in an adequate bound), no matter which oracle is used. The basic definition of the PCP setting is given in item 1 of Definition 3.1 below. Typically, the complexity measures introduced in item 2 of Definition 3.1 are of key importance, but this is not the case in the current work.

DEFINITION 3.1 (PCP—basic definition).

1. *A* probabilistically checkable proof (PCP) system with error bound $\epsilon : \mathsf{N} \to [0,1]$ for a set S *is a probabilistic polynomial-time oracle machine (called* verifier*), denoted by* V *satisfying the following:*
   - Completeness. *For every* $x \in S$ *there exists an oracle* π_x *such that* V*, on input* x *and access to oracle* π_x*, always accepts* x*.*
   - Soundness. *For every* $x \notin S$ *and every oracle* π*, machine* V*, on input* x *and access to oracle* π*, rejects* x *with probability at least* $1 - \epsilon(|x|)$*.*
2. *Let* r *and* q *be integer functions. The complexity class* $\mathcal{PCP}_\epsilon[r(\cdot), q(\cdot)]$ *consists of sets having a PCP system with error bound* ϵ *in which the verifier, on any input of length* n*, makes at most* $r(n)$ *coin tosses and at most* $q(n)$ *oracle queries.*

Note that if S has a PCP system with error bound ϵ, then $S \in \mathcal{PCP}_\epsilon[p(\cdot), p(\cdot)]$ for some polynomial p. Here we will care only that $S_{\mathcal{U}} \in \mathcal{NE}$ has a PCP system with an exponentially decreasing error bound (i.e., $\epsilon(n) = 2^{-n}$). Instead of caring about the refined complexity measures (of item 2), we will care about the following *additional properties* which are satisfied by some PCP systems, where only some of these properties were explicitly considered before (see discussion below).

DEFINITION 3.2 (PCP—auxiliary properties). *Let* V *be a PCP verifier with error* $\epsilon : \mathsf{N} \to [0,1]$ *for a set* $S \in \mathcal{NEXP}$*, and let* R *be a corresponding witness relation. That is, if* $S \in \mathrm{Ntime}(t(\cdot))$*, then we refer to a* polynomial-time decidable *relation* R *satisfying* $x \in S$ *if and only if there exists* w *of length at most* $t(|x|)$ *such that* $(x, w) \in R$*. We consider the following auxiliary properties:*

Relatively efficient oracle construction. This property holds if there exists a polynomial-time algorithm P *such that, given any* $(x, w) \in R$*, algorithm* P *outputs an oracle* π_x *that makes* V *always accept (i.e., as in the completeness condition).*

Nonadaptive verifier. This property holds if the verifier's queries are determined based only on the input and its internal coin tosses, independently of the answers given to previous queries. That is, V *can be decomposed into a pair of algorithms* Q *and* D *such that on input* x *and random tape* r*, the verifier makes the query sequence* $Q(x, r, 1), Q(x, r, 2), \ldots, Q(x, r, p(|x|))$*, obtains the answers* $b_1, \ldots, b_{p(|x|)}$*, and decides according to* $D(x, r, b_1 \cdots b_{p(|x|)})$*, where* p *is some fixed polynomial.*

Efficient reverse sampling. This property holds if there exists a probabilistic polynomial-time algorithm S *such that, given any string* x *and integers* i *and* j*, algorithm* S *outputs a uniformly distributed* r *that satisfies* $Q(x, r, i) = j$*, where* Q *is as defined in the previous item.*

A proof-of-knowledge property. This property holds if there exists a probabilistic polynomial-time oracle machine E such that the following holds:[13] *for every x and π, if $\Pr[V^\pi(x) = 1] > \epsilon(|x|)$, then there exists $w = w_1 \cdots w_t$ such that $(x, w) \in R$ and $\Pr[E^\pi(x, i) = w_i] > 2/3$ holds for every $i \in [t]$.*

Nonadaptive PCP verifiers were explicitly considered in several works, and in fact in some sources PCP is defined in terms of nonadaptive verifiers. (Needless to say, almost all PCP systems use nonadaptive verifiers.) The oracle-construction and proof-of-knowledge properties are implicit in some works, and are known to hold for many PCP systems (although we are not aware of a text that contains a proof of this fact). To the best of our knowledge, the reverse-sampling property was not considered before. Nevertheless, it can be verified that any $S \in \mathcal{NEXP}$ has a PCP system that satisfies all of the foregoing properties.

THEOREM 3.3. *For every $S \in \mathcal{NEXP}$ and for every $\epsilon : \mathsf{N} \to [0, 1]$ such that for some positive polynomial p it holds that $\epsilon(n) > 2^{-p(n)}$ for all n, there exists a PCP system with error ϵ for S such that this PCP satisfies the four properties listed in Definition* 3.2.

Proof sketch. For $S \in \mathrm{Ntime}(t(\cdot))$, we consider the $\mathcal{PCP}_{1/2}[O(\log t(\cdot)), \mathrm{poly}(\cdot)]$ system presented by Babai et al. [5] (i.e., the starting point of Arora et al. [2, 1]). (We stress that this PCP system, unlike the one of Feige et al. [14], uses oracles of length polynomial in t.) This PCP system is evidently nonadaptive, and it is well known to satisfy the oracle-construction property. It is also known (alas less known) that this PCP system satisfies the proof-of-knowledge property. Finally, it is easy to see that this PCP system (as well as any reasonable PCP system we know of) also satisfies the reverse-sampling property.[14] *Further details regarding the proof of all of the foregoing facts can be found in Appendix* A. Thus, we obtain a PCP system with error $1/2$ (for S) that satisfies all of the auxiliary properties listed in Definition 3.2. To obtain the desired error of ϵ, we apply straightforward error reduction, while noting that this process does not affect the oracle, and so the resulting (error-reduced) PCP preserves all of the auxiliary properties. □

3.3. The actual construction. The construction is an adaptation of Kilian's construction [21] (used also by Micali [23]). Using Theorem 3.3, we start with a PCP system with error $\epsilon(n) = 2^{-n}$ for $S_{\mathcal{U}}$ that satisfies the auxiliary properties in Definition 3.2. Actually, the corresponding witness relation will not be $R_{\mathcal{U}}$ as defined in section 1.2 but rather a minor modification of it, denoted $R'_{\mathcal{U}}$: the pair $((M, x, t), (w, 1^{t'}))$ is in $R'_{\mathcal{U}}$ if M accepts (x, w) in $t' \leq t$ steps. (The purpose of the modification is to obtain a relation that is decidable in polynomial time, as required in Definition 3.2.) Let V_{pcp} denote the aforementioned PCP system (or rather its verifier) and $P_{\mathrm{pcp}}, Q_{\mathrm{pcp}}, D_{\mathrm{pcp}}, S_{\mathrm{pcp}}$, and E_{pcp} denote the auxiliary algorithms (or machines) guaranteed by Definition 3.2 (i.e., P_{pcp} is the oracle-constructing procedure, Q_{pcp} determines the verifier's queries, D_{pcp} describes the verifier's final decision, S_{pcp} provides reverse sampling, and E_{pcp} is the "witness extractor" guaranteed in the proof-of-knowledge property).

[13] For negligible ϵ (as used below), this proof-of-knowledge property is stronger than the *standard* proof-of-knowledge property (as in [9] and [16, section 4.7.1]). Indeed, the proof-of-knowledge property in Definition 3.2 is analogous to the definition of a *strong* proof-of-knowledge (as in [16, section 4.7.6]).

[14] This property follows from the structure of the standard PCP systems. In our case, the system consists of a *sum check* (Lund et al. [22]) and a *low-degree test*. In both tests, the queries are selected in a very simple manner, and what is complex (at least in the case of low-degree tests) is the analysis of the test.

A second ingredient used in the construction is a family of *collision-resistant hashing* functions. That is, a collection of (uniformly polynomial-time computable) functions $\{h_\alpha : \{0,1\}^* \to \{0,1\}^{|\alpha|}\}$ such that for every (nonuniform) family of polynomial-size circuits $\{C_n\}_{n\in\mathsf{N}}$

$$\Pr_{\alpha\in\{0,1\}^n}[C_n(\alpha) = (x,y) \text{ s.t. } x \neq y \text{ and } h_\alpha(x) = h_\alpha(y)] = \mu(n),$$

where μ is a negligible function. Such families can be constructed based on, for example, the conjectured intractability of factoring (integers); see, e.g., [17, section 6.2.3].

CONSTRUCTION 3.4 (a universal argument for $S_{\mathcal{U}}$).

Common input: $y = (M, x, t)$, *supposedly in* $S_{\mathcal{U}}$. *Let* $n \stackrel{\text{def}}{=} |y|$.

Auxiliary input to the prover: w *such that supposedly* $(y, w) \in R_{\mathcal{U}}$ *holds.*

First verifier step (V1): *Uniformly select* $\alpha \in \{0,1\}^n$ *and send it to the prover.*

First prover step (P1): *When describing the prover's actions, we assume that* $(y, w) \in R_{\mathcal{U}}$.

1. Preliminary action by the prover. *The prover invokes* M *on input* (x, w) *and obtains* $t' = T_M(x, w)$. *Assuming that* $(y, w) \in R_{\mathcal{U}}$ *and letting* $w' = (w, 1^{t'})$, *the prover obtains an* $R'_{\mathcal{U}}$*-witness; that is,* $(y, w') \in R'_{\mathcal{U}}$.
2. Oracle construction. *Invoking* P_{pcp} *on* (y, w'), *the prover obtains* $\pi_y = P_{\text{pcp}}(y, w')$.

   Assume without loss of generality that $|\pi_y|$ *is a power of* 2, *and let* $d \stackrel{\text{def}}{=} \log_2 |\pi_y|$.
3. Construction of a hashing tree. *The prover constructs a binary tree of depth* d *and associates its nodes with binary strings of length at most* d *such that the root is associated with the empty string, and an internal node associated with* γ *has children associated with* $\gamma 0$ *and* $\gamma 1$. *Using the oracle* π_y (*just constructed*) *and the hashing function* h_α (*sent by the verifier*), *the prover* labels *the nodes of this tree as follows:*
   - *The* label of a leaf *associated with* $\gamma \in \{0,1\}^d$ *is the value of* π_y *at position* γ; *that is, this label denoted by* ℓ_γ *equals the answer of the oracle* π_y *to the query* γ.
   - *The* label of an internal node *associated with* $\gamma \in \cup_{i=0}^{d-1}\{0,1\}^i$ *is the value obtained by applying* h_α *to the string* $\ell_{\gamma 0}\ell_{\gamma 1}$. *This label is denoted by* ℓ_γ.

   Thus, the label of the node associated with $\gamma \in \cup_{i=0}^{d}\{0,1\}^i$ *is denoted by* ℓ_γ.
4. The actual message sent *by the prover is the depth of the tree and the label of its root. That is, the prover sends the pair* (d, ℓ_λ) *to the verifier.*

Second verifier step (V2). *The verifier selects uniformly a random tape* r *for the PCP system and sends* r *to the prover.*

Second prover step (P2). *The prover provides the corresponding* (PCP) *answers, augmented by* proofs of the consistency *of these answers with the label of the root as provided in step* (P1).

1. Determining the queries. *Invoking* Q_{pcp}, *the prover determines the sequence of queries that the PCP system makes on a random tape* r. *That is, for* $i = 1, \ldots, m$, *it computes* $q_i = Q_{\text{pcp}}(y, r, i)$, *where* $m \stackrel{\text{def}}{=} \text{poly}(n)$ *is the number of queries made by the system.*
2. The message sent. *For* $i = 1, \ldots, m$ *and* $j = 0, \ldots, d-1$, *the prover sends the pair* $(\ell_{\gamma_{i,j}0}, \ell_{\gamma_{i,j}1})$, *where* $\gamma_{i,j}$ *is the* j*-bit long prefix of* q_i. (Note that this message contains, for every $i \in [m]$, the value of ℓ_{q_i} as

well as information that enables the authentication of this value with respect to ℓ_λ.)

Verifier final decision step (V3): *The verifier checks that the answers provided by the prover would have been accepted by the PCP verifier and that the corresponding proofs of consistency (with the label of the root) are valid. That is, denoting by ℓ'_γ the label provided by the prover for the node associated with γ, the verifier accepts if and only if all of the following checks pass:*

1. *Invoking D_{pcp}, the verifier checks whether, on input y and random tape r, the PCP verifier would have accepted the answer sequence $\ell'_{q_1}, \ldots, \ell'_{q_m}$, where $q_i = Q_{\mathrm{pcp}}(y, r, i)$ (as in step (P2)). That is, it checks whether $D_{\mathrm{pcp}}(y, r, \ell'_{q_1} \cdots \ell'_{q_m}) = 1$, where r is the random tape chosen in step (V2).*
2. *Check whether the labels provided are consistent with the label of the root of the tree as sent in step P1. That is, for $i = 1, \ldots, m$ and $j = 0, \ldots, d-1$, check whether $\ell'_{\gamma_{i,j}} = h_\alpha(\ell'_{\gamma_{i,j}0}\ell'_{\gamma_{i,j}1})$, where $\gamma_{i,j}$ is the j-bit long prefix of q_i and $\ell'_\lambda \stackrel{\mathrm{def}}{=} \ell_\lambda$.*

We denote the foregoing verifier and prover strategies by V and P, respectively.

We highlight the fact that Construction 3.4 uses a constant number of rounds and is of the public-coin type. Furthermore, Construction 3.4 satisfies the first two requirements of Definition 2.1; that is, the verifier's strategy is implementable in probabilistic polynomial time, and completeness holds with respect to a prover strategy that (when given $y = (M, x, t)$ and w as above) runs in time polynomial in $T_M(x, w)$. We thus focus on establishing the two last requirements of Definition 2.1. In fact, computational soundness follows from the weak proof-of-knowledge property, because if some adversary can convince the verifier to accept y with nonnegligible probability, then the extractor (given oracle access to that adversary) outputs a valid witness for membership of y in $S_{\mathcal{U}}$ (which implies that y is indeed in $S_{\mathcal{U}}$). Thus, it suffices to establish the latter.

3.4. Establishing the weak proof-of-knowledge property. This subsection contains the main technical contribution of the current section. The novel aspect in the analysis is the use of a "local definition of a conflict" (i.e., considering conflicting values for individual oracle bits rather than conflicting values for the entire oracle) and the use of reverse sampling for deriving (in polynomial time) hashing collisions when given a conflict on any bit position in the oracle.

LEMMA 3.5. *Construction 3.4 satisfies the weak proof-of-knowledge property of Definition 2.1, provided that the family $\{h_\alpha\}$ is indeed collision-resistant.*

Combining Lemma 3.5 with the foregoing discussion, we establish Theorem 1.1.

Proof. Fixing any polynomial p, we present a probabilistic polynomial-time knowledge extractor that extracts witnesses from any feasible prover strategy that makes V accept with probability above the threshold specified by p. Specifically, for any family of (deterministic) polynomial-size circuits representing a possible prover strategy and for all sufficiently long y's, if the prover convinces V to accept y with probability at least $1/p(|y|)$, then, with noticeable probability (i.e., $1/p'(|y|)$), the knowledge extractor (given oracle access to the strategy) outputs the bits of a corresponding witness. ∎

We fix an arbitrary family $\{\widetilde{P}_n\}_{n\in\mathsf{N}}$ of (deterministic) polynomial-size circuits representing a possible prover strategy and a generic n and $y \in \{0,1\}^n$ such that $\Pr[(\widetilde{P}_n, V)(y) = 1] > \varepsilon \stackrel{\mathrm{def}}{=} 1/p(n)$. We consider a few key notions regarding the interaction of $\widetilde{P}_n$ and the designated verifier V on common input y. First, we consider

notions that refer to a specific interaction (corresponding to a fixed sequence of verifier coins, which consists of a pair of choices (α, r) that the verifier takes in steps (V1) and (V2), respectively):

- The ith *query* in such an interaction is $q_i = Q_{\mathrm{pcp}}(y, r, i)$, where r is the step (V2) message.
- The ith *answer* supplied by (the prover) $\widetilde{P}_n$ is the label (i.e., ℓ'_{q_i}) that the prover has provided (in step (P2)) for the leaf (associated with) the ith query (i.e., $q_i = Q_{\mathrm{pcp}}(y, r, i)$). The *corresponding authentication* is the corresponding sequence of pairs $\langle(\ell'_{\gamma_{i,j}0}, \ell'_{\gamma_{i,j}1}) : j = 0, \ldots, d-1\rangle$, where $\gamma_{i,j}$ is the j-bit long prefix of q_i.
  Note that the various parts of the prover's message in step (P2) are a function of α and r, and thus the notation ℓ'_γ is actually a shorthand for $\ell'_\gamma(\alpha, r)$.
- The ith answer supplied by $\widetilde{P}_n$ is said to be *proper* if the corresponding authentication passes the verifier's test (in step (V3)); that is, $\ell'_{\gamma_{i,j}} = h_\alpha(\ell'_{\gamma_{i,j}0}\ell'_{\gamma_{i,j}1})$ holds, for $j = 0, \ldots, d-1$ (where $\gamma_{i,j}$ is as described above and $\ell'_\lambda \stackrel{\mathrm{def}}{=} \ell_\lambda$).

Next, we consider the probability distribution induced by the verifier's coins. Note that these coins consist of the pair of choices (α, r) that the verifier takes in steps (V1) and (V2), respectively. Fixing any $\alpha \in \{0,1\}^n$, we consider the conditional probability denoted by $p_{y,\alpha}$ that the verifier accepts y when choosing α as step (V1). Clearly, for at least an $\varepsilon/2$ fraction of the possible α's, it holds that $p_{y,\alpha} \geq \varepsilon/2$. We fix any such α for the rest of the discussion. We now consider notions that refer to the residual probability space induced by a uniformly distributed $r \in \{0,1\}^{\mathrm{poly}(n)}$ (as selected by the verifier in step (V2)).

- For a query value $q \in \{0,1\}^d$, a query index $i \in [m]$, a possible answer $\sigma \in \{0,1\}$, and a parameter $\delta \in [0,1]$, we say that σ *is δ-strong for* (i, q) if, conditioned on the ith query being q, the probability that $\widetilde{P}_n$ *properly answers* the ith query with σ is at least δ. That is,

$$\Pr_r[\ell'_q = \sigma \text{ is proper} \mid q = Q_{\mathrm{pcp}}(y, r, i)] \;\geq\; \delta\,,$$

  where $\ell'_q = \ell'_{Q_{\mathrm{pcp}}(y,r,i)}(\alpha, r)$ as well as its being proper are determined based on α and r.
  When i and q are understood from the context, we just say that σ is a δ-strong answer.
- We say that a query $q \in \{0,1\}^d$ has *δ-conflicting answers* if there exist i and j (possibly $i = j$) such that 0 is δ-strong for (i, q) and 1 is δ-strong for (j, q).

We stress that throughout the rest of the analysis we consider a fixed $\alpha \in \{0,1\}^n$ and a uniformly distributed $r \in \{0,1\}^{\mathrm{poly}(n)}$.

Our goal is to show that if $p_{y,\alpha} \geq \varepsilon/2$, then we can extract a witness for y by using $\widetilde{P}_n$. We first show that using $\widetilde{P}_n$, we can reconstruct an adequate PCP oracle that convinces V_{pcp} (with probability at least $\mathrm{poly}(\varepsilon)$), although the strategy of $\widetilde{P}_n$ need not be consistent with any such oracle. That is, although a priori the strategy of $\widetilde{P}_n$ may answer queries in an inconsistent fashion, we shall show that in order to be convincing the answers of $\widetilde{P}_n$ must be "essentially" consistent.

As a preparation to the oracle reconstruction procedure, we first show (in Claim 3.5.1) that answers that are not adequately strong are quite rare (because

they are useless for convincing V). Indeed, the oracle reconstruction will be based on adequately strong answers (i.e., answers that appear frequently in interactions). Next, we show (via Claim 3.5.2) that reconstructing the oracle based on strong answers is essentially well-defined, because queries that have conflicting answers (which are both adequately strong) occur rarely in the interaction.

CLAIM 3.5.1. *The probability that the verifier accepts while receiving only δ-strong answers is at least $p_{y,\alpha} - m\delta$.*

(Recall that m is the number of queries asked by the PCP verifier V_{pcp}.) Thus, picking $\delta = p_{y,\alpha}/2m$, we may focus on the case that all of the prover's answers are δ-strong (since this case occurs with nonnegligible probability).

Proof. The key observation is that whenever the verifier accepts, it is the case that all answers are proper. Intuitively, answers that are not δ-strong (i.e., are rarely proper) are unlikely to appear in such interactions. Specifically, we just upper bound the probability that, for a uniformly distributed r, there exists $i \in [m]$ such that the answer $\ell'_{Q_{\mathrm{pcp}}(y,r,i)}$ is proper but not δ-strong for $(i, Q_{\mathrm{pcp}}(y,r,i))$. Fixing any i and any possible value of q_i, by definition (of being proper but not δ-strong), the probability that the answer ℓ'_{q_i} is proper but not δ-strong for (i,q_i) is smaller than δ. Averaging over the possible values of q_i (as emerging from $Q_{\mathrm{pcp}}(y,\cdot,i)$) and taking a union bound over all $i \in [m]$, the claim follows. □

CLAIM 3.5.2. *There exists a probabilistic polynomial-time oracle machine that, for any δ, given α and oracle access to $\widetilde{P}_n$, finds collisions with respect to h_α with a success probability that is polynomially related to δ/m and to the probability that the verifier makes a query that has δ-conflicting answers. That is, let η_α denote the probability that* (after choosing α in step (V1)) *the verifier makes a query that has δ-conflicting answers. Then, the probability of finding a collision* (i.e., $z' \neq z''$ such that $h_\alpha(z') = h_\alpha(z'')$) *is at least $\eta_\alpha \delta^2/m^3$.*

Thus, on a typical α (or rather on all but a negligible fraction of the α's) and for $\delta > 1/\mathrm{poly}(n)$, the quantity η_α must be negligible, because otherwise we derive a contradiction to the collision-resistant hypothesis of the family $\{h_\alpha\}$. Consequently, for $\delta = p_{y,\alpha}/2m > 1/\mathrm{poly}(n)$, we may focus on the case that the prover's answers are not $(\delta/2)$-conflicting.

Proof. We uniformly select $r \in \{0,1\}^{\mathrm{poly}(n)}$ and $i \in [m]$, hoping that $q_i = Q_{\mathrm{pcp}}(y,r,i)$ is δ-conflicting (which is the case with probability at least η_α/m). Uniformly selecting $i', i'' \in [m]$, and invoking the reverse-sampling algorithm S_{pcp} on inputs (y,i',q_i) and (y,i'',q_i), respectively, we obtain uniformly distributed r' and r'' that satisfy $q_i = Q_{\mathrm{pcp}}(y,r',i')$ and $q_i = Q_{\mathrm{pcp}}(y,r'',i'')$. We now invoke $\widetilde{P}_n$ twice, feeding it with α and r' (resp., α and r'') in the first (resp., second) invocation. Assuming that q_i is δ-conflicting, with probability at least $(\delta/m)^2$, both answers to q_i will be proper but with opposite values. Thus, with probability at least $(\eta_\alpha/m)\cdot(\delta/m)^2$, we have obtained two different *proper* answers to the same query q_i. In such a case, the authentication information corresponding to these two (proper) answers yields a collision under h_α because of the following considerations:

- Both answers to query q_i are authenticated with respect to the same pair (d, ℓ_λ) that was sent by $\widetilde{P}_n$ in step (P1). Note that these different values are provided as the label of the (same) leaf associated with the string $q_i \in \{0,1\}^d$.
- Each of the different values for the same leaf (associated with q_i) is authenticated with respect to the same value of the root (i.e., ℓ_λ). This means that a collision under h_α must occur somewhere along the path from the leaf to the root. The details follow.

Recall that when invoked with input α and r' (resp., α and r''), the circuit $\widetilde{P}_n$ provides authenticating information corresponding to the leaf q_i. This information takes the form of a sequence of pairs $\langle(\ell'_{\gamma_{i,j}0}, \ell'_{\gamma_{i,j}1}) : j = 0, \ldots, d-1\rangle$ (resp., $\langle(\ell''_{\gamma_{i,j}0}, \ell''_{\gamma_{i,j}1}) : j = 0, \ldots, d-1\rangle$), where $\gamma_{i,j}$ denotes the j-bit long prefix of q_i. Note that $\ell'_{q_i} \neq \ell''_{q_i}$ (i.e., the answers to q_i are different), while $\ell'_\lambda = \ell_\lambda = \ell''_\lambda$ (since both sequences refer to the same root value ℓ_λ). Thus, there exists a $j \in \{0, \ldots, d-1\}$ such that $\ell'_{\gamma_{i,j}} = \ell''_{\gamma_{i,j}}$ and $\ell'_{\gamma_{i,j+1}} \neq \ell''_{\gamma_{i,j+1}}$. It follows that $h_\alpha(\ell'_{\gamma_{i,j}0}\ell'_{\gamma_{i,j}1}) = \ell'_{\gamma_{i,j}} = \ell''_{\gamma_{i,j}} = h_\alpha(\ell''_{\gamma_{i,j}0}\ell''_{\gamma_{i,j}1})$ but $\ell'_{\gamma_{i,j}0}\ell'_{\gamma_{i,j}1} \neq \ell''_{\gamma_{i,j}0}\ell''_{\gamma_{i,j}1}$.

The claim follows. □

Suppose for a moment that (for $\delta = p_{y,\alpha}/2m$) *all* of the prover's answers are δ-strong, but none is $(\delta/2)$-conflicting. Then, we can use the prover's answers in order to construct (and not merely claim the existence of) an oracle for the PCP system that makes V_{pcp} accept with probability at least $p_{y,\alpha}/2$. Specifically, let the qth bit of the oracle be σ if and only if there exists an i such that σ is δ-strong for (i, q). This setting of the oracle bits can be determined in probabilistic polynomial time by using the reverse-sampling algorithm S_{pcp} to generate multiple samples of interactions in which these specific oracle bits are queried. Specifically, we want to determine the qth bit we generate, for every $i \in [m]$, multiple samples of interactions in which the ith oracle query equals q and determine the answer by using the gap provided by the hypothesis that for some i there is an answer that is δ-strong for (i, q), whereas (by the nonconflicting hypothesis) for every j the opposite answer is not $(\delta/2)$-strong for (j, q).

Recall that the foregoing outline relies on the simplifying assumption by which *all* of the prover's answers are δ-strong, but none is $(\delta/2)$-conflicting. In general, some queries may either have no strong answers or be conflicting (although these cases will occur rarely). In such a case, the procedure may fail to recover the corresponding entries in the PCP oracle, but this will not matter much (because with sufficiently high probability the PCP verifier will not query these badly recovered locations).

The oracle-recovery procedure. We present a probabilistic polynomial-time oracle machine that, on input (y, α) and $q \in \{0,1\}^d$ and oracle access to the prover $\widetilde{P}_n$, outputs a candidate for the qth bit of a PCP oracle. The procedure operates as follows, where $T \stackrel{\text{def}}{=} \text{poly}(n/\delta)$ and $\delta = \varepsilon/4m$:

1. For $i = 1, \ldots, m$ and $j = 1, \ldots, T$, invoke S_{pcp} on input (y, i, q) and obtain $r_{i,j}$.
2. For $i = 1, \ldots, m$ and $j = 1, \ldots, T$, invoke $\widetilde{P}_n$, feeding it with α and $r_{i,j}$, and if the ith answer is proper, then *record* (i, j) *as supporting this answer value.*
3. If for some $i \in [m]$, there are $(2\delta/3) \cdot T$ records for the form $(i, \cdot)$ supporting the value $\sigma \in \{0,1\}$, then define σ as a *candidate.* That is, σ is a *candidate* if there exists an i and at least $(2\delta/3) \cdot T$ different j's such that the ith answer of $\widetilde{P}_n(\alpha, r_{i,j})$ is proper and has value σ.
4. If a single value of $\sigma \in \{0,1\}$ is defined as a candidate, then set the qth bit accordingly. (Otherwise, do whatever you please.)

We call the query q *good* if it does not have $(\delta/2)$-conflicting answers and there exists an $i \in [m]$ and a bit value that is δ-strong for (i, q). As shown below, for a good query, with overwhelmingly high probability, the foregoing procedure will define the latter value as a unique candidate (less than $(\delta/2) \cdot T$, for every i'). Let us denote the PCP oracle induced by the above procedure by π.

CLAIM 3.5.3. *Let $\delta = \varepsilon/4m$, and recall that $p_{y,\alpha} \geq \varepsilon/2$. Suppose that the probability that V makes a query that has $(\delta/2)$-conflicting answers is at most $p_{y,\alpha}/4$. Then, with probability at least $1-2^{-n}$ taken over the reconstruction of π, the probability that ${V_{\mathrm{pcp}}}^{\pi}(y)$ accepts is lower bounded by $p_{y,\alpha}/4$.*

Proof. By definition, for each good query q, there exist $i \in [m]$ and $\sigma \in \{0,1\}$ such that σ is δ-strong for (i,q), whereas (for every i') the opposite bit $\bar{\sigma}$ is not $\delta/2$-strong for (i',q). It follows that, with probability at least $1-2^{-n^2}$, the bit σ is declared (in step 3) a candidate for the qth oracle bit, because each invocation of $\widetilde{P}_n(\alpha, S_{\mathrm{pcp}}(y,i,q))$ supports σ with probability at least δ. Similarly, with probability at least $1-m\cdot 2^{-n^2}$, the bit $\bar{\sigma}$ is not declared a candidate (for the qth oracle bit), because for every i' each invocation of $\widetilde{P}_n(\alpha, S_{\mathrm{pcp}}(y,i',q))$ supports $\bar{\sigma}$ with probability at most $\delta/2$. Thus, with probability at least $1-|\pi|\cdot(m+1)\cdot 2^{-n^2} > 1-2^{-n}$, the oracle π reconstructed by the procedure is such that for every good q the qth bit of π equals the (single) answer that is δ-strong. Combining the hypothesis (regarding $(\delta/2)$-conflicting answers) with Claim 3.5.1, we conclude that with probability at least $(p_{y,\alpha}-m\delta)-(p_{y,\alpha}/4) \geq p_{y,\alpha}/4$, taken solely over the choice of the random tape r, the verifier (of the interactive argument) accepts while making only good queries and receiving only δ-strong answers. Fixing any such random tape r and recalling that the (interactive argument) verifier V accepts only if V_{pcp} accepts the answers that V obtained, we conclude that in the latter case (i.e., when r is such that V accepts while making only good queries and receiving only δ-strong answers) it holds that ${V_{\mathrm{pcp}}}^{\pi}$ accepts too (when using the same r). The claim follows. □

Note that so far we have analyzed the behavior of the oracle-recovery procedure with respect to individual α's. Specifically, Claim 3.5.3 asserts that in some cases (i.e., those satisfying the claim's hypothesis) the procedure succeeds (i.e., yields an adequate oracle), whereas Claim 3.5.2 asserts that in the remaining relevant cases one can form collisions under the corresponding hashing function. Using the hypothesis that the family of hashing functions is collision-resistant, we infer that typically (i.e., for a random α) the oracle-recovery procedure works well. The details follow.

We call α *useful* if it satisfies the hypothesis of Claim 3.5.3 (i.e., if $p_{y,\alpha} \geq \varepsilon/2$ and the probability that V makes a query that has $(\varepsilon/8m)$-conflicting answers is at most $p_{y,\alpha}/4$). Indeed, Claim 3.5.3 asserts that, *for any useful α, with probability at least $1-2^{-n}$, the oracle-recovery procedure yields an oracle π such that ${V_{\mathrm{pcp}}}^{\pi}(y)$ accepts with probability at least $p_{y,\alpha}/4 \geq \varepsilon/8$.* By Claim 3.5.2, if the main hypothesis of Claim 3.5.3 does not hold (for α), then a collision (w.r.t. h_α) is formed with probability at least $(p_{y,\alpha}/4)\cdot(\varepsilon/8m)^2/m^3$. Thus, with overwhelmingly high probability over the choice of α, either $p_{y,\alpha}$ is negligible or the main hypothesis of Claim 3.5.3 holds for α. Recalling that $p_{y,\alpha} \geq \varepsilon/2$ with probability at least $\varepsilon/2$ (over the choices of α), it follows that in such a case the hypothesis of Claim 3.5.3 may fail only with negligible probability (for such a random α). We conclude that *a random α is useful with probability at least $(\varepsilon/2)-\mu(n) > \varepsilon/4$.*

So far we showed that if the interactive argument accepts with nonnegligible probability, then with similar probability we can reconstruct an oracle that convinces the PCP verifier with nonnegligible probability. The weak proof-of-knowledge property (of the interactive argument) now follows from the corresponding property of the PCP system. Specifically, combining the PCP extractor with the foregoing oracle-recovery procedure, we obtain the desired extractor (detailed next).

Extractor for the argument system. On input (y,i), where $y=(M,x,t)$ and $i \in [t]$, and access to a prover strategy $\widetilde{P}_n$, the extractor operates as follows (using $\delta = \varepsilon/4m$):

1. Uniformly select $\alpha \in \{0,1\}^n$, hoping that α is useful (which holds with probability at least $\varepsilon/4$). Fix α for the rest of the discussion.
2. Uniformly select coins ω for the oracle-recovery procedure, and fix ω for the rest of the discussion. Note that the oracle-recovery procedure (implicitly) provides oracle access to a PCP oracle π, which is determined by ($\widetilde{P}_n$, y, α, and ω).

   We say that ω is α-*useful* if the foregoing oracle-recovery procedure defines an oracle π such that ${V_{\rm pcp}}^{\pi}(y)$ accepts with probability at least $\varepsilon/8$. Recall that, by Claim 3.5.3, if α is useful, then, with probability at least $1-2^{-n}$, a random ω is α-useful.
3. Invoke $E_{\rm pcp}(y,i)$, providing it with oracle access to π. This means that each time $E_{\rm pcp}(y,i)$ makes a query q, we invoke the oracle-recovery procedure on input (y,q) (and with α and ω as fixed above) and obtain the qth bit of π, which we return as an answer to $E_{\rm pcp}(y,i)$. When $E_{\rm pcp}(y,i)$ provides an answer (supposedly the ith bit of a suitable witness w for y), we just output this answer.

Recall that if α is useful, and ω is α-useful, then with probability at least $2/3$ (over the coins of $E_{\rm pcp}$), the output of $E_{\rm pcp}$ (and thus of our extractor) will be correct (i.e., will yield the desired bit of a fixed witness for y). This follows by the proof-of-knowledge property of the PCP system, which refers to convincing $V_{\rm pcp}$ with probability at least 2^{-n}, while here $V_{\rm pcp}$ is convinced with probability at least $\varepsilon/8 > 2^{-n}$. Using suitable amplification, we can obtain (for each bit in the witness) the correct answer with probability at least $1-2^{-2n}$ (over the coins of $E_{\rm pcp}$), depending again on α and ω being useful. Denoting the coins of the amplified $E_{\rm pcp}$ by ρ, we infer that, for at least a fraction $1-t\cdot 2^{-2n} \geq 1-2^{-n}$ of the possible ρ's, the amplified $E_{\rm pcp}$ provides correct answers *for each of the possible t-bit locations*. We call such ρ's (α,ω)-*useful*.

Let us denote the foregoing extractor by E. The running time of E is dominated by the running time of the oracle-recovery procedure, whereas the latter is dominated by the $\mathrm{poly}(n/\varepsilon)$ invocations of $\widetilde{P}_n$ (during the oracle-recovery procedure). Using $\varepsilon = 1/p(n)$, it follows that E runs in polynomial time (specifically, the running time is polynomial in n and $p(n)$). The random choices of E correspond to the above three steps; that is, they consist of α, ω, and ρ. Whenever they are all useful (i.e., α is useful, ω is α-useful, and ρ is (α,ω)-useful), the extractor E recovers correctly each of the bits of a suitable witness (for y). The event in the condition (i.e., α, ω, and ρ being adequately useful) occurs with probability at least $(\varepsilon/4)\cdot(1-2^{-n})\cdot(1-2^{-n}) > \varepsilon/5 = 1/5p(n)$. Letting $p'(n) = 5p(n)$, the lemma follows. □

4. Application to zero-knowledge arguments. Using Theorem 1.1, we prove Theorem 1.2 in two steps:

1. Using any constant-round public-coin universal argument, we derive one that is witness indistinguishable. Here we follow the paradigm of "encrypted interactions" (introduced in [10] and also used in Barak's paper [6]). The construction and its analysis, which appear in section 4.1, differ from prior versions that appeared (or are outlined) in [8, 7, 17].
2. Using the result of the first step, we modify Barak's main construction [6] of a zero-knowledge argument (for any $S \in \mathcal{NP}$) such that it can be analyzed based on standard collision-resistant hashing. Specifically, rather than using any collision-resistant hashing (for the very first message in his protocol), we use tree hashing (as in step (P1) of Construction 3.4) composed with an error-correcting code. The construction and its analysis appear in section 4.2.

The reasons for the various modifications will be discussed in the corresponding subsections. But before turning to the constructions, we stress that the notion of witness indistinguishability (which is typically applied to proofs/argument systems for specific sets in $\mathcal{NP}$) needs to be redefined when applied to universal arguments. Specifically, this property should apply to any "fragment" of $R_{\mathcal{U}}$ that can be recognized in time that is polynomial in the length of the common input (where the polynomial is fixed after the universal argument system is specified). That is, we refer to the following definition.

DEFINITION 4.1 (witness indistinguishable universal argument). *A universal argument system (P,V) is called witness indistinguishable (WI) if, for every polynomial p, every polynomial-size circuit family $\{V_n^*\}_{n\in\mathsf{N}}$, and every three sequences $\langle y_n=(M_n,x_n,t_n):n\in\mathsf{N}\rangle$, $\langle w_n^1:n\in\mathsf{N}\rangle$, and $\langle w_n^2:n\in\mathsf{N}\rangle$ such that $|y_n|=n$, $t_n\leq p(|x_n|)$, and $(y_n,w_n^1),(y_n,w_n^2)\in R_{\mathcal{U}}$, the probability ensembles $\{\langle P(w_n^1),V^*\rangle(y_n)\}_{n\in\mathsf{N}}$ and $\{\langle P(w_n^2),V^*\rangle(y_n)\}_{n\in\mathsf{N}}$ are computationally indistinguishable, where $\langle P(w),V^*\rangle(y)$ denotes the output of V^* when interacting with $P(w)$ on common input y.*

Note the analogy to the discussion at the end of section 1.2 (regarding "natural applications of universal arguments").

4.1. Constructing witness indistinguishable universal arguments. Our starting point is any constant-round, public-coin universal argument (for $S_{\mathcal{U}}$) denoted by $(P_{\mathrm{ua}},V_{\mathrm{ua}})$. For the sake of simplicity, we assume (without loss of generality) that, on any n-bit long common input, each message sent by either parties has length $m=\mathrm{poly}(n)$. Using the public-coin clause this means that the protocol proceeds in rounds, where in each round the verifier selects uniformly an m-bit string, and the prover responds with an m-bit string determined based on its inputs and the messages it has received so far. We denote by c_{ua} the (constant) number of such rounds; in the case of Construction 3.4, $c_{\mathrm{ua}}=2$.

A second ingredient used in the construction is a (constant-round, public-coin) *nonoblivious statistically binding commitment scheme*. Loosely speaking, such a scheme allows a sender to "commit" to a value such that the value remains hidden from the receiver and still the sender is "committed" to this value. Furthermore, "statistically binding" means that, with high probability, if the commitment phase is concluded successfully, then there exists at most one value v that can be later revealed as a proper decommitment, whereas "nonoblivious" means that the sender actually knows this value v. For further discussion see Appendix B, where we also show that such a scheme can be constructed based on the existence of one-way functions. We denote this commitment scheme by $\mathtt{C}$ and the corresponding decommitment verification by $\mathtt{D}$. Furthermore, we denote by $(d,c)\leftarrow\mathtt{C}(v)$ an execution of $\mathtt{C}$ in which the sender enters the value v, the receiver obtains the commitment value c, and the sender obtains corresponding decommitment information d satisfying $\mathtt{D}((v,d),c)=1$. Recall that statistically binding means that, with overwhelmingly high probability, the protocol yields a commitment c such that if for any v,d,v', and d' it holds that $\mathtt{D}((v,d),c)=1$ and $\mathtt{D}((v',d'),c)=1$, then it must be that $v=v'$. The nonoblivious condition means that the sender knows the (at most) one value v for which there exists d such that $\mathtt{D}((v,d),c)=1$ holds; that is, there exists a knowledge extractor (as in the definition of the proofs of knowledge (see, e.g., [16, section 4.7.1])) that can extract from the sender this value v.

A third (and last) ingredient used in the construction is a (constant-round, public-coin) zero-knowledge proof *of constant soundness error* for some NP-complete set. Such a proof system can be constructed based on the existence of one-way func-

tions (see, e.g., [16, Chapter 4, Exercise 20]).[15] Let us denote such a system by $(P_{\rm zk}, V_{\rm zk})$.

The construction presented next is based on an "encrypted" emulation of the execution of the universal argument system $(P_{\rm ua}, V_{\rm ua})$. That is, the prover in our protocol responds to the verifier's messages by sending commitments to the messages that $P_{\rm ua}$ would have sent. This encrypted form of the prover's messages does not impair the new verifier that merely emulates $V_{\rm ua}$, because $V_{\rm ua}$ is of the public-coin type. At the end of the emulation phase, the prover provides a zero-knowledge proof that the committed values correspond to a transcript that $V_{\rm ua}$ would have accepted. The zero-knowledge property of the foregoing protocol is quite intuitive, and so we focus on its weak proof-of-knowledge property. Indeed, the fact that the commitment scheme is nonoblivious is used for extracting the corresponding transcript, but the acceptability of this transcript is guaranteed only when the new prover convinces the new verifier with constant probability (which originates in the constant soundness error of the zero-knowledge proof). To handle any nonnegligible acceptance probability, we repeat the foregoing protocol for a superlogarithmic number of times, where these repetitions are performed in parallel (so to maintain a constant number of rounds). These repetitions do not necessarily preserve the zero-knowledge property of the basic protocol, but they preserve its witness indistinguishability property. The resulting protocol is described next.

CONSTRUCTION 4.2 (a witness indistinguishable universal argument).

Common input: $y = (M, x, t)$, *supposedly in* $S_{\mathcal{U}}$. *Let* $n \stackrel{\rm def}{=} |y|$.

Auxiliary input to the prover: w *such that supposedly* $(y, w) \in R_{\mathcal{U}}$ *holds.*

Part 1. Encrypted emulations of $(P_{\rm ua}, V_{\rm ua})$. *The parties perform* n *parallel emulations of the* $(P_{\rm ua}, V_{\rm ua})$ *protocol, where each emulation is performed in a partially encrypted manner. Specifically, the verifier generates random messages exactly as* $V_{\rm ua}$*, but the prover answers with commitments to the corresponding responses of* $P_{\rm ua}$*. That is, for* $i = 1, \ldots, c_{\rm ua}$*, the parties emulate in parallel* n *copies of the* i*th round of* $(P_{\rm ua}, V_{\rm ua})$ *as follows:*

1. *The verifier selects uniformly at random* $r_i^1, \ldots, r_i^n \in \{0,1\}^m$ *and sends these strings to the prover.*
2. *The prover determines the answers of* $P_{\rm ua}$ *and responds with commitments to them. That is, for* $j = 1, \ldots, n$*, the prover first determines* $a_i^j \leftarrow P_{\rm ua}(y, w; r_1^j, \ldots, r_i^j)$*. Next, the parties invoke* n *parallel executions of* $\mathtt{C}$*, where the prover plays the sender and the verifier plays the receiver, such that the* j*th copy yields the output pair* $(s_i^j, e_i^j) \leftarrow \mathtt{C}(a_i^j)$*. If the verifier detects improper termination in any of these executions, then it halts and rejects.*

Part 2. Proving that $V_{\rm ua}$ accepts in the encrypted emulations. *The parties invoke the proof system* $(P_{\rm zk}, V_{\rm zk})$*, where the prover's goal is proving that the transcripts* $(r_1^j, e_1^j, \ldots, r_{c_{\rm ua}}^j, e_{c_{\rm ua}}^j)$ *generated in Part* 1 *correspond to encryptions* (or rather commitments) *of accepting* $(P_{\rm ua}, V_{\rm ua})$ *transcripts. That is, the parties run* n *parallel copies of* $(P_{\rm zk}, V_{\rm zk})$ *such that, in the* j*th copy, the NP statement being proved refers to the input* $(y, r_1, e_1, \ldots, r_{c_{\rm ua}}, e_{c_{\rm ua}})$ *and asserts that there exists* $((a_1^j, s_1^j), \ldots, (a_{c_{\rm ua}}^j, s_{c_{\rm ua}}^j))$ *such that*

[15] This construct replaces the *strong WI* proof system *of negligible soundness error* assumed in [8]. Unfortunately, contrary to prior misconceptions (cf. [16, section 4.6]), such protocols are not known to exist [17, Appendix C.3]. In fact, in our construction, we may use a *strong WI* proof system *of constant soundness error* (for some NP-complete set), but we do not know of such a protocol that is not zero-knowledge as well.

1. *for* $i = 1, \ldots, c_{\mathrm{ua}}$, *it holds that* $\mathtt{D}((a_i^j, s_i^j), e_i^j) = 1$;
2. $V_{\mathrm{ua}}(y; r_1^j, a_1^j, \ldots, r_{c_{\mathrm{ua}}}^j, a_{c_{\mathrm{ua}}}^j) = 1$.

Needless to say, the prover executes this copy of P_{zk} *using the NP witness* $((a_1^j, s_1^j), \ldots, (a_{c_{\mathrm{ua}}}^j, s_{c_{\mathrm{ua}}}^j))$, *where this sequence of pairs is as determined by it in Part* 1.

Note that the length of the NP statement being proven (*as well as the length of the corresponding NP witness*) *is bounded by a fixed polynomial in* $n + m$ (*and thus by a fixed polynomial in* n).

We denote the above verifier and prover strategies by V *and* P, *respectively.*

Clearly, Construction 4.2 is constant-round and public-coin and satisfies the first two requirements of Definition 2.1; that is, the verifier's strategy is implementable in probabilistic polynomial-time, and completeness holds with respect to a prover strategy that (given $y = (M, x, t)$ and w as above) runs in time polynomial in $T_M(x, w)$. To establish that Construction 4.2 is a WI universal argument, it remains to prove the following two properties of Construction 4.2:

1. the weak proof-of-knowledge property, which in turn implies also the computational soundness property;
2. the witness indistinguishability property (as per Definition 4.1).

We mention that (unlike in [8, Lemma 4.2]) the following proofs do not take advantage of the fact that the basic ingredients are constant-round protocols. We start with the witness indistinguishability property because its proof is significantly simpler.

LEMMA 4.3. *Construction* 4.2 *is WI* (as per Definition 4.1), *provided that* $(P_{\mathrm{zk}}, V_{\mathrm{zk}})$ *is zero-knowledge and that* $\mathtt{C}$ *is computationally hiding.*

Proof. We view Construction 4.2 as the result of n parallel executions of a basic protocol denoted by (P', V') such that (P', V') consists of performing a single encrypted execution of $(P_{\mathrm{ua}}, V_{\mathrm{ua}})$ followed by a (single) execution of $(P_{\mathrm{zk}}, V_{\mathrm{zk}})$, which refers to this encrypted transcript (and is aimed at establishing that this encrypted transcript encodes an accepting transcript of $(P_{\mathrm{ua}}, V_{\mathrm{ua}})$). Intuitively, this basic protocol is zero-knowledge, because it can be simulated by generating dummy commitments and invoking the simulator of $(P_{\mathrm{zk}}, V_{\mathrm{zk}})$ on these commitments. The computational indistinguishability of this simulation from the real execution is argued as follows:

- As a mental experiment, we consider a hybrid distribution in which the simulator of $(P_{\mathrm{zk}}, V_{\mathrm{zk}})$ is invoked on an encrypted transcript of $(P_{\mathrm{ua}}, V_{\mathrm{ua}})$.
- The computationally hiding property of the commitment scheme implies that the output of our simulator (which invokes the simulator of $(P_{\mathrm{zk}}, V_{\mathrm{zk}})$ on dummy commitments) is computationally indistinguishable from the foregoing hybrid distribution (which invokes the same simulator on commitments that correspond to a transcript of $(P_{\mathrm{ua}}, V_{\mathrm{ua}})$).
- By our hypothesis regarding the simulator of $(P_{\mathrm{zk}}, V_{\mathrm{zk}})$, the hybrid distribution is computationally indistinguishable from the real execution of the basic protocol (in which $(P_{\mathrm{zk}}, V_{\mathrm{zk}})$ is invoked on the encrypted transcript of $(P_{\mathrm{ua}}, V_{\mathrm{ua}})$).

Having established the zero-knowledge property of the basic protocol, we conclude that the basic protocol (i.e., (P', V')) is WI (in the sense of Definition 4.1). Furthermore, when confining our attention to common and auxiliary inputs that are admissible as per Definition 4.1, it is the case that P' runs in polynomial time (when given adequate auxiliary inputs). Thus, the witness indistinguishability of P' (on such inputs) is preserved under parallel composition (cf., e.g., [16, section 4.6.2]). The lemma follows. □

LEMMA 4.4. *Construction* 4.2 *satisfies the weak proof-of-knowledge property of Definition* 2.1, *provided that so does* $(P_{\rm ua}, V_{\rm ua})$ *and that* $\mathtt{C}$ *is statistically binding and nonoblivious.*

Proof. Here we decompose Construction 4.2 in a different way, considering Part 1 as a whole and Part 2 as a whole. We start with an overview of the proof. Loosely speaking, the nonoblivious property of the commitment scheme guarantees that we can extract the cleartext version of all encrypted transcripts (of $(P_{\rm ua}, V_{\rm ua})$), but at this point it is unclear whether any of these transcripts is accepting. Using the statistically binding property of the commitment scheme, we distinguish the case that some of these transcripts are accepting from the case that none of them is accepting. Using the (constant error) soundness of $(P_{\rm zk}, V_{\rm zk})$, we infer that the second case (which refers to multiple failures) happens with negligible probability, and so we may ignore it. Thus, either V detects an improper execution of the commitment scheme or we are able to extract an accepting transcript of $(P_{\rm ua}, V_{\rm ua})$. It follows that if V is convinced with some noticeable probability p, then for some $j \in [n]$, with probability at least p/n (or so), the jth transcript is accepting and extractable. At this point the lemma follows by invoking the weak proof-of-knowledge property of $(P_{\rm ua}, V_{\rm ua})$. We now turn to the actual proof.

Fixing an arbitrary prover strategy for Construction 4.2, we shall derive a related strategy for the underlying universal-argument system such that the circuit complexity (resp., the success probability) of the resulting strategy will be related to the circuit complexity (resp., the success probability) of the original strategy. Specifically, let us consider an arbitrary family $\{\widetilde{P}_n\}_{n\in\mathsf{N}}$ of (deterministic) polynomial-size circuits representing a possible prover strategy in the system (P, V). Fixing a generic n and $y \in \{0,1\}^n$, we let $p_y \stackrel{\rm def}{=} \Pr[(\widetilde{P}_n, V)(y) = 1]$. Using $\widetilde{P}_n$, we shall construct a corresponding prover strategy $\widetilde{P_{\rm ua}}$ that makes $V_{\rm ua}$ accept y with probability $\Omega((p_y - \mu(n))/n)$, where μ is some negligible function. Thus, once we are done constructing $\widetilde{P_{\rm ua}}$, the weak proof-of-knowledge property of Construction 4.2 will follow from the weak proof-of-knowledge property of the underlying universal argument system.

We thus turn to constructing $\widetilde{P_{\rm ua}}$, which starts by uniformly selecting $j \in [n]$ and tries to extract the cleartext messages that are encrypted (or rather committed) in the transcript of the jth interaction performed by $\widetilde{P}_n$ in Part 1. Specifically, after selecting j, the strategy $\widetilde{P_{\rm ua}}$ operates in $c_{\rm ua}$ iterations, where in each iteration it obtains from $\widetilde{P}_n$ a sequence of encrypted messages and extracts from it a (cleartext) message that it sends to $V_{\rm ua}$. That is, for $i = 1, \ldots, c_{\rm ua}$, the following occurs:

1. The strategy $\widetilde{P_{\rm ua}}$ obtains from the (real) verifier $V_{\rm ua}$ a (uniformly distributed) string denoted by $r_i \in \{0,1\}^m$.
2. The strategy $\widetilde{P_{\rm ua}}$ selects uniformly $r_i^1, \ldots, r_i^{j-1}, r_i^{j+1}, \ldots, r_i^n \in \{0,1\}^m$ and feeds $r_i^1, \ldots, r_i^{j-1}, r_i, r_i^{j+1}, \ldots, r_i^n$ to $\widetilde{P}_n$, obtaining a residual sender (i.e., a committer) for the current round of executions of the nonoblivious commitment scheme. Using this residual sender and the knowledge extractor guaranteed for the nonoblivious commitment scheme, the strategy $\widetilde{P_{\rm ua}}$ extracts the (unique) cleartext message that may correspond to the jth copy of the current executions of the nonoblivious commitment scheme. (Note that the nonoblivious/proof-of-knowledge property is preserved when the protocol is executed multiple times in parallel.)
3. The strategy $\widetilde{P_{\rm ua}}$ sends the aforementioned answer to the (real) verifier $V_{\rm ua}$.

Note that we do not claim, at this point, that the extracted values correspond to proper decommitments and furthermore that they yield an accepting transcript. At this point we wish only to establish that $\widetilde{P_{\mathrm{ua}}}$ extracts the only values that may be properly decommitted.

We now turn to the analysis of the size of $\widetilde{P_{\mathrm{ua}}}$ and its success probability. These quantities are determined by the size of $\widetilde{P}_n$ and its success probability denoted by p_y. We may indeed focus on the case that p_y is a noticeable function of $n = |y|$ (i.e., $p_y > 1/\mathrm{poly}(n)$). Recall that $\widetilde{P}_n$ executes $c_{\mathrm{ua}} + 1$ subprotocols, where the first c_{ua} protocols are n parallel executions of the nonoblivious commitment scheme and the last protocol consists of n parallel executions of the (constant-error) zero-knowledge proof system. (Indeed, we neglect the fact that each of the first c_{ua} protocols actually consists of a random $n \cdot m$-bit long message sent from the verifier to the prover, followed by n parallel executions of the nonoblivious commitment scheme.)[16] We first prove that, with probability at least $p_y/2$, the entire execution produces a transcript such that for every $i \in \{0, 1, \ldots, c_{\mathrm{ua}}\}$, given the partial transcript of the i previous executions, the next execution is successful with probability at least $p_y/2c_{\mathrm{ua}}$. This follows from the following general claim.

CLAIM 4.4.1. *For a finite set Ω and an integer m, consider an arbitrary $G \subseteq \Omega^m$, and let $\rho = |G|/|\Omega|^m$. For $i \in [m]$, a sequence $(e_1, \ldots, e_m) \in \Omega^m$ is called i-good if $\Pr_{e \in \Omega}[(e_1, \ldots, e_{i-1}, e) \in G_i] \geq \frac{\rho}{2(m-1)}$, where $(e'_1, \ldots, e'_i) \in G_i$ if and only if there exist $e'_{i+1}, \ldots, e'_m \in \Omega$ such that $(e'_1, \ldots, e'_m) \in G$. Then, at least half of the sequences in G are i-good for every $i \in [m]$.*

Needless to say, the foregoing sequences correspond to the executions of the different $m = c_{\mathrm{ua}} + 1$ protocols, and i-good sequences correspond to transcripts in which, given the partial transcript of the $i-1$ previous (successful) executions, the next execution is successful with probability at least $\frac{p_y}{2(m-1)}$. Actually, we give up on execution transcripts that are not fully successful, and yet for every $i \in [c+1]$, given the partial transcript of the $i-1$ previous executions, the next execution is successful with probability at least $\frac{p_y}{2(m-1)}$.

Proof. Let $B_i \stackrel{\mathrm{def}}{=} \{(e_1, \ldots, e_{i-1}) \in \Omega^{i-1} : \Pr_{e \in \Omega}[(e_1, \ldots, e_{i-1}, e) \in G_i] < \rho/2(m-1)\}$ be the set of all $(i-1)$-long prefixes of sequences that are not i-good. Note that $B_1 = \emptyset$, because $\Pr_{e \in \Omega}[e \in G_1] \geq \Pr_{\overline{e} \in \Omega^m}[\overline{e} \in G] = \rho$. Now, on one hand, every sequence in G that has no prefix in $\cup_{i=1}^m B_i$ is i-good for every i. On the other hand, the number of sequences in G that have a prefix in B_i is less than $\frac{\rho}{2(m-1)} \cdot |\Omega|^m$, because each such sequence has an i-long prefix $(e_1, \ldots, e_{i-1}, e_i) \in G_i$, whereas $\Pr_{e \in \Omega}[(e_1, \ldots, e_{i-1}, e) \in G_i] < \rho/2(m-1)$. The claim follows. ∎

Turning back to Construction 4.2, we note that (by Claim 4.4.1) a $p_y/2$ fraction of all executions is fully successful and furthermore each partial transcript of these executions leads to success in the next execution with probability at least $p_y/2c_{\mathrm{ua}}$. Thus, (1) in these executions each of the c_{ua} rounds of nonoblivious commitments is successful with probability at least $p_y/2c_{\mathrm{ua}}$, and (2) the same holds for the interactive proofs that take place in Part 2.

The first foregoing fact implies that (in these executions), for every choice of j and for $i = 1, \ldots, c_{\mathrm{ua}}$, the strategy $\widetilde{P_{\mathrm{ua}}}$ can extract the value committed in the jth copy of the ith iteration of Part 1 (or rather the only value that can be decommitted as such) by invoking $\widetilde{P}_n$ for $\frac{\mathrm{poly}(n)}{p_y/2c_{\mathrm{ua}}}$ times (and failing with negligible probability). Thus, we

[16] This ignored (random) message can be viewed as belonging to the previous subprotocol.

can bound the size of $\widetilde{P_{\rm ua}}$ by $\mathrm{poly}(n)/p_y$ times the size of $\widetilde{P}_n$ and conclude that (in these executions) $\widetilde{P_{\rm ua}}$ answers with messages that equal the values committed in the corresponding executions of $\widetilde{P}_n$ (or rather the only values that can be decommitted as such).

Combining the second foregoing fact, which refers to Part 2, with the constant soundness error of each execution of the proof system, it follows that at least one of the n parallel executions that took place in Part 1 corresponds (i.e., can be properly decommitted) to a $(P_{\rm ua}, V_{\rm ua})$-transcript that is accepting, because otherwise the probability that all of these executions of the interactive proof are successful is at most $s^n \ll p_y/2c_{\rm ua}$, where $s < 1$ denotes the constant soundness error of the proof system. We stress that the proper decommitment requirement guarantees that this transcript corresponds to the messages sent by $\widetilde{P_{\rm ua}}$.

Hence, with probability at least $(p_y/2) - \mu(n) > p_y/3$, for every choice of j, the strategy $\widetilde{P_{\rm ua}}$ sends messages that correspond to the only possible proper decommitments of the corresponding commitment of $\widetilde{P}_n$, and at least one of these n possible transcripts (corresponding to the choice of $j \in [n]$) is accepting. Conditioned on the foregoing, with probability at least $1/n$, the strategy $\widetilde{P_{\rm ua}}$ selects j such that the recovered $(P_{\rm ua}, V_{\rm ua})$-transcript is accepting. We conclude that $\widetilde{P_{\rm ua}}$ convinces $V_{\rm ua}$ with probability at least $p_y/3n$, and the lemma follows. □

Remarks. We stress again that Construction 4.2 is different from the corresponding construction presented in [8]. It is also different from the patch described in [7, Appendix A.4] and the one outlined in [17, Appendix C.3.3]. An important difference is that the current proof of Lemma 4.4 does not rely on the fact that the protocols employed have a constant number of rounds. We also mention that the main analysis of Construction 4.2, which is provided in the proofs of Lemmas 4.3 and 4.4, proceeds by decomposing the construction in two different ways. A similar strategy is employed in Appendix B (see the proof of Claims B.2.1 and B.2.2).

4.2. Modifying Barak's zero-knowledge argument. Here our starting point is any (constant-round, public-coin) strong WI universal argument (for $S_{\mathcal{U}}$) denoted by $(P_{\text{wi-ua}}, V_{\text{wi-ua}})$.

A second ingredient used in the construction is a tree-hashing scheme denoted by $\mathtt{TH}$, as used in Construction 3.4. Loosely speaking, such a scheme can be applied to arbitrary long strings and allows for the verification of the value of a particular bit in the string within time polynomial in the hash value (and possibly polylogarithmic in the length of the string). We stress that the verification does not require presenting the entire string to which the hashing was applied (but rather only auxiliary authentication information that is specific to that bit position). Recall that tree hashing is constructed based on some "basic" hashing function (which maps $2n$-bit strings to n-bit strings), and that conflicting values assigned to any bit position in the tree hashing yield a collision in the basic hashing. Specifically, when using a basic hashing function indexed by α and applying the tree-hashing procedure to an m-bit long string z that is placed at the leaves of the ($\log_2 m$-deep) tree, we denote the resulting label of the root by $\mathtt{TH}_\alpha(z)$ and denote the corresponding sequence of m authenticators by $\mathtt{auth}_\alpha(z)$.[17]

[17] That is, $\mathtt{TH}_\alpha(z) = \ell_\lambda$, where ℓ_i is the ith bit of z and $\ell_\gamma = h_\alpha(\ell_{\gamma 0}\ell_{\gamma 1})$. Actually, here it is more natural to let $\mathtt{TH}_\alpha(z) = \ell_{0,0}$, where $\ell_{d,i}$ is the ith bit of $z \in \{0,1\}^{2^d}$ and $\ell_{j,i} = h_\alpha(\ell_{j+1,2i}\ell_{j+1,2i+1})$. Similarly, the ith sequence in $\mathtt{auth}_\alpha(z)$ is $(\ell_{d,2\lfloor i/2\rfloor}, \ell_{d,2\lfloor i/2\rfloor+1}, \ell_{d-1,2\lfloor i/4\rfloor}, \ell_{d-1,2\lfloor i/4\rfloor+1}, \ldots, \ell_{1,2\lfloor i/2^d\rfloor}, \ell_{1,2\lfloor i/2^d\rfloor+1})$.

In addition, we use a standard statistically binding commitment scheme denoted by $\mathtt{C}$ and a binary error-correcting code of constant relative distance and polynomial-time encoding algorithm denoted by $\mathtt{ECC}$. Recall that a commitment scheme as described above can be constructed based on any one-way function (see, e.g., [16, section 4.4.1]), whereas even stronger forms of error-correcting codes are known to exist unconditionally (e.g., consider a concatenation code that combines a Reed–Solomon code with the encoding of the small field elements by a Hadamard code). As in Construction B.2, we let $\mathtt{C}_s(z)$ denote the receiver's view of the commitment phase (of $\mathtt{C}$) when the sender inputs the value z and uses randomness s.

The key idea in our modification of Barak's construction [6] is replacing an arbitrary collision-resistant hashing of strings by the following two-step (hashing) process:

1. Apply the error-correcting code to the input string.
2. Apply the tree hashing to the resulting code word.

The advantage of this two-step (hashing) process over standard hashing is that if two different strings are hashed to the same value, then we can quickly obtain a collision in the basic hashing function (underlying the tree hashing). We stress that this collision is found in time that is polynomial in the hash value (which may be polylogarithmic in the length of the strings being hashed). The reason is that, with (positive) constant probability, a uniformly selected bit position in the code word will have different values in the two code words, and in this case we obtain from the corresponding authentications a collision in the basic hashing. (The foregoing motivational discussion will be clarified by the proof of Lemma 4.6.)

CONSTRUCTION 4.5 (a zero-knowledge argument for $S \in \mathcal{NP}$ (with a corresponding witness relation R_S)).

Common input: *x, supposedly in S. Let $n \stackrel{\text{def}}{=} |x|$.*

Auxiliary input to the prover: *w such that supposedly $(x,w) \in R_S$ holds.*

Part 1. Introducing a trapdoor for the simulation. *The prover commits to a dummy value that allows cheating in the case that this value provides a description of the supposedly random value that is sent by the verifier after getting the said commitment. This is done as follows:*

1. *The verifier uniformly selects $\alpha \in \{0,1\}^n$* (i.e., a basic hash function) *and sends it to the prover.*
2. *The prover sends a dummy commitment* (i.e., a commitment to the value 0^{2n})*; that is, it sends $c \stackrel{\text{def}}{=} \mathtt{C}_s(0^{2n})$ to the verifier, where s denotes the sender's randomness in this execution of the commitment scheme.*
3. *The verifier uniformly selects $r \in \{0,1\}^n$ and sends it to the prover.*

Cheating in Part 2 will become possible if and only if r agrees with c in the sense that one may present a circuit Π such that $\Pi(c) = r$ and $c = C_s(|\mathtt{ECC}(\Pi)|, \mathtt{TH}_\alpha(\mathtt{ECC}(\Pi)))$.

Part 2. Effectively proving that $x \in S$. *Specifically, the prover will prove that he knows either a witness w for $x \in S$* (i.e., $(x,w) \in R_S$) *or a circuit Π such that $\Pi(c) = r$ and $c = C_s(|\mathtt{ECC}(\Pi)|, \mathtt{TH}_\alpha(\mathtt{ECC}(\Pi)))$. This is done as follows: Loosely speaking, the parties invoke the proof system $(P_{\text{wi-ua}}, V_{\text{wi-ua}})$ on common input (x, α, c, r), where the prover intends to prove that it knows a tuple (w, m, η, γ, s) such that either $(x,w) \in R_S$ or (η, γ, s) encodes authentication and decommitment information for a circuit Π such that $\Pi(c) = r$, where the encoding clause means that it holds that $\eta = \mathtt{ECC}(\Pi) \in \{0,1\}^m$, $\gamma = \mathtt{auth}_\alpha(\eta)$, and $c = C_s(|\eta|, \mathtt{TH}_\alpha(\eta))$.*[18] *Actually, the parties reduce the above instance*

[18] The reason that we include (in the witness) the authentication information (i.e., $\mathtt{auth}(\mathtt{ECC}(\Pi))$) rather than including Π itself will become clear in the proof of Lemma 4.6. Furthermore, for simplicity and clarity, we explicitly include in the witness both $\mathtt{ECC}(\Pi)$ and its length.

(x, α, c, r) to the triplet $y = (M'_S, (x, \alpha, c, r), 2^n)$, where $y \in \{0,1\}^{\mathrm{poly}(n)}$ is supposedly in $S_{\mathcal{U}}$ and M'_S is such that $M'_S((x, \alpha, c, r), (w, m, \eta, \gamma, s)) \stackrel{\mathrm{def}}{=} 1$ if and only if at least one of the following two conditions holds:

1. *$(x, w) \in R_S$.*
2. *$m = |\eta|$, $c = \mathtt{C}_s(m, \mathtt{TH}_\alpha(\eta))$, $\gamma = \mathtt{auth}_\alpha(\eta)$, and $\Pi(c) = r$, where $\Pi \leftarrow \mathtt{ECC}^{-1}(\eta)$ is a description of a circuit* (i.e., *$\eta = \mathtt{ECC}(\Pi)$*).

When invoking $P_{\text{wi-ua}}$, the prover provides it with the witness $(w, m_0, \eta_0, \gamma_0, s_0)$, where $m_0 = n$ and $\eta_0 = \gamma_0 = s_0 \stackrel{\mathrm{def}}{=} 0^n$ are (short) *dummy values.*

Note that the first condition can be evaluated in (fixed) *polynomial time* (in *$|x|$*)*, whereas the complexity of evaluating the second condition is dominated by the running time of Π on input c. Furthermore, if $(x, w) \in R_S$, then $(y, (w, m_0, \eta_0, \gamma_0, s_0)) \in R_{\mathcal{U}}$ and the running time of $P_{\text{wi-ua}}$ on $(y, (w, m_0, \eta_0, \gamma_0, s_0))$ is a fixed polynomial in $|x|$. We stress that, in any case, the length of the statement being proven is bounded by a fixed polynomial in $|x|$.*

We denote the above verifier and prover strategies by V and P, respectively.

Clearly, Construction 4.5 is constant-round and public-coin and employs a probabilistic polynomial-time verifier strategy. Furthermore, the designated prover satisfies the completeness property while running in polynomial time, given x and w as described above. Demonstrating that Construction 4.5 is zero-knowledge is done by following the ideas of [6]. We start with a rough sketch of this proof and then turn to establish the computational soundness property of Construction 4.5.

Construction 4.5 *is zero-knowledge.* We present a non–black-box simulator that, given the code of any feasible cheating verifier (represented by a polynomial-size circuit family $\{\widetilde{V}_n\}_{n \in \mathbf{N}}$), simulates the interaction of P with that verifier. Specifically, given $\widetilde{V}_n$, the simulator emulates Part 1 of the protocol, except that it sets $c \leftarrow \mathtt{C}_s(|\mathtt{ECC}(\widetilde{V}_n)|, \mathtt{TH}_\alpha(\mathtt{ECC}(\widetilde{V}_n)))$ instead of $c \leftarrow \mathtt{C}_s(0^{2n})$. Next, the simulator emulates Part 2 of the protocol by using the witness $(w_0, |\mathtt{ECC}(\widetilde{V}_n)|, \mathtt{ECC}(\widetilde{V}_n), \mathtt{auth}_\alpha(\mathtt{ECC}(\widetilde{V}_n)), s)$, where $w_0 = 0^n$ is a (short) dummy value, s was selected by the simulator when emulating Part 1, and $\widetilde{V}_n$ was given to it as an (auxiliary) input.

Needless to say, given $\widetilde{V}_n$, the simulator computes $\eta \leftarrow \mathtt{ECC}(\widetilde{V}_n)$ as well as the tree-hash value $\mathtt{TH}_\alpha(\eta)$ and the corresponding sequence of authenticators $\mathtt{auth}_\alpha(\eta)$ in polynomial time. It follows that, for every polynomial bounding the size of the verifier's strategy (i.e., $\widetilde{V}_n$), the simulator runs in poly(n)-time. It is thus left to show that, for every polynomial bounding the size of the verifier's strategy (i.e., $\widetilde{V}_n$), the simulator's output (produced when given $\widetilde{V}_n$ as auxiliary input) is computationally indistinguishable from a real execution (as in Construction 4.5). The proof proceeds as follows:

- As a mental experiment, we consider a hybrid distribution in which Part 1 is performed as in the simulation (i.e., by committing to the tree hashing of the encoding of $\widetilde{V}_n$) but Part 2 is performed as in the real execution (i.e., by using a witness w to the common input x).
- Combining the computationally hiding property of the commitment scheme and the fact that P (when given w) runs in poly(n) time, it follows that the hybrid distribution is computationally indistinguishable from the real execution of the protocol.
- The witness indistinguishability property of $P_{\text{wi-ua}}$ implies that the simulator's output (in which the witness $\widetilde{V}_n$ is used) is computationally indistinguishable from the hybrid distribution (in which the witness w is used). We stress that, when using the witness indistinguishability property of $P_{\text{wi-ua}}$, we refer to witnesses that are verifiable in fixed polynomial (in n) time (be-

cause the polynomial bounding the size of $\widetilde{V}_n$ has been fixed for the current discussion).

Thus, the zero-knowledge feature follows.

Construction 4.5 *is computationally sound.* We show that any feasible cheating strategy for the prover yields a feasible algorithm that forms collisions with respect to the basic hashing family $\{h_\alpha : \{0,1\}^{2|\alpha|} \to \{0,1\}^{|\alpha|}\}_{\alpha \in \{0,1\}^*}$. The main idea is using the (weak) proof-of-knowledge property of $V_{\text{wi-ua}}$ in order to *implicitly* reconstruct error-correcting code words that encode (different) valid witnesses that correspond to different executions of Part 1. We stress that since there is no a priori polynomial bound on the length of such witnesses, we cannot afford to *explicitly* reconstruct them (as done in [6], where only a contradiction to superpolynomial hardness is derived). However, implicit reconstruction of valid code words will suffice, because different witnesses will be encoded by code words that differ on a constant fraction of the bit locations.

LEMMA 4.6. *Construction* 4.5 *is computationally sound* (w.r.t. S)*, provided that the family* $\{h_\alpha\}$ *is indeed collision resistant.*

Proof. Suppose towards the contradiction that there exists a feasible prover strategy that fools V with nonnegligible probability (to accept inputs not in S). Specifically, let $\{\widetilde{P}_n\}_{n \in \mathbb{N}}$ be such a family and p be a polynomial such that for infinitely many $x \notin S$ it holds that $p_x \stackrel{\text{def}}{=} \Pr[(\widetilde{P}_n, V)(x) = 1] > 1/p(|x|)$. Let us fix a generic n and $x \in \{0,1\}^n \setminus S$ such that $p_x > 1/p(n)$. For simplicity, we incorporate this x in $\widetilde{P}_n$. Using $\{\widetilde{P}_n\}_{n \in \mathbb{N}}$, we present a family of circuits $\{C_n\}_{n \in \mathbb{N}}$ that try to form collisions. On input $\alpha \in \{0,1\}^n$, the circuit C_n proceeds as follows:

1. Invoking $\widetilde{P}_n$, on input α, the circuit C_n obtains $c \leftarrow \widetilde{P}_n(\alpha)$. This is supposedly a commitment produced by the cheating prover (in the second step of Part 1 of the protocol).
2. Uniformly selecting $r \in \{0,1\}^n$ and feeding it to $\widetilde{P}_n$ yields a residual prover $\widetilde{P}_n(\alpha, r)$ for Part 2 of the protocol. That is, $\widetilde{P_{\text{wi-ua}}} \stackrel{\text{def}}{=} \widetilde{P}_n(\alpha, r)$ is a prover strategy for the (WI) universal-argument system $(P_{\text{wi-ua}}, V_{\text{wi-ua}})$.

   We shall focus on the case that $\widetilde{P_{\text{wi-ua}}}$ convinces $V_{\text{wi-ua}}$ to accept (x, α, c, r) with probability at least $p_x/4 > 1/4p(n)$. In this case, the (weak) proof-of-knowledge property guarantees that we can implicitly reconstruct a witness (w, m, η, γ, s) that satisfies the second condition in Part 2 (because $x \notin S$ makes it impossible to satisfy the first condition (i.e., the condition $(x, w) \in R_S$)). Recall that the second condition implies that η encodes a circuit Π such that $\Pi(c) = r$ and futhermore that $m = |\eta|$, $c = \mathtt{C}_s(m, \mathtt{TH}_\alpha(\eta))$, and $\gamma = \mathtt{auth}_\alpha(\eta)$. In the following two steps, we shall first use the foregoing (implicit) reconstruction procedure to obtain m and next use it to obtain the ith bit of η as well as the corresponding (authentication) segment of γ, for a uniformly selected $i \in [m]$.
3. Invoking the knowledge extractor guaranteed for the system $(P_{\text{wi-ua}}, V_{\text{wi-ua}})$, while providing it with oracle access to $\widetilde{P_{\text{wi-ua}}}$, we reconstruct the values at bit locations $n+1, \ldots, 2n$ in the witness (i.e., the integer m that indicates the length of a code word).

   Recall that the values at bit locations $2n+1, \ldots, 2n+m$ are an error-correcting encoding of Π, and the subsequent m strings consist of authentication information for the corresponding bits.
4. The circuit C_n uniformly selects $i \in [m]$. Invoking the knowledge extractor again with oracle access to $\widetilde{P_{\text{wi-ua}}}$, it reconstructs the value of the ith bit of

the code word as well as the values in the bit locations that correspond to the authenticator of the ith bit in the code word.

5. We repeat Steps 2 and 4 with a new uniformly selected $r' \in \{0,1\}^n$ but with the same value of i as selected in Step 4. That is, analogously to Step 2, we first obtain a corresponding prover strategy $\widetilde{P'_{\text{wi-ua}}} \stackrel{\text{def}}{=} \widetilde{P}_n(\alpha, r')$ (for the (WI) universal argument system $(P_{\text{wi-ua}}, V_{\text{wi-ua}})$). We need not repeat Step 3 because the statistically binding property of $\mathtt{C}$ guarantees the uniqueness of m (obtained in Step 3). Analogously to Step 4, we invoke the knowledge extractor with oracle access to $\widetilde{P'_{\text{wi-ua}}}$ and obtain the value of the ith bit of a code word (which encodes a circuit Π' such that $\Pi'(c) = r'$) as well as the values in the bit locations that correspond to the authenticator of this bit. Recall that, since $x \notin S$, the witness used by $\widetilde{P'_{\text{wi-ua}}}$ must encode a program Π' such that $\Pi'(c) = r'$. Since (with probability $1 - 2^{-n}$ it holds that) $r \neq r'$ (and $\Pi(c) = r$), it must be the case that $\Pi' \neq \Pi$ (whereas $|\mathtt{ECC}(\Pi)| = m = |\mathtt{ECC}(\Pi')|$). We hope that $\mathtt{ECC}(\Pi)$ and $\mathtt{ECC}(\Pi')$ differ on the ith bit (which happens with constant probability), in which case we obtain authenticators for conflicting values (with respect to the same label of the root of the tree (where the uniqueness of this label is due to the statistically binding property of $\mathtt{C}$)).
6. The circuit C_n examines the authenticators obtained in Steps 4 and 5. If they authenticate conflicting values, then the circuit derives a collision under h_α (as in the proof of Claim 3.5.2).

The foregoing circuit family has a polynomial size (because each C_n is implementable by the same probabilistic polynomial-time oracle machine, which in turn is given access to the polynomial-size $\widetilde{P}_n$). We now turn to analyze the success probability of C_n.

CLAIM 4.6.1. *Given a uniformly distributed $\alpha \in \{0,1\}^n$, with probability at least $1/\text{poly}(n)$, the circuit C_n outputs a collision with respect to h_α.*

Proof. Recall that $\widetilde{P}_n$ makes V accept x with probability $p_x > 1/p(n)$, where the probability is taken over V's random choices in the two parts of Construction 4.5. Moreover, V's choices in Part 1 are (α, r), where α (resp., r) is uniformly selected in $\{0,1\}^n$.

We call α good if the probability that $\widetilde{P}_n$ makes V accept x, conditioned on V selecting α in the first step of Part 1, is at least $p_x/2$. Clearly, at least a $p_x/2$ fraction of the α's is good, and we focus on any such good α.

Similarly, we say that r is *α-good* if the probability that $\widetilde{P}_n$ makes V accept x, conditioned on V selecting α and r in Part 1, is at least $p_x/4$. We denote by $G = G_\alpha$ the set of α-good strings and note that $|G| > (p_x/4) \cdot 2^n$ (since α is good). That is, for every $r \in G$, the residual prover $\widetilde{P}_n(\alpha, r)$ convinces $V_{\text{wi-ua}}$ with probability at least $p_x/4 > 1/4p(n)$, and therefore the knowledge extractor (given oracle access to $\widetilde{P}_n(\alpha, r)$) implicitly extracts the corresponding witness with probability at least $q_n \stackrel{\text{def}}{=} 1/\text{poly}(n)$, where the polynomial depends on the polynomial p.

Observe that, with probability at least $(p_x/4)^2$, both r and r' selected in Steps 2 and 5, respectively, reside in G. Conditioned on this event, we (implicitly) extract both of the corresponding witnesses with probability at least q_n^2. We stress that the two witnesses must be of the same length by virtue of their lengths being committed to in c (sent by the prover in the second step of Part 1). Finally, with constant probability, these witnesses differ in bit position i (selected in Step 4), in which case C_n succeeds in forming a collision under h_α.

We conclude that, for any good α, the circuit C_n succeeds in forming a collision under h_α with probability at least $(p_x/4)^2 \cdot q_n^2 \cdot \Omega(1) = 1/\mathrm{poly}(n)$. Recalling that at least $p_x/2 = 1/\mathrm{poly}(n)$ of the α's are good, the claim follows. □

Using Claim 4.6.1, we derive a contradiction to the hypothesis that $\{h_\alpha\}$ is collision-resistant. The lemma follows. □

Achieving bounded concurrent zero knowledge. We have shown that Construction 4.5 satisfies the first two extra properties asserted in Theorem 1.2. To establish the third extra property, we slightly modify the construction (analogously to the way this is done in [7, Chapter 4], which constitutes the full version of [6]). Specifically, for a suitably chosen polynomial ℓ, in Part 1 we select r uniformly in $\{0,1\}^{\ell(n)+n}$ (rather than in $\{0,1\}^n$), and in Part 2 we relax the second condition (or case) such that now we require that there exists a string $z \in \{0,1\}^{\ell(n)}$ such that $\Pi(c,z) = r$ (rather than requiring that $\Pi(c) = r$). The extra string z allows us to encode information from n^2 concurrent executions of the protocol (see details in [7, section 4.4]) and so enables the simulator strategy to insert a "trapdoor" into the second step of Part 1 of the current execution (and thus proceed in an "execution-by-execution" manner). When demonstrating computational soundness, we merely observe that, for a uniformly distributed $r' \in \{0,1\}^{\ell(n)+n}$ (chosen in Step 5), it is unlikely that Π, which is (implicitly) recovered (in Step 4) obliviously of r', will satisfy $\Pi(c,z') = r'$ for some $z' \in \{0,1\}^{\ell(n)}$.

Appendix A. Auxiliary properties of popular PCP systems. We claim that the PCP system of Babai et al. [5] satisfies all of the auxiliary properties listed in Definition 3.2. As stated in the main text, it is clear that this PCP system is nonadaptive, and thus we turn to establish the following remaining properties:[19]

Relatively efficient oracle construction. The oracle in this PCP system consists of two parts: (1) a low-degree extension of a multivariate function that encodes the original witness, and (2) various partial sums of the values of this polynomial, where the number of these partial sums is smaller than the size of the domain of the low-degree extension. The low-degree polynomial can be constructed in time that is polynomial in the length of the *explicit* description of the aforementioned function, and the same holds with respect to each of the partial sums.

Efficient reverse sampling. The queries in this PCP system are either evaluations of the aforementioned polynomial at various points or queries regarding some partial sums of such values. Specifically, the queries belong either to the low-degree test or to the sum check, respectively. The queries of the low-degree test are points along a random line, while the queries of the sum check are prefixes of a random point. Thus, given i and q, it is easy to select uniformly a random tape for the verifier such that the ith query of the verifier (on this random tape) equals q.

A proof-of-knowledge property. The standard analysis of this PCP system actually establishes that if the verifier rejects with probability smaller than $1/2$, then part of the oracle is (very) close to a low-degree polynomial that extends a multivariate function that encodes a valid witness. Thus, by standard self-correction, we may (probabilistically) recover each bit in this witness in polynomial time. Hence, we obtain a polynomial-time oracle machine E such that for every x and π that satisfy $\Pr[V^\pi(x) = 1] > 1/2$ it follows that there

[19] Needless to say, we assume some familiarity with the work of Babai et al. [5]. In particular, the high-level overview provided in [18, section 9.3.2.2] suffices.

exists $w = w_1 \cdots w_t$ such that $(x, w) \in R$ and $\Pr[E^\pi(x, i) = w_i] > 2/3$ holds for every i.

As stated in the main text, to obtain the desired error of ϵ, we apply straightforward error reduction (on the PCP system) while noting that this process does not affect the oracle, and so the resulting (error-reduced) PCP preserves all of the auxiliary properties (including a proof-of-knowledge property that refers to a lower level of error). This completes the proof of Theorem 3.3.

We comment that the foregoing considerations are not specific to the PCP system of [5] but rather hold also with respect to many other PCP systems.

Appendix B. Nonoblivious commitment schemes. We first recall the definition of nonoblivious commitment schemes, following [16, section 4.9.2.1] and [17, section C.3.3]. This definition augments the definition of a standard commitment scheme as presented in [16, section 4.4.1.1]. The latter definition (i.e., [16, Definition 4.4.1]) refers to a scheme that is computationally hiding and statistically binding. Loosely speaking, such a commitment scheme is an efficient *two-phase* two-party protocol through which one party, called the *sender*, can commit itself to a *value* so that the following two conflicting requirements are satisfied:

Hiding. At the end of the first phase, the other party, called the *receiver*, does not gain any knowledge of the sender's value. This requirement has to be satisfied even if the receiver tries to cheat. The computational version asserts that the receiver's views of interactions regarding any two values used by the sender are computational indistinguishable.

Binding. Given the transcript of the interaction in the first phase, there exists at most one value that the receiver may later (i.e., in the second phase) accept as a legal "opening" of the commitment. This requirement has to be satisfied even if the sender tries to cheat. The statistical version asserts that this property holds with overwhelmingly high probability (even if the sender is compuationally unbounded), where the probability is taken solely over the receiver's randomness.

In addition, one should require that the protocol is *viable* in the sense that if both parties follow it, then, at the end of the second phase, the receiver gets the value committed to by the sender. Throughout this appendix we refer to commitment schemes that are computationally hiding and statistically binding. Actually, for the sake of simplicity, we assume that the binding propery is perfect (i.e., it holds with probability 1).[20]

It is indeed time to define formally the notion of a *proper opening* of a commitment, which is also known as proper decommitment. Typically, one considers a *canonical decommitment*, which consists of all randomness used by the sender in the commit phase. In this case, the value v and the sender's randomness s may be considered a proper decommitment to the receiver's view of the commitment phase if it is consistent with that view (i.e., using these values along with the receiver's randomness yields the transcript of messages seen by the receiver). However, a more

[20] We mention that such (perfectly binding) commitment schemes can be constructed based on any one-way permutation [16, section 4.4.1.2], but only commitment schemes with nonperfect statistical binding are known to be constructible based on any one-way function [16, section 4.4.1.3]. Definition B.1 can be extended (from the case of perfectly binding commitment schemes) to the case of statistically binding commitment schemes by referring to a proof of knowledge for a promise problem, where the promise set consists of all interaction transcripts that can be opened in at most one way (i.e., yielding one value).

general notion of proper decommitment may be beneficial. Specifically, we refer to an arbitrary algorithm $\mathtt{D}$ that satisfies the following two conditions:

1. If the commitment phase is performed properly using the sender's value v and the outcome is a pair (s, c), where s is given to the sender and c is given to the receiver, then $\mathtt{D}((v, s), c) = 1$. This means that (v, s) is accepted as a proper decommitment to c.
2. If the receiver follows the commitment phase properly, then the receiver output c is such that there exists at most one value of v such that the set $\{s : \mathtt{D}((v, s), c) = 1\}$ is nonempty.

Needless to say, the aforementioned canonical decommitment gives rise to such an algorithm $\mathtt{D}$. In what follows, we shall assume (without loss of generality) that the commitment c is contained in the information s has given to the sender.

Recall that the foregoing condition 2 mandates that, even when the sender cheats, there exists at most one value v that can be properly decommitted for the output c (i.e., at most one v satisfies $\{s : \mathtt{D}((v, s), c) = 1\} \neq \emptyset$). This does not mean that the sender necessarily knows v, and furthermore such a v may not exist at all (i.e., $\{s : \mathtt{D}((v', s), c) = 1\} = \emptyset$ may hold for every v'). The following nonobliviousness requirement mandates that the sender "knows" the set of values for which proper decommitment is impossible; that is, if the receiver does not detect cheating, then it is the case that the sender knows v such that for every $v' \neq v$ there is no proper decommitment to c that yields the value v' (i.e., $\{s : \mathtt{D}((v', s), c) = 1\} = \emptyset$ holds).

Definition B.1 (nonoblivious commitment schemes). *A commitment scheme is called* nonoblivious *if its commit phase consists of two subphases such that the first subphase is an ordinary commitment phase and the second subphase is a proof of knowledge of the only possible value that can be properly decommitted with respect to the first subphase. That is, the commitment scheme (S, R) decomposes into $S = (S_1, S_2)$ and $R = (R_1, R_2)$ such that*

1. *(S_1, R_1) is a commitment scheme with a decommitment-verification algorithm $\mathtt{D}$;*
2. *(S_2, R_2) is a proof-of-knowledge system* (with negligible error—see [16, section 4.7.1]) *for the relation*

$$\{(c, v) : \forall v' \neq v \, \forall s' \quad \mathtt{D}((v', s'), c) \neq 1\}, \tag{B.1}$$

and this proof system is invoked on common input c and the prover's auxiliary input (v, s), where (s, c) is a result of applying (S_1, R_1) to the value v.

Note that the relation defined in (B.1) is not necessarily an NP-witness relation (i.e., it is not necessarily polynomial-time recognizable), but the definition of a proof of knowledge applies nevertheless (see [16, section 4.7.1] and further discussions in [9]). A seemingly stronger notion (of nonoblivious commitment schemes) requires a proof of knowledge for an NP-witness relation R' such that (c, v) satisfies (B.1) if and only if there exists $w \in \{0,1\}^{\mathrm{poly}(|c|)}$ such that $(c, (v, w)) \in R'$ holds. We comment that Construction B.2 (below) satisfies this stronger definition.

We mention that, in [17, section C.3.3], Definition B.1 is referred to as a *relaxed version* of the notion of a nonoblivious commitment scheme, whereas in the nonrelaxed notion the second subphase is required to prove knowledge of the input as well as of the proper decommitment information. That is, in the strict (i.e., nonrelaxed) notion of nonoblivious commitment schemes (outlined in [17, section C.3.3]), the second subphase is a proof of knowledge of an input and decommitment information that are consistent with the receiver's view of the first subphase (i.e., a proof-of-knowledge

system for the relation $\{(c,(v,s)) : \mathtt{D}((v,s),c) = 1\}$). (In particular, this implies that this stage is a proof of membership for the corresponding language, hence proving that there does in fact exist a value v that can be properly decommitted.) Originally, we thought that we could provide a constant-round public-coin implementation of the strict notion, but a flaw in our reasoning was discovered by Haitner, Rosen, and Shaltiel. Although the relaxed notion suffices for our applications (as well as for other natural applications (see, e.g., [16, section 4.9.2.2])), we believe that the question of whether the strict notion can be implemented by a constant-round public-coin protocol is of independent interest.

Constructing nonoblivious commitment schemes. Our construction follows the outline provided in [17, section C.3.3]. The basic idea is augmenting a standard commitment scheme with an adequate zero-knowledge proof of knowledge, but the problem is that such a proof of knowledge that is also constant-round and public-coin is not known. As observed in [16, section 4.9.2.1], it suffices to use a *strong*-WI proof of knowledge, but such a protocol is not known either (see [17, section C.3]). We stress that in both cases we have referred to protocols with negligible soundness error and that corresponding protocols with constant soundness error do exist. The solution suggested in [17, section C.3.3] is using multiple commitments (via the standard scheme) and applying a *strong*-WI proof of knowledge of constant soundness error to each of the different commitments. In this setting (of statistically independent inputs), the *strong*-WI property is preserved under parallel executions (cf. [17, Lemma C.3.1]). The following construction merely spells out this suggestion.

CONSTRUCTION B.2 (a nonoblivious commitment scheme). *Let* $\mathtt{C}$ *be a standard statistically binding commitment scheme, and let* $\mathtt{C}_s(x)$ *denote the receiver's view of the commitment phase when the sender inputs the value* x *and uses randomness* s*. The following description refers to committing to the value* v *under the security parameter* n*, where* $|v| \leq \mathrm{poly}(n)$*:*

First commit subphase. *The parties invoke* $\mathtt{C}$*, in parallel, for* n *times. In all invocations the sender enters the value* v*, and in the* i*th invocation the receiver obtains the value* $c_i = \mathtt{C}_{s_i}(v)$*, where* s_i *denotes the sender's randomness.*

These n *invocations yield a standard commitment scheme with a decommitment algorithm* $\mathtt{D}$ *that accepts the value* v *if it is supported by* n *proper decommitments with respect to the basic commitment scheme; that is,* $\mathtt{D}((v,\overline{s}'),\overline{c}) = 1$ *if* $\overline{c} = (c_1,\ldots,c_n)$ *and* $\overline{s}' = (s'_1,\ldots,s'_n)$ *such that for every* $i \in [n]$ *it holds that* $c_i = \mathtt{C}_{s'_i}(v)$*.*

Second commit subphase. *The parties perform, in parallel,* n *copies of the following protocol. In the* i*th copy, the sender proves in zero knowledge that it knows the values* v *and* s_i *that were used in the corresponding copy of the first subphase. That is, the sender proves that it knows* (v,s_i) *such that* $c_i = \mathtt{C}_{s_i}(v)$*. Each of these proofs of knowledge has constant soundness error. If the receiver detects cheating in any of these executions, then it aborts, indicating that the sender is cheating. Otherwise, the receiver accepts the commitment* $(c_1,\ldots,c_n)$*.*

A proper decommitment to the value v *with respect to a transcript* $\overline{c} = (c_1,\ldots,c_n)$ *of the first subphase consists of a sequence of* n *strings* $(s'_1,\ldots,s'_n)$ *such that for every* $i \in [n]$ *it holds that* $c_i = \mathtt{C}_{s'_i}(v)$*.*

Construction B.2 inherits the statistical-binding property of the standard commitment $\mathtt{C}$ (since a proper decommitment in Construction B.2 requires proper decommitments of $\mathtt{C}$ to the same value). We first show that, although the zero-knowledge property may not be preserved in the parallel executions that take place in the second

commit subphase, this subphase preserves the computational-hiding property of the standard commitment $\mathtt{C}$.

CLAIM B.2.1. *Construction* B.2 *is computationally hiding.*

Proof. We view Construction B.2 as consisting of n parallel executions of a basic protocol in which the sender first commits to v and then proves (in zero knowledge) that it knows a proper decommitment. This basic protocol is computationally hiding because it consists of producing a computationally hiding commitment and running a zero-knowledge proof regarding this commitment.[21] Thus, it suffices to prove that any computationally hiding commitment scheme preserves this property under parallel executions. Indeed, the proof proceeds by a hybrid argument and is very similar to the proof of Lemma C.3.1 in [17]. □

It is left to establish the nonoblivious property of Construction B.2. To this end, we assume that the proof of knowledge employed is such that the verifier tosses a single coin (and indeed has knowledge error 1/2).[22] We note that such protocols (of constant soundness error) exist; see, e.g., [16, Chapter 4, Exercise 28.1].

CLAIM B.2.2. *Construction* B.2, *when implemented using a proof of knowledge in which the verifier tosses a single coin, is nonoblivious.*

Proof. We fix an arbitrary execution of the first (commit) subphase and consider a random execution of the second (commit) subphase, which amounts to n parallel executions of the proof-of-knowledge protocol. Fixing an arbitrary (deterministic) sender strategy, the underlying probability space consists of the n random (bit) choices made in the corresponding executions. We denote by p the probability that the receiver is convinced by all of these proofs, where here the probability is taken uniformly over all of the receiver's n (binary) choices. We call the ith copy *good* if, *for each choice of the verifier bit in this copy*, the receiver is convinced (in this copy) with probability at least p/n, where the probability is taken over the receiver's choices in all of the other $n-1$ copies. The current claim follows by combining two facts:

1. If $p > 2^{-n}$, then at least one of the indices is good.
   Otherwise, we reach a contraction by upper bounding the number of points in the probability space that cause the receiver to be convinced. Specifically, if all indices are not good, then for every $i \in [n]$ there exists a bit σ_i such that the number of convincing points in which the ith bit equals $1-\sigma_i$ is less than $(p/n) \cdot 2^{n-1}$. Thus, the total number of convincing points is less than $1 + n \cdot (p/n)2^{n-1}$, because the set of convincing points denoted by C is a subset of
   $$\{\sigma_1 \cdots \sigma_n\} \cup \{\alpha_1 \cdots \alpha_n \in C : \exists i \in [n] \text{ s.t. } \alpha_i = 1 - \sigma_i\}.$$
   It follows that $p \cdot 2^n < 1 + p \cdot 2^{n-1}$, which yields $p < 2^{-(n-1)}$. Recalling that p is defined with respect to a probability space of size 2^n, it follows that $p \leq 2^{-n}$, in contradiction to the hypothesis $p > 2^{-n}$.
2. If i is good, then the corresponding knowledge (i.e., a pair (v_i, s_i) such that $c_i = \mathtt{C}_{s_i}(v_i)$) can be extracted in $\mathrm{poly}(n)/p$ steps.
   By making $O(n/p)$ trials, we can generate a convincing transcript for each of the (two) possible choices of the verifier's random bit in the execution of the ith copy. This implies extraction (by the definition of a proof of knowledge).

[21] Indeed, it is instructive to note that the zero-knowledge property implies the *strong*-WI property (see [16, section 4.6.1.1]), whereas the latter property preserves the computational indistinguishability of $\mathtt{C}$-commitments (to different values).

[22] We believe that the argument can be extended to the general case (or at least to all standard proof-of-knowledge protocols). See the related discussion in [9, Appendix C.2].

Thus, assuming $p > 2^{-n}$, we can extract the relevant decommitment information (i.e., v as well as at least one corresponding s_i such that $c_i = \mathtt{C}_{s_i}(v)$) in time that is inversely proportional to the probability that the receiver is convinced in the second commit subphase. This information guarantess that the corresponding value (i.e., v) is the only value for which a proper decommitment exists. It follows that the second commit subphase (of Construction B.2) constitutes a proof of knowledge, with error 2^{-n}, of the only possible value that can be properly decommitted with respect to the first subphase. The claim follows. □

Recalling that all ingredients used in Construction B.2 can be implemented based on any one-way function (via constant-round public-coin protocols), we get the following theorem.

THEOREM B.3. *The existence of one-way functions implies the existence of nonoblivious commitment schemes. Furthermore, these systems are of the public-coin type and use a constant number of rounds.*

We also mention that the properties of nonoblivious commitment schemes are preserved when many copies of the scheme are executed in parallel (or even concurrently under arbitrary scheduling). The preservation of the standard properties of a commitment scheme follows by a hybrid argument (as employed in the proof of Claim B.2.1). The preservation of the nonoblivious (or rather the proof-of-knowledge) property follows by focusing on each individual copy and considering an auxiliary sender that emulates all of the other copies. (We stress that we do not claim here a reduction in the soundness error of the proof-of-knowledge property but rather a preservation of the proof-of-knowledge property at the same level of soundness error.)

Acknowledgments. We are grateful to the anonymous referees for their careful review and for numerous corrections and suggestions. We are indebted to Iftach Haitner, Alon Rosen, and Ronen Shaltiel for discovering a flaw in a previous presentation (see Appendix B).

EXPONENTIAL SEPARATION FOR ONE-WAY QUANTUM COMMUNICATION COMPLEXITY, WITH APPLICATIONS TO CRYPTOGRAPHY*

DMITRY GAVINSKY†, JULIA KEMPE‡, IORDANIS KERENIDIS§, RAN RAZ¶, AND RONALD DE WOLF‖

Abstract. We give an exponential separation between one-way quantum and classical communication protocols for a partial Boolean function (a variant of the Boolean hidden matching problem of Bar-Yossef et al.). Previously, such an exponential separation was known only for a relational problem. The communication problem corresponds to a *strong extractor* that fails against a small amount of *quantum* information about its random source. Our proof uses the Fourier coefficients inequality of Kahn, Kalai, and Linial. We also give a number of applications of this separation. In particular, we show that there are privacy amplification schemes that are secure against classical adversaries but not against quantum adversaries; and we give the first example of a key-expansion scheme in the model of bounded-storage cryptography that is secure against classical memory-bounded adversaries but not against quantum ones.

Key words. communication complexity, exponential separation, quantum communication, one-way communication, hidden matching problem, quantum cryptography, bounded-storage model, extractor, streaming model

1. Introduction.

One of the main goals of quantum computing is to exhibit problems where quantum computers are much faster (or otherwise better) than classical computers, preferably exponentially better. The most famous example, Shor's efficient quantum factoring algorithm [32], constitutes a separation only if one is willing to believe that efficient factoring is impossible on a classical computer—proving this would, of course, imply P $\neq$ NP. One of the few areas where one can establish *unconditional* exponential separations is communication complexity.

Communication complexity is a central model of computation, first defined by Yao [36]. It has found applications in many areas [20]. In this model, two parties, Alice

with input x and Bob with input y, collaborate to solve some computational problem that depends on both x and y. Their goal is to do this with minimal communication. The problem to be solved could be a function $f(x, y)$ or some relational problem where for each x and y several outputs are valid. The protocols could be *interactive (two-way)*, in which case Alice and Bob take turns sending messages to each other; *one-way*, in which case Alice sends a single message to Bob, who then determines the output; or *simultaneous*, where Alice and Bob each pass one message to a third party (the *referee*) who determines the output. The bounded-error *communication complexity* of the problem is the worst-case communication of the best protocol that gives (for every input x and y) a correct output with probability at least $1 - \varepsilon$ for some fixed constant $\varepsilon \in [0, 1/2)$, usually $\varepsilon = 1/3$.

Allowing the players to use *quantum* resources can reduce the communication complexity significantly. Examples of problems where quantum communication gives exponential savings were given by Buhrman, Cleve, and Wigderson for one-way and interactive protocols with zero error probability [8]; by Raz for bounded-error interactive protocols [28]; and by Buhrman et al. for bounded-error simultaneous protocols [9]. The first two problems are partial Boolean functions, while the third one is a total Boolean function. However, the latter separation does not hold in the presence of public coins.[1] Bar-Yossef, Jayram, and Kerenidis [4] showed an exponential separation for one-way protocols and simultaneous protocols with public coins, but they achieved this only for a relational problem, called the *hidden matching problem*. This problem can be solved efficiently by one quantum message of $\log n$ qubits, while classical one-way protocols need to send nearly $\sqrt{n}$ bits to solve it. However, Boolean functions are much more natural objects than relations both in the model of communication complexity and in the cryptographic settings that we consider later in this paper. Bar-Yossef et al. stated a Boolean version of their problem (a partial Boolean function) and conjectured that the same quantum-classical gap holds for this problem as well.

1.1. Exponential separation for a variant of Boolean hidden matching. In this paper we prove an exponential quantum-classical one-way communication gap for a variant of the Boolean hidden matching problem of [4]. Let us first state a non-Boolean communication problem. Suppose Alice has an n-bit string x, and Bob has a sequence M of αn disjoint pairs $(i_1, j_1), (i_2, j_2), \ldots, (i_{\alpha n}, j_{\alpha n}) \in [n] \times [n]$ for some parameter $\alpha \in (0, 1/2]$. This M may be viewed as a partial matching on the graph whose vertices are the n bits $x_1, \ldots, x_n$. We call this an *α-matching*. Together, x and M induce an αn-bit string z defined by the parities of the αn edges:

$$z = z(x, M) = (x_{i_1} \oplus x_{j_1}), (x_{i_2} \oplus x_{j_2}), \ldots, (x_{i_{\alpha n}} \oplus x_{j_{\alpha n}}).$$

Suppose Bob wants to learn some information about z. Let $x \in \{0,1\}^n$ be uniformly distributed, and let M be uniform over the set $\mathcal{M}_{\alpha n}$ of all α-matchings. Note that for any fixed M, a uniform distribution on x induces a uniform distribution on z. Hence Bob (knowing M but not x) knows nothing about z: from his perspective it is uniformly distributed. But now suppose Alice can send Bob a short message. How much can Bob learn about z, given that message and M?

The answer is very different depending on whether the message is quantum or classical. To state this difference, we need to introduce some terminology. For prob-

[1] In fact, whether there exists a superpolynomial separation for a total Boolean function in the presence of public coins is one of the main open questions in the area of quantum communication complexity.

ability distributions p and q whose supports are subsets of a set S, define their *total variation distance* as

$$\| p - q \|_{tvd} = \sum_{i \in S} |p(i) - q(i)|. \tag{1}$$

This distance is 0 if and only if $p = q$; it is 2 if and only if p and q have disjoint supports; and the value lies between 0 and 2 otherwise. Suppose we want to distinguish p from q, given a sample from one of the two. The best probability with which we can succeed is $\frac{1}{2} + \frac{||p-q||_{tvd}}{4}$. This well-known fact gives a clear intuitive meaning to the notion of total variation distance. Modifying the protocol of [4], it is easy to show that a short *quantum* message of about $\log(n)/2\alpha$ qubits allows Bob to learn a bit at a random position in the string z. This already puts a lower bound of 1 on the total variation distance between Bob's distribution on z and the uniform αn-bit distribution.

What about a short *classical* message? Using the birthday paradox, one can show that if Alice sends Bob about $\sqrt{n/\alpha}$ bits of x, then with constant probability there will be one edge (i_ℓ, j_ℓ) for which Bob receives both bits x_{i_ℓ} and x_{j_ℓ}. Since $z_\ell = x_{i_\ell} \oplus x_{j_\ell}$, this gives Bob a bit of information about z. Our key theorem says that this classical upper bound is essentially optimal: if Alice sends much fewer bits, then from Bob's perspective the string z will be close (in total variation distance) to uniformly distributed, so he does not even know one bit of z.

In order to be able to state this precisely, suppose Alice is deterministic and sends c bits of communication. Then her message partitions the set of 2^n x's into 2^c sets, one for each message. A typical message will correspond to a set A of about 2^{n-c} x's. Given this message, Bob knows the random variable X is drawn uniformly from this set A and he knows M, which is his input. Hence his knowledge of the random variable $Z = z(X, M)$ is fully described by the distribution

$$p_M(z) = \Pr[Z = z \mid \text{given } M \text{ and Alice's message}] = \frac{|\{x \in A \mid z(x, M) = z\}|}{|A|}.$$

Our main technical result says that if the communication c is much less than $\sqrt{n/\alpha}$ bits, then for a typical message and averaged over all matchings M, this distribution is very close to uniform in total variation distance. In other words, most of the time Bob knows essentially nothing about z.

THEOREM 1. *Let x be uniformly distributed over a set $A \subseteq \{0,1\}^n$ of size $|A| \geq 2^{n-c}$ for some $c \geq 1$, and let M be uniformly distributed over the set $\mathcal{M}_{\alpha n}$ of all α-matchings, for some $\alpha \in (0, 1/4]$. There exists a universal constant $\gamma > 0$ (independent of n, c, and α), such that for all $\varepsilon \in (0, 2]$, if $c \leq \gamma \varepsilon \sqrt{n/\alpha}$, then*

$$\mathbb{E}_M \left[\| p_M - U \|_{tvd} \right] \leq \varepsilon.$$

Note that the ε in this theorem is not the error probability of a protocol for a Boolean function, but an upper bound on the expected distance between Bob's distribution p_M and the uniform distribution. We prove Theorem 1 using the Fourier coefficients inequality of Kahn, Kalai, and Linial [16], which is a special case of the Bonami–Beckner inequality [7, 5]. We remark that Fourier analysis has been previously used in communication complexity by Raz [27] and Klauck [17].

This result allows us to turn the above communication problem into a partial Boolean function, as follows. Again we give Alice input $x \in \{0,1\}^n$, while Bob now receives two inputs: a partial matching M as before and an αn-bit string w. The

promise on the input is that w is either equal to $z = z(x, M)$ or to its complement $\overline{z}$ (i.e., z with all bits flipped). The goal is to find out which of these two possibilities is the case. We call this communication problem αPM, for *α-partial matching*. As mentioned before, Alice can allow Bob to learn a random bit of z with high probability by sending him an $O(\log(n)/\alpha)$-qubit message. Knowing one bit z_ℓ of z suffices to compute the Boolean function: just compare z_ℓ with w_ℓ. In contrast, if Alice sends Bob much less than $\sqrt{n/\alpha}$ classical bits, then Bob still knows essentially nothing about z. In particular, he cannot decide whether $w = z$ or $w = \overline{z}$! This gives the following separation result for the classical and quantum one-way communication complexities (with error probability fixed to $1/3$, say).

THEOREM 2. *Let $\alpha \in (0, 1/4]$. The classical bounded-error one-way communication complexity of the α-PM problem is $R^1(\alpha\mathrm{PM}) = \Theta(\sqrt{n/\alpha})$, while the quantum bounded-error one-way complexity is $Q^1(\alpha\mathrm{PM}) = O(\log(n)/\alpha)$.*

Fixing α to $1/4$, we obtain the promised exponential quantum-classical separation for one-way communication complexity of $O(\log n)$ qubits vs. $\Omega(\sqrt{n})$ classical bits.

As noted by Aaronson [1, section 5], Theorem 2 implies that his general simulation of bounded-error one-way quantum protocols by deterministic one-way protocols,

$$D^1(f) = O(mQ^1(f) \log Q^1(f)),$$

is tight up to a polylogarithmic factor. Here m is the length of Bob's input. This simulation works for any partial Boolean function f. Taking f to be our αPM for $\alpha = 1/4$, one can show that $D^1(f) = \Theta(n)$, $m = \Theta(n \log n)$, and $Q^1(f) = O(\log n)$. It also implies that his simulation of quantum bounded-error one-way protocols by classical bounded-error one-way protocols,

$$R^1(f) = O(mQ^1(f)),$$

cannot be considerably improved. In particular, the product on the right cannot be replaced by the sum: if we take $f = \alpha$PM with $\alpha = 1/\sqrt{n}$, then by Theorem 2 we have $R^1(f) \approx n^{3/4}$, $m \approx \sqrt{n} \log n$, and $Q^1(f) = O(\sqrt{n} \log n)$.

Remarks. The earlier conference version of this paper [13] had two different communication problems, establishing an exponential one-way separation for both of them in quite different ways. The present paper unifies these two approaches to something substantially simpler.

The original Boolean hidden matching problem stated in [4] is our αPM with $\alpha = 1/2$ (i.e., M is a perfect matching). Theorem 2, on the other hand, assumes $\alpha \leq 1/4$ for technical reasons. By doing the analysis in section 3 a bit more carefully, we can prove Theorem 2 for every α that is bounded away from $1/2$. Note that if $\alpha = 1/2$, then the parity of $z = z(x, M)$ equals the parity of x, so by communicating the parity of x in one bit, Alice can give Bob one bit of information about z. The conference version of this paper showed that one can prove a separation for the case where M is a perfect matching if the promise is that w is "close" to z or its complement (instead of being *equal* to z or its complement). One can think of w in this case as a "noisy" version of $z = z(x, M)$ (or its complement), while the w of our current version can be thought of as starting from a perfect matching M', and then "erasing" some of the $n/2$ bits of the string $z(x, M')$ to get the αn-bit string z (or its complement).

The separation given here can be modified to a separation in the simultaneous message passing model, between the models of classical communication with shared entanglement and classical communication with shared randomness. Earlier, such a separation was known only for a relational problem [4, 12], not for a Boolean function.

1.2. Application: Privacy amplification. Randomness *extractors* extract almost uniform randomness from an *imperfect* (i.e., nonuniform) source of randomness X with the help of an independent uniform seed Y. With a bit of extra work (see section 4), Theorem 1 actually implies that our function $z : \{0,1\}^n \times \mathcal{M}_{\alpha n} \to \{0,1\}^{\alpha n}$ is an extractor:

> If $X \in \{0,1\}^n$ is a random variable with min-entropy at least $n - \gamma\varepsilon\sqrt{n/\alpha}$ (i.e., $\max_x \Pr[X = x] \leq 2^{-(n-\gamma\varepsilon\sqrt{n/\alpha})}$) and Y is a random variable uniformly distributed over $\mathcal{M}_{\alpha n}$, then the random variable $Z := z(X,Y)$ is ε-close to the uniform distribution on $\{0,1\}^{\alpha n}$.

It is in fact a *strong* extractor: the pair (Y,Z) is ε-close to the uniform distribution on $\mathcal{M}_{\alpha n} \times \{0,1\}^{\alpha n}$.[2] Informally, this says that if there is a lot of uncertainty about X, then Z will be close to uniform even if Y is known.[3]

Extractors have found numerous applications in computer science, in particular in complexity theory (see, e.g., [31] and the references therein) and cryptography. One important cryptographic application is that of *privacy amplification*, introduced in [6, 15]. In this setting two parties called *Alice* and *Bob* start with a shared random variable X, about which an *adversary* has partial knowledge. The parties' goal is to generate a secret key Z, about which the adversary would have very little information.

They can achieve this by communicating an independent uniform seed Y over a *public* channel, and using a strong extractor to generate the key $Z(X,Y)$. Our extractor guarantees that if the shared variable X, conditioned upon the adversary's knowledge, has min-entropy at least $n - \gamma\varepsilon\sqrt{n/\alpha}$, then the generated αn-bit key Z, conditioned upon adversary's knowledge, is ε-close to uniform. On the other hand, we show that this scheme is *insecure* against a *quantum* adversary who uses only $O(\log n)$ qubits of storage. This is the first example of a privacy amplification scheme that is safe against classical adversaries with up to $\Theta(\sqrt{n})$ bits of storage (with some small constant in the $\Theta(\cdot)$), but not against quantum adversaries with *exponentially less* quantum storage.

This dependence on whether the adversary has quantum or classical memory is quite surprising, particularly in light of the following two facts. First, privacy amplification based on two-universal hashing provides exactly the same security against classical and quantum adversaries. The length of the key that can be extracted is given by the min-entropy both in the classical [6, 15] and the quantum case (see [19, 30], [29, Chapter 5]). Second, König and Terhal [18] have shown that for protocols that extract just *one* bit, the level of security against a classical and a quantum adversary (with the same information bound) is comparable.

1.3. Application: Key-expansion in the bounded-storage model. In privacy amplification, we can ensure that the adversary has much uncertainty about the random variable X by assuming that he has only bounded storage. The idea of basing cryptography on storage limitations of the adversary was introduced by Maurer [23] with the aim of implementing information-theoretically secure *key-expansion*. In this

[2] Note that $\mathbb{E}_M \left[\| p_M - U \|_{tvd} \right] = \| (Y,Z) - U \|_{tvd}$, where U on the left and right is uniform over different domains.

[3] It should be noted that the parameters of our extractor are quite bad, as far as these things go. First, the uniform input seed Y takes about $\alpha n \log n$ bits to describe, which is more than the αn bits that the extractor outputs; in a good extractor, we want the seed length to be much shorter than the output length. Second, our assumed lower bound on the initial min-entropy is quite stringent. Finally, the distance from uniform can be made polynomially small in n (by putting an $n - n^{1/2-\eta}$ lower bound on the min-entropy of X) but not exponentially small, which is definitely a drawback in cryptographic contexts. Still, this extractor suffices for our purposes here.

setting, a large random variable X is publicly but only temporarily available. Alice and Bob use a shared secret key Y to extract an additional key $Z = Z(X, Y)$ from X, in such a way that the adversary has only limited information about the pair (Y, Z). "Limited information" means that the distribution on (Y, Z) is ε-close to uniform even when conditioned on the information about X that the adversary stored. Thus Alice and Bob have expanded their shared secret key from Y to (Y, Z). Aumann, Ding, and Rabin [3] were the first to prove a bounded-storage scheme secure, and essentially tight constructions have subsequently been found [11, 22, 33].

It is an important open question whether any of these constructions remain secure if the adversary is allowed to store *quantum* information. One may even conjecture that a bounded-storage protocol secure against classical adversaries with a certain amount of memory should be roughly as secure against *quantum* adversaries with roughly the same memory bound. After all, Holevo's theorem [14] tells us that k qubits cannot contain more information than k classical bits. However, a key-expansion scheme based on our extractor refutes this conjecture. The scheme is essentially the same as the above privacy amplification scheme, but we describe it separately because the context is a bit different. Alice and Bob will compute $Z := z(X, Y)$ by applying our extractor to X and Y. If the adversary's memory is bounded by $\gamma\varepsilon\sqrt{n/\alpha}$ bits, then Z will be ε-close to uniform from the adversary's perspective. On the other hand, $O(\log n)$ qubits of storage suffice to learn one or more bits of information about Z, given Y, which shows that (Y, Z) is not good as a key against a quantum adversary. Thus we have an example of a key-expansion scheme that is secure against classical adversaries with nearly $\sqrt{n}$ bits of storage, but insecure against quantum adversaries even with exponentially less quantum storage.

1.4. Application: A separation in the streaming model. In the *streaming model* of computation, the input is given as a stream of bits and the algorithm is supposed to compute or approximate some function of the input, having only space of size S available. See, for instance, [2, 24].

There is a well-established connection between one-way communication complexity and the streaming model: if we view the input as consisting of two consecutive parts x and y, then the content of the memory after x has been processed, together with y, contains enough information to compute $f(x, y)$. Hence, a space-S streaming algorithm for f implies a one-way protocol for f of communication S with the same success probability. The classical lower bound for our Boolean communication complexity problem, together with the observation that our quantum protocol can be implemented in the streaming model, implies a separation between the quantum and classical streaming model. Namely, there is a partial Boolean function f that can be computed in the streaming model with small error probability using quantum space of $O(\log n)$ qubits, but requiring $\Omega(\sqrt{n})$ bits if the space is classical.

Le Gall [21] constructed a problem that can be solved in the streaming model using $O(\log n)$ qubits of space, while any classical algorithm needs $\Omega(n^{1/3})$ classical bits. His $\log n$-vs.-$n^{1/3}$ separation is a bit smaller than our $\log n$-vs.-$\sqrt{n}$, but his separation is for a *total* Boolean function while ours is only partial (i.e., requires some promise on the input). Le Gall's result predates ours, though we learned about it only after finishing the conference version of our paper. We remark also that Le Gall's separation holds only in the streaming model variant where the bits arrive in order, while ours holds in the more general model where we allow the different pieces of the input to arrive in any order.

The algorithm for solving our problem in the streaming model starts out with a

$\log n$-qubit superposition $\frac{1}{\sqrt{n}}\sum_{i=1}^{n}|i\rangle$. Whenever a bit x_i streams by in the input, the algorithm unitarily multiplies basis state $|i\rangle$ with a phase $(-1)^{x_i}$. Whenever an edge (i_ℓ, j_ℓ) streams by, the algorithm measures with operators $E_1 = |i_\ell\rangle\langle i_\ell| + |j_\ell\rangle\langle j_\ell|$ and $E_0 = I - E_1$; in case of outcome E_1, the algorithm records the values i_ℓ and j_ℓ (note that E_1 can be obtained at most once, as the edges are pairwise disjoint). And whenever a bit (i_ℓ, j_ℓ, w_ℓ) streams by, the algorithm unitarily multiplies basis state $|\min(i_\ell, j_\ell)\rangle$ with a phase $(-1)^{w_\ell}$. At the end, with probability 2α the algorithm is left with a classical record of $(i_\ell, j_\ell) \in M$ and the corresponding quantum state $\frac{1}{\sqrt{2}}((-1)^{x_{i_\ell}\oplus w_\ell}|i_\ell\rangle + (-1)^{x_{j_\ell}}|j_\ell\rangle)$. The algorithm can learn the function value $x_{i_\ell} \oplus x_{j_\ell} \oplus w_\ell$ from this by a final measurement.

2. The problem and its quantum and classical upper bounds. We assume basic knowledge of quantum computation [26] and (quantum) communication complexity [20, 34].

Before giving the definition of our variant of the Boolean hidden matching problem, we fix some notation. Part of Bob's input will be a sequence M of αn disjoint edges $(i_1, j_1), \ldots, (i_{\alpha n}, j_{\alpha n})$ over $[n]$, which we call an α-matching. We use $\mathcal{M}_{\alpha n}$ to denote the set of all such matchings. If $\alpha = 1/2$, then the matching is *perfect*; if $\alpha < 1/2$, then the matching is *partial*. We can view M as an $\alpha n \times n$ matrix over $GF(2)$, where the ℓth row has exactly two 1's, at positions i_ℓ and j_ℓ. Let $x \in \{0,1\}^n$. Then the matrix-vector product Mx is an αn-bit string $z = z_1, \ldots, z_\ell, \ldots, z_{\alpha n}$ where $z_\ell = x_{i_\ell} \oplus x_{j_\ell}$. Using this notation, we define the following αPM problem, whose one-way communication complexity we will study.

Alice: $x \in \{0,1\}^n$

Bob: an α-matching M and a string $w \in \{0,1\}^{\alpha n}$

Promise on the input: there is a bit b such that $w = Mx \oplus b^{\alpha n}$ (equivalently, $w = z$ or $w = \overline{z}$)

Function value: b

Actually, most of our analysis will not be concerned with Bob's second input w. Rather, we will show that, given only a short message about x, Bob will know essentially nothing about $z = Mx$. Note that to compute b, it suffices that Bob learns one bit z_ℓ of the string z, since $b = z_\ell \oplus w_\ell$. We will first give quantum and classical upper bounds on the message length needed for this.

Quantum upper bound. Suppose Alice sends a uniform superposition of her bits to Bob:

$$|\psi\rangle = \frac{1}{\sqrt{n}}\sum_{i=1}^{n}(-1)^{x_i}|i\rangle.$$

Bob completes his αn edges to a perfect matching in an arbitrary way, and measures with the corresponding set of $n/2$ 2-dimensional projectors. With probability 2α he will get one of the edges (i_ℓ, j_ℓ) of his input M. The state then collapses to

$$\frac{1}{\sqrt{2}}\left((-1)^{x_{i_\ell}}|i_\ell\rangle + (-1)^{x_{j_\ell}}|j_\ell\rangle\right),$$

from which Bob can obtain the bit $z_\ell = x_{i_\ell} \oplus x_{j_\ell}$ by measuring in the corresponding $|\pm\rangle$-basis. Note that this protocol has so-called zero-sided error: Bob knows when he didn't learn any bit z_ℓ. If Bob is given $O(k/\alpha)$ copies of $|\psi\rangle$, then with high probability (at least while $k \ll \alpha n$) he can learn k distinct bits of z.

Remark. This protocol can be modified to a protocol in the simultaneous message passing model in a standard way, first suggested by Buhrman (see [12]). Alice and Bob share the maximally entangled state $\frac{1}{\sqrt{n}}\sum_i |i,i\rangle$. Alice implements the transformation $|i\rangle \to (-1)^{x_i}|i\rangle$ on her half. Bob performs the measurement with his projectors on his half. If he gets one of the edges of his input, he sends the resulting (i_ℓ, j_ℓ) and w_ℓ to the referee. Now Alice and Bob perform a Hadamard transform on their halves, and measure and send the result to the referee, who has enough information to reconstruct z_ℓ.

Classical upper bound. We sketch an $O(\sqrt{n/\alpha})$ *classical* upper bound. Suppose Alice uniformly picks a subset of $d \approx \sqrt{n/\alpha}$ bits of x to send to Bob. By the birthday paradox, with high probability Bob will have both endpoints of at least one of his αn edges and so he can compute a bit of z (and hence the function value b) with good probability. In this protocol Alice would need to send about $d \log n$ bits to Bob, since she needs to describe the d indices as well as their bit values. However, by Newman's theorem [25], Alice can actually restrict her random choice to picking one out of $O(n)$ possible d-bit subsets, instead of one out of all $\binom{n}{d}$ possible subsets. Hence $d + O(\log n)$ bits of communication suffice. This matches our lower bound up to constant factors.

3. Main proof. In this section we prove our main technical result (Theorem 1), which shows that Bob knows hardly anything about the string $z = Mx$ unless Alice sends him a long message.

3.1. Preliminaries. We begin by providing a few standard definitions from Fourier analysis on the Boolean cube. For functions $f, g : \{0,1\}^n \to \mathbb{R}$ we define their inner product and ℓ_2-norm by

$$\langle f, g\rangle = \frac{1}{2^n}\sum_{x\in\{0,1\}^n} f(x)g(x), \quad \| f \|_2^2 = \langle f, f\rangle = \frac{1}{2^n}\sum_{x\in\{0,1\}^n} |f(x)|^2. \tag{2}$$

The Fourier transform of f is a function $\widehat{f} : \{0,1\}^n \to \mathbb{R}$ defined by

$$\widehat{f}(s) = \langle f, \chi_s\rangle = \frac{1}{2^n}\sum_{y\in\{0,1\}^n} f(y)\chi_s(y),$$

where $\chi_s : \{0,1\}^n \to \mathbb{R}$ is the character $\chi_s(y) = (-1)^{y\cdot s}$, with "$\cdot$" being the scalar product; $\widehat{f}(s)$ is the Fourier coefficient of f corresponding to s. We have the following relation between f and $\widehat{f}$:

$$f = \sum_{s\in\{0,1\}^n} \widehat{f}(s)\chi_s.$$

We will use two tools in our analysis, Parseval's identity and the Kahn–Kalai–Linial lemma.

LEMMA 3 (Parseval). *For every function $f : \{0,1\}^n \to \mathbb{R}$ we have $\| f \|_2^2 = \sum_{s\in\{0,1\}^n} \widehat{f}(s)^2$.*

Note in particular that if f is an arbitrary probability distribution on $\{0,1\}^n$ and U is the uniform distribution on $\{0,1\}^n$, then $\widehat{f}(0^n) = \widehat{U}(0^n) = 1/2^n$ and $\widehat{U}(s) = 0$ for nonzero s, hence

$$\| f - U \|_2^2 = \sum_{s\in\{0,1\}^n} (\widehat{f}(s) - \widehat{U}(s))^2 = \sum_{s\in\{0,1\}^n\setminus\{0^n\}} \widehat{f}(s)^2. \tag{3}$$

LEMMA 4 (Kahn–Kalai–Linial [16]). *Let f be a function $f : \{0,1\}^n \to \{-1,0,1\}$. Let $A = \{x \mid f(x) \neq 0\}$, and let $|s|$ denote the Hamming weight of $s \in \{0,1\}^n$. Then for every $\delta \in [0,1]$ we have*

$$\sum_{s \in \{0,1\}^n} \delta^{|s|} \widehat{f}(s)^2 \leq \left(\frac{|A|}{2^n}\right)^{\frac{2}{1+\delta}}.$$

We also need the following combinatorial lemma about uniformly chosen matchings.[4]

LEMMA 5. *Let $v \in \{0,1\}^n$. If $|v| = k$ for even k, then*

$$\Pr_M[\exists\, s \in \{0,1\}^{\alpha n} \text{ s.t. } M^T s = v] = \frac{\binom{\alpha n}{k/2}}{\binom{n}{k}},$$

where the probability is taken uniformly over all α-matchings M.

Proof. We can assume without loss of generality that $v = 1^k 0^{n-k}$. We will compute the fraction of matchings M for which there exists such an s. The total number of matchings M of αn edges is $n!/(2^{\alpha n}(\alpha n)!(n-2\alpha n)!)$. This can be seen as follows: Pick a permutation of n, view the first αn pairs as αn edges, and ignore the ordering within each edge, the ordering of the αn edges, and the ordering of the last $n - 2\alpha n$ vertices. Note that $\exists\ s$ s.t. $M^T s = v$ if and only if M has exactly $k/2$ edges in $[k]$ and $\alpha n - k/2$ edges in $[n]\backslash[k]$. The number of ways to pick $k/2$ edges in $[k]$ (i.e., a perfect matching) is $k!/(2^{k/2}(k/2)!)$. The number of ways to pick $\alpha n - k/2$ edges in $[n] - [k]$ is $(n-k)!/(2^{\alpha n - k/2}(\alpha n - k/2)!(n-2\alpha n)!)$. Hence the probability in the lemma equals

$$\frac{k!/(2^{k/2}(k/2)!) \cdot (n-k)!/(2^{\alpha n - k/2}(\alpha n - k/2)!(n-2\alpha n)!)}{n!/(2^{\alpha n}(\alpha n)!(n-2\alpha n)!)} = \frac{\binom{\alpha n}{k/2}}{\binom{n}{k}}. \qquad \square$$

This probability is exponentially small in k if $\alpha < 1/2$, but it equals 1 if $\alpha = 1/2$ and $v = 1^n$.

3.2. Proof of Theorem 1. In order to prove Theorem 1, consider any set $A \subseteq \{0,1\}^n$ with $|A| \geq 2^{n-c}$ and let $f : \{0,1\}^n \to \{0,1\}$ be its characteristic function (i.e., $f(x) = 1$ if and only if $x \in A$). Let $\varepsilon \in (0,2]$, $\alpha \in (0, 1/4]$, and $1 \leq c \leq \gamma\varepsilon\sqrt{n/\alpha}$ for some γ to be determined later.

With x uniformly distributed over A, we can write down Bob's induced distribution on z as

$$p_M(z) = \frac{|\{x \in A \mid Mx = z\}|}{|A|}.$$

We want to show that p_M is close to uniform for most M. By (3), we can achieve this by bounding the Fourier coefficients of p_M. These are closely related to the Fourier coefficients of f:

$$\begin{aligned}\widehat{p_M}(s) &= \frac{1}{2^{\alpha n}} \sum_{z \in \{0,1\}^{\alpha n}} p_M(z)(-1)^{z \cdot s} \\ &= \frac{1}{|A| 2^{\alpha n}} \left(|\{x \in A \mid (Mx) \cdot s = 0\}| - |\{x \in A \mid (Mx) \cdot s = 1\}|\right)\end{aligned}$$

[4] We use the standard convention $\binom{a}{b} = 0$ whenever $b > a$.

$$= \frac{1}{|A|2^{\alpha n}} \left(|\{x \in A \mid x \cdot (M^T s) = 0\}| - |\{x \in A \mid x \cdot (M^T s) = 1\}| \right)$$

$$= \frac{1}{|A|2^{\alpha n}} \sum_{x \in \{0,1\}^n} f(x)(-1)^{x \cdot (M^T s)}$$

$$= \frac{2^n}{|A|2^{\alpha n}} \cdot \widehat{f}(M^T s). \tag{4}$$

Note that the Hamming weight of $v = M^T s \in \{0,1\}^n$ is twice the Hamming weight of $s \in \{0,1\}^{\alpha n}$.

Using the Kahn–Kalai–Linial lemma, we get the following bound on the level sets of the Fourier transform of f.

LEMMA 6. *For every $k \in \{1, \ldots, 4c\}$ we have $\frac{2^{2n}}{|A|^2} \sum_{v:|v|=k} \widehat{f}(v)^2 \leq \left(\frac{4\sqrt{2}c}{k}\right)^k$.*

Proof. By the Kahn–Kalai–Linial inequality (Lemma 4), for every $\delta \in [0,1]$ we have

$$\frac{2^{2n}}{|A|^2} \sum_{v:|v|=k} \widehat{f}(v)^2 \leq \frac{2^{2n}}{|A|^2} \frac{1}{\delta^k} \left(\frac{|A|}{2^n}\right)^{2/(1+\delta)} = \frac{1}{\delta^k} \left(\frac{2^n}{|A|}\right)^{2\delta/(1+\delta)} \leq \frac{1}{\delta^k} \left(\frac{2^n}{|A|}\right)^{2\delta} \leq \frac{2^{2\delta c}}{\delta^k}.$$

Plugging in $\delta = k/4c$ (which is in $[0,1]$ by our assumption on the value of k) gives the lemma. □

We bound the expected *squared* total variation distance between p_M and U as follows:

$$\mathbb{E}_M[\| p_M - U \|_{tvd}^2] \leq 2^{2\alpha n} \mathbb{E}_M \left[\| p_M - U \|_2^2 \right]$$

$$= 2^{2\alpha n} \mathbb{E}_M \left[\sum_{s \in \{0,1\}^{\alpha n} \setminus \{0^{\alpha n}\}} \widehat{p_M}(s)^2 \right]$$

$$= \frac{2^{2n}}{|A|^2} \mathbb{E}_M \left[\sum_{s \in \{0,1\}^{\alpha n} \setminus \{0^{\alpha n}\}} \widehat{f}(M^T s)^2 \right],$$

where we used, respectively, the Cauchy–Schwarz inequality (recall that our definition of $\| \cdot \|_2^2$ in (2) already includes a factor $1/2^{\alpha n}$), (3), and (4). Note that for each $v \in \{0,1\}^n$, there is at most one $s \in \{0,1\}^{\alpha n}$ for which $M^T s = v$ (and the only s that makes $M^T s = 0^n$ is $s = 0^{\alpha n}$). This allows us to change the expectation over M into a probability and use Lemma 5:

$$= \frac{2^{2n}}{|A|^2} \mathbb{E}_M \left[\sum_{v \in \{0,1\}^n \setminus \{0^n\}} |\{s \in \{0,1\}^{\alpha n} \mid M^T s = v\}| \cdot \widehat{f}(v)^2 \right]$$

$$= \frac{2^{2n}}{|A|^2} \sum_{v \in \{0,1\}^n \setminus \{0^n\}} \Pr_M \left[\exists\, s \in \{0,1\}^{\alpha n} \text{ s.t. } M^T s = v \right] \cdot \widehat{f}(v)^2$$

$$= \frac{2^{2n}}{|A|^2} \sum_{\text{even } k=2}^{2\alpha n} \frac{\binom{\alpha n}{k/2}}{\binom{n}{k}} \sum_{v:|v|=k} \widehat{f}(v)^2.$$

We first upper bound the part of this sum with $k < 4c$. Applying Lemma 6 for each k, and using the standard estimates $(n/k)^k \leq \binom{n}{k} \leq (en/k)^k$ and our upper bound

$c \leq \gamma\varepsilon\sqrt{n/\alpha}$, we get

$$\frac{2^{2n}}{|A|^2}\sum_{\text{even } k=2}^{4c-2}\frac{\binom{\alpha n}{k/2}}{\binom{n}{k}}\sum_{v:|v|=k}\widehat{f}(v)^2 \leq \sum_{\text{even } k=2}^{4c-2}\frac{(2e\alpha n/k)^{k/2}}{(n/k)^k}\left(\frac{4\sqrt{2}c}{k}\right)^k \leq \sum_{\text{even } k=2}^{4c-2}\left(\frac{64e\gamma^2\varepsilon^2}{k}\right)^{k/2}.$$

Picking γ a sufficiently small constant, this is at most $\varepsilon^2/2$ (note that the sum starts at $k=2$).

In order to bound the part of the sum with $k \geq 4c$, note that the function $g(k) := \binom{\alpha n}{k/2}/\binom{n}{k}$ is decreasing for the range of even k up to $2\alpha n$ (which is $\leq n/2$ because $\alpha \leq 1/4$):

$$\begin{aligned}\frac{g(k-2)}{g(k)} &= \frac{\binom{\alpha n}{k/2-1}/\binom{n}{k-2}}{\binom{\alpha n}{k/2}/\binom{n}{k}}\\ &= \frac{(n-k+2)(n-k+1)k/2}{(\alpha n-k/2+1)(k-1)k}\\ &= \frac{(n-k+2)(n-k+1)}{(2\alpha n-k+2)(k-1)}\\ &\geq \frac{n-k+1}{k-1} \geq 1.\end{aligned}$$

We also have $\sum_{v\in\{0,1\}^n}\widehat{f}(v)^2 = \frac{|A|}{2^n}$ by Parseval (Lemma 3), and $\frac{2^n}{|A|} \leq 2^c$ by assumption. Hence

$$\frac{2^{2n}}{|A|^2}\sum_{\text{even } k=4c}^{2\alpha n} g(k)\sum_{v:|v|=k}\widehat{f}(v)^2 \leq 2^c g(4c) \leq \left(\frac{8\sqrt{2}e\alpha c}{n}\right)^{2c} \leq \left(8\sqrt{2}e\gamma\varepsilon\sqrt{\frac{\alpha}{n}}\right)^{2c} \leq \varepsilon^2/2,$$

where in the last step we used $\alpha/n \leq 1$ and $c \geq 1$, and picked γ a sufficiently small constant.

Hence we have shown $\mathbb{E}_M[\| p_M - U \|_{tvd}^2] \leq \varepsilon^2$. By Jensen's inequality we have

$$\mathbb{E}_M[\| p_M - U \|_{tvd}] \leq \sqrt{\mathbb{E}_M[\| p_M - U \|_{tvd}^2]} \leq \varepsilon.$$

This concludes the proof of Theorem 1. Let x be uniformly distributed over a set $A \subseteq \{0,1\}^n$ of size $|A| \geq 2^{n-c}$ for some $c \geq 1$, and let M be uniformly distributed over the set $\mathcal{M}_{\alpha n}$ of all α-matchings for some $\alpha \in (0, 1/4]$. There exists a universal constant $\gamma > 0$ (independent of n, c, and α), such that for all $\varepsilon \in (0,2]$, if $c \leq \gamma\varepsilon\sqrt{n/\alpha}$, then

$$\mathbb{E}_M\left[\| p_M - U \|_{tvd}\right] \leq \varepsilon.$$

The ε^2 upper bound on $\mathbb{E}_M[\| p_M - U \|_{tvd}^2]$ is essentially tight. This can be seen in the communication setting as follows. With probability $\Omega(\varepsilon^2)$ over the choice of M, at least one edge of M will have both endpoints in the first $c = \varepsilon\sqrt{n/\alpha}$ bits. Then if Alice just sends the first c bits of x to Bob, she gives him a bit of z. This makes $\| p_M - U \|_{tvd}$ at least 1, hence $\mathbb{E}_M[\| p_M - U \|_{tvd}^2] = \Omega(\varepsilon^2)$.

3.3. Proof of Theorem 2. Our Theorem 2, stated in the introduction, easily follows from Theorem 1. By the Yao principle [35], it suffices to analyze *deterministic*

protocols under some "hard" input distribution. Our input distribution will be uniform over $x \in \{0,1\}^n$ and $M \in \mathcal{M}_{\alpha n}$. The inputs x and M together determine the αn-bit string $z = Mx$. To complete the input distribution, with probability $1/2$ we set $w = z$ and with probability $1/2$ we set w to z's complement $\overline{z}$.

Fix $\varepsilon > 0$ to a small constant, say $1/1000$. Let $c = \gamma\varepsilon\sqrt{n/\alpha}$, and consider any classical deterministic protocol that communicates at most $C = c - \log(1/\varepsilon)$ bits. This protocol partitions the set of 2^n x's into 2^C sets $A_1, \ldots, A_{2^C}$, one for each possible message. On average, these sets have size 2^{n-C}. Moreover, by a simple counting argument, at most a $2^{-\ell}$-fraction of all $x \in \{0,1\}^n$ can sit in sets of size $\leq 2^{n-C-\ell}$. Hence with probability at least $1-\varepsilon$, the message that Alice sends corresponds to a set $A \subseteq \{0,1\}^n$ of size at least $2^{n-C-\log(1/\varepsilon)} = 2^{n-c}$. In that case, by Theorem 1 and Markov's inequality, for at least a $(1-\sqrt{\varepsilon})$-fraction of all M, the random variable $Z = MX$ (with X uniformly distributed over A) is $\sqrt{\varepsilon}$-close to the uniform distribution U. Given w, Bob needs to decide whether $w = Z$ or $w = \overline{Z}$. In other words, he is given one sample w, and needs to decide whether it came from distribution Z or $\overline{Z}$. As we mentioned after (1), he can do this only if the distributions of Z and $\overline{Z}$ have large total variation distance. But by the triangle inequality

$$\| Z - \overline{Z} \|_{tvd} \leq \| Z - U \|_{tvd} + \| \overline{Z} - U \|_{tvd} = 2\| Z - U \|_{tvd} \leq 2\sqrt{\varepsilon}.$$

Hence Bob's advantage over randomly guessing the function value will be at most ε (for the unlikely event that A is very small) plus $\sqrt{\varepsilon}$ (for the unlikely event that M is such that MX is more than $\sqrt{\varepsilon}$ away from uniform) plus $\sqrt{\varepsilon}/2$ (for the advantage over random guessing when $\| Z - U \| \leq \sqrt{\varepsilon}$). To sum up, if the communication is much less than $\sqrt{n/\alpha}$ bits, then Bob cannot decide the function value with probability significantly better than $1/2$.

4. Viewing our construction as an extractor. So far, we have proved that if the n-bit string X is uniformly distributed over a set A with $|A| \geq 2^{n-c}$ (i.e., a flat distribution on A), and Y is uniformly distributed over all α-matchings, then $(Y, Z(X,Y))$ is close to uniform. In order to conclude the result about extractors mentioned in section 1.2, we need to prove the same result in the more general situation when X has min-entropy at least $n-c$ (instead of just being uniform on a set of size at least 2^{n-c}). However, a result by Chor and Goldreich [10, Lemma 5], based on the fact that any distribution can be thought of as a convex combination of flat distributions, shows that the second statement follows from the first: flat distributions are the "worst distributions" for extractors.

5. Conclusion. In this paper we presented an extractor that is reasonably good when some small amount of *classical* information is known about the random source X (technically: $H_{min}(X) \geq n - O(\sqrt{n/\alpha})$), but that fails miserably if even a very small (logarithmic) amount of *quantum* information is known about X. We gave the following applications of this:

1. An exponential quantum-classical separation for one-way communication complexity for a Boolean function (which, in particular, implies near-optimality of Aaronson's classical simulations of quantum one-way protocols).
2. A classically-secure privacy amplification scheme that is insecure against a quantum adversary.
3. A key-expansion scheme that is secure against memory-bounded classical adversaries, but not against memory-bounded quantum adversaries.
4. An exponential quantum-classical separation in the streaming model of computation.

They all can be viewed as examples where *quantum memory is much more powerful than classical*. This contrasts, for instance, with the results about privacy amplification based on two-universal hashing [19, 30], where quantum memory is not significantly more powerful than classical memory.

Acknowledgments. Many thanks to Oded Regev for his ideas on simplifying the two proofs in the conference version of our paper to the current proof. Also many thanks to Renato Renner for explaining why min-entropy determines the key length when doing privacy amplification based on two-universal hashing (both in the classical and in the quantum case), and him, Yevgeniy Dodis, Christian Schaffner, and Barbara Terhal for discussions about the bounded-storage model. Thanks to Shengyu Zhang for bringing the streaming model to our attention, and to Scott Aaronson for prodding us to make explicit the dependence on α in Theorem 1 in light of the results mentioned at the end of section 1.1. Thanks to Guy Kindler and Jaikumar Radhakrishnan for various references that were needed for the earlier proofs in our conference paper (but that are no longer needed). Finally, thanks to the anonymous SICOMP referees for some comments that improved the presentation of the paper.

GRAPH DISTANCES IN THE DATA-STREAM MODEL*

JOAN FEIGENBAUM†, SAMPATH KANNAN‡, ANDREW MCGREGOR§, SIDDHARTH SURI¶, AND JIAN ZHANG‖

Abstract. We explore problems related to computing graph distances in the data-stream model. The goal is to design algorithms that can process the edges of a graph in an arbitrary order given only a limited amount of working memory. We are motivated by both the practical challenge of processing massive graphs such as the web graph and the desire for a better theoretical understanding of the data-stream model. In particular, we are interested in the trade-offs between model parameters such as per-data-item processing time, total space, and the number of passes that may be taken over the stream. These trade-offs are more apparent when considering graph problems than they were in previous streaming work that solved problems of a statistical nature. Our results include the following: (1) *Spanner construction:* There exists a single-pass, $\tilde{O}(tn^{1+1/t})$-space, $\tilde{O}(t^2n^{1/t})$-time-per-edge algorithm that constructs a $(2t+1)$-spanner. For $t = \Omega(\log n/\log\log n)$, the algorithm satisfies the semistreaming space restriction of $O(n \operatorname{polylog} n)$ and has per-edge processing time $O(\operatorname{polylog} n)$. This resolves an open question from [J. Feigenbaum et al., *Theoret. Comput. Sci.*, 348 (2005), pp. 207–216]. (2) *Breadth-first-search (BFS) trees:* For any even constant k, we show that any algorithm that computes the first k layers of a BFS tree from a prescribed node with probability at least 2/3 requires either greater than $k/2$ passes or $\tilde{\Omega}(n^{1+1/k})$ space. Since constructing BFS trees is an important subroutine in many traditional graph algorithms, this demonstrates the need for new algorithmic techniques when processing graphs in the data-stream model. (3) *Graph-distance lower bounds:* Any t-approximation of the distance between two nodes requires $\Omega(n^{1+1/t})$ space. We also prove lower bounds for determining the length of the shortest cycle and other graph properties. (4) *Techniques for decreasing per-edge processing:* We discuss two general techniques for speeding up the per-edge computation time of streaming algorithms while increasing the space by only a small factor.

Key words. stream algorithms, graph distances, spanners

1. Introduction.

In recent years, streaming has become an active area of research and an important paradigm for processing massive data sets [4, 23, 27]. Much of the existing work has focused on computing statistics of a stream of data elements,

e.g., frequency moments [4, 29], ℓ_p distances [23, 28], histograms [24, 26], and quantiles [25]. More recently, there have been extensions of the streaming research to the study of graph problems [6, 22, 27]. Solving graph problems in this model has raised new challenges, because many existing approaches to the design of graph algorithms are rendered useless by the sequential-access limitation and the space limitation of the streaming model.

Massive graphs arise naturally in many real-world scenarios. Two examples are the *call graph* and the *web graph*. In the call graph, nodes represent telephone numbers and edges correspond to calls placed during some time interval. In the web graph, nodes represent web pages, and the edges correspond to hyperlinks between pages. Also, massive graphs appear in structured data mining, where the relationships among the data items in the data set are represented as graphs. When processing these graphs it is often appropriate to use the streaming model. For example, the graph may be revealed by a web crawler or the graph may be stored on external-memory devices, where being able to process the edges in an arbitrary order improves I/O efficiency. Indeed, the authors of [33] argue that one of the major drawbacks of standard graph algorithms, when applied to massive graphs such as the web, is their need to have random access to the edge set.

In general it seems that most graph algorithms need to access the data in a very adaptive fashion. Since we cannot store the entire graph, emulating a traditional algorithm may necessitate an excessive number of passes over the data. There has been some success in estimating quantities that are of a statistical nature, e.g., counting triangles [6, 11, 31] or estimating frequency and entropy moments of the degrees in a multigraph [12, 15]. However, it seemed for a while that more "complicated" computation was not possible in this model. For example, Buchsbaum, Giancarlo, and Westbrook [10] demonstrated the intrinsic difficulty of computing common neighborhoods in the streaming model with small space. One possible way to ameliorate the situation is to consider algorithms that use $\Theta(n \operatorname{polylog} n)$ space, i.e., space roughly proportional to the number of nodes rather than the number of edges. This space restriction was identified as an apparent "sweet-spot" for graph streaming in a survey article by Muthukrishnan [37] and dubbed the *semistreaming* space restriction. This spurred further research on algorithms for graph problems in the streaming model such as distance estimation [19, 22], matchings [22, 36], and connectivity [21, 41], including the work described here. We will provide further discussion of the results on distance estimation in the next section.

A related model is the *semiexternal model*. This was introduced by Abello, Buchsbaum, and Westbrook [1] for computations on massive graphs. In this model, the vertex set can be stored in memory, but the edge set cannot. However, unlike in our model, random access to the edges, although expensive, was allowed. Finally, graph problems have been considered in a model that extends the stream model by allowing the algorithm to write to the stream during each pass [2, 16]. These *annotations* can then be utilized by the algorithm during successive passes. Aggarwal et al. [2] go further and suggest a model in which *sorting passes* are permitted, and the data-stream is sorted according to a key encoded by the annotations.

Designing algorithms for computing graph distances is a very well studied problem, and graph distances are a natural quantity to study when trying to understand properties of massive graphs such as the diameter of the world wide web [3]. We start with a formal definition of the relevant terms.

DEFINITION 1.1 (graph distance, diameter, and girth). *For an undirected, un-*

weighted graph $G = (V, E)$, we define a distance function $d_G : V \times V \to \{0, \ldots, n-1\}$, where $d_G(u, v)$ is the length of the shortest path in G between u and v. The diameter of G is the length of the longest shortest path, i.e.,

$$\mathrm{Diam}(G) = \max_{u,v \in V} d_G(u, v).$$

The girth of G is the length of the shortest cycle in G, i.e.,

$$\mathrm{Girth}(G) = 1 + \min_{(u,v) \in E} d_{G \setminus (u,v)}(u, v).$$

Classic algorithms such as Dijkstra, Bellman–Ford, and Floyd–Warshall are taught widely [14]. Recent research has focused on computing approximate graph distances [5, 7, 17, 40]. Unfortunately, these algorithms seem to be inherently unsuitable for computing distances in the streaming model; an important subroutine of many of the existing algorithms is the construction of breadth-first-search (BFS) trees, and one of our main results is a lower bound on the computational resources required to compute a BFS tree. For example, Thorup and Zwick provide a construction of distance oracles for approximating distances in graphs [40]. Although *all-pairs*-shortest-path distances can be approximated using this oracle, their oracle construction requires the computation of shortest-path trees for certain vertices. Indeed, many constructions of distance oracles have this requirement, i.e., they need to compute *some* distances between certain pairs of vertices in order to build a data structure from which the all-pairs-shortest-path distances can be approximated.

A common method for approximating graph distances is via the construction of *spanners*.

DEFINITION 1.2 (spanners). *A subgraph $H = (V, E')$ is an (α, β)-*spanner *of $G = (V, E)$ if, for any vertices $x, y \in V$,*

$$d_G(x, y) \le d_H(x, y) \le \alpha d_G(x, y) + \beta.$$

When $\beta = 0$, we call the spanner a multiplicative-spanner *and refer to α as the* stretch factor *of the spanner.*

In [22], a simple semistreaming spanner construction is presented. That algorithm constructs a $(\log n)$-spanner in one pass using $O(n \operatorname{polylog} n)$ space. However, this algorithm needs $O(n)$ time to process each edge in the input stream. Such a per-edge processing time is prohibitive, especially in the streaming model when edges may be arriving in quick succession. The work of [19] studies the construction of $(1 + \epsilon, \beta)$ spanners in the streaming model. However, the algorithm of [19] requires multiple passes over the input stream, while our construction needs only one pass.

Notation and terminology. We refer to an event's occurring "with high probability" if the probability of the event is at least $1 - 1/n^{\Omega(1)}$. We denote the set $\{1, \ldots, t\}$ by $[t]$. Let $\mathcal{P}(S)$ denote the power set of S, i.e., $\{S' : S' \subset S\}$.

1.1. Our results. Our results include the following.

1. *Spanner construction:* There exists a single-pass $O(tn^{1+1/t} \log^2 n)$ space, $O(t^2 n^{1/t} \log n)$ time-per-edge algorithm that constructs a $(2t + 1)$-spanner. For $t = \Omega(\log n / \log \log n)$, the algorithm satisfies the semistreaming space restriction of $O(n \operatorname{polylog} n)$ and has per-edge processing time $O(\operatorname{polylog} n)$. The algorithm is presented in section 3. This result resolves an open question from [22].

2. *BFS trees:* For any even constant k, any algorithm that computes the first k layers of a BFS tree from a prescribed node with probability at least $2/3$ requires either greater than $k/2$ passes or $\tilde{\Omega}(n^{1+1/k})$ space. This result is proved in section 4. Since constructing BFS trees is an important subroutine in many traditional graph algorithms, this demonstrates the need for new algorithmic techniques when processing graphs in the data-stream model.
3. *Lower bounds:* In section 5, we present lower bounds for the following problems:
   (a) *Connectivity and other balanced properties:* We show that testing any of a large class of graph properties, which we refer to as *balanced properties*, in one pass requires $\Omega(n)$ space. This class includes properties such as connectivity and bipartiteness. This result provides a formal motivation for the *semistreaming* space restriction, where algorithms are permitted $O(n \operatorname{polylog} n)$ space.
   (b) *Graph distances and graph diameter:* We show that any single-pass algorithm that returns a t-approximation of the graph distance between two given nodes with probability at least $3/4$ requires $\Omega(n^{1+1/t})$ bits of space. Furthermore, this bound also applies to estimating the diameter of the graph. Therefore, approximating a distance using the above spanner construction is only about a factor of 2 from optimal in terms of the approximation factor achievable for a given space restriction.
   (c) *Girth:* Any p-pass algorithm that ascertains whether the length of the shortest cycle is longer than g requires $\Omega\left(p^{-1}(n/g)^{1+4/(3g-4)}\right)$ bits of space.
4. *Techniques for decreasing per-edge processing:* In section 6, we present a method for local amortization of per-data-item complexity. We also present a technique for adapting existing partially dynamic graph algorithms to the semistreaming model.

The above results indicate various trade-offs between model parameters and accuracy. These include the smooth trade-off between the space a single-pass algorithm is permitted and the accuracy achievable when estimating graph distances. For multiple-pass algorithms, a smooth trade-off between passes and space is evident when trying to compute the girth of a graph. This trade-off is, in a sense, fundamental as it indicates that the only way to get away with using half the amount of space is essentially to make half as much progress in each pass. The trade-off between space and passes when computing BFS trees indicates that, as we restrict the space, no algorithm can do much better than emulating a trivial traditional graph algorithm and will consequently require an excessive number of passes.

Recent developments. Since the preliminary version of this paper appeared, improved spanner construction algorithms were presented by Baswana [8] and Elkin [18]. Extensions of ideas in section 6 have been developed by Zelke [41, 42].

2. Preliminaries. In this section, we give a formal definition of a graph stream.

DEFINITION 2.1 (graph stream). *For a data-stream $A = \langle a_1, a_2, \ldots, a_m \rangle$, where $a_j \in [n] \times [n]$, we define a graph G on n vertices $V = \{v_1, \ldots, v_n\}$ with edges $E = \{(v_i, v_k) : a_j = (i, k)$ for some $j \in [m]\}$.*

We usually assume that each a_j is distinct, but this assumption is often not necessary. When the data items are not distinct, the model can naturally be extended to consider multigraphs; i.e., an edge (v_i, v_k) has multiplicity equal to $|\{j : a_j = (i, k)\}|$. Similarly, we consider undirected graphs, but the definition can be generalized

to define digraph streams. Sometimes we will consider weighted graphs, and in this case $a_j \in [n] \times [n] \times \mathbb{N}$, where the third component of the data item indicates a weight associated with the edge. Note that some authors have also considered a special case of the model, the adjacency-list model, in which all incident edges are grouped together in the stream [6]. We will be interested in the fully general model.

3. Spanners. In this section, we present a single-pass streaming algorithm that constructs a $(2t+1)$-spanner for an unweighted, undirected graph. The algorithm uses some of the ideas from [7] and adapts them for use in the data-stream model. We then extend this algorithm to construct $(1+\epsilon)(2t+1)$-spanners for weighted, undirected graphs using a geometric grouping technique.

Overview of the algorithm. Intuitively, we want to cover each "dense subgraph" of the graph by a tree of small depth, i.e., one of depth $O(\log n)$, rooted at some node. If there are many edges between two such dense subgraphs, only one representative edge needs to be remembered. Edges between vertices that are not part of such dense subgraphs also need to be remembered, but we will argue that there are not too many of them. The construction requires a delicate balance between trying to include as many nodes as possible in a small number of dense subgraphs and ensuring that the depth of the spanning tree covering each dense subgraph is $O(\log n)$.

Our clusters are similar to those used in [5, 7, 17]. However, the constructions of the clusters in [5, 7, 17] all employ an approach similar to BFS; i.e., the clusters are constructed layer by layer. Such a layer-by-layer process is important to ensure that the clusters constructed in [5,7,17] have small diameters. In the streaming model, this would necessitate multiple passes over the input stream. Our labeling scheme employs a different strategy to control the clusters' diameters, thus bypassing the BFS.

In more detail, in the case in which we are constructing $O(\log n)$-spanners, we consider $\log n/2$ levels. Each node is present at the bottom level and is "promoted" to each successively higher level with probability $1/2$. Whenever a node is present at level i, a cluster at level i is dynamically grown around it as we process the edges. The expected number of clusters at level $i+1$ is half of the expected number of clusters at level i. At the top level, the expected number of clusters is $\sqrt{n}$. As the algorithm goes through the input stream of edges, a node in a lower-level cluster may join a higher-level cluster. The constructed spanner consists of three types of edges: (1) a small-diameter spanning tree for each cluster, (2) one edge between each pair of top-level clusters whose vertex sets have at least one edge between them, and (3) a small number of "other" edges that do not fit into either of these two categories and are necessary to preserve the spanner property.

The above ideas are applicable mutatis mutandis when a t-spanner is sought for other values of t. The description below is for arbitrary t.

The algorithm. A label l used in our construction is a positive integer. Given two parameters n and t, the set of labels L used by our algorithm is generated in the following way. Initially, we have labels $[n]$. We denote by L^0 this set of labels and call them the *level*-0 labels. Independently, and with probability $n^{-1/t}$, each label $l \in L^0$ will be put into a set S^0 and marked as *selected*. From each label l in S^0, we generate a new label $l' = l + n$. We denote by L^1 the set of newly generated labels and call them the *level*-1 labels. We then apply the above selection and new-label-generation procedure on L^1 to get the set of level-2 labels L^2. We continue this until the level-$\lfloor t/2 \rfloor$ labels $L^{\lfloor t/2 \rfloor}$ are generated. If a level-$(i+1)$ label l is generated from a level-i label l', we call l the *successor* of l' and denote it by $\mathrm{Succ}(l') = l$. The set of labels we will use in our algorithm is the union of labels of levels $0, 1, 2, \ldots, \lfloor t/2 \rfloor$, i.e.,

$L = \bigcup_0^{\lfloor t/2 \rfloor} L^i$. Note that L can be generated before the algorithm sees the edges in the stream. But, in order to generate the labels in L, except in the case $t = \Theta(\log n)$, the algorithm needs to know n, the number of vertices in the graph, before seeing the edges in the input stream. For $t = \Theta(\log n)$, a simple modification of the above method can be used to generate L without knowing n, because the probability for a label to be selected is constant.

At first glance, it might appear that our labeling scheme resembles the sequences of sets initially constructed by the algorithm of Thorup and Zwick [40]. In our construction, the generation of the clusters of vertices depends on both the labels and the edge set. Thorup and Zwick, however, generate their sequence of sets independently of the edges. But, this is just the first step in their algorithm. Subsequently, their algorithm computes the exact distance between a fixed vertex and each of the sets of vertices in the sequence. Computing the exact distances between a pair of vertices is difficult in the streaming model. Our algorithm takes a very different approach from [40] to avoid this difficulty.

While going through the stream, our algorithm will label each vertex with labels chosen from L. The algorithm may label a vertex v with multiple labels; however, v will be labeled by at most one label from L^i for $i \in [\lfloor t/2 \rfloor]$. Moreover, if v is labeled by a label l, and l is selected, the algorithm will also label v with the label $\mathrm{Succ}(l)$.

Denote by l^i a label of level i, i.e., $l^i \in L^i$. Let $L(v) = \{l^0, l^{k_1}, l^{k_2}, \ldots, l^{k_j}\}$ be the collection of labels that has been assigned to the vertex v, where $0 < k_1 < \cdots < k_j \leq \lfloor t/2 \rfloor$. Let

$$\mathrm{Height}(v) = \max\{j | l^j \in L(v)\}$$

and $\mathrm{Top}(v) = l^k \in L(v)$ s.t. $k = \mathrm{Height}(v)$. Let $C(l)$ be the collection of vertices that are labeled with the label l.

The sets $L(v)$ and $C(l)$ will grow while the algorithm goes through the stream and labels the vertices. For each $C(l)$, our algorithm stores a tree, $\mathrm{Tree}(l)$, on the vertices of $C(l)$ and the tree is rooted on the first vertex that gets labeled by l. We say an edge (u, v) connects $C(l)$ and $C(l')$ if u is labeled with l and v is labeled with l'. For some pairs of labels $l, l' \in L^{\lfloor t/2 \rfloor}$, our algorithm will store edges that connect $C(l)$ and $C(l')$. We denote by H the set of such edges stored by our algorithm. In addition, for each vertex v, we denote by $M(v)$ the other edges incident to v that are stored by our algorithm. Intuitively, the subgraph induced by $\cup_{v \in V} M(v)$ is the sparse part of the graph G. The spanner constructed by the algorithm is the union of the rooted trees for all the labels, $M(v)$ for all the vertices, and the set H. The detailed algorithm is given in Figure 3.1.

Analysis. We start with two preliminary lemmas showing that, with high probability, the spanner construction requires only a small amount of working space. Note that randomness is introduced in the generation of the labels in Algorithm 1; that is the reason that the bounds stated in both lemmas are true with high probability.

LEMMA 3.1. *With high probability, for all $v \in V$, $|M(v)| = O(tn^{1/t} \log n)$.*

Proof. Let $M^{(i)}(v) \subseteq M(v)$ be the set of edges added to $M(v)$ during the period when $\mathrm{Height}(v) = i$. Let $L(M(v)) = \cup_{(u,v) \in M(v)} L(u)$ be the set of labels that have been assigned to the vertices in $M(v)$. An edge (u, v) is added to $M(v)$ only in step 2(b)ii. Note that, in this case, $\lfloor \frac{t}{2} \rfloor \geq \mathrm{Height}(u) \geq \mathrm{Height}(v)$. Hence, the set $L_v(u)$ is not empty. Also, by the condition in step 2(b)ii, an edge (u, v) is added only when none of the labels in $L_v(u)$ appears in $L(M(v))$. Thus, if we add the edge in this step, we will introduce/add the label(s) in $L_v(u)$ to $L(M(v))$. Because $L_v(u)$

Algorithm 1 (efficient one pass spanner construction).
The input to the algorithm is an unweighted, undirected graph $G = (V, E)$, presented as a stream of edges, and two positive integer parameters n and t.

1. Generate the set L of labels as described. $\forall\ v_i \in V$, label vertex v_i with label $i \in L^0$. If i is selected, label v_i with $\mathrm{Succ}(i)$. Continue this until we encounter a label that is not selected. Set $M(v_i) \leftarrow \emptyset$ and $H \leftarrow \emptyset$.
2. Upon seeing an edge (u, v) in the stream, if $L(v) \cap L(u) \neq \emptyset$, drop the edge. Otherwise, consider the following cases:
   (a) If $\mathrm{Height}(v) = \mathrm{Height}(u) = \lfloor t/2 \rfloor$, and there is no edge in H that connects $C(\mathrm{Top}(v))$ and $C(\mathrm{Top}(u))$, set $H \leftarrow H \cup \{(u, v)\}$.
   (b) Otherwise, assume, without loss of generality, that $\lfloor t/2 \rfloor \geq \mathrm{Height}(u) \geq \mathrm{Height}(v)$. Consider the collection of labels
   $$L_v(u) = \{l^{k_1}, l^{k_2}, \ldots, l^{\mathrm{Height}(u)}\} \subseteq L(u),$$
   where $\mathrm{Height}(v) \leq k_1 \leq k_2 \leq \cdots \leq \mathrm{Height}(u)$. Let $l \in L_v(u)$ be the selected label whose level is the lowest among the selected labels in $L_v(u)$.
      i. If such a label l exists, label the vertex v with the successor $l' = \mathrm{Succ}(l)$ of l, i.e.,
      $$L(v) \leftarrow L(v) \cup \{l'\}.$$
      Incorporate the edge in the rooted tree $\mathrm{Tree}(l')$. If l' is selected, label v with $l'' = \mathrm{Succ}(l')$ and incorporate the edge in the tree $\mathrm{Tree}(l'')$. Continue until we see a label that is not marked as selected. (Note that $\mathrm{Height}(v)$ is increased by this process.)
      ii. If no such label l exists and there is no edge (u', v) in $M(v)$ such that u, u' are labeled with the same label $l \in L_v(u)$, add (u, v) to $M(v)$.
3. After seeing all the edges in the stream, output the union of the rooted trees for all the labels, $M(v)$ for all the vertices, and the set H as the spanner.

FIG. 3.1. *An efficient, one-pass algorithm for computing sparse spanners. See the descriptions before Lemma* 3.1 *for the definitions of* H, $M(v)$, $L(v)$, $C(l)$, $\mathrm{Tree}(l)$, $\mathrm{Succ}(l)$, $\mathrm{Top}(v)$, *and* $\mathrm{Height}(v)$.

is nonempty, it adds at least one new label to $L(M(v))$. This is the case for every edge in $M^{(i)}(v)$. Let B be the set of distinct labels that $M^{(i)}(v)$ adds to $L(M(v))$. Furthermore, because each edge in $M^{(i)}(v)$ adds at least one new label, the size of B is at least $|M^{(i)}(v)|$. Note that the labels in B are not marked as selected. Otherwise, the algorithm would have taken step 2(b)i instead of step 2(b)ii. Hence, the size of B satisfies

$$\Pr(|B| = k) \leq (1 - 1/n^{1/t})^k.$$

Thus, with high probability, $|M^{(i)}(v)| = O(n^{1/t} \log n)$. Because i can take only $O(t)$ values, with high probability,

$$|M(v)| = \sum_i |M^{(i)}(v)| = O(tn^{1/t} \log n). \qquad \square$$

LEMMA 3.2. *With high probability, the algorithm stores* $O(tn^{1+1/t}\log n)$ *edges.*

Proof. The algorithm stores edges in the set H, in the rooted trees for each cluster $C(l)$, and in the sets $M(v)$, for all $v \in V$. By the Chernoff bound and the union bound, with high probability the number of clusters at level $t/2$ is $O(\sqrt{n})$, and the size of the set H is $O(n)$.

For each label l, the algorithm stores a rooted tree for the set of vertices $C(l)$. The rooted tree is formed by the set of edges added when the vertices in $C(l)$ get labeled by the label l. This happens in step 2(b)i. In this step, we add an edge only at the time when a vertex becomes a member of $C(l)$. Therefore, the set of edges forms a tree on $C(l)$. We call this tree the rooted tree of $C(l)$. Note that two vertices u and v in $C(l)$ may share some other label l' of a different level. In this case, they both also belong to $C(l')$. The tree of $C(l')$ may have a path connecting u and v. Hence the subgraph of the spanner induced by the vertices in $C(l)$ is not necessarily a tree. When we say "the rooted tree of $C(l)$," we refer only to the edges added when the vertices in $C(l)$ get labeled by l.

Note that, for each level $i \in [\lfloor t/2 \rfloor]$, a vertex is labeled with at most one label in L^i. Hence, $\sum_{l \in L^i} |C(l)| \leq |V|$. Thus, the number of edges summed over the rooted trees for the labels at level i is $O(n)$, and the total number of edges in all the rooted trees is $O(tn)$. Finally, by Lemma 3.1, with high probability, $|M(v)| = O(tn^{1/t}\log n)$. By the union bound, with high probability, $\sum_{v \in V} |M(v)| = O(tn^{1+1/t}\log n)$. ∎

THEOREM 3.3. *Let G be an unweighted graph. There exists a single-pass $O(tn^{1+1/t}\log^2 n)$ space algorithm that constructs a $(2t+1)$-spanner of G with high probability and processes each edge in $O(t^2 n^{1/t}\log n)$ time.*

Proof. Consider Algorithm 1 in Figure 3.1. At the beginning of the algorithm, for all the labels $l \in L^0$, $C(l)$ is a singleton set, and the depth of the rooted tree for $C(l)$ is zero. We now bound, for label l^i, where $i > 0$, the depth of the rooted tree T^i on the vertices in $C(l^i)$. A tree grows when an edge (u, v) is incorporated into the tree in step 2(b)i. In this case, l^i is a successor of some label l^{i-1} of level $i-1$. Assume that the depth $d_{T^i}(v)$ of the vertex v in the tree is one more than the depth $d_{T^i}(u)$ of the vertex u. Then $u \in C(l^{i-1})$, and the depth $d_{T^{i-1}}(u)$ of u in the rooted tree T^{i-1} of $C(l^{i-1})$ is the same as $d_{T^i}(u)$. Hence, $d_{T^i}(v) = d_{T^{i-1}}(u) + 1$, where T^i is a tree of level i, and T^{i-1} is a tree of level $i-1$. Given that $d_{T^0}(x) = 0$ for all $x \in V$, the depth of a rooted tree for $C(l)$, where l is a label of level i, is at most i.

We proceed to show that, for any edge that the algorithm does not store, there is a path of length at most $2t+1$ that connects the two endpoints of the edge. The algorithm ignores three types of edges. First, if $L(u) \cap L(v) \neq \emptyset$, the edge (u, v) is ignored. In this case, let l be one of the label(s) in $L(u) \cap L(v)$. The nodes u and v are both on the rooted tree for $C(l)$; hence, there is a path of length at most t connecting u and v. Second, (u, v) will be ignored if $\text{Height}(v) = \text{Height}(u) = \lfloor t/2 \rfloor$, and there is already an edge connecting $C(\text{Top}(u))$ and $C(\text{Top}(v))$. In this case, the path connecting u and v has length at most $2t+1$. Finally, in step 2(b)ii, (u, v) will be ignored if there is already another edge in $M(v)$ that connects v to some $u' \in C(l)$, where $l \in L(u)$. Note that u and u' are both on the rooted tree of $C(l)$. Hence, there is a path of length at most $t+1$ connecting u and v.

Hence, the stretch factor of the spanner constructed by Algorithm 1 is $2t+1$. By Lemma 3.2, with high probability, the algorithm stores $O(tn^{1+1/t}\log n)$ edges and requires $O(tn^{1+1/t}\log^2 n)$ bits of space. Also note that the bottleneck in the processing of each edge lies in step 2(b)ii, where, for each label in $L_v(u)$, we need to examine the whole set of $M(v)$. This takes $O(t^2 n^{1/t}\log n)$ time. ∎

Extensions. Once the spanner is constructed, all-pairs-shortest-distances of the graph can be computed from the spanner. This computation does not need to access the input stream and thus can be viewed as postprocessing. We also note that the above algorithm can be used to construct a spanner of a weighted graph $G = (V, E)$ using a geometric grouping technique [13,22]. Namely, we can round each edge weight ω' up to $\min\{\omega(1+\epsilon)^i : i \in \mathbb{Z}, \omega(1+\epsilon)^i \geq \omega'\}$, where ω is the weight of the first edge, and $\epsilon > 0$ is a user-defined accuracy parameter. Let $G^i = (V, E^i)$ be the graph formed from G by removing all edges not of weight $\omega(1+\epsilon)^i$. For each G^i, we construct a spanner in parallel and take the union of these spanners. This leads to the following theorem.

THEOREM 3.4. *Let G be a weighted graph and W be the ratio between the maximum and minimum weights. There exists a single-pass $O(\epsilon^{-1}tn^{1+1/t}\log W \log^2 n)$ space algorithm that constructs a $(1+\epsilon)(2t+1)$-spanner of G with high probability and processes each edge in $O(t^2 n^{1/t}\log n)$ time.*

In the case where $t = \log n/\log\log n$, Algorithm 1 computes a $(2\log n/\log\log n + 1)$-spanner in one pass using $O(n\log^4 n)$ bits of space and processing each edge in $O(\log^4 n)$ time. This answers an open question we posed in [22]. Finally, note that constructing a $(2t+1)$-spanner gives a $(2t+1)$-approximation for the diameter and, indirectly, a $(2t+2)/3$-approximation of the girth. The diameter result is immediate. For the girth approximation, note that, if the constructed spanner is a strict subgraph of G, then the girth of G must have been between 3 and $2t+2$.

4. BFS trees lower bound. In this section, we prove a lower bound on the number of passes required to construct the first l layers of a BFS tree in the streaming model. The result is proved using a reduction from the communication-complexity problem "multivalued pointer chasing." This is a natural generalization of the pointer-chasing problem considered by Nisan and Wigderson [38].

Overview of proof. Nisan and Wigderson [38] considered the problem in which Alice and Bob have functions $f_A : [m] \to [m]$ and $f_B : [m] \to [m]$, respectively. The k-round pointer-chasing problem is to output the result of starting from 1 and alternatively applying f_A and f_B a total of k times, starting with f_A. Nisan and Wigderson proved that, if Bob speaks first, the communication complexity of any k-round communication protocol to solve this problem is $\Omega(m/k^2 - k\log m)$. Jain, Radhakrishnan, and Sen [30] gave a direct sum extension showing that, if there are d pairs of functions and the goal is to perform k-round pointer chasing as above on each pair, the communication-complexity lower bound is approximately d times the bound of [38]. More precisely, they showed a lower bound of $\Omega(dm/k^3 - dk\log m - 2d)$ for the problem.

We show how the lower bound of [30] implies a lower bound on the communication complexity of pointer chasing with "d-valued functions," i.e., functions that map $i \in [m]$ to a subset of $[m]$ of size at most d. If f_A and f_B are such functions, then the result of pointer chasing starting from 1 produces a set of size at most d^k. The key difference between this problem and the problem of [30] is that in the latter, one is concerned only with chasing "like" pointers. That is, if one gets to an element j using the function $f_{A,i}$, one can continue only with $f_{B,i}$. (We will present an example after the formal definition of the appropriate terms.) Nevertheless, we give a reduction that shows that the two problems have fairly similar communication complexity.

Finally, we create a an l-layered graph in which alternate layers have edges corresponding to d-valued functions f_A and f_B. In order to construct the BFS tree, we must solve the l-round, d-valued pointer-chasing problem and then apply the afore-

mentioned lower bound. This will lead to the following theorem.

THEOREM 4.1 (BFS lower bound). *For any constant k, any algorithm that computes the first k layers of a BFS tree with probability at least $2/3$ requires either $k/2$ passes or $\Omega(n^{1+1/k}/(\log n)^{1/k})$ space.*

We now present the above argument formally. Let F_d be the set of functions $f : \mathcal{P}([m]) \to \mathcal{P}([m])$ such that

$$\forall i \in [m],\ |f(i)| \le d \quad \text{and} \quad \forall A \subset [m],\ f(A) = \bigcup_{i \in A} f(i).$$

Throughout the rest of this section, we abuse notation and denote the singleton set $\{i\}$ by i when it appears as the input or the output of a function $f \in F_d$.

DEFINITION 4.2. *Define $g^{k,d} : F_d \times F_d \to \mathcal{P}([m])$ inductively as*

$$g^{0,d}(f_A, f_B) = \{1\} \quad \textit{and} \quad g^{i,d}(f_A, f_B) = \begin{cases} f_A(g^{i-1,d}(f_A, f_B)) & \textit{if } i \textit{ odd,} \\ f_B(g^{i-1,d}(f_A, f_B)) & \textit{if } i \textit{ even.} \end{cases}$$

Define $h^{k,d}$ as the d-fold direct sum of $g^{k,1}$, i.e.,

$$h^{k,d}(\langle f_{A,1}, \ldots, f_{A,d}\rangle, \langle f_{B,1}, \ldots, f_{B,d}\rangle) = \langle g^{k,1}(f_{A,1}, f_{B,1}), \ldots, g^{k,1}(f_{A,d}, f_{B,d})\rangle.$$

EXAMPLE 4.3. *Consider $f_{A,1}, f_{A,2}, f_{B,1}, f_{B,2} \in F_1$, where*

$$\begin{array}{llll} f_{A,1}: 1 \to 1 & f_{A,2}: 1 \to 2 & f_{B,1}: 1 \to 1 & f_{B,2}: 1 \to 3 \\ \quad 2 \to 2 & \quad 2 \to 3 & \quad 2 \to 2 & \quad 2 \to 1 \\ \quad 3 \to 3, & \quad 3 \to 1, & \quad 3 \to 3, & \quad 3 \to 2. \end{array}$$

Let $f_A, f_B \in F_2$ be defined by $f_A(j) := f_{A,1}(j) \cup f_{A,2}(j)$ and $f_B(j) := f_{B,1}(j) \cup f_{B,2}(j)$. Then

$$h^{2,2}(\langle f_{A,1}, f_{A,2}\rangle, \langle f_{B,1}, f_{B,2}\rangle) = \langle 1, 1\rangle, \textit{ whereas } g^{2,2}(f_A, f_B) = \{1, 2, 3\}.$$

Let Alice have function f_A and Bob have function f_B. Let $R^r_\delta(g_{d,k})$ be the r-round randomized communication complexity of $g_{d,k}$ where Bob speaks first, i.e., the number of bits sent in the worst case (over all inputs and random coin tosses) by the best r-round protocol Π in which, with probability at least $1-\delta$, both Alice and Bob learn $g_{d,k}$. The following theorem for $h^{k,d}$ was proved in [30] using an information-theoretic argument in combination with a result by Nisan and Wigderson [38].

THEOREM 4.4 (see Jain, Radhakrishnan, and Sen [30]). $R^k_{1/3}(h^{k,d}) = \Omega(dmk^{-3} - dk \log m - 2d)$.

We now use the above result to prove a bound on the communication complexity of $g^{k,d}$.

THEOREM 4.5. $R^k_{1/3}(g^{k,d}) = \Omega(dm/(k+1)^3 - d(k+1)\log m - 2d - 6d^{k+1} \lg m)$ *if k is even.*

Proof. The proof uses a reduction from $h^{k,d}$. Let $(\langle f_{A,1}, \ldots, f_{A,d}\rangle, \langle f_{B,1}, \ldots, f_{B,d}\rangle)$ be an instance of $h^{k,d}$. Define f^*_A and f^*_B as follows:

$$f^*_A(j) := \{f_{A,i}(j) : i \in [d]\} \text{ and } f^*_B(j) := \{f_{B,i}(j) : i \in [d]\}.$$

Assume that there exists a k-round protocol Π for $g^{k,d}$ that fails with probability at most $1/3$ and communicates $o(dm/(k+1)^3 - d(k+1)\log m - 2d - 12d^{k+1} \lg m - km)$ bits in the worst case. We will show how to transform Π into a $(k+1)$-round protocol

Π' for $h^{k+1,d}$ that fails with probability at most $1/3$ and communicates $o(dm/(k+1)^3 - d(k+1)\log m - 2d)$ bits in the worst case. This contradicts Theorem 4.4 and hence shows that there is no such protocol Π.

Let Π' be a protocol that simulates Π and, in addition, on the jth message $(1 < j \le k+1)$, sends the following set of triples:[1]

$$T_{j-1} = \{\langle a, b, f_{C,a}(b)\rangle : b \in g^{j-2,d}(f_A^*, f_B^*)\}, \quad \text{where} \quad C = \begin{cases} A & \text{if } j \text{ is even,} \\ B & \text{if } j \text{ is odd.} \end{cases}$$

Π is shown to be correct by an inductive argument and requires at most $3d^{j-1}\log m$ additional bits of communication per message, because $b \in g^{j-2,d}(f_A^*, f_B^*)$ and $|g^{j-2,d}(f_A^*, f_B^*)| \le d^{j-2}$, $a \in [d]$, and each $\langle a, b, f_{C,a}(b)\rangle$ can be encoded with at most $3\log m$ bits. However, if Π is successful, then the player who sends the kth message (which is Alice by assumption that k is even and Bob speaks first) of Π also knows $g^{k,d}(f_A^*, f_B^*)$. Hence, she can also send

$$T_{k+1} = \{\langle a, b, f_{A,a}(b)\rangle : b \in g^{k,d}(f_A^*, f_B^*)\}.$$

Hence, after $(k+1)$ rounds, $\bigcup_{i\in[k+1]} T_i$ is known to both parties with probability at least $2/3$ and can be used to deduce $g^{k+1,d}$. The total amount of extra communication required to transmit $\bigcup_{i\in[k+1]} T_i$ is $\sum_{i\in[k+1]} 3d^i \log m \le 6d^{k+1}\log m$. Hence Π' communicates $o(dm/(k+1)^3 - d(k+1)\log m - 2d)$ bits in the worst case. ∎

We are now in a position to prove Theorem 4.1.

Proof. The proof is a reduction from d-valued pointer chasing. Let $m = n/(k+1)$, and let $d = c(m/\log m)^{1/k}$ for some small constant c. Then, since k is constant by Theorem 4.5, $R^k_{1/3}(g^{k,d}) = \Omega(n^{1+1/k}/(\log n)^{1/k})$.

Consider an instance (f_A, f_B) of $g^{k,d}$. The graph described by the stream is on the following set V of $n = (k+1)m$ nodes:

$$V = \bigcup_{0\le i\le k} \{v_1^i, \ldots, v_m^i\}.$$

For $i \in [k]$, we define a set of edges $E(i)$ between $\{v_1^{i-1}, \ldots, v_m^{i-1}\}$ and $\{v_1^i, \ldots, v_m^i\}$ in the following way:

$$E(i) = \begin{cases} \{(v_j^{i-1}, v_\ell^i) : \ell \in f_A(j)\} & \text{if } i \text{ is odd,} \\ \{(v_j^{i-1}, v_\ell^i) : \ell \in f_B(j)\} & \text{if } i \text{ is even.} \end{cases}$$

Suppose there exists an algorithm $\mathcal{A}$ that computes the first k layers of the BFS tree from v_1^1 in p passes using memory M. Let L_r be set of nodes that are at distance exactly r from v_1^1. Note that, for all $r \in [k]$,

$$g^{r,d} = L_r \cap \{v_1^r, \ldots, v_m^r\}.$$

By simulating $\mathcal{A}$ on a stream starting with $\bigcup_{0\le i\le k:\text{even}} E(i)$ and concluding with $\bigcup_{i\in[k]:\text{odd}} E(i)$ in the natural way, we deduce that there exists a $(2p)$-round communication protocol for $g^{k,d}$ that uses only $2pM$ communication. (Note that $2p$ rounds of communication rather than $(2p-1)$ rounds are required, because we required both parties to learn $g^{k,d}$.) Hence, either $2p > k$ or $M = \Omega(n^{1+1/k})$. ∎

[1] Note that on the $(k+1)$th message there is no message of Π to simulate and only T_k is transmitted.

5. Other lower bounds. In this section, we present lower bounds on the space required to estimate graph distances, test whether a graph is connected, and compute the girth of a graph. Our lower bounds are reductions from problems in communication complexity. In the SET-DISJOINTNESS problem, Alice has a length-n binary string $x \in \{0,1\}^n$, and Bob has a length-n binary string $y \in \{0,1\}^n$, where $\sum_{i\in[n]} x_i = \sum_{i\in[n]} y_i = \lfloor n/4 \rfloor$. If Bob is to compute

$$\text{SET-DISJOINTNESS}(x,y) = \begin{cases} 1 & \text{if } x \cdot y = 0, \\ 0 & \text{if } x \cdot y \geq 1 \end{cases}$$

(where $x \cdot y = \sum_{i\in[n]} x_i y_i$) with probability at least 3/4, then it is known that $\Omega(n)$ bits must be communicated between Alice and Bob [32, 39]. In the INDEX problem, Alice has $x \in \{0,1\}^n$, and Bob has $j \in [n]$. If Bob is to compute $\text{INDEX}(x,j) = x_j$ with probability at least 3/4 after a single message from Alice, then it is known that this message must contain $\Omega(n)$ bits (e.g., [34]). To relate our graph-stream problems to these communication problems, we use reductions based upon results from random-graph theory and extremal combinatorics.

5.1. Connectivity and balanced properties. Our first result shows that a large class of problems, including connectivity, cannot be solved by single-pass streaming algorithms in small space. Specifically, we identify a general type of graph property[2] and show that testing any such graph property requires $\Omega(n)$ space.

DEFINITION 5.1 (balanced properties). *We say a graph property $\mathcal{P}$ is* balanced *if there exists a constant $c > 0$ such that, for all sufficiently large n, there exists a graph $G = (V,E)$ with $|V| = n$ and $u \in V$ such that*

$$\min\{|\{v : (V, E \cup \{(u,v)\}) \text{ has } \mathcal{P}\}|, |\{v : (V, E \cup \{(u,v)\}) \text{ has } \neg\mathcal{P}\}| \} \geq cn.$$

In other words, there are $\Omega(n)$ vertices v such that $(V, E \cup \{(u,v)\})$ has $\mathcal{P}$ and $\Omega(n)$ vertices v such that $(V, E \cup \{(u,v)\})$ does not have $\mathcal{P}$.

Many interesting properties are balanced, including connectivity, bipartiteness, and whether there exists a vertex of a certain degree.

THEOREM 5.2. *Testing for any balanced graph property $\mathcal{P}$ with probability 3/4 in a single pass requires $\Omega(n)$ space.*

Proof. Let c be a constant, $G = (V,E)$ be a graph on n vertices, and $u \in V$ be a vertex satisfying the relevant conditions. The proof is by a reduction to the communication complexity of INDEX. Let $(x,j) \in \{0,1\}^{cn} \times [cn]$ be an instance of INDEX. Let $G(x)$ be a relabeling of the vertices of G such that $u = v_n$ and, for $i \in [cn]$, $(V, E \cup \{(v_n, v_i)\})$ has $\mathcal{P}$ if and only if $x_i = 1$. Such a relabeling is possible, because $\mathcal{P}$ does not depend on the labeling of the vertices. Let $e(j) = (v_j, v_n)$. Hence the graph determined by the edges of $G(x)$ and $e(j)$ has $\mathcal{P}$ if and only if $x_j = 1$. Therefore, any single-pass algorithm for testing $\mathcal{P}$ using M bits of work space gives rise to a one-message protocol for solving INDEX, and this implies that $M = \Omega(n)$. ∎

For some balanced graph properties, the above theorem can be generalized. For example, it is possible to show that any p-pass algorithm that determines whether a graph is connected requires $\Omega(np^{-1})$ bits of space [27].

[2] A *graph property* is a boolean function whose inputs are the elements of the adjacency matrix of the graph but whose output is independent of the labeling of the nodes of the graph.

5.2. Graph distances and graph diameter. If we are interested only in estimating the distance between two nodes u and v, it may appear that constructing a graph spanner that gives no special attention to u or v, but rather approximates *all* distances, is an unnecessarily crude approach. In this section, however, we show that the spanner-construction approach yields an approximation at most a factor 2 from optimal. Our result is a generalization of one in [22] that applied to the semistreaming case. Integral to our proof is the notion of a *k-critical edge*.

DEFINITION 5.3. *In a graph $G = (V, E)$, an edge $e = (u, v) \in E$ is* k-critical *if* $d_{G\setminus(u,v)}(u, v) \geq k$.

In Lemma 5.4, we show the existence of a graph G with a large subset of edges E' such that each edge in E' is k-critical, but the removal of all edges in E' leaves a graph with relatively small diameter. The proof uses a probabilistic method.

LEMMA 5.4. *For sufficiently large n and $3 \leq k = o(\log n/\log\log n)$, there exists a set E of edges partitioned into two disjoint sets E_1 and E_2 on a set of n nodes V such that*

1. $|E_2| = \lceil n^{1+1/k}/144 \rceil$,
2. *every edge in E_2 is k-critical for $G = (V, E)$, and*
3. $\mathrm{Diam}(G_1) \leq k + 1$, *where $G_1 = (V, E_1)$.*

Proof. Let $\gamma = 1/k$. Consider choosing a random graph $G' = (V, E')$ on n nodes where each edge is (independently) present with probability $p = 1/(2n^{1-\gamma})$. This is commonly denoted as $G' \sim \mathcal{G}_{n,p}$. We will then construct $G_1 = (V, E_1)$ by deleting each edge in G' with probability $1/2$. We will show that, with nonzero probability, the sets E_1 and $E_2 = \{e \in E' \setminus E_1 : e \text{ is } k\text{-critical for } G'\}$ satisfy the three required properties.

The second property is satisfied by construction. It follows from the fact that, if an edge is k-critical in a graph G, then it is also k-critical in any subgraph of G. We now argue that the third property is satisfied with probability at least $99/100$. First note that the process that generates G_1 is identical to picking $G_1 \sim \mathcal{G}_{n,p/2}$. It can be shown that, with high probability, the diameter of such a graph is less than $1/\gamma + 1$ for sufficiently large n [9, Corollary 10.12].

We now show that the first property is satisfied with probability at least $8/100$. Applying the Chernoff bound and the union bound proves that, with probability at least $99/100$, the degree of every vertex in G' is between $n^\gamma/4$ and $3n^\gamma/4$.

Now consider choosing a random graph and a random edge in that graph simultaneously, i.e., $G' = (V, E') \sim \mathcal{G}_{n,p}$ and an edge $(u, v) \in_R E'$. We prove a lower bound on the probability that (u, v) is k-critical in G'. Let $\Gamma_i(v) = \{w \in V : d_{G'\setminus(u,v)}(v, w) \leq i\}$. For sufficiently large n, conditioned on the event that the maximum degree is at most $3n^\gamma/4$,

$$|\Gamma_k(v)| \leq \sum_{0\leq i\leq k} (3n/4)^{i\gamma} \leq 1.01(3n/4)^{k\gamma} \leq 4(n-1)/5.$$

As G' varies over all possible graphs, by symmetry, each vertex is equally likely to be in $\Gamma_k(v)$. Thus the probability that u is not in this set is at least $1/5$. By Markov's inequality,

$$\Pr\left(|\{(u, v) \in E' : d_{G'\setminus(u,v)}(u, v) \geq k\}| \geq |E'|/9\right) \geq 1/10.$$

Note that, if the degree of every vertex in G' is at least $n^\gamma/4$, then $|E'| \geq n^{1+\gamma}/8$. Hence,

$$\Pr\left(|\{(u, v) \in E' : d_{G'\setminus(u,v)}(u, v) \geq k\}| \geq n^{1+\gamma}/72\right) \geq 9/100.$$

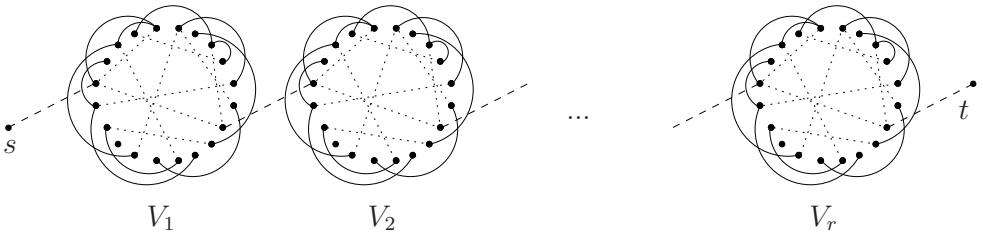

FIG. 5.1. *Diameter lower-bound construction. Edges E_x are dotted, E_j are dashed, and E_m are solid.*

Given that each edge in E' is deleted independently with probability $1/2$ to form E_1, by a further application of the Chernoff bound we deduce that

$$\Pr\left(|\{(u,v) \in E' \setminus E_1 : d_{G' \setminus (u,v)}(u,v) \geq k\}| \geq n^{1+\gamma}/144\right) \geq 8/100.$$

From this set of k-critical edges, we can choose a subset whose size is exactly $\lceil n^{1+\gamma}/144 \rceil$, as required by statement 1. Therefore, all three properties hold with probability at least $1 - 92/100 - 1/100 = 7/100$. □

THEOREM 5.5. *For $3 \leq k = o(\log n / \log\log n)$, any single-pass algorithm that, with probability at least $3/4$, returns $\tilde{D}$ such that*

$$\mathrm{Diam}(G) \leq \tilde{D} \leq (k-1)\,\mathrm{Diam}(G),$$

where G is a weighted graph on n nodes, requires $\tilde{\Omega}(n^{1+1/k})$ space.

Proof. Let $(x, j) \in \{0,1\}^t \times [t]$ be an instance of the INDEX problem. We will show how to transform an algorithm $\mathcal{A}$ for approximating the diameter of a graph into a protocol for INDEX.

Let $G = (V, E = E_1 \cup E_2)$ be a graph on $n' = (144t)^{1/(1+\gamma)}$ nodes with the properties listed in Lemma 5.4. We assume that both Alice and Bob know G and that, moreover, they agree on an ordered list $e_1, \ldots, e_t$ of the edges that are in E_2. This may be assumed, because Alice and Bob can generate identical enumerations of all graphs on n' nodes and all partitions of the edges of each graph into E_1 and E_2, test each graph and partition for the necessary properties, and use the first that passes all of the tests. Finding such a G may take exponential time, but that is all right, because it is only the communication complexity of the resulting INDEX protocol, not the time complexity, that concerns us.

Alice forms the graph $G_x = (V, E_m \cup E_x)$, where $E_x = \{e_i \in E_2 : x_i = 1\}$ and $E_m = E_1$. She then creates the prefix of a stream by taking r (to be determined later) copies of G_x, i.e., a graph on $n'r$ vertices $\{v_1^1, \ldots, v_{n'}^1, v_1^2, \ldots, v_{n'}^2, v_1^3, \ldots, v_{n'}^r\}$ and with edge set $\{(v_j^i, v_k^i) : i \in [r], (v_j, v_k) \in E_x\}$. All these edges have unit weight.

Let j be the index in the instance of INDEX, and let $e_j = (a, b)$. Bob determines the remaining edges E_j as follows: $r-1$ edges of zero weight, $\{(v_b^i, v_a^{i+1}) : i \in [r-1]\}$, and two edges of weight $k+1$, (s, v_a^1) and (v_b^r, t). See Figure 5.1 for a diagram of the construction.

Note that, regardless of the values of x and j, the diameter of the graph described by the stream equals $d_G(s,t)$. Note that $x_j = 1$ implies that $d_G(s,t) = r + 2k + 2$. However, if $x_j = 0$, then $d_G(s,t) = kr + 2k + 2$. Hence, for $r = 2k^2$, the ratio between $kr + 2k + 2$ and $r + 2k + 2$ is at least $k - 1$. Therefore, any single-pass algorithm that approximates the diameter to within a factor of $k - 1$ gives rise to a one-way protocol for solving INDEX. This implies that any such algorithm requires

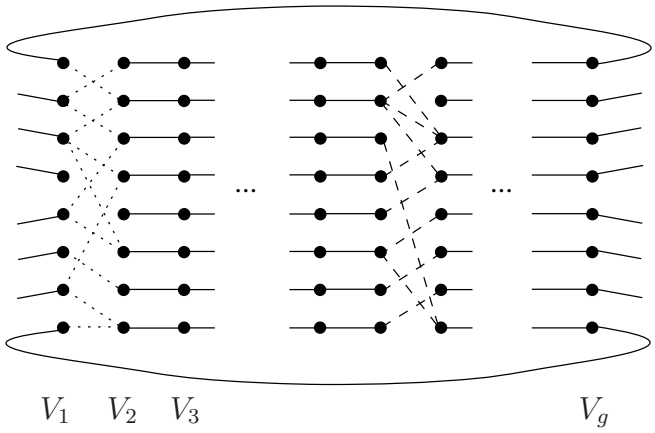

FIG. 5.2. *Girth lower-bound construction. Edges E_x are dotted, E_y are dashed, and E_m are solid.*

$\Omega(n^{1+1/k})$ bits of space, because the total number of nodes in the construction is $n = O((144t)^{1/(1+1/k)}k^2)$. □

5.3. Girth. In this section, we prove a lower bound on the space required by a (multipass) algorithm that tests whether a graph has girth at most g. We shall make use of the following result from [35].

LEMMA 5.6 (see Lazebnik, Ustimenko, and Woldar [35]). *Let $k \geq 1$ be an odd integer, $t = \lfloor \frac{k+2}{4} \rfloor$, and q be a prime power. There exists a bipartite, q-regular graph with at most $2q^{k-t+1}$ nodes and girth at least $k+5$.*

The following lower bound is established with a construction based on Lemma 5.6 that yields a reduction from SET-DISJOINTNESS to girth estimation.

THEOREM 5.7. *For $g \geq 5$, any p-pass algorithm that tests whether the girth of an unweighted graph is at most g requires $\Omega\left(p^{-1}(n/g)^{1+4/(3g-4)}\right)$ space. If g is odd, this can be strengthened to $\Omega\left(p^{-1}(n/g)^{1+4/(3g-7)}\right)$ space.*

Proof. Let q be a prime power; let $k = g-4$ if g is odd, and $k = g-3$ if g is even. Let $t = \lfloor \frac{k+2}{4} \rfloor$. Then,

$$k - t + 1 \leq k - \frac{k+2}{4} + 3/4 + 1 \leq \begin{cases} (3g-7)/4 & \text{if } g \text{ is odd,} \\ (3g-4)/4 & \text{if } g \text{ is even.} \end{cases}$$

Lemma 5.6 implies that there exists a q-regular graph $G' = (L \cup R, E')$ with at most $2n' \leq 2q^{k-t+1}$ nodes and girth at least $g+1$. Let $L = \{l_1, \ldots, l_{n'}\}$ and $R = \{r_1, \ldots, r_{n'}\}$ and, for each $i \in [n']$, $D_i = \Gamma(l_i)$.

We let $(x, y) \in \{0,1\}^r \times \{0,1\}^r$ be an instance of SET-DISJOINTNESS where $r = n'q$. It will be convenient to write $x = x^1 \ldots x^{n'}$ and $y = y^1 \ldots y^{n'}$, where $x^i, y^j \in \{0,1\}^q$. We will show how to transform a p-pass algorithm $\mathcal{A}$ for testing whether the girth of a graph is at most g into a protocol for SET-DISJOINTNESS. If $\mathcal{A}$ uses M bits of working memory, then the protocol will transmit $O(pM)$ bits. Hence $M = \Omega(p^{-1}n'q)$.

Alice and Bob construct a graph G based upon G', x, and y as follows. For $i \in [g]$, let $V_i = \{v_1^i, \ldots, v_{n'}^i\}$. For each $i \in [n']$, let $D_i(x) \subset D_i$ be the subset of D_i whose characteristic vector is x^i. $D_i(y)$ is defined similarly. There are three sets of edges on

these nodes:

$$E_m = \bigcup_{j=\lfloor g/2 \rfloor + 1}^{g} \{(v_i^j, v_i^{j+1}) : i \in [n']\},$$
$$E_x = \{(v_i^1, v_j^2) : j \in D_i(x), i \in [n']\}, \text{ and}$$
$$E_y = \{(v_j^{\lfloor g/2 \rfloor}, v_i^{\lfloor g/2 \rfloor + 1}) : j \in D_i(y), i \in [n']\}.$$

See Figure 5.2 for a diagram of the construction.

Note that $\text{Girth}(G) = g$ if there exists i such that $D_i(x) \cap D_i(y) \neq \emptyset$, i.e., x and y are not disjoint. However, if x and y are disjoint, then the shortest cycle is of length at least $4 + 2\lfloor \frac{g-2}{2} \rfloor \geq g + 1$. Hence, determining whether the girth is at most g determines whether x and y are disjoint. □

6. Toward fast per-item processing. In section 3, we gave a spanner construction that processes each edge much faster than previous spanner-construction algorithms. In this section, we explore two general methods for decreasing the per-edge computation time of a streaming algorithm. As a consequence, we will show how some results from [20] give rise to efficient graph-stream algorithms.

Our first observation is that we can locally amortize per-edge processing by using some of our storage space as a *buffer* for incoming edges. While the algorithm processes a time-consuming edge, subsequent edges can be buffered subject to the availability of space. This yields a potential decrease in the minimum allowable time between the arrival of consecutive pairs of incoming edges.

THEOREM 6.1. *Consider a streaming algorithm that runs in space $S(n)$ and uses computation time $\tau(m, n)$ to process the entire stream. This streaming algorithm can be simulated by a one-pass streaming algorithm that uses $O(S(n) \log n)$ storage space and has worst-case time per-edge $\tau(m, n)/S(n)$.*

Next we turn to capitalizing on work done to speed up *dynamic graph algorithms.* Dynamic graph algorithms allow edges to be inserted and deleted in any order and the current graph to be queried for a property $\mathcal{P}$ at any point. *Partially dynamic algorithms*, on the other hand, are those that allow only edge insertions and querying. In [20], the authors describe a technique called *sparsification* and use it to speed up existing dynamic graph algorithms that decide whether a graph has property $\mathcal{P}$. Sparsification is based on maintaining strong certificates throughout the updates to the graph.

DEFINITION 6.2. *For any graph property $\mathcal{P}$ and graph G, a* strong certificate *for G is a graph G' on the same vertex set such that, for any H, $G \cup H$ has property $\mathcal{P}$ if and only if $G' \cup H$ has it as well.*

It is easy to see that strong certificates obey a transitivity property: If G' is a strong certificate of property $\mathcal{P}$ for graph G, and G'' is a strong certificate for G', then G'' is a strong certificate for G. Strong certificates also obey a compositional property. If G' and H' are strong certificates of $\mathcal{P}$ for G and H, then $G' \cup H'$ is a strong certificate for $G \cup H$.

In order to achieve their speedup, the authors of [20] ensure that the certificates they maintain are not only strong but also sparse. A property is said to have *sparse certificates* if there is some constant c such that for every graph G on an n-vertex set, we can find a strong certificate for G with at most cn edges. Maintaining $\mathcal{P}$ over a sparse certificate allows an algorithm to run on a dense graph, using the (smaller) computational time required for a sparse graph.

TABLE 6.1
One-pass, $O(n \operatorname{polylog} n)$ space streaming algorithms given by Theorem 6.3.

Problem	Time/edge
Bipartiteness	$\alpha(n)$
Connected comps.	$\alpha(n)$
2-vertex connected comps.	$\alpha(n)$
3-vertex connected comps.	$\alpha(n)$
4-vertex connected comps.	$\log n$
MST	$\log n$
2-edge connected comps.	$\alpha(n)$
3-edge connected comps.	$\alpha(n)$
4-edge connected comps.	$n\alpha(n)$
Constant edge connected comps.	$n \log n$

In the streaming model, we are concerned only with edge insertion and need only query the property at the end of the stream. Moreover, observe that a sparse certificate fits in space $O(n \operatorname{polylog} n)$. The following theorem states that any algorithm that could be sped up via the three major techniques described in [20] yields a one-pass, $O(n \operatorname{polylog} n)$ space, streaming algorithm with the improved running time per input edge.

THEOREM 6.3. *Let $\mathcal{P}$ be a property for which we can find a sparse certificate in time $f(n, m)$. Then there exists a one-pass, semistreaming algorithm that maintains a sparse certificate for $\mathcal{P}$ using $f(n, O(n))/n$ time per edge.*

Proof. Let the edges in the stream be denoted $e_1, e_2, \ldots, e_m$. Let G_i denote the subgraph given by $e_1, e_2, \ldots, e_i$. Inductively, assume we have a sparse certificate C_{jn} for G_{jn}, where $1 \leq j \leq \lfloor m/n \rfloor$, constructed in time $f(n, O(n))/n$ per edge. Also, inductively assume that we have buffered the next n edges, $e_{jn+1}, e_{jn+2}, \ldots, e_{(j+1)n}$. Let $T = C_{jn} \cup \{e_{jn+1}, e_{jn+2}, \ldots, e_{(j+1)n}\}$. By the composability of strong certificates, T is a strong certificate for $G_{(j+1)n}$. Let $C_{(j+1)n}$ be the sparse certificate of T. By the transitivity of strong certificates, $C_{(j+1)n}$ is a sparse certificate of $G_{(j+1)n}$. Since C_{jn} is sparse, $|T| = (c+1)n$. Thus, computing $C_{(j+1)n}$ takes time $f(n, O(n))$. By Theorem 6.1, this results in $f(n, O(n))/n$ time per edge, charged over $e_{jn+1}, e_{jn+2}, \ldots, e_{(j+1)n}$. This computation can be done while the next n edges are being buffered. If $k = n\lfloor m/n \rfloor$, then the final sparse certificate will be $C_k \cup \{e_{k+1}, e_{k+2}, \ldots, e_m\}$. □

We note that, for $f(n, m)$ that is linear or sublinear in m, a better speedup may be achieved by buffering more than n edges, which is possible when we have more space. In [20], the authors provide many algorithms for computing various graph properties which they speed up using sparsification. Applying Theorem 6.3 to these algorithms yields the list of streaming algorithms outlined in Table 6.1. For $l \geq 2$, the l-vertex and l-edge connectivity problems either have not been explicitly considered in the streaming model or have algorithms with significantly slower time per edge [22].

Acknowledgments. We thank Martin Sauerhoff for helpful comments on the results in section 4 and the anonymous referees for their comments on the presentation.

PRIVATE APPROXIMATION OF SEARCH PROBLEMS*

AMOS BEIMEL†, PAZ CARMI†, KOBBI NISSIM†, AND ENAV WEINREB‡

Abstract. Many approximation algorithms have been presented in the last decades for $\mathcal{NP}$-hard search problems. The focus of this paper is on cryptographic applications, where it is desirable to design algorithms which do not leak unnecessary information. Specifically, we are interested in private approximation algorithms—efficient approximation algorithms whose output does not leak information not implied by the optimal solutions to the search problems. Privacy requirements add constraints on the approximation algorithms; in particular, known approximation algorithms usually leak a lot of information. For functions, Feigenbaum et al. [*ACM Trans. Algorithms*, 2 (2006), pp. 435–472] presented a natural requirement that a private algorithm should not leak information not implied by the original function. Generalizing this requirement to relations is not straightforward as an input may have many different outputs. We present a new definition that captures a minimal privacy requirement from such algorithms; applied to an input instance, it should not leak any information that is not implied by its *collection of exact solutions*. We argue that our privacy requirement is natural and quite minimal. We show that, even under this minimal definition of privacy, for well-studied problems such as vertex cover and max exact 3SAT, private approximation algorithms are unlikely to exist even for poor approximation ratios. Similarly to Halevi et al. [in *Proceedings of the 33rd ACM Symposium on Theory of Computing*, ACM, New York, 2001, pp. 550–559], we define a relaxed notion of approximation algorithms that leak (a little) information, and demonstrate the applicability of this notion by showing near optimal approximation algorithms for max exact 3SAT that leak a little information.

Key words. secure computation, private approximation, solution-list algorithms, vertex cover

1. Introduction.

Approximation algorithms are currently one of the main research fields in theoretical computer science. The design of algorithms for approximating computationally hard problems has attracted substantial attention in the last few decades, as has the research on proving hardness of approximation. Frequently, approximation algorithms are applied to sensitive data, as in the distributed cryptographic setup of secure computation. In this paper we study privacy issues related to approximation algorithms of search problems.

We consider an abstract client-server setting. This scenario, besides being interesting on its own, is important since the multiparty distributed setting can be reduced to this model using secure function evaluation protocols [28, 12] (see the discussion below). In the client-server setting, the server $\mathcal{S}$ is willing to let the client $\mathcal{C}$ learn a specific functionality f of its input. The standard requirement in this setting is that no other information would be leaked to $\mathcal{C}$. For concreteness, assume that $\mathcal{S}$ holds a graph G and consider the following examples:

1. If $f(G)$ is the diameter of G, then $\mathcal{S}$ can simply compute $f(G)$ and send it to $\mathcal{C}$. It is clear that $\mathcal{C}$ learns $f(G)$ but no other information about G.
2. If $f(G)$ is the number of perfect matchings in G, which is a well-known $\#\mathcal{P}$-complete problem, then $\mathcal{C}$ and $\mathcal{S}$ have to settle for an approximation $\hat{f}$. This raises the question of which approximation to use, as $\mathcal{S}$ is willing to reveal only $f(G)$, but $\hat{f}$ may leak some other information. This was the setting in the work by Feigenbaum et al. [10]. They defined the notion of *private approximation* that combines two requirements: (i) *approximation:* $\hat{f}$ is an approximation to f; and (ii) *functional privacy:* $\hat{f}(G)$ can be simulated given $f(G)$. In particular, functional privacy implies that if $f(x) = f(y)$, then $\hat{f}(x)$ and $\hat{f}(y)$ are indistinguishable. It turns out that an efficient private approximation algorithm exists for the number of perfect matchings in a graph [10].
3. A more general and more typical case is when the server $\mathcal{C}$ needs to learn a "solution" for an optimization problem, rather than the value of the objective function.[1] For example, one is usually interested in finding a vertex cover of minimum size in G, rather than just learning the size of the minimum vertex cover. Even if $\mathcal{C}$ and $\mathcal{S}$ are willing to settle for an approximation (i.e., finding a cover which is not much larger than the minimum), it is not clear which cover $\mathcal{C}$ should learn; the framework of private approximations of functions does not address this problem as there may be many solutions to the search problem.

This more general case, where one seeks a computation not of a function but of a solution to an optimization problem, is the focus of this work.

1.1. Our contribution. Our main conceptual contribution is supplying a minimal definition of private approximation of search problems. The generalization of the definition of (functional) private approximation to search problems is not straightforward. As one input may have many different outputs, it is not clear in which cases we need $\hat{f}(x)$ and $\hat{f}(y)$ to be indistinguishable. For our example of vertex cover, it seems that a minimal requirement is that a private approximation algorithm should not distinguish between graphs G_1, G_2 that are equivalent in the sense that they have exactly the same set of solutions; i.e., every minimum cover for G_1 is also a minimum cover for G_2 and vice versa. Note that this is a rather weak requirement, as it does not restrict the approximation algorithm with respect to nonequivalent graphs.[2] Furthermore, it might reveal more information than a single solution to the problem.

In general, given a search problem, we say that two inputs are equivalent if they have the same set of solutions; an algorithm is private if it does not distinguish between equivalent inputs. This definition is a generalization of the privacy requirement in secure function evaluation where each input has a single solution and the protocol should not distinguish between inputs with the same solution. Furthermore, this definition is a generalization of the requirement for private approximation of functions [10]. Thus, we believe that our definition is natural. Furthermore, it is minimal

[1] An optimization problem is a problem where for each input there is a set of feasible solutions and there is an objective function; the goal is given an input to find a feasible solution with a minimum (or maximum) objective vale.

[2] For the vertex cover problem, the number of equivalence classes of graphs is exponential in $|V|$; thus, there may be many equivalence classes that contain only a few graphs. This is in sharp contrast with privacy of the vertex cover problem size that divides the graphs to only $|V|$ equivalence classes, as there are $|V|$ possible answers to the function.

in the sense that weakening it will result in algorithms that cannot be considered private. It is plausible that there are meaningful definitions of privacy for search problems that are incomparable to our definition.

Impossibility results for private approximation of the optimization objective value for several $\mathcal{NP}$-hard problems (e.g., approximating the size of a minimum vertex cover) were proven by Halevi et al. [16] (a detailed summary of their results appears in section 1.2). In view of the result of [16], it seems that we already know all there is to know about private approximation of optimization problems. However, impossibility results for private approximation of the optimization objective value (e.g., approximating the size of a minimum vertex cover) do not imply impossibility results for the task of finding a feasible solution with near optimal optimization value (e.g., finding a small vertex cover). For nonprivate computation, if there is an efficient algorithm whose output is a near optimal solution, then one can compute its value. However, this reduction does not preserve privacy as it leaks more information than implied by the optimization value. Furthermore, for private approximation the above two tasks are incomparable as the privacy requirement of "not learning information" is applied to a different output. For example, consider two graphs G_1 and G_2 such that the sizes of minimum vertex covers of G_1 and G_2 are the same, but the sets of minimum covers are different. A private approximation algorithm for the search problem of vertex cover can return covers of different size, while a private approximation algorithm for the size of the vertex cover must return the same answer for G_1 and G_2.

Impossibility of private approximation. To understand the nature of private approximation of search problems, we concentrate in this work on two optimization problems with different characteristics—vertex cover and max exact 3SAT. The first problem is a minimization problem, while the second is a maximization problem. More importantly, for vertex cover we want a solution satisfying *all* constraints (covering all edges), and we compromise by allowing a solution whose size is not optimal. In contrast, for max exact 3SAT we seek a solution satisfying *most* constraints (i.e., clauses). The same methods we present in this paper for these two problems are applicable for other optimization problems (e.g., max-cut). Our first technical contribution is an impossibility result for private approximation of vertex cover.

Informal Theorem. *If $\mathcal{RP} \neq \mathcal{NP}$, then vertex cover cannot be approximated privately even within an approximation ratio as poor as $n^{1-\epsilon}$.*

A similar result is shown for max exact 3SAT. This means that although our notion of privacy is minimal and it seems that any reasonable notion of privacy for search problems should imply it, there are natural problems for which it is too strong.

Our proof techniques for the impossibility results are different from those used for obtaining the inapproximability results for the functional version of the problem [16]. We show how to use a private approximation algorithm for a problem in order to solve the problem *exactly* in polynomial time. All our lower bounds have the same structure, where a solution is constructed in an iterative manner. For example, for vertex cover, in each iteration a node is examined. If that node appears in some optimal solution, we add it to the solution and remove it and its neighbors from the graph. If there exists some optimal solution that does not include this node, we remove it from the graph. When both conditions are met, we choose one of them arbitrarily. The crux of the algorithm is that the private approximation algorithm is used for deciding which of the conditions hold.

Algorithms that leak a little information. In view of the impossibility results, it is natural to look for a relaxation of the definition. In the setting of functional privacy,

Halevi et al. [16] defined the notion of *almost private algorithms* that are allowed to leak (a little) information beyond what is disclosed by the exact functionality. This notion falls elegantly within our definitional framework, where it is generalized to search problems. We say that an algorithm leaks at most k bits if it refines each equivalence class by dividing it to at most 2^k subclasses. That is, the algorithm leaks only the subclass, which can be described by k bits. For max exact 3SAT, this relaxation results in a tremendous improvement.

INFORMAL THEOREM. *There exists an efficient deterministic approximation algorithm for max exact 3SAT with a near optimal approximation ratio of* $7/8 - \epsilon$ *that leaks only* $O(\log \log n)$ *bits of information (where the exact constant in the "O" notation depends on* ϵ*).*

Interestingly, the algorithm for max exact 3SAT and the algorithm we describe for vertex cover fall into a class of approximation algorithms that we call *solution-list algorithms*. This class of algorithms provides much stronger privacy guarantees. Intuitively, for every input size n, the solution-list algorithm determines in advance (before seeing the input) a list of possible outcomes. Upon seeing the actual input, the algorithm is restricted to output a solution from the list. Thus, the number of bits the algorithm leaks is at most the logarithm of the size of the list. Solution-list algorithms provide stronger privacy guarantees as they protect every pair of inputs (not only pairs of equivalent inputs). For max exact 3SAT, our algorithm efficiently computes a list of $\text{poly}((\log n)/\epsilon)$ assignments such that for every exact 3CNF (conjunctive normal form) formula ϕ there exists an assignment in the list that is a good approximation for ϕ; hence the algorithm leaks $O(\log \log n + \log 1/\epsilon)$ bits. For vertex cover, we obtain a solution-list algorithm that is also interesting, but not as dramatic as that for max exact 3SAT, and we obtain a tradeoff between the amount of leakage and approximation quality.

We also show an impossibility result for approximating vertex cover while leaking information.

INFORMAL THEOREM. *If* $\mathcal{RP} \neq \mathcal{NP}$*, then vertex cover cannot be approximated within an approximation ratio as poor as* $n^{1-\epsilon}$ *while leaking at most* $O(\epsilon \log n)$ *bits.*

The above result was improved in [5], where it was proven that any algorithm that $n^{1-\epsilon}$-approximates vertex cover must leak $\Omega(n^\epsilon)$ bits. This implies that the solution-list algorithm for the problem is optimal up to a constant factor.

Private computation of search problems in $\mathcal{P}$. The notion of private search is applicable also to search problems in $\mathcal{P}$. For example, suppose a server holds a graph G and a client wants to learn a maximum matching of this graph. What kind of information can the client derive from the server's output? Can the client rule out many input graphs given the answer? It is somewhat surprising that the problem of private computation of search problems in $\mathcal{P}$ was not considered in previous papers. For many problems in $\mathcal{P}$, there is an efficient private algorithm solving the search problem while satisfying our minimal definition of privacy. One option is choosing the lexicographically first exact solution (e.g., for maximum matching and shortest path). Another option is constructing a randomized algorithm that chooses a random exact solution according to some distribution. Both approaches are somewhat problematic. Following our work, in [6] two stronger definitions of private computation of search problems were suggested and discussed, and algorithmic techniques were developed for constructing algorithms satisfying these stronger definitions.

For some problems finding a solution privately imposes additional constraints on the algorithm. We show that these constraints can make the problem much harder.

INFORMAL THEOREM. *There exists a search problem which can be efficiently solved without privacy constraints but cannot be efficiently and privately solved unless* $\mathcal{NP} \subseteq \mathcal{P}/\text{poly}$.

Multiparty approximations of search problems. As mentioned before, the abstract client-server setting we consider in this paper is important since the multiparty distributed setting can be reduced to this model. Consider the following scenario in the multiparty model: There is some secret input shared by the parties (that is, all parties together can compute the input, while smaller sets of parties have no information on the input). The parties want to solve some search problem on the input and make the output public without disclosing extra information. Clearly, our impossibility results hold for this model as well. Furthermore, using general secure function evaluation protocols [28, 12], efficient private algorithms in the server/client model can be transformed into protocols in the multiparty model. That is, the efficient algorithm and the sharing of the secret input imply that there is a small circuit, whose inputs are the inputs of the parties, computing the private functionality. Using the constructions of [28, 12], there is a private protocol computing this private functionality.

1.2. Related work. Feigenbaum et al. [10] initiated the discussion of private approximation of functions. They observed that combining approximation algorithms and secure function evaluation protocols might result in protocols that are not private as the output of the approximation algorithm might leak information. The definition of functional privacy put forward by [10] is a simulation-based definition, where the simulator's input is the exact value $f(x)$ and its output distribution is computationally indistinguishable from $\hat{f}(x)$. Under this definition, they provided a protocol for approximating the Hamming distance of two n-bit strings with communication complexity $\tilde{O}(\sqrt{n})$, and polynomial-time solutions for approximating the permanent and other natural $\#\mathcal{P}$ problems. Other private approximation protocols published since include [11, 22, 19]. In particular, Indyk and Woodruff [19] provide a polylogarithmic communication approximation for the Hamming distance and a secure approximation of the nearest neighbor search problem.

Inapproximability results for computing the *size* of a minimum vertex cover within approximation $n^{1-\epsilon}$ were proved by Halevi et al. [16]. Their proof uses a special *sliding-window* reduction that given a SAT instance ϕ and an integer z constructs an instance G of vertex cover such that if ϕ is satisfiable, then G has a vertex cover of size z, and otherwise any vertex cover for G is of size at least $z+1$. These techniques do not apply in our setting, as the large number of equivalence classes does not allow a simple averaging argument such as that used in [16].

The notion of almost private approximation was introduced in [16]. Their definition modifies that of [10] by allowing the simulator to consult a deterministic predicate of the input. They showed that by this slight compromise in privacy, one can get fairly good approximations for any problem that admits a good deterministic approximation. For the functional version of vertex cover this yields an approximation ratio 4 while leaking one bit (more generally, there is a tradeoff between the leakage and the approximation ratio). A similar relaxation of privacy is the notion of additional information in secure two-party protocols [3]. Related ideas can be found in the study of knowledge complexity [15, 14, 7, 13, 27].

We next compare the possibility and impossibility results for vertex cover and max exact 3SAT to nonprivate computation and privately approximating the size of the solutions.

Vertex cover. Vertex cover can be (nonprivately) $(2-o(1))$-approximated in deterministic polynomial time [24, 4, 17], and if $\mathcal{P} \neq \mathcal{NP}$, then there is no polynomial-time 1.3606-approximation algorithm for vertex cover [9].[3] Furthermore, if $\mathcal{NP} \not\subseteq \mathcal{BPP}$, then for every constant $\epsilon > 0$ there is no private $n^{1-\epsilon}$-approximation algorithm for the size of the minimum vertex cover [16]. However, there is a 4-approximation algorithm for the size of the minimum vertex cover which leaks one bit, and more generally, there is a tradeoff between the leakage and the approximation ratio [16]. In contrast, we show that if $\mathcal{RP} \neq \mathcal{NP}$, then this problem cannot be privately $n^{1-\epsilon}$-approximated even if a leakage of $(\epsilon \log n)/6$ bits is allowed. In [5] this result was improved showing that every algorithm $n^{1-\epsilon}$-approximating the vertex cover problem must leak $\Omega(n^{\epsilon})$ bits.

Max exact 3SAT. The max exact 3SAT problem can be 7/8-approximated [20], and if $\mathcal{P} \neq \mathcal{NP}$ there is no polynomial-time $(7/8 + \epsilon)$-approximation algorithm for it [18]. The trivial algorithm that returns 7/8 is a private 7/8-approximation algorithm for the functional version of max exact 3SAT. We show that if $\mathcal{RP} \neq \mathcal{NP}$, then the search problem of max exact 3SAT cannot be privately $n^{1-\epsilon}$-approximated; however, with $O(\log \log n + \log 1/\epsilon)$ leakage there is a $(7/8 - \epsilon)$-approximation algorithm for it.

Organization. In section 2 we define private algorithms for search problems. In section 3 we provide impossibility results for the minimum vertex cover and the max exact 3SAT search problems. In section 4 we discuss algorithms that leak (a little) information and describe such algorithms for both search problems. Later, in section 5, we prove our strongest impossibility result, showing vertex cover cannot be privately approximated even if a leakage of $O(\log n)$ bits is allowed. In section 6, we present an impossibility result for a search problem in $\mathcal{P}$. In Appendix A, we discuss an equivalent definition for private algorithms for search problems. In Appendices B and C, we complete the proofs of the impossibility results.

2. Definition of private algorithms with respect to a privacy structure. There are two different aspects of private algorithms—the utility of the algorithm (what should be computed) and the privacy requirement (what should be protected, that is, what information should not be revealed by the computation). In computing functions this is quite straightforward; we want to compute (or approximate) a function, and we want to protect inputs with the same output. For search algorithms, we know what should be computed. However, since these algorithms may output different outputs on the same input, it is less clear what should be protected. We thus separate the specification of what we want to protect from what we compute. In general, we require the output of the algorithm on certain pairs of inputs to be indistinguishable. In this section we define the pairs of inputs that should be protected by a private algorithm.

DEFINITION 2.1 (privacy structure). *A privacy structure $\mathcal{R} \subseteq \{0,1\}^* \times \{0,1\}^*$ is an equivalence relation on instances. For $\langle x, y\rangle \in \mathcal{R}$, we use the notation $x \equiv_{\mathcal{R}} y$.*

We will discuss only privacy structures of the form $\mathcal{R} = \cup_{n \in \mathcal{N}} \mathcal{R}_n$, where $\mathcal{R}_n$ is an equivalence relation between instances of size n, such as graphs on n vertices or Boolean formulae over n variables. We say that an algorithm $\mathcal{A}$ is *private* with respect to a privacy structure $\mathcal{R}$ if the results of executing $\mathcal{A}$ on two $\mathcal{R}$-equivalent inputs are computationally indistinguishable.

[3] A hardness result with a larger nonapproximability factor was proved in [21]: Assuming the unique games conjecture, there is no polynomial-time $(2 - \epsilon)$-approximation algorithm for vertex cover for every constant $\epsilon > 0$.

DEFINITION 2.2 (private algorithm). *Let $\mathcal{R}$ be a privacy structure. A randomized polynomial-time algorithm $\mathcal{A}$ is* private *with respect to $\mathcal{R}$ if for every randomized polynomial-time algorithm $\mathcal{D}$ and for every positive polynomial $p(\cdot)$ there exists some $n_0 \in \mathbb{N}$ such that for every $x, y \in \{0,1\}^*$ such that $x \equiv_{\mathcal{R}} y$ and $|x| = |y| \geq n_0$*

$$\left| \Pr[\mathcal{D}(\mathcal{A}(x), x, y) = 1] - \Pr[\mathcal{D}(\mathcal{A}(y), x, y) = 1] \right| \leq \frac{1}{p(|x|)},$$

where the probabilities are taken over the random choices of $\mathcal{A}$ and $\mathcal{D}$. That is, when $x \equiv_{\mathcal{R}} y$, an algorithm $\mathcal{D}$ given an output of $\mathcal{A}$ cannot distinguish whether the input of $\mathcal{A}$ is x or y.

Example 2.3. Let $f : \{0,1\}^* \to \mathbb{N}$ be a function. Define

$$\mathcal{R}_f = \{\langle x, y\rangle : |x| = |y|, f(x) = f(y)\}.$$

The relation $\mathcal{R}_f$ is the relation implicitly considered when discussing private computation of functions. Furthermore, this is the relation implicitly considered in [10, 16] when considering private approximation of the objective function, where the privacy requirement is with respect to inputs with the same objective value.

In Appendix A, we present equivalent definitions of privacy which require "semantic security" and prove that these definitions are equivalent to Definition 2.2.

We next recall the definition of a search problem and define the privacy structure associated with it.

DEFINITION 2.4. *A bivariate relation Q is polynomially bounded if there exists a constant c such that $|w| \leq |x|^c$ for every $\langle x, w\rangle \in Q$. The* decision problem *for Q is, given an input x, to decide if there exists a w such that $\langle x, w\rangle \in Q$ or not. The* search problem *for Q is, given an input x, to* find *a w such that $\langle x, w\rangle \in Q$ if such a w exists.*

Search problems are the more common algorithmic task of finding a solution to a problem (rather than deciding whether the problem has a solution or not). To define a private solution or private approximation of a search problem, one must determine the privacy structure the algorithm should respect. It is a *minimal* requirement to demand that if two inputs have the same set of answers to the search problem, the output of the approximation algorithm should not enable distinguishing between them.

DEFINITION 2.5 (privacy structure of a search problem). *The privacy structure $\mathcal{R}_Q$ related to a relation Q is defined as follows: $x \equiv_{\mathcal{R}_Q} y$ iff*

- *$|x| = |y|$, and*
- *$\langle x, w\rangle \in Q$ iff $\langle y, w\rangle \in Q$ for every w.*

That is, $x \equiv_{\mathcal{R}_Q} y$ if they have the same set of solutions.

We first give an example of a search problem in $\mathcal{P}$.

Example 2.6. Let maxMatch be the maximum matching relation; that is, $\langle G, M\rangle \in$ maxMatch if M is a maximum matching in G. In this case, $\mathcal{R}_{\text{maxMatch}}$ contains all pairs of graphs $G_1 = \langle V, E_1\rangle, G_2 = \langle V, E_2\rangle$ for which M is a maximum matching for G_1 iff it is a maximum matching for G_2.

We give two examples of privacy structures, for specific relations, that would be the focus of this paper.

Example 2.7. A vertex cover of an undirected graph $G = (V, E)$ is a set $C \subseteq V$ that covers all edges in G; that is, $C \cap \{u, v\} \neq \emptyset$ for every $(u, v) \in E$. Let minVC be the minimum vertex cover relation; that is, $\langle G, C\rangle \in$ minVC if C is a minimum vertex cover in G. In this case, $\mathcal{R}_{\text{minVC}}$ contains all pairs of graphs $G_1 = \langle V, E_1\rangle, G_2 =$

$\langle V, E_2\rangle$ for which $C \subseteq V$ is a minimum vertex cover for G_1 iff it is a minimum vertex cover for G_2.

To understand the difference between privately approximating the size of the vertex and privately finding an approximated minimum vertex cover, consider two isomorphic graphs. The size of the minimum vertex cover in these two graphs is the same; thus, a private algorithm approximating the minimum vertex cover size has to "protect" them. However, in general, these two graphs have different sets of minimum vertex covers; thus, an algorithm finding an approximated minimum vertex cover can behave differently on these graphs.

Example 2.8. An exact 3CNF formula is a CNF formula that contains exactly three different literals in each clause. Let maxE3SAT be the max exact 3SAT relation; that is, $\langle \phi, a\rangle \in$ maxE3SAT if ϕ is an exact 3CNF formula over n variables, and a is an assignment to the n variables that satisfies the maximum possible number of clauses in ϕ. In this case, the privacy structure $\mathcal{R}_{\text{maxE3SAT}}$ contains all pairs of exact 3CNF formulae ϕ_1, ϕ_2 over n variables for which an assignment a satisfies the maximum possible number of clauses in ϕ_1 iff it satisfies the maximum possible number of clauses in ϕ_2. We stress that these two assignments need not satisfy the same number of clauses in ϕ_1 and ϕ_2.

We note that a related definition of private approximation was recently presented in the context of the nearest neighbor problem [19]. Their privacy requirement is that instances with identical sets of *approximate* solutions should not be told apart by the private approximation algorithm. This definition may be cast in our framework by constructing a privacy structure where instances that have the same collection of approximate solutions are considered equivalent.

Approximation algorithms. We next define approximation algorithms for a minimization problem (the definition for maximization problems is analogous). Given a bivariate relation Q and an objective function $f : \{0,1\}^n \to \mathbb{R}$ we define

$$\text{OPT}(x) = \min\{f(w) : \langle x, w\rangle \in Q\}.$$

We consider the minimization problem that given an input x finds a solution w such that $\langle x, w\rangle \in Q$ and $f(w) = \text{OPT}(x)$. The $c(n)$-approximation version of the problem is to find a solution w such that $f(w) \le c(n)\cdot\text{OPT}(x)$. Formally, we have the following definition.

DEFINITION 2.9. *For a function $c : \mathbb{N} \to \mathbb{R}$, we say that a randomized algorithm $\mathcal{A}$ is a $c(n)$-approximation algorithm for a minimization problem $\langle Q, f\rangle$ if for every input x with probability one it finds a solution w such that $\langle x, w\rangle \in Q$ and $f(w) \le c(n)\cdot\text{OPT}(x)$ (if x has a solution).*

A weaker definition of approximation requires that $\text{E}(f(\mathcal{A}(x))) \le c(n)\cdot\text{OPT}(x)$; namely, the expected value of the function f applied to the solution returned by the approximation algorithm is bounded by $c(n)\cdot\text{OPT}(x)$. Our impossibility result for vertex cover holds also for this definition. However, for maxE3SAT, the behavior with respect to the two definitions is different. The algorithm that returns a random assignment is a private algorithm for maxE3SAT in which the expected fraction of clauses satisfied is 7/8. In contrast, we prove that every private randomized approximation algorithm according to Definition 2.9 has an approximation ratio at least $n^{1-\epsilon}$ for every constant $\epsilon > 0$.

3. Impossibility results for private approximation.

3.1. Impossibility results for private approximation of vertex cover. In this section we show that private approximation of the vertex cover search problem with respect to $\mathcal{R}_{\text{minVC}}$ (defined in Example 2.7) is a hard task. We start with defining private approximation of vertex cover and then prove impossibility results for both the deterministic and the randomized settings.

DEFINITION 3.1 (private approximation of vertex cover). *An algorithm $\mathcal{A}$ is a* private $c(n)$-approximation *algorithm for* minVC *if* (i) *$\mathcal{A}$ runs in polynomial time;* (ii) *$\mathcal{A}$ is a $c(n)$-approximation algorithm for* minVC*, that is, for every graph G with n vertices, it returns with probability* 1 *a vertex cover whose size is at most $c(n)$ times the size of the smallest vertex cover of G;* (iii) *$\mathcal{A}$ is private with respect to $\mathcal{R}_{\text{minVC}}$.*

To illustrate our definitions, we present a private $(n/\log n)$-approximation algorithm for the vertex cover problem. This algorithm is based on the polynomial-time algorithm of [26] that returns a minimum vertex cover if the size of the vertex cover is at most $\log n$. Actually, in this case there are at most n^2 such covers,[4] and the algorithm can efficiently compute all of them. Thus, we can define any rule to choose one of them (e.g., the lexicographically first, a random vertex cover, or a cover chosen such that it satisfies the stronger definitions of privacy given in [6]). To approximate minVC we do the following:

> If there is a cover of size at most $\log n$,
> then return the lexicographically first minimum vertex cover.
> Otherwise, return the entire set of vertices.

We show impossibility results for privately approximating vertex cover in the deterministic and in the randomized setting.

THEOREM 3.2. *Let $\epsilon > 0$ be a constant.*

1. *If $\mathcal{P} \neq \mathcal{NP}$, then there is no* deterministic *private $n^{1-\epsilon}$-approximation algorithm for the search problem of* minVC.
2. *If $\mathcal{RP} \neq \mathcal{NP}$, then there is no* randomized *private $n^{1-\epsilon}$-approximation algorithm for the search problem of* minVC.

Part 1 of Theorem 3.2 is proven in the rest of this section. Part 2 of Theorem 3.2 is a special case of Theorem 5.1 proven in Appendix B.

3.1.1. Relevant and critical vertices. The framework for proving Theorem 3.2 is the following: We assume the existence of the appropriate private approximation algorithm and derive a greedy algorithm that solves vertex cover *exactly*. The following definitions are central for both the deterministic and the randomized cases.

DEFINITION 3.3 (critical vertices and relevant vertices). *Let $G = \langle V, E\rangle$ be a graph and $v \in V$ be a vertex of G. We say that v is* critical *for G if* every *minimum vertex cover of G contains v. We say that v is* relevant *for G if there* exists *a minimum vertex cover of G that contains v.*

OBSERVATION 3.4. *Every vertex is relevant or noncritical (or both).*

Example 3.5. To illustrate the relation $\mathcal{R}_{\text{minVC}}$ we show a pair of graphs that are equivalent under the relation. One way to create such a pair is to pick a graph and identify a vertex that is critical for this graph. For example, vertex v_3 in Figure 3.1(a) is a critical vertex. To get the second graph we connect the critical vertex to some

[4]The algorithm of [26] first finds a maximal matching of size at most $\log n$ (the size of any matching is a lower bound on the size of a vertex cover). Let P be the endpoints of the edges in this matching (thus, $|P| \leq 2\log n$). In [26] it is proven that any minimum cover is composed of a subset $P' \subseteq P$ and all the neighbors of $P \setminus P'$. As there are at most n^2 subsets of P, there are at most n^2 minimum vertex covers for the graph.

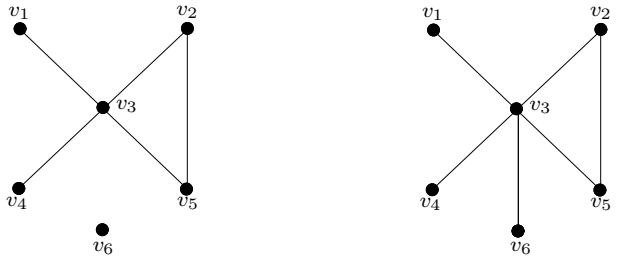

FIG. 3.1. *A pair of graphs equivalent under* $\mathcal{R}_{\text{minVC}}$.

other vertex. In Figure 3.1(b), vertex v_3 is connected to v_6. It is easy to verify that the set of minimum covers in both graphs is $\{\{v_3, v_2\}, \{v_3, v_5\}\}$. The equivalence can also be derived from Claim 3.8 below.

We design a greedy algorithm for exactly solving the vertex cover problem that in each step solves the following problem.

DEFINITION 3.6 (the relevant-noncritical problem).
INPUT: *A graph* $G = \langle V, E\rangle$ *and a vertex* $v \in V$.
OUTPUT: *One of the following:* (i) v *is relevant for* G. (ii) v *is noncritical for* G.

Algorithm `Greedy Vertex Cover`

INPUT: A graph $G = \langle V, E\rangle$.
OUTPUT: A minimum vertex cover of G.

1. If $V = \emptyset$, return $\emptyset$.
2. Pick a vertex $v \in V$ and execute Algorithm `Relevant-Noncritical` on G and v.
3. If the answer is "RELEVANT":
   (a) Run `Greedy Vertex Cover` on the graph $G \setminus \{v\}$. Denote the answer by C_v.
   (b) Return $C_v \cup \{v\}$.
4. If the answer is "NONCRITICAL":
   (a) Let $N(v)$ be the neighbors of v in G, that is, $N(v) = \{u : (u, v) \in E\}$.
   (b) Run `Greedy Vertex Cover` on the graph $G \setminus (\{v\} \cup N(v))$. Denote the answer by $C_{N(v)}$.
   (c) Return $C_{N(v)} \cup N(v)$.

FIG. 3.2. *A greedy algorithm using Algorithm* `Relevant-Noncritical` *to find a minimum vertex cover.*

In Figure 3.2, we describe a greedy algorithm for vertex cover that in each step uses an algorithm that solves the Relevant-Noncritical problem. In subsequent sections, we solve the latter using oracle access to private approximation algorithms for vertex cover. The following claim asserts the correctness of the greedy algorithm.

CLAIM 3.7. *If Algorithm* `Relevant-Noncritical` *is correct and runs in polynomial time, then Algorithm* `Greedy Vertex Cover` *is correct and runs in polynomial time.*

Proof. The proof is by induction on $|V|$. The algorithm is trivially correct for

$V = \emptyset$. Now suppose $V \neq \emptyset$, and we start from the case where v is relevant. In this case, there is a minimum cover C for G that contains v. Denote $d = |C|$, and note that the set $C \setminus \{v\}$ is a cover of size $d-1$ for the graph $G \setminus \{v\}$. By the induction hypothesis, the set C_v is a minimum cover for $G \setminus \{v\}$. We claim that $C_v \cup \{v\}$ is a minimum cover for G. First note that it is indeed a cover of G as any edge adjacent to v is covered by v, and all the rest are covered by C_v. Since C_v is a minimum cover of $G \setminus \{v\}$, it is of size at most $d-1$. Therefore, the size of $C_v \cup \{v\}$ is d, and it is a minimum cover of G.

In the other case, v is not critical for G. Thus, there is a minimum cover C' for G that does not contain v and therefore contains all vertices in $N(v)$. Denote $d' = |C'|$ and $h = |N(v)|$. In this case the set $C' \setminus N(v)$ is a cover of size $d' - h$ of the graph $G \setminus (N(v) \cup \{v\})$. By the induction hypothesis, the set $C_{N(v)}$ is a minimum cover for $G \setminus (N(v) \cup \{v\})$. We claim that $C_{N(v)} \cup N(v)$ is a minimum cover for G. First note that it is indeed a cover of G as any edge adjacent to $N(v) \cup \{v\}$ is covered by $N(v)$, and all other edges are covered by $C_{N(v)}$. Since $C_{N(v)}$ is a minimum cover of $G \setminus (N(v) \cup \{v\})$, it is of size at most $d' - h$. Therefore, the size of $C_{N(v)} \cup N(v)$ is d', and it is a minimum cover of G.

It is straightforward to verify that if `Relevant-Noncritical` runs in polynomial time, then the greedy algorithm runs in polynomial time. □

3.1.2. Combinatorial claims. The following combinatorial claims are helpful in designing algorithms for the Relevant-Noncritical problem in both the deterministic and the randomized settings. Intuitively, a private approximation algorithm must be "sensitive" to small changes in the set of minimum vertex covers of its input graph. We study the connection between the $\mathcal{R}_{\text{minVC}}$ relation and the set of critical and relevant vertices in a graph.

CLAIM 3.8. *Let $G = \langle V, E \rangle$ be a graph, $u, v \in V$ such that $(u, v) \notin E$, and $G^* = \langle V, E^* \rangle$, where $E^* = E \cup (u, v)$. If u is critical for G, then $G \equiv_{\mathcal{R}_{\text{minVC}}} G^*$.*

Proof. We first show that every minimum vertex cover of G is a minimum vertex cover of G^*. Let C be a minimum cover of G. As u is critical for G, we deduce that $u \in C$. Therefore, C covers the edge (u, v), and thus it is a cover of G^*. Note that every cover of G^* is also a cover of G, and thus C is a minimum cover of G^*.

For the other direction, let C^* be a minimum cover of G^*. Let c be the size of a minimum cover of G. As u appears in at least one minimum cover of G, which is also a cover of G^*, the size of C^* is at most c. On the other hand, as $E \subseteq E^*$, the set C^* is also a cover of G, and thus the size of C^* is exactly c. Therefore, C^* is a minimum cover of G. □

We will later see that if a vertex u is not in the result of the private approximation algorithm $\mathcal{A}$, then it is noncritical for the input graph G. However, if the vertex cover size of the input graph is large, the approximation algorithm may return the entire set V as its result. To avoid this, we add a large set of isolated vertices to G. (The size of this set is a function of the approximation ratio.) The mere fact that an isolated vertex is noncritical for G is of course not helpful. Nevertheless, we gain information by connecting this isolated vertex to the vertex v and running $\mathcal{A}$ on the new graph. It will also be helpful to consider duplicating the graph G and connecting the isolated vertex to both copies of the original vertex v.

DEFINITION 3.9 (the graphs G_2 and $G\binom{i}{\wedge}$). *Let $G = \langle V, E \rangle$ be a graph, $v \in V$ be a vertex, I be a set of vertices, and $i \in I$. The graph G_2 is defined as $G_2 = \langle V_2, E_2 \rangle$, where $V_2 \stackrel{def}{=} (V \times \{1,2\}) \cup I$ and $E_2 \stackrel{def}{=} \{(\langle u, j \rangle, \langle w, j \rangle) : (u, w) \in E, j \in \{1,2\}\}$. The graph $G\binom{i}{\wedge}$ is defined as $G\binom{i}{\wedge} = \langle V_2, E(\overset{i}{\wedge}) \rangle$, where $E(\overset{i}{\wedge}) \stackrel{def}{=} E_2 \cup \{(\langle v, j \rangle, i) : j \in \{1,2\}\}$.*

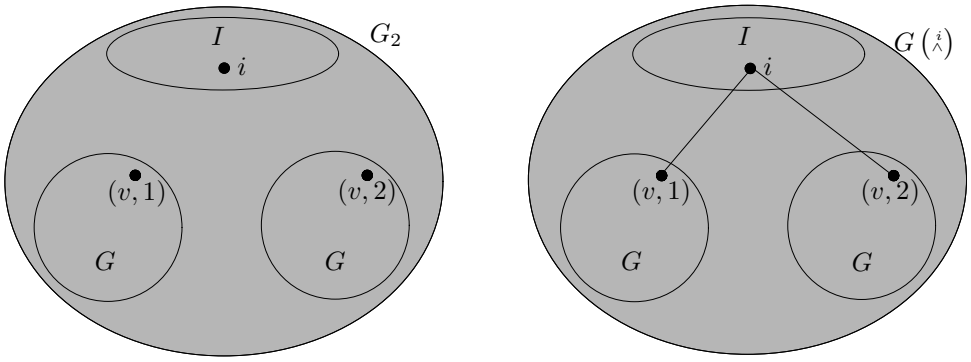

FIG. 3.3. *The graphs G_2 and $G(\binom{i}{\wedge})$.*

The graphs G_2 and $G\binom{i}{\wedge}$ are illustrated in Figure 3.3. The following claims summarize the properties of G_2 and $G\binom{i}{\wedge}$.

CLAIM 3.10. *If v is critical for G, then $G_2 \equiv_{\mathcal{R}_{\text{minVC}}} G\binom{i}{\wedge}$.*

Proof. Since G_2 contains two separate copies of G and v is critical for G, the vertices $\langle v,1\rangle$ and $\langle v,2\rangle$ are critical for G_2. Hence, by Claim 3.8, adding the edges $(\langle v,1\rangle, i)$ and $(\langle v,2\rangle, i)$ does not change the set of minimum vertex covers of the graph. □

CLAIM 3.11. *If v is not relevant for G, then i is critical for $G\binom{i}{\wedge}$.*

Proof. Assume toward contradiction that the vertex i is noncritical for $G\binom{i}{\wedge}$. Hence, there must be a minimum cover $C(\binom{i}{\wedge})$ of $G\binom{i}{\wedge}$ that contains $\langle v,1\rangle$ and $\langle v,2\rangle$. The intersection of $C(\binom{i}{\wedge})$ with each copy of G contains a cover of G that contains the appropriate copy of v. As v is not relevant for G, these covers are not optimal. Let c be the size of a minimum vertex cover of G. Then $\left|C(\binom{i}{\wedge})\right| \geq 2(c+1) = 2c+2$. On the other hand, let C be a minimum cover of G of size c. Then, the set $(C \times \{1,2\}) \cup \{i\}$ is a cover of $G\binom{i}{\wedge}$ of size $2c+1$, in a contradiction to the minimality of $C(\binom{i}{\wedge})$. Hence, i is critical for $G\binom{i}{\wedge}$. □

3.1.3. Impossibility result for deterministic private approximation. In this section we show an algorithm that solves the Relevant-Noncritical problem, given an oracle access to a deterministic private approximation algorithm for minVC.

CLAIM 3.12. *Let $\mathcal{A}$ be a deterministic private approximation algorithm for* minVC*, let $G = \langle V, E\rangle$ be a graph, and denote $W = \mathcal{A}(G)$. Then for any two different vertices $v_1, v_2 \in V \backslash W$, the vertex v_1 is not critical for G (and, similarly, v_2 is not critical).*

Proof. As v_1 and v_2 are not in W, and W is a cover of G, we infer that $(v_1, v_2) \notin E$. Let $E^* = E \cup \{(v_1, v_2)\}$, and define $G^* = \langle V, E^*\rangle$. We now consider a hypothetical execution of the algorithm $\mathcal{A}$ on G^* and denote $W^* = \mathcal{A}(G^*)$. The set W^* must cover the edge (v_1, v_2) and thus $W^* \neq W$.

If v_1 is critical for G, then, by Claim 3.8, the sets of minimum-size vertex cover of G and G^* are equal. However, since $\mathcal{A}$ is deterministic and private, and $W \neq W^*$, the set of minimum vertex covers of G and G^* must be different. Therefore, v_1 is not critical for G. □

In Figure 3.4, we present Algorithm `Relevant-Noncritical`. It takes a graph $G = \langle V, E\rangle$ and a vertex $v \in V$ as inputs and uses a private $n^{1-\epsilon}$-approximation

algorithm $\mathcal{A}$ to solve the Relevant-Noncritical problem.

Algorithm `Relevant-Noncritical`

INPUT AND OUTPUT: See Definition 3.6.

1. Let I be a set of vertices of size $(4n)^{1/\epsilon} - 2n$.
2. Construct the graph G_2 from G and I as in Definition 3.9.
3. Execute $\mathcal{A}$ on G_2 and denote $W_2 = \mathcal{A}(G_2)$.
4. Choose any vertex $v' \in I \backslash W_2$ (there must be at least two such vertices as the approximation algorithm cannot return all the sets I).
5. Construct $G(\overset{v'}{\wedge})$ from G, I, and v' as in Definition 3.9.
6. Execute $\mathcal{A}$ on $G(\overset{v'}{\wedge})$ and denote $W(\overset{v'}{\wedge}) = \mathcal{A}(G(\overset{v'}{\wedge}))$.
7. If $W_2 \neq W(\overset{v'}{\wedge})$ return "NOT CRITICAL." Else return "RELEVANT."

FIG. 3.4. *Algorithm* `Relevant-Noncritical` *for a private deterministic* $\mathcal{A}$.

The correctness of Algorithm `Relevant-Noncritical` stems from the following claims.

CLAIM 3.13. *If* $W_2 \neq W(\overset{v'}{\wedge})$, *then* v *is not critical for* G.

Proof. Assume toward contradiction that v is critical for G. By Claim 3.10, the graphs G_2 and $G\left(\overset{v'}{\wedge}\right)$ have the same set of minimum vertex covers. Hence, from the privacy of $\mathcal{A}$, we get that $W_2 = \mathcal{A}(G_2) = \mathcal{A}\left(G\left(\overset{v'}{\wedge}\right)\right) = W(\overset{v'}{\wedge})$, contradicting $W_2 \neq W(\overset{v'}{\wedge})$. ∎

We next show that there are at least two vertices we can choose in step 4 of the algorithm.

CLAIM 3.14. *Let* $\epsilon > 0$ *be a constant. There exist at least two vertices in* $I \setminus W_2$.

Proof. Let $N = |I| + 2n = (4n)^{1/\epsilon}$ be the number of vertices in G_2. The size of the minimum vertex cover of G_2 is twice the size of the minimum vertex cover of G; thus, it is at most $2(n-1)$. Since $\mathcal{A}$ is an $N^{1-\epsilon}$-approximation algorithm for vertex cover, the size of $W_2 = \mathcal{A}(G_2)$ is at most

$$\begin{aligned} 2(n-1) \cdot N^{1-\epsilon} &\leq 2n \cdot N^{1-\epsilon} - 2 \;=\; 2n \cdot ((4n)^{1/\epsilon})^{1-\epsilon} - 2 \;=\; \frac{(4n)^{1/\epsilon}}{2} - 2 \\ &\leq (4n)^{1/\epsilon} - 2n - 2 \;=\; |I| - 2. \end{aligned}$$

Consequently, there are at least two vertices in $I \setminus W_2$. ∎

CLAIM 3.15. *If* $W_2 = W(\overset{v'}{\wedge})$, *then* v *is relevant for* G.

Proof. As $W_2 = W(\overset{v'}{\wedge})$ and $v' \notin W_2$, we get $v' \notin W(\overset{v'}{\wedge})$. Since there are at least two vertices in $I \setminus W_2$, we can apply Claim 3.12 and deduce that the vertex v' is not critical for $G\left(\overset{v'}{\wedge}\right)$. Applying Claim 3.11, we infer that v is relevant for G. ∎

We extend the techniques described in this section to get an impossibility result with respect to a weaker notion of private approximation defined in section 4 (see Theorem 5.1).

3.2. Impossibility results for private approximation of exact 3SAT. Similar results are obtained for private approximation of maxE3SAT as stated in the following theorem.

THEOREM 3.16. *Let $\epsilon > 0$ be a constant.*

1. *If $\mathcal{P} \neq \mathcal{NP}$, then there is no* deterministic *private $1/n^{1-\epsilon}$-approximation algorithm for the search problem of* maxE3SAT.
2. *If $\mathcal{RP} \neq \mathcal{NP}$, then there is no* randomized *private $1/n^{1-\epsilon}$-approximation algorithm for the search problem of* maxE3SAT.

See Appendix C for a proof of the deterministic case. The proof of the randomized case follows, with modifications similar to those made in Appendix B for minVC.

4. Algorithms that leak a little information. As demonstrated in the previous section, in some cases it is impossible to design an efficient algorithm which is private with respect to a privacy structure $\mathcal{R}$. However, letting $\mathcal{R}'$ be a refinement of $\mathcal{R}$, we view a private algorithm with respect to $\mathcal{R}'$ as a private algorithm with respect to $\mathcal{R}$ that *leaks* information. The amount of information leaked is quantified according to the relation between $\mathcal{R}$ and $\mathcal{R}'$.

DEFINITION 4.1 (k-refinement). *Let $\mathcal{R}$ and $\mathcal{R}'$ be two privacy structures over $\{0,1\}^*$ and $k : \mathbb{N} \to \mathbb{N}$. We say that $\mathcal{R}'$ is a $k(n)$-refinement of $\mathcal{R}$ if $\mathcal{R}' \subseteq \mathcal{R}$ and for every $n \in \mathbb{N}$ every equivalence class of $\mathcal{R}$ of strings of size n is a union of at most $2^{k(n)}$ equivalence classes of $\mathcal{R}'$.*

DEFINITION 4.2 (algorithms leaking $k(n)$-bits). *Let $\mathcal{R}$ be a privacy structure. A randomized polynomial-time algorithm $\mathcal{A}$* leaks at most $k(n)$ bits *with respect to $\mathcal{R}$ if there exists a privacy structure $\mathcal{R}'$ such that* (i) *$\mathcal{R}'$ is a $k(n)$-refinement of $\mathcal{R}$, and* (ii) *$\mathcal{A}$ is private with respect to $\mathcal{R}'$.*

Informally, the algorithm leaks only the subclass of the equivalence class of the input; this subclass can be described by k bits; thus, the algorithm leaks at most k bits.

4.1. Solution-list algorithms. Solution-list algorithms are algorithms whose outcome is always in a small predetermined set, that is, in a set that is a function of $|x|$ but not of x itself. With respect to privacy, solution-list algorithms are valuable as they leak only a few bits with respect to any privacy structure—at most logarithmic in the number of their possible outcomes.

DEFINITION 4.3 (solution-list algorithm). *We say that a deterministic algorithm $\mathcal{A}$ is a $K(n)$-*solution-list *algorithm if for every $n \in \mathbb{N}$*

$$|\{\, y : \exists x \in \{0,1\}^n \text{ such that } \mathcal{A}(x) = y \,\}| \leq K(n).$$

That is, a solution-list algorithm is an algorithm that, for every input size n, "chooses" its outputs from a set of at most $K(n)$ possible outcomes.

We define the universal relation, denoted $\mathcal{U}^* = \cup_{n \in \mathcal{N}} \mathcal{U}^*_n$, as the privacy structure where every two instances of the same size are equivalent. Note that any privacy structure is a refinement of $\mathcal{U}^*$; hence if an algorithm is private with respect to $\mathcal{U}^*$, it is also private with respect to any privacy structure,[5] and similarly, if an algorithm leaks at most k bits with respect to $\mathcal{U}^*$, then such is the case with respect to any privacy structure.

OBSERVATION 4.4. *Any $K(n)$-solution-list algorithm leaks at most* $\log K(n)$ *bits with respect to $\mathcal{U}^*$, and, in particular, the algorithm leaks at most* $\log K(n)$ *bits with respect to every privacy structure.*

[5] An algorithm $\mathcal{A}$ is private with respect to $\mathcal{U}^*$ if only the instance size may be learned from its outcome.

4.2. Solution-list algorithms for exact 3SAT. In this section we present a $(7/8-\epsilon)$-approximation algorithm for maximum satisfiability on exact 3CNF formulae that leaks a little information, i.e., $O(\log\log n+\log 1/\epsilon)$ bits. The algorithm is a solution-list algorithm as defined in Definition 4.3. The approximation in our algorithm is nearly optimal, as by the result of Håstad [18], if $\mathcal{P}\neq\mathcal{NP}$, then there is no polynomial-time $(7/8+\epsilon)$-approximation algorithm for this problem.[6]

We start with a simple motivating example. Consider the following simple algorithm for the max-SAT problem.

If 0^n satisfies at least half of the clauses in ϕ, return 0^n. Otherwise, return 1^n.

For every clause, either 0^n or 1^n satisfy the clause. Thus, 0^n or 1^n satisfy at least half of the clauses in ϕ, and this is a 1/2-approximation of max-SAT. Since there are only two possible answers, this algorithm leaks at most one bit.

CLAIM 4.5. *There is a* 7/8*-approximation algorithm for* maxE3SAT *that leaks at most* $O(\log n)$ *bits with respect to* $\mathcal{R}_{\text{maxE3SAT}}$. *Furthermore, for every* $\epsilon>0$, *there is a* $(7/8-\epsilon)$*-approximation algorithm for* maxE3SAT *that leaks at most* $O(\log\log n+\log 1/\epsilon)$ *bits with respect to* $\mathcal{R}_{\text{maxE3SAT}}$.

Proof. We first describe the 7/8-approximation algorithm. Toward this goal, we construct for every n a list of poly(n) assignments such that for every exact 3CNF formula with n variables there is an assignment in the list that satisfies at least 7/8 of the clauses of the formula. Furthermore, there is an efficient algorithm that generates this list. Thus, the 7/8-approximation algorithm, with input ϕ, a formula with n variables, constructs this list and chooses the first assignment in the list that satisfies at least 7/8 of the clauses in ϕ.

We next explain how to construct the list, using ideas of the randomized 7/8-approximation algorithm of Johnson [20]. Fix a clause with three different literals. If we pick an assignment at random, then with probability at least 7/8 it satisfies the clause. Now, fix any exact 3CNF formula. If we pick an assignment at random, then the expected fraction of satisfied clauses is at least 7/8. Thus, there exists at least one assignment that satisfies a fraction of at least 7/8 of the clauses in the formula. This is true even if we pick the assignments from a 3-wise independent space. As there is a 3-wise independent space of size $O(n^3)$, this implies the existence of the list. To generate the assignments we can use any of the constructions of 3-wise independent spaces, e.g., the construction based on polynomials (see, e.g., [23, 1, 8]).

We next describe the $(7/8-\epsilon)$-approximation algorithm. As in the previous case, it suffices to show how to efficiently construct, for every n and $\epsilon>0$, a list of poly$(\frac{\log n}{\epsilon})$ assignments such that for every exact 3CNF formula with n variables there is an assignment in the list that satisfies at least $7/8-\epsilon$ of the clauses of the formula. To construct the list, notice that if we pick an assignment from an almost 3-wise independent space, that is, from an $(\epsilon,3)$-wise independent space, then the probability that a given clause is satisfied is at least $7/8-\epsilon$. Thus, the expected fraction of satisfied clauses is at least $7/8-\epsilon$, and there exists at least one assignment that satisfies a fraction of at least $7/8-\epsilon$ of the clauses in the formula. There are $(\epsilon,3)$-wise independent spaces of size poly$(\frac{\log n}{\epsilon})$. To generate the assignments we can use any of the constructions of [25, 2]. □

The next claim shows that the size of the solution list used in the proof of Claim 4.5 is nearly optimal.

[6] Any $(7/8+\epsilon)$-approximation solution-list algorithm that uses poly(n) solutions would imply that $\mathcal{NP}\subseteq\mathcal{P}/\text{poly}$ even if the list cannot be efficiently constructed.

CLAIM 4.6. *Every solution-list algorithm for* maxE3SAT *that achieves approximation ratio better than* $1/2$ *uses at least* $\log n - 1$ *solutions.*

Proof. Assume a solution-list algorithm for maxE3SAT, and let $a_1, \ldots, a_t$, where $t < \log n - 1$, be its list of possible output assignments on formulae over n variables $x_1, \ldots, x_n$. To each variable x_i we assign a *label* that is the concatenation of the truth values assigned to x_i by the t assignments $\langle a_1(x_i), \ldots, a_t(x_i)\rangle$. As there are at most 2^t different labels and $n/2^t > 2$, there exist three distinct variables $x_{i_1}, x_{i_2}, x_{i_3}$ that share the same label; i.e., for all $1 \le j \le t$ it holds that $a_j(x_{i_1}) = a_j(x_{i_2}) = a_j(x_{i_3})$.

Consider the formula $\phi = (x_{i_1} \vee x_{i_2} \vee x_{i_3}) \wedge (\neg x_{i_1} \vee \neg x_{i_2} \vee \neg x_{i_3})$. It is easy to see that ϕ is satisfied by exactly those assignments which do not assign the same truth value to all three variables $x_{i_1}, x_{i_2}, x_{i_3}$. However, as this is not the case for any of the t assignments, each of them satisfies exactly one clause in ϕ, achieving an approximation factor of at most $1/2$. □

4.3. Solution-list algorithms for vertex cover. In this section we present almost private search algorithms for minimum vertex cover. These algorithms are interesting but not as dramatic as the algorithms for maxE3SAT. For any $0 < \epsilon < 1$, there is an $n^{1-\epsilon}$-approximation algorithm that leaks $2n^\epsilon$ bits. The algorithms are solution-list algorithms, and we will prove that no solution-list algorithm can do better for this problem.

CLAIM 4.7. *For every* $0 < \epsilon < 1$*, there is an* $n^{1-\epsilon}$*-approximation algorithm for the minimum vertex cover problem which leaks at most* $2n^\epsilon$ *bits.*

Proof. The algorithm proceeds as follows:

INPUT: A graph G with n vertices.

1. Execute any deterministic 2-approximation algorithm for VC on G, and get a cover C.
2. Let $\ell \leftarrow 2n^\epsilon$.
3. Partition the n vertices into ℓ fixed sets, $V_1, \ldots, V_\ell$, each of size $n/\ell = n^{1-\epsilon}/2$.
4. Let $C' \leftarrow \bigcup_{\{i:V_i \cap C \neq \emptyset\}} V_i$.
5. Return C'.

The algorithm first finds a small cover. Then, if V_i contains at least one vertex in this cover, the algorithm returns the entire set V_i. This implies that the size of C' is at most $|C|n^{1-\epsilon}/2$, and since $|C|$ is at most twice the size of the minimum vertex cover, this algorithm is an $n^{1-\epsilon}$-approximation algorithm.

Notice that the algorithm has 2^ℓ possible outputs (it chooses only which of the sets V_i is in its output). That is, this is a solution-list algorithm with a list of size 2^ℓ; thus, it leaks at most $\ell = 2n^\epsilon$ bits. □

The private algorithms for maxE3SAT and for minVC that we presented are solution-list algorithms. For maxE3SAT, the algorithm generates the entire list and chooses the best candidate in the list. For minVC this is not possible as the size of the list is big. The deterministic algorithm generates a "good" candidate from the list without generating the entire list.

We next claim that any solution-list algorithm for minVC cannot use a shorter list than the algorithm we presented (up to a constant factor).

CLAIM 4.8. *Any solution-list algorithm that* $n^{1-\epsilon}$*-approximates* minVC *uses at least* $2^{n^\epsilon/6}$ *solutions.*

Proof. Assume that there is a list of covers that $n^{1-\epsilon}$-approximates minVC; that is, for every graph with n vertices and minimum vertex cover of size d, there exists

a cover of size at most $n^{1-\epsilon}d$ in the list. We construct a "big" family of graphs and show that every cover in the list covers "a few" graphs in the family; thus the size of the list must be "big."

Consider the following family of graphs. Each graph is defined by a subset I of size $d \stackrel{\text{def}}{=} n^\epsilon/6$. The graph G_I contains all edges between I and $V \setminus I$. Notice that the number of graphs in this family is

$$\binom{n}{d} \geq (n/d)^d. \tag{4.1}$$

The set I of size d is a vertex cover of the graph G_I. Since we assume that the list $n^{1-\epsilon}$-approximates minVC, there is a cover in the list that covers G_I and contains at most $n^{1-\epsilon}d = n^{1-\epsilon}n^\epsilon/6 = n/6$ vertices. However, every vertex cover of G_I contains either all vertices in I (and possibly vertices from $V \setminus I$) or all vertices of $V \setminus I$ (and possibly vertices from I). Since $|V \setminus I| = n - d > n/6$, this cover must contain I. The number of graphs in the family that a given cover of size at most $n/6$ covers is at most

$$\binom{n/6}{d} \leq \left(\frac{en/6}{d}\right)^d. \tag{4.2}$$

Thus, by (4.1) and (4.2), the number of covers in the list is at least

$$\frac{(n/d)^d}{(en/6d)^d} \geq 2^d = 2^{n^\epsilon/6}. \qquad \square$$

We emphasize that Claim 4.8 applies only to the size of lists used by solution-list algorithms and does not imply that there are no polynomial-time $n^{1-\epsilon}$-approximation algorithms that leak $o(n^\epsilon)$ bits.[7] However, it was proven in [5] that such approximation algorithms do not exist if $\mathcal{RP} \neq \mathcal{NP}$.

5. Impossibility result for vertex cover approximation that leaks $\log n$ bits. In this section we show that it is unlikely that there is an efficient approximation algorithm for minVC that leaks $\log n$ bits of information. Specifically, if there is such an $n^{1-\epsilon}$-approximation algorithm $\mathcal{A}$ that leaks at most $\frac{\epsilon}{6}\log n$ bits, then $\mathcal{RP} = \mathcal{NP}$.

THEOREM 5.1. *Let $\epsilon > 0$ be a constant. If $\mathcal{RP} \neq \mathcal{NP}$, then there is no randomized $n^{1-\epsilon}$-approximation algorithm for the search problem of* minVC *that leaks at most $\frac{\epsilon}{6}\log n$ bits.*

As in the proof of Theorem 3.2, we assume the existence of such an approximation algorithm and deduce an algorithm that solves vertex cover. Again, we do this by designing an algorithm that solves the Relevant-Noncritical problem (see Definition 3.6) and thus, by Claim 3.7, solves vertex cover. This algorithm, given the input G and v and an oracle access to an approximation algorithm $\mathcal{A}$ that leaks k bits, applies $\mathcal{A}$ on a set of inputs and decides whether v is relevant or noncritical for G according to the results. Note that Algorithm `Relevant-Noncritical` for the (perfectly) private case is not applicable; here, even assuming $\mathcal{A}$ is deterministic, the fact that $\mathcal{A}(G_1) \neq \mathcal{A}(G_2)$ does not directly imply that G_1 and G_2 are not equal under $\mathcal{R}_{\text{minVC}}$. However, as $\mathcal{A}$ leaks at most k bits, if there are $2^k + 1$ graphs with different outputs, then at least two of them are not equivalent.

[7] It can be proved that the algorithm we presented leaks $\Omega(n^\epsilon)$ bits.

We first deal in section 5.1 with a deterministic $\mathcal{A}$ that leaks at most one bit; then we deal in section 5.2 with a deterministic $\mathcal{A}$ that leaks at most $O(\log n)$ bits. The proof of the impossibility result for a randomized $\mathcal{A}$ that leaks at most $O(\log n)$ bits is deferred to Appendix B. We believe that presenting the proof through these stages is helpful for the reader.

Our inputs for Algorithm `Relevant-Noncritical` are generally constructed from a number of copies of the original input graph G and a big set of isolated vertices I. In each such graph we connect the different copies of the input vertex v with vertices from I and sometimes connect two different vertices from I. We will use the following notation to address these graphs.

DEFINITION 5.2. *Let $G = \langle V, E\rangle$ be a graph, $v \in V$ be some fixed vertex, I be a set of vertices (where $I \cap V = \emptyset$), t, m be indices such that $0 \le t \le m$, and $i_1, \ldots, i_m, j_1, \ldots, j_{2t} \in I$ be distinct vertices. The graph*

$$G\left(\begin{smallmatrix} j_1 & j_2 & & & j_{2t-1} & j_{2t} & i_{t+1} & & i_m \\ \vee & & & & \vee & & \wedge & & \wedge \\ i_1 & & \cdots & & i_t & & & \cdots & \end{smallmatrix}\right)$$

is defined as follows: its vertex set is $(V \times \{1, \ldots, 2m\}) \cup I$, and its edges are $E = E_m \cup E_\vee \cup E_\wedge$, where

$$\begin{aligned} E_m &\stackrel{def}{=} \{(\langle u, \ell\rangle, \langle w, \ell\rangle) : (u, w) \in E, \ell \in \{1, \ldots, m\}\}, \\ E_\vee &\stackrel{def}{=} \{(i_\ell, j_{2\ell-1}), (i_\ell, j_{2\ell}) : \ell \in \{1, \ldots, t\}\}, \text{ and} \\ E_\wedge &\stackrel{def}{=} \{(\langle v, 2\ell-1\rangle, i_\ell), (\langle v, 2\ell\rangle, i_\ell) : \ell \in \{t+1, \ldots, m\}\}. \end{aligned}$$

Informally, the graph has $2m$ copies of G (see Figure 5.1). It has t "vees," where the ℓth vee is associated with copies $2\ell-1$ and 2ℓ of G. It has $m-t$ "wedges," where the ℓth wedge connects i_ℓ to the copies of v in copies $2\ell-1$ and 2ℓ of G, for $t < \ell \le m$.

We next present two combinatorial lemmas, whose role is similar to Claims 3.10 and 3.11 in the case where $\mathcal{A}$ was perfectly private.

CLAIM 5.3. *Let $1 \le t \le m$, and $i_1, \ldots, i_m, j_1, \ldots, j_{2t}, i'_{t+1}, \ldots, i'_m \in I$ be distinct vertices. Furthermore, let*

$$H \stackrel{def}{=} G\left(\begin{smallmatrix} j_1 & j_2 & & & j_{2t-1} & j_{2t} & i_{t+1} & & i_m \\ \vee & & & & \vee & & \wedge & & \wedge \\ i_1 & & \cdots & & i_t & & & \cdots & \end{smallmatrix}\right) \quad \text{and} \quad H' \stackrel{def}{=} G\left(\begin{smallmatrix} j_1 & j_2 & & & j_{2t-1} & j_{2t} & i'_{t+1} & & i'_m \\ \vee & & & & \vee & & \wedge & & \wedge \\ i_1 & & \cdots & & i_t & & & \cdots & \end{smallmatrix}\right).$$

If v is critical for G, then $H \equiv_{\mathcal{R}_{\text{minVC}}} H'$.

Proof. By Claim 3.10, the graphs H and H' are unions of graphs that are equivalent; thus, H and H' are equivalent. ∎

CLAIM 5.4. *Let $0 \le t' < t \le m$ and $i_1, \ldots, i_m, j_1, \ldots, j_{2t} \in I$ be distinct vertices. Furthermore, let*

$$\begin{aligned} H &\stackrel{def}{=} G\left(\begin{smallmatrix} j_1 & j_2 & & & j_{2t'-1} & j_{2t'} & & & j_{2t-1} & j_{2t} & i_{t+1} & & i_m \\ \vee & & & & \vee & & & & \vee & & \wedge & & \wedge \\ i_1 & & \cdots & & i_{t'} & & \cdots & & i_t & & & \cdots & \end{smallmatrix}\right) \quad \text{and} \\ H' &\stackrel{def}{=} G\left(\begin{smallmatrix} j_1 & j_2 & & & j_{2t'-1} & j_{2t'} & i_{t'+1} & & i_m \\ \vee & & & & \vee & & \wedge & & \wedge \\ i_1 & & \cdots & & i_{t'} & & & \cdots & \end{smallmatrix}\right). \end{aligned}$$

If v is nonrelevant for G, then $H \equiv_{\mathcal{R}_{\text{minVC}}} H'$.

Proof. Note that the vertices $i_1, \ldots, i_m$ are critical for both H and H': It is straightforward that i_ℓ is critical for $\begin{smallmatrix} j_{2\ell-1} & j_{2\ell} \\ \vee & \\ i_\ell & \end{smallmatrix}$. By Claim 3.11, vertex i_ℓ is critical for $\begin{smallmatrix} i_\ell \\ \wedge \end{smallmatrix}$. Therefore, the two graphs have the same set of minimum vertex covers; hence they are equivalent under $\mathcal{R}_{\text{minVC}}$. ∎

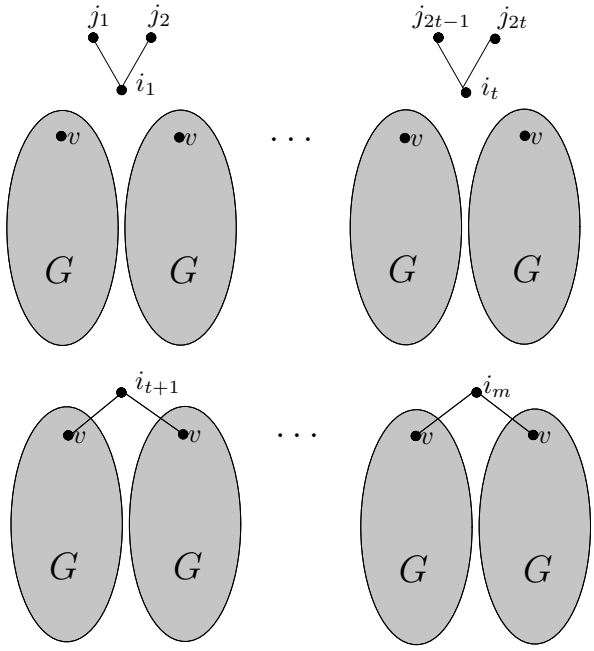

FIG. 5.1. *The graph* $G(\overset{j_1 j_2}{\underset{i_1}{\vee}} \cdots \overset{j_{2t-1} j_{2t}}{\underset{i_t}{\vee}} \ \overset{i_{t+1}}{\wedge} \cdots \overset{i_m}{\wedge})$.

In both claims we have the same graph H. In Claim 5.3, the graph H' has the same "vees" as H; however, the "wedges" have different vertices from I (namely, $i'_1, \ldots, i'_{t-1}$). In Claim 5.4, the sequence of i's is the same in H and H'; however, there are "vees" in H' in some places where there are "wedges" in H.

5.1. Handling one bit leakage. To simplify our presentation, we first present Algorithm `RelNonCrit—one bit` in Figure 5.2. This algorithm assumes that the deterministic algorithm $\mathcal{A}$ leaks at most one bit. This case is simpler and describes some of the ideas used for the $\log n$ bits leakage case.

CLAIM 5.5. *Algorithm* `RelNonCrit—one bit` *is correct.*

Proof. By Claim 5.3, if v is critical for G, then all graphs considered in step 1 of the algorithm are equivalent. As $\mathcal{A}$ leaks at most 1 bit, there can be at most two different answers on equivalent graphs. Hence, if there are more than two different answers in step 1, vertex v is noncritical for G. Similarly, if there are more than two different answers in step 2, vertex v is noncritical for G. Thus, if the algorithm outputs "Noncritical," vertex v is noncritical for G, and the algorithm is correct.

Else, let i_1, j_1, j_2 be the vertices chosen in step 2 of the algorithm, and fix any $i_2, j_3, j_4 \in I$ that did not appear in the result of any execution of $\mathcal{A}$ in Algorithm `RelNonCrit—one bit` (both in step 1 and in step 2), and note the following.

1. $\mathcal{A}(G\left(\overset{i_1}{\wedge} \ \overset{i_2}{\wedge}\right))$ *does not contain* any of $\{i_1, j_1, j_2\}$ (by the choice of the algorithm in step 2) and *does not contain* any of $\{i_2, j_3, j_4\}$.
2. $\mathcal{A}(G(\overset{j_1 j_2}{\underset{i_1}{\vee}} \ \overset{i_2}{\wedge}))$ *contains* at least one of $\{i_1, j_1\}$ (since the graph contains the edge (i_1, j_1)) and *does not contain* any of $\{i_2, j_3, j_4\}$.
3. $\mathcal{A}(G(\overset{j_1 j_2}{\underset{i_1}{\vee}} \ \overset{j_3 j_4}{\underset{i_2}{\vee}}))$ *contains* at least one of $\{i_2, j_3\}$ (since the graph contains the edge (i_2, j_3)).

Algorithm `RelNonCrit`—`one bit`

INPUT: A graph $G = \langle V, E \rangle$ and a vertex $v \in V$.
OUTPUT: One of the following: (i) The vertex v is relevant for G. (ii) The vertex v is not critical for G.

1. Execute $\mathcal{A}$ on all the graphs of the form $G(\overset{i_1}{\wedge}\ \overset{i_2}{\wedge})$, where $i_1, i_2 \in I$.
   (a) If these executions result in more than two different answers, return "Noncritical,"
   (b) Else, remove from I all the vertices that appeared in any of the above results.
2. Pick arbitrary $i_1, j_1, j_2 \in I$ and execute $\mathcal{A}$ on all the graphs of the form $G(\overset{j_1 j_2}{\underset{i_1}{\vee}}\ \overset{i_2}{\wedge})$, where $i_2 \in I \setminus \{i_1, j_1, j_2\}$.
   (a) If these executions result in more than two different answers, return "Noncritical."
   (b) Else, return "Relevant."

FIG. 5.2. *Algorithm* `RelNonCrit`—`one bit`.

Thus, these three results of $\mathcal{A}$ are all different. However, by Claim 5.4, if the vertex v is not relevant for G, then the three graphs are equivalent. Since $\mathcal{A}$ leaks at most one bit, there cannot be three different answers on three equivalent graphs. Thus, if the algorithm outputs "Relevant," vertex v is relevant for G, and the algorithm is correct. □

Similarly to the case where $\mathcal{A}$ is perfectly private, it is enough to set $|I| = O((4n)^{1/\epsilon} - 2n)$ to ensure there are enough vertices in I that are not returned by $\mathcal{A}$ (see Claim 3.14). As $|I|$ is polynomial in n, the number of calls to $\mathcal{A}$ in the algorithm is polynomial in n, and each execution of $\mathcal{A}$ runs in polynomial time. Thus, we have proved that if $\mathcal{P} \neq \mathcal{NP}$, then there is no deterministic $n^{1-\epsilon}$-approximation algorithm for vertex cover that leaks at most one bit.

5.2. Handling $\log n$-bits leakage. We next want to accommodate a deterministic algorithm $\mathcal{A}$ that leaks $\log n$ bits. Using an algorithm similar to that used in the one-bit leakage case with graphs that contain more copies of G, we can handle Algorithm $\mathcal{A}$ which leaks more bits. However, if $\mathcal{A}$ leaks $\omega(1)$ bits, the number of executions of $\mathcal{A}$ will be too big. To reduce the number of calls to $\mathcal{A}$, we choose the vertices from I at random.

In Figure 5.3, we present Algorithm `RelNonCrit`—log n `bits`, which assumes that Algorithm $\mathcal{A}$ is a deterministic $n^{1-\epsilon}$-approximation algorithm that leaks at most $\frac{\epsilon}{6} \log n$ bits. Algorithm `RelNonCrit`—log n `bits` is a randomized algorithm which returns a correct answer with probability at least $1 - \delta$ for some $0 < \delta < 1$. Given a graph G with n vertices, we construct the graphs from Definition 5.2. These graphs have $N \stackrel{\text{def}}{=} (12n/\delta)^{2/\epsilon}$ vertices, $2m$ copies of G, and a disjoint set of vertices I. We choose the number of copies to be $2m$, where

$$m \stackrel{\text{def}}{=} N^{\epsilon/6} = (12n/\delta)^{1/3}. \tag{5.1}$$

The size of the set I is $|I| = N - 2mn$. In the proof of Claim 5.7 it will become clear why we made these choices.

In the following we assume that, on graphs with n vertices, $\mathcal{A}$ leaks at most $k(n) = \frac{\epsilon}{6} \log n$ bits. Recall that we execute $\mathcal{A}$ on graphs with N vertices; thus, the

Algorithm `RelNonCrit`—log n `bits`

INPUT: A graph $G = \langle V, E \rangle$, a vertex $v \in V$, and a number $0 < \delta < 1$.
OUTPUT: One of the following: (i) The vertex v is relevant for G. (ii) The vertex v is not critical for G. The algorithms errs with probability at most δ.

1. Choose distinct $i_1, \ldots, i_m, j_1, \ldots, j_{2m}$ at random from I.
2. For $t = 0$ to $m - 1$ do:
   (a) Let $G_t = G(\overset{j_1 j_2}{\underset{i_1}{\vee}} \cdots \overset{j_{2t-1} j_{2t}}{\underset{i_t}{\vee}} \overset{i_{t+1}}{\wedge} \cdots \overset{i_m}{\wedge})$.
   (b) If $\mathcal{A}(G_t) \cap \{i_{t+1}, j_{2t+1}\} \neq \emptyset$, then return "Noncritical."
3. ($*$ all m sets do not contain the two vertices $*$)
   RETURN "Relevant."

FIG. 5.3. *Algorithm* `RelNonCrit`—log n `bits`.

approximation ratio is $N^{1-\epsilon}$, and the leakage is bounded by $k(N) = \frac{\epsilon}{6} \log N = \log m$. The next sequence of claims asserts the correctness of Algorithm `RelNonCrit`—log n `bits`.

CLAIM 5.6. *If v is nonrelevant, then Algorithm* `RelNonCrit`—log n `bits` *does not return "Relevant."*

Proof. Let $G_m = G(\overset{j_1 j_2}{\underset{i_1}{\vee}} \cdots \overset{j_{2m-1} j_{2m}}{\underset{i_m}{\vee}})$. If the algorithms returns "Relevant," then the for loop finishes. Thus, the sets $\mathcal{A}(G_0), \ldots, \mathcal{A}(G_m)$ are $m+1 = 2^{k(n)} + 1$ different sets; for $t' < t$ the cover $\mathcal{A}(G_t)$ must contain at least one of the vertices $i_{t'+1}, j_{2t'+1}$ (as it must cover the edge $(i_{t'+1}, j_{2t'+1})$), while $\mathcal{A}(G_{t'})$ contains none of them. Thus, there are $2^{k(n)} + 1$ graphs with pairwise different answers of $\mathcal{A}$, and, since $\mathcal{A}$ leaks at most $k(n)$ bits, at least two of the graphs are not equivalent according to $\mathcal{R}_{\text{minVC}}$. Thus, by Claim 5.4, the vertex v is relevant for G. ∎

CLAIM 5.7. *Let $0 \leq t \leq m$. For every $i_1, \ldots, i_t, j_1, \ldots, j_{2t} \in I$, consider the following experiment: choose $i_{t+1}, \ldots, i_m$ and j_{2t+1} at random with uniform distribution from I and return* 1 *if*

$$\mathcal{A}\left(G\left(\overset{j_1 j_2}{\underset{i_1}{\vee}} \cdots \overset{j_{2t-1} j_{2t}}{\underset{i_t}{\vee}} \overset{i_{t+1}}{\wedge} \cdots \overset{i_m}{\wedge}\right)\right) \cap \{i_{t+1}, j_{2t+1}\} \neq \emptyset.$$

If v is critical, then the probability that this experiment returns 1 *is at most δ/m.*

Proof. We first prove that we chose N, the number of vertices in the graphs we construct, such that the size of each cover $\mathcal{A}$ returns is at most $|I|/\alpha$, where $\alpha \stackrel{\text{def}}{=} 2m^2/\delta$. We will need the following requirement for our computations:

$$|I| = N - 2mn \geq N/2. \tag{5.2}$$

That is, we need to show that $N/2 \geq 2mn$. As $m = N^{\epsilon/6} \leq N^{1/6}$, it suffices to require that $N \geq (4n)^{6/5}$. By the choice of N

$$N = (12n/\delta)^{2/\epsilon} \geq (12n)^2 \geq (4n)^{6/5}$$

(since $0 < \delta, \epsilon \leq 1$); thus (5.2) holds.

We next upper-bound the size of the covers that $\mathcal{A}$ outputs. The size of a minimum vertex cover of these graphs is at most $(2n+1)m \leq 3nm$. Since $\mathcal{A}$ is an $N^{1-\epsilon}$-approximation algorithm for vertex cover, the size of its output is at most $3 \cdot nm \cdot N^{1-\epsilon}$.

Recall that $N = (\frac{12n}{\delta})^{2/\epsilon}$ and $m = N^{\epsilon/6}$, and thus, by (5.1),

$$12nm^3 = \delta(12n/\delta) \cdot N^{\epsilon/2} = \delta((12n/\delta)^{2/\epsilon})^{\epsilon/2} \cdot N^{\epsilon/2} = \delta N^{\epsilon/2} N^{\epsilon/2} = \delta N^{\epsilon}. \tag{5.3}$$

Therefore, the size of the cover returned by $\mathcal{A}$ is at most

$$3 \cdot nm \cdot N^{1-\epsilon} = \frac{3nmN}{N^{\epsilon}} \leq \frac{6nm|I|}{N^{\epsilon}} = \frac{12nm^3}{\delta N^{\epsilon}} \cdot \frac{\delta |I|}{2m^2} = \frac{\delta |I|}{2m^2} = \frac{|I|}{\alpha},$$

where the inequality above follows from (5.2) and the last two equalities follow (5.3) and the definition of α. Thus, with probability at most $1/\alpha$, a random vertex from I is in a given answer.

We now analyze the probability that the experiment returns 1. If v is critical, then, by Claim 5.3, every two choices of $i_{t+1}, \ldots, i_m$ result in equivalent graphs according to $\mathcal{R}_{\text{minVC}}$. Since $\mathcal{A}$ leaks at most $k(N) = \frac{\epsilon}{6} \log N = \log m$ bits, there are at most $2^{k(N)} = m$ different answers for all the different choices of $i_{t+1}, \ldots, i_m$. Thus, the size of the union of all the answers is at most $\frac{m|I|}{\alpha}$. The probability that at least one of the vertices i_{t+1}, j_{2t+1} is in the union of the m answers is, by the union bound, at most $\frac{2m}{\alpha}$. Thus, the probability of the experiment returning 1 is at most $\frac{2m}{\alpha} = \delta/m$, as required. ∎

Claim 5.8. *If vertex v is critical, then the probability that Algorithm* `RelNonCrit`—log n `bits` *returns "Noncritical" is at most δ.*

Proof. Algorithm `RelNonCrit`—log n `bits` repeats the experiment of Claim 5.7 m times and returns "Noncritical" if one of the experiments returns 1. Thus, by Claim 5.7 and the union bound, if vertex v is critical, then the probability that Algorithm `RelNonCrit`—log n `bits` returns "Noncritical" is at most δ. ∎

Algorithm `RelNonCrit`—log n `bits` executes the polynomial-time algorithm $\mathcal{A}$ m times on graphs with N vertices, where $N = (12n/\delta)^{2/\epsilon}$. Thus, we have the following claim.

Claim 5.9. *If $\mathcal{A}$ runs in polynomial time and $0 \leq \epsilon < 1$ is a constant, then the running time of Algorithm* `RelNonCrit`—log n `bits` *is* poly(n/δ).

We summarize the results of this section in the next lemma.

Lemma 5.10. *Let $\epsilon > 0$ be a constant. If $\mathcal{RP} \neq \mathcal{NP}$, then there is no deterministic $n^{1-\epsilon}$-approximation algorithm for the search problem of* vertex cover *that leaks at most $\frac{\epsilon}{6} \log n$ bits.*

Proof. Algorithm `Greedy Vertex Cover`, which solves vertex cover, executes at most n times Algorithm `RelNonCrit`—log n `bits` with graphs of size at most n. We execute these calls with $\delta = \frac{1}{4n}$ (where n is the original number of vertices in G); thus, all together, the error is at most $1/4$. By Claim 5.9, the running time of Algorithm `Greedy Vertex Cover` is polynomial. Thus, if there is an $n^{1-\epsilon}$-approximation algorithm for the search problem of vertex cover that leaks at most $k(n) = \frac{\epsilon}{6} \log n$ bits, then there is a polynomial-time randomized algorithm for minimum vertex cover that errs with probability $1/4$. This implies that $\mathcal{NP} \subseteq \mathcal{BPP}$.

To contradict $\mathcal{RP} \neq \mathcal{NP}$, this algorithm is transformed to a one-sided error algorithm for the decision problem of vertex cover: Given $\langle G, s \rangle$, decide if G has a vertex cover of size at most s. The transformation is simple; execute the algorithm for the search problem of vertex cover. If this algorithm returns a set that covers G and its size is at most s, return "yes"; otherwise return "no." ∎

6. Impossibility result for private computation of a search problem in $\mathcal{P}$. An algorithm solving a search problem can return any solution to the problem.

An algorithm solving a search problem *privately* has additional requirements on the solutions that it returns. In this section, we show that these additional requirements can make the problem much harder. That is, we show that there is a relation Q whose search problem is in $\mathcal{P}$; however, unless $\mathcal{NP} \subseteq \mathcal{P}/\text{poly}$, there is no polynomial-time private algorithm for Q with respect to $\mathcal{R}_Q$.

DEFINITION 6.1. *Let G be a graph and $C_1, C_2 \subseteq V$. We define the relation Q as follows: $\langle G, C_1\rangle$ and C_2 are in Q (that is, $\langle\langle G, C_1\rangle, C_2\rangle \in Q$) if $|C_1| = |C_2|$ and C_1 and C_2 are cliques in G.*

Clearly, the search problem of Q is easy; given $\langle G, C_1\rangle$, return C_1. Assume that there is a private algorithm for $\mathcal{R}_Q$. That is, if C_1 and C_2 are two disjoint cliques of the same size in a graph G, then a private algorithm has to return the same output distribution on $\langle G, C_1\rangle$ and $\langle G, C_2\rangle$. Intuitively, this implies that given a clique in the graph, there is an efficient algorithm that finds another clique. We will prove that this is impossible unless $\mathcal{NP} \subseteq \mathcal{P}/\text{poly}$.

THEOREM 6.2. *If $\mathcal{NP} \not\subseteq \mathcal{P}/\text{poly}$, then there is no polynomial-time private algorithm for the search problem of Q with respect to the privacy structure $\mathcal{R}_Q$.*

Proof. We assume toward contradiction that there exists a polynomial-time randomized private algorithm $\mathcal{A}$ for the search problem of Q with respect to the privacy structure $\mathcal{R}_Q$. We will use $\mathcal{A}$ to prove that the $\mathcal{NP}$-complete problem CLIQUE is in $\mathcal{P}/\text{poly}$. That is, we construct a sequence of polynomial-length advice strings $\langle a_n\rangle_{n\in\mathbb{N}}$ and a polynomial-time algorithm $\mathcal{B}$ such that, given a graph G with n vertices, an integer k, and the advice a_n, Algorithm $\mathcal{B}$ decides if G contains a clique of size k.

Given two graphs $G_0 = \langle V_0, E_0\rangle$ and $G_1 = \langle V_1, E_1\rangle$, where $V_1 \cap V_2 = \emptyset$, we define their disjoint union $G_0 \cup G_1$ as the graph $G = \langle V, E\rangle$, where $V = V_0 \cup V_1$ and $E = E_0 \cup E_1$. Every clique in $G_0 \cup G_1$ is either a clique in G_0 or a clique in G_1. Assume that C_0 and C_1 are cliques of size k in G_0 and G_1, respectively. Then, $\langle G_0 \cup G_1, C_0\rangle$ and $\langle G_0 \cup G_1, C_1\rangle$ have the same set of cliques of size k; that is, they are in $\mathcal{R}_Q$.

Algorithm $\mathcal{A}'$

INPUT: Two graphs G_0, G_1 with disjoint sets of vertices and a set C.
PROMISE: C is a clique in $G_0 \cup G_1$.

1. Execute $\mathcal{A}$ on $\langle G_0 \cup G_1, C\rangle$
   (a) Let j be the index such that $\mathcal{A}$ returns a clique in G_j.
   (b) Return j.

FIG. 6.1. *Algorithm $\mathcal{A}'$, which gets two graphs and a clique, executes $\mathcal{A}$ on their union, and checks in which graph $\mathcal{A}$ returns a clique.*

As a first step, we construct in Figure 6.1 an algorithm $\mathcal{A}'$ that will be used to construct Algorithm $\mathcal{B}$ and the advice strings. This algorithm gets two graphs G_0, G_1 and a clique C in one of them, executes $\mathcal{A}$ on their union, and checks in which graph $\mathcal{A}$ returns a clique. If only one graph G_i has a clique of size $|C|$, then, by the correctness requirement of $\mathcal{A}$, Algorithm $\mathcal{A}'$ must return i. However, if both graphs have a clique of size $|C|$, then, by the privacy requirement of $\mathcal{A}$, the output distribution of $\mathcal{A}'$ is approximately the same when C is a clique in G_0 and when C is a clique in G_1. That is, there is an integer n_0 such that for every pair of graphs with at least n_0 vertices, the difference between the probabilities that $\mathcal{A}'$ returns 0 in the two cases is small—for concreteness, at most 1/3 (the probabilities are taken over the random inputs of

algorithm $\mathcal{A}$).

We construct the advice string a_n as the concatenation of advice strings $a_{n,1}, \ldots, a_{n,n}$, where $a_{n,k}$ is used to decide if a graph G with n vertices has a clique of size k. Fix an integer n and an integer k, where $n \geq n_0$ and $1 \leq k \leq n$. For every graph G with n vertices that has a clique of size k, we fix some clique C_G of size k in G. Let G_0 and G_1 be two graphs that have a clique of size k.

DEFINITION 6.3. *We say that G_0 loses to G_1 if Algorithm $\mathcal{A}'$ returns 1 on input $\langle G_0, G_1, C_{G_0}\rangle$ with probability at least 1/3.*

That is, G_0 loses to G_1 if, when given a clique in G_0, Algorithm $\mathcal{A}$ "magically" manages to return with probability 1/3 a clique in the graph G_1; thus, G_0, C_{G_0} can aid in finding a clique in G_1.

If G_0 does not lose to G_1, then $\mathcal{A}'$ returns 0 with probability at least 2/3, and by the privacy requirement, with probability at least 1/3 Algorithm $\mathcal{A}'$ returns 0 on input $\langle G_0, G_1, C_{G_1}\rangle$.

OBSERVATION 6.4. *Let G_0 and G_1 be two graphs with n vertices that have a clique of size k. If G_0 does not lose to G_1, then G_1 loses to G_0. (It is possible that G_0 loses to G_1 and G_1 loses to G_0.)*

Thus, for every set of graphs with n vertices and a clique of size k, there exists a graph G_0 in the set that loses to at least half the graphs in the set. This is the idea of constructing the advice string $a_{n,k}$.

Construction of $a_{n,k}$

1. $a_{n,k} \leftarrow \emptyset$.
2. Initialize L as the set of all graphs with n vertices that have a clique of size k.
3. While $L \neq \emptyset$ do:
   (a) Choose a graph G in L that loses to at least half of the graphs in L.
   (b) $a_{n,k} \leftarrow a_{n,k} \cup \{\langle G, C_G\rangle\}$.
   (c) $L \leftarrow L \setminus \{G_1 : G \text{ loses to } G_1\}$.

Since there are $2^{O(n^2)}$ graphs with n vertices, the advice $a_{n,k}$ contains $O(n^2)$ graphs. We are ready to describe the nonuniform algorithm $\mathcal{B}$ that, given a graph G with n vertices, an integer k, and the advice a_n, decides if G contains a clique of size k.

Algorithm $\mathcal{B}$

INPUT: G, k, and $a_{n,k}$.

1. For every G_0 in $a_{n,k}$ execute $\mathcal{A}'$ on $\langle G_0, G, C_{G_0}\rangle$.
2. If there exists an execution of $\mathcal{A}'$ which returns 1, return "G has a clique of size k,"
3. Otherwise, return "FAIL."

If G does not have a clique of size k, then, by the correctness of $\mathcal{A}$, Algorithm $\mathcal{A}'$ always returns 0, and $\mathcal{B}$ always returns "FAIL." If G has a clique of size k, then there exists a graph G_0 in $a_{n,k}$ that loses to G; thus, with probability at least 1/3, Algorithm $\mathcal{A}'$ returns 1 on input $\langle G_0, G, C_{G_0}\rangle$, and, thus, with probability at least 1/3, Algorithm $\mathcal{B}$ returns "G has a clique of size k." That is, $\mathcal{B}$ is a randomized algorithm with advice strings that decides if $\langle G, k\rangle \in$ CLIQUE with a one-sided error of 2/3. By a standard amplification and union-bound arguments, we can get a deterministic polynomial-time nonuniform algorithm that decides if $\langle G, k\rangle \in$ CLIQUE without error. □

Appendix A. Semantic-security flavored definitions of private algorithms. In Definition 2.2, private algorithms are defined as those whose outputs on $\mathcal{R}$-equivalent instances are computationally indistinguishable. To shed a little more light on this definition we now compare it with two other definitions. Definition A.1 is of semantically secure private algorithms, where the outcome of the private algorithm $\mathcal{A}$ on x is simulated by an efficient simulator that is given access to an arbitrary representative y of the equivalence class of x. Definition A.2 is a (seeming) weakening of this definition, where the simulator is potentially much more powerful. Here, the simulator is given access to an arbitrary oracle O of its choice that answers queries about the equivalence class of x. For example, one may choose an oracle O that enumerates in lexicographic order the values y such that $x \equiv_{\mathcal{R}} y$, hence empowering the simulator to perform computations that may be otherwise intractable. It turns out that Definitions 2.2, A.1, and A.2 are equivalent. This gives a further indication that Definition 2.2 is a rather minimal notion of privacy.

DEFINITION A.1 (private algorithm—semantic security). *Let $\mathcal{R}$ be a privacy structure. A randomized polynomial-time algorithm $\mathcal{A}$ is* semantically private *with respect to $\mathcal{R}$ if there exists a randomized polynomial-time simulator $\mathcal{S}$, such that for every randomized polynomial-time algorithm $\mathcal{D}$ and for every positive polynomial $p(\cdot)$, there exists some $n_0 \in \mathbb{N}$ such that for every $x, y \in \{0,1\}^*$, where $x \equiv_{\mathcal{R}} y$ and $|x| = |y| \geq n_0$,*

$$\left| \Pr[\mathcal{D}(\mathcal{A}(x), x, y) = 1] - \Pr[\mathcal{D}(\mathcal{S}(y), x, y) = 1] \right| \leq \frac{1}{p(|x|)}.$$

That is, the simulator, on input y, outputs a distribution that is indistinguishable from the output of $\mathcal{A}$ on x.

For a string $y \in \{0,1\}^*$ define $\mathrm{Eq}(y) = \{z : y \equiv_{\mathcal{R}} z\}$ to be its equivalence class. Let $O : \{0,1\}^* \times \{0,1\}^* \to \{0,1\}^*$ be an oracle. We use the notation $O(\mathrm{Eq}(y), \cdot)$ to denote the oracle obtained from O by "hardwiring" its first input to $\mathrm{Eq}(y)$. Informally, O is a collection of oracles—one per each equivalence class. The oracle $O(\mathrm{Eq}(y), \cdot)$ answers queries about the equivalence class of y. For an oracle machine S, we use $S^{O(\mathrm{Eq}(y),\cdot)}$ to denote the Turing machine S with oracle access to $O(\mathrm{Eq}(y), \cdot)$. This way, S may use O to learn facts about the equivalence class of y.

DEFINITION A.2 (private algorithm—weak semantic security). *Let $\mathcal{R}$ be a privacy structure. A randomized polynomial-time algorithm $\mathcal{A}$ is* weakly semantically private *with respect to $\mathcal{R}$ if there exist an oracle $O : \{0,1\}^* \times \{0,1\}^* \to \{0,1\}^*$ and a randomized polynomial-time oracle machine[8] $\mathcal{S}$ (the simulator), such that for every randomized polynomial-time algorithm $\mathcal{D}$ and for every positive polynomial $p(\cdot)$, there exists some $n_0 \in \mathbb{N}$ such that, for every $x, y \in \{0,1\}^*$ such that $|x| = |y| \geq n_0$ and $x \equiv_{\mathcal{R}} y$,*

$$\left| \Pr[\mathcal{D}(\mathcal{A}(x), x, y) = 1] - \Pr[\mathcal{D}(\mathcal{S}^{O(\mathrm{Eq}(y),\cdot)}, x, y) = 1] \right| \leq \frac{1}{p(|x|)}.$$

That is, the simulator with oracle access to $O(\mathrm{Eq}(y), \cdot)$ outputs a distribution that is indistinguishable from the output of $\mathcal{A}$ on x.

THEOREM A.3. *Definitions* 2.2, A.1, *and* A.2 *are equivalent.*

Proof. Let $\mathcal{A}$ be an algorithm that is private with respect to a privacy structure $\mathcal{R}$ according to Definition 2.2. Taking the simulator $\mathcal{S}$ to be $\mathcal{A}$ itself shows that $\mathcal{A}$

[8] The choice of randomized polynomial-time is arbitrary, as S can delegate computations to the oracle O.

is private according to Definition A.1 as well. Privacy under Definition A.1 implies privacy under Definition A.2, as any simulator $\mathcal{S}$ in view of Definition A.1 can be transformed into an oracle simulator that asks for a representative of the class and proceeds like $\mathcal{S}$.

Finally, we prove that privacy under Definition A.2 implies privacy under Definition 2.2. Let $\mathcal{A}$ be an algorithm that is private under Definition A.2. Let x and y be inputs such that $x \equiv_{\mathcal{R}} y$, $\mathcal{S}$ be the corresponding simulator, and $\mathcal{D}$ be a distinguishing algorithm. By privacy under Definition A.2, the advantage of $\mathcal{D}$ in distinguishing $(\mathcal{A}(x), x, y)$ and $(\mathcal{S}^{O(\mathrm{Eq}(y),\cdot)}, x, y)$ is negligible. Furthermore, replacing the roles of x and y, the advantage of $\mathcal{D}$ in distinguishing $(\mathcal{A}(y), x, y)$ and $(\mathcal{S}^{O(\mathrm{Eq}(x),\cdot)}, x, y)$ is negligible. Therefore, as $\mathrm{Eq}(x) = \mathrm{Eq}(y)$, we get that the advantage of $\mathcal{D}$ in distinguishing $(\mathcal{A}(x), x, y)$ and $(\mathcal{A}(y), x, y)$ is also negligible, satisfying Definition 2.2. □

Appendix B. Impossibility result for randomized private approximation of vertex cover. In this section, we generalize the inapproximability results of section 5.2 to *randomized* private protocols that leak $O(\epsilon \log n)$ bits. We follow a strategy similar to that in the proof of Lemma 5.10 for deterministic private protocols that leak $O(\epsilon \log n)$ bits. In that proof we checked if $\mathcal{A}(G_t) \cap \{i_{t+1}, j_{2t+1}\} \neq \emptyset$. Here, we execute $\mathcal{A}(G_t)$ many times and estimate the probability that $\mathcal{A}(G_t) \cap \{i_{t+1}, j_{2t+1}\} \neq \emptyset$.

In Figure B.1, we present Algorithm `RelNonCrit—randomized` log n `bits`, which assumes that Algorithm $\mathcal{A}$ is a possibly randomized $n^{1-\epsilon}$-approximation algorithm that leaks at most $\frac{\epsilon}{6} \log n$ bits. Algorithm `RelNonCrit—randomized` log n `bits` is a randomized algorithm which returns a correct answer with probability at least $1 - \delta$ for a given $0 < \delta < 1$. Given a graph G with n vertices, we construct the graphs from Definition 5.2. These graphs have $N = (120n/\delta)^{2/\epsilon}$ vertices, $2m$ copies of G, and a disjoint set of vertices I. We choose the number of copies to be $2m$, where

$$m \stackrel{\mathrm{def}}{=} N^{\epsilon/6} = (120n/\delta)^{1/4}. \tag{B.1}$$

Therefore, the size of the set I is $|I| = N - 2mn$. In the proof of Claim B.4 it will become clear why we made these choices.

Algorithm `RelNonCrit—randomized` log n `bits`

INPUT: A graph $G = \langle V, E \rangle$, a vertex $v \in V$, and a number $0 < \delta < 1$.
OUTPUT: One of the following: (i) The vertex v is relevant for G. (ii) The vertex v is not critical for G. The algorithm errs with probability at most δ.

1. Choose distinct $i_1, \ldots, i_m, j_1, \ldots, j_{2m}$ at random from I.
2. For $t = 0$ to $m - 1$ do:
   (a) Let $G_t = G(\overset{j_1 j_2}{\vee}{}_{i_1} \cdots \overset{j_{2t-1} j_{2t}}{\vee}{}_{i_t} \; \overset{i_{t+1}}{\wedge} \cdots \overset{i_m}{\wedge})$.
   (b) Execute n times $\mathcal{A}(G_t)$.
   (c) If one of the vertices i_{t+1}, j_{2t+1} appears in more than $0.3n$ of the n answers of $\mathcal{A}$, then return "Noncritical."
3. RETURN "Relevant."

FIG. B.1. Algorithm `RelNonCrit—randomized` log n `bits`.

In the following we assume that, on graphs with n vertices, $\mathcal{A}$ leaks at most $k(n) = \frac{\epsilon}{6} \log n$ bits. Recall that we execute $\mathcal{A}$ on graphs with N vertices; thus, the approximation ratio is $N^{1-\epsilon}$, and the leakage is bounded by $k(N) = \frac{\epsilon}{6} \log N =$

$\log m$. The next sequence of claims asserts the correctness of Algorithm `RelNonCrit`—`randomized` $\log\ n$ `bits`.

Let $0 \leq p \leq 1$. We say that a vertex v is p-light for a graph H if $\Pr[v \in \mathcal{A}(H)] < p$ and v is p-heavy for H if $\Pr[v \in \mathcal{A}(H)] \geq p$. Let $\mathcal{R}'$ be a privacy structure that is a $k(N)$-refinement of $\mathcal{R}_{\text{minVC}}$ such that $\mathcal{A}$ is private with respect to $\mathcal{R}'$. The next observation follows from Chernoff's inequality.

OBSERVATION B.1. *Assume we execute n times $\mathcal{A}(H)$.*

- *If a vertex u is 0.4-heavy for H, then the probability that u appears in at most $0.3n$ of the n answers of $\mathcal{A}$ is $2^{-O(n)}$.*
- *If a vertex u is 0.2-light for H, then the probability that u appears in more than $0.3n$ of the n answers of $\mathcal{A}$ is $2^{-O(n)}$.*

A distinguishing algorithm can approximate the probability that a vertex is in $\mathcal{A}(H)$. Hence, for every two graphs H_0, H_1 such that $H_0 \equiv_{\mathcal{R}'} H_1$ and for every vertex u the probability that $u \in \mathcal{A}(H_0)$ is approximately the same as the probability that $u \in \mathcal{A}(H_1)$. This is formalized in the following claim.

CLAIM B.2. *Let $0 \leq p < 1$ and $0 < \gamma < 1 - p$ be constants. Then, there exists $n_0 \in \mathbb{N}$ such that if H_0 and H_1 are two graphs with $n \geq n_0$ vertices and there exists a vertex w that is p-light for H_0 and is $(p+\gamma)$-heavy for H_1, then H_0 and H_1 are not equivalent according to $\mathcal{R}'$.*

Proof. Consider the following distinguishing algorithm $\mathcal{D}$.

INPUT: Two graphs Γ_0, Γ_1 and a cover $C = \mathcal{A}(\Gamma_j)$ for some $j \in \{0,1\}$.

1. For $i \in \{0,1\}$, execute n times $\mathcal{A}(\Gamma_i)$.
2. For every $u \in V$ and $i \in \{0,1\}$, let $\tilde{p}_u^i$ be the fraction of executions in which u appears in the answers of $\mathcal{A}(\Gamma_i)$.
3. Choose a vertex u such that $\tilde{p}_u^1 - \tilde{p}_u^0 > 2\gamma/3$ (if no such u exists, return 1).
4. If $u \in C$, return 1; otherwise return 0.

For every $v \in V$ and $i \in \{0,1\}$ define $p_v^i \stackrel{\text{def}}{=} \Pr[v \in \mathcal{A}(\Gamma_i)]$. By Chernoff's inequality, with probability $1 - 2^{-O(n)}$, for every $v \in V$ and $i \in \{0,1\}$,

$$|p_v^i - \tilde{p}_v^i| < \gamma/6. \tag{B.2}$$

Now consider an execution of $\mathcal{D}$ on the graphs H_0 and H_1, and consider the vertex w guaranteed by the claim. Assume that (B.2) holds for every vertex in the graph. In particular,

$$\tilde{p}_w^1 - \tilde{p}_w^0 = p_w^1 - p_w^0 - (p_w^1 - \tilde{p}_w^1) - (\tilde{p}_w^0 - p_w^0) \ \geq \ \gamma - 2\gamma/6 \ = \ 2\gamma/3.$$

Thus, the probability that there is no such u in step 3 is negligible. Furthermore, for the u chosen in step 3, with overwhelming probability $p_u^1 - p_u^0 = \tilde{p}_w^1 - \tilde{p}_w^0 - (\tilde{p}_w^1 - p_w^1) - (p_w^0 - \tilde{p}_w^0) \geq \gamma/3$. Therefore,

$$|\Pr[\mathcal{D}(\mathcal{A}(\Gamma_1), \Gamma_0, \Gamma_1) = 1] - \Pr[\mathcal{D}(\mathcal{A}(\Gamma_0), \Gamma_0, \Gamma_1) = 1]| \geq \gamma/3 - 2^{-O(n)}.$$

This implies that H_0 and H_1 are not equivalent according to $\mathcal{R}'$, since $\mathcal{A}$ is private with respect to $\mathcal{R}'$. ∎

The following claim is analogous to Claim 5.6 for the deterministic case.

CLAIM B.3. *If a vertex v is nonrelevant, then the probability that Algorithm* `RelNonCrit`—`randomized` *log n* `bits` *returns "Relevant" is negligible.*

Proof. Let $G_m = G(\overset{j_1 j_2}{\underset{i_1}{\vee}} \cdots \overset{j_{2m-1} j_{2m}}{\underset{i_m}{\vee}})$. Since the vertex v is nonrelevant for G, by Claim 5.4, for every $0 \le t' < t \le m$ the graphs $G_{t'}$ and G_t are equivalent according to $\mathcal{R}_{\text{minVC}}$. As $\mathcal{A}$ leaks at most $k(n) = \log m$ bits, every equivalence class of $\mathcal{R}_{\text{minVC}}$ is partitioned into at most m equivalence classes of $\mathcal{R}'$. Since there are $m+1 = 2^k + 1$ graphs $G_0, \ldots, G_m$, there are two indices $0 \le t' < t \le m$, such that $G_{t'}$ and G_t are equivalent according to $\mathcal{R}'$.

As every cover of G_t must cover the edge $(i_{t'+1}, j_{2t'+1})$, at least one of $i_{t'+1}, j_{2t'+1}$ is 0.5-heavy for G_t. Applying Claim B.2 to G_t and $G_{t'}$, at least one of the vertices $i_{t'+1}, j_{2t'+1}$ is 0.4-heavy for $G_{t'}$. Thus, by Observation B.1, with high probability this vertex will appear at least $0.3n$ times in the answers of $\mathcal{A}(G_{t'})$, and the algorithm will return "Noncritical." ∎

To prove that Algorithm `RelNonCrit`—`randomized` log n `bits` is correct when v is critical, we need the following claim.

Claim B.4. *Let $0 \le t < m$. For every $i_1, \ldots, i_t, j_1, \ldots, j_{2t} \in I$, consider the following experiment: choose $i_{t+1}, \ldots, i_m$ and j_{2t+1} at random and with uniform distribution from I and return 1 if at least one of the vertices i_{t+1}, j_{2t+1} is 0.2-heavy for $G(\overset{j_1 j_2}{\underset{i_1}{\vee}} \cdots \overset{j_{2t-1} j_{2t}}{\underset{i_t}{\vee}} \overset{i_{t+1}}{\wedge} \cdots \overset{i_m}{\wedge})$. If v is critical, then the probability that this experiment returns 1 is at most δ/m.*

Proof. We chose N, the number of vertices in the graphs we construct, such that the size of each cover $\mathcal{A}$ returns is at most $|I|/(10\alpha)$ for $\alpha \stackrel{\text{def}}{=} 2m^2/\delta$. To show this, we shall need the following requirement:

$$|I| = N - 2mn \ge N/2. \tag{B.3}$$

That is, we need $N \ge 4mn$. As $m = N^{\epsilon/6} \le N^{1/6}$, it suffices to require $N \ge (4n)^{6/5}$. By the choice of N,

$$N = (120n/\delta)^{2/\epsilon} \ge (120n)^2 \ge (4n)^{6/5}$$

(since $0 < \delta, \epsilon \le 1$); thus (B.3) holds.

We next upper-bound the size of the covers that $\mathcal{A}$ outputs. The size of a minimum vertex cover of these graphs is at most $(2 \cdot n + 1)m \le 3nm$. Since $\mathcal{A}$ is an $N^{1-\epsilon}$-approximation algorithm for vertex cover, the size of its output is at most $3 \cdot nm \cdot N^{1-\epsilon}$. Recall that $N = (\frac{120n}{\delta})^{2/\epsilon}$ and $m = N^{\epsilon/6}$, and thus, using (B.1),

$$120nm^3 = \delta(120n/\delta) \cdot N^{\epsilon/2} = \delta((120n/\delta)^{2/\epsilon})^{\epsilon/2} \cdot N^{\epsilon/2} = \delta N^{\epsilon/2} N^{\epsilon/2} = \delta N^{\epsilon}. \tag{B.4}$$

Therefore, the size of the cover returned by $\mathcal{A}$ is at most

$$3 \cdot nm \cdot N^{1-\epsilon} = \frac{3nmN}{N^{\epsilon}} \le \frac{6nm|I|}{N^{\epsilon}} = \frac{120nm^3}{\delta N^{\epsilon}} \cdot \frac{\delta |I|}{20m^2} = \frac{\delta |I|}{20m^2} = \frac{|I|}{10\alpha},$$

where the inequality above follows from (B.3) and the last two equalities follow from (B.4) and the definition of α. Therefore, for *every* choice of $i_{t+1}, \ldots, i_m, j_{2t+1}, \ldots, j_{2m}$ there are at most $|I|/\alpha$ vertices that are 0.1-heavy for $G(\overset{j_1 j_2}{\underset{i_1}{\vee}} \cdots \overset{j_{2t-1} j_{2t}}{\underset{i_t}{\vee}} \overset{i_{t+1}}{\wedge} \cdots \overset{i_m}{\wedge})$.

We will show that if v is critical, then the number of vertices that are 0.2-heavy for $G(\overset{j_1 j_2}{\underset{i_1}{\vee}} \cdots \overset{j_{2t-1} j_{2t}}{\underset{i_t}{\vee}} \overset{i_{t+1}}{\wedge} \cdots \overset{i_m}{\wedge})$ for at least one choice of $i_{t+1}, \ldots, i_m, j_{2t+1}, \ldots, j_{2m}$ is at most $m|I|/\alpha$.

We first prove an upper bound on the number of 0.2 heavy vertices in a given equivalence class of $\mathcal{R}'$. Fix $i_{t+1}, \ldots, i_m, j_{2t+1}, \ldots, j_{2m}$ and let

$$H_0 = G\left(\overset{j_1 j_2}{\underset{i_1}{\vee}} \cdots \overset{j_{2t-1} j_{2t}}{\underset{i_t}{\vee}} \overset{i_{t+1}}{\wedge} \cdots \overset{i_m}{\wedge}\right).$$

If a vertex u is 0.2-heavy for some H such that $H \equiv_{\mathcal{R}'} H_0$, then by Claim B.2, it is (at least) 0.1-heavy for H_0. Thus, there are at most $|I|/\alpha$ vertices that are 0.2-heavy for at least one of the graphs in the equivalence class of H_0 with respect to $\equiv_{\mathcal{R}'}$.

We next bound the number of vertices that are 0.2-heavy vertices for at least one graph of the form $G(\overset{j_1 j_2}{\underset{i_1}{\vee}} \cdots \overset{j_{2t-1} j_{2t}}{\underset{i_t}{\vee}} \overset{i_{t+1}}{\wedge} \cdots \overset{i_m}{\wedge})$. If v is critical, then, by Claim 5.3, every two choices of $i_{t+1}, \ldots, i_m$ result in equivalent graphs according to $\mathcal{R}_{\text{minVC}}$. Since $\mathcal{A}$ leaks at most $k(N) = \frac{\epsilon}{6} \log N = \log m$ bits, there are at most $2^{k(N)} = m$ equivalence classes of $\mathcal{R}'$ for the different choices of $i_{t+1}, \ldots, i_m, j_{2t+1}, \ldots, j_{2m}$. Thus, there are at most $m|I|/\alpha$ vertices that are 0.2-heavy for at least one graph $G(\overset{j_1 j_2}{\underset{i_1}{\vee}} \cdots \overset{j_{2t-1} j_{2t}}{\underset{i_t}{\vee}} \overset{i_{t+1}}{\wedge} \cdots \overset{i_m}{\wedge})$ for some $i_{t+1}, \ldots, i_m, j_{2t+1}, \ldots, j_{2m}$.

We now analyze the probability that the experiment returns 1. The probability that at least one of the vertices i_{t+1}, j_{2t+1} is 0.2-heavy for some graph is, by the union bound, at most $\frac{2m}{\alpha}$. Therefore, the probability of the experiment returning 1 is at most $\frac{2m}{\alpha} = \delta/m$, as required. □

CLAIM B.5. *If v is critical, then the probability that Algorithm* `RelNonCrit`—`randomized` log n `bits` *returns "Noncritical" is at most δ.*

Proof. Assume v is critical. By Claim B.4, the probability that we choose $i_1, \ldots, i_m, j_1, \ldots, j_{2m}$ such that for some $0 \le t < m$ at least one of the vertices $i_{t+1}, \ldots, i_m, j_{2t+1}, \ldots, j_{2m}$ is 0.2-heavy for $G(\overset{j_1 j_2}{\underset{i_1}{\vee}} \cdots \overset{j_{2t-1} j_{2t}}{\underset{i_t}{\vee}} \overset{i_{t+1}}{\wedge} \cdots \overset{i_m}{\wedge})$ is at most δ. By Observation B.1, the probability that Algorithm `RelNonCrit`—`randomized` log n `bits` returns "Noncritical" in this case is, therefore, negligible. □

Algorithm `RelNonCrit`—`randomized` log n `bits` executes nm times the polynomial-time algorithm $\mathcal{A}$ on graphs with N vertices, where $N = (120n/\delta)^{2/\epsilon}$. Therefore, we have proved the following claim.

CLAIM B.6. *If $\mathcal{A}$ runs in polynomial time and $0 \le \epsilon < 1$ is a constant, then the running time of Algorithm* `RelNonCrit`—`randomized` log n `bits` *is* poly(n/δ).

We are ready to prove Theorem 5.1 (similarly to the proof of Lemma 5.10).

THEOREM 5.1 *Let $\epsilon > 0$ be a constant. If $\mathcal{RP} \neq \mathcal{NP}$, then there is no $n^{1-\epsilon}$-approximation algorithm for the search problem of* vertex cover *that leaks at most $\frac{\epsilon}{6} \log n$ bits.*

Proof. Algorithm `Greedy Vertex Cover`, which solves vertex cover, executes at most n times Algorithm `RelNonCrit`—`randomized` log n `bits` with graphs of size at most n. We execute these calls with $\delta = \frac{1}{4n}$ (where n is the original number of vertices in G); thus, all together, the error is at most 1/4. By Claim B.6, the running time of Algorithm `Greedy Vertex Cover` is polynomial.

Thus, if there is an $n^{1-\epsilon}$-approximation algorithm for the search problem of vertex cover that leaks at most $k(n) = \frac{\epsilon}{6} \log n$ bits, then there is a polynomial-time randomized algorithm for minimum vertex cover that errs with probability 1/4. This implies that $\mathcal{NP} \subseteq \mathcal{BPP}$.

To contradict $\mathcal{RP} \neq \mathcal{NP}$, this algorithm is transformed into a one-sided error algorithm for the decision problem of vertex cover: Given $\langle G, s \rangle$, decide if G has a vertex cover of size at most s. The transformation is simple; execute the algorithm for the search problem of vertex cover. If this algorithm returns a set that covers G and its size is at most s, return "yes." □

Appendix C. Negative result for private approximation of exact 3SAT. Recall that the privacy structure $\mathcal{R}_{\text{maxE3SAT}}$ contains all pairs of exact 3CNF formulae ϕ_1, ϕ_2 over n variables for which an assignment a satisfies the maximum possible number of clauses in ϕ_1 iff it satisfies the maximum possible number of clauses in ϕ_2.

DEFINITION C.1 (private approximation of maxE3SAT). *An algorithm $\mathcal{A}$ is a* private $c(n)$ approximation *algorithm for* maxE3SAT *if* (i) $\mathcal{A}$ *runs in polynomial time;* (ii) $\mathcal{A}$ *is a* $c(n)$*-approximation algorithm for* maxE3SAT*, that is, for every exact* 3*CNF formula* ϕ *over* n *variables it returns with probability* 1 *an assignment that satisfies at least* $c(n)$ *times the maximum possible number of clauses that are simultaneously satisfiable in* ϕ*;* (iii) $\mathcal{A}$ *is private with respect to the privacy structure* $\mathcal{R}_{\text{maxE3SAT}}$*.*

We now prove Theorem 3.16, part 1.

THEOREM 3.16 (part 1). *Let* $\epsilon > 0$ *be a constant. If* $\mathcal{P} \neq \mathcal{NP}$*, then there is no deterministic private* $1/n^{1-\epsilon}$*-approximation algorithm for the search problem of* maxE3SAT*.*

Sketch of proof. Similarly to the proof of Theorem 3.2, we will assume the existence of a deterministic private $1/n^{1-\epsilon}$-approximation algorithm $\mathcal{A}$, and use $\mathcal{A}$ to construct a deterministic algorithm for deciding the satisfiability of exact 3CNF formulae. We emphasize that we are solving the decision problem of satisfiability and not the optimization problem of maximum satisfiability.

DEFINITION C.2 (relevant assignment to a variable). *Let* ϕ *be an exact* 3*CNF formula over Boolean variables* $x_1, \ldots, x_n$*. We say that a variable* x_i *is* σ*-relevant (where* $\sigma \in \{0,1\}$*) if there exists an assignment* a *that satisfies the maximum possible number of clauses in* ϕ *such that* $a(x_i) = \sigma$*.*

Note that for every satisfiable formula, every variable is 0-relevant or 1-relevant (or both). Furthermore, if a variable is not σ-relevant, then, in each assignment that satisfies the formula, its value is $\neg\sigma$; that is, the variable is "$\neg\sigma$-critical."

We will first assume an algorithm `Relevant Variable-Assignment` that, given an exact 3CNF formula ϕ over variables $x_1, \ldots, x_n$ and $y_1, \ldots, y_n$, outputs an index i and a bit σ such that x_i is σ-relevant. The variables $y_1, \ldots, y_n$ are auxiliary variables that we add to the formula to ensure that the formula remains an exact 3CNF formula. Algorithm `Relevant Variable-Assignment` returns an index of a variable x_i (it never returns a variable y_i). For technical reasons, `Relevant Variable-Assignment` needs that ϕ includes at least 3 variables from $x_1, \ldots, x_n$ (negated or nonnegated). Algorithm `Greedy E3SAT`, described in Figure C.1, uses Algorithm `Relevant Variable-Assignment` to decide E3SAT.

Note that the algorithm terminates in at most $n-2$ iterations, as every iteration reduces the number of x variables in $\hat{\phi}$ by at least one. The final length of $\hat{\phi}$ is at most eight times that of ϕ as the replacement steps 2(c)ii and 2(c)iii are applied only to clauses including x variables, resulting in one less x variable in each of the two replacement clauses. Hence, if Algorithm `Relevant Variable-Assignment` runs in polynomial time, so does `Greedy E3SAT`.

We now prove the correctness of Algorithm `Greedy E3SAT`. Clearly, the only way `Greedy E3SAT` can err is by outputting 0 on a satisfiable formula ϕ; hence we assume from now on that ϕ is satisfiable and show that executing `Greedy E3SAT` results in outputting 1. Before proving the correctness of the algorithm, we will try to give the intuition behind it. In each step of the algorithm we have a partial assignment to ϕ that can be extended to an assignment that satisfies ϕ. On one hand, this partial assignment already satisfies some clauses in ϕ, and therefore we deleted them from $\hat{\phi}$. On the other hand, some literals in various clauses are not satisfied by the partial assignment. We would have liked to delete these literals from the clauses that they appear in, and continue. However, this might result in a 3CNF formula that is not an exact 3CNF formula. We therefore replace the literal ℓ_i that is not satisfied by an auxiliary variable y_i. By replacing each clause $(\ell_i \vee \ell_j \vee \ell_k)$ (where ℓ_j and ℓ_k are

Algorithm `Greedy E3SAT`

INPUT: An exact 3CNF formula ϕ on n variables $x_1, \ldots, x_n$.
OUTPUT: 1 if ϕ is satisfiable and 0 otherwise.

1. Let $\hat{\phi} = \phi$.
2. While $\hat{\phi}$ contains at least three variables in $x_1, \ldots, x_n$ do:
   (a) Execute Algorithm `Relevant Variable-Assignment` on $\hat{\phi}$. Denote the answer $\langle i, \sigma \rangle$.
   (b) Assign $a_i \leftarrow \sigma$.
   (c) Modify $\hat{\phi}$ as follows:
      i. Leave in $\hat{\phi}$ every clause that does not include x_i or $\neg x_i$.
      ii. If $\sigma = 0$, then replace every clause $(x_i \vee \ell_j \vee \ell_k)$ in $\hat{\phi}$ by the clauses $(y_i \vee \ell_j \vee \ell_k)$ and $(\neg y_i \vee \ell_j \vee \ell_k)$. Remove all clauses that include $\neg x_i$.
      iii. If $\sigma = 1$, then replace every clause $(\neg x_i \vee \ell_j \vee \ell_k)$ in $\hat{\phi}$ by the clauses $(y_i \vee \ell_j \vee \ell_k)$ and $(\neg y_i \vee \ell_j \vee \ell_k)$. Remove all clauses that include x_i.
3. For every variable x_i that is not in $\hat{\phi}$ and was not assigned a value in step 2b, assign $a_i \leftarrow 0$.
4. Exhaustively check all four assignments a that agree with the assignments made in step 2b and step 3. If at least one of these assignments satisfies ϕ, return 1; otherwise return 0.

FIG. C.1. *Algorithm* `Greedy E3SAT`.

literals—variables or negations) with two clauses $(y_i \vee \ell_j \vee \ell_k)$ and $(\neg(y_i) \vee \ell_j \vee \ell_k)$, one with y_i and one with $\neg y_i$, we ensure that a satisfying assignment to $\hat{\phi}$ must satisfy $\ell_j \vee \ell_k$.

The formal proof is by induction on the number of iterations in `Greedy E3SAT`: After executing the main iteration in Algorithm `Greedy E3SAT` for k times (i) $\hat{\phi}$ is satisfiable; (ii) k variables are assigned values in step 2(b); (iii) $\hat{\phi}$ does not contain these variables; and (iv) any assignment that extends the k assigned variables satisfies ϕ iff it satisfies $\hat{\phi}$. □

To conclude the proof, we present Algorithm `Relevant Variable-Assignment`. On input ϕ, the algorithm uses a private $1/n^{1-\epsilon}$-approximation algorithm $\mathcal{A}$ to produce an index i and a bit σ such that x_i is σ-relevant.

By our choice of ℓ_1, ℓ_2, ℓ_3, the clause $(\ell_1 \vee \ell_2 \vee \ell_3)$ is not satisfied by the assignment a. Hence, as $\mathcal{A}$ is a $1/n^{1-\epsilon}$-approximation algorithm, at least one of x_1, x_2, x_3 changes assignments between a and a'. Thus, step 5 in Algorithm `Relevant Variable-Assignment` is always possible. Furthermore, as $\mathcal{A}$ respects the privacy structure $\mathcal{R}_{\text{maxE3SAT}}$, we conclude that the formulae ϕ and ϕ' differ on their sets of maximum assignments. The following claim implies the correctness of Algorithm `Relevant Variable-Assignment`.

CLAIM C.3. *If $a'(x_i) \neq a(x_i)$ for some $i \in \{1, 2, 3\}$, then x_i is $a(x_i)$-relevant.*

Proof. Assume the contrary, i.e., that every assignment that satisfies the maximum possible number of clauses of ϕ assigns $a'(x_i)$ to x_i. It is easy to see that every such assignment of ϕ is also an assignment that satisfies the maximum possible number of clauses of ϕ' as it satisfies the added clauses $(\ell_1 \vee \ell_2 \vee \ell_3)$. In the reverse direction, note that every assignment that satisfies the maximum possible number of

Algorithm `Relevant Variable-Assignment`

INPUT: An exact 3CNF formula ϕ over Boolean variables $x_1, \ldots, x_n$ and $y_1, \ldots, y_n$. Without loss of generality, all variables x_1, x_2, x_3 appear in ϕ. Let m denote the number of clauses in ϕ.
OUTPUT: An index $i \in \{1, 2, 3\}$ and a bit σ such that x_i is σ-relevant.

1. Execute $\mathcal{A}$ on ϕ and denote $a = \mathcal{A}(\phi)$.
2. For $i \in \{1, 2, 3\}$, let $\ell_i = x_i$ if $a(x_i) = 0$ and $\ell_i = \neg x_i$ otherwise.
3. Set $\phi' = \phi \wedge (\ell_1 \vee \ell_2 \vee \ell_3) \wedge \cdots \wedge (\ell_1 \vee \ell_2 \vee \ell_3)$, where the clause $(\ell_1 \vee \ell_2 \vee \ell_3)$ is added $n^{1-\epsilon} \cdot (m + 1)$ times.
4. Execute $\mathcal{A}$ on ϕ' and denote $a' = \mathcal{A}(\phi')$.
5. Choose $i \in \{1, 2, 3\}$ such that $a'(x_i) \neq a(x_i)$. Let $\sigma = a(x_i)$.
6. Return $\langle i, \sigma \rangle$.

clauses of ϕ' also satisfies the maximum possible number of ϕ as the assignment to the two other variables from x_1, x_2, x_3 does not affect the satisfiability of the clause $(\ell_1 \vee \ell_2 \vee \ell_3)$. We get that $\langle \phi, \phi' \rangle \in \mathcal{R}_{\text{maxE3SAT}}$, contradicting $\mathcal{A}(\phi) \neq \mathcal{A}(\phi')$. □

Acknowledgments. We thank Yinnon Haviv for helpful discussions, and we thank Robi Krauthgamer for pointing out that we can use almost k-wise independent spaces. Finally, we thank the anonymous reviewer for useful comments.

APPROXIMATING MINIMUM MAX-STRETCH SPANNING TREES ON UNWEIGHTED GRAPHS*

YUVAL EMEK† AND DAVID PELEG†

Abstract. Given a graph G and a spanning tree T of G, we say that T is a *tree t-spanner* of G if the distance between every pair of vertices in T is at most t times their distance in G. The problem of finding a tree t-spanner minimizing t is referred to as the *Minimum Max-Stretch spanning Tree (MMST)* problem. This paper concerns the MMST problem on unweighted graphs. The problem is known to be NP-hard, and the paper presents an $O(\log n)$-approximation algorithm for it. Furthermore, it is established that unless P = NP, the problem cannot be approximated additively by any $o(n)$ term.

Key words. spanning trees, low stretch, spanners

1. Introduction.

1.1. The problem. Consider a connected n-vertex graph G. Let T be a spanning tree of G and let x and y be two vertices in G. The *stretch* of x and y in T, denoted $\mathrm{str}_T(x,y)$, is the ratio of the distance between x and y in T to their distance in G. The *maximum stretch*[1] of T, denoted max-str(T), is defined as the maximum of $\mathrm{str}_T(x,y)$, taken over all pairs of vertices x,y in G. The problem of finding a spanning tree T minimizing max-str(T) is referred to as the *Minimum Max-Stretch spanning Tree (MMST)* problem. In this paper we study the MMST problem on unweighted graphs. This problem is known to be NP-hard [5], and this paper presents the first nontrivial approximation algorithm for it, achieving an approximation ratio of $O(\log n)$. Our algorithm is inspired by the algorithm presented in [16] for the *Minimum Restricted Diameter spanning Tree (MRDT)* problem. We then establish a hardness of approximation result, showing that it is NP-hard to approximate the problem additively by a term of $o(n)$.

The MMST problem finds applications in network design and, in particular, in the context of distributed systems. One such application is the *arrow distributed directory protocol* introduced in [7]. This protocol supports the location of mobile objects in a distributed network. It is implemented over a spanning tree T that spans the network, and, as shown in [19], the worst case overhead ratio of the protocol is proportional to the maximum stretch of T. Therefore, a good candidate for the backbone of the arrow protocol is a spanning tree with low maximum stretch (see also [17]).

1.2. Related work. The notion of stretch can be defined for any spanning subgraph. Formally, given a graph G, a spanning subgraph H of G, and a pair of

[1] In some papers the notion of stretch refers to the maximum taken over all vertex pairs. To avoid misunderstanding, we distinguish between stretch, defined in the current paper for a specific vertex pair, and maximum stretch, defined for the whole tree.

vertices x, y in G, the stretch of x and y in H is defined as the ratio of the distance between x and y in H to their distance in G. A spanning subgraph with maximum stretch t is called a *t-spanner*. Spanners for general graphs were first introduced in [22]. Sparse spanners (namely, spanners with a small number of edges) were first studied in [20], where the problem of determining for a given graph G and a positive integer m whether G has a t-spanner with at most m edges is shown to be NP-complete for $t = 2$ while a polynomial time construction is presented for a $(4t + 1)$-spanner with $O\left(n^{1+1/t}\right)$ edges for every n-vertex graph and $t \geq 1$. Simple algorithms for constructing sparse spanners for arbitrary weighted graphs are presented in [2], including the construction of a $(2t+1)$-spanner with at most $n\left\lceil n^{1/t}\right\rceil$ edges for every n-vertex graph and $t > 0$. For any fixed $t \geq 3$ the problem of determining, for an arbitrary graph G and a positive integer m, whether G has a t-spanner with at most m edges is proved to be NP-complete in [4]. A polynomial time construction for a 3-spanner with $O\left(n^{3/2}\right)$ edges is presented in [9].

Cast in this terminology, the MMST problem can therefore be redefined as the attempt to find a *tree t-spanner* minimizing t. The NP-hardness of the MMST problem, even on unweighted graphs, is established in [5], where it is proved that determining whether an arbitrary weighted (respectively, unweighted) graph has a tree t-spanner is NP-complete for every fixed $t > 1$ (respectively, $t \geq 4$). The same paper also presents a polynomial time algorithm for constructing a tree 1-spanner in a weighted graph (if such a spanner exists) and a polynomial time algorithm for constructing a tree 2-spanner in an unweighted graph (if such a spanner exists).

Low stretch spanning trees in planar graphs were first studied in [12], where it is proved that finding a spanning tree T with minimum max-str(T) is NP-hard even for unweighted planar graphs. Polynomial time algorithms are presented therein for the problem of deciding for a fixed parameter t whether a planar unweighted graph with bounded face length has a tree t-spanner and for the problem of deciding whether an arbitrary unweighted planar graph has a tree 3-spanner. A polynomial time algorithm for the MMST problem on outerplanar graphs is presented in [21].

Hardness of approximation is established in [19], where it is shown that approximating the MMST problem within a factor better than $(1 + \sqrt{5})/2$ is NP-hard. This is improved in [18] by observing that the $2 - \epsilon$ inapproximabilty result established in [14] for the *min-max strictly fundamental cycle basis* problem also holds in the context of the MMST problem on unweighted graphs. A number of papers have studied the related but easier problem of finding a spanning tree with good *average* stretch factor [1, 3, 13, 10].

Given a complete graph $G = (V(G), E(G))$ with edge weights obeying the triangle inequality and a subset $R \subseteq E(G)$ called the *requirements* of G, the MRDT problem is to find a spanning tree T of G that minimizes the *restricted diameter* of T defined as the diameter of T restricted to vertex pairs in R. The MRDT problem is presented and proved to be NP-hard in [16]. The same paper presents an $O(\log n)$-approximation algorithm for this problem. It can be shown that the MMST problem on complete graphs with edge weights arising from the distances in some unweighted graph is a special case of the MRDT problem.

1.3. A brief description of the technique. Our main result is the first nontrivial approximation algorithm for the MMST problem on unweighted graphs. This algorithm relies on a graph decomposition technique that, given an unweighted graph G of size n, breaks it into disjoint connected components, each of size at most $n/2$, by discarding the edges internal to some ball B of radius proportional to the maximum

stretch ρ of an optimal solution to the MMST problem on G. The spanning trees generated by recursive invocations of the algorithm on each such connected component are combined with a single source shortest paths spanning tree of B to produce a spanning tree T of G.

Consider an arbitrary edge (x, y) in G. Our analysis relies on observing that the number of edges added to the unique path between x and y in T on each recursive level is $O(\rho)$. Since there are at most $\log n$ recursive levels (as the size of the graph decreases by a factor of 2 on each recursive level), the stretch of x and y in T is $O(\log n)$.

The technique presented in [16] for the approximation algorithm of the MRDT problem is similar to that described above. The novel approach in this paper is the adaptation of this technique to graphs which are not necessarily complete.

1.4. Outline of the paper. In section 2 we present the basic notation and definitions used throughout this paper. Two lower bounds on the minimum max-stretch of unweighted graphs are established in section 3. Our approximation algorithm, named Algorithm `Construct_Tree`, is presented in section 4. In section 5 we prove that the output of Algorithm `Construct_Tree` is a spanning tree, and in section 6 we analyze the performance guarantee of the algorithm, establishing an $O(\log n)$ upper bound on the approximation ratio. Our analysis is based on the lower bounds of section 3. In section 7 we prove that the analysis of the performance guarantee of the algorithm is tight. The hardness of approximating the MMST problem on unweighted graphs is studied in section 8, proving that unless P = NP, the problem cannot be approximated additively by a term of $o(n)$.

2. Preliminaries. Throughout, we consider a connected unweighted undirected n-vertex graph G. Let $V(G)$ and $E(G)$ denote the vertex and edge sets of G, respectively. The *length* of a path P in the graph is the number of edges in the path, denoted by $\text{len}(P)$. For two vertices u, v in $V(G)$, let $\text{dist}_G(u, v)$ denote the *distance* between them in G, i.e., the length of a shortest path between u and v. The definition of distance is extended to vertex subsets as follows. Let U and W be two subsets of $V(G)$. The *distance* between U and W is the minimum distance between any pair of vertices in U and W, denoted by $\text{dist}_G(U, W) = \min\{\text{dist}_G(u, w) \mid u \in U \text{ and } w \in W\}$.

For a subset $U \subseteq V(G)$, let $G(U)$ denote the subgraph of G *induced* by U, that is, $V(G(U)) = U$ and $E(G(U)) = E(G) \cap (U \times U)$. Denote the set of edges *internal* to U by $E(U) = E(G(U))$.

Although the notion of stretch can be defined for every spanning subgraph, our focus in the current paper is on spanning trees only. Consider some spanning tree T of G. Denote the *stretch* of u and v in T with respect to G by

$$\text{str}_{T,G}(u, v) = \frac{\text{dist}_T(u, v)}{\text{dist}_G(u, v)}.$$

Denote the *maximum stretch* of T with respect to G by

$$\text{max-str}(T, G) = \max_{x,y \in V(G)} \{\text{str}_{T,G}(x, y)\}.$$

When the graph G is clear from the context we may omit it and write simply $\text{str}_T(u, v)$ and $\text{max-str}(T)$. Denote the *minimum max-stretch* of G by

$$\text{max-str}(G) = \min\{\text{max-str}(T, G) \mid T \text{ is a spanning tree of } G\}.$$

Consider two metrics τ and δ over the vertices V. We say that τ *dominates* δ if $\tau(u,v) \geq \delta(u,v)$ for every $u,v \in V$. We say that τ is a *tree metric*[2] if τ is induced by the distances in some weighted tree over V. We extend the definitions of stretch and maximum stretch for tree metrics as follows. For every two vertices $u,v \in V$, denote the *stretch* of u and v in τ with respect to δ by

$$\mathrm{str}_{\tau,\delta}(u,v) = \frac{\tau(u,v)}{\delta(u,v)}.$$

The *maximum stretch* of τ with respect to δ, denoted $\text{max-str}(\tau,\delta)$, is defined accordingly.

Consider some metric δ over the vertices V. Given a vertex set $U \subseteq V$, we define the *diameter* of U with respect to δ as

$$\mathrm{diam}_\delta(U) = \max\{\delta(u,v) \mid u,v \in U\}.$$

Given a vertex $u \in V$ and some positive real ρ, we denote the *ball* centered at u of radius ρ with respect to δ by $B_\delta(u,\rho) = \{v \in V(G) \mid \delta(u,v) \leq \rho\}$.

A *partition* of a set S is a collection $P = \{U_1,\ldots,U_k\}$, where $U_i \cap U_j = \emptyset$ for every $1 \leq i < j \leq k$ and $\bigcup_{1\leq i\leq k} U_i = S$. Unless stated otherwise, we assume that U_i is nonempty for every $1 \leq i \leq k$. If S is the set of vertices of some graph, then the subsets $U_1,\ldots,U_k$ are called the *clusters* of the partition. (Note that our definition does not require a cluster to be connected in G.)

For a partition $P = \{U_1,\ldots,U_k\}$ of $V(G)$, let $E(P)$ denote the set of edges *internal* to the clusters of P, i.e., $E(P) = \bigcup_{U_i\in P} E(U_i)$. Denote the set of edges *external* to P, namely, the edges connecting vertices in two different clusters, by $\overline{E}(P) = E(G) - E(P)$. Every edge set $F \subseteq \overline{E}(P)$ *induces* a logical *cluster graph* on P, obtained by contracting each cluster in P into a single node and replacing each edge $(u,v) \in F$, where $u \in U_i$ and $v \in U_j$, by the edge (U_i,U_j). We say that F *induces a tree* on P if the cluster graph induced by F on P is a tree. For a subset $X \subseteq V(G)$, denote the set of clusters in P that intersect X by $\mathcal{I}(P,X) = \{U_i \in P \mid U_i \cap X \neq \emptyset\}$.

A central tool in our construction is a graph decomposition based on eliminating the edges of some ball of radius ρ. This decomposition is obtained as follows. For a metric δ over $V(G)$, a vertex $u \in V(G)$, and a positive integer ρ, erase from G the internal edges (but not the vertices) of the ball centered at u of radius ρ with respect to δ, $E(B_\delta(u,\rho))$, and let $G^1,\ldots,G^r$ be the connected components in the remaining graph. The collection $\{G^1,\ldots,G^r\}$ is referred to as the (u,ρ,δ)-*decomposition* of G. Figure 1 illustrates the $(u,2,\mathrm{dist}_G(\cdot,\cdot))$-decomposition of a graph G. We say that the vertex u is a ρ-*center* with respect to G and δ if $|V(G^i)| \leq n/2$ for every $1 \leq i \leq r$.

3. Lower bounds on the minimum max-stretch. In this section we establish some general lower bounds on the minimum max-stretch of a graph G. These lower bounds are used in section 6 to yield the performance guarantee of our approximation algorithm.

We begin with correlating the existence of a ρ-center with the minimum max-stretch of the graph.

THEOREM 3.1. *Consider a graph G and a connected vertex induced subgraph H of G, and let δ be the restriction of* $\mathrm{dist}_G(\cdot,\cdot)$ *to the vertices of H. Then H admits a (2κ)-center with respect to δ, where $\kappa = \text{max-str}(G)$.*

[2]Our definition of a tree metric differs from the standard definition, where τ is induced by the distances between pairs of vertices from V in some weighted tree over a superset of V. Clearly, a tree metric according to our definition is also a tree metric according to the standard definition.

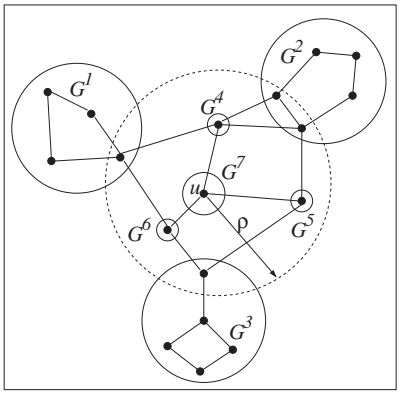

FIG. 1. *The decomposition of G with respect to $\mathrm{dist}_G(\cdot,\cdot)$, u, and $\rho = 2$. The dashed circle represents $B_{\mathrm{dist}_G(\cdot,\cdot)}(u,2)$.*

Proof. Clearly, every spanning tree of G induces a tree metric over $V(G)$ that dominates the distances in G. In particular, there exists such a tree metric τ with $\text{max-str}(\tau, \mathrm{dist}_G(\cdot,\cdot)) = \kappa$. In [15] it is proved that a tree metric τ over the vertex set V can be transformed into a tree metric τ' over an arbitrary vertex subset $U \subseteq V$, such that $\tau(x,y) \leq \tau'(x,y) \leq 8\,\tau(x,y)$ for every two vertices x, y in U. This result is improved in [16] for the special case where τ arises from the distances in an unweighted tree over V so that $\tau(x,y) \leq \tau'(x,y) \leq 4\,\tau(x,y)$. It follows that there exists a tree metric τ' over $V(H)$ that dominates δ such that $\text{max-str}(\tau', \delta) \leq 4\kappa$. We next show that this implies that H admits a (2κ)-center with respect to δ.

Recall that in every n-vertex tree T, there exists a vertex u, named the *centroid* of T, such that the removal of all edges incident with u disconnects T to subtrees of size at most $n/2$ each. Consider the tree T over $V(H)$ that corresponds to τ', and let u be a centroid of T. (Observe that T is not necessarily a spanning tree of H.) Let $T_1, \ldots, T_k$ be the subtrees of T obtained from the removal of all edges incident with u.

Let $\{H^1, \ldots, H^r\}$ be the $(u, 2\kappa, \delta)$-decomposition of H, namely, the connected components of H after erasing the internal edges of $B_\delta(u, 2\kappa)$. We claim that for every $1 \leq i \leq r$, there exists some $1 \leq j \leq k$ such that $V(H^i) \subseteq V(T_j)$; hence u is a (2κ)-center of H and the theorem holds. Assume by way of contradiction that the claim is false, and let H^i be a subgraph of H that falsifies the claim, i.e., such that $V(H^i) \not\subseteq V(T_j)$ for any $1 \leq j \leq k$. Since H^i is connected, it follows that there exists an edge $(x,y) \in E(H^i)$ such that $x \in V(T_j)$ and $y \in V(T_{j'})$ for some $1 \leq j < j' \leq k$. The edge (x,y) was not removed by the $(u, 2\kappa, \delta)$-decomposition of H; thus $\delta(u,x) \geq 2\kappa$ and $\delta(u,y) \geq 2\kappa$, where at least one of these two inequalities is strict. Therefore, $\delta(u,x) + \delta(u,y) > 4\kappa$. Since τ' dominates δ, it follows that $\tau'(u,x) + \tau'(u,y) > 4\kappa$. But x and y are in different subtrees obtained from the removal of the edges incident with u; therefore, $\tau'(x,y) = \tau'(u,x) + \tau'(u,y) > 4\kappa$, in contradiction to the fact that $\text{max-str}(\tau', \delta) \leq 4\kappa$. The theorem follows. □

Consider a graph G, and let H be a connected vertex induced subgraph of G. Let $\bar{H}$ be the subgraph induced on G by $V(G) - V(H)$. Denote the set of edges that cross between H and $\bar{H}$ by $F(H) = \{(x,y) \in E(G) \mid x \in V(H) \text{ and } y \in V(\bar{H})\}$. Let $W(H)$ be the set of endpoints of edges in $F(H)$. We say that H is a *κ-outspread subgraph* of G if $F(H)$ can be partitioned into two *remote parts* F_1 and F_2 with endpoints W_1

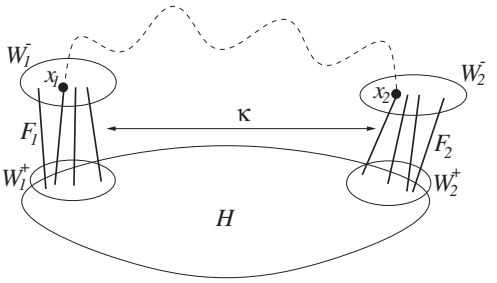

FIG. 2. *A κ-outspread subgraph H. The vertices x_1 and x_2 are connected in $\bar{H}$.*

and W_2, respectively, such that

- $\text{dist}_G(W_1, W_2) \geq \kappa$ and
- there exist two vertices $x_1 \in W_1 \cap V(\bar{H})$ and $x_2 \in W_2 \cap V(\bar{H})$ such that $\bar{H}$ admits a simple path between x_1 and x_2.

Note that $\bar{H}$ is not necessarily connected, but it is assumed to have some "connectivity" between endpoints of F_1 and endpoints of F_2. In what follows, we define $W_i^+ = W_i \cap V(H)$ and $W_i^- = W_i \cap V(\bar{H})$ for $i = 1, 2$. A κ-outspread subgraph is illustrated in Figure 2. The existence of an outspread subgraph in a graph implies a lower bound on its minimum max-stretch, as established in the following theorem.

THEOREM 3.2. *If a graph G admits a κ-outspread subgraph, then* $\text{max-str}(G) > \kappa$.

Proof. Consider a graph G, and let H be a κ-outspread subgraph of G, with remote parts F_1 and F_2 with endpoints W_1 and W_2. Let T be a spanning tree of G and suppose, toward deriving contradiction, that $\text{max-str}(T) \leq \kappa$.

We begin by strengthening the second requirement of a κ-outspread subgraph and proving that W_1^- and W_2^- are connected by a path fully contained in $T \cap \bar{H}$. To show this, we prove that T contains a subtree T' such that

- $V(T') \cap W_1^- \neq \emptyset$;
- $V(T') \cap W_2^- \neq \emptyset$;
- T' lies entirely in $\bar{H}$; and
- T' is maximal; namely, if T'' is a subtree of T and $V(T') \subset V(T'')$, then $V(T'') \cap V(H) \neq \emptyset$.

By definition, since H is a κ-outspread subgraph of G, the subgraph $\bar{H}$ admits a simple path between W_1^- and W_2^-. Let $\psi = (x_1^0, x_1^1, \ldots, x_1^s, x_2^t, x_2^{t-1}, \ldots, x_2^0)$ be the shortest such path, where $x_1^0 \in W_1^-$, $x_2^0 \in W_2^-$, $\kappa \leq \text{len}(\psi) = s + t + 1$, and $\frac{\text{len}(\psi)}{2} - 1 \leq s \leq t \leq \frac{\text{len}(\psi)}{2}$. Since ψ is a shortest path between W_1^- and W_2^-, it follows that $\text{dist}_G(x_i^j, W_i^-) = j$ for $i = 1, 2$ and every vertex x_i^j in ψ. By the definition of a κ-outspread subgraph, we have $\text{dist}_G(x_i^j, W_i^+) = j + 1$ and $\text{dist}_G(x_i^j, W_{3-i}^+) \geq \min\{\kappa + j + 1, s + t + 2 - j\}$ for $i = 1, 2$ and every x_i^j in ψ. Therefore, $\text{dist}_G(x_1^s, W_i^+) + \text{dist}_G(x_2^t, W_i^+) > \kappa$ for $i = 1, 2$. Consequently, the unique path between x_1^s and x_2^t in T does not contain any vertex in $W_1^+ \cup W_2^+$, as, otherwise, it is of length greater than κ, in contradiction to the assumption that $\text{max-str}(T) \leq \kappa$. Moreover, $\text{dist}_G(x_i^j, W_{3-i}^+) + \text{dist}_G(x_i^{j-1}, W_{3-i}^+) > \kappa$ for $i = 1, 2$ and every x_i^j and x_i^{j-1} in ψ; hence the unique path between x_i^j and x_i^{j-1} in T does not contain any vertex in W_{3-i}^+.

Let $\pi_{s,t}$ be the unique path between x_1^s and x_2^t in T. As $\pi_{s,t}$ does not contain any vertex in $W_1^+ \cup W_2^+$, it must lie entirely in $\bar{H}$. We would like to develop $\pi_{s,t}$ into a subtree T' as described above. For $i = 1, 2$, apply the following process to extend

$\pi_{s,t}$ up to a vertex in W_i^- without adding any edge of $F(H)$. Initialize the variable subtree Υ to be the path $\pi_{s,t}$. Initialize the variable integer j^{min} by $j^{min} = \min\{j \mid x_i^j \in V(\Upsilon)\}$ (j^{min} is well defined, as x_1^s and x_2^t are in Υ). If $j^{min} = 0$, then we are done since the subtree Υ now contains a W_i^- vertex and $V(\Upsilon) \subseteq V(\bar{H})$.

Otherwise, apply a "developing step" as follows. Let χ be the unique path between $x_i^{j^{min}}$ and $x_i^{j^{min}-1}$ in T. The path χ does not contain any edge in F_{3-i} since, otherwise, it also contains a vertex in W_{3-i}^+. If χ contains an edge in F_i, then it must contain a vertex in W_i^- right before that edge, in which case the subtree Υ can be extended up to a vertex in W_i^- without adding any $F(H)$ edge, and we are done. Otherwise, the path χ does not contain any $F(H)$ edge at all; thus Υ can be extended so that j^{min} decreases by a positive integral term without adding any edge in $F(H)$. We repeat the "developing step" until $j^{min} = 0$. Applying this process for $i = 1, 2$ yields a subtree T' of T such that T' contains a vertex in W_1^- and a vertex in W_2^- and $E(T') \cap F(H) = \emptyset$; hence T' lies entirely in $\bar{H}$. If T' is not maximal, then extend it by adding adjacent edges of $E(T) \cap E(\bar{H})$ as long as possible.

We now turn to label the vertices of H by their location in T with respect to the subtree T'. Pick an arbitrary vertex $r \in V(T')$ and direct the edges of T toward r. Consider a vertex v in $V(H)$, and let π_v be the unique path from v to r in T. If u is the first vertex on π_v such that $u \in V(T')$, then we say that v is *covered* by u with respect to T'. Since T' is maximal, if v is covered by u, then the edge entering u on π_v is in F and u must lie in W_i^- for some $i \in \{1, 2\}$. For $i = 1, 2$, let

$$U_i = \{v \in V(H) \mid v \text{ is covered by some vertex } u \in W_i^- \text{ with respect to } T'\}.$$

Note that $\{U_1, U_2\}$ is a partition of $V(H)$. For two vertices $x, y \in V(H)$, we say that x and y are *separated* by T' if $x \in U_1$ and $y \in U_2$ (or vice versa). Observe that this implies that the unique path between x and y in (the undirected) T contains an edge in F_1 and an edge in F_2; thus its length is at least $\kappa + 2$. It follows that for an edge (x, y) in $E(H)$, the vertices x and y cannot be separated by T' since, otherwise, we have max-str$(T) > \kappa$. But, by definition, the subgraph H is connected; therefore, $V(H) = U_i$ for some $i \in \{1, 2\}$ and $U_{3-i} = \emptyset$. Without loss of generality, suppose that $V(H) = U_1$.

Let y_2^- be a vertex in $V(T') \cap W_2^-$, and consider a neighbor $y_2^+ \in W_2^+$ of y in G. As y_2^+ is in U_1, it is covered by some vertex $y_1^- \in W_1^-$; hence $\text{dist}_T(y_2^-, y_2^+) = \text{dist}_T(y_2^-, y_1^-) + \text{dist}_T(y_2^+, y_1^-)$. Since $\text{dist}_G(W_1, W_2) \geq \kappa$, and since the distances in T dominate the distances in G, it follows that $\text{dist}_T(y_2^-, y_2^+) \geq 2\kappa$, in contradiction to the assumption that max-str$(T) \leq \kappa$. The theorem follows. ∎

4. The approximation algorithm.

4.1. Overview. The main idea behind our algorithm is that, given an n-vertex graph $\widehat{G}$ with max-str$(\widehat{G}) = \kappa$, there exists (as proved in Theorem 3.1) a vertex $u \in V(\widehat{G})$ with the property that discarding the internal edges of the ball centered at u of radius 2κ decomposes the graph into several connected components, each of size at most $n/2$, with no edges crossing between them. Using this fact, our algorithm is invoked on the integer test values $\rho \in (1, 2n]$, suspected of being 2κ. For every such test value, the algorithm tries to construct the output spanning tree $\widehat{T}$ by looking for a vertex u and a decomposition as above and merging a spanning tree T_{local} of the ball centered at u of radius $3\rho/2$ (a superset of the ball of radius ρ) with the spanning trees returned from the recursive calls made for every connected component of the decomposition. The $\rho/2$ gap between the radius of the ball used for decomposing

the graph and the radius of the ball being spanned by the tree T_{local} guarantees the connectivity of the spanning tree produced by the algorithm. A detailed description of this process is presented in the following sections.

4.2. Algorithm `Construct_Tree`. We present an algorithm named Algorithm `Construct_Tree`, that, given an n-vertex graph $\widehat{G}$ and integral test value ρ, constructs a spanning tree $\widehat{T}$ of $\widehat{G}$ with maximum stretch at most $3\rho \log n$ or reports failure. In section 6 we prove that the algorithm does not fail if $\rho \geq 2\text{max-str}(\widehat{G})$. Since the minimum max-stretch of $\widehat{G}$ is an integer in $[1, n]$, a test value $\rho \leq 2\text{max-str}(\widehat{G})$ on which the algorithm does not fail can be guessed in $O(\log n)$ attempts, to yield a $(6 \log n)$-approximation algorithm.

Algorithm `Construct_Tree` works in a "divide and conquer" (recursive) approach. Throughout the execution of the algorithm, we maintain a forest (i.e., a cycle-free subgraph containing all the vertices) $\mathcal{F}$ of the input graph $\widehat{G}$. The forest is a global data structure shared by all recursive invocations of the algorithm. Initially, the forest $\mathcal{F}$ is empty (does not contain any edge), and, upon termination of the algorithm, $\mathcal{F}$ contains the spanning tree $\widehat{T}$ of $\widehat{G}$. On each recursive invocation, Algorithm `Construct_Tree` gets a vertex induced subgraph G of $\widehat{G}$ as input and adds some edges of G to $\mathcal{F}$. Upon termination of the recursive invocation on G, the vertices of $V(G)$ all belong to a single tree in $\mathcal{F}$ (each connected component in $\mathcal{F}$ is a tree).

Consider a recursive invocation of Algorithm `Construct_Tree` on the vertex induced subgraph G of $\widehat{G}$. Due to some earlier recursive invocations, the forest $\mathcal{F}$ may already contain some edges of G. Let $\mathcal{P}$ be the partition of $V(G)$ that corresponds to the connected components of $\mathcal{F}$; that is, each cluster in $\mathcal{P}$ is a subset of $V(G)$, and two vertices $x, y \in V(G)$ are in the same cluster in $\mathcal{P}$ if and only if $\mathcal{F}$ admits a path between x and y. We refer to the partition $\mathcal{P}$ as the *connectivity partition* of $V(G)$ with respect to $\mathcal{F}$. To prevent the possibility of creating cycles in $\mathcal{F}$, the algorithm will add an edge $e \in E(G)$ to $\mathcal{F}$ only if e is external to $\mathcal{P}$. Let U be an arbitrary cluster in $\mathcal{P}$. Note that the vertex induced subgraph $G(U)$ is not necessarily connected, although every two vertices in U are connected by a path in $\mathcal{F}$ (it may be the case that some of the vertices of this path are missing in G).

Throughout we denote the metric defined by distances in $\widehat{G}$ by $\widehat{\delta}$. Let δ be the restriction of $\widehat{\delta}$ to the vertices of G. Algorithm `Construct_Tree` works as follows. It first finds a ρ-center u with respect to δ and identifies the set of clusters $\mathcal{I}(\mathcal{P}, B_\delta(u, 3\rho/2))$, namely, the clusters of $\mathcal{P}$ that intersect the ball centered at u of radius $3\rho/2$. If a ρ-center cannot be found, then the algorithm halts and reports "failure." Next, a subset of the external edges of the partition $\mathcal{P}$ that induces a tree (referred to as the *local tree* T_{local}) on these clusters is added to $\mathcal{F}$. The choice of the subset of edges that induces the local tree on the clusters $\mathcal{I}(\mathcal{P}, B_\delta(u, 3\rho/2))$ is made by Procedure `Construct_Local_Tree`. The edges internal to the ball centered at u of radius ρ (but not the vertices) are discarded from the graph, and subsequently the graph decomposes[3] into separate connected components $G^1, \ldots, G^r$. A recursive call is then made on the graph[4] $G(V(G^i))$ for every $1 \leq i \leq r$.

Let $\mathcal{F}'$ be the forest $\mathcal{F}$ after the edges of the local tree were added to it, and let $\mathcal{P}'$ be the connectivity partition of $V(G)$ with respect to $\mathcal{F}'$. Observe that the connec-

[3]The connected components of this graph decomposition should not be confused with the clusters of the connectivity partition $\mathcal{P}$.

[4]Observe that $G(V(G^i))$ is not necessarily identical to G^i, as some of the edges in $G(V(G^i))$ may be internal to $B_\delta(u, \rho)$. Such edges were discarded in the decomposition process, and they cannot be found in G^i.

tivity partition $\mathcal{P}'$ is obtained from the connectivity partition $\mathcal{P}$ (that corresponds to $\mathcal{F}$ before the edges of the local tree were added) by merging all clusters that intersect $B_\delta(u, 3\rho/2)$ into a single cluster, referred to as the *kernel cluster* U'. It is easy to verify (a stronger claim is proved later on) that the kernel cluster disintegrates into several connected components of the graph decomposition $G^1, \ldots, G^r$. Consequently, a pair of vertices in the kernel cluster may be *separated* on this recursive invocation. However, it is crucial for the correctness of Algorithm `Construct_Tree` that all other clusters in $\mathcal{P}'$ remain intact (see section 5). In fact, assuming that $\rho \geq 2\text{max-str}(\widehat{G})$, the $\rho/2$ gap between the radius of the ball used for decomposing the graph and that being spanned by the local tree ensures (as proved in section 6.1) that this is indeed the case.

Formally, we say that the connectivity partition $\mathcal{P}'$ is a *hub* with respect to the connected components $G^1, \ldots, G^r$ of the graph decomposition if, for every cluster $U \in \mathcal{P}' - \{U'\}$, there exists a connected component G^i, $1 \leq i \leq r$, such that $U \subseteq V(G^i)$. In other words, there is at most one cluster in $\mathcal{P}'$ that disintegrates into several connected components of the graph decomposition. (Recall that the connectivity partition is defined with respect to the global forest regardless of the connectivity in G; hence the subgraphs induced on G by its clusters are not necessarily connected to begin with. A cluster that induces a nonconnected subgraph on G may be disintegrated into several connected components even if none of its internal edges were discarded in the graph decomposition.) If $\mathcal{P}'$ is not a hub with respect to $G^1, \ldots, G^r$, then the algorithm halts and reports "failure."

The current recursive invocation of the algorithm is said to *succeed* if it manages to avoid the two failures, namely, if it finds a ρ-center and $\mathcal{P}'$ is a hub. Otherwise, we say that the current recursive invocation *fails*, in which case the algorithm should be reinvoked on $\widehat{G}$ with a larger test value ρ. A formal description of Algorithm `Construct_Tree` is given in Table 1.

TABLE 1
Algorithm `Construct_Tree`.

Input: A vertex induced subgraph G of $\widehat{G}$.
Let δ be the restriction of $\widehat{\delta}$ to the vertices $V(G)$.

1. If $|V(G)| = 1$, then return.
2. Find a ρ-center u with respect to G and δ.
   If none exists, then halt and report "failure."
3. $T_{\text{local}} \leftarrow$ `Construct_Local_Tree`(G, u).
4. Set $\mathcal{F} \leftarrow \mathcal{F} \cup T_{\text{local}}$.
5. Let $G^1, \ldots, G^r$ be the connected components of the graph remaining from G after discarding the edges in $E(B_\delta(u, \rho))$.
6. Let $\mathcal{P}'$ be the connectivity partition of $V(G)$ with respect to the (modified) forest $\mathcal{F}$.
7. If $\mathcal{P}'$ is not a hub with respect to $G^1, \ldots, G^r$, then halt and report "failure."
8. For every $1 \leq i \leq r$, invoke `Construct_Tree`$(G(V(G^i)))$.

Since the connected components $G^1, \ldots, G^r$ of the (u, ρ, δ)-decomposition of G are formed by discarding the edges internal to $B_\delta(u, \rho)$, we have the following.

OBSERVATION 4.1. *The vertex set $B_\delta(u, \rho)$ intersects G^i for every $1 \leq i \leq r$.*

4.3. Procedure `Construct_Local_Tree`. Consider a graph G. Let ξ be a metric over $V(G)$, and let $P = \{U_1, \ldots, U_k\}$ be a partition of $V(G)$. We say that the graph $\mathcal{R}$ is the *transitive graph* of G with respect to P and ξ if each cluster in P is completed

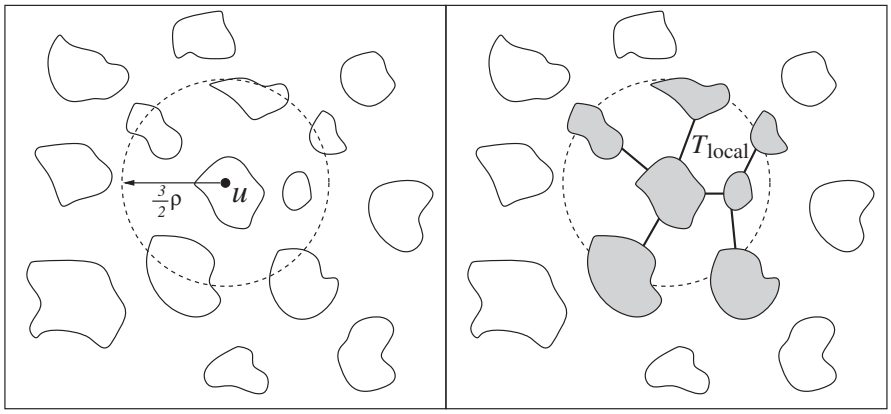

FIG. 3. *The operation of Procedure* `Construct_Local_Tree`. (a) *The clusters of* $\mathcal{P}$ *and the ball centered at* u *of radius* $3\rho/2$. (b) T_{local} *induces a tree on the clusters of* $\mathcal{I}(\mathcal{P}, B_\delta(u, 3\rho/2))$. *The shaded area forms the kernel cluster* U'.

into a clique in $\mathcal{R}$, namely,

- $V(\mathcal{R}) = V(G)$ and
- $E(\mathcal{R}) = \overline{E}(P) \cup \bigcup_{1 \le i \le k} (U_i \times U_i)$.

The graph $\mathcal{R}$ is weighted with edge lengths $\ell(e) = \xi(e)$ for every $e \in E(\mathcal{R})$. (Distances in a weighted graph are defined with respect to the length of the edges.)

Recall that $\mathcal{P}$ is the connectivity partition of $V(G)$ with respect to the forest $\mathcal{F}$ and that δ is the restriction of $\widehat{\delta}$ to the vertices $V(G)$. The purpose of the following procedure, named `Construct_Local_Tree`, is to find a subset T_{local} of external edges from $\overline{E}(\mathcal{P})$ that induces a tree on the clusters of $\mathcal{I}(\mathcal{P}, B_\delta(u, 3\rho/2))$. Let $\mathcal{P}'$ be the connectivity partition of $V(G)$ with respect to $\mathcal{F} \cup T_{\text{local}}$. Note that by the choice of T_{local}, it follows that $\mathcal{P}' - \mathcal{P}$ contains a single cluster, named the *kernel cluster* U', which is the union of all the clusters in $\mathcal{P}$ that intersect $B_\delta(u, 3\rho/2)$. (See Figure 3.) The subset T_{local} should be chosen so that the diameter of the kernel cluster is not much greater than the sum of diameters of the $\mathcal{P}$-clusters it replaces (this requirement is presented formally in section 6).

In principle, this task can be achieved by using a depth-$(3\rho/2)$ shortest path tree rooted at u on the transitive graph $\mathcal{R}$. However, a naive choice of such a shortest path tree might create cycles in the cluster graph induced on $\mathcal{P}$. Procedure `Construct_Local_Tree` carefully avoids this complication. The procedure begins by constructing the transitive graph $\mathcal{R}$ of G with respect to $\mathcal{P}$ and δ. Next, the vertex set U' is initiated to consist of the cluster of u in $\mathcal{P}$, and the edge set T_{local} is initiated to be empty. The vertices of $\mathcal{R}$ are then processed in increasing order of distances from the vertex u. In section 5 we prove that whenever Procedure `Construct_Local_Tree` is invoked, the distances in $\mathcal{R}$ agree with δ; hence if the procedure processes the vertex x before it processes the vertex y, then $\delta(u, x) \le \delta(u, y)$.

Consider a vertex v when it is processed by the procedure, and let U_i be v's cluster in the partition $\mathcal{P}$. If $v \notin U'$, then the procedure adds the vertices of U_i to U' and adds the edge (w, v) to T_{local}, where w is the predecessor of v in some shortest path from u to v. Note that (w, v) is an edge in $E(G)$. This is justified since v must be the first vertex in U_i to be processed by the procedure (as otherwise, it was already in U'), and since w was processed before v (as $\text{dist}_{\mathcal{R}}(u, w) < \text{dist}_{\mathcal{R}}(u, v)$). The procedure

halts when all vertices at distance at most $3\rho/2$ from u are processed and returns the edge set T_{local}. A formal description of Procedure `Construct_Local_Tree` is given in Table 2. Procedure `Construct_Local_Tree` can be implemented as a simple variant of the well-known Dijkstra algorithm for finding shortest paths from a single source [8, 6].

TABLE 2
Procedure `Construct_Local_Tree`.

Input: A vertex induced subgraph G of $\widehat{G}$ and a vertex $u \in V(G)$.
Output: An edge set $T_{\mathrm{local}} \subseteq \overline{E}(\mathcal{P})$ that induces a tree on the clusters of $\mathcal{I}(\mathcal{P}, B_\delta(u, 3\rho/2))$.

1. Construct the transitive graph $\mathcal{R}$ of G with respect to $\mathcal{P}$ and δ.
2. Let U be u's cluster in $\mathcal{P}$.
3. Set $U' \leftarrow U$ and $T_{\mathrm{local}} \leftarrow \emptyset$.
4. Let $v_1, \ldots, v_n$ be the vertices of $\mathcal{R}$ in increasing order of distances from u, namely, $v_1 = u$ and $\mathrm{dist}_{\mathcal{R}}(v_i, u) \leq \mathrm{dist}_{\mathcal{R}}(v_{i+1}, u)$ for every $1 \leq i < n$.
5. For $i = 2, \ldots, n$, and as long as $\mathrm{dist}_{\mathcal{R}}(v_i, u) \leq \frac{3\rho}{2}$, do:
   (a) Let U_i be v_i's cluster in $\mathcal{P}$.
   (b) If $v_i \notin U'$, then do:
      i. Set $U' \leftarrow U' \cup U_i$.
      ii. Let π be a shortest path from u to v_i in $\mathcal{R}$. Let w be the predecessor of v_i in π.
      iii. Set $T_{\mathrm{local}} \leftarrow T_{\mathrm{local}} \cup (w, v_i)$.
6. return T_{local}.

OBSERVATION 4.2. *The edge set T_{local} output by the procedure induces a tree on the clusters of $\mathcal{I}(\mathcal{P}, U')$.*

5. Correctness. In this section we prove that Algorithm `Construct_Tree` generates a spanning tree of the given graph. In what follows, $\widehat{G}$ and $\widehat{T}$ stand for the unweighted n-vertex connected graph input to the first invocation of the algorithm and the subgraph stored in $\mathcal{F}$ upon termination of the algorithm, respectively. In order to analyze the recursive algorithm, we shall *label* each recursive invocation with a string in $\mathbb{N}^*$. The labeling is done in an inductive manner. The top recursive invocation (on the graph $\widehat{G}$) is labeled with the empty string ω. Consider a recursive invocation labeled with the string σ on the graph G (which is a vertex induced subgraph of $\widehat{G}$) for some $\sigma \in \mathbb{N}^*$, and let $G^1, \ldots, G^r$ be the connected components of the graph decomposition of G (see line 5 of Algorithm `Construct_Tree`)). Then the recursive invocation on the graph $G(V(G^i))$ is labeled with the string σi for every $1 \leq i \leq r$. We refer to the recursive invocation labeled with the string σ as the *σ-recursive invocation*.

We shall use subscript σ to denote the various ingredients of the σ-recursive invocation. Let G_σ, δ_σ, and u_σ denote the input graph G, the restriction of $\widehat{\delta}$ to the vertices $V(G)$, and the center vertex u, respectively, in the σ-recursive invocation. Observe that the original graph $\widehat{G}$ input to the top recursive invocation is denoted by G_ω. Let $\mathcal{F}_\sigma$ and $\mathcal{F}'_\sigma$ be snapshots of the forest $\mathcal{F}$ at the beginning of the execution of the σ-recursive invocation and after the addition of the local tree, respectively. Let $\mathcal{P}_\sigma$ and $\mathcal{P}'_\sigma$ denote the connectivity partitions of $V(G_\sigma)$ with respect to $\mathcal{F}_\sigma$ and $\mathcal{F}'_\sigma$, respectively. Let U'_σ be the single cluster in $\mathcal{P}'_\sigma - \mathcal{P}_\sigma$ (the kernel cluster). Finally, let $\mathcal{R}_\sigma$ be the transitive graph of G_σ with respect to $\mathcal{P}_\sigma$ and δ_σ.

We begin with establishing a few fundamental facts regarding the execution of our algorithm.

LEMMA 5.1. *Consider the σ-recursive invocation for some string σ in $\mathbb{N}^*$.*

1. *If there exists a path π between some two vertices x and y in the graph $\widehat{G}$ such that* $\text{len}(\pi) > 1$ *and* $V(\pi) \cap V(G_\sigma) = \{x, y\}$*, then both x and y are in the same cluster in $\mathcal{P}_\sigma$. In fact, if $|\sigma| > 0$, then both x and y are in the same cluster in $\mathcal{P}'_{\sigma_{-1}}$, where σ_{-1} is the longest proper prefix of σ.*
2. *The distances in the transitive graph $\mathcal{R}_\sigma$ agree with δ_σ.*

Proof. We prove the two claims simultaneously by induction on the length of the string σ. On the top recursive invocation, which is labeled with the empty string ω, we have the following.

1. The graphs G_ω and $\widehat{G}$ are identical; hence such a path π does not exist and the first claim holds vacuously.
2. The graphs $\mathcal{R}_\omega$ and $\widehat{G}$ are identical and the second claim holds trivially.

Now assume that the claims hold for the σ_{-1}-recursive invocation, where σ_{-1} is the longest proper prefix of σ, and consider the σ-recursive invocation. We first prove claim 1. Consider a path π between the vertices x and y as in the claim. If all internal vertices of the path π (namely, vertices other than the endpoints x and y) were already missing on the previous recursion level, i.e., if $V(\pi) \cap V(G_{\sigma_{-1}}) = \{x, y\}$, then, due to the inductive hypothesis, x and y are in the same tree in $\mathcal{F}_{\sigma_{-1}}$; thus they remain in the same tree in $\mathcal{F}'_{\sigma_{-1}}$ (and in $\mathcal{F}_\sigma$) and the assertion holds. Otherwise, there must be some internal vertices of the path π that have existed in the graph $G_{\sigma_{-1}}$ on the previous recursion level.

We argue that vertex x must be in the kernel cluster $U'_{\sigma_{-1}}$. The same line of reasoning shows that $y \in U'_{\sigma_{-1}}$ as well; hence both x and y are in the same tree in $\mathcal{F}'_{\sigma_{-1}}$ (and they remain in the same tree in $\mathcal{F}_\sigma$) so that the assertion holds. Let w be the internal vertex of π that still existed in $G_{\sigma_{-1}}$ which is closest to x in π; that is, the vertex w satisfies $\text{dist}_\pi(w, x) \leq \text{dist}_\pi(w', x)$ for any vertex $w' \in V(\pi) \cap V(G_{\sigma_{-1}}) - \{x, y\}$. We consider two cases (illustrated in Figure 4).

Case (a). If (x, w) is an edge in $E(\widehat{G})$, then since w does not exist in G_σ, it follows that both w and x were in $B_{\delta_{\sigma_{-1}}}(u_{\sigma_{-1}}, \rho)$; hence $\delta_{\sigma_{-1}}(u_{\sigma_{-1}}, x) \leq \rho$. By the inductive hypothesis on claim 2, the distances in $\mathcal{R}_{\sigma_{-1}}$ agree with $\delta_{\sigma_{-1}}$; thus $\text{dist}_{\mathcal{R}_{\sigma_{-1}}}(u_{\sigma_{-1}}, x) \leq \rho$. Therefore, since Procedure `Construct_Local_Tree` halted at distance $3\rho/2$ from the center vertex $u_{\sigma_{-1}}$ (see line 5 of the procedure), it follows that x is in the kernel cluster $U'_{\sigma_{-1}}$.

Case (b). If (x, w) is not an edge in $E(\widehat{G})$, then let U_w be w's cluster in the partition $\mathcal{P}_{\sigma_{-1}}$. By the inductive hypothesis, the vertex x is in U_w as well (due to the subpath of π that starts at x and ends at w); thus w and x are in the same cluster in $\mathcal{P}_{\sigma_{-1}}$ and they remain in the same cluster $\bar{U}_w$ in $\mathcal{P}'_{\sigma_{-1}}$. Since w is not a vertex in G_σ, it follows that the cluster $\bar{U}_w$ disintegrated into different connected components in the decomposition of the graph $G_{\sigma_{-1}}$. Therefore, the cluster $\bar{U}_w$ must be the kernel cluster $U'_{\sigma_{-1}}$ since, otherwise, the recursive invocation of Algorithm `Construct_Tree` on $G_{\sigma_{-1}}$ would have failed as $\mathcal{P}'_{\sigma_{-1}}$ is not a hub (see line 7 of the algorithm).

We now turn to prove claim 2. Consider the transitive graph $\mathcal{R}_\sigma$ as in the claim. Let x and y be any two vertices in $V(G_\sigma)$, and let π be a shortest path between x and y in $\widehat{G}$. Some segments of the path π (namely, some consecutive sequences of vertices and edges between them) may be missing in the graph G_σ. Consider such a missing segment, and let x' and y' be the vertices in π right before and right after that missing segment, respectively; i.e., the path π consists of a segment between x and x', a segment between x' and y', and a segment between y' and y, where the internal vertices of the segment between x' and y' are all missing in G_σ. By claim 1, the vertices x' and y' must be in the same tree in $\mathcal{F}_\sigma$ (see Figure 5); hence they are in the same cluster in

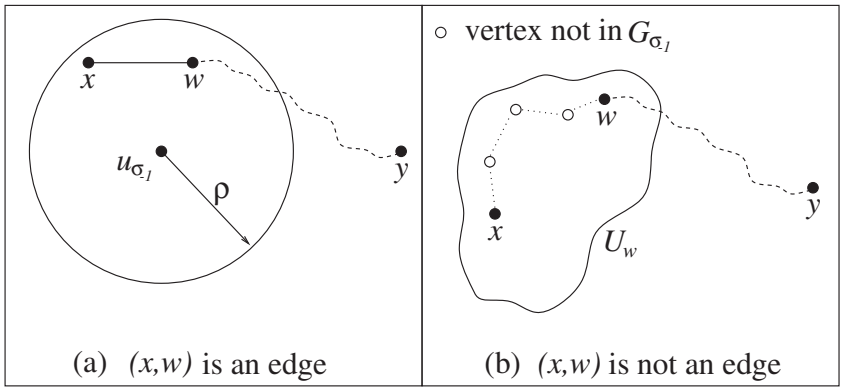

FIG. 4. *The two cases in the proof of Lemma* 5.1*'s claim* 1. *In both cases, the vertex* x *is in the kernel cluster* $U'_{\sigma_{-1}}$.

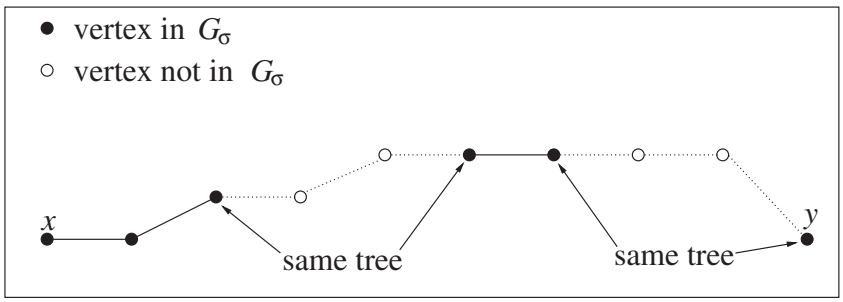

FIG. 5. *Proof of claim* 2 *of Lemma* 5.1. *The path* π *contains some missing segments.*

the partition $\mathcal{P}_\sigma$, and by the definition of the transitive graph $\mathcal{R}_\sigma$, we conclude that $\mathrm{dist}_{\mathcal{R}_\sigma}(x', y') = \delta_\sigma(x', y')$. The assertion follows as $\delta_\sigma(x, y) = \mathrm{len}(\pi)$. □

By claim 2 of the last lemma and since Procedure `Construct_Local_Tree` halts at distance $3\rho/2$ from the source vertex u (see line 5 of Procedure `Construct_Local_Tree`), we have the following.

COROLLARY 5.2. *Consider the* σ*-recursive invocation for some string* σ *in* $\mathbb{N}^*$. *The kernel cluster* U'_σ *satisfies*

$$B_{\delta_\sigma}(u_\sigma, \rho) \subseteq B_{\delta_\sigma}(u_\sigma, 3\rho/2) \subseteq U'_\sigma.$$

Next, we prove that the subgraph $\widehat{T}$ output by the algorithm is indeed a spanning tree of $\widehat{G}$.

PROPOSITION 5.3. *Consider an edge* $(x, y) \in E(\widehat{G})$. *There exists some string* σ *in* $\mathbb{N}^*$ *such that both* x *and* y *are in the kernel cluster* U'_σ.

Proof. Let σ be the longest string in $\mathbb{N}^*$ such that both x and y are in G_σ. This means that x and y are separated in the graph decomposition on the σ-recursive invocation; hence $x, y \in B_{\delta_\sigma}(u_\sigma, \rho)$. The assertion follows as Corollary 5.2 guarantees that $B_{\delta_\sigma}(u_\sigma, \rho) \subseteq U'_\sigma$. □

Since edges are added to $\mathcal{F}$ only if they are external to the connectivity partition $\mathcal{P}$ (see Procedure `Construct_Local_Tree`), it follows that $\widehat{T}$ is cycle-free. To see that $\widehat{T}$ is connected, consider an arbitrary edge $(x, y) \in E(\widehat{G})$. By Proposition 5.3, at some stage during the execution of the algorithm, both x and y belong to the kernel cluster

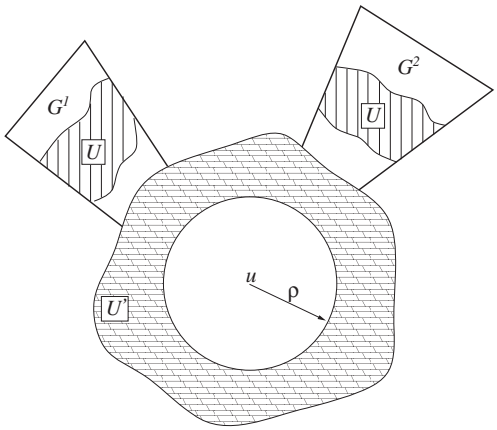

FIG. 6. *The cluster U decomposes into the connected components G^1 and G^2 of the graph decomposition.*

U'; hence the forest $\mathcal{F}$ at that stage admits a path between x and y. Therefore, $\widehat{T}$ admits a path between x and y. As $\widehat{G}$ is connected, we have the following.

THEOREM 5.4. *The graph $\widehat{T}$ output by Algorithm* `Construct_Tree` *is a spanning tree of the input graph $\widehat{G}$.*

6. Analysis. In this section we analyze the performance of our algorithm. In section 6.1 we prove that the recursive invocations of Algorithm `Construct_Tree` on all vertex induced subgraphs of $\widehat{G}$ succeed as long as the test value ρ is at least 2max-str($\widehat{G}$). The approximation ratio guaranteed by our algorithm is then established in section 6.2, where we prove that if the algorithm succeeds to generate a spanning tree $\widehat{T}$ with test value ρ, then max-str($\widehat{T}$) $\leq 3\rho\lceil\log n\rceil$. In section 6.3 we analyze the running time of the algorithm.

6.1. Successful recursive invocation. Consider some invocation of Algorithm `Construct_Tree` on the vertex induced subgraph G of $\widehat{G}$ with test value $\rho \geq$ 2max-str($\widehat{G}$). The proof that a ρ-center can be found (see line 2 of the algorithm) follows directly from Theorem 3.1. Let $G^1, \ldots, G^r$ be the connected components of the graph decomposition on this recursion level. In order to prove that the connectivity partition $\mathcal{P}'$ of $V(G)$ with respect to $\mathcal{F}'$ is a hub (see line 7 of the algorithm), we have to show that the kernel cluster is the only cluster in $\mathcal{P}'$ that decomposes into several connected components.

Suppose toward deriving contradiction that there exists a cluster U in $\mathcal{P}' - \{U'\}$ that decomposes into several connected components of the graph decomposition. (The execution of the algorithm halts at that stage.) Formally, let $X_i = U \cap V(G^i)$, where without loss of generality $X_i \neq \emptyset$ for $1 \leq i \leq t$ and $X_i = \emptyset$ for $t < i \leq r$, and suppose that $t \geq 2$. Figure 6 illustrates a cluster $U \in \mathcal{P} - \{U'\}$ that decomposes into two connected components.

Let δ be the restriction of $\widehat{\delta}$ to the vertices of G, and let u be the current ρ-center. By the definition of the graph decomposition, every edge e in $E(G)$ that crosses between $V(G^i)$ and $V(G^j)$, where $1 \leq i < j \leq r$, satisfies $e \in B_\delta(u,\rho) \times B_\delta(u,\rho)$. Thus, by Observation 4.1 and Corollary 5.2, we have the following.

OBSERVATION 6.1. *Every edge e that crosses between $V(G^i)$ and $V(G^j)$, where $1 \leq i < j \leq r$, is in $U' \times U'$. Furthermore, the kernel cluster U' satisfies $U' \cap V(G^i) \neq \emptyset$*

for every $1 \leq i \leq r$.

Let T be the tree in $\mathcal{F}$ that corresponds to the cluster U, and let H be the subgraph induced on $\widehat{G}$ by $V(T)$. We prove that H is a $\rho/2$-outspread subgraph of $\widehat{G}$ (refer to section 3 for the definition of an outspread subgraph), in contradiction to Theorem 3.2.

Following the notation of section 3, let $\bar{H}$ denote the subgraph induced on $\widehat{G}$ by the vertices in $V(\widehat{G}) - V(T)$. Let $F(H)$ be the set of edges in $E(\widehat{G})$ that cross between H and $\bar{H}$, and let $W(H)$ be the set of endpoints of edges in $F(H)$. Let $F_1 = \{e \in F(H) \mid e \in E(G^1)\}$; namely, the edge set F_1 consists of the edges that cross between U vertices and other vertices in the connected component G^1 of the decomposition of G. Let $F_2 = F(H) - F_1$. By the choice of U and by Observation 6.1, the connected components $G^1, \ldots, G^t$ contain some vertices in U and some vertices not in U; thus F_1 and F_2 are nonempty.

Let W_i be the endpoints of edges in F_i for $i = 1, 2$. Let $W_i^+ = W_i \cap V(H)$ and $W_i^- = W_i \cap V(\bar{H})$. In order to prove that H is a $\rho/2$-outspread subgraph of $\widehat{G}$, we have to show that the distance between W_1 and W_2 in $\widehat{G}$ is large and to establish some connectivity properties of H and $\bar{H}$. We start with the latter.

Clearly, the vertex induced subgraph H is connected (as T is a tree in $\mathcal{F}$). For $\bar{H}$ we have the following proposition.

PROPOSITION 6.2. *There exist two vertices* $x_1 \in W_1^-$ *and* $x_2 \in W_2^-$ *such that* $\bar{H}$ *admits a simple path between* x_1 *and* x_2.

Proof. Let T' be the tree in $\mathcal{F}$ that corresponds to the cluster U'. Consider the subgraph G' induced on $\widehat{G}$ by $V(T') \cup (V(G) - U)$. This subgraph is not necessarily connected; however, the vertices of T' all belong to the same connected component G'' of G' as T' is connected by its own rights. Since $U' \subseteq V(T') \subseteq V(G'')$, it follows due to Observation 6.1 that $V(G'') \cap V(G^j) \neq \emptyset$ for every $1 \leq j \leq t$. Therefore, there exists a vertex x_i in $W_i^- \cap V(G'')$ for $i = 1, 2$. The proposition follows as G'' is a (connected) subgraph of $\bar{H}$. ∎

We now turn to prove that $\mathrm{dist}_{\widehat{G}}(W_1, W_2) \geq \rho/2$. We first argue that if two adjacent vertices were separated in the graph decomposition on some recursive invocation, then on the subsequent recursive invocations, they both lie far away from the boundary of their corresponding clusters.

PROPOSITION 6.3. *Consider the* σ*-recursive invocation for some string* σ *in* $\mathbb{N}^*$. *Let* x *be a vertex in* $V(G_\sigma)$, *and let* U_x *be its cluster in the connectivity partition* $\mathcal{P}_\sigma$. *If* x *admits a neighbor* y *in* $\widehat{G}$ *such that* $y \notin V(G_\sigma)$, *then* $B_{\delta_\sigma}(x, \rho/2) \subseteq U_x$.

Proof. Let α be the longest string in $\mathbb{N}^*$ such that both x and y are in G_α. The vertices x and y must have been separated in the graph decomposition on the α-recursive invocation (α is a proper prefix of σ). As $(x, y) \in E(G_\alpha)$, this could have happened only if both x and y were in $B_{\delta_\alpha}(u_\alpha, \rho)$. By Corollary 5.2, the kernel cluster U'_α satisfies $B_{\delta_\alpha}(u_\alpha, 3\rho/2) \subseteq U'_\alpha$; thus $w \in U'_\alpha$ for every vertex $w \in V(G_\alpha)$ such that $\mathrm{dist}_{\widehat{G}}(w, x) = \delta_\alpha(w, x) \leq \rho/2$, and w remains in x's tree in the forest from that moment on. Therefore, if such a vertex w still exists in the graph G_σ, then it must lie in U_x. ∎

Recall that the vertex set W_1 consists of the endpoints of edges in F_1. Since every edge in F_1 crosses between different clusters of the connectivity partition $\mathcal{P}$, we have the following.

COROLLARY 6.4. *Every vertex* $x \in V(\widehat{G})$ *such that* $\mathrm{dist}_{\widehat{G}}(x, W_1) \leq \rho/2$ *is in* $V(G)$.

Assume by way of contradiction that $\mathrm{dist}_{\widehat{G}}(W_1, W_2) < \rho/2$. Let π be a shortest path in $\widehat{G}$ between any vertex in W_1 and any vertex in W_2. Since F is a cut, it follows that π lies entirely in H or in $\bar{H}$, but it does not cross between them (as, otherwise, π is not shortest). Corollary 6.4 implies that π lies entirely in the graph G as every vertex in π is at distance less than $\rho/2$ from W_1. By Observation 6.1, every path from W_1 to W_2 in G must intersect U'. Since $V(H) \cap V(G) = U$, it follows that π cannot lie entirely in H; thus π connects between W_1^- and W_2^- in the subgraph induced by $V(G) - U$ on G (and, in particular, in $\bar{H}$).

Recall that Algorithm `Construct_Tree` employs the ball centered at u of radius ρ to decompose the graph (see line 5 of the algorithm), while the ball of radius $(3\rho/2)$ is contained in the kernel cluster U' (see Corollary 5.2). Since every vertex in W_i^- has a neighbor outside U' for $i = 1, 2$, we conclude that $\mathrm{dist}_{\widehat{G}}(W_i^-, B_\delta(u, \rho)) \geq \rho/2$. As $\mathrm{len}(\pi) < \rho/2$, π cannot contain any edge internal to $B_\delta(u, \rho)$. But this implies that the all vertices of π should have been in the same connected component of the (u, ρ, δ)-decomposition of G, in contradiction to the fact that π has one endpoint in G^1 and another in G^j for some $1 < j \leq t$. This establishes the following theorem.

THEOREM 6.5. *Given an input graph* $\widehat{G}$ *and a test value* $\rho \geq 2\text{max-str}(\widehat{G})$*, Algorithm* `Construct_Tree` *succeeds on each recursive invocation.*

6.2. Approximation ratio. In this section we prove that if Algorithm `Construct_Tree` succeeds on each recursive invocation when invoked with test value ρ, then the output spanning tree $\widehat{T}$ satisfies $\mathrm{dist}_{\widehat{T}}(x, y) \leq 3\rho\lceil \log n \rceil$ for every edge (x, y) in $E(\widehat{G})$ (recall that n is the number of vertices in the input graph $\widehat{G}$). By Proposition 5.3, we know that at some stage during the execution of the algorithm, the vertices x and y are both in the kernel cluster. Consequently we would like to bound the diameter of the kernel cluster with respect to the distances in the output spanning tree $\widehat{T}$. In an attempt to establish such a bound, we will actually prove a stronger claim, stating that the sum of the diameters of many clusters, the kernel cluster being one of them, is sufficiently small.

Let $\widehat{\tau}$ be the metric defined by the distances in the output tree $\widehat{T}$. For a collection of vertex subsets $\Lambda = \{U_1, \ldots, U_k\}$, let

$$\varphi(\Lambda) \;=\; \sum_{1 \leq i \leq k} \mathrm{diam}_{\widehat{\tau}}(U_i).$$

Our subsequent analysis revolves on bounding the measure $\varphi(\mathcal{P}'_\sigma)$ as a function of the length of the string $\sigma \in \mathbb{N}^*$.

PROPOSITION 6.6. *Consider the* σ*-recursive invocation for some string* σ *in* $\mathbb{N}^*$*. The kernel cluster* U'_σ *satisfies*

$$\mathrm{diam}_{\widehat{\tau}}(U'_\sigma) \;\leq\; 3\rho + \varphi(\mathcal{I}(\mathcal{P}_\sigma, U'_\sigma)).$$

Proof. The execution of Procedure `Construct_Local_Tree` halts at distance $3\rho/2$ from the source vertex u_σ (see line 5 of the procedure). Therefore, the tree induced by T_{local} on the clusters of $\mathcal{I}(\mathcal{P}_\sigma, U'_\sigma)$ is of depth at most $3\rho/2$ (when the cluster containing u_σ is considered to be the root). Consider some two vertices $x, y \in U'_\sigma$, and let π be the unique path between x and y in $\widehat{T}$. The path π contains at most $2 \cdot (3\rho/2) = 3\rho$ edges from the local tree T_{local}. Let $\pi' = \pi - T_{\mathrm{local}}$ be the rest of the path π. Since π' is a collection of segments internal to the $\mathcal{P}_\sigma$-clusters replaced by U'_σ,

it follows that $\text{len}(\pi') \leq \varphi(\mathcal{I}(\mathcal{P}_\sigma, U'_\sigma))$. Therefore, $\text{len}(\pi) \leq 3\rho + \varphi(\mathcal{I}(\mathcal{P}_\sigma, U'_\sigma))$, and the assertion holds. ∎

The next proposition enables us to bound the sum of the diameters of the clusters in $\mathcal{I}(\mathcal{P}_\sigma, U'_\sigma)$.

LEMMA 6.7. *Consider the σ-recursive invocation for some string $\sigma = \alpha i$, where $\alpha \in \mathbb{N}^*$ and $i \in \mathbb{N}$. For every cluster U in $\mathcal{P}_\sigma$, there exists a cluster $\bar{U}$ in $\mathcal{P}'_\alpha$ such that $U \subseteq \bar{U}$.*

Proof. Suppose toward deriving contradiction that there exists a cluster $U \in \mathcal{P}_\sigma$ such that $U \nsubseteq \bar{U}$ for any cluster $\bar{U}$ in $\mathcal{P}'_\alpha$. This implies that $\mathcal{F}_\sigma$ contains a path π between some two vertices $x, y \in U$ that are not in the same cluster in $\mathcal{P}'_\alpha$. Let π be such a path of minimum length. The path π must satisfy $V(\pi) \cap V(G_\sigma) = \{x, y\}$, since, otherwise, there exists some subpath of π with endpoints $x', y' \in U$, where x' and y' are in different clusters in $\mathcal{P}'_\alpha$, in contradiction to π being the shortest such path.

The path π must contain some edges that do not exist in $\mathcal{F}'_\alpha$. Every such edge was added to $\mathcal{F}$ by some $\alpha j \beta$-recursive invocation, where $j \neq i$ and $\beta \in \mathbb{N}^*$. The graph $G_{\alpha j \beta}$ must contain some internal vertices of the path π; thus $\text{len}(\pi) > 1$. Therefore, Lemma 5.1, when applied to the σ-recursive invocation, implies that x and y are in the same cluster in $\mathcal{P}'_\alpha$, which derives a contradiction. The assertion follows. ∎

We are now ready to establish the main lemma of this section.

LEMMA 6.8. *Consider the σ-recursive invocation for some string σ in $\mathbb{N}^*$. The connectivity partition $\mathcal{P}_\sigma$ satisfies*

$$\varphi(\mathcal{P}_\sigma) \;\leq\; 3\rho(|\sigma| + 1).$$

Proof. We prove the assertion by induction on the length of the string σ. The only nonsingleton cluster in the connectivity partition $\mathcal{P}_\omega$ is the kernel cluster U'_ω, whose diameter with respect to the distances in $\widehat{T}$ is at most 3ρ. The diameter of a singleton cluster is 0. Therefore, the sum of the diameters of all clusters in $\mathcal{P}_\omega$ is at most 3ρ, and the assertion holds. Let $\sigma_{-1} \in \mathbb{N}^*$ be the longest proper prefix of σ, and assume that the assertion holds for σ_{-1}. Lemma 6.7 implies that for every cluster $U \in \mathcal{P}'_\sigma - \{U'_\sigma\}$, there exists a cluster $\bar{U} \in \mathcal{P}'_{\sigma_{-1}} - \mathcal{I}(\mathcal{P}'_{\sigma_{-1}}, U'_\sigma)$ such that $U \subseteq \bar{U}$. Since $\text{diam}_{\widehat{\tau}}(U)$ is monotone under set inclusion, i.e., $U \subseteq \bar{U}$ implies $\text{diam}_{\widehat{\tau}}(U) \leq \text{diam}_{\widehat{\tau}}(\bar{U})$, it follows that

$$\begin{aligned}\varphi(\mathcal{P}'_\sigma) - \text{diam}_{\widehat{\tau}}(U'_\sigma) = \varphi(\mathcal{P}'_\sigma - \{U'_\sigma\}) &\leq \varphi(\mathcal{P}'_{\sigma_{-1}} - \mathcal{I}(\mathcal{P}'_{\sigma_{-1}}, U'_\sigma)) \\ &= \varphi(\mathcal{P}'_{\sigma_{-1}}) - \varphi(\mathcal{I}(\mathcal{P}'_{\sigma_{-1}}, U'_\sigma)).\end{aligned}$$

Thus

$$\varphi(\mathcal{P}'_\sigma) \leq \text{diam}_{\widehat{\tau}}(U'_\sigma) - \varphi(\mathcal{I}(\mathcal{P}'_{\sigma_{-1}}, U'_\sigma)) + \varphi(\mathcal{P}'_{\sigma_{-1}}).$$

Another application of Lemma 6.7 guarantees that for every cluster $U \in \mathcal{I}(\mathcal{P}_\sigma, U'_\sigma)$, there exists a cluster $\bar{U} \in \mathcal{I}(\mathcal{P}'_{\sigma_{-1}}, U'_\sigma)$ such that $U \subseteq \bar{U}$; hence $\varphi(\mathcal{I}(\mathcal{P}_\sigma, U'_\sigma)) \leq \varphi(\mathcal{I}(\mathcal{P}'_{\sigma_{-1}}, U'_\sigma))$, and we can bound

$$\varphi(\mathcal{P}'_\sigma) \leq \text{diam}_{\widehat{\tau}}(U'_\sigma) - \varphi(\mathcal{I}(\mathcal{P}'_\sigma, U'_\sigma)) + \varphi(\mathcal{P}'_{\sigma_{-1}}).$$

Proposition 6.6 is employed to deduce that

$$\varphi(\mathcal{P}'_\sigma) \leq 3\rho + \varphi(\mathcal{P}'_{\sigma_{-1}}).$$

The assertion follows by the inductive hypothesis as $|\sigma_{-1}| = |\sigma| - 1$. ∎

Let (x, y) be an arbitrary edge in $E(\widehat{G})$. By Proposition 5.3, there exists a string $\sigma \in \mathbb{N}^*$ such that both x and y are in the kernel cluster U'_σ. Therefore,

$$\mathrm{dist}_{\widehat{T}}(x, y) \leq \mathrm{diam}_{\widehat{\tau}}(U'_\sigma) \leq \varphi(\mathcal{P}'_\sigma).$$

By Lemma 6.8, and since the depth of the recursion is at most $\lceil \log n \rceil$ (as the size of each graph input to the recursive algorithm decreases by a factor of at least 2), we conclude that

$$\mathrm{dist}_{\widehat{T}}(x, y) \leq 3\rho(|\sigma| + 1) \leq 3\rho\lceil \log n \rceil.$$

As the maximum stretch of a spanning tree is always obtained on a pair of vertices that form an edge in the original graph [5], Theorems 5.4 and 6.5 imply the following.

THEOREM 6.9. *Given an n-vertex graph $\widehat{G}$, Algorithm* `Construct_Tree` *can be invoked with $O(\log n)$ different test values to generate a spanning tree $\widehat{T}$ of $\widehat{G}$ satisfying* $\text{max-str}(\widehat{T}) = O(\log n) \cdot \text{max-str}(\widehat{G})$.

6.3. Running time. We now turn to analyze the running time of Algorithm `Construct_Tree` when invoked with test value ρ on input graph $\widehat{G}$ with $\widehat{n}$ vertices and $\widehat{m}$ edges. The distance metric $\widehat{\delta}$ is constructed in a preprocessing stage in time $O(\widehat{n}\widehat{m})$ (a trivial implementation); thus in what follows we assume that $\widehat{\delta}$ and its restrictions to subsets of $V(\widehat{G})$ are known.

Consider a recursive invocation of the algorithm on vertex induced subgraph G of $\widehat{G}$, and let δ be the restriction of $\widehat{\delta}$ to the vertices $V(G)$. Denote $n = |V(G)|$ and $m = |E(G)|$. Given a vertex $u \in V(G)$, we can construct the graph G' remaining from G after the edges in $E(B_\delta(u, \rho))$ are discarded in time $O(m)$. Identifying the connected components of G' can be done in time $O(m)$ as well; hence we can decide whether u is a ρ-center with respect to G and δ in time $O(m)$. By repeating this process for every vertex $u \in V(G)$, a ρ-center is found (if one exists) in time $O(nm)$.

Procedure `Construct_Local_Tree` is merely a variant of Dijkstra's single source shortest paths algorithm on the transitive graph $\mathcal{R}$ that has $O(n^2)$ edges; hence it can be implemented to run in time $O(n^2)$. Using a disjoint-set data structure [6], connectivity queries in the forest $\mathcal{F}$ are answered in near-constant time, and the condition that the connectivity partition $\mathcal{P}'$ is a hub is verified in near-linear time. Therefore, the dominant term in the running time of the recursive invocation on G is proportional to nm. Accounting for all recursive invocations, the running time of Algorithm `Construct_Tree` is $O(\min\{\widehat{n}\widehat{m}\log\widehat{n}, \widehat{n}^3\})$.

7. Tightness of the analysis. In this section we prove that the analysis presented in section 6 is tight. Recall that our approximation algorithm invokes Algorithm `Construct_Tree` with different test values $\rho \in (1, 2n]$, finally returning the output of a successful invocation with the smallest ρ. For the sake of the analysis, in this section we assume that the approximation algorithm ignores the spanning trees output by successful invocations with larger test values, although some of these spanning trees may admit smaller maximum stretch.

LEMMA 7.1. *For every $d \in \mathbb{N}_{>0}$ there exists an unweighted graph G_d with $n(d) = \Theta(2^d)$ vertices such that* $\text{max-str}(G_d)$ *is constant while Algorithm* `Construct_Tree`*, when invoked on G_d with test value $\rho = 2$, constructs a spanning tree with maximum stretch $\Omega(\log n)$.*

Proof. Given an integer $d \geq 1$, construct the unweighted graph G_d as follows. Let T and T' be two complete binary trees of depth d, with roots r and r', respectively.

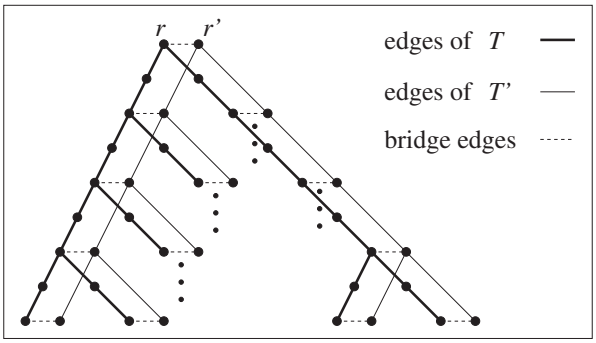

FIG. 7. G_d *for* $d = 4$.

Connect the two trees to each other by adding a *bridge* edge between every pair of corresponding vertices. Split every edge (x, y) in T by adding a new vertex z and replacing (x, y) with new edges (x, z) and (y, z). Figure 7 illustrates the construction of G_4.

Since the number of vertices in a depth d complete binary tree is $2^{d+1} - 1$ and since the number of new vertices added to T is $2^{d+1} - 2$ (equal to the number of edges in a depth d complete binary tree), it follows that

$$n(d) \;=\; |V(G_d)| \;=\; 2\,(2^{d+1} - 1) \,+\, 2^{d+1} - 2 \;=\; 6 \cdot 2^d - 4.$$

It is easy to verify that the spanning tree obtained by removing the edges of T' and remaining with the edges of T plus the bridge edges has maximum stretch 4. On the other hand, when Algorithm `Construct_Tree` is invoked on G_d with test value $\rho = 2$, if the "original" vertices of T (those that existed in T before splitting the edges) are chosen to be the 2-centers on each recursive invocation, then the spanning tree $\widehat{T}$ returned by the algorithm is merely the union of T and T' with their roots connected by an edge, i.e., $E(\widehat{T}) = E(T) \cup E(T') \cup \{(r, r')\}$.

Let l be an arbitrary leaf in T, and let l' be its corresponding leaf in T'. The unique path between l and l' in $\widehat{T}$ goes via the edge (r, r'), and it is of length $2d+1+d = 3d+1$. Therefore, $\widehat{T}$ has maximum stretch $\Omega(d) = \Omega(\log(n(d)))$. □

8. Hardness of approximation. As mentioned in section 1.2, it is NP-hard to decide, for an arbitrary unweighted graph G, whether or not max-str$(G) \leq 4$ [5]. Moreover, since the maximum stretch of a tree on an unweighted graph is always obtained on a pair of vertices that form an edge in the original graph, it follows that max-str(G) must be an integer. Therefore, we have the following.

COROLLARY 8.1. *It is NP-hard to approximate the MMST problem on unweighted graphs by a ratio better than* $5/4$.

We show that unless P = NP, the problem cannot be approximated additively by a term of $o(n)$.

LEMMA 8.2. *It is NP-hard to distinguish between unweighted graphs with minimum max-stretch at most* $5k - 1$ *and those with minimum max-stretch at least* $6k - 1$ *for any positive integer* k.

Proof. The proof is by reduction from the problem of deciding whether an arbitrary unweighted graph has minimum max-stretch at most 4. Consider some positive integer k. Given an arbitrary unweighted graph G, construct the unweighted graph G'_k by replacing every edge $(u, v) \in E(G)$ with a unique path $P_{u,v}$ of length k between u

and v. Observe that every spanning tree T' of G'_k corresponds to a spanning tree T of G where the edge (u,v) is in $E(T)$ if and only if all the edges of $P_{u,v}$ are in $E(T')$. Moreover, if the spanning tree T' of G'_k corresponds to the spanning tree T of G, then, since T' is connected, it follows that

$$|E(T') \cap E(P_{u,v})| \;=\; \begin{cases} k & \text{if } (u,v) \in E(T), \\ k-1 & \text{otherwise} \end{cases}$$

for every $(u,v) \in E(G)$; i.e., the tree T' is missing at most a single edge from every such path $P_{u,v}$. Therefore, $\text{max-str}(T', G'_k) = k \cdot (\text{max-str}(T,G)+1) - 1$. Thus if G has minimum max-stretch at most 4, then G'_k has minimum max-stretch at most $5k-1$. Otherwise, if G has minimum max-stretch at least 5, then G'_k has minimum max-stretch at least $6k-1$. □

Given an approximation algorithm A for the MMST problem on unweighted graphs and an unweighted graph G, let $A(G)$ denote the tree returned by A when invoked on G.

COROLLARY 8.3. *If there exist some real $\delta = o(n)$ and $\epsilon > 0$ and an approximation algorithm A for the MMST problem on unweighted graphs with performance guarantee*

$$\text{max-str}(A(G), G) \;\leq\; \delta + (6/5 - \epsilon) \cdot \text{max-str}(G)$$

for every unweighted graph G, then $P = NP$.

THE CSP DICHOTOMY HOLDS FOR DIGRAPHS WITH NO SOURCES AND NO SINKS (A POSITIVE ANSWER TO A CONJECTURE OF BANG-JENSEN AND HELL)*

LIBOR BARTO†, MARCIN KOZIK‡, AND TODD NIVEN†

Abstract. Bang-Jensen and Hell conjectured in 1990 (using the language of graph homomorphisms) a constraint satisfaction problem (CSP) dichotomy for digraphs with no sources or sinks. The conjecture states that the CSP for such a digraph is tractable if each component of its core is a cycle and is NP-complete otherwise. In this paper we prove this conjecture and, as a consequence, a conjecture of Bang-Jensen, Hell, and MacGillivray from 1995 classifying hereditarily hard digraphs. Further, we show that the CSP dichotomy for digraphs with no sources or sinks agrees with the algebraic characterization conjectured by Bulatov, Jeavons, and Krokhin in 2005.

Key words. constraint satisfaction problem, graph homomorphism, smooth digraphs

1. Introduction. The history of the constraint satisfaction problem (CSP) goes back more than thirty years and begins with the work of Montanari [Mon74] and Mackworth [Mac77]. Since that time many combinatorial problems in artificial intelligence and other areas of computer science have been formulated in the language of CSPs. The study of such problems, under this common framework, has applications in database theory [Var00], machine vision recognition [Mon74], temporal and spatial reasoning [SV98], truth maintenance [DD96], technical design [NL], scheduling [LALW98], natural language comprehension [All94], and programming language comprehension [Nad]. Numerous attempts to understand the structure of different CSPs has been undertaken, and a wide variety of tools ranging from statistical physics (e.g., [ANP05, KMRT$^+$07]) to universal algebra (e.g., [JCG97]) has been employed. Methods and results developed in seemingly disconnected branches of mathematics transformed the area. The conjecture proved in this paper resisted the approaches based in combinatorics and theoretical computer science for nearly twenty years. Only recent developments in the structural theory of finite algebras provided tools strong enough to solve this problem.

For the last ten years the study of CSPs has also been a driving force in theoretical computer science. The dichotomy conjecture of Feder and Vardi, published in [FV99], has origins going back to 1993. The conjecture states that a CSP, for any fixed language, is solvable in polynomial time or NP-complete. Therefore the class of CSPs would be a subclass of NP avoiding problems of intermediate difficulty. The logical

characterization of the class of CSPs (see [FV99] and [Kun]) provides arguments in support of the dichotomy; nevertheless the conjecture remains open.

One of the results of [FV99] shows that the CSP dichotomy conjecture is equivalent to the CSP dichotomy conjecture restricted to digraphs. Therefore the CSPs can be defined in terms of the (di)graph homomorphisms studied in graph theory for over forty years (cf. [Sab61, HP64, Lev73]). It adds a new dimension to a well-established problem and shows the importance of solving CSPs for digraphs. The classification of the complexity of the **H**-coloring problems for undirected graphs, discovered by Hell and Nešetřil [HN90], is an important step and provides a starting point towards proving, or refuting, the CSP dichotomy conjecture. There have since appeared many papers on the complexity of digraph coloring problems (see, e.g., [BJH90, BJHM95, Fed01, GWW92, HNZ96a, HNZ96b, HNZ96c, HZZ93, Mac91, Zhu95]), but as yet, no plausible conjecture on a graph theoretical classification has been proposed. Bang-Jensen and Hell [BJH90] did, however, conjecture a classification (implying the dichotomy) for the class of digraphs with no sources or sinks. Their conjecture significantly generalizes the result of Hell and Nešetřil.

In 1995, Bang-Jensen, Hell, and MacGillivray (in [BJHM95]) introduced the notion of hereditarily hard digraphs and conjectured their classification. Surprisingly, they were able to show that this conjecture and the one given in [BJH90] are equivalent. In this paper we prove the conjecture of Bang-Jensen and Hell and, as a consequence, the conjecture of Bang-Jensen, Hell, and MacGillivray.

Our paper relies on the interconnection between the CSP and algebra as first discovered by Jeavons, Cohen, and Gyssens in [JCG97] and refined by Bulatov, Jeavons, and Krokhin in [BJK05]. Using this connection, Bulatov, Jeavons, and Krokhin conjectured a full classification of the NP-complete CSPs. For a small taste of results in the direction of proving this classification, see [BIM$^+$06, Bul06, Dal05, Dal06, KV07]. A particularly interesting example, demonstrating the potency of the algebraic approach, is Bulatov's proof of the result of Hell and Nešetřil (see [Bul05]). A recent, purely algebraic result of Maróti and McKenzie [MM07] is one of the key ingredients in the proof of the conjecture of Bang-Jensen and Hell. This provides further evidence supporting the extremely strong bond between the CSP and universal algebra.

2. Preliminaries. We assume that the reader possesses a basic knowledge of universal algebra and graph theory. For an easy introduction to the notions of universal algebra that are not defined in this paper, we invite the reader to consult the monographs [BS81] and [MMT87]. Further information concerning the structural theory of finite algebras (called tame congruence theory) can be found in [HM88]. For an explanation of the basic terms in graph theory and graph homomorphisms, we recommend [HN04]. Finally, for an introduction to the connections between universal algebra and the CSP, we recommend [BJK05].

Throughout the paper we deviate from the standard definition of the CSP, with respect to a fixed language (found in, e.g., [BKJ00]), in favor of an equivalent definition from [FV99, LZ06]. The definitions of a *relational structure*, a *homomorphism*, or a *polymorphism* are presented further in this section in their full generality as well as in restriction to directed graphs.

A *directed graph* (or *digraph*) is a pair $\mathbf{G} = (V, E)$, where V is a set of vertices and $E \subseteq V \times V$ is a set of edges. More generally *a relational structure* $\mathcal{T} = (T, \mathcal{R})$ is an ordered pair, where T is a finite nonempty set and $\mathcal{R}$ is a finite set of finitary relations on T indexed by a set J. Let d_j denote the arity of the relation $R_j \in \mathcal{R}$. The indexed set of all the d_j constitutes the *signature* of $\mathcal{T}$.

A vertex of a digraph is called a *source* (resp., a *sink*) if it has no incoming (resp., outgoing) edges. An *oriented walk* is a sequence of vertices $(v_0, \dots, v_{n-1})$ such that $(v_i, v_{i+1}) \in E$ or $(v_{i+1}, v_i) \in E$ for any $i < n-1$ and the *length* of such a walk is $n-1$. A *walk* is an oriented walk such that $(v_i, v_{i+1}) \in E$ for any $i < n-1$. A *closed walk* is a walk such that $v_0 = v_{n-1}$. Given a digraph $\mathbf{G}$, we sometimes denote the set of vertices of $\mathbf{G}$ by $V(\mathbf{G})$ and similarly the edges of $\mathbf{G}$ by $E(\mathbf{G})$. A graph with n vertices is a *cycle* if its vertices can be ordered (i.e., $V = \{v_0, \dots, v_{n-1}\}$) in such a way that $E = \{(v_i, v_j) | \, j = i+1 \mod n\}$.

A *graph homomorphism* is a function between sets of vertices of two graphs mapping edges to edges. A graph is 3-colorable if and only if it maps homomorphically to the complete graph on three vertices (without loops). The notion of *colorability* is generalized using graph homomorphisms: a digraph, say $\mathbf{G}$, is $\mathbf{H}$-colorable if there exists a homomorphism mapping $\mathbf{G}$ to $\mathbf{H}$. For two relational structures of the same signature, say $\mathcal{T} = (T, \mathcal{R})$ and $\mathcal{U} = (U, \mathcal{S})$, a map $h : T \to U$ is a *homomorphism* if $h(T_j) \subseteq R_j$ for all $j \in J$ (where $h(T_j)$ is computed pointwise).

A *digraph polymorphism* is a homomorphism from a finite Cartesian power of a graph to the graph itself. Precisely, for a digraph $\mathbf{G} = (V, E)$ a function $h : V^n \to V$ is a *polymorphism* of $\mathbf{G}$ if, for any vertices $a_0, \dots, a_{n-1}, b_0, \dots, b_{n-1} \in V$,

$$\text{if } (a_i, b_i) \in E \text{ for all } i < n, \text{ then } (h(a_0, \dots, a_{n-1}), h(b_0, \dots, b_{n-1})) \in E.$$

The notion of a polymorphism is defined for relational structures as well. A *polymorphism* h of $\mathcal{T}$ is an operation $h : T^n \to T$ such that, for all relations $R \in \mathcal{R}$ of arity m, if

$$(a_{i,0}, a_{i,1}, \dots, a_{i,m-1}) \in R \qquad \text{for all } i < n,$$

then

$$(h(a_{0,0}, a_{1,0}, \dots, a_{n-1,0}), \dots, h(a_{0,m-1}, a_{1,m-1}, \dots, a_{n-1,m-1})) \in R.$$

A digraph $\mathbf{G} = (V, E)$ *retracts* to an induced subgraph $\mathbf{H} = (W, F)$ if there is an endomorphism $h : V \to V$ such that $h(V) = W$ and $h(a) = a$ for all $a \in W$. Such a map h is called a *retraction*. A *core* of a digraph is a minimal induced subgraph to which the digraph retracts. The definition of retraction and core clearly generalize to relational structures. It is a trivial fact that, for any digraph $\mathbf{H}$, and for a core of $\mathbf{H}$, say $\mathbf{H}'$, the set of $\mathbf{H}$-colorable digraphs coincides with the set of $\mathbf{H}'$-colorable digraphs.

An *algebra* is a tuple $\mathbf{A} = (A, f_0, \dots)$ consisting of a nonempty set A (called a *universe* of $\mathbf{A}$) and *operations* on A. An *operation* f_i is an n_i-ary function $f_i : A^{n_i} \to A$. With each operation we associate an *operation symbol* and, by an abuse of notation, denote it also by f_i. A set $B \subseteq A$ is a *subuniverse* of an algebra $\mathbf{A}$ if, for any number i, the operation f_i restricted to B^{n_i} has all the results in B. For a nonempty subuniverse B of an algebra $\mathbf{A}$ the algebra $\mathbf{B} = (B, f_0', \dots)$ (where f_i' is a restriction of f_i to B^{n_i}) is a *subalgebra* of $\mathbf{A}$. A *power* of an algebra $\mathbf{A}$ has a universe A^k and the operations f_i'' derived from the operations of $\mathbf{A}$ by computing coordinatewise. A subalgebra of a power of an algebra is often called a *subpower*. A *term function* of an algebra is any function that can be obtained by a composition using the operations of the algebra together with all the projections. A *term* is a formal way of denoting such a composition; i.e., a term function is attached to an algebra, but a term can be computed in a subalgebra or a power as well as in the original algebra. A set $C \subseteq A$

generates a subuniverse B in an algebra $\mathbf{A}$ if B is the smallest subuniverse containing C—such a subuniverse always exists and can be obtained by applying all the term functions of the algebra $\mathbf{A}$ to all the choices of arguments coming from C.

In this paper all relational structures, digraphs, and algebras are assumed to be finite.

3. The main result. For a relational structure $\mathcal{T} = (T, R)$ we define the language $\mathrm{CSP}(\mathcal{T})$, of relational structures with the same signature as $\mathcal{T}$, to be

$$\mathrm{CSP}(\mathcal{T}) = \{\, \mathcal{U} \mid \text{there is a homomorphism from } \mathcal{U} \text{ to } \mathcal{T} \,\}.$$

Alternatively we can view $\mathrm{CSP}(\mathcal{T})$ as a decision problem:

INPUT: a relational structure $\mathcal{U}$ with the same signature as $\mathcal{T}$
QUESTION: does there exist a homomorphism from $\mathcal{U}$ to $\mathcal{T}$?

In either approach we are concerned with the computational complexity (of membership of the language, or of the decision problem, respectively) for a given relational structure. The CSP dichotomy conjecture proposed in [FV99] can be stated as follows.

THE CSP DICHOTOMY CONJECTURE. *For a relational structure $\mathcal{T}$ the problem* $\mathrm{CSP}(\mathcal{T})$ *is solvable in polynomial time or NP-complete.*

The (di)graph coloring problems can be viewed as special cases of the CSP. Although a digraph $\mathbf{H} = (W, F)$ is technically different from a relational structure, the set of $\mathbf{H}$-colorable digraphs is obviously polynomially equivalent to the CSP for an appropriate relational structure, and therefore we denote the class of all $\mathbf{H}$-colorable digraphs by $\mathrm{CSP}(\mathbf{H})$. Due to the reduction presented in [FV99], every CSP is polynomially equivalent to a digraph homomorphism problem. Thus we can restate the CSP dichotomy conjecture in the following way.

THE CSP DICHOTOMY CONJECTURE. *For a fixed digraph $\mathbf{H}$, deciding whether a given digraph is $\mathbf{H}$-colorable is either NP-complete or solvable in polynomial time.*

This brings us to the main problem of the paper, a conjecture nearly ten years older than the CSP dichotomy conjecture, and a special case of it. It deals with digraphs with no sources or sinks and was first formulated by Bang-Jensen and Hell in [BJH90].

THE CONJECTURE OF BANG-JENSEN AND HELL. *Let $\mathbf{H}$ be a digraph without sources or sinks. If each component of the core of $\mathbf{H}$ is a cycle, then* $\mathrm{CSP}(\mathbf{H})$ *is polynomially decidable. Otherwise* $\mathrm{CSP}(\mathbf{H})$ *is NP-complete.*

Note that the above conjecture is a substantial generalization of the $\mathbf{H}$-coloring result of Hell and Nešetřil [HN90].

The notion of hereditarily hard digraphs was introduced by Bang-Jensen, Hell, and MacGillivray in [BJHM95]. A digraph $\mathbf{H}$ is said to be *hereditarily hard* if the $\mathbf{H}'$-coloring problem is NP-complete for all loopless digraphs $\mathbf{H}'$ that contain $\mathbf{H}$ as a subgraph (not necessarily induced). The following conjecture was posed and shown to be equivalent to the Bang-Jensen and Hell conjecture in [BJHM95].

THE CONJECTURE OF BANG-JENSEN, HELL, AND MACGILLIVRAY. *Let $\mathbf{H}$ be a digraph. If the digraph $R(\mathbf{H})$ (which is obtained by iteratively removing the sources and sinks from $\mathbf{H}$ until none remain) does not admit a homomorphism to a cycle of length greater than one, then $\mathbf{H}$ is hereditarily hard. Otherwise there exists a loopless digraph $\mathbf{H}'$ containing $\mathbf{H}$ (as a not necessarily induced subgraph) such that $\mathbf{H}'$-coloring is solvable in a polynomial time.*

In this section we prove the Bang-Jensen and Hell conjecture and therefore the conjecture of Bang-Jensen, Hell, and MacGillivray. In this proof we assume Theorem 3.1, which will be proved in the subsequent sections of the paper. The reasoning

uses weak near unanimity operations[1] and Taylor operations (used only to connect Theorems 3.2 and 3.3, and therefore not defined here [HM88, Tay77, LZ06]).

THEOREM 3.1. *If a digraph without sources or sinks admits a weak near unanimity polymorphism, then it retracts to the disjoint union of cycles.*

It is easy to see that the colorability by digraphs retracting to a disjoint union of cycles is tractable (see, e.g., [BJH90]). It remains to prove the NP-completeness of the digraphs not retracting to such a union. Before we do so, we recall two fundamental results.

It follows from [HM88, Lemma 9.4 and Theorem 9.6] that a part of the result of Máróti and McKenzie [MM07, Theorem 1.1] can be stated as follows.

THEOREM 3.2 (see [MM07]). *A finite relational structure $\mathcal{T}$ admits a Taylor polymorphism if and only if it admits a weak near unanimity polymorphism.*

The following result was originally proved in [BKJ00] and [LZ03] and, as stated below, can be found in [LZ06, Theorem 2.3]. It relies on a connection between relational structures and varieties generated by algebras of their polymorphisms. A lack of a Taylor polymorphism in such an algebra implies an existence of a "trivial" algebra in a variety and NP-completeness of the associated CSP.

THEOREM 3.3 (see [LZ06]). *Let $\mathcal{T}$ be a relational structure which is a core. If $\mathcal{T}$ does not admit a Taylor polymorphism, then* $\mathrm{CSP}(\mathcal{T})$ *is NP-complete.*

If a digraph $\mathbf{H}$ without sources or sinks does not retract to a disjoint union of cycles, then its core $\mathbf{H}'$ also does not. Thus, by Theorem 3.1, it follows that $\mathbf{H}'$ does not admit a weak near unanimity polymorphism, and by Theorems 3.2 and 3.3 it follows that $\mathrm{CSP}(\mathbf{H}')$ is NP-complete, completing the proof of the conjecture of Bang-Jensen and Hell.

The conjecture (posed in [BKJ00]), classifying the CSPs from the algebraic point of view, can be stated as follows (see, e.g., [LZ06]).

THE ALGEBRAIC CSP DICHOTOMY CONJECTURE. *Let $\mathcal{T}$ be a relational structure that is a core. If $\mathcal{T}$ admits a Taylor polymorphism, then* $\mathrm{CSP}(\mathcal{T})$ *is polynomial time solvable. Otherwise* $\mathrm{CSP}(\mathcal{T})$ *is NP-complete.*

Note that the proof of the conjecture of Bang-Jensen and Hell immediately implies that the structure of the NP-complete digraph coloring problems agrees with the algebraic CSP dichotomy conjecture. The remainder of the paper is dedicated to the proof of the Theorem 3.1.

4. Notation. In this section we introduce the notation required throughout the remainder of the paper.

4.1. Neighborhoods in graphs. For a fixed digraph $\mathbf{G} = (V, E)$ we denote $(a, b) \in E$ by $a \to b$, and we use $a \xrightarrow{k} b$ to say that there is a directed walk from a to b of length precisely k. More generally we call a digraph $\mathbf{H}$ a *pattern* if $V(\mathbf{H}) = \{0, \dots, n-1\}$ and $(u, v) \in E$ if and only if $|u - v| = 1$ and $(v, u) \notin E$. We denote patterns by lowercase Greek letters and, for a pattern α, we write $a \xrightarrow{\alpha} b$ if there exists a homomorphism ϕ from α into $\mathbf{G}$ such that $\phi(0) = a$ and $\phi(n-1) = b$. In such a case we say that a and b can be connected via the pattern α. The oriented walk connecting vertices a and b and consisting of the images of elements of α under ϕ is a *realization* of the pattern. For any $W \subseteq V$ we define

$$W^{+n} = \{v \in V \mid (\exists w \in W)\ w \xrightarrow{n} v\}$$

[1] A weak near unanimity operation is a function such that, for any choice of arguments a, b, $w(b, a, \dots, a) = w(a, b, \dots, a) = \cdots = w(a, a, \dots, b)$ and $w(a, \dots, a) = a$. These operations are described in more detail in section 4.

and similarly

$$W^{-n} = \{v \in V \mid (\exists w \in W)\ v \xrightarrow{n} w\}.$$

We define $W^0 = W$, and write a^{+n} (resp., a^{-n}, a^0) instead of $\{a\}^{+n}$ (resp., $\{a\}^{-n}, \{a\}^0$) for any $a \in V$. More generally, for a pattern α, we write

$$W^{\alpha} = \{v \in V \mid (\exists w \in W)\ w \xrightarrow{\alpha} v\}.$$

As before, we use a^{α} for $\{a\}^{\alpha}$. Sometimes, for ease of presentation, we write $a \xrightarrow{k,n} b$ to denote $a \xrightarrow{k} b$ and $a \xrightarrow{n} b$.

4.2. Digraph path powers. Let $\mathbf{G} = (V, E)$ be a digraph and α be a pattern. We define a path power of the digraph $\mathbf{G}$, which we denote by $\mathbf{G}^{\alpha}$, in the following way: the vertices of the power are the vertices of the digraph $\mathbf{G}$, and a pair $(c, d) \in V^2$ is an edge in $\mathbf{G}^{\alpha}$ if and only if $c \xrightarrow{\alpha} d$ in $\mathbf{G}$. Moreover, we set $\mathbf{G}^{+n} = \mathbf{G}^{\alpha}$ for the pattern α consisting of n arrows pointing forward. Note that if $f : V^m \to V$ is a polymorphism of $\mathbf{G}$, then it is also a polymorphism of any path power of this digraph. Path powers are special cases of primitive positive definitions (used in, e.g., [Bul05]) or indicator constructions introduced in [HN90] in order to deal with the colorability problem for undirected graphs.

4.3. Components. A *connected* digraph is a digraph such that there exists an oriented walk, consisting of at least one edge, between every choice of two vertices. A *strongly connected* digraph is a digraph such that, for every choice of two vertices, there is a walk connecting them. By a *component* (resp., *strong component*) of a digraph $\mathbf{G}$, we mean a maximal (under inclusion) induced subgraph that is connected (resp., strongly connected). Note that, according to this definition, a single vertex with the empty set of edges is not connected, and thus not every digraph decomposes into a union of components (or strong components). Given a digraph $\mathbf{G}$ with no sources or sinks, we say that a strong component $\mathbf{H}$ of $\mathbf{G}$ is a *top component* if $V(\mathbf{H})^{+1} = V(\mathbf{H})$. Similarly, we say that a strong component $\mathbf{H}$ of $\mathbf{G}$ is a *bottom component* if $V(\mathbf{H})^{-1} = V(\mathbf{H})$.

4.4. Algebraic length. The following definition is taken from [HNZ96b]. For a pattern α we define the *algebraic length* $al(\alpha)$ to be

$$al(\alpha) = |\{\text{edges going forward in } \alpha\}| - |\{\text{edges going backward in } \alpha\}|.$$

An *algebraic length of an oriented walk* is a shorthand expression for an algebraic length of a pattern which can be realized as such an oriented walk—the pattern is always clear from the context. For a digraph $\mathbf{G} = (V, E)$ we set

$$al(\mathbf{G}) = \min\{i > 0 \mid (\exists v \in V)\ (\exists \text{ a pattern } \alpha)\ v \xrightarrow{\alpha} v \text{ and } al(\alpha) = i\}$$

whenever the set on the right-hand side is nonempty and ∞ otherwise. In case of strongly connected digraphs in section 7 the algebraic length can be equivalently defined (cf. Corollary 5.7) as the greatest common divisor of the lengths of closed walks in a digraph. We note that for digraphs with no sources or sinks (or with a closed walk) the algebraic length of a nonempty digraph is always a natural number. It is folklore (cf. [HN04, Proposition 5.19]) that a connected digraph $\mathbf{G}$ retracts to a cycle if and only if it contains a closed walk of length $al(\mathbf{G})$.

4.5. Algebraic notation. By $\overline{a}$ we denote the tuple $(a, a, \dots, a)$ (the arity will always be clear by the context), and by $\overrightarrow{a}$ we denote the tuple $(a_0, a_1, \dots, a_n)$. Further, we extend the notation $\overline{a}$ to the sets in the following way. For a set W let $\overline{W}$ be an appropriate Cartesian power of W. Thus, for example, given a vertex a of a digraph $\mathbf{G}$, the set $\overline{a^{+n}}$ is the collection of all tuples whose coordinates are vertices reachable by a walk of length n from a.

An idempotent operation on a set A is an operation, say $f : A^n \to A$, such that $f(\overline{a}) = a$ for all $a \in A$. In accordance with [MM07], by a weak near unanimity operation we understand an idempotent operation $w(x_0, \dots, x_{n-1})$ that satisfies

$$w(y, x, \dots, x) = w(x, y, \dots, x) = \cdots = w(x, x, \dots, y),$$

for any choice of x and y in the underlying set. Moreover, for a term t of arity n, we define

$$t^{(i)}(x_0, x_1, \dots, x_{n-1}) = t(x_{n-i}, x_{n-i+1}, \dots, x_0, x_1, \dots, x_{n-i-1}),$$

for each $0 \le i < n$, where addition on the indices is performed modulo n.

5. Preliminary results on digraphs. We start with a number of basic results describing the connection between digraphs and their path powers. The following lemma reveals the behavior of the algebraic lengths of oriented walks in powers of a digraph.

LEMMA 5.1. *Let $\mathbf{G}$ be a digraph without sources or sinks. Let α be a pattern of algebraic length k, and let $a \xrightarrow{\alpha} b$ in $\mathbf{G}$. Then $a \xrightarrow{\beta} b$ in $\mathbf{G}^{+k}$ for some pattern β of algebraic length one.*

Proof. For a fixed, large enough number j, consider all oriented walks in $\mathbf{G}$ of the form $a \xrightarrow{l_1} a_1 \xleftarrow{l_2} a_2 \xrightarrow{l_3} \cdots \leftrightarrows a_{l_j} = b$, where $l_1 - l_2 + \cdots \pm l_j = k$. We will show that at least one of these walks has all the l_i's divisible by k. Let us choose an oriented walk in which k divides all the l_i in a maximal initial segment of the i, and let l_{i_0} be the last element of this segment. If $i_0 + 1 < j$, then (assuming without loss of generality that i_0 is odd) the walk

$$a \xrightarrow{l_1} \cdots \xrightarrow{l_{i_0}} a_{i_0} \xleftarrow{l_{i_0+1}} a_{i_0+1} \xrightarrow{l_{i_0+2}} a_{i_0+2} \cdots$$

can be altered, using the fact that a_{i_0+1} (and possibly other vertices) is not a source, to obtain

$$a \xrightarrow{l_1} \cdots \xrightarrow{l_{i_0}} a_{i_0} \xleftarrow{l'_{i_0+1}} a'_{i_0+1} \xrightarrow{l'_{i_0+2}} a_{i_0+2} \cdots,$$

where l'_{i_0+1} is greater than l_{i_0+1} and is divisible by k. This contradicts the choice of i_0.

If, on the other hand, $i_0 + 1 = j$, the number k divides $l_1 - l_2 + \cdots \pm l_{i_0}$ and, using the fact that $l_1 - l_2 + \cdots \pm l_{i_0} \mp l_{i_0+1} = k$, we infer that k divides l_{i_0+1}, again contradicting the choice of i_0. Thus $i_0 = j$ and we can find an oriented walk $a \xrightarrow{l_1} a_1 \xleftarrow{l_2} a_2 \xrightarrow{l_3} \cdots a_{l_j} = b$ with $l_1 - l_2 + \cdots \pm l_j = k$, where each l_i is divisible by k. This shows that a is connected to b via a pattern of algebraic length one in $\mathbf{G}^{+k}$. ∎

As a consequence we obtain the following fact.

COROLLARY 5.2. *Let $\mathbf{G}$ be a digraph, without sources or sinks, such that $al(\mathbf{G}) = 1$. Then $al(\mathbf{G}^{+k}) = 1$ for any natural number k.*

Proof. Let $a \xrightarrow{\alpha} a$, where α is a pattern of algebraic length one. Then, by following a realization of α k-many times, we obtain $a \xrightarrow{\beta} a$ in $\mathbf{G}$ for a pattern β of algebraic length k. Now the statement follows from the previous lemma. □

Theorem 3.1 is proved in section 7 for strongly connected digraphs first, and therefore we need some preliminary results on such digraphs. The following very simple lemma is needed to prove some of the further corollaries in this section.

LEMMA 5.3. *Let c be a vertex in a strongly connected digraph. Then the greatest common divisor (GCD) of the lengths of the closed walks in this digraph is equal to the GCD of the lengths of the closed walks containing c.*

Proof. Suppose, for contradiction, that the GCD, say n', of the lengths of the closed walks containing c is bigger than the GCD of the lengths of the closed walks for the entire digraph. Then there exists a walk $d \xrightarrow{l} d$ of length l such that n' does not divide l. On the other hand, since the digraph is strongly connected, $c \xrightarrow{l'} d$ and $d \xrightarrow{l''} c$ for some numbers l', l''. The number n', by definition, divides $l' + l''$ and $l' + l + l''$ and thus divides l, a contradiction. □

Moreover, the following easy proposition holds.

PROPOSITION 5.4. *Let $\mathbf{G}$ be a connected digraph $\mathbf{G}$ and α be a pattern. If $a \xrightarrow{\alpha} a$ for a vertex a in $\mathbf{G}$, then the number $al(\mathbf{G})$ divides $al(\alpha)$.*

Proof. Let $\mathbf{G}$ be a connected digraph and, for some vertex a, $a \xrightarrow{\alpha} a$ via a pattern α. Let b be a vertex in $\mathbf{G}$ such that $b \xrightarrow{\beta} b$ for a pattern β satisfying $al(\beta) = al(\mathbf{G})$. Since $\mathbf{G}$ is connected there is a pattern γ such that $b \xrightarrow{\gamma} a$ and thus $b \xrightarrow{\gamma} a \xrightarrow{\alpha} a \xrightarrow{\gamma'} b$ with $al(\gamma') = -al(\gamma)$. Following appropriate walks, we can obtain an oriented walk, from b to b, of algebraic length $al(\alpha) - k \cdot al(\mathbf{G})$, for any number k. The minimality of $al(\mathbf{G})$ implies that $al(\mathbf{G})$ divides $al(\alpha)$. □

The following lemma is heavily used in the proof of Theorem 3.1 for strongly connected digraphs in section 7.

LEMMA 5.5. *If, for a strongly connected digraph $\mathbf{G} = (V, E)$, the GCD of the lengths of the closed walks in $\mathbf{G}$ is equal to one, then*

$$(\exists m)\ (\forall a, b \in V)\ (\forall n)\ \text{if } n \geq m, \text{ then } a \xrightarrow{n} b.$$

Proof. Fix an arbitrary element $c \in V$. By Lemma 5.3 we find some closed walks containing c such that their lengths $k_1, \ldots, k_i$ satisfy $GCD(k_1, \ldots, k_i) = 1$. Thus c is contained in a closed walk of length l whenever l is a linear combination of $k_1, \ldots, k_i$ with nonnegative integer coefficients. It is easy to see that there is a natural number m' such that, for every $n' \geq m'$, n' can be expressed as such a linear combination; hence c is in a closed walk of length n' for each such n'. Now it suffices to set $m = m' + 2|V|$ since, for arbitrary vertices $a, b \in V$, there are walks of length at most $|V|$ from a to c and from c to b. □

The following easy corollary follows.

COROLLARY 5.6. *For a strongly connected digraph $\mathbf{G}$ with GCD of the lengths of the closed walks equal to one, and for any number n, the digraph $\mathbf{G}^{+n}$ is strongly connected.*

For strongly connected digraphs, the GCD of the lengths of the closed walks and the algebraic length of the digraph coincide.

COROLLARY 5.7. *For a strongly connected digraph, the GCD of the lengths of the closed walks is equal to the algebraic length of the digraph.*

Proof. Let us fix a digraph $\mathbf{G} = (V, E)$ and denote by n the GCD of the lengths of the closed walks in $\mathbf{G}$. Since, by Proposition 5.4, the algebraic length of $\mathbf{G}$ divides the length of every closed walk in $\mathbf{G}$, $al(\mathbf{G})$ divides n.

Conversely, let $a = a_0 \xrightarrow{l_0} b_0 \xleftarrow{k_0} a_1 \xrightarrow{l_1} \cdots \xleftarrow{k_{m-1}} a_m = a$ be a realization of a pattern of algebraic length $al(\mathbf{G})$. Let k_i' be such that $b_i \xleftarrow{k_i} a_{i+1} \xleftarrow{k_i'} b_i$ for all i. Note that n divides $k_i + k_i'$ and $\sum_{i<m} l_i + \sum_{i<m} k_i'$. Thus n divides $\sum_{i<m} l_i - \sum_{i<m} k_i = al(\mathbf{G})$, which shows that $n \leq al(\mathbf{G})$, and the lemma is proved. ∎

Finally, we remark that if α is a pattern of algebraic length one and $\mathbf{G}$ has no sources and no sinks, then $E(\mathbf{G}^\alpha) \supseteq E(\mathbf{G})$. In particular, if $al(\mathbf{G}) = 1$, then $al(\mathbf{G}^\alpha) = 1$.

6. A connection between graphs and algebra. In this section we present basic definitions and results concerning the connection between digraphs and algebras. Let $\mathbf{G} = (V, E)$ be a digraph admitting a weak near unanimity polymorphism $w(x_0, x_1, \ldots, x_{h-1})$. We associate with $\mathbf{G}$ an algebra $\mathbf{A} = (V, w)$ and note that E is a subuniverse of $\mathbf{A}^2$. Note that for any subuniverse of $\mathbf{A}$, say W, we can define the digraph $\mathbf{G}_{|W} = (W, E \cap W \times W)$ (or $(W, E_{|W})$) which admits the weak near unanimity polymorphism $w|_{W^h}$, and the algebra $(W, w|_{W^h})$ is a subalgebra of $\mathbf{A}$. For the remainder of this section we assume that $\mathbf{G}$ and $\mathbf{A}$ are as above.

The first lemma describes the influence of the structure of the digraph on the subuniverses of the algebra.

LEMMA 6.1. *For any subuniverse W of $\mathbf{A}$ the sets W^{+1} and W^{-1} are subuniverses of $\mathbf{A}$.*

Proof. Take any elements $a_0, \ldots, a_{h-1}$ from W^{+1} and choose $b_0, \ldots, b_{h-1} \in W$ such that $b_i \to a_i$ for all i. Then $w(b_0, \ldots, b_{h-1}) \to w(a_0, \ldots, a_{h-1})$ showing that $w(a_0, \ldots, a_{h-1}) \in W^{+1}$, and the claim is proved. The proof for W^{-1} is similar. ∎

Since the weak near unanimity operation is idempotent, all the one element subsets of V are subuniverses of $\mathbf{A}$. Using the previous lemma, the following result follows trivially.

COROLLARY 6.2. *For any $a \in V$, any pattern α, and any number n, the sets a^{+n}, a^{-n}, and a^α are subuniverses of $\mathbf{A}$.*

Subuniverses of $\mathbf{A}$ can also be obtained in another way.

LEMMA 6.3. *Let $\mathbf{H}$ be a strong component of $\mathbf{G}$. Assume that the GCD of the lengths of the cycles in $\mathbf{H}$ is equal to one. Then $V(\mathbf{H})$ is a subuniverse of $\mathbf{A}$.*

Proof. Using Lemma 5.5, we find a number m such that there is a walk $b \xrightarrow{m} c$ in $\mathbf{H}$ for all $b, c \in V(\mathbf{H})$. Fix a vertex $a \in V(\mathbf{H})$. There is a walk $a \xrightarrow{m} b$ for all $b \in V(\mathbf{H})$ and a walk $c \xrightarrow{m} a$ for all $c \in V(\mathbf{H})$. Thus, $V(\mathbf{H}) = a^{+m} \cap a^{-m}$ is a subuniverse. ∎

We present a second construction leading to a subuniverse of the algebra.

LEMMA 6.4. *If $\mathbf{H} = (W, F)$ is the largest induced subgraph of $\mathbf{G}$ without sources or sinks, then W is a subuniverse of $\mathbf{A}$.*

Proof. Clearly, the vertices of $\mathbf{H}$ can be described as those having arbitrarily long walks to and from them. Since $\mathbf{G}$ is finite, there exists a natural number k such that

$$W = \{w \mid (\exists v, v' \in V)\ v \xrightarrow{k} w \ \text{ and } \ w \xrightarrow{k} v'\}.$$

Thus $W = V^{+k} \cap V^{-k}$, and we are done, since both sets on the right-hand side are subuniverses. ∎

7. Strongly connected digraphs. In this section we present a proof Theorem 3.1 in the case of strongly connected digraphs.

THEOREM 7.1. *If a strongly connected digraph of algebraic length k admits a weak near unanimity polymorphism, then it contains a closed walk of length k (and thus retracts to a cycle of length k).*

Using Corollary 5.7, the result can be restated in terms of the GCD of the lengths of closed walks in $\mathbf{G}$, and we will freely use this duality. Theorem 7.1 is a consequence of the following result.

THEOREM 7.2. *If a strongly connected digraph $\mathbf{G}$ of algebraic length one admits a weak near unanimity polymorphism, then it contains a loop.*

We present a proof of Theorem 7.1, assuming Theorem 7.2, and devote the remainder of this section to proving Theorem 7.2.

Proof of Theorem 7.1. Fix an arbitrary vertex c in a strongly connected digraph of algebraic length k. Using Lemma 5.3 and Corollary 5.7, we obtain closed walks containing c with the GCD of their lengths equal to k. Thus, in the path power $\mathbf{G}^{+k}$, the GCD of lengths of closed walks containing c is equal to one. Let $\mathbf{H}$ be the strong component of $\mathbf{G}^{+k}$ containing c. Using Lemma 6.3, we infer that $V(\mathbf{H})$ is a subuniverse of the algebra $(V(\mathbf{G}^{+k}), w)$, and thus $\mathbf{H}$ admits a weak near unanimity polymorphism. The algebraic length of $\mathbf{H}$ (again by Corollary 5.7) is one, and therefore by Theorem 7.2 it follows that there is a loop in $\mathbf{G}^{+k}$. This trivially implies a closed walk of length k in $\mathbf{G}$, and the theorem is proved using the folklore proposition from section 4.4. □

The remaining part of this section is devoted to the proof of Theorem 7.2. We start by choosing a digraph $\mathbf{G} = (V, E)$ to be a minimal (with respect to the number of vertices) counterexample to Theorem 7.2. We fix a weak near unanimity polymorphism $w(x_0, \dots, x_{h-1})$ of this digraph and associate with it the algebra $\mathbf{A} = (V, w)$. The proof will proceed by a number of claims.

CLAIM 7.3. *The digraph $\mathbf{G}$ can be chosen to contain a closed walk of length 2.*

Proof. Using Lemma 5.5, we find a minimal k such that a closed walk of length 2^k is contained in $\mathbf{G}$. Consider the path power $\mathbf{G}^{+2^{k-1}}$. It contains a closed walk of length 2 and admits a weak near unanimity polymorphism. Moreover, since k was chosen to be minimal and $\mathbf{G}$ did not contain a loop, the path power $\mathbf{G}^{+2^{k-1}}$ does not contain a loop either. By Corollary 5.6 the path power is strongly connected, and by Corollary 5.2 it has algebraic length equal to one. Thus, the digraph $\mathbf{G}^{+2^{k-1}}$ is also a counterexample to Theorem 7.2 (with the same number of vertices as $\mathbf{G}$), and therefore we can use it as a substitute for $\mathbf{G}$. □

From this point on we assume that $\mathbf{G}$ contains a closed walk of length 2 (an undirected edge). The next claim allows us to choose and fix an undirected edge with special properties.

CLAIM 7.4. *There are vertices $a, b \in V$ forming an undirected edge in $\mathbf{G}$ and a binary term t of $\mathbf{A}$ such that $a = t(w(\overline{a}, b), w(\overline{b}, a))$.*

Proof. Let $M \subseteq V$ be a minimal (under inclusion) subuniverse of $\mathbf{A}$ containing an undirected edge, and let $a, b \in M$ be vertices in such an edge. Since vertices $w(\overline{a}, b)$, $w(\overline{b}, a) \in M$ form an undirected edge in $\mathbf{G}$, the set $\{w(\overline{a}, b), w(\overline{b}, a)\}$ generates, in the algebraic sense, the set M (by the minimality of M). Since every vertex in a subuniverse is a result of an application of some term function to the generators of the subuniverse, there exists a term t such that $t(w(\overline{a}, b), w(\overline{b}, a)) = a$. □

In the following claims we fix vertices a, b and a term $t(x, y)$ such that $a \to b \to a$ and $a = t(w(\overline{a}, b), w(\overline{b}, a))$ (provided by the previous claim). Note that, by the definition of the operation $w(x_0, \dots, x_{h-1})$, for any numbers $i, j < h$, we obtain $a = t(w^{(i)}(\overline{a}, b), w^{(j)}(\overline{b}, a))$.

Using Lemma 5.5, we find and fix a minimal number n such that $a^{+(n+1)} = V$. We put $W = a^{+n}$ and $F = (W \times W) \cap E$ so that $\mathbf{H} = (W, F)$ is an induced subgraph of the digraph $\mathbf{G}$. Using Corollary 6.2, we infer that W is a subuniverse of $\mathbf{A}$ and thus $\mathbf{H}$ admits a weak near unanimity polymorphism. In the following claims we will show that the algebraic length of some strong component of $\mathbf{H}$ is one, which will contradict the minimality of $\mathbf{G}$.

CLAIM 7.5. *For any vertex in W there exists a closed walk in $\mathbf{H}$ and a walk (also in $\mathbf{H}$) connecting the closed walk to this vertex.*

Proof. Let d_0 denote an arbitrary vertex of W. Since $a^{+(n+1)} = W^{+1} = V$ there is $d_1 \in W$ such that $d_1 \to d_0$. Similarly, there exists $d_2 \in W$ such that $d_2 \to d_1$. By repeating this procedure, we get both statements of the claim. □

The next claim will allow us to fix some more vertices necessary for further construction.

CLAIM 7.6. *There exist vertices $c, c' \in W$ and a number k such that*

1. *$c' \to a$,*
2. *$c \xrightarrow{k} c$ in $\mathbf{H}$, and*
3. *$c \xrightarrow{k-n-1} c'$ in $\mathbf{H}$.*

Proof. Since $W^{+1} = V$ there exists $c' \in W$ such that $c' \to a$. Let l be the length of a closed walk provided by Claim 7.5 for $c' \in W$. For a sufficiently large multiple k of l there is a walk in $\mathbf{H}$ of length $k - n - 1$ from some vertex of the closed walk to c'; we call this vertex c. This finishes the proof. □

From this point on we fix vertices c and c' in W and a number k to satisfy the conditions of the last claim. The following claims focus on uncovering the structure of the strong component containing c in $\mathbf{H}$.

CLAIM 7.7. *For any $m \leq n$ either $a^{+m} \subseteq a^{+n}$ or $a^{+m} \subseteq b^{+n}$.*

Proof. Since a is in a closed walk of length 2, we obviously have $a^{+n} \supseteq a^{+(n-2)} \supseteq a^{+(n-4)} \cdots$, which proves the claim for even m's. If, on the other hand, m is odd, we have $b^{+n} \supseteq a^{+(n-1)} \supseteq a^{+(n-3)} \cdots$, completing the proof. □

The next two claims are of major importance for the proof of Theorem 7.2. They are used to show that the algebraic length of the strong component of $\mathbf{H}$ containing c is one.

CLAIM 7.8. *For any $m \leq n$ and for any $0 \leq i, j < h$ the following inclusion holds:*

$$t(w^{(i)}(\overline{a^{+n}}, a^{+m}), w^{(j)}(\overline{a^{+m}}, a^{+n})) \subseteq a^{+n}.$$

Proof. Note that $a = t(w^{(i)}(\overline{a}, b), w^{(j)}(\overline{b}, a))$ and therefore, for any choice of arguments of the term reachable by walks of length n from corresponding arguments of $t(w^{(i)}(\overline{a}, b), w^{(j)}(\overline{b}, a))$, the result is reachable by a walk of the same length from a, i.e.,

$$a^{+n} \supseteq t(w^{(i)}(\overline{a^{+n}}, b^{+n}), w^{(j)}(\overline{b^{+n}}, a^{+n})).$$

By the same token, using $a = t(w^{(i)}(\overline{a}, a), w^{(j)}(\overline{a}, a))$ provided by the idempotency of the terms, we obtain

$$a^{+n} \supseteq t(w^{(i)}(\overline{a^{+n}}, a^{+n}), w^{(j)}(\overline{a^{+n}}, a^{+n})).$$

Now the claim follows directly from Claim 7.7. □

The following technical claim will allow us to find walks in the strong component of $\mathbf{H}$ containing c.

CLAIM 7.9. *The following implication holds in* $\mathbf{H}$ (*i.e., all the walks and vertices lie inside* $\mathbf{H}$). *For any numbers* $0 \leq i, j < h$ *and all* $e, e', f \in W$ *and* $\overrightarrow{d}, \overrightarrow{d'}, \overrightarrow{g} \in \overline{W}$,

$$\text{if} \quad \begin{matrix} e \\ \downarrow k \\ e' \end{matrix} \quad \text{and} \quad \begin{matrix} d_l \\ \downarrow k \\ d'_l \end{matrix} \quad \text{for all } l, \quad \text{then} \quad \begin{matrix} t(w^{(i)}(\overrightarrow{d}, c), w^{(j)}(\overline{c}, e)) \\ \downarrow k \\ t(w^{(i)}(\overrightarrow{d'}, f), w^{(j)}(\overrightarrow{g}, e')). \end{matrix}$$

Proof. Note that, by looking at the tuples of vertices pointwise, we can find the following walks in $\mathbf{G}$:

$$\begin{matrix} \overrightarrow{d} & & c & & \overline{c} & & e \\ \Big\downarrow & & \downarrow k-n-1 & & \downarrow k-n-1 & & \Big\downarrow \\ & & c' & & \overline{c'} & & \\ k & & \downarrow & & \downarrow & & k \\ & & a & & \overline{a} & & \\ & & \downarrow n & & \downarrow n & & \\ \overrightarrow{d'} & & f & & \overrightarrow{g} & & e' \end{matrix}$$

where the walks from c to c' are provided by Claim 7.6 and lie entirely in $\mathbf{H}$. Applying the appropriate term to the consecutive vertices of the walks (rows in the diagram above), we obtain a walk of length k connecting $t(w^{(i)}(\overrightarrow{d}, c), w^{(j)}(\overline{c}, e))$ to $t(w^{(i)}(\overrightarrow{d'}, f), w^{(j)}(\overrightarrow{g}, e'))$. It remains to prove that all the vertices of this walk are in W. The first $k-n-1$ vertices of the walks are in W, since W is a subuniverse and they are results of an application of a term to vertices of the subuniverse. For $m \geq 0$, the $(k-n+m)$th vertex of the walk is a member of $t(w^{(i)}(\overline{a^{+n}}, a^{+m}), w^{(j)}(\overline{a^{+m}}, a^{+n}))$ and thus in W by Claim 7.8. □

We now construct a closed walk in $\mathbf{H}$, that contains c, of length coprime to k.

CLAIM 7.10. *There exists a closed walk* $c \xrightarrow{(h+1)k-1} c$ *in digraph* $\mathbf{H}$.

Proof. In the proof of this claim we use only vertices and walks that lie inside $\mathbf{H}$. Fix $d \in W$ (provided by Claim 7.6) such that $c \to d \xrightarrow{k-1} c$ in $\mathbf{H}$. By repeatedly applying Claim 7.9 we obtain

$$\begin{matrix} t(w(c,\dots,c,c,c), w(c,c\dots,c)) & & \\ \downarrow k & & \\ t(w(c,\dots,c,c,d), w(d,c,\dots,c)) & = & t(w^{(1)}(c,\dots,c,d,c), w^{(1)}(c,\dots,c,d)) \\ & & \downarrow k \\ t(w^{(2)}(c,\dots,d,d,c), w^{(1)}(c,\dots,c,d)) & = & t(w^{(1)}(c,\dots,c,d,d), w^{(1)}(c,\dots,c,d)) \\ \vdots & & \\ & = & t(w^{(h-1)}(d,\dots,d,d,c), w^{(1)}(c,\dots,c,d)) \\ & & \downarrow k \\ & & t(w^{(h-1)}(d,\dots,d,d,d), w^{(1)}(d,\dots,d,d)) \end{matrix}$$

and since the algebra is idempotent, the starting point of this walk is c and the ending point is d. Thus $c \xrightarrow{hk} d$ (for h the arity of the operation $w(x_0,\dots,x_{h-1})$), which immediately gives us the claim. □

By Claims 7.6 and 7.10, the strong component of $\mathbf{H}$ containing c has GCD of the lengths of its closed walks equal to one, and thus, by Lemma 6.3, its vertex set forms a subuniverse of the algebra $\mathbf{A}$. As a digraph it admits a weak near unanimity polymorphism. By Corollary 5.7 it has algebraic length one, and (as an induced subgraph of $\mathbf{G}$) it has no loops. Since $\mathbf{H}$ was chosen to be strictly smaller than $\mathbf{G}$ we obtain a contradiction with the minimality of $\mathbf{G}$, and the proof of Theorem 7.2 is complete.

8. The general case. In this section we prove Theorem 3.1 in its full generality. Nevertheless the majority of this section is devoted to the proof of the following result.

THEOREM 8.1. *If a digraph with no sources or sinks has algebraic length one and admits a weak near unanimity polymorphism, then it contains a loop.*

Using the above result, we prove the core theorem of the paper, Theorem 3.1.

Proof of Theorem 3.1. Let $\mathbf{G}$ be a digraph with no sources or sinks which admits a weak near unanimity polymorphism. Let n be the algebraic length of some component of $\mathbf{G}$. The path power $\mathbf{G}^{+n}$ admits a weak near unanimity polymorphism, has no sources or sinks, and, by Lemma 5.1, has algebraic length equal to one. Thus, Theorem 8.1 applied to $\mathbf{G}^{+n}$ provides a loop in the path power and therefore a closed walk of length n in $\mathbf{G}$.

Let n be minimal, under divisibility, in the set of algebraic lengths of components of $\mathbf{G}$. Since the algebraic length of a component divides (by Proposition 5.4) the length of any closed walk in it, every closed walk of length n (for such a minimal n) forms a subgraph which is a cycle. Moreover, by the same reasoning, cycles obtained for two different minimal n's cannot belong to the same component. Thus each component of $\mathbf{G}$ maps homomorphically to an n-cycle (for any minimal n dividing the algebraic length of this component), and it is not difficult to see that these homomorphisms can be chosen so that their union is a retraction. This proves the theorem. ∎

Therefore the only missing piece of the proof to the conjecture of Bang-Jensen and Hell is Theorem 8.1. We prove this result by way of contradiction. Suppose that $\mathbf{G} = (V, E)$ is a minimal (with respect to the number of vertices) counterexample to Theorem 8.1, and let $\mathbf{A} = (V, w(x_0, \dots, x_{h-1}))$ be the algebra associated with $\mathbf{G}$, in the sense of section 6, for some weak near unanimity polymorphism $w(x_0, \dots, x_{h-1})$.

The first part of the proof is dedicated to finding a particular counterexample satisfying more restrictive conditions than $\mathbf{G}$. To do so we need to define a special family of digraphs called *tambourines*. The n-tambourine is the digraph $(\{d_0, \dots, d_{n-1}, u_0, \dots, u_{n-1}\}, F_n)$ such that

$$F_n = \bigcup_i \{(d_i, d_{i+1}), (d_i, u_i), (d_i, u_{i+1}), (u_i, u_{i+1})\},$$

where the addition on the indices is computed modulo n. The 12-tambourine can be found in Figure 1. We begin the proof of the theorem with the following claim.

CLAIM 8.2. *We can choose a digraph* $\mathbf{G}$ *and a number* n *such that*

1. *the* n*-tambourine maps homomorphically to* $\mathbf{G}$*,*
2. *every vertex of* $\mathbf{G}$ *is in a closed walk of length* n*, and*
3. $\mathbf{G}^{+(mn+1)} = \mathbf{G}$ *for any number* m*.*

To prove this claim, we begin with an easy subclaim and work towards replacing $\mathbf{G}$ with a particular path power of $\mathbf{G}$ which satisfies the additional conditions. Note that, for any pattern α, the path power G^α admits $w(x_0, \dots, x_{h-1})$ as a polymorphism and has no sources or sinks. If such a path power has algebraic length one and does not contain a loop, then it can be taken as a substitute for $\mathbf{G}$.

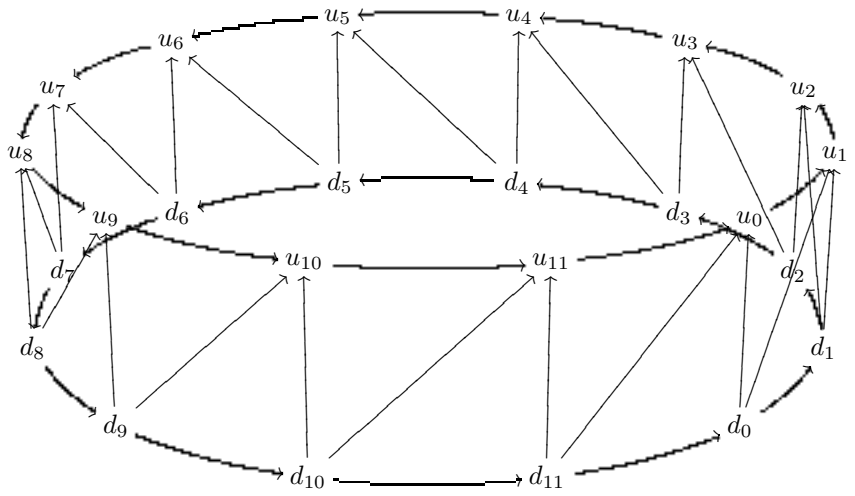

FIG. 1. *The* 12*-tambourine.*

SUBCLAIM 8.2.1. *The digraph* $\mathbf{G}$ *contains vertices* d *and* u *such that* $d \xrightarrow{|V|,|V|+1} u$.

Proof. Let α be the pattern

$$\underbrace{\rightarrow \ \cdots \rightarrow}_{|V|+1} \ \underbrace{\leftarrow \ \cdots \leftarrow}_{|V|}.$$

Using the fact that $al(\alpha) = 1$ and that $\mathbf{G}$ has no sources or sinks, it follows that $E(\mathbf{G}) \subseteq E(\mathbf{G}^\alpha)$. Moreover, let a, b be vertices in $\mathbf{G}$ such that b is contained in a closed walk and $a \xrightarrow{k} b$ for some k. Then $a \xrightarrow{k'} b$ for some $k' \leq |V|$, and choosing b' (from the closed walk containing b) such that $b' \xrightarrow{k'+1} b$, we obtain

$$b' \xrightarrow{k'+1} b \xrightarrow{(|V|+1)-(k'+1)} c \xleftarrow{(|V|+1)-(k'+1)} b \xleftarrow{k'} a \quad \text{for some } c.$$

Thus $b' \xrightarrow{\alpha} a$, and this implies that every component of $\mathbf{G}$ becomes a strong component of $\mathbf{G}^\alpha$.

Let $\mathbf{H} = (W, F)$ be a component of $\mathbf{G}$ with a closed walk realizing a pattern of algebraic length one. Then, for an appropriate F', containing F, the digraph $\mathbf{H}' = (W, F')$ is a strong component of $\mathbf{G}^\alpha$. The digraph $\mathbf{H}'$ contains $\mathbf{H}$ as a subgraph, and therefore its algebraic length is one. The path power $\mathbf{G}^\alpha$ admits $w(x_0, \ldots, x_{h-1})$ as a polymorphism, and thus, by Lemma 6.3, the digraph $\mathbf{H}'$ admits an appropriate restriction of $w(x_0, \ldots, x_{h-1})$. Theorem 7.2 provides a loop in $\mathbf{H}'$, which in turn implies the existence of vertices $d, u \in W$ such that $d \xrightarrow{|V|,|V|+1} u$ in $\mathbf{G}$. ∎

Proof of Claim 8.2. We fix $n = |V|!$ and argue that, for some k, the path power $\mathbf{G}_k = \mathbf{G}^{+(kn+1)}$ satisfies the assertions of the claim and therefore can be taken as a substitute for $\mathbf{G}$. Note that, for any number k, the digraph $\mathbf{G}_k$ admits $w(x_0, \ldots, x_{h-1})$ as a polymorphism, has no sources or sinks, and, by Corollary 5.2, has algebraic length one.

We first prove that, for all k, the digraph $\mathbf{G}_k$ does not contain a loop. If $\mathbf{G}_k$ does contain a loop, then there exists a closed walk of length $kn+1$ in some strong component of $\mathbf{G}$. In the same strong component in $\mathbf{G}$ there exists a closed walk of length smaller than n and thus coprime to $kn+1$; therefore the GCD of the lengths of closed walks in this strong component is one, and, using Corollary 5.7, Lemma 6.3, and Theorem 7.2, we obtain a loop in this strong component and therefore also in $\mathbf{G}$, a contradiction. Thus, to prove the claim, it remains to verify the additional required properties.

We now show that, for the fixed number n, the n-tambourine maps homomorphically to $\mathbf{G}_k$ for $k \geq 4$. Let d, u be vertices of $\mathbf{G}$ provided by Subclaim 8.2.1. Since $\mathbf{G}$ has no sources or sinks, we can find vertices d', u', each contained in a closed walk, such that d' is connected by a walk to d and u is connected by a walk to u'. By following the closed walks containing d' and u' multiple times, we get d'_0, u'_0, each contained in a closed walk, such that $d'_0 \xrightarrow{3n,3n+1} u'_0$. Moreover, again following the closed walks multiple times, we obtain

$$d'_0 \xrightarrow{n} d'_0 \xrightarrow{3n,3n+1} u'_0 \xrightarrow{n} u'_0.$$

Let d'_i denote the ith vertex of the closed walk $d'_0 \xrightarrow{n} d'_0$ and, similarly, u'_i the ith vertex of the closed walk $u'_0 \xrightarrow{n} u'_0$. Then, for any number $k \geq 4$ and any $i < n$, we have $d'_i \xrightarrow{kn+1} u'_i$ and $d'_i \xrightarrow{kn+1} u'_{(i+1) \bmod n}$. On the other hand, $d'_i \xrightarrow{kn+1} d'_{(i+1) \bmod n}$ and $u'_i \xrightarrow{kn+1} u'_{(i+1) \bmod n}$. Thus, for any $k \geq 4$, the map $d_i \mapsto d'_i$, $u_i \mapsto u'_i$ is a homomorphism from the n-tambourine in the path power $\mathbf{G}_k$.

To prove the second assertion of the claim we need to show that if $k \geq 4$, then any vertex of $\mathbf{G}_k$ is in a closed walk of length n. We fix such a number k and let $W \subset V$ be the subuniverse of $\mathbf{A}$ generated by $\{d'_0, \dots, d'_{n-1}, u'_0, \dots, u'_{n-1}\}$. Let $\mathbf{G}'_k$ be the subgraph induced by $\mathbf{G}_k$ on W. The digraph $\mathbf{G}'_k$ obviously admits a restriction of $w(x_0, \dots, x_{h-1})$ and (since the n-tambourine maps homomorphically to it) has algebraic length one. Choose an arbitrary $a \in W$. Then, by the definition of W, we have a term $t(x_0, \dots, x_{n-1}, y_0, \dots, y_{n-1})$ such that $a = t(d'_0, \dots, d'_{n-1}, u'_0, \dots, u'_{n-1})$. Therefore,

$$\left.\begin{array}{c} t(d'_0, \dots, d'_{n-2}, d'_{n-1}, u'_0, \dots, u'_{n-2}, u'_{n-1}) \\ \downarrow \\ t(d'_1, \dots, d'_{n-1}, d'_0, u'_1, \dots, u'_{n-1}, u'_0) \\ \vdots \\ t(d'_{n-1}, \dots, d'_{n-3}, d'_{n-2}, u'_{n-1}, \dots, u'_{n-3}, u'_{n-2}) \\ \downarrow \\ t(d'_0, \dots, d'_{n-2}, d'_{n-1}, u'_0, \dots, u'_{n-2}, u'_{n-1}) \end{array}\right\} n,$$

and thus a is in a closed walk of length n. This proves that $\mathbf{G}'_k$ has no sources and no sinks, and since it cannot be a counterexample smaller than $\mathbf{G}$, we infer that $W = V$. Therefore the second assertion holds for all the digraphs $\mathbf{G}_k$ with $k \geq 4$.

In the digraph $\mathbf{G}_4$ every vertex is in a closed walk of length n, and therefore $E(\mathbf{G}_4{}^{+(nm+1)}) \subseteq E(\mathbf{G}_4{}^{+(n(m+1)+1)})$ for any number m. Thus, there is a number l such that for any $m \geq l$ we have $\mathbf{G}_4{}^{+(nm+1)} = \mathbf{G}_4{}^{+(nl+1)}$. Take

$$\mathbf{G}' = \mathbf{G}_4{}^{+(nl+1)} = \mathbf{G}^{+(4n+1)(nl+1)} = \mathbf{G}_{(4nl+l+4)n+1}$$

and note that, according to the previous paragraphs of this proof, such a digraph satisfies all but the last assertion of the claim. Let m be arbitrary. Then $(\mathbf{G}')^{+(mn+1)} = \mathbf{G}_4{}^{+((mnl+l+m)n+1)} = \mathbf{G}_4{}^{+(nl+1)} = \mathbf{G}'$, and thus $\mathbf{G}'$ can be taken to substitute for $\mathbf{G}$ and the claim is proved. □

From this point on we substitute $\mathbf{G}$ with a digraph provided by the previous claim and fix it together with the number n. For ease of notation we denote the number modulo n using brackets (e.g., $[n+1] = 1$). We already know that the n-tambourine maps homomorphically to $\mathbf{G}$, but we must choose such a homomorphism carefully.

CLAIM 8.3. *The n-tambourine can be mapped homomorphically to $\mathbf{G}$ in such a way that, for some term $t(x_0, \dots, x_{n-1})$ of algebra $\mathbf{A}$,*

$$d'_i = t^{(i)}(w(\overline{d'_0}, d'_1), w(\overline{d'_1}, d'_2), \dots, w(\overline{d'_{n-1}}, d'_0)) \quad \text{for all } i < n,$$

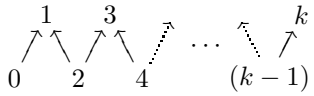
where d'_i is the image of d_i.

Proof. Let $d_i \mapsto d'_i, u_i \mapsto u'_i$ be a homomorphism from the n-tambourine to $\mathbf{G}$. Then, for any i, we have

$$\begin{array}{ccccc} w(\overline{u'_i}, u'_{[i+1]}) & \longrightarrow & w(\overline{u'_{[i+1]}}, u'_{[i+2]}) & \longrightarrow & \cdots \\ \uparrow & \nearrow & \uparrow & \cdots & \\ w(\overline{d'_i}, d'_{[i+1]}) & \longrightarrow & w(\overline{d'_{[i+1]}}, d'_{[i+2]}) & \longrightarrow & \cdots \end{array}$$

and thus $d_i \mapsto w(\overline{d'_i}, d'_{[i+1]}), u_i \mapsto w(\overline{u'_i}, u'_{[i+1]})$ is also a homomorphism from the n-tambourine to $\mathbf{G}$. By repeating this procedure, we obtain an infinite sequence of homomorphisms from the n-tambourine to $\mathbf{G}$, and thus some homomorphism has to appear twice in this sequence. This homomorphism satisfies the claim, since the term $t(x_0, \dots, x_{n-1})$ can be easily obtained as a composition of the polymorphism $w(x_0, \dots, x_{h-1})$ used in the construction of the sequence. □

In the remaining part of the proof we fix vertices $d'_0, \dots, d'_{n-1}, u'_0, \dots, u'_{n-1}$ provided by the previous claim and a term $t(x_0, \dots, x_{n-1})$ associated with them. Let φ_k be the pattern $0 \xrightarrow{\varphi_k} k$



with exactly k edges. (The last edge of the pattern is pointing forward for odd k, as in the above picture, and backward for even k.)

CLAIM 8.4. *The neighborhood $(d'_0)^{\varphi_n}$ contains all vertices of $\mathbf{G}$.*

Proof. Note that, in the n-tambourine, we have

$$(d_0)^{\varphi_n} = \{d_0, \dots, d_{n-1}, u_0, \dots, u_{n-1}\},$$

and thus in the digraph $\mathbf{G}$ we have

$$(d'_0)^{\varphi_n} \supseteq \{d'_0, \dots, d'_{n-1}, u'_0, \dots, u'_{n-1}\}.$$

Let $\mathbf{G}'$ denote the subgraph of $\mathbf{G}$ induced on the set $(d'_0)^{\varphi_n}$. Then, by Corollary 6.2, $\mathbf{G}'$ admits a restriction of $w(x_0, \dots, x_{h-1})$ as a polymorphism and has algebraic length one. Further restricting the digraph $\mathbf{G}'$, denote the largest induced subgraph of $\mathbf{G}'$ without sources or sinks by $\mathbf{G}''$. By Lemma 6.4 $\mathbf{G}''$ admits a weak near unanimity

polymorphism. Moreover, the vertices $\{d'_0, \dots, d'_{n-1}, u'_0, \dots, u'_{n-1}\}$ are among the vertices of $\mathbf{G}''$. Thus $\mathbf{G}''$ is a counterexample to Theorem 8.1 and therefore has to be equal to $\mathbf{G}$. This proves the claim. □

We choose (and fix) k to be a minimal number such that $(d'_0)^{\varphi_{k+1}} = V$. Define $W_i = (d'_i)^{\varphi_k}$, for each $i < n$. We set

$$W = \bigcap_{i<n} W_i,$$

and since W is an intersection of subuniverses of $\mathbf{A}$, by Corollary 6.2, it is itself a subuniverse of $\mathbf{A}$. We denote by $\mathbf{H}$ the subgraph of $\mathbf{G}$ induced by W and prove that $\mathbf{H}$ is a counterexample to Theorem 8.1, contradicting the minimality of $\mathbf{G}$.

The most involved part of the proof deals with constructing a closed realization of a pattern with the algebraic length one in $\mathbf{H}$. Two following claims introduce tools for "projecting" certain walks from $\mathbf{G}$ to $\mathbf{H}$.

CLAIM 8.5. *There exists a term $s(x_0, \dots, x_{p-1})$ of algebra $\mathbf{A}$ such that for every coordinate $q < p$ there exists i such that*

$$s^{(q)}(W_l, W, \dots, W) \subseteq W_{[i-l]} \cap W_{[i-l+1]} \quad \textit{for any } l < n.$$

Proof. Let $p = hn$ and let $s(x_0, \dots, x_{p-1})$ be defined by

$$t\left(w(x_0, \dots, x_{h-1}), w(x_h, \dots, x_{2h-1}), \dots, w(x_{(n-1)h}, \dots, x_{hn-1})\right).$$

For all $q < p$, let i be maximal such that $q = ih + q''$ for some nonnegative q''. Then, for all $l < n$

$$\begin{aligned} s^{(q)}(W_l, \overline{W}) &\subseteq t^{(i)}\left(w^{(q'')}(W_l, \overline{W}), w(\overline{W}), \dots, w(\overline{W})\right) \\ &\subseteq t^{(i)}\left(w^{(q'')}(\overline{W_l}, W_{[l+1]}), w(\overline{W_{[l+1]}}, W_{[l+2]}), \dots, w(\overline{W_{[l+n-1]}}, W_l)\right) \\ &= t^{([i-l])}\left(w(\overline{W_0}, W_1), \dots, w^{(q'')}(\overline{W_l}, W_{[l+1]}), \dots, w(\overline{W_{n-1}}, W_0)\right) \\ &\subseteq W_{[i-l]}, \end{aligned}$$

where the last inclusion follows from Claim 8.3 and the fact that

$$\begin{aligned} d'_{[i-l]} &= t^{([i-l])}(w(\overline{d'_0}, d'_1), \dots, w(\overline{d'_l}, d'_{[l+1]}), \dots, w(\overline{d'_{n-1}}, d'_0)) \\ &= t^{([i-l])}(w(\overline{d'_0}, d'_1), \dots, w^{(q'')}(\overline{d'_l}, d'_{[l+1]}), \dots, w(\overline{d'_{n-1}}, d'_0)). \end{aligned}$$

Similar reasoning shows that

$$\begin{aligned} s^{(q)}(W_l, \overline{W}) &\subseteq t^{(i)}\left(w^{(q'')}(W_l, \overline{W}), w(\overline{W}), \dots, w(\overline{W})\right) \\ &\subseteq t^{(i)}\left(w^{(q'')}(W_l, \overline{W_{[l-1]}}), w(W_{[l+1]}, \overline{W_l}), \dots, w(W_{[l+n-1]}, \overline{W_{[l+n-2]}})\right) \\ &= t^{[i-l+1]}\left(w(W_1, \overline{W_0}), \dots, w^{(q'')}(W_l, \overline{W_{[l-1]}}), \dots, w(W_0, \overline{W_{n-1}})\right) \\ &\subseteq W_{[i-l+1]}, \end{aligned}$$

and the proof is finished. □

Further, using the term constructed in the last claim, we can construct a term satisfying stronger conditions.

CLAIM 8.6. *There exists a term $r(x_0, \dots, x_{m-1})$ of algebra $\mathbf{A}$ such that for every coordinate $q < m$*

$$r^{(q)}\left(\bigcup_{l<n} W_l, W, \dots, W\right) \subseteq W.$$

Proof. Let $s(x_0, \dots, x_{p-1})$ be the p-ary term provided by the previous claim. Note that the term

$$s_2(x_0, x_1, \dots, x_{p^2-1}) = s(s(x_0, \dots, x_{p-1}), \dots, s(x_{p^2-p}, \dots, x_{p^2-1}))$$

has the property that for every coordinate $q < p^2 - 1$ there exists an i such that

$$s_2^{(q)}(W_l, \overline{W}) \subseteq W_{[i-l]} \cap W_{[i-l+1]} \cap W_{[i-l+2]}.$$

To prove a more general statement we recursively define a sequence of terms

- $s_1(x_0, \dots, x_{p-1}) = s(x_0, \dots, x_{p-1})$ and
- $s_{j+1}(x_0, \dots, x_{p^j-1}) = s(s_j(x_0, \dots, x_{p^{j-1}-1}), \dots, s_j(x_{(p-1)p^{j-1}}, \dots, x_{p^j-1}))$.

We claim that for any j, any $q < p^j$, and any $l < n$ there is an i such that

$$s_j^{(q)}\big(W_l, W, \dots, W\big) \subseteq W_{[i-l]} \cap \dots \cap W_{[i-l+j]}.$$

We prove this fact by induction on j. The first step of the induction holds via Claim 8.5. Assume that the fact holds for j; then for any l (setting q' to be the result of integer division of q by p^{j-1}, and q'' the remainder of this division) there exist i and i' such that

$$\begin{aligned} s_{j+1}^{(q)}(W_l, \overline{W}) &\subseteq s^{(q')}\big(s_j^{(q'')}(W_l, \overline{W}), s_j(\overline{W}), \dots, s_j(\overline{W})\big) \\ &\subseteq s^{(q')}\big(W_{[i-l]} \cap \dots \cap W_{[i-l+j]}, \overline{W}\big) \\ &\subseteq W_{[i'+i-l]} \cap \dots \cap W_{[i'+i-l+(j+1)]}, \end{aligned}$$

where the second inclusion follows from the induction step and the last one from Claim 8.5. Setting $r(x_0, \dots, x_{m-1})$ equal to $s_{n-1}(x_0, \dots, x_{p^n-1})$ proves the claim. □

From this point on we fix a term $r(x_0, \dots, x_{m-1})$ (of arity m) provided by the previous claim. To prove additional properties of the set W (e.g., the fact that it is not empty) we require the following easy claim.

CLAIM 8.7. *Let α be a pattern, and let $a_0 \to a_1$ and $b_0 \to b_1$ be edges that belong to closed walks. If $a_0 \xrightarrow{\alpha} b_0$, then $a_1 \xrightarrow{\alpha} b_1$.*

Proof. We prove the claim by induction with respect to the number of edges in α. Let the vertices a_0, a_1, b_0, b_1 be as in the statement of the claim. Assume that $a_0 \to b_0$. If i is the length of the closed walk containing the edge $a_0 \to a_1$, then, following this walk almost n times, $a_1 \xrightarrow{in-1} a_0 \to b_0 \to b_1$ and, by Claim 8.2, $a_1 \to b_1$. The same reasoning can be applied to the case of $a_0 \leftarrow b_0$, and the first step of the induction is proved.

For a pattern α consisting of more than one edge we can assume, without loss of generality, that the last edge is going forward. Then $a_0 \xrightarrow{\alpha'} a_0' \to b_0$ for some vertex a_0' (where α' is the pattern obtained by removing the last edge of α). By Claim 8.2, it follows that a_0' is in a closed walk of length n, and therefore $a_0' \to a_1' \xrightarrow{n-1} a_0'$ for some a_1'. By the induction hypothesis, $a_1 \xrightarrow{\alpha'} a_1'$ and, by the first step of the induction, $a_1' \to b_1$, which proves the claim. □

We recall the definition of the top and bottom components of the graph from subsection 4.3 and prove some basic properties of W.

CLAIM 8.8. *The digraph* $\mathbf{H}$ *has no sources and no sinks and*

1. *if* k *is even, then every bottom component is contained in* W*, and*
2. *if* k *is odd, then every top component is contained in* W*.*

Proof. First we show that, for any vertices a, b such that $a \xrightarrow{i} b \xrightarrow{j} a$ in $\mathbf{G}$ for some i, j,

$$\text{if } a \in W_l, \quad \text{then } b \in W_{[l+i]}.$$

To see this note that if $d'_l \xrightarrow{\varphi_k} a$ and $a \to b \xrightarrow{j} a$, then, using Claim 8.7 and the edge $d'_l \to d'_{[l+1]}$, we infer that $d'_{[l+1]} \xrightarrow{\varphi_k} b$. The same procedure repeated i-many times provides the result for arbitrary i.

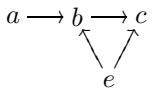
Let $a \in W$ be arbitrary and b be such that $a \xrightarrow{i} b \xrightarrow{j} a$ for some numbers i, j. Since $a \in W$ it follows, using the note above, that $b \in \bigcap_{l<n} W_{[l+i]} = W$, and this implies that W is a union of strong components. Since, by Claim 8.2, every vertex in $\mathbf{G}$ belongs to a closed walk of length n, the digraph $\mathbf{H}$ has no sources or sinks.

Let k be even and let a be a member of a bottom component. Since every vertex of the graph, by Claim 8.2, belongs to a closed walk, there exists b in the bottom component containing a such that $a \to b$. Since $(d'_0)^{\varphi_{k+1}} = V$, we have $d'_0 \xrightarrow{\varphi_{k-1}} c \leftarrow a' \to b$ for some a' and c. The vertex a is in a bottom component, and therefore a' must be a member of the same bottom component. This implies that $a' \to b \xrightarrow{i} a'$, for some i, and following the closed walk containing b almost n times, $a \to b \xrightarrow{n(i+1)-1} a' \to c$. Thus, by Claim 8.2, we have $a \to c$ and $a \in W_0$. Therefore every bottom component is contained in W_0. To see that every a from a bottom component is contained in an arbitrary W_l we find a b satisfying $a \xrightarrow{l} b \xrightarrow{i} a$ for some i and apply the note from the beginning of the proof of the claim. The claim is proved for even k's, and the same reasoning provides a proof for odd k and top components. ∎

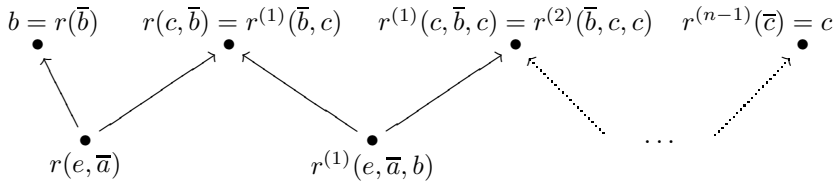
Now we are ready to prove the final claim of this section.

CLAIM 8.9. *The algebraic length of* $\mathbf{H}$ *is one.*

Proof. In the case where k is odd, we want to find $a, b, c \in W$ and $e \in W_0$ such that

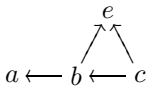


To find such vertices we set $e = d'_1$ and find, using Claim 8.8, $b \in W$ from a top component such that $u'_{[2]} \xrightarrow{in-1} b$ for some i. There exist a and c in the same component (and thus in W by Claim 8.8) such that $a \to b \to c$. Since $d'_1 \xrightarrow{1,2} u'_{[2]}$, we have $e \xrightarrow{in+1} b$ and $e \xrightarrow{in+1} c$, and therefore, by Claim 8.2, the vertices a, b, c, and e satisfy the required properties. Then, using the term $r(x_0, \dots, x_{m-1})$, we produce the following oriented walk:



By Claim 8.6, all the vertices of this walk belong to W. Thus we have constructed an oriented walk in $\mathbf{H}$ realizing a pattern of algebraic length zero connecting b to c. Since $b \to c$ we immediately obtain that the algebraic length of $\mathbf{H}$ is one.

In the case where k is even, we similarly find $a, b, c \in W$ and $e \in W_0$ (using u'_1 for e) such that



The construction of a closed oriented walk realizing a pattern of algebraic length one is the same as it is for odd k, with the exception that the direction of the edges is reversed. □

Thus $\mathbf{H}$ is a digraph without sources or sinks (by Claim 8.8), admitting a weak near unanimity polymorphism and, by the last claim, having algebraic length equal to one. Since, by the definition of W, the number of vertices in $\mathbf{H}$ is strictly smaller than the number of vertices in $\mathbf{G}$, we obtain a contradiction with the minimality of $\mathbf{G}$, and Theorem 8.1 is proved.

SPANNERS OF COMPLETE k-PARTITE GEOMETRIC GRAPHS*

PROSENJIT BOSE†, PAZ CARMI†, MATHIEU COUTURE†, ANIL MAHESHWARI†, PAT MORIN†, AND MICHIEL SMID†

Abstract. We address the following problem: Given a complete k-partite geometric graph K whose vertex set is a set of n points in $\mathbb{R}^d$, compute a spanner of K that has a "small" stretch factor and "few" edges. We present two algorithms for this problem. The first algorithm computes a $(5+\epsilon)$-spanner of K with $O(n)$ edges in $O(n \log n)$ time. The second algorithm computes a $(3+\epsilon)$-spanner of K with $O(n \log n)$ edges in $O(n \log n)$ time. The latter result is optimal: We show that for any $2 \leq k \leq n - \Theta(\sqrt{n \log n})$, spanners with $O(n \log n)$ edges and stretch factor less than 3 do not exist for all complete k-partite geometric graphs.

1. Introduction.

Let S be a set of n points in $\mathbb{R}^d$. A *geometric graph* with vertex set S is an undirected graph H whose edges are line segments $\overline{pq}$ that are weighted by the Euclidean distance $|pq|$ between p and q. For any two points p and q in S, we denote by $\delta_H(p,q)$ the length of a shortest path in H between p and q. For a real number $t \geq 1$, a subgraph G of H is said to be a *t-spanner* of H if $\delta_G(p,q) \leq t \cdot \delta_H(p,q)$ for all points p and q in S. The smallest t for which this property holds is called the *stretch factor* of G. Thus, a subgraph G of H with stretch factor t approximates the $\binom{n}{2}$ pairwise shortest-path lengths in H within a factor of t. If H is the complete geometric graph with vertex set S, then G is also called a t-spanner of the point set S.

Most of the work on constructing spanners has been done for the case when H is the complete graph. It is well known that, for any set S of n points in $\mathbb{R}^d$ and for any real constant $\epsilon > 0$, there exists a $(1+\epsilon)$-spanner of S containing $O(n)$ edges. Moreover, such spanners can be computed in $O(n \log n)$ time; see Salowe [8] and Vaidya [9]. For a detailed overview of results on spanners for point sets, see the book by Narasimhan and Smid [6].

For spanners of arbitrary geometric graphs, much less is known. Althöfer et al. [1] have shown that, for any $t > 1$, every weighted graph H with n vertices contains a subgraph with $O(n^{1+2/(t-1)})$ edges, which is a t-spanner of H. Observe that this result holds for any weighted graph; in particular, it is valid for any geometric graph. For geometric graphs, a lower bound was given by Gudmundsson and Smid [5]: They proved that, for every real number t with $1 < t < \frac{1}{4} \log n$, there exists a geometric graph H with n vertices, such that every t-spanner of H contains $\Omega(n^{1+1/t})$ edges. Thus, if we are looking for spanners with $O(n)$ edges of arbitrary geometric graphs, then the best stretch factor we can obtain is $\Theta(\log n)$.

In this paper, we consider the case when the input graph is a complete k-partite geometric graph. Let S be a set of n points in $\mathbb{R}^d$, and let S be partitioned into

subsets $C_1, C_2, \ldots, C_k$. Let $K_{C_1 \ldots C_k}$ denote the *complete k-partite graph on S*. This graph has S as its vertex set, and two points p and q are connected by an edge (of length $|pq|$) if and only if p and q are in different subsets of the partition. The problem we address is formally defined as follows.

PROBLEM 1.1. *Let $k \geq 2$ be an integer, let S be a set of n points in $\mathbb{R}^d$, and let S be partitioned into k subsets $C_1, C_2, \ldots, C_k$. Compute a t-spanner of the complete k-partite graph $K_{C_1 \ldots C_k}$ that has a "small" number of edges and whose stretch factor t is "small."*

The main contribution of this paper is to present an algorithm that computes such a t-spanner with $O(n)$ edges in $O(n \log n)$ time, where $t = 5+\epsilon$ for any constant $\epsilon > 0$. We also show that if one is willing to use $O(n \log n)$ edges, then our algorithm adapts easily to reach a stretch factor of $t = 3 + \epsilon$. Finally, we show that the latter result is optimal: For any k with $2 \leq k \leq n - \Theta(\sqrt{n \log n})$, spanners with $O(n \log n)$ edges and stretch factor less than 3 do not exist for all complete k-partite geometric graphs.

We remark that, in a recent paper, Bose et al. [2] considered the problem of constructing spanners of point sets that have $O(n)$ edges and whose chromatic number is at most k. This problem is different from ours: Bose et al. compute a spanner of the complete graph, and their algorithm can choose a "good" k-partition of the vertices. In our problem, the k-partition is given, and we want to compute a spanner of the complete k-partite graph.

Possible applications of our algorithm are in wireless networks having the property that communicating nodes are partitioned into sets such that two nodes can communicate if and only if they do not belong to the same set. This would be the case, for example, when time division multiplexing (TDMA) is used. Since the wireless medium prohibits simultaneous transmission and reception at one node, two nodes communicating during the same time slots cannot communicate with each other. For more details, we refer to Raman and Chebrolu [7]; see also Bose et al. [2].

The rest of this paper is organized as follows. In section 2, we recall properties of the well-separated pair decomposition (WSPD) that we use in our algorithm. In section 3, we provide an algorithm that solves the problem of constructing a spanner of the complete k-partite graph. In section 4, we show that the spanner constructed by this algorithm has $O(n)$ edges and that its stretch factor is bounded from above by a constant that depends only on the dimension d. In section 5, we show how a simple modification to our algorithm improves the stretch factor to $5 + \epsilon$ while still having $O(n)$ edges. In section 6, we show how to achieve a stretch factor of $3 + \epsilon$ using $O(n \log n)$ edges. We also prove that the latter result is optimal. We conclude in section 7.

2. The well-separated pair decomposition. In this section, we recall crucial properties of the WSPD of Callahan and Kosaraju [4] that we use for our construction. The reader who is familiar with the WSPD may go directly to section 3. Our presentation follows the one in Narasimhan and Smid [6]. Intuitively, a WSPD is a partition of the edges of a complete geometric graph such that all edges that are grouped together are *approximately* equal. To give a formal definition of the WSPD, we first need to define what it means for two sets to be well separated.

DEFINITION 2.1. *Let S be a set of points in $\mathbb{R}^d$. The* bounding box $\beta(S)$ *of S is the smallest axes-parallel hyperrectangle that contains S.*

DEFINITION 2.2. *Let X and Y be two sets of points in $\mathbb{R}^d$ and let $s > 0$ be a real number. We say that X and Y are* well separated *with respect to s if there exist two*

balls B_1 and B_2 such that

1. *B_1 and B_2 have the same radius, say ρ,*
2. *B_1 contains the bounding box of X,*
3. *B_2 contains the bounding box of Y, and*
4. *the distance $\min\{|xy| : x \in B_1, y \in B_2\}$ between B_1 and B_2 is at least $s\rho$.*

DEFINITION 2.3. *Let S be a set of points in $\mathbb{R}^d$ and let $s > 0$ be a real number. A* WSPD of S with separation constant s *is a set of unordered pairs of subsets of S that are well separated with respect to s such that for any two distinct points $p, q \in S$ there is a unique pair $\{X, Y\}$ in the WSPD such that $p \in X$ and $q \in Y$.*

LEMMA 2.4 (Lemma 9.1.2 in [6]). *Let $s > 0$ be a real number and let X and Y be two-point sets that are well separated with respect to s.*

1. *If $p, p', p'' \in X$ and $q \in Y$, then $|p'p''| \leq (2/s)|pq|$.*
2. *If $p, p' \in X$ and $q, q' \in Y$, then $|p'q'| \leq (1 + 4/s)|pq|$.*

The first part of this lemma states that distances within one set are very small compared to distances between pairs of points having one endpoint in each set. The second part states that all pairs of points having one endpoint in each set have approximately the same distance.

Callahan and Kosaraju [3] have shown how to construct a t-spanner of S from a WSPD: All one has to do is pick from each pair $\{X, Y\}$ an arbitrary edge (p, q) with $p \in X$ and $q \in Y$. Using induction on the rank of the length of the edges in the complete graph K_S, it can be shown that, when $s > 4$, this process leads to a $((s+4)/(s-4))$-spanner. Thus, by choosing s to be a sufficiently large constant, the stretch factor can be made arbitrarily close to 1.

In order to compute a spanner of S that has a linear number of edges, one needs a WSPD that has a linear number of pairs. Callahan and Kosaraju [4] showed that a WSPD with a linear number of pairs always exists and can be computed in time $O(n \log n)$. Their algorithm uses a split-tree.

DEFINITION 2.5. *Let S be a nonempty set of points in $\mathbb{R}^d$. The* split-tree *of S is defined as follows: If S contains only one point, then the split-tree is a single node that stores that point. Otherwise, the split-tree has a root that stores the bounding box $\beta(S)$ of S, as well as an arbitrary point of S called the* representative *of S and denoted by rep(S). Split $\beta(S)$ into two hyperrectangles by cutting its longest interval into two equal parts, and let S_1 and S_2 be the subsets of S contained in the two hyperrectangles. The root of the split-tree of S has two subtrees, which are recursively defined split-trees of S_1 and S_2.*

The precise way Callahan and Kosaraju used the split-tree to compute a WSPD with a linear number of pairs is of no importance to us. The only important aspect we need to retain is that each pair is uniquely determined by a pair of nodes in the tree. More precisely, for each pair $\{X, Y\}$ in the WSPD that is output by their algorithm, there are unique internal nodes u and v in the split-tree such that the sets S_u and S_v of points stored at the leaves of the subtrees rooted at u and v are precisely X and Y. Since there is such a unique correspondence, we will denote pairs in the WSPD by $\{S_u, S_v\}$, meaning that u and v are the nodes corresponding to the sets $X = S_u$ and $Y = S_v$. Also, although the WSPD of a point set is not unique, when we talk about *the* WSPD, we mean the WSPD that is computed by the algorithm of Callahan and Kosaraju.

Before we present our algorithm, we give the statement of the following lemmas that we use to analyze our algorithm in section 4. If R is an axes-parallel hyperrectangle in $\mathbb{R}^d$, then we use $L_{\max}(R)$ to denote the length of a longest side of R.

LEMMA 2.6 (Lemma 9.5.3 in [6]). *Let u be a node in the split-tree and let u' be a node in the subtree of u such that the path between them contains at least d edges. Then*

$$L_{\max}(\beta(S_{u'})) \leq \frac{1}{2} \cdot L_{\max}(\beta(S_u)).$$

LEMMA 2.7 (Lemma 11.3.1 in [6]). *Let $\{S_u, S_v\}$ be a pair in the WSPD, let ℓ be the distance between the centers of $\beta(S_u)$ and $\beta(S_v)$, and let $\pi(u)$ be the parent of u in the split-tree. Then*

$$L_{\max}(\beta(S_{\pi(u)})) \geq \frac{2\ell}{\sqrt{d}(s+4)}.$$

3. A first algorithm. We now show how the WSPD can be used to address the problem of computing a spanner of a complete k-partite graph. In this section, we introduce an algorithm that outputs a graph with constant stretch factor and $O(n)$ edges. The analysis of this algorithm is presented in section 4. In section 5, we show how this algorithm can be improved to achieve a stretch factor of $5 + \epsilon$.

The input set $S \subseteq \mathbb{R}^d$ is the disjoint union of k sets $C_1, C_2, \ldots, C_k$. We say that the elements of C_c have "color" c. The graph $K = K_{C_1 \ldots C_k}$ is the complete k-partite geometric graph.

DEFINITION 3.1. *Let T be the split-tree of S that is used to compute the WSPD of S.*

1. *For any node u in T, we denote by S_u the set of all points in the subtree rooted at u.*
2. *We define MWSPD to be the subset of the WSPD obtained by removing all pairs $\{S_u, S_v\}$ for which all points of $S_u \cup S_v$ have the same color.*
3. *A node u in T is called* multichromatic *if there exist points p and q in S_u and a node v in T such that p and q have different colors and $\{S_u, S_v\}$ is in the MWSPD.*
4. *A node u in T is called a c-*node *if all points of S_u have color c and there exists a node v in T such that $\{S_u, S_v\}$ is in the MWSPD.*
5. *A c-node u in T is called a c-*root *if it does not have a proper ancestor that is a c-node in T.*
6. *A c-node u in T is called a c-*leaf *if it does not have another c-node in its subtree.*
7. *A c-node u' in T is called a c-*child *of a c-node u in T if u' is in the subtree rooted at u and there is no c-node on the path strictly between u and u'. In this case, we also say that u is a c-*parent *of u'.*
8. *For each color c and for each c-node u in T, $rep(S_u)$ denotes a fixed arbitrary point in S_u.*
9. *For each multichromatic node u in T, $rep(S_u)$ and $rep'(S_u)$ denote two fixed arbitrary points in S_u that have different colors.*
10. *The* distance *between two sets S_v and S_w, denoted by $dist(S_v, S_w)$, is defined to be the distance between the centers of their bounding boxes.*
11. *Let u be a c-node in T. Consider all pairs $\{S_v, S_w\}$ in the MWSPD, where v is a c-node on the path in T from u to the root (this path includes u). Let $\{S_v, S_w\}$ be such a pair for which $dist(S_v, S_w)$ is minimum. We define $cl(S_u)$ to be the set S_w.*

Algorithm 1 computes a spanner of a complete k-partite geometric graph $K = K_{C_1 \ldots C_k}$. The intuition behind this algorithm is the following. First, the algorithm

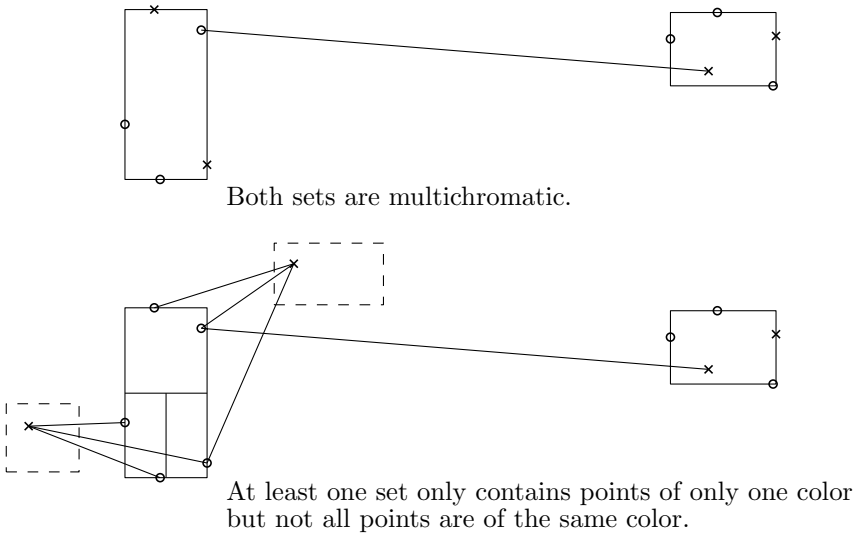

FIG. 1. *The two cases of Algorithm* 1.

computes the MWSPD. Then, it considers each pair $\{S_u, S_v\}$ of the MWSPD and decides whether or not to add an edge between S_u and S_v. The outcome of this decision is based on the following two cases, which are illustrated in Figures 1 and 2.

Case 1. Both S_u and S_v are multichromatic. In this case, Algorithm 1 adds one edge between S_u and S_v to the spanner; see lines 28–29. Observe that the two vertices of this edge do not have the same color. This edge will allow us to approximate each edge (p, q) of K, where $p \in S_u$, $q \in S_v$, and p and q have different colors.

Case 2. All points in S_u are of the same color c. In this case, an edge is added between $\text{rep}(S_u)$ and a representative of S_v whose color is not c; see lines 17–18. In order to approximate each edge of K having one vertex (of color c) in S_u and the other vertex (of a different color) in S_v, more edges have to be added. This is done in such a way that our final graph contains a "short" path between every point p of S_u and the representative $\text{rep}(S_u)$ of S_u. Observe that this path must contain points whose color is not equal to c; thus, these points are not in S_u. One way to achieve this is to add an edge between each point of S_u and a representative of $\text{cl}(S_u)$ whose color is not c; we call this construction a *star*. However, since the subtree rooted at u may contain other c-nodes, many edges may be added for each point in S_u, which could possibly lead to a quadratic number of edges in the final graph. To guarantee that the algorithm does not add too many edges, it introduces a star only if u is a c-leaf; see lines 8–11. If u is a c-node, the algorithm adds only one edge between $\text{rep}(S_u)$ and a representative of $\text{cl}(S_u)$ whose color is not c; see lines 14–15. Then, the algorithm links each c-node u'' that is not a c-root to its c-parent u'. This is done through an edge between $\text{rep}(S_{u''})$ and a representative of $\text{cl}(S_{u'})$ whose color is not c; see lines 21–22. This second case is illustrated in Figure 2.

4. Analysis of Algorithm 1.

LEMMA 4.1. *The graph G computed by Algorithm* 1 *has $O(|S|)$ edges.*

Proof. For each color c and for each c-leaf u', the algorithm adds $|S_{u'}|$ edges to G in lines 9–10. Since the sets $S_{u'}$, where u' ranges over all c-leaves and c ranges over

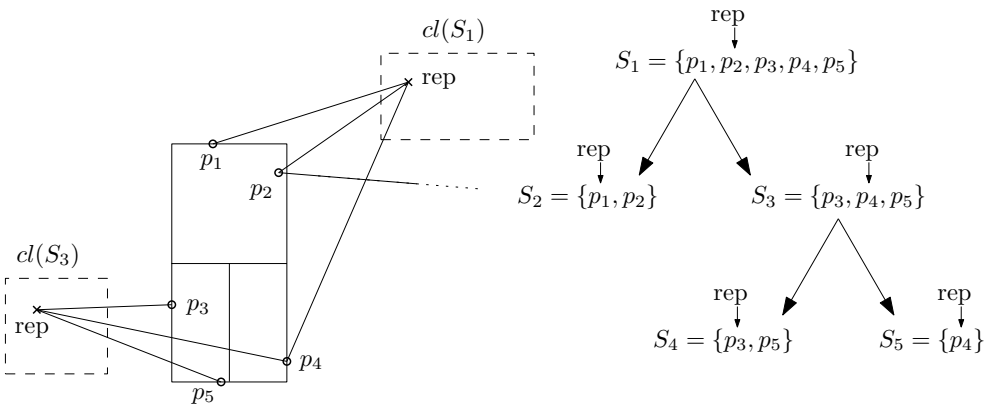

FIG. 2. *Handling a c-node.*

all colors, are pairwise disjoint, the total number of edges that are added in lines 9–10 is $O(|S|)$.

The total number of edges that are added in lines 17–18 and 28–29 is at most the number of pairs in the MWSPD. Since the WSPD contains $O(|S|)$ pairs (see [4]), the same upper bound holds for the number of edges added in lines 17–18 and 28–29.

The total number of edges that are added in lines 14–15 and 21–22 is at most twice the number of nodes in the split-tree, which is $O(|S|)$. □

LEMMA 4.2. *Let G be the graph computed by Algorithm* 1. *Let p and q be two points of S with different colors, and let $\{S_u, S_v\}$ be the pair in the MWSPD for which $p \in S_u$ and $q \in S_v$. Assume that u is a c-node for some color c. Then there is a path in G between p and $rep(S_u)$ whose length is at most $t'|pq|$, where*

$$t' = 4\sqrt{d}(\mu d + 1)(1 + 4/s)^3,$$

$$\mu = \left\lceil \log\left(\sqrt{d}(1 + 4/s)\right)\right\rceil + 1,$$

and s is the separation constant of the WSPD.

Proof. Let w be the c-leaf such that $p \in S_w$, and let $w = w_0, \ldots, w_k = u$ be the sequence of c-nodes that are on the path in T from w to u.

Recall from Definition 3.1 that each set S_{w_i}, $0 \le i \le k$, has a representative $\mathrm{rep}(S_{w_i})$ (of color c) associated with it. Also, recall the definition of the sets $\mathrm{cl}(S_{w_i})$, $0 \le i \le k$; see Definition 3.1. If $\mathrm{cl}(S_{w_i})$ is a c'-node for some color c', then this set has one representative $\mathrm{rep}(\mathrm{cl}(S_{w_i}))$ associated with it. Otherwise, $\mathrm{cl}(S_{w_i})$ is multichromatic, and this set has two representatives $\mathrm{rep}(\mathrm{cl}(S_{w_i}))$ and $\mathrm{rep}'(\mathrm{cl}(S_{w_i}))$ of different colors associated with it. We may assume without loss of generality that, for all $0 \le i \le k$, the color of $\mathrm{rep}(\mathrm{cl}(S_{w_i}))$ is not equal to c.

Let Π be the path

$$\begin{array}{rcccl} p & \to & \mathrm{rep}(\mathrm{cl}(S_{w_0})) & \to & \mathrm{rep}(S_{w_0}) \\ & \to & \mathrm{rep}(\mathrm{cl}(S_{w_1})) & \to & \mathrm{rep}(S_{w_1}) \\ & \vdots & & \vdots & \\ & \to & \mathrm{rep}(\mathrm{cl}(S_{w_k})) & \to & \mathrm{rep}(S_{w_k}) \quad = \quad \mathrm{rep}(S_u). \end{array}$$

Even though we use arrows to define this path, we remark that the graph G and, therefore, the path Π, is undirected.

ALGORITHM 1: Computing a sparse subgraph of $K_{C_1 \ldots C_k}$ whose stretch factor is bounded by a constant.

Input: A set S of points in $\mathbb{R}^d$, which is partitioned into k subsets $C_1, \ldots, C_k$.
Output: A spanner $G = (S, E)$ of the complete k-partite graph $K_{C_1 \ldots C_k}$.

```
1  compute the split-tree T of S;
2  using T, compute the WSPD with respect to a separation constant s > 0;
3  using the WSPD, compute the MWSPD;
4  E ← ∅;
5  for each color c in {1, 2, ..., k} do
6      for each c-root u in T do
7          for each c-leaf u' in the subtree of u do
8              for each p ∈ S_u' do
9                  if rep(cl(S_u')) does not have color c, then add (p, rep(cl(S_u'))) to E;
10                 else add (p, rep'(cl(S_u'))) to E;
11             end
12         end
13         for each c-node u' that is in the subtree of u (including u) do
14             if rep(cl(S_u')) does not have color c, then add (rep(S_u'), rep(cl(S_u'))) to
               E;
15             else add (rep(S_u'), rep'(cl(S_u'))) to E;
16             for each pair {S_u', S_v'} in the MWSPD do
17                 if rep(S_v') does not have color c, then add (rep(S_u'), rep(S_v')) to E;
18                 else add (rep(S_u'), rep'(S_v')) to E;
19             end
20             for each c-child u'' of u' do
21                 if rep(cl(S_u')) does not have color c, then add
                   (rep(S_u''), rep(cl(S_u'))) to E;
22                 else add (rep(S_u''), rep'(cl(S_u'))) to E;
23             end
24         end
25     end
26 end
27 for each {S_u, S_v} in the MWSPD for which both u and v are multichromatic do
28     if rep(S_u) and rep(S_v) have distinct colors, then add (rep(S_u), rep(S_v)) to E;
29     else add (rep(S_u), rep'(S_v)) to E;
30 end
31 return the graph G = (S, E)
```

The first edge on the path Π, i.e., $(p, \mathrm{rep}(\mathrm{cl}(S_{w_0})))$, is added to the graph G in lines 9–10 of the algorithm. The edges $(\mathrm{rep}(\mathrm{cl}(S_{w_i})), \mathrm{rep}(S_{w_i}))$, $0 \le i \le k$, are added to G in lines 14–15. Finally, the edges $(\mathrm{rep}(S_{w_{i-1}}), \mathrm{rep}(\mathrm{cl}(S_{w_i})))$, $1 \le i \le k$, are added to G in lines 21–22. It follows that Π is a path in G between p and $\mathrm{rep}(S_u)$. In the rest of the proof, we will show that the length of Π is at most $t'|pq|$.

Let i be an integer with $0 \le i \le k$. Recall the definition of $\mathrm{cl}(S_{w_i})$; see Definition 3.1: We consider all pairs $\{S_x, S_y\}$ in the MWSPD, where x is a c-node on the path in T from w_i to the root, and pick the pair for which $\mathrm{dist}(S_x, S_y)$ is minimum. We denote the pair picked by (S_{x_i}, S_{y_i}). Thus, x_i is a c-node on the path in T from w_i to the root, $\{S_{x_i}, S_{y_i}\}$ is a pair in the MWSPD, and $\mathrm{cl}(S_{w_i}) = S_{y_i}$. We define

$$\ell_i = \mathrm{dist}(S_{x_i}, S_{y_i}).$$

We start by proving an upper bound on the length of Π in terms of $\ell_0, \ell_1, \ldots, \ell_k$. Consider the first edge $(p, \text{rep}(\text{cl}(S_{w_0})))$ on the path Π. Since $p \in S_{w_0} \subseteq S_{x_0}$ and $\text{rep}(\text{cl}(S_{w_0})) \in S_{y_0}$, it follows from Lemma 2.4 that

$$|p, \text{rep}(\text{cl}(S_{w_0}))| \leq (1 + 4/s) \cdot \text{dist}(S_{x_0}, S_{y_0}) = (1 + 4/s)\ell_0.$$

Let $0 \leq i \leq k$ and consider the edge $(\text{rep}(\text{cl}(S_{w_i})), \text{rep}(S_{w_i}))$ on Π. Since $\text{rep}(S_{w_i}) \in S_{w_i} \subseteq S_{x_i}$ and $\text{rep}(\text{cl}(S_{w_i})) \in S_{y_i}$, it follows from Lemma 2.4 that

$$|\text{rep}(\text{cl}(S_{w_i})), \text{rep}(S_{w_i})| \leq (1 + 4/s) \cdot \text{dist}(S_{x_i}, S_{y_i}) = (1 + 4/s)\ell_i. \tag{4.1}$$

Let $1 \leq i \leq k$ and consider the edge $(\text{rep}(S_{w_{i-1}}), \text{rep}(\text{cl}(S_{w_i})))$ on Π. Since $\text{rep}(S_{w_{i-1}}) \in S_{w_{i-1}} \subseteq S_{x_i}$ and $\text{rep}(\text{cl}(S_{w_i})) \in S_{y_i}$, it follows from Lemma 2.4 that

$$|\text{rep}(S_{w_{i-1}}), \text{rep}(\text{cl}(S_{w_i}))| \leq (1 + 4/s) \cdot \text{dist}(S_{x_i}, S_{y_i}) = (1 + 4/s)\ell_i.$$

Thus, the length of the path Π is at most

$$\sum_{i=0}^{k} 2(1 + 4/s)\ell_i.$$

Therefore, it is sufficient to prove that

$$\sum_{i=0}^{k} \ell_i \leq 2\sqrt{d}(\mu d + 1)(1 + 4/s)^2|pq|.$$

Next, we prove an upper bound on ℓ_k in terms of $|pq|$. As a result, we will obtain an inequality (see (4.3) below) which implies the above inequality.

It follows from the definition of $\text{cl}(S_u) = \text{cl}(S_{w_k})$ that

$$\ell_k = \text{dist}(S_{x_k}, S_{y_k}) \leq \text{dist}(S_u, S_v).$$

Since, by Lemma 2.4, $\text{dist}(S_u, S_v) \leq (1 + 4/s)|pq|$, it follows that

$$\ell_k \leq (1 + 4/s)|pq|. \tag{4.2}$$

Thus, it is sufficient to prove that

$$\sum_{i=0}^{k} \ell_i \leq 2\sqrt{d}(\mu d + 1)(1 + 4/s)\ell_k. \tag{4.3}$$

For each i with $0 \leq i \leq k$, we define

$$a_i = L_{\max}(\beta(S_{w_i}));$$

i.e., a_i is the length of a longest side of the bounding box of S_{w_i}.

We now present an outline of the rest of the proof (which consists of proving (4.3)). As we will see below, Lemma 2.4 implies that (i) $a_i \leq \frac{2}{s}\ell_i$. It follows from Lemma 2.6 that (ii) $a_i \leq \frac{1}{2}a_{i+d}$. Finally, we will show that Lemma 2.7 implies that (iii) $\ell_i \leq \frac{\sqrt{d}(s+4)}{2}a_{i+1}$. By combining (i), (ii), and (iii), we obtain the inequality $\ell_i \leq \frac{1}{2}\ell_{i+1+\mu d}$, where μ is defined in the statement of the lemma. This allows us to split the summation $\sum_{i=0}^{k} \ell_i$ into $\mu d + 1$ geometric series. The final step is then

to prove that the total sum of these geometric series is at most the quantity on the right-hand side in (4.3). This approach makes sense only if k is sufficiently large. For small values of k, we will prove (4.3) by a direct argument.

We now present the details. If $k = 0$, then (4.3) obviously holds. Assume from now on that $k \geq 1$. Let $0 \leq i \leq k$. It follows from Lemma 2.4 that

$$L_{\max}(\beta(S_{x_i})) \leq \frac{2}{s}\ell_i.$$

Since w_i is in the subtree of x_i, we have $L_{\max}(\beta(S_{w_i})) \leq L_{\max}(\beta(S_{x_i}))$. Thus, we have

$$a_i \leq \frac{2}{s}\ell_i \quad \text{for } 0 \leq i \leq k. \tag{4.4}$$

Lemma 2.6 states that

$$a_i \leq \frac{1}{2}a_{i+d} \quad \text{for } 0 \leq i \leq k-d. \tag{4.5}$$

Let $0 \leq i \leq k-1$. Since w_i is a c-node, there is a node w_i' such that $\{S_{w_i}, S_{w_i'}\}$ is a pair in the MWSPD. Then it follows from the definition of $\mathrm{cl}(S_{w_i})$ that

$$\ell_i = \mathrm{dist}(S_{x_i}, S_{y_i}) \leq \mathrm{dist}(S_{w_i}, S_{w_i'}).$$

By applying Lemma 2.7, we obtain

$$\begin{aligned}\mathrm{dist}(S_{w_i}, S_{w_i'}) &\leq \frac{\sqrt{d}(s+4)}{2}\, L_{\max}(\beta(S_{\pi(w_i)})) \\ &\leq \frac{\sqrt{d}(s+4)}{2}\, L_{\max}(\beta(S_{w_{i+1}})) \\ &= \frac{\sqrt{d}(s+4)}{2}\, a_{i+1}.\end{aligned}$$

Thus, we have

$$\ell_i \leq \frac{\sqrt{d}(s+4)}{2}\, a_{i+1} \quad \text{for } 0 \leq i \leq k-1. \tag{4.6}$$

Recall the integer μ as defined in the statement of the lemma. First assume that $1 \leq k \leq \mu d$. Let $0 \leq i \leq k-1$. By using (4.6), the fact that the sequence $a_0, a_1, \ldots, a_k$ is nondecreasing, and (4.4), we obtain

$$\ell_i \leq \frac{\sqrt{d}(s+4)}{2}\, a_{i+1} \leq \frac{\sqrt{d}(s+4)}{2}\, a_k \leq \sqrt{d}\left(1 + \frac{4}{s}\right)\ell_k.$$

Therefore,

$$\sum_{i=0}^{k} \ell_i \leq k\sqrt{d}(1+4/s)\ell_k + \ell_k \leq (k+1)\sqrt{d}(1+4/s)\ell_k \leq (\mu d+1)\sqrt{d}(1+4/s)\ell_k,$$

which is less than the right-hand side in (4.3).

It remains to consider the case when $k > \mu d$. Let $i \geq 0$ and $j \geq 0$ be integers such that $i + 1 + jd \leq k$. By applying (4.6) once, (4.5) j times, and (4.4) once, we obtain

$$\ell_i \leq \frac{\sqrt{d}(s+4)}{2}\, a_{i+1} \leq \frac{\sqrt{d}(s+4)}{2} \left(\frac{1}{2}\right)^j a_{i+1+jd} \leq \sqrt{d}\left(1+\frac{4}{s}\right)\left(\frac{1}{2}\right)^j \ell_{i+1+jd}.$$

For $j = \mu = \lceil \log(\sqrt{d}(1+4/s)) \rceil + 1$, this implies that, for $0 \leq i \leq k-1-\mu d$,

$$\ell_i \leq \frac{1}{2}\ell_{i+1+\mu d}. \tag{4.7}$$

By rearranging the terms in the summation in (4.3), we obtain

$$\sum_{i=0}^{k} \ell_i = \sum_{h=0}^{\mu d} \sum_{j=0}^{\lfloor (k-h)/(\mu d+1) \rfloor} \ell_{k-h-j(\mu d+1)}.$$

Let j be such that $0 \leq j \leq \lfloor (k-h)/(\mu d+1) \rfloor$. By applying (4.7) j times, we obtain

$$\ell_{k-h-j(\mu d+1)} \leq \left(\frac{1}{2}\right)^j \ell_{k-h}.$$

It follows that

$$\sum_{j=0}^{\lfloor (k-h)/(\mu d+1) \rfloor} \ell_{k-h-j(\mu d+1)} \leq \sum_{j=0}^{\infty} \left(\frac{1}{2}\right)^j \ell_{k-h} = 2\ell_{k-h}.$$

Thus, we have

$$\sum_{i=0}^{k} \ell_i \leq 2 \sum_{h=0}^{\mu d} \ell_{k-h}.$$

By applying (4.6) and the fact that the sequence $a_0, a_1, \ldots, a_k$ is nondecreasing, followed by (4.4), we obtain, for $0 \leq i \leq k-1$ and $1 \leq j \leq k-i$,

$$\ell_i \leq \frac{\sqrt{d}(s+4)}{2}\, a_{i+1} \leq \frac{\sqrt{d}(s+4)}{2}\, a_{i+j} \leq \sqrt{d}\left(1+\frac{4}{s}\right)\ell_{i+j}.$$

Obviously, the inequality $\ell_i \leq \sqrt{d}(1+4/s)\ell_{i+j}$ also holds for $j = 0$. Thus, for $i = k-h$ and $j = h$, we get

$$\ell_{k-h} \leq \sqrt{d}(1+4/s)\ell_k \quad \text{for } 0 \leq h \leq \mu d.$$

It follows that

$$\sum_{i=0}^{k} \ell_i \leq 2 \sum_{h=0}^{\mu d} \sqrt{d}(1+4/s)\ell_k = 2\sqrt{d}(\mu d+1)(1+4/s)\ell_k,$$

completing the proof that (4.3) holds. □

LEMMA 4.3. *Assuming that the separation constant s of the WSPD is chosen sufficiently large, the graph G computed by Algorithm 1 is a t-spanner of the complete k-partite graph $K_{C_1 \ldots C_k}$, where $t = 2t' + 1 + 4/s$ and t' is as in Lemma 4.2.*

Proof. We denote the graph $K_{C_1 \ldots C_k}$ by K. It suffices to show that for each edge (p, q) of K, the graph G contains a path between p and q of length at most $t|pq|$. We will prove this by induction on the lengths of the edges in K.

Let p and q be two points of S with different colors, and let $\{S_u, S_v\}$ be the pair in the MWSPD for which $p \in S_u$ and $q \in S_v$.

The base case is when (p, q) is a shortest edge in K. Since $s > 2$, it follows from Lemma 2.4 that u is a c-node and v is a c'-node, for some colors c and c' with $c \neq c'$. In line 17 of Algorithm 1, the edge $(\mathrm{rep}(S_u), \mathrm{rep}(S_v))$ is added to G. By Lemma 2.4, the length of this edge is at most $(1 + 4/s)|pq|$. The claim follows from two applications of Lemma 4.2 to get from p to $\mathrm{rep}(S_u)$ and from $\mathrm{rep}(S_v)$ to q.

In the induction step, we distinguish four cases.

Case 1. u is a c-node and v is a c'-node, for some colors c and c' with $c \neq c'$.

This case is identical to the base case.

Case 2. u is a c-node for some color c and v is a multichromatic node.

In lines 17–18, the edge $(\mathrm{rep}(S_u), \mathrm{rep}(S_v))$ or $(\mathrm{rep}(S_u), \mathrm{rep}(S'_v))$ is added to G. We may assume without loss of generality that $(\mathrm{rep}(S_u), \mathrm{rep}(S_v))$ is added. By Lemma 2.4, the length of this edge is at most $(1 + 4/s)|pq|$.

By Lemma 4.2, there is a path in G between p and $\mathrm{rep}(S_u)$ whose length is at most $t'|pq|$.

First assume that q and $\mathrm{rep}(S_v)$ have the same color. Let r be a point in S_v that has a color different from q's color. Since $s > 2$, it follows from Lemma 2.4 that $|qr| < |pq|$. Thus, by induction, there is a path in G between q and r whose length is at most $t|qr|$, which, by Lemma 2.4, is at most $(2t/s)|pq|$. By a similar argument, since $|r, \mathrm{rep}(S_v)| < |pq|$, there is a path in G between r and $\mathrm{rep}(S_v)$ whose length is at most $(2t/s)|pq|$. Thus, G contains a path between q and $\mathrm{rep}(S_v)$ of length at most $(4t/s)|pq|$. If q and $\mathrm{rep}(S_v)$ have different colors, then, by induction, there is a path in G between q and $\mathrm{rep}(S_v)$ whose length is at most $(2t/s)|pq| < (4t/s)|pq|$.

Thus, the graph G contains a path between q and $\mathrm{rep}(S_v)$ of length at most $(4t/s)|pq|$.

We have shown that there is a path in G between p and q whose length is at most

$$(t' + (1 + 4/s) + 4t/s)\,|pq|. \tag{4.8}$$

By choosing s sufficiently large, this quantity is at most $t|pq|$.

Case 3. u is a multichromatic node and v is a c-node for some color c.

This case is symmetric to Case 2.

Case 4. Both u and v are multichromatic nodes.

In lines 28–29, the edge $(\mathrm{rep}(S_u), \mathrm{rep}(S_v))$ or $(\mathrm{rep}(S_u), \mathrm{rep}(S'_v))$ is added to G. We may assume without loss of generality that $(\mathrm{rep}(S_u), \mathrm{rep}(S_v))$ is added. By Lemma 2.4, the length of this edge is at most $(1 + 4/s)|pq|$.

As in Case 2, the graph G contains a path between p and $\mathrm{rep}(S_u)$ of length at most $(4t/s)|pq|$ and a path between q and $\mathrm{rep}(S_v)$ of length at most $(4t/s)|pq|$.

It follows that there is a path in G between p and q whose length is at most

$$((1 + 4/s) + 8t/s)\,|pq|. \tag{4.9}$$

By choosing s sufficiently large, this quantity is at most $t|pq|$. □

LEMMA 4.4. *The running time of Algorithm* 1 *is* $O(n \log n)$, *where* $n = |S|$.

Proof. Using the results of Callahan and Kosaraju [4], the split-tree T and the WSPD can be computed in $O(n \log n)$ time. The representatives of all sets S_u and all sets $\mathrm{cl}(S_u)$ can be computed in $O(n)$ time by traversing the split-tree in postorder

and preorder, respectively. The time for the rest of the algorithm, i.e., lines 3–31, is proportional to the sum of the size of T, the number of pairs in the WSPD, and the number of edges in the graph G. Thus, the rest of the algorithm takes $O(n)$ time. □

To summarize, we have shown the following: For any complete k-partite geometric graph K whose vertex set has size n, Algorithm 1 computes a t-spanner of K having $O(n)$ edges, where t is given in Lemma 4.3. The running time of this algorithm is $O(n \log n)$. By choosing the separation constant s sufficiently large, the stretch factor t converges to

$$8\sqrt{d}\left(d\left\lceil\frac{1}{2}\log d\right\rceil + d + 1\right) + 1.$$

In the next section, we show how to modify the algorithm so that the bound in Lemma 4.2 is reduced, thus improving the stretch factor. The price to pay is in the number of edges in G; however, it is still $O(n)$.

5. An improved algorithm. As before, we are given a set S of n points in $\mathbb{R}^d$ which is partitioned into k subsets $C_1, C_2, \ldots, C_k$. Intuitively, the way to improve the bound of Lemma 4.2 is by adding shortcuts along the path from each c-leaf to the c-root above it. More precisely, from (4.7) in the proof of Lemma 4.2, we know that if we go $1 + \mu d$ levels up in the split-tree T, then the length of the edge along the path doubles. Thus, for each c-node in T, we will add edges to all $2\delta(1 + \mu d)$ c-nodes above it in T. Here, δ is an integer constant that is chosen such that the best result is obtained in the improved bound.

DEFINITION 5.1. *Let $c \in \{1, 2, \ldots, k\}$, and let u and u' be c-nodes in the split-tree T such that u' is in the subtree rooted at u. For any integer $\zeta \geq 1$, we say that u is* ζ levels above *u' if there are exactly $\zeta - 1$ c-nodes on the path strictly between u and u'. We say that u' is a* ζ-level c-child *of u if u is at most ζ levels above u'.*

The improved algorithm is given as Algorithm 2. The following lemma generalizes Lemma 4.2.

LEMMA 5.2. *Let G be the graph computed by Algorithm 2. Let p and q be two points of S with different colors, and let $\{S_u, S_v\}$ be the pair in the MWSPD for which $p \in S_u$ and $q \in S_v$. Assume that u is a c-node for some color c. Then there is a path in G between p and $\mathrm{rep}(S_u)$ whose length is at most $(2 + \epsilon/3)|pq|$.*

Proof. Let w be the c-leaf such that $p \in S_w$, and let $w = w_0, w_1, \ldots, w_k = u$ be the sequence of c-nodes that are on the path in T from w to u. As in the proof of Lemma 4.2, we assume without loss of generality that, for all $0 \leq i \leq k$, the color of $\mathrm{rep}(\mathrm{cl}(S_{w_i}))$ is not equal to c.

Throughout the proof, we will use the variables x_i, y_i, ℓ_i, and a_i, for $0 \leq i \leq k$, that were introduced in the proof of Lemma 4.2.

We first assume that $0 \leq k \leq 2\delta(\mu d + 1)$. Let Π be the path

$$p \to \mathrm{rep}(\mathrm{cl}(S_w)) \to \mathrm{rep}(S_u).$$

It follows from Algorithm 2 that Π is a path in G. We have to prove that the length of Π is at most $(2 + \epsilon/3)|pq|$.

Since $p \in S_w = S_{w_0} \subseteq S_{x_0}$ and $\mathrm{rep}(\mathrm{cl}(S_w)) = \mathrm{rep}(\mathrm{cl}(S_{w_0})) \in S_{y_0}$, it follows from Lemma 2.4 that

$$|p, \mathrm{rep}(\mathrm{cl}(S_w))| \leq (1 + 4/s) \cdot \mathrm{dist}(S_{x_0}, S_{y_0}) = (1 + 4/s)\ell_0. \tag{5.1}$$

ALGORITHM 2: Computing a sparse $(5+\epsilon)$-spanner of $K_{C_1 \ldots C_k}$.

Input: A set S of points in $\mathbb{R}^d$, which is partitioned into k subsets $C_1, \ldots, C_k$, and a real constant $0 < \epsilon < 1$.

Output: A $(5+\epsilon)$-spanner $G = (S, E)$ of the complete k-partite graph $K_{C_1 \ldots C_k}$.

Choose a separation constant s such that $s \geq 12/\epsilon$ and $(1+4/s)^2 \leq 1+\epsilon/36$ and choose an integer constant δ such that $\frac{2^\delta}{2^\delta - 1} \leq 1 + \epsilon/36$.
The rest of the algorithm is the same as Algorithm 1, except for lines 20–23, which are replaced by the following:

$\zeta \leftarrow 2\delta(\mu d + 1)$;
for each ζ-level c-child u'' of u' **do**
  if $\text{rep}(\text{cl}(S_{u'}))$ does not have color c, **then** add $(\text{rep}(S_{u''}), \text{rep}(\text{cl}(S_{u'})))$ to E;
  else add $(\text{rep}(S_{u''}), \text{rep}'(\text{cl}(S_{u'})))$ to E;
  if $\text{rep}(\text{cl}(S_{u''}))$ does not have color c, **then** add $(\text{rep}(\text{cl}(S_{u''})), \text{rep}(S_{u'}))$ to E;
  else add $(\text{rep}'(\text{cl}(S_{u''})), \text{rep}(S_{u'}))$ to E;
end

Since $\{S_u, S_v\}$ is one of the pairs that is considered in the definition of $\text{cl}(S_{w_0})$, we have $\text{dist}(S_{x_0}, S_{y_0}) \leq \text{dist}(S_u, S_v)$. Again by Lemma 2.4, we have $\text{dist}(S_u, S_v) \leq (1+4/s)|pq|$. Thus, we have shown that

$$|p, \text{rep}(\text{cl}(S_w))| \leq (1+4/s)^2 |pq|.$$

By the triangle inequality, we have

$$|\text{rep}(\text{cl}(S_w)), \text{rep}(S_u)| \leq |\text{rep}(\text{cl}(S_w)), p| + |p, \text{rep}(S_u)|.$$

Since p and $\text{rep}(S_u)$ are both contained in S_u, it follows from Lemma 2.4 that $|p, \text{rep}(S_u)| \leq (2/s)|pq|$. Thus, we have

$$|\text{rep}(\text{cl}(S_w)), \text{rep}(S_u)| \leq (1+4/s)^2 |pq| + (2/s)|pq|.$$

We have shown that the length of the path Π is at most

$$\left(2(1+4/s)^2 + 2/s\right)|pq|,$$

which is at most $(2+\epsilon/3)|pq|$ by our choice of s in Algorithm 2.

In the rest of the proof, we assume that $k > 2\delta(\mu d + 1)$. We define

$$m = k \bmod (\delta(\mu d + 1))$$

and

$$m' = \frac{k - m}{\delta(\mu d + 1)}.$$

In the proof of Lemma 4.2, we defined the path Π between p and $\text{rep}(S_u)$ by using all c-nodes $w = w_0, w_1, \ldots, w_k = u$. Since Algorithm 2 adds shortcuts, it suffices to define Π using only the sequence

$$w = w_0, w_{\delta(\mu d+1)+m}, w_{2\delta(\mu d+1)+m}, w_{3\delta(\mu d+1)+m}, \ldots, w_k = u$$

of c-nodes. We define Π to be the path

$$\begin{array}{rcccccl} p & \to & \mathrm{rep}(\mathrm{cl}(S_{w_0})) & \to & \mathrm{rep}(S_{w_{\delta(\mu d+1)+m}}) & & \\ & \to & \mathrm{rep}(\mathrm{cl}(S_{w_{2\delta(\mu d+1)+m}})) & \to & \mathrm{rep}(S_{w_{2\delta(\mu d+1)+m}}) & & \\ & \to & \mathrm{rep}(\mathrm{cl}(S_{w_{3\delta(\mu d+1)+m}})) & \to & \mathrm{rep}(S_{w_{3\delta(\mu d+1)+m}}) & & \\ & \vdots & & \vdots & & & \\ & \to & \mathrm{rep}(\mathrm{cl}(S_{w_k})) & \to & \mathrm{rep}(S_{w_k}) & = & \mathrm{rep}(S_u). \end{array}$$

It follows from Algorithm 2 that Π is a path in G. Thus, it remains to show that the length of this path is at most $(2+\epsilon/3)|pq|$.

We start by proving an upper bound on the length of Π in terms of $|pq|$, $\ell_{\delta(\mu d+1)+m}$, $\ell_{2\delta(\mu d+1)+m}$, $\ell_{3\delta(\mu d+1)+m}, \ldots, \ell_k$.

We have already shown (see (5.1)) that the length of the first edge on Π satisfies

$$|p, \mathrm{rep}(\mathrm{cl}(S_{w_0}))| \le (1+4/s)\ell_0.$$

The length of the second edge satisfies

$$\begin{aligned} |\mathrm{rep}(\mathrm{cl}(S_{w_0})), \mathrm{rep}(S_{w_{\delta(\mu d+1)+m}})| &\le |\mathrm{rep}(\mathrm{cl}(S_{w_0})), p| + |p, \mathrm{rep}(S_{w_{\delta(\mu d+1)+m}})| \\ &\le (1+4/s)\ell_0 + |p, \mathrm{rep}(S_{w_{\delta(\mu d+1)+m}})|. \end{aligned}$$

Since p and $\mathrm{rep}(S_{w_{\delta(\mu d+1)+m}})$ are both contained in S_u, it follows from Lemma 2.4 that

$$|p, \mathrm{rep}(S_{w_{\delta(\mu d+1)+m}})| \le (2/s)|pq|.$$

Thus, the length of the second edge on Π satisfies

$$|\mathrm{rep}(\mathrm{cl}(S_{w_0})), \mathrm{rep}(S_{w_{\delta(\mu d+1)+m}})| \le (1+4/s)\ell_0 + (2/s)|pq|.$$

Let $2 \le j \le m'$. We have seen in (4.1) in the proof of Lemma 4.2 that the length of the edge

$$(\mathrm{rep}(\mathrm{cl}(S_{w_{j\delta(\mu d+1)+m}})), \mathrm{rep}(S_{w_{j\delta(\mu d+1)+m}}))$$

satisfies

$$|\mathrm{rep}(\mathrm{cl}(S_{w_{j\delta(\mu d+1)+m}})), \mathrm{rep}(S_{w_{j\delta(\mu d+1)+m}})| \le (1+4/s)\ell_{j\delta(\mu d+1)+m}.$$

Again, let $2 \le j \le m'$. Since

$$\mathrm{rep}(S_{w_{(j-1)\delta(\mu d+1)+m}}) \in S_{w_{j\delta(\mu d+1)+m}} \subseteq S_{x_{j\delta(\mu d+1)+m}}$$

and

$$\mathrm{rep}(\mathrm{cl}(S_{w_{j\delta(\mu d+1)+m}})) \in S_{y_{j\delta(\mu d+1)+m}},$$

it follows from Lemma 2.4 that the length of the edge

$$(\mathrm{rep}(S_{w_{(j-1)\delta(\mu d+1)+m}}), \mathrm{rep}(\mathrm{cl}(S_{w_{j\delta(\mu d+1)+m}})))$$

satisfies

$$|\mathrm{rep}(S_{w_{(j-1)\delta(\mu d+1)+m}}), \mathrm{rep}(\mathrm{cl}(S_{w_{j\delta(\mu d+1)+m}}))| \le (1+4/s)\ell_{j\delta(\mu d+1)+m}.$$

We have shown that the length of Π is at most

$$(2/s)|pq| + 2(1 + 4/s)\left(\ell_0 + \sum_{j=2}^{m'} \ell_{j\delta(\mu d+1)+m}\right).$$

The definition of $\ell_0, \ell_1, \ldots, \ell_k$ implies that this sequence is nondecreasing. Thus, $\ell_0 \leq \ell_{\delta(\mu d+1)+m}$, and it follows that the length of Π is at most

$$(2/s)|pq| + 2(1 + 4/s)\sum_{j=1}^{m'} \ell_{j\delta(\mu d+1)+m}.$$

Thus, it suffices to show that the above expression is at most $(2 + \epsilon/3)|pq|$. In the rest of the proof, we repeatedly apply inequality (4.7) in the proof of Lemma 4.2. As we will see, this allows us to estimate the summation in the above expression by a geometric series which evaluates to $\frac{2^\delta}{2^\delta - 1}\ell_k$. We then apply inequality (4.2) in the proof of Lemma 4.2, which estimates ℓ_k in terms of $|pq|$. By putting all these estimates together, it then follows that the length of Π is at most $(2 + \epsilon/3)|pq|$.

We now present the details. Recall inequality (4.7) in the proof of Lemma 4.2, which states that

$$\ell_i \leq \frac{1}{2}\ell_{i+\mu d+1}.$$

By applying this inequality δ times, we obtain

$$\ell_i \leq \left(\frac{1}{2}\right)^\delta \ell_{i+\delta(\mu d+1)}.$$

For $i = j\delta(\mu d + 1) + m$, this becomes

$$\ell_{j\delta(\mu d+1)+m} \leq \left(\frac{1}{2}\right)^\delta \ell_{(j+1)\delta(\mu d+1)+m}.$$

By repeatedly applying this inequality, we obtain, for $h \geq j$,

$$\ell_{j\delta(\mu d+1)+m} \leq \left(\frac{1}{2}\right)^{(h-j)\delta} \ell_{h\delta(\mu d+1)+m}.$$

For $h = m'$, the latter inequality becomes

$$\ell_{j\delta(\mu d+1)+m} \leq \left(\frac{1}{2}\right)^{(m'-j)\delta} \ell_k.$$

It follows that

$$\begin{aligned}
\sum_{j=1}^{m'} \ell_{j\delta(\mu d+1)+m} &\leq \sum_{j=1}^{m'} \left(\frac{1}{2}\right)^{(m'-j)\delta} \ell_k \\
&= \sum_{i=0}^{m'-1} \left(\frac{1}{2}\right)^{i\delta} \ell_k \\
&\leq \sum_{i=0}^{\infty} \left(\frac{1}{2^\delta}\right)^i \ell_k \\
&= \frac{2^\delta}{2^\delta - 1}\ell_k.
\end{aligned}$$

According to (4.2) in the proof of Lemma 4.2, we have

$$\ell_k \leq (1 + 4/s)|pq|.$$

We have shown that the length of the path Π is at most

$$\left(\frac{2}{s} + 2\left(1 + \frac{4}{s}\right)^2 \frac{2^\delta}{2^\delta - 1}\right)|pq|.$$

Our choices of s and δ (see Algorithm 2) imply that $2/s \leq \epsilon/6$, $(1+4/s)^2 \leq 1+\epsilon/36$, and $\frac{2^\delta}{2^\delta-1} \leq 1+\epsilon/36$. Therefore, the length of Π is at most

$$\left(\epsilon/6 + 2(1+\epsilon/36)^2\right)|pq| \leq (2+\epsilon/3)|pq|,$$

where the latter inequality follows from our assumption that $0 < \epsilon < 1$. This completes the proof. □

LEMMA 5.3. *Let $n = |S|$. The graph G computed by Algorithm 2 is a $(5+\epsilon)$-spanner of the complete k-partite graph $K_{C_1 \ldots C_k}$, and the number of edges of this graph is $O(n)$. The running time of Algorithm 2 is $O(n \log n)$.*

Proof. The proof for the upper bound on the stretch factor is similar to the one of Lemma 4.3. The difference is that instead of the value t' that was used in the proof of Lemma 4.3, we now use the value $t' = 2 + \epsilon/3$ of Lemma 5.2. Thus, the stretch factor for the base case of the induction and for Case 1 is at most

$$(1 + 4/s) + 2t' = 5 + 4/s + 2\epsilon/3,$$

which is at most $5+\epsilon$, because of our choice for s in Algorithm 2. For Cases 2 and 3, the stretch factor is at most (see (4.8) in the proof of Lemma 4.3, where $t = 5+\epsilon$)

$$t' + (1 + 4/s) + 4t/s = 3 + \epsilon/3 + (4/s)(6+\epsilon),$$

which is at most $5+\epsilon$, again because of our choice for s. Finally, the stretch factor for Case 4 is at most (see (4.9) in the proof of Lemma 4.3, where $t = 5+\epsilon$)

$$(1 + 4/s) + 8t/s = 1 + (4/s)(11 + 2\epsilon),$$

which is at most $5+\epsilon$, because of our choice for s.

The analysis for the number of edges is the same as in Lemma 4.1, except that the number of edges that are added to each c-node in the modified for-loop is $2\delta(\mu d + 1)$ instead of 1 as in Algorithm 1. Finally, the analysis of the running time is the same as in Lemma 4.4. □

We have proved the following result.

THEOREM 5.4. *Let $k \geq 2$ be an integer, let S be a set of n points in $\mathbb{R}^d$ which is partitioned into k subsets $C_1, C_2, \ldots, C_k$, and let $0 < \epsilon < 1$ be a real constant. In $O(n \log n)$ time, we can compute a $(5+\epsilon)$-spanner of the complete k-partite graph $K_{C_1 \ldots C_k}$ having $O(n)$ edges.*

6. Improving the stretch factor. We have shown how to compute a $(5+\epsilon)$-spanner with $O(n)$ edges of any complete k-partite graph. In this section, we show that if we are willing to use $O(n \log n)$ edges, the stretch factor can be reduced to $3+\epsilon$. We start by showing that a stretch factor less than 3, while using $O(n \log n)$ edges, is not possible.

THEOREM 6.1. *Let $c > 0$ be a constant and let n and k be positive integers with $2 \leq k \leq n - 2c\sqrt{n \log n}$. For every real number $0 < \epsilon < 1$, there exists a complete k-partite geometric graph K with n vertices such that the following is true: If G is any subgraph of K with at most $c^2 n \log n$ edges, then the stretch factor of G is at least $3 - \epsilon$.*

Proof. Let D_1, D_2, and D_3 be three disks of radius $\epsilon/12$ centered at the points $(0, 0)$, $(1 + \epsilon/6, 0)$, and $(2 + \epsilon/3, 0)$, respectively. We place $(n - k + 2)/2$ red points inside D_1 and $(n - k + 2)/2$ blue points inside D_2. The remaining $k - 2$ points are placed inside D_3, and each of these points has a distinct color (which is neither red nor blue). Let K be the complete k-partite geometric graph defined by these n points. We claim that K satisfies the claim in the theorem.

Let G be an arbitrary subgraph of K and assume that G contains at most $c^2 n \log n$ edges. We will show that the stretch factor of G is at least $3 - \epsilon$.

Assume that G contains all red-blue edges. Then the number of edges in G is at least $((n-k+2)/2)^2$. Since $k \leq n - 2c\sqrt{n \log n}$, this quantity is larger than $c^2 n \log n$. Thus, there is a red point r and a blue point b, such that (r, b) is not an edge in G. The length of a shortest path in G between r and b is at least 3. Since $|rb| \leq 1 + \epsilon/3$, it follows that the stretch factor of G is at least $\frac{3}{1+\epsilon/3}$, which is at least $3 - \epsilon$. ∎

THEOREM 6.2. *Let $k \geq 2$ be an integer, let S be a set of n points in $\mathbb{R}^d$ which is partitioned into k subsets $C_1, C_2, \ldots, C_k$, and let $0 < \epsilon < 1$ be a real constant. In $O(n \log n)$ time, we can compute a $(3 + \epsilon)$-spanner of the complete k-partite graph $K_{C_1 \ldots C_k}$ having $O(n \log n)$ edges.*

Proof. Consider the following variant of the WSPD. For every pair $\{X, Y\}$ in the standard WSPD, where $|X| \leq |Y|$, we replace this pair by the $|X|$ pairs $\{\{x\}, Y\}$, where x ranges over all points of X. Thus, in this new WSPD, each pair contains at least one singleton set. Callahan and Kosaraju [4] showed that this new WSPD consists of $O(n \log n)$ pairs.

We run Algorithm 2 on the set S, using this new WSPD. Let G be the graph that is computed by this algorithm. Observe that Lemma 5.2 still holds for G. In the proof of Lemma 5.3 of the upper bound on the stretch factor of G, we have to apply Lemma 5.2 only once. Therefore, the stretch factor of G is at most $3 + \epsilon$. ∎

7. Conclusion. We have shown that, for every complete k-partite geometric graph K in $\mathbb{R}^d$ with n vertices and for every constant $\epsilon > 0$,

1. a $(5+\epsilon)$-spanner of K having $O(n)$ edges can be computed in $O(n \log n)$ time,
2. a $(3+\epsilon)$-spanner of K having $O(n \log n)$ edges can be computed in $O(n \log n)$ time.

The latter result is optimal for $2 \leq k \leq n - \Theta(\sqrt{n \log n})$, because a spanner of K having stretch factor less than 3 and having $O(n \log n)$ edges does not exist for all complete k-partite geometric graphs.

We leave open the problem of determining the best stretch factor that can be obtained by using $O(n)$ edges.

Future work may include verifying other properties that are known for the general geometric spanner problem. For example, is there a spanner of a complete k-partite geometric graph that has bounded degree? Is there a spanner of a complete k-partite geometric graph that is planar? From a more general point of view, it seems that little is known about geometric spanners of graphs other than the complete graph. The unit disk graph has received much attention, but there is a large family of other graphs that also deserve attention.

PROFILES OF TRIES*

GAHYUN PARK†, HSIEN-KUEI HWANG‡, PIERRE NICODÈME§, AND WOJCIECH SZPANKOWSKI¶

Abstract. Tries (from re*trie*val) are one of the most popular data structures on words. They are pertinent to the (internal) structure of stored words and several splitting procedures used in diverse contexts. The *profile* of a trie is a parameter that represents the number of nodes (either internal or external) with the same distance from the root. It is a function of the number of strings stored in a trie *and* the distance from the root. Several, if not all, trie parameters such as height, size, depth, shortest path, and fill-up level can be uniformly analyzed through the (external and internal) profiles. Although profiles represent one of the most fundamental parameters of tries, they have hardly been studied in the past. The analysis of profiles is surprisingly arduous, but once it is carried out it reveals unusually intriguing and interesting behavior. We present a detailed study of the distribution of the profiles in a trie built over random strings generated by a memoryless source. We first derive recurrences satisfied by the expected profiles and solve them asymptotically for all possible ranges of the distance from the root. It appears that profiles of tries exhibit several fascinating phenomena. When moving from the root to the leaves of a trie, the growth of the expected profiles varies. Near the root, the external profiles tend to zero at an exponential rate, and then the rate gradually rises to being logarithmic; the external profiles then abruptly tend to infinity, first logarithmically and then polynomially; they then tend polynomially to zero again. Furthermore, the expected profiles of asymmetric tries are oscillating in a range where profiles grow polynomially, while symmetric tries are nonoscillating, in contrast to most shape parameters of random tries studied previously. Such a periodic behavior for asymmetric tries implies that the depth satisfies a central limit theorem but not a local limit theorem of the usual form. Also the widest levels in symmetric tries contain a linear number of nodes, differing from the order $n/\sqrt{\log n}$ for asymmetric tries, n being the size of the trees. Finally, it is observed that profiles satisfy central limit theorems when the variance goes unbounded, while near the height they are distributed according to Poisson laws. As a consequence of these results we find typical behaviors of the height, shortest path, fill-up level, and depth. These results are derived here by methods of analytic algorithmics such as generating functions, Mellin transform, Poissonization and de-Poissonization, the saddle-point method, singularity analysis, and uniform asymptotic analysis.

Key words. digital trees, tries, profile, depth, height, shortest path, fill-up level, analytic Poissonization, Mellin transform, saddle-point method, singularity analysis

1. Introduction.

Tries are prototype data structures useful for many indexing and retrieval purposes. They were first proposed by de la Briandais [9] in the late 1950s for information processing; Fredkin [27] suggested the current name as it is

part of re*trie*val. Tries are multiway trees whose nodes are vectors of characters or digits. Due to their simplicity and efficiency, tries found widespread use in diverse applications including document taxonomy, IP address lookup, data compression, dynamic hashing, partial-match queries, speech recognition, leader election algorithms, and distributed hashing tables (see [29, 50, 53, 79]). In this paper, we are concerned with probabilistic properties of the profiles of tries, where the *profile* of a tree is the sequence of numbers each corresponding to the number of nodes with the same distance from the root. We discover several new phenomena in the profiles of tries built over strings generated by a random memoryless source, and develop asymptotic tools to describe them.

Structure and usefulness of tries. Tries are a natural choice of data structure when the input records involve a notion of alphabets or digits. They are often used to store such data so that future retrieval can be made efficient. Given a sequence of n words over the alphabet $\{a_1, \ldots, a_m\}$, $m \geq 2$, we can construct a trie as follows. If $n = 0$, then the trie is empty. If $n = 1$, then a single (external) node holding the word is allocated. If $n \geq 1$, then the trie consists of a root (internal) node directing words to the m subtrees according to the first alphabet of each word, and words directed to the same subtree are themselves tries (see [50, 53, 79] for more details). For simplicity, we deal only with binary tries in this paper. Unlike other search trees such as digital search trees and binary search trees where records or keys are stored at the internal nodes, the *internal nodes* in tries are branching nodes used merely to direct records to each subtrie, with all records stored in *external nodes* that are leaves of such tries. A trie has more internal nodes than external nodes (fixed to be n throughout this paper), differing from almost all other search trees. In Figure 1 we plot a binary trie of five strings.

The simple organizing procedure used to construct tries and the general efficiency they achieve make tries one of the most popular digital search trees. Since their invention, tries have found frequent use in many computer science applications. For example, tries are widely used in algorithms for automatically correcting words in texts (see [51]) and in algorithms for taxonomies and toolkits of regular language (see the Ph.D. thesis [80]); they are also used to represent the event history in datarace detection for multithreaded object-oriented programs (see [6]); another example is the Internet IP address lookup problem (see [60, 74]), where the search time for the IP address problem is directly related to the distribution of the fill-up level (see below for a more precise definition) and other trie parameters. For applications to other problems in searching, sorting, dynamic hashing, coding, polynomial factorization, Lempel–Ziv compression schemes, and molecular biology, see [29, 79].

The structure of tries also has a close connection to several splitting procedures using coin-flipping; these include algorithms for resolving collisions in multiaccess (or broadcast) communication models, algorithms for loser selection or leader election, etc.; see [45]. Thus most shape parameters in tries have direct interpretations in terms of other related objects.

Random tries under the Bernoulli model. Throughout the paper, we write $B_{n,k}$ to denote the number of external nodes (leaves) at distance k from the root; the number of internal nodes at distance k from the root is denoted by $I_{n,k}$. For simplicity, we will refer to $B_{n,k}$ as the *external profile* and $I_{n,k}$ as the *internal profile*. Figure 1 shows a trie and its profiles.

In this paper we study the profiles of a trie built over n binary strings generated by a memoryless source. More precisely, we assume that the input is a sequence of n independent and identically distributed random variables, each being composed of an

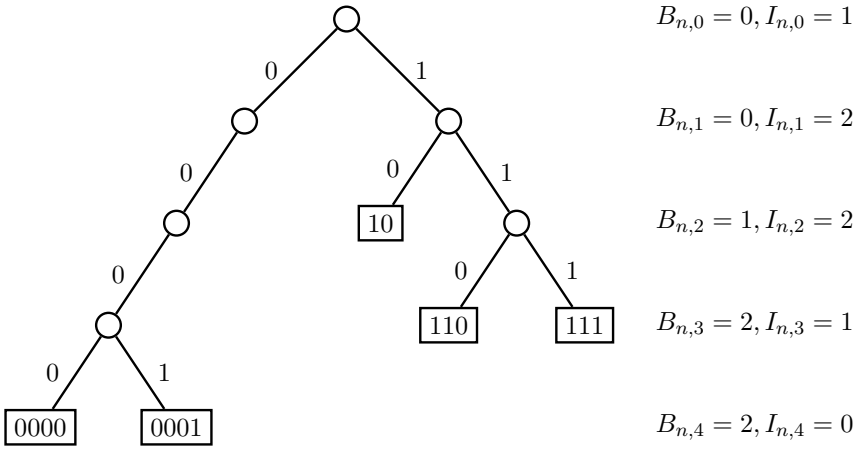

FIG. 1. *A trie of $n = 5$ records and its profiles: the circles represent internal nodes, and rectangles holding the records are external nodes.*

infinite sequence of Bernoulli random variables with mean p, where $0 < p < 1$ is the probability of a "1" and $q := 1 - p$ is the probability of a "0." The corresponding trie constructed from these n binary strings is called a *random trie*. This simple model may seem too idealized for practical purposes; however, the typical behaviors under such a model often hold under more general models such as Markovian or dynamical sources, although the technicalities are usually more involved (see, for example, [8, 12, 15, 35]).

The motivation of studying the profiles is multifold. First, they are fine shape measures closely connected to many other cost measures on tries; some of them are indicated below. Second, they are also asymptotically close to the profiles of suffix trees, which in turn have a direct combinatorial interpretation in terms of words; see [36, 59, 78, 79] for more information and another interpretation in terms of urn models. Third, not only are the analytic problems mathematically challenging, but the diverse new phenomena they exhibit are highly interesting and unusual. Fourth, our findings imply several new results on other shape parameters (see section 8). Finally, most properties of random tries have also a prototype character and are expected to hold for other varieties of digital search trees (and under more general random models), although the proofs are generally more complicated.

Major cost measures on random tries. Due to the usefulness of tries, many cost measures, discussed below, on random tries have been studied in the literature since the early 1970s, and most of these measures can be expressed and analyzed through the profiles studied in this paper:

- *depth*: the distance from the root to a randomly selected node; its distribution is given by the expected external profile divided by n; see [10, 12, 13, 20, 24, 33, 36, 42, 46, 52, 65, 69, 71, 75, 76];
- *total path length*: the sum of distances between nodes and the root, or, equivalently, $\sum_j jI_{n,j}$; see [8, 11, 24, 44, 58, 57, 70, 71, 72, 73, 75];
- *size*: the total number of internal nodes, or $\sum_j I_{n,j}$; see [8, 24, 34, 36, 40, 41, 43, 47, 50, 57, 67, 68, 69, 70, 71, 72, 73];
- *height*: the length of the longest path from the root, or $\max\{j : B_{n,j} > 0\}$; see [8, 11, 12, 13, 14, 22, 26, 33, 48, 64, 65, 77];
- *shortest path*: the length of the shortest path from the root to an external node, or $\min\{j : B_{n,j} > 0\}$; see [64, 65];

- *fill-up (or saturation) level*: the largest full level, or $\max\{j : I_{n,j} = 2^j\}$, where the *levels* of a tree denote the sets of nodes with the same distance from the root; see [49];
- *Horton–Strahler number and stack-size*: certain notions of heights related to the traversal of tries; see [4, 17, 54, 55, 56];
- *distance of two randomly chosen nodes*; see [1, 7];
- *pattern occurrences in tries (including page usage or b-tries)*; see [22, 42, 43, 58, 71, 76];
- *one-sided height (or leader election or loser selection)*; see [21, 39, 66, 81, 82].

The reader is referred to the book [79] and the papers [15, 37, 71] for a systematic treatment of several of these quantities.

The general analytic context. The major difference between most previous study and the current paper is that we are dealing with the asymptotics of bivariate recurrence, in contrast to univariate recurrences (with or without maximization or minimization) addressed in the literature.

To be more precise, we observe that, by assumption of the model, the probability generating function $P_{n,k}(y) := \mathbb{E}(y^{B_{n,k}})$ of the external profile satisfies the recurrence

$$P_{n,k}(y) = \sum_{0\le j\le n} \binom{n}{j} p^j q^{n-j} P_{j,k-1}(y) P_{n-j,k-1}(y) \qquad (n \ge 2;\ k \ge 1) \tag{1}$$

with the initial conditions $P_{n,k}(y) = 1 + \delta_{n,1}\delta_{k,0}(y-1)$ when either $n \le 1$ and $k \ge 0$ or $k = 0$ and $n \ge 0$, where $\delta_{a,b}$ is the Kronecker symbol. Observe that this recurrence depends on two parameters n and k, which makes the analysis quite challenging, as we will demonstrate in this paper. The probability generating functions of the internal profile satisfy the same recurrence (1) but with different initial conditions; see section 6.

From (1), the moments of $B_{n,k}$ and $I_{n,k}$ (centered or not) are seen to satisfy a recurrence of the form

$$x_{n,k} = a_{n,k} + \sum_{0\le j\le n} \binom{n}{j} p^j q^{n-j} \left(x_{j,k-1} + x_{n-j,k-1}\right)$$

with suitable initial conditions, where $a_{n,k}$ are known (either explicitly or inductively). A standard approach is to consider the Poisson generating function $\tilde{f}_k(z) := e^{-z}\sum_n x_{n,k} z^n/n!$, which in turn satisfies the functional equation

$$\tilde{f}_k(z) = \tilde{g}_k(z) + \tilde{f}_{k-1}(pz) + \tilde{f}_{k-1}(qz)$$

with a suitable $\tilde{g}_k(z)$. This equation can be solved explicitly by a simple iteration argument and asymptotically by using the Mellin transform (see [23, 79]). The final step is to invert from the asymptotics of the Poisson generating function $\tilde{f}_k(z)$ to recover the asymptotics of $x_{n,k}$. This last step is guided by the *Poisson heuristic*, which roughly states that

(2) *if a sequence $\{x_n\}_n$ is "smooth enough," then $x_n \sim e^{-n}\sum_{j\ge 0} x_j n^j/j!$,*

where $x_n \sim y_n$ if $\lim_{n\to\infty} x_n/y_n = 1$. Such a Poisson heuristic has appeared in diverse contexts under different forms such as Borel summability and Tauberian theorems; it dates back at least to Ramanujan's Notebooks; see the book by Berndt [3, pp. 57–66] for more details. It is known as *analytic de-Poissonization* when justified

by complex analysis and the saddle-point method, and was the subject of intensive analysis, resulting in a robust solution presented in [37].

By means of the Poisson heuristic (2), we expect that $\mu_{n,k} \sim e^{-n}\sum_{j\geq 0}\mu_{j,k}n^j/j!$. However, as we will see, such a heuristic holds in our case when $q^{2k}n \to 0$ but fails otherwise. The reason is that $\mu_{n,k}$ is too small in this range. Also it should be mentioned that the asymptotic analysis of the above functional equation is in general more intricate because we have an additional parameter k to be taken into account and we need uniformity for our asymptotic approximations in k (varying with n) and in z (in some region in the complex plane) in order to invert the results to obtain $x_{n,k}$ by suitable complex analysis.

Known results for profiles. As far as probabilistic properties of the profiles of random tries are concerned, very little is known in the literature. Since the distribution of the depth D_n in random tries is given by $\mathbb{P}(D_n = k) = \mu_{n,k}/n$, where $\mu_{n,k} := \mathbb{E}(B_{n,k})$, the asymptotics of the expected profile $\mu_{n,k}$ for $n \to \infty$ and varying $k = k(n)$ can be regarded as local limit theorems for D_n. Although many papers have addressed the limiting behaviors of the depth, none has dealt with the local limit theorem of D_n and the asymptotics of $\mu_{n,k}$ for varying k. We will see in section 8 that our result implies an unusual type of local limit theorem for D_n. However, it should be mentioned that the central limit theorem for the depth was developed in [13, 34, 35].

On the other hand, Pittel [65] showed that the distribution of the number of pairs of input-strings having a common prefix of length at least k is asymptotically Poisson when k is close to the height. Devroye [14] showed that

$$\text{if} \quad \frac{\mathbb{E}(B_{n,k})}{\sqrt{n}} \to \infty, \quad \text{then} \quad \frac{B_{n,k}}{\mathbb{E}(B_{n,k})} \to 1 \quad \text{in probability;}$$

$$\text{if} \quad \mathbb{E}(I_{n,k}) \to \infty, \quad \text{then} \quad \frac{I_{n,k}}{\mathbb{E}(I_{n,k})} \to 1 \quad \text{in probability,}$$

under very general assumptions on the underlying models (see also [15] for further refinements). References [65] and [14] represent known results concerning profiles. We will see that convergence in probability in the two "if statements" holds as long as the variance tends to infinity.

Sketch of the major phenomena. In the next section we present an in-depth discussion of our results. Here, we briefly summarize our main findings. We focus mostly on the profiles of asymmetric tries (when $p \neq q$) since the symmetric tries (when $p = q = 1/2$) are comparatively easier. We will first derive asymptotic approximations to the average external profile $\mu_{n,k}$ for all ranges of k.

Our results show inter alia that for $k \leq (1-\varepsilon)\log n/\log(1/q)$ the average profile $\mu_{n,k}$ is exponentially small where $\varepsilon > 0$ is small. When k increases and lies in the range $(\log n - \log\log\log n + O(1))/\log(1/q)$, then $\mu_{n,k}$ decays to zero logarithmically until $k > k^*$ for a specific threshold k^* in this range beyond which $\mu_{n,k}$ suddenly grows unbounded at a logarithmic rate. The rate becomes polynomial $\Theta(n^\upsilon)$ for some $0 < \upsilon \leq 1$ when

$$\frac{1}{\log(1/q)}(1+\varepsilon)\log n \leq k \leq \frac{2}{\log(1/(p^2+q^2))}(1-\varepsilon)\log n.$$

Surprisingly enough, for this range of k an oscillating factor emerges in the expected profile behavior; that is, $\mathbb{E}(B_{n,k}) \approx G(\log_{p/q} p^k n)n^v/\sqrt{\log n}$, where G is a bounded periodic function. Such behavior is a consequence of an infinite number of saddle-points appearing in the integrand of the associated Mellin integral transform. This

was first observed by Nicodème [59]. For larger values of k, these oscillations disappear since the behavior of the expected profile is dominated by a polar singularity.

Analogous results also hold for the internal profile. In addition, we prove that the variances of both profiles are asymptotically of the same order as their expected values. This suggests a central limit theorem for both external and internal profiles for a wide range of k. We show that this is indeed true; furthermore, we also show that for k near the height the limiting distribution of the profiles becomes Poisson. Some of these results were already anticipated in [63] and constitute the Ph.D. thesis of the first author [62].

Profiles of digital and nondigital log trees. In passing, we observe that most random trees in the discrete probability literature fall into two major categories according to their expected height being of order $\sqrt{n}$ (referred to as *square-root trees* for brevity) or of order $\log n$ (referred to as *log trees*), where n is the tree size. While most random square-root trees were introduced in combinatorics and probability, the majority of log trees arise from data structures and computer algorithms.

We can further classify log trees into "digital-type" and "nondigital-type" log trees, according to the nature of construction (or search) of the tree. Profiles of nondigital-type search trees of logarithmic height for which *binary search trees* are representative have received much recent attention and are shown to exhibit several interesting phenomena such as bimodality of the variance and multifaceted behaviors of the limiting distributions; see [5, 18, 19, 28, 31] for more information. In contrast, profiles of digital-type search trees have not been addressed as much, and most properties remain unknown; see [14, 15, 65] for tries and [2, 38] for digital search trees. We will show that the limiting behaviors of the profiles are very different from those of nondigital search trees. In particular, while in no range will the normalized profiles in random binary search trees lead to asymptotic normality (in the sense of convergence in distribution), profiles of random tries, when properly centered and normalized, all converge to the standard normal law when the variance goes unbounded in the limit. As is often the case for proving asymptotic normality, we need more precise asymptotic approximation to the variance, rendering our analysis more complicated.

Organization of the paper. The paper is organized as follows. In the next section, we present (rather informally) a more detailed summary of our main findings. This section is to help the reader to comprehend the richness of our results in their fullness but without resorting to rather abstruse mathematical formulations. Sections 3–8 are devoted to precise formulations of our results. This paper contains two major parts: The first, section 3, develops the asymptotic tools we need for deriving the diverse asymptotic approximations to the expected external profile $\mu_{n,k}$. Most proofs of the second part (sections 4–8) are then sketched because they extend the same methods of proof as in the first part. Except for sections 7 and 8, we assume $p \neq q$ throughout this paper. Among these sections, section 4 derives the asymptotics of the variance of $B_{n,k}$, the corresponding results of convergence in distribution being given in section 5. The internal profiles are addressed in section 6, and results for symmetric tries are given in section 7. Consequences of our findings are discussed in section 8, where we establish typical behaviors of the height, the width, the shortest path, the fill-up level, and the right-profile, as well as a rather atypical local limit theorem for the depth.

2. Summary of main results. In this section we discuss informally our main results. We focus here on describing the major phenomena arising in the analysis of

profiles rather than presenting the precise and complicated results to which we devote the remaining sections of this paper.

Crucial to our analysis of the profiles is the asymptotics of the expected profiles. Not only are the results fundamental and highly interesting, but the analytic methods we used are also of certain generality.

From (1), we see that the expected external profile $\mu_{n,k} := \mathbb{E}(B_{n,k})$ satisfies the following recurrence:

$$\mu_{n,k} = \sum_{0\le j\le n} \binom{n}{j} p^j q^{n-j} (\mu_{j,k-1} + \mu_{n-j,k-1}) \tag{3}$$

for $n \ge 2$ and $k \ge 1$ with the initial values $\mu_{n,0} = 0$ for all $n \ne 1$ and 1 for $n = 1$. Furthermore, $\mu_{0,k} = 0,\ k \ge 0$, and $\mu_{1,k} = 0$ for $k \ge 1$ and is equal to 1 when $k = 0$. Throughout we assume that $p > q = 1 - p$ unless stated otherwise.

The polynomial growth of $\mu_{n,k}$. In section 3, we solve asymptotically (3) for various ranges of k when $p \ne q$; a crude description of the asymptotics of $\mu_{n,k}$ is as follows:

$$\frac{\log \mu_{n,k}}{\log n} \to \begin{cases} 0 & \text{if } \alpha \le \alpha_1, \\ -\rho + \alpha \log(p^{-\rho} + q^{-\rho}) & \text{if } \alpha_1 \le \alpha \le \alpha_2, \\ 2 + \alpha \log(p^2 + q^2) & \text{if } \alpha_2 \le \alpha \le \alpha_3, \\ 0 & \text{if } \alpha \ge \alpha_3, \end{cases} \tag{4}$$

where

$$\alpha_1 := \frac{1}{\log(1/q)}, \quad \alpha_2 := \frac{p^2 + q^2}{p^2 \log(1/p) + q^2 \log(1/q)}, \quad \text{and} \quad \alpha_3 := \frac{2}{\log(1/(p^2 + q^2))} \tag{5}$$

are delimiters of $\alpha := \lim_n k/\log n$ $(k = k(n))$, and

$$\rho := \frac{1}{\log(p/q)} \log\left(\frac{1 - \alpha \log(1/p)}{\alpha \log(1/q) - 1}\right).$$

Note that $\alpha_1 \le \alpha_2$; see Figure 2. The limiting estimate (4) gives a rough picture of $\mu_{n,k}$ as follows: $\mu_{n,k}$ is of polynomial growth rate when $\alpha_1 + \varepsilon \le \alpha \le \alpha_3 - \varepsilon$ and is smaller than any polynomial powers when $0 \le \alpha \le \alpha_1 - \varepsilon$ and $\alpha \ge \alpha_3 + \varepsilon$. Near the two boundaries α_1 and α_3, the behaviors of $\mu_{n,k}$ will undergo phase changes from being subpolynomial to being polynomial or the other way around.

More refined asymptotics. To derive more precise asymptotics of $\mu_{n,k}$ than the phase transitions (4) of the polynomial order of $\mu_{n,k}$, we divide all possible values of k into four overlapping ranges.

(I) *Elementary range*: $1 \le k \le \alpha_1(\log n - \log\log\log n + O(1))$.
(II) *Saddle-point range*: $\alpha_1(\log n - \log\log\log n + K_n) \le k \le \alpha_2(\log n - K_n\sqrt{\log n})$.
(III) *Gaussian transitional range*: $k = \alpha_2 \log n + o((\log n)^{2/3})$.
(IV) *Polar singularity range*: $k \ge \alpha_2 \log n + K_n\sqrt{\log n}$,

where, throughout this paper, $K_n \ge 1$ represents a (generic) sequence tending to infinity.

More precisely, in Theorem 1 we prove that for k lying in range (I) the expected external profile $\mu_{n,k}$ first decays exponentially fast (asymptotic to $q^k n(1 - q^k)^{n-1}$).

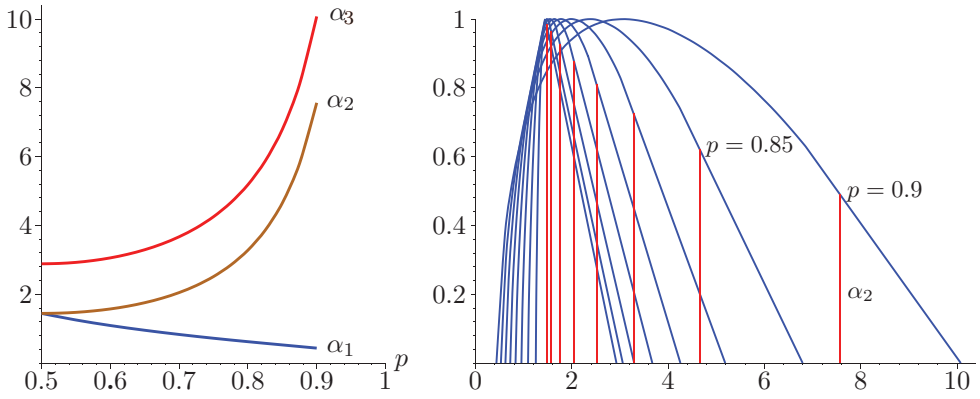

FIG. 2. *Left: a plot of α_1, α_2, and α_3 (defined in (5)) as functions of p. Right: the (nonzero) limiting order of $\log \mu_{n,k}/\log n$ plotted against $\alpha = \lim_n k/\log n$ for $p = 0.55, 0.6, \ldots, 0.9$ (the spans of the curves increase as p grows). The vertical lines represent the positions of α_2 (to the right of which the curves are straight lines); see (4).*

Then, when k is around $\alpha_1(\log n - \log\log\log n + \log(p/q - 1) + m\log(p/q))$ for some integer $m \geq 0$,

$$\mu_{n,k} \sim \frac{k^m}{m!} p^m q^{k-m} n e^{-np^m q^{k-m}},$$

which is of order

$$\mu_{n,k} = O\left(\frac{\log\log n}{\log^{\xi-m} n}\right)$$

for some ξ. Thus, for $m < \xi$ the expected external profile decays only logarithmically, but for $m \geq \xi$ it increases logarithmically.

The behavior of $\mu_{n,k}$ in range (II) is described in Theorem 2. The situation becomes highly nontrivial and interesting. More precisely, for $\alpha_1(1+\varepsilon)\log n \leq k \leq \alpha_2(1-\varepsilon)\log n$, we find that

$$\mu_{n,k} \sim G_1\left(\rho; \log_{p/q} p^k n\right) \frac{p^\rho q^\rho (p^{-\rho} + q^{-\rho})}{\sqrt{2\pi\alpha_{n,k}}\,\log(p/q)} \cdot \frac{n^{\upsilon_1}}{\sqrt{\log n}},$$

where ($\alpha_{n,k} := k/\log n$)

$$\upsilon_1 = -\rho + \alpha_{n,k}\log(p^{-\rho} + q^{-\rho}),$$
$$\rho = -\frac{1}{\log(p/q)} \log\left(\frac{-1 - \alpha_{n,k}\log q}{1 + \alpha_{n,k}\log p}\right),$$

and $G_1(\rho; x)$ is a periodic function. We plot in Figures 3 and 4 the periodic parts of $G_1(-1, x)$ for a few values of p and ρ, respectively. *Analytically*, these oscillations are consequences of an infinite number of saddle-points appearing in the integrand of the associated Mellin transform of the expected profile, but *visually* they look like certain sine waves due to the fact that the corresponding Fourier expansions involve a

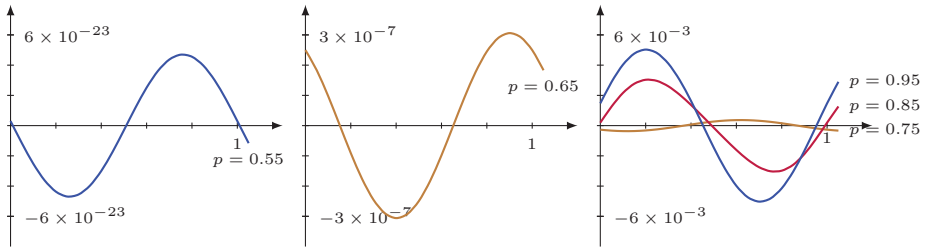

FIG. 3. *The fluctuating part around the mean of the periodic function* $G_1(-1;x)$ *for* $p = 0.55, 0.65, \ldots, 0.95$ *and for* x *in the unit interval; its amplitude tends to zero when* $p \to 0.5^+$.

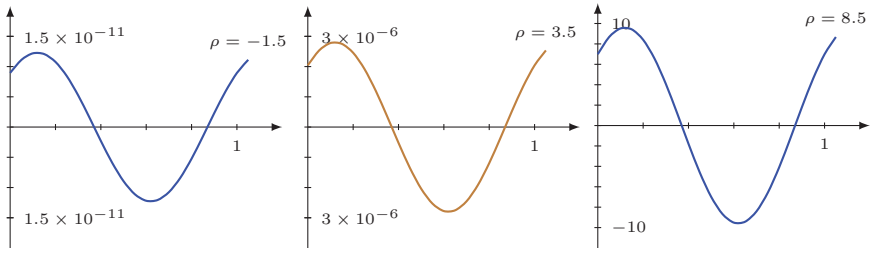

FIG. 4. *The fluctuating part around the mean of the periodic function* $G_1(\rho;x)$ *for* $\rho \in \{-1.5, 3.5, 8.5\}$ *and* $x \in [0,1]$. *The amplitude increases as* ρ *grows.*

Gamma function with increasing parameters, which decreases very fast along a fixed vertical line for an increasing imaginary part, so that only a few terms dominate.

Finally, in Theorem 3 we prove that for k in range (IV)

$$\mu_{n,k} \sim 2pqn^2(p^2+q^2)^{k-1} = \frac{2pq}{p^2+q^2}\, n^{\upsilon_2},$$

where $\upsilon_2 = 2 + \alpha_{n,k}\log(p^2+q^2)$, and the periodic function disappears. In this region, the asymptotic behavior of the expected profile is dictated by the expected number of pairs (of input-strings) having common prefixes of length at least k. This property is analytically reflected by a polar singularity in the associated Mellin transform. The asymptotics of $\mu_{n,k}$ in range (III) for $k = \alpha_2 \log n + o(\log^{2/3} n)$ are presented in Theorem 4. In this transitional range, the saddle-point coalesces with the polar singularity, so we use the Gaussian integral to describe the behavior of $\mu_{n,k}$.

In summary, our results roughly state that $\mu_{n,k} \to 0$ when $1 \le k \le k^*$ for some k^* close to $\alpha_1(\log n - \log\log\log n + O(1))$, and then $\mu_{n,k}$ tends *abruptly* to infinity at a logarithmic rate when $k > k^*$. Such an abrupt change has already been observed in the literature for the shortest path and the fill-up level (see [49, 65]), but not much is known for $\mu_{n,k}$ beyond that. Then we show that $\mu_{n,k}$ grows polynomially when k lies in the range $\alpha_1(1+\varepsilon)\log n \le k \le \alpha_3(1-\varepsilon)\log n$, reaching the peak where it is of order $n/\sqrt{\log n}$; it decays at a slower rate afterwards until it tends to zero again when $k \ge \alpha_3(\log n + K_n)$. A salient feature here is the presence of an oscillating function in the asymptotic approximation when $p \ne q$.[1] In Figure 5, a plot of the rough silhouettes of $\mu_{n,k}$ is presented.

[1] The expected values of many shape characteristics of random tries often exhibit the asymptotic pattern: $\sim F(\log_c n)n$ if $\log p/\log q$ is rational for some periodic function F and constant c expressible in terms of p, and $\sim Cn$ if $\log p/\log q$ is irrational; see [37, 71, 79].

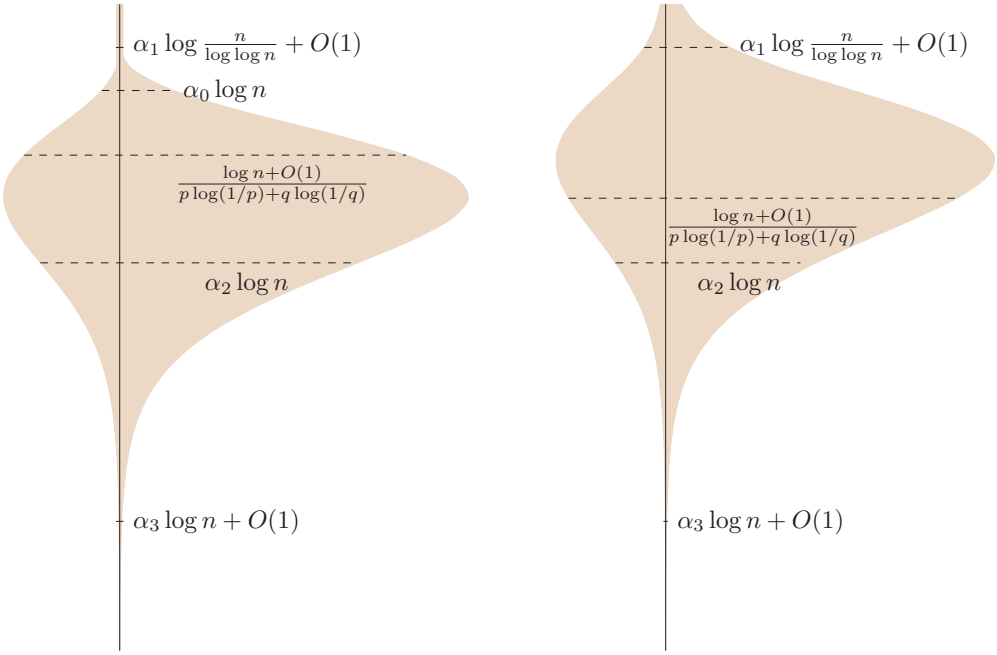

FIG. 5. *The silhouettes of the expected external (left) and internal (right) profiles of an asymmetric trie ($p = 0.75$). Note that the right subtrees of the asymmetric trie have more nodes than their left siblings since $p > 1/2$. Also, the first few levels contain almost no external nodes but are almost full of internal nodes.*

Asymptotics of the expected internal profile. The expected value of the internal profile $\mathbb{E}(I_{n,k})$ is discussed in section 6. In particular, the expected internal profile is asymptotically equivalent to 2^k for $k \le \alpha_0(\log n - K_n\sqrt{\log n})$, where $\alpha_0 := 2/(\log(1/p) + \log(1/q))$. When $k \ge \alpha_2(\log n + K_n\sqrt{\log n})$, then $\mathbb{E}(I_{n,k}) \sim (p^2+q^2)\mathbb{E}(B_{n,k})/pq$. Between these two ranges, it is again the infinite number of saddle-points that yield the dominant asymptotic approximation. Unlike $\mu_{n,k}$, an additional phase transition appears in the asymptotics of the $\mathbb{E}(I_{n,k})$ when $k = \alpha_0 \log n + O(\sqrt{\log n})$, reflecting the structural change of the internal nodes from being asymptotically full to being of the same order as the number of external nodes. The silhouettes of the expected internal profiles for a symmetric trie and an asymmetric ($p = 0.75$) trie are presented in Figure 6.

Variance and limiting distributions. In section 4 we deal with the variance of the profile. In particular, in Theorem 7 we derive asymptotic approximations to the variance of the profile, which asymptotically turns out to be of the same order as the expected value for all ranges of $k \ge 1$; namely, $\mathbb{V}(B_{n,k}) = \Theta(\mathbb{E}(B_{n,k}))$. In fact, we show that $\mathbb{V}(B_{n,k}) \sim \mathbb{E}(B_{n,k})$ in range (I), for range (IV) $\mathbb{V}(B_{n,k}) \sim 2\mathbb{E}(B_{n,k})$, and in range (II) (polynomial growth) the variance and the expected profile differ only by the oscillating functions. The variance of the internal profile behaves almost identically to the variance of the external profile; roughly, $\mathbb{V}(I_{n,k}) = \Theta(\mathbb{V}(B_{n,k}))$ for all k. The methods used to derive these results are the same as those used in section 3.

We then prove, in section 5, that both internal and external profiles, after proper normalization, are asymptotically normally distributed iff the variance tends to infinity (see Theorems 8 and 9). The limiting distribution is Poisson when the variance

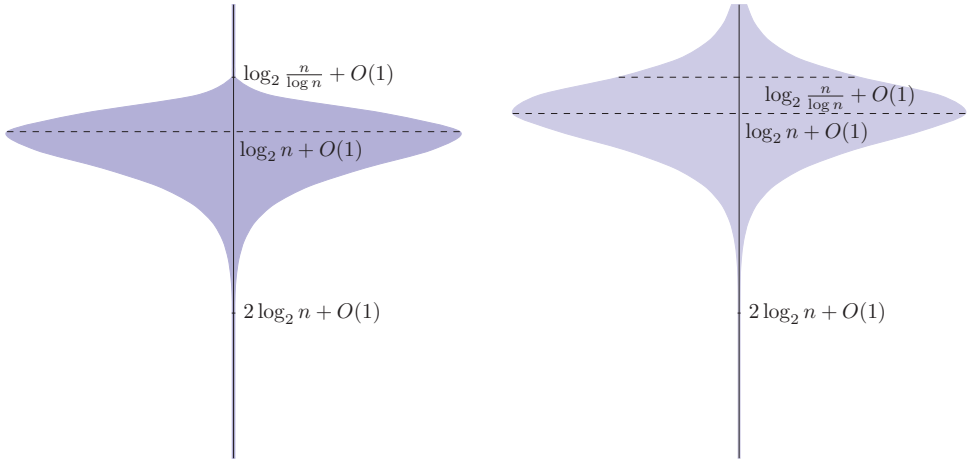

FIG. 6. *The silhouettes of the expected external and internal profiles of a symmetric; compare Figure* 5.

remains bounded away from zero and infinity. In particular, we will prove that when $\mathbb{V}(B_{n,k}) = \Theta(1)$,

$$\mathbb{P}\left(B_{n,k} = 2m\right) = \frac{\lambda_0^m}{m!}\, e^{-\lambda_0} + o(1) \quad \text{and} \quad \mathbb{P}\left(B_{n,k} = 2m+1\right) = o(1),$$

where $\lambda_0 := pqn^2(p^2+q^2)^{k-1}$, while for $\mathbb{V}(I_{n,k}) = \Theta(1)$, we find

$$\mathbb{P}(I_{n,k} = m) = \frac{\lambda_1^m}{m!}\, e^{-\lambda_1} + o(1) \qquad (m = 0, 1, \dots),$$

where $\lambda_1 := n^2(p^2+q^2)^k/2$. These results hold for both symmetric and asymmetric tries, but the ranges where the variances become unbounded are different.

Symmetric tries. For the symmetric case, we have $\alpha_1 = \alpha_2 = 1/\log 2$. This means that the two ranges separated by α_2 coalesce into one for symmetric tries; see Figure 2. The analysis then becomes simpler as shown in section 7. An interesting property is that unlike for asymmetric tries, the fattest levels of profiles of symmetric tries contain a linear number of nodes. The global picture of a random symmetric trie is roughly as follows ($\alpha_1 = 1/\log 2$):

- When $1 \le k \le \alpha_1(\log n - \log\log n + O((\log n)^{-1}))$, each level is almost full of internal nodes ($I_{n,k} \approx 2^k$), the number of external nodes tending to zero; in particular, the variances of both profiles tend to zero.
- When $\alpha_1(\log n - \log\log n + K_n/\log n) \le k \le 2\alpha_1(\log n - K_n)$, where K_n is any sequence tending to infinity, the variances of both profiles tend to infinity, and we prove the asymptotic normality of both profiles.
- When $k = 2\alpha_1(\log n + O(1))$, both profiles are asymptotically Poisson distributed, but $B_{n,k}$ assumes only even values.
- When $k \ge \alpha_1(\log n + K_n)$, then nodes appear very unlikely.

Section 8 describes some consequences of our main results. In particular, we point out a rather unusual form of the local limit theorem for the depth due to the oscillating factor in the expected profile. Then we apply our results to rederive typical behavior for the height, the shortest path, and the fill-up level. Also, the width and

the right-profile (counting only right branches and neglecting the left ones) are briefly discussed.

This completes the summary of our main results. Precise formulations and proofs are presented in the next five sections. Enjoy the reading!

3. Expected external profile. We derive asymptotic approximations to the expected external profile $\mu_{n,k}$ in this section, starting with a few useful expressions for $\mu_{n,k}$.

Notation. Throughout this paper, $p \in [1/2, 1)$ is fixed and $q = 1-p$. Let $k = k(n)$ and $\alpha := \lim_n k/\log n$, whenever the limit exists. The constants α_1, α_2, and α_3 are defined in (5). For convenience, we also write

$$L_n := \log n, \quad LL_n := \log\log n, \quad LLL_n := \log\log\log n.$$

The generic symbol ε is always used to represent a suitably small constant whose value may vary from one occurrence to another, and K_n denotes any sequence tending to infinity. The symbol $f(n) = \Theta(g(n))$ means that there are positive constants C and C' such that $C|g(n)| \le |f(n)| \le C'|g(n)|$.

3.1. Exact expressions and integral representations. Denote by $M_k(z)$ the probability generating function $\sum_{n\ge 0} \mu_{n,k} z^n/n!$ of $\mu_{n,k}$ and by $\tilde{M}_k(z)$ the corresponding Poisson generating function $\tilde{M}_k(z) := e^{-z} M_k(z)$.

LEMMA 1. *The Poisson generating function $\tilde{M}_k(z)$ satisfies the integral representation*

$$\tilde{M}_k(z) = \frac{1}{2\pi i} \int_{(\rho)} z^{-s} \Gamma(s+1) g(s) \left(p^{-s} + q^{-s}\right)^k \mathrm{d}s \tag{6}$$

for $k \ge 1$ and $\Re(z) > 0$, where Γ denotes the Gamma function, $g(s) := 1 - 1/(p^{-s} + q^{-s})$, and $\int_{(\rho)}$ stands for the integral $\int_{\rho-i\infty}^{\rho+i\infty}$. The integral with $\rho > -2$ is absolutely convergent for $\Re(z) > 0$.

Proof. By taking the derivative with respect to y on both sides of (1) and then substituting $y = 1$, we see that $\mu_{n,k}$ satisfies the recurrence (3) with the initial conditions $\mu_{n,k} = \delta_{n,1}\delta_{k,0}$ when either $n \le 1$ and $k \ge 0$ or $k = 0$ and $n \ge 0$. Note that

$$\mu_{n,1} = n\left(pq^{n-1} + qp^{n-1}\right) \qquad (n \ge 2).$$

It follows that

$$M_k(z) = e^{qz} M_{k-1}(pz) + e^{pz} M_{k-1}(qz) \qquad (k \ge 2),$$

with $M_1(z) = z(pe^{qz} + qe^{pz} - 1)$. Thus $\tilde{M}_k(z)$ satisfies

$$\tilde{M}_k(z) = \tilde{M}_{k-1}(pz) + \tilde{M}_{k-1}(qz). \tag{7}$$

Iterating this equation yields

$$\tilde{M}_k(z) = \sum_{0\le j<k} \binom{k-1}{j} \tilde{M}_1(p^j q^{k-1-j} z), \tag{8}$$

from which (6) follows since the Mellin transform

$$M_1^*(s) = \int_0^\infty z^{s-1} \tilde{M}_1(z) dz$$

of $\tilde{M}_1(z) = pze^{-pz} + qze^{-qz} - ze^{-z}$ equals

$$M_1^*(s) = \Gamma(s+1)(p^{-s} + q^{-s} - 1),$$

where $\Re(s) > -2$, and the Mellin transform of $M_1(p^j q^{k-1-j} z)$ is $p^{-sj} q^{-s(k-1-j)} M_1^*(s)$ (see [23, 79]).

To justify the absolute convergence of the integral, we apply the Stirling formula for the Gamma function (with complex parameter)

$$\Gamma(s+1) = \sqrt{2\pi s}\left(\frac{s}{e}\right)^s \left(1 + O\left(|s|^{-1}\right)\right),$$

uniformly as $|s| \to \infty$ and $|\arg s| \le \pi - \varepsilon$, which implies that

$$|\Gamma(\rho + it)| = \Theta(|t|^{\rho - 1/2} e^{-\pi|t|/2}), \tag{9}$$

uniformly for $|t| \to \infty$ and $\rho = o(|t|^{2/3})$.

The integrand in (6) is analytic for $\Re(s) > -2$ and bounded above by

$$\begin{aligned} &z^{-\rho-it}\Gamma(\rho+1+it)g(\rho+it)\left(p^{-\rho-it} + q^{-\rho-it}\right)^k \\ &\quad = O\left(|z|^{-\rho}|t|^{\rho+1/2}e^{-\pi|t|/2+\arg(z)t}(p^{-\rho} + q^{-\rho})^k\right) \end{aligned}$$

for large $|t|$. This completes the proof of the lemma. □

COROLLARY 1. *The expected external profile $\mu_{n,k}$ satisfies, for $n, k \ge 1$,*

$$\begin{aligned} \mu_{n,k} = &\sum_{0\le j\le k} \binom{k}{j} p^j q^{k-j} n \left(1 - p^j q^{k-j}\right)^{n-1} \\ &- \sum_{0\le j<k} \binom{k-1}{j} p^j q^{k-1-j} n \left(1 - p^j q^{k-1-j}\right)^{n-1} \end{aligned} \tag{10}$$

and the integral representation

$$\mu_{n,k} = \frac{1}{2\pi i}\int_{(\rho)} \frac{\Gamma(n+1)\Gamma(s+1)}{\Gamma(n+1+s)}\, g(s)\left(p^{-s} + q^{-s}\right)^k \mathrm{d}s \qquad (\rho > -2), \tag{11}$$

where $g(s) = 1 - 1/(p^{-s} + q^{-s})$.

Proof. By definition and (8)

$$M_k(z) = \sum_{0\le j<k} \binom{k-1}{j} p^j q^{k-1-j} z \left(pe^{(1-p^{j+1}q^{k-1-j})z} + qe^{(1-p^j q^{k-j})z} - e^{(1-p^j q^{k-1-j})z}\right).$$

Thus (the symbol $[z^n]f(z)$ denoting the coefficient of z^n in the Taylor expansion of $f(z)$),

$$\begin{aligned} \mu_{n,k} &= n![z^n]M_k(z) \\ &= \sum_{0\le j<k} \binom{k-1}{j}\left(p^{j+1}q^{k-1-j} n\left(1 - p^{j+1}q^{k-1-j}\right)^{n-1} + p^j q^{k-j} n\left(1 - p^j q^{k-j}\right)^{n-1}\right) \\ &\quad - \sum_{0\le j<k} \binom{k-1}{j} p^j q^{k-1-j} n\left(1 - p^j q^{k-1-j}\right)^{n-1}. \end{aligned}$$

Rearranging the indices of the first sum, we obtain (10).

On the other hand, it also follows from (7) that, denoting by $\tilde{\mu}_{n,k} := n![z^n]\tilde{M}_k(z)$,

$$\tilde{\mu}_{n,k} = (p^n + q^n)\tilde{\mu}_{n,k-1} \qquad (k \geq 2),$$

with

$$\tilde{\mu}_{n,1} = \sum_{2\leq j\leq n} \binom{n}{j} (-1)^{n-j}\mu_{j,1} = (-1)^n n\,(1 - p^n - q^n) \qquad (n \geq 1).$$

Iterating this recurrence yields

$$\tilde{\mu}_{n,k} = (-1)^n n\,(1 - p^n - q^n)\,(p^n + q^n)^{k-1} \qquad (n, k \geq 1).$$

By definition, we have for $n \geq 2$

$$\mu_{n,k} = \sum_{0\leq j\leq n} \binom{n}{j} \tilde{\mu}_{j,k} = \sum_{2\leq j\leq n} \binom{n}{j} (-1)^j j\left(1 - p^j - q^j\right)\left(p^j + q^j\right)^{k-1}. \tag{12}$$

The last sum falls under the so-called Rice integral representation for finite differences (see [25, 79]) from which we conclude

$$\mu_{n,k} = \frac{1}{2\pi i}\int_{(\rho)} \frac{\Gamma(n+1)\Gamma(-s)}{\Gamma(n+1-s)}\, s\,(1 - p^s - q^s)\,(p^s + q^s)^{k-1}\,\mathrm{d}s.$$

This gives (11). Absolute convergence of the integral in (11) when $\Re(s) > -2$ is justified as above. Note that $g(-1) = 0$. □

Remarks. The integral representation (11) follows formally from interchanging the Cauchy and Mellin integrals as shown below:

$$\begin{aligned}
\mu_{n,k} &= \frac{n!}{2\pi i}\int z^{-n-1}e^z \tilde{M}_k(z)\mathrm{d}z \\
&= \frac{n!}{2\pi i}\int z^{-n-1}e^z \left(\frac{1}{2\pi i}\int z^{-s}\Gamma(s+1)g(s)\left(p^{-s} + q^{-s}\right)^k \mathrm{d}s\right)\mathrm{d}z \\
&= \frac{n!}{2\pi i}\int \Gamma(s+1)g(s)\left(p^{-s} + q^{-s}\right)^k \left(\frac{1}{2\pi i}\int z^{-n-1-s}e^z \mathrm{d}z\right)\mathrm{d}s \\
&= \frac{n!}{2\pi i}\int \frac{\Gamma(s+1)}{\Gamma(n+s+1)} g(s)\left(p^{-s} + q^{-s}\right)^k \mathrm{d}s.
\end{aligned} \tag{13}$$

Although all steps here can be justified by analytic properties of the functions involved (which are essentially the estimates needed by the saddle-point method), the way we proved (11), based solely on finite differences, does not rely on any analytic properties.

Note that since the Mellin transform of $x(1-x)^{n-1}$, $x \in (0,1)$, equals $\Gamma(n)\Gamma(s+1)/\Gamma(n+1+s)$, the exact expression (10) also follows from (11) by expanding $(p^{-s} + q^{-s})^k$ and then integrating term by term. For numerical purposes, the expression (10) is preferable to (12), especially when k is not too large.

On the other hand, the closed-form expression (10) can also be proved directly by either a direct combinatorial argument (see [65] for similar details) or an urn model argument (see [59]).

3.2. Road map of the proof through de-Poissonization. From the preceding analysis, we have a choice of two different integral representations: the Rice integral (11) and the Cauchy integral (13). The approach via the Rice integral (11) is simpler than that via the Cauchy and Mellin integrals (13), but the latter can be easily amended for computing the variance and limiting distribution as will be evident from sections 4 and 5. It is for this reason that we use here the route via the Cauchy and Mellin integrals.

By the Poisson heuristic (2), we anticipate the asymptotic equivalence $\mu_{n,k} \sim \tilde{M}_k(n)$. We will see that this holds when $q^{2k}n \to 0$ but requires suitable modification when $q^{2k}n \not\to 0$.

A simple analytic de-Poissonization result. Define a sequence of (Charlier) polynomials $\tau_\ell(n)$ by

$$\tau_\ell(n) := n![z^n]e^z(z-n)^\ell = \ell![z^\ell](1+z)^n e^{-nz} \qquad (\ell = 0, 1, \dots).$$

Then $\tau_0(n) = 1$, $\tau_1(n) = 0$, $\tau_2(n) = -n$, $\tau_3(n) = 2n$, and $\tau_4(n) = 3n^2 - 6n$. Note that $\tau_\ell(n)$ is a polynomial in n of degree $\lfloor \ell/2 \rfloor$.

PROPOSITION 1. *Let $f(z) := \sum_n a_n z^n/n!$ be an entire function, where a_n is a given sequence, and let $\tilde{f}(z) := e^{-z}f(z)$. Write $z = re^{i\theta}$. If*

$$|f(z)| \le f(r)e^{-cr\theta^2} \tag{14}$$

holds uniformly for $r \ge 0$, $c > 0$, and $|\theta| \le \pi$, where $f(r) \ge 0$, and

$$\tilde{f}^{(\ell)}(ne^{i\theta}) = O\left(\delta(n)^\ell \tilde{f}(n)\right) \qquad (\ell = 0, 1, \dots) \tag{15}$$

holds uniformly for $|\theta| \le \theta_1$, where $\theta_1 \ge n^{-1/2+\varepsilon}$ and $\delta(n) = o(n^{-1/2})$, then for any $\ell_0 \ge 2$

$$a_n = \sum_{0 \le \ell < \ell_0} \frac{\tilde{f}^{(\ell)}(n)}{\ell!}\tau_\ell(n) + O\left(n^{\ell_0/2}\delta(n)^{\ell_0}\tilde{f}(n)\right). \tag{16}$$

Proof. By the Cauchy formula and the condition (14), we have

$$a_n = \frac{n!}{2\pi i}\int_{\substack{|z|=n \\ |\arg(z)|\le\theta_0}} z^{-n-1}e^z\tilde{f}(z)\mathrm{d}z + O\left(n!n^{-n}f(n)\int_{\theta_0}^{\infty} e^{-cn\theta^2}\mathrm{d}\theta\right), \tag{17}$$

where $\theta_0 = n^{-2/5}$. By Stirling's formula, we see that the O-term in (17) is bounded above by

$$O\left(n^{1/2}\tilde{f}(n)n^{-1/2}e^{-cn^{1/5}}\right) = O\left(e^{-cn^{1/5}}\tilde{f}(n)\right), \tag{18}$$

which is negligible in comparison to the main term $\tilde{f}(n)$. It remains to evaluate the first term in (17). To that purpose, we expand $\tilde{f}(z)$ at $z = n$ and then integrate term by term, the error term introduced being of the form

$$\frac{n!}{2\pi i(\ell_0-1)!}\int_{\substack{|z|=n \\ |\arg(z)|\le n^{-2/5}}} z^{-n-1}e^z(z-n)^{\ell_0}\int_0^1 (1-t)^{\ell_0-1}\tilde{f}^{(\ell_0)}(n+(z-n)t)\mathrm{d}t\mathrm{d}z,$$

for any $\ell_0 \geq 1$, which is easily seen, by (15), to be bounded above by the O-term in (16); see [30] for similar details. Since $\delta(n) = o(n^{-1/2})$, this proves the asymptotic nature of (16). □

Remark. In particular, we have

$$a_n = \tilde{f}(n) + O(n\delta^2(n)\tilde{f}(n)),$$
$$a_n = \tilde{f}(n) - \frac{n}{2}\tilde{f}''(n) + O\left(n^2\delta^4(n)\tilde{f}(n)\right) \tag{19}$$

for large n.

The theorem indicates that, when the *regularity condition* (14) and the *smoothness condition* (15) both hold for $\tilde{M}_k(z)$, the asymptotics of $\mu_{n,k}$ are reduced to those of their Poisson generating function $\tilde{M}_k(z)$ for large z near the real axis. Our effort in this section is mostly devoted to finding the uniform bounds for justifying the de-Poissonization result (16), which holds for $\mu_{n,k}$ when $q^{2k}n \to 0$. Note that although the condition (14) may seem too strong for our purposes, it can be checked rather systematically in the cases studied in this paper; see [37] for weaker conditions.

On the other hand, we show that when (16) fails (which is the case when $q^{2k}n \not\to 0$), the same proof given above through the Cauchy integral (17) can be appropriately amended because (18) also holds in this case. Thus when deriving our asymptotic estimates for $\mu_{n,k}$, we will either follow the de-Poissonization route through Proposition 1 or evaluate the integral (13) directly using (17).

3.3. Range (I): An elementary analysis. We show in this section that when $1 \leq k \leq \alpha_1(L_n - LLL_n + O(1))$, the asymptotics of $\mu_{n,k}$ are dictated by one or two terms in the first sum of (10). Although the asymptotics of $\mu_{n,k}$ in this range can be easily derived by (10) using only elementary arguments, we will use a lengthier analytic approach based on Cauchy's integral representation since this approach is readily amended later for the asymptotics of the variance. Define

$$k_m := \alpha_1\left(L_n - LLL_n + \log\left(\frac{p}{q} - 1\right) + m\log\frac{p}{q}\right) \qquad (m \geq 0), \tag{20}$$
$$S_{n,k,j} := \binom{k}{j} p^j q^{k-j} n\left(1 - p^j q^{k-j}\right)^{n-1} \qquad (0 \leq j \leq k).$$

For convenience, define $k_{-1} = 0$.

Our first result says that $\mu_{n,k}$ is asymptotic to $S_{n,k,m}$ when $k_{m-1} < k < k_m$ except when k is close to the boundaries, where the corresponding neighboring term (either $S_{n,k,m-1}$ or $S_{n,k,m+1}$) is of the same order.

THEOREM 1 (asymptotics of $\mu_{n,k}$ in range (I)). *Assume $m \geq 0$. If*

$$k_{m-1} + \frac{\alpha_1 K_n}{LL_n} \leq k \leq k_m - \frac{\alpha_1 K_n}{LL_n}, \tag{21}$$

then

$$\mu_{n,k} = S_{n,k,m}\left(1 + O((m+1)e^{-K_n})\right). \tag{22}$$

If $k = k_m + \alpha_1 x/LL_n$, where $x = o(\sqrt{LL_n})$, then

$$\mu_{n,k} = S_{n,k,m}\left(1 + \frac{p\alpha_1 e^x}{q(m+1)}\right)\left(1 + O\left(x^2 LL_n^{-1} + (m+1)L_n^{-(1-q/p)}\right)\right). \tag{23}$$

Remark. Since $\log(p/q) < 1$ for $p \in (1/2, e/(e+1))$, the interval (21) may contain no integer.

By Theorem 1, the proofs of the following special cases are straightforward.

COROLLARY 2. *If $k \geq 1$ and $q^k n \to \infty$, then*

$$\mu_{n,k} \sim q^k n (1-q^k)^{n-1};$$

if $q^{2k} n \to 0$ and $k \leq \alpha_1(L_n - LLL_n + K_n)$, then

$$S_{n,k,m} \sim \frac{k^m}{m!} p^m q^{k-m} n e^{-p^m q^{k-m} n} \qquad (m \geq 0).$$

On the other hand, the estimate

$$\mu_{n,k} = \Theta(S_{n,k,m}) \tag{24}$$

holds uniformly for $k_{m-1} \leq k \leq k_m$, $m \geq 0$.

The proof of Theorem 1 is based on evaluating the Cauchy integral (13) along the circle $|z| = n$ by the same arguments used in the proof of Proposition 1 (see (18)). Observe that

$$\mu_{n,k} = \frac{n!}{2\pi i} \int_{\substack{|z|=n \\ |\arg(z)| \leq \theta_0}} z^{-n-1} e^z \tilde{M}_k(z) \mathrm{d}z + O\left(e^{-cn^{1/5}} \tilde{M}_k(n)\right), \tag{25}$$

where the O-term is justified by applying the following estimate for $M_k(z)$.

LEMMA 2. *Uniformly for $r \geq 0$ and $|\theta| \leq \pi$*

$$|M_k(re^{i\theta})| \leq M_k(r) e^{-cr\theta^2} \qquad (r > 0; |\theta| \leq \pi) \tag{26}$$

for all $k = k(n) \geq 1$ and some constant $c > 0$.

The proof of (26) follows directly from the next proposition in view of (8) and $[z^n] M_1(z) \geq 0$.

PROPOSITION 2. *Let $f(z)$ be an entire function and let $z = re^{i\theta}$, where $r \geq 0$ and $|\theta| \leq \pi$. If*

$$|e^z f(z)| \leq e^r f(r) \qquad (r \geq 0; |\theta| \leq \pi), \tag{27}$$

where $f(r) \geq 0$, then the sum $f_k(z) := \sum_{0 \leq j \leq k} \binom{k}{j} f(p^j q^{k-j} z)$ satisfies

$$|e^z f_k(z)| \leq e^r f_k(r) e^{-cr\theta^2}, \tag{28}$$

uniformly for $k \geq 0$, $r \geq 0$, and $|\theta| \leq \pi$, where $c > 0$ is independent of z and k.

Proof. By (27) and the elementary inequality

$$1 - \cos\theta \geq \frac{2}{\pi^2} \theta^2 \qquad (|\theta| \leq \pi), \tag{29}$$

we obtain

$$\begin{aligned} |e^z f_k(z)| &\leq \sum_{0 \leq j \leq k} \binom{k}{j} e^{(1-p^i q^{k-j}) r \cos\theta} e^{p^j q^{k-j} r} f(p^j q^{k-j} r) \\ &\leq \sum_{0 \leq j \leq k} \binom{k}{j} e^{(1-p^i q^{k-j}) r (1 - 2\theta^2/\pi^2)} e^{p^j q^{k-j} r} f(p^j q^{k-j} r) \\ &\leq e^{-2r\theta^2 (1-p^k)/\pi^2} e^r f_k(r). \end{aligned}$$

This proves (28) with, say, $c = 2(1-p)/\pi^2$. ∎

Proof of (22) *in Theorem* 1. We next evaluate $\tilde{M}_k(z)$ more precisely in the following lemma whose proof is presented in Appendix A.

Let

$$S_{k,m}(z) := \binom{k-1}{m} p^m q^{k-m} z e^{-p^m q^{k-m} z}.$$

LEMMA 3. (i) $(m = 0)$. *If* $1 \le k \le k_0 - \alpha_1 K_n / LL_n$, *then*

$$\tilde{M}_k(z) = q^k z e^{-q^k z} \left(1 + O(e^{-K_n})\right), \tag{30}$$

uniformly for $|z| = n$ *and* $\arg(z) = o(LL_n^{-1/2})$.

(ii) $(m \ge 1)$. *If*

$$k = \alpha_1 \left(L_n - LLL_n + \log(p/q - 1) + m \log(p/q) - \eta\right), \tag{31}$$

where $m \ge 1$ *and*

$$\frac{K_n}{LL_n} \le \eta \le \log(p/q) - \frac{K_n}{LL_n},$$

then

$$\tilde{M}_k(z) = S_{k,m}(z) \left(1 + O(me^{-K_n})\right), \tag{32}$$

uniformly for $|z| = n$ *and* $\arg(z) = o(LL_n^{-1/2})$.

Using the above lemma, we now prove Theorem 1. It remains to evaluate the integral in (25). We first consider the case $m = 0$. By substituting (30) into the integral in (25), and by completing the arc $|\arg(z)| \le \theta_0$ to a full circle, we see that

$$\begin{aligned}\frac{n!}{2\pi i} \int_{\substack{|z|=n \\ |\arg(z)|\le\theta_0}} z^{-n-1} e^z \tilde{M}_k(z) \mathrm{d}z &= \frac{q^k n!}{2\pi i} \int_{\substack{|z|=n \\ |\arg(z)|\le\theta_0}} z^{-n} e^{(1-q^k)z} \mathrm{d}z + O(E_1) \\ &= q^k n! [z^{n-1}] e^{(1-q^k)z} + O(E_2) + O(E_1),\end{aligned}$$

where

$$\begin{aligned}E_1 &:= e^{-K_n} n! n^{-n} q^k n \int_{-\theta_0}^{\theta_0} e^{(1-q^k) n \cos\theta} \mathrm{d}\theta, \\ E_2 &:= q^k n! n^{1-n} \int_{\theta_0}^{\pi} e^{(1-q^k) n \cos\theta} \mathrm{d}\theta.\end{aligned}$$

By inequality (29), we have

$$\begin{aligned}E_1 &= O\left(e^{-K_n} n^{1/2} q^k n e^{-q^k n} \int_{-\infty}^{\infty} e^{-2n(1-q^k)\theta^2/\pi^2} \mathrm{d}\theta\right) \\ &= O\left(e^{-K_n} q^k n e^{-q^k n}\right).\end{aligned}$$

Similarly,

$$E_2 = O\left(q^k n e^{-q^k n} n^{-1/10} e^{-2n^{1/5}/\pi^2}\right).$$

This completes the proof of (22) when $m = 0$. For $m \ge 1$, we proceed in a similar manner but using part (ii) of Lemma 3.

Proof of (23) *in Theorem* 1. We now consider the remaining gaps when k is of the form (31) with $\eta = x/LL_n$, where $x = o(\sqrt{LL_n})$. In this case, the same analysis as above shows that both terms $S_{k,m}(z)$ and $S_{k,m+1}(z)$ are asymptotically close so that

$$\tilde{M}_k(z) = (S_{k,m}(z) + S_{k,m+1}(z))\,(1 + O(E_3))\,, \tag{33}$$

where the error E_3 introduced is bounded above by

$$\begin{aligned} E_3 &= O\left(\sum_{0\le j<m}\left|\frac{S_{k,j}(z)}{S_{k,m}(z)}\right| + \sum_{m+2\le j\le k}\left|\frac{S_{k,j}(z)}{S_{k,m}(z)}\right|\right)\\ &= O\left((m+1)L_n^{-(1-qe^{\eta}\cos\theta/p)}\right) + O\left(m!\sum_{j\ge 2}\frac{(p\alpha_1/q)^j}{(j+m)!}L_n^{j-\frac{(p/q)^j-1}{p/q-1}e^{\eta}\cos\theta}\right)\\ &= O\left((m+1)L_n^{-(1-q/p)} + (m+1)^{-1}L_n^{-(p/q-1)}\right)\\ &= O\left((m+1)L_n^{-(1-q/p)}\right), \end{aligned}$$

since $1 - q/p \le p/q - 1$, where we used the inequality

$$\frac{t^j - 1}{t-1} \ge \frac{t+1}{2}\,j \qquad (t > 1;\ j \ge 2),$$

and $\theta = o(LL_n^{-1/2})$. Thus the same analysis as above gives

$$\mu_{n,k} = \frac{k^m}{m!}p^m q^{k-m} n e^{-p^m q^{k-m} n}\left(1 + \frac{pL_n^{1-e^{\eta}}}{q(m+1)\log(1/q)}\right)\left(1 + O\left((m+1)L_n^{-(1-q/p)}\right)\right),$$

which implies (23). □

3.4. Range (II): A saddle-point analysis. We now assume that

$$\alpha_1\,(L_n - LLL_n + K_n) \le k \le \alpha_2(L_n - K_n\sqrt{L_n}), \tag{34}$$

and proceed by the saddle-point method (see [79, 83]) to derive the following main result of this subsection.

THEOREM 2 (asymptotics of $\mu_{n,k}$ in range (II)). *If k satisfies* (34), *then*

$$\mu_{n,k} = G_1\left(\rho; \log_{p/q} p^k n\right)\frac{n^{-\rho}\,(p^{-\rho} + q^{-\rho})^k}{\sqrt{2\pi\beta_2(\rho)k}}\left(1 + O\left(\frac{1}{k(p/q)^{\rho}} + \frac{1}{k(\rho+2)^2}\right)\right), \tag{35}$$

where $\rho = \rho(n,k) > -2$ is chosen to satisfy the saddle-point equation

$$\begin{cases} \dfrac{\mathrm{d}}{\mathrm{d}\rho}\left(\rho^{\rho}e^{-\rho}n^{-\rho}(p^{-\rho} + q^{-\rho})^k\right) = 0 & \text{if } \rho \ge 1,\\[2ex] \dfrac{\mathrm{d}}{\mathrm{d}\rho}\left(n^{-\rho}(p^{-\rho} + q^{-\rho})^k\right) = 0 & \text{if } \rho \le 1, \end{cases} \tag{36}$$

and

$$\beta_2(\rho) := \frac{p^{-\rho}q^{-\rho}\log(p/q)^2}{(p^{-\rho} + q^{-\rho})^2}, \tag{37}$$

$$G_1(\rho; x) = \sum_{j\in\mathbb{Z}} g(\rho + it_j)\Gamma(\rho + 1 + it_j)e^{-2j\pi i x} \qquad (t_j := 2j\pi/\log(p/q))$$

with $g(s) = 1 - 1/(p^{-s} + q^{-s})$*, and* $G_1(\rho, x)$ *is a* 1*-periodic function (see Figures* 3 *and* 4*).*

We devote the rest of this subsection to the proof of Theorem 2.

3.4.1. Two-step saddle-point method. Here we outline the main steps of the proof of Theorem 2. The approach may be called a two-step saddle-point method since the saddle-point method will be applied twice. First, we start from the Mellin integral (6) and apply the saddle-point method to obtain precise asymptotics of $\tilde{M}_k(re^{i\theta})$ for small θ (i.e., around the *real axis*) and large r. The proof here is complicated by the fact that

$$\left|p^{-\rho-it} + q^{-\rho-it}\right| = p^{-\rho} + q^{-\rho} \tag{38}$$

when $t = t_j = 2\pi j/\log(p/q)$, $j \in \mathbb{Z}$, which implies that the number of saddle-points with the same real part is *infinite*, yielding the 1-periodic function $G_1(\rho; x)$.

This first application of the saddle-point method yields a good approximation to $\tilde{M}_k(z)$ for z large and near the real axis; then we *de-Poissonize* $\tilde{M}_k(z)$ by another application of the saddle-point method and establish that $\mu_{n,k} \sim \tilde{M}_k(n)$. Ultimately, we will use the de-Poissonization result of Proposition 1; however, in the first approximation we do de-Poissonization by "bare hands" by applying the argument already used in the proof of Proposition 1, namely, (17) and (18). Thus we focus on the evaluation of the Cauchy integral (13) but with $|\theta| \le n^{-2/5}$ (the first integral of (25)).

3.4.2. Location of saddle-points. The integrand $z^{-s}\Gamma(s+1)g(s)\left(p^{-s} + q^{-s}\right)^k$ of the integral in (6) has simple poles at $s = -j$, $j = 2, 3, \ldots$, the rightmost (dominant) one being at $s = -2$; it also has saddle-points, which are the zeros of the equation

$$\frac{\mathrm{d}}{\mathrm{d}s}\left(\Gamma(s+1)n^{-s}(p^{-s} + q^{-s})^k\right) = 0 \tag{39}$$

(note that $g(s)$ is uniformly bounded for all s). In view of (38), there are infinitely many saddle-points of the form $\rho + it_j/\log(p/q)$ ($j = 0, \pm 1, \ldots$), where the real part ρ satisfies (39). Also it is easy to see that

$$\begin{cases} \rho \to +\infty & \text{if } \frac{k}{L_n} \downarrow \frac{1}{\log(1/q)}, \\ \rho \to -\infty & \text{if } \frac{k}{L_n} \uparrow \frac{1}{\log(1/p)}. \end{cases}$$

We distinguish between two cases $\rho \ge 1$ and $-2 < \rho < 1$. In the former, the saddle-points are asymptotically determined, by Stirling's formula for the Gamma function, by the first equation in (36), which is simpler than (39), while in the latter case they are asymptotically determined by the second equation of (36) since $\Gamma(\rho+1)$ is uniformly bounded and thus does not contribute significantly to the saddle-point location.

More precisely, first consider the case when $\rho \ge 1$ (the choice of 1 being arbitrary). In this case, by (36), we obtain

$$\frac{k}{L_n - \log\rho} = \frac{p^{-\rho} + q^{-\rho}}{p^{-\rho}\log(1/p) + q^{-\rho}\log(1/q)},$$

which can be written in the form

$$\rho = \frac{1}{\log(p/q)} \log\left(\frac{L_n - \log\rho - k\log(1/p)}{k\log(1/q) - L_n + \log\rho}\right),$$

whenever $L_n - \log \rho < k \log(1/q)$, which will be seen to be the case when k satisfies (34).

On the other hand, when $\rho \le 1$, we consider the second equation in (36) or

$$\frac{k}{L_n} = \frac{p^{-\rho} + q^{-\rho}}{p^{-\rho}\log(1/p) + q^{-\rho}\log(1/q)},$$

which is solved to be

$$\rho = \frac{1}{\log(p/q)} \log\left(\frac{L_n - k\log(1/p)}{k\log(1/q) - L_n}\right). \tag{40}$$

It follows that if k satisfies (34), then

$$\rho \le \frac{1}{\log(p/q)} \left(LL_n - \log K_n + \log \frac{\log(p/q)}{\log(1/q)} + o(1)\right), \tag{41}$$

implying, in particular, that $\rho = O(LL_n)$. Also, if $k = \alpha_1(L_n - LLL_n + \log\log(p/q) + K_n)$, then

$$\rho = \frac{1}{\log(p/q)} \left(LL_n - \log K_n + \log \frac{\log(p/q)}{\log(1/q)} + O(K_n^{-1})\right).$$

However, if k is close to the right boundary of (34), more precisely, $k = \alpha_2(1-\varepsilon_n)L_n$, where $\varepsilon_n = o(1)$, then

$$\rho = -2 + \frac{\varepsilon_n}{\alpha_2\beta_2(-2)} + O(\varepsilon_n^2).$$

Thus $\rho = O(1)$.

From (41), we see that if $\rho \ge 1$ and k satisfies (34), then $k\beta_2(\rho) = \Theta(k(p/q)^\rho)$ and

$$k(p/q)^\rho \ge \frac{K_n}{\log(p/q)} + o(1);$$

on the other hand, if $\rho \ge -2 + K_n L_n^{-1/2}$, then $k(\rho+2)^2 \ge K_n^2$. Thus the O-term in (35) is small if we choose K_n sufficiently large.

3.4.3. More transparent behaviors of $\mu_{n,k}$. Before we present a formal proof of Theorem 2, we first discuss more transparent behaviors of $\mu_{n,k}$ in some specified ranges.

The central range: $\alpha \in [\alpha_1 + \varepsilon, \alpha_2 - \varepsilon]$. In this case, G_1 is bounded and $G_1(\rho; x) \sim G_1(\rho'; x)$, where

$$\rho' := \frac{1}{\log(p/q)} \log\left(\frac{1 - \alpha\log(1/p)}{\alpha\log(1/q) - 1}\right); \tag{42}$$

also $\beta_2(\rho) \sim \beta_2(\rho')$. Note that $g(\rho + it_j) = 1 - p^{it_j}/(p^{-\rho} + q^{-\rho})$ and

$$G_1\left(\rho; \log_{p/q} p^k n\right) = G_1\left(\rho; \log_{p/q} q^k n\right).$$

More precisely, if $k = \alpha(L_n + x\sqrt{\alpha\beta_2(\rho')L_n})$, where $\alpha \in [\alpha_1+\varepsilon, \alpha_2-\varepsilon]$ and $x = o(L_n^{1/6})$, then

$$\mu_{n,k} = G_1\left(\rho'; \log_{p/q} p^k n\right) \frac{n^{-\rho'}\left(p^{-\rho'}+q^{-\rho'}\right)^k}{\sqrt{2\pi\alpha\beta_2(\rho')L_n}}\, e^{-x^2/2}\left(1+O\left(\frac{1+|x|^3}{\sqrt{L_n}}\right)\right),$$

uniformly in x. In particular, when $\alpha = 1/\mathrm{h}$, where $\mathrm{h} := p\log(1/p) + q\log(1/q)$ is the entropy of the Bernoulli variate, then $\rho' = -1$, and it follows that

$$\mu_{n,k} = \frac{\sqrt{\mathrm{h}}\, G_1\left(-1; \log_{p/q} p^k n\right)}{\log(p/q)\sqrt{2\pi pq}} \cdot \frac{n}{\sqrt{L_n}}\, e^{-x^2/2}\left(1+O\left(\frac{1+|x|^3}{\sqrt{L_n}}\right)\right), \tag{43}$$

uniformly for $x = o(L_n^{1/6})$. Other approximations can be derived for $L_n^{1/6} \ll x = o(\sqrt{L_n})$. Thus $\mu_{n,k}$ reaches the maximum for k near $L_n/\mathrm{h} + O(1)$; also, $\mu_{n,k}$ increases with k when $\alpha < 1/\mathrm{h}$ and decreases with k when $\alpha > 1/\mathrm{h}$; see Figure 2. See also Figure 3 for a plot of $G_1(-1; x)$ for a few p's.

The left boundary: $\rho \to -2^+$ *and* $\rho + 2 \gg L_n^{-1/2}$. In this case, the dominant periodicity vanishes because

$$G_1(\rho; x) \sim \frac{|g(-2)|}{\rho+2} = \frac{2pq}{(p^2+q^2)(\rho+2)};$$

thus

$$\mu_{n,k} \sim \frac{2}{\sqrt{2\pi}\,\log(p/q)(\rho+2)}\, k^{-1/2} n^{-\rho}\left(p^{-\rho}+q^{-\rho}\right)^k. \tag{44}$$

The right boundary: $k/L_n \to 1/\log(1/q)^+$. In this case, $\rho \to \infty$ and $\rho = O(LL_n)$. The periodicity in the leading term of (35) does not vanish because we have

$$G_1(\rho; x) \sim \sum_{j\in\mathbb{Z}} \Gamma(\rho+1+it_j) e^{-2j\pi i x},$$

and G_1 is not bounded. Indeed, the periodicity becomes more pronounced for increasing ρ since

$$\left|\frac{\Gamma(\rho+1+it)}{\Gamma(\rho+1)}\right| = O\left(e^{-t^2/(2\rho)+O(t^4/\rho^3)}\right)$$

for large ρ and $t = o(\rho)$; see Figure 4. This estimate also implies that

$$G_1(\rho; x) = O\left(\sum_{j\in\mathbb{Z}} |\Gamma(\rho+1+it_j)|\right) = O\left(e^{-\rho}\rho^{\rho+1}\right) = O\left(\rho^{1/2}\Gamma(\rho+1)\right).$$

The order is tight. This means that even if we normalize $G_1(\rho; x)$ by $\Gamma(\rho+1)$, $|G_1(\rho; x)|$ still goes to infinity with ρ.

3.4.4. Proof of Theorem 2. In view of (25) (more generally, de-Poissonization Proposition 1), we need only evaluate $\tilde{M}_k(n)$ and obtain precise local expansions for $\tilde{M}_k(ne^{i\theta})$ when $|\theta| \le \theta_0$ in order to estimate the first integral of (25). We first focus on estimating $\tilde{M}_k(n)$ and then extend the same approach to derive the asymptotics of $\tilde{M}_k(ne^{i\theta})$. This suffices to prove that $\mu_{n,k} \sim \tilde{M}_k(n)$. Later in subsection 3.8 we refine this analysis to obtain a better error term.

In order to evaluate $\tilde{M}_k(n)$ by the inverse Mellin transform, first we move the line of integration of (6) to $\Re(s) = \rho$ so that

$$\tilde{M}_k(n) = \frac{1}{2\pi} \int_{-\infty}^{\infty} J_k(n; \rho + it) \mathrm{d}t, \tag{45}$$

where $\rho > -2$ is the saddle-point chosen according to (36) and $J_k(n; s) := n^{-s}\Gamma(s + 1)g(s)(p^{-s}+q^{-s})^k$. We now show that the above integral with $|t| \ge \sqrt{L_n}$ is asymptotically smaller than the dominant term in (35) and then assess the main contribution of saddle-points falling into the range $|t| \le \sqrt{L_n}$.

Estimate of the integral when $|t| \ge \sqrt{L_n}$. Assume from now on that ρ is chosen as described above in (36).

Since our $\rho > -2$ satisfies (40), we have, by (9),

$$\begin{aligned}
\frac{1}{2\pi} \int_{|t|\ge\sqrt{L_n}} J_k(n; \rho + it) \mathrm{d}t &= O\left(n^{-\rho}(p^{-\rho} + q^{-\rho})^k \int_{\sqrt{L_n}}^{\infty} |\Gamma(\rho + 1 + it)| \mathrm{d}t \right) \\
&= O\left(n^{-\rho}(p^{-\rho} + q^{-\rho})^k \int_{\sqrt{L_n}}^{\infty} t^{\rho+1/2} e^{-\pi t/2} \mathrm{d}t \right) \\
&= O\left(L_n^{\rho/2+1/4} e^{-\pi\sqrt{L_n}/2} n^{-\rho}(p^{-\rho} + q^{-\rho})^k \right).
\end{aligned}$$

On the other hand, since $\rho = O(LL_n)$ and $\rho \ge -2 + K_n L_n^{-1/2}$, we then obtain

$$L_n^{\rho/2+1/4} e^{-\pi\sqrt{L_n}/2} = O\left(e^{-\pi\sqrt{L_n}/2 + O(LL_n^2)} \right) = O\left(\Gamma(\rho + 2) e^{-\sqrt{L_n}} \right)$$

for large enough n; the last O-term holds uniformly for $\rho \ge -2 + K_n L_n^{-1/2}$ and ρ satisfying (41).

Contribution from each saddle-point. Let j_0 be the largest integer j for which $2j\pi/\log(p/q) \le \sqrt{L_n}$. Then we can split the integral over $\int_{|t|\le\sqrt{L_n}}$ as follows:

$$\begin{aligned}
\int_{|t|\le\sqrt{L_n}} J_k(n; \rho + it) \mathrm{d}t = &\sum_{|j|<j_0} \int_{|t-t_j|\le\pi/\log(p/q)} J_k(n; \rho + it) \mathrm{d}t \\
&+ \int_{t_{j_0}\le|t|\le\sqrt{L_n}} J_k(n; \rho + it) \mathrm{d}t.
\end{aligned}$$

The last integral is bounded above by

$$O\left(\Gamma(\rho + 2) n^{-\rho}(p^{-\rho} + q^{-\rho})^k e^{-\sqrt{L_n}} \right),$$

by the same argument used above. It remains to evaluate the integrals

$$T_j := \frac{1}{2\pi} \int_{|t-t_j|\le\pi/\log(p/q)} J_k(n; \rho + it) \mathrm{d}t$$

for $|j| < j_0$.

We first derive a uniform bound for $|p^{-\rho-it}+q^{-\rho-it}|$. By the elementary inequalities (29) and

$$\sqrt{1-x} \le 1-\frac{x}{2} \qquad (x\in[0,1]),$$

we have

$$\begin{aligned}
\left|p^{-\rho-it}+q^{-\rho-it}\right| &= \left(p^{-\rho}+q^{-\rho}\right)\sqrt{1-\frac{2p^{-\rho}q^{-\rho}}{(p^{-\rho}+q^{-\rho})^2}\left(1-\cos\left(t\log\left(\frac{p}{q}\right)\right)\right)} \\
&\le \left(p^{-\rho}+q^{-\rho}\right)\left(1-\frac{p^{-\rho}q^{-\rho}}{(p^{-\rho}+q^{-\rho})^2}\left(1-\cos\left((t-t_j)\log\left(\frac{p}{q}\right)\right)\right)\right) \\
&\le \left(p^{-\rho}+q^{-\rho}\right)\left(1-\frac{2p^{-\rho}q^{-\rho}}{\pi^2(p^{-\rho}+q^{-\rho})^2}(t-t_j)^2\log\left(\frac{p}{q}\right)^2\right) \\
&\le \left(p^{-\rho}+q^{-\rho}\right)e^{-c_0(t-t_j)^2}, \qquad (46)
\end{aligned}$$

uniformly for $|t-t_j|\le \pi/\log(p/q)$, where

$$c_0 = c_0(\rho) := \frac{2p^{-\rho}q^{-\rho}\log(p/q)^2}{\pi^2(p^{-\rho}+q^{-\rho})^2} = \frac{2}{\pi^2}\,\beta_2(\rho).$$

We now take

$$v_0 := \begin{cases} k^{-2/5} & \text{if } -2<\rho\le 1, \\ (c_0k)^{-2/5} & \text{if } \rho\ge 1, \end{cases}$$

and split the integration range into two parts: $|t-t_j|\le v_0$ and $v_0<|t-t_j|\le \pi/\log(p/q)$. (We assume that k is so large that $v_0<\pi/\log(p/q)$.)

First consider the case when $-2<\rho\le 1$. From the inequality (46), it follows that

$$\begin{aligned}
T_j'' &:= \frac{1}{2\pi}\int_{v_0\le|t-t_j|\le\pi/\log(p/q)} J_k(n;\rho+it)\mathrm{d}t \qquad (47)\\
&= O\left(|\Gamma(\rho+2+it_j)|n^{-\rho}\left(p^{-\rho}+q^{-\rho}\right)^k\int_{k^{-2/5}}^{\infty}e^{-c_0kv^2}\mathrm{d}v\right) \\
&= O\left(n^{-\rho}\left(p^{-\rho}+q^{-\rho}\right)^k k^{-3/5}e^{-c_0k^{1/5}}\times\begin{cases}|\Gamma(\rho+1+it_j)| & \text{if } j\ne 0\\ 1 & \text{if } j=0\end{cases}\right)
\end{aligned}$$

for each $|j|\le j_0$.

When $\rho\ge 1$ and satisfies (34), we have

$$\begin{aligned}
T_j'' &= O\left(|\Gamma(\rho+1+it_j)|n^{-\rho}\left(p^{-\rho}+q^{-\rho}\right)^k\int_{(c_0k)^{-2/5}}^{\infty}e^{-c_0kv^2}\mathrm{d}v\right) \\
&= O\left(|\Gamma(\rho+1+it_j)|n^{-\rho}\left(p^{-\rho}+q^{-\rho}\right)^k(c_0k)^{-3/5}e^{-(c_0k)^{1/5}}\right)
\end{aligned}$$

for $|j|\le j_0$.

The dominant terms. It remains to evaluate the integrals T_j for t in the range $|t-t_j| \le v_0$. Note that, by our choice of t_j,

$$p^{-\rho-it_j} + q^{-\rho-it_j} = p^{-it_j}\left(p^{-\rho}+q^{-\rho}\right) = q^{-it_j}\left(p^{-\rho}+q^{-\rho}\right),$$

so that

$$\begin{aligned}\frac{p^{-\rho-it}+q^{-\rho-it}}{p^{-\rho-it_j}+q^{-\rho-it_j}} &= 1+\sum_{\ell\ge 1}\frac{i^\ell(t-t_j)^\ell}{\ell!}\cdot\frac{p^{-\rho-it_j}\log(1/p)^\ell + q^{-\rho-it_j}\log(1/q)^\ell}{p^{-\rho-it_j}+q^{-\rho-it_j}}\\ &= 1+\sum_{\ell\ge 1}\frac{i^\ell(t-t_j)^\ell}{\ell!}\cdot\frac{p^{-\rho}\log(1/p)^\ell + q^{-\rho}\log(1/q)^\ell}{p^{-\rho}+q^{-\rho}},\end{aligned}$$

where we recall that $t_j = 2\pi j/\log(p/q)$.

It follows that

$$\log\left(p^{-\rho-it}+q^{-\rho-it}\right) = \log\left(p^{-\rho-it_j}+q^{-\rho-it_j}\right) + \sum_{\ell\ge 1}\frac{\beta_\ell(\rho)}{\ell!}\,i^\ell(t-t_j)^\ell,$$

where, in particular,

$$\beta_1(\rho) = \frac{p^{-\rho}\log(1/p)+q^{-\rho}\log(1/q)}{p^{-\rho}+q^{-\rho}}.$$

The remaining manipulation by using the saddle-point method is then straightforward. We use the local expansions

$$\left(\frac{p^{-\rho-it}+q^{-\rho-it}}{p^{-\rho-it_j}+q^{-\rho-it_j}}\right)^k = \exp\left(k\sum_{1\le\ell\le 3}\frac{\beta_\ell(\rho)}{\ell!}i^\ell(t-t_j)^\ell + O(k|\beta_4(\rho)||t-t_j|^4)\right)$$

and

$$\begin{aligned}&\Gamma(\rho+1+it)g(\rho+it)\\ &\quad= \begin{cases} C_0 + C_1 i(t-t_j) + O\left(\dfrac{(t-t_j)^2}{(\rho+2)^2}\right) & \text{if } -2<\rho\le 1,\\ \Gamma(\rho+1+it_j)e^{(\log\rho)i(t-t_j)}\left(1+C_2 i(t-t_j)+O(|C_2|^3|t-t_j|^2)\right) & \\ \quad\times\left(g(\rho+it_j)+g'(\rho+it_j)i(t-t_j)+O\left(|t-t_j|^2\right)\right) & \text{if } \rho\ge 1,\end{cases}\end{aligned}$$

where

$$\begin{cases} C_0 := \Gamma(\rho+1+it_j)g(\rho+it_j),\\ C_1 := g(\rho+it_j)\Gamma(\rho+1+it_j)\psi(\rho+1+it_j) + g'(\rho+it_j)\Gamma(\rho+1+it_j),\end{cases}$$

$\psi(s) = \Gamma'(s)/\Gamma(s)$ being the logarithmic derivative of the Gamma function, and

$$C_2 := \psi(\rho+1+it_j) - \log\rho \qquad (\rho\ge 1).$$

Here C_0 and C_1 are defined to be their limits when $\rho=-1$ and $j=0$, namely,

$$\begin{cases} C_0 := p\log(1/p)+q\log(1/q),\\ C_1 := -\frac{2p-1}{2}\left(p\log(p)^2 - q\log(q)^2\right) - C_0\gamma - 2pq\log(p)\log(q).\end{cases}$$

Note that $\psi(\rho+1+it_j)-\log\rho = O(\log(1+|t_j|))$. It follows that for $|j|<j_0$

$$T_j = \frac{g(\rho+it_j)}{\sqrt{2\pi\beta_2(\rho)k}}\,\Gamma(\rho+1+it_j)n^{-\rho-it_j}\left(p^{-\rho}+q^{-\rho}\right)^k p^{-ikt_j} \times\left(1+O\left(\frac{1}{k\beta_2(\rho)}+\frac{1}{k(\rho+2)^2}\right)\right).$$

Summing over all $|j|<j_0$ and collecting all estimates, we obtain

$$\tilde{M}_k(n) = \frac{n^{-\rho}\left(p^{-\rho}+q^{-\rho}\right)^k}{\sqrt{2\pi\beta_2(\rho)k}}\sum_{|j|<j_0} g(\rho+it_j)\Gamma(\rho+1+it_j)(p^k n)^{-it_j} \times\left(1+O\left(\frac{1}{k(p/q)^\rho}+\frac{1}{k(\rho+2)^2}\right)\right).$$

An asymptotic approximation to $\tilde{M}_k(z)$. To complete the de-Poissonization, we need a more precise expansion of $\tilde{M}_k(ne^{i\theta})$ for small θ. The above proof by the saddle-point method can be easily extended mutatis mutandis to $\tilde{M}_k(z)$ for complex values of z lying in the right half-plane since we can write (7) as

$$\tilde{M}_k(ne^{i\theta}) = \frac{1}{2\pi i}\int_{(\rho)} n^{-s}e^{-i\theta s}\Gamma(s+1)g(s)\left(p^{-s}+q^{-s}\right)^k \mathrm{d}s,$$

where $\rho>-2$ and $|\theta|\le\pi/2-\varepsilon$. The result is

$$\tilde{M}_k(ne^{i\theta}) = \frac{(p^{-\sigma}+q^{-\sigma})^k}{\sqrt{2\pi\beta_2(\rho)k}}\sum_{|j|<j_0} g(\sigma+it_j)\Gamma(\sigma+1+it_j)(ne^{i\theta})^{-\rho-it_j}p^{-ikt_j} \times\left(1+O\left(\frac{1}{k(p/q)^\rho}+\frac{1}{k(\rho+2)^2}\right)\right), \tag{48}$$

uniformly for $|\theta|\le\pi/2-\varepsilon$ and k lying in the range (34). Note that the index of the sum can be extended to infinity, but it is easier to manipulate a finite sum than an infinite series since we substitute the right-hand side into the Cauchy integral (13) and then integrate term by term. This completes the proof of (35).

3.5. Range (IV): A singularity analysis. We consider range (IV) first, leaving to the next subsection the analysis in the transitional range when $k=\alpha_2 L_n + o(L_n^{2/3})$.

We show that, for $k\ge\alpha_2 L_n + K_n\sqrt{L_n}$, the asymptotics of the expected profile $\tilde{M}_k(n)$ are dictated by the simple pole at $s=-2$ in (6) or, structurally, by the number of pairs of input-strings sharing the same prefixes of length at least k.

THEOREM 3. *If*

$$k\ge\alpha_2\left(L_n+K_n\sqrt{\alpha_2\beta_2(-2)L_n}\right), \tag{49}$$

where β_2 *is defined in* (37)*, then*

$$\mu_{n,k} = 2pqn^2(p^2+q^2)^{k-1}\left(1+O\left(K_n^{-1}e^{-K_n^2/2+O(K_n^3/\sqrt{L_n})}\right)\right), \tag{50}$$

uniformly for $1\ll K_n = o(\sqrt{L_n})$.

Proof. To prove (50), we move the line of integration (by absolute convergence of the integral) of the integral in (6) to $\Re(s) = \varrho$, where

$$\varrho := -2 - \frac{K_n}{\sqrt{\alpha_2\beta_2(-2)L_n}}.$$

Thus $\tilde{M}_k(ne^{i\theta})$ equals the residue of the integrand at $s = -2$ (the dominant term in (50)) plus the integral along $\Re(s) = \varrho$:

$$\tilde{M}_k(ne^{i\theta}) = |g(-2)|n^2e^{2i\theta}(p^2+q^2)^k + \frac{1}{2\pi}\int_{-\infty}^{\infty} J_k(ne^{i\theta}; \varrho + it)\mathrm{d}t,$$

where $|g(-2)| = 2pq/(p^2+q^2)$. It remains only to estimate the last integral. By the same analysis used for T_j'' (see (47)) and the inequality (46), we have

$$\begin{aligned}
&\frac{1}{2\pi}\left(\int_{|t|\le \pi/\log(p/q)} + \sum_{|j|\ge 1}\int_{|t-t_j|\le \pi/\log(p/q)}\right) J_k(ne^{i\theta}; \varrho + it)\mathrm{d}t \\
&\quad = O\left(|\Gamma(\varrho+1)|n^{-\varrho}\left(p^{-\varrho}+q^{-\varrho}\right)^k \int_{|t|\le \pi/\log(p/q)} e^{-c_0kt^2}\mathrm{d}t\right) \\
&\qquad + O\left(n^{-\varrho}\left(p^{-\varrho}+q^{-\varrho}\right)^k \sum_{|j|\ge 1}\left|\Gamma\left(\varrho+1+\frac{2|j|-1}{\log(p/q)}\pi i\right)\right| e^{(2|j|+1)\pi|\theta|/\log(p/q)}\right. \\
&\qquad\qquad \left.\times \int_{|t-t_j|\le \pi/\log(p/q)} e^{-c_0k(t-t_j)^2}\mathrm{d}t\right) \\
&\quad = O\left(\frac{k^{-1/2}}{|\varrho+2|}\, n^{-\varrho}\left(p^{-\varrho}+q^{-\varrho}\right)^k\right) \\
&\quad = O\left(K_n^{-1}n^{-\varrho}\left(p^{-\varrho}+q^{-\varrho}\right)^k\right),
\end{aligned}$$

where we used (9) to bound the sum

$$\begin{aligned}
&\sum_{|j|\ge 1}\left|\Gamma\left(\varrho+1+\frac{2|j|-1}{\log(p/q)}\pi i\right)\right| e^{(2|j|+1)\pi|\theta|/\log(p/q)} \\
&\quad = O\left(\sum_{|j|\ge 1}(2|j|-1)^{\varrho+1/2}\exp\left(-\frac{\pi^2(2|j|-1)}{2\log(p/q)} + \frac{(2|j|+1)\pi|\theta|}{\log(p/q)}\right)\right) \\
&\quad = O(1),
\end{aligned}$$

uniformly for $|\theta| \le \pi/2 - \varepsilon$.

By our choice of ϱ and by straightforward expansion, we have

$$\begin{aligned}
\frac{K_n^{-1}n^{-\varrho}\left(p^{-\varrho}+q^{-\varrho}\right)^k}{n^2\left(p^2+q^2\right)^k} &= O\left(K_n^{-1}e^{-L_n(\varrho+2)+\frac{k}{\alpha_2}(\varrho+2)+\frac{k}{2}\beta_2(-2)(\varrho+2)^2+O\left(k|\varrho+2|^3\right)}\right) \\
&= O\left(K_n^{-1}e^{-K_n^2/2+O(K_n^3/\sqrt{L_n})}\right).
\end{aligned}$$

Thus

$$\tilde{M}_k(ne^{i\theta}) = |g(-2)|(ne^{i\theta})^2(p^2+q^2)^k\left(1+O\left(K_n^{-1}e^{-K_n^2/2+O(K_n^3/\sqrt{L_n})}\right)\right), \tag{51}$$

uniformly for $|\theta| \le \pi/2 - \varepsilon$. Substituting this into (25), we deduce the desired result (50). □

Remarks. (i) When $K_n \ge \varepsilon\sqrt{L_n}$, we can either take $K_n = \varepsilon\sqrt{L_n}$ or refine the analysis to give a better error term.

(ii) The asymptotic approximation (50) can also be derived from the exact expression (10) by using only elementary arguments.

(iii) Also note that the range (49) implies that the saddle-point ρ satisfies $\rho \le -2 - K_n/\sqrt{L_n}$, but the contribution from this saddle-point is asymptotically negligible (compared to the polar singularity).

3.6. Range (III): A uniform analysis. We consider in this subsection the transitional range $k = \alpha_2 L_n + o(L_n^{2/3})$ and show that the transitional behavior of $\mu_{n,k}$ in this range is well described by a Gaussian distribution function.

THEOREM 4. *If*

$$k = \alpha_2 \left(L_n + \xi \sqrt{\alpha_2 \beta_2(-2) L_n} \right), \tag{52}$$

where $\xi = \xi_{n,k} = o(L_n^{1/6})$, *then*

$$\mu_{n,k} = |g(-2)| \Phi(\xi) n^2 \left(p^2 + q^2\right)^k \left(1 + O\left(\frac{1+|\xi|^3}{\sqrt{L_n}}\right)\right), \tag{53}$$

uniformly in ξ, *where* $\Phi(\xi) = (2\pi)^{-1/2} \int_{-\infty}^{\xi} e^{-t^2/2} \mathrm{d}t$.

Proof. We assume first that k satisfies (52) and $k < \alpha_2 L$ (or $\xi < 0$). We move the line of integration of the integral in (11) to $\Re(s) = \rho$, where ρ is taken to be of the same form as in (40); asymptotically

$$\rho = -2 - \frac{\xi}{\sqrt{\alpha_2 \beta_2(-2) L_n}} + O\left(\xi^2 L_n^{-1}\right). \tag{54}$$

By a similar analysis as the proof of Theorem 3, we obtain

$$\begin{aligned} \tilde{M}_k(ne^{i\theta}) = {} & \frac{1}{2\pi} \int_{|t| \le L_n^{-2/5}} J_k(ne^{i\theta}; \rho + it) \mathrm{d}t \\ & + O\left(|\Gamma(\rho + 1 + iL_n^{-2/5})| n^{-\rho} \left(p^{-\rho} + q^{-\rho}\right)^k e^{-c_0 L_n^{1/5}} \right) \\ & + O\left(k^{-1/2} n^{-\rho} \left(p^{-\rho} + q^{-\rho}\right)^k \right), \end{aligned}$$

where $|\theta| < \pi/2$. By (54), we have

$$|\Gamma(\rho + 1 + iL_n^{-2/5})| = O\left(\frac{1}{|\xi| L_n^{-1/2} + L_n^{-2/5}} \right) = O(L_n^{2/5}).$$

It follows that

$$\tilde{M}_k(ne^{i\theta}) = \frac{1}{2\pi} \int_{|t| \le L_n^{-2/5}} J_k(ne^{i\theta}; \rho + it) \mathrm{d}t + O\left(k^{-1/2} n^{-\rho} \left(p^{-\rho} + q^{-\rho}\right)^k \right).$$

Note that since $s \mapsto \Gamma(s+1) + 1/(s+2)$ is analytic for $|s+2| \le 1 - \varepsilon$, we have

$$\begin{aligned} \tilde{M}_k(ne^{i\theta}) = {} & \frac{|g(-2)|}{2\pi} \int_{|t| \le L_n^{-2/5}} \frac{n^{-\rho - it} e^{-i\theta(\rho + it)}}{\rho + 2 + it} \left(p^{-\rho - it} + q^{-\rho - it}\right)^k \mathrm{d}t \\ & + O\left(k^{-1/2} n^{-\rho} \left(p^{-\rho} + q^{-\rho}\right)^k \right). \end{aligned}$$

The integral on the right-hand side is evaluated as follows:

$$\begin{aligned}
&\frac{|g(-2)|}{2\pi}\int_{|t|\le L_n^{-2/5}} \frac{n^{-\rho-it}e^{-i\theta(\rho+it)}}{\rho+2+it}\left(p^{-\rho-it}+q^{-\rho-it}\right)^k \mathrm{d}t \\
&\quad = \frac{|g(-2)|}{2\pi}\, n^{-\rho}e^{-i\theta\rho}\left(p^{-\rho}+q^{-\rho}\right)^k \int_{|t|\le L_n^{-2/5}} \frac{e^{\theta t-\beta_2(\rho)kt^2/2+O(k|t|^3)}}{\rho+2+it}\,\mathrm{d}t \\
&\quad = \frac{|g(-2)|}{2\pi}\, n^{-\rho}e^{-i\theta\rho}\left(p^{-\rho}+q^{-\rho}\right)^k \int_{-\infty}^{\infty} \frac{e^{-t^2/2}}{\xi_0+it}\left(1+O\left(\frac{|t|+|t|^3}{\sqrt{L_n}}\right)\right)\mathrm{d}t, \qquad (55)
\end{aligned}$$

where

$$\xi_0 := (\rho+2)\sqrt{\beta_2(\rho)k} > 0.$$

Note that $\xi_0 = -\xi + O\left(\xi^2 L_n^{-1/2}\right)$ by (52) and (54). Since $\xi_0 > 0$, we have

$$\begin{aligned}
\frac{1}{2\pi}\int_{-\infty}^{\infty}\frac{e^{-t^2/2}}{\xi_0+it}\,\mathrm{d}t &= \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{-t^2/2}\int_0^{\infty} e^{-v(\xi_0+it)}\mathrm{d}v\mathrm{d}t \\
&= \frac{1}{2\pi}\int_0^{\infty} e^{-v\xi_0}\int_{-\infty}^{\infty} e^{-t^2/2-itv}\mathrm{d}t\mathrm{d}v \\
&= \frac{1}{\sqrt{2\pi}}\int_0^{\infty} e^{-v^2/2-v\xi_0}\mathrm{d}v \\
&= e^{\xi_0^2/2}\Phi(-\xi_0).
\end{aligned}$$

The error term in (55) is estimated similarly and satisfies

$$L_n^{-1/2}\int_{-\infty}^{\infty}\frac{(|t|+|t|^3)e^{-t^2/2}}{|(\rho+2)\sqrt{\beta_2(\rho)k}+it|}\,\mathrm{d}t = O\left(L_n^{-1/2}\int_0^{\infty}(v+v^3)e^{-v^2/2-v\xi_0}\mathrm{d}v\right).$$

Observe that

$$e^{x^2/2}\Phi(-x) = \begin{cases} O\left(x^{-1}\right) & \text{if } x\to\infty, \\ O\left(e^{x^2/2}\right) & \text{if } x\to-\infty. \end{cases} \qquad (56)$$

Also

$$\int_0^{\infty}(v+v^3)e^{-v^2/2-vx}\mathrm{d}v = \begin{cases} O\left(x^{-2}\right) & \text{if } x\to\infty, \\ O\left(|x|^3e^{x^2/2}\right) & \text{if } x\to-\infty, \end{cases}$$

so that

$$\int_0^{\infty} v^3e^{-v^2/2-vx}\mathrm{d}v = O\left(e^{x^2/2}\Phi(-x)(1+|x|^3)\right).$$

Thus

$$\begin{aligned}
\tilde{M}_k(ne^{i\theta}) &= |g(-2)|(ne^{i\theta})^{-\rho}\left(p^{-\rho}+q^{-\rho}\right)^k e^{\xi_0^2/2}\Phi(-\xi_0)\left(1+O\left(\frac{1+|\xi|^3}{\sqrt{L_n}}\right)\right) \\
&\quad + O\left(k^{-1/2}n^{-\rho}\left(p^{-\rho}+q^{-\rho}\right)^k\right), \qquad (57)
\end{aligned}$$

uniformly for $|\theta| \le \pi/2 - \varepsilon$. Substituting this in (25) and using the expansions

$$n^{-\rho}\left(p^{-\rho}+q^{-\rho}\right)^k = n^2\left(p^2+q^2\right)^k e^{-\xi^2/2+O(|\xi|^3 L_n^{-1/2})},$$
$$e^{\xi_0^2/2}\Phi(\xi_0) = e^{\xi^2/2}\Phi(\xi)\left(1+O\left(|\xi|^3 L_n^{-1/2}\right)\right),$$

we deduce (53) when $\xi < 0$.

The restriction that $\xi < 0$ can now be removed by continuity (when $\xi_0 = 0$ the integral path has to be properly indented) or by a similar analysis. This proves (53).

One can easily check, by (56), that the asymptotic estimate (53) coincides with the two estimates (44) and (50) when $\xi \to -\infty$ and $\xi \to \infty$, respectively. □

Remark. The appearance of the normal distribution function is typical when a saddle-point coalesces with a simple pole; see [83]. Also, the polynomial order (4) of $\mu_{n,k}$ now follows from (35), (50), and (53).

3.7. The range where the expected profile grows unbounded. An important consequence of the preceding results is the following characterization of the range where $\mu_{n,k} \to \infty$, which also will be seen to be the range where $B_{n,k}$ is asymptotically normally distributed.

THEOREM 5. *Define*

$$m_0 := \left\lceil \frac{1}{p/q-1} \right\rceil \quad \textit{and} \quad \alpha_3 := \frac{2}{\log\frac{1}{p^2+q^2}}.$$

Then $\mu_{n,k} \to \infty$ *iff*

$$\alpha_1\left(L_n - LLL_n - \log m_0 + m_0 \log\left(\frac{p}{q}\right) - \frac{LLL_n - K_n}{m_0 LL_n}\right) \le k \le \alpha_3\left(L_n - K_n\right)$$

as $n \to \infty$.

Proof. Consider first the upper bound. If $k \le \alpha_3 L_n - x$, then

$$n^2(p^2+q^2)^k \ge (p^2+q^2)^{-x},$$

which tends to infinity if $x \to \infty$; on the other hand, if $k \ge \alpha_3 L_n - x$, then the reverse inequality holds and the right-hand side remains bounded if x is less than a positive constant.

For the lower bound, we use the estimate (24). First, if $k \le k_0 = \alpha - 1$ $(L_n - LLL_n + \log(p/q-1))$ (see (20)), then

$$\mu_{n,k} = \Theta(q^k n e^{-q^k n}) = o(1).$$

Next, if $k_{m-1} \le k \le k_m$, $m \ge 1$, then by (24)

$$\mu_{n,k} = \Theta(S_{n,k,m}) = \Theta(L_n^{m-e^\eta/(p/q-1)} LL_n),$$

where k is written in the form (31). Since $\eta \in [0, \log(p/q)]$, we have

$$m - \frac{p}{p-q} \le m - \frac{e^\eta}{p/q-1} \le m - \frac{q}{p-q}.$$

Also, by the definition of m_0, we have the inequalities

$$m_0 - 1 < \frac{q}{p-q} = \frac{1}{p/q-1} \le m_0.$$

Thus if $m \le m_0 - 1$, then

$$m - \frac{e^\eta}{p/q-1} \le m - \frac{q}{p-q} < m - m_0 + 1 \le 0,$$

implying that $\mu_{n,k} \to 0$ for $k \le k_{m_0-1}$. Similarly, since

$$m_0 \le \frac{p}{p-q} < m_0 + 1,$$

we have

$$m - \frac{e^\eta}{p/q-1} \ge m - \frac{p}{p-q} > m - m_0 - 1 \ge 0,$$

when $m \ge m_0 + 1$. Therefore, $\mu_{n,k} \to \infty$ if $k \ge k_{m_0}$ (and remains in the range $k \le \alpha_1(L_n - LLL_n + K_n)$).

The remaining range is $k_{m_0-1} \le k \le k_{m_0}$ in which $\mu_{n,k} = \Theta(L_n^{m_0 - e^\eta/(p/q-1)} LL_n)$, where

$$k = \alpha_1(L_n - LLL_n + \log(p/q-1) + m_0 \log(p/q) - \eta).$$

We distinguish three cases: (i) if

$$\eta \ge \log m_0 + \log(p/q-1) + \frac{LLL_n + K_n}{m_0 LL_n},$$

then $\mu_{n,k} = \Theta(L_n^{m - e^\eta/(p/q-1)} LL_n)$ and

$$L_n^{m - e^\eta/(p/q-1)} LL_n \le e^{-K_n} \to 0;$$

(ii) if

$$\eta = \log m_0 + \log(p/q-1) + \frac{LLL_n + x}{m_0 LL_n},$$

then

$$\mu_{n,k} \sim S_{n,k,m_0} \sim \frac{\alpha_1^{m_0}}{(m_0-1)!}\, e^{-x},$$

uniformly for $x = O(1)$; and

(iii) if

$$\eta \le \log m_0 + \log(p/q-1) + \frac{LLL_n - K_n}{m_0 LL_n},$$

then $\mu_{n,k} = \Theta(L_n^{m - e^\eta/(p/q-1)} LL_n)$ and

$$L_n^{m - e^\eta/(p/q-1)} LL_n \ge e^{K_n} \to \infty.$$

Thus $\mu_{n,k}$ is bounded away from zero and infinity in the second case.

This proves the theorem when k lies in ranges (I) and (IV). The remaining cases follow easily from (35) and (53). □

Let $\{x\}$ denote the fractional part of x. The lower bound can be further refined as follows.

COROLLARY 3. *Let*

$$\hat{k} := \alpha_1 \left(L_n - LLL_n - \log m_0 + m_0 \log(p/q) - \frac{LLL_n}{m_0 LL_n} \right), \tag{58}$$

where $m_0 = \lceil 1/(p/q-1) \rceil$. *Then* (i) $\mu_{n,k} \to \infty$ *for* $\lceil \hat{k} \rceil \le k \le \alpha_3(L_n - K_n)$; (ii) $\mu_{n,k} \to 0$ *for* $k \le \lceil \hat{k} \rceil - 2$; *and* (iii)

$$\mu_{n,\lceil \hat{k} \rceil - 1} \begin{cases} = \Theta(1) & \text{if } \{\hat{k}\} = O(LL_n^{-1}), \\ \to 0 & \text{otherwise.} \end{cases}$$

Proof. The proof is similar to that of Theorem 5. We consider only the last case. First write

$$\lceil \hat{k} \rceil - 1 = \hat{k} - \{\hat{k}\} = \alpha_1 \left(L_n - LLL_n + \log(p/q - 1) + m_0 \log(p/q) - \eta' \right),$$

where

$$\eta' = \log m_0 + \log \left(\frac{p}{q} - 1 \right) + \{\hat{k}\}/\alpha_1 + \frac{LLL_n}{m_0 LL_n}.$$

(We assume that $\hat{k}$ is not an integer.) Then we follow the same proof as above by distinguishing three cases. In particular, the case when $\hat{k}$ is an integer is also covered by the bounded case. □

The result is to be compared with Pittel's result in [65], which says that the probability that the shortest path equals either $\langle \kappa_n \rangle$ or $\langle \kappa_n \rangle + 1$ tends to 1, where $\langle x \rangle$ denotes the nearest integer to x and

$$\kappa_n = \alpha_1 \left(L_n - LLL_n - \log \max_{j \ge 1} j(q/p)^j \right).$$

Note that

$$-\log \max_{j \ge 1} j(q/p)^j = -\log m_0 + m_0 \log(p/q).$$

Our result is slightly more precise; see section 8.

3.8. Refinement of $\mu_{n,k}$ by de-Poissonization. All expansions for $\mu_{n,k}$ that we have derived so far are in terms of slowly decreasing powers of L_n^{-1} or LL_n^{-1}, which will turn out to be insufficient for the asymptotics of the variance because of cancellation of dominant terms. Thus in this section we derive a more effective expansion for $\mu_{n,k}$ in terms of $\tilde{M}_k(n)$ and its higher derivatives; namely, we derive an expression of the form (19). The major difference here is that we do not substitute the asymptotic expansions for $\tilde{M}_k(n)$ into the Cauchy integral representation for $\mu_{n,k}$, resulting in a less explicit asymptotic approximation to $\mu_{n,k}$ but with a much better error term.

We start with a lemma in which we again use $k_0 = \alpha_1(L_n - LLL_n + \log(p/q-1))$.

LEMMA 4. *Define*

$$\rho_0 := \begin{cases} q^k n & \text{if } 1 \le k \le k_0, \\ \rho & \text{if } \rho \ge 1 \text{ and } k \ge k_0, \\ 1 & \text{if } \rho \le 1, \end{cases} \tag{59}$$

where ρ is given by (36). *Then*

$$\tilde{M}_k^{(\ell)}(ne^{i\theta}) = O\left(\rho_0^\ell n^{-\ell}\tilde{M}_k(n)\right), \tag{60}$$

uniformly for $\theta = o(LL_n^{-1/2})$.

Proof. If $\ell \geq 1$, then, by (8),

$$\begin{aligned}\tilde{M}_k^{(\ell)}(z) &= \sum_{0\leq j<k}\binom{k-1}{j}(p^j q^{k-1-j})^\ell \tilde{M}_1^{(\ell)}(z)\\ &= \sum_{0\leq j<k}\binom{k-1}{j}(p^j q^{k-j})^{\ell+1} z e^{-p^j q^{k-j}z}\left(1+O\left(|z|^{-1}\right)\right)\end{aligned}$$

as $|z|\to\infty$ and $\Re(z)>0$. If $1\leq k\leq k_0$ (see (20)), then a proof similar to (and simpler than) that of (30) shows that

$$\tilde{M}_k^{(\ell)}(ne^{i\theta}) = O\left(q^{k(\ell+1)} n e^{-q^k n\cos\theta}\right) = O\left(\rho_0^\ell n^{-\ell}\tilde{M}_k(n)\right),$$

uniformly for $\theta = o(LL_n^{-1/2})$. If $k_{m-1}\leq k\leq k_m$, where $m\geq 1$, then the proof of (30) is also easily amended and we obtain

$$\tilde{M}_k^{(\ell)}(ne^{i\theta}) = O\left(k^m (p^m q^{k-m})^{\ell+1} n e^{-p^m q^{k-m} n\cos\theta}\right) = O\left(LL_n^\ell n^{-\ell}\tilde{M}_k(n)\right),$$

uniformly for $\theta = o(LL_n^{-1/2})$. Note that $\rho = O(LL_n)$ when $k_{m-1}\leq k\leq k_m$, $m\geq 1$. For the proof of (60) in the remaining ranges of k, we use the integral representation

$$\tilde{M}_k^{(\ell)}(z) = \frac{(-1)^\ell}{2\pi i}\int_{(\rho)} s(s+1)\cdots(s+\ell-1) z^{-s-\ell}\Gamma(s+1) g(s)\left(p^{-s}+q^{-s}\right)^k \mathrm{d}s$$

and a simpler analysis than that given above for $\tilde{M}_k(z)$. In particular, when k lies in the saddle-point range (II) and $\rho\geq 1$, we have, by the same analysis used for (46),

$$\begin{aligned}&\tilde{M}_k^{(\ell)}(ne^{i\theta})\\ &= O\left(n^{-\rho-\ell}\sum_{j\in\mathbb{Z}}|\rho+it_j|^\ell\,|\Gamma(\rho+1+it_j)|\int_{|t-t_j|\leq \pi/\log(p/q)}\left|(p^{-\rho-it}+q^{-\rho-it})^k\right|\mathrm{d}t\right)\\ &= O\left(k^{-1/2}(q/p)^{\rho/2}(p^{-\rho}+q^{-\rho})^k n^{-\rho-\ell}\rho^\ell\sum_{j\in\mathbb{Z}}|1+it_j|^\ell|\Gamma(\rho+1+it_j)|\right)\\ &= O\left(k^{-1/2}(q/p)^{\rho/2}(p^{-\rho}+q^{-\rho})^k n^{-\rho-\ell}\rho^\ell\right)\\ &= O\left(\rho^\ell n^{-\ell}\tilde{M}_k(n)\right),\end{aligned}$$

uniformly for $|\theta|\leq \pi/2-\varepsilon$. The other cases are treated similarly. Alternatively, we can use the estimates (48), (51), and (57) for $\tilde{M}_k(ne^{i\theta})$ and the integral formula

$$\tilde{M}_k^{(\ell)}(z) = \frac{\ell!}{2\pi i}\int_{|w-z|\leq\varepsilon|z|/\rho_0}\frac{\tilde{M}_k(w)}{(w-z)^{\ell+1}}\,\mathrm{d}w,$$

following a standard analysis (referred to as Ritt's theorem in [61, pp. 9–10]). □

An application of Proposition 1 (analytic de-Poissonization) and the above lemma leads to our refinement.

THEOREM 6. *If* $q^{2k}n \to 0$, *then*

$$\mu_{n,k} = \tilde{M}_k(n) - \frac{n}{2}\,\tilde{M}_k''(n) + O\left(\rho_0^4 n^{-2}\tilde{M}_k(n)\right), \tag{61}$$

where ρ_0 *is given in* (59).

Proof. By (26) and (60), we can take $\delta(n) = \rho_0/n$, which is $o(n^{-1/2})$ if $q^{2k}n \to 0$. □

Remark. The condition that $q^{2k}n \to 0$ is also necessary for $\mu_{n,k} \sim \tilde{M}_k(n)$ because otherwise $\mu_{n,k} \sim q^k n(1-q^k)^{n-1}$, which is not asymptotically equivalent to $\tilde{M}_k(n)$. Note also that (61) and (60) imply that $\mu_{n,k} = \tilde{M}_k(n)\left(1 + O(\rho_0^2 n^{-1})\right)$.

4. Variance of the external profile. Asymptotic approximations to $\sigma_{n,k}^2 := \mathbb{V}(B_{n,k})$ are derived in this section. It turns out that the variance is of the same order as the mean in all ranges, implying that the standard deviation is small; therefore we expect asymptotic normality when the variance tends to infinity with n. The calculations here are more involved due to the cancellation of dominant orders of $\mu_{n,k}^2$. The key idea is a suitable manipulation of the corresponding de-Poissonized approximations for the mean and the second moments.

4.1. Recurrence and generating functions of the second moment. Let $\nu_{n,k} := \mathbb{E}(B_{n,k}^2)$ denote the second moment of $B_{n,k}$. By (1), we have the recurrence

$$\nu_{n,k} = \sum_{0\le j\le n} \binom{n}{j} p^j q^{n-j}\left(\nu_{j,k-1} + \nu_{n-j,k-1}\right) + \omega_{n,k}$$

for $n, k \ge 1$ with $\nu_{n,0} = \delta_{n,1}$, where

$$\omega_{n,k} := 2\sum_{0\le j\le n} \binom{n}{j} p^j q^{n-j}\mu_{j,k-1}\mu_{n-j,k-1}.$$

Generating functions. Let $N_k(z) := \sum_n \nu_{n,k} z^n/n!$. Then $N_k(z)$ satisfies

$$N_k(z) = e^{qz}N_{k-1}(pz) + e^{pz}N_{k-1}(qz) + \omega_k(z) \qquad (k \ge 2)$$

with $N_1(z) = 2pqz^2 + M_1(z)$, where $\omega_k(z) := 2M_{k-1}(pz)M_{k-1}(qz)$. It follows that the Poisson generating function $\tilde{N}_k(z) := e^{-z}N_k(z)$ satisfies

$$\tilde{N}_k(z) = \tilde{N}_{k-1}(pz) + \tilde{N}_{k-1}(qz) + \tilde{\omega}_k(z),$$

where $\tilde{\omega}_k(z) = 2\tilde{M}_{k-1}(pz)\tilde{M}_{k-1}(qz)$. By iterating this functional equation, we obtain

$$\tilde{N}_k(z) = \sum_{0\le \ell<k} \binom{k-1}{\ell} \tilde{N}_1(p^\ell q^{k-1-\ell}z) + \sum_{0\le m\le k-2}\ \sum_{0\le \ell\le m} \binom{m}{\ell}\tilde{\omega}_{k-m}(p^\ell q^{m-\ell}z)$$

for $k \ge 2$.

Regularity of $N_k(z)$. The following estimate is useful in justifying the application of the saddle-point method and the de-Poissonization procedure.

LEMMA 5. *Let $z = re^{i\theta}$, where $r \geq 0$ and $|\theta| \leq \pi$. Then the estimate*

$$|N_k(z)| \leq N_k(r)e^{-cr\theta^2} \tag{62}$$

holds for $r \geq 0$ and $|\theta| \leq \pi$ for some constant c independent of r, k, and θ.

Proof. We start from

$$N_k(z) = e^z \sum_{0\leq \ell<k} \binom{k-1}{\ell} \tilde{N}_1(p^\ell q^{k-1-\ell} z) + \omega_k(z) + e^z \sum_{1\leq m\leq k-2} \sum_{0\leq \ell\leq m} \binom{m}{\ell} \tilde{\omega}_{k-m}(p^\ell q^{m-\ell} z)$$

and apply Lemma 2 to the first sum. For the second term, we observe first that, by (26),

$$|\omega_k(z)| \leq 2M_{k-1}(pr)M_{k-1}(qr)e^{-cr\theta^2} = \omega_k(r)e^{-cr\theta^2},$$

uniformly for $r \geq 0$ and $|\theta| \leq \pi$. It remains to estimate the last sum

$$\left| e^z \sum_{1\leq m\leq k-2} \sum_{0\leq \ell\leq m} \binom{m}{\ell} \tilde{\omega}_{k-m}(p^\ell q^{m-\ell} z) \right|,$$

for which we apply the same argument as that used in the proof of Lemma 2, yielding an estimate of the type (28). Collecting the three parts gives (62). ∎

An auxiliary function for asymptotic variance. As a good approximation to $\mathbb{V}(B_{n,k})$, define $\tilde{V}_k(z) := \tilde{N}_k(z) - \tilde{M}_k^2(z)$. Then $\tilde{V}_k(z)$ satisfies

$$\tilde{V}_k(z) = \tilde{V}_{k-1}(pz) + \tilde{V}_{k-1}(qz) \qquad (k \geq 2),$$

which, by iteration, yields

$$\tilde{V}_k(z) = \sum_{0\leq j<k} \binom{k-1}{j} \tilde{V}_1(p^j q^{k-1-j} z), \tag{63}$$

where

$$\tilde{V}_1(z) = \tilde{M}_1(z) + 2pqz^2e^{-z} - \tilde{M}_1^2(z).$$

It follows that

$$\tilde{V}_k(z) = \frac{1}{2\pi i} \int_{(\rho)} z^{-s}\Gamma(s+1)h(s)\left(p^{-s} + q^{-s}\right)^k \mathrm{d}s, \tag{64}$$

where $\rho > -2$ and

$$h(s) := 1 - \frac{1}{p^{-s} + q^{-s}} - \frac{s+1}{p^{-s} + q^{-s}} \left(\frac{p^{-s} + q^{-s} + 1}{2^{s+2}} - \frac{2p}{(1+p)^{s+2}} - \frac{2q}{(1+q)^{s+2}} \right);$$

compare (6).

4.2. Asymptotics of $\sigma^2_{n,k}$. In this section we show that the variance $\sigma^2_{n,k} := \mathbb{V}(B_{n,k})$ is asymptotically equivalent to $\mu_{n,k}$ when k lies in range (I) and $2\mu_{n,k}$ when k lies in ranges (III) and (IV), and is of the same order as $\mu_{n,k}$ in the central range (II).

THEOREM 7. (i) *If* $1 \le k \le \alpha_1(1+o(1))L_n$, *then*

$$\sigma^2_{n,k} \sim \mu_{n,k}. \tag{65}$$

(ii) *If* $\alpha_1(L_n - LLL_n + K_n) \le k \le \alpha_2(L_n - K_n\sqrt{L_n})$, *then*

$$\sigma^2_{n,k} = G_2\left(\rho; \log_{p/q} p^k n\right) \frac{n^{-\rho}\left(p^{-\rho}+q^{-\rho}\right)^k}{\sqrt{2\pi\beta_2(\rho)k}} \left(1 + O\left(\frac{1}{k(p/q)^\rho} + \frac{1}{k(\rho+2)^2}\right)\right), \tag{66}$$

where $\rho = \rho(n,k) > -2$ *is given in* (36) *and*

$$G_2(\rho; x) = \sum_{j\in\mathbb{Z}} h(\rho + it_j)\Gamma(\rho + 1 + it_j)e^{-2j\pi i x} \qquad (t_j := 2j\pi/\log(p/q)).$$

(iii) *If* $k \ge \alpha_2(1-o(1))L_n$, *then*

$$\sigma^2_{n,k} \sim 2\mu_{n,k}. \tag{67}$$

Proof. Since most details are similar to those for $\mu_{n,k}$, only the key differences will be highlighted. We separate the analysis into two overlapping cases: $1 \le k \le k_0 = \alpha_1(L_n - LLL_n + \log(p/q-1))$ and $q^{2k}n \to 0$.

Consider the first case when $1 \le k \le k_0$. In this range, $\tilde{M}_k(ne^{i\theta}) \to 0$ for $\theta = o(LL_n^{-1/2})$ by (30) and (33). By (63) and the same proof of (30), we have

$$\tilde{V}_k(ne^{i\theta}) = \tilde{M}_k(ne^{i\theta})\left(1 + O\left(q^k n e^{-q^k n\cos\theta}\right)\right),$$

uniformly for $\theta = o(LL_n^{-1/2})$. Then since

$$\nu_{n,k} = n![z^n]N_k(z) = n![z^n]e^z\left(\tilde{V}_k(z) + \tilde{M}_k^2(z)\right),$$

and $\mu_{n,k} \to 0$, it is straightforward to show, by (30), (62), and the proof of (22), that $\sigma^2_{n,k} \sim \mu_{n,k}$ in this case, which establishes (65).

We now consider the range $q^{2k}n \to 0$ that will cover the other two cases. We will show that $\mathbb{V}(B_{n,k}) \sim \tilde{V}_k(n)$, which in turn will imply (66) and (67) (indeed, $|h(-2)| = 2|g(-2)| = 4pq/(p^2+q^2)$).

In this case, by the integral representation (64) and the same method of proof for $\tilde{M}_k(z)$, we have

$$\tilde{V}_k^{(\ell)}(ne^{i\theta}) = O\left(\rho_0^\ell n^{-\ell}\tilde{V}_k(n)\right), \tag{68}$$

uniformly for $\theta = o(LL_n^{-1/2})$ whenever $q^{2k}n \to 0$. On the other hand, since $\tilde{M}_k(z)$ satisfies the estimate (60), we have

$$\frac{\mathrm{d}^\ell}{\mathrm{d}z^\ell}\tilde{M}_k^2(z)\Big|_{z=ne^{i\theta}} = O\left(\rho_0^\ell n^{-\ell}\tilde{M}_k^2(n)\right) \qquad (\ell = 0, 1, \dots),$$

uniformly for $\theta = o(LL_n^{-1/2})$. Thus $\tilde{N}_k(z) = \tilde{V}_k(z) + \tilde{M}_k^2(z)$ also satisfies condition (15) of Proposition 1. Therefore, by (19) of Proposition 1 we have

$$\nu_{n,k} = \tilde{N}_k(n) - \frac{n}{2}\,\tilde{N}_k''(n) + O\left(\rho_0^4 n^{-2}\tilde{N}_k(n)\right)$$

for $k \geq k_0$. Note that $\tilde{N}_k(n) = \Theta(\mu_{n,k}^2)$ when $\mu_{n,k} \to \infty$, but $\tilde{N}_k(n) = \Theta(\mu_{n,k})$ when $\mu_{n,k} \to 0$.

On the other hand, by (61),

$$\mu_{n,k}^2 = \tilde{M}_k^2(n) - n\tilde{M}_k(n)\tilde{M}_k''(n) + O\left(\rho_0^4 n^{-2}\tilde{M}_k^2(n)\right).$$

Therefore

$$\sigma_{n,k}^2 = \tilde{V}_k(n)\left(1 + O(\rho_0^2 n^{-1}\mu_{n,k})\right),$$

whenever $q^{2k}n \to 0$. Note that the O-term is at most of order $LL_n^2 L_n^{-1/2}$. In fact, a further refinement (see (16 or [37]) shows that

$$\sigma_{n,k}^2 = \tilde{V}_k(n) - n\tilde{M}_k'(n)^2 - \frac{n}{2}\,\tilde{V}_k''(n) + O\left(\rho_0^4 n^{-2}\tilde{N}_k(n)\right).$$

It remains to derive asymptotic approximations to $\tilde{V}_k(n)$, which follow the same methods of proof used for $\tilde{M}_k(n)$, the only difference being changing all occurrences of $g(s)$ to $h(s)$. In particular, $G_2(\rho; x) \sim G_1(\rho; x)$ when $\rho \to \infty$, which corresponds to $k \leq \alpha_1(1 + o(1))L_n$; also $|h(-2)| = 2|g(-2)| = 4pq/(p^2 + q^2)$. This proves (66) and (67). □

We conclude this section with two corollaries.

COROLLARY 4. *As $n \to \infty$, the variance $\sigma_{n,k}^2 \to \infty$ iff the mean $\mu_{n,k} \to \infty$.*

COROLLARY 5. *If $\mu_{n,k} \to \infty$, then $B_{n,k}/\mu_{n,k} \to 1$ in probability.*

Proof. The proof follows from Theorem 7 and Chebyshev's inequality. □

5. Limiting distribution. We prove in this section that the limiting distribution of $B_{n,k}$ is normal if $\sigma_{n,k} \to \infty$ and is Poisson if the variance remains bounded. Since the mean and the variance are asymptotically of the same order, the conditions can also be stated by replacing $\sigma_{n,k} \to \infty$ by $\mu_{n,k} \to \infty$. These results cover the range when $k \geq \alpha_1(L_n - LL_n + O(1))$ and $k \leq \alpha_2(L_n + O(1))$. Outside this range, $\mu_{n,k} \to 0$, so $B_{n,k} \to 0$ in probability.

THEOREM 8. (i) *If $\sigma_{n,k} \to \infty$, then*

$$\frac{B_{n,k} - \mu_{n,k}}{\sigma_{n,k}} \xrightarrow{d} \mathcal{N}(0,1), \tag{69}$$

where $\mathcal{N}(0,1)$ denotes a standard normal random variable and $\xrightarrow{d}$ stands for convergence in distribution.

(ii) *If $\sigma_{n,k} = \Theta(1)$, then*

$$\begin{cases} \mathbb{P}\left(B_{n,k} = 2m\right) = \dfrac{\lambda_0^m}{m!}\,e^{-\lambda_0} + o(1), \\ \mathbb{P}\left(B_{n,k} = 2m+1\right) = o(1), \end{cases} \tag{70}$$

uniformly for (finite) $m \geq 0$, where $\lambda_0 := pqn^2(p^2+q^2)^{k-1}$.

Note that (70) implies that $B_{n,k}$ takes asymptotically only even numbers when the mean is bounded. This indeed holds in the wider range when

$$k \geq \frac{3}{\log(1/(p^3+q^3))}(L_n + K_n).$$

Intuitively, this is the range where $\binom{n}{j}(p^j+q^j)^k \to 0$ for all $j \geq 3$, where $\binom{n}{j}(p^j+q^j)^k$ is the expected number of groups of j input-strings having common prefixes of length at least k; since $\sum_{j\geq 3}\binom{n}{j}(p^j+q^j)^k \to 0$, all nodes appearing at levels $\geq k$ are most likely only in pairs (see [32] for more precise local limit theorems for $B_{n,k}$).

Let $\tilde{\sigma}_{n,k} := \sqrt{\tilde{V}_k(n) - n\tilde{M}_k'(n)^2}$ (see Theorem 7). We will prove, by extending the above de-Poissonization procedure, that

$$\mathbb{E}\exp\left(\frac{B_{n,k} - \tilde{M}_k(n)}{\tilde{\sigma}_{n,k}}\, i\varphi\right) = e^{-\varphi^2/2}\left(1 + O\left(\frac{1+|\varphi|^3}{\sigma_{n,k}}\right)\right), \tag{71}$$

uniformly for $\varphi = o(\sigma_{n,k}^{1/5})$, which implies (69) by Lévy's continuity theorem since $\mu_{n,k} \sim \tilde{M}_k(n)$ and $\sigma_{n,k} \sim \tilde{\sigma}_{n,k}$ when $\mu_{n,k} \to \infty$. Note that as far as the central limit theorem is concerned, the validity of (71) in the range $\varphi = O(1)$ suffices; observe also that centering $B_{n,k}$ by the exact mean or normalizing $B_{n,k}$ by the exact variance will result in a poorer error term.

Our method of proof of (71) is roughly as follows. We start by deriving a closed-form expression for the bivariate generating function $\mathcal{P}_k(z,y) = \sum_{n\geq 0} P_{n,k}(y)z^n/n!$ by using the recurrence (1). We then will apply the Cauchy integral representation to prove (71), for which we need, as in the analytic de-Poissonization used above, a crude estimate for $|\mathcal{P}_k(ne^{i\theta}, e^{i\varphi})|$ for $|\theta|$ away from zero, as well as a more precise local expansion when $|\theta|$ is very close to zero. The proof for the Poisson limit law (70) is similar.

5.1. An exact expression for $\mathcal{P}_k(z,y)$. By (1), we have the functional equation

$$\mathcal{P}_k(z,y) = \mathcal{P}_{k-1}(pz,y)\mathcal{P}_{k-1}(qz,y) \qquad (k \geq 2)$$

with

$$\mathcal{P}_1(z,y) = e^z + (y-1)z\left(p(e^{qz}-1) + q(e^{pz}-1)\right) + pq(y-1)^2z^2.$$

By iterating this functional equation, we obtain

$$\mathcal{P}_k(z,y) = \prod_{0\leq j<k} \mathcal{P}_1(p^jq^{k-1-j}z, y)^{\binom{k-1}{j}} \qquad (k \geq 1). \tag{72}$$

This expression, although explicit, is less transparent from an asymptotic viewpoint.

5.2. A uniform estimate for $|\mathcal{P}_k(re^{i\theta}, y)|$. We first prove a uniform bound on $|\mathcal{P}_k(re^{i\theta}, y)|$ that is necessary for the proof of Theorem 8.

PROPOSITION 3. *Uniformly for $k \geq 1$, $r \geq 0$, $|\theta| \leq \pi$ and $|y| = 1$,*

$$|\mathcal{P}_k(re^{i\theta}, y)| \leq e^{r - cr\theta^2} \tag{73}$$

for some constant $c > 0$ independent of k, r, and θ.

In order to prove the above proposition we need a lemma.

LEMMA 6. *If $z = re^{i\theta}$, where $r \geq 0$ and $|\theta| \leq \pi$, then*

$$|e^z - 1 - z| \leq (e^r - 1 - r)e^{-c_1 r\theta^2}, \tag{74}$$

where $c_1 := 2/(3\pi^2)$. On the other hand, if $r \geq r_0$, where $r_0 \approx 1.37$ solves the equation $e^r - r = e^{r/3} + 1$, then

$$|e^z - z| \leq (e^r - r)e^{-c_1 r\theta^2/2} \qquad (|\theta| \leq \pi). \tag{75}$$

Proof. The first inequality is a special case of Pittel's inequality (see [65])

$$\left| e^z - \sum_{0\leq j<m} \frac{z^j}{j!} \right| \leq \left(e^r - \sum_{0\leq j<m} \frac{r^j}{j!} \right) e^{-2r\theta^2/(\pi^2(m+1))} \qquad (r \geq 0; |\theta| \leq \pi).$$

A simple proof of (74) (following [65]) is as follows:

$$\begin{aligned} |e^z - 1 - z| &= |e^{z/3}| \left| e^{2z/3} - (1+z)e^{-z/3} \right| \\ &= e^{r\cos(\theta)/3} \left| \sum_{j\geq 2} \frac{z^j}{j!3^j} \left(2^j + (-1)^j(3j-1)\right) \right| \\ &\leq e^{r\cos(\theta)/3}(e^{2r/3} - (1+r)e^{-r/3}), \end{aligned}$$

since $2^j + (-1)^j(3j-1) \geq 0$ for $j \geq 2$. Thus (74) follows from (29).

For the proof of inequality (75), we have

$$\begin{aligned} |e^z - z| &\leq |e^z - 1 - z| + 1 \\ &\leq (e^r - 1 - r)e^{-c_1 r\theta^2} + 1 \\ &\leq (e^r - r)e^{-c_1 r\theta^2/2}, \end{aligned}$$

since the last inequality is equivalent to

$$1 - e^{-c_1 r\theta^2} \leq (e^r - r)e^{-c_1 r\theta^2/2} \left(1 - e^{-c_1 r\theta^2/2}\right),$$

or $e^{c_1 r\theta^2/2} + 1 \leq e^r - r$, which follows from our choice of r in view of the inequalities $e^{c_1 r\theta^2/2} + 1 \leq e^{r/3} + 1 \leq e^r - r$. □

Proof of Proposition 3. We separate the proof into two cases: $r \leq r_0$ and $r \geq r_0$, where we recall that $r_0 \approx 1.37$ solves the equation $e^r - r = e^{r/3} + 1$. In the first case, we use the expansion

$$\mathcal{P}_1(z, y) = 1 + z + \frac{z^2}{2}\left(1 - 2pq(1-y^2)\right) + \sum_{j\geq 2} \frac{z^j}{j!}\left(1 - j(pq^{j-1} + qp^{j-1})(1-y)\right),$$

which yields

$$\begin{aligned} |\mathcal{P}_1(re^{i\theta}, e^{i\varphi})| &\leq |1 + re^{i\theta}| + \sum_{j\geq 2} \frac{r^j}{j!} \\ &\leq e^r - \frac{2r\theta^2}{\pi^2(1+r)} \\ &\leq e^{r - c_2 r\theta^2}, \end{aligned} \tag{76}$$

uniformly for $0 \le r \le r_0$ and $|\theta| \le \pi$, where we used again (29) and $c_2 := 2/(\pi^2(1+r_0)^2 e^{r_0})$.

Assume now $r \ge r_0$. We can write $\mathcal{P}_1(z,y)$ as follows:

$$\mathcal{P}_1(z,y) = a_1(pz)a_1(qz) + z + (qza_2(pz) + pza_2(qz))y + pqz^2y^2,$$

where $a_1(z) := e^z - z$ and $a_2(z) := e^z - 1 - z$. Note that $\mathcal{P}_1(z,1) = e^z$. By applying the two inequalities (74) and (75), we have

$$\begin{aligned}\left|\mathcal{P}_1(re^{i\theta}, e^{i\varphi})\right| &\le a_1(pr)a_1(qr)e^{-c_1 r\theta^2/2} + r + qra_2(pr)e^{-c_1 pr\theta^2} \\ &\quad + pra_2(qr)e^{-c_1 qr\theta^2} + pqr^2 \\ &\le \left(e^r - r - pqr^2\right) e^{-c_1 qr\theta^2} + r + pqr^2 \\ &\le e^{r - c_1 qr\theta^2/2}, \qquad (77)\end{aligned}$$

the last inequality following from an argument similar to the proof of (75). Indeed, it is equivalent to

$$(r + pqr^2)(e^{c_1 qr\theta^2/2} + 1) \le e^r,$$

but the left-hand side is less than $(r + r^2/4)(e^{r/6} + 1)$, which is in turn less than e^r for $r \ge 0.99$.

Collecting the two inequalities (76) and (77), we obtain

$$|\mathcal{P}_1(re^{i\theta}, e^{i\varphi})| \le e^{r - cr\theta^2} \qquad (c = \min\{c_1, c_2\}),$$

uniformly for $r \ge 0$ and $|\theta| \le \pi$. This implies (73) by (72). ∎

5.3. Local expansion of $\mathcal{P}_k(re^{i\theta}, e^{i\varphi})$. Recall that $\theta_0 := n^{-2/5}$ and ρ_0 is defined in (59).

PROPOSITION 4. *Assume that $\mu_{n,k} \to \infty$. Then uniformly for $|\theta| \le \theta_0$ and $\varphi = o(\sigma_{n,k}^{-2/3})$*

$$\mathcal{P}_k(ne^{i\theta}, e^{i\varphi}) = \exp\left(n - \frac{n}{2}\theta^2 + \tilde{M}_k(n)i\varphi - n\tilde{M}_k'(n)\varphi\theta - \frac{\tilde{V}_k(n)}{2}\varphi^2 + O(E_4)\right), \qquad (78)$$

where

$$E_4 := n|\theta|^3 + \rho_0^2\sigma_{n,k}^2|\varphi|\theta^2 + \rho_0\sigma_{n,k}^2\varphi^2|\theta| + \sigma_{n,k}^2|\varphi|^3.$$

Proof. Define

$$Q(z,y) := \log e^{-z}\mathcal{P}_1(z,y) = \log\left(1 + a_3(z)(y-1) + a_4(z)(y-1)^2\right),$$

where $a_3(z) := pze^{-pz} + qze^{-qz} - ze^{-z}$ and $a_4(z) := pqz^2e^{-z}$. Let

$$Q_k(z,y) := \sum_{0 \le j < k} \binom{k-1}{j} Q(p^j q^{k-1-j} z, y) = \log e^{-z}\mathcal{P}_k(z,y).$$

First, we prove in Lemma 7 of Appendix B that $\mathcal{P}_1(re^{i\theta}, e^{i\varphi})$ is away from zero for $r \ge 0$ and $|\theta| \le \varepsilon$, implying that $Q_k(z,y)$ is well defined when $|\arg(z)| \le \varepsilon$.

Then since $\mu_{n,k} \to \infty$, we need only consider $k \geq k_0$. To that purpose, we start from the expansion

$$Q(z,y) = \begin{cases} pq(y^2-1)z^2 + O(|y-1||z|^3) & \text{as } z \to 0, \\ q(y-1)ze^{-qz}\left(1+O(e^{-(p-q)\Re(z)})\right) & \text{as } z \to \infty, |\arg(z)| \leq \varepsilon. \end{cases} \tag{79}$$

By (79), we have

$$Q_k(z,y) = \frac{1}{2\pi i}\int_{(\rho)} z^{-s} Q^*(s,y)(p^{-s}+q^{-s})^{k-1}\mathrm{d}s, \tag{80}$$

where $\rho > -2$ and $Q^*(s,y) := \int_0^\infty z^{s-1}Q(z,y)\mathrm{d}z$ is well defined for $\Re(s) > -2$. Note that

$$Q(z,y) = a_3(z)(y-1) + \frac{2a_4(z)-a_3(z)^2}{2}(y-1)^2 + \bar{Q}(z,y)(y-1)^3,$$

where by Taylor's remainder formula

$$\bar{Q}(z,y) := \int_0^1 (1-t)^2(a_3(z)+2a_4(z)(y-1)t) \times \frac{(a_3(z)^2 - 3a_4(z) + a_3(z)a_4(z)(y-1)t + a_4(z)^2(y-1)^2t^2)}{(1+a_3(z)(y-1)t+a_4(z)(y-1)^2t^2)^3}\,\mathrm{d}t.$$

The exact form is of less importance here; we need instead the estimates $\bar{Q}(z,y) = O(|z|^4) = O(|z|^2)$ as $z \to 0$ and

$$\bar{Q}(z,y) = O\left(|z|^3 e^{-3q\Re(z)}\right) = O\left(|z|e^{-q\Re(z)}\right)$$

as $z \to \infty$ in the sector $\{z : |\arg(z)| \leq \varepsilon\}$. This expansion gives

$$Q_k(z,y) = \tilde{M}_k(z)(y-1) + \frac{\tilde{V}_k(z)-\tilde{M}_k(z)}{2}(y-1)^2 + \bar{Q}_k(z,y)(y-1)^3,$$

where

$$\bar{Q}_k(z,y) := \sum_{0\leq j<k}\binom{k-1}{j}\bar{Q}(p^j q^{k-1-j}z, y).$$

An application of Lemma 8 presented in Appendix C yields, with $z = ne^{i\theta}$,

$$Q_k(z,y) = \tilde{M}_k(z)(y-1) + \frac{\tilde{V}_k(z)-\tilde{M}_k(z)}{2}(y-1)^2 + O\left(|y-1|^3|\tilde{M}_k(ne^{i\theta})|\right),$$

where the O-term holds uniformly for $|\theta| \leq \varepsilon$ and $|y-1| = o(1)$. Since $\sigma_{n,k}^2 = \Theta(\mu_{n,k}) \to \infty$, this leads to (78) by expansions of $\tilde{M}_k(ne^{i\theta})$ and $\tilde{V}_k(ne^{i\theta})$ at $\theta = 0$, using the estimates (60) and (68). This completes the proof of Proposition 4. □

5.4. Proof of Theorem 8. We are now ready to prove Theorem 8.

Proof of the central limit theorem (69). By Cauchy's integral formula and the two estimates (73) and (78), we have, similar to (25),

$$\begin{aligned}\mathbb{E}\left(e^{B_{n,k}i\varphi}\right) &= \frac{n!}{2\pi i}\int_{|z|=n} z^{-n-1}\mathcal{P}_k(z,y)\mathrm{d}z\\ &= \frac{n!n^{-n}}{2\pi}\, e^{n+\tilde{M}_k(n)i\varphi-\tilde{V}_k(n)\varphi^2/2}\\ &\quad\times\int_{-\theta_0}^{\theta_0} e^{-n\theta^2/2-n\tilde{M}'_k(n)\varphi\theta}\left(1+O(E_4)\right)\mathrm{d}\theta + O\left(n^{-1/10}e^{-cn^{1/5}}\right),\end{aligned}$$

since $E_4\to 0$ in the range of integration and when $\varphi = o(\sigma_{n,k}^{-4/5})$. Applying Stirling's formula, extending the integration limits to $\pm\infty$, and making the change of variables $\theta\mapsto\theta n^{-1/2}$, we obtain

$$\begin{aligned}\mathbb{E}\left(e^{B_{n,k}i\varphi}\right) &= \frac{e^{\tilde{M}_k(n)i\varphi-\tilde{\sigma}^2_{n,k}\varphi^2/2}}{\sqrt{2\pi}}\int_{-\infty}^{\infty} e^{-(\theta+\sqrt{n}\,\tilde{M}'_k(n)\varphi)^2/2}\\ &\quad\times\left(1+O\left(\frac{1+|\theta|^3}{\sqrt{n}}+\frac{\theta^2}{n}\,\rho_0^2\sigma^2_{n,k}|\varphi|+\frac{|\theta|}{\sqrt{n}}\,\rho_0\sigma^2_{n,k}\varphi^2+\sigma^2_{n,k}|\varphi|^3\right)\right)\mathrm{d}\theta,\end{aligned}$$

uniformly in φ. A straightforward evaluation of the integral gives (71). This completes the proof of (69).

Proof of the Poisson limit theorem (70). The proof of (70) is similar to the previous proof but proceeds slightly differently. We first show that

$$Q_k(ne^{i\theta},y) := \log e^{-z}\mathcal{P}_k(z,y) = \lambda_0(y^2-1)e^{2i\theta} + O\left(|y-1|n^{-e(p)}\right), \tag{81}$$

uniformly for $|y|=1$ and $|\theta|\le\varepsilon$, where $e(p) := 2\log(p^3+q^3)/\log(p^2+q^2)-3\in(0,1)$ for $p\in(1/2,1)$.

This follows from the Mellin inversion integral (80) since the Mellin transform $Q^*(s,y)$ has a simple pole at $s=-2$ with residue $pq(y^2-1)$ and can be meromorphically continued into the whole s-plane. Indeed, by moving the line of integration of the integral in (80) to $\Re(s)=-3-\varepsilon$, we obtain

$$Q_k(ne^{i\theta},y) = \lambda_0(y^2-1)e^{2i\theta} + O\left(|y-1|n^3(p^3+q^3)^k\right),$$

whenever $|\theta|\le\pi/2-\varepsilon$ and

$$k\ge\frac{L_n+K_n}{\log((p^2+q^2)/(p^3+q^3))}.$$

Since $\mu_{n,k}=\Theta(1)$, we know that $k=\alpha_3L_n+O(1)$, and for such values of k, we have $n^3(p^3+q^3)^k=\Theta(n^{-e(p)})$. Thus (81) follows.

By (81) and the same choice of θ_0 and (73), we then deduce that

$$\begin{aligned}\mathbb{E}\left(e^{B_{n,k}i\varphi}\right) &= \frac{e^{\lambda_0(e^{2i\varphi}-1)}}{\sqrt{2\pi}}\int_{-n^{1/10}}^{n^{1/10}} e^{-\theta^2/2}\left(1+O\left(n^{-e(p)}|\varphi|\right)\right)\\ &\quad\times\left(1+\frac{12\lambda_0(e^{2i\varphi}-1)i\theta-i\theta^3}{6\sqrt{n}}+O\left(\frac{1+\lambda_0|\varphi|\theta^2+\theta^6}{n}\right)\right)\mathrm{d}\theta\\ &= e^{\lambda_0(e^{2i\varphi}-1)}\left(1+O(E_5)\right),\end{aligned}$$

uniformly for $|\varphi| \le \pi$, where $E_5 := |\varphi| n^{-e(p)} + (1+\lambda_0|\varphi|)n^{-1}$. Thus

$$\mathbb{P}\left(\frac{B_{n,k}}{2} = m\right) = \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{-im\varphi+\lambda_0(e^{i\varphi}-1)}\,(1+O(E_5))\,\mathrm{d}\varphi,$$

from which the even case in (70) follows since, by (50), $\mu_{n,k} \sim 2\lambda_0$. The odd case is similar. □

Remark. Note that λ_0 is periodic in nature since $k = \alpha_3 L_n + O(1) \in \mathbb{Z}$; indeed, we can write

$$k = \lfloor \alpha_3 L_n \rfloor + \ell = \alpha_3 L_n + \ell - \{\alpha_3 L_n\} \qquad (\ell \in \mathbb{Z}),$$

so that

$$n^2(p^2+q^2)^k = \exp\left(-\frac{2}{\alpha_3}\,(\ell - \{\alpha_3 L_n\})\right).$$

This is why we did not state the Poisson convergence (70) in the usual form: if $\lambda_0 \to \lambda < \infty$, then $B_{n,k}$ converges in distribution to $2\mathrm{Po}(\lambda)$, where $\mathrm{Po}(\lambda)$ denotes a Poisson variate with parameter λ.

6. The internal profile. We consider the internal profile in this section. All asymptotic results follow the same footsteps as in the proof we used for $B_{n,k}$; details will thus be omitted. The main differences are that $\mathbb{E}(I_{n,k})$ and $\mathbb{V}(I_{n,k})$ are not of the same order for all ranges of k, and $I_{n,k}$ assumes both odd and even values when $k = \alpha_3 L_n + O(1)$. These are intuitively clear since most levels close to the root are full and internal nodes do not necessarily appear in pairs near the fringes of the tree.

Let $P^{[I]}_{n,k}(y) = \mathbb{E}(y^{I_{n,k}})$ be the probability generating function of $I_{n,k}$. Then

$$P^{[I]}_{n,k}(y) = \sum_{0\le j\le n}\binom{n}{j} p^j q^{n-j} P^{[I]}_{j,k-1}(y) P^{[I]}_{n-j,k-1}(y) \qquad (n \ge 2; k \ge 1), \tag{82}$$

with the initial conditions

$$P^{[I]}_{n,k}(y) = \begin{cases} y & \text{if } n \ge 2 \text{ and } k = 0,\\ 1 & \text{if } n \le 1 \text{ and } k \ge 0.\end{cases}$$

From this, we obtain, defining $\mathcal{P}^{[I]}_k(z,y) := \sum_n P^{[I]}_{n,k}(y) z^n/n!$,

$$\mathcal{P}^{[I]}_k(z,y) = \prod_{0\le j\le k} \mathcal{P}^{[I]}_0(p^j q^{k-j} z, y)^{\binom{k}{j}} \qquad (k \ge 0), \tag{83}$$

with $\mathcal{P}^{[I]}_0(z,y) = ye^z + (1-y)(1+z)$. This suggests that we consider

$$\bar{I}_{n,k} := 2^k - I_{n,k},$$

so that the bivariate generating function $\mathcal{P}^{[\bar{I}]}_k(z,y) := \sum_n P^{[\bar{I}]}_{n,k}(y) z^n/n!$ is given by

$$\mathcal{P}^{[\bar{I}]}_k(z,y) = \prod_{0\le j\le k} \mathcal{P}^{[\bar{I}]}_0(p^j q^{k-j} z, y)^{\binom{k}{j}} \qquad (k \ge 0),$$

with $\mathcal{P}^{[\bar{I}]}_0(z,y) = e^z + (y^{-1}-1)(1+z)$.

6.1. Expected internal profile. We state without proof the asymptotics of $\mathbb{E}(I_{n,k})$ in this subsection. By (82) or (83), we deduce that the Poisson generating function

$$\tilde{M}_k^{[I]}(z) := e^{-z} \sum_{n\geq 0} \frac{\mathbb{E}(I_{n,k})}{n!} z^n$$

satisfies

$$\tilde{M}_k^{[I]}(z) = 2^k - \sum_{0\leq j\leq k} \binom{k}{j} \tilde{M}_0^{[I]}(p^j q^{k-j} z) \tag{84}$$

$$= 2^k - \frac{1}{2\pi i} \int_{(\rho)} z^{-s}(s+1)\Gamma(s)(p^{-s}+q^{-s})^k \mathrm{d}s, \tag{85}$$

where $\rho > 0$ and $\tilde{M}_0^{[I]}(z) = (1+z)e^{-z}$. Thus, in particular,

$$\mathbb{E}(I_{n,k}) = 2^k - \sum_{0\leq j\leq k} \binom{k}{j} \left(1 + p^j q^{k-j}(n-1)\right) \left(1 - p^j q^{k-j}\right)^{n-1}.$$

Due to the presence of 2^k or the simple pole at $s = 0$ in (85), we have an additional phase transition for $\mathbb{E}(I_{n,k})$ at $\rho = 0$ or, equivalently, at $k \sim \alpha_0 L_n$, where

$$\alpha_0 := \frac{2}{\log(1/p) + \log(1/q)}.$$

We now list asymptotic approximations of $\mathbb{E}(I_{n,k})$ for various ranges of k (without proofs since they follow the same lines as the derivations presented above for the external profile).

Asymptotics of $\mathbb{E}(I_{n,k})$ *when* $1 \leq k \leq \alpha_1(1+o(1))L_n$. Since

$$\tilde{M}_1^{[I]}(z) = 2^k - (1+pz)e^{-pz} + (1+qz)e^{-qz} = 2^k - qze^{-qz}\left(1 + O(|z|^{-1})\right)$$

as $|z| \to \infty$ in the sector $|\arg(z)| \leq \pi/2 - \varepsilon$, we see immediately that in this range

$$\mathbb{E}(I_{n,k}) = 2^k - \mathbb{E}(B_{n,k})(1+o(1)), \tag{86}$$

uniformly in k.

Asymptotics of $\mathbb{E}(I_{n,k})$ *when* $\alpha_1(L_n - LLL_n + K_n) \leq k \leq \alpha_0(L_n - K_n\sqrt{L_n})$. By applying the saddle-point method to the Mellin inversion integral in (85) and then de-Poissonizing, we deduce that in this range

$$\mathbb{E}(I_{n,k}) = 2^k - G_3\left(\rho; \log_{p/q} p^k n\right) \frac{n^{-\rho}\left(p^{-\rho}+q^{-\rho}\right)^k}{\sqrt{2\pi\beta_2(\rho)k}} \left(1 + O\left(\frac{1}{k(p/q)^\rho} + \frac{1}{k\rho^2}\right)\right),$$

where $\rho = \rho(n,k) > 0$ satisfies the saddle-point equation (36), $\beta_2(\rho)$ is the same as in (37), and

$$G_3(\rho; x) = \sum_{j\in\mathbb{Z}} (\rho + 1 + it_j)\Gamma(\rho + it_j)e^{-2j\pi i x},$$

where $t_j := 2j\pi/\log(p/q)$.

Asymptotics of $\mathbb{E}(I_{n,k})$ *when* $k = \alpha_0(L_n + o(L_n^{2/3}))$. In this range, we write

$$k = \alpha_0(L_n + \xi\sqrt{\alpha_0\beta_2(0)L_n}),$$

where $\alpha_0\beta_2(0) = 2(\log(1/p)+\log(1/q))/\log(p/q)^2$ and $\xi = o(L_n^{1/6})$. The same uniform asymptotic analysis we used for proving (53) gives

$$\mathbb{E}(I_{n,k}) = 2^k\Phi(-\xi)\left(1 + O\left(\frac{1+|\xi|^3}{\sqrt{L_n}}\right)\right),$$

uniformly in ξ, where $\Phi(x)$ denotes the standard normal distribution function.

Asymptotics of $\mathbb{E}(I_{n,k})$ *when* $\alpha_0(L_n + K_n\sqrt{L_n}) \le k \le \alpha_2(L_n - K_n\sqrt{L_n})$. The same saddle-point method and de-Poissonization procedure yield

(87)
$$\mathbb{E}(I_{n,k}) = G_3\left(\rho; \log_{p/q} p^k n\right)\frac{n^{-\rho}\left(p^{-\rho}+q^{-\rho}\right)^k}{\sqrt{2\pi\beta_2(\rho)k}}\left(1 + O\left(\frac{1}{k(p/q)^\rho} + \frac{1}{k(\rho+2)^2}\right)\right),$$

with ρ, $\beta_2(\rho)$, and G_3 as defined above.

Asymptotics of $\mathbb{E}(I_{n,k})$ *when* $k = \alpha_2(L_n + o(L_n^{2/3}))$. In this case, we write

$$k = \alpha_0(L_n + \xi\sqrt{\alpha_2\beta_2(-2)L_n}),$$

and we have

$$\mathbb{E}(I_{n,k}) = \frac{1}{2}\Phi(\xi)n^2(p^2+q^2)^k\left(1 + O\left(\frac{1+|\xi|^3}{\sqrt{L_n}}\right)\right),$$

uniformly for $\xi = o(L_n^{1/6})$.

Asymptotics of $\mathbb{E}(I_{n,k})$ *when* $k \ge \alpha_2(L_n + K_n\sqrt{L_n})$. In this case, the simple pole at $s = -2$ in the integrand of (85) dominates, and we have

$$\mathbb{E}(I_{n,k}) = \frac{1}{2}n^2(p^2+q^2)^k\left(1 + O\left(K_n^{-1}e^{-K_n^2/2+O(K_n^3L_n^{-1/2})}\right)\right)$$

as $n \to \infty$.

6.2. Asymptotics of $\mathbb{V}(I_{n,k})$. Since $\mathbb{V}(I_{n,k}) = \mathbb{V}(\bar{I}_{n,k})$, we can apply the same analysis used for proving Theorem 7 to derive asymptotic approximations to $\mathbb{V}(I_{n,k})$. The auxiliary function we need is

$$\tilde{V}_k^{[I]}(z) := e^{-z}\sum_{n\ge0}\frac{\mathbb{E}(\bar{I}_{n,k}^2)}{n!}z^n - \left(e^{-z}\sum_{n\ge0}\frac{\mathbb{E}(\bar{I}_{n,k})}{n!}z^n\right)^2,$$

which satisfies

$$\tilde{V}_k^{[I]}(z) = \sum_{0\le j\le k}\binom{k}{j}\tilde{V}_0^{[I]}(p^jq^{k-j}z) \qquad (k \ge 0), \tag{88}$$

where $\tilde{V}_0^{[I]}(z) = (1+z)e^{-z}(1-(1+z)e^{-z})$. Thus we have

$$\tilde{V}_k^{[I]}(z) = \frac{1}{2\pi i}\int_{(\rho)} z^{-s}(s+1)\Gamma(s)\left(1-2^{-s}-s2^{-s-2}\right)\left(p^{-s}+q^{-s}\right)^k\mathrm{d}s,$$

where $\rho > -2$.

Asymptotics of $\mathbb{V}(I_{n,k})$ *when* $1 \le k \le \alpha_1(1+o(1))L_n$. In this range, we have

$$\mathbb{V}(I_{n,k}) \sim \mathbb{V}(B_{n,k}) \sim \mathbb{E}(B_{n,k}).$$

Asymptotics of $\mathbb{V}(I_{n,k})$ *when* $\alpha_1(L_n - LLL_n + K_n) \le k \le \alpha_2(L_n - K_n\sqrt{L_n})$. We have

$$\mathbb{V}(I_{n,k}) = G_4\left(\rho; \log_{p/q} p^k n\right) \frac{n^{-\rho}\left(p^{-\rho}+q^{-\rho}\right)^k}{\sqrt{2\pi\beta_2(\rho)k}} \left(1 + O\left(\frac{1}{k(p/q)^\rho} + \frac{1}{k(\rho+2)^2}\right)\right),$$

where $\rho = \rho(n,k) > -2$ satisfies the saddle-point equation (36) and

$$G_4(\rho; x) = \sum_{j\in\mathbb{Z}} (\rho + 1 + it_j)\Gamma(\rho + it_j)\left(1 - 2^{-\rho-it_j} - (\rho+it_j)2^{-\rho-2-it_j}\right) e^{-2j\pi i x}.$$

Asymptotics of $\mathbb{V}(I_{n,k})$ *when* $k \ge \alpha_2(L_n + K_n\sqrt{L_n})$. In this case, the simple pole at $s = -2$ again dominates, and we have

$$\mathbb{V}(I_{n,k}) \sim \mathbb{E}(I_{n,k}).$$

Observe that, unlike for the external profile, the variance of the internal profile is asymptotically equivalent to the mean of the internal profile near the height of a trie.

From these asymptotic estimates and from Chebyshev's inequality, we see that $I_{n,k}/\mathbb{E}(I_{n,k}) \to 1$ in probability if $\mathbb{E}(I_{n,k}) \to \infty$; see [15].

6.3. Limiting distributions. The same limiting Gaussian–Poisson behavior for $B_{n,k}$ holds for $I_{n,k}$. We state formally our main result for the internal profile in the following theorem. The proof is indeed simpler than that for Theorem 8 since the base function $\mathcal{P}_0^{[I]}(z,y)$ has a simpler form than $\mathcal{P}_0(z,y)$.

THEOREM 9. (i) *If* $\mathbb{V}(I_{n,k}) \to \infty$, *then*

$$\frac{I_{n,k} - \mathbb{E}(I_{n,k})}{\sqrt{\mathbb{V}(I_{n,k})}} \xrightarrow{d} \mathcal{N}(0,1).$$

(ii) *If* $\mathbb{V}(I_{n,k}) = \Theta(1)$, *then, with* $\lambda_1 := n^2(p^2+q^2)/2$,

$$\mathbb{P}(I_{n,k} = m) = \frac{\lambda_1^m}{m!} e^{-\lambda_1} + o(1) \tag{89}$$

for all $m \ge 0$.

The theorem states that asymptotic normality (in the sense of convergence in distribution) holds as long as

$$\lceil \hat{k} \rceil \le k \le \alpha_3 L_n - K_n$$

for any sequence $K_n \to \infty$, where $\hat{k}$ is defined in (58).

On the other hand, $I_{n,k}$ is asymptotically Poisson distributed when $k = \alpha_3 L_n + O(1)$. A result related to (89) was given in [65] by a method of moments, as a key step in deriving the asymptotic distribution of the height.

7. Profiles under the unbiased Bernoulli model. All exact expressions we have derived up to now, as well as most asymptotic approximations, also hold when $p = q = 1/2$. The major difference is reflected by the fact that $\alpha_1 = \alpha_2$ (see Figure 2), so that the saddle-point range between α_1 and α_2 does not exist, and most of the analysis we give above becomes much simpler. For simplicity of presentation, we omit all error terms in our asymptotic estimates.

Expected external profile. By (8), the Poisson generating function of $\mathbb{E}(B_{n,k})$ is given exactly by

$$\tilde{M}_k(z) = z\left(e^{-z/2^k} - e^{-z/2^{k-1}}\right) \qquad (k \geq 1). \tag{90}$$

From this we deduce, by our de-Poissonization procedures, that

$$\mathbb{E}(B_{n,k}) \sim \begin{cases} n\left(1-2^{-k}\right)^{n-1} & \text{if } 2^{-k}n \to \infty, \\ \tilde{M}_k(n) & \text{if } 4^{-k}n \to 0, \end{cases} \tag{91}$$

where the condition $4^{-k}n \to 0$ is due to the properties that

$$\tilde{M}_k^{(\ell)}(z) = O\left(2^{-k\ell}|\tilde{M}_k(z)|\right) \qquad (|\arg(z)| \leq \pi/2 - \varepsilon)$$

and $2^{-k} = o(n^{-1/2})$; see Proposition 1 and compare with (61). In particular,

$$\mathbb{E}(B_{n,k}) \sim \begin{cases} ne^{-t}\left(1-e^{-t}\right) & \text{if } 2^{-k}n \to t \in (0,\infty), \\ 2^{-k}n^2 & \text{if } 2^{-k}n \to 0. \end{cases}$$

Note that these approximations can also be easily derived by the exact formula

$$\mathbb{E}(B_{n,k}) = n\left(1-2^{-k}\right)^{n-1} - n\left(1-2^{1-k}\right)^{n-1}, \tag{92}$$

by (90) or (10). But such an elementary approach becomes messier for the calculation of the variance. Also

$$\max_k \mathbb{E}(B_{n,k}) \sim \frac{n}{4},$$

which is reached when $k \sim \log_2 n - 1$.

Expected internal profile. In a similar manner, we have, by (84),

$$\tilde{M}_k^{[I]}(z) = 2^k - (2^k + z)e^{-z/2^k} \qquad (k \geq 0).$$

Therefore, the expected internal profiles satisfy

$$\mathbb{E}(I_{n,k}) \sim \begin{cases} 2^k - n\left(1-2^{-k}\right)^{n-1} & \text{if } 2^{-k}n \to \infty, \\ \tilde{M}_k^{[I]}(n) & \text{if } 4^{-k}n \to 0. \end{cases}$$

Consequently,

$$\mathbb{E}(I_{n,k}) \sim \begin{cases} 2^k\left(1-(1+t)e^{-t}\right) & \text{if } 2^{-k}n \to t \in (0,\infty), \\ 2^{-k-1}n^2 & \text{if } 2^{-k}n \to 0. \end{cases}$$

Note that

$$\mathbb{E}(I_{n,k}) = 2^k\left(1-\left(1-2^{-k}\right)^n\right) - n\left(1-2^{-k}\right)^{n-1}$$

and

$$\max_k \mathbb{E}(I_{n,k}) \sim c_3 n, \tag{93}$$

where $c_3 \approx 0.298$ denotes the maximum value achieved by the function $(1-(1+x)e^{-x})/x$ for $x \in \mathbb{R}^+$.

Asymptotics of the variances. Similarly, by (63) and (88), we have

$$\tilde{V}_k(z) = z\left(e^{-z/2^k} - e^{-z/2^{k-1}}\right) + 2^{-k}z^2e^{-z/2^{k-1}} - 2^{1-k}z^2\left(e^{-z/2^k} - e^{-z/2^{k-1}}\right)^2,$$
$$\tilde{V}_k^{[I]}(z) = (2^k+z)e^{-z/2^k} - 2^k\left(1+2^{-k}\right)^2 e^{-z/2^{k-1}};$$

accordingly, if $n/2^k \to \infty$, then

$$\mathbb{V}(B_{n,k}) \sim \mathbb{V}(I_{n,k}) \sim \mathbb{E}(B_{n,k}) \sim n\left(1-2^{-k}\right)^{n-1},$$

and if $n/4^k \to 0$, then

$$\mathbb{V}(B_{n,k}) \sim \tilde{V}_k(n) \quad \text{and} \quad \mathbb{V}(I_{n,k}) \sim \tilde{V}_k^{[I]}(n),$$

uniformly in k. These approximations imply that

$$\mathbb{V}(B_{n,k}) \sim \begin{cases} ne^{-t}\left(1-(1+t)e^{-t}+2te^{-2t}(2-e^{-t})\right) & \text{if } 2^{-k}n \to t \in (0,\infty), \\ 2\mathbb{E}(B_{n,k}) \sim 2^{1-k}n^2 & \text{if } 2^{-k}n \to 0 \end{cases} \tag{94}$$

and

$$\mathbb{V}(I_{n,k}) \sim \begin{cases} 2^k(1+t)e^{-t}\left(1-(1+t)e^{-t}\right) & \text{if } 2^{-k}n \to t \in (0,\infty), \\ \mathbb{E}(I_{n,k}) \sim 2^{-k-1}n^2 & \text{if } 2^{-k}n \to 0. \end{cases}$$

Limiting distributions. Both Theorems 8 and 9 (asymptotic normality of $B_{n,k}$ and $I_{n,k}$, respectively) hold when $p = q = 1/2$ by the same method of proof. Note that both bivariate generating functions become simpler (see (72) and (83)):

$$\mathcal{P}_k(z,y) = \left(e^{z/2^{k-1}} + (y-1)\frac{z}{2^{k-1}}\left(e^{z/2^k}-1\right) + (y-1)^2\frac{z^2}{4^k}\right)^{2^{k-1}},$$
$$\mathcal{P}_k^{[I]}(z,y) = \left(ye^{z/2^k} + (1-y)\left(1+\frac{z}{2^k}\right)\right)^{2^k}.$$

Observe that, as $n \to \infty$, $\mathbb{E}(B_{n,k}) \to \infty$ iff $\mathbb{V}(B_{n,k}) \to \infty$ iff $\mathbb{V}(I_{n,k}) \to \infty$ iff

$$\frac{1}{\log 2}\left(L_n - LL_n + \frac{K_n}{L_n}\right) \le k \le \frac{2}{\log 2}(L_n - K_n) \tag{95}$$

for any sequence $K_n \to \infty$ with n; compare Theorem 5 for the asymmetric case.

THEOREM 10. (i) *If k lies in the range* (95)*, then*

$$\frac{B_{n,k} - \mathbb{E}(B_{n,k})}{\sqrt{\mathbb{V}(B_{n,k})}} \xrightarrow{d} \mathcal{N}(0,1), \quad \frac{I_{n,k} - \mathbb{E}(I_{n,k})}{\sqrt{\mathbb{V}(I_{n,k})}} \xrightarrow{d} \mathcal{N}(0,1).$$

(ii) *If $k = 2(L_n + O(1))/\log 2$, then, with $\lambda_2 := 2^{-k-1}n^2$,*

$$\begin{cases} \mathbb{P}(B_{n,k} = 2m) = \dfrac{\lambda_2^m}{m!}e^{-\lambda_2} + o(1), \quad \mathbb{P}(B_{n,k} = 2m+1) = o(1), \\ \mathbb{P}(I_{n,k} = m) = \dfrac{\lambda_2^m}{m!}e^{-\lambda_2} + o(1), \end{cases}$$

uniformly for $m \ge 0$.

Note that when $p = q$, $\lambda_0 = \lambda_1 = \lambda_2$.

8. Applications of results. In this section, we briefly discuss a few properties of some shape characteristics of random tries, as implied either by our results or by our approaches. We consider only depth, height, shortest path, fill-up level, width, and right-profile.

Depth. The distribution of the depth D_n is given by $\mathbb{P}(D_n = k) = \mu_{n,k}/n$. Our asymptotic approximations for $\mu_{n,k}$ give very precise results for the distribution of D_n. First consider the case when $p \neq q$. By definition, we see that the result (4) for the limiting behaviors of $\log \mu_{n,k}/\log n$ also describes those of $-1 + \log \mathbb{P}(D_n = k)/\log n$, or essentially the large deviations of the distribution of D_n.

Furthermore, (43) can be regarded as a local limit theorem for D_n. Indeed, we have, for $k = \mathrm{h}^{-1}(L_n + x\sqrt{\mathrm{h}^{-1}\beta_2(-1)L_n})$, where $\mathrm{h} := p\log(1/p) + q\log(1/q)$ is the entropy rate,

$$\mathbb{P}(D_n = k) = G_1\left(-1; \log_{p/q} p^k n\right) \frac{e^{-x^2/2}}{\sqrt{2\pi \mathbb{V}(D_n)}} \left(1 + O\left(\frac{1+|x|^3}{\sqrt{L_n}}\right)\right), \tag{96}$$

uniformly for $x = o(L_n^{1/6})$, where $\mathbb{V}(D_n) \sim (\mathrm{h}_2 - \mathrm{h}^2)/\mathrm{h}^3 \log n$, with $\mathrm{h}_2 := p\log^2 p + q\log^2 q$ (see [33, 76]), is also rederived below in (97). Because of the appearance of the uncommon periodic function G_1, we see that D_n *satisfies a central limit theorem but not a local limit theorem (of the usual form).* It can be shown that the right-hand side indeed sums (over all k) asymptotically to 1. The result (96) is new.

If $p = q$, then, by the exact formula (92), we have

$$\mathbb{P}(D_n = k) = \left(1 - 2^{-k}\right)^{n-1} - \left(1 - 2^{1-k}\right)^{n-1},$$

which implies that

$$\mathbb{P}(D_n = \lfloor \log_2 n \rfloor + \ell) = \left(e^{-2^{-\ell+\{\log_2 n\}}} - e^{-2^{1-\ell+\{\log_2 n\}}}\right)\left(1 + O\left(n^{-1}2^{-\ell}\right)\right),$$

uniformly for $\ell \in \mathbb{Z}$, where $\{x\}$ denotes the fractional part of x.

On the other hand, if one is interested in the cumulative distribution functions or tail probabilities, then, by (6) and by partial summation,

$$\mathbb{P}(D_n \leq k) = (n-1)![z^n]\frac{e^z}{2\pi i}\int_{(\rho)} z^{-s}\Gamma(s+1)\left(p^{-s} + q^{-s}\right)^k \mathrm{d}s$$

for $k \geq 1$, where $\rho > -1$. Equivalently, by (11), we have (see [35])

$$\mathbb{P}(D_n \leq k) = \frac{1}{2\pi i}\int_{(\rho)} \frac{\Gamma(n)\Gamma(s+1)}{\Gamma(n+1+s)}\left(p^{-s} + q^{-s}\right)^k \mathrm{d}s,$$

where $\rho > -1$. Asymptotics of such integrals can be treated by our approaches, which give not only the central limit theorem of D_n with convergence rate (since there is a simple pole at $s = -1$) but also precise estimates for tail probabilities. Indeed, we have

$$\mathbb{P}\left(D_n \leq \mathrm{h}^{-1}(L_n + x\sqrt{\mathrm{h}^{-1}\beta_2(-1)L_n})\right) = \Phi(x)\left(1 + O\left(\frac{1+|x|^3}{\sqrt{L_n}}\right)\right),$$

uniformly for $x = o(L_n^{1/6})$, as already shown in [33, 35] (but without rate). Furthermore,

$$-\frac{\log \mathbb{P}(D_n \le \alpha L_n)}{\log n} \to \rho' + 1 - \alpha \log(p^{-\rho'} + q^{-\rho'}) \qquad (\alpha_1 \le \alpha \le \mathrm{h}^{-1}),$$
$$-\frac{\log \mathbb{P}(D_n \ge \alpha L_n)}{\log n} \to \begin{cases} \rho' + 1 - \alpha \log(p^{-\rho'} + q^{-\rho'}) & \text{if } \mathrm{h}^{-1} \le \alpha \le \alpha_2, \\ -1 - \alpha \log(p^2 + q^2) & \text{if } \alpha_2 \le \alpha \le \alpha_3, \end{cases}$$

both tails being asymptotic to -1 for smaller and larger α, respectively, where ρ' is given in (42). These results imply, in particular, that $\mathbb{E}(D_n) \sim L_n/\mathrm{h}$ and

$$\mathbb{V}(D_n) \sim \beta_2(-1)\mathrm{h}^{-3} L_n = \frac{pq \log^2(p/q)}{(p\log(1/p) + q\log(1/q))^3} L_n = \frac{\mathrm{h}_2 - \mathrm{h}^2}{\mathrm{h}^3} L_n, \tag{97}$$

where $\mathrm{h}_2 := p\log^2 p + q \log^2 q$; see [13, 76]. Note that the constant on the right-hand side becomes zero when $p = q$.

Width. The width of tries W_n is defined to be $W_n := \max_k I_{n,k}$, or the size of the most abundant level(s). As a natural lower bound for $\mathbb{E}(W_n)$, we consider $\max_k \mathbb{E}(I_{n,k})$. By (87) and a similar analysis for (43), we have, when $p \ne q$,

$$\mathbb{E}(I_{n,k}) = \frac{\sqrt{\mathrm{h}}\, G_3\left(-1; \log_{p/q} p^k n\right)}{\log(p/q)\sqrt{2\pi pq}} \times \frac{n}{\sqrt{L_n}} \left(1 + O(L_n^{-1/2})\right),$$

uniformly for $k = L_n/\mathrm{h} + O(1)$. This approximation, together with the estimates for $\mathbb{E}(I_{n,k})$ in other ranges given in section 6.1, yields

$$\mathbb{E}(W_n) \ge \max_k \mathbb{E}(I_{n,k}) = \Theta(nL_n^{-1/2}),$$

when $p \ne q$. Indeed, we have

$$\mathbb{E}(W_n) = \Theta(nL_n^{-1/2}).$$

The upper bound can be proved by applying the arguments used in [16], which start from the inequality

$$\mathbb{E}(W_n) \le \mathcal{M}_n + \sum_{|k - L_n/\mathrm{h}| \le \varepsilon L_n^{2/3}} \frac{\mathbb{V}(I_{n,k})}{\mathcal{M}_n - \mathbb{E}(I_{n,k})} + \sum_{|k - L_n/\mathrm{h}| > \varepsilon L_n^{2/3}} \mathbb{E}(I_{n,k}),$$

where $\mathcal{M}_n$: $\max_k \mathbb{E}(I_{n,k})$, and then using the asymptotics of $\mathbb{E}(I_{n,k})$ and $\mathbb{V}(I_{n,k})$ given in section 6.1. Details are omitted here. Finer results for $\mathbb{E}(W_n)$ can be derived, but the proof is more involved due to the presence of the periodic function G_3 (whose parameter involves k).

For symmetric tries, we easily have $\mathbb{E}(W_n) = \Theta(n)$, by (93) and the trivial bound $\mathbb{E}(W_n) \le n$. Thus *random symmetric tries are "fatter," and most nodes lie near the most abundant levels* $k = \log_2 n + O(1)$.

Height. We next derive an estimate for the height of random tries, as a consequence of our estimates for the external profiles together with the use of the first and second moment methods (see [79]).

COROLLARY 6 (height of a trie). *Let* $H_n := \max\{k : B_{n,k} > 0\}$ *be the height of a random trie. Then* $H_n/\log n \to \alpha_3$ *in probability.*

Proof. Let $k_H := \alpha_3 L_n$. First we derive an upper bound for H_n as follows:

$$\begin{aligned}\mathbb{P}(H_n > (1+\varepsilon)k_H) &\le \mathbb{P}(B_{n,k} \ge 1) \text{ (for some } k \ge (1+\varepsilon)k_H)\\ &\le \mathbb{E}(B_{n,k}) \to 0,\end{aligned}$$

where the last inequality follows from Theorem 3 when $p \neq q$ and (91) when $p = q$. For the lower bound, we use the second moment method (see [79]) to find

$$\begin{aligned}\mathbb{P}(H_n < (1-\varepsilon)k_H) &\le \mathbb{P}(B_{n,\lceil(1-\varepsilon)k_H\rceil} = 0)\\ &\le \frac{\mathbb{V}(B_{n,\lceil(1-\varepsilon)k_H\rceil})}{(\mathbb{E}(B_{n,\lceil(1-\varepsilon)k_H\rceil}))^2}\\ &= O\left(\frac{1}{\mathbb{E}(B_{n,\lceil(1-\varepsilon)k_H\rceil})}\right) \to 0\end{aligned}$$

by Theorems 3 and 7 and (94). Combining the two estimates, we obtain the required result. □

Corollary 6 is not new and has already been derived in Devroye [12], Pittel [64, 65], and Szpankowski [77].

Shortest path. The shortest path $S_n := \min\{j : B_{n,j} > 0\}$ of a random trie, discussed next, has attracted much less attention than the height (see [79]) in the literature. It is closely related to the behaviors of the external profile in range (I) near $k = \alpha_1(L_n - LLL_n + O(1))$ as discussed in Theorem 1 and its refinement in Corollary 3.

Define

$$\hat{k} := \begin{cases} \alpha_1\left(L_n - LLL_n - \log m_0 + m_0 \log(p/q) - \dfrac{LLL_n}{m_0 LL_n}\right) & \text{if } p \neq q,\\ \alpha_1(L_n - LL_n) & \text{if } p = q,\end{cases}$$

where $m_0 := \lceil 1/(p/q-1)\rceil$, and

$$k_S := \begin{cases} \lceil \hat{k} \rceil & \text{if } p \neq q,\\ \lfloor \hat{k} \rfloor & \text{if } p = q.\end{cases}$$

Corollary 7 (shortest path length of tries). *If $p \neq q$, then*

$$S_n = \begin{cases} k_S & \text{if } \{\hat{k}\}LL_n \to \infty,\\ k_S \text{ or } k_S - 1 & \text{if } \{\hat{k}\}LL_n = O(1)\end{cases}$$

with high probability;[2] *if $p = q = 1/2$, then*

$$S_n = \begin{cases} k_S + 1 & \text{if } \{\hat{k}\}L_n \to \infty,\\ k_S \text{ or } k_S + 1 & \text{if } \{\hat{k}\}L_n = O(1)\end{cases}$$

with high probability.

Proof. Assume $p \neq q$. Consider first the case $\{\hat{k}\}LL_n \to \infty$. In this case we have, by Corollary 3,

$$\begin{cases} \mu_{n,k_S} \to \infty,\\ \mu_{n,k} \to 0 \quad \text{for } \ k \le k_S - 1.\end{cases}$$

[2]We say that an event holds *with high probability* if it holds with probability tending to 1 as $n \to \infty$.

Thus, again by the second moment method,

$$\mathbb{P}(S_n > k_S) \le \mathbb{P}(B_{n,k_S} = 0) \le \frac{\mathbb{V}(B_{n,k_S})}{(\mathbb{E}(B_{n,k_S}))^2} = O\left(\frac{1}{\mu_{n,k_S}}\right) \to 0.$$

On the other hand, by using the first moment method, we have

$$\begin{aligned}\mathbb{P}(S_n < k_S) &\le \mathbb{P}(B_{n,k} \ge 1) \text{ (for some } k < k_S)\\ &\le \mu_{n,k} \to 0.\end{aligned}$$

These two estimates imply that $\mathbb{P}(S_n = k_S) \to 1$.

Now if $\{\hat{k}\}LL_n = O(1)$, then, again by Corollary 3,

$$\begin{cases} \mu_{n,k_S} \to \infty, \\ \mu_{n,k_S-1} = \Theta(1), \\ \mu_{n,k} \to 0 \text{ for } k \le k_S - 2. \end{cases}$$

Thus applying mutatis mutandis the same proof gives

$$\mathbb{P}(S_n = k_S) + \mathbb{P}(S_n = k_S - 1) \to 1.$$

The proof for the symmetric case is similar, because $\mu_{n,k} \to \infty$ when k lies in the range (95), and from this result we deduce that $\mu_{n,k_S+1} \to \infty$, $\mu_{n,k_S-1} \to 0$, and

$$\mu_{n,k_S} \begin{cases} \to 0 & \text{if } \{\hat{k}\}L_n \to \infty, \\ = \Theta(1) & \text{if } \{\hat{k}\}L_n = O(1). \end{cases}$$

This completes the proof. □

Fill-up level. We now consider the fill-up level $F_n = \max\{k : I_{n,k} = 2^k\}$ of a random trie, which was also analyzed previously by Devroye [12], Pittel [64, 65], and Knessl and Szpankowski [49].

COROLLARY 8 (fill-up level of a trie). *If $p \ne q$, then*

$$F_n = \begin{cases} k_S - 1 & \text{if } \{\hat{k}\}LL_n \to \infty, \\ k_S - 2 \text{ or } k_S - 1 & \text{if } \{\hat{k}\}LL_n = O(1) \end{cases}$$

with high probability; if $p = q = 1/2$, then

$$F_n = \begin{cases} k_S & \text{if } \{\hat{k}\}L_n \to \infty, \\ k_S \text{ or } k_S - 1 & \text{if } \{\hat{k}\}L_n = O(1). \end{cases}$$

Proof. Observe that

$$F_n = \max\{k : \bar{I}_{n,k} = 0\} = \min\{k : \bar{I}_{n,k} > 0\} - 1.$$

By (86), we have $\mathbb{E}(\bar{I}_{n,k}) \sim \mu_{n,k}$ when $k \le \alpha_1(1 + o(1))L_n$. Thus the proof of Corollary 7 applies with little modification. □

Profile enumerating only right branches. We consider the random variable $R_{n,k}$, which denotes the number of external nodes in random tries that are away from the root by k right branches. Since a right branch means a "1" in the input-string, $R_{n,k}$ enumerates the number of strings with exactly k 1's; it also has other concrete interpretations in splitting processes and conflict resolution algorithms. All of our

tools can be extended to $R_{n,k}$, although $R_{n,k}$ exhibits very different behaviors. For example, unlike $B_{n,k}$ or $I_{n,k}$, there is no need to distinguish between symmetric and asymmetric tries, all results being uniform in p; also, the Poisson heuristic holds for all $k \geq 0$. This example further reveals the power of our approaches.

The probability generating function $F_{n,k}(y) := \mathbb{E}(y^{R_{n,k}})$ of $R_{n,k}$ satisfies the recurrence

$$F_{n,k}(y) = \sum_{0\leq j\leq n} \binom{n}{j} p^j q^{n-j} F_{j,k-1}(y) F_{n-j,k}(y) \qquad (n \geq 2; k \geq 0),$$

with the initial conditions $F_{n,k}(y) = 1$ for $n \leq 1$ or $k < 0$ and $F_{2,1}(y) = y$. Thus the bivariate generating function $\mathcal{F}_k(z, y) := \sum_n F_{n,k}(y) z^n/n!$ satisfies

$$\mathcal{F}_k(z, y) = \mathcal{F}_k(qz, y)\mathcal{F}_{k-1}(pz, y) = \prod_{j\geq 0} \mathcal{F}_0(p^k q^j z, y)^{\binom{k+j-1}{j}},$$

where

$$\mathcal{F}_0(z, y) = e^{pz}\mathcal{F}_0(qz, y) + p(1 - p/2)(y - 1)z^2,$$

which is further solved to be

$$\mathcal{F}_0(z, y) = e^z + p(1 - p/2)(y - 1) \sum_{j\geq 0} (q^j z)^2 e^{(1-q^j)z}. \tag{98}$$

From this we deduce that the expected right-profile is given by

$$\mathbb{E}(R_{n,k}) = p(1 - p/2)n![z^n]\frac{e^z}{2\pi i} \int_{(\rho)} z^{-s}\Gamma(s + 2)\frac{p^{-ks}}{(1 - q^{-s})^{k+1}}\mathrm{d}s,$$

where $-2 < \rho < 0$. The integral is not of the same type as (6) but is similar, and our methods of proof easily extend. It has simple poles at $s = -2, -3, \ldots$ and poles of order $k+1$ at $s = 2j\pi i/\log(1/q)$, $j \in \mathbb{Z}$. Thus the asymptotics of $\mathbb{E}(R_{n,k})$ are divided into four overlapping ranges.

- If $0 \leq k = o(\log n)$, then the residues of the poles on the imaginary lines are dominant, and we have

$$\mathbb{E}(R_{n,k}) \sim p(1 - p/2)\frac{(\log p^k n)^k}{k!(\log(1/q))^{k+1}} \left(1 + \sum_{j\neq 0} \Gamma(1 + \chi_j)(p^k n)^{-\chi_j}\right),$$

  uniformly in k, where $\chi_j := 2j\pi i/\log(1/q)$.

- If $k \to \infty$ and $k \leq \alpha^*(L_n - K_n\sqrt{L_n})$, where $K_n \to \infty$ and

$$\alpha^* := \frac{1 - q^2}{(1 - q^2)\log(1/p) - q^2\log(1/q)},$$

  then by the saddle-point method

$$\mathbb{E}(R_{n,k}) \sim \frac{p(1 - p/2)q^{\rho/2}}{\sqrt{2\pi k}\log(1/q)} (p^k n)^{-\rho}(1 - q^{-\rho})^{-k} \sum_{j\in\mathbb{Z}} \Gamma(\rho + 1 + \chi_j)(p^k n)^{-\chi_j},$$

  uniformly in k, where

$$\rho = \log_{1/q} \frac{\log(p^k n)}{\log(p^k n/q^k)}.$$

- If $k = \alpha^* L_n + x\sqrt{\alpha^*(1+\alpha^*\log(p/q))(1+\alpha^*\log p)L_n}$, then

$$\mathbb{E}(R_{n,k}) \sim \frac{1}{2}\Phi(x)(p^k n)^2(1-q^2)^{-k},$$

  uniformly for $x = o(L_n^{1/6})$.
- If $k \geq \alpha^* L_n + K_n\sqrt{\alpha^*(1+\alpha^*\log(p/q))(1+\alpha\log p)L_n}$, then

$$\mathbb{E}(R_{n,k}) \sim \frac{1}{2}(p^k n)^2(1-q^2)^{-k}.$$

These results imply that, as $n \to \infty$, $\mathbb{E}(R_{n,k}) \to \infty$ iff

$$1 \leq k \leq \frac{2}{\log\frac{2-p}{p}}\, L_n - K_n,$$

where $K_n \to \infty$ with n. Note that

$$\log e^{-z}\mathcal{F}_0(z,y) = \log(1+(y-1)\tau(z)),$$

where $\tau(z) := p(1-p/2)\sum_{j\geq 0}(q^j z)^2 e^{-q^j z}$ satisfies $\tau(z) = O(|z|^2)$ as $z \to 0$, and, by Mellin transform, $\tau(z) = O(1)$ as $|z| \to \infty$ in a small sector containing the real axis. This yields, by a straightforward modification of our approaches, that $\mathbb{V}(R_{n,k}) = \Theta(\mathbb{E}(R_{n,k}))$ for all $k = k(n) \geq 0$ and that

$$\frac{R_{n,k} - \mathbb{E}(R_{n,k})}{\sqrt{\mathbb{V}(R_{n,k})}} \xrightarrow{d} \mathcal{N}(0,1)$$

whenever $\mathbb{E}(R_{n,k})$ or $\mathbb{V}(R_{n,k}) \to \infty$. Two remaining cases are $k = 0$ and $k = 2L_n/\log\frac{2-p}{p} + O(1)$. In the first case, $R_{n,0}$ by (98) is Bernoulli distributed with mean equal to $\tau(n)$, which is asymptotic to the periodic function

$$\frac{1}{\log(1/q)}\left(1 + \sum_{j\neq 0}\Gamma(2-\chi_j)n^{-\chi_j}\right),$$

and in the second case,

$$\mathbb{P}(R_{n,k} = m) = \frac{\lambda_3^m}{m!}\, e^{-\lambda_3} + o(1),$$

where $\lambda_3 := (p^k n)^2(1-q^2)^{-k}/2$.

Appendix A: Proof of Lemma 3. In this appendix, we prove Lemma 3. For part (i) let $z = ne^{i\theta}$, where $\theta = o(LL_n^{-1/2})$. By (8)

$$\begin{aligned}
\tilde{M}_k(z) &= \sum_{0\leq j<k}\binom{k-1}{j}p^j q^{k-j} z e^{-p^j q^{k-j} z}\left(1 + O\left(e^{-(p-q)p^j q^{k-1-j} n\cos\theta}\right)\right)\\
&= \sum_{0\leq j<k}\binom{k-1}{j}p^j q^{k-j} z e^{-p^j q^{k-j} z}\left(1 + O\left(e^{-(p-q)q^{k-1} n\cos\theta}\right)\right) \qquad (99)\\
&= q^k z e^{-q^k z}\left(1 + O(E_6)\right),
\end{aligned}$$

where

$$E_6 := \sum_{1\le j<k} \frac{(p\alpha_1/q)^j}{j!} L_n^j e^{-q^k n((p/q)^j-1)\cos\theta}.$$

Since $1 \le k \le k_0 - \alpha_1 K_n/LL_n$, we have

$$q^k n \ge \frac{LL_n}{p/q-1}\, e^{K_n/LL_n}.$$

It follows, by using the inequality

$$\frac{t^j-1}{t-1} \ge j \qquad (t>1; j\ge 1),$$

that

$$\begin{aligned} E_6 &\le \sum_{j\ge 1} \frac{(p\alpha_1/q)^j}{j!} L_n^{j-\frac{(p/q)^j-1}{p/q-1}\cos(\theta)e^{K_n/LL_n}} \\ &\le \sum_{j\ge 1} \frac{(p\alpha_1/q)^j}{j!} L_n^{-j(\cos(\theta)e^{K_n/LL_n}-1)} \\ &\le \sum_{j\ge 1} \frac{(p\alpha_1/q)^j}{j!} e^{-jK+O(j\theta^2 LL_n)} \\ &= O(e^{-K_n}), \end{aligned}$$

since $\theta = o(LL_n^{-1/2})$. This proves (30).

For part (ii), by (99),

$$\tilde{M}_k(z) = S_{k,m}(z)\left(1+O\left(e^{-(p-q)p^m q^{k-1-m} n\cos\theta} + E_7 + E_8\right)\right),$$

where

$$\begin{aligned} E_7 &:= \sum_{0\le j<m} \left|\frac{S_{k,j}(z)}{S_{k,m}(z)}\right| \left(1+O\left(e^{-(p-q)p^j q^{k-1-j} n\cos\theta}\right)\right), \\ E_8 &:= \sum_{m<j<k} \left|\frac{S_{k,j}(z)}{S_{k,m}(z)}\right| \left(1+O\left(e^{-(p-q)p^j q^{k-1-j} n\cos\theta}\right)\right). \end{aligned}$$

By (31), $p^m q^{k-m} n = e^\eta LL_n/(p/q-1)$. It follows, by changing j to $m-j$, that

$$\begin{aligned} E_7 &= O\left(m! \sum_{1\le j\le m} \frac{(q/p)^j}{(m-j)!}\, k^{-j} \exp\left(p^m q^{k-m} n\cos(\theta)\left(1-(q/p)^j\right)\right)\right) \\ &= O\left(m! \sum_{1\le j\le m} \frac{(q/p\alpha_1)^j}{(m-j)!} L_n^{-j+\frac{1-(q/p)^j}{p/q-1}\, e^\eta\cos\theta}\right) \\ &= O\left(m! \sum_{1\le j\le m} \frac{(q/p\alpha_1)^j}{(m-j)!} L_n^{-j(1-qe^\eta\cos\theta/p)}\right) \\ &= O\left(m_n^{-(1-qe^\eta\cos\theta/p)}\right) = O\left(me^{-K_n}\right), \end{aligned}$$

since $\eta \le \log(p/q) - K_n/LL_n$ and $\theta = o(LL_n^{-1/2})$.

Similarly,

$$\begin{aligned}
E_8 &= O\left(m!\sum_{j>m}\frac{(p/q)^{j-m}}{j!}\,k^{j-m}\exp\left(-p^m q^{k-m} n\cos(\theta)\left((p/q)^{j-m}-1\right)\right)\right)\\
&= O\left(m!\sum_{j\ge 1}\frac{(p\alpha_1/q)^j}{(j+m)!}L_n^{j-\frac{(p/q)^j-1}{p/q-1}\,e^\eta\cos\theta}\right)\\
&= O\left(m!\sum_{j\ge 1}\frac{(p\alpha_1/q)^j}{(j+m)!}L_n^{-j(e^\eta\cos\theta-1)}\right)\\
&= O\left(m^{-1}L_n^{-(e^\eta\cos\theta-1)}\right) = O\left(m^{-1}e^{-K_n}\right),
\end{aligned}$$

since $\eta \ge K_n/LL_n$. This completes the proof of (32). □

Appendix B: Well-definedness of $Q_k(z, y)$. We prove here the following lemma that is needed for the proof of Proposition 4.

LEMMA 7. *The function $Q_k(re^{i\theta}, y)$ is well defined for $r \ge 0$, $|\theta| \le \varepsilon$, and $|y| = 1$.*

Proof. We first show that

$$|a_3(r)(e^{i\varphi}-1) + a_4(r)(e^{i\varphi}-1)^2| < 1 \tag{100}$$

for $r \ge 0$ and $|y| = 1$. By direct calculation, we have

$$|a_3(r)(e^{i\varphi}-1) + a_4(r)(e^{i\varphi}-1)^2|^2 = a_3(r)^2\upsilon - a_4(r)(a_3(r)-a_4(r))\upsilon^2,$$

where $\upsilon := 2(1-\cos\varphi)$. Since

$$a_3(r) - a_4(r) \ge a_3(r) - 2a_4(r) = e^{-r}\left(pr(e^{qr}-1-qr) + qr(e^{pr}-1-pr)\right) \ge 0,$$

we have

$$|a_3(r)(e^{i\varphi}-1) + a_4(r)(e^{i\varphi}-1)^2| \le \sqrt{2}\,a_3(r).$$

By simple calculus, we have $a_3(r) < 2^{-1/2}$, which implies (100). Indeed, the inequality $a_3(r) < 2^{-1/2}$ is equivalent to

$$pre^{-pr} + qre^{-qr} - re^{-r} < 2^{-1/2} \qquad (r \ge 0),$$

and we have

$$pre^{-pr} + qre^{-qr} - re^{-r} \le \max_{r\ge 0} re^{-r}(e^{r/2}-1) \approx 0.52 < 2^{-1/2}.$$

This proves the lemma when $z = r$; then the assertion of the lemma follows from analyticity. □

Appendix C: A useful approximation. In the proof of Proposition 4 we need the following lemma.

LEMMA 8. *Let $f(z)$ be an entire function satisfying*

$$f(z) = \begin{cases} O(|z|^2) & \text{as } z \to 0,\\ O(|z|e^{-q\Re(z)}) & \text{as } z\to\infty,\ |\arg(z)| \le \bar{\varepsilon}, \end{cases} \tag{101}$$

where $\bar{\varepsilon} > 0$. *Then, uniformly for all* $k = k(n) \geq 1$ *and* $z = ne^{i\theta}$, $|\theta| \leq \bar{\varepsilon}$,

$$f_k(z) := \sum_{0 \leq j < k} \binom{k-1}{j} f(p^j q^{k-1-j} z) = \Theta(|\tilde{M}_k(z)|).$$

Proof. If $1 \leq k \leq k_0$, then it is easy to see that $f_k(z) = \Theta(|\tilde{M}_k(z)|)$ for $|\theta| \leq \bar{\varepsilon}$. When $k \geq k_0$, let $f^*(s) := \int_0^\infty x^{s-1} f(x) \mathrm{d}x$. Then $f^*(s)$ is well defined in the half-plane $\Re(s) > -2$ by (101). By the estimates in (101) and the same argument used in [23, Proposition 5], we have, assuming $\rho \geq 1$ and $t > 0$,

$$\begin{aligned} f^*(\rho + it) &= \int_0^{e^{i\bar{\varepsilon}}\infty} x^{\rho+it-1} f(x) \mathrm{d}x \\ &= e^{i\bar{\varepsilon}(\rho+it)} \int_0^\infty x^{\rho+it-1} f(xe^{i\bar{\varepsilon}}) \mathrm{d}x \\ &= O(e^{-\bar{\varepsilon}t} \int_0^1 x^{\rho+1} \mathrm{d}x) + O\left(e^{-\bar{\varepsilon}t} \int_1^\infty x^\rho e^{-qx\cos\bar{\varepsilon}} \mathrm{d}x \right) \\ &= O\left(e^{-\bar{\varepsilon}t} \rho^{-1} + e^{-\bar{\varepsilon}t} q^{-\rho} \rho^{1/2} (\rho/e)^\rho \right), \end{aligned}$$

uniformly in ρ and t. If $t < 0$, then changing $e^{i\bar{\varepsilon}}$ to $e^{-i\bar{\varepsilon}}$ gives

$$f^*(\rho + it) = O\left(e^{-\bar{\varepsilon}|t|} \rho^{-1} + e^{-\bar{\varepsilon}|t|} q^{-\rho} \rho^{1/2} (\rho/e)^\rho \right).$$

When $-2 < \rho \leq 1$, $f^*(\rho + it) = O(e^{-\bar{\varepsilon}|t|})$ for large $|t|$ by the same argument. On the other hand, by the first estimate in (101), we also have

$$f^*(s) = O\left(|s+2|^{-1} \right) \qquad (s \to 2).$$

With these estimates and the Mellin inversion integral

$$f_k(z) = \frac{1}{2\pi i} \int_{(\rho)} z^{-s} f^*(s) (p^{-s} + q^{-s})^{k-1} \mathrm{d}s,$$

we can apply the arguments used for $\tilde{M}_k(z)$ and prove that $f_k(z) = \Theta(|\tilde{M}_k(z)|)$ for $|\arg(z)| \leq \bar{\varepsilon}$. □

ON FIXED-POINTS OF MULTIVALUED FUNCTIONS ON COMPLETE LATTICES AND THEIR APPLICATION TO GENERALIZED LOGIC PROGRAMS*

UMBERTO STRACCIA†, MANUEL OJEDA-ACIEGO‡, AND CARLOS V. DAMÁSIO§

Abstract. Unlike monotone single-valued functions, multivalued mappings may have zero, one, or (possibly infinitely) many minimal fixed-points. The contribution of this work is twofold. First, we overview and investigate the existence and computation of minimal fixed-points of multivalued mappings, whose domain is a complete lattice and whose range is its power set. Second, we show how these results are applied to a general form of logic programs, where the truth space is a complete lattice. We show that a multivalued operator can be defined whose fixed-points are in one-to-one correspondence with the models of the logic program.

Key words. fixed-points, multivalued functions, complete lattices, logic programming

AMS subject classifications. 47H10, 06B23, 68N17, 68Q55

DOI. 10.1137/070695976

1. Introduction. It is well known that fixed-point theorems are useful in many completely disparate and unrelated scientific branches and, thus, in computer science. Among the main fixed-point results is the Tarski theorem [47] (often called the Knaster–Tarski theorem) stating that the set of fixed-points of a monotone *single-valued* function $f\colon L \to L$, over a complete lattice $\langle L, \leq \rangle$, is a complete lattice and therefore has a least fixed-point.

The topic of this work is the overview and investigation of the fixed-points of *multivalued* functions $f\colon L \to 2^L$ (multivalued functions are also called *correspondences*, or *set-valued functions*, in the literature). Such functions naturally arise, e.g., in the specification of the semantics of nondeterministic programming languages [7, 8, 11, 18, 31, 36, 37, 44], in game theory [6, 33, 45, 53], and in disjunctive logic programming [22, 27, 32, 42, 52]; those of the latter case motivated our work. Informally, (i) in the first case, the meaning of a nondeterministic[1] program P may be seen as a function $p : S \to 2^S$, where S is the set of states a program may assume. The image of p is a finite nonempty set, as at a given step of a program execution, due to a nondeterministic statement, more than one successive state is possible. The semantics of a program is then related to the fixed-points of such functions ($s \in p(s)$); (ii) in the second case, a game is represented as a function $g : S \to 2^S$, where S is the strategy space of the involved players, and fixed-points ($s \in g(s)$) are related to the so-called Nash equilibria of the game. The image of g is a nonempty (usually finite) set, as at each step of the game, more than one incomparable strategic choice is possible; and

[1] An example of a nondeterministic statement is "π_1 or π_2" with informal semantics "execute either program π_1 or program π_2."

(iii) in the third case, models of disjunctive logic programs are related to fixed-points ($I \in T_{\mathcal{P}}(I)$) of a function $T_{\mathcal{P}} \colon \hat{L} \to 2^{\hat{L}}$, where $\hat{L}$ is the set of interpretations of a disjunctive logic program. Here, $T_{\mathcal{P}}$ is a so-called immediate consequence operator, which at each "step" provides a better approximation of the models of a disjunctive logic program. The image of $T_{\mathcal{P}}$ is a *possibly empty, nonfinite* set, as at each step of the model approximation computation, either no approximations, or a potentially infinite number of incomparable better approximations, are possible.

We point out that, in all three cases, fixed-point computations may be seen roughly as a tree, where a node is an element of the domain and the children of it are the alternative (nondeterministic) choices provided by the image of the multivalued function.

Generally, multivalued functions present the following fundamental challenge to the ordinary fixed-point approach: unlike monotone single-valued functions, it is possible that zero, one, or (infinitely) many minimal fixed-points exist.

The contribution of this work is twofold:

- We provide conditions for the existence of fixed-points and minimal fixed-points and show how to recursively obtain them in a slightly more general setting than considered so far (such as when the image of a multivalued function may be empty; see below). A summary of our main findings in described in Table 3.1. To the best of our knowledge, we have compared the results obtained with respect to all related work using similar order-theoretic approaches; when a reformulation or easier proof of a known result is presented, then appropriate credit is given.
- The results are then applied to a general form of logic programs, encompassing the disjunctive and many-valued extensions. The rules in such logic programs have the form $g(B_1, \ldots, B_k) \leftarrow f(A_1, \ldots, A_n)$, where f, g are arbitrary computable functions over a complete lattice (which acts as the truth space) and B_i and A_j are atoms. The form of the rules is sufficiently expressive to generalize all approaches that we are aware of in (monotone) many-valued logic programming. The main difference in this application to, e.g., semantics of nondeterministic programming languages and game theory, is that the image of $T_{\mathcal{P}}(I)$ may be empty or of infinite size, while in the former two cases both $p(s)$ and $g(s)$ are nonempty and finite. We show that a multivalued operator $T_{\mathcal{P}}(I)$ can be defined whose fixed-points are in one-to-one correspondence with the models of the logic program. The obtained relationship is novel and addresses some fundamental theoretical problems that have been neglected so far in the logic programming literature. We conclude by showing that our results extend current well-known results for classical disjunctive logic programs, where rules are of the form $B_1 \vee \cdots \vee B_k \leftarrow A_1 \wedge \cdots \wedge A_n$.

2. Preliminaries. We recall some basic definitions and notations.

With $\mathcal{L} = \langle L, \leq \rangle$, where $\leq$ is a partial order ($x \leq y$ may be read as "x approximates y") over the nonempty set L, we denote a *complete lattice*, with *join* (*meet*) operator $\vee$ ($\wedge$), least (greatest) element $\bot$ ($\top$).

Given $S \subseteq L$, by $\min S$ ($\max S$) we denote the set of *minimal* (*maximal*) elements in S and by $\bigwedge S$ ($\bigvee S$) the greatest lower bound (least upper bound) of S.[2] A nonempty subset S of L is a *sublattice* of L if for any x, y of S, both $x \vee y$ and $x \wedge y$ belong to S. A nonempty subset S of L is $\wedge$-*closed* ($\vee$-*closed*) if for any subset U

[2]We recall that $\bigwedge S = \bigwedge_{s \in S} s$ and $\bigvee S = \bigvee_{s \in S} s$.

of S, $\bigwedge_{x\in U} x$ ($\bigvee_{x\in U} x$) belongs to S. Note that S is $\wedge$-closed ($\vee$-closed) iff S is a complete meet semilattice (complete join semilattice). Furthermore, we say that S is *closed* if S is both $\wedge$-closed and $\vee$-closed, i.e., S is a complete sublattice of L. Given two elements $a, b \in L$ with $a \leq b$, we denote by $[a, b]$ the *interval* $\{x \in L \mid a \leq x \leq b\}$. Clearly, $\mathcal{L} = \langle [a, b], \leq \rangle$ is a complete lattice as well. Finally, by $\bar{\mathcal{L}} = \langle L, \geq \rangle$ we denote the *dual* lattice of $\mathcal{L} = \langle L, \leq \rangle$, where $x \geq y$ iff $y \leq x$. Of course, $\bar{\mathcal{L}}$ is a complete lattice as well, where $\geq$ is the reversed order of $\leq$ and $\top$ ($\bot$) is the least (greatest) element of $\bar{\mathcal{L}}$.

Two sets X and Y are *equipollent* iff there is a bijection from X to an Y. The *cardinality* $|X|$ of a set X is the least ordinal α such that there is a bijection between X and α.

We use the notation $(x_\alpha)_{\alpha\in I}$ to denote a (possibly transfinite) nonempty *sequence* of elements $x_\alpha \in L$, where I is an ordinal. We say that the sequence is *increasing* (*decreasing*) iff $x_\alpha \leq x_{\alpha+1}$ ($x_{\alpha+1} \leq x_\alpha$) for all $\alpha \in I$.

If there is an ordinal $\beta \in I$ such that $x_\beta = x_\alpha$ for all $\beta \leq \alpha \in I$, we say that $(x_\alpha)_{\alpha\in I}$ is *eventually stationary or constant*. A property we will frequently rely on is the following well-known fact.

PROPOSITION 2.1. *An increasing (decreasing) sequence $(x_\alpha)_{\alpha\in I}$ of elements $x_\alpha \in L$ with $|I| > |L|$ has the property that there is an ordinal $\beta \in I$ such that $|\beta| \leq |L|$ and $x_\beta = x_\alpha$ for all $\beta \leq \alpha \in I$ ($|S|$ is the* cardinal *of a set S).*

For ease of presentation and by abuse of terminology, under the condition of Proposition 2.1, we will say that the sequence $(x_\alpha)_{\alpha\in I}$ *converges* to x_β.

A function $f\colon L \to L$ is *monotone* iff for all $x, y \in L$, $x \leq y$ implies $f(x) \leq f(y)$. f is *inflationary* iff for all $x \in L$, $x \leq f(x)$. A *fixed-point* of f is an element $x \in L$ such that $f(x) = x$. By $Fix(f)$ we denote the set of fixed-points of f. f is $\bigvee$*-preserving* ($\bigwedge$-*preserving*) iff for all increasing (decreasing) sequences $(x_\alpha)_{\alpha\in I}$, $f(\bigvee_\alpha x_\alpha) = \bigvee_\alpha f(x_\alpha)$ ($f(\bigwedge_\alpha x_\alpha) = \bigwedge_\alpha f(x_\alpha)$). f is *limit-preserving* iff it is both $\bigvee$- and $\bigwedge$-preserving. It is easy to prove that $\bigvee$- or $\bigwedge$-preserving functions are monotone. However, a limit-preserving (in particular a monotone) function need not be inflationary.

Example 1. Consider $f : \{0, 1\} \to \{0, 1\}$ with $f(x) = 0$ for all $x \in \{0, 1\}$; then f is limit preserving and, thus, monotone, but $1 \not\leq f(1)$ and, thus, f is not inflationary. The Tarski theorem [47] establishes that a monotone function $f\colon L \to L$ has a fixed-point, the set of fixed-points of f is a complete lattice, and, thus, f has a least and a greatest fixed-point. The least (greatest) fixed-point can be obtained by transfinite iteration of f over $\bot$ ($\top$). Furthermore, let $\Phi(f) = \{x \in L\colon f(x) \leq x\}$, $\Psi(f) = \{x \in L\colon x \leq f(x)\}$, and, thus, $\top \in \Phi(f)$, while $\bot \in \Psi(f)$. Then the least fixed-point is $\bigwedge \Phi(f)$, while the greatest fixed-point is $\bigvee \Psi(f)$. If f is inflationary, then f has a fixed-point (e.g., obtained by transfinite iteration of f over $\bot$, also $\top \leq f(\top) = \top$), and $x \in \Phi(f)$ iff x is a fixed-point of f. However, inflationary functions may not have a least fixed-point.

Example 2. Consider $L = [0, 1]$ and function f with $f(0) = 1$ and for $x > 0$, $f(x) = x$. Then f is not monotone and is inflationary, all $x > 0$ are fixed-points, $\Phi(f) = \{x : x > 0\}$, $\bigwedge \Phi(f) = 0 \notin \Phi(f)$, and 0 is not a fixed-point of f.

3. Multivalued functions. Given $\mathcal{L} = \langle L, \leq \rangle$, a *multivalued function* is a function $f\colon L \to 2^L$ (if for all $x \in L$, $|f(x)| = 1$, then f is single valued). Note that we do not require $f(x) \neq \varnothing$ for all $x \in L$. We say that $x \in L$ is a *fixed-point* of f iff $x \in f(x)$. For instance, see the following example.

Example 3. Let $L = \{0, 1, 2\}$. Consider $f\colon L \to 2^L$ defined as $f(0) = \{0, 1, 2\}$, $f(1) = \{0, 1\}$, and $f(2) = \{0\}$. Then 0 and 1 are fixed-points, whereas 2 is not a fixed-point.

Furthermore, we say that f is *nonempty* (resp., $\wedge$-*closed*, $\vee$-*closed*) iff for all $x \in L$ we have that $f(x) \neq \varnothing$ ($f(x)$ is, resp., $\wedge$-*closed*, $\vee$-*closed*).

In order to define the notion of a (multivalued) monotone function, as $f(x)$ is now a set of elements, we need to extend the partial order $\leq$ to sets of elements. There are mainly three well-known *preorders* (reflexive, transitive, but not antisymmetric), namely the *Smyth ordering*, the *Hoare ordering*, and the *Egli-Milner ordering*, which have been proposed in the context of nondeterministic programming languages (see, e.g., [1, 25]):[3]

$$X \preceq_S Y \quad \text{iff} \quad \forall y \in Y\ \exists x \in X \text{ s.t. (such that) } x \leq y \quad \text{(Smyth ordering)}, \tag{3.1}$$

$$X \preceq_H Y \quad \text{iff} \quad \forall x \in X\ \exists y \in Y \text{ s.t. } x \leq y \quad \text{(Hoare ordering)}, \tag{3.2}$$

$$X \preceq_{EM} Y \quad \text{iff} \quad X \preceq_S Y \text{ and } X \preceq_H Y \quad \text{(Egli-Milner ordering)}\ . \tag{3.3}$$

These orderings may be read as follows: (i) $X \preceq_S Y$ iff all $y \in Y$ are approximated by some $x \in X$; (ii) $X \preceq_H Y$ iff all $x \in X$ approximate some $y \in Y$; and (iii) $X \preceq_{EM} Y$ iff all $y \in Y$ are approximated by some $x \in X$ and all $x \in X$ approximate some $y \in Y$.

Clearly the Hoare ordering is equivalent to the Smyth ordering in the dual underlying lattice. Indeed it is straightforward to show the following.

PROPOSITION 3.1. *Let X, Y be two subsets of L. Then $X \preceq_S Y$ in $\mathcal{L}$ iff $Y \preceq_H X$ in $\bar{\mathcal{L}}$.*

As a consequence, many properties we state with respect to the Smyth ordering in $\mathcal{L}$ have their dual with respect to the Hoare ordering in $\bar{\mathcal{L}}$.

f is *Smyth-monotone*, or simply *S-monotone*, iff for all $x, y \in L$, if $x \leq y$, then $f(x) \preceq_S f(y)$ holds. The notions of *Hoare-monotone*, or simply *H-monotone*, and *Egli-Milner-monotone*, or simply *EM-monotone*, are defined similarly. By using Proposition 3.1, it is straightforward to prove the following.

PROPOSITION 3.2. *Let $f\colon L \to 2^L$ be a multivalued function. Then f is S-monotone in $\mathcal{L}$ iff f is H-monotone in $\bar{\mathcal{L}}$.*

We say that f is *inflationary* iff for all x, $\{x\} \preceq_S f(x)$; i.e., all elements in $f(x)$ are greater than or equal to x. Dually, we say that f is *deflationary* iff for all $x \in L$, $f(x) \preceq_H \{x\}$; i.e., all elements in $f(x)$ are smaller than or equal to x. Of course, a deflationary function is an inflationary function in the dual lattice $\bar{\mathcal{L}}$.

PROPOSITION 3.3. *Let $f\colon L \to 2^L$ be a multivalued function. Then f is deflationary in $\mathcal{L}$ iff f is inflationary in $\bar{\mathcal{L}}$.*

We next generalize the notion of a limit-preserving function to the multivalued case. A multivalued function $f\colon L \to 2^L$ is $\bigvee$-*preserving* iff for all increasing sequences $(x_\alpha)_{\alpha \in I}$,

$$f\left(\bigvee_\alpha x_\alpha\right) = \left\{ y \mid \text{ there is } (y_\alpha)_{\alpha \in I} \text{ s.t. } y_\alpha \in f(x_\alpha) \text{ and } y = \bigvee_\alpha y_\alpha \right\}\ . \tag{3.4}$$

Dually, we say that $f\colon L \to 2^L$ is $\bigwedge$-*preserving* iff for all decreasing sequences $(x_\alpha)_{\alpha \in I}$,

$$f\left(\bigwedge_\alpha x_\alpha\right) = \left\{ y \mid \text{ there is } (y_\alpha)_{\alpha \in I} \text{ s.t. } y_\alpha \in f(x_\alpha) \text{ and } y = \bigwedge_\alpha y_\alpha \right\}\ . \tag{3.5}$$

f is *limit-preserving* iff it is both $\bigvee$- and $\bigwedge$-preserving. For ease of presentation, sometimes we use the notation $\bigvee_\alpha f(x_\alpha)$ (resp., $\bigwedge_\alpha f(x_\alpha)$) to denote the right-hand

[3] [36] describes another order, called the *Plotkin order*, which extends the Egli-Milner ordering. However, we will not address it here.

side of (3.4) (resp., (3.5)). Note that if for all $x \in L$, $|f(x)| = 1$, then the definition reduces to the usual one for single-valued functions.

Of course, we have the following.

PROPOSITION 3.4. *Let $f\colon L \to 2^L$ be a multivalued function. Then f is $\bigwedge$-preserving in $\mathcal{L}$ iff f is $\bigvee$-preserving in $\bar{\mathcal{L}}$.*

We can prove the following.

PROPOSITION 3.5. *Consider a multivalued function $f\colon L \to 2^L$.*

1. *If f is $\bigvee$-preserving, then f is S-monotone.*
2. *If f is $\bigwedge$-preserving, then f is H-monotone.*
3. *If f is limit-preserving, then f is EM-monotone.*

Proof.

Case 1. Let $x_1 \leq x_2$ and f $\bigvee$-preserving. Then for the increasing sequence $x_1 \leq x_2$, $f(x_2) = f(x_1 \vee x_2) = \{y\colon$ there are $y_i \in f(x_i)$ s.t. $y = y_1 \vee y_2\} = X$. If $f(x_2) = \varnothing$, then trivially $f(x_1) \preceq_S f(x_2) = \varnothing$. If $f(x_1) = \varnothing$, then by definition $X = \varnothing$ and, thus, $f(x_2) = \varnothing$. Therefore, $\varnothing = f(x_1) \preceq_S f(x_2) = \varnothing$. Otherwise assume $f(x_1)$ and $f(x_2)$ nonempty. Therefore, as f is $\bigvee$-preserving, for $y \in f(x_2) = X$ there are $y_i \in f(x_i)$ $(i = 1, 2)$ such that $y = y_1 \vee y_2$. In particular, $y_1 \leq y$. Therefore, $f(x_1) \preceq_S f(x_2)$ and, thus, f is S-monotone.

Case 2. The proof is dual to Case 1 (see the appendix, Proposition A.1).

Case 3. This case is straightforward by Cases 1 and 2. □

Note that a $\bigwedge$-preserving function need not be S-monotone and, similarly, a $\bigvee$-preserving function need not be H-monotone and, thus, an EM-monotone function need not be limit-preserving.

Example 4. Consider $L = \{0, 1\}$ with $0 \leq 1$. Then the multivalued function $f : L \to 2^L$, $f(0) = \varnothing, f(1) = \{1\}$ is $\bigwedge$-preserving, but not S-monotone, as $0 \leq 1$ and $f(0) = \varnothing \not\preceq_S f(1) = \{1\}$. Similarly, the multivalued function $g : L \to 2^L$, $g(0) = \{0\}, g(1) = \varnothing$ is $\bigvee$-preserving, but not H-monotone, as $0 \leq 1$ and $g(0) = \{0\} \not\preceq_H g(1) = \varnothing$.

But, we can easily show the following.

PROPOSITION 3.6. *Consider a multivalued function $f\colon L \to 2^L$ and $x_1 \leq x_2$ with $f(x_1) \neq \varnothing \neq f(x_2)$.*

1. *If f is $\bigwedge$-preserving, then $f(x_1) \preceq_S f(x_2)$.*
2. *If f is $\bigvee$-preserving, then $f(x_1) \preceq_H f(x_2)$.*

Proof.

Case 1. For the decreasing sequence $x_2 \geq x_1$, as f is $\bigwedge$-preserving, $f(x_1) = f(x_2 \wedge x_1) = \{y\colon$ there are $y_i \in f(x_i)$ s.t. $y = y_2 \wedge y_1\} = X$. Now, for $y \in f(x_2)$ choose a $y' \in f(x_1) \neq \varnothing$ and consider $y'' = y \wedge y'$. Therefore, $y'' \in X = f(x_1)$, $y'' \leq y$ and, thus, $f(x_1) \preceq_S f(x_2)$.

Case 2. This is similar to Case 1 (see the appendix, Proposition A.2). □

Example 1 can be adapted to multivalued functions and prove that a limit-preserving (in particular an S-monotone) function need not be inflationary.

Example 5. *Consider $f : \{0, 1\} \to 2^{\{0,1\}}$ such that for all $x \in \{0, 1\}$, $f(x) = \{0\}$; then f is limit-preserving and, thus, S-monotone, but $\{1\} \not\preceq_S f(1) = \{0\}$.*

We next want to investigate the existence of (minimal) fixed-points of multivalued functions. Similarly to the single-valued case, for $f\colon L \to 2^L$, let us define

$$\Phi(f) = \{x \in L\colon f(x) \preceq_S \{x\}\},$$
$$\Psi(f) = \{x \in L\colon \{x\} \preceq_H f(x)\}\ .$$

Note that, unlike the single-valued case, not necessarily $\top \in \Phi(f)$ (i.e., if $f(\top) = \varnothing$). Similarly, $\bot \in \Psi(f)$ iff $f(\bot) \neq \varnothing$. Also, if $f(x) = \varnothing$, then $x \notin \Phi(f)$; i.e., if $x \in \Phi(f)$, then $f(x) \neq \varnothing$. Finally, note that if $f(\top) \neq \varnothing$, then $\top \in \Phi(f)$ (we will use these straightforward facts often in the paper). Furthermore, note that $\Phi(f)$ is related to the $\preceq_S$ order, while $\Psi(f)$ is related to $\preceq_H$. One might wonder why we did not consider, for instance, $\Phi_H(f) = \{x \mid f(x) \preceq_H \{x\}\}$. As we will see later, $\bigwedge \Phi(f)$ relates to the least fixed-point of f (if it exists), while $\bigvee \Psi(f)$ relates to the greatest fixed-point of f. Example 6 shows that $\bigwedge \Phi_H(f)$ is not related to the least fixed-point of f.

Example 6. Consider $L = \{0, 1\}$ and the multivalued function $f\colon L \to 2^L$, $f(0) = \{0, 1\}, f(1) = \{1\}$. Then f is EM-monotone, $Fix(f) = \{0, 1\}$, but $\Phi_H(f) = \{x \mid f(x) \preceq_H \{x\}\} = \{1\}$ and $1 = \bigwedge \Phi_H(f)$ is not the least fixed-point of f.

We can show the following.

PROPOSITION 3.7. *Let $f\colon L \to 2^L$ be a multivalued function.*

1. *If f is inflationary, then $x \in \Phi(f)$ iff x is a fixed-point of f.*
2. *If f is deflationary, then $x \in \Psi(f)$ iff x is a fixed-point of f.*

Proof.

Case 1. Let $x \in \Phi(f)$. As f is inflationary, $\{x\} \preceq_S f(x) \preceq_S \{x\}$ and, thus, for $x \in \{x\}$ there is $y \in f(x)$ such that $x \leq y \leq x$, i.e., $x = y \in f(x)$. Vice versa, if $x \in f(x)$, then $f(x) \preceq_S \{x\}$ and, thus, $x \in \Phi(f)$.

Case 2. This is similar to Case 1 (see the appendix, Proposition A.3). ∎

Note that Proposition 3.7 does not hold if a function is, e.g., S-monotone, but not inflationary.

Example 7. In Example 3, f is S-monotone, not inflationary with $2 \in \Phi(f)$, but $2 \notin f(2)$.

The following examples show that a multivalued S-monotone function $f\colon L \to 2^L$ may have several minimal fixed-points or even no minimal fixed-point at all.

Example 8. Consider Belnap's truth space $\mathcal{FOUR}$ [3], $L = \{\bot, f, t, \top\}$ with f, t incomparable. Here, besides f for "false" and t for "true," $\bot$ stands for "unknown," whereas $\top$ stands for inconsistency. $\leq$ is the so-called knowledge order. Consider the multivalued function $g\colon L \to 2^L$ defined as $g(\bot) = \{f, t, \top\}, g(f) = \{f, \top\}, g(t) = \{t, \top\}$, and $g(\top) = \{\top\}$. Then g is EM-monotone, inflationary, and $\bigvee$-preserving. Furthermore, $f \in g(f), t \in g(t)$, and $\top \in g(\top)$, but $\bot \notin g(\bot)$, and thus f, t, and $\top$ are fixed-points of g, while $\bot$ is not. The minimal fixed-points are f and t. Note that $g(x)$ does not have a least element (e.g., $g(\bot)$) for all x. Additionally, note that $\Phi(g) = \{f, t, \top\}$, $\bigwedge \Phi(g) = \bot \notin \Phi(g)$, and $\min \Phi(g) = \{f, t\}$. Therefore, unlike the single-valued case, $\bigwedge \Phi(g)$ is not a fixed-point of g.

The four-element Belnap's truth space $\mathcal{FOUR}$ was introduced as a very suitable setting for computerized reasoning; it has a bilattice structure, since two orderings can be naturally defined and, as a result, it can be viewed as a class of truth values that can accommodate incomplete and inconsistent information, and in certain cases, default information.

Example 9. Let $L = [0, 1]$. Consider the multivalued function $f\colon L \to 2^L$ defined as $f(x) = \{y \mid y > 0, y \geq x)\}$. Then f is nonempty, $\bigvee$-preserving, and inflationary. Furthermore, for all $x > 0$, $x \in f(x)$, but $0 \notin f(0)$, and thus all $x > 0$ are fixed-points of f, while 0 is not. Therefore, f has no minimal fixed-point. Also, note that $\Phi(f) = \{x \mid x > 0\}$, $\bigwedge \Phi(f) = 0 \notin \Phi(f)$, and $\min \Phi(f) = \varnothing$. Similar to Example 8, $0 = \bigwedge \Phi(f)$ is not a fixed-point of f, but now $\min \Phi(f) = \varnothing$. Also note that $f(0)$ has no least element.

Similarly, let us consider now $g(x) = \{y \mid y < 1, y \leq x\}$. Then g is nonempty, $\bigwedge$-preserving, and deflationary. $\Psi(g) = \{x \mid x < 1\}$, $\bigvee \Psi(g) = 1 \notin \Psi(g)$, $\max \Psi(g) = \varnothing$, and $1 \notin g(1)$. Hence, g has no greatest fixed-point.

Likewise, $h(x) = \{y \mid 0 < y < 1\}$. Then h is nonempty and EM-monotone. $\Phi(h) = \{x \mid x > 0\}$, $\Psi(h) = \{x \mid x < 1\}$, and h has neither a least nor a greatest fixed-point.

Like the single-valued case, a multivalued inflationary function may not have a minimal fixed-point, even if $f(x)$ has a least element for all $x \in L$.

Example 10. Consider $f\colon [0,1] \to 2^{[0,1]}$, where $f(0) = \{1\}$ and for $x > 0$, $f(x) = \{x\}$. Then f is not S-monotone but is inflationary. Also, $f(x)$ has a least element for all $x \in L$. All $x > 0$ are fixed-points as $x \in f(x)$, $\Phi(f) = \{x \mid x > 0\}$ (in accordance with Proposition 3.7), and $\bigwedge \Phi(f) = 0$, but $0 \notin f(0)$. Note that $\min \Phi(f) = \varnothing$.

However, we will show later in Proposition 3.10 that a multivalued S-monotone function, such that $f(x)$ has a least element for all $x \in L$, has indeed a least fixed-point.

We next show that if $\Phi(f)$ has minimals, then an S-monotone or inflationary function f has minimal fixed-points.

PROPOSITION 3.8. *Let $f\colon L \to 2^L$ be a multivalued function.*

1. *If f is an S-monotone or inflationary multivalued function, and $\Phi(f)$ has minimals, then all $y \in \min \Phi(f)$ are minimal fixed-points of f. In particular, if $x = \bigwedge \Phi(f) \in \Phi(f)$, then x is the least fixed-point of f.*
2. *If f is an H-monotone or deflationary multivalued function, and $\Psi(f)$ has maximals, then all $y \in \max \Psi(f)$ are maximal fixed-points of f. In particular, if $x = \bigvee \Psi(f) \in \Psi(f)$, then x is the greatest fixed-point of f.*

Proof.

Case 1. To begin with, let us show that any $y \in \min \Phi(f)$ is a fixed-point of f. As $\Phi(f)$ has minimals, $\min \Phi(f) \neq \varnothing$. So, let $y \in \min \Phi(f)$. As $\varnothing \neq f(y) \preceq_S \{y\}$, thus, there is $y' \in f(y)$ such that $y' \leq y$. If f is S-monotone, then $f(y') \preceq_S f(y)$, and thus for $y' \in f(y)$ there is $y'' \in f(y')$ such that $y'' \leq y'$. Therefore, $f(y') \preceq_S \{y'\}$, and thus $y' \in \Phi(f)$. But $y \in \min \Phi(f)$, so it cannot be $y' < y$. Therefore, $y = y' \in f(y)$; i.e., y is a fixed-point of f. If f is inflationary, by Proposition 3.7, y is a fixed-point of f.

Now, let us show that any $y \in \min \Phi(f)$ is also a minimal fixed-point of f. So, consider $y \in \min \Phi(f)$ and, thus, y is a fixed-point of f. Now, consider another fixed-point $x \in f(x)$. Therefore, $f(x) \preceq_S \{x\}$, and thus $x \in \Phi(f)$. But $y \in \min \Phi(f)$, so it cannot be $x < y$, and thus y is a minimal fixed-point of f.

Finally, consider $x = \bigwedge \Phi(f)$. By hypothesis, $x \in \Phi(f)$ and x is a least element of $\Phi(f)$. Hence, we know that $x \in f(x)$. Let $y \in f(y)$. Hence $y \in \Phi(f)$, and thus $x \leq y$. As a consequence, x is the least fixed-point of f.

Case 2. This is similar to Case 1 (see the appendix, Proposition A.4). □

Note that $\Phi(f)$ in Examples 3 and 8 has minimals, while $\Phi(f)$ in Example 9 does not.

The following proposition establishes a condition on an S-monotone function f under which $\Phi(f)$ has minimals and, thus, minimal fixed-points.

PROPOSITION 3.9. *Let $f\colon L \to 2^L$ be a multivalued function.*

1. *If f is a $\bigwedge$-preserving multivalued function with $\Phi(f) \neq \varnothing$, then $\Phi(f)$ has minimals and, thus, minimal fixed-points.*

2. *If f is a $\bigvee$-preserving multivalued function with $\Psi(f) \neq \varnothing$, then $\Psi(f)$ has maximals and, thus, maximal fixed-points.*

Proof.

Case 1. By hypothesis $\Phi(f) \neq \varnothing$. Let $(x_\alpha)_{\alpha \in I}$ be a decreasing sequence of $x_\alpha \in \Phi(f)$ and let $\bar{x} = \bigwedge_\alpha x_\alpha$. As f is $\bigwedge$-preserving, by definition $f(\bar{x}) = \{y\colon$ there is $(y_\alpha)_{\alpha \in I}$ s.t. $y_\alpha \in f(x_\alpha)$ and $y = \bigwedge_\alpha y_\alpha\}$. Now, for any α, $x_{\alpha+1} \leq x_\alpha$, by Proposition 3.6 and, as $x_\alpha \in \Phi(f)$, $f(x_{\alpha+1}) \preceq_S f(x_\alpha) \preceq_S \{x_\alpha\}$. Therefore, for any x_α there is $y_\alpha \in f(x_\alpha)$ and $y_{\alpha+1} \in f(x_{\alpha+1})$ such that $y_{\alpha+1} \leq y_\alpha \leq x_\alpha$. Note that if α is a limit ordinal, then, as $x_\alpha \leq x_\beta$ for all $\beta < \alpha$, it follows that $f(x_\alpha) \preceq_S f(x_\beta) \preceq_S \{x_\beta\}$ and, thus, $y_\alpha \leq y_\beta \leq x_\beta$ for all $\beta < \alpha$. Therefore, there is a decreasing sequence $(y_\alpha)_{\alpha \in I}$ of elements $y_\alpha \in f(x_\alpha)$ such that $\bar{y} = \bigwedge_\alpha y_\alpha \leq \bigwedge_\alpha x_\alpha = \bar{x}$. By definition of $f(\bar{x})$, $\bar{y} \in f(\bar{x})$ and, thus, $f(\bar{x}) \preceq_S \{\bar{x}\}$. Therefore $\bar{x} \in \Phi(f)$ and, thus, every decreasing sequence has a lower bound in $\Phi(f)$. So, by Zorn's lemma, $\Phi(f)$ has minimals, which by Proposition 3.8 are also minimal fixed-points.

Case 2. This is the same as Case 1 (see the appendix, Proposition A.5). □

The converse of Proposition 3.9 above is not true.

Example 11. Consider $L = \{0, 0.5, 1\}$, where $f\colon L \to 2^L$ with $f(0) = \{0\}$, $f(0.5) = \{0.5\}$, and $f(1) = \{0, 1\}$. Then $\Phi(f) = L$ has minimals, but f is not S-monotone: $0.5 \leq 1$ but $f(0.5) \not\preceq_S f(1)$. Therefore, by Proposition 3.6, f cannot be $\bigwedge$-preserving.

One might wonder whether an S-monotone $f\colon L \to 2^L$ such that for all $x \in L$, $f(x)$ has minimals implies that $\Phi(f)$ has minimals. This is not true, as the following example shows.

Example 12. Consider $Y = \{y_\alpha : \alpha \in \omega\}$, Y antichain, $X = \{x_\alpha : \alpha \in \omega\}$, $x_{\alpha+1} \leq x_\alpha$, $\bar{x} = \bigwedge_\alpha x_\alpha$, $y_\alpha \leq x_\alpha$, each pair $\bar{x}, y_\alpha$ incomparable, $L = \{\bar{x}\} \cup X \cup Y \cup \{\bot, \top\}$, and $f\colon L \to 2^L$ with $f(\bot) = Y$, $f(\bar{x}) = Y$, $f(x_\alpha) = \{x_\alpha\}$, $f(y_\alpha) = \{x_\alpha\}$, and $f(\top) = \{\top\}$. Then f is S-monotone, for all $x \in L$, $f(x)$ has minimals, $\Phi(f) = X \cup \{\top\}$, and $(x_\alpha)_{\alpha \in \omega}$ is a decreasing sequence of elements in $\Phi(f)$. As neither $\bar{x}$ nor $\bot$ is in $\Phi(f)$, $\Phi(f)$ does not have minimals.

However, we can prove the following.

PROPOSITION 3.10. *Let $f\colon L \to 2^L$ be a multivalued function.*

1. *If f is S-monotone and for all $x \in L$, $f(x)$ has a least element, then f has a least fixed-point.*
2. *If f is H-monotone and for all $x \in L$, $f(x)$ has a greatest element, then f has a greatest fixed-point.*

Proof.

Case 1. As for all $x \in L$, $f(x)$ has a least element, by definition $\bigwedge f(x) \in f(x) \neq \varnothing$. Therefore, $\Phi(f) \neq \varnothing$ as $\varnothing \neq f(\top) \preceq_S \{\top\}$. Consider $a = \bigwedge_{c \in \Phi(f)} c$. If $a \in \Phi(f)$, then by Proposition 3.8, a is the least fixed-point of f. So, let us show that $a \in \Phi(f)$. For $c \in \Phi(f)$ there is an $x_c \in f(c)$ such that $x_c \leq c$. As $a \leq c$ and f is S-monotone, $f(a) \preceq_S f(c)$ and, thus, for $x_c \in f(c)$ there is $y_c \in f(a)$ such that $y_c \leq x_c \leq c$. Since $f(a)$ has a least element, there is $y \in f(a)$ such that $y \leq \bigwedge_{c \in \Phi(f)} y_c \leq \bigwedge_{c \in \Phi(f)} x_c \leq \bigwedge_{c \in \Phi(f)} c = a$. Hence, $f(a) \preceq_S \{a\}$, i.e., $a \in \Phi(f)$.

Case 2. This is the same as Case 1 (see the appendix, Proposition A.6). □

Note that if, e.g., $f(x)$ has a least element for all $x \in L$, then this does not imply necessarily that f is $\bigwedge$-preserving or $\bigvee$-preserving.

Example 13. Consider Belnap's truth space $\mathcal{FOUR}$, $L = \{f, t, \bot, \top\}$. Let $h(\top) = \{f\}$, $h(t) = \{\bot, f\}$, $h(f) = \{\bot, t\}$, $h(\bot) = \{\bot\}$. Then for all $x \in L$, $h(x)$ has a least element. Consider the decreasing sequence $(\top, f)$. Then $h(\top \wedge f) = h(f) = \{\bot, t\}$,

while $h(\top) \wedge h(f) = \{\bot\}$ and, thus, h is not $\bigwedge$-preserving. Consider the increasing sequence $(f, \top)$. Then $h(f \vee \top) = h(\top) = \{f\}$, while $h(f) \vee h(\top) = \{f, \top\}$ and, thus, h is not $\bigvee$-preserving.

The following example shows that, e.g., an H-monotone function such that for all $x \in L$, $f(x)$ has a least element, does not imply that f has a least fixed-point.

Example 14. Consider the lattice $\mathcal{FOUR}$ as in Example 13. Let $g(\bot) = \{t\}, g(f) = \{f, t, \bot\}, g(t) = \{f, t, \bot\}, g(\top) = \{\top\}$. g is H-monotone, but not S-monotone. Furthermore, for all $x \in L$, $g(x)$ has a least element. As $Fix(g) = \{f, t, \top\}$, g has no least fixed-point.

The following example shows that an H-monotone or S-monotone nonempty function may not have a fixed-point at all.

Example 15. Consider $L = [0, 1]$ and a multivalued function f, with $f(x) = \{(x + 1)/2\}$ for $x < 1$ and $f(1) = \{1 - 1/n \mid n = 1, 2, \ldots\}$. Then f is H-monotone without any fixed-point.

Similarly, let $g(x) = \{x/2\}$ for $x > 0$ and $g(0) = \{1/n \mid n = 1, 2, \ldots\}$. Then g is S-monotone without any fixed-point.

Next, we describe properties of the structure of the set of fixed-points. The following example shows that the meet of two fixed-points of a monotone multivalued function may not be a fixed-point and, thus, the set of fixed-points may not be a sublattice.

Example 16. Consider $L = \{f, t, \bot, \top, c\}$, where $\bot \leq c$, $c \leq f \leq \top$, and $c \leq t \leq \top$. Let $g(\bot) = \{\bot\}, g(c) = \{\bot\}, g(t) = \{t\}, g(f) = \{f\}, g(\top) = \{\top\}$. Then g is EM-monotone, limit-preserving, deflationary, but not inflationary, and for all $x \in L$, $g(x)$ is a closed sublattice of L. However, $Fix(g) = \{\bot, \top, f, t\}$ is not a sublattice of L, e.g., $f, t \in Fix(f)$, but $c = f \wedge t \notin Fix(f)$ ($Fix(f)$ is not even a meet semilattice).

However, we can show the following.

PROPOSITION 3.11. *Let $f\colon L \to 2^L$ be an S-monotone, nonempty, and $\wedge$-closed multivalued function. Then*

1. *$\Phi(f)$ is $\wedge$-closed; and*
2. *f has a least fixed-point.*

Proof. Note that $\Phi(f) \neq \varnothing$ as $\varnothing \neq f(\top) \preceq_S \{\top\}$.

1. Consider a subset S of $\Phi(f)$ and $a = \bigwedge S$. Let us show that $a \in \Phi(f)$. We know that for each $c \in S$, $f(c) \preceq_S \{c\}$ holds; i.e., there is $x_c \in f(c)$ such that $x_c \leq c$. But, f is S-monotone and, thus, from $a \leq c$, $f(a) \preceq_S f(c) \preceq_S \{c\}$ follows. That is, there is $y_c \in f(a)$ such that $y_c \leq x_c \leq c$. Let $y = \bigwedge_{c \in S} y_c$. As f is $\wedge$-closed, $y \in f(a)$ follows. Therefore, $y = \bigwedge_{c \in S} y_c \leq \bigwedge_{c \in S} c = a$, $f(a) \preceq_S \{a\}$, and, thus, $a \in \Phi(f)$. Therefore, $\Phi(f)$ is $\wedge$-closed.

2. From point 1, $\Phi(f)$ has a least element a and, thus, by Proposition 3.8, f has a as a least fixed-point. □

Dually, we have the following.

PROPOSITION 3.12. *Let $f\colon L \to 2^L$ be an H-monotone, nonempty, and $\vee$-closed multivalued function. Then*

1. *$\Psi(f)$ is $\vee$-closed; and*
2. *f has a greatest fixed-point.*

Proof. This is the dual of proof of Proposition 3.11 (see the appendix, Proposition A.7). □

Clearly, from Propositions 3.11 and 3.12 we immediately have the following.

PROPOSITION 3.13. *Let $f\colon L \to 2^L$ be an EM-monotone multivalued function such that for any $x \in L$, $f(x)$ is a nonempty closed sublattice of L. Then f has a*

least fixed-point and a greatest fixed-point.

Also, the next proposition follows immediately from Proposition 3.7.

PROPOSITION 3.14. *Let $f\colon L \to 2^L$ be a nonempty multivalued function. Then*

1. *if f is S-monotone, inflationary, and $\wedge$-closed, then $Fix(f)$ is nonempty and $\wedge$-closed and, thus, has a least element; and*
2. *if f is H-monotone, deflationary, and $\vee$-closed, then $Fix(f)$ is nonempty and $\vee$-closed and, thus, has a greatest element.*

Note that if f is both inflationary and deflationary, then for all $x \in L$ such that $f(x) \neq \varnothing$, we can easily show that $f(x) = \{x\}$; i.e., f is a single-valued, constant, limit-preserving function, and each such x is a fixed-point, and, thus, is not interesting.

We have seen in Proposition 3.14 that under rather strong conditions, we have a rather strong structure on the set of fixed-points (e.g., the conjunction of two fixed-points is a fixed-point). On the other hand, Example 16 shows that, e.g., if we omit the inflationary condition, then $Fix(f)$ is not $\wedge$-closed (e.g., the conjunction of two fixed-points need not be a fixed-point) and, thus, $Fix(f)$ cannot be a closed sublattice of L.

The following proposition, due to [53], establishes that the set of fixed-points is a complete lattice, though not a closed sublattice.

PROPOSITION 3.15 (Zhou [53]). *Let $f\colon L \to 2^L$ be a multivalued function. If f is EM-monotone and for any $x \in L$, $f(x)$ is a nonempty closed sublattice of L, then $Fix(f)$ is a nonempty complete lattice.*

We next look at limit-preserving functions and their impact on the set of fixed-points. We first notice the following.

PROPOSITION 3.16. *Let $f\colon L \to 2^L$ be a multivalued function. Then*

1. *if f is $\bigwedge$-preserving, then f is $\wedge$-closed;*
2. *if f is $\bigvee$-preserving, then f is $\vee$-closed; and*
3. *if f is limit-preserving, then for any $x \in L$, $f(x)$ is a closed sublattice of L.*

Proof.

1. Consider $x \in L$. If $f(x)$ is empty, then it is also $\wedge$-closed. Otherwise, consider any subset of $f(x)$ in the form of a sequence $(y_\alpha)_{\alpha\in I}$ of elements $y_\alpha \in f(x)$. We show that $f(x)$ is $\wedge$-closed by showing that $y = \bigwedge_{\alpha\in I} y_\alpha \in f(x)$. So, consider the decreasing sequence $(x_\alpha)_{\alpha\in I}$, where $x = x_\alpha$, for all $\alpha \in I$. By construction, $x = \bigwedge_{\alpha\in I} x_\alpha$. As f is $\bigwedge$-preserving, we have that

$$\begin{array}{rcl} f(x) & = & f(\bigwedge_\alpha x_\alpha) \\ & = & \{z \mid \text{ there is } (z_\alpha)_{\alpha\in I} \text{ s.t. } z_\alpha \in f(x_\alpha) \text{ and } z = \bigwedge_\alpha z_\alpha\} \\ & = & \{z \mid \text{ there is } (z_\alpha)_{\alpha\in I} \text{ s.t. } z_\alpha \in f(x) \text{ and } z = \bigwedge_\alpha z_\alpha\} \ . \end{array}$$

Therefore, as for $(y_\alpha)_{\alpha\in I}$ we have $y_\alpha \in f(x)$, it follows that $y = \bigwedge_{\alpha\in I} y_\alpha \in f(\bigwedge_\alpha x_\alpha) = f(x)$, which concludes the proof.

The other points can be shown similarly. □

Note that the converse in Proposition 3.16 does not hold. For instance, in Example 14, the function g is such that for all $x \in L$, $g(x)$ is a closed sublattice, but g is not $\bigwedge$-preserving (as g is not S-monotone).

We already know from Proposition 3.9 that if f is $\bigwedge$-preserving and $\Phi(f) \neq \varnothing$ (e.g., $f(\top) \neq \varnothing$), then f has minimal fixed-points and, similarly, from Proposition 3.9 we know that if f is $\bigvee$-preserving and $\Psi(f) \neq \varnothing$ (e.g., $f(\bot) \neq \varnothing$), then f has maximal fixed-points. By further relying on Propositions 3.14 and 3.16, we have the following.

PROPOSITION 3.17. *Let $f\colon L \to 2^L$ be a nonempty multivalued function. Then*

1. *if f is $\bigwedge$-preserving and inflationary, then $Fix(f)$ is nonempty, $\wedge$-closed, and thus, has a least element;*
2. *if f is $\bigvee$-preserving and deflationary, then $Fix(f)$ is nonempty, $\vee$-closed, and thus, has a greatest element; and*
3. *if f is limit-preserving, then $Fix(f)$ is a nonempty complete lattice.*

Note that the condition for nonemptiness in the above proposition is mandatory as, e.g., a $\bigwedge$-preserving function f may not necessarily imply that f is nonempty, as the example below shows. This example also shows that Proposition 3.17 neither subsumes nor contrasts with Proposition 3.8.

Example 17. Consider the lattice $\mathcal{FOUR}$. Let g be a multivalued function on L such that $g(\bot) = \varnothing$, $g(\top) = \{\top\}$, $g(f) = \{f\}$, and $g(t) = \{t\}$. It can be easily verified that g is $\bigwedge$-preserving and deflationary, though $Fix(g) = \{f, t, \top\}$, and, thus, no least fixed-point exists. g has two minimal fixed-points instead.

As already pointed out, we are more interested in cases in which $f(x)$ may be empty for some $x \in L$. The literature we are aware of does not report results in such cases [6, 22, 33, 45, 53]. The following result (compare to Proposition 3.15) reveals the structure of the set of fixed-points for limit-preserving functions under weaker conditions than those in Proposition 3.17. It says that the set of fixed-points of a limit-preserving function, if not empty, is a complete multilattice. A *complete multilattice* [4, 29, 30] is a partially ordered set $\mathcal{M} = \langle M, \leq \rangle$, such that for every subset $X \subseteq M$, the set of upper (resp., lower) bounds of X has minimal (resp., maximal) elements, which are called *multisuprema* (resp., *multi-infima*). The sets of multisuprema and multi-infima of a set X are denoted multsup(X) and multinf(X).

PROPOSITION 3.18. *Let $f\colon L \to 2^L$ be a multivalued function. If f is limit-preserving and $Fix(f)$ is nonempty, then $Fix(f)$ is a complete multilattice.*

Proof. The proof is inspired by the proof of Proposition 3.15.

Let us show that $\langle Fix(f), \leq \rangle$ is a complete multilattice. By assumption, $Fix(f)$ is nonempty; by Proposition 3.5, f is EM-monotone; and by Proposition 3.16, for any $x \in L$, $f(x)$ is a closed sublattice of L. Let $S \subseteq Fix(f)$. Let us show that the set multsup(S) is nonempty in $\langle Fix(f), \leq \rangle$. So, consider $a = \bigvee S = \bigvee_{c \in S} c$ and the complete lattice $\mathcal{B} = \langle [a, \top], \leq \rangle$. Let g be the multivalued function from $[a, \top]$ to $2^{[a,\top]}$ defined by $g(s) = f(s) \cap [a, \top]$ for all $s \in [a, \top]$. Since both f and h, which assign to each $s \in [a, \top]$ the constant interval $[a, \top]$, are $\bigwedge$-preserving on S, it is not difficult to check that $g = f \cap h$ is $\bigwedge$-preserving on $[a, \top]$.

Now, let's show that $\Phi(g) \neq \varnothing$. For $c \in S$, as $c \leq a$ and f is H-monotone, $f(c) \preceq_H f(a)$ follows. Hence, for $c \in f(c)$ there is $x_c \in f(a)$ such that $c \leq x_c$. Consider $b = \bigvee_{c \in S} x_c$. Therefore, $a = \bigvee_{c \in S} c \leq \bigvee_{c \in S} x_c = b$. We show now that $b \in f(a)$. Consider the sequence $(a, a, \ldots, a)$ of length $|S|$. As f is limit-preserving and all $x_c \in f(a)$, we have that $b = \bigvee_{c \in S} x_c \in f(a \vee a \vee \cdots \vee a) = f(a)$, i.e., $b \in f(a)$. Now, consider $s \in [a, \top]$. As $a \leq s$ and f is H-monotone, $f(a) \preceq_H f(s)$ follows; i.e., for $b \in f(a)$ there is an $s_b \in f(s)$ such that $a \leq b \leq s_b$. It follows that $g(s) = f(s) \cap [a, \top] \neq \varnothing$ for all $s \in [a, \top]$. In particular, $g(\top) \neq \varnothing$ and, thus, $g(\top) \preceq_S \{\top\}$, i.e., $\top \in \Phi(g) \neq \varnothing$.

As a consequence, by Proposition 3.9, g has minimal fixed-points S'. Obviously, as $Fix(g) = Fix(f) \cap [a, \top]$, any $a' \in S'$ is also a fixed-point of f, with $a \leq a'$. In fact, a' is a minimal fixed-point of f, which is an upper bound of all elements of S; in other words, $a' \in$ multsup(S) and $a' \in Fix(f)$, which concludes the proof.

Similarly, it can be shown that multinf(S) is nonempty in $\langle Fix(f), \leq \rangle$, and, thus, we can conclude that $\langle Fix(f), \leq \rangle$ is a complete multilattice. □

Note that by Proposition 3.9, in Proposition 3.18 above, $\Phi(f) \neq \varnothing$ guarantees that $Fix(f)$ is nonempty.

For convenience, Table 3.1 reports a summary of the main results about $Fix(f)$ reported in this section. In the table, min (max) means that the set contains minimals (maximals), while $\bigwedge$ ($\bigvee$) means that the set contains a least (greatest) element.

For completeness, Table 3.2 summarizes the impact of the multivalued functions in the examples on the set of fixed-points.

3.1. Orbits. We next describe how to obtain minimal fixed-points (if they exist) of multivalued functions $f\colon L \to 2^L$. An *orbit*[4] of f is a (possibly transfinite) sequence $(x_\alpha)_{\alpha\in I}$ of elements $x_\alpha \in L$, with $|I| > |L|$ and

$$\begin{array}{lcl} x_0 & = & \bot, \\ x_{\alpha+1} & \in & f(x_\alpha), \\ x_\lambda & = & \bigvee_{\alpha<\lambda} x_\alpha \text{ for limit ordinals } \lambda\,. \end{array}$$

[4]The definition is a generalization of the usual iteration of f over $\bot$ for single-valued functions.

Some comments are in order:

- Due to the nondeterministic choice of $x_{\alpha+1}$, f may have many possible orbits.
- For the sake of this paper we consider the starting point of the orbit $x_0 = \bot$. However, this can be made more flexible by considering any $x_0 = a \in L$ as a starting point. We consider $x_0 = \bot$, as we are interested in how to obtain minimal fixed-points. Of course, a special and interesting alternative case is $x_0 = \top$ (in that case, we postulate that for limit ordinal λ, $x_\lambda = \bigwedge_{\alpha<\lambda} x_\alpha$), which relates to the computation of maximal fixed-points. We call such sequences $\top$-*orbits*.
- A sequence $x_0, x_1, \ldots, x_\alpha$, where $x_{\beta+1} \in f(x_\beta)$ for $\beta < \alpha$ and $f(x_\alpha) = \varnothing$, is *not* an orbit.
- For convenience, we require that the length $|I|$ of an orbit be strictly greater than $|L|$, so that, if the orbit is increasing (decreasing), we may apply Proposition 2.1, which guarantees then that the orbit eventually becomes stationary.
- If an orbit $(x_\alpha)_{\alpha\in I}$ becomes stationary, i.e., there is $\beta \in I$ such that $|\beta| \leq |L|$ and $x_\alpha = x_\beta$ for all $\beta \leq \alpha \in I$, then by construction $x_\beta = x_{\beta+1} \in f(x_\beta)$ and, thus, x_β is a fixed-point of f.
- As any increasing (decreasing) orbit converges to a fixed-point, it is clear that if we can guarantee that such an orbit exists, then also the existence of a fixed-point is shown.
- Of course, from a practical point of view, whenever we try to build an orbit, we may stop as soon as we have $x_\beta = x_{\beta+1}$.

Example 18. Consider the lattice $\mathcal{FOUR}$. Let g be a multivalued function such that $g(\bot) = \{f, t\}$, $g(f) = \{f, t\}$, $g(t) = \{f, t\}$, $g(\top) = \{\top\}$. It can easily be verified that g is S-monotone and $Fix(g) = \{f, t, \top\}$. Then, for instance, we may have the following orbits:

$$\begin{array}{lcl} o_1 & = & (\bot, f, f, f, f), \\ o_2 & = & (\bot, t, t, t, t, t), \\ o_3 & = & (\bot, f, t, t, t), \\ o_4 & = & (\bot, t, f, f, t), \\ o_5 & = & (\bot, f, t, f, t, f, t)\ . \end{array}$$

As already pointed out, unlike the single-valued case, Examples 9 and 18 show that, e.g., S-monotonicity does not guarantee the existence of a minimal fixed-point. Also, S-monotonicity does not guarantee that an orbit $(x_\alpha)_{\alpha\in I}$ eventually becomes stationary (consider the orbit $(0, 2, 0, 2, \ldots)$ in Example 3 or orbit o_5 in Example 18). Note also that in Example 18 no orbit converges to the fixed-point $\top$.

Our main contribution in this context is the following.

PROPOSITION 3.19. *For a multivalued function f,*

1. *if f is inflationary, then each orbit is increasing;*
2. *each increasing orbit converges to a fixed-point of f (if no fixed-point exists, then there is no orbit); and*
3. *if f is S-monotone and inflationary, then for any minimal fixed-point of f there is an orbit converging to it.*

Proof. Let $(x_\alpha)_{\alpha\in I}$ be an orbit of f. Recall that for ordinal α we have $x_{\alpha+1} \in f(x_\alpha) \neq \varnothing$. As f is inflationary, $\{x_\alpha\} \preceq_S f(x_\alpha)$. But, by the definition of $\preceq_S$, for $x_{\alpha+1} \in f(x_\alpha)$, $x_\alpha \leq x_{\alpha+1}$. For a limit ordinal λ, $x_\lambda = \bigvee_{\alpha<\lambda} x_\alpha$, $\{x_\lambda\} \preceq_S f(x_\lambda) \neq \varnothing$, and, thus, there is $x_{\lambda+1} \in f(x_\lambda)$ such that $x_\lambda \leq x_{\lambda+1}$.

For the second point, as $(x_\alpha)_{\alpha\in I}$ is an increasing sequence and $|I| > |L|$, by Proposition 2.1 there is an ordinal α such that $x_\alpha = x_{\alpha+1} \in f(x_\alpha)$. That is, x_α is a fixed-point of f.

Finally, for the third point, assume $\bar{x} \in f(\bar{x})$ is a minimal fixed-point of f. Now, let us show by (transfinite) induction on α that there is an increasing orbit $(x_\alpha)_{\alpha\in I}$ of f such that $x_\alpha \leq \bar{x}$ for all α.

The case where $\boldsymbol{\alpha = 0}$. $x_0 = \bot \leq \bar{x}$.

$\boldsymbol{\alpha}$ successor ordinal. By induction, $x_\alpha \leq \bar{x}$. As f is S-monotone and inflationary, $\{x_\alpha\} \preceq_S f(x_\alpha) \preceq_S f(\bar{x})$. But, $\bar{x} \in f(\bar{x})$, so we can choose $x_{\alpha+1} \in f(x_\alpha)$ such that $x_\alpha \leq x_{\alpha+1} \leq \bar{x}$.

$\boldsymbol{\alpha}$ limit ordinal. By induction, $x_\beta \leq \bar{x}$ holds for all $\beta < \alpha$, which implies that $x_\alpha = \bigvee_{\beta<\alpha} x_\beta \leq \bar{x}$.

The sequence $(x_\alpha)_{\alpha\in I}$ is increasing and, thus, by Proposition 2.1 there is an ordinal α such that $x_\alpha = x_{\alpha+1} \in f(x_\alpha)$. So, x_α is a fixed-point of f with $x_\alpha \leq \bar{x}$. As $\bar{x}$ is a minimal, $x_\alpha = \bar{x}$. ∎

Example 19. Consider the lattice $\mathcal{FOUR}$. Let g be a multivalued function such that $g(\bot) = \{f, t\}$, $g(f) = \{f\}$, $g(t) = \{t\}$, $g(\top) = \{\top\}$. It can easily be verified that g is S-monotone and inflationary and that $Fix(g) = \{f, t, \top\}$. Then, we may have the following orbits:

$$\begin{array}{rcl} o_1 & = & (\bot, f, f, f, f), \\ o_2 & = & (\bot, t, t, t, t, t)\ . \end{array}$$

Orbit o_1 converges to the minimal fixed-point f, while o_2 converges to the minimal fixed-point t.

Of course, the dual of Proposition 3.19 holds as well.

PROPOSITION 3.20. *For a multivalued function f,*

1. *if f is deflationary, then each $\top$-orbit is decreasing;*
2. *each decreasing $\top$-orbit converges to a fixed-point of f (if no fixed-point exists, then there is no orbit); and*
3. *if f is H-monotone and deflationary, then for any maximal fixed-point of f there is a $\top$-orbit converging to it.*

Proof. This is dual to Proposition 3.19 (see the appendix, Proposition A.8). ∎

By a straightforward adaptation of the proof of point 3 in Proposition 3.19, we can show the following.

PROPOSITION 3.21. *Let f be an H-monotone, nonempty multivalued function such that for any increasing sequence $(y_\alpha)_{\alpha\in I}$ there is $y \in f(\bigvee_{\alpha\in I} y_\alpha)$ such that $y_\alpha \leq y$ for all $\alpha \in I$. Then, there is an increasing orbit and, thus, a fixed-point of f.*

Proof. Let us show by (transfinite) induction on α that there is an increasing orbit $(x_\alpha)_{\alpha\in I}$ of f and that by Proposition 3.19, point 2, it converges to a fixed-point of f.

The case where $\boldsymbol{\alpha = 0}$. $x_0 = \bot$.

$\boldsymbol{\alpha}$ successor ordinal. By induction, $x_{\alpha-1} \leq x_\alpha$ and $x_\alpha \in f(x_{\alpha-1})$. As f is H-monotone, we have $f(x_{\alpha-1}) \preceq_H f(x_\alpha)$. So, for $x_\alpha \in f(x_{\alpha-1})$, there is $x_{\alpha+1} \in f(x_\alpha)$ s.t. $x_\alpha \leq x_{\alpha+1}$.

$\boldsymbol{\alpha}$ limit ordinal. Consider $(x_\beta)_{\beta\in\alpha}$. By hypothesis, there is $x_{\alpha+1} \in f(\bigvee_{\beta\in\alpha} x_\beta)$ with $x_\beta \leq x_{\alpha+1}$ for all $\beta < \alpha$, and, thus, $x_\alpha = \bigvee_{\beta<\alpha} x_\beta \leq x_{\alpha+1}$. ∎

Note that the condition on the limit is essential, as Example 15 shows: (0,0.5,0.75,. . .) is the increasing sequence that can be built, which converges to 1. But, there is no $x \in f(1)$ such that $1 \leq x$. The dual of Proposition 3.21 is as follows.

PROPOSITION 3.22 (Khamsi and Misane [22]). *Let f be an S-monotone, nonempty multivalued function such that for any decreasing sequence $(y_\alpha)_{\alpha\in I}$ there is $y \in f(\bigwedge_{\alpha\in I} y_\alpha)$ such that $y \leq y_\alpha$ for all $\alpha \in I$. Then there is a decreasing $\top$-orbit and, thus, a fixed-point of f.*

We recall that Proposition 3.22 is the main result described in [22] (see also [16]).

A closer look at the induction step in the previous proof of point 3 of Proposition 3.19 reveals a useful practical case. Indeed, rather than choosing an arbitrary $x_{\alpha+1} \in f(x_\alpha)$ s.t. $x_{\alpha+1} \leq \bar{x}$ with $x_\alpha \leq x_{\alpha+1}$, if $\min f(x_\alpha)$ is nonempty, we may choose an appropriate $x_{\alpha+1} \in \min f(x_\alpha)$.

In the following, let $(x_\alpha)_{\alpha\in I}$ be an orbit ($\top$-orbit) of f. We say that $(x_\alpha)_{\alpha\in I}$ is an *orbit ($\top$-orbit) of minimals (maximals)* of f iff $x_{\alpha+1} \in \min f(x_\alpha)$ if $\min f(x_\alpha) \neq \varnothing$ ($x_{\alpha+1} \in \max f(x_\alpha)$ if $\max f(x_\alpha) \neq \varnothing$). Hence, we have the following.

PROPOSITION 3.23. *Consider a multivalued function $f\colon L \to 2^L$.*

1. *If f is inflationary and S-monotone, then for any minimal fixed-point of f there is an orbit $(x_\alpha)_{\alpha\in I}$ of minimals converging to it.*
2. *If f is deflationary and H-monotone, then for any maximal fixed-point of f there is a $\top$-orbit$(x_\alpha)_{\alpha\in I}$ of maximals converging to it.*

Similarly, we have the following.

PROPOSITION 3.24. *Consider a multivalued function $f\colon L \to 2^L$.*

1. *If $f\colon L \to 2^L$ is S-monotone and for all $x \in L$, $f(x)$ has a least element, then there is an orbit $(x_\alpha)_{\alpha\in I}$ of least elements, i.e., $x_{\alpha+1} = \bigwedge f(x_\alpha)$, converging to the least fixed-point of f.*
2. *If $f\colon L \to 2^L$ is H-monotone and for all $x \in L$, $f(x)$ has a greatest element, then there is a $\top$-orbit $(x_\alpha)_{\alpha\in I}$ of greatest elements, i.e., $x_{\alpha+1} = \bigvee f(x_\alpha)$, converging to the greatest fixed-point of f.*

Proof.

1. From Proposition 3.10, we know that f has a least fixed-point $\bar{x}$. Now, we proceed similarly as for Proposition 3.19, point 3. Let us show by (transfinite) induction on α that there is an increasing orbit $(x_\alpha)_{\alpha\in I}$ of f s.t. $x_{\alpha+1} = \bigwedge f(x_\alpha)$ (if α ordinal), and $x_\alpha \leq \bar{x}$ for all α.

The case where $\boldsymbol{\alpha = 0}$. $x_0 = \bot \leq \bar{x}$.

$\boldsymbol{\alpha}$ successor ordinal. By induction, $x_{\alpha-1} \leq x_\alpha \leq \bar{x}$ and $x_\alpha = \bigwedge f(x_{\alpha-1})$. As f is S-monotone, $f(x_{\alpha-1}) \preceq_S f(x_\alpha) \preceq_S f(\bar{x})$. But, $\bar{x} \in f(\bar{x})$, and, thus, there is $y_1 \in f(x_\alpha)$ such that $y_1 \leq \bar{x}$. Consider $x_{\alpha+1} = \bigwedge f(x_\alpha)$. As $x_{\alpha+1} \in f(x_\alpha)$, $x_{\alpha+1} \leq y_1 \leq \bar{x}$ follows. But then, for $x_{\alpha+1} \in f(x_\alpha)$ there is $y_2 \in f(x_{\alpha-1})$ such that $y_2 \leq x_{\alpha+1}$. Consider $x_\alpha = \bigwedge f(x_{\alpha-1})$. By induction, $x_\alpha \in f(x_{\alpha-1})$ and, thus, $x_\alpha \leq y_2 \leq x_{\alpha+1} \leq y_1 \leq \bar{x}$.

$\boldsymbol{\alpha}$ limit ordinal. By induction, $x_\beta \leq x_{\beta+1} \leq \bar{x}$ holds for all $\beta < \alpha$, which implies that $x_\alpha = \bigvee_{\beta<\alpha} x_\beta = \bigvee_{\beta<\alpha} x_{\beta+1} \leq \bar{x}$. As f is S-monotone, $f(x_\beta) \preceq_S f(x_\alpha) \preceq_S f(\bar{x})$ for $\beta < \alpha$. But, $\bar{x} \in f(\bar{x})$, and, thus, there is $y_1 \in f(x_\alpha)$ such that $y_1 \leq \bar{x}$. Consider $x_{\alpha+1} = \bigwedge f(x_\alpha)$. As $x_{\alpha+1} \in f(x_\alpha)$, $x_{\alpha+1} \leq y_1 \leq \bar{x}$ follows. Similarly, as $f(x_\beta) \preceq_S f(x_\alpha)$, for $x_{\alpha+1} \in f(x_\alpha)$ and $x_{\beta+1} = \bigwedge f(x_\beta)$, we have by induction $x_{\beta+1} \in f(x_\beta)$ and, thus, $x_{\beta+1} \leq x_{\alpha+1}$. Therefore, $x_\beta \leq x_{\beta+1} \leq x_{\alpha+1} \leq \bar{x}$ and, thus, $x_\alpha = \bigvee_{\beta<\alpha} x_\beta = \bigvee_{\beta<\alpha} x_{\beta+1} \leq x_{\alpha+1} \leq \bar{x}$.

The sequence $(x_\alpha)_{\alpha\in I}$ is increasing and, thus, by Proposition 2.1 there is an ordinal α such that $x_\alpha = x_{\alpha+1} \in f(x_\alpha)$. So, x_α is a fixed-point of f with $x_\alpha \leq \bar{x}$. As $\bar{x}$ is the least fixed-point, $x_\alpha = \bar{x}$.

Point 2 can be shown similarly. □

Interestingly, f being S-monotone and inflationary does not guarantee that $\Phi(f)$ has minimals, and, thus, a minimal fixed-point may not exist (Example 9). However, we have the following.

PROPOSITION 3.25. *Let f be an inflationary, $\bigwedge$-preserving multivalued function such that $\Phi(f) \neq \varnothing$.*

1. *Then f has minimal fixed-points and there are orbits converging to them.*
2. *If f is also $\bigvee$-preserving, then ω steps are sufficient to reach a minimal fixed-point.*

Proof. The first item follows immediately from Propositions 3.7, 3.9, and 3.19. For the second item, consider an orbit $(x_\alpha)_{\alpha\in I}$ converging to a minimal fixed-point $\bar{x}$ of f. Let us show that x_ω is a fixed-point of f. As f is inflationary, the orbit is increasing. Then $x_\omega = \bigvee_{\alpha<\omega} x_\alpha$. As f is $\bigvee$-preserving we have that $f(x_\omega) = f(\bigvee_{\alpha<\omega} x_\alpha) = \{y\colon$ there is $(y_\alpha)_{\alpha<\omega}$ s.t. $y_\alpha \in f(x_\alpha)$ and $y = \bigvee_{\alpha<\omega} y_\alpha\}$. For $0 \leq \alpha < \omega$, let $y_\alpha = x_{\alpha+1}$. Therefore, $y_\alpha \in f(x_\alpha)$ and, thus, $x_\omega = y = \bigvee_{\alpha<\omega} y_\alpha \in f(x_\omega)$. That is, x_ω is a fixed-point of f and $x_\omega \leq \bar{x}$ and, thus, $x_\omega = \bar{x}$. □

Clearly, the dual of Proposition 3.25 holds as well.

PROPOSITION 3.26. *If a multivalued function f is deflationary and $\bigvee$-preserving, and $\Psi(f) \neq \varnothing$, then f has maximal fixed-points and there are $\top$-orbits converging to them. If f is also $\bigwedge$-preserving, then ω steps are sufficient to reach a maximal fixed-point.*

We conclude this part by showing a strict relationship between S-monotone and inflationary operators. For a multivalued function $f\colon L \to 2^L$, let us define

$$g(x) = x \oplus f(x) = \{x \vee y\colon y \in f(x)\}\ . \tag{3.6}$$

Note that if $f(x) = \varnothing$, then $g(x) = \varnothing$.

PROPOSITION 3.27. *For $f\colon L \to 2^L$, $g(x) = x \oplus f(x)$ is inflationary. Furthermore, if f is S-monotone, then*

1. *g is S-monotone;*
2. *$x \in f(x)$ implies $x \in g(x)$;*
3. *$x \in g(x)$ implies $f(x) \preceq_S \{x\}$;*
4. *if x is a minimal fixed point of g, then x is a minimal fixed point of f; and*
5. *if x is a minimal fixed point of f and f is also inflationary, then x is a minimal fixed point of g.*

Proof. Consider f and g. If $f(x) = \varnothing$, then $\{x\} \preceq_S g(x) = \varnothing$. Otherwise, for $y \in g(x)$, $x \leq y$. Therefore, $\{x\} \preceq_S g(x)$ and, thus, g is inflationary. Now, suppose f is S-monotone.

1. This is easy to prove, as g is a combination of S-monotone functions.

2. If $x \in f(x)$, then by definition of g, $x = x \vee x \in g(x)$.

3. If $x \in g(x)$, then for some $y \in f(x)$, $x = x \vee y$. Therefore, $y \leq x$ and, thus, $f(x) \preceq_S \{x\}$.

4. Assume x is a minimal fixed-point of g, i.e., $x \in g(x) = x \oplus f(x)$. Therefore, there is $y \in f(x)$ such that $y \leq x$. As f is S-monotone, $f(y) \preceq_S f(x)$. That is, there is $z \in f(y)$ such that $z \leq y$ and, thus, $y = y \vee z$. Therefore, $y \in g(y)$. As x is minimal and $y \leq x$, $y = x$ follows, and, thus, $x \in f(x)$. To prove that x is a minimal fixed-point of f, assume there is $y \leq x$ such that $y \in f(y)$. By point 2, $y \in g(y)$, and, thus, as x is a minimal fixed-point of g, $y = x$ follows.

5. Assume x is a minimal fixed-point of f. By point 2 $x \in g(x)$. To prove that x is a minimal fixed-point of g, assume there is $y \leq x$ such that $y \in g(y)$. Then by

point 3 $f(y) \preceq_S \{y\}$ and, thus, $y \in \Phi(f)$. By Proposition 3.7, $y \in f(y)$, and, thus, as x is a minimal fixed-point of f, $y = x$ follows. □

We note that the inflationary condition in point 5 in Proposition 3.27 is necessary.

Example 20. Consider $L = \{0\} \cup \{1/n : n = 1, 2, \dots\}$ and the multivalued mapping $f : L \to 2^L$ defined as follows:

$$f(0) = \{1/n : n = 1, 2, \dots\},$$
$$f(1/n) = \{1\} \cup \{1/(n+k) : k = 1, 2, \dots\}.$$

f is S-monotone, but not inflationary ($\{1/n\} \not\preceq_S f(1/n)$), and 1 is its only fixed-point. However, the function $g(x) = x \oplus f(x)$ has the following definition:

$$g(0) = \{1/n : n = 1, 2, \dots\},$$
$$g(1/n) = \{1, 1/n\} ,$$

which has infinitely many fixed points and none is minimal.

Of course, Proposition 3.27 has its dual as well. Let

$$h(x) = x \otimes f(x) = \{x \wedge y \colon y \in f(x)\} . \tag{3.7}$$

PROPOSITION 3.28. *For $f \colon L \to 2^L$, $h(x) = x \otimes f(x)$ is deflationary. Furthermore, if f is H-monotone, then*

1. *h is H-monotone;*
2. *$x \in f(x)$ implies $x \in h(x)$;*
3. *$x \in h(x)$ implies $\{x\} \preceq_H f(x)$;*
4. *if x is a maximal fixed point of h, then x is a maximal fixed point of f; and*
5. *if x is a maximal fixed point of f and f is also deflationary, then x is a maximal fixed point of h.*

Proof. This is dual to Proposition 3.27 (see the appendix, Proposition A.9). □

We report here some other related results known in the literature. For instance, [45] (which relies on [33]) gives a condition for the existence of a least fixed-point.

PROPOSITION 3.29 (Stouti [45]). *Let $f \colon L \to 2^L$ be a multivalued function, where $\mathcal{L} = \langle L, \preceq \rangle$ is a* complete partial order *(CPO) with $\perp$, i.e., any nonempty chain in L has a supremum in L, and $\perp \in L$. Assume that for any $x \in L$, $f(x)$ is nonempty, and that if for any $x, y \in L$ with $x < y$, then for every $a \in f(x)$ and $b \in f(y)$, we have that $a \leq b$.*[5]

1. *Then f has a least fixed-point.*
2. *If there is $a \in L$ such that for all $b \in f(a)$ we have $a \leq b$, then f has a least fixed-point in the subset $\{a \in L \mid a \leq x\}$.*

For completeness, we recall that [33] states the following.

PROPOSITION 3.30 (Orey [33]). *Let $f \colon L \to 2^L$ be a multivalued function, where $\mathcal{L} = \langle L, \preceq \rangle$ is a CPO with $\perp$, i.e., any nonempty chain in L has a supremum in L, and $\perp \in L$. Assume that for any $x \in L$, $f(x)$ is nonempty, and that if for any $x, y \in L$ with $x < y$, then for every $a \in f(x)$ and $b \in f(y)$, we have that $a \leq b$. If there is $a \in L$ such that $\{a\} \preceq_S f(a)$, then f has a fixed-point.*

The above proposition relies on the fact that under its condition we have that $\{a\} \preceq_S f(a) \preceq_S f^2(a) \preceq_S \cdots$, which allows us to build an increasing and, thus, eventually stationary, orbit.

[5] Hence, this is a strictly stronger monotonicity condition than the EM-monotonicity.

We conclude this section by extending $\leq$ to L^n pointwise: for $(x_1, \ldots, x_n) \in L^n$ and $(y_1, \ldots, y_n) \in L^n$, we say that $(x_1, \ldots, x_n) \leq (y_1, \ldots, y_n)$ iff for all i, $x_i \leq y_i$. For $\mathbf{x}, \mathbf{y} \in L^n$, $\mathbf{x} \wedge \mathbf{y}$ and $\mathbf{x} \vee \mathbf{y}$ are defined pointwise, i.e., $\mathbf{x} \wedge \mathbf{y} = (x_1 \wedge y_1, \ldots, x_n \wedge y_n)$ and $\mathbf{x} \vee \mathbf{y} = (x_1 \vee y_1, \ldots, x_n \vee y_n)$. Since $\mathcal{L} = \langle L, \leq \rangle$ is a complete lattice, so is $\mathcal{L}^n = \langle L^n, \leq \rangle$. All definitions and properties of single-valued functions and multivalued functions over the domain L of $\mathcal{L}$ can be extended to $\mathcal{L}^n$ as well.

4. Generalized logic programs. We now apply the results developed so far to a general form of logic programs. Consider a complete lattice $\mathcal{L} = \langle L, \leq \rangle$, which will act as our truth-value set. Formulae will have a degree of truth in L. Let $\mathcal{F}$ be a family of computable n-ary functions $f\colon L^n \to L$, called (logical) *connectors*.[6] Connectors will be used to build logical formulae from logical atoms. For instance, the join (disjunction function) $\vee$ and the meet (conjunction function) $\wedge$ are connectors. $f(x, y) = \max(0, x + y - 1)$ is also a connector over $[0, 1]^2$. Connectors need not necessarily be monotone functions. Let $\mathcal{V}$ be a set of variable symbols and $\mathcal{A}$ be a set of atomic formulae $P(t_1, \ldots, t_m)$, where P is an m-ary predicate symbol and all t_i are terms. A *term* is defined inductively, as usual, as being either a variable, a constant, or the application of a logical function symbol to terms [26].

A *formula* is either an atom A or an expression of the form $f(A_1, \ldots, A_n)$, where f is an n-ary connector and each A_i is an atom. For ease of presentation, the connectors $\wedge$ and $\vee$ are used in fix notation. The intuition behind a formula $f(A_1, \ldots, A_n)$ is that the truth degree of the formula is given by evaluating the truth degree of each A_i and then applying f to these degrees to obtain the final degree. Of course, the function f may well be the composition of functions, $f_1 \circ \cdots \circ f_n$. For instance, over $[0, 1]$, $\min(A(x, y), B(y, z)) \cdot \max(\neg R(z), 0.7) + G(x)$ is a formula. In this case, the truth of the formula is determined from the truth of the atoms $A(x, y), B(y, z), R(z)$, and $G(x)$ by applying the specified arithmetic functions. Truth degrees in L may appear in formulae (like 0.7 above).

A *logic program* $\mathcal{P}$ is a set of rules $\psi \leftarrow \varphi$, where ψ and φ are formulae (respectively, called the head and the body); i.e., rules are of the form

$$g(B_1, \ldots, B_k) \leftarrow f(A_1, \ldots, A_n) \ ,$$

where f, g are connectors and B_i and A_j are atoms. Free variables in a rule are understood to be *universally quantified*. For instance, over $[0, 1]$,

$$\max(A(x), B(x)) \leftarrow 0.7 \cdot \max(0, A(x, y) + B(y, z) - 1)$$

is a rule. The intuition is that the truth of either $A(x)$ or $B(x)$ is at least the truth degree of the body. We point out that the form of the rules is sufficiently expressive to encompass all approaches we are aware of to monotone many-valued logic programming.[7] So far, in many-valued logic programming, rules are either of the "deterministic" form $B \leftarrow f(A_1, \ldots, A_n)$ or of the form $B_1 \vee \ldots \vee B_k \leftarrow A_1 \wedge \ldots \wedge A_n$ (see, e.g., [46]).

In the following, by $\mathcal{P}^*$ we denote the ground instantiation of $\mathcal{P}$. If there is no constant in $\mathcal{P}$, then we consider some constant, say c, to form ground terms. Note

[6] By computable we mean that the result of f is computable in a finite amount of time.

[7] Also note that any classical first order clause $A_1 \vee \cdots \vee A_k \vee \neg B_1 \vee \cdots \neg B_n$ (with $k + n > 0$) is a rule of the form $A_1 \vee \cdots \vee A_k \leftarrow B_1 \wedge \cdots \wedge B_n$. If $k = 0$, we use $\bot$ in the left-hand side, while if $n = 0$, we use $\top$ in the right-hand side.

that $|\mathcal{P}^*|$ may be not finite, but it is countable. If we restrict a term to be either a variable or a constant, then $|\mathcal{P}^*|$ is finite.

We next consider the usual notion of interpretation and generalize the notion of satisfiability (see, e.g., [46]) to our setting. An *interpretation* is a mapping I from ground atoms to members of L. For a ground atom A, $I(A)$ indicates the degree of truth to which A is true under I. An interpretation I is extended from atoms to nonatomic formulae in the usual way as follows:

1. for $b \in L$, $I(b) = b$; and
2. $I(f(A_1, \ldots, A_n)) = f(I(A_1), \ldots, I(A_n))$.

An interpretation I *satisfies* (is a *model* of) a ground rule $\psi \leftarrow \varphi \in \mathcal{P}^*$, denoted $I \models \psi \leftarrow \varphi$ iff $I(\varphi) \leq I(\psi)$. Essentially, we postulate that the consequent ψ of the ground rule (implication) is at least as true as the antecedent φ. We further say that I *satisfies* (is a *model* of) a logic program $\mathcal{P}$, denoted $I \models \mathcal{P}$, iff I satisfies all ground rules in $\mathcal{P}^*$. Given an interpretation I, by $\mathcal{P}[I]$ we denote the set of ground rules of $\mathcal{P}^*$ in which the body has been evaluated by means of I, i.e.,

$$\mathcal{P}[I] = \{\psi \leftarrow I(\varphi) \colon \psi \leftarrow \varphi \in \mathcal{P}^*\} \ .$$

It is easily verified that $I \models \mathcal{P}$ iff $I \models \mathcal{P}[I]$.

Given two interpretations I, J, we define $I \leq J$ pointwise; i.e., $I \leq J$ iff for all ground atoms $I(A) \leq J(A)$. It is easily verified that the set of interpretations, denoted $\hat{L}$, forms a complete lattice as well, i.e., $\langle \hat{L}, \leq \rangle$ is a complete lattice, with least element $I_\bot$ (mapping all atoms to $\bot$) and greatest element $I_\top$ (mapping all atoms to $\top$). If L is countable, then so is $\hat{L}$. If L is finite and a term is either a variable or a constant, then $\hat{L}$ is finite as well.

It is worth noting that $I \leq J$ does not necessarily imply that $I(\psi) \leq J(\psi)$ for a formula ψ. However, as one may expect, if the functions involved in ψ are monotone, then from $I \leq J$, $I(\psi) \leq J(\psi)$ follows.

PROPOSITION 4.1. *Let I, J be two interpretations such that $I \leq J$. If ψ is a formula involving monotone functions $f \in \mathcal{F}$, then $I(\psi) \leq J(\psi)$.*

Proof. The proof is on the structure of ψ. Assume ψ is an atomic formula A. Then by definition of $I \leq J$, $I(A) \leq J(A)$. If $\psi = f(A_1, \ldots, A_n)$, then using induction on A_i and the fact that f is monotone we have that

$$\begin{aligned} I(f(A_1, \ldots, A_n)) &= f(I(A_1), \ldots, I(A_n)) \\ &\leq f(J(A_1), \ldots, J(A_n)) \\ &= J(f(A_1, \ldots, A_n)) \ , \end{aligned}$$

which concludes the proof. □

Note that the connectors $\wedge, \vee$ are monotone. More generally, let us define the *evaluation* function

$$e(I, \psi) = I(\psi) \ .$$

Then the above proposition establishes that the function $e(I, \psi)$ is monotone in I if all the connectors in ψ are monotone; i.e., if $I \leq J$, then $e(I, \psi) \leq e(J, \psi)$. Similarly, we can show that if all the connectors in ψ are $\bigvee$-preserving ($\bigwedge$-preserving), then $e(I, \psi)$ is $\bigvee$-preserving ($\bigwedge$-preserving) in I.

PROPOSITION 4.2. *If all the connectors in ψ are $\bigvee$-preserving ($\bigwedge$-preserving), then $e(I, \psi)$ is $\bigvee$-preserving ($\bigwedge$-preserving) in I.*

Proof. Let us prove the $\bigwedge$-preserving case. The other case is similar. Consider a decreasing sequence of interpretations $(I_\alpha)_{\alpha\in I}$. We have to show that $e(\bigwedge_\alpha I_\alpha, \psi) = \bigwedge_\alpha e(I_\alpha, \psi)$. That is, $(\bigwedge_\alpha I_\alpha)(\psi) = \bigwedge_\alpha I_\alpha(\psi)$. Let $\bar{I}$ be the interpretation $\bar{I} = \bigwedge_\alpha I_\alpha$. The proof is on the structure of ψ. Assume ψ is an atomic formula A. Then by definition, $e(\bar{I}, A) = \bar{I}(A) = (\bigwedge_\alpha I_\alpha)(A) = \bigwedge_\alpha I_\alpha(A) = \bigwedge_\alpha e(I_\alpha, A)$. If $\psi = f(A_1, \ldots, A_n)$, then using induction on A_i and the fact that f is $\bigwedge$-preserving we have that

$$\begin{aligned}
e(\bar{I}, f(A_1, \ldots, A_n)) &= \bar{I}(f(A_1, \ldots, A_n)) \\
&= f(\bar{I}(A_1), \ldots, \bar{I}(A_n)) \\
&= f(e(\bar{I}, A_1), \ldots, e(\bar{I}, A_n)) \\
&= f\left(\bigwedge_\alpha e(I_\alpha, A_1), \ldots, \bigwedge_\alpha e(I_\alpha, A_n)\right) \\
&= \bigwedge_\alpha f(e(I_\alpha, A_1), \ldots, e(I_\alpha, A_n)) \\
&= \bigwedge_\alpha f(I_\alpha(A_1), \ldots, I_\alpha(A_n)) \\
&= \bigwedge_\alpha I_\alpha(f(A_1, \ldots, A_n)) \\
&= \bigwedge_\alpha e(I_\alpha, f(A_1, \ldots, A_n)) \ ,
\end{aligned}$$

which concludes the proof. □

Useful to note is the following.

PROPOSITION 4.3. *$\vee$ ($\wedge$) is $\bigvee$-preserving ($\bigwedge$-preserving).*

Proof. Let us show that $\vee$ is $\bigvee$-preserving. Indeed, for all increasing sequences $(\langle x_\alpha, y_\alpha\rangle)_{\alpha\in I}$, we have that

$$\begin{aligned}
\vee\left(\bigvee_\alpha \langle x_\alpha, y_\alpha\rangle\right) &= \vee\left(\left\langle \bigvee_\alpha x_\alpha, \bigvee_\alpha y_\alpha \right\rangle\right) \\
&= \left(\bigvee_\alpha x_\alpha\right) \vee \left(\bigvee_\alpha y_\alpha\right) = \bigvee_\alpha (x_\alpha \vee y_\alpha) \\
&= \bigvee_\alpha \vee(x_\alpha, y_\alpha) \ .
\end{aligned}$$

In a similar way, $\wedge$ is $\bigwedge$-preserving. □

In general, $\vee$ ($\wedge$) is not $\bigwedge$- ($\bigvee$-) preserving.

Example 21 (see [5]). Let us show that the meet function is not $\bigvee$-preserving in general. Consider the complete lattice obtained from the set of closed subsets of the unit disk, with the meet defined as the set-intersection and the join defined as the topological closure of set-union (closure is needed here because the arbitrary union of closed sets need not be closed). This definition provides a complete distributive lattice structure. Now, for all $n \in \mathbb{N}$, define $x_{n,1} = a =$ the unit circle, i.e., the points $\langle x, y\rangle$ satisfying $x^2 + y^2 = 1$, and define $x_{n,2} =$ the disk of radius $1 - 1/n$, that is, the points $\langle x, y\rangle$ satisfying $x^2 + y^2 \leq 1 - 1/n$. The sequence $(\langle x_{n,1}, x_{n,2}\rangle)_{n\in\mathbb{N}}$ is an increasing sequence. $\bigvee_n x_{n,2}$ turns out to be the whole unit disk; therefore $(\bigvee_n x_{n,1}) \wedge (\bigvee_n x_{n,2}) = a \wedge (\bigvee_n x_{n,2})$ is the unit circle. On the other hand, $x_{n,1} \wedge x_{n,2} = a \wedge x_{n,2}$ is the empty set (which is a closed subset), and hence $\bigvee_n (x_{n,1} \wedge x_{n,2}) = \bigvee_n (a \wedge x_{n,2})$

is the empty set. As a consequence, $(\bigvee_n x_{n,1}) \wedge (\bigvee_n x_{n,2}) \neq \bigvee_n (x_{n,1} \wedge x_{n,2})$ and, thus, the meet function $\wedge$ is not $\bigvee$-preserving.

However, it can easily be shown that $\vee$ ($\wedge$) is $\bigwedge$- ($\bigvee$-) preserving if $\mathcal{L} = \langle L, \leq \rangle$ is *finite*, i.e., $|L| \in \mathbb{N}$. From a practical point of view this is a limitation we can live with, especially taking into account that computers have finite resources. In particular, this includes also the case of the rational numbers in $[0, 1]$ under a given fixed decimal precision p (e.g., $p = 2$) and the Boolean lattice over $\{0, 1\}$.

PROPOSITION 4.4. *If $\mathcal{L} = \langle L, \leq \rangle$ is* finite*, then $\vee$ and $\wedge$ are limit-preserving.*

Note that Proposition 4.4 can be extended to any *finite* n-ary meet (join) function. Furthermore, Proposition 4.4 holds also for any *infinite* n-ary meet (join) function, as for a finite lattice, an infinite meet (join) is equivalent to a finite meet (join). Indeed, only finitely many values can appear in the infinite meet (join). Another useful and special case is when $\mathcal{L} = \langle [0, 1], \leq \rangle$, as it is used in fuzzy logic programming (see, e.g., [48]).

PROPOSITION 4.5. *$\vee$ and $\wedge$ are limit-preserving on $[0, 1] \times [0, 1]$.*

4.1. Fixed-point characterization of logic programs. The aim of this section is to extend the usual fixed-point characterization of classical logic programs [26] to the case of generalized logic programs. So, let $\mathcal{P}$ be a logic program. Consider $\mathcal{L} = \langle L, \leq \rangle$ and the related complete lattice of interpretations $\langle \hat{L}, \leq \rangle$. We next define a multivalued function over $\hat{L}$ whose set of fixed-points coincides with the set of models of $\mathcal{P}$.

The *multivalued immediate consequence* operator mapping interpretations into sets of interpretations, $T_{\mathcal{P}} \colon \hat{L} \to 2^{\hat{L}}$, is defined as

$$T_{\mathcal{P}}(I) = \{J \colon J \models \mathcal{P}[I], I \leq J\} \ .$$

Note that either $T_{\mathcal{P}}(I_\top) = \varnothing$ or $T_{\mathcal{P}}(I_\top) = \{I_\top\}$. Also note that, unlike in the single-valued case, we do not necessarily have $T_{\mathcal{P}}(I) \neq \varnothing$.

Example 22. For any interpretation I and for $\mathcal{P} = \{A \vee B \leftarrow \top, \ \ \bot \leftarrow A, \ \ \bot \leftarrow B \ \}$, $T_{\mathcal{P}}(I) = \varnothing$ holds.

However, note that for the specific case of rules of the form below (where A_i, B_j is neither $\top$ nor $\bot$ and $k \geq 1$)

$$A_1 \vee \cdots \vee A_k \leftarrow f(B_1, \ldots, B_n) \ ,$$

it is easily verified that for any I, $I_\top \in T_{\mathcal{P}}(I) \neq \varnothing$, and in particular $T_{\mathcal{P}}(I_\top) = \{I_\top\}$. Also, note that $T_{\mathcal{P}}(I)$ may not be countable.

Example 23. Consider $L = [0, 1]$ and $\mathcal{P}$ with rule $A \leftarrow 0$. Then for any interpretation $I \neq I_\top$, $T_{\mathcal{P}}(I) = \{J \mid I \leq J \text{ and } J(A) \geq 0.3\}$ holds. Hence, $T_{\mathcal{P}}(I)$ is not countable.

The $T_{\mathcal{P}}$ function has the desired property in which models of logic programs are fixed-points and vice versa.

PROPOSITION 4.6. *$I \models \mathcal{P}$ iff $I \in T_{\mathcal{P}}(I)$.*

Proof. $I \models \mathcal{P}$ iff $I \models \mathcal{P}[I]$ iff $I \in T_{\mathcal{P}}(I)$. □

Example 24. Over $\mathcal{L} = \langle \{0, 1\}, \leq \rangle$, consider $\mathcal{P} = \{A \leftarrow 1 - B\}$ and $I(A) = 0, I(B) = 1$. Then

$$\begin{aligned} T_{\mathcal{P}}(I) &= \{J \mid J \models \mathcal{P}[I], I \leq J\} \\ &= \{J \mid J \models A \leftarrow 0, I \leq J\} \\ &= \{J \mid I \leq J\} \\ &= \{I, I'\}, \end{aligned}$$

where $I'(A) = I'(B) = 1$. Note that $I \in T_{\mathcal{P}}(I)$ and I is a model of $\mathcal{P}$. Note also that the truth combination function $f(x) = 1-x$ in rule $A \leftarrow 1-B$ is not monotone. Hence determining models of a logic program is equivalent to investigating the fixed-points of the multivalued function $T_{\mathcal{P}}$.

In the following, we will determine which properties of section 3 about multivalued functions apply to $T_{\mathcal{P}}$ and which are specific of $T_{\mathcal{P}}$ only. To start with, as definition $J \in T_{\mathcal{P}}(I)$ implies $I \leq J$ we immediately have the following.

PROPOSITION 4.7. *$T_{\mathcal{P}}$ is inflationary.*

Furthermore, we also can show the following.

PROPOSITION 4.8. *If all connector functions in the body φ of rules $\psi \leftarrow \varphi \in \mathcal{P}$ are $\bigvee$-preserving, then $T_{\mathcal{P}}$ is $\bigvee$-preserving and, thus, S-monotone.*

Proof. Let $(I_\alpha)_{\alpha\in I}$ be an increasing sequence of interpretations. Let $\bar{I} = \bigvee_\alpha I_\alpha$. We have to show that $T_{\mathcal{P}}(\bar{I}) = \{J\colon$ there is $(J_\alpha)_{\alpha\in I}$ s.t. $J_\alpha \in T_{\mathcal{P}}(I_\alpha)$ and $J = \bigvee_\alpha J_\alpha\}$ $(= \bigvee_\alpha T_{\mathcal{P}}(I_\alpha))$. So, let $J \in T_{\mathcal{P}}(\bar{I})$. Then $J \models \mathcal{P}[\bar{I}]$ and $\bar{I} \leq J$ and, thus, $I_\alpha \leq J$. Then, using Proposition 4.2, for all ground rules $\psi \leftarrow \varphi \in \mathcal{P}^*$, $I_\alpha(\varphi) \leq \bigvee_\alpha I_\alpha(\varphi) = \bar{I}(\varphi) \leq J(\psi)$. Therefore, $J \models \mathcal{P}[I_\alpha]$ and, thus, $J \in T_{\mathcal{P}}(I_\alpha)$. Hence, $J \in \bigvee_\alpha T_{\mathcal{P}}(I_\alpha)$. Vice versa, let $J \in \bigvee_\alpha T_{\mathcal{P}}(I_\alpha)$. Thus $J = \bigvee_\alpha J_\alpha$ with $J_\alpha \in T_{\mathcal{P}}(I_\alpha)$. It follows that $I_\alpha \leq J_\alpha \leq J$ and $J_\alpha \models P[I_\alpha]$. Then, using Proposition 4.2, for all ground rules $\psi \leftarrow \varphi \in \mathcal{P}^*$, $\bar{I}(\varphi) = \bigvee_\alpha I_\alpha(\varphi) \leq \bigvee_\alpha J_\alpha(\psi) = J(\psi)$ and, thus, $J \models \mathcal{P}[\bar{I}]$. As $\bar{I} = \bigvee_\alpha I_\alpha \leq \bigvee_\alpha J_\alpha = J$, $J \in T_{\mathcal{P}}(\bar{I})$ follows. S-monotonicity follows from Proposition 3.5. ∎

The analogue of Proposition 4.8 does not hold for $\bigwedge$-preserving connector functions.

Example 25. Consider $L = [0,1]$, $a \geq 1$, the function $f(x) = 1/(a+1-x)$, and the logic program $\mathcal{P} = \{\frac{1}{a+1} \leftarrow f(A)\}$. Consider a decreasing sequence of interpretations $I_n(A) = 1/n$, $n \in \mathbb{N}$. Then $\bar{I}(A) = \bigwedge_\alpha I_\alpha(A) = I_\perp(A) = 0$. The function f is monotone—more precisely, $\bigwedge$-preserving—, with maximum value $\frac{1}{a}$ and minimum value $\frac{1}{a+1}$. Furthermore, $f(I_1(A)) = \frac{1}{a}$, while $f(\bar{I}(A)) = \frac{1}{a+1}$ and $f(I_n(A)) = \frac{1}{a+1-1/n} > \frac{1}{a+1}$. Therefore, $T_{\mathcal{P}}(\bar{I}) = \{J\colon J$ interpretation$\}$. On the other hand, $T_{\mathcal{P}}(I_n) = \varnothing$ and, thus,[8] $\bigwedge_n T_{\mathcal{P}}(I_n) = \varnothing$. Therefore, $T_{\mathcal{P}}(\bigwedge_n I_n) \not\subseteq \bigwedge_n T_{\mathcal{P}}(I_n)$; i.e., $T_{\mathcal{P}}$ is not $\bigwedge$-preserving.

Let us define

$$G_{\mathcal{P}}(I) = \{J \vee I\colon J \models \mathcal{P}[I]\}\ . \tag{4.1}$$

Then it is easily verified that $T_{\mathcal{P}}(I) \subseteq G_{\mathcal{P}}(I)$ (from $I \leq J$, $J \vee I = J$). On the other hand, for $J \in G_{\mathcal{P}}(I)$, $J = J' \vee I$, $J' \models \mathcal{P}[I]$, $J' \leq J$, and $I \leq J$. If all connector functions in the head of rules in $\mathcal{P}$ are monotone, then for all ground rules $\psi \leftarrow \varphi \in \mathcal{P}^*$ (using Proposition 4.1), $I(\varphi) \leq J'(\psi) \leq J(\psi)$. Therefore, $J \in T_{\mathcal{P}}(I)$, i.e., $G_{\mathcal{P}}(I) \subseteq T_{\mathcal{P}}(I)$. Therefore we have what follows.

PROPOSITION 4.9. *For any interpretation I, $T_{\mathcal{P}}(I) \subseteq G_{\mathcal{P}}(I)$. If all connector functions in the head of rules in $\mathcal{P}$ are monotone, then $T_{\mathcal{P}}(I) = G_{\mathcal{P}}(I)$.*

Monotonicity is a necessary condition for guaranteeing equivalence among $T_{\mathcal{P}}$ and $G_{\mathcal{P}}$.

Example 26. Over $\mathcal{L} = \langle\{0,1\}, \leq\rangle$, consider the logic program $\mathcal{P} = \{\neg A \leftarrow A\}$. The negation function $\neg x = 1 - x$ is obviously not monotone. Consider $I(A) = 1$ and $J'(A) = 0$. Then, $J' \models \mathcal{P}[I]$ and, thus, $J = I \vee J' = I_\top \in G_{\mathcal{P}}(I)$, but $J \notin T_{\mathcal{P}}(I)$.

[8] Recall that $\bigwedge_n T_{\mathcal{P}}(I_n)$ is shorthand for the right-hand side of (3.5).

A closer analysis shows that we can write $G_{\mathcal{P}}$ similarly to (3.6). Indeed, let $F_{\mathcal{P}}$ be the multivalued function

$$F_{\mathcal{P}}(I) = \{J\colon J \models \mathcal{P}[I]\} \ .$$

Then, it can easily verified that

$$G_{\mathcal{P}}(I) = I \oplus F_{\mathcal{P}}(I) \ .$$

We can show the following.

PROPOSITION 4.10. *If all connector functions in the body φ of rules $\psi \leftarrow \varphi \in \mathcal{P}$ are monotone, then $F_{\mathcal{P}}$ is a multivalued S-monotone operator.*

Proof. Consider interpretations I, J s.t. $I \leq J$. Let us show that $F_{\mathcal{P}}(I) \preceq_S F_{\mathcal{P}}(J)$. If $F_{\mathcal{P}}(J) = \varnothing$, then obviously $F_{\mathcal{P}}(I) \preceq_S F_{\mathcal{P}}(J)$. Otherwise, assume $F_{\mathcal{P}}(J) \neq \varnothing$. Let $J' \in F_{\mathcal{P}}(J)$ and, thus, by definition $J' \models \mathcal{P}[J]$; i.e., for all ground rules $\psi \leftarrow \varphi \in \mathcal{P}^*$, $J(\varphi) \leq J'(\psi)$. But, $I \leq J$ and, using Proposition 4.1, $I(\varphi) \leq J(\varphi) \leq J'(\psi)$. Therefore, $J' \models \mathcal{P}[I]$ and, thus, $J' \in F_{\mathcal{P}}(I)$, which concludes the proof. □

Note that the proof of the proposition above shows in fact that if $I \leq J$, then $F_{\mathcal{P}}(J) \subseteq F_{\mathcal{P}}(I)$ and, thus, $F_{\mathcal{P}}(I) \preceq_S F_{\mathcal{P}}(J)$.

Now, taking into account Propositions 3.27, 4.7, and 4.9, the following analogue of Proposition 3.27 can be obtained.

PROPOSITION 4.11. *$G_{\mathcal{P}}$ is inflationary. Furthermore, if all connector functions in $\mathcal{P}$ are monotone, then* (i) *$T_{\mathcal{P}} = G_{\mathcal{P}}$;* (ii) *$T_{\mathcal{P}}$ is S-monotone;* (iii) *$I \in F_{\mathcal{P}}(I)$ implies $I \in T_{\mathcal{P}}(I)$;* (iv) *$I \in T_{\mathcal{P}}(I)$ implies $F_{\mathcal{P}}(I) \leq \{I\}$; and* (v) *for any interpretation I, I is a minimal fixed-point of $F_{\mathcal{P}}$ iff I is a minimal fixed-point of $T_{\mathcal{P}}$.*

By relying on Propositions 4.6, 3.7, and 3.19, we have the following.

PROPOSITION 4.12. *Let $\mathcal{P}$ be a logic program. Then*

1. *$\Phi(T_{\mathcal{P}}) \neq \varnothing$ iff $\mathcal{P}$ has a model;*
2. *each orbit of $T_{\mathcal{P}}$ is increasing and converges to a model of $\mathcal{P}$;*
3. *if I is a minimal model of $\mathcal{P}$ and all connector functions in $\mathcal{P}$ are monotone, then there is an orbit converging to I.*

Unlike the general case, for $T_{\mathcal{P}}$ we can be even more precise and reach any model.

PROPOSITION 4.13. *If I is a model of $\mathcal{P}$ and all connector functions in $\mathcal{P}$ are monotone, then there is an orbit converging to I.*

Proof. We show that if $I \models \mathcal{P}$, then there is an orbit converging to I. By Proposition 4.6, $I \in T_{\mathcal{P}}(I)$. The proof is similar for point 3 in Proposition 3.19. We know that each orbit of $T_{\mathcal{P}}$ converges to a model of $\mathcal{P}$. As in Proposition 3.19, we can show by induction on α that there is an orbit $(I_\alpha)_{\alpha \in I}$ of elements $I_{\alpha+1} \in T_{\mathcal{P}}(I_\alpha)$ with $I_0 = I_\perp$, such that $I_\alpha \leq I$ for all α. Therefore, the orbit converges to a model $I_{\bar{\alpha}}$ of $\mathcal{P}$, where $I_{\bar{\alpha}} = I_{\bar{\alpha}+1}$, $I_{\bar{\alpha}} \leq I$. By Proposition 4.6, $I_{\bar{\alpha}} \in T_{\mathcal{P}}(I_{\bar{\alpha}})$. Now, let us show that $I \in T_{\mathcal{P}}(I_{\bar{\alpha}})$. Indeed, from $I_{\bar{\alpha}} \models \mathcal{P}$ and $I \models \mathcal{P}$, for all $\psi \leftarrow \varphi \in \mathcal{P}^*$, from $I_{\bar{\alpha}} \leq I$, using Proposition 4.1, we have $I_{\bar{\alpha}}(\varphi) \leq I(\varphi) \leq I(\psi)$. Therefore, $I \in T_{\mathcal{P}}(I_{\bar{\alpha}})$ and, thus, the sequence $I_0 = \perp, \ldots, I_{\bar{\alpha}}, I, I, \ldots$ is an orbit converging to I. □

Example 27. Consider the logic program over the Boolean lattice on $\{0,1\}$, $\mathcal{P} = \{(a \vee b \leftarrow 1), (c \leftarrow a), (a \wedge c \wedge d \leftarrow b)\}$. The unique minimal model is $\bar{I}(a,b,c,d) = \langle 1,0,1,0\rangle$. The following are two orbits p_1, p_2 of $T_{\mathcal{P}}$:

$$p_1 = \langle 0,0,0,0\rangle \rightarrow \langle 1,0,0,0\rangle \rightarrow \langle 1,0,1,0\rangle \rightarrow \langle 1,0,1,0\rangle \ ,$$
$$p_2 = \langle 0,0,0,0\rangle \rightarrow \langle 0,1,0,0\rangle \rightarrow \langle 1,1,1,1\rangle \rightarrow \langle 1,1,1,1\rangle \ .$$

Both $\langle 1,0,1,0\rangle$ and $\langle 1,1,1,1\rangle$ are fixed-points, i.e., models, and p_1 reaches the minimal one.

Note that the previous two propositions allow us also to decide, if the lattice is *finite*, whether or not a logic program has a model. Indeed, it suffices to try to build an orbit, starting with $I_\bot$, and systematically use all alternatives (which are finite) at each step. If no orbit can be built, no model exists.

As for the general case (see Example 9), $T_\mathcal{P}$ may not have minimal fixed-points.

Example 28. Consider the logic program $\mathcal{P} = \{f(A) \leftarrow 1\}$, where $f(x) = 1$ if $x > 0$ and $f(0) = 0$. Then $I \models \mathcal{P}$ iff $I(A) > 0$, and no minimal model exists.

The following example shows that if a connector function is not $\bigwedge$-preserving, then there is a decreasing sequence of models not converging to a model.

Example 29. Consider $L = [0, 1]$ and the connector function f such that $f(0) = 0$ and for $x > 0$, $f(x) = 1$. Now, consider the logic program $\mathcal{P} = \{A \vee f(B) \leftarrow 1\}$. Then the decreasing sequence $(I_n)_{n\in\mathbb{N}}$ of interpretations I_n, where $I_n(A) = 0$ and $I_n(B) = 1/n$ is a decreasing sequence of models of $\mathcal{P}$ converging to the interpretation $I(A) = 0, I(B) = 0$, which, however, is not a model of $\mathcal{P}$. (Note: f is not $\bigwedge$-preserving.) Also note that $\mathcal{P}$ has a minimal model with $I(A) = 1$ and $I(B) = 0$, despite the fact that the connector function f is not $\bigwedge$-preserving.

We next want to establish a proposition like Proposition 3.9, guaranteeing the existence of minimal fixed points.

PROPOSITION 4.14. *If all connector functions in $\mathcal{P}$ are $\bigwedge$-preserving and $\mathcal{P}$ has models, then $\Phi(T_\mathcal{P})$ has minimals.*

Proof. As $\mathcal{P}$ has models, models are fixed-points of $T_\mathcal{P}$ (Proposition 4.6), and $T_\mathcal{P}$ is inflationary, by Proposition 3.7, $\Phi(T_\mathcal{P}) \neq \varnothing$. So, let $(I_\alpha)_{\alpha\in I}$ be a decreasing sequence of interpretations in $\Phi(T_\mathcal{P})$, and let $I = \bigwedge_\alpha I_\alpha$. Again, by Zorn's lemma it suffices to show that $I \in \Phi(T_\mathcal{P})$.

By Propositions 4.11 and 3.7, $I_\alpha \in T_\mathcal{P}(I_\alpha)$; i.e., I_α are fixed-points. Now, let us show that $I \in T_\mathcal{P}(I)$. From $I_\alpha \in T_\mathcal{P}(I_\alpha)$ and $\psi \leftarrow \varphi \in \mathcal{P}^*$, $I_\alpha(\varphi) \leq I_\alpha(\psi)$ holds. Therefore, by Proposition 4.2, $I(\varphi) = (\bigwedge_\alpha I_\alpha)(\varphi) = \bigwedge_\alpha I_\alpha(\varphi) \leq \bigwedge_\alpha I_\alpha(\psi) = (\bigwedge_\alpha I_\alpha)(\psi) = I(\psi)$. As a consequence, $I \models \mathcal{P}[I]$ and, thus, $I \in T_\mathcal{P}(I)$. Therefore, $I \in \Phi(T_\mathcal{P})$, which concludes the proof. □

We note that, by Proposition 3.19, if $T_\mathcal{P}(I_\top) \neq \varnothing$, then, as $T_\mathcal{P}$ is inflationary, $\mathcal{P}$ has a model. Then, by Propositions 3.8 and 4.6, the next proposition directly follows.

PROPOSITION 4.15. *If all connector functions in $\mathcal{P}$ are $\bigwedge$-preserving and $\mathcal{P}$ has models, then $T_\mathcal{P}$ has minimal fixed-points and, thus, $\mathcal{P}$ has minimal models.*

The analogue of Proposition 3.25 is as follows.

PROPOSITION 4.16. *If $\mathcal{P}$ has models and all connector functions in $\mathcal{P}$ are $\bigwedge$-preserving, then $\mathcal{P}$ has minimal models and there are orbits converging to them. If all connector functions in $\mathcal{P}$ are also $\bigvee$-preserving, then ω steps are sufficient to reach a minimal model.*

4.2. The case of classical logic programs. We conclude this part by applying our results to classical logic programs [26, 27, 32]. As already pointed out, any classical first order clause $A_1 \vee \cdots \vee A_k \vee \neg B_1 \vee \cdots \neg B_n$ (with $k + n > 0$) is a rule of the form

$$A_1 \vee \cdots \vee A_k \leftarrow B_1 \wedge \cdots \wedge B_n \ . \tag{4.2}$$

If $k = 0$, we use $\bot$ in the left-hand side, while if $n = 0$, we use $\top$ in the right-hand side. The truth space is $L = \{0, 1\}$. Note that usually in disjunctive logic programs $k \geq 1$ is assumed and A_i, B_j is neither $\top$ nor $\bot$. This slight difference has an impact on the set of models of a disjunctive logic program, as we show next.

Example 30. Consider the truth space $L = \{0, 1\}$ and consider $\mathcal{P}$ with rules

$$\bot \leftarrow A,$$
$$A \leftarrow \top\ .$$

The former rule states that A should be false, while the latter states that A should be true. Of course, $T_{\mathcal{P}}(I) = \emptyset$, for any interpretation I and, thus, $T_{\mathcal{P}}$ has no fixed-point; thus, $\mathcal{P}$ has no model.

On the other hand, if we assume that $k \geq 1$ and that A_i, B_j is neither $\top$ nor $\bot$, as usual for disjunctive logic programs, as L is finite, by Proposition 4.4, $\vee$ and $\wedge$ are limit-preserving. Furthermore, it is easily verified that for any I, $I_\top \in T_{\mathcal{P}}(I) \neq \varnothing$, in particular $T_{\mathcal{P}}(I_\top) = \{I_\top\}$, $T_{\mathcal{P}}$ is $\bigvee$-preserving (thus, S-monotone), and, as $T_{\mathcal{P}}$ inflationary, $\mathcal{P}$ has a model. By Propositions 4.16 and 3.23 we immediately have the following well-known fact [27, 32].

PROPOSITION 4.17. *Any classical disjunctive logic program $\mathcal{P}$ has minimal models and there are orbits (of length ω) of minimals converging to them.*

Finally, let us further restrict logic programs to the case where the head contains one atom only (i.e., $k = 1$). That is, rules are of the usual deterministic form

$$A \leftarrow B_1 \wedge \cdots \wedge B_n\ . \tag{4.3}$$

Then, for any I, $T_{\mathcal{P}}(I)$ has a least element.

PROPOSITION 4.18. *For any classical deterministic logic program $\mathcal{P}$ and interpretation I, $T_{\mathcal{P}}(I)$ has a least element.*

Proof. Consider $\bar{J} = \bigwedge T_{\mathcal{P}}(I)$. Let us show that $\bar{J} \in T_{\mathcal{P}}(I)$. As for all $J \in T_{\mathcal{P}}(I)$ we have $I \leq J$, it follows that $I \leq \bigwedge_{J \in T_{\mathcal{P}}(I)} J = \bar{J}$. Now, consider $A \leftarrow I(\varphi)$ with $A \leftarrow \varphi \in \mathcal{P}^*$. Then by Proposition 4.2, as for all $J \in T_{\mathcal{P}}(I)$, $I(\varphi) \leq J(A)$ holds,

$$I(\varphi) \ \leq \ \bigwedge_{J \in T_{\mathcal{P}}(I)} J(A) \ = \ \bigwedge_{J \in T_{\mathcal{P}}(I)} e(J, A) \ = \ e\left(\bigwedge_{J \in T_{\mathcal{P}}(I)}, A\right) \ = \ e(\bar{J}, A) \ = \ \bar{J}(A),$$

and, thus, $\bar{J} \models \mathcal{P}[I]$. As a consequence, $\bar{J} \in T_{\mathcal{P}}(I)$. □

Now, using Propositions 3.10, 3.24, and 4.17 we immediately have the following well-known fact [26].

PROPOSITION 4.19. *Any classical deterministic logic program $\mathcal{P}$ has a least model and there is an orbit (of length ω) of least elements converging to it.*

If terms are restricted to be either variables or constants, then for disjunctive logic programs the set of minimal models is finite (as there are finitely many interpretations). For both Propositions 4.17 and 4.19 the length of the orbits is finite.

5. Conclusions and related work. We have provided conditions for the existence of fixed-points, and minimal and maximal fixed-points of multivalued functions over complete lattices, and have shown how to obtain them. Our main contribution establishes that an inflationary, S-monotone, multivalued function with $\Phi(f) \neq \varnothing$ has minimal fixed-points, where each orbit converges to a fixed-point and for each minimal fixed-point an orbit converging to it exists. We have also shown that (see Table 3.1) the set of fixed-points of a limit-preserving multivalued function is a complete multilattice. We also reported the results of related work we are aware of.

We then applied our results to a general form of logic programs, where the truth space is a complete lattice. We have shown that a multivalued operator can be

defined whose fixed-points are in one-to-one correspondence with the models of the logic program.

Related work. To the best of our knowledge, the fixed-point theory over complete lattices is mainly single-value oriented. Nonetheless, [6, 14, 15, 16, 20, 21, 22, 33, 45, 53] establish a version of the Knaster–Tarski theorem, though requiring the condition that $f(x)$ be always nonempty and some other conditions. References [20, 21, 22, 14, 15, 16, 17, 38] also investigate the case where metric spaces or Banach spaces are considered in place of complete lattices, and then use the well-known contraction principle (see also [24, 41]) or continuity to guarantee the existence of a fixed-point (if $f(x)$ is always nonempty, of course). They also then apply some of their results to disjunctive logic programs (with nonmonotone negation). Close in spirit, using mainly Banach spaces, topological spaces, and metric spaces in place of complete lattices, are works of the mathematical community such as [2, 10, 19, 23, 49, 40, 34, 35, 43, 50, 51]. We point out that these works do not cover our results. As our initial objective was to study generalized many-valued logic programs, our analysis tried to parallel the usual analyses made for single-valued functions over complete lattices.

The research area of semantics for nondeterministic programming languages (see, e.g., [8, 36, 37, 44]) instead does not address multivalued functions directly, but rather "lifts" a multivalued function $f : D \to 2^D$ to a function $g : \mathcal{P}^*(D) \to \mathcal{P}^*(D)$, where $\mathcal{P}^*(D)$ is a rather complicated and appropriately ordered subset of the powerset of D (so-called *power domains* [1, 36, 44]), and then applies usual fixed-point theory. Here, D is a so-called *domain*, i.e., a complete partial ordered set with some additional constraints [1]. As in all order cases, $f(x)$ is assumed to be nonempty and finite. This constraint is related to the application of nondeterministic programming languages (as indeed, at each step of a program execution, there is at least one next state and there are at most finitely many possible nondeterministic alternatives).

Concerning the application of multivalued functions to logic programming, to the best of our knowledge, no work considers such general rules. Related to our approach are [14, 15, 16, 20, 21, 22] in which classical disjunctive logic programs have been considered with nonmonotone negation. We did not consider nonmonotonic negation so far, as an appropriate semantics (for generalized nonmonotone many-valued logic programs) has still to be developed. We also point to works such as [13, 39, 52] in which disjunctive logic programs are studied from a domain-theoretic (i.e., Smyth powerdomain) point of view. One feature of these works is that, by using an appropriate domain, as in the case of nondeterminsitic programming languages, the concept of a multivalued function is avoided by representing "disjunctive states"[9] (again, the image of a multivalued function is assumed to be nonempty and finite). On the other hand, we follow a direct approach, which requires less formal and abstract theory and is likely amenable to a less formal audience as well.

We envisage several directions for future research. The fixed-point theory of multivalued functions is interesting per se (there are many options worth investigating, such as using some other sets in place of complete lattices, CPOs, domains, Banach spaces, metric spaces, topological spaces, or some specific sets such as $[0, 1]$, etc., which have mainly been considered by mathematicians—see also [12]). On the other hand, related to general logic programs, besides considering special cases for connectors in the head and body, it would be interesting to generalize the stable model semantics

[9] This is similar to [42] in which an immediate consequence operator has been defined over sets of interpretations.

for classical disjunctive logic programs [9] to our case. More generally, we would like to bring the theory of fixed-points of multivalued functions to the attention of the knowledge representation and reasoning community, where multivalued functions may be applied to several problems and logic-based languages for knowledge representation.

Appendix A. Some other proofs.

PROPOSITION A.1. *Consider a multivalued function $f\colon L \to 2^L$. If f is $\bigwedge$-preserving, then f is H-monotone.*

Proof. Consider $x_1 \leq x_2$. Then for the decreasing sequence $x_2 \geq x_1$, $f(x_1) = f(x_2 \wedge x_1) = \{y\colon$ there are $y_i \in f(x_i)$ s.t. $y = y_2 \wedge y_1\} = X$. If $f(x_1) = \varnothing$, then trivially $\varnothing = f(x_1) \preceq_H f(x_2)$. If $f(x_2) = \varnothing$, then by definition $X = \varnothing$ and, thus, $f(x_1) = \varnothing$. Therefore, $\varnothing = f(x_1) \preceq_H f(x_2) = \varnothing$. Otherwise assume $f(x_1)$ and $f(x_2)$ are nonempty. Therefore, as f is $\bigwedge$-preserving, for $y \in f(x_1) = X$ there are $y_i \in f(x_i)$ $(i = 1, 2)$ such that $y = y_2 \wedge y_1$. In particular, $y \leq y_2$. Therefore, $f(x_1) \preceq_H f(x_2)$ and, thus, f is H-monotone. □

PROPOSITION A.2. *Consider a multivalued function $f\colon L \to 2^L$ and $x_1 \leq x_2$ with $f(x_1) \neq \varnothing \neq f(x_2)$. If f is $\bigvee$-preserving, then $f(x_1) \preceq_H f(x_2)$.*

Proof. For the increasing sequence $x_1 \leq x_2$, as f is $\bigvee$-preserving, $f(x_2) = f(x_1 \vee x_2) = \{y\colon$ there are $y_i \in f(x_i)$ s.t. $y = y_2 \vee y_1\} = X$. Now, for $y \in f(x_1)$ choose a $y' \in f(x_2) \neq \varnothing$ and consider $y'' = y \vee y'$. Therefore, $y'' \in X = f(x_2)$, $y \leq y''$, and, thus, $f(x_1) \preceq_H f(x_2)$. □

PROPOSITION A.3. *Let $f\colon L \to 2^L$ be a multivalued function. If f is deflationary, then $x \in \Psi(f)$ iff x is a fixed-point of f.*

Proof. Let $x \in \Psi(f)$. As f is deflationary, $\{x\} \preceq_H f(x) \preceq_H \{x\}$ and, thus, for $x \in \{x\}$ there is $y \in f(x)$ such that $x \leq y \leq x$, i.e., $x = y \in f(x)$. Vice versa, if $x \in f(x)$, then $\{x\} \preceq_H f(x)$ and, thus, $x \in \Psi(f)$. □

PROPOSITION A.4. *Let $f\colon L \to 2^L$ be a multivalued function. If f is an H-monotone or deflationary multivalued function, and $\Psi(f)$ has maximals, then all $y \in \max \Psi(f)$ are maximal fixed-points of f. In particular, if $x = \bigvee \Psi(f) \in \Psi(f)$, then x is the greatest fixed-point of f.*

Proof. As $\Psi(f)$ has maximals, $\max \Psi(f) \neq \varnothing$. So, let $y \in \max \Psi(f)$. Therefore, $\{y\} \preceq_H f(y) \neq \varnothing$ and, thus, there is $y' \in f(y)$ such that $y \leq y'$. If f is H-monotone, then $f(y) \preceq_H f(y')$ and, thus, for $y' \in f(y)$ there is $y'' \in f(y')$ such that $y' \leq y''$. Therefore, $\{y'\} \preceq_H f(y')$ and, thus, $y' \in \Psi(f)$. But $y \in \max \Psi(f)$, so it cannot be $y < y'$. Therefore, $y = y' \in f(y)$; i.e., y is a fixed-point of f. If f is deflationary, by Proposition 3.7, y is a fixed-point of f. Now, assume $x \in f(x)$. Therefore, $\{x\} \preceq_H f(x)$ and, thus, $x \in \Psi(f)$. But $y \in \max \Psi(f)$, so it cannot be $y < x$, and, thus, y is a maximal fixed-point of f. Finally, consider $x = \bigvee \Psi(f)$. By hypothesis, $x \in \Psi(f)$ and x is the greatest element of $\Psi(f)$. Hence, we know that $x \in f(x)$. Let $y \in f(y)$. Hence $y \in \Psi(f)$, and, thus, $y \leq x$. As a consequence, x is the greatest fixed-point of f. □

PROPOSITION A.5. *Let $f\colon L \to 2^L$ be a multivalued function. If f is a $\bigvee$-preserving multivalued function with $\Psi(f) \neq \varnothing$, then $\Psi(f)$ has maximals and, thus, maximal fixed-points.*

Proof. By hypothesis, $\Psi(f) \neq \varnothing$. Let $(x_\alpha)_{\alpha \in I}$ be an increasing sequence of $x_\alpha \in \Psi(f)$, and let $\bar{x} = \bigvee_\alpha x_\alpha$. As f is $\bigvee$-preserving, by definition, $f(\bar{x}) = \{y\colon$ there is $(y_\alpha)_{\alpha \in I}$ s.t. $y_\alpha \in f(x_\alpha)$ and $y = \bigvee_\alpha y_\alpha\}$.

Now, for any α, $x_\alpha \leq x_{\alpha+1}$, by Proposition 3.6 and, as $x_\alpha \in \Psi(f)$, $\{x_\alpha\} \preceq_H f(x_\alpha) \preceq_H f(x_{\alpha+1})$. Therefore, for any x_α there are $y_\alpha \in f(x_\alpha)$ and $y_{\alpha+1} \in f(x_{\alpha+1})$ such that $x_\alpha \leq y_\alpha \leq y_{\alpha+1}$.

Note that if α is a limit ordinal, then, as $x_\beta \leq x_\alpha$ for all $\beta < \alpha$, it follows that $\{x_\beta\} \preceq_H f(x_\beta) \preceq_H f(x_\alpha)$ and, thus, $x_\beta \leq y_\beta \leq y_\alpha$ for all $\beta < \alpha$. Therefore, there is an increasing sequence $(y_\alpha)_{\alpha \in I}$ of elements $y_\alpha \in f(x_\alpha)$ such that $\bar{x} = \bigvee_\alpha x_\alpha \leq \bigvee_\alpha y_\alpha = \bar{y}$. By definition of $f(\bar{x})$, $\bar{y} \in f(\bar{x})$, and, thus, $\{\bar{x}\} \preceq_H f(\bar{x})$. Therefore $\bar{x} \in \Psi(f)$, and, thus, every increasing sequence has an upper bound in $\Psi(f)$. So, by Zorn's lemma, $\Psi(f)$ has maximals, which by Proposition 3.8 are also maximal fixed-points. □

PROPOSITION A.6. *Let $f\colon L \to 2^L$ be a multivalued function. If f is an H-monotone, multivalued function, and for all $x \in L$, $f(x)$ has the greatest element, then f has the greatest fixed-point.*

Proof. As for all $x \in L$, $f(x)$ has the greatest element, by definition, $\bigvee f(x) \in f(x) \neq \varnothing$. Therefore, $\Psi(f) \neq \varnothing$ as $\{\bot\} \preceq_H f(\bot)$. Consider $a = \bigvee_{c \in \Psi(f)} c$. If $a \in \Psi(f)$, then by Proposition 3.8, a is the greatest fixed-point of f. So, let us show that $a \in \Psi(f)$. For $c \in \Psi(f)$ there is an $x_c \in f(c)$ such that $c \leq x_c$. As $c \leq a$ and f is H-monotone, $f(c) \preceq_H f(a)$, and, thus, for $x_c \in f(c)$ there is $y_c \in f(a)$ such that $c \leq x_c \leq y_c$. Since $f(a)$ has the greatest element, there is $y \in f(a)$ such that $a = \bigwedge_{c \in \Psi(f)} c \leq \bigwedge_{c \in \Psi(f)} x_c \leq \bigwedge_{c \in \Psi(f)} y_c \leq y$. Hence, $\{a\} \preceq_H f(a)$, i.e., $a \in \Psi(f)$. □

PROPOSITION A.7. *Let $f\colon L \to 2^L$ be an H-monotone, nonempty, and $\vee$-closed multivalued function. Then*

1. *$\Psi(f)$ is $\vee$-closed;*
2. *f has a greatest fixed-point.*

Proof. Note that $\Psi(f) \neq \varnothing$ as $\{\bot\} \preceq_H f(\top) \neq \varnothing$.

1. Consider a subset S of $\Psi(f)$ and $a = \bigvee S$. Let us show that $a \in \Psi(f)$. We know that for each $c \in S$, $\{c\} \preceq_H f(c)$ holds; i.e., there is $x_c \in f(c)$ such that $c \leq x_c$. But, f is H-monotone, and, thus, from $c \leq a$, $\{c\} \preceq_H f(c) \preceq_H f(a)$ follows. That is, there is $y_c \in f(a)$ such that $c \leq x_c \leq y_c$. Let $y = \bigvee_{c \in S} y_c$. As f is $\vee$-closed, $y \in f(a)$ follows. Therefore, $a = \bigvee_{c \in S} c \leq \bigvee_{c \in S} y_c = y$, $\{a\} \preceq_H f(a)$, and, thus, $a \in \Psi(f)$. Therefore, $\Psi(f)$ is $\vee$-closed.

2. From point 1, $\Psi(f)$ has the greatest element a, and, thus, by Proposition 3.8, f has a as the greatest fixed-point. □

PROPOSITION A.8. *For a multivalued function f,*

1. *if f is deflationary, then each $\top$-orbit is decreasing;*
2. *each decreasing $\top$-orbit converges to a fixed-point of f (if no fixed-point exists, then there is no orbit);*
3. *if f is H-monotone and deflationary, then for any maximal fixed-point of f there is a $\top$-orbit converging to it.*

Proof. Let $(x_\alpha)_{\alpha \in I}$ be an orbit of f. Recall that for ordinal α, $x_{\alpha+1} \in f(x_\alpha) \neq \varnothing$. As f is deflationary, $f(x_\alpha) \preceq_H \{x_\alpha\}$. But, by definition of $\preceq_H$, for $x_{\alpha+1} \in f(x_\alpha)$, $x_{\alpha+1} \leq x_\alpha$. For a limit ordinal λ, $x_\lambda = \bigvee_{\alpha<\lambda} x_\alpha$, $\varnothing \neq f(x_\lambda) \preceq_H \{x_\lambda\}$, and, thus, there is $x_{\lambda+1} \in f(x_\lambda)$ such that $x_{\lambda+1} \leq x_\lambda$.

For the second point, as $(x_\alpha)_{\alpha \in I}$ is a decreasing sequence and $|I| > |L|$, by Proposition 2.1 there is an ordinal α such that $x_\alpha = x_{\alpha+1} \in f(x_\alpha)$. That is, x_α is a fixed-point of f.

Finally, for the third point, assume $\bar{x} \in f(\bar{x})$ is a maximal fixed-point of f. Now, let us show by (transfinite) induction on α that there is a decreasing orbit $(x_\alpha)_{\alpha \in I}$ of f s.t. $\bar{x} \leq x_\alpha$ for all α.

The case when $\alpha = 0$. $\bar{x} \leq \top = x_0$.

α successor ordinal. By induction, $\bar{x} \leq x_\alpha$. As f is H-monotone and deflationary,

$f(\bar{x}) \preceq_H f(x_\alpha) \preceq_H \{x_\alpha\}$. But, $\bar{x} \in f(\bar{x})$, so we can choose $x_{\alpha+1} \in f(x_\alpha)$ s.t. $\bar{x} \leq x_{\alpha+1} \leq x_\alpha$.

α limit ordinal. By induction, $\bar{x} \leq x_\beta$ holds for all $\beta < \alpha$, which implies that $\bar{x} \leq \bigvee_{\beta<\alpha} x_\beta = x_\alpha$.

The sequence $(x_\alpha)_{\alpha\in I}$ is decreasing, and, thus, by Proposition 2.1 there is an ordinal α such that $x_\alpha = x_{\alpha+1} \in f(x_\alpha)$. So, x_α is a fixed-point of f with $\bar{x} \leq x_\alpha$. As $\bar{x}$ is maximal, $x_\alpha = \bar{x}$. □

PROPOSITION A.9. *For $f\colon L \to 2^L$, $h(x) = x \otimes f(x)$ is deflationary. Furthermore, if f is H-monotone, then*

1. *h is H-monotone;*
2. *$x \in f(x)$ implies $x \in h(x)$;*
3. *$x \in h(x)$ implies $\{x\} \preceq_H f(x)$;*
4. *if x is a maximal fixed point of h, then x is a maximal fixed point of f;*
5. *if x is a maximal fixed point of f, and f is also deflationary, then x is a maximal fixed point of h.*

Proof. Consider f and h. If $f(x) = \varnothing$, then $\varnothing = h(x) \preceq_H \{x\}$. Otherwise, for $y \in h(x)$, $y \leq x$. Therefore, $h(x) \preceq_H \{x\}$, and, thus, h is deflationary. Now, suppose f is H-monotone.

1. This is easy. h is a combination of H-monotone functions.

2. If $x \in f(x)$, then by definition of h, $x = x \wedge x \in h(x)$.

3. If $x \in h(x)$, then for some $y \in f(x)$, $x = x \wedge y$. Therefore, $x \leq y$ and, thus, $\{x\} \preceq_H f(x)$.

4. Assume x is a maximal fixed-point of h, i.e., $x \in h(x) = x \otimes f(x)$. Therefore, there is $y \in f(x)$ such that $x \leq y$. As f is H-monotone, $f(x) \preceq_H f(y)$. That is, there is $z \in f(y)$ such that $y \leq z$ and, thus, $y = y \wedge z$. Therefore, $y \in h(y)$. As x is maximal and $x \leq y$, $y = x$ follows and, thus, $x \in f(x)$. To prove that x is a maximal fixed-point of f, assume there is $x \leq y$ such that $y \in f(y)$. By point 2, $y \in h(y)$, and, thus, as x is a maximal fixed-point of h, $y = x$ follows.

5. Assume x is a maximal fixed-point of f. By point 2 $x \in h(x)$. To prove that x is a maximal fixed-point of h, assume there is $x \leq y$ such that $y \in h(y)$. Then by point 3 $\{y\} \preceq_H f(y)$ and, thus, $y \in \Psi(f)$. By Proposition 3.7, $y \in f(y)$, and, thus, as x is a maximal fixed-point of f, $y = x$ follows. □

IMPOSSIBILITY RESULTS AND LOWER BOUNDS FOR CONSENSUS UNDER LINK FAILURES*

ULRICH SCHMID†, BETTINA WEISS†, AND IDIT KEIDAR‡

Abstract. We provide a suite of impossibility results and lower bounds for the required number of processes and rounds for synchronous consensus under transient link failures. Our results show that consensus can be solved even in the presence of $O(n^2)$ moving omission and/or arbitrary link failures per round, provided that both the number of affected outgoing and incoming links of every process is bounded. Providing a step further toward the weakest conditions under which consensus is solvable, our findings are applicable to a variety of dynamic phenomena such as transient communication failures and end-to-end delay variations. We also prove that our model surpasses alternative link failure modeling approaches in terms of assumption coverage.

Key words. fault-tolerant distributed algorithms, consensus, transient link failures, impossibility results, lower bounds, assumption coverage analysis

1. Introduction.

Most research on fault-tolerant distributed algorithms conducted in the past rests on process failure models. Every failure occurring in a system is attributed to either the sending or the receiving process here, irrespectively of whether the actual error occurs at this process or rather on the intermediate communication path. Moreover, a process that commits a single failure is often "statically" considered faulty during the whole execution, even if its failure is transient.

Although such process failure models adequately capture many important scenarios, including crash failures, where a faulty process just stops operating, and Byzantine failures, where a faulty process can do anything, they are not particularly suitable for modeling more dynamic phenomena. In particular, given the steadily increasing dominance of communication over computation in modern distributed systems, in conjunction with the high reliability of modern processors and robust operating system designs, transient communication failures such as lost or unrecognized packets (synchronization errors), CRC errors (data corruption), and receiver overruns (packet buffer overflow) are increasingly dominating real-world failures. Another dynamic phenomenon that is encountered frequently in practice is unpredictable variations of the end-to-end delays in multihop networks such as the Internet, which are caused, for example, by temporary network congestion and intermediate router failures. Since excessive end-to-end delays appear as omissions in classic (semi)synchronous systems and other time(out)-based approaches, for example, [3, 4, 5, 53, 7, 51, 43, 39], such timing variations can also be considered as transient link failures.

The distinguishing properties of such failures are (a) that they affect the path (termed the *link* in what follows) connecting two processes, rather than the endpoints

(the processes), and (b) that they are *mobile* [58], as different links may fail at different times. Hence, the ability to communicate (in a timely manner) with other processes in the system cannot be statically attributed to a process here: If the link failure rate is sufficiently high, there will never be a nonempty set of processes that appear nonfaulty to each other, i.e., never send (timing) faulty messages to each other. As a consequence, classic process failure models are inappropriate for such applications.

This paper focuses on impossibility results and lower bounds for synchronous deterministic consensus in the presence of such mobile link failures. In the consensus problem (also called the "Byzantine agreement" problem [47]), processes have to agree on a common output value, despite failures, based on some input values distributed among the processes. Consensus is widely recognized as one of the most fundamental problems in fault-tolerant distributed computing. Synchronous consensus algorithms execute in a sequence of lock-step rounds $k = 1, 2, \ldots$, which consist of sending, receiving, and processing round k messages exchanged among all the processes.

Unfortunately, there is a discouraging impossibility result for deterministic synchronous consensus in the presence of general link failures (see Theorem 1 in section 3), which goes back to Gray's 1978 paper [33] on atomic commitment in distributed databases. This result was strengthened by Santoro and Widmayer [58], who introduced the *mobile omissive process failure model*: In each round, some process can be send-omissive (or omissive for short) in the sense that it can experience any number of transmission failures on its outgoing links. Even a single mobile omissive process failure was shown to render consensus unsolvable [58].

Despite those negative results, however, there are synchronous consensus algorithms for restricted link failure patterns. For example, it has been known for a long time that consensus can be solved when sufficient connectivity is always maintained [20, 37, 46].

More recently, Schmid, Weiss, and Rushby introduced a hybrid failure model for synchronous systems [66] which—in addition to classic process failures—admits up to $O(n^2)$ moving link failures per round. The link failure patterns must be such, however, that no more than f_ℓ^s outgoing links and no more than f_ℓ^r incoming links are affected at any process per round. An analysis of the assumption coverage [62] in the presence of independent, identically distributed probabilistic link failures confirmed that this model is suitable even for substantial link failure rates. Most existing consensus algorithms [48, 32, 47, 10, 68] were shown to work essentially unchanged under this hybrid failure model [65, 71, 14, 64, 11], provided that the number of processes n in the system is increased by $C_r f_\ell^r + C_s f_\ell^s$ for some small integers C_r, C_s that depend on the particular algorithm.

Naturally, the different values of C_r and C_s obtained for different consensus algorithms raised the question of lower bounds, both on the number of failures that can be tolerated and on the number of rounds required to solve consensus. In the present paper, we provide the results of our comprehensive theoretical study of this subject:

1. In section 2, we provide a precise definition of our system model, which involves both moving omission and moving arbitrary link failures (but no process failures).
2. In section 3, we use a refinement of the bivalency proof techniques introduced in [58] for proving a versatile generalization of Gray's result, which reveals the importance of unimpaired *bidirectional* communication for solving consensus.
3. Using this general result, as well as a new instance of an easy impossibility proof [28], we provide a complete suite of impossibility results and lower

bounds for the required number of processes (section 4) and rounds (section 5).

4. In section 6, we show that our lower bounds are tight and characterize the threshold that, when exceeded, turns a correct process exhibiting omission (resp., arbitrary link failures according to our model) into a classic omission (resp., Byzantine faulty process).
5. In section 7, we survey alternative approaches for modeling link failures and analyze their assumption coverage in a simple probabilistic setting. It turns out that our model is the only one with a coverage that approaches 1 (rather than 0) for large n.

Some conclusions and directions of future work in section 8 eventually complete our paper.

2. System model. We consider a system of n distributed *processes*, each identified by a unique id $p \in \Pi = \{1, \dots, n\}$. The processes are fully connected by a point-to-point network made up of unidirectional *links*. Every pair of processes p and $q \neq p$ is hence connected by a pair of links (p, q), from sender process p to receiver process q, and (q, p), from sender process q to receiver process p, which are considered independent of each other. To simplify our presentation, we also assume that there is a link (p, p) from every process $p \in \Pi$ to itself. Our system hence contains n^2 unidirectional links. Links may reorder messages, that is, are not assumed to be FIFO.

2.1. Computing model. For our computing model, we employ the standard lock-step round model as used in [58]. Every process p is modeled as a deterministic state machine—acting on some local state $state_p \in State_p$—that can send and receive messages from some (possibly infinite) alphabet $\mathcal{M}$. The initial state of process p is drawn from a set of initial states $Init_p \subseteq State_p$. All processes execute, in perfect synchrony, a sequence of atomic computing steps forming a sequence of lock-step rounds $k \in K = \{1, 2, \dots\}$: In round k, process p performs the following steps:

1. Initializes its *received messages vector* Rm_p to $\forall q \in \Pi : rm_p[q] = \emptyset$, where $\emptyset$ represents "no message," and sends at most one message $msg_p^k = Msg_p(state_p, k)$ to every process $q \in \Pi$ (including itself); $Msg_p : State_p \times K \to \mathcal{M} \cup \{\emptyset\}$ denotes the *message sending function* of the algorithm executed by p.
2. Waits for some time while receiving messages into Rm_p. This time must be sufficiently long to allow delivery of (most of) the round k messages. We assume that no messages arrive after this waiting period is over; practically, if late messages arrive, they are discarded.
3. Performs a state transition from $state_p$ to $state'_p = Trans_p(state_p, rm_p, k)$, where $Trans_p : State_p \times Rm_p \times K \to State_p$ denotes the *state transition function* of the algorithm executed by p.

Note that the round number k can be viewed as global time in this model and is typically part of $state_p$.

The distributed algorithm executed by the processes is hence specified by the pairs of message sending function and message transition function $\{(Msg_p, Trans_p) | \, p \in \Pi\}$.

The *configuration* C^k of the system at the end of round k is the vector of states $(state_1^k, \dots, state_n^k)$ obtained at the end of round k (after the state transition); the initial configuration is $C^0 = (init_1, \dots, init_n)$ with $\forall p \in \Pi : init_p \in Init_p$. The system-wide $n \times n$ *received messages matrix* $\mathcal{R}^k$ for round k is the column vector

$(rm_1^k, \ldots, rm_n^k)^T$ of all processes' received messages vectors in round k, i.e.,

$$\mathcal{R}^k = \begin{pmatrix} rm_1^k[1] & rm_1^k[2] & \ldots & rm_1^k[n] \\ rm_2^k[1] & rm_2^k[2] & \ldots & rm_2^k[n] \\ \vdots & \vdots & \vdots & \vdots \\ rm_n^k[1] & rm_n^k[2] & \ldots & rm_n^k[n] \end{pmatrix}, \tag{2.1}$$

with entry $rm_p^k[q]$ denoting the message that process p received from process q via its incoming link in round k, or $\emptyset$ if no such message was received.

A *run* (also termed *execution*) of the distributed algorithm is an infinite sequence $C^0, \mathcal{R}^1, C^1, \mathcal{R}^2, \ldots$ of configurations alternating with received messages matrices, starting from some initial configuration $C^0 \in (Init_1, \ldots, Init_n)$.

2.2. Failure model. We assume that all processes are correct,[1] but links may fail transiently.

Consider the system-wide $n \times n$ *sent messages matrix* $\mathcal{S}^k$ for round k, which consists of n identical rows containing the message sent by every process in round k, i.e.,

$$\mathcal{S}^k = \begin{pmatrix} msg_1^k & msg_2^k & \ldots & msg_n^k \\ msg_1^k & msg_2^k & \ldots & msg_n^k \\ \vdots & \vdots & \vdots & \vdots \\ msg_1^k & msg_2^k & \ldots & msg_n^k \end{pmatrix}, \tag{2.2}$$

with msg_p^k denoting the message process p sends to all processes via its outgoing links in round k, or $\emptyset$ if no message is sent.

Clearly, in case of no link failures in round k, $\mathcal{R}^k = \mathcal{S}^k$ since every message sent by p via its outgoing link to q is received faithfully by q via its incoming link from p. A link failure hitting the directed link (p, q) results in $rm_q^k[p] \neq msg_p^k$, however, so $\mathcal{R}^k \neq \mathcal{S}^k$ in this case. As in [58], we distinguish the following types of link failures of (p, q) in a single round k:

- *Correct link:* $rm_q^k[p] = msg_p^k$.
- *Lossy link:* $\emptyset = rm_q^k[p] \neq msg_p^k$.
- *Erroneous link (corruption):* $\emptyset \neq rm_q^k[p] \neq msg_p^k \neq \emptyset$.
- *Erroneous link (spurious):* $\emptyset \neq rm_q^k[p] \neq msg_p^k = \emptyset$.

For some round k, a lossy link is called *omission faulty*, an erroneous link (corrupted or spurious) is termed *arbitrary faulty*. A link producing either type of failure is termed *faulty*.

Our link failure model, originally introduced in [66, 65], is such that, system-wide, up to $c \cdot n^2$ links for some $c < 1$ may be faulty in any round. We cannot allow *any* set of $c \cdot n^2$ links to be hit by link failures, however, but require some restriction on the allowed link failure patterns: Let $\mathcal{F}^k$ be the $n \times n$ *failure pattern matrix* with entries

$$f_q^k[p] = \begin{cases} ok & \text{if } rm_q^k[p] = msg_p^k, \\ om & \text{if } \emptyset = rm_q^k[p] \neq msg_p^k, \\ arb(e) & \text{otherwise, where } e \text{ encodes the type of the actual error,} \end{cases}$$

which is just the difference of $\mathcal{R}^k$ and $\mathcal{S}^k$ interpreted as ok, om, or $arb(e)$ on a per entry basis, depending on the corresponding link behavior. The *feasible* pattern of

[1] Except for section 5, where we also allow process crashes.

system-wide link failures must be such that for every process p and every round k, the following hold:

- (A^r) p's row $(f_p[1], \ldots, f_p[n])$ in $\mathcal{F}^k$ contains at most f_ℓ^r entries $\neq ok$, with at most $f_\ell^{r,a} \leq f_\ell^r$ of those equal to $arb(.)$. Since row p corresponds to p acting as a receiver process, we say that p may perceive at most f_ℓ^r *receive link failures* (on its incoming links), with up to $f_\ell^{r,a}$ arbitrary ones among those.
- (A^s) p's column $(f_1[p], \ldots, f_n[p])^T$ in $\mathcal{F}^k$ contains at most f_ℓ^s entries $\neq ok$, with at most $f_\ell^{s,a} \leq f_\ell^s$ of those equal to $arb(.)$. Since column p corresponds to p acting as a sender process, we say that p may experience at most f_ℓ^s *send link failures* (on its outgoing links), with up to $f_\ell^{s,a}$ arbitrary ones among those.

Note that *every* process in the system may experience up to f_ℓ^s send link failures ($f_\ell^{s,a}$ of them arbitrary), and up to f_ℓ^r receive link failures ($f_\ell^{r,a}$ of them arbitrary) in every round. In addition, the particular links actually hit by a link failure may be different in different rounds. Of course, they may also remain the same, which makes our link failure model, for example, applicable to not fully connected networks as well; cf. [67].

In the above modeling, the primary failure instance is the link failure pattern in the matrix $\mathcal{F}^k$. It determines how many link failures could be experienced by every process, both as a sender (send link failures f_ℓ^s, $f_\ell^{s,a}$) and as a receiver (receive link failures f_ℓ^r, $f_\ell^{r,a}$). Clearly, assumptions (A^r) and (A^s) imply that at most nf_ℓ^s outgoing links and at most nf_ℓ^r incoming links may be hit by a link failure. Since every outgoing link is of course some receiver's incoming link, it follows that the maximum allowed number of link failures occurs when $f_\ell^s = f_\ell^r = f_\ell$.

In our subsequent analysis, however, our assumptions on send link failures, as captured by (A^s) and f_ℓ^s, $f_\ell^{s,a}$, will be independent of the assumptions made on receive link failures, as captured by (A^r) and f_ℓ^r, $f_\ell^{r,a}$. Doing this allows us to extend the range of applicability of our model. In particular, by restricting the assumption "*every* process may commit up to f_ℓ^s send link failures" to "at most f_ℓ^r processes in some fixed subset of the processes may commit up to f_ℓ^s send link failures," we can also model *restricted process failures*: For example, a restricted omission faulty process is perceived as omission faulty only by at most f_ℓ^s receiver processes per round (rather than by all receivers, as allowed in the case of a standard omission faulty process); see section 6 for details.

Note that adding classic process failures to the picture would provide a "fallback" in cases where the link failure restrictions (A^s) and/or (A^r) are violated: As long as the numbers of link failures experienced by a process p do not exceed the thresholds f_ℓ^r, $f_\ell^{r,a}$, f_ℓ^s, and $f_\ell^{s,a}$, process p can be considered correct. Otherwise, p can just be considered faulty, in which case the link failure restrictions of course do not apply. The resulting hybrid perception-based failure model has been applied successfully in the analysis of several different algorithms [66, 65, 71, 14, 64, 72, 11]. In order to focus on the intrinsic costs of link failures, we will not add standard process failures to the model of this paper, however.

2.3. The consensus problem. Binary consensus is the problem of computing a common binary output value from binary input values distributed among all processes. We assume that every process p has a read-only *input value* $x_p \in \{0, 1\}$ in $state_p$, which is supplied via the initial state $init_p \in Init_p$ to p's local instance of a synchronous deterministic distributed consensus algorithm. In addition, p has a write-once *output value* $y_p \in \{0, 1\}$ in $state_p$, initially undefined. Process p irreversibly computes ("decides upon") y_p according to the following requirements:

(C0) *Termination*: Every process decides within a finite number of rounds (that may be different for different processes and may depend on the particular execution).

(C1) *Agreement*: Every two processes p and q compute the same output value $y_p = y_q$.

(C2) *Weak validity* [29]: If all processes start with the same input value, then every process p computes
- $y_p = 1$ if $\forall q : x_q = 1$ and no link failure has occurred in the entire execution,
- $y_p = 0$ if $\forall q : x_q = 0$.

Note that practical consensus algorithms usually guarantee the following stronger validity property:

(C2') *Validity*: If all processes start with the same input value $\forall q : x_q = v$, then every process p computes $y_p = v$.

In particular, $y_p = 1$ in the case of $\forall q : x_q = 1$ even when link failures have occurred. We will employ the weaker form of validity in our proofs most of the time, since impossibility of consensus under (C2) obviously implies impossibility of consensus under (C2') as well.

3. Basic results. In this section, we will provide a generic analysis of consensus in our setting, which essentially follows the approach taken in [58]:[2] Using bivalence arguments, we will show that consensus is impossible if every process p can *withhold* its information from a nonempty subset $Q = Q(p)$ of processes for an arbitrary number of rounds. Withholding is a weaker property than the "adjacency-preserving" property used in [58], however, and so our generic results are slightly stronger than those of [58] and hence need a different proof. In particular, our findings reveal the importance of unimpaired *bidirectional* communication between processes for solving consensus.

In order to motivate the need for restricting failure patterns and to set the stage for our more advanced proofs, we start with Gray's well-known result [33], in the formalization of [50, Thm. 5.1]. It is devoted to the coordinated attack problem, which is just consensus with weak validity (C2) as stated in section 2.3. This result assumes, however, that there are no constraints on the link failure pattern matrices (except that only omission failures are allowed).

THEOREM 1 (Gray's impossibility [50, Thm. 5.1]). *There is no deterministic algorithm that solves the coordinated attack problem in a synchronous* 2*-process system with arbitrary lossy links.*

Proof. Suppose that the failure-free execution $\overline{E}$ of a 2-process system with omission faulty links terminates at the end of round r when starting with initial values $[1, 1]$. By validity, the common decision value must be 1 in $\overline{E}$. Since decisions are irreversible, we can safely drop all the messages some algorithm might send in rounds $> r$ without changing the decision value. The resulting "truncated" execution E shown in Figure 3.1 is obviously feasible.

By means of induction on the number of messages k sent in E, we show that the decision value 1 does not change even when we drop all messages in E: For $k = 0$, the claim holds trivially. For the induction step, assume that $k > 0$ messages are sent in E where both processes decide by some round r and no messages are sent after

[2] Note that we could also have employed the *layering framework* [52] by Moses and Rajsbaum, which provides generic consensus impossibility and lower bound results in a model-independent way. Although similar in its general structure, it is based on quite different lower level "tools," for example, potence instead of valence, which are—contrary to [42]—not required in our relatively simple setting.

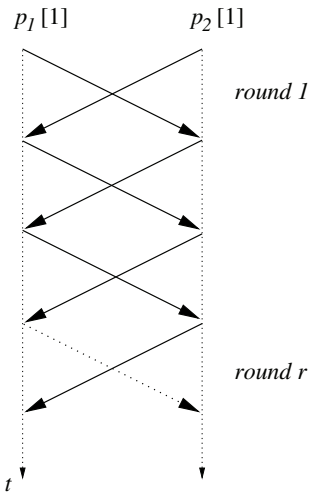

FIG. 3.1. *Execution of a 2-process synchronous consensus algorithm with unrestricted link omission failures, starting with initial values* $[1,1]$*, truncated after round* r *by which both processes decide.*

round r. Let m be the last message from, w.l.o.g., $p_1 \to p_2$ in E (cf. the dotted line in Figure 3.1). If m is dropped, the resulting execution $\overline{E}'$ is indistinguishable from E for p_1, so p_1 and, by agreement, also p_2 must eventually decide upon 1. Clearly, in $\overline{E}'$, process p_2 could decide after round r and even send out additional messages in some round $r' > r$—we can guarantee only that the decision value is the same. However, p_1 has already decided by round r and hence cannot make use of such "late" messages. Consequently, we can safely drop all those late messages in $\overline{E}'$, if any, leading to an execution E' where only $k-1$ messages are sent, both processes decide upon 1 by some round r', and no messages are sent after round r'. We can hence apply the induction hypothesis to E', which completes the induction step.

Since the processes are fully isolated from each other in the resulting execution where all messages have been dropped, changing the initial values to $[1,0]$ and then to $[0,0]$ cannot affect the decision value either, but now the outcome of the final execution would violate validity. □

As our first "real" result, we will now show that solving consensus is even impossible when a link—viewed as a pair of unidirectional links—loses or, in case of arbitrary link failures, corrupts messages only in one direction, i.e., when either process (but not necessarily both) can withhold information for an arbitrary number of rounds from the other. Eventually bidirectional communication is hence mandatory for any deterministic consensus algorithm. Solutions exist, however, if the direction of the message loss is fixed; see the remarks following Theorem 2 below.

Unfortunately, this stronger result cannot be shown by generalizing the proof of Theorem 1: We are not allowed to simply drop all messages in later rounds to "hide" the effect of dropping/restoring round r-messages here, since this would amount to a link failure in both directions and hence an infeasible execution. It was shown in [58], however, that bivalency arguments [29] can successfully be applied in this setting.

We start with some notation: Recall that we defined an execution as an infinite sequence $C^0, \mathcal{R}^1, C^1, \mathcal{R}^2, \ldots$ of configurations alternating with received message matrices, starting from some initial configuration $C^0 \in (Init_1, \ldots, Init_n)$. For a con-

figuration $C^k = (c_1^k, \ldots, c_n^k)$, let $state_p(C^k) = c_p^k$ denote the local state of process p in C^k. Since we are dealing with deterministic algorithms, executions are uniquely determined by the initial configuration, i.e., the initial values x_p for all processes p, and the sequence of link failure pattern matrices $\mathcal{F}^k$ in rounds $k \geq 1$. Consequently, we can unambiguously specify executions as infinite sequences $C^0, \mathcal{F}^1, C^1, \mathcal{F}^2, \ldots$ of configurations alternating with failure pattern matrices. Moreover, a finite sequence of failure pattern matrices $\mathcal{F}_x = \mathcal{F}^k, \ldots, \mathcal{F}^{k+x}$ starting from configuration C^{k-1} uniquely determines the finite *execution segment* $C^{k-1}, \mathcal{F}^k, C^k, \mathcal{F}^{k+1}, C^{k+1}, \ldots, \mathcal{F}^{k+x}, C^{k+x}$, and we write $C^{k+x} = \mathcal{F}_x(C^{k-1})$. An execution is called *feasible* if all $\mathcal{F}^k$ are feasible, i.e., adhere to the link failure pattern constraints (A^r) and (A^s) in section 2.2. Finally, a configuration C' is called *reachable* from configuration C if there is a feasible finite sequence of failure pattern matrices $\mathcal{F}_x$ such that $C' = \mathcal{F}_x(C)$. A configuration C is reachable if it is reachable from some initial configuration.

A configuration is called *v-decided* (*decided* for short) if all processes have decided on a common decision value $v \in \{0, 1\}$. A configuration C is *v-valent* (*univalent* if v is not known or irrelevant) if all decided configurations reachable from C are v-decided; in particular, it is impossible to reach a 1-decided configuration from a 0-valent C. On the other hand, C is *bivalent* if both 0-decided and 1-decided configurations can be reached from C.

For example, in the case of $n = 2$, given any configuration $C^{k-1} = (c_1^{k-1}, c_2^{k-1})$, there are only four possible *successor configurations* C_{00}^k, C_{01}^k, C_{10}^k, and C_{11}^k in the case of message omissions: Configuration C^{k-1} is followed by the successor configuration C_{xy}^k, depending on whether the message $p_2 \to p_1$ (x) and/or $p_1 \to p_2$ (y) is lost $(x, y = 0)$ or correct $(x, y = 1)$ in round $k \geq 1$.[3] Note that C_{00}^k is feasible only in the setting of Theorem 1, where unrestricted losses are allowed, since both messages are lost there. In the context of Theorem 2, however, C_{00}^k cannot be reached from C^{k-1} since losing both messages is not feasible.

The situation is more complicated in case of arbitrary link failures, however, where C^{k-1} can have more than four successor configurations: After all, different errors e, experienced, for example, by the message from $p_2 \to p_1$ due to an arbitrary link failure with $f_1^k[2] = arb(e)$ in the failure pattern matrix $\mathcal{F}^k$, might result in different states of p_1. Fortunately, we can keep the convenient assumption of just four successors if we replace a single successor state C_{xy}^k by the set of possible successor states. Using this extended interpretation, C_{01}^k actually consists of all configurations reachable from C^{k-1}, where only the message $p_2 \to p_1$ is lost or erroneous, for example. Univalence of a set of configurations C_{xy}^k means that all individual configurations $C^k \in C_{xy}^k$ are univalent, whereas bivalence means that at least one individual configuration $C^k \in C_{xy}^k$ is bivalent. Bivalence proofs are easily generalized to this extended interpretation.

Finally, our notation can be easily generalized to $n > 2$: (Sets of) successor configurations are indexed by strings of $n(n-1)$ 0's or 1's, corresponding to every link in a system of n processes, with 0 denoting a lost or faulty message, and 1 denoting a nonfaulty one.

Two successor configurations C_v^k and C_w^k are called *neighbors* if the received message matrices $\mathcal{R}_v^k$ and $\mathcal{R}_w^k$ that lead to C_v^k and C_w^k, respectively, differ in at most one entry: W.l.o.g., this entry contains the correct message in $\mathcal{R}_v^k$ but a lost/erroneous one in $\mathcal{R}_w^k$. Consequently, all configurations in C_{00}^k and C_{01}^k are neighbors in the

[3] Message "self-transmission," from $p_1 \to p_1$ and $p_2 \to p_2$, is always assumed to be failure-free here. Since we are dealing with impossibility results and lower bounds, this can safely be assumed.

above system, but the ones in C^k_{01} and C^k_{10} are not. The *successor graph* $\mathcal{G}_C$ of some configuration C consists of all successor configurations of C, where all neighbors are connected by an edge. We can make the following well-known observation.

LEMMA 1. *The successor graph $\mathcal{G}_C$ of any configuration C of a consensus algorithm under our system model is connected.*

Proof. Let $k \geq 1$ be the round at the end of which the transition from C to one of its successor configurations takes place. Obviously, the failure-free successor configuration $C_{1..1}$ where no round k messages has been lost or corrupted must be in $\mathcal{G}_C$. Let C_X be any other successor configuration caused by a feasible link failure pattern, with $\overline{\mathcal{M}}_X$ denoting the corresponding set of lost or faulty messages. Since the link failure pattern $\overline{\mathcal{M}}'_X$, obtained from $\overline{\mathcal{M}}_X$ by removing (= repairing) exactly one of the lost or faulty messages, is of course also feasible, the resulting successor configuration C'_X is a neighbor of C_X and obviously $C'_X \in \mathcal{G}_C$. Since $|\overline{\mathcal{M}}'_X| = |\overline{\mathcal{M}}_X| - 1$, this argument can be repeated until the failure-free successor configuration $C'_X = C_{1..1}$ is reached. Hence, there is a path from any C_X to $C_{1..1}$ in the successor graph $\mathcal{G}_C$. □

The result of Lemma 1 will be used primarily in conjunction with Lemma 2.

LEMMA 2. *Suppose that all successor configurations of some configuration C with successor graph $\mathcal{G}_C$ are univalent. If there are two arbitrary successor configurations C' and C'' among those that are* 0*-valent and* 1*-valent, respectively, then there are also two* neighboring *successor configurations $\overline{C}'$ and $\overline{C}''$ that are* 0*-valent and* 1*-valent.*

Proof. Since C' and C'' are connected in $\mathcal{G}_C$ and have different valences, there is a path of configurations connecting C' and C''. This implies that there must be neighbors $\overline{C}'$ and $\overline{C}''$ on this path where the valence changes. □

With these two lemmas, it is fairly easy to show that eventually bidirectional communication is mandatory for solving consensus in a 2-process system: Theorem 2 considers link omission failures only (that may change arbitrarily from round to round, however) and strengthens Gray's theorem, Theorem 1. Note that it could also be derived from the impossibility of consensus under a single moving process omission failure [58] in a system of $n = 2$ processes.

THEOREM 2 (unidirectional 2-process impossibility). *There is no deterministic algorithm that solves consensus in a synchronous system with two nonfaulty processes connected by a lossy link, even if communication is reliable in one direction in every round.*

Proof. Assume that there are algorithms $\mathcal{A}_{p_1}$ and $\mathcal{A}_{p_2}$ running on processes p_1 and p_2 that jointly solve consensus in a 2-process system with unidirectional communication. We will show inductively that every bivalent configuration has at least one bivalent successor. This implies that it is impossible to always reach a final decision within any finite number of rounds.

For the base case $k = 0$ of our inductive construction, we have to show that there is a bivalent initial configuration. Consider the configuration $C^0(01)$, where p_1 starts with initial value 0 and p_2 starts with initial value 1. If $C^0(01)$ is bivalent, we are done. If $C^0(01)$ is 0-valent, the execution where all messages from $p_1 \to p_2$ are lost in all rounds must also lead to a 0-decided configuration. However, this execution is indistinguishable for p_2 from the equivalent execution that starts from $C^0(11)$ (where p_1 has initial value 1 instead of 0), which implies that the common decision value must also be 0 here. Since $C^0(11)$ must lead to a 1-decided configuration in case of no link failures by validity, we have shown that $C^0(11)$ is bivalent in this case. An analogous argument can be used to show that $C^0(00)$ would be bivalent when $C^0(01)$

is 1-valent.

For the induction step $k \geq 1$, we assume that we have already reached a bivalent configuration C^{k-1} at the end of round $k-1$ and show that at least one of the feasible successor configurations C^k_{01}, C^k_{10}, and C^k_{11} reached at the end of round k is bivalent. Assuming the contrary, all of those must be univalent. The bivalence of C^{k-1} implies that at least one of C^k_{01}, C^k_{10}, and C^k_{11} must be 0-valent and one must be 1-valent (i.e., C^{k-1} must be a *fork* [69]). By Lemma 2 in conjunction with Lemma 1, either the neighbors C^k_{11} and C^k_{01}, or else C^k_{11} and C^k_{10} must be v-valent and $(1-v)$-valent, respectively. W.l.o.g. assume that C^k_{11} is v-valent and C^k_{01} is $(1-v)$-valent for some $v \in \{0,1\}$. Since the only difference between those two configurations is that the message from $p_2 \to p_1$ arrives in the former but not in the latter, we consider the execution C^{k*}_{11}, where all messages from $p_1 \to p_2$ are lost in all rounds $> k$. As p_1 cannot tell p_2 whether it has received a round k message, the execution C^{k*}_{11} starting from C^k_{11} is indistinguishable for p_2 from the same execution starting from C^k_{01}. Since p_2 must eventually decide upon the same value, C^k_{11} and C^k_{01} cannot have different valences. □

Remarks.

1. If message losses can occur only in one direction, and if that direction is known to the algorithm, then there is a trivial 1-round algorithm that solves consensus in a 2-process system: The process that can communicate with its peer sends its own value and decides upon it; the other process decides upon the value received from its peer.
2. If message losses can occur only in one and the same but unknown direction, there is a simple 2-round algorithm that solves consensus in a 2-process system: Every p_i initially sets $v_i := x_i$. In the first round, p_1 sends v_1 to p_2. If p_2 receives v from p_1, it sets $v_2 := v$. In the second round, p_2 sends its value v_2 to p_1. If p_1 receives v from p_2, it sets $v_1 := v$. At the end of the second round, process p_i, $i = 1, 2$, decides upon v_i. It is easy to verify that the decision values satisfy validity and agreement.

Our next goal will be to show that consensus cannot be solved in any system of $n \geq 2$ processes if, for every process, bidirectional communication with every peer cannot eventually be guaranteed. More specifically, we will show that this is the case when every process p can *withhold* its information from some nonempty subset $\mathcal{Q} = \mathcal{Q}(p)$ of processes (but not necessarily vice versa) from any round $k+1$ on, namely, when there is a sequence of failure pattern matrices for rounds $k+1, k+2, \ldots$ such that every $q \in \mathcal{Q}$ has the same view of the resulting execution after round $k+x$, independently of the state of p in the starting configuration C^k.

DEFINITION 1 (withholding). *A process p, in some reachable configuration C^k, can* withhold its information from round $k+1$ on*, if there is an infinite sequence of failure pattern matrices $\mathcal{F} = \mathcal{F}^{k+1}, \mathcal{F}^{k+2}, \ldots$ and a nonempty set $\mathcal{Q}$ of processes with $p \notin \mathcal{Q}$ (where both $\mathcal{F}$ and $\mathcal{Q}$ may depend on p and C^k) such that, for any reachable configuration $\overline{C}^k$ with $\forall q \in \mathcal{Q} : state_q(C^k) = state_q(\overline{C}^k)$, there exists an infinite sequence of failure pattern matrices $\overline{\mathcal{F}} = \overline{\mathcal{F}}^{k+1}, \overline{\mathcal{F}}^{k+2}, \ldots$ such that $\forall q \in \mathcal{Q} : state_q\big(\mathcal{F}_x(C^k)\big) = state_q\big(\overline{\mathcal{F}}_x(\overline{C}^k)\big)$ for any finite prefix $\mathcal{F}_x = \mathcal{F}^{k+1}, \ldots, \mathcal{F}^{k+x}$ of $\mathcal{F}$ and $\overline{\mathcal{F}}_x = \overline{\mathcal{F}}^{k+1}, \ldots, \overline{\mathcal{F}}^{k+x}$ of $\overline{\mathcal{F}}$.*

We say that p can withhold its information *if it can withhold its information from round $k+1$ on, for every $k \geq 0$, starting from any reachable configuration C^k.*

Definition 1 implies that if p can withhold its information, then, since $|\mathcal{Q}| \geq 1$,

there is at least one process $q = q(p)$ which never gets any useful information from p at all during $\mathcal{F}$—neither directly nor indirectly via other processes.

It is important to note that withholding is a weaker property than *adjacency-preserving*, on which the generic results of [58] are based: The latter requires that *all* processes $\neq p$ have the same state in $\mathcal{F}_x(C^k)$ and $\mathcal{F}_x(\overline{C}^k)$, i.e., correspond to p withholding its state from *every* $q \neq p$. Consequently, adjacency-preserving implies withholding, but not vice versa. In fact, the proofs of Theorems 3 and 6 will show that withholding—but not adjacency-preservation—is possible under our failure model for certain parameter values. Basically, this is due to some "unidirectional" partitioning of the n processes in the system, which is possible when (A^s) and (A^r) hold, provided that n is small enough.

As a consequence, we cannot use the generic consensus impossibility results from [58]. The following Lemma 3 reveals, however, that the ability of every process p to withhold its information from some nonempty subset of the processes arbitrarily long already prohibits a solution to the consensus problem.

LEMMA 3 (n-process impossibility). *Consider a synchronous n-process system with omission and/or arbitrary link failures. There is no deterministic algorithm that solves consensus in such a system if any process p can withhold its information in any configuration.*

Proof. The proof is a generalization of the proof of Theorem 2, although more involved: We assume here that there are n algorithms $\mathcal{A}_1, \ldots, \mathcal{A}_n$ running on the n processes $p_1, \ldots, p_n$ in the system that jointly solve consensus. We will show inductively that there is an infinite execution involving bivalent configurations only, which makes it impossible to always reach a decision within a finite number of rounds.

For the base case $k = 0$ of our inductive construction, we have to show that there is a bivalent initial configuration C^0. As in [29], we consider the initial configuration $C^0(111..1)$, where all processes start with the initial value 1. If this configuration is bivalent, we are done. Otherwise, $C^0(111..1)$ can only be 1-valent, since validity requires a decision value 1 in the failure-free case. Now consider $C^0(011..1)$, where process p_1 starts with 0 and all others with 1. If this configuration is bivalent, we are done. If not, we assume first that it is 0-valent and choose the execution starting from $C^0(011..1)$ where p_1 withholds its value from some process $q(p_1) = p_x \neq p_1$; such an execution must exist according to Definition 1 since p can withhold its information. This execution is indistinguishable for p_x from the analogous execution starting from $C^0(111..1)$, however, so p_x's (and hence the common) decision must be 1 here. This contradicts the stipulated 0-valence of $C^0(011..1)$, however, which could hence only be 1-valent.

The whole argument can now be repeated for p_2 in place of p_1, etc., until either a bivalent initial configuration has been found or the 1-valent initial configuration $C^0(0..001)$ has been reached; in $C^0(0..001)$, the processes $p_1, \ldots, p_{n-1}$ start with 0 and p_n starts with 1. We again consider the execution where p_n withholds its information from some process $q(p_n) = p_y \neq p_n$. For p_y, this execution is indistinguishable from the same one starting from $C^0(0..000)$, which must lead to a decision value of 0 by weak validity (C2). This contradicts the stipulated 1-valence of $C^0(0..001)$, however.

For the induction step $k \geq 1$, we assume that we have already reached a bivalent configuration C^{k-1} at the end of round $k-1$. We must show that at least one of the feasible successor configurations C^k that can be reached at the end of round k is bivalent. If this is true in the first place, we are done. If not, all successor configurations C^k must be univalent. However, the bivalence of C^{k-1} implies that at least

one of those must be 0-valent and one must be 1-valent (i.e., C^{k-1} must be a *fork* [69]). By Lemma 2, there must also be 0-valent and 1-valent successor configurations C_0^k and C_1^k, respectively, that are neighbors. Assume that they differ only in the state of process r that has some specific round k message correct in C_0^k but incorrect in C_1^k (or vice versa). Now consider the two executions starting with C_0^k and C_1^k, where r withholds its round k information from some process $q(r) = p_z \neq r$ in any future round $> k$. They are indistinguishable for p_z, which means that p_z and, by agreement, all other processes must compute the same decision in both executions. This contradicts the stipulated different valences of C_0^k and C_1^k, however. □

Lemma 3 has a number of important consequences. First, it reveals an interesting asymmetry in the "severeness" of receive link failures (A^r) versus send link failures (A^s). This can be seen by considering two instances of a 3-process system, where two processes A, B cannot communicate bidirectionally due to receive and/or send link failures: In the system shown in Figure 3.2 (called of type R), processes A and B may not receive the messages from both peers due to excessive receive link failures ($f_\ell^r = 2$ and $f_\ell^s = 1$). In the system shown in Figure 3.3 (of type S), processes A and B may fail to send to both peers due to excessive send link failures ($f_\ell^r = 1$ and $f_\ell^s = 2$).

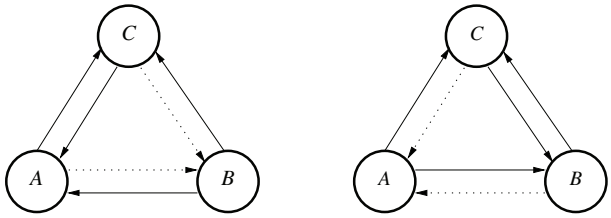

FIG. 3.2. *3-process system (type R), where processes A and B cannot communicate in one direction due to excessive receive link failures ($f_\ell^r = 2$ and $f_\ell^s = 1$). The left scenario shows the case $A \not\rightarrow B$ and the right one $B \not\rightarrow A$, which may alternate arbitrarily.*

It follows from Lemma 3 that no algorithm can solve consensus in a system of type R, even if process C is fixed and known to the algorithm. For, since A may fail to receive any information from any other process in the system, choosing $q(p) = A$ secures withholding by every $p \neq A$. Similarly, since B may also fail to receive the information from any peer, it provides the required $q(p)$ for withholding by process $p = A$. Hence, consensus is impossible in a 3-process system with $f_\ell^r = 2$ and $f_\ell^s = 1$; note that C is not fixed here, which makes consensus even harder to solve.

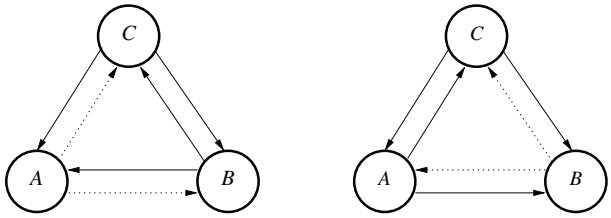

FIG. 3.3. *3-process system (type S), where processes A and B cannot communicate in one direction due to excessive send link failures ($f_\ell^r = 1$ and $f_\ell^s = 2$). The left scenario shows the case $A \not\rightarrow B$ and the right one $B \not\rightarrow A$, which may alternate arbitrarily.*

On the other hand, for systems of type S where C is fixed and known to the algorithm, there is a trivial solution that lets all processes decide upon the value of

process C. If process C is fixed but not known, consensus can be solved by means of the algorithm described in [34]. No solution exists in a system of type S only if C is not fixed—as is the case in a 3-process system with $f_\ell^r = 1$ and $f_\ell^s = 2$.

As a final remark, we note that the above observations are in accordance with the results of [43], where it was shown that bounded-time consensus is impossible in the $\diamond$MFM ("majority from majority") link timing model.

4. Number of processes. Using the results of section 3, we will first establish a lower bound for purely omissive link failures ($f_\ell^{r,a} = f_\ell^{s,a} = 0$).

For the special case $f_\ell^s = f_\ell^r = f_\ell > 0$, such a lower bound can be inferred from Theorem 2 (even from Theorem 1) by a straightforward simulation-type proof: Assume that there is a deterministic algorithm $\mathcal{C}$ that solves consensus for $n = 2f_\ell$. Using $\mathcal{C}$, it is possible to construct a solution for consensus in a 2-process system with lossy links, which is impossible, however.

The detailed proof is as follows: Partition the n processes into two subsets P_A and P_B of size f_ℓ each. Two *superprocesses* A and B are used to simulate the execution of the processes in P_A and P_B, respectively. All the links between the simulated processes in the two superprocesses are routed over a single *superlink*. For a superprocess's decision value, any simulated process's decision value can be taken. In order to ensure that $\mathcal{C}$ achieves consensus among all (simulated) processes, we must show that our link failure assumptions are not violated for any simulated process in any superprocess in case of a superlink failure: Any simulated process must not get more than $f_\ell^r = f_\ell$ receive link failures and must not produce more than $f_\ell^s = f_\ell$ send link failures. This is trivially satisfied since $f_\ell^s = f_\ell^r = f_\ell$, however. Hence, our solution would achieve consensus among the two superprocesses, which violates Theorem 2 (even Theorem 1, since bidirectional partitioning could happen here).

For the general case of arbitrary f_ℓ^s and f_ℓ^r, the lower bound for omission link failures can immediately be derived from Lemma 3.

THEOREM 3 (lower bound processes 1). *Any deterministic algorithm that solves consensus under our system model with $f_\ell^s, f_\ell^r > 0$ needs $n > f_\ell^r + f_\ell^s$.*

Proof. We first show that, for any process p, we can arbitrarily choose a set $\mathcal{P}$ of f_ℓ^r processes including p, where no process in $\mathcal{P}$ sends any messages to a process in $\mathcal{Q} = \Pi \backslash \mathcal{P}$ in case of $n = f_\ell^s + f_\ell^r$ in some feasible execution: Since there are $f_\ell^s \geq 1$ processes in $\mathcal{Q}$, every process in $\mathcal{P}$ may commit send link failures that omit all processes in $\mathcal{Q}$. Any process in $\mathcal{Q}$ thus experiences exactly f_ℓ^r receive link failures, which is also feasible with respect to our failure model. Hence, there is no information flow from processes in $\mathcal{P}$ to processes in $\mathcal{Q}$ at all, such that every process p can trivially withhold its information. According to Lemma 3, solving consensus is impossible here. ∎

Remarks.

1. According to Corollary 1 in section 6, the lower bound $n > f_\ell^r + f_\ell^s$ provided by Theorem 3 is tight; it is, for example, matched by the authenticated algorithm ZA [65].
2. The result of Theorem 3 implies that, in order to be able to solve consensus, link failures (A^s) and (A^r) may affect at most a minority of processes only. In the setting of Gray's theorem, Theorem 1, however, there is no point in considering this case at all: There is no nonempty minority of processes for $n = 2$. Focusing on overly simple cases hence sometimes hides ways of escaping impossibility results.

In order to find a lower bound for arbitrary link failures, we will again start with

the special case $f_\ell^s = f_\ell^r = f_\ell^{s,a} = f_\ell^{r,a} = f_\ell > 0$. Our derivation will be based on Theorem 4, which shows that no algorithm can solve consensus (with validity (C2')) in a 4-process system in the presence of a single arbitrary link failure per process ($f_\ell^{r,a} = f_\ell^{s,a} = 1$).

THEOREM 4 (4-process impossibility). *There is no deterministic algorithm that solves consensus with validity* (C2') *under our system model for a single arbitrary link failure in a* 4*-process system.*

Proof. We employ a new instance of the "easy impossibility proof techniques" of [28] to show that any deterministic algorithm violates agreement if every process may see an inconsistent value from one of its neighbors. Suppose that our four processes execute a distributed algorithm consisting of specific programs A, B, C, D, which solve consensus under our system model with $f_\ell^{r,a} = f_\ell^{s,a} = f_\ell^s = f_\ell^r = 1$. In order to derive a contradiction, we arrange eight processes in a cube as shown in Figure 4.1. For example, the lower leftmost process labeled $A[0]$ executes algorithm A starting with initial value 0 (the $\boxed{0}$ on its left displays this process's decision value, as explained below). Note carefully that all processes and all links are assumed to be nonfaulty here.

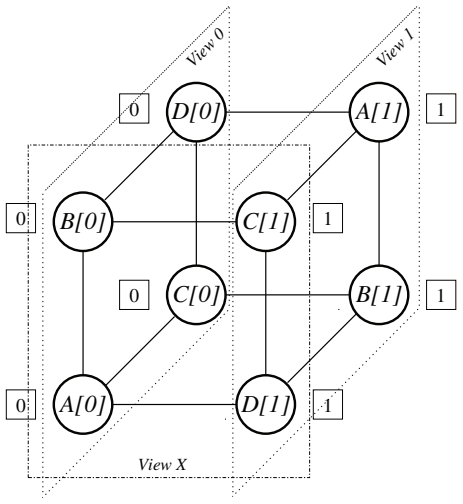

FIG. 4.1. *Topology used for proving the violation of agreement in a* 4*-process system. Eight nonfaulty processes with perfect links are arranged in a cube in a neighborhood-preserving way. The assignment of initial values ensures that all processes in view* 0 *(resp., view* 1*) decide* 0 *(resp.,* 1*), but this violates agreement in view* X*.*

Of course, dealing with a solution for a 4-process system, we cannot expect to achieve consensus in the 8-process system of Figure 4.1. However, due to the special assignment of algorithms to processes, each process observes a neighborhood as in a 4-process system. More specifically, the four processes at any side of the cube (we call it a *view*) can be interpreted as an instance of a legitimate 4-process system. In fact, as can be checked easily, our assignment ensures that any process in a view is connected to exactly one process outside this view. Since we assumed that every process may see an arbitrary faulty input from at most one neighbor, the input from the process outside the view may be arbitrary—it just appears as a process the links of which deliver arbitrary faulty messages.

Now consider the processes in view 0, which all have initial value 0. By the validity

property for consensus, all processes must decide 0 here (the initial value 1 of the processes outside view 0 does not matter, as the links to them are considered arbitrary faulty with respect to view 0). Similarly, in view 1, all processes must decide 1 since they have initial value 1. But now the processes in view X face a problem: Since e.g., the lower leftmost process $A[0]$ observes exactly the same messages in view X as in view 0 by construction, it must decide 0 as observed above. Similarly, as the lower rightmost process $D[1]$ observes exactly the same messages in view X as in view 1, it must decide 1—but this would violate agreement in the 4-process system corresponding to view X. We hence established the required contradiction, thereby completing the proof of Theorem 4. □

Using Theorem 4, a similar simulation-type argument as in the pure omission failure case can be used to show the lower bound $n > 4f_\ell$ for $f_\ell^s = f_\ell^{s,a} = f_\ell^r = f_\ell^{r,a} = f_\ell > 0$ arbitrary link failures. Corollary 1 in section 6 reveals that this lower bound is also tight; it is, for example, matched by the nonauthenticated algorithm OMH [66, 65].

THEOREM 5 (lower bound processes 2). *Any deterministic algorithm that solves consensus with validity* (C2') *under our system model with* $f_\ell^r = f_\ell^s = f_\ell^{s,a} = f_\ell^{r,a} = f_\ell > 0$ *needs* $n > 4f_\ell$.

Proof. Assume that there is a deterministic algorithm $\mathcal{C}$ that solves consensus for $n = 4f_\ell$ in our model. We use $\mathcal{C}$ to construct a solution for a 4-process system of Theorem 4, which provides the required contradiction.

We partition the set of all processes P into four subsets P_A, P_B, P_C, P_D of the same cardinality f_ℓ, and we let each *superprocess* A, B, C, D simulate all the instances of the algorithm in the respective subset. For the superprocess's decision value, any simulated process's decision value can be taken. In order to ensure that $\mathcal{C}$ achieves consensus among all (simulated) processes, we must show that our link failure assumptions are not violated for any process in any superprocess if at most one superlink per process may experience an arbitrary link failure. Since any superlink hosts the links to and from exactly f_ℓ processes, this is trivially fulfilled, however: In case of a superlink failure, every sender process commits at most f_ℓ send link failures (affecting the f_ℓ processes in the receiving superprocess), and every receiver process experiences at most f_ℓ receive link failures (from the f_ℓ processes in the sending superprocess).

Therefore, we have constructed an implementation of a consensus algorithm for a 4-process system which can withstand a single arbitrary link failure. Since this is impossible by Theorem 4, the proof of Theorem 5 is completed. □

Unfortunately, we did not find an easy way to generalize the above simulation-type argument for an arbitrary number $f_\ell^s, f_\ell^{s,a}, f_\ell^r, f_\ell^{r,a} \geq 0$ of link failures (and weak validity (C2)). In order to derive a lower bound for n for this general case, we must hence resort to our key lemma, Lemma 3, again. What needs to be shown here, however, is that every process p can withhold its information: Lemma 5 below will prove that as many as $f_\ell^r + f_\ell^{r,a}$ processes can withhold their information from as many as $f_\ell^s + f_\ell^{s,a}$ processes in case of $n = f_\ell^r + f_\ell^{r,a} + f_\ell^s + f_\ell^{s,a}$, provided that

$$\frac{f_\ell^{r,a}}{f_\ell^r} = \frac{f_\ell^{s,a}}{f_\ell^s}. \tag{4.1}$$

Hence, by Lemma 3, $n > f_\ell^r + f_\ell^{r,a} + f_\ell^s + f_\ell^{s,a}$ is a lower bound for solving consensus if (4.1) holds. If (4.1) does not hold, there are cases where consensus can be solved also for $n \leq f_\ell^r + f_\ell^{r,a} + f_\ell^s + f_\ell^{s,a}$. A lower bound in this case is $n > \overline{f}_\ell^r + \overline{f}_\ell^{ra} + \overline{f}_\ell^s + \overline{f}_\ell^{sa}$,

however, where $\overline{f}_\ell^{\,r} \le f_\ell^r$, $\overline{f}_\ell^{\,ra} \le f_\ell^{r,a}$, $\overline{f}_\ell^{\,s} \le f_\ell^s$, $\overline{f}_\ell^{\,sa} \le f_\ell^{s,a}$ are such that (4.1) holds and n is maximal (see the comments prior to Theorem 6 for details).

Diving into the details of our lower bound proof, we start with a simple "balls and boxes" technical lemma. It shows that it is possible to drop white, orange, and purple balls into a matrix such that each row and each column contain some specific numbers of balls of each color. This result will be used subsequently to assert the existence of a certain mapping of send and receive link failures, by interpreting a white, orange, and purple ball as a correct, omission faulty, and arbitrary faulty transmission between a particular sender process (column index) and receiver process (row index).

LEMMA 4 (balls and boxes). *Consider a matrix with $s + s^a$ rows and $r + r^a$ columns, where $s \ge s^a > 0$, $r \ge r^a > 0$, and*

$$r/r^a = s/s^a. \tag{4.2}$$

Then it is possible to drop white, orange, and purple balls into the matrix (one ball per entry) such that any single row contains exactly r^a white, $r - r^a$ orange, and r^a purple balls, whereas any single column contains exactly s^a white, $s - s^a$ orange, and s^a purple balls.

Proof. First, we note that summing up the number of balls of the same color by rows and columns, respectively, in any such assignment yields the same result: For example, we need $w_r = (s + s^a)r^a$ white balls when summing over rows and $w_c = s^a(r+r^a)$ white balls when summing over columns. Since (4.2) implies $sr^a = s^a r$, it follows that $w_r = w_c$. We will now construct such an assignment explicitly.

Consider the first row in our matrix, and let

$$\pi_0, \pi_1, \ldots, \pi_{r+r^a-1}$$

with $\pi_i \in \{\mathit{white}, \mathit{orange}, \mathit{purple}\}$ be its assignment of balls to places according to the following rule: For any integer $x \ge 0$,

$$\pi_x = \begin{cases} \mathit{orange} \vee \mathit{purple} & \text{if } x = c(i) \text{ for some integer } i \ge 0, \\ \mathit{purple} & \text{iff } x = c\big(a(j)\big) \text{ for some integer } j \ge 0, \\ \mathit{white} & \text{otherwise,} \end{cases}$$

where

$$\begin{aligned} c(i) &= \left\lfloor \frac{r + r^a}{r} \cdot i \right\rfloor, \\ a(j) &= \left\lfloor \frac{r}{r^a} \cdot j \right\rfloor, \\ p(j) = c\big(a(j)\big) &= \left\lfloor \frac{r + r^a}{r} \cdot \left\lfloor \frac{r}{r^a} \cdot j \right\rfloor \right\rfloor. \end{aligned}$$

This assignment distributes colored (orange or purple), as well as purple balls alone, as regularly as possible over the $r + r^a$ available places in the first row. The following periodicity properties are immediately apparent from the above definitions: For $0 \le i \le r - 1$, $0 \le j \le r^a - 1$, and any integer $y \ge 0$,

$$0 \le c(i) \le r + r^a - 1 \quad \text{and} \quad c(i + r) = c(i) + r + r^a, \tag{4.3}$$

$$0 \le p(j) \le r + r^a - 1 \quad \text{and} \quad p(j + r) = p(j) + r + r^a, \tag{4.4}$$

$$\pi_{y+r+r^a} = \pi_y. \tag{4.5}$$

From the properties of $c(i)$ and $p(j)$, it follows immediately that $\pi_0, \pi_1, \ldots, \pi_{r+r^a-1}$ contains exactly r colored balls and r^a white ones. Clearly, every cyclic permutation (rotation) $\pi_y, \pi_{y+1}, \ldots, \pi_{y+r+r^a-1}$ of the original $\pi_0, \pi_1, \ldots, \pi_{r+r^a-1}$ has this property as well. Note that index addition in this cyclic permutation should actually be modulo $r + r^a$; (4.5) reveals that this is automatically taken care of, however. Below, we will assign $\pi_y, \pi_{y+1}, \ldots, \pi_{y+r+r^a-1}$ to row y of our matrix to prove our lemma.

By using the equivalences $(r + r^a)/r = (s + s^a)/s$ and $r/r^a = s/s^a$, which follow immediately from (4.2), in the definitions of $c(i)$ and $p(i)$, we obtain similar periodicity properties for $0 \le i \le s-1$, $0 \le j \le s^a - 1$, and any integer $x \ge 0$:

$$0 \le c(i) \le s + s^a - 1 \quad \text{and} \quad c(i+s) = c(i) + s + s^a, \tag{4.6}$$

$$0 \le p(j) \le s + s^a - 1 \quad \text{and} \quad p(j+s) = p(j) + s + s^a, \tag{4.7}$$

$$\pi_{x+s+s^a} = \pi_x. \tag{4.8}$$

As before, this implies that $\pi_0, \pi_1, \ldots, \pi_{s+s^a-1}$ contains exactly s colored balls and s^a white ones. Even more, the periodicity properties (4.6) and (4.7) imply that every cyclic permutation (rotation) $\pi_x, \pi_{x+1}, \ldots, \pi_{x+s+s^a-1}$ of $\pi_0, \pi_1, \ldots, \pi_{s+s^a-1}$ has this property as well; again, (4.8) takes care of index addition modulo $s + s^a$.

Hence, we just have to assign $\pi_y, \pi_{y+1}, \ldots, \pi_{y+r+r^a-1}$ to row y of our matrix, meaning that the entry in column 0 of row y contains the same ball as the entry in column y of row 0, for example. Our findings on the number of balls in cyclic permutations of $\pi_0, \ldots, \pi_{r+r^a-1}$ shows that this assignment respects our lemma's requirement on rows. Similarly, inspection of the resulting matrix shows that column x contains the pattern $\pi_x, \pi_{x+1}, \ldots, \pi_{x+s+s^a-1}$, which respects our requirement on the number of balls in columns as well. For example, for $r = 4, r^a = 2, s = 2, s^a = 1$, we obtain the following assignment:

$$\begin{pmatrix} p & o & w & p & o & w \\ o & w & p & o & w & p \\ w & p & o & w & p & o \end{pmatrix}. \qquad \square$$

Now we are ready to prove our major Lemma 5, which shows that, in case of $n = f_\ell^r + f_\ell^{r,a} + f_\ell^s + f_\ell^{s,a}$ processes satisfying (4.1), any two executions that lead to two sufficiently "similar" configurations, in the sense that $|\mathcal{Q}| = f_\ell^s + f_\ell^{s,a}$ processes have identical states in both, can be extended by one round in a way that again yields two "similar" configurations for the processes in $\mathcal{Q}$. This implies that all the remaining $f_\ell^r + f_\ell^{r,a}$ processes can withhold their information in the resulting execution. Hence, Lemma 3 can be applied again, which will finally establish our general lower bound result.

LEMMA 5 (similarity). *Consider two configurations $C = (c_1, \ldots, c_n)$ and $C' = (c'_1, \ldots, c'_n)$ generated by executions E and E' in a system of $n = f_\ell^r + f_\ell^{r,a} + f_\ell^s + f_\ell^{s,a}$ processes satisfying $f_\ell^r / f_\ell^{r,a} = f_\ell^s / f_\ell^{s,a}$, where the states $c_1 = c'_1, \ldots, c_{f_\ell^s + f_\ell^{s,a}} = c'_{f_\ell^s + f_\ell^{s,a}}$ of $f_\ell^s + f_\ell^{s,a}$ processes are the same. Then, E and E' can be feasibly extended by one round, such that the same $f_\ell^s + f_\ell^{s,a}$ processes again have the same states $d_1 = d'_1, \ldots, d_{f_\ell^s + f_\ell^{s,a}} = d'_{f_\ell^s + f_\ell^{s,a}}$ in the resulting successor configurations $D = (d_1, \ldots, d_n)$ and $D' = (d'_1, \ldots, d'_n)$.*

Proof. Let $\mathcal{Q} = \{q_0, \ldots, q_{f_\ell^s + f_\ell^{s,a} - 1}\}$ be the set of processes with equal states in C and C', and let $\mathcal{P} = \{p_0, \ldots, p_{f_\ell^r + f_\ell^{r,a} - 1}\}$ be the set of the remaining processes with possibly different states in C and C'. We claim that there is a feasible link failure pattern $\mathcal{F}$ extending E by one round, yielding the execution $E \cup (\mathcal{F}, D)$, where $\cup$

denotes the concatenation operation. Therefore, every process in $\mathcal{Q}$ gets exactly $f_\ell^{r,a}$ arbitrary link failures from some processes in $\mathcal{P}$, delivering the message that would have been sent in the failure-free extension of E' (i.e., in the absence of link failures). In addition, every process in $\mathcal{Q}$ also experiences exactly $f_\ell^r - f_\ell^{r,a}$ omission link failures from some processes in $\mathcal{P}$, whereas the messages from the remaining $f_\ell^{r,a}$ processes in $\mathcal{P}$ are received correctly. All messages from processes in $\mathcal{Q}$ to processes in $\mathcal{Q}$, as well as all messages to processes in $\mathcal{P}$, are failure-free.

Not surprisingly, the required link failure pattern has already been established in Lemma 4: We just have to map $r = f_\ell^r$, $r^a = f_\ell^{r,a}$, $s = f_\ell^s$, and $s^a = f_\ell^{s,a}$ and interpret white, orange, and purple balls as correct, omission faulty, and arbitrary faulty transmissions from the $f_\ell^r + f_\ell^{r,a}$ processes in $\mathcal{P}$ (columns) to the $f_\ell^s + f_\ell^{s,a}$ processes in $\mathcal{Q}$ (rows). The results of Lemma 4 reveal that the corresponding link failure pattern respects both the maximum numbers of send and receive link failures.

Knowing that such an $\mathcal{F}$ indeed exists, our lemma follows from extending E with $\mathcal{F}$ and E' with the pattern matrix $\mathcal{F}'$, which is exactly $\mathcal{F}$ except that a process that committed an arbitrary send link failure in $\mathcal{F}$ transmits correctly in $\mathcal{F}'$, whereas a process that transmitted correctly in $\mathcal{F}$ commits an arbitrary send link failure in $\mathcal{F}'$, which (erroneously) delivers the message that would have been transmitted in the failure-free extension of E: After this round, every process in $\mathcal{Q}$ has the same view of the execution both in $E \cup (\mathcal{F}, D)$ and $E' \cup (\mathcal{F}', D')$ and hence reaches the same configuration in D and D' as asserted. □

Now it is not difficult to prove our general lower bound result as given by Theorem 6. It reveals that $n > f_\ell^r + f_\ell^{r,a} + f_\ell^s + f_\ell^{s,a}$ is required for solving consensus if (4.1) holds. According to Corollary 1 in section 6, this bound is tight and is, for example, matched by the exponential algorithm OMH [66, 65]. If (4.1) does not hold, consensus can be solved with fewer processes, namely, with $n > \overline{f}_\ell^r + \overline{f}_\ell^{ra} + \overline{f}_\ell^s + \overline{f}_\ell^{sa}$ ones. The quantities $\overline{f}_\ell^r$, $\overline{f}_\ell^{ra}$, $\overline{f}_\ell^s$, and $\overline{f}_\ell^{sa}$ are nonnegative integers solving (4.1), subject to the constraints $\overline{f}_\ell^r \le f_\ell^r$, $\overline{f}_\ell^{ra} \le f_\ell^{r,a}$, $\overline{f}_\ell^s \le f_\ell^s$, and $\overline{f}_\ell^{sa} \le f_\ell^{s,a}$, such that $\overline{f}_\ell^r + \overline{f}_\ell^{ra} + \overline{f}_\ell^s + \overline{f}_\ell^{sa}$ is maximal. Note that this is in accordance with the observation that, if (4.1) does not hold, OMH solves consensus also for $n = f_\ell^r + f_\ell^{r,a} + f_\ell^s + f_\ell^{s,a}$ (if it is allowed to execute some additional rounds). Although we do not know whether the lower bound given by Theorem 6 is also tight in this case, we nevertheless conjecture that this is the case.

THEOREM 6 (lower bound processes 3). *Any deterministic algorithm that solves consensus under our system model needs* $n > \overline{f}_\ell^r + \overline{f}_\ell^{ra} + \overline{f}_\ell^s + \overline{f}_\ell^{sa}$, *where* $\overline{f}_\ell^r \le f_\ell^r$, $\overline{f}_\ell^{ra} \le f_\ell^{r,a}$, $\overline{f}_\ell^s \le f_\ell^s$, $\overline{f}_\ell^{sa} \le f_\ell^{s,a}$ *are such that* $\overline{f}_\ell^r / \overline{f}_\ell^{ra} = \overline{f}_\ell^s / \overline{f}_\ell^{sa}$ *holds and the sum* $\overline{f}_\ell^r + \overline{f}_\ell^{ra} + \overline{f}_\ell^s + \overline{f}_\ell^{sa}$ *is maximal.*

Proof. Due to Theorem 3, it remains to provide an impossibility proof for $f_\ell^{s,a}, f_\ell^{r,a} > 0$. According to Lemma 3, we just have to show that every process p can withhold its information under the conditions of our theorem: More specifically, for every $k \ge 0$, we need a failure pattern for rounds $k+1, k+2, \ldots$ such that a nonempty set of processes $\mathcal{Q} = \mathcal{Q}(p)$ has the same view of the resulting execution after round $r \ge k+1$, independent of the information p has gathered by round r.

This follows easily from inductively applying Lemma 5, however: If we assume that p is just one of the $f_\ell^r + f_\ell^{r,a}$ processes in $\mathcal{P}$ that may have a different state in two k-round executions E (resp., E') leading to configurations C (resp., C'), we are guaranteed that the remaining $|\mathcal{Q}| = f_\ell^s + f_\ell^{s,a}$ processes that had identical states in E and E' have identical states in some 1-round extension $E \cup (\mathcal{F}, D)$ and $E' \cup (\mathcal{F}', D')$ of E and E' again. Hence, no such process ever gets information from p. Since this

can go on for an arbitrary number of rounds, Definition 1 reveals that every p can indeed withhold its information as required. □

5. Number of rounds. In this section, we will show that being able to handle link failures comes at the price of additional running time. More specifically, compared to the case without link failures, solving consensus in case of $f_\ell^s, f_\ell^r > 0$ requires one additional round. Our proofs are again based on bivalency arguments and reuse some of the results developed in the previous sections.

THEOREM 7 (lower bound rounds 1). *Any deterministic algorithm that solves consensus under our system model for $f_\ell^s, f_\ell^r > 0$ needs at least two rounds.*

Proof. Assume that there is a 1-round algorithm that solves consensus in the presence of link failures. Obviously, since any process p may suffer from a send link failure to any receiver process q, any process p can withhold its information from at least one process $q(p)$ here: The 1-round assumption does not allow other processes to learn about p's information in some later round. Therefore, Lemma 3 reveals that solving consensus is impossible here. Note that Lemma 3 is applicable here, since x-round consensus is an instance of consensus where no messages are sent in rounds $> x$. So if no consensus algorithms exists, as guaranteed by Lemma 3, x-round consensus is impossible also. □

The above result can be extended to the case where both process and link failures can occur. Using our ideas in the simple bivalency proof of the well-known $f + 1$ lower bound for the number of rounds required for solving consensus in the presence of f process crashes developed in [6], it is possible to show that $f + 2$ is a tight lower bound (matched, for example, by algorithm OMH of [66, 65] and also confirmed by Corollary 1 for $f = 0$).

THEOREM 8 (lower bound rounds 2). *Any deterministic algorithm that solves consensus under our system model with $n \geq f+f_\ell^s+f_\ell^r$, where f denotes the maximum number of process crash failures and $f_\ell^s, f_\ell^r > 0$, needs at least $f + 2$ rounds in the worst case.*

Proof. In [6], a simple forward induction based on a bivalency argument involving message losses due to process crashes is used to show that any consensus algorithm has executions that lead to at least one bivalent configuration at the end of round $f - 1$. The executions considered in this proof are such that at most one process may crash in every round; clearly, no link failures are assumed to occur here. The impossibility of consensus within f rounds follows by contradiction: It is shown in [6, Lemma 1] that the existence of such a solution would imply that all configurations reached after $f - 1$ rounds must be univalent.

In order to prove Theorem 8, we have only to provide an analogue to [6, Lemma 1]: The existence of a consensus algorithm that decides after $f+1$ rounds in our failure model would imply that all configurations reached after $f - 1$ rounds are univalent. The proof is by contradiction: Assuming that not all configurations reached after $f-1$ rounds are univalent, there must be a bivalent configuration C^{f-1} after round $f - 1$. Since at most one process may have crashed during each of the first $f - 1$ rounds, there is still one process p that may crash in round f or $f + 1$. Note that it is the crash of this process p and/or the occurrence of link failures in round f or $f + 1$ that "allows" C^{f-1} to be bivalent.

Let v be the algorithm's decision in the execution E, where no failure (i.e., neither a crash of p nor any link failure) occurs in the two rounds following C^{f-1}. Due to the bivalence of C^{f-1}, there must be a different execution $\overline{E}$ also starting from C^{f-1}, where the decision is $1 - v$. Assume first that p crashes in round f in $\overline{E}$. Then, there

must be two executions, E^q leading to the decision value v, and $\overline{E}^q$ leading to $1-v$, which differ only in that the (crashing) p sends its round f message to q in E^q but not in $\overline{E}^q$: Starting from E where p sends all its messages, we remove the messages p succeeds in sending one by one until the decision value changes; this happens at the latest when we arrive at the execution $\overline{E}^q$.

By construction, q is the only process that can distinguish between E^q and $\overline{E}^q$ after round f. If we allow q to produce a send link failure to some other correct process r (this process must exist since $n \geq f+2$) in the final round $f+1$, then r has the same view at the end of E^q and $\overline{E}^q$. Hence, the resulting decisions cannot be different, providing the required contradiction of some C^{f-1} being bivalent in this case.

We still have to deal with the case where p does not crash in round f in $\overline{E}$. Then, we claim that there is some bivalent configuration C^f reachable from C^{f-1} in round f. For the sake of contradiction, assume that all configurations reachable from C^{f-1} in a single round (where no process crashes) are univalent. Since C^{f-1} is bivalent, the configuration C^f reached by the link-failure-free single-round extension of C^{f-1} must be v-valent, whereas some configuration $\overline{C}^f$ reached by another single-round extension with link failures must be $(1-v)$-valent. Due to Lemma 2, there are two neighboring configurations C_q^f and $\overline{C}_q^f$ that are also v-valent and $(1-v)$-valent, respectively. Those configurations differ only in a single link failure from some sender $s \to q$ in round f, perceived by q in $\overline{C}_q^f$ but not in C_q^f.

Again, q is the only process that can distinguish between the resulting executions E^q and $\overline{E}^q$ after round f. If we allow q to produce a send link failure to some other correct process r (this process must exist since $n \geq f+2$) in the final round $f+1$, then r has the same view at the end of E^q and $\overline{E}^q$. Therefore, the resulting decisions cannot be different, contradicting the stipulated univalence of all C^f. Hence, there is indeed some reachable bivalent configuration C^f at the end of round f.

Since we still have a processor p to crash in round $f+1$ in this case, however, the original proof [6, Lemma 1] applies: In order to decide at the end of round $f+1$, all configurations at the end of round f must be univalent. Since C^f is bivalent, we have established the required contradiction also in this case. □

As a concluding remark, we note that the additional round required for solving consensus in the presence of link failures is not a new result. For $f=0$, it has been shown in [45] that two rounds are needed for solving consensus. Interestingly, the general case follows also from the general result of [25] on indulgent consensus algorithms. More specifically, link omission failures can be interpreted as false suspicions of a local failure detector module. Our algorithms tolerate such link failures and hence must be indulgent with respect to their "failure detectors" (= message reception). Note that our constraints (A^s) and (A^r) also ensure termination of such algorithms.

6. Other results. In this section, we will elaborate on some consequences of our model and the results obtained so far. We start with some considerations related to connectivity in the underlying communication graph in our model, which can be used for confirming the tightness of our lower bounds $n > f_\ell^s + f_\ell^r$ and $n > f_\ell^s + f_\ell^{s,a} + f_\ell^r + f_\ell^{r,a}$.

Consider the single-round communication graph G for some round k. It consists of n vertices corresponding to the processes in Π and contains a directed edge (p,q) iff there is no link failure on the link connecting $p \to q$ in round k. Recall from elementary graph theory that a graph G is *at least c-connected* if it remains connected when at

most $c-1$ vertices and their adjacent edges are removed. Two paths connecting processes p and q are called *process-disjoint* iff they do not have common processes except p and q.

THEOREM 9 (connectivity). *Every single-round communication graph G of a system of $n > f_\ell^s + f_\ell^r$ processes complying to our system model is at least c-connected with $c = n - f_\ell^s - f_\ell^r > 0$. In fact, every pair of processes p, q is connected by c process-disjoint paths consisting of at most two nonfaulty links.*

Proof. Since at least c-connectivity follows trivially if every pair of processes is connected by c process-disjoint paths, it suffices to show the latter: From (A^s), we know that p is connected to at least $n - f_\ell^s$ processes (possibly including itself) via nonfaulty links. From (A^r), it follows that q is connected to a set of at least $n - f_\ell^s - f_\ell^r = c$ of these processes via nonfaulty links. Let $\mathcal{I}$ with $|\mathcal{I}| \geq c$ be this set of processes. If $p \notin \mathcal{I}$ and $q \notin \mathcal{I}$ (i.e., if p and q are not adjacent), then p and q are connected by c paths consisting of two nonfaulty links routed over the processes in $\mathcal{I}$. Otherwise, there are only $c-1$ paths of length 2 and a direct path from p to q, which are of course also process-disjoint. ∎

Theorem 9 implies that one can build a 2-round simulation of reliable communication in our model by using the well-known echo broadcasting scheme [15] ("crusader's agreement" [23]): p sends (msg, p) to all in the first round, and every q rebroadcasts (msg, p) in the second round. One can easily show that this broadcasting scheme allows every q to deliver (msg, p) correctly if $c = n - f_\ell^s - f_\ell^r > 0$. Interestingly, as proved in [11, 12], this simulation even works in case of arbitrary link failures if n is sufficiently large.

COROLLARY 1 (reliable link simulation [11, Thm.2]). *There is a 2-round simulation, which implements reliable broadcasting in our link failure model if $n - f_\ell^s - f_\ell^{s,a} - f_\ell^r - f_\ell^{r,a} > 0$.*

Any synchronous consensus algorithm resilient to f classic process failures can hence be used in conjunction with this simulation for solving consensus in the hybrid failure model of [66, 65] (and therefore, trivially, in the model of section 2). Note, however, that this simulation doubles the number of rounds and is hence suboptimal: Theorem 8 revealed a lower bound of $f+2$ rounds for solving consensus in our model and the algorithms provided in [65] confirm that this bound is tight.

Certain consequences of the results of the previous sections also shed some light on classic process failures. After all, the effect of an omission (resp., arbitrary) faulty process on its peers is principally the same as the effect of omission (resp., arbitrary) send link failures (A^s) committed by a nonfaulty process: Some receiving processes inconsistently get no (resp., erroneous) messages instead of the correct ones. So, we question why f omission faulty processes require at least $f+1$ rounds of execution (Theorem 8), whereas any number of processes committing send link failures can be handled in just 2 rounds according to Corollary 1; cf. the exponential algorithm OMH [65, Thm. 5.4], for example.

From our link failure model, it is apparent that arbitrary send link failures (A^s) can also be viewed as the consequence of a *restricted process failure* with inconsistency limited to f_ℓ^s. Since $f_\ell^s < n$, however, the inconsistency caused by send link failures is strictly less than that of an arbitrary faulty process, since the latter is not restricted in the number of recipients that may get an erroneous message. If at most $f_\ell^r = f_\ell^{r,a}$ processes suffer from restricted process failures with inconsistency limited to $f_\ell^s = f_\ell^{s,a}$, both (A^s) and (A^r) are satisfied, which implies that this alternative interpretation leads to feasible link failure patterns in our model. Note carefully that (A^s) and (A^r)

admit more general failure patterns than just restricted process failures, however: A receive failure may hit any incoming link in the former but is restricted to one of the links from the f_ℓ^r restricted faulty processes in the latter.

Anyway, using the alternative interpretation of arbitrary link failures as restricted arbitrary process failures, the result of Theorem 6 allows us to characterize what makes a process failure a truly arbitrary (Byzantine) one: Choosing $f_\ell^r = f_\ell^{r,a} > 0$ arbitrary and fixing $n > 2f_\ell^{r,a}$, an optimal consensus algorithm such as OMH solves consensus with $n \geq 2f_\ell^{s,a} + 2f_\ell^{r,a} + 1$ in only two rounds. It hence tolerates $f_\ell^{r,a}$ restricted arbitrarily process failures with inconsistency limited to

$$f_\ell^{s,a} \leq \lfloor (n-1)/2 \rfloor - f_\ell^{r,a}. \tag{6.1}$$

For example, $n = 9$ processes are required for tolerating two restricted arbitrary failures with inconsistency $f_\ell^{s,a} = 2$ in just two (instead of three) rounds. Due to (6.1), at least $\lceil (n-1)/2 \rceil + f_\ell^{r,a}$ processes, i.e., a majority[4] of the nonfaulty processes, get the correct message, even in the broadcast of a restricted arbitrary faulty process. Provided that n is chosen appropriately, *any* number $f_\ell^{r,a}$ of process failures with inconsistency limited to $f_\ell^{s,a}$ can hence be tolerated in just two rounds here, i.e., in a number of rounds that does not depend on the number of failures $f_\ell^{r,a}$. If, on the other hand, more than $f_\ell^{s,a}$, i.e., more than a minority of the nonfaulty processes, can get a faulty message in the broadcast of a process, then the sender must be considered arbitrary faulty and thus increases the number of rounds required for solving consensus.

A similar observation can be made for omission failures. Choosing $f_\ell^{s,a} = f_\ell^{r,a} = 0$, and $f_\ell^r > 0$ arbitrary, and fixing $n > f_\ell^r$, an optimal consensus algorithm such as ZA [65] solves consensus for $n \geq f_\ell^r + f_\ell^s + 1$ in only two rounds. It hence tolerates f_ℓ^r restricted omission process failures with inconsistency

$$f_\ell^s \leq n - 1 - f_\ell^r. \tag{6.2}$$

It follows from (6.2) that at least $f_\ell^r + 1$ processes, i.e., at least one nonfaulty process, must get the correct message, even in the broadcast of a restricted omission faulty process. If this is warranted, any number f_ℓ^r of such restricted process failures can be tolerated within two rounds.

It hence follows that a process that disseminates inconsistent information cannot do much harm—in the sense of requiring additional rounds for solving consensus—if at most a certain number of recipients can get inconsistent information:

- A process must be considered arbitrary faulty if it can supply erroneous information to a majority of the nonfaulty processes.
- A process must be considered omission faulty if it can fail to provide information to any and all nonfaulty processes.

For suboptimal algorithms, the thresholds (numbers of affected receivers) are of course smaller.

Note, finally, that our observations do not contradict the lower bound $f+1$ for the number of rounds required for consensus in the presence of f faulty processes (recall Theorem 8 or [8, Sec. 5.1.4]), since this result relies heavily on the fact that a faulty process can disseminate inconsistent information to as many processes as desired.

[4]For a suboptimal algorithm, even more than a majority of the nonfaulty processes must get the correct message here.

7. Relation to other models. In this section, we will relate our model to alternative link failure modeling approaches. Particular emphasis will be put on the issue of assumption coverage, which will be analyzed and compared in detail in a simple probabilistic setting.

7.1. Overview of related approaches. It has long been known that consensus is impossible with arbitrarily lossy links [33]. Therefore, every useful failure model must restrict link failures in some way. Some previous work has considered links that eventually become reliable "for sufficiently long," at least among a majority of the processes, (e.g., [46, 24]), or "stubborn links" [36] that eventually deliver every message provided the message is sent sufficiently many times. These models in essence provide safety despite link failures but require communication to eventually become reliable in order to ensure liveness. A similar approach is employed in the crash-recovery model [2], which also deals with transient failures, albeit at the level of whole processes and on a much larger time-scale. There are only a few failure models for synchronous systems in the literature that deal with transient link failures that continue to occur indefinitely.

One straightforward way to deal with link failures is to map link failures to sender process failures [32] or, preferably, to general send/receive-omission failures [54]. Unfortunately, this approach suffers from poor model coverage (see section 7.2) and is also quite restrictive in the sense that only specific processes—the faulty ones—may experience link failures.

Another class of models [55, 61, 67] considers a small number of link failures explicitly: Those papers assume that at most $O(n)$ links may be faulty system-wide during the entire execution. Obviously, such models can be applied only when link failures are rare. Hadzilacos [37] presents a theoretical study of connectivity requirements for solving consensus in arbitrary networks with stopping and omission failures.

The most severe problem of the models surveyed so far is their inability to deal with the "moving" nature of transient link failures: In a real network, there is a positive probability for message loss (or delay) on every link. In the aforementioned models, once a single message is lost, either the link or the process is deemed faulty. Since failures are considered persistent during an execution in the above models, the "exhaustion" of nonfaulty processes and links progresses rapidly with every round. This makes any attempt to solve consensus in models such as those presented in [32, 54, 37] void in case of significant link failure rates (see section 7.2 for a detailed analysis). A more adequate approach to capturing message loss is to allow for transient failures that hit different processes or links in different communication rounds.

Santoro and Widmayer were the first to introduce this assumption: In [58, 60], they showed that consensus cannot be solved in the presence of $n-1$ (resp., $\lfloor n/2 \rfloor$) omission (resp., Byzantine) link failures per round, particularly if those link failures hit the same sender process. As a consequence, consensus cannot be solved in the presence of just a single *mobile* omission or Byzantine faulty process, i.e., a single process—which may be different in different rounds—that suffers from omission or even Byzantine failures. This result has been proven in [58] by means of a similar approach as employed in section 3 and reproven in the layering framework by Moses and Rajsbaum [52].

On the other hand, if the number of moving link failures is further restricted to less than $n-1$ (resp., $\lfloor n/2 \rfloor$) per round in case of omission (resp., Byzantine) link failures, consensus can be solved in a constant number of rounds [59, 49]. Other distributed computing problems [21] and special system architectures [22] have also

been studied under this model.

The failure model introduced in [56] can be seen as a first step in the direction of increasing the link failure resilience from $O(n)$ to $O(n^2)$: For a system with $n \geq 20f+1$ processes, at most f of which may be Byzantine faulty per round, a consensus algorithm was given that tolerates a small number $l = n/20$ of link failures at every node. A different (but related) model has been proposed in [31], which considers at most f Byzantine process failures per round that may move from one process to another with a certain maximum speed.

Cristian et al. [20] provide a suite of synchronous atomic broadcast protocols with much better link failure resilience (which is comparable to results we presented in an earlier paper [65]). Although atomic broadcast is usually investigated in a more communications-oriented context, it can be used to solve consensus as well; see, e.g., [38] for an overview. The three algorithms of Cristian et al. [20] tolerate an arbitrary number of processes with omission, timing, or Byzantine failures (if authentication is available) and work on general communication graphs subject to link failures. Instead of making the number of link failures explicit, however, it is just assumed that any two processes in the system are always connected via a path of nonfaulty links.

Unlike in the deterministic setting, link failures are easily tolerated by *randomized* consensus algorithms such as the one of [70]. Such algorithms circumvent Gray's impossibility result (cf. Theorem 1) by adding nondeterminism (coin tossing) to the computations. Still, due to the inherent nonzero probability of failure/nontermination within a fixed number of rounds, randomized algorithms are unsuitable for some applications. Moreover, there is a lower bound $1/(R+1)$ for the probability of disagreement after R rounds with arbitrary loss [50, Thm. 5.5]. It is interesting to note, however, that our link failure modeling approach also circumvents this lower bound: For a well-known randomized algorithm, Schmid and Fetzer established a probability of disagreement of only $(1/2)^R$ [64].

Though our paper primarily deals with message omissions in the synchronous timing model, our model can also be used to reason about *timeliness* of some links in otherwise asynchronous round-based systems (where late messages are discarded). In this context, our threshold f_ℓ^r (resp., f_ℓ^s) can be seen as a restriction on the number of late (or untimely) messages a process receives (resp., sends) in a round. Restrictions of this type have received much attention recently: A suite of papers [3, 4, 5, 53, 7, 51, 43, 39, 40, 44] provided weaker and weaker models that are still sufficiently strong for implementing failure detectors and/or solving consensus in the presence of at most f process crash failures and dynamic timing variations.

In particular, Keidar and Shraer introduced a model called *all from majority* ($\diamond$AFM) in their round-by-round GIRAF framework [43], which is closely related to the moving link failure model introduced in section 2.2: It allows $O(n^2)$ links per round to be nontimely, provided that every process has at least $m+1$ timely outgoing links and $n-m$ timely incoming links at any time for some suitable m. The set of timely links may be moving. $\diamond$AFM was shown in [44] to be the only model (out of those defined thus far in this context) that scales with n, in the sense that consensus can be guaranteed to terminate in a constant expected number of rounds in the independent identically distributed probabilistic link failure model, even for $n \to \infty$.

Our model is also related to the *heard-of model* (HO Model) developed by Charron-Bost and Schiper [18, 19]. The HO Model is a round-based distributed computing model, which unifies synchrony and (benign) failures of both processes and links. It has recently been extended to Byzantine failures [13] as well. Our link failure restric-

tions (A^s) and (A^r) can be elegantly expressed as simple communication predicates in the HO model, namely, $\forall p \in \Pi, k \geq 1 : |HO(p,k)| \geq n - f_\ell^r \wedge |TT(p,k)| \geq n - f_\ell^s$ in case of omission link failures, where $HO(p,k)$ is the set of processes p hears from in round k and $TT(p,k)$ is the set of processes p talks to in round k. Moreover, the reliable link simulation that led to Corollary 1 can be seen as a 2-round translation that simulates a global kernel (of size n, i.e., a failure-free system) in our model. It is also interesting to compare the upper bound results of [13] with our lower bounds: Theorem 5 reveals that we can allow at most $n/4$ arbitrary link failures per round. The algorithm $\mathcal{A}_{T,E}$ in [13] admits up to $n/4$ arbitrary receive link failures per round, without posing a restriction to send link failures, however. There is no contradiction here, due to the fact that the analysis of $\mathcal{A}_{T,E}$ separates safety and liveness: The algorithm actually needs some rounds with much less than $n/4$ link failures for guaranteed termination. By contrast, our lower bounds guarantee both safety and liveness simultaneously.

Finally, we already noted that, in the context of round-by-round fault detectors [30], false suspicions of a local failure detector [16] can also be interpreted as transient link failures. Our results, such as the lower bound of $f+2$ rounds for solving consensus, are hence also applicable to stable periods [26] and stable runs [41, 25] of indulgent [35] consensus algorithms.

An alternative way to cope with transient link failures involves reliable link simulation protocols based on retransmissions [1, 9, 2]. Asynchronous algorithms can then be used atop such protocols for solving consensus. However, since retransmission protocols can obviously mask omissions only (but not timing failures and/or erroneous messages), they are no panacea. Moreover, using time redundancy for tolerating link failures necessarily increases the end-to-end delay in case of a failure, which eventually affects the consensus algorithms' termination time. And, last but not least, since it is impossible to solve consensus in asynchronous systems with even a single crash failure [29], one has to add some synchrony to the system anyway [3, 4, 5, 53, 7, 51, 40, 43, 39]. This makes our synchronous lower bound results applicable again, at least to asynchronous algorithms designed for round-by-round-based frameworks such as [64, 18, 19, 43]. A detailed survey of link failures in partially synchronous and asynchronous systems can be found in [63].

Note that using reliable link protocols in conjunction with *synchronous* consensus algorithms is not particularly useful, since the duration of the rounds must be fixed a priori. As a consequence, only a certain number of retransmissions can be accomodated in a round, which is not sufficient for simulating reliable links in the presence of high link failure rates. In sharp contrast, our approach toward handling link failures uses additional processes (i.e., some larger value of n) instead of retransmissions and therefore does not suffer from this problem: The duration of a round just needs to encompass a single end-to-end delay.

7.2. Model coverage. In this section, we will prove that our link failure model also surpasses alternative approaches in terms of assumption coverage.

If link failures are just mapped to sender process failures, as in [32], even a single link failure per process and round ($f_\ell = 1$ in our terminology) would end up with $f = n$ faulty processes in some runs. Figure 7.1 shows an example for $n = 4$ and $f_\ell = 1$.

In the more elaborate send/receive-omission failure model of [54], an omission can be attributed to either the sender or the receiver process. Still, in the example of Figure 7.1, only at most two processes can be considered correct. Ending up with

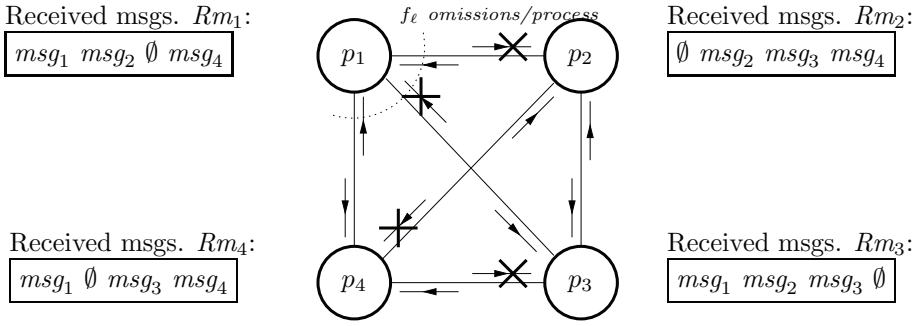

FIG. 7.1. *Example of a 4-process system with $f_\ell = 1$ send and receive omission failures per process in each round, where all processes must be considered faulty in traditional process failure models.*

less than a majority of correct processes renders uniform consensus unsolvable [17], however. Hence, by attributing link failures to processes, we may miss the opportunity to solve consensus in scenarios which can be handled in our model.

We now turn to examine whether the additional scenarios captured by our model are significant. After all, one could argue that failure patterns as depicted above almost never occur in practice, such that more refined models have only marginal added value. We counter this argument by quantifying the *coverage*[5] of various models, using a simple probabilistic "benchmarking scenario."

DEFINITION 2. *Consider a synchronous system of n processes, where each of the $n(n-1)$ unidirectional links fails with some independent probability $0 \leq p < 1$, independently in every round. The* coverage *$Cov(M)$ of a model M is the probability that the model assumptions hold true during the execution of an m-round algorithm for some arbitrary $m \geq 1$.*

Combining ideas from [62] and [44], we analyze the coverage of the following failure models:

- f general omission-faulty processes (GO_f) [54],
- at least one process with f nonmoving timely links (TL_f) [5],
- at most $n-2$ moving link failures per round (ML_{n-2}) [58],
- f_ℓ moving link failures per process and round (MLO_{f_ℓ}), the model of section 2.2.

It will turn out that the link failure model introduced in section 2.2 surpasses all other modeling approaches above in terms of coverage. In particular, it is the only model that scales with n, in the sense that, for example, $\mathrm{Cov}(MLO_{n/2}) \to 1$ for $n \to \infty$. By contrast, the coverage of all the other models even goes to 0 for $n \to \infty$ in comparable settings.

We should mention, though, that our coverage analysis does not aim at replacing a direct analysis of a distributed algorithm in our probabilistic "benchmarking scenario." A particular algorithm $\mathcal{A}$ may perform much better than our coverage analysis predicts, since $\mathcal{A}$ may also work well in executions where the deterministic model M is violated. Hence, $\mathrm{Cov}(M)$ is just a lower bound on the achievable performance of $\mathcal{A}$ but is of course a meaningful measure for assessing the quality of a deterministic

[5] We note that the term coverage suffers from overloading in the literature; throughout this paper, "coverage" must be read as "model coverage in synchronous systems with independent link failure probability p."

model independently of a particular protocol.

Analysis of f general omission-faulty processes (GO_f). Under this failure model, there must be a set K of at least $k = n - f$ processes that never commit a send nor a receive omission. This requirement is mapped to our probabilistic link failure setting as follows: All the links among the processes in K must be correct in all rounds, and the links connecting processes in $\Pi\backslash K$ with processes in $\Pi\backslash K$ may be either correct or faulty. The links to/from processes in K from/to processes in $\Pi\backslash K$ may also be either correct or faulty, since we can attribute a link failure to the adjacent process in $\Pi\backslash K$.

So let K be a subset of $k = n - f \geq 1$ distinct processes where all $k(k-1)$ links among processes in K never experience any omission failure during m rounds. Since there are $\binom{n}{k}$ different sets K of k processes out of n processes, the probability $P_n(k)$ that there is at least one such set in a run satisfies

$$P_n(k) \leq \binom{n}{k}(1-p)^{k(k-1)m}. \tag{7.1}$$

Note that $P_n(k)$ is not equal to $\binom{n}{k}(1-p)^{k(k-1)m}$, since there may be multiple sets K in a given run (recall that the links outside K can also be correct).

Hence, the model coverage of the standard general omission failure model with at most f faulty processes GO_f satisfies

$$\mathrm{Cov}(GO_f) = P_n(n-f) \leq \binom{n}{n-f}(1-p)^{(n-f)(n-f-1)m}. \tag{7.2}$$

In case of $f = \lambda n$ for any $0 < \lambda < 1$, it is not difficult to prove that $\mathrm{Cov}(GO_{\lambda n}) \to 0$ for $n \to \infty$. We will use asymptotic analysis for this purpose,[6] with Stirling's formula

$$n! \sim \sqrt{2\pi n} \cdot \left(\frac{n}{e}\right)^n \qquad \text{for } n \to \infty \tag{7.3}$$

as our major ingredient.

LEMMA 6 (asymptotic expansion $\binom{n}{n\lambda}$). *For any $0 < \lambda < 1$ and $n \to \infty$,*

$$\binom{n}{\lambda n} \sim \frac{1}{\sqrt{2\pi n\lambda(1-\lambda)}} \cdot \left((1-\lambda)^{-(1-\lambda)} \cdot \lambda^{-\lambda}\right)^n. \tag{7.4}$$

Proof. Using Stirling's formula in $\binom{n}{k} = \frac{n!}{(n-k)!\,k!}$, we find

$$\begin{aligned}
\binom{n}{\lambda n} &\sim \frac{\left(\frac{n}{e}\right)^n}{\left(\frac{n(1-\lambda)}{e}\right)^{n(1-\lambda)}\left(\frac{\lambda n}{e}\right)^{\lambda n}} \cdot \frac{\sqrt{2\pi n}}{\sqrt{2\pi n(1-\lambda)} \cdot \sqrt{2\pi\lambda n}} \\
&\sim \left(\frac{n}{n(1-\lambda)}\right)^n \cdot \left(\frac{n(1-\lambda)}{\lambda n}\right)^{\lambda n} \cdot \frac{1}{\sqrt{1-\lambda} \cdot \sqrt{2\pi\lambda n}} \\
&\sim (1-\lambda)^{-n} \cdot \left(\frac{1-\lambda}{\lambda}\right)^{\lambda n} \cdot \frac{1}{\sqrt{2\pi n\lambda(1-\lambda)}},
\end{aligned}$$

from which (7.4) follows immediately. ∎

[6] We use the notation $f(n) \sim g(n) \Leftrightarrow \lim_{n\to\infty} f(n)/g(n) = 1$ and $f(n) \propto g(n) \Leftrightarrow 0 \leq \lim_{n\to\infty} f(n)/g(n) \leq 1$.

Using the result of Lemma 6 in (7.2), the coverage of $GO_{n\lambda}$ evaluates to

$$\text{Cov}(GO_{n\lambda}) \propto \frac{\left((1-\lambda)^{-(1-\lambda)} \cdot \lambda^{-\lambda}\right)^n}{\sqrt{2\pi n\lambda(1-\lambda)}} \cdot (1-p)^{\left(n(1-\lambda)\right)\left(n(1-\lambda)-1\right)m}. \tag{7.5}$$

Since the exponent of $1-p<1$ is quadratic in n, it is obvious that $\text{Cov}(GO_{n\lambda}) \to 0$ for $n \to \infty$, for any $p>0$, $0<\lambda<1$, and $m \geq 1$. In particular, for $f = n/2$, we obtain

$$\text{Cov}(GO_{n/2}) \propto \frac{2^n}{\sqrt{\pi n/2}}(1-p)^{(n/2)(n/2-1)m}. \tag{7.6}$$

$\text{Cov}(GO_{n/2})$ hence very quickly goes to 0 for $n \to \infty$ for any $0<p<1$ and any $m \geq 1$. Figure 7.2 gives some numerical values which reveal that the coverage of the general omission process failure model in our benchmarking scenario is indeed very poor. For example, for $p=0.01$ and $m=2$ (first plot in the left figure), the coverage is only about 10^{-25} in a system of $n=40$ processes (log-scale)!

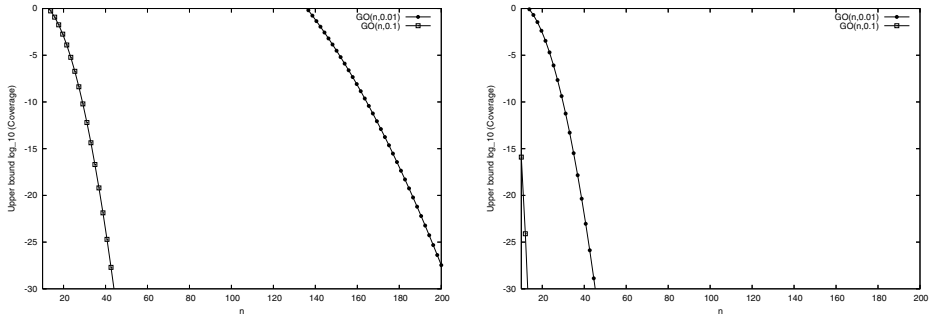

FIG. 7.2. *Coverage general process omission failure model: Upper bound on* $\log_{10}(Cov(GO_{n/2}))$ *over* n *with* $p=0.01$ *and* $p=0.1$ *for* $m=2$ *(left) and* $m=20$ *(right).*

Analysis of at least one process with f nonmoving timely links (TL_f). We now turn our attention to the "nonmoving" link timing models [3, 4, 5] used for solving Ω and consensus in an (almost) asynchronous system of n processes with up to f process crash failures and eventually reliable links. The weakest model among those (denoted TL_f here) assumes that (eventually) there is at least one process p with at least f timely outgoing links in each of its broadcasts. Note that those f links are fixed throughout the (suffix of the) execution.

We note that the model TL_f is actually too weak for solving consensus within *bounded* time: As shown in [43, 44], considerably more timely links are required to solve consensus within a bounded number m of (timely) rounds. We incorporate the analysis of TL_f here, however, since it provides sort of an "upper bound" with respect to coverage: Any model that, in addition to TL_f, requires additional timely links must have an even lower coverage in our benchmarking scenario. Bear in mind, however, that the number of rounds m should be considered large here.

With p representing the probability that a link is nontimely in a round here, the probability $P_{n-1}(f) = Cov(TL_f)$ that some process has at least f timely links during m rounds is at most $n\binom{n-1}{f}(1-p)^{fm}$: We have n processes, and there are $\binom{n-1}{f}$ different subsets of f processes among the $n-1$ neighbors of a process; $(1-p)^{fm}$

gives the probability that the links to a fixed set of f neighbors are correct during all m rounds. Hence,

$$\mathrm{Cov}(TL_f) \le n \cdot \binom{n-1}{f}(1-p)^{fm}. \tag{7.7}$$

As in the analysis of GO_f, this is only a (quite conservative) upper bound for $P_{n-1}(f)$, however, since the involved events are not independent.

For $f = \lambda(n-1) = \lambda n'$, $0 < \lambda < 1$, where we employed the abbreviation

$$n' = n - 1$$

used throughout this section, we obtain

$$\begin{aligned}\mathrm{Cov}(TL_{\lambda n'}) &\le (n'+1) \cdot \binom{n'}{\lambda n'}(1-p)^{m\lambda n'} \\ &\propto \sqrt{\frac{n'}{2\pi\lambda(1-\lambda)}} \cdot \left((1-\lambda)^{-(1-\lambda)} \cdot \lambda^{-\lambda}\right)^{n'} \cdot (1-p)^{m\lambda n'}. \end{aligned} \tag{7.8}$$

Choosing $\lambda = 1/2$, i.e., $f = (n-1)/2 = n'/2$, to facilitate comparison with our other results, we obtain

$$\mathrm{Cov}(TL_{n'/2}) \propto \sqrt{\frac{2n'}{\pi}}\left(4(1-p)^m\right)^{n'/2}. \tag{7.9}$$

The above bound goes to 0 for $n' \to \infty$ if $4(1-p)^m < 1$, i.e., when the number of rounds satisfies

$$m > -\frac{\log 4}{\log(1-p)} > \frac{\log 4}{p}, \tag{7.10}$$

according to the series expansion $\log(1-x) = -\sum_{k\ge 1} x^k/k$, valid for $|x| < 1$. For smaller values of m, (7.9) increases exponentially. Since $\mathrm{Cov}(TL_{n'/2}) = P_{n'}(n'/2)$ is a probability and hence ≤ 1, however, the question arises whether the range of m where $\mathrm{Cov}(TL_{n'/2}) \to 0$ could be extended by a refined analysis.

Some advanced results on the distribution of the maximum degree of nodes in a geometric random graph [57] can be used for this purpose: The sought probability $P_{n-1}(f)$ is just the probability that the maximum degree Δ of the nodes in a random graph with n nodes (where an edge exists, independently of the other edges, with some fixed probability $0 < q < 1$) satisfies $\Delta \ge f$. More specifically, we have to consider the random graph with n nodes, corresponding to our processes, where an edge (x, y) exists if there is no link failure on the link $x \to y$ during m rounds. Clearly, the probability of the latter event is $q = (1-p)^m$. Note that [57] actually deals with undirected graphs. Considering the undirected random graph RG corresponding to an execution, instead of its directed counterpart $\overline{RG}$, provides an upper bound: Since every directed edge in $\overline{RG}$ is also present in RG, it follows that $\mathbf{P}\{\Delta_{RG} \ge f\} \ge \mathbf{P}\{\Delta_{\overline{RG}} \ge f\}$.

THEOREM 10 (maximum degree in geometric random graphs [57]). *Given a geometric random graph with n nodes and edge probability q, the maximum degree Δ is strongly concentrated, in the sense that almost always*

$$\left|\Delta - qn - \sqrt{2q(1-q)n\log n} + \log\log n\sqrt{\frac{q(1-q)n}{8\log n}}\right| \le \log\log\sqrt{\frac{n}{\log n}}. \tag{7.11}$$

Moreover, the tail satisfies $\mathbf{P}\{\Delta < qn + b\sqrt{nq(1-q)}\} = \big(c(b) + o(1)\big)^n$ *for* $n \to \infty$, *where* $c(b) < 1$ *is the root of a certain equation;* $c(0) = 0.6102$*; and* $c(b)$ *is independent of* q.

According to our exposition above, we must set $q := (1-p)^m$, $n := n'+1$, and $f = n'/2$. Now, if $n'/2 > nq = (n'+1)(1-p)^m$ with $n'/2-(n'-1)(1-p)^m \geq C \cdot n'$ for some constant $C > 0$, then the area $\Delta \geq n'/2$ is to the right of the area of concentration $\big[nq - O(\sqrt{n \log n}), nq + O(\sqrt{n \log n})\big]$ of Δ given in (7.11) if n is sufficiently large. As a consequence, $\mathrm{Cov}(TL_{n'/2}) = \mathbf{P}\{\Delta_{\overline{RG}} \geq n'/2\} \leq \mathbf{P}\{\Delta_{RG} \geq n'/2\}$ actually goes to 0 for $n \to \infty$ if $(1-p)^m < 1/2$, i.e., when $m > \frac{\log 2}{p} > \frac{\log 2}{p}$; cf. (7.10). For smaller values of m, $\mathrm{Cov}(TL_{n'/2}) \to 1$ for $n \to \infty$ (with a fast transition phase in between, as usual in random graphs).

Figure 7.3 provides some numerical values in a system with $p = 0.1$ for $m = 20$ rounds. It reveals that the coverage of $n'/2$ fixed timely links in our benchmarking scenario is poor if m is above its critical value (7.10) with respect to p (which is the case for $m = 20$ and $p = 0.1$).

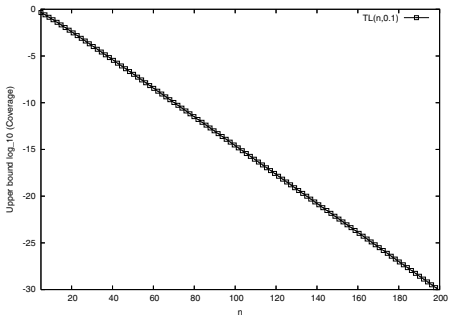

FIG. 7.3. *Coverage of nonmoving timely links: Upper bound on* $\log_{10}\big(Cov(TL_{n'/2})\big)$ *over* n *with* $p = 0.1$ *for* $m = 20$. *The number of rounds* $m = 20$ *is above its critical value* (7.10) *here.*

Analysis of $n-2$ moving link failures per round (ML_{n-2}). Classic moving link failure models, particularly [58], admit only $O(n)$ link failures per round. Let $ML_{\lambda n}$ be the model that admits at most λn link failures per round for some real constant $\lambda > 0$. In [58], it was shown that consensus possibility demands at most $\lambda n = n - 2$ link failures per round; hence $\lambda = (n-2)/n$ here.

We start our derivations with a simple bound on the tail of the binomial distribution taken from Feller's book [27],[7] which will also be required in the analysis of the coverage of our model MLO_{f_ℓ}. Consider the binomial distribution $B(\overline{n}, \overline{p})$, where $\overline{p}$ is the "success" probability, and let

$$p_{\overline{n}}(f_\ell) = \sum_{l=0}^{f_\ell} \binom{\overline{n}}{l} \overline{p}^l (1-\overline{p})^{\overline{n}-l} \tag{7.12}$$

be the probability of at most f_ℓ "successes," and let $q_{\overline{n}}(f_\ell) = 1 - p_{\overline{n}}(f_\ell)$ be the

[7]This method gives a better bound than Chernoff's, i.e., $q_n(f_\ell) \leq \min_{z \geq 1} B(z; n, p)/z^{f_\ell}$, where $B(z; n, p) = (pz + 1 - p)^n$ is the generating function of the binomial distribution.

probability of more than f_ℓ "successes." Clearly,

$$q_{\overline{n}}(f_\ell) = \sum_{l=f_\ell+1}^{\overline{n}} \binom{\overline{n}}{l} \overline{p}^l (1-\overline{p})^{\overline{n}-l}. \tag{7.13}$$

Lemma 7 gives an upper bound for this quantity.

LEMMA 7 (upper bound for binomial tail [27]). *For any $0 \le \overline{p} \le 1$, $\overline{n} \ge 1$, and $f_\ell + 1 > \overline{np}$, we have*

$$q_{\overline{n}}(f_\ell) \le \frac{(1-\overline{p})(f_\ell+1)}{f_\ell+1-\overline{np}} \cdot \binom{\overline{n}}{f_\ell+1} \overline{p}^{f_\ell+1} (1-\overline{p})^{\overline{n}-f_\ell-1}. \tag{7.14}$$

Proof. Following the argument [27, p. 151, eq. (3.4)], let $b(k;n,p) = \binom{n}{k} p^k (1-p)^{n-k}$, and note that $q_{\overline{n}}(f_\ell) = \sum_{k=0}^{\infty} b(k+f_\ell+1;\overline{n},\overline{p})$. Using the straightforward identity $\binom{n}{k} = \frac{n-k+1}{k}\binom{n}{k-1}$, one obtains for any $k \ge 1$

$$\begin{aligned}
b(k+f_\ell+1;n,p) &= \frac{(n-k-f_\ell-1+1)p}{(k+f_\ell+1)(1-p)} \cdot b(k-1+f_\ell+1;n,p) \\
&= \Big(1 - \frac{k+f_\ell+1-(n+1)p}{(k+f_\ell+1)(1-p)}\Big) \cdot b(k-1+f_\ell+1;n,p) \\
&= \prod_{j=1}^{k} \Big(1 - \frac{j+f_\ell+1-(n+1)p}{(j+f_\ell+1)(1-p)}\Big) \cdot b(f_\ell+1;n,p) \\
&= \prod_{j=1}^{k} \Big(1 - \frac{1-\frac{(n+1)p}{j+f_\ell+1}}{1-p}\Big) \cdot b(f_\ell+1;n,p).
\end{aligned}$$

Since it is easily checked that, for any $j \ge 1$,

$$1 - \frac{1-\frac{(n+1)p}{j+f_\ell+1}}{1-p} \le 1 - \frac{1-\frac{np}{f_\ell+1}}{1-p},$$

it follows that

$$b(k+f_\ell+1;n,p) \le \Big(1 - \frac{1-\frac{np}{f_\ell+1}}{1-p}\Big)^k \cdot b(f_\ell+1;n,p),$$

which holds even for $k \ge 0$. Consequently,

$$\begin{aligned}
q_{\overline{n}}(f_\ell) &= \sum_{k=0}^{\infty} b(k+f_\ell+1;\overline{n},\overline{p}) \le b(f_\ell+1;\overline{n},\overline{p}) \sum_{k=0}^{\infty} \Big(1 - \frac{1-\frac{\overline{np}}{f_\ell+1}}{1-\overline{p}}\Big)^k \\
&\le \frac{1-\overline{p}}{1-\frac{\overline{np}}{f_\ell+1}} \cdot \binom{\overline{n}}{f_\ell+1} \overline{p}^{f_\ell+1} (1-\overline{p})^{\overline{n}-f_\ell-1},
\end{aligned}$$

as asserted in (7.14). ∎

In case of $ML_{\lambda n}$, we set $\overline{n} := n(n-1)$, $\overline{p} := 1-p$, and $f_\ell := n(n-1) - \lambda n - 1 = n(n-1-\lambda) - 1$ in Lemma 7, such that $q_{n(n-1)}\big(n(n-1-\lambda)-1\big)$ is the probability that at least $n(n-1-\lambda)$ nonfaulty links (and hence at most λn faulty links) occur per round. It evaluates to

$$\begin{aligned}
q_{n(n-1)}\big(n(n-1-\lambda)-1\big) \le \frac{pn(n-1-\lambda)}{n(n-1-\lambda) - n(n-1)(1-p)} \\
\cdot \binom{n(n-1)}{n(n-1-\lambda)} (1-p)^{n(n-1-\lambda)} p^{\lambda n}.
\end{aligned}$$

By independence, the probability that at most λn link failures occur during m rounds is $\big[q_{n(n-1)}\big(n(n-1-\lambda)-1\big)\big]^m$, and thus

$$\text{Cov}(ML_{\lambda n}) \le \left[\frac{p\cdot(n-1-\lambda)}{p\cdot(n-1)-\lambda}\cdot\binom{n(n-1)}{n(n-1-\lambda)}(1-p)^{n(n-1-\lambda)}p^{\lambda n}\right]^m \tag{7.15}$$

by Lemma 7. In order to determine the asymptotic value of $\text{Cov}(ML_{\lambda n})$, we will need

$$\begin{aligned}\Big(1-\frac{x}{n}\Big)^n &\sim e^{-x} \qquad \text{for any fixed } x \text{ and } n\to\infty,\\ \Big(1-\frac{x}{n-1}\Big)^{n(n-1)} &= e^{n(n-1)\log\left(1-\frac{x}{n-1}\right)}\\ &= e^{n(n-1)\cdot\left(-\frac{x}{n-1}-\frac{x^2}{2(n-1)^2}+O(x^3/n^3)\right)}\\ &= e^{-nx-\frac{nx^2}{2(n-1)}+O(x^3/n)}\\ &\sim e^{-nx-\frac{x^2}{2}} \qquad \text{for } |x|<1,\end{aligned}$$

where we used the series expansion $\log(1-x) = -\sum_{k\ge1}x^k/k$. Applying Stirling's formula (7.3) again yields

$$\begin{aligned}\binom{n(n-1)}{n(n-1-\lambda)} &\sim \frac{\left(\frac{n(n-1)}{e}\right)^{n(n-1)}}{\left(\frac{n(n-1-\lambda)}{e}\right)^{n(n-1-\lambda)}\left(\frac{\lambda n}{e}\right)^{\lambda n}}\cdot\frac{\sqrt{2\pi n(n-1)}}{\sqrt{2\pi n(n-1-\lambda)}\cdot\sqrt{2\pi\lambda n}}\\ &\sim \Big(\frac{n-1}{n-1-\lambda}\Big)^{n(n-1)}\cdot\Big(\frac{n-1-\lambda}{\lambda}\Big)^{\lambda n}\cdot\frac{1}{\sqrt{1-\frac{\lambda}{n-1}}\cdot\sqrt{2\pi\lambda n}}\\ &\sim \frac{1}{\left(1-\frac{\lambda}{n-1}\right)^{n(n-1)}}\cdot\Big(\frac{n}{\lambda}\Big)^{\lambda n}\cdot\Big(1-\frac{\lambda\cdot(1+\lambda)}{\lambda n}\Big)^{\lambda n}\cdot\frac{1}{\sqrt{2\pi\lambda n}}\\ &\sim e^{\lambda n+\lambda^2/2}\cdot\Big(\frac{n}{\lambda}\Big)^{\lambda n}\cdot e^{-\lambda(1+\lambda)}\cdot\frac{1}{\sqrt{2\pi\lambda n}}\\ &\sim \frac{e^{-\lambda(1+\lambda/2)}}{\sqrt{2\pi\lambda n}}\cdot\Big(\frac{en}{\lambda}\Big)^{\lambda n} \qquad (7.16)\\ &\sim e^{\lambda n\log n+\lambda n(1-\log\lambda)-\frac12\cdot\log n-\lambda(1+\lambda/2)-\frac12\cdot\log(2\pi\lambda)}. \qquad (7.17)\end{aligned}$$

The dominant term in the exponent in (7.17) is clearly $\lambda n\log n>0$. On the other hand,

$$(1-p)^{n(n-1-\lambda)}p^{\lambda n} = e^{n^2\log(1-p)-(1+\lambda)n\log(1-p)+(\lambda n)\log p},$$

which rapidly goes to 0 for $n\to\infty$ since the dominant term in the exponent is $\log(1-p)n^2<0$. Multiplying this with (7.16) according to (7.15) hence yields

$$\text{Cov}(ML_{\lambda n}) \propto \left[\frac{e^{-\lambda(1+\lambda/2)}}{\sqrt{2\pi\lambda n}}\cdot\Big(\frac{enp}{\lambda}\Big)^{\lambda n}(1-p)^{n(n-1-\lambda)}\right]^m, \tag{7.18}$$

which quickly goes to 0 for $n\to\infty$, for any λ and m.

For the special case $\lambda = (n-2)/n$, which implies at most $n-2$ link failures per round, we obtain for $n \to \infty$

$$\begin{aligned}
\lambda &\sim 1,\\
\frac{e^{-\lambda(1+\lambda/2)}}{\sqrt{2\pi\lambda n}} &\sim \frac{e^{-3/2}}{\sqrt{2\pi n}},\\
\Big(\frac{enp}{\lambda}\Big)^{\lambda n} = \Big(\frac{enp}{\frac{n-2}{n}}\Big)^{n-2} &= \frac{(1-2/n)^2\cdot(enp)^{n-2}}{(1-2/n)^n} \sim \frac{(enp)^{n-2}}{e^{-2}},\\
(1-p)^{n(n-1-\lambda)} = (1-p)^{n(n-1)-n+2} &= \Big(\frac{1}{(1-p)^2}\Big)^{n-2}(1-p)^{n^2-2}.
\end{aligned}$$

Using this in expression (7.18) hence yields

$$\begin{aligned}
\mathrm{Cov}(ML_{n-2}) &\sim \Big(\frac{e^{-3/2}}{e^{-2}\sqrt{2\pi n}}\Big)^m \Big(\frac{enp}{(1-p)^2}\Big)^{(n-2)m}(1-p)^{(n^2-2)m}\\
&\sim \Big(\sqrt{\frac{e}{2\pi n}}\Big)^m \Big(\frac{enp}{(1-p)^2}\Big)^{(n-2)m}(1-p)^{(n^2-2)m},
\end{aligned}$$

which very quickly goes to 0 for $n \to \infty$. Figure 7.4 gives some numerical values which reveal that the coverage of this model in our benchmarking scenario is very poor even for relatively small system sizes n.

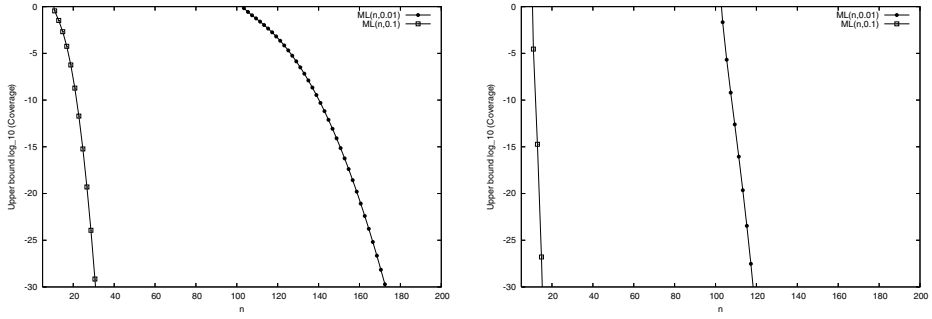

FIG. 7.4. *Coverage of $O(n)$ moving link failures per round: Upper bound on $\log_{10}\big(Cov(ML_{n-2})\big)$ over n with $p = 0.01$ and $p = 0.1$ for $m = 2$ (left) and $m = 20$ (right).*

7.2.1. Analysis of f_ℓ moving link failures per process and round (MLO_{f_ℓ}). Finally, we will show that the moving link omission failure model MLO_{f_ℓ} with $f_\ell^r = f_\ell^s = f_\ell$ introduced in section 2.2 does not suffer from poor coverage: On the contrary, in accordance with [44], we will show that $\mathrm{Cov}(MLO_{n\lambda}) \to 1$ for $n \to \infty$, for any $p < 1/2$ and $\lambda > p$.

Recalling (7.12), we have to set $\overline{n} := n-1$ and choose $\overline{p}$ to be our link failure probability p in this equation in order to obtain the probability $p_{n-1}(f_\ell)$ that at most f_ℓ outgoing links are faulty in the broadcast of a single process to its $n-1$ receivers in a round. Similarly, the probability $q_{n-1}(f_\ell) = 1 - p_{n-1}(f_\ell)$ that more than f_ℓ links are faulty in this event is given by (7.13), and Lemma 7 provides an upper bound for $q_{n-1}(f_\ell)$ for $f_\ell + 1 > (n-1)p$. Since we will eventually choose $f_\ell = (n-1)/2 - 1$ and $p < 1/2$, the latter condition is indeed satisfied. Note that there is a reasonably small upper bound for $q_{n-1}(f_\ell)$ also in case of small values $f_\ell + 1 \le (n-1)p$; see [62].

The probability that none of the n processes in the system experiences more than f_ℓ link failures on its outgoing links in a single round is $P_s = p_{n-1}(f_\ell)^n$, since the failures on the outgoing links of different processes are independent.

Obviously, (7.12) for $p_{n-1}(f_\ell)$ also provides the probability that a single receiver process experiences at most f_ℓ link failures on its incoming links. As before, the probability that none of the n processes in the system experiences more than f_ℓ link failures on its incoming links in a round is $P_r = p_{n-1}(f_\ell)^n$.

The probability P_{sr} that none of the n processes in the system experiences more than f_ℓ link failures on its outgoing links *and* no more than f_ℓ link failures on its incoming links is not just the product of P_s and P_r, however, since they are not independent. However, $P_{sr} = P_{r|s}P_s$, where $P_{r|s}$ denotes the conditional probability that no process perceives more than f_ℓ link failures on its incoming links, conditioned on the fact that no process experiences more than f_ℓ link failures on its outgoing links. Since trivially $P_{r|s} \geq P_r$, we obtain $P_{sr} \geq P_s P_r = p_{n-1}(f_\ell)^{2n}$ and hence

$$\mathrm{Cov}(MLO_{f_\ell}) = P_{sr}^m \geq (1 - q_{n-1}(f_\ell))^{2nm}.$$

By the Bernoulli inequality $(1+\alpha)^n \geq 1 + n\alpha$ for any $\alpha > -1$, we obtain

$$(1 - q_{n-1}(f_\ell))^{2nm} \geq 1 - 2nmq_{n-1}(f_\ell), \tag{7.19}$$

which is valid for $q_{n-1}(f_\ell) < 1$; since the latter is a probability < 1, this condition is of course satisfied.

Consequently, using Lemma 7, $1 - \mathrm{Cov}(MLO_{f_\ell})$ can be upper bounded by

$$1 - \mathrm{Cov}(MLO_{f_\ell}) \leq \frac{2nm(f_\ell+1)(1-p)}{f_\ell + 1 - (n-1)p}\binom{n-1}{f_\ell+1}p^{f_\ell+1}(1-p)^{n-1-f_\ell-1}. \tag{7.20}$$

A very similar analysis as for $ML_{\lambda n}$ proves that $\mathrm{Cov}(MLO_{f_\ell})$ quickly approaches 1 as $n \to \infty$ for any $f_\ell + 1 = \lambda(n-1)$ with $\lambda > p$ and $p < 1/2$: Recalling Lemma 6, we immediately obtain

$$\binom{n}{\lambda n}p^{\lambda n}(1-p)^{n(1-\lambda)} \sim \Big(\frac{1-p}{1-\lambda}\Big)^{n(1-\lambda)}\Big(\frac{p}{\lambda}\Big)^{\lambda n}\frac{1}{\sqrt{2\pi n\lambda(1-\lambda)}}.$$

Plugging $n' := n-1$ and $f_\ell + 1 = (n-1)\lambda = n'\lambda$ according into (7.20) into the above equation provides

$$1 - \mathrm{Cov}(MLO_{n'\lambda-1}) \propto \frac{m(1-p)}{\lambda - p}\cdot\sqrt{\frac{2n'\lambda}{\pi(1-\lambda)}}\left[\Big(\frac{1-p}{1-\lambda}\Big)^{1-\lambda}\Big(\frac{p}{\lambda}\Big)^{\lambda}\right]^{n'}.$$

Since $x^\lambda \leq x$ for any $0 \leq \lambda \leq 1$, and $p < \lambda$,

$$\Big(\frac{1-p}{1-\lambda}\Big)^{1-\lambda}\Big(\frac{p}{\lambda}\Big)^{\lambda} = \frac{1-p}{1-\lambda}\Big(\frac{p(1-\lambda)}{\lambda(1-p)}\Big)^{\lambda} \leq \frac{1-p}{1-\lambda}\cdot\frac{p(1-\lambda)}{\lambda(1-p)} = \frac{p}{\lambda} < 1,$$

so $\mathrm{Cov}(MLO_{(n-1)\lambda-1})$ indeed quickly approaches 1 as $n \to \infty$. In the special case $\lambda = 1/2 > p$, where $f_\ell + 1 = (n-1)/2 = n'/2$ with $n = n'+1 \sim n'$ for $n \to \infty$, we obtain

$$1 - \mathrm{Cov}(MLO_{n'/2-1}) \propto \frac{m(1-p)}{1/2 - p}\cdot\sqrt{\frac{2n'}{\pi}}\cdot\big(4p(1-p)\big)^{n'/2}, \tag{7.21}$$

which rapidly goes to 0 for $n \to \infty$, for any $p < 1/2$, and for any $m = O(n^k)$, with k arbitrary but fixed. Figure 7.5 confirms that our link failure model[8] indeed scales well with n and gives excellent coverage for any reasonable choice of parameters. Note carefully that those figures, in sharp contrast to all previous ones, show an upper bound on $1 - \mathrm{Cov}(MLO_{n'/2})$, i.e., the difference to ideal coverage.

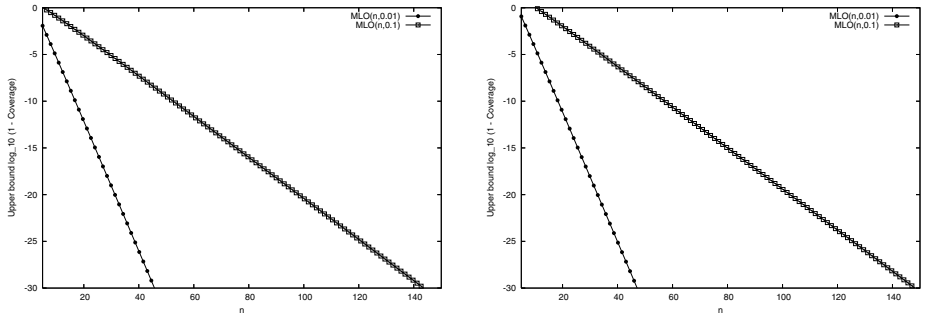

FIG. 7.5. *Coverage of f_ℓ moving link failures per round per process: Upper bound on* $\log_{10}\big(1 - Cov(MLO_{n'/2})\big)$ *over n with $p = 0.01$ and $p = 0.1$ for $m = 2$ (left) and $m = 20$ (right).*

Finally, Figure 7.6 compares our upper bounds on $\mathrm{Cov}(GO_{n/2})$, $\mathrm{Cov}(TL_{n'/2})$, and $\mathrm{Cov}(ML_{n-2})$ in a system of $n = 30$ processes, for $m = 2$ and $m = 20$ rounds, under varying link failure rates p; Figure 7.7 does the same for $n = 60$. The numerical results reveal that all those models provide poor coverage in our benchmarking scenario, particularly under substantial link failure rates. Note that this is also true for $TL_{n'/2}$, unless the number of rounds m is not below the critical value (7.10) with respect to p.

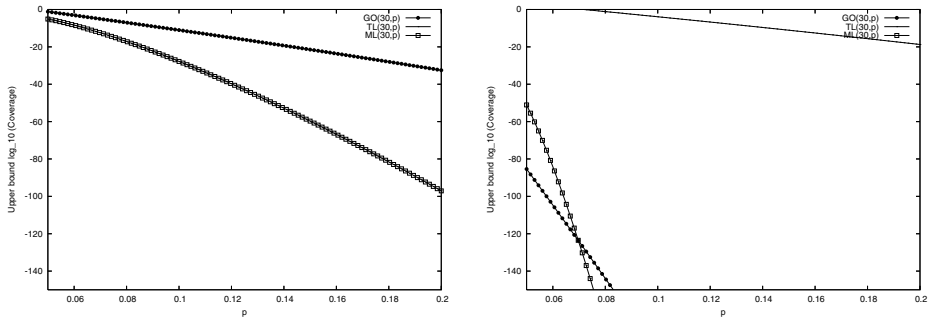

FIG. 7.6. *Upper bound on $Cov(GO_{n/2})$, $Cov(TL_{n'/2})$, and $Cov(ML_{n-1})$ over p for a system of $n = 30$ processes, for $m = 2$ (left) and $m = 20$ (right) rounds.*

By contrast, Figures 7.8 and 7.9 provide numerical results for our upper bound on $1 - \mathrm{Cov}(MLO_{n'/2})$, under the same parameter values for n and m as in Figures 7.6 and 7.7. They reveal a high coverage also under substantial link failure rates, as well as a remarkably low dependence on the number m of rounds. They finally justify our claim that MLO is the only model that performs well in our benchmarking scenario.

[8] As well as the moving timely link model for Ω and consensus of [39, 40], which can be analyzed in a similar way.

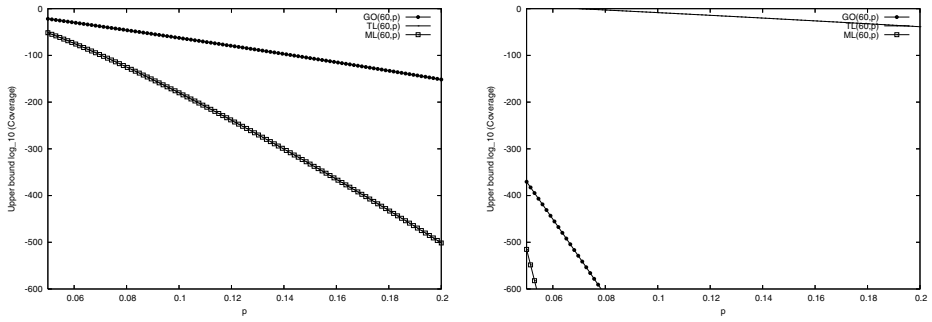

FIG. 7.7. *Upper bound on* $Cov(GO_{n/2})$, $Cov(TL_{n'/2})$, *and* $Cov(ML_{n-1})$ *over* p *for a system of* $n = 60$ *processes, for* $m = 2$ *(left) and* $m = 20$ *(right) rounds.*

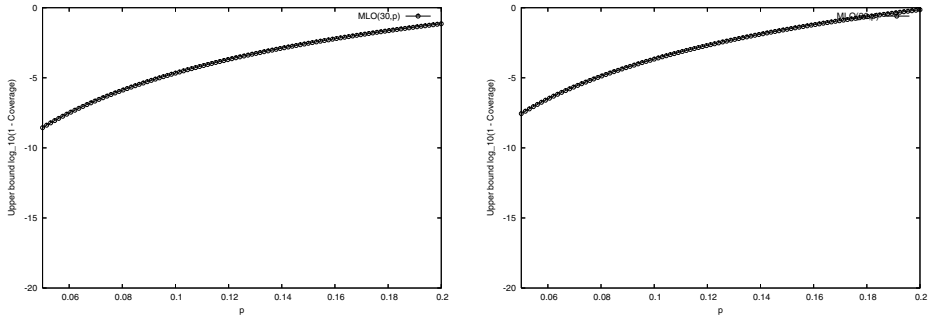

FIG. 7.8. *Upper bound on* $\log_{10}\big(1 - Cov(MLO_{n'/2})\big)$ *over* p *for a system of* $n = 30$ *processes, for* $m = 2$ *(left) and* $m = 20$ *(right) rounds.*

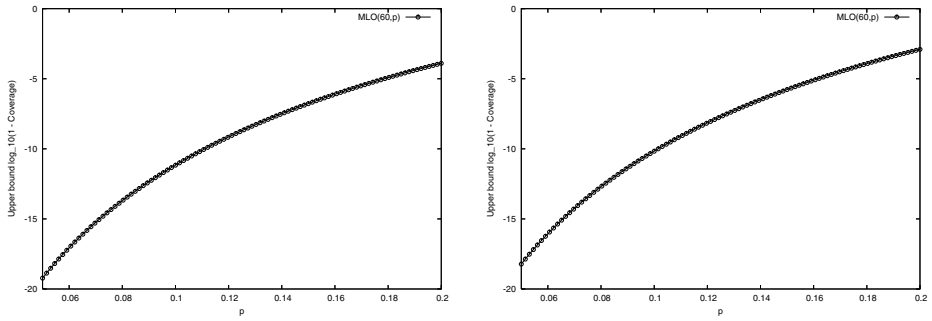

FIG. 7.9. *Upper bound on* $\log_{10}\big(1 - Cov(MLO_{n'/2})\big)$ *over* p *for a system of* $n = 60$ *processes, for* $m = 2$ *(left) and* $m = 20$ *(right) rounds.*

8. Conclusions. We provided a complete theoretical treatment of the impossibility of deterministic synchronous consensus under a novel link failure model, which grants every process a certain maximum number of send and receive link failures per round. Link failures may both be omissive and arbitrary and can hit messages to/from different processes in every round. Using novel instances of "easy impossibility" and bivalency proofs, we provided related lower bounds for the number of processes and rounds as well. Most of them are matched by existing consensus algorithms and hence

are tight. An analysis of the assumption coverage in a simple probabilistic setting revealed that our model is the only one with a coverage that approaches 1 (rather than 0) for large n.

Part of our current/future theoretical research in this area is devoted to consensus lower bounds under our fully fledged hybrid failure model, which captures both process and link failures simultaneously. We analyzed several algorithms under this model and found that the respective numbers of processes required just add up. This suggested that tolerating link failures and process failures is more or less orthogonal. In [11], however, it was shown that this is not true in general. Generalized lower bounds are hence required for reasoning about optimal algorithms here.

Acknowledgments. We are grateful to Michael Drmota for providing us with Theorem 10 from [57] and to the anonymous reviewers for their thorough and very helpful comments.

LOCALLY DECODABLE CODES FROM NICE SUBSETS OF FINITE FIELDS AND PRIME FACTORS OF MERSENNE NUMBERS*

KIRAN S. KEDLAYA† AND SERGEY YEKHANIN‡

Abstract. A k-query locally decodable code (LDC) encodes an n-bit message x as an N-bit codeword $C(x)$, such that one can probabilistically recover any bit x_i of the message by querying only k bits of the codeword $C(x)$, even after some constant fraction of codeword bits has been corrupted. The major goal of LDC related research is to establish the optimal trade-off between length and query complexity of such codes. Recently vast improvements in upper bounds for the length of LDCs were achieved via constructions that rely on existence of certain special ("nice") subsets of finite fields. In this work we extend the constructions of LDCs from "nice" subsets. We argue that further progress on upper bounds for LDCs via these methods is tied to progress on an old number theory question regarding the size of the largest prime factors of Mersenne numbers. Specifically, we show that every Mersenne number $m = 2^t - 1$ that has a prime factor $p > m^\gamma$ yields a family of $k(\gamma)$-query LDCs of length $\exp(n^{1/t})$. Conversely, if for some fixed k and all $\epsilon > 0$ one can use the "nice" subsets technique to obtain a family of k-query LDCs of length $\exp(n^\epsilon)$, then infinitely many Mersenne numbers have prime factors larger than currently known.

Key words. locally decodable codes, Mersenne primes

1. Introduction.

Classical error-correcting codes allow one to encode an n-bit string x into an N-bit codeword $C(x)$, in such a way that x can still be recovered even if $C(x)$ gets corrupted in a number of coordinates. It is well known [21] that codewords $C(x)$ of length $N = O(n)$ already suffice to correct errors in up to δN locations of $C(x)$ for any constant $\delta < 1/4$. The disadvantage of classical error-correction is that one needs to consider all or most of the (corrupted) codeword to recover anything about x. Now suppose that one is interested only in recovering one or a few bits of x. In such a case more efficient schemes are possible. Such schemes are known as locally decodable codes (LDCs). LDCs allow reconstruction of an arbitrary bit x_i from looking only at k randomly chosen coordinates of $C(x)$, where k can be as small as 2. LDCs have numerous applications in complexity theory [17, 33], cryptography [6, 13], and the theory of fault tolerant computation [28]. The following is a slightly informal definition of LDCs.

A (k, δ, ϵ)-LDC encodes n-bit strings to N-bit codewords $C(x)$, such that for every $i \in [n]$, the bit x_i can be recovered with probability $1 - \epsilon$ by a randomized decoding procedure that makes only k queries, even if the codeword $C(x)$ is corrupted in up to δN locations.

One should think of $\delta > 0$ and $\epsilon < 1/2$ as constants. The main parameters of interest in LDCs are the length N and the query complexity k. Ideally we would like to have both of them as small as possible. The concept of LDCs was explicitly discussed in various papers in the early 1990s [2, 32, 25]. Katz and Trevisan [17]

were the first to provide a formal definition of LDCs. Further work on LDCs includes [3, 10, 24, 4, 19, 35, 38, 37, 16, 27, 36, 15].

Below is a brief summary of what was known regarding the length of optimal LDCs prior to a recent paper of Yekhanin [38]. The length of optimal 2-query LDCs was settled by Kerenidis and de Wolf [19] and is $\exp(n)$.[1] The best upper bound for the length of 3-query LDCs is $\exp(n^{1/2})$ due to Beimel, Ishai, and Kushilevitz [3], and the best lower bound is $\tilde{\Omega}(n^2)$ [37]. For general (constant) k the best upper bound is $\exp(n^{O(\log\log k/(k\log k))})$ due to Beimel et al. [4], and the best lower bound is $\tilde{\Omega}(n^{1+1/(\lceil k/2\rceil-1)})$ [37].

The recent work of Yekhanin [38] improved the upper bounds to the extent that it changed the common perception of what may be achievable [14, 13]. Yekhanin [38] introduced a novel technique to construct codes from so-called nice subsets of finite fields and showed that every Mersenne prime $p = 2^t - 1$ yields a family of 3-query LDCs of length $\exp(n^{1/t})$. Based on the largest known Mersenne prime [7], this translates to a length of less than $\exp(n^{10^{-7}})$. Combined with the recursive construction from [4], this result yields vast improvements for all values of $k > 2$. It has often been conjectured that the number of Mersenne primes is infinite. If indeed this conjecture holds, Yekhanin [38] gets 3-query LDCs of length $N = \exp(n^{O(\frac{1}{\log\log n})})$ *for infinitely many* n. Finally, assuming that the conjecture of Lenstra, Pomerance, and Wagstaff (see [34, p. 388], [26]) regarding the density of Mersenne primes holds, Yekhanin [38] gets 3-query LDCs of length $N = \exp(n^{O(\frac{1}{\log^{1-\epsilon}\log n})})$ *for all* n, for every $\epsilon > 0$.

1.1. Our results. We address two natural questions left open by [38]:

1. Are Mersenne primes necessary for the constructions of [38]?
2. Has the technique of [38] been pushed to its limits, or can one construct better codes through a more clever choice of nice subsets of finite fields?

We extend the work of [38] and answer both of these questions. In what follows let $P(m)$ denote the largest prime factor of m. We show that one does not necessarily need to use Mersenne primes. It suffices to have Mersenne numbers with polynomially large prime factors. Specifically, every Mersenne number $m = 2^t - 1$ such that $P(m) \geq m^\gamma$ yields a family of $k(\gamma)$-query LDCs of length $\exp(n^{1/t})$. A partial converse also holds. Namely, if for some fixed $k \geq 3$ and all $\epsilon > 0$ one can use the technique of [38] to (unconditionally) obtain a family of k-query LDCs of length $\exp(n^\epsilon)$, then for infinitely many t we have

$$P(2^t - 1) \geq (t/2)^{1+1/(k-2)}. \tag{1}$$

The bound (1) may seem quite weak in light of the widely accepted conjecture that the number of Mersenne primes is infinite. However, (for any $k \geq 3$) this bound is substantially stronger than what is currently known unconditionally. Lower bounds for $P(2^t - 1)$ have received a considerable amount of attention in the number theory literature [29, 30, 11, 31, 23, 22, 12]. The strongest result to date is due to Stewart [31]. It says that, for all integers t ignoring a set of asymptotic density zero and for all functions $\epsilon(t) > 0$ where $\epsilon(t)$ tends to zero monotonically and arbitrarily slowly,

$$P(2^t - 1) > \epsilon(t)t\,(\log t)^2 \,/\, \log\log t. \tag{2}$$

There are no better bounds known to hold for infinitely many values of t, unless one is willing to accept some number theoretic conjectures [23, 22]. We hope that our

[1] Throughout the paper we use the standard notation $\exp(x) = e^{\Theta(x)}$.

work will further stimulate the interest in proving lower bounds for $P(2^t - 1)$ in the number theory community.

In summary, we show that one may be able to improve the unconditional bounds of [38] (say, by discovering a new Mersenne number with a very large prime factor) using the same technique. However, any attempts to reach the $\exp(n^\epsilon)$ length for some fixed query complexity and all $\epsilon > 0$ require either progress on an old number theory problem or a substantially different approach.

In this paper we deal only with binary codes for the sake of clarity of presentation. We remark, however, that our results as well as the results of [38] can be easily generalized to larger alphabets. Such a generalization is discussed in detail in [39].

1.2. Outline. In section 3 we introduce the key concepts of [38], namely, those of combinatorial and algebraic niceness of subsets of finite fields. We also briefly review the construction of LDCs from nice subsets. In section 4 we show how Mersenne numbers with large prime factors yield nice subsets of prime fields. In section 5 we prove a partial converse. Namely, we show that every finite field $\mathbb{F}_q$ containing a sufficiently nice subset is an extension of a prime field $\mathbb{F}_p$, where p is a large prime factor of a large Mersenne number. Our main results are summarized in sections 4.3 and 5.4.

2. Notation. We use the following standard mathematical notation:

- $[s] = \{1, \ldots, s\}$.
- $\mathbb{Z}_n$ denotes integers modulo n.
- $\mathbb{F}_q$ is the finite field of q elements.
- $d_H(x, y)$ denotes the Hamming distance between binary vectors x and y.
- (u, v) stands for the dot product of vectors u and v.
- For a linear space $L \subseteq \mathbb{F}_2^m$, $L^\perp$ denotes the *dual* space. That is, $L^\perp = \{u \in \mathbb{F}_2^m \mid \text{for all } v \in L,\ (u, v) = 0\}$.
- For an odd prime p, $\mathrm{ord}_p(2)$ denotes the smallest integer t such that $p \mid 2^t - 1$.

3. Nice subsets of finite fields and locally decodable codes. In this section we introduce the key technical concepts of [38], namely that of combinatorial and algebraic niceness of subsets of finite fields. We briefly review the construction of LDCs from nice subsets. Our review is concise although self-contained. We refer the reader interested in a more detailed and intuitive treatment of the construction to the original paper [38]. We start by formally defining LDCs.

DEFINITION 1. *A binary code $C : \{0,1\}^n \to \{0,1\}^N$ is said to be (k, δ, ϵ)-locally decodable if there exists a randomized decoding algorithm $\mathcal{A}$ such that the following hold:*

1. *For all $x \in \{0,1\}^n$, $i \in [n]$, and $y \in \{0,1\}^N$ such that $d_H(C(x), y) \le \delta N$, we have $Pr[\mathcal{A}(y, i) = x_i] \ge 1 - \epsilon$, where the probability is taken over the random coin tosses of the algorithm $\mathcal{A}$.*
2. *$\mathcal{A}$ reads at most k coordinates of y.*

We now introduce the concepts of combinatorial and algebraic niceness of subsets of finite fields. Our definitions are syntactically slightly different from the original definitions in [38]. We prefer these formulations since they are more appropriate for the purposes of the current paper. In what follows let $\mathbb{F}_q^*$ denote the multiplicative group of $\mathbb{F}_q$.

DEFINITION 2. *A set $S \subseteq \mathbb{F}_q^*$ is called t-combinatorially nice if for some constant $c > 0$ and every positive integer m there exist two $n = \lfloor cm^t \rfloor$-sized collections of vectors $\{u_1, \ldots, u_n\}$ and $\{v_1, \ldots, v_n\}$ in $\mathbb{F}_q^m$, such that*

1. *for all* $i \in [n]$, $(u_i, v_i) = 0$;
2. *for all* $i, j \in [n]$ *such that* $i \neq j$, $(u_j, v_i) \in S$.

DEFINITION 3. *A set* $S \subseteq \mathbb{F}_q^*$ *is called* k*-algebraically nice if* k *is odd and there exist an odd* $k' \leq k$ *and two sets* $S_0, S_1 \subseteq \mathbb{F}_q$ *such that*

1. S_0 *is not empty;*
2. $|S_1| = k'$;
3. *for all* $\alpha \in \mathbb{F}_q$ *and* $\beta \in S$, *we have* $|S_0 \cap (\alpha + \beta S_1)| \equiv 0 \bmod (2)$.

The following lemma shows that for an algebraically nice set S, the set S_0 can always be chosen to be large. It is a straightforward generalization of [38, Lemma 15].

LEMMA 4. *Let* $S \subseteq \mathbb{F}_q^*$ *be a* k*-algebraically nice set. Let* $S_0, S_1 \subseteq \mathbb{F}_q$ *be sets realizing the definition of* k*-algebraic niceness of* S. *One can always redefine the set* S_0 *to satisfy* $|S_0| \geq \lceil q/2 \rceil$.

Proof. Let L be the linear subspace of $\mathbb{F}_2^q$ spanned by the incidence vectors of the sets $\alpha + \beta S_1$ for $\alpha \in \mathbb{F}_q$ and $\beta \in S$. Observe that L is invariant under the actions of a 1-transitive permutation group (permuting the coordinates in accordance with addition in $\mathbb{F}_q$). This implies that the space $L^\perp$ is also invariant under the actions of the same group. Note that $L^\perp$ has positive dimension since it contains the incidence vector of the set S_0. The last two observations imply that $L^\perp$ has *full support*; i.e., for every $i \in [q]$ there exists a vector $v \in L^\perp$ such that $v_i \neq 0$. Note that the expected weight of a random vector in a linear subspace of $\mathbb{F}_2^q$ of full support is $q/2$. Let $v \in L^\perp$ be an arbitrary vector of weight $\lceil q/2 \rceil$. Redefining the set S_0 to be the set of nonzero coordinates of v, we conclude the proof. □

We now proceed to the core proposition of [38] that shows how sets exhibiting both combinatorial and algebraic niceness yield LDCs.

PROPOSITION 5. *Suppose* $S \subseteq \mathbb{F}_q^*$ *is* t*-combinatorially nice and* k*-algebraically nice; then for every message length* n *there exists a code of length* $\exp(n^{1/t})$ *that is* $(k, \delta, 2k\delta)$*-locally decodable for all* $\delta > 0$.

Proof. Our proof proceeds in three steps. We specify encoding and local decoding procedures for our codes and then argue the lower bound for the probability of correct decoding. We use the notation from Definitions 2 and 3.

Encoding. We assume that our message has length $n = \lfloor cm^t \rfloor$ for some integer value of m. (Otherwise we pad the message with zeros. It is easy to see that such padding does not affect the asymptotic length of the code.) Our code will be $\mathbb{F}_2$-linear. Therefore it suffices to specify the encoding of unit vectors $e_1, \ldots, e_n$, where e_j has length n and a unique nonzero coordinate j. We define the encoding of e_j to be a q^m long vector, whose coordinates are labelled by elements of $\mathbb{F}_q^m$. For all $w \in \mathbb{F}_q^m$ we set

$$\mathrm{Enc}(e_j)_w = \begin{cases} 1 & \text{if } (u_j, w) \in S_0, \\ 0 & \text{otherwise.} \end{cases} \tag{3}$$

It is straightforward to verify that we defined a code encoding n bits to $\exp(n^{1/t})$ bits.

Local decoding. Given a (possibly corrupted) codeword y and an index $i \in [n]$, the decoding algorithm $\mathcal{A}$ picks $w \in \mathbb{F}_q^m$ such that $(u_i, w) \in S_0$ uniformly at random, reads $k' \leq k$ coordinates of y, and outputs the modulo 2 sum

$$\sum_{\lambda \in S_1} y_{w + \lambda v_i}. \tag{4}$$

Probability of correct decoding. First we argue that decoding is always correct if $\mathcal{A}$ picks $w \in \mathbb{F}_q^m$ such that all bits of y in locations $\{w + \lambda v_i\}_{\lambda \in S_1}$ are not corrupted.

We need to show that for all $i \in [n]$, $x \in \{0,1\}^n$, and $w \in \mathbb{F}_q^m$, such that $(u_i, w) \in S_0$,

$$\sum_{\lambda \in S_1} \left(\sum_{j=1}^{n} x_j \operatorname{Enc}(e_j) \right)_{w+\lambda v_i} = x_i. \tag{5}$$

Note that

$$\begin{aligned} \sum_{\lambda \in S_1} \left(\sum_{j=1}^{n} x_j \operatorname{Enc}(e_j) \right)_{w+\lambda v_i} &= \sum_{j=1}^{n} x_j \sum_{\lambda \in S_1} \operatorname{Enc}(e_j)_{w+\lambda v_i} \\ &= \sum_{j=1}^{n} x_j \sum_{\lambda \in S_1} I\left[(u_j, w+\lambda v_i) \in S_0\right], \end{aligned} \tag{6}$$

where $I[\gamma \in S_0] = 1$ if $\gamma \in S_0$ and zero otherwise. Now note that

$$\begin{aligned} \sum_{\lambda \in S_1} I\left[(u_j, w+\lambda v_i) \in S_0\right] &= \sum_{\lambda \in S_1} I\left[(u_j, w) + \lambda(u_j, v_i) \in S_0\right] \\ &= \begin{cases} 1 & \text{if } i = j, \\ 0 & \text{otherwise.} \end{cases} \end{aligned} \tag{7}$$

The last identity in (7) for $i = j$ follows from $(u_i, v_i) = 0$, $(u_i, w) \in S_0$, and $k' = |S_1|$ is odd. The last identity for $i \neq j$ follows from $(u_j, v_i) \in S$ and the algebraic niceness of S. Combining identities (6) and (7), we get (5).

Now assume that up to δ fraction of bits of y are corrupted. Let T_i denote the set of coordinates whose labels belong to $\{w \in \mathbb{F}_q^m \mid (u_i, w) \in S_0\}$. Recall that by Lemma 4, $|T_i| \geq q^m/2$. Thus at most 2δ fraction of coordinates in T_i contain corrupted bits. Let $Q_i = \left\{\{w+\lambda v_i\}_{\lambda \in S_1} \mid w : (u_i, w) \in S_0\right\}$ be the family of k'-tuples of coordinates that may be queried by $\mathcal{A}$. The fact that $(u_i, v_i) = 0$ implies that every element of T_i belongs to the same number of k'-tuples from Q_i. Combining the last two observations, we conclude that with probability at least $1 - 2k\delta$ $\mathcal{A}$ picks an uncorrupted k'-tuple and outputs the correct value of x_i. □

All LDCs constructed in this paper are obtained by applying Proposition 5 to certain nice sets. Thus all our codes have the same dependence of ϵ (the probability of the decoding error) on δ (the fraction of corrupted bits). In what follows we often ignore these parameters and consider only the length and query complexity of codes.

4. Mersenne numbers with large prime factors yield nice subsets of prime fields. In what follows let $\langle 2 \rangle \subseteq \mathbb{F}_p^*$ denote the multiplicative subgroup of $\mathbb{F}_p^*$ generated by 2. In [38, Lemma 13] it is shown that for every Mersenne prime $p = 2^t - 1$ the set $\langle 2 \rangle \subseteq \mathbb{F}_p^*$ is simultaneously 3-algebraically nice and $\operatorname{ord}_p(2)$-combinatorially nice. In this section we prove the same conclusion for a substantially broader class of primes.

LEMMA 6. *Suppose p is an odd prime; then $\langle 2 \rangle \subseteq \mathbb{F}_p^*$ is $\operatorname{ord}_p(2)$-combinatorially nice.*

Proof. Let $t = \operatorname{ord}_p(2)$. Clearly, t divides $p-1$. We need to specify a constant $c > 0$ such that for every positive integer m there exist two $n = \lfloor cm^t \rfloor$-sized collections of vectors $\{u_1, \ldots, u_n\}$ and $\{v_1, \ldots, v_n\}$ in $\mathbb{F}_p^m$ satisfying

- for all $i \in [n]$, $(u_i, v_i) = 0$;
- for all $i, j \in [n]$ such that $i \neq j$, $(u_j, v_i) \in \langle 2 \rangle$.

We start with some notation. For $y \in \mathbb{F}_p^w$ and a positive integer l, let $y^{\otimes l} \in \mathbb{F}_p^{w^l}$ denote the lth tensor power of y. Coordinates of $y^{\otimes l}$ are labelled by all possible sequences in $[w]^l$ and $y^{\otimes l}_{i_1,\ldots,i_l} = \prod_{j=1}^{l} y_{i_j}$. The following identity relating tensor powers and dot products of vectors is standard. For every positive integer l and vectors u, v in $\mathbb{F}_p^w$,

$$\begin{aligned}(u^{\otimes l}, v^{\otimes l}) &= \sum_{(i_1,\ldots,i_l)\in[w]^l} \left(\prod_{j=1}^{l} u_{i_j} \prod_{j=1}^{l} v_{i_j}\right) \\ &= \sum_{(i_1,\ldots,i_l)\in[w]^l} \left(\prod_{j=1}^{l} u_{i_j} v_{i_j}\right) = \left(\sum_{i_1\in[w]} u_{i_1} v_{i_1}\right) \ldots \left(\sum_{i_l\in[w]} u_{i_l} v_{i_l}\right) = (u,v)^l.\end{aligned} \tag{8}$$

We now proceed to the construction of vectors $\{u_1, \ldots, u_n\}$ and $\{v_1, \ldots, v_n\}$ in $\mathbb{F}_p^m$. First assume that m has the shape $m = w^{(p-1)/t}$ for some integer $w \geq p-1$. Let $n = \binom{w}{p-1}$. Observe that $n \geq cm^t$ for a suitably chosen constant $c > 0$. For $i \in [n]$ let vectors u'_i in $\mathbb{F}_p^w$ be the incidence vectors of all possible subsets of $[w]$ of cardinality $(p-1)$ and let vectors v'_i be their complements (i.e., for every $i \in [n]$, $v_i = 1^w - u_i$). Observe that

- for all $i \in [n]$, $(u'_i, v'_i) = 0$;
- for all $i, j \in [n]$ such that $i \neq j$, $(u'_j, v'_i) \neq 0$.

Let $l = (p-1)/t$. For $i \in [n]$ set $u_i = u_i'^{\otimes l}$ and $v_i = v_i'^{\otimes l}$. Formula (8) and cyclicity of $\mathbb{F}_p^*$ imply that vectors $\{u_1, \ldots, u_n\}$, $\{v_1, \ldots, v_n\}$ in $\mathbb{F}_p^m$ have the desired properties, i.e.,

- for all $i \in [n]$, $(u_i, v_i) = 0$;
- for all $i, j \in [n]$ such that $i \neq j$, $(u_j, v_i) \in \langle 2 \rangle$.

Now assume that m does not have the right shape, and let m_1 be the largest integer smaller than m that does have it. In order to get vectors of length m we use vectors of length m_1 coming from the construction above padded with zeros. It is not hard to verify that such a construction still gives us $n \geq cm^t$ large families of vectors for a suitably chosen constant c. □

We use the standard notation $\overline{\mathbb{F}}$ to denote the algebraic closure of the field $\mathbb{F}$. Also let

$$C_p = \{x \in \overline{\mathbb{F}}_2^* \mid x^p = 1\}$$

denote the multiplicative subgroup of pth roots of unity in $\overline{\mathbb{F}}_2$. The next lemma generalizes [38, Lemma 14].

LEMMA 7. *Let p be a prime and k be odd. Suppose there exist $\zeta_1, \ldots, \zeta_k \in C_p$ such that*

$$\zeta_1 + \cdots + \zeta_k = 0; \tag{9}$$

then $\langle 2 \rangle \subseteq \mathbb{F}_p^*$ is k-algebraically nice.

Proof. In what follows we define the set $S_1 \subseteq \mathbb{F}_p$ and prove the existence of a set S_0 such that together S_0 and S_1 yield k-algebraic niceness of $\langle 2 \rangle$. Identity (9) and the fact that we are working in characteristic 2 imply that there exist an odd integer $k' \leq k$ and k' *distinct* pth roots of unity $\zeta'_1, \ldots, \zeta'_k \in C_p$ such that

$$\zeta'_1 + \cdots + \zeta'_{k'} = 0. \tag{10}$$

Let $t = \mathrm{ord}_p(2)$. Observe that $C_p \subseteq \mathbb{F}_{2^t}$. Let g be a generator of C_p. Identity (10) yields $g^{\gamma_1} + \cdots + g^{\gamma_{k'}} = 0$ for some distinct values $\{\gamma_i\}_{i\in[k']}$ in $\mathbb{Z}_p$. Set $S_1 = \{\gamma_1, \ldots, \gamma_{k'}\}$.

Consider a natural one-to-one correspondence between subsets S' of $\mathbb{F}_p$ and polynomials $\phi_{S'}(x)$ in the ring $\mathbb{F}_2[x]/(x^p - 1)$: $\phi_{S'}(x) = \sum_{s\in S'} x^s$. It is easy to see that for all sets $S' \subseteq \mathbb{F}_p$ and all $\alpha, \beta \in \mathbb{F}_p$, such that $\beta \neq 0$,

$$\phi_{\alpha+\beta S'}(x) = x^\alpha \phi_{S'}(x^\beta).$$

Let α be a variable ranging over $\mathbb{F}_p$ and β be a variable ranging over $\langle 2\rangle$. We are going to argue the existence of a set S_0 that has even intersections with all sets of the form $\alpha+\beta S_1$, by showing that all polynomials $\phi_{\alpha+\beta S_1}$ belong to a certain linear space $L \subset \mathbb{F}_2[x]/(x^p - 1)$ of dimension less than p. In this case any nonempty set $T \subseteq \mathbb{F}_p$ such that $\phi_T \in L^\perp$ can be used as the set S_0. Let $\tau(x) = \gcd(x^p - 1, \phi_{S_1}(x))$. Note that $\tau(x) \neq 1$ since g is a common root of $x^p - 1$ and $\phi_{S_1}(x)$. Let L be the space of polynomials in $\mathbb{F}_2[x]/(x^p - 1)$ that are multiples of $\tau(x)$. Clearly, $\dim L = p - \deg\tau$. Fix some $\alpha \in \mathbb{F}_p$ and $\beta \in \langle 2\rangle$. Let us prove that $\phi_{\alpha+\beta S_1}(x)$ is in L:

$$\phi_{\alpha+\beta S_1}(x) = x^\alpha \phi_{S_1}(x^\beta) = x^\alpha (\phi_{S_1}(x))^\beta.$$

The last identity above follows from the fact that for any $f \in \mathbb{F}_2[x]$ and any integer i we have $f(x^{2^i}) = (f(x))^{2^i}$. □

In what follows we present sufficient conditions for the existence of k-tuples of pth roots of unity in $\overline{\mathbb{F}}_2$ that sum to zero. We treat the $k = 3$ case separately since in that case we can use a specialized argument to derive a more explicit conclusion.

4.1. A sufficient condition for the existence of three *p*th roots of unity summing to zero.

LEMMA 8. *Let p be an odd prime. Suppose $\mathrm{ord}_p(2) < (4/3)\log_2 p$; then there exist three pth roots of unity in $\overline{\mathbb{F}}_2$ that sum to zero.*

Proof. Let $t = \mathrm{ord}_p(2)$. Note that $C_p \subseteq \mathbb{F}_{2^t}$. Consider the homogeneous equation

$$x_1^{(2^t-1)/p} + x_2^{(2^t-1)/p} + x_3^{(2^t-1)/p} = 0. \tag{11}$$

We count the $\mathbb{F}_{2^t}$-rational solutions to (11) up to multiplication by nonzero scalars. Let N_{2^t} denote the total number of such solutions. Davenport and Hasse [9] proved that

$$\left|N_{2^t} - (2^t + 1)\right| \leq (d-1)(d-2)2^{t/2}, \tag{12}$$

where $d = (2^t - 1)/p$ is the degree of (11). The estimate (12) is also a special case of the Weil bound [20, p. 330].

A solution $a = (x_1, x_2, x_3)$ to (11) is called trivial if one of the coordinates of a is zero. Observe that setting one of x_i, $1 \leq i \leq 3$, to zero in (11) leaves us with an equation $(x_j/x_k)^{(2^t-1)/p} = 1$ in the other two variables. Cyclicity of $\mathbb{F}_{2^t}^*$ implies that such an equation has exactly $(2^t - 1)/p$ solutions in $\mathbb{F}_{2^t}$ up to scalar multiplication. Therefore there are exactly $3(2^t - 1)/p$ trivial solutions to (11). Note that every nontrivial solution yields a triple of elements of C_p that sum to zero.

Identity (12) implies that in the case

$$2^t + 1 > \left(\frac{2^t - 1}{p} - 1\right)\left(\frac{2^t - 1}{p} - 2\right)2^{t/2} + 3\frac{2^t - 1}{p} \tag{13}$$

there exists a nontrivial solution to (11). Note that (13) follows from

$$2^t + 1 > \left(\frac{2^t}{p}\right)\left(\frac{2^t}{p}\right)2^{t/2} - \frac{2^{3t/2+1}}{p} + \frac{3\cdot 2^t}{p}, \tag{14}$$

and (14) follows from

$$2^t > 2^{2t+t/2}/p^2 \quad \text{and} \quad 2^{t/2+1} > 3.$$

Now note that the first inequality above follows from $t < (4/3)\log_2 p$, and the second follows from $t > 1$. □

Note that the constant $4/3$ in Lemma 8 cannot be improved to 2: there are no three elements of $C_{13264529}$ that sum to zero, even though $\mathrm{ord}_2(13264529) = 47 < 2\cdot\log_2 13264529 \approx 47.3$. We briefly discuss our method for verifying this at the end of section 5.3.

4.2. A sufficient condition for the existence of *k* *p*th roots of unity summing to zero. Our argument in this section proceeds in three steps. First we briefly review the notion of (additive) Fourier coefficients of subsets of $\mathbb{F}_{2^t}$. Next, we invoke a folklore argument to show that subsets of $\mathbb{F}_{2^t}$ with appropriately small nontrivial Fourier coefficients contain k-tuples of elements that sum to zero. Finally, we use a recent result of Bourgain and Chang [5] (generalizing the classical estimate for Gauss sums) to argue that (under certain constraints on p) all nontrivial Fourier coefficients of C_p are small.

For $x \in \mathbb{F}_{2^t}$ let $\mathrm{Tr}(x) = x + x^2 + \cdots + x^{2^{t-1}}$ denote the trace of x. It is a standard fact that for all x, $\mathrm{Tr}(x) \in \mathbb{F}_2$. Characters of $\mathbb{F}_{2^t}$ are homomorphisms from the additive group of $\mathbb{F}_{2^t}$ into the multiplicative group $\{\pm 1\}$. There exist 2^t characters. We denote characters by χ_a, where a ranges in $\mathbb{F}_{2^t}$, and set $\chi_a(x) = (-1)^{\mathrm{Tr}(ax)}$ [20]. Let $C(x)$ denote the incidence function of a set $C \subseteq \mathbb{F}_{2^t}$. For arbitrary $a \in \mathbb{F}_2^t$ the Fourier coefficient $\hat{C}(\chi_a)$ is defined by $\hat{C}(\chi_a) = \sum \chi_a(x)C(x)$, where the sum is over all $x \in \mathbb{F}_{2^t}$. Fourier coefficient $\hat{C}(\chi_0) = |C|$ is called trivial, and other Fourier coefficients are called nontrivial. In what follows $\sum_\chi$ stands for summation over all 2^t characters of $\mathbb{F}_{2^t}$. We need the following two standard properties of characters and Fourier coefficients:

$$\sum_\chi \chi(x) = \begin{cases} 2^t & \text{if } x = 0, \\ 0 & \text{otherwise,} \end{cases} \tag{15}$$

$$\sum_\chi \hat{C}^2(\chi) = 2^t|C|. \tag{16}$$

The following lemma is folklore.

LEMMA 9. *Let $C \subseteq \mathbb{F}_{2^t}$ and let $k \geq 3$ be a positive integer. Let F be the largest absolute value of a nontrivial Fourier coefficient of C. Suppose*

$$\frac{F}{|C|} < \left(\frac{|C|}{2^t}\right)^{1/(k-2)}; \tag{17}$$

then there exist k elements of C that sum to zero.

Proof. Let $M(C) = \#\{(\zeta_1, \ldots, \zeta_k) \in C^k \mid \zeta_1 + \cdots + \zeta_k = 0\}$. Formula (15) yields

$$M(C) = \frac{1}{2^t}\sum_{x_1,\ldots,x_k \in \mathbb{F}_{2^t}} C(x_1)\ldots C(x_k)\sum_\chi \chi(x_1 + \cdots + x_k). \tag{18}$$

Note that $\chi(x_1+\cdots+x_k)=\chi(x_1)\dots\chi(x_k)$. Changing the order of summation in (18), we get

$$M(C)=\frac{1}{2^t}\sum_{\chi}\sum_{x_1,\dots,x_k\in\mathbb{F}_{2^t}} C(x_1)\dots C(x_k)\chi(x_1)\dots\chi(x_k)=\frac{1}{2^t}\sum_{\chi}\hat{C}^k(\chi). \tag{19}$$

Note that

$$\begin{aligned}\frac{1}{2^t}\sum_{\chi}\hat{C}^k(\chi)&=\frac{|C|^k}{2^t}+\frac{1}{2^t}\sum_{\chi\neq\chi_0}\hat{C}^k(\chi)\\ &\geq\frac{|C|^k}{2^t}-F^{k-2}\frac{1}{2^t}\sum_{\chi}\hat{C}^2(\chi)=\frac{|C|^k}{2^t}-F^{k-2}|C|,\end{aligned} \tag{20}$$

where the last identity follows from (16). Combining (19) and (20) we conclude that (17) implies $M(C)>0$. □

The following lemma is a special case of [5, Theorem 1].

LEMMA 10. *Assume that $n\mid 2^t-1$ and satisfies the condition*

$$\gcd\left(n,\frac{2^t-1}{2^{t'}-1}\right)<2^{t(1-\epsilon)-t'}\quad \textit{for all}\quad 1\leq t'<t,\ t'\mid t,$$

where $\epsilon>0$ is arbitrary and fixed. Then for all $a\in\mathbb{F}_{2^t}^*$

$$\left|\sum_{x\in\mathbb{F}_{2^t}}(-1)^{\mathrm{Tr}(ax^n)}\right|<c_1 2^{t(1-\delta)}, \tag{21}$$

where $\delta=\delta(\epsilon)>0$ and $c_1=c_1(\epsilon)$ are constants.

Below is the main result of this section. Recall that C_p denotes the set of pth roots of unity in $\overline{\mathbb{F}}_2$.

LEMMA 11. *For every $c>0$ there exists an odd integer $k=k(c)$ such that the following implication holds. If p is an odd prime and $\mathrm{ord}_p(2)<c\log_2 p$, then some k elements of C_p sum to zero.*

Proof. Note that if there exist k' elements of a set $C\subseteq\overline{\mathbb{F}}_2$ that sum to zero, where k' is odd, then there exist k elements of C that sum to zero for every odd $k\geq k'$. Also note that the sum of all pth roots of unity is zero. Therefore given c it suffices to prove the existence of an odd $k=k(c)$ that works for all *sufficiently large* p. Let $t=\mathrm{ord}_p(2)$. Observe that $p>2^{t/c}$. Assume that p is sufficiently large so that $t>2c$. Next we show that the precondition of Lemma 10 holds for $n=(2^t-1)/p$ and $\epsilon=1/(2c)$. Let $t'\mid t$ and $1\leq t'<t$. Clearly $\gcd(2^{t'}-1,p)=1$. Therefore

$$\gcd\left(\frac{2^t-1}{p},\frac{2^t-1}{2^{t'}-1}\right)=\frac{2^t-1}{p(2^{t'}-1)}<\frac{2^{t(1-1/c)})}{2^{t'}-1}, \tag{22}$$

where the inequality follows from $p>2^{t/c}$. Clearly, $t>2c$ yields $2^{t/(2c)}/2>1$. Multiplying the right-hand side of (22) by $2^{t/(2c)}/2$ and using $2(2^{t'}-1)\geq 2^{t'}$ we get

$$\gcd\left(\frac{2^t-1}{p},\frac{2^t-1}{2^{t'}-1}\right)<2^{t(1-1/(2c))-t'}. \tag{23}$$

Combining (23) with Lemma 10 we conclude that there exist $\delta > 0$ and c_1 such that for all $a \in \mathbb{F}_{2^t}^*$

$$\left| \sum_{x \in \mathbb{F}_{2^t}} (-1)^{\mathrm{Tr}\left(ax^{(2^t-1)/p}\right)} \right| < c_1 2^{t(1-\delta)}. \tag{24}$$

Observe that $x^{(2^t-1)/p}$ takes every value in C_p exactly $(2^t-1)/p$ times when x ranges over $\mathbb{F}_{2^t}^*$. Therefore the left-hand side of (24) is

$$\left| (-1)^{\mathrm{Tr}(0)} + \frac{2^t-1}{p} \sum_{x \in C_p} (-1)^{\mathrm{Tr}(ax)} \right| = \left| 1 + \frac{2^t-1}{p} \hat{C}_p(\chi_a) \right|. \tag{25}$$

Let $F = \max_{a \in \mathbb{F}_2^*} |\hat{C}_p(\chi_a)|$ denote the largest absolute value of a nontrivial Fourier coefficient of C_p. Combining (24) and (25) we get

$$(2^t-1)(F/p) < c_1 2^{t(1-\delta)} + 1. \tag{26}$$

Assuming that t is sufficiently large, we get

$$(2^t-1)(F/p) < c_2 2^{t(1-\delta)} \tag{27}$$

for a suitably chosen constant c_2. Inequality (27) yields $F/p < (2c_2)2^{-\delta t}$. Pick $k \geq 3$ to be the smallest odd integer such that $(1-1/c)/(k-2) < \delta$. We now have

$$\frac{F}{p} < 2^{-\frac{(1-1/c)t}{(k-2)}} \tag{28}$$

for all sufficiently large values of p. Combining $p > 2^{t/c}$ with (28) we get

$$\frac{F}{|C_p|} < \left(\frac{|C_p|}{2^t} \right)^{1/(k-2)},$$

and the application of Lemma 9 concludes the proof. □

4.3. Summary. In this section we summarize our positive results and show that one does not necessarily need to use Mersenne primes to construct LDCs via the methods of [38]. It suffices to have Mersenne numbers with polynomially large prime factors. Recall that $P(m)$ denotes the largest prime factor of an integer m. Our first theorem gets 3-query LDCs from Mersenne numbers m with prime factors larger than $m^{3/4}$.

THEOREM 12. *Suppose $P(2^t-1) > 2^{0.75t}$; then for every message length n there exists a 3-query LDC of length $\exp(n^{1/t})$.*

Proof. Let $P(2^t-1) = p$. Observe that $p \mid 2^t-1$ and $p > 2^{0.75t}$ yield $\mathrm{ord}_p(2) < (4/3)\log_2 p$. Combining Lemmas 8, 7, and 6 with Proposition 5 we obtain the statement of the theorem. □

As an example application of Theorem 12 one can observe that $P(2^{23}-1) = 178481 > 2^{(3/4)*23} \approx 155872$ yields a family of 3-query LDCs of length $\exp(n^{1/23})$. Theorem 12 immediately yields the following theorem.

THEOREM 13. *Suppose that for infinitely many t we have $P(2^t-1) > 2^{0.75t}$; then for every $\epsilon > 0$ there exists a family of 3-query LDCs of length $\exp(n^{\epsilon})$.*

The next theorem gets constant-query LDCs from Mersenne numbers m with prime factors larger than m^γ for every value of γ.

THEOREM 14. *For every $\gamma > 0$ there exists an odd integer $k = k(\gamma)$ such that the following implication holds. Suppose that $P(2^t - 1) > 2^{\gamma t}$; then for every message length n there exists a k-query LDC of length $\exp(n^{1/t})$.*

Proof. Let $P(2^t - 1) = p$. Observe that $p \mid 2^t - 1$ and $p > 2^{\gamma t}$ yield $\mathrm{ord}_p(2) < (1/\gamma)\log_2 p$. Combining Lemmas 11, 7, and 6 with Proposition 5 we obtain the statement of the theorem. ∎

As an immediate corollary we get the following theorem.

THEOREM 15. *Suppose for some $\gamma > 0$ and infinitely many t we have $P(2^t - 1) > 2^{\gamma t}$; then there is a fixed k such that for every $\epsilon > 0$ there exists a family of k-query LDCs of length $\exp(n^\epsilon)$.*

5. Nice subsets of finite fields yield Mersenne numbers with large prime factors. We start the section with the following definition.

DEFINITION 16. *We say that a sequence $\{S_i \subseteq \mathbb{F}_{q_i}^*\}_{i\geq 1}$ of subsets of finite fields is k-nice if every S_i is k-algebraically nice and $t(i)$-combinatorially nice, for some integer valued strictly increasing function t.*

The core Proposition 5 asserts that a subset $S \subseteq \mathbb{F}_q^*$ that is k-algebraically nice and t-combinatorially nice yields a family of k-query LDCs of length $\exp(n^{1/t})$. Clearly, to get k-query LDCs of length $\exp(n^\epsilon)$ for some fixed k and every $\epsilon > 0$ via this proposition, one needs to exhibit a k-nice sequence. In this section we show how the existence of a k-nice sequence implies that infinitely many Mersenne numbers have large prime factors.

Our argument proceeds in two steps. In section 5.1 we show that a k-nice sequence yields an infinite sequence of primes $\{p_i\}_{i\geq 1}$, where every C_{p_i} contains a k-tuple of elements summing to zero. In sections 5.2 and 5.3 we show that C_p contains a (nontrivial) short additive dependence only if p is a large factor of a Mersenne number.

5.1. A nice sequence yields infinitely many primes p with short dependencies between pth roots of unity. Our argument in this section proceeds in three steps. First we study algebraically nice subsets of finite fields. Second we study combinatorially nice subsets of finite fields. Third we show how an interplay between the structural properties of algebraically and combinatorially nice subsets translates nice sequences into infinite families of primes p with short nontrivial additive dependencies in C_p.

Algebraically nice subsets of $\mathbb{F}_q^*$. We start with some notation. Consider a finite field $\mathbb{F}_q = \mathbb{F}_{p^l}$, where p is prime. Fix a basis $e_1, \ldots, e_l$ of $\mathbb{F}_q$ over $\mathbb{F}_p$. In what follows we often write $(\alpha_1, \ldots, \alpha_l) \in \mathbb{F}_p^l$ to denote $\alpha = \sum_{i=1}^l \alpha_i e_i \in \mathbb{F}_q$. Let R denote the ring $\mathbb{F}_2[x_1, \ldots, x_l]/(x_1^p - 1, \ldots, x_l^p - 1)$. Consider a natural one-to-one correspondence between subsets S_1 of $\mathbb{F}_q$ and polynomials $\phi_{S_1}(x_1, \ldots, x_l) \in R$:

$$\phi_{S_1}(x_1, \ldots, x_l) = \sum_{(\alpha_1,\ldots,\alpha_l)\in S_1} x_1^{\alpha_1} \ldots x_l^{\alpha_l}.$$

It is easy to see that for all sets $S_1 \subseteq \mathbb{F}_q$ and all $\alpha, \beta \in \mathbb{F}_q$

$$\phi_{(\alpha_1,\ldots,\alpha_l)+\beta S_1}(x_1, \ldots, x_l) = x_1^{\alpha_1} \ldots x_l^{\alpha_l} \phi_{\beta S_1}(x_1, \ldots, x_l). \tag{29}$$

Let Γ be a family of subsets of $\mathbb{F}_q$. It is straightforward to verify that a set $S_0 \subseteq \mathbb{F}_q$ has even intersections with every element of Γ if and only if ϕ_{S_0} belongs to $L^\perp$, where L is

the linear subspace of R spanned by $\{\phi_{S_1}\}_{S_1\in\Gamma}$. Combining the last observation with formula (29) we conclude that a set $S \subseteq \mathbb{F}_q^*$ is k-algebraically nice if and only if there exists a set $S_1 \subseteq \mathbb{F}_q$ of odd size $k' \leq k$ such that the ideal generated by polynomials $\{\phi_{\beta S_1}\}_{\{\beta\in S\}}$ is a proper ideal of R. Note that polynomials $\{f_1, \ldots, f_h\} \in R$ generate a proper ideal if and only if polynomials $\{f_1, \ldots, f_h, x_1^p - 1, \ldots, x_l^p - 1\}$ generate a proper ideal in $\mathbb{F}_2[x_1, \ldots, x_l]$. Also note that a family of polynomials generates a proper ideal in $\mathbb{F}_2[x_1, \ldots, x_l]$ if and only if it generates a proper ideal in $\overline{\mathbb{F}}_2[x_1, \ldots, x_l]$. Now an application of Hilbert's Nullstellensatz [8, p. 168] implies that a set $S \subseteq \mathbb{F}_q^*$ is k-algebraically nice if and only if there is a set $S_1 \subseteq \mathbb{F}_q$ of odd size $k' \leq k$ such that the polynomials $\{\phi_{\beta S_1}\}_{\{\beta\in S\}}$ and $\{x_i^p - 1\}_{1\leq i\leq l}$ have a common root in $\overline{\mathbb{F}}_2$.

LEMMA 17. *Let $\mathbb{F}_q = \mathbb{F}_{p^l}$, where p is prime. Suppose $\mathbb{F}_q$ contains a nonempty k-algebraically nice subset; then there exist $\zeta_1, \ldots, \zeta_k \in C_p$ such that $\zeta_1 + \cdots + \zeta_k = 0$.*

Proof. Assume that $S \subseteq \mathbb{F}_q^*$ is nonempty and k-algebraically nice. The discussion above implies that there exists $S_1 \subseteq \mathbb{F}_q$ of odd size $k' \leq k$ such that all polynomials $\{\phi_{\beta S_1}\}_{\{\beta\in S\}}$ vanish at some $(\zeta_1, \ldots, \zeta_l) \in C_p^l$. Fix an arbitrary $\beta_0 \in S$, and note that C_p is closed under multiplication. Thus each of the k' monomials of $\phi_{\beta_0 S_1}$ is a root of unity when evaluated at $(\zeta_1, \ldots, \zeta_l)$, and

$$\phi_{\beta_0 S_1}(\zeta_1, \ldots, \zeta_l) = 0 \tag{30}$$

yields k' pth roots of unity that sum to zero. It is readily seen that (since we are working in characteristic 2) one can extend (30) by adding an appropriate number of pairs of identical roots to obtain k pth roots of unity that sum to zero for any odd $k \geq k'$. □

Note that Lemma 17 does not suffice to prove that a k-nice sequence $\{S_i \subseteq \mathbb{F}_{q_i}^*\}_{i\geq 1}$ yields infinitely many primes p with short (nontrivial) additive dependencies in C_p. We need to argue that the set $\{\operatorname{char} \mathbb{F}_{q_i}\}_{i\geq 1}$ cannot be finite. This is our goal for the remainder of the section.

To proceed, we need some more notation. Recall that $q = p^l$ and p is prime. For $x \in \mathbb{F}_q$ let $\operatorname{Tr}(x) = x + \cdots + x^{p^{l-1}} \in \mathbb{F}_p$ denote the (absolute) trace of x. For $\gamma \in \mathbb{F}_q$, $c \in \mathbb{F}_p^*$ we call the set $\pi_{\gamma,c} = \{x \in \mathbb{F}_q \mid \operatorname{Tr}(\gamma x) = c\}$ a *proper-affine hyperplane* of $\mathbb{F}_q$.

LEMMA 18. *Let $\mathbb{F}_q = \mathbb{F}_{p^l}$, where p is prime. Suppose $S \subseteq \mathbb{F}_q^*$ is k-algebraically nice; then there exist $h \leq p^k$ proper-affine hyperplanes $\{\pi_{\gamma_r,c_r}\}_{1\leq r\leq h}$ of $\mathbb{F}_q$ such that $S \subseteq \bigcup_{r=1}^h \pi_{\gamma_r,c_r}$.*

Proof. The discussion preceding Lemma 17 implies that there exists a set $S_1 = \{\sigma_1, \ldots, \sigma_{k'}\} \subseteq \mathbb{F}_q$ of odd size $k' \leq k$ such that all polynomials $\{\phi_{\beta S_1}\}_{\{\beta\in S\}}$ vanish at some $(\zeta_1, \ldots, \zeta_l) \in C_p^l$. Let ζ be a generator of C_p. For every $1 \leq i \leq l$, pick $\omega_i \in \mathbb{Z}_p$ such that $\zeta_i = \zeta^{\omega_i}$. For every $\beta \in S$, $\phi_{\beta S_1}(\zeta_1, \ldots, \zeta_l) = 0$ yields

$$\sum_{\mu=(\mu_1,\ldots,\mu_l)\in\beta S_1} \zeta^{\sum_{i=1}^l \mu_i\omega_i} = 0. \tag{31}$$

Observe that for fixed values $\{\omega_i\}_{1\leq i\leq l} \in \mathbb{Z}_p$ the map $D(\mu) = \sum_{i=1}^l \mu_i\omega_i$ is a linear map from $\mathbb{F}_q$ to $\mathbb{F}_p$. It is a standard fact that every such map can be expressed as $D(\mu) = \operatorname{Tr}(\delta\mu)$ for an appropriate choice of $\delta \in \mathbb{F}_q$ [20]. Therefore we can rewrite (31) as

$$\sum_{\mu\in\beta S_1} \zeta^{\operatorname{Tr}(\delta\mu)} = \sum_{\sigma\in S_1} \zeta^{\operatorname{Tr}(\delta\beta\sigma)} = 0. \tag{32}$$

Let $W = \left\{(w_1, \dots, w_{k'}) \in \mathbb{Z}_p^{k'} \;\middle|\; \zeta^{w_1} + \dots + \zeta^{w_{k'}} = 0\right\}$ denote the set of exponents of k'-dependencies between powers of ζ. Clearly, $|W| \le p^k$. Identity (32) implies that every $\beta \in S$ satisfies

$$\begin{cases} \operatorname{Tr}((\delta\sigma_1)\beta) &= w_1, \\ \vdots & \\ \operatorname{Tr}((\delta\sigma_{k'})\beta) &= w_{k'} \end{cases} \tag{33}$$

for an appropriate choice of $(w_1, \dots, w_{k'}) \in W$. Note that the all-zeros vector does not lie in W since k' is odd and the characteristic is even. Therefore at least one of the identities in (33) has a nonzero right-hand side and defines a proper-affine hyperplane of $\mathbb{F}_q$. Collecting one such hyperplane for every element of W we get a family of $|W|$ proper-affine hyperplanes containing every element of S. □

Combinatorially nice subsets of $\mathbb{F}_q^*$. Lemma 18 gives us some insight into the structure of algebraically nice subsets of $\mathbb{F}_q$. Our next goal is to develop an insight into the structure of combinatorially nice subsets. We start by reviewing some relations between tensor and dot products of vectors. For vectors $u \in \mathbb{F}_q^m$ and $v \in \mathbb{F}_q^n$ let $u \otimes v \in \mathbb{F}_q^{mn}$ denote the tensor product of u and v. Coordinates of $u \otimes v$ are labelled by all possible elements of $[m] \times [n]$ and $(u \otimes v)_{i,j} = u_i v_j$. Also, let $u^{\otimes l}$ denote the lth tensor power of u and let $u \circ v \in \mathbb{F}_q^{m+n}$ denote the concatenation of u and v. The following identity is standard. For any $u, x \in \mathbb{F}_q^m$ and $v, y \in \mathbb{F}_q^n$,

$$(u \otimes v, x \otimes y) = \sum_{i \in [m],\, j \in [n]} u_i v_j x_i y_j = \left(\sum_{i \in [m]} u_i x_i\right)\left(\sum_{j \in [n]} v_j y_j\right) = (u, x)(v, y). \tag{34}$$

In what follows we need a generalization of identity (34). First we let $f(x_1, \dots, x_h) = \sum_i c_i x_1^{\alpha_1^{(i)}} \dots x_h^{\alpha_h^{(i)}}$ be a polynomial in $\mathbb{F}_q[x_1, \dots, x_h]$. Then we define $\bar{f} \in \mathbb{F}_q[x_1, \dots, x_h]$ by $\bar{f} = \sum_{i : c_i \ne 0} x_1^{\alpha_1^{(i)}} \dots x_h^{\alpha_h^{(i)}}$; i.e., we simply set all nonzero coefficients of f to 1. Assume that f has no free term. For vectors $u_1, \dots, u_h$ in $\mathbb{F}_q^m$ define

$$f(u_1, \dots, u_h) = \dots \circ \left(c_i u_1^{\otimes \alpha_1^{(i)}} \otimes \dots \otimes u_h^{\otimes \alpha_h^{(i)}}\right) \circ \dots, \tag{35}$$

where the concatenation is over all values of i. Note that to obtain $f(u_1, \dots, u_h)$ we replaced products in f by tensor products and replaced addition by concatenation. Clearly, $f(u_1, \dots, u_h)$ is a vector whose length may be larger than m.

LEMMA 19. *For every $f \in \mathbb{F}_q[x_1, \dots, x_h]$ and $u_1, \dots, u_h, v_1, \dots, v_h \in \mathbb{F}_q^m$,*

$$\left(f(u_1, \dots, u_h), \bar{f}(v_1, \dots, v_h)\right) = f((u_1, v_1), \dots, (u_h, v_h)). \tag{36}$$

Proof. Let $\mathbf{u} = (u_1, \dots, u_h)$ and $\mathbf{v} = (v_1, \dots, v_h)$. Observe that if (36) holds for polynomials f_1 and f_2 defined over disjoint sets of monomials, then it also holds for $f = f_1 + f_2$:

$$\begin{aligned} \left(f(\mathbf{u}), \bar{f}(\mathbf{v})\right) &= \left((f_1 + f_2)(\mathbf{u}), (\bar{f}_1 + \bar{f}_2)(\mathbf{v})\right) = \left(f_1(\mathbf{u}) \circ f_2(\mathbf{u}), \bar{f}_1(\mathbf{v}) \circ \bar{f}_2(\mathbf{v})\right) \\ &= f_1\left((u_1, v_1), \dots, (u_h, v_h)\right) + f_2\left((u_1, v_1), \dots, (u_h, v_h)\right) = f\left((u_1, v_1), \dots, (u_h, v_h)\right). \end{aligned}$$

Therefore it suffices to prove (36) for monomials $f = c x_1^{\alpha_1} \dots x_h^{\alpha_h}$. It remains to notice that identity (36) for monomials $f = c x_1^{\alpha_1} \dots x_h^{\alpha_h}$ follows immediately from formula (34) using induction on $\sum_{i=1}^h \alpha_i$. □

The next lemma bounds combinatorial niceness of certain subsets of $\mathbb{F}_q^*$.

LEMMA 20. *Let $\mathbb{F}_q = \mathbb{F}_{p^l}$, where p is prime. Let $S \subseteq \mathbb{F}_q^*$. Suppose there exist h proper-affine hyperplanes $\{\pi_{\gamma_r,c_r}\}_{1\le r\le h}$ of $\mathbb{F}_q$ such that $S \subseteq \bigcup_{r=1}^{h} \pi_{\gamma_r,c_r}$; then S is at most $h(p-1)$-combinatorially nice.*

Proof. Assume S is t-combinatorially nice. This implies that for some $c > 0$ and every m there exist two $n = \lfloor cm^t \rfloor$-sized collections of vectors $\{u_i\}_{i\in[n]}$ and $\{v_i\}_{i\in[n]}$ in $\mathbb{F}_q^m$, such that

- for all $i \in [n]$, $(u_i, v_i) = 0$;
- for all $i, j \in [n]$ such that $i \neq j$, $(u_j, v_i) \in S$.

For a vector $u \in \mathbb{F}_q^m$ and integer e let u^e denote the vector resulting from raising every coordinate of u to the power e. For every $i \in [n]$ and $r \in [h]$ define vectors $u_i^{(r)}$ and $v_i^{(r)}$ in $\mathbb{F}_q^{ml}$ by

$$u_i^{(r)} = (\gamma_r u_i) \circ (\gamma_r u_i)^p \circ \cdots \circ (\gamma_r u_i)^{p^{l-1}} \quad \text{and} \quad v_i^{(r)} = v_i \circ v_i^p \circ \cdots \circ v_i^{p^{l-1}}. \tag{37}$$

Note that for every $r_1, r_2 \in [h]$, $v_i^{(r_1)} = v_i^{(r_2)}$. It is straightforward to verify that for every $i, j \in [n]$ and $r \in [h]$,

$$\left(u_j^{(r)}, v_i^{(r)}\right) = \mathrm{Tr}(\gamma_r(u_j, v_i)). \tag{38}$$

Combining formula (38) with $\mathrm{Tr}(0) = 0$ and using the fact that the set S is covered by proper-affine hyperplanes $\{\pi_{\gamma_r,c_r}\}_{r\in[h]}$ we conclude that

- for all $i \in [n]$ and $r \in [h]$, $(u_i^{(r)}, v_i^{(r)}) = 0$;
- for all $i, j \in [n]$ such that $i \neq j$, there exists $r \in [h]$ such that $(u_j^{(r)}, v_i^{(r)}) \in \mathbb{F}_p^*$.

Pick $g(x_1, \ldots, x_h) \in \mathbb{F}_p[x_1, \ldots, x_h]$ to be a homogeneous degree h polynomial such that for $\mathbf{a} = (a_1, \ldots, a_h) \in \mathbb{F}_p^h : g(\mathbf{a}) = 0$ if and only if $\mathbf{a}$ is the all-zeros vector. The existence of such a polynomial g follows from [20, Example 6.7]. Set $f = g^{p-1}$. Note that for $\mathbf{a} \in \mathbb{F}_p^h : f(a) = 0$ if $\mathbf{a}$ is the all-zeros vector, and $f(a) = 1$ otherwise. For all $i \in [n]$ define

$$u_i' = f\left(u_i^{(1)}, \ldots, u_i^{(h)}\right) \circ (1) \quad \text{and} \quad v_i' = \bar{f}\left(v_i^{(1)}, \ldots, v_i^{(h)}\right) \circ (-1). \tag{39}$$

Note that f and $\bar{f}$ are homogeneous degree $(p-1)h$ polynomials in h variables. Therefore (35) implies that, for all i vectors, u_i' and v_i' have $m' \le h^{(p-1)h}(ml)^{(p-1)h} + 1$ coordinates. Combining identities (39) and (36) and using the properties of dot products between vectors $\{u_i^{(r)}\}$ and $\{v_i^{(r)}\}$ discussed above, we conclude that for every m there exist two $n = \lfloor cm^t \rfloor$-sized collections of vectors $\{u_i'\}_{i\in[n]}$ and $\{v_i'\}_{i\in[n]}$ in $\mathbb{F}_q^{m'}$ such that

- for all $i \in [n]$, $(u_i', v_i') = -1$;
- for all $i, j \in [n]$ such that $i \neq j$, $(u_j', v_i') = 0$.

It remains to notice that a family of vectors with such properties exists only if $n \le m'$, i.e.,

$$\lfloor cm^t \rfloor \le h^{(p-1)h}(ml)^{(p-1)h} + 1.$$

Given that we can pick m to be arbitrarily large, this implies that $t \le (p-1)h$. ∎

Summary. The next lemma presents the main result of this section.

LEMMA 21. *Let k be an odd integer. Suppose there exists a k-nice sequence; then for infinitely many primes p some k elements of C_p sum to zero.*

Proof. Assume that $\{S_i \subseteq \mathbb{F}_{q_i}^*\}_{i\geq 1}$ is k-nice. Let p be a fixed prime. Combining Lemmas 18 and 20 we conclude that every k-algebraically nice subset $S \subseteq \mathbb{F}_{p^l}^*$ is at most $(p-1)p^k$-combinatorially nice. Note that our bound on combinatorial niceness is independent of l. Therefore there are only finitely many extensions of the field $\mathbb{F}_p$ in the sequence $\{\mathbb{F}_{q_i}\}_{i\geq 1}$, and the set $\mathbb{P} = \{\operatorname{char}\mathbb{F}_{q_i}\}_{i\geq 1}$ is infinite. It remains to notice that according to Lemma 17 for every $p \in \mathbb{P}$ there exist k elements of C_p that sum to zero. ∎

In what follows we present necessary conditions for the existence of k-tuples of pth roots of unity in $\overline{\mathbb{F}}_2$ that sum to zero. We treat the $k = 3$ case separately since in that case we can use a specialized argument to derive a slightly stronger conclusion.

5.2. A necessary condition for the existence of k pth roots of unity summing to zero. We start the section with the following lemma.

LEMMA 22. *Let $k \geq 3$ be odd and p be a prime. Suppose there exist $\zeta_1, \dots, \zeta_k \in C_p$ such that $\sum_{i=1}^k \zeta_i = 0$; then*

$$\operatorname{ord}_p(2) \leq 2p^{1-1/(k-1)}. \tag{40}$$

Proof. Let $t = \operatorname{ord}_p(2)$. Note that $C_p \subseteq \mathbb{F}_{2^t}$. Note also that no element of C_p other than the multiplicative identity falls into a proper subfield of $\mathbb{F}_{2^t}$. Therefore, for every $\zeta \in C_p$ where $\zeta \neq 1$ and every nonzero $f(x) \in \mathbb{F}_2[x]$ such that $\deg f \leq t-1$, we have $f(\zeta) \neq 0$.

By multiplying $\sum_{i=1}^k \zeta_i = 0$ through by ζ_k^{-1}, we may reduce to the case $\zeta_k = 1$. Let ζ be a generator of C_p. For every $i \in [k-1]$ pick $w_i \in \mathbb{Z}_p$ such that $\zeta_i = \zeta^{w_i}$. We now have $\sum_{i=1}^{k-1} \zeta^{w_i} + 1 = 0$. Set $h = \lfloor (t-1)/2 \rfloor$. In what follows we interchangeably treat variables $\{i_l, i_l', j_l\}_{l\in[k-1]}$ that take integer values in the range $[-\lfloor p/2 \rfloor, \lfloor p/2 \rfloor]$ as taking values in $\mathbb{Z}$ or in $\mathbb{Z}_p$. Consider the $(k-1)$-tuples

$$(mw_1 + i_1, \dots, mw_{k-1} + i_{k-1}) \in \mathbb{Z}_p^{k-1} \quad \text{for} \quad m \in \mathbb{Z}_p \quad \text{and} \quad i_1, \dots, i_{k-1} \in [0, h]. \tag{41}$$

Suppose two of these coincide, say

$$(mw_1 + i_1, \dots, mw_{k-1} + i_{k-1}) = (m'w_1 + i_1', \dots, m'w_{k-1} + i_{k-1}')$$

with $(m, i_1, \dots, i_{k-1}) \neq (m', i_1', \dots, i_{k-1}')$. Set $n = m - m'$ and $j_l = i_l' - i_l$ for $l \in [k-1]$. We now have

$$(nw_1, \dots, nw_{k-1}) = (j_1, \dots, j_{k-1})$$

with $-h \leq j_1, \dots, j_{k-1} \leq h$. Observe that $n = 0$ would imply $m = m'$ and $i_l = i_l'$ for all $l \in [k-1]$. Therefore $n \neq 0$, and there exists a $g \in \mathbb{Z}_p$ such that $ng = 1$ modulo p. Consider a polynomial

$$P(z) = z^{j_1+h} + \dots + z^{j_{k-1}+h} + z^h \in \mathbb{F}_2[z].$$

Note that $\deg P \leq 2h \leq t-1$. Note also that $P(1) = 1$ and $P(\zeta^g) = 0$. The latter identity contradicts the fact that ζ^g is a proper element of $\mathbb{F}_{2^t}$. This contradiction implies that all $(k-1)$-tuples in (41) are distinct. This yields

$$p^{k-1} \geq p\left(\frac{t}{2}\right)^{k-1},$$

which is equivalent to (40). ∎

5.3. A necessary condition for the existence of three pth roots of unity summing to zero. In this section we slightly strengthen Lemma 22 in the special case when $k = 3$. Our argument is loosely inspired by the Agrawal–Kayal–Saxena deterministic primality test [1].

LEMMA 23. *Let p be a prime. Suppose there exist $\zeta_1, \zeta_2, \zeta_3 \in C_p$ that sum up to zero; then*

$$\operatorname{ord}_p(2) \le ((4/3)p)^{1/2}. \tag{42}$$

Proof. Let $t = \operatorname{ord}_p(2)$. Note that $C_p \subseteq \mathbb{F}_{2^t}$. Note also that no element of C_p other than the multiplicative identity falls into a proper subfield of $\mathbb{F}_{2^t}$. Therefore, for every $\zeta \in C_p$ where $\zeta \neq 1$ and every nonzero $f(x) \in \mathbb{F}_2[x]$ such that $\deg f \le t-1$, we have $f(\zeta) \neq 0$.

Observe that $\zeta_1+\zeta_2+\zeta_3 = 0$ implies $\zeta_1\zeta_2^{-1}+1 = \zeta_3\zeta_2^{-1}$. This yields $(\zeta_1\zeta_2^{-1}+1)^p = 1$. Put $\zeta = \zeta_1\zeta_2^{-1}$. Note that $\zeta \neq 1$ and $\zeta, 1+\zeta \in C_p$. Consider the products $\pi_{i,j} = \zeta^i(1+\zeta)^j \in C_p$ for $0 \le i, j \le t-1$. Note that $\pi_{i,j}, \pi_{k,l}$ cannot be the same if $i \ge k$, $l \ge j$, and $(i,j) \neq (k,l)$ as then ζ is a root of a polynomial

$$f(z) = z^{i-k} - (1+z)^{l-j},$$

which has degree less than t. In other words, if $\pi_{i,j} = \pi_{k,l}$ and $(i,j) \neq (k,l)$, then the pairs (i,j) and (k,l) are comparable under termwise comparison. In particular, either $(k,l) = (i+a,\, j+b)$ or $(i,j) = (k+a,\, l+b)$ for some pair (a,b) with $\pi_{a,b} = 1$.

We next check that there cannot be two distinct nonzero pairs $(a,b), (a',b')$ with $\pi_{a,b} = \pi_{a',b'} = 1$. As shown above, these pairs must be comparable; we may assume without loss of generality that $a \le a'$, $b \le b'$. The equations $\pi_{a,b} = 1$ and $\pi_{a'-a,\,b'-b} = 1$ force $a+b \ge t$ and $(a'-a)+(b'-b) \ge t$, so $a'+b' \ge 2t$. But $a', b' \le t-1$, a contradiction.

If there is no nonzero pair (a,b) with $0 \le a, b \le t-1$ and $\pi_{a,b} = 1$, then all $\pi_{i,j}$ are distinct, so $p \ge t^2$. Otherwise, as above, the pair (a,b) is unique, and the products $\pi_{i,j}$ with $0 \le i, j \le t-1$ and $(i,j) \not\ge (a,b)$ are pairwise distinct. The number of pairs excluded by the condition $(i,j) \not\ge (a,b)$ is $(t-a)(t-b)$; since $a+b \ge t$, $(t-a)(t-b) \le t^2/4$. Hence $p \ge t^2 - t^2/4 = 3t^2/4$ as desired. ∎

While the necessary condition given by Lemma 23 is quite far away from the sufficient condition given by Lemma 8, it nonetheless suffices for checking that for most primes p, there do not exist three pth roots of unity summing to zero. For instance, among the 664578 odd primes $p \le 10^8$, all but 550 are ruled out by Lemma 23. (There is an easy argument that t must be odd if $p > 3$; this cuts the list down to 273 primes.) Each remaining p can be tested by computing $\gcd(x^p+1,\, (x+1)^p+1)$; the only examples we found that did not satisfy the condition of Lemma 8 were $(p,t) = (73,9), (262657,27), (599479,33), (121369,39)$.

5.4. Summary. In the beginning of section 5 we argued that in order to use the method of [38] (i.e., Proposition 5) to obtain k-query LDCs of length $\exp(n^\epsilon)$ for some fixed k and all $\epsilon > 0$, one needs to exhibit a k-nice sequence of subsets of finite fields. In what follows we use technical results of the previous subsections to show that the existence of a k-nice sequence implies that infinitely many Mersenne numbers have large prime factors.

THEOREM 24. *Let k be odd. Suppose there exists a k-nice sequence of subsets of finite fields; then for infinitely many values of t we have*

$$P(2^t - 1) \ge (t/2)^{1+1/(k-2)}. \tag{43}$$

Proof. Using Lemmas 21 and 22 we conclude that a k-nice sequence yields infinitely many primes p such that $\mathrm{ord}_p(2) \le 2p^{1-1/(k-1)}$. Let p be such a prime and $t = \mathrm{ord}_p(2)$. Then $P(2^t - 1) \ge (t/2)^{1+1/(k-2)}$. □

A combination of Lemmas 21 and 23 yields a slightly stronger bound for the special case of 3-nice sequences.

THEOREM 25. *Suppose there exists a 3-nice sequence of subsets; then for infinitely many values of t we have*

$$P(2^t - 1) \ge (3/4)t^2. \tag{44}$$

We would like to remind the reader that although the lower bounds for $P(2^t - 1)$ given by (43) and (44) are extremely weak in light of the widely accepted conjecture stating that the number of Mersenne primes is infinite, they are substantially stronger than what is currently known unconditionally (2).

Acknowledgments. Sergey Yekhanin would like to thank Swastik Kopparty for providing the reference [5] and outlining the proof of Lemma 9. He would also like to thank Henryk Iwaniec, Carl Pomerance, and Peter Sarnak for their feedback regarding the number theory problems discussed in this paper. The authors would like to thank the reviewers for valuable comments.

THE COMPLEXITY OF WEIGHTED BOOLEAN #CSP*

MARTIN DYER†, LESLIE ANN GOLDBERG‡, AND MARK JERRUM§

Abstract. This paper gives a dichotomy theorem for the complexity of computing the partition function of an instance of a weighted Boolean constraint satisfaction problem. The problem is parameterized by a finite set $\mathcal{F}$ of nonnegative functions that may be used to assign weights to the configurations (feasible solutions) of a problem instance. Classical constraint satisfaction problems correspond to the special case of 0,1-valued functions. We show that computing the partition function, i.e., the sum of the weights of all configurations, is $\mathsf{FP}^{\#\mathsf{P}}$-complete unless either (1) every function in $\mathcal{F}$ is of "product type," or (2) every function in $\mathcal{F}$ is "pure affine." In the remaining cases, computing the partition function is in P.

1. Introduction.

This paper gives a dichotomy theorem for the complexity of the partition function of weighted Boolean constraint satisfaction problems. Such problems are parameterized by a set $\mathcal{F}$ of nonnegative functions that may be used to assign weights to configurations (solutions) of the instance. These functions take the place of the allowed constraint relations in classical constraint satisfaction problems (CSPs). Indeed, the classical setting may be recovered by restricting $\mathcal{F}$ to functions with range $\{0, 1\}$. The key problem associated with an instance of a weighted CSP is to compute its partition function, i.e., the sum of weights of all its configurations. Computing the partition function of a weighted CSP may be viewed as a generalization of counting the number of satisfying solutions of a classical CSP. Many partition functions from statistical physics may be expressed as weighted CSPs. For example, the *Potts model* [22] is naturally expressible as a weighted CSP, whereas in the classical framework only the "hard-core" versions may be directly expressed. (The hard-core version of the *antiferromagnetic* Potts model corresponds to graph coloring, and the hard-core version of the *ferromagnetic* Potts model is trivial—acceptable configurations color the entire graph with a single color.) A corresponding weighted version of the decision CSP was investigated by Cohen et al. [3]. This results in optimization problems.

We use $\#\mathsf{CSP}(\mathcal{F})$ to denote the problem of computing the partition function of weighted CSP instances that can be expressed using only functions from $\mathcal{F}$. We show in Theorem 4 below that if every function $f \in \mathcal{F}$ is "of product type," then computing the partition function $Z(I)$ of an instance I can be done in polynomial time. Formal definitions are given later, but the condition of being of product type is easily checked—it essentially means that the partition function factors. We show further in

Theorem 4 that if every function $f \in \mathcal{F}$ is "pure affine," then the partition function of $Z(I)$ can be computed in polynomial time. Once again, there is an algorithm to check whether $\mathcal{F}$ is pure affine. For each other set $\mathcal{F}$, we show in Theorem 4 that computing the partition function of a $\#\mathsf{CSP}(\mathcal{F})$ instance is complete for the class $\mathsf{FP}^{\#\mathsf{P}}$. The existence of algorithms for testing the properties of being purely affine or of product type means that the dichotomy is effectively decidable.

1.1. Constraint satisfaction. Constraint satisfaction, which originated in artificial intelligence, provides a general framework for modeling decision problems and has many practical applications. (See, for example, [17].) Decisions are modelled by *variables*, which are subject to *constraints*, modelling logical and resource restrictions. The paradigm is sufficiently broad that many interesting problems can be modelled, from satisfiability problems to scheduling problems and graph-theory problems. Understanding the complexity of CSPs has become a major and active area within computational complexity [7, 13].

A CSP typically has a finite *domain*, which we will denote by $[q] = \{0, 1, \ldots, q-1\}$ for a positive integer q.[1] A *constraint language* Γ with domain $[q]$ is a set of relations on $[q]$. For example, take $q = 2$. The relation $R = \{(0,0,1), (0,1,0), (1,0,0), (1,1,1)\}$ is a 3-ary relation on the domain $\{0,1\}$, with four tuples.

Once we have fixed a constraint language Γ, an *instance* of the CSP is a set of *variables* $V = \{v_1, \ldots, v_n\}$ and a set of *constraints*. Each constraint has a *scope,* which is a tuple of variables (for example, (v_4, v_5, v_1)) and a relation from Γ of the same arity, which constrains the variables in the scope. A *configuration* σ is a function from V to $[q]$. The configuration σ is *satisfying* if the scope of every constraint is mapped to a tuple that is in the corresponding relation. In our example above, a configuration σ satisfies the constraint with scope (v_4, v_5, v_1) and relation R if and only if it maps an odd number of the variables in $\{v_1, v_4, v_5\}$ to the value 1. Given an instance of a CSP with constraint language Γ, the *decision problem* $\mathsf{CSP}(\Gamma)$ asks us to determine whether any configuration is satisfying. The *counting problem* $\#\mathsf{CSP}(\Gamma)$ asks us to determine the *number* of (distinct) satisfying configurations.

Varying the constraint language Γ defines the classes CSP and $\#\mathsf{CSP}$ of decision and counting problems. These contain problems of different computational complexities. For example, if $\Gamma = \{R_1, R_2, R_3\}$, where R_1, R_2, and R_3 are the three binary relations defined by $R_1 = \{(0,1), (1,0), (1,1)\}$, $R_2 = \{(0,0), (0,1), (1,1)\}$, and $R_3 = \{(0,0), (0,1), (1,0)\}$, then $\mathsf{CSP}(\Gamma)$ is the classical 2-satisfiability problem, which is in P. On the other hand, there is a similar constraint language Γ' with four relations of arity 3 such that 3-satisfiability (which is NP-complete) can be represented in $\mathsf{CSP}(\Gamma')$. It may happen that the counting problem is harder than the decision problem. If Γ is the constraint language of 2-satisfiability above, then $\#\mathsf{CSP}(\Gamma)$ contains the problem of counting independent sets in graph, and is $\#\mathsf{P}$-complete [21] even if restricted to 3-regular graphs [12].

Any decision problem $\mathsf{CSP}(\Gamma)$ is in NP, but not every problem in NP can be represented as a CSP. For example, the question "Is G Hamiltonian?" cannot naturally be expressed as a CSP, because the property of being Hamiltonian cannot be captured by relations of bounded size. This limitation of the class CSP has an important advantage. If $\mathsf{P} \neq \mathsf{NP}$, then there are problems which are neither in P nor NP-complete [15]. But, for well-behaved smaller classes of decision problems, the situation can be simpler. We may have a *dichotomy theorem*, partitioning all problems in the class into those

[1] Usually $[q]$ is defined to be $\{1, 2, \ldots, q\}$, but it is more convenient here to start the enumeration of domain elements at 0 rather than 1.

which are in P and those which are NP-complete. There are no "leftover" problems of intermediate complexity. It has been conjectured that there is a dichotomy theorem for CSP. The conjecture is that CSP(Γ) is in P for some constraint languages Γ, and CSP(Γ) is NP-complete for all other constraint languages Γ. This conjecture appeared in a seminal paper of Feder and Vardi [10] but has not yet been proved.

A similar dichotomy, between FP- and #P-complete, is conjectured for #CSP [2]. The complexity classes FP and #P are the analogues of P and NP for counting problems. FP is simply the class of functions computable in deterministic polynomial time. #P is the class of integer functions that can be expressed as the number of accepting computations of a polynomial-time nondeterministic Turing machine. Completeness in #P is defined with respect to polynomial-time Turing reducibility [16, Chap. 18]. Bulatov and Dalmau [2] have shown in one direction that, if #CSP(Γ) is solvable in polynomial time, then the constraints in Γ must have certain algebraic properties (assuming #P $\not\subseteq$ FP). In particular, they must have a so-called *Mal'tsev polymorphism*. The converse is known to be false, though it remains possible that the dichotomy (if it exists) does have an algebraic characterization.

The conjectured dichotomies for CSP and #CSP are major open problems for computational complexity theory. There have been many important results for subclasses of CSP and #CSP. We mention the most relevant to our paper here. The first decision dichotomy was that of Schaefer [18], for the Boolean domain $\{0,1\}$. Schaefer's result is as follows.

THEOREM 1 (Schaefer [18]). *Let Γ be a constraint language with domain $\{0,1\}$. The problem* CSP(Γ) *is in* P *if Γ satisfies one of the conditions below. Otherwise,* CSP(Γ) *is* NP*-complete.*

1. *Γ is 0-valid or 1-valid.*
2. *Γ is weakly positive or weakly negative.*
3. *Γ is affine.*
4. *Γ is bijunctive.*

We will not give detailed definitions of the conditions in Theorem 1, but the interested reader is referred to the paper [18] or to Theorem 6.2 of the textbook [7]. An interesting feature is that the conditions in [7, Thm. 6.2] are all checkable. That is, there is an algorithm to determine whether CSP(Γ) is in P or NP-complete, given a constraint language Γ with domain $\{0,1\}$. Creignou and Hermann [6] adapted Schaefer's decision dichotomy to obtain a counting dichotomy for the Boolean domain. Their result is as follows.

THEOREM 2 (Creignou and Hermann [6]). *Let Γ be a constraint language with domain $\{0,1\}$. The problem* #CSP(Γ) *is in* FP *if Γ is affine. Otherwise,* #CSP(Γ) *is* #P*-complete.*

A constraint language Γ with domain $\{0,1\}$ is *affine* if every relation $R \in \Gamma$ is affine. A relation R is affine if the set of tuples $x \in R$ is the set of solutions to a system of linear equations over GF(2). These equations are of the form $v_1 \oplus \cdots \oplus v_n = 0$ and $v_1 \oplus \cdots \oplus v_n = 1$, where $\oplus$ is the *exclusive or* operator. It is well known (see, for example, Lemma 4.10 of [7]) that a relation R is affine if and only if $a, b, c \in R$ implies $d = a \oplus b \oplus c \in R$. (We will use this characterization below.) There is an algorithm for determining whether a Boolean constraint language Γ is affine, so there is an algorithm for determining whether #CSP(Γ) is in FP or #P-complete.

1.2. Weighted #CSP. The weighted graph homomorphism framework of [4] extends naturally to CSPs. Fix the domain $[q]$. Instead of constraining a length-k scope with an arity-k relation on $[q]$, we give a weight to the configuration on this scope by

applying a function f from $[q]^k$ to the nonnegative rationals. Let $\mathcal{F}_q = \{f : [q]^k \to \mathbb{Q}^+ \mid k \in \mathbb{N}\}$ be the set of all such functions (of all arities).[2] Given a function $f \in \mathcal{F}_q$ of arity k, the *underlying relation* of f is given by $R_f = \{x \in [q]^k \mid f(x) \neq 0\}$. It is often helpful to think of R_f as a table, with k columns corresponding to the positions of a k-tuple. Each row corresponds to a tuple $x = (x_1, \ldots, x_k) \in R_f$. The entry in row x and column j is x_j, which is a value in $[q]$.

A *weighted* #CSP problem is parameterized by a finite subset $\mathcal{F}$ of $\mathcal{F}_q$ and will be denoted by $\#\mathsf{CSP}(\mathcal{F})$. An instance I of $\#\mathsf{CSP}(\mathcal{F})$ consists of a set V of *variables* and a set $\mathcal{C}$ of *constraints*. Each constraint $C \in \mathcal{C}$ consists of a function $f_C \in \mathcal{F}$ (say of arity k_C) and a *scope*, which is a sequence $s_C = (v_{C,1}, \ldots, v_{C,k_C})$ of variables from V. The variables $v_{C,1}, \ldots, v_{C,k_C}$ need not be distinct. As in the unweighted case, a *configuration* σ for the instance I is a function from V to $[q]$. The *weight* of the configuration σ is given by

$$w(\sigma) = \prod_{C \in \mathcal{C}} f_C(\sigma(v_{C,1}), \ldots, \sigma(v_{C,k_C})).$$

Finally, the *partition function* $Z(I)$ is given, for instance I, by

$$Z(I) = \sum_{\sigma : V \to [q]} w(\sigma). \tag{1}$$

In the computational problem $\#\mathsf{CSP}(\mathcal{F})$, the goal is to compute $Z(I)$, given an instance I.

Note that an (unweighted) CSP counting problem $\#\mathsf{CSP}(\Gamma)$ can be represented naturally as a weighted CSP counting problem. For each relation $R \in \Gamma$, let f^R be the indicator function for membership in R. That is, if $x \in R$, we set $f^R(x) = 1$. Otherwise we set $f^R(x) = 0$. Let $\mathcal{F} = \{f^R \mid R \in \Gamma\}$. Then for any instance I of $\#\mathsf{CSP}(\Gamma)$ the number of satisfying configurations for I is given by the (weighted) partition function $Z(I)$ from (1).

This framework has been employed previously in connection with *graph homomorphisms* [1]. Suppose $H = (H_{ij})$ is any symmetric $q \times q$ matrix H of rational numbers. We view H as being an edge-weighting of an undirected graph $\mathcal{H}$, where a zero weight in H means that the corresponding edge is absent from $\mathcal{H}$. Given a (simple) graph $G = (V, E)$, we consider computing the partition function

$$Z_H(G) = \sum_{\sigma : V \to [q]} w(\sigma), \quad \text{where } w(\sigma) = \prod_{\{u,v\} \in E} H_{\sigma(u)\sigma(v)}.$$

Within our framework above, we view H as the binary function $h : [q]^2 \to \mathbb{R}$, and the problem is then computing the partition function of $\#CSP(\{h\})$.

Bulatov and Grohe [4] call H *connected* if $\mathcal{H}$ is connected and *bipartite* if $\mathcal{H}$ is bipartite. They give the following dichotomy theorem for nonnegative H.[3]

THEOREM 3 (Bulatov and Grohe [4]). *Let H be a symmetric matrix with nonnegative rational entries. Then we have the following:*

[2] We assume $0 \in \mathbb{N}$, so we allow nonnegative constants.

[3] This is not quite the original statement of the theorem. We have chosen here to restrict all inputs to be rational, in order to avoid issues of how to represent, and compute with, arbitrary real numbers.

1. *If H is connected and not bipartite, then computing Z_H is in* FP *if the rank of H is at most* 1*; otherwise computing Z_H is* #P*-hard.*
2. *If H is connected and bipartite, then computing Z_H is in* FP *if the rank of H is at most* 2*; otherwise computing Z_H is* #P*-hard.*
3. *If H is not connected, then computing Z_H is in* FP *if each of its connected components satisfies the corresponding conditions stated in* 1 *or* 2*; otherwise computing Z_H is* #P*-hard.*

Many partition functions arising in statistical physics may be viewed as weighted #CSP problems. An example is the q-state Potts model (which is, in fact, a weighted graph homomorphism problem). In general, weighted #CSP is very closely related to the problem of computing the partition function of a Gibbs measure in the framework of Dobrushin, Lanford, and Ruelle (see [1]). See also the framework of Scott and Sorkin [19].

1.3. Some notation. We will call the class of (rational) weighted #CSP problems *weighted* #CSP. The subclass having domain size $q = 2$ will be called weighted *Boolean* #CSP and will be the main focus of this paper. We will give a dichotomy theorem for weighted Boolean #CSP.

Since weights can be arbitrary nonnegative rational numbers, the solution to these problems is not an integer in general. Therefore $\#\mathsf{CSP}(\mathcal{F})$ is not necessarily in the class #P. However, Goldberg and Jerrum [11] have observed that $Z(I) = \tilde{Z}(I)/K(I)$, where $\tilde{Z}$ is a function in #P and $K(I)$ is a positive integer computable in FP. This follows because, for all $f \in \mathcal{F}$, we can ensure that $f(\cdot) = \tilde{f}(\cdot)/K(I)$, where $\tilde{f}(\cdot) \in \mathbb{N}$, by "clearing denominators." The denominator $K(I)$ can obviously be computed in polynomial time, and it is straightforward to show that computing $\tilde{Z}(I)$ is in #P, so the characterization of [11] follows. The resulting complexity class, comprising functions which are a function in #P divided by a function in FP, is named $\#\mathsf{P}_{\mathbb{Q}}$ in [11], where it is used in the context of approximate counting. Clearly we have

$$\mathsf{weighted}\,\#\mathsf{CSP} \subseteq \#\mathsf{P}_{\mathbb{Q}} \subseteq \mathsf{FP}^{\#\mathsf{P}}.$$

On the other hand, if $Z(I) \in \mathsf{weighted}\,\#\mathsf{CSP}$ is #P-hard, then, using an oracle for computing $Z(I)$, we can construct a #P oracle $\tilde{Z}(I)$ as outlined above. (Note that $Z(I) \notin \#\mathsf{P}$ in general.) Using this oracle, we can compute any function in $\mathsf{FP}^{\#\mathsf{P}}$ with a polynomial time-bounded oracle Turing machine. Thus any #P-hard function in $\mathsf{weighted}\,\#\mathsf{CSP}$ is complete for $\mathsf{FP}^{\#\mathsf{P}}$. We will use this observation to state our main result in terms of completeness for the class $\mathsf{FP}^{\#\mathsf{P}}$.

We make the following definition, which relates to the discussion above. We will say that $\mathcal{F} \subseteq \mathcal{F}_q$ *simulates* $f \in \mathcal{F}_q$ if, for each instance I of $\#\mathsf{CSP}(\mathcal{F} \cup \{f\})$, there is a polynomial time computable instance I' of $\#\mathsf{CSP}(\mathcal{F})$ such that $Z(I) = \varphi(I)Z(I')$ for some $\varphi(I) \in \mathbb{Q}$ which is FP-computable. This generalizes the notion of *parsimonious reduction* [16] among problems in #P. We will use $\leq_{\mathrm{T}}$ to denote the relation "is polynomial-time Turing-reducible to" between computational problems. Clearly, if $\mathcal{F}$ simulates f, we have $\#\mathsf{CSP}(\mathcal{F} \cup \{f\}) \leq_{\mathrm{T}} \#\mathsf{CSP}(\mathcal{F})$. Note also that, if $\tilde{f} = Kf$, for some constant $K > 0$, then $\{f\}$ simulates $\tilde{f}$. Thus there is no need to distinguish between "proportional" functions.

We use the following terminology for certain functions. Let $\chi_=$ be the binary *equality* function defined on $[q]$ as follows. For any element $c \in [q]$, $\chi_=(c, c) = 1$, and for any pair (c, d) of distinct elements of $[q]$, $\chi_=(c, d) = 0$. Let $\chi_{\neq}$ be the binary

disequality function given by $\chi_{\neq}(c,d) = 1 - \chi_{=}(c,d)$ for all $c, d \in [q]$.[4] We say that a function f is of *product type* if f can be expressed as a product of unary functions and binary functions of the form $\chi_{=}$ and $\chi_{\neq}$.

We focus attention in this paper on the Boolean case, $q = 2$. In this case, we say that a function $f \in \mathcal{F}_2$ has *affine support* if its underlying relation R_f, defined earlier, is affine. We say that f is *pure affine* if it has affine support and range $\{0, w\}$ for some $w > 0$. Thus a function is pure affine if and only if it is a positive real multiple of some (0,1-valued) function which is affine over GF(2).

1.4. Our result. Our main result is the following.

THEOREM 4. *Suppose* $\mathcal{F} \subseteq \mathcal{F}_2 = \{f : \{0,1\}^k \to \mathbb{Q}^+ \mid k \in \mathbb{N}\}$. *If every function in* $\mathcal{F}$ *is of product type, then* $\#\mathsf{CSP}(\mathcal{F})$ *is in* FP. *If every function in* $\mathcal{F}$ *is pure affine, then* $\#\mathsf{CSP}(\mathcal{F})$ *is in* FP. *Otherwise,* $\#\mathsf{CSP}(\mathcal{F})$ *is* $\mathsf{FP}^{\#\mathsf{P}}$*-complete.*

Proof. Suppose first that $\mathcal{F}$ is of product type. In this case the partition function $Z(I)$ of an instance I with variable set V is easy to evaluate because it can be factored into easy-to-evaluate pieces: Partition the variables in V into equivalence classes according to whether or not they are related by an equality or disequality function. (The equivalence relation on variables here is "depends linearly on.") An equivalence class consists of two (possibly empty) sets of variables U_1 and U_2. All of the variables in U_1 must be assigned the same value by a configuration σ of nonzero weight, and all variables in U_2 must be assigned the other value. Variables in $U_1 \cup U_2$ are not related by equality or disequality to variables in $V \setminus (U_1 \cup U_2)$. The equivalence class contributes one weight, say α, to the partition function if variables in U_1 are given value "0" by σ, and it contributes another weight, say β, to the partition function if variables in U_1 are given value "1" by σ. Thus, $Z(I) = (\alpha + \beta)Z(I')$, where I' is the instance formed from I by removing this equivalence class. Therefore, suppose we choose any equivalence class and remove its variables. Since $\mathcal{F}$ contains only unary, equality, or binary disequality constraints, we can also remove all functions involving variables in $U_1 \cup U_2$ to give $\mathcal{F}'$. Then I' is of product type with fewer variables, so we may compute $Z(I')$ recursively.

Suppose second that $\mathcal{F}$ if pure affine. Then $Z(I) = \prod_{f \in \mathcal{F}} w_f^{k_f} Z(I')$, where $\{0, w_f\}$ is the range of f, k_f is the number of constraints involving f in I, and I' is the instance obtained from I by replacing every function f by its underlying relation R_f (viewed as a function with range $\{0,1\}$). $Z(I')$ is easy to evaluate, because this is just counting solutions to a linear system over GF(2), as Creignou and Hermann have observed [6].

Finally, the #P-hardness in Theorem 4 follows from Lemma 5 below. □

LEMMA 5. *If* $f \in \mathcal{F}_2$ *is not of product type and* $g \in \mathcal{F}_2$ *is not pure affine, then* $\#\mathsf{CSP}(\{f, g\})$ *is* #P*-hard.*

Note that the functions f and g in Lemma 5 may be one and the same function. So $\#\mathsf{CSP}(\{f\})$ is #P-hard when f is not of product type nor pure affine. The rest of this article gives the proof of Lemma 5.

2. Useful tools for proving hardness of #CSP.

2.1. Notation. For any sequence $u_1, \ldots, u_k$ of variables of I and any sequence $c_1, \ldots, c_k$ of elements of the domain $[q]$, we will let $Z(I \mid \sigma(u_1) = c_1, \ldots, \sigma(u_k) = c_k)$ denote the contribution to $Z(I)$ from assignments σ with $\sigma(u_1) = c_1, \ldots, \sigma(u_k) = c_k$.

2.2. Projection. The first tool that we study is projection, which is referred to as "integrating out" in the statistical physics literature.

[4] A more general disequality function is defined in the appendix.

Let f be a function of arity k, and let $J = \{j_1, \ldots, j_r\}$ be a size-r subset of $\{1, \ldots, k\}$, where $j_1 < \cdots < j_r$.[5] We say that a k-tuple $x' \in [q]^k$ *extends* an r-tuple $x \in [q]^r$ on J (written $x' \sqsupseteq_J x$) if x' agrees with x on indices in J; that is to say, $x'_{j_i} = x_i$ for all $1 \le i \le r$. The *projection* g of f onto J is defined as follows. For every $x \in [q]^r$, $g(x) = \sum_{x' \sqsupseteq_J x} f(x')$.

The following lemma may be viewed as a weighted version of Proposition 2 of [2], where it is proved for the unweighted case. It is expressed somewhat differently in [2], in terms of counting the number of solutions to an existential formula.

LEMMA 6. *Suppose $\mathcal{F} \subseteq \mathcal{F}_q$. Let g be a projection of a function $f \in \mathcal{F}$ onto a subset of its indices. Then $\#\mathsf{CSP}(\mathcal{F} \cup \{g\}) \le_{\mathrm{T}} \#\mathsf{CSP}(\mathcal{F})$.*

Proof. Let k be the arity of f, and let g be the projection of f onto the subset J of its indices. Let I be an instance of $\#\mathsf{CSP}(\mathcal{F} \cup \{g\})$. We will construct an instance I' of $\#\mathsf{CSP}(\mathcal{F})$ such that $Z(I) = Z(I')$. The instance I' is identical to I except that every constraint C of I involving g is replaced with a new constraint C' of I' involving f. The corresponding scope $(v_{C',1}, \ldots, v_{C',k})$ is constructed as follows. If j_ℓ is the ℓth element of J, then $v'_{C',j_\ell} = v_{C,\ell}$. The other variables, $v_{C',j}$ $(j \notin J)$, are distinct new variables. We have shown that $\mathcal{F}$ simulates g with $\phi(I) = 1$. □

2.3. Pinning. For $c \in [q]$, δ_c denotes the unary function with $\delta_c(c) = 1$ and $\delta_c(d) = 0$ for $d \ne c$. The following lemma, which allows "pinning" CSP variables to specific values in hardness proofs, generalizes Theorem 8 of [2], which does the unweighted case. Again [2] employs different terminology, and its theorem is a statement about the full idempotent reduct of a finite algebra. The idea of pinning was used previously by Bulatov and Grohe of [4] in the context of counting weighted graph homomorphisms (see Lemma 32 of [4]). A similar idea was used by Dyer and Greenhill in the context of counting *unweighted* graph homomorphisms—in that context, Theorem 4.1 of [8] allows pinning all variables to a particular *component* of the target graph H.

LEMMA 7. *For every $\mathcal{F} \subseteq \mathcal{F}_q$, $\#\mathsf{CSP}(\mathcal{F} \cup \bigcup_{c \in [q]} \delta_c) \le_{\mathrm{T}} \#\mathsf{CSP}(\mathcal{F})$.*

The proof of Lemma 7 is deferred to the appendix. Since we use only the case $q = 2$ in this paper, we provide the (simpler) proof for the Boolean case here.

LEMMA 8. *For every $\mathcal{F} \subseteq \mathcal{F}_2$, $\#\mathsf{CSP}(\mathcal{F} \cup \{\delta_0, \delta_1\}) \le_{\mathrm{T}} \#\mathsf{CSP}(\mathcal{F})$.*

Proof. For $x \in [2]^k$, let $\overline{x}$ be the k-tuple whose ith component, $\overline{x}_i$, is $x_i \oplus 1$ for all i. Say that $\mathcal{F}$ is *symmetric* if it is the case that for every arity-k function $f \in \mathcal{F}$ and every $x \in [2]^k$, $f(\overline{x}) = f(x)$.

Given an instance I of $\#\mathsf{CSP}(\mathcal{F} \cup \{\delta_0, \delta_1\})$ with variable set V, we consider two instances I' and I'' of $\#\mathsf{CSP}(\mathcal{F})$. Let V_0 be the set of variables v of I to which the constraint $\delta_0(v)$ is applied. Let V_1 be the set of variables v of I to which the constraint $\delta_1(v)$ is applied. We can assume without loss of generality that V_0 and V_1 do not intersect. (Otherwise, $Z(I) = 0$ and we can determine this without using an oracle for $\#\mathsf{CSP}(\mathcal{F})$.) Let $V_2 = V \setminus (V_0 \cup V_1)$. The instance I' has variables $V_2 \cup \{t_0, t_1\}$, where t_0 and t_1 are distinct new variables that are not in V. Every constraint C of I involving a function $f \in \mathcal{F}$ corresponds to a constraint C' of I'. C' is the same as C except that variables in V_0 are replaced with t_0 and variables in V_1 are replaced with t_1. Similarly, the instance I'' has variables $V_2 \cup \{t\}$, where t is a new variable that is not in V. Every constraint C of I involving a function $f \in \mathcal{F}$ corresponds to a constraint C'' of I''. The constraint C'' is the same as C except that variables in $V_0 \cup V_1$ are replaced with t.

[5] It is not necessary to choose this particular ordering for J, but it is convenient to do so.

Case 1. $\mathcal{F}$ is symmetric: By construction,

$$Z(I') - Z(I'') = Z(I' \mid \sigma(t_0) = 0, \sigma(t_1) = 1) + Z(I' \mid \sigma(t_0) = 1, \sigma(t_1) = 0).$$

By symmetry, the summands are the same, so

$$Z(I') - Z(I'') = 2Z(I' \mid \sigma(t_0) = 0, \sigma(t_1) = 1) = 2Z(I).$$

Case 2. $\mathcal{F}$ is not symmetric: Let f be an arity-k function in $\mathcal{F}$, and let $x \in [2]^k$ so that $f(x) > f(\overline{x}) \geq 0$. Let $s = (t_{x_1}, \ldots, t_{x_k})$, and let I'_x be the instance derived from I' by adding a new constraint with function f and scope s. Similarly, let I''_x be the instance derived from I'' by adding a new constraint with function f and scope $(t, \ldots, t)$. Now

$$\begin{aligned} Z(I'_x) &= Z(I' \mid \sigma(t_0) = 0, \sigma(t_1) = 1) f(x) + Z(I' \mid \sigma(t_0) = 1, \sigma(t_1) = 0) f(\overline{x}) \\ &\quad + Z(I' \mid \sigma(t_0) = 0, \sigma(t_1) = 0) f(0, \ldots, 0) + Z(I' \mid \sigma(t_0) = 1, \sigma(t_1) = 1) f(1, \ldots, 1) \\ &= Z(I' \mid \sigma(t_0) = 0, \sigma(t_1) = 1) f(x) + Z(I' \mid \sigma(t_0) = 1, \sigma(t_1) = 0) f(\overline{x}) + Z(I''_x). \end{aligned}$$

Thus we have two independent equations,

$$\begin{aligned} Z(I'_x) - Z(I''_x) &= Z(I' \mid \sigma(t_0) = 0, \sigma(t_1) = 1) f(x) + Z(I' \mid \sigma(t_0) = 1, \sigma(t_1) = 0) f(\overline{x}), \\ Z(I') - Z(I'') &= Z(I' \mid \sigma(t_0) = 0, \sigma(t_1) = 1) \qquad + Z(I' \mid \sigma(t_0) = 1, \sigma(t_1) = 0) \qquad , \end{aligned}$$

in the unknowns $Z(I' \mid \sigma(t_0) = 0, \sigma(t_1) = 1)$ and $Z(I' \mid \sigma(t_0) = 1, \sigma(t_1) = 0)$. Solving these, we obtain the value of $Z(I' \mid \sigma(t_0) = 0, \sigma(t_1) = 1) = Z(I)$. □

2.4. #P-hard problems. To prove Lemma 5, we will give reductions from some known #P-hard problems. The first of these is the problem of counting homomorphisms from simple graphs to 2-vertex multigraphs. We use the following special case of Bulatov and Grohe's Theorem 3.

COROLLARY 9 (Bulatov and Grohe [4]). *Let H be a symmetric 2×2 matrix with nonnegative real entries. If H has rank 2 and at most one entry of H is 0, then* EVAL(H) *is #P-hard.*

We will also use the problem of computing the *weight enumerator* of a linear code. Given a *generating matrix* $A \in \{0,1\}^{r \times C}$ of rank r, a *code word* c is any vector in the linear subspace Υ generated by the rows of A over GF(2). For any real number λ, the *weight enumerator* of the code is given by $W_A(\lambda) = \sum_{c \in \Upsilon} \lambda^{\|c\|}$, where $\|c\|$ is the number of 1's in c. The problem of computing the weight enumerator of a linear code is in FP for $\lambda \in \{-1, 0, 1\}$ and is known to be #P-hard for every other fixed $\lambda \in \mathbb{Q}$ (see [22]). We could not find a proof, so we provide one here. We restrict our attention to positive λ, since that is adequate for our purposes.

LEMMA 10. *Computing the weight enumerator of a linear code is #P-hard for any fixed positive rational number $\lambda \neq 1$.*

Proof. We will prove hardness by reduction from a problem EVAL(H), for some appropriate H, using Corollary 9. Let the input to EVAL(H) be a connected graph $G = (V, E)$ with $V = \{v_1, \ldots, v_n\}$ and $E = \{e_1, \ldots, e_m\}$. Let B be the $n \times m$ incidence matrix of G, with $b_{ij} = 1$ if $v_i \in e_j$ and $b_{ij} = 0$ otherwise. Let A be the $(n-1) \times m$ matrix which is B with the row for v_n deleted. A will be the generating matrix of the weight enumerator instance, with $r = n - 1$ and $C = m$. It has rank $(n-1)$ since G contains a spanning tree. A code word c has $c_j = \bigoplus_{i \in U} b_{ij}$, where $U \subseteq V \setminus \{v_n\}$. Thus $c_j = 1$ if and only if e_j has exactly one endpoint in U, and the weight of c is λ^k, where k is the number of edges in the cut $U, V \setminus U$. Thus $W_A(\lambda) = \frac{1}{2} Z_H(G)$, where

H is the symmetric weight matrix with $H_{11} = H_{22} = 1$ and $H_{12} = H_{21} = \lambda$. The $\frac{1}{2}$ arises because we fixed which side of the cut contains v_n. Now H has rank 2 unless $\lambda = 1$, so this problem is #P-hard by Corollary 9. Note, by the way, that $Z_H(G)$ is the partition function of the Ising model in statistical physics [5]. □

3. The proof of Lemma 5. Throughout this section, we assume $q = 2$. The following lemma is a generalization of a result of Creignou and Hermann [6], which deals with the case in which f is a relation (or, in our setting, a function with range $\{0, 1\}$). The inductive technique used in the proof of Lemma 11 (combined with the follow-up in Lemma 12) is good for showing that $\#\mathsf{CSP}(\mathcal{F})$ is #P-hard when $\mathcal{F}$ contains a *single* function. A very different situation arises when $\#\mathsf{CSP}(\{f\})$ and $\#\mathsf{CSP}(\{g\})$ are in FP but $\#\mathsf{CSP}(\{f, g\})$ is #P-hard due to *interactions* between f and g—we deal with that problem later.

LEMMA 11. *Suppose that $f \in \mathcal{F}_2$ does not have affine support. Then $\#\mathsf{CSP}(\{f\})$ is #P-hard.*

Proof. Let k be the arity of f, and let us denote the ith component of k-tuple $a \in R_f$ by a_i. The proof is by induction on k. The lemma is trivially true for $k = 1$, since all functions of arity 1 have affine support.

For $k = 2$, we note that since R_f is not affine, it is of the form $R_f = \{(\alpha, \beta), (\bar{\alpha}, \beta), (\bar{\alpha}, \bar{\beta})\}$ for some $\alpha \in \{0, 1\}$ and $\beta \in \{0, 1\}$. We can show that $\#\mathsf{CSP}(\{f\})$ is #P-hard by reduction from $\text{EVAL}(H)$ using

$$H = \begin{pmatrix} f(0,0) & f(0,1) \\ f(1,0) & f(1,1) \end{pmatrix},$$

which has rank 2 and exactly one entry that is 0. Given an instance $G = (V, E)$ of $\text{EVAL}(H)$, we construct an instance I of $\#\mathsf{CSP}(\{f\})$ as follows. The variables of I are the vertices of G. For each edge $e = (u, v)$ of G, add a constraint with function f and variable sequence u, v. Corollary 9 now tells us that $\text{EVAL}(H)$ is #P-hard, so $\#\mathsf{CSP}(\{f\})$ is #P-hard.

Suppose $k > 2$. We start with some general arguments and notation. For any $i \in \{1, \ldots, k\}$ and any $\alpha \in \{0, 1\}$ let $f^{i=\alpha}$ be the function of arity $k-1$ derived from f by pinning the ith position to α. That is, $f^{i=\alpha}(x_1, \ldots, x_{k-1}) = f(x_1, \ldots, x_{i-1}, \alpha, x_{i+1}, \ldots, x_k)$. Also, let $f^{i=*}$ be the projection of f onto all positions apart from position i (see section 2.2). Note that $\#\mathsf{CSP}(\{f^{i=\alpha}\}) \leq_{\mathrm{T}} \#\mathsf{CSP}(\{f, \delta_0, \delta_1\})$, since $f^{i=\alpha}$ can obviously be simulated by $\{f, \delta_0, \delta_1\}$. Furthermore, by Lemma 8, $\#\mathsf{CSP}(\{f, \delta_0, \delta_1\}) \leq_{\mathrm{T}} \#\mathsf{CSP}(\{f\})$. Thus, we can assume that $f^{i=\alpha}$ has affine support—otherwise, we are finished by induction. Similarly, by Lemma 6, $\#\mathsf{CSP}(\{f^{i=*}\}) \leq_{\mathrm{T}} \#\mathsf{CSP}(\{f\})$. Thus we can assume that $f^{i=*}$ has affine support—otherwise, we are finished by induction.

Now, recall that R_f is not affine. Consider any $a, b, c \in R_f$ such that $d = a \oplus b \oplus c \notin R_f$. We have four cases.

Case 1. There are indices $1 \leq i < j \leq k$ such that $(a_i, b_i, c_i) = (a_j, b_j, c_j)$. Without loss of generality, suppose $i = 1$ and $j = 2$. Define the function f' of arity $(k - 1)$ by $f'(r_2, \ldots, r_k) = f(r_2, r_2, \ldots, r_k)$. Note that $R_{f'}$ is not affine since the condition $a \oplus b \oplus c \notin R_f$ is inherited by $R_{f'}$. So, by induction, $\#\mathsf{CSP}(\{f'\})$ is #P-hard. Now note that $\#\mathsf{CSP}(\{f'\}) \leq_{\mathrm{T}} \#\mathsf{CSP}(\{f\})$. To see this, note that any instance I_1 of $\#\mathsf{CSP}(\{f'\})$ can be turned into an instance I of $\#\mathsf{CSP}(\{f\})$ by repeating the first variable in the sequence of variables for each constraint.

Case 2. There is an index $1 \le i \le k$ such that $a_i = b_i = c_i$. Since d is not in R_f and $d_i = a_i$, we find that $f^{i=a_i}$ does not have affine support, contrary to earlier assumptions.

Having finished Cases 1 and 2, we may assume without loss of generality that we are in Case 3 or 4 below, where $\{\alpha, \beta\} \in \{0,1\}$, $\bar{\alpha} = 1 - \alpha$, $\bar{\beta} = 1 - \beta$, and $a', b', c' \in \{0,1\}^{k-2}$.

Case 3. $a = (\bar{\alpha}, \bar{\beta}, a')$, $b = (\bar{\alpha}, \beta, b')$, $c = (\alpha, \bar{\beta}, c')$. Since $R_{f^{1=*}}$ is affine and a, b, and c are in R_f, we must have either $d = (\alpha, \beta, d') \in R_f$ or $e = (\bar{\alpha}, \beta, d') \in R_f$, where $d' = a' \oplus b' \oplus c'$. In the first case, we are done (we have contradicted the assumption that $d \notin R_f$), so assume that $e \in R_f$ but $d \notin R_f$. Similarly, since $R_{f^{2=*}}$ is affine, we may assume that $g = (\alpha, \bar{\beta}, d') \in R_f$. Since $R_{f^{1=\bar{\alpha}}}$ is affine and a, b, and e are in R_f, we find that $h = a \oplus b \oplus e = (\bar{\alpha}, \bar{\beta}, c') \in R_f$. Since $R_{f^{2=\bar{\beta}}}$ is affine and a, c, and g are in R_f, we find that $i = (\bar{\alpha}, \bar{\beta}, b') \in R_f$. Also, since $R_{f^{2=\bar{\beta}}}$ is affine and a, h, and i are in R_f, we find that $j = (\bar{\alpha}, \bar{\beta}, d') \in R_f$. Let $f'(r_1, r_2) = f(r_1, r_2, d_3, \ldots, d_k)$. Since e, g, and j are in R_f but d is not, we have $(\bar{\alpha}, \beta), (\alpha, \bar{\beta}), (\bar{\alpha}, \bar{\beta}) \in R_{f'}$, but $(\alpha, \beta) \notin R_{f'}$. Thus, f' does not have affine support and $\#\mathsf{CSP}(\{f'\})$ is $\#\mathsf{P}$-hard by induction. Also, $\#\mathsf{CSP}(\{f'\}) \le_{\mathrm{T}} \#\mathsf{CSP}(\{f\})$ by Lemma 8.

Case 4. $a = (\bar{\alpha}, \alpha, a')$, $b = (\bar{\alpha}, \alpha, b')$, $c = (\alpha, \bar{\alpha}, c')$. Since $R_{f^{1=*}}$ is affine and a, b, and c are in R_f but d is not, we have $e = (\bar{\alpha}, \bar{\alpha}, d') \in R_f$. Similarly, since $R_{f^{2=*}}$ is affine and a, b, and c are in R_f but d is not, we have $g = (\alpha, \alpha, d') \in R_f$. Now since $R_{f^{1=\bar{\alpha}}}$ is affine and a, b, and e are in R_f, we have $h = (\bar{\alpha}, \bar{\alpha}, c') \in R_f$. Also, since $R_{f^{2=\alpha}}$ is affine and a, b, and g are in R_f, we have $i = (\alpha, \alpha, c') \in R_f$.

Let $f'(r_1, r_2) = f(r_1, r_2, c_3, \ldots, c_k)$. If $j = (\bar{\alpha}, \alpha, c') \notin R_f$, then f' does not have affine support (since c, h, and i are in R_f), so we finish by induction as in Case 3. Suppose $j \in R_f$. Since $R_{f^{1=\bar{\alpha}}}$ is affine and a, b, and j are in R_f, we have $\ell = (\bar{\alpha}, \alpha, d') \in R_f$. Let $f''(r_1, r_2) = f(r_1, r_2, d_3, \ldots, d_k)$. Then f'' does not have affine support (since e, g, and ℓ are in R_f but d is not), so we finish by induction as in Case 3. □

Lemma 11 showed that $\#\mathsf{CSP}(\{f\})$ is $\#\mathsf{P}$-hard when f does not have affine support. The following lemma gives another (rather technical, but useful) condition which implies that $\#\mathsf{CSP}(\{f\})$ is $\#\mathsf{P}$-hard. We start with some notation. Let f be an arity-k function. For a value $b \in \{0,1\}$, an index $i \in \{1, \ldots, k\}$, and a tuple $y \in \{0,1\}^{k-1}$, let $y^{i=b}$ denote the tuple $x \in \{0,1\}^k$ formed by setting $x_i = b$ and $x_j = y_j$ $(j \in \{1, \ldots, k\} \setminus \{i\})$.

We say that index i of f is *useful*, if there is a tuple y such that $f(y^{i=0}) > 0$ and $f(y^{i=1}) > 0$. We say that f is *product-like* if, for every useful index i, there is a rational number λ_i such that, for all $y \in \{0,1\}^{k-1}$,

$$f(y^{i=0}) = \lambda_i f(y^{i=1}). \tag{2}$$

If every position i of f is useful, then being product-like is the same as being of product type. However, being product-like is less demanding because it does not restrict indices that are not useful.

LEMMA 12. *If $f \in \mathcal{F}_2$ is not product-like, then $\#\mathrm{CSP}(\{f\})$ is $\#\mathsf{P}$-hard.*

Proof. We will use Corollary 9 to prove hardness, following an argument from [9]. Choose a useful index i so that there is no λ_i satisfying (2).

Suppose f has arity k. Let A be the $2 \times 2^{k-1}$ matrix such that for $b \in \{0,1\}$ and $y \in \{0,1\}^{k-1}$, $A_{b,y} = f(y^{i=b})$. Let $A' = AA^T$.

First, we show that $\text{EVAL}(A')$ is #P-hard. Note that A' is the following symmetric 2×2 matrix with nonnegative rational entries:

$$\begin{pmatrix} \sum_y A_{0,y}^2 & \sum_y A_{0,y}A_{1,y} \\ \sum_y A_{0,y}A_{1,y} & \sum_y A_{1,y}^2 \end{pmatrix} = \begin{pmatrix} \sum_y f(y^{i=0})^2 & \sum_y f(y^{i=0})f(y^{i=1}) \\ \sum_y f(y^{i=0})f(y^{i=1}) & \sum_y f(y^{i=1})^2 \end{pmatrix}.$$

Since index i is useful, all four entries of A' are positive. To show that $\text{EVAL}(A')$ is #P-hard by Corollary 9, we just need to show that its determinant is nonzero. By the Cauchy–Schwarz equation, the determinant is nonnegative and is zero only if λ_i exists, which we have assumed not to be the case. Thus $\text{EVAL}(A')$ is #P-hard by Corollary 9.

Now we reduce $\text{EVAL}(A')$ to $\#\text{CSP}(\{f\})$. To do this, take an undirected graph G which is an instance of $\text{EVAL}(A')$. Construct an instance Y of $\#\text{CSP}(\{f\})$. For every vertex v of G we introduce a variable x_v of Y. Also, for every edge e of G we introduce $k-1$ variables $x_{e,1}, \ldots, x_{e,k-1}$ of Y. We introduce constraints in Y as follows. For each edge $e = (v, v')$ of G we introduce constraints $f(x_v, x_{e,1}, \ldots, x_{e,k-1})$ and $f(x_{v'}, x_{e,1}, \ldots, x_{e,k-1})$ into Y, where we have assumed, without loss of generality, that the first index is useful.

It is clear that $\text{EVAL}(A')$ is exactly equal to the partition function of the $\#\text{CSP}(\{f\})$ instance Y. □

For $w \in \mathbb{Q}^+$, let U_w denote the unary function mapping 0 to 1 and 1 to w. Note that $U_0 = \delta_0$, and U_1 gives the constant (0-ary function) 1, occurrences of which leave the partition function unchanged. So, by Lemma 8, we can discard these constraints since they do not add to the complexity of the problem. Note, by the observation above about proportional functions, that the functions U_w include all unary functions except for δ_1 and the constant 0. We can discard δ_1 by Lemma 8, and if the constant 0 function is in $\mathcal{F}$, any instance I where it appears as a constraint has $Z(I) = 0$. So again we can discard these constraints since they do not add to the complexity of the problem.

Thus U_w will be called *nontrivial* if $w \notin \{0, 1\}$. Let $\oplus_k : \{0,1\}^k \to \{0,1\}$ be the arity-k parity function that is 1 if and only if its argument has an odd number of 1's. Let $\neg\oplus_k : \{0,1\}^k \to \{0,1\}$ be the function $1 - \oplus_k$. The following lemma shows that even a simple function like $\oplus_3$ can lead to intractable #CSP instances when it is combined with a nontrivial weight function U_λ.

LEMMA 13. *$\#\text{CSP}(\oplus_3, U_\lambda, \delta_0, \delta_1)$ and $\#\text{CSP}(\neg\oplus_3, U_\lambda, \delta_0, \delta_1)$ are both #P-hard, for any positive $\lambda \neq 1$.*

Proof. We give a reduction from computing the weight enumerator of a linear code, which was shown to be #P-hard in Lemma 10. In what follows, it is sometimes convenient to view $\oplus_k$, δ_0, etc., as relations as well as functions to $\{0, 1\}$.

We first argue that, for any k, the relation $\oplus_k$ can be simulated by $\{\oplus_3, \delta_0, \delta_1\}$. For example, to simulate $x_1 \oplus \cdots \oplus x_k$ for $k > 3$, take new variables y, z, and w and let $m = \lceil k/2 \rceil$ and use $x_1 \oplus \cdots \oplus x_m \oplus y$ and $x_{m+1} \oplus \cdots \oplus x_k \oplus z$ and $y \oplus z \oplus w$ and $\delta_0(w)$.

Since $\{\oplus_3, \delta_0, \delta_1\}$ can be used to simulate any relation $\oplus_k$, we can use $\{\oplus_3, \delta_0, \delta_1\}$ to simulate an arbitrary system of linear equations over GF(2). In particular, we can use them to simulate the subspace Υ of code words for a given generating matrix A.

Finally, we can use U_λ to simulate the function which evaluates the weight enumerator on Υ. Then, since $\lambda \neq 0, 1$, we can apply Lemma 10 to complete the argument. The same proof, with minor modifications, applies to $\neg\oplus_3$. □

LEMMA 14. *Suppose that $f \in \mathcal{F}_2$ is not of product type. Then, for any positive $\lambda \neq 1$, there exists a constant c, depending on f, such that $\#\mathsf{CSP}(\{f, \delta_0, \delta_1, U_\lambda, U_c\})$ is $\#\mathsf{P}$-hard.*

Proof. If f does not have affine support, the result follows by Lemma 11. So suppose f has affine support. Consider the underlying relation R_f, viewed as a table. The rows of the table represent the tuples of the relation. Let J be the set of columns on which the relation is not constant. That is, if $i \in J$, then there is a row x with $x_i = 0$ and a row y with $y_i = 1$. Group the columns in J into equivalence classes: two columns are equivalent if and only if they are equal or complementary. Let k be the number of equivalence classes. Take one column from each of the k equivalence classes as a representative, and focus on the arity-k relation R induced by those columns.

Case 1. Suppose that R is the complete relation of arity k. Let f^* be the projection of f onto the k columns of R. By Lemma 6,

$$\#\mathsf{CSP}(\{f^*\}) \leq_{\mathrm{T}} \#\mathsf{CSP}(\{f\}) \leq_{\mathrm{T}} \#\mathsf{CSP}(\{f, \delta_0, \delta_1, U_\lambda, U_c\}).$$

We will argue that $\#\mathsf{CSP}(\{f^*\})$ is $\#\mathsf{P}$-hard. To see this, note that every column of f^* is useful. Thus, if f^* were product-like, we could conclude that f^* was of product type. But this would imply that f is of product type, which is not the case by assumption. So f^* is not product-like, and hardness follows from Lemma 12.

Case 2. Suppose that R is not the complete relation of arity k. We had assumed that R_f is affine. This means that, given three vectors, x, y, and z in R_f, $x \oplus y \oplus z$ is in R_f as well. The arity-k relation R inherits this property, so is also affine.

Choose a minimal set of columns of R that do not induce the complete relation. This exists by assumption. Suppose that there are j columns in this minimal set. Observe that $j \neq 1$ because there are no constant columns in J. Also $j \neq 2$, since otherwise the two columns would be related by equality or disequality, contradicting the preprocessing step. The argument here is that on two columns, R cannot have exactly three tuples because it is affine, and having tuples x, y, and z in would require the fourth tuple $x \oplus y \oplus z$. But if it has two tuples, then, because there are no constant columns, the only possibilities are either $(0,0)$ and $(1,1)$ or $(0,1)$ and $(1,0)$. Both contradict the preprocessing step, so $j \geq 3$.

Let R' be the restriction of R to the j columns. Now R' of course has fewer than 2^j rows, and at least 2^{j-1} by minimality. It is affine, and hence must be $\oplus_j$ or $\neg\oplus_j$. To see this, first note that the size of R' has to be a power of 2 since R' is the solution to a system of linear equations. Hence the size of R' must be 2^{j-1}. Then, since there are j variables, there can only be one defining equation. And, since every subset of $j-1$ variables induces a complete relation, this single equation must involve all variables. Therefore, the equation is $\oplus_j$ or $\neg\oplus_j$.

Let f' be the projection of f onto the j columns just identified. Let f'' be further obtained by pinning all but three of the j variables to 0. Pinning $j-3$ variables to 0 leaves a single equation involving all three remaining variables. Thus $R_{f''}$ must be $\oplus_3$ or $\neg\oplus_3$.

Now define the symmetric function f''' by

$$f'''(a,b,c) = f''(a,b,c)f''(a,c,b)f''(b,a,c)f''(b,c,a)f''(c,a,b)f''(c,b,a).$$

Note that $R_{f'''}$ is $\oplus_3$ or $\neg\oplus_3$, since $R_{f''}$ is symmetric and hence $R_{f'''} = R_{f''}$.

To summarize: using f and the constant functions δ_0 and δ_1, we have simulated a function f''' such that its underlying relation $R_{f'''}$ is either $\oplus_3$ or $\neg\oplus_3$. Furthermore, if triples x and y have the same number of 1's, then $f'''(x) = f'''(y)$.

We can now simulate an unweighted version of $\oplus_3$ or $\neg\oplus_3$ using f''' and a unary function U_c, with c set to a conveniently chosen value. There are two cases. Suppose

first that the affine support of f''' is $\neg\oplus_3$. Then let w_0 denote the value of f''' when applied to the 3-tuple $(0,0,0)$, and let w_2 denote $f'''(0,1,1) = f'''(1,0,1) = f'''(1,1,0)$. Recall that $f'''(x) = 0$ for any other 3-tuple x. Now let $c = (w_0/w_2)^{1/2}$. Note from the definition of f''' that w_0 and w_2 are squares of rational numbers, so c is also rational. Define a function g of arity 3 by $g(\alpha,\beta,\gamma) = U_c(\alpha)U_c(\beta)U_c(\gamma)f'''(\alpha,\beta,\gamma)$. Note that $g(0,0,0) = w_0$ and $g(0,1,1) = g(1,0,1) = g(1,1,0) = c^2 w_2 = w_0$. Thus, g is a pure affine function with affine support $\neg\oplus_3$ and range $\{0, w_0\}$. The other case, in which the affine support of f''' is $\oplus_3$, is similar.

We have established a reduction from either $\#\mathsf{CSP}(\oplus_3, U_\lambda, \delta_0, \delta_1)$ or $\#\mathsf{CSP}(\neg\oplus_3, U_\lambda, \delta_0, \delta_1)$, which are both #P-hard by Lemma 13. □

LEMMA 15. *If $f \in \mathcal{F}_2$ is not of product type, then $\#\mathsf{CSP}(\{f, \delta_0, \delta_1, U_\lambda\})$ is #P-hard for any positive $\lambda \neq 1$.*

Proof. Take an instance I of $\#\mathsf{CSP}(\{f, \delta_0, \delta_1, U_\lambda, U_c\})$, from Lemma 14, with n variables $x_1, x_2, \ldots, x_n$. We want to compute the partition function $Z(I)$ using only instances of $\#\mathsf{CSP}(\{f, \delta_0, \delta_1, U_\lambda\})$, that is, instances which avoid using constraints U_c. For each i, let m_i denote the number of copies of U_c that are applied to x_i, and let $m = \sum_{i=1}^n m_i$. Then we can write the partition function as $Z(I) = Z(I; c)$, where

$$Z(I; w) = \sum_{\sigma \in \{0,1\}^n} \hat{Z}(\sigma) \prod_{i:\sigma_i = 1} w^{m_i} = \sum_{\sigma \in \{0,1\}^n} \hat{Z}(\sigma) w^{\sum_{i=1}^n m_i \sigma_i},$$

where $\hat{Z}(\sigma)$ denotes the value corresponding to the assignment $\sigma(x_i) = \sigma_i$, ignoring constraints applying U_c, and w is a variable. So $\hat{Z}(\sigma)$ is the weight of σ, taken over all constraints other than those applying U_c. Note also that $Z(I; w)$ is a polynomial of degree m in w. We can evaluate $Z(I; w)$ at the point $w = \lambda^j$ by replacing each U_c constraint with j copies of a U_λ constraint. This evaluation is an instance of $\#\mathsf{CSP}(\{f, \delta_0, \delta_1, U_\lambda\})$. So, using m different values of j and interpolating, we learn the coefficients of the polynomial $Z(I; w)$. Then we can set $w = c$ to evaluate $Z(I)$. □

LEMMA 16. *Suppose that $f \in \mathcal{F}_2$ is not of product type and $g \in \mathcal{F}_2$ is not pure affine. Then $\#\mathsf{CSP}(\{f, g, \delta_0, \delta_1\})$ is #P-hard.*

Proof. If g does not have affine support, we are done by Lemma 11. So suppose that g has affine support. Since g is not pure affine, the range of g contains at least two nonzero values.

The high-level idea will be to use pinning and bisection to extract a nontrivial unary weight function U_λ from g. Then we can reduce from $\#\mathsf{CSP}(\{f, \delta_0, \delta_1, U_\lambda\})$, which we proved #P-hard in Lemma 15.

Look at the relation R_g, viewed as a table. If every column were constant, then g would be pure affine, so this is not the case. Select a nonconstant column with index h. If there are two nonzero values in the range of g amongst the rows of R_g that are 0 in column h, then we derive a new function g' by pinning column h to 0. The new function g' is not pure affine, since the two nonzero values prevent this. So we will show inductively that $\#\mathsf{CSP}(\{f, g', \delta_0, \delta_1\})$ is #P-hard. This will give the result since $\#\mathsf{CSP}(\{f, g', \delta_0, \delta_1\})$ trivially reduces to $\#\mathsf{CSP}(\{f, g, \delta_0, \delta_1\})$.

If we don't finish this way, or symmetrically by pinning column h to 1, then we know that there are distinct positive values w_0 and w_1 such that, for every row x of R_g with 0 in column h, $g(x) = w_0$ and, for every row x of R_g with 1 in column h, $g(x) = w_1$. Now note that, because the underlying relation R_g is affine, it has the same number of 0's in column h as 1's. This is because R_g is the solution of a set of linear equations. Adding the equation $x_h = 0$ or $x_h = 1$ exactly halves the set of solutions in either case. We now project onto the index set $\{h\}$. We obtain the

unary weight function U_λ, with $\lambda = w_1/w_0$, on using the earlier observation about proportional functions. This was our goal and completes the proof. □

Lemma 5 now follows from Lemmas 8 and 16, completing the proof of Theorem 4.

Appendix. The purpose of this appendix is to prove Lemma 7 for an arbitrary fixed domain $[q]$. We used only the special case $q = 2$, which we stated and proved as Lemma 8. However, pinning appears to be a useful technique for studying the complexity of #CSP, so we give a proof of the general Lemma 7, which we believe will be applicable elsewhere.

In order to prove the lemma, we introduce a useful, but less natural, variant of #CSP. Suppose $\mathcal{F} \subseteq \mathcal{F}_q$. An instance I of $\#\mathsf{CSP}^{\neq}(\mathcal{F})$ consists of a set V of variables and a set $\mathcal{C}$ of constraints, just like an instance of $\#\mathsf{CSP}(\mathcal{F})$. In addition, the instance may contain a *single* extra constraint C applying the arity-q *disequality* relation $\chi_{\neq}$ with scope $(v_{C,1}, \ldots, v_{C,q})$.

The disequality relation $\chi_{\neq}$ is defined by $\chi_{\neq}(x_1, \ldots, x_q) = 1$ if $x_1, \ldots, x_q \in [q]$ are pairwise distinct, that is, if they are a permutation of the domain $[q]$. Otherwise, $\chi_{\neq}(x_1, \ldots, x_q) = 0$.

Lemma 7 follows immediately from Lemmas 17 and 18 below.

LEMMA 17. *For every* $\mathcal{F} \subseteq \mathcal{F}_q$, $\#\mathsf{CSP}(\mathcal{F} \cup \bigcup_{c\in[q]} \delta_c) \leq_{\mathrm{T}} \#\mathsf{CSP}^{\neq}(\mathcal{F})$.

Proof. We follow the proof lines of Lemma 8, but instead of subtracting the contribution corresponding to configurations in which some t_i's get the same value, we use the disequality relation to restrict the partition function to configurations in which they get distinct values.

Say that $\mathcal{F}$ is *symmetric* if it is the case that for every arity-k function $f \in \mathcal{F}$, every tuple $x \in [q]^k$, and every permutation $\pi : [q] \to [q]$, $f(x_1, \ldots, x_k) = f(\pi(x_1), \ldots, \pi(x_k))$.

Let I be an instance of $\#\mathsf{CSP}(\mathcal{F} \cup \bigcup_{c\in[q]} \delta_c)$ with variable set V. Let V_c be the set of variables $v \in V$ to which the constraint $\delta_c(v)$ is applied. Assume without loss of generality that the sets V_c are pairwise disjoint. Let $V_q = V \setminus \bigcup_{c\in[q]} V_c$. We construct an instance I' of $\#\mathsf{CSP}^{\neq}(\mathcal{F})$. The instance has variables $V_q \cup \{t_0, \ldots, t_{q-1}\}$. Every constraint C of I involving a function $f \in \mathcal{F}$ corresponds to a constraint C' of I'. Here C' is the same as C except that variables in V_c are replaced with t_c, for each $c \in [q]$. Also, we add a new disequality constraint to the new variables $t_0, \ldots, t_{q-1}$.

Case 1. $\mathcal{F}$ is symmetric. By construction, $Z(I') = \sum_{y_0,\ldots,y_{q-1}} Z(I' \mid \sigma(t_0) = y_0, \ldots, \sigma(t_{q-1}) = y_{q-1})$, where the sum is over all permutations $y_0, \ldots, y_{q-1}$ of $[q]$. By symmetry, the summands are all the same, so $Z(I') = q!Z(I' \mid \sigma(t_0) = 0, \ldots, \sigma(t_{q-1}) = q-1) = q!Z(I)$.

Case 2. $\mathcal{F}$ is not symmetric. Say that two permutations $\pi_1 : [q] \to [q]$ and $\pi_2 : [q] \to [q]$ are *equivalent* if, for every $f \in \mathcal{F}$ and every tuple $x \in [q]^k$, $f(\pi_1(x_1), \ldots, \pi_1(x_k)) = f(\pi_2(x_1), \ldots, \pi_2(x_k))$. Partition the permutations $\pi : [q] \to [q]$ into equivalence classes. Let h be the number of equivalence classes and n_i be the size of the ith equivalence class, so $n_1 + \cdots + n_h = q!$.[6] Let $\{\pi_1, \ldots, \pi_h\}$ be a set of representatives of the equivalence classes with π_1 being the identity. We know that $n_1 \neq q!$ since $\mathcal{F}$ is not symmetric.

For a positive integer ℓ we will now build an instance I'_ℓ by adding new constraints to I'. For each π_i other than π_1 we add constraints as follows. Choose a function $f_i \in \mathcal{F}$

[6] In fact, it can be shown that these equivalence classes are cosets of the symmetry group of f, and hence are of equal size, though we do not use this fact here.

and a tuple y such that $f_i(y_1,\ldots,y_k) \neq f_i(\pi_i(y_1),\ldots,\pi_i(y_k))$. If $f_i(y_1,\ldots,y_k) > f_i(\pi_i(y_1),\ldots,\pi_i(y_k))$, then define the k-tuple x^i by $(x^i_1,\ldots,x^i_k) = (y_1,\ldots,y_k)$. Otherwise, let n be the order of the permutation π_i and let g_r denote $f_i(\pi_i^r(y_1),\ldots,\pi_i^r(y_k))$. Since $g_0 < g_1$ and $g_n = g_0$ there exists an $\xi \in \{1,\ldots,n-1\}$ such that $g_\xi > g_{\xi+1}$. Let $(x^i_1,\ldots,x^i_k) = (\pi^\xi(y_1),\ldots,\pi^\xi(y_k))$ so $f_i(x^i_1,\ldots,x^i_k) > f_i(\pi_i(x^i_1),\ldots,\pi_i(x^i_k))$.

Let w_{ij} denote $f_i(\pi_j(x^i_1),\ldots,\pi_j(x^i_k))$ so, since π_1 is the identity, we have just ensured that $w_{i1} > w_{ii}$. Let $s^i = (t_{x^i_1},\ldots,t_{x^i_k})$, and let $0 \leq z_i \leq h$ $(i = 2,\ldots,h)$ be positive integers, which we will determine below. Add ℓz_i new constraints to I'_ℓ with relation f_i and scope s^i. Let $\lambda_i = \prod_{\gamma=2}^h w_{\gamma i}^{z_\gamma}$. Note that, given $\sigma(t_0) = \pi_i(0),\ldots,\sigma(t_{q-1}) = \pi_i(q-1)$, the contribution to $Z(I'_\ell)$ for the new constraints is

$$\begin{aligned}\prod_{\gamma=2}^h f_\gamma(\sigma(t_{x^\gamma_1}),\ldots,\sigma(t_{x^\gamma_k}))^{z_\gamma \ell} &= \prod_{\gamma=2}^h f_\gamma(\pi_i(x^\gamma_1),\ldots,\pi_i(x^\gamma_k))^{z_\gamma \ell} \\ &= \prod_{\gamma=2}^h w_{\gamma,i}^{z_\gamma \ell} = \Bigg(\prod_{\gamma=2}^h w_{\gamma,i}^{z_\gamma}\Bigg)^\ell = {\lambda_i}^\ell.\end{aligned}$$

So

$$Z(I'_\ell) = \sum_{i=1}^h n_i\, Z(\, I' \mid \sigma(t_0) = \pi_i(0),\ldots,\sigma(t_{q-1}) = \pi_i(q-1))\, \lambda_i^\ell.$$

We have ensured that $\lambda_1 > 0$, since $w_{i1} > w_{ii} \geq 0$, so $w_{i1} > 0$ for all $i = 2,\ldots,h$. We now choose the z_i's so that $\lambda_i \neq \lambda_1$ for all $i = 2,\ldots,h$. If $w_{\gamma i} = 0$ for any $\gamma = 2,\ldots,h$, we have $\lambda_i = 0$ and hence $\lambda_i \neq \lambda_1$. Thus we will assume, without loss of generality, that $w_{\gamma i} > 0$ for all $\gamma = 2,\ldots,h$ and $i = 2,\ldots,h'$, where $h' \leq h$. Then we have

$$\frac{\lambda_i}{\lambda_1} \;=\; \prod_{\gamma=2}^h \Big(\frac{w_{\gamma i}}{w_{\gamma 1}}\Big)^{z_\gamma} \;=\; e^{\sum_{\gamma=2}^h \alpha_{\gamma i} z_\gamma} \qquad (i = 2,\ldots,h'),$$

where $\alpha_{\gamma i} = \ln(w_{\gamma i}/w_{\gamma 1})$. Note that $\alpha_{ii} < 0$, since $w_{ii} < w_{i1}$. We need to find an integer vector $z = (z_2,\ldots,z_h)$ so that none of the linear forms $\mathcal{L}_i(z) = \sum_{\gamma=2}^h \alpha_{\gamma i} z_\gamma$ is zero, for $i = 2,\ldots,h'$. We do this using a proof method similar to the Schwartz–Zippel lemma. (See, for example, [20].) None of the $\mathcal{L}_i(z)$ is identically zero, since $\alpha_{ii} \neq 0$. Consider the integer vectors $z \in [h]^{h-1}$. At most h^{h-2} of these can make $\mathcal{L}_i(z)$ zero for any i, since the equation $\mathcal{L}_i(z) = 0$ makes z_i a linear function of z_γ $(\gamma \neq i)$. Therefore there are at most $(h'-1)h^{h-2} < h^{h-1}$ such z which make any $\mathcal{L}_i(z)$ zero. Therefore there must be a vector $z \in [h]^{h-1}$ for which none of the $\mathcal{L}_i(z)$ is zero, and this is the vector we require.

Now, by combining terms with equal λ_i and ignoring terms with $\lambda_i = 0$, we can view $Z(I'_\ell)$ as a sum $Z(I'_\ell) = \sum_i c_i \lambda_i^\ell$, where the λ_i's are positive and pairwise distinct and

$$c_1 = n_1 Z(I' \mid \sigma(t_0) = 0,\ldots,\sigma(t_{q-1}) = q-1).$$

Thus, by Lemma 3.2 of [8] we can interpolate to recover c_1. Dividing by n_1, we get

$$Z(I' \mid \sigma(t_0) = 0,\ldots,\sigma(t_{q-1}) = q-1) = Z(I). \qquad \square$$

LEMMA 18. *For every* $\mathcal{F} \subseteq \mathcal{F}_q$, $\#\mathsf{CSP}^{\neq}(\mathcal{F}) \leq_{\mathrm{T}} \#\mathsf{CSP}(\mathcal{F})$.

Proof. We use Möbius inversion for posets, following the lines of the proof of [2, Theorem 8].[7] Consider the set of partitions of $[q]$. Let $\underline{0}$ denote the partition with q singleton classes. Consider the partial order in which $\eta \leq \theta$ if and only if every class of η is a subset of some class of θ. Define $\mu(\underline{0}) = 1$, and for any $\theta \neq \underline{0}$ define $\mu(\theta) = -\sum_{\eta \leq \theta, \eta \neq \theta} \mu(\eta)$. Consider the sum $\sum_{\eta \leq \theta} \mu(\eta)$. Clearly, this sum is 1 if $\theta = \underline{0}$. From the definition of μ, it is also easy to see that the sum is 0 otherwise, since

$$\sum_{\eta \leq \theta} \mu(\eta) = \mu(\theta) + \sum_{\eta \leq \theta, \eta \neq \theta} \mu(\eta) = 0.$$

Now let I be an instance of $\#\mathsf{CSP}^{\neq}(\mathcal{F})$ with a disequality constraint applied to variables $t_0, \ldots, t_{q-1}$. Let V be the set of variables of I. Given a configuration $\sigma : V \to [q]$, let $\vartheta(\sigma)$ be the partition of $[q]$ induced by of $(\sigma(t_0), \ldots, \sigma(t_{q-1}))$. Thus i and j in $[q]$ are in the same class of $\vartheta(\sigma)$ if and only if $\sigma(t_i) = \sigma(t_j)$. We say that a partition η is consistent with σ (written $\eta \preccurlyeq \sigma$) if $\eta \leq \vartheta(\sigma)$. Note that $\eta \preccurlyeq \sigma$ means that for any i and j in the same class of η, $\sigma(t_i) = \sigma(t_j)$.

Let Ω be the set of configurations σ that satisfy all constraints in I except possibly the disequality constraint. Then $Z(I) = \sum_{\sigma \in \Omega} w(\sigma) \mathbb{1}_\sigma$, where $\mathbb{1}_\sigma = 1$ if σ respects the disequality constraint, meaning that $\vartheta(\sigma) = \underline{0}$, and $\mathbb{1}_\sigma = 0$ otherwise. By the Möbius inversion formula derived above,

$$Z(I) = \sum_{\sigma \in \Omega} w(\sigma) \sum_{\eta \leq \vartheta(\sigma)} \mu(\eta).$$

Changing the order of summation, we get

$$Z(I) = \sum_{\eta} \mu(\eta) \sum_{\eta \leq \theta} \sum_{\sigma \in \Omega : \vartheta(\sigma) = \theta} w(\sigma) = \sum_{\eta} \mu(\eta) \sum_{\sigma \in \Omega : \eta \preccurlyeq \sigma} w(\sigma).$$

Now note that $\sum_{\sigma : \eta \preccurlyeq \sigma} w(\sigma)$ is the partition function $Z(I_\eta)$ of an instance I_η of $\#\mathsf{CSP}(\mathcal{F})$. The instance I_η is formed from I by ignoring the disequality constraint and identifying variables in $t_0, \ldots, t_{q-1}$ whose indices are in the same class of η. Thus we can compute all the $Z(I_\eta)$ in $\#\mathsf{CSP}(\mathcal{F})$. Finally, $Z(I) = \sum_\eta \mu(\eta) Z(I_\eta)$, completing the reduction. □

ON THE COMPLEXITY OF NUMERICAL ANALYSIS*

ERIC ALLENDER†, PETER BÜRGISSER‡, JOHAN KJELDGAARD-PEDERSEN§, AND PETER BRO MILTERSEN¶

Abstract. We study two quite different approaches to understanding the complexity of fundamental problems in numerical analysis: (a) the Blum–Shub–Smale model of computation over the reals; and (b) a problem we call the "generic task of numerical computation," which captures an aspect of doing numerical computation in floating point, similar to the "long exponent model" that has been studied in the numerical computing community. We show that both of these approaches hinge on the question of understanding the complexity of the following problem, which we call PosSLP: Given a division-free straight-line program producing an integer N, decide whether $N > 0$. In the Blum–Shub–Smale model, polynomial-time computation over the reals (on discrete inputs) is polynomial-time equivalent to PosSLP when there are only algebraic constants. We conjecture that using transcendental constants provides no additional power, beyond *nonuniform* reductions to PosSLP, and we present some preliminary results supporting this conjecture. The generic task of numerical computation is also polynomial-time equivalent to PosSLP. We prove that PosSLP lies in the counting hierarchy. Combining this with work of Tiwari, we obtain that the Euclidean traveling salesman problem lies in the counting hierarchy—the previous best upper bound for this important problem (in terms of classical complexity classes) being PSPACE. In the course of developing the context for our results on arithmetic circuits, we present some new observations on the complexity of the arithmetic circuit identity testing (ACIT) problem. In particular, we show that if $n!$ is not ultimately easy, then ACIT has subexponential complexity.

1. Introduction.

The original motivation for this paper comes from a desire to understand the complexity of computation over the reals in the Blum–Shub–Smale model. In section 1.1 we give a brief introduction to this model, and we introduce the problem PosSLP and explain its importance in understanding the Blum–Shub–Smale model.

In section 1.2 we present yet another reason to be interested in PosSLP. We isolate a computational problem that lies at the root of the task of designing numerically stable algorithms. We show that this task is computationally equivalent to PosSLP. The material in sections 1.1 and 1.2 provides motivation for studying PosSLP and for attempting to place it within the framework of traditional complexity classes.

In section 1.3 we discuss our main technical contributions: proving upper and

lower bounds on the complexity of PosSLP. In section 1.4 we present applications of our main result with respect to the Euclidean traveling salesman problem and the sum-of-square-roots problem.

1.1. Polynomial time over the reals. The Blum–Shub–Smale model of computation over the reals provides a very well-studied complexity-theoretic setting in which to study the computational problems of numerical analysis. We refer the reader to Blum et al. [12] for detailed definitions and background material related to this model; here, we will recall only a few salient facts. In the Blum–Shub–Smale model, each machine computing over the reals has associated with it a finite set S of real *machine constants*. The inputs to a machine are elements of $\bigcup_n \mathbb{R}^n = \mathbb{R}^\infty$, and thus each polynomial-time machine over $\mathbb{R}$ accepts a "decision problem" $L \subseteq \mathbb{R}^\infty$. The set of decision problems accepted by polynomial-time machines over $\mathbb{R}$ using only constants from $S \cup \{0,1\}$ is denoted $\mathrm{P}_{\mathbb{R}}^S$. The union of the classes $\mathrm{P}_{\mathbb{R}}^S$ over all S is called *polynomial time over* $\mathbb{R}$ and is denoted $\mathrm{P}_{\mathbb{R}}$. The subclass $\mathrm{P}_{\mathbb{R}}^\emptyset$ of "constant-free polynomial time" is commonly denoted by $\mathrm{P}_{\mathbb{R}}^0$; cf. Bürgisser and Cucker [20].

There has been considerable interest in relating computation over $\mathbb{R}$ to the classical Boolean complexity classes such as P, NP, PSPACE, etc. This is accomplished by considering the *Boolean part* of decision problems over the reals. That is, given a problem $L \subseteq \mathbb{R}^\infty$, the Boolean part of L is defined as $\mathrm{BP}(L) := L \cap \{0,1\}^\infty$. (Here, we follow the notation of [12]; $\{0,1\}^\infty = \bigcup_n \{0,1\}^n$, which is identical to $\{0,1\}^*$.) The Boolean part of $\mathrm{P}_{\mathbb{R}}$, denoted $\mathrm{BP}(\mathrm{P}_{\mathbb{R}})$, is defined as $\{\mathrm{BP}(L) \mid L \in \mathrm{P}_{\mathbb{R}}\}$.

By encoding the advice function in a single real constant as in Koiran [44], one can show that $\mathsf{P}/\mathrm{poly} \subseteq \mathrm{BP}(\mathrm{P}_{\mathbb{R}})$. The best upper bound on the complexity of problems in $\mathrm{BP}(\mathrm{P}_{\mathbb{R}})$ that is currently known was obtained by Cucker and Grigoriev [27]:

$$\mathrm{BP}(\mathrm{P}_{\mathbb{R}}) \subseteq \mathsf{PSPACE}/\mathrm{poly}. \tag{1.1}$$

There has been *no* work pointing to lower bounds on the complexity of $\mathrm{BP}(\mathrm{P}_{\mathbb{R}})$; nobody has presented any compelling evidence that $\mathrm{BP}(\mathrm{P}_{\mathbb{R}})$ is not equal to P/poly. There has also been some suggestion that perhaps $\mathrm{BP}(\mathrm{P}_{\mathbb{R}})$ is equal to $\mathsf{PSPACE}/\mathrm{poly}$. For instance, certain variants of the RAM model that provide for unit-cost arithmetic can simulate all of PSPACE in polynomial time [10, 37]. Since the Blum–Shub–Smale model also provides for unit-time multiplication on "large" numbers, Cucker and Grigoriev [27] mention that researchers have raised the possibility that similar arguments might show that polynomial-time computation over $\mathbb{R}$ might be able to simulate PSPACE. Cucker and Grigoriev also observe that certain naïve approaches to providing such a simulation must fail.

One of our goals is to provide evidence that $\mathrm{BP}(\mathrm{P}_{\mathbb{R}})$ lies properly between P/poly and $\mathsf{PSPACE}/\mathrm{poly}$. Towards this goal, it is crucial to understand a certain decision problem PosSLP: *Decide, for a given division-free straight-line program, whether it represents a positive integer.* More generally, for a fixed finite subset $S \subset \mathbb{R}$, $\mathrm{PosSLP}(S)$ is the problem of deciding for a given division-free straight-line program, using constants from $S \cup \{0,1\}$, whether the real number represented by it is positive. (For precise definitions, see the next section.)

The immediate relationship between the Blum–Shub–Smale model and the problems $\mathrm{PosSLP}(S)$ is given by the proposition below.

PROPOSITION 1.1. *We have* $\mathsf{P}^{\mathrm{PosSLP}(S)} = \mathrm{BP}(\mathrm{P}_{\mathbb{R}}^S)$ *for all finite subsets* $S \subset \mathbb{R}$. *In particular,* $\mathsf{P}^{\mathrm{PosSLP}} = \mathrm{BP}(\mathrm{P}_{\mathbb{R}}^0)$.

Proof. It is clear that $\mathrm{PosSLP}(S)$ is in $\mathrm{BP}(\mathrm{P}_{\mathbb{R}}^S)$, since we can implement a standard SLP (straight-line program) interpreter in the real Turing machine framework

and evaluate the result in linear time using unit-cost instructions. The result is then obtained by one sign test. To show the other direction, assume that we have a polynomial-time machine over $\mathbb{R}$ using only the constants in $S \cup \{0, 1\}$. By a usual argument (separate computation of numerator and denominator), we may assume without loss of generality that the machine does not use divisions. Given a bit string as input, we simulate the computation by storing the straight-line program representation of the intermediate results instead of their values. Branch instructions can be simulated by using the oracle PosSLP(S) to determine if the contents of a given register (represented by a straight-line program) are greater than zero. □

It was shown by Chapuis and Koiran [24] that algebraic constants do not help. More specifically, $\mathrm{P}_{\mathbb{R}}^0$ is equal to the class of decision problems over the reals decided by polynomial-time Blum–Shub–Smale machines using real algebraic numbers as constants.

As already mentioned, by encoding the advice function in a single real constant, one can show that $\mathsf{P}/\mathrm{poly} \subseteq \mathrm{BP}(\mathrm{P}_{\mathbb{R}})$. The proof in fact shows even $\mathsf{P}^{\mathrm{PosSLP}}/\mathrm{poly} \subseteq \mathrm{BP}(\mathrm{P}_{\mathbb{R}})$. The real constant encoding the advice function, will, of course, in general be transcendental. Thus, there is a strong relationship between nonuniformity in the classical model of computation and the use of transcendental constants in the Blum–Shub–Smale model. We conjecture that this relationship can be further strengthened, as follows.

Conjecture 1. $\mathsf{P}^{\mathrm{PosSLP}}/\mathrm{poly} = \mathrm{BP}(\mathrm{P}_{\mathbb{R}})$.

In section 3 we present some preliminary results toward proving this conjecture. For instance, we prove that $\mathrm{BP}(\mathrm{P}_{\mathbb{R}}^{\{\alpha\}}) \subseteq \mathsf{P}^{\mathrm{PosSLP}}/\mathrm{poly}$ for almost all $\alpha \in \mathbb{R}$, in the sense of Lebesgue measure. We also show that $\mathrm{BP}(\mathrm{P}_{\mathbb{R}}^{\{\alpha\}}) \subseteq \mathsf{P}^{\mathrm{PosSLP}}/1$ (one bit of advice) if α is the value of an elementary function on a rational number. This is the case, for instance, for the well-known transcendental numbers e or π.

1.2. The task of a numerical analyst. The Blum–Shub–Smale model is a very elegant one, but it does not take into account the fact that actual numerical computations have to deal with *finitely* represented values. We next observe that even if we take this into account, the PosSLP problem still captures the complexity of numerical computation.

Let $u \neq 0$ be a dyadic rational number. The *floating point* representation of u is obtained by writing $u = v2^m$, where m is an integer and $\frac{1}{2} \leq |v| < 1$. The floating point representation is then given by the sign of v and the usual binary representations of the numbers $|v|$ and m. The floating point representation of 0 is the string 0 itself. We shall abuse notation and identify the floating point representation of a number with the number itself, using the term "floating point number" for the number as well as its representation.

Let $u \neq 0$ be a real number. We may write u as $u = u'2^m$, where $\frac{1}{2} \leq |u'| < 1$ and m is an integer. Then, we define a *floating point approximation of u with k significant bits* to be a floating point number $v2^m$ so that $|v - u'| \leq 2^{-(k+1)}$.

We will focus on one part of the job that is done by numerical analysts: the design of numerically stable algorithms. In our scenario, the numerical analyst starts out with a known function f, and the task is to design a "good" algorithm for it. When we say that the function f is "known," we mean that the analyst starts out with some method of computing (or at least approximating) f; we restrict attention to the "easy" case where the method for computing f uses only the arithmetic operations $+, -, *, \div$, and thus the description of f that the analyst is given can be presented as an arithmetic circuit with operations $+, -, *, \div$. Usually, the analyst also has to worry about the

problems that are caused by the fact that the inputs to f are not known precisely but are only given as floating point numbers that are approximations to the "true" inputs—but again we will focus on the "easy" case where the analyst will merely try to compute a good approximation for $f(x_1, \ldots, x_n)$ on the exact floating point numbers $x_1, \ldots, x_n$ that are presented as input, as follows.

THE GENERIC TASK OF NUMERICAL COMPUTATION (GTNC). *Given a straight-line program P (with $\div$), and given inputs $x_1, \ldots, x_n$ for P (as floating point numbers) and an integer k in unary, along with a promise that $P(x_1, \ldots, x_n)$ neither evaluates to zero nor does division by zero, compute a floating point approximation of the value of the output $P(x_1, \ldots, x_n)$ with k significant bits.*

The traditional approach that numerical analysts have followed in trying to solve problems of this sort is to study the numerical stability of the algorithm represented by the circuit and, in case of instability, to attempt to devise an equivalent computation that is numerically stable. Although stable algorithms have been found for a great many important functions, the task of devising such algorithms frequently involves some highly nontrivial mathematics and algorithmic ingenuity. There seems to be no expectation that there will ever be a purely automatic way to solve this problem, and indeed there seems to be no expectation that a numerically stable algorithm will exist in general. To summarize, there is substantial empirical evidence that the generic task of numerical computation is intractable. It would be of significant practical interest if, contrary to expectation, it should turn out to be very easy to solve (say, solvable in linear time).

We show that the generic task of numerical computation is equivalent in power to PosSLP.

PROPOSITION 1.2. *The GTNC is polynomial-time Turing equivalent to* PosSLP.

Proof. We first reduce PosSLP to the GTNC. Given a division-free straight-line program representing the number N, we construct a straight-line program computing the value $v = 2N - 1$. The only inputs $0, 1$ of this program can be considered to be floating point numbers, and this circuit clearly satisfies the promise of the GTNC. Then $N > 0$ if $v \geq 1$, and $N \leq 0$ if $v \leq -1$. Determining an approximation of v to one significant bit is enough to distinguish between these cases.

Conversely, suppose we have an oracle solving PosSLP. Given a straight-line program with inputs being floating point numbers, we first convert it to a straight-line program having only input 1; it is easy to see that this can be done in polynomial time. By standard techniques we move all $\div$ gates to the top, so that the program computes a value $v = v_1/v_2$, where v_1, v_2 are given by division-free straight-line programs. We can use the oracle to determine the signs of v_1 and v_2. Without loss of generality assume that v is positive. Next we use the oracle to determine whether $v_1 \geq v_2$. Suppose that this is indeed the case (the opposite case is handled similarly).

We then find the least r so that $2^{r-1} \leq v < 2^r$, by first comparing v_1 with $v_2 2^{2^i}$ for $i = 0, 1, 2, 3, \ldots$, using the oracle, thus finding the minimum i so that $v < 2^{2^i}$, and afterwards doing a binary search, again using the oracle to compare v_1 to $v_2 2^r$ for various values of r. This takes polynomial time.

The desired output is a floating point number $u = u'2^r$, where $|v - u'| \leq 2^{-(k+1)}$. To obtain u' we first want to find the integer w between 2^k and $2^{k+1} - 1$ so that $w/2^{k+1} \leq v/2^r < (w+1)/2^{k+1}$. Since $w/2^{k+1} \leq v/2^r < (w+1)/2^{k+1}$ iff $w2^r v_2 \leq v_1 2^{k+1} < (w+1)2^r v_2$, we can determine this by another binary search, using $O(k)$ calls to the oracle. We then output the sign of v, the binary representation of the rational $w/2^{k+1}$, and the binary representation of r, together forming the desired floating point approximation of v. ∎

The reader may wonder how GTNC fits into the numerical analysis literature. The long exponent model (LEM) of Demmel [31, 30] offers the closest parallel. Demmel considers the classic problem of computation of the determinant, and he identifies three ways of modeling the problem, which he calls the traditional model, the short exponent model (SEM), and the LEM. Computing determinants is easy in the SEM, while in the LEM the problem is equivalent to a special case of GTNC. Namely, it is equivalent to instances of GTNC where the circuit C that is provided as input is the polynomial-size SLP for determinants given by Berkowitz [9].

Demmel goes so far as to conjecture that, in the LEM, the problem of deciding whether the determinant is zero is NP-hard [31]. Since this problem is actually a special case of EquSLP and thus lies in BPP, Demmel's conjecture is almost certainly false. However, we agree with his underlying intuition, in that we believe that the problem of deciding whether the determinant is *positive* in the LEM very likely is intractable (even if we see no evidence that it is NP-hard) [57]. That is, this special case of PosSLP is recognized as a difficult problem by the numerical analysis community.

1.3. The complexity of PosSLP. We consider Proposition 1.2 to be evidence for the computational intractability of PosSLP. If PosSLP is in P/poly, then there is a polynomial-sized "cookbook" that can be used in place of the creative task of devising numerically stable computations. This seems unlikely.

We wish to emphasize that the generic task of numerical computation models the *discrete* computational problem that underlies an important class of computational problems. Thus it differs quite fundamentally from the approach taken in the Blum–Shub–Smale model.

We also wish to emphasize that, in defining the generic task of numerical computation, we are *not* engaging in the debate over which real functions are "efficiently computable." There is by now a large literature comparing and contrasting the relative merits of the Blum–Shub–Smale model with the so-called bit model of computing, and there are various competing approaches to defining what it means for a real-valued function to be feasible to compute; see [13, 17, 16, 67, 68] among others. Our concerns here are orthogonal to that debate. We are not trying to determine which real-valued functions are feasible; we are studying a discrete computational problem that is relevant to numerical analysis, with the goal of proving upper and lower bounds on its complexity.

The generic task of numerical computation is one way of formulating the notion of what is feasible to compute in a world where *arbitrary precision* arithmetic is available for free. In contrast, the Blum–Shub–Smale model can be interpreted as formulating the notion of feasibility in a world where *infinite precision* arithmetic is available for free. According to Proposition 1.2, both of these approaches are *equivalent* (and captured by $\mathsf{P}^{\mathrm{PosSLP}}$) when only algebraic constants are allowed in the Blum–Shub–Smale model. Conjecture 1 claims that this is also true when allowing arbitrary real constants.

As another demonstration of the computational power of PosSLP, we show in section 2 that the problem of determining the total degree of a multivariate polynomial over the integers given as a straight-line program reduces to PosSLP.

The above discussion suggests that PosSLP is not an easy problem. Can more formal evidence of this be given? Although it would be preferable to show that PosSLP is hard for some well-studied complexity class, the best that we can do is observe that a somewhat stronger problem (BitSLP) is hard for $\#\mathsf{P}$. This will be done in section 2.

The above discussion also suggests that nontrivial upper bounds for PosSLP are

of great interest. Prior to this paper, the best upper bound was PSPACE. Our main technical result is an improved upper bound: We show, based on results on the uniform circuit complexity of integer division and the relationship between constant depth circuits and subclasses of PSPACE [6, 39], that PosSLP lies in the counting hierarchy CH, a well-studied subclass of PSPACE that bears more or less the same relationship to #P as the polynomial hierarchy bears to NP [64, 66].

THEOREM 1.3. PosSLP *is in* $\mathsf{P}^{\mathsf{PP}^{\mathsf{PP}^{\mathsf{PP}}}}$.

Another interesting upper bound for PosSLP was recently discovered by Tarasov and Vyalyi [61], who give a reduction from PosSLP to the *semidefinite feasibility problem* (SDFP), i.e., the feasibility version of the optimization problem *semidefinite programming*. Their result can be seen as a lower bound for SDFP. SDFP is known to reduce to its complement and to lie in $\mathrm{NP}_{\mathbb{R}}$ [54]; also it is easy to see that SDFP reduces to the existential theory of the reals (for instance, see the discussion in [54]), and thus SDFP $\in$ PSPACE.

We suspect that PosSLP lies at an even lower level of CH. Note that, in presenting our upper bound, we do not exploit some powerful techniques that have been proved useful in computing certain bits of exponentially large numbers [40]. We leave as major open problems the question of providing better upper bounds for PosSLP and the question of providing any sort of hardness theorem, reducing a supposedly intractable problem to PosSLP.

Theorem 1.3, together with Proposition 1.1, implies that $\mathrm{BP}(\mathrm{P}^0_{\mathbb{R}}) \subseteq \mathsf{CH}$. It is reasonable to conjecture that $\mathrm{BP}(\mathrm{P}_{\mathbb{R}}) \subseteq \mathsf{CH}/\mathrm{poly}$—and indeed that would follow from Conjecture 1—but as yet we are not able to improve the upper bound of $\mathrm{BP}(\mathrm{P}_{\mathbb{R}}) \subseteq \mathsf{PSPACE}/\mathrm{poly}$ that was presented by Cucker and Grigoriev [27].

We believe that it would be very interesting to verify Conjecture 1, as this would give a characterization of $\mathrm{BP}(\mathrm{P}_{\mathbb{R}})$ in terms of classical complexity classes. But in fact, it would be equally interesting to refute it under some plausible complexity-theoretic assumption, as this would give evidence that the power of using transcendental constants in the sequential Blum–Shub–Smale model goes beyond the power of nonuniformity in classical computation.

1.4. Applications. The *sum-of-square-roots problem* is a well-known problem with many applications to computational geometry and elsewhere. The input to the problem is a list of integers $(d_1, \ldots, d_n)$ and an integer k, and the problem is to decide whether $\sum_i \sqrt{d_i} \geq k$. The complexity of this problem is posed as an open question by Garey, Graham, and Johnson [36] in connection with the Euclidean traveling salesman problem, which is not known to be in NP but which is easily seen to be solvable in NP relative to the sum-of-square-roots problem. See also O'Rourke [53, 52] and Etessami and Yannakakis [34] for additional information. Although it has been conjectured [51] that the problem lies in P, it seems that no classical complexity class smaller than PSPACE has been known to contain this problem. On the other hand, by observing that one can construct a polynomial-sized straight-line program with division that approximates the square root of any given integer with exponentially high precision, using Newton iteration, Tiwari [62] showed that this problem can be decided in polynomial time on an "algebraic random-access machine." In fact, it is easy to see that the set of decision problems decided by such machines in polynomial time is exactly $\mathrm{BP}(\mathrm{P}^0_{\mathbb{R}})$. Thus by Proposition 1.1 we see that the sum-of-square-roots problem reduces to PosSLP. Theorem 1.3 thus yields the following corollary.

COROLLARY 1.4. *The sum-of-square-roots problem and the Euclidean traveling salesman problem are in* CH.

2. Preliminaries. Our definitions of arithmetic circuits and straight-line programs are standard. An *arithmetic circuit* is a directed acyclic graph with input nodes labeled with the constants $0, 1$ or with indeterminates $X_1, \ldots, X_k$ for some k. Internal nodes are labeled with one of the operations $+, -, *, \div$. A *straight-line program* is a sequence of instructions corresponding to a sequential evaluation of an arithmetic circuit. If it contains no $\div$ operation, it is said to be *division-free*. Unless otherwise stated, all the straight-line programs considered will be division-free. Thus straight-line programs can be seen as very compact representations of a polynomial over the integers. In many cases, we will be interested in division-free straight-line programs using no indeterminates, which thus represent an integer.

By the n-bit binary representation of an integer N such that $|N| < 2^n$ we understand a bit string of length $n+1$ consisting of a *sign bit* followed by n bits encoding $|N|$ (padded with leading zeroes, if needed).

We consider the following problems:

EquSLP. Given a straight-line program representing an integer N, decide whether $N = 0$.

ACIT. Given a straight-line program representing a polynomial $f \in \mathbb{Z}[X_1, \ldots, X_k]$, decide whether $f = 0$.

DegSLP. Given a straight-line program representing a polynomial $f \in \mathbb{Z}[X_1, \ldots, X_k]$ and given a natural number d in binary, decide whether $\deg f \leq d$.

PosSLP. Given a straight-line program representing $N \in \mathbb{Z}$, decide whether $N > 0$.

BitSLP. Given a straight-line program representing N, and given $n, i \in \mathbb{N}$ in binary, decide whether the ith bit of the n-bit binary representation of N is 1.

It is not clear that any of these problems is in P, since straight-line program representations of integers can be exponentially smaller than ordinary binary representation.

There is an immediate relationship between the Blum–Shub–Smale model over the complex numbers $\mathbb{C}$ and the problem EquSLP. Let $\mathrm{P}_{\mathbb{C}}^0$ denote the class of decision problems over $\mathbb{C}$ decided by polynomial-time Blum–Shub–Smale machines using only the constants $0, 1$. Similarly as for Proposition 1.1 one can show that $\mathsf{P}^{\mathrm{EquSLP}} = \mathrm{BP}(\mathrm{P}_{\mathbb{C}}^0)$. On the other hand, it is known that constants can be eliminated in this setting [11, 45], and hence $\mathrm{BP}(\mathrm{P}_{\mathbb{C}}) = \mathrm{BP}(\mathrm{P}_{\mathbb{C}}^0)$. We therefore have the following result.

PROPOSITION 2.1. $\mathsf{P}^{\mathrm{EquSLP}} = \mathrm{BP}(\mathrm{P}_{\mathbb{C}})$.

Clearly, EquSLP is a special case of ACIT. Schönhage [57] showed that EquSLP is in coRP, using computation modulo a randomly chosen prime. Ibarra and Moran [41], building on DeMillo and Lipton [29], Schwartz [58], and Zippel [69], extended this to show that ACIT lies in coRP. In the spirit of Adleman's observation [1], Heintz and Schnorr [38] established the existence of nonuniform polynomial-time algorithms for an algebraic variant of the ACIT problem (allowing any field elements as constants). The problem ACIT has recently attracted much attention due to the work of Kabanets and Impagliazzo [42] who showed that a deterministic algorithm for ACIT would yield circuit lower bounds. (See [47] for some progress on finding deterministic algorithms for certain versions of the problem.) As far as we know, although the proof technique that we use in Proposition 2.2 is well known and has been applied various times over the years [3, 60], it has not been pointed out before that ACIT is actually polynomial-time equivalent to EquSLP. In other words, disallowing indeterminates in the straight-line program given as input does not make ACIT easier. Or more optimistically: It is enough to find a deterministic algorithm for this special case in order to have circuit lower bounds.

PROPOSITION 2.2. ACIT *is polynomial-time equivalent to* EquSLP.

Proof. We are given a straight-line program of size n with m indeterminates $X_1, \ldots, X_m$, computing the polynomial $p(X_1, \ldots, X_m)$. Define $B_{n,i} = 2^{2^{in^2}}$. Straight-line programs computing these numbers using iterated squaring can easily be constructed in polynomial time, so given a straight-line-program for p, we can easily construct a straight-line program for $p(B_{n,1}, \ldots, B_{n,m})$. We shall show that for $n \geq 3$, p is identically zero iff $p(B_{n,1}, \ldots, B_{n,m})$ evaluates to zero.

To see this, first note that the "only if" part is trivial, so we only have to show the "if" part. Thus, assume that $p(X_1, \ldots, X_m)$ is not the zero-polynomial. Let $q(X_1, \ldots, X_m)$ be the largest monomial occurring in p with respect to inverse lexicographic order,[1] and let k be the number of monomials. We can write $p = \alpha q + \sum_{i=1}^{k-1} \alpha_i q_i$, where $(q_i)_{i=1,\ldots,k-1}$ are the remaining monomials. An easy induction in the size of the straight-line program shows that $|\alpha_i| \leq 2^{2^{2n}}$, $k \leq 2^{2^n}$ and that the degree of any variable in any q_i is at most 2^n.

Now, our claim is that the absolute value $|\alpha q(B_{n,1}, \ldots, B_{n,m})|$ is strictly bigger than $|\sum_{i=1}^{k-1} \alpha_i q_i(B_{n,1}, \ldots, B_{n,m})|$, and thus we cannot have that $p(B_{n,1}, \ldots, B_{n,m}) = 0$.

Indeed, since the monomial q was the biggest in the inverse lexicographic ordering, we have that for any other monomial q_i there is an index j so that

$$\frac{q(B_{n,1}, \ldots, B_{n,m})}{q_i(B_{n,1}, \ldots, B_{n,m})} \geq \frac{2^{2^{jn^2}}}{\prod_{l=1}^{j-1} 2^{2^{ln^2} \cdot 2^n}} > 2^{2^{n^2-1}},$$

so we can bound

$$\left| \sum_{i=1}^{k-1} \alpha_i q_i(B_{n,1}, \ldots, B_{n,m}) \right| \leq 2^{2^n} 2^{2^{2n}} \left| \max_{i=1}^{k-1} q_i(B_{n,1}, \ldots, B_{n,m}) \right|$$

$$\leq 2^{2^n} 2^{2^{2n}} 2^{-2^{n^2-1}} |q(B_{n,1}, \ldots, B_{n,m})| < q(B_{n,1}, \ldots, B_{n,m}) \leq |\alpha q(B_{n,1}, \ldots, B_{n,m})|,$$

which proves the claim. □

We believe that Proposition 2.2 could be a useful tool for devising deterministic algorithms for ACIT. (See section 5 for one modest application in this direction.) Of course, it must also be acknowledged that multivariate polynomials exhibit a great deal of structure that is not so apparent in computation over the integers (as embodied by EquSLP), and algorithmic attacks on ACIT should also attempt to exploit this structure.

The problem DegSLP is not known to lie in BPP, even for the special case of univariate polynomials. Here, we show that it reduces to PosSLP.

PROPOSITION 2.3. DegSLP *polynomial-time many-one reduces to* PosSLP.

Proof. We first show the reduction for the case of univariate polynomials (i.e., straight-line programs with a single indeterminate), and afterwards we reduce the multivariate case to the univariate case.

Let $f \in \mathbb{Z}[X]$ be given by a straight-line program of length n. To avoid having to deal with the zero polynomial of degree $-\infty$ and to ensure that the image of the polynomial is a subset of the nonnegative integers, we first change the straight-line program computing f into a straight-line program computing $f_1(X) = (Xf(X) + 1)^2$

[1] $X_1^{\alpha_1} \cdots X_m^{\alpha_m}$ is greater than $X_1^{\beta_1} \cdots X_m^{\beta_m}$ in this order iff the right-most nonzero component of $\alpha - \beta$ is positive; cf. Cox, Little, and O'Shea [26, p. 59].

by adding a few extra lines. We can check whether the degree of f is at most d by checking whether the degree of f_1 is at most $D = 2(d+1)$ (except for $d = -\infty$, in which case we check whether the degree of f_1 is at most $D = 0$).

Let B_n be the integer $2^{2^{n^2}}$. As in the proof of Proposition 2.2, we can easily construct a straight-line program computing B_n and from this a straight-line program computing $f_1(B_n)$.

Now, suppose that $\deg f_1 \le D$. Using the same bounds on sizes of the coefficients as in the proof of Proposition 2.2 and assuming without loss of generality that $n \ge 3$, we then have

$$f_1(B_n) \le \sum_{i=0}^{D} 2^{2^{2n}} B_n^i < (2^n+1)2^{2^{2n}} B_n^D \le (2^{2^n}+1)2^{2^{2n}-2^{n^2}} B_n^{D+1} < \frac{B_n^{D+1}}{2}.$$

On the other hand, suppose that $\deg f_1 \ge D+1$. Then we have

$$f_1(B_n) \ge (B_n)^{D+1} - \sum_{i=0}^{D} 2^{2^{2n}} B_n^i \ge B_n^{D+1} - 2^{2^n} 2^{2^{2n}} 2^{-2^{n^2}} B_n^{D+1} > \frac{B_n^{D+1}}{2}.$$

Thus, to check whether $\deg f_1 \le D$, we just need to construct a straight-line-program for $2f_1(B_n) - B_n^{D+1}$ and check whether it computes a positive integer. This completes the reduction for the univariate case.

We next reduce the multivariate case to the univariate case. Thus, let f in $\mathbb{Z}[X_1, \ldots, X_m]$ be given by a straight-line program of length n. We define f^* in $\mathbb{Z}[X_1, \ldots, X_m, Y]$ by $f^*(X_1, \ldots, X_m, Y) = f(X_1 Y, \ldots, X_m Y)$. We claim that if we let $B_{n,i} = 2^{2^{in^2}}$ as in the proof of Proposition 2.2, then, for $n \ge 3$, the degree of the univariate polynomial $f^*(B_{n,1}, \ldots, B_{n,m}, Y)$ is equal to the total degree of f. Indeed, we can write f^* as a polynomial in Y with coefficients in $\mathbb{Z}[X_1, \ldots, X_m]$:

$$f^*(X_1, \ldots, X_m, Y) = \sum_{j=0}^{d^*} g_j(X_1, \ldots, X_m) Y^j,$$

where d^* is the degree of variable Y in the polynomial f^*. Note that this is also the total degree of the polynomial f. Now, the same argument as used in the proof of Proportion 2.2 shows that since g_{d^*} is not the zero-polynomial, $g_{d^*}(B_{n,1}, B_{n,2}, \ldots, B_{n,m})$ is different from 0. □

As PosSLP easily reduces to BitSLP, we obtain the chain of reductions

$$\text{EquSLP} \equiv \text{ACIT} \le_{\text{m}}^{\text{p}} \text{DegSLP} \le_{\text{m}}^{\text{p}} \text{PosSLP} \le_{\text{m}}^{\text{p}} \text{BitSLP}.$$

In section 4 we will show that all the above problems in fact lie in the counting hierarchy CH.

The complexity of BitSLP contrasts sharply with that of EquSLP.

PROPOSITION 2.4. BitSLP *is hard for* $\#\mathsf{P}$.

Proof. A similar result is stated without proof in [31]. The proof that we present is quite similar to that of Bürgisser [22, Proposition 5.3], which in turn is based on ideas of Valiant [65]. We show that computing the permanent of matrices with entries from {0,1} is reducible to BitSLP.

Given a matrix X with entries $x_{i,j} \in \{0, 1\}$, consider the univariate polynomial

$$f_n = \sum_i f_{n,i} Y^i = \prod_{i=1}^{n} \left(\sum_{j=1}^{n} x_{i,j} Y^{2^{j-1}} \right),$$

which can be represented by a straight-line program of size $O(n^2)$. Then $f_{n,2^n-1}$ equals the permanent of X. Let N be the number that is represented by the straight-line program that results from replacing the indeterminate Y with 2^{n^3}. It is easy to see that the binary representation of $f_{n,2^n-1}$ appears as a sequence of consecutive bits in the binary representation of N. □

Triggered by an earlier version of this paper [5], Koiran and Perifel [43] studied the variant of the problem DegSLP for computations of polynomials over the finite field $\mathbb{F}_p$. They proved a considerably better upper bound on this problem than what is currently known for DegSLP. Also, Koiran and Perifel [43] investigated the problem *zero monomial coefficient* of deciding for a polynomial f given by a straight-line program and a given monomial x^α whether the coefficient of this monomial in f equals zero. For computations of polynomials over the finite field $\mathbb{F}_p$, they managed to show that zero monomial coefficient is $\mathrm{Mod}_p P$ complete. However, for characteristic zero, no improvements upon the results in this paper were made in that respect.

3. Transcendental constants. We present here some first results toward establishing our Conjecture 1.

Let S denote a fixed finite subset of $\mathbb{R}$. By an *SLP over* S we shall understand a division-free straight-line program using constants from $S \cup \{0, 1\}$. Recall the following problem:

PosSLP(S). Given an SLP over S, decide whether the real number represented by it is positive.

Remark 1. We could have defined a variant of PosSLP(S) by allowing divisions in the straight-line programs. However, this variant is easily seen to be polynomial-time equivalent to PosSLP(S). Indeed, by computing separately with numerators and denominators we can transform an SLP representing α into two division-free SLPs representing numbers A, B such that $\alpha = A/B$. Hereby, the length of the SLPs increases at most by a factor of four. Now α is positive iff AB is positive.

A result by Chapuis and Koiran [24] implies that algebraic constants can be eliminated. It can be stated as follows.

PROPOSITION 3.1. *Let $S \subseteq \mathbb{R}$ be finite and $\alpha \in \mathbb{R}$ be algebraic over the field $\mathbb{Q}(S)$. Then $\mathsf{P}^{\mathrm{PosSLP}(S \cup \{\alpha\})} = \mathsf{P}^{\mathrm{PosSLP}(S)}$.*

Our first goal is to prove that almost all transcendental constants can be eliminated.

THEOREM 3.2. *For all $(\alpha_1, \alpha_2, \ldots, \alpha_k) \in \mathbb{R}^k$ except in a subset of Lebesgue measure zero we have $\mathsf{P}^{\mathrm{PosSLP}(\{\alpha_1,\ldots,\alpha_k\})}/\mathrm{poly} = \mathsf{P}^{\mathrm{PosSLP}}/\mathrm{poly}$.*

The proof will require some lemmas. The idea is to eliminate one by one the elements of such sets S, replacing each element with appropriate advice of polynomial size.

We denote by $R_n^S \subset \mathbb{R}$ the set of all real numbers that occur as a root of some nonzero univariate polynomial that is computed by an SLP of size n that uses constants in S. Note that $\mathbb{R} \setminus R_n^S$ consists of a collection of open intervals. Clearly, any univariate polynomial computed from S by an SLP of size n has constant sign on each of these intervals. For $\alpha \in \mathbb{R} \setminus R_n^S$, we denote by $I_n^S(\alpha)$ the unique interval containing α.

Remark 2. A real number α is transcendental over $\mathbb{Q}(S)$ iff $\alpha \notin R_n^S$ for all n (or equivalently, for infinitely many n).

DEFINITION 3.3. *We call a real number α* approximable with respect to *S if either α is algebraic over $\mathbb{Q}(S)$ or else α is transcendental over $\mathbb{Q}(S)$ and satisfies the following condition: there exists a polynomial p such that for all sufficiently large*

$n \in \mathbb{N}$ the interval $I_n^S(\alpha)$ contains an element x_n that can be represented by an SLP over S of size $p(n)$, possibly using divisions. (Note that this interval is well defined as $\alpha \notin R_n^S$; cf. Remark 2.) We say that α is approximable iff it is approximable with respect to the empty set.

LEMMA 3.4. *If $\alpha \in \mathbb{R}$ is approximable with respect to S, then* $\mathsf{P}^{\mathrm{PosSLP}(S\cup\{\alpha\})}/\mathrm{poly} = \mathsf{P}^{\mathrm{PosSLP}(S)}/\mathrm{poly}$.

Proof. Suppose that $\alpha \in \mathbb{R}$ is approximable with respect to S. By Proposition 3.1 we may assume that α is transcendental over $\mathbb{Q}(S)$. Then, for all sufficiently large n, there exist $x_n \in I_n^S(\alpha)$ computed by an SLP Γ_n over S (using divisions) of size polynomial in n.

It is sufficient to show that $\mathrm{PosSLP}(S \cup \{\alpha\})$ is contained in $\mathsf{P}^{\mathrm{PosSLP}(S)}/\mathrm{poly}$. Let C be an SLP (of size n) over $S \cup \{\alpha\}$ computing $v \in \mathbb{R}$. We want to decide whether v is positive. If we replace the constant α by the variable X, then this SLP computes a polynomial $f(X)$ and we have $v = f(\alpha)$. Since the sign of f is constant on the interval $I_{p(n)}^S(\alpha)$, v has the same sign as $f(x_{p(n)})$.

We interpret the SLP Γ_n over S as an advice of polynomial size. By concatenating Γ_n with the SLP for f, we obtain an SLP over S that computes $f(x_{p(n)})$. We eliminate the divisions in the concatenated SLP according to Remark 1. Then the sign of this number is obtained by one oracle call to $\mathrm{PosSLP}(S)$. ∎

LEMMA 3.5. *We have the following:*

1. $|R_n^S| \le (6(n + |S|))^n$.
2. *The minimal distance between two different elements of $R_n^\emptyset$ is at least $2^{-2^{N_n}}$ with $N_n = O(n \log n)$.*

Proof. Let F_n be the product of all nonzero univariate polynomials f that can be computed from the variable X by an SLP over S of size n. Note that such f have degree at most 2^n. Then R_n^S is the set of roots of F_n. There are at most $\prod_{i=1}^n 3(|S|+i-1)^2 \le (3(|S|+n)^2)^n$ SLPs over S. Therefore, $\deg F_n \le (6(|S|+n)^2)^n$, which shows the first assertion.

Before showing the second assertion we introduce a notation: let $\|g\|_1$ denote the sum of the absolute values of the coefficients of a univariate polynomial g. It is easy to see that $\|g \cdot h\|_1 \le \|g\|_1 \cdot \|h\|_1$.

Suppose now $S = \emptyset$. If $f(X)$ is computed by an SLP of size n over $\emptyset$ from the variable X, then one can show that $\log \|f\|_1 \le (n+1)2^n$; see, e.g., [21, Lemma 4.16]. By the submultiplicativity of $\| \ \|_1$ we conclude

$$\log \|F_n\|_1 \le (3n^2)^n \ (n+1)2^n \le 2^{O(n \log n)}.$$

Rump [55] showed that the distance between any two distinct real roots in a univariate polynomial P with integer coefficients and degree d is at least $2\sqrt{2}(d^{\frac{d}{2}+1}(\|P\|_1 + 1)^d)^{-1}$. The second assertion follows by applying this bound to the polynomial F_n. ∎

LEMMA 3.6. *For any finite $S \subset \mathbb{R}$, the set of real numbers that are not approximable with respect to S has Lebesgue measure zero.*

Proof. Let $\alpha \in \mathbb{R}$ and x_n be the binary approximation of α with a precision of n^2 digits, i.e., $|\alpha - x_n| < 2^{-n^2}$. Clearly, there is an SLP over $\{1/2\}$ of size $O(n^2)$ representing x_n. Furthermore, suppose that α has distance at least 2^{-n^2} from R_n^S for all sufficiently large n, say for $n \ge m$. Then x_n is contained in the interval $I_n^S(\alpha)$ for $n \ge m$. Hence, by definition, α is approximable with respect to S.

These reasonings show that for all $m \in \mathbb{N}$

$$B := \{\alpha \in \mathbb{R} \mid \alpha \text{ is not approximable w.r.t. } S\} \subseteq \bigcup_{n \geq m} U_n,$$

where $U_n := \{x \in \mathbb{R} \mid \exists \rho \in R_n^S \quad |x - \rho| < 2^{-n^2}\}$ denotes the 2^{-n^2}-neighborhood of R_n^S. Denoting by $\lambda(A)$ the Lebesgue measure of a set $A \subseteq \mathbb{R}$, we get from Lemma 3.5

$$\lambda(U_n) \leq 2\,|R_n^S|\; 2^{-n^2} \leq 2\,(6(n + |S|))^n 2^{-n^2} \leq 2^{-\frac{1}{2}n^2}$$

for sufficiently large n. Therefore, we conclude that for all sufficiently large m

$$\lambda(B) \leq \sum_{n=m}^{\infty} 2^{-\frac{1}{2}n^2}.$$

Since the series $\sum_n 2^{-\frac{1}{2}n^2}$ is convergent and m was arbitrary, we conclude that $\lambda(B) = 0$. □

Proof of Theorem 3.2. We consider for $\alpha := (\alpha_1, \ldots, \alpha_k) \in \mathbb{R}^k$ and $0 \leq i \leq k$ the complexity classes $\mathcal{C}_i(\alpha) := \mathsf{P}^{\mathrm{PosSLP}(\{\alpha_1,\ldots,\alpha_i\})}/\mathrm{poly}$. Clearly, $\mathcal{C}_k(\alpha) \neq \mathcal{C}_0(\alpha)$ implies that $\mathcal{C}_s(\alpha) \neq \mathcal{C}_{s-1}(\alpha)$ for some index s. By applying Lemma 3.4 to the set of constants $S = \{\alpha_1, \ldots, \alpha_{s-1}\}$, we obtain that $\{\alpha \in \mathbb{R}^k \mid \mathcal{C}_k(\alpha) \neq \mathcal{C}_0(\alpha)\}$ is a subset of

$$\subseteq \bigcup_{s=1}^{k} \left\{\alpha \in \mathbb{R}^k \mid \alpha_s \text{ is not approximable w.r.t. } \{\alpha_1, \ldots, \alpha_{s-1}\}\right\}.$$

Lemma 3.6 says that, for fixed $\alpha_1, \ldots, \alpha_{s-1}$, the set

$$\{\alpha_s \in \mathbb{R} \mid \alpha_s \text{ is not approximable w.r.t. } \{\alpha_1, \ldots, \alpha_{s-1}\}\}$$

has Lebesgue measure zero. It follows from Fubini's theorem that the right-hand subset of $\mathbb{R}^k$ has measure zero as well, which shows the assertion. □

We can actually prove for many specific real numbers that they are approximable. Indeed, quite surprisingly, for any elementary function $f(X)$ there exists a sequence $(R_n(X))$ of rational functions such that $|R_n(x) - f(x)| < 2^{-n}$ for all $x \in [0, 1]$, and such that $R_n(X)$ can be computed by a straight-line program of polylogarithmic size (using divisions) from X. The elementary functions include the algebraic functions, the natural logarithm, and the exponential function. For algebraic functions, such approximating rational functions can be constructed with Newton's method; see Kung and Traub [46]. For the natural logarithm, the construction of such approximations relies on the AGM (arithmetic-geometric mean) iteration going back to Gauss, Lagrange, and Legendre, which, in particular, gives very good approximations of π. The latter algorithms were discovered by Brent [18] and Salamin [56]. The book by Borwein and Borwein [15] provides a complete and in-depth exposition of this subject.

More precisely, we shall understand by an *elementary function* a function built up from rational constants by finitely many arithmetic operations, applications of exp, ln, and the operation of taking a solution of a polynomial equation. (For a formal definition see [19].)

THEOREM 3.7. *Let α be the value of an elementary function at a rational number. Then the following hold:*

1. *α is approximable. In particular, $e = \exp(1)$ and π are approximable.*
2. *We have $\mathsf{P}^{\mathrm{PosSLP}(\{\alpha\})} \subseteq \mathsf{P}^{\mathrm{PosSLP}}/1$, where $/1$ means one bit of advice.*

Proof. 1. By Lemma 3.5 we know that $\epsilon_n = 2^{-2^{N_n}}$ with $N_n = O(n \log n)$ is a lower bound on the minimum distance between two different elements of $R_n^{\emptyset}$. Note that there is an SLP over $\{1/2\}$ of polynomial size computing ϵ_n (repeated squaring).

Let α be as in the statement of the theorem. Without loss of generality we may assume that α is transcendental. According to Borwein and Borwein [14, Table 1], for each n there is an SLP of size $n^{O(1)}$ (using divisions) computing an approximation a_n of α that satisfies $|a_n - \alpha| < \frac{1}{2}\epsilon_n$. By checking the proofs (cf. Borwein and Borwein [15]) one sees that these SLPs are uniform; i.e., they can be constructed in polynomial time in n.

We claim that there exist $b_n \in \{0, 1\}$ such that $x_n = a_n + b_n \frac{1}{2}\epsilon_n$ lies in the interval $I_n^{\emptyset}(\alpha)$ and thus satisfies the requirement in Definition 3.3. Hence α is approximable.

Indeed, let ℓ_n and r_n denote the left and right endpoints of the interval $I_n^{\emptyset}(\alpha)$, and denote by $m_n := \frac{1}{2}(\ell_n + r_n)$ its midpoint. Consider first the case where $\alpha < m_n$. If $\alpha \le a_n$, then $a_n < \alpha + \frac{1}{2}\epsilon_n < m_n + \frac{1}{2}\epsilon_n \le r_n$, and hence $x_n := a_n \in I_n^{\emptyset}(\alpha)$. Else if $a_n < \alpha$, then $\alpha < a_n + \frac{1}{2}\epsilon_n < \alpha + \frac{1}{2}\epsilon_n \le r_n$, and hence $x_n := a_n + \frac{1}{2}\epsilon_n \in I_n^{\emptyset}(\alpha)$ does the job. In the case where $\alpha \ge m_n$ one argues similarly.

2. We follow the proof of Lemma 3.4. However, since the SLPs computing the approximation a_n are polynomial-time uniform, only one bit of advice (corresponding to b_n) is in fact needed to emulate the computation with α. ∎

We have not been able to find a specific number that is *provably* nonapproximable. It is quite possible that there are no nonapproximable numbers at all.

4. PosSLP lies in CH. The counting hierarchy CH was defined by Wagner [66] and was studied further by Torán [64]; see also [8, 6]. A problem lies in CH if it lies in one of the classes in the sequence $\mathsf{PP}, \mathsf{PP}^{\mathsf{PP}}$, etc.

THEOREM 4.1. BitSLP *is in* CH.

Proof. It was shown by Hesse, Allender, and Mix Barrington [39] that there are Dlogtime-uniform threshold circuits of polynomial size and constant depth that compute the following function:

Input: A number X in Chinese remainder representation. That is, a sequence of values indexed (p, j) giving the jth bit of X mod p, for each prime $p < n^2$, where $0 \le X \le 2^n$ (thus we view n as an appropriate "size" measure of the input).

Output: The binary representation of the unique natural number $X < \prod_{p \text{ prime}, p<n^2} p$ whose value modulo each small prime is encoded in the input.

Let this circuit family be denoted $\{D_n\}$.

Now, as in the proof of [6, Lemma 5], we consider the following exponentially big circuit family $\{E_n\}$, which computes BitSLP.

Given as input an encoding of a straight-line program representing integer W, we first build a new program computing the positive integer $X = W + 2^{2^n}$. Note that the bits of the binary representation of W (including the sign bit) can easily be obtained from the bits of X.

Level 1 of the circuit E_n consists of gates labeled (p, j) for each prime p such that $p < 2^{2n}$ and for each $j : 1 \le j \le \lceil \log p \rceil$. The output of this gate records the jth bit of X mod p. (Observe that there are exponentially many gates on level 1, and also note that the output of each gate (p, j) can be computed in time polynomial in the size of the binary encoding of p and the size of the given straight-line program representing X. Note also that the gates on Level 1 correspond to the gates on the input level of the circuit $D_{2^{2n}}$.)

The higher levels of the circuit are simply the gates of $D_{2^{2n}}$.

Now, similar to the proof of [6, Lemma 5], we claim that for each constant d the following language is in the counting hierarchy: $L_d = \{(F, P, b) : F$ is the name of a gate on level d of E_n and F evaluates to b when given straight-line program P as input$\}$.

We have already observed that this is true when $d = 1$. For the inductive step, assume that $L_d \in \mathsf{CH}$. Here is an algorithm to solve L_{d+1} using oracle access to L_d. On input (F, P, b), we need to determine whether the gate F is a gate of E_n, and if so, we need to determine whether it evaluates to b on input P. F is a gate of E_n iff it is connected to some gate G such that, for some b', $(G, P, b') \in L_d$. This can be determined in $\mathsf{NP}^{L_d} \subseteq \mathsf{PP}^{L_d}$, since D_n is Dlogtime-uniform. That is, we can guess a gate G, check that G is connected to F (this takes only linear time because of the uniformity condition), and then use our oracle for L_d. If F is a gate of E_n, we need to determine whether the majority of the gates that feed into it evaluate to 1. (Note that all of the gates in D_n are MAJORITY gates.) That is, we need to determine whether it is the case that for most bit strings G such that G is the name of a gate that is connected to F, $(G, P, 1)$ is in L_d. This is clearly computable in PP^{L_d}.

Thus in order to compute BitSLP, given program P and index i, compute the name F of the output bit of E_n that produces the ith bit of N (which is easy because of the uniformity of the circuits $D_{2^{2^n}}$) and determine if $(F, P, 1) \in L_d$, where d is determined by the depth of the constant-depth family of circuits presented in [39]. □

Theorem 4.1 shows that $\mathrm{BP}(\mathrm{P}^0_{\mathbb{R}})$ lies in CH. A similar argument can be applied to an analogous restriction of "digital" $\mathrm{NP}_{\mathbb{R}}$ (i.e., where nondeterministic machines over the reals can guess "bits" but cannot guess arbitrary real numbers). Bürgisser and Cucker [20] present some problems in PSPACE that are related to *counting* problems over $\mathbb{R}$. It would be interesting to know whether these problems lie in CH.

Although Theorem 4.1 shows that BitSLP and PosSLP both lie in CH, some additional effort is required in order to determine the level of CH where these problems reside. We present a more detailed analysis for PosSLP, since it is our main concern in this paper. (A similar analysis can be carried out for BitSLP, showing that it lies in $\mathsf{PH}^{\mathsf{PP}^{\mathsf{PP}^{\mathsf{PP}^{\mathsf{PP}}}}}$ [7].)

The following result implies Theorem 1.3, since Toda's theorem [63] shows that $\mathsf{PP}^{\mathsf{PH}^A} \subseteq \mathsf{P}^{\mathsf{PP}^A}$ for every oracle A.

THEOREM 4.2. $\mathrm{PosSLP} \in \mathsf{PH}^{\mathsf{PP}^{\mathsf{PP}}}$.

Proof. We will use the Chinese remaindering algorithm of [39] to obtain our upper bound on PosSLP. (Related algorithms, which do not lead directly to the bound reported here, have been used on several occasions [2, 28, 33, 48, 49].) Let us introduce some notation relating to Chinese remaindering.

For $n \in \mathbb{N}$ let M_n be the product of all odd primes p less than 2^{n^2}. By the prime number theorem, $2^{2^n} < M_n < 2^{2^{n^2+1}}$ for n sufficiently large. For such primes p let $h_{p,n}$ denote the inverse of M_n/p mod p.

Any integer $0 \leq X < M_n$ can be represented uniquely as a list (x_p), where p runs over the odd primes $p < 2^{n^2}$ and $x_p = X \bmod p$. Moreover, X is congruent to $\sum_p x_p h_{p,n} M_n/p$ modulo M_n. Hence X/M_n is the fractional part of $\sum_p x_p h_{p,n}/p$.

Define the family of approximation functions $app_n(X)$ to be $\sum_p B_p$, where $B_p = x_p h_{p,n} \sigma_{p,n}$ and $\sigma_{p,n}$ is the result of truncating the binary expansion of $1/p$ after 2^{n^4} bits. Note that for n sufficiently large and $X < M_n$, $app_n(X)$ is within $2^{-2^{n^3}}$ of X/M_n.

Let the input to PosSLP be a program P of size n representing the integer W,

and set $Y_n = 2^{2^n}$. Since $|W| \le Y_n$, the number $X := W + Y_n$ is nonnegative, and we can easily transform P into a program of size $2n+2$ representing X. Clearly, $W > 0$ iff $X > Y_n$. Note that if $X > Y_n$, then X/M_n and Y_n/M_n differ by at least $1/M_n > 2^{-2^{n^2+1}}$, which implies that it is enough to compare the binary expansions of $app_n(X)$ and $app_n(Y_n)$. (Interestingly, this seems to be somewhat easier than computing the bits of X directly.)

We can determine whether $X > Y_n$ in PH relative to the following oracle A: $A = \{(P, j, b, 1^n) :$ the jth bit of the binary expansion of $app_n(X)$ is b, where X is the number represented by straight-line program P and j is given in binary$\}$.

Lemma 4.3 completes the proof by showing that $A \in \mathsf{PH}^{\mathsf{PP}^{\mathsf{PP}}}$. □

LEMMA 4.3. $A \in \mathsf{PH}^{\mathsf{PP}^{\mathsf{PP}}}$.

Proof. Assume for the moment that we can show that $B \in \mathsf{PH}^{\mathsf{PP}}$, where $B := \{(P, j, b, p, 1^n) :$ the jth bit of the binary expansion of B_p $(= x_p h_{p,n} \sigma_{p,n})$ is b, where $p < 2^{n^2}$ is an odd prime, $x_p = X \bmod p$, X is the number represented by the straight-line program P, and j is given in binary$\}$. In order to recognize the set A, it clearly suffices to compute 2^{n^4} bits of the binary representation of the sum of the numbers B_p. A uniform circuit family for the iterated sum is presented by Maciel and Thérien in [50, Corollary 3.4.2] consisting of MAJORITY gates on the bottom (input) level, with three levels of AND and OR gates above. As in the proof of Theorem 4.1, the construction of Maciel and Thérien immediately yields a $\mathsf{PH}^{\mathsf{PP}^B}$ algorithm for A, by simulating the MAJORITY gates by PP^B computation, simulating the OR gates above the MAJORITY gates by $\mathsf{NP}^{\mathsf{PP}^B}$ computation, etc. The claim follows, since by Toda's theorem [63], $\mathsf{PH}^{\mathsf{PP}^B} \subseteq \mathsf{PH}^{\mathsf{PP}^{\mathsf{PH}^{\mathsf{PP}}}} = \mathsf{PH}^{\mathsf{PP}^{\mathsf{PP}}}$. It remains only to show that $B \in \mathsf{PH}^{\mathsf{PP}}$. □

LEMMA 4.4. $B \in \mathsf{PH}^{\mathsf{PP}}$.

Proof. Observe that, given (P, j, b, p), we can determine in polynomial time whether p is prime [4], and we can compute x_p.

In $\mathsf{PH} \subseteq \mathsf{P}^{\mathsf{PP}}$ we can find the least generator g_p of the multiplicative group of the integers mod p. The set $C = \{(q, g_p, i, p) : p \ne q$ are primes and i is the least number for which $g_p^i \equiv q \mod p\}$ is easily seen to lie in PH. We can compute the discrete log base g_p of the number $M_n/p \bmod p$ in $\#\mathsf{P}^C \subseteq \mathsf{P}^{\mathsf{PP}}$ by the algorithm that nondeterministically guesses q and i, verifies that $(q, g_p, i, p) \in C$, and if so generates i accepting paths. Thus we can compute the number $M_n/p \bmod p$ itself in P^{PP} by first computing its discrete log, and then computing g_p to that power, mod p. The inverse $h_{p,n}$ is now easy to compute in P^{PP}, by finding the inverse of $M_n/p \bmod p$.

Our goal is to compute the jth bit of the binary expansion of $x_p h_{p,n} \sigma_{p,n}$. We have already computed x_p and $h_{p,n}$ in P^{PP}, so it is easy to compute $x_p h_{p,n}$. The jth bit of $1/p$ is 1 iff $2^j \bmod p$ is odd, so bits of $\sigma_{p,n}$ are easy to compute in polynomial time. (Note that j is exponentially large.)

Thus our task is to obtain the jth bit of the product of $x_p h_{p,n}$ and $\sigma_{p,n}$, or (equivalently) adding $\sigma_{p,n}$ to itself $x_p h_{p,n}$ times. The problem of adding $\log^{O(1)} n$ many n-bit numbers lies in uniform AC^0 [32]. Simulating these AC^0 circuits leads to the desired $\mathsf{PH}^{\mathsf{PP}}$ algorithm for B. □

5. An observation on derandomizing ACIT. The connections between algebraic complexity and the counting hierarchy in the preceding section were first introduced in an earlier version of this paper [5]. Recently, these connections have led to further developments. Bürgisser shows in [23] that the counting hierarchy provides

a useful tool for showing implications among several hypotheses in algebraic complexity theory that were not previously known to be related. In that same paper, he also improves a theorem of Koiran, relating the arithmetic circuit complexity of the permanent to a frequently studied question about the complexity of expressing $n!$. We have some new observations to present on this topic, and we start by recalling some background and definitions.

We will follow the terminology of Shub and Smale [59], and say that $n!$ is *"easy"* if there is a sequence of SLPs C_n of size $\log^{O(1)} n$, where C_n represents the number $n!$. Following the same convention, we say that $n!$ is *"ultimately easy"* if there is a sequence of SLPs C_n of size $\log^{O(1)} n$, where C_n represents a nonzero multiple of the number $n!$. (It does not matter which multiple is represented.) Shub and Smale conjectured that $n!$ is not ultimately easy, and they showed that this condition implies that $\mathrm{P}_{\mathbb{C}} \neq \mathrm{NP}_{\mathbb{C}}$. It is also pointed out in [12] that if factoring is sufficiently hard to compute, it implies that $n!$ is not easy. There are a number of papers that touch on the questions of whether or not $n!$ is easy or ultimately easy. The reader is referred to [25, 23, 12] for more references. A goal of this section is to relate these questions to the complexity of ACIT.

Note that if $n!$ is not ultimately easy, it says merely that there are *infinitely many* n for which multiples of $n!$ require large circuits. It may be useful also to consider the hypothesis that this condition holds for *all* large n; that is, for all k there is an m such that for all $n > m$ there is no SLP of size $\log^k n$ representing a nonzero multiple of $n!$ Let us call this condition "$n!$ is ultimately hard."

The following implications are known to hold:

$$n! \text{ is ultimately hard} \Rightarrow n! \text{ is not ultimately easy} \Rightarrow n! \text{ is not easy}$$
$$\Rightarrow \text{the permanent requires arithmetic circuits of superpolynomial size} \Rightarrow \text{AFIT} \in \bigcap_{\epsilon>0} \text{io-[DTIME}(2^{n^\epsilon})],$$

where io-[DTIME$(t(n))$] denotes the class of problems A for which there is a deterministic algorithm running in time $t(n)$ that solves A correctly for all instances of length n, for infinitely many n, and where AFIT denotes arithmetic formula identity testing: a special case of ACIT. The third implication is from [23], the fourth is from [42, Theorem 7.7]. Derandomization results such as those of [42] usually come in two flavors. If one assumes that a particular function (such as the permanent) is hard on infinitely many input lengths, then one obtains only algorithms that work correctly on infinitely many input lengths. One can also obtain an algorithm that works correctly on all input lengths if one starts with a stronger assumption, such as that the permanent requires large circuits on all input lengths.

It has not been known whether any of these hypotheses are sufficiently strong to derandomize ACIT itself, although it is known that if ACIT is in $\bigcap_{\epsilon>0}\mathrm{DTIME}(2^{n^\epsilon})$ (or even in $\bigcap_{\epsilon>0}\mathrm{NTIME}(2^{n^\epsilon})$), then either the permanent requires arithmetic circuits of superpolynomial size or $\mathsf{NEXP} \not\subseteq \mathsf{P}/\mathrm{poly}$ [42]. We observe now that the following implication holds.

PROPOSITION 5.1. *We have the following:*

1. *If $n!$ is ultimately hard, then* ACIT $\in \bigcap_{\epsilon>0}\mathrm{DTIME}(2^{n^\epsilon})$.
2. *If $n!$ is not ultimately easy, then* ACIT $\in \bigcap_{\epsilon>0}\text{io-[DTIME}(2^{n^\epsilon})]$.

Proof. We prove only the second claim. The first is easier and follows by the same method.

First note that, by Proposition 2.2, it is sufficient to prove the implication for EquSLP instead of ACIT. Assume that $n!$ is not ultimately easy. Then for every k

there is an infinite set $I(k)$ of numbers such that for all $m \in I(k)$ no SLP of size at most $\log^k m$ can produce a nonzero multiple of $m!$.

Given $\epsilon > 0$, pick any γ such that $0 < \gamma < \epsilon$. Choose k to be the least integer larger than $1/\gamma$. For any $m \in I(k)$ set $n = \lfloor \log^k m \rfloor$.

Suppose we are given as input an SLP C of size n. Note that the binary encoding of m has length at most $n^{1/k}$—but we do not know what m is. Thus we try all numbers z having binary encoding of length at most $n^{1/k}$ (one of which will be m). We then compute the binary representation of $z!$ with the obvious algorithm, which takes time at most $z^2 \log^{O(1)} z$, which is less than 2^{n^γ} for sufficiently large n. Then we evaluate the SLP C modulo $z!$; we accept iff the result is zero for all of the numbers z. This algorithm works correctly, since by our assumption, the SLP C cannot produce a nonzero multiple of $m!$. The running time is $2^{O(n^\gamma)} 2^{O(n^\gamma)}$, which is less than 2^{n^ϵ} for all large n. □

We remark that this proof makes use of no special properties of the factorial function. As one of the referees has pointed out to us, the same upper bound follows if there is any sequence of numbers $(a(n))$ such that the binary representation of $a(n)$ can be computed from n in time polynomial in m, the length of the binary representation of $a(n)$, such that no multiple of $a(n)$ can be represented by an arithmetic circuit of size $\log^{O(1)} m$. If we drop the requirement that $a(n)$ be computable in time polynomial in m, then a simple counting argument (or Kolmogorov complexity argument) shows that *most* numbers $a(n)$ have this property.

6. Closing remarks. NP-hardness is firmly established as a useful tool for providing evidence of intractibility. We believe that PosSLP can become a useful tool for providing evidence of intractibility for problems that do not appear to be NP-hard and for providing evidence that certain problems do not lie in NP or reduce to NP. Indeed, results of this flavor have already started to appear: Etessami and Yannakakis have recently shown that PosSLP reduces to the problem of finding mixed strategy profiles close to exact Nash equilibria in three-person games [35]; i.e., they show that this fundamental but very challenging numerical problem of computational game theory is PosSLP-hard. We may regard this PosSLP-hardness result as evidence that the problem is not NP-easy. In contrast, the related, weaker, and much less elusive notion of computing a strategy profile approximately satisfying the equilibrium conditions is trivially NP-easy. It would be most interesting to establish similar PosSLP-hardness results for other natural numerical problems in the computational sciences (e.g., computational physics) for which no efficient and "fool-proof" methods, even nondeterministic ones, are known but which also do not appear to be NP-hard.

There are several directions for further research suggested by the results that we have presented. We would very much like to see a resolution of our Conjecture 1, and we think that it is likely that PosSLP lies at a lower level of the counting hierarchy than is proved in Theorem 1.3. Perhaps better upper bounds can be presented at least for the sum-of-square-roots problem. Can better evidence be presented for the intractibility of PosSLP? Can some important problems in $\mathrm{NP}_{\mathbb{R}}$ (such as the existential theory of the reals) be shown to lie in the counting hierarchy?

INTERVAL COMPLETION IS FIXED PARAMETER TRACTABLE*

YNGVE VILLANGER†, PINAR HEGGERNES†, CHRISTOPHE PAUL‡, AND JAN ARNE TELLE†

Abstract. We present an algorithm with runtime $O(k^{2k}n^3m)$ for the following NP-complete problem [M. Garey and D. Johnson, *Computers and Intractability: A Guide to the Theory of NP-Completeness*, W. H. Freeman and Co., San Francisco, 1979, problem GT35]: Given an arbitrary graph G on n vertices and m edges, can we obtain an interval graph by adding at most k new edges to G? This resolves the long-standing open question [H. Kaplan, R. Shamir, and R. E. Tarjan, *SIAM J. Comput.*, 28 (1999), pp. 1906–1922; R. G. Downey and M. R. Fellows, *Parameterized Complexity*, Springer-Verlag, New York, 1999; M. Serna and D. Thilikos, *Bull. Eur. Assoc. Theory Comput. Sci. EATCS*, 86 (2005), pp. 41–65; G. Gutin, S. Szeider, and A. Yeo, in *Proceedings IWPEC* 2006, Lecture Notes in Comput. Sci. 4169, Springer-Verlag, Berlin, 2006, pp. 60–71], first posed by Kaplan, Shamir, and Tarjan, of whether this problem was fixed parameter tractable. The problem has applications in profile minimization for sparse matrix computations [J. A. George and J. W. H. Liu, *Computer Solution of Large Sparse Positive Definite Systems*, Prentice-Hall, Englewood Cliffs, NJ, 1981; R. E. Tarjan, in *Sparse Matrix Computations*, J. R. Bunch and D. J. Rose, eds., Academic Press, 1976, pp. 3–22], and our results show tractability for the case of a small number k of zero elements in the envelope. Our algorithm performs bounded search among possible ways of adding edges to a graph to obtain an interval graph and combines this with a greedy algorithm when graphs of a certain structure are reached by the search.

Key words. interval graphs, profile minimization, edge completion, FPT algorithm, branching

1. Introduction and motivation.

Interval graphs are the intersection graphs of intervals of the real line and have a wide range of applications [13]. Connected with interval graphs is the following problem: Given an arbitrary graph G, what is the minimum number of edges that must be added to G in order to obtain an interval graph? This problem is NP-hard [18, 9]. The problem arises in sparse matrix computations, where one of the standard methods for reordering a matrix to get as few nonzero elements as possible during Gaussian elimination is to permute the rows and columns of the matrix so that nonzero elements are gathered close to the main diagonal [10]. The *profile* of a matrix is the smallest number of entries that can be enveloped within off-diagonal nonzero elements of the matrix. Translated to graphs, the profile of a graph G is exactly the minimum number of edges in an interval supergraph of G [26]. Originally, physical mapping of DNA was another motivation for this problem [12].

In this paper, we present an algorithm with runtime $O(k^{2k}n^3m)$ for the *k-interval completion* problem of deciding whether a graph on n vertices and m edges can be made into an interval graph by adding at most k edges. A parameterized problem

with parameter k and input size x that can be solved by an algorithm having runtime $f(k) \cdot x^{O(1)}$ is called *fixed parameter tractable (FPT)* (see [7] for an introduction to fixed parameter tractability and bounded search tree algorithms). The k-interval completion problem is thus FPT, which settles a long-standing open problem [17, 7, 25, 14]. An early paper (first appearance FOCS '94 [16]) in this line of research by Kaplan, Shamir and Tarjan [17] gives FPT algorithms for k-chordal completion, k-strongly chordal completion, and k-proper interval completion. In all these cases a bounded search tree algorithm identifies a subgraph which is a witness of nonmembership in the desired class of graphs, and branches recursively on all possible ways of adding an inclusion-minimal set of edges that gets rid of the witness. For example, since a graph is chordal if and only if it has no induced cycle on more than 3 vertices, the k-chordal completion algorithm [17, 2] takes as witness a subset C of vertices inducing a d-cycle, $4 \leq d \leq k+3$, and branches on all ways of adding the $d-3$ edges needed to make the subgraph induced by C chordal. The existence of an FPT algorithm for solving k-interval completion was left as an open problem by [17], with the following explanation for why a bounded search tree algorithm seemed unlikely: "An arbitrarily large obstruction X could exist in a graph that is not interval but could be made interval with the addition of any one out of $O(|X|)$ edges." Our FPT algorithm for this problem is nevertheless based heavily on applying the bounded search tree technique, supplemented with a greedy algorithm to circumvent the obstructions mentioned in the quote.

Let us mention some related work. Ravi, Agrawal, and Klein [24] gave an $O(\log^2 n)$-approximation algorithm for minimum interval completion, subsequently improved to an $O(\log n \log\log n)$-approximation by Even, Naor, Rao, and Schieber [8] and finally to an $O(\log n)$-approximation by Rao and Richa [23]. Heggernes, Suchan, Todinca, and Villanger showed that an inclusion-minimal interval completion can be found in polynomial time [15]. Kuo and Wang [20] gave an $O(n^{1.722})$ algorithm for minimum interval completion of a tree, subsequently improved to an $O(n)$ algorithm by Díaz, Gibbons, Paterson, and Torán [5]. Cai [2] proved that k-completion into any hereditary graph class having a finite set of forbidden subgraphs is FPT. Some researchers have been misled into thinking that this settled the complexity of k-interval completion; however, interval graphs do not have a finite set of forbidden subgraphs [21]. Gutin, Szeider, and Yeo [14] gave an FPT algorithm for deciding if a graph G has profile at most $k + |V(G)|$, but the more natural parameterization of the profile problem is to ask if G has profile at most $k + |E(G)|$, which is equivalent to the k-interval completion problem on G. Similar questions, asking if we can add/remove at most k vertices/edges to a graph such that a certain property is satisfied, have been investigated in the literature for various graph properties; see, e.g., [3].

Our algorithm for k-interval completion circumvents the problem of large obstructions (witnesses) by first getting rid of all small witnesses, in particular witnesses for the existence of an asteroidal triple (AT) of vertices. Three nonadjacent vertices a, b, c form an AT if there exists a path from any two of them avoiding the neighborhood of the third. Since a graph is an interval graph if and only if it is both chordal and AT-free [21], to complete into an interval graph we must destroy witnesses for nonchordality and witnesses for existence of an AT. Witnesses for nonchordality (chordless cycles of length > 3) must have size $O(k)$ and do not present a problem. Likewise, if an AT is witnessed by an induced subgraph S of size $O(k)$ it does not present a problem, as shown in section 3 of this paper. In section 4, we show that in every induced subgraph S witnessing the existence of an AT, one of the vertices of the AT is *shallow*, meaning that there is a short path from it to each of the other two vertices

of the AT. We give a branching rule for the case when G has no AT witnessed by a small subgraph, but it has at least $k+1$ shallow vertices. The most difficult case is when we have a chordal noninterval graph G with no AT having a small witness and with at most k shallow vertices. For this case we introduce *thick* AT-witnesses in section 5, consisting of an AT and all vertices on any chordless path between any two vertices of the AT avoiding the neighborhood of the third vertex of the AT. We define minimality for thick AT-witnesses and show that also in every minimal thick AT-witness one of the vertices of the AT is shallow. In section 6 we show how to carefully compute the set C of shallow vertices so that removing C from the graph gives an interval graph. Based on the cardinality of C, we show how to further continue branching in a bounded way. When no bounded branching is possible we show that the instance has enough structure that the best solution is a completion computed in a greedy manner. The presented algorithm consists of 4 branching rules in addition to the greedy completion.

2. Preliminaries. We work with simple and undirected graphs $G = (V, E)$, with vertex set $V(G) = V$ and edge set $E(G) = E$, and $n = |V|$, $m = |E|$. For $X \subset V$, $G[X]$ denotes the subgraph of G induced by the vertices in X. We will use $G - x$ to denote $G[V \setminus \{x\}]$ for $x \in V$, and $G - S$ to denote $G[V \setminus S]$ for $S \subseteq V$.

For neighborhoods, we use $N_G(x) = \{y \mid xy \in E\}$ and $N_G[x] = N_G(x) \cup \{x\}$. For $X \subseteq V$, $N_G[X] = \bigcup_{x \in X} N_G[x]$ and $N_G(X) = N_G[X] \setminus X$. We will omit the subscript when the graph is clear from the context. A vertex set X is a *clique* if $G[X]$ is complete, and a *maximal clique* if no superset of X is a clique. A vertex x is *simplicial* if $N(x)$ is a clique.

We will say that a path $P = v_1, v_2, \ldots, v_p$ is *between* v_1 and v_p, and we call it a *v_1, v_p-path.* The *length* of P is p. We will use $P - v_p$ and $P + v_{p+1}$ to denote the paths $v_1, v_2, \ldots, v_{p-1}$ and $v_1, v_2, \ldots, v_p, v_{p+1}$, respectively. We say that a path P *avoids* a vertex set S if P contains no vertex of S. A *chord* of a cycle (path) is an edge connecting two nonconsecutive vertices of the cycle (path). A *chordless* cycle (path) is an induced subgraph that is isomorphic to a cycle (path). A graph is *chordal* if it contains no chordless cycle of length at least 4.

A graph is an *interval graph* if intervals can be associated with its vertices such that two vertices are adjacent if and only if their corresponding intervals overlap. Three nonadjacent vertices form an *asteroidal triple (AT)* if there is a path between every two of them that does not contain a neighbor of the third. A graph is *AT-free* if it contains no AT. A graph is an interval graph if and only if it is chordal and AT-free [21]. A vertex set $S \subseteq V$ is called *dominating* if every vertex not contained in S is adjacent to some vertex in S. A pair of vertices $\{u, v\}$ is called a *dominating pair* if every u, v-path is dominating. Every interval graph has a dominating pair [4] and thus also a dominating chordless path.

A *clique tree* of a graph G is a tree T whose nodes (also called *bags*) are maximal cliques of G such that for every vertex v in G, the subtree T_v of T that is induced by the bags that contain v is connected. A graph is chordal if and only if it has a clique tree [1]. A *clique path* Q of a graph G is a clique tree that is a path. A graph G is an interval graph if and only if has a clique path [11]. An interval graph has at most n maximal cliques.

Given two vertices u and v in G, a vertex set S is a *u, v-separator* if u and v belong to different connected components of $G - S$. A u, v-separator S is *minimal* if no proper subset of S is a u, v-separator. S is a *minimal separator* of G if there exist two vertices u and v in G with S a minimal u, v-separator. For a chordal graph G, a

set of vertices S is a minimal separator of G if and only if S is the intersection of two neighboring bags in any clique tree of G [1].

An interval supergraph $H = (V, E \cup F)$ of a given graph $G = (V, E)$, with $E \cap F = \emptyset$, is called an *interval completion* of G. H is called a *k-interval completion* of G if $|F| \leq k$. The set F is called the set of *fill edges* of H. On input G and k, the *k-interval completion problem* asks whether there is an interval completion of G with at most k fill edges.

3. Nonchordality and small simple AT-witnesses: Rules 1, 2.

Branching Rule 1. If G is not chordal, find a chordless cycle C of length at least 4. If $|C| > k + 3$, answer no; otherwise:

- Branch on the at most $4^{|C|}$ different ways to add an inclusion minimal set of edges (of cardinality $|C| - 3$) between the vertices of C to make C chordal.

It is shown in [17, 2] that there are at most $4^{|C|}$ minimal sets of edges for making C chordal. If Rule 1 applies, we branch by creating at most $4^{|C|}$ recursive calls, each with new parameter value $k - (|C| - 3)$. The correctness of Rule 1 is well understood [17, 2]. Let us remark that each invocation of the recursive search tree subroutine will apply only one of four branching rules. Thus, if Rule 1 applies we apply it and branch, else if Rule 2 applies we apply it and branch, else if Rule 3 applies we apply it and branch, else apply Rule 4. Rules 2, 3, and 4 will branch on single fill edges, dropping the parameter by one. Also Rule 1 could have branched on single fill edges, simply by taking the set of nonedges of the induced cycle and branching on each nonedge separately. We continue with Rule 2.

Observation 3.1. Given a graph G, let $\{a, b, c\}$ be an AT in G. Let P'_{ab} be the set of vertices on a path between a and b in $G - N[c]$, let P'_{ac} be the set of vertices on a path between a and c in $G - N[b]$, and let P'_{bc} be the set of vertices on a path between b and c in $G - N[a]$. Then any interval completion of G contains at least one fill edge from the set $\{cx \mid x \in P'_{ab}\} \cup \{ax \mid x \in P'_{bc}\} \cup \{bx \mid x \in P'_{ac}\}$.

Proof. Otherwise $\{a, b, c\}$ would still be an independent set of vertices with a path between any two avoiding the neighborhood of the third; in other words it would be an AT. □

We introduce simple AT-witnesses and give a branching rule for small such witnesses.

DEFINITION 3.2. *Let $\{a, b, c\}$ be an AT in a graph G. There are three paths P_{ab}, P_{bc}, P_{bc}, where P_{ab} is the set of vertices on a* shortest *path between a and b in $G - N[c]$, P_{ac} is the set of vertices on a* shortest *path between a and c in $G - N[b]$, and P_{bc} is the set of vertices on a* shortest *path between b and c in $G - N[a]$. The induced subgraph $G_{abc} = G[P_{ab} \cup P_{bc} \cup P_{ac}]$ of G is called a* simple AT-witness *of this AT. We call $\{P_{ab}, P_{bc}, P_{bc}\}$ the* core *of G_{abc}.*

Observe that a simple AT-witness for $\{a, b, c\}$ and the mentioned shortest paths of its core exist if and only if $\{a, b, c\}$ is an AT. Furthermore, from the definition of an AT-witness G_{abc} for $\{a, b, c\}$, a, b, and c are vertices of G_{abc}.

Branching Rule 2. If G is chordal: For each triple $\{a, b, c\}$ check if $\{a, b, c\}$ is an AT. For each AT $\{a, b, c\}$, find a simple AT-witness G_{abc} for it with core $\{P_{ab}, P_{bc}, P_{bc}\}$. If there exists an AT $\{a, b, c\}$, such that $|\{cx \mid x \in P_{ab}\} \cup \{ax \mid x \in P_{bc}\} \cup \{bx \mid x \in P_{ac}\}| \leq k + 15$ for the simple AT-witness G_{abc}, then:

- Branch on each of the fill edges in the set $\{cx \mid x \in P_{ab}\} \cup \{ax \mid x \in P_{bc}\} \cup \{bx \mid x \in P_{ac}\}$.

By Observation 3.1, any interval completion contains at least one edge from the set branched on by Rule 2.

LEMMA 3.3. *Let G be a graph to which Rule* 1 *cannot be applied (i.e., G is chordal). There exists a polynomial time algorithm that finds a simple AT-witness G_{abc} with core $\{P_{ab}, P_{bc}, P_{bc}\}$, where $|\{cx \mid x \in P_{ab}\} \cup \{ax \mid x \in P_{bc}\} \cup \{bx \mid x \in P_{ac}\}| \leq k + 15$, if such an AT-witness exists.*

Proof. A simple AT-witness can be found in polynomial time: for a triple of vertices, check if there exists a shortest path between any two of them that avoids the neighborhood of the third vertex. Since shortest paths are used to define simple AT-witnesses and all shortest paths between a pair of vertices have the same length, then $|\{cx \mid x \in P_{ab}\} \cup \{ax \mid x \in P_{bc}\} \cup \{bx \mid x \in P_{ac}\}|$ will be the same for all cores $\{P_{ab}, P_{bc}, P_{bc}\}$ defining simple AT-witnesses for an AT $\{a, b, c\}$. □

4. Minimal simple AT-witnesses and shallow vertices: Rule 3. In this section we consider chordal graphs to which Rule 2 cannot be applied, which means chordal graphs containing no AT of small enough size. We introduce minimal simple AT-witnesses and show that they each have a shallow vertex.

DEFINITION 4.1. *A simple AT-witness G_{abc} for an AT $\{a, b, c\}$ is* minimal *if $G_{abc} - x$ is AT-free for any $x \in \{a, b, c\}$.*

Since the vertices of an AT belong to any AT-witness for that AT, it follows that not every AT has a minimal simple AT-witness. However, clearly, for each AT $\{a', b', c'\}$, we can find an AT $\{a, b, c\}$ that has a minimal simple AT-witness. Hence, as long as there is an AT in a chordal graph, there is also an AT that has a minimal simple AT-witness. Interestingly, by the following result of Lekkerkerker and Boland [21] and since minimal simple AT-witnesses are induced subgraphs, a minimal simple AT-witness of a chordal graph is either of constant size or it is a member of one of the two families of graphs shown in Figure 1.

THEOREM 4.2 (see ([21])). *Let G be a chordal graph with more than* 7 *vertices. Then G contains an AT, and no induced subgraph of G contains an AT, if and only if G belongs to the family of graphs shown in Figure* 1.

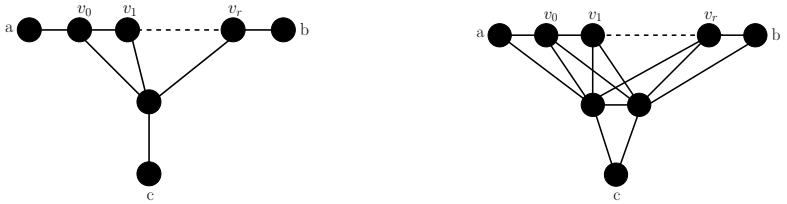

FIG. 1. *These two families of graphs ($r \geq 1$) are the only minimal simple AT-witnesses of nonconstant size that survive Rules* 1 *and* 2.

Since the chordal graphs that we study in this section contain no AT of size less than 15, the minimal simple AT-witnesses that we encounter from now on will always be one of the two types given in Figure 1. (The reader might be interested to know that, by the results of Lekkerkerker and Boland [21], any other possible minimal AT-witness in a chordal graph is of size exactly 7 and is one of two different graphs.)

DEFINITION 4.3. *Let $\{a, b, c\}$ be an AT in a chordal graph G. Vertex c is called* shallow *if shortest a, c-paths and shortest b, c-paths are of length at most* 4.

Observation 4.4. Let G be a graph to which neither Rule 1 (i.e., G is chordal) nor Rule 2 can be applied. Let G_{abc} be a minimal simple AT-witness for an AT $\{a, b, c\}$ in G. Then the following statements are true.

- Each of a, b, c is a simplicial vertex in G_{abc}.

- For any $x \in \{a, b, c\}$, $G_{abc} - x$ is an interval graph, and in this interval graph, $\{a, b, c\} \setminus \{x\}$ is a dominating pair.
- Let $\{P_{ab}, P_{bc}, P_{ac}\}$ be the core of G_{abc}, where $|P_{ab}| \geq |P_{bc}| \geq |P_{ac}|$. If $|P_{ab}| \geq 6$, then c is shallow.

Proof. Since neither Rule 1 nor Rule 2 apply to G and G_{abc} is minimal, then by Theorem 4.2 we know that G_{abc} belongs to one of the families in Figure 1. Each of a, b, c is either the end vertex of the long path or the vertex at the bottom for each of the graphs in Figure 1. Hence the observation follows. The vertex at the bottom is the shallow vertex. ∎

We are ready to give Branching Rule 3.

Branching Rule 3. Let $C(G)$ be the set of vertices of G each of which is shallow in some AT of G. This rule applies if Rules 1 and 2 do not apply and $|C(G)| > k$, in which case we let B be a subset of $C(G)$ with $|B| = k + 1$. For each $c \in B$ find a simple AT-witness G_{abc} with core $\{P_{ab}, P_{bc}, P_{ac}\}$, where c is shallow.

- For each $c \in B$, branch on the at most 8 fill edges $\{ax \mid x \in P_{bc}\} \cup \{bx \mid x \in P_{ac}\}$.
- Branch on the at most $|B|(|B| - 1)/2$ possible fill edges $\{uv \mid u, v \in B$ and $uv \notin E\}$.

Observe that Rule 3 only needs a subset of C of size $k+1$, and thus an algorithm can stop the computation of C when this size is reached.

LEMMA 4.5. *If Rule* 3 *applies to G, then any k-interval completion of G contains a fill edge which is branched on by Rule* 3.

Proof. In a k-interval completion we cannot add more than k fill edges. Thus, since $|B| = k+1$ any k-interval completion H of G either contains a fill edge between two vertices in B (and all these are branched on by Rule 3), or there exists a vertex $c \in B$ with no fill edge incident to it (since the opposite would require $k+1$ fill edges). If $c \in B$ does not have a fill edge incident to it, then by Observation 3.1 one of the edges in $\{ax \mid x \in P_{bc}\} \cup \{bx \mid x \in P_{ac}\}$ must be a fill edge (and all these are branched on for each $c \in B$ by Rule 3). ∎

LEMMA 4.6. *Let G be a graph to which Rule* 1 *and Rule* 2 *cannot be applied. There exists a polynomial time algorithm that finds the unique maximal set $C(G)$ of shallow vertices in G, and applies Rule* 3 *if $|C(G)| \geq k + 1$.*

Proof. A minimal simple AT-witness can be found in polynomial time: for a triple of vertices, check if there exists a shortest path between any two of them that avoids the neighborhood of the third vertex. If these three paths exist and induce a minimal simple AT-witness for the triple, add the shallow vertex to the set $C(G)$. Notice that every vertex that is shallow in some minimal simple AT-witness will be added to the set $C(G)$. Rule 3 is used on the set $C(G)$, when vertex number $k + 1$ is added. ∎

5. Thick AT-witnesses. In this section we introduce thick AT-witnesses and show that minimal thick AT-witnesses have a shallow vertex. These shallow vertices will be important for the fourth and final rule given in the next section.

We now consider graphs G to which none of the Rules 1, 2, or 3 can be applied. This means that G is chordal (Rule 1), the set $C(G)$ of shallow vertices in G has cardinality at most k (Rule 3), implying that (the connected components of) $G[C(G)]$ is an interval graph (Rule 2).

DEFINITION 5.1. *Let $\{a, b, c\}$ be an AT in a chordal graph G, and let $W = \{w \mid w$ be a vertex of a chordless a, b-path, a, c-path, or b, c-path in $G\}$. The graph $G_{Tabc} = G[W]$ is the (unique)* thick AT-witness *for the AT $\{a, b, c\}$.*

We denote the neighborhoods of a, b, and c in G_{Tabc} respectively by S_a, S_b, and

S_c, since these are minimal separators in G_{Tabc} and also in G by the following two observations.

Observation 5.2. Let G_{Tabc} be a thick AT-witness in a chordal graph G. For any $x \in \{a, b, c\}$, x is a simplicial vertex and $S_x = N_{G_{Tabc}}(x)$ is a minimal separator in G_{Tabc}.

Proof. We prove the observation for $x = a$; the other possibilities are symmetric. Because of the existence of a shortest b, c-path avoiding S_a, it follows that b and c are contained in the same connected component of $G_{Tabc} \setminus S_a$. Every neighbor of a in G_{Tabc} appears in a chordless path from a to either b or c or both. By the fact that b and c appear in the same connected component of $G_{Tabc} \setminus S_a$ and that neighbor of a in G_{Tabc} appears in a chordless path from a to either b or c, we can conclude that S_a is both a minimal a, b-separator and a minimal a, c-separator. In a chordal graph, every minimal separator is a clique [6]. Hence a is simplicial in G_{Tabc}. □

Observation 5.3. Let G_{Tabc} be a thick AT-witness in a chordal graph G. Then the set of minimal separators of G_{Tabc} are exactly the set of minimal a, b-separators, a, c-separators, and b, c-separators of G.

Proof. Let S be a minimal a, b-separator in G. Note that $S \subseteq G_{Tabc}$. There exist two connected components C_a and C_b of $G - S$, containing, respectively, a and b, such that $N_G(C_a) = N_G(C_b) = S$. For any vertex $z \in S$ we can now find a chordless shortest path in G from z to each of a and b, where every intermediate vertex is contained in, respectively, C_a and C_b. By joining these two paths, we get a chordless path from a to b that contains z. Since this holds for any vertex in S, it follows by the way we defined G_{Tabc} that any minimal a, b-separator of G is a minimal a, b-separator of G_{Tabc}. The argument can be repeated with a, c and b, c to show that every minimal a, c-separator or b, c-separator of G is also a minimal separator of G_{Tabc}.

Every minimal separator of G_{Tabc} separates two simplicial vertices appearing in two different leaf bags of any clique tree of G_{Tabc}. Since a, b, c are the only simplicial vertices in G_{Tabc} (every other vertex being an internal vertex of a chordless path), every minimal separator of G_{Tabc} is a minimal a, b-separator, b, c-separator, or a, c-separator. Let S be a minimal a, b-separator in G_{Tabc}. Vertex set S is a subset of a minimal a, b-separator of G, since the same chordless paths exist in G. But S cannot be a proper subset of a minimal a, b-separator of G, since every minimal a, b-separator of G is a minimal a, b-separator in G_{Tabc}, and thus S would not be a minimal separator in G_{Tabc} otherwise. The argument can be repeated with a, c and b, c. □

Definition 5.4. *A thick AT-witness G_{Tabc} is* minimal *if $G_{Tabc} - x$ is AT-free for every $x \in \{a, b, c\}$.*

Observation 5.5. Let G_{Tabc} be a minimal thick AT-witness in a chordal graph G. Then $G_{Tabc} - c$ is an interval graph, and in this interval graph $\{a, b\}$ is a dominating pair.

Proof. The graph $G' = G_{Tabc} - c$ is by definition an interval graph, since G_{Tabc} is a minimal thick AT-witness. For a contradiction assume that $\{a, b\}$ is not a dominating pair, and thus there exists a path P'_{ab} from a to b in $G' - N[y]$ for some vertex $y \in V(G') \setminus \{a, b\}$. Let Q be a clique path of G'. Vertex y does not appear in any bag of Q that contains a or b, and it does not appear in any bags between the subpaths Q_a and Q_b of Q. Let us without loss of generality assume that Q_a appears between Q_y and Q_b in Q. We show that y is then not in any chordless path between any pair of a, b, c, giving the contradiction. Due to the above assumptions, y is not contained in the component C_b of $G' - N[a]$ that contains b. Furthermore, a is a simplicial vertex by Observation 5.2, and P'_{ab} contains vertices from $N_{G'}(a)$; thus $y \notin N_{G'}(a)$ since P'_{ab}

would not avoid the neighborhood of y otherwise. The path $P_{bc} - c$ is contained in C_b since it contains no vertex of $N[a]$, and thus y is not adjacent to any vertex in $P_{bc} - c$. We know that $cy \notin E(G_{Tabc})$, since by Observation 5.2, $N_{G_{Tabc}}(c)$ is a clique, and thus y would be adjacent to the neighbor of c in P_{bc} if cy were an edge in $E(G_{Tabc})$. Now we have a contradiction since y is not in any chordless path between any pair of a, b, c. □

LEMMA 5.6. *Let G be a graph to which neither Rule* 1 *nor Rule* 2 *can be applied, and let G_{Tabc} be a minimal thick AT-witness in G where c is shallow. Then for every vertex $u \in S_c$ we have $S_a \cup S_b \subseteq N[u]$.*

Proof. Let $E' = E(G_{Tabc})$, and let us on the contrary and without loss of generality assume that $c'a' \notin E'$ for $c' \in S_c$ and $a' \in S_a$. Let $P_{ab} = (a = v_1, v_2, \ldots, v_r = b), P_{bc}$, and P_{ac} be the shortest paths used to define a simple AT-witness for $\{a, b, c\}$. We will show that either $\{a', b, c\}$ or $\{a, v_{r-1}, c\}$ is an AT in a subgraph of G_{Tabc}, contradicting its minimality.

Vertex set $\{a', b, c\}$ is an independent set since $cb \notin E'$, $a'b \notin E'$ due to $|P_{ab}| > 15 - 8$ (Rule 2), and $a'c \notin E'$ because c is simplicial in G_{Tabc}, and thus $c'a' \in E'$ if $a'c \in E'$. Either $v_2 = a'$, or $a'v_2 \in E'$ since a is simplicial in G_{Tabc}. $P_{ab} - a + a'$ is a path from a' to b that avoids the neighborhood of c. In the same way $P_{ac} - a + a'$ is a path from a' to c, and since we have already seen that $a'b \notin E'$ this path avoids the neighborhood of b. By Observation 5.5, c' is adjacent to some vertex on the path $P_{ab} = (a = v_1, v_2, \ldots, v_r = b)$. If c' is adjacent to some vertex v_i where $i > 3$, then there is a path $c, c', v_i, \ldots, v_r = b$ that avoids the neighborhood of a', and we have a contradiction since a', b, c would be an AT in $G_{Tabc} - a$. We can therefore assume that there is a $j \in \{2, 3\}$ such that $v_j c' \in E'$, and that there exists no $v_i c' \in E'$ for any $i > 3$. The set $\{a, v_{r-1}, c\}$ is an independent set, since $cv_{r-1}, av_{r-1} \notin E'$. The path $a, v_2, \ldots, v_{r-1}$ avoids the neighborhood of c, the path $c, c', v_j, \ldots, a$ avoids the neighborhood of v_{r-1}, and $P_{bc} - b + v_{r-1}$ is a path from c to v_{r-1} that avoids the neighborhood of a, since b is simplicial in G_{Tabc}. This is a contradiction since $G_{Tabc} - b$ contains the AT $\{a, v_{r-1}, c\}$. □

LEMMA 5.7. *Let $G = (V, E)$ be a graph to which neither Rule* 1 *nor Rule* 2 *can be applied. Let G_{Tabc} be a minimal thick AT-witness in G where c is shallow. Let C_c be the connected component of $G - S_c$ that contains c. Then every vertex of C_c has in G the same set of neighbors S_c outside C_c; in other words $\forall u \in C_c : N_G(u) \setminus C_c = S_c$.*

Proof. By definition $N_G(u) \setminus C_c \subseteq S_c$. Let us assume for a contradiction that $ux \notin E$ for some $x \in S_c$ and $u \in C_c$. Since C_c is a connected component there exists a path from u to c inside C_c. Let u', c' be two consecutive vertices on this path, such that $S_c \subseteq N_G(c')$ and $u'x' \notin E$ for some $x' \in S_c$. By Lemma 5.6 x' creates a short path from a to b that avoids the neighborhood of u', and by using $P_{ac} - c$ and $P_{bc} - c$ and the vertices c' and u' we can create short paths from a to u' and from b to u' that avoid the neighborhoods of b and a, respectively. This is now a contradiction, since $\{a, b, u'\}$ is an AT with a simple AT-witness where the number of branching fill edges are 5 for the path a, a', x', b', b, 5 for $P_{ac} - c$ and c', u', and 5 for $P_{bc} - c$ and c', u', giving a total of 15 branching edges. □

The following simple observations are needed for the proof of Lemma 5.10.

Observation 5.8. A vertex v is simplicial only if v is an end vertex of every chordless path that contains v.

Proof. Any vertex that appears as a nonend vertex in a chordless path has two neighbors that are not adjacent. □

Observation 5.9. Let G_{Tabc} be a minimal thick AT-witness in a graph G to which

neither Rule 1 nor Rule 2 can be applied. Then at least one of the vertices in the AT $\{a, b, c\}$ is shallow, and there exists a minimal simple AT-witness G_{abc} for $\{a, b, c\}$, where $V(G_{abc}) \subseteq V(G_{Tabc})$.

Proof. Let P_{ab}, P_{ac}, P_{bc} be shortest chordless paths contained in G_{Tabc}, and let G_{abc} be defined by P_{ab}, P_{ac}, P_{bc}. It is clear that G_{Tabc} is minimal only if G_{abc} is minimal. By Observation 4.4, Rule 2, and the fact that G_{abc} is a minimal AT-witness for $\{a, b, c\}$, we know that at least one of the vertices in $\{a, b, c\}$ is shallow. ∎

LEMMA 5.10. *Let G be a graph to which neither Rule 1 nor Rule 2 can be applied, and let G_{Tabc} be a thick AT-witness in G. Then there exists a minimal thick AT-witness G_{Txyz} in G, where $V(G_{Txyz}) \subseteq V(G_{Tabc})$ and z is shallow, such that $z \in \{a, b, c\}$.*

Proof. G_{Txyz} will be obtained from G_{Tabc} by deleting one of the simplicial vertices in the AT that defines G_{Tabc}, and repeat this until a minimal thick AT-witness G_{Txyz} is obtained. Note that only neighbors of the deleted vertex can become simplicial after each deletion, by Observation 5.8. As a result, the deleted vertices induce at most three connected components. Actually the number of components will be exactly three, since otherwise the connected components contain a chordless path between two of the vertices in $\{x, y, z\}$ which is a contradiction to the definition of a minimal thick AT-witness. Thus, each connected component is adjacent to one of the vertices x, y, z. By Observation 5.9 one of the vertices x, y, z is shallow. Let us without loss of generality assume that z is the shallow vertex in G_{Txyz}. By Lemma 5.3, minimal separators of G_{Txyz} are also minimal separators of G_{Tabc}, so let us assume without loss of generality that z and c are contained in the same connected component of $G_{Tabc} - N_{G_{Txyz}}(z)$. Notice that z and c might be the same vertex. By Lemma 5.7, c is shallow in the minimal thick AT-witness G_{Txyc}. ∎

Like Rules 2 and 3, Rule 4 will branch on single fill edges, but it will also consider minimal separators, based on the following two basic observations.

Observation 5.11. If G has a minimal thick AT-witness G_{Tabc} in which P_{ac} and P_{bc} are shortest a, c and b, c-paths avoiding $N(b)$ and $N(a)$, respectively, then any interval completion of G either contains a fill edge from the set $\{bx \mid x \in P_{ac}\} \cup \{ax \mid x \in P_{bc}\}$ or contains one of the edge sets $\{\{cx \mid x \in S\} \mid S$ is a minimal a, b-separator in $G_{Tabc}\}$.

Proof. By Observation 3.1, we know that at least one of the edges in $\{ax \mid x \in P_{bc}\} \cup \{bx \mid x \in P_{ac}\} \cup \{cx \mid x \in P_{ab}\}$ for the paths P_{ab}, P_{ac}, P_{bc} defined in the proof of Observation 5.9, is a fill edge of any interval completion of G. If an interval completion H does not contain any fill edge from the set $\{bx \mid x \in P_{ac}\} \cup \{ax \mid x \in P_{bc}\}$, then H contains at least one fill edge from the set $\{cx \mid x \in P'_{ab}\}$, where P'_{ab} is any chordless a, b-path in G that avoids the neighborhood of c. Thus, $N_H(c)$ contains a minimal a, b-separator in G (which by Observation 5.3 is also a minimal a, b-separator in G_{Tabc}) since every chordless and thus every a, b-path in $G - N[c]$ contains a vertex of $N_H(c)$. ∎

Observation 5.12. Let G be a graph to which neither Rule 1 nor Rule 2 can be applied, and let G_{Tabc} be a minimal thick AT-witness in G where c is shallow. Then $S_c \subset S$ for every minimal a, b-separator S different from S_a and S_b.

Proof. Let S be a minimal a, b-separator different from S_a and S_b. No minimal a, b-separator contains another minimal a, b-separator as a subset; thus there exists a vertex $a' \in S_a \setminus S$ and a vertex $b' \in S_b \setminus S$. S is then also a minimal a', b'-separator because of the edges aa' and bb'. It then follows from Lemma 5.6 that $S_c \subset N(a') \cap N(b')$, and thus $S_c \subset S$. ∎

6. Partitioning the shallow vertices: Rule 4. In this section we present the fourth and final rule and prove correctness of the resulting search tree algorithm. We start by detailing the computation of the set $C(G)$ of shallow vertices which will give us a partition of $C(G)$ that we will use in our Branching Rule 4.

DEFINITION 6.1. *Given a graph G to which Rules 1 and 2 do not apply, we compute a set $C(G) = C_1 \cup C_2 \cup \cdots \cup C_r$ of vertices that are shallow in some minimal thick AT-witness, with $G \setminus C(G) = R_r$ an interval graph, as follows:*
$R_0 := G$; $i := 0$; $C(G) := \emptyset$;
while *R_i is not an interval graph* **do**
  $i := i + 1$;
  Find $G_{Ta_ib_ic_i}$ a minimal thick AT-witness in R_{i-1} with c_i shallow;
  Let C_i be the connected component of $R_{i-1} - N_{G_{Ta_ib_ic_i}}(c_i)$ that contains c_i;
  for *each $c \in C_i$* **do** $G_{Ta_ib_ic} := G_{Ta_ib_ic_i} - c_i + c$;
  $R_i := R_{i-1} - C_i$;
  $C(G) := C(G) \cup C_i$;
end-while
$r := i$

The minimal thick AT-witness $G_{Ta_ib_ic_i}$ is found by first finding an AT $\{a, b, c\}$, then removing simplicial vertices different from a, b, c according to Observation 5.8 to get a thick AT-witness, and then applying the procedure in the proof of Lemma 5.10.

A priori we have no guarantee that there are no edges between a vertex in C_i and a vertex in C_j, for some $i \neq j$, but when $|C(G)| \leq k$ (which is ensured by Rule 3) this indeed holds, as shown in the following lemma.

LEMMA 6.2. *Let $G = (V, E)$ be a graph to which none of Rules $1, 2, 3$ can be applied, and let $C(G) = C_1 \cup C_2 \cup \cdots \cup C_r$ from Definition 6.1. Then C_i induces an interval graph that is a connected component of $G[C(G)]$, for each $1 \leq i \leq r$.*

Proof. First, $|C_i| \leq k$ since Rule 3 does not apply, and since Rules 1, 2 do not apply, it must induce an interval graph. To argue that it is a connected component, note first that by definition $G[C_i]$ is connected and $C_i \cap C_j = \emptyset$ for any $i \neq j$. For a contradiction we assume that $cz \in E$ for some $c \in C_i$ and $z \in C_j$ with $i < j$. Notice that $cz \in E$ implies that $z \in S_c$. Let G_{Tabc} be the minimal thick AT-witness in R_{i-1} with c the shallow vertex and $S_c = N_{G_{Tabc}}(c)$, and likewise let G_{Txyz} be the minimal thick AT-witness in R_{j-1} with z shallow and $S_z = N_{G_{Txyz}}(z)$. Let P_{ab} be a path from a to b in $G_{Tabc} \setminus N(c)$. There are now two cases.

Case I: There is a vertex $w \in P_{ab} \cap S_z$. Note that S_c and S_z are minimal separators in the chordal graphs R_{i-1} and R_{j-1}, respectively, and thus by Observation 5.3 S_c and S_z are cliques [6]. Thus, since $cw \notin E$ we must have $c \notin S_z$. But then we have c and z in the same component D_z of $G \setminus S_z$. By Lemma 5.7 c and z must therefore have the same neighbors outside D_z. But this contradicts the fact that $zw \in E$ while $cw \notin E$.

Case II: $P_{ab} \cap S_z = \emptyset$. Let D_z be the connected component of $G \setminus S_z$ that contains z. By Observation 5.5 $G_{Tabc} \setminus \{c\}$ is an interval graph where a, b is a dominating pair; thus $zw \in E$ for some $w \in P_{ab}$ since $z \in S_c$ and therefore $V(P_{ab}) \subseteq D_z$.

Since c is shallow we know that $|P_{ac}| + |P_{bc}| \leq 8$, and since Rule 2 cannot be applied we know that $|P_{ab}| + |P_{ac}| + |P_{bc}| \geq k + 16$. Thus we have at least $k + 16 - 8$ vertices in P_{ab} and thus $|D_z| \geq |P_{ab}| > k$. Assuming we can show the subset-property $D_z \subseteq C_1 \cup C_2 \cup \cdots \cup C_j$ we are done with the proof since this will lead to the contradiction $k < |D_z| \leq |C_1 \cup C_2 \cup \cdots \cup C_j| \leq |C(G)| \leq k$. Let us prove the subset-property. G has a perfect elimination ordering starting with the vertices of C_1, as

these vertices are a component resulting from removing a minimal separator from G. By induction, we have that G has a perfect elimination ordering α starting with the vertices in $C_1 \cup C_2 \cup \cdots \cup C_{j-1}$. For a contradiction assume there exists a vertex $t \in D_z \setminus (C_1 \cup C_2 \cup \cdots \cup C_j)$. As $t \in D_z$ there is a shortest chordless t,z-path P_{tz} in D_z. The edge $tz \notin E$ since this would make t a member of C_j (as $t \notin C_j$). Only vertices in $C_1 \cup C_2 \cup \cdots \cup C_{j-1}$ are removed from the graph, and these separate z from t in $G[D_z]$ (since $t \notin C_j$). Let s be the lowest numbered vertex in the ordering α that belongs to the path P_{tz}. This is now a contradiction, since a nonend vertex of a chordless path cannot be simplicial if two adjacent vertices eliminated later in the perfect elimination ordering are nonadjacent. ∎

Rule 4 will branch on a bounded number of single fill edges and it will also compute a greedy completion by choosing for each shallow vertex a minimal separator minimizing fill and making the shallow vertex adjacent to all vertices of that separator. We will prove that if none of the single fill edges branched on in Rule 4 are present in any k-interval completion, then the greedy completion gives an interval completion with the minimum number of edges. The greedy choices of separators are made as follows:

DEFINITION 6.3. *Let G be a graph to which none of Rules $1,2,3$ can be applied. Let Definition* 6.1 *give $C(G) = C_1 \cup C_2 \cup \cdots \cup C_r$, representative vertices $c_1, c_2, \ldots, c_r$ and minimal thick AT-witnesses $G_{Ta_ib_ic_i}$ and graphs $G = R_0 \supset R_1 \supset \cdots \supset R_r$, with R_r interval. Let M_i for $i = 1,2,\ldots,r$ be a minimal a_i,b_i-separator S in $G_{Ta_ib_ic_i}$ different from S_{a_i} and S_{b_i} and $N(C_j)$ for all $1 \le j \le r$, satisfying $S \cap C(G) = \emptyset$ and minimizing $|S \setminus N(C_i)|$. If no such S exists, define $M_i = null$.*

LEMMA 6.4. *If $M_i \neq null$, then M_i is a minimal separator in R_r.*

Proof. The vertex set M_i is a minimal separator in $G_{Ta_ib_ic_i}$ by construction, and since $G_{Ta_ib_ic_i}$ is a subgraph of the chordal graph R_i it is by Observation 5.3 also a minimal separator of R_i. We prove that M_i is also a minimal separator in R_j for any $i+1 \le j \le r$ by induction on j. Recall that R_j is obtained by removing C_j from R_{j-1}, where C_j is a component of $R_{j-1} \setminus S_{c_i}$ for a minimal separator S_{c_i} of R_{j-1}, and $S_{c_i} = N(C_j)$ by Lemma 5.7. Consider a clique tree of R_{j-1} and observe that any minimal separator of R_{j-1} that is not a minimal separator of R_j either is equal to $N(C_j)$ or contains a vertex of C_j. Finally, note that the minimal separator M_i has been chosen so that it is not of this type. ∎

Branching Rule 4. Rule 4 applies if none of Rules 1, 2, 3 apply, in which case we compute, as in Definitions 6.1 and 6.3, $C_1, C_2, \ldots, C_r$ (which are connected components of $G[C(G)]$ by Lemma 6.2), the minimal thick AT-witnesses $G_{Ta_ib_ic}$ with c shallow for each $c \in C_i$, and $M_1, \ldots, M_r$ (which are minimal separators of R_r by Lemma 6.4). For each $1 \le i \le r$ and each $c \in C_i$ choose $a'_i \in S_{a_i} \setminus S_c$ and $b'_i \in S_{b_i} \setminus S_c$ and find P_{a_ic} and P_{b_ic} (shortest paths in $G_{Ta_ib_ic}$ avoiding $N(b_i)$ and $N(a_i)$, respectively, of length at most 4 by Observation 5.9). For each pair $1 \le i \ne j \le r$, choose a vertex $v_{i,j} \in N(C_j) \setminus N(C_i)$ (if it exists).

- For $1 \le i \le r$ and $c \in C_i$, branch on the at most 8 fill edges $\{a_ix \mid x \in P_{b_ic}\} \cup \{b_ix \mid x \in P_{a_ic}\}$ and also on the 2 fill edges $\{ca'_i, cb'_i\}$.
- Branch on the at most $|C(G)|(|C(G)|-1)/2$ fill edges $\{uv \mid u,v \in C(G)$ and $uv \notin E\}$.
- Branch on the at most $|C(G)|r$ fill edges $\bigcup_{1 \le i \ne j \le r}\{cv_{i,j} \mid c \in C_i\}$.
- Finally, compute $H = (V,\ E \cup \bigcup_{1 \le i \le r}\{cx \mid c \in C_i$ and $x \in M_i\})$ and check if it is a k-interval completion of G (note that we do not branch on H).

LEMMA 6.5. *If G has a k-interval completion, and Rules $1,2,$ and 3 do not apply*

to G, and no k-interval completion of G contains any single fill edge branched on by Rule 4*, then the graph H, which Rule* 4 *obtains by adding fill edges from every vertex in C_i to every vertex in M_i for every $1 \leq i \leq r$, is a k-interval completion of G.*

Proof. By Observation 5.11, for each $c \in C_i$ either one of the edges in $\{a_i x \mid x \in P_{b_i c}\} \cup \{b_i x \mid x \in P_{a_i c}\}$ is a fill edge (and all these are branched on by Rule 4) or else the k-interval completion contains the edge set $\{cx \mid x \in S\}$ for some minimal a_i, b_i-separator S in $G_{Ta_i b_i c}$. Such an edge set in a k-interval completion is one of four types (listed below) depending on the separator S used to define it. For each type and any $c \in C_i$ we argue that Rule 4 considers it. Observe that $N(C_i) \setminus C_i = N(c) \setminus C_i$ by Lemma 5.7, and thus the fill edges from c will go to vertices in $S \setminus N(C_i)$, which is nonempty since there is an a_i, b_i-path avoiding $N(c)$. We now give the four types of minimal separators S and show that the first three are branched on by a single fill edge:

1. $S \cap C(G) \neq \emptyset$. Since $N(C_i) \cap C(G) = \emptyset$ by Lemma 6.2, we have in this case a fill edge between two vertices in $C(G)$ (between $c \in C_i$ and a vertex in $C(G) \cap S \setminus N(C_i)$), and all these are branched on by Rule 4.
2. $S = S_{a_i}$ or $S = S_{b_i}$, where S_{a_i}, S_{b_i}, S_c defined by $G_{Ta_i b_i c}$. We found in Rule 4 a pair of vertices $a'_i \in S_{a_i} \setminus S_c$ and $b'_i \in S_{b_i} \setminus S_c$ and branched on the fill edges ca'_i and cb'_i.
3. $S = N(C_j)$ for some $1 \leq j \leq r$. If $S = N(C_j)$, then $N(C_j) \setminus N(C_i) \neq \emptyset$ and we found in Rule 4 a vertex $v_{i,j} \in N(C_j) \setminus N(C_i)$ and branched on the fill edge $cv_{i,j}$.
4. S is none of the three types above. Note that M_i was chosen in Definition 6.3 by looping over all minimal a_i, b_i-separators S in $G_{Ta_i b_i c_i}$ (which by Lemma 5.7 are exactly the minimal a_i, b_i-separators of $G_{Ta_i b_i c}$) satisfying $S \cap C(G) = \emptyset$, $S \neq S_a$, $S \neq S_b$, and $S \neq N(C_j)$ for any j. Thus, of all separators of this fourth type, M_i is the one minimizing the fill.

The assumption is that G has a k-interval completion but no single edge branched on by Rule 4 is present in any k-interval completion. This means that only separators of the fourth type are used in any k-interval completion. Since H added the minimum possible number of fill edges while using only separators of the fourth type, any interval completion of G must add at least $|E(H) \setminus E(G)|$ edges. It remains to show that H is an interval graph. H is constructed from an interval graph R_r and the components $G[C_1], \ldots, G[C_r]$ of $G[C(G)]$, which are interval graphs by Lemma 6.2, and $M_1, \ldots, M_r$ which are minimal separators of R_r by Lemma 6.4. Since $M_i \neq S_{a_i}$ and $M_i \neq S_{b_i}$ we have by Observation 5.12 that $S_c = N(C_i) \subset M_i$ so that adding all edges between C_i and M_i for $1 \leq i \leq r$ gives the graph H. We show that H is an interval graph by induction on $0 \leq i \leq r$. Let $H_0 = R_r$ and let H_i for $i \geq 1$ be the graph we get from H_{i-1} and C_i by making all vertices of C_i adjacent to all vertices of the minimal separator M_i of R_r. H_0 is an interval graph by induction, and its minimal separators include all minimal separators of R_r. If $(K_1, K_2, \ldots, K_q)$ is a clique path of H_{i-1} with $M_i = K_j \cap K_{j+1}$, and $(K'_1, K'_2, \ldots, K'_p)$ is a clique path of $G[C_i]$, then $(K_1, K_2, \ldots, K_j, K'_1 \cup M_i, K'_2 \cup M_i, \ldots, K'_p \cup M_i, K_{j+1}, \ldots, K_q)$ is a clique path of H_i, and hence H_i is an interval graph. Finally, observe that the minimal separators of H_{i-1} and hence of R_r are also minimal separators of H_i. ∎

THEOREM 6.6. *The search tree algorithm applying Rules* $1, 2, 3,$ *and* 4 *in that order decides in $O(k^{2k} n^3 m)$ time whether an input graph G on n vertices and m edges can be completed into an interval graph by adding at most k edges.*

Proof. At least one of the rules will apply to any graph which is not interval.

The correctness of Rule 1 is well understood [17, 2]; that of Rules 2 and 3 follows by Observations 3.1 and 5.11 and of Rule 4 by Lemma 6.5. Each branching of Rules 2, 3, and 4 adds a single fill edge and drops k by one. As already mentioned, Rule 1 could also have added a single fill edge in each of its then at most k^2 branchings. The height of the tree is thus no more than k, before k reaches 0 and we can answer "no." If an interval graph is found we answer "yes."

Let us argue for the runtime. The graph we are working on never has more than $m + k$ edges. In Rule 1 we decide in linear time if the graph has a large induced cycle. In Rule 2 we may have to try all triples when searching for an AT with a small simple AT-witness, taking $O(n^3(m + k))$ time. In Rule 3 and 4 we need to find a minimal thick AT-witness at most $k + 1$ times. As observed earlier, the minimal thick AT-witness is found by first finding an AT $\{a, b, c\}$, which can be done in time $O(m + k)$ since G is a chordal graph [19], then remove simplicial vertices different from a, b, c to find the thick AT-witness, and then make it minimal. Using a clique tree we find in this way a single minimal thick AT-witness in time $O(n^3)$ and at most k of them in time $O(n^3k)$. Hence each rule takes time at most $O(n^3(m + k))$ and has branching factor at most k^2 (e.g., in Rule 1 and also in Rule 3 when branching on all fill edges between pairs of shallow vertices). The height of the search tree is at most k and the number of nodes therefore at most k^{2k}. We can assume $k \leq n \leq m$ since otherwise a brute-force algorithm easily solves minimum interval completion in n^{2n} steps. Thus each rule takes time $O(n^3m)$ for total runtime $O(k^{2k}n^3m)$. □

7. Concluding remarks. We have shown that k-interval completion is FPT. The runtime of our algorithm can probably be improved somewhat, at the expense of much more complicated data structures. In an earlier version of this paper, in the STOC 2007 proceedings, we asked if there was a hereditary graph class recognizable in polynomial time for which the k-completion problem into this graph class was not FPT. This question has been answered [22], since for the complements of wheel-free graphs the k-completion problem is $W[2]$-complete. It is still an open problem whether the complexity of k-completions into perfect graphs is FPT.

An alternative equivalent definition of the complexity class FPT relates to kernelization. In this formulation a parameterized problem is FPT if there exists a polynomial-time algorithm that for any instance outputs an equivalent "kernelized" instance whose size is a function of the parameter only. The quest for the smallest possible kernel size is orthogonal to the quest for the fastest possible FPT algorithm. The FPT algorithm given here for k-interval completion implies that this problem has an exponential-sized kernel. We leave as an open problem whether k-interval completion has a polynomial-sized kernel.

OPTIMIZING SCHEMA LANGUAGES FOR XML: NUMERICAL CONSTRAINTS AND INTERLEAVING*

WOUTER GELADE†, WIM MARTENS‡, AND FRANK NEVEN§

Abstract. The presence of a schema offers many advantages in processing, translating, querying, and storage of XML data. Basic decision problems such as equivalence, inclusion, and nonemptiness of intersection of schemas form the basic building blocks for schema optimization and integration, and algorithms for static analysis of transformations. It is thereby paramount to establish the exact complexity of these problems. Most common schema languages for XML can be adequately modeled by some kind of grammar with regular expressions at right-hand sides. In this paper, we observe that, apart from the usual regular operators of union, concatenation, and Kleene-star, schema languages also allow numerical occurrence constraints and interleaving operators. Although the expressiveness of these operators remains within the regular languages, the presence or absence of these operators has a significant impact on the complexity of the basic decision problems. We present a complete overview of the complexity of the basic decision problems for DTDs, XSDs, and Relax NG with regular expressions incorporating numerical occurrence constraints and interleaving. We also discuss chain regular expressions and the complexity of the schema simplification problem incorporating the new operators.

Key words. XML schema languages, complexity, optimization, regular expressions

1. Introduction. XML is the lingua franca for data exchange on the Internet [1]. Within applications or communities, XML data is usually not arbitrary but adheres to some structure imposed by a schema. The presence of such a schema not only provides users with a global view on the anatomy of the data, but, far more importantly, it enables automation and optimization of standard tasks such as (i) searching, integration, and processing of XML data (cf., e.g., [12, 23, 26, 44]), and (ii) static analysis of transformations (cf., e.g., [2, 17, 29, 34]). Decision problems such as equivalence, inclusion, and nonemptiness of intersection of schemas, hereafter referred to as *the basic decision problems*, constitute essential building blocks in solutions for the just mentioned optimization and static analysis problems. Additionally, the basic decision problems are fundamental for schema minimization (cf., e.g., [10, 30]). Because of their widespread applicability, it is therefore important to establish the exact complexity of the basic decision problems for the various XML schema languages.

The most common schema languages for XML are DTD, XML Schema [39], and Relax NG [9], and these can be modeled by grammar formalisms [33]. In particular, DTDs correspond to context-free grammars with regular expressions (REs) at right-hand sides, while Relax NG is abstracted by extended DTDs (EDTDs) [35]

or, equivalently, unranked tree automata [5], defining the regular unranked tree languages. While XML Schema is usually abstracted by unranked tree automata as well, recent results indicate that XSDs correspond to a strict subclass of the regular tree languages and are much closer to DTDs than to tree automata [27]. In fact, they can be abstracted by single-type EDTDs. As detailed in [28], the relationship between schema formalisms and grammars provides direct upper and lower bounds for the complexity of the basic decision problems.

A closer inspection of the various schema specifications reveals that the above abstractions in terms of grammars with regular expressions is too coarse. Indeed, in addition to the conventional regular expression operators such as concatenation, union, and Kleene-star, the XML Schema and the Relax NG specifications allow two other operators as well:

(1) Both the XML Schema and the Relax NG specifications allow a certain form of unordered concatenation: the `ALL` and the `interleave` operator, respectively. This operator is actually the resurrection of the &-operator from SGML DTDs that was excluded from the definition of XML DTDs. Although there are restrictions on the use of `ALL` and `interleave`, we consider the operator in its unrestricted form. We refer by RE(&) to such regular expressions with the interleaving operator.
(2) The XML Schema specification allows us to express numerical occurrence constraints which define the minimal and maximal number of times a regular construct can be repeated. We refer by RE(#) to such regular expressions with numerical occurrence constraints.

We illustrate these additional operators in Figure 1.1. Their formal definition is given in section 2. Although the new operators can be expressed by the conventional regular operators, they cannot do so succinctly [14], which has severe implications for the complexity of the basic decision problems.

The goal of this paper is to study the complexity of the basic decision problems for DTDs, XSDs, and Relax NG with regular expressions extended with interleaving and numerical occurrence constraints. The latter class of regular expressions is denoted by RE(#, &). As observed in section 5, the complexity of inclusion and equivalence of RE(#, &) expressions (and subclasses thereof) carries over to DTDs and single-type EDTDs. We therefore first establish the complexity of the basic decision problems for RE(#, &) expressions and frequently occurring subclasses. These results are summarized in Table 1.1 and Table 4.1. Of independent interest, we introduce NFA(#, &)s, an extension of NFAs with counter and split/merge states for dealing with numerical occurrence constraints and interleaving operators. Finally, we revisit the simplification problem introduced in [27] for schemas with RE(#, &) expressions. This problem is defined as follows: given an extended DTD, can it be rewritten into an equivalent DTD or a single-type EDTD?

In this paper, we do not consider deterministic or one-unambiguous regular expressions which form a strict subclass of the regular expressions [6]. The reason is twofold. First, one-unambiguity is a highly debatable constraint (cf., e.g., [42, p. 98] and [25, 40]) which is required only for DTDs and XML Schema, not for Relax NG. Actually, the only direct advantage of one-unambiguity is that it gives rise to PTIME algorithms for some of the basic decision problems for standard regular expressions. The latter does not hold anymore for RE(#, &) expressions rendering the notion even less attractive. Indeed, already intersection for one-unambiguous regular expressions is PSPACE-hard [28], and inclusion for one-unambiguous RE(#) expressions is coNP-hard [22]. A second reason is that, in contrast to conventional regular expressions, one-unambiguity is not yet fully understood for regular expressions with numerical occurrence constraints and interleaving operators. Some initial results are provided by Brüggemann-Klein [7] and Kilpeläinen and Tuhkanen [21] who give algorithms for deciding one-unambiguity of RE(&) and RE(#) expressions, respectively. However, the results of Brüggemann-Klein are on the SGML interleaving operator, which is not the same as the Relax NG interleaving operator considered here. Furthermore, no study investigating the properties of these one-unambiguous languages has been undertaken. Such a study, although definitely relevant, is outside the scope of this paper.

Outline. In section 2, we provide the necessary definitions. In section 3, we define NFA(#, &). In sections 4 and 5, we establish the complexity of the basic decision problems for regular expressions and schema languages, respectively. We discuss simplification in section 6. We conclude in section 7.

2. Definitions.

2.1. Regular expressions with counting and interleaving. For the rest of the paper, Σ always denotes a finite alphabet. A Σ-*symbol* (or simply symbol) is an element of Σ, and a Σ-*string* (or simply string) is a finite sequence $w = a_1 \cdots a_n$ of Σ-symbols. We define the length of w, denoted by $|w|$, to be n. We denote the

empty string by ε. The set of *positions of* w is $\{1, \ldots, n\}$, and the *symbol of* w *at position* i is a_i. By $w_1 \cdot w_2$ we denote the *concatenation* of two strings w_1 and w_2. For readability, we usually denote the concatenation of w_1 and w_2 by $w_1 w_2$. The set of all strings is denoted by Σ^*. A *string language* is a subset of Σ^*. For two string languages $L, L' \subseteq \Sigma^*$, we define their concatenation $L \cdot L'$ to be the set $\{ww' \mid w \in L, w' \in L'\}$. We abbreviate $L \cdot L \cdots L$ (i times) by L^i. By $w_1 \,\&\, w_2$ we denote the set of strings that is obtained by *interleaving* or *shuffling* w_1 and w_2 in every possible way. That is, for $w, w_1, w_2 \in \Sigma^*$ and $a, b \in \Sigma$, $w \,\&\, \varepsilon = \varepsilon \,\&\, w = \{w\}$, and $a \cdot w_1 \,\&\, b \cdot w_2 = (\{a\} \cdot (w_1 \,\&\, b \cdot w_2)) \cup (\{b\} \cdot (a \cdot w_1 \,\&\, w_2))$. Here, $\cdot$ has precedence over &. The operator & is then extended to languages in the canonical way.

The set of *regular expressions* over Σ, denoted by RE, is defined in the usual way, ε, and every Σ-symbol is a regular expression; when r and s are regular expressions, then rs, $r + s$, and r^* are also regular expressions. By RE(#, &) we denote RE extended with two new operators: *interleaving* and *numerical occurrence constraints*. That is, when r and s are RE(#, &) expressions, so are $r \,\&\, s$ and $r^{[k,\ell]}$ for $k, \ell \in \mathbb{N}$ with $k \leq \ell$ and $\ell > 0$. By RE(#) and RE(&), we denote RE extended only with counting and interleaving, respectively. Notice that we disallow $\emptyset$ as it does not occur in practical schema languages.

The language defined by a regular expression r, denoted by $L(r)$, is inductively defined as follows: $L(\varepsilon) = \{\varepsilon\}$; $L(a) = \{a\}$; $L(rs) = L(r) \cdot L(s)$; $L(r+s) = L(r) \cup L(s)$; $L(r^*) = \{\varepsilon\} \cup \bigcup_{i=1}^{\infty} L(r)^i$; $L(r^{[k,\ell]}) = \bigcup_{i=k}^{\ell} L(r)^i$; and $L(r \,\&\, s) = L(r) \,\&\, L(s)$. The *size* of a regular expression r over Σ, denoted by $|r|$, is the number of Σ-symbols and operators occurring in r plus the sizes of the binary representations of the integers. By $r?$ and r^+, we abbreviate the expression $r + \varepsilon$ and rr^*, respectively. We assume familiarity with finite automata such as nondeterministic finite automata (NFAs) and deterministic finite automata (DFAs) [16].

2.2. Schema languages for XML. The set of *unranked* Σ*-trees*, denoted by $\mathcal{T}_\Sigma$, is the smallest set of strings over Σ and the parenthesis symbols "(" and ")" such that, for $a \in \Sigma$ and $w \in (\mathcal{T}_\Sigma)^*$, $a(w)$ is in $\mathcal{T}_\Sigma$. So, a tree is either ε (empty) or is of the form $a(t_1 \cdots t_n)$, where each t_i is a tree. In the tree $a(t_1 \cdots t_n)$, the subtrees $t_1, \ldots, t_n$ are attached to the root labeled a. We write a rather than $a()$. Notice that there is no a priori bound on the number of children of a node in a Σ-tree; such trees are therefore *unranked*. For every $t \in \mathcal{T}_\Sigma$, the *set of nodes* of t, denoted by $\mathrm{Dom}(t)$, is the set defined as follows: (i) if $t = \varepsilon$, then $\mathrm{Dom}(t) = \emptyset$; and (ii) if $t = a(t_1 \cdots t_n)$, where each $t_i \in \mathcal{T}_\Sigma$, then $\mathrm{Dom}(t) = \{\varepsilon\} \cup \bigcup_{i=1}^{n} \{iu \mid u \in \mathrm{Dom}(t_i)\}$. In what follows, whenever we say tree, we always mean Σ-tree. A *tree language* is a set of trees.

We make use of the following definitions to abstract from the commonly used schema languages.

DEFINITION 2.1. *Let $\mathcal{R}$ be a class of regular expressions over Σ.*

1. *A* DTD($\mathcal{R}$) *over Σ is a tuple (Σ, d, s_d), where d is a function that maps Σ-symbols to elements of $\mathcal{R}$ and $s_d \in \Sigma$ is the start symbol. For convenience of notation, we denote (Σ, d, s_d) by d and leave the start symbol s_d implicit whenever this cannot give rise to confusion.*
   A tree t satisfies *d if* (i) *$lab^t(\varepsilon) = s_d$ and,* (ii) *for every $u \in Dom(t)$ with n children, $lab^t(u1) \cdots lab^t(un) \in L(d(lab^t(u)))$. By $L(d)$ we denote the set of trees satisfying d.*
2. *An* extended DTD (EDTD($\mathcal{R}$)) *over Σ is a 5-tuple $D = (\Sigma, \Sigma', d, s, \mu)$, where Σ' is an alphabet of* types*, (Σ', d, s) is a DTD($\mathcal{R}$) over Σ', and μ is a mapping from Σ' to Σ.*

A tree t then satisfies *an extended DTD if $t = \mu(t')$ for some $t' \in L(d)$. Here we abuse notation and let μ also denote its extension to define a homomorphism on trees. Again, we denote by $L(D)$ the set of trees satisfying D. For ease of exposition, we always take $\Sigma' = \{a^i \mid 1 \leq i \leq k_a, a \in \Sigma, i \in \mathbb{N}\}$ for some natural numbers k_a, and we set $\mu(a^i) = a$.*

3. *A* single-type EDTD (EDTD$^{\text{st}}(\mathcal{R})$) *over Σ is an EDTD($\mathcal{R}$) $D = (\Sigma, \Sigma', d, s, \mu)$ with the property that, for every $a \in \Sigma'$, in the regular expression $d(a)$ no two types b^i and b^j with $i \neq j$ occur.*

We denote by EDTD, EDTD(#), EDTD(&), and EDTD(#, &) the classes EDTD(RE), EDTD(RE(#)), EDTD(RE(&)), and EDTD(RE(#, &)), respectively. The same notation is used for EDTD$^{\text{st}}$s and DTDs.

For clarity, we sometimes write $a \to r$ rather than $d(a) = r$ in examples and proofs. Following this notation, a simple example of an EDTD is the following:

shop^1	$\to$	$(\text{cd}^1 + \text{cd}^2)^*\text{cd}^2(\text{cd}^1 + \text{cd}^2)^*$	title^1	$\to$	ε
cd^1	$\to$	$\text{title}^1\ \text{price}^1$	price^1	$\to$	ε
cd^2	$\to$	$\text{title}^1\ \text{price}^1\ \text{discount}^1$	discount^1	$\to$	ε

Here, cd^1 defines ordinary CDs, while cd^2 defines CDs on sale. The rule for shop^1 specifies that there should be at least one CD on sale. Notice that the above EDTD is not a single-type EDTD as cd^1 and cd^2 occur in the same rule.

As explained in [33, 27], EDTDs and single-type EDTDs correspond to Relax NG and XML Schema, respectively.

2.3. Decision problems. The following problems are fundamental to this paper.

DEFINITION 2.2. *Let $\mathcal{M}$ be a class of regular expressions, string automata, or extended DTDs. We define the following problems:*

- INCLUSION *for $\mathcal{M}$: Given two elements $e, e' \in \mathcal{M}$, is $L(e) \subseteq L(e')$?*
- EQUIVALENCE *for $\mathcal{M}$: Given two elements $e, e' \in \mathcal{M}$, is $L(e) = L(e')$?*
- INTERSECTION *for $\mathcal{M}$: Given an arbitrary number of elements $e_1, \ldots, e_n \in \mathcal{M}$, is $\bigcap_{i=1}^n L(e_i) \neq \emptyset$?*
- MEMBERSHIP *for $\mathcal{M}$: Given an element $e \in \mathcal{M}$ and a string or a tree f, is $f \in L(e)$?*

We recall the known results concerning the complexity of REs and EDTDs.

THEOREM 2.3.

(1) INCLUSION, EQUIVALENCE, *and* INTERSECTION *for REs are* PSPACE*-complete* [24, 41].
(2) INCLUSION *and* EQUIVALENCE *for RE(&) and RE(#) are* EXPSPACE*-complete* [31, 32].
(3) INCLUSION *and* EQUIVALENCE *for EDTDst are* PSPACE*-complete* [28]; INTERSECTION *for EDTDst is* EXPTIME*-complete* [28].
(4) INCLUSION, EQUIVALENCE, *and* INTERSECTION *for EDTDs are* EXPTIME*-complete* [37, 38].
(5) MEMBERSHIP *for RE(&) is* NP*-complete* [31].
(6) MEMBERSHIP *for RE(#) is in* PTIME [19].

2.4. Relating decision problems for regular expressions to DTDs and single-type EDTDs. In [28] it was shown for any subclass of the REs that the complexity of INCLUSION and EQUIVALENCE is the same as the complexity of the corresponding problem for DTDs and single-type EDTDs. The same holds for INTERSECTION and DTDs. The proofs of these theorems carry over literally to RE(#, &).

We call a complexity class $\mathcal{C}$ *closed under positive reductions* if the following holds for every $O \in \mathcal{C}$. Let L' be accepted by a deterministic polynomial-time Turing machine M with oracle O (denoted $L' = L(M^O)$). Let M further have the property that $L(M^A) \subseteq L(M^B)$ whenever $L(A) \subseteq L(B)$. Then L' is also in $\mathcal{C}$. For a more precise definition of this notion we refer the reader to [15]. For our purposes, it is sufficient that important complexity classes like PTIME, NP, coNP, PSPACE, and EXPSPACE have this property, and that every such class contains PTIME.

PROPOSITION 2.4 (see [28]). *Let $\mathcal{R}$ be a subclass of $RE(\#, \&)$ and let $\mathcal{C}$ be a complexity class closed under positive reductions. Then the following are equivalent:*

(a) INCLUSION *for $\mathcal{R}$ expressions is in $\mathcal{C}$.*
(b) INCLUSION *for $DTD(\mathcal{R})$ is in $\mathcal{C}$.*
(c) INCLUSION *for $EDTD^{st}(\mathcal{R})$ is in $\mathcal{C}$.*

The corresponding statement holds for EQUIVALENCE.

The previous proposition can be generalized to INTERSECTION of DTDs as well.

PROPOSITION 2.5 (see [28]). *Let $\mathcal{R}$ be a subclass of $RE(\#, \&)$ and let $\mathcal{C}$ be a complexity class which is closed under positive reductions. Then the following are equivalent:*

(a) INTERSECTION *for $\mathcal{R}$ expressions is in $\mathcal{C}$.*
(b) INTERSECTION *for $DTD(\mathcal{R})$ is in $\mathcal{C}$.*

The above proposition does not hold for single-type EDTDs. Indeed, there is a class of regular expressions $\mathcal{R}'$ for which INTERSECTION is NP-complete while INTERSECTION for $\text{EDTD}^{\text{st}}(\mathcal{R}')$ is EXPTIME-complete [28].

3. Automata for occurrence constraints and interleaving. We introduce the automaton model NFA$(\#, \&)$. In brief, an NFA$(\#, \&)$ is an NFA with two additional features: (i) split and merge transitions to handle interleaving; and (ii) counting states and transitions to deal with numerical occurrence constraints. The idea of split and merge transitions stems from Jędrzejowicz and Szepietowski [18]. Their automata are more general as they can express shuffle-closure which is not regular. Counting states are also used in the counter automata of Kilpeläinen and Tuhkanen [20] and Reuter [36] although these counter automata operate quite differently from NFA$(\#)$s. Dal-Zilio and Lugiez [11] also proposed an automaton model that incorporates counting and interleaving by means of Presburger formulas. None of the cited papers considers the complexity of the basic decision problems of their model. We will use NFA$(\#, \&)$s to obtain complexity upper bounds in sections 4 and 5.

For readability, we denote $\Sigma \cup \{\varepsilon\}$ by Σ_ε. We then define an NFA$(\#, \&)$ as follows.

DEFINITION 3.1. *An NFA$(\#, \&)$ is a 5-tuple $A = (Q, \Sigma, s, f, \delta)$, where the following hold:*

- *Q is a finite set of states. To every $q \in Q$, we associate a lower bound $\min(q) \in \mathbb{N}$ and an upper bound $\max(q) \in \mathbb{N}$.*
- *$s, f \in Q$ are the start and final states, respectively.*
- *δ is the transition relation and is a subset of the union of the following sets:*

(1)	$Q \times \Sigma_\varepsilon \times Q$	*ordinary transition (resets the counter)*
(2)	$Q \times \{store\} \times Q$	*transition that does not reset the counter*
(3)	$Q \times \{split\} \times Q \times Q$	*split transition*
(4)	$Q \times Q \times \{merge\} \times Q$	*merge transition*

Let $\max(A) = \max\{\max(q) \mid q \in Q\}$ be the largest upper bound occurring in A. A *configuration* γ is a pair (P, α), where $P \subseteq Q$ is a set of states and $\alpha : Q \to \{0, \ldots, \max(A)\}$ is the value function mapping states to the value of their counter. For a state $q \in Q$, we denote by α_q the value function mapping q to 1 and every

other state to 0. The initial configuration γ_s is $(\{s\}, \alpha_s)$. The final configuration γ_f is $(\{f\}, \alpha_f)$. When α is a value function, $\alpha[q = 0]$ and $\alpha[q^{++}]$ denote the functions obtained from α by setting the value of q to 0 and incrementing the value of q by 1, respectively, while leaving all other values unchanged.

We now define the transition relation between configurations. Intuitively, the value of the state at which the automaton arrives is always incremented by one. When exiting a state, the state's counter is always reset to zero, except when we exit through a *counting transition*, in which case the counter remains the same. In addition, exiting a state through a noncounting transition is allowed only when the value of the counter lies between the allowed minimum and maximum. The latter, hence, ensures that the occurrence constraints are satisfied. *Split* and *merge transitions* start and close a parallel composition.

A configuration $\gamma' = (P', \alpha')$ *immediately follows* a configuration $\gamma = (P, \alpha)$ by reading $\sigma \in \Sigma_\varepsilon$, denoted $\gamma \to_{A,\sigma} \gamma'$, when one of the following conditions hold:

1. *Ordinary transition.* There are a $q \in P$ and $(q, \sigma, q') \in \delta$ such that $\min(q) \leq \alpha(q) \leq \max(q)$, $P' = (P - \{q\}) \cup \{q'\}$, and $\alpha' = \alpha[q = 0][q'^{++}]$. That is, A is in state q and moves to state q' by reading σ (note that σ can be ε). The latter is allowed only when the counter value of q is between the lower and upper bounds. The state q is replaced in P by q'. The counter of q is reset to zero, and the counter of q' is incremented by one.
2. *Counting transition.* There are a $q \in P$ and $(q, \text{store}, q') \in \delta$ such that $\alpha(q) < \max(q)$, $P' = (P - \{q\}) \cup \{q'\}$, and $\alpha' = \alpha[q'^{++}]$. That is, A is in state q and moves to state q' by reading ε when the counter of q has not reached its maximal value yet. The state q is replaced in P by q'. The counter of q is not reset but remains the same. The counter of q' is incremented by one.
3. *Split transition.* There are a $q \in P$ and $(q, \text{split}, q_1, q_2) \in \delta$ such that $\min(q) \leq \alpha(q) \leq \max(q)$, $P' = (P - \{q\}) \cup \{q_1, q_2\}$, and $\alpha' = \alpha[q = 0][q_1{}^{++}][q_2{}^{++}]$. That is, A is in state q and splits into states q_1 and q_2 by reading ε when the counter value of q is between the lower and upper bounds. The state q in P is replaced by (split into) q_1 and q_2. The counter of q is reset to zero, and the counters of q_1 and q_2 are incremented by one.
4. *Merge transition.* There are $q_1, q_2 \in P$ and $(q_1, q_2, \text{merge}, q) \in \delta$ such that, for each $j = 1, 2$, $\min(q_j) \leq \alpha(q_j) \leq \max(q_j)$, $P' = (P - \{q_1, q_2\}) \cup \{q\}$, and $\alpha' = \alpha[q_1 = 0][q_2 = 0][q^{++}]$. That is, A is in states q_1 and q_2 and moves to state q by reading ε when the respective counter values of q_1 and q_2 are between the lower and upper bounds. The states q_1 and q_2 in P are replaced by (merged into) q, the counters of q_1 and q_2 are reset to zero, and the counter of q is incremented by one.

For a string w and two configurations γ, γ', we denote by $\gamma \Rightarrow_{A,w} \gamma'$ when there is a sequence of configurations $\gamma \to_{A,\sigma_1} \cdots \to_{A,\sigma_n} \gamma'$ such that $w = \sigma_1 \cdots \sigma_n$. The latter sequence is called a *run* when γ is the initial configuration γ_s. A string w is *accepted* by A if and only if $\gamma_s \Rightarrow_{A,w} \gamma_f$ with γ_f the final configuration. We usually denote $\Rightarrow_{A,w}$ simply by $\Rightarrow_w$ when A is clear from the context. We denote by $L(A)$ the set of strings accepted by A. The size of A, denoted by $|A|$, is $|Q| + |\delta| + \Sigma_{q \in Q} \log(\max(q))$. Thus, each $\max(q)$ is represented in binary.

An example of an NFA(#, &) defining $dvd^{[10,12]}$ & $cd^{[10,12]}$ is shown in Figure 3.1.

An NFA(#) is an NFA(#, &) without split and merge transitions. An NFA(&) is an NFA(#, &) without counting transitions. An NFA is an NFA(#) without counting transitions.

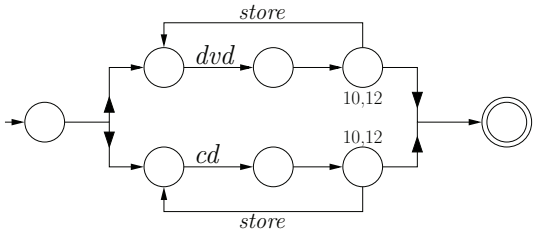

FIG. 3.1. *An NFA(#, &) for the language* $dvd^{[10,12]} \& cd^{[10,12]}$. *For readability, we only displayed the alphabet symbol on nonepsilon transitions and counters for states* q, *where* $\min(q)$ *and* $\max(q)$ *are different from one. The arrows from the initial state and to the final state are split and merge transitions, respectively. The arrows labeled* store *represent counting transitions.*

Clearly NFA(#, &)s accept all regular languages. The next theorem shows the complexity of translating between RE(#, &) and NFA(#, &), and NFA(#, &) and NFA.

THEOREM 3.2.

(1) *Given an RE(#, &) expression* r, *an equivalent NFA(#, &) can be constructed in time linear in the size of* r.
(2) *Given an NFA(#, &)* A, *an equivalent NFA can be constructed in time exponential in the size of* A.

Proof. (1) We prove the theorem by induction on the structure of RE(#, &)-expressions. For every r we define a corresponding NFA(#, &), $A(r) = (Q_r, \Sigma, s_r, f_r, \delta_r)$, such that $L(r) = L(A(r))$.

For r of the form ε, a, $r_1 \cdot r_2$, $r_1 + r_2$, and r_1^* these are the usual RE to NFA with ε-transition constructions as displayed in textbooks such as [16].

We perform the following steps for the numerical occurrence and interleaving operator which are graphically illustrated in Figure 3.2. The construction for the interleaving operator comes from [18].

(i) If $r = (r_1)^{[k,\ell]}$ and $A(r_1) = (Q_1, \Sigma, s_1, f_1, \delta_1)$, then
- $Q_r := Q_{r_1} \uplus \{s_r, f_r, q_r\}$;
- $\min(s_r) = \max(s_r) = \min(f_r) = \max(f_r) = 1$, $\min(q_r) = k$, and $\max(q_r) = \ell$;
- if $k \neq 0$, then $\delta_r := \delta_{r_1} \uplus \{(s_r, \varepsilon, s_{r_1}), (f_{r_1}, \varepsilon, q_r), (q_r, \text{store}, s_{r_1}), (q_r, \varepsilon, f_r)\}$; and,
- if $k = 0$, then $\delta_r := \delta_{r_1} \uplus \{(s_r, \varepsilon, s_{r_1}), (f_{r_1}, \varepsilon, q_r), (q_r, \text{store}, s_{r_1}), (q_r, \varepsilon, f_r), (s_r, \varepsilon, f_r)\}$.

(ii) If $r = r_1 \,\&\, r_2$, $A(r_1) = (Q_{r_1}, \Sigma, s_{r_1}, f_{r_1}, \delta_{r_1})$ and $A(r_2) = (Q_{r_2}, \Sigma, s_{r_2}, f_{r_2}, \delta_{r_2})$, then
- $Q_r := Q_{r_1} \uplus Q_{r_2} \uplus \{s_r, f_r\}$;
- $\min(s_r) = \max(s_r) = \min(f_r) = \max(f_r) = 1$;
- $\delta_r := \delta_{r_1} \uplus \delta_{r_2} \uplus \{(s_r, \text{split}, s_{r_1}, s_{r_2}), (f_{r_1}, f_{r_2}, \text{merge}, f_r)\}$.

Notice that in each step of the construction, a constant number of states are added to the automaton. Moreover, the constructed counters are linear in the size of r. It follows that the size of $A(r)$ is linear in the size of r. The correctness of the construction can easily be proved by induction on the structure of r. □

We next turn to the complexity of the basic decision problems for NFA(#, &).

THEOREM 3.3.

(1) EQUIVALENCE *and* INCLUSION *for NFA(#, &) are* EXPSPACE*-complete;*

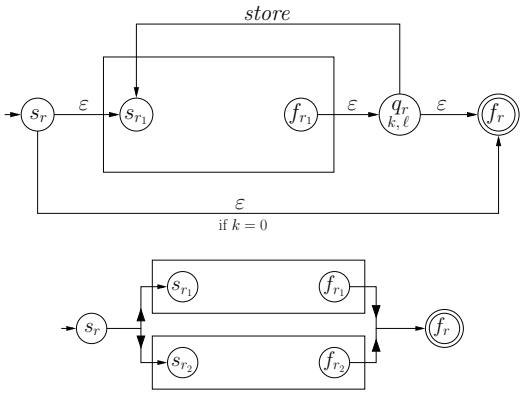

FIG. 3.2. *From RE(#, &) to NFA(#, &).*

(2) INTERSECTION *for NFA(#, &) is* PSPACE*-complete; and*

(3) MEMBERSHIP *for NFA(#) is* NP*-hard, and* MEMBERSHIP *for NFA(&) and NFA(#,&) are* PSPACE*-complete.*

Proof. (1) EXPSPACE-hardness follows from Theorem 3.2(1) and the EXPSPACE-hardness of EQUIVALENCE for RE(&) [31]. Membership in EXPSPACE follows from Theorem 3.2(2) and the fact that INCLUSION for NFAs is in PSPACE [41].

(2) The lower bound follows from [24]. We show that the problem is in PSPACE. For $j \in \{1, \ldots, n\}$, let $A_j = (Q_j, \Sigma, s_j, f_j, \delta_j)$ be an NFA(#, &). The algorithm proceeds by guessing a Σ-string w such that $w \in \bigcap_{j=1}^{n} L(A_j)$. Instead of guessing w at once, we guess it symbol by symbol and keep for each A_j one current configuration γ_j on the tape. More precisely, at each time instant, the tape contains for each A_j a configuration $\gamma_j = (P_j, \alpha_j)$ such that $\gamma_{s_j} \Rightarrow_{A_j, w_i} (P_j, \alpha_j)$, where $w_i = a_1 \cdots a_i$ is the prefix of w guessed up to now. The algorithm accepts when each γ_j is a final configuration. Formally, the algorithm operates as follows.

1. Set $\gamma_j = (\{s_j\}, \alpha_{s_j})$ for $j \in \{1, \ldots, n\}$;
2. While not every γ_j is a final configuration
   (i) Guess an $a \in \Sigma$.
   (ii) Nondeterministically replace each γ_j by a (P'_j, α'_j) such that $(P_j, \alpha_j) \Rightarrow_{A_j, a} (P'_j, \alpha'_j)$.

As the algorithm only uses space polynomial in the size of the NFA(#, &) and step 2(ii) can be done in PSPACE, the overall algorithm operates in PSPACE.

(3) The MEMBERSHIP problem for NFA(#, &)s is easily seen to be in PSPACE by an on-the-fly implementation of the construction in Theorem 3.2(2). Indeed, as a configuration of an NFA(#, &) $A = (Q, \Sigma, s, f, \delta)$ has size at most $|Q| + |Q| \cdot \log(\max(A))$, we can store a configuration using only polynomial space.

We show that the MEMBERSHIP problem for NFA(#)s is NP-hard by a reduction from a modification of INTEGER KNAPSACK. We define this problem as follows. Given a set of natural numbers $W = \{w_1, \ldots, w_k\}$ and two integers m and n, all in binary notation, the problem asks whether there exists a mapping $\tau : W \to \mathbb{N}$ such that $m \leq \sum_{w \in W} \tau(w) \times w \leq n$. The latter mapping is called a solution. This problem is known to be NP-complete [13].

We construct an NFA(#) $A = (Q, \Sigma, s, f, \delta)$ such that $L(A) = \{\varepsilon\}$ if W, m, n has a solution, and $L(A) = \emptyset$ otherwise.

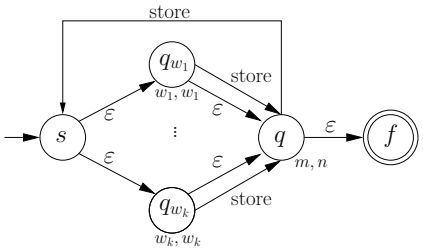

FIG. 3.3. NP-*hardness of* MEMBERSHIP *for NFA(#).*

The state set Q consists of the start and final states s and f, a state q_{w_i} for each weight w_i, and a state q. Intuitively, a successful computation of A loops at least m and at most n times through state q. In each iteration, A also visits one of the states q_{w_i}. Using numerical occurrence constraints, we can ensure that a computation accepts if and only if it passes at least m and at most n times through q and a multiple of w_i times through each q_{w_i}. Hence, an accepting computation exists if and only if there is a mapping τ such that $m \leq \sum_{w \in W} \tau(w) \times w \leq n$.

Formally, the transitions of A are the following:

- $(s, \varepsilon, q_{w_i})$ for each $i \in \{1, \ldots, k\}$;
- $(q_{w_i}, \text{store}, q)$ for each $i \in \{1, \ldots, k\}$;
- $(q_{w_i}, \varepsilon, q)$ for each $i \in \{1, \ldots, k\}$;
- (q, store, s); and,
- (q, ε, f).

We set $\min(s) = \max(s) = \min(f) = \max(f) = 1$, $\min(q) = m$, $\max(q) = n$, and $\min(q_{w_i}) = \max(q_{w_i}) = w_i$ for each q_{w_i}. The automaton is graphically illustrated in Figure 3.3.

Finally, we show that MEMBERSHIP for NFA(&)s is PSPACE-hard. Before giving the proof, we describe some n-ary merge and split transitions which can be rewritten in function of the regular binary split and merge transitions.

1. $(q_1, q_2, \text{merge-split}, q_1', q_2')$: States q_1 and q_2 are read and immediately split into states q_1' and q_2'.
2. $(q_1, q_2, q_3, \text{merge-split}, q_1', q_2', q_3')$: States q_1, q_2 and q_3 are read and immediately split into states q_1', q_2' and q_3'.
3. $(q_1, \text{split}, q_1', \ldots, q_n')$: State q_1 is read and is immediately split into states $q_1', \ldots, q_n'$.
4. $(q_1, \ldots, q_n, \text{merge}, q_1')$: States $q_1, \ldots, q_n$ are read and are merged into state q_1'.

Transitions of type 1 (resp., 2) can be rewritten using 2 (resp., 4) *regular* transitions and 1 (resp., 3) new auxiliary states. Transitions of types 3 and 4 can be rewritten using $(n-1)$ regular transitions and $(n-1)$ new auxiliary states. For example, the transition $(q_1, q_2, \text{merge-split}, q_1', q_2')$ is equal to the transitions $(q_1, q_2, \text{merge}, q_h)$ and $(q_h, \text{split}, q_1', q_2')$, where q_h is a new auxiliary state.

To show that MEMBERSHIP for NFA(&)s is PSPACE-hard, we reduce from CORRIDOR TILING. A *tiling instance* is a tuple $T = (X, H, V, \overline{b}, \overline{t}, n)$, where X is a finite set of tiles, $H, V \subseteq X \times X$ are the horizontal and vertical constraints, n is an integer in unary notation, and $\overline{b}, \overline{t}$ are n-tuples of tiles ($\overline{b}$ and $\overline{t}$ stand for *bottom row* and *top row*, respectively).

A *correct corridor tiling for* T is a mapping $\lambda : \{1, \ldots, m\} \times \{1, \ldots, n\} \to X$ for some $m \in \mathbb{N}$ such that the following constraints are satisfied:

- the bottom row is $\overline{b}$: $\overline{b} = (\lambda(1,1), \ldots, \lambda(1,n))$;
- the top row is $\overline{t}$: $\overline{t} = (\lambda(m,1), \ldots, \lambda(m,n))$;
- all vertical constraints are satisfied: $\forall i < m$, $\forall j \leq n$, $(\lambda(i,j), \lambda(i+1,j)) \in V$; and,
- all horizontal constraints are satisfied: $\forall i \leq m$, $\forall j < n$, $(\lambda(i,j), \lambda(i,j+1)) \in H$.

The CORRIDOR TILING problem asks, given a tiling instance, whether there exists a correct corridor tiling. The latter problem is PSPACE-complete [43].

Given a tiling instance $T = (X, H, V, \overline{b}, \overline{t}, n)$, we construct an NFA(&) A over the empty alphabet ($\Sigma = \emptyset$) which accepts ε if and only if there exists a correct corridor tiling for T.

The automaton constructs the tiling row by row. Therefore, A must at any time reflect the current row in its state set (recall that an NFA(&) can be in more than one state at once). To do this, A contains, for every tile x, a set of states $x^1, \ldots, x^n$, where n is the length of each row. If A is in state x^i, this means that the ith tile of the current row is x. For example, if $\overline{b} = x_1x_3x_1$ and $\overline{t} = x_2x_2x_1$, then the initial state set is $\{x_1^1, x_3^2, x_1^3\}$, and A can accept when the state set is $\{x_2^1, x_2^2, x_1^3\}$.

It remains to define how A can transform the current row ("state set") into a state set which describes a valid row on top of the current row. This transformation proceeds on a tile by tile basis and begins with the first tile, say x_i, in the current row which is represented by x_i^1 in the state set. Now, for every tile x_j for which $(x_i, x_j) \in V$, we allow x_i^1 to be replaced by x_j^1, since x_j can be the first tile of the row on top of the current row. For the second tile of the next row, we have to replace the second tile of the current row, say x_k, by a new tile, say x_ℓ, such that the vertical constraints between x_k and x_ℓ are satisfied and such that the horizontal constraints between x_ℓ and the tile we just placed at the first position of the first row, x_j, are satisfied as well.

The automaton proceeds in this manner for the remainder of the row. For this, the automaton needs to know at any time at which position a tile must be updated. Therefore, an extra set of states $p_1, \ldots, p_n$ is created, where the state p_i says that the tile at position i has to be updated. Thus, the state set always consists of one state p_i and a number of states which represent the current and next rows. Here, the states up to position i already represent the tiles of the next row, the states from position i still represent the current row, and i is the next position to be updated.

We can now formally construct an NFA(&) $A = (Q, \Sigma, s, f, \delta)$ which accepts ε if and only if there exists a correct corridor tiling for a tiling instance $T = (X, H, V, \overline{b}, \overline{t}, n)$ as follows:

- $Q = \{x^j \mid x \in X, 1 \leq j \leq n\} \cup \{p_i \mid 1 \leq i \leq n\} \cup \{s, f\}$.
- $\Sigma = \emptyset$.
- δ is the union of the following transitions:
  - $(s, \text{split}, p_1, \overline{b}_1^1, \ldots, \overline{b}_n^n)$. From the initial state the automaton immediately goes to the states which represent the bottom row.
  - $(p_1, \overline{t}_1^1, \ldots, \overline{t}_n^n, \text{merge}, f)$. When the state set represents a full row (the automaton is in state p_1) and the current row is the accepting row, all states are merged to the accepting state.
  - $\forall x_i, x_j \in X, (x_j, x_i) \in V$: $(p_1, x_j^1, \text{merge-split}, p_2, x_i^1)$. When the first tile has to be updated, the automaton only has to check the vertical constraints with the first tile of the previous row.
  - $\forall x_i, x_j, x_k \in X, m \in \mathbb{N}, 2 \leq m \leq n, (x_k, x_i) \in V, (x_j, x_i) \in H$:

$(p_m, x_k^m, x_j^{m-1}, \text{merge-split}, p_{(m \mod n)+1}, x_i^m, x_j^{m-1})$. When a tile at the mth ($m \neq 1$) position has to be updated, the automaton has to check the vertical constraint with the mth tile at the previous row, and the horizontal constraint with the $(m-1)$th tile of the new row.

Clearly, if there exists a correct corridor tiling for T, there exists a run of A accepting ε. Conversely, the construction of our automaton, in which the updates are always determined by the position p_i and the horizontal and vertical constraints, assures that when there is an accepting run of A on ε, this run simulates a correct corridor tiling for T. □

4. Complexity of regular expressions. Before we turn to schemas, we first deal with the complexity of regular expressions and frequently used subclasses as these are directly related to the complexities of DTDs and single-type EDTDs.

Mayer and Stockmeyer [31] and Meyer and Stockmeyer [32] already established the EXPSPACE-completeness of INCLUSION and EQUIVALENCE for RE(&) and RE(#), respectively. From Theorems 3.2(1) and 3.3(1) it then directly follows that allowing both operators does not increase the complexity. It further follows from Theorems 3.2(1) and 3.3(2) that INTERSECTION for RE(#, &) is in PSPACE. We stress that the latter results could also have been obtained without making use of NFA(#, &)s but by translating RE(#, &)s directly to NFAs. However, in the case of INTERSECTION such a construction should be done in an on-the-fly fashion to not go beyond PSPACE. Although such an approach is certainly possible, we prefer the shorter and more elegant construction using NFA(#, &)s.

THEOREM 4.1.

(1) EQUIVALENCE *and* INCLUSION *for RE(#, &) are in* EXPSPACE*; and*

(2) INTERSECTION *for RE(#, &) is* PSPACE*-complete.*

Proof. (1) The proof follows directly from Theorems 3.2(1) and 3.3(1).

(2) The upper bound follows directly from Theorems 3.2(1) and 3.3(2). The lower bound is already known for ordinary regular expressions. □

Bex, Neven, and Van den Bussche [4] established that the vast majority of regular expressions occurring in practical DTDs and XSDs are of a very restricted form as defined next. The class of *chain regular expressions (CHAREs)* are those REs consisting of a sequence of factors $f_1 \cdots f_n$, where every factor is an expression of the form $(a_1 + \cdots + a_n)$, $(a_1 + \cdots + a_n)?$, $(a_1 + \cdots + a_n)^+$, or $(a_1 + \cdots + a_n)^*$, where $n \geq 1$ and every a_i is an alphabet symbol. For instance, the expression $a(b + c)^* d^+ (e + f)?$ is a CHARE, while $(ab + c)^*$ and $(a^* + b?)^*$ are not.[1]

We introduce some additional notation to define subclasses and extensions of CHAREs. By CHARE(#) we denote the class of CHAREs where factors of the form $(a_1 + \cdots + a_n)^{[k,\ell]}$ also are allowed. For the following fragments, we list the admissible types of factors. Here, a, $a?$, and a^* denote the factors $(a_1 + \cdots + a_n)$, $(a_1 + \cdots + a_n)?$, and $(a_1 + \cdots + a_n)^*$, respectively, with $n = 1$, while $a\#$ denotes $a^{[k,\ell]}$, and $a\#^{>0}$ denotes $a^{[k,\ell]}$ with $k > 0$.

Table 4.1 lists the new and the relevant known results. We first show that adding numerical occurrence constraints to CHAREs increases the complexity of INCLUSION by one exponential. We reduce from EXP-CORRIDOR TILING.

THEOREM 4.2. INCLUSION *for CHARE(#) is* EXPSPACE*-complete.*

Proof. The EXPSPACE upper bound already follows from Theorem 4.1(1).

[1] We disregard here the additional restriction used in [3] that every symbol can occur only once.

TABLE 4.1

Overview of new and known complexity results concerning chain regular expressions. All results are completeness results, unless otherwise mentioned. The new results are printed in bold.

	INCLUSION	EQUIVALENCE	INTERSECTION
CHARE	PSPACE [28]	in PSPACE [41]	PSPACE [28]
CHARE(#)	**EXPSPACE**	**in EXPSPACE**	**PSPACE**
CHARE($a, a?$)	coNP [28]	in PTIME [28]	NP [28]
CHARE(a, a^*)	coNP [28]	in PTIME [28]	NP [28]
CHARE($a, a?, a\#$)	**coNP**	**in PTIME**	**NP**
CHARE($a, a\#^{>0}$)	**in PTIME**	**in PTIME**	**in PTIME**

The proof for the EXPSPACE lower bound is similar to the proof for PSPACE-hardness of INCLUSION for CHAREs in [28]. The main difference is that the numerical occurrence operator allows us to compare tiles over a distance exponential in the size of the tiling instance.

The proof is a reduction from EXP-CORRIDOR TILING. A *tiling instance* is a tuple $T = (X, H, V, x_\bot, x_\top, n)$, where X is a finite set of tiles, $H, V \subseteq X \times X$ are the horizontal and vertical constraints, $x_\bot, x_\top \in X$, and n is a natural number in unary notation. A *correct exponential corridor tiling for* T is a mapping $\lambda : \{1, \ldots, m\} \times \{1, \ldots, 2^n\} \to X$ for some $m \in \mathbb{N}$ such that the following constraints are satisfied:

- the first tile of the first row is $x_\bot$: $\lambda(1,1) = x_\bot$;
- the first tile of the mth row is $x_\top$: $\lambda(m,1) = x_\top$;
- all vertical constraints are satisfied: $\forall i < m, \forall j \leq 2^n, (\lambda(i,j), \lambda(i+1,j)) \in V$; and
- all horizontal constraints are satisfied: $\forall i \leq m, \forall j < 2^n, (\lambda(i,j), \lambda(i,j+1)) \in H$.

The EXP-CORRIDOR TILING problem asks, given a tiling instance, whether there exists a correct exponential corridor tiling. The latter problem is easily shown to be EXPSPACE-complete [43].

We proceed with the reduction from EXP-CORRIDOR TILING. Thereto, let $T = (X, H, V, x_\bot, x_\top, n)$ be a tiling instance. Without loss of generality (w.l.o.g.), we assume that $n \geq 2$. We construct two CHARE(#) expressions r_1 and r_2 such that

$$L(r_1) \subseteq L(r_2) \text{ if and only if } \text{there exists no correct exponential corridor tiling for } T.$$

As EXPSPACE is closed under complement, the EXPSPACE-hardness of INCLUSION for CHARE(#) follows.

Set $\Sigma = X \uplus \{\$, \triangle\}$. For ease of exposition, we denote $X \cup \{\triangle\}$ by $X_\triangle$ and $X \cup \{\triangle, \$\}$ by $X_{\triangle,\$}$. We encode candidates for a correct tiling by a string in which the rows are separated by the symbol $\triangle$, that is, by strings of the form

$$(\dagger) \qquad \triangle R_0 \triangle R_1 \triangle \cdots \triangle R_m \triangle,$$

in which each R_i represents a row, that is, belongs to X^{2^n}. Moreover, R_0 is the bottom row, and R_m is the top row. The following regular expressions detect strings of this form which do not encode a correct tiling for T:

- $X_\triangle^* \triangle X^{[0,2^n-1]} \triangle X_\triangle^*$. This expression detects rows that are too short, that is, contain fewer than 2^n symbols.

- $X^*_\triangle \triangle X^{[2^n+1,2^n+1]} X^* \triangle X^*_\triangle$. This expression detects rows that are too long, that is, contain more than 2^n symbols.
- $X^*_\triangle x_1 x_2 X^*_\triangle$ for every $x_1, x_2 \in X$, $(x_1, x_2) \notin H$. These expressions detect all violations of horizontal constraints.
- $X^*_\triangle x_1 X^{[2^n,2^n]}_\triangle x_2 X^*_\triangle$ for every $x_1, x_2 \in X$, $(x_1, x_2) \notin V$. These expressions detect all violations of vertical constraints.

Let $e_1, \ldots, e_k$ be an enumeration of the above expressions. Notice that $k = \mathcal{O}(|X|^2)$. It is straightforward that a string w in (†) does not match $\bigcup_{i=1}^k e_i$ if and only if w encodes a correct tiling.

Let $e = e_1 \cdots e_k$. Because of leading and trailing $X^*_\triangle$ expressions, $L(e) \subseteq L(e_i)$ for every $i \in \{1, \ldots, k\}$. We are now ready to define r_1 and r_2:

$$r_1 = \overbrace{\$e\$e\$\cdots\$e\$}^{k \text{ times } e} \triangle x_\perp X^{[2^n-1,2^n-1]} \triangle X^*_\triangle \triangle x_\top X^{[2^n-1,2^n-1]} \triangle \overbrace{\$e\$e\$\cdots\$e\$}^{k \text{ times } e},$$

$$r_2 = \$X^*_{\triangle,\$} \$e_1\$e_2\$\cdots\$e_k\$ X^*_{\triangle,\$}\$.$$

Notice that both r_1 and r_2 are in CHARE(#) and can be constructed in polynomial time. It remains to show that $L(r_1) \subseteq L(r_2)$ if and only if there is no correct tiling for T.

We first show the implication from left to right. Thereto, let $L(r_1) \subseteq L(r_2)$. Let uwu' be an arbitrary string in $L(r_1)$ such that $u, u' \in L(\$e\$e\$\cdots\$e\$)$ and $w \in \triangle x_\perp X^{[2^n-1,2^n-1]} \triangle X^*_\triangle \triangle x_\top X^{[2^n-1,2^n-1]} \triangle$. By assumption, $uwu' \in L(r_2)$.

Notice that uwu' contains $2k+2$ times the symbol "\$." Moreover, the first and the last "\$" of uwu' are always matched onto the first and last "\$" of r_2. This means that $k+1$ consecutive \$-symbols of the remaining $2k$ \$-symbols in uwu' must be matched onto the \$-symbols in $\$e_1\$e_2\$\cdots\$e_k\$$. Hence, w is matched onto some e_i. Thus, w does not encode a correct tiling. As the subexpression $\triangle x_\perp X^{[2^n-1,2^n-1]} \triangle X^*_\triangle \triangle x_\top X^{[2^n-1,2^n-1]} \triangle$ of r_1 defines all candidate tilings, the system T has no solution.

To show the implication from right to left, assume that there is a string $uwu' \in L(r_1)$ that is not in r_2, where $u, u' \in L(\$e\$e\$\cdots\$e\$)$. Then $w \notin \bigcup_{i=1}^k L(e_i)$, and, hence, w encodes a correct tiling. □

Adding numerical occurrence constraints to the fragment CHARE($a, a?$) keeps EQUIVALENCE in PTIME, INTERSECTION in NP, and INCLUSION in coNP.

THEOREM 4.3.

(1) EQUIVALENCE *for* CHARE($a, a?, a\#$) *is in* PTIME.
(2) INCLUSION *for* CHARE($a, a?, a\#$) *is* coNP*-complete.*[2]
(3) INTERSECTION *for* CHARE($a, a?, a\#$) *is* NP*-complete.*

Proof. (1) It is shown in [28] that two CHARE($a, a?$) expressions are equivalent if and only if they have the same *sequence normal form* (which is defined below). As $a^{[k,\ell]}$ is equivalent to $a^k(a?)^{\ell-k}$, it follows that two CHARE($a, a?, a\#$) expressions are equivalent if and only if they have the same sequence normal form. It remains to argue that the sequence normal form of CHARE($a, a?, a\#$) expressions can be computed in polynomial time. To this end, let $r = f_1 \cdots f_n$ be a CHARE($a, a?, a\#$) expression with factors $f_1, \ldots, f_n$. The *sequence normal form* is then obtained in the following way. First, we replace every factor of the form

- a by $a[1,1]$;
- $a?$ by $a[0,1]$; and
- $a^{[k,\ell]}$ by $a[k,\ell]$,

[2] In the previous version of this article presented at ICDT'07 the complexity was wrongly attributed to lie between PSPACE and EXPSPACE.

where a is an alphabet symbol. We call a the *base symbol* of the factor $a[i,j]$. Then, we replace successive subexpressions $a[i_1,j_1]$ and $a[i_2,j_2]$ carrying the same base symbol a by $a[i_1+i_2, j_1+j_2]$ until no further replacements can be made. For instance, the sequence normal form of $aa?a^{[2,5]}a?bb?b?b^{[1,7]}$ is $a[3,8]b[2,10]$. Obviously, the above algorithm to compute the sequence normal form of CHARE$(a, a?, a\#)$ expressions can be implemented in polynomial time. It can then be tested in linear time whether two sequence normal forms are the same.

(2) coNP-hardness is immediate since INCLUSION is already coNP-complete for CHARE$(a, a?)$ expressions [28].

We show that the problem remains in coNP. To this end, we represent strings w by their sequence normal form as discussed above, where we take each string w as the regular expression defining w. We call such strings *compressed*. Let r_1 and r_2 be two CHARE$(a, a?, a\#)$s. We can assume that they are in sequence normal form.

To show that $L(r_1) \not\subseteq L(r_2)$, we guess a compressed string w of polynomial size for which $w \in L(r_1)$, but $w \notin L(r_2)$. We guess $w \in L(r_1)$ in the following manner. We iterate from left to right over the factors of r_1. For each factor $a[k,\ell]$ we guess an h such that $k \leq h \leq \ell$, and add a^h to the compressed string w. This algorithm gives a compressed string of polynomial size which is defined by r_1. Furthermore, this algorithm is capable of guessing every possible string defined by r_1. It is, however, possible that in the compressed string there are two consecutive *elements* a^i, a^j with the same *base symbol* a. If this is the case we merge these elements to a^{i+j} which gives a proper compressed string.

The following lemma shows that testing $w \notin L(r_2)$ can be done in PTIME.

LEMMA 4.4. *Given a compressed string w and an expression r in sequence normal form, deciding whether $w \in L(r)$ is in* PTIME.

Proof. Let $w = a_1^{p_1} \cdots a_n^{p_n}$, and let $r = b_1[k_1,\ell_1] \cdots b_m[k_m,\ell_m]$. Denote $b_i[k_i,\ell_i]$ by f_i. For every position i of w $(0 < i \leq n)$, we define C_i as a set of factors $b[k,\ell]$ of r. Formally, $f_j \in C_i$ when $a_1^{p_1} \cdots a_{i-1}^{p_{i-1}} \in L(f_1 \cdots f_{j-1})$ and $a_i = b_j$. We compute the C_i as follows.

- C_1 is the set of all $b_j[k_j,\ell_j]$ such that $a_1 = b_j$ and $\forall h < j, k_h = 0$. These are all the factors of r which can match the first symbol of w.
- Then, $\forall\ i \in \{2,\ldots,n\}$, we compute C_i from C_{i-1}. In particular, $f_h = b_h[k_h,\ell_h] \in C_i$ when there is an $f_j = b_j[k_j,\ell_j] \in C_{i-1}$ such that $a_{i-1}^{p_{i-1}} \in f_j \cdots f_{h-1}$ and $a_i = b_h$. That is, the following conditions should hold:
  - $j < h$: f_h occurs after f_j in r.
  - $b_h = a_i$: f_h can match the first symbol of $a_i^{p_i}$.
  - $\forall e \in \{j,\ldots,h-1\}$, if $b_e \neq a_{i-1}$, then $k_e = 0$: in between factors f_j and f_h it is possible to match only symbols a_{i-1}.
  - Let $\min = \sum_{e\in\{j,\ldots,h-1\}, b_e = a_{i-1}} k_e$ and $\max = \sum_{e\in\{j,\ldots,h-1\}, b_e = a_{i-1}} \ell_e$. Then $\min \leq p_{i-1} \leq \max$. That is, p_{i-1} symbols a_{i-1} should be matched from f_j to f_{h-1}.

Then, $w \in L(r)$ if and only if there is an $f_j \in C_n$ such that $a_n^{p_n} \in L(f_j \cdots f_n)$. As the latter test and the computation of $C_1,\ldots,C_n$ can be done in PTIME, the lemma follows. □

(3) NP-hardness is immediate since INTERSECTION is already NP-complete for CHARE$(a, a?)$ expressions [28].

We show that the problem remains in NP. As in the proof of Theorem 4.3(2) we represent a string w as a compressed string. Let $r_1,\ldots,r_n$ be CHARE$(a, a?, a\#)$ expressions.

LEMMA 4.5. *If* $\bigcap_{i=1}^{n} L(r_i) \neq \emptyset$, *then there exists a string* $w = a_1^{p_1} \cdots a_m^{p_m} \in \bigcap_{i=1}^{n} L(r_i)$ *such that* $m \leq \min\{|r_i| \mid i \in \{1, \ldots, n\}\}$ *and, for each* $i \in \{1, \ldots, n\}$, j_i *is not larger than the largest integer occurring in* $r_1, \ldots, r_n$.

Proof. Suppose that there exists a string $w = a_1^{p_1} \cdots a_m^{p_m} \in \bigcap_{i=1}^{n} L(r_i)$, with $a_i \neq a_{i+1}$ for every $i \in \{1, \ldots, m-1\}$. Since w is matched by every expression $r_1, \ldots, r_n$, and since a factor of a CHARE$(a, a?, a\#)$ expression can never match a strict superstring of $a_i^{p_i}$ for $i \in \{1, \ldots, n\}$, we have that $m \leq \min\{|r_i| \mid i \in \{1, \ldots, n\}\}$.

Furthermore, since w is matched by every expression $r_1, \ldots, r_n$, no j_i can be larger than the largest integer occurring in $r_1, \ldots, r_n$. ∎

The NP algorithm then consists of guessing a compressed string w of polynomial size and verifying whether $w \in \bigcap_{i=1}^{n} L(r_i)$. If we represent $r_1, \ldots, r_n$ by their sequence normal form, this verification step can be done in polynomial time by Lemma 4.4. ∎

Finally, we exhibit a tractable subclass with numerical occurrence constraints.

THEOREM 4.6. INCLUSION, EQUIVALENCE, *and* INTERSECTION *for CHARE*$(a, a\#^{>0})$ *are in* PTIME.

Proof. The upper bound for EQUIVALENCE is immediate from Theorem 4.3(2).

For INCLUSION, let r_1 and r_2 be two CHARE$(a, a\#^{>0})$s in sequence normal form (as defined in the proof of Theorem 4.3). Let $r_1 = a_1[k_1, \ell_1] \cdots a_n[k_n, \ell_n]$ and $r_2 = a'_1[k'_1, \ell'_1] \cdots a'_{n'}[k'_{n'}, \ell'_{n'}]$. Notice that every number k_i and k'_j is greater than zero. We claim that $L(r_1) \subseteq L(r_2)$ if and only if $n = n'$ and for every $i \in \{1, \ldots, n\}$, $a_i = a'_i$, $k_i \geq k'_i$, and $\ell_i \leq \ell'_i$.

Indeed, if $n \neq n'$, or if there exists an i such that $a_i \neq a'_i$ or $k_i < k'_i$, then $a_1^{k_1} \cdots a_n^{k_n} \in L(r_1) - L(r_2)$. If there exists an i such that $\ell_i > \ell'_i$, then $a_1^{\ell_1} \cdots a_n^{\ell_n} \in L(r_1) - L(r_2)$. Conversely, it is immediate that every string in $L(r_1)$ is also in $L(r_2)$. It is straightforward to test these conditions in linear time.

For INTERSECTION, let, for every $i \in \{1, \ldots, n\}$, $r_i = a_{i,1}[k_{i,1}, \ell_{i,1}] \cdots a_{i,m_i}[k_{i,m_i}, \ell_{i,m_i}]$ be a CHARE$(a, a\#^{>0})$ in sequence normal form. Notice that every number $k_{i,j}$ is greater than zero. We claim that $\bigcap_{i=1}^{n} L(r_i) \neq \emptyset$ if and only if

(i) $m_1 = m_2 = \cdots = m_n$;
(ii) for every $i, j \in \{1, \ldots, n\}$ and $x \in \{1, \ldots, m_1\}$, $a_{i,x} = a_{j,x}$; and
(iii) for every $x \in \{1, \ldots, m_1\}$, $\max\{k_{i,x} \mid 1 \leq i \leq n\} \leq \min\{\ell_{i,x} \mid 1 \leq i \leq n\}$.

Indeed, if the above conditions hold, we have that $a_{1,1}^{K_1} \cdots a_{1,m_1}^{K_{m_1}}$ is in $\bigcap_{i=1}^{n} L(r_i)$, where $K_x = \max\{k_{i,x} \mid 1 \leq i \leq n\}$ for every $x \in \{1, \ldots, m_1\}$. If $m_i \neq m_j$ for some $i, j \in \{1, \ldots, n\}$, then the intersection between r_i and r_j is empty. So assume that condition (i) holds. If $a_{i,x} \neq a_{j,x}$ for some $i, j \in \{1, \ldots, n\}$ and $x \in \{1, \ldots, m_1\}$, then we also have that the intersection between r_i and r_j is empty. Finally, if condition (iii) does not hold, take i, j, and x such that $k_{i,x} = \max\{k_{i,x} \mid 1 \leq i \leq n\}$ and $\ell_{j,x} = \min\{\ell_{i,x} \mid 1 \leq i \leq n\}$. Then the intersection between r_i and r_j is empty.

Finally, testing conditions (i)–(iii) can be done in linear time. ∎

5. Complexity of schemas.

5.1. DTDs and single-type EDTDs. By Proposition 2.4 the results on the EQUIVALENCE and INCLUSION problem of the previous section carry over to DTDs and single-type EDTDs. For the INTERSECTION problem, the results carry over only to DTDs (Proposition 2.5). The only remaining problem is INTERSECTION for single-type EDTDs with counting and interleaving. However, INTERSECTION for EDTD$^{\text{st}}$(RE) is EXPTIME-hard, and in the next section we will see that even for EDTD$(\#, \&)$ INTERSECTION remains in EXPTIME. It immediately follows that INTERSECTION for EDTD$^{\text{st}}(\#)$, EDTD$^{\text{st}}(\&)$, and EDTD$^{\text{st}}(\#,\&)$ is also EXPTIME-complete.

5.2. Extended DTDs. We next consider the complexity of the basic decision problems for EDTDs with numerical occurrence constraints and interleaving. As the basic decision problems are EXPTIME-complete for EDTD(RE), the straightforward approach of translating every RE(#, &) expression into an NFA and then applying the standard algorithms gives rise to a double exponential time complexity. By using NFA(#, &), we can do better: EXPSPACE for INCLUSION and EQUIVALENCE and, more surprisingly, EXPTIME for INTERSECTION.

THEOREM 5.1.

(1) EQUIVALENCE *and* INCLUSION *for EDTD*(#, &) *are in* EXPSPACE*;*
(2) EQUIVALENCE *and* INCLUSION *for EDTD*(#) *and EDTD*(&) *are* EXPSPACE*-hard; and*
(3) INTERSECTION *for EDTD*(#, &) *is* EXPTIME*-complete.*

Proof. (1) We show that INCLUSION is in EXPSPACE. The upper bound for EQUIVALENCE then immediately follows.

First, we introduce some notation. For an EDTD $D = (\Sigma, \Sigma', d, s, \mu)$, we will denote elements of Σ', i.e., types, by τ. We denote by (D, τ) the EDTD D with start symbol τ. We define the *depth* of a tree t, denoted by $\text{depth}(t)$, as follows: if $t = \varepsilon$, then $\text{depth}(t) = 0$, and if $t = \sigma(t_1 \cdots t_n)$, then $\text{depth}(t) = \max\{\text{depth}(t_i) \mid i \in \{1, \ldots, n\}\} + 1$.

Suppose that we have two EDTDs $D_1 = (\Sigma, \Sigma'_1, d_1, s_1, \mu_1)$ and $D_2 = (\Sigma, \Sigma'_2, d_2, s_2, \mu_2)$. We provide an EXPSPACE algorithm that decides whether $L(D_1) \not\subseteq L(D_2)$. As EXPSPACE is closed under complement, the theorem follows. The algorithm computes a set E of pairs $(C_1, C_2) \in 2^{\Sigma'_1} \times 2^{\Sigma'_2}$, where $(C_1, C_2) \in E$ if and only if there exists a tree t such that $C_j = \{\tau \in \Sigma'_j \mid t \in L((D_j, \tau))\}$ for each $j = 1, 2$. That is, every C_j is the set of types that can be assigned by D_j to the root of t. Or, when viewing D_j as a tree automaton, C_j is the set of states that can be assigned to the root in a run on t. Therefore, we say that t *is a witness for* (C_1, C_2). Notice that $t \in L(D_1)$ (resp., $t \in L(D_2)$) if $s_1 \in C_1$ (resp., $s_2 \in C_2$). Hence, $L(D_1) \not\subseteq L(D_2)$ if and only if there exists a pair $(C_1, C_2) \in E$ with $s_1 \in C_1$ and $s_2 \notin C_2$.

We compute the set E in a bottom-up manner as follows:

1. Initially, set $E_1 := \{(C_1, C_2) \mid \exists a \in \Sigma, \tau_1 \in \Sigma'_1, \tau_2 \in \Sigma'_2$ such that $\mu_1(\tau_1) = \mu_2(\tau_2) = a$ and, for $i = 1, 2$, $C_i = \{\tau \in \Sigma'_i \mid \varepsilon \in d_i(\tau) \wedge \mu_i(\tau) = a\}\}$.
2. For every $k > 1$, E_k is the union of E_{k-1} and the pairs (C_1, C_2) for which there are $a \in \Sigma$, $n \in \mathbb{N}$, and a string $(C_{1,1}, C_{2,1}) \cdots (C_{1,n}, C_{2,n})$ in E^*_{k-1} such that

$$C_j = \{\tau \in \Sigma'_j \mid \mu_j(\tau) = a, \exists b_{j,1} \in C_{j,1}, \ldots, b_{j,n} \in C_{j,n} \text{ with } b_{j,1} \cdots b_{j,n} \in d_j(\tau)\} \text{ for each } j = 1, 2.$$

Let $E := E_\ell$ for $\ell = 2^{|\Sigma'_1|} \cdot 2^{|\Sigma'_2|}$. The algorithm then accepts when there is a pair $(C_1, C_2) \in E$ with $s_1 \in C_1$ and $s_2 \notin C_2$ and rejects otherwise.

We argue that the algorithm is correct. As $E_k \subseteq E_{k+1}$, for every k, it follows that $E_\ell = E_{\ell+1}$. Hence, the algorithm computes the largest set of pairs. The following lemma then shows that the algorithm decides whether $L(D_1) \not\subseteq L(D_2)$. The lemma can be proved by induction on k.

LEMMA 5.2. *For every* $k \geq 1$, $(C_1, C_2) \in E_k$ *if and only if there exists a witness tree for* (C_1, C_2) *of depth at most* k.

It remains to show that the algorithm can be carried out using exponential space. Step 1 reduces to a linear number of tests $\varepsilon \in L(r)$ for some RE(#, &) expressions r

which is in PTIME by [19]. For step 2, it suffices to argue that, when E_{k-1} is known, it is decidable in EXPSPACE whether a pair (C_1, C_2) is in E_k. As there are only an exponential number of such possible pairs, the result follows. To this end, we need to verify that there exists a string $W = (C_{1,1}, C_{2,1}) \cdots (C_{1,n}, C_{2,n})$ in E_{k-1}^* such that, for each $j = 1, 2$,

(A) for every $\tau \in C_j$, there exist $b_{j,1} \in C_{j,1}, \ldots, b_{j,n} \in C_{j,n}$ with $b_{j,1} \cdots b_{j,n} \in d_j(\tau)$; and
(B) for every $\tau \in \Sigma'_j \setminus C_j$, there do *not* exist $b_{j,1} \in C_{j,1}, \ldots, b_{j,n} \in C_{j,n}$ with $b_{j,1} \cdots b_{j,n} \in d_j(\tau)$.

Assume that $\Sigma'_1 \cap \Sigma'_2 = \emptyset$. Let, for each $j = 1, 2$ and $\tau \in \Sigma'_j$, $N(\tau)$ be the NFA(#, &) accepting $d_j(\tau)$. Intuitively, we guess the string W one symbol at a time and compute the set of reachable configurations Γ_τ for each $N(\tau)$.

Initially, Γ_τ is the singleton set containing the initial configuration of $N(\tau)$. Suppose that we have guessed a prefix $(C_{1,1}, C_{2,1}) \cdots (C_{1,m-1}, C_{2,m-1})$ of W and that we guess a new symbol $(C_{1,m}, C_{2,m})$. Then, we compute the set $\Gamma'_\tau = \{\gamma' \mid \exists b \in C_{j,m}, \gamma \in \Gamma_\tau \text{ such that } \gamma \Rightarrow_{N(\tau),b} \gamma'\}$ and set Γ_τ to Γ'_τ. Each set Γ'_τ can be computed in exponential space from Γ_τ. We accept (C_1, C_2) when, for every $\tau \in \Sigma'_j$, $\tau \in C_j$ if and only if Γ_τ contains an accepting configuration.

(2) It is shown by Mayer and Stockmeyer [31] and Meyer and Stockmeyer [32] that EQUIVALENCE and INCLUSION are EXPSPACE-hard for RE(&)s and RE(#), respectively. Hence, EQUIVALENCE and INCLUSION are also EXPSPACE-hard for EDTD(&) and EDTD(#).

(3) The lower bound follows from [38]. We argue that the problem is in EXPTIME. Thereto, let, for each $i \in \{1, \ldots, n\}$, $D_i = (\Sigma, \Sigma'_i, d_i, s_i, \mu_i)$ be an EDTD(#, &). We assume w.l.o.g. that the sets Σ'_i are pairwise disjoint. We also assume that the start type s_i never appears at the right-hand side of a rule. Finally, we assume that no derivation tree consists of only the root. For each type $\tau \in \Sigma'_i$, let $N(\tau)$ denote an NFA(#, &) for $d_i(\tau)$. According to Theorem 3.2, $N(\tau)$ can be computed from $d_i(\tau)$ in polynomial time. We provide an alternating polynomial space algorithm that guesses a tree t and accepts if $t \in L(D_1) \cap \cdots \cap L(D_n)$. As APSPACE = EXPTIME [8], this shows the theorem.

We guess t node by node in a top-down manner. For every guessed node v, the following information is written on the tape of the TM: for every $i \in \{1, \ldots, n\}$, the triple $c_i = (\tau_v^i, \tau_p^i, \gamma^i)$, where τ_v^i is the type assigned to v by grammar D_i, τ_p^i is the type of the parent assigned by D_i, and γ^i is the current configuration of $N(\tau_p^i)$ after reading the string formed by the left siblings of v. In the following, we say that $\tau \in \Sigma'_i$ is an a-type when $\mu_i(\tau) = a$.

The algorithm proceeds as follows:

1. As for each grammar the types of the roots are given, we start by guessing the first child of the root. That is, we guess an $a \in \Sigma$, and, for each $i \in \{1, \ldots, n\}$, we guess an a-type τ^i and write the triple $c_i = (\tau^i, s_i, \gamma_s^i)$ on the tape where γ_s^i is the start configuration of $N(s_i)$.
2. For $i \in \{1, \ldots, n\}$, let $c_i = (\tau^i, \tau_p^i, \gamma^i)$ be the triples on the tape. The algorithm now universally splits into two parallel branches as follows:
   (a) *Downward extension.* When for every i, $\varepsilon \in d_i(\tau^i)$, the current node can be a leaf node and the branch accepts. Otherwise, guess an $a \in \Sigma$ and for each i, guess an a-type θ^i. Replace every c_i by the triple $(\theta^i, \tau^i, \gamma_s^i)$ and proceed to step 2. Here, γ_s^i is the start configuration of $N(\tau^i)$.

(b) *Extension to the right.* For every $i \in \{1, \ldots, n\}$, compute a configuration γ'^i for which $\gamma^i \Rightarrow_{N(\tau_p^i),\tau^i} \gamma'^i$. When every γ'^i is a final configuration, we do not need to extend to the right anymore and the algorithm accepts. Otherwise, guess an $a \in \Sigma$ and for each i, guess an a-type θ^i. Replace every c_i by the triple $(\theta^i, \tau^i, \gamma'^i)$ and proceed to step 2.

We argue that the algorithm is correct. If the algorithm accepts, we have guessed a tree t and, for every $i \in \{1, \ldots, n\}$, a tree t'_i with $\mu_i(t'_i) = t$ and $t'_i \in L(d_i)$. Therefore, $t \in \bigcap_{i=1}^n L(D_i)$. For the other direction, suppose that there exists a tree $t \in \bigcap_{i=1}^n L(D_i)$ and t is minimal in the sense that no subtree t_0 of t is in $\bigcap_{i=1}^n L(D_i)$. Then, there is a run of the above algorithm that guesses t and guesses trees t'_i with $\mu_i(t'_i) = t$. The tree t must be minimal since the algorithm stops extending the tree as soon as possible.

The algorithm obviously uses only polynomial space. □

6. Simplification. The simplification problem is defined as follows: Given an EDTD, check whether it has an equivalent EDTD of a restricted type, i.e., an equivalent DTD or single-type EDTD. In [27], this problem was shown to be EXPTIME-complete for EDTDs with standard regular expressions. We revisit this problem in the context of RE(#, &).

We need a bit of terminology. Let t be a tree and v be a node. By anc-str$^t(v)$ we denote the string formed by the labels on the path from the root to v, i.e., $\text{lab}^t(\varepsilon)\text{lab}^t(i_1)\text{lab}^t(i_1 i_2)\cdots\text{lab}^t(i_1 i_2 \cdots i_k)$, where $v = i_1 i_2 \cdots i_k$.

We say that a tree language L is *closed under ancestor-guarded subtree exchange* if the following holds: whenever for two trees $t_1, t_2 \in L$ with nodes $u_1 \in \text{Dom}(t_1)$ and $u_2 \in \text{Dom}(t_2)$, anc-str$^{t_1}(u_1) =$ anc-str$^{t_2}(u_2)$ implies $t_1[u_1 \leftarrow \text{subtree}^{t_2}(u_2)] \in L$. Here, $t_1[u_1 \leftarrow \text{subtree}^{t_2}(u_2)]$ denotes the tree obtained from t_1 by replacing its subtree rooted at u_1 by the subtree rooted at u_2 in t_2.

We recall the following theorem from [27].

THEOREM 6.1 (Theorem 7.1 in [27]). *Let L be a tree language defined by an EDTD. Then the following conditions are equivalent.*

(a) *L is definable by a single-type EDTD.*

(b) *L is closed under ancestor-guarded subtree exchange.*

We are now ready for the following theorem.

THEOREM 6.2. *Given an EDTD(#, &), deciding whether it is equivalent to an EDTDst(#, &) or DTD(#, &) is* EXPSPACE*-complete.*

Proof. We first show that the problem is hard for EXPSPACE. We use a reduction from EQUIVALENCE of RE(#), which is EXPSPACE-complete [32].

Let r_1, r_2 be RE(#) expressions over Σ and let b and s be two symbols not occurring in Σ. By definition $L(r_j) \neq \emptyset$, for $j = 1, 2$. Define $D = (\Sigma \cup \{b, s\}, \Sigma \cup \{s, b^1, b^2\}, d, s, \mu)$ as the EDTD with the following rules:

$$\begin{array}{lcl} s & \to & b^1 b^2, \\ b^1 & \to & r_1, \\ b^2 & \to & r_2, \end{array}$$

where for every $\tau \in \Sigma \cup \{s\}$, $\mu(\tau) = \tau$ and $\mu(b^1) = \mu(b^2) = b$. We claim that D is equivalent to a single-type DTD or a DTD if and only if $L(r_1) = L(r_2)$. Clearly, if r_1 is equivalent to r_2, then D is equivalent to the DTD (and therefore also to a single-type EDTD)

$$\begin{array}{lcl} s & \to & bb, \\ b & \to & r_1. \end{array}$$

Conversely, suppose that there exists an EDTD$^{\text{st}}$ which defines the language $L(D)$. Toward a contradiction, assume that r_1 is not equivalent to r_2. Thus, there exists a string w_1 such that $w_1 \in L(r_1)$ and $w_1 \notin L(r_2)$, or $w_1 \notin L(r_1)$ and $w_1 \in L(r_2)$. We consider only the first case; the second is identical. Now, let w_2 be a string in $L(r_2)$ and consider the tree $t = s(b(w_1)b(w_2))$. Clearly, t is in $L(D)$. However, the tree $t' = s(b(w_2)b(w_1))$ obtained from t by switching its left and right subtree is not in $L(D)$. According to Theorem 6.1, every tree language defined by a single-type EDTD is closed under such an exchange of subtrees. So, this means that $L(D)$ cannot be defined by an EDTD$^{\text{st}}$, which leads to the desired contradiction.

We now proceed with the upper bounds. The following algorithms are along the same lines as the EXPTIME algorithms in [27] for the simplification problem without numerical occurrence or interleaving operators. We first give an EXPSPACE algorithm which decides whether an EDTD is equivalent to an EDTD$^{\text{st}}$. Let $D = (\Sigma, \Sigma', d, s, \mu)$ be an EDTD. Intuitively, we compute an EDTD$^{\text{st}}$ $D_0 = (\Sigma, \Sigma'_0, d_0, s, \mu_0)$ which is the closure of D under the single-type property. The EDTD$^{\text{st}}$ D_0 has the following properties:

(a) Σ'_0 is in general exponentially larger than Σ';
(b) the RE$(\#, \&)$ expressions in the definition of d_0 are only polynomially larger than the RE$(\#, \&)$ expressions in the definition of d;
(c) $L(D) \subseteq L(D_0)$; and
(d) $L(D_0) = L(D) \Leftrightarrow D$ is equivalent to an EDTD$^{\text{st}}$.

Hence, we have that D is equivalent to an EDTD$^{\text{st}}$ if and only if $L(D_0) \subseteq L(D)$.

We first show how D_0 can be constructed. We can assume w.l.o.g. that, for each type $a^i \in \Sigma'$, there exists a tree $t' \in L(d)$ such that a^i is a label in t'. Indeed, every *useless* type can be removed from D in a simple preprocessing step. Then, for a string $w \in \Sigma^*$ and $a \in \Sigma$, let types(wa) be the set of all types $a^i \in \Sigma'$ for which there are a tree t and a tree $t' \in L(d)$ with $\mu(t') = t$, and a node v in t such that anc-str$^t(v) = wa$ and the type of v in t' is a^i. We show how to compute types(wa) in exponential time. To this end, we enumerate all sets types(w). Let $s = c^1$. Initially, set $W := \{c\}$, Types$(c) := \{c^1\}$, and $R := \{\{c^1\}\}$. Repeat the following until W becomes empty:

(1) Remove a string wa from W.
(2) For every $b \in \Sigma$, let Types(wab) contain all b^i for which there exist an a^j in Types(wa) and a string in $d(a^j)$ containing b^i. If Types(wab) is not empty and not already in R, then add it to R and add wab to W.

Since we add every set only once to R, the algorithm runs in time exponential in the size of D. Moreover, we have that Types$(w) =$ types(w) for every w and that $R = \Sigma'_0$.

For each $a \in \Sigma$, let types(D, a) be the set of all nonempty sets types(wa), with $w \in \Sigma^*$. Clearly, each types(D, a) is finite. We next define $D_0 = (\Sigma, \Sigma'_0, d_0, s, \mu_0)$. Its set of types is $\Sigma'_0 := \bigcup_{a \in \Sigma}$ types(D, a). Note that $s \in \Sigma'_0$. For every $\tau \in$ types(D, a), set $\mu_0(\tau) = a$. In d_0, the right-hand side of the rule for each types(wa) is the disjunction of all $d(a^i)$ for $a^i \in$ types(wa), with each b^j in $d(a^i)$ replaced by types(wab).

We show that properties (a)–(d) hold. Since $\Sigma'_0 \subseteq 2^{\Sigma'}$, we immediately have that (a) holds. The RE$(\#, \&)$ expressions that we constructed in D_0 are unions of a linear number of RE$(\#, \&)$ expressions in D, but have types in $2^{\Sigma'}$ rather than in Σ'. Hence, the size of the RE$(\#, \&)$ expressions in D_0 is at most quadratic in the size of D. Finally, we note that it has been shown in Theorem 7.1 in [27] that (c) and (d) also hold.

It remains to argue that it can be decided in EXPSPACE that $L(D_0) \subseteq L(D)$. A direct application of the EXPSPACE algorithm in Theorem 5.1(1) leads to a 2EX-

PSPACE algorithm to test whether $L(D_0) \subseteq L(D)$, due to the computation of C_1. Indeed, the algorithm remembers, given the EDTDs $D_0 = (\Sigma, \Sigma'_0, d_0, s_0, \mu_0)$ and $D = (\Sigma, \Sigma', d, s, \mu)$, all possible pairs (C_1, C_2) such that there exists a tree t with $C_1 = \{\tau \in \Sigma'_0 \mid t \in L((D_0, \tau))\}$ and $C_2 = \{\tau \in \Sigma' \mid t \in L((D, \tau))\}$. It then accepts if there exists such a pair (C_1, C_2) with $s_0 \in C_1$ and $s \notin C_2$. However, when we use nondeterminism, notice that it is not necessary to compute the entire set C_1. Indeed, as we test only whether there *exist* elements in C_1 in the entire course of the algorithm, we can adapt the algorithm to compute pairs (c_1, C_2), where c_1 is an element of C_1, rather than the entire set. Since NEXPSPACE = EXPSPACE, we can use this adaption to test whether $L(D_0) \subseteq L(D)$ in EXPSPACE.

Finally, we give the algorithm which decides whether an EDTD $D = (\Sigma, \Sigma', d, s, \mu)$ is equivalent to a DTD. We compute a DTD (Σ, d_0, s_d) which is equivalent to D if and only if $L(D)$ is definable by a DTD. Thereto, let, for each $a^i \in \Sigma'$, $r_{a,i}$ be the expression obtained from $d(a^i)$ by replacing each symbol b^j in $d(a^i)$ by b. For every $a \in \Sigma$, define $d_0(a) = \bigcup_{a^i \in \Sigma'} r_{a,i}$. Again, it is shown in [27] that $L(D) = L(d_0)$ if and only if $L(D)$ is definable by a DTD. By Theorem 5.1(1) and since d_0 is of size polynomial in the size of D, this can be tested in EXPSPACE. □

7. Conclusion. The present work gives an overview of the complexity of the basic decision problems for abstractions of several schema languages including numerical occurrence constraints and interleaving. W.r.t. INTERSECTION the complexity remains the same, while for INCLUSION and EQUIVALENCE the complexity increases by one exponential for DTDs and single-type EDTDs, and goes from EXPTIME to EXPSPACE for EDTDs. The results w.r.t. CHAREs also follow this pattern. We further showed that the complexity of simplification increases to EXPSPACE.

We emphasize that this is a theoretical study delineating the worst case complexity boundaries for the basic decision problems. Although these complexities must be studied, we note that the regular expressions used in the hardness proofs do not correspond at all to those employed in practice. Further, w.r.t. XSDs, our abstraction is not fully adequate as we do not consider the one-unambiguity (or unique particle attribution) constraint. However, it is doubtful that this constraint is the right one to get tractable complexities for the basic decision problems. Indeed, already intersection for unambiguous regular expressions is PSPACE-hard [28] and inclusion for one-unambiguous RE(#) expressions is coNP-hard [22]. It would therefore be desirable to find robust subclasses for which the basic decision problems are in PTIME.

STREAM ORDER AND ORDER STATISTICS: QUANTILE ESTIMATION IN RANDOM-ORDER STREAMS*

SUDIPTO GUHA† AND ANDREW MCGREGOR‡

Abstract. When trying to process a data stream in small space, how important is the order in which the data arrive? Are there problems that are unsolvable when the ordering is worst case, but that can be solved (with high probability) when the order is chosen uniformly at random? If we consider the stream as if ordered by an adversary, what happens if we restrict the power of the adversary? We study these questions in the context of quantile estimation, one of the most well studied problems in the data-stream model. Our results include an $O(\text{polylog } n)$-space, $O(\log \log n)$-pass algorithm for exact selection in a randomly ordered stream of n elements. This resolves an open question of Munro and Paterson [*Theoret. Comput. Sci.*, 23 (1980), pp. 315–323]. We then demonstrate an exponential separation between the random-order and adversarial-order models: using $O(\text{polylog } n)$ space, exact selection requires $\Omega(\log n/\log \log n)$ passes in the adversarial-order model. This lower bound, in contrast to previous results, applies to fully general randomized algorithms and is established via a new bound on the communication complexity of a natural pointer-chasing style problem. We also prove the first fully general lower bounds in the random-order model: finding an element with rank $n/2 \pm n^{\delta}$ in the single-pass random-order model with probability at least $9/10$ requires $\Omega(\sqrt{n^{1-3\delta}/\log n})$ space.

1. Introduction.

One of the principal theoretical motivations for studying the data-stream model is to understand the role played by the order in which a problem is revealed. While an algorithm in the RAM model can process the input data in an arbitrary order, the key constraint of the data-stream model is that the algorithm must process (in small space) the input data in the order in which it arrives. Parameterizing the number of passes that an algorithm may have over the data establishes a spectrum between the RAM model and the one-pass data-stream model. How does the computational power of the model vary along this spectrum? To what extent does it matter how the stream is ordered?

These issues date back to one of the earliest papers on the data-stream model in which Munro and Paterson considered the problems of sorting and selection in limited space [21]. They showed that $\tilde{O}(n^{1/p})$ space was sufficient to find the exact median of a sequence of n numbers given p passes over the data. However, if the data were randomly ordered, $\tilde{O}(n^{1/(2p)})$ space sufficed. Based on this result and other observations, it seemed plausible that any p-pass algorithm in the random-order model could be simulated by a $2p$-pass algorithm in the adversarial-order model. This was posed as an open problem by Kannan [17], and further support for this conjecture came via work initiated by Feigenbaum et al. [6] that considered the relationship

between various property testing models and the data-stream model. It was shown by Guha, McGregor, and Venkatasubramanian [14] that several models of property testing can be simulated in the single-pass random-order data-stream model, while it appeared that a similar simulation in the adversarial-order model required two passes.

In this paper we resolve the conjecture and demonstrate the important role played by the stream order in the context of exact selection and quantile estimation. Before detailing our results, we first motivate the study of the random-order model. We believe that this motivation, coupled with the array of further questions that naturally arise, may establish a fruitful area of future research.

1.1. Motivation. In the literature to date, it is usually assumed that the stream to be processed is ordered by an omnipotent adversary that knows the algorithm and the set of elements in the stream. In contrast to the large body of work on adversarially ordered streams, the random-order model has received little explicit attention to date. Aside from the aforementioned work by Munro and Paterson [21] and Guha, McGregor, and Venkatasubramanian [14], the only other results were given by Demaine, López-Ortiz, and Munro [5] in a paper about frequency estimation. However, there are numerous motivations for considering this model.

First, the random-order model gives rise to a natural notion of *average-case analysis* which explains why certain data-stream problems may have prohibitive space lower bounds while being typically solvable in practice. When evaluating a permutation invariant function f on a stream, we observe that there are two orthogonal components to an instance: the set of data items in the stream, $\mathcal{O} = \{x_1, x_2, \ldots, x_n\}$, and π, the permutation of $\{1, 2, \ldots, n\}$ that determines the ordering of the stream. Since f is permutation invariant, $\mathcal{O}$ determines the value of f. One approach when designing algorithms is to make an assumption about $\mathcal{O}$ such as that the set of items is distributed according to a Gaussian distribution. While this approach has its merits, because we are trying to compute something about $\mathcal{O}$ it is often difficult to find a suitable assumption that would allow small-space computation while not directly implying the value of the function. We take an alternative view and, rather than making assumptions about $\mathcal{O}$, we consider which problems can be solved, with high probability, when the data items are ordered randomly. This approach is an average-case analysis, where π is chosen uniformly from all possible permutations while $\mathcal{O}$ is chosen worst case.

Second, if we consider π to be determined by an adversary, a natural complexity question is the relationship between the power of the adversary and the resources required to process a stream. If we impose certain computational constraints on the adversary, a popular idea in cryptography, how does this affect the space and time required to process the stream?

Lastly, there are situations in which it is reasonable to assume the stream is not ordered adversarially. These include the following scenarios, where the stream order is random either by design, by definition, or because of the semantics of data:

1. *Random by definition:* A natural setting in which a data stream would be ordered randomly is if each element of the stream is a sample drawn independently from some unknown distribution. Regardless of the source distribution, given the set of n samples, each of the $n!$ permutations of the sequence of samples was equally likely. Density estimation algorithms that capitalized on this were presented by Guha and McGregor [13].
2. *Random by semantics:* In other situations the semantics of the data in the stream may imply that the stream is randomly ordered. For example, consider

a database of employee records in which the records are sorted by surname. We wish to estimate some property of the employee salaries given a stream of ⟨surname, salary⟩ tuples. If there is no correlation between the lexicographic ordering of the surnames and the numerical ordering of salaries, then the salary values are ordered uniformly at random. We note that several query optimizers make such assumptions.

3. *Random by design:* Lastly, there are some scenarios in which we dictate the order of the stream. Naturally we can therefore ensure it is nonadversarial! An example is the "backing sample" architecture proposed by Gibbons and coworkers [7, 8] for maintaining accurate estimates of aggregate properties of a database. A large sample is stored on the disk and this sample is used to periodically correct estimates of the relevant properties.

1.2. Our contributions. We start with the following algorithmic results which are proved in section 3:

1. A single-pass algorithm using $O(\log n)$ space that, given any k, returns an element of rank $k \pm O(k^{1/2} \log^2 n \log \delta^{-1})$ with probability at least $1 - \delta$ if the stream is randomly ordered. The algorithm does not require prior knowledge of the length of the stream.
2. An algorithm using $O(\text{polylog}\, n)$ space that performs exact selection in only $O(\log \log n)$ passes. This was conjectured by Munro and Paterson [21] but has been unresolved for over 30 years.

In section 4, we introduce two notions of the order of the stream being "semi-random." The first is related to the computational power of an adversary ordering the stream, and the second is related to the random process that determines the order. We show how the performance of our algorithms degrades as the randomness of the order decreases according to either notion. These notions of semirandomness will also be critical for proving lower bounds in the random-order model. In sections 5 and 6, we prove the following lower bounds:

1. Any algorithm that returns an n^δ-approximate median, i.e., an element with rank $n/2 \pm n^\delta$, in the single-pass random-order model with probability at least $9/10$ requires $\Omega(\sqrt{n^{1-3\delta}/\log n})$ space. This is the first unqualified lower bound in this model. Previously, all that was known was that a single-pass algorithm that maintained a set of elements whose ranks (among the elements read thus far) are consecutive and as close to the current median as possible, required $\Omega(\sqrt{n})$ space to find the exact median in the random-order model [21]. Our result, which is fully general, uses a reduction from communication complexity but deviates significantly from the usual form of such reductions because of the novel challenges arising when proving a lower bound in the random-order model. We believe the techniques used will be useful in proving average-case lower bounds for a variety of data-stream problems.
2. Any algorithm that returns an n^δ-approximate median in p passes of an adversarially ordered stream requires $\Omega(n^{(1-\delta)/p} p^{-6})$ space. In particular, this implies that in the adversarial-order model any $O(\text{polylog}\, n)$-space algorithm for exact selection must use $\Omega(\log n / \log \log n)$ passes. This is established via a new bound on the communication complexity of a natural pointer-chasing style problem. The best previous result showed that any deterministic, comparison-based algorithm for exact selection required $\Omega(n^{1/p})$ space for constant p [21]. This resolves the conjecture of Kannan and establishes that existing multipass algorithms are optimal up to terms polynomial in p.

1.3. Related work on quantile estimation. Quantile estimation is perhaps the most extensively studied problem in the data-stream model [3,4,9,10,15,19,20,23]. Manku, Rajagopalan, and Lindsay [19,20] showed that we can find an element of rank $k \pm \epsilon n$ using $O(\epsilon^{-1} \log^2 \epsilon n)$ space, where n is the length of the stream and k is user specified. This was improved to a deterministic, $O(\epsilon^{-1} \log \epsilon n)$-space algorithm by Greenwald and Khanna [10]. Gilbert et al. [9] gave an algorithm for the model in which elements may also be "deleted" from the stream. Shrivastava et al. [23] presented another deterministic algorithm for insert-only streams that uses $O(\epsilon^{-1} \log U)$ space, where U is the size of the domain from which the input is drawn. Gupta and Zane [15] and Cormode et al. [3] presented algorithms for estimating *biased quantiles*, i.e., algorithms that return an element of rank $k \pm \epsilon k$ for any $k \in \{1, \ldots, n\}$. We note that all these algorithms are for the adversarial-order model and therefore are not designed to take advantage of a weak, or absent, adversary.

1.4. Recent developments. Since the initial submission of this paper, there has been follow-up work that presents lower bounds on the space required for multi-pass algorithms for randomly ordered data streams [1,2]. In particular, it was shown that any $O(\text{polylog}\, n)$-space algorithm that returns the median of a randomly ordered stream of length n with probability at least $9/10$ requires $\Omega(\log \log n)$ passes. Other problems were also considered in the random-order model, including estimating frequency moments, graph connectivity, and measuring information divergences [1].

2. Notation and preliminaries. Let $[n] = \{1, \ldots, n\}$. Let Sym_n be the set of all $n!$ permutations of $[n]$. We say $a = b \pm c$ if $|a - b| \leq c$ and write $a \in_R S$ to indicate that a is chosen, uniformly at random, from the set S. The next definition clarifies the rank of an element in a multiset.

DEFINITION 2.1 (rank and approximate selection). *The rank of an item x in a set S is defined as*

$$\text{RANK}_S(x) = |\{x' \in S | x' < x\}| + 1 \ .$$

Assuming there are no duplicate elements in S, we say x is an Υ-approximate k-rank element if $\text{RANK}_S(x) = k \pm \Upsilon$. If there are duplicate elements in S, we say x is an Υ-approximate k-rank element if there exists some way of breaking ties such that x is an Υ-approximate k-rank element.

At various points we will appeal to less common variants of Chernoff–Hoeffding bounds that pertain to sampling without replacement.

THEOREM 2.2 (Hoeffding [16]). *Consider a population C consisting of N values $\{c_1, \ldots, c_N\}$. Let the mean value of the population be $\mu = N^{-1} \sum_{i=1}^{N} c_i$ and let $c_{\max} = \max_{i \in N} c_i - \min_{i \in N} c_i$. Let $X_1, \ldots, X_n$ be a sequence of independent samples* without replacement *from C and $\bar{X} = n^{-1} \sum_{i=1}^{n} X_i$. Then,*

$$\Pr\left[\bar{X} \notin (\mu - a, \mu + b)\right] \leq \exp\left(-2na^2/{c_{\max}}^2\right) + \exp\left(-2nb^2/{c_{\max}}^2\right) \ .$$

The following corollary will also be useful. If $c_i = 1$ for $i \in [k]$ and 0 otherwise, then

$$\Pr\left[\bar{X} \notin (\mu - a, \mu + b)\right] \leq \exp\left(-2a^2n^2/k\right) + \exp\left(-2b^2n^2/k\right) \ .$$

3. Algorithms for random-order streams. In this section we show how to perform approximate selection of the kth smallest element in a single pass over a

Selection Algorithm:
1. Let $a = -\infty, b = +\infty$, and

$$\begin{aligned}\Upsilon &= 20\ln^2(n)\ln(\delta^{-1})\sqrt{k}\\ p &= 4(\log_{4/3}(n/\Upsilon) + (\ln(3/\delta)\log_{4/3}(n/\Upsilon))^{1/2})\\ l_1 &= n\Upsilon^{-1}\ln(3n^2p/\delta)\\ l_2 &= 2(n-1)\Upsilon^{-1}\sqrt{(k+\Upsilon)\ln(6np/\delta)}\end{aligned}$$

2. Partition stream as $S = \langle S_1, E_1, \ldots, S_p, E_p\rangle$ where $|S_i| = l_1$ and $|E_i| = l_2$
3. Phase $i \in [p]$:
(a) *Sample*: If $S_i \cap (a,b) = \emptyset$, return a, else let u be first element in $S_i \cap (a,b)$
(b) *Estimate*: Compute $r = \textsc{Rank}_{E_i}(u)$ and let $\tilde{r} = (n-1)(r-1)/l_2 + 1$
(c) *Update*: If $\tilde{r} < k - \Upsilon/2$, $a \leftarrow u$, $\tilde{r} > k + \Upsilon/2$, $b \leftarrow u$, else return u

FIG. 3.1. *The selection algorithm.*

randomly ordered stream of length n. As we are interested in massive data streams, we consider the space complexity and accuracy guarantees of the algorithm as n becomes large.

DEFINITION 3.1 (random order). *Consider a set of elements* $x_1, \ldots, x_n \in [\text{poly}(n)]$. *Then this set and* $\pi \in \text{Sym}_n$ *define a stream* $S = \langle x_{\pi(1)}, \ldots, x_{\pi(n)}\rangle$. *If* π *is chosen uniformly from* Sym_n, *then we say the stream is in* random order.

We will present the algorithm, assuming the exact value of the length of the stream, n, is known in advance. In a subsequent section, we will show that this assumption is not necessary. In what follows, we will assume that the stream contains distinct values. This can easily be achieved with probability at least $1-\delta$ by attaching a secondary value $y_i \in_R [n^2\delta^{-1}]$ to each item x_i in the stream. We say $(x_i, y_i) < (x_j, y_j)$ iff $x_i < x_j$ or $(x_i = x_j$ and $y_i < y_j)$. Note that breaking the ties arbitrarily results in a stream whose order is not random. We also may assume that $k \le n/2$ by symmetry.

3.0.1. Algorithm overview. Our algorithm proceeds in phases and each phase is composed of the following three distinct subphases: the *sample* subphase, the *estimate* subphase, and the *update* subphase. At all points, we maintain an open interval (a,b) such that we believe that the value of the element with rank k is between a and b. In each phase we aim to narrow the interval (a,b). The sample subphase finds a value $u \in (a,b)$. The estimate subphase estimates the rank of u. The update subphase replaces a or b by u depending on whether the rank of u is believed to be less than or greater than k. See Figure 3.1 for the algorithm.

3.0.2. Analysis. For the analysis we define the following quantity:

$$\Gamma(a,b) = |S \cap (a,b)| = |\{v \in S : a < v < b\}| \ .$$

LEMMA 3.2. *With probability* $1 - \delta/3$, *for all phases, if* $\Gamma(a,b) \ge \Upsilon$, *then there exists an element* u *in each sample subphase, i.e.,*

$$\Pr[\forall\ i \in [p] \text{ and } a, b \in S \text{ such that } \Gamma(a,b) \ge \Upsilon; S_i \cap (a,b) \ne \emptyset] \ge 1 - \delta/3 \ .$$

Proof. Fix $i \in [p]$ and $a, b \in S$ such that $\Gamma(a,b) \geq \Upsilon$. Then,

$$\Pr[S_i \cap (a,b) \neq \emptyset] \geq 1 - \left(1 - \frac{\Gamma(a,b)}{n}\right)^{l_1} \geq 1 - \exp\left(\frac{-\Upsilon l_1}{n}\right) = 1 - \frac{\delta}{3n^2p} \ .$$

The result follows by applying the union bound over all choices of i, a, and b. ∎

LEMMA 3.3. *With probability $1-\delta/3$, for all phases, we determine the rank of u with sufficient accuracy, i.e.,*

$$\Pr\left[\forall i \in [p],\ u \in S;\ \begin{array}{ll} \tilde{r} = \textsc{Rank}_S(u) \pm \Upsilon/2 & \text{if } \textsc{Rank}_S(u) < k + \Upsilon + 1 \\ \tilde{r} > k + \Upsilon/2 & \text{if } \textsc{Rank}_S(u) \geq k + \Upsilon + 1 \end{array}\right] \geq 1 - \delta/3 \ ,$$

where $\tilde{r} = (n-1)(\textsc{Rank}_{E_i}(u) - 1)/l_2 + 1$.

Proof. Fix $i \in [p]$ and $u \in S$. First, we consider u such that $\textsc{Rank}_S(u) < k+\Upsilon+1$. Let $X = \textsc{Rank}_{E_i}(u) - 1$ and note that $E[X] = l_2(\textsc{Rank}_S(u) - 1)/(n-1)$. Appealing to the second part of Theorem 2.2,

$$\begin{aligned} \Pr[\tilde{r} \neq \textsc{Rank}_S(u) \pm \Upsilon/2] = &\ \Pr\left[|X - E[X]| \geq \frac{l_2\Upsilon}{2(n-1)}\right] \\ \leq &\ 2\exp\left(\frac{-2(l_2\Upsilon/(2(n-1)))^2}{\textsc{Rank}_S(u) - 1}\right) \\ \leq &\ \frac{\delta}{3np} \ , \end{aligned}$$

where the last inequality follows because $(l_2\Upsilon/(2(n-1)))^2 = (k+\Upsilon)\ln(6np/\delta)$ (by definition of l_2) and $\textsc{Rank}_S(u) - 1 < k + \Upsilon$ (by assumption). Now assume that $\textsc{Rank}_S(u) \geq k + \Upsilon + 1$ and note that $\Pr[\tilde{r} \geq k + \Upsilon/2]$ is minimized for $\textsc{Rank}_S(u) = k + \Upsilon + 1$. Hence,

$$\begin{aligned} \Pr[\tilde{r} > k + \Upsilon/2] = &\ 1 - \Pr\left[E[X] - X \geq \frac{l_2\Upsilon}{2(n-1)}\right] \\ \geq &\ 1 - \exp\left(-\frac{(l_2\Upsilon)^2}{4(k+\Upsilon)(n-1)^2}\right) \\ = &\ 1 - \frac{\delta}{6np} \ . \end{aligned}$$

The result follows by applying the union bound over all choices of i and u. ∎

We now give the main theorem of this section.

THEOREM 3.4. *For $k \in [n]$, there exists a single-pass, $O(\log n)$-space algorithm in the random-order model that returns u such that $\textsc{Rank}_S(u) = k \pm 20\ln^2(n)\ln(\delta^{-1})\sqrt{k}$ with probability at least $1-\delta$.*

Proof. Consider $\Gamma(a,b) = |\{v \in S : a < v < b\}|$ in each phase of the algorithm. By Lemmas 3.2 and 3.3, with probability at least $1 - 2\delta/3$, in every phase, if we do not terminate, then $\Gamma(a,b)$ decreases and $\textsc{Rank}_S(a) \leq k \leq \textsc{Rank}_S(b)$. In particular, in each phase, with probability $1/4$, either we terminate or $\Gamma(a,b)$ decreases by at least a factor of $3/4$. Let Y be the number of phases in which $\Gamma(a,b)$ decreases by a factor of $3/4$. If the algorithm does not terminate, then $Y < \log_{4/3}(n/\Upsilon)$ since $\Gamma(a,b)$ is initially n and the algorithm will terminate if $\Gamma(a,b) < \Upsilon$. But,

$$\Pr\left[Y < \log_{4/3}(n/\Upsilon)\right] = \Pr\left[Y < E[Y] - \sqrt{\ln(3/\delta)\log_{4/3}(n/\Upsilon)}\right] \leq \delta/3 \ .$$

Hence with probability at least $1-\delta$ the algorithm returns a value with rank $k \pm \Upsilon$.

The space bound follows immediately from the fact that the algorithm only stores a constant number of polynomially sized values and maintains a counter that stores values in the range $[n]$. Finally, for sufficiently large n,

$$p(l_1+l_2) \leq 20\ln^2(n)\ln(\delta^{-1})n\Upsilon^{-1}\sqrt{k} = n,$$

and hence the stream is sufficiently long for all the phases to complete. □

3.1. Generalizing to unknown stream lengths. The algorithm in the previous section assumed prior knowledge of n, the length of the stream. We now discuss a simple way to remove this assumption. First we argue that, for our purposes, it is sufficient to look at only half the stream.

LEMMA 3.5. *Given a randomly ordered stream S of length n, let S' be a contiguous substream of length $\tilde{n} \geq n/2$. Then, with probability at least $1-\delta$, if u is the $\tilde{k}$th smallest element of S', then* $\text{RANK}_S(u) = \tilde{k}n/\tilde{n} \pm 2(8\tilde{k}\ln\delta^{-1})^{0.5}$.

Proof. Let $a = \tilde{k}/\tilde{n}$. Let the elements in the stream be $x_1 \leq \cdots \leq x_n$. Let $X = |\{x_1,\ldots,x_{an+b}\} \cap S'|$ and $Y = |\{x_1,\ldots,x_{an-b-1}\} \cap S'|$, where $b = 2(8\tilde{k}\ln\delta^{-1})^{0.5}$. The probability that the element of rank $\tilde{k} = a\tilde{n}$ in S' has rank in S outside the range $[an-b, an+b]$ is less than

$$\begin{aligned}\Pr[X < a\tilde{n} \text{ or } Y > a\tilde{n}] \leq\ & \Pr[X < E[X] - b/2 \text{ or } Y > E[Y] + b/2] \\ \leq\ & 2\exp\left(\frac{-(b/2)^2}{3(a\tilde{n}+b)}\right) \leq \delta\ .\end{aligned}$$

The lemma follows. □

To remove the assumption that we know n, we make multiple instantiations of the algorithm. Each instantiation corresponds to a guess of n. Let $\beta = 1.5$. Instantiation i guesses a length of $\lceil 4\beta^i \rceil - \lfloor \beta^i \rfloor + 1$ and is run on the stream starting with the $\lfloor \beta^i \rfloor$th data item and ending with the $\lceil 4\beta^i \rceil$th data item. We remember the result of the algorithm until the $2(\lceil 4\beta^i \rceil - \lfloor \beta^i \rfloor + 1)$th element arrives. We say the instantiation has been canceled at this point.

LEMMA 3.6. *At any time, there is only a constant number of instantiations. Furthermore, when the stream terminates, at least one instantiation has run on a substream of at least $n/2$.*

Proof. Consider the tth element of the data stream. By this point there have been $O(\log_\beta t)$ instantiations made. However, $\Omega(\log_\beta t/6)$ instantiations have been canceled. Hence $O(\log_\beta t - \log_\beta t/6) = O(1)$ instantiations are running. We now show that there always exists an instantiation that has been running on at least half the stream. The ith instantiation gives a useful result if the length of the stream $n \in U_i = \{\lfloor 4\beta^i \rfloor + 1, \ldots, 2(\lceil 4\beta^i \rceil - \lfloor \beta^i \rfloor + 1)\}$. But $\bigcup_{i\geq 0} U_i = \mathbb{N} \setminus \{0,1,2,3,4\}$ since for all $i > 1$, $\lfloor 4\beta^i + 1 \rfloor \leq 2(\lceil 4\beta^{i-1} \rceil - \lfloor \beta^{i-1} \rfloor + 1)$. □

We can therefore generalize Theorem 3.4 as follows.

THEOREM 3.7. *For $k \in [n]$, there exists a single-pass, $O(\log n)$-space algorithm in the random-order model that returns u such that* $\text{RANK}_S(u) = k \pm 11\ln^2(n)\ln(\delta^{-1})\sqrt{k}$ *with probability at least $1-\delta$. The algorithm need not know n in advance.*

3.2. Multipass exact selection. In this section we consider the problem of exact selection of an element of rank $k = \Omega(n)$. We will later show that this requires $\Omega(\sqrt{n})$ space if an algorithm is permitted only one pass over a stream in random order. However, if $O(\log\log n)$ passes are permitted, we now show that $O(\text{polylog}\, n)$

space is sufficient. We will again assume that the elements in the stream are distinct but we note that it is not difficult to avoid this assumption.

We use a slight variant of the single-pass algorithm in section 3 as a building block. Rather than returning a single candidate, we output the pair a and b. Using the analysis in section 3, it can be shown that, with probability $1-\delta$, $\textsc{Rank}_S(a) < k < \textsc{Rank}_S(b)$ and that

$$|\textsc{Rank}_S(a) - \textsc{Rank}_S(b)| \le O(\sqrt{n}\log^2 n \log \delta^{-1}) \ .$$

In one additional pass, $\textsc{Rank}_S(a)$ and $\textsc{Rank}_S(b)$ can be computed exactly. Hence, after two passes, by ignoring all elements outside the range (a,b), we have reduced the problem to that of finding an element of rank $k - \textsc{Rank}_S(a)$ in a stream of length $O(\sqrt{n}\log^3 n)$ if we assume that $\delta^{-1} = \text{poly}(n)$. If we repeat this process $O(\log\log n)$ times and then select the desired element by explicitly storing the remaining $O(\text{polylog}\, n)$-length stream, it would appear that we can perform exact selection in $O(\text{polylog}\, n)$ space and $O(\log\log n)$ passes. However, there is one crucial detail that needs to be addressed.

In the first pass, by assumption we are processing a data stream whose order is chosen uniformly from Sym_n. However, because the stream order is not rerandomized between each pass, it is possible that the previous analysis does not apply because of dependencies that may arise between different passes. Fortunately, the following straightforward, but necessary, observation demonstrates that this is not the case.

FACT 3.8. *Let a and b, respectively, be the lower and upper bound returned after a pass of the algorithm on the stream $\langle x_1, \ldots, x_n\rangle$. Let $\pi \in \text{Sym}_n$ satisfy $i = \pi(i)$ for all $i \in [n]$ such that $x_i \notin (a,b)$. Then the algorithm also would return the same bounds after processing the stream $\langle x_{\pi(1)}, \ldots, x_{\pi(n)}\rangle$.*

Therefore, conditioned on the algorithm returning a and b, the substream of elements in the range (a,b) are still ordered uniformly. This leads to the following theorem.

THEOREM 3.9. *For $k \in [n]$, there exists an $O(\text{polylog}\, n)$-space, $O(\log\log n)$-pass algorithm in the random-order model that returns the kth smallest value of a stream with probability $1 - 1/\text{poly}(n)$.*

3.3. Applications to equidepth histograms. In this section we briefly overview an application to constructing B-bucket equidepth histograms. Here, the histogram is defined by B buckets whose boundaries are defined by the items of rank $in/(B+1)$ for $i \in [B]$. Gibbons, Matias, and Poosala [8] consider the problem of constructing an approximate B-bucket equidepth histogram of data stored in a backing sample. The measure of "goodness of fit" they consider is

$$\mu = n^{-1}\sqrt{B^{-1}\sum_{i\in[B]}\epsilon_i^2} \ ,$$

where ϵ_i is the error in the rank of the boundary of the ith bucket. They show that μ can be made smaller than any $\epsilon > 0$ where the space used depends on ϵ. However, in their model it is possible to ensure that the data are stored in random order. As a consequence of the algorithm in section 3, we get the following theorem.

COROLLARY 3.10. *In a single pass over a backing sample of size n stored in random order, we can compute the B quantiles of the samples using $O(B\log n)$ memory with error $\tilde{O}(n^{-1/2})$. Since the error goes to zero as the sample size increases, we have the first consistent estimator for this problem.*

4. Semirandom order. In this section we consider two natural notions of "semirandom" ordering and explain how our algorithm can be adjusted to process streams whose order is semirandom under either definition. The first notion is stochastic in nature: we consider the distribution over orders which are "close" to the uniform order in terms of the variational distance. This will play a critical role when proving lower bounds.

DEFINITION 4.1 (ϵ-generated-random order). *Given set $\{x_1, \ldots, x_n\}$, $\pi \in \mathrm{Sym}_n$ defines a stream $\langle x_{\pi(1)}, \ldots, x_{\pi(n)} \rangle$. We say the order is* ϵ-generated random *(ϵ-GR) if π is chosen according to a distribution ν such that $\|\mu - \nu\|_1 \leq \epsilon$, where μ is the uniform distribution on* Sym_n.

The importance of this definition is captured in the following simple lemma.

LEMMA 4.2. *Let $\mathcal{A}$ be a randomized algorithm that succeeds (i.e., returns an estimate of some property with some accuracy guarantee) with probability at least $1 - \delta$ in the random-order model. Then $\mathcal{A}$ succeeds with probability at least $1 - \delta - \epsilon$ when the stream order is ϵ-GR.*

Proof. Let $\Pr_{\mu,\mathrm{coin}}[\cdot]$ denote the probability of an event over the internal coin tosses of $\mathcal{A}$ and the ordering of the stream when the stream order is chosen according to the uniform distribution μ. Similarly, define $\Pr_{\nu,\mathrm{coin}}[\cdot]$, where ν is any distribution satisfying $\|\mu - \nu\|_1 \leq \epsilon$:

$$\Pr_{\mu,\mathrm{coin}}[\mathcal{A} \text{ succeeds}] = \sum_{\pi \in \mathrm{Sym}_n} \Pr_{\mu}[\pi] \Pr_{\mathrm{coin}}[\mathcal{A} \text{ succeeds} | \pi] \leq \Pr_{\nu,\mathrm{coin}}[\mathcal{A} \text{ succeeds}] + \epsilon \ .$$

The lemma follows since $\Pr_{\mu,\mathrm{coin}}[\mathcal{A} \text{ succeeds}] \geq 1 - \delta$ by assumption. ∎

The next theorem follows immediately from Theorem 3.4 and Lemma 4.2.

THEOREM 4.3. *For $k \in [n]$, there exists a single-pass, $O(\log n)$-space algorithm in the ϵ-GR-order model that returns u such that $\mathrm{RANK}_S(u) = k \pm 11 \ln^2(n) \ln(\delta^{-1}) \sqrt{k}$ with probability at least $1 - \delta - \epsilon$.*

The second definition is computational in nature. We consider an adversary upstream of our algorithm that can reorder the elements subject to having limited memory to do this reordering.

DEFINITION 4.4 (t-bounded-adversary-random order). *A* t-bounded adversary *is an adversary that can only delay at most t elements at a time; i.e., when presented with a stream $\langle x_1, \ldots, x_n \rangle$, it can ensure that the received stream is $\langle x_{\pi(1)}, \ldots, x_{\pi(n)} \rangle$ if $\pi \in \mathrm{Sym}_n$ satisfies*

$$\forall i \in [n], |\{i < j \leq n : \pi(j) < \pi(i)\}| \leq t \ . \tag{4.1}$$

The order of a stream is t-bounded-adversary-random (t-BAR) if it is generated by a t-bounded adversary acting on a stream whose order is random.

For example, a 2-bounded adversary acting on the stream $\langle 1, 2, 3, 4, 5, 6, 7, 8, 9 \rangle$ can transform it into $\langle 3, 2, 1, 6, 5, 4, 9, 8, 7 \rangle$ or $\langle 3, 4, 5, 6, 7, 8, 9, 1, 2 \rangle$ but can not generate $\langle 9, 8, 7, 6, 5, 4, 3, 2, 1 \rangle$. In particular, in the adversarial-order model the stream order is $(n-1)$-BAR, while in the random-order model the order is 0-BAR.

LEMMA 4.5. *Consider streams $\langle x_1, \ldots, x_n \rangle$ and $\langle x_{\pi(1)}, \ldots, x_{\pi(n)} \rangle$, where π satisfies* (4.1). *Then for any $j, w \in [n]$, $|\{x_j, \ldots, x_{j+w-1}\} \cap \{x_{\pi(j)}, \ldots, x_{\pi(j+w-1)}\} \geq w - 2t$.*

We assume that $t \leq \sqrt{k}$. Given the above lemma, it is straightforward to transform the algorithm of the previous section into one that is correct (with prescribed probability) when processing a stream in t-BAR order. In particular, it is sufficient

to set $l_1 = O(n\Upsilon^{-1}\ln(3n^2p/\delta) + t\delta^{-1})$ and to choose a random u among $S_i \cap (a,b)$ in each sample phase. Note that $l_1 < l_2$ for $t \le \sqrt{k}$. In each estimate phase a t-bounded adversary can introduce an extra $2nt/l_2 \le t\Upsilon/\sqrt{k} \le \Upsilon$ error. Hence, the total error is at most 2Υ.

THEOREM 4.6. *For $k \in [n]$, there exists a single-pass, $O(\log n)$-space algorithm in the t-BAR-order model that returns u such that* $\text{RANK}_S(u) = k \pm 20\ln^2(n)\ln(\delta^{-1})\sqrt{k}$ *with probability at least $1-\delta$.*

5. Random-order lower bound. In this section we will prove a lower bound on the space required to n^δ approximate the median in the single-pass, random-order model. Our lower bound will be based on a reduction from the communication complexity of indexing [18]. However, the reduction is significantly more involved than typical reductions because different segments of a stream cannot be determined independently by different players if the stream is in random order.

Consider two players Alice and Bob, where Alice has a binary string σ of length s and Bob has an index $r \in [s]$, where s will be determined later. It is known that for Bob to determine $\text{INDEX}(\sigma, r) = \sigma_r$ after a single message from Alice with probability at least $4/5$, this message must consist of $\Omega(s)$ bits.

THEOREM 5.1 (see, e.g., [18]). $R_{1/5}^{1-\text{way}}(\text{INDEX}) \ge c^* s$ *for some constant $c^* > 0$.*

We start by assuming that there exists an algorithm $\mathcal{A}$ that computes an n^δ-approximate median in the single-pass, random-order model with probability at least $9/10$. We then use this to construct a one-way communication protocol that will allow Alice and Bob to solve their INDEX problem. They do this by simulating $\mathcal{A}$ on a stream of length n, where Alice determines a long prefix of the stream and Bob determines the remaining elements. For convenience we assume n is even and consider the median to be the element of rank $n/2$. The stream they construct consists of the union of the following sets of elements:

X: A size x set consisting of $n/2 + n^\delta - (2n^\delta + 1)r$ copies of 0.

Y: A size y set consisting of $n/2 - n^\delta - (2n^\delta + 1)(s - r)$ copies of $2s + 2$.

Z: A size $z = (2n^\delta + 1)s$ set consisting of $2n^\delta + 1$ copies of $\{2i + \sigma_i : i \in [s]\}$.

Note that any n^δ-approximate median of $U = S \cup X \cup Y$ is $2r + \sigma_r$. The difficulty we face is that we may only assume $\mathcal{A}$ returns an n^δ-approximate median of U if U is ordered randomly. Ensuring this seems to require a significant amount of communication between Alice and Bob. How else can Alice determine the balance of elements from X and Y in the prefix of the stream or can Bob know the elements of Z that should appear in the suffix of the stream?

In what follows we will argue that by carefully choosing the length of the prefix, suffix, and s, it is possible for Alice and Bob to ensure that the ordering of the stream is $1/20$-GR, while only communicating a sufficiently small number of bits with probability at least $19/20$. Then, by appealing to Lemma 4.2, we may assume that the protocol is correct with probability at least $4/5$.

5.1. Generating a stream in semirandom order. Let A be the set of elements in the prefix of the stream which is determined by Alice. Let $B = U \setminus A$ be the set of elements in the remaining part of the stream which is determined by Bob. Roughly speaking, A will consist of $n - \tilde{\Theta}(n^{1-\delta})$ of the stream elements, including most of the elements from Z. The number of elements from X and Y will be determined on the assumption that $x = y$. B will consist of the remaining $\tilde{\Theta}(n^{1-\delta})$ elements from $X \cup Y \cup Z$. The intuition is that if B is too large, then B will contain too many elements from Z whereas, if B is too small, the assumption that $x = y$ in

the determination of A will be problematic when it comes to arguing that the order of the stream is nearly random.

Let $p = c^*/(8n^\delta \log n)$ and consider the following protocol:

1. Alice determines $A \cap Z$ and $B \cap Z$ by placing an element from Z into B with probability p, and placing it in A otherwise. Alice picks t_0 according to $T_0 \sim \mathrm{Bin}(n/2-z, 1-p)$ and t_1 according to $T_1 \sim \mathrm{Bin}(n/2-z, 1-p)$. She places t_0 copies of 0 and t_1 copies of $2s+2$ into A. She sends a message encoding $B \cap Z$, t_0, t_1, and the memory state of $\mathcal{A}$ run on a random permutation of A.
2. Bob instantiates $\mathcal{A}$ with memory state sent by Alice and continues running it on a random permutation of $B = (B \cap Z) \cup \{x - t_0 \text{ copies of } 0\} \cup \{y - t_1 \text{ copies of } 2s+2\}$. Finally, Bob returns 1 if the output of the algorithm is odd, and 0 otherwise.

Let ν be the distribution over stream orders generated by the above protocol. The next lemma establishes that ν is almost uniform. This will be required to prove the correctness of the algorithm.

LEMMA 5.2. *If $z = 10^{-6}\sqrt{pn}$, then $\|\mu - \nu\|_1 \le 1/20$ where μ is the uniform distribution on* Sym_n.

Proof. Define the random variables $T_0' \sim \mathrm{Bin}(x, 1-p)$ and $T_1' \sim \mathrm{Bin}(y, 1-p)$ and let $a_0 = x - n/2 + z$ and $a_1 = y - n/2 + z$. Note that $a_0, a_1 \ge 0$ and $a_0 + a_1 = z$. We upper bound $\|\mu - \nu\|_1$ as follows:

$$\begin{aligned}\|\mu - \nu\|_1 &= \sum_{t_0,t_1} |\Pr[T_0 = t_0, T_1 = t_1] - \Pr[T_0' = t_0, T_1' = t_1]| \\ &\le \max_{\substack{t_0 \in (1-p)x \pm b^* \\ t_1 \in (1-p)y \pm b^*}} \left| \frac{\Pr[T_0 = t_0, T_1 = t_1]}{\Pr[T_0' = t_0, T_1' = t_1]} - 1 \right| \\ &\qquad + \Pr[\max\{|T_0 - E[T_0]|, |T_1 - E[T_1]|\} \ge b^* - pz] \\ &\qquad + \Pr[\max\{|T_0' - E[T_0']|, |T_1' - E[T_1']|\} \ge b^*],\end{aligned}$$

where $b^* = 10\sqrt{pn/2} + pz$. By the Chernoff bound,

$$\begin{aligned}&\Pr[\max\{|T_0 - E[T_0]|, |T_1 - E[T_1]|\} \ge b^* - pz] \\ &\quad + \Pr[\max\{|T_0' - E[T_0']|, |T_1' - E[T_1']|\} \ge b^*] \le 8\exp\left(-2(b^* - pz)^2/(3pn)\right),\end{aligned}$$

and hence the (sum of the) last two terms are upper bounded by $1/40$ for sufficiently large n.

Let $t_0 = (1-p)x + b_0$ and $t_1 = (1-p)x + b_1$ and assume that $|b_0|, |b_1| \le b^*$. Then,

$$\begin{aligned}\frac{\Pr[T_0 = t_0, T_1 = t_1]}{\Pr[T_0' = t_0, T_1' = t_1]} &= \frac{\binom{n/2-z}{t_0}\binom{n/2-z}{t_1}}{\binom{x}{t_0}\binom{y}{t_1}p^z} \\ &= \left(\prod_{i \in [a_0]} \frac{xp - i + 1 - b_0}{(x-i+1)p}\right)\left(\prod_{i \in [a_1]} \frac{yp - i + 1 - b_1}{(y-i+1)p}\right),\end{aligned}$$

and therefore

$$\exp\left(\frac{-zb^*}{p(x-z)} + \frac{-zb^*}{p(y-z)}\right) \le \frac{\Pr[T_0 = t_0, T_1 = t_1]}{\Pr[T_0' = t_0, T_1' = t_1]} \le \exp\left(\frac{2z^2 + zb^*}{p(x-z)} + \frac{2z^2 + zb^*}{p(y-z)}\right).$$

Substituting z establishes that $|\Pr[T_0 = t_0, T_1 = t_1] / \Pr[T_0' = t_0, T_1' = t_1] - 1| \le 1/40$ for sufficiently large n. The lemma follows. ∎

The next lemma will be necessary to bound the communication of the protocol.

LEMMA 5.3. $\Pr[|Z \cap B| \geq c^* s/(2\log n)] \leq 1/20$ *for* $s = \omega(\log n)$.

Proof. Note that $E[|Z \cap B|] = pz \leq 3c^* s/(8\log n)$. Then, by an application of the Chernoff bound,

$$\Pr[|Z \cap B| \geq c^* s/(2\log n)] = \Pr[|Z \cap B| \geq (4/3)E[|Z \cap B|]] \leq \exp(-c^* s/(72\log n)) \ . \quad \square$$

THEOREM 5.4. *Computing an* n^δ*-approximate median in the random-order model with probability at least* $9/10$ *requires* $\Omega(\sqrt{n^{1-3\delta}/\log n})$ *space.*

Proof. Let Alice and Bob follow the above protocol to solve their instance of INDEX using $\mathcal{A}$. Assume $\mathcal{A}$ uses M bits of space. By Lemmas 4.2 and 5.2, the protocol is correct with probability at least $9/10 - 1/20 = 17/20$. Furthermore, by Lemma 5.3, with probability at least $19/20$ the protocol requires at most $3c^* s/4 + M$ bits of communication (for sufficiently large n): $c^* s/2$ bits to transmit $Z \cap B$, $2\log n$ bits to transmit t_0 and t_1, and M bits for the memory state of $\mathcal{A}$. Therefore, there exists a protocol transmitting $3c^* s/4 + M$ bits that is correct with probability at least $17/20 - 1/20 = 4/5$. Hence, by Theorem 5.1, $M = \Omega(s) = \Omega(\sqrt{n^{1-3\delta}/\log n})$. $\square$

6. Adversarial-order lower bound. In this section we prove that any p-pass algorithm that returns an n^δ-approximate median in the adversarial-order model requires $\Omega(n^{(1-\delta)/p} p^{-6})$ space. This, coupled with the upper bound of Munro and Paterson [21], will resolve the space complexity of multipass algorithms for median finding up to polylogarithmic factors. The proof will use a reduction from the communication complexity of a generalized form of pointer chasing that we now describe.

DEFINITION 6.1 (generalized pointer chasing). *For* $i \in [p]$*, let* $f_i : [m] \to [m]$ *be an arbitrary function. Then* g_p *is defined by*

$$g_p(f_1, f_2, \ldots, f_p) = f_p(f_{p-1}(\ldots(f_1(1))\ldots)) \ .$$

Let the i*th player,* P_i*, have function* f_i*, and consider a protocol in which the players must speak in the reverse order, i.e.,* $P_p, P_{p-1}, \ldots, P_1, P_p, \ldots$*. We say the protocol has* r *rounds if* P_p *communicates* r *times. Let* $R^r_\delta(g_p)$ *be the total number of bits that must be communicated in an* r *round (randomized) protocol for* P_1 *to learn* g_p *with probability at least* $1 - \delta$*.*

Note that $R^p_0(g_p) = O(p\log m)$. We will be looking at $(p-1)$-round protocols. The proof of the next result will be deferred to the next section.

THEOREM 6.2. $R^{p-1}_{1/10}(g_p) = \Omega(m/p^4 - p^2\log m)$.

The next theorem is shown by reducing generalized pointer chasing to approximate selection.

THEOREM 6.3. *Finding an* n^δ*-approximate median in* p *passes with probability at least* $9/10$ *in the adversarial-order model requires* $\Omega(n^{(1-\delta)/p} p^{-6})$ *space.*

Proof. We will show how a p-pass algorithm $\mathcal{A}$ that computes a t-approximate median of a length n stream gives rise to a p-round protocol for computing g_{p+1} when $m = ((n/(2t+1))^{1/p} + 1)/2$. If $\mathcal{A}$ uses M bits of space, then the protocol uses at most $(p^2 + p - 1)M$ bits. Hence by Theorem 6.2, this implies that $M = \Omega(m/p^6) = \Omega((n/t)^{1/p} p^{-6})$.

The reduction proceeds as follows. Consider a $(p+1)$-level, m-ary tree T, where we say v has level j if the distance between v and the closest leaf is $j - 1$. We start by defining some notation:

1. For $j \in [p+1], i_p, \ldots, i_j \in [m]$, let $v[i_p, \ldots, i_j]$ denote the i_jth child of $v[i_p, \ldots, i_{j+1}]$, where $v[]$ is the root of the tree.

S_1	S_2	S_3
$(0,0,0)\times 5(3-f_1(1))$		
	$(1,0,0)\times(3-f_2(1))$	$(1,1,f_3(1)),(1,2,f_3(2)),(1,3,f_3(3))$
	$(1,4,0)\times(f_2(1)-1)$	
	$(2,0,0)\times(3-f_2(2))$	$(2,1,f_3(1)),(2,2,f_3(2)),(2,3,f_3(3))$
	$(2,4,0)\times(f_2(2)-1)$	
	$(3,0,0)\times(3-f_2(3))$	$(3,1,f_3(1)),(3,2,f_3(2)),(3,3,f_3(3))$
	$(4,4,0)\times(f_2(3)-1)$	
$(4,0,0)\times 5(f_1(1)-1)$		

FIG. 6.1. *Reduction from pointer chasing to exact median finding. A triple of the form* (x_2,x_1,x_0) *corresponds to the numerical value* $x_2\cdot 5^2+x_1\cdot 5^1+x_0\cdot 5^0$. *Note that* $\text{median}(S_1\cup S_2\cup S_3) = f_1(1)\cdot 5^2 + f_2(f_1(1))\cdot 5^1 + f_3(f_2(f_1(1)))\cdot 5^0$.

2. Let the $(p+1)$ tuple $(h_p,\ldots,h_0)$ denote $\sum_{i=0}^{p} h_i(m+2)^i$.
3. For each internal node of level j, e.g., $v = v[i_p,\ldots,i_j]$, we associated a multi-set of elements $S(v)$ of size a_j. Let $a_1 = 2t+1$ and $a_j = (m-1)b_{j-1}$, where

$$b_{j-1} = a_{j-1} + ma_{j-2} + m^2 a_{j-3} + \cdots + m^{j-2}a_1 \ .$$

Note that $|\cup_{v\in V(T)} S(v)| = b_{p+1} = (2m-1)^p(2t+1)$. $S(v)$ contains

$$b_{j-1}(m - f_{p+2-j}(i_j)) \text{ copies of } (i_p,\ldots,i_j,0,0,\ldots 0)$$
$$\text{and } b_{j-1}(f_{p+2-j}(i_j)-1) \text{ copies of } (i_p,\ldots,i_j,m+1,0,\ldots,0),$$

where we define $i_{p+1} = 1$.
4. For a leaf node, e.g., $v = v[i_p,\ldots,i_1]$, we generate $2t+1$ copies of

$$(i_p,\ldots,i_1,f_{p+1}(i_1)) \ .$$

It can be shown by induction that any t-approximate median of $\cup_{v\in V(T)}S(v)$ equals $(g_1,g_2,\ldots,g_{p+1})$. See Figure 6.1 for the case when $p=2, m=3$, and $t=0$.

Let S_j be the union of $S(v)$ over all v in the jth layer. Note that S_j can be determined by the $(p+2-j)$th player, P_{p+2-j}, who knows the function f_{p+2-j}. The players emulate $\mathcal{A}$ on the stream $\langle S_1,S_2,\ldots,S_{p+1}\rangle$ in the standard way: P_{p+1} runs $\mathcal{A}$ on S_1, transmits the memory state to P_p, who instantiates the algorithm with the transmitted memory state and continues running $\mathcal{A}$ on S_2, etc., until p passes of the algorithm have been emulated. Note that this is a p-round protocol in which $M(p(p+1)-1)$ bits are communicated. The result follows. □

6.1. Proof of Theorem 6.2. The proof is a generalization of a proof by Nisan and Widgerson [22]. We present the entire argument for completeness. In the proof we lower bound the $(p-1)$-round distributional complexity, $D^{p-1}_{1/20}(g_p)$; i.e., we will consider a deterministic protocol and an input chosen from some distribution. The theorem will then follow by Yao's lemma [24] since

$$D^{p-1}_{1/20}(g_p) \le 2R^{p-1}_{1/10}(g_p) \ .$$

Let T be the protocol tree of a deterministic p-round protocol. We consider the input distribution, where each f_i is chosen uniformly from F, the set of all m^m functions from $[m]$ to $[m]$. Note that this distribution over inputs gives rise to a distribution over paths from the root of T to the leaves. We will assume that in round j, P_i's message includes g_{j-1} if $i > j$ and g_j if $i \leq j$; e.g., for $p = 4$ the appended information is shown in the following table, where $g_0 = 1$.

	Round 1				Round 2				Round 3			
Player	4	3	2	1	4	3	2	1	4	3	2	1
Appended	g_0	g_0	g_0	g_1	g_1	g_1	g_2	g_2	g_2	g_3	g_3	-

This is possible with only $O(p^2 \log m)$ extra communication. Consequently we may assume that at each node, at least $\lg m$ bits are transmitted. We will assume that protocol T requires at most $\epsilon m/2$ bits of communication, where $\epsilon = 10^{-4}(p+1)^{-4}$, and derive a contradiction.

Consider a node z in the protocol tree of T corresponding to the jth round of the protocol when it is P_i's turn to speak. Let g_{t-1} be the appended information in the last transmission. Note that $g_0, g_1, \ldots, g_{t-1}$ are specified by the messages so far.

Denote the set of functions $f_1 \times \cdots \times f_p$ that are consistent with the messages already sent be $F_1^z \times \cdots \times F_p^z$. Note that the probability of arriving at node z is $|F|^{-p} \prod_{1 \leq j \leq p} |F_j^z|$. Also note that, conditioned on arriving at node z, $f_1 \times \cdots \times f_p$ is uniformly distributed over $F_1^z \times \cdots \times F_p^z$.

DEFINITION 6.4. *Let c_z be the total communication until z is reached. We say a node z in the protocol tree is* nice *if, for $\delta = \max\{4\sqrt{\epsilon}, 400\epsilon\}$, it satisfies the following two conditions:*

$$|F_j^z| \geq 2^{-2c_z}|F| \text{ for } j \in [p] \quad \text{and} \quad H(f_t^z(g_{t-1})) \geq \lg m - \delta \ ,$$

where $H(\cdot)$ is the binary entropy.

CLAIM 1. *Given the protocol reaches node z and z is nice,*

$$\Pr[\text{next node visited is nice}] \geq 1 - 4\sqrt{\epsilon} - 1/m \ .$$

Proof. Let w be a child of z and let $c_w = c_z + a_w$. For $l \neq i$ note that $|F_l^w| = |F_l^z|$ since P_l did not communicate at node z. Hence the probability that we reach node w given that we have reached z is $\prod_{1 \leq j \leq p} |F_j^w|/|F_j^z| = |F_i^w|/|F_i^z|$. Furthermore, since z is nice,

$$\Pr\left[|F_i^w| < 2^{-2c_w}|F|\right] \leq \Pr\left[\frac{|F_i^w|}{|F_i^z|} < 2^{-2a_w}\right] \leq \sum_w 2^{-2a_w} \leq \frac{1}{m} \sum_w 2^{-a_w} \leq \frac{1}{m},$$

where the second-to-last inequality follows from $a_w \geq \lg m$ and the last inequality follows by Kraft's inequality. Hence, with probability at least $1 - 1/m$, the next node in the protocol tree satisfies the first condition of being nice.

Proving the second condition is satisfied with high probability is more complicated. Consider two different cases, $i \neq t$ and $i = t$, corresponding to whether or not player i appended g_t. In the first case, since P_t did not communicate, $F_t^z = F_t^w$ and hence $H(f_t^w(g_{t-1})) = H(f_t^z(g_{t-1})) \geq \lg m - \delta$.

We now consider the second case. In this case we need to show that $H(f_{t+1}^w(g_t)) \geq \lg m - \delta$. Note that we can express f_{t+1}^w as the following vector of random variables, $(f_{t+1}^w(1), \ldots, f_{t+1}^w(m))$, where each $f_{t+1}^w(v)$ is a random variables in universe $[m]$. Note

there is no reason to believe that components of this vector are independent. By the subadditivity of entropy,

$$\sum_{v\in[m]} H(f^w_{t+1}(v)) \geq H(f^w_{t+1}) \geq \lg(2^{-2c_w}|F|) = \lg(|F|) - 2c_w \geq m\lg m - \epsilon m,$$

using the fact that f^w_{t+1} is uniformly distribution over F^w_{t+1}, $|F^w_{t+1}| \geq 2^{-2c_w}|F|$, and $c_w \leq \epsilon m/2$. Hence if v were chosen uniformly at random from $[m]$, then

$$\Pr\big[H(f^w_{t+1}(v)) \leq \lg m - \delta\big] \leq \epsilon/\delta$$

by Markov's inequality. However, we are not interested in a v chosen uniformly at random but rather $v = g_t = f^z_t(g_{t-1})$. But, since the entropy of $f^z_t(g_{t-1})$ is large, it is "almost" distributed uniformly. Specifically, since $H(f^z_t(g_{t-1})) \geq \lg m - \delta$,

$$\Pr\big[H(f^w_{t+1}(g_t)) \leq \lg m - \delta\big] \leq \frac{\epsilon}{\delta}\left(1 + \sqrt{\frac{4\delta}{\epsilon/\delta}}\right) \leq 4\sqrt{\epsilon}\ .$$

Hence, with probability at least $1 - 4\sqrt{\epsilon}$ the next node satisfies the second condition of being nice. The claim follows by the union bound. □

Note that the height of the protocol tree is $p(p-1)$ and that the root of the protocol tree is nice. Hence the probability of ending at a leaf that is not nice is at most $p(p-1)(1/m + 4\sqrt{\epsilon}) \leq 1/25$. If the final leaf node is nice, then $H(g_t)$ is at least $\lg m - \delta$, and hence the probability that g_t is guessed correctly is at most $(\delta+1)/\lg m$ using Fano's inequality. This is less than $1/100$ for sufficiently large m, and hence the total probability of P_1 guessing g_p correctly is at most $1 - 1/20$.

7. Conclusions. In this paper we motivated the study of random-order data streams and presented the first extensive study of the theoretical issues that arise in this model. We studied these issues in the context of quantile estimation, one of the most well studied problems in the data-stream model. Our results demonstrated some of the trade-offs that arise between space, passes, and accuracy in both the random-order and adversarial-order models. We resolved a long-standing open question of Munro and Paterson [21] by devising an $O(\text{polylog}\, n)$-space, $O(\log\log n)$-pass algorithm for exact selection in a randomly ordered stream of n elements. We also resolved an open question of Kannan [17] by demonstrating an exponential separation between the random-order and adversarial-order models: using $O(\text{polylog}\, n)$ space, exact selection requires $\Omega(\log n/\log\log n)$ passes in the adversarial-order model.

Acknowledgments. We would like to thank Anupam Gupta for suggesting that we consider biased quantiles in addition to median finding. We would also like to thank Joshua Brody, Amit Chakrabarti, and Piotr Indyk for helpful discussions.

SAMPLING ALGORITHMS AND CORESETS FOR ℓ_p REGRESSION*

ANIRBAN DASGUPTA†, PETROS DRINEAS‡, BOULOS HARB§, RAVI KUMAR†, AND MICHAEL W. MAHONEY¶

Abstract. The ℓ_p *regression problem* takes as input a matrix $A \in \mathbb{R}^{n\times d}$, a vector $b \in \mathbb{R}^n$, and a number $p \in [1,\infty)$, and it returns as output a number $\mathcal{Z}$ and a vector $x_{\text{OPT}} \in \mathbb{R}^d$ such that $\mathcal{Z} = \min_{x\in\mathbb{R}^d} \|Ax-b\|_p = \|Ax_{\text{OPT}}-b\|_p$. In this paper, we construct coresets and obtain an efficient two-stage sampling-based approximation algorithm for the very overconstrained ($n \gg d$) version of this classical problem, for all $p \in [1,\infty)$. The first stage of our algorithm nonuniformly samples $\hat{r}_1 = O(36^p d^{\max\{p/2+1,p\}+1})$ rows of A and the corresponding elements of b, and then it solves the ℓ_p regression problem on the sample; we prove this is an 8-approximation. The second stage of our algorithm uses the output of the first stage to resample $\hat{r}_1/\epsilon^2$ constraints, and then it solves the ℓ_p regression problem on the new sample; we prove this is a $(1+\epsilon)$-approximation. Our algorithm unifies, improves upon, and extends the existing algorithms for special cases of ℓ_p regression, namely, $p = 1, 2$ [K. L. Clarkson, in *Proceedings of the 16th Annual ACM–SIAM Symposium on Discrete Algorithms*, ACM, New York, SIAM, Philadelphia, 2005, pp. 257–266; P. Drineas, M. W. Mahoney, and S. Muthukrishnan, in *Proceedings of the 17th Annual ACM–SIAM Symposium on Discrete Algorithms*, ACM, New York, SIAM, Philadelphia, 2006, pp. 1127–1136]. In the course of proving our result, we develop two concepts—well-conditioned bases and subspace-preserving sampling—that are of independent interest.

Key words. randomized algorithms, sampling algorithms, ℓ_p regression

1. Introduction.

An important question in algorithmic theory is whether there exists a *small* subset of the input such that if computations are performed only on this subset, then the solution to the given problem can be *approximated* well. Such a subset is often known as a *coreset* for the problem. The concept of coresets has been extensively used in solving many problems in optimization and computational geometry; e.g., see the excellent survey by Agarwal, Har-Peled, and Varadarajan [2].

In this paper, we construct coresets and obtain efficient sampling algorithms for the classical ℓ_p regression problem, for all $p \in [1,\infty)$. Recall the ℓ_p *regression problem.*

PROBLEM 1 (ℓ_p regression problem). *Let $\|\cdot\|_p$ denote the p-norm of a vector. Given as input a matrix $A \in \mathbb{R}^{n\times m}$, a target vector $b \in \mathbb{R}^n$, and a real number $p \in [1,\infty)$, find a vector x_{OPT} and a number $\mathcal{Z}$ such that*

$$\mathcal{Z} = \min_{x\in\mathbb{R}^m} \|Ax-b\|_p = \|Ax_{\text{OPT}}-b\|_p . \tag{1}$$

In this paper, we will use the following ℓ_p *regression coreset* concept.

DEFINITION 2 (ℓ_p regression coreset). *Let $0 < \epsilon < 1$. A* coreset *for Problem 1 is a set of indices $\mathcal{I}$ such that the solution $\hat{x}_{\text{OPT}}$ to $\min_{x\in\mathbb{R}^m} ||\hat{A}x - \hat{b}||_p$, where $\hat{A}$ is composed of those rows of A whose indices are in $\mathcal{I}$ and $\hat{b}$ consists of the corresponding elements of b, satisfies $\|A\hat{x}_{\text{OPT}} - b\|_p \leq (1+\epsilon)\min_x \|Ax - b\|_p$.*

If $n \gg m$, i.e., if there are many more constraints than variables, then (1) is an *overconstrained ℓ_p regression problem*. In this case, there does not in general exist a vector x such that $Ax = b$, and thus $\mathcal{Z} > 0$. Overconstrained regression problems are fundamental in statistical data analysis and have numerous applications in applied mathematics, data mining, and machine learning [17, 10]. Even though convex programming methods can be used to solve the overconstrained regression problem in time $O((mn)^c)$ for $c > 1$, this is prohibitive if n is large.[1] This raises the natural question of developing more efficient algorithms that run in time $O(m^c n)$ for $c > 1$, while possibly relaxing the solution to (1). In particular, can we get a κ-approximation to the ℓ_p regression problem, i.e., a vector $\hat{x}$ such that $\|A\hat{x} - b\|_p \leq \kappa\mathcal{Z}$, where $\kappa > 1$? Note that a coreset of small size would strongly satisfy our requirements and result in an efficiently computed solution that is almost as good as the optimal. Thus, the question becomes: Do coresets exist for the ℓ_p regression problem, and if so, can we compute them efficiently?

Our main result is an efficient two-stage sampling-based approximation algorithm that constructs a coreset and thus achieves a $(1+\epsilon)$-approximation for the ℓ_p regression problem. The first stage of the algorithm is sufficient to obtain a (fixed) constant factor approximation. The second stage of the algorithm carefully uses the output of the first stage to construct a coreset and achieve arbitrary constant factor approximation.

1.1. Our contributions. Summary of results. For simplicity of presentation, we summarize the results for the case of $m = d = \text{rank}(A)$. Let $k = \max\{p/2+1,\ p\}$, and let $\phi(r, d)$ be the time required to solve an ℓ_p regression problem with r constraints and d variables. In the first stage of the algorithm, we compute a set of sampling probabilities $p_1, \ldots, p_n$ in time $O(nd^5 \log n)$, sample $\widehat{r_1} = O(36^p d^{k+1})$ rows of A and the corresponding elements of b according to the p_i's, and solve an ℓ_p regression problem on the (much smaller) sample; we prove this is an 8-approximation algorithm with a running time of $O\left(nd^5 \log n + \phi(\widehat{r_1}, d)\right)$. In the second stage of the algorithm, we use the residual from the first stage to compute a new set of sampling probabilities $q_1, \ldots, q_n$, sample an additional $\widehat{r_2} = O(\widehat{r_1}/\epsilon^2)$ rows of A and the corresponding elements of b according to the q_i's, and solve an ℓ_p regression problem on the (much smaller) sample; we prove this is a $(1+\epsilon)$-approximation algorithm with a total running time of $O\left(nd^5 \log n + \phi(\widehat{r_2}, d)\right)$ (section 4). We also show how to extend our basic algorithm to commonly encountered and more general settings of constrained, generalized, and weighted ℓ_p regression problems (section 5).

We note that the l_p regression problem for $p = 1, 2$ has been studied before. For $p = 1$, Clarkson [11] uses a subgradient-based algorithm to preprocess A and b and then samples the rows of the modified problem; these elegant techniques, however, depend crucially on the linear structure of the l_1 regression problem.[2] Furthermore, this algorithm does not yield coresets. For $p = 2$, Drineas, Mahoney, and Muthukrishnan [13] construct coresets by exploiting the singular value decomposition, a property

[1] For the special case of $p = 2$, vector space methods can solve the regression problem in time $O(m^2 n)$, and if $p = 1$ or ∞, linear programming methods can be used.

[2] Two ingredients of [11] use the linear structure: the subgradient-based preprocessing itself and the counting argument for the concentration bound.

peculiar to the l_2 space. Thus, in order to efficiently compute coresets for the ℓ_p regression problem for all $p \in [1, \infty)$, we need tools that capture the geometry of l_p-norms. In this paper we develop the following two tools that may be of independent interest (section 3).

(1) *Well-conditioned bases.* Informally speaking, if the the columns of matrix U form a well-conditioned basis for a d-dimensional subspace of $\mathbb{R}^n$, then for all $z \in \mathbb{R}^d$, $\|z\|_p$ should be close to $\|Uz\|_p$. We will formalize this by requiring[3] that for all $z \in \mathbb{R}^d$, $\|z\|_q$ multiplicatively approximates $\|Uz\|_p$ by a factor that can depend on d but is *independent* of n (where p and q are dual; i.e., $\frac{1}{q}+\frac{1}{p} = 1$). We show that these bases exist and can be constructed in time $O(nd^5 \log n)$. In fact, our notion of a well-conditioned basis can be interpreted as a computational analogue of the Auerbach and Lewis bases studied in functional analysis [28]. They are also related to the barycentric spanners recently introduced by Awerbuch and R. Kleinberg [5] (section 3.1). J. Kleinberg and Sandler [18] defined the notion of an ℓ_1-independent basis, and our well-conditioned basis can be used to obtain an exponentially better "condition number" than their construction. Further, Clarkson [11] defined the notion of an "ℓ_1-conditioned matrix," and he preprocessed the input matrix to an ℓ_1 regression problem so that it satisfies conditions similar to those satisfied by our bases.

(2) *Subspace-preserving sampling.* We show that sampling rows of A according to information in the rows of a well-conditioned basis of A minimizes the sampling variance, and, consequently, the rank of A is not lost by sampling. This is critical for our relative-error approximation guarantees. The notion of subspace-preserving sampling was used in [13] for $p = 2$, but we abstract and generalize this concept for all $p \in [1, \infty)$.

We note that for $p = 2$, our sampling complexity matches that of [13], which is $O(d^2/\epsilon^2)$; and for $p = 1$, it improves that of [11] from $O(d^{3.5}(\log d)/\epsilon^2)$ to $O(d^{2.5}/\epsilon^2)$.

Overview of our methods. Given an input matrix A, we first construct a well-conditioned basis for A and use that to obtain bounds on a slightly nonstandard notion of a p-norm condition number of a matrix. The use of this particular condition number is crucial since the variance in the subspace-preserving sampling can be upper-bounded in terms of it. An ε-net argument then shows that the first stage sampling gives us an 8-approximation. The next twist is to use the output of the first stage as a feedback to fine-tune the sampling probabilities. This is done so that the "positional information" of b with respect to A is also preserved in addition to the subspace. A more careful use of a different ε-net shows that the second stage sampling achieves a $(1 + \epsilon)$-approximation.

1.2. Related work. As mentioned earlier, in the course of providing a sampling-based approximation algorithm for ℓ_1 regression, Clarkson [11] shows that coresets exist and can be computed efficiently for a *controlled* ℓ_1 regression problem. Clarkson first preprocesses the input matrix A to make it well conditioned with respect to the ℓ_1-norm and then applies a subgradient-descent–based approximation algorithm to guarantee that the ℓ_1-norm of the target vector is conveniently bounded. Coresets of size $O(d^{3.5} \log d/\epsilon^2)$ are thereupon exhibited for this modified regression problem. For the ℓ_2 case, Drineas, Mahoney, and Muthukrishnan [13] designed sampling strategies to preserve the subspace information of A and proved the existence of a coreset of

[3]The requirement could equivalently be in terms of $\|z\|_p$, but the above form yields the tightest dependence on d, since we plan to use Hölder's inequality.

rows of size $O(d^2/\epsilon^2)$, for the *original* ℓ_2 regression problem; this leads to a $(1+\epsilon)$-approximation algorithm. Their algorithm used $O(nd^2)$ time to construct the coreset and solve the ℓ_2 regression problem, which is sufficient time to solve the regression problem without resorting to sampling. In a subsequent work, Sarlós [22] improved the running time for the $(1+\epsilon)$-approximation to $\tilde{O}(nd)$ by using random sketches based on the fast Johnson–Lindenstrauss transform of Ailon and Chazelle [3].

More generally, embedding d-dimensional subspaces of L_p into $\ell_p^{f(d)}$ using coordinate restrictions has been extensively studied [21, 23, 8, 25, 26, 24]. Using well-conditioned bases, one can provide a constructive analogue of Schechtman's existential L_1 embedding result [23] (see also [8]) that any d-dimensional subspace of $L_1[0,1]$ can be embedded in ℓ_1^r with distortion $(1+\epsilon)$ with $r = O(d^2/\epsilon^2)$, albeit with an extra factor of $\sqrt{d}$ in the sampling complexity. Coresets have been analyzed by the computational geometry community as a tool for efficiently approximating various extent measures [1, 2]; see also [16, 6, 14] for applications of coresets in combinatorial optimization. An important difference is that most of the coreset constructions are exponential in dimension and thus applicable only to low-dimensional problems, whereas our coresets are polynomial in dimension and thus applicable to high-dimensional problems.

2. Preliminaries. Given a vector $x \in \mathbb{R}^m$, its *p-norm* is $\|x\|_p = \sum_{i=1}^m (|x_i|^p)^{1/p}$, and the *dual norm* of $\|\cdot\|_p$ is denoted $\|\cdot\|_q$, where $1/p + 1/q = 1$. Given a matrix $A \in \mathbb{R}^{n\times m}$, its *generalized p-norm* is $|||A|||_p = (\sum_{i=1}^n \sum_{j=1}^m |A_{ij}|^p)^{1/p}$. This is a submultiplicative matrix norm that generalizes the Frobenius norm from $p = 2$ to all $p \in [1,\infty)$, but it is not a vector-induced matrix norm. The jth column of A is denoted $A_{\star j}$, and the ith row is denoted $A_{i\star}$. In this notation, $|||A|||_p = (\sum_j \|A_{\star j}\|_p^p)^{1/p} = (\sum_i \|A_{i\star}\|_p^p)^{1/p}$. For $x, x', x'' \in \mathbb{R}^m$, it can be shown using Hölder's inequality that $\|x - x'\|_p^p \le 2^{p-1}(\|x - x''\|_p^p + \|x'' - x'\|_p^p)$.

Two crucial ingredients in our proofs are ε-nets and tail inequalities. A subset $\mathcal{N}(D)$ of a set D equipped with a metric $\|\cdot\|$ is called an *ε-net* in D for some $\varepsilon > 0$ if for every $x \in D$ there is a $y \in \mathcal{N}(D)$ with $\|x - y\| \le \varepsilon$. In order to construct an ε-net for D it is enough to choose $\mathcal{N}(D)$ to be the maximal set of points that are pairwise ε apart. It is well known that the unit ball of a d-dimensional space has an ε-net of size at most $(3/\varepsilon)^d$ [8]. We will use the following version of the Bernstein's inequality.

THEOREM 3 (see [20, 7]). *Let $\{X_i\}_{i=1}^n$ be independent random variables with $E[X_i^2] < \infty$ and $X_i \ge 0$. Set $Y = \sum_i X_i$, and let $\gamma > 0$. Then*

$$\Pr[Y \le E[Y] - \gamma] \le \exp\left(\frac{-\gamma^2}{2\sum_i E[X_i^2]}\right). \tag{2}$$

If $X_i - E[X_i] \le \Delta$ for all i, then with $\sigma_i^2 = E[X_i^2] - E[X_i]^2$ we have

$$\Pr[Y \ge E[Y] + \gamma] \le \exp\left(\frac{-\gamma^2}{2\sum_i \sigma_i^2 + 2\gamma\Delta/3}\right). \tag{3}$$

Finally, throughout this paper, we will use the following sampling matrix formalism to represent our sampling operations. Given a set of n probabilities, $p_i \in (0,1]$ for $i = 1,\dots,n$, let S be an $n \times n$ diagonal sampling matrix such that S_{ii} is set to $1/p_i^{1/p}$ with probability p_i and to zero otherwise. Clearly, premultiplying A or b by S determines whether the ith row of A and the corresponding element of b will be included in the sample, and the expected number of rows/elements selected is $r' = \sum_{i=1}^n p_i$.

(In what follows, we will abuse notation slightly by ignoring zeroed-out rows and regarding S as an $r' \times n$ matrix and thus SA as an $r' \times m$ matrix.) Thus, e.g., sampling constraints from (1) and solving the induced subproblem may be represented as solving

$$\hat{\mathcal{Z}} = \min_{\hat{x} \in \mathbb{R}^m} \|SA\hat{x} - Sb\|_p . \tag{4}$$

A vector $\hat{x}$ is said to be a κ-*approximation* to the ℓ_p regression problem of (1) for $\kappa \geq 1$ if $\|A\hat{x} - b\|_p \leq \kappa \mathcal{Z}$.

3. Main technical ingredients.

3.1. Well-conditioned bases. We introduce the following notion of a "well-conditioned" basis.

DEFINITION 4 (well-conditioned basis). *Let A be an $n \times m$ matrix of rank d, let $p \in [1, \infty)$, and let q be its dual norm. Then an $n \times d$ matrix U is an* (α, β, p)–well-conditioned basis *for the column space of A if the columns of U span the column space of A and* (1) $|||U|||_p \leq \alpha$, *and* (2) *for all $z \in \mathbb{R}^d$, $\|z\|_q \leq \beta \|Uz\|_p$. We will say that U is a* p–well-conditioned basis *for the column space of A if α and β are $d^{O(1)}$, independent of m and n.*

Recall that any orthonormal basis U for span(A) satisfies both $|||U|||_2 = \|U\|_F = \sqrt{d}$ and also $\|z\|_2 = \|Uz\|_2$ for all $z \in \mathbb{R}^d$ and thus is a $(\sqrt{d}, 1, 2)$–well-conditioned basis. Thus, Definition 4 generalizes to an arbitrary p-norm for $p \in [1, \infty)$, the notion that an orthogonal matrix is well conditioned with respect to the 2-norm. Observe that the conditions are slightly different from those of the standard definition of a low-distortion embedding for the following reason. If U is a low distortion embedding, that is, if $\|z\|_p / C \leq \|Uz\|_p \leq \|z\|_p$ for some C, then we can easily see that U is a well-conditioned basis according to the above definition with α and β being $Cd^{O(1)}$. The reverse, however, does not hold. The well-conditioned basis definition above is intended to capture the essence of what is required of a basis for our subspace-sampling strategy to hold. Note also that duality is incorporated into Definition 4 since it relates the q-norm of the vector $z \in \mathbb{R}^d$ to the p-norm of the vector $Uz \in \mathbb{R}^n$, where p and q are dual[4] (i.e., $\frac{1}{q} + \frac{1}{p} = 1$).

The existence and efficient construction of these bases are given by the following.

THEOREM 5. *Let A be an $n \times m$ matrix of rank d, let $p \in [1, \infty)$, and let q be its dual norm. Then there exists an* (α, β, p)–well-conditioned basis U *for the column space of A such that if $p < 2$, then $\alpha = d^{\frac{1}{p} + \frac{1}{2}}$ and $\beta = 1$; if $p = 2$, then $\alpha = d^{\frac{1}{2}}$ and $\beta = 1$; and if $p > 2$, then $\alpha = d^{\frac{1}{p} + \frac{1}{2}}$ and $\beta = d^{\frac{1}{q} - \frac{1}{2}}$. Moreover, U can be computed in $O(nmd + nd^5 \log n)$ time (or in just $O(nmd)$ time if $p = 2$).*

Proof. Let $A = QR$, where Q is any $n \times d$ matrix that is an orthonormal basis for span(A) and R is a $d \times m$ matrix. If $p = 2$, then Q is the desired basis U; from the discussion following Definition 4, $\alpha = \sqrt{d}$ and $\beta = 1$, and computing the matrix U requires $O(nmd)$ time [15]. Otherwise, fix Q and p, and define the norm

$$\|z\|_{Q,p} \triangleq \|Qz\|_p .$$

[4] For $p = 2$, Drineas, Mahoney, and Muthukrishnan used this basis, i.e., an orthonormal matrix, to construct probabilities to sample the original matrix. For $p = 1$, Clarkson used a procedure similar to the one we describe in the proof of Theorem 5 to preprocess A such that the 1-norm of z is a $d\sqrt{d}$ factor away from the 1-norm of Az.

A quick check shows that $\|\cdot\|_{Q,p}$ is indeed a norm. ($\|z\|_{Q,p} = 0$ if and only if $z = 0$ since Q has full column rank; $\|\gamma z\|_{Q,p} = \|\gamma Q z\|_p = |\gamma| \|Qz\|_p = |\gamma| \|z\|_{Q,p}$; and $\|z + z'\|_{Q,p} = \|Q(z + z')\|_p \le \|Qz\|_p + \|Qz'\|_p = \|z\|_{Q,p} + \|z'\|_{Q,p}$.)

Consider the set $C = \{z \in \mathbb{R}^d : \|z\|_{Q,p} \le 1\}$, which is the unit ball of the norm $\|\cdot\|_{Q,p}$. In addition, define the $d \times d$ matrix F such that $\mathcal{E}_{\text{LJ}} = \{z \in \mathbb{R}^d : z^T F z \le 1\}$ is the Löwner–John ellipsoid of C. Since C is symmetric about the origin, $(1/\sqrt{d})\mathcal{E}_{\text{LJ}} \subseteq C \subseteq \mathcal{E}_{\text{LJ}}$; thus, for all $z \in \mathbb{R}^d$,

$$\|z\|_{\text{LJ}} \le \|z\|_{Q,p} \le \sqrt{d}\, \|z\|_{\text{LJ}}, \tag{5}$$

where $\|z\|_{\text{LJ}}^2 = z^T F z$ (see, e.g., [9, pp. 413–414]). Since the matrix F is symmetric positive definite, we can express it as $F = G^T G$, where G is full rank and upper triangular. Since Q is an orthogonal basis for span(A) and G is a $d \times d$ matrix of full rank, it follows that $U = QG^{-1}$ is an $n \times d$ matrix that spans the column space of A. Note that

$$A = QR = QG^{-1}GR = U\tau,$$

where $\tau = GR$. We claim that $U = QG^{-1}$ is the desired p–well-conditioned basis.

To establish this claim, let $z' = Gz$. Thus, $\|z\|_{\text{LJ}}^2 = z^T F z = z^T G^T G z = (Gz)^T Gz = z'^T z' = \|z'\|_2^2$. Furthermore, since G is invertible, $z = G^{-1}z'$, and thus $\|z\|_{Q,p} = \|Qz\|_p = \left\|QG^{-1}z'\right\|_p = \|Uz'\|_p$. By combining these expressions with (5), it follows that for all $z' \in \mathbb{R}^d$,

$$\|z'\|_2 \le \|Uz'\|_p \le \sqrt{d}\, \|z'\|_2. \tag{6}$$

Since $\|U\|_p^p = \sum_j \|U_{\star j}\|_p^p = \sum_j \|Ue_j\|_p^p \le \sum_j d^{\frac{p}{2}} \|e_j\|_2^p = d^{\frac{p}{2}+1}$, where the inequality follows from the upper bound in (6), it follows that $\alpha = d^{\frac{1}{p}+\frac{1}{2}}$. If $p < 2$, then $q > 2$ and $\|z\|_q \le \|z\|_2$ for all $z \in \mathbb{R}^d$; by combining this with (6), it follows that $\beta = 1$. On the other hand, if $p > 2$, then $q < 2$ and $\|z\|_q \le d^{\frac{1}{q}-\frac{1}{2}} \|z\|_2$; by combining this with (6), it follows that $\beta = d^{\frac{1}{q}-\frac{1}{2}}$.

In order to construct U, we need to compute Q and G and then invert G. Our matrix A can be decomposed into QR using the compact QR decomposition in $O(nmd)$ time [15]. The matrix F describing the Löwner–John ellipsoid of the unit ball of $\|\cdot\|_{Q,p}$ can be computed in $O(nd^5 \log n)$ time [19]. Finally, computing G from F takes $O(d^3)$ time, and inverting G takes $O(d^3)$ time. □

It is an open question whether the discontinuity at $p = 2$ in Theorem 5 is inherent in the structure of dual norms, or whether it is due to our inability to compute a better set of well-conditioned bases.

Connection to barycentric spanners. A point set $K = \{K_1, \ldots, K_d\} \subseteq D \subseteq \mathbb{R}^d$ is a *barycentric spanner* for the set D if every $z \in D$ may be expressed as a linear combination of elements of K using coefficients in $[-C, C]$ for $C = 1$. When $C > 1$, K is called a C-approximate barycentric spanner. Barycentric spanners were introduced by Awerbuch and R. Kleinberg in [5]. They showed that if a set is compact, then it has a barycentric spanner. Our proof shows that if A is an $n \times d$ matrix, then $B = \tau^{-1}/\sqrt{d} = R^{-1}G^{-1}/\sqrt{d} \in \mathbb{R}^{d \times d}$ is a $\sqrt{d}$-approximate barycentric spanner for $D = \{z \in \mathbb{R}^d : \|Az\|_p \le 1\}$. To see this, first note that each $B_{\star j}$ belongs to D since $\|AB_{\star j}\|_p = \frac{1}{\sqrt{d}} \|Ue_j\|_p \le \|e_j\|_2 = 1$, where the inequality is obtained

from (6). Moreover, since B spans $\mathbb{R}^d$, we can write any $z \in D$ as $z = B\nu$. Thus, $\nu = B^{-1}z = \sqrt{d}\tau z$. Hence,

$$\|\nu\|_\infty \leq \|\nu\|_2 \leq \|U\nu\|_p = \left\|\sqrt{d}U\tau z\right\|_p = \sqrt{d}\,\|Az\|_p \leq \sqrt{d},$$

where the second inequality is also obtained from (6). This shows that our basis has the added property that every element $z \in D$ can be expressed as a linear combination of elements (or columns) of B using coefficients whose ℓ_2-norm is bounded by $\sqrt{d}$.

Connection to Auerbach bases. An *Auerbach basis* $U = \{U_{\star j}\}_{j=1}^d$ for a d-dimensional normed space $\mathcal{A}$ is a basis such that $\|U_{\star j}\|_p = 1$ for all j and such that whenever $y = \sum_j \nu_j U_{\star j}$ is in the unit ball of $\mathcal{A}$, then $|\nu_j| \leq 1$. The existence of such a basis for every finite dimensional normed space was first proved by Auerbach [4] (see also [12, 27]). It can easily be shown that an Auerbach basis is an (α, β, p)–well-conditioned basis, with $\alpha = d$ and $\beta = 1$ for all p. Further, suppose U is an Auerbach basis for span(A), where A is an $n \times d$ matrix of rank d. Writing $A = U\tau$, it follows that τ^{-1} is an *exact* barycentric spanner for $D = \{z \in \mathbb{R}^d : \|Az\|_p \leq 1\}$. Specifically, each $\tau_{\star j}^{-1} \in D$ since $\|A\tau_{\star j}^{-1}\|_p = \|U_{\star j}\|_p = 1$. Now write $z \in D$ as $z = \tau^{-1}\nu$. Since the vector $y = Az = U\nu$ is in the unit ball of span(A), we have $|\nu_j| \leq 1$ for all $1 \leq j \leq d$. Therefore, computing a barycentric spanner for the compact set D—which is the preimage of the unit ball of span(A)—is equivalent (up to polynomial factors) to computing an Auerbach basis for span(A).

3.2. Subspace-preserving sampling. In the previous subsection (and in the notation of the proof of Theorem 5), we saw that given $p \in [1, \infty)$, any $n \times m$ matrix A of rank d can be decomposed as

$$A = QR = QG^{-1}GR = U\tau,$$

where $U = QG^{-1}$ is a p–well-conditioned basis for span(A) and $\tau = GR$. The significance of a p–well-conditioned basis is that we are able to minimize the variance in our sampling process by randomly sampling *rows* of the matrix A and elements of the vector b according to a probability distribution that depends on norms of the *rows* of the matrix U. This will allow us to preserve the subspace structure of span(A) and thus to achieve relative-error approximation guarantees.

More precisely, given $p \in [1, \infty)$ and any $n \times m$ matrix A of rank d decomposed as $A = U\tau$, where U is an (α, β, p)–well-conditioned basis for span(A), consider any set of sampling probabilities p_i for $i = 1, \ldots, n$ that satisfy

$$p_i \geq \min\left\{1, \frac{\|U_{i\star}\|_p^p}{|||U|||_p^p} r\right\}, \tag{7}$$

where $r = r(\alpha, \beta, p, d, \epsilon)$ to be determined below. Let us randomly sample the ith row of A with probability p_i for all $i = 1, \ldots, n$. Recall that we can construct a diagonal sampling matrix S, where each $S_{ii} = 1/p_i^{1/p}$ with probability p_i and 0 otherwise, in which case we can represent the sampling operation as SA.

The following theorem is our main result regarding this subspace-preserving sampling procedure.

THEOREM 6. *Let A be an $n \times m$ matrix of rank d, $\epsilon \leq 1/7$, and let $p \in [1, \infty)$. Let U be an (α, β, p)–well-conditioned basis for* span(A)*, and let us randomly sample rows of A according to the procedure described above using the probability distribution given*

by (7)*, where* $r \geq 16(2^p+2)(\alpha\beta)^p(d\ln(\frac{12}{\epsilon})+\ln(\frac{2}{\delta}))/(p^2\epsilon^2)$*. Then, with probability* $1-\delta$*, the following holds for all* $x \in \mathbb{R}^m$*:*

$$\left| \|SAx\|_p - \|Ax\|_p \right| \leq \epsilon \|Ax\|_p .$$

Proof. For simplicity of presentation, in this proof we will generally drop the subscript from our matrix and vector p-norms; i.e., unsubscripted norms will be p-norms. Note that it suffices to prove that, for all $x \in \mathbb{R}^m$,

$$(1-\epsilon)^p \|Ax\|^p \leq \|SAx\|^p \leq (1+\epsilon)^p \|Ax\|^p \tag{8}$$

with probability $1-\delta$. To this end, fix a vector $x \in \mathbb{R}^m$, define the random variable $X_i = (S_{ii}|A_{i\star}x|)^p$, and recall that $A_{i\star} = U_{i\star}\tau$ since $A = U\tau$. Clearly, $\sum_{i=1}^n X_i = \|SAx\|^p$. In addition, since $E[X_i] = |A_{i\star}x|^p$, it follows that $\sum_{i=1}^n E[X_i] = \|Ax\|^p$. To bound (8), first note that

$$\sum_{i=1}^{n} (X_i - E[X_i]) = \sum_{i:p_i<1} (X_i - E[X_i]) . \tag{9}$$

Equation (9) follows since, according to the definition of p_i in (7), p_i may equal 1 for some rows, and since these rows are always included in the random sample, $X_i = E[X_i]$ for these rows. To bound the right-hand side of (9), note that for all i such that $p_i < 1$,

$$\begin{aligned} |A_{i\star}x|^p / p_i &\leq \|U_{i\star}\|_p^p \|\tau x\|_q^p / p_i && \text{(by Hölder's inequality)} \\ &\leq |||U|||_p^p \|\tau x\|_q^p / r && \text{(by (7))} \\ &\leq (\alpha\beta)^p \|Ax\|^p / r && \text{(by Definition 4 and Theorem 5).} \end{aligned} \tag{10}$$

From (10) it follows that for each i such that $p_i < 1$,

$$X_i - E[X_i] \leq X_i \leq |A_{i\star}x|^p / p_i \leq (\alpha\beta)^p \|Ax\|^p / r.$$

Thus, we may define $\Delta = (\alpha\beta)^p \|Ax\|^p / r$. In addition, it also follows from (10) that

$$\begin{aligned} \sum_{i:p_i<1} E\left[X_i^2\right] &= \sum_{i:p_i<1} |A_{i\star}x|^p \frac{|A_{i\star}x|^p}{p_i} \\ &\leq \frac{(\alpha\beta)^p \|Ax\|^p}{r} \sum_{i:p_i<1} |A_{i\star}x|^p && \text{(by (10))} \\ &\leq (\alpha\beta)^p \|Ax\|^{2p} / r, \end{aligned}$$

from which it follows that $\sum_{i:p_i<1} \sigma_i^2 = \sum_{i:p_i<1} E\left[X_i^2\right] - (E[X_i])^2 \leq \sum_{i:p_i<1} E\left[X_i^2\right] \leq (\alpha\beta)^p \|Ax\|^{2p} / r$.

To apply the upper tail bound in Theorem 3, define $\gamma = ((1+\epsilon/4)^p - 1)\|Ax\|^p$. It follows that $\gamma^2 \geq (p\epsilon/4)^2 \|Ax\|^{2p}$ and also that

$$\begin{aligned} 2\sum_{i:p_i<1} \sigma_i^2 + 2\gamma\Delta/3 &\leq 2(\alpha\beta)^p \|Ax\|^{2p} / r + 2((1+\epsilon/4)^p - 1)(\alpha\beta)^p \|Ax\|^{2p} / 3r \\ &\leq \left(\frac{2}{3}\left(\frac{5}{4}\right)^p + \frac{4}{3}\right)(\alpha\beta)^p \|Ax\|^{2p} / r \\ &\leq (2^p+2)(\alpha\beta)^p \|Ax\|^{2p} / r, \end{aligned}$$

where the second inequality follows by standard manipulations since $\epsilon \leq 1$ and since $p \geq 1$. Thus, by (3) of Theorem 3, it follows that

$$\begin{aligned}\Pr\left[\|SAx\|^p > \|Ax\|^p + \gamma\right] &= \Pr\left[\sum_{i:p_i<1} X_i > E\left[\sum_{i:p_i<1} X_i\right] + \gamma\right] \\ &\leq \exp\left(\frac{-\gamma^2}{2\sum_{i:p_i<1}\sigma_i^2 + 2\gamma\Delta/3}\right) \\ &\leq \exp\left(\frac{-\epsilon^2 p^2 r}{16(2^p+2)(\alpha\beta)^p}\right).\end{aligned}$$

Similarly, to apply the lower tail bound of (2) of Theorem 3, define $\gamma = (1-(1-\epsilon/4)^p)\|Ax\|^p$. Since $\gamma \geq \epsilon\|Ax\|^p/4$, we can follow a similar line of reasoning to show that

$$\begin{aligned}\Pr\left[\|SAx\|^p < \|Ax\|^p - \gamma\right] &\leq \exp\left(\frac{-\gamma^2}{2\sum_{i:p_i<1}\sigma_i^2}\right) \\ &\leq \exp\left(\frac{-\epsilon^2 r}{32(\alpha\beta)^p}\right).\end{aligned}$$

Choosing $r \geq 16(2^p+2)(\alpha\beta)^p(d\ln(\frac{12}{\epsilon}) + \ln(\frac{2}{\delta}))/(p^2\epsilon^2)$, we get that for every fixed x, the following is true with probability at least $1 - \left(\frac{\epsilon}{12}\right)^d \delta$:

$$(1-\epsilon/4)^p\|Ax\|^p \leq \|SAx\|^p \leq (1+\epsilon/4)^p\|Ax\|^p.$$

Now, consider the ball $B = \{y \in \mathbb{R}^n : y = Ax, \|y\| \leq 1\}$, and consider an ε-net for B, with $\varepsilon = \epsilon/4$. The number of points in the ε-net is $\left(\frac{12}{\epsilon}\right)^d$. Thus, by the union bound, with probability $1-\delta$, (8) holds for all points in the ε-net. Now, to show that with the same probability (8) holds for all points $y \in B$, let $y^* \in B$ be such that $|\|Sy\| - \|y\||$ is maximized, and let $\eta = \sup\{|\|Sy\| - \|y\|| : y \in B\}$. Also, let $y_\varepsilon^* \in B$ be the point in the ε-net that is closest to y^*. By the triangle inequality,

$$\begin{aligned}\eta = |\|Sy^*\| - \|y^*\|| &= |\|Sy_\varepsilon^* + S(y^*-y_\varepsilon^*)\| - \|y_\varepsilon^* + (y^*-y_\varepsilon^*)\|| \\ &\leq |\|Sy_\varepsilon^*\| + \|S(y^*-y_\varepsilon^*)\| - \|y_\varepsilon^*\| + 2\|y^*-y_\varepsilon^*\| - \|y^*-y_\varepsilon^*\|| \\ &\leq |\|Sy_\varepsilon^*\| - \|y_\varepsilon^*\|| + |\|S(y^*-y_\varepsilon^*)\| - \|y^*-y_\varepsilon^*\|| + 2\|y^*-y_\varepsilon^*\| \\ &\leq \epsilon/4\|y_\varepsilon^*\| + \epsilon\eta/4 + \epsilon/2,\end{aligned}$$

where the last inequality follows since $\|y^*-y_\varepsilon^*\| \leq \varepsilon$, $(y^*-y_\varepsilon^*)/\varepsilon \in B$, and

$$|\|S(y^*-y_\varepsilon^*)/\varepsilon\| - \|(y^*-y_\varepsilon^*)/\varepsilon\|| \leq \eta.$$

Therefore, $\eta \leq \epsilon$ since $\|y_\varepsilon^*\| \leq 1$ and since we assume $\epsilon \leq 1/7$. Thus, (8) holds for all points $y \in B$, with probability at least $1-\delta$. Similarly, it holds for any $y \in \mathbb{R}^n$ such that $y = Ax$, since $y/\|y\| \in B$ and since $\|S(y/\|y\|) - y/\|y\|\| \leq \epsilon$ implies that $\|Sy - y\| \leq \epsilon\|y\|$, which completes the proof of the theorem. ∎

Several things should be noted about this result. First, it implies that $\text{rank}(SA) = \text{rank}(A)$, since otherwise we could choose a vector $x \in \text{null}(SA)$ and violate the theorem. In this sense, this theorem generalizes the subspace-preservation result of Lemma 4.1 of [13] to all $p \in [1,\infty)$. Second, regarding sampling complexity: if $p < 2$ the sampling complexity is $O(d^{\frac{p}{2}+2})$, if $p = 2$ it is $O(d^2)$, and if $p > 2$ it is $O(d(d^{\frac{1}{p}+\frac{1}{2}}d^{\frac{1}{q}-\frac{1}{2}})^p) = O(d^{p+1})$. Finally, note that this theorem is analogous to the main result of Schechtman [23], which uses the notion of Auerbach bases.

4. The sampling algorithm.

4.1. Statement of our main algorithm and theorem. Our main sampling algorithm for approximating the solution to the ℓ_p regression problem is presented in Figure 1. The algorithm takes as input an $n \times m$ matrix A of rank d, a vector $b \in \mathbb{R}^n$, and a number $p \in [1, \infty)$. It is a two-stage algorithm that returns as output a vector $\hat{x}_{\text{OPT}} \in \mathbb{R}^m$ (or a vector $\hat{x}_c \in \mathbb{R}^m$ if only the first stage is run). In either case, the output is the solution to the induced ℓ_p regression subproblem constructed on the randomly sampled constraints. Note that the set of constraints r_2 extracted by the second stage of the algorithm is a coreset for the ℓ_p regression problem.

Input: An $n \times m$ matrix A of rank d, a vector $b \in \mathbb{R}^n$, and $p \in [1, \infty)$.

Let $0 < \epsilon < 1/7$, and define $k = \max\{p/2 + 1, p\}$.

- Find a p–well-conditioned basis $U \in \mathbb{R}^{n \times d}$ for span(A) (as in the proof of Theorem 5).
- **Stage 1:** Define $p_i = \min\{1, \frac{\|U_{i\star}\|_p^p}{|||U|||_p^p} r_1\}$, where $r_1 = 16(2^p + 2)d^k \left(d \ln(8 \cdot 12) + \ln(200)\right)$.
  - Generate (implicitly) S where $S_{ii} = 1/p_i^{1/p}$ with probability p_i and 0 otherwise.
  - Let $\hat{x}_c$ be the solution to $\min_{x \in \mathbb{R}^m} \|S(Ax - b)\|_p$.
- **Stage 2:** Let $\hat{\rho} = A\hat{x}_c - b$, and unless $\hat{\rho} = 0$, define $q_i = \min\{1, \max\{p_i, \frac{|\hat{\rho}_i|^p}{\|\hat{\rho}\|_p^p} r_2\}\}$ with $r_2 = \frac{150 \cdot 24^p d^k}{\epsilon^2} \left(d \ln(\frac{280}{\epsilon}) + \ln(200)\right)$.
  - Generate (implicitly, a new) T where $T_{ii} = 1/q_i^{1/p}$ with probability q_i and 0 otherwise.
  - Let $\hat{x}_{\text{OPT}}$ be the solution to $\min_{x \in \mathbb{R}^m} \|T(Ax - b)\|_p$.

Output: $\hat{x}_{\text{OPT}}$ (or $\hat{x}_c$ if only the first stage is run).

FIG. 1. *Sampling algorithm for ℓ_p regression.*

The algorithm first computes a p–well-conditioned basis U for span(A), as described in the proof of Theorem 5. Then, in the first stage, the algorithm uses information from the norms of the rows of U to sample constraints from the input ℓ_p regression problem. In particular, roughly $O(d^{p+1})$ rows of A, and the corresponding elements of b, are randomly sampled according to the probability distribution given by

$$p_i = \min\left\{1, \frac{\|U_{i\star}\|_p^p}{|||U|||_p^p} r_1\right\}, \text{ where } r_1 = 16(2^p + 2)d^k \left(d \ln(8 \cdot 12) + \ln(200)\right), \tag{11}$$

implicitly represented by a diagonal sampling matrix S, where each $S_{ii} = 1/p_i^{1/p}$. For the remainder of the paper, we will use S to denote the sampling matrix for the first-stage sampling probabilities. The algorithm then solves, using any ℓ_p solver of one's choice, the smaller subproblem. If the solution to the induced subproblem is denoted $\hat{x}_c$, then, as we will see in Theorem 7, this is an 8-approximation to the original problem.[5]

In the second stage, the algorithm uses information from the residual of the 8-approximation computed in the first stage to refine the sampling probabilities. Define

[5]For $p = 2$, Drineas, Mahoney, and Muthukrishnan show that this first stage actually leads to a $(1+\epsilon)$-approximation. For $p = 1$, Clarkson develops a subgradient-based algorithm and runs it, after preprocessing the input, on all the input constraints to obtain a constant factor approximation in a stage analogous to our first stage. Here, however, we solve an ℓ_p regression problem on a small subset of the constraints to obtain the constant factor approximation. Moreover, our procedure works for all $p \in [1, \infty)$.

the residual $\hat{\rho} = A\hat{x}_c - b$ (and note that $\|\hat{\rho}\|_p \leq 8\,\mathcal{Z}$). Then, roughly $O(d^{p+1}/\epsilon^2)$ rows of A, and the corresponding elements of b, are randomly sampled according to the probability distribution

(12)
$$q_i = \min\left\{1, \max\left\{p_i, \frac{|\hat{\rho}_i|^p}{\|\hat{\rho}\|_p^p} r_2\right\}\right\}, \text{where } r_2 = \frac{150 \cdot 24^p d^k}{\epsilon^2}\left(d\ln\left(\frac{280}{\epsilon}\right) + \ln(200)\right).$$

As before, this can be represented as a diagonal sampling matrix T, where each $T_{ii} = 1/q_i^{1/p}$ with probability q_i and 0 otherwise. For the remainder of the paper, we will use T to denote the sampling matrix for the second-stage sampling probabilities. Again, the algorithm solves, using any ℓ_p solver of one's choice, the smaller subproblem. If the solution to the induced subproblem at the second stage is denoted $\hat{x}_{\text{OPT}}$, then, as we will see in Theorem 7, this is a $(1+\epsilon)$-approximation to the original problem.[6]

The following is our main theorem for the ℓ_p regression algorithm presented in Figure 1 showing that coresets exist for the ℓ_p regression problem and can be efficiently constructed.

THEOREM 7. *Let A be an $n \times m$ matrix of rank d, let $b \in \mathbb{R}^n$, let $p \in [1, \infty)$, and let $k = \max\{p/2+1, p\}$. Recall that $\epsilon \leq 1/7$, $r_1 = 16(2^p+2)d^k\,(d\ln(8\cdot 12) + \ln(200))$, and $r_2 = \frac{150\cdot 24^p d^k}{\epsilon^2}\left(d\ln(\frac{280}{\epsilon}) + \ln(200)\right)$. Then the following hold.*

- Constant factor approximation. *If only the first stage of the algorithm in Figure 1 is run, then with probability at least 0.6 the solution $\hat{x}_c$ to the sampled problem based on the p_i's of (7) is an 8-approximation to the ℓ_p regression problem.*
- Relative-error approximation. *If both stages of the algorithm are run, then with probability at least 0.5 the solution $\hat{x}_{\text{OPT}}$ to the sampled problem based on the q_i's of (12) is a $(1+\epsilon)$-approximation to the ℓ_p regression problem.*
- Running time. *The ith stage of the algorithm runs in time $O(nmd + nd^5 \log n + \phi(20ir_i, m))$, where $\phi(s,t)$ is the time taken to solve the regression problem $\min_{x\in\mathbb{R}^t} \|A'x - b'\|_p$, where $A' \in \mathbb{R}^{s\times t}$ is of rank d and $b' \in \mathbb{R}^s$.*

Note that since the algorithm of Figure 1 constructs the (α, β, p)–well-conditioned basis U using the procedure in the proof of Theorem 5, our sampling complexity depends on α and β. In particular, it will be $O(d(\alpha\beta)^p)$. Thus, if $p < 2$, our sampling complexity is $O(d \cdot d^{\frac{p}{2}+1}) = O(d^{\frac{p}{2}+2})$; if $p > 2$, it is $O(d(d^{\frac{1}{p}+\frac{1}{2}} d^{\frac{1}{q}-\frac{1}{2}})^p) = O(d^{p+1})$; and (although not explicitly stated, our proof will make it clear that) if $p = 2$, it is $O(d^2)$. Note also that we have stated the claims of the theorem as holding with constant probability, but they can be shown to hold with probability at least $1-\delta$ by using standard amplification techniques.

4.2. Proof for first-stage sampling: Constant factor approximation. To prove the claims of Theorem 7 having to do with the output of the algorithm after the first stage of sampling, we begin with two lemmas. First note that, because of our choice of r_1, we can use the subspace-preserving Theorem 6 with only a constant distortion $\epsilon = \frac{1}{8}$ and $\delta = \frac{1}{100}$; i.e., for all x, we have

(13)
$$\frac{7}{8}\|Ax\|_p \leq \|SAx\|_p \leq \frac{9}{8}\|Ax\|_p$$

[6] The subspace-based sampling probabilities (11) are similar to those used by Drineas, Mahoney, and Muthukrishnan [13], while the residual-based sampling probabilities (12) are similar to those used by Clarkson [11].

with probability at least 0.99. The first lemma below now states that the optimal solution to the original problem provides a small (constant factor) residual when evaluated in the sampled problem.

For simplicity of notation, we again drop the p-subscript from the norm notation, except where it might become confusing.

LEMMA 8. *$\|S(Ax_{\text{OPT}} - b)\| \leq 3\mathcal{Z}$, with probability at least $1 - 1/3^p$.*

Proof. Define $X_i = (S_{ii}|A_{i\star}x_{\text{OPT}} - b_i|)^p$. Thus, $\sum_i X_i = \|S(Ax_{\text{OPT}} - b)\|^p$, and the first moment is $E[\sum_i X_i] = \|Ax_{\text{OPT}} - b\|^p = \mathcal{Z}$. The lemma follows since, by Markov's inequality,

$$\Pr\left[\sum_i X_i > 3^p E\left[\sum_i X_i\right]\right] \leq \frac{1}{3^p};$$

i.e., $\|S(Ax_{\text{OPT}} - b)\|^p > 3^p \|Ax_{\text{OPT}} - b\|^p$ with probability no more than $1/3^p$. ∎

The next lemma states that if the solution to the sampled problem provides a constant factor approximation (when evaluated in the sampled problem), then when this solution is evaluated in the original regression problem we get a (slightly weaker) constant factor approximation.

LEMMA 9. *If $\|S(A\hat{x}_c - b)\| \leq 3\,\mathcal{Z}$, then with probability 0.99, $\|A\hat{x}_c - b\| \leq 8\,\mathcal{Z}$.*

Proof. We will prove the contrapositive: If $\|A\hat{x}_c - b\| > 8\,\mathcal{Z}$, then $\|S(A\hat{x}_c - b)\| > 3\,\mathcal{Z}$. To do so, note that, by Theorem 6 and the choice of r_1, we have that, with probability 0.99,

$$\frac{7}{8}\|Ax\|_p \leq \|SAx\|_p \leq \frac{9}{8}\|Ax\|_p.$$

Using this,

$$\begin{aligned}
\|S(A\hat{x}_c - b)\| &\geq \|SA(\hat{x}_c - x_{\text{OPT}})\| - \|S(Ax_{\text{OPT}} - b)\| && \text{(by the triangle inequality)}\\
&\geq \frac{7}{8}\|A\hat{x}_c - Ax_{\text{OPT}}\| - 3\,\mathcal{Z} && \text{(by Theorem 6 and Lemma 8)}\\
&\geq \frac{7}{8}(\|A\hat{x}_c - b\| - \|Ax_{\text{OPT}} - b\|) - 3\,\mathcal{Z} && \text{(by the triangle inequality)}\\
&> \frac{7}{8}(8\,\mathcal{Z} - \mathcal{Z}) - 3\,\mathcal{Z} && \text{(by the premise } \|A\hat{x}_c - b\| > 8\,\mathcal{Z})\\
&> 3\,\mathcal{Z},
\end{aligned}$$

which establishes the lemma. ∎

Clearly, $\|S(A\hat{x}_c - b)\| \leq \|S(Ax_{\text{OPT}} - b)\|$ (since $\hat{x}_c$ is an optimum for the sampled ℓ_p regression problem). Combining this with Lemmas 8 and 9, it follows that the solution $\hat{x}_c$ to the sampled problem based on the p_i's of (7) satisfies $\|A\hat{x}_c - b\| \leq 8\,\mathcal{Z}$; i.e., $\hat{x}_c$ is an 8-approximation to the original $\mathcal{Z}$.

To conclude the proof of the claims for the first stage of sampling, note that by our choice of r_1, Theorem 6 fails to hold for our first-stage sampling with probability no greater than $1/100$. In addition, the inequality in Lemma 8 fails to hold with probability no greater than $1/3^p$, which is no greater than $1/3$ for all $p \in [1, \infty)$. Finally, let $\widehat{r_1}$ be a random variable representing the number of rows chosen by our sampling scheme, and note that $E[\widehat{r_1}] \leq r_1$. By Markov's inequality, it follows that $\widehat{r_1} > 20r_1$ with probability less than $1/20$. Thus, the first stage of our algorithm fails to give an 8-approximation in the specified running time with a probability bounded by $1/3 + 1/20 + 1/100 < 2/5$.

4.3. Proof for second-stage sampling: Relative-error approximation. The proof of the claims of Theorem 7 having to do with the output of the algorithm after the second stage of sampling will parallel that for the first stage, but it will have several technical complexities that arise since the first triangle inequality approximation in the proof of Lemma 9 is too coarse for relative-error approximation. By our construction, since $q_i \geq p_i$, we have a finer result for subspace preservation. Thus, applying Theorem 6 with $\delta = \frac{1}{100}$, and a constant $\epsilon < \frac{1}{8}$, with probability 0.99, the following holds for all x:

$$(1-\epsilon)\left\|Ax\right\|_p \leq \left\|SAx\right\|_p \leq (1+\epsilon)\left\|Ax\right\|_p. \tag{14}$$

As before, we start with a lemma that states that the optimal solution to the original problem provides a small (now a relative-error) residual when evaluated in the sampled problem. This is the analogue of Lemma 8. An important difference is that the second-stage sampling probabilities significantly enhance the probability of success.

LEMMA 10. $\|T(Ax_{\text{OPT}} - b)\| \leq (1+\epsilon)\mathcal{Z}$ *with probability at least* 0.99.

Proof. Define the random variable $X_i = (T_{ii}|A_{i\star}x_{\text{OPT}} - b_i|)^p$, and recall that $A_{i\star} = U_{i\star}\tau$ since $A = U\tau$. Clearly, $\sum_{i=1}^n X_i = \|T(Ax_{\text{OPT}} - b)\|^p$. In addition, since $E[X_i] = |A_{i\star}x_{\text{OPT}} - b_i|^p$, it follows that $\sum_{i=1}^n E[X_i] = \|Ax_{\text{OPT}} - b\|^p$. We will use (3) of Theorem 3 to provide a bound for $\sum_i (X_i - E[X_i]) = \|T(Ax_{\text{OPT}} - b)\|^p - \|Ax_{\text{OPT}} - b\|^p$.

From the definition of q_i in (12), it follows that for some of the rows, q_i may equal 1 (just as in the proof of Theorem 6). Since $X_i = E[X_i]$ for these rows, $\sum_i (X_i - E[X_i]) = \sum_{i:q_i<1} (X_i - E[X_i])$, and thus we will bound this latter quantity with (3). To do so, we must first provide a bound for $X_i - E[X_i] \leq X_i$ and for $\sum_{i:q_i<1} \sigma_i^2 \leq \sum_i E\left[X_i^2\right]$. To that end, note that

$$\begin{aligned}
|A_{i\star}(x_{\text{OPT}} - \hat{x}_c)| &\leq \left\|U_{i\star}\right\|_p \left\|\tau(x_{\text{OPT}} - \hat{x}_c)\right\|_q \qquad \text{(by Hölders inequality)} \\
&\leq \left\|U_{i\star}\right\|_p \beta \left\|U\tau(x_{\text{OPT}} - \hat{x}_c)\right\|_p \qquad \text{(by Definition 4 and Theorem 5)} \\
&\leq \left\|U_{i\star}\right\|_p \beta \quad (\|Ax_{\text{OPT}} - b\| + \|A\hat{x}_c - b\|) \text{ (by the triangle inequality)} \\
&\leq \left\|U_{i\star}\right\|_p \beta 9\mathcal{Z}, \qquad (15)
\end{aligned}$$

where the final inequality follows from the definition of $\mathcal{Z}$ and the results from the first stage of sampling. Next, note that from the conditions on the probabilities q_i in (12), as well as by Definition 4 and the output of the first stage of sampling, it follows that

$$\frac{|\hat{\rho}_i|^p}{q_i} \leq \frac{\|\hat{\rho}\|^p}{r_2} \leq \frac{8^p\mathcal{Z}^p}{r_2} \quad \text{and} \quad \frac{\|U_{i\star}\|^p}{q_i} \leq \frac{\|\|U\|\|^p}{r_2} \leq \frac{\alpha^p}{r_2} \tag{16}$$

for all i such that $q_i < 1$.

Thus, since $X_i - E[X_i] \leq X_i \leq |A_{i\star}x_{\text{OPT}} - b_i|^p/q_i$, it follows that for all i such that $q_i < 1$,

$$\begin{aligned}
X_i - E[X_i] &\leq \frac{2^{p-1}}{q_i}\left(|A_{i\star}(x_{\text{OPT}} - \hat{x}_c)|^p + |\hat{\rho}_i|^p\right) \qquad (\text{since } \hat{\rho} = A\hat{x}_c - b\ ) \qquad (17) \\
&\leq 2^{p-1}\left(\frac{\|U_{i\star}\|_p^p \beta^p 9^p \mathcal{Z}^p}{q_i} + \frac{|\hat{\rho}_i|^p}{q_i}\right) \qquad \text{(by (15))} \\
&\leq 2^{p-1}\left(\alpha^p\beta^p 9^p\mathcal{Z}^p + 8^p\mathcal{Z}^p\right)/r_2 \qquad \text{(by (16))} \\
&\leq c_p(\alpha\beta)^p\mathcal{Z}^p/r_2, \qquad (18)
\end{aligned}$$

where we set $c_p = 2^{p-1}(9^p + 8^p) \le 18^p$. Thus, we may define $\Delta = c_p(\alpha\beta)^p \mathcal{Z}^p / r_2$. In addition, it follows that

$$\begin{aligned}\sum_{i:q_i<1} E\left[X_i^2\right] &= \sum_{i:q_i<1} |A_{i\star}x_{\text{OPT}} - b_i|^p \frac{|A_{i\star}x_{\text{OPT}} - b_i|^p}{q_i} \\ &\le \Delta \sum_i |A_{i\star}x_{\text{OPT}} - b_i|^p \qquad \text{(by (18))} \\ &\le c_p(\alpha\beta)^p \mathcal{Z}^{2p}/r_2. \qquad (19)\end{aligned}$$

To apply the upper tail bound of (3) of Theorem 3, define $\gamma = ((1+\epsilon)^p - 1)\mathcal{Z}^p$. We have $\gamma \ge p\epsilon\, \mathcal{Z}^p$, and since $\epsilon \le 1/7$, we also have $\gamma \le \left(\left(\frac{8}{7}\right)^p - 1\right) \mathcal{Z}^p$. Hence, by (3) of Theorem 3, it follows that

$$\begin{aligned}\ln \Pr\left[\|T(Ax_{\text{OPT}} - b)\|^p > \|Ax_{\text{OPT}} - b\|^p + \gamma\right] &\le \frac{-\gamma^2}{2\sum_{i:q_i<1} \sigma_i^2 + 2\gamma\Delta/3} \\ &\le \frac{-p^2\epsilon^2 r_2}{\left(2c_p + \frac{2c_p}{3}\left(\left(\frac{8}{7}\right)^p - 1\right)\right)(\alpha\beta)^p} \\ &\le \frac{-p^2\epsilon^2 r_2}{3 \cdot 18^p (\alpha\beta)^p}.\end{aligned}$$

Thus, $\Pr\left[\|T(Ax_{\text{OPT}} - b)\| > (1+\epsilon)\mathcal{Z}\right] \le \exp(\frac{-p^2\epsilon^2 r_2}{3\cdot 18^p(\alpha\beta)^p})$, from which the lemma follows by our choice of r_2. ∎

Next we show that if the solution to the sampled problem provides a relative-error approximation (when evaluated in the sampled problem), then when this solution is evaluated in the original regression problem we get a (slightly weaker) relative-error approximation. We first establish two technical lemmas.

The following lemma says that for all optimal solutions $\hat{x}_{\text{OPT}}$ to the second-stage sampled problem, $A\hat{x}_{\text{OPT}}$ is not too far from $A\hat{x}_c$, where $\hat{x}_c$ is the optimal solution from the first stage, in a p-norm sense. Hence, the lemma will allow us to restrict our calculations in Lemmas 12 and 13 to the ball of radius $12\,\mathcal{Z}$ centered at $A\hat{x}_c$.

LEMMA 11. $\|A\hat{x}_{\text{OPT}} - A\hat{x}_c\| \le 12\,\mathcal{Z}$ *with probability* 0.98.

Proof. With probability 0.98, both the inequalities in Lemma 9 and condition (14) hold true. By two applications of the triangle inequality, it follows that

$$\begin{aligned}\|A\hat{x}_{\text{OPT}} - A\hat{x}_c\| &\le \|A\hat{x}_{\text{OPT}} - Ax_{\text{OPT}}\| + \|Ax_{\text{OPT}} - b\| + \|A\hat{x}_c - b\| \\ &\le \|A\hat{x}_{\text{OPT}} - Ax_{\text{OPT}}\| + 9\mathcal{Z},\end{aligned}$$

where the second inequality follows since $\|A\hat{x}_c - b\| \le 8\,\mathcal{Z}$ from the first stage of sampling and since $\mathcal{Z} = \|Ax_{\text{OPT}} - b\|$. In addition, we have that

$$\begin{aligned}\|Ax_{\text{OPT}} - A\hat{x}_{\text{OPT}}\| &\le \frac{1}{(1-\epsilon)} \|T(A\hat{x}_{\text{OPT}} - Ax_{\text{OPT}})\| \qquad \text{(by Theorem 6)} \\ &\le (1+2\epsilon)\left(\|T(A\hat{x}_{\text{OPT}} - b)\| + \|T(Ax_{\text{OPT}} - b)\|\right) \\ &\qquad\qquad \text{(by the triangle inequality)} \\ &\le 2(1+2\epsilon)\|T(Ax_{\text{OPT}} - b)\| \\ &\le 2(1+2\epsilon)(1+\epsilon)\|Ax_{\text{OPT}} - b\| \qquad \text{(by Lemma 10)}\ ,\end{aligned}$$

where the third inequality follows since $\hat{x}_{\text{OPT}}$ is optimal for the sampled problem. The lemma follows since $\epsilon \le 1/8$. ∎

Thus, if we define the affine ball of radius $12\,\mathcal{Z}$ that is centered at $A\hat{x}_c$ and that lies in span(A),

$$B = \{y \in \mathbb{R}^n : y = Ax, x \in \mathbb{R}^m, \|A\hat{x}_c - y\| \leq 12\,\mathcal{Z}\}, \tag{20}$$

then Lemma 11 states that $A\hat{x}_{\text{OPT}} \in B$ for all optimal solutions $\hat{x}_{\text{OPT}}$ to the sampled problem. Let us consider an ε-net, and call it B_ε with $\varepsilon = \epsilon\,\mathcal{Z}$ for this ball B. Using arguments from [8], since B is a ball in a d-dimensional subspace, the size of the ε-net is $\left(\frac{3\cdot 12\,\mathcal{Z}}{\epsilon\,\mathcal{Z}}\right)^d = \left(\frac{36}{\epsilon}\right)^d$. The next lemma states that for all points in the ε-net, if that point provides a relative-error approximation (when evaluated in the sampled problem), then when this point is evaluated in the original regression problem we get a (slightly weaker) relative-error approximation.

LEMMA 12. *For all points Ax_ε in the ε-net, B_ε, if $\|T(Ax_\varepsilon - b)\| \leq (1+3\epsilon)\mathcal{Z}$, then $\|Ax_\varepsilon - b\| \leq (1+6\epsilon)\mathcal{Z}$ with probability* 0.99.

Proof. Fix a given point $y^*_\varepsilon = Ax^*_\varepsilon \in B_\varepsilon$. We will prove the contrapositive for this point; i.e., we will prove that if $\|Ax^*_\varepsilon - b\| > (1+6\epsilon)\mathcal{Z}$, then $\|T(Ax^*_\varepsilon - b)\| > (1+3\epsilon)\mathcal{Z}$ with probability at least $1 - \frac{1}{100}\left(\frac{\epsilon}{36}\right)^d$. The lemma will then follow from the union bound.

To this end, define the random variable $X_i = (T_{ii}|A_{i\star}x^*_\varepsilon - b_i|)^p$, and recall that $A_{i\star} = U_{i\star}\tau$ since $A = U\tau$. Clearly, $\sum_{i=1}^n X_i = \|T(Ax^*_\varepsilon - b)\|^p$. In addition, since $E[X_i] = |A_{i\star}x^*_\varepsilon - b_i|^p$, it follows that $\sum_{i=1}^n E[X_i] = \|Ax^*_\varepsilon - b\|^p$. We will use (2) of Theorem 3 to provide an upper bound for the probability of the event that $\|T(Ax^*_\varepsilon - b)\|^p \leq \|Ax^*_\varepsilon - b\|^p - \gamma$, where $\gamma = \|Ax^*_\varepsilon - b\|^p - (1+3\epsilon)^p\mathcal{Z}^p$, under the assumption that $\|Ax^*_\varepsilon - b\| > (1+6\epsilon)\mathcal{Z}$.

From the definition of q_i in (12), it follows that for some of the rows, q_i may equal 1 (just as in the proof of Theorem 6). Since $X_i = E[X_i]$ for these rows, $\sum_i (X_i - E[X_i]) = \sum_{i:p_i<1}(X_i - E[X_i])$, and thus we will bound this latter quantity with (2). To do so, we must first provide a bound for $\sum_{i:q_i<1} E\left[X_i^2\right]$. To that end, note that

$$\begin{aligned}
|A_{i\star}(x^*_\varepsilon - \hat{x}_c)| &= |U_{i\star}\tau(x^*_\varepsilon - \hat{x}_c)| \\
&\leq \|U_{i\star}\|_p \, \|\tau(x^*_\varepsilon - \hat{x}_c)\|_q && \text{(by Hölders inequality)} \\
&\leq \|U_{i\star}\|_p \, \beta \, \|U\tau(x^*_\varepsilon - \hat{x}_c)\|_p && \text{(by Definition 4 and Theorem 5)} \\
&\leq \|U_{i\star}\| \, \beta 12\mathcal{Z}, && (22)
\end{aligned} \tag{21}$$

where the final inequality follows from the radius of the high-dimensional ball in which the ε-net resides. From this, we can show that

$$\begin{aligned}
\frac{|A_{i\star}x^*_\varepsilon - b_i|}{q_i} &\leq \frac{2^{p-1}}{q_i}\left(|A_{i\star}x^*_\varepsilon - A_{i\star}\hat{x}_c|^p + |\hat{\rho}_i|^p\right) && \text{(since } \hat{\rho} = A\hat{x}_c - b \text{)} \\
&\leq 2^{p-1}\left(\frac{\|U_{i\star}\|^p \, 12^p\beta^p\mathcal{Z}^p}{q_i} + \frac{|\hat{\rho}_i|^p}{q_i}\right) && \text{(by (22))} \\
&\leq 2^{p-1}\left(\alpha^p 12^p\beta^p\mathcal{Z}^p + 8^p\mathcal{Z}^p\right)/r_2 && \text{(by (16))} \\
&\leq 24^p(\alpha\beta)^p\mathcal{Z}^p/r_2. && (23)
\end{aligned}$$

Therefore, we have that

$$\begin{aligned}\sum_{i:q_i<1} E\left[X_i^2\right] &= \sum_{i:q_i<1} |A_{i\star}x_\varepsilon^* - b_i|^p \frac{|A_{i\star}x_\varepsilon^* - b_i|^p}{q_i} \\ &\le \frac{24^p(\alpha\beta)^p \mathcal{Z}^p}{r_2} \sum_i |A_{i\star}x_\varepsilon^* - b_i|^p \qquad \text{(by (23))} \\ &\le 24^p(\alpha\beta)^p \left\|Ax_\varepsilon^* - b\right\|^{2p} / r_2. \qquad (24)\end{aligned}$$

To apply the lower tail bound of (2) of Theorem 3, define $\gamma = \|Ax_\varepsilon^* - b\|^p - (1+3\epsilon)^p\mathcal{Z}^p$. Thus, by (24) and by (2) of Theorem 3 it follows that

$$\begin{aligned}\ln[\|T(Ax_\varepsilon^* - b)\|^p &\le (1+3\epsilon)^p\mathcal{Z}^p] \\ &\le \frac{-r_2(\|Ax_\varepsilon^* - b\|^p - (1+3\epsilon)^p\mathcal{Z}^p)^2}{24^p(\alpha\beta)^p \|Ax_\varepsilon^* - b\|^{2p}} \\ &\le \frac{-r_2}{24^p(\alpha\beta)^p}\left(1 - \frac{(1+3\epsilon)^p\mathcal{Z}^p}{\|Ax_\varepsilon^* - b\|^p}\right)^2 \\ &< \frac{-r_2}{24^p(\alpha\beta)^p}\left(1 - \frac{(1+3\epsilon)^p\mathcal{Z}^p}{(1+6\epsilon)^p\mathcal{Z}^p}\right)^2 \qquad \text{(by the premise)} \\ &\le \frac{-r_2\epsilon^2}{24^p(\alpha\beta)^p}.\end{aligned}$$

The last line can be justified by the fact that $(1+3\epsilon)/(1+6\epsilon) \le 1-\epsilon$ since $\epsilon \le 1/3$, and that $(1-\epsilon)^p$ is maximized at $p=1$. Since $r_2 \ge 24^p(\alpha\beta)^p(d\ln(\frac{36}{\epsilon}) + \ln(200))/\epsilon^2$, it follows that $\|T(Ax_\varepsilon^* - b)\| \le (1+3\epsilon)\mathcal{Z}$ with probability no greater than $\frac{1}{200}\left(\frac{\epsilon}{36}\right)^d$. Since there are no more than $\left(\frac{36}{\epsilon}\right)^d$ such points in the ε-net, the lemma follows by the union bound. □

Finally, the next lemma states that if the solution to the sampled problem (in the second stage of sampling) provides a relative-error approximation (when evaluated in the sampled problem), then when this solution is evaluated in the original regression problem we get a (slightly weaker) relative-error approximation. This is the analogue of Lemma 9, and its proof will use Lemma 12.

LEMMA 13. *If* $\|T(A\hat{x}_{\text{OPT}} - b)\| \le (1+\epsilon)\mathcal{Z}$, *then* $\|A\hat{x}_{\text{OPT}} - b\| \le (1+7\epsilon)\mathcal{Z}$.

Proof. We will prove the contrapositive: If $\|A\hat{x}_{\text{OPT}} - b\| > (1+7\epsilon)\mathcal{Z}$, then $\|T(A\hat{x}_{\text{OPT}} - b)\| > (1+\epsilon)\mathcal{Z}$. Since $A\hat{x}_{\text{OPT}}$ lies in the ball B defined by (20) and since the ε-net is constructed in this ball, there exists a point $y_\varepsilon = Ax_\varepsilon$ (call it Ax_ε^*), such that $\|A\hat{x}_{\text{OPT}} - Ax_\varepsilon^*\| \le \epsilon\,\mathcal{Z}$. Thus,

$$\begin{aligned}\|Ax_\varepsilon^* - b\| &\ge \|A\hat{x}_{\text{OPT}} - b\| - \|Ax_\varepsilon^* - A\hat{x}_{\text{OPT}}\| \qquad \text{(by the triangle inequality)} \\ &\ge (1+7\epsilon)\mathcal{Z} - \epsilon\mathcal{Z} \qquad \text{(by assumption and the definition of } Ax_\varepsilon^*\text{)} \\ &= (1+6\epsilon)\mathcal{Z}.\end{aligned}$$

Next, since Lemma 12 holds for all points Ax_ε in the ε-net, it follows that

$$\|T(Ax_\varepsilon^* - b)\| > (1+3\epsilon)\mathcal{Z}. \qquad (25)$$

Finally, note that

$$\begin{aligned}
\|T(A\hat{x}_{\text{OPT}} - b)\| &\geq \|T(Ax^*_\varepsilon - b)\| - \|TA(x^*_\varepsilon - \hat{x}_{\text{OPT}})\| && \text{(by the triangle inequality)}\\
&> (1+3\epsilon)\mathcal{Z} - (1+\epsilon)\,\|A(x^*_\varepsilon - \hat{x}_{\text{OPT}})\| && \text{(by (25) and Theorem 6)}\\
&> (1+3\epsilon)\mathcal{Z} - (1+\epsilon)\epsilon\,\mathcal{Z} && \text{(by the definition of } A\hat{x}_\varepsilon)\\
&> (1+\epsilon)\mathcal{Z},
\end{aligned}$$

which establishes the lemma. □

Clearly, $\|T(A\hat{x}_{\text{OPT}} - b)\| \leq \|T(Ax_{\text{OPT}} - b)\|$, since $\hat{x}_{\text{OPT}}$ is an optimum for the sampled ℓ_p regression problem. Combining this with Lemmas 10 and 13, it follows that the solution $\hat{x}_{\text{OPT}}$ to the sampled problem based on the q_i's of (12) satisfies $\|A\hat{x}_{\text{OPT}} - b\| \leq (1+7\epsilon)\,\mathcal{Z}$; i.e., $\hat{x}_{\text{OPT}}$ is a $(1+7\epsilon)$-approximation to the original $\mathcal{Z}$.

To conclude the proof of the claims for the second stage of sampling, note that we can actually replace ϵ by $\epsilon/7$, thus getting the $(1+\epsilon)$-approximation with the corresponding bound on r_2 as in Theorem 7. To bound the failure probability, recall that the first stage failed with probability no greater than 2/5. Note also that by our choice of r_2, Theorem 6 fails to hold for our second-stage sampling with probability no greater than 1/100. In addition, Lemma 10 and Lemma 12 each fails to hold with probability no greater than 2/100 and 1/100, respectively. Finally, let $\widehat{r_2}$ be a random variable representing the number of rows actually chosen by our sampling scheme in the second stage, and note that $E[\widehat{r_2}] \leq 2r_2$. By Markov's inequality, it follows that $\widehat{r_2} > 40r_2$ with probability less than 1/20. Thus, the second stage of our algorithm fails with probability less than $1/20 + 1/100 + 2/100 + 1/100 < 1/10$. By combining both stages, our algorithm fails to give a $(1+\epsilon)$-approximation in the specified running time with a probability bounded from above by $2/5 + 1/10 = 1/2$.

Remark. It has been brought to our attention by an anonymous reviewer that one of the main results of this section can be obtained with a simpler analysis. Via an analysis similar to that of section 4.2, one can show that a relative factor (as opposed to a constant factor) approximation can be obtained in one stage by constructing the sampling probabilities using subspace information from both the data matrix A and the target vector b. In particular, we compute the sampling probabilities from a p–well-conditioned basis for the augmented matrix $[A\ \ b]$ as opposed to only from A. Although it simplifies the analysis, this scheme has the disadvantage that a p–well-conditioned basis needs to be constructed for each target vector b. Using our two-stage algorithm, one need only construct one such basis for A which can subsequently be used to compute probabilities for any target vector b (see, e.g., the extension to *generalized ℓ_p regression* in the next section).

5. Extensions. In this section we outline several immediate extensions of our main algorithmic result.

Constrained ℓ_p regression. Our sampling strategies are transparent to constraints placed on x. In particular, suppose we constrain the output of our algorithm to lie within a convex set $\mathcal{C} \subseteq \mathbb{R}^m$. If there is an algorithm to solve the constrained ℓ_p regression problem $\min_{z\in\mathcal{C}} \|A'x - b'\|$, where $A' \in \mathbb{R}^{s\times m}$ is of rank d and $b' \in \mathbb{R}^s$, in time $\phi(s,m)$, then by modifying our main algorithm in a straightforward manner, we can obtain an algorithm that gives a $(1+\epsilon)$-approximation to the constrained ℓ_p regression problem in time $O(nmd + nd^5 \log n + \phi(40r_2, m))$.

Generalized ℓ_p regression. Our sampling strategies extend to the case of generalized ℓ_p regression: given as input a matrix $A \in \mathbb{R}^{n\times m}$ of rank d, a target

matrix $B \in \mathbb{R}^{n\times p}$, and a real number $p \in [1,\infty)$, find a matrix $X \in \mathbb{R}^{m\times p}$ such that $|||AX - B|||_p$ is minimized. To do so, we generalize our sampling strategies in a straightforward manner. The probabilities p_i for the first stage of sampling are the same as before. Then, if $\hat{X}_c$ is the solution to the first-stage sampled problem, we can define the $n \times p$ matrix $\hat{\rho} = A\hat{X}_c - B$ and define the second-stage sampling probabilities to be $q_i = \min\left(1, \max\{p_i, r_2\|\hat{\rho}_{i\star}\|_p^p/|||\hat{\rho}|||_p^p\}\right)$. Then, we can show that the $\hat{X}_{\text{OPT}}$ computed from the second-stage sampled problem satisfies $|||A\hat{X}_{\text{OPT}} - B|||_p \le (1+\epsilon)\min_{X\in\mathbb{R}^{m\times p}} |||AX - B|||_p$ with probability at least 1/2.

Weighted ℓ_p regression. Our sampling strategies also generalize to the case of ℓ_p regression involving weighted p-norms: if $w_1,\dots,w_m$ are a set of nonnegative weights, then the weighted p-norm of a vector $x \in \mathbb{R}^m$ may be defined as $\|x\|_{p,w} = \left(\sum_{i=1}^m w_i|x_i|^p\right)^{1/p}$, and the weighted analogue of the matrix p-norm $|||\cdot|||_p$ may be defined as $|||U|||_{p,w} = \left(\sum_{j=1}^d \|U_{\star j}\|_{p,w}\right)^{1/p}$. Our sampling scheme proceeds as before. First, we compute a well-conditioned basis U for $\text{span}(A)$ with respect to this weighted p-norm. The sampling probabilities p_i for the first stage of the algorithm are then $p_i = \min(1, r_1 w_i \|U_{i\star}\|_p^p / |||U|||_{p,w}^p)$, and the sampling probabilities q_i for the second stage are $q_i = \min\left(1, \max\{p_i, r_2 w_i|\hat{\rho}_i|^p/\|\hat{\rho}\|_{p,w}^p\}\right)$, where $\hat{\rho}$ is the residual from the first stage.

General sampling probabilities. More generally, consider any sampling probabilities of the form $p_i \ge \min\{1, \max\{\frac{\|U_{i\star}\|_p^p}{|||U|||_p^p}, \frac{|(\rho_{\text{OPT}})_i|^p}{\mathcal{Z}^p}\}r\}$, where $\rho_{\text{OPT}} = Ax_{\text{OPT}} - b$ and $r \ge \frac{36^p d^k}{\epsilon^2}\left(d\ln(\frac{36}{\epsilon}) + \ln(200)\right)$ and where we adopt the convention that $\frac{0}{0} = 0$. Then, by an analysis similar to that presented for our two-stage algorithm, we can show that, by picking $O(36^p d^{p+1}/\epsilon^2)$ rows of A and the corresponding elements of b (in a single stage of sampling) according to these probabilities, the solution $\hat{x}_{\text{OPT}}$ to the sampled ℓ_p regression problem is a $(1+\epsilon)$-approximation to the original problem with probability at least 1/2. (Note that these sampling probabilities, if an equality is used in this expression, depend on the entries of the vector $\rho_{\text{OPT}} = Ax_{\text{OPT}} - b$; in particular, they require the solution of the original problem. This is reminiscent of the results of [13]. Our main two-stage algorithm shows that by solving a problem in the first stage based on coarse probabilities, we can refine our probabilities to approximate these probabilities and thus obtain an $(1+\epsilon)$-approximation to the ℓ_p regression problem more efficiently.)

HIERARCHICAL UNAMBIGUITY*

HOLGER SPAKOWSKI† AND RAHUL TRIPATHI‡

Abstract. We develop techniques to investigate relativized hierarchical unambiguous computation. We apply our techniques to generalize known constructs involving relativized unambiguity based complexity classes (UP and Promise-UP) to new constructs involving arbitrary higher levels of the relativized unambiguous polynomial hierarchy (UPH). Our techniques are developed on constraints imposed by hierarchical arrangement of *unambiguous* nondeterministic polynomial-time Turing machines, and so they differ substantially, in applicability and in nature, from standard methods (such as the switching lemma [J. Håstad, *Computational Limitations of Small-Depth Circuits*, MIT Press, Cambridge, 1987]), which play roles in carrying out similar generalizations. Aside from achieving these generalizations, we resolve a question posed by Cai, Hemachandra, and Vyskoč in [*Complexity Theory*, Cambridge University Press, Cambridge, UK, 1993, pp. 101–146], on an issue related to nonadaptive Turing access to UP and adaptive smart Turing access to Promise-UP.

Key words. unambiguous computation, computational complexity, promise problems, relativization

1. Introduction.

1.1. Background. Baker, Gill, and Solovay in their seminal paper [4] introduced the concept of relativization in complexity theory and showed that the bottom levels of the polynomial hierarchy P and NP separate in some relativized world. Baker and Selman [5] made progress in extending this relativized separation to the next levels of the polynomial hierarchy: They proved that there is a relativized world where $\Sigma_2^p \neq \Pi_2^p$. However, Baker and Selman [5] noted that their proof techniques do not apply at higher levels of the polynomial hierarchy because of certain constraints in their counting argument. Thus, it required the development of entirely different proof techniques for separating all the levels of the relativized polynomial hierarchy. The landmark paper by Furst, Saxe, and Sipser [23] established the connection between the relativization of the polynomial hierarchy and lower bounds for small depth circuits computing certain functions. Techniques for proving such lower bounds were developed in a series of papers [23, 45, 49, 29], which were motivated by questions about the relativized structure of the polynomial hierarchy. Yao [49] finally succeeded in separating the levels of the relativized polynomial hierarchy by applying these new techniques. Håstad [29] gave the most refined presentation of these techniques via the *switching lemma*. Even to date, Håstad's switching lemma [29] is used as an essential tool to separate relativized hierarchies, composed of classes stacked one on top of

another. (See, for instance, [29, 37, 9, 46], where the switching lemma is used as a strong tool for proving the feasibility of oracle constructions.)

A major contribution of our paper lies in demonstrating that known oracle constructions involving the initial levels of the unambiguous polynomial hierarchy (UPH) and the promise unambiguous polynomial hierarchy ($\mathcal{UPH}$), i.e., UP and $\mathrm{P}_s^{\text{Promise-UP}}$, respectively, can be extended to oracle constructions involving arbitrary higher levels of UPH by application only of pure counting arguments. Alongside this contribution, we resolve a question posed by Cai, Hemachandra, and Vyskoč [16] concerning the closure of UP under nonadaptive Turing reductions and the closure of Promise-UP under adaptive smart Turing reductions.

The class UP is the unambiguous version of NP. UP has proved to be useful, for instance, in studying worst-case one-to-one one-way functions [35, 26], obtaining potential counterexamples to the Berman–Hartmanis isomorphism conjecture [34], and studying the complexity of closure properties of #P [41]. Lange and Rossmanith [38] generalized the notion of unambiguity to higher levels of the polynomial hierarchy. They introduced the following unambiguity based hierarchies: AUPH, UPH, and $\mathcal{UPH}$. It is known that AUPH $\subseteq$ UPH $\subseteq \mathcal{UPH} \subseteq$ UAP [38, 18], where UAP (unambiguous alternating polynomial-time) is the analogue of UP for alternating polynomial-time Turing machines. These hierarchies received renewed interests in some recent papers (see, for instance, [1, 18, 46, 24]). Spakowski and Tripathi [46], further developing circuit complexity-theoretic proof techniques of Sheu and Long [44], and of Ko [37] obtained results on the relativized structure of these hierarchies. They proved that there is a relativized world where these hierarchies are infinite. They also proved that for each $k \geq 2$ there is a relativized world where these hierarchies collapse so that they have exactly k distinct levels and their kth levels collapse to PSPACE. The present paper supplements this investigation with a focus on the structure of the UPH.

1.2. Results. We prove a combinatorial lemma (Lemma 3.1) and demonstrate its usefulness in generalizing known relativization results involving classes such as UP and Promise-UP to new relativization results that involve arbitrary levels of the UPH.

In subsection 4.1, we use Lemma 3.1 to construct relativized worlds in which certain inclusion relationships between bounded ambiguity classes ($\mathrm{UP}_{O(1)}$ and FewP) and the levels of the UPH do not hold. Theorem 4.1 of this subsection subsumes an oracle result of Beigel [6] for any constant integer $k \geq 1$, and Corollary 4.5 generalizes a result of Cai, Hemachandra, and Vyskoč [16] from the case of $k = 2$ to the case of any arbitrary integer $k \geq 2$.

Subsection 4.2 studies the issue of simulating nonadaptive access to $\mathrm{U}\Sigma_h^p$, the hth level of the UPH, by adaptive access to $\mathrm{U}\Sigma_h^p$. Theorem 4.7 of this subsection generalizes a result of Cai, Hemachandra, and Vyskoč [15] from the case of $h = 1$ to the case of any arbitrary integer $h \geq 1$. Lemma 3.1 is used as a key tool for proving Theorem 4.7.

We improve upon Theorem 4.7 in subsection 4.3. There are compelling reasons for the transition from subsection 4.2 to subsection 4.3, which we discuss in subsection 4.3. Theorem 4.10 in that subsection not only resolves a question posed by Cai, Hemachandra, and Vyskoč [16] but also generalizes one of their results. In particular, Theorem 4.10 holds for any total, polynomial-time computable, and polynomially bounded function $k(\cdot)$ and arbitrary integer $h \geq 1$, while a similar result of Cai, Hemachandra, and Vyskoč [16] holds only for any arbitrary *constant* integer k and $h = 1$. Lemma 3.1 is one of the ingredients in the proof of this theorem.

Subsection 4.4 investigates the complimentary issue of simulating adaptive access to $\mathrm{U}\Sigma_h^p$ by nonadaptive access to $\mathrm{U}\Sigma_h^p$. Theorem 4.13 of this subsection generalizes a result of Cai, Hemachandra, and Vyskoč [16] from the case of $h = 1$ to the case of any arbitrary constant integer $h \geq 1$. Again, Lemma 3.1 is useful in making this generalization possible.

In subsection 4.5, we study the notion of one-sided helping introduced by Ko [36]. Theorem 4.17 of this subsection generalizes and improves one of the results of Cai, Hemachandra, and Vyskoč [16].

Finally, in section 5 we consider the possibility of imposing a more stringent restriction in the statement of Lemma 3.1. The investigation in this section leads to a generic oracle collapse of UPH to P under the assumption that P = NP in the unrelativized world. This extends a result of Blum and Impagliazzo [10], which showed a generic oracle collapse of UP (the first level of UPH) to P assuming that P = NP in the unrelativized world.

2. Preliminaries.

2.1. Notation. Let $\mathbb{N}^+$ denote the set of positive integers. Σ denotes the alphabet $\{0,1\}$. Let $[n] =_{df} \{1,2,\ldots,n\}$ for every $n \in \mathbb{N}^+$. NPTM stands for "nondeterministic polynomial-time Turing machine." For every oracle NPTM N, oracle A, and string $x \in \Sigma^*$, we use the shorthand $N^A(x)$ for "the computation tree of N with oracle A on input x." We fix a standard, polynomial-time computable and invertible, one-to-one, multiarity pairing function $\langle .,\ldots,. \rangle$ throughout the paper. Let $\circ$ denote the composition operator on functions. For any polynomial $p(.)$ and integer $i \geq 1$, let $(p\circ)^i(\cdot)$ denote

$$\underbrace{p \circ p \circ \cdots \circ p}_{i}(\cdot),$$

i.e., the polynomial obtained by i compositions of p. All polynomials $p(\cdot)$ appearing in this paper are without loss of generality nondecreasing and satisfy $p(n) \geq n$ for every $n \in \mathbb{N}^+$. Let σ be an equivalence relation on a set S. For each $x \in S$, the *equivalence class* $[x]$ of x determined by σ is $\{y \in S \mid x\sigma y\}$. The set S/σ of all equivalence classes determined by σ is called the *quotient set* determined by σ. For any set S, we use $\wp(S)$ to denote the *power set* of S, i.e., the set of all subsets of S. The *join* of two sets A and B over Σ is defined as $A \oplus B = \{0x \,\big|\, x \in A\} \cup \{1x \,\big|\, x \in B\}$.

We define the notion of a computation path of oracle machines independent of any concrete oracle. A *computation path* of an oracle NPTM N encodes a complete valid computation that N can have relative to some/any oracle; i.e., it contains the sequence of configurations including the query strings and the answers from the oracle. Hence two computation paths ρ_1 and ρ_2 of an oracle NPTM are equal if and only if the configuration sequences, oracle queries, and oracle answers are the same for the computation paths. For any computation path ρ, let $Q^+(\rho)$ denote the set of strings that are queried along ρ and answered positively, and let $Q^-(\rho)$ denote the set of strings that are queried along ρ and answered negatively. Let $Q(\rho) = Q^+(\rho) \cup Q^-(\rho)$. For any concrete oracle A and input x, a given path ρ may or may not appear in $N^A(x)$. For instance, if $\alpha \in Q^+(\rho)$, then ρ does not appear in $N^A(x)$ for any A with $\alpha \notin A$. In this case we also say "$N^A(x)$ does not have path ρ."

For any complexity class $\mathcal{C}$ and for any natural notion of polynomial-time reducibility r (e.g., $r \in \{m, dtt, tt, k\text{-}tt, T, k\text{-}T, b\}$), let $R_r^p(\mathcal{C})$ denote the closure of $\mathcal{C}$ under r. That is, $R_r^p(\mathcal{C}) =_{df} \{L \mid (\exists L' \in \mathcal{C})[L \leq_r^p L']\}$. We refer the reader to any

standard textbook in complexity theory (e.g., [11, 42, 31]) for complexity classes and reductions not defined in this paper.

Given a complexity class $\mathcal{C}$, the unique existential ($\exists!$), and the unique universal ($\forall!$) operators on $\mathcal{C}$ yield complexity classes. Formally, we have the following.

DEFINITION 2.1. *For any arbitrary complexity class $\mathcal{C}$, the following hold.*

1. *$\exists! \cdot \mathcal{C}$ is defined to be the class of all sets L for which there exist a polynomial $p(\cdot)$ and a set $L' \in \mathcal{C}$ such that for all $x \in \Sigma^*$,*

$$x \in L \Longrightarrow (\text{there exists a unique } y \in \Sigma^{p(|x|)})[\langle x, y\rangle \in L'], \text{ and}$$
$$x \notin L \Longrightarrow (\text{for all } y \in \Sigma^{p(|x|)})[\langle x, y\rangle \notin L'].$$

2. *$\forall! \cdot \mathcal{C}$ is defined to be the class of all sets L for which there exist a polynomial $p(\cdot)$ and a set $L' \in \mathcal{C}$ such that for all $x \in \Sigma^*$,*

$$x \in L \Longrightarrow (\text{for all } y \in \Sigma^{p(|x|)})[\langle x, y\rangle \in L'], \text{ and}$$
$$x \notin L \Longrightarrow (\text{there exists a unique } y \in \Sigma^{p(|x|)})[\langle x, y\rangle \notin L'].$$

We introduce the notion of a $\Sigma_k(A)$-system. This notion is useful for concisely representing the computation of a stack of oracle NPTMs.

DEFINITION 2.2.

1. *For any $k \in \mathbb{N}^+$ and $A \subseteq \Sigma^*$, we call a tuple $[A; N_1, N_2, \ldots, N_k]$, where A is an oracle and $N_1, N_2, \ldots, N_k$ are nondeterministic oracle Turing machines, a $\Sigma_k(A)$-system.* The language accepted by a $\Sigma_k(A)$-system*, denoted by $L[A; N_1, N_2, \ldots, N_k]$, is defined inductively as follows:*

$$L[A; N_1, N_2, \ldots, N_k] =_{df} \begin{cases} L(N_1^A) & \text{if } k = 1, \text{ and} \\ L(N_1^{L[A;N_2,N_3,\ldots,N_k]}) & \text{if } k > 1. \end{cases}$$

2. *The* computation of a $\Sigma_k(A)$-system $[A; N_1, N_2, \ldots, N_k]$ *on input x, denoted by $[A; N_1, N_2, \ldots, N_k](x)$, is defined as follows:*

$$[A; N_1, N_2, \ldots, N_k](x) =_{df} \begin{cases} N_1^A(x) & \text{if } k = 1, \text{ and} \\ N_1^{L[A;N_2,N_3,\ldots,N_k]}(x) & \text{if } k > 1. \end{cases}$$

We define the notion of unambiguity in $\Sigma_k(A)$-systems as follows.

DEFINITION 2.3.

1. *We say that a $\Sigma_k(A)$-system $[A; N_1, N_2, \ldots, N_k]$ is* unambiguous *if for every $1 \le i \le k$ and for every $x \in \Sigma^*$, $[A; N_i, N_{i+1}, \ldots, N_k](x)$ has at most one accepting path.*

2. *For any $\Sigma_k(A)$-system $[A; N_1, N_2, \ldots, N_k]$, we define*

$$L_{\text{unambiguous}}[A; N_1, N_2, \ldots, N_k] = \begin{cases} L[A; N_1, N_2, \ldots, N_k] & \text{if } [A; N_1, N_2, \ldots, N_k] \text{ is} \\ & \text{unambiguous,} \\ \text{undefined} & \text{otherwise.} \end{cases}$$

Roughly speaking, a property of an oracle machine is called *robust* if the machine retains that property with respect to every oracle. Below we define the property of *robust unambiguity* for a $\Sigma_k(A)$-system.

DEFINITION 2.4. *We say that a $\Sigma_k(\cdot)$-system $[\cdot; N_1, N_2, \ldots, N_k]$ is* robustly unambiguous *if for every set B, the $\Sigma_k(B)$-system $[B; N_1, N_2, \ldots, N_k]$ is unambiguous.*

As we will see in section 5, the notion of a robustly unambiguous $\Sigma_k(\cdot)$-system is useful in extending a result of Blum and Impagliazzo [10].

2.2. Promise problems and smart reductions. Even, Selman, and Yacobi [19] introduced and studied the notion of promise problems. Promise problems are generalizations of decision problems in that the set of Yes-instances and the set of No-instances must partition the set of all instances in a decision problem, whereas this is not necessarily the case with promise problems. Thus, for a promise problem, a set of disallowed strings may be defined, which represent neither Yes-instances nor No-instances. Over the years, the notion of promise problems has proved to be useful, in several areas of computational complexity theory. (See [25] for a nice survey of some applications of promise problems in computational complexity theory.)

DEFINITION 2.5 (based on [25]; cf. [19]). *A promise problem* $\Pi = (\Pi_{\text{yes}}, \Pi_{\text{no}})$ *is defined in terms of disjoint sets* $\Pi_{\text{yes}}, \Pi_{\text{no}} \subseteq \Sigma^*$. *The set* Π_{yes} *is called the set of Yes-instances, the set* Π_{no} *is called the set of No-instances, and the set* $\Pi_{\text{yes}} \cup \Pi_{\text{no}}$ *is called the promise set.*

Some technicalities are involved when oracle access to a promise problem is defined. If a query to a promise problem falls inside the promise set, then the answer to the query is well defined (i.e., the answer is 1 if q is a Yes-instance and 0 if q is a No-instance). However, if a query falls outside the promise set, then it is not immediately clear how that query should be handled by the promise problem, i.e., the oracle. Several natural models of oracle access to a promise problem are definable. (See [26, 16] for a few possible approaches to defining oracle access to promise problems.)

Grollmann and Selman [26] proposed a model of oracle access to a promise problem that *prohibits* queries that fall outside the promise set. In this model, a querying machine always asks queries from the promise set; i.e., the queries asked by the querying machine always obey the underlying promise of the promise problem. For instance, let us define a promise problem $\Pi_{\text{unique}} = (\Pi_{\text{yes}}, \Pi_{\text{no}})$ in terms of the acceptance mechanism of an NPTM N as follows: $\Pi_{\text{yes}} = \{x \in \Sigma^* \mid \#\text{acc}_N(x) = 1\}$ and $\Pi_{\text{no}} = \{x \in \Sigma^* \mid \#\text{acc}_N(x) = 0\}$. Then a Turing access to Π_{unique} in the model proposed by Grollmann and Selman [26] requires that for any query y asked by the querying machine on some input, the computation of N on y must be unambiguous; i.e., $\#\text{acc}_N(y)$ must be either 0 or 1. A Turing reduction that obeys the constraints of this model (i.e., any query ever asked belongs to the promise set) is called a *smart* Turing reduction [26]. The definition given below formally captures the notion of a smart Turing reduction from a decision problem to a promise problem.[1]

DEFINITION 2.6. *A set* L *polynomial-time* smart *Turing reduces to a promise problem* $\Pi = (\Pi_{\text{yes}}, \Pi_{\text{no}})$, *denoted by* $L \leq^p_{s,T} \Pi$ *or* $L \in \text{P}^{\Pi}_s$, *if there is a deterministic polynomial-time oracle Turing machine* M *such that for all* $x \in \Sigma^*$,

1. $x \in L \iff M^{\Pi}(x)$ *accepts, and*
2. *if* $M^{\Pi}(x)$ *asks a query* y *to* Π, *then* $y \in \Pi_{\text{yes}} \cup \Pi_{\text{no}}$.

If on all inputs $x \in \Sigma^*$ *the querying machine* M *asks at most* k *queries for some integer constant* $k \geq 1$, *then we say that the set of* L *polynomial-time* smart k*-Turing reduces to* Π, *and we write* $L \leq^p_{s,k\text{-}T} \Pi$ *or* $L \in \text{P}^{\Pi[k]}_s$.

In the above definition, we followed Grollmann and Selman's notion of smart Turing reductions from *decision* problems to *promise* problems. We may extend this notion to define reductions that reduce *promise* problems to *promise* problems. (See, for instance, [25] for a generalization of smart Turing reductions to reductions among promise problems.) In this paper, we will consider only smart Turing reductions (i.e.,

[1] Cai, Hemachandra, and Vyskoč [16] referred to Grollmann and Selman's *smart* oracle access by the term *guarded* access.

reductions from decision problems to promise problems) as given by Grollmann and Selman.

The following two definitions are standard.

DEFINITION 2.7. *Let* Π *be any promise problem.* $R^p_{s,T}(\Pi)$ *is the class of all sets* L *such that* $L \leq^p_{s,T} \Pi$*; for all* $k \in \mathbb{N}^+$, $R^p_{s,k\text{-}T}(\Pi)$ *is the class of all sets* L *such that* $L \leq^p_{s,k\text{-}T} \Pi$*;* $R^p_{s,b}(\Pi)$ *is the class of all sets* L *for which there exists some* $k \in \mathbb{N}^+$ *such that* $L \leq^p_{s,k\text{-}T} \Pi$.

DEFINITION 2.8. *For any class of promise problems* $\mathcal{C}$ *and any reduction* $r \in \{T, k\text{-}T, b\}$*, we define* $R^p_{s,r}(\mathcal{C}) =_{df} \bigcup_{\Pi\in\mathcal{C}} R^p_{s,r}(\Pi)$.

We will study the computational power of smart Turing reductions to a particular class of promise problems, namely, the class Promise-UP, which is defined as follows.

DEFINITION 2.9. Promise-UP *is the class of all promise problems* $\Pi = (\Pi_{\text{yes}}, \Pi_{\text{no}})$ *for which there exists an NPTM* N *such that for all* $x \in \Sigma^*$,

$$x \in \Pi_{\text{yes}} \Longrightarrow \#\text{acc}_N(x) = 1, \text{ and}$$
$$x \in \Pi_{\text{no}} \Longrightarrow \#\text{acc}_N(x) = 0.$$

The class $\text{P}^{\text{Promise-UP}}_s$ of sets that polynomial-time smart Turing reduce to Promise-UP is a prominent class that behaves remarkably differently than the related class P^{UP}. While $\text{P}^{\text{Promise-UP}}_s$ is known to contain the class FewP [16] and the graph isomorphism problem [2], similar results for the case of P^{UP} are unknown.[2]

2.3. Unambiguity based hierarchies. Niedermeier and Rossmanith [40] observed that the notion of unambiguity in NPTMs can be generalized in three ways, each of which defines an unambiguity based hierarchy.

DEFINITION 2.10 (unambiguity based hierarchies [38, 40]).

1. *The* alternating unambiguous polynomial hierarchy *is defined as follows:*

$$\text{AUPH} =_{df} \bigcup_{k\geq 0} \text{AU}\Sigma^p_k = \bigcup_{k\geq 0} \text{AU}\Pi^p_k,$$

where

$$\text{AU}\Sigma^p_k = \begin{cases} \text{P} & \text{if } k = 0, \\ \exists! \cdot \text{AU}\Pi^p_{k-1} & \text{if } k \geq 1, \end{cases} \quad \text{and} \quad \text{AU}\Pi^p_k = \begin{cases} \text{P} & \text{if } k = 0, \\ \forall! \cdot \text{AU}\Sigma^p_{k-1} & \text{if } k \geq 1. \end{cases}$$

2. *The* unambiguous polynomial hierarchy *is defined as follows:*

$$\text{UPH} =_{df} \bigcup_{k\geq 0} \text{U}\Sigma^p_k = \bigcup_{k\geq 0} \text{U}\Pi^p_k,$$

where

$$\text{U}\Sigma^p_k = \begin{cases} \text{P} & \text{if } k = 0, \\ \text{UP}^{\text{U}\Sigma^p_{k-1}} & \text{if } k \geq 1, \end{cases} \quad \text{and} \quad \text{U}\Pi^p_k = \begin{cases} \text{P} & \text{if } k = 0, \\ \text{coUP}^{\text{U}\Sigma^p_{k-1}} & \text{if } k \geq 1. \end{cases}$$

[2] Arvind and Kurur [2] showed that the graph isomorphism problem (GI) belongs to SPP, a class introduced in [27, 41, 20]. Subsequently, Crâsmaru et al. [18] observed that the proof of classifying GI into SPP, as given by Arvind and Kurur [2], actually yields a somewhat improved classification for GI: GI belongs to $R^p_{s,T}$(Promise-UP), a subclass of SPP [18].

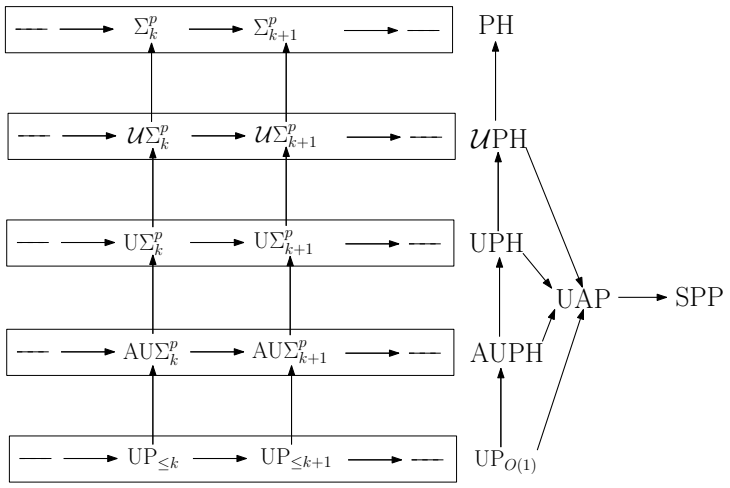

FIG. 1. *Known inclusion structure of unambiguity based classes and other central classes. The arrows point from subclasses to superclasses.*

3. *The* promise unambiguous polynomial hierarchy *is defined as follows:*

$$\mathcal{UPH} =_{df} \bigcup_{k\geq 0} \mathcal{U}\Sigma_k^p = \bigcup_{k\geq 0} \mathcal{U}\Pi_k^p,$$

where $\mathcal{U}\Sigma_0^p =_{df} \mathrm{P}$, $\mathcal{U}\Sigma_1^p =_{df} \mathrm{UP}$, *and for every* $k \geq 2$, $\mathcal{U}\Sigma_k^p$ *is the class of all sets* $L \in \Sigma_k^p$ *such that for some oracle* NPTM*s* N_1, N_2, ..., N_k, $L = L[\emptyset; N_1, N_2, \ldots, N_k]$, *and for every* $x \in \Sigma^*$ (i) $[\emptyset; N_1, N_2, \ldots, N_k](x)$ *has at most one accepting path, and* (ii) *for every* $1 \leq i \leq k-1$, *if* N_i *asks a query* w *to its oracle* $L[\emptyset; N_{i+1}, N_{i+2}, \ldots, N_k]$ *during the computation of* $[\emptyset; N_1, N_2, \ldots, N_k](x)$, *then* $[\emptyset; N_{i+1}, N_{i+2}, \ldots, N_k](w)$ *has at most one accepting path. For each* $k \geq 0$, *the class* $\mathcal{U}\Pi_k^p$ *is defined by* $\mathcal{U}\Pi_k^p =_{df} \mathrm{co}\mathcal{U}\Sigma_k^p$.

Notice that $\mathrm{U}\Sigma_k^p$ is also the class of all sets accepted by unambiguous $\Sigma_k(\emptyset)$-systems. Also notice that for any set $L = L[\emptyset; N_1, N_2, \ldots, N_k] \in \mathcal{U}\Sigma_k^p$, the $\Sigma_k(\emptyset)$-system $[\emptyset; N_1, N_2, \ldots, N_k]$ does not need to be unambiguous. In other words, for any string w that never appears as a query in the computation of $[\emptyset; N_1, N_2, \ldots, N_k]$ it may happen for some $1 \leq i \leq k$ that $[\emptyset; N_i, \ldots, N_k](w)$ has more than one accepting path.

The following inclusion relationships between unambiguity based classes and other central classes are known (see also Figure 1).

THEOREM 2.11.

1. *For all* $k \geq 0$, $\mathrm{AU}\Sigma_k^p \subseteq \mathrm{U}\Sigma_k^p \subseteq \mathcal{U}\Sigma_k^p \subseteq \Sigma_k^p$ [38].
2. *For all* $k \geq 1$, $\mathrm{UP}_{\leq k} \subseteq \mathrm{AU}\Sigma_k^p \subseteq \mathrm{U}\Sigma_k^p \subseteq \mathcal{U}\Sigma_k^p \subseteq \mathrm{UAP} \subseteq \mathrm{SPP}$ ([38] + [40] + [18]).
3. $\mathrm{P}^{\mathrm{FewP}} \subseteq \mathrm{P}_s^{\text{Promise-UP}}$ [16].

Despite the attention these hierarchies deserve, much less is known about the structure of these hierarchies since Lange and Rossmanith [38] first posed questions on their structure—such as, whether these hierarchies intertwine, or whether some unambiguity based hierarchy is contained in a fixed level of some other hierarchy, or whether some/all of these hierarchies collapse to a fixed level. On the positive side, there have been some advances in understanding the structure of these hierarchies. Hemaspaandra and Rothe [33] related the structure of these hierarchies to the exis-

tence of sparse Turing complete sets for UP. The structure of these hierarchies received renewed interest in some recent work (see [1, 18, 24, 46]). For instance, Spakowski and Tripathi [46] investigated the relativized structure of these hierarchies. They proved that the unambiguity based hierarchies AUPH, UPH, and $\mathcal{UPH}$ are infinite in some relativized world. They also proved a contrasting result on their relativized structure: For each $k \geq 2$, there is a relativized world where these hierarchies collapse so that they have exactly k distinct levels and their kth levels coincide with PSPACE.

3. Proof technique.

3.1. Main lemma. Our main lemma is Lemma 3.1, which we will use throughout this paper for generalizing known oracle constructions involving unambiguity based classes such as UP and Promise-UP to new oracle constructions involving arbitrary levels of the UPH. Roughly, Lemma 3.1 states computational limitations of a $\Sigma_k(\mathcal{O})$-system for any arbitrary $k \geq 1$, under certain weak conditions.

LEMMA 3.1. *Fix a $\Sigma_k(\mathcal{O})$-system $[\mathcal{O}; N_1, N_2, \ldots, N_k]$, a string $x \in \Sigma^*$, and a set $U \subseteq \Sigma^*$ such that $\mathcal{O} \cap U = \emptyset$. Let $r(.)$ be a polynomial that bounds the running time of each of the machines $N_1, N_2, \ldots, N_k$ (on any input and with any oracle). Then the following hold.*

(I) *Suppose $[\mathcal{O}; N_1, N_2, \ldots, N_k](x)$ accepts and for every $A \subseteq U$ with $||A|| \leq k$, $[\mathcal{O} \cup A; N_1, N_2, \ldots, N_k]$ is unambiguous. Let*

$$C = \{\alpha \in U \mid [\mathcal{O} \cup \{\alpha\}; N_1, N_2, \ldots, N_k](x) \text{ rejects}\}.$$

Then $||C|| \leq 5^k \cdot \prod_{i=1}^{k} (r\circ)^i(|x|)$.

(II) *Suppose $[\mathcal{O}; N_1, N_2, \ldots, N_k](x)$ rejects and for every $A \subseteq U$ with $||A|| \leq k+1$, $[\mathcal{O} \cup A; N_1, N_2, \ldots, N_k]$ is unambiguous. Let*

$$C = \{\alpha \in U \mid [\mathcal{O} \cup \{\alpha\}; N_1, N_2, \ldots, N_k](x) \text{ accepts}\}.$$

Then $||C|| \leq 5^k \cdot \prod_{i=1}^{k} (r\circ)^i(|x|)$.

Intuitively, this lemma says the following. If a $\Sigma_k(\mathcal{O})$-system is unambiguous when any subset A, which contains at most $k+1$ elements, of some fixed set U is added to the oracle $\mathcal{O}$, then this $\Sigma_k(\mathcal{O})$-system behaves similarly to a deterministic polynomial-time oracle Turing machine upon addition of single strings from U to $\mathcal{O}$. That is, if we want to change the acceptance behavior of the $\Sigma_k(\mathcal{O})$-system on some input x by adding a single string $\alpha \in U$ to the oracle $\mathcal{O}$, then we need to take α from a specific small (polynomial-size) subset C (which depends on x) of U.

Proof of Lemma 3.1. By induction on k, we prove the claim "For any oracle $\mathcal{O}$, any $\Sigma_k(\mathcal{O})$-system $[\mathcal{O}; N_1, N_2, \ldots, N_k]$, any $x \in \Sigma^*$, and any set $U \subseteq \Sigma^*$ such that $\mathcal{O} \cap U = \emptyset$, statements (I) and (II) hold."

For the base case $k = 1$ of (I), we have $[\mathcal{O}; N_1](x)$ accepts. Also, since $[\mathcal{O}; N_1]$ is unambiguous by the assumption made in (I), there is a unique accepting path in $[\mathcal{O}; N_1](x)$. Let C' be the set of all queries $w \in U$ along this unique accepting path. Then clearly $||C|| \leq ||C'|| \leq r(|x|)$. Thus (I) holds for the base case.

For the base case $k = 1$ of (II), we have $[\mathcal{O}; N_1](x)$ rejects. Suppose that $||C|| > 5 \cdot r(|x|)$. Note that for every $\alpha \in C$, $[\mathcal{O} \cup \{\alpha\}; N_1](x)$ accepts. Thus, for every $\alpha \in C$, let $\lambda(\alpha)$ be the accepting path in $[\mathcal{O} \cup \{\alpha\}; N_1](x)$. It is easy to show that $\lambda(\alpha_1) \neq \lambda(\alpha_2)$ for any distinct $\alpha_1, \alpha_2 \in C$. To see this, let $\rho = \lambda(\alpha)$ for some $\alpha \in C$. Then, by the definition of $\lambda(\alpha)$ and the assumption that $[\mathcal{O}; N_1](x)$ rejects, we notice that path ρ appears in $N_1^{\mathcal{O} \cup \{\alpha\}}(x)$ but does not appear in $N_1^{\mathcal{O}}(x)$. From this, it follows

that α must be answered positively along ρ, i.e., $\alpha \in Q^+(\rho)$, since otherwise ρ would also appear in $N_1^{\mathcal{O}}(x)$. Therefore, for any oracle $\mathcal{B}$ with $\alpha \notin \mathcal{B}$, ρ cannot appear in $N_1^{\mathcal{B}}(x)$. In particular, ρ cannot appear in $N_1^{\mathcal{O}\cup\{\alpha'\}}(x)$ for any α' with $\alpha' \neq \alpha$. Hence, we get that $\lambda(\alpha_1) \neq \lambda(\alpha_2)$ for any distinct $\alpha_1, \alpha_2 \in C$.

We define, for any $\alpha \in C$,

$$\text{conflicting}(\alpha) = \{\beta \in C \mid \lambda(\alpha) \text{ is not an accepting path in } [\mathcal{O} \cup \{\alpha, \beta\}; N_1](x)\}.$$

Since $N_1(x)$ with any oracle asks at most $r(|x|)$ queries, there can be at most $r(|x|)$ strings $\beta \in C$ that can cause $\lambda(\alpha)$ not to appear in $[\mathcal{O} \cup \{\alpha, \beta\}; N_1](x)$. In other words, for any $\alpha \in C$, it holds that $||\text{conflicting}(\alpha)|| \leq r(|x|)$. Thus, it follows by an easy counting argument and the assumption that $||C|| > 5 \cdot r(|x|)$ that there exist distinct $\alpha_1, \alpha_2 \in C$ such that $\alpha_1 \notin \text{conflicting}(\alpha_2)$ and $\alpha_2 \notin \text{conflicting}(\alpha_1)$. We have already shown that $\lambda(\alpha_1)$ and $\lambda(\alpha_2)$ are distinct paths for distinct $\alpha_1, \alpha_2 \in C$. Therefore, $[\mathcal{O} \cup \{\alpha_1, \alpha_2\}; N_1](x)$ has two distinct accepting paths, namely, $\lambda(\alpha_1)$ and $\lambda(\alpha_2)$. This contradicts our assumption that $[\mathcal{O} \cup A; N_1]$ is unambiguous for every $A \subseteq U$ with $||A|| \leq 2$. Thus (II) also holds for the base case.

Induction hypothesis. For $k \geq 1$, the following claim is true: For any oracle $\mathcal{O}$, any $\Sigma_k(\mathcal{O})$-system $[\mathcal{O}; N_1, N_2, \ldots, N_k]$, any $x \in \Sigma^*$, and any set $U \subseteq \Sigma^*$ such that $\mathcal{O} \cap U = \emptyset$, statements (I) and (II) hold.

Inductive step. Let $[\mathcal{O}; N_1, N_2, \ldots, N_{k+1}]$ be a $\Sigma_{k+1}(\mathcal{O})$-system, let $r(.)$ be a polynomial that bounds the running time of each of $N_1, N_2, \ldots, N_k, N_{k+1}$ (for any oracle), let $U \subseteq \Sigma^*$ such that $\mathcal{O} \cap U = \emptyset$, and let $x \in \Sigma^*$.

We first prove (I). Suppose $[\mathcal{O}; N_1, N_2, \ldots, N_{k+1}](x)$ accepts and $[\mathcal{O} \cup A; N_1, N_2, \ldots, N_{k+1}]$ is unambiguous for every $A \subseteq U$ with $||A|| \leq k+1$. Let λ denote the unique accepting path of $[\mathcal{O}; N_1, N_2, \ldots, N_{k+1}](x)$. For every query w along λ, the $\Sigma_k(\mathcal{O})$-system $[\mathcal{O}; N_2, N_3, \ldots, N_{k+1}]$ computes $[\mathcal{O}; N_2, N_3, \ldots, N_{k+1}](w)$. By Definition 2.3(1), for every $A \subseteq U$ with $||A|| \leq k+1$, the $\Sigma_k(\mathcal{O} \cup A)$-system $[\mathcal{O} \cup A; N_2, N_3, \ldots, N_{k+1}]$ is unambiguous. Thus, it follows by the induction hypothesis that for every query w along λ and for all but at most $5^k \cdot \prod_{i=1}^{k}(r\circ)^i(|w|) \leq 5^k \cdot \prod_{i=2}^{k+1}(r\circ)^i(|x|)$ strings $\alpha \in U$, adding $\alpha \in U$ to $\mathcal{O}$ does not change the decision (i.e., acceptance or rejection) of $[\mathcal{O}; N_2, N_3, \ldots, N_{k+1}](w)$. Since the number of such queries w along λ is at most $r(|x|)$, it follows that λ is an accepting path in $[\mathcal{O} \cup \{\alpha\}; N_1, N_2, \ldots, N_{k+1}](x)$ for all but at most $r(|x|) \cdot 5^k \cdot \prod_{i=2}^{k+1}(r\circ)^i(|x|) < 5^{k+1} \cdot \prod_{i=1}^{k+1}(r\circ)^i(|x|)$ strings $\alpha \in U$. This proves (I), the first part of the inductive step.

We now prove (II). Suppose that $||C|| > 5^{k+1} \cdot \prod_{i=1}^{k+1}(r\circ)^i(|x|)$. For any $\alpha \in C$, let $\lambda(\alpha)$ denote the unique accepting path in $[\mathcal{O} \cup \{\alpha\}; N_1, N_2, \ldots, N_{k+1}](x)$. We define an equivalence relation σ on C as follows: For every $\alpha_1, \alpha_2 \in C$,

$$\alpha_1 \sigma \alpha_2 \iff \lambda(\alpha_1) = \lambda(\alpha_2).$$

The following cases are exhaustive.

Case 1. There is an equivalence class of σ of size $> 5^k \cdot \prod_{i=1}^{k+1}(r\circ)^i(|x|)$. Let $[\alpha]$ be such an equivalence class. Then we have the following situation: The accepting path $\lambda(\alpha)$ does not appear in $[\mathcal{O}; N_1, N_2, \ldots, N_{k+1}](x)$, but for every $\beta \in [\alpha]$, path $\lambda(\alpha)$ appears in $[\mathcal{O} \cup \{\beta\}; N_1, N_2, \ldots, N_{k+1}](x)$. Hence for every query $w \in \Sigma^*$ along $\lambda(\alpha)$, it holds that for every $\beta, \beta' \in [\alpha]$, $[\mathcal{O} \cup \{\beta\}; N_2, N_3, \ldots, N_{k+1}](w)$ and $[\mathcal{O} \cup \{\beta'\}; N_2, N_3, \ldots, N_{k+1}](w)$ have the same acceptance behavior; i.e, $[\mathcal{O} \cup$

$\{\beta\}; N_2, N_3, \ldots, N_{k+1}](w)$ accepts if and only if $[\mathcal{O} \cup \{\beta'\}; N_2, N_3, \ldots, N_{k+1}](w)$ accepts. There must be at least one query $w' \in \Sigma^*$ along $\lambda(\alpha)$ such that for some $\beta \in [\alpha]$ (and hence by the previous sentence for *every* $\beta \in [\alpha]$), adding β to $\mathcal{O}$ changes the answer of $[\mathcal{O}; N_2, N_3, \ldots, N_{k+1}](w')$, since otherwise $\lambda(\alpha)$ would also appear in $[\mathcal{O}; N_1, N_2, \ldots, N_{k+1}](x)$. Also note that for every $A \subseteq U$ with $||A|| \leq k+1$, $[\mathcal{O} \cup A; N_2, N_3, \ldots, N_{k+1}]$ is unambiguous. Thus we get a contradiction with the induction hypothesis, since $|||[\alpha]||| > 5^k \cdot \prod_{i=1}^{k+1}(r\circ)^i(|x|) \geq 5^k \cdot \prod_{i=2}^{k+1}(r\circ)^i(|x|) \geq 5^k \cdot \prod_{i=1}^{k}(r\circ)^i(|w'|)$.

Case 2. Every equivalence class of σ is of size $\leq 5^k \cdot \prod_{i=1}^{k+1}(r\circ)^i(|x|)$. We need the following claim, which demonstrates that if σ is an equivalence relation over some set C consisting only of small equivalence classes, then C can be partitioned into two sufficiently large disjoint sets C_1 and C_2 such that every equivalence class is contained in either C_1 or C_2.

CLAIM 1. *Let σ be any equivalence relation over some set C, and let $||C|| > 5s$. If $|||[\alpha]||| \leq s$ for every $\alpha \in C$, then there is a partition (C_1, C_2) of C such that $||C_1||$, $||C_2|| > 2s$, and for every $\alpha \in C$, $[\alpha] \subseteq C_1$ or $[\alpha] \subseteq C_2$.*

Proof of Claim 1. Let D be any subset of C such that (i) for every $\alpha \in C$, $[\alpha] \subseteq D$ or $[\alpha] \cap D = \emptyset$, (ii) $||D|| \leq 2s$, and (iii) $||D \cup [\beta]|| > 2s$ for some $\beta \in C$. Such a set D exists because $||C|| > 5s$ and $|||[\alpha]||| \leq s$ for every $\alpha \in C$.

Let $C_1 = D \cup [\beta]$ for some $\beta \in C$ such that $||C_1|| > 2s$. Because $||\beta|| \leq s$, we have that $||C_1|| \leq ||D|| + |||[\beta]||| \leq 2s + s = 3s$. Now let $C_2 = C - C_1$. We see that $||C_2|| = ||C|| - ||C_1|| > 5s - 3s = 2s$. Moreover, every equivalence class is contained in either C_1 or C_2. This completes the proof of Claim 1. □

It is easy to see that our equivalence class σ over C satisfies the preconditions of Claim 1 for $s = 5^k \cdot \prod_{i=1}^{k+1}(r\circ)^i(|x|)$. Let (C_1, C_2) be the partition of C given by Claim 1. Then both $||C_1||$ and $||C_2||$ are greater than $2 \cdot 5^k \cdot \prod_{i=1}^{k+1}(r\circ)^i(|x|)$. For every $\alpha_1 \in C_1$ and $\alpha_2 \in C_2$, we define

$$\text{conflicting}(\alpha_1) = \{\beta_2 \in C_2 \mid \lambda(\alpha_1) \text{ is not an accepting path in } [\mathcal{O} \cup \{\alpha_1, \beta_2\}; N_1, N_2, \ldots, N_{k+1}](x)\},$$

and

$$\text{conflicting}(\alpha_2) = \{\beta_1 \in C_1 \mid \lambda(\alpha_2) \text{ is not an accepting path in } [\mathcal{O} \cup \{\alpha_2, \beta_1\}; N_1, N_2, \ldots, N_{k+1}](x)\}.$$

We claim that both $||\text{conflicting}(\alpha_1)||$ and $||\text{conflicting}(\alpha_2)||$ are no more than $5^k \cdot \prod_{i=1}^{k+1}(r\circ)^i(|x|)$. To prove this, first note that $N_1(x)$ with any oracle can ask at most $r(|x|)$ queries along a computation path. Second, for each $\gamma \in \{\alpha_1, \alpha_2\}$, we have that for any $A \subseteq U$ with $||A|| \leq k+1$, $[\mathcal{O} \cup \{\gamma\} \cup A; N_1, N_2, \ldots, N_{k+1}]$ is unambiguous. Therefore, it follows by the induction hypothesis (where now $\mathcal{O}$ is $\mathcal{O} \cup \{\gamma\}$ and $N_1, N_2, \ldots, N_k$ are $N_2, N_3, \ldots, N_{k+1}$) that for every query w made by $N_1(x)$ along $\lambda(\gamma)$ to the oracle $L[\mathcal{O} \cup \{\gamma\}; N_2, \ldots, N_{k+1}]$, there can be at most $5^k \cdot \prod_{i=1}^{k}(r\circ)^i(|w|) \leq 5^k \cdot \prod_{i=2}^{k+1}(r\circ)^i(|x|)$ strings $\beta \in U$ such that adding β to $\mathcal{O} \cup \{\gamma\}$ changes the decision (acceptance or rejection) of $[\mathcal{O} \cup \{\gamma\}; N_2, N_3, \ldots, N_{k+1}](w)$. These two facts imply the stated bound on $||\text{conflicting}(\alpha_1)||$ and $||\text{conflicting}(\alpha_2)||$.

With the bounds $||C_1||, ||C_2|| > 2 \cdot 5^k \cdot \prod_{i=1}^{k+1}(r\circ)^i(|x|)$, a simple counting argument now shows that there exist $\alpha_1 \in C_1$ and $\alpha_2 \in C_2$ such that $\alpha_1 \notin \text{conflicting}(\alpha_2)$ and $\alpha_2 \notin \text{conflicting}(\alpha_1)$. As a consequence, $[\mathcal{O} \cup \{\alpha_1, \alpha_2\}; N_1, N_2, \ldots, N_{k+1}](x)$

accepts along two distinct paths, namely, $\lambda(\alpha_1)$ and $\lambda(\alpha_2)$, which are indeed distinct since $[\alpha_1] \neq [\alpha_2]$. This gives a contradiction to the assumption that $[\mathcal{O} \cup A; N_1, N_2, \ldots, N_{k+1}]$ is unambiguous for every $A \subseteq U$ with $||A|| \leq k+1$. This completes the proof of Lemma 3.1. □

3.2. The notion of (h,t)-ambiguity for functions on $\wp(\Sigma^*)$. Any oracle machine can be interpreted as a function mapping a set of strings to another set of strings as follows: A machine N maps any set $\mathcal{O}$ to the set $L(N^{\mathcal{O}})$. Therefore, it makes sense to consider the (possibly partial) function $\mathcal{L} : \wp(\Sigma^*) \to \wp(\Sigma^*)$ defined by a $\Sigma_k(\cdot)$-system $[\cdot; N_1, N_2, \ldots, N_k]$. (That is, define $\mathcal{L}$ so that for every $\mathcal{O} \subseteq \Sigma^*$, $\mathcal{L}(\mathcal{O}) =_{df} L_{\text{unambiguous}}[\mathcal{O}; N_1, N_2, \ldots, N_k]$.) We introduce a convenient notion called "(h,t)-ambiguity" for (partial or total) functions, which we will later apply to functions defined by $\Sigma_k(\cdot)$-systems.

DEFINITION 3.2. *For any $h \in \mathbb{N}^+$ and polynomial $t(\cdot)$, we call a partial or total function $\mathcal{L} : \wp(\Sigma^*) \to \wp(\Sigma^*)$* (h,t)-ambiguous *if, for every $\mathcal{O}, U \subseteq \Sigma^*$ with $\mathcal{O} \cap U = \emptyset$, one of the following is true:*

1. *For some $A \subseteq U$ with $||A|| \leq h$, $\mathcal{L}(\mathcal{O} \cup A)$ is undefined, or*
2. *for every $w \in \Sigma^*$,*

$$||\{\alpha \in U \mid w \in \mathcal{L}(\mathcal{O} \cup \{\alpha\}) \iff w \notin \mathcal{L}(\mathcal{O})\}|| \leq t(|w|).$$

Many of the proofs in this paper apply Proposition 3.3 below. The proof of Proposition 3.3 is based on the definition of $L_{\text{unambiguous}}$ given in Definition 2.3 and on Lemma 3.1.

PROPOSITION 3.3. *For any $\Sigma_k(\cdot)$-system $[\cdot; N_1, N_2, \ldots, N_k]$, the function $\mathcal{L} : \wp(\Sigma^*) \to \wp(\Sigma^*)$ defined for any $\mathcal{B} \subseteq \Sigma^*$ by*

$$\mathcal{L}(\mathcal{B}) = L_{\text{unambiguous}}[\mathcal{B}; N_1, N_2, \ldots, N_k]$$

is $(k+1,t)$-ambiguous, where $t(\cdot) = 5^k \cdot \prod_{i=1}^{k} (p\circ)^i(\cdot)$ and $p(\cdot)$ is a polynomial that bounds the running time of the machines $N_1, N_2, \ldots, N_k$.

Proof. For every $\mathcal{O}, U \subseteq \Sigma^*$ with $\mathcal{O} \cap U = \emptyset$, we have the following two cases: either there is a set $A \subseteq U$ with $||A|| \leq k+1$ such that $[\mathcal{O} \cup A; N_1, N_2, \ldots, N_k]$ is ambiguous or there is no such set A. In the first case, $\mathcal{L}(\mathcal{O} \cup A)$ is undefined by the definition of $\mathcal{L}$ in the proposition and by Definition 2.3(2). In the second case, for every $A \subseteq U$ with $||A|| \leq k+1$, $[\mathcal{O} \cup A; N_1, N_2, \ldots, N_k]$ is unambiguous, and furthermore $\mathcal{L}(\mathcal{O} \cup A) = L[\mathcal{O} \cup A; N_1, N_2, \ldots, N_k]$. Thus, in this case, it follows by Lemma 3.1 that for every $w \in \Sigma^*$, there can be at most $t(|w|)$ strings $\alpha \in U$ such that adding α to $\mathcal{O}$ changes the membership of w in $\mathcal{L}(\mathcal{O})$. Clearly, in both cases we get that $\mathcal{L}$ is $(k+1,t)$-ambiguous. □

Some words are in order on the proof technique used in this paper. The machine N_1 in a $\Sigma_k(\mathcal{O})$-system $[\mathcal{O}; N_1, N_2, \ldots, N_k]$ has oracle access to the set $L[\mathcal{O}; N_2, N_3, \ldots, N_k]$. In many of our oracle constructions, we use the following central idea: At any stage, either there is a finite extension B of the current partial oracle $\mathcal{A}$ such that the $\Sigma_{k-1}(\mathcal{A} \cup B)$-system $[\mathcal{A} \cup B; N_2, N_3, \ldots, N_k]$ is ambiguous and simultaneously the constraints imposed by the construction at that stage are satisfied, or there is no such extension. In the first case, we extend $\mathcal{A}$ to $\mathcal{A} \cup B$, ensure that the $\Sigma_{k-1}(\mathcal{A}')$-system $[\mathcal{A}'; N_2, N_3, \ldots, N_k]$ remains ambiguous for the partial oracle $\mathcal{A}'$ at any later stage, and move to the next stage. In the second case, all finite extensions B of $\mathcal{A}$ that satisfy the imposed constraints lead to an unambiguous $\Sigma_{k-1}(\mathcal{A} \cup B)$-system $[\mathcal{A} \cup B; N_2, N_3, \ldots, N_k]$. So for these extensions B we have that $L_{\text{unambiguous}}[\mathcal{A} \cup$

$B; N_2, N_3, \ldots, N_k]$ equals $L[\mathcal{A} \cup B; N_2, N_3, \ldots, N_k]$. We define a function $\mathcal{L}'$ (as in Proposition 3.3) for any $\mathcal{B} \subseteq \Sigma^*$ by $\mathcal{L}'(\mathcal{B}) = L_{\text{unambiguous}}[\mathcal{B}; N_2, \ldots, N_k]$. Notice that by Proposition 3.3, $\mathcal{L}'$ is (k,t)-ambiguous. Moreover, for all finite extensions B of $\mathcal{A}$ mentioned above, $\mathcal{L}'(\mathcal{A} \cup B) = L[\mathcal{A} \cup B; N_2, N_3, \ldots, N_k]$.

It turns out that the (k,t)-ambiguity property of the function $\mathcal{L}'(\cdot)$, defined above for the $\Sigma_{k-1}(\cdot)$-subsystem $[\cdot; N_2, N_3, \ldots, N_k]$, is the only property of $\mathcal{L}'$ that is needed in our proofs. Therefore, we can assume without losing anything that in the $\Sigma_k(\mathcal{A})$-system $[\mathcal{A}; N_1, N_2, \ldots, N_k]$, the NPTM N_1 has oracle access to a set $\mathcal{L}(\mathcal{A})$, where $\mathcal{L}$ is an arbitrary (k,t)-ambiguous function, rather than to the set $\mathcal{L}'(\mathcal{A})$. This approach of using $\mathcal{L}(\mathcal{A})$ has its own advantages: It greatly simplifies our proof arguments and makes expressions compact, since we no longer need to deal with stacks of oracle NPTMs.

4. Applications. In this section, we demonstrate applications of our proof techniques. We show that our counting techniques are useful in generalizing certain known relativization results involving bounded ambiguity classes such as UP and Promise-UP to new results involving arbitrary levels of the UPH. This stands in contrast to generalizations achieved for relativization results involving levels of the PH. For instance, extending the relativized separation of initial levels of the PH [4, 5] to relativized separations of arbitrary levels of the PH [49] required applications of sophisticated circuit-theoretic techniques. For the case of the UPH, however, we show (via Theorem 4.1) that a relativized separation of its levels can be achieved by counting techniques alone, i.e., without resorting to circuit-theoretic tools and techniques.

4.1. Comparing bounded ambiguity classes with the levels of UPH. We compare classes defined by NPTMs having restrictions on the number of accepting paths ($\mathrm{UP}_{O(1)}$ and FewP) with levels of the UPH. It is known that $\mathrm{UP}_{\leq k} \subseteq \mathrm{U}\Sigma_k^p$ in all relativized worlds. Theorem 4.1 shows the optimality of this inclusion with respect to relativizable proof techniques. Beigel [6] constructed an oracle relative to which $\mathrm{UP}_{k(n)+1} \not\subseteq \mathrm{UP}_{k(n)}$ for every polynomial $k(n) \geq 2$. Theorem 4.1 subsumes this oracle result of Beigel [6] for any constant k.

By a slight modification of the oracle construction in Theorem 4.1, we can show that the second level $\mathcal{U}\Sigma_2^p$ of the promise unambiguous hierarchy $\mathcal{UPH}$ is not contained in the unambiguous polynomial hierarchy UPH. Results on relativized separations of levels of some unambiguity based hierarchy from another hierarchy have been investigated earlier. Rossmanith (see [40]) gave a relativized separation of $\mathrm{AU}\Sigma_k^p$ from $\mathrm{U}\Sigma_k^p$ for any $k \geq 2$. Spakowski and Tripathi [46] constructed an oracle relative to which $\mathrm{AU}\Sigma_k^p \not\subseteq \Pi_k^p$, for any $k \geq 1$. Our relativized separation of $\mathcal{U}\Sigma_2^p$ from UPH does not seem to be implied from these previous results in any obvious way.

THEOREM 4.1. *For any integer $k \geq 1$, there exists an oracle $\mathcal{A}$ such that* $\mathrm{UP}_{\leq k+1}^{\mathcal{A}} \not\subseteq \mathrm{U}\Sigma_k^{p,\mathcal{A}}$.

Proof. Our test language is $L(\mathcal{A}) = \{0^n \mid \mathcal{A}^{=n} \neq \emptyset\}$. We will create an oracle $\mathcal{A}$ that, for any length $n \in \mathbb{N}^+$, satisfies $||\mathcal{A}^{=n}|| \leq k+1$. Let $(N_{i,1}, N_{i,2}, \ldots, N_{i,k})$ be an enumeration of tuples, where $N_{i,\star}$ is a nondeterministic polynomial-time oracle Turing machine. Initially, $\mathcal{A} := \emptyset$.

Stage i. Let $p(\cdot)$ be a polynomial that bounds the running time of $N_{i,\star}$. Choose a large integer n such that (a) $2^n > 5^k \cdot \prod_{j=1}^{k} (p\circ)^j(n)$, (b) n satisfies the promises made in the previous stages, (c) no string of length $\geq n$ is ever queried in any of the previous stages, and (d) n is larger than the value in the previous stage. Because 2^n grows faster than any polynomial, it is easy to see that there always exists such an n.

If there exists a set $B \subseteq \Sigma^n$ such that $||B|| \leq k+1$ and $[\mathcal{A} \cup B; N_{i,1}, N_{i,2}, \ldots, N_{i,k}]$ is ambiguous, then set $\mathcal{A} := \mathcal{A} \cup B$. Promise to choose the value of n in the next stage to be larger than $(p\circ)^k(|w|)$, where w is an arbitrary string witnessing that $[\mathcal{A} \cup B; N_{i,1}, N_{i,2}, \ldots, N_{i,k}]$ is ambiguous, and then move to the next stage.

Otherwise, choose a string $\alpha \in \Sigma^n$ (as guaranteed by Lemma 3.1 and by our choice of n) such that

$$[\mathcal{A}; N_{i,1}, N_{i,2}, \ldots, N_{i,k}](0^n) \text{ accepts } \iff [\mathcal{A} \cup \{\alpha\}; N_{i,1}, N_{i,2}, \ldots, N_{i,k}](0^n) \text{ accepts.}$$

If $[\mathcal{A}; N_{i,1}, N_{i,2}, \ldots, N_{i,k}](0^n)$ accepts, then move to the next stage. Otherwise, if $[\mathcal{A}; N_{i,1}, N_{i,2}, \ldots, N_{i,k}](0^n)$ rejects, then set $\mathcal{A} := \mathcal{A} \cup \{\alpha\}$ and move to the next stage. *End of stage.*

Clearly the construction guarantees that $L(\mathcal{A}) \in \mathrm{UP}^{\mathcal{A}}_{\leq k+1} - \mathrm{U}\Sigma^{p,\mathcal{A}}_k$. □

A straightforward adaptation of the proof of Theorem 4.1 allows us to separate the second level, $\mathcal{U}\Sigma^p_2$, of the promise unambiguous polynomial hierarchy, $\mathcal{UPH}$, from the unambiguous polynomial hierarchy, UPH, in some relativized world. We obtain this relativized separation via Theorem 4.2, where the subclass $\mathrm{FewP}^{\mathcal{A}}$ of $\mathcal{U}\Sigma^{p,\mathcal{A}}_2$ (see Theorem 2.11(3)) is separated from $\mathrm{UPH}^{\mathcal{A}}$.

THEOREM 4.2. *There exists an oracle $\mathcal{A}$ such that* $\mathrm{FewP}^{\mathcal{A}} \not\subseteq \mathrm{UPH}^{\mathcal{A}}$.

Proof sketch. Take the test language $L(\mathcal{A})$ used in the proof of Theorem 4.1. Maintain the stipulation that the oracle $\mathcal{A}$ satisfies, for all $n \in \mathbb{N}^+$, $||\mathcal{A}^{=n}|| \leq n$; this ensures that $L(\mathcal{A}) \in \mathrm{FewP}^{\mathcal{A}}$. Finally, for all $k \in \mathbb{N}^+$, diagonalize against all tuples $(N_{i,1}, N_{i,2}, \ldots, N_{i,k})$ as in the proof of Theorem 4.1. □

COROLLARY 4.3. *There is a relativized world where $\mathcal{U}\Sigma^p_2$ is not contained in* UPH.

Cai, Hemachandra, and Vyskoč [16] proved that smart 2-Turing access to Promise-UP cannot be subsumed by $\mathrm{coNP}^{\mathrm{UP}} \cup \mathrm{NP}^{\mathrm{UP}}$ in some relativized world. As a consequence, they showed that there is a relativized world where smart bounded adaptive reductions to Promise-UP and smart bounded nonadaptive reductions to Promise-UP are nonequivalent, a characteristic that stands in contrast to the cases of UP and NP. (Both UP and NP are known to have equivalence between bounded adaptive reductions and bounded nonadaptive reductions in all relativized worlds (see [16, 48]).) We obtain a generalization of their result as a corollary of Theorem 4.4: There is a relativized world where smart k-Turing access to Promise-UP is not contained in $\mathrm{coNP}^{\mathrm{U}\Sigma^{p,\mathcal{A}}_{k-1}} \cup \mathrm{NP}^{\mathrm{U}\Sigma^{p,\mathcal{A}}_{k-1}}$ for any $k \geq 2$. The proof of Theorem 4.4 gives a first example of the role of (h,t)-ambiguity in derivations of our results.

THEOREM 4.4. *For any integer $k \geq 2$, there exists an oracle $\mathcal{A}$ such that*

$$\mathrm{UP}^{\mathcal{A}}_{\leq k} \not\subseteq \mathrm{coNP}^{\mathrm{U}\Sigma^{p,\mathcal{A}}_{k-1}}.$$

Proof. The test language $L(\mathcal{A})$ is the same as that in the proof of Theorem 4.1. We maintain the stipulation that for every $n \in \mathbb{N}^+$, $||\mathcal{A}^{=n}|| \leq k$; then, clearly $L(\mathcal{A}) \in \mathrm{UP}^{\mathcal{A}}_{\leq k}$. We will show that $L(\mathcal{A}) \notin \mathrm{coNP}^{\mathrm{U}\Sigma^{p,\mathcal{A}}_{k-1}}$.

Let $(N_{i,1}, N_{i,2}, \ldots, N_{i,k})$ be an enumeration of tuples, where $N_{i,\star}$ is a nondeterministic polynomial-time oracle Turing machine. Initially, $\mathcal{A} := \emptyset$.

Stage i. Let $p(\cdot)$ be a polynomial that bounds the running time of $N_{i,\star}$. Choose a large integer n such that (a) $2^n > 5^{k-1} \cdot \prod_{j=1}^{k} (p\circ)^j(n)$, (b) n satisfies any promises made in the previous stages, (c) n is larger than the value of n in the previous stages, and (d) no queries of length $\geq n$ are made in the previous stages.

If there exists a set $B \subseteq \Sigma^n$ such that $||B|| \leq k$ and $[\mathcal{A} \cup B; N_{i,2}, N_{i,3}, \ldots, N_{i,k}]$ is ambiguous, then set $\mathcal{A} := \mathcal{A} \cup B$. Promise to choose the value of n in the next stage to be larger than $(p\circ)^{k-1}(|w|)$, where w is any arbitrary string witnessing that $[\mathcal{A} \cup B; N_{i,2}, N_{i,3}, \ldots, N_{i,k}]$ is ambiguous, and then move to the next stage.

Otherwise proceed as follows. Let $\mathcal{L} : \wp(\Sigma^*) \to \wp(\Sigma^*)$ be the function defined so that for every $\mathcal{O} \subseteq \Sigma^*$,

$$\mathcal{L}(\mathcal{O}) =_{df} L_{\text{unambiguous}}[\mathcal{O}; N_{i,2}, N_{i,3}, \ldots, N_{i,k}].$$

It follows from Proposition 3.3 that $\mathcal{L}$ is (k,t)-ambiguous for polynomial $t(\cdot) =_{df} 5^{k-1} \cdot \prod_{j=1}^{k-1}(p\circ)^j(\cdot)$. Notice that for every $B \subseteq \Sigma^n$ satisfying $||B|| \leq k$, $\mathcal{L}(\mathcal{A} \cup B)$ is defined and moreover $\mathcal{L}(\mathcal{A} \cup B) = L[\mathcal{A} \cup B; N_{i,2}, N_{i,3}, \ldots, N_{i,k}]$.

If $N_{i,1}^{\mathcal{L}(\mathcal{A})}(0^n)$ rejects, then move to the next stage. Otherwise, fix an accepting path ρ in $N_{i,1}^{\mathcal{L}(\mathcal{A})}(0^n)$. For each query $w \in Q(\rho)$, let $C(w) =_{df} \{\alpha \in \Sigma^n \mid w \in \mathcal{L}(\mathcal{A} \cup \{\alpha\}) \iff w \notin \mathcal{L}(\mathcal{A})\}$. By the definition of (k,t)-ambiguity, for each $w \in Q(\rho)$, we have $||C(w)|| \leq t(|w|) \leq t(p(n))$. Because n is large enough, we can choose some $\alpha \in \Sigma^n$ such that $\alpha \notin \bigcup_{w \in Q(\rho)} C(w)$. Set $\mathcal{A} := \mathcal{A} \cup \{\alpha\}$ and move to the next stage. *End of stage.*

Clearly the construction guarantees that $L(\mathcal{A}) \notin \text{coNP}^{\text{U}\Sigma_{k-1}^{p,A}}$.

This completes the proof of Theorem 4.4. □

COROLLARY 4.5. *For any integer $k \geq 2$, there exists an oracle $\mathcal{A}$ such that*

$$R^p_{s,k\text{-}T}(\text{Promise-UP}^{\mathcal{A}}) \not\subseteq \text{coNP}^{\text{U}\Sigma_{k-1}^{p,A}} \cup \text{NP}^{\text{U}\Sigma_{k-1}^{p,A}}.$$

Proof. This follows from Theorem 4.4 because for all oracles $\mathcal{A}$, $\text{UP}^{\mathcal{A}}_{\leq k} \subseteq R^p_{s,k\text{-}T}(\text{Promise-UP}^{\mathcal{A}})$ and $R^p_{s,k\text{-}T}(\text{Promise-UP}^{\mathcal{A}})$ is closed under complementation. □

4.2. Simulating nonadaptive access by adaptive access (non–promise case). It is known that adaptive Turing access to NP is exponentially more powerful compared to nonadaptive Turing access to NP. That is, $R^p_{(2^k-1)\text{-}tt}(\text{NP}) \subseteq R^p_{k\text{-}T}(\text{NP})$ [7], and this inclusion relativizes. However, for the case of unambiguous nondeterministic computation, such a relationship between nonadaptive access and adaptive access is not known. Cai, Hemachandra, and Vyskoč [15] showed that even proving the superiority of adaptive Turing access over nonadaptive Turing access with one single query more might be nontrivial for unambiguous nondeterministic computation.

THEOREM 4.6 ([15]). *For any total, polynomial-time computable, and polynomially bounded function $k(\cdot)$, there exists an oracle $\mathcal{A}$ such that*

$$R^p_{(k(n)+1)\text{-}tt}(\text{UP}^{\mathcal{A}}) \not\subseteq R^{p,\mathcal{A}}_{k(n)\text{-}T}(\text{UP}^{\mathcal{A}}).$$

In the next theorem, we generalize this result to the higher levels of the unambiguous polynomial hierarchy UPH.

THEOREM 4.7. *For any total, polynomial-time computable, and polynomially bounded function $k(\cdot)$ and integer $h \geq 1$, there exists an oracle $\mathcal{A}$ such that*

$$\text{R}^p_{(k(n)+1)\text{-}dtt}(\text{UP}^{\mathcal{A}}_{\leq h}) \not\subseteq \text{R}^{p,\mathcal{A}}_{k(n)\text{-}T}(\text{U}\Sigma^{p,\mathcal{A}}_h),$$

and hence $\text{R}^p_{(k(n)+1)\text{-}dtt}(\text{U}\Sigma^{p,\mathcal{A}}_h) \not\subseteq \text{R}^{p,\mathcal{A}}_{k(n)\text{-}T}(\text{U}\Sigma^{p,\mathcal{A}}_h)$.

For the proof of Theorem 4.7, we need the following lemma.

LEMMA 4.8. *Fix an oracle* NPTM N *with running time bounded by some polynomial* $p(\cdot)$*, string* $x \in \Sigma^*$*, and sets* $\mathcal{O}, U_1, U_2 \subseteq \Sigma^*$ *such that* $\mathcal{O} \cap U_1 = \mathcal{O} \cap U_2 = U_1 \cap U_2 = \emptyset$*. Let* $\mathcal{L} : \wp(\Sigma^*) \to \wp(\Sigma^*)$ *be an* (h,t)*-ambiguous function such that* $\mathcal{L}(\mathcal{O} \cup A_1 \cup A_2)$ *is defined for every* $A_1 \subseteq U_1$ *and* $A_2 \subseteq U_2$ *with* $||A_1|| \leq h$ *and* $||A_2|| \leq h$*. Let*

$$C_1 = \{\alpha \in U_1 \mid N^{\mathcal{L}(\mathcal{O})}(x) \text{ accepts} \iff N^{\mathcal{L}(\mathcal{O}\cup\{\alpha\})}(x) \text{ rejects}\} \text{ and}$$
$$C_2 = \{\alpha \in U_2 \mid N^{\mathcal{L}(\mathcal{O})}(x) \text{ accepts} \iff N^{\mathcal{L}(\mathcal{O}\cup\{\alpha\})}(x) \text{ rejects}\}.$$

If $N^{\mathcal{L}(\mathcal{O}\cup A_1\cup A_2)}(x)$ *is unambiguous for every* $A_1 \subseteq U_1$ *and* $A_2 \subseteq U_2$ *with* $||A_1|| \leq 1$ *and* $||A_2|| \leq 1$*, then* $\min\{||C_1||, ||C_2||\} \leq 2 \cdot p(|x|) \cdot t(p(|x|)) \cdot (p(|x|) \cdot t(p(|x|)) + 1)$.

Proof. We start with the easier case that $N^{\mathcal{L}(\mathcal{O})}(x)$ accepts. Let ρ be the (unique) accepting computation path in $N^{\mathcal{L}(\mathcal{O})}(x)$. Then $N^{\mathcal{L}(\mathcal{O}\cup\{\alpha\})}(x)$ accepts unless for some query $w \in Q(\rho)$, it is the case that $w \in \mathcal{L}(\mathcal{O} \cup \{\alpha\}) \iff w \notin \mathcal{L}(\mathcal{O})$. Since $N^{\mathcal{L}(\mathcal{O})}(x)$ queries at most $p(|x|)$ queries along every path, since each query $w \in Q(\rho)$ is of length $\leq p(|x|)$, since $\mathcal{L}$ is (h,t)-ambiguous, and since $\mathcal{L}(\mathcal{O} \cup A_1 \cup A_2)$ is defined for every $A_1 \subseteq U_1$ and $A_2 \subseteq U_2$ with $||A_1||, ||A_2|| \leq h$, there cannot be more than $p(|x|) \cdot t(p(|x|))$ strings $\alpha \in U_1$ (or $\alpha \in U_2$) making $N^{\mathcal{L}(\mathcal{O}\cup\{\alpha\})}(x)$ reject. Hence $||C_1|| \leq p(|x|) \cdot t(p(|x|))$ and $||C_2|| \leq p(|x|) \cdot t(p(|x|))$.

For the other case, suppose that $N^{\mathcal{L}(\mathcal{O})}(x)$ rejects. To get a contradiction, assume that $\min\{||C_1||, ||C_2||\} > 2 \cdot p(|x|) \cdot t(p(|x|)) \cdot (p(|x|) \cdot t(p(|x|)) + 1)$. For every $\alpha \in C_1 \cup C_2$, denote by $s(\alpha)$ the unique accepting computation path in $N^{\mathcal{L}(\mathcal{O}\cup\{\alpha\})}(x)$. Define an equivalence relation σ_1 on C_1 as follows: For all $\alpha_1, \alpha_2 \in C_1$,

$$\alpha_1 \sigma_1 \alpha_2 \iff s(\alpha_1) = s(\alpha_2).$$

Let C_1/σ_1 be the quotient set of C_1 determined by σ_1. We first prove that

$$||C_1/\sigma_1|| \geq \frac{||C_1||}{p(|x|) \cdot t(p(|x|))}. \tag{4.1}$$

To this end, consider any $\alpha \in C_1$. Note that for every query $w \in Q(s(\alpha))$, there cannot be more than $t(|w|)$ different strings $\alpha' \in C_1$ such that

$$w \in \mathcal{L}(\mathcal{O} \cup \{\alpha'\}) \iff w \notin \mathcal{L}(\mathcal{O}).$$

This holds because $\mathcal{L}$ is (h,t)-ambiguous and because $\mathcal{L}(\mathcal{O} \cup A)$ is defined for every $A \subseteq U_1$ with $||A|| \leq h$. Also since there are at most $p(|x|)$ queries $w \in Q(s(\alpha))$ and each such query is of length $\leq p(|x|)$, there cannot be more than $p(|x|) \cdot t(p(|x|))$ strings $\alpha' \in C_1$ such that for some query $w \in Q(s(\alpha))$, it is the case that $w \in \mathcal{L}(\mathcal{O} \cup \{\alpha'\})$ if and only if $w \notin \mathcal{L}(\mathcal{O})$. In other words, for all but $p(|x|) \cdot t(p(|x|))$ strings $\alpha' \in C_1$, the membership in $\mathcal{L}(\mathcal{O})$ of every query $w \in Q(s(\alpha))$ remains unchanged on inclusion of α' to $\mathcal{O}$. Since, by assumption, $N^{\mathcal{L}(\mathcal{O})}(x)$ rejects, it follows that for no more than $p(|x|) \cdot t(p(|x|))$ strings $\alpha' \in C_1$, (accepting) path $s(\alpha)$ appears in $N^{\mathcal{L}(\mathcal{O}\cup\alpha')}(x)$. Hence there cannot be more than $p(|x|) \cdot t(p(|x|))$ different strings $\alpha' \in C_1$ such that $s(\alpha') = s(\alpha)$. Thus we have proved statement (4.1).

Analogously, the same can be proved for C_2 with appropriately defined equivalence class σ_2.

Define $\widetilde{C}_1$ to be a maximal subset of C_1 such that $s(\alpha_1) \neq s(\alpha_2)$ for every $\alpha_1, \alpha_2 \in \widetilde{C}_1$ with $\alpha_1 \neq \alpha_2$. Analogously, define $\widetilde{C}_2$. Clearly,

$$||\widetilde{C}_1|| \geq \frac{||C_1||}{p(|x|) \cdot t(p(|x|))} > 2 \cdot (p(|x|) \cdot t(p(|x|)) + 1), \tag{4.2}$$

and

$$||\widetilde{C}_2|| \geq \frac{||C_2||}{p(|x|) \cdot t(p(|x|))} > 2 \cdot (p(|x|) \cdot t(p(|x|)) + 1). \tag{4.3}$$

For every $\alpha_1 \in \widetilde{C}_1$, let

$$\begin{aligned}\text{conflicting}(\alpha_1) = \{\beta_2 \in \widetilde{C}_2 \,\big|\, & s(\alpha_1) \text{ does not appear in } N^{\mathcal{L}(\mathcal{O}\cup\{\alpha_1,\beta_2\})}(x) \\ & \text{or } s(\alpha_1) = s(\beta_2)\},\end{aligned}$$

and for every $\alpha_2 \in \widetilde{C}_2$, let

$$\begin{aligned}\text{conflicting}(\alpha_2) = \{\beta_1 \in \widetilde{C}_1 \,\big|\, & s(\alpha_2) \text{ does not appear in } N^{\mathcal{L}(\mathcal{O}\cup\{\alpha_2,\beta_1\})}(x) \\ & \text{or } s(\alpha_2) = s(\beta_1)\}.\end{aligned}$$

Fix an arbitrary $\alpha \in \widetilde{C}_1$. Since $\mathcal{L}$ is (h,t)-ambiguous and $\mathcal{L}(\mathcal{O} \cup A_1 \cup A_2)$ is defined for every $||A_1|| \leq 1$ and $||A_2|| \leq h$, it holds that for every query $w \in Q(s(\alpha))$ in $N^{\mathcal{L}(\mathcal{O}\cup\{\alpha\})}(x)$, there cannot be more than $t(|w|)$ different strings $\beta \in \widetilde{C}_2$ such that

$$w \in \mathcal{L}(\mathcal{O} \cup \{\alpha, \beta\}) \iff w \notin \mathcal{L}(\mathcal{O} \cup \{\alpha\}).$$

Also, since no more than $p(|x|)$ strings are queried on each path in $N^{\mathcal{L}(\mathcal{O}\cup\{\alpha\})}(x)$, since each queried string is of length $\leq p(|x|)$, and since, for distinct α_1 and α_2, $s(\alpha_1) \neq s(\alpha_2)$ whenever $\{\alpha_1, \alpha_2\} \subseteq \widetilde{C}_2$, we have that for any $\alpha \in \widetilde{C}_1$,

$$||\text{conflicting}(\alpha)|| \leq p(|x|) \cdot t(p(|x|)) + 1.$$

Analogously, we can prove that for any $\alpha' \in \widetilde{C}_2$,

$$||\text{conflicting}(\alpha')|| \leq p(|x|) \cdot t(p(|x|)) + 1.$$

With the lower bounds on $||\widetilde{C}_1||$ and $||\widetilde{C}_2||$ given by (4.2) and (4.3), it now follows by a simple counting argument that there is a pair $(\alpha_1, \alpha_2) \in \widetilde{C}_1 \times \widetilde{C}_2$ such that $\alpha_2 \notin \text{conflicting}(\alpha_1)$ and $\alpha_1 \notin \text{conflicting}(\alpha_2)$. Take two such strings α_1 and α_2. It is easy to see that both $s(\alpha_1)$ and $s(\alpha_2)$ appear in $N^{\mathcal{L}(\mathcal{O}\cup\{\alpha_1,\alpha_2\})}(x)$. Furthermore, $s(\alpha_1) \neq s(\alpha_2)$. Hence, $N^{\mathcal{L}(\mathcal{O}\cup\{\alpha_1,\alpha_2\})}(x)$ has two different accepting computation paths: $s(\alpha_1)$ and $s(\alpha_2)$. This gives a contradiction to the assumption that $N^{\mathcal{L}(\mathcal{O}\cup A_1\cup A_2)}$ is unambiguous whenever $A_1 \subseteq U_1$ and $A_2 \subseteq U_2$ with $||A_1|| \leq 1$ and $||A_2|| \leq 1$. This completes the proof of Lemma 4.8. □

Proof of Theorem 4.7. The test language $L(\mathcal{A})$ for our oracle construction is inspired by the one in [16, Theorem 3.1]. For length n, we will reserve the following segment of $k(n)+1$ regions $S_{n,f} = 1^n 01^f 0\Sigma^n$, where $f \in [k(n)+1]$. For $n \geq 1$, define $S_n = \bigcup_{f=1}^{k(n)+1} S_{n,f}$. For all $n \geq 1$ and $f \in [k(n)+1]$, we stipulate that $||\mathcal{A} \cap S_{n,f}|| \leq h$. Let

$$L(\mathcal{A}) = \{0^n \,\big|\, ||\mathcal{A} \cap S_n|| \geq 1\}.$$

Clearly, as long as the oracle set $\mathcal{A}$ maintains the stipulation that $||\mathcal{A} \cap S_{n,f}|| \leq h$, we have $L(\mathcal{A}) \in \mathrm{R}^p_{(k(n)+1)\text{-}dtt}(\mathrm{UP}^{\mathcal{A}}_{\leq h})$ and hence $L(\mathcal{A}) \in \mathrm{R}^p_{(k(n)+1)\text{-}dtt}(\mathrm{U}\Sigma^{p,\mathcal{A}}_h)$. We construct an oracle $\mathcal{A}$ such that $L(\mathcal{A}) \notin \mathrm{R}^p_{k(n)\text{-}T}(\mathrm{U}\Sigma^{p,\mathcal{A}}_h)$.[3]

[3]The construction can be easily modified to prove the stronger result that $L(\mathcal{A}) \notin \mathrm{R}^{p,\mathcal{A}}_{k(n)-T}(\mathrm{U}\Sigma^{p,\mathcal{A}}_h)$.

We give a brief informal outline of how the diagonalization for $L(\mathcal{A}) \notin \mathrm{R}^p_{k(n)\text{-}T}(\mathrm{U}\Sigma^{p,\mathcal{A}}_h)$ is carried out. Fix some input 0^n. The crucial fact is that we have $k(n)+1$ regions but only $k(n)$ adaptive Turing queries. There are two cases. The easier case is when we can destroy the unambiguity of one of the machines defining the $\mathrm{U}\Sigma^{p,\mathcal{A}}_h$ set by adding some strings to the current segment (but, of course, without violating the above stipulation, i.e., the stipulation that $||\mathcal{A} \cap S_{n,f}|| \leq h$ for every $f \in [k(n)+1]$). In this case we can simply add these strings to the oracle and move to the next stage. Otherwise, we can use Lemma 4.8 to show that each Turing query is *insensitive* to all but at most one of the $k(n)+1$ regions. A Turing query β is *insensitive* to a region if adding a single string α to that region does not change the answer to β, unless the string α comes from a very small (i.e., polynomially bounded) number of exceptions. But we have only $k(n)$ Turing queries. That is why there must be a region $S_{n,f}$ to which all Turing queries are insensitive. Since $S_{n,f}$ has exponentially many strings but only polynomially many exceptions, there must be at least one string $\alpha^* \in S_{n,f}$ that we can add to the current segment without changing the answers to any of the Turing queries, and hence without changing the decision (i.e, acceptance or rejection) of the deterministic machine M making the Turing reduction. We add this string α^* to the oracle (thereby changing the membership of 0^n in the test language) if and only if M rejects. This completes the construction in the current stage, and so we move to the next stage.

Now we come to the formal description of the diagonalization. Let $(N_{i,1}, N_{i,2}, \ldots, N_{i,h}, M_j)$ be an enumeration of tuples where $N_{i,*}$ is a nondeterministic polynomial-time oracle Turing machine, and M_j is a deterministic polynomial-time oracle Turing machine making, for any set $\mathcal{A}$ and any input of length n, at most $k(n)$ queries to $L[\mathcal{A}; N_{i,1}, N_{i,2}, \ldots, N_{i,h}]$. Initially, let $\mathcal{A} := \emptyset$.

Stage $\langle i, j\rangle$. Let $p(\cdot)$ be a polynomial that bounds the running time of both $N_{i,*}$ and M_j. Choose an integer n satisfying the following requirements: (a) $2^n > 2 \cdot k(n) \cdot p(p(n)) \cdot t(p(p(n))) \cdot (p(p(n)) \cdot t(p(p(n))) + 1)$, where $t(\cdot)$ is a polynomial defined later in this proof, (b) n is large enough so that n satisfies any promises made in the previous stages and no string of length greater than or equal to n is queried in any of the previous stages, and (c) n is larger than the value of n in the previous stage.

If there exists a set $B \subseteq S_n$ satisfying $||B \cap S_{n,f}|| \leq h$ for every $f \in [k(n)+1]$ such that $[\mathcal{A} \cup B; N_{i,1}, N_{i,2}, \ldots, N_{i,h}]$ is ambiguous, then set $\mathcal{A} := \mathcal{A} \cup B$. Promise to choose the value of n in the next stage to be larger than $(p\circ)^h(|w|)$, where w is an arbitrary input string witnessing that $[\mathcal{A} \cup B; N_{i,1}, N_{i,2}, \ldots, N_{i,h}]$ is ambiguous, and then move to the next stage.

Otherwise proceed as follows. Let $\mathcal{L} : \wp(\Sigma^*) \to \wp(\Sigma^*)$ be the function defined so that for every $\mathcal{O} \subseteq \Sigma^*$,

$$\mathcal{L}(\mathcal{O}) =_{df} \begin{cases} \mathcal{O} & \text{if } h = 1, \text{ and} \\ L_{\text{unambiguous}}[\mathcal{O}; N_{i,2}, N_{i,3}, \ldots, N_{i,h}] & \text{if } h \geq 2. \end{cases}$$

It is easy to see that for the case $h = 1$, $\mathcal{L}$ is (h,t)-ambiguous by Definition 3.2, where $t(\cdot) = 1$ is a constant polynomial, and for the case $h \geq 2$, $\mathcal{L}$ is (h,t)-ambiguous by Proposition 3.3, where $t(\cdot) = 5^{h-1} \cdot \prod_{\ell=1}^{h-1} (p\circ)^\ell(\cdot)$. Also, note that for all integers $h \geq 1$, $\mathcal{L}(\mathcal{A} \cup B)$ is defined for every $B \subseteq S_n$ satisfying $||B \cap S_{n,f}|| \leq h$ for every $f \in [k(n)+1]$.

If $M_j(0^n)$ with oracle $L(N_{i,1}^{\mathcal{L}(\mathcal{A})})$ is accepting, then move on to the next stage. If $M_j(0^n)$ with oracle $L(N_{i,1}^{\mathcal{L}(\mathcal{A})})$ is rejecting, then look for a string $\alpha \in S_n$ that can be

added to $\mathcal{A}$ without changing the decision (i.e., acceptance or rejection) of $M_j(0^n)$ with oracle $L(N_{i,1}^{\mathcal{L}(\mathcal{A})})$. Set $\mathcal{A} := \mathcal{A} \cup \{\alpha\}$ and move to the next stage. *End of stage.*

It remains to show that such a string α always exists. Consider $M_j(0^n)$ with oracle $L(N_{i,1}^{\mathcal{L}(\mathcal{A})})$. Let $\beta_1, \beta_2, \ldots, \beta_{k(n)}$ be the sequence of queries made by $M_j(0^n)$ to the oracle $L(N_{i,1}^{\mathcal{L}(\mathcal{A})})$. The following claim states that, for any $\beta \in \Sigma^*$, there is one special region $S_{n,\text{sensitive}(\beta)}$ such that, for all regions $S_{n,f}$ different from $S_{n,\text{sensitive}(\beta)}$, and for all but polynomially many $\alpha \in S_{n,f}$, the decision (i.e., acceptance or rejection) of $N_{i,1}^{\mathcal{L}(\mathcal{A})}(\beta)$ remains unchanged on the addition of α to $\mathcal{A}$.

CLAIM 2. *For each $\beta \in \Sigma^*$, there is an integer* $\text{sensitive}(\beta) \in [k(n)+1]$ *such that the following is true.*

For every $f \in [k(n)+1] - \{\text{sensitive}(\beta)\}$, there is a set $C_f(\beta) \subseteq S_{n,f}$ with $||C_f(\beta)|| \le 2 \cdot p(|\beta|) \cdot t(p(|\beta|)) \cdot (p(|\beta|) \cdot t(p(|\beta|)) + 1)$ such that, for every $\alpha \in S_{n,f} - C_f(\beta)$,

$$\beta \in L(N_{i,1}^{\mathcal{L}(\mathcal{A})}) \iff \beta \in L(N_{i,1}^{\mathcal{L}(\mathcal{A}\cup\{\alpha\})}).$$

Let us assume that the claim is true. There are $k(n)+1$ regions in S_n but only $k(n)$ queries $\beta_1, \beta_2, \ldots, \beta_{k(n)}$ made by $M_j(0^n)$ to $L(N_{i,1}^{\mathcal{L}(\mathcal{A})})$. Let $\ell \in [k(n)+1]$ such that $\ell \neq \text{sensitive}(\beta_e)$ for every $e \in [k(n)]$. Let $C = C_\ell(\beta_1) \cup C_\ell(\beta_2) \cup \cdots \cup C_\ell(\beta_{k(n)})$. Note that, for each $e \in [k(n)]$, $|\beta_e| \le p(n)$ and so $||C_\ell(\beta_e)|| \le 2 \cdot p(p(n)) \cdot t(p(p(n))) \cdot (p(p(n)) \cdot t(p(p(n))) + 1)$. Hence, by the assumption on our choice of n, $||C|| \le k(n) \cdot \max_{\ell \in [k(n)]}\{||C_\ell(\beta_e)||\} < 2^n$.

Let α be any string in $S_{n,\ell} - C$. Such a string exists because $||C|| < 2^n = ||S_{n,\ell}||$. It is easy to see by the above definition of the set C that we can add α to $\mathcal{A}$ without changing the decision of $N_{i,1}^{\mathcal{L}(\mathcal{A})}(\beta_e)$ for any $e \in [k(n)]$. Clearly, $M_j(0^n)$ with its $k(n)$ queries to $L(N_{i,1}^{\mathcal{L}(\mathcal{A})})$ accepts if and only if $M_j(0^n)$ with its $k(n)$ queries to $L(N_{i,1}^{\mathcal{L}(\mathcal{A}\cup\{\alpha\})})$ accepts. This completes the proof of Theorem 4.7. □

Proof of Claim 2. Suppose the claim were false. Then there exists $\beta \in \Sigma^*$ and $f_1, f_2 \in [k(n)+1]$ with $f_1 \neq f_2$ such that

- $C_{f_1}(\beta) =_{df} ||\{\alpha \in S_{n,f_1} \,|\, \beta \in L(N_{i,1}^{\mathcal{L}(\mathcal{A})}) \iff \beta \notin L(N_{i,1}^{\mathcal{L}(\mathcal{A}\cup\{\alpha\})})\}|| > 2 \cdot p(|\beta|) \cdot t(p(|\beta|)) \cdot (p(|\beta|) \cdot t(p(|\beta|)) + 1)$, and
- $C_{f_2}(\beta) =_{df} ||\{\alpha \in S_{n,f_2} \,|\, \beta \in L(N_{i,1}^{\mathcal{L}(\mathcal{A})}) \iff \beta \notin L(N_{i,1}^{\mathcal{L}(\mathcal{A}\cup\{\alpha\})})\}|| > 2 \cdot p(|\beta|) \cdot t(p(|\beta|)) \cdot (p(|\beta|) \cdot t(p(|\beta|)) + 1)$.

Apply Lemma 4.8 with $N := N_{i,1}$, $x := \beta$, $\mathcal{O} := \mathcal{A}$, $U_1 := S_{n,f_1}$, and $U_2 := S_{n,f_2}$. We obtain $\min\{||C_{f_1}(\beta)||, ||C_{f_2}(\beta)||\} \le 2 \cdot p(|\beta|) \cdot t(p(|\beta|)) \cdot (p(|\beta|) \cdot t(p(|\beta|)) + 1)$, which is a contradiction. □

4.3. Simulating nonadaptive access by adaptive access (promise case). Cai, Hemachandra, and Vyskoč [16] proved the following partial improvement of their Theorem 4.6.

THEOREM 4.9 ([16]). *For any constant k, there exists an oracle $\mathcal{A}$ such that*

$$R^p_{(k+1)\text{-}tt}(\text{UP}^{\mathcal{A}}) \not\subseteq R^{p,\mathcal{A}}_{s,k\text{-}T}(\text{Promise-UP}^{\mathcal{A}}).$$

Note that we have replaced "UP" by "Promise-UP" on the right-hand side of the noninclusion relation of Theorem 4.6. This is a significant improvement for the following reason. The computational powers of $R^p_b(\text{UP})$ and $R^p_{s,b}(\text{Promise-UP})$ (the bounded Turing closure of UP and the bounded smart Turing closure of Promise-UP, respectively) are known to be remarkably different in certain relativized worlds. While

it is easy to show that $\mathrm{UP}_{\leq k}$ is robustly (i.e., for every oracle) contained in $\mathrm{P}^{\text{Promise-UP}}_{s,k\text{-}T}$ for any $k \geq 1$, we have shown in the proof of Theorem 4.4 that for no $k \geq 2$ is $\mathrm{UP}_{\leq k}$ robustly contained in P^{UP}. Therefore, it is not immediately clear whether this improvement is impossible, i.e., whether $R^p_{(k+1)\text{-}tt}(\mathrm{UP}) \subseteq R^p_{s,k\text{-}T}(\text{Promise-UP})$ holds relative to all oracles.

However, Cai, Hemachandra, and Vyskoč [16, Theorem 3.1] could achieve this improvement only by paying a heavy price. In their own words:

> In our earlier version dealing with UP^A, the constant k can be replaced by any arbitrary polynomial-time computable function $f(n)$ with polynomially bounded value. It remains open whether the claim of the current strong version of Theorem 3.1 can be similarly generalized to nonconstant access.

We resolve this open question. We show that Theorem 4.9 holds with constant k replaced by any total, polynomial-time computable, and polynomially bounded function $k(\cdot)$. This result is subsumed as the special case $h = 1$ of our main result, Theorem 4.10, of this subsection.

THEOREM 4.10. *For any total, polynomial-time computable, and polynomially bounded function $k(\cdot)$, and integer $h \geq 1$, there exists an oracle $\mathcal{A}$ such that*

$$\mathrm{R}^p_{(k(n)+1)\text{-}dtt}(\mathrm{UP}^{\mathcal{A}}_{\leq h}) \not\subseteq \mathrm{R}^{p,\mathcal{A}}_{s,k(n)\text{-}T}(\text{Promise-UP}^{\mathrm{U}\Sigma^{p,\mathcal{A}}_{h-1}}),$$

and hence $\mathrm{R}^p_{(k(n)+1)\text{-}dtt}(\mathrm{U}\Sigma^{p,\mathcal{A}}_h) \not\subseteq \mathrm{R}^{p,\mathcal{A}}_{s,k(n)\text{-}T}(\text{Promise-UP}^{\mathrm{U}\Sigma^{p,\mathcal{A}}_{h-1}})$.

Theorem 4.10 is furthermore a generalization of Theorem 4.9 to higher levels of the unambiguous polynomial hierarchy.

The proof of Theorem 4.10 is much more challenging than the proof of Theorem 4.7 because we now require diagonalizing against $\mathrm{R}^{p,\mathcal{A}}_{s,k(n)\text{-}T}(\text{Promise-UP}^{\mathrm{U}\Sigma^{p,\mathcal{A}}_{h-1}})$ as opposed to diagonalizing against $R^{p,\mathcal{A}}_{k(n)\text{-}T}(\mathrm{UP}^{\mathrm{U}\Sigma^{p,\mathcal{A}}_{h-1}})$. To diagonalize against $R^{p,\mathcal{A}}_{k(n)\text{-}T}(\mathrm{UP}^{\mathrm{U}\Sigma^{p,\mathcal{A}}_{h-1}})$ as in the proof of Theorem 4.7, it was sufficient at any stage to extend the current oracle $\mathcal{A}$ so that the $\Sigma_h(\mathcal{A})$-system (corresponding to the stage) becomes ambiguous on some input string, even if the input string witnessing the ambiguity of the $\Sigma_h(\mathcal{A})$-system would never arise in a valid computation of the deterministic querying machine (corresponding to the same stage). This is, however, not sufficient when we diagonalize against $\mathrm{R}^{p,\mathcal{A}}_{s,k(n)\text{-}T}(\text{Promise-UP}^{\mathrm{U}\Sigma^{p,\mathcal{A}}_{h-1}})$. Any input string witnessing the ambiguity of the $\Sigma_h(\mathcal{A})$-system must now have its origin from a valid computation of the deterministic querying machine.

To prove Theorem 4.9, Cai, Hemachandra, and Vyskoč [16] presented the following combinatorial lemma.

LEMMA 4.11 (the gaming lemma [16]). *For $1 \leq i \leq m$, let $\mathcal{S}_i$ be a collection of nonempty subsets of $[n]$ with the following properties:*

1. $(\forall j \in [n])(\exists \ell \in [m])[\{j\} \in \mathcal{S}_\ell]$, *and*
2. $(\forall j \in [m])\,[(A, B \in S_j \text{ and } A \neq B) \Longrightarrow (\exists \ell \in [j-1])(\exists C \in \mathcal{S}_\ell)[C \subseteq A \cup B]]$.

Then $m \geq n$.

Cai, Hemachandra, and Vyskoč [16] gave the following informal interpretation of this lemma. Suppose a combinatorial game is to be played given the set $[n]$ at hand. The game is played in steps by a single player. At each step i, the player can generate a collection $\mathcal{S}_i$ of nonempty subsets of $[n]$ with a restriction: If sets $A, B \subseteq [n]$ are generated at some step $i > 1$, then there must be a previous step $j < i$ and a set C generated at that step such that $C \subseteq A \cup B$. The game ends as soon as all the

singletons $\{k\} \subseteq [n]$ are eventually produced. The gaming lemma states that this combinatorial game requires at least n steps.

Our proof of Theorem 4.10 also makes use of the gaming lemma. However, the actual diagonalization steps are considerably different from those in [16]. The most tricky part is the proof of Lemma 4.12. It demonstrates the existence of especially *nice* strings $\alpha_1, \alpha_2, \ldots, \alpha_r$ satisfying certain useful properties. Each string α_i serves as a representative for one region $S_{n,i}$ of the oracle. These strings satisfy a kind of *independence* property in the following sense. Let A and B be two different minimal subsets of $\{\alpha_1, \alpha_2, \ldots, \alpha_r\}$ that are minimal in the sense that adding A or B to an oracle makes an oracle NPTM N accept, but adding any proper subset of A or B to the oracle makes N reject. Then the independence property implies that adding all the strings in $A \cup B$ to the oracle will make N have at least two accepting paths.

In each stage of the diagonalization, there are two cases. The easier case is when we can destroy the unambiguity of the $\mathrm{U}\Sigma_{h-1}^{p,\mathcal{A}}$ oracle in the $\mathrm{NP}^{\mathrm{U}\Sigma_{h-1}^{p,\mathcal{A}}}$-machine, the machine against which we are diagonalizing, by adding some strings (but, of course, without violating certain requirements of the stage) to the oracle $\mathcal{A}$. In that case, we can simply add these strings to the oracle $\mathcal{A}$ and move to the next stage. Otherwise, we apply the gaming lemma (Lemma 4.11) to show that by adding only the *nice* strings α_i to the oracle $\mathcal{A}$, the desired diagonalization step for the current stage can be achieved. The existence of these *nice* strings α_i was a key idea that led us to the resolution of the question by Cai, Hemachandra, and Vyskoč [16] and in generalizing their result.

LEMMA 4.12. *Fix an oracle* NPTM N *with running time bounded by some polynomial* $p(\cdot)$*, a set* $\mathcal{O} \subseteq \Sigma^*$*, and sets* $X = \{x_1, x_2, \ldots, x_d\} \subseteq (\Sigma^*)^{\leq m}$ *and* $Y = \{y_1, y_2, \ldots, y_{d'}\} \subseteq (\Sigma^*)^{\leq m}$*. Let* $U_1, U_2, \ldots, U_r \subseteq \Sigma^*$ *be such that for each distinct* U_ℓ*,* $U_{\ell'}$*, it holds that* $\mathcal{O} \cap U_\ell = \mathcal{O} \cap U_{\ell'} = U_\ell \cap U_{\ell'} = \emptyset$ *and* $||U_\ell|| = ||U_{\ell'}|| \geq u$*. Let* $\mathcal{L}$ *be an* (h,t)*-ambiguous function such that* $\mathcal{L}(\mathcal{O} \cup (\bigcup_{\ell \in [r]} A_\ell))$ *is defined for every* $A_\ell \subseteq U_\ell$ *satisfying* $||A_\ell|| \leq h$*. If* $u > (3 \cdot d + d') \cdot r \cdot 2^{2r} \cdot p(m) \cdot t(p(m))$*, then there exist strings* $\alpha_1 \in U_1$*,* $\alpha_2 \in U_2, \ldots, \alpha_r \in U_r$ *such that the following properties hold.*

(A) *For every* $x \in X$ *and for every pair of distinct, nonempty sets* S_1*,* $S_2 \in \wp(\{1, 2, \ldots, r\})$*, if the following conditions are satisfied, then there are at least two accepting paths in* $N^{\mathcal{L}(\mathcal{O} \cup (\bigcup_{\ell \in S_1 \cup S_2} \{\alpha_\ell\}))}(x)$*:*

(A.1) $N^{\mathcal{L}(\mathcal{O} \cup (\bigcup_{\ell \in S_1} \{\alpha_\ell\}))}(x)$ *accepts and for all* $S_1' \subset S_1$*,* $N^{\mathcal{L}(\mathcal{O} \cup (\bigcup_{\ell \in S_1'} \{\alpha_\ell\}))}(x)$ *rejects, and*

(A.2) $N^{\mathcal{L}(\mathcal{O} \cup (\bigcup_{\ell \in S_2} \{\alpha_\ell\}))}(x)$ *accepts and for all* $S_2' \subset S_2$*,* $N^{\mathcal{L}(\mathcal{O} \cup (\bigcup_{\ell \in S_2'} \{\alpha_\ell\}))}(x)$ *rejects.*

(B) *For every* $y \in Y$ *and for every nonempty set* $S \in \wp(\{1, 2, \ldots, r\})$*, the following is true:*

if $N^{\mathcal{L}(\mathcal{O})}(y)$ *accepts, then* $N^{\mathcal{L}(\mathcal{O} \cup (\bigcup_{\ell \in S} \{\alpha_\ell\}))}(y)$ *also accepts.*

Proof. We prove the lemma using the probabilistic method. Choose $\alpha_1 \in U_1$, $\alpha_2 \in U_2, \ldots, \alpha_r \in U_r$ uniformly and independently at random. Let E_1 be the event that there exist an $x \in X$ and distinct, nonempty sets $S_1, S_2 \in \wp(\{1, 2, \ldots, r\})$ satisfying the conditions (A.1) and (A.2) given in the lemma, but $N^{\mathcal{L}(\mathcal{O} \cup (\bigcup_{\ell \in S_1 \cup S_2} \{\alpha_\ell\}))}(x)$ has at most one accepting path. Let E_2 be the event that there exist a $y \in Y$ and a nonempty set $S \in \wp(\{1, 2, \ldots, r\})$ such that $N^{\mathcal{L}(\mathcal{O})}(y)$ accepts, but $N^{\mathcal{L}(\mathcal{O} \cup (\bigcup_{\ell \in S} \{\alpha_\ell\}))}(y)$ rejects. We will prove that $\mathrm{Prob}(E_1) + \mathrm{Prob}(E_2) < 1$, thus completing the proof of the lemma.

We first make the following claim.

CLAIM 3. *Fix a string* $z \in \Sigma^*$*. Let* $\mathcal{O}$*,* $U_1, U_2, \ldots, U_r$ *be sets defined in the*

statement of Lemma 4.12. *Let $\mathcal{L}$ be an (h,t)-ambiguous function such that $\mathcal{L}(\mathcal{O} \cup (\bigcup_{\ell\in[r]} A_\ell))$ is defined for every $A_\ell \subseteq U_\ell$ satisfying $||A_\ell|| \leq h$. Let $T \subseteq [r]$. Fix $\alpha_i \in U_i$ for each $i \in T$ arbitrarily. If we choose $\alpha_j \in U_j$ for each $j \in [r]-T$, uniformly and independently at random, then for any T_1, $T_2 \subseteq [r]$ satisfying $(T_1 \Delta T_2) \cap T = \emptyset$,*

$$z \in \mathcal{L}\left(\mathcal{O} \cup \left(\bigcup_{\ell\in T_1}\{\alpha_\ell\}\right)\right) \Longleftrightarrow z \notin \mathcal{L}\left(\mathcal{O} \cup \left(\bigcup_{\ell\in T_2}\{\alpha_\ell\}\right)\right)$$

is true with probability $\leq r \cdot t(|z|)/u$.

Proof of Claim 3. Let $V = T_1 \cap T_2$. Because $\mathcal{L}$ is (h,t)-ambiguous, for any $j \in T_1 \Delta T_2$, the probability over uniform random choice of $\alpha_j \in U_j$ that

$$z \in \mathcal{L}\left(\mathcal{O} \cup \left(\bigcup_{\ell\in V}\{\alpha_\ell\}\right)\right) \Longleftrightarrow z \notin \mathcal{L}\left(\mathcal{O} \cup \left(\bigcup_{\ell\in V}\{\alpha_\ell\}\right) \cup \{\alpha_j\}\right)$$

is at most $t(|z|)/u$. Successively choose $\alpha_j \in U_j$ uniformly at random, where $j \in T_1 \Delta T_2$, and add j to V until V equals T_1. The probability that

$$z \in \mathcal{L}\left(\mathcal{O} \cup \left(\bigcup_{\ell\in T_1}\{\alpha_\ell\}\right)\right) \Longleftrightarrow z \notin \mathcal{L}\left(\mathcal{O} \cup \left(\bigcup_{\ell\in T_1\cap T_2}\{\alpha_\ell\}\right)\right)$$

is, therefore, at most $||T_1 - T_2|| \cdot t(|z|)/u$. Likewise, the probability that

$$z \in \mathcal{L}\left(\mathcal{O} \cup \left(\bigcup_{\ell\in T_2}\{\alpha_\ell\}\right)\right) \Longleftrightarrow z \notin \mathcal{L}\left(\mathcal{O} \cup \left(\bigcup_{\ell\in T_1\cap T_2}\{\alpha_\ell\}\right)\right)$$

is at most $||T_2 - T_1|| \cdot t(|z|)/u$. Hence the probability that

$$z \in \mathcal{L}\left(\mathcal{O} \cup \left(\bigcup_{\ell\in T_1}\{\alpha_\ell\}\right)\right) \Longleftrightarrow z \notin \mathcal{L}\left(\mathcal{O} \cup \left(\bigcup_{\ell\in T_2}\{\alpha_\ell\}\right)\right)$$

is at most $(||T_1-T_2||+||T_2-T_1||)\cdot t(|z|)/u \leq r\cdot t(|z|)/u$. Thus Claim 3 is proved. □

Using Claim 3, we obtain an upper bound on $\mathrm{Prob}(E_1)$ in Claim 4 and an upper bound on $\mathrm{Prob}(E_2)$ in Claim 5.

Claim 4. $\mathrm{Prob}(E_1) \leq 3 \cdot d \cdot r \cdot 2^{2r} \cdot p(m) \cdot t(p(m))/u$.

Proof of Claim 4. Let C_{x,S_1,S_2} stand for the condition "input x and the pair S_1, S_2 satisfy the conditions (A.1) and (A.2) given in the lemma." Fix an $x \in X$ and distinct, nonempty sets S_1 and S_2. Let E_{x,S_1,S_2} denote the event that C_{x,S_1,S_2} is satisfied but $N^{\mathcal{L}(\mathcal{O}\cup(\bigcup_{\ell\in S_1\cup S_2}\{\alpha_\ell\}))}(x)$ has at most one accepting path. Clearly, $\mathrm{Prob}(E_1) \leq \sum_{x,S_1,S_2} \mathrm{Prob}(E_{x,S_1,S_2})$. If condition C_{x,S_1,S_2} is satisfied, then for each $i \in \{1,2\}$, we can fix an accepting path $\rho(S_i)$ in $N^{\mathcal{L}(\mathcal{O}\cup(\bigcup_{\ell\in S_i}\{\alpha_\ell\}))}(x)$. For definiteness, let $\rho(S_i)$ be the lexicographically first accepting path in $N^{\mathcal{L}(\mathcal{O}\cup(\bigcup_{\ell\in S_i}\{\alpha_\ell\}))}(x)$.

If E_{x,S_1,S_2} occurs, then at least one of the events J, $H(S_1)$, or $H(S_2)$ occurs, where

- J is the event that condition C_{x,S_1,S_2} is satisfied, and $\rho(S_1)$ and $\rho(S_2)$ are equal,
- $H(S_1)$ is the event that condition C_{x,S_1,S_2} is satisfied, and $\rho(S_1)$ does not appear in $N^{\mathcal{L}(\mathcal{O}\cup(\bigcup_{\ell\in S_1\cup S_2}\{\alpha_\ell\}))}(x)$, and

- $H(S_2)$ is the event that condition C_{x,S_1,S_2} is satisfied, and $\rho(S_2)$ does not appear in $N^{\mathcal{L}(\mathcal{O}\cup(\bigcup_{\ell\in S_1\cup S_2}\{\alpha_\ell\}))}(x)$.

We first determine an upper bound on $\mathrm{Prob}(J)$. To this end, we determine an upper bound on $\mathrm{Prob}(J \mid \alpha_i = \beta_i \text{ for all } i \in S_1)$ for arbitrary fixed strings $\beta_i \in U_i$ for each $i \in S_1$. Hence, suppose henceforth that $\alpha_i = \beta_i$ for all $i \in S_1$. Because $S_1 \neq S_2$ and because we can assume that S_1 satisfies the condition (A.1) given in the lemma, the (accepting) path $\rho(S_1)$ in $N^{\mathcal{L}(\mathcal{O}\cup(\bigcup_{\ell\in S_1}\{\alpha_\ell\}))}(x)$ does not appear in $N^{\mathcal{L}(\mathcal{O}\cup(\bigcup_{\ell\in S_1\cap S_2}\{\alpha_\ell\}))}(x)$. Hence, for at least one string $z \in Q(\rho(S_1))$ queried along $\rho(S_1)$, we have

$$z \in \mathcal{L}\left(\mathcal{O}\cup\left(\bigcup_{\ell\in S_1\cap S_2}\{\alpha_\ell\}\right)\right) \iff z \notin \mathcal{L}\left(\mathcal{O}\cup\left(\bigcup_{\ell\in S_1}\{\alpha_\ell\}\right)\right). \tag{4.4}$$

Note that this condition depends only on strings α_i with $i \in S_1$, which are fixed by $\alpha_i = \beta_i$. Fix one string z satisfying statement (4.4). Applying Claim 3 with $T := S_1$, $T_1 := S_1 \cap S_2$, and $T_2 := S_2$, we get that

$$z \in \mathcal{L}\left(\mathcal{O}\cup\left(\bigcup_{\ell\in S_1\cap S_2}\{\alpha_\ell\}\right)\right) \iff z \in \mathcal{L}\left(\mathcal{O}\cup\left(\bigcup_{\ell\in S_2}\{\alpha_\ell\}\right)\right) \tag{4.5}$$

holds with probability $\geq 1 - r\cdot t(|z|)/u \geq 1 - r\cdot t(p(m))/u$. Statements (4.4) and (4.5) together imply that with probability $\geq 1 - r\cdot t(p(m))/u$,

$$z \in \mathcal{L}\left(\mathcal{O}\cup\left(\bigcup_{\ell\in S_1}\{\alpha_\ell\}\right)\right) \iff z \notin \mathcal{L}\left(\mathcal{O}\cup\left(\bigcup_{\ell\in S_2}\{\alpha_\ell\}\right)\right). \tag{4.6}$$

Hence with probability $\geq 1 - r\cdot t(p(m))/u$, path $\rho(S_1)$ does not appear in $N^{\mathcal{L}(\mathcal{O}\cup(\bigcup_{\ell\in S_2}\{\alpha_\ell\}))}(x)$, and therefore $\rho(S_1) \neq \rho(S_2)$. We have proven that for arbitrary fixed strings $\{\beta_i \in U_i \,|\, i \in S_1\}$, it holds that $\mathrm{Prob}(J \mid \alpha_i = \beta_i \text{ for all } i \in S_1) \leq r\cdot t(p(m))/u$. By the law of total probability, also $\mathrm{Prob}(J) \leq r\cdot t(p(m))/u$.

To determine an upper bound on $\mathrm{Prob}(H(S_1))$, we determine an upper bound on $\mathrm{Prob}(H(S_1) \mid \alpha_i = \beta_i \text{ for all } i \in S_1)$ for arbitrary fixed strings $\beta_i \in U_i$ for each $i \in S_1$. Hence, suppose henceforth that $\alpha_i = \beta_i$ for all $i \in S_1$. Clearly, $\rho(S_1)$ depends only on strings α_i with $i \in S_1$, which we have fixed by $\alpha_i = \beta_i$. Then the event $H(S_1)$ occurs only if it holds that $\rho(S_1)$ queries some string z with

$$z \in \mathcal{L}\left(\mathcal{O}\cup\left(\bigcup_{\ell\in S_1}\{\alpha_\ell\}\right)\right) \iff z \notin \mathcal{L}\left(\mathcal{O}\cup\left(\bigcup_{\ell\in S_1\cup S_2}\{\alpha_\ell\}\right)\right).$$

Note that path $\rho(S_1)$ in $N^{\mathcal{L}(\mathcal{O}\cup(\bigcup_{\ell\in S_1}\{\alpha_\ell\}))}(x)$ queries at most $p(m)$ strings, each of which is of length $\leq p(m)$. Applying Claim 3 with $T := S_1$, $T_1 := S_1$, and $T_2 := S_1 \cup S_2$, we get that $\mathrm{Prob}(H(S_1) \mid \alpha_i = \beta_i \text{ for all } i \in S_1) \leq p(m)\cdot r\cdot t(p(m))/u$. We have thus proven that for arbitrary fixed strings $\{\beta_i \in U_i \,|\, i \in S_1\}$, it holds that $\mathrm{Prob}(H(S_1) \mid \alpha_i = \beta_i \text{ for all } i \in S_1) \leq p(m)\cdot r\cdot t(p(m))/u$. Therefore, also $\mathrm{Prob}(H(S_1)) \leq p(m)\cdot r\cdot t(p(m))/u$.

Analogously, we can prove that $\mathrm{Prob}(H(S_2)) \leq p(m)\cdot r\cdot t(p(m))/u$.

Thus $\mathrm{Prob}(E_{x,S_1,S_2}) \leq \mathrm{Prob}(J \cup H(S_1) \cup H(S_2)) \leq \mathrm{Prob}(J) + \mathrm{Prob}(H(S_1)) + \mathrm{Prob}(H(S_2)) \leq 3\cdot p(m)\cdot r\cdot t(p(m))/u$. It follows that $\mathrm{Prob}(E_1) \leq 3\cdot d\cdot r\cdot 2^{2r}\cdot p(m)\cdot t(p(m))/u$. This completes the proof of Claim 4. □

CLAIM 5. $\mathrm{Prob}(E_2) \le d' \cdot r \cdot 2^r \cdot p(m) \cdot t(p(m))/u$.

Proof of Claim 5. Fix a $y \in Y$ and a nonempty set $S \in \wp(\{1, 2, \ldots, r\})$. Let $E_{y,S}$ denote the event that $N^{\mathcal{L}(\mathcal{O})}(y)$ accepts but $N^{\mathcal{L}(\mathcal{O} \cup (\bigcup_{\ell \in S} \{\alpha_\ell\}))}(y)$ rejects. Clearly, $\mathrm{Prob}(E_2) \le \sum_{y,S} \mathrm{Prob}(E_{y,S})$. If $N^{\mathcal{L}(\mathcal{O})}(y)$ accepts, then we can fix an accepting path ρ in $N^{\mathcal{L}(\mathcal{O})}(y)$. For definiteness, let ρ be the lexicographically first accepting path in $N^{\mathcal{L}(\mathcal{O})}(y)$.

Suppose $E_{y,S}$ occurs. Since $N^{\mathcal{L}(\mathcal{O} \cup (\bigcup_{\ell \in S} \{\alpha_\ell\}))}(y)$ rejects, the (accepting) path ρ in $N^{\mathcal{L}(\mathcal{O})}(y)$ does not appear in $N^{\mathcal{L}(\mathcal{O} \cup (\bigcup_{\ell \in S} \{\alpha_\ell\}))}(y)$. Hence for at least one string $z \in Q(\rho)$ queried along ρ, we have

$$z \in \mathcal{L}(\mathcal{O}) \iff z \notin \mathcal{L}\left(\mathcal{O} \cup \left(\bigcup_{\ell \in S} \{\alpha_\ell\}\right)\right).$$

Applying Claim 3 with $T := \emptyset$, $T_1 := \emptyset$, and $T_2 := S$, we get that for each $z \in Q(\rho)$,

$$z \in \mathcal{L}(\mathcal{O}) \iff z \notin \mathcal{L}\left(\mathcal{O} \cup \left(\bigcup_{\ell \in S} \{\alpha_\ell\}\right)\right)$$

holds with probability $\le r \cdot t(|z|)/u$. Since $||Q(\rho)|| \le p(m)$ and since the length of each query $z \in Q(\rho)$ is at most $p(m)$, with probability $\le p(m) \cdot r \cdot t(p(m))/u$ we have, for some $z \in Q(\rho)$,

$$z \in \mathcal{L}(\mathcal{O}) \iff z \notin \mathcal{L}\left(\mathcal{O} \cup \left(\bigcup_{\ell \in S} \{\alpha_\ell\}\right)\right).$$

Thus we have shown that $\mathrm{Prob}(E_{y,S}) \le p(m) \cdot r \cdot t(p(m))/u$. It follows that $\mathrm{Prob}(E_2) \le d' \cdot r \cdot 2^r \cdot p(m) \cdot t(p(m))/u$. Thus Claim 5 is proved. □

From Claim 4 and Claim 5, we get $\mathrm{Prob}(E_1) + \mathrm{Prob}(E_2) \le (3 \cdot d + d') \cdot r \cdot 2^{2r} \cdot p(m) \cdot t(p(m))/u < 1$, by our choice of u. This completes the proof of Lemma 4.12. □

Now it is relatively easy to prove the main result of this subsection.

Proof of Theorem 4.10. For each length n, we will reserve the following segment of $k(n) + 1$ regions $S_{n,f} = 1^n 01^f 0 \Sigma^{3k(n)+n}$, where $f \in [k(n) + 1]$. For $n \ge 1$, define $S_n = \bigcup_{f=1}^{k(n)+1} S_{n,f}$. We take the test language $L(\mathcal{A})$ used in the proof of Theorem 4.7. The oracle $\mathcal{A}$ is constructed in stages. Let $(N_{i,1}, N_{i,2}, \ldots, N_{i,h}, M_j)$ be an enumeration of tuples where $N_{i,*}$ is a nondeterministic polynomial-time oracle Turing machine, and M_j is a deterministic polynomial-time oracle Turing machine making, for any set $\mathcal{A}$ and any input of length n, at most $k(n)$ queries to $L[\mathcal{A}; N_{i,1}, N_{i,2}, \ldots, N_{i,h}]$ and at most polynomially many queries to $\mathcal{A}$. Initially $\mathcal{A} := \emptyset$.

Stage $\langle i, j \rangle$. Let $p(\cdot)$ be a polynomial that bounds the running time of both $N_{i,\star}$ and M_j. Choose a very large integer n such that (a) $2^{3k(n)+n} - p(n) > 4 \cdot k(n) \cdot (k(n) + 1) \cdot 2^{2(k(n)+1)} \cdot p(p(n)) \cdot t(p(p(n)))$, where $t(\cdot)$ is a polynomial defined later in this proof, (b) no string of length n or more is queried in any of the previous stages, (c) n is larger than the value in the previous stage, and (d) n satisfies any promises made in the previous stages.

The easy case. (i) For $h = 1$, if there exists a set $B \subseteq S_n$, satisfying $||B \cap S_{n,f}|| \le h$ for every $f \in [k(n)+1]$, such that the requirement R1 is satisfied, where R1 is defined as

- R1: $M_j(0^n)$ makes a query β to $L[\mathcal{A} \cup B; N_{i,1}]$ and $N_{i,1}^{\mathcal{A} \cup B}(\beta)$ has at least two accepting paths,

then set $\mathcal{A} := \mathcal{A} \cup B$. (ii) For $h \geq 2$, if there exists a set $B \subseteq S_n$, satisfying $||B \cap S_{n,f}|| \leq h$ for every $f \in [k(n)+1]$, such that at least one of the requirements R2 and R3 is satisfied, where R2 and R3 are defined as

- R2: $[\mathcal{A} \cup B; N_{i,2}, N_{i,3}, \ldots, N_{i,h}]$ is ambiguous,
- R3: $M_j(0^n)$ makes a query β to $L[\mathcal{A} \cup B; N_{i,1}, N_{i,2}, \ldots, N_{i,h}]$ and $N_{i,1}^{L[\mathcal{A}\cup B; N_{i,2}, N_{i,3}, \ldots, N_{i,h}]}(\beta)$ has at least two accepting paths,

then set $\mathcal{A} := \mathcal{A} \cup B$.

For both (i) and (ii), promise to choose the value of n in the next stage to be sufficiently large so that the requirements satisfied in this stage cannot become invalid in the next stage.

The hard case. This means that there is no set $B \subseteq S_n$ as described in (i) and (ii) above. We proceed as follows. Define function $\mathcal{L} : \wp(\Sigma^*) \to \wp(\Sigma^*)$ such that for every $\mathcal{O} \subseteq \Sigma^*$,

$$\mathcal{L}(\mathcal{O}) =_{df} \begin{cases} \mathcal{O} & \text{if } h = 1, \text{ and} \\ L_{\text{unambiguous}}[\mathcal{O}; N_{i,2}, N_{i,3}, \ldots, N_{i,h}] & \text{if } h \geq 2. \end{cases}$$

It is easy to see that for the case $h = 1$, $\mathcal{L}$ is (h,t)-ambiguous by Definition 3.2, where $t(\cdot) = 1$ is a constant polynomial, and for the case $h \geq 2$, $\mathcal{L}$ is (h,t)-ambiguous by Proposition 3.3, where $t(\cdot) = 5^{h-1} \cdot \prod_{\ell=1}^{h-1} (p\circ)^\ell(\cdot)$. Also, note that (since we are in the hard case) for all integers $h \geq 1$, $\mathcal{L}(\mathcal{A} \cup B)$ is defined for every $B \subseteq S_n$ that satisfies $||B \cap S_{n,f}|| \leq h$ for every $f \in [k(n)+1]$. We next use Claim 6 to successfully finish this stage.

Claim 6. *There is a string $\alpha \in S_n$ such that $M_j(0^n)$ with oracle $\mathcal{A} \oplus L(N_{i,1}^{\mathcal{L}(\mathcal{A})})$ is identical to $M_j(0^n)$ with oracle $(\mathcal{A} \cup \{\alpha\}) \oplus L(N_{i,1}^{\mathcal{L}(\mathcal{A}\cup\{\alpha\})})$.*

That is, if $M_j(0^n)$ with oracle $\mathcal{A} \oplus L(N_{i,1}^{\mathcal{L}(\mathcal{A})})$ rejects, then we set $\mathcal{A} := \mathcal{A} \cup \{\alpha\}$; otherwise, if $M_j(0^n)$ with oracle $\mathcal{A} \oplus L(N_{i,1}^{\mathcal{L}(\mathcal{A})})$ accepts, then we leave $\mathcal{A}$ unchanged. Finally, we move to the next stage. *End of stage.*

This completes the proof of Theorem 4.10. □

Proof of Claim 6. Let $\beta_1, \beta_2, \ldots, \beta_{k(n)}$ be the sequence of queries made by $M_j(0^n)$ to the oracle $L(N_{i,1}^{\mathcal{L}(\mathcal{A})})$. Let $I = \{\ell \mid N_{i,1}^{\mathcal{L}(\mathcal{A})}(\beta_\ell) \text{ accepts}\}$. Let $\widetilde{Q}$ be the set of strings that are queried by $M_j(0^n)$ to oracle $\mathcal{A}$. Clearly, $||\widetilde{Q}|| \leq p(n)$.

Apply Lemma 4.12 with $N := N_{i,1}$, $\mathcal{O} := \mathcal{A}$, $d := k(n)$, $d' := k(n)$, $X = \{\beta_1, \beta_2, \ldots, \beta_{k(n)}\}$, $Y = \{\beta_1, \beta_2, \ldots, \beta_{k(n)}\}$, $m := p(n)$, $r := k(n)+1$, $U_f := S_{n,f} - \widetilde{Q}$ for each $f \in [k(n)+1]$, and $u := 2^{3k(n)+n} - p(n)$. We obtain strings $\alpha_1 \in S_{n,1} - \widetilde{Q}$, $\alpha_2 \in S_{n,2} - \widetilde{Q}, \ldots, \alpha_{k(n)+1} \in S_{n,k(n)+1} - \widetilde{Q}$, which satisfy the properties (A) and (B) given in Lemma 4.12. Now assign to each query β_ℓ with $\ell \in [k(n)] - I$ a collection $\mathcal{S}_\ell \subseteq \wp([k(n)+1])$ in the following way: $\{f_1, f_2, \ldots, f_s\} \in \mathcal{S}_\ell$ if and only if

(a) adding $\{\alpha_{f_1}, \alpha_{f_2}, \ldots, \alpha_{f_s}\}$ to $\mathcal{A}$ makes $N_{i,1}^{\mathcal{L}(\mathcal{A})}(\beta_\ell)$ change from rejection to acceptance, i.e., $N_{i,1}^{\mathcal{L}(\mathcal{A})}(\beta_\ell)$ rejects but $N_{i,1}^{\mathcal{L}(\mathcal{A}\cup\{\alpha_{f_1}, \alpha_{f_2}, \ldots, \alpha_{f_s}\})}(\beta_\ell)$ accepts, and

(b) no set $T \subset \{f_1, f_2, \ldots, f_s\}$ satisfies (a), i.e., for no such set T does it hold that $N_{i,1}^{\mathcal{L}(\mathcal{A}\cup(\bigcup_{j\in T}\{\alpha_j\}))}(\beta_\ell)$ accepts.

Note that no collection $\mathcal{S}_\ell$ contains the empty set. However, some of these collections may be empty.

Suppose that Claim 6 is not true. Then, for every $e \in [k(n)+1]$, there is an $\ell \in [k(n)]$ such that

$$N_{i,1}^{\mathcal{L}(\mathcal{A})}(\beta_\ell) \text{ rejects } \iff N_{i,1}^{\mathcal{L}(\mathcal{A}\cup\{\alpha_e\})}(\beta_\ell) \text{ accepts.} \tag{4.7}$$

Because $\alpha_1, \alpha_2, \ldots, \alpha_{k(n)+1}$ satisfy property (B) of Lemma 4.12, statement (4.7) can only be true for $\ell \notin I$. This implies that for every $e \in [k(n)+1]$, there is an $\ell \in [k(n)] - I$ such that

$$N_{i,1}^{\mathcal{L}(\mathcal{A})}(\beta_\ell) \text{ rejects and } N_{i,1}^{\mathcal{L}(\mathcal{A}\cup\{\alpha_e\})}(\beta_\ell) \text{ accepts.}$$

It follows from the definition of the collections $\mathcal{S}_\ell$ that for every $e \in [k(n)+1]$, there is a collection $\mathcal{S}_\ell$ such that the singleton $\{\alpha_e\}$ is contained in $\mathcal{S}_\ell$. Thus we have proven condition 1 of Lemma 4.11 (the gaming lemma).

Now take two distinct sets $A, B \in \mathcal{S}_\ell$ for some $\ell \in [k(n)]$. Then by the definition of the collections $\mathcal{S}_\ell$ together with property (A) of Lemma 4.12, $N_{i,1}^{\mathcal{L}(\mathcal{A}\cup(\bigcup_{e\in A\cup B}\{\alpha_e\}))}(\beta_\ell)$ has at least two accepting paths. Notice that for any valid query β by $M_j(0^n)$ to $L(N_{i,1}^{\mathcal{L}(\mathcal{A}\cup(\bigcup_{e\in A\cup B}\{\alpha_e\}))})$, there can be at most one accepting path in $N_{i,1}^{\mathcal{L}(\mathcal{A}\cup(\bigcup_{e\in A\cup B}\{\alpha_e\}))}(\beta)$ (since we are in the *hard* case). Therefore, we can be sure that adding $\bigcup_{e\in A\cup B}\{\alpha_e\}$ to $\mathcal{A}$ changes the decision (i.e., acceptance or rejection) of $N_{i,1}^{\mathcal{L}(\mathcal{A})}$ for a previous query $\beta_{\ell'}$ with $\ell' < \ell$. The decision of $N_{i,1}^{\mathcal{L}(\mathcal{A})}(\beta_{\ell'})$ on the addition of $\bigcup_{e\in A\cup B}\{\alpha_e\}$ to $\mathcal{A}$ must change from rejection to acceptance, and not from acceptance to rejection, because $\alpha_1, \alpha_2, \ldots, \alpha_{k(n)+1}$ satisfy property (B) of Lemma 4.12. Hence there is a set $C \in \mathcal{S}_{\ell'}$ such that $C \subseteq A \cup B$. This proves condition 2 of Lemma 4.11. Lemma 4.11 implies that the number of queries $k(n)$ is greater than or equal to the number of regions $k(n)+1$, which is a contradiction. This completes the proof of Claim 6. □

4.4. Simulating adaptive access by nonadaptive access. Sections 4.2 and 4.3 studied the limitations of simulating nonadaptive queries to $\mathrm{UP}_{\leq h}$ by adaptive queries to $\mathrm{U}\Sigma_h^p$ in relativized settings. This section complements these investigations. In particular, Corollary 4.14 of this section shows that in a certain relativized world, it is impossible to simulate adaptive k-Turing access to $\mathrm{UP}_{\leq h}$ by nonadaptive (2^k-2)-tt access to $\mathrm{U}\Sigma_h^p$. This also implies optimality of robustly (i.e., for every oracle) simulating adaptive k-Turing accesses by nonadaptive (2^k-1)-tt accesses to classes such as $\mathrm{UP}_{\leq h}$ and $\mathrm{U}\Sigma_h^p$, since for any class $\mathcal{C}$ we can easily, via a brute-force method, simulate adaptive k-Turing reduction to $\mathcal{C}$ by nonadaptive (2^k-1)-tt reduction to $\mathcal{C}$.

The proof of Theorem 4.13 employs a technique of Buhrman, Spaan, and Torenvliet [12], which Cai, Hemachandra, and Vyskoč [16] referred to as the "force your way through the tree" technique. Buhrman, Spaan, and Torenvliet [12] used their technique to prove that NEXP has a set that is complete for k-Turing reductions but not complete for (2^k-2)-tt reductions. Cai, Hemachandra, and Vyskoč [16] used this technique to prove Theorem 4.13 for the case of $h = 1$. We use the same approach to generalize the result of Cai, Hemachandra, and Vyskoč [16] from the case of $h = 1$ to the case of arbitrary integer $h \geq 1$.

THEOREM 4.13. *For any integers $k, h \geq 1$, there exists an oracle $\mathcal{A}$ such that*

$$R_{k\text{-}T}^p(\mathrm{UP}_{\leq h}^{\mathcal{A}}) \not\subseteq R_{(2^k-2)\text{-}tt}^{p,\mathcal{A}}(\mathrm{NP}^{\mathrm{U}\Sigma_{h-1}^{p,\mathcal{A}}}).$$

Proof. The theorem clearly holds for $k = 1$ since there is an oracle that separates UP from P. Henceforth, we assume that $k \geq 2$. For each length n, we will reserve the following segment of $2^k - 1$ regions: $S_{n,f} = 1^n 0 f 0 \Sigma^n$, where $f \in (\Sigma^*)^{\leq k-1}$. For $n \geq 1$, define $S_n = \bigcup_{f\in(\Sigma^*)^{\leq k-1}} S_{n,f}$. For each length n and set $A \subseteq \Sigma^*$, we also

define a sequence $b^A_{n,1}b^A_{n,2}\dots b^A_{n,k}$ of bits as follows:

$$(\star) \qquad b^A_{n,1} = \begin{cases} 1 & \text{if } S_{n,\epsilon} \bigcap A \neq \emptyset, \\ 0 & \text{otherwise,} \end{cases}$$

and for each ℓ with $2 \leq \ell \leq k$,

$$b^A_{n,\ell} = \begin{cases} 1 & \text{if } S_{n,b^A_{n,1}b^A_{n,2}\dots b^A_{n,\ell-1}} \bigcap A \neq \emptyset, \\ 0 & \text{otherwise.} \end{cases}$$

Our test language is $L(\mathcal{A}) = \{0^n \mid b^{\mathcal{A}}_{n,k} = 1\}$. Note that our test language is the same as that in [16, Theorem 3.3]. We stipulate that for all $n \geq 1$ and for all $f \in (\Sigma^*)^{\leq k-1}$, $||S_{n,f}|| \leq h$. Clearly, if the oracle set $\mathcal{A}$ maintains this stipulation, then we have $L(\mathcal{A}) \in R^p_{k\text{-}T}(\mathrm{UP}^{\mathcal{A}}_{\leq h})$. We construct an oracle $\mathcal{A}$ such that $L(\mathcal{A}) \notin R^p_{(2^k-2)\text{-}tt}(\mathrm{NP}^{\mathrm{U}\Sigma^{p,\mathcal{A}}_{h-1}})$. The construction can be easily modified to prove the stronger result that $L(\mathcal{A}) \notin R^{p,\mathcal{A}}_{(2^k-2)\text{-}tt}(\mathrm{NP}^{\mathrm{U}\Sigma^{p,\mathcal{A}}_{h-1}})$.

Let $(N_{i,1}, N_{i,2}, \dots, N_{i,h}, M_j)$ be an enumeration of tuples, where $N_{i,*}$ is a nondeterministic polynomial-time oracle Turing machine, and M_j is a deterministic polynomial-time oracle Turing machine making, for any set $\mathcal{A}$ and for any input, at most $2^k - 2$ nonadaptive queries to $L[\mathcal{A}; N_{i,1}, N_{i,2}, \dots, N_{i,h}]$. Initially, let $\mathcal{A} := \emptyset$.

Stage $\langle i, j\rangle$. Let $p(\cdot)$ be a polynomial that bounds the running time of both $N_{i,\star}$ and M_j. Choose a very large integer n such that (a) $2^n > 2^{2k} \cdot p(p(n)) \cdot t(p(p(n)))$, where $t(\cdot)$ is a polynomial defined later in this proof, (b) no string of length n or more is queried in any of the previous stages, (c) n is larger than the value in the previous stage, and (d) n satisfies any promises made in the previous stages.

For the case $h \geq 2$, if there exists a set $B \subseteq S_n$ satisfying $||B \cap S_{n,f}|| \leq h$ for every $f \in (\Sigma^*)^{\leq k-1}$ such that $[\mathcal{A} \cup B; N_{i,2}, \dots, N_{i,h}]$ is not unambiguous, then set $\mathcal{A} := \mathcal{A} \cup B$. Promise to choose the value of n in the next stage to be larger than $(p\circ)^{h-1}(|w|)$, where w is an arbitrary string witnessing that $[\mathcal{A} \cup B; N_{i,2}, \dots, N_{i,h}]$ is not unambiguous, and then move to the next stage.

If no such set B exists for $h \geq 2$ or if $h = 1$, then we define a function $\mathcal{L} : \wp(\Sigma^*) \to \wp(\Sigma^*)$ as follows: For every $\mathcal{O} \subseteq \Sigma^*$, let

$$\mathcal{L}(\mathcal{O}) =_{df} \begin{cases} \mathcal{O} & \text{if } h = 1, \text{ and} \\ L_{\text{unambiguous}}[\mathcal{O}; N_{i,2}, N_{i,3}, \dots, N_{i,h}] & \text{if } h \geq 2. \end{cases}$$

It is easy to see that for the case $h = 1$, $\mathcal{L}$ is (h,t)-ambiguous by Definition 3.2, where $t(\cdot) = 1$ is a constant polynomial, and for the case $h \geq 2$, $\mathcal{L}$ is (h,t)-ambiguous by Proposition 3.3, where $t(\cdot) = 5^{h-1} \cdot \prod_{\ell=1}^{h-1}(p\circ)^\ell(\cdot)$. Also, note that for all integers $h \geq 1$, $\mathcal{L}(\mathcal{A} \cup B)$ is defined for every $B \subseteq S_n$ that satisfies $||B \cap S_{n,f}|| \leq h$ for every $f \in (\Sigma^*)^{\leq k-1}$.

Let $\beta_1, \beta_2, \dots, \beta_{2^k-2}$ be the sequence of nonadaptive queries made by $M_j(0^n)$ to the oracle $L(N^{\mathcal{L}(\mathcal{A})}_{i,1})$. Consider the following procedure *Diagonalize*.

Procedure Diagonalize($\{\alpha_f \in S_{n,f} \mid f \in (\Sigma^*)^{\leq k-1}\}$)
1. $\mathcal{A}_1 := \mathcal{A}$;
2. For $t := 1$ to $2^k - 1$ do
3. Let $b_{n,1}^{\mathcal{A}_t} b_{n,2}^{\mathcal{A}_t} \dots b_{n,k}^{\mathcal{A}_t}$ be the bit sequence given by ($\star$);
4. If ($b_{n,k}^{\mathcal{A}_t} = 0 \iff M_j^{L(N_{i,1}^{\mathcal{L}(\mathcal{A}_t)})}(0^n)$ accepts) is true, then
5. output $\mathcal{A}_t$ and terminate;
6. Else /* That is, $b_{n,k}^{\mathcal{A}_t} = 0 \iff M_j^{L(N_{i,1}^{\mathcal{L}(\mathcal{A}_t)})}(0^n)$ rejects */
(6.1) Let $s := \max\{\ell \in [k] \mid b_{n,\ell}^{\mathcal{A}_t} = 0\}$;
(6.2) $\mathcal{A}_{t+1} := \mathcal{A}_t \cup \{\alpha_{b_{n,1}^{\mathcal{A}_t} b_{n,2}^{\mathcal{A}_t} \cdots b_{n,s-1}^{\mathcal{A}_t}}\}$; /* That is, flip $b_{n,k}^{\mathcal{A}_t}$. */
(6.3) If for every query β_ℓ, where $\ell \in [2^k - 2]$, the following holds:
"if $N_{i,1}^{\mathcal{L}(\mathcal{A}_t)}(\beta_\ell)$ rejects, then $N_{i,1}^{\mathcal{L}(\mathcal{A}_{t+1})}(\beta_\ell)$ also rejects," then
output $\mathcal{A}_{t+1}$ and terminate.
(6.4) Else /* there is a query β_ℓ such that $N_{i,1}^{\mathcal{L}(\mathcal{A}_t)}(\beta_\ell)$ rejects, but $N_{i,1}^{\mathcal{L}(\mathcal{A}_{t+1})}(\beta_\ell)$ accepts. */
Return to the For loop;
End of Procedure

CLAIM 7. *For each $f \in (\Sigma^*)^{\leq k-1}$, there exists $\widehat{\alpha_f} \in S_{n,f}$ such that for each $t \in [2^k - 1]$ and for each $\ell \in [2^k - 2]$, the following holds in the execution of Diagonalize($\{\widehat{\alpha_f} \mid f \in (\Sigma^*)^{\leq k-1}\}$):*

$$\text{if } N_{i,1}^{\mathcal{L}(\mathcal{A}_t)}(\beta_\ell) \text{ accepts, then } N_{i,1}^{\mathcal{L}(\mathcal{A}_{t+1})}(\beta_\ell) \text{ also accepts.}$$

Let us assume that Claim 7 is true. Then there exist strings $\widehat{\alpha_f} \in S_{n,f}$ for each $f \in (\Sigma^*)^{\leq k-1}$, satisfying the property stated in the claim. Set $\mathcal{A} :=$ Diagonalize($\{\widehat{\alpha_f} \mid f \in (\Sigma^*)^{\leq k-1}\}$) and move to the next stage. *End of stage.*

For each $f \in (\Sigma^*)^{\leq k-1}$, let $\widehat{\alpha_f} \in S_{n,f}$ be the strings promised in that claim. Notice that the procedure Diagonalize($\{\widehat{\alpha_f} \mid f \in (\Sigma^*)^{\leq k-1}\}$) never adds more than one string in any region $S_{n,f}$. This follows because each region $S_{n,f}$ is associated with exactly one string $\widehat{\alpha_f} \in S_{n,f}$, and only these associated strings are ever considered for inclusion in the oracle. Also note that the effect of step (6.2) in the procedure is to increment the binary number $b_{n,1}^{\mathcal{A}_t} b_{n,2}^{\mathcal{A}_t} \dots b_{n,k}^{\mathcal{A}_t}$ by 1. That is, we have, for each $t \in [2^k - 1]$ considered until the termination of the For loop, $b_{n,1}^{\mathcal{A}_{t+1}} b_{n,2}^{\mathcal{A}_{t+1}} \dots b_{n,k}^{\mathcal{A}_{t+1}} := b_{n,1}^{\mathcal{A}_t} b_{n,2}^{\mathcal{A}_t} \dots b_{n,k}^{\mathcal{A}_t} + 1$. This implies that after the execution of step (6.2), the bit $b_{n,k}^{\mathcal{A}_t}$ is flipped; i.e., $b_{n,k}^{\mathcal{A}_{t+1}} = 1 - b_{n,k}^{\mathcal{A}_t}$.

If Diagonalize($\{\widehat{\alpha_f} \mid f \in (\Sigma^*)^{\leq k-1}\}$) terminates at step 5, then clearly $0^n \in L(\mathcal{A}) \iff 0^n \notin L(M_j^{L(N_{i,1}^{\mathcal{L}(\mathcal{A})})})$, and so we successfully finish the stage. Otherwise, Diagonalize($\{\widehat{\alpha_f} \mid f \in (\Sigma^*)^{\leq k-1}\}$) terminates at the execution of step (6.3) or it terminates because the For loop had finished iterating over the range of values of t.

If Diagonalize($\{\widehat{\alpha_f} \mid f \in (\Sigma^*)^{\leq k-1}\}$) terminates at the execution of step (6.3), then we have the following situation:

- $b_{n,k}^{\mathcal{A}_t} = 0 \iff M_j^{L(N_{i,1}^{\mathcal{L}(\mathcal{A}_t)})}(0^n)$ rejects.
- $b_{n,k}^{\mathcal{A}_{t+1}} = 1 - b_{n,k}^{\mathcal{A}_t}$.
- For every query β_ℓ, where $\ell \in [2^k - 2]$, if $N_{i,1}^{\mathcal{L}(\mathcal{A}_t)}(\beta_\ell)$ rejects, then $N_{i,1}^{\mathcal{L}(\mathcal{A}_{t+1})}(\beta_\ell)$ also rejects.
- For every query β_ℓ, where $\ell \in [2^k - 2]$, if $N_{i,1}^{\mathcal{L}(\mathcal{A}_t)}(\beta_\ell)$ accepts, then $N_{i,1}^{\mathcal{L}(\mathcal{A}_{t+1})}(\beta_\ell)$ also accepts, by Claim 7.

It follows that $b_{n,k}^{\mathcal{A}_{t+1}} = 1$ if and only if $M_j^{L(N_{i,1}^{\mathcal{L}(\mathcal{A}_{t+1})})}(0^n)$ rejects. Hence, we successfully finish the stage. We next claim that if Diagonalize($\{\widehat{\alpha_f} \mid f \in (\Sigma^*)^{\leq k-1}\}$) does not terminate at step 5, then it must terminate at the execution of step (6.3).

To this end, for each $t \in [2^k]$, let us define $Q_{\mathrm{acc}}(t)$ to be the set of queries β_ℓ on which $N_{i,1}$ with oracle $\mathcal{L}(\mathcal{A}_t)$ accepts. Formally, for any $t \in [2^k]$, let $Q_{\mathrm{acc}}(t) =_{df} \{\beta_\ell \mid \ell \in [2^k-2]$ and $N_{i,1}^{\mathcal{L}(\mathcal{A}_t)}(\beta_\ell)$ accepts$\}$. By Claim 7, once a query β_ℓ becomes a member of Q_t, the query β_ℓ remains accepted by $N_{i,1}^{\mathcal{L}(\mathcal{A}_{t'})}$ for any $t \leq t' \in [2^k]$. That is, $Q_{\mathrm{acc}}(t) \subseteq Q_{\mathrm{acc}}(t+1)$ for all $t \in [2^k-1]$. By the definition of the sets $Q_{\mathrm{acc}}(t)$, it follows that if the condition in step (6.4) is true at some iteration t of the For loop, then there exist queries $\beta_\ell \in Q_{\mathrm{acc}}(t+1) - Q_{\mathrm{acc}}(t)$; i.e., we have $||Q_{\mathrm{acc}}(t+1)|| > ||Q_{\mathrm{acc}}(t)||$ at these iterations t. Thus, there will be an iteration at which the condition in step (6.4) will not be true. (This follows because the number of iterations, (2^k-1), of the For loop is greater than the maximum possible size, 2^k-2, of $Q_{\mathrm{acc}}(t)$.) Therefore, at that iteration, the condition in step (6.3) will be true. Hence, Diagonalize($\{\widehat{\alpha_f} \mid f \in (\Sigma^*)^{\leq k-1}\}$) will terminate at the execution of step (6.3). This completes the proof of Theorem 4.13. □

Proof of Claim 7. Let f be arbitrary in $(\Sigma^*)^{\leq k-1}$. We will prove that there is a small set $\widetilde{Q}(f)$ such that for each $t \in [2^k-1]$ and for each $\ell \in [2^k-2]$, the following holds for all $\alpha_f \in S_{n,f} - \widetilde{Q}(f)$:

$$\text{if } N_{i,1}^{\mathcal{L}(\mathcal{A}_t)}(\beta_\ell) \text{ accepts, then } N_{i,1}^{\mathcal{L}(\mathcal{A}_t \cup \{\alpha_f\})}(\beta_\ell) \text{ also accepts.} \tag{4.8}$$

To this end, fix $t \in [2^k-1]$ and $\ell \in [2^k-2]$ and assume that $N_{i,1}^{\mathcal{L}(\mathcal{A}_t)}(\beta_\ell)$ accepts. Let ρ be an arbitrary accepting path in $N_{i,1}^{\mathcal{L}(\mathcal{A}_t)}(\beta_\ell)$. Because $\mathcal{L}$ is (h,t)-ambiguous, for each $z \in \Sigma^*$ there can be at most $t(|z|)$ strings $\alpha_f \in S_{n,f}$ such that

$$z \in \mathcal{L}(\mathcal{A}_t) \iff z \notin \mathcal{L}(\mathcal{A}_t \cup \{\alpha_f\}).$$

Since there are at most $p(p(n))$ strings queried on ρ, there is a set $\widetilde{Q}(f,t,\ell)$ with $||\widetilde{Q}(f,t,\ell)|| \leq p(p(n)) \cdot t(p(p(n)))$ ensuring that $N_{i,1}^{\mathcal{L}(\mathcal{A}_t \cup \{\alpha_f\})}(\beta_\ell)$ accepts for every $\alpha_f \in S_{n,f} - \widetilde{Q}(f,t,\ell)$.

It is easy to see that statement (4.8) is satisfied with $\widetilde{Q}(f) = \bigcup_{t,\ell} \widetilde{Q}(f,t,\ell)$. Clearly, $||\widetilde{Q}(f)|| \leq (2^k-1)\cdot(2^k-2)\cdot p(p(n))\cdot t(p(p(n))) < 2^n$ by our choice of n. Since $||S_{n,f}|| = 2^n$, there exists a string $\widehat{\alpha_f} \in S_{n,f}$ witnessing the correctness of Claim 7. Thus Claim 7 is proved. □

COROLLARY 4.14. *For any integers $k, h \geq 1$, there exists an oracle $\mathcal{A}$ such that*

$$R_{k\text{-}T}^{p}(\mathrm{UP}_{\leq h}^{\mathcal{A}}) \nsubseteq R_{(2^k-2)\text{-}tt}^{p,\mathcal{A}}(\mathrm{U}\Sigma_h^{p,\mathcal{A}}).$$

4.5. Fault-tolerant access. Ko [36] introduced the notion of *one-sided helping* by a set A in the computation of a set B. A set A is said to provide *one-sided help* to a set B if there is a deterministic oracle Turing machine M computing B and a polynomial $p(\cdot)$ such that (a) on any input $x \in B$, $M^A(x)$ accepts in time $p(|x|)$, and (b) for all inputs y and for all oracles C, $M^C(y)$ accepts (though perhaps $M^C(y)$ may take a longer time than $p(|y|)$) if and only if $y \in B$. Since the machine M, accepting the set B, is capable of answering correctly on faulty oracles, i.e., oracles C different from the oracle A that provides one-sided help to B, the oracle access mechanism is

termed fault-tolerant (see [16]). Ko [36] defined $\mathrm{P}_{\text{1-help}}(A)$ to be the class of all sets B that can be one-sided helped by A.

It is known that sets that can be one-sided helped (by any arbitrary helper) are precisely those in NP [36]. Therefore, the notion of one-sided helping provides an avenue for understanding the structure of NP. For instance, given any class $\mathcal{C} \subseteq \mathrm{NP}$, what class of sets in NP can help the computation of sets in $\mathcal{C}$? Given any class $\mathcal{C}'$ of helpers, what class $\mathcal{C} \subseteq \mathrm{NP}$ can be helped by sets in $\mathcal{C}'$? It is worth studying the relationships between helpers and help-receivers to gain more insights into the notion of one-sided helping.

A restriction of the notion of one-sided helping, called the concept of *helping*, was earlier introduced and studied by Schöning [43]. A set A is said to *help* a set B if B is computed by a deterministic oracle Turing machine M such that on any input $x \in \Sigma^*$, (a) $M^A(x)$ halts in polynomial time, and (b) for all oracles C, $M^C(x)$ accepts (though perhaps $M^C(x)$ may take a longer time than $M^A(x)$ to terminate for $C \neq A$) if and only if $x \in B$.

Definition 4.15 ([43, 36]).

1. *A deterministic oracle Turing machine M is* robust *if for all oracles A, M^A halts on each input and $L(M^A) = L(M^\emptyset)$.*

2. *A set L is in the class $\mathrm{P}_{\text{1-help}}(A)$ if there exist a robust deterministic oracle Turing machine M and a polynomial $p(\cdot)$ such that $L = L(M^\emptyset)$ and for all $x \in L$, $M^A(x)$ halts in $p(|x|)$ steps. If $\mathcal{C}$ is a complexity class, then $\mathrm{P}_{\text{1-help}}(\mathcal{C}) = \bigcup_{A \in \mathcal{C}} \mathrm{P}_{\text{1-help}}(A)$.*

3. *A set L is in the class $\mathrm{P}_{\text{help}}(A)$ if there exist a robust deterministic oracle Turing machine M and a polynomial $p(\cdot)$ such that $L = L(M^\emptyset)$ and for all $x \in \Sigma^*$, $M^A(x)$ halts in $p(|x|)$ steps. If $\mathcal{C}$ is a complexity class, then $\mathrm{P}_{\text{help}}(\mathcal{C}) = \bigcup_{A \in \mathcal{C}} \mathrm{P}_{\text{help}}(A)$.*

The following observation is a direct consequence of Definition 4.15.

Observation 4.16. *For any complexity $\mathcal{C}$, $\mathrm{P}_{\text{help}}(\mathcal{C}) \subseteq \mathrm{P}_{\text{1-help}}(\mathcal{C})$.*

There has been much investigation of the complexity of sets that can be one-sided helped by sets belonging to particular complexity classes. For instance, Ko [36] proved that $\mathrm{NP} = \mathrm{P}_{\text{1-help}}(\mathrm{NP})$, $\mathrm{UP} \subseteq \mathrm{P}_{\text{1-help}}(\mathrm{UP})$, and $\mathrm{P}_{\text{1-help}}(\mathrm{BPP}) \subseteq \mathrm{RP}$. Ko [36] posed the question of whether $\mathrm{P}_{\text{1-help}}(\mathrm{UP})$ is exactly the same as UP. Cai, Hemachandra, and Vyskoč [16] proved that relativizable proof techniques cannot resolve this question: There is a relativized world, where $\mathrm{P}_{\text{1-help}}(\mathrm{UP})$ is not contained in UP [16]. Cintioli and Silvestri [17] strengthened this result. They exhibited an oracle A such that $\mathrm{P}^A_{\text{help}}(\mathrm{UP}^A) \not\subseteq \mathrm{Few}^A$ and an oracle B such that $\mathrm{P}^B_{\text{help}}(\mathrm{UP}^B) \not\subseteq R^{p,B}_b(\mathrm{FewP}(n^{\mathrm{polylog}(n)})^B)$, where $\mathrm{FewP}(n^{\mathrm{polylog}(n)})$ is the class of all sets accepted by NPTMs with at most $n^{\mathrm{polylog}(n)}$ accepting paths on inputs of length n. Despite these negative (oracle) results on the provability of containment of $\mathrm{P}_{\text{help}}(\mathrm{UP})$ in classes such as UP, FewP, and Few, Cai, Hemachandra, and Vyskoč [16] were successful in obtaining an exact characterization of $\mathrm{P}_{\text{1-help}}(\mathrm{UP})$. They proved that $\mathrm{P}_{\text{1-help}}(\mathrm{UP})$ is the closure of UP under $\leq^p_{lpos}$ reductions, where $\leq^p_{lpos}$ is the polynomial-time *locally positive* reduction introduced by Hemachandra and Jain [30].

In Theorem 4.17 below, we generalize and improve the relativized separation of $\mathrm{P}_{\text{1-help}}(\mathrm{UP})$ from UP by Cai, Hemachandra, and Vyskoč [16]. In the case of $h = 1$, Theorem 4.17 gives a relativized separation of $\mathrm{P}_{\text{1-help}}(\mathrm{UP})$ from $R^p_{s,b}(\text{Promise-UP})$, which is a potentially larger class than UP.[4]

[4]There is an oracle relative to which $R^p_{s,b}(\text{Promise-UP}) \not\subseteq \mathrm{UP}$, which follows from Beigel's oracle relative to which $\mathrm{UP}_{\leq 2} \not\subseteq \mathrm{UP}$ [6] and the fact that $\mathrm{UP}_{\leq 2} \subseteq R^p_{s,b}(\text{Promise-UP})$ relative to all oracles.

It remains an open question whether any of the oracle results by Cintioli and Silvestri [17], i.e., existence of oracles A and B such that $\mathrm{P}^A_{\mathrm{help}}(\mathrm{UP}^A) \not\subseteq \mathrm{Few}^A$ and $\mathrm{P}^B_{\mathrm{help}}(\mathrm{UP}^B) \not\subseteq R^{p,B}_b(\mathrm{FewP}(n^{\mathrm{polylog}(n)})^B)$, can be easily extended to our result in Theorem 4.17 for the case of $h = 1$, or vice versa. It also remains an open question whether the oracle results by Cintioli and Silvestri [17] can be generalized so that they hold for $\mathrm{P}_{\mathrm{help}}(\mathrm{UP}_{\leq h})$, for any $h \geq 1$.

THEOREM 4.17. *For every integer $h \geq 1$, there exists an oracle $\mathcal{A}$ such that*

$$\mathrm{P}_{\text{1-help}}(\mathrm{UP}^{\mathcal{A}}_{\leq h}) \not\subseteq R^{p,\mathcal{A}}_{s,b}(\text{Promise-UP}^{\mathrm{U}\Sigma^{p,\mathcal{A}}_{h-1}}).$$

Proof. The proof relies on Ko's result that for any oracle A, $R^p_{dtt}(\mathrm{UP}^A) \subseteq \mathrm{P}_{\text{1-help}}(\mathrm{UP}^A)$ [36]. Cai, Hemachandra, and Vyskoč [16] used this result to construct an oracle $\mathcal{A}$ such that $\mathrm{P}_{\text{1-help}}(\mathrm{UP}^{\mathcal{A}}) \not\subseteq \mathrm{UP}^{\mathcal{A}}$. We note that Ko's proof extends easily to the case of $\mathrm{UP}_{\leq h}$. That is, for any oracle A, it holds that $R^p_{dtt}(\mathrm{UP}^A_{\leq h}) \subseteq \mathrm{P}_{\text{1-help}}(\mathrm{UP}^A_{\leq h})$.

It thus suffices to show that there is an oracle A such that $R^p_{dtt}(\mathrm{UP}^A_{\leq h})$ is not contained in $R^{p,A}_{s,b}(\text{Promise-UP}^{\mathrm{U}\Sigma^{p,A}_{h-1}})$. We claim that we can take the oracle $\mathcal{A}$ from Theorem 4.10 for $k(n) = n$. To see this, suppose that $R^p_{dtt}(\mathrm{UP}^{\mathcal{A}}_{\leq h}) \subseteq R^{p,\mathcal{A}}_{s,b}(\text{Promise-UP}^{\mathrm{U}\Sigma^{p,\mathcal{A}}_{h-1}})$. By definition, we know that $R^p_{(n+1)\text{-}dtt}(\mathrm{UP}^{\mathcal{A}}_{\leq h}) \subseteq R^p_{dtt}(\mathrm{UP}^{\mathcal{A}}_{\leq h})$. Further, we have $R^{p,\mathcal{A}}_{s,b}(\text{Promise-UP}^{\mathrm{U}\Sigma^{p,\mathcal{A}}_{h-1}}) \subseteq R^{p,\mathcal{A}}_{s,n\text{-}T}(\text{Promise-UP}^{\mathrm{U}\Sigma^{p,\mathcal{A}}_{h-1}})$ since an n-Turing reduction can make more queries than any bounded Turing reduction except for finitely many n, which can be handled by a look-up table.

The last three inclusions together imply that $R^p_{(n+1)\text{-}dtt}(\mathrm{UP}^{\mathcal{A}}_{\leq h}) \subseteq R^{p,\mathcal{A}}_{s,n\text{-}T}(\text{Promise-UP}^{\mathrm{U}\Sigma^{p,\mathcal{A}}_{h-1}})$, contradicting Theorem 4.10. □

5. Robust unambiguity. So far we have looked at several applications of Lemma 3.1 in constructing relativized worlds involving arbitrary levels of the unambiguous polynomial hierarchy. Lemma 3.1, in essence, shows computational limitations of $\Sigma_k(A)$-systems under certain weak restrictions. What happens if we impose a more stringent restriction on a $\Sigma_k(A)$-system? This question is relevant to the following investigation.

We study the power of robustly unambiguous $\Sigma_k(\cdot)$-systems in Theorem 5.1. (Recall from Definition 2.4 that a $\Sigma_k(\cdot)$-system $[\cdot; N_1, N_2, \ldots, N_k]$ is robustly unambiguous if for every oracle B, $[B; N_1, N_2, \ldots, N_k]$ is unambiguous.) Theorem 5.1 illustrates the following fact: A robustly unambiguous $\Sigma_k(\cdot)$-system is so weak that given any oracle set B and input x, the hierarchical nondeterministic polynomial-time oracle access to B in $[B; N_1, N_2, \ldots, N_k](x)$ can be stripped down and turned into a deterministic polynomial-time oracle access (to B) without changing the decision (i.e., acceptance or rejection) of the $\Sigma_k(B)$-system on input x. As a corollary, we obtain a generic oracle collapse of UPH to P assuming P = NP in the unrelativized case. (See, e.g., [10, 21] for generic oracles and concepts related to them.)

THEOREM 5.1. *For every $k \geq 1$, if the $\Sigma_k(\cdot)$-system $[\cdot; N_1, N_2, \ldots, N_k]$ is robustly unambiguous, then there is a deterministic polynomial-time oracle Turing machine M such that for every $B \subseteq \Sigma^*$,*

$$L[B; N_1, N_2, \ldots, N_k] = L(M^{\Sigma^p_k \oplus B}) \in \mathrm{P}^{\Sigma^p_k \oplus B}.$$

Proof. We prove by induction on k the following statement: For each robustly unambiguous $\Sigma_k(\cdot)$-system $[\cdot; N_1, N_2, \ldots, N_k]$, there is a deterministic polynomial-

time oracle Turing machine M such that for every $B \subseteq \Sigma^*$, $L[B; N_1, N_2, \ldots, N_k] = L(M^{\Sigma_k^p \oplus B}) \in \mathrm{P}^{\Sigma_k^p \oplus B}$.

The base case $k = 1$ follows by relativization of [28, Theorem 2.1]. Hence suppose that $k > 1$. For every $B \subseteq \Sigma^*$, let $L(B)$ denote $L[B; N_2, N_3, \ldots, N_k]$. Notice the following easily verifiable facts: For all $B \subseteq \Sigma^*$, we have (a) $L[B; N_1, N_2, \ldots, N_k] = L[L(B); N_1]$, (b) $[L(B); N_1]$ is unambiguous, and (c) $[\cdot; N_2, N_3, \ldots, N_k]$ is robustly unambiguous. Thus, by induction hypothesis, we have that there is a deterministic polynomial-time oracle Turing machine M such that for all $B \subseteq \Sigma^*$, $L(B) = L(M^{\Sigma_{k-1}^p \oplus B}) \in \mathrm{P}^{\Sigma_{k-1}^p \oplus B}$. Let D be any Σ_{k-1}^p-complete set. We can now construct a nondeterministic polynomial-time oracle Turing machine N_1' such that for all $B \subseteq \Sigma^*$

- $L[L(B); N_1] = L[D \oplus B; N_1']$, and
- $[D \oplus B; N_1']$ is unambiguous.

We let machine N_1' on any input x simulate $N_1(x)$, with only one change in the simulation behavior: Whenever $N_1(x)$ makes a query q to $L(B)$, machine N_1' executes $M^{D \oplus B}(q)$ and uses the output returned by this deterministic execution as the answer to q. Thus, N_1' is a nondeterministic polynomial-time oracle Turing machine that accesses oracle $D \oplus B$. Since, for every $B \subseteq \Sigma^*$, $L(B) = L(M^{\Sigma_{k-1}^p \oplus B})$ and $[L(B); N_1]$ is unambiguous, we have that for every $B \subseteq \Sigma^*$, $L[L(B); N_1] = L[D \oplus B; N_1']$ and $[D \oplus B; N_1']$ is unambiguous. The latter means that for every $B \subseteq \Sigma^*$, ${N_1'}^{D \oplus B}$ is unambiguous. By relativization of [28, Theorem 2.1], it follows that there is a deterministic polynomial-time oracle Turing machine $\widehat{M}$ such that for every $B \subseteq \Sigma^*$, $L[D \oplus B; N_1'] = L(\widehat{M}^{\mathrm{NP}^D \oplus B})$. Since $D \in \Sigma_{k-1}^p$, and for every $B \subseteq \Sigma^*$, $L[D \oplus B; N_1'] = L[B; N_1, N_2, \ldots, N_k]$, we also have for every $B \subseteq \Sigma^*$

$$L[B; N_1, N_2, \ldots, N_k] = L(\widehat{M}^{\Sigma_k^p \oplus B}) \in \mathrm{P}^{\Sigma_k^p \oplus B}.$$

This completes the inductive step. □

Theorem 5.1 leads to the following corollary, which can be easily proved using the same techniques found in, e.g., [10, 21].

COROLLARY 5.2. *If* P = NP*, then, relative to a (Cohen) generic* G*,* P = UPH.

This corollary generalizes the following result of Blum and Impagliazzo: If P = NP, then, relative to a (Cohen) generic G, $\mathrm{P}^G = \mathrm{UP}^G$ [10]. Fortnow and Yamakami [22] demonstrated that similar collapses relative to any (Cohen) generic G do not occur at higher levels of the polynomial hierarchy. They proved that for each $k \geq 2$, there exists a tally set in $\mathrm{UP}^{\Sigma_{k-1}^{p,G},G} \cap \Pi_k^{p,G}$ but not in $\mathrm{P}^{\Sigma_{k-1}^{p,G},G}$. Thus Corollary 5.2 contrasts with this generic separation by Fortnow and Yamakami.

6. Conclusion and open problems. We presented a counting technique to investigate the structure of relativized hierarchical unambiguous computation. However, two interesting problems have remained open, for whose resolutions the technique presented in this paper could be useful. These problems are as follows.

1. *Simultaneous immunity and simplicity in the relativized unambiguous polynomial hierarchy.* Complexity class separations can be evaluated in terms of their quality. A separation of a complexity class $\mathcal{C}_1$ from another class $\mathcal{C}_2$ by an *immune* set requires the existence of an infinite set L in $\mathcal{C}_1$ such that no infinite set in $\mathcal{C}_2$ can be a subset of L; the set L is called $\mathcal{C}_2$-*immune* or *immune* to $\mathcal{C}_2$. A separation of a complexity class $\mathcal{C}_1$ from a class $\mathcal{C}_2$ by a *simple* set requires the existence of a coinfinite set (i.e., a set whose complement is infinite) L in $\mathcal{C}_1$ such that L is not in $\mathcal{C}_2$ and $\overline{L}$ is immune to $\mathcal{C}_1$; the set L is called $\mathcal{C}_1$-*simple* or *simple* for $\mathcal{C}_1$. Finally, a separation of a

complexity class $\mathcal{C}_1$ from a class $\mathcal{C}_2$ by a set that is both *simple and immune* requires the existence of a set L in $\mathcal{C}_1$ such that L is $\mathcal{C}_1$-simple and $\mathcal{C}_2$-immune.

An oracle separation of a complexity class from another class by a set that is both simple and immune is considered a much more difficult problem than the oracle separations of the same classes by simple sets or by immune sets alone. This point has been discussed in [13], which we explain in our own words as follows: Intuitively, if a set L is $\mathcal{C}$-immune, then the set L must have low density since no infinite set in $\mathcal{C}$ can be a subset of L. Similarly, if a set L is $\mathcal{C}$-simple, then the set L must have high density since $\overline{L}$ is $\mathcal{C}$-immune. Consequently, separation of a complexity class $\mathcal{C}_1$ from another class $\mathcal{C}_2$ by a set $L \in \mathcal{C}_1$ that is both $\mathcal{C}_1$-simple and $\mathcal{C}_2$-immune requires the set L to have conflicting requirements: L must be dense enough so as to be $\mathcal{C}_1$-simple and must be thin enough so as to be $\mathcal{C}_2$-immune.

Buhrman and Torenvliet [13] showed that, relative to an oracle, the first level and the second level of the polynomial hierarchy separate by sets that are both simple and immune. Using Kolmogorov complexity for oracle constructions, they proved that, relative to an oracle A, NP has a set that is both NP-simple and (NP$\cap$coNP)-immune, and, relative to an oracle B, Π_2^p has a set that is both Π_2^p-simple and $(\Sigma_2^p \cap \Pi_2^p)$-immune. However, it is currently open whether there is an oracle relative to which the third level or any higher level of the polynomial hierarchy separates by a set that is both simple and immune. In fact, it is also open whether there is an oracle relative to which NP has a set that is both NP-simple and coNP-immune.

We expect that the situation for the UPH is quite different from the one for the polynomial hierarchy. We hope that it might be possible that an application of our proof technique in conjunction with the Kolmogorov arguments of Buhrman and Torenvliet [13] lead to a construction of an oracle relative to which all the levels of the UPH separate by sets that are both simple and immune.

2. *Random oracle separation of the relativized unambiguous polynomial hierarchy.* There has been an abundance of complexity theoretic results that hold with probability one relative to a random oracle. Some prominent random oracle results are (1) probability one separation of NP from P with bi-immunity, and of NP from coNP [8], (2) probability one separation of NP from P/poly [39], (3) probability one separation of coNP from NP with immunity [47], and (4) probability one separation of PSPACE from PH [14, 3]. Despite so many random oracle results, the probability one separation of the levels of the polynomial hierarchy relative to a random oracle is still an open problem. (See [32] for an extensive discussion of this problem.) Currently, only the circuit complexity-theoretic approach is known for separating the higher levels (levels beyond three) of the polynomial hierarchy, but the circuit approach has so far not been successful in resolving this longstanding open problem.

We believe that the case of the unambiguous polynomial hierarchy is easier. In Theorem 4.1, we have used our counting technique to show that for all $k \geq 1$, there is an oracle A such that $\mathrm{UP}^A_{\leq k+1}$ is not contained in $\mathrm{U}\Sigma_k^{p,A}$. Thus, unlike the case of the polynomial hierarchy for which only the circuit approach is known for the relativized separation of all its levels, the levels of the relativized UPH are separable by counting arguments alone, and thus by completely avoiding the machinery of circuit complexity. This raises our hope that a probability one separation of the levels of the UPH might be easier to achieve than its counterpart, i.e., a probability one separation of the levels of the PH relative to a random oracle.

Acknowledgments. We thank Lane Hemaspaandra and Jörg Rothe for their constant encouragement and support. We also thank the anonymous referees for their helpful comments.

SEPARATING AC^0 FROM DEPTH-2 MAJORITY CIRCUITS*

ALEXANDER A. SHERSTOV†

Abstract. We construct a function in AC^0 that cannot be computed by a depth-2 majority circuit of size less than $\exp(\Theta(n^{1/5}))$. This solves an open problem due to Krause and Pudlák [*Theoret. Comput. Sci.*, 174 (1997), pp. 137–156] and matches Allender's classic result [A note on the power of threshold circuits, in *Proceedings of the 30th Annual IEEE Symposium on Foundations of Computer Science (FOCS)*, Research Triangle Park, NC, 1989, pp. 580–584] that AC^0 can be efficiently simulated by depth-3 majority circuits. To obtain our result, we develop a novel technique for proving lower bounds on communication complexity. This technique, the *Degree/Discrepancy Theorem*, is of independent interest. It translates lower bounds on the threshold degree of any Boolean function into upper bounds on the discrepancy of a related function. Upper bounds on the discrepancy, in turn, immediately imply lower bounds on communication and circuit size. In particular, we exhibit the first known function in AC^0 with exponentially small discrepancy, $\exp(-\Omega(n^{1/5}))$, thereby establishing the separations $\Sigma_2^{cc} \not\subseteq \mathsf{PP}^{cc}$ and $\Pi_2^{cc} \not\subseteq \mathsf{PP}^{cc}$ in communication complexity.

1. Introduction.

A natural and important computational model is that of a polynomial-size circuit of majority gates. This model has been extensively studied for the past two decades [14, 15, 26, 27, 38, 43, 44, 45]. Research has shown that majority circuits of depth 2 and 3 already possess surprising computational power. Indeed, it is a long-standing open problem [21] to exhibit a Boolean function that *cannot* be computed by a depth-3 majority circuit of polynomial size. To illustrate, the arithmetic operations of powering, multiplication, and division on n-bit integer arguments can all be computed by depth-3 majority circuits of polynomial size [45]. An even more striking example is the addition of n n-bit integers, which is computable by a depth-2 majority circuit of polynomial size [45]. Depth-2 majority circuits of polynomial size can also compute every symmetric function (such as PARITY) and every disjunctive normal form (DNF) and conjunctive normal form (CNF) formula of polynomial size.

The chief goal of this paper is to relate the computational power of majority circuits to that of AC^0, another extensively studied class, which consists of polynomial-size constant-depth circuits of AND, OR, NOT gates. A well-known result due to Allender [1] states that every function in AC^0 can be computed by a depth-3 majority circuit of quasi-polynomial size. For over ten years, it has been an open problem to determine whether Allender's simulation is optimal. Specifically, Krause and Pudlák [21, sect. 6] ask whether every function in AC^0 can be computed by a depth-2 majority circuit of quasi-polynomial size. We solve this open problem completely, even in the

more general setting of majority-of-threshold circuits (i.e., depth-2 circuits in which a majority gate receives inputs from arbitrary linear threshold gates).

THEOREM 1.1 (main result). *There is a function $f : \{-1,1\}^n \to \{-1,1\}$, explicitly given and computable by an AC^0 circuit of depth 3, whose computation requires a majority vote of $\exp(\Omega(n^{1/5}))$ linear threshold gates.*

In other words, Allender's simulation is optimal in a strong sense. The lower bound in Theorem 1.1 is an exponential improvement over previous work. The best previous lower bound [15, 27] was quasi polynomial and followed trivially from the observation that AC^0 can compute INNER PRODUCT MODULO 2 on $\log^c n$ variables, for any constant $c > 1$.

1.1. A communication-complexity perspective. A different and perhaps more revealing view of this work is in terms of communication complexity [23]. The communication complexity of Boolean functions in different models has long been an active area of research, due to its inherent appeal as a complexity subject as well as its numerous applications in theoretical computer science. Our work contributes a novel and powerful technique for communication lower bounds, which is based on the representation of a Boolean function as the sign of a real-valued polynomial. Specifically, fix a Boolean function $f : \{-1,1\}^n \to \{-1,1\}$. Its *threshold degree*, $\deg_\pm(f)$, is defined as the minimum degree of a polynomial $p(x_1, x_2, \ldots, x_n)$ that represents f in sign: $f(x) \equiv \operatorname{sign}(p(x))$. This concept has played a prominent role in the study of circuit complexity [2, 21, 22, 26] and has yielded valuable insights in other areas, including computational learning theory [17, 20]. In many cases [26], it is straightforward to obtain strong lower bounds on the threshold degree. Since the threshold degree is a measure of the complexity of a given Boolean function, it is natural to wonder whether it can yield lower bounds on communication in a suitable setting. Our work confirms this intuition for every f.

More precisely, fix a Boolean function $f : \{-1,1\}^n \to \{-1,1\}$ with threshold degree d. Let N be a given integer, $N \geqslant n$. We introduce and study the two-party communication problem of computing,

$$f(x|_S),$$

where the Boolean string $x \in \{-1,1\}^N$ is Alice's input and the set $S \subset \{1,2,\ldots,N\}$ of size $|S| = n$ is Bob's input. The symbol $x|_S$ stands for the projection of x onto the indices in S, in other words, $x|_S = (x_{i_1}, x_{i_2}, \ldots, x_{i_n}) \in \{-1,1\}^n$, where $i_1 < i_2 < \cdots < i_n$ are the elements of S. Intuitively, this problem models a situation when Alice and Bob's joint computation depends on only n of the inputs $x_1, x_2, \ldots, x_N$. Alice knows the values of all the inputs $x_1, x_2, \ldots, x_N$ but does not know which n of them are relevant. Bob, on the other hand, knows which n inputs are relevant but does not know their values. As one would hope, we prove that d gives a lower bound on the communication requirements of this problem. We phrase our result in terms of *discrepancy*, a central quantity in communication complexity that immediately yields lower bounds on communication in a variety of models (see section 2.1).

THEOREM 1.2 (Degree/Discrepancy Theorem). *Let $f : \{-1,1\}^n \to \{-1,1\}$ be given with threshold degree $d \geqslant 1$. Then for $N \geqslant n$, the matrix $M = [f(x|_S)]_{x,S}$ has discrepancy*

$$\operatorname{disc}(M) \leqslant \left(\frac{4\mathrm{e}n^2}{Nd}\right)^{d/2},$$

where $\mathrm{e} = 2.718\ldots$.

Theorem 1.2, which we call the *Degree/Discrepancy Theorem* for obvious reasons, is a separate contribution of our work. Given a function f with threshold degree d, it generates a communication problem with discrepancy at most 2^{-d} (by setting $N \geqslant 16en^2/d$). This exponentially small upper bound on the discrepancy immediately translates into an $\Omega(d)$ lower bound on communication in a variety of models (deterministic, nondeterministic, randomized, quantum with and without entanglement). Moreover, the resulting lower bounds on communication remain valid when Alice and Bob merely seek to predict the answer with nonnegligible advantage, a critical aspect for lower bounds against threshold circuits. This contrasts with other communication-complexity methods [32, 34], which only apply to high-accuracy computation. Finally, discrepancy arises prominently in contexts beyond communication complexity, such as estimation of margin complexity [25, 40] and approximate rank [19]. For all these reasons, we believe that the Degree/Discrepancy Theorem is of considerable interest in its own right. We prove it by a novel application of Gordan's transposition theorem [37, sect. 7.8], which is a classical result from the theory of linear inequalities.

We are now in a position to outline the proof of our main result, Theorem 1.1. We start with a well-known DNF formula Φ, constructed by Minsky and Papert [26], that has high threshold degree. An application of Theorem 1.2 to Φ yields a communication problem with low discrepancy. By design, this communication problem can be viewed as an AC^0 circuit of depth 3. Recalling that its discrepancy is exponentially small, we immediately conclude that it cannot be computed by a depth-2 majority circuit of subexponential size. This completes the proof.

1.2. On the discrepancy of AC^0 circuits. Recall that a key component of our proof is the construction of an AC^0 circuit with exponentially small discrepancy. Prior to this work, it was not known whether such a circuit existed. In particular, all previously known functions with exponentially small discrepancy (see, e.g., [14, 27]) contain PARITY or MAJORITY as a subfunction and therefore cannot be computed in AC^0. In view of the intrinsic value of discrepancy as a complexity measure, we state this result on its own.

THEOREM 1.3 (discrepancy of AC^0 circuits). *There is a function $f : \{-1,1\}^n \times \{-1,1\}^n \to \{-1,1\}$, explicitly given and computable by an AC^0 circuit of depth 3, that has discrepancy $\exp(-\Omega(n^{1/5}))$ with respect to an explicitly given distribution.*

Theorem 1.3 is best possible in that every AC^0 circuit of depth 1 or 2 has discrepancy at least $n^{-O(1)}$ with respect to all distributions and all partitions of the variables (see section 5). As a direct corollary to Theorem 1.3, we separate communication classes Σ_2^{cc} and Π_2^{cc} from PP^{cc}.

COROLLARY 1.4. $\Sigma_2^{cc} \not\subseteq \mathsf{PP}^{cc}$, $\Pi_2^{cc} \not\subseteq \mathsf{PP}^{cc}$.

Here Σ_2^{cc} and Π_2^{cc} are the second level of the polynomial hierarchy in communication complexity, whereas PP^{cc} is the class of all communication matrices with nonnegligible discrepancy. Prior to this work, it was entirely conceivable that PP^{cc} contained both Σ_2^{cc} and Π_2^{cc} and the rest of the polynomial hierarchy PH^{cc}. See section 6 for further details.

Another AC^0 circuit of depth 3 with exponentially small discrepancy was constructed independently by Buhrman, Vereshchagin, and de Wolf [5, sect. 3]. Their proof uses quite different techniques (approximation theory and quantum communication complexity). Their circuit has discrepancy $\exp(-\Omega(n^{1/3}))$, which is a stronger bound than Theorem 1.3. An advantage of the construction in this paper is that it is self-contained and derived from first principles, whereas the work of Buhrman, Vereshchagin, and de Wolf builds on a subtle result of Razborov [35]. In addition,

our method is not restricted to AC^0 but, rather, applies to *any* function with high threshold degree.

1.3. Recent progress. We are pleased to report that the Degree/Discrepancy Theorem has inspired important progress in communication complexity by several researchers, which we briefly survey. The first of these new results is concerned with bounded-error communication. By combining the method of Theorem 1.2 with techniques from matrix analysis and approximation theory, the author [41] obtained strong lower bounds on bounded-error communication for a broad new class of problems. These lower bounds remain valid in the quantum model (regardless of prior entanglement) and subsume Razborov's breakthrough lower bounds for symmetric functions [35].

In another development [42], we used the method of Theorem 1.2 as a starting point to derive essentially optimal lower bounds on the *unbounded-error* communication complexity of every symmetric function. The unbounded-error model is more powerful than all the familiar models of communication (both classical and quantum), and proving lower bounds in it is a substantial challenge. The only previous nontrivial lower bounds for this model appeared in the groundbreaking work of Forster [12] and its extensions.

Razborov and Sherstov [36] recently obtained the first exponential lower bound on the *sign-rank* of AC^0, thereby solving a long-standing open problem due to Babai, Frankl, and Simon [3]. The results in [36] additionally give strong lower bounds for the probably approximately correct (PAC) learning of polynomial-size DNF and CNF formulas (see Remark 8.2). The method of the Degree/Discrepancy Theorem is one of the starting points in that work.

The Degree/Discrepancy Theorem has also found applications to multiparty communication complexity. The first of these is the work by Chattopadhyay [6], who observed that the method of Theorem 1.2 adapts in a straightforward manner to the multiparty model. Analogous to this adaptation, Lee and Shraibman [24] and Chattopadhyay and Ada [7] adapted to the multiparty model the author's recent work [41] on two-party bounded-error communication. They thereby obtained improved lower bounds on the bounded-error communication complexity of DISJOINTNESS for up to $\log\log n$ players. David and Pitassi [9] combined this line of work with the probabilistic method, establishing a separation of the communication classes NP^{cc}_k and BPP^{cc}_k for up to $k = (1-\epsilon)\log n$ players. Their construction was derandomized in a follow-up paper by David, Pitassi, and Viola [10], resulting in an explicit separation. See the survey article [39] for a unified guide to these results, complete with all the key proofs.

1.4. Organization. The remainder of this paper is organized as follows. Section 2 provides relevant background on communication complexity and threshold functions. Section 3 is devoted to the proof of the Degree/Discrepancy Theorem, our main technical tool. Section 4 studies a particular AC^0 circuit Φ with high threshold degree. Section 5 applies the Degree/Discrepancy Theorem to Φ, yielding an explicit AC^0 circuit f of depth 3 with exponentially small discrepancy. Section 6 uses this discrepancy result to separate the classes Σ_2^{cc} and Π_2^{cc} from PP^{cc} in communication complexity. In section 7, we derive our main result, an exponential lower bound on the size of depth-2 majority circuits that compute AC^0. Section 8 concludes with an application of our results to computational learning theory.

2. Preliminaries. Throughout this work, we identify -1 and 1 with "true" and "false," respectively. We view Boolean functions as mappings $X \to \{-1, 1\}$, where X

is a finite set such as $X = \{-1,1\}^n$. The symbol $[n]$ stands for the set $\{1,2,\ldots,n\}$. For integers N, n with $N \geqslant n$, the symbol $\binom{[N]}{n}$ denotes the family of all size-n subsets of $\{1,2,\ldots,N\}$. For a string $x \in \{-1,1\}^N$ and a set $S \in \binom{[N]}{n}$, we define $x|_S = (x_{i_1}, x_{i_2}, \ldots, x_{i_n}) \in \{-1,1\}^n$, where $i_1 < i_2 < \cdots < i_n$ are the elements of S. The notation $\mathbb{R}^{m\times n}$ refers to the family of all $m \times n$ matrices with real entries. We specify matrices by their generic entry, e.g., $A = [F(i,j)]_{i,j}$. As usual, we denote the base of the natural logarithm by $\mathrm{e} = 2.718\ldots$.

Recall that AC^0 is the family of polynomial-size unbounded-fanin constant-depth circuits with AND, OR, NOT gates. We adopt the following standard definition of the sign function:

$$\operatorname{sign}(t) = \begin{cases} 1 & \text{if } t > 0, \\ 0 & \text{if } t = 0, \\ -1 & \text{if } t < 0. \end{cases}$$

A *linear threshold gate* is a Boolean function $f : \{-1,1\}^n \to \{-1,1\}$ of the form $f(x) \equiv \operatorname{sign}(\sum_{i=1}^n a_i x_i - \theta)$ for some fixed reals $a_1, \ldots, a_n, \theta$. Observe that a linear threshold gate generalizes the familiar majority gate.

2.1. Communication complexity. We consider Boolean functions $f : X \times Y \to \{-1,1\}$. Typically $X = Y = \{-1,1\}^n$, but we also allow X and Y to be arbitrary finite sets. We identify a function f with its *communication matrix* $M = [f(x,y)]_{x\in X,\, y\in Y}$. In particular, we use the terms "communication complexity of f" and "communication complexity of M" interchangeably (and likewise for other complexity measures, such as discrepancy). The two communication models of interest to us are the randomized model and the deterministic model. The *randomized complexity* $\mathrm{R}_{1/2-\gamma/2}(f)$ of f is the minimum cost of a randomized protocol for f that computes $f(x,y)$ correctly with probability at least $\frac{1}{2} + \frac{1}{2}\gamma$ (equivalently, with *advantage* γ) on every input (x,y). The *public-coin randomized complexity* $\mathrm{R}^{\mathrm{pub}}_{1/2-\gamma/2}(f)$ is defined analogously, with the only difference that the communicating parties now have a source of shared random bits; i.e., they can observe tosses of a common coin without communicating. The *distributional complexity* $\mathrm{D}^{\mu}_{1/2-\gamma/2}(f)$ is the minimum cost of a deterministic protocol for f that has error at most $\frac{1}{2} - \frac{1}{2}\gamma$ (equivalently, *advantage* γ) with respect to the distribution μ over the inputs.

A *rectangle* of $X \times Y$ is any set $R = A \times B$ with $A \subseteq X$ and $B \subseteq Y$. For a fixed distribution μ over $X \times Y$, the *discrepancy* of f is defined as

$$\operatorname{disc}_\mu(f) = \max_R \left| \sum_{(x,y)\in R} \mu(x,y) f(x,y) \right|,$$

where the maximum is taken over all rectangles R. We define $\operatorname{disc}(f) = \min_\mu \operatorname{disc}_\mu(f)$. The *discrepancy method* is a fundamental technique that places a lower bound on the randomized and distributional complexity in terms of the discrepancy.

PROPOSITION 2.1 (Kushilevitz and Nisan [23, pp. 36–38]). *For every Boolean function $f : X \times Y \to \{-1,1\}$, every distribution μ on $X \times Y$, and every $\gamma > 0$,*

$$\mathrm{R}_{1/2-\gamma/2}(f) \;\geqslant\; \mathrm{R}^{\mathrm{pub}}_{1/2-\gamma/2}(f) \;\geqslant\; \mathrm{D}^{\mu}_{1/2-\gamma/2}(f) \;\geqslant\; \log_2 \frac{\gamma}{\operatorname{disc}_\mu(f)}.$$

The above definition of discrepancy is not convenient to work with. The following well-known lemma bounds the discrepancy in terms of a more analytically pleasing quantity. For completeness, we include a proof.

LEMMA 2.2 (discrepancy bound; cf. [4, 8, 11, 33]). *Let $f : X \times Y \to \{-1,1\}$ be given, and let μ be a probability distribution over $X \times Y$. Then*

$$\operatorname{disc}_\mu(f)^2 \leqslant |X| \sum_{y,y' \in Y} \left| \sum_{x \in X} \mu(x,y)\mu(x,y')f(x,y)f(x,y') \right|.$$

Proof (adapted from Raz [33]). Let $R = A \times B$ be a rectangle over which the discrepancy is achieved. Define $\alpha_x = 1$ for all $x \in A$, and likewise $\beta_y = 1$ for all $y \in B$. For all remaining x and y, let α_x and β_y be independent random variables distributed uniformly over $\{-1,1\}$. Passing to expectations,

$$\begin{aligned}
&\left| \mathbf{E}\left[\sum_{x,y} \alpha_x \beta_y \mu(x,y) f(x,y) \right] \right| \\
&\qquad = \left| \sum_{(x,y) \in R} \underbrace{\mathbf{E}[\alpha_x \beta_y]}_{=1} \mu(x,y) f(x,y) + \sum_{(x,y) \notin R} \underbrace{\mathbf{E}[\alpha_x \beta_y]}_{=0} \mu(x,y) f(x,y) \right| \\
&\qquad = \operatorname{disc}_\mu(M).
\end{aligned}$$

In particular, there exists a fixed assignment $\alpha_x, \beta_y \in \{-1,1\}$ for all x, y such that

$$\operatorname{disc}_\mu(f) \leqslant \left| \sum_{x,y} \alpha_x \beta_y \mu(x,y) f(x,y) \right|.$$

Squaring both sides and applying the Cauchy–Schwarz inequality,

$$\begin{aligned}
\operatorname{disc}_\mu(f)^2 &\leqslant |X| \sum_x \left(\alpha_x \sum_y \beta_y \mu(x,y) f(x,y) \right)^2 \\
&= |X| \sum_{y,y'} \beta_y \beta_{y'} \sum_x \mu(x,y)\mu(x,y') f(x,y) f(x,y') \\
&\leqslant |X| \sum_{y,y'} \left| \sum_x \mu(x,y)\mu(x,y') f(x,y) f(x,y') \right|,
\end{aligned}$$

as desired. □

A definitive resource for further details is the book of Kushilevitz and Nisan [23].

2.2. Threshold degree. Let $f : \{-1,1\}^n \to \{-1,1\}$ be a given Boolean function. The *threshold degree* of f, denoted $\deg_\pm(f)$, is the least degree of a polynomial $p(x_1, x_2, \ldots, x_n)$ such that $f(x) \equiv \operatorname{sign}(p(x))$. In view of the domain of f, any such polynomial p can be assumed to be multilinear. Note that any function f that depends on k or fewer of the n variables has threshold degree at most k. For a set $S \subseteq [n]$, we write $\chi_S = \prod_{i \in S} x_i$. In this notation, the threshold degree of f is the smallest d such that $f(x) \equiv \operatorname{sign}(\sum_{|S| \leqslant d} a_S \chi_S(x))$ for some fixed reals a_S. Threshold degree is also known in the literature as "strong degree" [2], "voting polynomial degree" [21], "polynomial threshold function (PTF) degree" [30], and "sign degree" [5].

Crucial to understanding the threshold degree is the following result from the theory of linear inequalities, which follows in a straightforward manner from linear-programming duality.

THEOREM 2.3 (Gordan's transposition theorem [37, sect. 7.8]). *Let $A \in \mathbb{R}^{m\times n}$. Then exactly one of the following statements holds:*

(i) *$u^{\mathsf{T}}A > 0$ for some vector u.*

(ii) *$Av = 0$ for some nonzero vector $v \geqslant 0$.*

The vector notation $u^{\mathsf{T}}A > 0$ and $v \geqslant 0$ above is to be understood entrywise, as usual. A consequence of Gordan's transposition theorem is the following well-known result regarding threshold representations.

THEOREM 2.4 (see [2, 30]). *Let $\phi_1, \phi_2, \ldots, \phi_k : \{-1,1\}^n \to \mathbb{R}$ be arbitrary real functions, and let $f : \{-1,1\}^n \to \{-1,1\}$ be a given Boolean function. Then exactly one of the following statements holds:*

(i) *$f(x) \equiv \operatorname{sign}(\sum_{i=1}^k a_i\phi_i(x))$ for some reals $a_1, a_2, \ldots, a_k$.*

(ii) *There is a distribution μ over $\{-1,1\}^n$ such that*

$$\mathop{\mathbf{E}}_{x\sim\mu}[f(x)\phi_i(x)] = 0, \qquad i = 1, 2, \ldots, k.$$

Proof. Consider the $k \times 2^n$ matrix $A = [f(x)\phi_i(x)]_{i,x}$. The claim follows from Theorem 2.3, with u playing the role of a set of coefficients $(a_1, a_2, \ldots, a_k) \in \mathbb{R}^k$, and v playing the role of a probability distribution. □

COROLLARY 2.5. *Let $f : \{-1,1\}^n \to \{-1,1\}$ be arbitrary and d be a nonnegative integer. Then exactly one of the following holds:*

(i) *$\deg_{\pm}(f) \leqslant d$.*

(ii) *There is a distribution μ over $\{-1,1\}^n$ such that*

$$\mathop{\mathbf{E}}_{x\sim\mu}[f(x)\chi_S(x)] = 0, \qquad |S| = 0, 1, \ldots, d.$$

3. The Degree/Discrepancy Theorem. This section marks the beginning of our proof. Its purpose is to establish Theorem 1.2 (the Degree/Discrepancy Theorem), which plays a central role in the development to follow.

THEOREM 1.2 (restated from section 1.1). *Let $f : \{-1,1\}^n \to \{-1,1\}$ be given with threshold degree $d \geqslant 1$. Let N be a given integer, $N \geqslant n$. Define $M = [f(x|_S)]_{x,S}$, where the indices range as follows: $x \in \{-1,1\}^N$, $S \in \binom{[N]}{n}$. Then*

$$\operatorname{disc}(M) \leqslant \left(\frac{4en^2}{Nd}\right)^{d/2}. \tag{3.1}$$

Proof. Let μ be a probability distribution over $\{-1,1\}^n$ with respect to which $\mathbf{E}_{z\sim\mu}[f(z)p(z)] = 0$ for every real-valued function p of $d-1$ or fewer of the variables $z_1, \ldots, z_n$. The existence of μ is assured by Corollary 2.5. Throughout this proof, the symbol $\mathcal{U}$ shall stand for the uniform distribution over the relevant domain. We will analyze the discrepancy of M with respect to the distribution

$$\lambda(x, S) = 2^{-N+n}\binom{N}{n}^{-1}\mu(x|_S).$$

By Lemma 2.2,

$$\operatorname{disc}_\lambda(M)^2 \leqslant 4^n \mathop{\mathbf{E}}_{(S,T)\sim\mathcal{U}}|\Gamma(S,T)|, \tag{3.2}$$

where we let

$$\Gamma(S,T) = \mathop{\mathbf{E}}_{x\sim\mathcal{U}}\left[\mu(x|_S)\mu(x|_T)f(x|_S)f(x|_T)\right].$$

To analyze this expression, we prove two key claims.

CLAIM 3.1. *Assume that* $|S \cap T| \leqslant d-1$. *Then* $\Gamma(S,T) = 0$.

Proof. For notational convenience, assume that $S = \{1,2,\ldots,n\}$. Then

$$\begin{aligned}\Gamma(S,T) &= \mathop{\mathbf{E}}_{x\sim\mathcal{U}}\Big[\mu(x_1,\ldots,x_n)\mu(x|_T)f(x_1,\ldots,x_n)f(x|_T)\Big] \\ &= \frac{1}{2^N}\sum_{x_1,\ldots,x_n}\mu(x_1,\ldots,x_n)f(x_1,\ldots,x_n)\sum_{x_{n+1},\ldots,x_N}\mu(x|_T)f(x|_T) \\ &= \frac{1}{2^N}\mathop{\mathbf{E}}_{(x_1,\ldots,x_n)\sim\mu}\left[f(x_1,\ldots,x_n)\cdot\underbrace{\left(\sum_{x_{n+1},\ldots,x_N}\mu(x|_T)f(x|_T)\right)}_{*}\right].\end{aligned}$$

Since $|S\cap T| \leqslant d-1$, the starred expression is a real-valued function of at most $d-1$ variables. The claim follows by the definition of μ. □

CLAIM 3.2. *Assume that* $|S \cap T| = k$. *Then* $|\Gamma(S,T)| \leqslant 2^{k-2n}$.

Proof. For notational convenience, assume that

$$\begin{aligned}S &= \{1,2,\ldots,n\}, \\ T &= \{1,2,\ldots,k\} \cup \{n+1, n+2, \ldots, n+(n-k)\}.\end{aligned}$$

We have

$$\begin{aligned}|\Gamma(S,T)| &\leqslant \mathop{\mathbf{E}}_{x\sim\mathcal{U}}\Big|\mu(x|_S)\mu(x|_T)f(x|_S)f(x|_T)\Big| \\ &= \mathop{\mathbf{E}}_{x_1,\ldots,x_{2n-k}}[\mu(x_1,\ldots,x_n)\mu(x_1,\ldots,x_k,x_{n+1},\ldots,x_{2n-k})] \\ &\leqslant \underbrace{\mathop{\mathbf{E}}_{x_1,\ldots,x_n}[\mu(x_1,\ldots,x_n)]}_{=2^{-n}}\cdot\max_{x_1,\ldots,x_k}\underbrace{\mathop{\mathbf{E}}_{x_{n+1},\ldots,x_{2n-k}}[\mu(x_1,\ldots,x_k,x_{n+1},\ldots,x_{2n-k})]}_{\leqslant 2^{-(n-k)}}.\end{aligned}$$

The bounds 2^{-n} and $2^{-(n-k)}$ follow because μ is a probability distribution. □

In view of Claims 3.1 and 3.2, inequality (3.2) simplifies to

$$\operatorname{disc}_\lambda(M)^2 \leqslant \sum_{k=d}^{n} 2^k\,\mathbf{P}[|S\cap T| = k].$$

Since

$$\mathbf{P}[|S\cap T| = k] = \binom{n}{k}\binom{N-n}{n-k}\binom{N}{n}^{-1} \leqslant \binom{n}{k}\left(\frac{n}{N}\right)^k \leqslant \left(\frac{\mathrm{e}n^2}{Nk}\right)^k,$$

and since the discrepancy cannot exceed 1, we conclude that

$$\operatorname{disc}_\lambda(M)^2 \leqslant \min\left\{1,\ \sum_{k=d}^{n}\left(\frac{2\mathrm{e}n^2}{Nk}\right)^k\right\} \leqslant \left(\frac{4\mathrm{e}n^2}{Nd}\right)^d.$$

This completes the proof of Theorem 1.2. □

Remark 3.3. The proof above analyzes the discrepancy of $M = [f(x|_S)]_{x,S}$ with respect to a certain distribution λ, derived directly from a distribution μ under which

f is uncorrelated with every function of fewer than $\deg_\pm(f)$ variables. Therefore, the discrepancy bound (3.1) is achieved with respect to an explicitly given distribution whenever μ is explicitly given.

Remark 3.4. The discrepancy bound (3.1) holds not only for M but also for any sign matrix that contains M. This observation is immediate from the definition of discrepancy. It allows a considerable degree of flexibility in applying Theorem 1.2, as will become apparent in section 5.

Remark 3.5. The discrepancy bound in Theorem 1.2 is not tight. In subsequent work [41, Thm. 7.3], the author strengthened it to $\mathrm{disc}(M) \leqslant (4n/N)^{d/2}$. Moreover, this new bound continues to hold when Bob's input S is restricted to have a particularly simple form. This stronger Degree/Discrepancy Theorem leads to quantitative improvements on this paper's Theorems 1.1 and 1.3; see [41, sect. 7] for details. These improvements are built around a matrix-analytic approach to estimating the discrepancy, as opposed to the combinatorial derivation above. However, the proof of the Degree/Discrepancy Theorem in this paper has the advantage that it easily adapts to the multiparty model and is the foundation of the recent multiparty results [6, 7, 9, 10, 24]. The matrix-analytic approach does not seem to extend to three or more communicating parties.

4. A function with high threshold degree. Consider the Boolean function MP_m on $n = 4m^3$ variables, given by

$$\mathrm{MP}_m(x) = \bigvee_{i=1}^{m} \bigwedge_{j=1}^{4m^2} x_{i,j}.$$

A moment's reflection shows that the threshold degree of MP_m is at most m. Indeed,

$$\mathrm{MP}_m(x) = \operatorname{sign}\left\{ -\frac{1}{2} + \prod_{i=1}^{m} (4m^2 + x_{i,1} + x_{i,2} + \cdots + x_{i,4m^2}) \right\}.$$

(Recall that $x_{i,j} \in \{-1, 1\}$, where -1 corresponds to "true.") Minsky and Papert [26], who originally defined this function, proved that this upper bound is tight.

THEOREM 4.1 (Minsky and Papert [26]). *MP_m has threshold degree m.*

Minsky and Papert's proof, while short and elegant, does not yield an explicit distribution over $\{-1, 1\}^{4m^3}$ with respect to which MP_m is orthogonal to all functions of fewer than m variables. The existence of such a distribution is assured by Corollary 2.5. The purpose of this section is to construct it. While this construction is not needed for our circuit lower bound (Theorem 1.1), it yields additional insight into the discrepancy of AC^0 (Theorem 1.3).

We shall construct the desired distribution by extending an earlier argument, due to O'Donnell and Servedio [29], that makes the crux of the Minsky–Papert construction explicit. A starting point in our discussion is the following fact.

PROPOSITION 4.2 (O'Donnell and Servedio [29]). *Let ν be the binomial distribution over $\{0, 1, \ldots, 2m\}$, i.e., $\nu(t) = 2^{-2m}\binom{2m}{t}$. Then for every polynomial p of degree at most $2m - 1$,*

$$\mathop{\mathbf{E}}_{t \sim \nu}[(-1)^t p(t)] = 0.$$

Proof. We present the proof from [29]. The claim holds for the monomials

$p = 1, t, t^2, \ldots, t^{2m-1}$ in view of the combinatorial identity

$$\sum_{t=0}^{2m} \binom{2m}{t} (-1)^t t^d = 0, \qquad d = 0, 1, \ldots, 2m-1.$$

By linearity of expectation, this completes the proof. □

O'Donnell and Servedio used Proposition 4.2 to obtain an explicit distribution over $\{0, 1, \ldots, 2m\}$ under which every low-degree symmetric polynomial has zero correlation with MP_m. However, what we seek is an explicit distribution over $\{-1, 1\}^{4m^3}$. To this end, we take the argument of O'Donnell and Servedio a step further. The technical exposition follows.

For $t = 0, 1, \ldots, 2m$, define

$$X_t = \left\{ x : \sum_{j=1}^{4m^2} \frac{1 - x_{i,j}}{2} = 4m^2 - (t - (2i-1))^2 \quad \text{for } i = 1, 2, \ldots, m \right\}. \tag{4.1}$$

Thus, $X_0, X_1, \ldots, X_{2m}$ are disjoint sets of inputs. The same sets of inputs figure in previous analyses [26, 29]. It is easy to verify that for $t = 0, 1, \ldots, 2m$,

$$x \in X_t \qquad \Longrightarrow \qquad \mathrm{MP}_m(x) = (-1)^t. \tag{4.2}$$

Let ν be the distribution from Proposition 4.2. We will work with the following distribution μ over $\{-1, 1\}^{4m^3}$:

$$\mu(x) = \begin{cases} \nu(0)/|X_0| & \text{if } x \in X_0, \\ \nu(1)/|X_1| & \text{if } x \in X_1, \\ \quad \vdots & \\ \nu(2m)/|X_{2m}| & \text{if } x \in X_{2m}, \\ 0 & \text{otherwise.} \end{cases} \tag{4.3}$$

We are now in a position to prove the main result of this section.

THEOREM 4.3 (explicit distribution for MP_m). *Let μ be given by* (4.3). *Then*

$$\mathop{\mathbf{E}}_{\mu}[\mathrm{MP}_m \cdot \chi_S] = 0, \qquad |S| = 0, 1, \ldots, m-1.$$

Proof. Let χ_S be arbitrary with $|S| \leqslant m-1$. Call the variables $x_{i,1}, x_{i,2}, \ldots, x_{i,4m^2}$ the *ith block* of x. Let $\sigma_1, \sigma_2, \ldots, \sigma_m$ be fixed permutations for blocks $1, 2, \ldots, m$, respectively. The theorem follows immediately from the following two claims.

CLAIM 4.4. $\mathbf{E}_\mu[\mathrm{MP}_m \cdot (\chi_S \circ (\sigma_1, \ldots, \sigma_m))] = \mathbf{E}_\mu[\mathrm{MP}_m \cdot \chi_S]$ *for all* $\sigma_1, \ldots, \sigma_m$.

CLAIM 4.5. $\sum_{\sigma_1, \ldots, \sigma_m} \mathbf{E}_\mu[\mathrm{MP}_m \cdot (\chi_S \circ (\sigma_1, \ldots, \sigma_m))] = 0$.

We prove these claims below. This completes the proof of the theorem. □

Proof of Claim 4.4. The functions $\mathrm{MP}_m(x)$ and $\mu(x)$ depend only on the sum of the bits in each block. Formally, $\mathrm{MP}_m \equiv \mathrm{MP}_m \circ (\sigma_1, \ldots, \sigma_m)$ and $\mu \equiv \mu \circ (\sigma_1, \ldots, \sigma_m)$. The claim follows. □

Proof of Claim 4.5. Write $\chi_S = \chi_{S_1} \chi_{S_2} \cdots \chi_{S_m}$, where

$$S_i = S \cap \{(i,1), \ldots, (i, 4m^2)\}, \qquad i = 1, 2, \ldots, m.$$

Then,

$$\begin{aligned}\sum_{\sigma_1,\ldots,\sigma_m} \mathop{\mathbf{E}}_{\mu}[\mathrm{MP}_m \cdot (\chi_S \circ (\sigma_1,\ldots,\sigma_m))] &= \sum_{\sigma_1,\ldots,\sigma_m} \mathop{\mathbf{E}}_{\mu}\left[\mathrm{MP}_m \cdot \prod_{i=1}^{m}(\chi_{S_i}\circ\sigma_i)\right] \\ &= \mathop{\mathbf{E}}_{\mu}\left[\mathrm{MP}_m \cdot \prod_{i=1}^{m}\left(\sum_{\sigma_i}\chi_{S_i}\circ\sigma_i\right)\right] \\ &= \mathop{\mathbf{E}}_{\mu}\left[\mathrm{MP}_m \cdot \prod_{i=1}^{m} p_i(x_{i,1}+x_{i,2}+\cdots+x_{i,4m^2})\right],\end{aligned}$$

where $p_1, p_2, \ldots, p_m$ are polynomials of degree at most $|S_1|, |S_2|, \ldots, |S_m|$, respectively. We now use the definition of μ as follows to simplify the last equation:

$$\begin{aligned}&\mathop{\mathbf{E}}_{\mu}\left[\mathrm{MP}_m \cdot \prod_{i=1}^{m} p_i(x_{i,1}+x_{i,2}+\cdots+x_{i,4m^2})\right] \\ &\quad= \sum_{x}\mu(x)\mathrm{MP}_m(x)\prod_{i=1}^{m} p_i(x_{i,1}+x_{i,2}+\cdots+x_{i,4m^2}) \\ &\quad= \sum_{t=0}^{2m}\sum_{x\in X_t}\frac{\nu(t)}{|X_t|}\mathrm{MP}_m(x)\prod_{i=1}^{m} p_i(x_{i,1}+x_{i,2}+\cdots+x_{i,4m^2}) \\ &\quad= \sum_{t=0}^{2m}\sum_{x\in X_t}\frac{\nu(t)}{|X_t|}(-1)^t \underbrace{\prod_{i=1}^{m} p_i(2[t-(2i-1)]^2-4m^2)}_{\text{call this } p(t)} \qquad \text{by (4.1), (4.2)} \\ &\quad= \sum_{t=0}^{2m}\nu(t)(-1)^t p(t) \\ &\quad= 0,\end{aligned}$$

where the last equality follows by Proposition 4.2 since $p(t)$ has degree at most $2\sum_i |S_i| = 2|S| \leqslant 2m-2$. □

5. Discrepancy of AC^0 circuits. This section proves an exponentially small upper bound on the discrepancy of an explicit function in AC^0.

THEOREM 1.3 (rephrased from section 1.2). *There exists a function $f : \{-1,1\}^N \times \{-1,1\}^N \to \{-1,1\}$, explicitly given and computable by an AC^0 circuit of depth 3, that has discrepancy $\exp(-\Omega(N^{1/5}))$ with respect to an explicitly given distribution.*

Proof. Consider the function MP_m on $n = 4m^3$ variables. Theorem 4.1 states that $\deg_{\pm}(\mathrm{MP}_m) = m$. Put $N = \lceil 16en^2/m\rceil = \lceil 256em^5\rceil$ and define the matrix $M = [\mathrm{MP}_m(x|_S)]_{x,S}$, where $x \in \{-1,1\}^N$ and $S \in \binom{[N]}{n}$. By Theorem 1.2,

$$\mathrm{disc}_\lambda(M) \leqslant 2^{-m} = \mathrm{e}^{-\Theta(N^{1/5})}$$

for a certain distribution λ. By Remark 3.3 and Theorem 4.3, the distribution λ is given explicitly in terms of (4.3).

Represent a set $S \subset [N]$ with elements $i_1 < i_2 < \cdots < i_n$ by the Boolean string $(y^{(1)}, y^{(2)}, \ldots, y^{(n)}) \in (\{-1,1\}^{\log N})^n$, where $y^{(k)}$ is the binary encoding of the integer i_k. We define $F : \{-1,1\}^N \times (\{-1,1\}^{\log N})^n \to \{-1,1\}$ by

$$F(x, y^{(1)}, y^{(2)}, \ldots, y^{(n)}) = \mathrm{MP}_m(x|_S),$$

where S is the set corresponding to $y^{(1)}, y^{(2)}, \ldots, y^{(n)}$. In the event that the strings $y^{(1)}, y^{(2)}, \ldots, y^{(n)}$ do not specify a legal set S (e.g., they are not all distinct or ordered), the value of F is irrelevant. By construction,

$$\operatorname{disc}_\lambda(F) = \operatorname{disc}_\lambda(M) \leqslant \mathrm{e}^{-\Theta(N^{1/5})}.$$

It remains to show that F is computable by an AC^0 circuit of depth 3. For this, observe that

$$F(x, y) = \mathrm{MP}_m(\phi(x, y^{(1)}), \ldots, \phi(x, y^{(n)})),$$

where $\phi(x, y^{(i)})$ computes $x_{\mathrm{decimal}(y^{(i)})}$, i.e., computes x_a with a being the decimal integer whose binary representation is $y^{(i)}$. Each $\phi(x, y^{(i)})$ is clearly computable by a CNF formula of size $O(N)$. Hence, F is computable by an AC^0 circuit of depth 3 (by collapsing the two middle layers of AND gates). □

Remark 5.1. The function F in Theorem 1.3 can be viewed as a communication problem in which Alice is given an input $x \in \{-1, 1\}^N$, Bob is given a polynomial-size DNF formula $f : \{-1, 1\}^N \to \{-1, 1\}$ (from a restricted set), and their objective is to evaluate $f(x)$. The proof of Theorem 1.3 shows that the communication matrix of this problem has discrepancy $\exp(-\Omega(N^{1/5}))$. We will revisit this observation in section 8.

Theorem 1.3 exhibits an AC^0 circuit of depth 3 with exponentially small discrepancy. At the same time, the discrepancy of every AC^0 circuit of depth 2 is at least $n^{-O(1)}$. To our knowledge, this fact has not been noted in the literature, and we present its proof below.

PROPOSITION 5.2. *Let $f : \{-1, 1\}^n \times \{-1, 1\}^n \to \{-1, 1\}$ be an AC^0 circuit of depth 1 or 2. Then $\operatorname{disc}_\mu(f) \geqslant n^{-O(1)}$ for every distribution μ.*

Proof. By assumption, f is a polynomial-size DNF or CNF formula. Without loss of generality, assume the former, i.e., $f = T_1 \vee T_2 \vee \cdots \vee T_s$, where $s = n^{O(1)}$ and each of $T_1, T_2, \ldots, T_s$ is a conjunction of literals. Observe that

$$f = \textsc{majority}(T_1, \ldots, T_s, T_{s+1}, \ldots, T_{2s-1}),$$

where we define $T_{s+1} = T_{s+2} = \cdots = T_{2s-1} = -1$ (identically true). Consider the public-coin randomized protocol in which the parties pick $i \in \{1, 2, \ldots, 2s-1\}$ uniformly at random, evaluate T_i using constant communication, and output the result. This protocol evaluates f correctly with probability at least $\frac{1}{2} + \Omega\left(\frac{1}{s}\right)$. Thus,

$$\mathrm{R}^{\mathrm{pub}}_{1/2-\Omega(1/s)}(f) = O(1).$$

Proposition 2.1 now implies that $\operatorname{disc}_\mu(f) \geqslant \Omega(1/s) \geqslant n^{-O(1)}$ for all μ. □

6. Discrepancy and the polynomial hierarchy. In this section, we will briefly digress from the main development and explore the consequences of Theorem 1.3 in the study of communication complexity classes $\mathsf{PP}^{cc}, \Sigma_2^{cc}, \Pi_2^{cc}$.

Throughout this section, the symbol $\{f_n\}$ shall stand for a family of functions $f_1, f_2, \ldots, f_n, \ldots$, where $f_n : \{-1, 1\}^n \times \{-1, 1\}^n \to \{-1, 1\}$.

Babai, Frankl, and Simon [3] originally defined the class PP^{cc} as the class of communication problems that have an efficient protocol with nonnegligible bias. For our purposes, it will be more convenient to use an equivalent characterization of PP^{cc} in terms of discrepancy, obtained by Klauck [16].

THEOREM 6.1 (Klauck [16]). *A family* $\{f_n\}$ *is in* PP^{cc} *if and only if for some constant* $c > 1$ *and all* n,

$$\operatorname{disc}(f_n) > 2^{-\log^c n}.$$

We now define classes Σ_2^{cc} and Π_2^{cc}, which represent the second level of the polynomial hierarchy in communication complexity. A function $f_n : \{-1,1\}^n \times \{-1,1\}^n \to \{-1,1\}$ is called a *rectangle* if there exist subsets $A, B \subseteq \{-1,1\}^n$ such that

$$f_n(x,y) = -1 \quad \Leftrightarrow \quad x \in A,\ y \in B.$$

We call f_n the *complement of a rectangle* if the negated function $\neg f_n = -f_n$ is a rectangle.

DEFINITION 6.2 (Babai, Frankl, and Simon [3, sect. 4]).

(1) *A family* $\{f_n\}$ *is in* Π_0^{cc} *if each* f_n *is a rectangle. A family* $\{f_n\}$ *is in* Σ_0^{cc} *if* $\{\neg f_n\}$ *is in* Π_0^{cc}.

(2) *Fix an integer* $k = 1, 2, \ldots$. *A family* $\{f_n\}$ *is in* Σ_k^{cc} *if for some constant* $c > 1$ *and all* n,

$$f_n = \bigvee_{i_1=1}^{2^{\log^c n}} \bigwedge_{i_2=1}^{2^{\log^c n}} \bigvee_{i_3=1}^{2^{\log^c n}} \cdots \bigodot_{i_k=1}^{2^{\log^c n}} g_n^{i_1,i_2,\ldots,i_k},$$

where $\bigodot = \bigvee$ *(resp.,* $\bigodot = \bigwedge$*) for* k *odd (resp., even), and each* $g_n^{i_1,i_2,\ldots,i_k}$ *is a rectangle (resp., the complement of a rectangle) for* k *odd (resp., even). A family* $\{f_n\}$ *is in* Π_k^{cc} *if* $\{\neg f_n\}$ *is in* Σ_k^{cc}.

(3) *The polynomial hierarchy is given by* $\mathsf{PH}^{cc} = \bigcup_k \Sigma_k^{cc} = \bigcup_k \Pi_k^{cc}$, *where* $k = 0, 1, 2, 3, \ldots$ *ranges over all constants.*

Thus, the zeroth level (Σ_0^{cc} and Π_0^{cc}) of the polynomial hierarchy consists of rectangles and complements of rectangles, the simplest functions in communication complexity. The first level is easily seen to correspond to functions with efficient nondeterministic or co-nondeterministic protocols: $\Sigma_1^{cc} = \mathsf{NP}^{cc}$ and $\Pi_1^{cc} = \mathsf{coNP}^{cc}$.

The circuit class AC^0 is related to the polynomial hierarchy PH^{cc} in communication complexity in the obvious way. Specifically, if $f_n : \{-1,1\}^n \times \{-1,1\}^n \to \{-1,1\}$, $n = 1, 2, 3, 4, \ldots$, is an AC^0 circuit family of depth k with an OR gate at the top (resp., AND gate), then $\{f_n\} \in \Sigma_{k-1}^{cc}$ (resp., $\{f_n\} \in \Pi_{k-1}^{cc}$). In particular, the depth-3 circuit family $\{f_n\}$ in Theorem 1.3 is in Σ_2^{cc}, whereas $\{\neg f_n\}$ is in Π_2^{cc}. In this light, Theorems 1.3 and 6.1 have the following corollary.

COROLLARY 1.4 (restated from section 1.2). $\Sigma_2^{cc} \not\subseteq \mathsf{PP}^{cc}$, $\Pi_2^{cc} \not\subseteq \mathsf{PP}^{cc}$.

Observe that the separations in Corollary 1.4 are achieved for explicit functions, constructed in Theorem 1.3. Corollary 1.4 is tight in that PP^{cc} trivially contains $\Sigma_0^{cc}, \Sigma_1^{cc}, \Pi_0^{cc}, \Pi_1^{cc}$.

7. Lower bounds for majority-of-threshold circuits. At last, we are in a position to prove the main result of this paper. We will follow an established argument, due to Nisan [27], that relates discrepancy to the size of majority-of-threshold circuits. The key piece of the argument is the following statement.

THEOREM 7.1 (Nisan [27]). *Let* $f : \{-1,1\}^n \to \{-1,1\}$ *be a linear threshold function. Then* $\mathrm{R}_\epsilon^{\mathrm{pub}}(f) = O(\log n + \log \frac{1}{\epsilon})$ *for any partition of the variables and any* $\epsilon = \epsilon(n)$.

We have the following theorem.

THEOREM 1.1 (rephrased from section 1). *There exists a function* $f : \{-1,1\}^N \times \{-1,1\}^N \to \{-1,1\}$*, explicitly given and computable by an* AC^0 *circuit of depth* 3*, whose computation requires a majority vote of* $\exp(\Omega(N^{1/5}))$ *linear threshold gates.*

Proof. Nisan [27, Thm. 4] proved an analogous statement for the function INNER PRODUCT MODULO 2, and we merely adapt his argument to our setting. Let F be the function in the statement of Theorem 1.3, with $\operatorname{disc}(F) = \exp(-\Omega(N^{1/5}))$. Proposition 2.1 implies that for any $\gamma > 0$,

$$\mathrm{R}^{\mathrm{pub}}_{1/2-\gamma/2}(F) = \Omega(N^{1/5}) - \log\frac{1}{\gamma}. \tag{7.1}$$

On the other hand, suppose that $F = \textsc{majority}(h_1, h_2, \ldots, h_s)$, where each h_i is a linear threshold function. Then the parties can randomly pick $i \in \{1,2,\ldots,s\}$, evaluate h_i correctly with probability $1 - 1/(4s)$ using Theorem 7.1, and output the result. This protocol would have communication cost $O(\log N + \log s)$ and would predict F correctly with probability at least $(\frac{1}{2} + \frac{1}{2s}) - \frac{1}{4s} = \frac{1}{2} + \frac{1}{4s}$ on every input. Thus,

$$\mathrm{R}^{\mathrm{pub}}_{1/2-1/4s}(F) = O(\log N + \log s). \tag{7.2}$$

Comparing (7.1) and (7.2), we see that $s = \exp(\Omega(N^{1/5}))$. □

8. An application to learning DNF formulas. We conclude with an application of our results to computational learning theory. Let $\mathcal{C}$ be an arbitrary set of Boolean functions $\{-1,1\}^n \to \{-1,1\}$. Suppose it is possible to fix polynomial-time computable Boolean functions $h_1, \ldots, h_d : \{-1,1\}^n \to \{-1,1\}$ such that every function $f \in \mathcal{C}$ can be represented as

$$f(x) \equiv \operatorname{sign}\left(\sum_{i=1}^{d} a_i h_i(x)\right)$$

for some integers $a_1, \ldots, a_d$ with $|a_1| + \cdots + |a_d| \leqslant W$. The obvious complexity measures of this representation are d and W. If d and W are polynomial in n, simple and efficient algorithms exist for learning $\mathcal{C}$ from random examples under every distribution, e.g., the classic perceptron algorithm [26, 28]. Such classes $\mathcal{C}$ admit learning with *large margin* and therefore possess a variety of desirable characteristics [18].

Given $\mathcal{C}$, it is thus natural to ask whether it is possible to choose $h_1, \ldots, h_d$ such that $d = \mathsf{poly}(n)$ and $W = \mathsf{poly}(n)$. The question is particularly intriguing for polynomial-size DNF and CNF formulas, a concept class that has eluded every attempt at an efficient, distribution-free learning algorithm. Our machinery yields a strong negative answer to this question. We restrict our attention to DNF formulas, as the CNF case is closely analogous.

THEOREM 8.1. *Let* $\mathcal{C}$ *denote the concept class of polynomial-size DNF formulas. Let* $h_1, \ldots, h_d : \{-1,1\}^n \to \{-1,1\}$ *be arbitrary Boolean functions such that every* $f \in \mathcal{C}$ *can be expressed as* $f(x) \equiv \operatorname{sign}(\sum_{i=1}^{d} a_i h_i(x))$ *for some integers* $a_1, \ldots, a_d$ *with* $|a_1| + \cdots + |a_d| \leqslant W$*. Then*

$$dW \geqslant \mathrm{e}^{\Omega(n^{1/5})}.$$

Proof. Consider the communication problem F in which Alice is given an input $x \in \{-1,1\}^n$, Bob is given a function $f \in \mathcal{C}$, and their objective is to compute $f(x)$.

By Remark 5.1, the communication matrix of this problem has discrepancy

$$\operatorname{disc}(F) \leqslant \mathrm{e}^{-\Omega(n^{1/5})}.$$

We will construct a cost-2 public-coin randomized protocol for the problem, with advantage $1/(dW)$ on every input. Proposition 2.1 will then imply that

$$\frac{1}{dW} \leqslant 4 \operatorname{disc}(F),$$

and the proof will be complete.

The idea behind the protocol is not original; see [13, 14, 25, 31] for similar work. First, the parties pick an index $i \in \{1, \ldots, d\}$ uniformly at random. Then Alice sends $h_i(x)$ to Bob. Bob retrieves the representation of f as $f(x) \equiv \operatorname{sign}(\sum_{i=1}^{d} a_i h_i(x))$ for some integers $a_1, \ldots, a_d$. With probability $\frac{1}{2} + \frac{1}{2} \cdot \frac{|a_i|}{|a_1|+\cdots+|a_d|}$, Bob announces $h_i(x) \cdot \operatorname{sign}(a_i)$ as the output. With the remaining probability, he announces $-h_i(x) \cdot \operatorname{sign}(a_i)$. Thus, Bob's expected output is $\frac{a_i h_i(x)}{|a_1|+\cdots+|a_d|}$. As a result, the protocol achieves the following desired advantage:

$$f(x) \cdot \sum_{i=1}^{d} \frac{1}{d} \cdot \frac{a_i h_i(x)}{|a_1| + \cdots + |a_d|} = \frac{1}{d} \cdot \frac{|a_1 h_1(x) + \cdots + a_d h_d(x)|}{|a_1| + \cdots + |a_d|} \geqslant \frac{1}{dW}. \qquad \square$$

Remark 8.2. Using subtle techniques, Razborov and Sherstov [36] have recently proved the following substantially stronger result. Let $h_1, \ldots, h_d : \{-1, 1\}^n \to \mathbb{R}$ be arbitrary real functions such that every DNF formula f of linear size is representable as $f(x) \equiv \operatorname{sign}(\sum_{i=1}^{d} a_i h_i(x))$ for some reals $a_1, \ldots, a_d$. Then $d \geqslant \exp(\Omega(n^{1/3}))$. This lower bound on d is essentially optimal [17] and rules out the possibility of PAC learning DNF formulas in the important *dimension complexity* framework; see [36] for details.

Acknowledgments. I would like to thank Anna Gál, Adam Klivans, and Sasha Razborov for helpful discussions and feedback on an earlier version of this manuscript. I am thankful to Adam Klivans for pointing me to the problem of separating AC^0 from depth-2 majority circuits.

INTERPOLATION OF DEPTH-3 ARITHMETIC CIRCUITS WITH TWO MULTIPLICATION GATES*

AMIR SHPILKA†

Abstract. In this paper we consider the problem of constructing a small arithmetic circuit for a polynomial for which we have oracle access. Our focus is on n-variate polynomials, over a finite field $\mathbb{F}$, that have depth-3 arithmetic circuits (with an addition gate at the top) with two multiplication gates of degree at most d. We obtain the following results: 1. *Multilinear case.* When the circuit is multilinear (multiplication gates compute multilinear polynomials) we give an algorithm that outputs, with probability $1-o(1)$, *all* the depth-3 circuits with two multiplication gates computing the polynomial. The running time of the algorithm is $\mathrm{poly}(n,|\mathbb{F}|)$. 2. *General case.* When the circuit is not multilinear we give a quasi-polynomial (in $n,d,|\mathbb{F}|$) time algorithm that outputs, with probability $1-o(1)$, a succinct representation of the polynomial. In particular, if the depth-3 circuit for the polynomial is not of small *depth*-3 *rank* (namely, after removing the g.c.d. (greatest common divisor) of the two multiplication gates, the remaining linear functions span a not too small linear space), then we output the depth-3 circuit itself. In the case that the rank is small we output a depth-3 circuit with a quasi-polynomial number of multiplication gates. ⋄ Prior to our work there have been several interpolation algorithms for restricted models. However, all the techniques used there completely fail when dealing with depth-3 circuits with even just two multiplication gates. Our proof technique is new and relies on the factorization algorithm for multivariate black-box polynomials, on lower bounds on the length of linear locally decodable codes with two queries, and on a theorem regarding the structure of identically zero depth-3 circuits with four multiplication gates.

Key words. arithmetic circuits, exact learning, interpolation, reconstruction, depth-3

1. Introduction.

In this work we consider the problem of constructing a small arithmetic circuit for a polynomial for which we have oracle access. That is, there is a black box holding a polynomial f, and we would like to find a small arithmetic circuit that computes f. We are allowed to pick inputs (adaptively) and query the black box for the value of f on those inputs. The focus of this work is on n-variate polynomials that have small depth-3 arithmetic circuits[1] over some finite field $\mathbb{F}$. We consider the *simplest* such circuits, that is, those with only two multiplication gates (also known as $\Sigma\Pi\Sigma(2)$ circuits). We obtain the following results. Let f be a polynomial, for which we have oracle access, that is computed by a $\Sigma\Pi\Sigma(2)$ circuit. When f is computed by a *multilinear* $\Sigma\Pi\Sigma(2)$ circuit we give a polynomial time algorithm that outputs, with high probability, *all* the multilinear $\Sigma\Pi\Sigma(2)$ circuits that compute f. When f does not have a multilinear $\Sigma\Pi\Sigma(2)$ circuit, we output in quasi-polynomial time, with high probability (w.h.p.), a short description for f (depending on a technical condition, we output either a $\Sigma\Pi\Sigma(2)$ circuit for it or a depth-3 circuit of quasi-polynomial size).

[1]In this work, whenever we say *depth*-3 *circuit* we mean a circuit with an addition gate at the top—the reason being that, by factoring the circuit and then applying known interpolation algorithms for depth-2 circuits, it is easy to reconstruct depth-3 circuits that have a multiplication gate at the top.

The problem of reconstructing a small arithmetic circuit for a polynomial using queries is a basic problem in algebraic complexity and is closely related to problems in learning theory. We now give some background that explains why studying depth-3 circuits is the next natural step given our current state of knowledge.

1.1. Computational learning theory. This paper considers the task of exact learning of algebraic functions. The analogous problem for Boolean functions is well studied, and we first summarize the state of knowledge there. The question of whether we can compute a small description for a Boolean function, for which we have oracle access, is a fundamental problem in learning theory. The problem, also known as the exact learning problem using membership queries, attracted a lot of research, and both positive and negative results were proved. On the negative side it was shown that if a class of Boolean circuits $\mathcal{C}$ contains *trapdoor functions* or *pseudorandom functions*, then there are no efficient learning algorithms for it [OGM86, KV94, Kha95]. In particular, there are no efficient interpolation algorithms for the class TC^0_4 (the class of depth-4 threshold circuits), under a widely believed cryptographic assumption [KL01, NR04]. Moreover, in [RR97] it was proved that if we consider a class of circuits $\mathcal{C}$ that can compute pseudorandom functions efficiently, then it is hard to determine, in exponential time, whether a function given by its truth table can be computed efficiently by a circuit from $\mathcal{C}$. In other words, even if the algorithm is given the whole truth table as input, it cannot determine whether f has a polynomial size circuit in $\mathcal{C}$ or not, in exponential time (i.e., in time polynomial in the size of the truth table).

On the positive side, there are many works showing that in some restricted models of computation, e.g., when f has a small circuit from a restricted class of circuits, exact learning from membership queries is possible (see, e.g., [SS96, BBV96, BBTV97, BBB$^+$00]). However, no exact learning algorithms are known for the class of bounded depth Boolean circuits. Moreover, even if we allow the algorithm to run in exponential time and have access to the truth table of the function, it is still not known how to compute a small bounded depth circuit for it.

To conclude, exact learning is known only for very restricted classes of circuits, and we cannot hope to learn the class of depth-4 threshold circuits if certain cryptographic assumptions hold.

1.2. Interpolation of arithmetic circuits. As mentioned above, we consider the algebraic analogue of the exact learning problem. Let $\mathcal{A}$ be a class of arithmetic circuits over a field $\mathbb{F}$. We are given oracle access to a polynomial $f(x_1, \ldots, x_n) \in \mathbb{F}[x_1, \ldots, x_n]$ that can be computed by an arithmetic circuit from $\mathcal{A}$. We are allowed to ask for the value of the polynomial at points of our choice, and we would like to output a succinct representation for it.[2] Ideally we would like to output an arithmetic circuit from $\mathcal{A}$ that computes the polynomial. This problem is also known as the polynomial interpolation problem.

Unlike the exact learning scenario, there are almost no results that show the impossibility of interpolating arithmetic circuits. To the best of our knowledge, the only hardness result was obtained by Fortnow and Klivans [FK06], who proved that polynomial time interpolation of arithmetic circuits implies a lower bound for the class $\mathrm{ZPEXP}^{\mathrm{RP}}$. A probable explanation for the lack of stronger hardness results is that no reasonable notion of *pseudorandom polynomials* is known in the algebraic domain. However, it is widely believed that, analogously to the exact learning case, it is impossible to efficiently interpolate arithmetic circuits of a certain constant depth. The

[2] In the case of finite fields we may ask for the value over an algebraic extension field of $\mathbb{F}$.

reason for this belief is that depth-3 arithmetic circuits can compute the arithmetic analogue of threshold functions (see, e.g., [SW01]), and as efficient exact learning of TC^0_4 is believed to be impossible, we also expect efficient interpolation of bounded depth arithmetic circuits to be impossible. It is natural to ask then, what is the maximal depth for which efficient interpolation is possible.

Similarly to the exact learning version, a lot of effort was invested in trying to interpolate restricted classes of arithmetic circuits. In particular, the class of depth-2 arithmetic circuits[3] received a great deal of attention, and several interpolation algorithms were devised for it [BOT88, GKS94, KS96, Man95, SS96, KS01]. Many works also focused on circuits that can be represented by small *multiplicity automata* [BBV96, BBTV97, BBB+00, KS06] and on the class of read-once arithmetic formulae [HH91, BHH95, BC98, BB98, SV08]. One unifying feature of all these classes is that they all compute polynomials whose partial derivatives span a low dimensional space (see, e.g., [KS06], where depth-3 circuits of a very special form are discussed). In contrast, it is easy to give an example of a multilinear $\Sigma\Pi\Sigma(2)$ circuit that computes a polynomial whose partial derivatives span a high dimensional space. Thus, known techniques cannot give efficient algorithms for interpolating polynomials computed by multilinear $\Sigma\Pi\Sigma(2)$ circuits. This highlights the gap in our understanding of depth-2 circuits and depth-3 circuits (even those with only two multiplication gates).

Thus, current techniques are incapable of interpolating depth-3 circuits, even those with two multiplication gates, and it is believed that above some constant depth efficient interpolation is impossible.

In this work we introduce new techniques that enable us to give interpolation algorithms to the class of depth-3 circuits with two multiplication gates. Before presenting our results we need to give several definitions.

1.3. Some definitions and statement of our results. Let f be a polynomial computed by a $\Sigma\Pi\Sigma(2)$ circuit. Then f has the following form:

$$f(\bar{x}) = \prod_{i=1}^{d_1} L_i^{(1)}(\bar{x}) + \prod_{i=1}^{d_2} L_i^{(2)}(\bar{x}), \tag{1}$$

where the $L_i^{(j)}$'s are linear functions in the variables $\bar{x} = (x_1, \ldots, x_n)$, over the field $\mathbb{F}$:

$$L_i^{(j)}(\bar{x}) = \sum_{k=1}^{n} \alpha_{i,j,k} x_k + \alpha_{i,j,0}$$

for $\alpha_{i,j,k} \in \mathbb{F}$. Let M_1 and M_2 be the multiplication gates of the circuit. That is,

$$M_1 = \prod_{i=1}^{d_1} L_i^{(1)}(\bar{x}) \text{ and } M_2 = \prod_{i=1}^{d_2} L_i^{(2)}(\bar{x}).$$

For a $\Sigma\Pi\Sigma(2)$ circuit C we denote by $\deg(C)$ the maximal degree of its multiplication gates. For example, if C is given by (1), then $\deg(C) = \max(d_1, d_2)$. Our first result deals with the case of multilinear $\Sigma\Pi\Sigma(2)$ circuits. A multilinear circuit is a circuit in which every multiplication gate computes a multilinear polynomial. In particular, the degree of a multilinear circuit is bounded by n.

[3]Polynomials computed by small depth-2 circuits are also known as sparse polynomials, i.e., polynomials with a small number of monomials.

THEOREM 1. *Let f be a multilinear polynomial in n variables that is computed by a degree d multilinear $\Sigma\Pi\Sigma(2)$ circuit, over a field $\mathbb{F}$. Then there is a randomized interpolation algorithm that, given black-box access to f and the parameters d and n, runs in* $\mathrm{poly}(n, |\mathbb{F}|)$*-time and with probability* $1 - o(1)$ *outputs* all *the $\Sigma\Pi\Sigma(2)$ circuits computing f. When $|\mathbb{F}| < n^5$ the algorithm is allowed to make queries to f from a polynomial size algebraic extension field of $\mathbb{F}$.*

Notice that we output all the multilinear $\Sigma\Pi\Sigma(2)$ circuits computing f. While this was not our purpose when first studying the problem, it is a nice consequence of our techniques (and in particular implies that there are only polynomially many such circuits).

In order to state our main theorem we need some more definitions. Let $\mathcal{C}$ be as in (1). Define

$$\gcd(C) \stackrel{\triangle}{=} \text{g.c.d.}(M_1, M_2)$$

as the greatest common divisor of the multiplication gates. It is clear that we can write $\gcd(C) = \prod_{i=1}^{k} L_i(\bar{x})$ for some set of linear functions. Following the notations of [DS06] we define the simplification of C, $\mathrm{sim}(C)$, to be the circuit

$$\mathrm{sim}(C) \stackrel{\triangle}{=} C/\gcd(C).$$

From the definition of $\mathrm{sim}(C)$ it is clear that there exists a subset[4] $I_1 \subseteq [d_1]$ and a subset $I_2 \subseteq [d_2]$, such that $|I_1| = d_1 - k$, $|I_2| = d_2 - k$, and

$$\mathrm{sim}(C) = \prod_{i \in I_1} L_i^{(1)}(\bar{x}) + \prod_{i \in I_2} L_i^{(2)}(\bar{x}). \tag{2}$$

We shall also need the notions of the rank of a $\Sigma\Pi\Sigma(2)$ circuit, which we denote by $\mathrm{rank}(C)$, and of *depth-3 rank* of f, which we denote by $\mathrm{rank}(f)$. Given a $\Sigma\Pi\Sigma(2)$ arithmetic circuit C, let $\mathrm{sim}(C), I_1$, and I_2 be as in (2). We define

$$\mathrm{rank}(C) \stackrel{\triangle}{=} \dim\left(\mathrm{span}\left\{L_i^{(1)}, L_j^{(2)} \ : \ i \in I_1,\ j \in I_2\right\}\right).$$

In other words, the rank of C is defined to be the dimension of the space spanned by the linear functions in $\mathrm{sim}(C)$. Let $\mathrm{rank}_d(f)$ be the minimum, over all $\Sigma\Pi\Sigma(2)$ circuits C of degree $\leq d$ that compute f, of $\mathrm{rank}(C)$. The motivation for the definition will become clearer in the analysis of our algorithm. When the degree d is clear from the context, we drop the subscript d and simply write $\mathrm{rank}(f)$ instead of $\mathrm{rank}_d(f)$.

We can now state our second result that deals with general $\Sigma\Pi\Sigma(2)$ circuits.

THEOREM 2. *Let f be an n-variate polynomial computed by a $\Sigma\Pi\Sigma(2)$ circuit of degree d, over a field $\mathbb{F}$. Then there is a randomized interpolation algorithm that, given black-box access to f and the parameters d and n, runs in quasi-polynomial time (in n, d, $|\mathbb{F}|$) and has the following properties:*

- *If* $\mathrm{rank}(f) = \Omega\left(\log^2(d)\right)$*, then with probability* $1 - o(1)$ *the algorithm outputs the (unique) $\Sigma\Pi\Sigma(2)$ circuit for f.*
- *If* $\mathrm{rank}(f) = O\left(\log^2(d)\right)$*, then the algorithm outputs, with probability* $1 - o(1)$*, a polynomial* $\mathrm{Lin}(f)$*, a polynomial $Q(y_1, \ldots, y_k)$, and k linear functions $L_1, \ldots, L_k$, where $k \leq \mathrm{rank}(f)$, such that* $\mathrm{Lin}(f)$ *is the product of all the linear factors of f and* $\mathrm{Lin}(f) \cdot Q(L_1, \ldots, L_k) = f$.

[4] As usual, $[k]$ stands for the set $\{1, \ldots, k\}$.

When $|\mathbb{F}| < \max(d^5, n^5)$, the algorithm is allowed to make queries to f from a polynomial size extension field of $\mathbb{F}$.

We note that in the case when $\mathrm{rank}(f) = O\left(\log^2(d)\right)$, the polynomial $Q(L_1, \ldots, L_k)$ can be easily represented as a $\Sigma\Pi\Sigma$ circuit with quasi-polynomially many multiplication gates (as Q has at most a quasi-polynomial number of monomials).

1.4. Our techniques. Our algorithms are based on the following scheme. We first restrict the inputs to the unknown polynomial to a low dimensional random subspace of $\mathbb{F}^n$ (although in the multilinear case the subspace is not completely random, the intuition is the same). We then interpolate the polynomial on this subspace. The next step is to lift the representation that we found to the whole space. While this is the general scheme, it has different realizations in the multilinear case and the general case, and even within each case we have to deal differently with the case of high rank and the case of low rank. However, similar problems lie at the core of the different cases. The following questions give a good intuition to the difficulties that the algorithm has to overcome:

1. Let $V_1, \ldots, V_k$ be subspaces of codimension 1 inside a linear space V. Given circuits $C_1, \ldots, C_k$ such that C_i computes $f|_{V_i}$ (the restriction of f to V_i), how can we construct from them a single circuit C for $f|_V$?
2. Given linear spaces $V \subseteq U$ such that V is of codimension 1 in U, and a circuit C computing $f|_V$, how many circuits C' are there that compute $f|_U$, and whose restriction $C'|_V$ is equal to C?

The first question arises in the case of general $\Sigma\Pi\Sigma(2)$ circuits of high rank when we interpolate the restriction of f to a random subspace V. Our algorithm first interpolates the restrictions of one of the multiplication gates to codimensional 1 subspaces of V and then combines the different results to get a representation of that gate over V (then by using the factoring algorithms of [Kal85, KT90, Kal95] we are able to interpolate $f|_V$).

To deal with the problem, we consider linear functions in the different C_i's that look similar to each other, and we try to glue them together to get a new function. This process may fail if for any linear function in, say, C_1 there are many other linear functions in C_1 that are at Hamming distance 1 from it. In such a situation it is hard for us to tell what is the "true" image of that linear function in the other C_i's. On the other hand, if this is indeed the case, then the linear functions in C_1 generate a *locally decodable code* and, using the results of [GKST06, DS06] on the length of such codes, we can prove that such an anomaly cannot occur. Therefore we can always find a linear function to learn, until eventually we find the whole multiplication gate.

The motivation for the second question is that when we lift the representation that we found over V to U there may be many different circuits that are possible lifts, and we somehow have to pick the right one with which to continue the lifting process. To deal with this problem we note that if a polynomial has two different lifts, then the difference of the lifts is the zero polynomial. By a result of [DS06] regarding the structure of identically zero depth-3 circuits, we get that the different lifts must be of small rank. This enables us to solve the problem for the high rank case (as in this case the lift is unique). The low rank case is indeed more problematic, and this is why we need to output a circuit with quasi-polynomially many multiplication gates when f has low rank (although in the multilinear case, we manage to overcome this difficulty by proving that the total number of possible lifts is polynomial).

1.5. Recent progress. In a recent joint work with Karnin [KS08] we managed to extend this result to the case of $\Sigma\Pi\Sigma(k)$ circuits. Moreover, we managed to get a

deterministic reconstruction algorithm (the algorithms in this paper are all randomized). The ideas in the current paper serve as a basic building block to the ideas of [KS08]; however, some new ideas were required for the more general case.

1.6. Organization. The paper is organized as follows. In section 2 we give some definitions and describe the results of [DS06] regarding identically zero depth-3 circuits. The algorithm and proof for the multilinear case are given in section 3. In section 4 we give the algorithm (and proof) for the general case.

2. Preliminaries. For a natural number n we denote $[n] = \{1, \ldots, n\}$. For a set $S \subset [n]$ we denote by $\bar{S}$ the complement of S.

Let $\mathbb{F}$ be a field. We denote by $\mathbb{F}^n$ the n-dimensional vector space over $\mathbb{F}$. We shall use the notation $\bar{x} = (x_1, \ldots, x_n)$ to denote the vector of n indeterminates. For $v \in \mathbb{F}^n$ we denote by $\mathrm{wt}(v)$ the weight of v, i.e., the number of nonzero coordinates in v. For two nonzero linear functions L_1, L_2 we will write $L_1 \sim L_2$ whenever L_1 and L_2 are linearly dependent. Let $V = V_0 + v_0 \subseteq \mathbb{F}^n$ be an affine subspace, where $v_0 \in \mathbb{F}^n$, and where $V_0 \subseteq \mathbb{F}^n$ is a linear subspace. Let $L(\bar{x})$ be a linear function. We denote by $L|_V$ the restriction of L to V. We say that a set of linear functions $\{L_1, \ldots, L_k\}$ is linearly independent over V if the only linear combination of the L_i's whose restriction to V is identically zero is the all zero combination. We now introduce coordinates to the space V. Let $v_1, \ldots, v_s$ be a basis of V_0. Let $L(\bar{x})$ be a linear function. We consider the restriction of L to V with respect to the basis $\{v_i\}$. Then $L|_V$ can be written as a function in s variables. In particular if $v = \alpha_1 v_1 + \cdots + \alpha_s v_s + v_0$, then we define $L|_V(\alpha_1, \ldots, \alpha_s) = L(v) = L(\alpha_1 v_1 + \cdots + \alpha_s v_s) + L(v_0)$.

For a polynomial f we denote by $\mathrm{Lin}(f)$ the product of all the linear factors of f (with the appropriate multiplicities). We also define $\mathrm{sim}(f) = f/\mathrm{Lin}(f)$ to be the simplification of f. Clearly $\mathrm{sim}(f)$ does not have any linear factors.

2.1. Identically zero depth-3 circuits. In this section we state some results of [DS06] regarding identically zero depth-3 circuits. We start by giving some necessary definitions. A $\Sigma\Pi\Sigma(k)$ circuit (that is, a depth-3 circuit with k multiplication gates) is identically zero if it computes the zero polynomial. Notice that this is a syntactic definition; we are thinking of the circuit as computing a polynomial and not as computing a function over the field.[5] Let $C = M_1 + \cdots + M_k$ be an identically zero $\Sigma\Pi\Sigma(k)$ circuit, where the M_i's are the multiplication gates. We say that C is minimal if there is no $\emptyset \neq I \subsetneq [k]$ such that $\sum_{i \in I} M_i \equiv 0$. C is simple if the g.c.d. of its multiplication gates is 1. The following theorem gives a bound on the degree of multilinear $\Sigma\Pi\Sigma(k)$ circuits that are identically zero.

THEOREM 3 (Corollary 6.9 of [DS06]). *There exists an integer function $D(k) = 2^{O(k^2)}$ such that every simple, minimal, identically zero multilinear $\Sigma\Pi\Sigma(k)$ circuit is of degree $d \leq D(k)$.*

In other words, if C is an identically zero $\Sigma\Pi\Sigma(k)$ multilinear circuit that is simple and minimal, then the degree of C is bounded by a constant depending on k. We will need to use the result only for $\Sigma\Pi\Sigma(4)$ circuits. We state this as a corollary and introduce the constant D_4 that will play a part in our interpolation algorithms.

COROLLARY 4. *There exists a constant D_4, such that every identically zero multilinear $\Sigma\Pi\Sigma(4)$ circuit that is simple and minimal is of degree $\leq D_4$.*

The next theorem deals with a general $\Sigma\Pi\Sigma(k)$ circuit.

[5] In our case the field size is much larger than the degree of the polynomial and so the syntactic definition and the semantic one are the same. However, we mention this distinction as it is sometimes a cause of confusion.

THEOREM 5 (Lemma 5.2 of [DS06]). *Let $k \geq 3$, $d \geq 2$ be integers and $\mathcal{C} \equiv 0$ be a simple and minimal $\Sigma\Pi\Sigma(k)$ circuit. Then* $\text{rank}(\mathcal{C}) \leq 2^{O(k^2)} \log^{k-2}(d)$.

As before, we shall need the following corollary and the constant R_4.

COROLLARY 6. *There exists a constant R_4 such that every identically zero $\Sigma\Pi\Sigma(4)$ circuit, of degree d, that is simple and minimal is of rank at most $R_4 \cdot \log^2(d)$.*

The following corollary shows how to use Corollaries 4 and 6 to guarantee uniqueness of a $\Sigma\Pi\Sigma(2)$ circuit.

COROLLARY 7. *Let d be some integer, and let D_4 and R_4 be as in Corollaries* 4 and 6*, respectively. If a polynomial f has a degree d (multilinear), $\Sigma\Pi\Sigma(2)$ circuit and* $\text{rank}(f) > R_4 \cdot \log^2(d)$ $(\deg(f) > D_4)$*, then f has a unique (multilinear) $\Sigma\Pi\Sigma(2)$ circuit of degree d.*

Proof. We prove the claim only for general $\Sigma\Pi\Sigma(2)$ circuits. The proof for the multilinear case is identical. Let $C_1 = A_1 + A_2$ be a $\Sigma\Pi\Sigma(2)$ circuit for f, where A_1, A_2 are its multiplication gates. By our assumption on $\text{rank}(f)$ we know that

$$\text{rank}\left(C_1/\text{g.c.d.}(A_1, A_2)\right) > R_4 \cdot \log^2(d).$$

Assume that $C_2 = B_1 + B_2$ is another $\Sigma\Pi\Sigma(2)$ circuit for f, where B_1, B_2 are its multiplication gates. Consider the circuit $C = A_1 + A_2 - B_1 - B_2$; then C is a $\Sigma\Pi\Sigma(4)$ circuit, and $C \equiv 0$. By the assumption on $\text{rank}(C_1)$ we get that $\text{rank}(C) > R_4 \cdot \log^2(d)$. By Corollary 6 (for the case of multilinear circuits, we use Corollary 4) this implies that C is either not simple or not minimal. Note that by the assumption on $\text{rank}\left(C_1/\text{g.c.d.}(A_1, A_2)\right)$ we get that, even if we remove the g.c.d. of C, the remaining circuit still has rank $> R_4 \cdot \log^2(d)$. From this we conclude that C is not minimal. As $C_1 \not\equiv 0$, we get that $A_1 - B_1 \equiv 0$ or $A_1 - B_2 \equiv 0$. □

3. Multilinear circuits. In this section we prove Theorem 1. For ease of reading we repeat it here.

THEOREM 1. *Let f be a multilinear polynomial in n variables that is computed by a degree d multilinear $\Sigma\Pi\Sigma(2)$ circuit, over a field $\mathbb{F}$. Then there is a randomized interpolation algorithm that, given black-box access to f and the parameters d and n, runs in* $\text{poly}(n, |\mathbb{F}|)$*-time and with probability* $1 - o(1)$ *outputs* all *the $\Sigma\Pi\Sigma(2)$ circuits computing f. When $|\mathbb{F}| < n^5$ the algorithm is allowed to make queries to f from a polynomial size algebraic extension field of $\mathbb{F}$.*

Before sketching the proof we repeat some of the notations that we will use. We shall have the following representation of f in mind: $f = M_1 + M_2$, where M_1 and M_2 are the multiplication gates of a multilinear $\Sigma\Pi\Sigma(2)$ circuit for f that are given by the equations

$$M_1 = \prod_{i=1}^{d} L_i(S_i) \quad \text{and} \quad M_2 = \prod_{j=1}^{d'} L'_j(S'_j), \tag{3}$$

where the L_i's (resp., L'_j's) are linear functions, and the sets $\{S_i\}_{i\in[d]}$ $(\{S'_j\}_{j\in[d']})$ form a partition of the set of variables (recall that M_1 and M_2 compute multilinear polynomials). In particular,

$$f(\bar{x}) = \prod_{i=1}^{d} L_i(S_i) + \prod_{j=1}^{d'} L'_j(S'_j). \tag{4}$$

To prove the theorem we will give an algorithm for reconstructing all the $\Sigma\Pi\Sigma(2)$ circuits for f and prove its correctness. The algorithm basically follows the scheme

that was described in section 1.4. We have two cases, the low rank case and the high rank case (in fact we look at low degree and high degree, but for multilinear circuits these correspond to low rank and high rank). More precisely, in the multilinear setting low rank means constant rank (where the constant depends on D_4 as defined in Corollary 4). This makes life easier compared to the general case that we will study in section 4 in which low rank can be as large as $O(\log^2(d))$. We now give a slightly more detailed sketch of the proof as follows:

- *Preprocessing*: The first step in the proof is a preprocessing step in which we find all the linear factors of f. We then show that in the multilinear case each linear factor of f is also a linear factor of both multiplication gates in every $\Sigma\Pi\Sigma(2)$ circuit for f. This enables us to reduce the problem of finding all the circuits for f to finding the circuits for $\mathrm{sim}(f)$. After this step the algorithm treats separately low degree circuits and high degree circuits.
- *Low degree circuits*: The idea is to consider all the restrictions of $\mathrm{sim}(f)$ to small subsets of the variables. Namely, for a set S the restriction of $\mathrm{sim}(f)$ to S is done by setting the variables not in S to zero. We denote the restriction of $\mathrm{sim}(f)$ to S with $\mathrm{sim}(f)(S)$. We will consider only sets S of small size, and so we can find (in a brute force manner) all the simple multilinear $\Sigma\Pi\Sigma(2)$ circuits for $\mathrm{sim}(f)(S)$. Then we will prove that for every multilinear $\Sigma\Pi\Sigma(2)$ circuit C for $\mathrm{sim}(f)$ there exists a set S and a simple multilinear circuit A on the variables in S such that A is the restriction of C to S (which is defined in a similar manner to $\mathrm{sim}(f)(S)$) and that there is a relatively easy way of reconstructing C from A by "revealing" each variable separately.
- *High degree circuits*: The algorithm for the high degree case is similar in spirit to the low degree case with a few exceptions. The first difference is that we will not restrict the variables not in S to zero but rather substitute random values from $\mathbb{F}$ to each of them. The second difference is that in the low degree case the degree of the circuit A (that was described in the previous item) is the same as the degree of C, whereas in the high degree case after restricting the circuit to a small set the degree must drop (it can be at most $|S|$ as the circuit is multilinear).

3.1. Preprocessing step. Before describing the algorithms for the low rank and high rank cases, we have a preprocessing step in which we find all the linear factors of f. We will show that in the case of multilinear $\Sigma\Pi\Sigma(2)$ circuits we actually get that the linear factors of f are also linear factors of each multiplication gate separately. This allows us to reduce the case of reconstructing multilinear $\Sigma\Pi\Sigma(2)$ circuits to the problem of interpolating multilinear $\Sigma\Pi\Sigma(2)$ circuits that do not have linear factors. We start by showing that we can find the linear factors efficiently. The following theorem is an immediate corollary of the results of [Kal85, KT90, Kal95]. The theorem requires that the field that we are working with is not too small, so from now on we shall assume that $|\mathbb{F}| \geq n^5$ (we can make this assumption as we are allowed to query f on inputs from an extension field).

THEOREM 8. *Let d, n be integers. Let $\mathbb{F}$ be a finite field. Then there is a randomized algorithm A that gets as input a black-box access to f and the parameters n and d, and outputs, in $\mathrm{poly}(n, d, \log|\mathbb{F}|)$ time, with probability $1 - \exp(-n)$, all the linear factors, with their multiplicities, of f.*

Let $\mathrm{Lin}(f)$ be the product of all the linear factors of f. The following lemma shows that if f is not a product of linear functions, then every linear function in its factorization also divides the multiplication gates M_1 and M_2 (note that this is not

the case for nonmultilinear $\Sigma\Pi\Sigma(2)$ circuits).[6]

LEMMA 9. *Let f be a polynomial that is computable by a multilinear $\Sigma\Pi\Sigma(2)$ circuit (as in (4)). Assume that f cannot be represented as a product of linear functions. Then if a linear function L divides f, then L must also divide both multiplication gates, in any multilinear $\Sigma\Pi\Sigma(2)$ circuit for f.*

Proof. Consider a multilinear $\Sigma\Pi\Sigma(2)$ circuit for f. Assume w.l.o.g. that it is given by (4). As we assume that f cannot be represented as a product of linear functions, we can also assume w.l.o.g. that g.c.d.$(M_1, M_2) = 1$. Assume for a contradiction that L does not divide M_1 (and therefore does not divide M_2). Consider the (affine) subspace on which $L = 0$. We must have that $f|_{L=0} = 0$. This implies that $M_1|_{L=0} = -M_2|_{L=0}$. As M_1 and M_2 are both products of linear functions, we get that they share the same linear factors modulo L. In particular we can assume w.l.o.g. that $d' = d$ and $L_i|_{L=0} \sim L'_i|_{L=0}$.[7] By examination we get that the support of L (that is, the set of nonzero coordinates of L) is contained in the union of the supports of L_i and L'_i, for every $1 \leq i \leq d$ (recall that we assume that g.c.d.$(M_1, M_2) = 1$). If $d > 2$, then this is not possible, as the circuit for f is multilinear and the S_i's are disjoint (and so are the S'_j's). Thus we get that $d = 2$ (recall that we assumed that we removed the g.c.d.). However, if $d = 2$ and L divides f, then there is another linear function L' such that $f = L \cdot L'$ in contradiction to the assumption that f is not a product of linear functions. □

Thus, contrary to the general case (i.e., nonmultilinear circuits), every linear factor of f is also a linear factor of both multiplication gates in every multilinear $\Sigma\Pi\Sigma(2)$ circuit for f (unless f itself is a product of linear functions). Recall that $\mathrm{sim}(f) = f/\mathrm{Lin}(f)$. Thus, if we have $\mathrm{Lin}(f)$ at hand, then it is easy to simulate oracle access to $\mathrm{sim}(f)$ by making queries to f.[8] Moreover, as we assume that we are given the degree d of a multilinear $\Sigma\Pi\Sigma(2)$ circuit for f, then it is easy to compute $D \stackrel{\Delta}{=} d - \deg(\mathrm{Lin}(f))$. Hence, in the rest of the section we will reconstruct all the simple multilinear $\Sigma\Pi\Sigma(2)$ circuits for $\mathrm{sim}(f)$ of degree D, and from them we will immediately get all the multilinear $\Sigma\Pi\Sigma(2)$ circuits for f.

As described in the sketch we have two cases, the case that $D \leq D_4$ (low degree case) and the case that $D > D_4$ (high degree case).[9] We begin with the low degree case.

3.2. Multilinear circuits: Low degree case. In this section we give an algorithm that finds all the multilinear $\Sigma\Pi\Sigma(2)$ circuits of degree $D \leq D_4$ that compute $\mathrm{sim}(f)$. We assume w.l.o.g. that the number of variables in $\mathrm{sim}(f)$ is more than $10D_4$, as otherwise we can find all the circuits for $\mathrm{sim}(f)$ by a brute force search (this assumption is used in Lemma 11).

We start with a sketch of the algorithm. We first compute the sum-product representation of f. Note that as the degree of $\mathrm{sim}(f)$ is at most D_4, we can interpolate $\mathrm{sim}(f)$ in polynomial time. This will be helpful in future steps where we have to verify that a given circuit computes a certain restriction of $\mathrm{sim}(f)$. In the next step, for each

[6] E.g., consider the circuit $(x + w)(x + y)(x + z) - wyz$. It is not hard to see that it is divisible by x but cannot be represented as a product of linear functions.

[7] We can also have $d = d' \pm 1$ but the analysis remains the same.

[8] Given $\mathrm{Lin}(f)$, an oracle access to f, and a point $\alpha \in \mathbb{F}^n$, we would like to output $\mathrm{sim}(f) = f(\alpha)/\mathrm{Lin}(f)(\alpha)$. There may be a problem when $\mathrm{Lin}(f)(\alpha) = 0$; however, this can be easily taken care of by passing a line through α that contains enough (e.g., more than d) points on which $\mathrm{Lin}(f)$ does not vanish. This is a routine procedure and so we omit its details here.

[9] Recall that D_4 is defined in Corollary 4.

subset S of the variables of size $|S| = 10D_4$, we consider the restriction of $\mathrm{sim}(f)$ in which every variable not in S is set to zero. We denote this polynomial by $\mathrm{sim}(f)(S)$. We then find, in a brute force manner, all the degree $\leq D$ multilinear $\Sigma\Pi\Sigma(2)$ circuits that compute $\mathrm{sim}(f)(S)$. We now wish to construct all the circuits computing $\mathrm{sim}(f)$ from the circuits for the different $\mathrm{sim}(f)(S)$'s. To do so, we consider for every such set S all the sets of the form $S \cup \{i\}$ for $i \notin S$. For each such new set we again compute all the circuits for $\mathrm{sim}(f)(S \cup \{i\})$. Now we try to combine circuits for $\mathrm{sim}(f)(S \cup \{1\}), \ldots, \mathrm{sim}(f)(S \cup \{n\})$ into a single circuit for $\mathrm{sim}(f)$. At first sight it may not be clear how to do this combination; however, we prove that for every circuit for $\mathrm{sim}(f)$ there is a set S for which such a combination will be easy to find. We now give a more formal description of the algorithm (Algorithm 1).

Algorithm 1 shows how to find all the multilinear $\Sigma\Pi\Sigma(2)$ circuits that compute $\mathrm{sim}(f)$, when its degree D is at most D_4. As we are looking for multilinear circuits and we have $\mathrm{Lin}(f)$, we shall only consider variables that do not belong to $\mathrm{Lin}(f)$. In order to not add further notations we shall assume that the variables appearing in $\mathrm{sim}(f)$ are $\{x_1, \ldots, x_n\}$.

ALGORITHM 1 (multilinear circuits of low degree).

1. Interpolate the polynomial $\mathrm{sim}(f)$ to get an explicit representation of it as a sum of monomials.
2. $\forall S \subseteq [n]$ of size $|S| = 10D_4$ find all the degree D *simple* multilinear circuits in the variables of S that compute $\mathrm{sim}(f)(S)$ (recall that $\mathrm{sim}(f)(S)$ is the polynomial obtained after setting the variables not in S to zero).
3. For each such set S and circuit A computing $\mathrm{sim}(f)(S)$ do the following: for $i \notin S$ set $S_i = S \cup \{i\}$. Repeat the previous steps and find all the multilinear $\Sigma\Pi\Sigma(2)$ circuits A_i that compute $\mathrm{sim}(f)(S_i)$ and such that $A_i|_{x_i=0} \equiv A$ (i.e., after substituting $x_i = 0$ the circuits are identical). If for some i there is no such circuit, then move to the next circuit A for $\mathrm{sim}(f)(S)$.
4. For each S and A for which we found $\{A_i\}_{i \in \bar{S}}$ combine, if possible, the different circuits into one multilinear $\Sigma\Pi\Sigma(2)$ circuit: for every linear function $L \in A$ let $L_i \in A_i$ be such that $L_i|_{x_i=0} = L$. Denote $L_i = L + \alpha_i \cdot x_i$. Replace L with $\tilde{L} = L + \sum_{i \notin S} \alpha_i \cdot x_i$.
5. For each circuit found in the previous step verify that it computes $\mathrm{sim}(f)$.

Before giving the analysis of the algorithm we explain the way in which it follows the scheme described in section 1.4. Recall that according to the sketch in section 1.4 we first have to restrict $\mathrm{sim}(f)$ to a random subspace of the inputs. As restriction to a subspace does not preserve multilinearity (imagine the polynomial xy restricted to the subspace $x = y$), we only consider subspaces in which some of the variables are restricted to zero. Clearly a restriction to such a subspace preserves multilinearity. Indeed, in step 2 we basically interpolate all the restrictions of $\mathrm{sim}(f)$ to subspaces of this form that have a low dimension. The lifting is preformed in step 4.

The following theorem summarizes the required properties of Algorithm 1.

THEOREM 10. *Let f be a multilinear polynomial that can be computed by a multilinear $\Sigma\Pi\Sigma(2)$ circuit. Assume that $\deg(\mathrm{sim}(f)) > 3$. Then Algorithm 1, when given oracle access to $\mathrm{sim}(f)$, outputs all the multilinear $\Sigma\Pi\Sigma(2)$ circuits of degree D computing $\mathrm{sim}(f)$. The running time of the algorithm is polynomial in n and $|\mathbb{F}|$.*

Note that the theorem only discusses polynomials f such that $\mathrm{sim}(f)$ has degree larger than 3. This is because when the degree of $\mathrm{sim}(f)$ is too small, there may be more possible circuits computing it. We deal with this case in section 3.2.1.

Proof. Before proving the correctness of the algorithm, we first analyze its running time. The first step in the algorithm is a simple interpolation of a multilinear polynomial of degree D in (at most) n variables. This step runs in time polynomial in n^D (we simply query the polynomial on all inputs in $\{0,1\}^n$ of weight at most D, and solve a system of linear equations to find the coefficients, remembering to look only at coefficients of monomials of degree at most D). Hence we can assume that we have an explicit representation of $\mathrm{sim}(f)$ as sum of monomials. It is clear that in the second step we get a polynomial number of circuits. Indeed, there are at most n^{10D_4} many sets S, and for each set S there are at most $|\mathbb{F}|^{2D\cdot(10D_4+1)}$ multilinear $\Sigma\Pi\Sigma(2)$ circuits in the variables of S (we just count the number of sets of at most $2D$ linear functions, in $10D_4$ variables). In the same way we see that computing the different A_i's also requires polynomial time. As we have a description of $\mathrm{sim}(f)$ at our disposal, it is easy to verify whether a given circuit computes $\mathrm{sim}(f)(S)$. Thus, steps 1–3 can be computed in polynomial time (in $|\mathbb{F}|$ and n). It is also clear that step 4 requires a polynomial time, as the number of circuits that we computed in the previous steps is also polynomial. The last step (verification step) also requires a polynomial running time, and hence the total running time is polynomial in n and $|\mathbb{F}|$.

The correctness of the algorithm follows from the next two lemmas. The first lemma (Lemma 11) shows that there exists a set S such that $\mathrm{sim}(f)(S)$ does not have linear factors, and hence step 2 can be implemented for $\mathrm{sim}(f)$. The second lemma (Lemma 12) shows that if S satisfies a certain property and A computes $\mathrm{sim}(f)(S)$, then for every $i \notin S$ there is a unique circuit A_i that computes $\mathrm{sim}(f)(S \cup \{i\})$ and that equals A after setting $x_i = 0$.

LEMMA 11. *Let $g(x_1,\ldots,x_n)$ be a polynomial on $n > 2d+1$ variables (recall our assumption at the beginning of section* 3.2*) that has no linear factors and that can be computed by a $\Sigma\Pi\Sigma(2)$ circuit of degree d. Then there exists a variable x_k such that $g|_{x_k=0}$ has no linear factors.*

Proof. Let $C = \prod_{i=1}^{d_1} L_i + \prod_{i=1}^{d_2} L'_i$ be some $\Sigma\Pi\Sigma(2)$ circuit computing g, for some $d_1, d_2 \le d$. It is clear that $\dim(\mathrm{span}(\{1, L_1,\ldots,L_{d_1}, L'_1,\ldots,L'_{d_2}\})) \le 2d+1$. In particular there is $1 \le i \le n$ such that x_i is not spanned by the linear functions in the circuit (and the constant function). Assume w.l.o.g. that $i = n$. It is now clear that if we set x_n to zero, then the resulting circuit C' will be "isomorphic" to C in the following sense: there exists an invertible linear transformation $\phi : \mathbb{F}^n \to \mathbb{F}^n$ such that for every $(a_1,\ldots,a_n) \in \mathbb{F}^n$ we have that $C(a_1,\ldots,a_n) = C'(\phi(a_1,\ldots,a_n))$ (we think of C' as a circuit in n variables although x_n does not appear in it). In particular if C' has a linear factor, then so does C (as C is equal to the composition of C' with a linear transformation). As C has no linear factors (by our assumption on g) we get that $C' = C|_{x_n=0}$ has no linear factors as well. ∎

Note that the lemma works for any $\Sigma\Pi\Sigma(2)$ circuit and not just multilinear circuits. We also note that it is not difficult to change the proof of the lemma to hold also for the case that $n = 2d+1$ (we just need to consider the homogeneous part of each L_i and L'_j and not consider the constant function 1). In addition, it is also easy to see that we cannot have $n = 2d$ because of the following example: $f(x_1,\ldots,x_{2d}) = \prod_{i=1}^{d} x_i + \prod_{i=d+1}^{2d} x_i$. The next lemma shows that if $D > 3$, then for every S_i and circuit A that was computed in step 2 there is at most one multilinear $\Sigma\Pi\Sigma(2)$ circuit A_i with $A_i = \mathrm{sim}(f)(S_i)$ and $A_i|_{x_i=0} \equiv A$. The proof is by a simple manipulation of polynomials. Note that this implies that if there exists a circuit C for f such that A is its restriction to the variables S (that is, A is the resulting circuit after setting all the variables not in S to zero), then step 4 will return the circuit C

(because of the uniqueness, we are assured that we combine the linear functions in the different A_i's in the only possible way).

LEMMA 12. *Let $g(x_1,\ldots,x_t)$ be a polynomial of degree $D>3$ that does not have any linear factors. Assume that we have a multilinear $\Sigma\Pi\Sigma(2)$ circuit computing $g|_{x_t=0}$. In other words, we have*

$$g(x_1,\ldots,x_t)|_{x_t=0}=\prod_{i=1}^{D}L_i+\prod_{j=1}^{D'}L'_j.$$

Then there is at most one multilinear circuit of the form

$$\prod_{i=1}^{D}(L_i+\alpha_i x_t)+\prod_{j=1}^{D'}(L'_j+\alpha'_j x_t)$$

that computes g (note that such a circuit may not exist).

Proof. Assume for a contradiction that there are two different multilinear circuits of that form that compute g. Assume w.l.o.g. that the first circuit is

$$g=C_1=(L_1+\alpha x_t)\cdot\prod_{i=2}^{D}L_i+(L'_1+\alpha' x_t)\cdot\prod_{j=2}^{D'}L'_j.$$

There are three canonical options for the second circuit:

$$C_2=L_1\cdot(L_2+\beta x_t)\cdot\prod_{i=3}^{D}L_i+L'_1\cdot(L'_2+\beta' x_t)\cdot\prod_{j=3}^{D'}L'_j, \tag{5}$$

$$C_2=(L_1+\beta x_t)\cdot L_2\cdot\prod_{i=3}^{D}L_i+L'_1\cdot(L'_2+\beta' x_t)\cdot\prod_{j=3}^{D'}L'_j, \tag{6}$$

$$C_2=(L_1+\beta x_t)\cdot L_2\cdot\prod_{i=3}^{D}L_i+(L'_1+\beta' x_t)\cdot L'_2\cdot\prod_{j=3}^{D'}L'_j. \tag{7}$$

We shall only analyze the first case (given in (5)), as it is the more interesting one. The analysis of the other cases is similar (and somewhat simpler).

So let us assume that C_2 is given by (5). As $C_1=C_2$ we get, by exchanging sides, that

$$x_t\cdot(\alpha L_2-\beta L_1)\cdot\prod_{i=3}^{D}L_i=x_t\cdot(\beta' L'_1-\alpha' L'_2)\cdot\prod_{j=3}^{D'}L'_j.$$

Since $D>3$, there is $3\le i\le D$ such that $L_i\not\mid(\beta' L'_1-\alpha' L'_2)$, and so there must be $3\le j\le D$ such that $L_i\sim L'_j$. This implies that L_i divides g. However, we assumed that g does not have linear factors, so we have a contradiction. ∎

The proof of Theorem 10 now follows easily. Indeed, by Lemma 11 we know that for every circuit C for $\mathrm{sim}(f)$ there exists a set S of size $|S|=10D_4$ and a simple multilinear circuit A that compute $\mathrm{sim}(f)(S)$. Lemma 12 and the discussion proceeding it show that C will be one of the circuits computed in step 4. It is clear that the last step will keep only the correct circuits. ∎

We now handle the cases of $D=3$ and $D=2$ (note that Lemma 12 says nothing for such D's and indeed, the claim is not true in this case).

3.2.1. Case $D \leq 3$. Algorithm 1 in its current form cannot compute all the circuits of degree ≤ 3 for $\mathrm{sim}(f)$. However, the required change is minor and so we describe it here and do not repeat the algorithm itself. We also give a sketch of a proof, as the proof itself contains easy manipulations similar in spirit to those that were already performed for the case $D > 3$. The basic difference is in steps 3 and 4. Instead of computing a circuit A_i for $\mathrm{sim}(f)(S \cup \{i\})$ we need to compute a circuit $A_{i,j}$ for $\mathrm{sim}(f)(S \cup \{i,j\})$. Another change is that it may be the case that for some i the circuit A_i is not the unique lift (in contrast to what Lemma 12 guarantees for higher degrees). However, in such a case we prove that $A_{i,j}$ is unique for every $j \notin S \cup \{i\}$. The rest of the proof should now be clear (given that we prove the above claim regarding $A_{i,j}$). In fact, this discussion is true only for $D = 3$ and for $D = 2$, yet another slight modification is required, but it is similar in spirit and so we omit it.

We first analyze the case $D = 3$. The only possible difference from the case $D > 3$ is when there is some index i such that there are two (or more) different ways of extending the circuit A to a circuit A_i. From the proof of Lemma 12 we get that w.l.o.g. A has the following form:

$$A = L_1 \cdot L_2 \cdot L_3 + L'_1 \cdot L'_2 \cdot L'_3,$$

and the two different lifts are[10]

$$A_i = (L_1 + \alpha_2 x_i) \cdot L_2 \cdot L_3 + (L'_1 - \beta_2 x_i) \cdot L'_2 \cdot L'_3$$

and

$$A'_i = L_1 \cdot (L_2 - \alpha_1 x_i) \cdot L_3 + L'_1 \cdot (L'_2 + \beta_1 x_i) \cdot L'_3$$

for constant $\alpha_1, \alpha_2, \beta_1$, and β_2. In particular we must have that $L_3 = c \cdot (\beta_1 L'_1 + c_2 \cdot \beta_2 L'_2)$ and $L'_3 = c \cdot (\alpha_1 L_1 + \alpha_2 L_2)$ for some $c \neq 0$. Using the same reasoning as in the proof of Lemma 12, it is easy to show that for any variable $j \notin S \cup \{i\}$ there is at most one circuit $A_{i,j}(S \cup \{i,j\})$ satisfying

$$A_{i,j} = g(S \cup \{i,j\})$$

and

$$A_{i,j}|_{x_j=0} \equiv A_i.$$

In other words, for the case $D = 3$ we have to perform steps 3 and 4 of Algorithm 1 for the circuit $A_i(S \cup \{i\})$ and its possible lifts $A_{i,j}(S \cup \{i,j\})$.

To conclude, if we have an index i with two different lifts A_i and A'_i (as described above), then, as in the case of $D > 3$, we get that there are at most two circuits $\hat{A}$ and $\hat{A}'$ that for every $j \notin S \cup \{i\}$ satisfy

$$\hat{A}(S \cup \{i,j\}) \equiv A_{i,j}$$

and

$$\hat{A}'(S \cup \{i,j\}) \equiv A'_{i,j}.$$

[10]There are two more cases to consider (corresponding to (6) and (7)) but the analysis follows from similar arguments.

Therefore we get, again, that at most polynomially many circuits are found by the algorithm, that those polynomials are computed in polynomial time, and that they contain all the possible representations for $\mathrm{sim}(f)$ (we can find those circuits by repeating step 4 of Algorithm 1 for each of the A_i's and the corresponding set $\{A_{i,j}\}$). Hence we can find in polynomial time all the different multilinear $\Sigma\Pi\Sigma(2)$ circuits for f.

The case $D = 2$ follows by a similar case analysis. We omit the proof, as this case (as well as the case $D = 3$) is not very interesting and the proofs are simple and resemble the proofs seen so far.

3.3. Multilinear circuits: High degree case. We now turn to the high degree case. As described above, the algorithm for this case is similar to Algorithm 1 with the exception that we do not substitute zeroes for the variables outside S and that "gluing" the different circuits for $\mathrm{sim}(f)(S \cup \{i\})$ is slightly more complicated. Algorithm 2 shows how to interpolate the circuit in the case when $\deg(\mathrm{sim}(f)) > D_4$.

ALGORITHM 2 (multilinear circuits of high degree).

$\forall S \subseteq [n]$ *such that* $|S| = 2D_4$do the following:

1. $\forall i \notin S$ pick a random assignment to x_i from $\mathbb{F}$. Denote the final assignment with ρ. Let $\mathrm{sim}(f)|_\rho$ be the polynomial $\mathrm{sim}(f)$ after substituting the partial assignment ρ.
2. For every simple multilinear $\Sigma\Pi\Sigma(2)$ circuit in the variables $\{x_i\}_{i\in S}$, over $\mathbb{F}$, of *degree greater than* D_4 (and at most $2D_4$ of course), check whether the circuit computes $\mathrm{sim}(f)|_\rho$. If no such circuit computing $\mathrm{sim}(f)|_\rho$ is found, then move to the next S.
3. For every $i \neq j$ such that $i, j \notin S$, set $S_{i,j} = S \cup \{i, j\}$. Find a simple multilinear $\Sigma\Pi\Sigma(2)$ circuit $A_{i,j}$ that computes $\mathrm{sim}(f)|_{\rho_{i,j}}$, where $\rho_{i,j}$ is the assignment that equals ρ on all the coordinates outside $S_{i,j}$ (namely, we "forget" the assignments to x_i and x_j).
4. Glue the different circuits for the $S_{i,j}$'s to a single multilinear $\Sigma\Pi\Sigma(2)$ circuit. That is, find the unique circuit C whose restriction to $\rho_{i,j}$ equals $A_{i,j}$ (the exact way of gluing will be explained in the analysis of the algorithm).

If no circuit is found, then output "fail."

The basic intuition behind the algorithm is the following. As we will see in Lemma 15 there is a unique circuit for $\mathrm{sim}(f)$ of degree greater than D_4 (given that one exists). Moreover, we will see that w.h.p. even when we substitute random field elements for most of the variables, there is still a unique circuit for the restricted polynomial. Thus, in order to find the circuit for $\mathrm{sim}(f)$ we first find the circuit for the restricted polynomial $\mathrm{sim}(f)|_\rho$ (steps 1 and 2) and then find the unique way of recovering the other variables. The main difference from the low degree case is that by exposing the other variables, new linear functions may appear (as the degree of the restricted polynomial is at most $|S|$), and in order to find the partition of the other variables to the new linear functions we have to consider pairs of variables (i.e., find the circuit for $\mathrm{sim}(f)(S \cup \{i, j\})$ instead of just finding a circuit for $\mathrm{sim}(f)(S \cup \{i\})$). This is done in steps 3 and 4. The following theorem shows that Algorithm 2 is indeed correct and analyzes its running time.

THEOREM 13. *Let f be a multilinear polynomial such that* $\mathrm{sim}(f)$ *can be computed by a multilinear* $\Sigma\Pi\Sigma(2)$ *circuit of degree $D > D_4$. Then Algorithm* 2*, when given oracle access to* $\mathrm{sim}(f)$*, outputs with probability* $\geq 1 - (n+1)^2/|F|$ *the unique multilinear* $\Sigma\Pi\Sigma(2)$ *circuits of degree D computing* $\mathrm{sim}(f)$*. The running time of the algorithm is polynomial in n and $|\mathbb{F}|$.*

Note that in particular the theorem implies that there is a unique degree D $\Sigma\Pi\Sigma(2)$ circuit for $\mathrm{sim}(f)$. This is, however, a simple fact given Corollary 7 (and in Lemma 15 we prove a slightly more general version of this fact).

Proof. The idea of the proof is the following. We first show (Lemma 14) that for every set S, w.h.p. over the choice of ρ, there is no linear factor dividing $\mathrm{sim}(f)|_\rho$ (i.e., no new linear factor was introduced). We then show (Lemma 15) that this implies that there is a unique $\Sigma\Pi\Sigma(2)$ circuit for $\mathrm{sim}(f)|_\rho$ of degree larger than D_4, if such a circuit exists. Combining the two lemmas, we see that there is a set S and an assignment ρ for which there is a unique $\Sigma\Pi\Sigma(2)$ circuit of degree larger than D_4 for $\mathrm{sim}(f)|_\rho$ (the set S is picked so that the degree of the circuit for $\mathrm{sim}(f)_\rho$ is larger than D_4 w.h.p. over the choice of ρ). At this point we will have at hand the unique circuit for $\mathrm{sim}(f)|_\rho$ and we would like to add to it the variables not in S to get the circuit for $\mathrm{sim}(f)$. To do so we find (again the unique) $\Sigma\Pi\Sigma(2)$ circuit for $\mathrm{sim}(f)|_{\rho_{i,j}}$. From that circuit we can immediately find whether x_i and x_j belong to the same linear function (for each of the multiplication gates) and what is the ratio between their coefficients. Given this information for all pairs of variables it is easy to construct the two multiplication gates. We now give the formal proof.

Let $S \subset [n]$ be a set of size $2D_4$ and $C = M_1 + M_2$ be a multilinear $\Sigma\Pi\Sigma(2)$ circuit for $\mathrm{sim}(f)$ of degree higher than D_4. We say that the assignment ρ is *good* for C if no new linear factors were introduced (note that the degree of $\mathrm{sim}(f)|_\rho$ may be smaller though). In other words, ρ is good if $\mathrm{Lin}(\mathrm{sim}(f)|_\rho) = 1$.

LEMMA 14. *Let $S \subset [n]$ be a set of size $2D_4$ and $C = M_1 + M_2$ be a multilinear $\Sigma\Pi\Sigma(2)$ circuit for $\mathrm{sim}(f)$ of degree $D > D_4$. The probability that an assignment ρ, to the variables not in S, is not good for C is smaller than $(n+1)^2/|\mathbb{F}|$.*

The proof of the lemma is a simple union bound over the event that two linearly independent linear functions in the circuit for $\mathrm{sim}(f)$ become linearly dependent nonconstant linear functions after substituting ρ.

Proof. We first bound the probability that M_1 or M_2 were set to zero. This may happen only if a linear function from any of them was set to zero, and this happens with probability $1/|\mathbb{F}|$. As there are $2D$ linear functions, we get an upper bound on the probability of $2D/|\mathbb{F}|$ (recall that we work only with the variables that do not belong to $\mathrm{Lin}(f)$). To get a bound on the probability that a new linear factor was introduced, we note that this is possible only if there is a linear function L_1 dividing M_1 and a linear function L_2 dividing M_2 such that $L_1|_\rho \sim L_2|_\rho$, and they were not set to constants. As there is only one possible coefficient c for which $L_1|_\rho = c \cdot L_2|_\rho$ (i.e., c depends only on S, L_1, and L_2 and not on ρ), we see that the probability that this happened is equal to the probability that the part in $L_1 - cL_2$ that depends on the variables outside S was set to zero. As before, this happens with probability $1/|\mathbb{F}|$. As there are at most D^2 such pairs we get an upper bound of $D^2/|\mathbb{F}|$ on the probability. Thus, the overall probability is bounded by $(D^2 + 2D)/|\mathbb{F}| < (D+1)^2/|\mathbb{F}| \le (n+1)^2/|\mathbb{F}|$. ∎

The next lemma shows that if there is a multilinear $\Sigma\Pi\Sigma(2)$ circuit $C = M_1 + M_2$, of degree $D > D_4$, for $\mathrm{sim}(f)$, then it is unique and that if S and ρ are such that ρ is good for C, then there is a unique multilinear $\Sigma\Pi\Sigma(2)$ circuit for $\mathrm{sim}(f)|_\rho$ (and that circuit is $M_1|_\rho + M_2|_\rho$). This lemma generalizes Corollary 7 (by taking $S = [n]$ and ρ to be the "empty" substitution, we get the claim regarding the uniqueness of the circuit for $\mathrm{sim}(f)$).

LEMMA 15. *Let $\mathrm{sim}(f)$ be computed by a multilinear $\Sigma\Pi\Sigma(2)$ circuit $C = M_1 + M_2$. For a set S and a good assignment ρ, if $\deg(\mathrm{sim}(f)|_\rho) > D_4$, then there is a unique simple multilinear $\Sigma\Pi\Sigma(2)$ circuit that computes $\mathrm{sim}(f)|_\rho$. Moreover, this circuit is $M_1|_\rho + M_2|_\rho$.*

Proof. By our assumption we have that $\deg(\mathrm{sim}(f)|_\rho) > D_4$. Assume for a contradiction that there is a multilinear $\Sigma\Pi\Sigma(2)$ circuit $C' = A_1 + A_2$ such that $C' = \mathrm{sim}(f)|_\rho$ and $C' \neq M_1|_\rho + M_2|_\rho$. Therefore the circuit $\tilde{C} = M_1|_\rho + M_2|_\rho - A_1 - A_2$ is identically zero and of degree $> D_4$. Notice that as ρ is a good assignment, we have that $\tilde{C}$ is simple. By Corollary 4 we are assured that it is not minimal, and so we must have that $A_1 = M_1|_\rho$ or $A_1 = M_2|_\rho$, which is a contradiction. ∎

Given the two lemmas it is easy to explain steps 1 and 2 of the algorithm. Let C be *the* unique multilinear $\Sigma\Pi\Sigma(2)$ circuit for $\mathrm{sim}(f)$ of degree higher than D_4. Let S be a set of size $2D_4$ such that the degree of C in the variables of S is larger than D_4 (think of the other variables as constants and view C as a circuit over the variables in S and compute its degree). By Lemma 14 we get that with probability $\geq 1-(n+1)^2/|F|$ the substitution ρ is such that $C|_\rho$ is the unique circuit for $\mathrm{sim}(f)|_\rho$. Thus, for this set S we get that with probability $\geq 1-(n+1)^2/|F|$ steps 1 and 2 find the unique circuit $C|_\rho$ (and this circuit is of degree greater than D_4). We now continue and show that if such S and good ρ were found, then steps 3 and 4 return the circuit C.

As ρ is good for C, it immediately follows that $\rho_{i,j}$ is good for C (and $S \cup \{i,j\}$). Thus the circuits found in step 3 are the unique circuits computing the different $f|_{\rho_{i,j}}$'s (i.e., those circuits are identical to the $C|_{\rho_{i,j}}$'s). We now explain how step 4 is performed. Consider a linear function L that belongs to M_1. There are two possibilities. Either $L|_\rho$ is constant or not. If $L|_\rho$ is not constant, then for every variable x_i we will find its coefficient in L by considering the circuit, say, $C|_{\rho_{1,i}}$ (assuming that $i \neq 1$; otherwise consider the circuit $C|_{\rho_{1,2}}$). If L was restricted to a constant, then denote $L = \sum_{i=1}^n \alpha_i \cdot x_i$. Notice that in $C|_{\rho_{i,j}}$ there will be a linear function of the form $c\cdot(\alpha_i \cdot x_i + \alpha_j \cdot x_j)$, for some nonzero field element c. In particular, if for some chosen x_i that appears in L, we chose to normalize its coefficient to always be 1, then we can find in this manner all the coefficients of the other variables appearing with it in L and so reconstruct (a nonzero multiple of) L. In this way we can find all the linear functions appearing in M_1 and M_2. Note that we found all the linear factors up to some nonzero multiple, so it only remains to find a constant that will give the correct normalization of each M_i. This can be easily done by querying $\mathrm{sim}(f)$ on two points, one on which M_1 vanishes and not M_2 and vice versa. We note that we do not have to verify that we found the correct circuit for $\mathrm{sim}(f)$, as by Lemma 15 and step 2 we are guaranteed that we have the correct circuit for $\mathrm{sim}(f)|_\rho$ (assuming that ρ is good) and it is clear that starting from this circuit we find the unique circuit C for $\mathrm{sim}(f)$. Thus, with probability at least $1-(n+1)^2/|F|$ the algorithm finds the unique multilinear circuit for $\mathrm{sim}(f)$.

It only remains to analyze the running time of the algorithm. Given a set S and an assignment ρ we check whether $\mathrm{sim}(f)|_\rho$ has new linear factors by applying Theorem 8, which requires polynomial time and succeeds w.h.p. In step 2 we have to go over all possible simple multilinear $\Sigma\Pi\Sigma(2)$ circuits for $\mathrm{sim}(f)|_\rho$ of degree greater than D_4 (and at most $2D_4$). Note that as there are only $|\mathbb{F}|^{2D_4+1}$ linear functions in the variables $\{x_i\}_{i\in S}$, there are polynomially many such circuits ($|\mathbb{F}|^{2D_4\cdot(2D_4+1)}$ is an obvious upper bound). Among all those circuits we shall find, by going over all $0,1$ assignments to $\{x_i\}_{i\in S}$, a circuit that computes $\mathrm{sim}(f)|_\rho$. As the size of S is constant, this costs only a constant factor in the running time. Verifying that the circuit is simple is pretty obvious and requires time polynomial in the degree of the circuit and linear in n. Next, for each pair (i,j) the complexity of step 3 is similar to the complexity of step 2. Finally, the procedure described above for "gluing" the different $C|_{\rho_{i,j}}$'s requires polynomial time (in n). Hence, the overall running time is

polynomial in n and $|\mathbb{F}|$, and with probability $\geq 1-(n+1)^2/|F|$ the algorithm outputs the unique multilinear $\Sigma\Pi\Sigma(2)$ circuit for $\mathrm{sim}(f)$. Note that failure can occur only if we failed to find a good ρ. This completes the proof of Theorem 13. □

We now combine the preprocessing step and Theorems 10 and 13 to get Theorem 1 (the argument is straightforward).

3.4. Proof of Theorem 1. The proof of the theorem is easy given the two algorithms. First, we find $\mathrm{Lin}(f)$ and compute $D = d - \deg(\mathrm{Lin}(f))$. If $D \leq D_4$, then we run the low degree algorithm. If $D > D_4$, then we run the high degree algorithm. We are assured that if we get an answer, then it is going to be correct. The probability of failure in both algorithms is polynomially small in n (and can be easily decreased, e.g., by repeating the algorithm) and so the theorem follows.

4. General circuits. In this section we prove Theorem 2. For convenience we repeat it here.

THEOREM 2. *Let f be an n-variate polynomial computed by a $\Sigma\Pi\Sigma(2)$ circuit of degree d, over a field $\mathbb{F}$. Then there is a randomized interpolation algorithm that, given black-box access to f and the parameters d and n, runs in quasi-polynomial time (in n, d, $|\mathbb{F}|$) and has the following properties:*

- *If $\mathrm{rank}(f) = \Omega\left(\log^2(d)\right)$, then with probability $1-o(1)$ the algorithm outputs the (unique) $\Sigma\Pi\Sigma(2)$ circuit for f.*
- *If $\mathrm{rank}(f) = O\left(\log^2(d)\right)$, then the algorithm outputs, with probability $1-o(1)$, a polynomial $\mathrm{Lin}(f)$, a polynomial $Q(y_1,\ldots,y_k)$, and k linear functions $L_1,\ldots,L_k$, where $k \leq \mathrm{rank}(f)$, such that $\mathrm{Lin}(f)$ is the product of all the linear factors of f and $\mathrm{Lin}(f)\cdot Q(L_1,\ldots,L_k) = f$.*

When $|\mathbb{F}| < \max(d^5, n^5)$, the algorithm is allowed to make queries to f from a polynomial size extension field of $\mathbb{F}$.

From now on we shall assume, w.l.o.g., that the underlying field $\mathbb{F}$ is of size greater than $\max(d^5, n^5)$. We shall have the following representation of f in mind:

$$f(\bar{x}) = \prod_{i=1}^{d} L_i^{(1)}(\bar{x}) + \prod_{i=1}^{d} L_i^{(2)}(\bar{x}). \tag{8}$$

Note that in order to ease the notations we assume that the degrees of both multiplication gates are equal. As described in section 1.4 there are two conceptual steps in the proof. First, we restrict the inputs to come from a random subspace V of dimension $O(\log^2(d))$, where $d = \deg(f)$. We then learn the restriction of f to V which we denote by $f|_V$. The second step is to learn the restriction of f to larger subspaces and then glue the different representations together. While this is the general picture, there is a difference in the way that we handle functions with high rank and functions with low rank. We start by describing the algorithm for the low rank case.

4.1. Interpolation for the low rank case. In this section we give an interpolation algorithm for polynomials that are computed by $\Sigma\Pi\Sigma(2)$ circuits of degree d and that have rank at most $10R_4 \cdot \log^2(d)$ (recall the definition of R_4 from Corollary 6). Let f be such a polynomial. Algorithm 3 is an interpolation algorithm for f. Before giving the algorithm, we describe each of its steps.

Let C be any $\Sigma\Pi\Sigma(2)$ circuit computing f, e.g., the one given by (8). We start by computing $\mathrm{Lin}(f)$. This can be easily done using Theorem 8. After this step we can assume, as before, that we get oracle access to $\mathrm{sim}(f) = f/\mathrm{Lin}(f)$.[11] Note, that as

[11] Unlike the multilinear case, it may be the case that $\mathrm{sim}(C)$ does not compute $\mathrm{sim}(f)$.

$\text{sim}(f) = f/\text{Lin}(f)$ divides $\text{sim}(C)$ and $\text{rank}(f) \leq 10R_4 \cdot \log^2(d)$, we get that $\text{sim}(f)$ can be represented as a polynomial in $\leq 10R_4 \cdot \log^2(d)$ linear functions. Namely, there exists a polynomial $P(y_1, \ldots, y_k)$ and linearly independent linear functions $\{L_i\}_{i\in[k]}$ such that $\text{sim}(f) = P(L_1, \ldots, L_k)$ (we will always think of k as the minimal possible integer allowing such a representation). The goal of Algorithm 3 is to find such a representation for $\text{sim}(f)$. There are two main steps for doing that. First, we pick a random subspace V of dimension $O(R_4 \cdot \log^2(d))$ and look for a polynomial Q and linear functions $\ell_1, \ldots, \ell_k$ such that $\text{sim}(f)|_V = Q(\ell_1, \ldots, \ell_k)$ (we do not necessarily find the polynomial P and restricted linear functions $\{L_i|_V\}$ given above; however, the two different representations are closely related, as shown in Lemma 23). In the second step we "lift" the ℓ_i's and find ℓ_i^*'s such that for every i, $\ell_i^*|_V = \ell_i$ and $\text{sim}(f) = Q(\ell_1^*, \ldots, \ell_k^*)$. This may seem like a big leap from the outcome of the first step; however, we manage take it so by exposing one variable at a time (in a similar way to step 4 of Algorithm 1). The important ingredients of this "lifting" procedure are Lemmas 23 and 24 which basically show that if V' is a subspace containing V, then there exist unique linear functions (that can be easily found) $\{\ell_i'\}_{i=1}^k$, over V', that satisfy $\text{span}(\{L_i|_{V'}\}) = \text{span}(\{\ell_i'\})$, $\ell_i'|_V = \ell_i$, and $Q(\ell_1', \ldots, \ell_k') = \text{sim}(f)|_{V'}$. We now give the formal description of the algorithm.

ALGORITHM 3 (general $\Sigma\Pi\Sigma(2)$ circuits of low rank).

1. **Computing Lin(f):** Find the linear factors of f using the factoring algorithm of Theorem 8.
2. **Interpolating on a low dimensional random subspace:** Pick a random subspace V of dimension $s = 20R_4 \cdot \log^2(d) + \log^2(n)$. Find $k' \leq 10R_4 \cdot \log^2(d)$ linearly independent linear functions $\{\ell_i\}_{i\in[k']}$, such that $\text{sim}(f)|_V = Q(\ell_1, \ldots, \ell_{k'})$, for some polynomial Q of degree $\deg(Q) \leq d$, and such that no such representation is possible for any $k'' < k'$. In other words, do the following: For $k' = 1, \ldots, 10R_4 \cdot \log^2(d)$ consider all sets of k' linearly independent linear functions over V. For every such set $\{\ell_i\}_{i\in[k']}$ find, using brute force interpolation, a polynomial $Q(y_1, \ldots, y_{k'})$ of degree at most d, such that $Q(\ell_1, \ldots, \ell_{k'}) = \text{sim}(f)|_V$, if such a polynomial exists. Finally, output the first set $\{\ell_i\}_{i\in[k']}$ for which such a polynomial Q was found.
3. **Lifting from V to $\mathbb{F}^n$:** Find linear functions $\{\ell_i^*\}_{i\in[k']}$, over $\mathbb{F}^n$, such that $Q(\ell_1^*, \ldots, \ell_{k'}^*) = \text{sim}(f)$ using the following procedure (a more detailed explanation will be given when analyzing the algorithm):
   (a) Let $\{v_i\}_{i\in[n]}$ be a basis to $\mathbb{F}^n$, such that $\{v_i\}_{i=1}^s$ is a basis to V. For every $i \in [n-s]$ let $V_i = \text{span}(V \cup \{v_{s+i}\})$. For each V_i find a representation for $\text{sim}(f)|_{V_i}$ of the form $\text{sim}(f)|_{V_i} = Q(\ell_1^{(i)}, \ldots, \ell_k^{(i)})$, where for each i and j we have that $\ell_j^{(i)}|_V = \ell_j$.
   (b) Find the unique linear functions $\{\ell_i^*\}_{i\in[k]}$ that satisfy $\ell_j^*|_{V_i} = \ell_j^{(i)}$, for each i and j, in a way analogous to step 4 of Algorithm 1.

   If no such representation is found, then output "fail."

The next theorem shows the correctness of Algorithm 3 and analyzes its running time.

THEOREM 16. *Let f be a polynomial that can be computed by a $\Sigma\Pi\Sigma(2)$ circuit of* $\text{rank} \leq 10R_4 \cdot \log^2(d)$. *Then with probability $\geq 1 - |\mathbb{F}|^{-\Omega(\log^2(n))}$ Algorithm 3, when given oracle access to f, computes* $\text{Lin}(f)$, *a natural number $k \leq 10R_4 \cdot \log^2(d)$, a polynomial $Q(y_1, \ldots, y_k)$, and k linear functions $\{\ell_i^*\}_{i=1,\ldots,k}$ such that $Q(\ell_1^*, \ldots, \ell_k^*) =$* $\text{sim}(f)$. *The running time of the algorithm is quasi polynomial in n, d, and $|\mathbb{F}|$ (i.e., it is* $\exp(\text{poly}(\log|\mathbb{F}|, \log n, \log d))$).

The proof of correctness of the algorithm is composed of three parts. First, we study properties of polynomials that can be written as functions of exactly k linear functions. In particular we show that this property is preserved (w.h.p.) when we restrict the polynomial to a random subspace of sufficient dimension (Corollary 22). Then we consider $\mathrm{sim}(f)$ and a random subspace V of dimension $10R_4 \cdot \log^2(d)$ and show how to find the relevant linear functions for it. This will complete the analysis of step 2. After that we prove a lemma mentioned above (Lemma 24) that shows how we can "lift" the linear functions found in the previous step to functions over $\mathbb{F}^n$. This will complete the analysis of step 3. The analysis of the running time will be quite simple. For sake of modularity, in the next subsection we discuss properties of polynomials that depend on k linear functions and then proceed with the proof.

4.1.1. Polynomials depending on k linear functions. In this subsection we study the notion of a polynomial that depends on exactly k linear functions. We first define this property in a formal manner.

DEFINITION 17. *Let $h(x_1, \ldots, x_n)$ be a polynomial. We say that h is a polynomial in* exactly *k linear functions if there is a polynomial $P(y_1, \ldots, y_k)$ and k linear functions $L_1, \ldots, L_k$ such that $h = P(L_1, \ldots, L_k)$, and there is no such representation for h with less than k linear functions. We say that h is a polynomial in k linear functions if there exists a $k' \leq k$ such that h is a polynomial in exactly k' linear functions.*

The following lemma gives a sufficient and necessary condition for being a function of k linear functions.

LEMMA 18. *Let $h(x_1, \ldots, x_n)$ be a polynomial over $\mathbb{F}$. Then h can be written as a polynomial in k linear functions if and only if there is a subspace $V^* \subseteq \mathbb{F}^n$ of dimension $n-k$ such that for every $u \in \mathbb{F}^n$ and $v \in V^*$ we have that $h(u) = h(v+u)$.*

Note that the lemma does not speak about h being a function of exactly k linear functions. However, it is clear that if there is a subspace V^* of dimension $n-k$ that satisfies the condition in the lemma, and there is no subspace U^* of dimension $> n-k$ that satisfies the condition of the lemma, then h is a function of exactly k linear functions.

Proof. Assume w.l.o.g. that h is a polynomial in exactly k linear functions. Denote $h = P(L_1, \ldots, L_k)$, where the L_i's are homogeneous linear functions. Let $V^* = \{\bar{x} \in \mathbb{F}^n : \forall i\ L_i(\bar{x}) = 0\}$. Clearly $\dim(V^*) = n-k$. Let $u \in \mathbb{F}^n$ and $v \in V^*$ be two vectors. We have that $h(v+u) = P(L_1(u+v), \ldots, L_k(v+u)) = P(L_1(u), \ldots, L_k(u)) = h(u)$.

For the other direction, given such V^*, let $L_1, \ldots, L_k$ be k linearly independent linear functions such that for every $v \in V^*$ and $i \in [k]$ we have that $L_i(v) = 0$. Let $V \subset \mathbb{F}^n$ be a k-dimensional subspace such that $V \cap V^* = \{0\}$. Clearly $\mathbb{F}^n = V \oplus V^*$. It is also clear that the linear functions $\{L_i|_V\}$ are linearly independent. As $\dim(V) = k$, it follows that there is some polynomial $Q(y_1, \ldots, y_k)$ such that for every $v \in V$ it holds that $h(v) = Q(L_1(v), \ldots, L_k(v))$. Now, given $u \in \mathbb{F}^n$ write $u = v + v^*$ for $v \in V$ and $v^* \in V^*$. We now have that $h(u) = h(u - v^*) = h(v) = Q(L_1(v), \ldots, L_k(v)) = Q(L_1(v+v^*), \ldots, L_k(v+v^*)) = Q(L_1(u), \ldots, L_k(u))$. Hence, $h = Q(L_1, \ldots, L_k)$. ∎

We now give some easy corollaries of this lemma.

COROLLARY 19. *Let $h(\bar{x}) = P(L_1, \ldots, L_k)$ be a polynomial in exactly k linear functions. Let V be a subspace of $\mathbb{F}^n$. Then $h|_V$ is a polynomial in exactly k linear functions if and only if the restrictions $L_1|_V, \ldots, L_k|_V$ are linearly independent.*

COROLLARY 20. *Let h be a polynomial in exactly k linear functions. Let $V \subseteq \mathbb{F}^n$ be an s-dimensional subspace such that $h|_V$ is a polynomial in $k' < k$ linear functions. Let $v_1, \ldots, v_{n-s}$ be vectors such that $\mathrm{span}(V \cup \{v_i\}_{i \in [n-s]}) = \mathbb{F}^n$. Denote $V_i = \mathrm{span}(V \cup \{v_i\})$. Then for some $i \in [n-s]$ we have that $h|_{V_i}$ is a polynomial in*

more than k' linear functions.

In the analysis of Algorithm 3 we will be interested in restrictions to random subspaces. The following lemmas show that if h is a polynomial in exactly k linear functions and V is a subspace of sufficiently high dimension chosen at random, then w.h.p. $h|_V$ is also a polynomial in exactly k linear functions.

LEMMA 21. *Let $\{\ell_i\}_{i\in[t]}$ be a set of linearly independent linear functions over $\mathbb{F}^n$. Let $V \subseteq \mathbb{F}^n$ be a random s-dimensional subspace. Then the probability that the set $\{\ell_i|_V\}_{i\in[t]}$ is linearly dependent is at most $|\mathbb{F}|^{t-s}$.*

Proof. Clearly, $\ell_1, \ldots, \ell_t$ are linearly dependent on V if and only if there is a nonzero linear combination $\alpha_1\ell_1 + \cdots + \alpha_k\ell_k$ that vanishes on V. Given V let us define $\mathcal{L}^* = \{\ell(x_1, \ldots, x_n) : \ell|_V = 0\}$. Note that as V is random, so is $\mathcal{L}^*$. Namely, $\mathcal{L}^*$ is a random $n-s$-dimensional subspace of linear functions. Thus, $\ell_1, \ldots, \ell_t$ are linearly dependent on V if and only if there is a nonzero function in the span of the ℓ_i's that belongs to $\mathcal{L}^*$. In other words, we have to bound the probability that a random subspace of dimension $n - s$ (i.e., $\mathcal{L}^*$) intersects a given subspace of dimension $\leq t$ (i.e., $\text{span}(\ell_1, \ldots, \ell_t)$). As the probability that a random nonzero vector belongs to a given t-dimensional subspace is $(|\mathbb{F}|^t - 1)/(|\mathbb{F}|^n - 1)$ we get by the union bound that the probability of a nontrivial intersection is upper bounded by $(|\mathbb{F}|^{n-s} - 1) \cdot (|\mathbb{F}|^t - 1)/(|\mathbb{F}^n| - 1) < |\mathbb{F}|^{t-s}$. ∎

From Corollary 19 and Lemma 21 we get the following corollary.

COROLLARY 22. *Let h be a function of exactly k linear forms.*[12] *Let V be a random subspace of dimension $\geq k + \log^2(n)$. Then the probability that $h|_V$ is not a function of exactly k linear forms is at most $|\mathbb{F}|^{-\log^2(n)}$.*

The next lemma shows that if a polynomial in k linear functions, h, has two different representations as a polynomial in exactly k linear functions, then these representations are closely related.

LEMMA 23. *Let $h(\bar{x})$ be a polynomial in exactly k linear functions. Let $P(\ell'_1, \ldots, \ell'_k) = h = Q(\ell_1, \ldots, \ell_k)$ be two different representations for h. Then $\text{span}(\{\ell'_i\}_{i\in[k]}) = \text{span}(\{\ell_i\}_{i\in[k]})$. In particular this implies that there is an invertible linear transformation $T : \mathbb{F}^k \to \mathbb{F}^k$ such that $Q(y_1, \ldots, y_k) = (P \circ T)(y_1, \ldots, y_k)$.*

Proof. Assume for a contradiction that, w.l.o.g., $\ell'_1, \ell_1, \ldots, \ell_k$ are linearly independent. Let W be the codimension 1 subspace on which ℓ'_1 vanishes. It is clear that $\ell_1|_W, \ldots, \ell_k|_W$ are linearly independent, whereas $\ell'_1|_W, \ldots, \ell'_k|_W$ are linearly dependent (as $\ell'_1|_W = 0$). In particular, by Corollary 19 we get that $h|_W$ is a function of at most $k - 1$ linear functions (when considering the representation according to the $\ell'_i|_W$'s) and is a function of exactly k linear functions (when considering the representation according to the $\ell_i|_W$'s), which is a contradiction. Now, let $T : \mathbb{F}^n \to \mathbb{F}^n$ be an invertible linear transformation taking $(\ell_i)_i$ to $(\ell'_i)_i$. Namely, $T(\ell_1(v), \ldots, \ell_k(v)) = (\ell'_1(v), \ldots, \ell'_k(v))$ for every $v \in \mathbb{F}^n$. We get that for every $v \in \mathbb{F}^n$ it holds that

$$P \circ T(\ell_1(v), \ldots, \ell_k(v)) = P(\ell'_1(v), \ldots, \ell'_k(v)) = h(v) = Q(\ell_1(v), \ldots, \ell_k(v)).$$

As the ℓ_i's are linearly independent, it follows that we must have $P \circ T = Q$ (as otherwise we will have two low degree polynomials representing the same function over a large field). ∎

4.1.2. Proof of Theorem 16. We are now ready to give the proof of Theorem 16.

[12] A linear form is a homogeneous linear function.

Proof of Theorem 16. By our assumption that $\text{rank}(f) \leq 10R_4 \cdot \log^2(d)$, we get that $\text{sim}(f)$ can be written as a polynomial in at most $10R_4 \cdot \log^2(d)$ linear functions. For simplicity we shall assume that it is a polynomial of exactly $k = \text{rank}(f)$ linear functions. Let

$$\text{sim}(f) = P(L_1, \ldots, L_k), \tag{9}$$

where $P(y_1, \ldots, y_k)$ is a polynomial and $\{L_i\}_{i=1}^k$ are linear forms. We shall later use this representation. We now analyze separately each step of the algorithm. Step 1 is an immediate application of Theorem 8 and does not require special analysis.

Step 2: Interpolating on a low dimensional random subspace. Recall that in this step we pick a random subspace $V \subseteq \mathbb{F}^n$ of dimension $s = 20R_4 \cdot \log^2(d) + \log^2(n)$, and interpolate $\text{sim}(f)$ over it. By Corollary 22 we get that with probability $\geq 1 - |F|^{-\log^2(n)}$ the polynomial $\text{sim}(f)|_V$ is a polynomial in exactly k linear functions. We now find a representation of the form $\text{sim}(f)|_V = Q(\ell_1, \ldots, \ell_k)$.

The idea is pretty simple. We go over all possible values for k (recall that we do not know k in advance). For each $k' \leq 10R_4 \cdot \log^2(d) + \log^2(n)$ we go over all possible sets of k' linearly independent linear functions over V, and for each set $\{\ell_i\}_{i \in [k']}$ we try to represent $\text{sim}(f)|_V$ as a polynomial $Q(\ell_1, \ldots, \ell_{k'})$. Note that given $\{\ell_i\}_{i \in [k']}$ we can find such a polynomial Q (if such Q exists) by a simple brute force interpolation. As this is routine, we skip it here (for completeness we give a description of this process in Appendix A).

Using the approach above we may get many different representations for $\text{sim}(f)|_V$. Among all those representations we pick one with the smallest possible k'. As mentioned above, by Corollary 22 we get that w.h.p. $k' = k$. Moreover, Corollary 20 gives a way to verify that indeed, $k' = k$. So, to conclude, after the first step of the algorithm we can be sure that[13] $k' = k$ and that we have a representation of the form $\text{sim}(f)|_V = Q(\ell_1, \ldots, \ell_k)$.

The running time of this step is dominated by the number of different subsets of at most $10R_4 \cdot \log^2(d)$ linearly independent linear functions over V. Clearly there are at most $|\mathbb{F}|^{10R_4 \cdot \log^2(d) + \log^2(n)}$ linear functions over V, and so we go over at most $|\mathbb{F}|^{(10R_4 \cdot \log^2(d) + \log^2(n)) \cdot (10R_4 \cdot \log^2(d))}$ such subsets. The brute force interpolation algorithm (as described in Appendix A) is slightly faster and so the total running time of this step is $|\mathbb{F}|^{O(\log^2(d) \cdot (\log^2(d) + \log^2(n)))} = \exp(\log|\mathbb{F}| \cdot \log^2(d) \cdot (\log^2(d) + \log^2(n)))$.

We now move to the next step, in which we show how to lift the representation of $\text{sim}(f)|_V$ to $\mathbb{F}^n$.

Step 3: Lifting from V to $\mathbb{F}^n$. Recall that in this step we look for linear functions $\{\ell_i^*\}_{i \in [k]}$ such that $\ell_i^*|_V = \ell_i$ and $\text{sim}(f) = Q(\ell_1^*, \ldots, \ell_k^*)$. The existence of such functions will follow from the next lemma.

LEMMA 24. *Let $\{L_i\}_{i \in [k]}$ be the linear functions in* (9) *and $\{\ell_i\}_{i \in [k]}$ be the linear functions found in step* 2 *of Algorithm* 3. *Assume that $\{\ell_i^*\}_{i \in [k]}$ satisfy $\ell_i^*|_V = \ell_i$ and $\text{span}\left(\{\ell_j^*\}_{j \in [k]}\right) = \text{span}\left(\{L_j\}_{j \in [k]}\right)$. Then $Q(\ell_1^*, \ldots, \ell_k^*) = \text{sim}(f)$.*

Proof. We shall use the same notations as in (9). By the assumption that $\text{span}\left(\{\ell_j^*\}_{j \in [k]}\right) = \text{span}\left(\{L_j\}_{j \in [k]}\right)$, we see that there is a polynomial $Q'(y_1, \ldots, y_k)$, of degree $\deg(Q') = \deg(P)$, such that $Q'(\ell_1^*, \ldots, \ell_k^*) = P(L_1, \ldots, L_k) = \text{sim}(f)$. By

[13] In the algorithm we do not check whether $k' = k$ (by going one dimension up, using Corollary 20) but we can just as well add such a check without much change to the running time. For the sake of simplicity we did not add this step to the algorithm.

considering the restriction to V, we get

$$Q(\ell_1,\ldots,\ell_k) = \mathrm{sim}(f)|_V = P(L_1,\ldots,L_k)|_V = Q'(\ell_1^*,\ldots,\ell_k^*)|_V$$

$$= Q'(\ell_1^*|_V,\ldots,\ell_k^*|_V) = Q'(\ell_1,\ldots,\ell_k).$$

As the functions $\{\ell_i\}_{i\in[k]}$ are linearly independent, and the degrees of Q and Q' are smaller than the size of the field, we get that $Q \equiv Q'$. In other words, $Q(y_1,\ldots,y_k)$ and $Q'(y_1,\ldots,y_k)$ are the same polynomial. In particular $Q(\ell_1^*,\ldots,\ell_k^*) = Q'(\ell_1^*,\ldots,\ell_k^*) = \mathrm{sim}(f)$, which is what we wanted to prove. □

With the help of the lemma, we now explain why step 3 indeed finds the required representation for $\mathrm{sim}(f)$. In that step we first construct $n-s$ linear spaces $\{V_i\}_{i\in[n-s]}$ of dimension $s+1$, such that $\cap_i V_i = V$ and $\mathrm{span}(\cup_i V_i) = \mathbb{F}^n$. For each such subspace we look for linear functions $\{\ell_j^{(i)}\}_{j\in[k]}$ such that $\ell_j^{(i)}|_V = \ell_j$, for every $j \in [k]$, and $Q(\ell_1^{(i)},\ldots,\ell_k^{(i)}) = \mathrm{sim}(f)|_{V_i}$. The reason that such $\ell_j^{(i)}$'s exist follows from Lemmas 23 and 24. Indeed, Lemma 23 implies that $\mathrm{span}(\{L_i|_V\}_{i\in[k]}) = \mathrm{span}(\{\ell_i\}_{i\in[k]})$. Hence, if we consider the $k \times n$ matrix A, whose rows correspond to the L_t's and columns correspond to the basis vectors $\{v_i\}_{i\in[n]}$, in which the (t,j)th position equals $L_t(v_j)$, then there exists an invertible linear transformation $T : \mathbb{F}^k \to \mathbb{F}^k$, such that for $1 \le j \le k$, the (t,j)th entry in $T \cdot A$ is equal to $\ell_t(v_j)$. It follows that if we consider the linear functions $\ell_t^{(i)}$ defined by $\ell_t^{(i)}(v_j) = (T\cdot A)_{t,j}$, for $j \in [k]\cup\{i\}$, then this gives the required $\ell_t^{(i)}$'s. In particular such $\ell_t^{(i)}$'s exist and we can find them by a simple interpolation. Therefore we are guaranteed that step 3(a) succeeds. Moreover, this argument also shows the uniqueness of the $\ell_j^{(i)}$'s (this follows from the fact that T is invertible). Hence, by the explanation above, it is clear that we can easily construct the matrix $T\cdot A$ by simply letting $(T\cdot A)_{t,j} = \ell_t^{(j)}(v_j)$ for $k < j$, and $(T\cdot A)_{t,j} = \ell_t(v_j)$ for $j \le k$. If we now pick ℓ_i^* to be the linear function defined by $\ell_i^*(v_j) = (T\cdot A)_{i,j}$, for $j \in [n]$, then by Lemma 24 we are guaranteed that $Q(\ell_1^*,\ldots,\ell_k^*) = \mathrm{sim}(f)$. This shows the correctness of step 3(b) (and the algorithmic way for constructing the ℓ_i^*'s). An interesting thing to notice is that we have no knowledge of neither the linear functions $\{L_i\}$ nor the linear transformation T, yet we are able to construct the matrix $T\cdot A$ using the (simple) conclusions of Lemmas 23 and 24.

The running time of step 3 is at most a polynomial factor times the running time of step 2. The main factor is repeating step 2 for each V_i. Then, finding the ℓ_i^*'s is quite simple and can be done in time polynomial in n, as described above. This completes the proof of Theorem 16. □

We note that as $k = O(\log^2(d))$ and $\deg(Q) \le d$, then $Q(\ell_1^*,\ldots,\ell_k^*)$ can be represented as a depth-3 circuit with quasi-polynomially many multiplication gates.

4.2. Interpolation for the high rank case. In this section we deal with the case that f has a circuit of rank higher than $10R_4\cdot\log^2(d)$. We shall use the notation $f = M_1+M_2$, where M_1 and M_2 are the two multiplication gates in the $\Sigma\Pi\Sigma(2)$ circuit for f. We note that from Corollary 7 and the assumption that $\mathrm{rank}(f) \ge 10R_4\cdot\log^2(d)$, we get that f has a unique $\Sigma\Pi\Sigma(2)$ circuit of degree d.

Before giving the algorithm itself we first describe its main steps. The algorithm follows the sketch of section 1.4. We first restrict the circuit to a low dimensional space V (where low means $\mathrm{poly}(\log d)$). Then we reconstruct $f|_V$, which is the main technical difficulty of the algorithm. Finally, we lift the circuit for $f|_V$ to a circuit for f. This step is done in a similar manner to the lifting process of Algorithm 2

(steps 3 and 4 there) and is based on the uniqueness of the circuit for f. We now say a few more words on the way to find a circuit for $f|_V$. The idea is to find a large set (of size $O(\log^2(d))$) of linearly independent linear functions $\{\ell_i\}$ that all divide, say, $M_1/\gcd(C)$. Such a set exists because of the assumption on the rank of f. Then we consider each of those linear functions and define the subspace $V_i = V|_{\ell_i=0}$ (i.e., the subspace of V on which ℓ_i vanishes).[14] Note that for every i it holds that $M_1|_{V_i} = 0$ and so by querying f on V_i we get oracle access to $M_2|_{V_i}$. Thus, by simple factoring we get all the circuits $M_2|_{V_i}$. The challenge now is to combine all of them to get the circuit $M_2|_V$. We later discuss this step in more detail. We now give the formal algorithm (Algorithm 4).

For convenience we divide the analysis of the three steps of the algorithm into three different subsections. We begin with the analysis of step 1.

4.2.1. Step 1: Interpolating on a low dimensional subspace I.

LEMMA 25. *With probability* $\geq 1 - |F|^{-\Omega(\log^2 n)}$, *over the choice of* V, *step* 1 *of Algorithm* 4, *when given oracle access to* f, *finds*[15] *a set of* $t = 100 \log d$ *linearly independent linear functions* $\{\ell_i\}_{i\in[t]}$ *such that* $\prod_{i=1}^{t} \ell_i | M_j$ *for some* $j \in \{1,2\}$, *but no* ℓ_i *divides* M_{3-j} *(the other multiplication gate). The running time of step* 1 *is* $\exp(\text{poly}(\log n, \log d, \log |\mathbb{F}|))$.

ALGORITHM 4 (general circuits of high rank).

1. **Interpolating on a low dimensional subspace I:** Pick a random subspace $V \subseteq \mathbb{F}^n$ of dimension $s \stackrel{\triangle}{=} 20R_4 \cdot \log^2(d) + \log^2(n)$. Consider the restriction $f|_V$. For every set of $t = 100\log(d)$ linearly independent linear functions $\{\ell_i\}_{i\in[t]}$ over V, check whether *for every* $i \in [t]$ the restriction of f to the (affine) subspace $V_i \stackrel{\triangle}{=} V \cap \{x : \ell_i(x) = 0\}$ is equal to a product of linear functions (by factoring).
2. **Interpolating on a low dimensional subspace II:** For each choice of $\{\ell_i\}_{i\in[t]}$, for which factoring was possible, merge (again, only if possible) the different factors into one multiplication gate (using Algorithm 5). For each multiplication gate, M, found check whether $f|_V - M$ is a product of linear functions (using the factoring algorithm from Theorem 8). If this is the case, then output the representation found for $f|_V$. If no such representation is found, then output "fail."
3. **Lifting from V to $\mathbb{F}^n$:** Lift the representation found over V to a representation over $\mathbb{F}^n$ (using the same method as in steps 3 and 4 of Algorithm 2). Namely, if $\{v_i\}_{i\in[s]}$ is a basis for V and $\{v_i\}_{i\in[n]}$ is a basis for $\mathbb{F}^n$ that extends the basis of V, then let $W_i = \text{span}(V \cup v_i)$ for $s < i \leq n$. Repeat steps 1 and 2 for each W_i to get the corresponding circuit C_i. If none of the steps failed for any of the W_i's, then combine the different C_i's to get C. Combining the circuits is done as follows. Let $\{z_i\}_{i\in[n]}$ be the dual basis to $\{v_i\}_{i\in[n]}$, i.e., $z_i(v_j) = \delta_{i,j}$. Each linear function in $C \cup \{C_i\}_{i=s+1}^{n}$ can be written as a linear combination of the z_i's and the constant function. Given a linear function ℓ in C, find the unique ℓ_i in C_i such that $\ell_i|_{z_i=0} = \ell$ (possibly after multiplying ℓ_i by a constant from $\mathbb{F}$). If no such ℓ_i exists, or if it is not unique (i.e., there is $\ell_i' \not\sim \ell_i$ with $\ell_i'|_{z_i=0} = \ell$), then output "fail." Otherwise, if $\ell = \ell_i + \alpha_i \cdot z_i$, then let $\ell' = \ell + \sum_{i=s+1}^{n} \alpha_i \cdot z_i$. Now, replace each linear function ℓ in C with the corresponding ℓ'. Denote the resulting circuit with C'. Output C'.

[14] This is actually an affine subspace, but for simplicity we assume that it is a linear space.

[15] Of course many other sets are found but only those sets interest us.

Proof. In the heart of the proof of the lemma is the fact that w.h.p., over the choice of V, we have that $\text{rank}(f)|_V \geq 10R_4 \cdot \log^2(d)$. We prove this fact in Lemma 26. It will be easy to show that when $\text{rank}(f|_V)$ is high, then the required set $\{\ell_i\}$ exists. Recall that $\gcd(C) = \text{g.c.d.}(M_1, M_2)$, and that

$$\text{sim}(C) = C/\gcd(C) = M_1' + M_2' \tag{10}$$

is a $\Sigma\Pi\Sigma(2)$ circuit. From Corollary 7 and the assumption that $\text{rank}(f) \geq 10R_4 \cdot \log^2(d)$ we get that $\text{sim}(C)$ is the unique $\Sigma\Pi\Sigma(2)$ circuit for $f/\gcd(C)$. Let $V \subseteq \mathbb{F}^n$ be a random subspace of dimension $s = 20R_4 \cdot \log^2(d) + \log^2(n)$. The following lemma shows that w.h.p. $\text{rank}(f|_V)$ is high (the intuition is the same as in Corollary 22).

LEMMA 26. $\Pr[\text{rank}(f|_V) \leq 10R_4 \cdot \log^2(d)] \leq |\mathbb{F}|^{-\Omega(\log^2 n)}$.

Proof of Lemma 26. To prove the claim we show that w.h.p. the rank of the circuit $M_1|_V + M_2|_V$ is not too small, and then, by Corollary 7, we get that this is actually the *unique* representation of $f|_V$ as a $\Sigma\Pi\Sigma(2)$ circuit. The lemma will follow from this fact.

LEMMA 27.

$$\Pr\left[\text{rank}\left(\frac{M_1|_V + M_2|_V}{\text{g.c.d.}(M_1|_V, M_2|_V)}\right) \leq 10R_4 \log^2(n)\right] \leq |\mathbb{F}|^{-\Omega(\log^2(n))}.$$

Proof of Lemma 27. In order to show that the rank of $M_1|_V + M_2|_V$ does not decrease by much, we first show that w.h.p., $\text{g.c.d.}(M_1|_V, M_2|_V) = \text{g.c.d.}(M_1, M_2)|_V$, and then using Lemma 21 we complete the proof.

LEMMA 28. $\Pr[\text{g.c.d.}(M_1|_V, M_2|_V) \neq \text{g.c.d.}(M_1, M_2)|_V] \leq d^2(|\mathbb{F}| + 1)/|\mathbb{F}|^s = |\mathbb{F}|^{-\Omega(\log^2(n))}$.

Proof of Lemma 28. It is not hard to see that $\text{g.c.d.}(M_1|_V, M_2|_V)$ is larger than $\text{g.c.d.}(M_1, M_2)|_V$ only if there are two linearly independent linear functions L_1, L_2, such that $L_i | M_i$, and such that $L_1|_V \sim L_2|_V$. The probability, over the choice of V, that this will happen is at most $(|\mathbb{F}| + 1)/|\mathbb{F}|^s$. As there are at most d^2 such pairs of linear functions, the overall probability that the degree of the g.c.d. increases is at most $d^2(|\mathbb{F}| + 1)/|\mathbb{F}|^s$. □

We continue with the proof of Lemma 27. We know that w.h.p., $\text{g.c.d.}(M_1|_V, M_2|_V) = \text{g.c.d.}(M_1, M_2)|_V$. Therefore, w.h.p.,

$$(M_1|_V + M_2|_V)/\text{g.c.d.}(M_1|_V, M_2|_V) = M_1'|_V + M_2'|_V$$

(as defined in (10)). By the assumption on $\text{rank}(f)$, we get that the rank of the linear functions in $M_1' + M_2'$ is at least $10R_4 \cdot \log^2(d)$. The result now follows by using Lemma 21 with the parameters[16] $s = 20R_4 \cdot \log^2(d) + \log^2(n)$ and $t = 10R_4 \cdot \log^2(d)$. The lemma implies that

$$\Pr\left[\text{rank}\left(M_1'|_V + M_2'|_V\right) \leq 10R_4 \cdot \log^2(d)\right] \leq |\mathbb{F}|^{-\log^2(n)}.$$

This completes the proof of Lemma 27. □

We now continue with the proof of Lemma 26. Notice that whenever $\text{rank}(M_1|_V + M_2|_V) > 10R_4 \cdot \log^2(d)$ we get by Corollary 7 that $M_1|_V + M_2|_V$ is the unique $\Sigma\Pi\Sigma(2)$ circuit for $f|_V$ of degree $\leq d$. In this case we of course get that

[16] Although the rank is at least $10R_4 \cdot \log^2(d)$, we consider only a subset of the linear functions of dimension exactly $10R_4 \cdot \log^2(d)$.

$\operatorname{rank}(f) > 10R_4 \cdot \log^2(d)$. As $\Pr\left[\operatorname{rank}\left(M_1'|_V + M_2'|_V\right) \leq 10R_4 \cdot \log^2(d)\right] \leq |\mathbb{F}|^{-\log^2(n)}$ we get that $\Pr\left[\operatorname{rank}(f) \leq 10R_4 \cdot \log^2(d)\right] \leq |\mathbb{F}|^{-\log^2(n)}$. This completes the proof of Lemma 26. □

Now that we established that (w.h.p.) $\operatorname{rank}(f|_V)$ is high we continue with the proof of Lemma 25. Assuming that $\operatorname{rank}(f|_V) \geq 10R_4 \cdot \log^2(d)$ we get that, w.l.o.g., there are at least $5R_4 \cdot \log^2(d)$ linearly independent linear functions dividing $M_1|_V$ and not $M_2|_V$. In particular there exist $t = 100 \log d$ linearly independent linear functions $\{\ell_i\}_{i\in[t]}$ such that $\prod_{i=1}^t \ell_i$ divides M_1 but no ℓ_i divides M_2.

We bound the running time in the obvious manner. During the step, we simply have to run over all sets of $t = 100 \log d$ linear functions and, for each such set $\{\ell_i\}$, check whether the functions are linearly independent and whether the restriction of f to $V_i = V \cap \{x : \ell_i(x) = 0\}$ completely factorizes to a product of linear functions. Clearly the running time is equal (up to a polynomial factor in $n, |\mathbb{F}|$) to the number of such sets. As the dimension of V is $s = 20R_4 \log^2(d) + \log^2(n)$, the number of sets that we have to consider is $|\mathbb{F}|^{100\log(d)\cdot s}$, which is quasi polynomial in n, d, and $|\mathbb{F}|$. This completes the proof of Lemma 25. □

4.2.2. Step 2: Interpolating on a low dimensional subspace II. As we showed in Lemma 25, we can assume that one of the sets of linearly independent linear functions $\{\ell_i\}_{i\in[t]}$ found in step 1 satisfies that, w.l.o.g., $\prod_{i=1}^t \ell_i$ divides $M_1|_V$ but no ℓ_i divides $M_2|_V$. When studying step 2 we will focus on this set to show that one of the output circuits is indeed $C|_V$.

Before giving the analysis of step 2 we first explain how to computes $M_2|_V$ from the different $M_2|_{V_i}$'s (given that the ℓ_i's satisfy the property above). The idea behind the reconstruction algorithm is the following. We have to reconstruct the set of linear functions appearing in $M_2|_V$. Since a linear function can divide M_2 several times we can speak about the *multiset* of linear functions dividing $M_2|_V$, which we denote with $\mathcal{L}$. As we have oracle access to each V_i, using the factoring algorithm of Theorem 8, we can assume that we have as input the t multisets $\{\mathcal{L}_i\}_{i=1}^t$, where $\mathcal{L}_i$ is the multiset composed of the linear functions dividing $M_2|_{V_i}$. What the algorithm actually does is merge the different $\mathcal{L}_i$'s to get $\mathcal{L}$. To simplify notations we shall make several assumptions on V and $\{\ell_i\}_{i\in[t]}$ that will be w.l.o.g. and will ease the reading of the algorithm.[17] First, we assume that

$$V = \{(a_1, \ldots, a_s, 0, \ldots, 0) \ : \ \forall i \ a_i \in \mathbb{F}\}.$$

Hence, every linear function defined on V is of the form

$$L(v) = \sum_{i=1}^{s} \alpha_i a_i + \alpha_0$$

for the vector $v = (a_1, \ldots, a_s, 0, \ldots, 0)$. We shall also assume that

$$\ell_i(v) = \ell_i\left((a_1, \ldots, a_s, 0, \ldots, 0)\right) = a_i.$$

In other words, we assume that ℓ_i is a projection on the ith coordinate. Notice that as we can apply linear transformations to $\mathbb{F}^n$, this can be assumed w.l.o.g.[18] Thus, by

[17] If we were to describe the most general case, then we had to use the dual basis as in step 3.

[18] Actually, ℓ_i can be an affine function and so should be of the form $a_i + \nu_i$ for some constant ν_i. However, this will not change the algorithm and will only add unnecessary complications to the presentation.

our assumption we get that $V_i = \{(a_1, \ldots, a_{i-1}, 0, a_{i+1}, \ldots, a_s, \ldots, 0) \ : \ \forall j \ a_j \in \mathbb{F}\}$. Thus, the multiset $\mathcal{L}_i$ is the multiset obtained after deleting the ith variable from all the linear functions in the multiset $\mathcal{L}$. Hence, from our assumptions (that can be made w.l.o.g.) we see that our goal is to reconstruct a multiset of linear functions $\mathcal{L}$, from its t different projections $\{\mathcal{L}_\rangle\}_{i\in[t]}$ on $s-1 \geq t-1$ variables. Algorithm 5 solves exactly this task. In fact the algorithm assumes that we have only t variables (and not s) and is still able to solve the problem. Hence, using Algorithm 5 we are able to reconstruct the set $\mathcal{L}$ and from it get $M_2|_V$.

To explain how Algorithm 5 works we shall use the following terminology. We say that a linear function T has multiplicity k in a multiset $\mathcal{T}$ if there are exactly k linear functions in $\mathcal{T}$ that are linearly dependent on T (that is, that are equal to some multiple of T). The idea behind the algorithm is the following. First, it finds a linear function $L \in \mathcal{L}_1$ that has the following property: assume that L appears k times in $\mathcal{L}_1$. Then there exists $i \in \{2, \ldots, t\}$ such that $L|_{x_i=0}$ also has multiplicity k in $\mathcal{L}_1|_{x_i=0}$. In other words, L has the property that there is no other linear function $L' \in \mathcal{L}_1$ such that L and L' together span x_i. Note that it is not clear why such a linear function L should exist; however, using known lower bounds on *locally decodable codes* (see Appendix B) we can prove its existence. Now, given such L, we note that by considering $\mathcal{L}_i$ there are exactly k linear functions $\{L_i\}_{i=1}^k$ that, after erasing their first coordinate, are equal to (a constant multiple of) $L|_{x_i=0}$. Thus, we are assured that there are exactly k linear function $\{\ell_i\}_{i=1}^k$ in $\mathcal{L}$, such that $\ell_i|_{x_1=0} = L$ and $\ell_i|_{x_i=0} = L_i$. In particular, to get ℓ_i we simply add the first coordinate of L_i to L for each $i \in [k]$ (after making the appropriate normalization). Now, we can remove the k projections of $\{\ell_i\}_{i=1}^k$ from the different $\mathcal{L}_i$'s and repeat the algorithm until no linear function is left. From this description it is clear that the main technical point is proving that such a linear function $L \in \mathcal{L}_1$ exists. We now give the formal description of Algorithm 5 and then analyze it. After that it will be clear how to analyze step 2.

ALGORITHM 5 (gluing the different $M_2|_{V_i}$'s together).

Input: Multisets of linear functions $\mathcal{L}_i = \mathcal{L}|_{x_i=0}$, for $i = 1, \ldots, t$, containing $m < \exp((t-1)/60 - 1)$ linear functions each.

Output: a multiset $\tilde{\mathcal{L}}$.

Set $\tilde{\mathcal{L}} \leftarrow \emptyset$.

1. Find a linear function $L \in \mathcal{L}_1$ and an index $1 < i \leq t$ such that the following holds: denote by k the multiplicity of L in $\mathcal{L}_1$. Then the number of $L' \in \mathcal{L}_i$ such that $L'|_{x_1=0} \sim L|_{x_i=0}$ is exactly k (and in particular, $L|_{x_i=0}$ is not a constant).
2. Denote by $\{L_j\}_{j=1}^k \subset \mathcal{L}_i$ those k linear functions. Let $\{c_j\}_{j=1}^k$ be such that $L|_{x_i=0} = c_j \cdot L_j|_{x_1=0}$. Let $a_{j,1}$ be the coefficient of x_1 in the linear function $c_j \cdot L_j$. Let $\ell_j \stackrel{\Delta}{=} L + a_{j,1} \cdot x_1$, for $j = 1, \ldots, k$.
3. Set $\tilde{\mathcal{L}} \leftarrow \tilde{\mathcal{L}} \cup \{\ell_j\}_{j\in[k]}$.
4. For each $l \in [t]$, set $\mathcal{L}_l \leftarrow \mathcal{L}_l \setminus \{\ell_j|_{x_l=0}\}_{j=1}^k$ (more accurately, remove from $\mathcal{L}_l$ k linear functions $\ell'_1, \ldots, \ell'_k$ such that $\ell'_j = \ell_j|_{x_l=0}$).
5. If the $\mathcal{L}_i$'s are empty, then return $\tilde{\mathcal{L}}$; otherwise go to step 1.

The following theorem proves correctness and gives the analysis of Algorithm 5.

THEOREM 29. *Let $\mathcal{L} = \{L_i\}_{i=1}^m$ be a multiset of linear functions in $t > 60 \log m + 61$ variables; i.e., a linear function may appear more than once in $\mathcal{L}$. Denote by $\mathcal{L}_i \stackrel{\Delta}{=} \mathcal{L}|_{x_i=0}$ the multiset resulting from $\mathcal{L}$ after removing the ith variable from all the linear functions in it. Then, given the multisets $\{\mathcal{L}_i\}_{i\in t}$, Algorithm 5 reconstructs*

a multiset $\tilde{\mathcal{L}}$ such that $\prod_{\ell\in\tilde{\mathcal{L}}}\ell = c\cdot\prod_{\ell'\in\mathcal{L}}\ell'$, for some nonzero constant c, in time polynomial in m.

Proof. First, we show that if a linear function L was found in step 1, and its multiplicity in $\mathcal{L}_1$ is k, then there are exactly k linear functions $\{\tilde{\ell}_j\}_{j\in[k]}$ in $\mathcal{L}$ that satisfy $\tilde{\ell}_j|_{x_1=0}\sim L$ for each $j\in[k]$. Moreover, these linear functions are equal, up to a multiplicative factor, to the linear functions $\{\ell_j\}_{j\in[k]}$ that were found in step 2 of the algorithm. Namely, possibly after reordering it holds that $\tilde{\ell}_j\sim\ell_j$ for $j\in[k]$. Indeed, let L and i be the linear function and index that were found in step 1 (of Algorithm 5). Denote by k the multiplicity of L in $\mathcal{L}_1$ and let $\{\tilde{\ell}_j\}_{j\in[k]}\subset\mathcal{L}$ be such that $\tilde{\ell}_j|_{x_1=0}\sim L$. From the definition of i these are exactly the functions in $\mathcal{L}$ that satisfy that $\tilde{\ell}_j|_{x_1=0,x_i=0}\sim L|_{x_i=0}$. We therefore have the following. Let a_j be such that $a_j\cdot\tilde{\ell}_j|_{x_1=0}=L$. Let c_j and L_j (for $j\in[k]$) be as in step 2. It must be the case that (possible after reordering) $a_j\cdot\tilde{\ell}_j|_{x_i=0}=c_j\cdot L_j$. In particular if we define $\ell_j=\alpha_{j,1}\cdot x_1+L$, where $\alpha_{j,1}$ is the coefficient of x_1 in $c_j\cdot L_j$, then it must be the case that $\tilde{\ell}_j\sim\ell_j$, as required (note that a different way of defining ℓ_j is by letting $\ell_j=c_j\cdot L_j+\alpha_i\cdot x_i$, where α_i is the coefficient of x_i in L). In particular this shows that step 3 adds to $\tilde{\mathcal{L}}$ linear functions that are equal to the $\tilde{\ell}_j$'s up to a constant factor and step 4 removes the "images" of those functions from the different $\mathcal{L}_i$'s. Thus, if we can always find such L and i, then we are guaranteed that the output will be a set $\tilde{\mathcal{L}}$ for which there is a 1-1 correspondence between the linear functions in $\mathcal{L}$ and those in $\tilde{\mathcal{L}}$ that matches functions that are equal up to a (nonzero) constant factor. This completes the first part of our proof.

We now prove that if $m<\exp((t-1)/60-1)$, then such L and i exist. Assume for a contradiction that no such L and i exist. Then it must be the case that for every $L\in\mathcal{L}_1$ and i there is $L'\in\mathcal{L}_1$ such that $x_i\in\operatorname{span}(L,L')$. In other words, if we consider the mapping $E:\mathbb{F}^{t-1}\to\mathbb{F}^m$ that maps $(x_2,\ldots,x_t)$ to $\{L(x_2,\ldots,x_t)\}_{L\in\mathcal{L}_1}$, then we have that for every $j\in\{2,\ldots,t\}$ there are, say, at least $m/3$ disjoint pairs of linear functions $L,L'\in\mathcal{L}_1$ such that $x_j\in\operatorname{span}(L,L')$. In other words, we can reconstruct x_j by looking at one of the $m/3$ disjoint pairs of indices in the mapping E. A mapping that satisfies this property is called a 2-query locally decodable code, and it is known (Theorem 33) that in such a code it must be the case that $m\geq\exp((t-1)/60-1)$. However, we assumed that $m<\exp((t-1)/60-1)$, and so we reached a contradiction. Hence a linear function L and an index i can be found. For completeness we discuss locally decodable codes in Appendix B.

The claim regarding the running time of Algorithm 5 is clear. This completes the proof of Theorem 29. ∎

To conclude, from Theorem 29 and the discussion at the beginning of section 4.2.2 we see that in step 2 of Algorithm 4, for one of the sets $\{\ell_i\}_{i\in[t]}$ we manage to reconstruct the multiplication gate $M_2|_V$. To be more accurate, note that for the multiset $\tilde{\mathcal{L}}$ computed in Algorithm 5 we may have that $\prod_{\ell\in\tilde{\mathcal{L}}}\ell=c\cdot\prod_{\ell'\in\mathcal{L}}\ell'$ for some nonzero constant c. However, c can be easily found by comparing $\prod_{\ell\in\tilde{\mathcal{L}}}\ell|_{x_1=0}$ to $M_2|_{x_1=0}$. Therefore, we can multiply some $\ell\in\tilde{\mathcal{L}}$ by c to get that $\prod_{\ell\in\tilde{\mathcal{L}}}\ell=\prod_{\ell'\in\mathcal{L}}\ell'=M_2|_V$.

Now, given $M_2|_V$ we can use the oracle to f to factor $f|_V-M_2|_V$ and get $M_1|_V$. In particular we compute the circuit $C|_V=M_1|_V+M_2|_V$ in step 2. We now notice that if V is such that $\operatorname{rank}(f|_V)\geq R_4\log^2(d)$ (which happens w.h.p. according to Lemma 26), then by Corollary 6 this is the only possible representation for $f|_V$ (as a $\Sigma\Pi\Sigma(2)$ circuit) and so the circuit computed at the end of this step is indeed

$M_1|_V + M_2|_V$. The running time of step 2 is equal to the number of different sets $\{\ell_i\}_{i\in[t]}$ considered times the running times of Algorithm 5 and the factoring algorithm of Theorem 8. Thus, we just proved the following theorem.

THEOREM 30. *Step 2 of Algorithm 4 runs in time* $\exp(\mathrm{poly}(\log n, \log d, \log|\mathbb{F}|))$, *and if V is such that* $\mathrm{rank}(f|_V) \geq R_4 \log^2(d)$, *then the circuit computed at the end of the step is* $C|_V = M_1|_V + M_2|_V$.

4.2.3. Step 3: Lifting. We first give the intuition behind the way that the algorithm combines the different circuits for $f|_{W_i}$. For convenience let us assume w.l.o.g., again, that

$$V = \{v = (a_1, \ldots, a_s, 0, \ldots, 0) \mid \forall i\ a_i \in \mathbb{F}\}.$$

Also assume w.l.o.g. that for $1 \leq i \leq n-s$ we have that

$$W_i = \{w = (a_1, \ldots, a_s, 0, \ldots, 0, a_{s+i}, 0, \ldots, 0) \mid \forall j\ a_j \in \mathbb{F}\}.$$

Note that as we are working with the v_i's and their dual basis $\{z_i\}$, we can make this assumption. Let us assume that $\mathrm{rank}(f|_V) \geq R_4 \cdot \log^2(d)$. Theorem 30 now guarantees that the algorithm computes correctly the circuits $C_i = M_1|_{W_i} + M_2|_{W_i}$ for $s < i \leq n$. Assume that our original $\Sigma\Pi\Sigma(2)$ for f has the following form:

$$f(\bar{x}) = \prod_{i=1}^{d} L_i^{(1)}(\bar{x}) + \prod_{i=1}^{d} L_i^{(2)}(\bar{x}),$$

where $M_1 = \prod_{i=1}^{d} L_i^{(1)}(\bar{x})$ and $M_2 = \prod_{i=1}^{d} L_i^{(2)}(\bar{x})$. Denote

$$L_i^{(k)} = \sum_{j=1}^{n} \alpha_{i,j}^{(k)} x_j + \alpha_{i,0}^{(k)}$$

for $k = 1, 2$. If $\mathrm{rank}(f|_V) > R_4 \cdot \log^2(d)$, then by Theorem 30 we get that

$$f|_{W_i} = \prod_{k=1}^{d} L_k^{(1)}(\bar{x})|_{W_i} + \prod_{k=1}^{d} L_k^{(2)}(\bar{x})|_{W_i}$$

$$= \prod_{k=1}^{d} \left(\sum_{j=1}^{s} \alpha_{k,j}^{(1)} x_j + \alpha_{k,s+i}^{(1)} x_{s+i} + \alpha_{k,0}^{(1)} \right) + \prod_{k=1}^{d} \left(\sum_{j=1}^{s} \alpha_{k,j}^{(2)} x_j + \alpha_{k,s+i}^{(2)} x_{s+i} + \alpha_{k,0}^{(2)} \right).$$

Therefore all that we have to do is to find all the linear functions of the form $\sum_{j=1}^{s} \alpha_{k,j}^{(1)} x_j + \alpha_{k,s+i}^{(1)} x_{s+i} + \alpha_{k,0}^{(1)}$, for $i \in [n-s]$, and glue them together to get all the linear functions $\{\sum_{j=1}^{n} \alpha_{k,j}^{(1)} x_j\}_k$ (similarly with $\sum_{j=1}^{s} \alpha_{k,j}^{(2)} x_j + \alpha_{k,s+i}^{(2)} x_{s+i} + \alpha_{k,0}^{(2)}$ and $\{\sum_{j=1}^{n} \alpha_{k,j}^{(2)} x_j\}_k$). To do so we must be sure that there are no two linearly independent linear functions in f that their restrictions to V are linearly dependent. Note that if such a pair exists, e.g., if $\ell|_V \sim \ell'|_V$, where ℓ and ℓ' are linearly independent, then for some W_i and constants $\alpha, \alpha', \alpha''$ such that $\alpha \neq \alpha''$, the circuit C_i will contain two different functions $\tilde{\ell} = \ell + \alpha \cdot x_i$ and $\tilde{\ell}' = \ell' + \alpha' \cdot x_i \sim \ell + \alpha'' \cdot x_i$, and we will not know which of them to attach to ℓ and which to attach to ℓ' when combining appropriate linear functions from the different C_i's.

Now, if no such pair exists, then it is very easy to combine the different circuits C_i into one circuit C' for f: for every linear function ℓ in C, that does not divide both its multiplication gates, there is a unique linear function ℓ_i in C_i such that their restrictions to $x_i = 0$ are linearly dependent (note that by Lemma 28 we can assume that g.c.d.$(M_1|_V, M_2|_V) =$ g.c.d.$(M_1, M_2)|_V$. Hence, if ℓ divides both multiplication gates in C, then there is a unique ℓ_i that divides both multiplication gates in C_i, and the continuation is the same for this case as well). Therefore there is only one way of generating a linear function L such that $\ell'|_V \sim \ell$ and $\ell'|_{x_i=0} \sim \ell_i$ for every i. This explanation shows that in step 3 we combine the different circuits in the only possible way. Moreover, it is clear that combining the C_i's into a single circuit can be done efficiently. It remains only to justify the assumption that there are no two linearly independent linear functions in f that their restrictions to V are linearly dependent.

To see that, we notice that as we picked V to be a random subspace of dimension $\Omega(\log^2(d))$, Lemma 21 assured us that with probability greater than $1-\exp(-\log^2(n))$ no two linearly independent linear functions from C become linearly dependent when restricted to V. Thus, w.h.p. we can complete this step. Notice that by the above explanation it is also very easy to verify that indeed, no two linearly independent linear functions from the circuit for f became dependent on V. The following theorem summarizes what we have shown in this section.

THEOREM 31. *Step* 3 *of Algorithm* 4 *runs in time* $\mathrm{poly}(n, d, \log|\mathbb{F}|))$ *and w.h.p. over the choice of* V *outputs the unique* $\Sigma\Pi\Sigma(2)$ *circuit for* f.

Thus, Algorithm 4 outputs w.h.p. over the choice of V the unique $\Sigma\Pi\Sigma(2)$ for f. We now show how to combine Algorithms 3 and 4 to get Theorem 2.

4.3. Completing the proof of Theorem 2. We note that if we know $\mathrm{rank}(f)$, then the algorithms described in sections 4.1 and 4.2 give the required result. As we don't know what the rank is, we run the high rank algorithm for every rank between $10R_4 \cdot \log^2(d)$ and d. Once the algorithm outputs a $\Sigma\Pi\Sigma(2)$ circuit we verify that its rank is indeed larger than $10R_4 \cdot \log^2(d)$. If this is the case, then we stop and output that circuit. Theorem 31 guarantees that w.h.p. we have found the unique $\Sigma\Pi\Sigma(2)$ circuit C' that computes f. If none of the executions of the high rank algorithm resulted in a $\Sigma\Pi\Sigma(2)$ circuit, then we run the low rank algorithm for each rank between 1 and $10R_4 \cdot \log^2(d)$.

To analyze the error probability of the algorithm we note that the possible errors are in the choice of V and in the factoring algorithm. Indeed, when we are at the "correct" rank and V is such that the rank of $f|_V$ is the same as $\mathrm{rank}(f)$ and no two linearly independent linear functions from C become linearly dependent when restricted to V, then we are assured that we compute a correct representation for f. Recall that V is "bad" for us with probability $1/p(n, d)$, where p is some quasi-polynomial function of n and d. In addition we can repeat the factoring algorithm of Theorem 8 polynomially many times to reduce the error probability. Thus the overall error is quasi-polynomially small (and can be further reduced to be exponentially small by repeating the algorithm several times). This completes the proof of the theorem.

Appendix A. Brute force interpolation. In this section we show how to interpolate a polynomial that can be written as a polynomial in a few linear functions. In fact we need to consider a slightly more complicated scenario as described in the following lemma.

LEMMA 32. *Let*[19] $h(x_1,\ldots,x_s) = \mathrm{Lin}(h)\cdot Q(\ell_1,\ldots,\ell_k)$ *be a polynomial, where* Q *is a polynomial and* $\{L_i\}_{i\in[k]}$ *are linear functions. Let* $d = \deg(h) < |\mathbb{F}|$. *Then, there is a deterministic algorithm that, given oracle access to* h, $\mathrm{Lin}(h)$, d, *and the set of linear functions* $\{\ell_i\}_{i\in[k]}$, *finds* Q. *The running time of the algorithm is* $\mathrm{poly}(|\mathbb{F}|^s, d^k)$.

Proof. Consider a generic degree d polynomial Q' in the ℓ_i's. Such a polynomial has $< (d+1)^k$ monomials of the form $\prod_{i=1}^k {\ell_i}^{e_i}$, such that $\sum_{i=1}^k e_i \le d$. Thus we have a number of unknown coefficients which we can find by a simple interpolation procedure that we now describe: let $\ell_{k+1},\ldots,\ell_s$ be linear functions such that[20] $\ell_1,\ldots,\ell_s$ form a basis to the space of linear functions over $\mathbb{F}^s$. Let

$$Q'(y_1,\ldots,y_k) = \sum_{\{\bar{e}=(e_1,\ldots,e_k):\sum e_i\le d\}} c_{\bar{e}}\cdot\prod {y_i}^{e_i}. \tag{11}$$

Next we represent $\mathrm{Lin}(h)$ as a polynomial in the ℓ_i's. Let $P_{\mathrm{Lin}}(y_1,\ldots,y_s)$ be a polynomial satisfying

$$\mathrm{Lin}(h) = P_{\mathrm{Lin}}(\ell_1,\ldots,\ell_s) = \sum_M \alpha_M\cdot M(\ell_1,\ldots,\ell_s), \tag{12}$$

where the sum is over all monomials M of degree at most d. Note that as we have oracle access to $\mathrm{Lin}(h)$, it is easy to find the α_M's (by the usual interpolation process). We get that h can be written as

$$h = P_{\mathrm{Lin}}(\ell_1,\ldots,\ell_s)\cdot Q'(\ell_1,\ldots,\ell_k) = \sum_M \gamma_M\cdot M(\ell_1,\ldots,\ell_s), \tag{13}$$

where each coefficient γ_M is a linear function in the $c_{\bar{e}}$'s. By querying h on all the points in $\mathbb{F}^s$ and using the standard interpolation method, we can easily find all the coefficients γ_M, and from them we can get the coefficients $c_{\bar{e}}$'s by solving a system of linear equations. We note that once we know the γ_M's, there is a unique solution to the $c_{\bar{e}}$'s (in case that such a solution exists). The reason is that if two different solutions exist, then they give rise to two polynomials $P_{\mathrm{Lin}}\cdot Q_1$ and $P_{\mathrm{Lin}}\cdot Q_2$ that are equal over $\mathbb{F}^s$. However, the degree of each of the polynomials is at most d, which is smaller than the size of the field that we are working with, and so the two polynomials must be the same. In particular we have that $Q' = Q$. ∎

Appendix B. Locally decodable codes. In this section we define the notion of locally decodable codes and state the result that we need. The reader interested in a more complete background is referred to [KT00, GKST06]. We start with the definition of locally decodable codes. We fix in advance some of the parameters to constants in order to simplify the definition. Let $E:\mathbb{F}^t\to\mathbb{F}^n$ be a linear map. We say that E is a 2-query locally decodable code if there exists a probabilistic oracle

[19] In section 4.1.2 we needed to interpolate $\mathrm{sim}(f)|_V$ for an s-dimensional space V, so we assume that h is a polynomial in s variables.

[20] We assume w.l.o.g. that $\ell_1,\ldots,\ell_k$ are linearly independent.

machine A such that

- A makes at most two queries (nonadaptively) to the oracle.
- for every $x \in \mathbb{F}^t$, for every $y \in \mathbb{F}^n$ with $\Delta(y, E(x)) < n/10$, and for every $i \in [t]$, we have $\Pr[A^y(i) = x_i] \geq 2/3$, where the probability is taken over the internal coin tosses of A, and $\Delta(\cdot, \cdot)$ is the Hamming distance function.

The following theorem of [DS06] gives a lower bound on the length of such locally decodable codes over arbitrary fields.

THEOREM 33 (Theorem 1.2 of [DS06]). *Let $\mathbb{F}$ be a field, and let $E : \mathbb{F}^t \to \mathbb{F}^n$ be a linear 2-query locally decodable code, as in the definition above; then $n \geq 2^{\frac{t}{60}-1}$.*

We note that Goldreich et al. [GKST06] were the first to prove a lower bound for linear locally decodable codes with two queries; however, for large fields their result is not optimal. In particular, [GKST06] proved a lower bound of the form $n \geq 2^{\Omega(t)-\log|\mathbb{F}|}$ on the length of such codes over $\mathbb{F}$, which deteriorates with the field size.

Acknowledgments. I would like to thank Amir Yehudayoff and Nader Bshouty for many helpful discussions, Erich Kaltofen and Joachim von zur Gathen for answering my questions regarding factorization algorithms, and Avi Wigderson and the anonymous reviewers for helpful comments. Thanks to Oded Goldreich and Ran Raz for their encouragement. The seed for this work was planted in the BIRS workshop "Recent Advances in Computation Complexity." I thank the organizers for inviting me and thank BIRS for hosting the workshop.

BREAKING A TIME-AND-SPACE BARRIER IN CONSTRUCTING FULL-TEXT INDICES*

WING-KAI HON†, KUNIHIKO SADAKANE‡, AND WING-KIN SUNG§

Abstract. Suffix trees and suffix arrays are the most prominent full-text indices, and their construction algorithms are well studied. In the literature, the fastest algorithm runs in $O(n)$ time, while it requires $O(n \log n)$-bit working space, where n denotes the length of the text. On the other hand, the most space-efficient algorithm requires $O(n)$-bit working space while it runs in $O(n \log n)$ time. It was open whether these indices can be constructed in both $o(n \log n)$ time and $o(n \log n)$-bit working space. This paper breaks the above time-and-space barrier under the unit-cost word RAM. We give an algorithm for constructing the suffix array, which takes $O(n)$ time and $O(n)$-bit working space, for texts with constant-size alphabets. Note that both the time and the space bounds are optimal. For constructing the suffix tree, our algorithm requires $O(n \log^{\epsilon} n)$ time and $O(n)$-bit working space for any $0 < \epsilon < 1$. Apart from that, our algorithm can also be adopted to build other existing full-text indices, such as compressed suffix tree, compressed suffix arrays, and FM-index. We also study the general case where the size of the alphabet Σ is not constant. Our algorithm can construct a suffix array and a suffix tree using optimal $O(n \log |\Sigma|)$-bit working space while running in $O(n \log \log |\Sigma|)$ time and $O(n(\log^{\epsilon} n + \log |\Sigma|))$ time, respectively. These are the first algorithms that achieve $o(n \log n)$ time with optimal working space. Moreover, for the special case where $\log |\Sigma| = O((\log \log n)^{1-\epsilon})$, we can speed up our suffix array construction algorithm to the optimal $O(n)$.

Key words. text indexing, preprocessing, suffix trees, suffix arrays

1. Introduction.

Due to the advances in information technology and biotechnology, the amount of text data is increasing exponentially. To assist users in locating their required information, the role of indexing data structures has become more and more important. For texts with a word boundary such as English, inverted index [7] is used since it enables fast queries and is space efficient. However, for texts without word boundary, such as DNA/protein sequences or Chinese/Japanese texts, inverted index is not suitable. In this case, we need full-text indices, that is, indexing data structures which make no assumption on the word boundary. Suffix trees [20] and suffix arrays [19] are two fundamental full-text indices in the literature that find applications in numerous areas, including data mining [28] and biological research [8]. For the other full-text indices, almost all of them originate from these two data structures.

Suffix trees and suffix arrays are very useful since they allow us to perform pattern searching efficiently. Consider a text with n characters. Given the suffix tree, we can search for a pattern P within the text using $O(|P|)$ time, which is independent of the text size. For the suffix array, the searching time is $O(|P| + \log n)$,[1] which is only a bit slower. One more advantage of the suffix array is that even if this indexing structure is placed in external memory, it still can achieve good I/O performance for searching [3]. In spite of that, suffix trees and suffix arrays cannot be built easily when n is large. The construction algorithms for both of them either are too slow or require too much working space.

For instance, when we optimize the construction time, based on the work from Weiner [30], McCreight [20], Ukkonen [29], and Farach [4], a suffix tree and a suffix array can be built in $O(n)$ time. However, the working space required is $\Omega(n \log n)$ bits.

On the other hand, when we optimize the construction working space, based on the recent work by Lam et al. [18], we can first build the compressed suffix array (CSA) of [6] and then convert it into the suffix tree and the suffix array. Although such an approach reduces the working space to $O(n)$ bits, the execution time is increased to $O(n \log n)$. Another solution is to rely on external memory [3] to control the working space. However, the time complexity, not to mention the increase in I/O burden, is even worse.

It was open whether the suffix tree and the suffix array can be constructed in $o(n \log n)$ time and $o(n \log n)$-bit working space. The need to break this time-and-space barrier is illustrated in a concrete example that arises in practice. Suppose we would like to construct a suffix array for a human genome (of length approximately 3 billion). The fastest known algorithm runs in linear time. However, it requires 40 gigabytes working space [17]. Such a memory requirement far exceeds the capacity of ordinary computers. On the other hand, if we apply the most space-efficient algorithm, the working space required is roughly 3 gigabytes, which is possible to implement on a PC nowadays. The time required, however, is more than 20 hours [18], which is a bit slow.

Apart from suffix trees and suffix arrays, we observe that the other full-text indices also suffer from the same time-and-space barrier during the construction phase. Such a barrier may prevent these indices from becoming useful for large-scale applications.[2] Table 1 summarizes the performance of the best known algorithms for constructing these full-text indices.

1.1. Our results. Our results are based on the following model. First, we assume a unit-cost RAM with a word size of $O(\log U)$ bits, where $n \leq U$, in which standard arithmetic and bitwise boolean operations on word-sized operands can be performed in constant time [1, 9]. Second, to compare our work fairly with the other main-memory algorithms, we add the following assumptions: (1) We restrict our algorithms to running within the main memory, in which no I/O operations are involved in the intermediate steps; (2) for counting the working space, we do not include the space for the output of the full-text indices (this can be justified, as output can be written directly to the secondary storage upon completion without occupying the main memory). Under the above model, this paper proposes the following construction

[1] We use the notation $\log_b^c n = (\log n / \log b)^c$ to denote the cth power of the base-b logarithm of n. Unless specified otherwise, we use $b = 2$.

[2] Zobel, Moffat, and Ramamohanarao [32] and Crauser and Ferragina [3] both mentioned the importance of construction algorithms to the usefulness of the index.

TABLE 1

Construction times for full-text indices. The acronyms ST, SA, CST, CSA, FM represent suffix tree, suffix array, compressed suffix tree, compressed suffix array, and FM-index, respectively. Also, ϵ is any fixed real number with $0 < \epsilon < 1$.

Index	Algorithm	Time	Space (bits)
SA, CSA, or FM	opt time [19]	$O(n)$	$O(n \log n)$
	opt space [18]	$O(n \log n)$	$O(n)$
	this paper	$O(n)$	$O(n)$
ST or CST	opt time [4]	$O(n)$	$O(n \log n)$
	opt space [12]	$O(n \log n)$	$O(n)$
	this paper	$O(n \log^{\epsilon} n)$	$O(n)$

algorithms for full-text indices, where the input text is assumed to be over a constant-size alphabet:

1. An algorithm which constructs the suffix array in $O(n)$ time and $O(n)$-bit working space;
2. an algorithm which constructs the suffix tree in $O(n \log^{\epsilon} n)$ time and $O(n)$-bit working space for $0 < \epsilon < 1$.

To the best of our knowledge, these are the first algorithms known to run in $o(n \log n)$ time and $o(n \log n)$-bit working space.

Our algorithms can actually be adopted to build other full-text indices, including the CSA, CST [12], and FM-index [5]. The performance of our algorithms for constructing these indices is summarized in Table 1. Another application of our algorithm is that it can act as a time- and space-efficient algorithm for block sorting [2], which is a widely used process in various compression schemes, such as `bzip2` [27].

We also study the general case where the alphabet size is not constant. Let Σ be the alphabet, and let $|\Sigma|$ denote its size. Our algorithm can construct the suffix array and the suffix tree using $O(n \log |\Sigma|)$-bit working space, while running in $O(n \log \log |\Sigma|)$ time and $O(n(\log^{\epsilon} n + \log |\Sigma|))$ time, respectively, for any fixed ϵ with $0 < \epsilon < 1$. These are the first algorithms that achieve $o(n \log n)$ time with optimal working space. Moreover, for the special case where $\log |\Sigma| = O((\log \log n)^{1-\epsilon})$, we can apply Pagh's data structure for constant-time rank queries [24] to further improve the running time of the suffix array construction to the optimal $O(n)$.

Remark. Recently, Na and Park [23] proposed another algorithm for the construction of the CSA, FM-index, and the (BW) transform. The running time is $O(n)$ time, which is independent of the alphabet size. The working space is increased slightly to $O(n \log |\Sigma| \log^{\alpha}_{|\Sigma|} n)$ bits, where $\alpha = \log_3 2$.

1.2. The main techniques. To achieve a small working space, we use the Ψ function [6] of the CSA and the BW text [2] as our tools, where they can act as an implicit representation of any suffix tree generated during construction. Both the Ψ function and the BW text can be stored in $O(n)$-bit space. Moreover, given them, we can construct the suffix tree and the suffix array in $O(n \log^{\epsilon} n)$ time and $O(n)$ time, respectively, for $0 < \epsilon < 1$.

Apart from the space concern, another reason for using these two data structures as our tools is that each one's strength complements nicely the other's weaknesses: The Ψ function allows for efficient pattern query, while it is difficult to update the function in response to the change in the underlying suffix tree; the plain BW text can be easily and quickly updated, though it does not support efficient pattern query. In our construction algorithm, efficient queries and fast updates are frequently required, so we use both data structures alternately in order to utilize their strengths.

Another finding that leads to improvement is related to the backward search algorithm, which is used to find a pattern within the text based on the Ψ function. If we apply a known method [26], given the Ψ function for the text, each step of the algorithm requires $O(\log n)$ time in general. This paper presents a novel auxiliary data structure of $O(n)$ bits which supports each backward search step in $O(\log\log|\Sigma|)$ time instead. As our construction algorithm frequently executes the backward search, the overall running time is thus sped up because of this improvement.

Finally, our algorithm borrows the framework of Farach's linear-time suffix tree construction algorithm [4], which first constructs two suffix trees, one for odd-position suffixes and another for even-position suffixes, and then merges the two trees together. The difference, however, lies in the actual implementation, as we have carefully avoided storing the suffix pointers explicitly, thus saving $O(n\log n)$ bits in total.

The remainder of this paper is organized as follows. Section 2 is a preliminary section, which gives the definitions for the CSA and BW text and discusses the relationship between them. Section 3 shows the improved result in the backward search algorithm. Section 4 describes the framework for the construction algorithm, while sections 5 and 6 detail the main steps of the algorithm. In section 7, we give details on the improvement we can achieve when the alphabet size is sufficiently small, precisely when $\log|\Sigma| = O((\log\log n)^{1-\epsilon})$. Finally, we give a conclusion in section 8.

2. Preliminaries. This section is divided into three parts. The first part gives the basic notation and introduces the suffix array, the Ψ function, and the BW text. In the second part, we describe the representation of the Ψ function that is used throughout the paper. Finally, in the third part we discuss the duality between the Ψ function and the BW text.

2.1. Basic notation. First, we review some of the basic notation and assumptions. A text T of length n over an alphabet Σ is denoted by $T[0\ldots n-1]$. Each character of Σ is uniquely encoded by an integer in $[0,|\Sigma|-1]$, which occupies $\log|\Sigma|$ bits. In addition, a character c is alphabetically larger than a character c' if and only if the encoding of c is larger than the encoding of c'. Also, we assume that $T[n-1]$ is a special character that does not appear elsewhere in the text.

For any $i=0,\ldots,n-1$, the string $T[i\ldots n-1]$ is called a suffix of T. The suffix array $\mathrm{SA}[0\ldots n-1]$ of T is an array of integers such that $T[\mathrm{SA}[i]\ldots n-1]$ is lexicographically the ith smallest suffix of T. The Ψ_T function, or simply Ψ, is the main component of the CSA [6]. It is defined as follows:

- $\Psi[i]=\mathrm{SA}^{-1}[\mathrm{SA}[i]+1]$ if $\mathrm{SA}[i]\neq n-1$;
- $\Psi[i]=\mathrm{SA}^{-1}[0]$ otherwise.

Immediately, we have the following observation.

OBSERVATION 1. *For the suffix array and the Ψ function of the text T,*

1. *characters $T[\mathrm{SA}[i]]$ $(i=1,2,\ldots,n)$ are alphabetically sorted.*
2. *suppose that $T[\mathrm{SA}[i]]=T[\mathrm{SA}[j]]$. Then $\Psi[i]<\Psi[j]$ if and only if $i<j$.*

On the other hand, the BW text W [2] is a transformation on T such that $W[i]=T[\mathrm{SA}[i]-1]$ if $\mathrm{SA}[i]>0$, and $W[i]=T[n-1]$ otherwise. Intuitively, $W[i]$ is the preceding character of the ith smallest suffix of T in T. This transformation process is widely used in various compression schemes, such as `bzip2` [27], and it constitutes the main part of the construction of the FM-index [5].

See Figure 1 for an example of the suffix array, the Ψ function, and the BW text of a string $S=$ `acaaccg$`. In the example, we have $\Sigma=\{\mathtt{a},\mathtt{c},\mathtt{g},\mathtt{t}\}$, and the last character of S is \$, which is unique among the other characters in S. We also assume that \$ is alphabetically smaller than each character in Σ.

i	$W[i]$	SA$[i]$	$\Psi[i]$	$S[\text{SA}[i] \dots n-1]$
0	g	7	2	$
1	c	2	3	a a c c g $
2	$	0	4	a c a a c c g $
3	a	3	5	a c c g $
4	a	1	1	c a a c c g $
5	a	4	6	c c g $
6	c	5	7	c g $
7	c	6	0	g $

FIG. 1. *Suffix array, the Ψ function, and the BW text W of a string $S =$* acaaccg$.

2.2. Representation of Ψ. Observation 1 implies that the Ψ function is piecewise increasing. In addition, each Ψ value is less than n. Therefore, we can use a function $\rho(c, x) = enc(c) \cdot n + x$ and obtain a total increasing function $\Psi'[i] = \rho(T[SA[i]], \Psi[i])$, where $enc(c)$ denotes the encoding of the character c. Note that value of Ψ' is less than $n|\Sigma|$.

Based on the total increasing property, Ψ' can be stored as follows. We divide each $\Psi'[i]$, which takes $\log n + \log|\Sigma|$ bits, into two parts q_i and r_i, where q_i is the first (or most significant) $\log n$ bits, and r_i is the remaining $\log|\Sigma|$ bits. We encode the values $q_0, q_1 - q_0, \dots, q_{n-1} - q_{n-2}$ in a bit-vector B_1 using unary codes. (Recall that the unary code for an integer $x \geq 0$ is encoded as x 0's followed by a 1.) Note that the encoding has exactly n 1's where the $(i+1)$th 1, which corresponds to $\Psi[i]$, is at position $i + q_i$. Also, the total number of 0's is q_{n-1}, which is at most n. Thus, B_1 uses $2n$ bits. The r_i's are stored explicitly in an array $B_2[0 \dots n-1]$, where each entry occupies $\log|\Sigma|$ bits. Thus, B_2 occupies $n \log|\Sigma|$ bits. Moreover, an auxiliary data structure of $O(n/\log\log n)$ bits is constructed in $O(n)$ time to enable constant-time *rank* and *select* queries, and thus supporting the retrieval of any q_i in constant time [13, 22]. Then, the total size is $n(\log|\Sigma| + 2) + o(n)$ bits. Since q_i and r_i can be retrieved in constant time, so can $\Psi'[i] = |\Sigma|q_i + r_i$. This gives the following lemma.

LEMMA 1. *The Ψ' function can be encoded in $O(n \log|\Sigma|)$ bits so that each $\Psi'[i]$ can be retrieved in constant time.*

COROLLARY 1. *The Ψ function can be encoded as Ψ' in $O(n \log|\Sigma|)$ bits so that each $\Psi[i]$ can be retrieved in constant time.*

Proof. The retrieval time follows since $\Psi[i] = \Psi'[i] \bmod n$. □

2.3. Duality between Ψ and W. It is known that Ψ and W are one-to-one corresponding. In the section, we show that the transformation between them can be done in linear time and in $O(n \log|\Sigma|)$-bit space.

We first give a property relating W and Ψ.

DEFINITION 1. *Given an array of characters $x[0 \dots n-1]$, we define the* stable sorting order *of $x[i]$ in x to be the number of characters in x which is alphabetically smaller than $x[i]$, plus the number of characters $x[j]$ with $j < i$ which is equal to $x[i]$. This is in fact the position of $x[i]$ after stable sorting.*

LEMMA 2 (see [2]). *Let k be the stable sorting order of $W[i]$ in W. Then, $\Psi[k] = i$.*

Proof. Let Y_i denote the suffix $T_{\text{SA}[i]-1}$ when SA$[i] > 0$, and the suffix $T[n-1]$ otherwise. Note that when $i < j$, if Y_i and Y_j are starting with the same character, Y_i will be lexicographically smaller than Y_j. The reason is that, by excluding the first character, the remaining part of Y_i (which is $T_{\text{SA}[i]}$) is lexicographically smaller than the remaining part of Y_j (which is $T_{\text{SA}[j]}$). Also, observe that the first character of Y_i

is equal to $W[i]$. Then, it follows that the stable sorting order of $W[i]$ in W is equal to the rank of Y_i among the set of all Y_i's, which is the set of all suffixes of T.

Thus, we have $k = \mathrm{SA}^{-1}[\mathrm{SA}[i] - 1]$ when $\mathrm{SA}[i] > 0$, and $k = \mathrm{SA}^{-1}[n-1]$ otherwise. In the former case, $\mathrm{SA}[k] = \mathrm{SA}[i] - 1 < n - 1$, so $\Psi[k] = \mathrm{SA}^{-1}[\mathrm{SA}[k] + 1] = \mathrm{SA}^{-1}[\mathrm{SA}[i]] = i$. For the latter case, we have $i = \mathrm{SA}^{-1}[0]$ and $\mathrm{SA}[k] = n - 1$. Thus we have $\Psi[k] = \mathrm{SA}^{-1}[0] = i$. In summary, $\Psi[k] = i$ for all cases, and the lemma follows. □

The next two lemmas show the linear-time conversion between W and Ψ.

LEMMA 3. *Given W, we can store Ψ in $O(n)$ time and in $O(n \log |\Sigma|)$ bits. The working space is $O(n \log |\Sigma|)$ bits.*

Proof. The conversion is simply based on counting sort. We present the details below for completeness. We construct Ψ' in section 2.2 from W as an encoding of Ψ (Corollary 1). To construct Ψ', we create a bit-vector $B_1[0 \ldots 2n-1]$ and initialize all bits to 0. We also create an array $B_2[0 \ldots n-1]$, where each entry occupies $\log |\Sigma|$ bits.

Now, we show how to compute the stable sorting order of $W[i]$ in W, for $i = 0, 1, 2, \ldots$. To do so, we use three auxiliary arrays. The first array is L_1 such that $L_1[c]$ stores the number of occurrences of the character c in W. This array can be initialized by scanning W once. The second array is L_2 such that $L_2[c]$ stores the number of occurrences of a character that is smaller than c in W. This array can be initialized by scanning L_1 once. Finally, the third array is L_3 such that $L_3[c]$ stores the number of occurrences of c seen so far. Initially, all entries of L_3 are initialized to 0.

Now, we proceed to read $W[0]$, $W[1]$, and so on. Note that during the process, when we read a character c, we maintain the correctness of L_3 by increasing $L_3[c]$ just before the next character is read. Thus, at the beginning of step i, the counter $L_3[W[i]]$ will be storing the number of occurrences of $W[i]$ in $W[0 \ldots i-1]$, and the stable sorting order of $W[i]$ can be computed by $L_2[W[i]] + L_3[W[i]]$.

Let k be the stable sorting order of $W[i]$ that is computed at step i in the above algorithm. By Lemma 2, $\Psi[k] = i$. Thus, we have $\Psi'[k] = x = \rho(T[\mathrm{SA}[k]], \Psi[k]) = \rho(W[i], i)$. By our scheme, x is divided into two parts q and r, where $q = x \text{ div } |\Sigma|$ is the first $\log n$ bits, and $r = x \bmod |\Sigma|$ is the remaining bits. For q, a 1 is stored at $B_1[k+q]$. For r, it is stored at $B_2[k]$.

As the stable sorting order of each $W[i]$ is different, all possible $\Psi[k]$'s will be eventually computed and stored. A summary of the overall algorithm is shown in Figure 2. It is easy to see that the overall time is $O(n + |\Sigma|)$. For the space complexity, note that L_1, L_2, and L_3 each occupies $|\Sigma| \log n$ bits, which is at most $n \log |\Sigma|$ bits because $|\Sigma| \leq n$. Thus, we use $O(n \log |\Sigma|)$-bit working space. □

LEMMA 4. *Given Ψ and T, we can store W in $O(n)$ time and in $O(n \log |\Sigma|)$ bits. The working space is $O(n \log |\Sigma|)$ bits.*

Proof. Let $t = \mathrm{SA}^{-1}[0]$. Then, we have $\Psi[t] = \mathrm{SA}^{-1}[1]$. In general, $\Psi^k[t] = \mathrm{SA}^{-1}[k]$.

Hence, we have $W[\Psi^k[t]] = T[k-1]$. To construct W, we can first compute t. Recall that $T[n-1]$ is a unique character in T. By scanning T, we compare each character of T with $T[n-1]$. Then, we obtain the value $x = \mathrm{SA}^{-1}[n-1]$, which is equal to the number of occurrences of a character in T that is smaller than $T[n-1]$. Then, by definition, $\Psi[x] = \mathrm{SA}^{-1}[0]$, which is equal to t. Thus, t can be found in $O(n)$ time. Afterwards, we iteratively compute $\Psi^i[t]$ and set $W[\Psi^i[t]] = T[i-1]$, for $i = 1 \ldots n$. As $\Psi^i[t]$ corresponds to the rank of a different suffix of T for different i, all

1. Compute $L_1[c]$ to store the number of occurrences of each $c \in \Sigma$.
2. Compute $L_2[c]$ to store the number of occurrences of a character that is smaller than c. That is, $L_2[c] = \sum_{d<c} L_1[c]$ for $c \in \Sigma$.
3. Let L_3 be an array such that $L_3[c]$ stores the number of occurrences of the character c seen so far.
4. Initialize all entries of L_3 to be 0.
5. For $i = 1, 2, \ldots, n$,
   Let $c = W[i]$, $k = L_2[c] + L_3[c]$.
   Compute $x = \rho(c, i)$.
   Let $q = x$ div $|\Sigma|$, $r = x \bmod |\Sigma|$.
   Set $B_1[k + q] = 1$ and $B_2[k] = r$.
   Increase $L_3[c]$ by one.
6. Compute the $O(n/\log\log n)$-bit auxiliary data structure for B_1.

FIG. 2. *Computing* Ψ *from* W.

the characters of W will be eventually computed and stored by the above algorithm. The total time of the algorithm is $O(n)$, and the spaces for W, T, and Ψ are all $O(n \log |\Sigma|)$ bits. The lemma thus follows. □

3. Improving the backward search algorithm. Let S be a text of length m over an alphabet Δ. In this section, we present an $O(m + |\Delta|)$-bit auxiliary data structure for the Ψ function of S that improves each step in the backward search algorithm from $O(\log m)$ time to $O(\log\log |\Delta|)$ time.

We first present in section 3.1 a data structure that supports fast rank query and show that such a data structure can be constructed efficiently in terms of time and working space. Then, in section 3.2, we describe the improved backward search algorithm based on the result of section 3.1.

3.1. Efficient data structure for fast rank query. Let Q be a set of distinct numbers. For any integer x, the *rank* of x in Q is the number of elements in Q smaller than x. We begin with two supporting lemmas prior to the description of our data structure. The first one is on a perfect hash function, which is obtained by rephrasing the result of section 4 of [10] as follows.

LEMMA 5. *Given x b-bit numbers, where $b = \Theta(\log x)$, a data structure of size $O(xb)$ bits supporting an $O(1)$-time existential query can be constructed in $O(x \log x)$ time and $O(xb)$-bit working space.*

The second lemma is derived from a result in [21, 31] based on Lemma 5.

LEMMA 6. *Given z w-bit numbers, where $w = \Theta(\log z)$, a data structure of size $O(zw^2)$ bits supporting $O(\log w)$-time* rank *queries can be constructed in $O(zw \log(zw))$ time and $O(zw^2)$-bit working space.*

Proof. It is shown that *rank* queries can be solved in $O(\log w)$ time if the existential query for all prefixes of the z numbers can be answered in $O(1)$ time [21, 31].[3] The

[3] In the original papers, the results are for another query called *predecessor*, which finds the largest element in the z numbers that is smaller than the input w-bit number k. However, such a result can be modified easily for the *rank* query as follows. For each number i in the z numbers, it is replaced by the number iz + the rank of i (so that the number now has $w + \log z$ bits), and we construct the *predecessor* data structure for these modified numbers. For the intended *rank* query, we first try to find the predecessor for kz in the modified numbers, and if no predecessor is found, the rank of k in the z numbers is 0. Otherwise, let this predecessor be p. It is easy to see that the required result is equal to (p mod z) + 1.

idea is that, given a w-bit number k, its longest common prefix with the z numbers can be found by binary search (on the length) using $O(\log w)$ existential queries, and such a prefix uniquely determines the *rank* of k.

Notice that only $O(zw)$ strings can be a prefix of the z numbers, and each can be represented in $\Theta(w)$ bits. Applying Lemma 5 on this set of strings (with $x = O(zw)$ and $b = \Theta(w)$), we have the required data structure. The lemma thus follows. □

Now, we are ready to describe our new data structure, whose performance is summarized below.

THEOREM 1. *Let Q be a set of n numbers, each of length $\Theta(\log n)$ bits. Then, a data structure of size $O(n \log n)$ bits supporting an $O(\log \log n)$-time* rank *query in Q can be constructed in $O(n)$ time and $O(n \log n)$-bit working space.*

Proof. We construct the following data structure for Q:

1. Let $k_0 < k_1 < \cdots < k_{n-1}$ be n numbers of Q stored in ascending order by an array.
2. Partition the n numbers into n/w^2 lists, each containing w^2 numbers. Precisely, the lists are in the form $\{k_i, k_{i+1}, \ldots, k_{i+w^2-1}\}$, where $i \equiv 0 \pmod{w^2}$.
3. Let the smallest element in each list be its representative. Construct a data structure for *rank* query for these representatives based on Lemma 6.

The above data structure occupies $O(nw)$ bits and can be constructed in $O(n)$ time and $O(nw)$-bit working space. With such a data structure, the *rank* of x among the n numbers can be found in $O(\log w)$ time as follows.

1. Find the *rank* of x among the n/w^2 representatives of the lists. Let this be r.
2. Then, the *rank* of x among the n numbers must now lie in $[rw^2, (r+1)w^2 - 1]$. Do a binary search on the w^2 elements $\{k_{rw^2}, k_{rw^2+1}, \ldots, k_{(r+1)w^2-1}\}$ to find the *rank* of x.

Both steps thus take $O(\log w)$ time. This completes the proof of Theorem 1. □

Note that, in contrast to the existing data structures for the *rank* query [13, 25], our data structure requires either less space for storage (when compared with [13]) or less time in the construction (when compared with [25]); the drawback is a blow-up in query time. Based on Theorem 1, we can use some extra space to achieve a more generalized result, as shown in the following corollary.

COROLLARY 2. *Let Q' be a set of n values, each of length $\log \ell + \Theta(\log n)$ bits for any ℓ. Then, a data structure of size $O(n \log n + \ell)$ bits supporting an $O(\log \log n)$-time* rank *query in Q' can be constructed in $O(n + \ell)$ time and $O(n \log n + \ell)$-bit working space.*

Proof. The idea is to apply Theorem 1 by transforming the set Q' into another set such that each value takes only $\Theta(\log n)$ bits. First, we scan Q' and create a bit-vector $B[0 \ldots \ell - 1]$ such that $B[i] = \texttt{1}$ if there is some number in Q' whose first $\log \ell$ bits represent a value i, and $B[i] = \texttt{0}$ otherwise. Afterwards, we construct an auxiliary data structure for B of size $o(\ell)$ bits to support constant-time *rank* and *select* queries [13, 22].

Now, we transform each number in Q' as follows: If the first $\log \ell$ bits of the number represent the value i, these bits are replaced by the binary bit-sequence for the rank of i in B. Note that the rank of i is less than n, as there are only n numbers. Thus, after the transformation, each value takes $\Theta(\log n)$ bits, and, in addition, the transformation preserves the ordering among the elements in Q'.

Let the set of the transformed values be Q. We create the data structure of Theorem 1 on Q. To perform a *rank* query for x in Q' (we assume that x has the same length as any number in Q'), we first obtain the first $\log \ell$ bits of x. Suppose that these bits represent the value i_x. Then there are two cases.

Case 1. If $B[i_x] = 1$, we replace the first $\log \ell$ bits of x by the $\log n$-bits that represent the rank of i_x in B, and obtain a new value y. Then, it is easy to see that the rank of x in Q' is equal to the rank of y in Q.

Case 2. Otherwise, we replace the first $\log \ell$ bits of x by the $\log n$-bits that represent the rank of i_x in B, while setting the remaining $\Theta(\log n)$ bits to zeros, and obtain a new value z. Then, it is easy to see that the rank of x in Q' is equal to the rank of z in Q.

Finally, for the time and space complexity, B and its auxiliary data structures can be created in $O(\ell)$ time and stored in $\ell + o(\ell)$ bits, while the data structure for the *rank* query in Q can be created in $O(n)$ time and stored in $O(n \log n)$ bits (by Theorem 1). The lemma thus follows. □

3.2. The improved backward search algorithm. First, a *backward search step* is defined as follows.

DEFINITION 2. *For any pattern P, suppose that the rank of P among all suffixes of S is known. A* backward search step *then computes the rank of cP among the suffixes of S for any character $c \in \Delta$.*

Let Ψ' denote the total increasing function such that $\Psi'[i] = \rho(S[\mathrm{SA}[i]], \Psi[i])$ and $\rho(c, x) = enc(c) \cdot m + x$. Then, we have the following lemma.

LEMMA 7. *Let r be the rank of P among all suffixes of S. Then, the rank of cP among all suffixes of S is equal to $j \in [0, m]$ such that $\Psi'[j-1] < \rho(c, r) \leq \Psi'[j]$. (As a sentinel, we let $\Psi'[-1] = -1$ and $\Psi'[m] = m|\Delta|$.)*

Proof. It is easy to check that for all $i = 0, 1, \ldots, j-1$, the rank-i suffix of S must either start with a character smaller than c or start with c but with the remaining part lexicographically smaller than P. Thus, for all $i = 0, 1, \ldots, j-1$, the rank-i suffix of S is lexicographically smaller than cP. On the other hand, for all $i \geq j$, the rank-i suffix of S is lexicographically greater than or equal to cP. Thus, the rank of cP is j. □

Essentially, a backward search step that computes the rank of cP in the above lemma is equivalent to finding the rank of $\rho(c, r)$ in the set of all Ψ' values. Then based on the data structure for the *rank* query in section 3.1 (Corollary 2), we can obtain the main result of this section as follows.

LEMMA 8. *Let S be a text of length m over an alphabet Δ. Suppose that the Ψ function of S is given, which is stored as Ψ' using the scheme in section 2.2. Then, an auxiliary data structure for the Ψ function of S can be constructed in $O(m+|\Delta|)$ time, which supports each backward search step in $O(\log \log |\Delta|)$ time. The space requirement is $O(m + |\Delta|)$ bits.*

Proof. Let V denote the set of all Ψ' values. To prove the lemma, it suffices to show a data structure of $O(m + |\Delta|)$ bits that supports the *rank* query for any x in V in $O(\log \log |\Delta|)$ time.

First, recall that in our encoding of Ψ', each value in V is stored in two parts, where the first $\log m$ bits are encoded by unary codes in a bit-vector B_1, and the remaining $\log |\Delta|$ bits are encoded in an array B_2 as it is. In addition, there is an auxiliary data structure supporting constant-time *rank* and *select* queries.

Let G_i be the set of Ψ' values whose first $\log m$ bits represent the value i. Among the sets of G_i's, we are concerned with those sets whose size is greater than $\log |\Delta|$. Let $G_{i_1}, G_{i_2}, \ldots, G_{i_k}$ be such sets, where $i_1 < i_2 < \cdots < i_k$.

Note that each of the groups $G_{i_1}, G_{i_2}, \ldots, G_{i_k}$ has size between $\log |\Delta|$ and $|\Delta|$. Now, we combine the groups, from left to right, into supergroups of size $\Theta(|\Delta|)$. More precisely, we start from G_{i_1}, merge it with G_{i_2}, G_{i_3}, and so on, until the size exceeds $|\Delta|$. Then, we merge the next unmerged group with its succeeding group and

so on, until the size exceeds $|\Delta|$. The process is repeated until all groups are within a supergroup. (To ensure that each supergroup has size $\Theta(|\Delta|)$, we add a dummy group $G_m = \{m|\Delta|, m|\Delta|+1, \ldots, (m+1)|\Delta|-1\}$ as a sentinel.)

For each supergroup $\mathcal{G}$, let $v_0, v_1, \ldots, v_p$ be its $\Theta(|\Delta|)$ elements. Now, we pick every $\log|\Delta|$ elements (i.e., $v_0, v_{\log|\Delta|}, v_{2\log|\Delta|}, \ldots$), subtract each of them by v_0, and make them the representatives of this supergroup. Then, we construct the data structure for the *rank* query of Corollary 2 over these representatives.

With the above data structure, a *rank* query for any x in $\mathcal{G}$ can be supported as follows. We first check if $x \leq v_0$. If so, the *rank* of x is 0. Otherwise, we find the *rank* of $x - v_0$ among the representatives, which takes $O(\log\log|\Delta|)$ time. Suppose the rank is r. Then, the rank of x in $\mathcal{G}$ must lie between $r\log|\Delta|$ and $(r+1)\log|\Delta|-1$, and this can be found by a binary search in the elements $\{v_{r\log|\Delta|}, \ldots, v_{(r+1)\log|\Delta|-1}\}$, which takes $O(\log\log|\Delta|)$ time. In summary, the time required is $O(\log\log|\Delta|)$.

Now, let us complete the whole picture to show how to perform the *rank* query for x in V. First, we extract the first $\log m$ bits of x by dividing it with $|\Delta|$. Let $i' = x \text{ div } |\Delta|$ be its value. Next, we determine the size of $G_{i'}$, which can be done in constant time using rank and select queries on B_1. If the size is 0 (i.e., $G_{i'}$ is empty), the rank of x in V can be computed immediately (precisely, the required rank is equal to the number of 1's in $B_1[0 \ldots i'-1]$, which can be computed in constant time using B_1 and its auxiliary data structure). If the size is smaller than $\log|\Delta|$, the rank of x can be found by performing a binary search with the elements in $G_{i'}$, which takes $O(\log\log|\Delta|)$ time. Finally, if the size is greater than $\log|\Delta|$, we locate the supergroup $\mathcal{G}$ that contains the elements of $G_{i'}$, and we retrieve the rank r of its smallest element v_0 in V. Then, the required rank is r plus the rank of x in $\mathcal{G}$. We now claim that locating the supergroup and retrieving r can be done in constant time (to be proved shortly), so that the total time is $O(\log\log|\Delta|)$.

We prove the above claim as follows. To support finding the smallest element in each supergroup, and retrieval of its rank in V, we use a bit-vector B_1' of $O(m)$ bits, obtained from B_1 by keeping only those 1's whose corresponding Ψ' value is a smallest element in some supergroup. Also, we augment B_1' with constant-time *rank* and *select* data structures. Then, the smallest value of the $(i+1)$th supergroup, and its rank in V, can be found by consulting B_1 and B_1' in constant time. In addition, for any G_i (with size greater than $\log|\Delta|$), the rank of its supergroup among the other supergroups can be found by consulting B_1' in constant time.

On the other hand, to support locating the *rank* data structure of the supergroup, we first analyze the space requirement of these data structures. For a particular supergroup $\mathcal{G} = \{v_0, v_1, \ldots, v_p\}$, the data structure is built for $p/\log\Delta = \Theta(\Delta/\log\Delta)$ elements, each of which has value in $[0, v_p - v_0]$, so that the space is $O(v_p - v_0 + \frac{p}{\log|\Delta|} \cdot \log|\Delta|)$ bits (by Corollary 2), which is $O(v_p - v_0)$ bits since $p \leq v_p - v_0$. Thus, the total space requirement is $O(m + |\Delta|)$ bits,[4] and we assume that the data structures of the supergroups are stored consecutively according to the rank of its smallest element. Then, we create a bit-vector B_3 whose length is identical to the above data structures, which is used to mark the starting position of each data structure. Also, we augment the bit-vector with an $o(m+|\Delta|)$-bit auxiliary data structure to support constant-time *rank* and *select* queries. Thereafter, when we want to locate a supergroup for G_i, we find its rank r among the other supergroups using B_1', and then this rank-r supergroup can be accessed in constant time using B_3.

[4]The additional $O(|\Delta|)$ bits are due to the dummy group G_m.

In summary, our data structure takes a total space of $O(m+|\Delta|)$ bits and supports each backward search step in $O(\log\log|\Delta|)$ time. For the construction, it takes at most $O(m+|\Delta|)$ time. The lemma thus follows. □

4. The framework for constructing the CSA and the FM-index. Recall that $T[0\ldots n-1]$ is a text of length n over an alphabet Σ, and we assume that $T[n-1]$ is a special character that does not appear elsewhere in T. This section describes how to construct the Ψ function and the BW text W of T in $O(n\log\log|\Sigma|)$ time. Our idea is based on Farach's framework for linear-time construction of the suffix tree [4], which first constructs the suffix tree for even-position suffixes by recursion, based on which it induces the suffix tree for odd-position suffixes, and then merges the two suffix trees to obtain the required one.

For our case, we first assume that the length of T is a multiple of $2^{\lceil\log\log_{|\Sigma|}n\rceil+1}$. (Otherwise, we add enough \$ and a \$′ at the end of T, where \$′ is a character alphabetically smaller than the other characters in T, and proceed with the algorithm. The Ψ of this modified string can be converted into the Ψ of T in $O(n)$ time.) Let h be $\lceil\log\log_{|\Sigma|}n\rceil$. For $0\le k\le h$, we define T^k to be the string over the alphabet Σ^{2^k}, which is formed by concatenating every 2^k characters in T to make one character. That is, $T^k[i]=T[i\cdot 2^k+1\ldots(i+1)\cdot 2^k-1]$, for $1\le i\le n/2^k$. By definition, $T^0=T$.

In addition, we introduce the following definitions associated with a string. For any string $S[0\ldots m-1]$ with even number of characters, denote S_e and S_o to be the strings of length $m/2$ formed by *merging* every 2 characters in $S[0\ldots m-1]$ and $S[1\ldots m-1]S[0]$, respectively; more precisely, $S_e[i]=S[2i]S[2i+1]$ and $S_o[i]=S[2i+1]S[2i+2]$, where we set $S[m]=S[0]$. Intuitively, the suffixes of S_e and S_o correspond to the even-position and odd-position suffixes of S, respectively. We have the following observation.

OBSERVATION 2. $T_e^i=T^{i+1}$.

Also, note that the last characters of T_o^i and T_e^i are unique among the corresponding string. This makes the results in sections 2 and 3 applicable for both texts.

Our basic framework is to use a bottom-up approach to construct Ψ of T^i, or Ψ_{T^i}, for $i=\lceil\log\log_{|\Sigma|}n\rceil$ down to 0, thereby obtaining Ψ of T in the end. Precisely,

- for step $i=\lceil\log\log_{|\Sigma|}n\rceil$, Ψ_{T^i} is constructed by first building the suffix tree for T^i using Farach's algorithm [4] and then converting it back into the Ψ function.
- for the remaining steps, we construct the Ψ_{T^i} based on the $\Psi_{T^{i+1}}$, the latter of which is in fact $\Psi_{T_e^i}$ by Observation 2. We first obtain $\Psi_{T_o^i}$ based on T^i and $\Psi_{T_e^i}$. Afterwards, we merge $\Psi_{T_o^i}$ and $\Psi_{T_e^i}$ to give Ψ_{T^i}. The complete algorithm is shown in Figure 3.

1. For $i=\lceil\log\log_{|\Sigma|}n\rceil$,
   (a) construct suffix tree for T^i.
   (b) construct Ψ_{T^i} from the suffix tree.
2. For $i=\lceil\log\log_{|\Sigma|}n\rceil-1$ to 0,
   (a) construct $\Psi_{T_o^i}$ based on $\Psi_{T_e^i}$. (Note: $\Psi_{T_e^i}=\Psi_{T^{i+1}}$.)
   (b) construct Ψ_{T^i} based on the $\Psi_{T_o^i}$ and $\Psi_{T_e^i}$.

FIG. 3. *The construction algorithm of Ψ function of T.*

Sections 5 and 6 describe in details how to obtain $\Psi_{T_o^i}$ from $\Psi_{T_e^i}$ and T^i, and how to merge $\Psi_{T_o^i}$ and $\Psi_{T_e^i}$ to obtain Ψ_{T^i}, respectively. This gives the main theorem of this section.

THEOREM 2. *The Ψ function and the BW text W of T can be constructed in $O(n \log\log|\Sigma|)$ time and $O(n \log|\Sigma|)$-bit working space.*

Proof. We refer to the algorithm in Figure 3, which has two phases. For phase 1, we have $i = \lceil \log\log_{|\Sigma|} n \rceil$. We first construct the suffix tree for T^i whose size is $n/2^{\lceil \log\log_{|\Sigma|} n \rceil} \leq n \log|\Sigma|/\log n$. This requires $O(n \log|\Sigma|/\log n)$ time and $O(n \log|\Sigma|)$-bit space by using Farach's suffix tree construction algorithm [4]. Then, Ψ_{T^i} can be constructed in $O(n \log|\Sigma|/\log n)$ time and $O(n \log|\Sigma|)$-bit working space. Thus, phase 1 in total takes $O(n)$ time and $O(n \log|\Sigma|)$-bit space.

For every step i in phase 2, we construct Ψ_{T^i}. Let Δ_i be the alphabet of T^i. Then, part (a) takes $O(|T^i| + |\Delta_i|)$ time (Lemma 12), and part (b) takes $O(|T^i| \log\log|\Delta_i| + |\Delta_i|)$ time (Lemma 14). For the space, both require $O(|T^i| \log|\Delta_i| + |\Delta_i|)$ bits. Note that $|T^i| = n/2^i$ and $|\Delta_i| \leq |\Sigma|^{2^i} \leq n$, so the space used by step i is $O(|T^i| \log|\Delta_i| + |\Delta_i|) = O(n \log|\Sigma|)$ bits, and the time is $O(|T^i| \log\log|\Delta_i| + |\Delta_i|) = O((n/2^i) \cdot (i + \log\log|\Sigma|) + |\Sigma|^{2^i})$. In total, the space for phase 2 is $O(n \log|\Sigma|)$ bits and the time is

$$\sum_{i=1}^{\lceil \log\log_{|\Sigma|} n \rceil - 1} O\left(\frac{n}{2^i}(i + \log\log|\Sigma|) + |\Sigma|^{2^i}\right) = O(n \log\log|\Sigma|).$$

The whole algorithm for constructing Ψ of T therefore takes $O(n \log\log|\Sigma|)$ time and $O(n \log|\Sigma|)$-bit space. Finally, the BW text W can be constructed from Ψ using Lemma 4 in $O(n)$ time and $O(n \log|\Sigma|)$-bit space. This completes the proof. □

Once the BW transformation is completed, the FM-index can be created by encoding the transformed text W using move-to-front encoding and run-length encoding [5]. When the alphabet size is small, precisely, when $|\Sigma| \log|\Sigma| = O(\log n)$, move-to-front encoding and run-length encoding can be done in $O(n)$ time based on a precomputed table of $o(n)$ bits. In summary, this encoding procedure takes $O(n)$ time using $o(n)$-bit space in addition to the output index. Thus, we have the following result.

THEOREM 3. *The FM-index of T can be constructed in $O(n \log\log|\Sigma|)$ time and $O(n \log|\Sigma|)$-bit working space, when $|\Sigma| \log|\Sigma| = O(\log n)$.*

4.1. Further discussion. The compressed suffix tree (CST) [12] is a compact representation of the suffix tree taking $O(n \log|\Sigma|)$ bits of space. The core of the CST consists of (1) the CSA of the input text, (2) parentheses encoding of the tree structure of the suffix tree, and (3) an *Hgt* array that enables efficient computation of the longest common prefix (LCP) query. It is shown in [12, 11] that once the CSA of the input text is computed, the CST can be constructed in $O(n \log^\epsilon n)$ time and $O(n \log|\Sigma|)$-bit working space, for any fixed ϵ with $0 < \epsilon < 1$.

Once the CST is constructed, we can simulate a preorder traversal of the original suffix tree in $O(n(\log^\epsilon n + \log|\Sigma|))$ time [12, 11], thereby constructing the original suffix tree along the traversal. Summarizing, we have the following result.

THEOREM 4. *The CST and suffix tree of T can be constructed in $O(n \log^\epsilon n)$ time and $O(n(\log^\epsilon n + \log|\Sigma|))$ time, respectively, for any fixed ϵ with $0 < \epsilon < 1$. Both construction algorithms require $O(n \log|\Sigma|)$-bit working space.*

FIG. 4. *Consider* $S =$ acaaccg$. (a) *The relationship between* $x[i]$, $y[i]$, *and* X_i. *Note that* X_i *corresponds to a suffix of* S_o. (b) *After stable sorting on the array* x, *the array* y *becomes* C_o.

5. Constructing Ψ_{S_o}. Given $S[0 \dots m-1]$ and Ψ_{S_e}, this section describes how to construct Ψ_{S_o}. Our approach is indirect, as prior to obtaining Ψ_{S_o}, we need to construct the BW text C_o of S_o.

Let Δ be the alphabet of S. Define $x[0 \dots m/2-1]$ to be an array of characters such that $x[i] = S[2SA_e[i]-1]$, where $2SA_e[i]-1$ is computed in modulo-m arithmetic. Let X_i be the string $x[i]S_e[SA_e[i] \dots m/2-1]S[0]$.

OBSERVATION 3. X_i *is a suffix of* S_o *if* $SA_e[i] \neq 0$. *Otherwise, the first character of* X_i *is* $S[m-1]$, *which is unique among other characters in* S.

Let X be the set $\{X_k | 0 \leq k \leq m/2-1\}$. Intuitively, X is the same as the set of suffixes of S_o. See Figure 4(a) for an example of X_i.

LEMMA 9. *The stable sorting order of* $x[i]$ *in* x *equals the rank of* X_i *in* X.

Proof. By omitting the first character of every X_i, we see that these X_i's are of the form $S_e[SA_e[i] \dots m/2-1]S[0]$, which are already sorted. Thus, the rank of X_i is equal to the stable sorting order of $x[i]$ in x. □

LEMMA 10. *Given* Ψ_{S_e} *and* S, *we can construct* C_o *in* $O(m + |\Delta|)$ *time and* $O(m \log |\Delta| + |\Delta|)$*-bit space.*

Proof. Let $y[0 \dots m/2-1]$ be an array such that $y[i]$ stores the two characters that immediately precede $x[i]$ in S (i.e., $S[2SA_e[i]-3]S[2SA_e[i]-2]$). In fact, $y[i]$ is the preceding character of X_i in S_o. Using a similar approach as in Lemma 4, x and y can be computed in $O(m)$ time, and both arrays occupy $O(m \log |\Delta|)$ bits.

To construct C_o, we perform a stable sort on x as in Lemma 3, and we iteratively compute the stable sorting order k of $x[i]$, which is equal to the rank of X_i by Lemma 9. During the process, we set $C_o[k] = y[i]$. The total time is $O(m + |\Delta|)$ and the total space is $O(m \log |\Delta| + |\Delta|)$ bits. See Figure 4 for an example. □

LEMMA 11. Ψ_{S_o} *can be constructed from* C_o *in* $O(m+|\Delta|)$ *time and* $O(m \log |\Delta| + |\Delta|)$*-bit space.*

Proof. The proof is similar to that of Lemma 3. □

Thus, we conclude this section with the following lemma.

LEMMA 12. *Given* Ψ_{S_e} *and* S, *we can construct* Ψ_{S_o} *in* $O(m + |\Delta|)$ *time and* $O(m \log |\Delta| + |\Delta|)$*-bit space.*

6. Merging Ψ_{S_o} and Ψ_{S_e}. In this section, we construct Ψ_S from Ψ_{S_o} and Ψ_{S_e}. The idea is to determine the rank of any suffix of S among all suffixes of S, and based on this information, we construct the BW text C of S. Finally, we convert C to Ψ_S by Lemma 3.

Let s be any suffix of S. Observe that the rank of s among the suffixes of S is equivalent to the sum of the rank of s among the odd-position suffixes and that among the even-position suffixes of S. Based on this observation, we can construct the C array (the BW transformation of S) as follows.

First, we construct the auxiliary data structures of Lemma 8 for Ψ_{S_o} and for Ψ_{S_e}. Next, we perform backward searches for S_e on Ψ_{S_o} and Ψ_{S_e} simultaneously by Lemma 7, so that at step i, we obtain the ranks of $S_e[m/2-i \ldots m/2-1]$ among the odd-position suffixes and even-position suffixes of S, respectively. By summing these two ranks, we get the rank k of $S_e[m/2-i \ldots m/2-1]$ among all suffixes of S. Then, we set $C[k]$ to be $S[m-2i-1]$, which is the preceding character of the suffix $S[m-2i \ldots m-1] = S_e[m/2-i \ldots m/2-1]$.

Similarly, we perform a simultaneous backward search for S_o on Ψ_{S_o} and Ψ_{S_e} to complete the remaining entries of C. Thus, we obtain C by $O(m)$ backward search steps. The algorithm is depicted as MERGECSA in Figure 5.

MERGECSA

1. Construct the auxiliary data structures for Ψ_{S_o} and for Ψ_{S_e} to support efficient backward search.
2. Backward search for S_e on Ψ_{S_o} and Ψ_{S_e} simultaneously, and
   (a) at step i, we obtain the rank of $S_e[m/2-i \ldots m/2-1]$ among the odd-position suffixes and that among the even-position suffixes of S. Let the sum of the ranks be k.
   (b) Set $C[k] = S[m-2i-1]$.
3. Backward search for S_o on Ψ_{S_o} and Ψ_{S_e} simultaneously, and fill in $C[k]$ accordingly.

FIG. 5. *Merging* Ψ_{S_o} *and* Ψ_{S_e}.

The following lemma shows the correctness of our algorithm.

LEMMA 13. *The algorithm* MERGECSA *in Figure* 5 *constructs* $C[0 \ldots m-1]$ *correctly.*

Proof. Recall that for every suffix $S[i \ldots m-1]$, $C[SA^{-1}[i]]$ equals the preceding character of $S[i \ldots m-1]$. For every even-position suffix $S[i \ldots m-1] = S_e[i/2 \ldots m/2-1]$, step 2 computes its rank k among all odd-position and even-position suffixes. By definition, $k = SA^{-1}[i]$. Therefore, step 2 correctly assigns $C[k]$ to be the preceding character of $S[i \ldots m-1]$. By the same argument, step 3 handles the odd-position suffixes and correctly assigns $C[SA^{-1}[i]]$ to be the preceding character of $S[i \ldots m-1]$.

Therefore, after steps 2 and 3, MERGECSA completely constructs $C[0 \ldots m-1]$. The lemma thus follows. □

By Lemma 8, the auxiliary data structures can be constructed in $O(m+|\Delta|)$ time and $O(m+|\Delta|)$-bit space, and then each backward search step is done in $O(\log\log|\Delta|)$ time. On the other hand, the Ψ function occupies $O(m\log|\Delta|)$-bit space. Thus, we have the following lemma.

LEMMA 14. *Given* Ψ_{S_o} *and* Ψ_{S_e}, *we can construct* Ψ_S *in* $O(m\log\log|\Delta|+|\Delta|)$ *time and* $O(m\log|\Delta|+|\Delta|)$*-bit space.*

7. Improvement when $\log|\Sigma| = O((\log\log n)^{1-\epsilon})$. In case the alphabet size is small, precisely, when $\log|\Sigma| = O((\log\log n)^{1-\epsilon})$, we can improve the construction time of the CSA and the FM-index to $O(n)$, which is optimal. The improvement is based on the following data structure of Pagh for supporting constant-time rank queries [24].

THEOREM 5 (see [24]). *Given* n *distinct numbers in* $[0, m-1]$ *such that* $m = n\log^{O(1)} n$, *a data structure of size* $B + O(\frac{n(\log\log n)^2}{\log n})$ *bits supporting constant-*

time rank *queries can be constructed in* $O(n)$ *time and* $O(B)$*-bit space, where* $B = \lceil \log \binom{m}{n} \rceil = n \log \frac{m}{n} + O(n)$.

We apply the same algorithm as in section 4 for the construction of the CSA, but we make changes only in the encodings of Ψ_{T^i}, for $i < \log\log\log|\Sigma|$. For those values of i, we have $|T^i| = n/2^i$, and the alphabet size of T^i is $|\Sigma|^{2^i}$. When $\log|\Sigma| = O((\log\log n)^{1-\epsilon})$, we have $|\Sigma|^{2^i} = \log^{O(1)}|T^i|$.[5] Thus, the total increasing sequence of such Ψ'_{T^i}'s can be encoded by Theorem 5, and each backward search step on these Ψ functions can be done in constant time. This gives the following theorem.

THEOREM 6. *If* $\log|\Sigma| = O((\log\log n)^{1-\epsilon})$*, the CSA, FM-index and BW text* W *of* T *can be constructed in* $O(n)$ *time and* $O(n \log|\Sigma|)$*-bit working space.*

Proof. We refer to the algorithm in Figure 3. After the change in the encodings of Ψ_{T^i} for $i < \log\log\log|\Sigma|$, the time required by each phase is as follows.

- Phase 1 takes $O(n)$ time;
- for $i \geq \log\log\log|\Sigma|$, step i in phase 2 takes $O((n/2^i)\cdot(i + \log\log|\Sigma|) + |\Sigma|^{2^i})$ time;
- for $i < \log\log\log|\Sigma|$, step i in phase 2 takes $O(n/2^i + |\Sigma|^{2^i})$ time.

It follows that the total time required is $O(n)$. For the space complexity, it remains $O(n \log|\Sigma|)$ bits. Thus, the CSA and the BW text W of T can be constructed in the stated time and space, while the FM-index can be constructed in $O(n)$ time and $O(n \log|\Sigma|)$-bit space once W is obtained. This completes the proof. □

8. Concluding remarks. We have shown that suffix trees, suffix arrays, and other full-text indices can be constructed in $o(n \log n)$ time and $o(n \log n)$-bit space, giving a positive answer to an open problem.

Recently, linear-time algorithms for constructing suffix arrays have been proposed [15, 16, 14]. Though using interesting techniques, those algorithms require $O(n \log n)$-bit working space, and they will imply only $O(n \log^{\epsilon} n)$ time algorithms for constructing suffix arrays if the working space is limited to $O(n \log|\Sigma|)$ bits. Thus, the algorithm proposed in this paper is best suited for suffix array construction under practical consideration, where the input text is very long but the alphabet size is small.

One of the open problems remaining is whether we can construct a suffix tree in optimal $O(n)$ time for texts with general alphabet, while using optimal $O(n \log|\Sigma|)$-bit working space. Another direction of research is to further reduce the working space for constructing full-text indices from $O(n \log|\Sigma|)$ bits to an input-dependent $O(nH)$ bits, where H is the entropy of the input text.

LINEAR-TIME HAPLOTYPE INFERENCE ON PEDIGREES WITHOUT RECOMBINATIONS AND MATING LOOPS*

MEE YEE CHAN†, WUN-TAT CHAN‡, FRANCIS Y. L. CHIN†, STANLEY P. Y. FUNG§, AND MING-YANG KAO¶

Abstract. In this paper, an optimal linear-time algorithm is presented to solve the haplotype inference problem for pedigree data when there are no recombinations and the pedigree has no mating loops. The approach is based on the use of graphs to capture SNP, Mendelian, and parity constraints of the given pedigree. This representation allows us to capture the constraints as the edges in a graph, rather than as a system of linear equations as in previous approaches. Graph traversals are then used to resolve the parity of these edges, resulting in an optimal running time.

1. Introduction.

The modeling of human genetic variation is critical to the understanding of the genetic basis for complex diseases. *Single nucleotide polymorphisms* (SNPs) [5] are the most frequent form of this variation, and it is useful to analyze *haplotypes*, which are sequences of linked SNP genetic markers (small segments of DNA) on a single chromosome. In diploid organisms, such as humans, chromosomes come in pairs, and experiments often yield *genotypes*, which blend haplotypes for the chromosome pair. This gives rise to the problem of inferring haplotypes from genotypes.

Before defining our problem, some preliminary definitions are needed. The physical position of a marker on a chromosome is called a *locus* and its state is called an *allele*. Without loss of generality, the allele of a *biallelic* SNP can be denoted by 0 and 1, and a haplotype with m loci is represented as a length-m string in $\{0,1\}^m$, and a genotype as a length-m string in $\{0,1,2\}^m$. Haplotype pair $\langle h_1, h_2\rangle$ is *SNP-consistent* with genotype g if where the two alleles of h_1 and h_2 are the same at the same locus, say 0 (respectively, 1), the corresponding locus of g is also 0 (respectively, 1), which denotes a *homozygous* locus; otherwise, where the two alleles of h_1 and h_2 are different, the corresponding locus of g is 2, which denotes a *heterozygous* locus (i.e., SNP). A genotype with s heterozygous loci can have 2^{s-1} SNP-consistent haplotype solutions. For example, genotype $g = 012212$ with $s = 3$ has four SNP-consistent haplotype pairs: $\{\langle 01\underline{1}1\underline{1}1, 01\underline{0}0\underline{1}0\rangle, \langle 01\underline{1}1\underline{1}0, 01\underline{0}0\underline{1}1\rangle, \langle 01\underline{1}0\underline{1}1, 01\underline{0}1\underline{1}0\rangle, \langle 01\underline{1}0\underline{1}0, 01\underline{0}1\underline{1}1\rangle\}$.

A *pedigree* is a fundamental connected structure used in genetics. Figure 1 shows the pictorial representation of a pedigree with four nodes, with a square representing

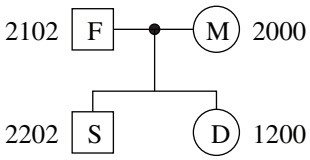

FIG. 1. *Example of a pedigree with four nodes.*

a male node and a circle representing a female node and children placed under their parents: in particular, a *father* (node F), a *mother* (node M), and two *children* (son node S and daughter node D). Each node in the pedigree is associated with a genotype. In Figure 1, for example, 2102 is the genotype for F and 2000 is the genotype for M. We assume that there are no *mating loops*; i.e., the pedigree does not contain loops. For example, marriage between descendants of a common ancestor forms a mating loop. However, polygamy or remarriage is allowed in the sense that stepchildren can exist. A precise definition of a mating loop will be given in section 2. Note that mating loops are rare in real data sets, especially for humans [2].

A *consistent haplotype configuration* (with no recombinations) for a given pedigree is an assignment of a pair of haplotypes to each individual node such that (i) all the haplotype pairs are SNP-consistent with their corresponding genotypes and (ii) the haplotypes of each child are *Mendelian-consistent*; i.e., one of the child's haplotype is exactly the same as one of its father's and the other is the same as one of its mother's.

Haplotyping Pedigree Data (with No Recombinations) Problem (HPD-NR): Given a pedigree P where each individual node of P is associated with a genotype, find a consistent haplotype configuration (CHC) for P.

Wijsman [7] proposed a 20-rule algorithm, and O'Connell [4] described a genotype elimination algorithm, both of which can be used for solving the HPD-NR problem. Li and Jiang [2] formulated the problem as a system of linear equations with $O(mn)$ equations and $O(mn)$ variables, where n is the number of individuals in the pedigree and m is the number of loci for each individual. The equations are then solved by Gaussian elimination. This gives a $O(m^3n^3)$ time algorithm. Xiao, Liu, Xia, and Jiang [8] later improved the time complexity to $O(mn^2 + n^3 \log^2 n \log\log n)$. For the case without mating loops, their algorithm runs in $O(mn^2 + n^3)$ time.

It has long been conjectured that an $O(mn)$ time algorithm exists, but it should be appreciated that finding such an algorithm has been elusive and far less straightforward than many researchers have initially thought.

In this paper, we propose a new 4-stage algorithm that can either find a CHC solution or report "no solution" in optimal $O(mn)$ time when the pedigree has no mating loops. The main idea of our algorithm is to construct a tree to model the predigree. Each vertex in the tree represents a haplotype; i.e., each genotype corresponds to a pair of vertices. Different types of edges are added between the nodes to enforce the SNP and Mendelian consistencies. This is carried out gradually in Stages 1 and 2 in our algorithm, and Stage 3 is to add more edges to unify vertices of the same haplotype so that a connected tree is formed. The main difficulty in our approach is to resolve the correct alleles at the heterozygous loci in the CHC solution. We have developed a routine to resolve the heterozygous loci for tree vertices in a connected component, which is executed in Stages 2, 3, and 4. As a connected tree is formed after Stage 3, either a CHC solution is constructed or "no solution" is reported. This approach allows us to find a CHC solution without (directly) solving a system of linear equations, as in previous approaches [2, 8].

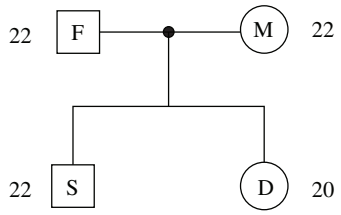

FIG. 2. *Pedigree with a family problem.*

2. Preliminaries.

DEFINITION 1 (pedigree graph and mating loop). *A* pedigree graph *is a graph derived naturally from the pedigree as follows. Each individual in the pedigree becomes a node in the graph. Whenever two individuals mate and produce children, there is an additional* mating node*, and there are undirected edges connecting the mating node to the two parents as well as to each of the children. A* mating loop *is a cycle in the pedigree graph, and a pedigree does not have a mating loop if the associated pedigree graph does not have cycles; i.e., the pedigree graph is a tree. A* trio *consists of a father, a mother and one of their children. A* nuclear family *consists of a father, a mother, and all of their (shared) children.*

We assume without loss of generality that the pedigree, and hence the pedigree graph, is connected.

DEFINITION 2 (family problem). *If there exists a family with father* F*, mother* M*, and two children* C_1 *and* C_2 *in the pedigree and two loci i and j such that i and j are heterozygous in* F*,* M*, and* C_1 *but are homozygous and heterozygous, respectively, in* C_2*, then we say that the pedigree has a* family problem*.*

Figure 2 gives a simple example of a pedigree with a family problem. It can be easily checked that this, and any other pedigree with a family problem, has no CHC solution.

For each trio T, we define $het(T)$ as the set of all loci that are heterozygous for the father, the mother, and the child in T, and $hom(T)$ as the set of all loci that are heterozygous for the father and the mother but homozygous for the child. These two sets for all trios can be computed easily in $O(mn)$ time.

Consider a nuclear family, which consists of a number of trios. The following observation is crucial: the nuclear family has no family problem if and only if for any two trios T_i, T_j in the family, $het(T_i)$ and $het(T_j)$ are either identical or disjoint. Note that $het(T_i) \cup hom(T_i) = het(T_j) \cup hom(T_j)$. Using this observation, we can check the pedigree for family problems in $O(mn)$ time as follows.

LEMMA 1. *The family problems in the pedigree can be identified in* $O(mn)$ *time.*

Proof. Consider each nuclear family in the pedigree. We maintain sets $S_0, S_1, \ldots$ of trios where trios belonging to the same S_i have identical $het()$'s and trios belonging to different S_i's have disjoint $het()$'s. We extend the definition of $het()$ and $hom()$ to S_i naturally: $het(S_i)$ is the set of loci in $het(T)$ for $T \in S_i$, and $hom(S_i)$ is similarly defined. S_0 is a special set of trios with empty $het()$, and initially $S_1 = \{T_1\}$ where T_1 is a trio with non-empty $het()$. We then consider each trio one by one, and do the following:

For each new trio T,
- (a) If $het(T)$ is empty, add T to S_0 and go to next T.
- (b) Otherwise, for each S_i, $i \geq 1$,
  - (i) If some loci in $het(S_i)$ are in $hom(T)$ but some are in $het(T)$, report *"family problem"* and halt.

(ii) Else if all loci in $het(S_i)$ are in $hom(T)$, go to next i. If this is the last i, create a new S_j with T as a member, and go to next T.
(iii) Else (all loci in $het(S_i)$ are in $het(T)$) check whether all other loci in T are homozygous. If this is false, then report *"family problem"* and halt. If this is true, add this T as a member of S_i, and skip to next T (no need to test the other S_j's).

The processing of each trio takes $O(m)$ time even though it may need to compare with all S_i (and there can be $O(n)$ of them), because the running time of steps (b)(i) and (b)(ii) is $O(|het(S_i)|)$, and the sum of all $|het(S_i)|$ is at most m. Thus the checking of family problems over the entire pedigree takes $O(mn)$ time. □

3. The algorithm.

3.1. Stage 1—setting up the local graph *G*.

Stage 1A—Checking for family problems. Our algorithm begins by checking for family problems. Only if there are no family problems will the algorithm continue; otherwise, "no solution" is reported.

Stage 1B—Generating vector-pairs. For each trio in the given pedigree, let the respective genotypes of the father F, the mother M, and the child C be: $x_1x_2\dots x_m$, $y_1y_2\dots y_m$, and $z_1z_2\dots z_m$ where $x_i, y_i, z_i \in \{0,1,2\}$. We determine a pair of vectors (or vector-pair) each for the father, the mother, and the child, namely: $\langle f_1, f_2\rangle$, $\langle m_1, m_2\rangle$, and $\langle c_1, c_2\rangle$, respectively, where $f_1 = x_{1,1}x_{1,2}\dots x_{1,m}$ and $f_2 = x_{2,1}x_{2,2}\dots x_{2,m}$; $m_1 = y_{1,1}y_{1,2}\dots y_{1,m}$ and $m_2 = y_{2,1}y_{2,2}\dots y_{2,m}$; $c_1 = z_{1,1}z_{1,2}\dots z_{1,m}$ and $c_2 = z_{2,1}z_{2,2}\dots z_{2,m}$. The vector-pairs are determined in the following manner.

1. For each locus i, for f_1 and f_2:
   (a) If $x_i = 0$, then $x_{1,i} = x_{2,i} = 0$.
   (b) If $x_i = 1$, then $x_{1,i} = x_{2,i} = 1$.
   (c) If $x_i = 2$ and $z_i = 0$, then $x_{1,i} = 0$ and $x_{2,i} = 1$.
   (d) If $x_i = 2$ and $z_i = 1$, then $x_{1,i} = 1$ and $x_{2,i} = 0$.
   (e) If $x_i = 2$ and $z_i = 2$ and $y_i = 0$, then $x_{1,i} = 1$ and $x_{2,i} = 0$.
   (f) If $x_i = 2$ and $z_i = 2$ and $y_i = 1$, then $x_{1,i} = 0$ and $x_{2,i} = 1$.
   (g) If $x_i = 2$ and $z_i = 2$ and $y_i = 2$, then $x_{1,i} = ?$ and $x_{2,i} = ?$.
2. m_1 and m_2 are similarly determined.
3. Set $\langle c_1, c_2\rangle = \langle f_1, m_1\rangle$. Check that $\langle c_1, c_2\rangle$ is consistent with C's genotype $z_1z_2\dots z_m$; otherwise, report *"no solution."* □

The vector-pairs are the initial assignment of haplotypes, assuming that C inherits f_1 from F and m_1 from M, i.e., $\langle c_1, c_2\rangle = \langle f_1, m_1\rangle$. For example, in Step 1(c), $z_i = 0$ and, hence, $z_{1,i} = z_{2,i} = 0$. Since c_1 is inherited from f_1, we can conclude $x_{1,i} = 0$ and, therefore, $x_{2,i} = 1$. When there is not enough information to deduce the value of a locus in the haplotype, a ? is used.

Observe that if a particular node N in the pedigree belongs to k different trios, then k vector-pairs, or $2k$ vectors, will be created for N in Stage 1B. These need to be unified eventually as a single vector-pair, because there is only one pair of haplotype for each node. This will be handled later when Endgame-consistency is defined, but first notice that we can define SNP-consistency and Mendelian-consistency in terms of vector-pairs. Let Φ(N) be the multiset comprised of these k vector-pairs of a node N. It is sometimes convenient to refer to the vectors rather than the vector-pairs. Thus, we let Γ(N) be the multiset of $2k$ vectors, containing the two vectors of each vector-pair in Φ(N).

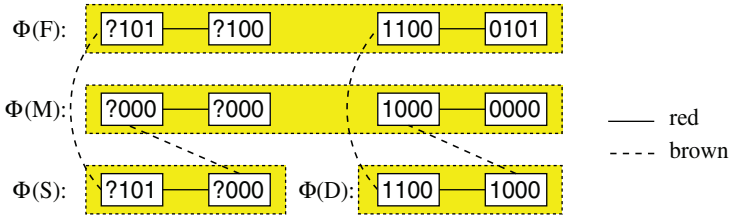

FIG. 3. *Graph G for Example* 1.

DEFINITION 3 (SNP-consistency condition). SNP-consistency is said to be maintained *if and only if, for all nodes* N *in the pedigree, each vector-pair in* Φ(N) *is SNP-consistent with* N*'s genotype. Vector-pair* $\langle h_1, h_2 \rangle$ *is said to be* SNP-consistent *with genotype g if either* (i) *if* h_1 *and* h_2 *are both 0 (respectively,* 1*) at the same locus, then the corresponding locus of g is also* 0 *(respectively,* 1*); or* (ii) *if* h_1 *is* 0 *(respectively,* 1*) and* h_2 *is* 1 *(respectively,* 0*) at the same locus, then the corresponding locus of g is* 2.

DEFINITION 4 (Mendelian-consistency condition [1, 6]). Mendelian-consistency is said to be maintained *if and only if, for all nodes* N *in the pedigree,* N *is a child in a trio comprised of* F, M, *and* N, *then* Φ(N) *contains a vector-pair* $\langle c_1, c_2 \rangle = \langle f_1, m_1 \rangle$ *where* $f_1 \in \Gamma(\mathrm{F})$ *and* $m_1 \in \Gamma(\mathrm{M})$.

Stage 1C—Constructing the local graph $G = (V, E)$. Let V be the multiset of all the vectors created in Stage 1B, and let E be the set of *red* and *brown* edges defined below:

1. A **red** edge is introduced to join the two vectors of each vector-pair generated in Stage 1A. It indicates that a ? appearing at locus i of both vectors must be resolved differently in the later stages of the algorithm (the two vectors can be different or the same at the other non-? locus positions). The red edges enforce SNP-consistency.
2. For each F-M-C trio, let $\langle f_1, f_2 \rangle$, $\langle m_1, m_2 \rangle$, and $\langle c_1, c_2 \rangle$ be vector-pairs in Φ(F), Φ(M), and Φ(C), respectively, associated with this trio. Two **brown** edges are introduced, one connecting c_1 and f_1, and the other connecting c_2 and m_1. A brown edge between two vectors means that the two vectors must be the same at *all* locus positions. The brown edges enforce Mendelian-consistency. □

Example 1. Consider the pedigree with F (father), M (mother), S (son), and D (daughter) shown in Figure 1. Stage 1 produces the graph G in Figure 3 with 12 vertices and 10 edges (6 red and 4 brown), comprised of two connected components, one for each of the two trios, F-M-S and F-M-D, in the pedigree.

DEFINITION 5. *For any locus i in a connected component* $\mathcal{G}$ *of G, we say*

1. *Locus i is* resolved *in* $\mathcal{G}$ *if and only if all vectors in* $\mathcal{G}$ *have* 0 *or* 1 *at locus i.*
2. *Locus i is* unresolved *in* $\mathcal{G}$ *if and only if all vectors in* $\mathcal{G}$ *have* ? *at locus i.*
3. *Otherwise, locus i is* mixed *(it is a mix of* ? *and non-*? *at i).*

In Example 1, the connected component for trio F-M-S has one unresolved locus (locus 1) and three resolved loci (loci 2, 3, and 4). Meanwhile, the component for trio F-M-D has no unresolved loci and four resolved loci (loci 1, 2, 3, and 4).

LEMMA 2. *The time complexity of Stage* 1 *(Stages* 1*A,* 1*B, and* 1*C) is* $O(mn)$, *where n is the number of nodes in the pedigree and m is the number of loci in each genotype. Furthermore, after Stage* 1*, all loci are either resolved or unresolved in each*

connected component of G (no mixed loci), and each connected component has six vertices. G has $O(n)$ vertices and edges and is acyclic.

Proof. Checking for family problems takes $O(mn)$ time (Lemma 1). With $O(n)$ trios and six vectors generated per trio with each vector having m loci, Stage 1B takes $O(mn)$ time. With $O(n)$ trios and six vertices and five edges (three red and two brown) per trio introduced in G, Stage 1C takes $O(n)$ time altogether, and furthermore, G has $O(n)$ vertices and edges. G is acyclic because each connected component of G is a path consisting of 6 vectors, 3 red edges, and 2 brown edges of a trio. □

In later stages of our algorithm, no vector-pairs will be added to or deleted from each $\Phi(\mathrm{N})$, and all loci resolved in Stage 1 will remain unchanged. Components of G will later be merged with the addition of **green** (added in Stage 2) or **white** (added in Stage 3) edges until G becomes a single connected component. Before we explain why and how these edges are added, we first note that these new edges can always be added between two vectors in the same $\Gamma(\mathrm{N})$. This structured way of adding edges to make G connected is possible given Lemma 3 below.

LEMMA 3. *If G has more than one connected component, then there exists a node* N *such that there are two vector-pairs in* $\Phi(\mathrm{N})$ *which belong to two different connected components.*

Proof. Suppose to the contrary that, for all N, the vector-pairs in $\Phi(\mathrm{N})$ are all connected. We make use of the fact that the brown edges in G preserve the connectivity of any two nodes in the pedigree, which we have assumed to be connected. Therefore, if vector-pairs in $\Phi(\mathrm{N})$ are all connected for all N, then all vectors are connected together in a single connected component, which contradicts the assumption that G has more than one connected component. □

There are two reasons why we need to merge the connected components of G. First, each multiset $\Phi(\mathrm{N})$ may contain more than one vector-pair; precisely, it contains k vector-pairs if N belongs to k different trios. However, by the time all loci are resolved, for all nodes N, each multiset $\Phi(\mathrm{N})$ must contain k copies of one unique vector-pair $\langle h_1, h_2\rangle$, which represents the haplotype-pair in a CHC for N. The green and white edges enforce this constraint by connecting vectors in $\Gamma(\mathrm{N})$ that are supposed to be identical (because they have identical values at some resolved heterozygous loci). For example, consider two vector-pairs $\langle u_1, u_2\rangle$, $\langle v_1, v_2\rangle$ of a node N. If at a heterozygous locus i, u_1 is 0 and v_1 is also 0, then we know u_1 must be identical to v_1 (and u_2 identical to v_2). However, if there is another heterozygous locus j where u_1 is 0 and v_1 is 1, then it is impossible to give a unique vector-pair, and there is no CHC solution. We capture this observation by defining the following type of consistency:

DEFINITION 6 (endgame-consistency condition). *Vector-pairs $\langle u_1, u_2\rangle$, $\langle v_1, v_2\rangle \in \Phi(\mathrm{N})$ of a node N are said to be* Endgame-inconsistent *if the vector values at some heterozygous loci i and j $(i \neq j)$ for u_1, u_2, v_1, and v_2 are a permutation of the four possibilities:* $00, 01, 10$, *and* 11, *and* Endgame-consistent *otherwise. The node* N *is said to be* Endgame-inconsistent *if there exist vector-pairs in* $\Phi(\mathrm{N})$ *that are Endgame-inconsistent, and* Endgame-consistent *otherwise.* Endgame-consistency is said to be maintained *if and only if, for all nodes* N *in the pedigree,* N *is Endgame-consistent.*

The second reason of adding green and white edges to connect the components of G is to further resolve the unresolved loci of each connected component of G with SNP-consistency and Mendelian-consistency maintained: vectors connected by green or white edges are supposed to be identical, and if a locus is resolved in one of the connected components but not in the other, the new connection allows us to resolve the locus in the other connected component as well. In the next subsection we will develop a procedure for resolving the values of loci in a connected component of G.

Our algorithm achieves a solution if, at the end of Stage 4, (a) graph G comprises a single connected component; (b) all loci are resolved in G; and (c) SNP-consistency, Mendelian-consistency, and Endgame-consistency are maintained. However, our algorithm may report "no solution" if some N is Endgame-inconsistent before the end of Stage 4.

3.2. Stage 2—Adding green edges. One of the most important aspects of our algorithm is that, at all stages, we maintain the property that each connected component of G has only resolved and unresolved loci (i.e., no mixed loci). In order to do this, we make extensive use of a subroutine called LOCUS_RESOLVE. LOCUS_RESOLVE($\mathcal{G}$) attempts to resolve ?'s in a connected component $\mathcal{G}$ of G. It looks at each locus in turn, identifies a resolved locus, and uses this to resolve the locus at other vertices in the connected component by traversing in a manner consistent with the colors of the edges. We do not lose any feasible solution in this procedure because any feasible solution must satisfy SNP-consistency, Mendelian-consistency, and Endgame-consistency, which are specified by the colors of the edges.

Define $v(i)$ to be the value of locus i ($= 0, 1$, or ?) at vector v.

LOCUS_RESOLVE($\mathcal{G}$):

For each locus i:

1. Traverse the connected component $\mathcal{G}$ to find a vector v where $v(i)$ is resolved ($= 0$ or 1). If no such v exists, go to the next locus.
2. Traverse $\mathcal{G}$ using a linear-time graph traversal procedure (such as depth-first search), starting at v. For any edge $e = (v_1, v_2)$ traversed where $v_1(i) = x$ (0 or 1) and $v_2(i) = ?$,
   (i) If e is a red edge, set $v_2(i) = 1 - x$.
   (ii) Else set $v_2(i) = x$.

LEMMA 4. *LOCUS_RESOLVE($\mathcal{G}$) runs in $O(|\mathcal{G}|m)$ time, where $|\mathcal{G}|$ is the number of vectors in $\mathcal{G}$. All loci in $\mathcal{G}$ are either resolved or unresolved after running the procedure.*

Proof. LOCUS_RESOLVE performs m graph traversals, one for each locus, and each traversal takes $O(\mathcal{G})$ time. Hence the time complexity. At any locus i, if at least one vector is resolved at i, this will be identified in Step 1, and since $\mathcal{G}$ is connected, all other vectors will then be resolved at locus i in Step 2. □

Stage 2 will consider the nuclear families in the pedigree one by one and will try to connect the trios within the same nuclear family, in such a way as to respect Endgame-consistency. Specifically, green edges are added to connect two unconnected vectors in Γ(N) that have the value 0 at heterozygous locus i of N, where N is the father or mother of the nuclear family. Green edges are like brown edges requiring that the ?s in the two vectors connected by the edge to be resolved the same.

There are two types of nuclear families: namely, the **Type A** families where there exists a locus that is heterozygous in either one of, but not both, the parents; and the **Type B** families where each locus is either heterozygous in both parents or homozygous in both parents. Stage 2 consists of Stages 2A and 2B, which process all Type A and Type B nuclear families, respectively.

For each Type A nuclear family, there exists a locus i that is heterozygous in either of, but not both of, F and M. Observe that locus i will be resolved in all vectors of the nuclear family comprised of father F, mother M and their children (that is how Stage 1B works). We can, therefore, connect all the vector-pairs into one single connected component by adding green edges between vectors in Γ(N) with 0 at locus i, where N is the parent with heterozygous locus i. This we do in Stage 2A.

Stage 2A—Processing Type A families. For each nuclear family, which is comprised of, say, father F, mother M, and their children, where there exists a locus i that is heterozygous in either (not both) of F and M, do the following:

1. Let $V = \{v \in \Gamma(\mathrm{N}) \mid v(i) = 0$ and v belongs to this nuclear family$\}$ where N is the parent (either M or F) such that i is heterozygous in N. Pick one vector from V and call it u.
2. For each vector $v \in V$, $v \neq u$, add a green edge to join u and v. After this, the vectors in the nuclear family are connected as a single connected component.
3. Run LOCUS_RESOLVE($\mathcal{G}$) where $\mathcal{G}$ is the connected component containing u.
4. Check for Endgame-consistency within the family, reporting *"no solution"* if it is not maintained. □

For each Type B nuclear family, we make use of the sets $het()$ and $hom()$ defined in section 2. If there is a trio T where $hom(T)$ is empty, then $het(T)$ contains all loci (where F and M are also heterozygous). Since all distinct $het()$'s are disjoint, this implies any other trio T' in the nuclear family either has $het(T')$ empty, or $het(T') = het(T)$ (and $hom(T')$ is empty). In this case all trios with empty $hom()$ cannot be connected (in Stage 2B). So in Stage 2B we consider only trios where $hom(T)$ is nonempty.

We first consider each S_i as defined in the proof of Lemma 1, and connect all trios in the same S_i by adding green edges between them. All trios in the same S_i have identical $het()$ and hence identical (and nonempty) $hom()$; thus they share a resolved locus, which allows us to add a green edge correctly.

Then we will add edges connecting S_i and S_{i+1} for all i. If S_i and S_{i+1} share some common locus in their $hom()$'s, then this allows us to add a green edge correctly using the resolved loci. If they do not share any common locus in their $hom()$'s, then this implies that the union of their $het()$'s equals the set of all loci (where F and M are heterozygous). This means that they are the only two S_i's (call them S_1 and S_2) which have nonempty $het()$. If there are trios in S_0 (which has an empty $het()$), then S_0 shares some common resolved locus with both S_1 and S_2 and all S_i's can be connected by green edges. Otherwise if there are no trios in S_0, then S_1 and S_2 cannot be connected together.

Stage 2B—Processing Type B families. For each nuclear family, which is comprised of, say, father F, mother M, and their children, where each locus is either homozygous in both F and M, or heterozygous in both F and M:

1. If there exists a locus i that is heterozygous in F (and also M), then do the following:
   (a) Let the sets of loci $het()$ and $hom()$ of each trio and the S_i's be as defined in the proof of Lemma 1.
   (b) For each S_i with corresponding trios $T_1, T_2, \ldots, T_k$:
      i. Pick a locus x in $hom(T_1)$. This is also in $hom(T_j)$ for all other j. If such x does not exist, go to the next S_i.
      ii. For each trio T_j other than T_1, add a green edge to join u and v, where $u, v \in \Gamma(\mathrm{F})$ are vectors for trios T_1 and T_j with value 0 at locus x.
   (c) For each pair of S_i and S_{i+1}:
      (i) Pick a T in S_i and a T' in S_{i+1}.
      (ii) If $hom(T)$ and $hom(T')$ share some common locus x, then add a green edge to join u and v, where $u, v \in \Gamma(\mathrm{F})$ are vectors for trios T and T' with value 0 at locus x.

(iii) Otherwise (i.e., no such common locus exists), S_i and S_{i+1} are the only two such sets with a nonempty $het()$. Call them S_1 and S_2. If there are trios in S_0, then add a green edge between S_1 and S_0, and between S_2 and S_0, as in Step (c)(ii). If there are no trios in S_0, then no green edges are added.

(d) Run LOCUS_RESOLVE() on each connected component of G of the nuclear family with the green edges added above.

(e) Check for Endgame-consistency within the family, reporting *"no solution"* if it is not maintained.

2. Otherwise, no green edges are added for this family. □

LEMMA 5. *The time complexity of Stage* 2 *(Stages* 2*A and* 2*B) is* $O(mn)$. *Furthermore, after Stage* 2*, all loci are either resolved or unresolved in each connected component of* G*, and* G *has* $O(n)$ *vertices and edges, and is acyclic.*

Proof. Stage 2A considers the nuclear families of the pedigree one by one. For each nuclear family, with, say, k children: locus i can be determined in $O(m)$ time; Step 1 takes $O(k)$ time with V containing one vector per trio of the family; Step 2 takes $O(k)$ time; Step 3 takes $O(km)$ time; and Step 4, which checks for Endgame-consistency, can be done in $O(km)$ time. Therefore, the total time complexity of Stage 2A is $O(mn)$.

Stage 2B processes the nuclear families similarly. Each addition of a green edge in Steps 1(b) and 1(c) takes $O(m)$ time, and thus for a nuclear family with k children, Steps 1(b) and 1(c) take $O(km)$ time. Steps 1(d) and 1(e) take $O(mn)$ time as in Stage 2A. Hence the time complexity of Stage 2B is also $O(mn)$.

The execution of LOCUS_RESOLVE after green edges are added ensures all loci are either resolved or unresolved in each connected component of G. No vertices are added to G and only up to $k-1$ green edges are added for each family with k children. Thus, G continues to have $O(n)$ vertices and edges. All green edges are added between vectors of the same individual node, and within a nuclear family, green edges are added in either the father or the mother but not both. Hence, in the absence of mating loops, G remains acyclic. □

LEMMA 6. *If a connected component* $\mathcal{G}$ *of* G *has only resolved and unresolved loci (no mixed loci), then all possible ways of resolving ?'s in vectors in* $\mathcal{G}$ *such that SNP-consistency and Mendelian-consistency are maintained will either all make all vector-pairs Endgame-consistent or all make some vector-pairs Endgame-inconsistent.*

Proof. Consider a particular resolution of ?'s in the vectors in $\mathcal{G}$ such that SNP-consistency and Mendelian-consistency are maintained. Suppose Endgame-inconsistency occurs at node N; i.e., there exist two vector-pairs $\langle x_1, x_2\rangle$, $\langle y_1, y_2\rangle \in \Phi(\mathrm{N})$ such that the vector values at some heterozygous loci i and j $(i \neq j)$ for x_1, x_2, y_1, and y_2 are a permutation of the four possibilities: 00, 01, 10, and 11. We can assume, without loss of generality, that the value at such i and j for x_1, x_2, y_1, and y_2 are 00, 11, 01, and 10, respectively. Consider the following three cases for the state of loci i and j prior to the resolution:

Case 1: Loci i and j were both unresolved in $\mathcal{G}$. Then, for all other possible resolutions, the values at loci i and j for x_1, x_2, y_1, and y_2 would either be 00, 11, 01, and 10 respectively, or 11, 00, 10, and 01, respectively, and Endgame-consistency would also be violated.

Case 2: Only one of locus i and j was unresolved, say i, in $\mathcal{G}$. Then, for all other possible resolutions, the values at loci i and j for x_1, x_2, y_1, and y_2 would either be 00, 11, 01, and 10 respectively, or 10, 01, 11, and 00, respectively, and Endgame-consistency would also be violated.

Case 3: Both loci i and j were resolved. Then, Endgame-inconsistency existed prior to any resolution of ?'s. □

The green edges are essential to the next stage of our algorithm by ensuring that certain trios are connected. This is established in Lemmas 7 and 8 below.

LEMMA 7. *Consider a nuclear family within the pedigree with father* F*, mother* M*, and their children. If there exists a locus i that is heterozygous in either one (not both) of* F *and* M*, then after Stage* 2*A, the family will be represented by a single connected component in G.*

Proof. This follows straightforwardly from how Stage 2A works. □

LEMMA 8. *Consider a nuclear family within the pedigree comprised of father* F*, mother* M*, and their children and with no family problems. If there exists a locus that is heterozygous in both* F *and* M *but homozygous in both* C_1 *and* C_2*,* C_1 *and* C_2 *being children of* F *and* M*, then the components for trios* F-M-C_1 *and* F-M-C_2 *will become connected during Stage* 2*B.*

Proof. All trios with a nonempty *hom*() will be connected to other trios within the same S_i in Step 1(b) of Stage 2B, which in turn will be connected to all other S_j's in Step 1(c) of Stage 2B. All such S_i's will be connected to a single connected component since any two of them must share at least one common locus in their *hom*() (since otherwise, all trios will form into two S_1 and S_2 with disjoint *het*() and *hom*(); see the discussion just before Stage 2B is defined). Thus the two trios, which share a common locus in their *hom*()'s, will be connected in Stage 2B. □

The previous two lemmas lead up to Lemma 9 below, which defines the Mother-Father Property. The Mother-Father Property helps us from not having to check for Endgame-consistency for the mother if the father is Endgame-consistent, or vice versa. This will become important in Stage 3.

LEMMA 9 (mother-father property). *Suppose (a)* M *and* F *are the mother and father of two unconnected trios in G after Stage* 2 *and (b) the given pedigree has no family problems. Then, for all possible way(s) of resolving ?s in vectors in the two trios such that SNP-consistency and Mendelian-consistency are maintained,* M *and* F *are either both Endgame-consistent or both Endgame-inconsistent.*

Proof. Suppose F is Endgame-inconsistent. Without loss of generality, let the values at loci i and j for x_1, x_2, y_1, and y_2 be 00, 11, 01, and 10, respectively, where $\langle x_1, x_2\rangle$, $\langle y_1, y_2\rangle \in \Phi(\mathrm{F})$. This means that loci i and j are heterozygous loci for F. Since the two trios are not connected by a green edge, loci i and j are also heterozygous for M (Lemma 7). Let C_1 and C_2 be the two respective children of F connected to $\langle x_1, x_2\rangle$ and $\langle y_1, y_2\rangle$ by brown edges. In the absence of family problems and green edges connecting the two trios, there are only three cases to consider (there is no need to consider i or j being homozygous for both C_1 and C_2 according to Lemma 8): (i) when loci i and j are both heterozygous for both C_1 and C_2; (ii) when loci i and j are both heterozygous for C_1 and both homozygous for C_2; and (iii) when locus i is heterozygous for C_1 and homozygous for C_2 while locus j is homozygous for C_1 and heterozygous for C_2. It can be readily shown that in all three cases, M is also Endgame-inconsistent.

The argument is similar supposing M is Endgame-inconsistent. Thus, if F (or M) is Endgame-inconsistent, then M (respectively, F) is Endgame-inconsistent, and the contrapositive implies that, if M (or F) is Endgame-consistent, then F (respectively, M) is Endgame-consistent. The lemma follows. □

3.3. Stage 3—Adding white edges. After Stage 2, suppose G is left with more than one connected component. The idea of Stage 3 is to connect components

of G together with white edges, so that a single connected component results and loci can be further resolved. Before we present the various substages of Stage 3 formally, we first give an intuitive idea.

Suppose a pedigree has a CHC solution. Then for any node N with vector-pairs $\langle u_1, u_2\rangle$ and $\langle v_1, v_2\rangle$, if these vector-pairs are not already connected by green edges in Stage 2, then we need to add a white edge to connect either u_1 to v_1, or connect u_1 to v_2. These represent the two different ways of resolving the haplotypes in N so as to maintain Endgame-consistency (i.e., either u_1 should be identical to v_1, or it should be identical to v_2). Thus white edges are analogous to green edges and they are treated as "nonred" edges by LOCUS_RESOLVE.

While it may appear at first sight that each of these white edges can be added arbitrarily, it turns out that this is not true when multiple white edges are considered together, and we need a way to determine which of the two ways is the correct way of connecting the vectors. To do this, we first construct a **support graph *H*** in Stage 3A. The support graph contains unlabeled edges, each corresponding to a white edge in G, and which will be labeled with either 0 or 1 in Stage 3C. Suppose e is an unlabeled edge in H corresponding to the white edge between the vector-pairs $\langle u_1, u_2\rangle$ and $\langle v_1, v_2\rangle$ as defined in the previous paragraph. A label of 0 on e denotes that the white edge in G should connect u_1 and v_1, while a label of 1 denotes that the white edge should connect u_1 to v_2. This is how H is used. In order to find this labeling, we will construct another graph J in Stage 3B which captures the constraints on how the unlabeled edges can be labeled.

We start with the construction of H in Stage 3A.

Stage 3A—Constructing the support graph *H*.

1. For each nuclear family:
   If the vector-pairs in the family consist of $k > 1$ connected components,[1] then do the following. Pick a vector from each of the connected components in either the father or the mother, but not both (all vectors must be from the same parent). Create a vertex in H for each such vector. Add $k-1$ *unlabeled edges* to join these vertices in H.
2. For each pedigree node N:
   Suppose this individual N belongs to k' different nuclear families. Within each such nuclear family, any two vectors of N in G are either already connected in Stage 2, or they belong to connected components with corresponding vertices in H that are connected in Step 1 above. Vectors of N from different nuclear families are, however, not connected in either G or H. Pick one vector from N from each of these nuclear families. Create a vertex in H for each such vector. Add $k'-1$ new *unlabeled edges* to connect them in H.
3. For each connected component $\mathcal{G}$ in G:
   (a) Let k'' be the number of vectors in $\mathcal{G}$ that are chosen as vertices in H in Steps 1 or 2 above.
   (b) Join these vertices in H with $k''-1$ *labeled edges*. The label is 0 if the path between the two vectors in G has an even number of red edges, and 1 otherwise. □

[1] After Stage 2, Type A families have $k = 1$, and vector-pairs of each Type B family are connected into at most two connected components except those trios whose $hom()$ is empty, which are still unconnected.

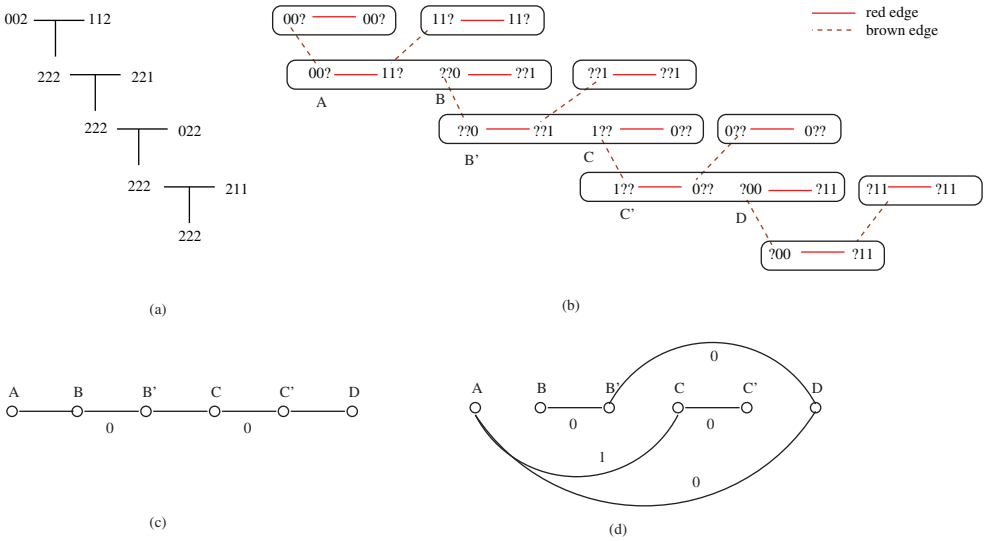

FIG. 4. *An example showing the steps in Stage* 3. (a) *The pedigree.* (b) *The local graph* G. (c) *The support graph* H. *Two edges are labeled with* 0. (d) *The parity constraint graph* J. *Three constraints are added.*

Figures 4(a) and 4(b) show a pedigree and the corresponding local graph G. Figure 4(c) shows the support graph H. In this example, since each nuclear family has only one connected component, Step 1 is skipped. Unlabeled edges (A, B), (B', C), and (C', D) are added in Step 2, and labeled edges (B, B') and (C, C') with label 0 are added in Step 3. In this case H happens to be a path, but it can be more general. Lemma 10 shows that H is always acyclic.

LEMMA 10. *If there are no mating loops in the pedigree, then* H *is acyclic.*

Proof. If there is a cycle in H, it cannot involve only vectors in one nuclear family, by our construction (Step 1 of Stage 3A). Any other cycle is impossible without mating loops. □

LEMMA 11. H *is connected, has* $O(n)$ *vertices and edges, and can be constructed in* $O(n)$ *time.*

Proof. Vertices in H which correspond to vectors in the same connected component in G are connected by labeled edges. The different connected components of G can always be connected by adding edges joining vectors in the same Φ(N) for some node N (Lemma 3); these correspond to the unlabeled edges in H. Hence, H is connected.

H clearly has $O(n)$ vertices since the set of vertices is a subset of those of G. Since H has no cycles by Lemma 10, it has $O(n)$ edges.

Steps 1 and 2 of Stage 3A take $O(n)$ time since the time to process each nuclear family or individual is proportional to the number of vectors in them. We can check for connectivity easily by preprocessing (e.g., traversing G to identify connected components). Step 3 also takes $O(n)$ time, where the only tricky part is computing the labels on the labeled edges. This can be done in constant time per label, once the following preprocessing step is done. By traversing each connected component $\mathcal{G}$ of G, we can compute, for each vertex v in $\mathcal{G}$, whether the number of red edges in the path from a fixed vertex t in $\mathcal{G}$ is odd or even, i.e., the parity. Since G has $O(n)$

edges, this can be done in $O(n)$ time and is only done once as a preprocessing step. Then, the parity of the path in G between any pair of vertices u and v in the same connected component can be computed in constant time from the parity of the path between u and t and that between t and v. □

In Stage 3B, we construct a **parity constraint graph J** to represent the constraints on the labeling of H. One of the essential differences between H and J is that H shows connections between "neighboring" components while J captures all parity constraints between far-apart components.

Figure 4(d) shows the graph J which is derived from the graph H in Figure 4(c). The vertices in J are the same as the vertices in H. Since the vertices in H correspond to vertices (vectors) in G, we can extend the terminology of vectors to the vertices in H: for example, we say that a vertex u in H is heterozygous at locus i when i is heterozygous in a pedigree node N where $u \in \Gamma(\mathrm{N})$. Simlarly we can speak of a vertex as homozygous, resolved, unresolved, etc., at a locus i.

Assume white edges have been added to G. G remains acyclic by a reasoning similar to showing that G is acyclic after adding green edges (Lemma 5). Hence, a path between any two vectors u and v in G is unique. If u and v are heterozygous and resolved (have 0 or 1) at locus i but all other vectors (if any) in the path between u and v are unresolved at locus i, then there is a constraint on how the unresolved loci can be resolved (equivalently, how the white edges should be added): namely, the number of red edges in the path in G must be even (or odd) if u and v have the same (respectively, different) parity of resolved loci at a locus i. This is because the unresolved loci at the two ends of each red edge must have different parity. To represent this constraint, we add an edge (u, v) labeled L between u and v in J, where L is 1 if u and v are resolved differently at locus i, and 0 otherwise.

A straightforward implementation of the above idea will lead to too many edges. Stage 3B below adds only $O(mn)$ edges to J, and Lemma 12 shows that this is sufficient to represent all parity constraints.

Stage 3B—Constructing the parity constraint graph J.

1. The vertices in J are the same as the vertices in H.
2. Add an edge between two vectors u and v in J if (u, v) is labeled in H. Furthermore, the label of this edge in J is the same as its label in H.
3. For each locus i, consider the tree H as if it is separated into subtrees at all vertices where i is homozygous. That is, each subtree does not contain any vertex homozygous at i. For each subtree, we root the subtree at an arbitrary vertex that is heterozygous and resolved at i. (If there is no such vertex, go to the next subtree.) Traverse the subtree and find, for each vertex v that is heterozygous and resolved at locus i, its lowest ancestor u that is also heterozygous and resolved at locus i. Add an edge between u and v in J. Label this edge with 0 (or 1) if u and v have same (respectively, different) parity of locus value. Note that there may already be such an edge in J, with the same or different labels, due to other loci. If it is the same label, do not add the edge (which is redundant). If the label is different, report *"no solution."*
4. Check whether all cycles in J have an even number of edges labeled 1. Report *"no solution"* and stop if there is a cycle in J with an odd number of edges labeled 1.
5. Note that J may not be connected. To make J connected, add edge (u, v) to J if u and v are in different connected components in J and (u, v) is an edge in H. This is always possible because H is a connected graph, and J and H

have the same set of vectors as the vertices. Arbitrarily label this edge with 0. We call the corresponding edge in H a **free edge** because we have the freedom to label (u, v) with 1 instead. We continue adding edges until J is connected. □

In effect, the graph J represents a set of linear equations modulo 2; in the example in Figure 4(d) the equations are $x_{AB} + x_{B'C} = 1, x_{B'C} + x_{C'D} = 0$, and $x_{AB} + x_{B'C} + x_{C'D} = 0$. The free edges in Step 5 correspond to the edges in H that are still unlabeled after Step 4, and are the result of the degrees of freedom in the system of equations. These unlabeled edges are "free" by themselves, in the sense that they can be assigned either 0 or 1, but once an assignment is made on one of the free edges, the other free edges may become nonfree. For example, consider Figure 4(d). There are no free edges since H is one connected component (and the system of linear equations has no degree of freedom). If we assume the edge connecting A and D does not exist, then there are two connected components, and AB, $B'C$, and $C'D$ are all potential free edges. But there is only one degree of freedom since if we assign AB to, say, 0, then all other "free" edges have their values fixed.

Lemma 12 below shows that Step 3 in Stage 3B adds sufficient edges in J to represent the parity constraints.

LEMMA 12. *Suppose there is a path between two vertices u and v in H and there is a locus i such that both u and v are heterozygous and resolved at i while all other vertices in this path are not resolved at i. Let $L = 0$ if u and v have the same resolved value at i, and 1 otherwise. Then, there is a path in J connecting u and v so that the result of applying the logical operation exclusive or (XOR) to all labels in this path equals L.*

Proof. Since all other vertices in this path are not resolved, u and v must be in the same subtree in Step 3 of Stage 3B. If one of u or v is an ancestor of the other in the rooted subtree (for locus i), not necessarily the lowest ancestor, then by the construction in Step 3 of Stage 3B, there is a sequence of edges $(u, v_0), \ldots, (v_k, v)$ in J connecting u and v, such that all these vertices are resolved at locus i. If this path is a single edge (in the case of the lowest ancestor), then we are done. Otherwise, we can assume by induction that the XOR of the labels on the path between u and v_k is equal to the parity difference of u and v_k. Adding the edge from v_k to v, with the label equal to the parity difference of v_k and v, the claim follows.

Otherwise, if neither u nor v is an ancestor of the other in the subtree, let w be the lowest common ancestor of u and v which is resolved at i. We then have two paths, one from w to u and the other from w to v, which by a similar argument to the above, have the correct labels. Hence, there is a path from u to v (through w) in J, and the XOR of the labels on this path is equal to the parity difference of u and w XORed with the parity difference of w and v, the result of which is the parity difference of u and v. □

LEMMA 13. *If Steps 3 and 4 of Stage 3B report "no solution," then there is no CHC solution. Otherwise, J has no odd cycle (an odd cycle is a cycle where the number of 1-labeled edges is odd).*

Proof. In Step 3, if "no solution" is reported, there are two conflicting constraints. In Step 4, if "no solution" is reported, then there is an odd cycle. Each edge with label 1 denotes that the resolved loci at two ends of the edge must be of different parity (and label 0 implies same parity). It follows that there is no way of resolving the loci consistently along an odd cycle. □

The free edges introduced in Step 5 are to make J connected so that we can determine the parity difference between any two nodes in J and completely label all

edges in H. The following lemma shows that these free edges can be added freely and labeled arbitrarily without affecting the existence of the CHC solution.

LEMMA 14. *If there is a CHC solution of the pedigree, then any label (*0 *or* 1*) on the free edges introduced in Step* 5 *of Stage* 3*B will make all vector-pairs SNP-consistent, Mendelian-consistent, and Endgame-consistent. On the other hand, if there is no CHC solution, none of the labels on the free edges can achieve Endgame-consistency for all vector-pairs.*

Proof. It is obvious that SNP-consistency and Mendelian consistency will always be maintained because of the red and brown edges. Since a free edge (u, v) is only added when J is not connected, u and v must be two vectors in different connected components of J and there must not exist two vectors, one in each connected component, where locus i is resolved and the vectors in the path in H between these two vectors are unresolved at locus i.

As edge (u, v) is in H, u and v must be in the same $\Phi(\mathrm{N})$ for some node N whose loci are either homozygous or heterozygous. If N is heterozygous at locus i, then locus i will be unresolved in all vectors in either u's connected component, or v's connected component, or both connected components (otherwise J cannot be disconnected). In all these cases, it can be shown that, from Lemma 6, Endgame-consistency will be maintained or not maintained no matter whether the free edge is labeled with 0 or 1. Thus the lemma is proved. □

LEMMA 15. *J has $O(mn)$ edges and can be constructed in $O(mn)$ time.*

Proof. There are $O(n)$ vertices and edges in H. Thus, Steps 1 and 2 of Stage 3B can be done in $O(n)$ time.

Step 3 can be done in $O(mn)$ time using a recursive traversal of each subtree of H for each locus as follows. We start at the root noting itself as the lowest resolved ancestor, and recursively traverse each child, passing down the ancestor information in the recursive calls. At each child, its lowest resolved ancestor is the lowest resolved ancestor of the parent. If the child itself is resolved heterozygous, then the child notes itself as the lowest resolved ancestor in subsequent traversal of its own children. Thus, it takes $O(n)$ time to perform such traversal for each locus.

Each traversal of a locus adds at most $O(n)$ edges to J, so J has at most $O(mn)$ edges.

In Step 4 we need to identify cycles with an odd number of edges labeled 1. If we imagine contracting every edge in J with label 0, then the problem reduces to checking whether the contracted graph has an odd cycle, which amounts to checking bipartiteness. Thus Step 4 can be done in $O(mn)$ time.

Step 5 can also be done in $O(mn)$ time as follows. First, for each vertex x in J, keep a list $\mathrm{LIST}(x)$ of vertices adjacent to x in H. Next, we perform a two-pass traversal as follows. Start with an arbitrary vertex X, traverse the connected component, and label the vertices traversed as "marked." Then we go back and traverse the connected component again starting at X. When traversing vertex x, we check whether all the vertices in $\mathrm{LIST}(x)$ are marked. If there is a vertex y that is unmarked, we add (x, y) to J and perform the same two-pass traversal for the connected component of y; in effect we are doing a traversal within traversal. In this way, we grow from one connected component of J and add free edges to connect to other connected components. The two-pass approach is employed to prevent adding edges which are not actually free after other free edges are added. Since the graph has $O(mn)$ edges, Step 5 takes $O(mn)$ time.

Thus, the total time complexity of Stage 3B is $O(mn)$. □

Next, we use J to complete the labeling of H.

Stage 3C—Completing the labeling of *H*.

1. Traverse J, computing, for each vertex v in J, the parity (odd or even) of the number of 1-labeled edges in the path from a fixed vertex t in J.
2. For each unlabeled edge (u, v) in H, if u and v have the same parity in J, then label edge (u, v) in H with 0, otherwise with 1. □

LEMMA 16. *All edges in H can be labeled with 0 or 1 in $O(mn)$ time in Stage 3C, and the labels in H are consistent with the parity constraints specified in J in the sense that the parity between any two vectors u and v specified in J is the same as the parity of the number of 1-labeled edges in the path between u and v in H.*

Proof. Note that J specifies a unique parity between any two vertices because J has no odd cycle. Consider a path $P = (v_0, v_1), (v_1, v_2), \ldots, (v_{k-1}, v_k)$ in H. Each unlabeled edge (v_i, v_{i+1}) in P receives a label equal to the parity between v_i and v_{i+1} in J in Step 1 of Stage 3C, which is equal to the parity of the number of 1-labeled edges between v_i and v_{i+1} in J. Each labeled edge (v_i, v_{i+1}) in P has the same edge (with the same label) in J, and hence the label of this edge in H is also equal to the parity of the number of 1-labeled edges between v_i and v_{i+1} in J. Hence, the parity of the number of 1-labeled edges in P is equal to the XOR of the labels on all edges in P, which in turn is equal to the XOR of the parity between v_i and v_{i+1} in J over all i, which is the parity between v_0 and v_k in J.

As far as the time complexity is concerned, since H has $O(n)$ edges and J has $O(mn)$ edges, the total time complexity of Stage 3C is $O(mn)$. □

Stage 3D—Adding white edges to *G*.

1. For each edge (u, v) in H that became labeled during Stage 3C:
   (a) If the edge is labeled 1, then let x be the vector adjacent to v by a red edge; otherwise, let x be v.
   (b) Add a white edge between u and x.
2. G now becomes a single connected component. Run LOCUS_RESOLVE(G).

LEMMA 17. *Stage 3D can be done in $O(mn)$ time, and after Stage 3D, G will be a single connected component with only unresolved and resolved loci.*

Proof. Step 1 of Stage 3D considers each of the $O(n)$ edges of H one by one, each taking constant time; thus this step takes $O(n)$ time. Step 2 takes $O(mn)$ time. The time complexity thus follows.

H is a connected graph that contains at least one vertex from each connected component of G, and the newly labeled edges in H are between vertices that were not connected in G (while the edges that were already labeled are between vertices that were already connected in G). Therefore, each white edge added results in one fewer connected component in G, and G will become a single connected component after Step 1 finishes.

LOCUS_RESOLVE ensures that G, as a single connected component, has only unresolved and resolved loci. □

Figure 5 shows the graph H of the same example in Figure 4 after the edges are labeled. The resulting white edges are added to G and the loci resolved.

LEMMA 18. *If the pedigree has a CHC solution, Stage 3D maintains Endgame-consistency.*

Proof. Suppose, to the contrary, that some node N becomes Endgame-inconsistent after Stage 3D. Without loss of generality, let the values at loci i and j for x_1, x_2, y_1, and y_2 be 00, 11, 01, and 10, respectively, where $\langle x_1, x_2\rangle, \langle y_1, y_2\rangle \in \Phi(\mathrm{N})$.

Consider the situation prior to Stage 3D. Since the pedigree has a CHC solution, given Lemma 6, the vector-pairs in each connected component are Endgame-consistent. Thus $\langle x_1, x_2\rangle$ and $\langle y_1, y_2\rangle$ must belong to different connected components;

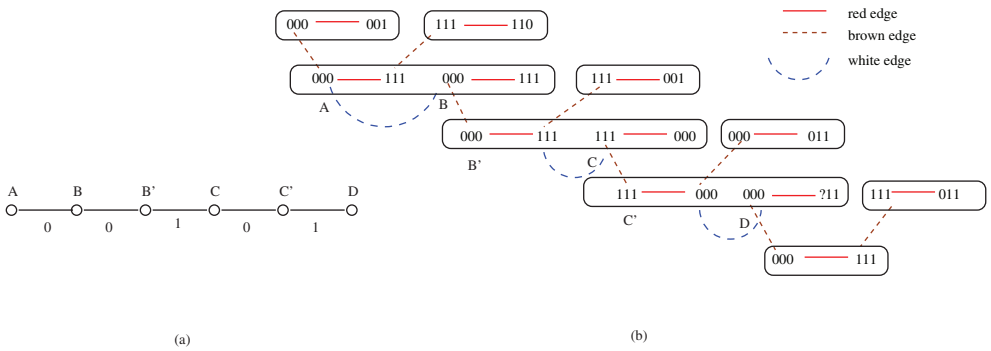

FIG. 5. *The same example from Figure* 4 *showing the result of Stages* 3*C and* 3*D.* (a) *The graph H with the correct labels. In this case there is a unique solution.* (b) *The local graph G after addition of white (dashed) edges. Loci values are also resolved.*

call them G_1 and G_2, respectively. Now suppose $\langle x_1, x_2\rangle$ and $\langle y_1, y_2\rangle$ become connected during Stage 3D after the addition of a white edge e, which connects G_1 and G_2. There are four cases to consider:

Case 1: e connects $\langle x_1, x_2\rangle$ and $\langle y_1, y_2\rangle$. White edge e corresponds to an edge in H, and since H is acyclic, it is the unique edge between the vector-pairs and is labeled with a unique parity. Without loss of generality, suppose e connects x_1 and y_1 and is labeled 0. This white edge will make x_1 and y_1 equal and, therefore, the value of loci i and j cannot possibly become 00 for x_1 and 01 for y_1.

Case 2: e connects $\langle x_3, x_4\rangle$ in G_1 and $\langle y_3, y_4\rangle$ in G_2 where $\langle x_3, x_4\rangle$ and $\langle y_3, y_4\rangle \in \Phi(\mathrm{N})$. Since the pedigree has a CHC solution, and G_1 has only resolved and unresolved loci, according to Lemma 6, vector-pairs of N that are in G_1 must be Endgame-consistent. This implies that $\langle x_1, x_2\rangle$ and $\langle x_3, x_4\rangle$, which are in G_1, are Endgame-consistent. Likewise, $\langle y_1, y_2\rangle$ and $\langle y_3, y_4\rangle$ must also be Endgame-consistent. By the argument in Case 1, $\langle x_3, x_4\rangle$ and $\langle y_3, y_4\rangle$ must also be Endgame-consistent. This makes it impossible for $\langle x_1, x_2\rangle$ and $\langle y_1, y_2\rangle$ to be Endgame-inconsistent.

Case 3: e connects $\langle x_3, x_4\rangle$ in G_1 and $\langle y_3, y_4\rangle$ in G_2 where $\langle x_3, x_4\rangle$ and $\langle y_3, y_4\rangle \in \Phi(\mathrm{M})$ and M is N's spouse. Suppose $\langle u_1, u_2\rangle \in \Phi(\mathrm{M})$ belongs to the same trio as $\langle x_1, x_2\rangle$ and suppose $\langle v_1, v_2\rangle \in \Phi(\mathrm{M})$ belongs to the same trio as $\langle y_1, y_2\rangle$. According to Lemma 9, $\langle u_1, u_2\rangle$ and $\langle v_1, v_2\rangle$ are also Endgame-inconsistent. Thus, we can consider $\langle u_1, u_2\rangle$ and $\langle v_1, v_2\rangle$ instead of $\langle x_1, x_2\rangle$ and $\langle y_1, y_2\rangle$, and accordingly, apply the arguments of Case 2.

Case 4: e connects $\langle x_3, x_4\rangle$ in G_1 and $\langle y_3, y_4\rangle$ in G_2 where $\langle x_3, x_4\rangle$ and $\langle y_3, y_4\rangle \in \Phi(\mathrm{M})$ and M is neither N nor N's spouse. Assuming no mating loops, this case does not exist. □

3.4. Stage 4—Finishing up. At this point, our graph G has only one connected component, and it only has resolved or unresolved (no mixed) loci, since this is the property we maintain by our locus resolve procedures. If all loci are resolved, then of course we are done. For those loci that are still unresolved, Lemma 6 tells us that any way of resolving makes no difference: we can arbitrarily resolve them in an SNP-consistent and Mendelian-consistent manner, and it will not affect Endgame-consistency in the sense that either all vector-pairs will be Endgame-consistent for all resolutions, or there will be Endgame-inconsistent vector-pairs for all resolutions. This means the algorithm does not need to try all possibilities; any one will do. This is crucial for avoiding an exponential blow-up.

Hence, we do the following as the final stage of our algorithm.

Stage 4—Dealing with a single connected component.

1. Arbitrarily pick a vector u of G. For all unresolved loci i, assign a value of 0 to each of them. Then run LOCUS_RESOLVE(G).
2. For all N, check Φ(N) for Endgame-consistency and report *"no solution"* if it is not maintained.

LEMMA 19. *Stage* 4 *runs in* $O(mn)$ *time.*

Proof. After Stage 3D, G is a single connected component and has no mixed loci. By Lemma 6, we do not have to try all possible resolutions; any one will do. Let s be the number of unresolved loci in G. The time complexity of resolving all of these unresolved loci is $O(sn)$ since LOCUS_RESOLVE runs in $O(n)$ time per locus. Checking all N for Endgame-consistency can be done in $O(mn)$ time. ∎

Note that assigning a value of 1 instead of 0 to any locus before running LOCUS_RESOLVE would work equally well (Lemma 6); the effect is that all 1's become 0 and all 0's become 1 at each such locus, giving another solution. In general, if there are s unresolved loci after Stage 3D and the pedigree admits a consistent solution, then there are 2^s different CHC solutions. However, if every node in the pedigree has exactly s heterozygous loci, then there are only 2^{s-1} different CHC solutions due to symmetry.

THEOREM 1. *For a given pedigree, we can either achieve a solution that represents a CHC for the given pedigree, or report "no solution" when there is no solution, in* $O(mn)$ *time where* n *is the number of nodes in the pedigree and* m *is the number of loci.*

Proof. Each of the stages of our algorithm runs in $O(mn)$ time. The algorithm reports "no solution" only when there can be no CHC solution. If the algorithm does not report "no solution," then after Stage 4, all loci are resolved and SNP-consistency, Mendelian-consistency, and Endgame-consistency are all maintained. Thus, the resolved loci values represent a CHC solution. ∎

4. Open problems. In this paper, an optimal linear-time algorithm is presented to solve the haplotype problem for pedigree data when there are no recombinations and the pedigree has no mating loops. It remains an open problem to extend the algorithm to handle mating loops. For the haplotyping problem with recombinations, the problem becomes intractable even when at most one recombination is allowed at each haplotype of a child, or when the problem is to find a feasible haplotype with the minimum number of recombinations (even without mating loops) [3]. However, there is still much scope for further study. For example, in practice, pedigree data often contain a significant amount of missing alleles (up to 14–15% of the alleles belonging to a block could be missing in the pedigree data studied). In some cases, the deduction of the missing information on alleles is possible. The goal is then to devise an efficient algorithm to determine as many missing alleles as possible.

Acknowledgments. We thank Tao Jiang and the referees for their valuable comments.

EFFICIENT ALGORITHMS FOR RECONSTRUCTING ZERO-RECOMBINANT HAPLOTYPES ON A PEDIGREE BASED ON FAST ELIMINATION OF REDUNDANT LINEAR EQUATIONS*

JING XIAO†, LAN LIU‡, LIRONG XIA§, AND TAO JIANG¶

Abstract. Computational inference of haplotypes from genotypes has attracted a great deal of attention in the computational biology community recently, partially driven by the international HapMap project. In this paper, we study the question of how to efficiently infer haplotypes from genotypes of individuals related by a pedigree, assuming that the hereditary process was free of mutations (i.e., the Mendelian law of inheritance) and recombinants. The problem has recently been formulated as a system of linear equations over the finite field of $F(2)$ and solved in $O(m^3n^3)$ time by using standard Gaussian elimination, where m is the number of loci (or markers) in a genotype and n the number of individuals in the pedigree. We give a much faster algorithm with running time $O(mn^2 + n^3 \log^2 n \log\log n)$. The key ingredients of our construction are (i) a new system of linear equations based on some spanning tree of the pedigree graph and (ii) an efficient method for eliminating redundant equations in a system of $O(mn)$ linear equations over $O(n)$ variables. Although such a fast elimination method is not known for general systems of linear equations, we take advantage of the underlying pedigree graph structure and recent progress on low-stretch spanning trees.

1. Introduction.

For centuries, human beings have fought the battle against deadly diseases, such as diabetes, cancer, stroke, heart disease, depression, and asthma. Genetic factors are believed to play a significant role for preventing, diagnosing, and treating these diseases. In recent years, *gene mapping* [2, 20, 31], whose goal is to establish connections between diseases and some specific genetic variations, has become one of the most active areas of research in human genetics. In October 2002, a multicountry collaboration, namely, the international *HapMap* project was launched [18]. One of the main objectives of the HapMap project is to identify the *haplotype* (i.e., the states of genetic markers from a single chromosome) structure of humans and common haplotypes among various populations. This information will greatly facilitate the mapping of many important disease-susceptible genes. However, the human genome is a *diploid* (i.e., its chromosomes come in pairs, with one being paternal and

*Received by the editors April 9, 2007; accepted for publication (in revised form) September 15, 2008; published electronically March 4, 2009. An extended abstract of this paper, entitled "Fast elimination of redundant linear equations and reconstruction of recombination-free Mendelian inheritance on a pedigree," appeared in *Proceedings of the* 18*th ACM-SIAM Symposium on Discrete Algorithms (SODA)*, New Orleans, LA, 2007. This research was supported in part by NSF grant CCR-0309902, NIH grant LM008991-01, NSFC grants 60528001 and 60553001, National Key Project for Basic Research (973) grants 2002CB512801 and 2007CB807901, and a fellowship from the Center for Advanced Study, Tsinghua University. The authors wish it to be known that the first two authors should be regarded as joint first authors of this paper.

the other maternal), and, in practice, haplotype data are not collected directly, especially in large-scale sequencing projects, mainly due to cost considerations. Instead, *genotype* data (i.e., the states of genetic markers from all chromosomes, without specifying which chromosome gives rise to each particular marker state) are collected routinely. Hence, combinatorial algorithms and statistical methods for the inference of haplotypes from genotypes, which is also commonly referred to as *phasing*, are urgently needed and have been intensively studied.

This paper is concerned with the inference of haplotypes from genotypes of individuals related by a *pedigree*, which describes the parent-offspring relationship among the individuals. Figure 1 gives an illustrative example of pedigree, genotype, and haplotype, as well as *recombination*, where the haplotypes of a parent recombine to produce a haplotype of her child. (See the appendix for more detailed definitions of these concepts.) Pedigree data is often collected in family-based gene association/mapping studies in addition to genotype data. It is generally believed that haplotypes inferred from pedigrees are more accurate than those from population data. Moreover, some family-based statistical gene association tests such as TDT (i.e., *transmission disequilibrium test*) and its variants (e.g., [32, 39], among others) require access to haplotype information for each member in a pedigree.

By utilizing some biological assumptions, such as the *Mendelian law of inheritance*, i.e., one haplotype of each child is inherited from the father while the other is inherited from the mother free of mutations, and the *minimum-recombination principle*, which says that genetic recombination is rare for closely linked markers and thus haplotypes with fewer recombinants should be preferred in haplotype inference [29, 30], several combinatorial approaches for inferring haplotypes from genotypes on a pedigree have been proposed recently and shown to be powerful and practical [5, 8, 23, 24, 25, 29, 30, 33, 36, 38]. These methods essentially propose polynomial-time heuristics or exponential-time exact algorithms for the so-called the *minimum-recombinant haplotype configuration (MRHC)* problem, which requires a haplotype solution for the input pedigree with the minimum number of recombinants (i.e., recombination events) and is known to be NP-hard [23]. (See the appendix for a more formal definition of the MRHC problem.)

A closely related problem, called the *zero-recombinant haplotype configuration (ZRHC)* problem, where we would like to enumerate all haplotype solutions requiring no recombinant (if such solutions exist), was studied in [23]. The ZRHC problem was proposed under a more stringent biological assumption that the pedigree is also recombination-free. (See the appendix for a more formal definition of the ZRHC problem.) ZRHC is interesting because recent genetic research has shown that human genomic DNAs can be partitioned into long blocks (called *haplotype blocks*) such that recombination within each block is rare or even nonexistent [7, 11, 19], especially when restricted to a single pedigree [24, 25]. An efficient algorithm for ZRHC could also be useful for solving the general MRHC problem as a subroutine, when the number of recombinants is expected to be small. We note in passing that recent work on haplotype inference for population data based on perfect phylogenies also assumes the data is recombination-free [10, 15, 16, 17]. Observe that, when the solution for ZRHC is not unique, it would really be useful to be able to enumerate all of the solutions instead of finding only one feasible solution, so that the solutions can be examined in subsequent analysis (e.g., likelihood distribution of haplotypes [24, 25, 28], linkage between different haplotype blocks [1, 14, 21], etc.) by geneticists.

The algorithmic problem and our result. The ZRHC problem can also be stated abstractly as a simple inheritance reconstruction problem as follows. We have

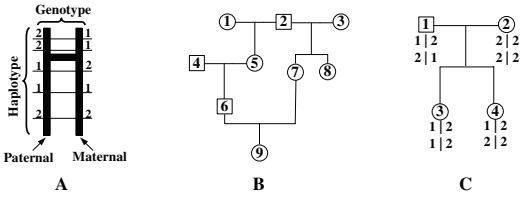

FIG. 1. A. *The structure of a pair of chromosomes from a mathematical point of view. In the figure, each numeric value (*1 *or* 2*) represents a marker state or an* allele. *The haplotype inherited from the father (or the mother) is called paternal haplotype (or maternal haplotype, respectively). The paternal and maternal haplotypes are thus strings* 22112 *and* 11212*, and they form the genotype* $\{1,2\}\{1,2\}\{1,2\}\{1,1\}\{2,2\}$*, which is a string of unordered pairs of alleles at each locus.* B. *An illustration of a pedigree with* 9 *members with a* mating loop*, where circles represent females and boxes represent males. Children are shown under their parents with line connections. For example, individuals* 7 *and* 8 *are children of individuals* 2 *and* 3*. Individuals without parents, such as individuals* 1 *and* 2*, are called* founders*. A pedigree with no mating loops is called* tree pedigree *conventionally.* C. *An example of recombination event where the haplotypes of individual* 1 *recombine to produce the paternal haplotype of individual* 3*. The numbers inside the circles/boxes are individual IDs. Here, a "|" is used to indicate the phase of the two alleles at a marker locus, with the left allele being paternal and the right maternal. Both loci of individual* 2 *and the second locus of individual* 4 *are* homozygous*, while all of the other loci in the pedigree are* heterozygous.

a pedigree connecting n individuals where each individual j has two haplotypes (i.e., strings) defined on m marker loci $a_{j,1}\cdots a_{j,m}$ and $b_{j,1}\cdots b_{j,m}$ inherited from j's father and mother, respectively. That is, if individuals j_1 and j_2 are the parents of j, then $a_{j,1}\cdots a_{j,m} \in \{a_{j_1,1}\cdots a_{j_1,m}, b_{j_1,1}\cdots b_{j_1,m}\}$ and $b_{j,1}\cdots b_{j,m} \in \{a_{j_2,1}\cdots a_{j_2,m}, b_{j_2,1}\cdots b_{j_2,m}\}$. The haplotypes are unknown, but the genotype of each individual j is given to us in the form of string $\{a_{j,1}, b_{j,1}\}\cdots\{a_{j,m}, b_{j,m}\}$. We would like to reconstruct all of the haplotype solutions that could have resulted in the genotypes.

Li and Jiang presented an $O(m^3n^3)$ time algorithm for ZRHC by formulating it as a system of $O(mn)$ linear equations with mn variables over the finite field of $F(2)$ and applying Gaussian elimination [23]. Although this algorithm is polynomial, it is inadequate for large-scale pedigree analysis where both m and n can be in the order of tens or even hundreds, and we may have to examine many pedigrees and haplotype blocks. There are, for example, over five million SNP markers in the public database dbSNP [18]. This challenge motivates us to find more efficient algorithms for ZRHC. Several attempts have been made recently in [4, 26], but the authors failed to prove the correctness of their algorithms in all cases, especially when the input pedigree has mating loops. Chan et al. proposed a linear-time algorithm in [3], but the algorithm works only for pedigrees without mating loops (i.e., the tree pedigrees).

In this paper, we present a much faster algorithm for ZRHC with running time $O(mn^2+n^3\log^2 n\log\log n)$. Our construction begins with a new system of linear equations over $F(2)$ for ZRHC. Although the system still has $O(mn)$ variables and $O(mn)$ equations, it can be effectively reduced to an equivalent system with $O(mn)$ equations and at most $2n$ variables, by exploring the underlying pedigree graph structure. By using standard Gaussian elimination, this already gives an improved algorithm with running time $O(mn^3)$. We then show how to reduce the number of equations further to $O(n\log^2 n\log\log n)$ (assuming that $m \geq \log^2 n\log\log n$, which usually holds in practice), by giving an $O(mn)$ time method for eliminating redundant equations in the system. Although such a fast elimination method is not known for general systems of linear equations, we again take advantage of the underlying pedigree graph structure and recent progress on low-stretch spanning trees in [9]. In particular, the

low-stretch spanning tree result helps upper bound the number of equations that need to be kept in the elimination process. We also show that our algorithm actually runs in $O(mn^2 + n^3)$ time when the input pedigree is a tree pedigree with no mating loops (which is often true for human pedigrees) or when there is a locus that is heterozygous across the entire pedigree. Moreover, our algorithm produces a general solution[1] to the original system of linear equations at the end that represents all feasible solutions to the ZRHC problem.

Related work on solving systems of (sparse) linear equations. The search for efficient algorithms for solving systems of linear equations is a classical problem in linear algebra. Besides Gaussian elimination, methods based on fast matrix multiplication algorithms have been proposed and could achieve an asymptotic speed of $O(n^{2.376})$ on n equations with n unknowns [6, 35]. However, these methods are only of theoretical interest since they are hard to implement and do not outperform Gaussian elimination unless n is very large. Moreover, they assume that the coefficient matrix is of full rank, which is an unreasonable assumption in ZRHC (considering the linear systems derived for ZRHC so far).

Observe that the linear system given in [23] for ZRHC is actually very sparse since each of its equations has at most four variables. Thus, a plausible way to speed up is to utilize fast algorithms for solving sparse linear systems. The Lanczos and conjugate gradient algorithms [13] and the Wiedemann algorithm [37] are some of the best known algorithms for solving sparse linear system over finite fields. The Wiedemann algorithm runs in (expected) quadratic time (which is in fact slower than our algorithm when applied to linear systems for ZRHC), while the Lanczos and conjugate gradient algorithms are only heuristics [22]. However, they use randomization and do not find all solutions. Furthermore, the algorithms cannot check if the system has no solution [12]. A randomized algorithm with quadratic expected time for certifying inconsistency of linear systems is given in [12].

The rest of our paper is organized as follows. We will describe a new system of linear equations for ZRHC and some useful graphs derived from a pedigree in section 2. The $O(mn^3)$ time algorithm is presented in section 3, and the $O(mn^2 + n^3 \log^2 n \log\log n)$ time algorithm is given in section 4. Some concluding remarks are given in section 5. The appendix contains some related biological definitions concerning MRHC and an example execution of the main algorithm.

2. A system of linear equations for ZRHC and the pedigree graph.

In this section, we first present a new formulation of ZRHC in terms of linear equations and then define some graph structures which will be used in our algorithm.

2.1. The linear system.

Throughout this paper, n denotes the number of the individuals (or members) in the input pedigree and m the number of marker loci. Without loss of generality, suppose that each allele in the given genotypes is numbered numerically as 1 or 2 (i.e., the markers are assumed to be *biallelic*, which makes the hardest case for MRHC/ZRHC [23]), and the pedigree is free of genotype errors (i.e., the two alleles at each locus of a child can always be obtained from her respective parents). Hence, we can represent the genotype of member j as a ternary vector $\mathbf{g}_j$ as follows: $g_j[i] = 0$ if locus i of member j is homozygous with both alleles being 1's, $g_j[i] = 1$ if the locus is homozygous with both alleles being 2's, and $g_j[i] = 2$ otherwise

[1] A general solution of any linear system is denoted by the span of a basis in the solution space to its associated homogeneous system, offset from the origin by a vector, namely by any particular solution.

(i.e., the locus is heterozygous). For any heterozygous locus i of member j, we use a binary variable $p_j[i]$ to denote the *phase* at the locus as follows: $p_j[i] = 1$ if allele 2 is paternal, and $p_j[i] = 0$ otherwise. When the locus is homozygous, the variable is set to $g_j[i]$ for some technical reasons (so that the equations below involving $p_j[i]$ will hold). Hence, the vector $\mathbf{p}_j$ describes the paternal and maternal haplotypes of member j. Observe that the vectors $\mathbf{p}_1, \ldots, \mathbf{p}_n$ represent a complete haplotype configuration of the pedigree. In fact, the sparse linear system in [23] was based on these vectors. Also for technical reasons, define a vector $\mathbf{w}_j$ for member j such that $w_j[i] = 0$ if its ith locus is homozygous and $w_j[i] = 1$ otherwise.

Suppose that member j_r is a parent of member j. We introduce an auxiliary binary variable $h_{j_r,j}$ to indicate which haplotype of j_r is passed to j. If j_r gives its paternal haplotype to j, then $h_{j_r,j} = 0$; otherwise, $h_{j_r,j} = 1$. Suppose that j is a nonfounder member with her father and mother being j_1 and j_2, respectively. We can define two linear (constraint) equations over $F(2)$ to describe the inheritance of paternal and maternal haplotypes at j, respectively, following the Mendelian law of inheritance and zero-recombinant assumption:

$$\mathbf{p}_{j_1} + h_{j_1,j} \cdot \mathbf{w}_{j_1} = \mathbf{p}_j \qquad \text{and} \qquad \mathbf{p}_{j_2} + h_{j_2,j} \cdot \mathbf{w}_{j_2} = \mathbf{p}_j + \mathbf{w}_j. \tag{2.1}$$

If we let $\mathbf{d}_{j_1,j}$ denote the vector $\mathbf{0}$ and $\mathbf{d}_{j_2,j}$ denote $\mathbf{w}_j$, then the above equations can be unified into a single equation as

$$\mathbf{p}_{j_r} + h_{j_r,j} \cdot \mathbf{w}_{j_r} = \mathbf{p}_j + \mathbf{d}_{j_r,j} \qquad (r = 1,\ 2). \tag{2.2}$$

Formally, we can express the ZRHC problem as a system of linear equations:

$$\begin{cases} p_k[i] + h_{k,j} \cdot w_k[i] = p_j[i] + d_{k,j}[i], & 1 \le i \le m,\ 1 \le j,k \le n, k \text{ is a parent of } j, \\ p_j[i] = g_j[i], & 1 \le i \le m,\ 1 \le j \le n,\ g_j[i] \ne 2, \\ w_j[i] = 1, & 1 \le i \le m,\ 1 \le j \le n,\ g_j[i] = 2, \\ w_j[i] = 0, & 1 \le i \le m,\ 1 \le j \le n,\ g_j[i] \ne 2, \\ d_{k,j}[i] = w_j[i], & 1 \le i \le m,\ 1 \le j,k \le n,\ k \text{ is the mother of } j, \\ d_{k,j}[i] = 0, & 1 \le i \le m,\ 1 \le j,k \le n,\ k \text{ is the father of } j, \end{cases} \tag{2.3}$$

where $g_j[i], w_j[i], d_{k,j}[i]$ are all constants depending on the input genotypes, and $p_j[i], h_{k,j}$ are the unknowns. Note that the number of p-variables is exactly mn and the number of h-variables is at most $2n$ since every child has two parents and there are at most n children in the pedigree.

Remark. Observe that, for any member j, if the member itself or one of its parents is homozygous at locus i, then $p_j[i]$ is fixed based on (2.3). In the rest of this paper, we will assume that all such variables $p_j[i]$ are *predetermined* (without any conflict) and use them as "anchor points" to define some new constraints about the h-variables.

2.2. The pedigree graph and locus graphs. To apply combinatorial techniques, we transform the input pedigree into a graph, called the *pedigree graph*, by connecting each parent directly to her children. See Figure 2(B) for an example. Although the edges in the pedigree represent the inheritance relationship between a parent and a child and are directed, we will think of the pedigree graph, and, more importantly, the subsequent locus graphs, as undirected in future definitions and constructions. This is because each edge (j,k) of the pedigree graph (and locus graphs) will be used to represent the constraint between the vectors $\mathbf{p}_j$ and $\mathbf{p}_k$ (i.e., the phases

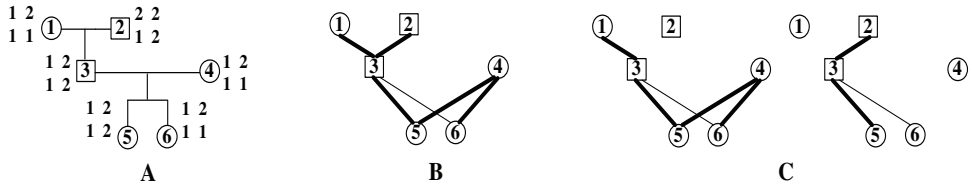

FIG. 2. A. *An example pedigree with genotype data. Here, the alleles at a locus are ordered according to their ID numbers instead of phase (which is unknown).* B. *The pedigree graph with a spanning tree. The tree edges are highlighted. at j and k) via the variable $h_{j,k}$, which is symmetric, as can be seen from Lemma 1 and Corollaries 2 and 3 below.[2]

Clearly, such a pedigree graph $G = (V, E)$ may be cyclic due to mating loops or multiple children shared by a pair of parents. Let $\mathcal{T}(G)$ be any spanning tree of G. $\mathcal{T}(G)$ partitions the edge set E into two subsets: *tree edges* and *nontree edges*. For simplicity, the nontree edges will be called *cross edges*. Let $E^{\mathbb{X}}$ denote the set of cross edges. Since $|E| \leq 2n$ and the number of edges in $\mathcal{T}(G)$ is $n-1$, we have $|E^{\mathbb{X}}| \leq n+1$. Figure 2(B) gives an example of tree edges and cross edges.

For any fixed locus i, the value $w_k[i]$ can be viewed as the weight of each edge $(k, j) \in E$, where k is a parent of j. We construct the *ith locus graph* G_i as the subgraph of G induced by the edges with weight 1. Formally, $G_i = (V, E_i)$, where $E_i = \{(k, j) |\ k \text{ is a parent of } j, w_k[i] = 1\}$. The ith locus graph G_i induces a subgraph of the spanning tree $\mathcal{T}(G)$. Since the subgraph is a forest, it will be referred to as the *ith locus forest* and denoted by $\mathcal{T}(G_i)$. Figure 2(C) shows the locus graphs and the locus forests of the given pedigree.

The locus graphs can be used to identify some implicit constraints on the h-variables as follows. First, we need to "symmetrize" of the h-variables and d-constants: for any edge $(k, j) \in E$, define $h_{k,j} = h_{j,k}$ and $\mathbf{d}_{k,j} = \mathbf{d}_{j,k}$.

LEMMA 1. *For any path $\mathcal{P} = j_0, \ldots, j_k$ in locus graph G_i connecting vertices j_0 and j_k, we have*

$$p_{j_0}[i] + p_{j_k}[i] + \sum_{r=0}^{k-1} (h_{j_r, j_{r+1}} + d_{j_r, j_{r+1}}[i]) = 0.$$

Proof. The equation follows easily from (2.3) and an induction on the length k of the path. □

Note that the above constraint remains the same no matter in which direction path $\mathcal{P}$ is read, since the addition is over field $F(2)$ and the h-variables and d-constants are symmetric. From the lemma, we can see that for a cycle in G_i the summation of all of the h-variables corresponding to the edges on the cycle is a constant. The constant is said to be *associated* with the cycle.

COROLLARY 2. *For any cycle $\mathcal{C} = j_0, \ldots, j_k, j_0$ in G_i, there exists a binary constant b defined as $b = \sum_{r=0}^{k} d_{j_r, j_{r+1 \bmod k+1}}[i]$ such that $\sum_{r=0}^{k} h_{j_r, j_{r+1 \bmod k+1}} = b$.*

[2]The reader can also verify that the direction of an edge will not affect the graph traversal and the ensuing treatment of constraint equations to be discussed in the next two sections.

Proof. This follows from Lemma 1 and the fact that $p_{j_0}[i] + p_{j_0}[i] = 0$. ∎

From Lemma 1, we can easily see that if the p-variables at the endpoints of a path are predetermined, then the summation of all of the h-variables corresponding to the edges on the path is a constant. The constant is said to be *associated* with the path. We construct constraints on h-variables as follows. Again, notice that the following constant b does not depend on the direction that path $\mathcal{P}$ is read.

COROLLARY 3. *Suppose that $\mathcal{P} = j_0, \ldots, j_k$ is a path in G_i connecting vertices j_0 and j_k, and the variables $p_{j_0}[i]$ and $p_{j_k}[i]$ are predetermined. Then there exists a binary constant b defined as $b = p_{j_0}[i] + p_{j_k}[i] + \sum_{r=0}^{k-1} d_{j_r,j_{r+1}}[i]$ such that $\sum_{r=0}^{k-1} h_{j_r,j_{r+1}} = b$.*

3. An $O(mn^3)$ time algorithm for ZRHC. Since the number of h-variables is at most $2n$, our key idea is to first derive a system of $O(mn)$ linear equations on the h-variables. We use paths and cycles in G_i and the predetermined p-variables as mentioned in the last section to build the linear system, and then we find a *general* solution to the system by using Gaussian elimination so that all inherent freedom in (2.3) is kept. This new system of equations about the h-variables is clearly necessary for (2.3). The crux of the construction is to show that it is also sufficient, and thus the p-variables can be determined from the values of the h-variables by a simple traversal of the locus graphs.

3.1. Linear constraints on the h-variables. We will introduce constraint equations to "cover" all of the edges in each locus graph. As mentioned above, these equations connect the p-variables and will suffice to help determine their values. Note that, since the edges broken in each locus graph involve predetermined p-variables, we do not have to introduce constraints to cover them. The constraints can be classified into two categories with respect to the spanning tree $\mathcal{T}(G)$: constraints for cross edges and constraints for tree edges.

Cross edge constraints. Adding a cross edge e to the spanning tree $\mathcal{T}(G)$ yields a cycle $\mathcal{C}$ in the pedigree graph G. Let $length(\mathcal{C})$ denote the length of cycle $\mathcal{C}$. Suppose that the edge e exists in the ith locus graph G_i, and consider two cases of the cycle $\mathcal{C}$ with respect to graph G_i.

Case 1. The cycle exists in G_i. We introduce a constraint along the cycle as in Corollary 2. This constraint is called a *cycle constraint*. The set of such cycle constraints for edge e in all locus graphs is denoted by $C^{\mathbb{C}}(e)$, i.e.,

$$C^{\mathbb{C}}(e) = \{(b, e) \mid b \text{ is associated with the cycle in } \mathcal{T}(G_i) \cup \{e\},\ 1 \le i \le m\}.$$

The set of cycle constraints for all cross edges is denoted by $C^{\mathbb{C}} = \biguplus_{e \in E^{\mathbb{X}}} C^{\mathbb{C}}(e)$.

Case 2. Some of the edges of the cycle do not exist in G_i. This means that the cycle $\mathcal{C}$ is broken into several disjoint paths in G_i by the predetermined vertices. Since e exists in G_i, exactly one of these paths, denoted as $\mathcal{P}$, contains e. Observe that both endpoints of $\mathcal{P}$ are predetermined, and thus Corollary 3 could give us a constraint concerning the h-variables along the path. Such a constraint will be called a *path constraint*. The set of such path constraints for e in all locus graphs G_i is denoted by $C^{\mathbb{P}}(e)$, i.e.,

$$C^{\mathbb{P}}(e) = \left\{ (k, j, b, e) \;\middle|\; \begin{array}{l} \text{in } \mathcal{T}(G_i) \cup \{e\},\ b \text{ is associated with the path containing } e \\ \text{connecting two predetermined vertices } k \text{ and } j,\ 1 \le i \le m \end{array} \right\}.$$

The set of path constraints for all cross edges is denoted by $C^{\mathbb{P}} = \biguplus_{e \in E^{\mathbb{X}}} C^{\mathbb{P}}(e)$.

Please refer to **Procedure** CROSS_EDGE_CONSTRAINTS in Figure 3 to see the generation of $C^{\mathbb{C}}$ and $C^{\mathbb{P}}$.

Tree edge constraints. By Corollary 3, there is an implicit constraint concerning the h-variables along each path between two predetermined vertices in the same connected component of $\mathcal{T}(G_i)$. Therefore, for each connected component $\mathcal{T}$ of $\mathcal{T}(G_i)$, we arbitrarily pick a predetermined vertex in the component as the *seed* vertex, and generate a constraint for the unique path in $\mathcal{T}(G_i)$ between the seed and each of the other predetermined vertices in the component, as in Corollary 3. Such a constraint will be called a *tree constraint*. Notice that if there exists any component having no predetermined vertices, then locus i must be heterozygous across the entire pedigree and $\mathcal{T}(G_i)$ is actually a spanning tree. Such a locus will be referred to as an *all-heterozygous* locus. For such a locus i, we arbitrarily pick a vertex in $\mathcal{T}(G_i)$ as the seed, but we will not generate at tree constraints.

To conform with the notation of path constraints and for the convenience of presentation, we arbitrarily pick a tree edge denoted as e_0 and write the set of tree constraints at all loci as

$$C^{\mathbb{T}} = \left\{ (k, j, b, e_0) \;\middle|\; \begin{array}{l} \text{in a connected component of } \mathcal{T}(G_i) \text{ with seed } k,\ b \text{ is} \\ \text{associated with the path connecting vertices } k \text{ and} \\ \text{a predetermined vertex } j,\ 1 \le i \le m \end{array} \right\}.$$

Note that e_0 is the same for all of the tree constraints and will be used as an *indicator* to distinguish tree constraints from path constraints defined by cross edges. The formal construction of $C^{\mathbb{T}}$ is described in **Procedure** Tree_Edge_Constraints in Figure 3.

Again, we need to symmetrize path constraints and tree constraints: given any constraint (k, j, b, e) generated for a path connecting two predetermined vertices k and j in a locus graph, define $(k, j, b, e) = (j, k, b, e)$. The above constructions of $C^{\mathbb{C}}$, $C^{\mathbb{P}}$, and $C^{\mathbb{T}}$ are more formally described as pseudocode in Figure 3. We can easily see that the following holds.

Lemma 4. $|C^{\mathbb{C}}| + |C^{\mathbb{P}}| + |C^{\mathbb{T}}| = O(mn)$.

3.2. Solving the linear system for ZRHC using the new constraints. We now describe how to solve the system in (2.3) in $O(mn^3)$ time. The pseudocode for solving the system is formally given as Algorithm **ZRHC_Phase** in Figure 4. Here, we first construct the cycle, path, and tree constraints on the h-variables, and pick a vertex as the seed for every connected component in the locus forests $\mathcal{T}(G_i)$, as described in the last subsection. Then we solve these constraints by using Gaussian elimination to obtain a general solution of the h-variables, which may contain some *free* h-variables. Next, for each connected component with no predetermined vertices, we set the p-variable of the seed as a *free* variable and treat it as a determined value. Finally, we perform a breadth-first search (BFS) on the spanning forest $\mathcal{T}(G_i)$ of each locus graph G_i. For each connected component of $\mathcal{T}(G_i)$, we start from the seed and propagate its p-variable value to the undetermined vertices in the component by using the solution for the h-variables, which will result in functions of the *free* h-variables and at most one *free* p-variable. Note that, in the last step of the algorithm, $p_k[i]$ is expressed as a linear combination of the free variables in $p_j[i]$ and the free h-variables with an appropriate constant term.

To show the correctness of the algorithm, we need only show that the solution found by the algorithm is a feasible solution for (2.3) and vice versa. Since we determine the p-variables based on the linear system for the h-variables derived from (2.3), any feasible solution to (2.3) will be included in the (general) solution found by our algorithm. In other words, we do not lose any degrees of freedom in the solution process. Hence, it suffices to show that our solution satisfies (2.3).

end.

FIG. 3. *The procedure for generating constraints.*

LEMMA 5. *The p-variables and h-variables determined by Algorithm* **ZRHC_Phase** *satisfy the linear system in* (2.3).

Proof. Denote the solution found by our algorithm as $\mathbf{p}$ and $\mathbf{h}$. We need only care about the first equations in (2.3). If the $w_k[i]$ in such an equation is 0, then the equation involves only two predetermined p-values, which holds trivially since Step 1 of our algorithm explicitly takes care of predetermined p-values. Otherwise, each such equation corresponds to an edge in some locus graph. Let $e = (j_1, j_2)$ be an edge in locus graph G_i. It represents an equation $p_{j_1}[i] + h_{j_1,j_2} = p_{j_2}[i] + d_{j_1,j_2}[i]$, i.e., the first equation on edge e in (2.3).

Algorithm ZRHC_Phase
[**Improved ZRHC_Phase**]
input: pedigree $G = (V, E)$ and genotype $\{\mathbf{g}_j\}$
output: a general solution of $\{\mathbf{p}_j\}$
begin
Step 1. *Preprocessing*
Construct a [**low-stretch**] spanning tree $\mathcal{T}(G)$ on G;
Let e_0 be an arbitrary tree edge;
for each locus i
Generate the locus graph G_i;
Generate the locus forest $\mathcal{T}(G_i)$;
Identify the predetermined nodes;
Step 2. *Constraint generation*
Cross_Edge_Constraints($G_{[1..m]}, \mathcal{T}(G),\ C^{\mathbb{C}},\ C^{\mathbb{P}}$);
Tree_Edge_Constraints($\mathcal{T}(G_{[1..m]}),\ C^{\mathbb{T}}, e_0$);
[**Step 2′. *Redundant constraint elimination***
Compact_Constraints($C^{\mathbb{C}},\ C^{\mathbb{P}},\ C^{\mathbb{T}},\ e_0$ **)**;]
Step 3. *Solve the h-variables*
Apply Gaussian elimination on $C^{\mathbb{C}} \uplus C^{\mathbb{P}} \uplus C^{\mathbb{T}}$
to get a general solution of the h-variables;
Step 4. *Solve the p-variables by propagation*
for each locus i
for each connected component $\mathcal{T}$ in $\mathcal{T}(G_i)$
if $\mathcal{T}$ has no predetermined vertices
Set the p-variable of the seed as a free variable and
treat it as a determined value;
Traverse $\mathcal{T}$ by BFS starting from the seed;
for each edge (j, k) in $\mathcal{T}$
if $p_j[i]$ is determined but $p_k[i]$ is undetermined
$p_k[i] = p_j[i] + h_{j,k} + d_{j,k}[i]$;
return $\{\mathbf{p}_j\}$;
end.

FIG. 4. *The $O(mn^3)$ time algorithm* ZRHC_Phase *and the $O(mn^2 + n^3 \log^2 n \log\log n)$ time algorithm* Improved_ZRHC_Phase. *The additional instructions in* Improved_ZRHC_Phase *are highlighted by bold font in square brackets. In order to save running time, we use disjoint union (i.e., $\uplus$) in Algorithms* ZRHC_Phase *and* Improved_ZRHC_Phase.

Given any two vertices j_s and j_t in a same connected component of $\mathcal{T}(G_i)$, we denote by $\mathcal{P}(j_s, j_t)$ the unique path in the component connecting j_s and j_t. Suppose that vertex j_0 is the seed of the component. The key observation here is that for any vertex j_t, regardless of whether vertex j_t is predetermined or not, our solution satisfies the equation

$$p_{j_t}[i] \ = \ p_{j_0}[i] \ + \sum_{(k,\ j)\ \in\ \mathcal{P}(j_0,\, j_t)} (h_{k,j} + d_{k,j}[i]). \tag{3.1}$$

More precisely, if vertex j_t is predetermined, then (3.1) holds because of the tree constraint for path $\mathcal{P}(j_0, j_t)$ defined in Step 2 of the algorithm. Otherwise, $p_{j_t}[i]$ is assigned the value as given in (3.1) during the traversal from the seed j_0 to j_t in Step 4. More generally, we can build a relationship between the p-values of two vertices j_s and j_t from (3.1) as follows:

$$p_{j_t}[i] \;=\; p_{j_s}[i] \;+ \sum_{(k,\ j)\ \in\ \mathcal{P}(j_t,\, j_s)} (h_{k,j} + d_{k,j}[i]). \tag{3.2}$$

Notice that, as long as j_s and j_t are in the same connected component of $\mathcal{T}(G_i)$, the above equation is satisfied by our solution. With the help of (3.2), we now show that our solution satisfies the equation represented by edge e.

Case 1. e is a tree edge. Clearly, vertices j_1 and j_2 belong to the same connected component of $\mathcal{T}(G_i)$. We replace j_s and j_t by j_1 and j_2, respectively, in (3.2) and obtain $p_{j_1}[i] \;=\; p_{j_2}[i] \;+\sum_{(k,\ j)\ \in\ \mathcal{P}(j_1,\, j_2)}(h_{k,j} + d_{k,j}[i]) \;=\; p_{j_2}[i] \;+ h_{j_1,j_2} + d_{j_1,j_2}[i]$, which means that our solution satisfies the equation represented by the tree edge e, since the constant $w_{j_1}[i]$ is assumed to be 1.

Case 2. e is a cross edge. Denote by $\mathcal{C}$ the cycle in $\mathcal{T}(G_i) \cup \{e\}$. There are two subcases.

Case 2.1. $\mathcal{C}$ exists in G_i. In this case, we have a cycle constraint for $\mathcal{C}$ in G_i. Suppose that the cycle constraint is $0 = \sum_{(k,j)\in\mathcal{C}}(h_{k,j} + d_{k,j}[i])$. Observe that vertices j_1 and j_2 are in the same connected component of $\mathcal{T}(G_i)$; thus we have $p_{j_1}[i] \;=\; p_{j_2}[i] \;+\sum_{(k,\ j)\ \in\ \mathcal{P}(j_1,\, j_2)}(h_{k,j} + d_{k,j}[i])$ as shown in (3.2). Observe that cycle $\mathcal{C}$ can be decomposed into path $\mathcal{P}(j_1, j_2)$ and cross edge $e = (j_1, j_2)$. Therefore, summing up the above two equations, we can get $p_{j_1}[i] \;=\; p_{j_2}[i] + h_{j_1,j_2} + d_{j_1,j_2}[i]$, which means that our solution satisfies the equation represented by the cross edge e.

Case 2.2. $\mathcal{C}$ is broken into several disjoint paths in G_i by predetermined vertices. Suppose that the unique path containing e is $\mathcal{P}$. Without loss of generality, suppose that vertices k_1 and k_2 are the endpoints of $\mathcal{P}$, and $\mathcal{P}$ has the form $\mathcal{P}(k_1, j_1); e; \mathcal{P}(j_2, k_2)$. Since vertices k_1 and k_2 are predetermined, our algorithm defines a path constraint for $\mathcal{P}$ in G_i, i.e., $p_{k_1}[i] \;=\; p_{k_2}[i] \;+\sum_{(k,\ j)\ \in\ \mathcal{P}}(h_{k,j} + d_{k,j}[i])$. Observe that vertices k_1 and j_1 are in the same connected component of $\mathcal{T}(G_i)$. Therefore, $p_{k_1}[i] = p_{j_1}[i] + \sum_{(k,\ j)\ \in\ \mathcal{P}(k_1,\, j_1)}(h_{k,j} + d_{k,j}[i])$ based on (3.2). Similarly, vertices j_2 and k_2 are in the same connected component of $\mathcal{T}(G_i)$, and $p_{j_2}[i] = p_{k_2}[i] + \sum_{(k,\ j)\ \in\ \mathcal{P}(j_2,\, k_2)}(h_{k,j} + d_{k,j}[i])$. Since path $\mathcal{P} = \mathcal{P}(k_1, j_1); e; \mathcal{P}(j_2, k_2)$, summing up the above three equations yields equality $p_{j_2}[i] = p_{j_1}[i] + h_{j_1,j_2} + d_{j_1,j_2}[i]$, which means that our solution satisfies the equation represented by the cross edge e.

In conclusion, the solution produced by Algorithm **ZRHC_Phase** satisfies the equations on all edges, and thus the lemma holds. ∎

THEOREM 6. *The running time of Algorithm* **ZRHC_Phase** *is* $O(mn^3)$.

Proof. Step 1 needs $O(n)$ time for each locus, which takes $O(mn)$ time in total. In Step 2, we need at most $O(n)$ time for generating a constraint. Since there are at most $O(mn)$ constraints, it takes at most $O(mn^2)$ time. In Step 3, the system has $O(n)$ h-variables and $O(mn)$ constraints. So, Gaussian elimination requires $O(mn^3)$ time. In Step 4, every edge is visited just once in the traversal. Since each h-variable is expressed as a linear combination of at most n free h-variables at the end of Step 3,every p-variable is expressed as at most n free h-variables and at most one free p-

variable on the same locus. Thus, this steps takes $O(mn^2)$ time altogether. Therefore, the entire process takes $O(mn^3)$ time. □

4. Speeding up the algorithm by fast elimination of redundant equations. The bottleneck in the above algorithm is Step 3, where we have to spend $O(mn^3)$ time to solve a system of $O(mn)$ equations over $O(n)$ variables. Clearly, most of the equations are redundant and can be expressed as linear combinations of other equations. The question is how to detect and eliminate these redundant equations (without using Gaussian elimination, of course). To the best of our knowledge, there are no methods that would eliminate redundant equations for any system of linear equations over any field faster than Gaussian elimination asymptotically in the worst case. Here, we give such a method taking advantage of the underlying pedigree structure. We first give a general method to compact path and tree constraints that correspond to paths on a cycle in the pedigree graph.

Let $\mathcal{C}$ be a cycle in the pedigree graph G induced by cross edge e_1. For convenience, we say that a path/tree constraint is on the cycle $\mathcal{C}$ if it corresponds to a path/edge on $\mathcal{C}$. The following lemma shows that the path/tree constraints on a cycle can be greatly compacted and is the key to our algorithm to eliminate redundant constraints.

LEMMA 7. *Given a set C of path/tree constraints on cycle $\mathcal{C}$, we can reduce C to an equivalent constraint set of size at most $2 \cdot length(\mathcal{C})$ in time $O(|C|)$.*

Proof. Recall that e_0 represents the fixed tree edge introduced in subsection 3.1 for defining the tree constraints. We use $\widehat{C}$ to denote the equivalent constraint set (to be constructed). Initially, we set $\widehat{C} = \emptyset$.

For convenience, we say that a path/tree constraint *connects* vertices j and k if the constraint has the form (k, j, b, e). To depict a more clear picture of the relationship between the constraints in C, we define a *constraint graph* G^*[3] as follows. For each vertex k of the cycle $\mathcal{C}$, we create a vertex in G^*. For each path/tree constraint in C connecting k and j, we build an edge connecting k and j in G^*. Observe that the connected components in G^* naturally partition the constraints in C into disjoint subsets. We will compact the constraints in each of these disjoint subsets separately and put the resultant equivalent constraint sets into $\widehat{C}$. More precisely, for each connected component of G^*, we pick an arbitrary vertex as the *root* of the component and construct new constraints connecting the root and the other vertices in the component. The details of the construction will be given in the next paragraph. Here, the term root is meant to be synonymous to the term seed defined in subsection 3.1, although each seed is defined for a single locus, whereas a root may be used to deal with constraints concerning multiple loci.

Now, we give the details of how to construct $\widehat{C}$. Consider each connected component S of G^*. Suppose that its root is k_0. We process the constraints of C induced by S in the order of increasing distance between the root and the vertices connected by the constraints. In other words, we traverse S by BFS starting from the root. Suppose that we are now visiting vertex j. For each edge (k_0, j), we directly put into $\widehat{C}$ the constraints that created the edge (k_0, j) in G^*. For each edge (k, j) where k $(k \neq k_0)$ is visited before j, our construction guarantees that $\widehat{C}$ will have constraints connecting the root k_0 and k. Suppose that one of such constraints is $c' = (k_0, k, b', e')$. Let $c = (k, j, b, e) \in C$ denote the constraint that created the edge (k, j) in G^*. We generate a new constraint $c'' = (k_0, j, b'', e'')$, where $b'' = b + b'$ and e'' is defined as

[3]Note that a constraint graph might actually be a multigraph, but this will not affect the correctness of Lemma 7.

follows:

$$e'' = \begin{cases} e_1 & \text{if } \{e\} \cup \{e'\} = \{e_0, e_1\}, \\ e_0 & \text{otherwise.} \end{cases}$$

Because c can be represented as the summation of c'' and $c' \in \widehat{C}$, c is equivalent to c'' given $\widehat{C}$. Then we add c'' to $\widehat{C}$. Here, again the fixed tree e_0 and cross edge e_1 are used to indicate tree and path constraints, respectively. Observe that the above constraint c'' resulted from the combination of constraints c' and that c involves only tree edges if and only if both or none of c' and c corresponds to paths containing e. Otherwise, c'' corresponds to some path across e_1.

The BFS creates an equivalent constraint in $\widehat{C}$ for every constraint in C, and thus $\widehat{C} \equiv C$. Recall that each constraint in $\widehat{C}$ has the form (k_0, j, b, e), where j is a vertex in $\mathcal{C}$, e is either e_0 or e_1, and k_0 is the root of the connected component of G^* containing j. It is easy to see that two constraints (k_0, j, b', e) and (k_0, j, b'', e) that differ only in the associated b-constants are consistent with each other if and only if $b' = b''$. Hence, $\widehat{C}$ has at most $2 \cdot length(\mathcal{C})$ different constraints, or otherwise the input linear system has no feasible solutions. The construction can be done in $O(|C|)$ time, as more formally described by Procedure **Compact_PT_Const** in Figure 5. Hence, the lemma holds. □

The reader may refer to the example in Appendix B (Step 2′) for a simple illustration of how the construction in the above proof works. An immediate application of Lemma 7 is to remove redundancy from each path constraint set $C^{\mathbb{P}}(e)$, since the path constraints in $C^{\mathbb{P}}(e)$ are all on the cycle induced by e.

COROLLARY 8. *Given the path constraint set $C^{\mathbb{P}}(e)$, we can reduce it to an equivalent constraint set of size at most $2 \cdot length(\mathcal{C})$ in time $O(|C^{\mathbb{P}}(e)|)$, where $\mathcal{C}$ is the cycle induced by cross edge e.*

We can also use Lemma 7 to remove redundant tree constraints. Note that the construction in the proof of Lemma 7 still works if the constraints in C are all tree constraints involving no cross edge e_1. Moreover, the resultant set $\widehat{C}$ contains only constraints of the form (k_0, j, b, e_0). This implies that $|\widehat{C}| \leq n$. Therefore, the following corollary holds.

COROLLARY 9. *Given the tree constraint set $C^{\mathbb{T}}$, we can reduce it to an equivalent constraint set of size at most n in $O(|C^{\mathbb{T}}|)$ time.*

4.1. Elimination of redundant cycle constraints. Each cross edge e induces a unique cycle $\mathcal{C}$. Since every constraint in $C^{\mathbb{C}}(e)$ concerns the same set of h-variables corresponding to the edges on $\mathcal{C}$, each $C^{\mathbb{C}}(e)$ contains only one independent constraint. Moreover, these constraints are consistent with each other if and only if their associated constants are identical, which can be checked in $O(m)$ time. Because the total number of cross edges are at most $n + 1$ we have the following lemma.

LEMMA 10. *Given the cycle constraint set $C^{\mathbb{C}}$, we can reduce it to an equivalent constraint set of size at most $n + 1$ in $O(mn)$ time.*

4.2. Elimination of redundant path constraints. We will show how to reduce the path constraints $C^{\mathbb{P}}$ on a general pedigree to an equivalent set of path constraints with size $O(n \log^2 n \log \log n)$ in $O(mn)$ time (assuming $\log^2 n \log \log n < m$). Furthermore, for tree pedigrees (i.e., pedigrees with no mating loops) we can make the equivalent constraint set as small as $O(n)$. For pedigrees with an all-heterozygous locus across the entire pedigree, we can first transform $C^{\mathbb{P}}$ into an equivalent tree con-

```

```

FIG. 5. *The procedure for compacting path and tree constraints on a cycle.*

straint set with size $O(mn)$, and then we will remove its redundancy via Corollary 9. We first start with the special cases.

Elimination of redundant path constraints on tree pedigrees. Observing that the length of each (simple) cycle in the pedigree graph of a tree pedigree is a constant (i.e., 4, of which an example is given in Figure 2(B)), we can upper bound the total number of path constraints as follows.

LEMMA 11. *Given the path constraint set $C^{\mathbb{P}}$ on a tree pedigree, we can reduce it to an equivalent path constraint set of size $O(n)$ in $O(mn)$ time.*

Proof. By Corollary 8, we can reduce $C^{\mathbb{P}}(e)$ for each cross edge e to an equivalent set of at most eight path constraints in $O(m)$ time. Since there are at most $n+1$ cross edges, the set $C^{\mathbb{P}}$ can be reduced to an equivalent set of size $O(n)$ in $O(mn)$ time, and thus the lemma holds. □

Transformation of path constraints on pedigrees with an all-heterozygous locus. Observe that for a pedigree with an all-heterozygous locus i each cross edge induces a cycle that exists in the locus graph G_i and has a cycle constraint in the (reduced) set $C^{\mathbb{C}}$. This allows us to transform all of the path constraints into tree constraints given the cycle constraints as follows.

COROLLARY 12. *Given the path constraint set $C^{\mathbb{P}}$ on a pedigree with an all-heterozygous locus, we can construct an equivalent tree constraint set of size $O(mn)$ in $O(mn)$ time.*

Proof. Let us first focus on a cross edge e. Suppose that the cycle $\mathcal{C}$ is induced by e in $\mathcal{T}(G) \cup \{e\}$, the compact $C^{\mathbb{C}}(e)$ is $\{(b', e)\}$, and e_0 is the fixed tree edge defined in subsection 3.1. Notice that the cycle $\mathcal{C}$ has two disjoint paths connecting each pair of two vertices on the cycle. One of them consists of only tree edges and may be used to define a tree constraint, while the other contains the cross edge and may be used to represent a path constraint. Therefore, with the help of the cycle constraint (b', e), we can transform the path constraint set $C^{\mathbb{P}}(e)$ into a tree constraint set $C(e)$ of the same size as follows:

$$C(e) = \{(k, j,\ b - b',\ e_0) \mid (k, j,\ b,\ e) \in C^{\mathbb{P}}(e)\}.$$

It is not hard to see that $C(e) \cup C^{\mathbb{C}}(e) \equiv C^{\mathbb{P}}(e) \cup C^{\mathbb{C}}(e)$, and $C(e)$ can be constructed in $|C^{\mathbb{P}}(e)|$ time.

Let $C = \cup_{e \in E^{\mathbb{X}}} C(e)$. Obviously, $C \equiv C^{\mathbb{P}}$ and $|C| = O(mn)$ since $|C^{\mathbb{P}}| = O(mn)$. Hence, the lemma holds. ∎

Elimination of redundant path constraints on a general pedigree. Now, we consider how to compact path constraints in the general case. As shown in Corollary 8, given a cross edge e inducing cycle $\mathcal{C}$, we can compact the constraints in $C^{\mathbb{P}}(e)$ so that at most $2 \cdot length(\mathcal{C})$ constraints are kept. Clearly, the compact $C^{\mathbb{P}}$ has size at most $O(n^2)$ since the number of cross edges is at most $n + 1$ and the length of a cycle containing a cross edge is at most n. This bound can be improved by observing that the total length of all cycles in G is related to the average *stretch* [9] of G with respect to the spanning tree $\mathcal{T}(G)$. Hence, we can obtain a sharper upper bound on $|C^{\mathbb{P}}|$ by using a low-stretch spanning tree $\mathcal{T}(G)$ as constructed in [9].

We first give a formal definition of the *stretch* of an unweighted connected graph with respect to a spanning tree. Given a spanning tree $\mathcal{T}$ on an unweighted connected graph $G = (V, E)$ (e.g., the pedigree graph), we define the stretch of an edge $(k, j) \in E$, denoted as $stretch_{\mathcal{T}}(k, j)$, to be the length of the unique path (i.e., the number of edges on the path) in $\mathcal{T}$ between k and j. The average stretch of G with respect to $\mathcal{T}$ is then defined as $avg\text{-}stretch_{\mathcal{T}}(E) = \frac{1}{|E|} \sum_{(k,j) \in E} stretch_{\mathcal{T}}(k, j)$.

LEMMA 13. *Given a pedigree G, we can build a low-stretch spanning tree $\mathcal{T}(G)$ in $O(n \log n)$ time such that $|C^{\mathbb{P}}| = O(n \log^2 n \cdot \log \log n)$ after compacting.*

Proof. In [9], Elkin et al. showed that every unweighted connected graph $G = (V, E)$ contains a spanning tree, into which each edge of the graph can be embedded with an average stretch of $O(\log^2 n \log \log n)$. Moreover, this tree can constructed in $O(|E| \log |V|)$ time. In our situation, such a low-stretch spanning tree $\mathcal{T}(G)$ can be built in $O(n \log n)$ time because $|E| \leq 2n$ and $|V| = n$. The following inequality establishes the relationship between $|C^{\mathbb{P}}|$ and the average stretch of E with respect to

$\mathcal{T}(G)$. From Corollary 8, we have

$$\begin{aligned}
|C^{\mathbb{P}}| &= \sum_{e \in E^{\mathbb{X}}} |C^{\mathbb{P}}(e)| \\
&\leq \sum_{\mathcal{C} \text{ induced by } e \in E^{\mathbb{X}}} 2 \cdot length(\mathcal{C}) \\
&= \sum_{e \,=\, (k,j) \in E^{\mathbb{X}}} 2 \cdot \big(stretch_{\mathcal{T}}(k,j) + 1\big) \\
&\leq 2 \sum_{(k,j) \in E} stretch_{\mathcal{T}}(k,j) + 2n \\
&\leq 2 \cdot |E| \cdot avg\text{-}stretch_{\mathcal{T}}(E) + 2n \\
&\leq 2 \cdot (2n) \cdot O(\log^2 n \log\log n) + 2n \\
&= O(n \cdot \log^2 n \log\log n) \qquad \square
\end{aligned}$$

4.3. Elimination of redundant tree constraints and the final algorithm. After we process (i.e., compact or transform) the path constraints, we eliminate redundant tree constraints and obtain a compact tree constraint set containing at most n constraints as shown in Corollary 9. The complete algorithm for eliminating redundant cycle, path, and tree constraints is given in Figure 6 as Procedure **Compact_Constraints**. The next theorem summarizes the above discussion.

THEOREM 14. *Given the constraint sets $C^{\mathbb{C}}$, $C^{\mathbb{P}}$, and $C^{\mathbb{T}}$ on a pedigree, we can reduce them to an equivalent constraint set of size $O(n \cdot \log^2 n \log\log n)$ in $O(mn)$ time. In particular, for tree pedigrees and pedigrees with an all-heterozygous locus, the equivalent constraint set has size $O(n)$.*

We can incorporate the above redundant constraint elimination procedure **Compact_Constraints** into the $O(mn^3)$ time algorithm for ZRHC in order to obtain an improved algorithm **Improved_ZRHC_Phase** as shown in Figure 4. (An example of how **Improved_ZRHC_Phase** works is given in the appendix.) The following theorem is obvious given Theorem 14.

THEOREM 15. *Algorithm* **Improved_ZRHC_Phase** *solves the ZRHC problem correctly on any pedigree in $O(mn^2 + n^3 \log^2 n \log\log n)$ time. Moreover, it solves ZRHC on tree pedigrees or pedigrees with an all-heterozygous locus in $O(mn^2 + n^3)$ time.*

5. Concluding remarks. It remains interesting if the time complexity for ZRHC on general pedigrees can be improved to $O(mn^2+n^3)$ or lower. Another open question is how to use the algorithm to solve MRHC on pedigrees that require only a small (constant) number of recombinants.

Appendix.

A. Some related biological definitions. The genome of an organism consists of *chromosomes* that are double strand DNAs. Locations on a chromosome can be labelled using *markers*, which are small segments of DNA with some specific features. A physical position of a marker on a chromosome is called a *marker locus* and a marker state is called an *allele*. In *diploid* organisms, chromosomes come in pairs. The status of two alleles at a particular marker locus of a pair of chromosomes is called a *marker genotype*. The genotype information at a locus will be denoted using a set, e.g., $\{a, b\}$. If the two alleles a and b are the same, then the genotype is *homozygous*.

Procedure COMPACT_CONSTRAINTS
input: $C^{\mathbb{C}}$, $C^{\mathbb{P}}$, $C^{\mathbb{T}}$, and a fixed tree edge e_0
output: compact $C^{\mathbb{C}}, C^{\mathbb{P}}$, and $C^{\mathbb{T}}$
begin

Step 1. *Removing redundant cycle constraints*

for each cross edge e
  Pick an arbitrary constraint, say $c = (e, b)$, from $C^{\mathbb{C}}(e)$;
  if there exists a constraint $(e, b+1) \in C^{\mathbb{C}}(e)$
    exit "The input genotypes are inconsistent.";
  $C^{\mathbb{C}} = C^{\mathbb{C}} - C^{\mathbb{C}}(e) \biguplus \{c\}$;

Step 2. *Processing path constraints*

if G is a tree pedigree
  for each cross edge e
    $\widehat{C}^{\mathbb{P}}(e) = \emptyset$;
    for each constraint $c = (k, j, b, e) \in C^{\mathbb{P}}(e)$
      if there exists a constraint $(k, j, b+1, e) \in C^{\mathbb{P}}(e)$
        exit "The input genotypes are inconsistent.";
      $\widehat{C}^{\mathbb{P}}(e) = \widehat{C}^{\mathbb{P}}(e) \biguplus \{c\}$;
    $C^{\mathbb{P}} = C^{\mathbb{P}} - C^{\mathbb{P}}(e) \biguplus \widehat{C}^{\mathbb{P}}(e)$;

else if G has an all-heterozygous locus
  for each cross edge e
    Let (b', e) be the cycle constraint for e in $C^{\mathbb{C}}$;
    for each constraint $c = (k, j, b, e)$ in $C^{\mathbb{P}}(e)$
      Construct a new constraint $c' = (k, j, b - b', e_0)$;
      $C^{\mathbb{T}} = C^{\mathbb{T}} \biguplus \{c'\}$;

else (i.e., G is a general pedigree)
  for each cross edge e
    $\widehat{C}^{\mathbb{P}}(e) =$ COMPACT_PT_CONST($C^{\mathbb{P}}(e)$, e_0);
    $C^{\mathbb{P}} = C^{\mathbb{P}} - C^{\mathbb{P}}(e) \biguplus \widehat{C}^{\mathbb{P}}(e)$;

Step 3. *Removing redundant tree constraints*

$C^{\mathbb{T}} =$ COMPACT_PT_CONST($C^{\mathbb{T}}$, e_0);

end.

FIG. 6. *The procedure for removing redundant constraints.*

Otherwise, it is *heterozygous*. A *haplotype* consists of all alleles, one from each locus, that are on the same chromosome. Figure 1(A) illustrates the above concepts, where alleles are represented by their numerical IDs.

A pedigree can be defined formally as follows.

DEFINITION 16. *A pedigree graph is a weakly connected directed acyclic graph (DAG) $G = (V, E)$, where $V = M \cup F$, M stands for the male nodes, and F stands for the female nodes. The in-degree of each node is* 0 *(founders) or* 2 *(nonfounders). If the in-degree of a node is* 2*, then one edge must start from a male node (called father) and the other edge from a female node (called mother), and the node itself is a child of its parents (father and mother).*

A *mating loop* consists of two distinct paths from a node x to a node y. Figure 1(B) illustrates an example pedigree with a mating loop. The Mendelian law of inheritance states that the alleles of a child must come from the alleles of its parents at each marker locus (i.e., assuming no mutations within a pedigree). In other words, the two alleles at each locus of the child have different origins: one is from its father (which is called the *paternal* allele) and the other from its mother (which is called the *maternal* allele). Usually, a child inherits a complete haplotype from each parent. However, *recombination* may occur, where the two haplotypes of a parent get shuffled due to a crossover of chromosomes and one of the shuffled copies is passed on to the child. Such an event is called a recombination event, and its result is called a *recombinant*. Since markers are usually short DNA sequences, we assume that recombination occurs only between markers. Figure 1(C) illustrates an example where the paternal haplotype of member 3 is the result of a recombinant. The paternal allele and maternal allele at each locus is separated by a "|" in this figure.

We use the term *haplotype configuration* to describes not only the paternal and maternal haplotypes of an individual but also the grandpaternal or grandmaternal origin of each allele on the haplotypes. Observe that the number of recombinants required in a pedigree can be easily computed once the haplotype configuration of each member of the pedigree is given. The MRHC problem is defined as follows.

DEFINITION 17 (MRHC). *Given a pedigree and genotype information for each member of the pedigree, find a haplotype configuration for the pedigree that requires the minimum number of recombinants.*

Namely, the ZRHC problem is a special case of MRHC with the following definition.

DEFINITION 18 (ZRHC). *Given a pedigree and genotype information for each member of the pedigree, find a haplotype configuration for the pedigree that requires no recombinant (if such solution exists).*

B. An example execution of Algorithm Improved_ZRHC_phase. The example in Figure 7 aims to demonstrate how Algorithm **Improved_ZRHC_phase** works (see Figure 6 for the pseudocode of the algorithm). The input pedigree with genotype data is shown in Figure 7(A), and the corresponding pedigree graph is in Figure 7(B).

In Step 1, we generate the locus graphs (or forests) as illustrated in Figure 7(C) and identify the predetermined vertices in Figure 7(D). Moreover, we arbitrarily pick a tree edge, say $e_{1,4}$, as the *indicator* to distinguish tree constraints from path constraints, which is defined in subsection 3.1.

In Step 2, we generate cycle, path, and tree constraints as follows. For example, given the cycle $\mathcal{C} = v_2v_5v_3v_6v_2$ in the second locus graph of Figure 7(D), we denote the cycle constraint $h_{2,5} + h_{3,5} + h_{3,6} + h_{2,6} = 0$ by the form $(0, e_{2,6})$. Afterwards, we have $C^{\mathbb{C}} = \{(0, e_{2,6}), (0, e_{2,6})\}$, $C^{\mathbb{P}} = \{(v_4, v_9, 0, e_{4,9}), (v_9, v_8, 1, e_{4,9})\}$ and $C^{\mathbb{T}} = \{(v_6, v_8, 0, e_{1,4}), (v_6, v_9, 1, e_{1,4}), (v_4, v_8, 1, e_{1,4})\}$.

In Step 2′, we first remove redundant cycle constraints and obtain $C^{\mathbb{C}} = \{(0, e_{2,6})\}$. Next, we need to take care of path constraints. For instance, given the path constraints $(v_4, v_9, 0, e_{4,9})$ and $(v_9, v_8, 1, e_{4,9})$ induced by the cross edge $e_{4,9}$, we draw the constraint graph as illustrated in Figure 7(E) to help remove redundant path constraints and obtain $C^{\mathbb{P}} = \{(v_4, v_9, 0, e_{4,9}), (v_9, v_8, 1, e_{4,9})\}$ based on Lemma 7. Then we construct the constraint graph as shown in Figure 7(E) for tree constraints and obtain $C^{\mathbb{T}} = \{(v_4, v_8, 1, e_{1,4}), (v_4, v_6, 1, e_{1,4}), (v_4, v_9, 0, e_{1,4})\}$, according to Lemma 7.

In Step 3, we apply Gaussian elimination to the following linear system, which is

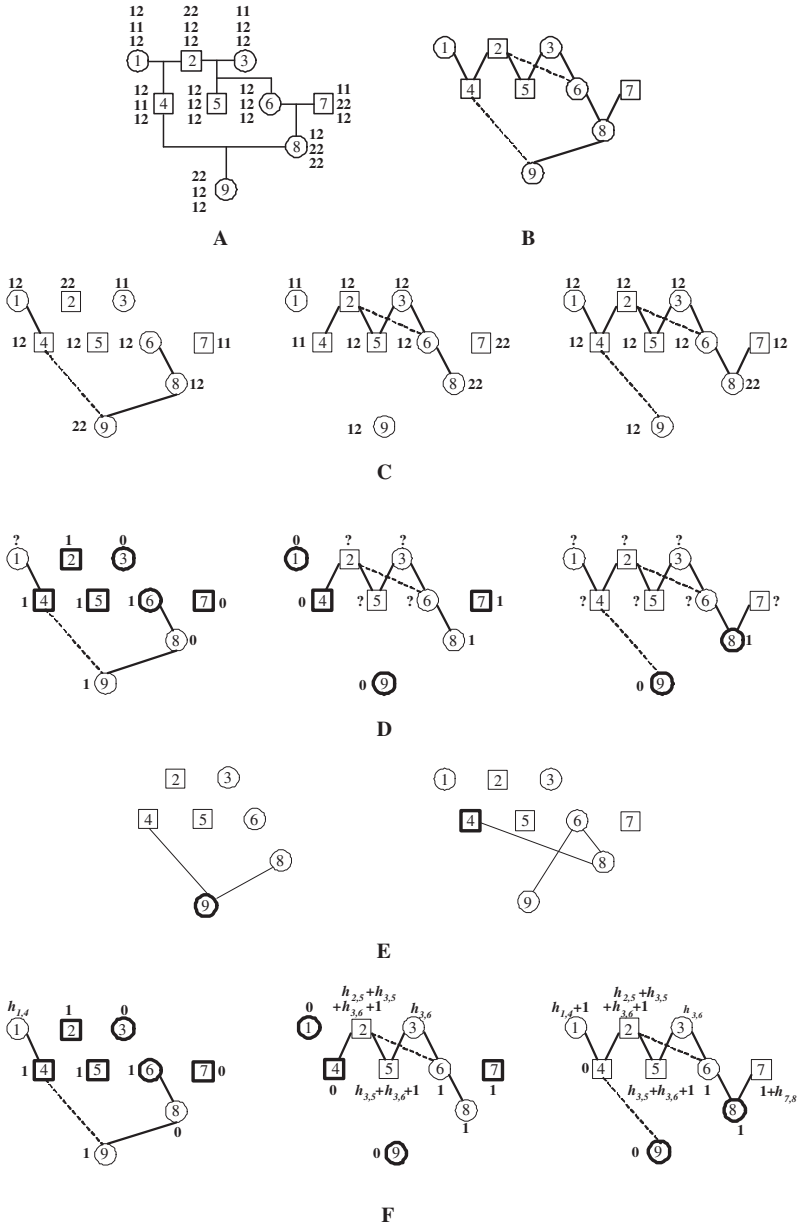

FIG. 7. A. *An example input pedigree with genotype data. Here, the alleles at a locus are ordered according to their ID numbers instead of phase (which is unknown).* B. *The pedigree graph with a spanning tree. The tree edges are highlighted.* C. *Locus graphs for the three loci, respectively. The locus forests are highlighted.* D. *The predetermined nodes. In the locus graphs, the predetermined nodes are indicated by their corresponding p-value (i.e., the number* 0 *or* 1 *near the nodes), while the undetermined nodes are accompanied by the question mark (i.e., "?"). The seeds in the graphs are highlighted by thick borders.* E. *The constraint graphs. The left graph is for removing redundant path constraints generated by the cross edge* $e_{4,9}$*, while the right graph is for tree constraints. The roots (see Lemma* 7 *for the definition) in the graphs are highlighted by thick borders.* F. *The locus graphs with propagated p-values. The notations are the same as those in Figure* 7(D)*, except that the question marks on the undermined nodes are replaced by their resolved p-values. The resolved p-values are expressed as a linear combination of the free variables in* $p_j[i]$ *and the free h-variables with an appropriate constant term.*

equivalent to $C^{\mathbb{C}} \biguplus C^{\mathbb{P}} \biguplus C^{\mathbb{T}}$:

$$\begin{cases} h_{2,5}+h_{3,5}+h_{3,6}+h_{2,6}=0, & \text{i.e., the cycle constraint } (0, e_{2,6}),\\ h_{4,9}=0, & \text{i.e., the path constraint } (v_4, v_9, 0, e_{4,9}),\\ h_{4,9}+h_{2,4}+h_{2,5}+h_{3,5}+h_{3,6}+h_{6,8}=1, & \text{i.e., the path constraint } (v_9, v_8, 1, e_{4,9}),\\ h_{2,4}+h_{2,5}+h_{5,3}+h_{3,6}+h_{6,8}=1, & \text{i.e., the tree constraint } (v_4, v_8, 1, e_{1,4}),\\ h_{2,4}+h_{2,5}+h_{5,3}+h_{3,6}=1, & \text{i.e., the tree constraint } (v_4, v_6, 1, e_{1,4}),\\ h_{2,4}+h_{2,5}+h_{5,3}+h_{3,6}+h_{6,8}+h_{8,9}=0, & \text{i.e., the tree constraint } (v_4, v_9, 0, e_{1,4}). \end{cases}$$

Then we obtain the following general solution:

$$\begin{cases} h_{4,9}=0,\\ h_{6,8}=0,\\ h_{8,9}=1,\\ h_{2,6}=h_{2,5}+h_{3,5}+h_{3,6},\\ h_{2,4}=h_{2,5}+h_{3,5}+h_{3,6}+1, \end{cases}$$

where $h_{2,5}, h_{3,5}, h_{3,6}, h_{1,4}$, and $h_{7,8}$ are free variables.

In Step 4, we solve the unknown p-values by propagation from the seeds and obtain all p-values as shown in Figure 7(F).

Acknowledgments. We would like to thank Jing Li and Cliff Zhang for many useful discussions on ZRHC, and the anonymous referees for several constructive suggestions.

POLYLOGARITHMIC INDEPENDENCE CAN FOOL DNF FORMULAS*

LOUAY M. J. BAZZI†

Abstract. We show that any k-wise independent probability distribution on $\{0,1\}^n$ $O(m^{2.2}2^{-\sqrt{k}/10})$-fools any boolean function computable by an m-clause disjunctive normal form (DNF) (or conjunctive normal form (CNF)) formula on n variables. Thus, for each constant $e > 0$, there is a constant $c > 0$ such that any boolean function computable by an m-clause DNF (or CNF) formula is m^{-e}-fooled by any $c \log^2 m$-wise probability distribution. This resolves up to an $O(\log m)$ factor the depth-2 circuit case of a conjecture due to Linial and Nisan [*Combinatorica*, 10 (1990), pp. 349–365]. The result is equivalent to a new characterization of DNF (or CNF) formulas by low degree polynomials. It implies a similar statement for probability distributions with the small bias property. Using known explicit constructions of small probability spaces having the limited independence property or the small bias property, we directly obtain a large class of explicit pseudorandom generators of $O(\log^2 m \log n)$-seed length for m-clause DNF (or CNF) formulas on n variables, improving previously known seed lengths.

Key words. limited independence, DNF formulas, harmonic analysis, posets, pseudorandomness, polynomial approximation

1. Introduction.

If μ is a probability distribution on $\{0,1\}^n$ and $g : \{0,1\}^n \to \{0,1\}$ is a boolean function, we say that μ *ϵ-fools* g [8, 27] if

$$|Pr_{x\sim\mu}[g(x) = 1] - Pr_{x\in\{0,1\}^n}[g(x) = 1]| \leq \epsilon,$$

where the second probability is with respect to the uniform probability distribution on $\{0,1\}^n$.

Let μ be a probability distribution on $\{0,1\}^n$, and let $k \geq 0$ be an integer. We say that μ is *k-wise independent* (e.g., [15, 26]) if any k or fewer of the underlying n binary random variables are statistically independent and each is equally likely to be zero or one.[1]

A *disjunctive normal form (DNF) formula* on n variables $x_1, \ldots, x_n$ is an OR of AND gates, called *clauses*, on the *literals* $x_1, \neg x_1, \ldots, x_n, \neg x_n$. Similarly, a *conjunctive normal form (CNF) formula* is an AND of OR gates.

We consider in this paper the following problem: how large should k be in terms of ϵ, n, and m so that any k-wise independent probability distribution on $\{0,1\}^n$ ϵ-fools any boolean function computable by an m-clause DNF (or CNF) formula on n variables?

The main contribution of this paper is the following theorem.

*Received by the editors May 18, 2007; accepted for publication (in revised form) September 24, 2008; published electronically March 4, 2009. An extended abstract of this paper appeared in *Proceedings of the 48th Annual IEEE Symposium on Foundations of Computer Science*, 2007, pp. 63–73.

[1]For technical convenience, we allow $k = 0$ in the sense that any probability distribution on $\{0,1\}^n$ is 0-wise independent.

THEOREM 1.1. *Any k-wise independent probability distribution on $\{0,1\}^n$ $(16m^{2.2}2^{-\sqrt{k}/10})$-fools any boolean function computable by an m-clause DNF (or CNF) formula on n variables.*

The proof is based on harmonic and poset analysis techniques. It uses Hastad's switching lemma [9] indirectly via the Linial–Mansour–Nisan (LMN) energy bound [13], applied to many DNF formulas derived from the DNF formula under consideration. The proof can be regarded as a sequence of reductions between some L_1- and L_2-approximations of DNF formulas and auxiliary functions by low degree polynomials with real coefficients.

COROLLARY 1.2. *For each constant $e > 0$, there is a constant $c > 0$ such that any boolean function computable by an m-clause DNF (or CNF) formula is m^{-e}-fooled by any $c\log^2 m$-wise probability distribution.*

The above problem was first proposed by Linial and Nisan [14]. Motivated by this problem, they derived a general bound on approximate inclusion-exclusion from which they concluded that any boolean function computable by an m-clause DNF (or CNF) formula is $o(1)$-fooled by any $\lfloor\sqrt{m}\log m\rfloor$-wise independent probability distribution. They conjectured that any boolean function computable by a size-M depth-d unbounded-fanin AND/OR circuit is ϵ-fooled by any $\log^{d-1} M$-wise independent probability distribution, where $\epsilon = 0.1$. Corollary 1.2 resolves up to an $O(\log m)$ factor this conjecture for depth-2 circuits, reducing the $\sqrt{m}\log m$ bound of [14] to $O(\log^2 m)$. Note that the conjecture's strict parameters are not correct: Luby and Velickovic [16] reported a counterexample which exhibits for each power m of 2 and for all $n \geq \log m$ a function $f : \{0,1\}^n \to \{0,1\}$ computable by an m-clause DNF formula, and a $\log m$-wise independent probability distribution μ on $\{0,1\}^n$ such that μ does not $\frac{1}{2}$-fool f. Theorem 1.1 leaves the region between $O(\log m)$ and $o(\log^2 m)$ open for depth-2 circuits.

Next we explain the linear programming (LP)-dual of Theorem 1.1 which is a new approximation of DNF (or CNF) formulas by low degree polynomials and compare it with the related literature.

1.1. Dual problem. Let $g : \{0,1\}^n \to \{0,1\}$ be a boolean function, $k \geq 0$ an integer, and $\epsilon \geq 0$. Then saying that "any k-wise independent probability distribution ϵ-fools g" is equivalent to saying "there exist $g_l, g_u : \{0,1\}^n \to \mathbb{R}$ such that

- (*low degree*[2]) $deg(g_l) \leq k$ and $deg(g_u) \leq k$;
- (*sandwiching polynomials*) $g_l \leq g \leq g_u$;
- (*small L_1-approximation error*) $E(g - g_l) \leq \epsilon$ and $E(g_u - g) \leq \epsilon$,

where the expectation is over the uniform probability distribution."

We show this in section 4 (see Theorem 4.2). Thus the dual problem is about an L_1-approximation of DNF (or CNF) formulas by low degree sandwiching polynomials with real coefficients. Via this duality, Theorem 1.1 is (up to a constant factor) equivalent to the following theorem.

THEOREM 1.3. *Let $g : \{0,1\}^n \to \{0,1\}$ be a boolean function computable by an m-clause DNF (or CNF) formula, and let $k \geq 0$ be an integer. Then there exist two real-valued functions $g_l, g_u : \{0,1\}^n \to \mathbb{R}$ each of degree at most k such that $g_l \leq g \leq g_u$, $E(g - g_l) = O(m^{2.2}2^{-\sqrt{k}/10})$, and $E(g_u - g) = O(m^{2.2}2^{-\sqrt{k}/10})$, where the expectation is over the uniform probability distribution.*

We will actually establish the dual statement.

[2]The degree of a function $f : \{0,1\}^n \to \mathbb{R}$ is the smallest degree of a polynomial $p \in \mathbb{R}[x_1, \ldots, x_n]$ such that $p(x) = f(x)$ for all $x \in \{0,1\}^n$.

Theorem 1.3 implies the following weaker L_1-approximation.

COROLLARY 1.4. *Let $g : \{0,1\}^n \to \{0,1\}$ be a boolean function computable by an m-clause DNF (or CNF) formula, and let $k \geq 0$ be an integer. Then there exists a real-valued function $p : \{0,1\}^n \to \mathbb{R}$ of degree at most k such that $E|g-p| = O(m^{2.2}2^{-\sqrt{k}/10})$.*

Proof. Set $p = g_l$ or g_u. □

Small constant-depth unbounded-fanin AND/OR circuits can be approximated by low degree polynomials with real coefficients in different ways [1, 7, 13]. They can be also approximated by low degree polynomials with coefficients over finite fields [22]. We compare our sandwiching L_1-approximation with [1, 7, 13] specialized to depth-2 circuits. The approximation in [13] is an L_2-approximation based on Hastad's switching lemma.

THEOREM 1.5 (see [13]). *Let $g : \{0,1\}^n \to \{0,1\}$ be computable by an m-clause DNF (or CNF) formula, and let $k \geq 0$ be an integer. Then there exists a real-valued function $p : \{0,1\}^n \to \mathbb{R}$ of degree at most k such that $E(g-p)^2 \leq 2m2^{-\sqrt{k}/20}$.*

The proof of Theorem 1.1 uses a variation of this L_2-approximation (see Theorem 9.1) applied to many DNF formulas derived from the DNF formula under consideration.

The approximation in [1, 7] does not use Hastad's switching lemma and is in terms of probabilistic polynomials.

THEOREM 1.6 (see [1, 7]). *Let $g : \{0,1\}^n \to \{0,1\}$ be computable by an m-clause DNF (or CNF) formula. For all $\epsilon > 0$, there exists a (finite) family of polynomials $\{p_\alpha\}_\alpha$, where each p_α is a real polynomial (with integer coefficients) on the variables $x_1, \ldots, x_n$ of degree $O(\log^2(m/\epsilon)\log^2 m \log^2 n)$ such that $Pr_\alpha[p_\alpha(x) \neq g(x)] \leq \epsilon$ for all $x \in \{0,1\}^n$. Thus, in particular, $Pr_x[p_\alpha(x) \neq g(x)] \leq \epsilon$ for some α.*

The polynomials do not give a good L_1-approximation ($E_x|p_\alpha(x)-g(x)|$ is potentially as large as $2^{O(\log^2(m/\epsilon)\log^2 m \log^2 n)}$), but we believe that they probably can be used indirectly to establish a weak version of Theorem 1.1 which is naturally extensible to AC_0 circuits. See [5, sections 5.7 and 5.8] for a work in this direction.

A final remark is that one cannot hope to obtain a good L_∞-approximation of DNF formulas by low degree polynomials. This follows from [20].

1.2. Paper outline. In section 2, we give direct applications of Theorem 1.1. Section 3 contains Fourier transform preliminaries. Section 4 highlights the dual characterization of the class of boolean functions that are fooled by the limited independence property. The remainder of the paper is about the proof of Theorem 1.1, starting with the proof outline in section 5. The proof consists of sections 5, 6, 7, 8, and 9. The proof depends on sections 3 and 4, but does not use section 2 or section 10, which branches from the proof and ends with an open problem.

2. Some direct applications. This section can be skipped without loss of continuity. In section 2.1, we conclude from Theorem 1.1 that probability spaces with quasi-polynomially small[3] bias also fool all polynomial size DNF (or CNF) formulas. Using known explicit constructions of small probability spaces having the limited independence property or the small bias property, we directly obtain in section 2.2 a large class of explicit pseudorandom generators (PRGs) of $O(\log^2 m \log n)$-seed length for m-clause DNF (or CNF) formulas on n variables, improving previously known (unconditional) seed lengths. Finally, we highlight in section 2.3 a direct application of

[3] By quasi-polynomially small we mean $2^{-\log^{\Theta(1)}(n)}$.

Theorem 1.1 to the distribution of patterns in linear codes.

2.1. Extension to small bias probability spaces. We can conclude from Theorem 1.1 that probability spaces with quasi-polynomially small bias also fool all polynomial size DNF (or CNF) formulas.

Let μ be a probability distribution on $\{0,1\}^n$, $k \geq 0$ be an integer, and $\delta > 0$. We say that μ is (δ, k)-*biased* [18] if μ δ-fools all parity functions on k or fewer of the n binary variables. This is a relaxation of the k-wise independent property since the latter is equivalent to the $(0, k)$-bias property. If μ is (δ, n)-biased, it is called δ-*biased* [18].

We need the following relation.

THEOREM 2.1 (see [3]). *Any (δ, k)-biased probability distribution μ on $\{0,1\}^n$ is $n^k\delta$-close to a k-wise independent probability distribution μ' on $\{0,1\}^n$ in the sense that $|\mu(A) - \mu'(A)| \leq n^k\delta$ for all $A \subset \{0,1\}^n$. Thus if $f : \{0,1\}^n \to \{0,1\}$ is such that any k-wise independent probability distribution on $\{0,1\}^n$ ϵ-fools f, then any (δ, k)-biased probability distribution on $\{0,1\}^n$ $(\epsilon + \delta n^k)$-fools f.*

Using Theorems 1.1 and 2.1, we get the following corollary.

COROLLARY 2.2. *Any (δ, k)-biased probability distribution on $\{0,1\}^n$ $(16m^{2.2}$ $2^{-\sqrt{k}/10} + \delta n^k)$-fools any boolean function computable by an m-clause DNF (or CNF) formula on n variables.*

COROLLARY 2.3. *There is a function $\delta(m, n, \epsilon) = 2^{-\Theta(\log^2 \frac{m}{\epsilon} \log n)}$ such that for all positive integers m and n, and all $0 < \epsilon < 1$, any $\delta(m, n, \epsilon)$-biased probability distribution on $\{0,1\}^n$ ϵ-fools any boolean function computable by an m-clause DNF (or CNF) formula on n variables.*

Proof. Set $k = \lceil (10 \log \frac{32m^{2.2}}{\epsilon})^2 \rceil$ in Corollary 2.2 so that $16m^{2.2}2^{-\sqrt{k}/10} \leq \epsilon/2$ and $\delta n^k \leq \epsilon/2$ if $\delta \leq \epsilon 2^{-\lceil (10 \log \frac{32m^{2.2}}{\epsilon})^2 \rceil \log n - 1} \stackrel{\text{def}}{=} \delta(n, n, \epsilon)$. □

Related previously known bounds in [4, 16, 25] work for DNF formulas with very small fanins. We call a DNF formula an s-*DNF* if each clause contains at most s literal. We call a probability distribution on $\{0,1\}^n$ k-*wise* δ-*dependent* if it δ-fools all AND gates on at most k literals. Ajtai and Wigderson [4], and Luby and Velickovic [16] show that for all integers $1 \leq s \leq n$, any k-wise δ-dependent probability distribution μ on $\{0,1\}^n$ $(e^{-k/(s2^s)} + 2^s\delta)$-fools all boolean functions computable by s-DNF (or s-CNF) formulas on n variables. This implies that there is a function $\delta(s, \epsilon) = 2^{-O(s2^s \log(1/\epsilon))}$ such that for all $0 < \epsilon < 1$ and all integers $1 \leq s \leq n$, any $\delta(s, \epsilon)$-biased probability distribution μ on $\{0,1\}^n$ ϵ-fools all boolean functions computable by s-DNF (or s-CNF) formulas on n variables [25]. The bound is good for $s = O(1)$ and is nontrivial only if the condition $k > s2^s$ is satisfied. For general DNF formulas, we can restrict our attention to the case when $s = \log m + O(\log \frac{1}{\epsilon})$ (see section 5.4), but that will not help here since then the condition $k > s2^s$ would require $k > m \log m$.

2.2. A large class of PRGs for DNF formulas. The problem of derandomizing AC_0 circuits (polynomial-size constant-depth unbounded-fanin AND/OR circuits) was first studied by Ajtai and Wigderson [4]. Using Hastad's parity lower bound [9], Nisan [19] constructed a quasi-polynomial complexity[4] PRG for AC_0 circuits of seed length $O(\log^{2d+6} n)$, where d is the circuit depth and n is the input length. This initiated the hardness-versus-randomness approach which was developed in [21, 10] and others. Nisan's generator was optimized by Luby, Velickovic, and Wigderson [17] for depth-2 circuits reducing the seed length from $O(\log^{10} n)$ to $O(\log^4 mn)$, where m

[4] By quasi-polynomial complexity we mean $2^{\log^{\Theta(1)}(n)}$.

is the number of clauses of the DNF (or CNF) formula. Using classical linear code–based constructions of small probability spaces having the k-wise independent or the δ-bias property, we directly obtain from Theorem 1.1 a large class of explicit PRGs for depth-2 circuits of seed length $O(\log^3 mn)$.

Small probability spaces having the k-wise independence property can be constructed from linear codes. The following construction is folklore. If $C \subset \{0,1\}^n$ is a binary linear code whose dual $C^\perp \stackrel{\text{def}}{=} \{x \in \{0,1\}^n : \sum_i x_i y_i = 0 \pmod 2$ for all $y \in C\}$ has minimum distance greater than k, then the uniform distribution on the codewords of C is k-wise independent as a probability distribution on $\{0,1\}^n$. Classical linear code–explicit constructions achieve $|C| = n^{\Theta(k)}$.

COROLLARY 2.4. *For all positive integers m, n and every $\epsilon > 0$, there are an integer $t = O(\log^2 \frac{m}{\epsilon} \log n)$ and an explicit generator $G : \{0,1\}^t \to \{0,1\}^n$, constructible in poly$(n)$-time and computable in $O(tn)$-time, such that for every boolean function $g : \{0,1\}^n \to \{0,1\}$ computable by an m-clause DNF (or CNF) formula on n variables, we have*

$$|Pr_{x\in\{0,1\}^t}[g(G(x)) = 1] - Pr_{x\in\{0,1\}^n}[g(x) = 1]| \le \epsilon.$$

Proof. Without loss of generality, assume that $\log^2 \frac{m}{\epsilon} \log n = o(n)$ (otherwise, set $t = n$ and let G be the identity map). Given n, m, and ϵ, let

$$k \stackrel{\text{def}}{=} \left\lceil \left(10 \log \frac{16m^{2.2}}{\epsilon} \right)^2 \right\rceil;$$

thus $16m^{2.2}2^{-\sqrt{k}/10} \le \epsilon$. Construct in *poly*$(n, k)$-time the parity check matrix $H_{t\times n}$ of an explicit binary linear code D of block length n, message length $n - t$, and minimum distance at least $k + 1$, where $t = O(k \log n) = O(\log^2 \frac{m}{\epsilon} \log n)$. We can achieve $t = O(k \log n)$ using, for instance, a Reed–Solomon code or an algebraic geometry code reduced to a binary code by plain binarization or by concatenation, and punctured if necessary. Thus the probability distribution on $\{0,1\}^n$ resulting from choosing a random codeword from the dual $C = D^\perp$ of D is k-wise independent. This distribution is induced by the uniform distribution on $\{0,1\}^t$ via the $\mathbb{F}_2$-linear map $G : \{0,1\}^t \to \{0,1\}^n$ defined by $G(x) = xH$. □

Probability distributions with the δ-bias property can be explicitly constructed from linear codes with support size $\left(\frac{n}{\delta}\right)^{\Theta(1)}$ [18, 2]. Using those constructions and Corollary 2.3, we get a variation of Corollary 2.4 of asymptotically the same seed length, i.e., $t = O(\log^2 \frac{m}{\epsilon} \log n)$ (see also Corollary 11.2). Explicit constructions of (δ, k)-biased probability distributions of support size $(\frac{k \log n}{\delta})^{\Theta(1)}$ [18, 2] can also be used via Corollary 2.2 to achieve asymptotically the same seed length for $k = \lceil (10 \log \frac{32m^{2.2}}{\epsilon})^2 \rceil$ and $\delta = \frac{\epsilon}{2n^k}$.

For $\epsilon = n^{-O(1)}$, Corollary 2.4 and its variations give us PRGs of $O(\log^2 m \log n)$-seed lengths for m-clause DNF (or CNF) formulas.

Note that, when $\epsilon = n^{-O(1)}$, each of the above PRGs leads to a $2^{O(\log^2 m \log n)}$-time algorithm for the *DNF formula approximate counting problem* (given a DNF formula and $\epsilon > 0$, approximate the fraction of its satisfying assignments within $\pm\epsilon$ additive error). We should mention here that this does not improve the best known time for the DNF formula approximate counting problem; the algorithm of Luby and Velickovic [16], which is not based on a PRG, solves this problem in $(m \log n)^{exp(O(\sqrt{\log \log n}))}$-time when ϵ is constant.

The problems of constructing a logarithmic seed length (unconditional) PRG for DNF formulas or finding a polynomial-time algorithm for the DNF formula approximate counting problem remain open.

2.3. Patterns in binary linear codes. If $I \subset [n]$ and $\alpha \in \{0,1\}^I$, we call the pair (I,α) an *n-pattern*. We say that a string $x \in \{0,1\}^n$ *contains* an n-pattern $p = (I,\alpha)$ if $x_i = \alpha_i$ for all $i \in I$.

If $C \subset \{0,1\}^n$ is a binary linear code whose dual has minimum distance greater than k, then the uniform distribution on the codewords of C is k-wise independent as a probability distribution on $\{0,1\}^n$. Specialized to such k-wise independent distributions, Theorem 1.1 can be rephrased as an estimate of the probability that a random codeword of C contains a pattern from a given set of patterns.

COROLLARY 2.5. *Let A be a set consisting of m n-patterns, and let $C \subset \{0,1\}^n$ be a linear code whose dual has minimum distance greater than k. Then*

$$\left| Pr_{x\in C}\begin{bmatrix}\exists p \in A \text{ s.t.}\\ x \text{ contains } p\end{bmatrix} - Pr_{x\in\{0,1\}^n}\begin{bmatrix}\exists p \in A \text{ s.t.}\\ x \text{ contains } p\end{bmatrix}\right| \le 16m^{2.2}2^{-\sqrt{k}/10}.$$

Proof. Let μ be the k-wise independent probability distribution resulting from choosing a random codeword of C, and let F be the DNF formula whose clauses correspond to the patterns in A, i.e.,

$$F = \bigvee_{(I,\alpha)\in A}\left(\bigwedge_{i\in I:\alpha_i=1} x_i \wedge \bigwedge_{i\in I:\alpha_i=0}\neg x_i\right).$$

Apply Theorem 1.1 on μ and F. □

For instance, consider the following concrete case.

COROLLARY 2.6. *Let $C \subset \{0,1\}^n$ be a linear code whose dual has minimum distance greater than k, and let $1 \le t \le n$ be an integer. Then*

$$\left| Pr_{x\in C}\begin{bmatrix}x \text{ contains } t\\ \text{consecutive ones}\end{bmatrix} - Pr_{x\in\{0,1\}^n}\begin{bmatrix}x \text{ contains } t\\ \text{consecutive ones}\end{bmatrix}\right| \le 16(n-t+1)^{2.2}2^{-\sqrt{k}/10}.$$

Note that if the maximum size s of a pattern in A in Corollary 2.5 is $o(\sqrt{k})$, the bound can be improved via Corollary 9.6.

3. Fourier transform preliminaries. The study of boolean function using harmonic analysis methods dates back to the late 1960s. See, for instance, [12, 11, 13].

We assemble below some needed preliminaries: Fourier transform definition, Parseval's equality, the degree of a boolean function, and the Fourier truncation operator.

We identify the hypercube $\{0,1\}^n$ with the group $\mathbb{Z}_2^n \stackrel{\text{def}}{=} (\mathbb{Z}/2\mathbb{Z})^n$. The *characters* of the abelian group $\mathbb{Z}_2^n$ are $\{\mathcal{X}_y\}_{y\in\mathbb{Z}_2^n}$, where $\mathcal{X}_y(x) \stackrel{\text{def}}{=} (-1)^{\sum_{i=1}^n x_i y_i}$. Those characters form an orthogonal basis of the space of real-valued functions defined on $\mathbb{Z}_2^n$. They are orthogonal with respect to the uniform distribution; i.e., $E\mathcal{X}_y\mathcal{X}_{y'} = 0$ if $y \ne y'$ and 1 otherwise. If g is a real-valued function on $\mathbb{Z}_2^n$, we denote by $\widehat{g}$ the *Fourier transform* of g with respect to the characters of the abelian group $\mathbb{Z}_2^n$. That is, if $g : \{0,1\}^n \to \mathbb{R}$, its Fourier transform $\widehat{g} : \{0,1\}^n \to \mathbb{R}$ is given by the coefficients of the expansion of g in terms of the $\{\mathcal{X}_z\}_z$ basis:

$$g(x) = \sum_y \widehat{g}(y)\mathcal{X}_y(x) \quad \text{and} \quad \widehat{g}(y) = \frac{1}{2^n}\sum_x g(x)\mathcal{X}_y(x).$$

Parseval's equality relates the expected value of the square of a boolean function $g : \{0,1\}^n \to \mathbb{R}$ to the L_2-norm of its Fourier transform:

$$Eg^2 = \sum_y \widehat{g}(y)^2 = \|\widehat{g}\|_2^2.$$

The equality follows from the orthogonality of the characters $\{\mathcal{X}_y\}_y$.

If $x \in \mathbb{Z}_2^n$, the *weight* of x, which we denote by $|x|$, is the number of nonzero coordinates of x. The *degree* of $g : \{0,1\}^n \to \mathbb{R}$ is the smallest degree of a polynomial $p \in \mathbb{R}[x_1, \ldots, x_n]$ such that $p(x) = g(x)$ for all $x \in \{0,1\}^n$. Equivalently, in terms of the basis $\{\mathcal{X}_y\}_y$, the *degree* of g is equal to the maximal weight of $y \in \{0,1\}^n$ such that $\widehat{g}(y) \neq 0$.

Finally, we define the Fourier truncation operator. Denote by $L(\{0,1\}^n)$ the space of real-valued functions on $\{0,1\}^n$. If $t \geq 0$ is an integer, define the *Fourier truncation operator* $\mathrm{Trn}_t : L(\{0,1\}^n) \to L(\{0,1\}^n)$ by

$$\mathrm{Trn}_t\ g = \sum_{y:|y|\leq t} \widehat{g}(y)\mathcal{X}_y.$$

The truncation operator Trn_t kills the high frequencies of g and produces a function $\mathrm{Trn}_t\ g$ of degree at most t. Equivalently, $\mathrm{Trn}_t\ g$ can be defined as the optimal solution f^* of the following L_2-approximation problem: given g and t, minimize $E(g-f)^2$ over the choice of $f : \{0,1\}^n \to \mathbb{R}$ of degree at most t. This follows from solving the underlying least square problem in the orthogonal basis $\{\mathcal{X}_y\}_y$. Note that, by Parseval's equality, the smallest L_2-approximation error is

$$E(g - \mathrm{Trn}_t g)^2 = \sum_{y:|y|>k} \widehat{g}(y)^2.$$

4. LP duality perspective.

DEFINITION 4.1. *We say that a distribution* property ϵ-fools *a function* $g : \{0,1\}^n \to \{0,1\}$ *if any probability distribution on* $\{0,1\}^n$ *with this property* ϵ*-fools* g.

We note that LP duality gives a purely analytical characterization of the class of boolean functions that are fooled by the k-wise independence property. The characterization is in terms of L_1-approximability by sandwiching polynomials of degree at most k. In particular, we show that the following theorem holds.

THEOREM 4.2. *Let* $g : \{0,1\}^n \to \{0,1\}$, $k \geq 0$ *be an integer, and* $\epsilon \geq 0$. *Then the* k*-wise independence property* ϵ*-fools* g *if and only if there exist* $g_l, g_u : \{0,1\}^n \to \mathbb{R}$ *such that*

(i) (low degree) $deg(g_l) \leq k$ *and* $deg(g_u) \leq k$;
(ii) (sandwiching polynomials) $g_l \leq g \leq g_u$;
(iii) (small L_1-approximation error) $E(g - g_l) \leq \epsilon$ *and* $E(g_u - g) \leq \epsilon$, *where the expectation is over the uniform probability distribution.*

We show the LP duality calculations in Appendix A in the more general context of the (δ, k)-bias property. Since the k-wise independence property is the $(0,k)$-bias property, Theorem 4.2 follows from Theorem A.1 in Appendix A by setting $\delta = 0$.

The proof of the main result of this paper in Theorem 1.1 depends only on the if part of Theorem 4.2. We give in this section a direct verification of the if part which does not involve LP duality calculations.

In terms of the $\{\mathcal{X}_y\}_y$ basis, the definition of k-wise independence can be rephrased as follows. Let μ be a probability distribution on $\{0,1\}^n$, and let $k \geq 0$ be an integer. Then the following are equivalent:

(a) μ is k-wise independent;
(b) $E_\mu \mathcal{X}_y = 0$ for each nonzero y in $\{0,1\}^n$ whose weight is less than or equal to k;
(c) $E_\mu p = Ep$ for each $p : \{0,1\}^n \to \mathbb{R}$ such that $deg(p) \leq k$, where the second expectation is with respect to the uniform probability distribution.

The equivalence between (a) and (b) is immediate. To relate to (c), write p as $p = \sum_{y:|y|\leq k} \widehat{p}(y)\mathcal{X}_y$; thus $E_\mu p = \widehat{p}(0) + \sum_{y\neq 0:|y|\leq k} \widehat{p}(y) E_\mu \mathcal{X}_y$.

This equivalence is the key relation between k-wise independent probability distributions and polynomials of degree at most k. Using this relation, we establish below the if part of Theorem 4.2. Let $g : \{0,1\}^n \to \{0,1\}$, $k \geq 0$ be an integer, and $\epsilon \geq 0$. Assume the existence of sandwiching polynomials g_l and g_u satisfying (i), (ii), and (iii). Let μ be a k-wise independent probability measure. We want to show that μ ϵ-fools g. Since g_u has degree at most k, $E_\mu g_u = Eg_u$. Hence

$$\begin{aligned} Pr_{x\sim\mu}[g(x) = 1] - Pr_{x\in\{0,1\}^n}[g(x) = 1] &= E_\mu g - Eg \\ &= E_\mu(g - g_u) + E(g_u - g) \leq E(g_u - g) \leq \epsilon, \end{aligned}$$

where the first inequality follows from the fact that $g_u \geq g$. Similarly, using g_l, we get

$$\begin{aligned} -Pr_{x\sim\mu}[g(x) = 1] + Pr_{x\in\{0,1\}^n}[g(x) = 1] &= -E_\mu g + Eg \\ &= E_\mu(g_l - g) + E(g - g_l) \leq E(g - g_l) \leq \epsilon. \end{aligned}$$

That is, μ ϵ-fools g.

5. Outline of proof. We outline and overview in this section the proof of Theorem 1.1, restated below.

THEOREM 1.1 *Any k-wise independent probability distribution on $\{0,1\}^n$ $(16m^{2.2}2^{-\sqrt{k}/10})$-fools any boolean function computable by an m-clause DNF (or CNF) formula on n variables.*

The proof is based on harmonic and poset analysis techniques. It uses Hastad's switching lemma [9] indirectly via the LMN energy bound [13], applied to many DNF formulas derived from the original DNF formula. The proof can be regarded as a sequence of reductions between some L_1- and L_2-approximations of DNF formulas and auxiliary functions by low degree polynomials with real coefficients. After some simplifications in section 5.1, we define those approximation notions in section 5.2, and then we outline the main steps in the proof in section 5.3.

5.1. Simplifications and notation. Without loss of generality, we restrict our attention to DNF formulas since any CNF formula is the negation of a DNF formula with the same number of clauses, and a probability distribution ϵ-fools a boolean function if and only if it ϵ-fools its negation.

To avoid degenerate cases, we assume that the DNF formula has at least one clause and that each clause has at least one literal. We can do this without loss of generality since any probability distribution 0-fools the identically one boolean function and the identically zero boolean function.

A final notational technicality is that if F is a DNF formula, we abuse notation and also denote by F the boolean function computed by F. That is, if $A_1, \ldots, A_m$ are

the clauses of F, we will denote by F also the boolean function $F : \{0,1\}^n \to \{0,1\}$ given by $F(x) = \bigvee_{c=1}^{m} A_c(x)$.

5.2. Approximation notions used in the proof. The proof uses the following three approximation notions of real-valued functions on the hypercube by low degree polynomials with real coefficients.

DEFINITION 5.1 (sandwiched L_1-approximation: bias). *If $g : \{0,1\}^n \to \{0,1\}$ is a boolean function and $k \geq 0$ is an integer, define the* k-bias of g, *denoted by bias$(g;k)$, to be the minimum value of ϵ such that there exist $g_l, g_u : \{0,1\}^n \to \mathbb{R}$ each of degree at most k such that $g_l \leq g \leq g_u$, $E(g_u - g) \leq \epsilon$, and $E(g - g_l) \leq \epsilon$. We call g_l and g_u sandwiching polynomials of g.*

Equivalently, by LP duality (Theorem 4.2), bias$(g;k)$ is the minimum value of ϵ such that any k-wise independent probability distribution μ on $\{0,1\}^n$ ϵ-fools g.

The term bias should not be confused with its other various meanings in the literature.

DEFINITION 5.2 (L_2-approximation: energy). *If $g : \{0,1\}^n \to \mathbb{R}$ is a real-valued function and $t \geq 0$ is an integer, define the* t-energy of g *to be energy$(g;t) = \min_f E(g-f)^2$ over the choice of a polynomial $f : \{0,1\}^n \to \mathbb{R}$ of degree at most t.*

Equivalently (see section 3),

$$\textit{energy}(g;t) = \sum_{y:|y|>t} \widehat{g}(y)^2.$$

That is, energy$(g;t)$ is the high energy content of g at frequencies above t, and hence the "energy" terminology.

We are allowing g to take real values since eventually we will be working with nonboolean-valued functions derived from DNF formulas.

DEFINITION 5.3 (constrained L_2-approximation: zero-energy). *If $g : \{0,1\}^n \to \{0,1\}$ is a boolean function and $t \geq 0$ is an integer, define the* t-zero-energy of g *to be zeroEnergy$(g;t) = \min_f E(g-f)^2$ over the choice of a polynomial $f : \{0,1\}^n \to \mathbb{R}$ of degree at most t satisfying the* zeros-constraint*: $f = 0$ whenever $g = 0$; i.e., $f(x) = 0$ for each $x \in \{0,1\}^n$ such that $g(x) = 0$.*

The zero-energy has no natural interpretation in the Fourier domain. The terminology is motivated by the above energy terminology and the zeros-constraint.

5.3. Main steps in the proof. Given an m-clause DNF formula F and $k \geq 0$, we want to bound its sandwiched L_1-approximation error bias$(F;k)$. The bound claimed in Theorem 1.1 is bias$(F;k) \leq 16m^{2.2}2^{-\sqrt{k}/10}$.

To get a concrete sense of the parameters, keep in mind the typical case when $k = \Theta(\log^2 m)$, and note that, although the number n of variables of F does not appear in the above bound or the subsequent ones, we care about the typical case when m is polynomial in n.

The proof can be regarded as a sequence of reductions between the above approximation notions in the context of DNF formulas and auxiliary functions. At a high level, we reduce the DNF sandwiched L_1-approximation problem to the DNF L_2-approximation problem, to which we apply the LMN energy bound. The DNF constrained L_2-approximation problem serves as an intermediate problem in this reduction.

The LMN energy bound [13] says that for each m-clause DNF formula F and each integer $t \geq 0$, energy$(F;t) \leq 2m2^{-\sqrt{t}/20}$.

To get started, we restrict our attention to DNF formulas with at most s literals per clause, where $s = \Theta(\sqrt{k})$. We call such DNF formulas s-DNF formulas. We can do that without loss of generality by paying a small additive error as noted in section 5.4 of this outline. Note that $s = \Theta(\log m)$ in the typical case when $k = \Theta(\log^2 m)$.

The first step of the proof reduces the problem of estimating the k-bias of an s-DNF formula to that of estimating its t-zero-energy, where $t = \lfloor (k-s)/2 \rfloor \approx k/2$. The argument is short and is in section 5.5 of this outline. Hence $s = \Theta(\sqrt{t})$, and $t = \Theta(\log^2 m)$ in the typical case when $k = \Theta(\log^2 m)$.

The second and more difficult step of the proof is estimating the zero-energy of an s-DNF formula, i.e., the s-DNF constrained L_2-approximation problem. We reduce this problem to the s-DNF L_2-approximation problem. The argument is long and involves two intermediate reductions to L_2-approximation problems of auxiliary nonboolean-valued functions associated with DNF formulas. First, we reduce the problem of bounding the t-zero-energy of an s-DNF formula F to that of bounding the t'-energies of auxiliary real-valued functions associated with DNF formulas derived from F, where $t' = t - s \approx t$. We give an overview of this in sections 5.6, 5.7, and 5.8. Then we reduce the problem of bounding the t'-energies of each of those auxiliary functions to that of bounding the t'-energies of additional derived DNF formulas, which finally enables us to use the LMN energy bound. We give an overview of this in section 5.9. We conclude in sections 5.10 and 5.11.

The arguments in the second step are based on harmonic and poset analysis machinery, which we develop in section 6. In this outline section, we give an overview of the underlying constructions and the end results without using the language of section 6.

5.4. Ignoring large clauses. If $s \geq 1$ is an integer, we call a DNF formula F an *s-DNF* if each clause of F contains at most s literals. By paying a small additive error, we can assume without loss of generality that the DNF formula does not contain very large clauses.

LEMMA 5.4. *Let $k \geq s \geq 1$ be integers and $\epsilon \geq 0$. If bias$(F;k) \leq \epsilon$ for each m-clause s-DNF formula F, then bias$(F;k) \leq \epsilon + m2^{-s}$ for each m-clause DNF formula F.*

At the end, we will set $s = \Theta(\sqrt{k})$. Hence $s = \Theta(\log m)$ in the typical case when $k = \Theta(\log^2 m)$.

Proof. The argument is easy. It is more direct in this lemma to work with the primal definition of the bias. That is, we argue on probability distribution and not on sandwiching polynomials.

Assume that the hypothesis is correct. Let F be an m-clause DNF formula on n variables, and let μ be a k-wise independent probability distribution on $\{0,1\}^n$. We want to show that $|Pr_\mu[F=1] - Pr[F=1]| \leq \epsilon + m2^{-s}$.

Let $A_1, \ldots, A_m$ be the clauses of F; thus $F = \bigvee_{c=1}^m A_c$. Let $C' \subset [m]$ be the set of indices of clauses each containing at most s literals, $F' = \bigvee_{c \in C'} A_c$, $C'' = [m] \backslash C'$, and $F'' = \bigvee_{c \in C''} A_c$.

Since F' is an s-DNF formula, we have $|Pr_\mu[F'=1] - Pr[F'=1]| \leq \epsilon$ because bias$(F';k) \leq \epsilon$ by the lemma hypothesis.

Since $F = F' \vee F''$, we have $Pr_\mu[F'=1] \leq Pr_\mu[F=1] \leq Pr_\mu[F'=1] + Pr_\mu[F''=1]$ and $-Pr[F'=1] - Pr[F''=1] \leq -Pr[F=1] \leq -P[F'=1]$. Thus

$$-\epsilon - Pr[F''=1] \leq Pr_\mu[F=1] - Pr_\mu[F=1] \leq \epsilon + Pr_\mu[F''=1].$$

The lemma then follows from the inequalities $Pr[F''=1] \leq |C''|2^{-(s+1)} \leq m2^{-s}$

and $Pr_\mu[F'' = 1] \leq |C''|2^{-s} \leq m2^{-s}$. The first inequality is immediate since each clause of F'' contains at least $s+1$ literals. To verify the second inequality, construct another DNF formula G from F'' by arbitrarily removing literals from each clause of F'' to make its size equal to s. By construction, G is satisfied by all the satisfying assignments of F; hence $Pr_\mu[F'' = 1] \leq Pr_\mu[G = 1]$. Since μ is k-wise independent and $k \geq s$, each clause of G is satisfied with a probability exactly 2^{-s} with respect to μ. Thus $Pr_\mu[G = 1] \leq |C''|2^{-s}$. □

5.5. From bias to zero-energy. In this section, we reduce the s-DNF sandwiched L_1-approximation problem to the s-DNF constrained L_2-approximation problem. In particular, we reduce the problem of estimating the k-bias of an s-DNF formula to that of estimating its t-zero-energy, where $t = \lfloor \frac{k-s}{2} \rfloor$.

To justify this move from L_1 to L_2, we briefly mention in Appendix B natural L_1-approaches which fall short of bounding the k-bias of s-DNF formulas.

We show that the following lemma holds.

LEMMA 5.5 (bias $\preccurlyeq$ zero-energy). *Let F be an m-clause s-DNF formula, and let $k \geq s$ be an integer. Then bias$(F; k) \leq m \times$ zeroEnergy$(F; t)$, where $t = \lfloor \frac{k-s}{2} \rfloor$.*

Note that $t \approx k/2$ when $s = \Theta(\sqrt{k})$. Moreover, $t = \Theta(\log^2 m)$ in the typical case when $k = \Theta(\log^2 m)$.

Proof. Assume that we have $f : \{0,1\}^n \to \mathbb{R}$ such that $deg(f) \leq \lfloor \frac{k-s}{2} \rfloor$, and that f satisfies the zeros-constraint: $f(x) = 0$ for each $x \in \{0,1\}^n$ such that $F(x) = 0$.

The approach is to construct the sandwiching polynomials f_l and f_u of F as

$$f_l \stackrel{\text{def}}{=} 1 - (1-f)^2 \text{ and}$$
$$f_u \stackrel{\text{def}}{=} 1 - \left(1 - \sum_{c=1}^{m} A_c\right)(1-f)^2,$$

where $A_1, \ldots, A_m$ are the clauses of F realized as polynomials on the variables $x_1, \ldots, x_n$. Since F is an s-DNF, the degree of each A_c is at most s. Hence, by construction, $deg(f_l), deg(f_u) \leq k$.

We want to show that

(i) $f_l \leq F \leq f_u$ and

(ii) $E(F - f_l) \leq mE(F-f)^2$ and $E(f_u - F) \leq mE(F-f)^2$.

To establish (i), let $x \in \{0,1\}^n$, and consider two cases depending on whether $F(x) = 0$ or 1.

If $F(x) = 0$, then $f(x) = 0$ by the zeros-constraint on f. Moreover, none of the clauses of F is satisfied by x; i.e., $A_c(x) = 0$ for each clause A_c of F. Hence $f_l(x) = 1 - (1-0)^2 = 0$ and $f_u(x) = 1 - (1-0)(1-0)^2 = 0$. That is, (i) holds with equality when $F(x) = 0$.

If $F(x) = 1$, there exists at least one clause c such that $A_c(x) = 1$; hence $1 - \sum_c A_c(x) \leq 0$. It follows that

$$f_u(x) = 1 - \left(1 - \sum_c A_c(x)\right)(1 - f(x))^2 \geq 1 = F(x).$$

Moreover, $f_l(x) = 1 - (1-f(x))^2 \leq 1 = F(x)$, which verifies (i) when $F(x) = 1$.

To establish (ii), it is enough to argue that $E(f_u - f_l) \leq mE(F-f)^2$ since (by (i)) $E(f_u - f_l)$ is an upper bound on both $E(F - f_l)$ and $E(f_u - F)$.

We have

$$f_u(x) - f_l(x) = \sum_c A_c(x)(1 - f(x))^2 = \sum_c A_c(x)(F(x) - f(x))^2.$$

To verify the second equality, consider two cases depending on whether $F(x) = 1$ or 0. The $F(x) = 1$ case is immediate. If $F(x) = 0$, then $A_c(x) = 0$ for each c, and hence the equality holds because both terms are zero. It follows that

$$E(f_u - f_l) = E\left(\sum_{c=1}^{m} A_c\right)(F - f)^2 \le mE(F - f)^2. \qquad \square$$

We derive in section 10 a compact form of the optimal solution of the least square problem underlying the definition of the t-zero-energy of an s-DNF formula (we focus on the monotone case for simplicity). Unable to estimate the optimal solution, we leave the problem open and construct next a suboptimal solution.

5.6. Construction overview. Let F be an m-clause s-DNF formula and $t \ge s$ be an integer. We want to upper bound the t-zero-energy of F, i.e., construct $f : \{0,1\}^n \to \mathbb{R}$ of degree at most t such that the mean square error $E(F - f)^2$ is small, and f satisfies the zeros-constraint: $f = 0$ whenever $F = 0$.

In this section we explain a construction of a function f satisfying the zeros-constraints. We do not analyze the corresponding mean square error, but we give some intuition as to why one would speculate that it is small. The mean square error analysis is fully presented in section 7. In a first reading, the reader may skip this overview section without loss of formal continuity and move to the end results in sections 5.7 and 5.8.

The zeros-constraint is behind the difficulty of the problem. It is worth mentioning that it excludes setting f to the truncation $\mathrm{Trn}_t F$ of F by the Fourier truncation operator Trn_t (defined in section 3). This choice minimizes the mean square error, but it is not an option for us because $\mathrm{Trn}_t F$ typically violates the zeros-constraint as it is rarely equal to 0 (or 1). We will not truncate the formula F, but we will apply truncation to carefully chosen components arising from rewriting the formula using inclusion-exclusion as we explain next.

For simplicity, we assume in this overview section that the DNF formula F is monotone. A DNF formula is called *monotone* if none of its clauses contains a negated variable. Represent F by a bipartite graph $F = (C, [n], N)$ between the set $C = [m]$ of clauses and the set $[n]$ of variable indices. For each clause $c \in C$, $N(c)$ is the neighborhood of c consisting of the indices of the variables in c. If $S \subset C$ is a set of clauses, let $N(S)$ be the neighborhood of S; i.e., $N(S) \stackrel{\text{def}}{=} \cup_{c \in S} N(c)$. If $z \subset [n]$ is a set of variable indices, denote the corresponding monotone AND gate by AND_z, i.e.,

$$AND_z(x) \stackrel{\text{def}}{=} \bigwedge_{i \in z} x_i = \prod_{i \in z} x_i,$$

for all $x \in \{0,1\}^n$. Thus

$$F(x) = \bigvee_{c \in C} AND_{N(c)}(x).$$

To construct f, expand F as follows:

$$\begin{aligned} F(x) &= 1 - \prod_{c \in C} \left(1 - \prod_{i \in N(c)} x_i\right) \\ &= \sum_{S \subset C : S \neq \emptyset} -(-1)^{|S|} \prod_{i \in N(S)} x_i \\ &= \sum_{S \subset C : S \neq \emptyset} -(-1)^{|S|} AND_{N(S)}(x). \end{aligned} \tag{5.1}$$

A direct way to obtain from this summation a low degree function which satisfies the zeros-constraint is to throw away the terms where $N(S)$ is larger than t. This reduces the degree to t and satisfies the zeros-constraint (since if $F = 0$, then $AND_{N(c)} = 0$ for each $c \in C$, and hence $AND_{N(S)} = 0$ for each $S \neq \emptyset \subset C$). But this does not work since the resulting mean square error may grow exponentially as t grows (the simplest example is when the DNF formula consists of a single OR gate on the n variables, i.e., $C = [n]$ and $N(i) = \{i\}$ for each $i \in C$).

Instead of throwing away the large terms, we will modify them while guaranteeing that each is still zero on the zeros of F. Let $S \subset C$ such that $S \neq \emptyset$, and consider the term corresponding to S. For each $c \in S$, we have

$$AND_{N(S)} = AND_{N(c)} AND_{N(S) \setminus N(c)}.$$

Averaging over all $c \in S$, we trivially get

$$AND_{N(S)} = E_{c \in S} AND_{N(c)} AND_{N(S) \setminus N(c)};$$

hence we can express F as

$$F = \sum_{S \subset C : S \neq \emptyset} -(-1)^{|S|} E_{c \in S} AND_{N(c)} AND_{N(S) \setminus N(c)}.$$

Consider constructing f by truncating each $AND_{N(S) \setminus N(c)}$ to a degree-$(t - |N(c)|)$ polynomial via the Fourier truncation operator $\mathrm{Trn}_{t-|N(c)|}$. That is, define

$$f \stackrel{\text{def}}{=} \sum_{S \subset C : S \neq \emptyset} -(-1)^{|S|} E_{c \in S} AND_{N(c)} \mathrm{Trn}_{t-|N(c)|} AND_{N(S) \setminus N(c)}.$$

The degree of each $\mathrm{Trn}_{t-|N(c)|} AND_{N(S) \setminus N(c)}$ is at most $t - |N(c)|$, and the degree of each $AND_{N(c)}$ is $|N(c)|$. Thus, by construction, $deg(f) \leq t$.

The key point is that if $F(x) = 0$, then $AND_{N(c)}(x) = 0$ for each clause $c \in C$, and hence $f(x) = 0$. That is, f satisfies the zeros-constraint.

To sum up, let F be a monotone s-DNF formula and $t \geq s$ be an integer. Then we have the bound

$$\mathrm{zeroEnergy}(F; t) \leq E(F - f)^2 = \|\widehat{F - f}\|_2^2, \tag{5.2}$$

where $F - f$ is the construction error term given by

$$F - f = \sum_{S \subset C : S \neq \emptyset} -(-1)^{|S|} E_{c \in S} AND_{N(c)} (1 - \mathrm{Trn}_{t-|N(c)|}) AND_{N(S) \setminus N(c)}. \tag{5.3}$$

Needless to say, the signs $(-1)^{|S|}$ in the above summation are critical. That is, using a triangular inequality to upper bound $E(F-f)^2$ does not give a nontrivial bound since we have exponentially many terms whose values are not small enough to make the sum value less than 1.

Estimating the mean square error $E(F-f)^2 = \|\widehat{F-f}\|_2^2$ as t grows is difficult. Before proceeding with that, we give some intuition as to why one would speculate that the mean square error of this construction decays as t grows.

It can be shown that $\widehat{f}(y) = \widehat{\mathrm{Trn}_t F}(y)$ if $|y| \le t-s$ and that $\widehat{f}(y) = \widehat{\mathrm{Trn}_t F}(y) = 0$ if $|y| > t$ (see section 7 for a verification). In the region $t-s < |y| \le t$, $\widehat{f}(y)$ behaves oddly. Since $\widehat{f}(y)$ and $\widehat{\mathrm{Trn}_t F}(y)$ are equal outside this region, and since we know from the LMN energy bound (Theorem 5.8) that $\mathrm{energy}(F;t) = \|F - \widehat{\mathrm{Trn}_t F}\|_2^2$ decays quickly as t grows, we can hope that $\widehat{f}(y)$ is not too bad in the region $t-s < |y| \le t$ and hence speculate that $E(F-f)^2 = \|\widehat{F-f}\|_2^2$ also decays in some way with t. This makes f a potential candidate for bounding the t-zero-energy of F, but unfortunately this intuition does not help in the analysis as the frequencies in the region $t-s < |y| \le t$ are too many to handle separately by trivial bounds.

Using analytical means, we bound $\|\widehat{F-f}\|_2^2$ in section 7 in terms of the energies of auxiliary functions associated with DNF formulas derived from F, which reduces via (5.2) the problem of bounding the t-zero-energy of F to that of bounding the energies of those functions. After defining the auxiliary functions in section 5.7, we state the reduction in section 5.8 without going into the above construction of f.

5.7. Skin and cover auxiliary functions. The proof uses the following auxiliary functions associated with DNF formulas.

DEFINITION 5.6. *Let G be a DNF formula on n variables whose clauses are $A_1, \ldots, A_m$.*

- (Skin) *If $u \ge 0$, define the* u-skin of G *to be the real-valued function $\mathit{skin}_{G,u} : \{0,1\}^n \to \mathbb{R}$ given by*

$$\mathit{skin}_{G,u}(x) \stackrel{\mathrm{def}}{=} 1 - (1-e^{-u})^{\sum_{c=1}^m A_c(x)}.$$

  Note that $\sum_{c=1}^m A_c(x)$ is the number of clauses of G satisfied by x. The function $\mathit{skin}_{G,u}$ is extended to $u=0$ by continuity; i.e., $\mathit{skin}_{G,0} = G$.
- (Cover) *Define the* cover of G *to be the real-valued function $\mathit{cover}_G : \{0,1\}^n \to \mathbb{R}$ given by*

$$\mathit{cover}_G(x) \stackrel{\mathrm{def}}{=} \int_0^\infty \mathit{skin}_{G,u}(x) e^{-u} du = 1 - \frac{1}{1+\sum_{c=1}^m A_c(x)}.$$

To evaluate the integral, note that

$$\int_0^\infty (1-(1-e^{-u})^a) e^{-u} du = \int_0^\infty e^{-u} du - \int_0^1 (1-e^{-u})^a d(1-e^{-u}) = 1 - \frac{1}{1+a}$$

for all $a \ne -1$.

Remark 5.7. The function $\mathrm{skin}_{G,u}$ converges to G from above as u approaches 0, and hence the name u-skin of G. Moreover, $\mathrm{cover}_G \ge G$, and hence the name cover of G. The fact that both functions are greater than G is not used in the proof. Note that we defined cover_G as an integral. The fact that this integral evaluates to $1 - 1/(1+\sum_{c=1}^m A_c)$ is not used either in the proof (it is needed, however, to justify

the "cover" name). The proof is based on those functions in the Fourier domain. The origin of the skin and cover functions is the construction overviewed in section 5.6 above. We show in section 7 that the Fourier transform of the cover function naturally appears when analyzing the Fourier transform of the construction error term given in (5.3), and the skin function naturally appears when trying to recover the cover function from its Fourier transform.

5.8. From zero-energy to the energies of auxiliary functions. In this section, we state the end results of section 7 in which we reduce the problem of bounding the t-zero-energy of an s-DNF formula F to that of bounding the $(t-s)$-energies of cover and skin auxiliary functions associated with DNF formulas derived from F.

First, we reduce the problem of bounding the t-zero-energy of an s-DNF formula F to that of bounding the $(t-s)$-energies of the cover functions of DNF formulas derived from F as follows.

For simplicity, we start by stating the reduction in the context of monotone DNF formulas.

THEOREM 7.3 (zero-energy $\preccurlyeq$ energy of cover). *Let F be an s-DNF formula on the variables $x_1, \dots, x_n$, and let $t \geq s$ be an integer. Let $A_1, \dots, A_m$ be the clauses of F, and let $C = [m]$ be the set of indices of the clauses of F.*

(a) (Monotone case) *Assume that F is monotone and $m \geq 2$. For each clause index $c \in C$, let F_c be the DNF formula on the variables $x_1, \dots, x_n$ whose clauses are $\{A_c \wedge A_d\}_{d \in C \setminus \{c\}}$. That is, F_c is the formula resulting from removing from F the clause A_c and adding the variables of A_c to each of the remaining clauses. Then*

$$zeroEnergy(F; t) \leq m^2 \max_{c \in C} energy(cover_{F_c}; t - s).$$

(b) (General case) *We call two clauses A_c and A_d consistent if they have a common satisfying assignment. If $c \in C$, let C_c be the set of indices of clauses other than A_c which are consistent with A_c; i.e., $C_c = \{d \in C \setminus \{c\} : A_c$ and A_d are consistent$\}$. Let C_{main} be the set of indices of the clauses of F which are consistent with at least one clause of F other than themselves; i.e., $C_{main} = \{c \in C : C_c \neq \emptyset\}$.*

For each clause index $c \in C_{main}$, let F_c be the DNF formula on the variables $x_1, \dots, x_n$ whose clauses are $\{A_c \wedge A_d\}_{d \in C_c}$. That is, F_c is the formula resulting from removing from F the clause A_c and all the clauses not consistent with A_c, and adding the literals of A_c to each of the remaining clauses. Then

$$zeroEnergy(F; t) \leq |C_{main}|^2 \max_{c \in C_{main}} energy(cover_{F_c}; t - s).$$

Thus if F is monotone, then $C_c = C \setminus \{c\}$ for each $c \in C$, and $C_{main} = C$.

The proof of Theorem 7.3 is in section 7 and uses the machinery developed in section 6. The construction underlying the reduction is overviewed in section 5.6.

Note that each F_c is a $2s$-DNF formula on n variables with at most $m-1$ clauses and at least one clause (by the definition of C_{main}). That is, the complexity of each F_c is in the worst case comparable to that of F. Recall from section 5.5 that we care about the case when $s = \Theta(\sqrt{t})$ (since $t = \lfloor \frac{k-s}{2} \rfloor$ and $s = \Theta(\sqrt{k})$); hence $t - s \approx t$. Moreover, typically $t = \Theta(\log^2 m)$ (in the typical case when $k = \Theta(\log^2 m)$).

Therefore, in general, we can now focus on estimating the t-energy of the cover of a DNF formula G, where $t \geq 0$ is an integer. Unable to argue directly on the cover

function, we move to the u-skin function. The fact that $\text{cover}_G = \int_0^\infty \text{skin}_{G,u} e^{-u} du$ immediately reduces the problem of estimating the t-energy of the cover function of a DNF to that of estimating the t-energies of its u-skin functions for all $u \geq 0$. In particular, we have the following bound, which is verified via the Cauchy–Schwarz inequality in section 7.4.

LEMMA 7.4 (energy of cover $\preccurlyeq$ energy of skin). *Let G be a DNF formula, and let $t \geq 0$ be an integer. Then*

$$\textit{energy}(\textit{cover}_G; t) \leq \sup_{u \geq 0} \textit{energy}(\textit{skin}_{G,u}; t).$$

5.9. Back to DNF formulas. Let G be a DNF formula, $u \geq 0$, and $t \geq 0$ be an integer. We want to estimate the t-energy of the u-skin of G. We bound in section 8 the t-energy of the u-skin of G by the t-energies of DNF formulas derived from G by adding new auxiliary variables, which enables us to use the LMN energy bound.

First we state the reduction in the special case when there exists a nonnegative integer v such that $e^{-u} = 2^{-v}$. We construct from G a new DNF formula G_v by adding v new auxiliary nonnegated variables to each clause of G. Thus, the total number of variables of G_v is $n + mv$. We show in section 8 that $\text{energy}(\text{skin}_{G,u}; t) \leq \text{energy}(G_v; t)$. The proof is based on examining the Fourier transforms of $\text{skin}_{G,u}$ and uses the machinery developed in section 6.

In general, if v is not necessarily an integer, we show in section 8 that the following theorem holds.

THEOREM 8.1 (energy of skin $\preccurlyeq$ energy). *Let G be a DNF formula whose clauses are $A_1, \ldots, A_m$, and let $t \geq 0$ be an integer. If $d \in \mathbb{N}^m$, construct from G a new DNF formula G_d by adding d_c new auxiliary nonnegated variables to each clause A_c. That is, the clauses of G_d are $\{A_c \wedge \bigwedge_{i=1}^{d_c} \ddot{x}_{ci}\}_{c=1}^m$, where $\{\ddot{x}_{ci}\}_{i=1}^{d_c}$ are the new auxiliary variables added to clause A_c.*

Let $u \geq 0$ and let $v \geq 0$ such that $e^{-u} = 2^{-v}$; i.e., $v = u/\ln 2$. Then

$$\textit{energy}(\textit{skin}_{G,u}; t) \leq \max_{d \in \{\lfloor v \rfloor, \lceil v \rceil\}^m} \textit{energy}(G_d; t).$$

Note that for each $d \in \{\lfloor v \rfloor, \lceil v \rceil\}^m$, the formula G_d is an m-clause DNF on $n + \sum_c d_c$ variables.

This enables us to use the bound derived from Hastad's switching lemma in [13] on the t-energy of a DNF formula.

THEOREM 5.8 (LMN energy bound [13]). *Let G be an m-clause DNF formula, and let $t \geq 0$ be an integer; then $\textit{energy}(G; t) \leq 2m2^{-\sqrt{t}/20}$.*

The proof of (an asymptotic version of) Theorem 1.1 follows by first substituting the bound of Theorem 5.8 in Theorem 8.1 and backtracking the bounds till Lemma 5.4. We summarize in section 5.10; then we backtrack the bounds in section 5.11.

5.10. Summary. Tables 1 and 2 below summarize the main definitions and reductions.

The full presentation in sections 7 and 8 uses the machinery in section 6. In sections 6, 7, and 8, we separate between the monotone case and the general case to introduce the arguments in a simple context. We recommend that the reader first traverse the monotone part of the full sections in the following order: sections 6.1, 6.2, 6.3, 7.1, 7.2, 7.4, introduction of section 8.

For future reference in sections 5.11 and 9, we list below compact statements of the above reductions.

- LEMMA 5.4 (focus on s-DNF). Let $k \geq s \geq 1$ be integers, and let $\epsilon \geq 0$. If $\mathrm{bias}(F;k) \leq \epsilon$ for each m-clause s-DNF formula F, then $\mathrm{bias}(F;k) \leq \epsilon + m2^{-s}$ for each m-clause DNF formula F.
  At the end, we will set $s = \Theta(\sqrt{k})$. Thus $s = \Theta(\log m)$ in the typical case when $k = \Theta(\log^2 m)$.
- LEMMA 5.5 (bias $\preccurlyeq$ zero-energy). Let F be an m-clause s-DNF formula, and let $k \geq s$ be an integer. Then $\mathrm{bias}(F;k) \leq m \times \mathrm{zeroEnergy}(F;t)$, where $t = \lfloor \frac{k-s}{2} \rfloor$.
  Note that $t \approx k/2$ for $s = \Theta(\sqrt{k})$. Moreover, $t = \Theta(\log^2 m)$ in the typical case when $k = \Theta(\log^2 m)$.
- THEOREM 7.3 (zero-energy $\preccurlyeq$ energy of cover). Let F be an s-DNF formula on the variables $x_1, \ldots, x_n$, and let $t \geq s$ be an integer. Let $A_1, \ldots, A_m$ be the clauses of F. Let $C = [m]$ be the set of indices of the clauses of F. If $c \in C$, let $C_c = \{d \in C \backslash \{c\} : A_c \text{ and } A_d \text{ are consistent}\}$. Let $C_{main} = \{c \in C : C_c \neq \emptyset\}$. For each $c \in C_{main}$, let F_c be the DNF formula on the variables $x_1, \ldots, x_n$ whose clauses are $\{A_c \wedge A_d\}_{d \in C_c}$. Then

$$\mathrm{zeroEnergy}(F;t) \leq |C_{main}|^2 \max_{c \in C_{main}} \mathrm{energy}(\mathrm{cover}_{F_c}; t-s).$$

  Note that for each $c \in C_{main}$, F_c is a $2s$-DNF formula with at most $m-1$ clauses and least one clause. Moreover, $|C_{main}| \leq |C| = m$. Note also that $t - s \approx t \approx k/2$ for $t = \lfloor \frac{k-s}{2} \rfloor$ and $s = \Theta(\sqrt{k})$.
- LEMMA 7.4 (energy of cover $\preccurlyeq$ energy of skin). Let G be a DNF formula, and let $t \geq 0$ be an integer. Then

$$\mathrm{energy}(\mathrm{cover}_G; t) \leq \sup_{u \geq 0} \mathrm{energy}(\mathrm{skin}_{G,u}; t).$$

- THEOREM 8.1 (energy of skin $\preccurlyeq$ energy). Let G be a DNF formula, whose clauses are $A_1, \ldots, A_m$, and let $t \geq 0$ be an integer. If $d \in \mathbb{N}^m$, construct from G a new DNF formula G_d by adding d_c new auxiliary nonnegated variables to each clause A_c. Let $u \geq 0$ and $v = u/\ln 2$. Then

$$\mathrm{energy}(\mathrm{skin}_{G,u}; t) \leq \max_{d \in \{\lfloor v \rfloor, \lceil v \rceil\}^m} \mathrm{energy}(G_d; t).$$

Note that for each d, the number of clauses of G_d is equal to that of G.

- THEOREM 5.8 (LMN energy bound). Let G be an m-clause DNF formula, and let $t \geq 0$ be an integer; then $\text{energy}(G;t) \leq 2m2^{-\sqrt{t}/20}$.

5.11. Backtracking. In this section, we derive an asymptotic version of Theorem 1.1 by substituting the bound of Theorem 5.8 in Theorem 8.1 and backtracking the bounds via Lemma 7.4, Theorem 7.3, Lemma 5.5, till Lemma 5.4. Namely, we show that if F is an m-clause DNF formula and $k \geq 1$ is an integer, then $\text{bias}(F;k) = O(m^{\Theta(1)}2^{-\Theta(\sqrt{k})})$. Since the bound of Theorem 5.8 does not depend on the maximum number of literals in a clause, the needed calculations are minimal.

Let G be an m-clause DNF formula, and let $t \geq 0$. Substituting the bound of Theorem 5.8 in Theorem 8.1, we get that $\text{energy}(\text{skin}_{G,u};t) \leq 2m2^{-\sqrt{t}/20}$ for all $u \geq 0$. Substituting in Lemma 7.4, we obtain $\text{energy}(\text{cover}_G;t) \leq 2m2^{-\sqrt{t}/20}$. Thus, by Theorem 7.3, if F is an m-clause s-DNF formula and $t \geq s$ is an integer, then $\text{zeroEnergy}(F;t) \leq 2m^2(m-1)2^{-\sqrt{t-s}/20}$. It follows from Lemma 5.5 that if $k \geq s$ is an integer, then $\text{bias}(F;k) \leq 2m^3(m-1)2^{-\sqrt{\lfloor (k-s)/2 \rfloor - s}/20}$. Finally, substituting in Lemma 5.4, we get that if F is an m-clause DNF formula and $k \geq 1$ is an integer, then

$$\text{bias}(F;k) \leq m2^{-s} + 2m^3(m-1)2^{-\sqrt{\lfloor (k-s)/2 \rfloor - s}/20}$$

for all integers s such that $k \geq s \geq 1$. Optimizing on s, we obtain $\text{bias}(F;k) = O(m^4 2^{-\Theta(\sqrt{k})})$ for $s = \Theta(\sqrt{k})$.

The exact bound $m^{2.2}2^{-\sqrt{k}/10}$ of Theorem 1.1 is derived in section 9. It uses another form of the LMN energy bound which is tighter than Theorem 5.8 for s-DNF formulas when s is not relatively large (Theorem 9.1 in section 9), and a sharper form of Lemma 7.4 (part (a) of Lemma 7.4 in section 7).

6. Möbius and Fourier analysis of DNF formulas and auxiliary functions. We develop in this section the proof machinery used in sections 7 and 8.

We develop the monotone machinery in sections 6.2 and 6.3. Monotone DNF formulas and their skin and cover auxiliary functions have natural expansions as linear combinations of monotone AND gates. We are interested in the coefficients of those expansions. The Fourier transforms of those functions can be extracted from those coefficients by a basis change. When expanding a real-valued function f defined on the hypercube as a linear combination of monotone AND gates, it is convenient to view the hypercube as the poset B_n of subsets of $[n]$ ordered by inclusion. We note in section 6.2 that this enables us to interpret the coefficients of the expansion of f as the Möbius transform of f with respect to the poset B_n. We also derive a simple change of basis formula to extract the Fourier transform of a function from its Möbius transform. In section 6.3, we compute the Möbius and Fourier transforms of monotone DNF formulas and their auxiliary functions. The monotone machinery is used in sections 7.1 and 8.

The poset language is essential to generalize to nonnecessarily monotone DNF formulas. The monotone machinery naturally generalizes to the nonnecessarily monotone case by essentially replacing the poset B_n with another poset $B_n^{(2)}$, defined in section 6.4. We develop the general machinery in sections 6.4 and 6.5. It is used in section 7.3.

6.1. Posets preliminaries. For a general reference on posets, see [24]. We need only a few elementary definitions. A *poset* (partially ordered set) X is a set X with

a reflexive, antisymmetric, and transitive binary relation $\leq_X$. We denote $\leq_X$ by $\leq$ when there is no confusion. We implicitly assume that X is finite. We denote the set of real-valued functions on X by $L(X) = \{f : X \to \mathbb{R}\}$. The *zeta function* ζ_X of X is the linear transformation $\zeta_X : L(X) \to L(X)$ given by

$$(\zeta_X f)(x) = \sum_{y \leq x} f(y) = \sum_{y \in X} \zeta_X(y, x) f(y).$$

That is, the matrix coefficients $(\zeta_X(y, x))_{x,y}$ of ζ_X are given by

$$\zeta_X(y, x) = \begin{cases} 1 & \text{if } y \leq x, \\ 0 & \text{otherwise.} \end{cases} \tag{6.1}$$

The zeta function ζ_X is always nonsingular. The inverse ζ_X^{-1} of ζ_X is called the *Möbius function* of X and is denoted by $\mu_X = \zeta_X^{-1}$.

We are interested in two posets defined in sections 6.2 and 6.4.

6.2. Poset B_n. Let $[n] \stackrel{\text{def}}{=} \{1, \ldots, n\}$. Let B_n be the poset of subsets of $[n]$ ordered by inclusion. We denote the subset inclusion $a \subset b$ by $a \leq b$ and $b \geq a$.

We identify the hypercube $\{0, 1\}^n$ with the poset B_n by associating $x \in \{0, 1\}^n$ with $\text{support}(x) \stackrel{\text{def}}{=} \{i \in [n] : x_i = 1\} \in B_n$. Thus $x \in B_n$ means both a subset of $[n]$ and a vector in $\{0, 1\}^n$ depending on the context.

If $z \in B_n$, define the monotone AND function $AND_z : B_n \to \{0, 1\}$ by

$$AND_z(x) \stackrel{\text{def}}{=} \bigwedge_{i \in z} x_i.$$

The functions $\{AND_z\}_{z \in B_n}$ form a basis of $L(B_n)$. When working with the $\{AND_z\}_{z \in B_n}$ basis, it is convenient to view the hypercube as the poset B_n since

$$AND_z(x) = \zeta_{B_n}(z, x) \tag{6.2}$$

by (6.1). That is, the functions $\{AND_z\}_{z \in B_n}$ are the rows of the matrix of the zeta function ζ_{B_n} of the poset B_n. Any function $f \in L(B_n)$ can be expressed as

$$f = \sum_{z \in B_n} \widetilde{f}(z) AND_z$$

for some $\widetilde{f} \in L(B_n)$. By (6.2),

$$f(x) = \sum_{z \in B_n} \widetilde{f}(z) \zeta_{B_n}(z, x) = (\zeta_{B_n} \widetilde{f})(x).$$

That is, $f = \zeta_{B_n} \widetilde{f}$, and hence $\widetilde{f} = \mu_{B_n} f$. We call $\widetilde{f} = \mu_{B_n} f$ the *Möbius transform* of f.

Our interest in the Möbius transform on B_n is motivated by the fact that monotone DNF formulas and auxiliary functions have natural expansions in the $\{AND_z\}_z$ basis from which we can extract their Möbius transforms. We show that in section 6.3.

Given the Möbius transform of a function, its Fourier transform can be extracted via a simple weighted summation, which we derive next. Recall the $(\mathbb{Z}/2\mathbb{Z})^n$ group structure on $\{0, 1\}^n$ from section 3. In terms of the identification of $\{0, 1\}^n$ with B_n, B_n is an abelian group under the set exclusive union operation, which we denote by

$\oplus$. In the B_n-terminology, the characters of this abelian group defined in section 3 are $\{\mathcal{X}_y(x) = (-1)^{|x\cap y|}\}_{y\in B_n}$.

To extract the Fourier transform of a function $f \in L(B_n)$ from its Möbius transform, we need a change of basis formula between the $\{AND_z\}_z$ basis and the $\{\mathcal{X}_y\}_y$ basis of $L(B_n)$. We have

$$AND_z(x) = \bigwedge_{i\in z} x_i = \prod_{i\in z} x_i = \prod_{i\in z} \frac{1-(-1)^{x_i}}{2} = \frac{1}{2^{|z|}} \sum_{y\le z} (-1)^{|y|}(-1)^{\sum_{i\in y} x_i}.$$

That is,

$$AND_z(x) = \frac{1}{2^{|z|}} \sum_{y\le z} (-1)^{|y|} \mathcal{X}_y(x). \tag{6.3}$$

Note that if $z = \emptyset$, by convention $\prod_{i\in z} x_i = \bigwedge_{i\in z} x_i = 1$. Thus

$$\begin{aligned} f(x) &= \sum_z \widetilde{f}(z) AND_z(x) \\ &= \sum_z \widetilde{f}(z) 2^{-|z|} \sum_{y\le z} (-1)^{|y|} \mathcal{X}_y(x) \\ &= \sum_y \mathcal{X}_y(x) (-1)^{|y|} \sum_{z\ge y} 2^{-|z|} \widetilde{f}(z). \end{aligned}$$

Therefore, the desired change of basis formula is

$$\widehat{f}(y) = (-1)^{|y|} \sum_{z\ge y} 2^{-|z|} \widetilde{f}(z) \quad \text{for all } y \in B_n \text{ and } f \in L(B_n). \tag{6.4}$$

Conversely, one can verify that

$$\widetilde{f}(z) = (-1)^{|z|} 2^{|z|} \sum_{y\ge z} \widehat{f}(y),$$

but we will not use that.

Finally, if $f : \{0,1\}^n \to \mathbb{R}$, the degree of f is the smallest degree of a polynomial $p \in \mathbb{R}[x_1, \ldots, x_n]$ such that $p(x) = f(x)$ for all $x \in \{0,1\}^n$. In terms of the $\{\mathcal{X}_y\}_y$ basis, the degree of f is equal to the maximal cardinality of $y \in B_n$ such that $\widehat{f}(y) \neq 0$. In terms of the $\{AND_z\}_z$ basis, the degree of f is equal to the maximal cardinality of $z \in B_n$ such that $\widetilde{f}(z) \neq 0$.

6.3. Monotone DNF formulas and auxiliary functions. In this section we compute the Möbius and Fourier transforms of monotone DNF formulas and auxiliary functions.

A DNF formula is called *monotone* if none of its clauses contains a negated variable. We represent a monotone DNF formula F on n variables by a bipartite graph $F = (C, [n], N)$ between the set C of clauses and the set $[n]$ of variables indices. For each clause $c \in C$, $N(c)$ is the neighborhood of c consisting of the indices of the variables in c. To avoid degenerate cases, we assume that we have at least one clause, i.e., $|C| \ge 1$, and that each clause contains at least one variable, i.e., $N(c) \neq \emptyset$, for each $c \in C$. If $S \subset C$, $N(S)$ denotes the neighborhood of S, i.e., $N(S) = \cup_{c\in S} N(c)$. Finally, if $s \ge 1$ is an integer, we call a monotone DNF formula $F = (C, [n], N)$ an

s-DNF formula if each clause contains at most s variables, i.e., $|N(c)| \leq s$, for each $c \in C$.

We chose the bipartite graph representation to allow for duplicate clauses; formulas possibly containing duplicate clauses will be derived in the proof of Theorem 1.1 (see section 7.2.C).

If $F = (C, [n], N)$ is a monotone DNF formula, we abuse notation and denote by F also the boolean function computed by F. That is, the boolean function $F : B_n \to \{0, 1\}$ is given by

$$F(x) \stackrel{\text{def}}{=} \bigvee_{c \in C} AND_{N(c)}(x) \qquad \text{for } x \in B_n.$$

Monotone DNF formulas and auxiliary functions have natural expansions in the $\{AND_z\}_z$ basis from which we can extract their Möbius transforms. To get the Fourier transforms, we use the change of basis formula (6.4). To warm up, let us compute the Möbius and Fourier transforms of F.

LEMMA 6.1. *Let $F = (C, [n], N)$ be a monotone DNF formula. Then for all $z, y \in B_n$,*

$$\widetilde{F}(z) = \sum_{S \neq \emptyset \subset C : N(S) = z} -(-1)^{|S|}, \tag{6.5}$$

$$\widehat{F}(y) = (-1)^{|y|} \sum_{S \neq \emptyset \subset C : N(S) \geq y} -(-1)^{|S|} 2^{-|N(S)|}. \tag{6.6}$$

Proof. By expanding $F(x)$ as in (5.1) and grouping terms, we get

$$F(x) = \sum_{S \subset C : S \neq \emptyset} -(-1)^{|S|} AND_{N(S)}(x) = \sum_{z \in B_n} AND_z(x) \sum_{S \neq \emptyset \subset C : N(S) = z} -(-1)^{|S|},$$

which verifies (6.5). The correctness of (6.6) follows from (6.5) via (6.4):

$$\begin{aligned} \widehat{F}(y) &= (-1)^{|y|} \sum_{z \geq y} 2^{-|z|} \sum_{S \neq \emptyset \subset C : N(S) = z} -(-1)^{|S|} \\ &= (-1)^{|y|} \sum_{S \neq \emptyset \subset C : N(S) \geq y} -(-1)^{|S|} 2^{-|N(S)|}. \end{aligned}$$

□

If $F = (C, [n], N)$ is a monotone DNF formula and $u \geq 0$, recall from Definition 5.6 the auxiliary functions u-skin of F and cover of F: $\text{skin}_{F,u}, \text{cover}_F \in L(B_n)$ are given by

$$\begin{aligned} \text{skin}_{F,u}(x) &\stackrel{\text{def}}{=} 1 - (1 - e^{-u})^{\sum_{c \in C} AND_{N(c)}(x)}, \\ \text{cover}_F(x) &\stackrel{\text{def}}{=} \int_0^\infty \text{skin}_{F,u}(x) e^{-u} du, \end{aligned}$$

where $\text{skin}_{F,u}$ is extended to $u = 0$ by continuity, i.e., $\text{skin}_{F,0} = F$.

We compute below their Möbius and Fourier transforms which play a critical role in the proof of Theorem 1.1 as shown in sections 7 and 8.

LEMMA 6.2. *Let $F = (C, [n], N)$ be a monotone DNF formula, and let $u \geq 0$. Then for all $z, y \in B_n$,*

$$\widetilde{skin}_{F,u}(z) = \sum_{S \neq \emptyset \subset C : N(S) = z} -(-1)^{|S|} e^{-u|S|}, \tag{6.7}$$

$$\widetilde{cover}_F(z) = \sum_{S \neq \emptyset \subset C : N(S) = z} -(-1)^{|S|} \frac{1}{|S|+1}, \tag{6.8}$$

$$\widehat{skin}_{F,u}(y) = (-1)^{|y|} \sum_{S \neq \emptyset \subset C : N(S) \geq y} -(-1)^{|S|} 2^{-|N(S)|} e^{-u|S|}, \tag{6.9}$$

$$\widehat{cover}_F(y) = (-1)^{|y|} \sum_{S \neq \emptyset \subset C : N(S) \geq y} -(-1)^{|S|} 2^{-|N(S)|} \frac{1}{|S|+1}. \tag{6.10}$$

Remark 6.3.

1. Our interest in the cover and skin functions originates from the last summation in (6.10). The analysis of the construction error term overviewed in section 5.6 and fully presented in section 7 leads to summations like the right-hand side of (6.10) (see the proof of Lemma 7.1 and section 7.2.A). To interpret this summation, we expressed $\frac{1}{|S|+1}$ as $\frac{1}{|S|+1} = \int_0^\infty e^{-u|S|} e^{-u} du$, which led us to the right-hand side of (6.9). Using the Fourier–Möbius change of basis formula (6.4), we obtained (6.7) which we identified as the Möbius transform of the skin function as shown in the proof below.
2. Comparing Lemmas 6.1 and 6.2, we see that the Möbius and Fourier transforms of the u-skin and cover of F are smoothed or weighted versions of those of F. The smoothing or weighting factor of the u-skin function is $e^{-u|S|}$, and that of the cover function is $\frac{1}{|S|+1}$.

Proof. We start with (6.7). It is enough to verify it under the assumption that $u > 0$. The $u = 0$ case follows from (6.5). We have

$$1 - (1 - e^{-u})^{\sum_{c \in C} AND_{N(c)}(x)} = 1 - \prod_{c \in C} (1 - e^{-u})^{AND_{N(c)}(x)}.$$

Since $u > 0$, we have $(1 - e^{-u})^{AND_{N(c)}(x)} = 1 - e^{-u} AND_{N(c)}(x)$ for all $c \in C$ and all $x \in \{0,1\}^n$ (if $AND_{N(c)}(x) = 0$, both terms are 1; if $AND_{N(c)}(x) = 1$, both terms are $1 - e^{-u}$). Thus

$$\begin{aligned} 1 - (1 - e^{-u})^{\sum_{c \in C} AND_{N(c)}(x)} &= 1 - \prod_{c \in C} (1 - AND_{N(c)}(x) e^{-u}) \\ &= \sum_{S \neq \emptyset \subset C} -(-e^{-u})^{|S|} \prod_{c \in S} AND_{N(c)}(x) \\ &= \sum_{S \neq \emptyset \subset C} -(-1)^{|S|} e^{-u|S|} AND_{N(S)}(x) \\ &= \sum_{z \in B_n} AND_z(x) \sum_{S \neq \emptyset \subset C : N(S) = z} -(-1)^{|S|} e^{-u|S|}, \end{aligned} \tag{6.11}$$

which verifies (6.7). Applying the linear operator μ_{B_n} to $\mathrm{cover}_F = \int_0^\infty \mathrm{skin}_{F,u} e^{-u} du$,

we get

$$\begin{aligned}\widetilde{\mathrm{cover}}_F(z) &= \int_0^\infty \widetilde{\mathrm{skin}}_{F,u}(z)e^{-u}du \\ &= \sum_{S\neq\emptyset\subset C:N(S)=z} -(-1)^{|S|}\int_0^\infty e^{-u(|S|+1)}du \\ &= \sum_{S\neq\emptyset\subset C:N(S)=z} -(-1)^{|S|}\frac{1}{|S|+1},\end{aligned}$$

which verifies (6.10). Finally, as in Lemma 6.1, (6.10) and (6.9) follow immediately from (6.8) and (6.7) via (6.4). □

6.4. The poset $B_n^{(2)}$. To generalize the monotone machinery in sections 6.2 and 6.3 to the nonnecessarily monotone case, we basically only have to replace the poset B_n with another poset $B_n^{(2)}$, which we study in this section. Below, we define this poset and give the corresponding analogues of (6.2) and (6.4).

When the DNF formula is not necessarily monotone, the AND gates are of the form

$$ANDz_{(z',z'')}(x) = \bigwedge_{i\in z'} x_i \wedge \bigwedge_{i\in z'} \neg x_i = ANDz_{z'}(x)\wedge ANDz_{z''}(x^c) \quad \text{for } x\in B_n,$$

where $(z',z'')\in B_n\times B_n$ are such that $z'\cap z''=\emptyset$ and $x^c \stackrel{\text{def}}{=} [n]\backslash x \in B_n$.

This motivates looking at the poset $B_n^{(2)}$ defined as follows. Consider the product poset $B_n^2 \stackrel{\text{def}}{=} B_n\times B_n$; i.e., the order relation on B_n^2 is given by $(x',x'')\le(y',y'')$ if $x'\le y'$ and $x''\le y''$. Let $B_n^{(2)}$ be the poset given by

$$B_n^{(2)} \stackrel{\text{def}}{=} \{(x',x'')\in B_n^2 : x'\cap x''=\emptyset\} \tag{6.12}$$

and ordered via the ordered relation of B_n^2. That is, $B_n^{(2)}$ is the subposet of B_n^2 given by (6.12).

If $x\in B_n^{(2)}$, we denote by x' and x'' the elements of B_n such that $x=(x',x'')$.

If $z\in B_n^{(2)}$, the corresponding AND gate $ANDz_z : B_n\to\{0,1\}$ is given by

$$ANDz_z(x) \stackrel{\text{def}}{=} ANDz_{z'}(x)\wedge ANDz_{z''}(x^c) \quad \text{for } x\in B_n.$$

To get a relation similar to (6.2), lift $ANDz_z$ to $B_n^{(2)}$ as follows. If $z\in B_n^{(2)}$, define $\overline{ANDz}_z : B_n^{(2)}\to\{0,1\}$ by

$$\overline{ANDz}_z(x) \stackrel{\text{def}}{=} ANDz_{z'}(x')\wedge ANDz_{z''}(x'') = \zeta_{B_n^{(2)}}(z,x).$$

Thus

$$ANDz_z(x) = \overline{ANDz}_z(x,x^c) \quad \text{for } x\in B_n,$$

and

$$\overline{ANDz}_z(x) = \zeta_{B_n^{(2)}}(z,x) \quad \text{for } x\in B_n^{(2)}, \tag{6.13}$$

which is the analogue of (6.2) on $B_n^{(2)}$. We are using the bar-notation to indicate that $\overline{AND}_z$ is the *lift* of AND_z from B_n to $B_n^{(2)}$ (the bar-notation should not be confused with negation).

The functions $\{\overline{AND}_z\}_{z\in B_n^{(2)}}$ form a basis for $L(B_n^{(2)})$ since by (6.13) they are the rows of the matrix of the invertible linear transformation $\zeta_{B_n^{(2)}}$. Any function $f \in L(B_n^{(2)})$ can be expressed as

$$f = \sum_{z\in B_n^{(2)}} \widetilde{f}(z)\overline{AND}_z$$

for some $\widetilde{f} \in L(B_n^{(2)})$. Indeed, by (6.13),

$$f(x) = \sum_z \widetilde{f}(z)\zeta_{B_n^{(2)}}(z,x) = (\zeta_{B_n^{(2)}} f)(x).$$

That is, $\widetilde{f} = \mu_{B_n^{(2)}} f$ and $f = \zeta_{B_n^{(2)}} \widetilde{f}$. We call $\widetilde{f} = \mu_{B_n^{(2)}} f$ the *Möbius transform* of f.

We need an analogue of (6.4) on $B_n^{(2)}$. If $f \in L(B_n^{(2)})$, we relate next the Fourier transform of its projection to B_n to the Möbius transform of f.

Consider the injective embedding $B_n \to B_n^{(2)}$, $x \mapsto (x, x^c)$. It induces the linear map $\text{Proj} : L(B_n^{(2)}) \to L(B_n)$ given by $(\text{Proj } f)(x) = f(x, x^c)$. In terms of Proj, we have $AND_z = \text{Proj } \overline{AND}_z$; thus

$$(\text{Proj } f)(x) = \sum_z \widetilde{f}(z) AND_z(x).$$

If $f \in L(B_n^{(2)})$, we show below how to extract $\widehat{\text{Proj } f}$ from $\widetilde{f}$. Let $z \in B_n^{(2)}$. From (6.3), we have

$$AND_{z'}(x) = 2^{-|z'|} \sum_{y'\le z'} (-1)^{|y'|} \mathcal{X}_{y'}(x)$$

and

$$AND_{z''}(x^c) = 2^{-|z''|} \sum_{y''\le z''} (-1)^{|y''|} \mathcal{X}_{y''}(x^c).$$

Now

$$\mathcal{X}_{y''}(x^c) = (-1)^{|y''\cap x^c|} = (-1)^{|y''|-|y''\cap x|} = (-1)^{|y''|}\mathcal{X}_{y''}(x);$$

hence

$$AND_{z''}(x) = 2^{-|z''|} \sum_{y''\le z''} \mathcal{X}_{y''}(x).$$

It follows that

$$\begin{aligned} AND_z(x) &= AND_{z'}(x) AND_{z''}(x^c) \\ &= 2^{-|z'|} \sum_{y'\le z'} (-1)^{|y'|} \mathcal{X}_{y'}(x) 2^{-|z''|} \sum_{y''\le z''} \mathcal{X}_{y''}(x) \\ &= 2^{-|z|} \sum_{y\le z} (-1)^{|y'|} \mathcal{X}_{y'\oplus y''}(x) \\ &= 2^{-|z|} \sum_{y\le z} (-1)^{|y'|} \mathcal{X}_{y'\cup y''}(x), \end{aligned} \tag{6.14}$$

where $y' \oplus y'' = y' \cup y''$ since $y' \cap y'' = \emptyset$. Note that we are working in $B_n^{(2)}$ and not in B_n^2; i.e., if $z \in B_n^{(2)}$, then summing over all $y \le z$ ($y \ge z$, respectively) means summing over all $y \in B_n^{(2)}$ such that $y \le z$ ($y \ge z$, respectively). Thus

$$\begin{aligned}(\text{Proj } f)(x) &= \sum_z \widetilde{f}(z) 2^{-|z|} \sum_{y \le z} (-1)^{|y'|} \mathcal{X}_{y' \cup y''}(x) \\ &= \sum_{w \in B_n} \mathcal{X}_w(x) \sum_{a \le w} (-1)^{|a|} \sum_{z \ge (a, w \setminus a)} 2^{-|z|} \widetilde{f}(z).\end{aligned}$$

That is, the desired analogue of the change of basis formula (6.4) on $B_n^{(2)}$ is

(6.15)
$$\widehat{(\text{Proj } f)}(w) = \sum_{a \le w} (-1)^{|a|} \sum_{z \ge (a, w \setminus a)} 2^{-|z|} \widetilde{f}(z) \qquad \text{for all } w \in B_n \text{ and } f \in L(B_n^{(2)}).$$

Finally, we define some basic notions on $B_n^{(2)}$ used in section 7.3.

- *Size.* If $x \in B_n^{(2)}$, define the *size* or *rank* of x to be $|x| \stackrel{\text{def}}{=} |x' \cup x''| = |x'| + |x''|$, and note that $0 \le |x| \le n$.
- *Consistent elements and union.* We call two elements $x, y \in B_n^{(2)}$ *consistent* if x' and y'' are disjoint and x'' and y' are disjoint. It is straightforward to verify that two elements x and y of $B_n^{(2)}$ are consistent if and only if they have an *upper bound* (i.e., an element z of $B_n^{(2)}$ such that $z \ge x$ and $z \ge y$), or equivalently, a *least upper bound* (i.e., an upper bound $\le$ all upper bounds of x and y). If $x, y \in B_n^{(2)}$ are consistent, their least upper bound, which we also call *union* and denote by $x \cup y$, is given by $x \cup y \stackrel{\text{def}}{=} (x' \cup y', x'' \cup y'') \in B_n^{(2)}$. Let $y, z \in B_n^{(2)}$. If y and z are consistent, then $\overline{AND}_y \overline{AND}_z = \overline{AND}_{y \cup z}$. If y and z are not consistent, then $\overline{AND}_y(x) \overline{AND}_z(x) = 0$ for all $x \in B_n^{(2)}$. The reason is that if $\overline{AND}_y(x) \overline{AND}_z(x) = 1$, then $y \le x$ and $z \le x$. Hence y and z have an upper bound; i.e., they are consistent.
- *Intersection and complement.* To avoid degenerate cases, we define the *intersection* $x \cap y$ and *complement* $x \setminus y$ only for consistent elements $x, y \in B_n^{(2)}$ as follows. Let $x \cap y \stackrel{\text{def}}{=} (x' \cap y', x'' \cap y'') \in B_n^{(2)}$ and $y \setminus x \stackrel{\text{def}}{=} (y' \setminus x', y'' \setminus x'') \in B_n^{(2)}$. Note that $x \cap y \le y$, $y \setminus x \le y$, and $(x \cap y) \cup (y \setminus x) = y$. Note also that if $x \le y$, then x and y are obviously consistent; hence $y \setminus x$ is defined.
- *Separated elements.* We call two elements $x, y \in B_n^{(2)}$ *separated* if x', x'', y', y'' are mutually disjoint. Separated elements are consistent. If x and y are separated, then $|y \cup x| = |y| + |x|$. If x and y are consistent, but not necessarily separated, then $y \setminus x$ and x are separated and $(y \setminus x) \cup x = y \cup x$; hence $|y \cup x| = |y \setminus x| + |x|$.

6.5. General DNF formulas and auxiliary functions. In this section we compute the Möbius and Fourier transforms of general DNF formulas and auxiliary functions.

We represent a DNF formula F on n variables by two bipartite graphs $(C, [n], N')$ and $(C, [n], N'')$ both between the set C of clauses and the set $[n]$ of variable indices. For each clause $c \in C$, $N'(c)$ is the neighborhood of c consisting of the indices of the nonnegated variables of c, and $N''(c)$ is the neighborhood of c consisting of the indices of the negated variables in c. We assume that $N'(c) \cap N''(c) = \emptyset$ for each clause $c \in C$. To avoid degenerate cases, we assume, as in the monotone case, that

we have at least one clause, i.e., $|C| \geq 1$, and that each clause contains at least one literal, i.e., $N'(c) \cup N''(c) \neq \emptyset$ for each $c \in C$. Let $N \stackrel{\text{def}}{=} (N', N'')$, i.e., $N(c) \stackrel{\text{def}}{=} (N'(c), N''(c)) \in B_n^{(2)}$ for each clause $c \in C$, and $N(S) \stackrel{\text{def}}{=} (N'(S), N''(S)) \in B_n^2$ for each set of clauses $S \subset C$. Note that $N(S)$ is not necessarily in $B_n^{(2)}$ since possibly $N'(S) \cap N''(S) \neq \emptyset$. We denote F by $F = (C, [n], N)$. Finally, if $s \geq 1$ is an integer, we call a DNF formula $F = (C, [n], N)$ an *s-DNF* formula if each clause contains at most s literals, i.e., $|N(c)| \leq s$ for each $c \in C$.

Let $F = (C, [n], N)$ be a DNF formula. We have the boolean function computed by F, which by notational abuse we denote by $F \in L(B_n)$. We also have the u-skin and cover functions $\text{cover}_F, \text{skin}_{F,u} \in L(B_n)$ associated with F (for $u \geq 0$). They are given by Definition 5.6 as $F \stackrel{\text{def}}{=} \bigvee_{c \in C} AND_{N(c)}$, $\text{skin}_{F,u} \stackrel{\text{def}}{=} 1 - (1 - e^{-u})^{\sum_{c \in C} AND_{N(c)}}$, $\text{cover}_F \stackrel{\text{def}}{=} \int_0^\infty \text{skin}_{F,u} e^{-u} du$, where $\text{skin}_{F,0} = F$ by taking the limit. By lifting each of the AND gates of the DNF from B_n to $B_n^{(2)}$, we get the following natural lifts of F as a boolean function, cover_F, and $\text{skin}_{F,u}$.

DEFINITION 6.4 (lifted DNF boolean function, skin, and cover). *Let $F = (C, [n], N)$ be a DNF formula and $u \geq 0$, and define $\overline{F}, \overline{cover}_F, \overline{skin}_{F,u} \in L(B_n^{(2)})$ as*

$$\begin{aligned}
\overline{F}(x) &\stackrel{\text{def}}{=} \bigvee_{c \in C} \overline{AND}_{N(c)}(x), \\
\overline{skin}_{F,u}(x) &\stackrel{\text{def}}{=} 1 - (1 - e^{-u})^{\sum_{c \in C} \overline{AND}_{N(c)}(x)}, \\
\overline{cover}_F(x) &\stackrel{\text{def}}{=} \int_0^\infty \overline{skin}_{F,u}(x) e^{-u} du
\end{aligned}$$

for all $x \in B_n^{(2)}$. Thus $F = Proj\ \overline{F}$, $cover_F = Proj\ \overline{cover}_F$, and $skin_{F,u} = Proj\ \overline{skin}_{F,u}$.

Those lifted functions have natural expansions in the $\{\overline{AND}_z\}_z$ basis from which we can extract their Möbius transforms. To get the Fourier transforms of the original functions, we use (6.15).

We have the following analogue of Lemmas 6.1 and 6.2.

LEMMA 6.5. *Let $F = (C, [n], N)$ be a DNF formula, and let $u \geq 0$. Then for all $z \in B_n^{(2)}$ and $w \in B_n$,*

$$\widetilde{\overline{F}}(z) = \sum_{S \neq \emptyset \subset C : N(S) = z} -(-1)^{|S|}, \tag{6.16}$$

$$\widetilde{\overline{skin}}_{F,u}(z) = \sum_{S \neq \emptyset \subset C : N(S) = z} -(-1)^{|S|} e^{-u|S|}, \tag{6.17}$$

$$\widetilde{\overline{cover}}_F(z) = \sum_{S \neq \emptyset \subset C : N(S) = z} -(-1)^{|S|} \frac{1}{|S| + 1}, \tag{6.18}$$

$$\widehat{F}(w) = \sum_{a \leq w} (-1)^{|a|} \sum_{S \neq \emptyset \subset C \,:\, N'(S) \cap N''(S) = \emptyset \;\&\; N(S) \geq (a, w \setminus a)} -(-1)^{|S|} 2^{-|N(S)|}, \tag{6.19}$$

$$\widehat{\overline{skin}}_{F,u}(w) = \sum_{a \leq w} (-1)^{|a|} \sum_{S \neq \emptyset \subset C \,:\, N'(S) \cap N''(S) = \emptyset \;\&\; N(S) \geq (a, w \setminus a)} -(-1)^{|S|} 2^{-|N(S)|} e^{-u|S|}, \tag{6.20}$$

$$\widehat{\overline{cover}}_F(w) = \sum_{a \leq w} (-1)^{|a|} \sum_{S \neq \emptyset \subset C \,:\, N'(S) \cap N''(S) = \emptyset \;\&\; N(S) \geq (a, w \setminus a)} -(-1)^{|S|} 2^{-|N(S)|} \frac{1}{|S| + 1}. \tag{6.21}$$

Proof. For $u \geq 0$, we have

$$1 - \prod_{c\in C}(1 - \overline{AND}_{N(c)}(x)e^{-u}) = \sum_{S\neq\emptyset\subset C} -(-e^{-u})^{|S|} \prod_{c\in S} \overline{AND}_{N(c)}(x)$$
$$= \sum_{S\neq\emptyset\subset C} -(-e^{-u})^{|S|} AND_{N'(S)}(x')AND_{N''(S)}(x'').$$

If $AND_{N'(S)}(x')AND_{N''(S)}(x'') = 1$, then $N'(S) \leq x'$ and $N''(S) \leq x''$, and hence $N'(S)$ and $N''(S)$ must be disjoint since x' and x'' are disjoint; i.e., we can exclude from the sum the sets S such that $N'(S) \cap N''(S) \neq \emptyset$. Thus

$$1 - \prod_{c\in C}(1 - \overline{AND}_{N(c)}(x)e^{-u}) = \sum_{S\neq\emptyset\subset C: N'(S)\cap N''(S)=\emptyset} -(-1)^{|S|}e^{-u|S|}\overline{AND}_{N(S)}(x)$$
$$= \sum_{z\in B_n^{(2)}} \left(\sum_{S\neq\emptyset\subset C: N(S)=z} -(-1)^{|S|}e^{-u|S|} \right) \overline{AND}_z(x).$$

Setting $u = 0$, we get (6.16). To establish (6.17), it is enough to note that, for $u > 0$, we have

$$1 - (1 - e^{-u})^{\sum_{c\in C}\overline{AND}_{N(c)}(x)} = 1 - \prod_{c\in C}(1 - e^{-u})^{\overline{AND}_{N(c)}(x)}$$
$$= 1 - \prod_{c\in C}(1 - \overline{AND}_{N(c)}(x)e^{-u}).$$

This verifies (6.17) for $u > 0$. The $u = 0$ case follows by taking the limit.

Applying the linear operator $\mu_{B_n^{(2)}}$ to $\overline{\text{cover}}_F = \int_0^\infty \overline{\text{skin}}_{F,u}e^{-u}du$, we get

$$\widetilde{\overline{\text{cover}}}_F(z) = \int_0^\infty \widetilde{\overline{\text{skin}}}_{F,u}(z)e^{-u}du$$
$$= \sum_{S\neq\emptyset\subset C: N(S)=z} -(-1)^{|S|} \int_0^\infty e^{-u(|S|+1)}du$$
$$= \sum_{S\neq\emptyset\subset C: N(S)=z} -(-1)^{|S|}\frac{1}{|S|+1},$$

which establishes (6.18).

The correctness of (6.19) follows from (6.16) via (6.15):

$$\widehat{F}(w) = \sum_{a\leq w}(-1)^{|a|} \sum_{z\geq(a,w\setminus a)} 2^{-|z|} \sum_{S\neq\emptyset\subset C: N(S)=z} -(-1)^{|S|}$$
$$= \sum_{a\leq w}(-1)^{|a|} \sum_{S\neq\emptyset\subset C: N'(S)\cap N''(S)=\emptyset \ \ \&N(S)\geq(a,w\setminus a)} -(-1)^{|S|}2^{-|N(S)|}.$$

Similarly, (6.20) and (6.21) follow from (6.17) and (6.18) via (6.15). □

6.6. Miscellaneous remarks. This section can be skipped without loss of continuity. In poset terminology,[5] $B_n^{(2)}$ can be alternatively defined as the order ideal of B_n^2 generated by the antichain $A_n \stackrel{\text{def}}{=} \{(x, x^c) : x \in B_n\} \subset B_n^2$.

[5] An *antichain* of a poset X is a subset A of X such that any two distinct elements of A are incomparable. A subset I of X is called an *order ideal* if $x \in I$ and $y \leq x$; then $y \in I$. We say that an order ideal is *generated by* a subset a A of X if $I = \{x \in X : x \leq y \text{ for some } y \in A\}$. Any order ideal has a generating antichain.

If X is a poset, the matrix coefficients of μ_X are denoted by $(\mu_X(y,x))_{x,y}$; i.e.,

$$(\mu_X f)(x) = \sum_{y \in X} \mu_X(y,x) f(y). \tag{6.22}$$

Since ζ_X is lower triangular, μ_X is also lower triangular; i.e., $\mu_X(y,x) = 0$ if $y \not\leq x$.

It is worth mentioning that the coefficients of the Möbius functions of the posets B_n and $B_n^{(2)}$ have the following simple expressions:

(i) $\mu_{B_n}(y,x) = (-1)^{|x \setminus y|}$ if $y \leq x \in B_n$ (see [24]).

(ii) $\mu_{B_n^{(2)}}(y,x) = (-1)^{|x \setminus y|}$ if $y \leq x \in B_n^{(2)}$. This can be derived from (i) via the fact that $B_n^{(2)}$ is an order ideal of $B_n^2 = B_n \times B_n$. (In general, if I is an order ideal of a poset X regarded as a subposet of X, then $\mu_I(y,x) = \mu_X(y,x)$ for all $x, y \in I$.)

Those expressions are not used in the proof since, instead of using (6.22) to compute the Möbius transforms of DNF formulas and their auxiliary functions, we extracted the Möbius transforms from natural expansions of the functions in the $\{AND_z\}_z$ basis.

7. From zero-energy to energies of auxiliary functions. In this section, we reduce the problem of bounding the t-zero-energy of an s-DNF formula F to that of bounding the $(t-s)$-energies of auxiliary functions derived from F.

Let $F = (C, [n], N)$ be an s-DNF formula, and let $t \geq s$ be an integer. We want to bound the t-zero-energy of F. That is, we want to construct $f \in L(B_n)$ of degree at most t such that the mean square error $E(F-f)^2$ is small and f satisfies the zeros-constraint: $f = 0$ whenever $F = 0$ (i.e., $f(x) = 0$ for each $x \in \{0,1\}^n$ such that $F(x) = 0$). For any such f, we have the bound $\text{zeroEnergy}(F;t) \leq E(F-f)^2 = \|\widehat{F-f}\|_2^2$.

We presented the construction of f in the monotone case in section 5.6 without analyzing its mean square error. In sections 7.1 and 7.2, we analyze the Fourier transform of the construction error term $\widehat{F-f}$ in the monotone case. Then we generalize to arbitrary DNF formulas in section 7.3. The analysis of $\widehat{F-f}$ naturally leads us to the cover and u-skin functions. In Lemmas 7.1 and 7.2, we express $\widehat{F-f}$ in terms of the Fourier transforms of cover functions of DNF derived from F. The analysis in sections 7.1, 7.2, and 7.3 uses the machinery developed in section 6.

In section 7.4, we apply two simple bounds to the obtained expression of $\widehat{F-f}$. The first bound reduces the problem of bounding the t-zero-energy of F to that of bounding the $(t-s)$-energies of the cover functions of the derived DNF formulas. The second bound reduces the latter problem to bounding the $(t-s)$-energies of the u-skin functions of the derived formulas, for all $u \geq 0$.

7.1. Monotone case error analysis. This section uses the monotone machinery developed in sections 6.2 and 6.3.

In this section we analyze the mean square error of the monotone construction defined in section 5.6. Assume that $F = (C, [n], N)$ is monotone and construct f as in section 5.6. That is, define $f \in L(B_n)$ as

$$f \stackrel{\text{def}}{=} \sum_{S \subset C : S \neq \emptyset} -(-1)^{|S|} E_{c \in S} AND_{N(c)} \text{Trn}_{t-|N(c)|} AND_{N(S) \setminus N(c)}. \tag{7.1}$$

We know from section 5.6 that $deg(f) \leq t$ and f satisfies the zeros-constraint.

The difficult part is estimating the mean square error $E(F-f)^2 = \|\widehat{F-f}\|_2^2$ as t grows. Toward this end, we start analyzing $\widehat{F-f}$ by first computing the Fourier transform of f, which gives some intuition as to why one would speculate that the mean square error of this construction decays as t grows. Then we interpret $\widehat{F-f}$ in Lemma 7.1 in terms of the Fourier transforms of cover functions of DNF formulas derived from F.

Recall from (6.6) that

$$\widehat{F}(y) = (-1)^{|y|} \sum_{S\neq\emptyset\subset C:N(S)\geq y} -(-1)^{|S|}2^{-|N(S)|}. \tag{7.2}$$

We show below that the Fourier transform of f is given by

$$\widehat{f}(y) = (-1)^{|y|} \sum_{S\neq\emptyset\subset C:N(S)\geq y} -(-1)^{|S|}2^{-|N(S)|} Pr_{c\in S}[|y\cup N(c)|\leq t]. \tag{7.3}$$

Proof of (7.3). Recall from (6.3) that

$$AND_z = \frac{1}{2^{|z|}}\sum_{y\leq z}(-1)^{|y|}\mathcal{X}_y.$$

Let $S\neq\emptyset\subset C$, and let $c\in S$. Then

$$AND_{N(c)} = \frac{1}{2^{|N(c)|}}\sum_{y_1\leq N(c)}(-1)^{|y_1|}\mathcal{X}_{y_1},$$

and

$$\mathrm{Trn}_{t-|N(c)|}AND_{N(S)\setminus N(c)} = \frac{1}{2^{|N(S)\setminus N(c)|}}\sum_{y_2\leq N(S)\setminus N(c):|y_2|\leq t-|N(c)|}(-1)^{|y_2|}\mathcal{X}_{y_2}.$$

Thus

$$\begin{aligned} AND_{N(c)}\mathrm{Trn}_{t-|N(c)|}AND_{N(S)\setminus N(c)} &= \frac{1}{2^{|N(S)|}}\sum_{\substack{y_1\leq N(c),\\ y_2\leq N(S)\setminus N(c):\\ |y_2|\leq t-|N(c)|}}(-1)^{|y_1|+|y_2|}\mathcal{X}_{y_1\oplus y_2} \\ &= \frac{1}{2^{|N(S)|}}\sum_{y\leq N(S):|y\cup N(c)|\leq t}(-1)^{|y|}\mathcal{X}_y, \end{aligned} \tag{7.4}$$

where we used the fact that $y_1\oplus y_2 = y_1\cup y_2$ since y_1 and y_2 are disjoint because $N(c)$ and $N(S)\setminus N(c)$ are disjoint.

Substituting (7.4) in (7.1) and writing the expectation operator in (7.1) as $E_{c\in S} = \frac{1}{|S|}\sum_{c\in S}$, we get

$$\begin{aligned} f &= \sum_{S\subset C:S\neq\emptyset} -(-1)^{|S|}\frac{1}{|S|}\sum_{c\in S}2^{-|N(S)|}\sum_{y\leq N(S):|y\cup N(c)|\leq t}(-1)^{|y|}\mathcal{X}_y \\ &= \sum_y \mathcal{X}_y(-1)^{|y|}\sum_{S\neq\emptyset\subset C:N(S)\geq y} -(-1)^{|S|}2^{-|N(S)|}\ \frac{1}{|S|}\sum_{c\in S:|y\cup N(c)|\leq t}1 \end{aligned}$$

after rearranging the summations. Noting that $\frac{1}{|S|}\sum_{c\in S:|y\cup N(c)|\le t} 1 = Pr_{c\in S}[|y \cup N(c)| \le t]$, we obtain (7.3). ∎

Comparing the expressions of $\widehat{F}$ and $\widehat{f}$ in (7.2) and (7.3), and noting that $|N(c)| \le s \le t$ for each $c \in C$ since F is an s-DNF formula, we get

$$\widehat{f}(y) = \begin{cases} \widehat{F}(y) & \text{if } |y| \le t-s, \\ 0 & \text{if } |y| > t. \end{cases}$$

This relation gives some intuition why the mean square error $\|\widehat{F-f}\|_2^2$ of this construction decays as t grows. It says that $\widehat{f}(y) = \widehat{\mathrm{Trn}_t F}(y)$ if $|y| \le t-s$ or $|y| > t$. We know from the LMN energy bound (Theorem 5.8) that $E(F-\mathrm{Trn}_t F)^2 = \|\widehat{F-\mathrm{Trn}_t F}\|_2^2$ decays quickly as t grows. Thus, we can hope that $\widehat{f}(y)$ is not too bad in the region $t-s < |y| \le t$ and accordingly speculate that the mean square error $\|\widehat{F-f}\|_2^2$ also decays as t grows.

Unfortunately, we could not turn this intuition into a bound on $\|\widehat{F-f}\|_2^2$ since the frequencies in the region $t-s < |y| \le t$ are too many to handle separately by trivial bounds. We can think of other equally intuitive constructions, which we briefly mention in section 7.2.4. The reason behind favoring this choice of f is analytical. Using analytical means, we managed to bound $\|\widehat{F-f}\|_2^2$ by interpreting the Fourier transform of the error term $f-F$ in terms of the Fourier transforms of cover functions of DNF formulas derived from F as shown in Lemma 7.1. We consider $f-F$ instead of $F-f$ for technical convenience.

LEMMA 7.1 (error interpretation). *Let $F = (C, [n], N)$ be a monotone s-DNF formula, and let $t \ge s$ be an integer. Assume that $|C| \ge 2$. Let $f \in L(B_n)$ be given by*

$$f = \sum_{S\subset C: S\neq\emptyset} -(-1)^{|S|} E_{c\in S} AND_{N(c)}\, Trn_{t-|N(c)|} AND_{N(S)\setminus N(c)}. \tag{7.5}$$

For each clause $c \in C$, define the new DNF formula $F_c = (C_c, [n], N_c)$ resulting from removing the clause c from F and adding its variables to all the other clauses; i.e., $C_c = C\setminus\{c\}$ and $N_c(d) = N(d) \cup N(c)$ for each $d \in C_c$.

Then (i) *$deg(f) \le t$;* (ii) *f satisfies the zeros-constraint $f = 0$ whenever $F = 0$; and* (iii) *for each $y \in B_n$,*

$$\widehat{(f-F)}(y) = \sum_{c\in C:|y\cup N(c)|>t} \widehat{cover}_{F_c}(y). \tag{7.6}$$

We show in section 7.4 that (7.6) immediately leads to a bound on $\|\widehat{f-F}\|_2^2$ in terms of the $(t-s)$-energies of the covers of the derived DNF formulas.

It is important to note that the following error analysis is the origin of the cover and skin functions. We highlight in section 7.2.1 how the error analysis in the proof below naturally leads to the definitions of skin and cover.

Proof of Lemma 7.1. We have (i) and (ii) from section 5.6. We need to establish (7.6). Let

$$\Delta \stackrel{\text{def}}{=} f - F.$$

Subtracting the summation (7.2) from (7.3), we get

$$\widehat{\Delta}(y) = (-1)^{|y|} \sum_{S\neq\emptyset\subset C: N(S)\ge y} (-1)^{|S|} 2^{-|N(S)|} \frac{1}{|S|} \sum_{c\in S:|y\cup N(c)|>t} 1 \tag{7.7}$$

for all $y \in B_n$.

First, for technical convenience, we note that the summation $\sum_{S\subset C:S\neq\emptyset}$ in (7.7) can be replaced by $\sum_{S\subset C:|S|>1}$. The condition $|S|>1$ is nonrestrictive since the size-1 subsets S of C do not contribute to the summation. Indeed, assume that $|S|=1$; hence $S=\{c_0\}$ for some $c_0 \in C$. Thus the expression in (7.7) is nonzero only if $N(c_0) \geq y$ and $|y \cup N(c_0)| > t$. But then we get $|N(c_0)| > t$ since $y \cup N(c_0) = N(c_0)$ because $N(c_0) \geq y$. This is not possible since $|N(c_0)| \leq s$ because F is an s-DNF and $s \leq t$ by the lemma hypothesis.

If we replace $\sum_{S\subset C:S\neq\emptyset}$ by $\sum_{S\subset C:|S|>1}$ and reverse the order of the summations in (7.7), we get

$$\begin{aligned}\widehat{\Delta}(y) &= \sum_{\substack{c\in C:\\ |y\cup N(c)|>t}} (-1)^{|y|} \sum_{\substack{S\subset C:|S|>1\\ N(S)\geq y\\ c\in S}} (-1)^{|S|} 2^{-|N(S)|} \frac{1}{|S|} \\ &= \sum_{\substack{c\in C:\\ |y\cup N(c)|>t}} (-1)^{|y|} \sum_{z\geq y} \left(\sum_{\substack{S\subset C:|S|>1\\ N(S)=z \ \&\ c\in S}} (-1)^{|S|} \frac{1}{|S|} \right) 2^{-|z|}.\end{aligned}$$

Using the change of basis formula (6.4), we obtain

$$\widehat{\Delta}(y) = \sum_{c\in C:|y\cup N(c)|>t} \widehat{X}_c(y),$$

where $X_c \in L(B_n)$ is a function given by its Möbius transform

$$\widetilde{X}_c(z) = \sum_{\substack{S\subset C:|S|>1\\ N(S)=z\\ c\in S}} (-1)^{|S|} \frac{1}{|S|}.$$

By a change of variables from S to $T = S\backslash\{c\}$, we can write this as

$$\widetilde{X}_c(z) = \sum_{\substack{T\neq\emptyset\subset C\backslash\{c\}:\\ N(T\cup\{c\})=z}} (-1)^{|T|+1} \frac{1}{|T|+1}.$$

By the definition of the formula F_c, we have $C_c = C\backslash\{c\}$ and $N_c(d) = N(d) \cup N(c)$ for each $d \in C_c$. Hence for each $T \subset C_c$, $N_c(T) = \cup_{d\in T} N_c(d) = \cup_{d\in T\cup\{c\}} N(d) = N(T \cup \{c\})$. Thus

$$\widetilde{X}_c(z) = \sum_{T\neq\emptyset\subset C_c:N_c(T)=z} -(-1)^{|T|} \frac{1}{|T|+1}. \tag{7.8}$$

Using (6.8), we identify this as the Möbius transform of the cover of F_c, i.e., $X_c = \text{cover}_{F_c}$, which proves (7.6). □

7.2. Discussion. In this section, we make some remarks related to the above construction.

7.2.1. Origin of the cover and skin functions. Equation (7.6) is the reason behind our interest in the cover and skin functions. We explain below how the analysis of $\widehat{f-F}$ led us to the cover and skin functions. As shown in the proof of Lemma 7.1, $\widehat{f-F}$ can be expressed as

$$(\widehat{f-F})(y) = \sum_{c\in C:|y\cup N(c)|>t} \widehat{X}_c(y)$$

for some function $X_c \in L(B_n)$ whose Möbius transform is given by (7.8). By expressing $\frac{1}{|T|+1}$ as $\frac{1}{|T|+1} = \int_0^\infty e^{-u|T|}e^{-u}du$ we concluded that $X_c = \int_0^\infty Y_{c,u}e^{-u}du$, for some family of functions $Y_{c,u} \in L(B_n)$ whose Möbius transforms are given by

$$\widetilde{Y}_{c,u}(z) = \sum_{T\neq\emptyset\subset C_c:N_c(T)=z} -(-1)^{|T|}e^{-u|T|}.$$

The u-skin function was identified from its Möbius transform via (6.11) with respect to F_c:

$$\sum_{z\in B_n}\left(\sum_{T\neq\emptyset\subset C_c:N_c(T)=z} -(-1)^{|T|}e^{-u|T|}\right) AND_z(x) = 1-(1-e^{-u})^{\sum_{d\in C_c} AND_{N_c(d)}(x)}.$$

That is, we first did the computations in Lemma 6.2 backward on F_c to conclude that $Y_{c,u} = \mathrm{skin}_{F_c,u}$, and hence $X_c = \mathrm{cover}_{F_c}$ by evaluating the integral $\int_0^\infty \mathrm{skin}_{F_c,u}\, e^{-u}du$.

The right way to understand (7.6) is in the Fourier domain. It does not have a simple analogue outside this domain due to the condition $|y\cup N(c)| > t$ on y in the summation.

We do not have an intuitive nonanalytical explanation of (7.6). Recall that we constructed f so that it satisfies the zeros-constraint and the low degree condition. As explained in the discussion preceding the theorem statement, the construction intuition is "hopefully $\widehat{f}(y)$ is not too bad in the region $t-s<|y|\le t$." The same intuition applies to other similar constructions of f which we failed to analyze (see below). The issue is that we could not turn this intuition into an argument. We managed instead in (7.6) to interpret the construction error term using analytical means which led us to the cover and skin functions.

7.2.2. Identifying the components of (7.6). From a big perspective, the components of (7.6) can be identified with the definition of f in (7.5) as follows. Write the expectation operator in (7.5) as $E_{c\in S} = \frac{1}{|S|}\sum_{c\in S}$. The summation on c in $E_{c\in S}$ corresponds to the summation on c in (7.6). The latter summation is subject to the condition $|y\cap N(c)| > t$ which comes from the truncation operator in (7.5). The $\frac{1}{|S|}$ term of the expectation operator $E_{c\in S}$ corresponds to the $\frac{1}{|T|+1}$ weighting factor in (7.8) via the change of variables done in the proof of Lemma 7.1 from S to $T = S\backslash\{c\}$. Note that this $\frac{1}{|T|+1}$ weighting factor is what distinguishes the cover of F_c from F_c in the Möbius and Fourier domains (see item 2 of Remark 6.3).

7.2.3. Duplicate clause issue. It is possible that there exist $c, d_1, d_2 \in C$ such that $N(d_1) \neq N(d_2)$, but $N(c)\cup N(d_1) = N(c)\cup N(d_2)$; i.e., $N_c(d_1) = N_c(d_2)$. Thus it is possible that the DNF formula F_c has duplicate clauses even if F does not. Duplicate clauses in F_c affect the function cover_{F_c}. This is the reason why we chose to represent a DNF formula by a bipartite graph and not a set of clauses, i.e., a subset of B_n (or $B_n^{(2)}$ in the general case).

7.2.4. Alternative constructions. In what follows, we briefly mention two intuitive alternative constructions of f which we failed to analyze. Instead of starting from (5.1), it is natural to try grouping terms first; i.e., express

$$F(x) = \sum_{z \in B_n} \widetilde{F}(z) AND_z(x),$$

where the Möbius transform of F is given in (6.5) by $\widetilde{F}(z) = \sum_{S \neq \emptyset \subset C : N(S) = z} -(-1)^{|S|}$. Starting from this expression, we can define

$$f' = \sum_z \widetilde{F}(z) E_{c \in N^{-1}(z)} AND_{N(c)} \mathrm{Trn}_{t-|N(c)|} AND_{z \setminus N(c)},$$

where $N^{-1}(z) = \{c \in C : c \leq z\}$. Here again the degree of f' is at most t, f' satisfies the zeros-constraint, and the same intuition behind the above construction of f applies to f'. We can also express $\widehat{(f' - F)}(y)$ similarly to (7.6) as a sum over $c \in C$ of the Fourier coefficients of some functions. The issue, however, is that, unlike the covers of the derived formulas, those functions are hard to analyze and they have no clear interpretation.

The second construction is the following. Rather than averaging over all the $c \in S$, we could have fixed an arbitrary map $\alpha : 2^C \to C$ which attaches to each $S \subset C$ a fixed element $c_S \stackrel{\text{def}}{=} \alpha(S) \in S$ (e.g., the smallest clause in S). Then we can define

$$f_\alpha = \sum_{S \subset C : S \neq \emptyset} -(-1)^{|S|} AND_{N(c_S)} \mathrm{Trn}_{t-|N(c_S)|} AND_{N(S) \setminus N(c_S)}.$$

Here again, the degree of f_α is at most t, f_α satisfies the zeros-constraint, and the same intuition behind the above construction of f applies to f_α. The issue is again in the difficulty of interpreting and analyzing the functions in the resulting analogue of (7.6). We can view f, however, as the average of f_α over all the maps α, i.e., $f = E_\alpha f_\alpha$.

7.3. General case construction. This section uses the general machinery in sections 6.4 and 6.5.

If F is not necessarily monotone, the monotone case construction generalizes naturally as follows. Following the derivations in the proof of Lemma 6.5 (for $u = 0$), expand F as

$$\begin{aligned}
F(x) &= 1 - \prod_{c \in C} (1 - AND_{N(c)}(x)) \\
&= \sum_{S \neq \emptyset \subset C} -(-1)^{|S|} \prod_{c \in S} AND_{N(c)}(x) \\
&= \sum_{S \neq \emptyset \subset C} -(-1)^{|S|} AND_{N'(S)}(x') AND_{N''(S)}(x'') \\
&= \sum_{S \neq \emptyset \subset C : N'(S) \cap N''(S) = \emptyset} -(-1)^{|S|} AND_{N'(S)}(x') AND_{N''(S)}(x'') \\
&= \sum_{S \neq \emptyset \subset C : N'(S) \cap N''(S) = \emptyset} -(-1)^{|S|} AND_{N(S)}(x).
\end{aligned}$$

Let $S \subset C$ such that $S \neq \emptyset$ and $N'(S) \cap N''(S) = \emptyset$; i.e., $N(S) \in B_n^{(2)} \backslash \{(\emptyset, \emptyset)\}$. For each $c \in S$, we have

$$AND_{N(S)} = AND_{N(c)} AND_{N(S)\backslash N(c)}.$$

Recall from section 6.4 that we defined $y \backslash x \in B_n^{(2)}$ for consistent elements $x, y \in B_n^{(2)}$, and note that $N(c)$ and $N(S)$ are consistent since $N(c) \leq N(S)$. Averaging over all $c \in S$, we trivially get

$$AND_{N(S)} = E_{c \in S} AND_{N(c)} AND_{N(S)\backslash N(c)};$$

hence

$$F = \sum_{S \neq \emptyset \subset C : N'(S) \cap N''(S) = \emptyset} -(-1)^{|S|} E_{c \in S} AND_{N(c)} AND_{N(S)\backslash N(c)}.$$

We construct f as in the monotone case by truncating each $AND_{N(S)\backslash N(c)}$ to $\mathrm{Trn}_{t-|N(c)|} AND_{N(S)\backslash N(c)}$.

LEMMA 7.2 (error interpretation). *Let $F = (C, [n], N)$ be an s-DNF formula, and let $t \geq s$ be an integer. Let $f \in L(B_n)$ be given by*

$$f = \sum_{S \subset C : S \neq \emptyset \ \& N'(S) \cap N''(S) = \emptyset} -(-1)^{|S|} E_{c \in S} AND_{N(c)} \, Trn_{t-|N(c)|} AND_{N(S)\backslash N(c)}.$$

If $c \in C$, let C_c be the set of clauses other than c which are consistent with c, i.e., $C_c = \{d \in C \backslash \{c\} : N(d)$ and $N(c)$ are consistent$\}$. Let C_{main} be the set of clauses which are consistent with at least one clause of F other than themselves, i.e., $C_{main} = \{c \in C : C_c \neq \emptyset\}$.

For each clause $c \in C_{main}$, define the new DNF formula $F_c = (C_c, [n], N_c)$, where $N_c(d) = N(d) \cup N(c)$ for each $d \in C_c$. That is, F_c is the formula resulting from removing from F the clause c and all the clauses not consistent with c, and adding the literals of c to each of the remaining clauses.

Then (i) *$deg(f) \leq t$;* (ii) *f satisfies the zeros-constraint $f = 0$ whenever $F = 0$; and* (iii) *for each $w \in B_n$*

$$\widehat{(f - F)}(w) = \sum_{c \in C_{main} : |w \cup N'(c) \cup N''(c)| > t} \widehat{cover}_{F_c}(w). \tag{7.9}$$

Proof. We have $deg(f) \leq t$ since the degree of each $\mathrm{Trn}_{t-|N(c)|} AND_{N(S)\backslash N(c)}$ is at most $t - |N(c)|$ and the degree of $AND_{N(c)}$ is $|N(c)|$. Moreover, if $F(x) = 0$, then $AND_{N(c)}(x) = 0$ for each $c \in C$; thus $f(x) = 0$, and hence (ii). We have to establish (7.9). Let

$$\Delta \stackrel{\mathrm{def}}{=} f - F.$$

We have

$$\begin{aligned} \Delta &= \sum_{S \neq \emptyset \subset C : N'(S) \cap N''(S) = \emptyset} (-1)^{|S|} E_{c \in S} AND_{N(c)} (1 - \mathrm{Trn}_{t-|N(c)|}) AND_{N(S)\backslash N(c)} \\ &= \sum_{S \subset C : |S| > 1 \ \& \ N'(S) \cap N''(S) = \emptyset} (-1)^{|S|} E_{c \in S} AND_{N(c)} (1 - \mathrm{Trn}_{t-|N(c)|}) AND_{N(S)\backslash N(c)}. \end{aligned} \tag{7.10}$$

As in the monotone case, we impose the nonrestrictive condition $|S| > 1$ for technical convenience. This is nonrestrictive since if $|S| = 1$, then $S = \{c_0\}$ for some $c_0 \in C$; hence $AND_{N(S)\backslash N(c_0)} = 1$. Therefore $(1 - \mathrm{Trn}_{t-|N(c_0)|})AND_{N(S)\backslash N(c_0)} = 0$ since $t - |N(c_0)| \geq 0$ because $|N(c_0)| \leq s$ as F is an s-DNF and $t \geq s$ by the lemma hypothesis.

Recall from (6.14) that

$$AND_z = \sum_{y \leq z} (-1)^{|y'|} \mathcal{X}_{y' \cup y''},$$

and recall also that we are working in $B_n^{(2)}$ and not in B_n^2; i.e., if $z \in B_n^{(2)}$, then summing over all $y \leq z$ ($y \geq z$, respectively) means summing over all $y \in B_n^{(2)}$ such that $y \leq z$ ($y \geq z$, respectively).

Let $S \neq \emptyset \subset C$ such that $N'(S) \cap N''(S) = \emptyset$, i.e., such that $N(S) \in B_n^{(2)}$, and let $c \in S$. Then

$$AND_{N(c)} = \frac{1}{2^{|N(c)|}} \sum_{y_1 \leq N(c)} (-1)^{|y_1'|} \mathcal{X}_{y_1' \cup y_1''}$$

and

$$(1 - \mathrm{Trn}_{t-|N(c)|})AND_{N(S)\backslash N(c)} = \frac{1}{2^{|N(S)\backslash N(c)|}} \sum_{y_2 \leq N(S)\backslash N(c) : |y_2| > t - |N(c)|} (-1)^{|y_2'|} \mathcal{X}_{y_2' \cup y_2''}.$$

Thus

$$\begin{aligned} &AND_{N(c)}(1 - \mathrm{Trn}_{t-|N(c)|})AND_{N(S)\backslash N(c)} \\ &= \frac{1}{2^{|N(S)|}} \sum_{\substack{y_1 \leq N(c), \\ y_2 \leq N(S)\backslash N(c): \\ |y_2| > t - |N(c)|}} (-1)^{|y_1'| + |y_2'|} \mathcal{X}_{y_1' \cup y_1'' \oplus y_2' \cup y_2''} \\ &= \frac{1}{2^{|N(S)|}} \sum_{y \leq N(S) : |y \backslash N(c)| > t - |N(c)|} (-1)^{|y'|} \mathcal{X}_{y' \cup y''}. \end{aligned} \tag{7.11}$$

To verify (7.11), recall first from section 6.4 the definitions of basic operations in $B_n^{(2)}$. Equation (7.11) follows from the fact that $N(c)$ and $N(S)\backslash N(c)$ are separated and hence y_1 and y_2 are separated. Thus summing over $y_1 \leq N(c)$ and $y_2 \leq N(S)\backslash N(c)$ is equivalent to summing over $y = y_1 \cup y_2 \leq N(c) \cup (N(S)\backslash N(c)) = N(S)$. Since y_1 and y_2 are separated, i.e., y_1', y_1'', y_2', y_2'' are mutually disjoint, we have $y_1' \cup y_1'' \oplus y_2' \cup y_2'' = y_1' \cup y_1'' \cup y_2' \cup y_2'' = y' \cup y''$ and $|y_1'| + |y_2'| = |y_1' \cup y_2'| = |y'|$.

Now, note that

$$|y\backslash N(c)| + |N(c)| = |y \cup N(c)| = |(y \cup N(c))' \cup (y \cup N(c))''| = |y' \cup N'(c) \cup y'' \cup N''(c)|. \tag{7.12}$$

The first equality holds because, in general, if x and y are consistent, then $|y \cup x| = |y\backslash x| + |x|$ as noted at the end of section 6.4 (y and $N(c)$ are consistent as they have the upper bound $N(S)$ in $B_n^{(2)}$). The second (third, respectively) equality follows from the definition of size (union, respectively) in $B_n^{(2)}$.

Substituting (7.12) in (7.11), and then (7.11) in (7.10), we get

$$\Delta = \sum_{\substack{S\subset C:|S|>1\\ N'(S)\cap N''(S)=\emptyset}} (-1)^{|S|}\frac{1}{|S|}\sum_{c\in S}\frac{1}{2^{|N(S)|}} \sum_{\substack{y\le N(S):\\ |(y'\cup y'')\cup N'(c)\cup N''(c)|>t}} (-1)^{|y'|}\mathcal{X}_{y'\cup y''}.$$

By rearranging the summations, we extract the Fourier coefficients of Δ: $\Delta = \sum_{w\in B_n}\widehat{\Delta}(w)\mathcal{X}_w$, where

$$\begin{aligned}\widehat{\Delta}(w) &= \sum_{\substack{S\subset C:|S|>1\\ N'(S)\cap N''(S)=\emptyset}} (-1)^{|S|}\frac{1}{|S|} \sum_{\substack{c\in S:\\ |w\cup N'(c)\cup N''(c)|>t}} \frac{1}{2^{|N(S)|}} \sum_{\substack{a\le w:\\ (a,w\setminus a)\le N(S)}} (-1)^{|a|}\\ &= \sum_{\substack{c\in C:\\ |w\cup N'(c)\cup N''(c)|>t}} \sum_{a\le w}(-1)^{|a|} \sum_{\substack{S\subset C:|S|>1\\ N'(S)\cap N''(S)=\emptyset\\ N(S)\ge(a,w\setminus a)\\ c\in S}} (-1)^{|S|}2^{-|N(S)|}\frac{1}{|S|}\\ &= \sum_{\substack{c\in C:\\ |w\cup N'(c)\cup N''(c)|>t}} \sum_{a\le w}(-1)^{|a|} \sum_{z\ge(a,w\setminus a)} \left(\sum_{\substack{S\subset C:|S|>1\\ N(S)=z\ \&\ c\in S}} (-1)^{|S|}\frac{1}{|S|}\right) 2^{-|z|}.\end{aligned}$$

Using (6.15), we obtain

$$\widehat{\Delta}(w) = \sum_{\substack{c\in C:\\ |w\cup N'(c)\cup N''(c)|>t}} \widehat{\mathrm{Proj}\ X_c}(w), \tag{7.13}$$

where $X_c \in L(B_n^{(2)})$ is given by its Möbius transform

$$\begin{aligned}\widetilde{X}_c(z) &= \sum_{\substack{S\subset C:|S|>1\\ N(S)=z\ \&\ c\in S}} (-1)^{|S|}\frac{1}{|S|}\\ &= \sum_{T\ne\emptyset\subset C\setminus\{c\}:N(T\cup\{c\})=z} (-1)^{|T|+1}\frac{1}{|T|+1}\end{aligned}$$

after a change of variables from S to $T = S\setminus\{c\}$.

We will show that $X_c = \overline{\mathrm{cover}}_{F_c}$ if $c \in C_{main}$, and $X_c = 0$ if $c \in C\setminus C_{main}$.

First we handle the degenerate case when $c \in C\setminus C_{main}$. Assume $c \in C\setminus C_{main}$; thus there is no $d \ne c \in C$ such that $N(d)$ and $N(c)$ are consistent. Hence $T = \emptyset$ is the only $T \subset C\setminus\{c\}$ such that $N(T\cup\{c\}) \in B_n^{(2)}$. But $T = \emptyset$ is not allowed in the summation. It follows that $X_c = 0$.

Now, assume that $c \in C_{main}$. By the definition of the formula F_c, $C_c = \{d \in C\setminus\{c\} : N(d)$ and $N(c)$ are consistent$\} \ne \emptyset$, and $N_c(d) = N(d)\cup N(c)$ for each $d \in C_c$. Hence for each $T \subset C_c$,

$$N_c(T) = (N'_c(T), N''_c(T)) = (N'(T\cup\{c\}), N''(T\cup\{c\})) = N(T\cup\{c\}).$$

Moreover, if $T \subset C\setminus\{c\}$, but $T \not\subset C_c$, then T contains an element d of C such that $N(c)$ and $N(d)$ are not consistent. Consequently, $N'(\{c,d\}) \cap N''(\{c,d\}) \ne \emptyset$,

and hence $N'(T \cup \{c\}) \cap N''(T \cup \{c\}) \neq \emptyset$; i.e., $N(T \cup \{c\}) \notin B_n^{(2)}$. Therefore T does not contribute to the summation. It follows that

$$\widetilde{X}_c(z) = \sum_{T \neq \emptyset \subset C_c : N_c(S) = z} -(-1)^{|T|} \frac{1}{|T|+1}.$$

Using (6.18), we identify this as the Möbius transform of the lifted cover of F_c, i.e., $X_c = \overline{\text{cover}}_{F_c}$. Thus Proj $X_c = \text{cover}_{F_c}$, and hence (7.9) follows from (7.13). ∎

7.4. Bounds. The analysis in sections 7.1 and 7.3 consists of exact derivations not because we are interested in exact evaluations, but because we could not use approximations since the involved summations have exponentially many terms of alternating signs. The expression of $\widehat{f - F}$ in Lemma 7.1 (or Lemma 7.2) can be regarded as a way to hide those huge summations in the Fourier transforms of the cover functions.

In this section, we apply two simple bounds to this expression. The first bound (Theorem 7.3) reduces the problem of bounding the t-zero-energy of F to that of bounding the $(t-s)$-energies of the cover functions of DNF formulas derived from F. The second bound (Lemma 7.4) reduces the latter problem to bounding the $(t-s)$-energies of the u-skin functions of the derived formulas for all $u \geq 0$.

THEOREM 7.3 (zero-energy $\preccurlyeq$ energy of cover). *Let $F = (C, [n], N)$ be an s-DNF formula, and let $t \geq s$ be an integer.*

(a) (Monotone case) *Assume that F is monotone and $|C| \geq 2$. For each clause $c \in C$, define the new DNF formula $F_c = (C_c, [n], N_c)$ resulting from removing the clause c from F and adding its variables to all the other clauses, i.e., $C_c = C \backslash \{c\}$ and $N_c(d) = N(d) \cup N(c)$ for each $d \in C_c$. Then*

$$\textit{zeroEnergy}(F; t) \leq |C|^2 \max_{c \in C} \textit{energy}(\textit{cover}_{F_c}; t-s).$$

(b) (General case) *In general, if $c \in C$, let C_c be the set of clauses other than c which are consistent with c, i.e., $C_c = \{d \in C \backslash \{c\} : N(d)$ and $N(c)$ are consistent$\}$. Let C_{main} be the set of clauses which are consistent with at least one clause of F other than themselves, i.e., $C_{main} = \{c \in C : C_c \neq \emptyset\}$.*
For each clause $c \in C_{main}$, define the new DNF formula $F_c = (C_c, [n], N_c)$, where $N_c(d) = N(d) \cup N(c)$ for each $d \in C_c$. That is, F_c is the formula resulting from removing from F the clause c and all the clauses not consistent with c, and adding the literals of c to each of the remaining clauses. Then

$$\textit{zeroEnergy}(F; t) \leq |C_{main}|^2 \max_{c \in C_{main}} \textit{energy}(\textit{cover}_{F_c}; t-s).$$

Proof. (a) Let $f \in L(B_n)$ be as defined in the statement of Lemma 7.1. Thus

$$\text{zeroEnergy}(F; t) \leq E(F-f)^2 = \|\widehat{f - F}\|_2^2$$

and

$$(\widehat{f - F})(y) = \sum_{c \in C : |y \cup N(c)| > t} \widehat{\text{cover}}_{F_c}(y),$$

for each $y \in B_n$. To hide the dependency of the summation on y, for each $c \in C$, define $a_c \in L(B_n)$ by

$$a_c(y) = \begin{cases} \widehat{\text{cover}}_{F_c}(y) & \text{if } |y \cup N(c)| > t, \\ 0 & \text{otherwise.} \end{cases}$$

Thus $\widehat{f-F} = \sum_{c\in C} a_c$. Applying a triangular inequality, we get

$$\begin{aligned}\|\widehat{f-F}\|_2 &\le \sum_{c\in C} \|a_c\|_2 \\ &= \sum_{c\in C} \left(\sum_{y\in B_n : |y\cup N(c)|>t} \widehat{\mathrm{cover}}_{F_c}(y)^2 \right)^{1/2} \\ &\le \sum_{c\in C} \left(\sum_{y\in B_n : |y|>t-s} \widehat{\mathrm{cover}}_{F_c}(y)^2 \right)^{1/2} \\ &= \sum_{c\in C} \sqrt{\mathrm{energy}(\mathrm{cover}_{F_c}; t-s)},\end{aligned}$$

where the second inequality follows from the fact that $|y\cup N(c)| \le |y|+|N(c)| \le |y|+s$ since F is an s-DNF. If follows that

$$\begin{aligned}\mathrm{zeroEnergy}(F;t) &\le \left(\sum_{c\in C} \sqrt{\mathrm{energy}(\mathrm{cover}_{F_c}; t-s)} \right)^2 \\ &\le |C|^2 \max_{c\in C} \mathrm{energy}(\mathrm{cover}_{F_c}; t-s).\end{aligned}$$

(b) The general case follows from exactly the same argument. Just replace Lemma 7.1 with Lemma 7.2, y with w, C with C_{main}, and $N(c)$ with $N'(c)\cup N''(c)$. ∎

It is not clear how to estimate the t-energy of the cover function without resorting to the u-skin function for all $u \ge 0$.

LEMMA 7.4 (energy of cover $\preccurlyeq$ energy of skin). *Let G be a DNF formula, and let $t \ge 0$ be an integer. Then*

(a)

$$\mathit{energy}(\mathit{cover}_G; t) \le \left(\int_0^\infty \sqrt{\mathit{energy}(\mathit{skin}_{G,u}; t)} e^{-u} du \right)^2,$$

(b)

$$\mathit{energy}(\mathit{cover}_G; t) \le \sup_{u\ge 0} \mathit{energy}(\mathit{skin}_{G,u}; t).$$

Proof. Part (b) follows immediately from part (a) since $(\int_0^\infty e^{-u}du)^2 = 1$.

Part (a) follows from the fact that $\mathrm{cover}_G = \int_0^\infty \mathrm{skin}_{G,u} e^{-u} du$ via the Cauchy–Schwarz inequality as we explain next. Let $a_u = \mathrm{skin}_{G,u}$ and $b = \int_0^\infty a_u e^u du$. Thus $\widehat{b} = \int_0^\infty \widehat{a}_u e^u du$ by the linearity of the Fourier transform operator. Hence

$$\widehat{b}(y)^2 = \int_0^\infty \int_0^\infty \widehat{a}_{u_1}(y)\widehat{a}_{u_2}(y) e^{-u_1-u_2} du_1 du_2$$

for all $y \in \{0,1\}^n$. It follows from the Cauchy–Schwarz inequality that

$$\begin{aligned}\sum_{y:|y|>t} \widehat{b}(y)^2 &= \int_0^\infty \int_0^\infty \left(\sum_{y:|y|>t} \widehat{a}_{u_1}(y)\widehat{a}_{u_2}(y) \right) e^{-u_1-u_2} du_1 du_2 \\ &\le \int_0^\infty \int_0^\infty \sqrt{\sum_{y:|y|>t} \widehat{a}_{u_1}(y)^2} \sqrt{\sum_{y:|y|>t} \widehat{a}_{u_2}(y)^2}\; e^{-u_1-u_2} du_1 du_2 \\ &= \left(\int_0^\infty \sqrt{\sum_{y:|y|>t} \widehat{a}_u(y)^2} e^{-u} du \right)^2 \\ &= \left(\int_0^\infty \sqrt{\mathrm{energy}(a_u;t)} e^{-u} du \right)^2. \qquad \square\end{aligned}$$

PROBLEM 7.5. *Let $G = (C, [n], N)$ be a DNF formula, $t \ge 0$ be an integer, and $u \ge 0$. If G is monotone, it follows from* (6.10) *and* (6.9) *that*

$$\begin{aligned}\mathit{energy}(\mathit{cover}_G; t) &= \sum_{y \in B_n : |y|>t} \left(\sum_{S \subset C : N(S) \ge y} (-1)^{|S|} 2^{-|N(S)|} \frac{1}{|S|+1} \right)^2, \\ \mathit{energy}(\mathit{skin}_{G,u}; t) &= \sum_{y \in B_n : |y|>t} \left(\sum_{S \subset C : N(S) \ge y} (-1)^{|S|} 2^{-|N(S)|} e^{-u|S|} \right)^2.\end{aligned}$$

In general, it follows from (6.21) *and* (6.20) *that*

$$\begin{aligned}\mathit{energy}(\mathit{cover}_G; t) &= \sum_{w \in B_n : |w|>t} \left(\sum_{a \le w} (-1)^{|a|} \sum_{S \subset C : N'(S) \cap N''(S) = \emptyset \;\&\; N(S) \ge (a, w \setminus a)} (-1)^{|S|} 2^{-|N(S)|} \frac{1}{|S|+1} \right)^2, \\ \mathit{energy}(\mathit{skin}_{G,u}; t) &= \sum_{w \in B_n : |w|>t} \left(\sum_{a \le w} (-1)^{|a|} \sum_{S \subset C : N'(S) \cap N''(S) = \emptyset \;\&\; N(S) \ge (a, w \setminus a)} (-1)^{|S|} 2^{-|N(S)|} e^{-u|S|} \right)^2.\end{aligned}$$

Analyze and estimate those sums without using the technique of section 8. *In the monotone case the sums are expressions associated with bipartite graphs. Note also that, experimentally, it is evident that energy$(\mathit{skin}_{G,u}; t)$ exponentially decreases with u for fixed G and t.*

8. Back to DNF formulas. Let G be a DNF formula, $u \ge 0$, and $t \ge 0$ be an integer. We want to estimate the t-energy of the u-skin of G. In this section, we bound the t-energy of the u-skin of G by the t-energies of DNF formulas derived from G by adding new auxiliary variables.

To motivate the technique, assume for simplicity that G is monotone. Let $G = (C, [n], N)$. The key idea behind the reduction can be easily pointed out using the Fourier transform expression of the u-skin function derived in section 6.3.

We have

$$\mathrm{energy}(\mathrm{skin}_{G,u}; t) = \sum_{y:|y|>t} \widehat{\mathrm{skin}}_{G,u}(y)^2$$

with

$$\widehat{\mathrm{skin}}_{G,u}(y) = (-1)^{|y|} \sum_{S \neq \emptyset \subset C : N(S) \geq y} -(-1)^{|S|} 2^{-|N(S)|} e^{-u|S|}$$

by (6.9). Recall also from (6.6) that

$$\widehat{G}(y) = (-1)^{|y|} \sum_{S \neq \emptyset \subset C : N(S) \geq y} -(-1)^{|S|} 2^{-|N(S)|}.$$

We have a bound on energy$(G;t)$ from the LMN energy bound (Theorem 5.8). Since $G = \mathrm{skin}_{G,0}$, this is a bound on energy$(\mathrm{skin}_{G,u};t)$ for $u = 0$. We need a bound for all $u \geq 0$.

The key observation is the following. Consider the special case when $e^{-u} = 2^{-v}$, where v is a nonnegative integer. Then

$$\widehat{\mathrm{skin}}_{G,u}(y) = (-1)^{|y|} \sum_{S \neq \emptyset \subset C : N(S) \geq y} -(-1)^{|S|} 2^{-(|N(S)| + v|S|)}.$$

Construct from G a new monotone DNF formula G_v by adding v new auxiliary variables to each clause $c \in C$. That is, for each $c \in C$, let $\ddot{N}(c)$ be a size-v set of variable indices such that $\ddot{N}(c_1) \cap \ddot{N}(c_2) = \emptyset$ and $\ddot{N}(c_1) \cap [n] = \emptyset$ for all $c_1 \neq c_2 \in C$. Let $\ddot{I} = \cup_{c \in C} \ddot{N}(c)$. Then $G_v = (C, [n] \cup \ddot{I}, N_v)$, where $N_v(c) = N(c) \cup \ddot{N}(c)$ for each $c \in C$.

If $S \subset C$, then $N_v(S) = N(S) \cup \ddot{N}(S)$ and hence $|N_v(S)| = |N(S)| + v|S|$. Moreover, if $y \subset [n]$, then $N(S) \geq y$ if and only if $N_v(S) \geq y$ because $\ddot{I}$ and $[n]$ are disjoint. Thus

$$\widehat{\mathrm{skin}}_{G,u}(y) = (-1)^{|y|} \sum_{S \neq \emptyset \subset C : N_v(S) \geq y} -(-1)^{|S|} 2^{-|N_v(S)|} \qquad \text{for all } y \subset [n].$$

This leads us to the *key Fourier relation*

$$\widehat{\mathrm{skin}}_{G,u}(y) = \widehat{G}_v(y) \qquad \text{for all } y \subset [n], \tag{8.1}$$

which is the key point behind adding new auxiliary variables. It immediately implies that

$$\begin{aligned} \mathrm{energy}(\mathrm{skin}_{G,u};t) &= \sum_{y \subset [n] : |y| > t} \widehat{\mathrm{skin}}_{G,u}(y)^2 \\ &= \sum_{y \subset [n] : |y| > t} \widehat{G}_v(y)^2 \\ &\leq \sum_{y \subset [n] \cup \ddot{I} : |y| > t} \widehat{G}_v(y)^2 \qquad (8.2) \\ &= \mathrm{energy}(G_v;t), \end{aligned}$$

which enables us to use the LMN energy bound. The same argument works if G is not necessarily monotone. The above argument assumes that v is an integer. If v is not necessarily an integer and G is not necessarily monotone, we prove the following theorem.

THEOREM 8.1 (energy of skin $\preccurlyeq$ energy). *Let $G = (C, [n], N)$ be a DNF formula, and let $t \geq 0$ be an integer.*

If $d \in \mathbb{N}^C$, construct from G a new DNF formula G_d by adding d_c new auxiliary nonnegated variables to each clause $c \in C$. That is, for each $c \in C$, let $\ddot{N}(c)$ be a size-d_c set of variables indices such that $\ddot{N}(c_1) \cap \ddot{N}(c_2) = \emptyset$ and $\ddot{N}(c_1) \cap [n] = \emptyset$ for all $c_1 \neq c_2 \in C$. Let $\ddot{I} = \cup_{c \in C} \ddot{N}(c)$. Then $G_d = (C, [n] \cup \ddot{I}, N_d)$, where $N_d(c) = (N'(c) \cup \ddot{N}(c), N''(c))$ for each $c \in C$.

Let $u \geq 0$ and let $v \geq 0$ such that $e^{-u} = 2^{-v}$; i.e., $v = u/\ln 2$.

Then

$$\mathit{energy}(\mathit{skin}_{G,u}; t) \leq \max_{d \in \{\lfloor v \rfloor, \lceil v \rceil\}^C} \mathit{energy}(G_d; t).$$

The underlying analogue of the key Fourier relation in (8.1) is the following. If v is not necessarily an integer, let $0 \leq p \leq 1$ such that $p2^{-\lceil v \rceil} + (1-p)2^{-\lfloor v \rfloor} = 2^{-v} = e^{-u}$. We note in the proof below that $\widehat{\mathrm{skin}_{G,u}}(y) = E_D\, \widehat{G}_D(y)$, for each $y \subset [n]$, where D is a random vector chosen from $\{\lfloor v \rfloor, \lceil v \rceil\}^C$ by independently setting each of its entries to $\lceil v \rceil$ with probability p and to $\lfloor v \rfloor$ with probability $1-p$.

As noted above, the key point behind adding new auxiliary variables is (8.1), which can be easily seen by examining the summation in the expression of the Fourier transform of the u-skin function. We can directly verify (8.1) and its analogue without going into this summation, but with little insight into what is going on. We do that below to avoid the messy summations in the nonnecessarily monotone case.

Remark 8.2.

1. It is not clear how tight the bound is; i.e., it is not clear how much we are losing in (8.2).
2. Experimentally, it is evident that $\mathrm{energy}(\mathrm{skin}_{G,u}; t)$ exponentially decreases with u for fixed G and t. We conjecture that there is a bound on $\mathrm{energy}(\mathrm{skin}_{G,u}; t)$ in terms of u, the number m of clauses, and t which exponentially decreases with u.
   Note that $\mathrm{skin}_{G,u}(x)$ is a strictly decreasing function in u for fixed G and x. But this fact alone is not enough to conclude anything about the variation of its energy $\mathrm{energy}(\mathrm{skin}_{G,u}; t)$ with u for fixed G and t.
3. It is not clear whether the bound of Theorem 8.1 decays exponentially with u for fixed m and t. It is not hard to derive an exponentially decaying bound for $t = 1$. We were not able to do that for larger values of t.
4. It is worth mentioning that the u-skin of G does not simplify to a low degree polynomial under random restrictions, which excludes the possibility of directly adapting the argument in [13] to the u-skin function without going into the process of deriving the formulas G_d from G. The same holds for the cover function.

8.1. Proof of Theorem 8.1. We view G_d and $\widehat{G}_d$ as functions defined on $\{0,1\}^n \times \{0,1\}^{\ddot{I}}$. We denote the elements of $\{0,1\}^n \times \{0,1\}^{\ddot{I}}$ by $(x, \ddot{x})$ or $(y, \ddot{y})$.

Let $0 \leq p \leq 1$ such that $p2^{-\lceil v \rceil} + (1-p)2^{-\lfloor v \rfloor} = 2^{-v} = e^{-u}$. Such p exists since $2^{-\lceil v \rceil} \leq 2^{-v} \leq 2^{-\lfloor v \rfloor}$. Consider the random vector $D = (D_c)_{c \in C} \in \{\lfloor v \rfloor, \lceil v \rceil\}^C$ whose entries are chosen independently by setting each to $\lceil v \rceil$ with probability p and to $\lfloor v \rfloor$ with probability $1-p$. Thus $E_{D_c} 2^{-D_c} = 2^{-v} = e^{-u}$, for each $c \in C$, by the definition of p.

We show below that

$$\widehat{\mathrm{skin}}_{G,u}(y) = E_D \widehat{G}_D(y, 0) \tag{8.3}$$

for each $y \in \{0,1\}^n$.

Theorem 8.1 follows from (8.3) as follows. We have

$$\widehat{\text{skin}}_{G,u}(y)^2 = \left(E_D\ \widehat{G}_D(y,0)\right)^2 \le E_D\ \widehat{G}_D(y,0)^2,$$

since $0 \le E(X - EX)^2 = EX^2 - (EX)^2$ for any random variable X. Thus

$$\begin{aligned}
\text{energy}(\text{skin}_{G,u};t) &= \sum_{y\in\{0,1\}^n:|y|>t} \widehat{\text{skin}}_{G,u}(y)^2 \\
&\le E_D \sum_{y\in\{0,1\}^n:|y|>t} \widehat{G}_D(y,0)^2 \\
&\le E_D \sum_{(y,\ddot{y})\in\{0,1\}^n\times\{0,1\}^{\ddot{\imath}}:|(y,\ddot{y})|>t} \widehat{G}_D(y,\ddot{y})^2 \\
&= E_D\ \text{energy}(G_D;t) \\
&\le \max_{d\in\{\lfloor v\rfloor,\lceil v\rceil\}^C} \text{energy}(G_d;t).
\end{aligned}$$

To establish (8.3), we use an intermediate function. If $d \in \mathbb{N}^C$, define $\text{shell}_{G,d} : \{0,1\}^n \to \mathbb{R}$ as

$$\text{shell}_{G,d}(x) \stackrel{\text{def}}{=} 1 - \prod_{c\in C}(1 - 2^{-d_c} AND_{N(c)}(x)).$$

This is a nonuniform variation of the skin function where the clauses are weighted differently.

LEMMA 8.3. *If $d \in \mathbb{N}^C$, then*

$$\widehat{G_d}(y,0) = \widehat{shell}_{G,d}(y)$$

for each $y \in \{0,1\}^n$.

LEMMA 8.4. *For all $u \ge 0$,*

$$E_D\ shell_{G,D} = skin_{G,u}.$$

Thus, by the linearity of the Fourier transform operator,

$$\begin{aligned}
\widehat{\text{skin}}_{G,u}(y) &= E_x\ \text{skin}_{G,u}(x)\mathcal{X}_y(x) \\
&= E_x E_D\ \text{shell}_{G,D}(x)\mathcal{X}_y(x) \\
&= E_D E_x\ \text{shell}_{G,D}(x)\mathcal{X}_y(x) \\
&= E_D\ \widehat{\text{shell}}_{G,D}(y) \\
&= E_D\ \widehat{G}_D(y,0),
\end{aligned}$$

which verifies (8.3).

Proof of Lemma 8.3. We have

$$\widehat{G}_d(y,\ddot{y}) = E_{(x,\ddot{x})} G_d(x,\ddot{x})\mathcal{X}_{(y,\ddot{y})}(x,\ddot{x}).$$

Thus

$$\begin{aligned}
\widehat{G}_d(y,0) &= E_{(x,\ddot{x})} G_d(x,\ddot{x})\mathcal{X}_{(y,0)}(x,\ddot{x}) = E_{(x,\ddot{x})} G_d(x,\ddot{x})\mathcal{X}_y(x) \\
&= E_{x\in\{0,1\}^n}\left(E_{\ddot{x}\in\{0,1\}^{\ddot{\imath}}} G_d(x,\ddot{x})\right)\mathcal{X}_y(x). \qquad (8.4)
\end{aligned}$$

First note that if $c \in C$ and $(x, \ddot{x}) \in \{0,1\}^n \times \{0,1\}^{\ddot{I}}$, then

$$AND_{N_d(c)}(x, \ddot{x}) = AND_{N(c)}(x) AND_{\ddot{N}(c)}(\ddot{x}).$$

Thus

$$G_d(x, \ddot{x}) = \bigvee_{c \in C} AND_{N_d(c)}(x, \ddot{x}) = 1 - \prod_{c \in C} \left(1 - AND_{N(c)}(x) AND_{\ddot{N}(c)}(\ddot{x})\right).$$

Since each of the new auxiliary variables belongs to one and only one clause, by decomposing $\ddot{x} \in \{0,1\}^{\ddot{I}}$ as $\ddot{x} = (\ddot{x}_c)_{c \in C} \in \prod_{c \in C} \{0,1\}^{\ddot{N}(c)}$, we get

$$\begin{aligned} E_{\ddot{x} \in \{0,1\}^{\ddot{I}}} G_d(x, \ddot{x}) &= 1 - \prod_{c \in C} \left(1 - AND_{N(c)}(x) \left(E_{\ddot{x}_c \in \{0,1\}^{\ddot{N}(c)}} AND_{\ddot{N}(c)}(\ddot{x}_c)\right)\right) \\ &= 1 - \prod_{c \in C} \left(1 - AND_{N(c)}(x) 2^{-d_c}\right) \\ &= \text{shell}_{G,d}(x). \end{aligned}$$

Substituting in (8.4), we get

$$\widehat{G}_d(y, 0) = E_{x \in \{0,1\}^n} \text{ shell}_{G,d}(x) \mathcal{X}_y(x) = \widehat{\text{shell}}_{G,d}(y). \qquad \square$$

Proof of Lemma 8.4. Since, by construction, the entries of the random vector D are independent and the expected value of each is e^{-u}, we have

$$\begin{aligned} E_D \text{ shell}_{G,D}(x) &= 1 - E_D \prod_{c \in C} (1 - 2^{-D_c} AND_{N(c)}(x)) \\ &= 1 - \prod_{c \in C} (1 - (E_{D_c} 2^{-D_c}) AND_{N(c)}(x)) \\ &= 1 - \prod_{c \in C} (1 - e^{-u} AND_{N(c)}(x)). \end{aligned}$$

If $u = 0$, we get $E_D \text{ shell}_{G,D}(x) = 1 - \prod_{c \in C}(1 - AND_{N(c)}(x)) = G(x) = \text{skin}_{G,0}(x)$ by the definition of the extension of $\text{skin}_{G,u}$ to $u = 0$.

If $u > 0$, we have $1 - e^{-u} AND_{N(c)}(x) = (1 - e^{-u})^{AND_{N(c)}(x)}$ for all $c \in C$ and all $x \in \{0,1\}^n$ (if $AND_{N(c)}(x) = 0$, both terms are 1; if $AND_{N(c)}(x) = 1$, both terms are $1 - e^{-u}$). Thus

$$\begin{aligned} E_D \text{ shell}_{G,D}(x) &= 1 - \prod_{c \in C} (1 - e^{-u})^{AND_{N(c)}(x)} \\ &= 1 - (1 - e^{-u})^{\sum_{c \in C} AND_{N(c)}(x)} \\ &= \text{skin}_{G,u}(x). \end{aligned}$$

It follows that $E_D \text{ shell}_{G,D}(x) = \text{skin}_{G,u}(x)$ for all $u \geq 0$. $\square$

9. A sharper bound. We derived in section 5.11 an asymptotic version of Theorem 1.1 based on the LMN energy bound stated in Theorem 5.8. In this section, we drive the exact bound $16m^{2.2} 2^{-\sqrt{k}/10}$ of Theorem 1.1 using (1) another form of the LMN energy bound (Theorem 9.1 below), and (2) part (a) instead of part (b) of Lemma 7.4.

If we know that F is an s-DNF formula, we can extract from [13] the following bound which is tighter than that of Theorem 5.8 when s is not relatively large.

THEOREM 9.1 (LMN energy bound for s-DNF [13]). *Let G be an m-clause s-DNF formula and $t \geq 0$ be an integer; then energy$(G;t) \leq 2e^{-t/(10es)}$ if $t > 40es$.*

Proof. It follows from Lemmas 5 and 6 in [13] that if $f : \{0,1\}^n \to \{0,1\}$ and $pt > 8$, then

$$\text{energy}(f;t) \leq 2Pr_\rho[deg\,(f_\rho) > pt/2],$$

where ρ is a random p-restriction. Corollary 1 in [13] on Hastad's switching lemma asserts that if G is an s-DNF formula, then

$$Pr_\rho[deg\,(G_\rho) > k] < (5ps)^k,$$

where ρ is a random p-restriction. It follows that $\text{energy}(G;t) \leq 2(5ps)^{pt/2}$ if $pt > 8$. Setting $p = 1/(5es)$ to minimize $(5ps)^{pt/2}$, we get $\text{energy}(G;t) \leq 2e^{-t/(10es)}$ if $t > 40es$. □

First, we substitute the bound of Theorem 9.1 in Theorem 8.1.

COROLLARY 9.2 (energy of skin). *Let G be an m-clause s-DNF formula, $u \geq 0$, and let $t \geq 0$ be an integer. Then*

$$energy(skin_{G,u};t) \leq 2\exp\left(-\frac{t}{10e(s+\lceil u/\ln 2\rceil)}\right)$$

if $t > 40e(s + \lceil u/\ln 2\rceil)$.

Proof. It is enough to note that in the setting of Theorem 8.1, for each $d \in \{\lfloor v\rfloor, \lceil v\rceil\}^m$, G_d is by construction an $(s + \lceil v\rceil)$-DNF whose number of clauses equals that of G. □

Remark 9.3. In section 5.11, we obtained from Theorem 8.1 via Theorem 5.8 the bound $\text{energy}(\text{skin}_{G,u};t) \leq 2m2^{-\sqrt{t}/20}$. This bound does not depend on u. In the above corollary, we used Theorem 9.1 to derive a bound on $\text{energy}(\text{skin}_{G,u};t)$ which depends on u. If u is less than some value, this bound is better than $2m2^{-\sqrt{t}/20}$. However, the bound increases with u for s and t fixed, contradicting the experimental behavior of $\text{energy}(\text{skin}_{G,u};t)$. This stems from the fact that the special structure of G_d (the large number of new auxiliary variables) was not exploited when bounding $\text{energy}(G_d;t)$. Is it possible to exploit this structure to get a better bound? See also Remark 8.2 and Problem 7.5 for related open problems and improvement directions. Now we substitute the bound of Corollary 9.2 in part (a) of Lemma 7.4, which says that

$$\text{energy}(\text{cover}_G;t) \leq \left(\int_0^\infty \sqrt{\text{energy}(\text{skin}_{G,u};t)}e^{-u}du\right)^2$$

for each DNF formula G and each integer $t \geq 0$.

COROLLARY 9.4 (energy of cover). *Let G be an m-clause s-DNF formula and $t \geq 0$ be an integer. Then*

$$energy(cover_G;t) \leq 6 \times 2^{-\left(\sqrt{t/(5e\ln 2)+(s+1)^2}-(s+1)\right)}$$

if $\sqrt{t/(5e\ln 2)+(s+1)^2} - (s+1) > 4/\ln 2$.

Proof. To bound $\text{energy}(\text{cover}_G;t)$ in terms of s, we divide the integral into two parts $\int_0^{u_0}$ and $\int_{u_0}^\infty$, where $u_0 > 0$ is a parameter we optimize on. In the range

$0 < u \le u_0$, we use the bound of Corollary 9.2. For $u > u_0$, we use the trivial bound $\text{energy}(\text{skin}_{G,u}; t) \le \sum_y \widehat{\text{skin}}^2_{G,u}(y) = E[\text{skin}^2_{G,u}] \le 1$ (we can do better than that for $u > u_0$, but that will not significantly help). That is,

$$\begin{aligned}\sqrt{\text{energy}(\text{cover}_G; t)} &\le \int_0^{u_0} \sqrt{\text{energy}(\text{skin}_{G,u}; t)} e^{-u} du + \int_{u_0}^{\infty} \sqrt{\text{energy}(\text{skin}_{G,u}; t)} e^{-u} du \\ &\le \left(2 \exp\left(-\frac{t}{10e(s + \lceil u_0/\ln 2 \rceil)}\right)\right)^{1/2} \int_0^{u_0} e^{-u} du + \int_{u_0}^{\infty} e^{-u} du \\ &\le \sqrt{2} \exp\left(-\frac{t}{20e(s + u_0/\ln 2 + 1)}\right) + e^{-u_0},\end{aligned}$$

since $\int_0^{u_0} e^{-u} du \le 1$ and $\int_{u_0}^{\infty} e^{-u} du = e^{-u_0}$. This holds assuming that $t > 40e(s + \lceil u_0/\ln 2 \rceil)$, which is satisfied if $t > 40e(s + u_0/\ln 2 + 1)$. We use a suboptimal value of u_0 to simplify the bound. Set $u_0 \ge 0$ so that the two exponents are equal, i.e., $t = 20e(s + u_0/\ln 2 + 1)u_0$. Solving the quadratic equation, we get $2u_0/\ln 2 = \sqrt{t/(5e \ln 2) + (s+1)^2} - (s+1)$. Since $t = 20e(s + u_0/\ln 2 + 1)u_0$, the condition on t is equivalent to $u_0 > 2$, i.e., $2u_0/\ln 2 > 4/\ln 2$. Therefore $\text{energy}(\text{cover}_G; t) \le ((1+\sqrt{2})e^{-u_0})^2 < 6e^{-2u_0} = 6 \times 2^{-2u_0/\ln 2}$. ∎

Then we substitute the bound of Corollary 9.4 in Theorem 7.3.

COROLLARY 9.5 (zero-energy of s-DNF). *Let F be an m-clause s-DNF formula and $t \ge s$ be an integer. Then*

$$\textit{zeroEnergy}(F; t) \le 6m^2 2^{-\left(\sqrt{(t-s)/(5e \ln 2) + (2s+1)^2} - (2s+1)\right)} \tag{9.1}$$

if $m \ge 4$.

Proof. It is enough to note that, in the language of part (b) of Theorem 7.3, for each $c \in C_{main}$, F_c is a $2s$-DNF formula with at most $m-1$ clauses and at least one clause (by the definition of C_{main}). Moreover, $|C_{main}| \le |C| = m$. Theorem 7.3 implies (9.1) subject to the condition $\sqrt{(t-s)/(5e \ln 2) + (2s+1)^2} - (2s+1) > 4/\ln 2$. If this condition is not satisfied, then the upper bound in (9.1) is $\ge 6m^2 2^{-4/\ln 2} = 6m^2 e^{-4} > 1$ if $m \ge 4$. That is, under the assumption $m \ge 4$, the upper bound in (9.1) is trivial when the condition is not satisfied. ∎

Substituting the bound of Corollary 9.5 in Lemma 5.5 for $t = \lfloor \frac{k-s}{2} \rfloor$, we obtain the following corollary.

COROLLARY 9.6 (bias of s-DNF). *Let F be an m-clause s-DNF formula and $k \ge 3s$ be an integer; then*

$$\text{bias}(F; k) \le 6m^3 2^{-\left(\sqrt{(k-3s-1)/(10e \ln 2) + (2s+1)^2} - (2s+1)\right)}.$$

Proof. The condition $t = \lfloor \frac{k-s}{2} \rfloor \ge s$ is equivalent to $k \ge 3s$. To simplify the exponent, we used the bound $t = \lfloor \frac{k-s}{2} \rfloor \ge \frac{k-s}{2} - \frac{1}{2}$; hence $t - s \ge \frac{k-3s-1}{2}$. Finally, we drop the condition $m \ge 4$ since if $m < 4$, then F has at most $ms \le 3s$ variables, in which case the condition $k \ge 3s$ implies that $\text{bias}(F; k) = 0$. ∎

Finally, substituting the bound in Corollary 9.6 in Lemma 5.4 and optimizing on s, we conclude the proof of Theorem 1.1. We set below $s = \Theta(\sqrt{k})$ if $k = \Omega(\log^2 m)$.

COROLLARY 9.7 (bias of DNF). *Let F be an m-clause DNF formula and $k \ge 0$ be an integer; then*

$$\text{bias}(F; k) \le 16m^{2.2} 2^{-\sqrt{k}/10}.$$

Proof. Let $\epsilon = \mathrm{bias}(F;k)$. Substituting the bound of Corollary 9.6 in Lemma 5.4, we get that, for each integer $s \geq 1$ such that $k \geq 3s$, we have

$$\begin{aligned}\epsilon &\leq 6m^3 2^{-\left(\sqrt{(k-3s-1)/(10e\ln 2)+(2s+1)^2}-(2s+1)\right)} + m2^{-s} \\ &= m\left(2^{-\left(\sqrt{(k-3s-1)/(10e\ln 2)+(2s+1)^2}-(2s+1)-\log(6m^2)\right)} + 2^{-s}\right).\end{aligned}$$

Allowing s to take noninteger values, we obtain

$$\begin{aligned}\epsilon &\leq m\left(2^{-\left(\sqrt{(k-3\lfloor s\rfloor-1)/(10e\ln 2)+(2\lfloor s\rfloor+1)^2}-(2\lfloor s\rfloor+1)-\log(6m^2)\right)} + 2^{-\lfloor s\rfloor}\right) \\ &\leq m\left(2^{-\left(\sqrt{(k-3s-1)/(10e\ln 2)+(2s-1)^2}-(2s+1)-\log(6m^2)\right)} + 2^{-(s-1)}\right) \qquad (9.2)\end{aligned}$$

for each real number $s \geq 1$ such that $k \geq 3s$. We will equate the two exponents of (9.2) and solve for s. If s is a real number such that the two exponents are equal, i.e.,

$$\sqrt{(k-3s-1)/(10e\ln 2)+(2s-1)^2} - (2s+1) - \log(6m^2) = s-1, \qquad (9.3)$$

then $\epsilon \leq 2m2^{-(s-1)}$. Note that we ignored the conditions on s: $s \geq 1$ and $k \geq 3s$. We can do that since if $s < 1$, then $m2^{-(s-1)} > m \geq 1$, and hence the right-hand side of (9.2) is a trivial bound on ϵ since $\epsilon \leq 1$. Similarly, if $k < 3s$ and $s \geq 1$, then $m2^{-\left(\sqrt{(k-3s-1)/(10e\ln 2)+(2s-1)^2}-(2s+1)-\log(6m^2)\right)} > m \geq 1$, which again makes the right-hand side of (9.2) a trivial bound on ϵ. We verify below that

$$s = \sqrt{\frac{k}{M} + \alpha\log^2(6m^2) + \beta\log(6m) + \gamma} - a\log(6m^2) - b \qquad (9.4)$$

is a solution of (9.3), where $M \approx 94.208$, $\alpha = 0.16$, $\beta \approx 0.499$, $\gamma \approx 0.362$, $a = 2.2$, and $b \approx 0.416$. It follows that

$$\begin{aligned}\epsilon &\leq 2m2^{-(s-1)} = 2^2 m 2^{-\sqrt{k/M+\alpha\log^2(6m^2)+\beta\log(6m^2)+\gamma}+a\log(6m^2)+b} \\ &< 2^2 m 2^{-\sqrt{k/M}+a\log(6m^2)+b} = (2^{2+b}6^a)m^{1+2a}2^{-\sqrt{k/M}} \\ &< 16m^{2.2}2^{-\sqrt{k}/10}.\end{aligned}$$

To verify that (9.4) is a solution of (9.3), write (9.3) as

$$\begin{aligned}0 &= \left(3s+\log(6m^2)\right)^2 - (2s-1)^2 - \frac{k-3s-1}{10e\ln 2} \\ &= 5s^2 + \left(6\log(6m^2)+4+\frac{3}{10e\ln 2}\right)s + \log^2(6m^2) - 1 + \frac{1}{10e\ln 2} - \frac{k}{10e\ln 2} \\ &= 5\left(s^2 + 2(a\log(6m^2)+b)s + c\log^2(6m^2) - d - \frac{k}{M}\right),\end{aligned}$$

where $a = 0.6$, $b = 0.4 + \frac{3}{100e\ln 2} \approx 0.416$, $c = 0.2$, $d = 0.2 - \frac{1}{50e\ln 2} \approx 0.189$, and $M = 50e\ln 2 \approx 94.208$. The larger solution is

$$\begin{aligned}s &= \sqrt{\frac{k}{M} + (a\log(6m^2)+b)^2 - c\log^2(6m^2) + d} - a\log(6m^2) - b \\ &= \sqrt{\frac{k}{M} + \alpha\log^2(6m^2) + \beta\log(6m^2) + \gamma} - a\log(6m^2) - b,\end{aligned}$$

where $\alpha = a^2 - c = 0.16$, $\beta = 2ab \approx 0.499$, and $\gamma = b^2 + d \approx 0.362$. ∎

10. Optimal solution. The proof of Theorem 1.1 does not depend on this section since the former is based on the suboptimal solution constructed in section 7.

Let $F = (C, [n], N)$ be a DNF formula, and let $t \geq 0$. Recall that zeroEnergy$(F; t)$ is the minimum value of $E(F-f)^2$ over the choice of $f \in L(B_n)$ such that $deg(f) \leq t$, and f satisfies the *F-zeros-constraint* $f(x) = 0$ for each $x \in B_n$ such that $F(x) = 0$.

In this section, we derive a compact form of the optimal solution of the least square problem underlying the definition of zeroEnergy$(F; t)$. For simplicity, we restrict our attention to the case when F is a monotone DNF formula. The optimal solution can be characterized in terms of the zeta function of the dual order ideal P_F of B_n consisting of satisfying assignments of F. Unable to estimate the optimal solution, we leave the problem open.

Recall first the posets terminology in section 6.1. We need the following additional elementary poset notions. An *antichain* of a poset X is a subset A of X such that any two distinct elements of A are incomparable. A subset I of X is called a *dual order ideal* if $x \in I$ and $y \geq x$; then $y \in I$. We say that a dual order ideal is *generated by* a subset A of X if $I = \{x \in X : x \geq y \text{ for some } y \in A\}$. Any dual order ideal has a generating antichain.

Let $F = (C, [n], N)$ be a monotone DNF. We can associate with F the subposet P_F of B_n consisting of the satisfying assignments of F, i.e., $P_F = \{x \in B_n : F(x) = 1\}$. Let A_F be the set of clauses of F regarded as subsets of $[n]$, i.e., $A_F = \{N(c) : c \in C\} \subset B_n$. Equivalently, P_F is the dual order ideal of B_n generated by A_F. We call a dual order ideal of B_n *nontrivial* if it is not the empty ideal or B_n itself. Recall that we assumed in the definition of a DNF formula that it contains at least one clause and no empty clauses to avoid degenerate cases. Thus P_F is a nontrivial dual order ideal of B_n. Conversely, to each nontrivial dual order ideal P of B_n and to each set of generator A of P, we can associate a monotone DNF formula F such that $A_F = A$ and $P_F = P$. The formula F is unique up to duplicate clauses. Note also that A_F is an antichain if and only if no clause of F can be removed without changing the boolean function computed by F.

A key remark is the following.

LEMMA 10.1. *Let F be a monotone DNF formula on n variables. If $f \in L(B_n)$, then f satisfies the F-zeros-constraint if and only if f is a linear combination of $\{AND_z\}_{z \in P_F}$.*

Proof. Let $Z_F = B_n \backslash P_F = \{x \in B_n : F(x) = 0\}$. Thus the F-zeros-constraint on f is $f|_{Z_F} = 0$. The if part follows from the fact that, by the definitions of Z_F and P_F, $AND_z|_{Z_F} = 0$ for all $z \in P_F$. One way to demonstrate the only if part is to note that, since $\{AND_z\}_{z \in B_n}$ are linearly independent, dim $span\{AND_z\}_{z \in P_F} = |P_F| = \dim\{f \in L(P_F) : f|_{Z_F} = 0\}$. ∎

We cast the zero-energy problem in the language of zeta functions of dual order ideals.

DEFINITION 10.2. *Say that P is a nontrivial dual order of ideal of B_n, and let $t \geq 0$ be an integer. Let $P_t = \{z \in P : |z| \leq t\}$, and define the projection map $\pi_t : L(P) \to L(P_t)$, $f \mapsto f|_{P_t}$, and its transpose $\pi_t^T : L(P_t) \to L(P)$, the extension by zeros map. Consider the zeta function ζ_P of P as a linear transformation $L(P) \to L(P)$, and consider the linear transformation $\zeta_P \pi_t^T : L(P_t) \to L(P)$. Define*

$$\Delta_t(P) \stackrel{\text{def}}{=} \min_{g \in L(P_t)} \|1_P - \zeta_P \pi_t^T g\|_2^2,$$

where $1_P \in L(P)$ is the all ones function and $\|.\|_2$ is the L_2-norm on $L(P)$. Note that if $P_t = \emptyset$, by convention, $L(P_t)$ consists of the zero function.

That is, $\Delta_t(P)$ is the least square L_2-approximation error resulting from approximating the all ones function on P by $\zeta_P \pi_t^T g$ over the choice of $g \in L(P_t)$.

LEMMA 10.3. *Let F be a monotone DNF formula on n variables, and let $t \geq 0$ be an integer; then $2^n zeroEnergy(F;t) = \Delta_t(P_F)$.*

Proof. Let $P = P_F$, $Z = B_n \backslash P = \{x \in B_n : F(x) = 0\}$, and $V_t = \{f \in L(B_n) : f|_Z = 0 \text{ and } deg(f) \leq t\}$. Thus

$$2^n \text{zeroEnergy}(F;t) = \min_{f \in V_t} 2^n E(F-f)^2 = \min_{f \in V_t} \|1_P - f|_P\|_2^2,$$

since $F|_Z = f|_Z = 0$ and $F|_P = 1_P$. The lemma then follows from the key remark in Lemma 10.1, which says that if $f \in L(B_n)$, then $f|_Z = 0$ if and only if there exists $g \in L(P)$ such that $f = \sum_{z \in P} g(z) AND_z$. Note that (1) $deg(f) \leq t$ if and only if $g \in \pi_t^T L(P_t)$, and (2) $f = \sum_{z \in P} g(z) AND_z$ can be expressed as $f = \pi_P^T \zeta_P g$, where $\pi_P^T : L(P) \to L(B_n)$ is the extension by zeros map (the transpose of the projection map $\pi_P : L(B_n) \to L(P)$, $f \mapsto f|_P$). □

LEMMA 10.4. *Let P be a nontrivial dual order of ideal of B_n, and let $t \geq 0$ be an integer such that $P_t \neq \emptyset$. Let $v = \pi_t \zeta_P^T 1_P$, and let $M = \pi_t \zeta_P^T \zeta_P \pi_t^T$; i.e., M is the P_t-truncation of the matrix $\zeta_P^T \zeta_P$. Then M is invertible and*

$$\Delta_t(P) = |P| - v^T M^{-1} v. \tag{10.1}$$

Moreover,

$$v = 2^n (2^{-|x|})_{x \in P_t}, \tag{10.2}$$

$$M = 2^n (2^{-|x \cup y|})_{x,y \in P_t}. \tag{10.3}$$

We can also express $\Delta_t(P)$ as follows. Let

$$M^* = \begin{bmatrix} 1 & v^T \\ v & M \end{bmatrix},$$

and let D be the value which, when added to the $(\emptyset,\emptyset)$-entry of the matrix M^*, makes it singular; then

$$\Delta_t(P) = |P| - D - 1 \tag{10.4}$$

$$= |P| + \frac{\det(M^*)}{\det(M)} - 1. \tag{10.5}$$

Proof. We have a least square problem of the form $\min_g \|b - Ag\|_2^2$, where $b = 1_P$ and $A = \zeta_P \pi_t^T$. The matrix A has full column rank since ζ_P is nonsingular. The optimal solution is $\|b - Ag^*\|_2^2 = b^T b - (A^T b)^T g^*$, where $A^T A g^* = A^T b$. Since A has full column rank, the matrix $A^T A$ is invertible. In our case, we have $b^T b = 1_P^T 1_P = |P|$, $A^T b = \pi_t \zeta_P^T 1_p = v$, and $A^T A = \pi_t \zeta_P^T \zeta_P \pi_t^T = M$. This proves (10.1).

To verify (10.2), let $x \in P$. We have $(\zeta_P^T 1_P)(x) = \sum_{y \in P : x \leq y} 1 = \sum_{y \in B_n : x \leq y} 1$ since $x \in P$ and P is a dual order ideal of B_n. Thus $(\zeta_P^T 1_P)(x) = 2^{|[n] \backslash x|} = 2^n 2^{-|x|}$. Then (10.2) follows from restricting x to P_t. To verify (10.3), let $f \in L(P)$ and $x \in P$. We have

$$(\zeta_P^T \zeta_P f)(x) = \sum_{z \in P : z \geq x} \sum_{y \in P : y \leq z} f(y) = \sum_{y \in P} f(y) \sum_{z \in P : z \geq x,y} 1.$$

Since $x \in P$ and P is a dual order ideal, we have

$$\sum_{z \in P : z \geq x,y} 1 = \sum_{z \in B_n : z \geq x,y} 1 = \sum_{z \in B_n : z \geq x \cup y} 1 = 2^{|[n] \setminus (x \cup y)|} = 2^n 2^{-|x \cup y|}.$$

Hence $(\zeta_P^T \zeta_P f)(x) = 2^n \sum_{y \in P} f(y) 2^{-|x \cup y|}$. Then (10.3) follows by restricting f to $L(P_t)$ and x to P_t.

To verify (10.4), write (10.1) as $\Delta_t(P) = |P| - v^T g^*$, where $Mg^* = v$. In matrix form, we can express this system as

$$\begin{bmatrix} 1+D & v^T \\ v & M \end{bmatrix} \begin{bmatrix} 1 \\ -g^* \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix},$$

where $D = |P| - 1 - \Delta_t(P)$. Then (10.4) follows from the fact that the $\emptyset$-entry of any vector in the null space of the perturbation of M^* by D must be nonzero since M is nonsingular.

Finally, (10.5) follows from (10.4). In general if M is a $p \times p$ matrix, $M^* = \left[\begin{smallmatrix} a & * \\ * & M \end{smallmatrix}\right]$ is a $(p+1) \times (p+1)$ augmentation of M, and $M^{*\prime} = \left[\begin{smallmatrix} a+D & * \\ * & M \end{smallmatrix}\right]$ is a perturbation of $M^{*\prime}$, then $\det(M^{*\prime}) = \det(M^*) + D \det(M)$. Thus when $M^{*\prime}$ is singular and M is nonsingular, we get $D = -\det(M^*)/\det(M)$. ∎

PROBLEM 10.5. *Let P be a nontrivial dual order ideal of B_n, generated by m elements of B_n, and let $t \geq 0$. Study and bound $\Delta_t(P)$ in terms of m and t starting from the characterization in Lemma* 10.4.

We leave this problem open. We can conclude the following bounds from Lemma 10.3 and Corollary 9.5.

COROLLARY 10.6. *Let P be a nontrivial dual order of ideal of B_n generated by m elements of B_n each of size at most s, and let $t \geq s$ be an integer. Then we have the following bound:*

$$2^{-n} \Delta_t(P) \leq 6m^2 2^{-\left(\sqrt{(t-s)/(5e \ln 2) + (2s+1)^2} - (2s+1)\right)}$$

if $m \geq 4$.

11. Concluding remarks. After the results of this paper were described in a preliminary form [6], Razborov [23] obtained a simpler construction of a function satisfying the zeros-constraint leading to a simpler proof of an asymptotic version of our main result in Theorem 1.1. The construction of Razborov is randomized and simplifies the second step of the proof, which reduces the s-DNF constrained L_2-approximation problem to the s-DNF L_2-approximation problem.

We conclude with some problems.

The bound in Theorem 1.1 probably can be improved by studying the problems in Remarks 8.2 and 9.3 and Problems 7.5 and 10.5.

Is it possible to somehow generalize the argument of Theorem 1.1 from depth-2 circuits to AC_0 circuits, i.e., to show that $\log^{O(d)} n$-wise independence $o(1)$-fools polynomial-size depth-d circuits? A different approach toward proving this is the low degree polynomial predictor approach in [5] (see section 5.7).

One of the basic questions motivating the work reported in this paper is the quadratic residue PRG introduced in [2]. Let p be an odd prime, and denote by $\mathbb{F}_p$ the finite field of size p. Fix a subset[6] $I \subset \mathbb{F}_p$ of size $n \geq 1$. The *quadratic residue*

[6] In [2], $I = \{0, 1, \ldots, n-1\}$, but the authors' analysis does not use this restriction.

PRG (QR-PRG) is given by $G_p^I : \mathbb{F}_p \to \{0,1\}^I$, where for each $t \in I$, $G_p^I(a)_t = 1$ if $a + t$ is a quadratic residue and 0 otherwise.

The irregularity of the quadratic residue distribution promises great derandomization capabilities and has intrigued mathematicians long before complexity theory existed. The following conjecture was the motivation behind the work reported in this paper.

CONJECTURE 11.1. *For all positive integers m, n and every $\epsilon > 0$, there is an integer $p_0 = poly(m, n, \frac{1}{\epsilon})$ such that if $p \geq p_0$ is a prime and $I \subset \mathbb{F}_p$ is of size n, then the QR-PRG G_p^I ϵ-fools any boolean function computable by an m-clause DNF (or CNF) formula on n variables.*

The QR-PRG was introduced in [2] as a $\frac{n}{\sqrt{p}}$-biased probability distribution. This follows from Weil's theorem on the analogue of the Riemann hypothesis for curves over finite fields. Using the $\frac{n}{\sqrt{p}}$-bias property of the QR-PRG, we obtain from Corollary 2.3 the following quasi-polynomial version.

COROLLARY 11.2. *For all positive integers m, n and every $\epsilon > 0$, there is an integer $p_0 = 2^{O(\log^2 \frac{m}{\epsilon} \log n)}$ such that if $p \geq p_0$ is a prime and $I \subset \mathbb{F}_p$ is of size n, then the QR-PRG G_p^I ϵ-fools any boolean function computable by an m-clause DNF (or CNF) formula on n variables.*

The conjecture would imply the first (unconditional) polynomial complexity PRG for depth-2 circuits. Note that there is no reason not to believe that the derandomization capabilities of the QR-PRG are far beyond the small bias property. Conjecture 11.1 is a natural starting point. At the other extreme, can one construct an infinite family of (unrestricted) circuits $\{C_n\}_n$, where C_n is a polynomial-size circuit on n variables, such that the prime cannot be made polynomially large enough in n and $\frac{1}{\epsilon}$ in order for the QR-PRG to ϵ-fool C_n?

Appendix A. LP duality calculations. In this appendix we show the LP duality calculations needed to characterize the class of functions that are fooled by the (δ, k)-bias property. The characterization is in Theorem A.1 below and is in terms of L_1-approximability by sandwiching polynomials of degree at most k and small L_1-norm in the Fourier domain.

Recall that we stated in Theorem 4.2 the special case of Theorem A.1 corresponding to the k-wise independence property, i.e., when $\delta = 0$.

Let μ be a probability distribution on $\{0,1\}^n$, $k \geq 0$ be an integer, and $\delta \geq 0$. By definition μ has *the (δ, k)-bias property* if μ δ-fools all parity functions on k or fewer of the n binary variables. In terms of the characters $\{\mathcal{X}_y\}_y$, this is equivalent to saying that $|E_\mu \mathcal{X}_y| \leq 2\delta$ for each nonzero y in $\{0,1\}^n$ whose weight is less than or equal to k.

THEOREM A.1. *Let $g : \{0,1\}^n \to \{0,1\}$, $k \geq 0$ be an integer, and $\delta, \epsilon \geq 0$. Then the (δ, k)-bias property ϵ-fools g if and only if there exist $g_l, g_u : \{0,1\}^n \to \mathbb{R}$ such that*

(i) *$deg(g_l) \leq k$ and $deg(g_u) \leq k$,*
(ii) *$g_l \leq g \leq g_u$,*
(iii) *$2\delta \sum_{y \neq 0} |\widehat{g_l}(y)| + E(g - g_l) \leq \epsilon$ and $2\delta \sum_{y \neq 0} |\widehat{g_u}(y)| + E(g_u - g) \leq \epsilon$, where the expectation is over the uniform probability distribution.*

Therefore, asymptotically and for $\delta > 0$, the (δ, k)-bias property $o(\epsilon)$-fools a boolean function $g : \{0,1\}^n \to \{0,1\}$ if and only if there exist $g_l, g_u : \{0,1\}^n \to \mathbb{R}$ such that

- (low degree) *$deg(g_l) \leq k$ and $deg(g_u) \leq k$,*
- (sandwiching polynomials) *$g_l \leq g \leq g_u$,*
- (small L_1-norm in the Fourier domain) *$\|\widehat{g_l}\|_1 = o\left(\frac{\epsilon}{\delta}\right)$ and $\|\widehat{g_u}\|_1 = o\left(\frac{\epsilon}{\delta}\right)$,*
- (small L_1-approximation error) *$E(g_u - g_l) = o(\epsilon)$.*

Proof. The proof is by LP duality. Let $M_k \subset \mathbb{R}^{\{0,1\}^n}$ be the convex polytope of (δ, k)-biased probability distributions μ on $\{0,1\}^n$.

If μ is a probability distribution μ on $\{0,1\}^n$, then by definition μ is (δ, k)-biased if $|E_\mu \mathcal{X}_y| \leq 2\delta$ for each nonzero y in $\{0,1\}^n$ whose weight is less than or equal to k.

Thus M_k consists of all $\mu : \{0,1\}^n \to \mathbb{R}$ such that $\mu \geq 0$, $\sum_x \mu(x) = 1$, and $-2\delta \leq \sum_x \mu(x)\mathcal{X}_y(x) \leq 2\delta$ for each $y \in N_k^*$, where $N_k^* = \{y \in \{0,1\}^n : y \neq 0 \text{ and } |y| \leq k\}$.

Fix $g : \{0,1\}^n \to \{0,1\}$, and note that if μ is a probability distribution on $\{0,1\}^n$, then $Pr_{x\sim\mu}[g(x) = 1] = E_\mu g$ since g takes binary values.

We have two feasible linear programs:

$$P_u = \max_{\mu \in M_k} E_\mu g - Eg \quad \text{and} \quad P_l = \max_{\mu \in M_k} Eg - E_\mu g.$$

It is enough to show that the dual linear programs are as follows:

(I) $P_u = \min_{g_u} E(g_u - g) + 2\delta \sum_{y\neq 0} |\widehat{g}_u(y)|$, where we are minimizing over all $g_u : \{0,1\}^n \to \mathbb{R}$ such that $deg(g_u) \leq k$ and $g_u(x) \geq g(x)$ for all $x \in \{0,1\}^n$.

(II) $P_l = \min_{g_l} E(g - g_l) + 2\delta \sum_{y\neq 0} |\widehat{g}_l(y)|$, where we are minimizing over all $g_l : \{0,1\}^n \to \mathbb{R}$ such that $deg(g_l) \leq k$ and $g_l(x) \leq g(x)$ for all $x \in \{0,1\}^n$.

Actually, we have to establish only (I) since (II) follows from (I) by replacing g with $1 - g$ and performing a change of variable from g_u to $1 - g_u$.

Explicitly, $P_u = \max_\mu \sum_x \mu(x)g(x) - Eg$, where $\mu : \{0,1\}^n \to \mathbb{R}$ is subject to the constraints

$$\begin{aligned} \sum_x \mu(x) &= 1, \\ \sum_x \mu(x)\mathcal{X}_y(x) &\leq 2\delta \text{ for all } y \in N_k^*, \\ -\sum_x \mu(x)\mathcal{X}_y(x) &\leq 2\delta \text{ for all } y \in N_k^*, \\ \mu(x) &\geq 0 \text{ for all } x \in \{0,1\}^n. \end{aligned}$$

Its dual is thus $P_u = \min \alpha_0 + 2\delta \sum_{y\in N_k^*}(\alpha'_y + \alpha''_y) - Eg$, where α_0, $\{\alpha'_y\}_{y\in N_k^*}$ and $\{\alpha''_y\}_{y\in N_k^*}$ are real coefficients subject to the constraints

$$\begin{aligned} \alpha_0 + \sum_{y\in N_k^*} (\alpha'_y - \alpha''_y)\mathcal{X}_y(x) &\geq g(x) \text{ for all } x \in \{0,1\}^n, \\ \alpha'_y, \alpha''_y &\geq 0 \text{ for all } y \in N_k^*. \end{aligned}$$

In general, if a is real number, then $\min\{a' + a'' : a', a'' \geq 0 \text{ such that } a' - a'' = a\} = |a|$. Applying this to $a' = \alpha'_y$, $a'' = \alpha''_y$, and $a = \alpha_y = \alpha'_y - \alpha''_y$, we get $P_u = \min \alpha_0 + 2\delta \sum_{y\in N_k^*} |\alpha_y| - Eg$, where α_0 and $\{\alpha_y\}_y$ are real coefficients subject to the constraints

$$\alpha_0 + \textstyle\sum_{y\in N_k^*} \alpha_y \mathcal{X}_y(x) \geq g(x) \quad \text{for all } x \in \{0,1\}^n.$$

Let $g_u = \alpha_0 + \sum_{y\in N_k^*} \alpha_y \mathcal{X}_y$. Noting that $\alpha_0 = Eg_u$ and $\alpha_y = \widehat{g}_u(y)$ for all $y \in N_k^*$, we get $P_u = \min E(g_u - g) + 2\delta \sum_{y\neq 0} |\widehat{g}_u(y)|$, where we are minimizing over all $g_u : \{0,1\}^n \to \mathbb{R}$ such that $deg(g_u) \leq k$ and $g_u(x) \geq g(x)$ for all $x \in \{0,1\}^n$. ∎

Appendix B. What will not work. To justify the move from L_1 to L_2 in section 5.5, it is appropriate to briefly mention two natural L_1-approaches which fall short of bounding the k-bias of s-DNF formulas.

Inclusion-exclusion. It is natural to try to construct the sandwiching polynomials of an s-DNF formula by inclusion-exclusion as explained in [5] (see section 5.5). This approach can be used to resolve the case of read-once DNF formulas (i.e., distinct clauses do not share variables), but we were unable to push it beyond the read-once case.

Lift and reduce to a linear program. Let F be an s-DNF formula on n variables, and let $A_1, \ldots, A_m$ be the clauses of F. Let μ be a k-wise independent probability distribution on $\{0,1\}^n$ such that $k > s$. Let μ_{unif} be the uniform probability distribution on $\{0,1\}^n$. Consider the map $L : \{0,1\}^n \to \{0,1\}^m$, $x \mapsto (A_c(x))_{c=1}^m$. Let μ^* (μ^*_{unif}, respectively) be the probability distribution induced via L on $\{0,1\}^m$ by μ (μ_{unif}, respectively). Thus $Pr_{\mu}[F(x) = 0] = \mu^*(0)$, $Pr_{\mu_{unif}}[F(x) = 0] = \mu^*_{unif}(0)$, and $E_{\mu^*}\mathcal{X}_y = E_{\mu^*_{unif}}\mathcal{X}_y$ for each $y \in \{0,1\}^m$ such that $|y| \leq \lfloor k/s \rfloor$.

This suggests relaxing the problem to the following linear program: $\max_{\mu_1,\mu_2} |\mu_1(0) - \mu_2(0)|$, where μ_1, μ_2 are probability distributions on $\{0,1\}^m$ such that $E_{\mu_1}\mathcal{X}_y = E_{\mu_2}\mathcal{X}_y$, for each $y \in \{0,1\}^m$ such that $|y| \leq t$, where $t = \lfloor k/s \rfloor$.

Unfortunately, that will not work. This follows from the approximate inclusion-exclusion lower bound of [14], which implies that the maximum of the above linear program cannot be made arbitrarily small unless $t = \Omega(\sqrt{m})$. One of the issues of this relaxation is that it ignores the actual values of the t-moments[7] of μ_1 and μ_2. It uses only the fact that the t-moments of μ_1 and μ_2 are equal. The values of those moments are simple and easy to derive from F, but taking them into consideration gives us an intriguing linear program, which is not clear how to bound.

Acknowledgments. The author would like to thank Sanjoy Mitter, Daniel Spielman, and Madhu Sudan for very helpful discussions on this material; Widad Machmouchi for valuable comments on the first and second drafts of the paper; and the anonymous referees for valuable comments which significantly improved the presentation of the paper.

ON THE VALUE OF COORDINATION IN NETWORK DESIGN*

SUSANNE ALBERS†

Abstract. We study network design games where n self-interested agents have to form a network by purchasing links from a given set of edges. We consider Shapley cost sharing mechanisms that split the cost of an edge in a fair manner among the agents using the edge. It is well known that the price of anarchy of these games is as high as n. Another line of research has focused on evaluating the price of stability, i.e., the cost of the best Nash equilibrium relative to the social optimum. In this paper we investigate to which extent coordination among agents can improve the quality of solutions. We resort to the concept of *strong Nash equilibria*, which were introduced by Aumann and are resilient to deviations by coalitions of agents. We analyze the price of anarchy of strong Nash equilibria and develop lower and upper bounds for unweighted and weighted games in both directed and undirected graphs. These bounds are tight or nearly tight for many scenarios. It shows that, by using coordination, the price of anarchy drops from linear to logarithmic bounds. We complement these results by also proving the first superconstant lower bound on the price of stability of standard equilibria (without coordination) in undirected graphs. More specifically, we show a lower bound of $\Omega(\log W/\log\log W)$ for weighted games, where W is the total weight of all the agents. This almost matches the known upper bound of $O(\log W)$. Our results imply that, for most settings, the worst-case performance ratios of strong coordinated equilibria are essentially always as good as the performance ratios of the best equilibria achievable without coordination. These settings include unweighted games in directed graphs as well as weighted games in both directed and undirected graphs.

1. Introduction.

Communication networks are pervasive and critical to modern society. Nonetheless, the formation and evolution of large networks is not well understood, a major reason being that these networks typically are not built by a central authority but rather by many economic agents that have selfish interests. For this reason, research on network design has focused on game-theoretic approaches over the past years; see, e.g., [2, 3, 5, 6, 7, 8, 9, 11, 16, 21, 22].

We study network design games that have recently received a lot of attention [2, 3, 6, 7, 15, 18] and are simple yet powerful enough to capture the two most important objectives of agents: connection establishment and cost minimization. Consider a directed or undirected graph G where each edge e has a nonnegative cost $c(e)$. There are n agents, each of which has to connect a set of terminals. The agents form a network by selecting edges. A strategy S_i of an agent i is a set of edges connecting the desired terminals. The cost of the edges used by all the agents has to be covered. A fundamental cost sharing mechanism is *Shapley cost sharing*, which was proposed by Anshelevich et al. [3] for network design games and has been studied with respect to

other networking problems as well [12, 17]. In Shapley cost sharing, the cost of an edge is shared in a fair manner among the agents using that edge. In an *unweighted game*, if k agents use an edge e in their strategies, then each of these agents pays a share of $c(e)/k$. In a *weighted game*, each agent i has a weight w_i and contributes a share of $c(e)w_i/W_e$, where W_e is the total weight of agents using e. We are interested in stable networks where no agent has the incentive to deviate from its strategy. Stability is modeled by considering Nash equilibria. A combination $\mathcal{S} = (S_1, \ldots, S_n)$ of strategies forms a Nash equilibrium if no agent has a better strategy with a strictly smaller cost if all the other agents adhere to their strategies. A widely accepted performance measure for evaluating the quality of Nash equilibria is the *price of anarchy* [19], which is the maximum ratio of the total cost incurred by any Nash equilibrium to the cost spent by the social optimum. Unfortunately, for our network design games, the price of anarchy is as high as n. An interesting alternative quality measure, proposed by Anshelevich et al. [2], is *price of stability* which is the ratio of the best Nash equilibrium relative to the social optimum. Anshelevich et al. [2] proved that the price of stability in unweighted network design games is $O(\log n)$.

The scenario described so far assumes that agents are completely noncooperative, isolated entities. However, for long-term decisions such as network design, given today's communication infrastructure, this assumption is not entirely realistic. It is more natural that agents will discuss possible strategies and, as in other economic markets, form coalitions taking strategic actions that are beneficial to all members of the group. In such cooperative environments we again seek stable solutions. In this context, in 1959 Aumann [4] introduced the concept of *strong Nash equilibria*, which ensure stability against deviations by every conceivable coalition of agents. More specifically, no coalition can cooperatively deviate in a way that benefits all its members, taking the actions of the agents outside the coalition as given. With respect to network design, an important question is whether coordination among agents yields strictly better solutions. Is it possible to achieve significant improvements? We prove that this is the case. When coordination is allowed, the price of anarchy of strong Nash equilibria drops from n to $O(\log n)$ in unweighted games. Similar improvements show in weighted games. Obviously, any strong Nash equilibrium is a standard Nash equilibrium, which is immune to deviations of single agents. Hence strong Nash equilibria cannot be better than the best standard Nash equilibria. A second natural question is how strong Nash equilibria rank relative to the best standard Nash equilibrium. When coordination is allowed, is the worst-case performance of stable states close to that of the best stable states achievable without cooperation? We answer this question in the affirmative in terms of anarchy and stability measures. For most settings, the price of anarchy of strong Nash equilibria is essentially always as good as the corresponding stability bounds of standard equilibria. These settings include unweighted games in directed graphs as well as weighted games in both directed and undirected graphs.

Previous results. Research on the network design games defined above was initiated by Anshelevich et al. [3]. In this paper the authors considered general cost sharing schemes that are not restricted to Shapley mechanisms. Anshelevich et al. studied undirected graphs and first addressed scenarios where each agent has to connect one terminal to a common destination. They designed Nash equilibria whose cost is equal to the cost of the optimum. Furthermore Anshelevich et al. [3] investigated the general scenario that each agent has to connect a set of terminals. In this case there are graphs that do not admit Nash equilibria. The authors therefore studied *α-approximate Nash equilibria* in which no agent can improve its cost by a factor of more than α, where $\alpha > 1$. Anshelevich et al. proved that there always exists a

3-approximate Nash equilibrium whose cost is equal to that of the optimum. Furthermore, they derived a polynomial time algorithm that gives a $(4.65 + \epsilon)$-approximate Nash equilibrium whose cost is twice the optimum.

In the following two paragraphs we describe the results known for network design games with Shapley cost sharing. The setting was introduced in a second paper by Anshelevich et al. [2] who first analyzed unweighted games. Using elegant potential function arguments based on a potential by Monderer and Shapley [20], the authors proved that every directed or undirected graph admits a Nash equilibrium and that the price of stability is upper bounded by $H(n)$. Here $H(n) = \sum_{i=1}^{n} 1/i$ is the nth harmonic number, which is closely approximated by the natural logarithm, i.e., $\ln(n+1) \leq H(n) \leq \ln n + 1$. The upper bound of $H(n)$ on the price of stability is tight for directed graphs. For undirected graphs Anshelevich et al. [2] showed a lower bound of 4/3 on the price of stability; the lower bound construction uses two agents that have to establish a connection to a common destination. Additionally, Anshelevich et al. [2] considered weighted games and showed the existence of Nash equilibria in two-agent games. For directed graphs they gave a lower bound of $\Omega(\max\{n, \log W\})$ on the price of stability, where W is the total weight of all the agents.

Chen and Roughgarden [7] further investigated weighted games in directed graphs. They showed that there are graphs that do not admit Nash equilibria. Chen and Roughgarden then demonstrated that, for any $\alpha = \Omega(\log w_{\max})$, α-approximate Nash equilibria do exist and that the price of stability is $O((\log W)/\alpha)$. Here $w_{\max}$ is the maximum weight of any agent. These trade-offs are nearly tight. Further work on unweighted games was presented by Fiat et al. [15] and Chekuri et al. [6].

We became aware that, independent of our work, very recently Epstein, Feldman, and Mansour [10] studied strong Nash equilibria for unweighted network design games in directed graphs. They assumed that each agent has to connect a pair of terminals and considered Shapley as well as general cost sharing mechanisms. Epstein, Feldman, and Mansour first observed that there are directed graphs that do not admit strong Nash equilibria. As their main contribution they presented topological characterizations for equilibrium existence. More specifically, they showed that if each agent has to connect a terminal to a common destination, each series parallel graph has a strong Nash equilibrium. If arbitrary terminal pairs are allowed, every extension parallel graph admits a strong Nash equilibrium when Shapley cost sharing is adopted. Furthermore, they analyzed the quality of strong Nash equilibria, showing a bound of $\Theta(\log n)$ on the price of anarchy for Shapley cost sharing and a bound of 1 for general cost sharing schemes when each agent has to connect to a common destination.

Finally, the authors of [1, 13, 14] studied the strong Nash equilibria in scheduling and load balancing games.

Our contribution. This paper presents an in-depth study of network design games with Shapley cost sharing when coordination among agents is allowed. We present upper and lower bounds on the price of anarchy achieved by strong Nash equilibria. We study scenarios with unrestricted coordination, i.e., coalitions of any size (or weight) may be formed, and we also consider settings where the size (or weight) of a coalition is limited.

The first part of the paper addresses unweighted network design games. We first observe that there are directed as well as undirected graphs that do not admit strong Nash equilibria and then give a sufficient existence condition. More specifically, we show that α-approximate strong Nash equilibria exist in any directed or undirected graph, for any $\alpha \geq H(c)$, if coalitions of size up to c, $1 \leq c \leq n$, are allowed. Again, $H(c)$ is the cth harmonic number. An α-approximate strong Nash equilibrium, for

$\alpha \geq 1$, is one where no coalition (of prescribed size or weight) can deviate such that every member of the coalition improves its cost by a factor of more than α.

We next prove that the price of anarchy of strong Nash equilibria is upper bounded by $H(n) \approx \ln n$, allowing coalitions of any size. This upper bound holds for any directed or undirected graph that admits a strong Nash equilibrium. Hence, using coordination, we achieve an exponential improvement in terms of the price of anarchy, compared to noncooperative environments. We show that the upper bound of $H(n)$ is tight in directed graphs. For undirected graphs we develop a lower bound of $\Omega(\sqrt{\log n})$ on the price of anarchy. These results can be generalized to α-approximate strong Nash equilibria for any $\alpha \geq 1$. In this case all the upper and lower bounds multiply by a factor of α. For the generalized setting that coalitions of size up to c, $1 \leq c \leq n$, are allowed, we prove an upper bound of $\alpha \frac{n}{c} H(c)$ on the price of anarchy of α-approximate strong Nash equilibria. Again, this bound holds for any directed or undirected graph that admits an α-approximate strong Nash equilibrium for some $\alpha \geq 1$, and not just for the range $\alpha \geq H(c)$. Suppose that $\alpha = 1$. If $c = 1$, we obtain the anarchy ratio of n achieved by standard equilibria. If $c = n$, we obtain the best ratio of $H(n)$. Since $H(n)$ is a lower bound on the price of stability of (standard) Nash equilibria in directed graphs [2], we conclude that in directed graphs the worst-case performance ratios of strong Nash equilibria are essentially always as good as the performance ratios achievable by the best standard Nash equilibria.

In the second part of the paper we extend the above results to weighted network design games. We first give a sufficient condition for the existence of α-approximate strong Nash equilibria. We then prove that in directed and undirected graphs the price of anarchy of strong Nash equilibria is at most $1 + \ln W$ if the formation of coalitions is not restricted. Here W is the sum of the weights of all agents. For directed graphs we show a matching lower bound of $\Omega(\log W)$. For undirected graphs we prove a lower bound of $\Omega(\sqrt{\log W})$. Again, for any $\alpha \geq 1$, the results extend to α-approximate strong Nash equilibria, where the lower and upper bounds simply multiply by α. When coordination among agents is limited, we consider two scenarios: (1) As usual, the number of agents in a coalition might be limited. (2) The sum of the weights of the agents forming a coalition may be limited so that agents of high weight cannot leave agents of low weight in costly configurations. For this general setting we present bounds trading the price of anarchy vs. the coalition size or weight. Furthermore, we prove a lower bound on the price of stability of standard Nash equilibria in undirected graphs. We construct a family of graphs in which the price of stability is $\Omega(\log W / \log \log W)$. No superconstant lower bound was known for undirected graphs, for neither weighted nor unweighted games. Our lower bound holds even if every agent has to connect only a pair of terminals. However, individual terminal pairs are allowed. Together with the known lower bound of $\Omega(\log W)$ for directed graphs [2], we conclude that, in undirected as well as directed graphs, anarchy bounds of strong Nash equilibria essentially match the stability bounds of standard Nash equilibria.

We remark that our set of results is disjoint from that of Epstein, Feldman, and Mansour [10], except for the observation that graphs do not necessarily admit strong Nash equilibria, the upper bound of $\frac{n}{c} H(c)$, and the lower bound of $H(n)$ on the price of anarchy in unweighted games. While the upper bound proof by Epstein, Feldman, and Mansour is based on the potential function by Monderer and Shapley, in our paper we use new combinatorial arguments to establish the result. Generally speaking, our study here is more comprehensive in that we allow each agent to connect a set of terminals and consider directed and undirected graphs as well as unweighted and weighted games.

Analysis techniques. As mentioned above, our upper bounds on the price of anarchy are achieved using new combinatorial arguments that do not rely on potential functions: Starting from a strong Nash equilibrium, we perform a sequence of specific strategy changes for varying size coalitions. For each strategy change there exists one unsatisfied agent whose original cost can be bounded relative to the optimum. From a technical point of view, our strongest contribution is the lower bounds for undirected graphs. We present a new recursive framework for constructing lower bounds in network design games. Applying the recursive construction for varying parameters, we are able to obtain anarchy as well as stability bounds in both unweighted and weighted games. The protocol could also be applied to derive bounds for directed graphs, but simpler constructions work in the directed case. While the same recursive framework can be applied to construct graphs for anarchy and stability bounds, the analyses of the graphs differ. To establish anarchy bounds we have to prove that no coalition can deviate, which turns out to be a nontrivial task because all possible coalitions and strategy changes over the recursive levels must be examined. To establish a stability bound, we have to show that no better Nash equilibria exist. In fact, we will prove that our graphs admit only one Nash equilibrium.

2. Problem statement and definitions. We formally introduce the network design problems and game-theoretic concepts studied in this paper.

Network design games. Consider a graph $G = (V, E, c)$ with a nonnegative cost function $c : E \mapsto \mathbb{R}_+^0$ defined on the edges. Graph G may be directed or undirected as we will study network design in both directed and undirected graphs. Associated with G are n selfish agents, each of which has certain connectivity requirements. More specifically, let $T_i \subseteq V$ be the set of terminals that agent i wishes to connect. If G is a directed graph, then for (selected) terminal pairs $t, t' \in T_i$ we additionally have to specify which direction between the pair should be established. A strategy of an agent i consists of a set $S_i \subseteq E$ of edges satisfying the connection requirements. We assume that strategies S_i are minimal; i.e., dropping any edge of S_i leads to a configuration in which the connectivity requirements of agent i are not satisfied anymore. A combination $\mathcal{S}$ of strategies is the vector $\mathcal{S} = (S_1, \ldots, S_n)$ of individual agent strategies. Edges used by the agents have to be paid for. We consider Shapley cost sharing mechanisms that split the cost $c(e)$ of an edge e in a fair manner among the agents using that edge. In an *unweighted game*, if k agents use an edge e, then each of the k agents pays a share of $c(e)/k$ for that edge. Thus, for a combination $\mathcal{S}$ of strategies, the total cost of agent i is equal to $cost_i(\mathcal{S}) = \sum_{e \in S_i} c(e)/|\{j : e \in S_j\}|$. In a *weighted game* each agent i has a weight w_i and pays a share proportional to its weight. For any edge $e \in S_i$, agent i pays a share of $c(e)w_i/W_e$, where $W_e = \sum_{j:e \in S_j} w_j$ is the total weight of the agents j using e in their strategies. Formally, the cost of agent i in a weighted game is $cost_i(\mathcal{S}) = \sum_{e \in S_i} c(e)w_i/W_e$.

Strong Nash equilibria. We are interested in stable solutions where agents have no incentive to deviate from their strategies. Previous work has considered Nash equilibria that are resilient to deviations of single agents. A weakness of Nash equilibria is their vulnerability to deviations by coalitions of agents. To overcome this problem, Aumann [4] defined the notion of *strong Nash equilibria*. A strong Nash equilibrium is resilient to deviations of coalitions; i.e., there exists no coalition of agents that can jointly change strategies such that every agent in the coalition has a strictly smaller cost. Formally, let I be a nonempty coalition of agents. For a combination $\mathcal{S}$ of strategies, let $\mathcal{S}_I$ be the projection of $\mathcal{S}$ on I; i.e., $\mathcal{S}_I$ are the strategies of agents $i \in I$. Similarly, $\mathcal{S}_{-I}$ represents the strategies of agents $i \notin I$.

For coalition I, let $\mathcal{S}'_I$ be another choice of strategies. A combination $\mathcal{S}$ of strategies forms a strong Nash equilibrium if, for no nonempty coalition I, there exists a strategy change $\mathcal{S}'_I$ such that $cost_i(\mathcal{S}'_I, \mathcal{S}_{-I}) < cost_i(\mathcal{S})$ for all agents $i \in I$. Note that a standard Nash equilibrium is a strong Nash equilibrium where only coalitions of size one are allowed. In this spirit one can consider generalized settings in which coalitions of size at most c are permitted, $1 \leq c \leq n$. As for weighted games we will also be interested in scenarios where the total weight of agents forming a coalition is limited. This ensures that agents of high weight cannot impose too much control on agents outside a coalition.

As we shall see, strong Nash equilibria do not always exist. For this reason we relax the notion of stability, calling a combination of strategies stable if agents cannot improve their cost by a factor of more than α. More specifically, for a real value $\alpha \geq 1$, a combination $\mathcal{S}$ of strategies forms an α-approximate strong Nash equilibrium if, for no nonempty coalition I, there exists a strategy change $\mathcal{S}'_I$ such that $cost_i(\mathcal{S}'_I, \mathcal{S}_{-I}) < cost_i(\mathcal{S})/\alpha$ for all agents $i \in I$. Similarly, we can define α-approximate Nash equilibria when the size or weight of a coalition is limited. We remark that in the context of α-approximate strong equilibria another definition seems reasonable. We could call a combination of strategies an α-approximate strong Nash equilibrium if no coalition can improve its *total* cost by a factor of more than α, while still requiring that every agent of the coalition performs strictly better than before. Obviously, an α-approximate Nash equilibrium according to this second definition is an α-approximate equilibrium under the former definition but not vice versa. Thus, our original definition allows for more configurations representing equilibrium states. For this reason and because our first definition requires a sufficiently high benefit for *each* agent of a coalition to perform a strategy change, we adopt the original definition in this paper. However, all the results that we will present in the following sections also hold for the second definition as well.

Performance measures. We are interested in the performance of strong Nash equilibria relative to the social optimum. Let $cost(\mathcal{S}) = \sum_{i=1}^{n} cost_i(\mathcal{S})$ be the total cost of all the agents, and let $cost(OPT)$ be the cost of the globally optimal solution. We say that strong Nash equilibria *achieve a price of anarchy of* c if $\max_{\mathcal{S}} \frac{cost(\mathcal{S})}{cost(OPT)} \leq c$, where the maximum is taken over all strong Nash equilibria. The notion can be extended to (α-approximate) strong Nash equilibria with coalitions of limited size or weight. In this paper we will also be interested in the *price of stability* of standard Nash equilibria where coordination among agents is not allowed. The price of stability is $\min_{\mathcal{S}} \frac{cost(\mathcal{S})}{cost(OPT)}$, where the minimum is taken over all Nash equilibria.

3. Upper bounds for unweighted games. We study the existence of strong Nash equilibria and then develop upper bounds on the price of anarchy. The proof of the following proposition is presented in the appendix.

PROPOSITION 3.1. *There exist directed and undirected graphs that do not admit strong Nash equilibria.*

THEOREM 3.2. *In any directed or undirected graph, α-approximate strong Nash equilibria exist, for any $\alpha \geq H(c)$, if coalitions of size up to c are allowed.*

Proof. We use a classical potential function by Monderer and Shapley [20] to show the existence of α-approximate strong Nash equilibria. Given a graph $G = (V, E, c)$ and a combination $\mathcal{S} = (S_1, \ldots, S_n)$ of strategies, let n_e be the number of agents currently using edge $e \in E$ in their strategies, i.e., $n_e = |\{i : e \in S_i\}|$. The potential is defined as $\Phi(\mathcal{S}) = \sum_{e \in E} c(e) H(n_e)$. We will show that, while $\mathcal{S}$ does not form an α-approximate strong Nash equilibrium, when allowing coalitions of size up to c,

any α-*improvement move* strictly decreases the potential. An α-improvement move, for a coalition I with $|I| \leq c$, is a strategy change $\mathcal{S}'_I$ such that $cost_i(\mathcal{S}'_I, \mathcal{S}_{-I}) < cost_i(\mathcal{S})/\alpha$ for any agent $i \in I$. Suppose that we perform a sequence of such α-improvement moves starting from the social optimum. As the potential is upper bounded by $H(n)cost(OPT)$ and lower bounded by 0, the sequence of improvement moves must converge to an α-approximate strong Nash equilibrium.

We analyze an α-improvement move, performed by a coalition I with $|I| \leq c$. The strategy change $\mathcal{S}'_I$ of I can be viewed as being executed in two steps: (1) In a first step agents $i \in I$ drop all the edges used in strategies S_i. At this point no agent $i \in I$ shares the cost of any edge. (2) In a second step agents $i \in I$ join the edges they want to use in their new strategies $\mathcal{S}'_I$. Let E_1 be the set of edges dropped in step (1), and let E_2 be the set of edges added in step (2). These edge sets need not be disjoint. For any $e \in E$, let n_e^1 be the number of agents sharing e just after step (1), and let n_e^2 be the number of agents sharing e after step (2). The absolute value of the cost reduction experienced by I due to step (1) is

$$cost^- = \sum_{e \in E_1} c(e) \frac{n_e - n_e^1}{n_e},$$

because $e \in E_1$ is dropped by $n_e - n_e^1$ agents that each paid a share of $c(e)/n_e$. The value of this cost reduction is equal to the cost of I in the original configuration, i.e., $cost^- = \sum_{i \in I} cost_i(\mathcal{S})$, because after step (1) the cost of I is 0. The cost increase of I due to step (2) is

$$cost^+ = \sum_{e \in E_2} c(e) \frac{n_e^2 - n_e^1}{n_e^2},$$

since $e \in E_2$ is bought by $n_e^2 - n_e^1$ agents $i \in I$ who pay $c(e)/n_e^2$ each. This cost increase is equal to the cost of I in the new configuration, i.e., $cost^+ = \sum_{i \in I} cost_i(\mathcal{S}'_I, \mathcal{S}_{-I})$, because the cost of I was 0 before step (2) and the strategy change is complete after step (2). By the definition of an α-improvement move, $\sum_{i \in I} cost_i(\mathcal{S}'_I, \mathcal{S}_{-I}) < \sum_{i \in I} cost_i(\mathcal{S})/\alpha$ and hence

$$\alpha cost^+ - cost^- < 0. \tag{3.1}$$

Next we consider the potential change $\Delta\Phi$. The potential change stems from edges $e \in E_1 \cup E_2$ where cost shares change. Let Φ^- be the absolute value of the potential drop due to step (1) of the improvement move, and let Φ^+ be the potential increase due to step (2). We will show $-\Phi^- \leq -cost^-$ and $\Phi^+ \leq \alpha cost^+$. This implies $\Delta\Phi = -\Phi^- + \Phi^+ \leq -cost^- + \alpha cost^+$, and using (3.1) we obtain $\Delta\Phi < 0$, which is to be proved.

To verify $-\Phi^- \leq -cost^-$ we observe

$$\Phi^- = \sum_{e \in E_1} c(e)(H(n_e) - H(n_e^1)) \geq \sum_{e \in E_1} c(e) \frac{n_e - n_e^1}{n_e} = cost^-.$$

The inequality holds because $H(n_e) - H(n_e^1) = 1/(n_e^1 + 1) + 1/(n_e^1 + 2) + \cdots + 1/n_e \geq (n_e - n_e^1)/n_e$. It remains to prove $\Phi^+ \leq \alpha cost^+$. The potential increase is given by $\Phi^+ = \sum_{e \in E_2} c(e)(H(n_e^2) - H(n_e^1))$. We show that, for any $e \in E_2$,

$$H(n_e^2) - H(n_e^1) \leq H(n_e^2 - n_e^1) \frac{n_e^2 - n_e^1}{n_e^2}. \tag{3.2}$$

The desired inequality for the potential increase then follows because $n_e^2 - n_e^1 \leq c$ as at most c agents can join any edge in step (2) and $H(c) \leq \alpha$. The expressions in (3.2) are

$$H(n_e^2) - H(n_e^1) = \frac{1}{n_e^1+1} + \frac{1}{n_e^1+2} + \cdots + \frac{1}{n_e^2},$$
$$H(n_e^2 - n_e^1)\frac{n_e^2 - n_e^1}{n_e^2} = \left(1 + \frac{1}{2} + \cdots + \frac{1}{n_e^2 - n_e^1}\right)\frac{n_e^2 - n_e^1}{n_e^2}.$$

We compare the kth terms of these expressions, for $k = 1, \ldots, n_e^2 - n_e^1$, and establish (3.2) by proving $\frac{1}{n_e^1+k} \leq \frac{1}{k} \cdot \frac{n_e^2 - n_e^1}{n_e^2}$. This is equivalent to showing $0 \leq n_e^1(n_2^2 - n_e^1) - kn_e^1$, and this holds because $f(k) = n_e^1(n_2^2 - n_e^1) - kn_e^1$ is decreasing in k and $f(n_e^2 - n_e^1) = 0$. □

THEOREM 3.3. *In any directed or undirected graph and for any $\alpha \geq 1$, the price of anarchy of α-approximate strong Nash equilibria is upper bounded by $\frac{\alpha n}{c} H(c)$ if coalitions of size up to c are allowed.*

If there are no restrictions on the coalition size and we are interested in true strong Nash equilibria (i.e., $\alpha = 1$), we obtain the following corollary.

COROLLARY 3.4. *In any directed or undirected graph the price of anarchy of strong Nash equilibria is upper bounded by $H(n)$.*

Proof of Theorem 3.3. Let G be a graph that admits α-approximate strong Nash equilibria for some $\alpha \geq 1$, and let $\mathcal{S} = (S_1, \ldots, S_n)$ be such an equilibrium state. The basic idea of the proof is to consider all coalitions of size exactly c. For each coalition I we perform a process consisting of exactly c steps in which the agents of I try to buy the edges of the social optimum. At the end of each step exactly one agent will leave the process. Making use of the fact that in $\mathcal{S}$ no coalition of size up to c can improve its cost by a factor of more than α, we will be able to upper bound $cost_i(\mathcal{S})$ of the agent i leaving the process relative to the cost of the social optimum. More specifically, we will prove that, for any coalition I of size exactly c,

$$\sum_{i \in I} cost_i(\mathcal{S}) \leq \alpha H(c) cost(OPT). \tag{3.3}$$

Let $\mathcal{I}$ be the set of all coalitions of size exactly c. Summing (3.3) over all the $\binom{n}{c}$ coalitions $I \in \mathcal{I}$, we obtain $\sum_{I \in \mathcal{I}} \sum_{i \in I} cost_i(\mathcal{S}) \leq \alpha \binom{n}{c} H(c) cost(OPT)$. Any fixed agent i, $1 \leq i \leq n$, occurs in exactly $\binom{n-1}{c-1}$ coalitions $I \in \mathcal{I}$. Hence $\sum_{I \in \mathcal{I}} \sum_{i \in I} cost_i(\mathcal{S}) = \binom{n-1}{c-1} cost(\mathcal{S})$. We conclude that

$$cost(\mathcal{S}) \leq \binom{n}{c} / \binom{n-1}{c-1} \cdot \alpha H(c) cost(OPT) = \frac{n}{c} \cdot \alpha H(c) cost(OPT),$$

which establishes the stated price of anarchy.

Fix an arbitrary coalition I of size exactly c. We will prove (3.3). Let E^{OPT} be the set of edges bought by the social optimum and, for any $i \in I$, let E_i^{OPT} be a minimal set of edges necessary to connect the terminals of agent i within the optimal solution. We now start the process mentioned above. Let $I_1 := I$ be the initial coalition consisting of c agents. Suppose that we have already performed $k-1$ steps of the process, where initially $k = 1$, and let I_k be the coalition given at the beginning of the kth step, where $1 \leq k \leq c$. The kth step proceeds as follows. Starting from initial configuration $\mathcal{S}$, the agents of I_k perform a strategy change $\mathcal{S}_{I_k}^k$ in which $i \in I_k$

buys set E_i^{OPT}. Let $\mathcal{S}^k = (\mathcal{S}^k_{I_k}, \mathcal{S}_{-I_k})$ be the resulting configuration. The new cost of agent $i \in I_k$ is

$$cost_i(\mathcal{S}^k) = \sum_{e \in E_i^{OPT}} \frac{c(e)}{|\{j \in I_k : e \in E_j^{OPT}\} \cup \{j \notin I_k : e \in S_j\}|} \leq \sum_{e \in E_i^{OPT}} \frac{c(e)}{|\{j \in I_k : e \in E_j^{OPT}\}|}.$$

Since the original configuration $\mathcal{S}$ forms an α-approximate strong Nash equilibrium, the strategy change cannot improve the cost of every agent $i \in I_k$ by a factor of more than α. Thus there must exist an agent i_k with $cost_{i_k}(\mathcal{S}^k) \geq cost_{i_k}(\mathcal{S})/\alpha$ and hence

$$cost_{i_k}(\mathcal{S}) \leq \alpha \sum_{e \in E_{i_k}^{OPT}} \frac{c(e)}{|\{j \in I_k : e \in E_j^{OPT}\}|}. \tag{3.4}$$

This agent i_k leaves the coalition I_k. If there is more than one agent satisfying the above cost inequality, we select an arbitrary one of them. The new coalition at the end of the step is $I_{k+1} := I_k \setminus \{i_k\}$. The process ends after exactly c steps when the coalition is empty. Summing (3.4) over all of the c steps and taking into account that the sequence of agents leaving the process forms I, we find

$$\sum_{i \in I} cost_i(\mathcal{S}) \leq \alpha \sum_{k=1}^{c} \sum_{e \in E_{i_k}^{OPT}} \frac{c(e)}{|\{j \in I_k : e \in E_j^{OPT}\}|}. \tag{3.5}$$

We analyze the right-hand side of the above inequality, which sums edge costs $c(e)$ over edges $e \in E^{OPT}$. Consider any fixed edge $e \in E^{OPT}$, and let $n_e = |\{i \in I : e \in E_i^{OPT}\}|$ be the number of agents in I using e in the described strategy changes. The cost of e contributes to the right-hand side of (3.5) whenever one of the n_e agents leaves the process. The ℓth time this happens, the contribution is $c(e)/(n_e - \ell + 1)$ for $\ell = 1, \ldots, n_e$. Thus, the cost contribution is $c(e)H(n_e) \leq c(e)H(c)$, and we conclude that $\sum_{i \in I} cost_i(\mathcal{S}) \leq \alpha \sum_{e \in E^{OPT}} c(e)H(c) = \alpha H(c) cost(OPT)$. ∎

4. Lower bounds for unweighted games. We first present a lower bound for directed graphs. This lower bound implies that if there is no restriction on the coalition size, our upper bound of Corollary 3.4 is optimal.

THEOREM 4.1. *In directed graphs and for any $\alpha \geq 1$, the price of anarchy of α-approximate strong Nash equilibria is at least $\alpha \max\{n/c, H(n)\}$ if coalitions of size at most c are allowed.*

Proof. We modify lower bound graphs that were presented previously in the literature [2]. For the bound of $\alpha n/c$, consider a simple graph consisting of two vertices s and t that are connected by two parallel edges of cost αn and $c + \epsilon$, respectively; see Figure 4.1(a). Associated with the graph are n agents, all of which have to connect terminals s and t. An optimal solution will buy the edge of cost $c + \epsilon$. On the other hand, the configuration in which all of the n agents share the expensive edge of cost αn, each one paying a cost of α, represents an α-approximate strong Nash equilibrium: Any coalition of size up to c, when performing a strategy change and buying the edge of cost $c + \epsilon$, incurs a cost of at least $1 + \epsilon/c$ per agent. Hence the agents of the coalition do not save a factor of more than α in cost.

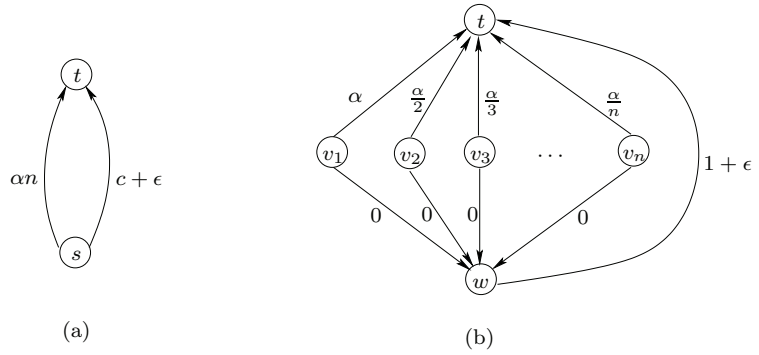

FIG. 4.1. *Directed graphs enforcing a high price of anarchy.*

In order to establish the lower bound of $\alpha H(n)$, we use the graph depicted in Figure 4.1(b). There are n vertices $v_1, \ldots, v_n$, where v_i is connected to a vertex t via a directed edge (v_i, t) of cost α/i and to a vertex w via a directed edge (v_i, w) of cost 0. Additionally, there is a directed edge (w, t) of cost $1 + \epsilon$. Associated with the graph are n agents, where agent i has to connect v_i to t. An optimal solution satisfies the connection requirements by buying the edges of cost 0 and the edge (w, t) of cost $1+\epsilon$. The configuration in which agent i connects v_i to t using its private edge (v_i, t) of cost α/i forms an α-approximate strong Nash equilibrium. Any coalition of size, say c, that performs a strategy change and purchases edge (w, t) incurs a cost of $(1 + \epsilon)/c$ per agent. However, there is at least one agent in the coalition whose original cost was at most α/c and to whom the incentive of changing is not sufficiently high. □

We next develop a lower bound for undirected networks. Our lower bound construction is quite involved, and we therefore concentrate on the most general scenario where there is no limit on the coalition size.

THEOREM 4.2. *For any $\alpha \geq 1$, there exists a family of undirected graphs, each admitting an α-approximate strong Nash equilibrium whose cost is $\Omega(\alpha\sqrt{\log n})$ times that of the social optimum.*

Proof. For ease of exposition we first prove the theorem for $\alpha = 1$ and then show how to adapt the proof for any $\alpha > 1$. In the following we first define our family of graphs. We then identify the social optimum and prove that there exists an expensive strong Nash equilibrium.

The graphs G are defined recursively. Let n be a positive integer such that $\lfloor\sqrt{\log n}\rfloor \geq 2$. In this proof logarithms are taken to the base 3. Let $d_{\max} = \lfloor\sqrt{\log n}\rfloor - 1$. The recursive construction proceeds in $d_{\max} + 1$ steps. At the bottom level of the recursion, i.e., at maximum depth $d_{\max}$, G consists of graphs $G^{d_{\max}}$ *of order* $d_{\max}$; cf. Figure 4.2(a). A graph $G^{d_{\max}}$ is composed of a *stem edge* $\{v, w\}$ of cost $s_{d_{\max}} = 1/3^{d_{\max}}$ and a *bridge* $\{u, v\}$ *of order* $d_{\max}$ having cost $b_{d_{\max}} = 2/3^{2d_{\max}}$. The bridge and the stem are joined at vertex v. Vertices u and w are connected via an *arc* $\{u, w\}$ *of order* $d_{\max}$ having cost $a_{d_{\max}} = 1/3^{d_{\max}}$. We call u the *base* and w the *tip* of $G^{d_{\max}}$. Associated with $G^{d_{\max}}$ are $n_{d_{\max}} = \lceil n/3^{d_{\max}(d_{\max}+1)}\rceil$ *agents of order* $d_{\max}$, each having to connect terminals u and w. By the choice of $d_{\max}$ we have $n_{d_{\max}} \geq 1$.

Assume that graphs of order $d_{\max}, d_{\max} - 1, \ldots, d + 1$ are defined. Then a graph G^d *of order* d, which resides at depth d of the recursion, is constructed as follows;

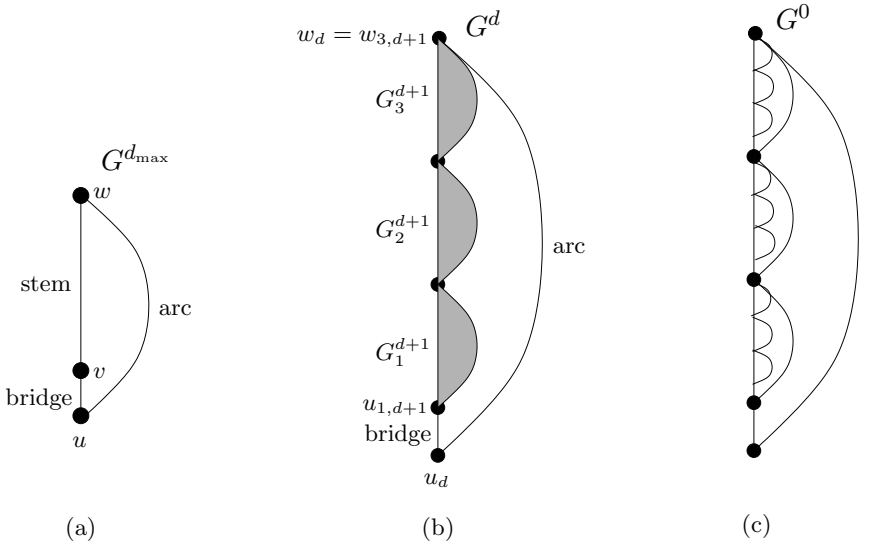

FIG. 4.2. *The recursive construction of graphs G^d.*

see Figure 4.2(b). Graph G^d consists of three graphs G_1^{d+1}, G_2^{d+1}, and G_3^{d+1} of order $d+1$ that are attached to each other. More specifically, the tip of G_1^{d+1} and the base of G_2^{d+1} are merged, i.e., the two vertices are united, and the tip of G_2^{d+1} is merged with the base of G_3^{d+1}. Let $u_{1,d+1}$ be the base of G_1^{d+1}. Attached to this vertex is a bridge $\{u_d, u_{1,d+1}\}$ of order d having a cost of $b_d = 2/3^{2d}$. Let $w_{3,d+1}$ be the tip of G_3^{d+1} and set $w_d := w_{3,d+1}$. We call u_d the *base* and w_d the tip of G^d. Additionally, G^d contains an arc $\{u_d, w_d\}$ of order d connecting the base and the tip. This arc has cost $a_d = 1/3^d$. Associated with G^d are $n_d = \lceil n/3^{d(d+1)} \rceil - 3\lceil n/3^{(d+1)(d+2)} \rceil$ agents of order d, all of which have to connect u_d to w_d. As we shall see, these agents will govern the connection decisions within G^d. The bridge will have the effect that, in a strong Nash equilibrium, the order-d agents will establish their connections using the arc of order d instead of routing through the graphs G_k^{d+1}, $1 \le k \le 3$.

The construction proceeds down to a depth $d = 0$. Associated with graph G^0 are $n_0 = \lceil n/3^0 \rceil - 3\lceil n/3^2 \rceil = n - 3\lceil n/3^2 \rceil$ agents of order 0 that have to connect the outermost vertices of G^0. Graph $G := G^0$ is the graph we will work with. A high level sketch of $G = G^0$ is given in Figure 4.2(c).

We start with some observations on G. First, all the vertices and terminals of the graph are located on a *backbone* consisting of all the stem edges and bridges. The nested structure of G contains 3^d subgraphs of order d for any $0 \le d \le d_{\max}$.

PROPOSITION 4.3. *The least expensive path connecting the base and the tip of a graph G^d using only edges of G^d has a total edge cost of exactly $1/3^d$ for any $0 \le d \le d_{\max}$.*

Proof. The statement holds for $d = d_{\max}$ as the arc of $G^{d_{\max}}$ has cost $a_{d_{\max}} = 1/3^{d_{\max}}$, while the path crossing the bridge has cost $b_{d_{\max}} + s_{d_{\max}} = 2/3^{2d_{\max}} + 1/3^{d_{\max}}$. Suppose that the statement holds for depths $d_{\max}, \ldots, d+1$. In G^d the arc of order d has cost $a_d = 1/3^d$, while, using the inductive hypothesis, any path using the bridge of order d has a cost of at least $b_d + 3 \cdot 1/3^{d+1} = 2/3^{2d} + 1/3^d > 1/3^d$. ∎

The total number of agents associated with G and all of its subgraphs is equal to

$$\begin{aligned} N_0 &= \sum_{d=0}^{d_{\max}-1} 3^d(\lceil n/3^{d(d+1)}\rceil - 3\lceil n/3^{(d+1)(d+2)}\rceil) + 3^{d_{\max}}\lceil n/3^{d_{\max}(d_{\max}+1)}\rceil \\ &= n - 3^{d_{\max}}\lceil n/3^{d_{\max}(d_{\max}+1)}\rceil + 3^{d_{\max}}\lceil n/3^{d_{\max}(d_{\max}+1)}\rceil \\ &= n. \end{aligned}$$

More generally, in G the total number of agents associated with all the order-d graphs G^d and the subgraphs therein is, for any d with $0 \le d \le d_{\max}$,

$$\begin{aligned} N_d &= \sum_{i=d}^{d_{\max}-1} 3^i(\lceil n/3^{i(i+1)}\rceil - 3\lceil n/3^{(i+1)(i+2)}\rceil) + 3^{d_{\max}}\lceil n/3^{d_{\max}(d_{\max}+1)}\rceil \\ &= 3^d\lceil n/3^{d(d+1)}\rceil, \end{aligned}$$

which is equal to $n/3^{d^2}$ when ignoring ceilings.

The social optimum in G buys the backbone of the graph. As there are $3^{d_{\max}}$ graphs of order $d_{\max}$, the total cost of the stem edges is $3^{d_{\max}}s_{d_{\max}} = 3^{d_{\max}} \cdot 1/3^{d_{\max}} = 1$. There are 3^d graphs of order d, $0 \le d \le d_{\max}$, and hence the total cost of order-d bridges is $3^d b_d = 3^d \cdot 2/3^{2d} = 2/3^d$. Summing over all d we find that the total cost of the bridges is $\sum_{d=0}^{d_{\max}} 2/3^d \le 3$. We conclude that the cost of the social optimum is bounded by 4.

Consider the configuration $\mathcal{S}$ in which, for any graph G^d within G, any order-d agent associated with this graph G^d establishes its required connection via the corresponding arc of order d. That is, $\mathcal{S}$ buys all the arcs but no bridges or stem edges. As we will show in the remainder of this proof, $\mathcal{S}$ forms a strong Nash equilibrium. We evaluate the cost of $\mathcal{S}$. As there are 3^d graphs of order d, the total cost of order-d arcs is $3^d a_d = 3^d \cdot 1/3^d = 1$ for any fixed d with $0 \le d \le d_{\max}$. Summing over all d, we obtain $cost(\mathcal{S}) = d_{\max} + 1 \ge \lfloor\sqrt{\log n}\rfloor$, and this establishes the desired performance ratio.

It remains to show that $\mathcal{S}$ is indeed a strong Nash equilibrium. To this end we have to show that no coalition I of agents has an *improvement move*. We will always consider nonempty coalitions. An improvement move, for a coalition I, is a strategy change $\mathcal{S}'_I$ such that $cost_i(\mathcal{S}'_I, \mathcal{S}_{-I}) < cost_i(\mathcal{S})$ for any agent $i \in I$. In our graph G, as all the agents have to connect pairs of terminals, a strategy of an agent is a simple path connecting the desired vertices. The property that there does not exist an improvement move follows from Lemma 4.4, which we prove below.

LEMMA 4.4. *For $d = 0, \ldots, d_{\max}$, no coalition involving agents of order d has an improvement move.*

For the proof of Lemma 4.4 we need Lemma 4.5, which we prove first.

LEMMA 4.5. *Consider a fixed d, $0 \le d \le d_{\max}$, and suppose that no coalition involving agents of order smaller than d has an improvement move. Furthermore, assume that no coalition I involving agents of order d has an improvement move in which an order-d agent $i \in I$ associated with a graph $G^d(i)$ chooses a path containing edges outside $G^d(i)$. Then no coalition involving agents of order d has an improvement move.*

Proof of Lemma 4.5. Let I be a coalition that involves agents of order d. We have to show that I has no improvement move. Based on the assumptions of the lemma, we can restrict ourselves to coalitions I that do not contain agents of order smaller

than d. Furthermore, based on the assumptions, we only have to consider strategy changes where each order-d agent $i \in I$ establishes the required connection within its graph $G^d(i)$. Let $I' \subseteq I$ be any maximal subcoalition of order-d agents that are associated with the same graph $G^d(I')$. We will show that any strategy change $\mathcal{S}'_{I'}$ that consists of choosing connection paths within $G^d(I')$ leads to a strictly higher cost for that subcoalition; i.e., at least one agent $i \in I'$ has a strictly higher cost, and the strategy change is no improvement move.

Graph $G^d(I')$ has n_d order-d agents associated with it. Let f be the fraction defecting, i.e., $f = |I'|/n_d$. In the original configuration $\mathcal{S}$, when routing through the arc of order d, subcoalition I' paid a cost of $fa_d = f/3^d$. When changing strategy and choosing a different connection route within $G^d(I')$, each $i \in I'$ selects a path P_i that crosses the bridge of order d and then, if $d = d_{\max}$, traverses the stem edge of $G^{d_{\max}}(I')$ (see Figure 4.2(a)). If $d < d_{\max}$, path P_i then traverses the order-$(d+1)$ graphs $G_k^{d+1}(I')$, $1 \le k \le 3$, located within $G^d(I')$ (see Figure 4.2(b)). If $d = d_{\max}$, then the total cost of edges on P_i is $b_{d_{\max}} + s_{d_{\max}} \ge (1 + 2/3^d)/3^d$. If $d < d_{\max}$, then the total cost is at least $b_d + 3 \cdot 1/3^{d+1} \ge (1 + 2/3^d)/3^d$ because, by Proposition 4.3, the least expensive path traversing an order-$(d+1)$ graph has cost $1/3^{d+1}$. In both cases we have the same lower bound on the cost, expressed in terms of d. The cost of P_i is not shared by agents of order smaller than d, as they are not part of the original coalition I, nor is the cost shared by order-d agents associated with other graphs $G^d \neq G^d(I')$. The cost of P_i can be shared only by agents of order larger than d, and there exist N_{d+1} such agents if $d < d_{\max}$. If $d = d_{\max}$, the cost is not shared by other agents.

If $d = d_{\max}$, we are done because the new cost of I' is $(1 + 2/3^d)/3^d$, while the original cost was $f/3^d \le 1/3^d$. If $d < d_{\max}$, then at best all the N_{d+1} agents of order larger than d support the edges traversed by I', and the new cost of I' is at least $cost'_{I'} \ge \frac{fn_d}{fn_d + N_{d+1}}(1 + \frac{2}{3^d})\frac{1}{3^d}$. We need to show that $cost'_{I'}$ is higher than the original cost of $f/3^d$, which is equivalent to proving $\frac{n_d}{fn_d + N_{d+1}}(1 + \frac{2}{3^d}) > 1$. Since $0 < f \le 1$ it suffices to show that

$$\frac{n_d}{n_d + N_{d+1}}\left(1 + \frac{2}{3^d}\right) > 1.$$

Using the definition of n_d, eliminating ceilings, we find

$$\begin{aligned} n_d &> n/3^{d(d+1)} - n/3^{(d+1)^2+d} - 3 = \frac{n3^d}{3^{(d+1)^2}}\left(3 - \frac{1}{3^{2d}} - \frac{3^{d^2+d+2}}{n}\right) \\ &\ge \frac{n3^d}{3^{(d+1)^2}}\left(2 - \frac{3^{(d+1)(d+2)}}{n}\right) \\ &\ge \frac{n3^d}{3^{(d+1)^2}}. \end{aligned}$$

The second inequality holds because $1/3^{2d} \le 1$. For the third inequality note that $d < d_{\max}$ and $d_{\max} = \lfloor\sqrt{\log n}\rfloor - 1$ imply $(d+1)(d+2) \le \log n$ and hence $3^{(d+1)(d+2)} \le n$. Moreover, we have $N_{d+1} < 2n/3^{(d+1)^2}$. We conclude that

$$\frac{n_d}{n_d + N_{d+1}}\left(1 + \frac{2}{3^d}\right) > \frac{3^d}{3^d + 2}\left(1 + \frac{2}{3^d}\right) = \frac{3^d}{3^d + 2} \cdot \frac{3^d + 2}{3^d} = 1. \qquad \square$$

Proof of Lemma 4.4. We prove the lemma inductively for increasing values of d. For $d = 0$, the statement follows immediately from Lemma 4.5 as the assumptions of

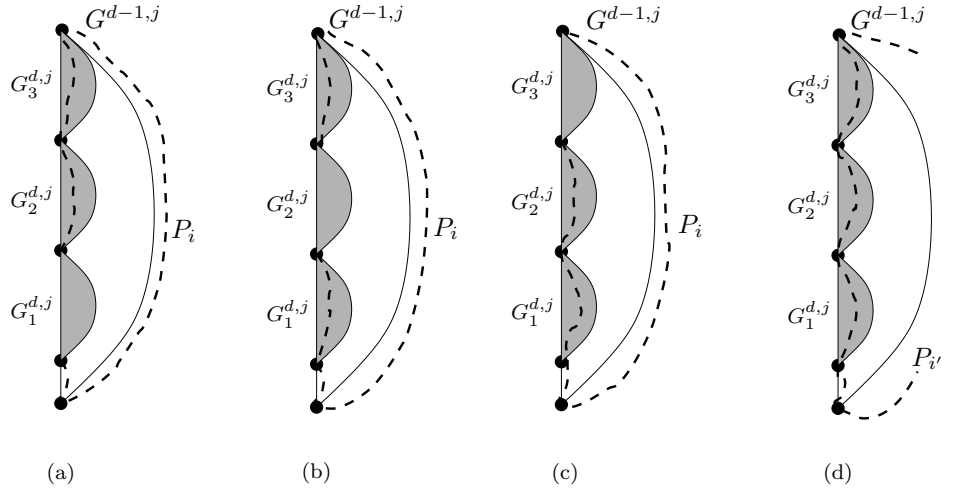

FIG. 4.3. *The paths traversed after strategy change.*

that lemma are trivially satisfied: There are no agents of order smaller than 0, and an agent of order 0 cannot connect its terminals using edges outside G^0. Suppose that the statement of Lemma 4.4 holds for depth $0, \ldots, d-1$. We prove that no coalition I involving order-d agents has an improvement move in which an order-d agent $i \in I$ associated with a graph $G^d(i)$ chooses a path using edges outside $G^d(i)$. The inductive step then follows from Lemma 4.5.

So consider a coalition I involving agents of order d and a corresponding strategy change $\mathcal{S}'_I$ in which at least one order-d agent chooses edges outside its order-d graph to connect the desired terminals. We show that the strategy change is not an improvement move. By the inductive hypothesis, we can restrict ourselves to coalitions I not involving agents of order smaller than d. Thus I contains only agents of order d or larger. Let $I' \subseteq I$ be the maximum subcoalition of order-d agents i choosing connection paths outside their graph $G^d(i)$. As $d \geq 1$, each such graph belongs to a graph G^{d-1} in the nested structure of G^0. Consider all graphs of order $d-1$ containing at least one $G^d(i)$, $i \in I'$, and number these order-$(d-1)$ graphs in an arbitrary way. Let J be the resulting index set. Each graph $G^{d-1,j}$, $j \in J$, contains three graphs $G_1^{d,j}, G_2^{d,j}, G_3^{d,j}$ of order d. For $k = 1, 2, 3$, let f_k^j be the fraction of the order-d agents associated with $G_k^{d,j}$ that are members of I'; i.e., $f_k^j = |\{i \in I' : i \text{ is order-}d \text{ agent associated with } G_k^{d,j}\}|/n_d$. Recall that n_d is the number of agents associated with an order-d graph. We have $0 \leq f_k^j \leq 1$ and $f_1^j + f_2^j + f_3^j > 0$.

In the original configuration $\mathcal{S}$, coalition I' buys the order-d arcs and hence pays a total cost of $cost_{I'} = \sum_{j \in J} \sum_{k=1}^{3} f_k^j a_d$. This expression holds even if some of the f_k^j are zero. We show in the following that the new cost $cost'_{I'}$ of I' is strictly higher than $cost_{I'}$. Hence at least one agent in I' does not improve its cost, and the strategy change is not an improvement move.

In order to estimate $cost'_{I'}$ consider an agent $i \in I'$, and let $G^{d-1,j}$, with $j \in J$, be the graph where i's graph $G^d(i)$ is located. First suppose that $G^d(i) = G_1^{d,j}$; cf. Figure 4.3(a). After the strategy change, i connects the base and the tip of $G_1^{d,j}$ on a path P_i that uses edges outside $G_1^{d,j}$. Since strategies are simple paths, all the edges of P_i are

outside $G_1^{d,j}$. Starting at the base of $G_1^{d,j}$, path P_i has to traverse the bridge of order $d-1$ in $G^{d-1,j}$. To reach the tip of $G_1^{d,j}$, path P_i has to travel to the tip of $G^{d-1,j}$. This can be done using the arc of order $d-1$ or using another subpath outside $G^{d-1,j}$. After having reached the tip of $G^{d-1,j}$, path P_i traverses $G_3^{d,j}$ and $G_2^{d,j}$, reaching the desired terminal. Ignoring edges visited between the base and the tip of $G^{d-1,j}$, agent i has to pay a share for the order-$(d-1)$ bridge and for the subpaths of P_i within $G_2^{d,j}$ and $G_3^{d,j}$. The total cost of edges traversed within graph $G_k^{d,j}$, $k \in \{2,3\}$, is at least $1/3^d$ by Proposition 4.3. The cost may be shared with other agents.

If $G^d(i) = G_2^{d,j}$ or $G^d(i) = G_3^{d,j}$, the situation is similar; see Figures 4.3(b) and (c), respectively. In the first case, P_i has to traverse $G_1^{d,j}$ and the order-$(d-1)$ bridge. From there it has to travel to the tip of $G^{d-1,j}$ and pass through $G_3^{d,j}$. Edges used within a graph $G_k^{d,j}$, $k \in \{1,3\}$, have a total cost of at least $1/3^d$; cost sharing may occur. If $G^d(i) = G_3^{d,j}$, path P_i passes through $G_2^{d,j}$ and $G_1^{d,j}$. After traversing the bridge of order $d-1$ it connects to the tip of $G^{d-1,j}$, which is also the tip of $G_3^{d,j}$ representing the desired terminal.

Next let C^j be the total number of agents $i' \in I'$ that are *not* associated with $G_1^{d,j}$, $G_2^{d,j}$, or $G_3^{d,j}$, but choose edges of these graphs when performing the strategy change. In order to use such edges, the new path $P_{i'}$ of i' must pass through the base and the tip of $G^{d-1,j}$; see Figure 4.3(d). The path between these two vertices crosses the bridge of order $d-1$ and must consist of subpaths within $G_k^{d,j}$, $k = 1,2,3$.

We are ready to lower bound the new cost $cost'_{I'}$ of I'. To this end we will consider only the cost spent in graphs $G_k^{d,j}$, $1 \le k \le 3$ and $j \in J$, and on order-$(d-1)$ bridges in $G^{d-1,j}$. Fix a $j \in J$. Graph $G_1^{d,j}$ is traversed by exactly $(f_2^j + f_3^j)n_d + C^j$ agents from I', each using edges of cost at least $1/3^d$. The cost is shared by at most $(f_2^j + f_3^j)n_d + C^j + (1 - f_1^j)n_d + N_{d+1}$ agents. Here $(1 - f_1^j)n_d$ is the number of order-d agents associated with $G_1^{d,j}$ that establish their connection within this graph, and N_{d+1} is the total number of agents of order larger than d that may participate in the strategy change and reside in the entire coalition I. If $d = d_{\max}$, then we set $N_{d+1} = 0$. Thus subcoalition I' spends a cost of at least

$$\frac{1}{3^d} \cdot \frac{(f_2^j + f_3^j)n_d + C^j}{(1 - f_1^j + f_2^j + f_3^j)n_d + N_{d+1} + C^j}$$

in graph $G_1^{d,j}$. Similarly, in $G_2^{d,j}$ and $G_3^{d,j}$ the costs are

$$\frac{1}{3^d} \cdot \frac{(f_1^j + f_3^j)n_d + C^j}{(1 - f_2^j + f_1^j + f_3^j)n_d + N_{d+1} + C^j} \quad \text{and} \quad \frac{1}{3^d} \cdot \frac{(f_1^j + f_2^j)n_d + C^j}{(1 - f_3^j + f_1^j + f_2^j)n_d + N_{d+1} + C^j}.$$

Finally the bridge of order $d-1$ has cost $b_{d-1} = 2/3^{2(d-1)}$, which is shared by $(f_1^j + f_2^j + f_3^j)n_d + N_{d+1} + C^j$ agents, and I' incurs a cost of $\frac{2}{3^{2(d-1)}}((f_1^j + f_2^j + f_3^j)n_d + C^j)/((f_1^j + f_2^j + f_3^j)n_d + N_{d+1} + C^j)$.

Note that for any $k \in \{1,2,3\}$ the other two indices from that set can be expressed as $k' = k \bmod 3 + 1$ and $k'' = (k+1) \bmod 3 + 1$. We conclude that

$$cost'_{I'} \ge \sum_{j \in J} \left(\sum_{k=1}^{3} \frac{(f_{k'}^j + f_{k''}^j)n_d + C^j}{(1 - f_k^j + f_{k'}^j + f_{k''}^j)n_d + N_{d+1} + C^j} \cdot \frac{1}{3^d} + \frac{(f_1^j + f_2^j + f_3^j)n_d + C^j}{(f_1^j + f_2^j + f_3^j)n_d + N_{d+1} + C^j} \cdot \frac{2}{3^{2(d-1)}} \right).$$

Ratios of the form $(x+c)/(y+c)$ are increasing in c if $x \le y$. Hence we can drop the terms C^j and obtain

$$cost'_{I'} \ge \sum_{j\in J}\left(\sum_{k=1}^{3}\frac{(f^j_{k'}+f^j_{k''})n_d}{(1-f^j_k+f^j_{k'}+f^j_{k''})n_d+N_{d+1}}\cdot\frac{1}{3^d} + \frac{(f^j_1+f^j_2+f^j_3)n_d}{(f^j_1+f^j_2+f^j_3)n_d+N_{d+1}}\cdot\frac{2}{3^{2(d-1)}}\right).$$

Reordering the expression in the brackets, by focusing on one particular f^j_k in the numerators, we find

$$cost'_{I'} \ge \sum_{j\in J}\sum_{k=1}^{3}\left(\left(\frac{f^j_k n_d}{(1+f^j_k-f^j_{k'}+f^j_{k''})n_d+N_{d+1}} + \frac{f^j_k n_d}{(1+f^j_k+f^j_{k'}-f^j_{k''})n_d+N_{d+1}}\right)\cdot\frac{1}{3^d} + \frac{f^j_k n_d}{(f^j_1+f^j_2+f^j_3)n_d+N_{d+1}}\cdot\frac{2}{3^{2(d-1)}}\right).$$

To simplify the last expression we observe that for any real values x, y, and c inequality $\frac{1}{x-y+c}+\frac{1}{x+y+c}\ge\frac{2}{x+c}$ holds, which we apply for $x=f^j_k n_d$ and $y=(f^j_{k'}-f^j_{k''})n_d$ as well as $c=n_d+N_{d+1}$. Thus the two terms in the inner bracket sum to at least $\frac{2f^j_k n_d}{(1+f^j_k)n_d+N_{d+1}}$. Furthermore, as for the last term in the above expression,

$$\frac{f^j_k n_d}{(f^j_1+f^j_2+f^j_3)n_d+N_{d+1}} \ge \frac{f^j_k n_d}{(f^j_k+2)n_d+N_{d+1}} \ge \frac{1}{2}\cdot\frac{f^j_k n_d}{(1+f^j_k)(n_d+N_{d+1})}.$$

Hence

$$cost'_{I'} \ge \sum_{j\in J}\sum_{k=1}^{3}\left(\frac{2f^j_k n_d}{(1+f^j_k)n_d+N_{d+1}}\cdot\frac{1}{3^d}+\frac{f^j_k n_d}{(1+f^j_k)(n_d+N_{d+1})}\cdot\frac{1}{3^{2(d-1)}}\right) > \sum_{j\in J}\sum_{k=1}^{3}\frac{2f^j_k n_d}{(1+f^j_k)(n_d+N_{d+1})}\left(1+\frac{2}{3^d}\right)\frac{1}{3^d}.$$

The last line follows because $\frac{1}{3^{2(d-1)}}\ge 2\frac{2}{3^d}\frac{1}{3^d}$.

As shown at the end of the proof of Lemma 4.5, $\frac{n_d}{n_d+N_{d+1}}(1+\frac{2}{3^d})>1$ if $d<d_{\max}$. If $d=d_{\max}$, then $N_{d+1}=0$ and the inequality is also satisfied. In each case

$$cost'_{I'} > \sum_{j\in J}\sum_{k=1}^{3}\frac{2f^j_k}{1+f^j_k}\frac{1}{3^d} \ge \sum_{j\in J}\sum_{k=1}^{3} f^j_k\frac{1}{3^d},$$

and the new cost of I' is strictly larger than the original cost of I' in configuration $\mathcal{S}$. □

This completes the proof of Theorem 4.2 for $\alpha=1$. Finally, we show how to adapt the proof for any $\alpha>1$. In the construction of the graphs G^d only the costs of

the arcs change. An arc of order d now has cost αa_d. All other costs remain the same. This increases the cost of configuration $\mathcal{S}$ by a factor of α, i.e., $cost(\mathcal{S}) \geq \alpha\lfloor\sqrt{\log n}\rfloor$, while the cost of the social optimum remains the same. This establishes a performance ratio of $\Omega(\alpha\sqrt{\log n})$.

In the statements of Lemmas 4.4 and 4.5, the term "improvement move" has to be replaced by "α-improvement move." An α-improvement move, for a coalition I, is a strategy change $\mathcal{S}'_I$ such that $cost_i(\mathcal{S}'_I, \mathcal{S}_{-I}) < cost_i(\mathcal{S})/\alpha$ for any agent $i \in I$. In the proof of Lemma 4.5 we considered any coalition I involving agents of order d or larger and investigated strategy changes where order-d agents establish connections with their respective graph of order d. We identified a subcoalition I', with $f = |I'|/n_d$, incurring a new cost of $cost'_{I'} > f/3^d$. This cost inequality still holds in our modified graph as edge costs did not decrease. Since $cost'_{I'} > f/3^d = (\alpha f/3^d)/\alpha$ and $\alpha f/3^d$ is the original cost of I' in the scaled graph, the strategy change is not an α-improvement move.

In the proof of Lemma 4.4 we studied coalitions I involving agents of order d or larger. We analyzed strategy changes in which order-d agents buy edges outside their graph of order d and identified a subcoalition I' of order-d agents incurring a new total cost of $cost'_{I'} > \sum_{j\in J}\sum_{k=1}^{3} f_k^j/3^d$, where $G_k^{d,j}$ were the graphs the agents $i \in I'$ are associated with. Again, when arcs are scaled by a factor of α, this cost inequality still holds. As the original cost of I' in the scaled graph is $\sum_{j\in J}\sum_{k=1}^{3} \alpha f_k^j/3^d$, the strategy change is not an α-improvement move. ∎

5. Weighted games. In this section we study weighted network design games where each agent i has a positive weight w_i. We scale the weights such that the minimum weight is equal to 1, and hence $w_i \geq 1$ for all agents. Let $W = \sum_{i=1}^{n} w_i$ be the total weight of all the agents.

If agents are allowed to coordinate their strategies, two scenarios are of interest. In a first setting we assume that coalitions of size up to c are allowed for any $1 \leq c \leq n$. In this case let W^c be the maximum total weight of any coalition having size at most c. In a second setting we assume that the total weight of a coalition is upper bounded so that agents of high weight cannot impose too much control on agents of low weight. In this case let $W_{\max}$ be the maximum total weight any coalition may have.

We extend our results shown for unweighted games.

5.1. Upper bounds. We first give a sufficient condition for the existence of strong Nash equilibria in weighted games and evaluate their performance in terms of the price of anarchy.

THEOREM 5.1. *In any directed or undirected graph α-approximate strong Nash equilibria exist for any $\alpha \geq 1 + \ln(1 + \overline{W})$. Here $\overline{W} = W^c$ if coalitions of size up to c are allowed, and $\overline{W} = W_{\max}$ if coalitions of weight up to $W_{\max}$ are allowed.*

Proof. We again use potential function arguments to show the existence of α-approximate strong Nash equilibria but have to work with a more general potential function, compared to that used in unweighted games. Given a graph $G = (V, E, c)$ and a configuration $\mathcal{S} = (S_1, \ldots, S_n)$, let $E_{\mathcal{S}} = \cup_{i=1}^{n} S_i$ be the union of all edges used by the agents. For any $e \in E_{\mathcal{S}}$, let $W_e = \sum_{i:e\in S_i} w_i$ be the total weight of the agents currently using e in their strategies. Define

$$\Phi(\mathcal{S}) = \sum_{e\in E_{\mathcal{S}}} c(e)(1 + \ln W_e).$$

We show that while $\mathcal{S}$ does not form an α-approximate strong Nash equilibrium, an α-improvement move of a coalition I strictly decreases the potential. This ensures

that a sequence of improvement moves starting from the social optimum will converge because, at any time, $0 \leq \Phi \leq (1 + \ln W)cost(OPT)$.

Consider an α-improvement move of a coalition I of agents. Again, we view the move as being performed in two steps: (1) Agents $i \in I$ first drop all the edges of their strategies S_i. Let E_1 be this set of edges. (2) Agents $i \in I$ buy the edges they wish to have in their new strategies. Let E_2 be the set of edges involved. In the following, let $cost^-$ be the absolute value of the cost reduction experienced by I due to step (1). Note that $cost^-$ is equal to the cost of I in configuration $\mathcal{S}$. Let Φ^- be the absolute value of the potential drop. Similarly, let $cost^+$ be the value of the cost increase of I in step (2), and let Φ^+ be the corresponding potential increase. The value of $cost^+$ is equal to the cost of I in the new configuration after their strategy change. Using the definition of an α-improvement move, we find $\alpha cost^+ - cost^- < 0$. It remains to show that $cost^- \leq \Phi^-$ and $\Phi^+ \leq \alpha cost^+$, which implies $\Delta\Phi = -\Phi^- + \Phi^+ < 0$.

For any edge $e \in E$, let W_e^1 be the total weight of agents sharing e after step (1). The cost reduction experienced by I due to edge $e \in E_1$ is $cost_e^- = c(e)(W_e - W_e^1)/W_e$. For any $e \in E_1$, let Φ_e^- denote the potential drop caused by this edge. If $W_e^1 = 0$, then $cost_e^- = c(e) \leq c(e)(1 + \ln W_e) = \Phi_e^-$. If $W_e^1 > 0$, then $W_e^1 \geq 1$ and

$$cost_e^- = c(e)\frac{W_e - W_e^1}{W_e} \leq c(e)\int_{W_e^1}^{W_e} \frac{1}{z}dz = c(e)(\ln W_e - \ln W_e^1) = \Phi_e^-.$$

We conclude that $cost^- = \sum_{e \in E_1} cost_e^- \leq \sum_{e \in E_1} \Phi_e^- = \Phi^-$.

For any $e \in E_2$ let W_e^2 be the total weight of agents sharing e after step (2). The cost increase experienced by I due to edge $e \in E_2$ is $cost_e^+ = c(e)(W_e^2 - W_e^1)/W_e^2$ because agents in I purchasing e have a total weight of $W_e^2 - W_e^1$. Let Φ_e^+ be the potential increase caused by $e \in E_2$. If $W_e^1 = 0$, then $\Phi_e^+ = c(e)(1 + \ln W_e^2) \leq c(e)(1 + \ln(1 + \overline{W})) \leq \alpha cost_e^+$. If $W_e^1 > 0$, then $\Phi_e^+ = c(e)(\ln W_e^2 - \ln W_e^1) = c(e)\ln(W_e^2/W_e^1)$. To establish $\Phi_e^+ \leq \alpha cost_e^+$, we prove that

$$f(W_e^2) = \ln(W_e^2/W_e^1) - (1 + \ln(1 + \overline{W}))\frac{W_e^2 - W_e^1}{W_e^2}$$

is upper bounded by 0 for all $W_e^2 \geq W_e^1$. This implies, as desired, $\Phi^+ = \sum_{e \in E_2} \Phi_e^+ \leq \sum_{e \in E_2} \alpha cost_e^+ = \alpha cost^+$, because $\alpha \geq 1 + \ln(1 + \overline{W})$. Computing the first derivative of f, we find that f is decreasing for values of W_e^2 between W_e^1 and $(1+\ln(1+\overline{W}))W_e^1$ and increasing for larger values. Since $f(W_e^1) = 0$, we obtain that f is upper bounded by 0 for any W_e^2 with $W_e^1 \leq W_e^2 \leq (1 + \ln(1 + \overline{W}))W_e^1$. If $W_e^2 > (1 + \ln(1 + \overline{W}))W_e^1$, then $W_e^1 < W_e^2/(1 + \ln(1 + \overline{W}))$ and

$$(1 + \ln(1 + \overline{W}))(W_e^2 - W_e^1)/W_e^2 \geq \ln(1 + \overline{W}).$$

Hence

$$\begin{aligned} f(W_e^2) &\leq \ln(W_e^2/W_e^1) - \ln(1 + \overline{W}) \\ &= \ln\left(1 + \frac{W_e^2 - W_e^1}{W_e^1}\right) - \ln(1 + \overline{W}) \\ &\leq \ln(1 + \overline{W}) - \ln(1 + \overline{W}) = 0. \end{aligned}$$

The last inequality follows because $\frac{W_e^2 - W_e^1}{W_e^1} \leq W_e^2 - W_e^1$, since $W_e^1 \geq 1$, and $W_e^2 - W_e^1 \leq \overline{W}$, since agents of total weight at most $\overline{W}$ can join any edge e. ∎

THEOREM 5.2. *In any directed or undirected graph and for any $\alpha \geq 1$, the price of anarchy of α-approximate strong Nash equilibria is upper bounded by $\frac{\alpha n}{c}(1+\ln W^c)$ if coalitions of size up to c are allowed. The price of anarchy is upper bounded by $\frac{2\alpha W}{W_{\max}}(1+\ln W_{\max})$ if coalitions of weight up to $W_{\max}$ are allowed.*

If there are no restrictions on the coalitions being formed and for $\alpha = 1$, we obtain the following corollary.

COROLLARY 5.3. *In any directed or undirected graph the price of anarchy of strong Nash equilibria is upper bounded by $1+\ln W$.*

Proof of Theorem 5.2. We generalize the proof of Theorem 3.3. Given an α-approximate strong Nash equilibrium $\mathcal{S} = (S_1, \ldots, S_n)$, we consider a coalition I of legal size or weight and show

$$\sum_{i \in I} cost_i(\mathcal{S}) \leq \alpha(1+\ln W_I) cost_i(OPT), \tag{5.1}$$

where W_I it the total weight of agents $i \in I$. If coalitions of size up to c are allowed, inequality (5.1) gives $\sum_{i\in I} cost_i(\mathcal{S}) \leq \alpha(1+\ln W^c) cost(OPT)$. Summing this inequality over all the $\binom{n}{c}$ coalitions of size exactly c, we obtain $cost(\mathcal{S}) \leq \frac{\alpha n}{c}(1+\ln W^c) cost(OPT)$. If coalitions of weight up to $W_{\max}$ are allowed, we partition the n agents into maximal possible coalitions of admissible weight. This partitioning consists of at most $2W/W_{\max}$ coalitions because only one of these coalitions can have a total weight of at most $W_{\max}/2$ and the total weight of any two coalitions is larger than $W_{\max}$. For each coalition of the partitioning we sum up (5.1) and obtain $cost(\mathcal{S}) \leq \frac{2\alpha W}{W_{\max}}(1+\ln W_{\max}) cost(OPT)$.

In order to establish (5.1), for any fixed coalition I, we perform the same process as in the proof of Theorem 3.3, where subcoalitions of I change strategy and purchase the edge set E^{OPT} of the social optimum. For any $i \in I$, let $E_i^{OPT} \subseteq E^{OPT}$ be a minimal edge set necessary to connect the terminals of agent i in the optimal solution. The process starts with $I_1 := I$. In the kth step, for $k = 1, \ldots, |I|$, agents i in the remaining subcoalition I_k change strategies and connect their terminals using E_i^{OPT}. Since the original configuration $\mathcal{S}$ is an α-approximate strong Nash equilibrium, there must exist one agent i_k whose cost in the original configuration $\mathcal{S}$ is bounded by

$$cost_{i_k}(\mathcal{S}) \leq \alpha \sum_{e \in E_{i_k}^{OPT}} c(e) \frac{w_{i_k}}{W_{I_k}^e}, \tag{5.2}$$

where $W_{I_k}^e$ is the total weight of agents sharing e, i.e., $W_{I_k}^e = \sum_{i \in I_k^e} w_i$ with $I_k^e = \{i : i \in I_k \text{ and } e \in E_i^{OPT}\}$. This agent i_k leaves the process, and $I_{k+1} := I_k \setminus \{i_k\}$. Summing (5.2) over all the $|I|$ steps, we obtain

$$\sum_{i \in I} cost_i(\mathcal{S}) \leq \alpha \sum_{k=1}^{|I|} \sum_{e \in E_{i_k}^{OPT}} c(e) \frac{w_{i_k}}{W_{I_k}^e}. \tag{5.3}$$

We estimate the contribution of $c(e)$, for a fixed edge $e \in E^{OPT}$, in the right-hand side expression of (5.3). A contribution to the sum occurs whenever an agent $i \in I$ with $e \in E_i^{OPT}$ leaves the process. Let $i_1, \ldots, i_\ell \in I$ be the agents using e, i.e., $e \in E_{i_j}^{OPT}$ for $j = 1, \ldots, \ell$, and assume that these agents are numbered according to the time when they leave the process of strategy changes. For $j = 1, \ldots, \ell$, let $s_j = w_{i_j} + \cdots + w_{i_\ell}$

be the suffix sum of these agents' weights. Then edge e contributes a total of

$$\begin{aligned}
&c(e)\left(\frac{w_{i_1}}{w_{i_1}+\cdots+w_{i_\ell}}+\frac{w_{i_2}}{w_{i_2}+\cdots+w_{i_\ell}}+\cdots+\frac{w_{i_\ell}}{w_{i_\ell}}\right)\\
&\le c(e)\left(\sum_{j=1}^{\ell-1}\int_{s_{j+1}}^{s_j}\frac{1}{z}dz+1\right)\le c(e)\left(1+\int_{s_\ell}^{s_1}\frac{1}{z}dz\right)\\
&\le c(e)\left(1+\int_{1}^{s_1}\frac{1}{z}dz\right)=c(e)(1+\ln s_1)\\
&\le c(e)(1+\ln W_I).
\end{aligned}$$

The third inequality holds because $s_\ell = w_\ell \ge 1$. Summing this cost estimate over all edges $e \in E^{OPT}$, we obtain the desired bound on $\sum_{i\in I} cost_I(\mathcal{S})$. ∎

5.2. Lower bounds. We develop lower bounds on the performance of strong Nash equilibria in directed and undirected graphs.

THEOREM 5.4. *In directed graphs the price of anarchy of α-approximate strong Nash equilibria is at least $\Omega(\alpha \max\{n/c, \log W\})$ if coalitions of size at most c are allowed, and at least $\Omega(\alpha \max\{W/W_{\max}, \log W\})$ if coalitions of weight up to $W_{\max}$ are allowed.*

Proof. In the setting where coalitions of size up to c are permitted, a lower bound of $\alpha n/c$ was already shown for unweighted games in Theorem 4.1. We first prove the lower bound of $\alpha W/W_{\max}$ if coalitions of weight up to $W_{\max}$ are feasible. Consider n agents with arbitrary weights w_i, $1 \le i \le n$. We use the simple network depicted in Figure 4.1(a) but change the costs of the two parallel edges. The expensive edge now has cost αW, whereas the inexpensive one costs $W_{\max}+\epsilon$. Recall that all the n agents have to connect terminals s and t. The state in which all the agents establish their connection using the expensive edge forms an α-approximate strong Nash equilibrium: Any legal coalition incurs a cost of at most $\alpha W \frac{W_{\max}}{W} = \alpha W_{\max}$ on the expensive edge. Switching to the inexpensive edge results in a cost of $W_{\max}+\epsilon$ for the coalition, which is not attractive enough. Obviously, the social optimum routes connections via the inexpensive edge.

We next show a lower bound of $\Omega(\alpha \log W)$ for both scenarios, where either the size or the weight of a coalition is limited. Without loss of generality let W be a power of 2 and let $n = \log_2 W + 1$. We use the graph of Figure 4.1(b) but change the costs of the edges. Each edge (v_i, t) now has cost α, $1 \le i \le n$, and edge (w, t) has cost $2+\epsilon$. The edges (v_i, w) still have a cost of 0. Agent i, $1 \le i < n$, has a weight of $W/2^i$ and wishes to connect terminals v_i and t. The last agent n has a weight of 1 and has to connect v_n to t. The total weight of all of the n agents is exactly W. The state in which every agent i, $1 \le i \le n$, establishes its connection using edge (v_i, t) represents an α-approximate strong Nash equilibrium: In any coalition I of legal size or weight, the agent $i_0 \in I$ of maximum weight in I dominates the other agents in I; i.e., the weight of i_0 is at least as large as the total weight of all the other agents in I. Hence, when I changes strategy and purchases edge (w, t), agent i_0 has to pay at least $1+\epsilon/2$, and this is not smaller than an α-fraction of the cost incurred for the private edge (v_{i_0}, t). The cost of the strong Nash equilibrium is $\alpha(1+\log_2 W)$ while the social optimum incurs a cost of $2+\epsilon$. ∎

THEOREM 5.5. *For any $\alpha \ge 1$, there exists a family of undirected graphs, each admitting an α-approximate strong Nash equilibrium whose cost is $\Omega(\alpha\sqrt{\log W})$ times that of the social optimum.*

Proof. We extend the proof of Theorem 4.2 and first concentrate on $\alpha = 1$. Let W be a real weight with $\lfloor \sqrt{\log W} \rfloor \geq 2$. Again logarithms are taken to the base 3. As before we construct a graph $G = G^0$ in a recursive manner, choosing $d_{\max} = \lfloor \sqrt{\log W} \rfloor - 1$ in the case of weighted games. In any graph G^d, $0 \leq d \leq d_{\max}$, the edge costs are the same as those defined in the proof of Theorem 4.2. However, the number of associated agents changes. Associated with a graph $G^{d_{\max}}$ is *one* agent of order $d_{\max}$ having a weight of $w_{d_{\max}} = W/3^{d_{\max}(d_{\max}+1)}$. Associated with a graph G^d, $0 \leq d < d_{\max}$, is *one* agent of order d having a weight of $w_d = W/3^{d(d+1)} - 3W/3^{(d+1)(d+2)}$. The total weight of all the agents is exactly W. The total weight of all the agents associated with order-d graphs G^d and the subgraphs therein is $W_d = W/3^{d^2}$ for any $0 \leq d \leq d_{\max}$.

As edge costs have not changed, the social optimum is still constant. As usual, let $\mathcal{S}$ be the configuration in which an order-d agent purchases the arc of order-d within its graph. Then $cost(\mathcal{S}) \geq d_{\max} + 1 \geq \lfloor \sqrt{\log W} \rfloor$.

To show that $\mathcal{S}$ forms a strong Nash equilibrium, we can extend Lemmas 4.4 and 4.5 in a straightforward way. In the arguments agent numbers such as n_d and N_{d+1} are to be replaced by weights w_d and W_{d+1}. Some of the arguments and calculations in the proofs simplify because ceilings can be ignored and fractions f and f_k^j, reflecting portions of order-d agents that defect from routing through their order-d arcs, are now equal to either 0 or 1. Finally, for $\alpha > 1$, we again scale the arc costs by α. □

6. The price of stability in undirected graphs. In this section we address the price of stability of standard Nash equilibria in weighted games. Anshelevich et al. [2] showed a lower bound of $\Omega(\log W)$ for directed graphs. Again, $W = \sum_{i=1}^{n} w_i$ is the total weight of all the agents. We prove a lower bound for undirected graphs. No superconstant lower bound was known for undirected graphs, for neither unweighted nor weighted games.

THEOREM 6.1. *In undirected graphs the price of stability is* $\Omega(\log W / \log\log W)$. *This lower bound holds even if each agent has to connect only a pair of terminals. Individual terminal pairs are allowed.*

Proof. We construct a family of graphs, each admitting only one Nash equilibrium. The cost of this equilibrium will be $\Omega(\log W / \log\log W)$ times that of the social optimum. The basic structure of the graphs is the same as those constructed in the proof of Theorem 4.2. However, the parameters are chosen differently here. Let W be a positive integer with $\log W \geq 3$. Again, logarithms are taken to the base 3. Let $d_{\max} = \lfloor \log W / (\log\log W + 1) \rfloor$. Inequality $\log W \geq 3$ implies $d_{\max} \geq 1$.

In the basic graphs $G^{d_{\max}}$ a stem edge has cost $s_{d_{\max}} = 1/3^{d_{\max}}$, and the bridge of order $d_{\max}$ has cost $b_{d_{\max}} = 3/(3^{d_{\max}} \log W)$. The arc of order $d_{\max}$ costs $a_{d_{\max}} = 1/3^{d_{\max}}$. Associated with any $G^{d_{\max}}$ is one order-$d_{\max}$ agent of weight $w_{d_{\max}} = W/(3\log W)^{d_{\max}}$ wishing to connect the base and the tip of $G^{d_{\max}}$.

For any d, $0 \leq d < d_{\max}$, in a graph G^d of order d, the bridge of order d has cost $b_d = 3/(3^d \log W)$, and the arc of order d costs $a_d = 1/3^d$. Associated with G^d is one order-d agent of weight $w_d = W/(3\log W)^d - 3W/(3\log W)^{d+1}$ having to connect the base and the tip of G^d. The outermost graph $G = G^0$ is the graph we will work with.

The total weight of agents associated with one order-d graph G^d and all the subgraphs therein is $W_d = W/(3\log W)^d$. This holds for $d = d_{\max}$. Suppose that the property holds for orders $d_{\max}, d_{\max} - 1, \ldots, d + 1$. Since a graph of order d is composed of three graphs of order $d + 1$, the total weight of agents in G^d is equal to

$$W_d = w_d + 3W/(3\log W)^{d+1} = W/(3\log W)^d.$$

In particular, we obtain that the total weight of agents in $G = G^0$ is exactly W.

PROPOSITION 6.2. *The least expensive path connecting the base and the tip of a graph G^d using only edges of G^d has a total edge cost of exactly $1/3^d$ for any $0 \le d \le d_{\max}$.*

Proof. The statement of the proposition holds for $d = d_{\max}$ because the arc of $G^{d_{\max}}$ has cost $a_{d_{\max}} = 1/3^{d_{\max}}$, while the path crossing the bridge has cost $b_{d_{\max}} + s_{d_{\max}} = 3/(3^{d_{\max}} \log W) + 1/3^{d_{\max}}$. Assume that the statement of the proposition holds for depths $d_{\max}, \ldots, d+1$. In G^d the arc of order d has cost $a_d = 1/3^d$, while, by the induction hypothesis, any path using the bridge of order d has a cost of at least $b_d + 3 \cdot 1/3^{d+1} = 3/(3^d \log W) + 1/3^d > 1/3^d$. ∎

The social optimum in G buys the backbone consisting of stem edges and bridges. There exist exactly $3^{d_{\max}}$ subgraphs of order $d_{\max}$, and hence the total cost of stem edges is $3^{d_{\max}} s_{d_{\max}} = 1$. For any fixed d, $0 \le d \le d_{\max}$, graph G contains 3^d graphs of order d, each being equipped with an order-d bridge of cost $b_d = 3/(3^d \log W)$. Thus the total cost of order-d bridges is $3^d b_d = 3^d \cdot 3/(3^d \log W) = 3/\log W$. Summing over all d we find that the total cost of bridges is upper bounded by $(d_{\max} + 1) \cdot 3/\log W \le (2 \log W/\log\log W)(3/\log W) \le 6/\log\log W \le 6$. Hence the cost of the social optimum is constant.

Consider configuration $\mathcal{S}$ in which, for any graph G^d within G, the order-d agent associated with G^d purchases the order-d arc in this graph. We will prove in the following that $\mathcal{S}$ is a Nash equilibrium and that it is the only Nash equilibrium in G. As there are 3^d graphs of order d, the total cost of order-d arcs is $3^d a_d = 3^d \cdot 1/3^d = 1$, and summing over all d we obtain $cost(\mathcal{S}) = d_{\max} + 1 \ge \log W/(\log\log W + 1)$, which gives the stated lower bound on the price of stability.

In the remainder of this proof we show, in a first step, that $\mathcal{S}$ forms a Nash equilibrium and then, in a second step, that $\mathcal{S}$ is the only equilibrium in G.

We proceed with the proof that $\mathcal{S}$ forms an equilibrium state. Let i be an order-d agent associated with a graph G^d. We show that any strategy change performed by i yields a strictly higher cost. If i deviates from its original strategy in $\mathcal{S}$, it can establish the required connection either (1) by using a path within G^d or (2) by using a path of edges outside G^d.

In case (1), the path P_i used by agent i to connect its terminal pair has to traverse the order-d bridge in G^d, which has a cost of $b_d = 3/(3^d \log W)$. If $d = d_{\max}$, path P_i continues on the stem edge of cost $s_{d_{\max}} = 1/3^{d_{\max}}$. If $d < d_{\max}$, then P_i has to traverse three graphs of order $d+1$, the total cost of which is at least $3 \cdot 1/3^{d+1} = 1/3^d$. The total weight of agents that can share the cost of P_i is upper bounded by W_d. Thus agent i incurs a cost of at least

$$\frac{w_d}{W_d} \cdot \frac{1}{3^d}\left(1 + \frac{3}{\log W}\right).$$

If $d = d_{\max}$, then $w_d = W_d$ and the latter expression is larger than the cost of $1/3^{d_{\max}}$ incurred for buying the order-$d_{\max}$ arc in $G_{d_{\max}}$. If $d < d_{\max}$, then we have

$$\begin{aligned}
\frac{w_d}{W_d} \cdot \frac{1}{3^d}\left(1 + \frac{3}{\log W}\right) &= \frac{W/(3\log W)^d - 3W/(3\log W)^{d+1}}{W/(3\log W)^d} \cdot \frac{1}{3^d}\left(1 + \frac{3}{\log W}\right) \\
&= \left(1 - \frac{1}{\log W}\right)\left(1 + \frac{3}{\log W}\right)\frac{1}{3^d} \\
&= \frac{\log^2 W + 2\log W - 3}{\log^2 W} \cdot \frac{1}{3^d} \\
&> 1/3^d,
\end{aligned}$$

because $\log W \geq 3$. Again, buying the order-d arc of cost $a_d = 1/3^d$ is a strictly better strategy.

In case (2), we have $d > 0$, and the path P_i used by agent i crosses the bridge of order $d-1$ and visits the base of graph G^{d-1} containing G^d. The structure of P_i is depicted in Figures 4.3(a)–(c), which we used in the proof of Theorem 4.2; the situation here is the very same. To reach the tip of G^d, path P_i must visit the tip of G^{d-1}, from where it can continue. Path P_i must fully traverse two subgraphs of order d within G^{d-1}. Such a subgraph can be traversed on an arc of order d, having cost $a_d = 1/3^d$, where the weight of the agent that bought this arc in $\mathcal{S}$ is w_d. Thus the cost of a_d can be shared among two order-d agents. If P_i does not use the order-d arc, the total cost of edges traversing an order-d subgraph is at least $1/3^d$, and the total weight of agents sharing the edge cost is $W_d - w_d < w_d$. Thus, for the traversal of the two order-d subgraphs, agent i pays at least

$$2\frac{w_d}{2w_d} \cdot \frac{1}{3^d} = \frac{1}{3^d}.$$

Since the traversal of the order-$(d-1)$ bridge has positive cost, path P_i incurs a cost strictly higher than that of the original strategy of i in $\mathcal{S}$.

It remains to show that $\mathcal{S}$ is the only Nash equilibrium. To this end we will prove that in any Nash equilibrium, an order-d agent associated with a given graph G^d must buy the corresponding order-d arc in G^d. In other words, an equilibrium state must be equal to $\mathcal{S}$. The desired statement that in any Nash equilibrium an order-d agent purchases the corresponding order-d arc in its graph G^d follows from the next lemma. Loosely speaking, this lemma says that in a Nash equilibrium connections in G are established locally. We first state the lemma and then explain its implications.

LEMMA 6.3. *Consider a fixed order-d graph G^d in G and assume that in any Nash equilibrium all the agents associated with G^d and its subgraphs establish their connections using only edges of G^d. Furthermore, assume that all agents* not *associated with G^d or its subgraphs do* not *use any edges of G^d when routing their connections. Then in any Nash equilibrium the following two properties hold.*

(a) *The order-d agent associated with G^d buys the arc of order d in G^d.*

(b) *If $d < d_{\max}$, then for any of the three order-$(d+1)$ subgraphs G_k^{d+1}, $1 \leq k \leq 3$, within G^d, the agents associated with G_k^{d+1} and its subgraphs establish their connections using only edges of G_k^{d+1}.*

Using this lemma we can finish the proof of our theorem: For $d = 0$, trivially, all agents associated with $G = G^0$ and its subgraphs must establish connections within G^0, and there exist no agents outside G^0 that could use edges of G^0. Thus the conditions of Lemma 6.3 are met, and we obtain that the order-0 agent buys the arc of order 0 (part (a)) and that, for any of the three subgraphs G_k^1, $1 \leq k \leq 3$, agents associated with any G_k^1 and its subgraphs establish connections using only edges of this graph G_k^1 (part (b)). Inductively, Lemma 6.3 yields that, for any d, (a) any order-d agent purchases the order-d arc within its graph and (b) for any subgraph G^{d+1} of order $d+1$, all agents associated with G^{d+1} at its subgraphs establish the required connections locally within G^{d+1}.

Proof of Lemma 6.3. Part (a): Suppose that in a Nash equilibrium, an order-d agent associated with a graph G^d does not purchase the arc of order d. Let P be the path used by the agent to connect its terminal pair. Since, by assumption of the lemma, the agent establishes its connection within G^d, path P must cross the order-d bridge; see Figures 4.2(a) and (b). If $d = d_{\max}$, then the path traverses the stem edge

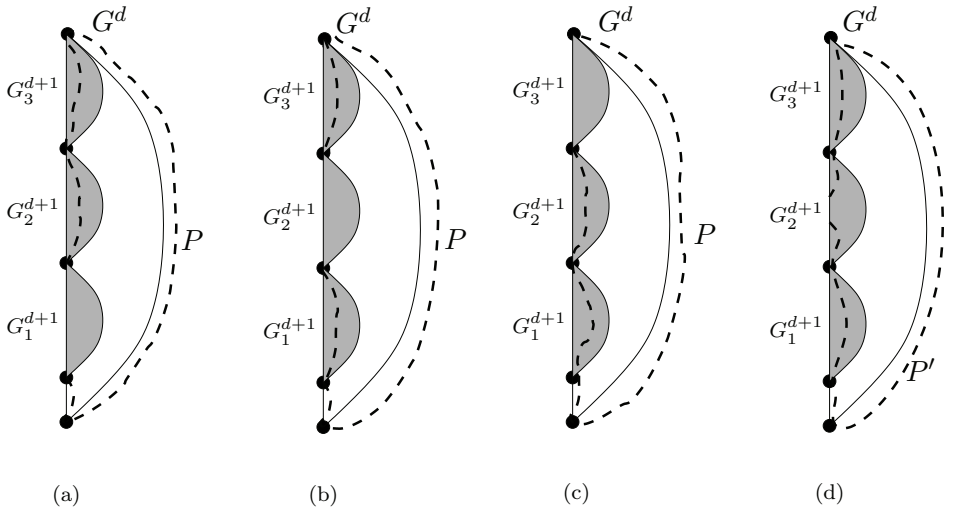

FIG. 6.1. *The paths taken by an order-$(d+1)$ agent within G_k^d, $1 \le k \le 3$.*

of cost $s_{d_{\max}} = 1/3^{d_{\max}}$ in $G^d = G^{d_{\max}}$ to reach the tip of the graph. If $d < d_{\max}$, path P traverses the three subgraphs G_k^{d+1}, $1 \le k \le 3$, to reach the tip of G^d. When traversing the subgraphs, then by Proposition 6.2 path P visits edges of total cost at least $3 \cdot 1/3^{d+1} = 1/3^d$. Hence, in any case, the total cost of edges traversed by P is at least $b_d + 1/3^d = 3/(3^d \log W) + 1/3^d = (1 + 3/\log W)/3^d$. By assumption of the lemma, agents not associated with G^d or its subgraphs do not use edges of G^d. Hence the cost of P is shared by agents of total weight at most $W_d = W/(3 \log W)^d$ that are associated with G^d and its subgraphs. Hence the total cost of the order-d agent is at least $\frac{w_d}{W_d} \frac{1}{3^d}(1 + \frac{3}{\log W})$. We argue that this expression is strictly larger than $a_d = 1/3^d$, which is the cost of purchasing the arc of order d. If $d = d_{\max}$, then $w_d = W_d$ and we are done. If $d < d_{\max}$, then as shown on the previous page we have $\frac{w_d}{W_d} \frac{1}{3^d}(1 + \frac{3}{\log W}) > \frac{1}{3^d}$.

Part (b): We first prove that any order-$(d+1)$ agent associated with a graph G_k^{d+1}, $1 \le k \le 3$, establishes its connection within G_k^{d+1}. We then show that agents of order larger than $d+1$ associated with subgraphs of G_k^{d+1}, if such subgraphs exist, also route their connections within G_k^{d+1}.

In a first step we lower bound the cost incurred by order-$(d+1)$ agents if they buy edges outside their graph. In the following, if $d+1 = d_{\max}$, we set $W_{d+2} = 0$.

CLAIM 1. *If the agent of order $d+1$ associated with a graph G_k^{d+1} establishes its connection using edges outside G_k^{d+1}, then its total cost is at least $C = \frac{2w_{d+1}}{2w_{d+1}+9W_{d+2}} \frac{1}{3^{d+1}}(1 + \frac{3}{\log W})$.*

Proof. We first show that if the order-$(d+1)$ agent associated with G_k^{d+1} implements its connection using edges outside G_k^{d+1}, then the path P used by this agent must traverse the bridge of order d as well as the other two graphs of order $d+1$ within G^d. We consider all possible values of k and refer the reader to Figures 6.1(a)–(c) for the structure of P. The situation is the same as that described in Figures 4.3(a)–(c); the only difference is that here the outer graph has order d instead of $d-1$. Recall that strategies are simple paths connecting the desired terminals. If $k = 1$ (cf. Figure 6.1(a)), then the order-$(d+1)$ agent associated with G_1^{d+1} must traverse the order-d

bridge of G^d. In order to reach the tip of G_1^{d+1}, path P must visit the tip of G^d from where P traverses G_3^{d+1} and G_2^{d+1}. Similarly, if $k = 2$ (cf. Figure 6.1(b)), then path P traverses G_1^{d+1}, crosses the bridge of order d, travels to the tip of G^d, and visits G_3^{d+1} to reach the tip of G_2^{d+1}. Finally, if $k = 3$ (cf. Figure 6.1(c)), path P must traverse G_2^{d+1} and G_1^{d+1}. The path then crosses the bridge of order d and travels to the tip of G^d, which is also the tip of G_3^{d+1}.

We lower bound the cost incurred by the order-$(d+1)$ agent associated with G_k^{d+1} for path P. For brevity, we will denote this agent by i_k. By the assumptions of the lemma to be proved, agents not associated with G^d or its subgraphs do not use edges of G^d. Graph G^d contains three order-$(d+1)$ agents of total weight $3w_{d+1}$. If $d \le d_{\max} - 2$, then G^d also contains nine graphs of order $d+2$, each hosting agents of total weight W_{d+2}. We set $W_{d+2} = 0$ if $d = d_{\max} - 1$. We argued in the last paragraph that path P must cross the bridge of order d, which has a cost of $b_d = 3/(3^d \log W)$. This cost is split among agents of total weight at most $3w_{d+1} + 9W_{d+2}$. Hence, for the bridge of order d, agent i_k pays at least

$$\frac{w_{d+1}}{3w_{d+1} + 9W_{d+2}} \cdot \frac{3}{3^d \log W} \ge \frac{2w_{d+1}}{2w_{d+1} + 9W_{d+2}} \cdot \frac{3}{3^{d+1} \log W}. \tag{6.1}$$

Also, as argued in the last paragraph, path P connecting the terminals of i_k has to traverse the other two subgraphs of order $d+1$ in G^d, which are indexed $k' = k \bmod 3 + 1$ and $k'' = (k+1) \bmod 3 + 1$. To traverse one such subgraph, path P traverses edges of total cost at least $1/3^{d+1}$. We distinguish cases depending on whether the order-$(d+1)$ agents associated with $G_{k'}^{d+1}$ and $G_{k''}^{d+1}$ implement their connections using edges inside or outside their respective graphs. First, assume that the order-$(d+1)$ agents associated with $G_{k'}^{d+1}$ and $G_{k''}^{d+1}$ establish connections within their respective subgraphs. In this case path P encounters other agents of total weight at most $w_{d+1} + 9W_{d+2}$ in each of these subgraphs. Thus, the traversal cost of P is shared among agents of total weight at most $2w_{d+1} + 9W_{d+2}$. We obtain that agent i_k incurs a cost of at least

$$2\frac{w_{d+1}}{2w_{d+1} + 9W_{d+2}} \cdot \frac{1}{3^{d+1}} \tag{6.2}$$

for the traversal of $G_{k'}^{d+1}$ and $G_{k''}^{d+1}$. Next, assume that the order-$(d+1)$ agents associated with $G_{k'}^{d+1}$ and $G_{k''}^{d+1}$ establish connections using edges outside their graphs. In this case, again, path P encounters other agents of total weight at most $w_{d+1} + 9W_{d+2}$ when traversing any of these subgraphs (in $G_{k'}^{d+1}$ the associated order-$(d+1)$ agent is not present; the analogous statement holds for $G_{k''}^{d+1}$). Hence the cost incurred in traversing any of the two subgraphs $G_{k'}^{d+1}$ and $G_{k''}^{d+1}$ is shared among agents of total weight at most $2w_{d+1} + 9W_{d+2}$, and we obtain the same cost bound as that given in (6.2). Finally, assume that in exactly one of the subgraphs among $G_{k'}^{d+1}$ and $G_{k''}^{d+1}$ the associated order-$(d+1)$ agent establishes its connection within its subgraph. As for the other of the two subgraphs, the associated order-$(d+1)$ agent uses edges outside its graph. Without loss of generality let $G_{k'}^{d+1}$ be the graph where connections are made inside, and let $G_{k''}^{d+1}$ be the graph where connections are established using edges outside. The other case is symmetric. When P traverses $G_{k'}^{d+1}$, agents of total weight at most $2w_{d+1} + 9W_{d+2}$ are present, and cost sharing on edges can be done among agents of weight at most $3w_{d+1} + 9W_{d+2}$. When P visits $G_{k''}^{d+1}$, agents of total weight at most $9W_{d+2}$ are present: The order-$(d+1)$ agent associated with $G_{k'}^{d+1}$ is

not present because it uses connections inside its graph, and the order-$(d+1)$ agent associated with $G_{k''}^{d+1}$ is not present because it uses a strategy outside its graph. Hence cost sharing on edges can be done among agents of total weight at most $w_{d+1}+9W_{d+2}$ and the cost incurred by i_k in traversing the two other order-$(d+1)$ graphs is at least

$$\left(\frac{w_{d+1}}{3w_{d+1}+9W_{d+2}}+\frac{w_{d+1}}{w_{d+1}+9W_{d+2}}\right)\frac{1}{3^{d+1}} \geq 2\frac{w_{d+1}}{2w_{d+1}+9W_{d+2}}\cdot\frac{1}{3^{d+1}},$$

which is the same expression as (6.2). Summing the costs incurred for crossing the order-d bridge and for traversing other order-$(d+1)$ graphs (see (6.1) and (6.2)), we conclude that agent i_k pays at least the cost of C stated in the claim. □

If the order-$(d+1)$ agent associated with G_k^{d+1} purchases the arc of order $d+1$ within G_k^{d+1}, its cost is at most $a_{d+1}=1/3^{d+1}$. A strategy using edges outside the graph incurs a cost of at least C as stated in the above claim. We show that $C > a_{d+1}$, which proves that in a Nash equilibrium the order-$(d+1)$ agent associated with G_k^{d+1} establishes the required connection via the order-$(d+1)$ arc. If $d = d_{\max}-1$, then $W_{d+2}=0$, and we are done because $C=\frac{1}{3^{d+1}}(1+\frac{3}{\log W})>\frac{1}{3^{d+1}}$.

If $d \leq d_{\max}-2$, then

$$C=\frac{2w_{d+1}}{2w_{d+1}+9W_{d+2}}\frac{1}{3^{d+1}}\left(1+\frac{3}{\log W}\right)=\frac{1}{1+(9W_{d+2}/2w_{d+1})}\frac{1}{3^{d+1}}\left(1+\frac{3}{\log W}\right).$$

It remains to show $9W_{d+2}/(2w_{d+1}) < 3/\log W$, which proves the desired inequality $C > 1/3^{d+1}$. We have

$$\frac{9W_{d+2}}{2w_{d+1}}=\frac{9W/(3\log W)^{d+2}}{2W/(3\log W)^{d+1}-6W/(3\log W)^{d+2}}=\frac{3}{2\log W-2}<\frac{3}{\log W}.$$

The last inequality holds because $\log W \geq 3$.

To finish the proof of part (b) of the lemma we have to show that if $d \leq d_{\max}-2$, then any agent i of order $d+2$ or larger that is associated with a subgraph of G_k^{d+1}, $1 \leq k \leq 3$, establishes its connection within G_k^{d+1}. Suppose this were not the case. Then agent i chooses a path P that leaves G_k^{d+1} through its base. Figure 6.1(d) shows a sample path for $k=2$. To connect to the desired terminal, path P must visit the tip of G_k^{d+1} from where it can continue on edges inside G_k^{d+1}. Since P uses edges outside G_k^{d+1}, it does not use the arc of order $d+1$ in G_k^{d+1} and hence must traverse the bridge of order d in G^d. The cost of this bridge is shared by agents of total weight at most $9W_{d+2}$ because we have shown that all the agents of order $d+1$ in G^d establish connections within their respective subgraphs and the order-d agent associated with G^d purchases the arc of order d (see part (a)). Let P' be the subpath of P connecting the base and the tip of G_k^{d+1}. On P' agent i incurs a cost of at least

$$cost(P') \geq \frac{w(i)}{9W_{d+2}}\frac{3}{3^d\log W},$$

where $w(i)$ is the weight of agent i. In the given Nash equilibrium, consider the strategy used by the order-$(d+1)$ agent associated with G_k^{d+1}. The cost of this agent is at most $1/3^{d+1}$ because this is the cost incurred when buying the order-$(d+1)$ arc in G_k^{d+1}, which is always an option. This order-$(d+1)$ agent has to connect the base and the tip of G_k^{d+1} and, as shown in the previous paragraphs, use edges within G_k^{d+1}. Now, agent i can replace P' by the strategy used by the order-$(d+1)$ agent of G_k^{d+1},

incurring a cost of at most $w(i)/(w(i)+w_{d+1})\cdot 1/3^{d+1} \le w(i)/w_{d+1}\cdot 1/3^{d+1}$. We show that the latter expression is strictly smaller than the cost $cost(P')$, contradicting the fact that the configuration in which i used edges outside G_k^{d+1} was a Nash equilibrium. Inequality $cost(P') > w(i)/w_{d+1}\cdot 1/3^{d+1}$ is equivalent to showing $9W_{d+2}/w_{d+1} < 9/\log W$. We have

$$\frac{9W_{d+2}}{w_{d+1}} = \frac{9W/(3\log W)^{d+2}}{W/(3\log W)^{d+1} - 3W/(3\log W)^{d+2}} \le \frac{3}{\log W - 1} < \frac{9}{\log W},$$

since $\log W \ge 3$. □

This completes the proof of the theorem. □

The lower bound of Theorem 6.1 is nearly tight. First, the potential function arguments of the proof of Theorem 5.1 imply that there exists an α-approximate Nash equilibrium whose cost is at most $1+\ln W$ times that of the social optimum if $\alpha \ge 1+\ln(1+w_{\max})$. Here $w_{\max}$ is the maximum weight of any agent. Second, Chen and Roughgarden [7] showed that in directed graphs, for any $\alpha = \Omega(\log w_{\max})$, the price of stability of α-approximate Nash equlibria is $O((\log W)/\alpha)$. This result can be extended to undirected graphs.

7. Conclusions. In this paper we have investigated the value of coordination in network design games. We have developed lower and upper bounds on the price of anarchy attained by strong Nash equilibria in unweighted and weighted games, considering both undirected and directed graphs. It shows that strong Nash equilibria achieve much better performance ratios than standard Nash equilibria and that these ratios are often as good as those of the best standard equilibrium states. There is still room for improvements. For undirected graphs we have developed an upper bound of $H_n \approx \ln n$ and a lower bound of $\Omega(\sqrt{\log n})$ on the price of anarchy in unweighted games. In weighted games the bounds are $1+\ln W$ and $\Omega(\sqrt{\log W})$, respectively. An interesting open problem is to determine the true ratios for undirected graphs.

Furthermore, in this paper we have also devised the first superconstant lower bound on the price of stability in undirected graphs. More specifically, we proved a lower bound of $\Omega(\log W/\log\log W)$ for weighted network design games. A challenging open problem is to determine the price of stability in unweighted games.

Appendix.

Proof of Proposition 3.1. We prove the result for undirected graphs and then show how to direct edges to obtain the desired statement for directed networks as well. Consider the graph given in Figure A.1. We have a vertex set $V = \{v_1, v_2, v_3, w_1, w_2, w_3, t\}$, where vertex w_i is connected to t via a *main edge* $\{w_i, t\}$ of cost 1, $1 \le i \le 3$. Furthermore, there are *auxiliary edges* $\{v_i, w_i\}$ of cost $1/2$ and *auxiliary edges* $\{v_i, w_{i \bmod 3+1}\}$ of cost $1/2+\epsilon$, $1 \le i \le 3$. Here $\epsilon > 0$ is an arbitrarily small value. Associated with the graph are three agents, where agent i has to connect terminals v_i and t, $1 \le i \le 3$. We will consider all possible states and show that none represents a strong Nash equilibrium. Any state in which all of the three main edges are purchased does not form a strong Nash equilibrium because two agents i and $i' = i \bmod 3 + 1$ could team up, sharing the main edge $\{w_{i'}, t\}$. As the original cost of each of the two agents was at least $1+1/6 = 7/6$ and the new cost is at most $1+\epsilon$, this yields a cost reduction for each member of the coalition.

Next suppose that there exists a strong Nash equilibrium in which two agents share a main edge $\{w_i, t\}$, while the third agent buys a second main edge $\{w_j, t\}$, $j \ne i$. Then agent i is one of the agents sharing $\{w_i, t\}$ and connects to w_i using

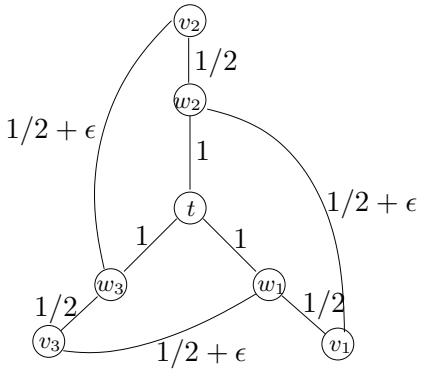

FIG. A.1. *A graph without a strong Nash equilibrium.*

edge $\{v_i, w_i\}$ since otherwise agent i could strictly improve its cost by purchasing a third of $\{w_i, t\}$. We now distinguish cases depending on whether $j = i \bmod 3 + 1$ or $j = (i + 1) \bmod 3 + 1$. Note that our graph is symmetric in vertex index and agent number i. Thus we may assume without loss of generality that $i = 1$; i.e., agent 1 and some other agent share $\{w_1, t\}$. A third agent buys $\{w_j, t\}$, where $j = 2$ or $j = 3$. We distinguish cases depending on whether $j = 2$ or $j = 3$.

If $j = 2$, then agent 2 must be the one buying $\{w_2, t\}$ as connecting v_2 to w_1 requires the traversal of three auxiliary edges, the cost of which is at least $1/2 + \epsilon/3$. This cost is higher than that of buying $\{v_2, w_2\}$, and hence agent 2 would prefer to share $\{w_2, t\}$ instead of $\{w_1, t\}$. Thus agent 3 shares main edge $\{w_1, t\}$ and connects to w_1 using edge $\{v_3, w_1\}$ of cost $1/2+\epsilon$ because any other path of auxiliary edges has a strictly higher cost. We conclude that agent 2 pays a cost of $3/2$ and agent 3 a cost of $1/2 + \epsilon + 1/2 = 1 + \epsilon$. Now agents 2 and 3 can form a coalition, sharing main edge $\{w_3, t\}$. The new cost of agent 2 is $1/2+\epsilon+1/2 < 3/2$ and the new cost of agent 3 is $1/2+1/2 < 1+\epsilon$, contradicting the assumption that the original configuration was a strong Nash equilibrium.

If $j = 3$, then again agent 3 buys main edge $\{w_3, t\}$: If agent 3 shared $\{w_1, t\}$ and agent 2 bought $\{w_3, t\}$, agent 2 would connect to w_3 using edge $\{v_2, w_3\}$ and agent 3 would connect to w_1 using edge $\{v_3, w_1\}$ as other paths of auxiliary edges are strictly more expensive. Both agents pay a cost of $1/2 + \epsilon$ for these connections. In this situation agent 3 could strictly improve its cost by connecting to w_3 and sharing $\{w_3, t\}$ instead of $\{w_1, t\}$. We conclude that agent 2 shares main edge $\{w_1, t\}$ and connects to w_1 at a cost of $1 + \epsilon + 1/4$. Now agent 2 can improve its cost by buying edge $\{v_2, w_3\}$ at a cost of $1/2 + \epsilon$ and sharing edge $\{w_3, t\}$ instead of $\{w_1, t\}$. We obtain a contradiction to the fact that the original configuration was a strong Nash equilibrium.

We finally have to investigate the case that a configuration buys only one main edge $\{w_i, t\}$, the cost of which is shared among the three agents. Again we may assume without loss of generality that $i = 1$. Then agent 3 connects to w_1 using edge $\{v_3, w_1\}$ and agent 2 connects to w_1 using a path of auxiliary edges that results in a cost of at least $1 + \epsilon + 1/4$. Hence the total cost of agent 2 is at least $1 + 1/4 + 1/3 + \epsilon > 3/2$, and agent 2 can improve its strategy by buying edges $\{v_2, w_2\}$ and $\{w_2, t\}$.

We note that the graph can be extended to any agent number n by inserting nodes $v_4, \ldots, v_n$ affiliated with agents numbered 4 to n, where agent i wishes to connect v_i to t, $4 \le i \le n$. Each such v_i is connected to t via a private edge.

This concludes the analysis of undirected graphs. To obtain the result for directed graphs we simply direct edges toward the destination t. We have *main edge* (w_i, t) as well as *auxiliary edges* (v_i, w_i) and $(v_i, w_{i \bmod 3+1})$, $1 \leq i \leq 3$. Directing the edges only restricts the set of possible states, while all strategy changes proposed above can still be performed. □

METRIC EMBEDDINGS WITH RELAXED GUARANTEES*

T.-H. HUBERT CHAN†, KEDAR DHAMDHERE‡, ANUPAM GUPTA§, JON KLEINBERG¶, AND ALEKSANDRS SLIVKINS‖

Abstract. We consider the problem of embedding finite metrics with *slack*: We seek to produce embeddings with small dimension and distortion while allowing a (small) constant fraction of all distances to be arbitrarily distorted. This definition is motivated by recent research in the networking community, which achieved striking empirical success at embedding Internet latencies with low distortion into low-dimensional Euclidean space, provided that some small slack is allowed. Answering an open question of Kleinberg, Slivkins, and Wexler [in *Proceedings of the* 45*th IEEE Symposium on Foundations of Computer Science*, 2004], we show that provable guarantees of this type can in fact be achieved in general: Any finite metric space can be embedded, with constant slack and constant distortion, into constant-dimensional Euclidean space. We then show that there exist stronger embeddings into ℓ_1 which exhibit *gracefully degrading* distortion: There is a single embedding into ℓ_1 that achieves distortion at most $O(\log \frac{1}{\epsilon})$ on all but at most an ϵ fraction of distances *simultaneously* for all $\epsilon > 0$. We extend this with distortion $O(\log \frac{1}{\epsilon})^{1/p}$ to maps into general ℓ_p, $p \geq 1$, for several classes of metrics, including those with bounded doubling dimension and those arising from the shortest-path metric of a graph with an excluded minor. Finally, we show that many of our constructions are tight and give a general technique to obtain lower bounds for ϵ-slack embeddings from lower bounds for low-distortion embeddings.

Key words. metric embeddings, low-distortion embeddings, metric spaces, metric decompositions, randomized algorithms

1. Introduction.

Over the past decade, the field of metric embeddings has gained much importance in algorithm design. The central genre of problem in this area is the mapping of a given metric space into a "simpler" one, in such a way that the distances between points do not change too much. More formally, an *embedding* of a finite metric space (V, d) into a *target* metric space (V', d') is a map $\varphi : V \to V'$. Recent work on embeddings has used *distortion* as the fundamental measure of quality; the distortion of an embedding is the worst multiplicative factor by which distances

are increased by the embedding[1]. The popularity of distortion has been driven by its applicability to approximation algorithms: If the embedding $\varphi : V \to V'$ has a distortion of D, then the cost of solutions to some optimization problems on (V, d) and on $(\varphi(V), d')$ can differ only by some function of D; this idea has led to numerous approximation algorithms [24].

In parallel with theoretical work on embeddings, there has been a surge of interest in the networking community on *network embedding* problems closely related to the framework above (see, e.g., [13, 37, 42]). This work is motivated by different applications: One takes the point-to-point latencies among nodes in a network such as the Internet, treats this as a distance matrix,[2] and embeds the nodes into a low-dimensional space so as to approximately preserve the distances. In this way, each node is assigned a short sequence of virtual "coordinates," and distances between nodes can be approximated simply by looking up their coordinates and computing the distance, rather than having to interact with the relevant nodes themselves. As location-aware applications in networks become increasingly prevalent—for example, finding the nearest server in a distributed application with replicated services or finding the nearest copy of a file or resource in a peer-to-peer system—having such distance information in a compact and easily usable form is an issue of growing importance (see, e.g., the discussion in [13]).

In the context of these networking applications, however, distortion as defined above has turned out to be too demanding an objective function—many metrics cannot be embedded into Euclidean space with constant distortion; many of those that can be so embedded require a very large number of dimensions; and the algorithms to achieve these guarantees require a type of centralized coordination (and extensive measurement of distances) that is generally not feasible in Internet settings. Instead, the recent networking work has provided *empirical* guarantees of the following form: If we allow a small fraction of all distances to be *arbitrarily* distorted, we can embed the remainder with (apparently) constant distortion in constant-dimensional Euclidean space. Such guarantees are natural for the underlying networking applications; essentially, a very small fraction of the location-based lookups may yield poor performance (due to the arbitrary distortion), but for the rest the quality of the embedding will be very good.

These types of results form a suggestive contrast with the theoretical work on embeddings. In particular, are the strong empirical guarantees for Internet latencies the result of fortuitous artifacts of this particular set of distances, or is something more general going on? To address this, Kleinberg, Slivkins, and Wexler [28] defined the notion of embeddings with *slack*: In addition to the metrics (V, d) and (V', d') in the initial formulation above, we are also given a *slack parameter* ϵ, and we want to find a map φ whose distortion is bounded by some quantity $D(\epsilon)$ on all but an ϵ fraction of the pairs of points in $V \times V$. (Note that we allow the distortion on the remaining ϵn^2 pairs of points to be arbitrarily large.) Roughly, Kleinberg, Slivkins, and Wexler [28] showed that any metric of bounded doubling dimension—in which every ball can be covered by a constant number of balls of half the radius—can be embedded with

[1]Formally, for an embedding $\varphi : V \to V'$, the *distortion* is the smallest D so that $\exists\, \alpha, \beta \geq 1$ with $\alpha \cdot \beta \leq D$ such that $\frac{1}{\alpha}\, d(x, y) \leq d'(\varphi(x), \varphi(y)) \leq \beta\, d(x, y)$ for all pairs $x, y \in V \times V$. Note that this definition of distortion is slightly nonstandard—since $\alpha, \beta \geq 1$, it is no longer invariant under arbitrary scaling; however, this is merely for notational convenience, and all of our results can be cast in the usual definitions of distortion.

[2]While the triangle inequality can be violated by network latencies, empirical evidence suggests that these violations are small and/or infrequent enough to make metric methods a useful approach.

constant distortion into constant-dimensional Euclidean space, allowing a constant slack ϵ. Such metrics, which have been extensively studied in their own right, have also been proposed on several occasions as candidates for tractable abstractions of the set of Internet latencies (see, e.g., [16, 26, 37, 39]).

There were two main open questions posed in [28].

(1) There was no evidence that the main embedding result of [28] needed to be restricted to metrics of bounded doubling dimension. Could it be the case that for *every* finite metric space, and every $\epsilon > 0$, there is an embedding of the metric with distortion $f(\epsilon)$ into Euclidean space?
(2) Rather than have the embedding depend on the given slack parameter ϵ, a much more flexible and powerful alternative would be to have a *single* embedding of the metric with the property that, for some (slowly growing) function $D(\cdot)$, it achieved distortion $D(\epsilon)$ on all but an ϵ fraction of distance pairs for all $\epsilon > 0$. We call such an embedding *gracefully degrading* [28] and ask whether such an embedding (with a polylogarithmic function $D(\cdot)$) could exist for all metrics.

In this paper we resolve the first of these questions in the affirmative, showing constant distortion with constant slack for all metrics. Moreover, the embedding we design to achieve this guarantee is *beacon-based*, requiring only the measurement of distances involving a small set of distinguished "beacon nodes"; see section 2. Approaches that measure only a small number of distances are crucial in networking applications, where the full set of distances can be enormous; see, e.g., [21, 17, 29, 37, 38, 43] for beacon-based approaches and further discussions. We then resolve the second question in the affirmative for metrics that admit an $O(1)$-padded decomposition (a notion from previous work on embeddings that we specify precisely in section 1.1); this includes several well-studied classes of metrics including those with bounded doubling dimension and those arising from the shortest-path metric of a graph with an excluded minor. We further show that gracefully degrading distortion can be achieved in the ℓ_1 norm for all metrics. The second question has been subsequently solved in full in [2] (see also the bibliographic notes in what follows), providing an embeddings with gracefully degrading distortion for all metrics in ℓ_p for every $p \geq 1$. Finally, we show that many of our constructions are tight and give a general technique to obtain lower bounds for ϵ-slack embeddings from lower bounds for low-distortion embeddings.

Basic definitions. Before we formally present our results, let us present some of the notions that will be used throughout the paper. We will assume that the metric space (V, d) is also represented as a graph on the nodes V, with the length of edge uv being $d(u, v) = d_{uv}$. We imagine this graph as having n^2 edges, one for each pair $u, v \in V \times V$; this makes the exposition cleaner and does not change the results in any significant way. For a map $\varphi : V \to V'$ let us define the notion of the *distortion of a set S of edges* under embedding φ as the smallest $D \geq 1$ such that for some positive constant K and all edges $(u, v) \in S$ we have

$$d(u, v) \leq d'(\varphi(u), \varphi(v))/K \leq D \cdot d(u, v).$$

Note that the distortion of φ (as given in Footnote 1) is the same as the distortion of the set of all edges.

DEFINITION 1.1 (ϵ-slack distortion). *Given ϵ, an embedding $\varphi : V \to V'$ has* distortion D with ϵ-slack *if a set of all but an ϵ-fraction of edges has distortion at most D under φ.*

We will also consider a stronger notion of slack, for which we need the following definition. Let $\rho_u(\epsilon)$ be the radius of the smallest ball around u that contains at least ϵn nodes. Call an edge uv *ϵ-long* if $d_{uv} \geq \min(\rho_u(\epsilon), \rho_v(\epsilon))$. Then there are at least $(1-\epsilon)\,n^2$ edges that are ϵ-long. For any such edge uv, at least one end point u is at least as far from the other end point v as the (ϵn)th closest neighbor of v.

DEFINITION 1.2 (ϵ-uniform slack distortion). *Given ϵ, an embedding $\varphi : V \to V'$ has* distortion D with ϵ-uniform slack *if the set of all ϵ-long edges has distortion at most D.*

Note that for an ϵ-uniform slack embedding, the number of ignored edges incident on any node is at most ϵn.

While the above notions of embeddings with slack allow the map φ to depend on the slack ϵ, the following notion asks for a single map that is *good for all ϵ simultaneously.*

DEFINITION 1.3 (gracefully degrading distortion). *An embedding $\psi : V \to V'$ has a* gracefully degrading distortion $D(e)$ *if, for each $\epsilon > 0$, the distortion of the set of all ϵ-long edges is at most $D(\epsilon)$.*

Our results. We now make precise the main results described above and also describe some further results in the paper. Our first result shows that if we are allowed constant slack, we can indeed embed *any* metric space into constant dimensions with constant distortion.

THEOREM 1.4. *For any source metric space (V, d), any target metric space ℓ_p, $p \geq 1$, and any parameter $\epsilon > 0$, we give the following two $O(\log \frac{1}{\epsilon})$-distortion embeddings:*

(a) *with ϵ-slack into $O(\log^2 \frac{1}{\epsilon})$ dimensions, and*

(b) *with ϵ-uniform slack into $O(\log n \log \frac{1}{\epsilon})$ dimensions.*

Both embeddings can be computed with high probability by randomized beacon-based algorithms.

These results extend Bourgain's theorem on embedding arbitrary metrics into ℓ_p, $p \geq 1$, with distortion $O(\log^2 n)$ [10] and are proved in a similar manner.

Note that the bounds on both the distortion as well as the dimension in Theorem 1.4(a) are independent of the number of nodes n, which suggests that they could be extended to infinite metrics; this is further discussed in section 2. In part (b), the dimension is proportional to $\log n$; we show that, for arbitrary metrics, this dependence on n is indeed inevitable. As an aside, let us mention that metrics of bounded doubling dimension do not need such a dependence on n: In Slivkins [43], these metrics are embedded into any ℓ_p, $p \geq 1$, with ϵ-uniform slack, distortion $O(\log \frac{1}{\epsilon} \log\log \frac{1}{\epsilon})$, and dimension $(\log \frac{1}{\epsilon})^{O(\log \frac{1}{\epsilon})}$.

We then study *embeddings into trees.* We extend the known results of probabilistic embedding into trees [5, 6, 14, 7] to obtain embeddings with slack. In particular, we use the technique of Fakcharoenphol, Rao, and Talwar [14] to obtain the following two results.

THEOREM 1.5. *For any input metric space (V, d) and any parameter $\epsilon > 0$ there exists an embedding into a tree metric with ϵ-uniform slack and distortion $O(\frac{1}{\epsilon} \log \frac{1}{\epsilon})$.*

In fact, the tree metric in Theorem 1.5 is induced by a *hierarchically separated tree* (*HST*) [5], which is a rooted tree with edge weights w_e such that $w_e < w_{e'}/2$ whenever edge e' is on the path from the root to edge e.

THEOREM 1.6. *For any input metric space (V, d), the randomized embedding of* [14] *into tree metrics has expected gracefully degrading distortion $D(\epsilon) = O(\log \frac{1}{\epsilon})$.*[3]

[3]More formally, we show that if an edge uv is ϵ-long, then $d_{uv} \leq E_T[d_T(u,v)] \leq O(\log \frac{1}{\epsilon})\, d_{uv}$, where d_T is the tree metric generated by the randomized algorithm in [14].

Since tree metrics are isometrically embeddable into L_1, this immediately implies that we can embed any metric into L_1 with gracefully degrading distortion $D(\epsilon) = O(\log \frac{1}{\epsilon})$.

However, the dimension of the above embedding into L_1 may be prohibitively large. To overcome this hurdle and to extend this embedding to ℓ_p, $p > 1$, we explore a different approach.

THEOREM 1.7. *Consider a metric space (V, d) which admits β-padded decompositions. Then it can be embedded into ℓ_p, $p \geq 1$, with $O(\log^2 n)$ dimensions and gracefully degrading distortion $D(\epsilon) = O(\beta)(\log \frac{1}{\epsilon})^{1/p}$.*

For the reader unfamiliar with padded decompositions, let us mention that $\beta \leq O(\dim_V)$, the doubling dimension of the metric, which in turn is always bounded above by $O(\log n)$. Moreover, doubling metrics and metrics induced by planar graphs have $\beta = O(1)$; hence Theorem 1.7 implies that such metrics admit embeddings into ℓ_p, $p \geq 1$, with gracefully degrading distortion $O(\log \frac{1}{\epsilon})^{1/p}$. Note that for $p > 1$ this result can be seen as a strengthening of Theorem 1.4(b) on embeddings with ϵ-uniform slack.

The proof of Theorem 1.7 is technically the most involved part of the paper; at a high level, we develop a set of scale-based embeddings which are then combined together (as in most previous embeddings)—however, since the existing ways to perform this do not seem to guarantee gracefully degrading distortion, we construct new ways of defining distance scales.

Finally, we prove *lower bounds* on embeddings with slack: We give a very general theorem that allows us to convert lower bounds on the distortion and dimension of embeddings that depend only on $n = |V|$ into lower bounds in terms of the slack parameter ϵ. This result works under very mild conditions and allows us to prove matching or nearly matching lower bounds for all of our results on ϵ-slack embeddings. These lower bounds are summarized in Table 5.1 on page 2322.

Related work. This work is closely related to the large body of work on metric embeddings in theoretical computer science; see the surveys [24, 25] for a general overview of the area. Our results build on much of the previous work on embeddings into ℓ_p, including [10, 33, 41, 34, 19, 30, 31], and on embeddings of metrics into distributions of trees [3, 5, 6, 20, 14, 7]. Among the special classes of metrics we consider are *doubling metrics* [4, 19, 44, 22]; the book by Heinonen [23] gives more background on the analysis of metric spaces.

All of these papers consider low-distortion embeddings *without slack*. Note that an embedding with $(\epsilon = 1/2n^2)$-slack or $(\epsilon = 1/2n)$-uniform-slack is the same as an embedding with no slack; for many of our results, plugging in these values of ϵ gives us the best known slackless results—hence our results can be viewed as extensions of these previous results.

The notion of embedding with slack can be viewed as a natural variant of metric Ramsey theory. The first work on metric Ramsey-type problems was by Bourgain, Figiel, and Milman [11], and a comprehensive study was more recently developed by Bartal and coworkers [8, 9]. In the original metric Ramsey problem we seek a large subset of the points in the metric space which admit a low-distortion embedding, whereas an embedding with slack provides low distortion for a subset of the pairs of points.

Bibliographic note. The results in this paper have been obtained independently by Abraham, Bartal, and Neiman, which led to a merged publication [1]. The results on lower bounds (section 5) and on embedding into distributions of trees (Theorem 1.6) were proved similarly by both groups. For the rest of the results, the

techniques are quite different. The two groups of authors have agreed to write up the full versions of their results separately.

Extensions and further directions. The main question left open by this work is whether every metric admits a low-dimensional embedding into ℓ_p, $p \geq 1$, with gracefully degrading distortion $D(\epsilon)$. This has been answered affirmatively in Abraham, Bartal, and Neiman [2], with $D(\epsilon) = O(\log \frac{1}{\epsilon})$ and dimension $O(\log n)$, using a new type of more advanced metric decomposition. They also show a tight result of $O(1/\sqrt{\epsilon})$ distortion for ϵ-slack embedding into a tree metric and improve the distortion in Theorem 1.7 by a factor of $\beta^{1/p}$.

For specific families of metrics it is still interesting to provide embeddings into ℓ_p with gracefully degrading distortion $D(\epsilon) = o(\log \frac{1}{\epsilon})$; recall that Theorem 4.1 gives such embeddings for decomposable metrics. In particular, we would like to ask this question for embedding arbitrary subsets of ℓ_1 into ℓ_2.

1.1. Notation and preliminaries. Throughout the paper (V, d) is the metric space to be embedded, and $d_{uv} = d(u, v)$ is the distance between nodes $u, v \in V$. Define the closed ball $\mathbf{B}_u(r) = \{v \in V \mid d_{uv} \leq r\}$. The distance between a node u and set $S \subseteq V$ is denoted $d(u, S) = \min_{v \in S} d_{uv}$, and hence $d(u, V \setminus \mathbf{B}_u(r)) > r$. We will assume that the smallest distance in the metric is 1 and the largest distance (or the diameter) is Φ_d.

A *coordinate map* f is a function from V to $\mathbb{R}$; for an edge uv define $f(uv) = |f(u) - f(v)|$. Call such map 1-*Lipschitz* if for every edge $f(uv) \leq d_{uv}$. For $k \in \mathbb{N}$ define $[k]$ as the set $\{0, 1, \ldots, k-1\}$.

Doubling metrics and measures. A metric space (V, d) is *s-doubling* if every set $S \subseteq V$ of diameter Δ can be covered by s sets of diameter $\Delta/2$; the *doubling dimension* of such a metric is $\lceil \log s \rceil$ [23, 19]. A doubling metric is one whose doubling dimension is bounded. A *measure* is *s-doubling* if the measure of any ball $B_u(r)$ is at most s times larger than the measure of $B_u(r/2)$. It is known that for any s-doubling metric there exists an s-doubling measure; moreover, such measure can be efficiently computed [23, 22].

Padded decompositions. Let us recall the definition of a *padded decomposition* (see, e.g., [19, 30]). Given a finite metric space (V, d), a positive parameter $\Delta > 0$, and $\beta : V \to \mathbb{R}$, a Δ-bounded *β-padded decomposition* is a distribution Π over partitions of V such that the following conditions hold.

(a) For each partition P in the support of Π, the diameter of every cluster in P is at most Δ.

(b) If P is sampled from Π, then each ball $\mathbf{B}_x(\frac{\Delta}{\beta(x)})$ is partitioned by P with probability at most $\frac{1}{2}$.

For simplicity say that a metric *admits β-padded decompositions* (where β is a number) if for every $\Delta > 0$ it admits a Δ-bounded β-padded decomposition. It is known that any finite metric space admits $O(\log n)$-padded decomposition [5]. Moreover, metrics of doubling dimension $\dim_V$ admit $O(\dim_V)$-padded decompositions [19]; furthermore, if a graph G excludes a K_r-minor (e.g., if it has treewidth $\leq r$), then its shortest-path metric admits $O(r^2)$-padded decompositions [27, 41, 15].

2. Embeddings with slack into ℓ_p. In this section we show that for any $\epsilon > 0$ any metric can be embedded into ℓ_p for $p \geq 1$ with ϵ-slack and distortion $O(\log \frac{1}{\epsilon})$, thus resolving one of the two main questions left open by [28].

Let us fix $\epsilon > 0$ and write $\rho_u = \rho_u(\epsilon)$. Recall that an edge uv is *ϵ-long* if $d_{uv} \geq \min(\rho_u, \rho_v)$; call it *$\epsilon$-good* if $d_{uv} \geq 4 \min(\rho_u, \rho_v)$. We partition all of the ϵ-long

edges into two groups, namely, those which are ϵ-good and those which are not, and use a separate embedding (i.e., a separate block of coordinates) to handle each of the groups. Specifically, we handle ϵ-good edges using a Bourgain-style embedding from [28], and for the rest of the ϵ-long edges we use an auxiliary embedding such that for any edge uv the embedded uv-distance is $\Theta(\rho_u+\rho_v)$. The combined embedding has dimension $O(\log^2 \frac{1}{\epsilon})$ and achieves distortion $O(\log \frac{1}{\epsilon})$ on a set of all but an ϵ-fraction of edges.

There are several ways in which this result can be refined. First, we can ask for low ϵ-*uniform-slack* distortion and require distortion $O(\log \frac{1}{\epsilon})$ on the set of all ϵ-*long* edges; we can indeed get this, but we have to boost the number of dimensions to $O(\log n \log \frac{1}{\epsilon})$. As Theorem 2.2 shows, this increase is indeed required. We note that this logarithmic increase in the number of dimensions is not the case for doubling metrics: Slivkins [43] shows how these metrics are embedded into any ℓ_p, $p \geq 1$, with ϵ-uniform slack, distortion $O(\log \frac{1}{\epsilon} \log\log \frac{1}{\epsilon})$, and dimension $(\log \frac{1}{\epsilon})^{O(\log \frac{1}{\epsilon})}$.

Second, this embedding can be computed in a distributed *beacon-based* framework. Here a small number of nodes are selected independently and uniformly at random and designated as *beacons*. Then the coordinates of each node are computed as a (possibly randomized) function of its distances to the beacons.

Third, note that, for the ϵ-slack result, the target dimension is independent of n, which suggests that this result can be extended to infinite metrics. To state such an extension, let us modify the notion of slack accordingly. Following [43], let us assume that an infinite metric space is equipped with a probability measure μ on nodes. This measure induces a *product measure* $\mu \times \mu$ on edges. We say that a given embedding ϕ has *distortion D with (ϵ, μ)-slack* if some set of edges of product measure at least $1-\epsilon$ incurs distortion at most D under ϕ. Note that, in the finite case, ϵ-slack coincides with (ϵ, μ)-slack when μ is the counting measure, i.e., when all nodes are weighted equally.

In the embedding algorithm, instead of selecting beacons uniformly at random (i.e., with respect to the counting measure) we select them with respect to measure μ. The proof carries over without much modification; we omit it from this version of the paper.

THEOREM 2.1. *For any source metric space (V, d), any target metric space ℓ_p, $p \geq 1$, and any parameter $\epsilon > 0$, we give the following two $O(\log \frac{1}{\epsilon})$-distortion embeddings:*

(a) *with ϵ-slack into $O(\log^2 \frac{1}{\epsilon})$ dimensions, and*

(b) *with ϵ-uniform slack into $O(\log n \log \frac{1}{\epsilon})$ dimensions.*

These embeddings can be computed with high probability by randomized beacon-based algorithms that use, respectively, only $O(\frac{1}{\epsilon} \log \frac{1}{\epsilon})$ and $O(\frac{1}{\epsilon} \log n)$ beacons.

Proof. Let $\delta > 0$ be the desired total failure probability. The embedding algorithm is essentially the same for both parts, with one difference: We let $k = O(\log \frac{1}{\delta} + \log \frac{1}{\epsilon})$ for part (a) and $k = O(\log \frac{1}{\delta} + \log n)$ for part (b). We describe a centralized algorithm first and prove that it indeed constructs the desired embedding. Then we show how to make this algorithm beacon-based.

We use two blocks of coordinates of size kt and k, respectively, where $t = \lceil \log \frac{1}{\epsilon} \rceil$. The first block comes from a Bourgain-style embedding without the smaller distance scales. For each $i \in [t]$ choose k independent random subsets of V of size 2^i each; call them S_{ij}, $j \in [k]$. The first-block coordinates of a given node u are

$$f_{ij}(u) = (kt)^{-1/p}\, d(u, S_{ij}), \text{ where } i \in [t],\ j \in [k]. \tag{2.1}$$

For every node u and every $j \in [k]$, choose a number $\beta_{ui} \in \{-1, 1\}$ independently and

uniformly at random. The second-block coordinates of u are $g_j(u) = k^{-1/p}\,\rho_u\,\beta_{uj}$, where $j \in [k]$. This completes the embedding.

For an edge uv, let $f(uv)$ and $g(uv)$ denote the ℓ_p-distance between u and v in the first and the second block of coordinates, respectively. By construction, $f(uv) \le d_{uv}$ and $g(uv) \le \rho_u + \rho_v$. Moreover,

(2.2) for every ϵ-good edge uv, $f(uv) \ge \Omega(d_{uv}/t)$ with probability $\ge 1 - t/2^{\Omega(k)}$.

Indeed, fix an ϵ-good edge uv and let $d = d_{uv}$. Let α_i be the minimum of the following three quantities: $\rho_u(2^{-i})$, $\rho_v(2^{-i})$, and $d/2$. The numbers α_i are nonincreasing; $\alpha_0 = d/2$. Moreover, since uv is ϵ-good, we have $\alpha_t \le \min(\rho_u, \rho_v, d/2) \le d/4$. By a standard Bourgain-style argument it follows that for each i the event

$$\sum_j |d(u, S_{ij}) - d(v, S_{ij})| \ge \Omega(k)(\alpha_i - \alpha_{i+1})$$

happens with failure probability at most $1/2^{\Omega(k)}$. (We omit the details from this version of the paper.) Therefore, with failure probability at most $t/2^{\Omega(k)}$, this event happens for all $i \in [t]$ simultaneously, in which case

$$\sum_{ij} |d(u, S_{ij}) - d(v, S_{ij})| \ge \sum_{i \in [t]} \Omega(k)(\alpha_i - \alpha_{i+1}) = \Omega(k)(\alpha_0 - \alpha_t) \ge \Omega(kd),$$

so $f(uv) \ge \Omega(d/t)$ for the case $p = 1$. It is easy to extend this to $p > 1$ using standard inequalities. This proves the claim (2.2).

Furthermore, we claim that for each edge uv, $g(uv) = \Omega(\rho_u + \rho_v)$ with failure probability at most $1/2^{\Omega(k)}$. Indeed, let N_j be the indicator random variable for the event $\beta_{uj} \ne \beta_{vj}$. Since N_j's are independent and their sum N has expectation $k/2$, by Chernoff bounds (Lemma A.1(a)) $N \ge k/4$ with the desired failure probability. This completes the proof of the claim.

Now fix an ϵ-long edge uv and let $d = d_{uv}$. Without loss of generality assume $\rho_u \le \rho_v$; note that $\rho_u \le d$. Since $B_u(\rho_u) \subset B_v(\rho_u + d)$, the cardinality of the latter ball is at least ϵn. It follows that $\rho_v \le \rho_u + d$, so $g(uv) \le \rho_u + \rho_v \le 3d$. Since $f(uv) \le d$, the embedded uv-distance is $O(d)$.

To lower-bound the embedded uv-distance, note that with failure probability at most $t/2^{\Omega(k)}$ the following happens: If edge uv is ϵ-good, then this distance is $\Omega(d/t)$ due to $f(uv)$; else it is $\Omega(d)$ due to $g(uv)$. For part (a) we use the Markov inequality to show that with failure probability at most δ this happens for all but an ϵ-fraction of ϵ-long edges. For part (b) we take a union bound to show that with failure probability at most δ this happens for *all* ϵ-long edges. This completes the proof of correctness for the centralized embedding.

It remains to provide the beacon-based version of the algorithm. Let S be the union of all sets S_{ij}. The Bourgain-style part of the algorithm depends only on distances to the $\Theta(k/\epsilon)$ nodes in S, so it can be seen as beacon-based, with all nodes in S acting as beacons. To define the second block of coordinates we need to know the ρ_u's, which we do not. However, we will estimate them using the same set S of beacons.

Fix a node u. Let B be the open ball around u of radius ρ_u, i.e., the set of all nodes v such that $d_{uv} < \rho_u$. Let B' be the smallest ball around u that contains at least $4\epsilon n$ nodes. Note that S is a set of ck/ϵ beacons chosen independently and uniformly at random for some constant c.

In expectation at most ck beacons land in B and at least $4ck$ beacons land in B'. By Chernoff bounds (Lemma A.1(a) and (b) with failure probability at most $1/2^{\Omega(k)}$ the following event E_u happens: At most $2ck$ beacons land in B and at least $2ck$ beacons land in B'. Rank the beacons according to their distance from u, and let w be the $(2ck)$th closest beacon. Define our estimate of ρ_u as $\rho'_u = d_{uw}$. Note that if event E_u happens, then ρ'_u lies between ρ_u and $\rho_u(4\epsilon)$.

Consider a 4ϵ-good edge uv such that both E_u and E_v happen. Then (as in the non-beacon-based proof) we can upper-bound the embedded uv-distance by $O(d_{uv})$ and lower-bound it by $\Omega(d_{uv}/t)$ with high probability. For part (a) we use the Markov inequality to show that with failure probability at most δ event E_u happens for all but an ϵ-fraction of nodes. For part (b) we take a union bound to show that with failure probability at most δ this event happens for all nodes. □

The following theorem lower-bounds the target dimension required for ϵ-uniform slack, essentially showing that in part (b) of the above theorem the dependence on $\log n$ is indeed necessary.

THEOREM 2.2. *For any $\epsilon < \frac{1}{2}$ there is a metric space (V, d) such that any ϵ-uniform slack embedding into l_p, $p \geq 1$, with distortion D requires $\Omega(\log_D n)$ dimensions.*

Proof. Take a clique on $\epsilon\, n$ red and $(1-\epsilon)n$ blue nodes, assign length two to each of the blue-blue edges, and assign unit lengths to all of the remaining edges. Consider the metric induced by this graph. Now all of the blue-blue edges are ϵ-long, and thus any distortion-D ϵ-uniform-slack embedding must maintain all of the distances between the blue vertices. But this is just a uniform metric on $(1-\epsilon)n$ nodes, and the lower bound follows by a simple volume argument. □

3. Embeddings into trees. Probabilistic embedding of finite metric space into trees was introduced in [5]. Fakcharoenphol, Rao, and Talwar [14] proved that finite metric space embeds into a distribution of dominating trees with distortion $O(\log n)$ (slightly improving the result of [6]); other proofs can be found in [7]. In this section we exploit the technique of [14] to obtain embeddings with slack. First we show that it gives a probabilistic embedding of arbitrary metrics into tree metrics with *expected* gracefully degrading distortion $D(\epsilon) = O(\log 1/\epsilon)$. For technical convenience, we will treat n-point metrics as functions from $[n] \times [n]$ to reals. Note that all metrics d_T generated by the algorithm in [14] are *dominating*; i.e., for any edge uv we have $d(u, v) \leq d_T(u, v)$.

THEOREM 3.1. *For any input metric space (V, d), let d_T be the dominating HST metric on V constructed by the randomized algorithm in Fakcharoenphol, Rao, and Talwar* [14]. *Then the embedding from (V, d) to (V, d_T) has* expected *gracefully degrading distortion $D(\epsilon) = O(\log 1/\epsilon)$. Specifically, for any parameter $\epsilon > 0$ and any ϵ-long edge uv we have*

$$d_{uv} \leq E_\varphi[d_T(u, v)] \leq O(\log 1/\epsilon)\, d_{uv}. \tag{3.1}$$

Since tree metrics are isometrically embeddable into L_1, it follows that we can embed any metric into L_1 with gracefully degrading distortion $D(\epsilon) = O(\log \frac{1}{\epsilon})$.

Proof. For simplicity let us assume that all distances in (V, d) are distinct; otherwise we can perturb them a little bit and make them distinct, without violating the triangle inequality; see the full version of this paper for details. In what follows we will assume a working knowledge of the decomposition scheme in [14].

Let us fix the parameter $\epsilon > 0$ and an ϵ-long edge uv, and let $d = d(u, v)$. Let us assume without loss of generality that $\rho_u(\epsilon) \leq \rho_v(\epsilon)$. Then $\rho_u(\epsilon) \leq d$, so $|\mathbf{B}_u(d)| \leq \epsilon n$.

Run the randomized algorithm of [14] to build a tree T and the associated tree metric d_T. The decomposition scheme will separate u and v at some distance scale $2^i \geq d/2$. Let Δ be the maximum distance in the input metric. Under the distribution over tree metrics d_T that is induced by the algorithm, the expected distance $E[d_T(u,v)]$ between u and v in tree T is equal to the sum

$$\sum_{i \geq \log d - 1}^{\log \Delta} 4 \cdot 2^i \times \Pr[(u,v) \text{ first separated at level } 2^i].$$

Look at the sum for i such that $d/2 \leq 2^i < 4d$; this is at most $48d$. By the analysis of [14], the rest of the sum, i.e., the sum for $i \geq \log 4d$, is at most

$$\sum_{i \geq \log 4d}^{\log \Delta} 4 \cdot 2^i \times \frac{2d}{2^i} \log \frac{|\mathbf{B}_u, 2^i)|}{|\mathbf{B}_u, 2^{i-2})|}.$$

Since the above sum telescopes, it is at most

$$8d \cdot 2 \log (n/|\mathbf{B}_u(d)|) \leq O(d \log 1/\epsilon),$$

which proves the second inequality in (3.1). The first inequality in (3.1) holds trivially because all metrics d_T generated by the algorithm in [14] are dominating. ∎

The above embedding into ℓ_1 can be made algorithmic by sampling from the distribution and embedding each sampled tree into ℓ_1 using a fresh set of coordinates; however, the number of trees now needed to give a small distortion may be as large as $\Omega(n \log n)$. We will see how to obtain gracefully degrading distortion with a smaller number of dimensions in the next section.

A slightly modified analysis yields an embedding into a *single tree*.

THEOREM 3.2. *For any source metric space (V,d) and any parameter $\epsilon > 0$ there exists an embedding into a dominating HST metric with ϵ-uniform slack and distortion $O(\frac{1}{\epsilon} \log \frac{1}{\epsilon})$.*

4. Low-dimensional embeddings with gracefully degrading distortion. In this section we prove our result on embeddings into ℓ_p, $p \geq 1$, with gracefully degrading distortion.

THEOREM 4.1. *Consider a metric space (V,d) which admits β-padded decompositions. Then it can be embedded into ℓ_p, $p \geq 1$, with $O(\log^2 n)$ dimensions and gracefully degrading distortion $D(\epsilon) = O(\beta)(\log \frac{1}{\epsilon})^{1/p}$. The embedding procedure is given as a randomized algorithm which succeeds with high probability.*

The proof of this theorem builds on the well-known embedding algorithms of Bourgain [10] and Linial, London, and Rabinovich [33] and combines ideas given in [41, 19, 28, 43, 30] with some novel ones. To the best of our understanding, the embeddings given in the previous papers do not directly give us gracefully degrading distortion, and hence the additional machinery indeed seems to be required.

Let us fix $k = O(\log n)$, where the constant will be specified later. We will construct an embedding $\varphi : V \to \ell_p$ with $7k^2$ dimensions; the coordinates of φ will be indexed by triples $(i,j,l) \in [k] \times [k] \times [7]$.

We will show how to construct the map φ in the rest of this section, which has the following conceptual steps. We first define a concrete notion of "distance scales" in section 4.1, in terms in which we can cast many previous embeddings, and specify the desired properties for the distance scales in our embedding. We then show how to construct the distance scales as well as the claimed embedding φ in section 4.2 and show that it has gracefully degrading distortion in section 4.3.

4.1. Distance scales and scale bundles. Our algorithm, just like the algorithms in [10, 33, 41, 19, 28, 30, 31], operates on distance scales that start around the diameter of the metric and go all the way down to the smallest distance in the metric. Informally, the embedding φ has a block of coordinates for each distance scale such that if the true uv-distance for some edge uv is within this scale, then the uv-distance in these coordinates of φ is roughly equal to the true distance. These blocks of coordinates are then combined into an embedding that works for all scales simultaneously.

Different embeddings use very different notions of distance scales; in cases like the Rao-style embeddings [41, 19], there are clear coordinates for each distance that is a power of 2—but in Bourgain-style embeddings, this is not the case. To be able to give a unified picture, let us formally define a *distance scale* f to be a coordinate map $f : V \to \mathbb{R}$. A *scale bundle* $\{f_{ij}\}$ is then a collection of coordinate maps f_{ij} such that, for every fixed index j and node u, the values $f_{ij}(u)$ are *decreasing* with i.

We can now cast and interpret previous embeddings in this language: In the Bourgain-style embeddings [10, 33], $f_{ij}(u)$ is the radius of the smallest ball around u containing 2^{n-i} nodes, and hence the cardinality of $\mathbf{B}_u(f_{ij}(u))$ halves as we increase i. In the Rao-style embeddings, the scales are $f_{ij}(u) = \text{diameter}(V)/2^i$, and hence the distance scales halve as we increase i. The measured descent embedding in [30] essentially ensures a judicious mixture of the above two properties: As we increase i, the ball $\mathbf{B}_u(f_{ij}(u))$ either halves in radius or halves in cardinality, whichever comes first.

For our embedding, we need *both* the radius and the cardinality of $\mathbf{B}_u(f_{ij}(u))$ to halve—and hence we have to define the scale bundles accordingly. This would be easy to achieve by itself; however, to give good upper bounds on the embedded distance, we also need each distance scale to be sufficiently smooth, by which we mean that all of the distance scales f_{ij} must themselves be 1-Lipschitz. In other words, we want that $|f_{ij}(u) - f_{ij}(v)| \le d(u, v)$. The construction of the scale bundle $\{f_{ij}\}$ with both halving and smoothness properties turns out to be a bit nontrivial, the details of which are given in the next section.

4.2. The embedding algorithm. Let us construct the embedding for Theorem 4.1. We have not attempted to optimize the multiplicative constant for distortion, having chosen the constants for ease of exposition while ensuring that the proofs work.

First we will construct a *scale bundle* $\{f_{ij} : i, j \in [k]\}$. For a fixed j, the maps f_{ij} are constructed by an independent random process, inductively from $i = 0$ to $i = k - 1$. We start with $f_{(0,j)}(\cdot)$ equal to the diameter Φ_d of the metric. Given f_{ij}, we construct $f_{(i+1,j)}$ as follows. Let U_{ij} be a random set such that each node u is included independently with probability $1/|\mathbf{B}_u(4f_{ij}(u))|$. Assuming U_{ij} is nonempty, define $f_{(i+1,j)}(u)$ as the minimum of $d(u, U_{ij})$ and $f_{ij}(u)/2$. If U_{ij} is empty, set $f_{(i+1,j)}(u) = f_{ij}(u)/2$. This completes the construction of the scale bundle.

To proceed, let us state a lemma that captures, for our purposes, the structure of the source metric space: This is the only place in the proof of Theorem 4.1 where we use padded decomposition.

LEMMA 4.2. *Consider a metric space (V, d) which admits β-padded decompositions. Then for any 1-Lipschitz coordinate map f and any $p \ge 1$ there is a randomized embedding g into ℓ_p with $t = 6$ dimensions so that*

(a) *each coordinate of g is positive, 1-Lipschitz, and upper-bounded by f; and*
(b) *if $f(u)/d_{uv} \in [\frac{1}{4}; 4]$ for some edge uv, then, with probability $\Omega(1)$,*

$$\|g(u) - g(v)\|_p \ge \Omega(d_{uv}\, t^{1/p}/\beta). \tag{4.1}$$

In short, this lemma transforms a "smooth" distance scale f into a "smooth" low-dimensional embedding g which approximately preserves distances along the "relevant" edges. Here "smooth" means "1-Lipschitz," an edge (u, v) is relevant to f if $d_{uv} \approx f(u)$ or $d_{uv} \approx f(v)$, and distances are preserved in the sense of (4.1). Once the relevant edges are taken care of, we want the coordinates of g to be as small as possible in order to upper-bound the embedded distance on larger distance scales.

Sections 4.4 and 4.6 contain two different proofs of this lemma; the first one uses padded decomposition techniques from [19, 30], and the other uses some Bourgain-style ideas [10, 33] which we believe are novel and possibly of independent interest.[4]

Fix a pair $i, j \in [k]$. Apply Lemma 4.2 to the map f_{ij}, and obtain a 6-dimensional embedding; denote these 6 coordinates as $g_{(i,j,l)}$, $1 \le l \le 6$. Let W_{ij} be a random set such that each node u is included independently with probability $1/|\mathbf{B}_u(f_{ij}(u)/2)|$. Define $g_{(i,j,0)}(u)$ as the minimum of $f_{ij}(u)$ and $d(u, W_{ij})$. Finally, we set

$$\varphi_{(i,j,l)} = k^{-1/p}\, g_{(i,j,l)}. \tag{4.2}$$

LEMMA 4.3. *The maps f_{ij}, g_{ij}, and $\varphi_{(i,j,l)}$ are 1-Lipschitz.*

Proof. Indeed, $f_{(0,j)}$ is 1-Lipschitz by definition, and the inductive step follows since the min of two 1-Lipschitz maps is 1-Lipschitz. For the same reason, the maps $g_{(i,j,l)}$ are 1-Lipschitz as well, and therefore so are the maps $\varphi_{(i,j,l)}$. □

Since $k = O(\log n)$, it immediately follows that the embedded distance is at most $O(\log n)$ times the true distance. In the next section we will prove a sharper upper bound of $O(d_{uv})(\log \frac{1}{\epsilon})^{1/p}$ for any ϵ-long edge uv and a lower bound $\Omega(d_{uv}/\beta)$ for any edge.

4.3. Analysis. In this section we complete the proof of Theorem 4.1 by giving bounds on the stretch and contraction of the embedding φ. The following definition will be useful: For a node u, an interval $[a, b]$ is *u-broad* if a or b is equal to d_{uv} for some v, $a \le b/4$ and $|\mathbf{B}_u(a)| \le \frac{1}{32}|\mathbf{B}_u(b)|$.

Let us state two lemmas that capture the useful properties of the maps f_{ij} and $g_{(i,j,0)}$, respectively; note that these properties are independent of the doubling dimension of the underlying metric. The proofs are deferred to section 4.5.

LEMMA 4.4. *With high probability it is the case that*

(a) *for any 1-Lipschitz maps $f'_{ij} \le f_{ij}$ and any ϵ-long edge uv it is the case that $\sum_{ij} f'_{ij}(uv) \le O(k d_{uv} \log \frac{1}{\epsilon})$.*

(b) *for each node u each u-broad interval contains values f_{ij} for $\Omega(k)$ different values of j.*

LEMMA 4.5. *Fix edge uv and indices ij; let $R = f_{ij}(u)$ and $d = d_{uv}$. Given that $R \ge 4d$ and $|\mathbf{B}_u(d/4)| = c\,|\mathbf{B}_u(R)|$, the event $g_{(i,j,0)}(uv) \ge \Omega(d)$ happens with conditional probability $\Omega(c)$.*

Proof of Theorem 4.1. Recall that the final embedding φ is defined by (4.2). Fix an ϵ-long edge uv, and let $d = d_{uv}$. Since $g_{(i,j,l)} \le f_{ij}$ for each l, by Lemma 4.4(a) the embedded uv-distance is upper-bounded by $O(d \log \frac{1}{\epsilon})$ for $p = 1$; the same argument gives an upper bound of $O(d)(\log \frac{1}{\epsilon})^{1/p}$ for $p > 1$.

It remains to lower-bound the embedded uv-distance by $\Omega(d/\beta)$, where β is the parameter in Theorem 4.1 and Lemma 4.2. Denote by $g_{ij}(uv)$ the total ℓ_p-distance between u and v in the coordinates $g_{(i,j,l)}$, $l \ge 1$. Denote by $\mathcal{E}_{ij}$ the event that

[4] More precisely, the second proof is for the important special case when β is the doubling dimension. In this proof the target dimension becomes $t = O(\beta \log \beta)$, which results in target dimension $O(\log^2 n)(\beta \log \beta)$ in Theorem 4.1.

$g_{(i,j,0)}(uv)$ or $g_{ij}(uv)$ is at least $\Omega(d/\beta)$. It suffices to prove that with high probability events $\mathcal{E}_{ij}$ happen for at least $\Omega(k)$ (i,j)-pairs. We consider two cases, depending on whether $\rho_u(\epsilon/32) \geq d/4$.

Case a. If $\rho_u(\epsilon/32) \geq d/4$, then the interval $I = [d/4; d]$ is u-broad, so by Lemma 4.4(b) there are $\Omega(k)$ different j's such that $f_{ij}(u) \in I$ for some i. By Lemma 4.2 and Chernoff bounds (Lemma A.1(a)) for $\Omega(k)$ of these ij pairs, we have $g_{ij}(uv) \geq \Omega(d/\beta)$, Case a complete.

Case b. Assume $\rho_u(\epsilon/32) < d/4$; consider interval $I = [d; \max[4d, \rho_u(32\epsilon)]]$. We claim that

$$\Pr[\mathcal{E}_{ij} \mid f_{ij}(u) \in I] \geq \Omega(1) \text{ for each } (i,j)\text{-pair}. \tag{4.3}$$

Indeed, fix ij and suppose $f = f_{ij}(u) \in I$. There are two cases $f \in [d; 4d]$ and $f \in (4d; \rho_u(32\epsilon)]$. In the first case by Lemma 4.2 $g_{ij}(uv) \geq \Omega(d/\beta)$ with conditional probability at least $\Omega(1)$. In the second case

$$|\mathbf{B}_u(d/4)| \geq \epsilon n/32 \geq 2^{-10}\,(32\epsilon n) \geq 2^{-10}\,|\mathbf{B}_u(f)|,$$

so by Lemma 4.5 $g_{(i,j,0)}(uv) \geq \Omega(d)$ with conditional probability $\Omega(1)$. This completes the proof of (4.3).

Let X_j be the indicator variable of the following random event: $\mathcal{E}_{ij}$ and $f_{ij}(u) \in I$ for some i. Since the interval I is u-broad, by Lemma 4.4(b) there are $\Omega(k)$ different j's such that $f_{ij}(u) \in I$ for some i. Let J be the set of all such j's. Then conditional on J, $\{X_j, j \in J\}$ are $\Omega(k)$ independent 0-1 random variables of expectation $\Omega(1)$. By Chernoff bounds (Lemma A.1(a)) their sum is $\Omega(1)$ with high probability, completing the proof for Case b. □

4.4. Analysis: Proof of Lemma 4.2. In this section we use padded decomposition techniques from [19, 30] to prove Lemma 4.2. Let us recall the definitions of a *padded decomposition* and a *decomposition bundle* [19, 30].

DEFINITION 4.6. *Given a finite metric space (V,d), a positive parameter $\Delta > 0$, and a mapping $\beta : V \to \mathbb{R}$, a* Δ*-bounded* β-padded decomposition *is a distribution* Π *over partitions of V such that the following conditions hold.*

(a) *For each partition P in the support of* Π*, the diameter of every cluster in P is at most Δ.*

(b) *If P is sampled from* Π*, then each ball $\mathbf{B}_x(\Delta/\beta(x))$ is partitioned by P with probability $< \frac{1}{2}$.*

Given a function $\beta : V \times \mathbb{Z} \to \mathbb{R}$, a β-padded decomposition bundle *on V is a set of padded decompositions $\{\eta(i) : i \in \mathbb{Z}\}$ such that each $\eta(i)$ is a 2^i-bounded $\beta(\cdot, i)$-padded decomposition of V.*

If a metric admits a β-padded decomposition bundle such that β is constant, we simply say that this metric *admits β-padded decompositions.*

The randomized construction. Let η be a β-padded decomposition bundle. For each $s \in \mathbb{Z}$, let the decomposition P_s be chosen according to the distribution $\eta(s)$. We denote $P_s(x)$ to be the unique cluster in P_s containing x.

Moreover, for $s \in \mathbb{Z}$, let $\{\sigma_s(C) : C \subseteq V\}$ be independently and identically distributed (i.i.d.) unbiased $\{0,1\}$-random variables. Let $T = \{0, 1, \ldots, 5\}$. Let $s(x) := \lceil \log_2 f(x) \rceil$. For each $t \in T$, we define a (random) subset

$$W^t := \{x \in V : \sigma_{s(x)-t}(P_{s(x)-t}(x)) = 0\}, \tag{4.4}$$

from which we obtain $g_t(\cdot) = \min\{d(\cdot, W^t), f(\cdot)\}$.

Bounding the contraction of the embedding. We fix vertices $x, y \in V$ and let $d = d(x, y)$. Consider the embedded distance between them. The aim is to show that, under some condition, there exists t such that $|g_t(x) - g_t(y)| \geq \rho d$ happens with constant probability, where ρ depends on the β-padded decomposition bundle.

LEMMA 4.7. *Suppose $f(x) \in [\frac{d}{4}, 4d]$ and $t \in T$ is the integer such that $\hat{s} := s(x) - t$ satisfies $2^{\hat{s}} \in [d/8, d/4)$. Let $J := \{-1, 0, 1\}$ and $\rho := \min\{\frac{1}{32\beta(x,s)} : s \in \hat{s} + J\}$. Then the event $|g_t(x) - g_t(y)| \geq \rho d$ happens with probability at least $1/64$.*

Proof. Consider the random process that determines the coordinate g_t. We like to show that the union of the following two disjoint events happens with constant probability, which implies our goal. There are two cases.

Case 1. The set W^t contains x but is disjoint with $B_y(\rho d)$.

Case 2. The set W^t contains no points from $B_x(2\rho d)$ but at least one point from $B_y(\rho d)$.

Let us define the following auxiliary events.

- Event $\mathcal{E}_1$ occurs when x is contained in W^t.
- Event $\mathcal{E}_2$ occurs when W^t is disjoint with $B_y(\rho d)$.
- Event $\mathcal{E}_3$ occurs when, for all $z \in B_x(2\rho d)$ and $s \in \hat{s} + J$, x and z are in the same cluster in $\eta(s)$.
- Event $\mathcal{E}_4$ occurs if, for all $s \in \hat{s} + J$, $\sigma_s(P_s(x)) = 1$.

Observe that the event $\mathcal{E}_1 \cap \mathcal{E}_2$ implies the event in Case 1. Note that, given a decomposition $\eta(\hat{s})$, the point x lies in a cluster different from those intersecting $B_y(\rho d)$, because $2^{\hat{s}} < \frac{d}{4} < (1 - \rho)d$. Hence the events $\mathcal{E}_1$ and $\mathcal{E}_2$ are conditionally independent, given $\eta(\hat{s})$; this in turn implies that

$$\Pr[\mathcal{E}_1 \cap \mathcal{E}_2 | \eta(\hat{s})] = \Pr[\mathcal{E}_1 | \eta(\hat{s})] \Pr[\mathcal{E}_2 | \eta(\hat{s})] = \tfrac{1}{2} \Pr[\mathcal{E}_2 | \eta(\hat{s})].$$

Since this fact holds for all decompositions $\eta(\hat{s})$, it follows that $\Pr[\mathcal{E}_1 \cap \mathcal{E}_2] = \frac{1}{2} \Pr[\mathcal{E}_2]$.

Observe that the event $\mathcal{E}_3 \cap \mathcal{E}_4 \cap \overline{\mathcal{E}_2}$ implies the event in Case 2. This follows from the fact that $|s(x) - s(z)| \in J$. Since $f(x) \geq \frac{d}{4}$, f is 1-Lipschitz, and $d(x, z) \leq 2\rho d \leq \frac{d}{8}$, it follows that $f(x)$ and $f(z)$ are within a multiplicative factor of 2 from each other. Hence $s(x)$ and $s(z)$ differ by at most one. Again, given the decompositions $\eta(s)$, $s \in \hat{s} + J$, the event $\mathcal{E}_4$ is independent of the event $\mathcal{E}_3 \cap \overline{\mathcal{E}_2}$. Hence

$$\Pr\left[\mathcal{E}_3 \cap \mathcal{E}_4 \cap \overline{\mathcal{E}_2}\right] = \Pr[\mathcal{E}_4] \Pr\left[\mathcal{E}_3 \cap \overline{\mathcal{E}_2}\right] = \tfrac{1}{8} \Pr\left[\mathcal{E}_3 \cap \overline{\mathcal{E}_2}\right].$$

Finally, it follows that the union of the events in Cases 1 and 2 happens with probability at least

$$\tfrac{1}{2} \Pr[\mathcal{E}_2] + \tfrac{1}{8} \Pr[\mathcal{E}_3 \cap \overline{\mathcal{E}_2}] \geq \tfrac{1}{8} \Pr[\mathcal{E}_3 \cap \mathcal{E}_2] + \tfrac{1}{8} \Pr[\mathcal{E}_3 \cap \overline{\mathcal{E}_2}] = \tfrac{1}{8} \Pr[\mathcal{E}_3].$$

In order to show that $\mathcal{E}_3$ happens with constant probability, we make use of the properties of β-padded decomposition bundle. Since for all $s \in \hat{s} + J$ we have

$$2\rho d \leq 2/32\beta(x, s) \cdot d \leq 2^s/\beta(x, s),$$

it follows that $\mathcal{E}_3$ happens with probability at least $1/8$. Therefore, it follows that the desired event happens with probability at least $1/64$. ∎

4.5. Analysis: Maps f_{ij} and $g_{(i,j,0)}$. In this subsection we prove Lemmas 4.4 and 4.5. First we prove part (a) of Lemma 4.4, which is essentially the upper bound on the embedded distance for the case $p = 1$. We start with a local smoothness property of the sets U_{ij}.

CLAIM 4.8. *Fix $i, j \in [k]$ and an edge uv. Condition on the map f_{ij}; i.e., pause our embedding algorithm right after f_{ij} is constructed; let $r = f_{ij}(u)$. If $d_{uv} \le r/4$, then*

$$\Pr[v \in U_{ij}] \le 1/|\mathbf{B}_u(r)| \le \Pr\left[v \in U_{(i+3,j)}\right].$$

Proof. Let $B = \mathbf{B}_u(r)$. For the right-hand side inequality, letting $r' = f_{(i+3,j)}(v)$ we have

$$4r' \le f_{ij}(v)/2 \le (r + d_{uv})/2 \le 5r/8,$$

so $d_{uv} + 4r' < r$. It follows that $\mathbf{B}_v(r') \subset B$, so $v \in U_{(i+3,j)}$ with probability $1/|\mathbf{B}_v(4r')| \ge 1/|B|$.

For the left-hand side inequality, letting $r' = f_{ij}(v)$ we have

$$4r' \ge 4(r - d_{uv}) \ge r + d_{uv},$$

so $B \subset \mathbf{B}_v(4r')$. Therefore, $v \in U_{ij}$ with probability $1/|\mathbf{B}_v(4r')| \le 1/|B|$. ∎

Fix a node u; for simplicity assume $k = 4k_0 + 1$ for some $k_0 \in \mathbb{N}$. Let $B_{ij} = \mathbf{B}_u(f_{ij})$, and let X_{ij} be the indicator random variable for the event that $|B_{(4i+4,\,j)}| \le |B_{(4i,\,j)}|/2$. Note that, for a fixed j, the random variables X_{ij} are not independent. However, we can show that, given all previous history, the ijth event happens with at least a constant probability.

CLAIM 4.9. *For each $i \in [k_0]$, $j \in [k]$, and $q = 1 - e^{-1/2}$ we have*

$$\Pr[X_{ij} = 1 \mid f_{lj}, l < i] \ge q.$$

Proof. Indeed, fix ij, and let $f = f_{(4i,j)}(u)$ and $f' = f_{(4i+4,j)}(u)$. Let r be the radius of the smallest ball around u that contains at least $|B_{(4i,\,j)}|/2$ nodes, and let $B = \mathbf{B}_u(r)$.

Clearly, $X_{ij} = 1$ if and only if $f' \le r$. By definition of f_{ij}'s we have $f' \le f/16$, so we are done if $r \ge f/16$. Else by Claim 4.8 any node $v \in B$ included into the set $U_{(4i+3,j)}$ with probability at least $1/2|B|$, so the probability of including at least one node in B into this set (in which case $f' \le r$) is at least $1 - (1 - 1/2|B|)^{|B|} \ge q$. ∎

For a random variable X define the *distribution function* $F_X(t) = \Pr[X < t]$. For two random variables X and Y, say Y *stochastically dominates* X (written as $Y \succeq X$ or $X \preceq Y$) if $F_Y(t) \le F_X(t)$ for all $t \in \mathbb{R}$. Note that if $X \ge Y$, then $X \succeq Y$. Consider a sequence of i.i.d. Bernoulli random variables $\{Y_i\}$ with success probability q. By Claim 4.9 and Lemma A.3 (proved in Appendix A) we have the following:

$$\sum_{i=0}^{t} X_{ij} \succeq \sum_{i=0}^{t} Y_i \text{ for any } t \in [k_0] \text{ and each } j \in [k]. \tag{4.5}$$

We'll use (4.5) to prove the following crucial claim.

CLAIM 4.10. *Fix node u and $\epsilon > 0$; for each j let T_j be the smallest i such that $f_{ij}(u) \le \rho_u(\epsilon)$ or k if no such i exists. Then $\sum_j T_j = O(k \log \frac{1}{\epsilon})$ with high probability.*

Proof. Let $\alpha = \lceil \log \frac{1}{\epsilon} \rceil$. Let L_j be the smallest t such that $\sum_{i=0}^{t} X_{ij} \ge \alpha$ or k_0 if such t does not exist; note that $T_j \le 4L_j$. For the sequence $\{Y_i\}$, let Z_r be the number of trials between the $(r-1)$th success and the rth success. Let $A_j = \sum_{r=(j-1)\alpha+1}^{j\alpha} Z_r$ and $Z = \sum_{r=1}^{k\alpha} Z_r$. By (4.5) for any integer $t \in [k_0]$

$$\Pr[L_j > t] = \Pr\left[\sum_{i=0}^{t} X_{ij} < \alpha\right] \le \Pr\left[\sum_{i=0}^{t} Y_i < \alpha\right] = \Pr\left[\sum_{r=1}^{\alpha} Z_r > t\right] = \Pr[A_1 > t]. \tag{4.6}$$

Since $\{A_j\}$ are i.i.d., by (4.6) and Lemma A.2 it follows that $\sum_j L_j \succeq \sum_j A_j = Z$. Therefore, by Lemma A.4

$$\Pr\left[\sum T_j > 8k\alpha/q\right] \leq \Pr\left[\sum L_j > 2k\alpha/q\right] \leq \Pr[Z > 2k\alpha/q] < (0.782)^{k\alpha},$$

which is at most $1/n^3$ when $k = O(\log n)$ with large enough constant. □

Now we have all tools to prove Lemma 4.4(a).

Proof of Lemma 4.4(a). Use $T_j = T_j(u)$ from Claim 4.10. Fix some ϵ-long edge uv, and let $d = d_{uv}$. Let $t_j = \max(T_j(u), T_j(v))$. Then by the 1-Lipschitz property $f'_{ij}(uv) \leq d$ for all ij; moreover, for any ij such that $i \geq t_j$ both $f_{ij}(u)$ and $f_{ij}(v)$ are at most $d/2^{i-t_j}$. Then $f'_{ij}(uv)$ is at most twice that much (since $f'_{ij} \leq f_{ij}$), so taking the sum of the geometric series we see that

$$\sum_{ij} f'_{ij}(uv) \leq \sum_j \left(dt_j + \sum_{i \geq t_j} \tfrac{d}{2}^{i-t_j}\right) \leq \sum_j O(dt_j) = O\left(kd \log \tfrac{1}{\epsilon}\right),$$

where the last inequality follows by Claim 4.10. □

To prove part (b) of Lemma 4.4, let us recall the definition of a u-broad interval: For a node u, an interval $[a, b]$ is *u-broad* if a or b is equal to d_{uv} for some v, $a \leq b/4$ and $|\mathbf{B}_u(a)| \leq \frac{1}{32}|\mathbf{B}_u(b)|$.

Proof of Lemma 4.4(b). It suffices to consider the u-broad intervals $[a, b]$ such that one of the end points is equal to d_{uv} for some v and the other is the largest a or the smallest b, respectively, such that the interval is u-broad. Call these intervals *u-interesting*; note that there are at most $2n$ such intervals for each u.

Fix node u and a u-broad interval $I = [a, b]$, fix j, and let $r_i = f_{ij}(u)$. It suffices to show that with constant probability some r_i lands in I. Indeed, then we can use Chernoff bounds (Lemma A.1(a)), and then we can take the union bound over all nodes u and all u-interesting intervals.

Denote by $\mathcal{E}_i$ the event that $r_i > b$ and $r_{i+1} < a$; note that these events are disjoint. Since some r_i lands in I if and only if none of the $\mathcal{E}_i$'s happen, we need to bound the probability of $\cup\mathcal{E}_i$ away from 1.

For each integer $l \geq 0$ define the interval

$$I_l = \left[\rho_u\left(\epsilon\, 2^l\right),\ \rho_u\left(\epsilon\, 2^{l+1}\right)\right), \text{ where } \epsilon n = |\mathbf{B}_u(b)|.$$

For each $\alpha \in \{0, 1, 2, 3\}$ let $N_{(l,\alpha)}$ be the number of i's such that $r_{4i+\alpha} \in I_l$. We claim that $E[N_{(l,\alpha)}] \leq 1/q$.

Consider the case $\alpha = 0$; other cases are similar. Let $N_l = N_{(l,\alpha)}$, and suppose $N_l \geq 1$. Let i_0 be the smallest i such that $r_{4i} \leq I_l$. Then $N_l \geq t$ implies $X_{ij} = 0$ for each $i \in [i_0; i_0 + t - 2]$. Recall that the construction of the maps f_{ij} starts with $f_{(0,j)}$. Given the specific map $f = f_{(i_0,j)}$, the construction of the maps f_{ij}, $i > i_0$, is equivalent to a similarly defined construction that starts with $f_{(i_0,j)} = f$. Therefore, by (4.5) (applied to this modified construction) we have

$$\Pr[N_l \geq t] \leq \Pr\left[\sum_{\beta=0}^{t-2} X_{(i_0+\beta,\,j)} = 0\right] \leq \Pr\left[\sum_{\beta=0}^{t-2} Y_\beta = 0\right] = (1-q)^{t-1},$$

$$E[N_l] = \sum_{t=1}^{\infty} \Pr\left[N_l \geq t\right] \leq \sum_{t=1}^{\infty} (1-q)^{t-1} = \frac{1}{q},$$

claim proved. For simplicity assume $k = 4k_0 + 1$; it follows that

$$\sum_{i=0}^{k-1} \Pr[r_i \in I_l] = \sum_{\alpha=0}^{3} \sum_{i=0}^{k_0-1} \Pr[r_{4i+\alpha} \in I_l] = \sum_{\alpha=0}^{3} E\left[N_{(l,\alpha)}\right] \le 4/q. \tag{4.7}$$

By Claim 4.8 if $r_i \in I_l$, then $r_{i+1} \le a$ with conditional probability at most $|\mathbf{B}_u(a)|/|\mathbf{B}_u(r_u)| \le 2^{-l}/32$. Therefore, $\Pr[\mathcal{E}_i \,|\, r_i \in I_l] \le 2^{-l}/32$. By (4.7) it follows that

$$\begin{aligned}\Pr[\cup\mathcal{E}_i] &= \sum_{i=0}^{k-1} \Pr[\mathcal{E}_i] = \sum_{i=0}^{k-1}\sum_{l=0}^{\infty} \Pr\left[r_i \in I_l \text{ and } \mathcal{E}_i\right] \le \sum_{i=0}^{k-1}\sum_{l=0}^{\infty} \Pr[r_i \in I_l] \times \frac{2^{-l}}{32} \\ &= \frac{1}{32}\sum_{l=0}^{\infty} 2^{-l} \sum_{i=0}^{k-1} \Pr[r_i \in I_l] \le \frac{1}{8q}\sum_{l=0}^{\infty} 2^{-l} = \frac{1}{4q} < 1,\end{aligned}$$

so some r_i lands in I with at least a constant probability. □

It remains to prove Lemma 4.5 about the maps $g_{(i,j,0)}$.

Proof of Lemma 4.5. Let's pause our embedding algorithm right after the map f_{ij} is chosen and consider the probability space induced by the forthcoming random choices. Let $X_w = f_{ij}(w)$. First we claim that

$$\Pr\left[g_{(i,j,0)}(u) \le r \,|\, r \le X_u/8\right] \ge \Omega(\beta_r), \tag{4.8}$$

where $\beta_r = |\mathbf{B}_u(r)|/|\mathbf{B}_u(X_u)|$. Indeed, suppose $r \le X_u/8$, let $B = \mathbf{B}_u(r)$, and consider any $w \in B$. Then by (4.11)

$$\begin{aligned}\Pr[w \in W_{ij}] &= 1/|\mathbf{B}_w(X_w/2)| \ge 1/|\mathbf{B}_u(X)| \ge \beta_r|B|, \\ \Pr\left[\,g_{(i,j,0)}(u) \le r\,\right] &= \Pr[W_{ij} \text{ hits } B] \ge 1 - (1-\beta_r|B|)^{|B|} \ge 1 - e^{-\beta_r} \ge \Omega(\beta_r),\end{aligned}$$

proving (4.8). Now let $B = \mathbf{B}_v(X_v/8)$; then by (4.11) any $w \in B$ is included into the set W_{ij} with probability at most $1/B$, so

$$\Pr\left[\,g_{(i,j,0)}(v) \ge X_v/8\right] = \Pr[W_{ij} \text{ misses } B] \ge (1 - 1/|B|)^{|B|} \ge 1/4. \tag{4.9}$$

Finally, let's combine (4.8) and (4.9) to prove the claim. Let $r = d/4$, and suppose $X \ge 4d$. Since $X_v \ge X - d_{uv} \ge 3d$, by (4.9) event $g_{(i,j,0)}(v) \ge 3d/8$ happens with probability at least $1/4$. This event and the one in (4.8) are independent since they depend only on what happens in the balls $\mathbf{B}_u(d/4)$ and $\mathbf{B}_v(3d/8)$, respectively, which are disjoint. Therefore, with probability at least $\Omega(\beta_r)$ both events happen, in which case $g_{(i,j,0)}(uv) \ge d/8$. □

4.6. A Bourgain-style proof of Lemma 4.2 for doubling metrics. In this section we use the ideas of [10, 33] to derive an alternative proof of Lemma 4.2 for the important special case when β is the doubling dimension. In this proof the target dimension becomes $t = O(\beta \log \beta)$, which results in target dimension $O(\log^2 n)(\beta \log \beta)$ in Theorem 4.1.

Let us note that in the well-known embedding algorithms of Bourgain [10] and Linial, London, and Rabinovich [33] any two nodes are sampled with the same probability, i.e., with respect to the counting measure. Here use a nontrivial extension of Bourgain's technique where we sample with respect to a doubling measure transformed with respect to a given 1-Lipschitz map.

We state our result as follows.

LEMMA 4.11. *Consider a finite metric space (V, d) equipped with a nondegenerate measure μ and a 1-Lipschitz coordinate map f; write $f_u = f(u)$. For every node u let*

$$\beta_\mu(u) = 2\mu[\,\mathbf{B}_u(f_u)\,] \,/\, \mu[\,\mathbf{B}_u(f_u/16)\,].$$

Then for any $k, t \in \mathbb{N}$ there is a randomized embedding g into ℓ_p, $p \geq 1$, with dimension kt so that

(a) *each coordinate map of g is 1-Lipschitz and upper-bounded by f; and*

(b) $\|g(u) - g(v)\|_p \geq \Omega(d_{uv}/t)(kt)^{1/p}$ *with failure probability at most $< t/2^{\Omega(k)}$ for any edge uv such that*

$$f(u)/d_{uv} \in [1/4;\, 4] \text{ and } \max_{w \in \{u,v\}} \beta_\mu(w) \leq 2^t. \tag{4.10}$$

To prove Lemma 4.2 for a metric of doubling dimension β, recall that for any such metric there exists a 2^β-doubling measure μ. Plug this measure in Lemma 4.11, with $t = 4\beta + 1$ and $k = O(\log \beta)$; note that $\beta_\mu(u) \leq 2^t$ for every node u. We get the embedding in ℓ_p with $O(\beta \log \beta)$ dimensions that satisfies the conditions in Lemma 4.2.

We'll need the following simple fact:

(4.11)
If $d_{uv} \leq f(u)/8$ for some edge uv, then $\mathbf{B}_u(f(u)/8) \subset \mathbf{B}_v(f(v)/2) \subset \mathbf{B}_u(f(u))$.

Indeed, letting $f_u = f(u)$ the first inclusion follows since $f_v/2 \geq (f_u - d_{uv})/2 \geq f_u/8 + d_{uv}$, and the second one holds since $d_{uv} + f_v/2 \leq d_{uv} + (f_u + d_{uv})/2 < f_u$.

Proof of Lemma 4.11. Define the transformation of μ with respect to f as $\mu_f(u) = \mu(u)/2\mu(B)$, where $B = \mathbf{B}_u(f_u/2)$. The coordinates are indexed by ij, where $i \in [t]$ and $j \in [k]$. For each (i, j)-pair construct a random set U_{ij} by selecting $\lceil 2^i \mu_f(V) \rceil$ nodes independently according to the probability distribution $\mu_f(\cdot)/\mu_f(V)$. Let us define the ijth coordinate of u as $g_{ij}(u) = \min(f_u, d(u, U_{ij}))$.

Note that each map g_{ij} is 1-Lipschitz as the minimum of two 1-Lipschitz maps. Therefore, part (a) holds trivially. The hard part is part (b). Fix an edge uv; let $d = d_{uv}$. For any node w let $\alpha_w(\epsilon)$ be the smallest radius r such that $\mu_f[\mathbf{B}_w(r)] \geq \epsilon$, and let

$$\rho_i = \max[\psi_u(2^{-i}), \psi_v(2^{-i})], \text{ where } \psi_w(\epsilon) = \min[\alpha_w(\epsilon), d/2, f_w].$$

CLAIM 4.12. *For each $i \geq 1$ and each $j \in [k]$ with probability $\Omega(1)$ we have*

$$g_{ij}(uv) := |g_{ij}(u) - g_{ij}(v)| \geq \rho_i - \rho_{i+1}.$$

Then by Chernoff bounds (Lemma A.1(a)) with probability at least $1 - 2^{-\Omega(k)}$

$$\sum_{ij} g_{ij}(uv) \geq \sum_{i=1}^{t} \Omega(k)(\rho_i - \rho_{i+1}) = \Omega(k)(\rho_1 - \rho_t). \tag{4.12}$$

Proof of Claim 4.12. Fix $i \geq 1$ and j, and note that if $\rho_{i+1} = d/2$, then $\rho_i = d/2$, in which case the claim is trivial. So let's assume $\rho_{i+1} < d/2$ and without loss of generality suppose $\psi_u(2^{-i}) \geq \psi_v(2^{-i})$. Consider the open ball B of radius ρ_i around u. Since $\rho_i = \psi_u(2^{-i}) \leq \alpha_u(2^{-i})$, it follows that $\mu_f(B) \leq 2^{-i}$. Now there are two cases:

- If $\rho_{i+1} = f_v$, then the desired event $g_{ij}(uv) \geq \rho_i - \rho_{i+1}$ happens whenever U_{ij} misses B, which happens with at least a constant probability since $\mu_f(B) \leq 2^{-i}$.
- If $\rho_{i+1} < f_v$, then the desired event happens whenever U_{ij} misses B and hits $B' = \mathbf{B}_v(\rho_{i+1})$. This happens with at least a constant probability by Claim 4.14 since $\rho_{i+1} \geq \psi_v(1/2^{i+1}) \geq \alpha_v(1/2^{i+1})$ and therefore $\mu_f(B') \geq 1/2^{i+1}$, and the two balls B and B' are disjoint.

This completes the proof of the claim. ∎

CLAIM 4.13. *For any node w we have $\alpha_w(\frac{1}{2}) \geq f_w/8$ and $\alpha_w(1/\beta_\mu(w)) \leq f_w/16$.*

Proof. Let $B = \mathbf{B}_w(f_w/8)$. By (4.11) for any $w' \in B$

$$\mu(w) \,/\, 2\mu[\,\mathbf{B}_w(f_w)\,] \;\leq\; \mu_f(w') \;\leq\; \mu(w)/2\mu(B),$$

so $\mu_f(B) \leq \frac{1}{2}$ and $\mu_f[\,\mathbf{B}_w(f_w/16)\,] \geq 1/\beta_\mu(w)$. ∎

Suppose (4.10) holds; let $x = \max(f_u, f_v)$. Then by Claim 4.13 and the definitions of ρ_i and ψ_w we have

$$\rho_1 \geq \max_{w\in\{u,v\}} \min(f_w/8, d/2) \geq \min(x/8, d/2),$$

$$\rho_t \leq \max_{w\in\{u,v\}} \alpha_w(2^{-t}) \leq \max_{w\in\{u,v\}} \alpha_w\left(1/\beta_\mu(w)\right) \leq \max_{w\in\{u,v\}} f_w/16 \leq x/16.$$

By (4.12) for $p = 1$ it remains to show that $\rho_1 - \rho_t \geq \Omega(d)$. There are two cases:

- If $f_v \leq 4d$, then $\rho_1 \geq x/8$, so $\rho_1 - \rho_t \geq x/16 \geq \Omega(d)$.
- If $f_v > 4d$, then $\rho_1 \geq d/2$ and (since f is 1-Lipschitz)

$$\rho_t \;\leq\; f_v/16 \;\leq\; (f_u + d)/16 \;\leq\; 5d/16,$$

so $\rho_1 - \rho_t \geq 3d/16$.

This completes the proof for the case $p = 1$. To extend it to $p > 1$, note that the embedded uv-distance is

$$\left(\sum_{ij} g_{ij}(uv)^p\right)^{1/p} = (kt)^{1/p}\left(\frac{1}{kt}\sum_{ij} g_{ij}(uv)^p\right)^{1/p}$$

$$\geq (kt)^{1/p}\left(\frac{1}{kt}\sum_{ij} g_{ij}(uv)\right) \geq \Omega\left(\frac{d}{t}\right)(kt)^{1/p}.$$

This completes the proof of the lemma. ∎

In the above proof we used the following claim which is implicit in [33] and also stated in [28]; we prove it here for the sake of completeness.

CLAIM 4.14. *Let μ be a probability measure on a finite set V. Consider disjoint events $E, E' \subset V$ such that $\mu(E) \geq q$ and $\mu(E') \leq 2q < 1/2$ for some number $q > 0$. Let S be a set of $\lceil 1/q \rceil$ points sampled independently from V according to μ. Then S hits E and misses E' with at least a constant probability.*

Proof. Obviously, the probability that S hits E and misses E' can decrease only if we set $\Pr[E] = q$ and $\Pr[E'] = 2q$. Treat sampling a given point as three independent random choices (which result in exactly the same selection probabilities): First we choose, with probability $1-2q$, whether this point misses E'; then (if it indeed misses) we choose, with probability $q' = \frac{q}{1-2q} \leq 2q$, whether it hits E; and finally the specific point is chosen from, respectively, E, E', or $V \setminus (E \cup E')$. Without loss of generality rearrange the order of events: First we choose whether all points miss E' and then

upon success choose whether at least one point hits E. These two events happen independently with probabilities, respectively, $(1-2q)^{1/q} \geq 2^{-1/2}$ and

$$1-(1-q')^{1/q} \geq 1-(1-2q)^{1/q} \geq 1-e^{-2}.$$

So the total success probability is at least $c = (1-e^{-2})/\sqrt{2}$, which is an absolute constant as required. □

5. Lower bounds on embeddings with slack. In this section we describe a general technique to derive lower bounds for ϵ-slack embeddings from lower bounds for ordinary embeddings. For simplicity of exposition, we will first give a concrete example proving lower bounds for ϵ-slack embeddings into ℓ_p (which will follow from a lower bound for embedding expanders into ℓ_p [34]). Then we provide the general technique; the bounds obtained by this technique are given in Table 5.1. Let us mention that allowing arbitrary *expansions* is crucial to our results: If we insisted that *none of the pairwise distances should increase*, the lower bound of $\Omega(\frac{1}{p}\log n)$ distortion [34] for embeddings into ℓ_p holds even with ϵ-slack (see section 5.2 for more details).

THEOREM 5.1. *For an arbitrarily small positive ϵ there exists a finite metric space on arbitrarily many nodes that requires distortion $\Omega(\frac{1}{p}\log\frac{1}{\epsilon})$ to embed into ℓ_p, $p \geq 1$, with ϵ-slack.*

Proof. Given an ϵ such that $0 < \epsilon \leq 1/12$, let $k = 1/(3\sqrt{\epsilon})$. Fix n, the number of nodes in our counterexample.

We now construct a graph G on n vertices. Consider a constant degree expander graph H on k vertices. Let (H,d) be the shortest path metric defined by H. For each vertex $s \in H$, let L_s be a path containing n/k vertices. Attach the path L_s to s at one of its end points. The length of each edge of L_s is small enough so that if δ is the length of path L_s, then $\delta \cdot D \leq 1/2$. Let the new graph be G and the shortest path metric defined on it be (G,d). We now prove that if (G,d) can be embedded into ℓ_p with distortion D and ϵ-slack, then H can be embedded into ℓ_p with distortion $4D$ *without any slack*.

Let $\varphi : G \to \ell_p$ be the embedding of (G,d) into ℓ_p with distortion D and ϵ-slack. Let E denote the set of *ignored* pairs; i.e., let us assume that the complement of E incurs distortion at most D. Note that ϵ-slack means that $|E| \leq \epsilon n^2 2$. We delete all of the vertices that participate in more than $\sqrt{\epsilon}n$ pairs in E. By a simple counting argument, at most $\sqrt{\epsilon}n$ vertices of G can be deleted. Therefore, at least one point from each path survives. For each $s \in H$, let v_s denote a survived vertex from the path L_s. We define an embedding ψ of H into ℓ_p as $\psi(s) = \varphi(v_s)$.

We now bound the distortion of the embedding ψ by $4D$. Let x, y be two vertices in H. Then v_x and v_y are the survivors in L_x and L_y, respectively. Note that v_x and

TABLE 5.1

Embeddings with slack ϵ. Lower bounds on distortion. Here $\mathcal{F}$ is the family of doubling metrics that are induced by planar graphs. Bounds for ϵ-uniform slack can be obtained by replacing $\sqrt{\epsilon}$ by ϵ.

Type of embedding	Our lower bound	Original example
All metrics into ℓ_p, $p \geq 1$	$\Omega(\frac{1}{p})(\log\frac{1}{\epsilon})$	Constant-degree expanders [34]
$\mathcal{F}$ into ℓ_p, $p \in (1,2]$	$\Omega(p-1)\sqrt{\log 1/\epsilon}$	Laakso fractal [32]
Growth-constrained ℓ_1-metrics into ℓ_1^d	$\Omega(\sqrt{\log_d 1/\epsilon})$	Laakso fractal [32]
$\mathcal{F}$ into distributions of dominating trees	$\Omega(\log\frac{1}{\epsilon})$	$n \times n$ grid [3]
All metrics into tree metrics	$\Omega(1/\sqrt{\epsilon})$	n-cycle [40, 18]
ℓ_2^{2m+1} into ℓ_2^{2m}	$\Omega(1/\sqrt{\epsilon})^{1/m}$	[36]

v_y participate in at most $\sqrt{\epsilon}n$ pairs in E. Since $|L_y| = 3\sqrt{\epsilon}n$, it follows that there is another survivor $t \in L_y$ such that neither $\{t, v_x\}$ nor $\{t, v_y\}$ is in E. Since the distortion of the map φ is D, we can assume that for edge $(u, v) \notin E$,

$$d(u, v) \le \|\varphi(u) - \varphi(v)\|_p \le D \cdot d(u, v).$$

Now we can bound $\psi(xy) := \|\psi(x) - \psi(y)\|_p$ as follows:

$$\begin{aligned}\psi(xy) &= \|\varphi(v_x) - \varphi(v_y)\|_p \\ &\le \|\varphi(v_x) - \varphi(t)\| + \|\varphi(t) - \varphi(v_y)\| \\ &\le D\,(d(v_x, t) + d(t, v_y)) \\ &\le D\,(1 + 3\delta)\,d(x, y) \le 2D\,d(x, y).\end{aligned}$$

Similarly,

$$\begin{aligned}\psi(xy) &\ge \|\varphi(v_x) - \varphi(t)\|_p - \|\varphi(t) - \varphi(v_y)\|_p \\ &\ge d(v_x, t) - Dd(t, v_y) \ge (1 - D\delta)d(x, y) \\ &\ge d(x, y)/2.\end{aligned}$$

Hence $\frac{1}{2}d(u, v) \le \psi(uv) \le 2D \cdot d(u, v)$, and so ψ is a map from H to ℓ_p with distortion $4D$.

To finish the proof of the theorem, we note that a constant-degree expander on k vertices requires $\Omega(\log k/p)$ distortion to embed into ℓ_p [34]. □

5.1. General lower-bounding technique. The technique used in Theorem 5.1 of starting with a $O(1)$-degree expander H_k on k vertices, replacing each vertex with a path on n/k vertices to get G, and for suitable $k \approx O(1/\sqrt{\epsilon})$ arguing that ϵ-slack embeddings of G_n give us slackless embeddings of H_k with (roughly) the same distortion is quite general. In fact, we use it to obtain lower bounds on *both the distortion and dimensions of embeddings* into ℓ_p from similar lower bounds for slackless embeddings; similar results can be obtained for embeddings into trees or distributions of trees. We summarize these results in Table 5.1.

THEOREM 5.2. *Suppose for each k there exists a k-node metric H_k such that any embedding of H_k into ℓ_p with $L(k)$ dimensions has distortion at least $D(k)$. Then for an arbitrarily small positive ϵ there exist finite metrics M, M^* on an arbitrarily large number of nodes such that any embedding of*

(a) *M into ℓ_p with $L(\frac{1}{3\sqrt{\epsilon}})$ dimensions has ϵ-slack distortion $\Omega(D(\frac{1}{3\sqrt{\epsilon}}))$.*

(b) *M^* into ℓ_p with $L(\frac{1}{3\epsilon})$ dimensions has ϵ-uniform slack distortion $\Omega(D(\frac{1}{3\epsilon}))$.*

Moreover, if metrics $\{H_k\}$ are planar (resp., K_r-minor-free, doubling, ℓ_p^d), then so are M and M^*.

Note that this result can be used to translate, e.g., the Brinkman and Charikar [12] lower bound for dimensionality reduction in ℓ_1 into the realm of ϵ-slack as well.

Similarly, we provide a lower bound theorem for (probabilistic) embeddings into trees.

THEOREM 5.3. *Suppose for each k there exists a k-node metric H_k such that any (probabilistic) embedding of H_k into trees has distortion at least $D(k)$. Then for an arbitrarily small positive ϵ there exist finite metrics M, M^* on an arbitrarily large number of nodes such that any (probabilistic) embedding of*

(a) *M into trees has ϵ-slack distortion $\Omega(D(\frac{1}{3\sqrt{\epsilon}}))$.*

(b) *M^* into trees has ϵ-uniform slack distortion $\Omega(D(\frac{1}{3\epsilon}))$.*

Moreover, if metrics $\{H_k\}$ are planar (resp., K_r-minor-free, doubling, ℓ_p^d), then so are M and M^*.

For instance, we can now derive a lower bound of $\Omega(1/\sqrt{\epsilon})$ on the distortion incurred when embedding the n-cycle into a single tree.

The proofs of the two above theorems are based on the following lemma.

LEMMA 5.4 (master lemma). *Suppose H is a metric on k points and $\mathcal{T}$ is a collection of metrics on k points such that any embedding of H into $\mathcal{T}$ incurs a distortion at least D. Suppose $\mathcal{S}$ is a collection of metrics such that every subset of k points in each metric in $\mathcal{S}$ embeds into $\mathcal{T}$ with distortion at most ρ. Setting $\epsilon = 1/9k^2$, there exist arbitrarily large metrics that embed into $\mathcal{S}$ with ϵ-slack distortion $\Omega(\frac{D}{\rho})$.*

Remark. In order to obtain lower bounds for *ϵ-uniform slack* embeddings instead of ϵ-slack embeddings, we need to set $\epsilon = 1/3k$ instead of $\epsilon = 1/9k^2$; the rest of the proof remains essentially unchanged.

Before we prove Lemma 5.4, let us show how to derive the above results from it.

Proof of Theorem 5.2. Suppose $\{H_k\}$ is the given family of metrics. Let us fix a large enough k such that $\epsilon = 1/9k^2$ is small enough. Now in Lemma 5.4, let us set H to be H_k and $\mathcal{T}$ to be the collection of metrics with k points in ℓ_p with at most $L(k)$ dimensions. Hence H embeds into $\mathcal{T}$ with distortion at least $D(k) = D(\frac{1}{3\sqrt{\epsilon}})$. We set $\mathcal{S}$ to be the family of metrics in ℓ_p with at most $L(k) = L(\frac{1}{3\sqrt{\epsilon}})$ dimensions. It follows that any subset of k points in any metric in $\mathcal{S}$ embeds into $\mathcal{T}$ with distortion 1. Hence we conclude that there exists a family of metrics, each of which embeds into ℓ_p with at most $L(\frac{1}{3\sqrt{\epsilon}})$ dimensions with ϵ-slack distortion at least $\Omega(D(\frac{1}{3\sqrt{\epsilon}}))$. □

The application of Lemma 5.4 to prove the lower bounds for embeddings into trees is very similar; we sketch it here to emphasize the general patterns, as well as the slight changes required.

Proof of Theorem 5.3. Again, we fix a large enough k, and set $\epsilon = 1/9k^2$. As before, H is set to be H_k. We set $\mathcal{T}$ to be the family of tree metrics on k points (or distribution of tree metrics on k points). Again, H embeds into $\mathcal{T}$ with distortion at least $D(k) = D(\frac{1}{3\sqrt{\epsilon}})$. We set $\mathcal{S}$ to be the family of tree metrics (or distribution of tree metrics). Note that, by a result of Gupta [18], any subset of k points in any metric in $\mathcal{S}$ embeds into $\mathcal{T}$ with distortion at most 8. Now the result of Theorem 5.3 follows from Lemma 5.4 as before. □

Let us now prove the Lemma 5.4: First we show how to construct a family of metrics with the desired properties. Suppose $H = (S, d)$ is a metric such that $|S| = k$. Moreover, H embeds into $\mathcal{T}$ with distortion at least D. Without loss of generality, assume that the pairwise distance in H is at least 1. For each n that is a multiple of $3k$, we define a metric $\hat{H}$ with n points in the following way. These would be the family of metrics that exhibits the lower bound for slack embeddings.

Consider a uniform line metric with point set L of size $\frac{n}{k}$ such that the two terminal points are at distance δ away from each other, where δ is small and whose value will be specified later. For each $s \in S$, we identify s with a terminal point of a copy L_s of the line metric L. We call the augmented metric $\hat{H} = (V, d)$ with point set $V = \cup_{s \in S} L_s$. If H is already in some host space X, we just need the condition that, for each $s \in S$, we can embed a copy of L of length δ isomorphically into X that identifies one end point with s. Common metric spaces like ℓ_p certainly satisfy this condition. (Note that to avoid too many symbols, we use d for the various metrics.) Hence, for $u \in L_x$ and $v \in L_y$, $|d(u, v) - d(x, y)| \leq 2\delta$.

PROPOSITION 5.5. *Let H and $\hat{H}$ be metrics defined as above. Then (a) if H is a metric induced by a K_r-minor-free graph, then so is $\hat{H}$, and (b) if H is a doubling metric, then so is $\hat{H}$.*

The next lemma states a crucial property of the edges that are ignored by any ϵ-slack embedding.

LEMMA 5.6. *Suppose an ϵ-slack embedding of some metric space (V, d) ignores the set of edges E. Then there exists a subset $T \subseteq V$ of size at least $(1 - \sqrt{\epsilon})n$ such that each vertex in T intersects with at most $\sqrt{\epsilon}n$ edges in E.*

Proof. It suffices to show that it is impossible to have a subset $S \subseteq V$ of size greater than $\sqrt{\epsilon}n$ such that each vertex in S intersects more than $\sqrt{\epsilon}n$ edges in E. Otherwise, the total number of edges ignored would be greater than $(\sqrt{\epsilon}n)^2/2 > \epsilon n^2/2 > \epsilon\binom{n}{2}$. ∎

Note that, for an *ϵ-uniform slack* embedding, the number of ignored edges incident on any node is at most ϵn by definition; this is one place in the proof which changes when considering uniform slack.

The following lemma implies Lemma 5.4.

LEMMA 5.7. *Let $H = (S, d)$ be a metric space on k points. Suppose $\mathcal{T}$ and $\mathcal{S}$ are families of metrics such that H embeds into $\mathcal{T}$ with distortion at least D, and every subset of k points in each metric in $\mathcal{S}$ embeds into $\mathcal{T}$ with distortion at most ρ.*

Suppose δ is small enough such that $(\frac{D}{4\rho} + 2)\delta \leq \frac{1}{2}$. Let $\hat{H} = (V, d)$ be the metric space defined as above. Let $\epsilon := 1/9k^2$. Then, $\hat{H}$ embeds into $\mathcal{S}$ with ϵ-slack distortion at least $D/4\rho$.

Proof. Suppose, on the contrary, φ is an embedding of $\hat{H}$ into $\mathcal{S}$ with ϵ-slack distortion $R < D/4\rho$ that ignores the set E of edges. Then, by Lemma 5.6, there exists a subset T of V such that $|T| \geq (1 - \sqrt{\epsilon})n$ and, for all $v \in T$, v intersects at most $\sqrt{\epsilon}n$ edges in E.

For each $s \in S$, the set L_s contains $\frac{n}{k} = 3\sqrt{\epsilon}n$ points, and hence there exists some point in $T \cap L_s$, which we call v_s. We define an embedding ψ of H into $\mathcal{S}$ given by $\psi(s) := \varphi(v_s)$. We next bound the distortion of the embedding ψ. Let $x, y \in S$. Since v_x and v_y are in T, each of them has at most $\sqrt{\epsilon}n$ neighbors. Observing that $|L_y| = 3\sqrt{\epsilon}n$, it follows that there exists a point $t \in L_y$ such that neither $\{v_x, t\}$ nor $\{v_y, t\}$ is contained in E. We can assume that for $\{u, v\} \notin E$, $d(u, v) \leq ||\varphi(u) - \varphi(v)|| \leq Rd(u, v)$.

Hence it follows that

$$\begin{aligned}\|\psi(x) - \psi(y)\| =& \|\varphi(v_x) - \varphi(v_y)\| \\ \leq& \|\varphi(v_x) - \varphi(t)\| + \|\varphi(t) - \varphi(v_y)\| \\ \leq& R(d(v_x, t) + d(t, v_y)) \leq R(d(x, y) + 3\delta) \\ \leq& R(1 + 3\delta)d(x, y) \leq 2Rd(x, y),\end{aligned}$$

and, similarly,

$$\begin{aligned}\|\psi(x) - \psi(y)\| \geq& \|\varphi(v_x) - \varphi(t)\| - \|\varphi(t) - \varphi(v_y)\| \\ \geq& d(v_x, t) - Rd(t, v_y) \geq d(x, y) - 2\delta - R\delta \\ \geq& (1 - (R + 2)\delta)d(x, y) \geq d(x, y)/2,\end{aligned}$$

where the last inequality follows from the fact that $(R + 2)\delta \leq 1/2$. It then follows that ψ embeds H into $\mathcal{S}$ with distortion at most $4R$. However, since any metric in $\mathcal{S}$ embeds into $\mathcal{T}$ with distortion at most ρ, it follows that H embeds into $\mathcal{T}$ with distortion at most $4\rho R < D$, from which we obtain the desired contradiction. ∎

5.2. Lower bounds for contracting embeddings. Let us consider contracting embeddings with slack. Formally, a contracting embedding has distortion D with ϵ-slack if no pairwise distance expands and all but ϵ-fraction of the pairs contract by no more than D. We show that such embeddings incur an $\Omega(\log n)$ distortion in order to embed constant-degree expander graphs into ℓ_p, $p \geq 1$.

THEOREM 5.8. *For the shortest-paths metric of a bounded-degree expander on n vertices, distortion of any contracting embedding into ℓ_p, $p \geq 1$, is $\Omega(\frac{1}{p}\log n)$ even if we allow slack $\epsilon < \frac{1}{2}$.*

Proof. Let $G = (V, E)$ be a bounded-degree expander on n vertices, and let ρ denote its shortest-path metric. Let φ be a contracting embedding of this metric to ℓ_p, $p \geq 1$, with distortion D and slack $\epsilon < \frac{1}{2}$. Let σ denote the metric on ℓ_p; to simplify the notation, we will denote $\varphi(V) \subseteq \ell_p$ by V. Define

$$R(\sigma) = \sqrt{\sigma^2(V \times V)/\sigma^2(E)}\,, \text{ where}$$
$$\sigma^2(S) = \textstyle\sum_{(x,y)\in S} \sigma(x,y)^2 \text{ for any set } S \subseteq V \times V.$$

First we show that $R(\sigma) \leq O(\sqrt{n})$. The proof is exactly the same as that of Theorem 15.5.1 in Matŏusek [35] and works despite the fact that we allow $\varepsilon \cdot n^2$ pairwise distances to be as low as 0. Note that

$$\sigma^2(E) = \sum_{(x,y)\in E} \sigma(x,y)^2 \leq \sum_{(x,y)\in E} \rho(x,y)^2 = O(n).$$

Now we bound $\sigma^2(V \times V)$ from below. If all n^2 pairs were contracted by at most D, then we would get

$$\sigma^2(V \times V) \geq \sum_{(u,v)} \left(\frac{\rho(u,v)}{D}\right)^2 \geq \frac{n^2 \log^2 n}{D^2}.$$

However, we need to take into account the fact that $\varepsilon \cdot n^2$ pairs of vertices could have distance 0 between them. Therefore, $\sigma^2(V \times V)$ is at least $(n/D)^2(\log^2 n)$ minus the loss due to the slack. To upper-bound this loss, consider a pair (x, y) of nodes for which the distortion is bigger than D. The pair will contribute 0 instead of $\rho(x, y)/D$. Thus the loss due to the pair (x, y) is at most $(\log n)/D$. Therefore, the total loss due to the slack is at most $\epsilon(n/D)^2(\log^2 n)$. Therefore, since $R(\sigma) \leq O(\sqrt{n})$, it follows that $D = \Omega(\log n)$. ∎

Appendix A. Tools from probability theory. Here we state some tools from probability theory that we used in section 4.

LEMMA A.1 (Chernoff bounds). *Consider the sum X of n independent random variables on $[0, \Delta]$.*

(a) *For any $\mu \leq E(X)$ and any $\epsilon \in (0, 1)$ we have*

$$\Pr[X < (1-\epsilon)\mu] \leq \exp(-\epsilon^2\mu/2\Delta).$$

(b) *For any $\mu \geq E(X)$ and any $\beta \geq 1$ we have* $\Pr[X > \beta\mu] \leq \left[\frac{1}{e}(e/\beta)^\beta\right]^{\mu/\Delta}$.

For a random variable X define the *distribution function* $F_X(t) = \Pr[X < t]$. For two random variables X and Y, say Y *stochastically dominates* X (written as $Y \succeq X$ or $X \preceq Y$) if $F_Y(t) \leq F_X(t)$ for all $t \in \mathbb{R}$.

LEMMA A.2. *Consider two sequences of independent random variables $\{X_i\}$ and $\{Y_i\}$ such that all X_i and Y_i have finite domains and $X_i \preceq Y_i$ for each i. Then for each k we have $\sum_{i=1}^k X_i \preceq \sum_{i=1}^k Y_i$.*

LEMMA A.3. *Consider two sequences of Bernoulli random variables* $\{X_i\}$ *and* $\{Y_i\}$ *such that variables* $\{Y_i\}$ *are independent and*

$$\Pr[X_i = 1 \mid X_j, j < i] \geq \Pr[Y_i = 1]$$

for each i. *Then* $\sum_{i=1}^{k} X_i \succeq \sum_{i=1}^{k} Y_i$ *for each* k.

Proof. We first show that for all $t \in [T]$,

$$\Pr\left[\sum_{r=1}^{t} X_r + \sum_{r=t+1}^{T} Y_r \leq m\right] \leq \Pr\left[\sum_{r=1}^{t-1} X_r + \sum_{r=t}^{T} Y_r \leq m\right], \tag{A.1}$$

which would immediately imply the lemma. Observe that for any fixed number a (or in general any random variable that is measurable in the σ-field generated by the random variables $\{X_r : r < t\}$), we have

$$\Pr\left[X_t \leq a | X_r, r < t\right] \leq Pr[Y_t \leq a] = \Pr\left[Y_t \leq a | X_r, r < t\right].$$

Note that the interesting case is when $a \in [0, 1)$. The inequality comes from the assumption concerning the conditional probabilities of the sequence $\{X_r\}$, and the equality comes from the fact that Y_t is independent of the sequence $\{X_r\}$.

Since both X_t and Y_t are independent of $\{Y_r : r > t\}$, the above inequality would still hold if we further condition on the random variables $\{Y_r : r > t\}$. Finally, setting $a = m - \sum_{i<t} X_r - \sum_{i>t} Y_r$, which is measurable in the σ-field generated by $J := \{X_r : r < t\} \cup \{Y_r : r > t\}$, we obtain

$$\Pr\left[\sum_{r=1}^{t} X_r + \sum_{r=t+1}^{T} Y_r \leq m \,|\, J\right] \leq \Pr\left[\sum_{r=1}^{t-1} X_r + \sum_{r=t}^{T} Y_r \leq m \,|\, J\right].$$

Taking the expectation on both sides gives (A.1). ∎

LEMMA A.4. *Consider a sequence of i.i.d. Bernoulli random variables* $\{Y_i\}$ *with success probability* q. *Let* Z_r *be the number of trials between the* $(r-1)$*th success and the* r*th success. Then*

$$\Pr\left[\sum_{r=1}^{k} Z_r > 2k/q\right] \leq (0.782)^k. \tag{A.2}$$

Proof. Each Z_r has a geometric distribution with parameter q, so its moment generating function is

$$E\left[e^{tZ_r}\right] = \frac{qe^t}{q - (1-q)e^t}.$$

Let $Z = \sum_{r=1}^{k} Z_r$. Since Z_r's are i.i.d., it follows that

$$E\left[e^{tZ}\right] = E\left[\prod_r e^{tZ_r}\right] = \left(E\left[e^{tZ_1}\right]\right)^k.$$

By the Markov inequality for any $t > 0$ we have

$$Pr\left[Z > 2\frac{k}{q}\right] = Pr\left[e^{tZ} > e^{2tk/q}\right] \leq E\left[e^{tZ}\right] e^{-2tk/q} \leq \left(\frac{qe^t}{(1-(1-q)e^t)e^{2t/q}}\right)^k.$$

Plugging in $q = 1 - 1/\sqrt{e}$ and $t = q$ we have (A.2). ∎

THE CONNECTIVITY OF BOOLEAN SATISFIABILITY: COMPUTATIONAL AND STRUCTURAL DICHOTOMIES*

PARIKSHIT GOPALAN†, PHOKION G. KOLAITIS‡, ELITZA MANEVA‡, AND CHRISTOS H. PAPADIMITRIOU§

Abstract. Boolean satisfiability problems are an important benchmark for questions about complexity, algorithms, heuristics, and threshold phenomena. Recent work on heuristics and the satisfiability threshold has centered around the structure and connectivity of the solution space. Motivated by this work, we study structural and connectivity-related properties of the space of solutions of Boolean satisfiability problems and establish various dichotomies in Schaefer's framework. On the structural side, we obtain dichotomies for the kinds of subgraphs of the hypercube that can be induced by the solutions of Boolean formulas, as well as for the diameter of the connected components of the solution space. On the computational side, we establish dichotomy theorems for the complexity of the connectivity and *st*-connectivity questions for the graph of solutions of Boolean formulas. Our results assert that the intractable side of the computational dichotomies is PSPACE-complete, while the tractable side—which includes but is not limited to all problems with polynomial-time algorithms for satisfiability—is in P for the *st*-connectivity question, and in coNP for the connectivity question. The diameter of components can be exponential for the PSPACE-complete cases, whereas in all other cases it is linear; thus, diameter and complexity of the connectivity problems are remarkably aligned. The crux of our results is an expressibility theorem showing that in the tractable cases, the subgraphs induced by the solution space possess certain good structural properties, whereas in the intractable cases, the subgraphs can be arbitrary.

Key words. Boolean satisfiability, computational complexity, PSPACE, PSPACE-completeness, dichotomy theorems, graph connectivity

1. Introduction.

In 1978, Schaefer [31] introduced a rich framework for expressing variants of Boolean satisfiability and proved a remarkable *dichotomy theorem*: the satisfiability problem is in P for certain classes of Boolean formulas, while it is NP-complete for all other classes in the framework. This result pinpoints the computational complexity of numerous well-known variants of Boolean SAT, such as 3-SAT, HORN 3-SAT, NOT-ALL-EQUAL 3-SAT, and 1-IN-3 SAT. Schaefer's dichotomy theorem yields a classification of the computational complexity of constraint satisfaction problems (CSPs) over the Boolean domain. Feder and Vardi [15] conjectured that a dichotomy theorem holds for the complexity of CSPs over arbitrary finite domains. This conjecture remains open to date, in spite of concerted efforts and some partial progress, such as the case of domains of size 3 [8].

In this article we concentrate on the Boolean CSPs, but we ask a new set of questions, which was motivated from the study of random instances of satisfiability. In recent years, the structure of the space of solutions for random instances has been the main consideration at the basis of both algorithms for and mathematical analysis of the satisfiability problem [3, 26, 28, 25]. It has been conjectured for 3-SAT [28, 4] and proved for 8-SAT [27, 1] that the solution space fractures as one approaches the *critical region* from below. This apparently leads to performance deterioration of the standard satisfiability algorithms, such as WalkSAT [32] and DPLL [2]. It is also the main consideration behind the design of the survey propagation algorithm, which has far superior performance on random instances of satisfiability [28]. This body of work has served as a motivation for us to pursue the investigation reported here.

Our aim in this article is to carry out a comprehensive exploration of the *connectivity properties* of the space of solutions of Boolean formulas from a worst-case point of view. The solutions (satisfying assignments) of a given n-variable Boolean formula φ induce a subgraph $G(\varphi)$ of the n-dimensional hypercube. Thus, the following two decision problems, called the *connectivity problem* and the *st-connectivity problem*, arise naturally: (i) Given a Boolean formula φ, is $G(\varphi)$ connected? (ii) Given a Boolean formula φ and two solutions $\mathbf{s}$ and $\mathbf{t}$ of φ, is there a path from $\mathbf{s}$ to $\mathbf{t}$ in $G(\varphi)$?

While there has been an intensive study of the structure of the solution space of Boolean satisfiability problems for random instances, our work seems to be the first to explore this issue from a worst-case viewpoint. A priori, it is not clear what to expect. Is the hardness of the satisfiability question for a given CSP at all correlated with the properties of the graphs realizable as $G(\varphi)$ of formulas in the given class? What kinds of graphs are realizable? Are there Boolean CSPs whose connectivity graphs can have connected components with exponential diameter and, if yes, can we characterize these CSPs? What is the complexity of the *st*-connectivity and the connectivity problem, and is it correlated with the answer to the previous question?

In this article, we investigate the above questions for Boolean CSPs and obtain answers for all of them. Our first complexity-theoretic result is a dichotomy theorem for the *st*-connectivity problem. This result reveals that the tractable side is much more generous than the tractable side for satisfiability, while the intractable side is PSPACE-complete. Specifically, Schaefer showed that the satisfiability problem is solvable in polynomial time precisely for formulas built from Boolean relations all of which are bijunctive, or all of which are Horn, or all of which are dual Horn, or all of which are affine. We identify new classes of Boolean relations, called *tight* relations, that properly contain the classes of bijunctive, Horn, dual Horn, and affine relations. We show that *st*-connectivity is solvable in linear time for formulas built from tight relations, and PSPACE-complete in all other cases. Our second main result is a dichotomy theorem for the connectivity problem: it is in coNP for formulas built from tight relations, and PSPACE-complete in all other cases.

In addition to these two complexity-theoretic dichotomies, we establish a structural dichotomy theorem for the diameter of the connected components of the solution space of Boolean formulas. This result asserts that, in the PSPACE-complete cases, the diameter of the connected components can be exponential, but in all other cases it is linear. Thus, small diameter and tractability of the *st*-connectivity problem are remarkably aligned.

To establish our results, the main challenge is to show that for noneasy relations, both the connectivity problem and the *st*-connectivity problem are PSPACE-hard. In Schaefer's dichotomy theorem, NP-hardness of satisfiability was a consequence of

an *expressibility* theorem, which asserted that every Boolean relation can be obtained as a projection over a formula built from clauses in the "hard" relations. Schaefer's notion of expressibility is inadequate for our problem. Instead, we introduce and work with a delicate and stricter notion of expressibility, which we call *structural expressibility*. Intuitively, structural expressibility means that, in addition to definability via a projection, the space of witnesses of the existential quantifiers in the projection has certain strong connectivity properties that allow us to capture the graph structure of the relation that is being defined. It should be noted that Schaefer's dichotomy theorem can also be proved using a Galois connection and Post's celebrated classification of the lattice of Boolean clones (see [5]). This method, however, does not appear to apply to connectivity, as the boundaries discovered here cut across Boolean clones. Thus, the use of structural expressibility or some other refined definability technique seems unavoidable.

The first step towards proving PSPACE-completeness is to show that both connectivity and *st*-connectivity are hard for 3-CNF-formulas; this is proved by a reduction from a generic PSPACE computation. Next, we identify the simplest relations that are not tight: these are ternary relations whose graph is a path of length 4 between assignments at Hamming distance 2. We show that these paths can structurally express all 3-CNF clauses. The crux of our hardness result is an *expressibility* theorem to the effect that one can structurally express such a path from any set of relations which is not tight.

Finally, we show that all *tight* relations have "good" structural properties. Specifically, in a tight relation every component has a unique minimum element, or every component has a unique maximum element, or the Hamming distance coincides with the shortest-path distance in the relation. These properties are inherited by every formula built from tight relations and yield both small diameter and linear algorithms for *st*-connectivity.

Related work. In parallel and independently of our work, a similar dichotomy was found for the k-colorability problem by Bonsma and Cereceda [6] and Cereceda, van den Heuvel, and Johnson [9]. Specifically, Cereceda, van den Heuvel, and Johnson [9] showed that the case of 3-colorability has properties similar to our tight problems—its structure implies (by a proof that is much more intricate than ours for tight problems) that the diameter of connected components of the graph of 3-colorings is at most quadratic in the number of vertices. This implies that the *st*-connectivity question for 3-colorability is in coNP. Furthermore, Bonsma and Cereceda [6] showed that for $k \geq 4$, *st*-connectivity is PSPACE-complete. This result shows an interesting complexity-theoretic difference between 3-colorability and 4-colorability. It also indicates that an extension of our result to larger domains will be quite challenging, since one would have to identify a set of "tight" problems that includes 3-colorability. It is conceivable that characterizing the complexity of the connectivity question is easier than characterizing the complexity of the satisfiability question, but at present there is no conjecture that generalizes both the Boolean case and the case of colorings.

In an earlier piece of related work, Brightwell and Winkler [7] considered the connectivity of the graph of solutions of the graph-homomorphism problems (which are a subclass of CSPs). They characterized those graphs H for which the graph-homomorphism problem with template H, also known as the H-coloring problem, has a graph of solutions that is always connected. Their motivation is the study of uniqueness of Gibbs measures, which is related to the performance of standard Markov chain algorithms for sampling and counting solutions. We note that the state-space

of many of the Markov chains studied in this area is the set of solutions, and steps of the chain are single-variable flips, so that the chain is just a random walk on the graph of solutions considered here.

In a different direction, there has been a substantial body of work on dichotomy theorems for various aspects of constraint satisfaction on the Boolean domain, including optimization [10, 14, 21], counting [12], inverse satisfiability [20], minimal satisfiability [22], lexicographically minimal satisfiability [30], and propositional abduction [13]. Our results contribute to this body of work.

Finally, it is worth mentioning that satisfiability in the context of random instances has also been considered not only for specific CSPs such as k-SAT and k-colorability, but also for general CSPs. Several models of general random CSPs have been studied by Creignou and Daudé [11], and independently by Molloy [29].

2. Basic concepts and statements of results. A CNF-formula is a Boolean formula of the form $C_1 \wedge \cdots \wedge C_n$, where each C_i is a clause, i.e., a disjunction of literals. If k is a positive integer, then a k-CNF-formula is a CNF-formula $C_1 \wedge \cdots \wedge C_n$ in which each clause C_i is a disjunction of at most k literals.

A *logical relation* R is a nonempty subset of $\{0,1\}^k$ for some $k \geq 1$; k is the *arity* of R. Let $\mathcal{S}$ be a finite set of logical relations. A CNF($\mathcal{S}$)*-formula* over a set of variables $V = \{x_1, \ldots, x_n\}$ is a finite conjunction $C_1 \wedge \cdots \wedge C_n$ of clauses built using relations from $\mathcal{S}$, variables from V, and the constants 0 and 1; this means that each C_i is an expression of the form $R(\xi_1, \ldots, \xi_k)$, where $R \in \mathcal{S}$ is a relation of arity k, and each ξ_j is a variable in V or one of the constants 0, 1. Note that the constants 0 and 1 are allowed in CNF($\mathcal{S}$)-formulas; this is equivalent to assuming that the set $\mathcal{S}$ contains the singleton logical relations $\{0\}$ and $\{1\}$. One could also consider CNF($\mathcal{S}$)-formulas without constants. In fact, this class of formulas has already been considered by Schaefer [31], as well as by other researchers in subsequent investigations. In particular, Schaefer [31] also established a dichotomy theorem for the complexity of the satisfiability problem for CNF($\mathcal{S}$)-formulas without constants. A *solution* of a CNF($\mathcal{S}$)-formula φ is an assignment $s = (a_1, \ldots, a_n)$ of Boolean values to the variables that makes every clause of φ true. A CNF($\mathcal{S}$)-formula is *satisfiable* if it has at least one solution.

The *satisfiability problem* SAT($\mathcal{S}$) associated with a finite set $\mathcal{S}$ of logical relations asks the following: Given a CNF($\mathcal{S}$)-formula φ, is it satisfiable? Many well-known restrictions of Boolean satisfiability, such as 3-SAT, NOT-ALL-EQUAL 3-SAT, and POSITIVE 1-IN-3 SAT, can be cast as SAT($\mathcal{S}$) problems, for a suitable choice of $\mathcal{S}$. For instance, let $R_0 = \{0,1\}^3 \backslash \{000\}$, $R_1 = \{0,1\}^3 \backslash \{100\}$, $R_2 = \{0,1\}^3 \backslash \{110\}$, $R_3 = \{0,1\}^3 \backslash \{111\}$. Then 3-SAT is the problem SAT($\{R_0, R_1, R_2, R_3\}$). Similarly, POSITIVE 1-IN-3SAT is SAT($\{R_{1/3}\}$), where $R_{1/3} = \{100, 010, 001\}$.

Schaefer [31] identified the complexity of *every* satisfiability problem SAT($\mathcal{S}$), where $\mathcal{S}$ ranges over all finite sets of logical relations. To state Schaefer's main result, we need to define some basic concepts.

DEFINITION 2.1. *Let R be a logical relation.*

1. *R is* bijunctive *if it is the set of solutions of a* 2-CNF*-formula.*
2. *R is* Horn *if it is the set of solutions of a Horn formula, where a Horn formula is a* CNF*-formula such that each conjunct has at most one positive literal.*
3. *R is* dual Horn *if it is the set of solutions of a dual Horn formula, where a dual Horn formula is a* CNF*-formula such that each conjunct has at most one negative literal.*
4. *R is* affine *if it is the set of solutions of a system of linear equations over $\mathbb{Z}_2$.*

Each of these types of logical relations can be characterized in terms of *closure* properties [31]. In what follows, we use boldface letters to denote vectors of Boolean values or vectors of variables. A relation R is bijunctive if and only if it is closed under the *majority* operation; this means that if $\mathbf{a}, \mathbf{b}, \mathbf{c} \in R$, then $\text{maj}(\mathbf{a}, \mathbf{b}, \mathbf{c}) \in R$, where $\text{maj}(\mathbf{a}, \mathbf{b}, \mathbf{c})$ is the vector whose ith bit is the majority of a_i, b_i, c_i. A relation R is Horn if and only if it is closed under $\wedge$; this means that if $\mathbf{a}, \mathbf{b} \in R$, then $\mathbf{a} \wedge \mathbf{b} \in R$, where $\mathbf{a} \wedge \mathbf{b}$ is the vector whose ith bit is $a_i \wedge b_i$. Similarly, R is dual Horn if and only if it is closed under $\vee$. Finally, R is affine if and only if it is closed under $\mathbf{a} \oplus \mathbf{b} \oplus \mathbf{c}$.

DEFINITION 2.2. *A set $\mathcal{S}$ of logical relations is* Schaefer *if at least one of the following conditions holds:*

1. *Every relation in $\mathcal{S}$ is bijunctive.*
2. *Every relation in $\mathcal{S}$ is Horn.*
3. *Every relation in $\mathcal{S}$ is dual Horn.*
4. *Every relation in $\mathcal{S}$ is affine.*

A logical relation R is Schaefer *if the singleton $\{R\}$ is Schaefer.*

Since the property of a set being Schaefer is characterized in terms of closure under operations that are binary or ternary, it follows that there is a cubic algorithm to determine whether or not a given a finite set $\mathcal{S}$ of logical relations is Schaefer (assuming that each relation in $\mathcal{S}$ is given as a list of Boolean vectors).

THEOREM 2.3 (Schaefer's dichotomy theorem [31]). *Let $\mathcal{S}$ be a finite set of logical relations. If $\mathcal{S}$ is Schaefer, then* SAT($\mathcal{S}$) *is in* P*; otherwise,* SAT($\mathcal{S}$) *is* NP*-complete.*

Theorem 2.3 is called a dichotomy theorem because Ladner [23] has shown that if P $\neq$ NP, then there are problems in NP that are neither in P nor NP-complete. Thus, Theorem 2.3 asserts that no SAT($\mathcal{S}$) problem is a problem of the kind discovered by Ladner. Note that the aforementioned characterization of Schaefer sets in terms of closure properties yields a cubic algorithm for determining, given a finite set $\mathcal{S}$ of logical relations, whether SAT($\mathcal{S}$) is in P or is NP-complete (here, the input size is the sum of the sizes of the relations in $\mathcal{S}$).

The more difficult part of the original proof of Schaefer's dichotomy theorem is to show that if $\mathcal{S}$ is not Schaefer, then SAT($\mathcal{S}$) is NP-complete. This is a consequence of a powerful result about the expressibility of logical relations. We say that a relation R is *expressible from* a set $\mathcal{S}$ of relations if there is a CNF($\mathcal{S}$)-formula $\varphi(\mathbf{x}, \mathbf{y})$ such that $R = \{\mathbf{a} |\ \exists \mathbf{y} \varphi(\mathbf{a}, \mathbf{y})\}$.

THEOREM 2.4 (Schaefer's expressibility theorem [31]). *Let $\mathcal{S}$ be a finite set of logical relations. If $\mathcal{S}$ is not Schaefer, then every logical relation is expressible from $\mathcal{S}$.*

In this paper, we are interested in the connectivity properties of the space of solutions of CNF($\mathcal{S}$)-formulas. If φ is a CNF($\mathcal{S}$)-formula with n variables, then the *solution graph* $G(\varphi)$ of φ denotes the subgraph of the n-dimensional hypercube induced by the solutions of φ. This means that the vertices of $G(\varphi)$ are the solutions of φ, and there is an edge between two solutions of $G(\varphi)$ precisely when they differ in exactly one variable.

We consider the following two algorithmic problems for CNF($\mathcal{S}$)-formulas.

Problem 1. *The Connectivity Problem* CONN($\mathcal{S}$). Given a CNF($\mathcal{S}$)-formula φ, is $G(\varphi)$ connected? (If φ is unsatisfiable, then the answer to this problem is "yes.")

Problem 2. *The st-Connectivity Problem* ST-CONN($\mathcal{S}$). Given a CNF($\mathcal{S}$)-formula φ and two solutions $\mathbf{s}$ and $\mathbf{t}$ of φ, is there a path from $\mathbf{s}$ to $\mathbf{t}$ in $G(\varphi)$?

To pinpoint the computational complexity of CONN($\mathcal{S}$) and ST-CONN($\mathcal{S}$), we need to introduce certain new types of relations.

DEFINITION 2.5. *Let $R \subseteq \{0,1\}^k$ be a logical relation.*

1. *R is* componentwise bijunctive *if every connected component of the graph $G(R)$ is a bijunctive relation.*
2. *R is* OR-free *if the relation* $\mathrm{OR} = \{01, 10, 11\}$ *cannot be obtained from R by setting $k-2$ of the coordinates of R to a constant $\mathbf{c} \in \{0,1\}^{k-2}$. In other words, R is* OR*-free if $(x_1 \vee x_2)$ is not definable from R by fixing $k-2$ variables.*
3. *R is* NAND-free *if the relation* $\mathrm{NAND} = \{00, 01, 10\}$ *cannot be obtained from R by setting $k-2$ of the coordinates of R to a constant $\mathbf{c} \in \{0,1\}^{k-2}$. In other words, R is* NAND*-free if $(\bar{x}_1 \vee \bar{x}_2)$ is not definable from R by fixing $k-2$ variables.*

We are now ready to introduce the key concept of a *tight* set of relations.

DEFINITION 2.6. *A set $\mathcal{S}$ of logical relations is* tight *if at least one of the following three conditions holds:*

1. *Every relation in $\mathcal{S}$ is componentwise bijunctive.*
2. *Every relation in $\mathcal{S}$ is* OR*-free.*
3. *Every relation in $\mathcal{S}$ is* NAND*-free.*

A logical relation R is tight *if the singleton $\{R\}$ is tight.*

In section 4, we show that if $\mathcal{S}$ is Schaefer, then it is tight. Moreover, we show that the converse does not hold. It is also easy to see that there is a polynomial-time algorithm (in fact, a cubic algorithm) for testing whether a given relation is tight.

Just as Schaefer's dichotomy theorem follows from an expressibility statement, our dichotomy theorems are derived from the following theorem, which we will call the structural expressibility theorem. The precise definition of the concept of *structural expressibility* is given in section 3. Intuitively, this concept strengthens the concept of expressibility with the requirement that the space of the witnesses to the existentially quantified variables has certain strong connectivity properties.

THEOREM 2.7 (structural expressibility theorem). *Let $\mathcal{S}$ be a finite set of logical relations. If $\mathcal{S}$ is not tight, then every logical relation is structurally expressible from $\mathcal{S}$.*

Using the structural expressibility theorem, we obtain the following dichotomy theorems for the computational complexity of $\textsc{Conn}(\mathcal{S})$ and $\textsc{st-Conn}(\mathcal{S})$.

THEOREM 2.8. *Let $\mathcal{S}$ be a finite set of logical relations. If $\mathcal{S}$ is tight, then* $\textsc{Conn}(\mathcal{S})$ *is in* coNP*; otherwise, it is* PSPACE*-complete.*

THEOREM 2.9. *Let $\mathcal{S}$ be a finite set of logical relations. If $\mathcal{S}$ is tight, then* $\textsc{st-Conn}(\mathcal{S})$ *is in* P*; otherwise,* $\textsc{st-Conn}(\mathcal{S})$ *is* PSPACE*-complete.*

We also show that if $\mathcal{S}$ is tight, but not Schaefer, then $\textsc{Conn}(\mathcal{S})$ is coNP-complete.

Example 1. The set $\mathcal{S} = \{R_{1/3}\}$, where $R_{1/3} = \{100, 010, 001\}$, is tight (actually, it is componentwise bijunctive), but not Schaefer. It follows that $\textsc{Sat}(\mathcal{S})$ is NP-complete (recall that this problem is POSITIVE 1-IN-3 SAT), $\textsc{st-Conn}(\mathcal{S})$ is in P, and $\textsc{Conn}(\mathcal{S})$ is coNP-complete.

Example 2. The set $\mathcal{S} = \{R_{\mathrm{NAE}}\}$, where $R_{\mathrm{NAE}} = \{0,1\}^3 \setminus \{000, 111\}$, is not tight; hence $\textsc{Sat}(\mathcal{S})$ is NP-complete (this problem is POSITIVE NOT-ALL-EQUAL 3-SAT), while both $\textsc{st-Conn}(\mathcal{S})$ and $\textsc{Conn}(\mathcal{S})$ are PSPACE-complete.

Example 3. The set $\mathcal{S} = \{R_V\}$, where $R_V = \{110, 100, 000, 001, 011\}$, is not tight. It is OR-free, but not NAND-free or componentwise bijunctive, and it is not Schaefer. Hence $\textsc{Sat}(\mathcal{S})$ is NP-complete, $\textsc{st-Conn}(\mathcal{S})$ is in P, and $\textsc{Conn}(\mathcal{S})$ is in coNP.

Remark. The last example illustrates that OR-free (NAND-free) relations cannot be thought of as componentwise Horn (dual Horn).

The dichotomy in the computational complexity of CONN($\mathcal{S}$) and ST-CONN($\mathcal{S}$) is accompanied by a parallel structural dichotomy in the size of the diameter of $G(\varphi)$ (where, for a CNF($\mathcal{S}$)-formula φ, the *diameter of* $G(\varphi)$ is the maximum of the diameters of the components of $G(\varphi)$).

THEOREM 2.10. *Let $\mathcal{S}$ be a finite set of logical relations. If $\mathcal{S}$ is tight, then for every* CNF($\mathcal{S}$)*-formula φ, the diameter of $G(\varphi)$ is linear in the number of variables of φ; otherwise, there are* CNF($\mathcal{S}$)*-formulas φ such that the diameter of $G(\varphi)$ is exponential in the number of variables of φ.*

Our results and their comparison to Schaefer's dichotomy theorem are summarized in the table below.

$\mathcal{S}$	SAT($\mathcal{S}$)	ST-CONN($\mathcal{S}$)	CONN($\mathcal{S}$)	Diameter
Schaefer	P	P	coNP	$O(n)$
Tight, non-Schaefer	NP-complete	P	coNP-complete	$O(n)$
Nontight	NP-complete	PSPACE-complete	PSPACE-complete	$2^{\Omega(\sqrt{n})}$

We conjecture that the complexity of CONN($\mathcal{S}$) exhibits a *trichotomy*, that is, for every finite set $\mathcal{S}$ of logical relations, one of the following holds:

1. CONN($\mathcal{S}$) is in P.
2. CONN($\mathcal{S}$) is coNP-complete.
3. CONN($\mathcal{S}$) is PSPACE-complete.

As mentioned above, we will show that if $\mathcal{S}$ is tight but not Schaefer, then CONN($\mathcal{S}$) is coNP-complete. We will also show that if $\mathcal{S}$ is bijunctive or affine, then CONN($\mathcal{S}$) is in P. Hence, to settle the above conjecture, it remains to pinpoint the complexity of CONN($\mathcal{S}$) whenever $\mathcal{S}$ is Horn and whenever $\mathcal{S}$ is dual Horn. In the conference version [16] of the present paper, we further conjectured that if $\mathcal{S}$ is Horn or dual Horn, then CONN($\mathcal{S}$) is in P. In other words, we conjectured that if $\mathcal{S}$ is Schaefer, then CONN($\mathcal{S}$) is in P. This second conjecture, however, was subsequently disproved by Makino, Tamaki, and Yamamoto [24], who discovered a particular Horn set $\mathcal{S}$ such that CONN($\mathcal{S}$) is coNP-complete. Here, we go beyond the results obtained in the conference version of the present paper and identify additional conditions on a Horn set $\mathcal{S}$ implying that CONN($\mathcal{S}$) is in P. These new results suggest a natural dichotomy within Schaefer sets of relations and, thus, provide evidence for the trichotomy conjecture.

The remainder of this paper is organized as follows. In section 3, we prove the structural expressibility theorem, establish the hard side of the dichotomies for CONN($\mathcal{S}$) and for ST-CONN($\mathcal{S}$), and contrast our result to Schaefer's expressibility and dichotomy theorems. In section 4, we describe the easy side of the dichotomy—the polynomial-time algorithms and the structural properties for tight sets of relations. In addition, we obtain partial results towards the trichotomy conjecture for CONN($\mathcal{S}$).

3. The hard case of the dichotomy: Nontight sets of relations. In this section, we address the *hard* side of the dichotomy, where we deal with the more computationally intractable cases. This is also the harder part of our proof. We define the notion of structural expressibility in section 3.1 and prove the structural expressibility theorem in section 3.2. This theorem implies that for all nontight sets $\mathcal{S}$ and $\mathcal{S}'$, the connectivity problems CONN($\mathcal{S}$) and CONN($\mathcal{S}'$) are polynomial-time equivalent; moreover, the same holds for the connectivity problems ST-CONN($\mathcal{S}$) and ST-CONN($\mathcal{S}'$). In addition, the diameters of the solution graphs of CNF($\mathcal{S}$)-formulas and CNF($\mathcal{S}'$)-formulas are also related polynomially. In section 3.3, we prove that for 3-CNF-formulas the connectivity problems are PSPACE-complete, and the diameter can be exponential. This fact combined with the structural expressibility

theorem yields the hard side of all of our dichotomy results, as well as the exponential size of the diameter.

We will use $\mathbf{a}, \mathbf{b}, \ldots$ to denote Boolean vectors, and $\mathbf{x}$ and $\mathbf{y}$ to denote vectors of variables. We write $|\mathbf{a}|$ to denote the Hamming weight (number of 1's) of a Boolean vector $\mathbf{a}$. Given two Boolean vectors $\mathbf{a}$ and $\mathbf{b}$, we write $|\mathbf{a}-\mathbf{b}|$ to denote the Hamming distance between $\mathbf{a}$ and $\mathbf{b}$. Finally, if $\mathbf{a}$ and $\mathbf{b}$ are solutions of a Boolean formula φ and lie in the same component of $G(\varphi)$, then we write $d_\varphi(\mathbf{a}, \mathbf{b})$ to denote the shortest-path distance between $\mathbf{a}$ and $\mathbf{b}$ in $G(\varphi)$.

3.1. Structural expressibility. As stated in the previous section, in his dichotomy theorem, Schaefer [31] used the following notion of expressibility: a relation R is *expressible from* a set $\mathcal{S}$ of relations if there is a CNF($\mathcal{S}$)-formula φ so that $R = \{\mathbf{a}|\ \exists \mathbf{y} \varphi(\mathbf{a}, \mathbf{y})\}$. This notion is not sufficient for our purposes. Instead, we introduce a more delicate notion which we call *structural expressibility*. Intuitively, we view the relation R as a subgraph of the hypercube, rather than just a subset, and require that this graph structure also be captured by the formula φ.

DEFINITION 3.1. *A relation R is* structurally expressible *from a set of relations $\mathcal{S}$ if there is a* CNF($\mathcal{S}$)*-formula φ such that the following conditions hold:*

1. $R = \{\mathbf{a}|\ \exists \mathbf{y} \varphi(\mathbf{a}, \mathbf{y})\}$.
2. *For every $\mathbf{a} \in R$, the graph $G(\varphi(\mathbf{a}, \mathbf{y}))$ is connected.*
3. *For $\mathbf{a}, \mathbf{b} \in R$ with $|\mathbf{a} - \mathbf{b}| = 1$, there exists $\mathbf{w}$ such that $(\mathbf{a}, \mathbf{w})$ and $(\mathbf{b}, \mathbf{w})$ are solutions of φ.*

For $\mathbf{a} \in R$, the *witnesses* of $\mathbf{a}$ are the $\mathbf{y}$'s such that $\varphi(\mathbf{a}, \mathbf{y})$ is true. The last two conditions say that the witnesses of $\mathbf{a} \in R$ are connected, and that neighboring $\mathbf{a}, \mathbf{b} \in R$ have a common witness. This allows us to simulate an edge $(\mathbf{a}, \mathbf{b})$ in $G(R)$ by a path in $G(\varphi)$, and thus relate the connectivity properties of the solution spaces. There is, however, a price to pay: it is much harder to come up with formulas that structurally express a relation R. An example is when $\mathcal{S}$ is the set of all paths of length 4 in $\{0,1\}^3$, a set that plays a crucial role in our proof. While 3-SAT relations are easily expressible from $\mathcal{S}$ in Schaefer's sense, the CNF($\mathcal{S}$)-formulas that structurally express 3-SAT relations are fairly complicated and have a large witness space.

An example of the difference between a structural and a nonstructural expression is shown in Figure 3.1. Consider the logical relation given by the formula $(x_1 \vee x_2 \vee x_3)$; the graph of this logical relation is depicted in Figure 3.1(a). Consider also the NOT-ALL-EQUAL relation $R_{\text{NAE}} = \{0,1\}^3 \setminus \{000, 111\}$. Figure 3.1(b) depicts the graph of the expression $\varphi(x_1, x_2, x_3, y_1, y_2) = R_{\text{NAE}}(x_1, x_2, y_1) \wedge R_{\text{NAE}}(x_2, x_3, y_2) \wedge R_{\text{NAE}}(y_1, y_2, 1)$. This is a structural expression because $(x_1 \vee x_2 \vee x_3) \equiv \exists y_1, y_2 \varphi(x_1, x_2, x_3, y_1, y_2)$ and connectivity is preserved. Finally, Figure 3.1(c) depicts the graph of the expression $\psi(x_1, x_2, x_3, y_1) = R_{\text{NAE}}(x_1, x_2, y_1) \wedge R_{\text{NAE}}(\bar{y}_1, x_3, 0) \wedge R_{\text{NAE}}(y_1, x_2, 1)$. Even though $(x_1 \vee x_2 \vee x_3) \equiv \exists y_1 \psi(x_1, x_2, x_3, y_1)$, this is *not* a structural expression because connectivity is not preserved.

LEMMA 3.2. *Let $\mathcal{S}$ and $\mathcal{S}'$ be sets of relations such that every $R \in \mathcal{S}'$ is structurally expressible from $\mathcal{S}$, and, moreover, there is a polynomial-time algorithm that produces a structural expression from $\mathcal{S}$ for every $R \in \mathcal{S}'$. Given a* CNF($\mathcal{S}'$)*-formula $\psi(\mathbf{x})$, one can efficiently construct a* CNF($\mathcal{S}$)*-formula $\varphi(\mathbf{x}, \mathbf{y})$ such that*

1. *$\psi(\mathbf{x}) \equiv \exists \mathbf{y}\ \varphi(\mathbf{x}, \mathbf{y})$;*
2. *if $(\mathbf{s}, \mathbf{w^s}), (\mathbf{t}, \mathbf{w^t}) \in \varphi$ are connected in $G(\varphi)$ by a path of length d, then there is a path from $\mathbf{s}$ to $\mathbf{t}$ in $G(\psi)$ of length at most d;*
3. *if $\mathbf{s}, \mathbf{t} \in \psi$ are connected in $G(\psi)$, then for every witness $\mathbf{w^s}$ of $\mathbf{s}$, and every witness $\mathbf{w^t}$ of $\mathbf{t}$, there is a path from $(\mathbf{s}, \mathbf{w^s})$ to $(\mathbf{t}, \mathbf{w^t})$ in $G(\varphi)$.*

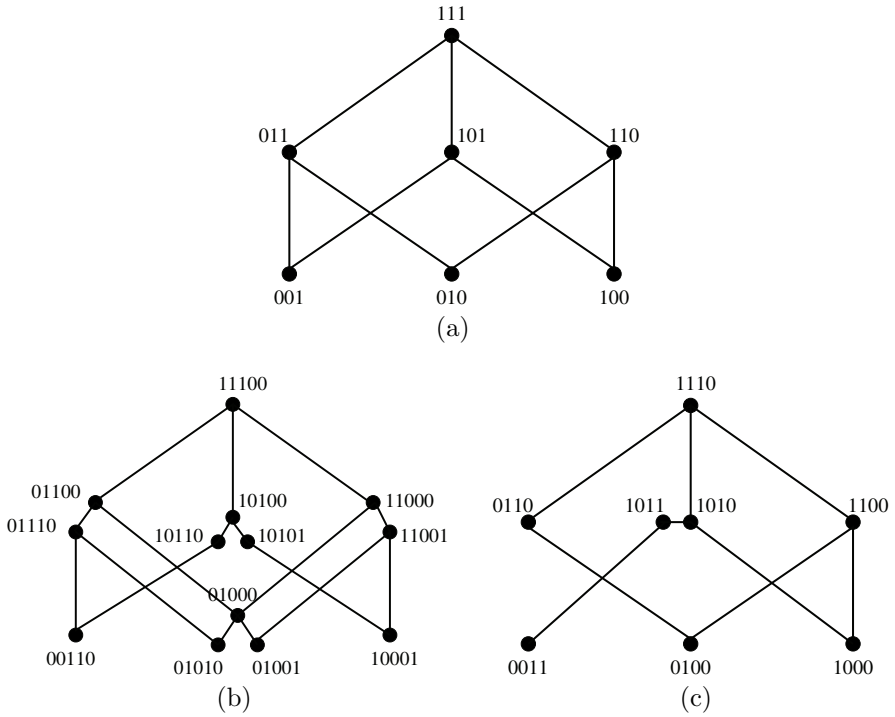

FIG. 3.1. *Expressing the relation* $(x_1 \vee x_2 \vee x_3)$ *from the* R_{NAE} *relation.*

Proof. Suppose ψ is a formula on n variables that consists of m clauses $C_1, \ldots, C_m$. For clause C_j, assume that the set of variables is $V_j \subseteq [n] = \{1, \ldots, n\}$, and that it involves relation $R_j \in \mathcal{S}$. Thus, $\psi(\mathbf{x})$ is $\wedge_{j=1}^{m} R_j(\mathbf{x}_{V_j})$. Let φ_j be the structural expression for R_j from $\mathcal{S}'$, so that $R_j(\mathbf{x}_{V_j}) \equiv \exists \mathbf{y}_j \ \varphi_j(\mathbf{x}_{V_j}, \mathbf{y}_j)$. Let $\mathbf{y}$ be the vector $(\mathbf{y}_1, \ldots, \mathbf{y}_m)$ and let $\varphi(\mathbf{x}, \mathbf{y})$ be the formula $\wedge_{j=1}^{m} \varphi_j(\mathbf{x}_{V_j}, \mathbf{y}_j)$. Then $\psi(\mathbf{x}) \equiv \exists \mathbf{y}\ \varphi(\mathbf{x}, \mathbf{y})$.

Statement 2 follows from 1 by projection of the path on the coordinates of $\mathbf{x}$. For statement 3, consider $\mathbf{s}, \mathbf{t} \in \psi$ that are connected in $G(\psi)$ via a path $\mathbf{s} = \mathbf{u^0} \to \mathbf{u^1} \to \cdots \to \mathbf{u^r} = \mathbf{t}$. For every $\mathbf{u^i}, \mathbf{u^{i+1}}$, and clause C_j, there exists an assignment $\mathbf{w^i}_j$ to $\mathbf{y}_j$ such that both $(\mathbf{u^i}_{V_j}, \mathbf{w^i}_j)$ and $(\mathbf{u^{i+1}}_{V_j}, \mathbf{w^i}_j)$ are solutions of φ_j, by condition 2 of structural expressibility. Thus $(\mathbf{u^i}, \mathbf{w^i})$ and $(\mathbf{u^{i+1}}, \mathbf{w^i})$ are both solutions of φ, where $\mathbf{w^i} = (\mathbf{w^i}_1, \ldots, \mathbf{w^i}_m)$. Further, for every $\mathbf{u^i}$, the space of solutions of $\varphi(\mathbf{u^i}, \mathbf{y})$ is the product space of the solutions of $\varphi_j(\mathbf{u^i}_{V_j}, \mathbf{y}_j)$ over $j = 1, \ldots, m$. Since these are all connected by condition 3 of structural expressibility, $G(\varphi(\mathbf{u^i}, \mathbf{y}))$ is connected. The following describes a path from $(\mathbf{s}, \mathbf{w^s})$ to $(\mathbf{t}, \mathbf{w^t})$ in $G(\varphi)$: $(\mathbf{s}, \mathbf{w^s}) \rightsquigarrow (\mathbf{s}, \mathbf{w^0}) \to (\mathbf{u^1}, \mathbf{w^0}) \rightsquigarrow (\mathbf{u^1}, \mathbf{w^1}) \to \cdots \rightsquigarrow (\mathbf{u^{r-1}}, \mathbf{w^{r-1}}) \to (\mathbf{t}, \mathbf{w^{r-1}}) \rightsquigarrow (\mathbf{t}, \mathbf{w^t})$. Here $\rightsquigarrow$ indicates a path in $G(\varphi(\mathbf{u^i}, \mathbf{y}))$. □

COROLLARY 3.3. *Suppose* $\mathcal{S}$ *and* $\mathcal{S}'$ *are sets of relations such that every* $R \in \mathcal{S}'$ *is structurally expressible from* $\mathcal{S}$*, and, moreover, there is a polynomial-time algorithm that produces a structural expression from* $\mathcal{S}$ *for every* $R \in \mathcal{S}'$*.*

1. *There are polynomial-time reductions from* CONN($\mathcal{S}'$) *to* CONN($\mathcal{S}$)*, and from* ST-CONN($\mathcal{S}'$) *to* ST-CONN($\mathcal{S}$)*.*
2. *If there exists a* CNF($\mathcal{S}'$)*-formula* $\psi(\mathbf{x})$ *with* n *variables,* m *clauses, and diameter* d*, then there exists a* CNF($\mathcal{S}$)*-formula* $\varphi(\mathbf{x}, \mathbf{y})$*, where* $\mathbf{y}$ *is a vector of* $O(m)$ *variables, such that the diameter of* $G(\phi)$ *is at least* d*.*

3.2. The structural expressibility theorem. In this subsection, we prove the structural expressibility theorem. The main step in the proof is Lemma 3.4, which shows that if $\mathcal{S}$ is not tight, then we can structurally express the 3-clause relations from the relations in $\mathcal{S}$. If $k \geq 2$, then a *k-clause* is a disjunction of k variables or negated variables. For $0 \leq i \leq k$, let D_i be the set of all satisfying truth assignments of the k-clause whose first i literals are negated, and let $\mathcal{S}_k = \{D_0, D_1, \ldots, D_k\}$. Thus, $\mathrm{CNF}(\mathcal{S}_k)$ is the collection of k-CNF-formulas.

LEMMA 3.4. *If set $\mathcal{S}$ of relations is not tight, $\mathcal{S}_3$ is structurally expressible from $\mathcal{S}$.*

Proof. First, observe that all 2-clauses are structurally expressible from $\mathcal{S}$. There exists $R \in \mathcal{S}$ which is not OR-free, so we can express $(x_1 \vee x_2)$ by substituting constants in R. Similarly, we can express $(\bar{x}_1 \vee \bar{x}_2)$ using a relation that is not NAND-free. The last 2-clause $(x_1 \vee \bar{x}_2)$ can be obtained from OR and NAND by a technique that corresponds to reverse resolution. $(x_1 \vee \bar{x}_2) = \exists y\ (x_1 \vee y) \wedge (\bar{y} \vee \bar{x}_2)$. It is easy to see that this gives a structural expression. From here onwards we assume that $\mathcal{S}$ contains all 2-clauses. The proof now proceeds in four steps. First, we will express a relation in which there exist two elements that are at graph distance larger than their Hamming distance. Second, we will express a relation that is just a single path between such elements. Third, we will express a relation which is a path of length 4 between elements at Hamming distance 2. Finally, we will express the 3-clauses.

Step 1. *Structurally expressing a relation in which some distance expands.* For a relation R, we say that the distance between $\mathbf{a}$ and $\mathbf{b}$ *expands* if $\mathbf{a}$ and $\mathbf{b}$ are connected in $G(R)$, but $d_R(\mathbf{a}, \mathbf{b}) > |\mathbf{a} - \mathbf{b}|$. In section 4.2, Lemma 4.3, we will show that no distance expands in componentwise bijunctive relations. The same also holds true for the relation $R_{\mathrm{NAE}} = \{0,1\}^3 \setminus \{000, 111\}$, which is not componentwise bijunctive. Nonetheless, we show here that if R is not componentwise bijunctive, then, by adding 2-clauses, we can structurally express a relation Q in which some distance expands. For instance, when $R = R_{\mathrm{NAE}}$, then we can take $Q(x_1, x_2, x_3) = R_{\mathrm{NAE}}(x_1, x_2, x_3) \wedge (\bar{x_1} \vee \bar{x}_3)$, as shown in Figure 3.2. The distance between $\mathbf{a} = 100$ and $\mathbf{b} = 001$ in Q expands. Similarly, in the general construction, we identify $\mathbf{a}$ and $\mathbf{b}$ on a cycle, and add 2-clauses that eliminate all the vertices along the shorter arc between $\mathbf{a}$ and $\mathbf{b}$.

Since $\mathcal{S}$ is not tight, it contains a relation R which is not componentwise bijunctive. If R contains $\mathbf{a}, \mathbf{b}$ where the distance between them expands, we are done. So assume that for all $\mathbf{a}, \mathbf{b} \in G(R)$, $d_R(\mathbf{a}, \mathbf{b}) = |\mathbf{a} - \mathbf{b}|$. Since R is not componentwise bijunctive, there exists a triple of assignments $\mathbf{a}, \mathbf{b}, \mathbf{c}$ lying in the same component such that $\mathrm{maj}(\mathbf{a}, \mathbf{b}, \mathbf{c})$ is not in that component. Choose the triple such that the sum of pairwise distances $d_R(\mathbf{a}, \mathbf{b}) + d_R(\mathbf{b}, \mathbf{c}) + d_R(\mathbf{c}, \mathbf{a})$ is minimized. Let $U = \{i | a_i \neq b_i\}$, $V = \{i | b_i \neq c_i\}$, and $W = \{i | c_i \neq a_i\}$. Since $d_R(\mathbf{a}, \mathbf{b}) = |\mathbf{a} - \mathbf{b}|$, a shortest path does not flip variables outside of U, and each variable in U is flipped exactly once. The same holds for V and W. We note some useful properties of the sets U, V, W:

1. *Every index $i \in U \cup V \cup W$ occurs in exactly two of U, V, W.* Consider going by a shortest path from $\mathbf{a}$ to $\mathbf{b}$ to $\mathbf{c}$ and back to $\mathbf{a}$. Every $i \in U \cup V \cup W$ is seen an even number of times along this path since we return to $\mathbf{a}$. It is seen at least once, and at most thrice, so in fact it occurs twice.
2. *Every pairwise intersection $U \cap V, V \cap W$, and $W \cap U$ is nonempty.* Suppose the sets U and V are disjoint. From property 1, we must have $W = U \cup V$. But then it is easy to see that $\mathrm{maj}(\mathbf{a}, \mathbf{b}, \mathbf{c}) = \mathbf{b}$. This contradicts the choice of $\mathbf{a}, \mathbf{b}, \mathbf{c}$.

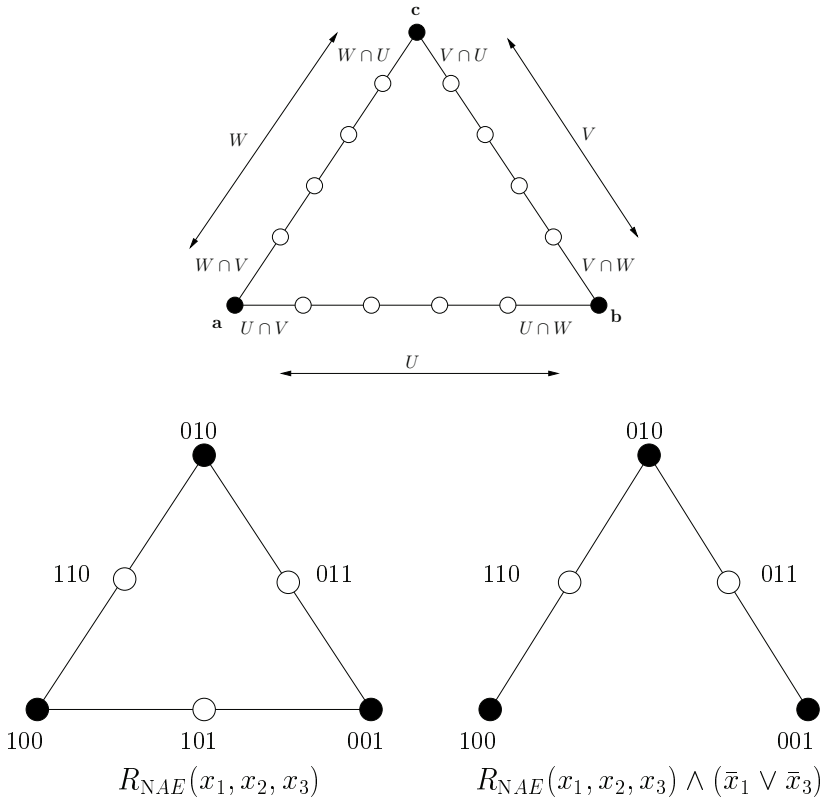

FIG. 3.2. *Step* 1 *of the proof of Lemma* 3.4*, and an example.*

3. *The sets* $U \cap V$ *and* $U \cap W$ *partition the set* U. By property 1, each index of U occurs in one of V and W as well. Also since no index occurs in all three sets U, V, W this is in fact a disjoint partition.
4. *For each index* $i \in U \cap W$*, it holds that* $\mathbf{a} \oplus \mathbf{e}_i \notin R$. Assume for the sake of contradiction that $\mathbf{a}' = \mathbf{a} \oplus \mathbf{e}_i \in R$. Since $i \in U \cap W$ we have simultaneously moved closer to both $\mathbf{b}$ and $\mathbf{c}$. Hence we have $d_R(\mathbf{a}', \mathbf{b}) + d_R(\mathbf{b}, \mathbf{c}) + d_R(\mathbf{c}, \mathbf{a}') < d_R(\mathbf{a}, \mathbf{b}) + d_R(\mathbf{b}, \mathbf{c}) + d_R(\mathbf{c}, \mathbf{a})$. Also $\mathrm{maj}(\mathbf{a}', \mathbf{b}, \mathbf{c}) = \mathrm{maj}(\mathbf{a}, \mathbf{b}, \mathbf{c})$. But this contradicts our choice of $\mathbf{a}, \mathbf{b}, \mathbf{c}$.

Property 4 implies that the shortest paths to $\mathbf{b}$ and $\mathbf{c}$ diverge at $\mathbf{a}$, since for any shortest path to $\mathbf{b}$ the first variable flipped is from $U \cap V$, whereas for a shortest path to $\mathbf{c}$ it is from $W \cap V$. Similar statements hold for the vertices $\mathbf{b}$ and $\mathbf{c}$. Thus along the shortest path from $\mathbf{a}$ to $\mathbf{b}$ the first bit flipped is from $U \cap V$ and the last bit flipped is from $U \cap W$. On the other hand, if we go from $\mathbf{a}$ to $\mathbf{c}$ and then to $\mathbf{b}$, all the bits from $U \cap W$ are flipped before the bits from $U \cap V$. We use this crucially to define Q. We will add a set of 2-clauses that enforce the following rule on paths starting at $\mathbf{a}$: *Flip variables from* $U \cap W$ *before variables from* $U \cap V$. This will eliminate all shortest paths from $\mathbf{a}$ to $\mathbf{b}$ since they begin by flipping a variable in $U \cap V$ and end with $U \cap W$. The paths from $\mathbf{a}$ to $\mathbf{b}$ via $\mathbf{c}$ survive since they flip $U \cap W$ while going from $\mathbf{a}$ to $\mathbf{c}$ and $U \cap V$ while going from $\mathbf{c}$ to $\mathbf{b}$. However, all remaining paths have length at least $|\mathbf{a} - \mathbf{b}| + 2$ since they flip twice some variables not in U.

Take all pairs of indices $\{(i, j) | i \in U \cap W, j \in U \cap V\}$. The following conditions

hold from the definition of U, V, W: $a_i = \bar{c}_i = \bar{b}_i$ and $a_j = c_j = \bar{b}_j$. Add the 2-clause C_{ij} asserting that the pair of variables $x_i x_j$ must take values in $\{a_i a_j, c_i c_j, b_i b_j\} = \{a_i a_j, \bar{a}_i a_j, \bar{a}_i \bar{a}_j\}$. The new relation is $Q = R \wedge_{i,j} C_{ij}$. Note that $Q \subset R$. We verify that the distance between $\mathbf{a}$ and $\mathbf{b}$ in Q expands. It is easy to see that for any $j \in U$, the assignment $\mathbf{a} \oplus \mathbf{e}_j \notin Q$. Hence there are no shortest paths left from $\mathbf{a}$ to $\mathbf{b}$. On the other hand, it is easy to see that $\mathbf{a}$ and $\mathbf{b}$ are still connected, since the vertex $\mathbf{c}$ is still reachable from both.

Step 2. *Isolating a pair of assignments whose distance expands.* The relation Q obtained in Step 1 may have several disconnected components. This *cleanup* step isolates a single pair of assignments whose distance expands. By adding 2-clauses, we show that one can express a path of length $r+2$ between assignments at distance r.

Take $\mathbf{a}, \mathbf{b} \in Q$ whose distance expands in Q and $d_Q(\mathbf{a}, \mathbf{b})$ is minimized. Let $U = \{i | a_i \neq b_i\}$ and $|U| = r$. Shortest paths between $\mathbf{a}$ and $\mathbf{b}$ have certain useful properties:

1. *Each shortest path flips every variable from U exactly once.* Observe that each index $j \in U$ is flipped an odd number of times along any path from $\mathbf{a}$ to $\mathbf{b}$. Suppose it is flipped thrice along a shortest path. Starting at $\mathbf{a}$ and going along this path, let $\mathbf{b}'$ be the assignment reached after flipping j twice. Then the distance between $\mathbf{a}$ and $\mathbf{b}'$ expands, since j is flipped twice along a shortest path between them in Q. Also $d_Q(\mathbf{a}, \mathbf{b}') < d_Q(\mathbf{a}, \mathbf{b})$, contradicting the choice of $\mathbf{a}$ and $\mathbf{b}$.
2. *Every shortest path flips exactly one variable $i \notin U$.* Since the distance between $\mathbf{a}$ and $\mathbf{b}$ expands, every shortest path must flip some variable $i \notin U$. Suppose it flips more than one such variable. Since $\mathbf{a}$ and $\mathbf{b}$ agree on these variables, each of them is flipped an even number of times. Let i be the first variable to be flipped twice. Let $\mathbf{b}'$ be the assignment reached after flipping i the second time. It is easy to verify that the distance between $\mathbf{a}$ and $\mathbf{b}'$ also expands, but $d_Q(\mathbf{a}, \mathbf{b}') < d_Q(\mathbf{a}, \mathbf{b})$.
3. *The variable $i \notin U$ is the first and last variable to be flipped along the path.* Assume the first variable flipped is not i. Let $\mathbf{a}'$ be the assignment reached along the path before we flip i the first time. Then $d_Q(\mathbf{a}', \mathbf{b}) < d_Q(\mathbf{a}, \mathbf{b})$. The distance between $\mathbf{a}'$ and $\mathbf{b}$ expands since the shortest path between them flips the variables i twice. This contradicts the choice of $\mathbf{a}$ and $\mathbf{b}$. Assume $j \in U$ is flipped twice. Then as before we get a pair $\mathbf{a}', \mathbf{b}'$ that contradict the choice of $\mathbf{a}, \mathbf{b}$.

Every shortest path between $\mathbf{a}$ and $\mathbf{b}$ has the following structure: first a variable $i \notin U$ is flipped to $\bar{a}_i$, then the variables from U are flipped in some order, and finally the variable i is flipped back to a_i.

Different shortest paths may vary in the choice of $i \notin U$ in the first step and in the order in which the variables from U are flipped. Fix one such path $T \subseteq Q$. Assume that $U = \{1, \ldots, r\}$ and the variables are flipped in this order, and the additional variable flipped twice is $r+1$. Denote the path by $\mathbf{a} \to \mathbf{u^0} \to \mathbf{u^1} \to \cdots \to \mathbf{u^r} \to \mathbf{b}$. Next we prove that we cannot flip the $r+1$th variable at an intermediate vertex along the path.

4. *For $1 \leq j \leq r-1$ the assignment $\mathbf{u^j} \oplus \mathbf{e_{r+1}} \notin Q$.* Suppose that for some j we have $\mathbf{c} = \mathbf{u^j} \oplus \mathbf{e_{r+1}} \in Q$. Then $\mathbf{c}$ differs from $\mathbf{a}$ on $\{1, \ldots, i\}$ and from $\mathbf{b}$ on $\{i+1, \ldots, r\}$. The distance from $\mathbf{c}$ to at least one of $\mathbf{a}$ or $\mathbf{b}$ must expand, or else we get a path from $\mathbf{a}$ to $\mathbf{b}$ through $\mathbf{c}$ of length $|\mathbf{a}-\mathbf{b}|$, which contradicts the fact that this distance expands. However, $d_Q(\mathbf{a}, \mathbf{c})$ and $d_Q(\mathbf{b}, \mathbf{c})$ are strictly less than $d_Q(\mathbf{a}, \mathbf{b})$, so we get a contradiction to the choice of $\mathbf{a}, \mathbf{b}$.

We now construct the path of length $r+2$. For all $i \geq r+2$ we set $x_i = a_i$ to get a relation on $r+1$ variables. Note that $\mathbf{b} = \bar{a}_1 \dots \bar{a}_r a_{r+1}$. Take $i < j \in U$. Along the path T the variable i is flipped before j so the variables $x_i x_j$ take one of three values $\{a_i a_j, \bar{a}_i a_j, \bar{a}_i \bar{a}_j\}$. So we add a 2-clause C_{ij} that requires $x_i x_j$ to take one of these values and take $T = Q \wedge_{i,j} C_{ij}$. Clearly, every assignment along the path lies in T. We claim that these are the only solutions. To show this, take an arbitrary assignment $\mathbf{c}$ satisfying the added constraints. If for some $i < j \leq r$ we have $c_i = a_i$ but $c_j = \bar{a}_j$, this would violate C_{ij}. Hence the first r variables of $\mathbf{c}$ are of the form $\bar{a}_1 \dots \bar{a}_i a_{i+1} \dots a_r$ for $0 \leq i \leq r$. If $c_{r+1} = \bar{a}_{r+1}$, then $\mathbf{c} = \mathbf{u}^i$. If $c_{r+1} = a_{r+1}$, then $\mathbf{c} = \mathbf{u}^i \oplus \mathbf{e}_{r+1}$. By property 4 above, such a vector satisfies Q if and only if $i = 0$ or $i = r$, which correspond to $\mathbf{c} = \mathbf{a}$ and $\mathbf{c} = \mathbf{b}$, respectively.

Step 3. *Structurally expressing paths of length* 4. Let $\mathcal{P}$ denote the set of all ternary relations whose graph is a path of length 4 between two assignments at Hamming distance 2. Up to permutations of coordinates, there are 6 such relations. Each of them is the conjunction of a 3-clause and a 2-clause. For instance, the relation $M = \{100, 110, 010, 011, 001\}$ can be written as $(x_1 \vee x_2 \vee x_3) \wedge (\bar{x}_1 \vee \bar{x}_3)$. (It is named so because its graph looks like the letter M on the cube.) These relations are "minimal" examples of relations that are not componentwise bijunctive. By projecting out intermediate variables from the path T obtained in Step 2, we structurally express one of the relations in $\mathcal{P}$. We structurally express other relations in $\mathcal{P}$ using this relation.

We will write all relations in $\mathcal{P}$ in terms of $M(x_1, x_2, x_3) = (x_1 \vee x_2 \vee x_3) \wedge (\bar{x}_1 \vee \bar{x}_3)$ by negating variables. For example, $M(\bar{x}_1, x_2, x_3) = (\bar{x}_1 \vee x_2 \vee x_3) \wedge (x_1 \vee \bar{x}_3) = \{000, 010, 110, 111, 101\}$.

Define the relation $P(x_1, x_{r+1}, x_2) = \exists x_3 \dots x_r \; T(x_1, \dots, x_{r+1})$. The table below, listing all tuples in P and their witnesses, shows that the conditions for structural expressibility are satisfied, and $P \in \mathcal{P}$.

x_1, x_2, x_{r+1}	$x_3, \dots, x_r$
$a_1 a_2 a_{r+1}$	$a_3 \dots a_r$
$a_1 a_2 \bar{a}_{r+1}$	$a_3 \dots a_r$
$\bar{a}_1 a_2 \bar{a}_{r+1}$	$a_3 \dots a_r$
$\bar{a}_1 \bar{a}_2 \bar{a}_{r+1}$	$a_3 \dots a_k,\ \bar{a}_3 a_4 \dots a_r,\ \bar{a}_3 \bar{a}_4 a_5 \dots a_r,\ \dots,\ \bar{a}_3 \bar{a}_4 \dots \bar{a}_r$
$\bar{a}_1 \bar{a}_2 a_{r+1}$	$\bar{a}_3 \bar{a}_4 \dots \bar{a}_r$

Let $P(x_1, x_2, x_3) = M(l_1, l_2, l_3)$, where l_i is one of $\{x_i, \bar{x}_i\}$. We can now use P and 2-clauses to express every other relation in $\mathcal{P}$. Given $M(l_1, l_2, l_3)$, every relation in $\mathcal{P}$ can be obtained by negating some subset of the variables. Hence it suffices to show that we can express structurally $M(\bar{l}_1, l_2, l_3)$ and $M(l_1, \bar{l}_2, l_3)$ (M is symmetric in x_1 and x_3). In the following let λ denote one of the literals $\{y, \bar{y}\}$, such that it is $\bar{y}$ if and only if l_1 is $\bar{x}_1$.

$$\begin{aligned} M(\bar{l}_1, l_2, l_3) &= (\bar{l}_1 \vee l_2 \vee l_3) \wedge (l_1 \vee \bar{l}_3) \\ &= \exists y \; (\bar{l}_1 \vee \bar{\lambda}) \wedge (\lambda \vee l_2 \vee l_3) \wedge (l_1 \vee \bar{l}_3) \\ &= \exists y \; (\bar{l}_1 \vee \bar{\lambda}) \wedge (\lambda \vee l_2 \vee l_3) \wedge (l_1 \vee \bar{l}_3) \wedge (\bar{\lambda} \vee \bar{l}_3) \\ &= \exists y \; (\bar{l}_1 \vee \bar{\lambda}) \wedge (l_1 \vee \bar{l}_3) \wedge M(\lambda, l_2, l_3) \\ &= \exists y \; (\bar{l}_1 \vee \bar{\lambda}) \wedge (l_1 \vee \bar{l}_3) \wedge P(y, x_2, x_3). \end{aligned}$$

In the second step the clause $(\bar{\lambda} \vee \bar{l}_3)$ is implied by the resolution of the clauses $(\bar{l}_1 \vee \bar{\lambda}) \wedge (l_1 \vee \bar{l}_3)$.

For the next expression let λ denote one of the literals $\{y, \bar{y}\}$, such that it is negated if and only if l_2 is $\bar{x}_2$.

$$\begin{aligned} M(l_1, \bar{l}_2, l_3) &= (l_1 \vee \bar{l}_2 \vee l_3) \wedge (\bar{l}_1 \vee \bar{l}_3) \\ &= \exists y\ (l_1 \vee l_3 \vee \lambda) \wedge (\bar{\lambda} \vee \bar{l}_2) \wedge (\bar{l}_1 \vee \bar{l}_3) \\ &= \exists y\ (\bar{\lambda} \vee \bar{l}_2) \wedge M(l_1, \lambda, l_3) \\ &= \exists y\ (\bar{\lambda} \vee \bar{l}_2) \wedge P(x_1, y, x_3). \end{aligned}$$

The above expressions are both based on resolution, and it is easy to check that they satisfy the properties of structural expressibility.

Step 4. *Structurally expressing* $\mathcal{S}_3$. We structurally express $(x_1 \vee x_2 \vee x_3)$ from M using a formula derived from a gadget in [17]. This gadget expresses $(x_1 \vee x_2 \vee x_3)$ in terms of "Protected OR," which corresponds to our relation M.

$$\begin{aligned} (x_1 \vee x_2 \vee x_3) = \exists y_1 \dots y_5\ &(x_1 \vee \bar{y}_1) \wedge (x_2 \vee \bar{y}_2) \wedge (x_3 \vee \bar{y}_3) \wedge (x_3 \vee \bar{y}_4) \\ &\wedge M(y_1, y_5, y_3) \wedge M(y_2, \bar{y}_5, y_4). \end{aligned} \tag{3.1}$$

The table below, listing the witnesses of each assignment for (x_1, x_2, x_3), shows that the conditions for structural expressibility are satisfied.

x_1, x_2, x_3	$y_1 \dots y_5$											
111	00011	00111	00110	00100	01100	01101	01001	11001	11000	10000	10010	10011
110							01001	11001	11000	10000		
100										10000		
101	00011	00111	00110	00100						10000	10010	10011
001	00011	00111	00110	00100								
011	00011	00111	00110	00100	01100	01101	01001					
010							01001					

From the relation $(x_1 \vee x_2 \vee x_3)$ we derive the other 3-clauses by reverse resolution, for instance,

$$(\bar{x}_1 \vee x_2 \vee x_3) = \exists y\ (\bar{x}_1 \vee \bar{y}) \wedge (y \vee x_2 \vee x_3). \qquad \square$$

To complete the proof of the structural expressibility theorem, we show that an arbitrary relation can be expressed structurally from $\mathcal{S}_3$.

LEMMA 3.5. *Let* $R \subseteq \{0,1\}^k$ *be any relation of arity* $k \geq 1$. R *is structurally expressible from* $\mathcal{S}_3$.

Proof. If $k \leq 3$, then R can be expressed as a formula in $\mathrm{CNF}(\mathcal{S}_3)$ with constants, without introducing witness variables. This kind of expression is always structural.

If $k \geq 4$, then R can be expressed as a formula in $\mathrm{CNF}(\mathcal{S}_k)$, without witnesses (i.e., structurally). We will show that every k-clause can be expressed structurally from $\mathcal{S}_{k-1}$. Then, by induction, it can be expressed structurally from $\mathcal{S}_3$. For simplicity we express a k-clause corresponding to the relation D_0. The remaining relations are expressed equivalently. We express D_0 in a way that is standard in other complexity reductions and turns out to be structural:

$$(x_1 \vee x_2 \vee \dots \vee x_k) = \exists y\ (x_1 \vee x_2 \vee y) \wedge (\bar{y} \vee x_3 \vee \dots \vee x_k).$$

This is the reverse operation of resolution. For any satisfying assignment for $\mathbf{x}$, its witness space is either $\{0\}$, $\{1\}$, or $\{0,1\}$, so in all cases it is connected. Furthermore, the only way two neighboring satisfying assignments for x can have no common witness

is if one of them has witness set $\{0\}$ and the other one has witness set $\{1\}$. This implies that the first one has $(x_3, \ldots, x_k) = (0, \ldots, 0)$, and the other one has $(x_1, x_2) = (0, 0)$, and thus they differ in the assignments of at least two variables: one from $\{x_1, x_2\}$ and one from $\{x_3, \ldots, x_k\}$. In that case they cannot be neighboring assignments. Therefore all requirements of structural expressibility are satisfied. □

3.3. Hardness results for 3-CNF-formulas. From Lemma 3.4 and Corollary 3.3, it follows that, to prove the hard side of our dichotomy theorems, it suffices to focus on 3-CNF-formulas.

The proof that CONN($\mathcal{S}_3$) and ST-CONN($\mathcal{S}_3$) are PSPACE-complete is fairly intricate; it entails a direct reduction from the computation of a space-bounded Turing machine. The result for ST-CONN can also be proved easily using results of Hearne and Demaine on nondeterministic constraint logic [17]. However, it does not appear that completeness for CONN follows from their results.

LEMMA 3.6. ST-CONN($\mathcal{S}_3$) *and* CONN($\mathcal{S}_3$) *are* PSPACE*-complete.*

Proof. Given a CNF($\mathcal{S}_3$)-formula φ and satisfying assignments $\mathbf{s}, \mathbf{t}$, we can guess a path of length at most 2^n between them and verify that each vertex along the path is indeed a solution to φ. Hence ST-CONN($\mathcal{S}_3$) is in NPSPACE, which equals PSPACE by Savitch's theorem. Similarly for CONN($\mathcal{S}_3$), by reusing space we can check for all pairs of assignments whether they are satisfying and, if they both are, whether they are connected in $G(\varphi)$. It follows that both problems are in PSPACE.

Next we show that CONN($\mathcal{S}_3$) and ST-CONN($\mathcal{S}_3$) are PSPACE-hard. Let A be a language decided by a deterministic Turing machine $M = (Q, \Sigma, \Gamma, \delta, q_0, q_{\text{accept}}, q_{\text{reject}})$ in space n^k for some constant $k \geq 1$, where n is the length of the input. We give a polynomial-time reduction from A to ST-CONN($\mathcal{S}_3$) and CONN($\mathcal{S}_3$).

The reduction maps a string w (with $|w| = n$) to a 3-CNF-formula φ and two satisfying assignments for the formula, which are connected in $G(\varphi)$ if and only if M accepts w. Furthermore, all satisfying assignments of φ are connected to one of these two assignments, so that $G(\varphi)$ is connected if and only if M accepts w.

Before we show how to construct φ, we modify M in several ways to obtain a new machine M' which depends on w:

1. We define the tape of M' to be cyclical of length $n^k + 1$ with a special symbol # written in cell 0 which cannot be overwritten. The input w is placed after this symbol. Notice that the machine M accepts or rejects w within n^k space, and therefore the # symbol is never read when the machine is initialized in a legal way (at the state q_0, input from Σ^*, and the head at the initial position). The # symbol may be read if the machine is initialized at a different configuration. We modify the transitions of M so that if the # symbol is read, the machine M' goes into the state q_{reject}.
2. We add to M' a clock that counts from 0 to $n^k \times |Q| \times |\Gamma|^{n^k} = 2^{O(n^{k+1})}$, which is the total number of possible distinct configurations of M when it uses only n^k space. For this, M' uses a separate tape of length $O(n^{k+1})$ with the alphabet $\{0, 1\}$. Before a transition happens, control is passed on to the clock, its counter is incremented, and finally the transition is completed.
3. We define a standard accepting configuration. Whenever q_{accept} is reached, the clock is stopped and set to zero, the original tape is erased (except for #) and the head is placed in the initial position, always in state q_{accept}.
4. Whenever q_{reject} is reached the machine goes into its initial configuration. First w is written back on the input tape after the # symbol. This step requires adding n states to the machine in order to write the n letters of w.

This increases the number of states of M' to $O(n)$. Next, the rest of the tape is erased, the clock is set to zero, the head is placed in the initial position, and the state is set to q_0 (and thus the computation resumes).

5. Whenever the clock overflows, the machine goes into q_{reject}.

The new machine M' runs forever if w is not in A, and it accepts if w is in A. It also has the property that every configuration having # in position 0 leads either to the accepting configuration or to the initial configuration with input w. Therefore the space of such configurations is connected if and only if $w \in A$. Let's denote by Q' the states of M' and by δ' its transitions. As mentioned earlier, $|Q'| = O(n)$, and M' runs on two tapes, one of size $N = n^k$ and the other (for the clock) of size $N_c = O(n^{k+1})$. The alphabet of M' on one tape is Γ, and on the other $\{0,1\}$. For simplicity we can also assume that at each transition the machine uses only one of the two tapes and moves its head either left or right.

Next, we construct an intermediate CNF-formula ψ whose solutions are the configurations of M'. However, the space of solutions of ψ is disconnected.

For each $i \in [N]$ and $a \in \Gamma$, we have a variable $x(i,a)$. If $x(i,a) = 1$, this means that the ith tape cell contains symbol a. For every $i \in [N]$ there is a variable $y(i)$ which is 1 if the head is at position i. For every $q \in Q'$, there is a variable $z(q)$ which is 1 if the current state is q. Similarly for every $j \in [N_c]$ and $a \in \{0,1\}$ we have variables $x_c(j,a)$ and a variable $y_c(j)$ which is 1 if the head of the clock tape is at position j.

We enforce the following conditions:

1. Every cell contains some symbol and cell 0 contains #:

$$\psi_1 = \bigwedge_{i\in[N]} \left(\vee_{a\in\Gamma} \;\; x(i,a)\right) \bigwedge_{j\in[N_c]} \left(\vee_{a\in\{0,1\}} \;\; x_c(j,a)\right) \wedge x(0,\#).$$

2. No cell contains two symbols:

$$\psi_2 = \bigwedge_{i\in[N]} \bigwedge_{a\neq a'\in\Gamma} \left(\overline{x(i,a)} \vee \overline{x(i,a')}\right) \bigwedge_{j\in[N_c]} \left(\overline{x_c(j,0)} \vee \overline{x_c(j,1)}\right).$$

3. The head is in some position, the clock head is in some position, and the machine is in some state:

$$\psi_3 = \left(\vee_{i\in[N]} \;\; y(i)\right) \bigwedge \left(\vee_{j\in[N_c]} \;\; y_c(j)\right) \bigwedge \left(\vee_{q\in Q'} \;\; z(q)\right).$$

4. The main tape head is in a unique position, the clock head is in a unique position, and the machine is in a unique state:

$$\psi_4 = \bigwedge_{i\neq i'\in[N]} \left(\overline{y(i)} \vee \overline{y(i')}\right) \bigwedge_{j\neq j'\in[N_c]} \left(\overline{y_c(j)} \vee \overline{y_c(j')}\right) \bigwedge_{q\neq q'\in Q'} \left(\overline{z(q)} \vee \overline{z(q')}\right).$$

Solutions of $\psi = \psi_1 \wedge \psi_2 \wedge \psi_3 \wedge \psi_4$ are in 1-1 correspondence with configurations of M'. Furthermore, the assignments corresponding to any two distinct configurations differ in at least two variables (hence the space of solutions is totally disconnected).

Next, to connect the solution space along valid transitions of M', we relax conditions 2 and 4 by introducing new transition variables, which allow the head to have two states or a cell to have two symbols at the same time. This allows us to go from one configuration to the next.

Consider a transition $\delta'(q,a) = (q', b, R)$, which operates on the first tape, for example. Fix the position of the head of the first tape to be i. The variables that are

changed by the transition are $x(i,a)$, $y(i)$, $z(q)$, $x(i,b)$, $y(i+1)$, $z(q')$ (some of these may be the same variable, such as if $a = b$, but at least two are guaranteed to be different since the head has to move left or right). Before the transition the first three are set to 1, the second three are set to 0, and after the transition they are all flipped. Corresponding to this transition (which is specified by i, q, and a), we introduce a transition variable $t(i,q,a)$. We now relax conditions 2 and 4 as follows:

- Replace $\big(\overline{x(i,a)} \vee \overline{x(i,b)}\big)$ by $\big(\overline{x(i,a)} \vee \overline{x(i,b)} \vee t(i,q,a)\big)$.
- Replace $\big(\overline{y(i)} \vee \overline{y(i+1)}\big)$ by $\big(\overline{y(i)} \vee \overline{y(i+1)} \vee t(i,q,a)\big)$.
- Replace $\big(\overline{z(q)} \vee \overline{z(q')}\big)$ by $\big(\overline{z(q)} \vee \overline{z(q')} \vee t(i,q,a)\big)$.

This is done for every value of q, a, and i (and also for transitions acting on the clock tape). We add the transition variables to the corresponding clauses so that, for example, the clause $\big(\overline{x(i,a)} \vee \overline{x(i,b)}\big)$ could potentially become very long, such as

$$\Big(\overline{x(i,a)} \vee \overline{x(i,b)} \vee t(i,q_1,a) \vee t(i,q_2,a) \vee \cdots\Big).$$

However, the total number of transition variables is only polynomial in n. We also add a constraint for every pair of transition variables $t(i,q,a)$, $t(i',q',a')$, saying they cannot be 1 simultaneously: $(\overline{t(i,q,a)} \vee \overline{t(i',q',a')})$. This ensures that only one transition can be happening at any time. The effect of adding the transition variables to the clauses of ψ_2 and ψ_4 is that by setting $t(i,q,a)$ to 1, we can simultaneously set $x(i,a)$ and $x(i,b)$ to 1, and so on. This gives a path from the initial configuration to the final configuration as follows: Set $t(i,q,a) = 1$, set $x(i,b) = 1$, $y(i+1) = 1$, $z(q') = 1$, $x(i,a) = 0$, $y(i) = 0$, $z(q) = 0$, then set $t(i,q,a) = 0$. Thus consecutive configurations are now connected. To avoid connecting to other configurations, we also add an expression to ensure that these are the only assignments the 6 variables can take when $t(i,q,a) = 1$:

$$\psi_{i,q,a} = \overline{t(i,q,a)} \vee ((x(i,a), y(i), z(q), x(i,b)), y(i+1), z(q')) \in \{111000, 111100, 111110, 111111, 011111, 001111, 000111\}.$$

This expression can of course be written in conjunctive normal form.

Call the resulting CNF-formula $\varphi(\mathbf{x}, \mathbf{x_c}, \mathbf{y}, \mathbf{y_c}, \mathbf{z}, \mathbf{t})$. Note that $\varphi(\mathbf{x}, \mathbf{x_c}, \mathbf{y}, \mathbf{y_c}, \mathbf{z}, \mathbf{0}) = \psi(\mathbf{x}, \mathbf{x_c}, \mathbf{y}, \mathbf{y_c}, \mathbf{z})$, so a solution where all transition variables are 0 corresponds to a configuration of M'. To see that we have not introduced any shortcut between configurations that are not valid machine transitions, notice that in any solution of φ, at most a single transition variable can be 1. Therefore none of the transitional solutions belonging to different transitions can be adjacent. Furthermore, out of the solutions that have a transition variable set to 1, only the first and the last correspond to a valid configuration. Therefore none of the intermediate solutions (between the starting and the ending configuration of a transition) can be adjacent to a solution with all transition variables set to 0.

Finally, we define the assignment $\mathbf{s}$ to be the one corresponding to the initial configuration of M' with w on the tape, and $\mathbf{t}$ to be the assignment corresponding to the accepting configuration—where the state is q_{accept}, and the tape has only the # symbol at position 0. This completes the reduction.

The formula φ is a CNF-formula where clause size is unbounded. We use the same algorithm for producing structural expressions for k-clauses as in the proof of Lemma 3.5 to get a 3-CNF-formula. By Lemma 3.2 and Corollary 3.3, ST-CONN and CONN for $\mathcal{S}_3$ are PSPACE-complete. ∎

By Lemma 3.4 and Corollary 3.3, this completes the proof of the hardness part of the dichotomies for CONN and ST-CONN (Theorems 2.8 and 2.9).

Finally, we show that 3-CNF-formulas can have exponential diameter by inductively constructing a path of length at least $2^{\frac{n}{2}}$ on n variables and then identifying it with the solution space of a 3-CNF-formula with $O(n^2)$ clauses. By Lemma 3.4 and Corollary 3.3, this implies the hardness part of the diameter dichotomy (Theorem 2.10).

LEMMA 3.7. *For n even, there is a* 3-CNF*-formula φ_n with n variables and $O(n^2)$ clauses, such that $G(\varphi_n)$ is a path of length greater than $2^{\frac{n}{2}}$.*

Proof. The construction is in two steps: We first exhibit an induced subgraph G_n of the n-dimensional hypercube with large diameter. We then construct a 3-CNF-formula φ_n so that $G_n = G(\varphi_n)$.

The graph G_n is a path of length $2^{\frac{n}{2}}$. We construct it using induction. For $n = 2$, we take $V(G_2) = \{(0,0),(0,1),(1,1)\}$ which has diameter 2. Assume that we have constructed G_{n-2} with $2^{\frac{n-2}{2}}$ vertices, and with distinguished vertices $\mathbf{s_{n-2}}, \mathbf{t_{n-2}}$ such that the shortest path from $\mathbf{s_{n-2}}$ to $\mathbf{t_{n-2}}$ in G_{n-2} has length $2^{\frac{n-2}{2}}$. We now describe the set $V(G_n)$. For each vertex $\mathbf{v} \in V(G_{n-2})$, $V(G_n)$ contains two vertices $(\mathbf{v},0,0)$ and $(\mathbf{v},1,1)$. Note that the subgraph induced by these vertices alone consists of two disconnected copies of G_{n-2}. To connect these two components, we add the vertex $\mathbf{m} = (\mathbf{t},0,1)$ (which is connected to $(\mathbf{t},0,0)$ and $(\mathbf{t},1,1)$ in the induced subgraph). Note that the resulting graph G_n is connected, but any path from $(\mathbf{u},0,0)$ to $(\mathbf{v},1,1)$ must pass through $\mathbf{m}$. Further note that by induction the graph G_n is also a path. The vertices $\mathbf{s_n} = (\mathbf{s_{n-2}},0,0)$ and $\mathbf{t_n} = (\mathbf{s_{n-2}},1,1)$ are diametrically opposite ends of this path. The path length is at least $2 \cdot 2^{\frac{n-2}{2}} + 2 > 2^{\frac{n}{2}}$. Also $\mathbf{s_2} = (0,0)$, $\mathbf{s_n} = (\mathbf{s_{n-2}},0,0)$, $\mathbf{t_n} = (\mathbf{s_{n-2}},1,1)$ and hence $\mathbf{s_n} = (0,\ldots,0), \mathbf{t_n} = (0,\ldots,0,1,1)$.

We construct a sequence of 3-CNF-formulas $\varphi_n(x_1,\ldots,x_n)$ so that $G_n = G(\varphi_n)$. Let $\varphi_2(x_1,x_2) = \bar{x}_1 \vee x_2$. Assume we have $\varphi_{n-2}(x_1,\ldots,x_{n-2})$. We add two variables x_{n-1} and x_n and the clauses

$$\varphi_{n-2}(x_1,\ldots,x_{n-2}), \quad \bar{x}_{n-1} \wedge x_n,$$

$$x_{n-1} \vee \bar{x}_n \vee \bar{x}_i \qquad \text{for } \ i \le n-4, \tag{3.2}$$

$$x_{n-1} \vee \bar{x}_n \vee x_i \qquad \text{for } \ i = n-3, n-2. \tag{3.3}$$

Note that a clause in (3.2) is just the implication $(\bar{x}_{n-1} \wedge x_n) \to \bar{x}_i$. Thus clauses (3.2), (3.3) enforce the condition that $x_{n-1} = 0, x_n = 1$ implies that $(x_1,\ldots,x_{n-2}) = \mathbf{t_{n-2}} = (0,\ldots,0,1,1)$. ∎

4. The easy case of the dichotomy: Tight sets of relations.

4.1. Schaefer sets of relations. We begin by showing that all Schaefer sets of relations are tight. Schaefer relations are characterized by closure properties. We say that an r-ary relation R is closed under some k-ary operation $\alpha : \{0,1\}^k \to \{0,1\}$ if for every $\mathbf{a^1}, \mathbf{a^2}, \ldots, \mathbf{a^k} \in R$, the tuple $(\alpha(a_1^1, a_1^2, \ldots, a_1^k), \ldots, \alpha(a_r^1, \ldots, a_r^k))$ is in R. We denote this tuple by $\alpha(\mathbf{a^1}, \ldots, \mathbf{a^k})$.

We will use the following lemma about closure properties on several occasions.

LEMMA 4.1. *If a logical relation R is closed under an operation $\alpha : \{0,1\}^k \to \{0,1\}$ such that $\alpha(1,1,\ldots,1) = 1$ and $\alpha(0,0,\ldots,0) = 0$ (a.k.a. an idempotent operation), then every connected component of $G(R)$ is closed under α.*

Proof. Consider $\mathbf{a^1}, \ldots, \mathbf{a^k} \in R$, such that they all belong to the same connected component of $G(R)$. It suffices to prove that $\mathbf{a} = \alpha(\mathbf{a^1}, \ldots, \mathbf{a^k})$ is in the same connected component of $G(R)$. To that end we will first prove that for any $\mathbf{s}, \mathbf{t} \in R$ if there

is a path from $\mathbf{s}$ to $\mathbf{t}$ in $G(R)$, then there is a path from $\alpha(\mathbf{b^1}, \ldots, \mathbf{b^{i-1}}, \mathbf{s}, \mathbf{b^{i+1}}, \ldots, \mathbf{b^k})$ to $\alpha(\mathbf{b^1}, \ldots, \mathbf{b^{i-1}}, \mathbf{t}, \mathbf{b^{i+1}}, \ldots, \mathbf{b^k})$ for any $\mathbf{b^1}, \ldots, \mathbf{b^k} \in R$. This observation implies that there is a path from $\mathbf{a^1} = \alpha(\mathbf{a^1}, \mathbf{a^1}, \ldots, \mathbf{a^1})$ to $\alpha(\mathbf{a^1}, \mathbf{a^2}, \mathbf{a^1}, \ldots, \mathbf{a^1})$, from there to $\alpha(\mathbf{a^1}, \mathbf{a^2}, \mathbf{a^3}, \mathbf{a^1}, \ldots, \mathbf{a^1})$ and so on, to $\alpha(\mathbf{a^1}, \mathbf{a^2}, \ldots, \mathbf{a^k}) = \mathbf{a}$. Thus $\mathbf{a}$ is in the same connected component of $G(R)$ as $\mathbf{a^1}$.

Let the path from $\mathbf{s}$ to $\mathbf{t}$ be $\mathbf{s} = \mathbf{s^1} \to \mathbf{s^2} \to \ldots \mathbf{s^m} = \mathbf{t}$. For every $j \in \{1, 2, \ldots, m-1\}$, the tuples $\alpha(\mathbf{b^1}, \ldots, \mathbf{b^{i-1}}, \mathbf{s^j}, \mathbf{b^{i+1}}, \ldots, \mathbf{b^m})$ and $\alpha(\mathbf{b^1}, \ldots, \mathbf{b^{i-1}}, \mathbf{s^{j+1}}, \mathbf{b^{i+1}}, \ldots, \mathbf{b^m})$ differ in at most one position (the position in which $\mathbf{s^j}$ and $\mathbf{s^{j+1}}$ are different); therefore they belong to the same component of $G(R)$. Thus $\alpha(\mathbf{b^1}, \ldots, \mathbf{b^{i-1}}, \mathbf{s^1}, \mathbf{b^{i+1}}, \ldots, \mathbf{b^m})$ and $\alpha(\mathbf{b^1}, \ldots, \mathbf{b^{i-1}}, \mathbf{s^m}, \mathbf{b^{i+1}}, \ldots, \mathbf{b^m})$ belong to the same component. □

We are ready to prove that all Schaefer relations are tight.

LEMMA 4.2. *Let R be a logical relation.*

1. *If R is bijunctive, then R is componentwise bijunctive.*
2. *If R is Horn, then R is* OR*-free.*
3. *If R is dual Horn, then R is* NAND*-free.*
4. *If R is affine, then R is componentwise bijunctive,* OR*-free, and* NAND*-free.*

Proof. The case of bijunctive relations follows immediately from Lemma 4.1 and the fact that a relation is bijunctive if and only if it is closed under the ternary majority operation maj, which is idempotent.

The cases of Horn and dual Horn are symmetric. Suppose an r-ary Horn relation R is not OR-free. Then there exist $i, j \in \{1, \ldots, r\}$ and constants $t_1, \ldots, t_r \in \{0, 1\}$ such that the relation $R(t_1, \ldots, t_{i-1}, x, t_{i+1}, \ldots, t_{j-1}, y, t_{j+1}, \ldots, t_r)$ on variables x and y is equivalent to $x \vee y$, i.e.,

$$R(t_1, \ldots, t_{i-1}, x, t_{i+1}, \ldots, t_{j-1}, y, t_{j+1}, \ldots, t_r) = \{01, 11, 10\}.$$

Thus the tuples $\mathbf{t^{00}}, \mathbf{t^{01}}\mathbf{t^{10}}, \mathbf{t^{11}}$ defined by $(t_i^{ab}, t_j^{ab}) = (a, b)$ and $t_k^{ab} = t_k$ for every $k \notin \{i, j\}$, where $a, b, \in \{0, 1\}$ satisfy $\mathbf{t^{10}}, \mathbf{t^{11}}, \mathbf{t^{01}} \in R$ and $\mathbf{t^{00}} \notin R$. However, since every Horn relation is closed under $\wedge$, it follows that $\mathbf{t^{01}} \wedge \mathbf{t^{10}} = \mathbf{t^{00}}$ must be in R, which is a contradiction.

For the affine case, a small modification of the last step of the above argument shows that an affine relation also is OR-free; therefore, dually, it is also NAND-free. Namely, since a relation R is affine if and only if it is closed under ternary $\oplus$, it follows that $\mathbf{t^{01}} \oplus \mathbf{t^{11}} \oplus \mathbf{t^{10}} = \mathbf{t^{00}}$ must be in R.

Since the connected components of an affine relation are both OR-free and NAND-free, the subgraphs that they induce are hypercubes, which are also bijunctive relations. Therefore an affine relation is also componentwise bijunctive. □

These containments are proper. For instance, $R_{1/3} = \{100, 010, 001\}$ is componentwise bijunctive, but not bijunctive as $\text{maj}(100, 010, 001) = 000 \notin R_{1/3}$.

4.2. Structural properties of tight sets of relations. In this section, we explore some structural properties of the solution graphs of tight sets of relations. These properties provide simple algorithms for CONN($\mathcal{S}$) and ST-CONN($\mathcal{S}$) for tight sets $\mathcal{S}$, and also guarantee that for such sets, the diameter of $G(\varphi)$ of CNF($\mathcal{S}$)-formula φ is linear.

LEMMA 4.3. *Let $\mathcal{S}$ be a set of componentwise bijunctive relations and φ a* CNF($\mathcal{S}$)*-formula. If $\mathbf{a}$ and $\mathbf{b}$ are two solutions of φ that lie in the same component of $G(\varphi)$, then $d_\varphi(\mathbf{a}, \mathbf{b}) = |\mathbf{a} - \mathbf{b}|$, i.e., no distance expands.*

Proof. Consider first the special case in which every relation in $\mathcal{S}$ is bijunctive. In this case, φ is equivalent to a 2-CNF-formula and so the space of solutions of φ is closed under majority. We show that there is a path in $G(\varphi)$ from $\mathbf{a}$ to $\mathbf{b}$

such that along the path only the assignments on variables with indices from the set $D = \{i | a_i \neq b_i\}$ change. This implies that the shortest path is of length $|D|$ by induction on $|D|$. Consider any path $\mathbf{a} \to \mathbf{u^1} \to \cdots \to \mathbf{u^r} \to \mathbf{b}$ in $G(\varphi)$. We construct another path by replacing $\mathbf{u^i}$ by $\mathbf{v^i} = \text{maj}(\mathbf{a}, \mathbf{u^i}, \mathbf{b})$ for $i = 1, \ldots, r$ and removing repetitions. This is a path because for any i $\mathbf{v^i}$ and $\mathbf{v^{i+1}}$ differ in at most one variable. Furthermore, $\mathbf{v^i}$ agrees with $\mathbf{a}$ and $\mathbf{b}$ for every i for which $a_i = b_i$. Therefore, along this path only variables in D are flipped.

For the general case, we show that every component F of $G(\varphi)$ is the solution space of a 2-CNF-formula φ'. Let $R \in \mathcal{S}$ be a relation with two components, R_1, R_2, each of which are bijunctive. Consider a clause in φ of the form $R(x_1, \ldots, x_k)$. The projection of F onto $x_1, \ldots, x_k$ is itself connected and must satisfy R. Hence it lies within one of the two components R_1, R_2; assume it is R_1. We replace $R(x_1, \ldots, x_k)$ by $R_1(x_1, \ldots, x_k)$. Call this new formula φ_1. $G(\varphi_1)$ consists of all components of $G(\varphi)$ whose projection on $x_1, \ldots, x_k$ lies in R_1. We repeat this for every clause. Finally we are left with a formula φ' over a set of bijunctive relations. Hence φ' is bijunctive and $G(\varphi')$ is a component of $G(\varphi)$. So the claim follows from the bijunctive case. □

COROLLARY 4.4. *Let $\mathcal{S}$ be a set of componentwise bijunctive relations. Then*

1. *for every $\varphi \in \text{CNF}(\mathcal{S})$ with n variables, the diameter of each component of $G(\varphi)$ is bounded by n;*
2. *st-Conn$(\mathcal{S})$ is in* P*;*
3. *Conn$(\mathcal{S})$ is in* coNP*.*

Proof. The bound on diameter is an immediate consequence of Lemma 4.3.

The following algorithm solves st-Conn$(\mathcal{S})$ given vertices $\mathbf{s}, \mathbf{t} \in G(\varphi)$. Start with $\mathbf{u} = \mathbf{s}$. At each step, find a variable x_i so that $u_i \neq t_i$ and such that if we flip x_i, the assignment would still be satisfying. Repeat until $\mathbf{t}$ is reached. If at any stage no such variable exists, then declare that $\mathbf{s}$ and $\mathbf{t}$ are not connected. If the $\mathbf{s}$ and $\mathbf{t}$ are disconnected, the algorithm is bound to fail. So assume that they are connected. Correctness is proved by induction on $d = |\mathbf{s} - \mathbf{t}|$. It is clear that the algorithm works when $d = 1$. Assume that the algorithm works for $d - 1$. If s and t are connected and are distance d apart, Lemma 4.3 implies there is a path of length d between them in $G(\varphi)$. In particular, the algorithm will find a variable x_i to flip. The resulting assignment is at distance $d - 1$ from $\mathbf{t}$, so now we proceed by induction.

Next we prove that Conn$(\mathcal{S}) \in$ coNP. A short certificate that the graph is not connected is a pair of assignments $\mathbf{s}$ and $\mathbf{t}$ which are solutions from different components. To verify that they are disconnected it suffices to run the algorithm for st-Conn. □

We consider sets of OR-free relations. Define the *coordinatewise partial order* $\leq$ on Boolean vectors as follows: $\mathbf{a} \leq \mathbf{b}$ if $a_i \leq b_i$ for each i. A monotone path between $\mathbf{a}$ and $\mathbf{b}$ is a path in $G(\varphi)$, $\mathbf{a} \to \mathbf{u^1} \to \cdots \to \mathbf{u^r} \to \mathbf{b}$ such that $\mathbf{a} \leq \mathbf{u^1} \leq \cdots \leq \mathbf{u^r} \leq \mathbf{b}$.

LEMMA 4.5. *Let $\mathcal{S}$ be a set of* OR*-free relations and φ a* CNF$(\mathcal{S})$*-formula. Every component of $G(\varphi)$ contains a minimum solution with respect to the coordinatewise order; moreover, every solution is connected to the minimum solution in the same component via a monotone path.*

Proof. We call a satisfying assignment locally minimal if it has no neighboring satisfying assignments that are smaller than it. We will show that there is exactly one such assignment in each component of $G(\varphi)$.

Suppose there are two distinct locally minimal assignments $\mathbf{u}$ and $\mathbf{u'}$ in some component of $G(\varphi)$. Consider the path between them where the maximum Hamming weight of assignments on the path is minimized. If there are many such paths, pick

one where the smallest number of assignments have the maximum Hamming weight. Denote this path by $\mathbf{u} = \mathbf{u^1} \to \mathbf{u^2} \to \cdots \to \mathbf{u^r} = \mathbf{u'}$. Let $\mathbf{u^i}$ be an assignment of largest Hamming weight in the path. Then $\mathbf{u^i} \neq \mathbf{u}$ and $\mathbf{u^i} \neq \mathbf{u'}$, since $\mathbf{u}$ and $\mathbf{u'}$ are locally minimal. The assignments $\mathbf{u^{i-1}}$ and $\mathbf{u^{i+1}}$ differ in exactly 2 variables, say, in x_1 and x_2. So $\{u_1^{i-1}u_2^{i-1},\ u_1^i u_2^i,\ u_1^{i+1}u_2^{i+1}\} = \{01, 11, 10\}$. Let $\hat{\mathbf{u}}$ be such that $\hat{u}_1 = \hat{u}_2 = 0$, and $\hat{u}_i = u_i$ for $i > 2$. If $\hat{\mathbf{u}}$ is a solution, then the path $\mathbf{u^1} \to \mathbf{u^2} \to \cdots \to \mathbf{u^{i-1}} \to \hat{\mathbf{u}} \to \mathbf{u^{i+1}} \to \cdots \to \mathbf{u^r}$ contradicts the way we chose the original path. Therefore, $\hat{\mathbf{u}}$ is not a solution. This means that there is a clause that is violated by it but is satisfied by $\mathbf{u^{i-1}}$, $\mathbf{u^i}$, and $\mathbf{u^{i+1}}$. So the relation corresponding to that clause is not OR-free, which is a contradiction.

The unique locally minimal solution in a component is its minimum solution, because starting from any other assignment in the component, it is possible to keep moving to neighbors that are smaller, and the only time it becomes impossible to find such a neighbor is when the locally minimal solution is reached. Therefore, there is a monotone path from any satisfying assignment to the minimum in that component. □

COROLLARY 4.6. *Let $\mathcal{S}$ be a set of* OR*-free relations. Then*

1. *for every $\varphi \in \mathrm{CNF}(\mathcal{S})$ with n variables, the diameter of each component of $G(\varphi)$ is bounded by $2n$;*
2. ST-CONN$(\mathcal{S})$ *is in* P*;*
3. CONN$(\mathcal{S})$ *is in* coNP*.*

Proof. Given solutions $\mathbf{s}$ and $\mathbf{t}$ in the same component of $G(\varphi)$, there is a monotone path from each to the minimal solution $\mathbf{u}$ in the component. This gives a path from $\mathbf{s}$ to $\mathbf{t}$ of length at most $2n$. To check if $\mathbf{s}$ and $\mathbf{t}$ are connected, we just check that the minimal assignments reached from $\mathbf{s}$ and $\mathbf{t}$ are the same. □

Sets of NAND-free relations are handled dually to OR-free relations. In this case there is a maximum solution in every connected component of $G(\phi)$ and every solution is connected to it via a monotone path. Finally, putting everything together, we complete the proofs of all our dichotomy theorems.

COROLLARY 4.7. *Let $\mathcal{S}$ be a tight set of relations. Then*

1. *for every $\varphi \in \mathrm{CNF}(\mathcal{S})$ with n variables, the diameter of each component of $G(\varphi)$ is bounded by $2n$;*
2. ST-CONN$(\mathcal{S})$ *is in* P*;*
3. CONN$(\mathcal{S})$ *is in* coNP*.*

4.3. The complexity of CONN for tight sets of relations. We pinpoint the complexity of CONN$(\mathcal{S})$ for the tight cases which are not Schaefer, using a result of Juban [19].

LEMMA 4.8. *For $\mathcal{S}$ tight, but not Schaefer,* CONN$(\mathcal{S})$ *is* coNP*-complete.*

Proof. The problem ANOTHER-SAT$(\mathcal{S})$ is as follows: Given a formula φ in CNF$(\mathcal{S})$ and a solution $\mathbf{s}$, does there exist a solution $\mathbf{t} \neq \mathbf{s}$? Juban [19, Theorem 2] shows that if $\mathcal{S}$ is not Schaefer, then ANOTHER-SAT is NP-complete. He also shows [19, Corollary 1] that if $\mathcal{S}$ is not Schaefer, then the relation $x \neq y$ is expressible from $\mathcal{S}$ through substitutions.

Since $\mathcal{S}$ is not Schaefer, ANOTHER-SAT$(\mathcal{S})$ is NP-complete. Let $\varphi, \mathbf{s}$ be an instance of ANOTHER-SAT on variables $x_1, \ldots, x_n$. We define a CNF$(\mathcal{S})$-formula ψ on the variables $x_1, \ldots, x_n, y_1, \ldots, y_n$ as

$$\psi(x_1, \ldots, x_n, y_1, \ldots, y_n) = \varphi(x_1, \ldots, x_n) \wedge_i (x_i \neq y_i).$$

It is easy to see that $G(\psi)$ is connected if and only if $\mathbf{s}$ is the unique solution to φ. □

We are left with the task of determining the complexity of CONN($\mathcal{S}$) for the case when $\mathcal{S}$ is a Schaefer set of relations. In Lemmas 4.9 and 4.10 we show that CONN($\mathcal{S}$) is in P if $\mathcal{S}$ is affine or bijunctive. This leaves the case of Horn and dual Horn, which we discuss at the end of this section.

LEMMA 4.9. *If $\mathcal{S}$ is a bijunctive set of relations, then there is a polynomial-time algorithm for* CONN($\mathcal{S}$).

Proof. Consider a formula $\phi(x_1, \ldots, x_n)$ in CNF($\mathcal{S}$). Since $\mathcal{S}$ is a bijunctive set of relations ϕ can be written as a 2-CNF-formula. Since satisfiability of 2-CNF-formulas is decidable in polynomial time, it is easy to decide for a given variable x_i whether there exist solutions in which it takes a particular value in $\{0, 1\}$. The variables which can take only one value are assigned that value. Without loss of generality we can assume that the resulting 2-CNF formula is $\psi(x_1, \ldots, x_m)$.

Consider the graph of implications of ψ defined in the following way: The vertices are the literals $x_1, \ldots, x_m, \bar{x}_1, \ldots, \bar{x}_m$. There is a directed edge from literal l_1 to literal l_2 if and only if ψ contains a clause containing l_2 and the negation of l_1, which we denote by $\bar{l}_1$ (if l_1 is a negated variable $\bar{x}$, then $\bar{l}_1$ denotes x). The directed edge represents the fact that in a satisfying assignment if the literal l_1 is assigned true, then the literal l_2 is also assigned true. We will show that $G(\psi)$ is disconnected if and only if the graph of implications contains a directed cycle. This property can be checked in polynomial time.

Suppose the graph of implications contains a directed cycle of literals $l_1 \to l_2 \to l_3 \to \cdots \to l_k \to l_1$. By the construction, the graph also contains a directed cycle on the negations of these literals, but in the opposite direction: $\bar{l}_k \to \bar{l}_{k-1} \to \cdots \to \bar{l}_2 \to \bar{l}_1 \to \bar{l}_k$. There is a satisfying assignment $\mathbf{s}$ in which l_1 is assigned 1, and also a satisfying assignment $\mathbf{t}$ in which $\bar{l}_1$ is assigned 1. By the implications, in $\mathbf{s}$ the literals $l_1, l_2, \ldots, l_k$ are assigned 1, and in $\mathbf{t}$ $\bar{l}_1, \bar{l}_2, \ldots, \bar{l}_k$ are assigned 1. Suppose there is a path from $\mathbf{s}$ to $\mathbf{t}$. Then let l_i be the first literal in the cycle whose value changes along the path from $\mathbf{s}$ to $\mathbf{t}$. Then there is a satisfying assignment in which l_i is assigned 0, whereas all other literals on the cycle are assigned 1. On the other hand, this cannot be a satisfying assignment because the edge (l_{i-1}, l_i) implies that there is a clause containing only l_i and the negation of l_{i-1}, and this clause is violated by the assignment. This is a contradiction, and therefore there can be no path from $\mathbf{s}$ to $\mathbf{t}$.

Next, suppose the graph of implications contains no directed cycle, and $G(\psi)$ is disconnected. Let $\mathbf{s}$ and $\mathbf{t}$ be satisfying assignments from different connected components of $G(\psi)$ that are at minimum Hamming distance. Let U be the set of variables on which $\mathbf{s}$ and $\mathbf{t}$ differ. There are two literals corresponding to each variable, and let $U^{\mathbf{s}}$ and $U^{\mathbf{t}}$ denote, respectively, the literals that are true in $\mathbf{s}$ and in $\mathbf{t}$. Since the directed graph induced by $U^{\mathbf{s}}$ in the implications graph contains no directed cycle, there exists a literal $l \in U^{\mathbf{s}}$ without an incoming edge from another literal in $U^{\mathbf{s}}$. Otherwise, by following the incoming edges we would find a cycle in the graph induced by $U^{\mathbf{s}}$. In addition, for every literal $l' \notin U^{\mathbf{s}}$ that is assigned true by $\mathbf{s}$, there is no edge from l' to l because that would contradict the fact that $\mathbf{t}$ is also a satisfying assignment (by the definition of U, l' is assigned true by $\mathbf{t}$). Therefore, with respect to $\mathbf{s}$ the literal l does not appear in any clause in which it is implied, i.e., in which it is the only satisfying literal. Thus, the value of the corresponding variable can be flipped and the resulting assignment is still satisfying. This assignment is in the same component as $\mathbf{s}$ but it is closer to $\mathbf{t}$, which contradicts our choice of $\mathbf{s}$ and $\mathbf{t}$. □

LEMMA 4.10. *If $\mathcal{S}$ is an affine set of relations, then there is a polynomial-time algorithm for* CONN($\mathcal{S}$).

Proof. An affine formula can be described as the set of solutions of a linear system of equations. For any solution, if only a variable that appears in at least one of the equations is flipped, the resulting assignment is not a solution. Therefore it suffices to check whether the system has more than one solution (after variables that don't appear in any equation are removed), which is easily done by checking the rank of the matrix obtained from the Gaussian elimination algorithm. □

We are left with characterizing the complexity of CONN for sets of Horn relations and for sets of dual Horn relations. In the conference version [16] of the present paper, we had conjectured that if $\mathcal{S}$ is Horn or dual Horn, then CONN($\mathcal{S}$) is in P, but this was disproved by Makino, Tamaki, and Yamamoto [24]. They showed that CONN($\{R_2\}$) is coNP-complete, where $R_2 = \{0,1\}^3 \backslash \{110\}$; hence there exist Horn (and by symmetry also dual Horn) sets of relations for which CONN is coNP-complete. Their proof is via a reduction from POSITIVE NOT-ALL-EQUAL 3-SAT, which as seen earlier is SAT($\{R_{\text{NAE}}\}$), where $R_{\text{NAE}} = \{0,1\}^3 \setminus \{000, 111\}$. This problem is also known as 3-hypergraph 2-colorability,

The relation R_2 is a 3-clause with one positive literal. We will describe a natural set of Horn relations first introduced in [14], which cannot be used to express R_2. We show that for this set there is a polynomial-time algorithm for CONN.

DEFINITION 4.11. *A logical relation R is* implicative hitting set-bounded− *(*IHSB−*) if it is the set of solutions of a Horn formula in which all clauses of size greater than* 2 *have only negative literals. Similarly, R is* implicative hitting set-bounded+ *(*IHSB+*) if it is the set of solutions of a dual Horn formula in which all clauses of size greater than* 2 *have only positive literals.*

These types of logical relations can be characterized by closure properties. A relation R is IHSB− if and only if it is closed under $\mathbf{a} \wedge (\mathbf{b} \vee \mathbf{c})$; in other words if $\mathbf{a}, \mathbf{b}, \mathbf{c} \in R$, where R is of arity r, then $\mathbf{a} \wedge (\mathbf{b} \vee \mathbf{c}) = (a_1 \wedge (b_1 \vee c_1), a_2 \wedge (b_2 \vee c_2), \ldots, a_r \wedge (b_r \vee c_r)) \in R$. A relation R is IHSB+ if and only if it is closed under $\mathbf{a} \vee (\mathbf{b} \wedge \mathbf{c})$. While the definition may at first look unnatural, it comes from Post's classification of Boolean functions (see [5]). One of the consequences of this classification is that IHSB− relations cannot express all Horn relations, and in particular R_2, even in the sense of Schaefer's expressibility. For the purposes of structural expressibility we can define an even larger class of relations which cannot structurally express R_2 (unless P = coNP).

DEFINITION 4.12. *A logical relation R is* componentwise IHSB− (IHSB+) *if every connected component of $G(R)$ is IHSB− (IHSB+).*

By Lemma 4.1, every relation that is IHSB− (IHSB+) is also componentwise IHSB− (IHSB+). Of course, the class of componentwise IHSB− relations is much broader and in fact includes relations that are not even Horn, such as $R_{1/3}$. However, in the following lemma we consider only componentwise IHSB− (IHSB+) relations which are Horn (dual Horn). We will say that a set of relations $\mathcal{S}$ is componentwise IHSB− (IHSB+) if every relation in $\mathcal{S}$ is componentwise IHSB− (IHSB+).

LEMMA 4.13. *If $\mathcal{S}$ is a set of relations that are Horn (dual Horn) and componentwise IHSB− (IHSB+), then there is a polynomial-time algorithm for* CONN($\mathcal{S}$).

Proof. First we consider the case in which every relation in $\mathcal{S}$ is IHSB−. The formula can be written as a conjunction of Horn clauses, such that clauses of length greater than 2 have only negative literals. Let all unit clauses be assigned and propagated—their variables take the same value in all satisfying assignments. The

resulting formula is also IHSB− and has two kinds of clauses: 2-clauses with one positive and one negative literal, and clauses of size 2 or more with only negative literals. The assignment of zero to all variables is satisfying. There is more than one connected component if and only if there is another assignment that is locally minimal by Lemma 4.5. A locally minimal satisfying assignment is such that if any of the variables assigned 1 is changed to 0 the resulting assignment is not satisfying. Thus all variables assigned 1 appear in at least one 2-clause with one positive and one negative literal for which both variables are assigned 1. We say that such an assignment certifies the disconnectivity.

To describe the algorithm, we first define the following implication graph G. The vertices are the set of variables. There is a directed edge (x_i, x_j) if and only if $(x_j \vee \bar{x}_i)$ is a clause in the IHSB− representation. Let $S_1, \ldots, S_m$ be the sets of variables in clauses with only negative literals. For every variable x_i let T_i denote the set of variables reachable from x_i in the directed graph. If $x_i \in T_i$, then x_i lies in a directed cycle. Note that if x_i is set to 1, then every variable in T_i must also be set to 1. The algorithm rejects if and only if there exists a variable x_i such that $x_i \in T_i$ and T_i does not contain S_j for any $j \in \{1, \ldots, m\}$. We show that this happens if and only if the solution graph is disconnected. Note that the algorithm runs in polynomial time.

Assume that the graph of solutions is disconnected and consider the satisfying assignment $\mathbf{s}$ that certifies disconnectivity. Let U be the set of variables x_i such that $s_i = 1$. Since every variable in U appears in at least one 2-clause for which both variables are from U, the directed graph induced by U is such that every vertex has an incoming edge. By starting at any vertex in U and following the incoming edge backwards until we repeat some vertex, we find a cycle in the subgraph induced by U. For any variable x_i in such a cycle it holds that $x_i \in T_i$. Further $T_i \subseteq U$, since setting x_i to 1 forces all variables in T_i to be 1. Also T_i cannot contain S_j for any j, else the corresponding clause would not be satisfied by $\mathbf{s}$. Thus the algorithm rejects whenever the solution graph is disconnected.

Conversely, if the algorithm rejects, there exists a variable x_i such that $x_i \in T_i$ and T_i does not contain S_j for any $j \in \{1, \ldots, m\}$. Consider the assignment in which all variables from T_i are assigned 1, and the rest are assigned 0. We will show that this assignment is satisfying and it is a certificate for disconnectivity. Clauses which contain only negated variables are satisfied since $S_j \not\subset T_i$ for all j. Now consider a clause of the form $(x_j \vee \bar{x}_k)$ and note that there is a directed edge (x_k, x_j). If $x_k = 0$, this is satisfied. If $x_k = 1$, then $x_k \in T_i$, and hence $x_j \in T_i$ because of the edge (x_k, x_j). But then x_j is set to 1, so the clause is satisfied. To show that this solution is minimal, consider trying to set $x_k \in T_i$ to 0. There is an incoming edge (x_j, x_k) for some $x_j \in T_i$, and hence a clause $(x_k \vee \bar{x}_j)$, which will become unsatisfied if we set $x_k = 0$. Thus we have a certificate for the space being disconnected.

Next, consider a formula $\phi(x_1, \ldots, x_n)$ in CNF($\mathcal{S}$). We reduce the connectivity question to one for a formula with IHSB− relations. Since satisfiability of Horn formulas is decidable in polynomial time and every connected component of a Horn relation is a Horn relation by Lemma 4.1, it is easy to decide for a given clause and a given connected component of its corresponding relation (the relation obtained after identifying repeated variables) whether there exists a solution for which the variables in this clause are assigned a value in the specified connected component. If there exists a clause for which there is more than one connected component for which solutions exist, then the space of solutions is disconnected. This follows from the fact that the projection of $G(\phi)$ onto the hypercube corresponding to the variables appearing in

this clause is disconnected. Therefore we can assume that the relation corresponding to every clause has a single connected component. Since that component is IHSB− the relation itself is IHSB−. □

It is still open whether CONN is coNP-complete for every remaining Horn set of relations, i.e., every set of Horn relations that contains at least one relation that is not componentwise IHSB−. Following the same line of reasoning as in the proof of our structural expressibility theorem, we are able to show that one of the paths of length 4 defined in section 3.2, namely, $M(\bar{x}_1, \bar{x}_2, x_3)$, can be expressed structurally from every such set of relations. Thus the trichotomy would be established if one shows that CONN($\{M(\bar{x}_1, \bar{x}_2, x_3)\}$) is coNP-hard.

5. Discussion and open problems. In section 2, we conjectured a trichotomy for CONN($\mathcal{S}$). In view of the results established here, what remains is to pinpoint the complexity of CONN($\mathcal{S}$) when $\mathcal{S}$ is Horn but not componentwise IHSB−, and when $\mathcal{S}$ is dual Horn but not componentwise IHSB+. We conjecture that for those cases CONN($\mathcal{S}$) is coNP-complete.

We mentioned that one could also consider CNF($\mathcal{S}$)-formulas without constants, and the extension of our results to this setting is still an open problem. A more interesting and challenging direction is the extension of our results to larger domains.

Finally, our techniques may shed light on other connectivity-related problems, such as approximating the diameter and counting the number of components, or proving hardness of other configuration connectivity problems. An example of the latter appears in recent work of Ito et al. [18].

THE UNDECIDABILITY OF THE INFINITE RIBBON PROBLEM: IMPLICATIONS FOR COMPUTING BY SELF-ASSEMBLY*

LEONARD ADLEMAN†, JARKKO KARI‡, LILA KARI§, DUSTIN REISHUS†, AND PETR SOSIK¶

Abstract. Self-assembly, the process by which objects autonomously come together to form complex structures, is omnipresent in the physical world. Recent experiments in self-assembly demonstrate its potential for the parallel creation of a large number of nanostructures, including possibly computers. A systematic study of self-assembly as a mathematical process has been initiated by L. Adleman and E. Winfree. The individual components are modeled as square tiles on the infinite two-dimensional plane. Each side of a tile is covered by a specific "glue," and two adjacent tiles will stick iff they have matching glues on their abutting edges. Tiles that stick to each other may form various two-dimensional "structures" such as squares and rectangles, or may cover the entire plane. In this paper we focus on a special type of structure, called a ribbon: a non-self-crossing rectilinear sequence of tiles on the plane, in which successive tiles are adjacent along an edge and abutting edges of consecutive tiles have matching glues. We prove that it is undecidable whether an arbitrary finite set of tiles with glues (infinite supply of each tile type available) can be used to assemble an infinite ribbon. While the problem can be proved undecidable using existing techniques if the ribbon is required to start with a given "seed" tile, our result settles the "unseeded" case, an open problem formerly known as the "unlimited infinite snake problem." The proof is based on a construction, due to R. Robinson, of a special set of tiles that allow only aperiodic tilings of the plane. This construction is used to create a special set of directed tiles (tiles with arrows painted on the top) with the "strong plane-filling property"—a variation of the "plane-filling property" previously defined by J. Kari. A construction of "sandwich" tiles is then used in conjunction with this special tile set, to reduce the well-known undecidable tiling problem to the problem of the existence of an infinite directed zipper (a special kind of ribbon). A "motif" construction is then introduced that allows one tile system to simulate another by using geometry to represent glues. Using motifs, the infinite directed zipper problem is reduced to the infinite ribbon problem, proving the latter undecidable. An immediate consequence of our result is the undecidability of the existence of arbitrarily large structures self-assembled using tiles from a given tile set.

Key words. DNA computing, molecular computing, self-assembly, tiling, undecidability

1. Introduction. Self-assembly, the process by which objects autonomously come together to form complex structures, is omnipresent in the physical world. Atoms bind to each other by chemical bonds to form molecules, molecules may form crystals or macromolecules, and cells interact to form biological organisms. Recently it has been suggested that complex self-assembly processes will ultimately be used in circuit fabrication, nanorobotics, DNA computation, and amorphous computing. Indeed, in electronics, engineering, medicine, material science, manufacturing, and other disciplines, there is a continuous drive toward miniaturization. Unfortunately, current "top-down" techniques such as lithography may not be capable of efficiently creating structures with features the size of molecules or atoms. Self-assembly provides a "bottom-up" approach by which such fine structures might be created.

Experimental research on self-assembly includes simulation of one-dimensional cellular automata by using macroscopic plastic tiles that assemble at an oil/water interface [38], studies of self-directed growth of hybrid organic molecules on a silicon substrate [31], self-assembly of regular lipid hollow icosahedra [14], self-assembly of patterns of lead on a copper surface as templates for fabricating nanostructures [35], formation of electrical networks by self-assembly of small plastic and metal objects [22], [49], self-assembly of molecular machines [20], the construction by self-assembly of a molecular-thickness transistor [43], and DNA nanomachines made by self-assembly (e.g., molecular switches [30], tweezers [53], [33], walkers [44], autonomous DNA motors [47], [9], [23]), as well as algorithmic self-assembled Sierpinski triangles [41], self-assembled cloneable DNA octahedra [45], stiff self-assembled tetrahedra for three-dimensional electronic circuits [21], and DNA origami [40].

Investigations into DNA computing [2] and amorphous computing [1] have pointed out a strong connection between self-assembly and computation. While [52], [29], [36], [50] have shown the potential of DNA self-assembly for computation, [51] has experimentally demonstrated the self-assembly of periodic two-dimensional arrays from DNA "tiles," in which "binding" is regulated by the "sticky" ends of the DNA tiles. Reference [32] has demonstrated the execution of logical operations (cumulative XOR) by self-assembly of DNA triple cross-over molecules and [10] has demonstrated the potential for programmable self-assembled computing devices.

A systematic study of self-assembly as a computational process has been initiated in [3]. The individual components are therein modeled as square tiles on the infinite two-dimensional plane. The tiles cannot be rotated. Each side of a tile is covered by a specific "glue," and two adjacent tiles will stick iff they have matching glues on their abutting edges. As such, tiles have been previously studied in the context of classic questions about tilings of the plane [48]. The tiling problem, for example (proved undecidable in [11], [37]), asks whether a given set of tiles (supply of each tile type unlimited) can be used to correctly tile the entire plane. However, the new requirements of experimental self-assembly of tiles into required nanoscale shapes pose new types of questions. What is the minimal number of tiles required for the self-assembly of a desired shape [5], [19], [13], [46], [25], [39]? What is the running time of such a self-assembly [5], [4]? Do the results still hold if one generalizes the model by making the "sticking" reversible, or by defining different bond strengths and requiring more than one bond for sticking to occur [42], [4], [6], [5]? Do reversible self-assemblies achieve equilibrium [6]? What is the optimal initial concentration of tile types that guarantees the fastest assembly of a required shape [5]? Can a self-assembled shape recover from the loss of arbitrary many tiles [12]? What are possible computational primitives for algorithmic self-assembly [8]?

One of the interesting problems of self-assembly is whether or not a given set of

tiles allows uncontrollable growth, that is, whether arbitrarily large structures can be produced. It turns out that this question is equivalent to asking whether or not, given a set of tiles, there exists an infinite ribbon that can be formed with tiles from this set. A *ribbon* is a non-self-crossing sequence of tiles on the plane, in which successive tiles are adjacent along an edge and abutting edges of consecutive tiles have matching glues. If a given "seed" tile is specified, the problem of existence of an infinite ribbon starting at that tile has been proved undecidable [16], [15], [17]. However, when no such seed is specified, existing proof techniques failed to produce an answer and the problem was declared open in [17]. The unseeded problem is also relevant given that, in some physical simulations of self-assembly [38], the growth mechanism was deemed incompatible with computations that use a chosen input. (More recently, in [18], successful experimental "seeded" self-assembly of fixed-length Sierpinski-patterned ribbons was reported. The assemblies, which use DNA tiles, start their growth from DNA "origami seeds"—special DNA tiles obtained by using the origami method [40].) Here we prove that the unseeded problem is also undecidable. This result settles an open problem known hitherto as the "unlimited infinite snake problem" [17]. Our results are placed within the framework of the "classical" tiling by self-assembly, in that our model does not take into account physical phenomena that may affect experimental DNA self-assembly such as concentrations of tiles, different glue strengths, and glue-matching errors.

The paper is organized as follows. Section 2 introduces the notions of tile, glue, tile system, sticking, ribbon, zipper, valid tiling of the plane, and directed tiles. In particular, a zipper is a ribbon with the additional requirement that even nonconsecutive tiles that touch must have matching glues at their abutting edges.

Section 3 starts with defining a directed tile system with the strong plane-filling property: in such a system, any infinite directed zipper is forced to follow a specific plane-filling self-similar path, and, moreover, an infinite directed zipper is always guaranteed to exist. The construction of a directed tile system with the above property uses a 3×3 block construction based on directed tiles defined in [27], [26], which, in turn, resemble tiles devised by Robinson in [37] to produce only aperiodic tilings of the plane. These tiles were augmented in [26], [27] with directions that forced any directed tiled path to form a self-similar plane-filling Hilbert curve that recursively fills arbitrarily large squares by filling each of their quadrants. The original construction used the condition that no glue mismatch be present in the 3×3 neighborhood of any tile on the path, to force the path to follow the desired curve. Here, the additional 3×3 block construction is needed to ensure that the weaker condition of no glue mismatch between any two tiles on the directed tiled path is enough to force its course.

Section 4 then proves the undecidability of the existence of an infinite directed zipper by reducing the tiling problem to it. The reduction is based on a construction of sandwich tiles, which have directed tiles from the directed tile system with the strong plane-filling property on top and undirected tiles from a given tile system on the bottom. The next result of the section proves the undecidability of the existence of an infinite ribbon by reducing the undecidable infinite directed zipper problem to it. The proof uses a "ribbon motif" construction that simulates each directed zipper tile by a ribbon of undirected tiles following its contours, and it uses geometry (bumps and dents) to simulate zipper-tile glues.

Sections 5 and 6 point to the implications of the undecidability of existence of infinite ribbons for the problem of self-assembly of arbitrarily large supertiles, and they summarize our results.

2. Notation and definitions. A tile is an oriented unit square. The north, east, south, and west edges of the tile are each labeled with a symbol called a *glue* from a finite alphabet X. Tiles can be placed on the plane but not rotated. The positions of the tiles on the plane are indexed by $\mathbb{Z}^2$, the set of pairs of integers.

Formally, a *tile* t is a quadruple $t = (t_N, t_E, t_S, t_W) \in X^4$, where X is a finite set. The components t_N, t_E, t_S, t_W will be called the glues on the north, east, south, and west edges of the tile, respectively. A *tile system* T is a finite subset of X^4. For all tiles $t = (t_N, t_E, t_S, t_W)$ and $t' = (t'_N, t'_E, t'_S, t'_W)$, t *sticks* on the north to t' iff $t_N = t'_S$. Sticking on the east, south, and west is defined similarly.

The directions $\mathcal{D} = \{N, E, S, W\}$ are functions from $\mathbb{Z}^2$ to $\mathbb{Z}^2$: $N(x, y) = (x, y+1)$, $E(x, y) = (x+1, y)$, $S(x, y) = (x, y-1)$, $W(x, y) = (x-1, y)$. We say that the positions (x, y) and (x', y') are *adjacent* iff $(x', y') \in \{N(x, y), E(x, y), S(x, y), W(x, y)\}$. In addition, (x, y) *abuts* (x', y') on the north iff $(x', y') = N(x, y)$, and similarly for the other directions.

Given a tile system T, a *T-tiling of the plane* is a total function $f : \mathbb{Z}^2 \longrightarrow T$. The tiling f is *valid at position* (x, y) iff $f(x, y)$ sticks on the north to $f(N(x, y))$, $f(x, y)$ sticks on the east to $f(E(x, y))$, $f(x, y)$ sticks on the south to $f(S(x, y))$, and $f(x, y)$ sticks on the west to $f(W(x, y))$. That is to say, f is valid at (x, y) iff the tile at position (x, y) sticks on the appropriate sides to all the tiles that are at positions adjacent to it. The tiling is *valid* iff it is valid at every position $(x, y) \in \mathbb{Z}^2$. The well-known *tiling problem* posed by Wang asks the following: Given a tile system T, does there exist a valid T-tiling of the plane? The tiling problem was first proved undecidable by Berger [11], and the result was improved by Robinson [37]. One can generalize the notion of T-tiling of the entire plane by defining a *partial T-tiling* as a partial function $g : \mathbb{Z}^2 \longrightarrow T$. A partial tiling g is *valid on a region* $R \subseteq \mathrm{dom}(g)$ iff, for all $(x_1, y_1), (x_2, y_2) \in R$, if (x_1, y_1) abuts (x_2, y_2) on the north (east, south, west), then $g(x_1, y_1)$ sticks to $g(x_2, y_2)$ on the north (east, south, west). The partial tiling g is called *valid* iff it is valid on the entire $\mathrm{dom}(g)$.

A *path* is a function $P : I \longrightarrow \mathbb{Z}^2$, where I is a set of consecutive integers and for all $(i, i+1 \in I)$, $P(i)$ and $P(i+1)$ are adjacent. That is, a path is a sequence of adjacent positions on the plane. For all $i \in I$, we denote $P(i)$ as (x_i, y_i). We say that (x, y) is on P iff $(x, y) \in \mathrm{range}(P)$. For all tile systems T, a *T-tiled path* is a pair (P, r), where P is a path and r is a function $r : \mathrm{range}(P) \longrightarrow T$.

A T-tiled path (P, r) is a *T-ribbon* iff

(a) P is one-to-one, and

(b) for all $(i, i+1 \in \mathrm{dom}(P))$, if (x_{i+1}, y_{i+1}) abuts (x_i, y_i) on the north (south, east, west), then $r(x_{i+1}, y_{i+1})$ sticks to $r(x_i, y_i)$ on the north (south, east, west).

Informally, a tiled path is a ribbon iff it does not cross itself and the glue between tiles at consecutive positions along the path match.

A T-ribbon (P, r) is a *T-zipper* iff for all $(x, y), (x', y')$ on P, if (x', y') abuts (x, y) on the north (south, east, west), then $r(x', y')$ sticks to $r(x, y)$ on the north (south, east, west). Note that the notion of a zipper is more restrictive than the notion of a ribbon in that a zipper requires all of its tiles (consecutive or not) in adjacent positions to stick.

A *directed tile system* is a pair (T, d), where T is a tile system and $d : T \longrightarrow \{N, E, S, W\}$ is a function from the tile system to the direction functions. A directed tile system can be thought of as a tile system in which each tile has an arrow painted on it pointing north, east, south, or west.

A (T, d)-*directed tiled path* is a pair (P, r), where (P, r) is a T-tiled path and for all $(i, i+1 \in \mathrm{dom}(P))$ we have that $(x_{i+1}, y_{i+1}) = d(r(x_i, y_i))(x_i, y_i)$. A directed tiled path is a tiled path in which each tile points to its successor on the path. If (P, r) is a (T, d)-directed tiled path and (P, r) is a T-ribbon (zipper), then (P, r) is a (T, d)-directed ribbon (zipper).

A path, (directed) tiled path, (directed) ribbon, or (directed) zipper is called finite, semi-infinite, or infinite iff the domain of the associated path is finite, has a least or greatest element and is infinite, or is $\mathbb{Z}$, respectively.

To prove the undecidability of existence of infinite ribbons, we shall first prove the undecidability of existence of infinite directed zippers. Afterwards, a "ribbon motif" construction will be employed to prove the result for ribbons: the construction simulates a directed zipper by a ribbon motif of smaller tiles that goes around the contours of the zipper tiles, and it uses geometry to simulate zipper-tile glues.

In order to prove the undecidability of existence of infinite directed zippers, we shall use the undecidability of the tiling problem in conjunction with a sandwich construction that makes use of the existence of a directed tile system with the so-called *strong plane-filling property.*

DEFINITION 2.1. *A directed tile system* (T, d) *has the* strong plane-filling property *iff*

(i) *there exists an infinite* (T, d)*-directed zipper, and*
(ii) *for all infinite* (T, d)*-directed zippers* (P, r)*, for all natural numbers* n *there exists* (x, y) *such that* $(x + i, y + j)$ *is on* P *for* $i = 0, 1, 2, \ldots, n$ *and* $j = 0, 1, 2, \ldots, n$.

If a directed zipper (or ribbon or path) (P, r) satisfies the property in Definition 2.1(ii), we also say that it *covers arbitrarily large squares.*

Definition 2.1 states that in a directed tile system with the strong plane-filling property any infinite directed zipper is forced to be plane-filling (by filling arbitrarily large squares) and, moreover, that such an infinite directed zipper always exists.

3. A directed tile system with the strong plane-filling property. An essential element of our subsequent proofs will be the main result of this section, Theorem 3.1, namely the construction of a directed tile system that satisfies the strong plane-filling property of Definition 2.1. In fact, our directed tiles satisfy an even stronger requirement than (ii): any infinite directed tiled path is either plane-filling or it has a glue mismatch between two of its tiles. In particular, using our tiles, an infinite directed tiled path may not even form a loop without encountering a glue mismatch along the way. Consequently, every infinite directed tiled path that does not fill the plane must necessarily contain two neighboring tiles with a glue mismatch. The constructed tiles therefore satisfy a stronger version of Definition 2.1, thus satisfying a stronger property than the original plane-filling property defined in [26, 27].

In [27], any infinite directed tiled path was forced to be plane-filling unless there was a mismatch of glues inside the 3×3 neighborhood of some tile of the path. As described in subsections 3.2 and 3.3, directed tiles with this weaker plane-filling property were explicitly constructed by augmenting Robinson's aperiodic tiles [37] with directions. With these tiles, all directed tiled paths consisting of tiles without errors in their 3×3 neighborhood formed self-similar plane-filling curves of the kind used by Hilbert [24] to show that the unit square is a continuous image of the unit segment. The constructed tiles filled arbitrarily large squares recursively, by first filling the individual quadrants of a square. The process was guided by the direction associated

with each tile, which forced the construction to proceed along the self-similar Hilbert curve that traversed each quadrant of a square and linked the quadrants to each other.

In the present application we need the stronger variant of the plane-filling property introduced in Definition 2.1. In our case the infinite directed tiled path must be forced to be plane-filling even under the weak assumption that there is no glue mismatch between any two tiles belonging to it. It turns out that such a directed tile system is obtained by taking 3×3 blocks of the tiles in [27], as described in subsection 3.4. For this particular set of tiles, our 3×3 block construction ensures that the weak requirement of absence of glue mismatches between any two tiles belonging to the directed tiled path is sufficient to determine its uniqueness. Namely, we can prove that the constructed directed tile system has the property that, starting with any arbitrary tile, the only way to build an infinite error-free directed zipper is by forming a Hilbert curve that covers arbitrarily large squares.

3.1. Generalized tile systems. We begin by generalizing the notion of neighborhood from section 2, where the "neighbors" of a position were the positions at its north, east, south, and west.

DEFINITION 3.1. *A* neighborhood vector *is a* k*-tuple*

$$V = (\bar{x_1}, \bar{x_2}, \ldots, \bar{x_k}), \quad \bar{x_i} \in \mathbb{Z}^2, \quad 1 \leq i \leq k.$$

The neighbors *of a position* $\bar{x} \in \mathbb{Z}^2$ *are the positions* $\bar{x} + \bar{x_i}$ *for* $1 \leq i \leq k$.

The classical *von Neumann neighborhood* is defined by the vector

$$V_{vN} = [(0,0), (1,0), (0,1), (-1,0), (0,-1)].$$

In the von Neumann neighborhood, each position has five neighbors: itself and its four adjacent positions, as defined in section 2. In fact, all notions defined in section 2 are based on the von Neumann neighborhood.

Another particular neighborhood of interest, the *Moore neighborhood*, is defined as follows:

$$V_M = [(-1,1), (0,1), (1,1), (-1,0), (0,0), (1,0), (-1,-1), (0,-1), (1,-1)].$$

The Moore neighborhood of a position is a 3×3 block centered at that position, where the eight directions of the compass are used when we refer to the eight surrounding positions.

In contrast, in the generalized sense of Definition 3.1, the neighbors of a position need not be adjacent to it. Under this generalized definition, the neighborhood of a position may even have holes in it; i.e., adjacent positions may not belong to its neighborhood, while positions further away may. For example, $V = [(-2,2), (0,2), (2,2), (-1,1), (1,1), (-2,0), (0,0), (2,0), (-1,-1), (1,-1), (-2,-2), (0,-2), (2,-2)]$ defines a checkerboard type of neighborhood, where the neighbors of the center "white" position are all the "white" positions in the 5×5 square centered at it.

We shall now use the generalized notion of neighborhood to define a generalized tile system and its corresponding notion of valid tiling.

DEFINITION 3.2. *A* generalized tile system *is a triple* (T, V, R)*, where* T *is a finite set,* $V = (\bar{x}_1, \bar{x}_2, \ldots, \bar{x}_k)$*,* $\bar{x}_i \in \mathbb{Z}^2, 1 \leq i \leq k$*, is a neighborhood vector, and* $R \subseteq T^k$ *is a* k*-ary relation on* T.

As usual, a (partial) (T, V, R)-tiling (shortly T-tiling if the other elements are obvious from the context) is a (partial) function $\psi : \mathbb{Z}^2 \xrightarrow{o} T$.

DEFINITION 3.3. *A (T, V, R)-tiling ψ is* valid *at $\bar{x} \in \mathrm{dom}(\psi)$ iff there exists $r \in R$ such that, for all i, $1 \leq i \leq k$, either $(\bar{x} + \bar{x}_i) \in \mathrm{dom}(\psi)$ and $\psi(\bar{x} + \bar{x}_i) = r(i)$ or otherwise $\psi(\bar{x} + \bar{x}_i)$ is undefined.*

A (T, V, R)-tiling ψ is valid on a region $S \subseteq \mathrm{dom}(\psi)$ iff $\psi|_S$ is valid at every point $\bar{x} \in S$. We say that ψ is valid iff it is valid on $\mathrm{dom}(\psi)$. If ψ is valid on $\mathbb{Z}^2$, then ψ is called a valid (T, V, R)-tiling of the plane.

As before, we can define a *generalized directed tile system* (T, V, R, d), where (T, V, R) is a generalized tile system and $d : T \longrightarrow \{N, E, S, W\}$ is a function from the generalized directed tile system to the direction functions.

3.2. Microtiles. The starting point of our construction of a directed tile system (T_0, d_0) with the strong plane-filling property will be a generalized directed tile system $(T_\mu, V_\mu, R_\mu, d_\mu)$ constructed in [27]. The elements of T_μ are called *microtiles*. Instead of glues, they use labeled arrows to define their correspondence so that arrow heads match arrow tails on the edges of tiles. A T_μ-tiling will sometimes be called *microtiling*.

There are five different types of microtiles in T_μ (Figure 1): (a) single and (b) double crosses, (c) single, (d) double, and (e) mixed arms. The arms can be horizontal or vertical arms. There are also labeled diagonal arrows assigned to microtiles in [27]. They play a role in proofs of Lemmata 3.1 and 3.2. Since these proofs are not reproduced here, we omit the description of the diagonal arrows.

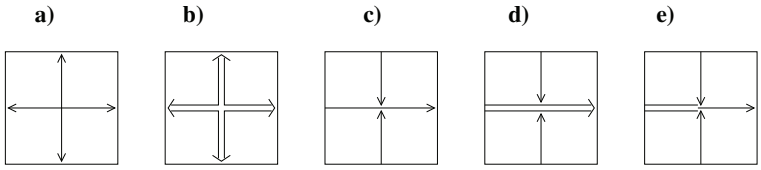

FIG. 1. *The five types of microtiles:* (a) *single cross,* (b) *double cross,* (c) *single arm,* (d) *double arm, and* (e) *mixed arm. Diagonal arrows are not shown. Reprinted from the Journal of Computer and System Sciences, Volume* 48*, Jarkko Kari, Reversibility and surjectivity problems of cellular automata, pages* 149–182*,* 1994*, with permission from Elsevier.*

A cross, either single or double, has its arrow heads labeled from $\{SE, SW, NE, NW\}$, but all four arrow heads must have the same label. The principal arrow of an arm (single, double, or mixed) has a label from $\{SE, SW, NE, NW\}$, with the same label on both ends. The side arrows of mixed arms have labels as described in Figure 2. A single or double horizontal arm has its upper (lower) arrow labeled SX (NX, respectively) for $X \in \{E, W\}$. A single or double vertical arm has its left (right) arrow labeled YE (YW, respectively) for $Y \in \{N, S\}$. To conclude the description of microtiles, we note that more labels will be described in the next section.

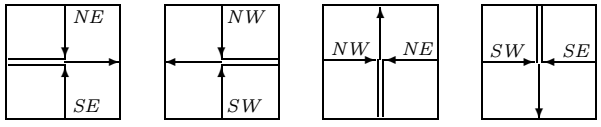

FIG. 2. *The possible labels of the two side arrows on a mixed arm. Reprinted from the Journal of Computer and System Sciences, Volume* 48*, Jarkko Kari, Reversibility and surjectivity problems of cellular automata, pages* 149–182*,* 1994*, with permission from Elsevier.*

DEFINITION 3.4 (see [27]). *A* microtile system *is a generalized directed tile system $(T_\mu, V_\mu, R_\mu, d_\mu)$, where*

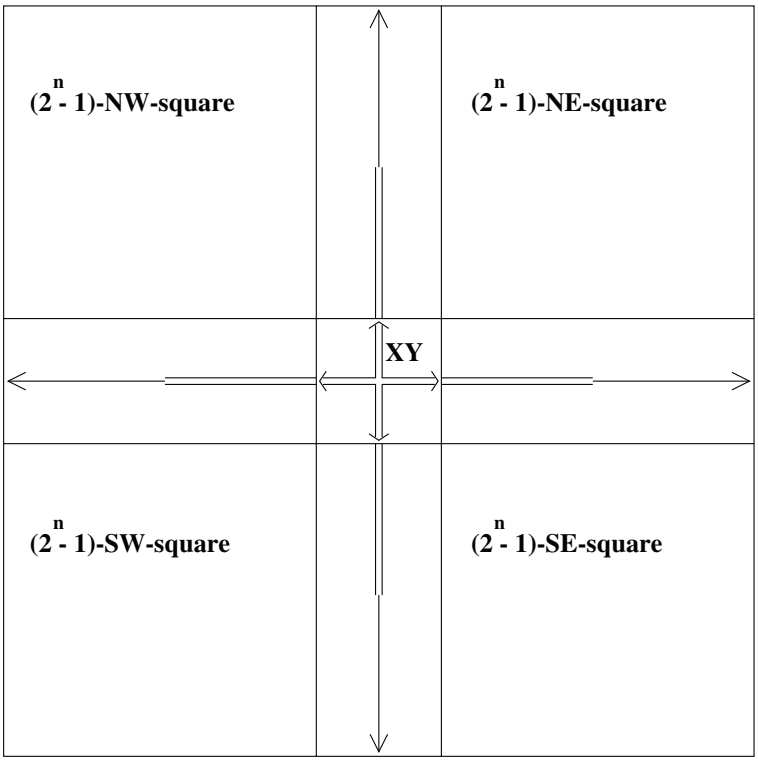

FIG. 3. *Constructing the* $(2^{n+1}-1)$*-*XY*-square. Reprinted from the Journal of Computer and System Sciences, Volume* 48*, Jarkko Kari, Reversibility and surjectivity problems of cellular automata, pages* 149–182*,* 1994*, with permission from Elsevier.*

- T_μ *is the set of tiles with labeled arrows described above;*
- V_μ *is the Moore neighborhood;*
- R_μ *is the set of all* $v \in T_\mu^9$ *such that in the* 3×3 *tiling* $\{(V_\mu(i), v(i)) \mid 1 \le i \le 9\}$ *all arrow heads meet on the edges of tiles matching arrow tails with the same labels and vice versa.*

The labeling of microtiles described above allows that, for each $n \in \mathbb{N}$, four special squares called (2^n-1)-XY*-squares* can be defined recursively.

DEFINITION 3.5. *A* (2^n-1)-XY-square*,* $n \ge 1$*,* $XY \in \{NE, NW, SE, SW\}$*, is a microtiling* $f_{XY} : S_n \longrightarrow T_\mu$*, where* $S_n = \{(x+i, y+j) \mid 1 \le i, j \le 2^n - 1\}$ *for some* $(x, y) \in \mathbb{Z}^2$*. It is iteratively constructed in the following way.*

A single cross labeled XY *is a* 1-XY*-square. A* $(2^{n+1}-1)$-XY-square *consists of four* (2^n-1)-$X'Y'$*-squares,* $X'Y' \in \{NW, NE, SW, SE\}$*, ordered as in Figure* 3*. These squares are separated by a double cross labeled* XY *at the position* $(x+2^n, y+2^n)$*, called the* central cross *of the square, and rows of arms radiating from it. The arms are double near the central cross, but halfway the mixed arms make them single.*

The iterative construction is illustrated in Figure 3. By the construction of a microtile system, all (2^n-1)-XY-squares are valid microtilings. Figure 4 provides an example of a 7-XY-square. We may sometimes refer to a (2^n-1)-XY-square as (2^n-1)-square if XY is arbitrary. Proofs of the following results can be found in [27].

LEMMA 3.1 (see [27]). *Let* $f : S^{(1)} \longrightarrow T_\mu$*,* $g : S^{(2)} \longrightarrow T_\mu$ *be two* (2^n-1)*-squares with the same* n*. If* $f|_{S^{(1)} \cap S^{(2)}} = g|_{S^{(1)} \cap S^{(2)}}$ *and there exists* $(x, y) \in S^{(1)} \cap S^{(2)}$ *such*

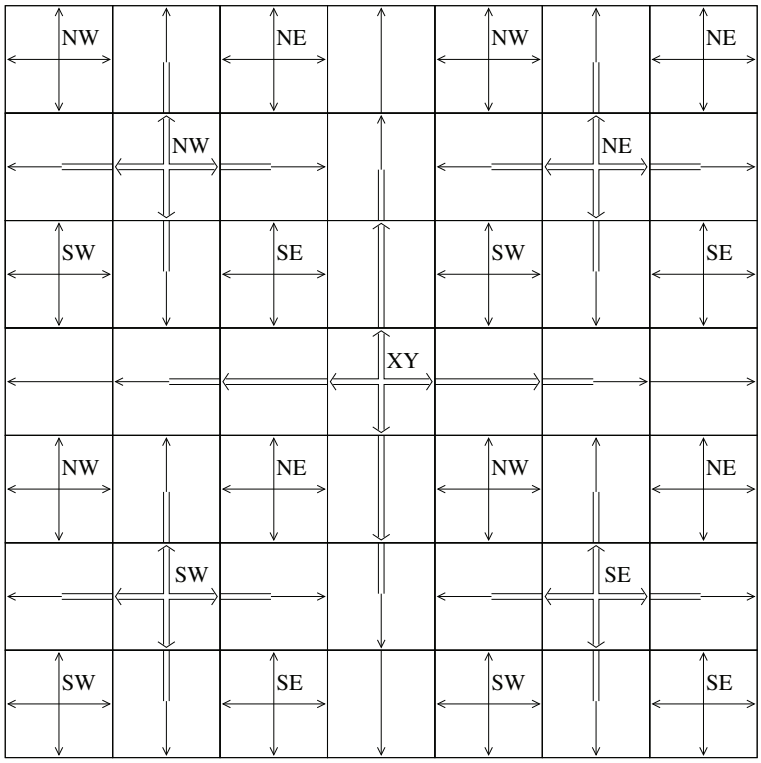

FIG. 4. *The 7-XY-square with the labels on the crosses. Only the principal arrows of the arms are drawn. Reprinted from the Journal of Computer and System Sciences, Volume* 48*, Jarkko Kari, Reversibility and surjectivity problems of cellular automata, pages* 149–182*,* 1994*, with permission from Elsevier.*

that $f(x, y)$ is a single cross, then $S^{(1)} = S^{(2)}$.

In other words, if $S^{(1)}$ and $S^{(2)}$ have a nonempty common overlap containing a single cross, then they are identical.

LEMMA 3.2 (see [27]). *Let $f : \mathbb{Z}^2 \longrightarrow T_\mu$ be a microtiling of the plane and assume there exists a $(2^n - 1)$-XY-square $f_{XY} : S_n \longrightarrow T_\mu$ such that $f|_{S_n} = f_{XY}$ and, moreover, f is valid on S_n. Let $XY = SW$ (NW, NE, SE). Then*

(i) *the microtile just outside the NE (SE, SW, NW, respectively) corner of the square is a double cross;*

(ii) *the row of arms radiating Y-wise (X-wise) from this double cross has the length $2^n - 1$ and consists of $2^{n-1} - 1$ horizontal (vertical) double arms, followed by a horizontal (vertical) mixed arm, and then followed by $2^{n-1} - 1$ horizontal (vertical) single arms;*

(iii) *the microtile just outside the SE (NE, NW, SW, respectively) corner is a horizontal arm and the microtile just outside the NW (SW, SE, NE, respectively) corner is a vertical arm.*

In Figure 4, for example, the double cross right outside the NE corner of the 3-*SW*-square is the double cross microtile labeled XY, with the row of microtiles radiating westwise and southwise as required.

3.3. Minitiles. Another type of tile needed in our construction is a *minitile* [27]. Each minitile will be a 2×2 block of microtiles that has *exactly one single cross* in

its *upper right corner*; see Figure 8(center).

DEFINITION 3.6. *Consider the microtile system* $(T_\mu, V_\mu, R_\mu, d_\mu)$. *A* minitile *is a quadruple* $a = (\mu_1^a, \mu_2^a, \mu_3^a, \mu_4^a) \in T_\mu^4$ *such that* μ_1^a *is a single cross,* $\mu_2^a, \mu_3^a, \mu_4^a$ *are not, and the microtiling* $\{((1,1), \mu_1^a), ((1,0), \mu_2^a), ((0,0), \mu_3^a), ((0,1), \mu_4^a)\}$ *is valid.*

Therefore, by the above definition, all the arrow heads and tails between $\mu_1^a, \mu_2^a, \mu_3^a, \mu_4^a$ match. Let T_m be a set of minitiles; then a T_m-tiling will be called *minitiling*. If $f : \mathbb{Z}^2 \xrightarrow{o} T_m$ is a minitiling, then its corresponding microtiling $m(f) : \mathbb{Z}^2 \xrightarrow{o} T_\mu$ is defined as follows. If $f(x, y) = a = (\mu_1^a, \mu_2^a, \mu_3^a, \mu_4^a)$, then

$$m(f)(2x+1, 2y+1) = \mu_1^a,$$
$$m(f)(2x+1, 2y) = \mu_2^a,$$
$$m(f)(2x, 2y) = \mu_3^a,$$
$$m(f)(2x, 2y+1) = \mu_4^a.$$

Next, directions are added to minitiles. As we restricted ourselves to 2×2 blocks having exactly one single cross located in the upper right corner, attaching directions to minitiles will amount to attaching directions to single-cross microtiles. Let us describe first the types of directed minitiled paths (or simply paths, if no danger of confusion exists) these directions will define. The paths are constructed recursively through squares of size $2^n \times 2^n$ minitiles.

DEFINITION 3.7. *For each* $n \geq 0$ *we define recursively an* A_{2^n} *(*B_{2^n}, C_{2^n}, D_{2^n}*) -minitiled path as follows. For* $n = 0$, *a minitile with its single cross labeled* X *is an* X_1*-path for* $X \in \{A, B, C, D\}$.

For each $n \geq 0$, *a* $A_{2^{n+1}}$ *(*$B_{2^{n+1}}$, $C_{2^{n+1}}$, $D_{2^{n+1}}$*)-path is built recursively from four* X_{2^n}*-paths,* $X \in \{A, B, C, D\}$, *as described in Figure* 5.

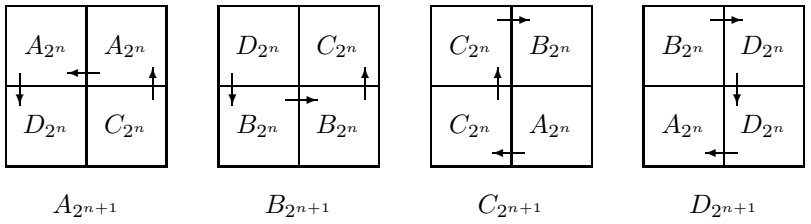

FIG. 5. *Constructing paths through squares of* $2^{n+1} \times 2^{n+1}$ *minitiles. Reprinted from the Journal of Computer and System Sciences, Volume* 48, *Jarkko Kari, Reversibility and surjectivity problems of cellular automata, pages* 149–182, 1994, *with permission from Elsevier.*

For example, the A_4-path starts in the lower right corner of the square, visits all its minitiles, and ends in the lower left corner (see Figure 6). Paths created using Definition 3.7 form the familiar Hilbert curve. One can easily verify the following result.

LEMMA 3.3. *For each* $n \geq 0$ *the* A_{2^n} *(*B_{2^n}, C_{2^n}, D_{2^n}*)-path starts in the SE (NW, SE, NW, respectively) corner, ends in the SW (NE, NE, SW, respectively) corner, visits all minitiles of the underlying* $2^n \times 2^n$ *minitile square, and does not visit any minitiles outside of the underlying square.*

Let $f_{XY} : S_{n+1} \longrightarrow T_\mu$ be a $(2^{n+1} - 1)$-XY-square of microtiles, where $S_{n+1} = \{(x+i, y+j) \mid 1 \leq i, j \leq 2^{n+1}-1\}$. Then, by the iterative construction in Definition 3.5, those (and only those) microtiles at positions $(x+2i-1, y+2j-1)$, $1 \leq i, j \leq 2^n$, are

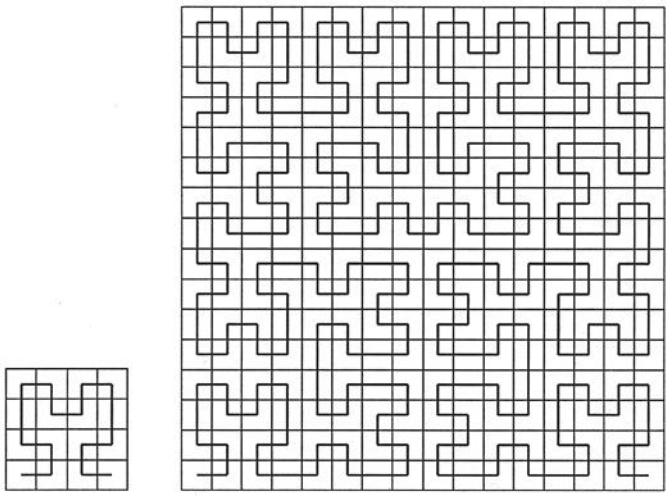

FIG. 6. *The paths A_4 and A_{16}. Reprinted from the Journal of Computer and System Sciences, Volume* 48*, Jarkko Kari, Reversibility and surjectivity problems of cellular automata, pages* 149–182*,* 1994*, with permission from Elsevier.*

TABLE 1

The labeling of mixed arms. The four rows of the table represent (i) *the direction of the principal arrow of the arm,* (ii) *the label of the principal arrow,* (iii) *the label of the arrow situated clockwise relative to the principal arrow, and* (iv) *the label of the arrow situated counterclockwise relative to the principal arrow.*

(i)	E	W	N	S	E	W	N	S	E	W	N	S	E	W	N	S
(ii)	A	A	A	A	B	B	B	B	C	C	C	C	D	D	D	D
(iii)	C	A	A	D	B	D	C	B	A	C	B	C	D	B	D	A
(iv)	A	D	A	C	C	B	D	B	B	C	C	A	D	A	B	D

single crosses. Since, moreover, f_{XY} is a valid microtiling, all 2×2 squares of S_{n+1} with single crosses in their upper right corner form minitiles. The single crosses in the leftmost column and the bottommost row of S_{n+1} can be easily completed by adding another column and a row of microtiles to f_{XY} so that they again form valid 2×2 squares of microtiles. Therefore, by Definition 3.6, we obtain a (partial) minitiling $f : \mathbb{Z}^2 \xrightarrow{o} T_m$ from which the square f_{XY} arose, i.e., $m(f)|_{S_{n+1}} = f_{XY}$.

If a minitile has its single cross in S_{n+1}, we say that it is *attached* to S_{n+1}. Recall that there are exactly $2^n \times 2^n$ single crosses in S_{n+1}; therefore there will be $2^n \times 2^n = 4^n$ minitiles attached to it. The directions will be defined in such a way that the path these minitiles form is exactly an A_{2^n}-, B_{2^n}-, C_{2^n}-, or D_{2^n}-path.

In order to control which of the four possible paths the directions define in a specific square, additional labels are assigned to arrows in microtiles [27]. Each arrow (single or double) can be given any label from the set $\{A, B, C, D\}$, the only restrictions we impose on crosses and mixed arms. As usual, in each cross all four arrow heads must have the same label. The central cross of each $(2^{n+1} - 1)$-square will determine the type of path the directions define on the square (see Lemma 3.6). The labeling of mixed arms is crucial for the composition of A-, B-, C-, or D-squares and is specified in Table 1. As usual, in a valid microtiling the meeting arrow heads and arrow tails must have the same label.

One can verify that the labels in Table 1 correspond exactly to the construction

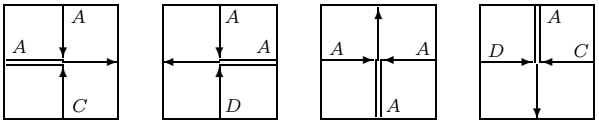

FIG. 7. *The labeling of mixed arms whose principal arrow has the label A.*

of the paths in Figure 5. For example, the mixed arms in the first four columns in Table 1 are illustrated in Figure 7. The first of these mixed arms has its principal arrow labeled A. This indicates that the mixed arm is a connector in a $(2^{n+1}-1)$-square whose central cross is labeled A and which therefore contains an $A_{2^{n+1}}$-path. The vertical arrow incoming from the north (south) is labeled A (C, respectively). These facts indicate that the (2^n-1)-*NE*-square on top of the mixed arm contains an A_{2^n}-path, and that the (2^n-1)-*SE*-square below it contains a C_{2^n}-path, as they should, according to the recursive construction of A_{2^n}-paths in Figure 5.

TABLE 2

The definition of directions assigned to minitiles (or to their respective single crosses). Reprinted from the Journal of Computer and System Sciences, Volume 48*, Jarkko Kari, Reversibility and surjectivity problems of cellular automata, pages* 149–182*,* 1994*, with permission from Elsevier.*

	The direction of a single cross is
N	if its NE neighbor is a double cross with label C or a vertical arm whose left edge has a side arrow with label A or B,
E	if its NE neighbor is a double cross with label B or a horizontal arm whose lower edge has a side arrow with label C or D,
S	if its SW neighbor is a double cross with label D or a vertical arm whose right edge has a side arrow with label A or B,
W	if its SW neighbor is a double cross with label A or a horizontal arm whose upper edge has a side arrow with label C or D.

The definitions of directions are summarized in Table 2. It has been shown in [27] that if $f_{XY} : S_n \longrightarrow T_\mu$ is a (2^n-1)-XY-square, then for each single cross whose Moore neighborhood is contained in S_n there exists exactly one rule in Table 2 that can be applied. All the above defined elements forming the directed paths, i.e., the new labels A, B, C, D and the directions of minitiles, are unified together by means of the neighborhood relation R_m. Now we can complete the formal definition of a minitile system, based on the above described microtile system $(T_\mu, V_\mu, R_\mu, d_\mu)$.

DEFINITION 3.8. *A* minitile system *is a generalized directed tile system* (T_m, V_m, R_m, d_m) *such that*

(i) T_m *is the set of all minitiles as defined in Definition* 3.6*;*

(ii) V_m *is the Moore neighborhood;*

(iii) R_m *is the set of all* 9*-tuples* $r \in T_m^9$ *such that all the following conditions are met:*

  (a) *the underlying* 6×6 *microtiling* $m(\{(V_m(i), r(i)) \mid 1 \le i \le 9\})$ *is valid;*

  (b) *exactly one rule in Table* 2 *is applicable to the single cross* $\mu_1^{r(5)}$ *of the central minitile* $r(5)$;

  (c) *exactly one of the following four conditions holds:* $d_m(r(2)) = S$, $d_m(r(4)) = E$, $d_m(r(6)) = W$, $d_m(r(8)) = N$;

(iv) $d_m(a) = d_\mu(\mu_1^a)$ *for each* $a = (\mu_1^a, \mu_2^a, \mu_3^a, \mu_4^a) \in T_m$.

Recall that a 9-tuple $r \in R_m$ corresponds to a 3×3 block of minitiles. The condition (a) states that a necessary condition for the minitiling f to be valid at

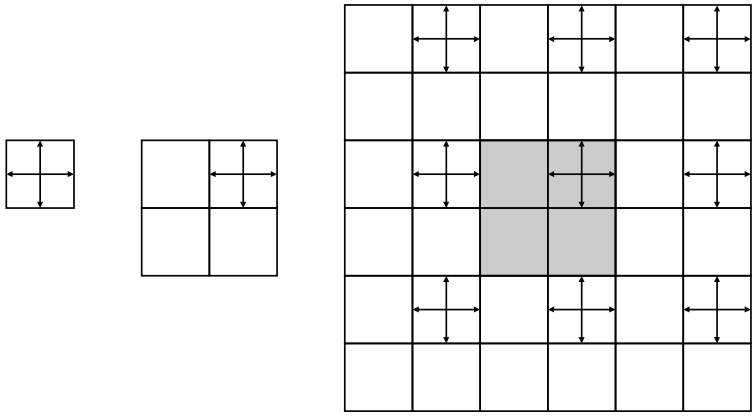

FIG. 8. *Left: a microtile; center: a minitile is a* 2×2 *block of microtiles having exactly one single cross, in its upper right corner; right: a macrotile (shaded); the nonshaded minitiles define the "glues" of the macrotile.*

$(x, y) \in \mathbb{Z}^2$ is that its corresponding microtiling $m(f)$ be valid at $(2x + i, 2y + j)$ for all $-1 \leq i, j \leq 2$. In other words, inside the 6×6 block of microtiles corresponding to the 3×3 Moore neighborhood of (x, y), all arrow heads match meeting arrow tails and their labels match as well, including the new labels A, B, C, D.

The condition (b) adds another necessary requirement that the direction of the minitile at (x, y) must be uniquely defined via Table 2. Finally, by the condition (c) a minitiling is not valid at (x, y) unless exactly one of the four adjacent minitiles at its N, S, E, W has its direction pointing towards it.

Recall that, due to Definition 3.3, if some minitiles in the Moore neighborhood of (x, y) are missing, we consider the minitiling valid at (x, y) if the missing positions can be filled with minitiles such that conditions (iii)(a)–(c) would be met.

3.4. Macrotiles: The 3×3 block construction. In this section we finalize the construction of a directed tile system (T_0, d_0) with the strong plane-filling property. We will use the generalized directed tile system of minitiles (T_m, V_m, R_m, d_m) constructed so far to obtain the directed tile system of *macrotiles* (T_0, d_0). When dealing with (T_0, d_0) we revert to the usual notion of tiles sticking by glues as defined in section 2.

The idea of the construction is as follows. Consider all the validly minitiled Moore neighborhoods as defined by R_m. With each such 9-tuple, which intuitively is a 3×3 block of minitiles, we associate a *macrotile* (see Figure 8). The position of the macrotile in a plane is identical with the position of its center minitile. The glues of a macrotile will be the 2×3 and 3×2 subblocks of minitiles corresponding to each side. Two adjacent macrotiles will stick if they have the same glues at their abutting edges (see Figure 9).

DEFINITION 3.9. *Consider the minitile system* (T_m, V_m, R_m, d_m). *A* macrotile system *is a directed tile system* (T_0, d_0), $T_0 \subseteq X_0^4$, *where the following hold:*

(i) $X_0 = T_m^6$.

(ii) T_0 *is constructed as follows. For each validly minitiled Moore neighborhood* $t \in R_m$, *there exists a* macrotile $t^* \in T_0$ *with glues*
$t_N^* = (t(1), t(2), t(3), t(4), t(5), t(6))$,
$t_S^* = (t(4), t(5), t(6), t(7), t(8), t(9))$,

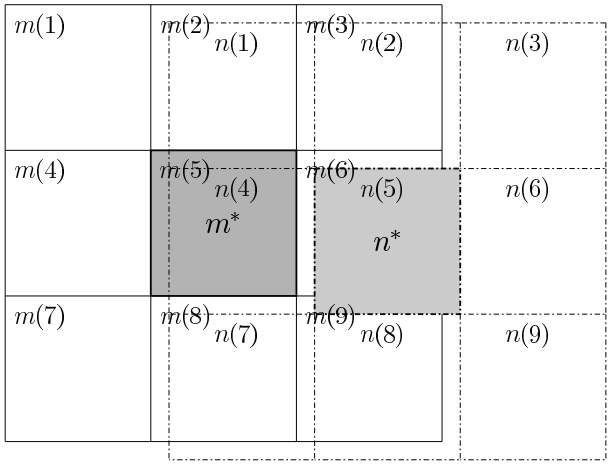

FIG. 9. *Two adjacent macrotiles m^* and n^* (shaded) stick iff their glues at the abutting edges are equal. This means that the overlapping 2×3 portions of their Moore neighborhoods coincide, i.e., $m(2) = n(1)$, $m(3) = n(2)$, $m(5) = n(4)$, etc.*

$t^*_E = (t(2), t(3), t(5), t(6), t(8), t(9))$,
$t^*_W = (t(1), t(2), t(4), t(5), t(7), t(8))$.

(iii) $d_0(t^*) = d_m(t(5))$.

If intuitively a macrotile corresponds to a 3×3 block of minitiles, its north glue is the 2×3 top subblock, the south glue is the bottom 2×3 subblock, the west glue the left 3×2 subblock, and the east glue the right 3×2 subblock of minitiles.

The direction of a macrotile t^* is the direction of its center minitile $t(5)$ which we will denote also by $c(t^*)$. Similarly as with minitiles, we say that t^* is *attached* to a $(2^n - 1)$-square $S_n \longrightarrow T_\mu$ if the single cross of $c(t^*)$ is located within S_n.

Two adjacent macrotiles will stick iff the glues on their abutting edges are identical. For example, two macrotiles at positions (x, y), $(x + 1, y)$ will stick if, when viewed as 3×3 blocks centered at (x, y), respectively, $(x + 1, y)$, their overlapping minitiles coincide. (See Figure 9.)

DEFINITION 3.10. *Consider the macrotile system (T_0, d_0) and a T_0-tiling $f : \mathbb{Z}^2 \xrightarrow{o} T_0$.*

(i) *The* overlap map *$o(f) : \mathbb{Z}^2 \xrightarrow{o} 2^{T_m}$ is a function defined as follows. For all $\bar{x} \in \mathrm{dom}(f)$, if $f(\bar{x}) = t^*$, then $t(i) \in o(f)(\bar{x} + V_m(i))$.*

(ii) *The* projection map *$p(f) : \mathbb{Z}^2 \xrightarrow{o} T_m$ is a function defined as follows: If $(x, y) \in \mathrm{dom}(f)$ and $f(x, y) = t^*$, then $p(f)(x, y) = c(t^*)$.*

In other words, the *overlap map* of a set of macrotiles situated on the plane will place at each position all the minitiles that would occupy it if we were to view each macrotile at (x, y) as a 3×3 block centered at (x, y) and covering a 3×3 neighborhood around it. The *projection map* replaces each macrotile at (x, y) with the minitile $c(t^*)$ at its center. Note that, while $\mathrm{dom}(p(f)) = \mathrm{dom}(f), \mathrm{dom}(f) \subseteq \mathrm{dom}(o(f))$.

Consider the following special case of the overlap map: for all $(x, y) \in \mathbb{Z}^2$, either $o(f)$ is undefined or $\mathrm{card}(o(f)) = 1$. Such a one-to-one overlap map is called a *perfect overlap*. The following results are straightforward.

LEMMA 3.4. *Let $f : \mathbb{Z}^2 \xrightarrow{o} T_0$ be a T_0-tiling with $\mathrm{dom}(f) = \{(x, y), (x', y')\}$ and the positions (x, y) and (x', y') be adjacent; then $f(x, y)$ will stick to $f(x', y')$ iff $o(f)$ is a perfect overlap.*

In other words, two macrotiles situated at adjacent positions will *stick* (in the glue-match-at-abutting-edges sense defined in section 2) iff the overlap map they define is one-to-one.

Let us introduce the following notation for the set of positions on the plane belonging to the Moore neighborhood of $\bar{x} \in \mathbb{Z}^2$: $N_M(\bar{x}) = \{\bar{x} + V_M(i) \mid 1 \leq i \leq 9\}$.

LEMMA 3.5. *Let $f : \mathbb{Z}^2 \xrightarrow{o} T_0$ be a T_0-tiling and let $\bar{x}, \bar{y} \in \mathrm{dom}(f)$. Further let f contain a T_0-ribbon (P, r) such that $\{\bar{x}, \bar{y}\} \subseteq \mathrm{range}(P)$ and*

$$N_M(\bar{x}) \cap N_M(\bar{y}) \subseteq \bigcap_{\bar{z} \in \mathrm{range}(P)} N_M(\bar{z}).$$

Then the overlap map $o(f|_{\{\bar{x},\bar{y}\}})$ is perfect.

Informally, let two macrotiles x^* and y^* be connected with a (short) ribbon such that the intersection of the Moore neighborhoods of x^* and y^* is included in (and hence is equal to) the intersection of the Moore neighborhoods of all tiles in the ribbon. Then, by Lemma 3.4, each two adjacent tiles in the ribbon have perfect overlap. By transitivity, we deduce that the intersection of overlap maps of all the tiles in the ribbon is one-to-one and hence so is the common overlap map of x^* and y^*.

The following lemma states that each infinite directed zipper of macrotiles covers arbitrarily large squares.

LEMMA 3.6. *Let $n \in \mathbb{N}$ and let (P, r) be a T_0-directed zipper, $P : I \longrightarrow \mathbb{Z}^2$, $r : \mathrm{range}(P) \longrightarrow T_0$, such that there exists $i \in I$ with $\min(I) + 4^n \leq i \leq \max(I) - 4^n$. Denote $P(i) = (x_i, y_i)$ and $r(x_i, y_i) = t^*$. Then the following hold:*

(i) *There exists a $(2^{n+1} - 1)$-square $f_{XY} : S_{n+1} \longrightarrow T_\mu$ such that $(2x_i + 1, 2y_i + 1) \in S_{n+1}$, $S_{n+1} \subseteq \mathrm{dom}(m(p(r)))$ and $f_{XY} = m(p(r))|_{S_{n+1}}$.*

(ii) *Let $Q = \{(k, l) \in \mathbb{Z}^2 \mid (2k+1, 2l+1) \in S_{n+1}\}$. If the central cross of S_{n+1} has label A (B, C, D), then $p(r|_Q)$ is an A_{2^n} (B_{2^n}, C_{2^n}, D_{2^n}, respectively)-path.*

(iii) *The overlap map $o(r|_Q)$ is a perfect overlap.*

Informally, consider a directed zipper of macrotiles that passes through a macrotile t^* and extends for at least 4^n positions preceding and the 4^n positions succeeding the position of t^*. Then (i) the single cross of the minitile $c(t^*)$ belongs to a $(2^{n+1} - 1)$-square $f_{XY} : S_{n+1} \longrightarrow T_\mu$. Moreover, (ii) the projection of the portion of the directed zipper consisting of the macrotiles attached to S_{n+1} is an A_{2^n}-, B_{2^n}-, C_{2^n}-, or D_{2^n}-directed minitiled path if the central cross microtile of the square has label A, B, C, or D, respectively. Last, (iii) the overlap map of that portion of the directed zipper is a perfect overlap.

Proof. The proof is by induction on n.

$n = 0$. Assume there is no zipper error involving $4^0 = 1$ macrotile before and one macrotile after t^*. Then the required $2^{n+1} - 1 = 2^1 - 1 = 1$-square consists of only the single cross at the upper right corner of the minitile $c(t^*)$ and the statement is vacuously true.

Assuming the statement holds for $n - 1$, we prove it for n. Assume there are no zipper errors involving any of the 4^n macrotiles that precede or succeed t^*. By induction hypothesis (I.H.) (i), the minitile $c(t^*)$ is attached to a $(2^n - 1)$-square $S^{(1)} \longrightarrow T_\mu$ with the required properties. Assume that it is a $(2^n - 1)$-SW-square (the other cases are analogous.)

Properties of the square $S^{(1)}$.

Let $Q_1 = \{(k, l) \in \mathbb{Z}^2 \mid (2k + 1, 2l + 1) \in S^{(1)}\}$ be the square of macrotiles attached to $S^{(1)}$. By I.H. (iii), the overlap map of $r|_{Q_1}$ is perfect (one-to-one). The underlying microtiling $m(o(r|_{Q_1}))$ covers $S^{(1)}$ and the Moore neighborhood of all its

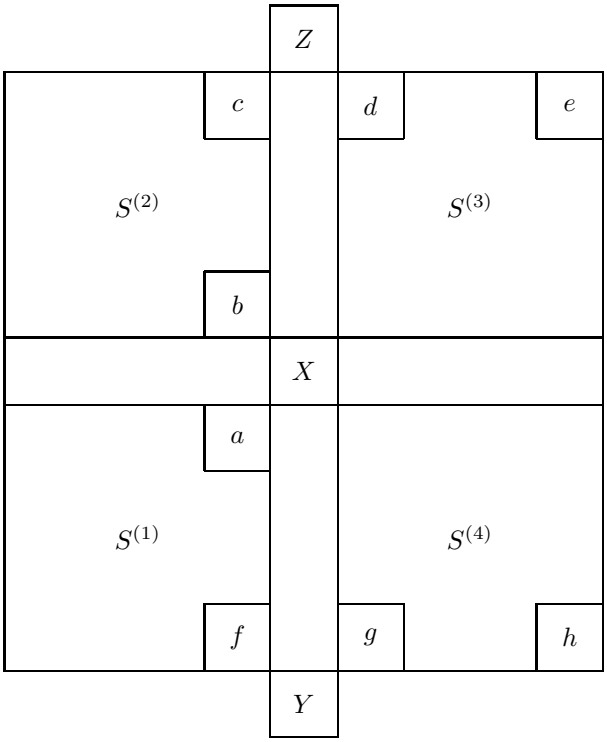

FIG. 10. *The* $(2^{n+1}-1)$*-square constructed during the proof of Lemma* 3.6. *Reprinted from the Journal of Computer and System Sciences, Volume* 48*, Jarkko Kari, Reversibility and surjectivity problems of cellular automata, pages* 149–182*,* 1994*, with permission from Elsevier.*

tiles (actually, it is even larger) and, by Definitions 3.8 and 3.9, is valid. Then, by Lemma 3.2, the microtile just outside the upper right corner of $S^{(1)}$ is a double cross, denoted by X in Figure 10. The double cross can have any of the four labels A, B, C, D. Assume it has label C.

By Lemma 3.2 again, the microtiles exactly on top of $S^{(1)}$ are horizontal arms (first double arms, then one mixed arm, then single arms) radiating westwise, with the same label C. Then, by Table 1, the lower edge of the mixed arm has a side arrow labeled C (column 10, row 4 of the table). Then the central cross of $S^{(1)}$ has the same label C, due to the column of arms radiating from it northwise to the mentioned mixed arm (see Definition 3.5). This means the path through $S^{(1)}$ is, by I.H. (ii), a C-path which, by Lemma 3.3, starts at a single cross f and ends at a single cross a (Figure 10).

Adding the square $S^{(2)}$*.*

As a has at its NE a double cross labeled C, according to Table 2, the direction of a is N. This means that the path of macrotiles, passing through the macrotile a^* with the center single cross a, will proceed to b^*. Denote by b the single cross of $c(b^*)$ (Figure 10).

Recall that for the macrotile t^* attached to $S^{(1)}$ we assumed that it is preceded and succeeded by at least 4^n macrotiles on the path P. Since there are exactly 4^{n-1} macrotiles attached to $S^{(1)}$, the distance of t^* and b^* on the path P is at most 4^{n-1}, by Lemma 3.3. Hence the I.H. can be applied to b^* because the number of macrotiles preceding and succeeding b^* on P is at least $4^n - 4^{n-1} = 3 \cdot 4^{n-1} > 4^{n-1}$. By I.H. (i),

b belongs to a (2^n-1)-square $S^{(2)} \longrightarrow T_\mu$.

Observe that a is not in $S^{(2)}$ (otherwise, by Lemma 3.1, $S^{(1)}$ and $S^{(2)}$ would coincide, which is impossible as b is in $S^{(2)} - S^{(1)}$). Hence $S^{(1)}$ and $S^{(2)}$ are disjoint. By I.H. (ii), $S^{(2)}$ contains an A-, B-, C-, or D-path. As $c(b^*)$ is the first minitile of the path, and b is located just above a, by Lemma 3.3 the path must be either an A-path or C-path. In both cases b is located in the SE corner of $S^{(2)}$, and we conclude that $S^{(2)}$ is above $S^{(1)}$.

As $S^{(2)}$ has all the properties conferred by I.H., we repeat for $S^{(2)}$ the steps previously made for $S^{(1)}$. In particular, let $Q_2 = \{(k,l) \in \mathbb{Z}^2 |\ (2k+1, 2l+1) \in S^{(2)}\}$. By I.H. (iii), the overlap map $o(r|_{Q_2})$ of the macrotiles attached to $S^{(2)}$ is one-to-one. Hence, the microtiling $m(o(r|_{Q_2}))$ covering $S^{(2)}$ and its Moore neighborhood is valid.

By definition of mixed arms in Figure 2, the mixed arm under $S^{(2)}$ has an upper edge with a side arrow labeled NW. As there is a column of arms connecting this arrow with the central microtile of $S^{(2)}$, we have that $S^{(2)}$ is a (2^n-1)-NW-square. By Lemma 3.2 we have to the right of $S^{(2)}$ a column of vertical arms with a mixed arm in the middle. By Table 1, the left edge of this mixed arm has a side arrow labeled C, and hence the central cross of $S^{(2)}$ is also labeled C. By I.H. (ii), the path through $S^{(2)}$ is a C-path. By Lemma 3.3, the path enters through b^* and exits through c^* (Figure 10).

We know already that, when taken separately, the overlap maps of the partial tilings with macrotiles attached to $S^{(1)}$, respectively, $S^{(2)}$, are one-to-one. When considering the overlap map associated with $S^{(1)}$ *and* $S^{(2)}$, we have to inspect the cases when there are two macrotiles, x^* attached to $S^{(1)}$ and y^* attached to $S^{(2)}$, such that their Moore neighborhoods overlap. The possible cases are those described in Figure 11 and the symmetrical ones. Recall that, by Lemma 3.3, the zipper (P, r) visits all the macrotiles attached to $S^{(1)} \cup S^{(2)}$. Hence any adjacent pair of them sticks and any tiled path forms a ribbon. Then, in each of the cases in Figure 11 the figure also shows the short ribbon required by Lemma 3.5. (These ribbons have nothing to do with the zipper (P, r).) Hence, by Lemma 3.5, the common overlap map of x^* and y^* is perfect. This further implies that the overlap map $o(r|_{Q_1 \cup Q_2})$ of all the macrotiles attached to $S^{(1)}$ and $S^{(2)}$ is one-to-one.

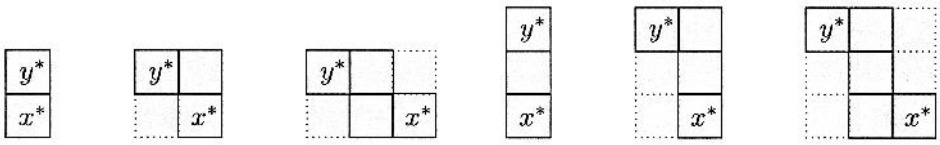

FIG. 11. *Pairs of macrotiles attached to $S^{(1)}$ and $S^{(2)}$ with nonempty common overlap.*

Adding the square $S^{(3)}$.

By Lemma 3.2(ii) applied to $S^{(2)}$, there is a row of vertical arms labeled C to the right of $S^{(2)}$ which ends just to the right of the single cross c. By Lemma 3.2(iii) Z must be a horizontal arm whose lower edge has its side arrow labeled C. As Z is the NE neighbor of c, by Table 2, the direction of c is E. We can reason similarly as in the case of tile b in $S^{(2)}$ to conclude that d is the first single cross in a B-path through a (2^n-1)-NE-square $S^{(3)} \longrightarrow T_\mu$ situated at the right side of $S^{(2)}$. The path ends at tile e (Figure 10).

Reasoning as in the case of $S^{(1)}$ and $S^{(2)}$ we can conclude that the overlap map of macrotiles associated with $S^{(2)}$ and $S^{(3)}$ is one-to-one. To conclude that the overlap

map associated with $S^{(1)}$ *and* $S^{(2)}$ *and* $S^{(3)}$ is one-to-one, we have to consider pairs of macrotiles, x^* attached to $S^{(1)}$ and y^* attached to $S^{(3)}$, such that their Moore neighborhoods overlap. One can easily verify that there are at most nine such pairs. Similarly as in the case of common overlap of $S^{(1)}$ and $S^{(2)}$, for each of these pairs there exists a short ribbon satisfying the requirements of Lemma 3.5. By reasoning similar to the previous case, the overlap map of x^* and y^* is one-to-one and so is the common overlap map of macrotiles attached to $S^{(1)} \cup S^{(2)} \cup S^{(3)}$.

Adding the square $S^{(4)}$.

Consider the overlap map of macrotiles attached to $S^{(1)}$, $S^{(2)}$, and $S^{(3)}$ which forms a valid minitiling. Let f^* be the macrotile with the center single cross f, where the C-path through $S^{(1)}$ starts. The overlap map extends one minitile to the east and south of f^*, hence covering both microtiles g and Y. By Lemma 3.2, Y is a horizontal arm whose upper edge has a side arrow labeled C. As Y is the SW neighbor of the single cross g, it implies, by Table 2, that g has to have direction W.

Moreover, by the nonexistence of a zipper error on the path segment considered, and the definition of the overlap map, there is no tiling error in the overlap map of $S^{(1)}$, $S^{(2)}$, and $S^{(3)}$. Recall that, by Definition 3.8, in a valid minitiling each single cross has only one other single cross pointing towards it. Consequently, g is the unique predecessor of f on the path; therefore g^* uniquely precedes f^*.

According to I.H. (i), g is known to belong to a $(2^n - 1)$-square $S^{(4)} \longrightarrow T_\mu$. In the same way as before, we conclude that $S^{(4)}$ is situated at the right side of $S^{(1)}$, and the path through $S^{(4)}$ is an A-path starting at h and ending at g that visits all its single crosses. We can also reason as before to prove that the overlap map of macrotiles involved in $S^{(1)}$, $S^{(2)}$, $S^{(3)}$, *and* $S^{(4)}$ is one-to-one.

Conclusion.

Altogether, by Definition 3.5 and Lemma 3.2, the squares $S^{(1)}$, $S^{(2)}$, $S^{(3)}$, and $S^{(4)}$ form a $(2^{n+1} - 1)$-square $f_{XY} : S_{n+1} \longrightarrow T_\mu$. All its single crosses are visited by the projection of the path and the macrotile t^* is on this path, as required in the statement (i) of the lemma.

Furthermore, by Definition 3.7, the A-, C-, C-, and B-paths through f_{XY} form a $C_{2^{n+1}}$-path. As we have started with the assumption that the central cross X of S_{n+1} is labeled C, the statement (ii) of the lemma holds, too.

Finally, we have also shown that the common overlap map of the partial macrotiling with macrotiles attached to $S^{(1)}$, $S^{(2)}$, $S^{(3)}$, and $S^{(4)}$ is a perfect overlap. This verifies the statement (iii) of the lemma and concludes the induction step. The other cases (X labeled by A, B, D, and $S^{(1)}$ having other label than SW) are analogous. □

THEOREM 3.1. *There exists a directed macrotile system* (T_0, d_0) *with the strong plane-filling property.*

Proof. Consider the macrotile system (T_0, d_0) from Definition 3.9. Observe that there exists an infinite directed zipper of macrotiles from T_0, namely the zipper (P, r) constructed inductively in the proof of Lemma 3.6. Moreover, by the statement of Lemma 3.6(i), any infinite path following the directions, which in addition has no zipper errors, covers arbitrarily large squares. □

4. Undecidability of existence of infinite ribbons. We shall now use Theorem 3.1 to prove the undecidability of existence of an infinite directed zipper.

THEOREM 4.1. *The set* $\{(T, d) | (T, d)$ *is a directed tile system and there exists an infinite* (T, d)*-directed zipper* $\}$ *is undecidable.*

Proof. Reduce the undecidable tiling problem to our problem.

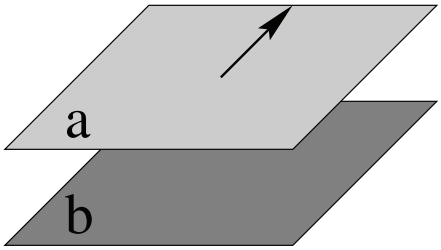

FIG. 12. *A sandwich tile $\sigma(a,b)$ consists of a directed tile $a \in T_0$ placed on top of a tile $b \in T_1$. The direction of $\sigma(a,b)$ is $d(\sigma(a,b)) = d_0(a)$, the direction of its top tile.*

By Theorem 3.1 there exists a directed tile system (T_0, d_0) with the strong plane-filling property.

Let T_1 be a tile system. Consider the following "sandwich tiles," each consisting of a tile from T_0 placed on top of a tile from T_1. That is, create a new directed tile system (T, d) of sandwich tiles such that $T = \{\sigma(a,b) | a \in T_0 \text{ and } b \in T_1\}$, where, for all $a = (a_N, a_E, a_S, a_W) \in T_0$ and $b = (b_N, b_E, b_S, b_W) \in T_1$, the sandwich tile $\sigma(a,b) = ((a_N, b_N), (a_E, b_E), (a_S, b_S), (a_W, b_W))$ and the direction of the sandwich tile is $d(\sigma(a,b)) = d_0(a)$ (see Figure 12).

Hence, a sandwich tile $\sigma(a,b)$ sticks on the north (east, south, west) to $\sigma(a',b')$ iff a sticks on the north (east, south, west) to a' and b sticks on the north (east, south, west) to b'.

We will show now that there exists a valid T_1-tiling of the plane iff there exists an infinite (T,d)-directed zipper.

"$\Rightarrow$" Assume that there exists a valid T_1-tiling of the plane $f : \mathbb{Z}^2 \longrightarrow T_1$. Consider an infinite (T_0, d_0)-directed zipper (P, r) (which exists, since (T_0, d_0) has the strong plane-filling property). Consider the T-tiled path (P, q) of sandwich tiles such that, for all (x, y) on P, $q(x, y) = \sigma(r(x, y), f(x, y))$. Informally, the directed tiled path of sandwich tiles consists of the infinite (T_0, d_0)-directed zipper on its top and the corresponding partial valid T_1-tiling $f|_{\text{range}(P)}$ on the bottom. It is clear that in fact (P, q) is an infinite (T, d)-directed zipper of sandwich tiles.

"$\Leftarrow$" Assume that there exists an infinite (T, d)-directed zipper (P, q) of sandwich tiles. Then, let (P, r) be its top layer; i.e., for all (x, y) on P, $r(x, y) = a$ iff $q(x, y) = \sigma(a, b)$ for some $b \in T_1$. Then clearly, (P, r) is an infinite (T_0, d_0)-directed zipper. Hence, as (T_0, d_0) has the strong plane-filling property, P contains "arbitrarily large squares": for all n there exists (x, y) such that, $(x+i, y+j)$ is on P for $i = 0, 1, 2, \ldots, n$ and $j = 0, 1, 2, \ldots, n$. Let (P, z) be the bottom layer of (P, q), i.e., the T_1-tiled path such that, for all (x, y) on P, $z(x, y) = b$ iff $q(x, y) = \sigma(a, b)$. Then clearly, (P, z) is in fact an infinite T_1-zipper. It follows that $\text{range}(P) = \text{dom}(z)$ contains arbitrarily large squares and, moreover, for all n, $z : \text{range}(P) \longrightarrow T_1$ is a partial tiling valid on a square of size n. It now follows from the König infinity lemma [28] that there exists a valid T_1-tiling of the plane. □

Having proved the undecidability of existence of an infinite directed zipper, we shall use this result to show that the existence of an infinite ribbon is also undecidable.

THEOREM 4.2. *The set $\{T | T$ is a tile system and there exists an infinite T-ribbon$\}$ is undecidable.*

Proof. Reduce the set of Theorem 4.1 to this set.

Given a directed tile system (T, d), we will construct a tile system T' such that there exists an infinite (T, d)-directed zipper iff there exists an infinite T'-ribbon.

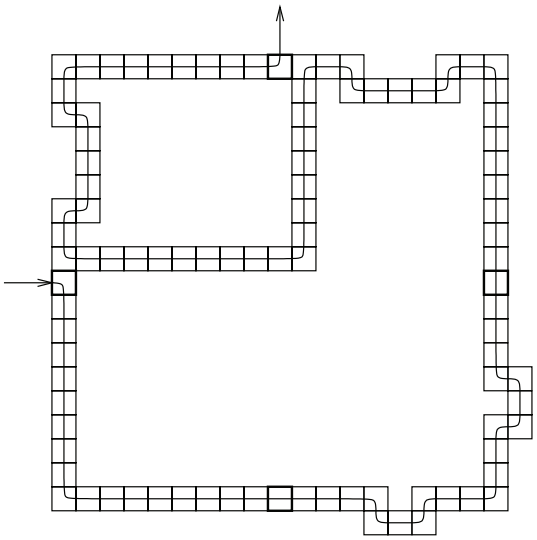

FIG. 13. *A ribbon motif with input tile on the west and output tile on the north.*

Recall that a zipper differs from a ribbon in that in a ribbon only consecutive tiles are required to have matching glues on abutting edges, while on a zipper even nonconsecutive neighboring tiles have to have matching glues on their abutting edges.

The construction is as follows. For each directed tile $t \in T$, construct three T'-*motifs*. A motif is a finite T'-ribbon (P, r) of special form. We construct these ribbon motifs as follows (see Figure 13).

Each motif is essentially a tiled path that outlines the contours of a square. There are dents and bumps on the north, east, south, and west sides of the motif. In addition, if (P, r) is a motif, then the first position on P is midway along one side of the motif. This side is called the input side of the motif and the tile at the first position is called the input tile of the motif. The last position on P is midway along a side of the motif different from the input side. This side is called the output side of the motif and the tile at the last position is called the output tile of the motif.

Given a directed tile $t \in T$, we construct the three possible motifs with output side $d(t)$. We call these three motifs the "variants" of t (see Figure 14). On each variant, we put a bump on the east (south) side, to encode the glue on the east (south) side of t. We also put a dent on the west (north) side, to encode the glue on the west (north) side of t. The dents and bumps are designed so that if, for example, t_1 sticks on the north to t_2, then the dents on the north of t_1 variant motifs fit the bumps on the south of t_2 variants (see Figure 15). If, however, t_1 does not stick on the north to t_2, then the north sides of t_1 variant motifs will overlap the bumps on the south of t_2 variants. Since overlaps are not allowed in ribbons, if t_1 does not stick on the north to t_2, no T'-ribbon can have a t_2 variant motif directly north of a t_1 variant motif.

The glues on tiles in T' are chosen so that each tile can occur in exactly one variant motif, and in each variant motif it occurs exactly once. To this aim, the two edges of each ribbon tile connecting it with the preceding (succeeding) tile on a variant motif are labeled so that this is the only sticking that can form along those edges. The only exception to this rule are the input (output) tiles of motifs, which have the edges connecting them to the preceding (succeeding) tiles labeled differently, as detailed below.

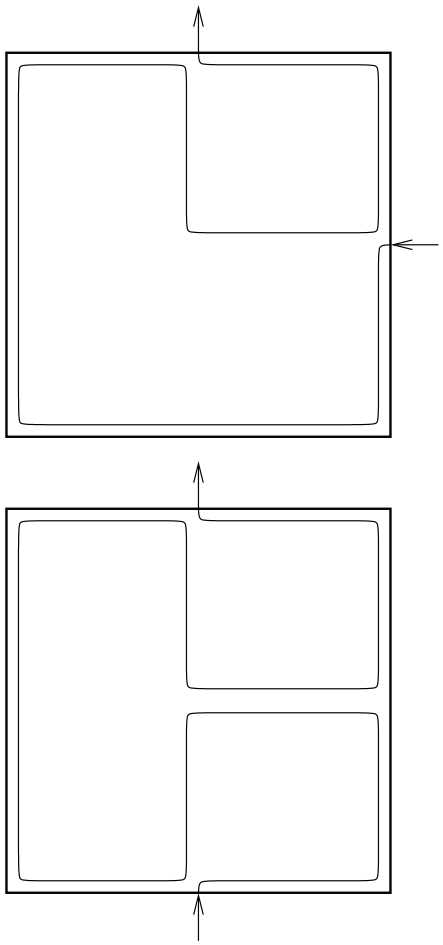

FIG. 14. *The two remaining variant motifs corresponding to a directed zipper tile with direction north (the first one is depicted in Figure* 13*). The bumps and dents are omitted from the variant motifs for clarity.*

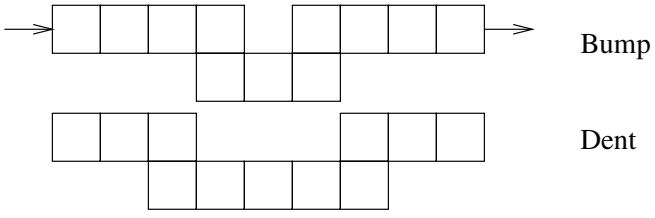

FIG. 15. *The bump-and-dent pair that simulates a glue. Each glue is assigned a unique position on the side of a motif. If the glues on two directed zipper tiles situated at adjacent positions match, then the bump on the first motif will be placed exactly at the necessary position to fit in the dent of the second motif.*

So far, the bumps and dents were used to simulate the glues of zipper tiles. We now simulate the direction of a zipper tile by incorporating it in the glues of the input and output tiles of its variant motifs. We namely use four new glues, *West-to-East*, *East-to-West*, *North-to-South*, and *South-to-North* as follows. If the direction of a directed zipper tile t_1 is north, i.e., $d(t_1) = N$, then

(a) the output ribbon-tiles of all three variant motifs of t_1 will have their north edge labeled *South-to-North*, and

(b) the input tile of the variant motif of t_1 with a west (east, south) input side will have its west (east, south) edge labeled *West-to-East* (*East-to-West*, *South-to-North*).

We label in a similar way the appropriate edges of the input and output tiles of other motifs, namely those edges that are meant to connect the motifs to each other. This labeling ensures that the variant motifs will be connected to each other in the proper order dictated by the direction of the originating directed zipper tiles.

Last, we want to ensure that only motifs of the kind described above can form, and that motifs can connect to each other only through their input and output tiles. To this aim, we have two new different "null" glues: *null(1)* and *null(2)*. We label, for all the above constructed ribbon tiles, the so-far-unlabeled north and west edges with *null(1)* and the unlabeled east and south edges with *null(2)*. Because *null(1)* matches only *null(1)*, and *null(1)* is used only on the west and north edges, the edges of tiles labeled with these glues will not stick to any other tiles along those edges. The same is true for *null(2)*. These "nonstick" glues ensure that the ribbon will only follow the intended motif and will not fill it in, or stick to anything outside it, except at the input and output tiles.

To summarize, given the directed tile system (T, d) we can construct the tile system T' consisting of the ribbon tiles used in all variant motifs of tiles in T, as described above.

Assume that there exists an infinite directed (T, d)-zipper (P, r). One can easily construct an infinite T'-ribbon (P', r'). The idea is that, for each position (x_i, y_i) on P, the tile $r(x_i, y_i)$ is replaced by one of its variant motifs. The variant chosen is one with input side opposite $d(r(x_{i-1}, y_{i-1}))$.

Conversely, assume that there exists an infinite T'-ribbon, (P', r'). It is clear from our choice of ribbon tiles and glues that (P', r') must consist of an infinite sequence of motifs. Hence we can construct an infinite (T, d)-directed zipper by replacing each motif with the tile t of which it is a variant. □

Theorem 4.2 proves the undecidability of existence of an infinite ribbon. This settles the open problem [17], stating the following: "Problem 4.1. Given a tiling system T, is there an infinite T-snake within the infinite grid $G = \mathbb{Z} \times \mathbb{Z}$?"

In the terminology of [17], a tiling system T is exactly as defined in section 2, a finite set of tiles, i.e., of squares with colored edges that cannot be rotated and with infinitely many copies of each tile available. The grid G is the integer grid of positions in the plane. An infinite T-snake is a sequence of tiles on the plane in which successive tiles are adjacent along an edge and touching edges have the same color; i.e., infinite T-snakes are (possibly self-crossing) 2-way infinite ribbons where identical tiles must be present at the crossing sites. In general [17], [34], an infinite snake problem asks, given a tiling system T, and some portion P of the plane, whether there is an infinite T-snake that lies entirely within P. Reference [17] proves that, given T and a strip of width $k \in N$, the existence of an infinite T-snake that lies entirely within the strip is decidable. Given a tile system T, and a specific tile $t_0 \in T$, the problem of whether there exists an infinite T-snake that contains t_0 is proved undecidable in [17]

using methods in [16] (the case of a 1-way infinite snake starting at t_0 was proven undecidable in [15]). If the special "seed" tile is not specified, like in Problem 4.1, [17] conjectures the problem undecidable but states that "[...] it seems that this would be difficult to prove. We have not been able to adjust the proof techniques of other undecidability results for this purpose."

Theorem 4.2, by showing the undecidability of existence of infinite non-self-crossing snakes, proves Problem 4.1 undecidable.

5. Undecidability of self-assembly of arbitrarily large supertiles. Let us return to the discussion of self-assembly. Supertiles are constructed by an incremental process starting from a single tile and proceeding by addition of single tiles that "stick" to the hitherto built structure. The problem we are addressing is whether or not, given a tile system, an infinite supertile can self-assemble with tiles from that system. To formalize our notions, we have the following definition.

DEFINITION 5.1. *A shape is a function $f : I \longrightarrow \mathbb{Z}^2$ such that I is a set of consecutive natural numbers, $0 \in I$, and the following condition holds. For all $i \in I$, if $i > 0$, then there exists $j \in I$ such that $j < i$ and $f(i)$ and $f(j)$ are adjacent.*

A shape thus describes a connected region of the plane. The size of a shape f is the cardinality of its range, i.e., the number of positions it contains, regardless of how many times they are visited. If we fill in each position of a shape with tiles from a given tile system T, we obtain the notion of a T-supertile.

DEFINITION 5.2. *For all tile systems T, a T-supertile is a pair (f, g), where f is a shape and $g : range(f) \longrightarrow T$ is a function such that the following condition holds. For all $i \in dom(f)$, if $i > 0$, then there exists $j \in dom(f)$ such that $j < i$ and $f(i)$ abuts $f(j)$ on the north (east, south, west) and $g(f(i))$ sticks on the north (east, south, west) to $g(f(j))$.*

The size of a T-supertile (f, g) is the size of its corresponding shape f. Two T-supertiles (f, g) and (f', g') are equivalent iff there exists $i, j \in \mathbb{Z}$ such that for all $(x, y) \in \mathbb{Z}^2$, $(x, y) \in \text{range}(f)$ iff $(x+i, y+j) \in \text{range}(f')$ and for all $(x, y) \in \text{range}(f)$, $g(x, y) = g'(x+i, y+j)$. That is, the T-supertile (f', g') is equivalent to the T-supertile (f, g) iff (f', g') can be obtained by translating (f, g) on the plane.

Note that the definitions of shape and supertile may differ in other papers. The ideas are similar, but the details may not be the same. The problem stated at the beginning of this section is settled by the following result.

THEOREM 5.1. *The following sets are undecidable:*

$S_1 = \{T | T$ is a tile system and there exists an infinite T-supertile$\}$;

$S_2 = \{T | T$ is a tile system and there exists infinitely many nonequivalent finite T-supertiles$\}$.

Proof. It is easily shown that sets S_1 and S_2 are identical to the set $\{T | T$ is a tile system and there exists an infinite T-ribbon $\}$. Hence Theorem 5.1 follows from Theorem 4.2. □

6. Conclusion. In this paper we prove the undecidability of the "unseeded version" of the problem of distinguishing tile systems that allow infinite ribbons to self-assemble from those that do not. The proof includes the construction of a special set of directed tiles with the so-called strong plane-filling property, whereby any directed zipper (a special kind of ribbon) is forced to be plane-filling and, moreover, such an infinite directed zipper always exists.

This result settles an open problem formerly known as the "unlimited infinite snake problem."

We also prove the undecidability of the "unseeded version" of the problem of distinguishing tile systems that allow the self-assembly of infinite supertiles from those that do not.

We introduce a "motif" construction that allows one tile system to simulate another by using geometry to represent glues. This construction may be useful in other contexts.

Acknowledgments. We thank David Harel for pointing out that the "infinite ribbon problem" had been open since 1992 under the name "unlimited infinite snake problem," and Dale Myers and Yael Etzion-Petruschka for clarifications of [17]. We thank Qi Cheng, Ashish Goel, Ming-Deh Huang, Pablo Moisset de Espanes, and Paul Rothemund for discussion and comments.

DYNAMIC PROGRAMMING OPTIMIZATION OVER RANDOM DATA: THE SCALING EXPONENT FOR NEAR-OPTIMAL SOLUTIONS*

DAVID J. ALDOUS†, CHARLES BORDENAVE‡, AND MARC LELARGE§

Abstract. A very simple example of an algorithmic problem solvable by dynamic programming is to maximize, over $A \subseteq \{1, 2, \ldots, n\}$, the objective function $|A| - \sum_i \xi_i \mathbb{1}(i \in A, i+1 \in A)$ for given $\xi_i > 0$. This problem, with random (ξ_i), provides a test example for studying the relationship between optimal and near-optimal solutions of combinatorial optimization problems. We show that, amongst solutions differing from the optimal solution in a small proportion δ of places, we can find near-optimal solutions whose objective function value differs from the optimum by a factor of order δ^2 but not of smaller order. We conjecture this relationship holds widely in the context of dynamic programming over random data, and Monte Carlo simulations for the Kauffman–Levin NK model are consistent with the conjecture. This work is a technical contribution to a broad program initiated in [D. J. Aldous and A. G. Percus, *Proc. Natl. Acad. Sci. USA*, 100 (2003), pp. 11211–11215] of relating such scaling exponents to the algorithmic difficulty of optimization problems.

Key words. dynamic programming, local weak convergence, Markov chain, near-optimal solutions, optimization, probabilistic analysis of algorithms, scaling exponent

1. Introduction and motivation.

1.1. Near-optimal solutions in combinatorial optimization. Consider a combinatorial optimization problem which is "size n" in the sense that a feasible solution $\mathbf{x} = (x_i, 1 \le i \le n)$ consists of n elements (e.g., edges of a graph; binary digits) subject to some constraints, and the objective function $f(\mathbf{x})$ is akin to a sum over i of costs or rewards associated with each x_i. In such a setting one can define the relative distance between the structure of a feasible solution $\mathbf{x}$ and the optimal solution $\mathbf{x}^*$ by

$$\delta_n(\mathbf{x}) = n^{-1}|\{i : x_i \neq x_i^*\}|,$$

and the relative difference in objective function is $n^{-1}|f(\mathbf{x}) - f(\mathbf{x}^*)|$. So the quantity

$$\varepsilon_n(\delta) := \min\{n^{-1}|f(\mathbf{x}) - f(\mathbf{x}^*)| \ : \delta_n(\mathbf{x}) \ge \delta\} \tag{1}$$

measures how close we can get to the optimal value using feasible solutions which have nonnegligibly different structure from the optimal solution. A program initiated in [3] is to study this quantity for combinatorial optimization problems over *random* data. In this setting $\varepsilon_n(\delta)$ becomes a random variable, but in many cases one expects that

as $n \to \infty$ there is a *deterministic* limit function $\varepsilon(\delta)$. Motivation for this program is a conjecture that (within some suitable class of problems)

$$\varepsilon(\delta) \asymp \delta^{\alpha} \text{ as } \delta \to 0$$

for some *scaling exponent* α, whose value is robust under model details, and that for "algorithmically easy" problems we have $\alpha = 2$ (which of course mimics the behavior we expect by calculus for smooth functions $f : \mathbb{R}^d \to \mathbb{R}$) whereas for "algorithmically hard" problems we have $\alpha > 2$. Here is the previous evidence in support of this conjecture.

(i) *Traveling salesman problem* and *minimum matching problem* [3]. In the random link (mean-field) model, a cavity method analysis (nonrigorous but generally regarded as accurate) enables one to compute $\varepsilon(\delta)$ numerically and to observe scaling exponent $\alpha = 3$. In the random Euclidean model, Monte Carlo simulations suggest the same $\alpha = 3$.

(ii) *Minimum spanning tree.* Here we expect $\alpha = 2$. This is proved in [2] for the $d \geq 2$ dimensional random Euclidean model and also for a "disordered lattice" model.

The purpose of this paper is to consider some problems which are algorithmically easy to solve via dynamic programming, and where we therefore expect $\alpha = 2$. We first give a trivial but instructive case (section 1.2) and then describe a prototypical "interesting" case, the Kauffman–Levin NK model (section 1.3). Here both a heuristic argument and simulations suggest $\alpha = 2$, but we do not have a proof. Our main focus is on giving a complete analysis of a simple nontrivial model (section 1.4), where we are required to pick a subset $A \subseteq [n] := \{1, 2, \ldots, n\}$ of items with a reward of 1 per item picked and independent and identically distributed (i.i.d.) costs ξ_i incurred if both items i and $i + 1$ are picked. Theorem 2 establishes $\alpha = 2$ for this specific model. In these dynamic programming examples and the minimum spanning tree example, the key structural property is that the near-optimal solutions attaining the minimum in (1) differ from the optimal solution via only "local changes," each local change affecting only a number of items which remains $O(1)$ as $\delta \to 0$. It is natural to speculate that this structural property corresponds quite generally to the $\alpha = 2$ case.

Related work. We do not know any other lines of research in theoretical computer science which are close to the topic of this paper. A recent survey of average-case complexity of NP problems is given in [7]. Interest in the average-case gap between optimal and second-optimal solutions arises in several contexts; see, e.g., [5]. Closer in spirit is the statistical physics of disordered systems, where for low temperatures the Gibbs distribution on configurations concentrates on near-minimal-cost configurations. In the context of random energy models (the precise analogue of optimization over random data), two random picks from the Gibbs distribution over the same random choice of energy are called *replicas*, and study of such replicas and their overlaps is a central theme of the *replica method* [15, 17]. So that topic studies the structural difference between two *typical* near-optimal configurations, whereas we study the *maximal* (over all near-optimal configurations) structural difference from the optimal configuration. Our mathematical arguments are much less sophisticated than those in statistical physics, but there are some intriguing parallels, described briefly in section 5.2.

1.2. A trivial example. Let $(X_i, i \geq 1)$ be i.i.d. real-valued random variables with continuous density $h(x)$ and $\mathrm{E}X < \infty$. For each n consider the problem of finding

$$M_n = \max_{A \subseteq [n]} \sum_{i \in A} (X_i - 1).$$

The maximum is obviously obtained by choosing $A = \{i : X_i > 1\}$ and then as $n \to \infty$

$$n^{-1} M_n \to \mathrm{E}(X_1 - 1)^+ \text{ a.s.}$$

Fix $0 < \delta < 1$. It is also obvious that the subset A' that minimizes

$$M'_n = \max_{A' \subseteq [n]} \sum_{i \in A'} (X_i - 1)$$

$$\text{subject to } |A' \triangle A| \geq \delta n$$

is the subset $A' = A \triangle D$, where D is the set of indices of the $\lceil \delta n \rceil$ smallest values of $|X_i - 1|$. So as $n \to \infty$

$$n^{-1}(M_n - M'_n) \to_{L_1} \varepsilon(\delta) := \int_{1-a(\delta)}^{1+a(\delta)} |x - 1| h(x)\, dx,$$

where $a(\delta)$ is defined by

$$\delta = \int_{1-a(\delta)}^{1+a(\delta)} h(x)\, dx.$$

So by continuity of $h(x)$, and assuming $0 < h(1) < \infty$, as $\delta \downarrow 0$ we have

$$a(\delta) \sim \tfrac{\delta}{2h(1)}; \quad \varepsilon(\delta) \sim a^2(\delta) h(1) \sim \tfrac{\delta^2}{4h(1)}, \tag{2}$$

which is the desired "scaling exponent = 2" result.

Discussion. (i) This example illustrates a feature that arises in other examples, that proving $\alpha = 2$ reduces to showing that the density of a certain measure at a certain point is finite and nonzero. In nontrivial examples the measure in question arises in the *analysis* of the problem rather than the statement of the problem: see Lemma 19 below and Proposition 8 of [2].

(ii) In this example we could see the form of the best near-optimal solution by inspection, but a systematic method is to use Lagrange multipliers. In this example, introduce a parameter $\theta > 0$ and consider for each n

$$A_\theta := \arg\max_A \left(\sum_{i \in A} (X_i - 1) + \theta |A \triangle A^*| \right),$$

where $A^* = \{i : X_i > 1\}$ is the optimal solution. By inspection the solution is

$$A_\theta = \{i : \ 1 - \theta \leq X_i \leq 1 \text{ or } 1 + \theta \leq X_i\}.$$

Although now $|A_\theta \triangle A^*|$ is random, we can use the law of large numbers to obtain existence of the limits

$$\delta(\theta) := \lim_{n \to \infty} n^{-1} |A^* \triangle A_\theta| = \int_{1-\theta}^{1+\theta} h(x)\, dx,$$

$$\varepsilon(\theta) := \lim_{n \to \infty} n^{-1} \left(\sum_{i \in A^*} (X_i - 1) - \sum_{i \in A_\theta} (X_i - 1) \right) = \int_{1-\theta}^{1+\theta} |x - 1|\, dx.$$

By the interpretation of Lagrange multipliers, this is an implicit function representation of ε as a function of δ and rederives the limit (2) above.

$$\begin{array}{ll} 01100011010010111010001001101010101101111000101011010 & \mathbf{x}^N \\ 01100011\underline{011}0101110100010011010\underline{10001110100}0000101011010 & \mathbf{y} \end{array}$$

FIG. 1. *Excursions of lengths* $l = 3$ *and* 11. *Here* $K = 2$.

1.3. The NK model. The Kauffman–Levin NK model of random fitness landscape has attracted extensive literature in statistical physics [10, 19] and has been studied by probabilists [9, 11]. For our version of the model we fix $K \geq 2$. We seek to minimize, over binary sequences $\mathbf{x} = (x_1, \ldots, x_N)$, the objective function $H_N(\mathbf{x}) = \sum_{i=1}^{N-K} W_i(x_i, x_{i+1}, \ldots, x_{i+K})$, where the values $(W_i(b_0, b_1, \ldots, b_K) : i \geq 1, \mathbf{b} \in \{0,1\}^{K+1})$ are independent exponential(1) random variables. This is algorithmically easy via dynamic programming. Write $\mathbf{x}^N$ for the minimizing sequence. By subadditivity there is an a.s. limit $N^{-1}H_N(\mathbf{x}^N) \to c_K$. For a general sequence $\mathbf{y} = \mathbf{y}^N$ write

$$\delta_N(\mathbf{y}) = N^{-1}|\{1 \leq i \leq N-K : (y_i, \ldots, y_{i+K}) \neq (x_i^N, \ldots, x_{i+K}^N)\}|,$$

$$\varepsilon_N(\mathbf{y}) = N^{-1}(H_N(\mathbf{y}) - H_N(\mathbf{x}^N))$$

and then set

$$\varepsilon_N(\delta) = \min\{\varepsilon_N(\mathbf{y}) : \ \delta_N(\mathbf{y}) \geq \delta\}. \tag{3}$$

We expect existence of a deterministic limit

$$\varepsilon(\delta) = \ \text{a.s.-}\lim_{N\to\infty} \varepsilon_N(\delta).$$

A heuristic analysis. The purpose of this section is to give a heuristic argument for $\varepsilon(\delta) \asymp \delta^2$. Given i and $l \geq K+1$, consider the set of sequences $\mathbf{y}$ such that

$$(y_j, \ldots, y_{j+K}) = (x_j^N, \ldots, x_{j+K}^N) \quad \forall j \notin [i+1, i+l],$$

$$(y_j, \ldots, y_{j+K}) \neq (x_j^N, \ldots, x_{j+K}^N) \quad \forall j \in [i+1, i+l].$$

Over this set, let $D_{i,l}$ be the minimum of $H_N(\mathbf{y}) - H_N(\mathbf{x}^N)$ and let $\mathbf{y}^{(i,l)}$ be the minimizing sequence. The distribution of $D_{i,l}$ essentially depends only on l, not on i or N; write $f_l(0+)$ for its density at $0+$. Let us assume

$$\sum_{l \geq K+1} l^2 f_l(0+) = A < \infty. \tag{4}$$

It is intuitively clear how to choose a sequence $\mathbf{y}$ which minimizes $\varepsilon_N(\mathbf{y})$ for a given δ. Just fix a small $\eta > 0$ and create a sequence of "excursion" away from $\mathbf{x}^N$ as follows. For each pair (i,l) such that $D_{i,l} < \eta l$, choose $\mathbf{y}$ to equal $\mathbf{y}^{(i,l)}$ on the sites $[i+K+1, i+l]$; set $\mathbf{y} = \mathbf{x}^N$ elsewhere. See Figure 1.

With this scheme, δ will be the mean length of possible excursions starting from a given site, that is,

$$\delta \sim \sum_{l \geq K+1} l \cdot \eta l f_l(0+).$$

TABLE 1

Monte Carlo simulations with $K = 3, N = 10,000$; 1000 repeats. These are exact optimizations done by introducing a Lagrange multiplier θ which penalizes matching $(K+1)$-tuples. We find $c_3 = 0.3065$.

And ε is the mean increment of H_N associated with possible excursions starting from a given site, that is,

$$\varepsilon \sim \sum_{l \geq K+1} (\eta l/2) \cdot \eta l f_l(0+).$$

In other words $\delta \sim A\eta$, $\varepsilon \sim A\eta^2/2$, giving $\varepsilon \sim (2A)^{-1}\delta^2$, which is the desired "scaling exponent = 2" result.

Why should assumption (4) be true? Well, for large l we expect central limit behavior: $D_l \approx \mathrm{Normal}(\mu l, \sigma^2 l)$ for some $\mu > 0$ and $0 < \sigma^2 < \infty$. This in turn suggests that $f_l(0+)$ should decrease at least geometrically fast in l.

Note that the optimizing $\mathbf{y}^N$ in (3) will have (in the $N \to \infty$ limit) some distribution L_δ of excursion lengths. The heuristic argument predicts that as $\delta \downarrow 0$ we have $L_\delta \xrightarrow{d} L$, where the limit distribution has $\mathrm{P}(L = l) \propto l f_l(0+)$ and $\mathrm{E}L < \infty$.

Simulations (Table 1) with $K = 3$ are consistent with both the predicted scaling exponent 2 and the prediction of existence of a $\delta \downarrow 0$ limit distribution L for excursion lengths. Making a rigorous proof seems difficult, and so we turn to a simpler example.

1.4. Main model and results. Let $(\xi_i, i \geq 1)$ be i.i.d. copies of a strictly positive random variable ξ, and write $G(x) = \mathrm{P}(\xi \leq x)$. Define the *benefit* function

$$f_n(A) = \left(|A| - \sum_{i=1}^{n-1} \xi_i \mathbb{1}(i \in A, i+1 \in A) \right), \quad A \subseteq \{1, 2, \ldots, n\}, \tag{5}$$

where $\mathbb{1}(B) = \mathbb{1}_B$ denotes the indicator random variable associated with an event B. Intuitively, we choose a set A of items, getting reward 1 from each item chosen but paying cost ξ_i if we choose both i and $i+1$; we seek to maximize benefit = reward − cost. So we shall study

$$M_n := \max_{A \subseteq \{1,2,\ldots,n\}} f_n(A). \tag{6}$$

To simplify exposition we will assume

$$G \text{ has bounded continuous density } g \text{ with } g(\tfrac{1}{2}) > 0, \tag{7}$$

which implies

$$0 < G(\tfrac{1}{2}) < 1, \tag{8}$$

though we suspect that Theorems 1 and 2 remain true under some much weaker nondegeneracy assumptions. See section 5.1 for further remarks.

We will first prove the following.

THEOREM 1. *There exists* $\frac{1}{2} \le c \le 1$ *such that, a.s. and in* L^1,

$$\lim_{n\to\infty} n^{-1} M_n = c.$$

The constant c *is given by the forthcoming formula* (31). *If* ξ *is an exponential random variable with parameter* $\lambda > 0$, *then*

$$c = (1 - e^{-\lambda})^{-1} - \lambda^{-1}.$$

We record the explicit value of c only in the exponential case, but one could use formula (31) to obtain explicit values for other standard distributions.

We now formalize the setup in the introduction. The optimization problem (6) has a solution, a random subset $A_n^{\text{opt}} \subseteq \{1, 2, \ldots, n\}$, and Corollary 4 will show the solution is unique with probability $\to 1$ as $n \to \infty$. Define the random variable:

$$\varepsilon_n(\delta) := \min\left\{ n^{-1}(f_n(A_n^{\text{opt}}) - f_n(B)) : |B \triangle A_n^{\text{opt}}| \ge \delta n \right\}, \tag{9}$$

where the minimum is over all subsets $B \subset \{1, \ldots, n\}$ such that the symmetric difference with A_n^{opt} is at least δn. Our main result is the following.

THEOREM 2. $\bar{\varepsilon}(\delta) := \lim_n \mathrm{E}\varepsilon_n(\delta)$ *exists for all* $0 < \delta < 1$, *and*

$$\limsup_{\delta \downarrow 0} \delta^{-2} \bar{\varepsilon}(\delta) < \infty, \tag{10}$$

$$\liminf_{\delta \downarrow 0} \delta^{-2} \bar{\varepsilon}(\delta) \ > 0. \tag{11}$$

We now outline the key ideas in the proof and the organization of this paper.

Dynamic programming over i.i.d. data is essentially just study of a related Markov chain (section 2.2), and in our model there are simple *inclusion criteria* for whether item i is in the optimal solution. The inclusion criterion involves two Markov chains (one looking left, one looking right) and the cost ξ_i (Table 2 and Lemma 5). By considering the related infinite-time *stationary* Markov chain and using the same inclusion criteria, we can define a random subset $A^{\text{opt}} \subset \mathbb{Z}$ interpretable as the solution of an infinite optimization problem (section 2.3). The $n \to \infty$ limit benefit in Theorem 1 is just the mean benefit per item using A^{opt} in the infinite problem (section 2.4).

Study of $\varepsilon_n(\delta)$ is an "optimization under constraint" problem, most naturally handled via introduction of a Lagrange multiplier θ. So the B_n^{opt} attaining the maximum in (9) can be studied as above by introducing a more complicated Markov chain parametrized by θ (section 4.1), finding the inclusion criteria (Table 3), formulating the parallel optimization under constraint problem, and observing that $\bar{\varepsilon}(\delta)$ is representable via functions $\delta(\theta), \varepsilon(\theta)$ defined in terms of the stationary distribution of the more complicated Markov chain (Proposition 12). Without trying to write details, it seems intuitively clear that the methodology above could be implemented in more general dynamic programming models such as the NK model of section 1.3. However, to complete the argument we need to analyze the $\theta \to 0$ behavior of the functions $\delta(\theta), \varepsilon(\theta)$. Even in our simple model, we do not have any useful explicit expression for the needed stationary distribution, so we proceed via inequalities rather than using the exact formulas. For the upper bound (10) we just identify a "local configuration" which can be replaced by a different local configuration at small extra cost (section 3). For the lower bound, we decompose the process into blocks by breaking at certain special configurations, and then we get bounds on the chance that B_n^{opt} differs from

	g	$-$	$(g+1)$	$-$				$-$	$(d-1)$	$-$	d
A_1	$\circ$	$-$	$\bullet$	$-$	$\circ$	$\ldots$	$\bullet$	$-$	$\circ$	$-$	$\bullet$
A_2	$\bullet$	$-$	$\circ$	$-$	$\bullet$	$\ldots$	$\circ$	$-$	$\bullet$	$-$	$\circ$

FIG. 2. *Included items marked* $\bullet$*, excluded items marked* $\circ$.

A_n^{opt} on a block and bounds on the mean decrease in benefit if it does differ (section 4.5). But these arguments rely on the particular combinatorial structure of our special model. It is not clear how readily they can be extended to general models.

2. Analysis of optimal solutions.

2.1. Nonuniqueness. In the case $n = 2$, if $\xi_1 > 1$, then both $\{1\}$ and $\{2\}$ attain the maximum value 1 of the optimization problem (6): the optimizing set is not unique. Corollary 4 shows that, provided some $\xi_i + \xi_{i+1} < 1$ is less than 1, the optimizing set A_n^{opt} is unique, and by assumption (8) this proviso holds with probability $\to 1$ as $n \to \infty$. After this section we generally ignore the possibility of nonuniqueness.

We start with some terminology that will also be used later. For an integer interval $[g, d]$ with $d - g + 1$ even, the two *complementary alternating subsets* A_1, A_2 are as shown in Figure 2.

LEMMA 3. *Let* $n \geq 2$. *For almost all realizations of* $\xi_1, \ldots, \xi_{n-1}$*, the following are equivalent:*

(a) *The subset maximizing* (6) *is not unique.*

(b) n *is even and the only optimal solutions are the two complementary alternating subsets of* $[1, n]$.

(c) n *is even and* $M_n = n/2$.

Proof. Either of (b), (c) implies (a), so it is enough to show (a) implies (b) and (c). Suppose distinct subsets B_1 and B_2 attain the maximum. Then a.s. the values of ξ_i used in the optimal sum are identical, that is,

$$\{i : \ (i, i+1) \subset B_1\} = \{i : \ (i, i+1) \subset B_2\} := \mathcal{S}, \text{ say.} \tag{12}$$

First suppose $\mathcal{S}$ is empty. Then each of B_1 and B_2 has only isolated elements. But amongst such sets, the maximum of (6) is attained (for n odd) uniquely by the alternating subset giving $M_n = (n+1)/2$, or (for n even) only by the complementary alternating subsets. So $\mathcal{S}$ empty implies (b) and (c). For general $\mathcal{S}$, take some $i \in B_1 \triangle B_2$, and then take the maximal interval $i \in [g, d] \subset [1, n]$ which is disjoint from $\mathcal{S}$. Repeating the argument above, the restrictions of B_1 and B_2 to $[g, d]$ must be complementary alternating subsets. If $[g, d] \neq [1, n]$, then either $d + 1$ or $g - 1$ is in $\mathcal{S}$—say $d + 1$—and so $d + 1 \in B_1 \cap B_2$. But exactly one of B_1, B_2 contains d, contradicting (12). So $[g, d] = [1, n]$, and so $\mathcal{S}$ is empty. □

COROLLARY 4. *If* $\xi_i + \xi_{i+1} < 1$ *for some* $1 \leq i \leq n-2$*, then a.s.* A_n^{opt} *is unique.*

Proof. Fix i with $\xi_i + \xi_{i+1} < 1$ and let B be the alternating subset of $[1, n]$ containing i and $i+2$. Replacing B by $B \cup \{i+1\}$ increases the benefit by $1 - \xi_i - \xi_{i+1} > 0$, so B cannot be optimal, and the result follows from Lemma 3. □

2.2. Dynamic programming. Finding the maximum value and the maximizing subset of (6) is algorithmically easy by dynamic programming, as follows. Define

$$V_{n,i}^L = \max_{i \in A \subseteq \{1,\ldots,i-1,i\}} \left(|A| - \sum_{j=1}^{i-1} \xi_j \mathbb{1}(j \in A, j+1 \in A) \right), \tag{13}$$

$$W_{n,i}^L = \max_{i \notin A \subseteq \{1,\dots,i-1,i\}} \left(|A| - \sum_{j=1}^{i-1} \xi_j \mathbb{1}(j \in A, j+1 \in A) \right), \tag{14}$$

which differ in that the former requires $i \in A$ and the latter requires $i \notin A$. The superscripts L here and R later indicate *left* and *right*. Note that in fact $V_{n,i}^L, W_{n,i}^L$ above and $X_{n,i}^L$ below do not depend on n, but the notation is useful to distinguish from the limit process X_i^L later.

From (13), (14) we see $V_{n,1}^L = 1, W_{n,1}^L = 0$, and by induction over $1 \le i$

$$V_{n,i+1}^L = 1 + \max(V_{n,i}^L - \xi_i, W_{n,i}^L),$$

$$W_{n,i+1}^L = \max(V_{n,i}^L, W_{n,i}^L),$$

the two terms in the max indicating the choice of using or not using element i. Then $M_n = \max(V_{n,n}^L, W_{n,n}^L)$, and by examining which max term is used at each stage leading to M_n we can recover the optimizing subset A_n^{opt}.

We now describe an alternative, more useful way to obtain A_n^{opt}. First, consider the evolution rule for the process

$$X_{n,i}^L := V_{n,i}^L - W_{n,i}^L \tag{15}$$

as i increases; the rule is

$$\begin{aligned} X_{n,i+1}^L &= 1 + \max(0, X_{n,i}^L - \xi_i) - \max(0, X_{n,i}^L) \\ &= 1 + \max(-X_{n,i}^L, -\xi_i)\mathbb{1}(X_{n,i}^L \ge 0). \end{aligned} \tag{16}$$

One can check by induction that $0 \le X_{n,i}^L \le 1$ and thus rewrite the recursion as

$$X_{n,i+1}^L = \max(1 - X_{n,i}^L, 1 - \xi_i).$$

For n fixed we define the right processes analogously:

$$V_{n,i}^R = \max_{i \in A \subseteq \{i,i+1,\dots,n\}} \left(|A| - \sum_{j=i}^{n-1} \xi_j \mathbb{1}(j \in A, j+1 \in A) \right), \tag{17}$$

$$W_{n,i}^R = \max_{i \notin A \subseteq \{i,i+1,\dots,n\}} \left(|A| - \sum_{j=i}^{n-1} \xi_j \mathbb{1}(j \in A, j+1 \in A) \right), \tag{18}$$

with $V_{n,n}^R = 1, W_{n,n}^R = 0$. Observe that the evolution rule for the process

$$X_{n,i}^R := V_{n,i}^R - W_{n,i}^R \tag{19}$$

as i decreases does not depend on n. In fact, we have

$$X_{n,i-1}^R = \max(1 - X_{n,i}^R, 1 - \xi_{i-1}). \tag{20}$$

The point is that we can determine the optimizing random set A_n^{opt} in terms of the quantities above. Fix i, consider the quantities $(X_{n,i}^L, V_{n,i}^L, W_{n,i}^L)$, ξ_i, and $(X_{n,i+1}^R, V_{n,i+1}^R, W_{n,i+1}^R)$, and drop subscripts. We have four choices of whether to include

TABLE 2
Inclusion criteria for $i, i+1$ in A_n^{opt}.

$-i-(i+1)-$	Absolute benefit	Relative benefit	When used
$-\bullet--\bullet-$	$V^L+V^R-\xi$	$X^L+X^R-\xi$	$\xi<\min(X^L,X^R)$
$-\bullet--\circ-$	V^L+W^R	X^L	if $X^R<\min(X^L,\xi)$
$-\circ--\bullet-$	W^L+V^R	X^R	if $X^L<\min(X^R,\xi)$
$-\circ--\circ-$	W^L+W^R	0	never

(marked as $\bullet$ in Table 2) or exclude (marked as $\circ$ in Table 2) items i and $i+1$ in the optimal set A_n^{opt}. For each choice, the table shows the absolute benefit of that choice and then the relative benefit (relative to the choice to exclude both items). For each i the optimal A_n^{opt} will contain, in positions $(i, i+1)$, the combination with the largest relative benefit, and the final column indicates the criteria for use of each combination. (The case of nonuniqueness of A_n^{opt}, Lemma 3, is the case where X_i^L and X_i^R alternate between 0 and 1 throughout the interval $[1,n]$, and where we have equalities $X_i^L = X_{i+1}^R < \xi_i$. Outside this case, one of the three strict inequalities holds. We ignore the nonuniqueness possibility in the summary below.)

We summarize the argument above as follows.

LEMMA 5. *For each n define $X_{n,i}^L, 1\le i\le n$, and $X_{n,i}^R, 1\le i\le n$, by*

$$X_{n,1}^L = 1; \quad X_{n,i+1}^L = \max(1-X_{n,i}^L, 1-\xi_i), \quad 1\le i\le n-1, \tag{21}$$

$$X_{n,n}^R = 1; \quad X_{n,i-1}^R = \max(1-X_{n,i}^R, 1-\xi_{i-1}), \quad 2\le i\le n. \tag{22}$$

Then A_n^{opt} is the random subset of $\{1,2,\dots,n\}$ specified by the following: for each $1\le i\le n-1$,

$$\text{if } \xi_i < \min(X_{n,i}^L, X_{n,i+1}^R), \quad \text{then} \quad i\in A_n^{opt}, \quad i+1\in A_n^{opt},$$

$$\text{if } X_{n,i+1}^R < \min(X_{n,i}^L, \xi_i), \quad \text{then} \quad i\in A_n^{opt}, \quad i+1\notin A_n^{opt},$$

$$\text{if } X_{n,i}^L < \min(X_{n,i+1}^R, \xi_i), \quad \text{then} \quad i\notin A_n^{opt}, \quad i+1\in A_n^{opt}.$$

Let us emphasize two points:

- whether or not $i\in A_n^{\mathrm{opt}}$ depends only on the three random variables $X_{n,i}^L$, $\xi_i, X_{n,i+1}^R$;
- the only place where the value of n enters is as the boundary condition $X_{n,n}^R = 1$.

In the next section, we show how to define a corresponding stationary process

$$((X_i^L, \xi_i, X_{i+1}^R),\ -\infty < i < \infty).$$

By applying the specification in Lemma 5 to this process, we will define a set $A^{\mathrm{opt}}\subseteq\mathbb{Z}$ which will be shown (Lemma 8) to be the limit of A_n^{opt}. As a consequence, we will be able to derive the limit of M_n/n.

2.3. A stationary Markov chain and the infinite limit problem. The recursion (21) specifies a Markov chain on the continuous state space $[0,1]$ with transitions

$$x\to \max(1-x, 1-\xi), \tag{23}$$

where ξ has distribution function G. Write $F(x) = \mathrm{P}(X^L \le x)$ for a stationary distribution function for this chain. Then

$$\begin{aligned} F(x) &= \mathrm{P}(\max(1 - X^L, 1 - \xi) \le x) \\ &= \mathrm{P}(\min(X^L, \xi) > 1 - x) \\ &= \overline{G}(1-x)\overline{F}(1-x), \end{aligned}$$

where for any distribution function F we write $\overline{F}(x) = 1 - F(x)$. Iterating this identity once gives

$$F(x) = \overline{G}(1-x)\left(1 - \overline{G}(x)\overline{F}(x)\right),$$

and solving this equation gives

$$F(x) = \frac{\overline{G}(1-x)\overline{G}(x)}{1 - \overline{G}(x)\overline{G}(1-x)}. \tag{24}$$

The assumption (7) that G has a density implies that F has a density, so in what follows we do not need to distinguish carefully between weak and strict inequalities for random variables with these distributions.

Now consider the infinite line graph, with vertices $-\infty < i < \infty$ and with i.i.d. edge-costs ξ_i on edge $(i, i+1)$ such that $\mathrm{P}(\xi_0 + \xi_1 < 1) > 0$, which is ensured by the condition $\overline{G}(1/2) < 1$.

LEMMA 6. *The recursion*

$$X^L_{i+1} = \max(1 - X^L_i, 1 - \xi_i), \quad -\infty < i < \infty, \tag{25}$$

defines uniquely a joint distribution for $((\xi_i, X^L_i), -\infty < i < \infty)$ *in which* (X^L_i) *is the stationary Markov chain with transition kernel* (23) *and stationary distribution* (24). *And*

$$X^L_i = \phi(\ldots, \xi_{i-2}, \xi_{i-1}) \tag{26}$$

for a certain function ϕ *not depending on* i.

Proof. Having proved existence and uniqueness of the stationary distribution at (24), it remains only to prove the measurability property (26). Iterating (25) once shows

$$1 - \xi_i \le X^L_{i+1} \le \max(1 - \xi_i, \xi_{i-1}). \tag{27}$$

So outside the event $\{1 - \xi_i < \xi_{i-1}\}$ the value of X^L_{i+1} depends only on (ξ_{i-1}, ξ_i) and not on the value of X^L_i. So inductively on $Q \ge 1$ there exists a measurable function ϕ_Q such that

$$X^L_1 = \phi_Q(\xi_{-2Q-1}, \xi_{-2Q}, \ldots, \xi_0) \text{ outside } \cap_{q=-Q}^{0} \{1 - \xi_{2q} < \xi_{2q-1}\}.$$

Now (26) follows because $\mathrm{P}\left(\cap_{q=-Q}^{0}\{1 - \xi_{2q} < \xi_{2q-1}\}\right) = \left(\mathrm{P}(\xi_0 + \xi_1 > 1)\right)^{Q+1} \to 0$. □

If we define an "i decreasing" process by

$$X^R_i = \phi(\ldots, \xi_{i+2}, \xi_{i+1}, \xi_i), \tag{28}$$

then (X_i^R) satisfies the analogous recursion

$$X_i^R = \max(1 - X_{i+1}^R, 1 - \xi_i), \quad -\infty < i < \infty, \tag{29}$$

and is distributed as the same stationary Markov chain. Hence we have a rigorous definition of a unique (in distribution) stationary process $((X_i^L, \xi_i, X_{i+1}^R),\ -\infty < i < \infty)$ satisfying (25), (29) which we will call the *triple process*. Note that from (26), (28)

(30) for each i the three random variables X_i^L, ξ_i, X_{i+1}^R are independent.

LEMMA 7. *Let $(X_i^L, \xi_i, X_{i+1}^R),\ -\infty < i < \infty$, be the stationary triple process. Then there is a random subset A^{opt} of $\mathbb{Z}$ specified by the following: for each $-\infty < i < \infty$,*

$$\text{if } \xi_i < \min(X_i^L, X_{i+1}^R), \quad \text{then} \quad i \in A^{opt}, \quad i+1 \in A^{opt},$$

$$\text{if } X_{i+1}^R < \min(X_i^L, \xi_i), \quad \text{then} \quad i \in A^{opt}, \quad i+1 \notin A^{opt},$$

$$\text{if } X_i^L < \min(X_{i+1}^R, \xi_i), \quad \text{then} \quad i \notin A^{opt}, \quad i+1 \in A^{opt}.$$

Proof. We need only check that the definition of A^{opt} is consistent, in that the criterion for item i to be excluded should be the same whether we look at the pair $(i, i+1)$ or the pair $(i-1, i)$. (Of course this is intuitively clear from the consistency in the finite setting of Lemma 5, but let us give an algebraic verification anyway.) We need to check

$$\{X_i^L < \min(X_{i+1}^R, \xi_i)\} \stackrel{?}{=} \{X_i^R < \min(X_{i-1}^L, \xi_{i-1})\}.$$

Using the recursions (29), (25) for X_i^R and X_i^L, we need to check

$$\{\max(1-X_{i-1}^L, 1-\xi_{i-1}) < \min(X_{i+1}^R, \xi_i)\} \stackrel{?}{=} \{\max(1-X_{i+1}^R, 1-\xi_i) < \min(X_{i-1}^L, \xi_{i-1})\}.$$

But these are equal by applying the transformation $u \to 1 - u$ to the right-hand side. □

Because the rule defining A^{opt} is translation-invariant, the augmented triple process

$$((X_i^L, \xi_i, X_{i+1}^R, \mathbb{1}(i \in A^{\text{opt}})),\ -\infty < i < \infty)$$

is also stationary. The next lemma shows this process is the limit of the corresponding finite-n process. The mode of convergence can be viewed as a very elementary case of *local weak convergence* [4] of random graphical structures. In other words, it asserts that relative to a random time-origin the finite processes approximate the limit process.

LEMMA 8. *Let U_n be uniform on $\{1, \dots, n\}$. As $n \to \infty$*

$$((X_{n,U_n+i}^L, \xi_{U_n+i}, X_{n,U_n+i+1}^R, \mathbb{1}(U_n + i \in A_n^{opt})),\ -\infty < i < \infty)$$

$$\stackrel{d}{\to}\ ((X_i^L, \xi_i, X_{i+1}^R, \mathbb{1}(i \in A^{opt})),\ -\infty < i < \infty),$$

where the left-hand side is defined arbitrarily for $U_n + i \notin \{1, \dots, n\}$ and where convergence in distribution is with respect to the usual product topology on infinite sequence space.

Proof. Because the X's are bounded and the ξ's are i.i.d., the sequence of processes is tight in the product topology. Write

$$((\hat{X}_i^L, \hat{\xi}_i, \hat{X}_{i+1}^R, \mathbb{1}(i \in \hat{A}^{\rm opt})),\ -\infty < i < \infty)$$

for a subsequential weak limit. Clearly $(\hat{\xi}_i) \stackrel{d}{=} (\xi_i)$. Because for each n the process $(X_{n,i}^L, \xi_i)$ satisfies recursion (21), the limit $(\hat{X}_i^L, \hat{\xi}_i)$ satisfies this recursion, and so by the "uniqueness of joint distribution" assertion of Lemma 6, $(\hat{X}_i^L, \hat{\xi}_i) \stackrel{d}{=} (X_i^L, \xi_i)$. Applying the same argument to X^R we deduce

$$((X_{U_n+i}^L, \xi_{U_n+i}, X_{n,U_n+i+1}^R),\ -\infty < i < \infty) \stackrel{d}{\to} ((X_i^L, \xi_i, X_{i+1}^R),\ -\infty < i < \infty).$$

For fixed i_0 the event $i_0 \in A^{\rm opt}$ is a function of the limit process, the function implied by Lemma 7, and by a standard fact [6, Theorem 5.2] it is enough to check that this function is a.s. continuous with respect to the limit process. But this just requires that the probability of an *equality* between some two of $X_{i_0}^L, \xi_{i_0}, X_{i_0+1}^R$ should be zero, which follows from their independence (30) and existence of densities (7), (24). □

2.4. Proof of Theorem 1. Because

$$M_n = \sum_{i=1}^{n} \mathbb{1}(i \in A_n^{\rm opt}) - \sum_{i=1}^{n-1} \xi_i \mathbb{1}(i \in A_n^{\rm opt}, i+1 \in A_n^{\rm opt}),$$

we can write

$$n^{-1}\mathrm{E}M_n = \mathrm{P}(U_n \in A_n^{\rm opt}) - \mathrm{E}\xi_{U_n}\mathbb{1}(U_n \in A_n^{\rm opt}, U_n + 1 \in A_n^{\rm opt})\mathbb{1}(U_n \neq n)$$

and then by Lemma 8

$$n^{-1}\mathrm{E}M_n \to c := \mathrm{P}(0 \in A^{\rm opt}) - \mathrm{E}\xi_0 \mathbb{1}(0 \in A^{\rm opt}, 1 \in A^{\rm opt}).$$

Note that clearly $c \leq 1$; the other inequality $c \geq 1/2$ holds because the subset $\{1, 3, 5, \ldots\}$ is a feasible choice.

We now exploit the *method of bounded differences* [12] in a very routine way. We observe that $M_n = m_n(\xi_1, \ldots, \xi_n)$ for a certain function m_n with the property

> changing any one argument of $m_n(z_1, \ldots, z_n)$ changes the value of $m_n(\cdot)$ by at most 1

This property holds because $A_n^{\rm opt}$ will never contain a pair $(i, i+1)$ for which $\xi_i > 1$. And this property implies the well-known Azuma–Hoeffding inequality of the form (see, e.g., [16])

$$\mathrm{P}(|M_n - \mathrm{median}(M_n)| \geq t) \leq 4\exp(-\tfrac{t^2}{4n}).$$

It is now routine to use this large deviation inequality to establish the a.s. and L^1 convergence of $n^{-1}M_n$ to c.

To evaluate c, abbreviate (X_0^L, ξ_0, X_1^R) to (X^L, ξ, X^R) and use the Lemma 7 definition of $A^{\rm opt}$ to write

$$\begin{aligned}
\mathrm{P}(0 \in A^{\rm opt}) &= 1 - \mathrm{P}(X^L < \min(X^R, \xi)) \\
&= 1 - \tfrac{1}{2}(1 - \mathrm{P}(\xi < \min(X^L, X^R))) \text{ by symmetry} \\
&= \tfrac{1}{2} + \tfrac{1}{2}\mathrm{P}(\xi < \min(X^L, X^R))
\end{aligned}$$

and then

$$c = \tfrac{1}{2} + \tfrac{1}{2}\mathrm{P}(\xi < \min(X^L, X^R)) - \mathrm{E}\xi\mathbb{1}(\xi < \min(X^L, X^R)). \tag{31}$$

Recall that X^L, ξ, and X^R are independent and that X^L and X^R have common distribution F given in terms of G by (24). So (31) constitutes a formula for c in terms of the underlying distribution function G of ξ.

We now evaluate c in the special case where ξ has the exponential(λ) distribution:

$$\overline{G}(x) = e^{-\lambda x}, \quad 0 < x < \infty,$$

so that, from formula (24), we have

$$F(x) = \frac{e^{-\lambda(1-x)}(1 - e^{-\lambda x})}{1 - e^{-\lambda}} = \frac{e^{\lambda x} - 1}{e^{\lambda} - 1}.$$

We deduce

$$\begin{aligned}
\mathrm{P}(\xi < \min(X^L, X^R)) &= \int_0^1 \lambda e^{-\lambda u} P^2(X^L > u)\, du \\
&= \frac{\lambda}{(e^\lambda - 1)^2} \int_0^1 e^{-\lambda u} \left(e^\lambda - e^{\lambda u}\right)^2 du \\
&= \frac{\lambda}{(e^\lambda - 1)^2} \left(e^{2\lambda} \int_0^1 e^{-\lambda u} du - 2e^\lambda + \int_0^1 e^{\lambda u} du \right) \\
&= \frac{e^{2\lambda} - 2\lambda e^\lambda - 1}{(e^\lambda - 1)^2},
\end{aligned}$$

$$\begin{aligned}
\mathrm{E}\xi\mathbb{1}(\xi < \min(X^L, X^R)) &= \int_0^1 u\lambda e^{-\lambda u} P^2(X^L > u)\, du \\
&= \frac{\lambda}{(e^\lambda - 1)^2} \int_0^1 u e^{-\lambda u} \left(e^\lambda - e^{\lambda u}\right)^2 du \\
&= \frac{\lambda}{(e^\lambda - 1)^2} \left(e^{2\lambda} \int_0^1 u e^{-\lambda u} du - e^\lambda + \int_0^1 u e^{\lambda u} du \right) \\
&= \frac{1}{\lambda(e^\lambda - 1)^2} \left(e^{2\lambda} - (\lambda^2 + 2)e^\lambda + 1 \right).
\end{aligned}$$

Combining,

$$\begin{aligned}
c &= \frac{1}{2} + \frac{\frac{\lambda}{2}(e^{2\lambda} - 2\lambda e^\lambda - 1) - (e^{2\lambda} - (\lambda^2 + 2)e^\lambda + 1)}{\lambda(e^\lambda - 1)^2} \\
&= \frac{1}{1 - e^{-\lambda}} - \frac{1}{\lambda}.
\end{aligned}$$

3. The upper bound in Theorem 2. Local weak convergence (Lemma 8 above and Lemma 11 below) provides one sense in which the $n \to \infty$ limit of the solution $A_n^{\rm opt}$ of the size-n optimization problem is $A^{\rm opt}$. A logically different sense is provided by coupling, as follows. Part of the stationary triple process is the doubly infinite i.i.d. sequence $(\ldots, \xi_{-1}, \xi_0, \xi_1, \xi_2, \ldots)$. For each n use these same random variables $\xi_1, \ldots, \xi_n$ to construct $A_n^{\rm opt}$. Because of boundary effects it is not always true that $A^{\rm opt} \cap [1, n] = A_n^{\rm opt}$. But we expect the sets to coincide "away from the boundary," and Lemma 9(b) below provides one expression of this equality. We call this technique *localization*.

3.1. Optimality properties of $A^{\rm opt}$. Lemma 7 gave a concise definition of $A^{\rm opt}$ but did not explicitly identify its optimality properties. Lemma 9 below will relate $A^{\rm opt}$ to certain finite optima and thereby allow us to deduce some explicit properties.

The benefit function $f_n(A)$ and its maximum value M_n defined at (5), (6) refer to subsets of $[1, n]$, and it is convenient to make the corresponding definitions for an arbitrary interval $[\ell, m]$:

$$f_{[\ell,m]}(A) := |A| - \sum_{i=\ell}^{m-1} \xi_i \mathbb{1}(i \in A, i+1 \in A), \quad A \subseteq \{\ell, \ell+1, \ldots, m\}, \tag{32}$$

$$M_{[\ell,m]} := \max_{A \subseteq \{\ell, \ell+1, \ldots, m\}} f_{[\ell,m]}(A), \tag{33}$$

and denote by $A_{[\ell,m]}^{\rm opt}$ the corresponding optimizing set.

LEMMA 9. (a) *If $\xi_{i-1} + \xi_i \le 1$, then $i \in A^{opt}$.*

(b) *If $\ell < m$ and $\xi_{\ell-1} + \xi_\ell \le 1$ and $\xi_{m-1} + \xi_m \le 1$, then $A_{[\ell,m]}^{opt}$ is unique and*

$$A^{opt} \cap [\ell, m] = A_{[\ell,m]}^{opt}. \tag{34}$$

If, furthermore, $[\ell, m] \subseteq [1, n]$, then $A_n^{opt} \cap [\ell, m] = A_{[\ell,m]}^{opt}$ (interpreting $\xi_0 = 0$ if $\ell = 1$).

(c) *If both $i, i+1 \in A^{opt}$, then $\xi_i \le 1$.*

(d) *If $\xi_i + \xi_{i+1} > 1$, then $i, i+1$ and $i+2$ together cannot belong to A^{opt}.*

(e) *Let $k \ge 2$. If $[g, g+2k-1]$ is an interval such that $\xi_g > \xi_{g+1} > \cdots > \xi_{g+2k-1} > \xi_{g+2k}$ and*

$$\xi_j + \xi_{j+1} > 1, \quad g \le j \le g + 2k - 2,$$

then $A^{opt} \cap [g, g+2k-1]$ must be one of the two complementary alternating sequences in $[g, g+2k-1]$.

Proof. (a) If $\xi_{i-1} + \xi_i \le 1$, then $X_i^L \ge 1 - \xi_{i-1} \ge \xi_i$, and hence from the Lemma 7 definition we see that for any possible value of X_{i+1}^R, we have $i \in A^{\rm opt}$.

(b) First note that both ℓ and m are in $A_{[\ell,m]}^{\rm opt}$; otherwise adding each element would increase $f_{[\ell,m]}(A_{[\ell,m]}^{\rm opt})$ by at least $1 - \xi_\ell$ and $1 - \xi_{m-1}$, respectively. Next note that by rewriting Lemma 5 (which concerns the special case $[\ell, m] = [1, n]$) for general $[\ell, m]$, we have a construction of $A_{[\ell,m]}^{\rm opt}$ in terms of processes $X_{[\ell,m],i}^L$ and $X_{[\ell,m],i}^R$ for $\ell \le i \le m$ defined by the recursions analogous to (21), (22). By (a) both ℓ and m are in $A^{\rm opt}$. We have now shown $X_{[\ell,m],\ell}^L = 1 - \xi_{\ell-1} = X_\ell^L$ and $X_{[\ell,m],m-1}^R = 1 - \xi_{m-1} = X_{m-1}^R$; because the restricted and unrestricted processes have the same boundary conditions and satisfy the same recursions over $[l, m]$ they must agree throughout the interval. Finally, because both endpoints ℓ and m are in $A_{[\ell,m]}^{\rm opt}$

it cannot fit the "complementary alternating sequences" criteria for nonuniqueness (Lemma 3). The same argument works for A_n^{opt}.

One could prove (c), (d), (e) algebraically from the definition of A^{opt}, but it is more intuitive to exploit the finite optimality criterion as follows. From assumption (8) there are infinitely many ℓ with $\xi_{\ell-1}+\xi_\ell \le 1$, and so for any given i there is a (random) long interval $[\ell, m]$ containing i for which by (b) $A^{\mathrm{opt}} \cap [\ell, m] = A^{\mathrm{opt}}_{[\ell,m]}$. In other words, the restriction of A^{opt} to $[\ell, m]$ is the solution of the finite optimization problem (32), and we can derive its properties by considering the effect of local changes. Now (c) and (d) follow from the following observations:

(for (c)): if $i, i+1$ are in A^{opt}, then removing $i+1$ will give a relative benefit of at least $\xi_i - 1$.

(for (d)): if $i, i+1, i+2$ are all in A^{opt}, then removing $i+1$ will give a relative benefit of $\xi_i + \xi_{i+1} - 1$.

For (e), consider $j \in [g, g+2k]$. By (d) we cannot have $\{j, j+1, j+2\} \subset A^{\mathrm{opt}}$. If j and $j+1$ but not $j+2$ are in A^{opt}, then deleting $j+1$ while adding $j+2$ would increase the benefit by at least $\xi_j - \xi_{j+2} > 0$, which is impossible. It follows that we cannot have $\{j, j+1\} \subset A^{\mathrm{opt}}$. Thus $A^{\mathrm{opt}} \cap [g, g+2k-1]$ contains only isolated elements. It is now easy to check that one can change $A^{\mathrm{opt}} \cap [g, g+2k-1]$ into one of the alternating sequences on $[g, g+2k-1]$ in such a way that the cardinality does not decrease, and the end items $g, g+2k-1$ change (if at all) only from included to excluded. Thus the change can only increase the benefit; appealing to the uniqueness property (b) in a larger interval establishes (e). □

3.2. Proof of upper bound. In this section we prove the bound

$$\limsup_{\delta \downarrow 0} \delta^{-2} \limsup_n \mathrm{E}\varepsilon_n(\delta) < \infty \tag{35}$$

via a simple construction of near-optimal sets. We first describe a particular configuration. Let $g, d \in \mathbb{Z}$ such that $d - g = 2k$ for some $k \ge 2$, and consider the sets A and B below:

	g	$-$	$(g+1)$	$-$							$(g+2k-1)$	$-$	$g+2k$
A	$\bullet$	$-$	$\circ$	$-$	$\bullet$	$-$	$\circ$	$\dots$	$\bullet$	$-$	$\circ$	$-$	$\bullet$
B	$\bullet$	$-$	$\bullet$	$-$	$\circ$	$-$	$\bullet$	$\dots$	$\circ$	$-$	$\bullet$	$-$	$\bullet$

where $|A \triangle B| = 2k-1$ and the difference between the benefits of A and B is

$$\begin{aligned} f_{[g,g+2k]}(A) - f_{[g,g+2k]}(B) &= (k+1) - ((k+2) - \xi_g - \xi_{g+2k-1}) \\ &= \xi_g + \xi_{g+2k-1} - 1. \end{aligned} \tag{36}$$

Now fix $k \ge 2$ and $\alpha > 0$ such that $\alpha k < 1/2$. Consider the event Ω_g defined by

$$\xi_g > \xi_{g+1} > \xi_{g+2} > \cdots > \xi_{g+2k-2} > \xi_{g+2k-1} > \tfrac{1}{2} > \xi_{g+2k};$$

$$\xi_{g-1} + \xi_g < 1; \quad \xi_{g+2k-1} + \xi_{g+2k} < 1.$$

By assumption (7) this event has nonzero probability. If this event occurs, Lemma 9(a) shows that A^{opt} contains g and $g+2k$, and then Lemma 9(e) implies that $A^{\mathrm{opt}} \cap [g, g+2k]$ is the set A above. By applying Lemma 9(b) to $[\ell, m] = [g, g+2k]$ we have the analogue in the finite n setting: if Ω_g occurs for $[g, g+2k] \subset [1, n]$, then

$A_n^{\text{opt}} \cap [g, g+2k]$ is the set A above. So if we change A_n^{opt} by replacing pattern A by pattern B on such an interval, then from (36) the decrease in benefit equals $\xi_g + \xi_{g+2k-1} - 1 > 0$. Now define

$$\Omega_g^{(\alpha)} = \Omega_g \cap \{1 < \xi_g + \xi_{g+2k-1} < 1 + 2k\alpha\},$$

$$q(\alpha) = \mathrm{P}(\Omega_g^{(\alpha)}),$$

$$r(\alpha) = \mathrm{E}(\xi_g + \xi_{g+2k-1} - 1)\mathbb{1}(\Omega_g^{(\alpha)})$$

so that $r(\alpha)$ is the unconditional mean increase in benefit from the possible change, now performed only if event $\Omega_g^{(\alpha)}$ happens. Using assumption (7) we see that $(\xi_g + \xi_{g+2k-1})$ restricted to $\Omega_g^{(\alpha)}$ has a continuous density which is nonzero at 1, which easily implies that for fixed k

$$q(\alpha) \sim \bar{q}\alpha, \quad r(\alpha) \sim \bar{r}\alpha^2 \text{ as } \alpha \downarrow 0 \tag{37}$$

for constants $\bar{q}, \bar{r} \in (0, \infty)$.

Given n and the optimal set A_n^{opt}, construct a near-optimal set $B_n^{(\alpha)}$ as follows. Let $g_1 = 1$ and let

$$[g_1, g_1 + 2k], \quad [g_2, g_2 + 2k], \quad [g_3, g_3 + 2k], \ldots, [g_{j_n}, g_{j_n} + 2k]$$

be the adjacent disjoint intervals in $[1, n]$ containing $2k + 1$ integers. For each such $g = g_j$, if event $\Omega_g^{(\alpha)}$ occurs, then on $[g, g + 2k]$ replace pattern A by pattern B.

Letting $n \to \infty$ and using the weak law of large numbers, we get

$$\tfrac{1}{n}|B_n^{(\alpha)} \triangle A_n^{\text{opt}}| \to 2kq(\alpha)/(2k+1) \text{ in probability,}$$

$$\tfrac{1}{n}(f_n(A_n^{\text{opt}}) - f_n(B_n^{(\alpha)})) \to r(\alpha)/(2k+1) \text{ in probability.}$$

If $\frac{1}{n}|B_n^{(\alpha)} \triangle A_n^{\text{opt}}| \le kq(\alpha)/(2k+1)$, then redefine $B_n^{(\alpha)}$ to be the empty set. Then (taking $k = 3$ for concreteness)

$$\tfrac{1}{n}|B_n^{(\alpha)} \triangle A_n^{\text{opt}}| \ge 3q(\alpha)/7,$$

$$\lim_n \tfrac{1}{n}(\mathrm{E}f_n(A_n^{\text{opt}}) - \mathrm{E}f_n(B_n^{(\alpha)})) = r(\alpha)/7.$$

The upper bound (35) now follows from the $\alpha \to 0$ asymptotics (37).

4. Proof of Theorem 2: The lower bound.

4.1. Analysis of near-optimal solutions: The quintuple process. Throughout section 4 we fix a constant $\tau > 0$ such that

$$G\left(\tfrac{1}{2} - \tau\right) > 0. \tag{38}$$

Such a constant exists by assumption (7). To study near-optimal solutions, fix a Lagrange multiplier θ such that

$$0 < \theta < \tau. \tag{39}$$

We will derive the existence of, and derive an exact expression for, the function $\bar{\varepsilon}(\delta) = \lim_n \mathrm{E}\varepsilon_n(\delta)$ when δ is sufficiently small. The expression is an implicit function

representation $\bar{\varepsilon}(\delta(\theta)) = \varepsilon(\theta)$ via two functions $\varepsilon(\theta), \delta(\theta)$ defined (49), (50) in terms of the stationary distribution of a certain *quintuple process*.

We study the modified optimization problem in which we get an extra reward θ for choosing an item which is not in A_n^{opt} or for not choosing an item which is in A_n^{opt}:

$$\max_{A\subseteq[n]} \left(|A| - \sum_{i=1}^{n} \xi_i \mathbb{1}(i \in A, i+1 \in A) + \theta |A \triangle A_n^{\mathrm{opt}}| \right). \tag{40}$$

To study this we modify (13), (14) to

$$\widetilde{V}_{n,i}^L = \max_{i\in A\subseteq\{1,2,\ldots,i\}} \left(|A| - \sum_{j=1}^{i-1} \xi_j \mathbb{1}(j, j+1 \in A) + \theta \, |(A \triangle A_n^{\mathrm{opt}}) \cap \{1,2,\ldots,i\}| \right), \tag{41}$$

$$\widetilde{W}_{n,i}^L = \max_{i\notin A\subseteq\{1,2,\ldots,i\}} \left(|A| - \sum_{j=1}^{i-1} \xi_j \mathbb{1}(j, j+1 \in A) + \theta \, |(A \triangle A_n^{\mathrm{opt}}) \cap \{1,2,\ldots,i\}| \right). \tag{42}$$

We also define $\widetilde{M}_n = \max(\widetilde{V}_{n,n}^L, \widetilde{W}_{n,n}^L)$ and write B_n^{opt} for the corresponding optimizing set. Note that these quantities depend on θ. Analogous to the definition (15) of $X_{n,i}^L$ we define

$$Z_{n,i}^L := \widetilde{V}_{n,i}^L - \widetilde{W}_{n,i}^L.$$

Then as the analogue of (16) we can obtain the recursion

$$Z_{n,i+1}^L = 1 - \min(Z_{n,i}^L, \xi_i)\mathbb{1}(Z_{n,i}^L > 0) + \theta J_{n,i+1},$$

where

$$Z_{n,1}^L = 1 + \theta J_{n,1},$$

$$J_{n,i} = \mathbb{1}(i \notin A_n^{\mathrm{opt}}) - \mathbb{1}(i \in A_n^{\mathrm{opt}}).$$

Recall from section 2.3 the stationary triple process $((X_i^L, \xi_i, X_{i+1}^R), -\infty < i < \infty)$ and define

$$J_i = \mathbb{1}(i \notin A^{\mathrm{opt}}) - \mathbb{1}(i \in A^{\mathrm{opt}}).$$

Just as the stationary triple process is interpretable (Lemma 8) as an $n \to \infty$ limit of the process $(X_{n,i}^L, \xi_i, X_{n,i+1}^R)$, we want to define a process which will be the limit of $(Z_{n,i}^L, X_{n,i}^L, \xi_i, X_{n,i+1}^R)$. So define a *quadruple process* $(Z_i^L, X_i^L, \xi_i, X_{i+1}^R)$ to be a process such that

(i) $(X_i^L, \xi_i, X_{i+1}^R)$ evolves as the triple process,

(ii) Z_i^L satisfies the recursion

$$Z_{i+1}^L = 1 - \min(Z_i^L, \xi_i)\mathbb{1}(Z_i^L > 0) + \theta J_{i+1}. \tag{43}$$

Recall $0 < \theta < \tau$.

LEMMA 10. *The quadruple process* $((Z_i^L, X_i^L, \xi_i, X_{i+1}^R), -\infty < i < \infty)$ *has a unique stationary distribution, for which*

$$Z_i^L = \psi(\dots, \xi_{i-2}, \xi_{i-1}, \xi_i, X_{i+1}^R) \tag{44}$$

for a certain function ψ *not depending on* i. *On the event* $\{\xi_{i-1} + \xi_i \le 1 - \tau\}$, *we have*

$$X_{i+1}^L = 1 - \xi_i, Z_{i+1}^L = 1 - \xi_i + \theta J_{i+1}. \tag{45}$$

Proof. Recursion (43) implies $Z_{i+1}^L \ge 1 - \xi_i + \theta J_{i+1}$. Thus iterating once (43) and using this last inequality, we obtain

$$1 - \xi_i + \theta J_{i+1} \le Z_{i+1}^L \le 1 - \min(1 - \xi_{i-1} + \theta J_i, \xi_i)\mathbb{1}(1 - \xi_{i-1} + \theta J_i > 0) + \theta J_{i+1}.$$

Thus, on the event $\{\xi_{i-1} + \xi_i \le 1 - \theta\}$ we have $Z_{i+1}^L = 1 - \xi_i + \theta J_{i+1}$ and also, by (27), we have $X_{i+1}^L = 1 - \xi_i$, establishing (45). Assumption (7) implies that the event $\{\xi_{i-1} + \xi_i \le 1 - \tau\}$ occurs for infinitely many $i < 0$, so in particular $K := \max\{i < 0 : \xi_{i-1} + \xi_i \le 1 - \tau\}$ is finite. By the recursion (43) we can write Z_0^L in the form

$$Z_0^L = \psi^1(\xi_{K+1}, \xi_{K+2}, \dots, \xi_{-1}; Z_{K+1}^L; J_{K+2}, J_{K+3}, \dots, J_0)$$

for some function ψ^1. Then by (45) with $Z_i^L = Z_{K+1}^L$ we can rewrite as

$$Z_0^L = \psi^2(\xi_K, \xi_{K+1}, \xi_{K+2}, \dots, \xi_{-1}; J_{K+1}, J_{K+2}, J_{K+3}, \dots, J_0).$$

By the definition of A^{opt}, each J_i is a function of X_i^L, ξ_i, X_{i+1}^R, and then from the recursions for X_i^L and X_i^R

$$Z_0^L = \psi^3(\xi_K, \xi_{K+1}, \xi_{K+2}, \dots, \xi_0; X_{K+1}^L, X_1^R).$$

By (45) with $X_i^L = X_{K+1}^L$ this is of the form

$$Z_0^L = \psi(\dots, \xi_{-2}, \xi_{-1}, \xi_0, X_1^R).$$

Now (44) defines a stationary version of the quadruple process. □

Just as $X_{n,i}^R$ was the "looking right" analogue of the "looking left" process $X_{n,i}^L$, we can define a "looking right" process $Z_{n,i}^R$ analogous to $Z_{n,i}^L$ as follows. Define

$$\widetilde{V}_{n,i}^R = \max_{i \in A \subseteq \{i, i+1, \dots, n\}} \left(|A| - \sum_{j=i}^{n-1} \xi_j \mathbb{1}(j, j+1 \in A) + \theta \, |(A \triangle A^{\text{opt}}) \cap \{i, i+1, \dots, n\}| \right), \tag{46}$$

$$\widetilde{W}_{n,i}^R = \max_{i \notin A \subseteq \{i, i+1, \dots, n\}} \left(|A| - \sum_{j=i}^{n-1} \xi_j \mathbb{1}(j, j+1 \in A) + \theta \, |(A \triangle A^{\text{opt}}) \cap \{i, i+1, \dots, n\}| \right). \tag{47}$$

Then the difference $Z_{n,i}^R = \widetilde{V}_{n,i}^R - \widetilde{W}_{n,i}^R$ satisfies the recursion

$$Z_{n,i}^R = 1 - \min(Z_{n,i+1}^R, \xi_i)\mathbb{1}(Z_{n,i+1}^R > 0) + \theta J_{n,i}; \quad Z_{n,n}^R = 1 + \theta J_{n,n}.$$

TABLE 3
Inclusion criteria for $i, i+1$ in B_n^{opt}.

$-i-(i+1)-$	Absolute benefit	Relative benefit	When used
$-\bullet--\bullet-$	$\widetilde{V}^L + \widetilde{V}^R - \xi$ $+\theta(\mathbb{1}_{i\notin A^{\rm opt}} + \mathbb{1}_{i+1\notin A^{\rm opt}})$	$Z^L + Z^R - \xi$ $-\theta(J_i + J_{i+1})$	$\xi < \min(Z^L - \theta J_i,$ $Z^R - \theta J_{i+1})$
$-\bullet--\circ-$	$\widetilde{V}^L + \widetilde{W}^R$ $+\theta(\mathbb{1}_{i\notin A^{\rm opt}} + \mathbb{1}_{i+1\in A^{\rm opt}})$	$Z^L - \theta J_i$	$(Z^R - \theta J_{i+1})^+$ $< \min(Z^L - \theta J_i, \xi)$
$-\circ--\bullet-$	$\widetilde{W}^L + \widetilde{V}^R$ $+\theta(\mathbb{1}_{i\in A^{\rm opt}} + \mathbb{1}_{i+1\notin A^{\rm opt}})$	$Z^R - \theta J_{i+1}$	$(Z^L - \theta J_i)^+$ $< \min(Z^R - \theta J_{i+1}, \xi)$
$-\circ--\circ-$	$\widetilde{W}^L + \widetilde{W}^R$ $+\theta(\mathbb{1}_{i\in A^{\rm opt}} + \mathbb{1}_{i+1\in A^{\rm opt}})$	0	otherwise

Recall that $B_n^{\rm opt}$ attains $\max_{A\subseteq\{1,\dots,n\}}(|A| - \sum_{i=1}^{n-1}\xi_i \mathbb{1}(i\in A, i+1\in A) + \theta|A \triangle A_n^{\rm opt}|)$. As in section 2.2, we can write down the benefits of each of the four possible choices for including or excluding items i and $i+1$, and thereby obtain criteria for which combination is used in $B_n^{\rm opt}$. See Table 3, in which $(Z_{n,i}^L, \xi_i, Z_{n,i+1}^R)$ is abbreviated to (Z^L, ξ, Z^R) and the n subscript is dropped. It should now be clear that the stationary quadruple process can be extended to a *stationary quintuple process*

$$(Z_i^L, X_i^L, \xi_i, X_{i+1}^R, Z_{i+1}^R), \quad -\infty < i < \infty,$$

in which Z^R satisfies the recursion

$$Z_i^R = 1 - \min(Z_{i+1}^R, \xi_i)\mathbb{1}(Z_{i+1}^R > 0) + \theta J_i, \quad -\infty < i < \infty,$$

satisfied by $Z_{n,i}^R$. By "reflection symmetry" between Z^R and Z^L, the functional relationship (44) holds for Z^R in reflected form with the same function ψ:

$$Z_i^R = \psi(\dots, \xi_{i+1}, \xi_i, \xi_{i-1}, X_{i-1}^L). \tag{48}$$

We can now use the stationary quintuple process to define a random subset $B^{\rm opt} \subset \mathbb{Z}$ by specifying that, for each pair $(i, i+1)$, we use the one of the four choices which has the largest relative benefit in Table 3. Analogously to Lemma 7 one can check that this definition is consistent. The local weak convergence property (Lemma 8) extends to the present setting as follows.

LEMMA 11. *Let U_n be uniform on $\{1,\dots,n\}$. As $n\to\infty$*

$$\begin{aligned}&((Z_{n,U_n+i}^L, X_{n,U_n+i}^L, \xi_{U_n+i}, X_{n,U_n+i+1}^R, Z_{n,U_n+i+1}^R,\\ &\qquad \mathbb{1}(U_n+i\in A_n^{opt}), \mathbb{1}(U_n+i\in B_n^{opt})))_{-\infty<i<\infty}\\ &\xrightarrow{d} ((Z_i^L, X_i^L, \xi_i, X_{i+1}^R, Z_{i+1}^R, \mathbb{1}(i\in A^{opt}), \mathbb{1}(i\in B^{opt})))_{-\infty<i<\infty}.\end{aligned}$$

Proof. The proof repeats the proof of Lemma 8, using (44), (48) to incorporate the (Z^L, Z^R) terms. In order to incorporate the $B^{\rm opt}$ component, we need to check that the function $\mathbb{1}(0\in B^{\rm opt})$ is a.s. continuous with respect to the stationary distribution of $(Z_0^L, X_0^L, \xi_0, X_1^R, Z_1^R)$. From Table 3, we get that $\{0\in B^{\rm opt}\} = \{Z_0^L - \theta J_0 > \min(\xi_0, \max(Z_1^R - \theta J_1, 0)\}$. Hence, it requires that the probability of an equality between some of two $Z_0^L - \theta J_0, \xi_0, Z_1^R - \theta J_1$ is zero. We check only that $\mathrm{P}(Z_0^L - \theta J_0 = \xi_0) = 0$. The recursion satisfied by Z_0^L reads $Z_0^L - \theta J_0 =$

$1 - \min(Z_{-1}^L, \xi_{-1})\mathbb{1}(Z_{-1}^L > 0)$. Thus, arguing as in the proof of Lemma 10, $Z_0^L - \theta J_0$ is a function of $(Z_{K+1}^L, \xi_{K+1}, \ldots, \xi_{-1}, J_{K+1}, J_{K+2}, \ldots, J_{-1})$ with $K = \max\{i < 0 : \xi_{i-1} + \xi_i \le 1 - \tau\}$. Since $Z_{K+1}^L = 1 - \xi_K + \theta J_{K+1}$ and $J_i \in \{-1, 1\}$, we deduce by recursion that there exists a pair of integers (i_0, n) with $K \le i_0 \le -1$ and $-K \le n \le K$ such that $Z_0^L \in \{1 - \xi_{i_0} + n\theta, \xi_{i_0} + n\theta\}$. The independence of ξ_i and ξ_0 for $i < 0$ and assumption (7) imply that $\mathrm{P}(Z_0^L - \theta J_0 = \xi_0) = 0$. □

Now define

$$\delta(\theta) = \mathrm{P}(\{0 \in A^{\mathrm{opt}}\} \triangle \{0 \in B^{\mathrm{opt}}\}), \tag{49}$$

$$\begin{aligned}\varepsilon(\theta) = {} & \mathrm{P}(0 \in A^{\mathrm{opt}}) - \mathrm{E}\xi_0 \mathbb{1}(0 \in A^{\mathrm{opt}}, 1 \in A^{\mathrm{opt}}) - \mathrm{P}(0 \in B^{\mathrm{opt}}) \\ & + \mathrm{E}\xi_0 \mathbb{1}(0 \in B^{\mathrm{opt}}, 1 \in B^{\mathrm{opt}}).\end{aligned} \tag{50}$$

So $\delta(\theta)$ is the proportion of items at which A^{opt} and B^{opt} differ, and $\varepsilon(\theta)$ is the difference in mean benefit per item between A^{opt} and B^{opt}. By Lemma 11,

$$\begin{aligned}\frac{1}{n}\mathrm{E}|A_n^{\mathrm{opt}} \triangle B_n^{\mathrm{opt}}| &= \mathrm{E}|\mathbb{1}(U_n \in A_n^{\mathrm{opt}}) - \mathbb{1}(U_n \in B_n^{\mathrm{opt}})| \\ &\to \mathrm{P}(\{0 \in A^{\mathrm{opt}}\} \triangle \{0 \in B^{\mathrm{opt}}\}) = \delta(\theta),\end{aligned} \tag{51}$$

and similarly the mean benefits satisfy

$$n^{-1}(\mathrm{E}f_n(A_n^{\mathrm{opt}})) - \mathrm{E}f_n(B_n^{\mathrm{opt}})) \to \varepsilon(\theta). \tag{52}$$

PROPOSITION 12. *Let $\widetilde{M}_n = f_n(B_n^{opt})$ be the benefit associated with B_n^{opt}; then a.s. and in L^1*

$$\lim_{n\to\infty} n^{-1}|B_n^{opt} \triangle A_n^{opt}| = \delta(\theta), \tag{53}$$

$$\lim_{n\to\infty} n^{-1}(M_n - \widetilde{M}_n) = \varepsilon(\theta). \tag{54}$$

Moreover for any choice B_n' satisfying (53) *in L^1, the associated benefit $M_n' = f_n(B_n')$ satisfies*

$$\liminf_n n^{-1}\mathrm{E}(M_n - M_n') \ge \varepsilon(\theta).$$

Proof. The convergence assertions (53), (54) follow from (51), (52) and the same concentration argument used in the proof of Theorem 1; we will not repeat the details. By construction, for any B_n' the associated reward M_n' satisfies

$$M_n' + \theta|B_n' \triangle A_n^{\mathrm{opt}}| \le \widetilde{M}_n + \theta|B_n^{\mathrm{opt}} \triangle A_n^{\mathrm{opt}}|.$$

Then because both (B_n^{opt}) and (B_n') satisfy (53), we see that

$$\mathrm{E}M_n' \le \mathrm{E}\widetilde{M}_n + o(n). \qquad \square$$

Discussion. For $0 < \theta < \tau$ and for $\delta = \delta(\theta)$, Proposition 12 implies that the limit $\bar{\varepsilon}(\delta) = \lim_n \mathrm{E}\varepsilon_n(\delta)$ exists and that

$$\bar{\varepsilon}(\delta(\theta)) = \varepsilon(\theta).$$

So to prove Theorem 2 it should be enough to prove

$$\delta(\theta) \sim \alpha\theta, \quad \varepsilon(\theta) \sim \beta\theta^2 \text{ as } \theta \to 0 \tag{55}$$

for positive constants α, β. Now the definitions (49), (50) enable us to rewrite (using Table 3) $\delta(\theta)$ and $\varepsilon(\theta)$ in terms of the stationary distribution $(Z_0^L, X_0^L, \xi_0, X_1^R, Z_1^R)$ of the quintuple process, as

$$\delta(\theta) = \mathrm{P}\left(\{X_0^L > \min(X_1^R, \xi_0)\} \triangle \{Z_0^L - \theta J_0 > \min((Z_1^R - \theta J_1)^+, \xi_0)\}\right), \tag{56}$$

$$\begin{aligned}\varepsilon(\theta) = {} & \mathrm{P}(X_0^L > \min(X_1^R, \xi_0)) - \mathrm{P}(Z_0^L - \theta J_0 > \min((Z_1^R - \theta J_1)^+, \xi_0)) \\ & - \mathrm{E}\xi_0\left(\mathbb{1}(\xi_0 < \min(X_0^L, X_1^R)) - \mathbb{1}(\xi_0 < \min(Z_0^L - \theta J_0, Z_1^R - \theta J_1))\right).\end{aligned}$$

So if we had an explicit formula for the stationary distribution $(Z_0^L, X_0^L, \xi_0, X_1^R, Z_1^R)$, then we could derive an explicit formula for $\delta(\theta)$ and $\varepsilon(\theta)$ and seek to prove (55) by calculus. But we do not have such an explicit formula—note the independence property (30) of the triple process does not hold for the quintuple process—and we have not completely succeeded in that program. We could prove the $\delta(\theta) \sim \alpha\theta$ part of (55), though we use only the weaker upper bound, proved by a simpler argument in section 4.2. To handle $\varepsilon(\theta)$ we show how to rewrite $\delta(\theta)$ and $\varepsilon(\theta)$ in a different way (Proposition 18) that allows us to derive inequalities, which will establish the stated form of Theorem 2.

4.2. Existence of the limit function $\bar{\varepsilon}(\delta)$. There is a minor technical point we deal with first. We expect intuitively that the function $\delta(\theta)$ should be continuous monotone, but neither property is obvious. If there were small values of δ which were not of the form $\delta = \delta(\theta)$ for some θ, then we cannot use Proposition 12 to establish existence of a limit $\bar{\varepsilon}(\delta)$. Instead we outline an argument (reusing previous methods) to prove more abstractly (Lemma 13) that the limit $\bar{\varepsilon}(\delta)$ always exists. We could have started the proof of Theorem 2 this way, but we wanted to emphasize the Lagrange multiplier approach as more useful for calculation.

LEMMA 13. *$\bar{\varepsilon}(\delta) := \lim_n \mathrm{E}\varepsilon_n(\delta)$ exists for each $0 < \delta < 1$.*

Note that $\varepsilon_n(\delta)$ is a priori nondecreasing in δ, and hence $\bar{\varepsilon}(\cdot)$ is nondecreasing.

Outline proof. Fix $0 < \delta < 1$. Let $B_n^{(\delta)}$ attain the minimum in the definition (9) of $\varepsilon_n(\delta)$. Set $\bar{\varepsilon}_*(\delta) = \liminf_n \mathrm{E}\varepsilon_n(\delta)$. There exists a subsequence (of the subsequence of n attaining the liminf) in which the local weak convergence (Lemma 8) of A_n^{opt} to A^{opt} extends to joint convergence of $B_n^{(\delta)}$ to some limit random set $B^{(\delta)}$. The analogues of (49), (50) with $B^{(\delta)}$ in place of B^{opt} equal δ and $\bar{\varepsilon}_*(\delta)$. For arbitrary n, start with the restriction (B_n^*, say) of $B^{(\delta)}$ to $[1, n]$ and then show that by modifying B_n^* near the endpoints we can construct B_n^{**} satisfying $|B_n^{**} \triangle A_n^{\mathrm{opt}}| \geq \delta n$ and $\mathrm{E}[n^{-1}(f_n(A_n^{\mathrm{opt}}) - f_n(B_n^{**}))] \to \bar{\varepsilon}_*(\delta)$. □

The following lemma (to be proved in section 4.4) allows us to complete the proof of Theorem 2.

LEMMA 14. *There exist positive constants C_1, C_2 such that, for all $0 < \theta < \tau$,*

$$\delta(\theta) \leq C_1\theta, \tag{57}$$

$$\varepsilon(\theta) \geq C_2\theta^2. \tag{58}$$

We now finish the proof of Theorem 2. Recall that Proposition 12 showed $\bar{\varepsilon}(\delta(\theta)) = \varepsilon(\theta)$, and that (Lemma 13) $\bar{\varepsilon}(\cdot)$ is a nondecreasing function. Using (57)

$$\bar{\varepsilon}(C_1\theta) \geq \bar{\varepsilon}(\delta(\theta)) = \varepsilon(\theta) \geq C_2\theta^2,$$

and setting $\delta = C_1\theta$ gives $\bar{\varepsilon}(\delta) \geq C_2\delta^2/C_1^2$. This establishes the lower bound (11) and completes the proof of Theorem 2.

4.3. A cycle formula representation.

LEMMA 15. *If $\xi_{i-1} + \xi_i < 1 - \tau$, then $i \in A^{opt}$ and $i \in B^{opt}$.*

Proof. Suppose $\xi_{i-1} + \xi_i < 1 - \tau$. Lemma 9(a) showed $i \in A^{\mathrm{opt}}$. Recall that B_n^{opt} maximizes (40). If $i \notin A$, then the increase in the benefit at (40) obtained by including i is at least $1 - \xi_i - \xi_{i-1} - \theta$, so by our standing assumption (39) the increase is positive, and so $i \in B_n^{\mathrm{opt}}$. Letting $n \to \infty$ and using Lemma 11 gives the same conclusion for B^{opt}. □

We next need a lemma (analogous to Lemma 9(b)) giving conditions under which we can "localize" A^{opt} and B^{opt} by forcing them to coincide with the optimal sets A_n^{opt} and B_n^{opt} for the optimization problem on $[1, n]$ for suitable n, which we now write as $t - 1$.

LEMMA 16. *Let $t \geq 2$. Suppose $\xi_{i-1} + \xi_i < 1 - \tau$ for each of $i = 0, 1, t-1, t$. Then the following hold:*

(a) *A^{opt} and B^{opt} contain $\{0, 1, t-1, t\}$.*

(b) *The restrictions of A^{opt} and B^{opt} to $[1, t-1]$ coincide with A_{t-1}^{opt} and B_{t-1}^{opt}.*

(c) *For any $B \subseteq \{1, 2, \ldots, t-1\}$, either $B = A_{t-1}^{opt}$ or $f_{t-1}(B) < f_{t-1}(A_{t-1}^{opt})$.*

(d) *In particular, either $A_{t-1}^{opt} = B_{t-1}^{opt}$ or $f_{t-1}(A_{t-1}^{opt}) > f_{t-1}(B_{t-1}^{opt})$.*

Proof. (a) follows from Lemma 15. Observe that A_{t-1}^{opt} and B_{t-1}^{opt} contain 1 and $t - 1$, because $\xi_1 < 1 - \tau$ and $\xi_{t-2} < 1 - \tau$. If we consider the solutions $A_{[\ell,m]}^{\mathrm{opt}}$, $B_{[\ell,m]}^{\mathrm{opt}}$ for some interval $[\ell, m]$ strictly containing $[0, t]$, then they contain 1 and $t - 1$ by the argument for Lemma 15. Thus by optimality the restrictions of $A_{[\ell,m]}^{\mathrm{opt}}$ and $B_{[\ell,m]}^{\mathrm{opt}}$ to $[1, t-1]$ must coincide with A_{t-1}^{opt} and B_{t-1}^{opt}. So (b) follows from weak convergence, Lemma 11. And (c) follows from the uniqueness result, Lemma 3. □

We start by quoting a standard form (cf. [8, Exercise 6.3.4]) of Kac's identity for stationary processes.

LEMMA 17. *Let $(\Xi_i, -\infty < i < \infty)$ be a stationary ergodic sequence on some state space, let $\mathrm{P}(\Xi_1 \in \bar{D}) > 0$, and let $h(\Xi_1)$ be real-valued and integrable. For any $t_0 \geq 1$, define $T = t_0 \min\{i \geq 2 : \Xi_{it_0} \in \bar{D})$. Then*

$$\mathrm{E}h(\Xi_1) = \mathrm{E}\left[\mathbb{1}(\Xi_1 \in \bar{D}) \sum_{i=1}^{T-1} h(\Xi_i)\right].$$

We apply this to $\Xi_i = (Z_i^L, X_i^L, \xi_i, \xi_{i-1}, \xi_{i-2}, X_{i+1}^R, Z_{i+1}^R)$, $t_0 = 3$, and

$$D := \{\xi_{-1} + \xi_0 < 1 - \tau,\ \xi_0 + \xi_1 < 1 - \tau\} = \{\Xi_1 \in \bar{D}\} \tag{59}$$

for suitable $\bar{D}$, making the T in Lemma 17 be

$$T = 3\min\{t \geq 2 : \xi_{3t-2} + \xi_{3t-1} < 1 - \tau,\ \xi_{3t-1} + \xi_{3t} < 1 - \tau\}. \tag{60}$$

Now definition (49) says $\delta(\theta) = \mathrm{E}h(\Xi_0)$ for

$$h(\Xi_0) = \mathbb{1}(\{0 \in A^{\mathrm{opt}}\} \triangle \{0 \in B^{\mathrm{opt}}\}).$$

So $\sum_{i=1}^{T-1} h(\Xi_i)$ equals the cardinality of $A^{\mathrm{opt}} \triangle B^{\mathrm{opt}}$ restricted to $[1, T-1]$. On the event D, Lemma 16 identifies this restriction as $A^{\mathrm{opt}}_{T-1} \triangle B^{\mathrm{opt}}_{T-1}$, so Kac's identity gives (61) below. Similarly, definition (50) says $\varepsilon(\theta) = \mathrm{E}h(\Xi_0)$ for

$$h(\Xi_0) = \mathbb{1}(0 \in A^{\mathrm{opt}}) - \xi_0 \mathbb{1}(0 \in A^{\mathrm{opt}}, 1 \in A^{\mathrm{opt}}) - \mathbb{1}(0 \in B^{\mathrm{opt}}) + \xi_0 \mathbb{1}(0 \in B^{\mathrm{opt}}, 1 \in B^{\mathrm{opt}}),$$

and on the event D the sum $\sum_{i=1}^{T-1} h(\Xi_i)$ equals the difference $f_{T-1}(A^{\mathrm{opt}}_{T-1}) - f_{T-1}(B^{\mathrm{opt}}_{T-1})$ between the benefits. This establishes (62), and the final assertion (63) follows from Lemma 16(d). To summarize:

PROPOSITION 18. *Let D be the event* (59) *and let T be the random time* (60). *Then*

$$\delta(\theta) = \mathrm{E}[\mathbb{1}_D \times |A^{opt}_{T-1} \triangle B^{opt}_{T-1}|], \tag{61}$$

$$\varepsilon(\theta) = \mathrm{E}[\mathbb{1}_D \times (f_{T-1}(A^{opt}_{T-1}) - f_{T-1}(B^{opt}_{T-1}))], \tag{62}$$

$$\text{on } D, \text{ either } A^{opt}_{T-1} = B^{opt}_{T-1} \text{ or } f_{T-1}(A^{opt}_{T-1}) - f_{T-1}(B^{opt}_{T-1}) > 0. \tag{63}$$

4.4. An integration lemma. Let us rewrite the difference in (62) as

$$W(\theta) := f_{T-1}(A^{\mathrm{opt}}_{T-1}) - f_{T-1}(B^{\mathrm{opt}}_{T-1})$$

to emphasize its dependence on θ; and note D does not depend on θ. The key ingredient in the proof of the lower bound is the following lemma, to be proved in section 4.5.

LEMMA 19. *There exists $C_3 > 0$ such that for all $0 < \theta < \tau$, for all $k \geq 0$, and $x > 0$,*

$$\mathrm{P}(T \geq k,\ 0 < \mathbb{1}_D W(\theta) < x) \leq C_3 x (k+1) \mathrm{P}(T \geq k).$$

Taking $k = 0$ in this lemma we get

$$\mathrm{P}(0 < \mathbb{1}_D W(\theta) < x) \leq C_3 x. \tag{64}$$

Recall a simple integration lemma (for a more general result see [2, Lemma 6(a)]).

LEMMA 20. *Let $V \geq 0$ be a real-valued random variable such that*

$$\mathrm{P}(0 < V < x) \leq Cx, \quad 0 < x < \infty.$$

Then

$$\mathrm{E}V \geq \frac{[\mathrm{P}(V > 0)]^2}{2C}.$$

By (64) and Lemma 20, we get

$$\begin{aligned} \varepsilon(\theta) &= \mathrm{E}(\mathbb{1}_D W(\theta)) \text{ by (62)} \\ &\geq \frac{[\mathrm{P}(W(\theta)\mathbb{1}_D > 0)]^2}{2C_3}. \end{aligned} \tag{65}$$

To finish the proof of (58), we need the following lemma.

LEMMA 21. *There exists a positive constant C_4 such that, for all $0 < \theta < \tau$,*

$$\mathrm{P}(W(\theta)\mathbb{1}_D > 0) \geq C_4\theta. \tag{66}$$

Proof. By assumption (7) we may assume that the constant τ at (38) is such that

$$\inf_{1/2-2\tau<x<1/2\tau} g(x) > 0, \tag{67}$$

where g is the density function for ξ_i. Consider the following event:

$$\Omega(\theta) = \{\xi_{-1} \in (0, 1/2),\ \xi_0 \in (0, 1/2-\tau),\ \xi_1 \in (1/2-\tau, 1/2),$$
$$\xi_2 \in (1-\xi_1-\theta, 1-\xi_1),\ \xi_3 \in (0, 1/2-2\tau)\}.$$

Using (67) there exists $C_4 > 0$ such that

$$\mathrm{P}(\Omega(\theta)) \geq C_4\theta.$$

Assume this event $\Omega(\theta)$ happens. Then $\xi_{-1}+\xi_0 \leq 1-\tau$, $\xi_0+\xi_1 \leq 1-\tau$, $1-\theta < \xi_1+\xi_2 < 1$, and $\xi_2+\xi_3 \leq 1-\tau$. So D happens and, using Lemma 9(a), we have $\{1,2,3\} \in A^{\mathrm{opt}}$, and by Lemma 16(b) the same holds true for A^{opt}_{T-1}. Still assuming $\Omega(\theta)$ occurs, we see that for $B = A^{\mathrm{opt}}_{T-1}\backslash\{2\}$, we have $f_{T-1}(A^{\mathrm{opt}}_{T-1}) - f_{T-1}(B) = 1-\xi_1-\xi_2 \in (0,\theta)$ and therefore $f_{T-1}(B) + \theta|A^{\mathrm{opt}}_{T-1} \triangle B| > f_{T-1}(A^{\mathrm{opt}}_{T-1})$, implying $0 < W(\theta)$ by (63). In particular

$$\mathrm{P}(W(\theta)\mathbb{1}_D > 0) \geq \mathrm{P}(\Omega(\theta)) \geq C_4\theta,$$

and we have proved assertion (66). □

From (65) and (66), we directly get the second assertion (58) of Lemma 14. We now show how to obtain the first assertion of Lemma 14. Recall that, by definition, we have

$$f_{T-1}(B^{\mathrm{opt}}_{T-1}) + \theta|A^{\mathrm{opt}}_{T-1} \triangle B^{\mathrm{opt}}_{T-1}| \geq f_{T-1}(A^{\mathrm{opt}}_{T-1});$$

hence we get $\theta T > \theta|A^{\mathrm{opt}}_{T-1} \triangle B^{\mathrm{opt}}_{T-1}| \geq W(\theta)$. In particular, by Proposition 18, we have $D \cap \{W(\theta) > 0\} \subset D \cap \{\theta T > W(\theta) > 0\}$. Also, by Lemma 19, we have

$$\begin{aligned}
\delta(\theta) &\leq \mathrm{E}[T\mathbb{1}_D\mathbb{1}(W(\theta) > 0)] \text{ by (61)} \\
&\leq \sum_j j\mathrm{P}(T \geq j, \theta j > W(\theta) > 0) \\
&\leq C_3\theta \sum_j j^2(j+1)\mathrm{P}(T \geq j) \\
&\leq C_3\theta\mathrm{E}[(T+1)^4],
\end{aligned}$$

and $T/3$ has a geometric distribution so that assertion (57) of Lemma 14 follows.

4.5. Proof of Lemma 19. Write $W = W(\theta)$. Consider the random collection

$$\mathcal{B}(T-1) := \{B \subseteq \{1,2,\dots,T-1\} :\ B \neq A^{\mathrm{opt}}_{T-1}, 1 \in B, T-1 \in B\}.$$

By Proposition 18

$$\text{on } D, \text{ either } W = 0 \text{ or } W \geq \min_{B \in \mathcal{B}(T-1)} (f_{T-1}(A^{\mathrm{opt}}_{T-1}) - f_{T-1}(B)) > 0. \tag{68}$$

Our first goal is to derive a lower bound (Lemma 24) for the right-hand side of (68) in terms of the ξ_i's. Until the end of the proof of Lemma 24, we are working on the event D.

Let $C = \arg\min_{B \in \mathcal{B}(T-1)} (f_{T-1}(A^{\mathrm{opt}}_{T-1}) - f_{T-1}(B))$ be the optimal perturbation of A^{opt} on $[1, T-1]$. For any subinterval $\mathcal{I} = [\ell, m] \subseteq [1, T-1]$ write $\mathcal{I}_e = [\max(\ell - 1, 1), \min(m+1, T-1)]$. Decompose $A^{\mathrm{opt}} \triangle C$ as $\cup_i \mathcal{I}_i$, where the $\mathcal{I}_i$'s are disjoint maximal intervals of $A^{\mathrm{opt}} \triangle C$. Then

$$\begin{aligned} f_{T-1}(A^{\mathrm{opt}}) - f_{T-1}(C) &= \sum_i \left(f_{(\mathcal{I}_i)_e}(A^{\mathrm{opt}} \cap (\mathcal{I}_i)_e) - f_{(\mathcal{I}_i)_e}(C \cap (\mathcal{I}_i)_e) \right) \\ &= \sum_i \left(f_{T-1}(A^{\mathrm{opt}}_{T-1}) - f_{T-1}(C_i) \right), \end{aligned}$$

where $C_i = (A^{\mathrm{opt}}_{T-1} \cap \mathcal{I}_i{}^c) \cup (C \cap (\mathcal{I}_i)_e)$. This implies that $A^{\mathrm{opt}} \triangle C$ is a *single* subinterval $\mathcal{I}$ of $[1, T-1]$.

We now look at the possible perturbations of A^{opt} on the interval $[0, T]$. Recall that we are working on the event D, and that A^{opt} contains $0, 1, T-1, T$. Let $L_0, L_1, \dots, L_K$ be the maximal subintervals $[a, b] \subseteq A^{\mathrm{opt}} \cap [0, T]$ for which $b > a$, that is, with at least two elements. So we can partition $[0, T]$ as $L_0 \cup S_0 \cup L_1 \cup S_1 \cup \ldots \cup L_K$, where the S_k's are the complementary intervals. We call the L_k's *lakes* and the S_k's *switches*.

LEMMA 22. *Let $L = [a, b]$ be a lake. For any set $B \in \mathcal{B}(T-1)$ such that $B \cap L^c = A^{opt} \cap L^c$ and hence $B \cap L \neq A^{opt} \cap L$, we have*

$$f_{T-1}(A^{opt}) - f_{T-1}(B) \geq \min \left\{ 1 - \xi_a, 1 - \xi_{b-1}, \min_{a \leq i \leq b-1} 1 - \xi_{i-1} - \xi_i \right\} > 0. \tag{69}$$

Proof. First suppose B is obtained by removing from A^{opt} a single item. If this item is a, we have $f_{T-1}(A^{\mathrm{opt}}) - f_{T-1}(B) = 1 - \xi_a$; if it is b, we have $f_{T-1}(A^{\mathrm{opt}}) - f_{T-1}(B) = 1 - \xi_{b-1}$, and if it is $i \in (a, b)$, then we have $f_{T-1}(A^{\mathrm{opt}}) - f_{T-1}(B) = 1 - \xi_{i-1} - \xi_i$. So by optimality of A^{opt}_{T-1} the first inequality in (69) holds for these B, and Lemma 16 implies the last inequality in (69). Now recall that Lemma 9(c) shows $\min_{a \leq i \leq b-1} 1 - \xi_i \geq 0$. So construct a general B by removing items from A^{opt} one by one, and for items after the first the benefit can only decrease. So the first inequality holds generally. □

LEMMA 23. *Let $S = [a, b]$ be a switch and $S_e = [a-1, b+1]$. For any set B such that $B \cap S_e^c = A^{opt} \cap S_e^c$ and $B \cap S \neq A^{opt} \cap S$, we have*

$$\begin{aligned} f_{S_e}(A^{opt}) - f_{S_e}(B) \geq \min \Bigg\{ & \min_{a-1 \leq i < j \leq b} \xi_i + \xi_j - 1, \min_{a-1 \leq i \leq b} \xi_i, \min_{a \leq i \leq b} \xi_i - \xi_{a-2}, \\ & \min_{a \leq i \leq b} \xi_i - \xi_{b+1}, 1 - \xi_{a-2} - \xi_{b+1} \Bigg\}. \end{aligned}$$

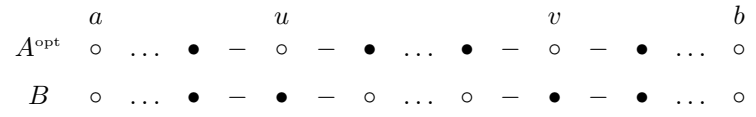

FIG. 3. *Case* $[\circ \dots \circ]$, *where* $a \le u \le v \le b$. *Benefit change* $= \xi_{u-1} + \xi_v - 1$.

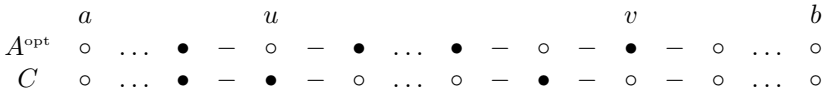

FIG. 4. *Case* $[\circ \dots \bullet]$, *where* $a \le u \le v \le b - 1$. *Benefit change* $= \xi_{u-1}$.

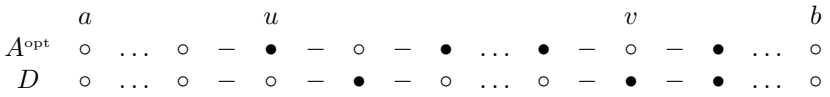

FIG. 5. *Case* $[\bullet \dots \circ]$, *where* $a + 1 \le u \le v \le b$. *Benefit change* $= \xi_v$.

TABLE 4

$[u, v]$	$[a-1, \circ]$	$[a-1, \bullet]$	$[\circ, b+1]$	$[\bullet, b+1]$	$[a-1, b+1]$
benefit change	$\xi_v - \xi_{a-2}$	$1 - \xi_{a-2}$	$\xi_u - \xi_{b+1}$	$1 - \xi_{b+1}$	$1 - \xi_{a-2} - \xi_{b+1}$

Proof. By construction a switch starts and ends with items not in A^{opt}, and the two items before and after the switch are in A^{opt}. Moreover, Table 2 shows that two adjacent items cannot both be not in A^{opt}, so the items in a switch $[a, b]$ must strictly alternate between in and not in A^{opt}, as illustrated in Figure 3.

We first consider a set B obtained from A^{opt} by flipping all items in some subinterval $[u, v]$ of $[a, b]$. There are four cases, corresponding to whether the endpoints u, v are in or not in A^{opt}. We exhibit three cases in Figures 3, 4, and 5, labeled as, e.g., $[\bullet \dots \circ]$, together with the value of the benefit change $f_{S_e}(A^{\text{opt}}) - f_{S_e}(B)$. In the fourth case $[\bullet \dots \bullet]$, the benefit change equals 1.

We also need to consider cases where the flipped subinterval $[u, v]$ has $u = a - 1$ or $v = b + 1$ or both. There are five cases, indicated in Table 4.

Now consider any subset B satisfying the hypothesis of Lemma 23. Decompose $A^{\text{opt}} \triangle B$ into disjoint maximal intervals $\mathcal{I}_i$. It is easy to check that the benefit change between A^{opt} and B is just the sum of the separate benefit changes between A^{opt} and A^{opt} with interval $\mathcal{I}_i$ flipped. Thus the minimum over B is attained by one of the cases we have considered, establishing the lemma. ∎

LEMMA 24. *Set* $w = \min_{1 \le i < j \le T-1} \{|\xi_i + \xi_j - 1|; \xi_i; |1 - \xi_i|; |\xi_i - \xi_j|\}$. *On the event* D, *either* $W = 0$ *or* $W \ge w$.

Proof. We need only consider the case $W > 0$. Recall that $C = \arg\min_{B \in \mathcal{B}(T-1)} (f_{T-1}(A^{\text{opt}}_{T-1}) - f_{T-1}(B))$ is such that $A^{\text{opt}} \triangle C$ is a *single* subinterval $\mathcal{I}$ of $[1, T-1]$. It is enough to show that C satisfies the assumptions of Lemmas 22 (for some lake) or the assumptions of Lemma 23 (for some switch), for then the lower bound w follows from the lower bounds in those lemmas.

We argue by contradiction: if false, then $\mathcal{I}$ intersects some lake and some adjacent switch, say L_k and S_k (the case of L_k and S_{k-1} is similar). So there exists $a < b < c$ such that $b = \sup L_k$ and $\mathcal{I} = [a, c]$. Now check the following:

If $c \in A^{\mathrm{opt}}$, then $f(B) - f(C) = 1$, for $B := C \cup \{b, b+2, b+4, \dots, c\} \backslash \{b+1, b+3, \dots, c-1\}$.

If $c \notin A^{\mathrm{opt}}$, then $f(B) - f(C) = \xi_c$, for $B := C \cup \{b, b+2, b+4, \dots, c-1\} \backslash \{b+1, b+3, \dots, c\}$.

Either case contradicts the optimality of C. □

We may now complete the proof of Lemma 19. The key point is that the bound w in Lemma 24 does not depend on θ. From Lemma 24,

$$\begin{aligned}
&\mathrm{P}(T \geq 3k,\ 0 < W(\theta)\mathbb{1}_D < x) \\
&\leq \mathrm{P}(T \geq 3k,\ D; 0 < w < x) \leq \mathrm{P}(T \geq 3k,\ w < x) \\
&\leq \mathrm{P}\left(T \geq 3k,\ \min_{1 \leq i < j \leq T-1} |\xi_i + \xi_j - 1| < x\right) + \mathrm{P}\left(T \geq 3k,\ \min_{1 \leq i \leq T-1} \xi_i < x\right) \\
&\quad + \mathrm{P}\left(T \geq 3k,\ \min_{1 \leq i \leq T-1} |\xi_i - 1| < x\right) + \mathrm{P}\left(T \geq 3k,\ \min_{1 \leq i < j \leq T-1} |\xi_i - \xi_j| < x\right).
\end{aligned}$$

The four terms on the right-hand side are treated similarly: we will just study the final term and will prove that there exists $C > 0$ independent of k such that

$$\mathrm{P}\left(\min_{1 \leq i < j \leq T-1} |\xi_i - \xi_j| < x \,\middle|\, T \geq 3k\right) \leq C(k+1)x. \tag{70}$$

The effect of conditioning on the event $\{T \geq 3k\}$ is that each nonoverlapping triple $(\xi_{3m}, \xi_{3m+1}, \xi_{3m+2})$ is conditioned to satisfy either $\{\xi_{3m} + \xi_{3m+1} \geq 1 - \tau\} \cup \{\xi_{3m+1} + \xi_{3m+2} \geq 1 - \tau\}$ or $\{\xi_{3m} + \xi_{3m+1} < 1 - \tau,\ \xi_{3m+1} + \xi_{3m+2} < 1 - \tau\}$ (for $m = T$). It follows that, for any $i < j$,

$$\mathrm{P}((\xi_i, \xi_j) \in \cdot | T > j) \leq a^{-2} \mathrm{P}((\xi_i, \xi_j) \in \cdot), \tag{71}$$

where

$$\begin{aligned}
a = \min \big(&\mathrm{P}(\{\xi_0 + \xi_1 \geq 1 - \tau\} \cup \{\xi_1 + \xi_2 \geq 1 - \tau\}),\ \\
&\mathrm{P}(\xi_0 + \xi_1 < 1 - \tau, \xi_1 + \xi_2 < 1 - \tau)\big).
\end{aligned}$$

From assumption (7) the density of $\xi_j - \xi_i$ is bounded by some constant b, and so

$$\begin{aligned}
&\mathrm{P}\left(\min_{1 \leq i < j \leq T-1} |\xi_i - \xi_j| < x \,\middle|\, T \geq 3k\right) \\
&\leq \sum_{i<j} \mathrm{P}(|\xi_i - \xi_j| < x, T \geq j | T \geq 3k) \\
&= \sum_{i<j} \mathrm{P}(|\xi_i - \xi_j| < x | T \geq \max(j+1, 3k)) \mathrm{P}(T \geq j+1 | T \geq 3k) \\
&\leq b a^{-2} x \sum_{j \geq 3k-1} (j-1) \mathrm{P}(T \geq j+1 | T \geq 3k) \\
&\leq b a^{-2} x \sum_{j \geq k} 3(j+1) \mathrm{P}(T \geq 3j | T \geq 3k)
\end{aligned}$$

$$= ba^{-2}x \sum_{j \geq k} 3(j+1)\mathrm{P}(T \geq 3(j-k))$$

$$\leq ba^{-2}x(k\mathrm{E}[T] + \mathrm{E}[T(T+1)]),$$

where we used the fact that $T/3$ has a geometric distribution. This concludes the proof of Lemma 19.

5. Final remarks.

5.1. Technical assumptions on G. We stated a single assumption (7) on G. What we actually used was three consequences of this assumption:

- $\mathrm{P}(\xi < 1/2) > 0$, which implies $\mathrm{P}(\xi_i + \xi_{i+1} < 1) > 0$, was used in Lemma 15 and thereby throughout section 4 (because it implies $i \in A^{\mathrm{opt}}$) to implement "localization" arguments.
- $\mathrm{P}(\xi \leq 1/2) < 1$ was used in section 3.2 to show $P(\Omega_g) > 0$. Note that if $\mathrm{P}(\xi \leq 1/2) = 1$, then the optimization problem is degenerate in that the optimal $A_n^{\mathrm{opt}} = \{1, 2, \ldots, n\}$.
- $\xi_1 + \xi_2$ has density bounded below in some interval $(1, 1+\eta)$, which was used in section 3.2 to obtain (37).

The latter two are used only in a convenient way to exhibit one near-optimal set. The "localization" arguments essentially just require one to find some event of positive probability involving $(\xi_{-k}, \ldots, \xi_k)$ which forces items 0 and 1 to be in (or not in) A^{opt}. Lemma 15 is just a simple way to exhibit such an event. So we expect Theorem 2 to remain true under much weaker assumptions on G.

5.2. Parallels with the cavity method. The arguments in this paper in the context of i.i.d.-DP (dynamic programming) may be compared with the more sophisticated arguments from the statistical physics *cavity method* [14], as reformulated in more probabilistic language in [1, 4], whose prototype example we take to be the analysis of the traveling salesman problem (TSP) in the "mean-field" model of geometry where there are n points and each of the $\binom{n}{2}$ interpoint links has random length. Of course *algorithmically* DP and TSP are quite different, but there are striking parallels between the analysis of optimal solutions of i.i.d.-DP and mean-field-TSP, as follows:

- There are $n \to \infty$ limits for the random data; in DP this is just the obvious infinite i.i.d. sequence, while for mean-field-TSP it is a certain random infinite tree.
- The "inclusion criterion" for i.i.d.-DP involves X_i^L, X_{i+1}^R and the edge-cost ξ_i. Finite-n TSP has of course no simple inclusion criteria, but in the $n \to \infty$ limit of mean-field-TSP there is an analogous criterion for inclusion of an edge (i, j) in terms of quantities Z_i^L, Z_j^R and the edge-length ξ_{ij}. Each Z is interpreted (cf. (19) for DP) as the difference between costs of two optimal solutions (subject to different local constraints) on one side of the tree.
- The distribution we use for X in i.i.d.-DP, the stationary distribution of a Markov chain, is the solution of an equation with abstract structure $X \stackrel{d}{=} h(\xi, X^1)$. The distribution we use for Z in mean-field-TSP, by a recursion on the limit tree, is the solution of an equation with abstract structure $Z \stackrel{d}{=} h(\xi; Z^1, Z^2, Z^3, \ldots)$, where the Z^j's are i.i.d. copies of the unknown distribution Z.

These parallels provide a glimpse of how the analogue of Theorem 1, a formula for the asymptotic expected cost in mean-field-TSP, may be derived (the original nonrigorous

argument was in [13]; a rigorous proof was given only recently via more combinatorial methods [18]). The analogue of Theorem 2 for mean-field-TSP, using Lagrange multipliers as in this paper, and leading to a nonrigorous argument that the scaling exponent equals 3, was given in [3].

Acknowledgment. We thank Vlada Limic for discussions regarding the NK model and Guilhem Semerjian for explaining to us an alternative proof of the $\delta(\theta) \sim \alpha\theta$ part of (55).
