STOCHASTIC APPROXIMATION FOR NONEXPANSIVE MAPS: APPLICATION TO Q-LEARNING ALGORITHMS*

JINANE ABOUNADI†, DIMITRI P. BERTSEKAS†, AND VIVEK BORKAR‡

Abstract. We discuss synchronous and asynchronous iterations of the form

$$x^{k+1} = x^k + \gamma(k)(h(x^k) + w^k),$$

where h is a suitable map and $\{w^k\}$ is a deterministic or stochastic sequence satisfying suitable conditions. In particular, in the stochastic case, these are stochastic approximation iterations that can be analyzed using the ODE approach based either on Kushner and Clark's lemma for the synchronous case or on Borkar's theorem for the asynchronous case. However, the analysis requires that the iterates $\{x^k\}$ be bounded, a fact which is usually hard to prove. We develop a novel framework for proving boundedness in the deterministic framework, which is also applicable to the stochastic case when the deterministic hypotheses can be verified in the almost sure sense. This is based on scaling ideas and on the properties of Lyapunov functions. We then combine the boundedness property with Borkar's stability analysis of ODEs involving nonexpansive mappings to prove convergence (with probability 1 in the stochastic case). We also apply our convergence analysis to Q-learning algorithms for stochastic shortest path problems and are able to relax some of the assumptions of the currently available results.

1. Introduction.

The motivation for this paper has been the analysis of Q-learning algorithms, which have emerged as a powerful simulation tool for solving dynamic programming problems when a model is not known and/or the problem must be solved on-line as the data become available. Q-learning algorithms were first formulated by Watkins (1989), who gave a partial convergence analysis that was later amplified by Watkins and Dayan (1992). A more comprehensive analysis was given by Tsitsiklis (1994) (also reproduced in Bertsekas and Tsitsiklis (1996)), which made the connection between Q-learning and stochastic approximation. (A related treatment of a class of algorithms that include Q-learning and TD(λ) also appeared around the same time in Jaakola, Jordan, and Singh (1994). It may be recalled here that TD(λ) is a learning scheme for estimating the value function of a policy based on an exponentially weighted average (with weights λ^n for some $\lambda \in (0,1)$) of the so-called n-step truncated returns—see Bertsekas and Tsitsiklis (1996) for a detailed description.) In particular, Q-learning algorithms for discounted cost problems or stochastic shortest path (SSP) problems were viewed as asynchronous stochastic approximation versions of well-known value iteration algorithms in dynamic programming. This connection paved the way for a general analysis based on classic stochastic approximation techniques and dynamic programming-related contraction and monotonicity properties.

A weakness of the methodology developed so far is that it deals in an ad hoc way with the question of boundedness of the Q-learning iterates. In particular, the analysis of Tsitsiklis required a special argument for proving boundedness with probability 1 (w.p.1), and for the case of SSP problems it also required that the cost per stage be nonnegative, unless boundedness is imposed as an assumption (see Bertsekas and Tsitsiklis (1996), Prop. 5.6).

Our purpose in this paper is to provide a new and powerful general framework for establishing boundedness and proving convergence in synchronous and asynchronous stochastic approximation methods involving nonexpansive maps, including as a special case Q-learning algorithms. Our framework relies strongly on nonexpansiveness and combines ideas from several fields, including asynchronous stochastic approximation analysis via the limiting ODE technique and nonlinear analysis of ODEs. Our method for dealing with boundedness bears a similarity to an idea from the paper by Jaakola, Jordan, and Singh (1994), which addressed the convergence of TD(λ) using stochastic approximation methods (see section 2). Also see Csibi (1975) and Gerencser (1992) for work in a similar spirit. As a special case of our analysis, we improve on Tsitsiklis' convergence result by dispensing with the boundedness assumption for the iterates of SSP Q-learning, in the case where the cost per stage may be negative. The methodology developed in this paper also provides an essential foundation for a convergence analysis of Q-learning algorithms for average cost dynamic programming problems given in a companion paper (Abounadi, Bertsekas, and Borkar (2001)).

Our results, in fact, can be cast as a powerful *deterministic* principle, because the conditions on the noise required to ensure its applicability can be cast in simple deterministic terms. These can, in turn, be verified in the almost sure sense for the stochastic approximation algorithms of interest here. The deterministic formulation also requires weaker conditions on the stepsizes. Thus we shall initially state our results in a deterministic framework, enlarging their scope beyond the applications to stochastic approximation.

The general framework that we propose applies to synchronous and asynchronous variants of algorithms of the form

$$x^{k+1} = x^k + \gamma(k)\big(h(x^k) + w^k\big). \tag{1}$$

Here x^k is a sequence in $\Re^n$, w^k is a deterministic noise sequence, h is Lipschitz, $\gamma(k)$ is a positive stepsize sequence, and the aim is to find a solution of the equation $h(x) = 0$. This is the synchronous implementation in which all components are updated together at each time with full information about past iterates. The asynchronous model that we use is based on the formulation of Borkar (1998) and is of the form

$$x_i^{k+1} = x_i^k + \gamma\big(\nu(k,i)\big)\big(h_i(x^k) + w_i^k\big)I(i \in Y^k) \tag{2}$$

for $i = 1, \ldots, n$, where Y^k is the subset of $\{1, 2, \ldots, n\}$ denoting components being updated at time k, $I(\cdot)$ is the indicator function, and $\nu(k,i)$ is the number of times the component x_i of the vector x has been updated by time k.

For the synchronous algorithm (1), a powerful analysis technique is the ODE method introduced by Ljung (1977), formally treated by Kushner and Clark (1978), and Benveniste, Metivier, and Priouret (1990). For the asynchronous algorithm (2), a similar technique has been developed by Borkar (1998). (See also Kushner and Yin (1997) and references therein for related work.) The major idea behind these two techniques is to find a limiting deterministic continuous-time ODE for the stochastic discrete-time processes, using interpolation with the appropriate time scaling. The

main result is that if the ODE has an asymptotically stable equilibrium point, then under appropriate assumptions, which include boundedness of the generated iterates, the discrete-time iteration converges to this point w.p.1. Thus, in ODE techniques, boundedness must be independently verified.

This paper's methodology for dealing with the boundedness issue involves three steps:

1. obtaining a related scaled iteration and establishing its convergence,
2. showing that the sequence $\{x^k\}$ generated by the original iteration is bounded as a consequence of the convergence of the scaled iteration,
3. showing that the boundedness of $\{x^k\}$ implies convergence by invoking a standard ODE limiting argument.

For each of the steps above, we will impose appropriate sufficient conditions on the mapping h, the stepsize, and the noise. A central assumption in our later applications is that the mapping h is of the form $h(x) = T(x) - x$, where the map T is nonexpansive with respect to some norm $\|\cdot\|_p$ with $p \in (1, \infty]$ for the synchronous case, and with respect to the sup-norm $\|\cdot\|_\infty$ for the asynchronous case. To our knowledge, ours is the first general method for dealing with the boundedness issues in the ODE approach where the underlying mapping T is not a contraction. (See, however, the recent work by Borkar and Meyn (2000), which is discussed later in this section.) Note that the class of fixed-point problems which involve nonexpansive mappings arises in a number of different applications (see the book by Bertsekas and Tsitsiklis (1989) and the papers by Tseng, Bertsekas, and Tsitsiklis (1990), Borkar and Soumyanath (1997), and Soumyanath and Borkar (1999)). In particular, it includes value iteration algorithms for various dynamic programming formulations, including Q-learning algorithms.

Step 1 of the scheme described above is carried out by choosing the scaling based on a Lyapunov function of an appropriate ODE. The scaling works like a projection on an appropriate bounded set when the iterates lie outside a certain level set of the Lyapunov function. Note that we do not need to know the Lyapunov function; all we need to know is that such a function exists. For this we will use a general converse Lyapunov theorem that guarantees the existence of a smooth Lyapunov function if the ODE has a globally asymptotically stable equilibrium point (Wilson (1969)). Given this scaling scheme, we will be able to show that the scaled iteration has the same deterministic limiting ODE and hence converges. The argument is similar to the standard limiting ODE argument of Kushner and Clark (1978). We need to consider the Skorohod topology instead of the "uniform convergence on compacts" topology on $C([0, \infty); \Re^n)$. Step 2 involves the idea of comparing the original iteration and its scaled counterpart and showing that the difference between the two is bounded due to the nonexpansiveness of the mapping F. The idea of comparing the two iterations appeared first in Jaakola, Jordan, and Singh (1994) in a more limited setting. Step 3 is an application of standard ODE limiting arguments since boundedness is already established.

It is instructive to compare this approach with that of Borkar and Meyn (2000). While both are motivated by the same class of algorithms, viz., Q-learning, they exploit different features of the latter. While our approach is solely based on the nonexpansivity of an associated map, Borkar and Meyn use a scaling limit of this map, in the spirit of fluid models in queueing theory. To underscore the difference, note that the stochastic gradient scheme can be viewed as a fixed-point seeking iteration of an L_2-nonexpansive map when the associated Hessian is uniformly bounded—see section III.B of Soumyanath and Borkar (1999). Thus it comes under the purview of

the present scheme, but not under that of Borkar and Meyn (2000) in the absence of any specification of how the gradient in question behaves near infinity. On the other hand, the requirement that a convenient scaling limit hold in their sense can be met without the map being nonexpansive: the former concerns only the behavior near infinity, but the latter is a global requirement. Thus the approach of Borkar and Meyn and that of the present paper are quite distinct, and given the paucity of general purpose criteria for the stability of stochastic recursions of this type, both are of interest, despite the fact that currently they are aimed at broadly the same class of problems. More generally, our scheme will work (under mild technical assumptions) for the recursions wherein the distance between iterates for two instantiations of the algorithm with the same random inputs, but with two different initial conditions, remains bounded by a function of the initial conditions.

Finally, we note that for recursive algorithms the idea of using projection as a way of forcing boundedness is not new. The difference in our approach is that the use of scaling is only a method of proof, and the objective is to establish the boundedness of the original iteration without altering the iterates by forcing them to be bounded.

2. Boundedness lemmas. The results in this paper will be divided into two parts: the boundedness lemmas and the convergence analysis of appropriately scaled synchronous and asynchronous iterations. The boundedness lemmas are given in the present section, and rely on the nonexpansiveness property of the concerned map with respect to some norm $\|\cdot\|_p$, $p \in (1, \infty]$, for the synchronous case, and the sup-norm for the asynchronous case. The convergence of the scaled iteration is analyzed in the next section.

For a set $\mathcal{A}$ of $\Re^n$, we denote by $\partial\mathcal{A}$ and $\bar{\mathcal{A}}$ the boundary and closure of $\mathcal{A}$, respectively (i.e., $\bar{\mathcal{A}} = \mathcal{A} \cup \partial\mathcal{A}$). We introduce via scaling a map that "projects" any point onto a bounded and open set $\mathcal{B}$ that contains the origin. This is done each time the point leaves a given set $\mathcal{C}$ that contains $\mathcal{B}$. The map is defined as follows.

DEFINITION 2.1. *Let $\mathcal{B}$ be an open and bounded subset of $\Re^n$ containing the origin, and let $\mathcal{C}$ be a subset of $\Re^n$ that contains $\mathcal{B}$. We define the mapping $\Pi_{\mathcal{B},\mathcal{C}} : \Re^n \mapsto \bar{\mathcal{B}}$ by*

$$\Pi_{\mathcal{B},\mathcal{C}}(x) = \gamma_{\mathcal{B},\mathcal{C}}(x) \cdot x,$$

where $\gamma_{\mathcal{B},\mathcal{C}} : \mathbb{R}^n \to (0, 1]$ is given by

$$\gamma_{\mathcal{B},\mathcal{C}}(x) = \begin{cases} 1 & \text{if } x \in \mathcal{C}, \\ \max\{\beta > 0 : \beta x \in \bar{\mathcal{B}}\} & \text{if } x \notin \mathcal{C}. \end{cases}$$

Since $\bar{\mathcal{B}}$ is compact, it can be seen that $\Pi_{\mathcal{B},\mathcal{C}}$ is well defined as a real-valued function. If $\mathcal{B}$ is an open ball with respect to the Euclidean norm centered at the origin, the map $\Pi_{\mathcal{B},\mathcal{C}}$ is like a projection on $\mathcal{B}$, but the decision to project depends on whether the point is outside the larger set $\mathcal{C}$.

Our first result is inspired by a lemma of Jaakola, Jordan, and Singh (1994), which guarantees convergence of an iteration as long as a scaled version converges. Their lemma uses a strong homogeneity assumption, which is unnecessary for our purposes.

LEMMA 2.1. *Let $\mathcal{B}$ be an open and bounded subset of $\Re^n$ containing the origin, and let $\mathcal{C}$ be a subset of $\Re^n$ that contains $\mathcal{B}$. Consider the algorithm*

$$x^{k+1} = G^k(x^k, \xi^k), \tag{3}$$

where we assume the following:

1. $\{\xi^k\}$ *is a sequence in a measurable space* $(\Omega, \mathcal{F})$.
2. G^k *is nonexpansive in* x *with respect to some norm* $\|\cdot\|$ *for every* $\xi \in \Omega$*:*

$$\|G^k(x,\xi) - G^k(y,\xi)\| \le \|x - y\| \qquad \forall\ x, y, \xi.$$

3. *The sequence* $\{\tilde{x}^k\}$ *generated by the scaled iteration*

$$\tilde{x}^{k+1} = G^k\big(\Pi_{\mathcal{B},\mathcal{C}}(\tilde{x}^k), \xi^k\big), \qquad \tilde{x}^0 = x^0,$$

converges to some vector $x^* \in \mathcal{B}$.

Then $\{x^k\}$ *is bounded.*

Proof. Since $\mathcal{B}$ is open, there exists a large enough $\overline{k}$ such that $\tilde{x}^k \in \mathcal{B}$ for $k \ge \overline{k}$. In other words, there exists a large enough $\overline{k}$ such that

$$\gamma_{\mathcal{B},\mathcal{C}}(\tilde{x}^k) = 1 \qquad \forall\ k \ge \overline{k}, \tag{4}$$

and hence

$$\tilde{x}^{k+1} = G^k(\tilde{x}^k, \xi^k) \qquad \forall\ k \ge \overline{k}. \tag{5}$$

Therefore, for $k \ge \overline{k}$,

$$\|x^{k+1} - \tilde{x}^{k+1}\| = \|G^k(x^k, \xi^k) - G^k(\tilde{x}^k, \xi^k)\| \le \|x^k - \tilde{x}^k\| \le \cdots \le \|x^{\overline{k}} - \tilde{x}^{\overline{k}}\|.$$

Since $\{\tilde{x}^k\}$ is bounded, it follows that $\{x^k\}$ is bounded. □

3. Analysis of the scaled iteration. Our objective is to apply Lemma 2.1 to the synchronous and asynchronous algorithms given by (1) and (2). To this end, we will first establish the convergence of scaled versions of iterations (1) and (2) by using ODE-type arguments and conclude boundedness of the unscaled versions. However, the scaling (i.e., the sets $\mathcal{B}$ and $\mathcal{C}$ in Lemma 2.1) must be chosen so that we can find a limiting ODE that is easily analyzed. In particular, if the scaling is not done appropriately, the scaled iteration might not converge. The iterates could, for example, keep hitting the boundary of $\mathcal{B}$ infinitely often and thus never converge, or the scaling could generate additional fixed points at the boundary that the iterates might converge to.

Given an ODE $\dot{x} = h(x)$ in $\Re^n$ with a global asymptotically stable equilibrium point x^*, a smooth Lyapunov function $V : \Re^n \mapsto \Re$ is a continuously differentiable function satisfying $V(x^*) = 0$, $V(x) > 0$ for all $x \ne x^*$, and such that the inner product of its gradient $\nabla V(x)$ and $h(x)$ is negative for all $x \ne x^*$. A necessary and sufficient condition for x^* to be a global asymptotically stable equilibrium point is the existence of a corresponding Lyapunov function (see Yoshizawa (1966)). Using some smoothing techniques, Wilson showed that the Lyapunov function can be taken to be smooth (in fact, infinitely differentiable; see Theorem 3.2 in Wilson (1969)). The following lemma will be useful to us.

LEMMA 3.1. *Let* $\dot{x} = h(x)$ *be an ODE with a global asymptotically stable equilibrium point* x^*. *Let* V *be a smooth Lyapunov function for the ODE. For any* $R > 0$, *there is a* $C > 0$ *such that the closed ball* $\bar{B}(x^*, R)$ *of radius* R *centered at* x^* *is in the interior of the level set* $L = \{x \in \Re^n : V(x) \le C\}$.

Proof. Consider the closure $\bar{B}(x^*, R)$ of $B(x^*, R)$. Since V is continuous and $\bar{B}(x^*, R)$ is compact, the maximum of V over $\bar{B}(x^*, R)$ is attained. Let $\overline{C} = \max_{x \in \bar{B}(x^*, R)} V(x)$. Any level set of the form $L = \{x \in \Re^n : V(x) \le C\}$, where $C > \overline{C}$, contains $\bar{B}(x^*, R)$ in its interior. □

3.1. Analysis of the scaled iteration-synchronous case. The scaled version of the synchronous algorithm of (1) is given by

$$\begin{aligned} \tilde{x}^{k+1} &= x^k + \gamma(k)\big(h(x^k) + w^k\big), \\ x^{k+1} &= \Pi_{\mathcal{B},\mathcal{C}}(\tilde{x}^{k+1}). \end{aligned} \tag{6}$$

We first show, under appropriate conditions, that this iteration converges w.p.1 to the unique equilibrium point of an appropriate ODE. The scaled iteration (6) can be written as

$$x^{k+1} = x^k + \gamma(k)\big(h(x^k) + w^k\big) + g^k, \tag{7}$$

where

$$g^k = \Pi_{\mathcal{B},\mathcal{C}}\big[x^k + \gamma(k)\big(h(x^k) + w^k\big)\big] - \big[x^k + \gamma(k)\big(h(x^k) + w^k\big)\big]. \tag{8}$$

We formally state our assumptions, which for completeness include some of our earlier assertions on the existence of a global asymptotically stable equilibrium x^*, the choice of the sets $\mathcal{B}$ and $\mathcal{C}$, etc., as follows.

ASSUMPTION 3.1. *The stepsizes $\gamma(k)$ satisfy*

$$0 < \gamma(k) \to 0, \qquad \sum_{k=0}^{\infty} \gamma(k) = \infty.$$

ASSUMPTION 3.2.

1. *There exists D such that $\|w^k\| \le D$ for all k.*
2. $\lim_{k\to\infty} \sum_{m=k}^{m_T(k)} \gamma(m) w^m = 0$ *for all T, where*

$$m_T(k) = \min\left\{ m \ge k : \sum_{l=k}^{m} \gamma(l) \ge T \right\}.$$

3. *h is Lipschitz continuous; i.e., for some $L > 0$,*

$$\|h(x) - h(y)\| \le L\|x - y\|.$$

4. *The ODE $\dot{x} = h(x)$ has a globally asymptotically stable equilibrium point x^*.*

Remark 3.1. Note that the boundedness condition in Assumption 3.2 is for the rescaled iterations, *not* for the original iterations. For the applications we have in mind, $||w^k||$ will be bounded by an affine function of $||x^k||$ and therefore will be bounded whenever the latter is. But the latter is bounded, by construction, for the rescaled iterations, and thus Assumption 3.2.1 is satisfied. It is being neither assumed nor implied a priori that the noise sequence $\{w^k\}$ in the original iterations is bounded; this will, in fact, be a consequence of our stability result. More generally, it will suffice to have $||w^k||$ bounded by a continuous function of x^k.

Remark 3.2. This remark concerns Assumption 3.2. The important thing to note here is that we are imposing this assumption on the *projected* algorithm, for which the boundedness of iterates is true by construction, not for the original scheme, whose stability we intend to prove.

In our analysis, we will use Lemma 2.1 with $\mathcal{B} = B(0, R)$ and $\mathcal{C} = \{x \in \Re^n : V(x) < C\}$, where $R > \|x^*\|$, V is a smooth Lyapunov function for the ODE $\dot{x} = h(x)$, and the constant C is large enough so that $\mathcal{C}$ contains $B(0, \bar{R})$ for some $\bar{R} > R$. Note

that the vector field of the ODE is transversal to the level sets of V, implying that if $x \in \partial\mathcal{C}$, then $(x + \Delta h(x)) \in \mathcal{C}$ for small enough $\Delta > 0$. This motivates the choice of the scaling sets $\mathcal{B}$ and $\mathcal{C}$ above. Intuitively, if the stepsize is small enough, we can think of the algorithm as starting at the boundary of $\mathcal{B}$ and moving around initially in $\mathcal{C}$. As it approaches the boundary of $\mathcal{C}$, it gets pushed back to the interior of $\mathcal{C}$, thanks to the fact that the vector field of the ODE on the boundary points inward and in spite of the noise term.

In order to proceed with our convergence analysis, we need to define piecewise linear or piecewise constant interpolated processes based on the iterates $\{x^k\}$. Let

$$t_k = \sum_{m=0}^{k-1} \gamma(m), \qquad k \geq 1,$$

with $t_0 = 0$. Let

$$\tilde{x}^{k+1} = x^k + \gamma(k)\big(h(x^k) + w^k\big), \qquad k \geq 0,$$

$$X_l(t) = \begin{cases} x^k & \text{for } t = t_k, \\ \big(1 - \frac{t-t_k}{\gamma(k)}\big)x^k + \frac{t-t_k}{\gamma(k)}\tilde{x}^{k+1} & \text{for } t \in [t_k, t_{k+1}), \end{cases}$$

$$X_c(t) = x^k, \qquad k \geq 0, \qquad \text{for } t \in [t_k, t_{k+1}),$$

$$G_c(t) = \sum_{m=0}^{k-1} g^m \qquad \text{for } t \in [t_k, t_{k+1}),$$

$$W_l(t) = \begin{cases} \sum_{m=0}^{k-1} \gamma(m) w^m & \text{for } t = t_k, \\ \big(1 - \frac{t-t_k}{\gamma(k)}\big)W_l(t_k) + \frac{t-t_k}{\gamma(k)} W_l(t_{k+1}) & \text{for } t \in [t_k, t_{k+1}). \end{cases}$$

Thus $X_l(\cdot)$ is right-continuous with left limits (r.c.l.l., for short); that is, $X_l(t^+) = \lim_{\delta \downarrow 0} X_l(t + \delta)$ and $X_l(t^-) = \lim_{\delta \downarrow 0} X_l(t - \delta)$ are well defined, with $X_l(t) = X_l(t^+)$. In fact, $X_l(\cdot)$ is piecewise linear and continuous everywhere, except at times t_k for which $g^k \neq 0$, where it has a jump discontinuity. Define the left-shifted versions of these processes as follows, for $t \geq 0$:

$$X_l^k(t) = X_l(t + t_k),$$

$$W_l^k(t) = W_l(t + t_k) - W_l(t_k),$$

$$X_c^k(t) = X_c(t + t_k),$$

$$G_c^k(t) = G_c(t + t_k) - G_c(t_k).$$

Then it is easy to see that for $t \geq -t_k$

$$\begin{aligned} X_l^k(t) &= X_l^k(0) + \int_0^t h\big(X_c^k(\tau)\big)d\tau + W_l^k(t) + G_c^k(t) \\ &= X_l^k(0) + \int_0^t h\big(X_l^k(\tau)\big)d\tau + W_l^k(t) + G_c^k(t) + e^k(t), \end{aligned}$$

where

$$e^k(t) = \int_0^t h\big(X_c^k(\tau)\big)d\tau - \int_0^t h\big(X_l^k(\tau)\big)d\tau.$$

By Assumption 3.2, $\{W_l^k(\cdot)\}$ converges to zero uniformly on finite intervals as $k \to \infty$. We show next that $\{e^k(\cdot)\}$ and $\{G_c^k(\cdot)\}$ behave analogously.

LEMMA 3.2. *For any $T > 0$, $\sup_{t\in[0,T]} \|e^k(t)\| \to 0$ as $k \to \infty$.*

Proof. By Assumptions 3.2,

$$\|e^k(t)\| \le \int_0^t \big\|h\big(X_c^k(\tau)\big) - h\big(X_l^k(\tau)\big)\big\|d\tau \le L\int_0^t \big\|X_c^k(\tau) - X_l^k(\tau)\big\|d\tau.$$

Letting

$$m_T(k) = \min\left\{m \ge k \ : \ \sum_{l=k}^{m}\gamma(m) \ge T\right\},$$

we have

$$\begin{aligned}
\sup_{t\in[0,T]} \|e^k(t)\| &\le L\int_0^T \big\|X_c^k(\tau) - X_l^k(\tau)\big\|d\tau \\
&\le \sum_{m=k}^{m_T(k)} \gamma(m)L \sup_{\tau\in[t_m,t_{m+1})} \big\|X_c^k(\tau) - X_l^k(\tau)\big\| \\
&\le \sum_{m=k}^{m_T(k)} \gamma(m)L(t_{m+1} - t_m)\big\|h(x^m) + w^m\big\| \\
&\le \sum_{m=k}^{m_T(k)} \gamma^2(m)LD',
\end{aligned}$$

where

$$D' = D + \sup_{x\in C}\|h(x)\|,$$

and the second inequality is a consequence of the definitions of $X_l^k(\cdot)$ and $X_c^k(\cdot)$. By Assumption 3.1, we have $\sum_{m=k}^{m_T(k)} \gamma^2(m) \to 0$ as $k \to \infty$, implying the result. ∎

To analyze the r.c.l.l. processes $X_l^k(\cdot)$, $G_c^k(\cdot)$, we recall from Billingsley (1968) the space $D([0,T];\Re^n)$ of r.c.l.l. functions from $[0,T]$ to $\Re^n$ (where $T > 0$), equipped with the Skorohod topology. This topology is defined so that $f^k(\cdot) \to f(\cdot)$ in $D([0,T];\Re^n)$ if and only if there exist continuous, nondecreasing, onto functions $\lambda^k : [0,T] \to [0,T]$ such that $f^k(\lambda^k(t)) \to f(t)$ and $\lambda^k(t) \to t$, uniformly on $[0,T]$. We denote by $D([0,\infty);\Re^n)$ the space of r.c.l.l. functions from $[0,\infty)$ to $\Re^n$, defined such that $f^k(\cdot) \to f(\cdot)$ in $D([0,\infty);\Re^n)$ if and only if their respective restrictions to $[0,T]$ converge in $D([0,T];\Re^n)$ for every $T > 0$. Both $D([0,T];\Re^n)$ and $D([0,\infty);\Re^n)$ are separable and metrizable with a complete metric.

We recall from Billingsley (1968, p. 118) the following characterization of relative compactness in $D([0,T];\Re^n)$: a set $A \subset D([0,T];\Re^n)$ is relatively compact if and only if

$$\sup_{x(\cdot)\in A}\sup_{t\in[0,T]}\|x(t)\| < \infty \tag{9}$$

and

$$\lim_{\delta\to 0}\sup_{x(\cdot)\in A}\sup_{t_1\le t\le t_2,\, t_2-t_1\le\delta}\min\bigl\{\|x(t)-x(t_1)\|,\,\|x(t_2)-x(t)\|\bigr\}=0, \tag{10a}$$

$$\lim_{\delta\to 0}\sup_{x(\cdot)\in A}\sup_{t_1,t_2\in[0,\delta)}\|x(t_2)-x(t_1)\|=0, \tag{10b}$$

$$\lim_{\delta\to 0}\sup_{x(\cdot)\in A}\sup_{t_1,t_2\in[T-\delta,T)}\|x(t_2)-x(t_1)\|=0. \tag{10c}$$

This generalizes the well-known Arzelà–Ascoli theorem for $C([0,T];\Re^n)$, the space of continuous functions from $[0,T]$ to $\Re^n$ with the sup-norm.

LEMMA 3.3. *The sequences* $\{X_l^k(\cdot)\}$ *and* $\{G_c^k(\cdot)\}$ *are relatively compact in* $D([0,\infty);\Re^n)$.

Proof. It suffices to check the relative compactness of their restrictions to $[0,T]$ in $D([0,T];\Re^n)$ for arbitrary $T>0$. Let us fix $T>0$. Since $\{x^k\}$ and $\{g^k\}$ are bounded, so are the sequences $\{X_l^k(\cdot)\}$ and $\{G_c^k(\cdot)\}$. Thus (9) above holds. It is easy to see that (10a)–(10c) will follow if any two discontinuity points of $x(\cdot)\in A$ are separated by at least some $\Delta>0$. For the processes under consideration, discontinuities occur at some of the t_k's. Let there be a discontinuity at t_k for some k. Then $g^{k-1}\neq 0$ and $x^k\in\partial B$. Let

$$d=\min_{x\in\partial B,\, y\in\partial C}\|x-y\|>0,$$

and define

$$m(k)=\max\left\{j\ :\ \sum_{i=0}^{j}\gamma(k+i)\le\frac{d}{D'}\right\},$$

where D' is as before. We claim that $x^{k+1},x^{k+2},\ldots,x^{k+m(k)}$ are in the interior of C. To see this, notice that if

$$\gamma(k)<\frac{d}{D'},$$

then

$$\|\tilde{x}^{k+1}-x^k\|<d,$$

implying that $\tilde{x}^{k+1}$ is in the interior of C and thus $x^{k+1}=\tilde{x}^{k+1}$. Therefore, $g^k=0$, implying no discontinuity at t_{k+1}. Similarly, if

$$\sum_{i=0}^{j-1}\gamma(k+i)<\frac{d}{D'},$$

then x^{k+i} is in the interior of C for $i=1,\ldots,j$. This implies the claim that there are no discontinuities in the interval $[t_k,t_k+d/D')$. Let $\Delta=d/2D'$. □

Let $K=\{k\ :\ g^k=0\}$. Let $\{X_l^k(\cdot)\}$ and $\{G_c^k(\cdot)\}$ converge in $D([0,T];\Re^n)$ to some $X(\cdot)$ and $G(\cdot)$, respectively, along a subsequence of K. (From the above proof, it is easy to see that K will be infinite: once k is large enough so that $\gamma(k)<\frac{d}{D'}$, each k with $g^k\neq 0$ will lead to $g^{k+1}=0$.) Then the limits must satisfy

$$X(t)=X(0)+\int_0^t h\bigl(X(\tau)\bigr)d\tau+G(t).$$

Furthermore, from the nature of our notion of convergence in $D([0,T];\Re^n)$, it is clear that $G(\cdot)$ is piecewise constant r.c.l.l. with $G(0)=0$ and that any two discontinuities of $G(\cdot)$ (hence of $X(\cdot)$) are separated by at least Δ on the time axis. Recall that for $x(\cdot)\in D([0,T];\Re^n)$, $x(t^+)=\lim_{t<s\to t} x(s)$ and $x(t^-)=\lim_{t>s\to t} x(s)$.

LEMMA 3.4. *We have $G(\cdot)\equiv 0$, implying $\dot{X}(t)=h(X(t))$.*

Proof. Let

$$\tau=\inf\{t>0\ :\ X(t^+)\neq X(t^-)\}.$$

By the right continuity at 0 and the fact that any two discontinuity points are separated by at least $\Delta>0$, it follows that $\tau>0$. Let $\|X(\tau^+)-X(\tau^-)\|=\delta>0$. Then, by our notion of convergence, we can find $\tau_k<\tau_k'$, $k\geq 0$, such that $\tau_k'-\tau_k\to 0$ and

$$\left\|X_l^{n(k)}(\tau_k')-X(\tau^+)\right\|\to 0, \tag{11}$$

$$\left\|X_l^{n(k)}(\tau_k)-X(\tau^-)\right\|\to 0. \tag{12}$$

Recall that $\|h(\cdot)\|$ is bounded on C and that $e^k(\cdot)$ and $W_l^k(\cdot)$ converge to 0 uniformly on compact sets. Also, any two discontinuities of $X_l^n(\cdot)$ must be at least Δ apart. Thus, for sufficiently large k, there must exist a $\hat{\tau}_k\in[\tau_k,\tau_k']$ such that

$$\left\|X_l^{n(k)}(\hat{\tau}_k)-X_l^{n(k)}(\hat{\tau}_k^-)\right\|\geq\frac{\delta}{2}.$$

But then $X_l^{n(k)}(\hat{\tau}_k^+)\in\partial B$, and $X_l^{n(k)}(\hat{\tau}_k^-)$ is not in the interior of C. Once again, using (11) and (12) and the fact that two discontinuities of $X_l^n(\cdot)$ must be at least Δ apart, we conclude that $X(\tau^+)\in\partial B$ and $X(\tau^-)\in\partial C$. But then $X(\cdot)$ satisfies $\dot{X}(t)=h(X(t))$ on $[0,\tau)$ (since $G(\cdot)\equiv 0$ on $[0,\tau)$), and therefore an interior trajectory of this ODE in C hits ∂C, a contradiction of our choice of C. (Since C is a level set of the Lyapunov function $V(\cdot)$, $h(\cdot)$ is transversal to ∂C everywhere and is directed towards the interior.) This contradiction proves that $G(\cdot)\equiv 0$. ∎

The preceding lemma allows us to prove the following proposition, the proof of which proceeds along standard lines; see, e.g., Kushner and Clark (1978), Benveniste, Metivier, and Priouret (1990).

PROPOSITION 3.1. *Let Assumptions* 3.1 *and* 3.2 *hold. The scaled synchronous algorithm* (6) *converges to x^*.*

3.2. Analysis of the scaled iteration-asynchronous case. The scaled version of the asynchronous algorithm of (2) is given by

$$\begin{aligned}\tilde{x}_i^{k+1}&=x_i^k+\gamma\big(\nu(k,i)\big)\left(h_i(x^k)+w_i^k\right)I(i\in Y^k),\\ x^{k+1}&=\Pi_{\mathcal{B},\mathcal{C}}(\tilde{x}^{k+1}).\end{aligned} \tag{13}$$

We confine ourselves to nonexpansive mappings with respect to the sup-norm. We also impose a further assumption on the stepsize. In particular, we will use the following assumptions in place of Assumption 3.1. We use $[a]$ to denote the integer part of a real number a.

ASSUMPTION 3.3. *The stepsizes $\gamma(k)$ are eventually nonincreasing and satisfy*

$$0<\gamma(k)\to 0,\qquad \sum_{k=0}^{\infty}\gamma(k)=\infty.$$

In addition, for all $\beta \in (0,1)$,

$$\sup_k \frac{\gamma([k\beta])}{\gamma(k)} < \infty$$

and

$$\lim_{k\to\infty} \frac{\sum_{m=0}^{[k\overline{\beta}]} \gamma(m)}{\sum_{m=0}^{k} \gamma(m)} = 1, \qquad \textit{uniformly in } \overline{\beta} \in [\beta, 1].$$

ASSUMPTION 3.4. *There exists a* $\Gamma > 0$ *such that for all* i

$$\liminf_{k\to\infty} \frac{1}{k+1}\nu(k,i) \geq \Gamma.$$

Furthermore, for all $T > 0$, *the limit*

$$\lim_{n\to\infty} \frac{\sum_{k=\nu(n,i)}^{\nu(m_T(n),i)} \gamma(k)}{\sum_{k=\nu(n,j)}^{\nu(m_T(n),j)} \gamma(k)}$$

exists for all i, j.

Theorem 3.2 of Borkar (1998) implies that the above limit will in fact be 1, a fact we use later. In addition, we change Assumption 3.2 to the following.

ASSUMPTION 3.2′. *For* $T, m_T(k)$ *as before,*

$$\lim_{k\to\infty} \sum_{m=k}^{m_T(k)} \gamma(m) w^{l(m)} = 0,$$

where $\{l(m)\}$ *is any increasing sequence of nonnegative integers satisfying* $l(m) \geq m$ *for all* m.

Examples of stepsizes that satisfy Assumption 3.3 include $\gamma(k) = 1/k$, $\gamma(k) = 1/(k \log k)$, etc., for $k \geq 2$, with suitable modifications for $k = 0, 1$. The essential meaning of Assumption 3.4 is that all components are updated comparably often.

Under Assumptions 3.2′, 3.3, and 3.4, the analysis closely mimics that of the synchronous case, except that the ODE-based convergence analysis of Kushner and Clark (1978) and Benveniste, Metivier, and Priouret (1990) is replaced by the corresponding analysis of Borkar (1998). In order to avoid undue repetition, we shall provide only a brief sketch. The key result of Borkar (1998) that is used here is briefly described in the appendix.

The first simplifying assumption that we make is that Y^k is a singleton for all k; i.e., only one component is updated at a time. This is justified as in Borkar (1998), the idea being that one unfolds a single iteration that updates d components, $d \geq 2$, into d iterations, in which each iteration updates a single component. There is, however, a complication in that this artificially introduces bounded delays; that is, the update of the ith component at time $k+1$ may use the value of the jth component updated not at time k, but at time $k-m$ for some $m \leq n$. These delays can be handled as in Borkar (1998). For simplicity of exposition, we ignore the delays here.

Thus we have $Y^k = \{\phi^k\}$, where ϕ^k is the index of the component updated at time k, and the iteration (13) is written as

$$x^{k+1} = x^k + D^k(h(x^k) + w^k) + g^k,$$

where

$$D^k = \mathrm{diag}\big[\gamma(\nu(k,1))I(\phi^k = 1), \ldots, \gamma(\nu(k,n))I(\phi^k = n)\big]$$

and

$$g^k = \Pi_{\mathcal{B},\mathcal{C}}\big[x^k + D^k(h(x^k) + w^k)\big] - \big[x^k + D^k(h(x^k) + w^k)\big].$$

Let us denote

$$\bar{\mu}^k = \big[I(\phi^k = 1), \ldots, I(\phi^k = n)\big]$$

and set $\bar{\gamma}(m,j) = \gamma(\nu(m,j))$, $\hat{\gamma}(m) = \bar{\gamma}(m, \phi^m)$, $t_0 = 0$, and $t_k = \sum_{m=0}^{k-1} \hat{\gamma}(m)$, $k \geq 1$. Let us define piecewise linear and piecewise constant processes as follows:

$$\mu(t) = \bar{\mu}^k \qquad \text{for } t \in [t_k, t_{k+1}),$$

$$X_c(t) = x^k \qquad \text{for } t \in [t_k, t_{k+1}),$$

$$G_c(t) = \sum_{m=0}^{k-1} g^m \qquad \text{for } t \in [t_k, t_{k+1}),$$

$$X_l(t) = \begin{cases} x^k & \text{for } t = t_k, \\ \big(1 - \frac{t-t_k}{\gamma(k)}\big)x^k + \frac{t-t_k}{\gamma(k)}\tilde{x}^{k+1} & \text{for } t \in [t_k, t_{k+1}), \end{cases}$$

where

$$\tilde{x}^{k+1} = x^k + D^k\big(h(x^k) + w^k\big),$$

$$W_l(t) = \begin{cases} \sum_{m=0}^{k-1} D^m w^m & \text{for } t = t_k, \\ \big(1 - \frac{t-t_k}{\gamma(\nu(k,\phi^k))}\big)W_l(t_k) + \frac{t-t_k}{\gamma(\nu(k,\phi^k))}W_l(t_{k+1}) & \text{for } t \in [t_k, t_{k+1}). \end{cases}$$

Define the corresponding left-shifted processes as follows, for $t \geq 0$:

$$X_l^k(t) = X_l(t + t_k),$$

$$X_c^k(t) = X_c^k(t + t_k),$$

$$W_l^k(t) = W_l(t + t_k) - W_l(t_k),$$

$$G_c^k(t) = G_c(t + t_k) - G_c(t_k),$$

$$\mu^k(t) = \mu(t + t_k).$$

For an n-dimensional probability vector $p = [p_1, \ldots, p_n]$, let $\mathrm{diag}(p)$ denote the diagonal matrix whose ith diagonal entry is p_i. Then, letting μ^* denote the uniform probability vector $[1/n, \ldots, 1/n]$, we have, for $t \geq 0$,

$$X_l^k(t) = X_l^k(0) + \int_0^t \mathrm{diag}(\mu^*)h\big(X_l^k(\tau)\big)d\tau + W_l^k(t) + G_c^k(t) + e^k(t) + \eta^k(t),$$

$$\eta^k(t) = \int_0^t \big(\mathrm{diag}(\mu^k(\tau)) - \mathrm{diag}(\mu^*)\big)h\big(X_l^k(\tau)\big)d\tau,$$

$$e^k(t) = \int_0^t \mathrm{diag}\big(\mu^k(\tau)\big)\big(h\big(X_c^k(\tau)\big) - h\big(X_l^k(\tau)\big)\big)d\tau.$$

The convergence of $\{W_l^k(\cdot)\}$ to 0 follows from Assumption 3.2′. Convergence of $\{e^k(\cdot)\}$ to 0 follows along the lines of the preceding subsection. The proof of Lemma 3.3 now goes through as before, with $D' = \sup_{z\in\mathcal{C}} \max_i |h_i(z)| + D$. We also have the following.

LEMMA 3.5. *For each $T > 0$,*

$$\lim_{k\to\infty} \sup_{t\in[0,T]} ||\eta^k(t)|| = 0.$$

Proof. As before, one verifies that the set $\{\{X_l^k(t), t \in [0,T]\}, k \geq 1\}$ is relatively compact in $D([0,T];\Re^n)$. Thus one may drop to a subsequence of $\{k\}$, denoted by $\{k\}$ again by abuse of notation, such that $X_l^k(\cdot) \to Z(\cdot)$ for some $Z(\cdot) \in D([0,T];\Re^n)$. Since the map $x(\cdot) \in D([0,T];\Re^n) \to x(t) \in \Re^n$ for any $t \in [0,T]$ is continuous at $z(\cdot)$ if $z(\cdot)$ is continuous at t (see Billingsley (1968, p. 121)), and also any $x(\cdot) \in D([0,T];\Re^n)$ has at most countably many points of discontinuity (see Borkar (1998, p. 119)), it follows that $X_l^k(t) \to Z(t)$ for almost every $t \in [0,T]$. By the dominated convergence theorem, one then has

$$\lim_{k\to\infty} \int_0^t \big(\mathrm{diag}(\mu^k(\tau)) - \mathrm{diag}(\mu^*)\big)\big(h(X_l^k(\tau)) - h(Z(\tau))\big)d\tau = 0.$$

Since the left-hand side (L.H.S.) has a bounded derivative in t, it is equicontinuous. It is clearly bounded for each fixed t. Thus a straightforward application of the Arzelà–Ascoli theorem shows that the above convergence is uniform in $t \in [0,T]$. Therefore the claim would follow if we show that

$$\lim_{k\to\infty} \int_0^t \big(\mathrm{diag}(\mu^k(\tau)) - \mathrm{diag}(\mu^*)\big)h(Z(\tau))d\tau = 0,$$

uniformly in $[0,T]$. The uniformity of convergence over $[0,T]$ will follow as before from the Arzelà–Ascoli theorem if we prove pointwise convergence on $[0,T]$. In turn, the latter follows if we show that for each t

$$\lim_{k\to\infty} \int_0^t \big(\mathrm{diag}(\mu^k(\tau)) - \mathrm{diag}(\mu^*)\big)f(\tau)d\tau = 0$$

for any $f \in L_2([0,T];\Re^n)$. Consider $\mu^k(\cdot)$, $k \geq 1$, as elements of the space $\mathcal{U}$ of measurable maps from $[0,\infty)$ to the space of probability vectors in $\Re^n$, with the coarsest topology that renders continuous the maps $\mu(\cdot) \in \mathcal{U} \to \int_0^t \langle \mu(s), f(s)\rangle ds$ for all $t > 0$ and f as above. It is easy to deduce from the Banach–Alaoglu theorem that $\mathcal{U}$ is compact metrizable. Let $\bar{\mu}(\cdot)$ be any limit point of $\{\mu^k(\cdot)\}$ in $\mathcal{U}$ as $k \to \infty$. It follows from Theorem 3.2 of Borkar (1998) that $\bar{\mu} = \mu^*$. The claim follows. □

The proof of Lemma 3.4 now goes through as before. Thus the asynchronous iterates, suitably interpolated, track the ODE $\dot{x}(t) = (1/n)h(x(t))$, which has the same qualitative behavior as $\dot{x}(t) = h(x(t))$—the difference is a mere time scaling. As in Borkar (1998), we then obtain the following proposition.

PROPOSITION 3.2. *Let Assumptions* 3.2′, 3.3, *and* 3.4 *hold. The scaled asynchronous algorithm* (6) *converges to* x^*.

The only difference with Borkar (1998) will be that we are dealing with the projected algorithm here; therefore we have to allow for discontinuous trajectories. But this can be dealt with exactly as in the synchronous case.

4. Convergence theorems for stochastic approximation. Now we consider the situation in which $\{w^k\}$ is a random noise sequence. Specifically, we assume that it is adapted to a family of increasing σ-fields $\{\mathcal{F}^{k+1}\}$ to which $\{x^{k+1}\}$ is also adapted and satisfies

$$E[w^k/\mathcal{F}^k] = 0$$

for $k \geq 1$. We strengthen Assumption 3.1 to include

$$\sum_0^\infty \gamma(k)^2 < \infty,$$

which is a standard assumption in stochastic approximation theory. We further assume, in place of Assumptions 3.1 and 3.2′, that

$$E[||w^k||^2/\mathcal{F}^k] \leq H(x^k)$$

for some continuous $H(\cdot)$. Assumptions 3.3, 3.4 remain as before. We shall refer to the modified Assumptions 3.1, 3.2 as Assumptions 3.1(m), 3.2(m), respectively.

Note that the only use of Assumption 3.2 has been to ensure that there exists a $\Delta > 0$ such that consecutive jump times of $X_l(\cdot)$ are at least Δ apart. However, this Δ can depend on sample path in the present case without affecting the proof in any way. Since we are seeking almost sure convergence, it suffices to show the following.

LEMMA 4.1. *There exists w.p.*1 *a (possibly sample path dependent)* Δ *with the above property.*

Proof. Suppose that the claim is not true for some sample path. Let $\{t^{m(k)}\}$ denote the successive jump times, with $+\infty$ being a possible value for these. (In particular, $t^{m(k)} = \infty$ for $k > k_0$ if there are only k_0 jumps.) Then for the sample path under consideration, these are all finite, and moreover, there exist consecutive jump times $t^{m(k(l)+1)} > t^{m(k(l))}$ such that $t^{m(k(l)+1)} - t^{m(k(l))} \to 0$ as $l \to \infty$. Let $K = \sup_{x\in\mathcal{C}}||h(x)||$. Since the iterates move from $\partial\mathcal{B}$ to $\partial\mathcal{C}$ between $(t^{m(k(l))})^+$ and $(t^{m(k(l)+1)})^-$, we must have

$$\left\| \sum_{i=m(k(l))}^{m(k(l)+1)-1} \gamma(i) w^i \right\| \geq d - \left(t^{m(k(l)+1)} - t^{m(k(l))} \right) K \geq \frac{d}{2}$$

for l sufficiently large. Letting Ψ^l denote the L.H.S. above, it then follows that $\Psi^l \geq \frac{d}{2}$ infinitely often (i.o.). We shall prove that

$$P\left(\Psi^l \geq \frac{d}{2}, \text{ i.o.} \right) = 0,$$

which will imply the desired claim. By the Chebyshev inequality, we have

$$\sum_k P\left(\psi^k \geq \frac{d}{2} \right) \leq \sum_k \frac{4E[||\sum_{i=m(k)}^{m(k+1)-1} \gamma(i) w^i||^2 I(t^{m(k)} < \infty)]}{d^2}.$$

Summing over k, the R.H.S. sums to a quantity bounded by

$$\frac{4\sum_i \gamma(i)^2 E[||w^i||^2]}{d^2} \leq \frac{4(\sum_i \gamma(i)^2)\sup_{x\in\mathcal{C}}|H(x)|}{d^2} < \infty,$$

in view of our hypotheses on $\{w^k\}$. The claim follows from the Borel–Cantelli lemma. □

Our hypotheses also ensure that Assumption 3.2 holds a.s. To see this, let $M^k = \sum_{i=0}^k \gamma(i)w^i$ for $i \geq 0$. Then $(M^k, \mathcal{F}^{k+1})$ is a square-integrable martingale. Its quadratic variation process is

$$\sum_{i=0}^k \gamma(i)^2 \left(E\left[\frac{||w^i||^2}{\mathcal{F}^{i-1}}\right] - \left\| E\left[\frac{w^i}{\mathcal{F}^{i-1}}\right]\right\|^2 \right),$$

which is bounded by the finite quantity $2\sup_{x\in\mathcal{C}}|H(x)|\sum_i \gamma(i)^2$. By Theorem 3.3.4, p. 53, of Borkar (1995), $\{M^k\}$ converges a.s. It then follows that Assumption 3.2 holds a.s. Hence we have the following counterpart of Proposition 3.1.

LEMMA 4.2. *Under the above hypotheses, the scaled synchronous algorithm* (5) *converges to* x^* *a.s.*

For the asynchronous case, note that $(\sum_{m=0}^k \gamma(\nu(m,i))w_i^m, \mathcal{F}^k)$ is a (square-integrable) martingale for each i. Considerations similar to those above then lead to the following stochastic counterpart of Proposition 3.2.

LEMMA 4.3. *Under the above hypotheses, the scaled asynchronous algorithm converges to* x^* *a.s.*

We now specialize to algorithms of the form

$$x^{k+1} = x^k + \gamma(k)(F(x^k, \xi^k) - x^k)$$

in synchronous form and

$$x_i^{k+1} = x_i^k + \gamma(\nu(k,i))(F_i(x^k, \xi^k) - x_i^k)I(i \in Y^k)$$

in asynchronous form, where $\{\xi^k\}$ is an independently and identically distributed (i.i.d.) stochastic noise sequence taking values in some measurable space, and the function $F(\cdot,\cdot)$ is assumed to satisfy the nonexpansivity property:

$$||F(x,u) - F(y,u)||_p \leq ||x-y||_p$$

for some $p \in (0,\infty]$ and all x, y, u. Let $T(x) = E[F(x,\xi^k)]$. Then

$$||T(x) - T(y)||_p \leq ||x-y||_p.$$

The aim is to find a fixed point x^* of $T(\cdot)$, i.e., a point x^* satisfying $x^* = T(x^*)$, which we assume to exist uniquely. Define $h(x) = T(x) - x$ and $w^k = F(x^k,\xi^k) - T(x^k)$, which casts this algorithm into the form analyzed above. Note, in particular, that in view of our hypotheses on F, $E[||w^k||^2/\mathcal{F}^k] \leq c(||x^k||^2 + 1)$ for some $c > 0$. The foregoing then leads to the following.

PROPOSITION 4.1. *Let* $\{x^k\}$ *be generated by the synchronous stochastic approximation algorithm* (1). *Let Assumptions* 3.1(m) *and* 3.2(m) *hold. Then the sequence* $\{x^k\}$ *converges to* x^* *w.p.*1.

Proof. The theorem is an application of Lemmas 2.1 and 4.2, the global asymptotic stability of the equilibrium x^* for the ODE $\dot{x}(t) = T(x(t)) - x(t)$ being proved in Borkar and Soumyanath (1997). □

PROPOSITION 4.2. *Let $\{x^k\}$ be generated by the asynchronous version of the above algorithm. Let Assumptions* 3.1(m)*,* 3.2(m)*,* 3.3*, and* 3.4 *hold with the modifications stated above. Then the sequence $\{x^k\}$ converges to x^* w.p.*1.

Proof. The theorem is an application of Lemmas 2.1 and 4.3, the global asymptotic stability of the ODE $\dot{x}(t) = (1/n)(T(x(t)) - x(t))$ being ensured as before by observing that the scalar $1/n$ on its R.H.S. represents a mere time scaling. □

5. Analysis of *Q*-learning algorithms. The convergence theorems above are directly applicable to the analysis of Q-learning algorithms for discounted and SSP dynamic programming problems. As discussed in Bertsekas (2001, Vol. 1), discounted cost problems can be formulated as SSP problems. We will therefore restrict ourselves to SSP problems. Here we have a controlled discrete-time dynamic system where at state i the use of a control u specifies the transition probability $p_{ij}(u)$ to the next state j. There are a finite number of states. At state i, the control u is constrained to take values from a given finite control set $U(i)$. The cost of using u at state i and moving to state j is denoted by $g(i, u, j)$. We assume that there is a special cost-free termination state 0. Once the system reaches that state, it remains there at no further cost; that is, $p_{00}(u) = 1$ for all u. We denote by $1, \ldots, n$ the states other than the termination state 0.

The total expected cost associated with an initial state i and a policy $\pi = \{\mu_0, \mu_1, \ldots\}$, where each μ_k maps states i into controls $\mu_k(i) \in U(i)$, is

$$J_\pi(i) = \lim_{N\to\infty} E\left\{\sum_{k=0}^{N} g\big(x_k, \mu_k(x_k), x_{k+1}\big) \;\Big|\; x_0 = i\right\}.$$

Note that the discounted cost problem with discount factor $\alpha \in (0, 1)$ and states $i = 1, \ldots, n$ is obtained as the special case of an SSP problem, where $p_{i0}(u) = 1 - \alpha$ and $g(i, u, 0) = 0$ for all $i = 1, \ldots, n$ and $u \in U(i)$.

A stationary policy is a policy of the form $\pi = \{\mu, \mu, \ldots\}$, and its corresponding cost function is denoted by $J_\mu(i)$. We call a stationary policy π *proper* if there exists an integer m such that

$$\max_{i=1,\ldots,n} P\{x_m \neq 0 \mid x_0 = i, \pi\} < 1,$$

and call π *improper* otherwise. We assume the following.

ASSUMPTION 5.1. *There exists at least one proper policy.*

ASSUMPTION 5.2. *Every improper policy results in infinite expected cost from at least one initial state.*

These assumptions, introduced by Bertsekas and Tsitsiklis (1991), have become standard in the analysis of SSP problems and are sufficient to show the validity of the major types of dynamic programming results. For example, the value iteration method converges to the optimal cost function J^*, which is the unique solution of Bellman's equation

$$J^*(i) = \min_{u\in U(i)} \sum_{j=0}^{n} p_{ij}(u)\big(g(i, u, j) + J^*(j)\big), \qquad i = 1, \ldots, n,$$

$$J^*(0) = 0.$$

Q-learning algorithms update estimates of the Q-factors, defined for all pairs (i,u) by

$$Q^*(i,u) = \sum_{j=0}^{n} p_{ij}(u)\big(g(i,u,j) + J^*(j)\big).$$

From this definition and Bellman's equation, we see that the Q-factors are the unique solution of the following system of equations:

$$Q(i,u) = \sum_{j=0}^{n} p_{ij}(u)\left(g(i,u,j) + \min_{v\in U(j)} Q(j,v)\right), \qquad i = 1,\dots,n,\ u \in U(i),$$

$$Q(0,u) = 0,$$

which may be viewed as Bellman's equation for Q-factors.

Let us generically denote by Q the vector of Q-factors. The synchronous version of Q-learning is given by

$$Q^{k+1} = Q^k + \gamma(k)\big(F(Q^k,\xi^k) - Q^k\big), \tag{14}$$

where $\{\xi^k\}$ is a sequence of independent vector-valued random variables taking the values $0,1,\dots,n$, with probabilities Prob $(\xi^k_{iu} = j) = p_{ij}(u)$ for all k,

$$F(Q,\xi)(i,u) = g(i,u,\xi_{iu}) + \min_{v\in U(\xi_{iu})} Q(\xi_{iu},v).$$

The initial condition is assumed to satisfy $Q^0(0,u) = 0$, which ensures that $Q^k(0,u) = 0$ for all k. Also, for $i = 0$, $\xi_{iu} = 0$ w.p.1. Thus $g(i,u,\xi_{iu}) = g(0,u,0) = 0$ (because 0 is a cost-free state) and $Q(\xi_{iu},u) = Q(0,u) = 0$ for all u. Thus $F(Q,\xi)(0,u) = 0$ for all u. In fact, this permits us to consider the iteration of $Q^k(i,u)$ for $1 \le i \le n$ alone, which we denote again by Q^k by abuse of notation. Define

$$T(Q)(i,u) = \sum_{j=1}^{n} p_{ij}(u)F(Q,j)$$

and

$$w^k = F(Q^k,\xi^k) - T(Q^k).$$

Assumption 3.2 applies to the stepsize $\gamma(k)$ and the noise w^k for the *rescaled* iterates.

The following two properties of the mapping T are significant for our purposes:

1. T is nonexpansive with respect to the sup-norm.
2. The unique fixed point Q^* of the mapping T is a global asymptotically stable equilibrium of the ODE $\dot{Q} = T(Q) - Q$.

Property 1 follows from the nonexpansiveness of F, which can be verified by noting that for all $Q_1, Q_2 \in \mathbb{R}^{n+m}$ we have

$$\begin{aligned} F(Q_1,\xi)(i,u) - F(Q_2,\xi)(i,u) &= \min_{u'} Q_1(\xi_{iu},u') - \min_{u'} Q_2(\xi_{iu},u') \\ &\le Q_1(\xi_{iu},u_2) - Q_2(\xi_{iu},u_2) \\ &\le \max_{(i,u)} |Q_1(i,u) - Q_2(i,u)| \\ &\le \|Q_1 - Q_2\|_\infty, \end{aligned}$$

where u_2 achieves the minimum in $\min_{u'} Q_2(\xi_{iu}, u')$. A symmetric argument shows that

$$F(Q_2, \xi)(i,u) - F(Q_1, \xi)(i,u) \le \|Q_1 - Q_2\|_\infty.$$

Property 2 follows from the analysis of Bellman's equation for SSP problems (see e.g., Bertsekas (2001, Vol. 2)), and from the analysis of ODE maps involving nonexpansive mappings in Borkar and Soumyanath (1997). Using the facts that Q^* is the unique fixed point of T and that T is nonexpansive, it follows that any solution trajectory $Q(t)$ converges to Q^*. Moreover, the analysis in Borkar and Soumyanath (1997) implies that $\|Q(t) - Q^*\|_\infty$ is nonincreasing, establishing that Q^* is a global asymptotically stable equilibrium point for the ODE.

The mapping F, in addition to being nonexpansive, satisfies

$$E\big[F(Q^k, \xi^k) \mid \mathcal{F}^k\big] = T(Q^k),$$

where

$$\mathcal{F}^k = \sigma(x^k, \ldots, x^0, \xi^{k-1}, \ldots, \xi^0).$$

The properties above are sufficient to show that all of the assumptions of Proposition 4.1 are satisfied, thus implying the following convergence result.

PROPOSITION 5.1. *The sequence* $\{Q^k\}$ *generated by the synchronous* Q*-learning iteration* (14) *converges to* Q^* *w.p.*1.

5.1. Analysis of the SSP asynchronous Q-learning. The asynchronous version of (14) is what is usually referred to as the Q-learning algorithm. It is written as

$$Q^{k+1}(i,u) = Q^k(i,u) + \gamma\big(\nu(k,\phi^k)\big)\big(F(Q^k,\xi^k)(i,u) - Q^k(i,u)\big)I\big((i,u) = \phi^k\big), \tag{15}$$

where $\{\xi^k\}$ is as defined above and $\{\phi^k\}$ is a random process. Again we impose Assumption 3.2′ on the stepsize, and we assume in addition that

1.
$$\liminf_{k\to\infty} \frac{1}{k+1}\nu(k,i,a) \ge \Delta \qquad \text{for some } \Delta > 0.$$

Furthermore, for all $T > 0$, the limit

$$\lim_{n\to\infty} \frac{\sum_{k=\nu(n,i,a)}^{\nu(m_T(n),i,a)} \gamma(k)}{\sum_{k=\nu(n,j,b)}^{\nu(m_T(n),j,b)} \gamma(k)}$$

exists w.p.1 for all i, j, a, b.

2. $\{\gamma(k)\}$ is as in Assumption 3.3.

Again the mapping F satisfies

$$E\big[F(Q^k, \xi^k) \mid \mathcal{F}^k\big] = T(Q^k),$$

with

$$\mathcal{F}^k = \sigma(x^k, \ldots, x^0, \xi^{k-1}, \ldots, \xi^0, \phi^k, \ldots, \phi^0).$$

Similarly, the assumptions of Proposition 4.2 are satisfied, and we have the following.

PROPOSITION 5.2. *The sequence* $\{Q^k\}$ *generated by the asynchronous* Q*-learning iteration* (15) *converges to* Q^* *w.p.*1.

As already mentioned, the case in which more than one component is updated at a time can be reduced to the one above, modulo bounded delays, which can be separately taken care of as in Borkar (1998).

Remark 5.1. The usual formalism for Q-learning algorithms (see, e.g., Bertsekas and Tsitsiklis (1996)) presupposes the availability of a simulation device that generates independent random variables $\{\xi^k\}$ as above. Alternatively, one may consider it as an on-line scheme where the samples are generated by a single simulation or actual run $\{X^k\}$ of the controlled Markov chain with the control process $\{Z^k\}$. Then it is asynchronous, with $\phi^k = (X^k, Z^k)$. The above framework still applies if we use the representation $X^{k+1} = f(X^k, Z^k, \xi^k)$, where $\{\xi^k\}$ are i.i.d. and f is a suitable map. Such a representation is always possible (albeit on a possibly augmented probability space) by the stochastic realization theoretic results of Borkar (1993). See Kifer (1986) for the uncontrolled case.

6. Some extensions. This section points out some important extensions of the preceding analysis. The first is an extension of Lemma 2.1. It is possible to replace the assumption of nonexpansivity with respect to a norm there by nonexpansivity with respect to the span seminorm $||\cdot||_s$, defined by

$$||x||_s = \max_{i=1,\ldots,n} x_i - \min_{i=1,\ldots,n} x_i,$$

where $x_1, \ldots, x_n$ are the components of x. In this case, however, a weaker boundedness result is obtained, which is the subject of the following lemma. This lemma is used crucially in our companion paper on Q-learning in average cost control (Abounadi, Bertsekas, and Borkar (2001)).

LEMMA 6.1. *Let* $\mathcal{B}$ *be an open and bounded subset of* $\Re^n$ *containing the origin, and let* $\mathcal{C}$ *be a subset of* $\Re^n$ *that contains* $\mathcal{B}$*. Consider the algorithm*

$$x^{k+1} = G^k(x^k, \xi^k),$$

where we assume the following:

1. $\{\xi^k\}$ *is a sequence in a measurable space* $(\Omega, \mathcal{F})$.
2. G^k *is nonexpansive in* x *with respect to the span seminorm; i.e., for every* $\xi \in \Omega$,

$$||G^k(x,\xi) - G^k(y,\xi)||_s \le ||x - y||_s \qquad \forall\ x, y, \xi.$$

3. *The sequence* $\{\tilde{x}^k\}$ *generated by the scaled iteration*

$$\tilde{x}^{k+1} = G^k(\Pi_{\mathcal{B},\mathcal{C}}(\tilde{x}^k), \xi^k), \qquad \tilde{x}^0 = x^0,$$

converges to some vector $x^* \in \mathcal{B}$.

Then $\{||x^k||_s\}$ *remain bounded.*

Proof. The proof is identical to that of Lemma 2.1. □

The second extension relates to the Q-learning schemes described above. One can also allow for random costs under mild technical conditions. Thus, let a real or simulated transition from i to j under control u at time k lead to a random cost ζ_{iuj}^{k+1}. We suppose that $E[\zeta_{iuj}^{k+1} \mid \mathcal{F}^{k+1}] = g(i,u,j)$ and $E[(\zeta_{iuj}^{k+1})^2 \mid \mathcal{F}^{k+1}] \le M$ w.p.1 for some constant $M < \infty$. (Compare with Remark 3.2.) Then the foregoing analysis

goes through exactly as before with one modification: the "martingale difference" sequence w^k gets replaced by $\hat{w}^k$, defined as follows: its (iu)th component is $\hat{w}^k_{iu} = w^k_{iu} + \zeta^{k+1}_{iu\xi^k_{iu}} - g(i,u,\xi^k_{iu})$, where w^k_{iu} is the (iu)th component of w^k. Note that $\{\hat{w}^k\}$ is also a martingale difference sequence. An example is the case in which $\zeta^{k+1}_{iuj} = g(i,u,j)+\psi^{k+1}_{iuj}$, where $\{\psi^n_{iuj}\}$ are i.i.d. zero mean, bounded variance random variables representing additive noise.

7. Conclusions. In this paper we have studied the convergence of synchronous and asynchronous algorithms involving nonexpansive maps and additive deterministic or stochastic noise. We have used the ODE approach, but we have dispensed with the restrictive boundedness assumption on the generated iterates that this approach requires. The nonexpansiveness property ensures that the distance between the iterates of two instantiations of the algorithm, driven by the same noise sequence and differing only in the initial conditions, remains bounded. In fact, our arguments will work for any algorithm for which this is true, and the associated ODE has a globally asymptotically stable equilibrium, under mild technical conditions on noise as above. As a special case of our analysis, we have discussed Q-learning algorithms for SSP problems, and we have refined the assumptions under which convergence can be proved. Our results used Lemma 2.1 for the boundedness argument. We can likewise use Lemma 6.1 to prove boundedness for certain Q-learning algorithms for the average cost dynamic programming problem. The analysis of these algorithms requires considerable additional machinery and is given separately in a companion paper (Abounadi, Bertsekas, and Borkar (2001)).

Appendix. Here we briefly recall the main results of Borkar (1998) that are used in the paper. Let $F(\cdot,\cdot) = [F_1(\cdot,\cdot),\ldots,F_d(\cdot,\cdot)]^T : \mathcal{R}^d \times \mathcal{R}^m \to \mathcal{R}^d$ be Lipschitz in its first argument uniformly w.r.t. the second. Consider the stochastic approximation algorithm of the form

$$x^{k+1} = x^k + \gamma(k)F(x^k,\xi^k), \quad k \geq 0,$$

for $x^k = [x^k_1,\ldots,x^k_d]$. Let $h(x) = E[F(x,\xi^1)]$. We assume that the ODE $\dot{x}(t) = h(x(t))$ has a globally asymptotically stable equilibrium x^*. The asynchronous version of this algorithm is given by

$$x^{k+1}_i = x^k_i + \gamma\big(\nu(k,i)\big)I(i \in Y^k)F_i(x_1^{k-\tau_{1i}(k)},\ldots,x_d^{k-\tau_{di}(k)},\xi^k), \quad 1 \leq i \leq d,$$

for $k \geq 0$, where

(1) $\{Y^k\}$ is a set-valued random process taking values in the subsets of the set $\{1,\ldots,d\}$, representing the components that do get updated at time k.
(2) $\{\tau_{ij}(k), 1 \leq i,j \leq d, k \geq 0\}$ are bounded random delays. One usually takes $\tau_{ii}(k) = 0$ for all i, though this is not necessary. (Borkar (1998) also relaxes the boundedness condition on delays to a conditional moment bound.)
(3) $\nu(k,i) = \sum_{m=0}^{k} I(i \in Y^m)$ denotes the number of times component i gets updated until time k.

Let Assumptions 3.1–3.4 hold. The main result of Borkar (1998) is the following.

THEOREM A.1. *If $\{x^k\}$ remain w.p.1 bounded, they converge to x^* w.p.1.*

We shall briefly describe what the proof entails, using the notation of section 3.2 above. The intuition behind why the bounded delays don't affect the asymptotics is simple. Recall that the passage from the discrete iteration to an interpolated "approximation to ODE" involves the time scaling $k \to t^k$. This scaling shrinks the

time axis more and more as k increases, because $t^{k+1} - t^k \to 0$. If K denotes a bound on the delays, the intervals $[k, k+1, \ldots, k+K]$ map to $[t^k, t^k + \sum_{m=k}^{k+K-1} \gamma(m)]$, which become smaller and smaller as k increases, because of which the delays as seen by the ODE approximation on the rescaled time become smaller and smaller, becoming asymptotically negligible. This intuition can be made precise quite easily. In fact, it simply contributes one additional asymptotically negligible error term to the usual ODE analysis of stochastic approximations. See Lemma 3.3 of Borkar (1998) for details.

The harder problem is to deal with the Y^k's, i.e., with the fact that not all components are getting updated at each step. As in section 3.2 above, one has $X_l^k(t) = X_l^k(0) + \int_0^t \mathrm{diag}(\mu^k(\tau))h(X_l^k(\tau))d\tau$ + error terms, the latter going to zero w.p.1 as $k \to \infty$. View $\mu^k(\cdot)$ as elements of the space of measurable maps $[0, \infty) \to \{d$-dimensional probability vectors$\}$, with the coarsest topology that renders continuous the maps $\mu(\cdot) \to \int_0^T \langle \mu(t), g(t) \rangle dt$ for any $T > 0$ and any $g : [0, T] \to \mathcal{R}^d$ that satisfies $\int_0^T ||g(t)||^2 dt < \infty$. (Recall Lemma 3.5 above.) This is a compact metrizable topology. Let $\mu^k(\cdot)$ converge along a subsequence to some $\hat{\mu}(\cdot)$ in this topology. Then the limiting trajectory of $X_l^k(\cdot)$ along this subsequence will satisfy the nonautonomous ODE

$$\dot{x}(t) = \mathrm{diag}(\hat{\mu}(t))h(x(t)).$$

The additional conditions on $\gamma(k)$ stipulated in Assumptions 3.3 and 3.4 are required to further ensure that $\hat{\mu}(t)$ in fact equals μ^* for almost every t. See Borkar (1998) for details.

One can, in fact, work with the nonautonomous ODE itself to draw the same conclusions by using Lemma 2.4 of Borkar (1998), the only requirement being that the components of $\hat{\mu}(t)$ remain uniformly bounded away from zero from below for almost every t. This is a weaker version of the statement "all components get updated comparably often." Unfortunately, no simple transparent sufficient condition to ensure this (short of Assumptions 3.3, 3.4) seems available.

Acknowledgment. Thanks are due to John Tsitsiklis, whose suggestions resulted in important simplifications of the lemmas in section 2.

IDENTIFIABILITY AND WELL-POSEDNESS OF SHAPING-FILTER PARAMETERIZATIONS: A GLOBAL ANALYSIS APPROACH*

CHRISTOPHER I. BYRNES†, PER ENQVIST‡, AND ANDERS LINDQUIST‡

Abstract. In this paper, we study the well-posedness of the problems of determining shaping filters from combinations of finite windows of cepstral coefficients, covariance lags, or Markov parameters. For example, we determine whether there exists a shaping filter with a prescribed window of Markov parameters and a prescribed window of covariance lags. We show that several such problems are well-posed in the sense of Hadamard; that is, one can prove existence, uniqueness (identifiability), and continuous dependence of the model on the measurements. Our starting point is the global analysis of linear systems, where one studies an entire class of systems or models as a whole, and where one views measurements, such as covariance lags and cepstral coefficients or Markov parameters, from data as functions on the entire class. This enables one to pose such problems in a way that tools from calculus, optimization, geometry, and modern nonlinear analysis can be used to give a rigorous answer to such problems in an algorithm-independent fashion. In this language, we prove that a window of cepstral coefficients and a window of covariance coefficients yield a bona fide coordinate system on the space of shaping filters, thereby establishing existence, uniqueness, and smooth dependence of the model parameters on the measurements from data.

1. Introduction.

It is common to model a (real, zero-mean) stationary process $\{y(t) \mid t \in \mathbb{Z}\}$ as a convolution

$$y(t) = \sum_{k=-\infty}^{t} w_{t-k} u_k$$

of an excitation signal $\{u(t) \mid t \in \mathbb{Z}\}$, which is a white noise, i.e., $\mathrm{E}\{u(t)u(s)\} = \delta_{ts}$, where δ_{ts} is one if $t = s$ and zero otherwise. In the language of systems and control, under suitable finiteness conditions this amounts to passing the white noise u through a linear filter with the transfer function $w(z)$ having the Laurent expansion

$$w(z) = \sum_{k=0}^{\infty} w_k z^{-k} \tag{1.1}$$

for all $z \geq 1$, thus obtaining the process y as the output, as depicted in Figure 1. In addition, we assume that $w_0 \neq 0$ and that $w(z)$ is a rational function, the latter assumption being the finiteness condition required in systems and control theory. Such a filter will be called a *shaping filter*, and the coefficients $w_0, w_1, w_2, \ldots$ will be called the *Markov parameters*.

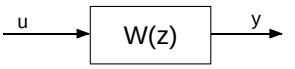

FIG. 1. *Representing a signal as the output of a black box.*

Clearly, any shaping filter must be *stable* in the sense that $w(z)$ has all of its poles in the open unit disc. To begin, we also assume that all zeros are located in the open unit disc. Such a shaping filter will be called a *minimum-phase shaping filter*.

Then the stationary stochastic process y has a rational spectral density

$$\Phi(e^{i\theta}) = |w(e^{i\theta})|^2,$$

which is positive for all θ. It is well known that the spectral density has a Fourier expansion

$$\Phi(e^{i\theta}) = r_0 + 2\sum_{k=1}^{\infty} r_k \cos k\theta,$$

where the Fourier coefficients

$$r_k = \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{ik\theta}\Phi(e^{i\theta})d\theta \tag{1.2}$$

are the covariance lags $r_k = \mathrm{E}\{y(t+k)y(t)\}$.

The spectral density $\Phi(z)$ is analytic in an annulus containing the unit circle and has there the representation

$$\Phi(z) = f(z) + f(z^{-1}),$$

where f is a rational function with all of its poles and zeros in the open unit disc. Hence, in particular, f is analytic outside the unit disc, and

$$f(z) = \frac{1}{2}r_0 + r_1 z^{-1} + r_2 z^{-2} + r_3 z^{-3} + \cdots . \tag{1.3}$$

Moreover,

$$\Phi(e^{i\theta}) = 2\mathrm{Re}\{f(e^{i\theta})\} > 0$$

for all θ, and, therefore, f is a real function which maps $\{|z| \geq 0\}$ into the right half-plane $\{\mathrm{Re}\, z > 0\}$; such a function is called *positive real*. For this to hold, the Toeplitz matrices

$$T_k = \begin{bmatrix} r_0 & r_1 & \cdots & r_k \\ r_1 & r_0 & \cdots & r_{k-1} \\ \vdots & \vdots & \ddots & \vdots \\ r_k & r_{k-1} & \cdots & r_0 \end{bmatrix} \tag{1.4}$$

must be positive definite for $k = 0, 1, 2, \ldots$.

Another way of representing the distribution of the stationary process is via the so-called *cepstrum*

$$\log \Phi(e^{i\theta}) = c_0 + 2\sum_{k=1}^{\infty} c_k \cos k\theta. \tag{1.5}$$

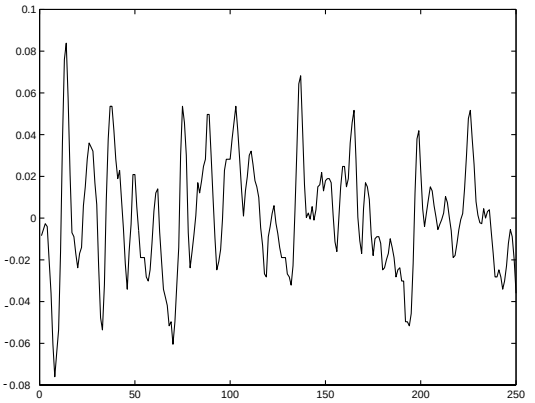

FIG. 2. *A frame of speech for the voiced nasal phoneme [ng].*

The Fourier coefficients

$$c_k = \frac{1}{2\pi} \int_{-\pi}^{\pi} e^{ik\theta} \log \Phi(e^{i\theta}) d\theta \tag{1.6}$$

are known as the *cepstral coefficients*.

Finite windows of covariance lags and cepstral coefficients can be estimated from an observed data record

$$y_0, y_1, y_2, \ldots, y_N$$

of the process $\{y(t) \mid t \in \mathbb{Z}\}$. In fact, a limited number of covariance lags can be estimated via some ergodic estimate

$$r_k = \frac{1}{N+1-n} \sum_{t=0}^{N-n} y_{t+k} y_k. \tag{1.7}$$

However, we can only estimate

$$r_0, r_1, \ldots, r_n, \tag{1.8}$$

where $n << N$, with some precision. A complementary set of observables are given by the window

$$c_0, c_1, \ldots, c_n \tag{1.9}$$

of cepstral coefficients. One topic considered in this paper is to investigate the conditions under which these estimated coefficients can be used to determine minimum-phase shaping filters, i.e., to determine the identifiability of such shaping filters from covariance and cepstral windows.

As an example, to which we shall return several times in this paper, let us consider a 30 ms frame of speech from the voiced nasal phoneme [ng], depicted in Figure 2. Here $N = 250$, a typical sample length for a mobile telephone.

Figure 3 depicts a periodogram of this signal, i.e., a spectral estimate obtained by fast Fourier transform. This spectral estimate can be modeled as a smooth spectral envelope perturbed by contributions from an excitation signal. The spectral envelope

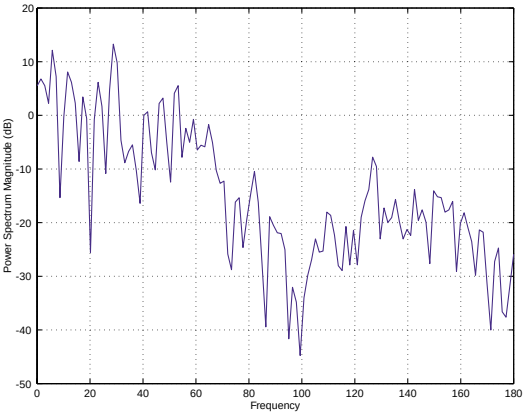

FIG. 3. *Periodogram for the voiced nasal phoneme [ng].*

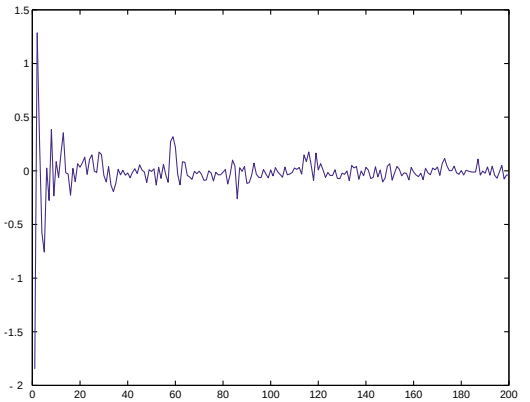

FIG. 4. *Cepstrum of voice speech signal.*

corresponds to the shaping of the vocal tract, which is described by the minimum-phase shaping filter.

As the Fourier transform of a convolution, the contributions of the shaping filter and the excitation signal to the spectral estimate are multiplicative. If we consider the logarithm of the spectral density Φ, the cepstrum, instead of Φ itself, the contribution of the excitation signal is additively superimposed on the that of the shaping filter.

Figure 4 shows the estimated cepstral coefficients of a frame of voiced speech. A contribution of the excitation signal is seen as spikes at multiples of the pitch period, corresponding to approximately $n_0 = 57$ in Figure 4. The spectral envelope can be estimated from a finite window

$$c_0, c_1, \dots, c_n \tag{1.10}$$

of cepstral coefficients, where $n < n_0$.

For minimum-phase shaping filters, the cepstral coefficients used in signal processing are closely related to the Markov parameters $w_0, w_1, w_2, \dots$ defined by (1.1). In more general systems problems, the minimum-phase requirement is relaxed to allow

σ to be an arbitrary (monic) polynomial. In this case, a record

$$w_0, w_1, \ldots, w_n \tag{1.11}$$

of Markov parameters are typically determined from the impulse response of an underlying system and not from data such as a finite time series, and for this reason Markov parameters can be quite useful in model reduction problems, starting from an underlying system. Nonetheless, for minimum-phase shaping filters, the cepstral coefficients used in signal processing are closely related to the Markov parameters of the shaping filter $w(z)$. Indeed, in section 6, we shall see that there is a one-to-one correspondence between windows of cepstral and Markov parameters of the same length.

In this paper, we are interested in the mathematical nature of the transformation of measurements, such as covariance lags and cepstral coefficients or Markov parameters, from data into the parameters of systems which produce such data. Our starting point will be the global analysis of linear systems, where one studies an entire class of systems or models as a whole and where one views measurements from data or model parameters as functions on the entire class. This point of view has been pioneered in [2, 4, 27, 16, 24]; see [5] for a survey. The central issue is whether the transformation from a set of measurements, viewed as functions, to a set of model parameters is well-posed, for example, in the sense of Hadamard. To be more precise, suppose the class of models is the class of (minimum-phase) shaping filters of bounded degree. This class can be viewed as a smooth manifold, for which any such shaping filter may be viewed as a point, and on which the coefficients of the numerator and denominator polynomials are a bona fide system of smooth coordinates on the global geometrization of this class of shaping filters. Matters being so, one can now ask, for example, whether a window of cepstral coefficients and a window of covariance coefficients also yield a bona fide coordinate system, so that, for example, the change of coordinates is a transformation which is smooth, one-to-one, onto, and with a smooth inverse. That is, the problem of passing from such data to models is indeed well-posed. Global analysis enables one to pose such problems in a way that tools from calculus, optimization, geometry, and modern nonlinear analysis can be used to give a rigorous answer to such problems.

In the next section, we shall review some of the basic spaces of systems we will use in our global analysis of certain transformations from data to models. In section 3, we will state our principal results, which we then prove in the following sections. These results focus on the identifiability of the models from collections of partial windows of covariance lags, cepstral coefficients, and Markov parameters and the questions of whether these parameters can be used to smoothly coordinatize spaces of shaping filters. For example, in section 4, a partial window of covariance lags and a partial window of cepstral coefficients are shown to jointly provide a system of local coordinates for shaping filters in the context of the geometry of certain foliations on the space of positive real functions.

In section 5, we prove that these are global coordinates, using methods from convex optimization theory. These schemes begin with an extension of the maximum entropy method, from the classical case of maximizing the zeroth cepstral gain to the problem of maximizing a "positive" linear combination of the entire partial cepstral window. This gives a new primal problem whose dual solves the rational covariance extension problem. In section 6, we provide a fairly complete local and global analysis of the use of a partial window of covariance lags and a partial window of cepstral

coefficients. In lieu of a convex optimization argument, we used an extension of the solution to the rational covariance extension problem and the Lefschetz fixed point theorem as a generalization of the Brower fixed point theorem for the spaces of Schur polynomials. We conclude the paper in section 7 with a discussion and illustrations of the applications of some of these constructions to speech synthesis.

2. Some geometric representations of classes of models. Suppose the positive real function f is given by

$$f(z) = \frac{1}{2}\frac{a(z)}{b(z)}, \tag{2.1}$$

where

$$\begin{aligned} a(z) &= a_0 z^n + a_1 z^{n-1} + \cdots + a_n, \\ b(z) &= b_0 z^n + b_1 z^{n-1} + \cdots + b_n \end{aligned}$$

are (real) polynomials of degree n. Clearly, a_0 and b_0 must have the same sign. We assume that they are both positive. Then, since

$$f(z) + f(z^{-1}) = w(z)w(z^{-1}),$$

we must have

$$w(z) = \frac{\sigma(z)}{a(z)}, \tag{2.2}$$

where

$$\sigma(z) = \sigma_0 z^n + \sigma_1 z^{n-1} + \cdots + \sigma_n$$

is the unique polynomial with all roots in the open unit disc satisfying

$$\sigma(z)\sigma(z^{-1}) = \frac{1}{2}[a(z)b(z^{-1}) + a(z^{-1})b(z)] \tag{2.3}$$

and $\sigma_0 > 0$. We shall denote the class of such polynomials by $\hat{\mathcal{S}}_n$, and we shall denote the n-dimensional submanifold of monic (Schur) polynomials in $\hat{\mathcal{S}}_n$ by $\mathcal{S}_n$. Now, in order for f to be positive real, the pseudopolynomial

$$a(z)b(z^{-1}) + a(z^{-1})b(z)$$

must be positive on the unit circle, and $a(z)$ must belong to $\hat{\mathcal{S}}_n$. Then $b(z)$ also must belong to $\hat{\mathcal{S}}_n$.

Clearly, it is no restriction to take $a \in \mathcal{S}_n$ in (2.3). For each such $a(z)$, let

$$S(a)v = a(z)v(z^{-1}) + a(z^{-1})v(z)$$

define an operator $S(a) : V_n \to \mathcal{Z}_n$ from the vector space V_n of polynomials having degree less than or equal to n into the vector space $\mathcal{Z}_n$ of pseudopolynomials of degree at most n. Then (2.3) may be written as

$$S(a)b = 2\sigma\sigma^*, \tag{2.4}$$

where $\sigma^*(z) := \sigma(z^{-1})$. Now it is well known that $S(a)$ is bijective when $a \in \mathcal{S}_n$ (see, e.g., [8, p. 760]), and hence (2.4) establishes a one-to-one correspondence between f and w. We may normalize this relation by taking either $b(z)$ or $\sigma(z)$, but not both, in $\mathcal{S}_n$.

The normalization $b_0 = 1$ corresponds to taking $r_0 = 1$ in (1.3). We denote by $\mathcal{P}_n$ the set of all $(a, b) \in \mathcal{S}_n \times \mathcal{S}_n$ such that (2.1) is positive real. We know [13] that $\mathcal{P}_n$ is a smooth, connected, real manifold of dimension $2n$ and that it is diffeomorphic to $\mathbb{R}^{2n}$.

Choosing instead the normalization $\sigma \in \mathcal{S}_n$, corresponding to setting $w_0 = 1$ in (2.2) and $c_0 = 0$ in (1.5), we obtain an alternative coordinatization of $\mathcal{P}_n$ in terms of (a, σ). In fact, for each $(a, \sigma) \in \mathcal{S}_n \times \mathcal{S}_n$, we obtain the corresponding $(a, b) \in \mathcal{P}_n$ by dividing $b = 2S(a)^{-1}(\sigma\sigma^*)$ by b_0, thus normalizing it to form a monic b. This is a diffeomorphism, establishing that $\mathcal{P}_n$ is diffeomorphic to $\mathcal{S}_n \times \mathcal{S}_n$. In fact, the inverse of this coordinate transformation is the stable spectral factorization of $\frac{1}{2}S(a)b$ followed by the normalization of $\sigma(z)$. Since $\mathcal{S}_n$ is diffeomorphic to $\mathbb{R}^n$ (see Appendix A), spectral factorization gives an alternative method of exhibiting a diffeomorphism between $\mathcal{P}_n$ and $\mathbb{R}^{2n}$.

We shall generally use (a, σ)-coordinates to describe the geometry of $\mathcal{P}_n$. This normalizes the cepstral window (1.10) and the Markov window (1.11), fixing c_0 at zero and w_0 at one. However, a covariance window which is normalized in (a, b)-coordinates will not be normalized in (a, σ)-coordinates, and hence, to avoid increasing the dimension of the problem, we shall need to consider instead the *normalized covariance lags*

$$r_k = \frac{\int_{-\pi}^{\pi} e^{ik\theta}\Phi(e^{i\theta})d\theta}{\int_{-\pi}^{\pi} \Phi(e^{i\theta})d\theta}, \quad k = 1, 2, \ldots, n, \tag{2.5}$$

when working in (a, σ)-coordinates. In fact, in all of these descriptions, the polynomials $a(z)$, $b(z)$, and $\sigma(z)$ are monic. Working with unnormalized covariance lags (1.2), as we shall occasionally do, requires an extra parameter, bringing the number of coordinates to $2n + 1$.

There are several other spaces of models which we will need in this analysis. We denote by $\mathcal{P}_n^*$ the (dense) open subspace of $\mathcal{P}_n$ consisting of those pairs (a, σ) of polynomials which are coprime. Following the arguments in Appendix A, we see that $\mathcal{P}_n$ is diffeomorphic to the space of coprime pairs of real monic polynomials of degree n with poles and zeros in $\mathbb{C}$, first studied in [4] using the notation $\mathrm{Rat}(n)$. The space $\mathrm{Rat}(n)$ is a $2n$-dimensional manifold with $n + 1$ path-connected components, some of which have a rather complicated topology (see [4, 34, 37, 6]).

We shall also need to study the space Π_n of real, monic, degree n-polynomials, which is, of course, diffeomorphic to $\mathbb{R}^n$. Our interest in this space comes from the Markov expansion (1.11), where we take σ to be in Π_n and a to be in $\mathcal{S}_n$. Consequently, we allow (a, σ) to vary over the larger space

$$\mathcal{Q}_n := \mathcal{S}_n \times \Pi_n.$$

We shall also need to consider the space $\mathcal{Q}_n^*$, the (dense) open subspace of $\mathcal{Q}_n$ consisting of those pairs (a, σ) of polynomials which are coprime.

3. Main results. Our first results show that it is possible to parameterize minimum-phase shaping filters in terms of a window of cepstral coefficients and a

window of covariance lags, both of which can be estimated from data. It is tempting, of course, to argue the plausibility of this result by counting parameters. This method typically works only when there is a rigorous way to compute the dimension of some geometric object—in this case, the smooth $2n$-dimensional manifold $\mathcal{P}_n$. In this setting, the implicit function theorem enables one to compute dimensions by computing the rank of certain Jacobian matrices or, equivalently, the linear independence of differentials. The following theorem is proved in section 4 (see Remark 4.7).

THEOREM 3.1. *The normalized covariance lags $r_1, r_2, \dots, r_n$ and the cepstral coefficients $c_1, c_2, \dots, c_n$ form a bona fide smooth coordinate system on the open subset $\mathcal{P}_n^*$ of $\mathcal{P}_n$; i.e., the map from $\mathcal{P}_n^*$ to $\mathbb{R}^{2n}$ with components $(r_1, r_2, \dots, r_n, c_1, c_2, \dots, c_n)$ has an everywhere invertible Jacobian matrix.*

Accordingly, when viewed as functions on $\mathcal{P}_n^*$, $(r_1, r_2, \dots, r_n, c_1, c_2, \dots, c_n)$ form local coordinates for the space $\mathcal{P}_n^*$ of pole-zero filters of degree n. At this point, one might hope to be able to use a global inverse function theorem, such as Hadamard's theorem, to show that these data define a global coordinate system. In part because of the complicated topology of $\mathcal{P}_n^*$, this is not possible, and instead we use a convex optimization scheme to conclude one of the important features of a global inverse function theorem. Indeed, the very nontrivial consequence of our next observation, to be proved in section 5, is that there is a one-to-one correspondence between the $2n$ coefficients $r_1, r_2, \dots, r_n, c_1, c_2, \dots, c_n$ of the minimum-phase shaping filter (2.2) and the $2n$ coefficients $a_1, a_2, \dots, a_n, \sigma_1, \sigma_2, \dots, \sigma_n$ of the denominator and numerator polynomials of (2.2), provided the degree of w is *exactly* n.

THEOREM 3.2. *Each shaping filter in $\mathcal{P}_n^*$ determines and is uniquely determined by its window $r_1, r_2, \dots, r_n$ of normalized covariance lags and its window $c_1, c_2, \dots, c_n$ of cepstral coefficients.*

As we have indicated, uniqueness follows from the remarkable fact that such a modeling filter arises as the minimum of a (strictly) convex optimization problem (see section 5). This optimization problem has, of course, antecedents in the literature, beginning with maximum entropy methods. Recall that linear predictive coding (LPC) is the most common method for determining shaping filters in signal processing. Given the window of (unnormalized) covariance data

$$r_0, r_1, \dots, r_n \tag{3.1}$$

with a positive definite Toeplitz matrix T_n, find the (unnormalized) shaping filter $w(z)$ and the corresponding spectral density

$$\Phi(e^{i\theta}) = |w(e^{i\theta})|^2,$$

which maximizes the entropy gain

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} \log \Phi(e^{i\theta}) d\theta, \tag{3.2}$$

subject to the covariance-matching condition

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} e^{ik\theta}\Phi(e^{i\theta}) d\theta = r_k, \quad k = 0, 1, \dots, n. \tag{3.3}$$

For this reason, the LPC filter is often called the *maximum entropy filter*.

Now observe that the entropy gain (3.2) is precisely the zeroth cepstral coefficient

$$c_0 = \frac{1}{2\pi}\int_{-\pi}^{\pi} \log \Phi(e^{i\theta}) d\theta.$$

However, in cepstral analysis, one is interested not only in c_0 but in a finite window

$$c_0, c_1, \dots, c_n \tag{3.4}$$

of cepstral coefficients. It is natural, therefore, to maximize instead some (positive) linear combination

$$p_0c_0 + p_1c_1 + \cdots + p_nc_n \tag{3.5}$$

of the cepstral coefficients in the window (3.4). In view of (1.6), this may be written as a generalized entropy gain

$$\mathbb{I}_P(f) = \frac{1}{2\pi}\int_{-\pi}^{\pi} P(e^{i\theta}) \log \Phi(e^{i\theta}) d\theta, \tag{3.6}$$

where P is the symmetric pseudopolynomial

$$P(z) = p_0 + \frac{1}{2}p_1(z + z^{-1}) + \cdots + \frac{1}{2}p_n(z^n + z^{-n}), \tag{3.7}$$

and f is the positive real part (1.3) of Φ. We shall say that $P \in \mathcal{D}$ if P is nonnegative on the unit circle and $P \in \mathcal{D}_+$ if it is positive there. We note that the covariance matching condition (3.3) becomes

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} e^{ik\theta}\Phi(e^{i\theta}) d\theta = r_k, \quad k = 0, 1, \dots, n, \tag{3.8}$$

in terms of $\Phi(e^{i\theta}) = |w(e^{i\theta})|^2$.

Indeed, in section 5, we show that the problem of maximizing (3.5) subject to (3.8) has a finite solution only if the pseudopolynomial (3.7) belongs to $\mathcal{D}$. Indeed, if $P \in \mathcal{D}_+$, there is a unique solution Φ, and this solution has the form

$$\Phi(z) = \frac{P(z)}{Q(z)},$$

where

$$Q(z) = q_0 + \tfrac{1}{2}q_1(z + z^{-1}) + \cdots + \tfrac{1}{2}q_n(z^n + z^{-n})$$

belongs to $\mathcal{D}_+$.

In particular, we see that if we take P to be

$$P(z) = \sigma(z)\sigma(z^{-1})$$

and let $a(z)$ be the unique stable polynomial satisfying

$$Q(z) = a(z)a(z^{-1}),$$

then we have also determined the unique shaping filter (2.2) that matches the covariance data (3.1). Hence we have an alternative proof of the following result, first appearing in [11].

THEOREM 3.3. *Let $r_0, r_1, \dots, r_n$ be a partial covariance sequence, i.e., real numbers such that the Toeplitz matrix* (1.4) *is positive definite. Then, to any stable polynomial*

$$\sigma(z) = z^n + \sigma_1 z^{n-1} + \cdots + \sigma_{n-1}z + \sigma_n$$

of degree n, there corresponds a unique real stable polynomial

$$a(z) = a_0 z^n + a_1 z^{n-1} + \cdots + a_{n-1} z + a_n$$

of degree n such that

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} e^{ik\theta} \left| \frac{\sigma(e^{i\theta})}{a(e^{i\theta})} \right|^2 d\theta = r_k, \quad k = 0, 1, \ldots, n. \tag{3.9}$$

Theorem 3.3 was conjectured by Georgiou [21] as a solution to the partial covariance extension problem posed by Kalman [25]. Georgiou had already established the existence part, but a complete proof of the conjecture was given much later in [11]. Similarly, in [11], we also showed the following theorem.

THEOREM 3.4. *The normalized covariance lags $r_1, r_2, \ldots, r_n$ and the zero coefficients $\sigma_1, \sigma_2, \ldots, \sigma_n$ form a bona fide smooth coordinate system on the open manifold $\mathcal{P}_n$; i.e., the map from $\mathcal{P}_n$ to $\mathbb{R}^{2n}$ with components $(r_1, r_2, \ldots, r_n, \sigma_1, \sigma_2, \ldots, \sigma_n)$ has an everywhere invertible Jacobian matrix.*

In section 6, we derive the following results for coordinatization by covariance data and Markov parameters.

THEOREM 3.5. *The normalized covariance lags $r_1, r_2, \ldots, r_n$ and the normalized Markov parameters $w_1, w_2, \cdots, w_n$ form a bona fide smooth coordinate system on $\mathcal{Q}_n^*$; i.e., the map from $\mathcal{Q}_n^*$ to $\mathbb{R}^{2n}$ with components $(r_1, r_2, \ldots, r_n, w_1, w_2, \ldots, w_n)$ has an everywhere invertible Jacobian matrix. For each choice of a covariance window and a Markov window, there exists exactly one shaping filter matching these windows.*

The last statement of this theorem is related to a class of results found in the literature on Q-Markov covers (see, e.g., [31, 29, 1]). Allowing windows of Markov parameters for which $w_0 = 0$, as in the literature cited above, would only add filters $w(z)$, which can be recovered from those of Theorem 3.5 by multiplying $w(z)$ by some power of z^{-1}.

4. Global analysis on $\mathcal{P}_n$. We choose to represent minimum-phase shaping filters (2.2) by a pair $(a, \sigma) \in \mathcal{S}_n \times \mathcal{S}_n$. This imposes the normalization discussed in section 2. There is a geometric manifestation of the fact that (a, σ) are smooth coordinates on $\mathcal{P}_n$, which we will use to show that the cepstral and covariance windows also form bona fide coordinate systems. First note that tangent vectors to $\mathcal{P}_n$ at (a, σ) may be represented as a perturbation $(a + \epsilon u, \sigma + \epsilon v)$, where u, v are polynomials of degree less than or equal to $n - 1$. If, as before, we denote the real vector space of polynomials of degree less than or equal to d by V_d, then the tangent space to $\mathcal{P}_n$ at a point (a, σ) is canonically isomorphic to $V_{n-1} \times V_{n-1}$.

Now, for $a \in \mathcal{S}_n$, define $\mathcal{P}_n(a)$ to be the space of all points in $\mathcal{P}_n$ with the polynomial a fixed. If we define $\mathcal{P}_n(\sigma)$ analogously, then $\mathcal{P}_n(a)$ and $\mathcal{P}_n(\sigma)$ are real, smooth, connected n-manifolds. In fact, both are clearly diffeomorphic to $\mathcal{S}_n$ and hence to $\mathbb{R}^n$ [7] (see also Appendix A). The tangent space to the submanifold $\mathcal{P}_n(a)$ at a point (a, σ) is, therefore,

$$T_{(a,\sigma)}\mathcal{P}_n(a) = \{(u, v) \in V_{n-1} \times V_{n-1} \mid u = 0\}.$$

Similarly, the tangent space to $\mathcal{P}_n(\sigma)$ is given by

$$T_{(a,\sigma)}\mathcal{P}_n(\sigma) = \{(u, v) \in V_{n-1} \times V_{n-1} \mid v = 0\}.$$

Now the n-manifolds $\{\mathcal{P}_n(a) \mid a \in \mathcal{S}_n\}$ form the leaves of a foliation of $\mathcal{P}_n$, as do the n-manifolds $\{\mathcal{P}_n(\sigma) \mid \sigma \in \mathcal{S}_n\}$. Moreover, these two foliations are complementary in

the sense that if a leaf of one intersects a leaf of the other, the tangent spaces intersect in just $(0,0)$. This transversality property is equivalent to the fact that the functions (a,σ) form a local system of coordinates.

We now turn to the cepstral functions and the covariance functions. Let $g : \mathcal{P}_n \to \mathbb{R}^n$ be the map which sends (a,σ) to the vector $c \in \mathbb{R}^n$ with components

$$c_k = \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{ik\theta}\log|w(e^{i\theta})|^2 d\theta, \quad k = 1,2,\ldots,n, \tag{4.1}$$

and let $\mathcal{C}_n := g(\mathcal{P}_n)$. Moreover, for each $c \in \mathcal{C}_n$, define the subset

$$\mathcal{P}_n(c) = g^{-1}(c).$$

We wish to show that $\mathcal{P}_n(c)$ is a smooth submanifold of dimension n. To this end, we will need to compute the Jacobian matrix of g, evaluated at tangent vectors to a point $(a,\sigma) \in \mathcal{P}_n$.

Thus, for each component

$$g_k(a,\sigma) = \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{ik\theta}\log\left|\frac{\sigma(e^{i\theta})}{a(e^{i\theta})}\right|^2 d\theta$$

of g, we form the directional derivative

$$D_{(u,v)}g_k(a,\sigma) = \lim_{\epsilon\to 0}\frac{1}{\epsilon}\left[g_k(a+\epsilon u,\sigma+\epsilon v) - g_k(a,\sigma)\right]$$

in the direction $(u,v) \in V_{n-1}\times V_{n-1}$. A straightforward calculation yields

$$D_{(u,v)}g_k(a,\sigma) = \frac{1}{2\pi}\int_{-\pi}^{\pi} 2\mathrm{Re}\left\{\frac{v(e^{i\theta})}{\sigma(e^{i\theta})} - \frac{u(e^{i\theta})}{a(e^{i\theta})}\right\} e^{ik\theta}d\theta \tag{4.2}$$

$$= \frac{1}{2\pi}\int_{-\pi}^{\pi}\left[\frac{S(\sigma)v}{\sigma\sigma^*} - \frac{S(a)u}{aa^*}\right] e^{ik\theta}d\theta. \tag{4.3}$$

Now, for any $\varphi \in \mathcal{S}_n$, define the linear map $G_\varphi : V_{n-1} \to \mathbb{R}^n$ by

$$G_\varphi u = \frac{1}{2\pi}\int_{-\pi}^{\pi}\frac{S(\varphi)u}{\varphi\varphi^*}\begin{bmatrix} e^{i\theta} \\ e^{i2\theta} \\ \vdots \\ e^{in\theta}\end{bmatrix} d\theta.$$

Then the kernel of the Jacobian of g at (a,σ) is given by

$$\ker \mathrm{Jac}(g)|_{(a,\sigma)} = \{(u,v) \mid G_\sigma v = G_a u\}. \tag{4.4}$$

LEMMA 4.1. *The linear map G_φ is a bijection.*

Proof. Suppose that $G_\varphi u = 0$. Then

$$\frac{1}{2\pi}\int_{-\pi}^{\pi}\frac{S(\varphi)u}{\varphi\varphi^*}e^{ik\theta}d\theta = 0 \tag{4.5}$$

for $k = 1,2,\ldots,n$. By symmetry this also holds for $k = -1,-2,\ldots,-n$. Moreover, since

$$\frac{S(\varphi)u}{\varphi\varphi^*}(z) = \frac{u(z)}{\varphi(z)} + \frac{u(z^{-1})}{\varphi(z^{-1})}$$

and $\frac{u(z)}{\varphi(z)}$ is strictly proper and analytic for $|z| \geq 1$, (4.5) holds for $k = 0$ also so that integration against $\frac{S(\varphi)u}{\varphi\varphi^*}$ annihilates all trigonometric pseudopolynomials of degree at most n. In particular, we obtain

$$\frac{1}{2\pi}\int_{-\pi}^{\pi}\left|\frac{S(\varphi)u}{\varphi}\right|^2 d\theta = 0,$$

which in turn yields $S(\varphi)u = 0$. But $S(\varphi)$ is nonsingular, and hence $u = 0$, establishing injectivity of G_φ. However, since the range and domain of G_φ are the same dimension, namely n, the map is also surjective. □

PROPOSITION 4.2. *For each $c \in \mathcal{C}_n$, the space $\mathcal{P}_n(c)$ is a smooth n-manifold. The tangent space $T_{(a,\sigma)}\mathcal{P}_n(c)$ at (a,σ) consists of precisely all $(u,v) \in V_{n-1} \times V_{n-1}$ such that*

$$\frac{1}{2\pi}\int_{-\pi}^{\pi}\frac{S(\sigma)v}{\sigma\sigma^*}e^{ik\theta}d\theta = \frac{1}{2\pi}\int_{-\pi}^{\pi}\frac{S(a)u}{aa^*}e^{ik\theta}d\theta \tag{4.6}$$

for $k = 0, 1, \dots, n$.

Proof. The tangent vectors of $\mathcal{P}_n(c)$ at (a,σ) are precisely the vectors in the null space of the Jacobian of g at (a,σ), as computed above. Consequently, by (4.4), (4.6) holds for $k = 1, 2, \dots, n$. However, as pointed out in the proof of Lemma 4.1, (4.5) holds for $k = 0$, and hence (4.6) holds for $k = 0$ also. Moreover, by (4.4) and Lemma 4.1, the tangent space has dimension n. Therefore, the rank of $\mathrm{Jac}(g)|_{(a,\sigma)}$ is full, and the rest of the claim follows from the implicit function theorem. □

Because the rank of $\mathrm{Jac}(g)|_{(a,\sigma)}$ is everywhere n, the connected components of the submanifolds $\mathcal{P}_n(c)$ form the leaves of a foliation of $\mathcal{P}_n$. However, according to Lemma C.1, the submanifolds $\mathcal{P}_n(c)$ are themselves connected.

PROPOSITION 4.3. *The n-manifolds $\{\mathcal{P}_n(c) \mid c \in \mathcal{C}_n\}$ are connected and hence form the leaves of a foliation of $\mathcal{P}_n$.*

As an example of the more involved calculation we shall next undertake with the covariance window, we note a simple consequence of the results proven so far.

COROLLARY 4.4. *The foliations $\{\mathcal{P}_n(a) \mid a \in \mathcal{S}_n\}$ and $\{\mathcal{P}_n(c) \mid c \in \mathcal{C}_n\}$ are complementary; i.e., any intersecting pair of leaves, with one leaf from each foliation, intersects transversely. Moreover, any intersecting pair of leaves intersects in at most one point.*

Proof. Setting $u = 0$ in (4.4), we obtain $G_\sigma v = 0$. Hence, by Lemma 4.1, $v = 0$ so that the foliations are transverse. If a leaf $\mathcal{P}_n(a)$ intersects a leaf $\mathcal{P}_n(c)$ at a point (a,σ), then the a-coordinates, and hence the roots of a, are known. According to Appendix B, the value of the cepstral coefficients coincides with the difference of the Newton sums of the powers of the roots of a and the roots of σ. Therefore, the Newton sums of the powers of the roots of σ are known, and, therefore, by the Newton identities, so is σ. □

A similar statement for the foliation $\{\mathcal{P}_n(\sigma) \mid \sigma \in \mathcal{S}_n\}$ can be proved by the mirror image of this proof and will be omitted.

Next, let $f : \mathcal{P}_n \to \mathbb{R}^n$ be the map which sends (a,σ) to the vector $r \in \mathbb{R}^n$ of normalized covariance lags with components

$$r_k = \frac{\int_{-\pi}^{\pi} e^{ik\theta}\left|w(e^{i\theta})\right|^2 d\theta}{\int_{-\pi}^{\pi}\left|w(e^{i\theta})\right|^2 d\theta}, \quad k = 1, 2, \dots, n, \tag{4.7}$$

and let $\mathcal{R}_n := f(\mathcal{P}_n)$. Of course, any $r \in \mathcal{R}_n$ satisfies the positivity condition

$$T_n = \begin{bmatrix} 1 & r_1 & \cdots & r_n \\ r_1 & 1 & \cdots & r_{n-1} \\ \vdots & \vdots & \ddots & \vdots \\ r_n & r_{n-1} & \cdots & 1 \end{bmatrix} > 0.$$

Now, for each $r \in \mathcal{R}_n$, we want to show that

$$\mathcal{P}_n(r) = f^{-1}(r)$$

is a smooth manifold of dimension n. To this end, note that the function $f : \mathcal{P}_n \to \mathbb{R}^n$ has the components

$$f_k(a,\sigma) = \frac{h_k(a,\sigma)}{h_0(a,\sigma)},$$

where

$$h_k(a,\sigma) = \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{ik\theta}\left|\frac{\sigma(e^{i\theta})}{a(e^{i\theta})}\right|^2 d\theta, \quad k = 0,1,2,\ldots,n.$$

Clearly, $h_0(a,\sigma) > 0$ for all $(a,\sigma) \in \mathcal{P}_n$.

A straightforward calculation shows that the directional derivative of f at $(a,\sigma) \in \mathcal{P}_n$ in the direction $(u,v) \in V_{n-1} \times V_{n-1}$ is

$$D_{(u,v)}f_k(a,\sigma) = \frac{1}{h_0(a,\sigma)}D_{(u,v)}h_k(a,\sigma) - \frac{h_k(a,\sigma)}{h_0(a,\sigma)^2}D_{(u,v)}h_0(a,\sigma), \tag{4.8}$$

where

$$D_{(u,v)}h_k(a,\sigma) = \frac{1}{2\pi}\int_{-\pi}^{\pi}\left[\frac{S(\sigma)v}{aa^*} - \frac{S(a)u}{aa^*}\frac{\sigma\sigma^*}{aa^*}\right]e^{ik\theta}d\theta. \tag{4.9}$$

Therefore, defining

$$\varphi(a,\sigma;u,v) := D_{(u,v)}\log h_0(a,\sigma) = \frac{D_{(u,v)}h_0(a,\sigma)}{h_0(a,\sigma)},$$

the kernel of the Jacobian of f at (a,σ) consists of those $(u,v) \in V_{n-1} \times V_{n-1}$ for which

$$\frac{1}{2\pi}\int_{-\pi}^{\pi}\frac{S(\sigma)v}{aa^*}e^{ik\theta}d\theta = \frac{1}{2\pi}\int_{-\pi}^{\pi}\frac{S(a)u}{aa^*}\frac{\sigma\sigma^*}{aa^*}e^{ik\theta}d\theta + \varphi(a,\sigma;u,v)\frac{1}{2\pi}\int_{-\pi}^{\pi}\frac{\sigma\sigma^*}{aa^*}e^{ik\theta}d\theta$$

for $k = 0,1,\ldots,n$. In fact, this equation holds trivially for $k = 0$, and so, to simplify the notation in what follows, we add this equation.

PROPOSITION 4.5. *The space $\mathcal{P}_n(r)$ is a smooth, connected, n-manifold, and its tangent space $T_{(a,\sigma)}\mathcal{P}_n(r)$ consists of those $(u,v) \in V_{n-1} \times V_{n-1}$ for which*

$$\frac{1}{2\pi}\int_{-\pi}^{\pi}\frac{S(\sigma)v}{aa^*}e^{ik\theta}d\theta = \frac{1}{2\pi}\int_{-\pi}^{\pi}\frac{S(a)u}{aa^*}\frac{\sigma\sigma^*}{aa^*}e^{ik\theta}d\theta + \frac{\varphi}{2\pi}\int_{-\pi}^{\pi}\frac{\sigma\sigma^*}{aa^*}e^{ik\theta}d\theta \tag{4.10}$$

for $k = 0, 1, \dots, n$, where

$$\varphi = \frac{1}{h_0(a,\sigma)} \frac{1}{2\pi} \int_{-\pi}^{\pi} \left[\frac{S(\sigma)v}{aa^*} - \frac{S(a)u}{aa^*} \frac{\sigma\sigma^*}{aa^*} \right] d\theta. \tag{4.11}$$

The n-manifolds $\{\mathcal{P}_n(r) \mid r \in \mathcal{R}_n\}$ form the leaves of a foliation of $\mathcal{P}_n$.

Proof. The tangent space $T_{(a,\sigma)}\mathcal{P}_n(r)$ is the kernel of the Jacobian of f and is hence given by (4.10). Defining $p \in V_n$ as

$$p(z) := u(z) + \frac{1}{2}\varphi a(z),$$

these tangent equations may also be written as

$$Fp = Hv,$$

where $F : V_n \to \mathbb{R}^{n+1}$ and $H : V_{n-1} \to \mathbb{R}^{n+1}$ are the linear operators

$$Fp = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{S(a)p}{aa^*} \frac{\sigma\sigma^*}{aa^*} \begin{bmatrix} 1 \\ e^{i\theta} \\ \vdots \\ e^{in\theta} \end{bmatrix} d\theta, \qquad Hv = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{S(\sigma)v}{aa^*} \begin{bmatrix} 1 \\ e^{i\theta} \\ \vdots \\ e^{in\theta} \end{bmatrix} d\theta. \tag{4.12}$$

To see this, note that

$$\frac{1}{2} \frac{S(a)a}{aa^*} = 1.$$

Now the linear map F is nonsingular. In fact, supposing that $Fp = 0$ and, as in the proof of Lemma 4.1, taking the appropriate linear combination, we obtain

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{|S(a)p|^2}{aa^*} \frac{\sigma\sigma^*}{aa^*} d\theta = 0,$$

which holds if and only if $S(a)p = 0$. But since a is a Schur polynomial, $S(a)$ is nonsingular, and hence $Fp = 0$ if and only if $p = 0$. Since the range and the domain of F have the same dimension, F is nonsingular, as claimed. Then, since the leading term of the n-polynomial

$$p = F^{-1}Hu$$

is precisely $\frac{1}{2}\varphi$, φ is a linear function of u. This defines a linear map $L : V_{n-1} \to V_{n-1}$, which sends v to $u := p - \frac{1}{2}\varphi a$ so that $T_{(a,\sigma)}\mathcal{P}_n(r)$ consists of those (u, v) such that $u = Lv$. This establishes that $T_{(a,\sigma)}\mathcal{P}_n(r)$ is n-dimensional and that $\mathcal{P}_n(r)$ is an n-manifold. Since the rank of $\mathrm{Jac}(f)|_{(a,\sigma)}$ is full, smoothness follows from the implicit function theorem. The connectedness of $\mathcal{P}_n(r)$ was proven in [7]. Since the rank of $\mathrm{Jac}(f)|_{(a,\sigma)}$ is everywhere n, the connected submanifolds $\mathcal{P}_n(r)$ form the leaves of a foliation of $\mathcal{P}_n$. □

The relation between the foliations $\{\mathcal{P}_n(r) \mid r \in \mathcal{R}_n\}$ and $\{\mathcal{P}_n(c) \mid c \in \mathcal{C}_n\}$ is indeed interesting.

THEOREM 4.6. *For each $(a, \sigma) \in \mathcal{P}_n(r) \cap \mathcal{P}_n(c)$, the dimension of*

$$\Theta := T_{(a,\sigma)}\mathcal{P}_n(r) \cap T_{(a,\sigma)}\mathcal{P}_n(c)$$

equals the degree of the greatest common divisor of the polynomials $a(z)$ and $\sigma(z)$.

Proof. Any $(u, v) \in \Theta$ satisfies both (4.6) and (4.10). Taking the linear combinations of these equations corresponding to the coefficients of $\sigma\sigma^*$ and aa^*, respectively, we obtain

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} S(\sigma)v d\theta = \frac{1}{2\pi}\int_{-\pi}^{\pi} S(a)u\frac{\sigma\sigma^*}{aa^*}d\theta,$$
$$\frac{1}{2\pi}\int_{-\pi}^{\pi} S(\sigma)v d\theta = \frac{1}{2\pi}\int_{-\pi}^{\pi} S(a)u\frac{\sigma\sigma^*}{aa^*}d\theta + \varphi\|\sigma\|^2,$$

demonstrating that φ must be equal to zero. With $\varphi = 0$, (4.6) and (4.10) become

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} \frac{S(\sigma)v}{\sigma\sigma^*}e^{ik\theta}d\theta = \frac{1}{2\pi}\int_{-\pi}^{\pi} \frac{S(a)u}{aa^*}e^{ik\theta}d\theta, \quad k = 0, 1, \dots, n, \tag{4.13}$$

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} \frac{S(\sigma)v}{aa^*}e^{ik\theta}d\theta = \frac{1}{2\pi}\int_{-\pi}^{\pi} \frac{S(a)u}{aa^*}\frac{\sigma\sigma^*}{aa^*}e^{ik\theta}d\theta, \quad k = 0, 1, \dots, n. \tag{4.14}$$

Taking the appropriate linear combinations of (4.13) and (4.14), respectively, we obtain

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} \frac{|S(\sigma)v|^2}{\sigma\sigma^*}d\theta = \frac{1}{2\pi}\int_{-\pi}^{\pi} \frac{[S(a)u][S(\sigma)v]}{aa^*}d\theta,$$
$$\frac{1}{2\pi}\int_{-\pi}^{\pi} \frac{[S(\sigma)v][S(a)u]}{aa^*}d\theta = \frac{1}{2\pi}\int_{-\pi}^{\pi} \frac{|S(a)u|^2}{aa^*}\frac{\sigma\sigma^*}{aa^*}d\theta.$$

Now, setting

$$f_1 := \frac{S(\sigma)v}{\sigma^*} \quad \text{and} \quad f_2 := \frac{\sigma S(a)u}{aa^*},$$

these equations can be written as

$$\|f_1\|^2 = \langle f_1, f_2\rangle \quad \text{and} \quad \langle f_1, f_2\rangle = \|f_2\|^2$$

in the inner product and norm of $L^2[-\pi, \pi]$. Using the parallelogram law yields

$$\|f_1 - f_2\|^2 = \|f_1\|^2 + \|f_2\|^2 - 2\langle f_1, f_2\rangle = 0,$$

which in turn implies that $f_1 = f_2$. Therefore,

$$\frac{S(\sigma)v}{\sigma\sigma^*} = \frac{S(a)u}{aa^*}$$

on the unit circle or, equivalently,

$$\operatorname{Re}\left\{\frac{v}{\sigma}\right\} = \operatorname{Re}\left\{\frac{u}{a}\right\}. \tag{4.15}$$

However, since these are harmonic functions, (4.15) must hold in the whole complex plane. In particular, as $a(z)$ and $\sigma(z)$ are real polynomials, this becomes

$$\frac{v}{\sigma} = \frac{u}{a} \tag{4.16}$$

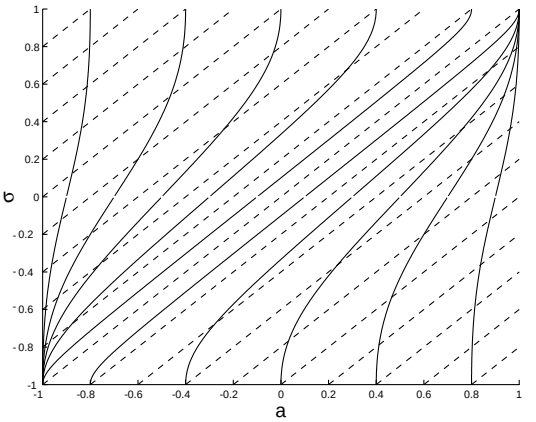

FIG. 5. *Cepstral (dotted line) and covariance (solid line) matching foliations of* $\mathcal{P}_1$.

on the real line. However, these functions are analytic outside the unit disc, and so, by the identity theorem, (4.16) is valid in the whole complex plane. Clearly, $u = v = 0$ satisfy (4.16), but let us see if there are nontrivial $u(z)$ and $v(z)$ of degree $n-1$. If so, (4.16) can also be written as

$$\frac{v}{u} = \frac{\sigma}{a},$$

which, of course, has no solution if $a(z)$ and $\sigma(z)$ are coprime. If $a(z)$ and $\sigma(z)$ have a greatest common factor of degree d, $u(z)$ and $v(z)$ could be polynomials of degree less than or equal to $n-1$ and have an arbitrary common factor of degree $d-1$, hence defining a vector space of dimension d, as claimed. □

Remark 4.7. It follows from Theorem 4.6 that the foliations $\{\mathcal{P}_n(r) \mid r \in \mathcal{R}_n\}$ and $\{\mathcal{P}_n(c) \mid c \in \mathcal{C}_n\}$ are complementary at any point $(a, \sigma) \in \mathcal{P}_n$, where a and σ are coprime, as illustrated in Figure 5 for $n = 1$. From this it follows that the kernels of $\mathrm{Jac}(g)|_{(a,\sigma)}$ and $\mathrm{Jac}(f)|_{(a,\sigma)}$ are complementary at any point (a, σ) in $\mathcal{P}_n^*$. In particular, the Jacobian of the joint map $(a, \sigma) \to (r_1, r_2, \dots, r_n, c_1, c_2, \dots, c_n)$ has full rank, and, by the inverse function theorem, the joint map forms a smooth local coordinate system on $\mathcal{P}_n^*$. This proves Theorem 3.1.

5. Identifiability of shaping filters from cepstral and covariance windows. In this section, we shall show that the window of n cepstral coefficients and the window of n normalized covariance lags do indeed determine the (normalized) shaping filter which generates these data, provided the filter has degree n, thus proving Theorem 3.2. As a preliminary to this argument, however, we want to return to the generalization of the maximum entropy integral in terms of "positive" linear combinations of the entire cepstral window. Not only is this an appealing idea, but it also turns out to give a novel derivation of a result which is of independent interest in itself, a solution of the rational covariance extension problem. We now formalize our analysis of this generalized maximum entropy problem.

THEOREM 5.1. *If the pseudopolynomial* (3.7) *belongs to* $\mathcal{D}_+$*, the problem to maximize* (3.5) *subject to* (3.8) *has a unique solution* Φ*, and this solution has the form*

$$\Phi(z) = \frac{P(z)}{Q(z)}, \tag{5.1}$$

where

$$Q(z) = q_0 + \frac{1}{2}q_1(z + z^{-1}) + \cdots + \frac{1}{2}q_n(z^n + z^{-n}) \tag{5.2}$$

also belongs to $\mathcal{D}_+$.

It turns out that the algorithm needed to determine Q is precisely the convex optimization algorithm presented in [12]. In fact, the algorithm is based on the dual problem, in the sense of mathematical programming, of the problem to maximize (3.6) subject to (3.8). More precisely, let $\mathcal{F}_+$ be the set of bounded positive real functions

$$f(z) = \frac{1}{2}f_0 + f_1 z^{-1} + f_2 z^{-2} + \cdots$$

such that $\Phi(e^{i\theta}) := 2\mathrm{Re}\{f(e^{i\theta})\}$ is bounded away from zero, and consider the (primal) problem to maximize the generalized entropy (3.6) over $\mathcal{F}_+$, i.e.,

$$\max_{f\in\mathcal{F}_+} \mathbb{I}_P(f),$$

subject to (3.8). Then duality theory amounts to forming the Lagrangian

$$\begin{aligned} L(f,q) &= \mathbb{I}_P(f) + \sum_{k=0}^{n} q_k \left[r_k - \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{ik\theta}\Phi(e^{i\theta})d\theta \right] \\ &= \frac{1}{2\pi}\int_{-\pi}^{\pi} P(e^{i\theta})\log\Phi(e^{i\theta})d\theta + r'q - \frac{1}{2\pi}\int_{-\pi}^{\pi} Q(e^{i\theta})\Phi(e^{i\theta})d\theta \end{aligned} \tag{5.3}$$

and determining the Lagrange multipliers $q \in \mathbb{R}^{n+1}$ by minimizing the dual functional

$$\psi(q) := \sup_{f\in\mathcal{F}_+} L(f,q).$$

Clearly, $\psi(q) < \infty$ only if both P and Q belong to $\mathcal{D}$. If the function $f \mapsto L(f,q)$ has a maximum in the open region $\mathcal{F}_+$, then

$$\frac{\partial L}{\partial f_k} = 0, \quad k = 0, 1, 2, \ldots,$$

in the maximizing point. This stationarity condition becomes

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} e^{ik\theta}\left[P(e^{i\theta})\Phi(e^{i\theta})^{-1} - Q(e^{i\theta})\right]d\theta = 0, \quad k = 0, 1, 2, \ldots,$$

which is satisfied if and only if (5.1) or, equivalently,

$$f_k = \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{ik\theta}\frac{P(e^{i\theta})}{Q(e^{i\theta})}d\theta \tag{5.4}$$

holds. Inserting this into (5.3) yields the dual functional

$$\psi(q) = \mathbb{J}_P(q) + \frac{1}{2\pi}\int_{-\pi}^{\pi} P(e^{i\theta})[\log P(e^{i\theta}) - 1]d\theta \tag{5.5}$$

for all $P, Q \in \mathcal{D}$, where

$$\mathbb{J}_P(q) = r_0 q_0 + r_1 q_1 + \cdots + r_n q_n - \frac{1}{2\pi}\int_{-\pi}^{\pi} P(e^{i\theta})\log Q(e^{i\theta})d\theta. \tag{5.6}$$

Since the last term in (5.5) does not depend on q, we shall call the optimization problem

$$\min_{Q\in\mathcal{D}} \mathbb{J}_P(Q) \tag{5.7}$$

the *dual problem.* The functional (5.6) is strictly convex, and, therefore, the minimum is unique, provided one exists. This is precisely the optimization problem considered in [12], where the following theorem was proven.

THEOREM 5.2. *The dual problem has a unique solution, and it belongs to* $\mathcal{D}_+$.

Since thus $\mathbb{J}_P$ takes its minimum in an interior point,

$$\frac{\partial \mathbb{J}_P}{\partial q_k} = r_k - \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{ik\theta}\frac{P(e^{i\theta})}{Q(e^{i\theta})}d\theta \tag{5.8}$$

equals zero there for $k = 0, 1, \dots, n$. This stationarity condition is precisely the covariance matching condition. The dual problem is easily solved by Newton's method [12, 14]. The statement of Theorem 5.2 is nontrivial. In fact, the proof [12] relies on the fact that the gradient (5.8) tends to infinity as Q tends to the boundary of $\mathcal{D}$.

Proof of Theorem 5.1. Let $\hat{Q} \in \mathcal{D}_+$ be the unique solution to the dual problem (5.7), let $\hat{q} \in \mathbb{R}^{n+1}$ be the corresponding vector of coefficients, and let

$$\hat{f}_k = \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{ik\theta}\frac{P(e^{i\theta})}{\hat{Q}(e^{i\theta})}d\theta.$$

Clearly, $\hat{f} \in \mathcal{F}_+$. Since the gradient (5.8) is zero for $Q = \hat{Q}$, the covariance matching condition (3.8) is fulfilled for $f = \hat{f}$, and, therefore, $\mathbb{I}_P(\hat{f}) = L(\hat{f}, \hat{q})$. But, by the construction above,

$$L(\hat{f}, \hat{q}) = \sup_{f\in\mathcal{F}_+} L(f, \hat{q}) \geq L(f, \hat{q})$$

for all $f \in \mathcal{F}_+$. Then, for any $f \in \mathcal{F}_+$ which satisfies the covariance matching condition (3.8),

$$\mathbb{I}_P(f) = L(f, \hat{q}) \leq \mathbb{I}_P(\hat{f}),$$

which establishes the optimality of $\hat{f}$. □

This analysis motivates the construction of a functional which will be the key in establishing uniqueness of minimum-phase shaping filters having prescribed windows $r_0, r_1, \dots, r_n$ and $c_1, c_2, \dots, c_n$ of covariance lags and cepstral coefficients, respectively. More precisely, consider the (primal) problem of finding a spectral density

$$\Phi(e^{i\theta}) = f_0 + 2\sum_{k=1}^{\infty} f_k \cos k\theta,$$

which minimizes

$$\mathbb{I}(f) = \sum_{k=1}^{n}\left|\frac{1}{2\pi}\int_{-\pi}^{\pi} e^{ik\theta}\log\Phi(e^{i\theta})d\theta - c_k\right| - \frac{1}{2\pi}\int_{-\pi}^{\pi}\log\Phi(e^{i\theta})d\theta \tag{5.9}$$

subject to the covariance-lag matching condition

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} e^{ik\theta}\Phi(e^{i\theta})d\theta = r_k, \quad k = 0, 1, \dots, n. \tag{5.10}$$

The objective function (5.9) is the (ℓ_1) "cepstral error" minus the entropy gain. As discussed in section 3, the entropy gain is precisely what is maximized in the LPC solution, and it is identical to the zeroth cepstral coefficient corresponding to Φ. This term compensates for the absence of a zeroth term in the cepstral error.

To obtain a suitable dual problem, we reformulate the *primal problem* to minimize

$$\sum_{k=0}^{n} \epsilon_k - \frac{1}{2\pi} \int_{-\pi}^{\pi} \log \Phi(e^{i\theta}) d\theta$$

subject to the covariance matching condition (5.10) and

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} e^{ik\theta} \log \Phi(e^{i\theta}) d\theta - c_k - \epsilon_k \leq 0, \quad k = 1, 2, \ldots, n, \tag{5.11}$$

$$-\frac{1}{2\pi} \int_{-\pi}^{\pi} e^{ik\theta} \log \Phi(e^{i\theta}) d\theta + c_k - \epsilon_k \leq 0, \quad k = 1, 2, \ldots, n. \tag{5.12}$$

Taking $q_0, q_1, \ldots, q_n$ to be the Lagrange multipliers for the constraints (5.10) and $\lambda_1, \lambda_2, \ldots, \lambda_n$ and $\mu_1, \mu_2, \ldots, \mu_n$ to be nonnegative Lagrange multipliers for the sets of constraints (5.11) and (5.12), respectively, we obtain the Lagrangian

$$\begin{aligned} L(f, \epsilon, q, \lambda, \mu) = \sum_{k=1}^{n} \epsilon_k &- \frac{1}{2\pi} \int_{-\pi}^{\pi} \log \Phi(e^{i\theta}) d\theta \\ &+ \sum_{k=0}^{n} q_k \left[\frac{1}{2\pi} \int_{-\pi}^{\pi} e^{ik\theta} \Phi(e^{i\theta}) d\theta - r_k \right] \\ &+ \sum_{k=1}^{n} \lambda_k \left[\frac{1}{2\pi} \int_{-\pi}^{\pi} e^{ik\theta} \log \Phi(e^{i\theta}) d\theta - c_k - \epsilon_k \right] \\ &- \sum_{k=1}^{n} \mu_k \left[\frac{1}{2\pi} \int_{-\pi}^{\pi} e^{ik\theta} \log \Phi(e^{i\theta}) d\theta - c_k + \epsilon_k \right]. \end{aligned}$$

Now, setting

$$p_0 = 1, \qquad p_k := \mu_k - \lambda_k, \quad k = 1, 2, \ldots, n, \tag{5.13}$$

we can write this in the more compact form

$$\begin{aligned} L(f, \epsilon, q, \lambda, \mu) = &\sum_{k=1}^{n} (1 - \lambda_k - \mu_k) \epsilon_k \\ &+ c_1 p_1 + c_2 p_2 + \cdots + c_n p_n - r_0 q_0 - r_1 q_1 - \cdots - r_n q_n \\ &+ \frac{1}{2\pi} \int_{-\pi}^{\pi} Q(e^{i\theta}) \Phi(e^{i\theta}) d\theta - \frac{1}{2\pi} \int_{-\pi}^{\pi} P(e^{i\theta}) \log \Phi(e^{i\theta}) d\theta, \end{aligned}$$

which clearly can have a finite minimum only for those values of the Lagrange multipliers for which both P and Q belong to $\mathcal{D}$ and $\lambda_k + \mu_k \leq 1$ for $k = 1, 2, \ldots, n$. For such Lagrange multipliers, if the function $(f, \epsilon) \to L(f, \epsilon, q, \lambda, \mu)$ has a minimum, then

$$\frac{\partial L}{\partial f_k} = 0, \quad k = 0, 1, 2, \ldots, \tag{5.14}$$

and

$$(1-\lambda_k-\mu_k)\epsilon_k=0, \quad k=1,2,\dots,n, \tag{5.15}$$

in the minimizing point. The stationarity condition (5.14) becomes

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} e^{ik\theta}\left[P(e^{i\theta})\Phi(e^{i\theta})^{-1}-Q(e^{i\theta})\right]d\theta=0, \quad k=0,1,2,\dots,$$

or, equivalently,

$$\Phi(z)=\frac{P(z)}{Q(z)},$$

which, inserted together with (5.15) into the Lagrangian with P given by (5.13), yields the dual functional

$$\inf_{(f,\epsilon)\in\mathcal{F}_+\times\mathbb{R}^+} L(f,\epsilon,q,\lambda,\mu)=\mathbb{J}(P,Q)+1,$$

where the functional

$$\begin{aligned}\mathbb{J}(P,Q)&=c_1p_1+c_2p_2+\cdots+c_np_n-r_0q_0-r_1q_1-\cdots-r_nq_n\\ &\quad-\frac{1}{2\pi}\int_{-\pi}^{\pi}P(e^{i\theta})\log\frac{P(e^{i\theta})}{Q(e^{i\theta})}d\theta\end{aligned} \tag{5.16}$$

is concave but not necessarily strictly concave.

THEOREM 5.3. *The dual problem to maximize $\mathbb{J}(P,Q)$ over all $(P,Q)\in\mathcal{D}\times\mathcal{D}$ such that $p_0=1$ has a solution $(\hat{P},\hat{Q})$, and, for any such solution, $\hat{Q}\in\mathcal{D}_+$, and*

$$\Phi(z)=\frac{\hat{P}(z)}{\hat{Q}(z)} \tag{5.17}$$

satisfies the covariance matching condition (5.10). *If, in addition, $\hat{P}\in\mathcal{D}_+$, then* (5.17) *is a solution of the primal problem with $\epsilon_1=\epsilon_2=\cdots=\epsilon_n=0$, i.e., there is both covariance matching and cepstral matching. A maximizing point $(\hat{P},\hat{Q})\in\mathcal{D}_+\times\mathcal{D}_+$ is unique if and only if $\hat{P}$ and $\hat{Q}$ are coprime.*

Proof. It can be shown along the same lines as in [12] that the functional $\mathbb{J}$ has compact sublevel sets in $\mathcal{D}\times\mathcal{D}$. Hence $\mathbb{J}$ has a maximal point $(\hat{P},\hat{Q})$ there. The boundary of $\mathcal{D}\times\mathcal{D}$ consists of those points where either $\hat{P}$ or $\hat{Q}$ or both have zeros on the unit circle. Now a straightforward calculation shows that

$$\frac{\partial\mathbb{J}}{\partial q_k}=\frac{1}{2\pi}\int_{-\pi}^{\pi}e^{ik\theta}\frac{P(e^{i\theta})}{Q(e^{i\theta})}d\theta-r_k, \quad k=0,1,\dots,n, \tag{5.18}$$

$$\frac{\partial\mathbb{J}}{\partial p_k}=c_k-\frac{1}{2\pi}\int_{-\pi}^{\pi}e^{ik\theta}\log\frac{P(e^{i\theta})}{Q(e^{i\theta})}d\theta, \quad k=1,2,\dots,n. \tag{5.19}$$

From this and the argument in [12], it can be shown that the gradient (5.18) becomes infinite when Q lies on the boundary and hence that $\hat{Q}\in\mathcal{D}_+$. Therefore, since the functional $\mathbb{J}$ is concave, (5.18) must be zero at $(\hat{P},\hat{Q})$, and hence (5.17) satisfies the covariance matching condition (5.10).

Next suppose that $\hat{P} \in \mathcal{D}_+$. Then (5.19) must also be zero at $(\hat{P}, \hat{Q})$, and hence there is also cepstral matching. For any $f \in \mathcal{F}_+$ satisfying (5.10) and $\epsilon > 0$,

$$\mathbb{I}(f) \geq L(f, \epsilon, \hat{q}, \hat{\lambda}, \hat{\mu}) \geq \mathbb{J}(\hat{P}, \hat{Q}) + 1,$$

where $\hat{q}$, $\hat{\lambda}$, and $\hat{\mu}$ are Lagrange multipliers corresponding to $(\hat{P}, \hat{Q})$. On the other hand, if $\hat{f}$ is the positive-real part of (5.17), then

$$\mathbb{I}(\hat{f}) = L(\hat{f}, 0, \hat{q}, \hat{\lambda}, \hat{\mu}) = \mathbb{J}(\hat{P}, \hat{Q}) + 1,$$

and hence $\hat{f}$ minimizes $\mathbb{I}$, and $\hat{\epsilon} = 0$, as claimed.

Clearly, the maximizing solution $(\hat{P}, \hat{Q})$ cannot be unique if $\hat{P}$ and $\hat{Q}$ are not coprime. Therefore, the last statement of the theorem would follow if we could show that $\mathbb{J}$ is *strictly* concave over some neighborhood of $\mathcal{D}_+ \times \mathcal{D}_+$ if $\hat{P}$ and $\hat{Q}$ are coprime. To this end, we consider the Hessian. Let

$$\delta\mathbb{J}(P, Q; \delta P, \delta Q) = \lim_{\epsilon \to 0} \frac{\mathbb{J}(P + \delta P, Q + \epsilon\delta Q) - \mathbb{J}(P, Q)}{\epsilon}$$

denote the directional derivative in the direction $(\delta P, \delta Q)$. The admissible directions $(\delta P, \delta Q)$ are symmetric pseudopolynomials such that $(P + \epsilon\delta P, Q + \epsilon\delta Q) \in \mathcal{D}_+ \times \mathcal{D}_+$ for sufficiently small $\epsilon > 0$. Since $p_0 = 1$, we must also have $\delta p_0 = 0$. It is straightforward to see that

$$\begin{aligned}\delta\mathbb{J}(P, Q; \delta P, \delta Q) = {} & c_1\delta p_1 + c_2\delta p_2 + \cdots + c_n\delta p_n - r_0\delta q_0 - r_1\delta q_1 - \cdots - r_n\delta q_n \\ & + \frac{1}{2\pi}\int_{-\pi}^{\pi} \delta Q(e^{i\theta}) \frac{P(e^{i\theta})}{Q(e^{i\theta})} d\theta - \frac{1}{2\pi}\int_{-\pi}^{\pi} \delta P(e^{i\theta}) \log \frac{P(e^{i\theta})}{Q(e^{i\theta})} d\theta,\end{aligned}$$

and hence second differentiation yields

$$\delta^2\mathbb{J}(P, Q; \delta P, \delta Q) = -\left\langle (P\delta Q - Q\delta P)^2, \frac{1}{PQ^2} \right\rangle \leq 0,$$

where equality holds if and only if $P\delta Q - Q\delta P = 0$, i.e., if and only if

$$\frac{\delta P}{\delta Q} = \frac{P}{Q}.$$

However, this is impossible if $\hat{P}$ and $\hat{Q}$ are to be coprime, since $p_0 = 1$ and $\delta p_0 = 0$. Consequently, $\mathbb{J}$ is strictly concave at $(\hat{P}, \hat{Q})$, as claimed. □

Now, given the minimizing pair of pseudopolynomials $(\hat{P}, \hat{Q})$ of Theorem 5.3, let $a(z)$ and $\sigma(z)$ be the normalized, polynomial spectral factors of $\hat{Q}$ and $\hat{P}$, respectively, i.e., the Schur polynomials satisfying

$$a(z)a(z^{-1}) = \frac{1}{a_0^2}\hat{Q}(z), \qquad \sigma(z)\sigma(z^{-1}) = \frac{1}{\sigma_0^2}\hat{P}(z),$$

where a_0^2 and σ_0^2 are the appropriate normalizing factors. Then Theorem 5.3 provides a procedure for determining, from a combined window $(r_0, r_1, \ldots, r_n, c_1, \ldots, c_n)$ of covariance lags and cepstral coefficients, a pair (a, σ), which is unique if and only if $a(z)$ and $\sigma(z)$ are coprime, i.e., $(a, \sigma) \in \mathcal{P}_n^*$, and a corresponding (unnormalized) shaping filter

$$w(z) = \frac{\sigma_0}{a_0}\frac{\sigma(z)}{a(z)}.$$

Therefore, in particular, we have proved Theorem 3.2. In fact, given any $(a, \sigma) \in \mathcal{P}_n^*$, a window $(r_1, \dots, r_n, c_1, \dots, c_n)$ is uniquely determined from (4.7) and (4.1). Conversely, given $(r_1, \dots, r_n, c_1, \dots, c_n)$, the optimization problem of Theorem 5.3 yields an $(a, \sigma) \in \mathcal{P}_n$, which matches this window and is unique if and only if $(a, \sigma) \in \mathcal{P}_n^*$.

6. The simultaneous partial realization problem. While the *stochastic realization problem* [25, 21, 26, 10, 30] amounts to determining shaping filters w having a fixed window of covariance lags $r_0, r_1, \dots, r_n$, the object of the *deterministic realization problem* (see, e.g., [3, 23]) is to find shaping filters w with a fixed window $w_0, w_1, \dots, w_n$ of Markov parameters (1.11). An important question is whether the two problems can be solved simultaneously so that both interpolation conditions are satisfied at the same time. This problem has been studied in the literature as the Q-Markov cover problem (see [31, 29, 1], where it has been used as a tool for performing model reduction).

This basic question will also be addressed in this section using geometric methods. Thus we would ask whether the two problems can be solved simultaneously and, if so, whether this solution is unique. We find a positive answer to the existence question in $\mathcal{Q}_n$ using fixed point methods. We also determine where these windows provide a bona fide set of smooth coordinates. Finally, we give a geometric proof of the uniqueness of the corresponding shaping filter, i.e., of identifiability of the shaping filter from covariance and Markov windows, providing an independent proof of a result which is basic to the existing theory of the Q-Markov cover problem. These results prove the assertions in Theorem 3.5. We also provide an independent proof of Theorem 3.4.

To address these issues, let $\psi : \mathcal{Q}_n \to \mathbb{R}^n$ be the map which sends (a, σ) to

$$w := \begin{bmatrix} w_1 \\ w_2 \\ \vdots \\ w_n \end{bmatrix},$$

and let $\mathcal{W}_n := \psi(\mathcal{Q}_n)$. Given any $w \in \mathcal{W}_n$, define

$$\mathcal{Q}_n(w) := \psi^{-1}(w).$$

Now, multiplying (2.2) by $a(z)$ and identifying coefficients of nonnegative powers in z, we have

$$\begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \vdots \\ \sigma_n \end{bmatrix} = \begin{bmatrix} w_1 \\ w_2 \\ \vdots \\ w_n \end{bmatrix} + \begin{bmatrix} 1 & & & \\ w_1 & 1 & & \\ \vdots & \vdots & \ddots & \\ w_{n-1} & w_{n-2} & \cdots & 1 \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \\ \vdots \\ a_n \end{bmatrix}. \tag{6.1}$$

Identifying coefficients in negative powers of z yields the appropriate Hankel system. From (6.1) we see first that $\mathcal{W}_n = \mathbb{R}^n$. Second, given w, a can be chosen arbitrarily in $\mathcal{S}_n$. Hence, $\mathcal{Q}_n(w)$ is completely parameterized by $a \in \mathcal{S}_n$, and hence it is a connected n-manifold, diffeomorphic to $\mathbb{R}^n$. Its boundary is characterized by a having a root on the unit circle. Clearly, the closure $\overline{\mathcal{Q}_n(w)}$ is the graph of a continuous function $\gamma : \overline{\mathcal{S}_n} \to \Pi_n$, defined by (6.1). Although the manifold $\mathcal{Q}_n$ is not bounded, $\mathcal{Q}_n(w)$ is. Moreover, $\overline{\mathcal{Q}_n(w)}$ is homeomorphic to $\overline{\mathcal{S}_n}$, which is compact with a contractible interior (see Appendix A).

THEOREM 6.1. *Any continuous map* $T : \overline{\mathcal{S}_n} \to \overline{\mathcal{S}_n}$ *has a fixed point.*

Proof. We first note that $\overline{\mathcal{S}_n}$ is contained in the (Euclidean) space of real monic polynomials with roots in the open disc of radius $1 + \epsilon$ for any positive ϵ. As in Appendices A and C, the continuous retraction $r : \mathbb{D}_{1+\epsilon} \to \mathbb{D}$, defined by

$$r(x) = \begin{cases} x \text{ if } \|x\| \leq 1, \\ \frac{x}{\|x\|} \text{ if } \|x\| \geq 1, \end{cases}$$

induces a continuous retraction of $\mathcal{P}_{\mathbb{D}_{1+\epsilon}}(n) \to \overline{\mathcal{S}_n}$. In particular, $\overline{\mathcal{S}_n}$ is a Euclidean neighborhood retract, and, therefore, the Lefschetz fixed point theorem applies to continuous maps of $\overline{\mathcal{S}_n}$ to itself [18, p. 209]. The Lefschetz fixed point theorem asserts that a continuous map f from a space X to itself has a fixed point provided its Lefschetz number is nonzero. More precisely, to define the Lefschetz number, we need to introduce the homology (real) vector spaces $H_i(X; \mathbb{R})$, defined for each $i = 0, 1, 2, \ldots$. If X is a compact Euclidean neighborhood retract in $\mathbb{R}^N$, then each $H_i(X; \mathbb{R})$ is finite-dimensional and vanishes for $i > N$. In this case, the Lefschetz number of f, $\mathrm{Lef}(f)$, is defined as

$$\mathrm{Lef}(f) = \sum_{i=0}^{n} \mathrm{tr}(f_{*i}),$$

where (f_{*i}) is the linear transformation

$$f_{*i} : H_i(X; \mathbb{R}) \to H_i(X; \mathbb{R})$$

introduced by f. For $X = \overline{\mathcal{S}_n}$, we have

$$H_i(\overline{\mathcal{S}_n}, \mathbb{R}) = \{0\} \quad \text{for } i \geq 1$$

since $\overline{\mathcal{S}_n}$ is contractable. Moreover, since $\overline{\mathcal{S}_n}$ is therefore connected,

$$H_0(\overline{\mathcal{S}_n}, \mathbb{R}) \sim \mathbb{R},$$

and the map f_{*i} is the identity. In summary, $\mathrm{Lef}(f) = 1$, and the Lefschetz fixed point theorem therefore implies that f has a fixed point. ∎

Remark 6.2. One might hope that the Brower fixed point theorem would apply directly to $\overline{\mathcal{S}_n}$. Even in the case when $n = 2$, this does not work. In fact, the space $\overline{\mathcal{S}_2}$ is represented by a triangle in the plane, and its interior is a manifold with corners and not a disc. While in this simple case the closure of the Schur region is homeomorphic to a disc, a proof in arbitrary dimensions has not yet been formulated, but the current standard methods of the Lefschetz fixed point theorem apply readily.

The tangent space of $\mathcal{Q}_n(w)$ at (a, σ) is given by the following proposition.

PROPOSITION 6.3. *For each* $w \in \mathcal{W}_n$, *the space* $\mathcal{Q}_n(w)$ *is a smooth, connected* n*-manifold with the tangent space*

$$T_{(a,\sigma)}\mathcal{Q}_n(w) = \{(u, v) \in V_{n-1} \times V_{n-1} \mid av - \sigma u = \rho;\ \deg \rho \leq n - 1\} \tag{6.2}$$

at $(a, \sigma) \in \mathcal{Q}_n(w)$. *The* n*-manifolds* $\{\mathcal{Q}_n(w) \mid w \in \mathcal{W}_n\}$ *form the leaves of a foliation of* $\mathcal{Q}_n$.

Proof. We have already established that $\mathcal{Q}_n(w)$ is a connected n-manifold, diffeomorphic to $\mathbb{R}^n$. To prove that $T_{(a,\sigma)}\mathcal{Q}_n(w)$ is given by (6.2), observe that the

directional derivative

$$D_{(u,v)}\psi(a,\sigma) = \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{ik\theta}\left[\frac{v}{a} - \frac{\sigma u}{a^2}\right] d\theta$$
$$= \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{ik\theta}\frac{av-\sigma u}{a^2} d\theta$$

is zero for $k = 0, 1, \dots, n$ if and only if the polynomial $\rho = av - \sigma u$ has degree at most $n-1$. In fact, $z^k\rho(z)/a(z)^2$ is analytic for $z \geq 1$ and strictly proper precisely when $\deg \rho < 2n - k$. Since the tangent space has dimension n, the rank of $\mathrm{Jac}(\psi)|_{(a,\sigma)}$ is everywhere n, and hence the connected submanifolds $\mathcal{Q}_n(w)$ form the leaves of a foliation of $\mathcal{Q}_n$. □

As pointed out in the introduction, for *minimum-phase* shaping filters, there is a close relation between the cepstral coefficients and the Markov parameters of the corresponding shaping filter w. To establish these relations, make a Laurent expansion of

$$\log \Phi(z) = \log w(z) + \log w(z^{-1}) \tag{6.3}$$

on a subset Ω of the complex plane, where Ω is the intersection between an annulus containing the unit circle but none of the zeros of $w(z)$ or $w(z^{-1})$ and a sector containing the positive-real axis. The purpose of the sector is to avoid circling the origin. Then the Laurent expansion obtained from the series expansions on the corresponding segment of the real line of $\log w(z)$ and $\log w(z^{-1})$ extends to all of Ω and hence, in particular, to the arc on the unit circle contained in Ω. Then, however, the uniqueness of the Fourier transform ensures that the Laurent expansion also holds there. From this we see

$$\begin{aligned}
c_0 &= 2\log w_0,\\
c_1 &= \frac{w_1}{w_0},\\
c_2 &= \frac{w_2}{w_0} - \frac{1}{2}\left(\frac{w_1}{w_0}\right)^2,\\
c_3 &= \frac{w_3}{w_0} - \frac{1}{2}\left(2\frac{w_1}{w_0}\frac{w_2}{w_0}\right) + \frac{1}{3}\left(\frac{w_1}{w_0}\right)^3.\\
&\vdots
\end{aligned}$$

Indeed, these equations form a triangular system, and hence the Markov parameters can also be obtained from the cepstral coefficients, and vice versa. Setting $w_0 = 1$, we obtain the usual normalization with $c_0 = 0$. Therefore, the nonempty submanifolds $\mathcal{Q}_n(w) \cap \mathcal{P}_n$ are precisely the leaves of the foliation $\{\mathcal{P}_n(c) \mid c \in \mathcal{C}_n\}$. In fact, let $\phi : \mathcal{P}_n \to \mathbb{R}^n$ be the restriction of ψ to $\mathcal{P}_n$, and define $\mathcal{P}_n(w) := \phi^{-1}(w)$ for each $w \in \mathcal{M}_n := \phi(\mathcal{P}_n)$. Then we have the following corollary.

COROLLARY 6.4. *The n-manifolds $\{\mathcal{P}_n(w) \mid w \in \mathcal{M}_n\}$ form the leaves of a foliation of $\mathcal{P}_n$, which is identical to $\{\mathcal{P}_n(c) \mid c \in \mathcal{C}_n\}$.*

In the present setting, however, we also consider nonminimum phase shaping filters, allowing σ to be an arbitrary real monic polynomial. Whereas in $\mathcal{P}_n$ there is a one-to-one correspondence between windows of cepstral coefficients and Markov parameters, this is no longer the case in $\mathcal{Q}_n$. The tangent vectors of $\mathcal{P}_n(w)$ at (a,σ)

do satisfy (4.6) of Proposition 4.2, but this does not extend to the situation where $\sigma(z)$ is no longer a Schur polynomial. Indeed, the first integral in (4.6) is not even defined when $\sigma(z)$ has a root on the unit circle. Nevertheless, we have the following lemma, which is all we need below.

LEMMA 6.5. *Any* $(u, v) \in T_{(a,\sigma)}\mathcal{Q}_n(w)$ *satisfies the equation*

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} S(\sigma)v\,d\theta = \frac{1}{2\pi}\int_{-\pi}^{\pi} S(a)u\frac{\sigma\sigma^*}{aa^*}d\theta. \tag{6.4}$$

Proof. By Proposition 6.3, the tangent space $T_{(a,\sigma)}\mathcal{Q}_n(w)$ consists of those (u, v) for which the polynomial $\rho := av - \sigma u$ has degree at most $n-1$. Since

$$v = \frac{\sigma u}{a} + \frac{\rho}{a},$$

we have

$$S(\sigma)v = S(a)u\frac{\sigma\sigma^*}{aa^*} + \sigma^*\frac{\rho}{a} + \sigma\left(\frac{\rho}{a}\right)^*. \tag{6.5}$$

However, ρ/a is strictly proper and analytic for $|z| \geq 1$, and hence it has a Laurent expansion

$$\frac{\rho}{a} = \alpha_1 z^{-1} + \alpha_2 z^{-2} + \cdots,$$

which is valid on the unit circle. Therefore,

$$\frac{1}{2\pi}\int_{-\pi}^{\pi}\left[\sigma^*\frac{\rho}{a} + \sigma\left(\frac{\rho}{a}\right)^*\right]d\theta = 0, \tag{6.6}$$

and hence (6.4) follows. □

Next let $\phi : \mathcal{Q}_n \to \mathbb{R}^n$ be the map that sends (a, σ) to the vector $r \in \mathbb{R}^n$ of normalized covariance lags (4.7). Clearly, $\phi(\mathcal{Q}_n) = \mathcal{R}_n := f(\mathcal{P}_n)$. Given any $r \in \mathcal{R}_n$, define

$$\mathcal{Q}_n(r) := \phi^{-1}(r).$$

The following proposition is a $\mathcal{Q}_n$-version of Proposition 4.5, and the proof is the same mutatis mutandis.

PROPOSITION 6.6. *For each* $r \in \mathcal{R}_n$, $\mathcal{Q}_n(r)$ *is a smooth, connected manifold of dimension* n. *The tangent space* $T_{(a,\sigma)}\mathcal{Q}_n(r)$ *consists of those* $(u, v) \in V_{n-1} \times V_{n-1}$ *for which*

$$\frac{1}{2\pi}\int_{-\pi}^{\pi}\frac{S(\sigma)v}{aa^*}e^{ik\theta}d\theta = \frac{1}{2\pi}\int_{-\pi}^{\pi}\frac{S(a)u}{aa^*}\frac{\sigma\sigma^*}{aa^*}e^{ik\theta}d\theta + \frac{\varphi}{2\pi}\int_{-\pi}^{\pi}\frac{\sigma\sigma^*}{aa^*}e^{ik\theta}d\theta \tag{6.7}$$

for $k = 0, 1, \ldots, n$, *where*

$$\varphi = \frac{1}{h_0(a,\sigma)}\frac{1}{2\pi}\int_{-\pi}^{\pi}\left[\frac{S(\sigma)v}{aa^*} - \frac{S(a)u}{aa^*}\frac{\sigma\sigma^*}{aa^*}\right]d\theta. \tag{6.8}$$

The n*-manifolds* $\{\mathcal{Q}_n(r) \mid r \in \mathcal{R}_n\}$ *form the leaves of a foliation of* $\mathcal{Q}_n$.

In the case in which $a(z)$ and $\sigma(z)$ are coprime, we can now show that if the tangent spaces $T_{(a,\sigma)}\mathcal{Q}_n(w)$ and $T_{(a,\sigma)}\mathcal{Q}_n(r)$ do intersect, they intersect transversely.

PROPOSITION 6.7. *Suppose that the polynomials $a(z)$ and $\sigma(z)$ are coprime. Then*

$$T_{(a,\sigma)}\mathcal{Q}_n(w) \cap T_{(a,\sigma)}\mathcal{Q}_n(r) = 0 \tag{6.9}$$

for any $(a,\sigma) \in \mathcal{Q}_n(w) \cap \mathcal{Q}_n(r)$.

Proof. Suppose that $(u,v) \in T_{(a,\sigma)}\mathcal{Q}_n(w) \cap T_{(a,\sigma)}\mathcal{Q}_n(r)$. Then (u,v) satisfies (6.7) for $k = 0, 1, \dots, n$ and, by symmetry, also for $k = -1, -2, \dots, -n$. Taking the linear combination corresponding to the coefficients of aa^*, we obtain

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} S(\sigma)v\,d\theta = \frac{1}{2\pi}\int_{-\pi}^{\pi} S(a)u\frac{\sigma\sigma^*}{aa^*}d\theta + \varphi\|\sigma\|^2.$$

However, by Lemma 6.5, (u,v) also satisfies (6.4), and hence, since $\|\sigma\| > 0$, we must have $\varphi = 0$.

Consequently, $T_{(a,\sigma)}\mathcal{Q}_n(w) \cap T_{(a,\sigma)}\mathcal{Q}_n(r)$ consists of those $(u,v) \in V_{n-1} \times V_{n-1}$ which satisfy both

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} \frac{S(\sigma)v}{aa^*}e^{ik\theta}d\theta = \frac{1}{2\pi}\int_{-\pi}^{\pi} \frac{S(a)u}{aa^*}\frac{\sigma\sigma^*}{aa^*}e^{ik\theta}d\theta, \quad k = 0, 1, \dots, n, \tag{6.10}$$

and

$$av - \sigma u = \rho, \quad \deg\rho \le n-1. \tag{6.11}$$

In view of (6.5), we have

$$\frac{S(\sigma)v}{aa^*} = \frac{S(a)u}{aa^*}\frac{\sigma\sigma^*}{aa^*} + \frac{S(a\sigma)\rho}{(aa^*)^2},$$

which, inserted into (6.10), yields

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} \frac{S(a\sigma)\rho}{(aa^*)^2}e^{ik\theta}d\theta = 0, \quad k = 0, 1, \dots, n. \tag{6.12}$$

Clearly, there is a decomposition

$$\frac{S(a\sigma)\rho}{(aa^*)^2} = \frac{d}{a^2} + \frac{d^*}{(a^*)^2} = \frac{S(a^2)d}{(aa^*)^2}, \tag{6.13}$$

where $d(z)$ is a real polynomial of degree at most $2n$. Since $a(z)$ has all of its roots in the open unit disc, there is also a Laurent expansion

$$\frac{d(z)}{a(z)^2} = \frac{1}{2}\beta_0 + \sum_{j=1}^{\infty}\beta_j z^{-j}$$

valid on the unit circle, having real coefficients $\beta_0, \beta_1, \beta_2, \dots$, in terms of which

$$\frac{S(a\sigma)\rho}{(aa^*)^2} = \sum_{j=-\infty}^{\infty}\beta_j e^{-ij\theta},$$

where $\beta_{-j} = \beta_j$ for all j. Inserting this into (6.12), we see that $\beta_0, \beta_1, \dots, \beta_n = 0$, and hence the polynomial $d(z)$ has degree at most $n-1$, precisely as $\rho(z)$ has.

Now from (6.13) we also have

$$S(a\sigma)\rho = S(a^2)d$$

or, equivalently,

$$a(\sigma^*\rho - a^*d)^* + a^*(\sigma^*\rho - a^*d) = 0.$$

Introducing the reversed polynomials $a_*(z) := z^n a(z^{-1})$ and $\sigma_*(z) := z^n\sigma(z^{-1})$, we may write this as

$$S(z^n a)(\sigma_*\rho - a_*d) = 0,$$

which is well defined since $\deg(\sigma_*\rho - a_*d) = 2n - 1 < \deg(z^n a)$. Then, since the polynomial $z^n a$ has all of its roots in the open unit disc, $\ker S(z^n a) = 0$, and hence

$$\sigma_*\rho = a_*d. \tag{6.14}$$

Now, if $\rho \neq 0$,

$$\frac{d_*}{\rho_*} = \frac{\sigma}{a},$$

where $\rho_*(z) := z^{n-1}\rho(z^{-1})$ and $d_*(z) := z^{n-1}d(z^{-1})$. But this is impossible when $a(z)$ and $\sigma(z)$ are coprime because the left member is a proper rational function of degree at most $n-1$, while the right member has degree n. Hence only $\rho = d = 0$ satisfies (6.14). However, for $\rho = 0$, (6.11) has only the solution $u = v = 0$, as claimed. In fact, if $v \neq 0$,

$$\frac{v}{u} = \frac{\sigma}{a},$$

which has no solution if $a(z)$ and $\sigma(z)$ are coprime. □

Just as in Remark 4.7, this establishes that the Jacobian of the joint map $(a, \sigma) \to (r_1, r_2, \ldots, r_n, w_1, w_2, \ldots, w_n)$ has full rank, and, by the inverse function theorem, the joint map forms a smooth local coordinate system on $\mathcal{Q}_n^*$. This proves the first statement of Theorem 3.5.

Figure 6 illustrates the fact that the covariance foliation and the Markov foliation are everywhere transverse. Also note that the shaded region in Figure 6 is identical to Figure 5, thus illustrating Corollary 6.4.

Figure 6 also suggests that each leaf of the Markov foliation meets each leaf of the covariance matching foliation, a fact that we shall now establish in a slightly generalized form. As above, $\overline{\mathcal{Q}_n(r)}$ and $\overline{\mathcal{Q}_n(w)}$ denote the closures of the submanifolds $\mathcal{Q}_n(r)$ and $\mathcal{Q}_n(w)$, respectively.

THEOREM 6.8. *The closure of every leaf of the Markov foliation intersects the closure of any leaf of the covariance matching foliation. Moreover, either the leaves themselves intersect, or every point of intersection is of the form (a, σ), where a has some roots on the unit circle and σ vanishes at each of these roots, while the ratio has the prescribed covariance and Markov windows.*

Proof. The basic space we work on is the product $\overline{\mathcal{S}_n} \times \Pi_n$. We have already seen that $\overline{\mathcal{Q}_n(w)}$ is the graph of a continuous function $\gamma : \overline{\mathcal{S}_n} \to \Pi_n$. We wish to exhibit $\overline{\mathcal{Q}_n(r)}$ as the graph of a continuous function $\delta : \Pi_n \to \overline{\mathcal{S}_n}$. Assuming this for the moment, we deduce from Theorem 6.1 that the continuous map

$$\delta \circ \gamma : \overline{\mathcal{S}_n} \to \overline{\mathcal{S}_n}$$

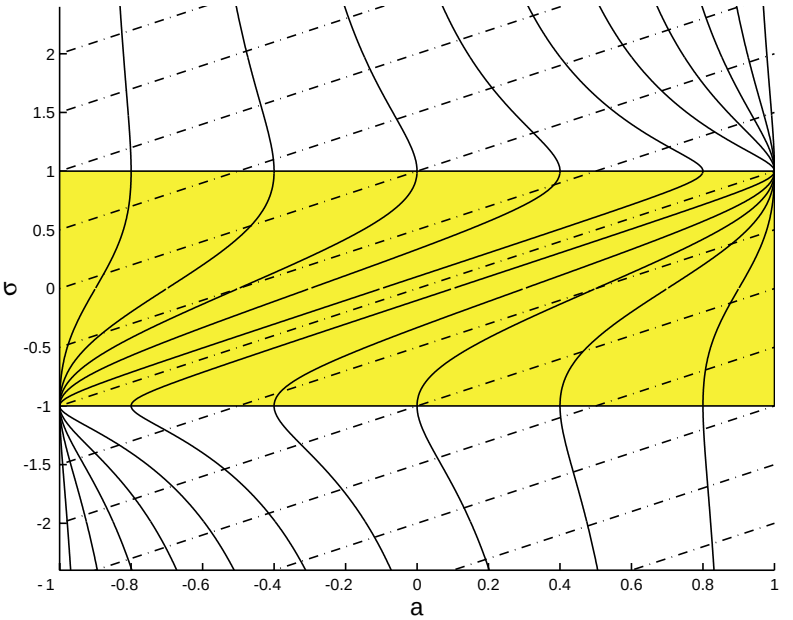

FIG. 6. *Markov (dotted line) and covariance (solid line) matching foliations of* $\mathcal{Q}_1$.

has a fixed point $\bar{a}$; i.e., $(\delta \circ \gamma)(\bar{a}) = \bar{a}$. If $\bar{\sigma} = \gamma(\bar{a})$, then $(\bar{a}, \bar{\sigma})$ is a point lying on both $\overline{\mathcal{Q}_n(w)}$ and $\overline{\mathcal{Q}_n(r)}$. To see this, note that $(\bar{a}, \bar{\sigma}) = (\bar{a}, \gamma(\bar{a}))$ by definition and that $(\bar{a}, \bar{\sigma}) = (\delta \circ \gamma(\bar{a}), \gamma(\bar{a}))$ by construction.

Therefore, it remains to construct δ. If σ is a Schur polynomial, then, according to Theorem 3.3, there exists a unique Schur polynomial a such that (a, σ) lies in $\mathcal{P}_n(r) \subset \mathcal{Q}_n(r)$. We shall write $\delta(\sigma) = a$. According to Theorem 3.4, δ is a smooth function on $\mathcal{S}_n$. Since this is crucial for what follows, we give an independent proof of Theorem 3.4, using the global analysis developed in section 4.

First, we note that the foliations $\{\mathcal{P}_n(r) \mid r \in \mathcal{R}_n\}$ and $\{\mathcal{P}_n(\sigma) \mid \sigma \in \mathcal{S}_n\}$ are complementary. To see this, we ask whether a tangent vector $(u, 0)$ to $\mathcal{P}_n(\sigma)$ at a point (a, σ) could also be tangent to the leaf $\mathcal{P}_n(r)$ through (a, σ). To this end, just as in the proof of Proposition 4.5, we first observe that (6.7) may be written as

$$Fp = Hv,$$

where $p(z) := u(z) + \frac{1}{2}\varphi a(z)$ and F, H are the linear maps (4.12). Then, substituting $(u, 0)$ into (6.7), we obtain $Fp = 0$. However, we also established in the proof of Proposition 4.5 that F is nonsingular, and hence $p = 0$, which, in turn, implies that $\varphi = 0$ and thus that $u = 0$.

Now consider the map $\eta : \mathcal{P}_n \to \mathcal{S}_n$ defined via $\eta(a, \sigma) = \sigma$. The kernel of the Jacobian of η at any point is the tangent space to $\mathcal{P}_n(\sigma)$ at that point. In particular, the kernel of the Jacobian of the map $\eta_r : \mathcal{P}_n(r) \to \mathcal{S}_n$ defined via $\eta_r(a, \sigma) = \sigma$ is zero at every point of $\mathcal{P}_n(r)$. According to Theorem 3.3, the map η_r has an inverse δ. Moreover, by the inverse function theorem, δ is smooth and hence continuous.

In [22], Georgiou proves that δ has a continuous extension to $\overline{\mathcal{S}_n}$ with a very interesting property. If σ has roots on the unit circle, $a = \delta(\sigma)$ may have roots on the unit circle, but σ must vanish at each of these roots, yielding a lower degree

ratio having the prescribed covariance window. Of course, Theorem 3.3 and the constructions in [11, 22] start with the pseudopolynomial

$$d(z, z^{-1}) = \sigma(z)\sigma(z^{-1})$$

rather than σ itself. Since d is taken to be an arbitrary pseudopolynomial of degree less than or equal to zero and nonnegative on the unit circle, the continuity of δ on $\overline{\mathcal{S}_n}$ is equivalent to the continuity of δ on the larger space Π_n. This enables us to form the continuous function $\delta \circ \gamma$ on $\overline{\mathcal{S}_n}$ and apply the Lefschetz fixed point theorem, yielding the statement of the theorem. □

Since, according to Theorem 6.8, any intersection between $\overline{\Omega_n(r)}$ and $\overline{\Omega_n(w)}$ on the boundary of Ω_n defines a pair (a, σ) of polynomials whose roots on the unit circle are common, after cancellation, $w(z) = \sigma(z)/a(z)$ has all of its poles in open unit disc and is thus a bona fide shaping filter. Consequently, Theorem 6.8 establishes the existence part of the last statement of Theorem 3.5. The uniqueness part follows from the following proposition.

PROPOSITION 6.9. *There is at most one shaping filter $w(z)$ having given windows $(1, w_1, \ldots, w_n)$ and $(1, r_1, \ldots, r_n)$ of normalized Markov parameters and normalized covariance lags, respectively.*

Proof. Let $w_1(z)$ and $w_2(z)$ be two shaping filters having the same window $(1, w_1, \ldots, w_n)$ of normalized Markov parameters. Then, if

$$w_1(z) = \frac{\sigma_1(z)}{a_1(z)}, \qquad w_2(z) = \frac{\sigma_2(z)}{a_2(z)},$$

where (a_1, σ_1) and (a_2, σ_2) are coprime pairs of monic polynomials, the degree of the polynomial

$$\rho := \sigma_1 a_2 - \sigma_2 a_1$$

is at most $n - 1$. In fact, the first n Markov parameters of

$$\frac{\sigma_1}{a_1} - \frac{\sigma_2}{a_2} = \frac{\rho}{a_1 a_2}$$

are zero.

Without restriction, we may order the shaping filters so that $\lambda_1 \geq \lambda_2$, where

$$\lambda_1 := \left(\frac{1}{2\pi} \int_{-\pi}^{\pi} \left| \frac{\sigma_1}{a_1} \right|^2 d\theta \right)^{-1}, \quad \lambda_2 := \left(\frac{1}{2\pi} \int_{-\pi}^{\pi} \left| \frac{\sigma_2}{a_2} \right|^2 d\theta \right)^{-1}.$$

Then, assuming that $w_1(z)$ and $w_2(z)$ also have the same normalized covariance lags $(1, r_1, \ldots, r_n)$, we have

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} e^{ik\theta} \Psi(e^{i\theta}) d\theta = 0, \quad 0, 1, \ldots, n,$$

where

$$\Psi := \lambda_1 \left| \frac{\sigma_1}{a_1} \right|^2 - \lambda_2 \left| \frac{\sigma_2}{a_2} \right|^2.$$

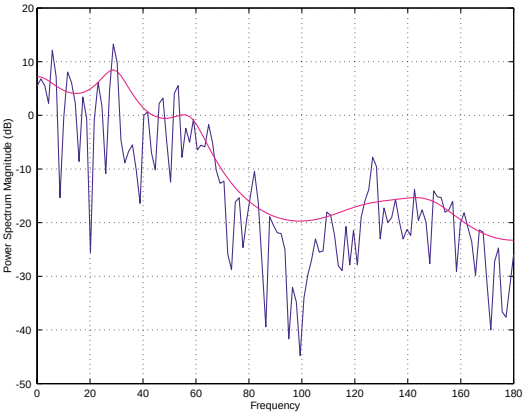

FIG. 7. *Spectral envelope of* 10*th order LPC filter.*

We want to show that $\rho = 0$. To this end, note that, in particular,

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} |a_2(e^{i\theta})|^2 \Psi(e^{i\theta}) d\theta = 0, \tag{6.15}$$

where

$$|a_2|^2\Psi = \lambda_1 \frac{|\rho|^2}{|a_1|^2} + \lambda_1 \frac{\sigma_2 \rho^*}{a_1^*} + \lambda_1 \frac{\sigma_2^* \rho}{a_1} + (\lambda_1 - \lambda_2)|\sigma_2|^2.$$

However, for the same reason as in (6.6),

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} \left[\sigma_2 \left(\frac{\rho}{a_1}\right)^* + \sigma_2^* \left(\frac{\rho}{a_1}\right)\right] d\theta = 0,$$

and hence (6.15) can be written as

$$\left\| \frac{\rho}{a_1} \right\|^2 + \left(1 - \frac{\lambda_2}{\lambda_1}\right) \|\sigma_2\|^2 = 0.$$

Since $\|\sigma_2\| > 0$ and $1 - \lambda_2/\lambda_1 > 0$, this implies that $\lambda_1 = \lambda_2$ and $\rho = 0$. Hence $w_1 = w_2$, as claimed. □

7. Zero assignability vs. cepstral assignability. The theory derived in this paper was developed for dealing with problems encountered in applying Theorem 3.3 to the identification of speech segments. The maximum entropy solution described in section 3, often called the LPC method in the speech processing community, is a standard tool for representing the spectral envelope of speech signals [17]. Its popularity is mainly due to its low computation costs and nice matching of spectral peaks. The latter property is illustrated in Figure 7, which shows the periodogram of Figure 3 together with the spectral envelope determined by a tenth order LPC filter, based on ergodic estimates of $r_0, r_1, \ldots, r_{10}$ from the data in Figure 2.

However, it is well known that this estimate of the spectral envelope may not reproduce the notches of the spectrum very well, especially for nasal sounds, where the spectra have a deep valley because of the dead end formed by the mouth. This "flatness" of the spectral envelope, illustrated by Figure 7, is one of the shortcomings

of LPC filtering. It is due to the fact that the zeros of the modeling filter, being at the origin, are maximally removed from the unit circle, where the spectral density is evaluated. There is thus a need for introducing nontrivial zeros in the shaping filter.

By Theorem 3.3, to any Schur polynomial $\sigma(z)$, there is a unique shaping filter having $\sigma(z)$ as its numerator polynomial and matching the covariance window $r_0, r_1, \dots, r_n$ in the same way as the LPC filter. In fact, there is even a convex optimization procedure, based on (5.7), to determine this shaping filter. However, this does leave us with the problem of how to choose the zeros.

It is generally agreed that a finite window (1.9) of cepstral coefficients contains more information about the zeros than does a finite window (1.8) of covariance lags. In fact, differentiate the expansion

$$\log \frac{\sigma(z)}{a(z)} = \frac{c_0}{2} + \sum_{k=1}^{\infty} c_k z^{-k},$$

obtained from (6.3), with respect to z to obtain

$$\frac{\sigma'(z)a(z) - \sigma(z)a'(z)}{\sigma(z)a(z)} = -\sum_{k=1}^{\infty} k c_k z^{-k-1}. \tag{7.1}$$

Consequently, $\{-kc_k\}$ are the Markov parameters of a filter whose poles are the original poles and zeros. Therefore, modulo deciding which are which, both the poles and the zeros can be determined from a finite number of *exact* cepstral coefficients by solving a Hankel system. In so-called homomorphic prediction, e.g., the method of Shanks [35], the zeros are estimated according to these principles once the poles have been determined using LPC analysis. Indeed, it is well known [32] that the LPC envelope has a nonuniform spectral weighting and that it matches the peaks much more accurately than the valleys, i.e., giving much better estimates of poles than zeros. While, in theory, these methods provide estimates of a shaping filter, and hence of a spectral envelope, they do not achieve covariance matching and may produce shaping filters that are neither stable nor minimum-phase. Therefore, these ad hoc methods do not as such provide an alternative to an algorithm based on Theorem 3.3, but they could provide the required zero estimates.

In this context, we suggest an alternative method for estimating the zeros: Given estimates of spectral values of a periodogram at equidistant points on the unit circle,

$$\Phi(e^{i\theta_k}), \quad k = 1, 2, \dots, N, \tag{7.2}$$

find, by linear programming, pseudopolynomials P and Q which minimize

$$\max_k |Q(e^{i\theta_k})\hat{\Phi}(e^{i\theta_k}) - P(e^{i\theta_k})| \tag{7.3}$$

subject to the constraints that $|P(e^{i\theta_k}| \geq \epsilon$ and $|Q(e^{i\theta_k}| \geq \epsilon$ for some $\epsilon > 0$. Again, the shaping filter P/Q obtained in this way would have the same undesirable properties describe above, but we can use P as the pseudopolynomial required in the dual problem (5.7) to determine a new Q such that P/Q satisfies the covariance matching condition. In this procedure, the Q obtained via (7.3) can be used as an initial condition when applying Newton's method to solve the dual problem. For all the reasons described above, it is better to use a *cepstrally smoothed periodogram* in determining (7.2). Explicitly, the cepstral parameters are calculated from the data (1.9) using an

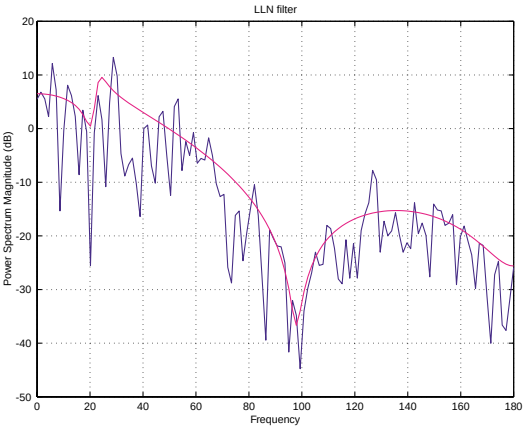

FIG. 8. *Spectral envelope of a* 6*th order LLN filter.*

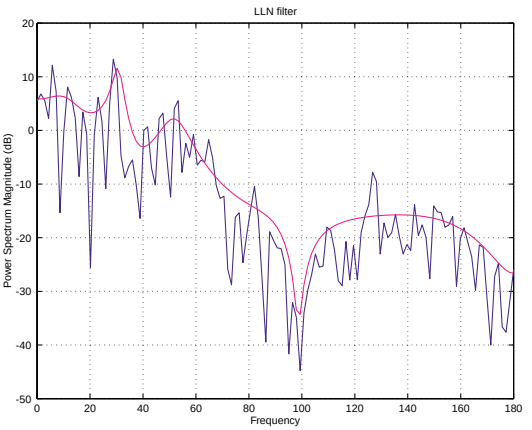

FIG. 9. *Spectral envelope of* 10*th order LLN filter.*

inverse discrete Fourier transform on the logarithm of the periodogram, after which the cepstral coefficients are windowed and inversely transformed [33, pp. 494–495]. As we have seen, the logarithm evens out the difference of energy in the valleys and the peaks and then treats valleys and peaks the same. In Figure 8, we show the spectral envelope of the signal in Figure 2 obtained from a sixth order shaping filter computed by this method. This spectral envelope should be compared with that of the tenth order LPC filter in Figure 7. Instead using a tenth order filter, we obtain the spectral envelope in Figure 9.

However, instead of matching covariance lags and zeros, we may match covariance lags and cepstral coefficients, thus applying an algorithm based on the dual problem to maximize (5.16) described in Theorem 5.3. The covariance and cepstrum interpolation problem is very appealing since both the covariances and the cepstral parameters can be estimated directly from data using ergodicity. Estimation of covariances is well analyzed (see e.g., the books [28, 36]), whereas the estimation of the cepstrum is a less studied problem. One method based on taking the discrete Fourier transform of the periodogram has been analyzed in, e.g., [20]. Using estimated covariance and cepstrum parameters, the filter depicted in Figure 10 was determined.

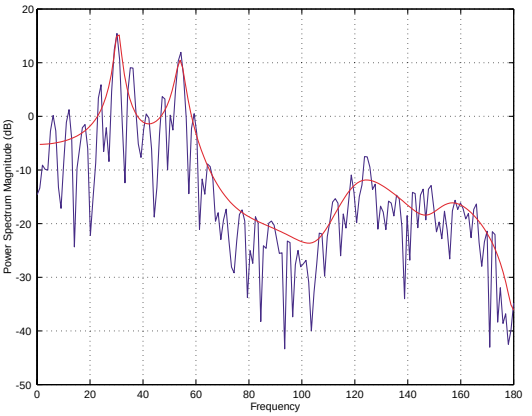

FIG. 10. *Spectral envelope of* 10*th order cepstral match filter.*

More specifically, Figure 10 shows the periodogram of a frame of speech for the phoneme [s] together with a tenth order spectral envelope produced by this method. In this case, $P \in \mathcal{D}_+$, so there is both covariance and cepstral matching. In general, however, this is not the case, as Theorem 5.3 states. This can be seen already in the case when $n = 1$. In Figure 5, the covariance matching foliation (straight lines) is depicted together with the cepstral matching foliation (curved). Clearly, a leaf in one foliation in general does not intersect all leaves in the other. Therefore, methods for determining approximate solutions in the interior $\mathcal{D}_+$ have been developed [19].

The problem that P may tend to the boundary of $\mathcal{D}$ led us to relax the stability constraint of the numerator polynomial σ and hence, in view of the bijection between cepstral and Markov parameters, prompted us to consider the simultaneous partial realization problem of section 7.

Appendix A. Divisors and polynomials. In global analysis, we shall also need to recognize spaces of real polynomials which are diffeomorphic to $\mathbb{R}^n$ as well as certain subsets of polynomials having certain properties, e.g., connectivity, in the relative topology. For this reason, we will adapt the standard treatment of divisors and elementary symmetric functions to the real case.

Let Ω be a self-conjugate, open subset of $\mathbb{C}$, which we take to be path-connected. For such an Ω we denote by $\mathcal{P}_\Omega(n)$ the space of real monic polynomials $p(z)$, of degree n, with all roots lying in Ω. Now the roots of any $p \in \mathcal{P}_\Omega(n)$ determine a self-conjugate, unordered n-tuple $(\lambda_1, \ldots, \lambda_n)$ of points $\lambda_i \in \mathbb{C}$, not necessarily distinct, known as a real *divisor* of degree n on Ω. We denote this divisor by D_p and refer to the space of such divisors as the *real symmetric product* $\Omega^{(n)}$ of Ω.

Alternatively, it is standard to construct the symmetric product $\Omega^{(n)}$ by letting the permutation group S_n on n-letters act on the ordinary Cartesian product Ω^n by permuting the coordinates of n-vectors with entries in Ω. The set of equivalence classes, or orbits of S_n, in the Cartesian product form the points in the symmetric product. In general, the real symmetric product $\Omega^{(n)}$ is always a smooth n-manifold; in fact, $\Omega^{(n)}$ is diffeomorphic to $\mathcal{P}_\Omega(n)$ using the identification

$$(\lambda_1, \ldots, \lambda_n) \to (p_1, \ldots, p_n),$$

where $p(z) = z^n + p_1 z^{n-1} + \cdots + p^n := \prod_{k=1}^n (z - \lambda_k)$. For example, we see that the real symmetric product $\Omega^{(n)}$ for $\Omega = \mathbb{C}$ is diffeomorphic to $\mathbb{R}^n$. For the unit disc,

$\mathbb{D}$, the real symmetric product is diffeomorphic to the space of real Schur polynomials, i.e., those real polynomials satisfying the Schur–Cohn conditions, while for the open left half-plane the real symmetric product is diffeomorphic to the space of those real monic polynomials satisfying the Routh–Hurwitz conditions. Each of these real symmetric products is in turn diffeomorphic with $\mathbb{R}^n$, although not via the standard correspondence given above. Indeed, if $\Omega \subset \mathbb{C}$ is a self-conjugate open subset of the Riemann sphere, with a simple, closed, rectifiable, orientable curve as boundary, then $\mathcal{P}_\Omega(\backslash)$ is diffeomorphic to $\mathbb{R}^n$. As noted in [7], this follows from the Riemann mapping theorem and the corresponding result for the open unit disc $\mathbb{D}$. For $\Omega = \mathbb{D}$ this may be explicitly represented using the real diffeomorphism T of $\mathbb{D}$ to $\mathbb{C}$, defined in polar coordinates via

$$T(r,\theta) = \left(\tan\frac{r\pi}{2}, \theta\right).$$

In general, the projection $P_n : \Omega^n \to \Omega^{(n)}$ is smooth, and any diffeomorphism $T : \Omega_1^{(n)} \to \Omega_2^{(n)}$ is induced by a unique S_n-invariant diffeomorphism $\tilde{T} : \Omega_1^n \to \Omega_2^n$. In particular, if $T : \Omega_1 \to \Omega_2$ is a diffeomorphism, then the induced map $\bar{T} : \Omega_1^{(n)} \to \Omega_2^{(n)}$ defined on divisors of degree n via

$$\bar{T}(\lambda_1, \dots, \lambda_n) = (T(\lambda_1), \dots, T(\lambda_n))$$

is a diffeomorphism. In particular, $\mathcal{P}_\mathbb{D}(n)$ is diffeomorphic with $\mathcal{P}_\mathbb{C}(n)$, which is diffeomorphic to $\mathbb{R}^n$.

Appendix B. Calculation of cepstral coefficients. Suppose

$$\Phi(e^{i\theta}) = \rho^2 \left| \frac{\sigma(e^{i\theta})}{a(e^{i\theta})} \right|^2,$$

where

$$a(z) = z^n + a_1 z^{n-1} + \cdots + a_n$$

and

$$\sigma(z) = z^n + \sigma_1 z^{n-1} + \cdots + \sigma_n$$

are Schur polynomials, i.e., have all of their roots in the open unit disc, and ρ is a real number. Then the cepstral coefficients, i.e., the Fourier coefficients in the expansion (1.5), are given by

$$\begin{aligned} c_0 &= 2\log\rho, \\ c_k &= \frac{1}{k}\{s_k(a) - s_k(\sigma)\}, \qquad k = 1, 2, 3, \dots, \end{aligned}$$

where

$$\begin{aligned} s_k(a) &= p_1^k + p_1^k + \cdots + p_n^k, \\ s_k(\sigma) &= z_1^k + z_1^k + \cdots + z_n^k, \end{aligned}$$

in which $p_1, p_2, \dots, p_n$ are the roots of $a(z)$ and $z_1, z_2, \dots, z_n$ are the roots of $\sigma(z)$.

For the case of maximal entropy (or LPC) filters, we have $z_i = 0$, and the above formula is well known. For pole-zero models, this formula is, to the best of our

knowledge, new but straightforward to derive using the basic algebraic properties of the logarithm.

Moreover, using Newton's identities [15, p. 5], one derives the following recursions:

$$s_k(a) = -ka_k - \sum_{j=1}^{k-1} a_{k-j} s_j(a),$$

$$s_k(\sigma) = -k\sigma_k - \sum_{j=1}^{k-1} \sigma_{k-j} s_j(\sigma).$$

These equations also hold for $k > n$ provided we set $a_k = 0$ and $\sigma_k = 0$ whenever $k > n$.

Appendix C. Connectivity of $\mathcal{P}_n(c)$. We also need to know about various coordinates on $\mathcal{P}_\Omega(n)$ and hence about C^∞ functions. If $f : \Omega^{(n)} \to \mathbb{R}$ is C^∞, then f lifts to a C^∞ function on Ω^n which is S_n-invariant, and, conversely, any C^∞ function on Ω^n which is S_n-invariant descends to a C^∞ function defined on $\Omega^{(n)}$. We denote the algebra of C^∞ functions on $\Omega^{(n)}$ by $\mathcal{C}^\infty[\Omega^{(n)}]$ and the algebra of S_n-invariant C^∞ functions on Ω^n by $\mathcal{C}^\infty[\Omega^n]^{S_n}$. In light of the remarks made above, $\mathcal{C}^\infty[\Omega^{(n)}]$ is canonically isomorphic to $\mathcal{C}^\infty[\Omega^n]^{S_n}$.

Whenever a real diffeomorphism M maps such a domain Ω_1 onto such a domain Ω_2, M commutes with the actions of S_n on Ω_1^n and on Ω_2^n, so that composition with M induces an isomorphism between $\mathcal{C}^\infty[\Omega_2^n]^{S_n}$ and $\mathcal{C}^\infty[\Omega_1^n]^{S_n}$ and hence between $\mathcal{C}^\infty[\Omega_2^{(n)}]$ and $\mathcal{C}^\infty[\Omega_1^{(n)}]$. Therefore, composition with M^{-1} will map generators of $\mathcal{C}^\infty[\Omega_1^n]^{S_n}$ to generators of $\mathcal{C}^\infty[\Omega_2^{(n)}]$.

As an example, consider $\Omega = \mathbb{C}$. Then the algebra of S_n-invariant real polynomials is generated by the coefficients p_i of the polynomials $p(z)$, treated as the points of the real symmetric product. We denote this by writing

$$\mathcal{C}^\infty[\mathbb{C}^{(n)}] = \mathcal{C}^\infty[p_1, \ldots, p_n].$$

Any diffeomorphism of $\mathbb{R}^n$ with itself will give another set of n generators, and, conversely, any other choice of n generators will define a diffeomorphism. Indeed, consider the self-conjugate polynomials in λ,

$$s_k(\lambda) = \lambda_1^k + \cdots + \lambda_n^k,$$

which are invariant under the action of S_n on the n-fold Cartesian product of $\mathbb{C}$. Each $s_k(\lambda)$ lies in $\mathcal{C}^\infty[\mathbb{C}^{(n)}]$ and is in fact a real polynomial in $(\lambda_1, \ldots, \lambda_n)$, as described by the Newton identities [15, p. 5]

$$s_k(\lambda) = -k\lambda_k - \sum_{j=1}^{k-1} \lambda_{k-j} s_j(\lambda),$$

where we set $a_k = 0$ and $\sigma_k = 0$ whenever $k > n$.

Conversely, the Newton identities also show that the λ_i are real polynomials in the s_k, and so we may write

$$\mathcal{C}^\infty[\mathbb{C}^{(n)}] = \mathcal{C}^\infty[\lambda_1, \ldots, \lambda_n].$$

To put this another way, the functions s_k form a system of smooth coordinates on the real Euclidean n-space, $\mathbb{C}^{(n)}$.

If

$$\tilde{c}_k(\tilde{T}(a), \tilde{T}(\sigma)) = c_k(\sigma, a),$$

then the functions $\tilde{c}_k$ form a set of generators for $\mathcal{C}^\infty[\mathbb{C}^{(n)}]$. In particular, in these coordinates, the sets are affine planes and are hence connected.

EFFICIENT CONSTRAINED MODEL PREDICTIVE CONTROL WITH ASYMPTOTIC OPTIMALITY*

MARK CANNON† AND BASIL KOUVARITAKIS†

Abstract. A computationally inexpensive model predictive control strategy for constrained linear systems is presented. We describe an efficiently computed suboptimal control law which is exponentially stabilizing in the presence of constraints and which converges asymptotically to the conditions for constrained optimality with respect to the receding horizon optimization. The free parameters in input predictions are adapted online on the basis of the gradient of the predicted performance index and the boundary of the admissible set for an autonomous prediction system. A differential description of the admissible set boundary enables efficient detection of active constraints. The approach is illustrated via simulation examples.

Key words. receding horizon control, constrained control, optimality conditions, asymptotic convergence

1. Introduction.

Model predictive control (MPC) is a feedback strategy in which a control law is computed by repeatedly minimizing a predicted performance index online. MPC algorithms have proved effective in a wide range of commercial applications [19] primarily because they enable constraints on inputs and states to be handled systematically. For the case of linear dynamics and quadratic cost considered in this paper, the online optimization subject to linear input/state constraints is a quadratic programming (QP) problem, which can be solved efficiently and reliably using commercially available software. However, the computational burden of QP can be prohibitive, particularly for high-dimensional systems or rapid sampling applications, and considerable research effort has recently been devoted to reducing this burden [20, 7, 8, 3, 22, 2]. The objective of this paper is to develop an efficient MPC strategy suitable for millisecond sample intervals and small or medium-scale problems (up to, say, 10 states/inputs).

The computational burden of MPC can be reduced significantly if the receding horizon optimization is replaced by an approximate problem of reduced complexity. In [3, 22, 13], the feasible sets for the optimization variables are approximated via ellipsoids, thus reducing the online optimization to a 2-norm minimization subject to a single quadratic constraint which can be solved extremely efficiently. However, [3] and [22] are necessarily suboptimal, and although suboptimality can be reduced to insignificant levels through scaling [13], the use of ellipsoidal constraint set approximations can lead to conservative stabilizable initial condition sets. Larger stabilizable sets are obtained with low-complexity polytopic sets in place of ellipsoids [16] but only at the expense of increased online computation, which then becomes a linear programming (LP) problem.

An alternative approach computes the optimal solution of the MPC cost minimization using algorithms tailored to specific applications, thus obtaining computational savings over generic solvers. For example, [7] describes a customized MPC algorithm for paper machine cross-directional control which uses physical insights into the problem of controlling web-forming processes to initialize the solution of the receding horizon optimization. In the same application area, [20] derives an efficient QP solver by exploiting the banded structure and sparsity of data matrices, which results from retaining predicted states as well as inputs as variables in the receding horizon optimization problem. However, like [7], this approach is highly specialized since it introduces additional variables into the online QP, and, as a result, its computational advantages are limited to large-scale problems (100 decision variables or more).

Efficient MPC algorithms with wider applicability can be derived by customizing the online optimization using parametric programming methods. Parametric programming is concerned with finding the solution of an optimization problem which is a perturbation of another problem for which a solution is known. The technique is particularly useful in MPC because of the similarity between the receding horizon optimizations solved at successive sampling instants [8]; in fact, "warm starting" (where a previous solution is used to initialize the current optimization) is employed in many commercial MPC algorithms. In [2], parametric programming is used to compute offline the solution of the online MPC optimization as a piecewise linear state feedback law, the parameters of which are state-dependent. Although this approach provides an explicit expression for the state feedback law associated with MPC, its applicability is likely to be limited by the large computational burden concurrent with identifying the regions of state-space on which each of the possible combinations of constraints are active at the solution of the MPC optimization.

In this paper, we use a parametric programming technique based on a differential description of the boundary of the feasible set for the plant state and the free parameters in predicted inputs. This enables efficient online computation of the active constraints corresponding to the current plant state and prediction parameters and hence simplifies the problem of determining a feasible control trajectory and feasible update direction for prediction parameters. The characterization of the feasible set is obtained by expressing input predictions as the sum of a stabilizing unconstrained state feedback law and a linear expansion over a set of exponential basis functions. Predicted input trajectories are governed by an autonomous system with initial state given by the plant state augmented by prediction parameters, and the feasible set is therefore given by the maximal admissible set (as defined in [10]) for the autonomous prediction system state.

Starting from a feasible but suboptimal point computed offline, the proposed algorithm successively updates the prediction parameters on the basis of the gradient of the predicted cost subject to input/state constraints. The approach is similar to the strategy of "early termination" of an optimization routine at a feasible but suboptimal point, which is used extensively in commercial MPC algorithms to reduce online computational burden [19]. The stability properties of MPC algorithms employing early termination are well known: closed-loop stability is unaffected by the suboptimality of predicted input trajectories provided that future feasibility is ensured and the predicted cost decreases sufficiently rapidly along closed-loop trajectories [18, 21]. However, in this paper, we make further use of the analysis of the closed-loop convergence of the predicted cost in order to derive update laws for prediction parameters which steer the closed-loop system asymptotically to a point satisfying the conditions for constrained optimality.

The current paper extends the algorithm proposed in [4] in respect of both the detection of active constraints and the prediction parameter update law. Here we make explicit use of the convexity of the feasible set to derive a simpler algorithm for constraint detection based on the intersections of the boundary of this set with a sequence of linear subspaces. Furthermore, we characterize the prediction parameter update law in terms of a simplified subproblem and describe an efficient method for its solution.

The paper is organized as follows. Section 2 defines the control problem and gives the autonomous formulation of prediction dynamics. Sections 3 and 4 describe the feasible set and the method of online constraint detection. The prediction parameter update law and its closed-loop optimality properties are described in section 5, and simulation examples are presented in section 6.

2. Prediction dynamics. Consider the linear plant dynamics described by the model

$$\dot{x}(t) = A_m x(t) + B_m u(t) \quad \forall t \geq 0, \tag{1}$$

where $x \in \mathbb{R}^{n_x}$ and $u \in \mathbb{R}^{n_u}$ is the input. This paper is concerned with optimal regulation of (1) subject to input constraints of the form

$$u \in \mathcal{U},\ \mathcal{U} = \big\{u;\ \underline{U} \leq u(t) \leq \overline{U},\ \underline{U}' \leq \dot{u}(t) \leq \overline{U}' \quad \forall t \geq 0\big\}. \tag{2}$$

Note that the approach described below is also applicable to systems with polytopic state constraints and that tracking problems can be handled analogously. The control law is developed with the objective of approximating the solutions of the optimization problem

(3)
$$\begin{array}{ll} \underset{\hat{u}_t}{\text{minimize}} & J(t),\ \ J(t) = \displaystyle\int_0^\infty \big(\hat{x}_t^T(\tau) Q \hat{x}_t(\tau) + \hat{u}_t^T(\tau) R \hat{u}_t(\tau)\big)\, d\tau,\ \ Q \geq 0,\ \ R > 0, \\ \text{subject to} & \dot{\hat{x}}_t(\tau) = A_m \hat{x}_t(\tau) + B_m \hat{u}_t(\tau) \quad \forall \tau \geq 0,\ \ \hat{x}_t(0) = x(t), \\ & \hat{u}_t \in \mathcal{U}. \end{array}$$

Here $\hat{x}_t$ and $\hat{u}_t$ are predictions at time t of the plant state and input on the interval $[t, \infty)$, and to ensure the existence of a stabilizing solution to (3) for some nontrivial set of initial plant states, we assume that $(A_m, B_m, Q^{1/2})$ is controllable and observable. We define a continuous-time receding horizon control law by setting $u(t) = \hat{u}_t(0)$, where $\hat{u}_t$ is determined continuously in t on the basis of a gradient descent algorithm.

To make the constrained optimization (3) tractable, we restrict the predicted input $\hat{u}_t$ to a finite-dimensional class. In order to avoid numerical sensitivity in predictions, this class is chosen to include a control law, which stabilizes the plant in the absence of constraints. Furthermore, it is often desirable to include the optimal control for the unconstrained dynamics (1) in the prediction class since this necessarily becomes feasible with respect to (3) at some future time under any control law which asymptotically stabilizes the constrained plant. Input predictions are therefore specified as

$$\hat{u}_t(\tau) = K \hat{x}_t(\tau) + \Phi(\tau) c(t) \quad \forall \tau \geq 0, \tag{4}$$

where $\hat{u}_t = K\hat{x}_t$ is the solution of the following linear-quadratic problem: $\text{minimize}_{\hat{u}_t} J(t)$ subject to $\dot{\hat{x}}_t(\tau) = A_m \hat{x}_t(\tau) + B_m \hat{u}_t(\tau)$ for all $\tau \geq 0$, $\hat{x}_t(0) = x(t)$. Also, $c \in \mathbb{R}^{n_c}$

is a vector of prediction parameters, and $\Phi : \mathbb{R} \to \mathbb{R}^{n_u \times n_c}$ is a matrix of fixed basis functions.

The stability of the receding horizon control law proposed in this paper is based on a guarantee of the feasibility of (3) given past feasibility. This in turn is ensured if the input prediction class employed at each instant t contains the extension to time t of the prediction associated with the input implemented at a previous instant $t - \delta$, $\delta > 0$ since this satisfies constraints by assumption. Appendix A shows that this condition, applied in the limit as $\delta \to 0$ to avoid conflict with the rate constraints of (2), is satisfied by the linear expansion of (4) if and only if the basis functions Φ have the exponential form

$$\Phi(\tau) = \Phi(0)\mathrm{e}^{A_\phi \tau} \quad \forall \tau \geq 0, \tag{5}$$

for some $A_\phi \in \mathbb{R}^{n_c \times n_c}$.

The predictions implied by (4) and (5) are governed by an autonomous system of order $n = n_x + n_c$ and are given by

$$\begin{aligned} \hat{u}_t(\tau) &= G\mathrm{e}^{A\tau} z(t), \quad G = \begin{bmatrix} \Phi(0) & K \end{bmatrix}, \\ z(t) &= \begin{bmatrix} c(t) \\ x(t) \end{bmatrix}, \quad A = \begin{bmatrix} A_\phi & 0 \\ B_m\Phi(0) & A_m + B_m K \end{bmatrix}. \end{aligned} \tag{6}$$

The choice of A_ϕ affects both the limits on achievable performance and the set of stabilizable plant states under a receding horizon control law based on the predictions of (6). Here we simply note that A_ϕ must be strictly Hurwitz in order that the prediction dynamics are stable, and the eigenvalues of A_ϕ should be chosen so that the maximum distance between the feedback law $K\hat{x}_t$ for any initial plant state x and the function space spanned by the elements of Φ is in some sense minimized.

3. Admissible set. The (maximal) admissible set for the prediction system (6) under the constraint $\hat{u}_t \in \mathcal{U}$ is defined by

$$\Omega = \left\{ z;\ \underline{U} \leq G\mathrm{e}^{A\tau} z \leq \overline{U},\ \underline{U}' \leq GA\mathrm{e}^{A\tau} z \leq \overline{U}' \quad \forall \tau \geq 0 \right\}. \tag{7}$$

This set is central to the receding horizon control problem since it consists of all prediction system initial states for which the constraint $\hat{u}_t \in \mathcal{U}$ is satisfied. The constrained optimization of predicted performance at time t, therefore, corresponds to the minimization of $J(t)$ over the prediction parameters c in the intersection of Ω with the subspace $\left\{ z \in \mathbb{R}^n;\ [0 \quad \mathrm{I}_{n_x}] z = x(t) \right\}$ (where I_{n_x} denotes the identity in $\mathbb{R}^{n_x \times n_x}$). This section gives a parametric description of the admissible set boundary, denoted by $\partial\Omega$, in terms of the prediction times τ at which $\hat{u}_t(\tau)$ reaches constraints.

Clearly, (7) is the intersection of the admissible sets associated with each of the individual constraints $u \geq \underline{U}$, $u \leq \overline{U}$, $\dot{u} \geq \underline{U}'$, $\dot{u} \leq \overline{U}'$. For simplicity we consider only a single constraint on the ith element of u in this section and in section 4 and accordingly redefine Ω as

$$\Omega = \left\{ z;\ g\mathrm{e}^{A\tau} z \leq \overline{u} \quad \forall \tau \geq 0 \right\},$$

where g is the ith row of G and $\overline{u}$ is the ith element of $\overline{U}$. In addition, we assume that (g, A) is observable; this assumption involves no loss of generality since the following arguments apply to the observable subspace alone in the case that (g, A) contains unobservable modes.

Noting that Ω can be equivalently expressed in terms of the intersection

$$\Omega = \bigcap_{\tau\in[0,\infty)} \left\{z;\ g\mathrm{e}^{A\tau}z \le \overline{u}\right\},$$

the following properties are immediately obvious:

(P1) Ω is convex.

(P2) $z \in \partial\Omega$ only if $g\mathrm{e}^{A\tau}z = \overline{u}$ for some $\tau \ge 0$.

(P3) $(g\mathrm{e}^{A\tau})^T$ is normal to $\partial\Omega$ at a point $z \in \partial\Omega$ such that $g\mathrm{e}^{A\tau}z = \overline{u}$.

Property (P3) is the basis of the method described in section 5 of adapting the prediction parameters $c(t)$ so that the prediction system (6) converges asymptotically to the conditions for optimality with respect to (3). While constraints are inactive (i.e., while the initial prediction system state $z(t)$ lies in the interior of Ω), this approach adapts $c(t)$ via $\dot{c}(t)$ in the direction of the gradient of $J(t)$. Alternatively, whenever $z(t)$ lies in the boundary of Ω, satisfaction of the constraint $\hat{u}_t \in \mathcal{U}$ is ensured by specifying $\dot{c}(t)$ as a function of the gradient of $J(t)$ projected into the subspace of $\mathbb{R}^n$ which is tangent to $\partial\Omega$ at $z(t)$. The required projection is determined from (P3) and the prediction times τ corresponding to active constraints, namely the values of τ such that $g\mathrm{e}^{A\tau}z(t) = \overline{u}$.

Active constraints can be detected by tracking points $\xi(t)$ lying in the boundary of Ω and the corresponding values of $\tau(t)$ satisfying $g\mathrm{e}^{A\tau(t)}\xi(t) = \overline{u}$, where $\xi(t)$ is such that $z(t) \in \partial\Omega$ if and only if $z(t) = \xi(t)$. This approach, which is described in section 4, is based on (P2) and the additional property that Ω is positively invariant for the prediction dynamics (6). Specifically, the positive invariance of Ω implies that a point $z \in \partial\Omega$ such that $g\mathrm{e}^{A\tau}z = \overline{u}$ for some $\tau > 0$ must also satisfy $gA\mathrm{e}^{A\tau}z = 0$, and z, therefore, lies on a trajectory of (6) which is tangent to the hyperplane $\left\{z;\ gz = \overline{u}\right\}$. Defining $\mathcal{G}_1$ as the set of trajectories of (6) that are tangent to $\left\{z;\ gz = \overline{u}\right\}$ so that

$$\mathcal{G}_1 = \left\{z;\ g\mathrm{e}^{A\tau}z = \overline{u},\ gA\mathrm{e}^{A\tau}z = 0,\ \tau \ge 0\right\},$$

we therefore have the following additional property:

(P4) $\partial\Omega \subset \left\{z;\ gz = \overline{u}\right\} \cup \mathcal{G}_1$.

Property (P4) allows the active constraints associated with a given prediction system state $z(t)$ to be determined by checking whether $gz(t) = \overline{u}$ or $z(t) \in \mathcal{G}_1$.

4. Constraint detection. This section describes a mechanism for determining the set of active constraints as the prediction parameters are adapted in continuous time. As in section 2, for simplicity we consider here a single constraint in the form of an upper bound $\overline{u}$ on an element of u. The approach is based on tracking points in the state-space of the prediction system (6) lying in the set $\mathcal{G}_1$ or the hyperplane $\left\{z;\ gz = \overline{u}\right\}$. Before giving the details of the method, we first determine the smoothness properties of $\mathcal{G}_1$.

From the total derivatives of $g\mathrm{e}^{A\tau}z$ and $gA\mathrm{e}^{A\tau}z$, the tangent vector $(dz, d\tau)$ to $\mathcal{G}_1$ (considered as a hypersurface in $\mathbb{R}^n \times \mathbb{R}^+$) at $(z,\tau) \in \mathcal{G}_1$ satisfies

$$\begin{aligned} g\mathrm{e}^{A\tau}\,dz + gA\mathrm{e}^{A\tau}z\,d\tau = g\mathrm{e}^{A\tau}\,dz = 0,\\ gA\mathrm{e}^{A\tau}\,dz + gA^2\mathrm{e}^{A\tau}z\,d\tau = 0. \end{aligned}$$

For any $dz \in \mathbb{R}^n$, it is possible to find $d\tau$ satisfying the second equation whenever $gA^2\mathrm{e}^{A\tau}z \ne 0$. The first equation, therefore, implies that the normal vector to $\mathcal{G}_1$ (considered as a hypersurface in $\mathbb{R}^n$) is given by $(g\mathrm{e}^{A\tau})^T$ at any point $z \in \mathcal{G}_1$ such

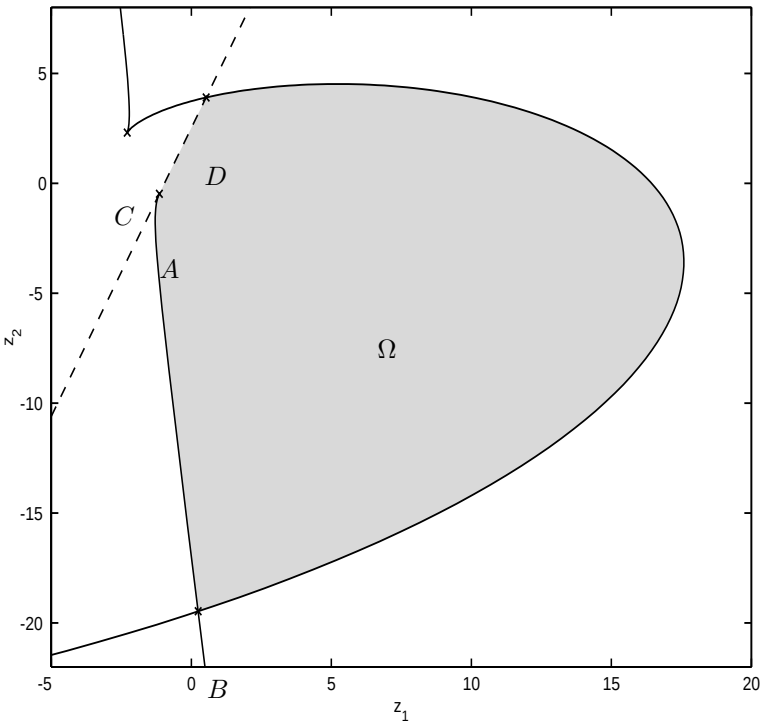

FIG. 1. *Example of the intersection of the admissible set Ω with the z_1, z_2-plane for a prediction system of order $n = 3$ with constraint $\overline{u} = 1$. The boundary $\partial\Omega$ consists of points lying in $\mathcal{G}_1$ (solid line) and the hyperplane $\{z;\ gz = \overline{u}\}$ (dashed line). Also shown are the following: A is an initial prediction system state $z \in \mathcal{G}_1$ such that $gz = \overline{u}$ and $gAz = 0$; B is a state $z \in \mathcal{G}_1$ satisfying $g\mathrm{e}^{A\tau_1}z = g\mathrm{e}^{A\tau_4}z = \overline{u}$ and $gA\mathrm{e}^{A\tau_1}z = gA\mathrm{e}^{A\tau_4}z = 0$ for some $\tau_1, \tau_4 > 0$; C is a state $z \in \mathcal{G}_2$ satisfying $g\mathrm{e}^{A\tau_2}z = \overline{u}$ and $gA\mathrm{e}^{A\tau_2}z = gA^2\mathrm{e}^{A\tau_2}z = 0$ for some $\tau_2 > 0$; D is a state $z \in \mathcal{G}_1$ satisfying $gz = g\mathrm{e}^{A\tau_3}z = \overline{u}$ and $gA\mathrm{e}^{A\tau_3}z = 0$ for some $\tau_3 > 0$; where $0 < \tau_1 < \tau_2 < \tau_3 < \tau_4$.*

that $gA^2\mathrm{e}^{A\tau}z \neq 0$, which is in agreement with properties (P3) and (P4). From the second equation, we have

$$\frac{\partial\tau}{\partial z} = -\frac{gA\mathrm{e}^{A\tau}}{gA^2\mathrm{e}^{A\tau}z},$$

and by the implicit function theorem, we have a value of τ such that $(z, \tau) \in \mathcal{G}_1$ is, therefore, a smooth (C^∞) function of z provided that $gA^2\mathrm{e}^{A\tau}z \neq 0$. Denoting $\mathcal{G}_2$ as the set

$$\mathcal{G}_2 = \big\{z;\ g\mathrm{e}^{A\tau}z = \overline{u},\ gA\mathrm{e}^{A\tau}z = 0,\ gA^2\mathrm{e}^{A\tau}z = 0,\ \tau \geq 0\big\},$$

it follows that $(g\mathrm{e}^{A\tau})^T$ is a smooth function of z for all $z \in \mathcal{G}_1 - \mathcal{G}_2$, and $\mathcal{G}_1$ is, therefore, a smooth $(n-1)$-dimensional hypersurface in $\mathbb{R}^n$ at every point $z \in \mathcal{G}_1 - \mathcal{G}_2$. A similar argument shows that $\mathcal{G}_2$ has dimension less than or equal to $n-2$, and $\mathcal{G}_2$, therefore, corresponds to a cusp in $\mathcal{G}_1$ in $\mathbb{R}^n$. This situation is illustrated graphically in Figure 1.

More generally, define $\mathcal{G}_k$ by

$$\mathcal{G}_k = \big\{z;\ g\mathrm{e}^{A\tau}z = \overline{u},\ gA\mathrm{e}^{A\tau}z = 0, \ldots,\ gA^k\mathrm{e}^{A\tau}z = 0,\ \tau \geq 0\big\}$$

for $k = 1, 2, \dots, n-1$. Then it is clear that

$$\mathcal{G}_1 \supset \mathcal{G}_2 \supset \cdots \supset \mathcal{G}_{n-1},$$

and Appendix B shows that $\mathcal{G}_k$ is locally a smooth $(n-k)$-dimensional hypersurface in $\mathbb{R}^n$ at every point $z \in \mathcal{G}_k - \mathcal{G}_{k+1}$ for $k = 1, 2, \dots, n-2$. Furthermore, $\mathcal{G}_{n-1}$, which consists of a single trajectory of (6), is everywhere smooth and of dimension 1.

The method of detecting active constraints is based on tracking the points of intersection with $\partial\Omega$ of a linear subspace $\mathcal{L}_1$, containing z, defined by

$$\mathcal{L}_1 = \{\xi;\ V_1(\xi - z) = 0\}.$$

Here $V_1 \in \mathbb{R}^{n-1\times n}$ can be chosen arbitrarily subject to the requirement that $\operatorname{rank}(V_1) = n-1$. The convexity of Ω ensures that a point $z \in \Omega$ lies in the boundary $\partial\Omega$ if and only if z coincides with the point of intersection of $\mathcal{L}_1$ with $\partial\Omega$. From property (P4), it follows that the active constraints can be determined from the intersection points $\mathcal{L}_1 \cap \mathcal{G}_1$ and $\mathcal{L}_1 \cap \{z;\ gz = \overline{u}\}$. Using convexity arguments, we show below that the intersection points $\mathcal{L}_1 \cap \{\mathcal{G}_1 - \mathcal{G}_2\}$ are continuous functions of z and can therefore be tracked in continuous time as z varies in $\Omega - \partial\Omega$. However, it is clear from the preceding discussion that $\mathcal{L}_1 \cap \mathcal{G}_1$ can be discontinuous whenever $\mathcal{L}_1 \cap \mathcal{G}_1 \in \mathcal{G}_2$, and for this reason it is also necessary to detect nonempty intersections of $\mathcal{L}_1$ with $\mathcal{G}_2$. The existence of points of intersection $\mathcal{L}_1 \cap \mathcal{G}_2$ can in turn be determined from the intersections of $\mathcal{G}_2$ with a linear subspace $\mathcal{L}_2$, where

$$\mathcal{L}_2 = \{\xi;\ V_2(\xi - z) = 0\}$$

and V_2 consists of (say) the first $n-2$ rows of V_1; and it can likewise be shown that $\mathcal{L}_2 \cap \mathcal{G}_2$ is continuous if $\mathcal{L}_2 \cap \mathcal{G}_2 \notin \mathcal{G}_3$. The remainder of this section, therefore, derives an algorithm for stable tracking of the intersections $\mathcal{L}_k \cap \mathcal{G}_k$, $k = 1, \dots, n-1$, as z varies in Ω, where $\mathcal{L}_k$ is defined as

$$\mathcal{L}_k = \{\xi;\ V_k(\xi - z) = 0\}$$

and $V_k \in \mathbb{R}^{n-k\times n}$ consists of the first $n-k$ rows of V_{k-1} for $k = 2, \dots, n-1$.

To determine the points of intersection of $\mathcal{L}_1$ with $\mathcal{G}_1$, let W_1 lie in the kernel of V_1. Then a point $\xi \in \mathcal{L}_1$ is a member of $\mathcal{G}_1$ if and only if

$$\xi = z + W_1\alpha \quad \begin{cases} g\mathrm{e}^{A\tau}W_1\alpha = \overline{u} - g\mathrm{e}^{A\tau}z, \\ gA\mathrm{e}^{A\tau}(z + W_1\alpha) = 0 \end{cases}$$

for some $\tau \geq 0$ and $\alpha \in \mathbb{R}$. If z lies in the interior of Ω, then $g\mathrm{e}^{A\tau}z < \overline{u}$ by definition, and it follows that $g\mathrm{e}^{A\tau}W_1 \neq 0$ for any τ corresponding to an intersection point $\mathcal{L}_1 \cap \mathcal{G}_1$. Therefore, $\xi \in \mathcal{L}_1 \cap \mathcal{G}_1$ if and only if $\xi = z + W_1(\overline{u} - g\mathrm{e}^{A\tau}z)/g\mathrm{e}^{A\tau}W_1$, where τ is a nonnegative solution of

$$gA\mathrm{e}^{A\tau}\left[z + W_1(\overline{u} - g\mathrm{e}^{A\tau}z)/g\mathrm{e}^{A\tau}W_1\right] = 0.$$

The following theorem generalizes this argument for the case of $k = 2, \dots, n-1$.

THEOREM 4.1. *Let the columns of W_k form a basis for the kernel of V_k, and, for given $\tau \in \mathbb{R}$, define M_k by*

$$M_k = \begin{bmatrix} g \\ gA \\ \vdots \\ gA^{k-1} \end{bmatrix} \mathrm{e}^{A\tau}.$$

Then, for any $z \in \Omega - \partial\Omega$, $\xi \in \mathcal{L}_k \cap \mathcal{G}_k$ if and only if $\xi = z + W_k\alpha$, where

$$\alpha = (M_k W_k)^{-1}(\overline{u}e_1 - M_k z), \quad e_1 = \begin{bmatrix} 1 & 0 & \cdots & 0 \end{bmatrix}^T \in \mathbb{R}^k, \tag{8}$$

and τ is a nonnegative solution of

$$gA^k \mathrm{e}^{A\tau}\left[z + W_k(M_k W_k)^{-1}(\overline{u}e_1 - M_k z)\right] = 0. \tag{9}$$

Proof. At $\xi \in \mathcal{L}_k \cap \mathcal{G}_{k-1}$ we have $\xi = z + W_k\alpha$, and $M_k W_k \alpha = \overline{u}e_1 - M_k z$ for some $\tau \geq 0$. Since an intersection point $\mathcal{L}_k \cap \mathcal{G}_k$ necessarily lies in $\mathcal{G}_{k-1}$, a solution for α must exist. Furthermore, the assumption that $z \in \Omega - \partial\Omega$ implies that $M_k z \neq \overline{u}e_1$, and it follows that $\operatorname{rank}(M_k W_k) = k$. Therefore, every intersection point $\mathcal{L}_k \cap \mathcal{G}_k$ is given by $z + W_k\alpha$, where α is defined by (8) and $\tau \geq 0$ satisfies (9). ∎

We next determine the continuity properties of the intersections $\mathcal{L}_k \cap \mathcal{G}_k$ by considering the derivatives with respect to z of α in (8) and τ satisfying (9).

THEOREM 4.2. *For all $z \in \Omega - \partial\Omega$, an intersection point $\mathcal{L}_k \cap \mathcal{G}_k$ is a continuous function of z if and only if $\mathcal{L}_k \cap \mathcal{G}_k \notin \mathcal{G}_{k+1}$ for $k = 1, \ldots, n-2$; and the intersection $\mathcal{L}_{n-1} \cap \mathcal{G}_{n-1}$ is a continuous function of z.*

Proof. The derivatives with respect to z of α satisfying (8) and solutions τ to (9) are given by

$$\frac{\partial \alpha}{\partial z} = -(M_k W_k)^{-1} M_k, \tag{10a}$$

$$\frac{\partial \tau}{\partial z} = -\frac{gA^k \mathrm{e}^{A\tau}}{gA^{k+1}\mathrm{e}^{A\tau}(z + W_k\alpha)}\left[\mathrm{I} - W_k(M_k W_k)^{-1} M_k\right]. \tag{10b}$$

From Theorem 4.1, $M_k W_k$ in (10a) and (10b) has full rank if z lies in the interior of Ω. It follows that α and τ are continuous functions of z provided that $gA^{k+1}\mathrm{e}^{A\tau}(z + W_k\alpha) \neq 0$, which is equivalent to $\mathcal{L}_k \cap \mathcal{G}_k \notin \mathcal{G}_{k+1}$. In the special case of $k = n-1$, α and τ are continuous functions of z for all $z \in \Omega - \partial\Omega$ since $gA^n \mathrm{e}^{A\tau}(z + W_k\alpha)$ is necessarily nonzero due to the observability of (g, A). ∎

Remark 4.3. Theorem 4.2 shows that, for $k = 1, \ldots, n-2$, the intersection of $\mathcal{L}_k$ with $\mathcal{G}_k$ as z varies continuously in the interior of Ω can be discontinuous if and only if $\mathcal{L}_k \cap \mathcal{G}_k \in \mathcal{G}_{k+1}$. In fact, a nonempty intersection of $\mathcal{L}_k$ with $\mathcal{G}_{k+1}$ is precisely the condition under which new intersection points $\mathcal{G}_k \cap \mathcal{L}_k$ are created or existing intersections $\mathcal{G}_k \cap \mathcal{L}_k$ disappear since $\mathcal{G}_{k+1}$ constitutes a cusp in $\mathcal{G}_k$. However, a consequence of Theorem 4.2 is that changes in the number of intersections $\mathcal{L}_k \cap \mathcal{G}_k$ can be detected given a knowledge of the intersection points $\mathcal{L}_{k+1} \cap \mathcal{G}_{k+1}$: from the definition of $\mathcal{L}_{k+1}$, a point $z + W_{k+1}\alpha \in \mathcal{L}_{k+1} \cap \mathcal{G}_{k+1}$ is coincident with $\mathcal{L}_k$ if and only if $e_{k+1}^T \alpha = 0$ (where $e_k = [0 \quad 0 \quad \cdots \quad 1]^T \in \mathbb{R}^k$).

In order to track an intersection point $\mathcal{L}_k \cap \mathcal{G}_k$, it is sufficient to determine the corresponding prediction time τ satisfying (9) since $\xi \in \mathcal{L}_k \cap \mathcal{G}_k$ can then be computed using $\xi = z + W_k\alpha$ and (8). In the absence of disturbances, this could be done by solving (9) for $z = z(0)$ offline and integrating $\dot{\tau} = (\partial\tau/\partial z)\dot{z}$ online. However, this approach is likely to be numerically unstable, and we propose instead a stable adaptation law of the form

$$\dot{\tau} = -\frac{gA^k \mathrm{e}^{A\tau}\left(\left[\mathrm{I} - W_k(M_k W_k)^{-1} M_k\right]\dot{z} + \gamma_\tau(z + W_k\alpha)\right)}{gA^k \mathrm{e}^{A\tau}\left[\mathrm{I} - W_k(M_k W_k)^{-1} M_k\right] A(z + W_k\alpha)}, \tag{11}$$

where α is given by (8) and $\gamma_\tau > 0$ is an adaptive gain.

THEOREM 4.4. *Under the adaptation law* (11), $gA^k\mathrm{e}^{A\tau}\big[z+W_k(M_kW_k)^{-1}(\overline{u}e_1-M_kz)\big]\to 0$ *exponentially in* t.

Proof. Let $\xi = z + W_k\alpha$, where α is defined for given τ by (8). Then

$$gA^k\mathrm{e}^{A\tau}\big[z+W_k(M_kW_k)^{-1}(\overline{u}e_1-M_kz)\big] = gA^k\mathrm{e}^{A\tau}\xi,$$

and it suffices to show that $gA^k\mathrm{e}^{A\tau}\xi\to 0$ exponentially in t to prove the theorem. The derivative of ξ with respect to t is given by $\dot\xi = \dot z + W_k\dot\alpha$, and, differentiating (8),

$$\begin{aligned}\dot\alpha &= -(M_kW_k)^{-1}M_k\dot z - (M_kW_k)^{-1}M_kA\big[z+W_k(M_kW_k)^{-1}(\overline{u}e_1-M_kz)\big]\dot\tau\\ &= -(M_kW_k)^{-1}M_k(\dot z + A\xi\dot\tau),\end{aligned}$$

we therefore have $\dot\xi = \big[\mathrm{I}-W_k(M_kW_k)^{-1}M_k\big]\dot z - W_k(M_kW_k)^{-1}M_kA\xi\dot\tau$. Hence

$$\begin{aligned}\frac{d}{dt}(gA^k\mathrm{e}^{A\tau}\xi) &= gA^k\mathrm{e}^{A\tau}\dot\xi + gA^{k+1}\mathrm{e}^{A\tau}\xi\dot\tau\\ &= gA^k\mathrm{e}^{A\tau}\big[\mathrm{I}-W_k(M_kW_k)^{-1}M_k\big]\dot z\\ &\quad + gA^k\mathrm{e}^{A\tau}\big[\mathrm{I}-W_k(M_kW_k)^{-1}M_k\big]A\xi\dot\tau,\end{aligned}$$

and since $\dot\tau$ as defined in (11) can be expressed as

$$\dot\tau = -\frac{gA^k\mathrm{e}^{A\tau}[\mathrm{I}-W_k(M_kW_k)^{-1}M_k]\dot z + \gamma_\tau gA^k\mathrm{e}^{A\tau}\xi}{gA^k\mathrm{e}^{A\tau}[\mathrm{I}-W_k(M_kW_k)^{-1}M_k]A\xi},$$

it follows that $d(gA^k\mathrm{e}^{A\tau}\xi)/dt = -\gamma_\tau gA^k\mathrm{e}^{A\tau}\xi$ for all $t\ge 0$. ∎

Remark 4.5. A finite constraint horizon T_{con} such that, for any $z\in\Omega$, $g\mathrm{e}^{A\tau}z = \overline{u}$ only if $\tau\le T_{\mathrm{con}}$ can be determined using the admissible set approximation approach described in [10]. Consequently, the active constraint set can be determined from a finite number of intersection points $\mathcal{L}_k\cap\mathcal{G}_k$ corresponding to prediction times $\tau\in[0,T_{\mathrm{con}}]$.

Theorem 4.4 is the basis of an algorithm for stable tracking of every intersection point $\mathcal{L}_k\cap\mathcal{G}_k$, $k=1,\dots,n-1$, corresponding to $\tau\in[0,T_{\mathrm{con}}]$ as $z(t)$ varies continuously in Ω. The approach (which is summarized in Algorithm 4.6) involves finding all solutions to (9) for $k=1,\dots,n-1$ on the interval $[0,T_{\mathrm{con}}]$ offline and then adapting these solutions online via (11) in response to the prediction state derivative $\dot z(t)$. The appearance of new solutions and the disappearance of existing solutions are handled via Theorem 4.2 and Remark 4.3.

In particular, let τ_i be a solution to (9) for $z=z(t)$ and $k=k_i$, and define α_i as the corresponding value of α in (8). Denote the set of all solutions to (9) for $k=1,\dots,n-1$ such that $\tau_i\in[0,T_{\mathrm{con}}]$ as $\{(\tau_i)_{i\in\mathcal{I}}\}$. Then Theorem 4.4 shows that (11) is an asymptotically stable estimator for each τ_i, $i\in\mathcal{I}$, such that $\dot\tau_i$ is well defined at time t. Alternatively, if τ_i is discontinuous at time t, then Theorem 4.2 shows that $\mathcal{L}_{k_i}\cap\mathcal{G}_{k_i}\in\mathcal{G}_{k_i+1}$, and, therefore, $gA^{k_i+1}\mathrm{e}^{A\tau_i}(z+W_{k_i}\alpha_i)=0$ is necessarily satisfied; in this case, i is removed from the index set $\mathcal{I}$, indicating that the prediction time τ_i is no longer to be tracked. On the other hand, from Remark 4.3 and the continuity of $\mathcal{L}_{n-1}\cap\mathcal{G}_{n-1}$, a new solution on the interval $(0,T_{\mathrm{con}})$ to (9) can appear at time t only if $\mathcal{L}_{k_i}\cap\mathcal{G}_{k_i}\in\mathcal{L}_{k_i-1}$ (which implies $e_{k_i}^T\alpha_i=0$) for some $i\in\mathcal{I}$ at time t, and, in this case, a new solution is given by $\tau=\tau_i$ for $k=k_i-1$. Accordingly, we introduce new indices $\{i_1,i_2\}$ into the set $\mathcal{I}$ whenever $e_{k_i}^T\alpha_i=0$ for some $i\in\mathcal{I}$ and set $k_{i_1}=k_{i_2}=k_i-1$, $\tau_{i_1}=\tau_i-\epsilon$, $\tau_{i_2}=\tau_i+\epsilon$ for some suitably small ϵ. Furthermore, to ensure that $\tau_i\in[0,T_{\mathrm{con}}]$ for each $i\in\mathcal{I}$, we remove i from $\mathcal{I}$ whenever

$\tau_i = 0$ and $\dot{\tau}_i < 0$ or $\tau_i = T_{\text{con}}$ and $\dot{\tau}_i > 0$. Finally, new intersection points $\mathcal{L}_k \cap \mathcal{G}_k$ corresponding to $\tau = 0$ and $\tau = T_{\text{con}}$ are detected and introduced to the scheme by continuously monitoring the values of the left-hand side of (9) for $\tau = 0$, $\tau = T_{\text{con}}$, and $k = 1, \dots, n-1$.

ALGORITHM 4.6. *Offline: Determine the solutions* $\{(\tau_i)_{i\in\mathcal{I}}\}$ *to* (9) *for* $k = 1, \dots, n-1$ *satisfying* $\tau_i \in [0, T_{\text{con}}]$. *Online at times* $t \geq 0$*:*

1. *For each* $i \in \mathcal{I}$*:*

Remark 4.7. From property (P4) and Remark 4.5, Algorithm 4.6 enables $z(t) \in \partial\Omega$ to be detected by checking the following simple conditions:

(i) $\alpha_i = 0$ for some $i \in \mathcal{I}$ such that $k_i = 1$.
(ii) $gz(t) = \overline{u}$.

Furthermore, the prediction times associated with active constraints are given by τ_i if (i) is satisfied or by 0 if (ii) is satisfied.

5. Prediction parameter adaptation. From the definition of Ω, the prediction parameters $c^*(t)$ that minimize $J(t)$ over the prediction class (4) are the solution of the following problem:

$$\begin{array}{ll} \underset{c}{\text{minimize}} & J(t) \\ \text{subject to} & \begin{bmatrix} c \\ x(t) \end{bmatrix} \in \Omega. \end{array} \tag{12}$$

Below we describe a method of incrementally optimizing performance by adapting the prediction parameters $c(t)$ online via $\dot{c}(t)$ and specifying the control law as

$$\dot{c}(t) = A_\phi c(t) + \theta(t), \tag{13a}$$

$$u(t) = -kx(t) + \phi(0)^T c(t), \tag{13b}$$

where the direction $\theta(t)$ of adaptation is chosen according to the gradient of $J(t)$ subject to the constraint that $z(t)$ remains in Ω. This approach ensures that the rate of decrease of $J(t)$ is greater than along the prediction system trajectory passing through $z(t)$ while maintaining the feasibility of the receding horizon optimization problem. As a result, (13) exponentially stabilizes the plant from any initial condition $x(0)$ for which a predicted control law of the form (4) is stabilizing (i.e., from any $x(0)$ for which there exists some $c(0)$ such that $z(0) \in \Omega$).

We also show below that this approach guarantees asymptotic convergence of $z(t)$ to a point $z^*(t) = \begin{bmatrix} c^{*T}(t) & x^T(t) \end{bmatrix}^T$, which is optimal with respect to (12) for the given value of $x(t)$, provided the direction $\theta(t)$ in which $c(t)$ is adapted satisfies an optimality criterion. This direction is determined simply by the gradient of $J(t)$

if $z(t)$ lies in the interior of Ω and by a projection of the cost gradient into the subspace tangent to the surface of Ω if $z(t)$ lies in the boundary of Ω. We describe an efficient method of computing a suitable projection based on a knowledge of the normal subspace to $\partial\Omega$ at $z(t)$. Noting that the normal subspace to $\partial\Omega$ at a point $z(t) \in \partial\Omega$ can be determined using Algorithm 4.6 and property (P3), the adaptation law (13a) can be implemented online and, in conjunction with (13b), results in a receding horizon control law with guaranteed stability and asymptotic convergence to a solution of (12).

The predicted performance index evaluated along trajectories of (6) is given by the quadratic form $J(t) = z^T(t)Pz(t)$, where P is defined by

$$PA + A^T P = -\overline{Q}, \;\; \overline{Q} = \begin{bmatrix} 0 & 0 \\ 0 & Q \end{bmatrix} + G^T R G.$$

In the following, we assume that $(\overline{Q}^{1/2}, A)$ is observable so that P is positive definite; given that $(A_m, B_m, Q^{1/2})$ is controllable and observable, this is ensured if $(\Phi(0), A_\phi)$ is observable. From (13) we have

$$\dot{z}(t) = Az(t) + \begin{bmatrix} \theta(t) \\ 0 \end{bmatrix} \tag{14}$$

along closed-loop trajectories, and the derivative of $J(t)$ can therefore be expressed as

$$\dot{J}(t) = -z^T(t)\overline{Q}z(t) + [\nabla_c J(t)]^T \theta(t), \tag{15}$$

where $\nabla_c J(t)$ denotes the gradient of J with respect to c evaluated at $z(t)$. The following theorem uses standard monotonicity arguments (see, e.g., [17]) to show that (13b) asymptotically stabilizes the plant (1) when combined with any adaptation law of the form (13a) with the property that $\nabla_c J^T \theta$ is nonpositive and which ensures that $z(t)$ remains in Ω at all times t.

THEOREM 5.1. *If $\theta(t)$ in* (13a) *satisfies $[\nabla_c J(t)]^T \theta(t) \le 0$ and $z(t) \in \Omega$ for all $t \ge 0$, then $x = 0$ is an asymptotically stable equilibrium of the closed-loop system of* (1) *under* (13b).

Proof. If $\theta(t)$ satisfies $[\nabla_c J(t)]^T \theta(t) \le 0$ and $z(t) \in \Omega$, then from (15), $\dot{J}(t) \le -z^T(t)\overline{Q}z(t)$ for all $t \ge 0$, and it follows that $z = 0$ is a stable equilibrium of the closed-loop dynamics (14). The integral of this bound over $t \ge 0$ gives

$$\int_0^\infty z^T(t')\overline{Q}z(t')\,dt' \le J(0) - \lim_{t\to\infty} J(t),$$

and since $\theta(t)$ is finite for all t by assumption, it follows from Barbalat's lemma [14] that $\lim_{t\to\infty} z^T(t)\overline{Q}z(t) = 0$, which implies that $\lim_{t\to\infty} z(t) = 0$ due to the observability of $(\overline{Q}^{1/2}, A)$. □

We define the unconstrained adaptation law by setting

$$\theta(t) = -\gamma_c \nabla_c J(t) \tag{16}$$

in (13a), where $\gamma_c > 0$ is an adaptation gain. It is easy to show that (16) forces $c(t)$ to converge exponentially to the unconstrained optimal prediction parameters $c = 0$, and provided that γ_c is sufficiently large, (16) will therefore drive $z(t)$ to the admissible

set boundary if the unconstrained optimal control $u(t) = -kx(t)$ is initially infeasible. In order to ensure that $z(t)$ remains in Ω whenever $z(t) \in \partial\Omega$ and that $z(t)$ converges to a constrained optimal point $z^*(t)$, a modified adaptation law for $c(t)$ based on a projection of $\nabla_c J(t)$ into $\partial\Omega$ is needed.

Before describing the constrained adaptation law, we first give conditions for an optimal point $z^*(t)$. In the following, we denote the set of (outward) normal vectors to $\partial\Omega$ at a point $z \in \partial\Omega$ as $\{(n_i)_{i\in\mathcal{I}_a}\}$ and define $n_{i,c} = [\mathrm{I}_{n_c} \quad 0]n_i$ for all $i \in \mathcal{I}_a$. Thus in the case of the single input constraint $u(t) \le \overline{u}$, for example, every $i \in \mathcal{I}_a$ corresponds to a prediction time $\tau_i \ge 0$ for which $g\mathrm{e}^{A\tau_i}z = \overline{u}$, and $n_i = (g\mathrm{e}^{A\tau_i})^T$ for all $i \in \mathcal{I}_a$.

LEMMA 5.2. *$z(t) = z^*(t)$ if and only if there exist multipliers λ_i, $i \in \mathcal{I}_a$, satisfying*

$$\begin{aligned} &\sum_{i\in\mathcal{I}_a} \lambda_i n_{i,c} = -\nabla_c J(t), \\ &\lambda_i \ge 0 \quad \forall i \in \mathcal{I}_a. \end{aligned} \tag{17}$$

Proof. These are the Kuhn–Tucker (KT) conditions for constrained optimality applied to problem (12). The necessity of (17) can be shown by considering the effect on J of a perturbation $c = c^* + \delta c$. If $\nabla_c J$ does not lie in the span of $\{(n_i)_{i\in\mathcal{I}_a}\}$ or if $\lambda_i < 0$ for some $i \in \mathcal{I}_a$, then there exists a direction s such that $n_{i,c}^T s \le 0$ for all $i \in \mathcal{I}_a$ and $\nabla_c J^T s < 0$. A reduction in J can therefore be achieved without violating constraints by choosing $\delta c = \epsilon s$ for sufficiently small $\epsilon > 0$, and, in this case, c^* cannot be a minimizer of (12). The sufficiency of (17) follows from the convexity of J and of Ω. □

From (15) it can be seen that an adaptation law for c should minimize $\nabla_c J^T\theta$ in order to maximize the rate of convergence of $J(t)$. At a point $z(t) \in \partial\Omega$, we require, in addition, that $n_i^T\dot{z}$ be negative for all $i \in \mathcal{I}_a$ in order that $z(t)$ remains in Ω. These criteria are conveniently expressed as a linear program: minimize $\nabla_c J^T\theta$ over θ subject to $n_{i,c}^T\theta \le -n_i^T Az$ for all $i \in \mathcal{I}_a$. However, as a consequence of Lemma 5.2, the solution of this problem is unbounded for any $z \ne z^*$. In order to define a meaningful optimization on which to base the design of the constrained adaptation law, we therefore include the additional constraint $\theta^T S\theta \le r^2$ for some symmetric positive definite S and $r > 0$ and consider the following convex subproblem:

$$\begin{aligned} \underset{\theta}{\text{minimize}} \quad & \nabla_c J^T\theta \\ \text{subject to} \quad & n_{i,c}^T\theta \le -n_i^T Az \quad \forall i \in \mathcal{I}_a, \\ & \theta^T S\theta \le r^2. \end{aligned} \tag{18}$$

Introducing Lagrange multipliers λ_i, $i \in \mathcal{I}_a$, and λ^0 and defining the Lagrangian function

$$L(\theta, (\lambda_i)_{i\in\mathcal{I}_a}, \lambda^0) = \nabla_c J^T\theta + \sum_{i\in\mathcal{I}_a} \lambda_i(n_{i,c}^T\theta + n_i^T Az) + \frac{1}{2}\lambda^0(\theta^T S\theta - r^2),$$

the solution θ^* of (18) is characterized by the conditions

$$\nabla_\theta L = \nabla_c J + \sum_{i\in\mathcal{I}_a} \lambda_i n_{i,c} + \lambda^0 S\theta = 0, \tag{19a}$$

$$\lambda_i > 0, \quad n_{i,c}^T\theta^* = -n_i^T Az \quad \forall i \in \mathcal{A}^*, \tag{19b}$$

$$\lambda_i = 0, \quad n_{i,c}^T\theta^* \le -n_i^T Az \quad \forall i \in \mathcal{I}_a - \mathcal{A}^*, \tag{19c}$$

$$\lambda^0 \ge 0, \quad \lambda^0(\theta^{*T} S\theta^* - r^2) = 0, \tag{19d}$$

where $\mathcal{A}^* \subseteq \mathcal{I}_a$ is the set of active constraints at the solution. The following theorem shows that the solution of the subproblem (18) ensures asymptotic convergence to a point z^* satisfying the KT conditions of Lemma 5.2, subject to mild conditions on S and r.

THEOREM 5.3. *If S and $r > 0$ are continuous functions of z and $\theta(t) = \theta^*(t)$ in* (13a)*, then $z(t)$ converges asymptotically to $z^*(t)$.*

Proof. The solution θ^* of (18) is also the solution of the QP problem

$$\begin{array}{ll} \underset{\theta}{\text{minimize}} & \nabla_c J^T \theta + \frac{1}{2}\lambda^0 \theta^T S \theta \\ \text{subject to} & n_{i,c}^T \theta \le -n_i^T A z \quad \forall i \in \mathcal{I}_a, \end{array} \tag{20}$$

where λ^0 is defined by the optimality conditions (19). From the definition of the admissible set boundary, we have $n_i^T A z \le 0$ for all $i \in \mathcal{I}_a$, and it follows that $\theta = 0$ satisfies the constraints of (20), which implies that $\nabla_c J^T \theta^* + \frac{1}{2}\lambda^0 \theta^{*T} S \theta^* \le 0$. Noting that $\theta^{*T} S \theta^* = r^2$ whenever $z \ne z^*$ since the constraint $\theta^T S \theta \le r^2$ is then necessarily active, we have

$$\nabla_c J^T \theta \le -\frac{1}{2} r^2 \lambda^0.$$

The integral of (15) with $\theta(t) = \theta^*(t)$ therefore gives

$$\frac{1}{2}\int_0^t r^2 \lambda^0(t')\, dt' \le J(0) - J(t).$$

The right-hand side of this expression is finite, and since λ^0 is nonnegative and continuous (due to the continuous dependence of the constraints and objective of (18) on z), Barbalat's lemma shows that $\lambda^0 \to 0$ as $t \to \infty$. Furthermore, from (19a), we have

$$\sum_{i \in \mathcal{I}_a} \lambda_i n_{i,c} + \lambda^0 S \theta^* = -\nabla_c J, \quad \lambda_i \ge 0 \ \ \forall i \in \mathcal{I}_a,$$

for all $t \ge 0$, and $\lambda^0 \to 0$ therefore implies that the conditions of Lemma 5.2 are satisfied asymptotically. ∎

The solution of (18) is easily computed if $\{(n_i)_{i \in \mathcal{I}_a}\}$ consists of a single normal vector. In practice, this is often the case since the argument of Appendix B shows that the set of points in $\partial\Omega$ at which $\operatorname{span}\{(n_i)_{i \in \mathcal{I}_a}\}$ has dimension greater than 1 has zero measure on $\partial\Omega$. However, the computation of θ^* is nontrivial if $\{(n_i)_{i \in \mathcal{I}_a}\}$ contains several elements and may require a number of iterative steps. To overcome this difficulty, we make use of the freedom in choice of S to derive an efficiently computed suboptimal solution which nevertheless ensures convergence to z^*.

The approach is based on decoupling the Lagrange multipliers for the linear constraints in (18). Define $\lambda \in \mathbb{R}^{n_a}$ as the vector of multipliers λ_i $i \in \mathcal{I}_a$ and $N \in \mathbb{R}^{n \times n_a}$ as the matrix with columns n_i $i \in \mathcal{I}_a$, and let $N_c = [\mathrm{I}_{n_c} \quad 0]N$; then (19a) can be expressed as

$$N_c^T S^{-1} N_c \lambda = -N_c^T S^{-1} \nabla_c J - \lambda^0 N_c^T \theta.$$

Provided the normal vectors $\{(n_{i,c})_{i \in \mathcal{I}_a}\}$ are linearly independent, the factor $N_c^T S^{-1} N_c$ can be diagonalized by defining S^{-1} in terms of a generalized left inverse of N_c. This is conveniently done via a QR factorization of N_c:

$$N_c = Q \begin{bmatrix} R \\ 0 \end{bmatrix} = \begin{bmatrix} Q_1 & Q_2 \end{bmatrix} \begin{bmatrix} R \\ 0 \end{bmatrix} = Q_1 R,$$

where $Q \in \mathbb{R}^{n_c \times n_c}$ is orthogonal, $R \in \mathbb{R}^{n_a \times n_a}$ is upper triangular, and $Q_1 \in \mathbb{R}^{n_c \times n_a}$, $Q_2 \in \mathbb{R}^{n_c \times n_c - n_a}$. Then the definition

$$S^{-1} = Q_1 R^{-T} R^{-1} Q_1^T + Q_2 Q_2^T \Leftrightarrow S = Q_1 R R^T Q_1^T + Q_2 Q_2^T$$

yields $\lambda = -R^{-1} Q_1^T \nabla_c J - \lambda^0 N^T \theta$, and the active set $\mathcal{A}^*$ (defined as the set of indices of constraints which are active at the solution θ^*) is given simply by

$$\mathcal{A}^* = \left\{ i;\ -e_i^T (R^{-1} Q_1^T \nabla_c J - \lambda^0 N^T A z) > 0 \right\}$$

(where e_i denotes the ith column of the identity I_{n_a}).

Computation of λ^0 requires a knowledge of λ at the solution, however, and to avoid this complication we choose a suboptimal active set $\mathcal{A} \supseteq \mathcal{A}^*$ as

$$\mathcal{A} = \{ i;\ -e_i^T R^{-1} Q_1^T \nabla_c J > 0 \}. \tag{21}$$

Setting $\lambda_i = 0$ for all $i \in \mathcal{I}_a - \mathcal{A}$, the corresponding solution for θ is given by

$$\begin{aligned} \theta &= -\frac{1}{\lambda^0} \Pi \nabla_c J - Q_1 R^{-T} E_{\mathcal{A}} E_{\mathcal{A}}^T N^T A z, \\ \lambda^0 &= \frac{\|\nabla_c J\|_\Pi}{[r^2 - \|E_{\mathcal{A}}^T N^T A z\|^2]^{1/2}}, \\ \Pi &= Q_1 R^{-T} (\mathrm{I}_{n_a} - E_{\mathcal{A}} E_{\mathcal{A}}^T) R^{-1} Q_1^T + Q_2 Q_2^T, \end{aligned}$$

where $E_{\mathcal{A}} = [(e_i)_{i \in \mathcal{A}}]$ and $\|\nabla_c J\|_\Pi^2 = \nabla_c J^T \Pi \nabla_c J$.

Remark 5.4. The requirement that the normal vectors $\{(n_{i,c})_{i \in \mathcal{I}_a}\}$ are linearly independent can be enforced by removing index i from $\mathcal{I}_a$ if the absolute value of the ith diagonal element of R falls below a threshold.

Defining $r^2 = \gamma_c^2 + \|E_{\mathcal{A}}^T N^T A z\|^2$ for some adaptation gain γ_c, the corresponding constrained adaptation law is given by (13a) with

$$\theta(t) = -\gamma_c \frac{\Pi \nabla_c J(t)}{\|\nabla_c J(t)\|_\Pi} - Q_1 R^{-T} E_{\mathcal{A}} E_{\mathcal{A}}^T N^T A z(t). \tag{22}$$

This suboptimal choice for $\theta(t)$ is shown below to satisfy the conditions for closed-loop stability of Theorem 5.1 and to ensure asymptotic convergence of $z(t)$ to $z^*(t)$.

LEMMA 5.5. *The constrained adaptation law defined by* (13a) *and* (22) *ensures that $z(t)$ remains in Ω and that $[\nabla_c J(t)]^T \theta(t) \le 0$ for all $t \ge 0$.*

Proof. From the definition of $\mathcal{A}$, we have $e_i^T R^{-1} Q_1^T \nabla_c J < 0$ if $i \in \mathcal{A}$ and $e_i^T R^{-1} Q_1^T \nabla_c J \ge 0$ if $i \in \mathcal{I}_a - \mathcal{A}$. Hence

$$n_{i,c}^T \theta = \begin{cases} -n_i^T A z & \text{if } i \in \mathcal{A}, \\ -\frac{1}{\lambda^0} e_i^T R^{-1} Q_1^T \nabla_c J \le 0 \le -n_i^T A z & \text{if } i \in \mathcal{I}_a - \mathcal{A}, \end{cases}$$

which implies that $n_i^T \dot{z} \le 0$ whenever $z \in \partial\Omega$. Also,

$$\nabla_c J^T \theta = -\gamma_c \|\nabla_c J\|_\Pi - \nabla_c J^T Q_1 R^{-T} E_{\mathcal{A}} E_{\mathcal{A}}^T N^T A z \le -\gamma_c \|\nabla_c J\|_\Pi \tag{23}$$

(where $n_i^T A z \le 0$ for all $i \in \mathcal{I}_a$ has been used). ∎

THEOREM 5.6. *Under the constrained adaptation law of* (13a) *with* (22), *$z(t)$ is asymptotically convergent to $z^*(t)$.*

Proof. The integral of (15) with the bound (23) gives

$$\gamma_c \int_0^t \|\nabla_c J(t')\|_\Pi \, dt' \leq J(0) - J(t),$$

and since $\nabla_c J$ and Π are continuous in z, it follows from Barbalat's lemma that $\Pi \nabla_c J \to 0$ as $t \to \infty$. This implies that $-\nabla_c J \to \sum_{i \in \mathcal{I}_a} \lambda_i n_{i,c}$ and $\lambda^0 \to 0$. Furthermore, $\lambda_i = 0$ if $i \in \mathcal{I}_a - \mathcal{A}$ and $\lambda_i - \lambda^0 N^T A z > 0$ if $i \in \mathcal{A}$, so conditions of Lemma 5.2 are satisfied asymptotically. □

Remark 5.7. As well as providing a feasible gradient descent direction, (22) has the property that $\nabla_c J^T \theta = 0$ only if $\theta = 0$. From (15), this implies that it is always possible to construct an exponentially convergent upper bound for $J(t)$. For example, if $\theta(t_0) \neq 0$, then there must exist $t_1 > t_0$ such that $J(t) \leq z^T(t_0) \mathrm{e}^{A^T(t-t_0)} P \mathrm{e}^{A(t-t_0)} z(t_0)$ for all $t \in [t_0, t_1]$. On the other hand, this bound clearly holds with equality if $\theta(t) = 0$ for $t \in [t_0, t_1]$. It follows that (13) ensures exponential convergence $z(t) \to 0$ along closed-loop trajectories.

The following algorithm summarizes the receding horizon control law, which by Theorem 5.1 and Remark 5.7 is exponentially stable and from Theorem 5.6 is asymptotically optimal with respect to (12).

ALGORITHM 5.8. *At $t = 0$: Perform the offline calculations of Algorithm* 4.6 *and find $c(0)$ such that $z(0) \in \Omega$. At times $t \geq 0$:*

1. *Update $\mathcal{I}$ via Algorithm* 4.6 *and determine $\mathcal{I}_a$ using Remark* 4.7.
2. *Update $c(t)$ using* (13a) *and* (16) *if $\mathcal{I}_a = \emptyset$ or* (22) *otherwise.*
3. *Implement $u(t) = Kx(t) + \Phi(0)^T c(t)$.*

Remark 5.9. The solution (22) for θ resembles part of a single iteration of a primal active set method for QP (see, e.g., [11]). This observation emphasizes the computational advantages of Algorithm 5.8; online computational load is reduced significantly by exploiting prior knowledge of the dependence of the active constraint set on the plant state. The approach proposed in [2] is similar in that the optimal active constraint sets corresponding to different regions of state-space are computed offline so that the online computation reduces to checking in which region the plant state lies. However, Algorithm 5.8 has the further advantage of an explicit characterization of the state-space in terms of active constraints, and this results in lower online computational burden than the approach of [2], which can require checking large numbers of linear inequalities online. This reduction in computational load is gained at the expense of suboptimality since Algorithm 5.8 can only ensure asymptotic convergence to a solution of the receding horizon optimization.

Remark 5.10. The closed-loop cost, $\mathfrak{J}(t)$, is defined as the objective of (3) evaluated along closed-loop trajectories under Algorithm 5.8 as follows:

$$\mathfrak{J}(t) = \int_t^\infty (x^T(t')Qx(t') + u^T(t')Ru(t')) \, dt' = \int_t^\infty z^T(t') \overline{Q} z(t') \, dt' \tag{24}$$

and can be expressed using (15) as

$$\mathfrak{J}(t) = J(t) + \int_t^\infty [\nabla_c J(t')]^T \theta(t') \, dt'.$$

Although Algorithm 5.8 is based on the MPC strategy of minimizing the predicted cost $J(t)$, the policy of minimizing $\nabla_c J^T \theta$ also turns out to be optimal with respect to

the constrained minimization of $\mathfrak{J}(t)$ under certain conditions which we now discuss. Substituting for $\nabla_c J^T\theta$ using (15), the minimization of (18) is equivalent to

$$\min_{\theta}\{\nabla J^T\dot{z} + z^T\overline{Q}z \quad \text{subject to} \quad (14) \text{ and } n_i^T\dot{z} \le 0,\ i \in \mathcal{I}_a\} = \nabla_c J^T\theta^*. \tag{25}$$

This is an HJB equation which shows that ∇J is the gradient of the optimal closed-loop cost for the dynamics of (14) subject to $z \in \Omega$ and that θ^* is the corresponding optimal value of θ [1] whenever $\nabla_c J^T\theta^* = 0$. This condition requires that $z = z^*$ and $n_i^T Az = 0$ for all $i \in \mathcal{A}^*$ (i.e., all active constraints correspond to predicted trajectories that are tangent at future points in time to their constraint boundaries).

6. Simulation examples. This section describes example simulations which compare the performance and computational load of Algorithm 5.8 with QP-based MPC strategies. Given the plant state-space realization (A_m, B_m, C_m), the predicted performance cost is defined by (3), with

$$Q = C_m^T C_m, \qquad R = 1.$$

The matrix A_ϕ is chosen in both examples as

$$A_\phi = \text{diag}\{-\sigma_1, \ldots, -\sigma_{n_c}\}, \quad \sigma_i > 0,$$

with $\sigma_1, \ldots, \sigma_{n_c}$ logarithmically spaced on the interval $[\omega_{3\text{dB}}/\sqrt{n_c}, \sqrt{n_c}\omega_{3\text{dB}}]$, where $\omega_{3\text{dB}}$ is the 3dB bandwidth of the closed-loop system under $u = Kx$; and $\Phi(0) = [\ 1 \quad \ldots \quad 1\ ]$ is employed. The initial point $z(0) \in \Omega$ is determined in each simulation by choosing $c(0)$ as the center of an ellipsoidal bound (derived from a small number of discrete samples of the continuous-time constraints) on the set $\{c;\ [\ c^T \quad x^T(0)\ ]^T \in \Omega\}$.

Example 1. Consider the third order plant

$$A_m = \begin{bmatrix} -0.50356 & 2.4417 & -1.8849 \\ 8 & 0 & 0 \\ 0 & 2 & 0 \end{bmatrix}, \quad B_m = \begin{bmatrix} 2 \\ 0 \\ 0 \end{bmatrix}, \quad C_m = \begin{bmatrix} -0.79081 \\ 0.10112 \\ 0.94243 \end{bmatrix}^T$$

subject to input constraints

$$-1 \le u \le 1$$

for which the unconstrained LQ-optimal feedback gain is $k = [\ 5.0662 \quad 3.4678 \quad 0.3297\ ]$. The unconstrained closed-loop system under $u = -kx$ has poles at $\{-5.3073, -2.7261 \pm 0.7773i\}$, and we choose a prediction class of dimension $n_c = 3$ and set $A_\phi = \text{diag}\{-1.6207, -2.8072, -4.8622\}$.

The performance of Algorithm 5.8 is compared with a QP-based MPC law described in [5] in Figures 2 and 3 and in Table 1. The QP-based controller uses the same parameterization of predicted inputs as Algorithm 5.8 (i.e., the exponential basis functions of (4)–(5), with $n_c = 3$ and A_ϕ as defined above) but solves the corresponding receding horizon optimization (12) periodically with period $T = 0.1$. In order to formulate (12) as a QP problem, this algorithm approximates the continuous-time constraints (2) by a set of discrete-time constraints which are artificially tightened to ensure the satisfaction of (2) at all prediction times.

The input and output responses of Figure 2 show that Algorithm 5.8 with $\gamma_c = 1$ gives poorer performance than the QP-based algorithm. This is due to the use of a

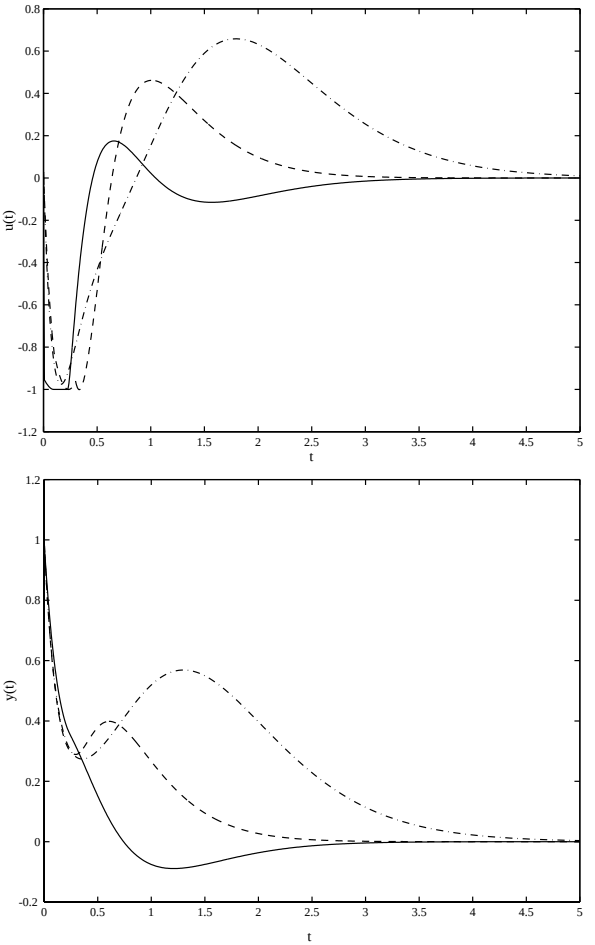

FIG. 2. *Input and output responses for Example* 1. *Solid line:* $\gamma_c = 100$. *Dashed-dotted:* $\gamma_c = 1$. *Dashed: Exponential basis functions and optimization via QP.*

very suboptimal value for $z(0)$, as can be seen from the difference in initial prediction costs $J(0)$ (Figure 3(a)). In fact, $z(t)$ remains in the interior of Ω for all $t \geq 0$ if $\gamma_c = 1$ in this example since $\|\nabla_c J\|_\Pi = \|\nabla_c J\|$ at all times (Figure 3(c)). However, the use of $\gamma_c = 100$ results in faster convergence of $J(t)$ than is achieved by the QP-based algorithm (Figure 3(a)) and, moreover, forces $z(t)$ to converge to a point in the boundary of Ω satisfying the KT conditions for constrained optimality for $0.15 \lesssim t \lesssim 0.3$ (Figure 3(c)), at which point the unconstrained optimal control becomes feasible.

Closed-loop performance is measured in Table 1 by the value of the closed-loop cost

$$\mathfrak{J} = \int_0^\infty [x^T(t)Qx(t) + u^T(t)Ru(t)]\, dt.$$

The computation times refer to average CPU times required by the parameter update law in Algorithm 5.8 and the QP solver (initialized using "warm starts") in the QP-based algorithm, with both controllers implemented in Matlab on a 440MHz Sun Ultra workstation. The computational load of Algorithm 5.8 per iteration is clearly

subject to input constraints

$$-2 \leq u \leq 2.$$

The unconstrained LQ gain is $k = [\ 25.19 \quad -39.93 \quad 29.06 \quad 28.07 \quad 87.58\ ]$, and the corresponding closed-loop poles are located at $\{-8.43, -9.81 \pm 7.03i, -16.57 \pm 86.58i\}$. For a prediction class of dimension $n_c = 4$, we choose $A_\phi = \text{diag}\{-1.89, -3.78, -5.66, -7.55\}$.

Figures 4 and 5 and Table 2 compare the performance of Algorithm 5.8 with the QP-based receding horizon control law described in Example 1 and also with a discrete-time MPC law employing piecewise-constant predicted input trajectories centered on the unconstrained discrete-time LQ-optimal controller. Both QP-based algorithms use "warm starts" determined from the solution to the previous optimization problem. This control problem is considerably more challenging than Example 1

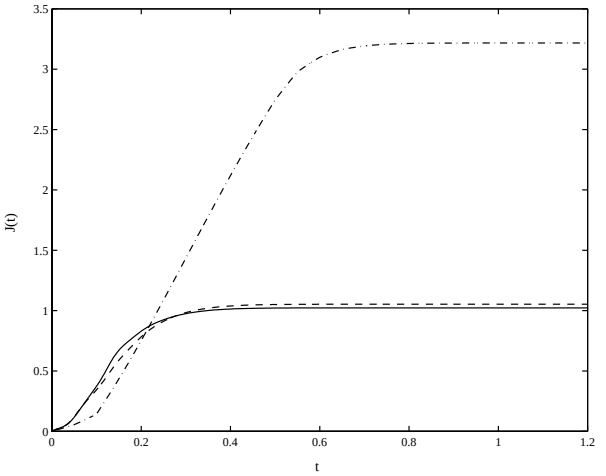

FIG. 5. *The evolution of closed-loop costs* $\mathfrak{J}(t)$ *for Example* 2. *Solid line: Algorithm* 5.8 *with* $\gamma_c = 100$. *Dashed: Exponential basis functions and QP optimization. Dashed-dotted: Discrete-time inputs and QP optimization.*

TABLE 2
Closed-loop costs and computation times for Example 2.

	Cost $\mathfrak{J}$	CPU time (ms)
Alg. 5.8, $n_c = 4$	1.0270	1.37
QP – exponential BF, $n_c = 4$	1.0532	380
QP – piecewise constant BF, $n_c = 10$	3.2175	232

since the plant has an almost uncontrollable unstable mode. For a sample period of $T = 0.05$, the discrete-time algorithm needs at least 10 degrees of freedom to stabilize the plant, and its closed-loop performance is considerably worse than the two other algorithms, which are centered on a continuous-time LQ-optimal control law. The long prediction horizon required in this example makes the QP-based algorithm employing exponential basis functions computationally expensive. On the other hand, Algorithm 5.8 combines good performance with low computational burden.

Appendix A. Conditions on predictions for feasibility given past feasibility. This section determines conditions on the structure of the class of input predictions given by (4) in order that the optimization problem (3) remains feasible at all times $t > 0$ given feasibility at $t = 0$. The receding horizon control law $u(t) = \hat{u}_t(0)$ is implemented for all $t \geq 0$, where $\hat{u}_t$ has the form (4). If the input to the plant on the interval $[t-\delta, t)$ for some $\delta > 0$ is $u(t+\tau) = \hat{u}_{t-\delta}(\tau+\delta)$, $\tau \in [-\delta, 0)$, then feasibility at t is guaranteed if the prediction defined by $\hat{u}_t(\tau) = \hat{u}_{t-\delta}(\tau+\delta)$, $\tau \geq 0$, is realizable by the prediction class of (4) since $\hat{u}_{t-\delta} \in \mathcal{U}$ by assumption. The following theorem determines an equivalent condition on Φ, the matrix of basis functions in the linear expansion of (4).

THEOREM A.1. *If* $u(t+\tau) = \hat{u}_{t-\delta}(\tau+\delta)$ *is implemented for all* $\tau \in [-\delta, 0)$ *for some* $\delta > 0$, *then at time* t *the prediction class* (4) *contains the signal* $\{\hat{u}_{t-\delta}(\tau+\delta),\ \tau \geq 0\}$ *if and only if* $M : \mathbb{R} \to \mathbb{R}^{n_c \times n_c}$ *exists satisfying*

$$\Phi(\tau+\delta) = \Phi(\tau)M(\delta) \quad \forall \tau \geq 0. \tag{26}$$

Proof. In the absence of disturbances, we have $x(t) = \hat{x}_{t-\delta}(\delta)$, so $\hat{u}_{t-\delta}$ can be expressed using (4) as

$$\hat{u}_{t-\delta}(\tau+\delta) = K\hat{x}_t(\tau) + \Phi(\tau+\delta)c(t-\delta) \quad \forall \tau \geq 0.$$

The prediction class of (4), therefore, contains $\{\hat{u}_{t-\delta}(\tau+\delta),\ \tau \geq 0\}$ if and only if $c(t)$ exists satisfying

$$\Phi(\tau)c(t) = \Phi(\tau+\delta)c(t-\delta) \quad \forall \tau \geq 0. \tag{27}$$

If Φ satisfies (26), then (27) holds for any $c(t-\delta) \in \mathbb{R}^{n_c}$ with the choice $c(t) = M(\delta)c(t-\delta)$. To show the necessity of (26), suppose that Φ satisfies

$$\Phi(\tau+\delta) = \Phi(\tau)M(\delta) + \Psi \quad \forall \tau \geq 0, \tag{28}$$

for some $\Psi \in \mathbb{R}^{n_u \times n_c}$ and that (27) holds for some $c(t) \in \mathbb{R}^{n_c}$. Assuming, without loss of generality, that Φ is full rank and solving (27) for $c(t)$ for the case when $n_u < n_c$, we have

$$c(t) = M(\delta)c(t-\delta) + \Phi^T(\tau)\big(\Phi(\tau)\Phi^T(\tau)\big)^{-1}\Psi c(t-\delta) + \Phi_\perp(\tau)\gamma,$$

where $\Phi_\perp(\tau)\gamma$ is a matrix representation of the kernel of $\Phi(\tau)$. On the other hand, if $n_u < n_c$, then $\tilde{\Phi}_\perp^T(\tau)\Psi c(t-\delta) = 0$ must hold in order that (27) has a solution for $c(t)$ (where the columns of $\tilde{\Phi}_\perp(\tau)$ form a basis for the kernel of $\Phi^T(\tau)$), and the solution is then given by

$$c(t) = M(\delta)c(t-\delta) + \big(\Phi^T(\tau)\Phi(\tau)\big)^{-1}\Phi^T(\tau)\Psi c(t-\delta).$$

However, $c(t)$ is independent of τ, and it follows that either $\gamma = 0$ and $\Psi c(t-\delta) = 0$ or $\Phi(\tau)$ is constant. For nonconstant Φ and arbitrary $c(t-\delta)$, (27) therefore holds for some $c(t)$ only if $\Psi = 0$ in (28). ∎

Applying (26) in the limit as $\delta \to 0$, with the additional condition $\Phi \in C^1$ (which is necessary due to the rate constraints of (2)), we have $M(0) = \mathrm{I}$ and $\dot{\Phi}(\tau) = \Phi(\tau)\dot{M}(0)$ for all $\tau \geq 0$. It follows that

$$\Phi(\tau) = \Phi(0)\mathrm{e}^{A_\phi \tau} \quad \forall \tau \geq 0,$$

where $A_\phi = \dot{M}(0)$.

Appendix B. Dimension of $\mathcal{G}_k$. This section determines the dimension and smoothness of the hypersurface defined by

$$\mathcal{G}_k = \{z \in \mathbb{R}^n;\ g\mathrm{e}^{A\tau}z = \overline{u},\ gA^i\mathrm{e}^{A\tau}z = 0,\ i = 1, \dots, k,\ \tau \geq 0\}$$

for $k = 1, \dots, n-1$.

THEOREM B.1. *At every point $z \in \mathcal{G}_k - \mathcal{G}_{k+1}$, $\mathcal{G}_k$ is locally a smooth hypersurface in $\mathbb{R}^n$ of dimension $n-k$ for $k = 1, \dots, n-2$.*

Proof. For any $z \in \mathcal{G}_k$, there exists $\tau \geq 0$ such that $f_i(z,\tau) = 0$ for $i = 0, \dots, k$, where

$$f_i(z,\tau) = \begin{cases} g\mathrm{e}^{A\tau}z - \overline{u}, & i = 0, \\ gA^i\mathrm{e}^{A\tau}z, & i = 1, \dots, k. \end{cases}$$

Let F denote the Jacobian matrix

$$\begin{bmatrix} \partial f_0/\partial z & \partial f_0/\partial \tau \\ \vdots & \vdots \\ \partial f_k/\partial z & \partial f_k/\partial \tau \end{bmatrix};$$

then, for all $(z,\tau) \in \mathcal{G}_k \times \mathbb{R}$ such that $f_i(z,\tau) = 0$, $i = 0, \dots, k$, F is given by

$$F(z,\tau) = \begin{bmatrix} g\mathrm{e}^{A\tau} & 0 \\ \vdots & \vdots \\ gA^{k-1}\mathrm{e}^{A\tau} & 0 \\ gA^k\mathrm{e}^{A\tau} & gA^{k+1}\mathrm{e}^{A\tau}z \end{bmatrix}.$$

The observability of (g, A), therefore, implies that $\operatorname{rank}(F(z,\tau)) = k+1$ for all $(z,\tau) \in \mathcal{G}_k \times \mathbb{R}$ such that $f_i(z,\tau) = 0$, $i = 0, \dots, k$, and $gA^{k+1}\mathrm{e}^{A\tau}z \neq 0$. Since f_i, $i = 0, \dots, k$, are C^∞ functions (i.e., infinitely continuously differentiable with respect to z and τ), it follows from the implicit function theorem that $\mathcal{G}_k - \mathcal{G}_{k+1}$ is a smooth hypersurface in $\mathbb{R}^n$ of dimension $n-k$. Specifically, let $z^T = [z_1^T \ z_2^T]$, where $z_2 \in \mathbb{R}^k$. Then it is clear that the Jacobian matrix

$$\begin{bmatrix} \partial f_0/\partial z_2 & \partial f_0/\partial \tau \\ \vdots & \vdots \\ \partial f_k/\partial z_2 & \partial f_k/\partial \tau \end{bmatrix}$$

is nonsingular for all $(z,\tau) \in \mathcal{G}_k \times \mathbb{R}$ such that $f_i(z,\tau) = 0$, $i = 0, \dots, k$, and $gA^{k+1}\mathrm{e}^{A\tau}z \neq 0$; and z_2, τ, therefore, are C^∞ functions of z_1 by the implicit function theorem. This implies that $\mathcal{G}_k$ is a smooth hypersurface parameterized by the $n-k$ coordinates of z_1 in a neighborhood of every point $z \in \mathcal{G}_k - \mathcal{G}_{k+1}$. ∎

COROLLARY B.2. *$\mathcal{G}_{n-1}$ is a smooth 1-dimensional hypersurface in $\mathbb{R}^n$.*

Proof. For $k = n-1$, the argument of Theorem B.1 shows that $\mathcal{G}_{n-1}$ is smooth and one-dimensional for all $(z,\tau) \in \mathcal{G}_{n-1} \times \mathbb{R}$ such that $f_i(z,\tau) = 0$, $i = 0, \dots, n-1$, and $gA^n\mathrm{e}^{A\tau}z \neq 0$. However, for any $z \in \mathbb{R}^n$, there is no value of $\tau \in \mathbb{R}$ such that $f_i(z,\tau) = 0$, $i = 0, \dots, n-1$, and $gA^n\mathrm{e}^{A\tau}z = 0$, due to the observability of (g, A). It follows that $\mathcal{G}_{n-1}$ is everywhere smooth and of dimension one. ∎

A STOCHASTIC JURDJEVIC–QUINN THEOREM*

PATRICK FLORCHINGER†

Abstract. The purpose of this paper is to state sufficient conditions for the stabilizability of stochastic differential systems when both the drift and diffusion terms are affine in the control. This result extends to stochastic differential systems the well-known theorem of Jurdjevic–Quinn [*J. Differential Equations*, 28 (1978), pp. 381–389] and incorporates earlier stabilization results proved in [P. Florchinger, *Stochastic Anal. Appl.*, 12 (1994), pp. 473–480] and [R. Chabour and M. Oumoun, *Stochastic Anal. Appl.*, 16 (1998), pp. 43–50].

Key words. stochastic differential system, asymptotic stability in probability, Lyapunov theorem, La Salle's invariance principle

Introduction. The stabilization of deterministic nonlinear control systems has been widely studied in past years by many authors. Among all of the results proved in this area of research, we wish to outline that of Jurdjevic–Quinn [3], giving stabilizing state feedback laws for deterministic systems affine in the control provided the control Lie algebra of the system has full rank. This result has been the starting point for different works on this topic since it appears that many engineering systems are of "Jurdjevic–Quinn type" (see [6], [8], or [7], for example). Note that the result exposed in [3] has been revisited in [7], where a more easily computable rank condition for stabilizability is stated.

A stochastic version of Jurdjevic–Quinn's theorem has been established by Florchinger [2] for stochastic differential systems, the drift of which is affine in the control. In fact, it is proved in [2] that the stabilizer given in [3] for the deterministic part of the system remains valid in the stochastic context provided the system coefficients satisfy a rank condition, which can easily be deduced from that stated in [7]. An extension of this result has been obtained by Chabour and Oumoun in [1], where it is proved that under the stabilizability condition provided in [2] one can compute stabilizing state feedback laws for stochastic differential systems in the form

$$x_t = x_0 + \int_0^t (b(x_s) + uf(x_s))\, ds + \int_0^t \sigma(x_s) dw_s + \int_0^t ug(x_s) d\tilde{w}_s,$$

where $(w_t)_{t\geq 0}$ and $(\tilde{w}_t)_{t\geq 0}$ are two independent Wiener processes.

The technique used in the last two cited papers is based on the stochastic Lyapunov analysis developed by Khasminskii [4] and the stochastic version of La Salle's invariance principle proved by Kushner [5]. However, in the proofs of the main results in [2] and [1], all of the information given by applying Itô's formula, when using the stochastic La Salle theorem, has not been used. The aim of this paper is to take this fact into account to improve the stabilizability conditions stated in [2] and [1] in order to be able to design stabilizers for a wider class of stochastic differential systems than that considered in [2] and [1].

This paper is divided into four sections and is organized as follows. In section one, we recall some basic facts on the asymptotic stability in probability for the equilibrium solution of a stochastic differential equation. In section two, we introduce the class of control stochastic differential systems we are dealing with in this paper. In section three, we prove the main result of the paper. In section four, we apply the result proved in section three to a working example which cannot be stabilized by using the results proved in [2] and [1].

1. Asymptotic stability in probability. The purpose of this section is to recall some basic facts concerning the Lyapunov analysis for the asymptotic stability in probability of the equilibrium solution of a stochastic differential system that we need in what follows.

For a complete exposition on the subject, we refer to the book of Khasminskii [4].

Let $(\Omega, \mathcal{F}, P)$ be a complete probability space, and denote by $(w_t)_{t\geq 0}$ a standard $\mathbb{R}^m$-valued Wiener process defined on this space.

Consider the stochastic process solution $x_t \in \mathbb{R}^n$ of the stochastic differential equation written in the sense of Itô,

$$x_t = x_0 + \int_0^t f(x_s)ds + \sum_{i=1}^m \int_0^t g_i(x_s)dw_s^i, \tag{1}$$

where the following hold:

1. x_0 is given in $\mathbb{R}^n$.
2. f and g_i, $1 \leq i \leq m$, are functions mapping $\mathbb{R}^n$ into $\mathbb{R}^n$, vanishing in the origin, and such that there exists a nonnegative constant K such that
$$|f(x)|^2 + \sum_{i=1}^m |g_i(x)|^2 \leq K(1+|x|^2) \quad \forall x \in \mathbb{R}^n,$$
$$|f(x)-f(y)| + \sum_{i=1}^m |g_i(x)-g_i(y)| \leq K|x-y| \quad \forall x, y \in \mathbb{R}^n.$$

For any $s \geq 0$ and $x \in \mathbb{R}^n$, denote by $x_t^{s,x}$, $s \leq t$, the solution at time t of the stochastic differential equation (1) starting from the state x at time s.

Then one can introduce the notion of asymptotic stability in probability for the equilibrium solution of the stochastic differential equation (1) as follows.

DEFINITION 1.1. (1) *The equilibrium solution $x_t \equiv 0$ of the stochastic differential equation* (1) *is stable in probability if, for any $s \geq 0$ and $\epsilon > 0$,*

$$\lim_{x\to 0} P\left(\sup_{s\leq t} |x_t^{s,x}| > \epsilon\right) = 0.$$

(2) *The equilibrium solution $x_t \equiv 0$ of the stochastic differential equation* (1) *is asymptotically stable in probability if it is stable in probability and, for any $s \geq 0$ and $x \in \mathbb{R}^n$,*

$$P\left(\lim_{t\to+\infty} |x_t^{s,x}| = 0\right) = 1.$$

Denoting by L the infinitesimal generator of the stochastic process solution of the stochastic differential equation (1), one can prove the following criterion, which gives sufficient conditions in terms of the Lyapunov function for the asymptotic stability in probability of the equilibrium solution of the stochastic differential equation (1).

THEOREM 1.2 (see Khasminskii [4]). *Assume that there exists a Lyapunov function V defined on $\mathbb{R}^n$ (i.e., a proper C^2 function V mapping $\mathbb{R}^n$ into $\mathbb{R}$ such that $V(0) = 0$ and $V(x) > 0$ for any $x \in \mathbb{R}^n$, $x \neq 0$) such that*

$$LV(x) \leq 0 \quad (\textit{respectively},\ LV(x) < 0)$$

for any $x \in \mathbb{R}^n$, $x \neq 0$. Then the equilibrium solution $x_t \equiv 0$ of the stochastic differential equation (1) *is stable (respectively, asymptotically stable) in probability.*

To conclude this section, recall the stochastic version of La Salle's invariance principle, which gives the ω-limit set of a stochastic process stable in probability.

THEOREM 1.3 (see Kushner [5]). *Assume that there exists a Lyapunov function V defined on $\mathbb{R}^n$ such that*

$$LV(x) \leq 0$$

for any $x \in \mathbb{R}^n$. Then the stochastic process solution x_t of the stochastic differential equation (1) *tends to the largest invariant set whose support is contained in the locus $LV(x_t) = 0$ for any $t \geq 0$ with probability* 1.

2. Problem setting. The purpose of this section is to introduce the class of control stochastic differential systems we are dealing with in the rest of the paper.

Consider the stochastic process solution $x_t \in \mathbb{R}^n$ of the multi-input stochastic differential system written in the sense of Itô,

$$\begin{aligned} x_t = x_0 &+ \int_0^t \left(f_0(x_s) + \sum_{k=1}^{p} u^k f_k(x_s) \right) ds \\ &+ \sum_{i=1}^{m} \int_0^t \left(g_{i,0}(x_s) + \sum_{k=1}^{p} u^k g_{i,k}(x_s) \right) dw_s^i, \end{aligned} \tag{2}$$

where the following hold:

1. x_0 is given in $\mathbb{R}^n$.
2. u^k, $1 \leq k \leq p$, are real-valued measurable control laws.
3. f_k, $0 \leq k \leq p$, and $g_{i,k}$, $1 \leq i \leq m$, $0 \leq k \leq p$, are smooth Lipschitz functions mapping $\mathbb{R}^n$ into $\mathbb{R}^n$, vanishing in the origin, and such that there exists a nonnegative constant K such that

$$\sum_{k=0}^{p} \left(|f_k(x)|^2 + \sum_{i=1}^{m} |g_{i,k}(x)|^2 \right) \leq K(1 + |x|^2) \qquad \forall x \in \mathbb{R}^n.$$

The aim of this paper is to design a state feedback law u such that the equilibrium solution of the closed-loop system deduced from the stochastic differential system (2) is asymptotically stable in probability. Note that this problem has already been solved in [2] when the diffusion term in (2) does not depend on the control, i.e., when $g_{i,k} \equiv 0$ for every $i \in \{1, \ldots, m\}$ and $k \in \{1, \ldots, p\}$.

3. The main result. Before stating the main result of the paper, which extends to the stochastic differential system (2) the well-known theorem of Jurdjevic–Quinn established in [3], we introduce the following notation.

Denote by L_0 the infinitesimal generator of the stochastic process solution of the unforced stochastic differential system deduced from (2); that is, L_0 is the second

order differential operator defined for any function ϕ in $C^2(\mathbb{R}^n;\mathbb{R})$ by

$$L_0\phi(x) = \sum_{i=1}^n f_0^i(x)\frac{\partial\phi(x)}{\partial x_i} + \frac{1}{2}\sum_{k,r=1}^n\sum_{j=1}^m g_{j,0}^k(x)g_{j,0}^r(x)\frac{\partial^2\phi(x)}{\partial x_k\partial x_r}.$$

For any $i \in \{1,\dots,p\}$, denote by L_i the second order differential operator defined for any function ϕ in $C^2(\mathbb{R}^n;\mathbb{R})$ by

$$L_i\phi(x) = \sum_{k=1}^n f_i^k(x)\frac{\partial\phi(x)}{\partial x_k} + \sum_{k,r=1}^n\sum_{j=1}^m g_{j,0}^k(x)g_{j,i}^r(x)\frac{\partial^2\phi(x)}{\partial x_k\partial x_r},$$

and, for any $i,j \in \{1,\dots,p\}$, denote by L_{ij} the second order differential operator defined for any function ϕ in $C^2(\mathbb{R}^n;\mathbb{R})$ by

$$L_{ij}\phi(x) = \frac{1}{2}\sum_{k,r=1}^n\sum_{\nu=1}^m g_{\nu,i}^k(x)g_{\nu,j}^r(x)\frac{\partial^2\phi(x)}{\partial x_k\partial x_r}.$$

Moreover, for any $i \in \{1,\dots,m\}$, denote by G_i the first order differential operator defined for any function ϕ in $C^1(\mathbb{R}^n;\mathbb{R})$ by

$$G_i\phi(x) = \sum_{k=1}^n g_{i,0}^k(x)\frac{\partial\phi(x)}{\partial x_k}.$$

Then the following result, which gives sufficient conditions for asymptotic stabilizability in probability of the stochastic differential system (2), holds.

THEOREM 3.1. *Assume that there exists a smooth Lyapunov function V defined on $\mathbb{R}^n$ such that the following hold:*

(1) *$L_0V(x) \le 0$ for every $x \in \mathbb{R}^n$.*

(2) *The set*

$$\mathcal{K} = \Bigg\{ x \in \mathbb{R}^n \;/\; G_{i_0}^{\alpha_0}L_0^{\beta_0}\cdots G_{i_k}^{\alpha_k}L_0^{\beta_k}L_jV(x) = 0$$
$$\text{and} \quad G_{i_0}^{\alpha_0}L_0^{\beta_0}\cdots G_{i_k}^{\alpha_k}L_0^{\beta_k+1}V(x) = 0$$
$$\forall j \in \{1,\dots,p\}, \forall k \in \mathbb{N}, \forall i_0,\dots,i_k \in \{1,\dots,m\},$$
$$\forall \alpha_0,\beta_0,\dots,\alpha_k,\beta_k \in \{0,\dots,k\},$$
$$\text{such that } \sum_{i=0}^k(\alpha_i+\beta_i) = k \Bigg\}$$

is reduced to $\{0\}$.

Then the control law u, defined on $\mathbb{R}^n$ by

$$u^j(x) = -\frac{L_jV(x)}{\beta(x)} \quad 1 \le j \le p, \tag{3}$$

where $\beta(x) = 1 + (\sup_{1\le i,j\le p} L_{ij}V(x))^2$, renders the stochastic differential system (2) asymptotically stable in probability.

REMARK 3.2. (1) *Hypothesis (1) implies, according to the stochastic Lyapunov theorem (Theorem 1.2), that the equilibrium solution of the unforced stochastic differential system deduced from (2) is stable in probability.*

(2) *In the definition of the control law u given in* (3)*, one can choose, instead of the one given above, any positive function β mapping $\mathbb{R}^n$ into $\mathbb{R}$ such that*

$$L_{ij}V(x) < \beta(x)$$

for any $x \in \mathbb{R}^n$ and $i, j \in \{1, \ldots, p\}$.

(3) *The existence of a unique solution for the closed-loop system deduced from* (2) *is ensured by the application of Theorem* 4.1 *from Khasminskii* [4].

Proof of Theorem 3.1. Denoting by $\mathcal{L}$ the infinitesimal generator of the stochastic process solution of the closed-loop system deduced from (2) with the state feedback law u given by (3), one gets, for every $x \in \mathbb{R}^n$,

$$\mathcal{L}V(x) = L_0V(x) - \frac{1}{\beta(x)}\sum_{i=1}^{p}(L_iV(x))^2 + \frac{1}{\beta(x)^2}\sum_{i,j=1}^{p} L_iV(x)L_jV(x)L_{ij}V(x). \tag{4}$$

Then, taking hypothesis (1) and the definition of $\beta(x)$ into account, one has

$$\mathcal{L}V(x) \leq 0$$

for every $x \in \mathbb{R}^n$, and, according to the stochastic Lyapunov theorem (Theorem 1.2), the equilibrium solution $x_t \equiv 0$ of the closed-loop system deduced from (2) is stable in probability.

Furthermore, the stochastic version of La Salle's invariance theorem (Theorem 1.3) asserts that the stochastic process solution of the closed-loop system tends to the largest invariant set whose support is contained in the locus $\mathcal{L}V(x_t) \equiv 0$ for every $t \geq 0$ with probability 1.

However, one can deduce easily from (4) that $\mathcal{L}V(x_t) \equiv 0$ for every $t \geq 0$ if and only if $L_iV(x_t) \equiv 0$, $0 \leq i \leq p$, for every $t \geq 0$.

Moreover, applying Itô's formula to the stochastic processes $L_iV(x_t)$, $0 \leq i \leq p$, yields that if $L_iV(x_t) \equiv 0$, $0 \leq i \leq p$, for every $t \geq 0$, one has $L_0^2V(x_t) \equiv 0$, $G_iL_0V(x_t) \equiv 0$, $1 \leq i \leq m$, $L_0L_iV(x_t) \equiv 0$, $1 \leq i \leq p$, and $G_i(L_jV)(x_t) \equiv 0$, $1 \leq i \leq m$, $1 \leq j \leq p$, for every $t \geq 0$.

Therefore, by inductive applications of Itô's formula, one can prove that if $\mathcal{L}V(x_t) \equiv 0$ for every $t \geq 0$, one has $x_t \in \mathcal{K}$ for every $t \geq 0$ and, consequently, according to hypothesis (2), $x_t \equiv 0$ for every $t \geq 0$.

Hence, according to Theorem 1.3, the stochastic process solution of the closed-loop system deduced from (2) tends to 0 with probability 1 and thus is asymptotically stable in probability. □

Remark 3.3. *As in* [2]*, by not fully using all of the information obtained after applying Itô's formula to the stochastic processes $L_iV(x_t) \equiv 0$, $0 \leq i \leq p$, one does not take into account the fact that $G_jL_iV(x_t) \equiv 0$, $1 \leq j \leq m$, $0 \leq i \leq p$, for every $t \geq 0$. As a consequence, the stabilizability condition obtained in* [2] *is simpler than that stated in hypothesis* (2) *but does not allow us to compute stabilizing state feedback laws in many applications. In particular, if the Lyapunov function V is such that $L_0V(x) \equiv 0$ for every $x \in \mathbb{R}^n$, then the result proved in* [2] *does not permit us to make a conclusion about the asymptotic stabilizability in probability of the system, whereas the result of the above theorem still applies.*

4. A working example. Let x_0 be given in $\mathbb{R}^2$, and denote by $x_t \in \mathbb{R}^2$ the solution of the stochastic differential system

$$dx_t = \begin{pmatrix} -\frac{1}{2}x_{1,t} \\ -\frac{1}{2}x_{2,t} \end{pmatrix} dt + u \begin{pmatrix} x_{2,t} \\ 0 \end{pmatrix} dt + \begin{pmatrix} x_{2,t} \\ x_{1,t} \end{pmatrix} dw_t, \tag{5}$$

where $(w_t)_{t\geq 0}$ is a standard real-valued Wiener process and u is a real-valued measurable control law.

Note that the equilibrium solution of the stochastic differential system (5) is stable in probability but not asymptotically stable in probability.

Then, taking the Lyapunov function V defined on $\mathbb{R}^2$ by

$$V(x) = \frac{1}{2}\left(x_1^2 + x_2^2\right),$$

one has

$$L_0V(x) = 0, \qquad L_1V(x) = x_1x_2, \qquad \text{and} \qquad L_0L_1V(x) = 0$$

for every $x \in \mathbb{R}^2$, and the stabilizability conditions stated in Theorem 3.2 in [2] are not satisfied.

However, for any $x \in \mathbb{R}^2$, one has

$$G_1L_1V(x) = x_1^2 + x_2^2,$$

and hence it is obvious that the set $\mathcal{K}$ defined in hypothesis (2) of Theorem 3.1 is reduced to $\{0\}$.

Therefore, by application of the result of Theorem 3.1, one gets that the state feedback law u defined on $\mathbb{R}^2$ by

$$u(x) = -x_1x_2$$

renders the stochastic differential system (5) asymptotically stable in probability.

STABILITY OF PLANAR SWITCHED SYSTEMS: THE LINEAR SINGLE INPUT CASE*

UGO BOSCAIN†

Abstract. We study the stability of the origin for the dynamical system $\dot{x}(t) = u(t)Ax(t) + (1 - u(t))Bx(t)$, where A and B are two 2×2 real matrices with eigenvalues having strictly negative real part, $x \in \mathbf{R}^2$, and $u(.) : [0, \infty[\to [0, 1]$ is a completely random measurable function. More precisely, we find a (coordinates invariant) necessary and sufficient condition on A and B for the origin to be asymptotically stable for each function $u(.)$.

The result is obtained without looking for a common Lyapunov function but studying the locus in which the two vector fields Ax and Bx are collinear. There are only three relevant parameters: the first depends only on the eigenvalues of A, the second depends only on the eigenvalues of B, and the third contains the interrelation among the two systems, and it is the cross ratio of the four eigenvectors of A and B in the projective line $\mathbf{C}P^1$. In the space of these parameters, the shape and the convexity of the region in which there is stability are studied.

This bidimensional problem assumes particular interest since linear systems of higher dimensions can be reduced to our situation.

Key words. stability, planar, random switching function, switched systems

AMS subject classifications. 93D20, 37N35

1. Introduction.

By a switched system we mean a family of continuous-time dynamical systems and a rule that determines at any time which dynamical system is responsible for the time evolution. More precisely, let $\{f_u : \ u \in U\}$ be a (finite or infinite) set of sufficiently regular vector fields on a manifold M, and consider the family of dynamical systems:

$$\dot{x} = f_u(x), \quad x \in M. \tag{1}$$

The rule is given assigning the so-called switching function $u(.) : [0, \infty[\to U$. Here we consider the situation in which the switching function cannot be predicted a priori; it is given from outside and represents some phenomena (e.g., a disturbance) that it is not possible to control or include in the dynamical system model.

In the following, we use the notation $u \in U$ to label a fixed individual system and $u(.)$ to indicate the switching function.

Suppose now that all of the f_u have a given property for every $u \in U$. A typical problem is to study under which conditions this property holds for the system (1) for arbitrary switching functions. For a discussion of various issues related to switched systems, we refer the reader to [8].

In [1, 7] the case of switched linear systems was considered:

$$\dot{x} = A_u x, \quad x \in \mathbf{R}^n, \quad A_u \in \mathbf{R}^{n \times n}, \quad u \in U, \tag{2}$$

and the problem of the asymptotic stability of the origin for arbitrary switching functions was investigated. Clearly we need the asymptotic stability of each single

subsystem $\dot{x} = A_u x$, $u \in U$, in order to have the asymptotic stability of (2) for each switching function (i.e., the eigenvalues of each matrix A_u must have strictly negative real part). This will be assumed to be the case throughout the paper.

Notice the important point that in the case of linear systems, the asymptotic stability for arbitrary switching functions is equivalent to the more often quoted property of global exponential stability, uniform with respect to switching (GUES); see, for example, [2] and references therein.

In [1, 7], it is shown that the structure of the Lie algebra generated by the matrices A_u,

$$\mathbf{g} = \{A_u : \ u \in U\}_{L.A.},$$

is crucial for the stability of the system (2) (i.e., the interrelation among the systems). The main result of [7] is the following theorem.

THEOREM 1.1 (Hespanha, Morse, Liberzon). *If* $\mathbf{g}$ *is a solvable Lie algebra, then the switched system* (2) *is asymptotically stable for each switching function* $u(.) : [0, \infty[\to U$.

In [1] a generalization was given. Let $\mathbf{g} = \mathbf{r} \ \exists \!\!\!+ \ \mathbf{s}$ be the Levi decomposition of $\mathbf{g}$ in its radical (i.e., the maximal solvable ideal of $\mathbf{g}$) and a semisimple subalgebra, where the symbol $\exists \!\!\!+$ indicates the semidirect sum.

THEOREM 1.2 (Agrachev, Liberzon). *If* $\mathbf{s}$ *is a compact Lie algebra, then the system* (2) *is asymptotically stable for every switching function* $u(.) : [0, \infty[\to U$.

Theorem 1.2 contains Theorem 1.1 as a special case. Anyway, the converse of Theorem 1.2 is not true in general: if $\mathbf{s}$ is noncompact, the system can be stable or unstable. This case was also investigated. In particular, if $\mathbf{s}$ is noncompact, then it contains as a subalgebra $sl(2, \mathbf{R})$. Due to that, in the case in which $\mathbf{g}$ has dimension at most 4 as Lie algebra, the authors were able to reduce the problem of the asymptotic stability of the system (2) to the problem of the asymptotic stability of an auxiliary bidimensional system. We refer the reader to [1] for details. For this reason, the bidimensional problem assumes particular interest, and in this paper we give the complete description of that case for a single input system.

More precisely, we study the stability of the origin for the switched system

$$\dot{x}(t) = u(t)Ax(t) + (1 - u(t))Bx(t), \tag{3}$$

where A and B are two 2×2 real matrices with eigenvalues having strictly negative real part, $x \in \mathbf{R}^2$, and $u(.) : [0, \infty[\to [0, 1]$ is an arbitrary measurable switching function.

It is well known that asymptotic stability for linear switching systems is equivalent to the existence of a common Lyapunov function. In [11] necessary and sufficient conditions were obtained for linear bidimensional systems to share a common *quadratic* Lyapunov function, but there are linear bidimensional systems for which this function may fail to be quadratic (see [6]) so that the problem of finding necessary and sufficient conditions on A and B for the asymptotic stability of the system (3) was open in general.

In this paper, we give the solution to this problem. Our result is obtained with a direct method without looking for a common Lyapunov function but analyzing the locus in which the two vector fields are collinear, to build the "worst trajectory," similarly to what people do in optimal synthesis problems on the plane (see [4, 5, 9, 10]). We also use the concept of feedback. The idea of building the worst trajectory was used also in [6] for analyzing an example.

Three cases are analyzed separately. In the first case, both matrices have complex eigenvalues (in the following **(CC)** case). In the second case, one of the two matrices has real and the other has complex eigenvalues (in the following **(RC)** case). In the third case, both the matrices have real eigenvalues (in the following **(RR)** case).

There are only three relevant parameters: one depends on the eigenvalues of A, one on the eigenvalues of B (we call them, respectively, ρ_A and ρ_B), and the last contains the interrelation among the two systems, and it is the cross ratio of the four eigenvectors of A and B in the projective line $\mathbf{C}P^1$.

The result can be obtained quite easily except in one case in which the integration of the vector fields has to be done. In this case, the computations are not difficult but long, and they are collected in Appendices A and B. In the **(CC)** and **(RR)** cases, we are even able to write the final result in a relatively compact way (see formulas (5) and (7)).

Fixing the value of the cross ratio, we study the region $\mathcal{R}$ in which the system is asymptotically stable for arbitrary switching functions in the space of the parameters ρ_A and ρ_B. In the **(CC)** and **(RR)** cases it is constituted by one or two open unbounded convex regions, while in the **(RC)** case it is an open unbounded region but not always convex.

In section 2 we give the basic definitions, we study the properties of the parameters describing the problem, and we state the stability theorem giving the main ideas of the proof. In section 3 we prove the stability theorem separately for the three cases **(CC)**, **(RC)**, **(RR)**, and we give some examples. In section 4 we study the shape and the convexity of the region $\mathcal{R}$ for fixed values of the cross ratio. In section 5 we make some final remarks.

2. Basic definitions and statement of the main results. Let A and B be two diagonalizable 2×2 real matrices with eigenvalues having strictly negative real part. Consider the following property:

($\mathcal{P}$) The dynamical system in $\mathbf{R}^2$: $\dot{x}(t) = u(t)Ax(t) + (1-u(t))Bx(t)$ is asymptotically stable at the origin for each measurable function $u(.) : [0, \infty[\to [0, 1]$.

In this section we state the necessary and sufficient conditions on A and B under which ($\mathcal{P}$) holds. Moreover, we state under which conditions we have at least stability (not asymptotic) for each function $u(.)$.

Set $M(u) := uA + (1-u)B$, $u \in [0,1]$. In the class of constant functions the asymptotic stability of the origin of the system (3) occurs iff the matrix $M(u)$ has eigenvalues with strictly negative real part for each $u \in [0,1]$. So this is a necessary condition. On the other hand, it is known that if $[A, B] = 0$, then the system (3) is asymptotically stable for each function $u(.)$. So in the following we will always assume the following conditions:

H1. Let λ_1, λ_2 (resp., λ_3, λ_4) be the eigenvalues of A (resp., B). Then $\mathrm{Re}(\lambda_1)$, $\mathrm{Re}(\lambda_2)$, $\mathrm{Re}(\lambda_3)$, $\mathrm{Re}(\lambda_4) < 0$.

H2. $[A, B] \neq 0$. (That implies that neither A nor B are proportional to the identity.)

For simplicity we will also assume the following.

H3. A and B are diagonalizable. (Notice that if **H2** and **H3** hold, then $\lambda_1 \neq \lambda_2$, $\lambda_3 \neq \lambda_4$.)

H4. Let $\mathbf{V}_1, \mathbf{V}_2 \in \mathbf{C}P^1$ (resp., $\mathbf{V}_3, \mathbf{V}_4 \in \mathbf{C}P^1$) be the eigenvectors of A (resp., B). From **H2** and **H3** we know that they are uniquely defined, and $\mathbf{V}_1 \neq \mathbf{V}_2$ and $\mathbf{V}_3 \neq \mathbf{V}_4$. We assume $\mathbf{V}_i \neq \mathbf{V}_j$ for $i \in \{1,2\}$, $j \in \{3,4\}$.

The degenerate cases, in which **H1** and **H2** hold and **H3** or **H4** or both do not, are the following:

- A or B is not diagonalizable. This case (in which $(\mathcal{P})$ can be true or false) can be treated with techniques entirely similar to the ones of this paper.
- A or B is diagonalizable, but one eigenvector of A coincides with one eigenvector of B. In this case, using arguments similar to the ones of the next section, it is possible to conclude that $(\mathcal{P})$ is true.

Remark 1. One can easily prove that (under the hypotheses **H2** and **H3**), **H4** can be violated only in the **(RR)** case (see also subsection 3.3). Moreover, hypotheses **H2**, **H3**, and **H4** imply that $\mathbf{V}_i \neq \mathbf{V}_j$ for $i, j \in \{1, 2, 3, 4\}$, $i \neq j$. This fact permits us to define the cross ratio without additional hypotheses (see the definition of cross ratio below).

Theorem 2.3 gives necessary and sufficient conditions for the stability of the system (3) in terms of three (coordinates invariant) parameters defined in Definition 2.1. The first (ρ_A) depends on the eigenvalues of A, the second (ρ_B) depends on the eigenvalues of B, and the third ($\mathcal{K}$) depends on $\mathrm{Tr}(AB)$, which is a standard scalar product in the space of 2×2 matrices. Proposition 2.2 gives some properties of these parameters. Finally, Proposition 2.4 shows the geometrical meaning of $\mathcal{K}$. It is in one-to-one correspondence with the cross ratio of the four points in the projective line $\mathbf{C}P^1$ that corresponds to the four eigenvectors of A and B. This parameter contains the interrelation among the two systems.

Definition 2.1. *Let A and B be two 2×2 real matrices, and suppose that* **H1**, **H2**, **H3**, *and* **H4** *hold. Moreover, choose the labels* $(_1)$ *and* $(_2)$ *(resp.,* $(_3)$ *and* $(_4)$*) in such a way that* $|\lambda_2| > |\lambda_1|$ *(resp.,* $|\lambda_3| > |\lambda_4|$*) if they are real or* $\mathrm{Im}(\lambda_2) < 0$ *(resp.,* $\mathrm{Im}(\lambda_4) < 0$*) if they are complex. Define*

$$\rho_A := -i\frac{\lambda_1 + \lambda_2}{\lambda_1 - \lambda_2}; \qquad \rho_B := -i\frac{\lambda_3 + \lambda_4}{\lambda_3 - \lambda_4}; \qquad \mathcal{K} := 2\frac{\mathrm{Tr}(AB) - \frac{1}{2}\mathrm{Tr}(A)\mathrm{Tr}(B)}{(\lambda_1 - \lambda_2)(\lambda_3 - \lambda_4)}.$$

Moreover, define the following function of $\rho_A, \rho_B, \mathcal{K}$:

$$\mathcal{D} := \mathcal{K}^2 + 2\rho_A\rho_B\mathcal{K} - (1 + \rho_A^2 + \rho_B^2). \tag{4}$$

Notice that $\rho_A \in \mathbf{R}$, $\rho_A > 0$, iff A has complex eigenvalues and $\rho_A \in i\mathbf{R}$, $\rho_A/i > 1$, iff A has real eigenvalues. The same holds for B. Moreover, $\mathcal{D} \in \mathbf{R}$. The parameter $\mathcal{K}$ contains important information about the matrices A and B. They are stated in the following proposition, which can be easily proved using the systems of coordinates of the next section (see also [3]).

Proposition 2.2. *Let A and B be as in Definition* 2.1. *We have the following:*

- *if A and B have both complex eigenvalues, then $\mathcal{K} \in \mathbf{R}$ and $|\mathcal{K}| > 1$;*
- *if A and B have both real eigenvalues, then $\mathcal{K} \in \mathbf{R} \setminus \{\pm 1\}$;*
- *A and B have one complex and the other real eigenvalues iff $\mathcal{K} \in i\mathbf{R}$.*

Theorem 2.3. *Let A and B be two real matrices such that* **H1**, **H2**, **H3**, *and* **H4** *hold, and define $\rho_A, \rho_B, \mathcal{K}, \mathcal{D}$ as in Definition* 2.1. *We have the following stability conditions:*

Case (CC) *If A and B have both complex eigenvalues, then:*

Case (CC.1) *if $\mathcal{D} < 0$, then $(\mathcal{P})$ is true;*

Case (CC.2) *if $\mathcal{D} > 0$, then:*

Case (CC.2.1) *if $\mathcal{K} < -1$, then $(\mathcal{P})$ is false;*

Case (CC.2.2) *if $\mathcal{K} > 1$, then $(\mathcal{P})$ is true iff the following condition holds:*

$$\rho_{CC} := \exp\left[-\rho_A \arctan\left(\frac{-\rho_A\mathcal{K}+\rho_B}{\sqrt{\mathcal{D}}}\right) - \rho_B \arctan\left(\frac{\rho_A-\rho_B\mathcal{K}}{\sqrt{\mathcal{D}}}\right) - \frac{\pi}{2}(\rho_A+\rho_B)\right] \times \sqrt{\frac{(\rho_A\rho_B+\mathcal{K})+\sqrt{\mathcal{D}}}{(\rho_A\rho_B+\mathcal{K})-\sqrt{\mathcal{D}}}} < 1. \tag{5}$$

Case (CC.3) *If $\mathcal{D} = 0$, then $(\mathcal{P})$ is true or false according, respectively, to the fact that $\mathcal{K} > 1$ or $\mathcal{K} < -1$.*

Case (RC) *If A and B have one complex and the other real eigenvalues, define $\chi := \rho_A\mathcal{K} - \rho_B$, where ρ_A and ρ_B are chosen in such a way that $\rho_A \in i\mathbf{R}$, $\rho_B \in \mathbf{R}$. Then:*

Case (RC.1) *if $\mathcal{D} > 0$, then $(\mathcal{P})$ is true;*

Case (RC.2) *if $\mathcal{D} < 0$, then $\chi \neq 0$, and we have:*

Case (RC.2.1) *if $\chi > 0$, then $(\mathcal{P})$ is false. Moreover, in this case $\mathcal{K}/i < 0$;*

Case (RC.2.2) *if $\chi < 0$, then:*

Case (RC2.2.A) *if $\mathcal{K}/i \leq 0$, then $(\mathcal{P})$ is true;*

Case (RC2.2.B) *if $\mathcal{K}/i > 0$, then $(\mathcal{P})$ is true iff the following condition holds:*

$$\rho_{RC} := e^{-\rho_B(\xi^+-\xi^-)}\sqrt{\frac{\cos^2\xi^+ + E^2\sin^2\xi^+}{\cos^2\xi^- + E^2\sin^2\xi^-}} \times \sqrt{\left(\frac{m^+}{m^-}\right)^{\frac{1}{2}(-\rho_A/i+1)}\cos^2\theta^+ + \left(\frac{m^+}{m^-}\right)^{\frac{1}{2}(-\rho_A/i-1)}\sin^2\theta^+} < 1, \tag{6}$$

where:
$$E := \mathcal{K}/i + \sqrt{-\mathcal{K}^2+1},$$
$$m^\pm := \frac{-\chi \pm \sqrt{-\mathcal{D}}}{(-\rho_A/i-1)\mathcal{K}/i},$$
$$\theta^+ := \arctan m^+,$$
$$\xi^\pm := \arctan\left(\frac{m^\pm - 1}{E(m^\pm+1)}\right), \quad \xi^+ \in]\xi^-, \xi^- + \pi[.$$

Case (RC.3) *If $\mathcal{D} = 0$, then $(\mathcal{P})$ is true or false according, respectively, to the fact that $\chi < 0$ or $\chi > 0$.*

Case (RR) *If A and B have both real eigenvalues, then:*

Case (RR.1) *if $\mathcal{D} < 0$, then $(\mathcal{P})$ is true. Moreover, we have $|\mathcal{K}| > 1$;*

Case (RR.2) *if $\mathcal{D} > 0$, then $\mathcal{K} \neq -\rho_A\rho_B$ (notice that $-\rho_A\rho_B > 1$) and:*

Case (RR.2.1) *if $\mathcal{K} > -\rho_A\rho_B$, then (P) is false*

Case (RR.2.2) *if $\mathcal{K} < -\rho_A\rho_B$, then:*

Case (RR.2.2.A) *if $\mathcal{K} > -1$, then (P) is true;*

Case (RR.2.2.B) *if $\mathcal{K} < -1$, then (P) is true iff the following condition holds:*

$$\rho_{RR} := -f^{sym}(\rho_A,\rho_B,\mathcal{K})f^{asym}(\rho_A,\rho_B,\mathcal{K}) \times f^{asym}(\rho_B,\rho_A,\mathcal{K}) < 1, \tag{7}$$

where:

$$f^{sym}(\rho_A,\rho_B,\mathcal{K}) := \frac{1+\rho_A/i+\rho_B/i+\mathcal{K}-\sqrt{\mathcal{D}}}{1+\rho_A/i+\rho_B/i+\mathcal{K}+\sqrt{\mathcal{D}}};$$

$$f^{aym}(\rho_A,\rho_B,\mathcal{K}) := \left(\frac{\rho_B/i-\mathcal{K}\rho_A/i-\sqrt{\mathcal{D}}}{\rho_B/i-\mathcal{K}\rho_A/i+\sqrt{\mathcal{D}}}\right)^{\frac{1}{2}(\rho_A/i-1)}.$$

Case (RR.3) *If $\mathcal{D}=0$, then $(\mathcal{P})$ is true or false according, respectively, to the fact that $\mathcal{K}<-\rho_A\rho_B$ or $\mathcal{K}>-\rho_A\rho_B$.*

Finally, if $(\mathcal{P})$ is false, then in case **(CC.2.2)** *with $\rho_{CC}=1$, case* **(RC.2.2.B)** *with $\rho_{RC}=1$, case* **(RR.2.2.B)** *with $\rho_{RR}=1$, case* **(CC.3)** *with $\mathcal{K}<-1$, case* **(RC.3)** *with $\chi>0$, and case* **(RR.3)** *with $\mathcal{K}>-\rho_A\rho_B$, for every $C>0$, there exists $C'\le C$ such that if $|\gamma(0)|<C'$, then $|\gamma(t)|<C$ for every $t\in[0,\infty[$ (i.e., we have stability of the origin). In the other cases, there exists a trajectory $\gamma(t)$ such that $\lim_{t\to\infty}|\gamma(t)|=\infty$.*

Notice that the expressions (5) and (7) are invariant if we exchange ρ_A with ρ_B. The last statement says when we have at least stability (not asymptotic) for every switching function.

Let us study the geometric meaning of $\mathcal{K}$. Let $\mathbf{V}_1,\mathbf{V}_2,\mathbf{V}_3,\mathbf{V}_4$ belong to the complex projective line $\mathbf{C}P^1$. Suppose $\mathbf{V}_1\neq\mathbf{V}_2\neq\mathbf{V}_3$, and let (v_1,v_1'), (v_2,v_2'), (v_3,v_3'), (v_4,v_4') be the corresponding homogeneous coordinates. The *cross ratio* $\beta(\mathbf{V}_1,\mathbf{V}_2,\mathbf{V}_3,\mathbf{V}_4)$ is defined in the following way. Make a Moebius transformation such that $\mathbf{V}_1,\mathbf{V}_2$ become the fundamental points (i.e., of homogeneous coordinates, respectively, $(0,1)$ and $(1,0)$) and $\mathbf{V}_3$ the unity point (i.e., of homogeneous coordinates $(1,1)$), and let $(\bar v_4,\bar v_4')$ be the new homogeneous coordinates of $\mathbf{V}_4$. By definition we have

$$\beta(\mathbf{V}_1,\mathbf{V}_2,\mathbf{V}_3,\mathbf{V}_4) := \bar v_4'/\bar v_4 = \frac{\begin{vmatrix} v_1 & v_4 \\ v_1' & v_4' \end{vmatrix}\begin{vmatrix} v_2 & v_3 \\ v_2' & v_3' \end{vmatrix}}{\begin{vmatrix} v_2 & v_4 \\ v_2' & v_4' \end{vmatrix}\begin{vmatrix} v_1 & v_3 \\ v_1' & v_3' \end{vmatrix}}. \tag{8}$$

Now the four eigenvectors of A and B are exactly four directions in $\mathbf{C}^2$; i.e., they can be regarded as four points of $\mathbf{C}P^1$, and under the conditions **H2**, **H3**, **H4**, it makes sense to compute their cross ratio (cf. Remark 1).

One can immediately obtain (suggestion: use the systems of coordinates of the next section) the following proposition.

PROPOSITION 2.4. *Let A and B be two 2×2 real matrices such that* **H1**, **H2**, **H3**, *and* **H4** *hold, and let $\mathbf{V}_1,\mathbf{V}_2,\mathbf{V}_3,\mathbf{V}_4$ be the four points in the space $\mathbf{C}P^1$ corresponding, respectively, to the four eigenvectors of A and B chosen in such a way that they correspond, respectively, to $\lambda_1,\lambda_2,\lambda_3,\lambda_4$ (see Definition* 2.1*). Let $\beta(\mathbf{V}_1,\mathbf{V}_2,\mathbf{V}_3,\mathbf{V}_4)$ be their cross ratio and $\mathcal{K}$ the quantity defined in Definition* 2.1*. Then $\beta(\mathbf{V}_1,\mathbf{V}_2,\mathbf{V}_3,\mathbf{V}_4)$ and $\mathcal{K}$ are in the one-to-one relation from $\mathbf{C}\cup\{\infty\}$ to $\mathbf{C}\cup\{\infty\}$:*

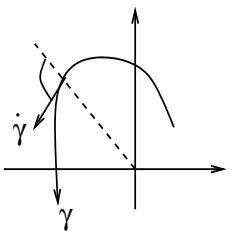
$$\mathcal{K}=\frac{\beta(\mathbf{V}_1,\mathbf{V}_2,\mathbf{V}_3,\mathbf{V}_4)+1}{\beta(\mathbf{V}_1,\mathbf{V}_2,\mathbf{V}_3,\mathbf{V}_4)-1},\qquad \beta(\mathbf{V}_1,\mathbf{V}_2,\mathbf{V}_3,\mathbf{V}_4)=\frac{\mathcal{K}+1}{\mathcal{K}-1}.$$

Notice that $\mathcal{K} \neq \infty$ so that $\beta \neq 1$. From Proposition 2.4 and Definition 2.1 we have the following expression for the cross ratio of the eigenvectors of A and B:

$$\beta = \frac{\mathrm{Tr}(AB) - (\lambda_1\lambda_4 + \lambda_2\lambda_3)}{\mathrm{Tr}(AB) - (\lambda_1\lambda_3 + \lambda_2\lambda_4)}.$$

Theorem 2.3 is proved in the next section. Here we describe the main idea of the proof.

We build the "worst trajectory," i.e., the trajectory that at each point has the velocity forming the angle, with the (exiting) radial direction, having the smallest absolute value, without taking care of the module of the velocity.

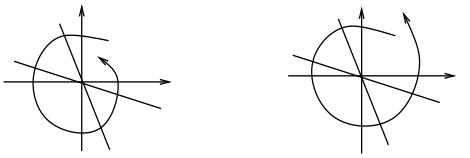


The main idea is that the system (3) is asymptotically stable iff this trajectory tends to the origin. The worst trajectory is constructed in the following way. We study the locus $Q^{-1}(0)$ (the notation is clarified later) in which the two vector fields Ax and Bx are collinear. We have several cases:

- If $Q^{-1}(0)$ contains only the origin, then, in the **(CC)** and **(RC)** cases, one vector field always points on the same side of the other, and the worst trajectory is a trajectory of the vector field Ax or Bx. In this case, the system is asymptotically stable (cases **(CC.1)** and **(RC.1)** of Theorem 2.3).

  
  The situation is similar in case **(RR.1).** (The worst trajectory tends to the origin.)
- If $Q^{-1}(0)$ does not contain only the origin, then it is a couple of straight lines passing from the origin (see the next section). If at each point of $Q^{-1}(0)$ the two vector fields have opposite versus, then there exists a trajectory going to infinity corresponding to a constant switching function (see the following figure).

  
  This corresponds to cases **(CC.2.1)**, **(RC.2.1)**, and **(RR.2.1)** of Theorem 2.3, and it is the situation in which there exists $u \in [0, 1]$ such that the matrix $M(u)$ admits an eigenvalue with positive real part. If at each point of Q the two vector fields have the same versus, then the system is asymptotically stable iff the worst trajectory turns around the origin and after one turn the distance from the origin is increasing.



This corresponds to cases **(CC.2.2)**, **(RC.2.2)**, and **(RR.2.2)** of Theorem 2.3.

- Finally, **(CC.3)**, **(RC.3)**, and **(RR.3)** are the degenerate cases in which the two straight lines coincide.

More details are given later.

3. Proof of the stability theorem. In the following, we prove Theorem 2.3 separately for the three cases in which A and B have both complex, one complex and the other real, and both real eigenvalues.

3.1. The case in which A and B have both complex eigenvalues. Let $-\delta_A \pm i\omega_A$ $(\delta_A, \omega_A > 0)$ be the eigenvalues of A and $-\delta_B \pm i\omega_B$ $(\delta_B, \omega_B > 0)$ be the eigenvalues of B. We have $\rho_A = \delta_A/\omega_A$, $\rho_B = \delta_B/\omega_B$. Choose a system of coordinates in which

$$A = \begin{pmatrix} -\delta_A & -\omega_A/E \\ \omega_A E & -\delta_A \end{pmatrix}, \qquad B = \begin{pmatrix} -\delta_B & -\omega_B \\ \omega_B & -\delta_B \end{pmatrix},$$

where $E \in \mathbf{R}\setminus\{0\}$. This corresponds to put B in the normal form in which its integral curves are "circular spirals" and then, using the invariance of B under rotation, to rotate the coordinates in such a way that the integral curves of A are elliptical spirals with axes corresponding to the x_1 and x_2 directions (see, for example, Figure 3.1). We have

$$[A, B] = \omega_A\omega_B(E - 1/E)\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$

so we assume $E \neq \pm 1$; otherwise, $[A, B] = 0$. In this case we have $\mathcal{K} = \frac{1}{2}(E + \frac{1}{E})$, and without loss of generality we may assume $|E| > 1$.

The locus in which Ax and Bx are collinear is $Q^{-1}(0)$, where

$$\begin{aligned} Q = \det(Ax, Bx) &= x_1^2(-\delta_A\omega_B + \delta_B\omega_A E) \\ &+ x_1x_2(\omega_A\omega_B(E - 1/E)) + x_2^2(-\delta_A\omega_B + \delta_B\omega_A/E) \end{aligned}$$

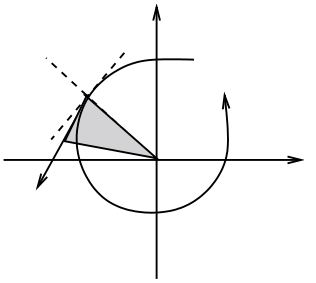
and $x = (x_1, x_2)$. Now let D_{CC} be the discriminant of the quadratic form Q. We have

$$\begin{aligned} D_{CC} &= \omega_A^2\omega_B^2(E - 1/E)^2 - 4(-\delta_A\omega_B + \delta_B\omega_A E)(-\delta_A\omega_B + \delta_B\omega_A/E) \\ &= 4\omega_A^2\omega_B^2\mathcal{D}, \end{aligned} \tag{9}$$

where $\mathcal{D}$ is defined in Definition 2.1.

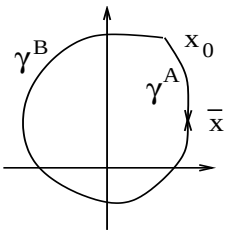
Case 1. If $\mathcal{D} < 0$, then the quadratic form Q has strictly defined sign and $Q^{-1}(0) = \{0\}$. In this case, one vector field always points on the same side of the other. Making a suitable change of coordinates and possibly exchanging the labels $(_A)$ and $(_B)$, we can realize the situation in which Ax always points on the left of Bx for every $x \in \mathbf{R}^2 \setminus \{0\}$. We have two cases.

- Suppose first that $E > 1$. In this case, Ax always points in the grey region of the following picture.



Fix an arbitrary measurable switching function $u(.) : [0, \infty[\to [0, 1]$, and let $(x_1(t), x_2(t))$ (resp., $(\rho(t), \theta(t))$) be the Cartesian (resp., polar) coordinates of the solution of $\dot{x}(t) = u(t)Ax(t) + (1-u(t))Bx(t)$, $x(0) = x_0 \in \mathbf{R}^2 \setminus \{0\}$. In this case, we have $\dot{\rho}(t) < 0$ for almost every $t \in [0, +\infty[$ and $(\mathcal{P})$ is true.

- Suppose now that $E < -1$. Fix $x_0 \in \mathbf{R}^2 \setminus \{0\}$, and let γ be a trajectory of the switched system (3) such that $\gamma(0) = x_0$. Let $\gamma^A : [0, t_A] \to \mathbf{R}^2$ (resp., $\gamma^B : [0, t_B] \to \mathbf{R}^2$) be a trajectory of the vector field Ax (resp., Bx) such that $\gamma^A(0) = x_0$ (resp., $\gamma^B(0) = x_0$), and define t_A and t_B in such a way that $\gamma^A(t_A) = \gamma^B(t_B) =: \bar{x}$ is the first intersection point of γ^A and γ^B after x_0.



Let Ω be the simply connected closed set whose border is

$$\partial\Omega = \mathrm{Supp}(\gamma^A|_{[0,t_A]} \cup \gamma^B|_{[0,t_B]}).$$

For every $x \in \partial\Omega$ we have the following. Define $V_u = uAx + (1-u)Bx$. For each $u \in]0, 1[$, V_u points inside Ω. Moreover, if $x \notin \{x_0, \bar{x}\}$, V_1 (resp., V_0) points inside Ω or it is tangent to $\partial\Omega$. Fix $\bar{t} > \max\{t_A, t_B\}$. We clearly have $\bar{x} := \gamma(\bar{t}) \in \mathrm{int}(\Omega)$. Using homothety invariance of the system (3), we may easily conclude that $\lim_{t\to\infty} \gamma(t) = 0$ and $(\mathcal{P})$ is true. This proves case **(CC.1)** of Theorem 2.3 (see Example 1 below).

Case 2. If $\mathcal{D} > 0$, then Q has no definite sign and $Q^{-1}(0)$ is a couple of noncoinciding straight lines passing from the origin and forming the following angles with the x_1 axis:

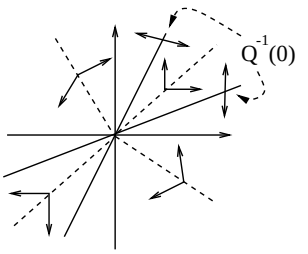
$$\theta^{\pm} = \arctan(m^{\pm}), \text{ where} \tag{10}$$

$$\begin{aligned} m^{\pm} &= \frac{-\omega_A\omega_B(E - 1/E) \pm \sqrt{D_{CC}}}{2(-\delta_A\omega_B + \delta_B\omega_A/E)} \\ &= \frac{-(E - 1/E) \pm 2\sqrt{\mathcal{D}}}{2(-\rho_A + \rho_B/E)} \text{ if } -\rho_A + \rho_B/E \neq 0, \end{aligned} \tag{11}$$

$$\begin{aligned} m^- = \infty, \quad m^+ &= \frac{\delta_A\omega_B - \delta_B\omega_A E}{\omega_A\omega_B(E - 1/E)} \\ &= \frac{\rho_A - \rho_B E}{E - 1/E} \text{ if } -\rho_A + \rho_B/E = 0, \end{aligned} \tag{12}$$

where we assume that $\theta^- \in [-\frac{\pi}{2}, \frac{\pi}{2}[$ and $\theta^+ \in]\theta^-, \theta^- + \pi[$. Notice that if $E < -1$, then $4(-\delta_A\omega_B + \delta_B\omega_A E)(-\delta_A\omega_B + \delta_B\omega_A/E) > 0$, which implies that $\theta^\pm \in [-\frac{\pi}{2}, 0[$.

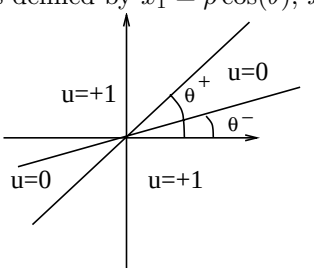
Case 2.1. If $E < -1$ ($\mathcal{K} < -1$), then at each point of $Q^{-1}(0) \setminus \{0\}$ the two vector fields have opposite versus. Consider the four connected components of $\mathbf{R}^2 \setminus Q^{-1}(0)$. In this case, for each point x_0 belonging to two of these regions (see the figure below), it is possible to find $u_0 \in [0, 1]$ such that $u_0 Ax_0 + (1 - u_0)Bx_0$ has the exiting radial direction. So the system is not stable for arbitrary switching functions. This situation corresponds to the case in which there exists $u \in [0, 1]$ such that $M(u) := uA + (1 - u)B$ admits an eigenvalue with positive real part; i.e., there exist trajectories γ corresponding to constant switching functions such that $\lim_{t\to\infty} |\gamma(t)| = \infty$. Case **(CC.2.1)** of Theorem 2.3 is proved (see Example 4 below).



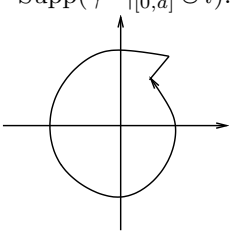
Case 2.2. If $E > 1$ ($\mathcal{K} > 1$), then at each point of $Q^{-1}(0) \setminus \{0\}$ the two vector fields have the same versus (counterclockwise). Fix $x_0 \in \mathbf{R}^2 \setminus \{0\}$, and let $\gamma^M : [0, \infty[\to \mathbf{R}^2$, $\gamma^M(0) = x_0$ be the trajectory corresponding to the feedback

$$u^M(x) = \begin{cases} 0 \text{ if } \theta \in [\theta^-, \theta^+[\text{ or } \theta \in [\theta^- + \pi, \theta^+ + \pi[, \\ +1 \text{ if } \theta \in [\theta^+, \theta^- + \pi[\text{ or } \theta \in [\theta^+ + \pi, \theta^- + 2\pi[, \end{cases} \tag{13}$$

where $\theta \in [\theta^-, \theta^- + 2\pi[$ is defined by $x_1 = \rho\cos(\theta)$, $x_2 = \rho\sin(\theta)$.



Let $(\rho^M(t), \theta^M(t))$ be the polar coordinates of γ^M and a the time defined by $\theta^M(a) = \theta^M(0) + 2\pi$. If $\rho^M(a) < \rho^M(0)$, then let l be the segment joining the points $(\rho^M(0), \theta^M(0))$ with $(\rho^M(a), \theta^M(a))$ and Ω the simply connected region whose border is $\partial\Omega := \mathrm{Supp}(\gamma^M|_{[0,a]} \cup l)$.



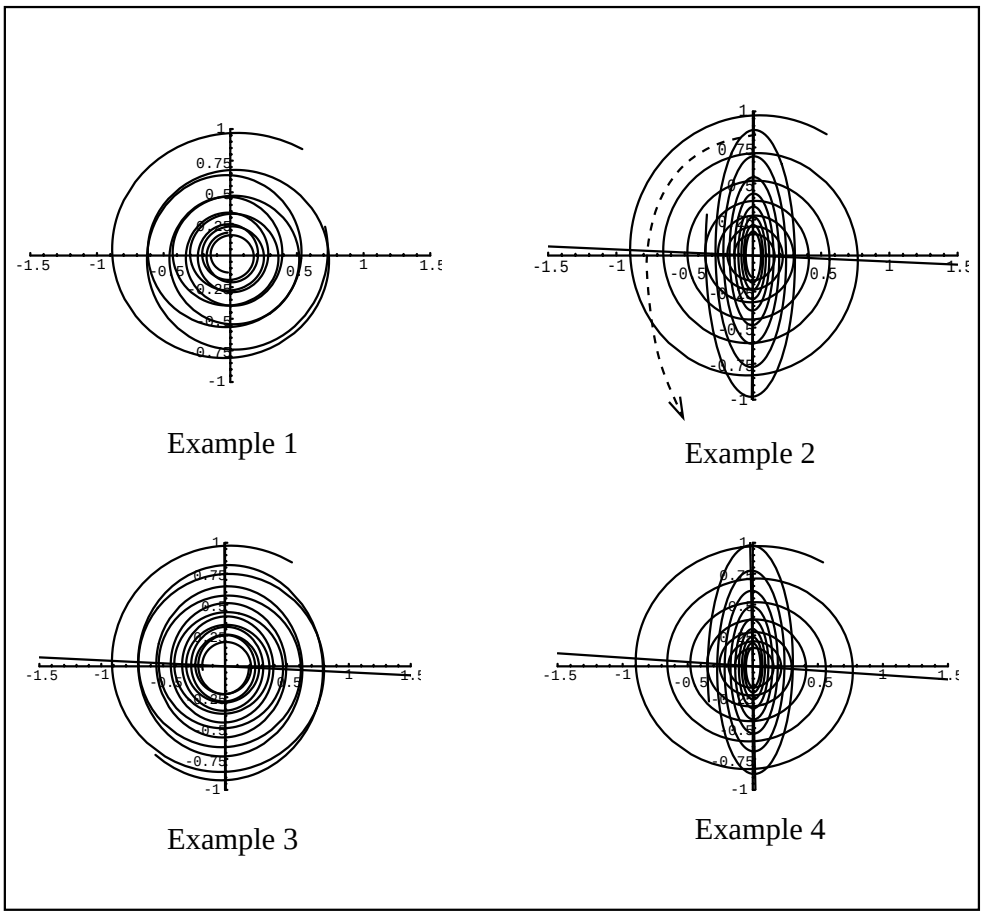


FIG. 3.1. *Examples in the* **(CC)** *case.*

For every $x \in \partial\Omega$, we have the following. Define V_u as in Case 1, $E < -1$. For each $u \in]0,1[$, V_u points inside Ω. Moreover, if $x \notin \{\gamma^M(0), \gamma^M(a)\}$, V_1 (resp., V_0) points inside Ω or is tangent to $\partial\Omega$. Similarly to Case 1 ($E < 1$), we can conclude that $(\mathcal{P})$ is true (see Example 3 below). On the other hand if $\rho^M(a) \geq \rho^M(0)$, then $\gamma^M(t)$ does not tend to the origin and $(\mathcal{P})$ is false (see Example 2 below). The condition $\rho^M(a) < \rho^M(0)$ is satisfied iff condition (5) holds. Formula (5) is obtained in Appendix A . The condition $\rho^M(a) = \rho^M(0)$ (i.e., $\boldsymbol{\rho_{CC} = 1}$) is the case in which we have at least stability (not asymptotic) for every switching function. This concludes the proof of case **(CC.2.2)**.

Case 3. If $\mathcal{D} = 0$, then the two straight lines coincide. If $E > 1$, it is easy to understand that we are in the same situation as that of Case 1. If $E < -1$, then to every $x \in Q$ there exists $u \in [0,1]$ such that $uAx + (1-u)Bx = 0$. In this case, $(\mathcal{P})$ is false, but we have at least stability (not asymptotic). This proves case **(CC.3)** of Theorem 2.3.

Examples. In the following, we give some examples of the various situations in the **(CC)** case. We refer to Figure 3.1.

Example 1. $\rho_A = 0.05$, $\rho_B = 0.06$, $\mathcal{K} = -1.005$. In this case, $\mathcal{D} \sim -0.002$,

and $(\mathcal{P})$ is true. In Figure 3.1, two integral curves of the vector fields Ax and Bx are shown. A similar situation but with the two trajectories rotating with the same versus can be obtained with the same values of ρ_A and ρ_B but with $\mathcal{K} = +1.00001$. In this case, $\mathcal{D} \sim -0.00008$ and $(\mathcal{P})$ is true (see case **(CC.1)**).

Example 2. $\rho_A = 0.0375,\ \rho_B = 0.05,\ \mathcal{K} = 1.67$. In this case, $\mathcal{D} \sim 1.79,\ \rho_{CC} \sim 2.62$ and $(\mathcal{P})$ is false. In Figure 3.1, two integral curves of the vector fields Ax and Bx, $\mathcal{D}$ that are the two straight lines (one almost coincides with the x_2 axis) and a trajectory γ such that $\lim_{t\to\infty} |\gamma(t)| = \infty$ (cf. case **(CC.2.2)**) are shown.

Example 3. $\rho_A = 0.0375,\ \rho_B = 0.0425,\ \mathcal{K} = 1.00455$. In this case, $\mathcal{D} \sim 0.0091,\ \rho_{CC} \sim 0.96$, and $(\mathcal{P})$ is true (cf. case **(CC.1)**).

Example 4. Suppose $\rho_A = 0.0375,\ \rho_B = 0.05,\ \mathcal{K} = -1.67$. In this case, $\mathcal{D} \sim 1.77$ and $(\mathcal{P})$ is false (cf. case **(CC.2.1)**).

3.2. The case in which A and B have one complex and the other real eigenvalues. Suppose that A has real eigenvalues $\lambda_1,\ \lambda_2$ $(\lambda_1, \lambda_2 < 0,\ |\lambda_2| > |\lambda_1|)$ and B complex eigenvalues $\lambda_3 = -\delta + i\omega,\ \lambda_4 = -\delta - i\omega$ $(\delta, \omega > 0)$. We have $\rho_A = -i(\lambda_1 + \lambda_2)/(\lambda_1 - \lambda_2)$ and $\rho_B = \delta/\omega$. We recall that $\rho_A/i > 1,\ \rho_B > 0$. Define

$$R(\varphi) := \begin{pmatrix} \cos(\varphi) & \sin(\varphi) \\ -\sin(\varphi) & \cos(\varphi) \end{pmatrix} \in SO(2), \tag{14}$$

and choose a system of coordinates in which

$$A = \begin{pmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{pmatrix}, \tag{15}$$

$$\begin{aligned} B &= \begin{pmatrix} a & b \\ c & d \end{pmatrix} := R^{-1}(\varphi) \begin{pmatrix} -\delta & -\omega/E \\ \omega E & -\delta \end{pmatrix} R(\varphi) \\ &= \begin{pmatrix} -\delta - \omega(E - 1/E)\sin(\varphi)\cos(\varphi) & -\omega(E\sin^2(\varphi) + 1/E\cos^2(\varphi)) \\ \omega(E\cos^2(\varphi) + 1/E\sin^2(\varphi)) & -\delta + \omega(E - 1/E)\sin(\varphi)\cos(\varphi) \end{pmatrix}. \end{aligned} \tag{16}$$

We have $\mathcal{K} = i(E - 1/E)\cos(\varphi)\sin(\varphi) \in i\mathbf{R}$, and without loss of generality we may assume that $\varphi \in [0, \pi/2[$, $|E| \geq 1$. Notice that in this case

$$[A, B] = (\lambda_1 - \lambda_2) \begin{pmatrix} 0 & b \\ -c & 0 \end{pmatrix} \neq 0 \text{ for each } \mathcal{K} \in i\mathbf{R}.$$

Similarly to the previous subsection, the locus in which Ax and Bx are collinear is $Q^{-1}(0)$, where

$$Q = \det(Ax, Bx) = x_1^2(\lambda_1 c) + x_1 x_2 \bar{\chi} + x_2^2(-\lambda_2 b),$$

and by definition $\bar{\chi} := \lambda_1 d - \lambda_2 a = (\lambda_1 + \lambda_2)\omega\mathcal{K}/i - (\lambda_1 - \lambda_2)\delta = (\lambda_1 - \lambda_2)\omega\chi$, where $\chi := \rho_A\mathcal{K} - \rho_B$ (see Theorem 2.3). In this case, the discriminant of the quadratic form Q is

$$D_{RC} = \bar{\chi}^2 + 4\lambda_1\lambda_2 bc = \bar{\chi}^2 - 4\lambda_1\lambda_2\omega^2(-\mathcal{K}^2 + 1) = -\omega^2(\lambda_1 - \lambda_2)^2\mathcal{D}. \tag{17}$$

Notice that $\chi = 0$ implies $\bar{\chi} = 0$, which implies $D_{RC} < 0$, i.e., $\mathcal{D} > 0$. Moreover, $\chi > 0$ implies $\mathcal{K}/i < 0$, which implies $E < -1$. Similarly to the previous subsection, we have the following cases.

Case 1. If $D_{RC} < 0$ $(\mathcal{D} > 0)$, then $(\mathcal{P})$ is true (see Example 1 below).

Case 2. If $D_{RC} > 0$ ($\mathcal{D} < 0$), then $Q^{-1}(0)$ is a couple of noncoinciding straight lines passing from the origin and forming the following angles with the x_1 axis:

$$\theta^{\pm} = \arctan(m^{\pm}), \tag{18}$$
$$m^{\pm} := \frac{-\bar{\chi} \pm \sqrt{D_{RC}}}{2(-\lambda_2 b)} = \frac{-\chi \pm \sqrt{-\mathcal{D}}}{2\frac{\lambda_2}{\lambda_1-\lambda_2}(E\sin^2(\varphi) + 1/E\cos^2(\varphi))}.$$

From (17) it follows that $D_{RC} < \bar{\chi}^2$ (i.e., $-\mathcal{D} < \chi^2$) so that in this case we have $\chi \neq 0$ and we may assume

$$\begin{cases} \theta^-, \theta^+ \in]0, \pi/2[\text{ if } \chi \text{ and } E \text{ have the same sign,} \\ \theta^-, \theta^+ \in]-\pi/2, 0[\text{ if } \chi \text{ and } E \text{ have opposite sign.} \end{cases}$$

Case 2.1 If $\chi > 0$, then $\mathcal{K}/i < 0$, which implies $E < -1$, and we have $\theta^-\theta^+ \in]-\pi/2, 0[$. In this case, at each point of $Q^{-1}(0) \setminus \{0\}$ the two vector fields have opposite versus. The same argument of Case 2.1 of section 3.1 shows that $(\mathcal{P})$ is false (see Example 4 below).

Case 2.2 If $\chi < 0$, then in both cases where $E \geq 1$, $E \leq -1$ at each point of $Q^{-1}(0) \setminus \{0\}$ the two vector fields have the same versus.

Case 2.2.A If $E \leq -1$ (which implies $\mathcal{K}/i \leq 0$), then $(\mathcal{P})$ is true because of the following argument.

From $\chi = \rho_A\mathcal{K} - \rho_B < 0$ we have

$$-\frac{\mathcal{K}/i}{\rho_B} < \frac{1}{\rho_A/i} < 1. \tag{19}$$

Now let γ be an integral of the vector field Bx and $(\rho(t), \theta(t))$ its polar coordinates. We have

$$\gamma(t) = R(\varphi) \begin{pmatrix} \rho_0 e^{-\delta t}\cos(\omega t + \varphi_0) \\ \rho_0 E e^{-\delta t}\sin(\omega t + \varphi_0), \end{pmatrix}$$

and $\rho(t) = \rho_0 e^{-\delta t}\sqrt{\cos^2(\omega t + \varphi_0) + E^2\sin^2(\omega t + \varphi_0)}$. Now we prove that the condition (19) implies $\dot{\rho}(t) \leq 0$ for every $t \in Dom(\gamma)$, which clearly implies that $(\mathcal{P})$ is true. We have

$$\dot{\rho}(t) = \rho_0 e^{-\delta t}\left(\frac{(E^2-1)\omega\sin(\omega t + \varphi_0)\cos(\omega t + \varphi_0)}{\sqrt{\cos^2(\omega t + \varphi_0) + E^2\sin^2(\omega t + \varphi_0)}} - \delta\sqrt{\cos^2(\omega t + \varphi_0) + E^2\sin^2(\omega t + \varphi_0)}\right).$$

Therefore, $\dot{\rho}(t) < 0$ iff

$$\frac{(E^2-1)\omega\sin(\omega t + \varphi_0)\cos(\omega t + \varphi_0)}{\sqrt{\cos^2(\omega t + \varphi_0) + E^2\sin^2(\omega t + \varphi_0)}} - \delta\sqrt{\cos^2(\omega t + \varphi_0) + E^2\sin^2(\omega t + \varphi_0)} < 0$$

or, equivalently, iff

$$\cos^2(\omega t + \varphi_0) + E^2\sin^2(\omega t + \varphi_0) - (E^2-1)\frac{\omega}{\delta}\sin(\omega t + \varphi_0)\cos(\omega t + \varphi_0) > 0. \tag{20}$$

Now if $(E^2-1)\omega/\delta \leq -2E$ (that choosing a system of coordinates in which $\varphi = \pi/4$ is equivalent to $-\mathcal{K}/(i\rho_B) \leq 1$; see Appendix B), then the condition (20) is satisfied. Hence from (19) we can conclude that $\dot{\rho}(t) < 0$ for each $t \in Dom(\gamma)$ and $(\mathcal{P})$ is true (see Example 5 below).

Case 2.2.B If $E \geq 1$ (which implies $\mathcal{K}/i \geq 0$), then $(\mathcal{P})$ is true iff condition (6) is satisfied (see Appendix B). Notice that in the case where $\mathcal{K} = 0$ we clearly have that $\rho_{RC} < 1$ and $(\mathcal{P})$ is true (see Examples 2 and 3 below). The case in which $\rho_{RC} = 1$ is the case in which we have at least stability (but not asymptotic) for every switching function.

Case 3. If $\mathcal{D} = 0$, then the two straight lines coincide. If $\chi < 0$, it is easy to understand that we are in the same situation as that of Case 1. If $\chi > 0$, then to every $x \in Q^{-1}(0)$ there exists $u \in [0,1]$ such that $uAx+(1-u)Bx = 0$. In this case, $(\mathcal{P})$ is false, but we have at least stability (not asymptotic). This proves case **(RC.3)** of Theorem 2.3.

This concludes the proof of cases **(RC)**.

Examples. In the following, we give some examples of the various situations in the **(RC)** case. We refer to Figure 3.2.

Example 1. $\rho_A/i = 1.11$, $\rho_B = 0.045$, $\mathcal{K}/i = 0.095$. In this case, $\chi \sim -0.15$, $\mathcal{D} \sim 0.2$, and $(\mathcal{P})$ is true (cf. case **(RC.1)**).

Example 2. $\rho_A/i = 1.11$, $\rho_B = 0.02$, $\mathcal{K}/i = 1.33$. In this case, $\chi \sim -1.49$, $\mathcal{D} \sim -1.62$, $\rho_{RC} \sim 1.4$, and $(\mathcal{P})$ is false (cf. case **(RC.2.2.B)**).

Example 3. $\rho_A/i = 1.11$, $\rho_B = 0.03$, $\mathcal{K}/i = 0.75$. In this case, $\chi \sim -0.85$, $\mathcal{D} \sim -0.37$, $\rho_{RC} \sim 0.98$, and $(\mathcal{P})$ is true (cf. case **(RC.2.2.B)**).

Example 4. $\rho_A/i = 1.11$, $\rho_B = 0.045$, $\mathcal{K}/i = -2.4$. In this case, $\chi \sim 2.6$, $\mathcal{D} \sim -5.3$, and $(\mathcal{P})$ is false (cf. case **(RC.2.1)**).

Example 5. $\rho_A/i = 1.14$, $\rho_B = 1.67$, $\mathcal{K}/i = -0.42$. In this case, $\chi \sim -1.19$, $\mathcal{D} \sim -1.06$, and $(\mathcal{P})$ is true (cf. case **(RC.2.2.A)**).

3.3. The case in which *A* and *B* have both real eigenvalues. Let λ_1, λ_2 $(\lambda_1, \lambda_2 < 0,\ |\lambda_2| > |\lambda_1|)$ be the eigenvalues of A and λ_3, λ_4 $(\lambda_3, \lambda_4 < 0,\ |\lambda_4| > |\lambda_3|)$ be the eigenvalues of B. Choose a system of coordinates such that

$$A = \begin{pmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{pmatrix}, \tag{21}$$

$$\begin{aligned} B = \begin{pmatrix} a & b \\ c & d \end{pmatrix} &:= R^{-1}(\pi/4) \begin{pmatrix} \lambda_3 & \alpha(\lambda_4-\lambda_3) \\ 0 & \lambda_4 \end{pmatrix} R(\pi/4) \\ &= \frac{1}{2} \begin{pmatrix} (\lambda_3+\lambda_4)-\alpha(\lambda_4-\lambda_3) & (\lambda_3-\lambda_4)+\alpha(\lambda_4-\lambda_3) \\ (\lambda_3-\lambda_4)-\alpha(\lambda_4-\lambda_3) & (\lambda_3+\lambda_4)+\alpha(\lambda_4-\lambda_3) \end{pmatrix}, \end{aligned} \tag{22}$$

where $R(\varphi)$ is defined as in formula (14) and $\alpha \in \mathbf{R} \setminus \{\pm 1\}$. In this system of coordinates the eigenvectors of A are proportional to $\mathbf{V}_1 = (1,0)$, $\mathbf{V}_2 = (0,1)$ and the eigenvectors of B to $\mathbf{V}_3 = (1,1)$, $\mathbf{V}_4 = ((\alpha-1)/(\alpha+1), 1)$. The geometric meaning of α is the following. $\mathrm{Arctan}(\alpha)$ is the angle between the vector $(-1,1)$ and $\mathbf{V}_4$, measured clockwise. We have $\mathcal{K} = \alpha$. Notice that

$$[A,B] = -\frac{1}{2}(\lambda_1-\lambda_2)(\lambda_3-\lambda_4) \begin{pmatrix} 0 & (\alpha-1) \\ (\alpha+1) & 0 \end{pmatrix},$$

so $[A,B] \neq 0$ for every value of α. The case $\alpha = \pm 1$ is excluded (otherwise $\mathbf{V}_4$ is parallel to $\mathbf{V}_2$ or to $\mathbf{V}_1$, respectively, and **(H4)** fails).

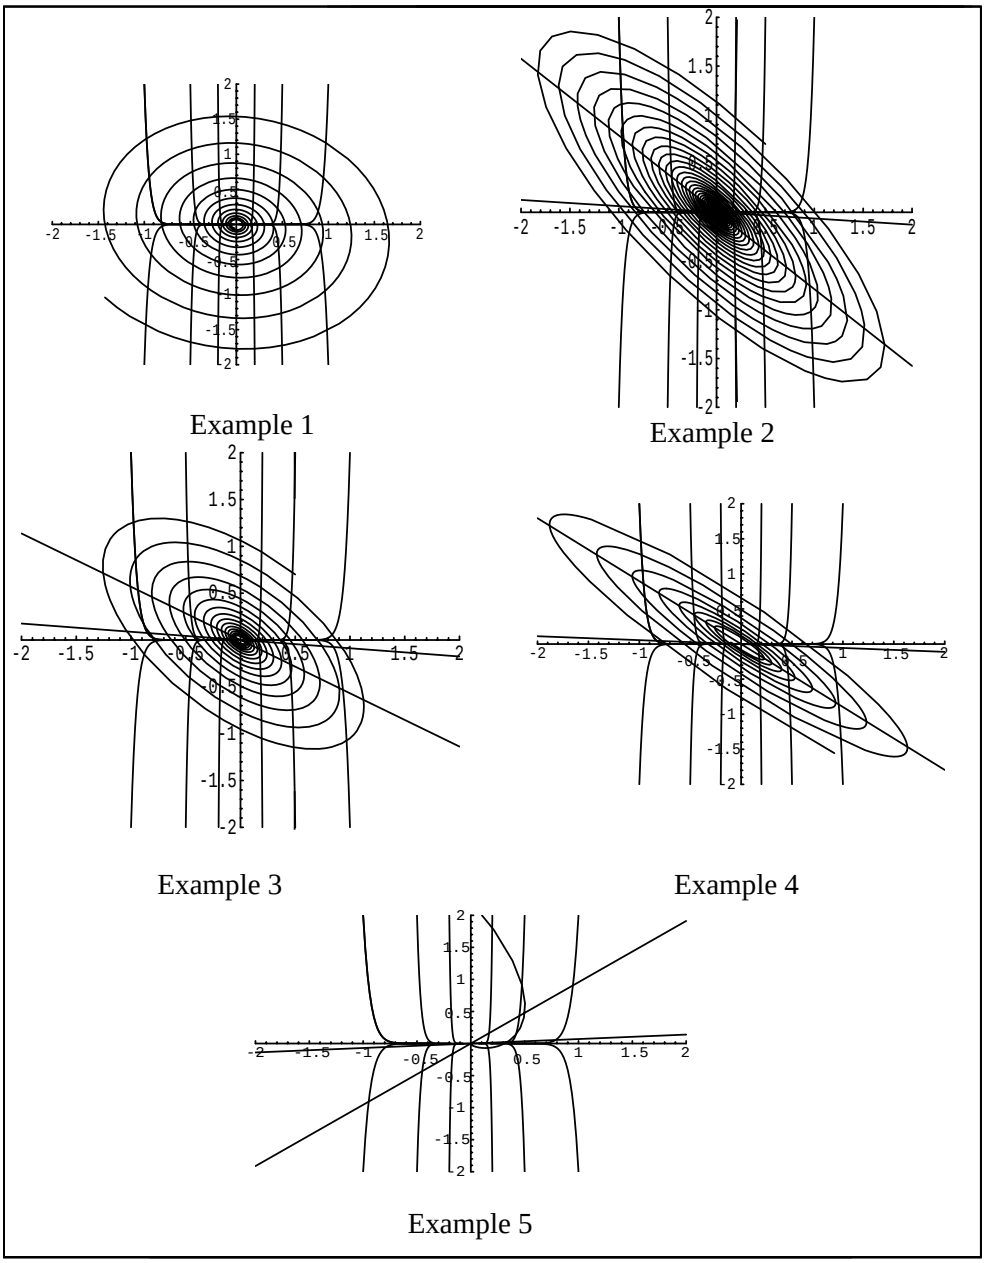

FIG. 3.2. *Examples in the* **(RC)** *case.*

The locus in which Ax and Bx are collinear is $Q^{-1}(0)$, where

$$Q = \det(Ax, Bx) = x_1^2(\lambda_1 c) + x_1 x_2 \bar{\chi} + x_2^2(-\lambda_2 b),$$

and by definition $\bar{\chi} := \lambda_1 d - \lambda_2 a = \frac{1}{2}((\lambda_1 - \lambda_2)(\lambda_3 + \lambda_4) - \mathcal{K}(\lambda_1 + \lambda_2)(\lambda_3 - \lambda_4)) = -\frac{1}{2}i(\lambda_1 - \lambda_2)(\lambda_3 - \lambda_4)\chi$, where $\chi := \rho_A \mathcal{K} - \rho_B \in i\mathbf{R}$. In this case, the discriminant

of the quadratic form Q is

$$D_{RR} = \bar{\chi}^2 + 4\lambda_1\lambda_2 bc = \bar{\chi}^2 + \lambda_1\lambda_2(\lambda_3-\lambda_4)^2(-\mathcal{K}^2+1) = \frac{1}{4}(\lambda_1-\lambda_2)^2(\lambda_3-\lambda_4)^2\mathcal{D}. \tag{23}$$

Notice that if $\mathcal{K} < 1$, then $\mathcal{D} > 0$. The following lemma states that in the case where $|\mathcal{K}| < 1$ $(\mathcal{P})$ is true.

LEMMA 3.1. *Let A, B be two 2×2 real matrices satisfying* **H1**, **H2**, **H3**, *and* **H4** *and such that their eigenvalues are real. Fix an arbitrary measurable switching function $u(.) : [0,\infty[\to[0,1]$, and let $(x_1(t), x_2(t))$ (resp., $(\rho(t),\theta(t))$) be the Cartesian (resp., polar) coordinates of the solution of $\dot{x}(t) = u(t)Ax(t) + (1-u(t))Bx(t)$, $x(0) = x_0 \in \mathbf{R}^2\setminus\{0\}$. If $\mathcal{K}\in]-1,1[$, we have that $\dot{\rho}(t) < 0$ for almost every $t\in[0,+\infty[$.*

Proof. In this case, it is possible to choose a system of coordinates such that

$$A = \begin{pmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{pmatrix},$$
$$B = R^{-1}(\varphi)\begin{pmatrix} \lambda_3 & 0 \\ 0 & \lambda_4 \end{pmatrix} R(\varphi) = \begin{pmatrix} \cos^2(\varphi)\lambda_3 + \sin^2(\varphi)\lambda_4 & (\lambda_3-\lambda_4)\sin(\varphi)\cos(\varphi) \\ (\lambda_3-\lambda_4)\sin(\varphi)\cos(\varphi)(\lambda_3-\lambda_4) & \sin^2(\varphi)\lambda_3 + \cos^2(\varphi)\lambda_4 \end{pmatrix},$$

where we assume $\varphi\in]0,\pi/2[$. Notice that $\varphi = 0$ is excluded (otherwise $[A,B]=0$). We have

$$\begin{aligned}\dot{\rho}(t) &= \dot{x}_1(t)\cos\theta(t) + \dot{x}_2(t)\sin\theta(t)\\ &= \rho(t)\big(u(t)(\lambda_1\cos^2\theta(t) + \lambda_2\sin^2\theta(t))\\ &\quad + (1-u(t))(\lambda_3\cos^2(\theta(t)-\varphi) + \lambda_4\sin^2(\theta(t)-\varphi)\big).\end{aligned}$$

This means that $\rho(t)$ has the expression

$$\rho(t) = \rho(0)\exp\left(\int_0^t (u(t)f_1(t) + (1-u(t))f_2(t))\,dt\right),$$

where f_1 and f_2 are analytic functions satisfying $f_1 < \lambda_1$, $f_2 < \lambda_3$. ∎

If $|\mathcal{K}| > 1$ we have the following cases.

Case 1. If $\mathcal{D} < 0$, then $(\mathcal{P})$ is true.

Case 2. If $\mathcal{D} > 0$, then $Q^{-1}(0)$ is a couple of noncoinciding straight lines passing from the origin and forming the following angles with the x_1 axis:

$$\theta^{\pm} = \arctan(m^{\pm}),\quad m^{\pm} := \frac{-\bar{\chi}\pm\sqrt{D_{RR}}}{2(-\lambda_2 b)} = \frac{-\chi/i\pm\sqrt{\mathcal{D}}}{(\rho_A/i+1)(1-\mathcal{K})}. \tag{24}$$

From (23) it follows that $D_{RR} < \bar{\chi}^2$ so that in this case we have $\chi\neq 0$ and we may assume

$$\begin{cases} \theta^-,\theta^+\in]0,\pi/2[\text{ if } \chi/i \text{ and } \mathcal{K} \text{ have the same sign,}\\ \theta^-,\theta^+\in]-\pi/2,0[\text{ if } \chi/i \text{ and } \mathcal{K} \text{ have opposite sign.}\end{cases}$$

We have the following lemma.

LEMMA 3.2. *Let $\mathcal{D} > 0$; then*

(a) $\mathcal{K} > -\rho_A\rho_B$;
(b) *at each point of* $Q^{-1}(0)\setminus\{0\}$, *Ax and Bx have the same (resp., opposite) sign iff* $\mathcal{K} < -\rho_A\rho_B$ *(resp.,* $\mathcal{K} > -\rho_A\rho_B$*).*

Proof. (a) can be checked directly. Let us prove (b). Define $\Lambda^{\pm} := \mathcal{K} \pm \sqrt{\mathcal{D}} - \rho_A\rho_B$. By direct computation it follows that

- $\Lambda^{\pm} > 0$ iff $\mathcal{K} > -\rho_A\rho_B$;
- $(\frac{Ax}{\|Ax\|}) = (\frac{Bx}{\|Bx\|})$ for every $x = (h, m^{\pm}h),\ h \in \mathbf{R}\setminus\{0\},$ iff $\Lambda^{\pm} < 0$;
- $(\frac{Ax}{\|Ax\|}) = -(\frac{Bx}{\|Bx\|})$ for every $x = (h, m^{\pm}h),\ h \in \mathbf{R}\setminus\{0\},$ iff $\Lambda^{\pm} > 0$.

This concludes the proof. □

From Lemma (3.2) we have the following cases (notice that $-\rho_A\rho_B > 1$).

Case 2.1 If $\mathcal{K} > -\rho_A\rho_B$, then $(\mathcal{P})$ is false.

Case 2.2 If $\mathcal{K} < -\rho_A\rho_B$, then:

Case 2.2.A If $\mathcal{K} > 1$, one can easily check that the worst trajectory cannot rotate around the origin and $(\mathcal{P})$ is true.

Case 2.2.B If $\mathcal{K} < -1$, then the worst trajectory rotates around the origin and $(\mathcal{P})$ is true iff condition (7) is satisfied. Condition (7) can be obtained with arguments entirely similar to the ones of Appendices A and B. The case in which $\rho_{RC} = 1$ is the case in which we have at least stability (not asymptotic) for every switching function.

Case 3. If $\mathcal{D} = 0$, then the two straight lines coincide. Similarly to the **(CC)** and **(RC)** cases, if $\mathcal{K} < -\rho_A\rho_B$, then $(\mathcal{P})$ is true. Vice versa, if $\mathcal{K} > -\rho_A\rho_B$, then $(\mathcal{P})$ is false but we have stability (not asymptotic).

4. Asymptotic stability in the space of parameters. Fix a value of the cross ratio, and let $\mathcal{R}$ (resp., $\bar{\mathcal{R}}$) be the region in the (ρ_A, ρ_B) plane in which the system is asymptotically stable (resp., asymptotically stable or only stable) for arbitrary switching functions. In this section, we study the shape and the convexity of $\mathcal{R}$ and $\bar{\mathcal{R}}$.

4.1. The complex-complex case. In Figure 4.1 we show $\mathcal{R}$ for a fixed value of $\mathcal{K}$ in the case in which both A and B have complex eigenvalues.

In the case $\mathcal{K} < -1$, $\mathcal{R}$ is determined by the condition $\mathcal{D} < 0$. The set of values of ρ_A and ρ_B such that $\mathcal{D} = 0$ is the two curved lines of equations $\rho_B = \rho_A\mathcal{K} \pm \sqrt{(\rho_A^2+1)(\mathcal{K}^2-1)}$ of Figure 4.1 (case $\mathcal{K} < -1$). The points of intersection with the two axes are

$$(\rho_A, \rho_B) = (\sqrt{\mathcal{K}^2-1}, 0), \tag{25}$$

$$(\rho_A, \rho_B) = (0, \sqrt{\mathcal{K}^2-1}). \tag{26}$$

In this case, $\mathcal{R}$ is constituted by two connected open convex unbounded regions, while to get $\bar{\mathcal{R}}$ we have to add the points in which $\mathcal{D} = 0$.

In the case where $\mathcal{K} > 1$, $\mathcal{R}$ is determined by the condition $\rho_{CC} < 1$. In Figure 4.1 (case $\mathcal{K} > 1$) the locus $\mathcal{D} = 0$ is drawn with dotted lines, while the locus $\rho_{CC} = 1$ is drawn with a solid line. The points in which the two loci intersect each other and intersect the two axes are given again by formulas (25) and (26). In this case, to study the convexity of $\mathcal{R}$, we have to check if, expressing the locus $\rho_{CC} = 0$ as $\rho_B = f_{\mathcal{K}}(\rho_A)$, we find a convex function. In the following, the label $(_{\mathcal{K}})$ is a parameter, and it will be dropped. Let us indicate the derivative of ρ_{CC} with respect to the first and second

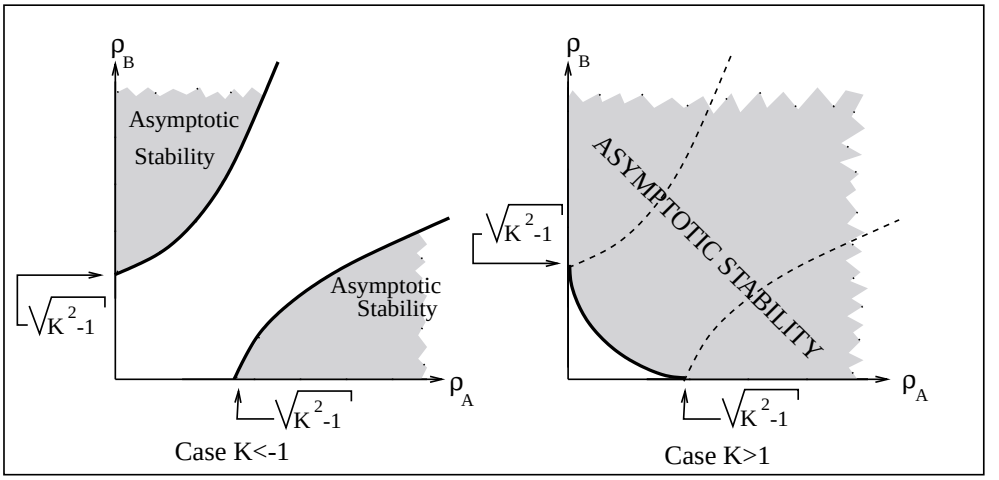

FIG. 4.1. *$\mathcal{R}$ (the grey region) for a fixed value of $\mathcal{K}$, in the complex–complex case.*

variable as $(\rho_{CC})_1$ and $(\rho_{CC})_2$. We have that

$$f'(\rho_A) = F\left(\rho_A, f(\rho_A)\right), \text{ where } F(\rho_A,\rho_B) := -\frac{(\rho_{CC})_1}{(\rho_{CC})_2} = -\frac{\arctan(\frac{\rho_B-\rho_A\mathcal{K}}{\sqrt{\mathcal{D}}})+\frac{\pi}{2}}{\arctan(\frac{\rho_A-\rho_B\mathcal{K}}{\sqrt{\mathcal{D}}})+\frac{\pi}{2}},$$

$$f''(\rho_A) = G\left(\rho_A, f(\rho_A)\right), \text{ where}$$

$$\begin{aligned}
G(\rho_A,\rho_B) &= \frac{\partial F(\rho_A,\rho_B)}{\partial\rho_A} + \frac{\partial F(\rho_A,\rho_B)}{\partial\rho_B}F(\rho_A,\rho_B)\\
&= \frac{2}{(1+\rho_A^2)\,(1+\rho_B^2)\,\sqrt{\mathcal{D}}\left(\pi+2\,\arctan(\frac{\rho_A-\rho_B\mathcal{K}}{\sqrt{\mathcal{D}}})\right)^3}\\
&\times \Bigg(\left[\rho_A^3\,\rho_B+\rho_A\,\rho_B^3+2(1+\rho_A^2+\rho_B^2+\rho_A\rho_B+\rho_A^2\rho_B^2)+\mathcal{K}(2+\rho_A^2+\rho_B^2)\right]\pi^2\\
&\quad+4\left(1+\rho_B^2\right)\left(1+\rho_A^2+\rho_A\,\rho_B+\mathcal{K}\right)\pi\,\arctan\left(\frac{\rho_A-\rho_B\,\mathcal{K}}{\sqrt{\mathcal{D}}}\right)\\
&\quad+4\left(1+\rho_A^2\right)\left(1+\rho_B^2+\rho_B\,\rho_A+\mathcal{K}\right)\pi\,\arctan\left(\frac{\rho_B-\rho_A\,\mathcal{K}}{\sqrt{\mathcal{D}}}\right)\\
&\quad+4\left(1+\rho_A^2\right)\left(\rho_A\,\rho_B+\mathcal{K}\right)\arctan\left(\frac{\rho_B-\rho_A\,\mathcal{K}}{\sqrt{\mathcal{D}}}\right)^2\\
&\quad+4\left(1+\rho_B^2\right)\left(\rho_A\,\rho_B+\mathcal{K}\right)\arctan\left(\frac{\rho_A-\rho_B\,\mathcal{K}}{\sqrt{\mathcal{D}}}\right)^2\\
&\quad+8\left(1+\rho_A^2\right)\left(1+\rho_B^2\right)\arctan\left(\frac{\rho_B-\rho_A\,\mathcal{K}}{\sqrt{\mathcal{D}}}\right)\arctan\left(\frac{\rho_A-\rho_B\,\mathcal{K}}{\sqrt{\mathcal{D}}}\right)\Bigg).
\end{aligned}$$

Now the only terms that can be negative are the ones in the third and fourth rows, but it is easy to check numerically that the sum of these two terms with the one in the second row is always bigger than zero. The convexity follows. In this case, $\mathcal{R}$ is a convex open unbounded region, while $\bar{\mathcal{R}}$ is a convex not-open unbounded region (we

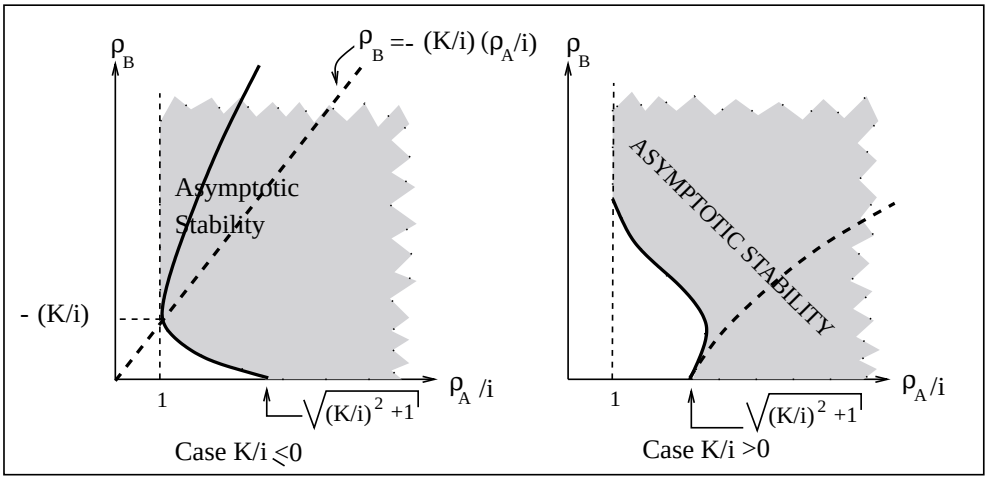

FIG. 4.2. $\mathcal{R}$ *(the grey region) for a fixed value of* $\mathcal{K}$*, in the* **(RC)** *case.*

have to add the points such that $\rho_{CC} = 1$).

4.2. The real-complex case. In the case in which A and B have one complex and the other real eigenvalues, $\mathcal{R}$ is drawn in Figure 4.2. We recall that $\rho_A/i > 1$, $\rho_B > 0$, $\mathcal{K}/i \in \mathbf{R}$.

In the case where $\chi > 0$ (which implies $\mathcal{K}/i < 0$ and $\rho_B < (-\mathcal{K}/i)(\rho_A/i)$), $\mathcal{R}$ is determined by the condition $\mathcal{D} > 0$. The locus $\mathcal{D} = 0$ is the set of points such that $\rho_B = -(\rho_A/i)(\mathcal{K}/i) \pm \sqrt{(-(\rho_A/i)^2 + 1)(-(\mathcal{K}/i)^2 - 1)}$. The intersection point with the ρ_A axis is

$$(\rho_A/i, \rho_B) = (\sqrt{(\mathcal{K}/i)^2 + 1}, 0), \tag{27}$$

and the intersection with the $\rho_A/i = 1$ set is

$$(\rho_A/i, \rho_B) = (1, -(\mathcal{K}/i)).$$

In the case when $\chi < 0$ and $\mathcal{K}/i \leq 0$, we have asymptotic stability. We conclude that in the case when $\mathcal{K}/i \leq 0$, $\mathcal{R}$ is a convex open unbounded region (see Figure 4.2 (case $\mathcal{K}/i \leq 0$)), while to get $\bar{\mathcal{R}}$, we have to add the points in which $\mathcal{D} = 0$.

In the case when $\chi < 0$ and $\mathcal{K}/i > 0$, $\mathcal{R}$ is determined by the condition $\rho_{RC} < 1$. In Figure 4.2 (case $\mathcal{K}/i > 0$), the locus $\mathcal{D} = 0$ is drawn with a dotted line, while the locus $\rho_{CC} = 1$ is drawn with a solid line. The points in which the two loci intersect each other are given by formula (27). In this case, $\mathcal{R}$ is a nonconvex open unbounded region. Again the points in which we have at least stability are the points in which we have asymptotic stability plus the points such that $\rho_{RC} = 1$.

4.3. The real-real case. In the case in which A and B have both real eigenvalues, $\mathcal{R}$ is drawn in Figure 4.3. We recall that $\rho_A/i, \rho_B/i > 1$, $\mathcal{K} \in \mathbf{R} \setminus \{\pm 1\}$. If $\mathcal{K} < -1$, $\mathcal{R}$ is determined by $\rho_{RR} > 0$, while, if $\mathcal{K} > 1$, $\mathcal{R}$ is determined by $\mathcal{D} > 0$. Similarly to the **(CC)** case, we can conclude that $\mathcal{R}$ is a convex open unbounded region, while $\bar{\mathcal{R}}$ is a convex not-open unbounded region. (We have to add the points such that $\rho_{CC} = 1$ and $\mathcal{D} = 0$.)

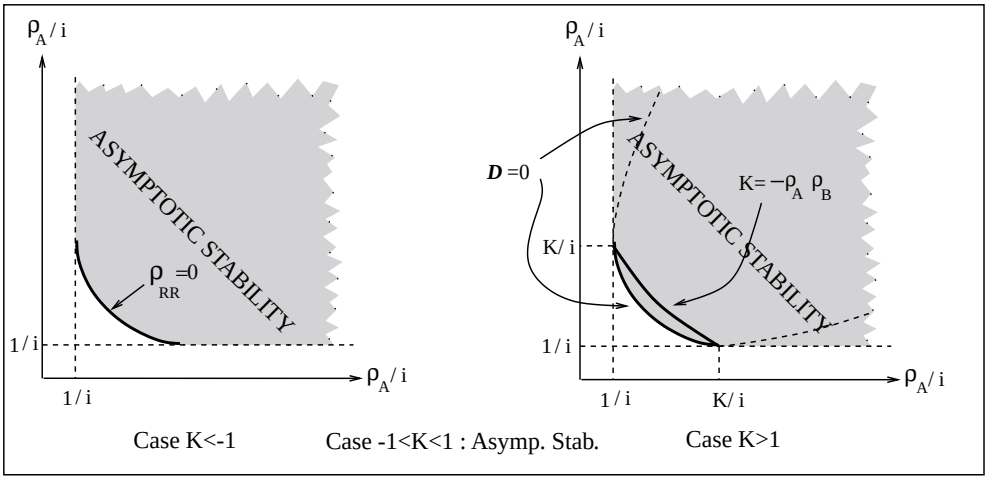

FIG. 4.3. $\mathcal{R}$ *(the grey region) for a fixed value of* $\mathcal{K}$*, in the* **(RR)** *case.*

5. Final remarks. Using the results of [1, 7] and by Theorem 2.3, we have a complete algorithm to study the asymptotic stability of a switched linear system in any dimension at least in the case in which

$$A_u = uA^1x + (1-u)A^2x, \qquad u \in [0,1], \quad A^1, A^2 \in \mathbf{R}^{n\times n},$$

where A and B are diagonalizable and $\dim\{A_1, A_2\}_{L.A.} \leq 4$. The case in which A or B is not diagonalizable can be treated with similar techniques.

Generalization can be done for more complex sets U. One is the following m-input system:

$$\dot{x} = \sum_{i=1}^{m} u_i A^i x, \quad \sum_{i=1}^{m} u_i = 1, \quad u_i \geq 0 \ \ (i = 1, \ldots, m), \quad x \in \mathbf{R}^n, \quad A^1, \ldots, A^m \in \mathbf{R}^{n\times n}.$$

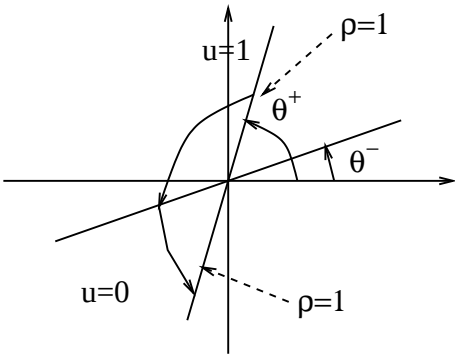
With exactly the same techniques used in this paper, one can find a coordinates invariant necessary and sufficient condition for the stabilizability of a control system of the kind (2), where all the matrices have eigenvalues with strictly *positive* real part. This problem was also studied in [12] but not in terms of a minimum number of coordinate-free parameters. We refer to [12] for details.

Some results can be obtained for the nonlinear version of the problem treated in this paper,

$$\dot{x} = uF(x) + (1-u)G(x), \tag{28}$$

where $x \in \mathbf{R}^2$, $F(.)$, $G(.)$ are $\mathcal{C}^\infty$ generic functions from $\mathbf{R}^2$ to $\mathbf{R}^2$ such that $F(0) = 0$, $G(0) = 0$, and the two dynamical systems $\dot{x} = F(x)$, $\dot{x} = G(x)$ are globally asymptotically stable at the origin. We are interested in studying under which conditions on $F(.)$ and $G(.)$ the origin of the system (28) is globally asymptotically stable for every measurable function $u(.) : [0, \infty[\to [0, 1]$.

Appendix A: Proof of formula (5). We refer to the following figure.



Let $\rho(t)$, $\theta(t)$ (resp., $x(t), y(t)$) be the polar coordinates (resp., Cartesian) of $\gamma^M(t)$, where we fix the initial condition by setting $\rho(0) = 1$, $\theta(0) = \theta^+$. We have to check if at the time a such that $\theta(a) = \theta(0) + 2\pi$ we have $\rho(a) < 1$. Due to the symmetries of the system, this happens iff at the time $\bar{t}$ such that $\theta(\bar{t}) = \theta^+ + \pi$ we have $\rho_{RC} := \rho(\bar{t}) < 1$. Notice that $\bar{t} = a/2$. The trajectory $\gamma^M(t)$ corresponds to the constant switching function $u = +1$ up to the time t' in which $\theta(t') = \theta^- + \pi$. This time is defined by the equations

$$
\begin{aligned}
&x(t') = \rho_0 e^{-\delta_A t'} \cos(\omega_A t' + \theta_E^+),\\
&y(t') = \rho_0 E e^{-\delta_A t'} \sin(\omega_A t' + \theta_E^+),\\
&\theta_E^+ = \arctan\left(\frac{m^+}{E}\right) \in \begin{cases} [-\pi/2, \pi/2[\text{ if } \theta^+ \in [-\pi/2, \pi/2[,\\ ]\pi/2, 3\pi/4[\text{ if } \theta^+ \in]\pi/2, 3\pi/4[, \end{cases}\\
&\rho_0 = (\cos^2(\theta_E^+) + E^2 \sin^2(\theta_E^+))^{-1/2},\\
&y(t') = m^- x(t').
\end{aligned}
$$

It follows that $\tan(\omega_A t' + \theta_E^+) = m^-/E$. If we set $\theta_E^- = \arctan(m^-/E) \in]\theta_E^+, \theta_E^+ + \pi[$, we have $t' = (\theta_E^- - \theta_E^+)/\omega_A$.

After time t', $\gamma^M(t)$ corresponds to the constant switching function $u = 0$ up to the first time $\bar{t}$ in which $\theta(\bar{t}) = \theta^+ + \pi$. This time is defined by the equations

$$
\begin{aligned}
&x(\bar{t}) = \rho(t') e^{-\delta_B(\bar{t} - t')} \cos(\omega_B(\bar{t} - t') + \theta^- + \pi),\\
&y(\bar{t}) = \rho(t') e^{-\delta_B(\bar{t} - t')} \sin(\omega_B(\bar{t} - t') + \theta^- + \pi),\\
&\rho(t') = \rho_0 e^{-\frac{\delta_A}{\omega_A}(\theta_E^- - \theta_E^+)} \sqrt{\cos^2(\theta_E^-) + E^2 \sin^2(\theta_E^-)},\\
&y(\bar{t}) = m^+ x(\bar{t}).
\end{aligned}
$$

It follows that $\tan(\omega_B(\bar{t} - t') + \theta^- + \pi) = \tan(\omega_B(\bar{t} - t') + \theta^-) = m^+ = \tan(\theta^+)$, and we have $\bar{t} = (\theta^+ - \theta^-)/\omega_B + t'$. Finally,

$$
\bar{\rho} = \rho(\bar{t}) = \rho(t') e^{-\frac{\delta_B}{\omega_B}(\bar{t} - t')} = e^{-\frac{\delta_A}{\omega_A}(\theta_E^- - \theta_E^+) - \frac{\delta_B}{\omega_B}(\theta^+ - \theta^-)} \sqrt{\frac{\cos^2\theta_E^- + E^2 \sin^2(\theta_E^-)}{\cos^2\theta_E^+ + E^2 \sin^2(\theta_E^+)}}.
$$

This formula is not in a good form because it is not explicitly invariant for the exchange of δ_A, ω_A with δ_B, ω_B and because the quantity E does not appear only in the form $E + 1/E$. Recalling the definition of $\rho_A, \rho_B, \mathcal{K}$ (see Definition 2.1) and using the equality

$$
\arctan a - \arctan b = \arctan\left(\frac{ab + 1}{b - a} + \pi/2\right),
$$

which holds for $a > b$, it is possible to obtain the relations

$$-\frac{\delta_A}{\omega_A}(\theta_E^- - \theta_E^+) = -\rho_A\left(\arctan\left(\frac{-\rho_A\mathcal{K}+\rho_B}{\sqrt{\mathcal{D}}}\right)+\pi/2\right),$$
$$-\frac{\delta_B}{\omega_B}(\theta^+ - \theta^-) = -\rho_B\left(\arctan\left(\frac{\rho_A-\rho_B\mathcal{K}}{\sqrt{\mathcal{D}}}\right)+\pi/2\right).$$

Moreover, with elementary computation we can show that

$$\sqrt{\frac{\cos^2\theta_E^- + E^2\sin^2(\theta_E^-)}{\cos^2\theta_E^+ + E^2\sin^2(\theta_E^+)}} = \sqrt{\frac{\rho_A\rho_B+\sqrt{\mathcal{D}}}{\rho_A\rho_B-\sqrt{\mathcal{D}}}}.$$

Formula (5) is obtained.

Appendix B: Proof of formula (6). To obtain a result that explicitly does not depend on the choice of the system of coordinates, we need to write the formulas of section 3.2 in a more invariant way. Set

$$\psi = \sqrt{\frac{E\cos^2\varphi + 1/E\sin^2\varphi}{E\sin^2\varphi + 1/E\cos^2\varphi}},$$

and make the coordinates transformation

$$x \to \Psi(\psi)x, \quad \text{where } \Psi(\psi) := \begin{pmatrix} 1 & 0 \\ 0 & \psi \end{pmatrix}.$$

In this case ($E \geq 1$), the new coordinates A, B, and $\theta^\pm$ have the expressions

$$A = \Psi^{-1}(\psi)\begin{pmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{pmatrix}\Psi(\psi) = \begin{pmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{pmatrix},$$
$$B = \Psi^{-1}(\psi)\begin{pmatrix} a & b \\ c & d \end{pmatrix}\Psi(\psi) = \begin{pmatrix} -\delta-\omega\mathcal{K}/i & -\omega\sqrt{-\mathcal{K}^2+1} \\ +\omega\sqrt{-\mathcal{K}^2+1} & -\delta+\omega\mathcal{K}/i \end{pmatrix},$$
$$\theta^\pm = \arctan m^\pm, \quad m^\pm = \frac{-\chi\pm\sqrt{-\mathcal{D}}}{2\frac{\lambda_2}{\lambda_1-\lambda_2}\sqrt{-\mathcal{K}^2+1}} = \frac{-\chi\pm\sqrt{-\mathcal{D}}}{(-\rho_A/i-1)\sqrt{-\mathcal{K}^2+1}}.$$

Equivalently, we can use the expressions (15), (16), (18) for $A, B, \theta^\pm$ with $E \geq 1$ and $\varphi = \pi/4$.

$$A = \begin{pmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{pmatrix},$$
$$B = R^{-1}(\pi/4)\begin{pmatrix} -\delta & -\omega/E \\ \omega E & -\delta \end{pmatrix}R(\pi/4),$$
$$\theta^\pm = \arctan m^\pm, \quad m^\pm := \frac{-\chi\pm\sqrt{-\mathcal{D}}}{\frac{\lambda_2}{\lambda_1-\lambda_2}(E+1/E)} = 2\frac{-\chi\pm\sqrt{-\mathcal{D}}}{(-\rho_A/i-1)(E+1/E)}. \tag{29}$$

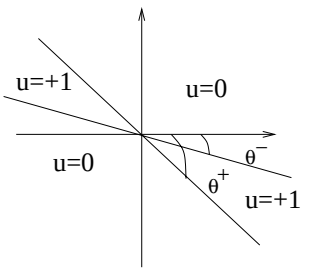
The relation between $\mathcal{K}$ and E is

$$\mathcal{K} = i\frac{1}{2}(E-1/E), \quad E = \mathcal{K}/i + \sqrt{-\mathcal{K}^2+1}.$$

Moreover, we are considering the case $\chi < 0$ so that $\theta^+, \theta^- \in]-\pi/2, 0[$. From (29) it follows that $\theta^+ < \theta^-$.

In this case, $\gamma^M(.)$ corresponds to the feedback (see the following figure):

$$u(x) = \begin{cases} 1 \text{ if } \theta \in]\theta^+, \theta^-[\text{ or } \theta \in]\theta^+ + \pi, \theta^- + \pi[, \\ 0 \text{ if } \theta \in]\theta^-, \theta^+ + \pi[\text{ or } \theta \in]\theta^- + \pi, \theta^+ + 2\pi[. \end{cases}$$



Make the following coordinates transformation: $x \to \bar{x} = R(\pi/4)x$. We have

$$\begin{aligned} A \to \bar{A} &= R(\pi/4) \begin{pmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{pmatrix} R^{-1}(\pi/4), \\ B \to \bar{B} &= \begin{pmatrix} -\delta & -\omega/E \\ \omega E & -\delta \end{pmatrix}, \\ \theta^\pm \to \bar{\theta}^\pm &= \theta^\pm - \pi/4 = \arctan \bar{m}^\pm \in [3/4\pi, \pi/4[, \quad \bar{m}^\pm := \frac{m^\pm - 1}{m^\pm + 1}. \end{aligned}$$

Similarly to Appendix A, we compute γ^M in polar coordinates with the initial condition $\rho(0) = 1,\ \theta(0) = \bar{\theta}^-$. Let t' be the first time such that $\theta(t') = \bar{\theta}^+ + \pi$. We have

$$\begin{aligned} t' &= (\xi^+ - \xi^-)/\omega, \\ \rho(t') &= e^{-\frac{\delta}{\omega}(\xi^+ - \xi^-)} \sqrt{\frac{\cos^2 \xi^+ + E^2 \sin^2 \xi^+}{\cos^2 \xi^- + E^2 \sin^2 \xi^-}}, \end{aligned}$$

where $\xi^\pm := \arctan(\bar{m}^\pm/E), \quad \xi^+ \in]\xi^-, \xi^- + \pi[$.

Now we come back to the old coordinates ($\bar{x} \to x = R^{-1}(\pi/4)\bar{x}$), and we integrate Bx up to the first time $\bar{t}$ such that $\theta(\bar{t}) = \theta^- + \pi$. We have

$$\begin{aligned} x(\bar{t}) &= \rho(t') \cos(\theta^+ + \pi) e^{\lambda_1(\bar{t} - t')}, \\ y(\bar{t}) &= \rho(t') \sin(\theta^+ + \pi) e^{\lambda_2(\bar{t} - t')}, \\ y(\bar{t}) &= m^- x(\bar{t}). \end{aligned}$$

It follows that

$$m^+ e^{((\lambda_2 - \lambda_1)(\bar{t} - t'))} = n^- \Longrightarrow \bar{t} - t' = \frac{1}{\lambda_2 - \lambda_1} \ln\left(\frac{m^-}{m^+}\right).$$

Finally,

$$\begin{aligned} \rho_{RC} := \rho(\bar{t}) &= \rho(t') \sqrt{\cos^2 \theta^+ e^{\frac{\lambda_1}{\lambda_2 - \lambda_1} \ln(m^-/m^+)} + \sin^2 \theta^+ e^{\frac{\lambda_2}{\lambda_2 - \lambda_1} \ln(m^-/m^+)}} \\ &= e^{-\frac{\delta}{\omega}(\xi^+ - \xi^-)} \sqrt{\frac{\cos^2 \xi^+ + E^2 \sin^2 \xi^+}{\cos^2 \xi^- + E^2 \sin^2 \xi^-}} \end{aligned}$$

$$\times\sqrt{\cos^2\theta^+\left(\frac{m^-}{m^+}\right)^{\frac{\lambda_1}{\lambda_2-\lambda_1}}+\sin^2\theta^+\left(\frac{m^-}{m^+}\right)^{\frac{\lambda_2}{\lambda_2-\lambda_1}}}$$

$$= e^{-\rho_B(\xi^+-\xi^-)}\sqrt{\frac{\cos^2\xi^+ + E^2\sin^2\xi^+}{\cos^2\xi^- + E^2\sin^2\xi^-}}$$

$$\times\sqrt{\cos^2\theta^+\left(\frac{m^+}{m^-}\right)^{\frac{1}{2}(-\rho_A/i+1)}+\sin^2\theta^+\left(\frac{m^+}{m^-}\right)^{\frac{1}{2}(-\rho_A/i-1)}},$$

which is formula (6). This formula is complicated but acceptable because there are no further symmetries.

Acknowledgment. The author is grateful to Andrei Agrachev for suggesting the problem and for helpful discussions that contributed to finding the right invariant.

DISCRETE-TIME AND SAMPLED-DATA LOW-GAIN CONTROL OF INFINITE-DIMENSIONAL LINEAR SYSTEMS IN THE PRESENCE OF INPUT HYSTERESIS*

H. LOGEMANN† AND A. D. MAWBY†‡

Abstract. We introduce a general class of causal dynamic discrete-time nonlinearities which have certain monotonicity and Lipschitz continuity properties. In particular, the discretizations of a large class of continuous-time hysteresis operators obtained by applying the standard sampling and hold operations belong to this class. It is shown that closing the loop around a power-stable, linear, infinite-dimensional, discrete-time, single-input, single-output system, subject to an input nonlinearity from the class under consideration and compensated by a discrete-time integral controller, guarantees asymptotic tracking of constant reference signals, provided that (a) the positive integrator gain is sufficiently small and (b) the reference value is feasible in a very natural sense. We apply this result in the development of sampled-data low-gain integral control for exponentially stable, regular, linear, infinite-dimensional, continuous-time systems subject to input hysteresis.

Key words. continuous-time regular infinite-dimensional systems, discrete-time infinite-dimensional systems, hysteresis nonlinearities, integral control, robust tracking, sampled-data control

1. Introduction.

The present paper extends the line of work on low-gain integral control of infinite-dimensional linear systems subject to input nonlinearities initiated by the recent papers [9], [11], [14], [15]. Underpinning these contributions are generalizations of the well-known principle (see, for example, [4], [17], [18], and [22]) that closing the loop around a stable, linear, continuous-time, single-input, single-output plant, with transfer function $\mathbf{G}^c(s)$ compensated by a pure integral controller k/s, will result in a stable closed-loop system that achieves asymptotic tracking of arbitrary constant reference signals, provided that $|k|$ is sufficiently small and $\mathbf{G}^c(0)k > 0$.[1] In particular, Logemann and Mawby [11] have shown that the above principle remains true for exponentially stable, regular, linear, infinite-dimensional, continuous-time, single-input, single-output systems subject to input hysteresis belonging to a certain class $\mathcal{C}(\lambda)$ of hysteresis operators, provided the reference value r is feasible in a natural sense. The class $\mathcal{C}(\lambda)$ consists of hysteresis operators which, among other conditions, satisfy a certain Lipschitz condition with Lipschitz constant $\lambda > 0$. We emphasize that $\mathcal{C}(\lambda)$ encompasses a large number of hysteresis nonlinearities important in applications such as relay, backlash, elastic-plastic, and Prandtl hysteresis.

In this paper, we provide discrete-time and sampled-data analogues of the continuous-time results in [11]. More precisely, the contribution of the present work is twofold.

[1] Therefore, under the above assumptions on the plant, the problem of tracking constant reference signals reduces to that of tuning the gain parameter k. This so-called tuning regulator theory [4] has been successfully applied in process control (see [3], [19]).

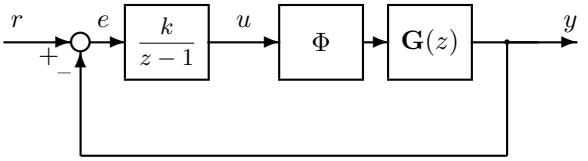

FIG. 1. *Low-gain control with input nonlinearity.*

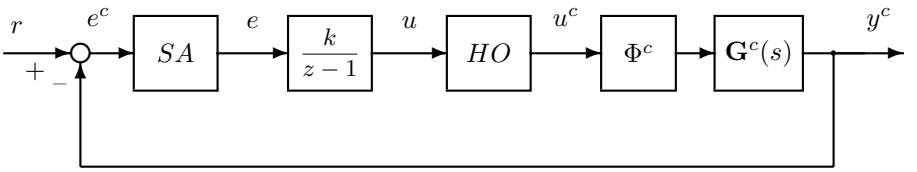

FIG. 2. *Sampled-data low-gain control.*

(i) We introduce a class $\mathcal{D}(\lambda)$ of causal dynamic discrete-time nonlinearities which have a number of properties, one of them being that a functional Lipschitz condition with Lipschitz constant $\lambda > 0$ is satisfied. The class $\mathcal{D}(\lambda)$ contains a large number of discrete-time hysteresis operators, in particular discretizations of continuous-time hysteresis operators in $\mathcal{C}(\lambda)$ obtained by sampling/hold. We derive a discrete-time version of the continuous-time tuning regulator result in [11] by showing that for a power-stable, linear, infinite-dimensional, discrete-time, single-input, single-output plant with transfer function $\mathbf{G}(z)$, subject to a dynamic input nonlinearity $\Phi \in \mathcal{D}(\lambda)$, the output $y(n)$ of the closed-loop system, shown in Figure 1, converges to the reference value r as $n \to \infty$, provided that $\mathbf{G}(1) > 0$, r is feasible in some natural sense, and $k \in (0, K/\lambda)$, where K is the supremum of the set of all numbers $k > 0$ such that

$$1 + k \operatorname{Re} \frac{\mathbf{G}(z)}{z-1} \geq 0 \quad \forall\, |z| > 1\,.$$

(ii) We apply the discrete-time theory in the development of a sampled-data counterpart to the continuous-time low-gain control result in [11]—see Figure 2—where HO denotes a standard hold operation and SA denotes a sampling operation. In the case of unbounded observation, the latter involves an averaging operation. Specifically, we show that for an exponentially stable, regular, linear, infinite-dimensional, continuous-time, single-input, single-output plant with transfer function $\mathbf{G}^c(s)$, subject to a continuous-time dynamic input nonlinearity $\Phi^c \in \mathcal{C}(\lambda)$, the output $y^c(t)$ of the closed-loop system, shown in Figure 2, converges to the reference value r as $t \to \infty$, provided that $\mathbf{G}^c(0) > 0$, r is feasible in some natural sense, and $k > 0$ is sufficiently small. The class of regular, linear, infinite-dimensional, continuous-time systems, introduced by Weiss [25], [26], [27], [28], is rather general. It includes most distributed parameter systems and all time-delay systems (retarded and neutral) which are of interest in applications. With respect to (i), while the structure of the discrete-time analysis parallels that of the continuous-time analysis in [11], there are several points where these analyses differ in an essential manner. With reference to (ii), the sampled-data results constitute the main contribution of the paper. In the derivation of these results, the discrete-time theory plays a central role.

We mention that there exists a substantial literature on the mathematical theory of hysteresis phenomena; see, for example, Brokate [1], Brokate and Sprekels [2], and Krasnosel'skiĭ and Pokrovskiĭ [8]. Of particular importance in a systems and control context is the pioneering work [8]. Our treatment of continuous-time hysteresis operators in section 4 has been strongly influenced by chapter 2 in [2].

The paper is organized as follows. In section 2, we introduce the class $\mathcal{D}(\lambda)$ of dynamic discrete-time nonlinearities, while section 3 contains the low-gain tuning regulator result for discrete-time systems subject to input nonlinearities belonging to $\mathcal{D}(\lambda)$. In section 4, we introduce the class $\mathcal{C}(\lambda)$ of dynamic continuous-time nonlinearities and establish several important properties enjoyed by nonlinearities in this class. At the end of this section, we discretize continuous-time hysteresis operators and show that the resultant discrete-time operators are contained in the class $\mathcal{D}(\lambda)$. In section 5, the low-gain tracking problem for exponentially stable, regular, linear, infinite-dimensional, continuous-time, single-input, single-output systems with input nonlinearity in $\mathcal{C}(\lambda)$ is solved using sampled-data integral control. In section 6, we illustrate our results in the context of a simple linear diffusion process subject to input hysteresis: relay as well as backlash nonlinearities are considered. Finally, several technical details relating to the infinite-dimensional discrete-time positive-real lemma have been relegated to the appendix.

Notation. We define

$$\mathbb{R}_+ := \{x \in \mathbb{R} \,|\, x \geq 0\}, \quad \mathbb{Z}_+ = \{x \in \mathbb{Z} \,|\, x \geq 0\}.$$

For sets M and N, we denote the set of all functions $f : M \to N$ by $F(M, N)$. If $I \subset \mathbb{R}$ is a compact interval, then $AC(I, \mathbb{R})$ denotes the space of absolutely continuous real-valued functions defined on I; $AC(\mathbb{R}_+, \mathbb{R})$ denotes the space of real-valued functions defined on $\mathbb{R}_+$ which are absolutely continuous on any compact interval $I \subset \mathbb{R}_+$, i.e., a function $f \in F(\mathbb{R}_+, \mathbb{R})$ is in $AC(\mathbb{R}_+, \mathbb{R})$ if and only if there exists a function $g \in L^1_{\mathrm{loc}}(\mathbb{R}_+, \mathbb{R})$ such that

$$f(t) = f(0) + \int_0^t g(\tau)\, d\tau \quad \forall\, t \geq 0.$$

We say that a function $f \in F(\mathbb{R}_+, \mathbb{R})$ is *piecewise monotone* if there exists a sequence $0 = t_0 < t_1 < t_2 < \cdots$ such that $\lim_{i\to\infty} t_i = \infty$ and f is monotone on each of the intervals (t_i, t_{i+1}). A function $f \in F(\mathbb{R}_+, \mathbb{R})$ is called *piecewise continuous* if there exists a sequence $0 = t_0 < t_1 < t_2 < \cdots$ such that $\lim_{i\to\infty} t_i = \infty$, f is continuous on each of the intervals (t_i, t_{i+1}), and the right and left limits of f exist and are finite at each t_i. We denote the space of all piecewise continuous functions $f : \mathbb{R}_+ \to \mathbb{R}$ by $PC(\mathbb{R}_+, \mathbb{R})$. As usual, for $f \in PC(\mathbb{R}_+, \mathbb{R})$, we define

$$f(t+) := \lim_{\tau \downarrow t} f(\tau) \text{ (for } t \geq 0) \quad \text{and} \quad f(t-) := \lim_{\tau \uparrow t} f(\tau) \text{ (for } t > 0).$$

Let $\mathbb{T} = \mathbb{R}_+, \mathbb{Z}_+$; a function $f \in F(\mathbb{T}, \mathbb{R})$ is called *ultimately constant* if there exists $T \in \mathbb{T}$ such that f is constant on $[T, \infty) \cap \mathbb{T}$. $L(X, Y)$ denotes the space of bounded linear operators from a Banach space X to a Banach space Y, and we set $L(X) := L(X, X)$. The Laplace transform is denoted by $\mathfrak{L}$.

2. A class of discrete-time nonlinear operators. For each $n \in \mathbb{Z}_+$, we define a projection operator $\mathbf{Q}_n : F(\mathbb{Z}_+, \mathbb{R}) \to F(\mathbb{Z}_+, \mathbb{R})$ by

$$(\mathbf{Q}_n u)(m) = \begin{cases} u(m) & \text{for } m \in [0, n] \cap \mathbb{Z}_+, \\ u(n) & \text{for } m \in \mathbb{Z}_+ \setminus [0, n]. \end{cases}$$

Recall that an operator $\Phi : F(\mathbb{Z}_+, \mathbb{R}) \to F(\mathbb{Z}_+, \mathbb{R})$ is called *causal* if for all $u, v \in F(\mathbb{Z}_+, \mathbb{R})$ and all $n \in \mathbb{Z}_+$ with $u(m) = v(m)$ for all $m \in [0, n] \cap \mathbb{Z}_+$ it follows that $(\Phi(u))(m) = (\Phi(v))(m)$ for all $m \in [0, n] \cap \mathbb{Z}_+$.

Let $u \in F(\mathbb{Z}_+, \mathbb{R})$. The function u is called *ultimately nondecreasing* if there exists $m \in \mathbb{Z}_+$ such that u is nondecreasing on $\mathbb{Z}_+ \setminus [0, m]$.

The *numerical value set* $\operatorname{NVS} \Phi$ of an operator $\Phi : F(\mathbb{Z}_+, \mathbb{R}) \to F(\mathbb{Z}_+, \mathbb{R})$ is defined by

$$\operatorname{NVS} \Phi := \{(\Phi(u))(n) \,|\, u \in F(\mathbb{Z}_+, \mathbb{R}),\, n \in \mathbb{Z}_+\}.$$

We introduce the following five assumptions on the operator $\Phi : F(\mathbb{Z}_+, \mathbb{R}) \to F(\mathbb{Z}_+, \mathbb{R})$:

(D1) Φ is causal;

(D2) for all $u \in F(\mathbb{Z}_+, \mathbb{R})$ and all $n \in \mathbb{Z}_+$

$$(\Phi(\mathbf{Q}_n u))(k) = (\Phi(\mathbf{Q}_n u))(n) \quad \forall\, k \in \mathbb{Z}_+ \setminus [0, n];$$

(D3) there exists $\lambda > 0$ such that for all $u \in F(\mathbb{Z}_+, \mathbb{R})$ and all $n \in \mathbb{Z}_+$

$$u(n) \neq u(n+1) \Longrightarrow \frac{(\Phi(u))(n+1) - (\Phi(u))(n)}{u(n+1) - u(n)} \in [0, \lambda];$$

(D4) if $u \in F(\mathbb{Z}_+, \mathbb{R})$ is ultimately nondecreasing and $\lim_{n\to\infty} u(n) = \infty$, then $(\Phi(u))(n)$ and $(\Phi(-u))(n)$ converge to $\sup \operatorname{NVS} \Phi$ and $\inf \operatorname{NVS} \Phi$, respectively, as $n \to \infty$;

(D5) if, for $u \in F(\mathbb{Z}_+, \mathbb{R})$, $L := \lim_{n\to\infty} (\Phi(u))(n)$ exists with $L \in \operatorname{int}(\operatorname{clos}(\operatorname{NVS} \Phi))$, then u is bounded.

REMARK 2.1. (1) *We note that if* (D1) *and* (D2) *hold, then* (D3) *is implied by the monotonicity condition*

$$[(\Phi(u))(n+1) - (\Phi(u))(n)][u(n+1) - u(n)] \geq 0 \quad \forall\, u \in F(\mathbb{Z}_+, \mathbb{R}),\ \ \forall\, n \in \mathbb{Z}_+,$$

together with the Lipschitz continuity condition

$$\sup_{n\in\mathbb{Z}_+} |(\Phi(u))(n) - (\Phi(v))(n)| \leq \lambda \sup_{n\in\mathbb{Z}_+} |u(n) - v(n)| \quad \forall\, u, v \in F(\mathbb{Z}_+, \mathbb{R}).$$

(2) *Assumption* (D2) *says that if the input u of the nonlinearity Φ is constant on $\mathbb{Z}_+ \setminus [0, n-1]$, then the output $\Phi(u)$ is constant and equal to $(\Phi(u))(n)$ on $\mathbb{Z}_+ \setminus [0, n-1]$.*

(3) *If* (D1)–(D3) *hold, then*

$$|(\Phi(u))(n+1) - (\Phi(u))(n)| \leq \lambda\, |u(n+1) - u(n)| \quad \forall\, u \in F(\mathbb{Z}_+, \mathbb{R}),\ \ \forall\, n \in \mathbb{Z}_+.$$

Thus if (D4) *also holds,* $\operatorname{clos}(\operatorname{NVS} \Phi)$ *is an interval. However, it can be shown that* $\operatorname{NVS} \Phi$ *is not necessarily an interval; see Mawby* [21] *for a counterexample.*

(4) *If* (D1)–(D3) *hold, then for all $u \in F(\mathbb{Z}_+, \mathbb{R})$ there exists $d : \mathbb{Z}_+ \to [0, \lambda]$ such that $(\Phi(u))(n+1) - (\Phi(u))(n) = d(n)(u(n+1) - u(n))$ for all $n \in \mathbb{Z}_+$.*

If $\Phi : F(\mathbb{Z}_+, \mathbb{R}) \to F(\mathbb{Z}_+, \mathbb{R})$ satisfies (D3), then any number $l > 0$ such that (D3) holds for $\lambda = l$ is called a *Lipschitz constant* of Φ. We are now in a position to define the class of nonlinear operators we will be considering in the context of the discrete-time integral control problem in section 3.

DEFINITION 2.2. *Let $\lambda > 0$. The set of all operators $\Phi : F(\mathbb{Z}_+, \mathbb{R}) \to F(\mathbb{Z}_+, \mathbb{R})$ satisfying* (D1)–(D5) *and having Lipschitz constant λ is denoted by $\mathcal{D}(\lambda)$.*

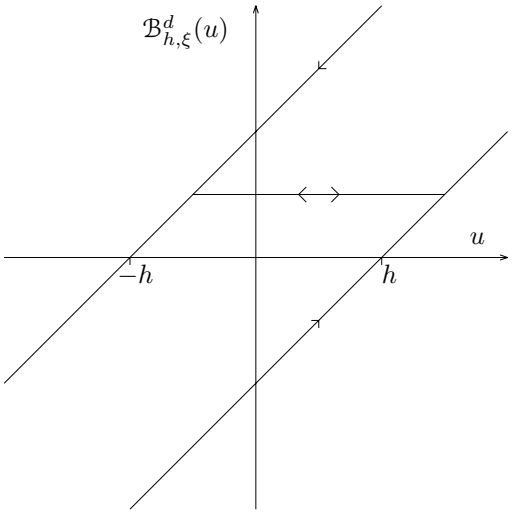

FIG. 3. *Backlash hysteresis.*

We now consider two examples of nonlinearities which satisfy (D1)–(D5).

Static nonlinearities. For a function $f : \mathbb{R} \to \mathbb{R}$, define the corresponding static nonlinearity by

$$\mathcal{S}_f : F(\mathbb{Z}_+, \mathbb{R}) \to F(\mathbb{Z}_+, \mathbb{R}), \quad u \mapsto f \circ u.$$

It is clear that if $f : \mathbb{R} \to \mathbb{R}$ is nondecreasing and globally Lipschitz with Lipschitz constant $\lambda > 0$, then $\mathcal{S}_f \in \mathcal{D}(\lambda)$.

Backlash hysteresis. Let $h \in \mathbb{R}_+$ be arbitrary. Define the function $b_h : \mathbb{R}^2 \to \mathbb{R}$ by

$$b_h(v, w) = \max\{v - h, \min\{v + h, w\}\}. \tag{2.1}$$

We note that

$$b_h(v, w) \in [v - h, v + h] \quad \forall\, v, w \in \mathbb{R}, \tag{2.2}$$

$$b_h(v, w) = w \quad \forall\, (v, w) \in \{(z_1, z_2) \,|\, z_1 \in \mathbb{R}, z_2 \in [z_1 - h, z_1 + h]\}, \tag{2.3}$$

$$(b_h(v_1, w) - b_h(v_2, w))(v_1 - v_2) \geq 0 \quad \forall\, v_1, v_2, w \in \mathbb{R}. \tag{2.4}$$

For each $\xi \in \mathbb{R}$, we introduce the discrete-time backlash operator $\mathcal{B}^d_{h,\,\xi} : F(\mathbb{Z}_+, \mathbb{R}) \to F(\mathbb{Z}_+, \mathbb{R})$ by defining recursively

$$(\mathcal{B}^d_{h,\,\xi}(u))(n) = \begin{cases} b_h(u(0), \xi) & \text{for } n = 0, \\ b_h(u(n), (\mathcal{B}^d_{h,\,\xi}(u))(n-1)) & \text{for } n \in \mathbb{Z}_+ \setminus \{0\}. \end{cases}$$

We remark that ξ plays the role of an "initial state." The discrete-time backlash operator $\mathcal{B}^d_{h,\,\xi}$ is illustrated in Figure 3.

We show that $\mathcal{B}^d_{h,\xi} \in \mathcal{D}(1)$. It is immediately clear from the definition that $\mathcal{B}^d_{h,\xi}$ satisfies (D1). Using (2.2) and (2.3), we see that (D2) holds. Combining (2.1)–(2.4) leads to

(2.5)
$$[(\mathcal{B}^d_{h,\xi}(u))(n+1) - (\mathcal{B}^d_{h,\xi}(u))(n)][u(n+1) - u(n)] \geq 0 \quad \forall\, u \in F(\mathbb{Z}_+, \mathbb{R}), \quad \forall\, n \in \mathbb{Z}_+.$$

It is not difficult to show (see [2, p. 42]) that

$$|b_h(v_1, w_1) - b_h(v_2, w_2)| \leq \max(|v_1 - v_2|, |w_1 - w_2|) \quad \forall\, v_1, v_2, w_1, w_2 \in \mathbb{R}.$$

Thus

$$|(\mathcal{B}^d_{h,\xi}(u))(n+1) - (\mathcal{B}^d_{h,\xi}(u))(n)| \leq |u(n+1) - u(n)| \quad \forall\, u \in F(\mathbb{Z}_+, \mathbb{R}), \quad \forall\, n \in \mathbb{Z}_+,$$

which, combined with (2.5), implies that (D3) holds for $\lambda = 1$. Note that $\operatorname{NVS} \mathcal{B}^d_{h,\xi} = \mathbb{R}$. By (2.2), for all $u \in F(\mathbb{Z}_+, \mathbb{R})$ and all $n \in \mathbb{Z}_+$, $(\mathcal{B}^d_{h,\xi}(u))(n) \in [u(n) - h, u(n) + h]$, showing that (D4) holds. Finally, it is clear that

$$v \in [b_h(v, w) - h, b_h(v, w) + h] \quad \forall\, v, w \in \mathbb{R},$$

and so

$$u(n) \in [(\mathcal{B}^d_{h,\xi}(u))(n) - h, (\mathcal{B}^d_{h,\xi}(u))(n) + h] \quad \forall\, u \in F(\mathbb{Z}_+, \mathbb{R}), \quad \forall\, n \in \mathbb{Z}_+,$$

showing that (D5) is satisfied. We have shown that (D1)–(D5) hold for $\mathcal{B}^d_{h,\xi}$ (with $\lambda = 1$), and hence $\mathcal{B}^d_{h,\xi} \in \mathcal{D}(1)$. We direct the reader to section 4 for a discussion of the backlash operator in a continuous-time setting.

3. Discrete-time integral control. Consider a single-input, single-output, discrete-time system

$$x(n+1) = Ax(n) + Bu(n), \quad x(0) = x_0 \in X, \tag{3.1a}$$
$$y(n) = Cx(n) + Du(n), \tag{3.1b}$$

evolving on a real Hilbert space X. Here $A \in L(X)$, $B \in L(\mathbb{R}, X)$, $C \in L(X, \mathbb{R})$, and $D \in \mathbb{R}$. A system of the form (3.1) is called *power-stable* if A is power-stable, i.e., there exist $M \geq 1$ and $\theta \in (0, 1)$ such that

$$\|A^n\| \leq M\theta^n \quad \forall\, n \in \mathbb{Z}_+.$$

The transfer function $\mathbf{G}$ of (3.1) is given by

$$\mathbf{G}(z) = C(zI - A)^{-1}B + D.$$

Suppose that system (3.1) is subject to a causal input nonlinearity $\Phi : F(\mathbb{Z}_+, \mathbb{R}) \to F(\mathbb{Z}_+, \mathbb{R})$, yielding the nonlinear system

$$x(n+1) = Ax(n) + B(\Phi(u))(n), \quad x(0) = x_0 \in X, \tag{3.2a}$$
$$y(n) = Cx(n) + D(\Phi(u))(n). \tag{3.2b}$$

Denoting the reference value by r, the control law

$$u(n+1) = u(n) + k(r - y(n)),$$

where k is a real parameter, then leads to the following nonlinear system of difference equations:

$$x(n+1) = Ax(n) + B(\Phi(u))(n), \quad x(0) = x_0 \in X, \tag{3.3a}$$

$$u(n+1) = u(n) + k(r - Cx(n) - D(\Phi(u))(n)), \quad u(0) = u_0 \in \mathbb{R}. \tag{3.3b}$$

If $\mathbf{G}$ is holomorphic and bounded on $\{z \in \mathbb{C} \,|\, |z| > \alpha\}$ for some $\alpha < 1$ (which is the case if (3.1) is power-stable) and $\mathbf{G}(1) > 0$, then it can be shown that

$$1 + k \operatorname{Re} \frac{\mathbf{G}(z)}{z-1} \geq 0 \quad \forall\, |z| > 1, \tag{3.4}$$

for all sufficiently small $k > 0$; see [16]. We define

$$K := \sup\{k > 0 \,|\, (3.4) \text{ holds}\}. \tag{3.5}$$

We can now state the main result of this section.

THEOREM 3.1. *Let $\lambda > 0$. Assume that $\Phi \in \mathcal{D}(\lambda)$, (3.1) is power-stable, $\mathbf{G}(1) > 0$, $k \in (0, K/\lambda)$, and $r \in \mathbb{R}$ is such that $\tilde{r} := r/\mathbf{G}(1) \in \operatorname{clos}(\operatorname{NVS}\Phi)$. Then for all $(x_0, u_0) \in X \times \mathbb{R}$, the solution (x, u) of (3.3) satisfies the following:*

(1) $\lim_{n\to\infty}(\Phi(u))(n) = \tilde{r}$;

(2) $\lim_{n\to\infty} x(n) = (I - A)^{-1}B\tilde{r}$;

(3) $\lim_{n\to\infty} y(n) = r$, *where* $y(n) = Cx(n) + D(\Phi(u))(n)$;

(4) *if* $\tilde{r} \in \operatorname{int}(\operatorname{clos}(\operatorname{NVS}\Phi))$, *then u is bounded.*

Proof. Denote the solution of (3.3) by (x, u), and introduce new variables by defining

$$z(n) := x(n) - (I - A)^{-1}B(\Phi(u))(n), \quad v(n) := (\Phi(u))(n) - \tilde{r} \quad \forall\, n \in \mathbb{Z}_+.$$

By Remark 2.1, part (4), there exists $d : \mathbb{Z}_+ \to [0, \lambda]$ such that $(\Phi(u))(n+1) - (\Phi(u))(n) = d(n)(u(n+1) - u(n))$ for all $n \in \mathbb{Z}_+$. Using the identity $A(I - A)^{-1} = (I - A)^{-1} - I$, a straightforward calculation yields

$$z(n+1) = Az(n) - (I - A)^{-1}Bw(n), \quad z(0) = z_0, \tag{3.6a}$$

$$v(n+1) = v(n) + w(n), \quad v(0) = v_0, \tag{3.6b}$$

where

$$w(n) = -kd(n)(Cz(n) + \mathbf{G}(1)v(n)),$$

and

$$z_0 := x_0 - (I - A)^{-1}B(\Phi(u))(0), \quad v_0 := (\Phi(u))(0) - \tilde{r}.$$

Choose $c \in (k\lambda, K)$, and define

$$\mathbf{H}(z) = -C(zI - A)^{-1}(I - A)^{-1}B + J,$$

where $J := 1/c - \mathbf{G}(1)/2$. Then

$$\mathbf{H}(z) = \frac{1}{z-1}(\mathbf{G}(z) - \mathbf{G}(1)) + J.$$

Since $c < K$, there exists $\varepsilon > 0$ such that

$$\frac{1}{c} + \operatorname{Re} \frac{\mathbf{G}(z)}{z-1} \geq \varepsilon \quad \forall\, |z| > 1,$$

and hence, using the identity

$$\operatorname{Re}\left(\frac{1}{e^{i\theta}-1}\right) = -\frac{1}{2} \quad \forall\, \theta \in (0, 2\pi),$$

we may conclude that

$$\operatorname{Re} \mathbf{H}(e^{i\theta}) \geq \varepsilon \quad \forall\, \theta \in [0, 2\pi).$$

An application of the discrete-time positive-real lemma (see the appendix) shows that there exist $P \in L(X)$, $P = P^* \geq 0$, $L \in L(\mathbb{R}, X)$, and $W \in \mathbb{R}$ such that

$$A^*PA - P = -LL^*, \tag{3.7a}$$

$$A^*P(I-A)^{-1}B = LW - C^*, \tag{3.7b}$$

$$W^2 = 2J - B^*(I-A^*)^{-1}P(I-A)^{-1}B. \tag{3.7c}$$

For $n \in \mathbb{Z}_+$, define

$$V(n) = \langle z(n), Pz(n) \rangle + \mathbf{G}(1)v(n)^2.$$

Using (3.6) and (3.7), we obtain for all $n \in \mathbb{Z}_+$

$$\begin{aligned}
V(n+1) - V(n) &= \langle z(n+1), Pz(n+1) \rangle - \langle z(n), Pz(n) \rangle + \mathbf{G}(1)(v(n+1)^2 - v(n)^2) \\
&= -(L^*z(n))^2 - 2(L^*z(n))Ww(n) + 2(Cz(n))w(n) \\
&\qquad + w(n)(2J - W^2)w(n) + \mathbf{G}(1)(w(n)^2 + 2w(n)v(n)) \\
&= -(L^*z(n))^2 - (Ww(n))^2 - 2(L^*z(n))Ww(n) \\
&\qquad + 2(Cz(n))w(n) + \frac{2}{c}w(n)^2 + 2\mathbf{G}(1)w(n)v(n) \\
&= -(L^*z(n) + Ww(n))^2 + 2(Cz(n))w(n) \\
&\qquad + \frac{2}{c}w(n)^2 - 2\mathbf{G}(1)kd(n)[\mathbf{G}(1)v(n)^2 + (Cz(n))v(n)] \\
&= -(L^*z(n) + Ww(n))^2 + \frac{2}{c}w(n)^2 - 2kd(n)(\mathbf{G}(1)v(n) + Cz(n))^2 \\
&= -(L^*z(n) + Ww(n))^2 - 2\left(kd(n) - \frac{k^2d(n)^2}{c}\right)(\mathbf{G}(1)v(n) + Cz(n))^2.
\end{aligned}$$

Summing from $n = 0$ to $n = \infty$ then gives

$$2\sum_{n=0}^{\infty}\left(kd(n) - \frac{k^2d(n)^2}{c}\right)(\mathbf{G}(1)v(n) + Cz(n))^2 \leq V(0) < \infty. \tag{3.8}$$

Now, since $c > k\lambda$ and $d(n) \in [0, \lambda]$, we have

$$kd(n) - \frac{k^2d(n)^2}{c} = kd(n)\left(1 - \frac{kd(n)}{c}\right) \geq kd(n)\left(1 - \frac{k\lambda}{c}\right) \geq k\frac{\delta}{\lambda}d(n)^2 \quad \forall\, n \in \mathbb{Z}_+,$$

where $\delta := 1 - k\lambda/c > 0$. Therefore, (3.8) implies that

$$d(Cz + \mathbf{G}(1)v) \in l^2(\mathbb{Z}_+), \tag{3.9}$$

and hence

$$w \in l^2(\mathbb{Z}_+). \tag{3.10}$$

Appealing to the fact that A is power-stable, we may conclude from (3.6a) and (3.10) that

$$z \in l^2(\mathbb{Z}_+). \tag{3.11}$$

Consequently, $Cz \in l^2(\mathbb{Z}_+)$, and hence, by (3.9) and the boundedness of d,

$$dv \in l^2(\mathbb{Z}_+). \tag{3.12}$$

From (3.11) and (3.12) we obtain that

$$(Cz)dv \in l^1(\mathbb{Z}_+). \tag{3.13}$$

Using (3.8), (3.11)–(3.13), and the boundedness of d it follows that

$$dv^2 \in l^1(\mathbb{Z}_+). \tag{3.14}$$

It follows from (3.6b) that, for all $m \in \mathbb{Z}_+$,

$$v(m+1)^2 = v(0)^2 + \sum_{n=0}^{m} w(n)^2 + 2\sum_{n=0}^{m} v(n)w(n). \tag{3.15}$$

Combining (3.15) with (3.10), (3.13), and (3.14) and recalling that $w = -kd(Cz + \mathbf{G}(1)v)$, we see that there exists a number $\nu \in \mathbb{R}_+$ such that

$$\lim_{n\to\infty} v(n)^2 = \nu. \tag{3.16}$$

In order to prove statement (1), it is sufficient to show that $\nu = 0$. Seeking a contradiction, suppose that $\nu > 0$. By (3.10), $\lim_{n\to\infty} w(n) = 0$, and thus we may conclude from (3.6b) that

$$\lim_{n\to\infty} (v(n+1) - v(n)) = 0. \tag{3.17}$$

Since $\nu > 0$, (3.16) and (3.17) yield that $v(n)$ does not change sign for sufficiently large n, and so

$$\lim_{n\to\infty} v(n) = \sqrt{\nu} \qquad \text{or} \qquad \lim_{n\to\infty} v(n) = -\sqrt{\nu}.$$

Assuming that $\lim_{n\to\infty} v(n) = -\sqrt{\nu}$ (the case $\lim_{n\to\infty} v(n) = \sqrt{\nu}$ can be dealt with in an entirely analogous fashion), we obtain that

$$\Phi_\infty := \lim_{n\to\infty} (\Phi(u))(n) < \tilde{r}, \tag{3.18}$$

and thus

$$\lim_{n\to\infty} x(n) = (I - A)^{-1} B\Phi_\infty. \tag{3.19}$$

It then follows from (3.3b), (3.18), and (3.19) that

(3.20)
$$\lim_{n\to\infty}(u(n+1)-u(n)) = k(r - C(I-A)^{-1}B\Phi_\infty - D\Phi_\infty) = k\mathbf{G}(1)(\tilde{r}-\Phi_\infty) > 0.$$

Therefore, $\lim_{n\to\infty} u(n) = \infty$, and u is ultimately nondecreasing, so by (D4) and the assumption that $\tilde{r} \in \operatorname{clos}(\operatorname{NVS}\Phi)$ we obtain

$$\Phi_\infty = \lim_{n\to\infty}(\Phi(u))(n) = \sup(\operatorname{NVS}\Phi) \geq \tilde{r},$$

contradicting (3.18). Therefore, $\lim_{n\to\infty} v(n) = 0$, and, consequently, $\lim_{n\to\infty}(\Phi(u))(n) = \tilde{r}$, which is statement (1).

Statement (2) follows immediately from statement (1). Statement (3) is an easy consequence of statements (1) and (2). Finally, to prove statement (4), let $\tilde{r} \in \operatorname{int}(\operatorname{clos}(\operatorname{NVS}\Phi))$. Then the boundedness of u follows immediately from statement (1) and (D5). □

We see from the proof of Theorem 3.1 that (D5) is needed only for statement (4).

One of the conditions imposed in Theorem 3.1 is that $r/\mathbf{G}(1) \in \operatorname{clos}(\operatorname{NVS}\Phi)$. The following proposition shows that this condition is close to being necessary for tracking insofar as, if tracking of r is achievable while maintaining the boundedness of $\Phi(u)$, then $r/\mathbf{G}(1) \in \operatorname{clos}(\operatorname{NVS}\Phi)$.

PROPOSITION 3.2. *Let $\lambda > 0$ and $r \in \mathbb{R}$. Suppose that $\Phi \in \mathcal{D}(\lambda)$, A is power-stable, and $\mathbf{G}(1) > 0$. If there exist an initial condition $x_0 \in X$ and a function $u \in F(\mathbb{Z}_+, \mathbb{R})$ such that $\Phi(u)$ is bounded and*

$$\lim_{n\to\infty}[Cx(n) + D(\Phi(u))(n)] = r\,,$$

where $x \in F(\mathbb{Z}_+, X)$ is given by (3.2a)*, then $r/\mathbf{G}(1) \in \operatorname{clos}(\operatorname{NVS}\Phi)$.*

Proof. Since $\Phi(u)$ is bounded and A is power-stable, x is bounded. Let $n \in \mathbb{Z}_+$, and define $y : \mathbb{Z}_+ \to \mathbb{R}$ by (3.2b); then

$$y(n) = C(x(n) - (I-A)^{-1}B(\Phi(u))(n)) + \mathbf{G}(1)(\Phi(u))(n),$$

and therefore

$$C(A-I)^{-1}(x(n+1)-x(n)) = y(n) - \mathbf{G}(1)(\Phi(u))(n).$$

For $p, m \in \mathbb{Z}_+$ with $p > m$, summing the above from m to $p-1$ gives

$$C(A-I)^{-1}(x(p)-x(m)) = \sum_{k=m}^{p-1}(y(k) - \mathbf{G}(1)(\Phi(u))(k)). \tag{3.21}$$

Seeking a contradiction, let us suppose that $r/\mathbf{G}(1) \notin \operatorname{clos}(\operatorname{NVS}\Phi)$. Since $\lim_{n\to\infty} y(n) = r$ and $\operatorname{clos}(\operatorname{NVS}\Phi)$ is an interval (see Remark 2.1, part (3)), there exist $\varepsilon > 0$, $\beta \in \{-1, 1\}$, and $m \in \mathbb{Z}_+$ such that

$$\beta(y(n) - \mathbf{G}(1)(\Phi(u))(n)) \geq \varepsilon \quad \forall\, n \geq m.$$

Combining the above with (3.21), it follows that

$$\beta C(A-I)^{-1}(x(n)-x(m)) = \sum_{k=m}^{n-1}\beta(y(k) - \mathbf{G}(1)(\Phi(u))(k)) \geq \varepsilon(n-m) \quad \forall\, n > m.$$

Therefore, $\lim_{n\to\infty} \beta C(A-I)^{-1}x(n) = \infty$, contradicting the boundedness of x. □

4. A class of continuous-time hysteresis operators and their discretizations. We call a function $f : \mathbb{R}_+ \to \mathbb{R}_+$ a *time transformation* if f is continuous and nondecreasing and satisfies $f(0) = 0$ and $\lim_{t\to\infty} f(t) = \infty$, i.e., f is continuous, nondecreasing, and surjective. We denote the set of all time transformations $f : \mathbb{R}_+ \to \mathbb{R}_+$ by $\mathcal{T}$. For all $\tau \in \mathbb{R}_+$, we define a (continuous-time) projection operator $\mathbf{Q}^c_\tau : F(\mathbb{R}_+, \mathbb{R}) \to F(\mathbb{R}_+, \mathbb{R})$ by

$$(\mathbf{Q}^c_\tau v)(t) = \begin{cases} v(t) & \text{for } 0 \le t \le \tau, \\ v(\tau) & \text{for } t > \tau. \end{cases}$$

In the following, let $\mathcal{F} \subset F(\mathbb{R}_+, \mathbb{R})$, $\mathcal{F} \neq \emptyset$. We introduce the following two assumptions on $\mathcal{F}$:

(F1) $v \circ f \in \mathcal{F}$ for all $v \in \mathcal{F}$ and all $f \in \mathcal{T}$;

(F2) $\mathbf{Q}^c_t(\mathcal{F}) \subset \mathcal{F}$ for all $t \in \mathbb{R}_+$.

We call an operator $\Phi : \mathcal{F} \to F(\mathbb{R}_+, \mathbb{R})$ *causal* if for all $v, w \in \mathcal{F}$ and all $\tau \in \mathbb{R}_+$ with $v(t) = w(t)$ for all $t \in [0, \tau]$ it follows that $(\Phi(v))(t) = (\Phi(w))(t)$ for all $t \in [0, \tau]$. An operator $\Phi : \mathcal{F} \to F(\mathbb{R}_+, \mathbb{R})$ is called *rate independent* if $\mathcal{F}$ satisfies (F1) and

$$(\Phi(v \circ f))(t) = (\Phi(v))(f(t)) \quad \forall\, v \in \mathcal{F}, \quad \forall\, f \in \mathcal{T}, \quad \forall\, t \in \mathbb{R}_+.$$

A functional $\varphi : \mathcal{F} \to \mathbb{R}$ is called *rate independent* if $\mathcal{F}$ satisfies (F1) and

$$\varphi(u \circ f) = \varphi(u) \quad \forall\, u \in \mathcal{F}, \quad \forall\, f \in \mathcal{T}.$$

DEFINITION 4.1. *Let $\mathcal{F} \subset F(\mathbb{R}_+, \mathbb{R})$, $\mathcal{F} \neq \emptyset$. An operator $\Phi : \mathcal{F} \to F(\mathbb{R}_+, \mathbb{R})$ is called a hysteresis operator if $\mathcal{F}$ satisfies* (F1) *and Φ is causal and rate independent.*

For $\mathcal{F} \subset F(\mathbb{R}_+, \mathbb{R})$, $\mathcal{F} \neq \emptyset$, let $\mathcal{F}^{\mathrm{uc}}$ denote the set of all ultimately constant $u \in \mathcal{F}$, i.e.,

$$\mathcal{F}^{\mathrm{uc}} = \{u \in \mathcal{F} \,|\, u \text{ is ultimately constant}\}.$$

Clearly, if $\mathcal{F}$ satisfies (F2), then $\mathcal{F}^{\mathrm{uc}} \neq \emptyset$. Moreover, if $\mathcal{F}$ satisfies (F1), then so does $\mathcal{F}^{\mathrm{uc}}$. The proof of the following proposition can be found in [10].

PROPOSITION 4.2. *Let $\mathcal{F} \subset F(\mathbb{R}_+, \mathbb{R})$, $\mathcal{F} \neq \emptyset$, and assume that* (F1) *and* (F2) *are satisfied. If $\Phi : \mathcal{F} \to F(\mathbb{R}_+, \mathbb{R})$ is a hysteresis operator, then the following statements hold:*

(1) *for all $v \in \mathcal{F}$ and all $\tau \in \mathbb{R}_+$*

$$(\Phi(\mathbf{Q}^c_\tau v))(t) = (\Phi(v))(\tau) \quad \forall\, t \ge \tau;$$

(2) *the functional*

$$\varphi : \mathcal{F}^{\mathrm{uc}} \to \mathbb{R}, \quad v \mapsto \lim_{t\to\infty} (\Phi(v))(t) \tag{4.1}$$

is rate independent and satisfies

$$(\Phi(v))(t) = \varphi(\mathbf{Q}^c_t v) \quad \forall\, v \in \mathcal{F}, \quad \forall\, t \in \mathbb{R}_+. \tag{4.2}$$

Conversely, if $\varphi : \mathcal{F}^{\mathrm{uc}} \to \mathbb{R}$ is a rate independent functional, then $\Phi : \mathcal{F} \to F(\mathbb{R}_+, \mathbb{R})$ given by (4.2) *is a hysteresis operator and satisfies*

$$\lim_{t\to\infty} (\Phi(v))(t) = \varphi(v) \quad \forall\, v \in \mathcal{F}^{\mathrm{uc}}. \tag{4.3}$$

For a hysteresis operator $\Phi : \mathcal{F} \to F(\mathbb{R}_+, \mathbb{R})$, we call the rate independent functional φ defined by (4.1) the *representing functional* of Φ.

For any $v \in F(\mathbb{R}_+, \mathbb{R})$ and any $t \in \mathbb{R}_+$, we define

$$M(v,t) := \{\tau \in (t,\infty) \,|\, v \text{ is monotone on } (t,\tau)\}.$$

If v is piecewise monotone, then $M(v,t) \neq \emptyset$ for all $t \in \mathbb{R}_+$ and the *standard monotonicity partition* $t_0 < t_1 < t_2 < \cdots$ of v is defined recursively by setting $t_0 = 0$ and $t_{i+1} = \sup M(v,t_i)$ for all $i \in \mathbb{Z}_+$ such that $M(v,t_i)$ is bounded. If v is piecewise monotone and ultimately constant, then the standard monotonicity partition of v is finite.

The space of all piecewise monotone $v \in C(\mathbb{R}_+, \mathbb{R})$ is denoted by $C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$. We define $C^{\mathrm{uc}}_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$ to be the space of all ultimately constant $v \in C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$. Let $F^{\mathrm{uc}}(\mathbb{Z}_+, \mathbb{R})$ denote the space of ultimately constant $v : \mathbb{Z}_+ \to \mathbb{R}$. We define the *restriction operator* $R : C^{\mathrm{uc}}_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R}) \to F^{\mathrm{uc}}(\mathbb{Z}_+, \mathbb{R})$ by

$$(R(v))(k) = \begin{cases} v(t_k) & \text{for } k \in [0,m] \cap \mathbb{Z}_+, \\ \lim_{t\to\infty} v(t) & \text{for } k \in \mathbb{Z}_+ \setminus [0,m], \end{cases}$$

where $0 = t_0 < t_1 < \cdots < t_m$ is the standard monotonicity partition of v.

In the following, we want to extend hysteresis operators defined on $C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$ to spaces of piecewise continuous functions. This requires some preparation. For $\tau > 0$, we define the *prolongation operator* $P_\tau : F(\mathbb{Z}_+, \mathbb{R}) \to C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$ by letting $P_\tau u$ be the linear interpolate for the values $(P_\tau u)(i\tau) = u(i)$. Let $NPC(\mathbb{R}_+, \mathbb{R}) \subset PC(\mathbb{R}_+, \mathbb{R})$ denote the space of all *normalized piecewise continuous* functions $v : \mathbb{R}_+ \to \mathbb{R}$; that is, v is piecewise continuous and is right-continuous or left-continuous at each point $t \in \mathbb{R}_+$. The space of all piecewise monotone functions $v \in NPC(\mathbb{R}_+, \mathbb{R})$ is denoted by $NPC_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$, while $NPC^{\mathrm{uc}}_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$ denotes the space of ultimately constant $v \in NPC_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$. We note that $NPC_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$ and $NPC^{\mathrm{uc}}_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$ both satisfy (F1) and (F2). For $v \in NPC^{\mathrm{uc}}_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$, we define $v(\infty) := \lim_{\tau\to\infty} v(\tau)$.

Let $v \in NPC^{\mathrm{uc}}_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$, and let $0 = t_0 < t_1 < \cdots < t_m$ be the standard monotonicity partition of v. We define the operator $\rho : NPC^{\mathrm{uc}}_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R}) \to F^{\mathrm{uc}}(\mathbb{Z}_+, \mathbb{R})$ by

$$\rho(v) = (v(t_0), v(t_1-), v(t_1+), v(t_2-), v(t_2+), \dots, v(t_m-), v(t_m+), v(\infty), v(\infty), \dots).$$

For $\tau > 0$, define

$$R_e : NPC^{\mathrm{uc}}_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R}) \to F^{\mathrm{uc}}(\mathbb{Z}_+, \mathbb{R}), \quad v \mapsto R((P_\tau \circ \rho)(v)).$$

The operator R_e is an extension of R, and the definition of R_e is independent of τ (see [10]). The function v, shown in Figure 4, is a normalized piecewise continuous function which is piecewise monotone and ultimately constant, so $v \in NPC^{\mathrm{uc}}_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$. It has standard monotonicity partition $0 = t_0 < t_1 < t_2 < t_3 < t_4$,

$$\rho(v) = (v_0, v_7, v_6, v_4, v_4, v_5, v_3, v_7, v_2, v_1, v_1, v_1, \dots),$$

and

$$R_e(v) = (v_0, v_7, v_4, v_5, v_3, v_7, v_1, v_1, v_1, \dots).$$

For any rate independent $\varphi : C^{\mathrm{uc}}_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R}) \to \mathbb{R}$, we define

$$\varphi_e : NPC^{\mathrm{uc}}_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R}) \to \mathbb{R}, \quad v \mapsto \varphi((P_\tau \circ R_e)(v)), \tag{4.4}$$

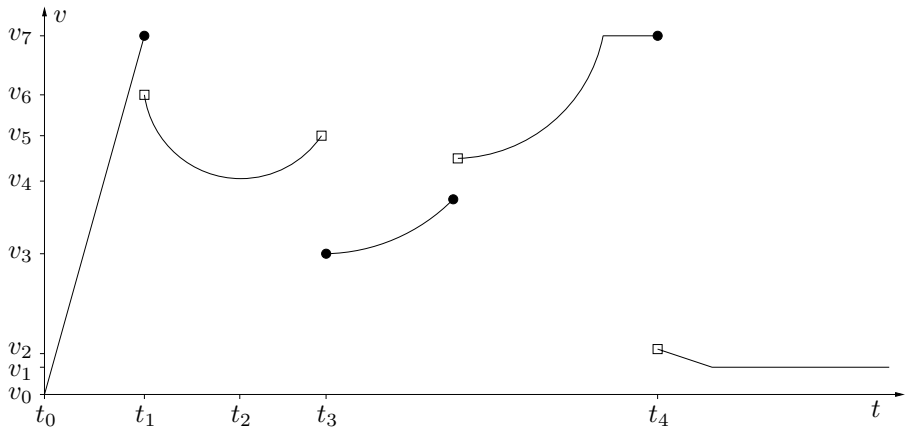

FIG. 4. *Example of a function in* $NPC^{\mathrm{uc}}_{\mathrm{pm}}(\mathbb{R}_+,\mathbb{R})$.

where $\tau > 0$. From [10] we know that φ_e does not depend on τ and that φ_e is a rate independent extension of φ.

Let $\Phi : C_{\mathrm{pm}}(\mathbb{R}_+,\mathbb{R}) \to C(\mathbb{R}_+,\mathbb{R})$ be a hysteresis operator, and let $\varphi : C^{\mathrm{uc}}_{\mathrm{pm}}(\mathbb{R}_+,\mathbb{R}) \to \mathbb{R}$ be the representing functional of Φ. Define

$$\Phi_e : NPC_{\mathrm{pm}}(\mathbb{R}_+,\mathbb{R}) \to F(\mathbb{R}_+,\mathbb{R})$$

by setting

$$(\Phi_e(v))(t) = \varphi_e(\mathbf{Q}^c_t\, v) \quad \forall\, t \in \mathbb{R}_+, \tag{4.5}$$

where φ_e is the extension of φ to $NPC^{\mathrm{uc}}_{\mathrm{pm}}(\mathbb{R}_+,\mathbb{R})$ given by (4.4).

Define $\mathcal{S}_\tau$ to be the set of all right-continuous step functions $v : \mathbb{R}_+ \to \mathbb{R}$ of step length $\tau > 0$. The following result was proved in [10].

PROPOSITION 4.3. *Let* $\Phi : C_{\mathrm{pm}}(\mathbb{R}_+,\mathbb{R}) \to C(\mathbb{R}_+,\mathbb{R})$ *be a hysteresis operator. Then*

(1) Φ_e *is an extension of* Φ;
(2) Φ_e *is a hysteresis operator with representing functional* φ_e;
(3) *for* $v, w \in NPC_{\mathrm{pm}}(\mathbb{R}_+,\mathbb{R})$ *and* $t \in \mathbb{R}_+$

$$R_e(\mathbf{Q}^c_t\, v) = R_e(\mathbf{Q}^c_t\, w) \quad \Longrightarrow \quad (\Phi_e(v))(t) = (\Phi_e(w))(t);$$

(4) $\Phi_e(NPC_{\mathrm{pm}}(\mathbb{R}_+,\mathbb{R})) \subset NPC(\mathbb{R}_+,\mathbb{R})$;
(5) $\Phi_e(\mathcal{S}_\tau) \subset \mathcal{S}_\tau$.

For given $v \in \mathcal{S}_\tau$ we introduce continuous piecewise monotone "approximations" $v_k \in C_{\mathrm{pm}}(\mathbb{R}_+,\mathbb{R})$ $(k = 1, 2, \dots)$ as follows: let $\varepsilon_k \in (0,\tau)$ with $\lim_{k\to\infty} \varepsilon_k = 0$, and define the following:

(i) if $t \in [(i+1)\tau - \varepsilon_k, (i+1)\tau)$, $i \in \mathbb{Z}_+$,

$$v_k(t) = v(i\tau) + \frac{v((i+1)\tau) - v(i\tau)}{\varepsilon_k}(t - (i+1)\tau + \varepsilon_k);$$

(ii) $v_k(t) = v(t)$ otherwise.

(See Figure 5 for an illustration.)

The following result shows that, for a given $v \in \mathcal{S}_\tau$, the functions $\Phi(v_k)$ approximate $\Phi_e(v)$ pointwise.

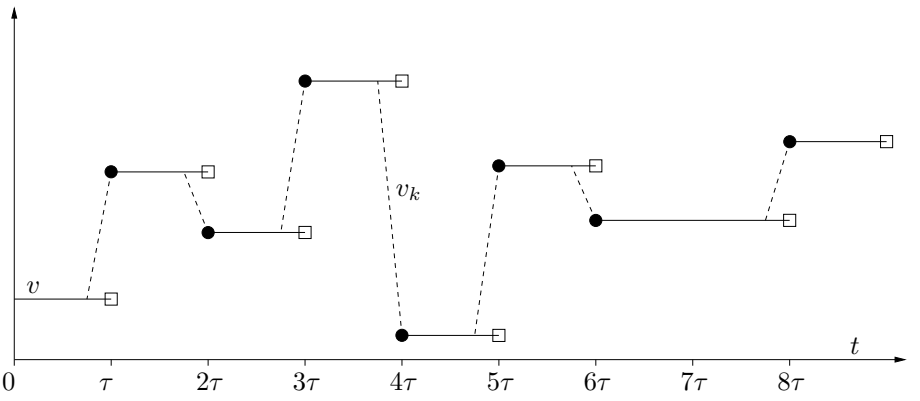

FIG. 5. *Example of $v \in \mathcal{S}_\tau$ and its approximation v_k.*

PROPOSITION 4.4. *Let $\Phi : C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R}) \to C(\mathbb{R}_+, \mathbb{R})$ be a hysteresis operator. Then*

$$(\Phi_e(v))(t) = \lim_{k\to\infty} (\Phi(v_k))(t) \quad \forall\, v \in \mathcal{S}_\tau, \quad \forall\, t \in \mathbb{R}_+.$$

Proof. Let $t \in \mathbb{R}_+$, and let $m \in \mathbb{Z}_+$ and $s \in [0, \tau)$ be such that $t = m\tau + s$. Choose k sufficiently large so that

$$t - m\tau = s < (1 - \varepsilon_k)\tau. \tag{4.6}$$

Then, using Proposition 4.3, part (5), we have

$$(\Phi_e(v))(t) = (\Phi_e(v))(m\tau) = \varphi_e(\mathbf{Q}^c_{m\tau}\, v) = \varphi((P_\tau \circ R_e)(\mathbf{Q}^c_{m\tau}\, v)). \tag{4.7}$$

Now $R_e(\mathbf{Q}^c_{m\tau}\, v) = R(\mathbf{Q}^c_{m\tau}\, v_k) = R_e(\mathbf{Q}^c_{m\tau}\, v_k)$, and hence, using (4.6), (4.7), Proposition 4.2, part (1), and Proposition 4.3, we obtain for all sufficiently large k

$$\begin{aligned}(\Phi_e(v))(t) &= \varphi((P_\tau \circ R_e)(\mathbf{Q}^c_{m\tau}\, v_k)) = \varphi_e(\mathbf{Q}^c_{m\tau}\, v_k) = (\Phi_e(v_k))(m\tau) \\ &= (\Phi(v_k))(m\tau) = (\Phi(v_k))(t). \qquad \square\end{aligned}$$

A function $v \in F(\mathbb{R}_+, \mathbb{R})$ is called *ultimately nondecreasing* if there exists $T \in \mathbb{R}_+$ such that v is nondecreasing on $[T, \infty)$. Let $\mathcal{F} \subset F(\mathbb{R}_+, \mathbb{R})$, $\mathcal{F} \neq \emptyset$. The *numerical value set* $\mathrm{NVS}\,\Phi$ of an operator $\Phi : \mathcal{F} \to F(\mathbb{R}_+, \mathbb{R})$ is defined by

$$\mathrm{NVS}\,\Phi := \{(\Phi(v))(t) \,|\, v \in \mathcal{F},\, t \in \mathbb{R}_+\}.$$

For $\alpha \geq 0$, $u \in C_{\mathrm{pm}}([0, \alpha], \mathbb{R})$, and $\delta_1, \delta_2 > 0$, we define $\mathcal{C}_{\mathrm{pm}}(u; \delta_1, \delta_2)$ to be the set of all $v \in C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$ such that

$$v(t) = u(t)\ \ \forall\, t \in [0, \alpha] \qquad \text{and} \qquad |v(t) - u(\alpha)| \leq \delta_1\ \ \forall\, t \in [\alpha, \alpha + \delta_2].$$

We introduce the following seven assumptions on the operator $\Phi : C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R}) \to C(\mathbb{R}_+, \mathbb{R})$:

(C1) Φ is causal;
(C2) Φ is rate independent;
(C3) $\Phi(AC(\mathbb{R}_+, \mathbb{R}) \cap C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})) \subset AC(\mathbb{R}_+, \mathbb{R})$;

(C4) Φ is monotone in the sense that, for all $v \in AC(\mathbb{R}_+, \mathbb{R}) \cap C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$ with $\Phi(v) \in AC(\mathbb{R}_+, \mathbb{R})$,

$$\frac{d}{dt}(\Phi(v))(t)\,\dot{v}(t) \geq 0, \quad \text{a.e. } t \in \mathbb{R}_+;$$

(C5) there exists $\lambda > 0$ such that for all $\alpha \in \mathbb{R}_+$, $u \in C_{\mathrm{pm}}([0,\alpha], \mathbb{R})$, there exist numbers $\delta_1, \delta_2 > 0$ such that for all $v, w \in \mathcal{C}_{\mathrm{pm}}(u; \delta_1, \delta_2)$

$$\sup_{t\in[\alpha,\alpha+\delta_2]} |(\Phi(v))(t) - (\Phi(w))(t)| \leq \lambda \sup_{t\in[\alpha,\alpha+\delta_2]} |v(t) - w(t)|;$$

(C6) if $v \in C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$ is ultimately nondecreasing and $\lim_{t\to\infty} v(t) = \infty$, then $\Phi(v)(t)$ and $\Phi(-v)(t)$ converge to $\sup \mathrm{NVS}\,\Phi$ and $\inf \mathrm{NVS}\,\Phi$, respectively, as $t \to \infty$;

(C7) if, for $v \in C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$, $L := \lim_{t\to\infty}(\Phi(v))(t)$ exists with $L \in \operatorname{int} \mathrm{NVS}\,\Phi$, then v is bounded.

REMARK 4.5. *We note that if* Φ *satisfies* (C1) *and* (C6)*, then* $\mathrm{NVS}\,\Phi$ *is an interval.*

If $\Phi : C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R}) \to C(\mathbb{R}_+, \mathbb{R})$ satisfies (C5), then any number $l > 0$ such that (C5) holds for $\lambda = l$ is called a *Lipschitz constant* of Φ.

DEFINITION 4.6. *Let* $\lambda > 0$*. The set of all operators* $\Phi : C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R}) \to C(\mathbb{R}_+, \mathbb{R})$ *satisfying* (C1)–(C7) *and having Lipschitz constant* λ *is denoted by* $\mathcal{C}(\lambda)$*.*

We consider four examples of hysteresis operators which satisfy (C1)–(C7).

Static nonlinearities. For $f \in F(\mathbb{R}, \mathbb{R})$, the corresponding static nonlinearity

$$F(\mathbb{R}_+, \mathbb{R}) \to F(\mathbb{R}_+, \mathbb{R}), \quad u \mapsto f \circ u$$

is in $\mathcal{C}(\lambda)$, provided that f is nondecreasing and globally Lipschitz with Lipschitz constant λ.

Relay. Relay (also called *passive* or *positive*) hysteresis, has been discussed in a mathematically rigorous context in a number of references; see, for example, [11] and [20]. To give a formal definition of relay, let $a_1, a_2 \in \mathbb{R}$ with $a_1 < a_2$, and let $\rho_1 : [a_1, \infty) \to \mathbb{R}$ and $\rho_2 : (-\infty, a_2] \to \mathbb{R}$ be nondecreasing and globally Lipschitz (both with Lipschitz constant $\lambda > 0$) and such that $\rho_1(a_1) = \rho_2(a_1)$ and $\rho_1(a_2) = \rho_2(a_2)$. For $v \in C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$ and $t \geq 0$ define

$$S(v,t) := v^{-1}(\{a_1, a_2\}) \cap [0,t], \quad \tau(v,t) := \begin{cases} \max S(v,t) & \text{if } S(v,t) \neq \emptyset, \\ -1 & \text{if } S(v,t) = \emptyset. \end{cases}$$

Following Macki, Nistri, and Zecca [20], for each $\xi \in \mathbb{R}$, we define an operator $\mathcal{R}_\xi : C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R}) \to C(\mathbb{R}_+, \mathbb{R})$ by

$$(\mathcal{R}_\xi(v))(t) = \begin{cases} \rho_2(v(t)) & \text{if } v(t) \leq a_1, \\ \rho_1(v(t)) & \text{if } v(t) \geq a_2, \\ \rho_2(v(t)) & \text{if } v(t) \in (a_1, a_2),\ \tau(v,t) \neq -1, \text{ and } v(\tau(v,t)) = a_1, \\ \rho_1(v(t)) & \text{if } v(t) \in (a_1, a_2),\ \tau(v,t) \neq -1, \text{ and } v(\tau(v,t)) = a_2, \\ \rho_1(v(t)) & \text{if } v(t) \in (a_1, a_2),\ \tau(v,t) = -1, \text{ and } \xi > 0, \\ \rho_2(v(t)) & \text{if } v(t) \in (a_1, a_2),\ \tau(v,t) = -1, \text{ and } \xi \leq 0. \end{cases}$$

The number ξ plays the role of an "initial state" which determines the output value $(\mathcal{R}_\xi(v))(t)$ if $v(s) \in (a_1, a_2)$ for all $s \in [0,t]$. The relay hysteresis operator $\mathcal{R}_\xi$ is

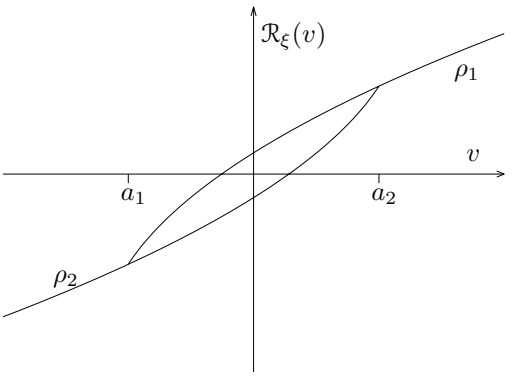

FIG. 6. *Relay hysteresis.*

illustrated in Figure 6. It is trivial that $\mathcal{R}_\xi$ is causal and rate independent (i.e., (C1) and (C2) hold). From [11] we know that $\mathcal{R}_\xi$ satisfies (C3)–(C7) and that λ is a Lipschitz constant of $\mathcal{R}_\xi$. It follows that $\mathcal{R}_\xi \in \mathcal{C}(\lambda)$.

Backlash. A discussion of the continuous-time *backlash* operator (also called the *play* operator) can be found in a number of references; see, for example, [1], [2], [8], and [11]. For all $h \in \mathbb{R}_+$ and all $\xi \in \mathbb{R}$, we define the continuous-time backlash operator $\mathcal{B}_{h,\xi} : C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R}) \to C(\mathbb{R}_+, \mathbb{R})$ by

$$(\mathcal{B}_{h,\xi}(v))(t) = \begin{cases} b_h(v(0), \xi) & \text{for } t = 0\,, \\ b_h(v(t), (\mathcal{B}_{h,\xi}(v))(t_i)) & \text{for } t_i < t \le t_{i+1}, \quad i \in \mathbb{Z}_+, \end{cases}$$

where the function $b_h : \mathbb{R}^2 \to \mathbb{R}$ is given by (2.1) and $0 = t_0 < t_1 < t_2 < \cdots$ is such that $\lim_{n\to\infty} t_n = \infty$ and v is monotone on each interval (t_i, t_{i+1}). We remark that ξ plays the role of an "initial state." It is not difficult to show that the definition is independent of the choice of the partition (t_i); see [11]. The diagram illustrating how $\mathcal{B}_{h,\xi}$ acts is the same as in the discrete-time case; see Figure 3. It is trivial that $\mathcal{B}_{h,\xi}$ is causal (i.e., $\mathcal{B}_{h,\xi}$ satisfies (C1)). Furthermore, it is well known and easy to check that $\mathcal{B}_{h,\xi}$ is rate independent (i.e., $\mathcal{B}_{h,\xi}$ satisfies (C2)). From [11] we know that $\mathcal{B}_{h,\xi}$ satisfies (C3)–(C7) and that $\lambda = 1$ is a Lipschitz constant of $\mathcal{B}_{h,\xi}$. Therefore, we may conclude that $\mathcal{B}_{h,\xi} \in \mathcal{C}\,(1)$.

Elastic-plastic. The *elastic-plastic* operator (also called the *stop* operator) has been discussed in a mathematically rigorous context in a number of references; see, for example, [1], [2], [8], and [11]. To give a formal definition of the elastic-plastic operator, define for each $h \in \mathbb{R}_+$ the function $e_h : \mathbb{R} \to \mathbb{R}$ by

$$e_h(w) = \min\{h, \max\{-h, w\}\}.$$

For all $h \in \mathbb{R}_+$ and all $\xi \in \mathbb{R}$, we define an operator $\mathcal{E}_{h,\xi} : C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R}) \to C(\mathbb{R}_+, \mathbb{R})$ by

$$(\mathcal{E}_{h,\xi}(v))(t) = \begin{cases} e_h(v(0) - \xi) & \text{for } t = 0, \\ e_h(v(t) - v(t_i) + (\mathcal{E}_{h,\xi}(v))(t_i)) & \text{for } t_i < t \le t_{i+1}, \quad i \in \mathbb{Z}_+, \end{cases}$$

where $0 = t_0 < t_1 < t_2 < \cdots$ is such that $\lim_{n\to\infty} t_n = \infty$ and v is monotone on each interval (t_i, t_{i+1}). Again, ξ plays the role of an "initial state." The backlash and

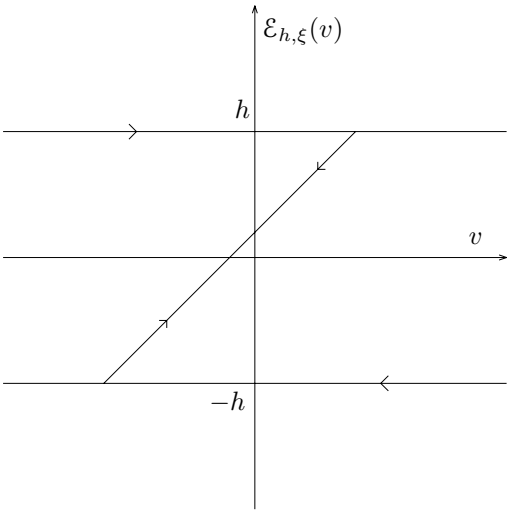

FIG. 7. *Elastic-plastic hysteresis.*

elastic-plastic operators are closely related:

$$\mathcal{E}_{h,\xi}(v) + \mathcal{B}_{h,\xi}(v) = v \quad \forall\, v \in C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R}); \tag{4.8}$$

see [2, p. 44]. The elastic-plastic operator $\mathcal{E}_{h,\xi}$ is illustrated in Figure 7. Since $\mathcal{B}_{h,\xi}$ is causal and rate independent, it follows from (4.8) that $\mathcal{E}_{h,\xi}$ is causal and rate independent; i.e., (C1) and (C2) hold. From [11] we know that $\mathcal{E}_{h,\xi}$ satisfies (C3)–(C7) and that $\lambda = 2$ is a Lipschitz constant of $\mathcal{E}_{h,\xi}$. Therefore, $\mathcal{E}_{h,\xi} \in \mathcal{C}(2)$.

We remark that a large class of Prandtl and Preisach hysteresis operators satisfy (C1)–(C7); see [11] for details.

The following lemma will be needed later in this section.

LEMMA 4.7. *Let $\Phi \in \mathcal{C}(\lambda)$; then for every $v \in C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R}) \cap AC(\mathbb{R}_+, \mathbb{R})$ and $t_2 > t_1 \geq 0$, there exists a constant $\eta \in [0, \lambda]$ such that*

$$v \text{ affine linear on } [t_1, t_2] \quad \Longrightarrow \quad (\Phi(v))(t_2) - (\Phi(v))(t_1) = \eta(v(t_2) - v(t_1)).$$

Proof. Let $\Phi \in \mathcal{C}(\lambda)$, $v \in C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R}) \cap AC(\mathbb{R}_+, \mathbb{R})$, and $t_2 > t_1 \geq 0$, and assume that v is affine linear on $[t_1, t_2]$. By Proposition 4.2, part (1) and [11, Lemma 3.2, part (c)] there exists a measurable function $d : \mathbb{R}_+ \to [0, \lambda]$ such that

$$(\Phi(v))(t_2) - (\Phi(v))(t_1) = \int_{t_1}^{t_2} d(t)\dot{v}(t)\, dt. \tag{4.9}$$

Since v is affine linear on $[t_1, t_2]$, $\dot{v} \equiv (v(t_2) - v(t_1))/(t_2 - t_1)$ on (t_1, t_2). Combining this with (4.9) gives

$$(\Phi(v))(t_2) - (\Phi(v))(t_1) = \frac{v(t_2) - v(t_1)}{t_2 - t_1} \int_{t_1}^{t_2} d(t)\, dt = \eta(v(t_2) - v(t_1)),$$

where $\eta = 1/(t_2 - t_1) \int_{t_1}^{t_2} d(t)\, dt \in [0, \lambda]$. ∎

In the following section, we want to apply the discrete-time result of section 3 to the sampled-data low-gain integral control problem. Therefore, we need to investigate

the properties of the discretization of a given $\Phi^c \in \mathcal{C}(\lambda)$ obtained by standard hold and sampling operations. To this end, define the hold operator $H : F(\mathbb{Z}_+, \mathbb{R}) \to \mathcal{S}_\tau$ by

$$(Hu)(n\tau + t) = u(n) \quad \forall\, u \in F(\mathbb{Z}_+, \mathbb{R}), \quad \forall\, n \in \mathbb{Z}_+, \quad \forall\, t \in [0, \tau), \tag{4.10}$$

and the sampling operator $S : PC(\mathbb{R}_+, \mathbb{R}) \to F(\mathbb{Z}_+, \mathbb{R})$ by

$$(Sv)(n) = v(n\tau) \quad \forall\, v \in PC(\mathbb{R}_+, \mathbb{R}), \quad \forall\, n \in \mathbb{Z}_+, \tag{4.11}$$

where $\tau > 0$ denotes the sampling period.

Let $\Phi^c : C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R}) \to C(\mathbb{R}_+, \mathbb{R})$ be a continuous-time hysteresis operator. We define a discrete-time operator $\Phi : F(\mathbb{Z}_+, \mathbb{R}) \to F(\mathbb{Z}_+, \mathbb{R})$ by

$$\Phi := S\, \Phi_e^c\, H, \tag{4.12}$$

where Φ_e^c denotes the extension of Φ^c to $NPC_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$ given by (4.5). We remark that as a simple consequence of the rate independence of Φ_e^c (cf. Proposition 4.3) the definition of Φ is independent of the choice of the sampling period τ. For $v \in \mathcal{S}_\tau$, we have $HSv = v$, and so, by Proposition 4.3, part (5),

$$\Phi_e^c\, H = H\, \Phi. \tag{4.13}$$

The proof of the following result can be found in [10].

Lemma 4.8. *Let $\Phi^c : C_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R}) \to C(\mathbb{R}_+, \mathbb{R})$ be a hysteresis operator, and define the operator $\Phi : F(\mathbb{Z}_+, \mathbb{R}) \to F(\mathbb{Z}_+, \mathbb{R})$ by* (4.12). *Then*

$$(\Phi(u))(n) = (\Phi^c(P_\tau u))(n\tau) \quad \forall\, u \in F(\mathbb{Z}_+, \mathbb{R}), \quad \forall\, n \in \mathbb{Z}_+, \tag{4.14}$$

and $\mathrm{NVS}\, \Phi = \mathrm{NVS}\, \Phi^c$.

The following proposition is the main result of this section.

Proposition 4.9. *Let $\Phi^c \in \mathcal{C}(\lambda)$, and define $\Phi : F(\mathbb{Z}_+, \mathbb{R}) \to F(\mathbb{Z}_+, \mathbb{R})$ by* (4.12). *Then $\Phi \in \mathcal{D}(\lambda)$.*

Proof. Note that (D1) (causality) follows from (4.14) and the causality of Φ^c, while (D2) follows from Proposition 4.2, part (1) and (4.14). Furthermore, let $u \in F(\mathbb{Z}_+, \mathbb{R})$, $n \in \mathbb{Z}_+$, and suppose that $u(n+1) \neq u(n)$. Then by (4.14) and Lemma 4.7 there exists a constant $\eta \in [0, \lambda]$ such that

$$\begin{aligned} (\Phi(u))(n+1) - (\Phi(u))(n) &= (\Phi^c(P_\tau\, u))((n+1)\tau) - (\Phi^c(P_\tau\, u))(n\tau) \\ &= \eta[(P_\tau\, u)((n+1)\tau) - (P_\tau\, u)(n\tau)] \\ &= \eta[u(n+1) - u(n)], \end{aligned}$$

and thus (D3) holds. Since $\mathrm{NVS}\, \Phi = \mathrm{NVS}\, \Phi^c$ (by Lemma 4.8) and Φ^c satisfies (C6), (D4) follows from an application of (4.14). Finally, to show that (D5) is satisfied, let $u \in F(\mathbb{Z}_+, \mathbb{R})$ be such that $\lim_{n\to\infty}(\Phi(u))(n)$ exists and

$$L := \lim_{n\to\infty} (\Phi(u))(n) \in \mathrm{int}\,(\mathrm{clos}\,(\mathrm{NVS}\, \Phi)). \tag{4.15}$$

By (4.14),

$$\lim_{n\to\infty} (\Phi^c(P_\tau\, u))(n\tau) = L. \tag{4.16}$$

Clearly $P_\tau u$ is monotone on $[n\tau,(n+1)\tau]$ for each $n \in \mathbb{Z}_+$, and therefore, by the fact that Φ^c satisfies (C4), $\Phi^c(P_\tau u)$ is monotone on $[n\tau,(n+1)\tau]$ for each $n \in \mathbb{Z}_+$. Combining this with (4.16) shows that

$$\lim_{t\to\infty}(\Phi^c(P_\tau u))(t) = L.$$

By Remark 4.5, $\mathrm{NVS}\Phi^c$ is an interval; since, by Lemma 4.8, $\mathrm{NVS}\Phi = \mathrm{NVS}\Phi^c$, it follows from (4.15) that $L \in \operatorname{int}(\mathrm{NVS}\,\Phi^c)$. Now Φ^c satisfies (C7), and so we may conclude that $P_\tau u$ and thus u are bounded. □

5. Sampled-data integral control in the presence of input hysteresis. In the following, the underlying linear system is assumed to be a single-input, single-output, continuous-time, regular system Σ (for details on regular systems see Weiss [25], [26], [27], [28]) with state-space X (a real Hilbert space) and with generating operators (A^c, B^c, C^c, D^c). This means, in particular, that A^c generates a strongly continuous semigroup $\mathbf{T} = (\mathbf{T}_t)_{t\ge 0}$, $C^c \in L(X_1, \mathbb{R})$ is an admissible observation operator for $\mathbf{T}$, and $B^c \in L(\mathbb{R}, X_{-1})$ is an admissible control operator for $\mathbf{T}$. Here X_1 denotes the domain of A^c endowed with the graph norm, and X_{-1} denotes the completion of X with respect to the norm $\|x\|_{-1} = \|(s_0 I - A^c)^{-1}x\|$, where s_0 is any fixed element in the resolvent set of A^c. The norm on X is denoted by $\|\cdot\|$, while $\|\cdot\|_1$ and $\|\cdot\|_{-1}$ denote the norms on X_1 and X_{-1}, respectively. Then $X_1 \hookrightarrow X \hookrightarrow X_{-1}$, and $\mathbf{T}$ restricts (respectively, extends) to a strongly continuous semigroup on X_1 (respectively, X_{-1}). The exponential growth constant

$$\omega(\mathbf{T}) := \lim_{t\to\infty}\frac{1}{t}\ln\|\mathbf{T}_t\|$$

is the same on all three spaces. The generator of $\mathbf{T}$ on X_{-1} is an extension of A^c to X (which is bounded as an operator from X to X_{-1}). We shall use the same symbol $\mathbf{T}$ (respectively, A^c) for the original semigroup (respectively, its generator) and the associated restrictions and extensions. With this convention, we may write $A^c \in L(X, X_{-1})$. Considered as a generator on X_{-1}, the domain of A^c is X.

We regard a regular system Σ as synonymous with its generating operators and simply write $\Sigma = (A^c, B^c, C^c, D^c)$. The regular system is said to be *exponentially stable* if the semigroup $\mathbf{T}$ is exponentially stable, that is, $\omega(\mathbf{T}) < 0$. The control operator B^c (respectively, observation operator C^c) is said to be *bounded* if $B^c \in L(\mathbb{R}, X)$ (respectively, $C^c \in L(X, \mathbb{R})$); otherwise, B^c (respectively, C^c) is said to be *unbounded*. In terms of the generating operators (A^c, B^c, C^c, D^c), the transfer function $\mathbf{G}^c(s)$ can be expressed as

$$\mathbf{G}^c(s) = C^c_L(sI - A^c)^{-1}B^c + D^c,$$

where C^c_L denotes the so-called Lebesgue extension of C^c. The transfer function $\mathbf{G}^c(s)$ is bounded and holomorphic in any half-plane $\operatorname{Re} s > \alpha$ with $\alpha > \omega(\mathbf{T})$. Moreover,

$$\lim_{s\to\infty,\, s\in\mathbb{R}} \mathbf{G}^c(s) = D^c.$$

For any $x_0 \in X$ and $u^c \in L^2_{\mathrm{loc}}(\mathbb{R}_+, \mathbb{R})$, the state and output functions $x^c(\cdot)$ and $y^c(\cdot)$, respectively, satisfy the equations

$$\dot{x}^c(t) = A^c x^c(t) + B^c u^c(t), \quad x^c(0) = x_0, \tag{5.1a}$$

$$y^c(t) = C^c_L x^c(t) + D^c u^c(t) \tag{5.1b}$$

for almost all $t \geq 0$. The derivative on the left-hand side of (5.1a), of course, has to be understood in X_{-1}. In other words, if we consider the initial-value problem (5.1a) in the space X_{-1}, then for any $x_0 \in X$ and $u^c \in L^2_{\mathrm{loc}}(\mathbb{R}_+, \mathbb{R})$, (5.1a) has unique strong solution (in the sense of Pazy [24, p. 109]) given by the variation of parameters formula

$$x^c(t) = \mathbf{T}_t x_0 + \int_0^t \mathbf{T}_{t-\tau} B^c u^c(\tau)\, d\tau. \tag{5.2}$$

For future reference we state the following lemma, the proof of which can be found in [15].

LEMMA 5.1. *Assume that* $\mathbf{T}$ *is exponentially stable and that* $B^c \in L(\mathbb{R}, X_{-1})$ *is an admissible control operator for* $\mathbf{T}$. *If* $u^c \in L^\infty(\mathbb{R}_+, \mathbb{R})$ *is such that* $\lim_{t\to\infty} u^c(t) = u_\infty$ *exists, then for all* $x_0 \in X$ *the state trajectory* x^c *given by* (5.2) *satisfies*

$$\lim_{t\to\infty} \|x^c(t) + (A^c)^{-1} B^c u_\infty\| = 0.$$

The aim in this section is to show that for an exponentially stable, regular, linear, infinite-dimensional, continuous-time, single-input, single-output plant with transfer function $\mathbf{G}^c(s)$, subject to a continuous-time dynamic input nonlinearity $\Phi^c \in \mathcal{C}(\lambda)$, the output $y^c(t)$ of the sampled-data closed-loop system, shown in Figure 2, converges to the reference value r as $t \to \infty$, provided that $\mathbf{G}^c(0) > 0$, r is feasible in some natural sense, and $k > 0$ is sufficiently small.

Let $u \in F(\mathbb{Z}_+, \mathbb{R})$, and apply the continuous-time signal

$$u^c = Hu \tag{5.3}$$

(where H is the standard hold operator defined in (4.10)) to the continuous-time system given by (5.1). Then the state $x^c(n\tau + t)$ satisfies

$$x^c(n\tau + t) = \mathbf{T}_t x^c(n\tau) + (\mathbf{T}_t - I)(A^c)^{-1} B^c u(n) \quad \forall\, n \in \mathbb{Z}_+, \quad \forall\, t \in [0, \tau). \tag{5.4}$$

Accordingly, we define $x : \mathbb{Z}_+ \to X$ by

$$x(n) = x^c(n\tau). \tag{5.5}$$

Clearly, $\mathbf{T}_\tau \in L(X)$ and $(\mathbf{T}_\tau - I)(A^c)^{-1} B^c \in L(\mathbb{R}, X)$ define appropriate state-space operators for the state evolution of the discretization of (5.1a). However, in general, regularity guarantees only that $y^c \in L^2_{\mathrm{loc}}(\mathbb{R}_+, \mathbb{R})$ so that, even with piecewise constant input functions, standard sampling of the output is not defined. Moreover, even if the output function is continuous (in which case standard sampling is defined), in general the resulting discrete-time system will not have a bounded observation operator. We therefore distinguish two cases: bounded and unbounded continuous-time observation.

Bounded observation. Assume that $C^c = C^c_L \in L(X, \mathbb{R})$. If $x_0 \in X$ and u^c is given by (5.3), then the output y^c given by (5.1b) is piecewise continuous, the discontinuities being at $n\tau$. It is clear that y^c is right-continuous at $n\tau$ for all $n \in \mathbb{Z}_+$. We define

$$y := Sy^c \tag{5.6}$$

(where S is the standard sampling operator defined in (4.11)) and

$$\begin{pmatrix} A & B \\ C & D \end{pmatrix} := \begin{pmatrix} \mathbf{T}_\tau & (\mathbf{T}_\tau - I)(A^c)^{-1} B^c \\ C^c & D^c \end{pmatrix}. \tag{5.7}$$

The proof of the following proposition is an immediate consequence of Proposition 4.1 in [16].

PROPOSITION 5.2. *Suppose that* $\mathbf{T}_t$ *is exponentially stable and that the observation operator* C^c *is bounded. Let* $\tau > 0$ *and* $u \in F(\mathbb{Z}_+, \mathbb{R})$. *If* u^c *given by* (5.3) *is applied to* (5.1), *then* x *and* y *given by* (5.5) *and* (5.6), *respectively, satisfy* (3.1), *where* (A, B, C, D) *is given by* (5.7). *Moreover,* A *is power-stable, and, setting* $\mathbf{G}(z) = C(zI - A)^{-1}B + D$, *we have that*

$$\mathbf{G}(1) = C(I - A)^{-1}B + D = \mathbf{G}^c(0). \tag{5.8}$$

Let $\Phi^c \in \mathcal{C}(\lambda)$, and let Φ^c_e denote the extension of Φ^c to $NPC_{\mathrm{pm}}(\mathbb{R}_+, \mathbb{R})$ given by (4.5). Consider the continuous-time system (5.1) with continuous-time input nonlinearity Φ^c_e,

$$\dot{x}^c = A^c x^c + B^c \Phi^c_e(u^c), \quad x^c(0) = x_0 \in X, \tag{5.9a}$$

$$y^c = C^c_L x^c + D^c \Phi^c_e(u^c), \tag{5.9b}$$

controlled by the sampled-data integrator

$$u^c(t) = u(n) \quad \text{for } t \in [n\tau, (n+1)\tau), \quad n \in \mathbb{Z}_+, \tag{5.10a}$$

$$y(n) = y^c(n\tau), \quad n \in \mathbb{Z}_+, \tag{5.10b}$$

$$u(n+1) = u(n) + k(r - y(n)), \quad u(0) = u_0 \in \mathbb{R}, \quad n \in \mathbb{Z}_+. \tag{5.10c}$$

THEOREM 5.3. *Let* $\lambda > 0$. *Assume that* $\Phi^c \in \mathcal{C}(\lambda)$, C^c *is bounded,* $\mathbf{T}_t$ *is exponentially stable,* $\mathbf{G}^c(0) > 0$, *and* $r \in \mathbb{R}$ *is such that* $\tilde{r}^c := r/\mathbf{G}^c(0) \in \operatorname{clos}(\operatorname{NVS}\Phi^c)$. *Let* $K > 0$ *be defined by* (3.5), *where* $\mathbf{G}(z) = C(zI - A)^{-1}B + D$, *with* (A, B, C, D) *given by* (5.7). *Then, for all* $k \in (0, K/\lambda)$ *and all* $(x_0, u_0) \in X \times \mathbb{R}$, *the unique solution* $(x^c(\cdot), u^c(\cdot))$ *of the closed-loop system given by* (5.9) *and* (5.10) *satisfies the following:*

(1) $\lim_{t\to\infty}(\Phi^c_e(u^c))(t) = \tilde{r}^c$;
(2) $\lim_{t\to\infty} \|x^c(t) + (A^c)^{-1}B^c\tilde{r}^c\| = 0$;
(3) $\lim_{t\to\infty} y^c(t) = r$;
(4) *if* $\tilde{r}^c \in \operatorname{int}(\operatorname{NVS}\Phi^c)$, *then* u^c *is bounded.*

Proof. Let $(x^c(\cdot), u^c(\cdot))$ be the unique solution of the closed-loop system given by (5.9) and (5.10). Define $\Phi \in \mathcal{D}(\lambda)$ by (4.12), and so

$$(\Phi^c_e(u^c))(n\tau) = (\Phi^c_e(Hu))(n\tau) = (\Phi(u))(n) \quad \forall\, n \in \mathbb{Z}_+.$$

Note that by Lemma 4.8

$$\operatorname{NVS}\Phi = \operatorname{NVS}\Phi^c. \tag{5.11}$$

Defining $x \in F(\mathbb{Z}_+, \mathbb{R})$ by (5.5), it follows from Proposition 5.2 that (x, u) satisfies the closed-loop discrete-time equations (3.3), where (A, B, C, D) is given by (5.7). Therefore, using Theorem 3.1, Propositions 4.9 and 5.2, and (5.11), we see that for all $k \in (0, K/\lambda)$

$$\lim_{n\to\infty}(\Phi(u))(n) = \tilde{r}^c. \tag{5.12}$$

This implies that for all $k \in (0, K/\lambda)$, $\lim_{t\to\infty}(H(\Phi(u)))(t) = \tilde{r}^c$, and so by (4.13), $\lim_{t\to\infty}(\Phi^c_e(u^c))(t) = \tilde{r}^c$, which is statement (1). Statement (2) is a consequence of statement (1) and Lemma 5.1. Statement (3) follows easily from statements (1) and (2) and the boundedness of C^c. Finally, to prove statement (4), assume that $\tilde{r}^c \in \operatorname{int}\operatorname{NVS}\Phi^c$. Then, by (5.11), $\tilde{r}^c \in \operatorname{int}\operatorname{NVS}\Phi$. Boundedness of u and thus boundedness of u^c now follow immediately from (5.12) and the fact that (D5) holds for Φ (by Proposition 4.9). ∎

Unbounded observation. As mentioned earlier, in this case, we cannot define a sampled output via (5.6). Instead, we introduce a generalized sampling operation. In the following, let $w \in L^2([0,\tau],\mathbb{R})$ be a function satisfying the conditions

$$\text{(5.13)} \qquad \text{(i)} \quad \int_0^\tau w(t)\,dt = 1 \quad \text{and} \quad \text{(ii)} \quad \int_0^\tau w(t)\mathbf{T}_t\,x\,dt \in X_1 \quad \forall\, x \in X.$$

While condition (5.13) (ii) is difficult to check for general w, it is easy to show (using integration by parts) that (5.13) (ii) holds if there exists a partition $0 = t_0 < t_1 < \cdots < t_m = \tau$ such that $w|_{(t_{i-1},t_i)} \in W^{1,1}((t_{i-1},t_i),\mathbb{R})$ for $i = 1, 2, \ldots, m$.

We define a generalized sampling operation by

$$\text{(5.14)} \qquad y(n) = \int_0^\tau w(t)y^c(n\tau + t)\,dt \quad \forall\, n \in \mathbb{Z}_+.$$

Introducing the linear operator

$$L : X \to X_1, \quad x \mapsto \int_0^\tau w(t)\mathbf{T}_t\,x\,dt,$$

we define

$$\text{(5.15)} \qquad \begin{pmatrix} A & B \\ C & D \end{pmatrix} := \begin{pmatrix} \mathbf{T}_\tau & (\mathbf{T}_\tau - I)(A^c)^{-1}B^c \\ C^cL & C^cL(A^c)^{-1}B^c + \mathbf{G}^c(0) \end{pmatrix}.$$

The following result is an immediate consequence of Proposition 3.4 in [12].

PROPOSITION 5.4. *Suppose that $\mathbf{T}_t$ is exponentially stable. Let $\tau > 0$ and $u \in F(\mathbb{Z}_+,\mathbb{R})$. If u^c given by* (5.3) *is applied to* (5.1)*, then x and y given by* (5.5) *and* (5.14)*, respectively, satisfy* (3.1)*, where (A,B,C,D) is given by* (5.15)*. Moreover, A is power-stable, $C \in L(X,\mathbb{R})$, and, setting $\mathbf{G}(z) = C(zI - A)^{-1}B + D$,* (5.8) *is satisfied.*

Consider the following sampled-data low-gain controller for (5.9):

$$\text{(5.16a)} \qquad u^c(t) = u(n) \quad \text{for } t \in [n\tau,(n+1)\tau), \quad n \in \mathbb{Z}_+,$$

$$\text{(5.16b)} \qquad y(n) = \int_0^\tau w(t)y^c(n\tau + t)\,dt, \quad n \in \mathbb{Z}_+,$$

$$\text{(5.16c)} \qquad u(n+1) = u(n) + k(r - y(n)), \quad u(0) = u_0 \in \mathbb{R}, \quad n \in \mathbb{Z}_+.$$

THEOREM 5.5. *Let $\lambda > 0$. Assume that $\Phi^c \in \mathcal{C}(\lambda)$, $\mathfrak{L}^{-1}(\mathbf{G}^c)$ is a finite signed Borel measure on $\mathbb{R}_+$, $\mathbf{T}_t$ is exponentially stable, $\mathbf{G}^c(0) > 0$, and $r \in \mathbb{R}$ is such that $\tilde{r}^c := r/\mathbf{G}^c(0) \in \operatorname{clos}(\operatorname{NVS}\Phi^c)$. Let $K > 0$ be defined by* (3.5)*, where $\mathbf{G}(z) = C(zI - A)^{-1}B + D$, with (A,B,C,D) given by* (5.15)*. Then, for all $k \in (0, K/\lambda)$ and all $(x_0,u_0) \in X \times \mathbb{R}$, the unique solution $(x^c(\cdot),u^c(\cdot))$ of the closed-loop system given by* (5.9) *and* (5.16) *satisfies the following:*

(1) $\lim_{t\to\infty}(\Phi_e^c(u^c))(t) = \tilde{r}^c$;
(2) $\lim_{t\to\infty}\|x^c(t) + (A^c)^{-1}B^c\tilde{r}^c\| = 0$;
(3) $\lim_{t\to\infty}[r - y^c(t) + C_L^c\mathbf{T}_t x_0] = 0$;
(4) *if $\tilde{r}^c \in \operatorname{int}(\operatorname{NVS}\Phi^c)$, then u^c is bounded.*

REMARK 5.6. (1) *Since $C_L^c\mathbf{T}_t x_0$ converges exponentially to 0 as $t \to \infty$ for all $x_0 \in X_1$, it follows from statement* (3) *that the error $e^c(t) = r - y^c(t)$ converges to 0 for all $x_0 \in X_1$. If C^c is bounded, then this statement is true for all $x_0 \in X$. If C^c is unbounded and $x_0 \notin X_1$, then $e^c(t)$ does not necessarily converge to 0 as $t \to \infty$.*

However, it follows from the proof below that $e^c(t)$ *is small for large* t *in the sense that* $e^c(t) = e_1^c(t) + e_2^c(t)$*, where the function* e_1^c *is bounded with* $\lim_{t\to\infty} e_1^c(t) = 0$ *and the function* $t \mapsto e_2^c(t)\exp(\alpha t)$ *is in* $L^2(\mathbb{R}_+, \mathbb{R})$ *for some* $\alpha > 0$.

(2) *The assumption that* $\mathfrak{L}^{-1}(\mathbf{G}^c)$ *is a finite signed Borel measure on* $\mathbb{R}_+$ *is not very restrictive and seems to be satisfied in all practical examples of exponentially stable regular systems. In particular, this assumption is satisfied if* B^c *or* C^c *is bounded (see* [13, Lemma 2.3]*).*

Proof of Theorem 5.5. By using Proposition 5.4 instead of Proposition 5.2, all statements with the exception of (3) follow exactly as in the proof of Theorem 5.3. Due to the unboundedness of C^c, we cannot use statement (2) in order to show that $y^c(t)$ converges to r as $t \to \infty$. However, we have

$$y^c(t) = C_L^c \mathbf{T}_t x_0 + (\mathfrak{L}^{-1}(\mathbf{G}^c) \star \Phi_e^c(u^c))(t). \tag{5.17}$$

By assumption, $\mathfrak{L}^{-1}(\mathbf{G}^c)$ is a finite signed Borel measure, and since $\lim_{t\to\infty}(\Phi_e^c(u^c))(t) = \tilde{r}^c$ (by statement (1)), it follows from [5, Theorem 6.1, part (ii), p. 96] that

$$\lim_{t\to\infty} [\mathfrak{L}^{-1}(\mathbf{G}^c) \star \Phi_e^c(u^c)](t) = \mathbf{G}^c(0)\tilde{r}^c = r.$$

Combining this with (5.17) shows that statement (3) holds. □

6. Example: Sampled-data control of a diffusion process with output delay subject to input hysteresis. Consider a diffusion process (with diffusion coefficient $\kappa > 0$ and with Dirichlet boundary conditions) on the one-dimensional spatial domain $[0, 1]$, with scalar nonlinear pointwise control action (applied at point $x_1 \in (0, 1)$, via an operator $\Phi^c \in \mathcal{C}(\lambda)$) and delayed (delay $T \geq 0$) scalar observation generated by a spatial averaging of the delayed state over an ε-neighborhood of a point $x_2 \in (0, 1)$ with $x_2 > x_1$.

We formally write this single-input, single-output system as

$$\begin{aligned} z_t(t, x) &= \kappa z_{xx}(t, x) + \delta(x - x_1)(\Phi_e^c(u^c))(t)\,, \\ y^c(t) &= \frac{1}{2\varepsilon}\int_{x_2-\varepsilon}^{x_2+\varepsilon} z(t - T, x)\,dx, \end{aligned}$$

with boundary conditions

$$z(t, 0) = 0 = z(t, 1) \quad \forall\, t > 0.$$

For simplicity, we assume zero initial conditions

$$z(t, x) = 0 \quad \forall\,(t, x) \in [-T, 0] \times [0, 1].$$

With input $(\Phi_e^c(u^c))(\cdot)$ and output $y^c(\cdot)$, this example qualifies as a regular linear system with bounded observation and with transfer function given by

$$\mathbf{G}^c(s) = \frac{e^{-sT}\sinh\left(x_1\sqrt{s/\kappa}\right)\left[\cosh\left((1 - x_2 + \varepsilon)\sqrt{s/\kappa}\right) - \cosh\left((1 - x_2 - \varepsilon)\sqrt{s/\kappa}\right)\right]}{2\varepsilon s \sinh\sqrt{s/\kappa}}.$$

Since the observation is bounded, we may sample the output using the standard sampling operation given by (5.6). Further analysis (invoking application of the maximum principle for the heat equation, which, for brevity, we omit here) confirms the physical intuition that the impulse response $\mathfrak{L}^{-1}(\mathbf{G}^c)$ is nonnegative-valued. Consequently,

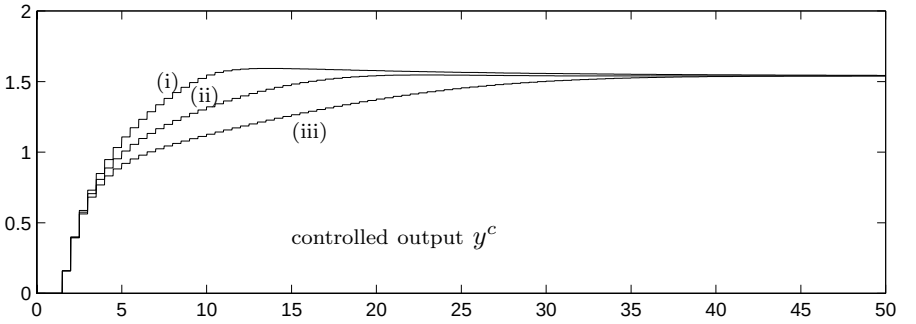

FIG. 8. *Controlled output.*

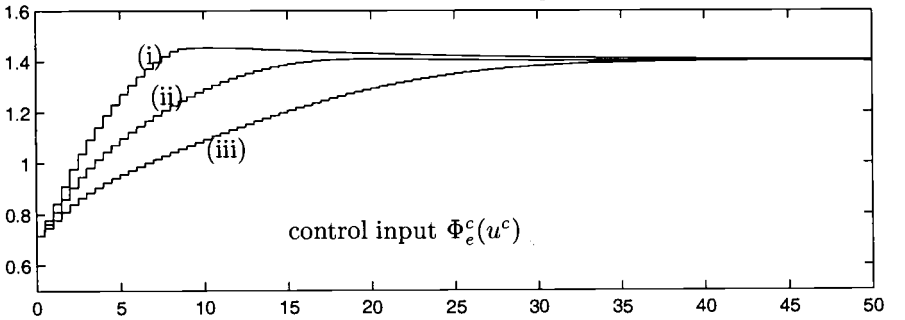

FIG. 9. *Control input.*

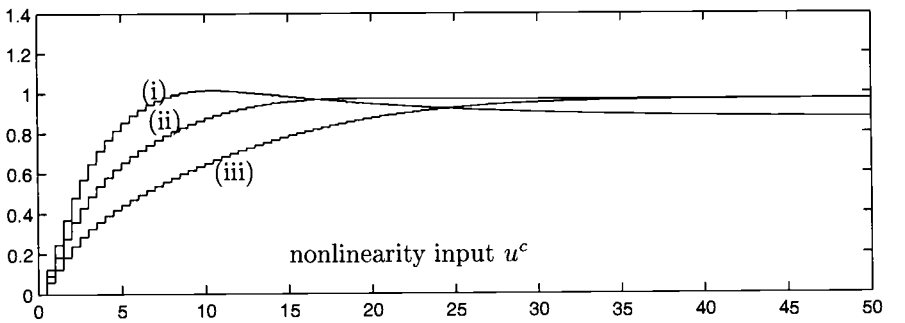

FIG. 10. *Input of relay hysteresis nonlinearity.*

the corresponding step-response is nondecreasing, and therefore we may apply a result by Özdemir and Townley [23] (see Remark 3.7 in [23]) to obtain the following lower bound for K:

$$K \geq \frac{1}{|(\mathbf{G}^c)'(0)|/\tau + 3\mathbf{G}^c(0)/2} =: K_L. \tag{6.1}$$

A simple calculation yields that

$$\mathbf{G}^c(0) = \frac{x_1(1-x_2)}{\kappa}, \quad (\mathbf{G}^c)'(0) = -\frac{x_1(1-x_2)(6T\kappa + 1 - \varepsilon^2 - x_1^2 - (1-x_2)^2)}{6\kappa^2},$$

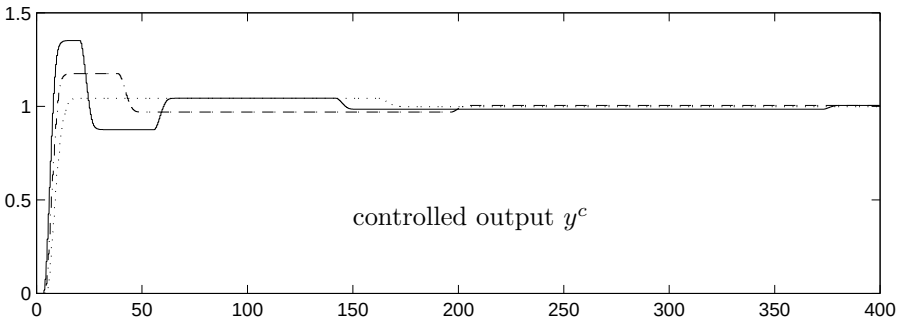

FIG. 11. *Controlled output.*

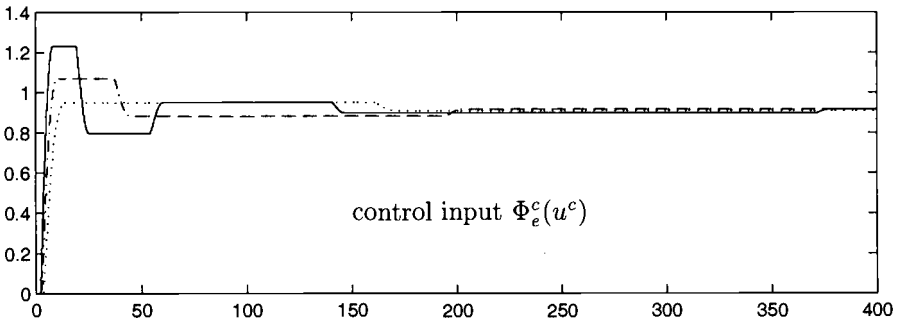

FIG. 12. *Control input.*

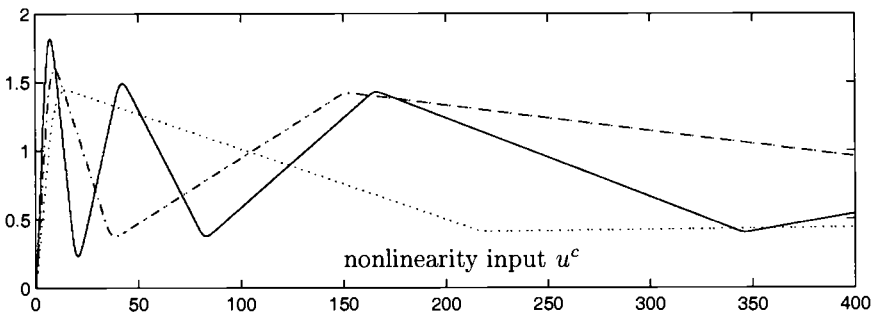

FIG. 13. *Input of backlash hysteresis nonlinearity.*

and therefore, using (6.1),

$$K \geq K_L = \frac{6\kappa^2\tau}{x_1(1-x_2)(6T\kappa + 1 - \varepsilon^2 - x_1^2 - (1-x_2)^2 + 9\kappa\tau)}.$$

By Theorem 5.3, for all $k \in (0, K_L/\lambda) \subset (0, K/\lambda)$, the sampled-data control (5.10) guarantees asymptotic tracking of all reference values r which are feasible in the sense that $r/\mathbf{G}^c(0) \in \operatorname{clos}(\operatorname{NVS}\Phi^c)$. For purposes of illustration, we adopt the following values:

$$\kappa = 0.1, \quad x_1 = \frac{1}{3}, \quad x_2 = \frac{2}{3}, \quad T = 1, \quad \tau = 0.5, \quad \varepsilon = 0.01.$$

For these specific values we obtain $K_L \approx 0.147$.

We consider relay and backlash hysteresis operators:

(a) Let $\Phi^c = \mathcal{R}_0$ be a relay hysteresis operator, where $a_1 = -1$, $a_2 = 1$, $\rho_1(v) = \sqrt{v + 1.1}$, and $\rho_2(v) = \sqrt{0.1} + \sqrt{2.1} - \sqrt{1.1 - v}$ (see section 4 for the definition and [11] for more details). Then $\Phi^c \in \mathcal{C}\,(1.6)$, and $\mathrm{NVS}\,\Phi^c = \mathrm{im}\,\rho_1 \cup \mathrm{im}\,\rho_2 = \mathbb{R}$. For reference value $r = 1.54$

$$\tilde{r}^c = \frac{r}{\mathbf{G}^c(0)} = \frac{r\kappa}{x_1(1 - x_2)} = 1.386 \in \mathrm{int}\,(\mathrm{NVS}\,\Phi^c).$$

In each of the following three cases of admissible controller gain,

$$\text{(i) } k = 0.08, \quad \text{(ii) } k = 0.06, \quad \text{(iii) } k = 0.04,$$

Figure 8 depicts the output behavior of the system under integral control, Figure 9 depicts the corresponding control input, and Figure 10 shows the input u^c of the relay nonlinearity. We see from Figure 10 that for (i), $\lim_{t\to\infty} u^c(t) = \rho_1^{-1}(\Phi_r^c)$, and for (ii) and (iii), $\lim_{t\to\infty} u^c(t) = \rho_2^{-1}(\Phi_r^c)$.

(b) Let $\Phi^c = \mathcal{B}_{0.5,\,0}$ be a backlash hysteresis operator (see section 4 for the definition and [11] for more details). Then $\Phi^c \in \mathcal{C}\,(1)$, and $\mathrm{NVS}\,\Phi^c = \mathbb{R}$. For reference value $r = 1$

$$\tilde{r}^c = \frac{r}{\mathbf{G}^c(0)} = \frac{r\kappa}{x_1(1 - x_2)} = 0.9 \in \mathrm{int}\,(\mathrm{NVS}\,\Phi^c).$$

In each of the following three cases of admissible controller gain,

$$\text{(i) } k = 0.145 \text{ (solid line)}, \quad \text{(ii) } k = 0.11 \text{ (dashdot line)}, \quad \text{(iii) } k = 0.08 \text{ (dotted line)},$$

Figure 11 depicts the output behavior of the system under sampled-data control, Figure 12 depicts the corresponding control input, and Figure 13 shows the input u^c of the backlash nonlinearity. We remark that the convergence of $u^c(t)$ as $t \to \infty$ is not guaranteed by Theorem 5.5, and in fact it seems that u^c does not converge in all three cases.

Figures 8–13 were generated using SIMULINK Simulation Software within MATLAB, wherein a truncated eigenfunction expansion, of order 10, was adopted to model the diffusion process.

Appendix. The infinite-dimensional discrete-time positive-real lemma. The following result is a version of the discrete-time infinite-dimensional positive-real lemma.

LEMMA A.1. *For a real Hilbert space X, let $A \in L(X)$, $B \in L(\mathbb{R}, X)$, $C \in L(X, \mathbb{R})$, and $D \in \mathbb{R}$, and set $\mathbf{G}(z) := C(zI - A)^{-1}B + D$. Assume that A is power-stable and*

$$\mathrm{Re}\,\mathbf{G}(e^{i\theta}) > 0 \quad \forall\, \theta \in [0, 2\pi).$$

Then there exist $P \in L(X)$, $P = P^* \geq 0$, $L \in L(\mathbb{R}, X)$, and $W \in \mathbb{R}$ such that

$$\begin{aligned} A^*PA - P &= -LL^*, \\ A^*PB &= C^* - WL, \\ W^2 &= 2D - B^*PB. \end{aligned}$$

Although Lemma A.1 should be well known, we were not able to locate it in the literature. Lemma A.1 can be obtained from Lemma A.2 (an infinite-dimensional

version of the continuous-time positive-real lemma stated below) combined with standard fractional transformation techniques (as used in [6] for the finite-dimensional case). For the sake of brevity, we omit the lengthy but straightforward details, which can be found in [21].

LEMMA A.2. *For a real Hilbert space X, let $A^c \in L(X)$, $B^c \in L(\mathbb{R}, X)$, $C^c \in L(X, \mathbb{R})$, and $D^c \in \mathbb{R}$; let $\sigma(A^c)$ denote the spectrum of A^c, and set $\mathbf{G}^c(s) := C^c(sI - A^c)^{-1}B^c + D^c$. Assume that $\sigma(A^c) \subset \{s \in \mathbb{C} \,|\, \operatorname{Re} s < 0\}$ and*

$$\operatorname{Re} \mathbf{G}^c(i\omega) > 0 \quad \forall\, \omega \in \mathbb{R} \cup \{\pm\infty\}. \tag{A.1}$$

Then there exist $P^c \in L(X)$, $P^c = (P^c)^* \geq 0$, $L^c \in L(\mathbb{R}, X)$, and $W^c > 0$ such that

$$P^c A^c + (A^c)^* P^c = -L^c (L^c)^*, \tag{A.2a}$$

$$P^c B^c = (C^c)^* - W^c L^c, \tag{A.2b}$$

$$2D^c = (W^c)^2. \tag{A.2c}$$

In a different form, Lemma A.2 is due to Yakubovich [30] (see also Wexler [29]). For completeness, we include a proof which is based on the positive-real Riccati equation theory developed in van Keulen [7].

Proof of Lemma A.2. By (A.1) we have that $D^c > 0$; defining $W^c := \sqrt{2D^c}$ gives (A.2c). Furthermore, again by (A.1), it follows from [7] (see Theorem 3.10 and Remark 3.14 in [7]) that there exists $Q^c \in L(X)$, $Q^c = (Q^c)^*$, such that

$$Q^c A^c + (A^c)^* Q^c = (1/W^c)^2 ((B^c)^* Q^c + C^c)^* \, ((B^c)^* Q^c + C^c).$$

Setting

$$P^c := -Q^c, \quad L^c := (1/W^c)(C^c - (B^c)^* P^c)^*$$

yields (A.2a) and (A.2b). Since $\sigma(A^c) \subset \{s \in \mathbb{C} \,|\, \operatorname{Re} s < 0\}$, it follows from (A.2a) by a routine argument that $P^c \geq 0$. ∎

ASYMPTOTIC PROPERTIES OF INPUT-OUTPUT OPERATORS NORM ASSOCIATED WITH SINGULARLY PERTURBED SYSTEMS WITH MULTIPLICATIVE WHITE NOISE*

VASILE DRAGAN†, TOADER MOROZAN†, AND PENG SHI‡

Abstract. In this paper, we study the problem of the asymptotic property of the norm of input-output operators related to a class of singularly perturbed stochastic linear systems. The system is under perturbation of multiplicative white noise. By using reduction order and boundary layer techniques, it is shown that the norm of the operator of the perturbed system is less than a given number γ when the small perturbation ε tends to zero if both the related norms of the reduced subsystem and the boundary layer subsystem are less than γ. Furthermore, a stabilizing robust controller is designed, which is independent of perturbation ε.

Key words. singularly perturbed system, input-output operator, stability, Riccati equation

1. Introduction.

Singularly perturbed control systems (SPCS) evolving in discrete time scale arise in many applications as well as in the construction of the difference approximations of SPCS evolving in continuous time. A great amount of effort has been made on SPCS in the past three decades; see, e.g., [34] and the references therein. A popular approach adopted to deal with these systems is based on the so-called reduced technique [41]. The composite design based on separate designs for slow and fast subsystems has been systematically reviewed in [47]. Moreover, a number of averaging-type methods allowing us to treat general SPCS in continuous time were developed recently (see [1, 2, 16, 17, 18, 19, 24, 26, 52]). These methods are much more adaptable to the discrete time scale. For example, a full analogy between the averaging procedures in problems of optimal control of SPCS evolving in continuous and discrete times was established in [25]. The research on singularly perturbed systems in the H_∞ sense is of great practical importance and has attracted a lot of interest in the last few years; see, e.g., [28, 48, 51]. The state-space solution of the H_∞ control problem [3] was used to approximate the solution of singularly perturbed H_∞ control using slow and fast subproblems [48]; see also [51]. A sequential procedure was described in [28] to decompose the problem into slow and fast subproblems, and a composite compensator was provided. Recently, the H_∞-optimal control of singularly perturbed linear systems, under either perfect state measurements or imperfect state measurements, for both finite and infinite horizons, has been investigated in [42, 43] via a differential game theoretic approach. In the meantime, [4] studied the asymptotic expansions for game theoretic Riccati equations and showed how they may be used in singularly perturbed H_∞ control. More recently, [13, 14] considered a construction of high-order approximations to a controller that guarantees a desired performance level on the basis of the exact decomposition of the full-order Riccati

equations to the reduced-order slow and fast equations. The problems of H_∞-norms and disturbance attenuation for systems with fast transients have been tackled by [5], and it has been shown that, for a singularly perturbed system, the H_∞ of the transfer function tends to the largest of the H_∞-norms for the boundary layer system and for the reduced slow model. More recently, a singularly perturbed zero-sum dynamic game with full information has been considered in [21], and it has been demonstrated that, when the singular perturbations parameter tends to zero, similar to singularly perturbed differential games [20], the upper (lower) value function of the dynamic game has a limit which coincides with a viscosity solution of a Hamilton–Jacobi–Isaacs-type equation. A composite linear controller has been designed in [49] based on the slow and fast problems such that both robust stability and a prescribed H_∞ performance for the full-order system are achieved, irrespective of the uncertainties. The problem of H_∞ control for singularly perturbed linear continuous-time systems with Markovian jump parameters has been studied in [12], in which the asymptotic structure of the composite mode-dependent controller is characterized.

It is worthwhile to mention that an important issue in the theory of SPCS is a justification of a so-called reduction technique approach (RTA). According to this approach, the fast variables are replaced by their steady states obtained with "frozen" slow variables and controls, and the slow dynamics is approximated by the corresponding reduced-order system. Although the RTA may fail to provide a proper approximation for the SPCS in a general case [17, 18, 19], its application was very successful in many important special cases (see [23, 35, 31, 32, 44, 45] and the references therein). In the differential game context, the efficiency of the RTA was established for singularly perturbed linear quadratic games in [22, 29] and for the singularly perturbed H^∞ problem with linear dynamics in [42, 43].

On the other hand, the control of stochastic systems with multiplicative white noise has received much attention in the past half century. For the results concerning the stability for stochastic systems with state-dependent noise, we refer readers to, for example, [7, 10, 36, 37] and the references therein. The linear quadratic problem associated to a linear stochastic system with multiplicative white noise was investigated; see, for example, [53, 54]. Robust stabilization for the above class of stochastic system was intensively studied in [9, 8] and the references therein.

In this paper, we investigate the asymptotic behavior of the input-output operator norm of the singularly perturbed linear continuous-time systems with multiplicative white noise. We consider the norms of both the slow/reduced subsystem and the fast/boundary layer subsystem. We demonstrate that when the perturbation ε goes to zero, then the input-output norm of the original system is less than the maximum of the norms corresponding to the both subsystems. A robust controller, which is free of perturbation ε, is designed to stabilizing the singularly perturbed stochastic systems.

2. Problem formulation. Let us consider the linear controlled system described by its differential equations

$$dx_1(t) = [A_{11}x_1(t) + A_{12}x_2(t) + B_1u(t)]dt + \sum_{j=1}^{N}[A_{11}^j x_1(t) + A_{12}^j x_2(t)]dw_j(t),$$

(2.1)

$$\varepsilon dx_2(t) = [A_{21}x_1(t) + A_{22}x_2(t) + B_2u(t)]dt + \varepsilon^\nu \sum_{j=1}^{N}[A_{21}^j x_1(t) + A_{22}^j x_2(t)]dw_j(t)$$

and the output

$$y(t) = C_1 x_1(t) + C_2 x_2(t) + Du(t), \tag{2.2}$$

where $x_i \in \mathbf{R}^{n_i}, i = 1, 2$, are state vectors, $u \in \mathbf{R}^m$ is the input vector, $A_{lk}, A_{lk}^j, B_l, C_k$, $l, k = 1, 2, j = 1, 2, \ldots, N, D$ are real matrices with corresponding dimensions, $\varepsilon > 0$ is a small parameter, and $\nu > \frac{1}{2}$. $w(t) = (w_1(t), w_2(t), \ldots, w_N(t)), t \geq 0$, is a standard Wiener process on a given probability space $(\Omega, \mathcal{F}, \mathcal{P})$.

We also consider the uncontrolled system associated to (2.1):

$$\begin{aligned} dx_1(t) &= [A_{11}x_1(t) + A_{12}x_2(t)]dt + \sum_{j=1}^{N} [A_{11}^j x_1(t) + A_{12}^j x_2(t)]dw_j(t), \\ \varepsilon dx_2(t) &= [A_{21}x_1(t) + A_{22}x_2(t)]dt + \varepsilon^\nu \sum_{j=1}^{N} [A_{21}^j x_1(t) + A_{22}^j x_2(t)]dw_j(t). \end{aligned} \tag{2.3}$$

For each $t_0 \geq 0$, we denote $\mathcal{X}(t_0)$ the set of n-dimensional random vectors ($n = n_1 + n_2$), which are $\mathcal{F}_{t_0}$-measurable, and

$$E[|x_0|^2] < \infty.$$

Obviously, $\mathbf{R}^n \subset \mathcal{X}(t_0)$. Let $\varepsilon > 0$ be fixed. Then, for each $t_0 \geq 0$ and $x_0 = \binom{x_{10}}{x_{20}} \in \mathcal{X}(t_0)$, system (2.3) has a unique solution

$$x(t, t_0, x_0, \varepsilon) = \begin{pmatrix} x_1(t, t_0, x_0, \varepsilon) \\ x_2(t, t_0, x_0, \varepsilon) \end{pmatrix},$$

which verifies the initial condition

$$x(t_0, t_0, x_0, \varepsilon) = x_0$$

(see, e.g., [15, 40, 54]). Moreover, the dependence $x_0 \to x(\cdot, t_0, x_0, \varepsilon)$ is linear.

Let $\Phi(t, t_0, \varepsilon) = (\Phi_1(t, t_0, \varepsilon) \quad \Phi_2(t, t_0, \varepsilon) \ldots \Phi_n(t, t_0, \varepsilon))$ be the $n \times n$ matrix having the columns $\Phi_j(t, t_0, \varepsilon) = x(t, t_0, e_j, \varepsilon), t \geq t_0 > 0, \varepsilon > 0, j = 1, 2, \ldots, n$. $e_j = (0, \ldots, 0, 1, 0, \ldots, 0)^*$ is a vector of the canonic basis of $\mathbf{R}^n$. Hence $t \to \Phi(t, t_0, \varepsilon)$ is a matrix solution of system (2.3) which verifies

$$\Phi(t_0, t_0, \varepsilon) = I_n.$$

From the uniqueness of the solution, it follows that

$$x(t, t_0, x_0, \varepsilon) = \Phi(t, t_0, \varepsilon)x_0, \quad (\forall) t \geq t_0 > 0, \ \varepsilon > 0, \ x_0 \in \mathcal{X}(t_0).$$

Throughout this paper, the matrix $\Phi(t, t_0, \varepsilon)$ will be termed as the *fundamental matrix solution* of system (2.3).

We recall the following definition, which will be referred to throughout the paper.

DEFINITION 2.1. *We say that the zero solution (that is, $x(t) = 0$ for all $t \in [0, \infty)$) of system* (2.3) *is exponentially stable in mean square (ESMS) (alternatively, system* (2.3) *generates a mean square stable evolution) if there exist constants $\alpha > 0$ and $\beta \geq 1$ such that $E|\Phi(t, t_0, \varepsilon)x_o|^2 \leq \beta e^{-\alpha(t-t_0)}|x_0|^2$ for all $t \geq t_0 \geq 0, x_o \in \mathbf{R}^{n_1+n_2}$.*

For each $t \geq 0$, we denote $\mathcal{F}_t \subset \mathcal{F}$ the smallest σ-algebra containing all sets $S \in \mathcal{F}$ with $\mathcal{P}(S) = 0$ and with respect to which all functions $w_j(s), 0 \leq s \leq t, 1 \leq j \leq N$ are measurable.

Let $L^2_w\{[0,\infty) \times \Omega, \mathbf{R}^d\}$ be the set of all functions $u \in L^2\{[0,\infty) \times \Omega, \mathbf{R}^d\}$ with the additional property that $u(t)$ are $\mathcal{F}_t$-measurable for all $t \geq 0$.

Since $\mathcal{F}_t$ contains all sets $S \in \mathcal{F}$ with $\mathcal{P}(S) = 0$, it can be easily proved that $L^2_w\{[0,\infty) \times \Omega, \mathbf{R}^d\}$ is closed in $L^2\{[0,\infty) \times \Omega, \mathbf{R}^d\}$, and hence it is itself a real Hilbert space with the inner product

$$\langle u, v \rangle_{L^2_w} = E \int_0^\infty u^*(t) v(t) dt.$$

Let us suppose that the zero solution of system (2.3) is ESMS.

If $u \in L^2_w\{[0,\infty) \times \Omega, \mathbf{R}^m\}$, we denote by

$$x(t, \varepsilon, u) = \begin{pmatrix} x_1(t, \varepsilon, u) \\ x_2(t, \varepsilon, u) \end{pmatrix}$$

the solution of system (2.1) with initial zero condition (i.e., $x_1(0, \varepsilon, u) = 0, x_2(0, \varepsilon, u) = 0$).

Applying Proposition 1 in [38], we deduce that $x(t, \varepsilon, u) \in L^2_w\{[0,\infty) \times \Omega, \mathbf{R}^{n_1+n_2}\}$ and $\lim_{t\to\infty} E|x(t, \varepsilon, u)|^2 = 0$.

Moreover, there exists a $\gamma > 0$ such that

$$||x(\cdot, \varepsilon, u)||^2 = E \int_0^\infty |x(t, \varepsilon, u)|^2 dt \leq \gamma^2 E \int_0^\infty |u(t)|^2 dt = \gamma^2 ||u||^2. \tag{2.4}$$

Thus the linear operator $\mathbf{T}_\varepsilon$ is well defined. $\mathbf{T}_\varepsilon : L^2_w([0,\infty) \times \Omega, \mathbf{R}^m) \to L^2_w([0,\infty) \times \Omega, \mathbf{R}^p)$ by

$$(\mathbf{T}_\varepsilon u)(t) = (C_1 \quad C_2) x(t, \varepsilon, u) + Du(t) \quad \forall t \geq 0. \tag{2.5}$$

From (2.4), we have that T_ε is a linear bounded operator and it will be called an input-output operator associated to system (2.1)–(2.2), and system (2.1)–(2.2) will be termed the "state-space realization" of the operator $\mathbf{T}_\varepsilon$.

REMARK 2.1. *When system* (2.1) *is a deterministic one (i.e.,* $A^j_{lk} = 0, l, k = 1, 2, j = 1, 2, \ldots, N$*), the transfer matrix function* G *is the frequency domain version of the input-output operator.*

However, in stochastic framework, we are not able to define, in a standard way, a transfer matrix function associated to system (2.1)–(2.2)*, and, therefore, we consider input-output operators instead of transfer matrices even if the coefficients of the given system are time invariant.*

Our aim in this paper is to investigate the asymptotic behavior of the norm of operator $\mathbf{T}_\varepsilon$ when ε approaches zero.

We shall extend the results in [5, 50] to the case of controlled systems described by Ito differential equations of type (2.1)–(2.2).

To this end, we associate to system (2.1)–(2.2) two systems with lower dimensions not depending upon the small parameter ε, namely the reduced subsystem and the boundary layer subsystem.

Setting $\varepsilon = 0$ and assuming that A_{22} is an invertible matrix, we can associate the following reduced subsystem to system (2.1)–(2.2):

$$dx_1(t) = [A_r x_1(t) + B_r u(t)]dt + \sum_{j=1}^{N} A_r^j x_1(t) dw_j(t),$$

$$y_r(t) = C_r x_1(t) + D_r u(t), \tag{2.6}$$

where

$$A_r = A_{11} - A_{12}A_{22}^{-1}A_{21},\ A_r^j = A_{11}^j - A_{12}^j A_{22}^{-1}A_{21},$$
$$B_r = B_1 - A_{12}A_{22}^{-1}A_{21},\ C_r = C_1 - C_2 A_{22}^{-1}A_{21},$$
$$D_r = D - C_2 A_{22}^{-1}B_2.$$

The unforced reduced subsystem is as follows:

$$dx_1(t) = A_r x_1(t)dt + \sum_{j=1}^{N} A_r^j x_1(t) dw_j(t). \tag{2.7}$$

If the zero solution of system (2.7) is ESMS, then we can associate to system (2.6) the corresponding input-output operator

$$\mathbf{T}_r : L_w^2[(0,\infty)\times\Omega, \mathbf{R}^m] \to L_w^2[(0,\infty)\times\Omega, \mathbf{R}^p]$$

by

$$(\mathbf{T}_r u)(t) = C_r x_1(t,u) + D_r u(t),$$

where $x_1(t,u)$ is a solution of the system (2.6) with initial condition $x_1(0,u) = 0$.

For the given system (2.1), we associate the so-called boundary layer system, described by

$$x'(\tau) = A_{22}x_2(\tau) + B_2 u(\tau),$$

$$y(\tau) = C_2 x_2(\tau) + Du(\tau), \tag{2.8}$$

with $\tau = \frac{t}{\varepsilon}$, which is a deterministic system.

The transfer matrix function corresponding to system (2.8) is

$$G_f(s) = C_2(sI_{n_2} - A_{22})^{-1}B_2 + D.$$

Again, our objective in this paper is to prove that $||\mathbf{T}_\varepsilon||$ tends to $\max\{||\mathbf{T}_r||, ||G_f||_\infty\}$.

3. Some preliminary results.

3.1. A Klimusev–Krasovski-type result. In this subsection, we extend the results of Klimusev–Krakovski [30] to the singularly perturbed systems of Ito differential equations of type (2.3).

THEOREM 3.1. *Assume that all eigenvalues of matrix A_{22} are located in the half plane of* $\mathrm{Re}(s) < 0$ *and the zero solution of the reduced subsystem* (2.7) *is ESMS.*

Then there exists an $\varepsilon_0 > 0$ *such that, for any arbitrary* $\varepsilon \in (0, \varepsilon_0]$, *the zero solution of the full system* (2.3) *is ESMS.*

Moreover, if

$$\begin{pmatrix} \Phi_{11}(t,t_0,\varepsilon) & \Phi_{12}(t,t_0,\varepsilon) \\ \Phi_{21}(t,t_0,\varepsilon) & \Phi_{22}(t,t_0,\varepsilon) \end{pmatrix}$$

is the partition of the fundamental matrix solution $\Phi(t,t_0,\varepsilon)$ *of system* (2.3), *then the following estimates hold:*

$$E|\Phi_{11}(t,t_0,\varepsilon)|^2 \le \beta_1 e^{-\alpha_1(t-t_0)},$$

$$E|\Phi_{12}(t,t_0,\varepsilon)|^2 \le \beta_1 \varepsilon e^{-\alpha_1(t-t_0)},$$

$$E|\Phi_{21}(t,t_0,\varepsilon)|^2 \le \beta_2 e^{-\alpha_1(t-t_0)},$$

$$E|\Phi_{22}(t,t_0,\varepsilon)|^2 \le \beta_2 (e^{\frac{-\alpha_2(t-t_0)}{\varepsilon}} + \varepsilon e^{-\alpha_1(t-t_0)})$$

for all $t \ge t_0 \ge 0$, $\varepsilon \in (0, \varepsilon_0]$, *where* $\alpha_i > 0$ *and* $\beta_i \ge 1, i = 1, 2$, *are independent of* ε, t, t_0.

Proof. Let us consider the nonlinear algebraic equation

$$A_{21} + A_{22}S_{21} = \varepsilon S_{21}(A_{11} + A_{12}S_{21}) \tag{3.1}$$

with unknown $S_{21} \in \mathbf{R}^{n_2 \times n_1}$.

By an implicit function argument (see, for example, [6]), we deduce that there exist an $\varepsilon_1 > 0$ and an analytic function $S_{21} : (-\varepsilon_1, \varepsilon_1) \to \mathbf{R}^{n_2 \times n_1}$ having the asymptotic structure $S_{21}(\varepsilon) = -A_{22}^{-1}A_{21} + O(\varepsilon)$, which solves (3.1).

Also, we consider the linear algebraic equation

$$S_{12}(A_{22} - \varepsilon S_{21}(\varepsilon)A_{12}) - \varepsilon(A_{11} + A_{12}S_{21}(\varepsilon)) = A_{12} \tag{3.2}$$

with unknown $S_{12} \in \mathbf{R}^{n_1 \times n_2}$. By an implicit function argument again, we conclude that there exist an $\varepsilon_2 \in (o, \varepsilon_1]$ and an analytic function $S_{12} : (-\varepsilon_2, \varepsilon_2) \to \mathbf{R}^{n_1 \times n_2}$ having the asymptotic structure $S_{12}(\varepsilon) = A_{12}A_{22}^{-1} + O(\varepsilon)$, which solves (3.2).

If $\binom{x_1(t,\varepsilon)}{x_2(t,\varepsilon)}$ is a solution of system (2.3), we define

$$\begin{pmatrix} \xi_1(t,\varepsilon) \\ \xi_2(t,\varepsilon) \end{pmatrix} = \begin{pmatrix} I_{n_1} & -\varepsilon S_{12}(\varepsilon) \\ 0 & I_{n_2} \end{pmatrix} \begin{pmatrix} I_{n_1} & 0 \\ -S_{21}(\varepsilon) & I_{n_2} \end{pmatrix} \begin{pmatrix} x_1(t,\varepsilon) \\ x_2(t,\varepsilon) \end{pmatrix},$$
$$t \ge 0, \quad \varepsilon \in (0, \varepsilon_2].$$

It is easy to see that the process $\binom{\xi_1(t,\varepsilon)}{\xi_2(t,\varepsilon)}, t \ge 0$, is a solution of the following system of Ito differential equations:

$$\begin{aligned} d\xi_1(t) &= \hat{A}_{11}(\varepsilon)\xi_1(t)dt + \sum_{j=1}^{N}[\hat{A}_{11}^j(\varepsilon)\xi_1(t) + \hat{A}_{12}^j(\varepsilon)\xi_2(t)]dw_j(t), \\ \varepsilon d\xi_2(t) &= \hat{A}_{22}(\varepsilon)\xi_2(t)dt + \varepsilon^{\nu_1}\sum_{j=1}^{N}[\hat{A}_{21}^j(\varepsilon)\xi_1(t) + \hat{A}_{22}^j(\varepsilon)\xi_2(t)]dw_j(t), \end{aligned} \tag{3.3}$$

where

$$\hat{A}_1(\varepsilon) = A_r + O(\varepsilon), \quad \hat{A}_{11}^j(\varepsilon) = A_r^j + O(\varepsilon),$$

$$\hat{A}_{12}^j(\varepsilon) = A_{12}^j + O(\varepsilon), \quad \hat{A}_{22}(\varepsilon) = A_{22} + O(\varepsilon),$$

$$\hat{A}_{21}^j(\varepsilon) = A_{21}^j - A_{22}^j A_{22}^{-1} A_{21} + O(\varepsilon),$$

$$\hat{A}_{22}^j(\varepsilon) = A_{22}^j + O(\varepsilon), \qquad \nu_1 = \min\{\nu, 1\}.$$

Applying Lemma A.1 (in the appendix) for

$$f_0(t) = 0, f_j(t) = \hat{A}_{12}^j(\varepsilon)\xi_2(t,\varepsilon), \quad j = 1, 2, \ldots, N,$$

we obtain from the first equation of system (3.3) that

$$E|\xi_1(t,\varepsilon)|^2 \le \hat{\beta}_1 \left[e^{-\hat{\alpha}_1(t-t_0)} E|\xi_1(t_0)|^2 + \sum_{j=1}^{N} \int_{t_0}^{t} e^{-\hat{\alpha}_1(t-s)} E|\xi_2(s,\varepsilon)|^2 ds \right] \tag{3.4}$$

for all $t \ge t_0 > 0$, where $\hat{\alpha}_1 > 0$ and $\hat{\beta}_1 \ge 1$.

Using Lemma A.2 (in the appendix) for

$$g_0(t) = 0, \; g_i(t) = \hat{A}_{21}^j(\varepsilon)\xi_1(t,\varepsilon), \quad j = 1, 2, \ldots, N,$$

one obtains

$$E|\xi_2(t,\varepsilon)|^2 \le \hat{\beta}_2 \left[e^{-\alpha_2 \frac{(t-t_0)}{\varepsilon}} E|\xi_2(t_0,\varepsilon)|^2 + \varepsilon^{2\nu_1 - 2} \sum_{j=1}^{N} \int_{t_0}^{t} e^{-\alpha_2 \frac{t-s}{\varepsilon}} E|\xi_1(s,\varepsilon)|^2 ds \right]. \tag{3.5}$$

Replacing (3.5) with (3.4) and changing the order of integration we deduce

$$E|\xi_1(t,\varepsilon)|^2 \le \hat{\beta}_1 e^{-\hat{\alpha}_1(t-t_0)} E|\xi_1(t_0,\varepsilon)|^2 + \hat{\beta}_1\hat{\beta}_2 \int_{t_0}^{t} e^{-\hat{\alpha}_1(t-s)} e^{-\alpha_2 \frac{s-t_o}{\varepsilon}} ds$$
$$\cdot E|\xi_2(t_0,\varepsilon)|^2 + \varepsilon^{2\nu_1-2}\hat{\beta}_1\hat{\beta}_2 \sum_{j=1}^{N} \int_{t_0}^{t} \int_{s}^{t} e^{-\hat{\alpha}_1(t-\sigma)} e^{-\alpha_2 \frac{\sigma-s}{\varepsilon}} d\sigma E|\xi_1(s,\varepsilon)|^2 ds.$$

Hence

$$E|\xi_1(t,\varepsilon)|^2 \le \hat{\beta}_3 e^{-\hat{\alpha}_1(t-t_0)} [E|\xi_1(t_0,\varepsilon)|^2 + \varepsilon E|\xi_2(t_0,\varepsilon)|^2]$$
$$+ \hat{\beta}_4 \varepsilon^{2\nu_1 - 1} \sum_{j=1}^{N} \int_{t_0}^{t} e^{-\hat{\alpha}_1(t-s)} E|\xi_1(s,\varepsilon)|^2 ds$$

with $\hat{\beta}_3 > 0$ and $\hat{\beta}_4 > 0$. By using the Gronwall lemma [6], we obtain from the above inequality

$$E|\xi_1(t,\varepsilon)|^2 \le \hat{\beta}_3 e^{-(\hat{\alpha}_1 - \varepsilon^{2\nu_1} N\hat{\beta}_4)(t-t_0)} [E|\xi_1(t_0,\varepsilon)|^2 + \varepsilon E|\xi_2(t_0,\varepsilon)|^2] \quad \forall t \ge t_0 \ge 0.$$

Thus, for all $\varepsilon \in (0, \frac{\frac{\hat{\alpha}_1}{N} - \alpha_1}{\hat{\beta}_4})$, we conclude that

$$E|\xi_1(t,\varepsilon)|^2 \le \hat{\beta}_3 e^{-N\alpha_1(t-t_0)}[E|\xi_1(t_0,\varepsilon)|^2 + \varepsilon E|\xi_2(t_0,\varepsilon)|^2] \quad \forall t \ge t_0 \ge 0. \tag{3.6}$$

Now, taking into account (3.6), we deduce from (3.5) that

$$\begin{aligned} E|\xi_2(t,\varepsilon)|^2 &\le \hat{\beta}_5 e^{-\alpha_2 \frac{(t-t_0)}{\varepsilon}} E|\xi_2(t_0,\varepsilon)|^2 \\ &\quad + \hat{\beta}_6 \varepsilon^{2\nu_1 - 1} e^{-\alpha_1(t-t_0)}[E|\xi_1(t_0,\varepsilon)|^2 + \varepsilon E|\xi_2(t_0,\varepsilon)|^2]. \end{aligned} \tag{3.7}$$

Since $x_1(t,\varepsilon) = \xi_1(t,\varepsilon) + \varepsilon S_{12}(\varepsilon)\xi_2(t,\varepsilon)$, one has

$$E|x_1(t,\varepsilon)|^2 \le \beta_1 e^{-\alpha_1(t-t_0)}[E|x_1(t_0,\varepsilon)|^2 + \varepsilon E|x_2(t_0,\varepsilon)|^2] \tag{3.8}$$

for some $\beta_1 \ge 1$ not depending upon ε.

On the other hand, since $x_2(t,\varepsilon) = \xi_2(t,\varepsilon) + S_{21}(\varepsilon)x_1(t,\varepsilon)$, and taking into account (3.7) and (3.8), we have

$$E|x_2(t,\varepsilon)|^2 \le \beta_2[e^{-\alpha_2(t-t_0)}E|\xi_2(t_0,\varepsilon)|^2 + e^{-\alpha_1(t-t_0)}(E|x_1(t_0,\varepsilon)|^2 + \varepsilon E|x_2(t_0,\varepsilon)|^2)] \tag{3.9}$$

for all $t \ge t_0 \ge 0$, for some $\beta_2 \ge 1$ not depending upon ε.

The inequalities (3.8) and (3.9) ensure the exponential stability of the zero solution of the full system (2.3). The estimates for the block components $\Phi_{ij}(t,t_0,\varepsilon)$ of the fundamental matrix $\Phi(t,t_0,\varepsilon)$ are directly obtained from (3.8) and (3.9). Thus the proof is finished. □

It should be noted that Theorem 3.1 can be used to design a stabilizing state feedback controller for the full system of type (2.1) based on separately designing the stabilizing feedback gain for two subsystems of lower dimension which do not depend on the small parameter ε. To be more precise, let us consider the controlled system

$$\begin{aligned} dx_1(t) &= [A_{11}x_1(t) + A_{12}x_2(t) + B_1u(t)]dt + \sum_{j=1}^{N}[A_{11}^j x_1(t) + A_{12}^j x_2(t)]dw_j(t), \\ \varepsilon dx_2(t) &= [A_{21}x_1(t) + A_{22}x_2(t) + B_2u(t)]dt + \varepsilon^\nu \sum_{j=1}^{N}[A_{21}^j x_1(t) + A_{22}^j x_2(t)]dw_j(t), \end{aligned} \tag{3.10}$$

where $\varepsilon > 0, \nu > \frac{1}{2}, u \in \mathbf{R}^m$ are the vectors of the control parameters. If we take $u(t) = F_1x_1(t) + F_2x_2(t)$, the resulting closed loop system is

$$\begin{aligned} dx_1(t) &= [(A_{11} + B_1F_1)x_1(t) + (A_{12} + B_1F_2)x_2(t)]dt \\ &\quad + \sum_{j=1}^{N}[A_{11}^j x_1(t) + A_{12}^j x_2(t)]dw_j(t), \\ \varepsilon dx_2(t) &= [(A_{21} + B_2F_1)x_1(t) + (A_{22} + B_2F_2)x_2(t)]dt \\ &\quad + \varepsilon^\nu \sum_{j=1}^{N}[A_{21}^j x_1(t) + A_{22}^j x_2(t)]dw_j(t). \end{aligned} \tag{3.11}$$

Applying Theorem 3.1 to system (3.11), we may construct a stabilizing control

$$u(t) = F_1x_1(t) + F_2x_2(t)$$

for system (3.10). This is done in the following corollary.

COROLLARY 3.2. *Assume that A_{22} is invertible and $\tilde{F} \in \mathbf{R}^{m\times n_1}$ is chosen such that the zero solution of the closed loop system*

$$dx_1(t) = [A_r + B_r\tilde{F}]x_1(t)dt + \sum_{j=1}^{N}[A_r^j + B_r^j\tilde{F}]x_1(t)dw_j(t) \tag{3.12}$$

is ESMS and $F_2 \in \mathbf{R}^{m\times n_2}$ is chosen such that $A_{22}+B_2F_2$ is a Hurwitz matrix (A_r, B_r being defined as in the case of system (2.6)). Set $F_1 = (I_m + F_2A_{22}^{-1}B_2)\tilde{F} + F_2A_{22}^{-1}A_{21}$; then the control

$$u(t) = F_1x_1(t) + F_2x_2(t) \tag{3.13}$$

stabilizes system (3.10) for arbitrary $\varepsilon > 0$ small enough. (It means that there exists an $\varepsilon_0 > 0$ such that the zero solution of the corresponding closed loop system (3.11) is ESMS for any arbitrary $\varepsilon \in (0, \varepsilon_0)$.)

Proof. The closed loop system obtained by coupling the control (3.13) to system (3.10) is

$$\begin{aligned} dx_1(t) &= [(A_{11} + B_1F_1)x_1(t) + (A_{12} + B_1F_2)x_2(t)]dt \\ &\quad + \sum_{j=1}^{N}[A_{11}^jx_1(t) + A_{12}^jx_2(t)]dw_j(t), \\ \varepsilon dx_2(t) &= [(A_{21} + B_2F_1)x_1(t) + (A_{22} + B_2F_2)x_2(t)]dt \\ &\quad + \varepsilon_\nu \sum_{j=1}^{N}[A_{21}^jx_1(t) + A_{22}^jx_2(t)]dw_j(t). \end{aligned} \tag{3.14}$$

Setting $\varepsilon = 0$ in (3.14), we obtain the reduced subsystem

$$\begin{aligned} dx_1(t) &= [A_{11} + B_1F_1 - (A_{12} + B_1F_2)(A_{22} + B_2F_2)^{-1}(A_{21} + B_2F_1)]x_1(t)dt \\ &\quad + \sum_{j=1}^{N}[A_{11}^j - A_{12}^j(A_{22} + B_2F_2)^{-1}(A_{21} + B_2F_1)]x_1(t)dw_j(t). \end{aligned} \tag{3.15}$$

After some algebraic computation, similar to that in the deterministic framework (e.g., [33, 6]), we can show that (3.15) is just (3.12). Now the conclusion is immediate from Theorem 3.1. □

REMARK 3.1. *The designing of the matrix gain $\tilde{F}$ in order to guarantee the ESMS of the zero solution of the system (3.12) may be done by using, for instance, the result of Theorem 1 in [46], and the designing of the matrix gain F_2 may be done by using any known methods for the stabilization of a linear time invariant finite dimensional system in the deterministic framework.*

3.2. Representation formula for the stabilizing solution of a class of algebraic Riccati equations. Let us consider the controlled system described by the differential Ito equation

$$dx(t) = [Ax(t) + Bu(t)]dt + \sum_{i=1}^{N} A^ix(t)dw_i(t) \tag{3.16}$$

and the output

$$y = Cx(t) + Du(t). \tag{3.17}$$

If the uncontrolled system

$$dx(t) = Ax(t)dt + \sum_{i=1}^{N} A^i x(t)dw_i(t) \tag{3.18}$$

associated to (3.16) generates an exponentially stable evolution, then system (3.16)–(3.17) defines an input-output operator $T : L_w^2\{(0,\infty) \times \Omega, \mathbf{R}^m\} \to: L_w^2\{(0,\infty) \times \Omega, \mathbf{R}^p\}$ by $(\mathbf{T}u)(t) = Cx_u(t) + Du(t), t \geq 0$, where $x_u(\cdot) \in L_w^2\{(0,\infty) \times \Omega, \mathbf{R}^n\}$ is the solution of (3.14) with initial condition $x_u(0) = 0$.

The result of the following theorem gives a stochastic version of the well-known bounded real lemma.

THEOREM 3.3 (see [38, 39]). *Under the considered assumptions, the following statements are equivalent:*

(i) *the uncontrolled system* (3.18) *defines a mean square exponentially stable evolution, and the input-output operator* $\mathbf{T}$ *associated to* (3.16)–(3.17) *verifies*

$$||\mathbf{T}|| < \gamma;$$

(ii) $D^*D < \gamma^2 I_m$, *and the algebraic Riccati-type equation*

$$\begin{aligned} A^*X + XA + \sum_{i=1}^{N} (A^i)^* X A^i \\ + (XB + C^*D)(\gamma^2 I_m - D^*D)^{-1}(B^*X + D^*C) + C^*C = 0 \end{aligned} \tag{3.19}$$

has a unique stabilizing solution $\tilde{X} = \tilde{X}^* \geq 0$.

Recall that $\tilde{X}$ is a "stabilizing solution" of (3.19) if the system

$$dx(t) = (A + B\tilde{F})x(t)dt + \sum_{i=1}^{N} A^i x(t)dw_i(t)$$

defines a mean square exponentially stable evolution with

$$\tilde{F} = (\gamma^2 I_m - D^*D)^{-1}(B^*\tilde{X} + D^*C).$$

Combining the results in Proposition 3 and Theorem 1 in Morozan [38, 39], we obtain a useful representation formula of the stabilizing solution $\tilde{X}$ of the Riccati-type equation (3.19).

THEOREM 3.4. *Suppose that the statement* (i) *in Theorem* 3.3 *holds. Then the stabilizing solution of* (3.19) *has the representation formula*

$$\tilde{X} = \mathcal{P}^0 - \mathcal{P}\mathcal{R}_\gamma^{-1}\mathcal{P}^* \tag{3.20}$$

with $\mathcal{P}^0 : \mathbf{R}^n \to \mathbf{R}^n, \mathcal{P} : L_w^2((0,\infty) \times \Omega, \mathbf{R}^m) \to \mathbf{R}^n, \mathcal{R}_\gamma : L_w^2((0,\infty) \times \Omega, \mathbf{R}^m) \to L_w^2((o,\infty) \times \Omega, \mathbf{R}^m)$ *by*

$$\mathcal{P}^0 = E\int_0^\infty \Phi^*(t,0)C^*C\Phi(t,0)dt,$$

$$\mathcal{P}u = E\int_0^\infty \Phi^*(t,0)C^*\left[C\int_0^t \Phi(t,s)Bu(s)ds + Du(t)\right]dt$$
$$= E\int_0^\infty \Phi^*(t,0)C^*(Tu)(t)dt \ \forall u \in L^2_w((0,\infty)\times\Omega,\mathbf{R}^m),$$
$$\mathcal{R}_\gamma = T^*T - \gamma^2 I,$$

where $\Phi(t,0)$ *is the fundamental random matrix associated to the uncontrolled system* (3.18).

Proof. Consider the quadratic cost function

$$J_\gamma(x_0,u) = E\int_0^\infty [|y_u(t)|^2 - \gamma^2|u(t)|^2]dt.$$

Since $||\mathbf{T}|| < \gamma$, applying Proposition 3 in [38], we deduce that $u \to J_\gamma(x_0,u)$ is a continuous and a concave function.

Setting $y_u(t) = C\Phi(t,0)x_0 + [Tu](t)$, we can easily show that

$$\max\{J_\gamma(x_0,u)|u \in L^2_w((0,\infty)\times\Omega,\mathbf{R}^m)\} = x_0^*(\mathcal{P}^0 - \mathcal{P}\mathcal{R}_\gamma^{-1}\mathcal{P}^*)x_0. \tag{3.21}$$

On the other hand, applying Theorem 1 in [38], we get

$$J_\gamma(x_0,u) = x_0^*\tilde{X}x_0 - E\int_0^\infty (u(t)-\tilde{F}x(t))^*(\gamma^2 I_m - D^*D)(u(t)-\tilde{F}x(t))dt$$
$$\forall u \in L^2_w((0,\infty)\times\Omega,\mathbf{R}^m).$$

Hence one has

$$\max\{J_\gamma(x_0,u)|u \in L^2_w((0,\infty)\times\Omega,\mathbf{R}^m)\} = x_0^*\tilde{X}x_0. \tag{3.22}$$

Thus, from (3.21) and (3.22), (3.20) follows, and the proof is complete. □

4. Main results. We make the following assumptions throughout this section and thereafter:

$\mathbf{H_1}$. The linear unforced system (2.7) defines an exponentially stable evolution in mean square.

$\mathbf{H_2}$. All eigenvalues of matrix A_{22} are located in the half plane of $\mathrm{Re}(s) < 0$.

PROPOSITION 4.1. *Under assumptions* $\mathbf{H_1}$–$\mathbf{H_2}$, *if there exists a sequence* $\{\varepsilon_k\}_{k\in\mathbf{N}}$ *such that* $\lim_{k\to\infty}\varepsilon_k = 0$ *and* $||\mathbf{T}_{\varepsilon_k}|| < \gamma$ *for all* $k \in \mathbf{N}$, *then* $\gamma \geq \max\{||\mathbf{T}_r||, ||\mathbf{G}_f||_\infty\}$.

Proof. Let $\gamma' < \gamma$ be fixed. Then $||\mathbf{T}_{\varepsilon_k}|| < \gamma'$ for all $k \in \mathbf{N}$. Set

$$A(\varepsilon_k) = \begin{pmatrix} A_{11} & A_{12} \\ \varepsilon^{-1}A_{21} & \varepsilon^{-1}A_{22} \end{pmatrix},\ A^i(\varepsilon_k) = \begin{pmatrix} A^i_{11} & A^i_{12} \\ \varepsilon_k^{\nu-1}A^i_{21} & \varepsilon_k^{\nu-1}A^i_{22} \end{pmatrix},$$
$$B(\varepsilon_k) = \begin{pmatrix} B_1 \\ \varepsilon_k^{-1}B_2 \end{pmatrix}.$$

Applying Theorem 3.1, we have that for all k large enough, the system

$$dx(t) = A(\varepsilon_k)x(t)dt + \sum_{j=1}^N A^j(\varepsilon_k)x(t)dw_j(t)$$

defines an exponentially stable evolution. Using statements (i) and (ii) in Theorem 3.3, we conclude that the algebraic Riccati-type equation

$$A^*(\varepsilon_k)X + XA(\varepsilon_k) + \sum_{j=1}^{N} A^{j*}(\varepsilon_k)XA^j(\varepsilon_k) + (XB(\varepsilon_k) + C^*D)(\gamma^2 I_m - D^*D)^{-1} \cdot (B^*(\varepsilon_k)X + D^*C) + C^*C = 0 \tag{4.1}$$

has a stabilizing solution $X(\varepsilon_k) = X^*(\varepsilon_k) \geq 0$.

From Theorem 3.4, we deduce that the stabilizing solution $X(\varepsilon_k, \gamma)$ of (4.1) has the representation formula

$$X(\varepsilon_k, \gamma') = \mathcal{P}^0(\varepsilon_k) - \mathcal{P}(\varepsilon_k)\mathcal{R}^{-1}_{\gamma'}(\varepsilon_k)\mathcal{P}^*(\varepsilon_k).$$

Let

$$\begin{pmatrix} X_{11}(\varepsilon_k, \gamma') & X_{12}(\varepsilon_k, \gamma') \\ X^*_{12}(\varepsilon_k, \gamma') & X_{22}(\varepsilon_k, \gamma') \end{pmatrix}$$

be the partition of the solution $X(\varepsilon_k, \gamma')$ compatible with the partition of the coefficient matrix of system (2.1).

Taking into account the estimations in Theorem 3.1, we shall deduce estimations for $X_{ij}(\varepsilon_k, \gamma')$.

First, notice that

$$-\mathcal{R}_{\gamma'}(\varepsilon_k) = (\gamma'^2 - \gamma^2)I - \mathcal{R}_{\gamma}(\varepsilon_k) \geq (\gamma'^2 - \gamma^2)I.$$

Since $\mathcal{R}_{\gamma'}(\varepsilon_k) = \mathcal{R}^*_{\gamma'}(\varepsilon_k)$, where $\mathcal{R}^*_{\gamma'}(\varepsilon_k)$ stands for the adjoint operator of $\mathcal{R}_{\gamma'}(\varepsilon_k)$, we obtain that $\mathcal{R}_{\gamma'}(\varepsilon_k)$ is invertible on $L^2_w((0,\infty) \times \Omega, \mathbf{R}^m)$ with bounded inverse. Moreover, we have

$$||\mathcal{R}^{-1}_{\gamma'}(\varepsilon_k)|| \leq (\gamma'^2 - \gamma^2)^{-1/2}$$

for all $k \in \mathbf{N}$ large enough. On the other hand, we may write

$$\mathcal{P}(\varepsilon_k) = \begin{pmatrix} \mathcal{P}_1(\varepsilon_k) \\ \mathcal{P}_2(\varepsilon_k) \end{pmatrix},\ \mathcal{P}_j(\varepsilon_k) : L^2_w((0,\infty) \times \Omega; \mathbf{R}^m) \to \mathbf{R}^{n_j}, \quad j = 1, 2,$$

$$\mathcal{P}_j(\varepsilon_k)u = E\int_0^\infty [\Phi^*_{1j}(t, 0, \varepsilon_k)C_1^* + \Phi^*_{2j}(t, 0, \varepsilon_k)C_2^*]y(t, \varepsilon_k)dt,$$

where

$$y(t, \varepsilon_k) = \begin{pmatrix} C_1 & C_2 \end{pmatrix} \int_0^t \Phi(t, 0, \varepsilon_k)B(\varepsilon_k)u(s)ds + Du(t).$$

Using the estimates in Theorem 3.1, we obtain that there exist constants $c_1 > 0$ and $c_2 > 0$ not depending on k but possibly depending on γ', such that

$$\|\mathcal{P}_1(\varepsilon_k)\| \leq c_1, \quad \|\mathcal{P}_2(\varepsilon_k)\| \leq c_2\varepsilon_k, \ \ (\forall)\ k \geq 1.$$

With these inequalities, we may conclude that the stabilizing solution $X(\varepsilon_k)$ of (4.1) has the following asymptotic structure:

$$X(\varepsilon_k) = \begin{pmatrix} X_{11}(\varepsilon_k) & \varepsilon_k X_{12}(\varepsilon_k) \\ \varepsilon_k X^*_{12}(\varepsilon_k) & \varepsilon_k X_{22}(\varepsilon_k) \end{pmatrix}$$

with $|X_{ij}(\varepsilon_k)| \le c_3(\gamma')$, where $c_3(\gamma') > 0$ does not depend on k.

We define

$$\begin{aligned} F(\varepsilon_k) &= (F_1(\varepsilon_k) \qquad F_2(\varepsilon_k)) \\ &= (\gamma'^2 I_m - D^*D)^{-1}\left[\begin{pmatrix} B_1^* & \dfrac{1}{\varepsilon_k}B_2^* \end{pmatrix} X(\varepsilon_k) + D^*(C_1 \qquad C_2)\right]. \end{aligned}$$

With this notation, we have that (4.1) is equivalent to a system with unknowns $X_{11}(\varepsilon_k), X_{12}(\varepsilon_k), X_{22}(\varepsilon_k), F_1(\varepsilon_k), F_2(\varepsilon_k)$, and thus the rest of the proof can be carried out along the same lines as that in the deterministic framework [4]. □

Based on the result in Proposition 4.1, we can easily show the following theorem.

THEOREM 4.2. *Under assumptions* $\mathbf{H_1}$–$\mathbf{H_2}$*, the norm of the input-output operator defined by system* (2.1)–(2.2) *verifies*

$$\liminf_{\varepsilon \searrow 0} \|\mathbf{T}_\varepsilon\| \ge \max\{\|\mathbf{T}_r\|, \|\mathbf{G}_f\|_\infty\}.$$

In the remainder of this section, we will consider a controlled system described by

$$\begin{aligned} dx_1(t) &= [A_{11}x_1(t) + A_{12}x_2(t) + B_1u(t)]dt \\ &\quad + \sum_{i=1}^{N}[A_{11}^i x_1(t) + \varepsilon^\mu A_{12}^i x_2(t)]dw_i(t), \\ \varepsilon dx_2(t) &= [A_{21}x_1(t) + A_{22}x_2(t) + B_2u(t)]dt \\ &\quad + \varepsilon^\nu \sum_{i=1}^{N}[A_{21}^i x_1(t) + A_{22}^i x_2(t)]dw_i(t) \end{aligned} \tag{4.2}$$

and the output

$$y(t) = C_1x_1(t) + C_2x_2(t) + Du(t), \tag{4.3}$$

where $x_i, A_{ij}, B_i, C_j, D, \nu$, and ε are as in system (2.1)–(2.2) and $\mu > 0$ is independent of ε.

When $\mu = 0$, system (4.2)–(4.3) is just the system (2.1)–(2.2).

In this case (when $\mu > 0$), the reduced subsystem obtained by setting $\varepsilon = 0$ in (4.2)–(4.3) is (2.6), where $A_r^j = A_{11}^j, j = 1, 2, \ldots, N$. The corresponding boundary layer subsystem is (2.8).

It is easy to see that the result of Theorem 4.2 also holds for the input-output operator corresponding to system (4.2)–(4.3). In the case of system (4.2)–(4.3), we may derive a result concerning the superior limit of the norm of operator $\mathbf{T}_\varepsilon$ defined by this system.

First, we present the following result.

PROPOSITION 4.3. *Assume that* $\mathbf{H_1}$–$\mathbf{H_2}$ *hold for system* (4.2)–(4.3). *Then, for all*

$$\gamma > \max\{\|\mathbf{T}_r\|, \|\mathbf{G}_f\|_\infty\}, \tag{4.4}$$

there exists an $\varepsilon_0(\gamma) > 0$ *such that for arbitrary* $\varepsilon \in (0, \varepsilon_0(\gamma))$ *we have* $\|\mathbf{T}_\varepsilon\| < \gamma$.

REMARK 4.1. *In Proposition* 4.3, *that assumption* $\mathbf{H_1}$ *holds for system* (4.2)–(4.3) *means that the assumption is true when the control input* $u(t)$ *is zero (i.e., unforced situation).*

Proof. We show that, under the considered assumptions, there exists an $\varepsilon_0(\gamma) > 0$ such that for arbitrary $\varepsilon \in (0, \varepsilon_0(\gamma))$ the algebraic Riccati equation

$$\begin{aligned} &A^*(\varepsilon)X + XA(\varepsilon) + \sum_{i=1}^{N}(A^i)^*(\varepsilon)XA^i(\varepsilon) \\ &\quad + (XB(\varepsilon) + C^*D)(\gamma^2 I_m - D^*D)^{-1}(B^*(\varepsilon)X + D^*C) + C^*C = 0 \end{aligned} \tag{4.5}$$

has a stabilizing solution $\tilde{X}(\varepsilon) = \tilde{X}^*(\varepsilon) \geq 0$. Then, applying the results in [38, 39], we may conclude that $\|\mathbf{T}_\varepsilon\| < \gamma, \varepsilon \in (0, \varepsilon_0(\gamma))$.

If (4.4) holds, then $\|\mathbf{G}_f\|_\infty < \gamma$, and we get $D^*D < \gamma^2 I_m$, and thus (4.5) is well defined.

Set

$$F = (F_1 \qquad F_2) = (\gamma^2 I_m - D^*D)^{-1}(B^*(\varepsilon)X + D^*C),\ X = \begin{pmatrix} X_{11} & \varepsilon X_{12} \\ \varepsilon X_{12}^* & \varepsilon X_{22} \end{pmatrix}.$$

We obtain that (4.5) is equivalent to the following system:

$$\begin{aligned}
&B_1^*X_{11} + B_2^*X_{12}^* + D^*C_1 = (\gamma^2 I_m - D^*D)F_1, \\
&\varepsilon B_1^*X_{12} + B_2^*X_{22} + D^*C_2 = (\gamma^2 I_m - D^*D)F_2, \\
&A_{11}^*X_{11} + A_{21}^*X_{12}^* + X11A_{11} + X_{12}A_{21} + \sum_{i=1}^{N}[(A_{11}^i)^*X_{11}A_{11}^i \\
&\qquad + \varepsilon^\nu (A_{21}^i)^*X_{12}^*A_{11}^i + \varepsilon^\nu (A_{11}^i)^*X_{12}A_{21}^i + \varepsilon^{2\nu-1}(A_{21}^i)^*X_{22}A_{21}^i] \\
&\qquad + F_1^*(\gamma^2 I_m - D^*D)F_1 + C_1^*C_1 = 0, \\
&\varepsilon A_{11}^*X_{12} + A_{21}^*X_{22} + X_{11}A_{12} + X_{12}A_{22} + \sum_{i=1}^{N}[\varepsilon^\mu (A_{11}^i)^*X_{11}A_{12}^i \\
&\qquad + \varepsilon^{\mu+\nu}(A_{21}^i)^*X_{12}^*A_{12}^i + \varepsilon^\nu (A_{11}^i)^*X_{12}A_{22}^i + \varepsilon^{2\nu-1}(A_{21}^i)^*X_{22}A_{22}^i] \\
&\qquad + F_1^*(\gamma^2 I_m - D^*D)F_2 + C_1^*C_2 = 0, \\
&\varepsilon A_{12}^*X_{12} + A_{22}^*X_{22} + \varepsilon X_{12}^*A_{12} + X_{22}A_{22} + \sum_{i=1}^{N}[\varepsilon^{2\mu}(A_{12}^i)^*X_{11}A_{12}^i + \varepsilon^{\mu+\nu}(A_{22}^i)^*X_{12}^*A_{12}^i \\
&\qquad + \varepsilon^{\mu+\nu}(A_{12}^i)^*X_{12}A_{22}^i + \varepsilon^{2\nu-1}(A_{22}^i)^*X_{22}A_{22}^i] \\
&\qquad + F_2^*(\gamma^2 I_m - D^*D)F_2 + C_2^*C_2 = 0
\end{aligned}$$

with unknowns $F_j \in \mathbf{R}^{m\times n_j}, X_{ij} \in \mathbf{R}^{n_i\times n_j}, X_{ii} = X_{ii}^*, i, j = 1, 2$. We associate the following implicit function problem:

$$\begin{aligned}
&B_1^*X_{11} + B_2^*X_{12}^* + D^*C_1 = (\gamma^2 I_m - D^*D)F_1, \\
&\eta_1 B_1^*X_{12} + B_2^*X_{22} + D^*C_2 = (\gamma^2 I_m - D^*D)F_2, \\
&A_{11}^*X_{11} + A_{21}^*X_{12}^* + X11A_{11} + X_{12}A_{21} + \sum_{i=1}^{N}[(A_{11}^i)^*X_{11}A_{11}^i + \eta_2(A_{21}^i)^*X_{12}^*A_{11}^i \\
&\qquad + \eta_2(A_{11}^i)^*X_{12}A_{21}^i + \eta_3(A_{21}^i)^*X_{22}A_{21}^i] \\
&\qquad + F_1^*(\gamma^2 I_m - D^*D)F_1 + C_1^*C_1 = 0, \\
&\eta_1 A_{11}^*X_{12} + A_{21}^*X_{22} + X_{11}A_{12} + X_{12}A_{22} + \sum_{i=1}^{N}[\eta_4(A_{11}^i)^*X_{11}A_{12}^i + \eta_2\eta_4(A_{21}^i)^*X_{12}^*A_{12}^i
\end{aligned} \tag{4.7}$$

$$
\begin{aligned}
&+ \eta_2 (A_{11}^i)^* X_{12} A_{22}^i + \eta_3 (A_{21}^i)^* X_{22} A_{22}^i] \\
&+ F_1^* (\gamma^2 I_m - D^* D) F_2 + C_1^* C_2 = 0, \\
\eta_1 A_{12}^* X_{12} + A_{22}^* X_{22} + \eta_1 X_{12}^* A_{12} + X_{22} A_{22} + \sum_{i=1}^{N} &[\eta_4^2 (A_{12}^i)^* X_{11} A_{12}^i \\
&+ \eta_2 \eta_4 (A_{22}^i)^* X_{12}^* A_{12}^i + \eta_2 \eta_4 (A_{12}^i)^* X_{12} A_{22}^i + \eta_3 (A_{22}^i)^* X_{22} A_{22}^i] \\
&+ F_2^* (\gamma^2 I_m - D^* D) F_2 + C_2^* C_2 = 0
\end{aligned}
$$

with unknowns $F_j, X_{ij}, i, j = 1, 2$ and the free parameters $\eta_1, \eta_2, \eta_3, \eta_4$.

The rest of the proof follows in the same way as in the deterministic case [4]. □

From Proposition 4.3, we get the following theorem.

THEOREM 4.4. *Under* $\mathbf{H_1}$–$\mathbf{H_2}$, *the norm of the input-output operator defined by system* (4.2)–(4.3) *verifies*

$$\limsup_{\varepsilon \searrow 0} \|\mathbf{T}_\varepsilon\| \leq \max\{\|\mathbf{T}_r\|, \|\mathbf{G}_f\|_\infty\}.$$

Combining the results of Theorem 4.2 and Theorem 4.4, we have the following result.

THEOREM 4.5. *Under assumptions* $\mathbf{H_1}$–$\mathbf{H_2}$, *the norm of the input-output operator defined by system* (4.2)–(4.3) *verifies*

$$\lim_{\varepsilon \searrow 0} \|\mathbf{T}_\varepsilon\| = \max\{\|\mathbf{T}_r\|, \|\mathbf{G}_f\|_\infty\}.$$

5. Robust stabilization via an ε-independent controller for a class of singularly perturbed linear stochastic systems. In Corollary 3.2, it has been shown how the Klimusev–Krasovski-type result of Theorem 3.1 could be used to design a composite stabilizing control for a singularly perturbed linear stochastic system.

In this section, we will show how the results of Theorems 3.1 and 4.5 can be used to analyze the robustness properties of an ε-independent stabilizing controller for a linear stochastic system with two time scales.

Consider the system

$$
\begin{aligned}
dx_1(t) &= [A_{11} x_1(t) + A_{12} x_2(t) + B_1^1 v(t) + B_2^1 u(t)] dt \\
&\quad + \sum_{k=1}^{N} [A_{11}^k x_1(t) + \varepsilon^\mu A_{12}^k x_2(t)] dw_k(t), \\
\varepsilon dx_2(t) &= [A_{21} x_1(t) + A_{22} x_2(t) + B_1^2 v(t) + B_2^2 u(t)] \\
&\quad + \varepsilon^\nu \sum_{k=1}^{N} [A_{21}^k x_1(t) + A_{22}^k x_2(t)] dw_k(t), \qquad (5.1) \\
y_1(t) &= C_{11} x_1(t) + C_{12} x_2(t) + D_{11} v(t) + D_{12} u(t), \\
dy_2(t) &= [C_{21} x_1(t) + C_{22} x_2(t) + D_{21} v(t)] dt + \sum_{k=1}^{N} [C_{21}^k x_1(t) + \varepsilon^\lambda C_{22}^k x_2(t)] dw_k(t),
\end{aligned}
$$

having control inputs $u \in \mathbf{R}^{m_2}$, exogenous disturbances $v \in \mathbf{R}^{m_1}$ (which are supposed to be adapted stochastic processes), controlled outputs $y_1 \in \mathbf{R}^{p_1}$, and measured outputs $y_2 \in \mathbf{R}^{p_2}$. $\mu > 0, \lambda > 0$, and ν and ε are as in (2.1)–(2.2).

If $A_{ij}^k = 0, i, j = 1, 2, k = 1, 2, \ldots, N$, then (5.1) is a deterministic system having the measured output subjected to some random disturbances modeled by multiplicative white noise. In this section, we investigate the problem of designing of a robust stabilizing controller with a single time scale. We shall use both strict proper controllers of the form

$$\begin{aligned} dx_c(t) &= A_c x_c(t)dt + B_c dy_2(t), \\ u_2(t) &= C_c x_c(t) \end{aligned} \tag{5.2}$$

and proper controllers of the form

$$\begin{aligned} dx_c(t) &= A_c x_c(t)dt + B_c dy_2(t), \\ du_2 &= C_c x_c(t)dt + D_c dy_2(t). \end{aligned} \tag{5.3}$$

The closed loop system by coupling the controller (5.2) to system (5.1) is

$$\begin{aligned} dx_1(t) &= [A_{11}x_1(t) + B_2^1 C_c x_c(t) + A_{12}x_2(t) + B_1^1 v(t)]dt \\ &\quad + \sum_{k=1}^{N} [A_{11}^k x_1(t) + \varepsilon^\mu A_{12}^k x_2(t)]dw_k(t), \\ dx_c(t) &= [B_c C_{21} x_1(t) + A_c x_c(t) + B_c C_{22} x_2(t) + B_c D_{21} v(t)]dt \\ &\quad + \sum_{k=1}^{N} [B_c C_{21}^k x_1(t) + \varepsilon^\lambda B_c C_{22}^k x_2(t)]dw_k(t), \\ \varepsilon dx_2(t) &= [A_{21}x_1(t) + B_{22}C_c x_c(t) + A_{22}x_2(t) + B_1^2 v(t)]dt \\ &\quad + \varepsilon^\nu \sum_{k=1}^{N} [A_{21}^k x_1(t) + A_{22}^k x_2(t)]dw_k(t), \\ y_1(t) &= C_{11}x_1(t) + D_{12}C_c x_c(t) + C_{12}x_2(t) + D_{11}v(t). \end{aligned} \tag{5.4}$$

This system may be rewritten in the following form:

$$\begin{aligned} d\xi(t) &= [\hat{A}_{11}\xi(t) + \hat{A}_{12}x_2(t) + \hat{B}_1 v(t)]dt + \sum_{k=1}^{N} [\hat{A}_{11}^k \xi(t) + \hat{A}_{12}^k x_2(t)]dw_k(t), \\ \varepsilon dx_2(t) &= [\hat{A}_{21}\xi(t) + \hat{A}_{22}x_2(t) + \hat{B}_2 v(t)]dt + \varepsilon^\nu \sum_{k=1}^{N} [\hat{A}_{21}^k \xi(t) + \hat{A}_{22}^k x_2(t)]dw_k(t), \\ y_1(t) &= \hat{C}_1 \xi(t) + \hat{C}_2 x_2(t) + \hat{D}_{11} v(t), \end{aligned} \tag{5.5}$$

where $\xi(t) = \binom{x_1(t)}{x_c(t)}$ is the slow component of the state and

$$\hat{A}_{11} = \begin{pmatrix} A_{11} & B_2^1 C_c \\ B_c C_2^1 & A_c \end{pmatrix}, \quad \hat{A}_{12} = \begin{pmatrix} A_{12} \\ B_c C_{22} \end{pmatrix}, \quad \hat{A}_{21} = \begin{pmatrix} A_{21} & B_2^2 C_c \end{pmatrix}, \quad \hat{A}_{22} = A_{22},$$

$$\hat{A}_{11}^k = \begin{pmatrix} A_{11}^k & 0 \\ B_c C_{21}^k & 0 \end{pmatrix}, \quad \hat{A}_{12}^k = \begin{pmatrix} \varepsilon^\nu A_{12}^k \\ \varepsilon^\lambda B_c C_{22}^k \end{pmatrix}, \quad \hat{B}_1 = \begin{pmatrix} B_1^1 \\ B_c D_{21} \end{pmatrix}, \quad \hat{B}_2 = B_1^2,$$

$$\hat{C}_1 = (C_{11} \quad D_{12}C_c), \;\; \hat{C}_2 = C_{12}, \;\; \hat{D}_{11} = D_{11}.$$

In the same way, the closed loop system obtained by coupling the controller (5.3) to system (5.1) may be written as

$$\begin{aligned}
d\xi(t) &= [\check{A}_{11}\xi(t) + \check{A}_{12}x_2(t) + \check{B}_1 v(t)]dt + \sum_{k=1}^{N}[\check{A}_{11}^k\xi(t) + \check{A}_{12}^k x_2(t)]dw_k(t),\\
\varepsilon dx_2(t) &= [\check{A}_{21}\xi(t) + \check{A}_{22}x_2(t) + \check{B}_2 v(t)]dt + \sum_{k=1}^{N}[\check{A}_{21}^k\xi(t) + \check{A}_{22}x_2(t)]dw_k(t),\\
y_1(t) &= \check{C}_1\xi(t) + \check{C}_2 x_2(t) + \check{D}_{11}v(t),
\end{aligned} \tag{5.6}$$

where $\xi = \binom{x_1}{x_c}$ is the slow state, x_2 is the fast state, and the coefficient matrices are

$$\begin{aligned}
&\check{A}_{11} = \begin{pmatrix} A_{11} + B_2^1 D_c C_{21} & B_2^1 \\ B_c C_{12} & A_c \end{pmatrix}, \;\; \check{A}_{12} = \begin{pmatrix} A_{12} + B_2^1 D_c C_{22}) \\ B_c C_{22} \end{pmatrix},\\
&\check{A}_{21} = \begin{pmatrix} A_{21} + B_2^2 D_c C_{21} & B_2^2 C_c \end{pmatrix}, \;\; \check{A}_{22} = A_{22} + B_2^2 D_c C_{22},\\
&\check{A}_{11}^k = \begin{pmatrix} A_{11}^k + B_2^1 D_c C_{21}^k & 0 \\ B_c C_{21}^k & 0 \end{pmatrix}, \;\; \check{A}_{12}^k = \begin{pmatrix} \varepsilon^\nu A_{12}^k + \varepsilon^\lambda B_2^1 D_c C_{22}^k \\ \varepsilon^\lambda B_c C_{22}^k \end{pmatrix},\\
&\check{A}_{21}^k = \begin{pmatrix} \varepsilon^\nu A_{21}^k + B_2^2 D_c C_{21}^k & 0 \end{pmatrix}, \;\; \check{A}_{22}^k = \varepsilon^\nu A_{22}^k + \varepsilon^\lambda B_2^2 D_c C_{22}^k,\\
&\check{B}_1 = \begin{pmatrix} B_1^1 + B_2^1 D_c D_{21} \\ B_c D_{21} \end{pmatrix}, \;\; \check{B}_2 = B_1^2 + B_2^2 D_c D_{21},\\
&\check{C}_1 = (C_{11} + D_{12} D_c C_{21} \quad D_{12}C_c), \;\; \check{C}_2 = C_{12} + D_{12} D_c C_{22},\\
&\check{C}_{1j}^k = D_{12} D_c \check{C}_2^k, \;\; j = 1, 2, \; k = 1, 2, \ldots N, \;\; \check{D}_{11} = D_{11} + D_{12} D_c D_{21}.
\end{aligned}$$

REMARK 5.1. *The output of the closed loop system* (5.6) *is directly affected by the white noises which are presented in the measured output of the plant* (5.1). *The stochastic systems of type* (5.6) *exceed the class of stochastic systems investigated in this paper. Hence, when a proper controller of type* (5.3) *is used to stabilize a stochastic system of type* (5.1), *we shall assume that* $C_{2j}^k = 0, j = 1, 2, k = 1, \ldots, N$. *However, since systems of type* (5.6) *appear in a natural way, an investigation of this type of system would be of interest.*

Assuming that A_{22} is invertible, we associate two subsystems of lower dimensions and independent of the small parameter ε:

$$\begin{aligned}
dx_r(t) &= [A_r x_r(t) + B_{r1} v_r(t) + B_{r2} u_r(t)]dt + \sum_{k=1}^{N} A_r^k x_r(t) dw_k(t),\\
y_{r1}(t) &= C_{r1} x_r(t) + D_r^{11} v_r(t) + D_r^{12} u_r(t),\\
dy_{r2}(t) &= [C_{r2} x_r(t) + D_r^{21} v_r(t) + D_r^{22} u_r(t)]dt + \sum_{k=1}^{N} C_{r2}^k x_r(t) dw_k(t),
\end{aligned} \tag{5.7}$$

which will be termed as "reduced subsystem" or "slow subsystem" associated with (5.1), where

$$\begin{aligned}
&A_r = A_{11} - A_{12}A_{22}^{-1}A_{21}, && A_r^k = A_{11}^k, \;\; k = 1, 2, \ldots, N,\\
&B_{rj} = B_j^1 - A_{12}A_{22}^{-1}B_j^2, \;\; j = 1, 2, && C_{ri} = C_{i1} - C_{i2}A_{22}^{-1}A_{21}, \;\; i = 1, 2,\\
&C_r^k = C_{21}^k, k = 1, 2, \ldots, N, && D_r^{ij} = D_{ij} - C_{i2}A_{22}^{-1}B_j^2, \; i, j = 1, 2.
\end{aligned}$$

We also associate the subsystem

$$\begin{aligned} x_f'(\tau) &= A_{22}x_f(\tau) + B_1^2 v_f(\tau) + B_2^2 u_f(\tau),\\ y_{f1}(\tau) &= C_{12}x_f(\tau) + D_{11}v_f(\tau) + D_{12}u_f(\tau),\\ y_{f2}(\tau) &= C_{22}x_f(\tau) + D_{21}v_f(\tau), \end{aligned} \tag{5.8}$$

where $\tau = \frac{t}{\varepsilon}$, which is the "boundary layer subsystem" or "fast subsystem" corresponding to system (5.1).

The closed loop system obtained by coupling a strict proper controller of type (5.2) to the reduced subsystem (5.7) is described by

$$\begin{aligned} dx_r(t) &= [A_r x_r(t) + B_{r2}C_c x_c(t) + B_{r1}v_r(t)]dt + \sum_{k=1}^{N} A_r^k x_r(t)dw_k(t),\\ dx_c(t) &= [B_c C_{r2}x_r + (A_c + B_c D_r^{22}C_c)x_c + B_c D_r^{21}v_r]dt + \sum_{k=1}^{N} B_c C_{22}^k x_r(t)dw_k(t),\\ y_{r1}(t) &= C_{r1}x_r(t) + D_r^{12}C_c x_c(t) + D_r^{11}v_r(t). \end{aligned} \tag{5.9}$$

We denote by $\mathbf{T}_r^{cl} : \tilde{L}^2([0,\infty), \mathbf{R}^{m_1}) \to \tilde{L}^2([0,\infty); \mathbf{R}^{p_1})$ the input-output operator defined by system (5.8).

The first result in this section is presented by the following theorem.

THEOREM 5.1. *Assume:* (a) *All eigenvalues of matrix A_{22} are located in the half plane of* $\mathrm{Re}(s) < 0$*; and* (b) *A strict proper controller of type* (5.2) *was designed in order to stabilize the reduced subsystem* (5.7). *Under these assumptions, there exists an $\hat{\varepsilon} > 0$, such that the same strict proper controller stabilizes the full system* (5.1) *for any arbitrary $\varepsilon \in (0, \hat{\varepsilon})$. Moreover, the input-output operator $\mathbf{T}_\varepsilon^{cl}$ of the corresponding closed loop system* (5.5) *has the asymptotic behavior*

$$\lim_{\varepsilon \to 0} \|\mathbf{T}_\varepsilon^{cl}\| = \max\{\|\mathbf{T}_r^{cl}\|;\ \|C_{12}(sI_{n_2} - A_{22})^{-1}B_1^2 + D_{11}\|_\infty\}. \tag{5.10}$$

Proof. To show that the designed controller stabilizes system (5.1), we shall apply Theorem 3.1 to system (5.5).

To this end, we remark that the coefficient matrix of the boundary layer subsystem is just A_{22}, which is stable.

On the other hand, by direct calculation, we obtain that the reduced subsystem associated to the closed loop system (5.5) is just (5.9).

By assumption (b), the zero state equilibrium of system (5.9) (with $v_r = 0$) is ESMS.

Finally, the asymptotic behavior of the norm of the input-output operator associated to the closed loop system can be obtained by applying Theorem 4.5. □

REMARK 5.2. *Based on the stochastic version of the small gain theorem (see, e.g.,* [7]), *it follows that the level of robustness achieved by a stabilizing controller is measured by the norm of the input-output operator associated to the closed loop system.*

From Theorem 5.1, it follows that, if a strict proper controller of type (5.2) was designed to stabilize the reduced subsystem (5.7) and to achieve $\|\mathbf{T}_r^{cl}\| < \gamma$ for a prefixed tolerance $\gamma > 0$, then the same controller will achieve a level of attenuation less than $\gamma + \mathcal{O}(\varepsilon)$ for the full system (5.1) only if

$$\|C_{12}(sI_{n_2} - A_{22})^{-1}B_1^2 + D_{11}\|_\infty < \|\mathbf{T}_r^{cl}\|.$$

Hence equality (5.10) gives a measure of loss-level of robustness when a robustly stabilizing controller (5.2) designed to stabilize the subsystem (5.7) is used in the full system (5.1) with stable fast dynamics.

REMARK 5.3. *From the expressions of the coefficient matrices of the closed loop system* (5.6), *it follows that the coefficient matrix of the boundary layer subsystem may be unstable even if* A_{22} *is stable.*

Then, under a proper controller, the fast dynamics may become unstable. We recall that, if A_{22} *is stable, then* $A_{22} + B_2^2 D_c C_{22}$ *is also stable if and only if*

$$\|D_c\| < [\|C_{22}(sI_{n_2} - A_{22})^{-1}B_2^2\|_\infty]^{-1}.$$

For details, see [27].

THEOREM 5.2. *Assume that* (a) *The matrix* A_{22} *is stable and* $C_{2j}^k = 0$, $j = 1, 2$, $k = 1, \ldots, N$, *and* (b) *a controller of the form*

$$\begin{aligned} \dot{x}_c(t) &= \tilde{A}_c x_c(t) + \tilde{B}_c y_2(t), \\ \dot{u}_2(t) &= \tilde{C}_c x_c(t) + \tilde{D}_c y_2(t) \end{aligned} \tag{5.11}$$

was designed in order to stabilize the system obtained from (5.7) *taking* $D_r^{22} = 0$. *In addition, the following conditions are satisfied:*

$$\begin{aligned} &\text{(i)} \quad A_{22} - B_{22}\tilde{D}_c C_{22} \text{ is invertible, and} \\ &\text{(ii)} \quad \|\tilde{D}_c(I_{p_2} - C_{22}A_{22}^{-1}B_2^2\tilde{D}_c)^{-1}\| < (\|C_{22}(sI_{n_2} - A_{22})^{-1}B_2^2\|_\infty)^{-1}. \end{aligned} \tag{5.12}$$

Set

$$\begin{aligned} A_c &= \tilde{A}_c + \tilde{B}_c(I_{p_2} - C_{22}A_{22}^{-1}B_2^2\tilde{D}_c)^{-1}C_{22}A_{22}^{-1}B_2^2\tilde{C}_c, \\ B_c &= \tilde{B}_c(I_{p_2} - C_{22}A_{22}^{-1}B_2^2\tilde{D}_c)^{-1}, \\ C_c &= \tilde{C}_c + \tilde{D}_c(I_{p_2} - C_{22}A_{22}^{-1}B_2^2\tilde{D}_c)^{-1}C_{22}A_{22}^{-1}B_2^2\tilde{C}_c, \\ D_c &= \tilde{D}_c(I_{p_2} - C_{22}A_{22}^{-1}B_2^2\tilde{D}_c)^{-1}. \end{aligned} \tag{5.13}$$

Under these conditions there exists an $\tilde{\varepsilon} > 0$ *such that the controller of type* (5.3) *having the coefficient matrix defined in* (5.13) *stabilizes system* (5.1) *for any arbitrary* $\varepsilon \in (0, \tilde{\varepsilon})$.

Moreover, the norm of the input-output operator defined by the corresponding closed loop system verifies

$$\lim_{\varepsilon \to \infty} \|\mathbf{T}_\varepsilon^{cl}\| = \max\{\|\tilde{\mathbf{T}}_r^{cl}\|, \|\tilde{G}_f\|_\infty\}, \tag{5.14}$$

where $\tilde{\mathbf{T}}_r^{cl}$ *is the input-output operator obtained by coupling the controller* (5.11) *to the reduced system* (5.7) *with* $D_r^{22} = 0$ *and*

$$\begin{aligned} \tilde{G}_f(s) = {} & (C_{12} + D_{12}D_c C_{22})(sI_{n_2} - A_{22} - B_2^2 D_c C_{22})^{-1}(B_1^2 - B_2^2 D_c D_{21}) \\ & + D_{11} + D_{12}D_c D_{21}. \end{aligned} \tag{5.15}$$

Proof. If $A_{22} - B_2^2\tilde{D}_c C_{22}$ is invertible, then, by direct calculation, it can be checked that $I_{p_2} - C_{22}A_{22}^{-1}B_2^2\tilde{D}_c$ is an invertible matrix, and therefore the formulae (5.13) are well defined. Now, the conclusion of the theorem follows in the same way as in the case of Theorem 5.1 by applying Theorems 3.1 and 4.5. ∎

REMARK 5.4. *From Theorem* 5.2, *we may conclude that if we design a controller* (5.11) *in order to stabilize the slow subsystem associated to the given system* (5.1) *and to achieve a prescribed level of disturbance attenuation for that slow subsystem, then such a controller may deteriorate the properties concerning the stabilization and the level of disturbance attenuation of the fast subsystem, and, as a consequence, it may deteriorate properties concerning the disturbances attenuation of the closed loop system defined by* (5.1) *and* (5.13).

An alternative algorithm of designing of an ε-independent stabilizing controller for singularly perturbed systems of type (5.1) could be as follows.

Step 1. Choose a matrix D_c such that the control $u_f = D_c x_f$ stabilizes the fast subsystem (5.8) and $\|\tilde{G}_f(s)\|_\infty < \gamma$, $\tilde{G}_f(s)$ being defined in (5.15).

Step 2. Make the change $u(t) = D_c y_2 + \tilde{u}_2$ in the space of controls of system (5.1).

Thus we obtain the modified system

$$
\begin{aligned}
dx_1(t) &= [(A_{11} + B_2^1 D_c C_{21})x_1(t) + (A_{12} + B_2^2 D_c C_{22})x_2(t) \\
&\quad + (B_1^1 + B_2^1 D_c D_{21})v(t) + B_2^1 \tilde{u}_2(t)]dt + \sum_{k=1}^{N} [A_{11}^k x_1(t) + \varepsilon^\mu A_{12}^k x_2(t)]dw_k(t), \\
\varepsilon dx_2(t) &= [(A_{21} + B_2^2 D_c C_{21})x_1(t) + (A_{22} + B_2^2 D_c C_{22})x_2(t) + (B_1^2 + B_2^2 D_c D_{21})v(t) \\
&\quad + B_2^2 \tilde{u}_2(t)]dt + \varepsilon^{nu} \sum_{k=1}^{N} [A_{21}^k x_1(t) + A_{22}^k x_2(t)]dw_k(t), \qquad (5.16) \\
y_1(t) &= (C_{11} + D_{12} D_c C_{21})x_1(t) + (C_{12} + D_{12} D_c C_{22})x_2(t) \\
&\quad + (D_{11} + D_{12} D_c D_{21})v(t) + D_{12} \tilde{u}_2(t), \\
y_2(t) &= C_{21} x_1(t) + C_{22} x_2(t) + D_{21} v(t).
\end{aligned}
$$

Step 3. Design (if possible) a strict proper controller of type (5.2) which stabilizes the reduced subsystem associated to system (5.16) obtained by setting $\varepsilon = 0$. Again using Theorem 3.1, we obtain that the controller

$$
\begin{aligned}
u_2(t) &= D_c y_2(t) + \tilde{u}_2(t), \\
\tilde{u}_2(t) &= C_c x_c(t), \qquad (5.17) \\
\dot{x}_c &= A_c x_c(t) + B_c y_2(t)
\end{aligned}
$$

stabilizes system (5.1) for arbitrary $\varepsilon > 0$ small enough. By applying Theorem 4.5, we may obtain information concerning the level of disturbance attenuation provided by the controller (5.17) in system (5.1).

REMARK 5.5. *In general, the reduced subsystem associated to system* (5.16) *is proper and not strict proper, and, in this case, a strict proper controller cannot provide a good level of disturbance attenuation for the slow closed loop system. Hence the controllers of type* (5.17) *designed to improve the level of disturbance attenuation for the fast subsystem of system* (5.1) *may deteriorate the properties of disturbance attenuation of the slow close loop system. The main conclusion of this section is that a stabilizing controller achieving a satisfactory level of disturbance attenuation for both the slow part and the fast part of the closed loop system must be a controller with two time scales.*

Appendix.

LEMMA A.1. *Consider the affine system*

$$dx(t) = [A_0x(t) + F_0(t)]dt + \sum_{i=1}^{N}[A_ix(t) + F_i(t)]dw_i(t), \tag{A.1}$$

where $F_i \in L_w^2((0,\infty)\times\Omega,\mathbf{R}^n), i = 0,1,2,\ldots,N$. *If the zero solution of the linear system*

$$dx(t) = A_0x(t)dt + \sum_{i=1}^{N} A_ix(t)dw_i(t)$$

is ESMS, then there exist positive constants c *and* α *such that all the solutions of system* (A.1) *verify*

$$E|x(t)^2 \le c\left[e^{-\alpha(t-t_0)}E|x(t_0)|^2 + \sum_{i=0}^{N}\int_{t_0}^{t} e^{-\alpha(t-s)}E|F_i(s)|^2ds\right] \quad \forall t \ge t_0 \ge 0.$$

Proof. The proof can be carried out by the same approach as that used in Proposition 1 in [10] or as in Theorem 5.1 in [11], which is based on a Lyapunov functional technique. □

It should be mentioned that the proof of this inequality cannot be conducted by direct estimation from the constant variation formula, as in the deterministic framework.

LEMMA A.2. *Consider the affine system with singular perturbation*

$$\varepsilon dx(t) = [A_0x(t) + g_0(t)]dt + \varepsilon^{\nu}\sum_{i=1}^{N}[A_ix(t) + g_i(t)]dw_i(t), \tag{A.2}$$

where $\nu > \frac{1}{2}, g_i \in L_w^2((0,\infty)\times\Omega,\mathbf{R}^n), i = 0,1,2,\ldots,N$. *If* A_0 *is Hurwitz, then there exist positive constants* c *and* α *such that all solutions of system* (A.2) *verify*

$$E|x(t,\varepsilon)|^2 \le c\left[e^{\frac{-\alpha(t-t_0)}{\varepsilon}}E|x(t_0,\varepsilon)|^2 + \sum_{i=0}^{N}\int_{t_0}^{t} e^{\frac{-\alpha(t-s)}{\varepsilon}}E|g_i(s)|^2ds\right] \quad \forall t \ge t_0 \ge 0,$$

where $\varepsilon > 0$ *is small enough.*

Proof. The desired result can be carried out by using Lemma A.1. □

Acknowledgment. The authors wish to thank the referees for their constructive comments and suggestions, which have improved the presentation.

ON THE MODELLING AND STABILIZATION OF FLOWS IN NETWORKS OF OPEN CANALS*

GUENTER LEUGERING† AND E. J. P. GEORG SCHMIDT‡

Abstract. In this paper, we present a model for the controlled flow of a fluid through a network of canals using a coupled system of St. Venant equations. We then generalize in a variety of ways recent results of Coron, d'Ándréa-Novel, and Bastin concerning the stabilizability around equilibrium of the flow through a single channel. This work is based on the theory of quasilinear hyperbolic systems and, in particular, on a delicate result of Li Ta-tsien concerning the existence and decay of global classical solutions.

Key words. St. Venant equations, hyperbolic systems, stabilizability, control of canals

1. Introduction.

The St. Venant equations are a nonlinear hyperbolic system first introduced in [10] to model the flow of fluid through a canal (or channel). They have, in particular, become a standard tool for hydraulic engineers used in the modelling of the dynamics of canals and rivers.

The book [4] provides a useful engineering reference to this topic. A recent paper [2] has considered the flow along a canal between two large bodies of water controlled by sluice gates at the ends of the canal. The settings of these gates determine the fluid velocity at the two ends, and the main result shows that suitable feedback boundary conditions can be used to exponentially stabilize a given operational state of the canal. This result depends on a subtle theorem of Greenberg and Li [5], which guarantees the exponential decay of solutions to certain hyperbolic systems in two variables subject to boundary conditions which impose damping. See also the monograph by Li [8] and [1], [3].

Our main contributions in this paper are

- to derive a model for the flow of fluid through a network of canals;
- to prove the feedback stabilizability of certain equilibrium operating states in a system of canals meeting at one "multiple node" for a broad class of feedback controls acting at the "simple nodes"; and
- to prove feedback null controllability using an absorbing feedback law.

Furthermore, we shall generalize the result of [2], allowing canals of nonrectangular cross section and using a broad class of boundary conditions. In order to prove stabilizability for a system of canals, we shall use a generalization of the "boundary damping" result in [5] to be found in [8] which applied to hyperbolic systems with arbitrarily many variables. As was the case for the previously cited papers, our

methods are entirely nonlinear but do remain within the realm of classical, shock-free solutions.

We end this introduction with some comments on notation. We shall denote derivatives of functions of a single scalar variable by D or sometimes by D_s, where s is the variable. In the presence of other variables, we let ∂_s denote partial differentiation with respect to s. We let $\bigtriangledown$ or $\bigtriangledown_{\mathbf{s}} = (\partial_{s_1}, \ldots, \partial_{s_n})$ denote the gradient of a function with respect to a vectorial argument $\mathbf{s} = (s_1, \ldots, s_n)$. We also introduce some norms. For an m-vector $\boldsymbol{\xi} = (\xi_1, \ldots, \xi_m)$ and an $l \times m$ matrix A, we define

$$|\boldsymbol{\xi}|_\infty = \max\{|\xi_i| : i = 1, \ldots, m\}, \quad \| A \|_\infty = \max \left\{ \sum_{j=1}^{m} |A_{ij}| : i = 1, \ldots, l \right\}.$$

One then has

$$|A\boldsymbol{\xi}|_\infty \leq \| A \|_\infty \, |\boldsymbol{\xi}|_\infty \quad \text{and} \quad \| AB \|_\infty \leq \| A \|_\infty \| B \|_\infty,$$

where B is a second matrix having m rows. Let $C([0, L]; \mathbb{R}^n)$ and $C^1([0, L]; \mathbb{R}^n)$ denote, respectively, the spaces of continuous and continuously differentiable functions from $[0, L]$ to $\mathbb{R}^n$ with corresponding norms

$$\| \boldsymbol{\xi}(\cdot) \| = \sup\{|\boldsymbol{\xi}(x)|_\infty : x \in [0, L]\}, \quad \| \boldsymbol{\xi}(\cdot) \|_1 = \max\{\| \boldsymbol{\xi}(\cdot) \|, \| D\boldsymbol{\xi}(\cdot) \|\}.$$

2. The model. We consider first a single canal parametrized lengthwise by $x \in [0, L]$. Let $Y_b(x)$ denote the altitude above sea level of the bed of the canal at x. The variable $y = y(x) \in [0, d(x)]$ denotes the elevation above the canal bed, where $d(x)$ denotes the depth of the canal. See Figure 2.1. Let $\sigma(x, y)$ denote the width of the canal cross section at x and elevation y. Let $A(x, t)$ denote the area of the cross section at x occupied by water at time t. We assume that the water level is constant across the canal at height $h(x, t) \in [0, d(x)]$. Clearly, $A = A(x, h)$ and $h = h(x, A)$. See Figure 2.2. In particular, leaving aside t dependence for the moment,

$$A(x, h) = \int_0^h \sigma(x, y)\, dy \quad \text{and} \quad A = \int_0^{h(x,A)} \sigma(x, y)\, dy. \tag{2.1}$$

It follows that

$$\partial_h A(x, h) = b(x, h) \quad \text{and} \quad \partial_A h(x, A) = \frac{1}{b(x, A)}, \tag{2.2}$$

where $b(x, h) \triangleq \sigma(x, h)$ (or $b(x, A) \triangleq \sigma(x, h(x, A))$) is the width of the water surface at x.

It turns out to be convenient to choose $A(x, t)$, rather than $h(x, t)$, as our geometric state variable describing the distribution of water along the canal at a given time since it conveniently leads to a system of conservation laws. The derivation of the St. Venant equations depends on the assumption that the flow of water along the canal can be represented by a scalar velocity function $V(x, t)$ in the direction of the channel from 0 to L. This can be thought of either as a constant or as an average velocity over the cross section of the channel. For a more detailed physical discussion of the underlying assumptions of the St. Venant model, see [4, p. 8].

Assuming a constant density ($\rho \equiv 1$, say), the mass flow rate of the liquid along the channel is given by $Q(x, t) \triangleq A(x, t)V(x, t)$. Conservation of mass is then expressed by the conservation equation

$$\partial_t A + \partial_x [AV] = 0, \tag{2.3}$$

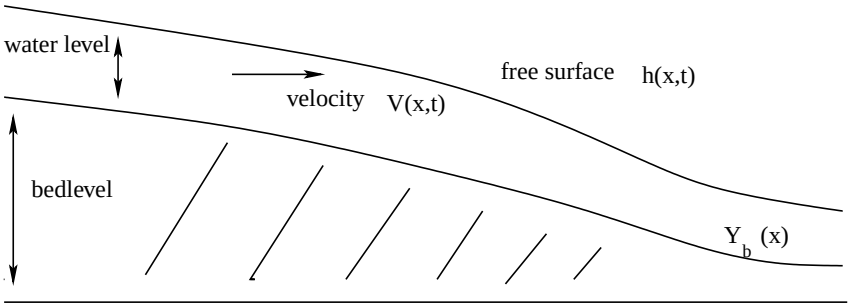

FIG. 2.1. *The configuration.*

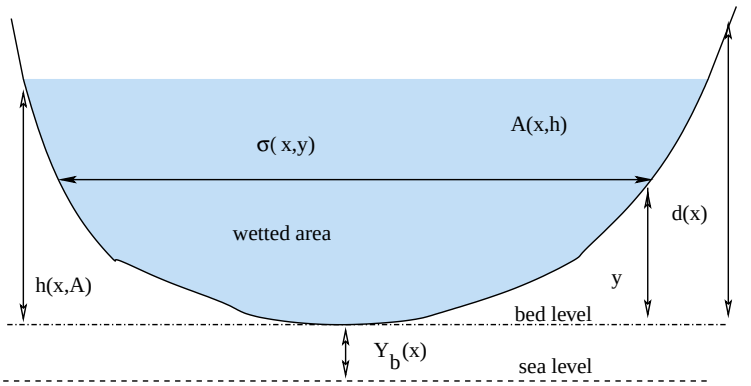

FIG. 2.2. *Cross section at x.*

or, in the weak form,

$$\int\int [A\partial_t\phi + AV\partial_x\phi]\, dx\, dt = 0 \tag{2.4}$$

for smooth test functions.

To obtain the St. Venant system, the conservation equation has to be complemented with a dynamical equation. We derive this from Hamilton's principle applied to the Lagrangian functional

$$\mathcal{L}(A,V) \triangleq \int_0^T \int_0^L \left[\frac{1}{2}AV^2 - g\int_0^{h(x,A)} [Y_b(x)+y]\sigma(x,y)\, dy\right] dxdt \tag{2.5}$$

obtained as the difference between the kinetic and potential energies, where g is the gravitational constant. Here A and $Q = AV$ are assumed to satisfy (2.3), and the same will have to be true of the variations δA and $\delta Q = (A+\delta A)(V+\delta V) - AV = A\delta V + V\delta A$. Now if we let $\delta A = \partial_x\phi$ and $\delta Q = -\partial_t\phi$, with ϕ a smooth function of x and t with support in $(0,L)\times(0,T)$, then (2.3) is indeed satisfied. So we get

$$\delta A = \partial_x\phi, \quad A\delta V = \delta Q - V\delta A = -\partial_t\phi - V\partial_x\phi.$$

Noting that

$$\int_0^{h(x,A)} Y_b(x)\sigma(x,y)\, dy = AY_b(x),$$

using (2.2), and recalling that $b(x, A) = \sigma(x, h(x, A))$, we now get

$$\begin{aligned}\frac{d}{d\lambda}\mathcal{L}(A+\lambda\delta A, V+\lambda\delta V)\Big|_{\lambda=0} &= \int_0^T \int_0^L \left[\frac{1}{2}V^2\delta A + AV\delta V - gY_b(x)\delta A - gh(x,A)\delta A\right] dxdt \\ &= \int_0^T \int_0^L \left[\left[\frac{1}{2}V^2 - gh(x,A) - gY_b(x)\right]\partial_x\phi - V[\partial_t\phi + V\partial_x\phi]\right] dxdt.\end{aligned}$$

Setting this equal to 0, we get

$$\int_0^T \int_0^L \left[\left[\frac{1}{2}V^2 + gh(x,A) + gY_b(x)\right]\partial_x\phi + V\partial_t\phi\right] dxdt = 0, \tag{2.6}$$

the weak form of

$$\partial_t V + \partial_x\left[\frac{1}{2}V^2 + gh(x,A) + gY_b(x)\right] = 0. \tag{2.7}$$

REMARK 1. *One can add an empirically motivated resistance, or friction, term to the left-hand side of the last equation. Various alternatives occur in the engineering literature (see, for example,* [4, pp. 19–22]). *Generically these are of the form* $F(x, A, V)$ *satisfying*

$$F(x, A, 0) = 0 \quad \textit{and} \quad VF(x, A, V) \geq 0. \tag{2.8}$$

We may also take into account sign conditions on the partial derivatives of F. Now we consider networks of canals. We use notation similar to that introduced in [6] for networks of strings and beams. We index the canals, and the quantities associated with the canals, by $i \in \mathcal{I} = \{1, \ldots, n\}$. We label the locations of the end points of the canals, which we shall refer to as nodes, by $j \in \{1, \ldots, m\}$. We distinguish between multiple nodes, indexed by $j \in \mathcal{J}_M$, at which various canals come together, and the simple nodes, indexed by $j \in \mathcal{J}_S$, which are endpoints of a single canal. For $j \in \mathcal{J}$, we introduce

$$\mathcal{I}_j = \{i \in \mathcal{I} : \text{ the } i\text{th canal meets the } j\text{th node}\}.$$

For $i \in \mathcal{I}_j$, we set $x_{ij} = 0$ or L_i corresponding to the end which meets the other canals at the jth node. We also set $\epsilon_{ij} = 1$ if $x_{ij} = L_i$ or $\epsilon_{ij} = -1$, if $x_{ij} = 0$.

At simple nodes, we shall later impose boundary conditions through which controls can be imposed on the network. At multiple nodes, we shall first impose the following condition expressing conservation of fluid in the flow through the node indexed by $j \in \mathcal{J}_M$:

$$\sum_{i\in\mathcal{I}_j} \epsilon_{ij} Q_i(x_{ij}, t) = \sum_{i\in\mathcal{I}_j} \epsilon_{ij} A_i(x_{ij}, t) V_i(x_{ij}, t) = 0 \quad \text{for } j \in \mathcal{J}_M. \tag{2.9}$$

We shall derive a second dynamic node condition from Hamilton's principle.

For each $i \in \mathcal{I}$, we require that $A_i(x, t)$ and $V_i(x, t)$ satisfy the continuity equation

$$\partial_t A_i + \partial_x[A_i V_i] = 0. \tag{2.10}$$

Let $\mathbf{A} = (A_1, \dots, A_n)$ and $\mathbf{V} = (V_1, \dots, V_n)$. We introduce the Lagrangian functional

$$\mathcal{L}(\mathbf{A}, \mathbf{V}) \triangleq \sum_{i \in \mathcal{I}} \int_0^T \int_0^{L_i} \left[\frac{1}{2} A_i V_i^2 - g \int_0^{h_i(x, A_i)} [Y_{bi}(x) + y] \sigma_i(x, y)\, dy \right] dx dt. \tag{2.11}$$

The components of $\mathbf{A}$ and of $\mathbf{V}$ and their variations have to satisfy (2.9) and (2.10). This can be achieved, much as before, for variations generated by

$$\delta A_i = \partial_x \phi_i, \quad A_i \delta V_i = \delta Q_i - V_i \delta A_i = -\partial_t \phi_i - V \partial_x \phi_i, \tag{2.12}$$

where the set of smooth functions $\phi_i(x, t)$ satisfy

$$\sum_{i \in \mathcal{I}_j} \epsilon_{ij} \partial_t \phi_i(x_{ij}, t) = 0 \quad \text{for each } j \in \mathcal{J}. \tag{2.13}$$

Exactly as before, we then get

$$\begin{aligned} &\frac{d}{d\lambda} \mathcal{L}(\mathbf{A} + \lambda \delta \mathbf{A}, \mathbf{V} + \lambda \delta \mathbf{V}) \Big|_{\lambda = 0} \\ &\quad = - \sum_{i \in \mathcal{I}} \int_0^T \int_0^{L_i} \left[\left(\frac{1}{2} V_i^2 + g h_i(x, A_i) + g Y_{bi}(x) \right) \partial_x \phi_i + V_i \partial_t \phi_i \right] dx dt. \end{aligned}$$

Now we set this equal to zero using the variations in two different ways. First, we restrict our attention to one index i; letting ϕ_i have support in $(0, L) \times (0, T)$ and setting variations in the other components equal to zero, we get the indexed version of (2.6) with indexed quantities, the weak form of

$$\partial_t V_i + \partial_x \left[\frac{1}{2} V_i^2 + g h_i(x, A_i) + g Y_{bi}(x) \right] = 0. \tag{2.14}$$

Second, we concentrate on the jth node, making variations only in A_i and V_i for $i \in \mathcal{I}_j$ with $j \in \mathcal{J}_M$. In fact, we choose any two indices $k, l \in \mathcal{I}_j$ and set $\phi_i \equiv 0$ for $i \neq k, l$. Supposing that $x_{kj} = 0$ and $x_{lj} = 0$, we can choose $\phi \in C_0^\infty([0, \check{L}) \times (0, T))$ with $\check{L} = \min\{L_k, L_l\}$ and set $\phi_k = \phi$ and $\phi_l = -\phi$ to get admissible variations. We introduce the notation

$$S_i \triangleq \frac{1}{2} V_i^2 + g h_i(x, A_i) + g Y_{bi}(x)$$

(a quantity which, divided by g, is called the *specific energy*) and get

$$\int_0^T \int_0^{\tilde{L}} \left[(S_k - S_l) \partial_x \phi + (V_k - V_l) \partial_t \phi \right] dx dt = 0 \tag{2.15}$$

for any $\phi \in C_0^\infty([0, \check{L}) \times (0, T))$. Assuming sufficient regularity, we can integrate by parts and use (2.14) and the support properties of $\phi(x, t)$ to get

$$\int_0^T [S_k(0, t) - S_l(0, t)] \phi(0, t)\, dt = 0.$$

Since ϕ can be chosen so that $\phi(0, t)$ is an arbitrary function in $C_0^\infty((0, T))$, we can conclude that

$$S_k(x_{kj}, t) \equiv S_l(x_{lj}, t).$$

The above argument can be modified to deal with the various cases in which x_{kj} and x_{lj} are not both zero. So we end up with the following dynamic node condition for each $j \in \mathcal{J}_M$:

$$\left[\frac{1}{2}V_i^2 + gh_i(\cdot, A_i) + gY_{bi}\right](x_{ij}, t) \text{ coincide for } i \in \mathcal{I}_j. \tag{2.16}$$

REMARK 2. *One can, in fact, derive this node condition from* (2.15) *without assuming differentiability of* A_i *and* V_i. *This is done by a mollification argument. So, in fact,*

$$\sum_{i\in\mathcal{I}} \int_0^T \int_0^{L_i} \left[\left(\frac{1}{2}V_i^2 + gh_i(x, A_i) + gY_{bi}(x)\right)\partial_x\phi_i + V_i\partial_t\phi_i\right] dxdt = 0 \tag{2.17}$$

for test functions $\phi_i \in C_0^\infty([0, L_i) \times (0, T))$ *satisfying that* (2.13) *is a suitable weak formulation of both the dynamic equations* (2.14) *and the dynamic node conditions* (2.16).

To summarize, the network is described by (2.14) and supplemented by the multiple node conditions (2.9) and (2.16) as well as boundary conditions to be imposed at the simple nodes and initial conditions prescribing $\mathbf{A}(x, 0)$ and $\mathbf{V}(x, 0)$. The discussion of the boundary conditions will be given later, taking into account issues concerning hyperbolic systems.

We end this section with a comment on energy conservation. Let

$$\begin{aligned} E(A, V) &\triangleq \frac{1}{2}AV^2 + g\int_0^{h(x,A)} [Y_b(x) + y]\sigma(x, y)\, dy \\ &= \frac{1}{2}AV^2 + gAY_b(x) + g\int_0^{h(x,A)} y\sigma(x, y)\, dy, \end{aligned} \tag{2.18}$$

where A and V satisfy (2.3) and (2.7). Then one easily verifies

$$\partial_t E + \partial_x[QS] = 0. \tag{2.19}$$

This of course also holds in indexed form for each canal, and if one introduces the total energy

$$\mathcal{E}(t) = \mathcal{E}(\mathbf{A}(\cdot, t), \mathbf{V}(\cdot, t)) \triangleq \sum_{i\in\mathcal{I}} \int_0^{L_i} E_i(A_i, V_i)(x, t)\, dx,$$

one obtains, using the multiple node conditions,

$$D_t\mathcal{E}(t) = \sum_{j\in\mathcal{J}_S} Q(x_{ij}, t)S(x_{ij}, t)$$

so that energy is conserved if, for example, there is no flow through the simple nodes of the canal network.

REMARK 3. *Friction can be introduced with a friction term* $F_i(x, A_i, V_i)$ *in the left-hand side of each equation* (2.14). *One then gets the following index-free variant of* (2.19)*:*

$$\partial_t E + \partial_x[QS] + F(x, A, V) = 0$$

as well as

$$D_t\mathcal{E}(t) = \sum_{j\in\mathcal{J}_S} Q(x_{ij},t)S(x_{ij},t) - \sum_{i\in\mathcal{I}} \int_0^{L_i} A_iV_iF_i(x,A_i,V_i)\,dx.$$

The friction terms lead to energy decay because of the assumption (2.8).

3. Equilibrium flows and their perturbations. We seek solutions $\overline{\mathbf{A}}$ and $\overline{\mathbf{V}}$ of the network system described in the previous section which depend only on x and not on t. Explicitly, they are required to satisfy

$$\begin{cases} \partial_x[\overline{A}_i\overline{V}_i] = 0 \ \text{ on } [0,L_i] & \text{for } i\in\mathcal{I}, \\ \partial_x[\frac{1}{2}\overline{V}_i^2 + gh_i(x,\overline{A}_i) + gY_{bi}(x)] = 0 \ \text{ on } [0,L_i] & \text{for } i\in\mathcal{I}, \\ \sum_{i\in\mathcal{I}_j}\epsilon_{ij}\overline{A}_i(x_{ij})\overline{V}_i(x_{ij}) = 0 & \text{for } j\in\mathcal{J}_M, \\ \frac{1}{2}\overline{V}_i(x_{ij})^2 + gh_i(x_{ij},\overline{A}_i(x_{ij})) + gY_{bi}(x) \text{ coincide} & \text{for } j\in\mathcal{J}_M, i\in\mathcal{I}_j. \end{cases} \tag{3.1}$$

It is easy to deduce that one must have

$$\overline{A}_i(x)\overline{V}_i(x) \equiv \overline{Q}_i \ \text{ with } \sum_{i\in\mathcal{I}_j}\epsilon_{ij}\overline{Q}_{ij} = 0, \tag{3.2}$$

$$\overline{S}_i(x) = \frac{1}{2}\overline{V}_i(x)^2 + gh_i(x,\overline{A}_i(x)) + gY_{bi}(x) \equiv \overline{S}, \tag{3.3}$$

where $\overline{Q}_i$ and $\overline{S}$ are constants.

We say that the fluid in the canals is *still* if $\mathbf{V} = \mathbf{0}$. In that case, the components of $\mathbf{A}(x)$ are determined from

$$h_i(x,\overline{A}_i(x)) = \frac{1}{g}[\overline{S} - gY_{bi}(x)],$$

which will have a solution respecting the depth restriction on each canal if and only if

$$0 \le \frac{1}{g}[\overline{S} - gY_{bi}(x)] \le d_i(x) \ \text{ for all } i\in\mathcal{I}.$$

The equilibria which are not still are more difficult to determine. For the purposes of this paper, we now make two restrictive assumptions, namely

- the canals are *prismatic*, which means that the cross sections of the canals do not depend on x (so d_i, h_i, σ_i, and b_i do not depend directly on x); and
- the system of canals is *level*, the beds of the canals all lying at the same constant elevation Y_b.

In this case, equilibria $\mathbf{A},\mathbf{V}$ will not depend on x. One can think of canals designed with certain operating conditions in mind. For example, one can specify a standard water height of $\overline{h}$ for the whole canal system with $\overline{h} < d_i$ for each $i\in\mathcal{I}$. For each canal, one can fix the flow direction, encoding this by $\epsilon_i = 1$ or -1 depending on whether $\overline{V}_i$ is to be positive or negative. This is to be done in such a way that at each multiple node flows occur both into and out of the node. We then try to design the cross sections of each canal in such a way that $\overline{A}_i = A_i(\overline{h})$ satisfy

$$\sum_{i\in\mathcal{I}_j}\epsilon_{ij}\epsilon_i\overline{A}_i = 0. \tag{3.4}$$

If this is possible, we can set $\overline{V}_i = \epsilon_i \overline{V}$, where $\overline{V}$ is any given positive velocity, and easily check that the conditions (3.1) are satisfied. To clarify the meaning of the above condition, we note that, when $\epsilon_{ij}\epsilon_i = 1$, the flow in the ith canal is into the jth node while, when $\epsilon_{ij}\epsilon_i = -1$, that flow is away from the node. For canals of rectangular cross section with b_i the breadth of the ith canal, one can require

$$\sum_{i \in \mathcal{I}_j} \epsilon_{ij}\epsilon_i b_i = 0, \tag{3.5}$$

independently of the value $\overline{h}$. It is almost obvious that the above process always works in the following particular network configurations:

- star configurations in which n canals all meet at one multiple node;
- tree configurations in which the direction of flow is always toward the trunk or always away from the trunk.

REMARK 4. *One can easily experiment with a variety of particular networks and direction assignments to find many other configurations in which the above process works. These may include closed paths.*

A general goal now is to stabilize the flow around such an equilibrium flow by means of suitable feedback boundary conditions at the simple nodes, which lie at the extremities of the canal network, i.e., at the points where water flows into or out of the system of canals. At present, we can do this only for star configurations. In fact, we first consider a single canal for which our results are also in large part new.

4. Stabilization and null controllability for a single canal. We consider one level, prismatic canal and study perturbations of constant equilibrium flows.

First we make use of the standard method of Riemann invariants for hyperbolic systems to be found, for example, in Taylor [9, Chapter 16]. We begin with a single canal. Evaluating the x derivatives in (2.3) and (2.7), we can rewrite these equations as a system

$$\partial_t \begin{pmatrix} A \\ V \end{pmatrix} + \begin{pmatrix} V & A \\ g/b(A) & V \end{pmatrix} \partial_x \begin{pmatrix} A \\ V \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}. \tag{4.1}$$

The eigenvalues of the matrix are

$$\lambda_\pm(A,V) = V \pm \gamma(A), \quad \text{where } \gamma(A) = \sqrt{gA/b(A)} \tag{4.2}$$

with $\lambda_+ > 0$ and $\lambda_- < 0$ in the *subcritical* case that

$$V^2 < gA/b(A). \tag{4.3}$$

The corresponding left eigenvectors are

$$\mathbf{l}_\pm(A) = \frac{1}{2}(\pm\sqrt{g/[Ab(A)]}, 1).$$

Riemann invariants are then obtained by solving

$$\bigtriangledown \xi_\pm(A,V) = (\partial_A, \partial_V)\xi_\pm(A,V) = \mathbf{l}_\pm(A).$$

We can take

$$\xi_\pm(A,V) = \frac{1}{2}\left(V \pm \int_0^A q(\alpha)\, d\alpha\right) \quad \text{with} \quad q(\alpha) = \sqrt{\frac{g}{\alpha b(\alpha)}}.$$

The system (4.1) is now equivalent to

$$\partial_t \xi_\pm(A,V) + \lambda_\pm(A,V)\partial_x \xi_\pm(A,V) = 0.$$

For solutions A and V, the *Riemann invariants* $\xi_\pm$ are constant along characteristic curves $(x_\pm(t),t)$ with

$$D_t x_\pm(t) = \lambda_\pm(A(x_\pm(t),t),V(x_\pm(t),t)).$$

Now we consider perturbations $A = \overline{A} + a$ and $V = \overline{V} + v$ of an equilibrium state. We assume that the equilibrium flow is subcritical so that this will continue to be the case for small perturbations. The system becomes

$$\partial_t \begin{pmatrix} a \\ v \end{pmatrix} + \begin{pmatrix} \overline{V}+v & \overline{A}+a \\ g/b(\overline{A}+a) & \overline{V}+v \end{pmatrix} \partial_x \begin{pmatrix} a \\ v \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}. \tag{4.4}$$

In terms of the perturbation variables a and v, the eigenvalues of the matrix are

$$\lambda_\pm(a,v) = \overline{V} + v \pm \beta(a), \quad \text{where } \beta(a) = \sqrt{g\frac{\overline{A}+a}{b(\overline{A}+a)}}, \tag{4.5}$$

corresponding to Riemann invariants

$$\xi_\pm(a,v) = \frac{1}{2}\left(v \pm \int_0^a p(\alpha)\,d\alpha\right) \quad \text{with} \quad p(\alpha) = q(\overline{A}+\alpha). \tag{4.6}$$

The characteristic curves $(x_\pm(t),t)$ are now determined by solving

$$D_t x_\pm(t) = \lambda_\pm(a(x_\pm(t),t),v(x_\pm(t),t)). \tag{4.7}$$

We shall often indicate the values of functions evaluated at equilibrium (i.e., with $a = 0$ and $v = 0$) by a bar. For a and v small, the characteristics will lie close to those of the subcritical equilibrium, namely $(\overline{x}_\pm(t),t)$, with

$$\overline{x}_\pm(t) = x_0 + (\overline{V} \pm \overline{\beta})(t - t_0), \tag{4.8}$$

where (x_0,t_0) are arbitrary initial data. We note that the map

$$(a,v) \mapsto (\xi_+(a,v),\xi_-(a,v))$$

is invertible with

$$v = \xi_+ + \xi_- \quad \text{and} \quad a = a(\xi_+ - \xi_-),$$

where $a(\xi)$ is defined implicitly by $\xi = \int_0^{a(\xi)} p(\alpha)\,d\alpha$. We note that $Da(\xi) = 1/p(a(\xi))$.

We next turn to the feedback stabilization of a single canal, which should drive perturbations a and v to zero exponentially in time. The system has to be complemented by initial conditions

$$a(x,0) = a^0(x), \quad v(x,0) = v^0(x). \tag{4.9}$$

In terms of the Riemann invariants, it is well known that one can impose boundary conditions of the form

$$\xi_+(0,t) = g^0(\xi_-(0,t)) \quad \text{and} \quad \xi_-(L,t) = g^L(\xi_+(L,t)).$$

In particular, one could impose the absorbing boundary conditions

$$\xi_+(0,t) = 0 \quad \text{and} \quad \xi_-(L,t) = 0, \tag{4.10}$$

equivalent to the following feedback boundary conditions in terms of a and v:

$$v(0,t) = -P(a(0,t)), \quad v(L,t) = P(a(L,t)) \quad \text{with} \quad P(a) = \int_0^a p(\alpha)\, d\alpha. \tag{4.11}$$

One could also replace $P(a)$ by Taylor approximations $P_1(a) = p(0)a$ or $P_2(a) = p(0)a + p'(0)a^2/2$, say, or, alternatively, by other functions of a.

We shall need the following lemma.

LEMMA 1. *Consider boundary conditions of the form*

$$v(0,t) = f^0(a(0,t)), \quad v(L,t) = f^L(a(L,t)), \tag{4.12}$$

where f^0 and f^L are continuously differentiable functions of a near 0 and satisfy

$$f^0(0) = 0,\ Df^0(0) \neq p(0),\ f^L(0) = 0,\ Df^L(0) \neq -p(0).$$

Then, for small enough values of the variables, the boundary conditions can be rewritten as

$$\xi_+(0,t) = g^0(\xi_-(0,t)), \quad \xi_-(L,t) = g^L(\xi_+(L,t))$$

with

$$g^0(0) = 0,\ Dg^0(0) = \frac{Df^0(0) + p(0)}{Df^0(0) - p(0)},\ g^L(0) = 0,\ Dg^L(0) = \frac{Df^L(0) - p(0)}{Df^L(0) + p(0)}.$$

Proof. We prove the assertions concerning the boundary condition at 0. From $v = \xi_+ + \xi_- = f^0(a(\xi_+ - \xi_-))$, where we suppress the argument $(0,t)$ in all the functions, one gets

$$\xi_- = \phi^0(\xi_+ - \xi_-), \quad \text{with } \phi^0(\xi) = \frac{1}{2}[-\xi + f^0(a(\xi))].$$

Now $D\phi^0(0) = \frac{1}{2}[-1 + Df^0(0)/p(0)]$, which is not zero as long as $Df^0(0) \neq p(0)$. Hence ϕ^0 has a local inverse near 0. So locally $\xi_+ - \xi_- = {\phi^0}^{-1}(\xi_-)$ or $\xi_+ = \xi_- + {\phi^0}^{-1}(\xi_-) = g^0(\xi_-)$ and

$$Dg^0(0) = 1 + \frac{1}{D\phi^0(0)} = \frac{Df^0(0) + p(0)}{Df^0(0) - p(0)}.$$

The other boundary condition is treated similarly starting from

$$\xi_+ = \phi^L(\xi_+ - \xi_-), \quad \text{with } \phi^L(\xi) = \tfrac{1}{2}[\xi + f^L(a(\xi))]. \qquad \square$$

REMARK 5. *If $Df^0(0) = -p(0)$, as is the case when $f^0(a) = -P(a)$ or a Taylor approximation to $P(a)$, one has $Dg^0(0) = 0$ implying strong damping at 0. The situation is similar at L if $Df^L(0) = p(0)$.*

In order to obtain continuously differentiable solutions of (4.4) with initial conditions (3.4) and boundary conditions (4.12), we need to impose the compatibility conditions

$$
\begin{aligned}
& v^0(0) = f^0(a^0(0)), \quad v^0(L) = f^L(a^0(L)), \\
& \frac{g}{b(\overline{A} + a^0(0))} Da^0(0) + (\overline{V} + v^0(0)) Dv^0(0) \\
& \qquad = Df^0(a^0(0)) \left[((\overline{V} + v^0(0)) Da^0(0) + (\overline{A} + a^0(0)) Dv^0(0) \right], \\
& \frac{g}{b(\overline{A} + a^0(L))} Da^0(L) + (\overline{V} + v^0(L)) Dv^0(L) \\
& \qquad = Df^L(a^0(L)) \left[(\overline{V} + v^0(L)) Da^0(L) + (\overline{A} + a^0(L)) Dv^0(L) \right].
\end{aligned} \tag{4.13}
$$

These intricate, but obviously necessary, conditions are automatically satisfied for initial data with compact support in $(0, L)$. At this point, the following generalization of Theorem 1 of [2] is a direct consequence of Theorem 2 of [5] or, alternatively, of Theorem 1.3 of [8].

THEOREM 2. *Consider the St. Venant system* (4.4) *with boundary conditions* (4.12) *and initial conditions* (4.9) *satisfying the compatibility conditions* (4.13). *Suppose that*

$$
|Dg^0(0) Dg^L(0)| = \left| \frac{Df^0(0) + p(0)}{Df^0(0) - p(0)} \frac{Df^L(0) - p(0)}{Df^L(0) + p(0)} \right| < 1. \tag{4.14}
$$

Then if $\| (a^0, v^0) \|_1$ *is sufficiently small, there exists a unique continuously differentiable solution* $(a(x,t), v(x,t))$ *to the problem which is defined for all positive* t *and satisfies an estimate*

$$
\| (a(\cdot, t), v(\cdot, t)) \|_1 < Ce^{-\alpha t} \| (a^0, v^0) \|,
$$

where C *and* α *are suitable positive constants.*

REMARK 6. *In the notation of* [2], *the boundary conditions* (2.16) *of that paper can be written*

$$
\begin{aligned}
u_0 &= -\left(\frac{\overline{V}}{2} + \lambda_0 \right) \frac{y_0 - \overline{y}}{\overline{y} + (y_0 - \overline{y})} \triangleq f^0(y_0 - \overline{y}), \\
u_L &= -\left(\frac{\overline{V}}{2} - \lambda_L \right) \frac{y_L - \overline{y}}{\overline{y} + (y_L - \overline{y})} \triangleq f^L(y_L - \overline{y}).
\end{aligned}
$$

The variables y_0, y_L, *and* $\overline{y}$ *correspond to* $A(0,t)$, $A(L,t)$, *and* $\overline{A}$, *with* $y_0 - \overline{y}$ *corresponding to* $a(0,t)$, *etc. In our notation,* $u_0 = u(0,t)$ *and* $u_L = u(L,t)$. *The quantities calculated in the proof of their Theorem* 1 *correspond directly to our calculation of* $Dg^0(0)$ *and* $Dg^L(0)$. *Our result is more general in that it allows for a broad class of boundary conditions and does not require rectangular cross sections. For this purpose, the use of variables* A *and* V *is advantageous since they lead to equations in divergence form, which is not the case if one uses the variables* h *and* V *except in the case of rectangular cross sections. We, however, do not relate our boundary conditions to Liapunov conditions as is done in* [2]. *The nice discussion of boundary conditions in* [2] *justify the assertion that control of the velocity variables can be achieved by means of adjusting sluice gate heights (through* (2.12) *of that paper).*

Next we show that the use of an absorbing feedback boundary condition takes the perturbations a and u to zero in finite time.

THEOREM 3. *Consider the St. Venant system* (4.4) *with boundary conditions*

$$v(0,t) = f^0(a(0,t)) \quad \textit{and} \quad v(L,t) = P(a(L,t)) \tag{4.15}$$

(where $Df^0(0) \neq p(0)$*) and initial conditions* (4.9) *satisfying the compatibility conditions* (4.13). *Let* $T_\star$ *satisfy*

$$T_\star > \frac{L}{|\overline{V} - \overline{\beta}|} + \frac{L}{\overline{V} + \overline{\beta}}.$$

Then, if $\| (a^0, v^0) \|_1$ *is sufficiently small, the corresponding solution is defined for all positive times, and, in fact,*

$$a(\cdot, t) \equiv 0 \quad \textit{and} \quad v(\cdot, t) \equiv 0 \quad \textit{for } t \geq T_\star.$$

Proof. In this case, we have that $\xi_-(L,t) \equiv 0$ or $g^L(\cdot) \equiv 0$ so that condition (4.14) of Theorem 2 is automatically satisfied, and, therefore, for small enough initial data, solutions are defined for all t and decay exponentially.

That the solutions in fact vanish for $t \geq T_\star$ follows from the following observations. Since $\xi_-(x,t)$ is constant along characteristics of negative slope, this function vanishes identically for all (x,t) lying above the characteristic of negative slope emanating from $(L,0)$. If that characteristic reaches $x = 0$ at time T_1, say, one can conclude from the boundary condition at $x = 0$ that $\xi_+(0,t) \equiv 0$ for $t \geq T_1$, and hence $\xi_+(x,t)$ vanishes identically above the characteristic of positive slope starting from $(0, T_1)$ which meets $x = L$ at time $T_1 + T_2$. For $t \geq T_1 + T_2$, both Riemann invariants and hence also $a(x,t)$ and $v(x,t)$ vanish identically. To estimate the "traverse times," we note that, for sufficiently small initial data, the characteristics lie arbitrarily close to those of the equilibrium given by the linear functions (4.8), and hence the traverse times T_1 and T_2 can be made arbitrarily close to

$$\frac{L}{|\overline{V} - \overline{\beta}|} \quad \text{and} \quad \frac{L}{\overline{V} + \overline{\beta}},$$

respectively, for sufficiently small initial data. The result follows. ∎

REMARK 7. *If the absorbing boundary condition is also imposed at* $x = 0$*, one can choose a smaller value of* $T_\star$ *satisfying*

$$T_\star > \max \left\{ \frac{L}{|\overline{V} - \overline{\beta}|}, \frac{L}{\overline{V} + \overline{\beta}} \right\}.$$

REMARK 8. *If one does not impose absorbing boundary conditions, which involve the somewhat complicated function* $P(a)$*, one can also expect rapid stabilization for boundary functions* f^0 *and* f^L *satisfying* $Df^0(0) = -p(0)$ *and* $Df^L(0) = p(0)$ *and, in particular, for the very simple linear conditions*

$$v(0,t) = -p(0)a(0,t) \quad \textit{and} \quad v(L,t) = p(0)a(L,t)$$

with $p(0) = \sqrt{g/[\overline{A}\,\overline{b}]}$. *In fact, one can prove that, with such a choice of boundary conditions, one can achieve an arbitrary exponential rate of decay for sufficiently small initial data.*

5. Stabilization and null controllability for a star configuration of canals. Now we consider a star configuration of canals and perturbations $\mathbf{A} = \overline{\mathbf{A}} + \mathbf{a}$ and $\mathbf{V} = \overline{\mathbf{V}} + \mathbf{v}$ of equilibrium states $\overline{\mathbf{A}}, \overline{\mathbf{V}}$ constructed at the end of the previous section. We assume that the equilibrium flow is subcritical on each canal so that this will continue to be the case for small perturbations. The flow in each canal is governed by (4.4) with all the quantities indexed by i and $x \in [0, L_i]$. It is convenient to suppose that, for each i, the parameter value $x = 0$ corresponds to that end of the ith canal which lies at the multiple node. It is then useful to parametrize all the canals with a parameter x over a common interval $[0, L]$, where L could, for example, be the average canal length. For the ith canal, this would entail a parameter change $x \mapsto L/L_i\, x$, and the system corresponding to that canal becomes

$$\partial_t \begin{pmatrix} a_i \\ v_i \end{pmatrix} + \frac{L}{L_i} \begin{pmatrix} \overline{V}_i + v_i & \overline{A}_i + a_i \\ g/b_i(\overline{A}_i + a_i) & \overline{V}_i + v_i \end{pmatrix} \partial_x \begin{pmatrix} a_i \\ v_i \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}. \tag{5.1}$$

The corresponding eigenvalues of the matrix are now

$$\lambda^i_\pm(a_i, v_i) = \frac{L}{L_i}(\overline{V}_i + v_i \pm \beta_i(a_i)).$$

The Riemann invariants $\xi^i_\pm$ are unaffected by the parameter change and given by the indexed form of (4.6).

This gives us a hyperbolic system of $2n$ equations on $[0, L] \times [0, T]$. Such systems are discussed in the appendix, which uses a different indexing of the Riemann invariants, setting

$$\xi_i = \begin{cases} \xi^i_+ & \text{for } i = 1, \dots, n, \\ \xi^{i-n}_- & \text{for } i = n+1, \dots, 2n. \end{cases}$$

In our case, the equations are pairwise decoupled, and it is convenient to stay with the indexing $\xi^i_\pm$. Initial conditions are given by

$$\mathbf{a}(x, 0) = \mathbf{a}^0(x), \quad \mathbf{v}(x, 0) = \mathbf{v}^0(x). \tag{5.2}$$

At $x = L$, we can introduce decoupled boundary conditions acting independently on each canal:

$$v_i(L, t) = f^L_i(a_i(L, t)) \quad \text{or} \quad \xi^i_-(L, t) = g^L_i(\xi^i_+(L, t)). \tag{5.3}$$

The coupling between the variables occurs through the multiple node conditions which translate into a boundary condition at $x = 0$. Let

$$\begin{aligned} S_i(a_i, v_i) &\triangleq \frac{1}{2}(\overline{V}_i + v_i)^2 + g h_i(\overline{A}_i + a_i), \\ Q_i(a_i, v_i) &\triangleq (\overline{A}_i + a_i)(\overline{V}_i + v_i). \end{aligned}$$

Then we have the following set of n multiple node conditions in $2n$ variables holding at $(0, t)$:

$$\begin{cases} S_i(a_i, v_i) - S_n(a_n, v_n) = 0 \quad \text{for } i = 1, \dots, n-1, \\ \sum_{i=1}^n \epsilon_i Q_i(a_i, v_i) = 0. \end{cases} \tag{5.4}$$

To show that this system represents admissible boundary conditions at $x = 0$, we need to show that implicitly these equations determine

$$\boldsymbol{\xi}_+(0,t) \triangleq (\xi_+^1(0,t), \ldots, \xi_+^n(0,t))$$

as a function of

$$\boldsymbol{\xi}_-(0,t) = (\xi_-^1(0,t), \ldots, \xi_-^n(0,t)).$$

To do this, we have to show that the following Jacobian matrix is nonsingular:

$$J_+ \triangleq \begin{pmatrix} \partial_{\xi_+^1} S_1 & 0 & 0 & \ldots & 0 & -\partial_{\xi_+^n} S_n \\ 0 & \partial_{\xi_+^2} S_2 & 0 & \ldots & 0 & -\partial_{\xi_+^n} S_n \\ \ldots & \ldots & \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & 0 & \ldots & \partial_{\xi_+^{n-1}} S_{n-1} & -\partial_{\xi_+^n} S_n \\ \partial_{\xi_+^1} Q_1 & \partial_{\xi_+^2} Q_2 & \partial_{\xi_+^3} Q_3 & \ldots & \partial_{\xi_+^{n-1}} Q_{n-1} & \partial_{\xi_+^n} Q_n \end{pmatrix},$$

where all the partial derivatives are evaluated at $(a, v) = (0, 0)$. We have, since $v_i = \xi_{i+} + \xi_{i-}$ and $P_i(a_i) = \xi_{i+} - \xi_{i-}$, that

$$\partial_{\xi_+^i} S_i = \partial_{a_i} S_i \partial_{\xi_+^i} a_i + \partial_{v_i} S_i \partial_{\xi_+^i} v_i = \frac{g}{b_i(\overline{A}_i + a_i)} \frac{1}{p_i(\overline{A}_i + a_i)} + (\overline{V}_i + v_i),$$

and so, noting that

$$\frac{g}{\overline{b}_i \overline{p}_i} = \sqrt{g\overline{A}_i/\overline{b}_i} = \overline{\beta}_i,$$

we get

$$\partial_{\xi_+^i} S_i(0,0) = \overline{V}_i + \frac{g}{\overline{b}_i \overline{p}_i} = \overline{V}_i + \overline{\beta}_i.$$

Similarly,

$$\partial_{\xi_+^i} Q_i(0,0) = \overline{A}_i + \frac{\overline{v}_i}{\overline{p}_i} = \frac{1}{\overline{p}_i}(\overline{V}_i + \overline{\beta}_i).$$

We note also that $\overline{V}_i + \overline{\beta}_i = (L_i/L)\overline{\lambda}_+^i$, where $\overline{\lambda}_+^i$ is the positive eigenvalue of the system associated with the ith canal after reparametrization. We introduce the diagonal matrices

$$\overline{\Lambda}_\pm \triangleq \operatorname{diag}\left(\frac{L_1}{L}\overline{\lambda}_\pm^1, \ldots, \frac{L_n}{L}\overline{\lambda}_\pm^n\right) = \operatorname{diag}(\overline{V}_1 \pm \overline{\beta}_1, \ldots, \overline{V}_n \pm \overline{\beta}_n),$$

where $\operatorname{diag}(\mu_1, \ldots, \mu_n)$ denotes the $n \times n$ diagonal matrix with specified diagonal elements μ_i. We also introduce the two matrices

$$G_\pm \triangleq \begin{pmatrix} 1 & 0 & 0 & \ldots & 0 & -1 \\ 0 & 1 & 0 & \ldots & 0 & -1 \\ \ldots & \ldots & \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & 0 & \ldots & 1 & -1 \\ \pm\frac{1}{\overline{p}_1} & \pm\frac{1}{\overline{p}_2} & \pm\frac{1}{\overline{p}_3} & \ldots & \pm\frac{1}{\overline{p}_{n-1}} & \pm\frac{1}{\overline{p}_n} \end{pmatrix}.$$

One now easily checks that the Jacobian matrix of the system (5.4) with respect to $\boldsymbol{\xi}_+$ is of the form $J_+ = G_+\overline{\Lambda}_+$. One can similarly evaluate the Jacobian of the system with respect to $\boldsymbol{\xi}_-$ to get $J_- = G_-\overline{\Lambda}_-$. By the implicit function theorem, the system (43) of node conditions can therefore be written as an admissible boundary condition at 0:

$$\boldsymbol{\xi}_+(0,t) = \mathbf{g}^0(\boldsymbol{\xi}_-(0,t)), \tag{5.5}$$

with

$$\nabla_{\boldsymbol{\xi}_-}\mathbf{g}^0(\mathbf{0}) = J_+^{-1}J_- = \overline{\Lambda}_+^{-1}[G_+^{-1}G_-]\overline{\Lambda}_-. \tag{5.6}$$

Now the following theorem concerning the stabilizability (and indeed the existence) of solutions for our star configuration of canals follows easily from Theorem 1.3 of [8].

THEOREM 4. *Consider the systems* (5.1) *with boundary conditions* (5.4) *(equivalent to* (5.5)*) and* (5.3) *holding at* $x = 0$ *and* $x = L$*, respectively, and initial conditions* (5.2) *with data satisfying the appropriate compatibility conditions. Suppose that*

$$\begin{aligned} &\| \nabla_{\boldsymbol{\xi}_-}\mathbf{g}^0(\mathbf{0}) \|_\infty \max_{1\le i\le n} |Dg_i^L(0)| \\ &\quad = \| \overline{\Lambda}_+^{-1}[G_+^{-1}G_-]\overline{\Lambda}_- \|_\infty \max_{1\le i\le n} \left| \frac{Df_i^L(0) - p_i(0)}{Df_i^L(0) + p_i(0)} \right| < 1. \end{aligned} \tag{5.7}$$

Then, for $\| (\mathbf{a}^0, \mathbf{v}^0) \|_1$ *sufficiently small, there exists a unique continuously differentiable solution to the problem which is defined for all positive* t *and satisfies*

$$\| (\mathbf{a}(\cdot,t), \mathbf{v}(\cdot,t)) \|_1 < Ce^{-\alpha t} \| (\mathbf{a}^0, \mathbf{v}^0) \|,$$

where C *and* α *are suitable positive constants.*

In order to apply the cited theorem, we recall the following definition of the "minimal characteristic number" of a square matrix used by Li in formulating the hypothesis of boundary damping:

$$\| A \|_{\min} = \inf \left\{ \| \gamma A \gamma^{-1} \|_\infty \mid \gamma \text{ is an invertible, square, diagonal matrix} \right\}.$$

The damping hypothesis required by Li is that $\| \theta \|_{\min} < 1$, where

$$\theta = \begin{pmatrix} 0 & \nabla_{\boldsymbol{\xi}_+}\mathbf{g}^L(\mathbf{0}) \\ \nabla_{\boldsymbol{\xi}_-}\mathbf{g}^0(\mathbf{0}) & 0 \end{pmatrix}$$

with $\nabla_{\boldsymbol{\xi}_-}\mathbf{g}^0(\mathbf{0})$ given by (5.6) and

$$\nabla_{\boldsymbol{\xi}_+}\mathbf{g}^L(\mathbf{0}) = \operatorname{diag}(\dots, Dg_i^L(0), \dots) = \operatorname{diag}\left(\dots, \frac{Df_i^L(0) - p_i(0)}{Df_i^L(0) + p_i(0)}, \dots \right).$$

Note that $\| A \|_{\min} = \| \gamma A \gamma^{-1} \|_{\min}$, that $\| A \|_{\min} \le \| A \|_\infty$, and that, if A is diagonal, $\| A \|_{\min} = \| A \|_\infty = \max_{1\le i\le n} |A_{ii}|$. Now consider partitioned matrices A of the form

$$A = \begin{pmatrix} 0 & B \\ C & 0 \end{pmatrix},$$

where both B and C are $n \times n$ matrices and B is diagonal. Using diagonal matrices of the form $\gamma = \mathrm{diag}(\lambda\gamma_1, \gamma_1)$, where γ_1 is a diagonal $n \times n$ invertible matrix and λ is an arbitrary positive scalar, it is not difficult to obtain the following estimate using the definition of $\|\cdot\|_{\min}$ and the previously stated properties:

$$\|A\|_{\min} \leq \|C\|_{\min} \max_{1\leq i\leq n} |B_{ii}|.$$

This gives estimate (5.7).

REMARK 9. *With some additional care, one can prove the following estimate, which can replace* (5.7) *as damping hypothesis:*

$$\|G_+^{-1}G_-\|_{\min} \max_{1\leq i\leq n} \frac{\overline{V}_i + \overline{\beta}_i}{|\overline{V}_i - \overline{\beta}_i|} \left| \frac{Df_i^L(0) - p_i(0)}{Df_i^L(0) + p_i(0)} \right| < 1.$$

REMARK 10. *It would be helpful to have a good estimate for* $\|G_+^{-1}G_-]\|_\infty$ *or for* $\|G_+^{-1}G_-]\|_{\min}$. *Since* $G_- = \mathrm{diag}(1, \ldots, 1, -1)G_+$, *one has*

$$G_+^{-1}G_- = G_+^{-1}\mathrm{diag}(1, \ldots, 1, -1)G_+$$

so that the eigenvalues of $G_+^{-1}G_-$ *are* 1 *with multiplicity* $n-1$ *and* -1 *with multiplicity* 1. *Unfortunately this does not imply anything about* $\|G_+^{-1}G_-\|_\infty$, *and what it may imply for* $\|G_+^{-1}G_-\|_{\min}$ *is not yet clear. However, in some situations (all canals and all data equal), the two norms coincide.*

Finally, it is also not difficult to see that the proof of Theorem 3 can be adapted to prove the following result on null controllability for the star system.

THEOREM 5. *Consider the systems* (5.1) *with boundary conditions* (5.4) *(equivalent to* (5.5)*) holding at* $x = 0$, *absorbing boundary conditions*

$$v_i(L,t) = P_i(a_i(L,t)) \quad \textit{for } i = 1, \ldots, n,$$

and holding at $x = L$ *and initial conditions* (5.2) *with data satisfying the appropriate compatibility conditions. Let* $T_\star$ *satisfy*

$$T_\star > \max_{1\leq i\leq n} \frac{L^2}{L_i(|\overline{V}_i - \overline{\beta}_i|)} + \max_{1\leq i\leq n} \frac{L^2}{L_i(\overline{V}_i + \overline{\beta}_i)}.$$

Then, for small enough initial data, the solution is defined for all positive times and, in fact,

$$\mathbf{a}(\cdot, t) \equiv \mathbf{0} \quad \textit{and} \quad \mathbf{v}(\cdot, t) \equiv \mathbf{0} \quad \textit{for } t \geq T_\star.$$

Acknowledgments. We note that an "open loop" controllability result for a *single* link being equivalent to the system governing the Riemann invariants discussed in section 4 has been given by Li, Rao, and Jin [7]. The authors thank the referees for their helpful suggestions.

ON REACHABILITY UNDER UNCERTAINTY*

A. B. KURZHANSKI† AND P. VARAIYA‡

Abstract. The paper studies the problem of reachability for linear systems in the presence of uncertain (unknown but bounded) input disturbances that may also be interpreted as the action of an adversary in a game-theoretic setting.

It defines possible notions of reachability under uncertainty emphasizing the differences between reachability under open-loop and closed-loop control. Solution schemes for calculating reachability sets are then indicated. The situation when observations arrive at given isolated instances of time leads to problems of anticipative (maxmin) or nonanticipative (minmax) piecewise open-loop control with corrections and to the respective notions of reachability. As the number of corrections tends to infinity, one comes in both cases to reachability under nonanticipative feedback control. It is shown that the closed-loop reach sets under uncertainty may be found through a solution of the forward Hamilton–Jacobi–Bellman–Isaacs (HJBI) equation.

The basic relations are derived through the investigation of superpositions of value functions for appropriate sequential maxmin or minmax problems of control.

Key words. reachability, reach sets, differential inclusions, alternated integral, funnel equations, open-loop control, closed-loop control, dynamic programming, uncertainty, differential games, HJBI equation

Introduction. Recent developments in real-time automation have promoted new interest in the reachability problem—the computation of the set of states reachable by a controlled process through available controls. Being one of the basic problems of control theory, it was studied from the very beginning of investigations in this field (see [19]). The problem was usually studied in the absence of disturbances, under complete information on the system equations and the constraints on the control variables. It was shown, in particular, that the set of states reachable at a given time t under bounded controls is one and the same whether one uses open-loop or closed-loop (feedback) controls. It was also indicated that these "reachability sets" could be calculated as level sets for the (perhaps generalized) solutions to a "forward" Hamilton–Jacobi–Bellman equation [19], [20], [3], [16], [18].

However, in reality, the situation may be more complicated. Namely, if the system is subject to unknown but bounded disturbances, it may become necessary to compute the set of states reachable *despite the disturbances* or, if exact reachability is impossible, to find guaranteed errors for reachability.

These questions have implicitly been present in traditional studies on feedback control under uncertainty for continuous-time systems [11], [28], [4], [10], [13]. They have also appeared in studies on hybrid and other types of transition systems [1], [29], [22], [5].

This leads us to the topic of the present paper, which is the investigation of

reachability under uncertainty for continuous-time linear control systems subjected to unknown input disturbances, with prespecified geometric (hard) bounds on the controls and the unknowns. The paper indicates various notions of reachability, studies the properties of respective reach sets, and indicates routes for calculating them.

The first question here is to distinguish whether reachability under open-loop and closed-loop controls yields the same reach sets. Indeed, since closed-loop control is based on better information, namely, on the possibility of continuous on-line observations of the state space variable (with no knowledge of the disturbance), it must produce, generally speaking, a result which is at least "not worse," for example, than the one by an open-loop control which allows no such observations but only the knowledge of the initial state, with no knowledge of the disturbance. An open-loop control of the latter type is further referred to as "nonanticipative."

However, there are many other possibilities of introducing open-loop or piecewise open-loop controls, with or without the availability of some type of isolated on-line measurements of the state space variable, as well as with or without an a priori knowledge of the disturbance. Thus, in order to study the reachability problem in detail, we introduce a hierarchy of reachability problems formulated under an array of different "intermediate" information conditions. These are formulated in terms of some auxiliary extremal problems of the maxmin or minmax type.

Starting with open-loop controls, we first distinguish the case of *anticipative control* from *nonanticipative control.* The former, for example, is when a reachable set, from a given initial state x^0, at given time τ, is defined as the set $X_\mu^- = X^-(\tau, t_0, x^0, \mu)$ of such states x, that for any admissible disturbance given in advance, for the whole interval under consideration, there exists an admissible control that steers the system to a μ-neighborhood $\mathcal{B}_\mu(x) = \{z : (z-x, z-x) \leq \mu^2\}$. Here the respective auxiliary extremal problem is of the maxmin type (maximum in the disturbance and minimum in the control). On the other hand, for the *latter,* the disturbance is not known in advance. Then the reachability set from a given initial state is defined as the set $X_\mu^+ = X^+(\tau, t_0, x^0, \mu)$ of such states x whose μ-neighborhoods $\mathcal{B}_\mu(x)$ may be reached with the same admissible control *for all* admissible disturbances. Now the respective auxiliary problem is of the minmax type.

It is shown that always $X_\mu^+ \subseteq X_\mu^-$ and that the closed-loop reach set $\mathcal{X}_\mu = X(\tau, t_0, x^0, \mu)$ attained under *nonanticipative but feedback control* lies in between, namely,

$$X_\mu^+ \subseteq \mathcal{X}_\mu \subseteq X_\mu^-.$$

There are also some intermediate situations when the observations of the state space variable arrive at given N isolated instants of time. In that case, one has to deal with *reachability under possible corrections* of the control at these N time instants. Here again we distinguish between corrections implemented through anticipative control (when the future disturbance is known for each time interval in between the corrections) and nonanticipative control (when it is unknown). The respective extremal problems are of sequential maxmin and minmax types accordingly, and the controls are piecewise open-loop: at isolated time instants of correction, there arrives information on the state space variable, while in between these instants, the control is open-loop (either anticipative or not). Both cases produce respective sequences $X_{\mu,N}^- = X_N^-(\tau, t_0, x^0, \mu), X_{\mu,N}^+ = X_N^+(\tau, t_0, x^0, \mu)$ of "piecewise open-loop reach sets (OLRSs)." The relative positions of the reach sets in the hierarchical scheme are as

follows:

$$X_\mu^+ \subseteq X_{\mu,N}^+ \subseteq \mathcal{X}_\mu \subseteq X_{\mu,N}^- \subseteq X_\mu^-.$$

Finally, in the limit, as the number of corrections N tends to infinity, *both sequences* of reachability sets *converge to the closed-loop reach set.*[1]

The adopted scheme is based on constructing superpositions of value functions for open-loop control problems. In the limit these relations reflect the *principle of optimality* under set-membership uncertainty. This principle then allows one to describe the closed-loop reach set as a level set for the solution to the *forward HJBI (Hamilton–Jacobi–Bellman–Isaacs) equation*. The final results are then presented either in terms of value functions for this equation or in terms of set-valued relations.

Schemes of such type have been used in synthesizing solution strategies for differential games and related problems and were constructed in backward time [23], [12], [27], [28].

The topics of this paper were motivated by applied problems and also by the need for a theoretical basis for further algorithmic schemes.

1. Uncertain dynamics. Reachability under open-loop controls. In this section, we introduce the system under consideration and define two types of open-loop reachability sets. Namely, we discuss *reachability* under unknown but bounded disturbances for the system

$$\dot{x} = A(t)x + B(t)u + C(t)v(t), \tag{1}$$

with continuous matrix coefficients $A(t), B(t), C(t)$. Here $x \in \mathbb{R}^n$ is the *state* and $u \in \mathbb{R}^p$ is the *control* that may be selected either as an *open-loop control* OLC, a Lebesgue-measurable function of time t, restricted by the inclusion

$$u(t) \in \mathcal{P}(t), \tag{2}$$

or as a *closed-loop control* CLC, a *set-valued strategy*

$$u = \mathcal{U}(t,x) \subseteq \mathcal{P}(t). \tag{3}$$

Here $v \in \mathbb{R}^q$ is the unknown *input disturbance* with values

$$v(t) \in \mathcal{Q}(t), \tag{4}$$

and $\mathcal{P}(t), \mathcal{Q}(t)$ are set-valued continuous functions with convex compact values ($\mathcal{P} \in comp\mathbb{R}^p$, $\mathcal{Q} \in comp\mathbb{R}^q$).[2]

The class of OLCs $u(\cdot)$ bounded by inclusion (2) is denoted by $U_{\mathcal{O}}$, and the class of input disturbances $v(\cdot)$ bounded by (4) is denoted by $V_{\mathcal{O}}$. The strategies $\mathcal{U}$ are taken to be in $U_{\mathcal{C}}$—the class $U_{\mathcal{C}}$ of CLCs that are multivalued maps $\mathcal{U}(t,x)$ bounded by the inclusion (3), which guarantee the solutions to (1), $u = \mathcal{U}(t,x)$ (which now turns into a differential inclusion) for any Lebesgue-measurable function $v(\cdot)$.[3]

[1] As indicated in what follows, this is true when all of the sets involved are nonempty and when the problems satisfy some regularity conditions.

[2] Set-valued functions $\mathcal{P}(t)$ with values in $comp\mathbb{R}^p$ are defined to be continuous in $t \in [t_0, t_1]$ if the support functions $\rho(l|\mathcal{P}(t)) = \max\{(l,x)|x \in \mathcal{P}(t)\}$ are continuous in $t \in [t_0, t_1]$ uniformly in $\{l : (l,l) \leq 1\}$.

[3] For example, the class of set-valued functions with values in $comp\mathbb{R}^n$, upper semicontinuous in x and continuous in t.

We distinguish two types of OLRSs—the *maxmin* type and the *minmax* type. As we will see in the next section, the names *maxmin* and *minmax* assigned to these sets are due to the underlying optimization problems used for their calculation.

DEFINITION 1.1. *An OLRS of the* maxmin type *(from set $X^0 = X(t_0)$, at time $\tau \geq t_0$) is the set $X^-(\tau, t_0, X^0)$ of all vectors x such that for every disturbance $v(t) \in \mathcal{Q}(t)$, there exist an initial state $x^0 \in X^0$ and an OLC $u(t) \in \mathcal{P}(t)$ which steer the trajectory $x(t)$, $t_0 \leq t \leq \tau$, from state $x^0 = x(t_0)$ to state*

$$x(\tau) = x. \tag{5}$$

The set X^0 is assumed to be convex and compact ($X^0 \in comp\mathbb{R}^n$).

If $X^-(\tau, t_0, X^0)$ turns out to be empty, one may introduce the open-loop *μ-reachable set* $X^-(\tau, t_0, X^0, \mu)$ as in Definition 1.1 except that (5) is replaced by

$$x(\tau) \in \mathcal{B}_\mu(x).$$

Here

$$\mathcal{B}_\mu(x) = \{x : (x(\tau) - x, x(\tau) - x) \leq \mu^2\} = x + \mathcal{B}_\mu(0), \quad \mu \geq 0,$$

is the ball of radius μ with center x.

Thus the OLRS $X^-(\tau, t_0, X^0)$ of the maxmin type is the set of points $x \in \mathbb{R}^n$ that can be reached, for any disturbance $v(t) \in \mathcal{Q}(t)$ given in advance, for the whole interval $t_0 \leq t \leq \tau$, from some point $x(t_0) \in X^0$, through some open-loop control $u(\cdot) \in U_\mathcal{O}$.

The open-loop *μ-reach set* (μ-OLRS) $X^-(\tau, t_0, X^0, \mu)$ is the set of points $x \in \mathbb{R}^n$ whose μ-neighborhood $\mathcal{B}_\mu(x)$ may be reached, for any disturbance $v(t)$ given in advance, through some $x(t_0) \in X^0, u(\cdot) \in U_\mathcal{O}$.

By taking $\mu \geq 0$ large enough, we may assume $X^-(\tau, t_0, X^0, \mu) \neq \emptyset$.

Denote $x(t, t_0, x^0 | u(\cdot), v(\cdot))$ to be the unique trajectory corresponding to $x(t_0) = x^0$, control $u(\cdot)$, and disturbance $v(\cdot)$. Then

$$\cup\{x(t, t_0, x^0 | u(\cdot), v(\cdot)) | x(t_0) \in X^0,\ u(\cdot) \in U_\mathcal{O}\} = X(t, t_0, X^0 | \mathcal{P}(\cdot), v(\cdot))$$

is the *reach set* in the variable $u(\cdot) \in U_\mathcal{O}$ (at time t from set X^0) with fixed disturbance input $v(\cdot)$.

LEMMA 1.1.

$$X^-(\tau, t_0, X^0) = \cap\{X(t, t_0, X^0 | \mathcal{P}(\cdot), v(\cdot)) | v(\cdot) \in V_\mathcal{O}\}. \tag{6}$$

This formula follows from Definition 1.1. Recall the definition of the geometrical (Minkowski) difference $\mathcal{P} \dot{-} \mathcal{Q}$ of sets $\mathcal{P}, \mathcal{Q}$,

$$\mathcal{P} \dot{-} \mathcal{Q} = \{c : c + \mathcal{Q} \subseteq \mathcal{P}\}.$$

Then, directly from (1), one gets

$$X^-(\tau, t_0, X^0) = \left(S(t_0, \tau)X^0 + \int_{t_0}^{\tau} S(s, \tau)B(s)\mathcal{P}(s)ds\right) \dot{-} \int_{t_0}^{\tau} S(s, \tau)(-C(s)\mathcal{Q}(s))ds. \tag{7}$$

Here $S(s,t)$ stands for the matrix solution of the adjoint equation

$$\partial S(s,t)/\partial s = -S(s,t)A(t),\ S(t,t) = I.$$

In other words, the set

$$X^-(\tau, t_0, X^0) = X(t, t_0, X^0|\mathcal{P}(\cdot), \{0\}) \dot{-} X(t, t_0, 0|\{0\}, \mathcal{Q}(\cdot))$$

is the geometric difference of two "ordinary" reach sets, namely, the set $X(t, t_0, X^0|\mathcal{P}(\cdot), \{0\})$ taken from $X(t_0) = X^0$ and calculated in the variable u, with $v(t) \equiv 0$, and the set $X(t, t_0, 0|\{0\}, \mathcal{Q}(\cdot))$ taken from $x(t_0) = 0$ and calculated in the variable v, with $u(\cdot) \equiv 0$. This simple geometrical interpretation is, of course, due to the linearity of (1).

For the μ-reachable set, we have the following lemma.

LEMMA 1.2. *The set $X^-(\tau, t_0, X^0, \mu)$ may be expressed as*

$$\begin{aligned} X^-(\tau, t_0, X^0, \mu) &= \cap\{X(t, t_0, X^0|\mathcal{P}(\cdot), v(\cdot)) + \mathcal{B}_\mu(0)|v(\cdot) \in V_{\mathcal{O}}\} \\ &= (X(t, t_0, X^0|\mathcal{P}(\cdot), \{0\}) + \mathcal{B}_\mu(0)) \dot{-} X(t, t_0, 0|\{0\}, \mathcal{Q}(\cdot)) \end{aligned} \tag{8}$$

and also as

$$X^-(\tau, t_0, X^0, \mu_1) \subseteq X^-(\tau, t_0, X^0, \mu_2),\ \ \mu_1 \leq \mu_2.$$

Remark 1.1. Definition (8) of $X^-(\tau, t_0, X^0, \mu)$ may also be rewritten as

$$X^-(\tau, t_0, X^0, \mu) = \cap_v \cup_u \cup_{x^0} \{X(t, t_0, x^0|u(\cdot), v(\cdot)) + \mathcal{B}_\mu(0)|x^0 \in X^0, u(\cdot) \in U_{\mathcal{O}}, v(\cdot) \in V_{\mathcal{O}}\}.$$

We now define another class of OLRSs under uncertainty—the OLRS of the *min-max* type.

DEFINITION 1.2. *A μ-OLRS of the* minmax type *(from set $X^0 = X(t_0)$, at time $\tau \geq t_0$) is the set $X^+(\tau, t_0, X^0, \mu)$ of all x for each of which there exists a control $u(t) \in \mathcal{P}(t)$ that assigns to each $v(t) \in \mathcal{Q}(t)$ a vector $x^0 \in X^0$, such that the respective trajectory $x[t] = x(t, t_0, x^0|u(\cdot), v(\cdot))$ ends in $x[\tau] \in \mathcal{B}_\mu(x)$.*

Thus the μ-OLRS of minmax type consists of all x whose μ-neighborhood $\mathcal{B}_\mu(x)$ contains the states $x[\tau]$ generated by system (1) under some control $u(t) \in \mathcal{P}(t)$ and all $\{v(t) \in \mathcal{Q}(t), t_0 \leq t \leq \tau\}$ with $x^0 \in X^0$ selected depending on u, v.[4]

A reasoning similar to the above leads to the following lemma.

LEMMA 1.3. *The set $X^+(\tau, t_0, X^0, \mu)$ may be expressed as*

$$X^+(\tau, t_0, X^0, \mu) = \cup\{(X(\tau, t_0, X^0|u(\cdot), \{0\}) + \mathcal{B}_\mu(0)) \dot{-} X(t, t_0, 0|\{0\}, \mathcal{Q}(\cdot))|u(\cdot) \in \mathcal{U}_{\mathcal{O}}\} \tag{9}$$

and

$$X^+(\tau, t_0, X^0, \mu_1) \subseteq X^+(\tau, t_0, X^0, \mu_2), \quad \mu_1 \leq \mu_2.$$

Remark 1.2. Definition (9) of $X^+(\tau, t_0, X^0, \mu)$ may be rewritten as

$$\cup_u \cap_v \cup_{x^0} \{(x(t, t_0, x^0|u(\cdot), \{0\}) + \mathcal{B}_\mu(0)) - x(t, t_0, 0|\{0\}, v(\cdot))|x^0 \in X^0, u(\cdot) \in U_{\mathcal{O}}, v(\cdot) \in V_{\mathcal{O}}\}.$$

Direct calculation, based on the properties of set-valued operations, allows us to conclude the following.

[4] With $\mu = 0$ and X^0 single-valued, it usually turns out that $X^+_\mu = \emptyset$.

LEMMA 1.4. *When* $X^+(\tau, t_0, X^0, \mu), X^-(\tau, t_0, X^0, \mu)$ *are both nonempty for some* $\mu > 0$*, we have*

$$X^+(\tau, t_0, X^0, \mu) \subseteq X^-(\tau, t_0, X^0, \mu).$$

We shall now calculate the OLRSs defined above, using the techniques of convex analysis [25], [13], [16].

2. The calculation of OLRSs. Here we shall calculate the two basic types of OLRSs. The relations of this section will also serve as the basic elements for further constructions which will be produced as some superpositions of the relations of this section.

The calculations of this section and especially of later sections related to reachability under feedback control require a number of rather cumbersome calculations of geometrical (Minkowski) differences and their support functions. In order to simplify these calculations, we transform system (1) to a simpler form. Taking the transformation $z = S(t, t_0)x$, one gets

$$\dot{z} = B_1(t)u - C_1(t)v,$$

where $B_1(t) = S(t, t_0)B(t)$ and $C_1(t) = S(t, t_0)C(t)v$. (With this transformation, the terms in S will disappear from (7).)

Keeping the previous notations x, B, C for z, B_1, C_1, we thus come, without loss of generality, to the system

$$\dot{x} = B(t)u + C(t)v, \tag{10}$$

with the same constraints on u, v as before. For (10), consider the following two problems (where the condition $x(t_0) \in X^0$ is dropped).

Problem (I). Given a set X^0 and $x(t_0) \in \mathbb{R}^n$, find

$$V^-(\tau, x, \mu) = \max_v \min_u \min_{x(\tau)} d(x(t_0), X^0), \quad \tau \geq t_0,$$

under conditions $x(\tau) \in \mathcal{B}_\mu(x),\ u(\cdot) \in U_\mathcal{O},\ v(\cdot) \in V_\mathcal{O}$.

Problem (II). Given a set X^0 and $x(t_0) \in \mathbb{R}^n$, find

$$V^+(\tau, x, \mu) = \min_u \max_v \min_{x(\tau)} d(x(t_0), X^0), \quad \tau \geq t_0,$$

under conditions $x(\tau) \in \mathcal{B}_\mu(x), u(\cdot) \in U_\mathcal{O},\ v(\cdot) \in V_\mathcal{O}$.

Here

$$d^2(x, z) = (x - z, x - z),\ d(x, \mathcal{G}) = \min\{d(x, z) | z \in \mathcal{G})\},$$

and $\mathcal{G}$ is a closed set in $\mathbb{R}^n$. Thus

$$d(x, \mathcal{G}) = h_+(x, \mathcal{G}),$$

where $h_+(\mathcal{Q}, \mathcal{G})$ is the *Hausdorff semidistance* between compact sets $\mathcal{Q}, \mathcal{G}$, defined as

$$h_+(\mathcal{Q}, \mathcal{G}) \ = \ \max_x \min_z \{(x - z, x - z)^{1/2} | x \in \mathcal{Q}, z \in \mathcal{G}\}.$$

The *Hausdorff distance* is $h(\mathcal{Q}, \mathcal{M}) = \max\{h_+(\mathcal{Q}, \mathcal{G}), h_+(\mathcal{G}, \mathcal{Q})\}$.

In order to calculate the function V^- explicitly, we use the relations

$$x(t) = x(t_0) + \int_{t_0}^{t} (B(s)u(s) + C(s)v(s))ds \tag{11}$$

and (see [11], [16] for the next formula)

$$d(x, \mathcal{G}) = \max_l \{(l, x) - \rho(l|\mathcal{G})|(l, l) \leq 1\},^5$$

where

$$\rho(l|\mathcal{G}) = \sup\{(l, x)|x \in \mathcal{G}\}$$

is *the support function of* $\mathcal{G}$ [16]. (For compact $\mathcal{G}$, sup may be substituted by max.)

We thus need to calculate

$$V^-(\tau, x, \mu) = \max_v \min_u \min_{x(\tau)} \{d(x(t_0), X^0)|x(\tau) \in \mathcal{B}_\mu(x), u(\cdot) \in U_\mathcal{O}, v \in V_\mathcal{O}\},$$

which gives, after an application of the formula for $d(x, \mathcal{G})$ and of (11) and a further interchange of $\min_u, \min_{x(\tau)}$, and $\max_l$ (see [7]),

$$V^-(\tau, x, \mu) \tag{12}$$

$$= \max_l \left\{ (l, x) - \rho(l|X^0) - \mu(l, l)^{\frac{1}{2}} - \int_{t_0}^{\tau} (\rho(l|B(s)\mathcal{P}(s)) - \rho(-l|C(s)\mathcal{Q}(s))ds|(l, l) \leq 1 \right\}.$$

Due to (11), the last formula says simply that V^- is given by

$$V^-(\tau, x, \mu) = d(x, X^-(\tau, t_0, x^0, \mu)), \tag{13}$$

where

$$X^-(\tau, t_0, x^0, \mu) = \left(X^0 + \mathcal{B}_\mu(0) + \int_{t_0}^{\tau} B(t)\mathcal{P}(s)ds \right) \dot{-} \int_{t_0}^{\tau} (-C(s))\mathcal{Q}(s)ds. \tag{14}$$

It then follows that

$$X^-(\tau, t_0, X^0, \mu) = \{x : V^-(\tau, x, \mu) \leq 0\}, \tag{15}$$

and so (12) implies that $x \in X^-(\tau, t_0, X^0, \mu)$ iff

$$(l, x) \leq \rho(l|X^0) + \mu(l, l)^{\frac{1}{2}} + \int_{t_0}^{\tau} (\rho(l|B(t)\mathcal{P}(s)) - \rho(-l|C(t)\mathcal{Q}(s)))ds \quad \forall l \in \mathbb{R}^n.$$

(Of course, $\{x : V^-(\tau, x, \mu) \leq 0\} = \{x : V^-(\tau, x, \mu) = 0\}$. Even though $V^-(\tau, x, \mu)$ is nonnegative, we retain the notation $\{V^- \leq 0\}$ to suggest that for purposes of approximation it may be useful to consider $\{V^- \leq \epsilon\}$.) This gives, from the definitions of support function and geometrical difference,

[5] This formula is always interpreted as $d(x, \mathcal{G}) = \max\{0, \max_l\{(l, x) - \rho(l|\mathcal{G})|(l, l) \leq 1\}\}$.

$$\rho(l|X^-(\tau,t_0,X^0,\mu)) \tag{16}$$

$$= \rho\left(l\,\middle|\left(X^0+\mathcal{B}_\mu(0)+\int_{t_0}^{\tau}B(s)\mathcal{P}(s)ds\right)\dot{-}\int_{t_0}^{\tau}(-C(s)\mathcal{Q}(s))ds\right),$$

which, interpreted as integrals of multivalued functions, again results in (14).

THEOREM 2.1. *The set* $X^-(\tau,t_0,X^0,\mu)$ *is given by formula* (14) *and its support function* $\rho(l|X^-(\tau,t_0,X^0,\mu))$ *by* (16).

It is clear that if the difference

$$\int_{t_0}^{\tau}B(t)\mathcal{P}(s)ds\dot{-}\int_{t_0}^{\tau}C(s)(-\mathcal{Q}(s))ds\neq\emptyset,$$

then $X^-(\tau,t_0,x^0,0)\neq\emptyset$.

Note that function $V^-(\tau,x,\mu)$ may also be defined as the solution to

Problem (I*). Given X^0, find

$$V_*^-(\tau,x,\mu)=\max_v\min_u\min_{x(t_0)}\{d(x(\tau),\mathcal{B}_\mu(x))|x(t_0)\in X^0,u(\cdot)\in U_{\mathcal{O}},v(\cdot)\in V_{\mathcal{O}}\}.$$

Direct calculations then produce the formula

$$\{x:V_*^-(\tau,x,\mu)\leq 0\}=X^-(\tau,t_0,X^0,\mu), \tag{17}$$

which gives the same result as Problem (I).

Similarly, we may calculate

$$V^+(\tau,x,\mu)=\min_u\max_v\min_{x(\tau)}\{d(x(t_0),X^0)|x(\tau)\in\mathcal{B}_\mu(x),u(\cdot)\in U_{\mathcal{O}},v(\cdot)\in V_{\mathcal{O}}\}.$$

Taking into account the minmax theorem of [7] and the fact that

$$\max_l g(l)=\max_l(conc\ g)(l),\ (l,l)\leq 1,$$

we come to

$$V_+(\tau,x,\mu)=\max_l\left\{(l,x)-\int_{t_0}^{\tau}\rho(l|B(s)\mathcal{P}(s))ds+(conc(-h))(l)|(l,l)\leq 1\right\}, \tag{18}$$

$$h(l)=\rho(l|X^0)+\mu(l,l)^{\frac{1}{2}}-\int_{t_0}^{\tau}\rho(-l|C(s)\mathcal{Q}(s))ds.$$

Here $(conc\ h)(l)$ is the *closed concave hull* of $h(l)$. Note that

$$(conc\ h)(l)=-(conv(-h))(l),$$

where $(conv\ h)(l)=h^{**}(l)$ is the *closed convex hull* and also the Fenchel second conjugate $h^{**}(l)$ of $h(l)$ (see [25], [13] for the definitions).

Therefore,

$$V^+(\tau,x,\mu)=d(x,X^+(\tau,t_0,X^0,\mu)), \tag{19}$$

where

$$X^+(\tau, t_0, X^0, \mu) \tag{20}$$

$$= \left(\left(X^0 + \mathcal{B}_\mu(0) \right) \dot{-} \int_{t_0}^{\tau} (-C(s)) \mathcal{Q}(s) ds \right) + \int_{t_o}^{\tau} B(s) \mathcal{P}(s) ds.$$

It then follows that

$$X^+(\tau, t_0, X^0, \mu) = \{x : V^+(\tau, x, \mu) \leq 0\}. \tag{21}$$

Similarly, (18) implies that $V^+(\tau, x, \mu) \leq 0$ iff

$$(l, x) \leq (l, x^0) + \int_{t_0}^{\tau} (\rho(l|B(s)\mathcal{P}(s)) ds - (conv\ h)(l)\ \forall l \in \mathbb{R}^n$$

so that the support function

$$\rho(l|X^+(\tau, t_0, X^0, \mu)) \tag{22}$$

$$= \rho\left(l \left| \int_{t_0}^{\tau} B(s)\mathcal{P}(s) ds \right. \right) + \rho\left(l \left| \left(X^0 + \mathcal{B}_\mu(0) \right) \dot{-} \int_{t_0}^{\tau} (-C(s)) \mathcal{Q}(s) ds \right. \right).$$

THEOREM 2.2. *The set $X^+(\tau, t_0, X^0, \mu)$ is given by* (20) *and its support function $\rho(l|X^+(\tau, t_0, X^0, \mu))$ by* (22).

It can be seen from (22) that $X^+(\tau, t_0, x^0, 0)$ may be empty. At the same time, in order that $X^+(\tau, t_0, x^0, \mu) \neq \emptyset$, it is sufficient that

$$\mathcal{B}_\mu(0) \dot{-} \int_{t_0}^{\tau} (-C(s)) \mathcal{Q}(s) ds \neq \emptyset,$$

which holds for $\mu > 0$ sufficiently large.

It is worth mentioning that a minmax OLRS may be also be specified through an alternative definition.

DEFINITION 2.1. *A μ-OLRS of the* minmax type *(from set X^0, at time $\tau \geq t_0$) is the union*

$$X^+(\tau, t_0, X^0, \mu) = \cup \{X^+(\tau, t_0, x^0, \mu) | x^0 \in X^0\}, \tag{23}$$

where

$$X^+(\tau, t_0, x^0, \mu) = \{x : X(\tau, t_0, x^0 | u(\cdot), \mathcal{Q}(\cdot)) \subseteq \mathcal{B}_\mu(x)\}$$

for some $u(\cdot) \in U_\mathcal{P}$ with $\mu \geq 0$ given and each set $X^+(\tau, t_0, x^0, \mu) \neq \emptyset$.

This leads to the following problem.

Problem (II*). Given set X^0, and vector $x \in \mathbb{R}^n$, find

$$V_*^+(\tau, x, \mu) = \min_u \max_v \min_{x(\tau)} d(x(\tau), \mathcal{B}_\mu(x)), \quad \tau \geq t_0,$$

under conditions $x(t_0) \in X^0, u(\cdot) \in U_\mathcal{O},\ v(\cdot) \in V_\mathcal{O}$.

Direct calculations here lead to the formula

$$X^+(\tau, t_0, x^0, \mu) = \{x : V_*^+(\tau, x, \mu) \leq 0\},$$

which is the same result as that of Problem (II).

The equivalence of Problems (II) and (II*) means that Definitions 1.2 and 2.1 both lead to the same set $X^+(\tau, t_0, x^0, \mu)$. As we shall see, this is not so for the problem of reachability with corrections. A similar observation holds for Problems (I) and (I*).

Remark 2.1. For the case in which $X^0 = \{x^0\}$ is a singleton, one should recognize the following. The OLRS of the *maxmin* type is the set of points reachable at time τ from a given point x^0 for any disturbance $v(\cdot) \in V_{\mathcal{O}}$, provided function $v(t)$, $t_0 \le t \le \tau$, is communicated to the controller *in advance, before the selection of control* $u(t)$. As mentioned above, the control $u(\cdot)$ is then selected through an *anticipative control* procedure.

On the other hand, for the construction of the μ-reach set of the *minmax* type, there is *no information provided in advance on the realization of* $v(\cdot)$, which becomes known only *after* the selection of u. Indeed, given point $x(t_0) = x^0$, one has to select the control $u(t)$ for the whole time interval $t_0 \le t \le \tau$, whatever the unknown $v(t)$ over the same interval is. The control $u(\cdot)$ is then selected through a *nonanticipative control* procedure. Such a definition allows us to specify an OLRS as consisting of points x, each of which is complemented by a neighborhood $\mathcal{B}_\mu(x)$, so that

$$X(\tau, t_0, x^0 | u(\cdot), \mathcal{Q}(\cdot)) \subseteq \mathcal{B}_\mu(x)$$

for a certain control $u(\cdot) \in U_{\mathcal{O}}$. This requires $\mu > 0$ to be sufficiently large.

As a first step toward reachability under feedback, we consider *piecewise open-loop controls* with the possibility of corrections at fixed instants of time.

3. Piecewise open-loop controls: Reachability with corrections. Here we define and calculate reachability sets under a finite number of corrections. This is done either through the solution of problems of sequential maxmin and minmax or through operations on set-valued integrals.

Taking a given instant of time $t^* \in [t_0, t_1] = T$ that divides the interval T in two, namely,

$$T_1 = [t_0, t_0 + \sigma), \;\; T_2 = [t_0 + \sigma, t_1], \; \sigma = t^* - t_0,$$

consider the following *sequential maxmin* problem.

Problem (I_1). Given set X^0, $x \in \mathbb{R}^n$, and numbers $\mu_1 \ge 0, \mu_2 \ge 0$, find

$$V_1^-(t_0 + \sigma, x, \mu_1)$$

$$= \max_v \min_u \min_{x(t_0+\sigma)} \{d(x(t_0), X^0) | x(t_0 + \sigma) \in \mathcal{B}_{\mu_1}(x); u(t) \in \mathcal{P}(t), v(t) \in \mathcal{Q}(t), t \in T_1\},$$

and then find

$$V_1^-(\tau, x, \{\mu_1, \mu_2\}) \tag{24}$$

$$= \max_v \min_u \min_{x(\tau)} \{V_1^-(t_0+\sigma, x(t_0+\sigma), \mu_1) | x(\tau) \in \mathcal{B}_{\mu_2}(x), u(t) \in \mathcal{P}(t), v(t) \in \mathcal{Q}(t), t \in T_2\}.$$

The latter is a problem on finding a sequential maxmin with one "point of correction" $t = t^*$. Using the notation $\mu[1,2] = \{\mu_1, \mu_2\}$, denote

$$X_1^-(\tau, t_0, \mu[1,2]) = \{x : V_1^-(\tau, x, \mu[1,2]) \le 0\}.$$

Let us find $X_1^-(\tau, t_0, \mu[1,2]), V_1^-(\tau, x, \mu[1,2])$, using the technique of convex analysis. According to section 2 (see (11)), we have

$$V_1^-(t_0+\sigma, x(t_0+\sigma), \mu_1)$$

$$= \max\Bigg\{(l, x(t_0+\sigma)) - \mu_1(l,l)^{\frac{1}{2}} - \rho(l|X^0)$$

$$-\int_{t_0}^{t_0+\sigma}(\rho(l|B(s)\mathcal{P}(s))) - \rho(-l|C(s)\mathcal{Q}(s))ds|(l,l) \le 1\Bigg\}$$

$$= d(x(t_0+\sigma), Z_1^-(t_0+\sigma, t_0, \mu_1)),$$

where

$$Z_1^-(t_0+\sigma, t_0, \mu_1) = \left(X^0 + \mathcal{B}_{\mu_1}(0) + \int_{t_0}^{t_0+\sigma} B(s)\mathcal{P}(s)ds\right) \dot{-} \int_{t_0}^{t_0+\sigma}(-C(s))\mathcal{Q}(s))ds.$$

Substituting this in (24), we have

$$V_1^-(\tau, x, \mu[1,2])$$

$$= \max_v \min_u \min_{x(\tau)} \max_l \Bigg\{(l, x(\tau)) - \int_{t_0+\sigma}^{\tau}(l, u(s)+v(s))ds - \rho(l|Z_1^-(t_0+\sigma, t_0, \mu_1))|$$

$$|(l,l) \le 1, x(\tau) \in \mathcal{B}_{\mu_2}(x), u(t) \in \mathcal{P}(t), v(t) \in \mathcal{Q}(t), t \in T_2\Bigg\}.$$

Continuing the calculation, we come to

$$V_1^-(\tau, x, \mu[1,2]) \tag{25}$$

$$= \max_l \Bigg\{(l,x) - \mu_2(l,l)^{\frac{1}{2}} - \int_{t_0+\sigma}^{\tau}(\rho(l|B(s)\mathcal{P}(s)))ds + \int_{t_0+\sigma}^{\tau}(\rho(-l|C(s)\mathcal{Q}(s)))ds$$

$$-(conv\ h_1)(l)\Bigg\},$$

where

$$h_1(l) = \rho(l|X^0) + \mu_1(l,l)^{\frac{1}{2}} + \int_{t_0}^{t_0+\sigma}(\rho(l|B(s)\mathcal{P}(s)) - \rho(-l|C(s)\mathcal{Q}(s)))ds.$$

So $(conv\ h_1)(l)$ is the support function of the set

$$\left(X^0 + \mathcal{B}_{\mu_1}(0) + \int_{t_0}^{t_0+\sigma} B(s)\mathcal{P}(s)ds\right) \dot{-} \int_{t_0}^{t_0+\sigma}(-C(s)\mathcal{Q}(s))ds.$$

Together with (25), this allows us, as in section 2, to express $V_1^-(\tau, x, \mu[1,2])$ as

$$V_1^-(\tau, x, \mu[1,2]) = d(x, X_1^-(\tau, t_0, x^0, \mu[1,2])),$$

where

$$X_1^-(\tau, t_0, x^0, \mu[1,2]) \tag{26}$$

$$= \left(\left(\left(X^0 + \mathcal{B}_{\mu_1}(0) + \int_{t_0}^{t_0+\sigma} B(s)\mathcal{P}(s)ds\right) \dot{-} \int_{t_0}^{t_0+\sigma} (-C(s))\mathcal{Q}(s)ds\right)\right.$$

$$\left. + \mathcal{B}_{\mu_2}(0) + \int_{t_0+\sigma}^{\tau} B(s)\mathcal{P}(s)ds\right) \dot{-} \int_{t_0+\sigma}^{\tau} (-C(s))\mathcal{Q}(s)ds.$$

Formula (26) shows that $X_1^-(\tau, t_0, x^0, \mu[1,2])$ (defined as the level set of V_1^-) is also the reach set with one correction. In particular, $X_1^-(\tau, t_0, x^0, 0)$ consists of all states x that may be reached *for any* function $v(\cdot) \in V_{\mathcal{P}}$, whose values are communicated in two stages, through two consecutive selections of some open-loop control $u(t)$ according to the following scheme.

Stage 1. *Given at time* t_0 are the initial state x^0 and the function $v(t)$ for $t \in T_1$; select at time t_0 the control $u(t)$ for $t \in T_1$.

Then at the *instant of correction* $t_* = t_0 + \sigma$ comes additional information for stage 2.

Stage 2. *Given at time* t^* are the state $x(t^*)$ and the function $v(t)$ for $t \in T_2$; select at time $t = t^*$ the control $u(t)$ for $t \in T_2$.

This proves Theorem 3.1.

THEOREM 3.1. *The set*

$$X_1^-(\tau, t_0, x^0, \mu[1,2]) = \{x : V_1^-(\tau, x, \mu[1,2]) \le 0\}$$

is the maxmin OLRS with one correction at instant $t_0 + \sigma$ *and is given by formula* (26).

We refer to $X_1^-(\tau, t_0, x^0, \mu[1,2])$ as *the maxmin OLRS with one correction* at instant $\tau_1 = t_0 + \sigma$.

The two-stage scheme may be further propagated to the class of piecewise open-loop controls with k corrections. Taking the interval $T = [t_0, \tau]$, introduce a partition

$$\Sigma_k = \{t_0 = \tau_0, \tau_1, \dots, \tau_k, \tau = \tau_{k+1}\},\ \tau_i - \tau_{i-1} = \sigma_i \ge 0, \quad i = 1, \dots, k+1,$$

so that the interval T is now divided into $k+1$ parts

$$T_1 = [t_0, \tau_1),\ T_2 = [\tau_1, \tau_2), \dots, T_{k+1} = [t_1 - \tau_k, t_1],$$

where

$$\tau_i = t_0 + \sum_{j=1}^{i} \sigma_j, \quad i = 1, \dots, k,$$

are *the points of correction.*

Consider also a nondecreasing continuous function $\mu(t) \geq 0,\ \mu(t_0) = 0$ denoting

$$\mu_1 = \mu(\tau_1) - \mu(\tau_0),\ \mu_i = \mu(\tau_i) - \mu(\tau_{i-1}),\ \ i = 1, \ldots, k+1;\ \ \mu = \mu(\tau_{k+1}) - \mu(\tau_0)$$

and also

$$\mu[1, i] = \{\mu_1, \ldots, \mu_i\}, \quad k \geq i > 1.$$

Problem (I_k). Solve the following consecutive optimization problems.
Find

$$V_k^-(\tau_1, x, \mu_1)$$

$$= \max_v \min_u \min_{x(\tau_1)} \{d(x(t_0), X^0) | x(\tau_1) \in \mathcal{B}_{\mu_1}(x), u(t) \in \mathcal{P}(t), v(t) \in \mathcal{Q}(t), t \in T_1\};$$

then find

$$V_k^-(\tau_2, x, \mu[1, 2])$$

$$= \max_v \min_u \min_{x(\tau_2)} \{V_k^-(\tau_1, x(t_0 + \sigma_1), \mu_1) | x(\tau_2) \in \mathcal{B}_{\mu_2}(x), u(t) \in \mathcal{P}(t), v(t) \in \mathcal{Q}(t), t \in T_2\};$$

then, consecutively, for $i = 3, \ldots, k$, find

$$V_k^-(\tau_i, x, \mu[1, i])$$

$$= \max_v \min_u \min_{x(\tau_i)} \{V_k^-(\tau_{i-1}, x(\tau_{i-1}), \mu[1, i-1]) | x(\tau_i) \in \mathcal{B}_{\mu_i}(x), u(t) \in \mathcal{P}(t),$$

$$v(t) \in \mathcal{Q}(t), t \in T_i\},$$

and, finally,

$$V_k^-(\tau, x, \mu[1, k+1])$$

$$= \max_v \min_u \min_{x(\tau)} \{V_k^-(\tau_k, x(\tau_k), \mu[1, \ldots, k]) | x(\tau) \in \mathcal{B}_{\mu_{k+1}}(x), u(t) \in \mathcal{P}(t),$$

$$v(t) \in \mathcal{Q}(t), t \in T_{k+1}\}.$$

Direct calculation gives

$$V_k^-(\tau_1, x, \mu_1) = d(x, X_k(\tau_1, t_0, X^0, \mu_1)), \tag{27}$$

with

$$X_k(\tau_1, t_0, X^0, \mu_1) = \left(X^0 + \mathcal{B}_{\mu_1}(0) + \int_{t_0}^{\tau_1} B(s)\mathcal{P}(s)ds \right) \dot{-} \int_{t_0}^{\tau_1} (-C(s))\mathcal{Q}(s)ds;$$

then

$$V_k^-(\tau_2, x, \mu[1, 2]) = d(x, X_k(\tau_2, t_0, X^0, \mu[1, 2])) = d(x, X_k^-(\tau_2, \tau_1, X_k^-(\tau_1, t_0, X^0, \mu_1), \mu_2)),$$

with

$$X_k(\tau_2, t_0, X^0, \mu[1,2])$$

$$= \left(\left(\left(X^0 + \mathcal{B}_{\mu_1}(0) + \int_{t_0}^{\tau_1} B(s)\mathcal{P}(s)ds\right) \dot{-} \int_{t_0}^{\tau_1} (-C(s))\mathcal{Q}(s)ds\right) + \mathcal{B}_{\mu_2}(0)\right.$$

$$\left. + \int_{\tau_1}^{\tau_2} B(s)\mathcal{P}(s)ds\right) \dot{-} \int_{\tau_1}^{\tau_2} (-C(s))\mathcal{Q}(s)ds;$$

then, consecutively,

$$\begin{aligned} V_k^-(\tau_i, x, \mu[1,i]) &= d(x, X_k^-(\tau_i, t_0, X^0, \mu[1,i])) \\ &= d(x, X_k^-(\tau_i, \tau_{i-1}, X_k^-(\tau_{i-1}, t_0, X^0, \mu[1,i-1]), \mu_i)), \end{aligned}$$

with

$$X_k^-(\tau_i, t_0, X^0, \mu[1,i]) = \left(\cdots\left(X^0 + \mathcal{B}_{\mu_1}(0) + \int_{t_0}^{\tau_1} B(s)\mathcal{P}(s)ds\right) \dot{-} \int_{t_0}^{\tau_1} (-C(s))\mathcal{Q}(s)ds\right)$$

$$+ \cdots + \mathcal{B}_{\mu_i}(0) + \int_{\tau_{i-1}}^{\tau_i} B(s)\mathcal{P}(s)ds\Big) \dot{-} \int_{\tau_{i-1}}^{\tau_i} (-C(s))\mathcal{Q}(s)ds;$$

and, finally,

$$V_k^-(\tau, x, \mu[1,k+1]) = d(x, X_k^-(\tau, t_0, X^0, \mu[1,k+1])), \tag{28}$$

where

$$X_k^-(\tau, t_0, x^0, \mu[1,k+1]) = \left(\cdots\left(X^0 + \mathcal{B}_{\mu_1}(0) + \int_{t_0}^{\tau_1} B(s)\mathcal{P}(s)ds\right)\right. \tag{29}$$

$$\left. \dot{-} \int_{t_0}^{\tau_1} (-C(s))\mathcal{Q}(s))ds\right) + \cdots$$

$$+\mathcal{B}_{\mu_i}(0) + \int_{\tau_i - 1}^{\tau_i} B(s)\mathcal{P}(s)ds\Big) \dot{-} \int_{\tau_i - 1}^{\tau_i} (-C(s))\mathcal{Q}(s)ds\Big) + \cdots$$

$$+\mathcal{B}_{\mu_{k+1}}(0) + \int_{\tau_k}^{\tau} B(s)\mathcal{P}(s)ds\Big) \dot{-} \int_{\tau_k}^{\tau} (-C(s))\mathcal{Q}(s)ds.$$

We refer to $X_k^-(\tau, t_0, \mu[1,k+1])$ as the *maxmin OLRS with k corrections* at points $\tau_i, i = [1 \dots k]$.

THEOREM 3.2. *The set*

$$X_k^-(\tau, t_0, X^0, \mu[1,k+1]) = \{x : V_k^-(\tau, t_0, x, \mu[1,k+1]) \le 0\} \tag{30}$$

is given by formula (29).

We denote

$$V_0^-(\tau, x, \mu_1) = V^-(\tau, x, \mu_1)$$

and also introduce additional notation for the functions $V_i^-(\tau, x, \mu[1, i+1])$. Denote

$$V_i^-(\tau, x, \mu[1, i+1]) = V_i^-(\tau, x, \mu[1, i+1])|V_i^-(t_0, \cdot, 0),$$

emphasizing the dependence of $V_i^-(\tau, x, \mu[1, i+1])$ on the initial condition $V_i^-(t_0, \cdot, 0)$.

We further assume that $V(t_0, x, 0) = d(x, X^0)$ and also take $d(x, X^0) = V_i^-(t_0, x, 0)$ for all i.

Note that the number of nodes τ_j in any partition Σ_k is $k+2$ as $j = 0, \ldots, k+1$. The partition applied to a function V_k is precisely Σ_k. Consequently, the increment

$$\mu = \mu(\tau) - \mu(t_0) = \sum_{j=1}^{k+1} \mu_j$$

is presented as a sum of $k+1$ increments $\mu_j \geq 0$ once it is applied to a function V_k with index k.

A sequence of partitions Σ_k is *monotone* in k if for every $k_1 < k_2$ partition Σ_{k_2} contains all the nodes τ_j of partition Σ_{k_1}.

THEOREM 3.3. *Given are a monotone sequence of partitions Σ_k, $k = 1, 2, \ldots, N, \ldots$ and a continuous nondecreasing function $\mu(t) \geq 0, \mu(t_0) = 0$ that generates for any partition Σ_k a sequence of numbers $\mu_j = \mu(\tau_j) - \mu(\tau_{j-1}), j = 1, \ldots, k+1$.*

Given also are a sequence of value functions $V_k^-(\tau_i, t_0, \mu[1, i])$, each of which is formed by the partition Σ_k, and a sequence $\mu_j, j = 1, \ldots, k+1$ (k is the index of V_k^-).

Then the following relations are true.

(i) *For any fixed τ, x, one has*

$$V_0^-(\tau, x, \mu_1) \leq \cdots \leq V_i^-(\tau, x, \mu[1, i+1]) \leq V_{i+1}^-(\tau, x, \mu[1, i+2]) \leq \cdots \tag{31}$$

$$\cdots \leq V_k^-(\tau, x, \mu[1, \cdots, k+1]).$$

(ii) *For any fixed τ, x, and index $i \in [1, k]$, one has*

$$V_i^-(\tau, x, \mu[1, i+1]) \leq V_i^-(\tau, x, \mu^*[1, i+1]), \tag{32}$$

provided $\mu_j \leq \mu_j^*, j = 1, \ldots, i+1$.

(iii) *The following inclusions are true for $i \in [1, k]$:*

$$X_{i-1}^-(\tau, t_0, X^0, \mu[1, i]) \supseteq X_i^-(\tau, t_0, X^0, \mu[1, i+1]), \tag{33}$$

where the sets X_i^- are defined by (30).

The proofs are based on the following properties of the geometrical (Minkowski) sums and differences of sets $\mathcal{P}_1, \mathcal{P}_2, \mathcal{P}_3$:

$$(\mathcal{P}_1 + \mathcal{P}_2) \dot{-} \mathcal{P}_3 \supseteq \mathcal{P}_1 + (\mathcal{P}_2 \dot{-} \mathcal{P}_3), \ \mathcal{P}_1 \dot{-} (\mathcal{P}_2 + \mathcal{P}_3) = (\mathcal{P}_1 \dot{-} \mathcal{P}_2) \dot{-} \mathcal{P}_3,$$

and the fact that, in general, a maxmin does not exceed a minmax. Direct calculations indicate that the following superpositions will also be true.

LEMMA 3.1. *The functions* V_k^- *satisfy the property*

$$V_k^-(\tau_i, x, \mu[1,i]\ |V_k^-(t_0,\cdot,0)) = V_k^-(\tau_i, x, \mu[j+1,i]\ |V_k^-(\tau_j,\cdot,\mu[1,j]\ |V_k^-(t_0,\cdot,0))), \tag{34}$$

provided $k+1 \geq i \geq j \geq 1$.

This follows from Theorem 3.2 and the definitions of the respective functions V_i^-.

Remark 3.1. Formula (34) reflects a *semigroup* property but *only for the selected points of correction* $\tau_i,\ i = 1,\dots,k$.

The reasoning above indicates, for example, that $X_k^-(\tau, t_0, x^0, 0)$ is the set of states that may be reached *for any* function $v(\cdot) \in V_{\mathcal{O}}$, whose values are communicated in advance in k stages, through $k+1$ consecutive selections of some open-loop control $u(t)$ according to the following scheme.

Stage 1. *Given at time* t_0 are the initial state x^0 and the function $v(t)$ for $t \in T_1$; select at time t_0 control $u(t)$, for $t \in T_1$.

Then at *instant of correction* τ_j comes additional information for stage $(j+1)$.

Stage j $(j = 2,\dots,k)$. *Given at time* τ_j are the state $x(\tau_j)$ and the function $v(t)$ for $t \in T_{j+1}$; select at time τ the control $u(t)$ for $t \in T_{j+1}$.

Remark 3.2. There is a case when all the functions $V_k^-(\tau, x, 0)$ taken for all the integers $k \geq 0$ coincide. This is when system (10) satisfies the so-called *matching conditions*:

$$B(t)\mathcal{P}(t) \equiv \alpha(t)C(t)\mathcal{Q}(t), \quad \alpha(t) \in [0,1), \quad t \in [t_0, \tau].$$

We now pass to the problem of *sequential minmax*, with one correction at instant $t_0 + \sigma = t^*$, using the notation for Problem (I_1).

Problem (II_1). Given set X^0, vector $x \in \mathbb{R}^n$, and numbers $\mu_1, \mu_2 \geq 0$, find

$$V_1^+(t_0+\sigma, x, \mu_1)$$

$$= \min_u \max_v \min_{x(t_0+\sigma)} \{d(x(t_0), X^0) | x(t_0+\sigma) \in \mathcal{B}_{\mu_1}(x); u(t) \in \mathcal{P}(t), v(t) \in \mathcal{Q}(t), t \in T_1\};$$

then find

$$V_1^+(\tau, x, \mu[1,2]) \tag{35}$$

$$= \min_u \max_v \min_{x(\tau)} \{V_1^+(t_0+\sigma, x(t_0+\sigma), \mu_1) | x(\tau) \in \mathcal{B}_{\mu_2}(x), u(t) \in \mathcal{P}(t), v(t) \in \mathcal{Q}(t), t \in T_2\}.$$

The latter is a problem of finding a sequential minmax with one point of correction $t = t^*$.

Denoting

$$X_1^+(\tau, t_0, X^0, \mu[1,2]) = \{x : V_1^+(\tau, x, \mu[1,2]) \leq 0\},$$

let us find $X_1^+(\tau, t_0, X^0, \mu[1,2]), V_1^+(\tau, x, \mu[1,2])$ using the techniques of convex analysis (as above, with obvious changes).

This gives

$$V_1^+(t_0+\sigma, x, 0) = d(x, Z_1^+(t+\sigma, t_0, \mu_1)),$$

where

$$Z_1^+(t+\sigma,t_0,0)=\left((X^0+\mathcal{B}_{\mu_1}(0))\dot{-}\int_{t_0}^{t_0+\sigma}(-C(s))\mathcal{Q}(s)ds\right)+\int_{t_0}^{t_0+\sigma}B(s)\mathcal{P}(s)ds.$$

Continuing the calculations, we have

$$V_1^+(\tau,x,\mu)$$

$$=\min_u\max_v\min_{x(\tau)}\{d(x(t+\sigma),Z_1^+(t+\sigma,t_0,0))|x(\tau)\in\mathcal{B}_{\mu_2}(x),u(t)\in\mathcal{P}(t),v(t)\in\mathcal{Q}(t),t\in T_2\}$$

$$=d(x,X_1^+(\tau,t_0,X^0,\mu[1,2])),$$

where

$$X_1^+(\tau,t_0,X^0,\mu[1,2]) \tag{36}$$

$$=\left(\left(Z_1^+(t+\sigma,t_0,0)+\mathcal{B}_{\mu_2}(0)\right)\dot{-}\int_{t_0+\sigma}^{\tau}(-C(s))Q(s)ds\right)+\int_{t_0+\sigma}^{\tau}B(s)\mathcal{P}(s)ds.$$

This proves Theorem 3.4.

THEOREM 3.4. *The set*

$$X_1^+(\tau,t_0,X^0,\mu[1,2])=\{x:V_1^+(\tau,x,\mu[1,2])\le 0\}$$

is the minmax OLRS with one correction at instant $t=t_0+\sigma$*, given by formula* (36).

Here the problem is again solved in two stages, according to the following scheme.

Stage 1. *Given at time* t_0 are set X^0 and $x\in\mathbb{R}^n$. Select control $u(t)$ (*one and the same for all* v) and for each $v(t),t\in T_1$, assign a vector $x(t_0)\in X^0$ that jointly with u,v produces $x(\tau)\in\mathcal{B}_{\mu_1}(0)$.

Then at instant of correction $t^*=t_0+\sigma$ comes additional information for Stage 2.

Stage 2. Given at time t^* are $x(t^*)$ and vector $x\in\mathbb{R}^n$. Select control $u(t),t\in T_2$ (one and the same for all v), and for each $v(t),t\in T_2$, assign a vector $x(t+\sigma)\in Z^+(t_0+\sigma,t_0,\mu_1)$ that jointly with u,v steers the system to state $x(\tau)\in\mathcal{B}_{\mu_2}(x)$.

We now propagate this *minmax* procedure to a sequential minmax problem in the class of piecewise open-loop controls with k corrections, using the notations of Problem (I_k).

Problem (II_k). Solve the following consecutive optimization problems.

Find

$$V_k^+(\tau_1,x,\mu_1)$$

$$=\min_u\max_v\min_{x(\tau_1)}\{d(x(t_0),X^0)|x(\tau_1)\in\mathcal{B}_{\mu_1}(x);u(t)\in\mathcal{P}(t),v(t)\in\mathcal{Q}(t),t\in T_1\};$$

then, consecutively, for $i=2,\dots,k$, find

$$V_k^-(\tau_i,x,\mu[1,i])$$

$$= \min_u \max_v \min_{x(\tau_{i-1})} \{V_k^+(\tau_{i-1}, x(\tau_{i-1}), \mu[1, i-1]) \,|x(\tau_i) \in \mathcal{B}_{\mu_i}(x), \\ u(t) \in \mathcal{P}(t), v(t) \in \mathcal{Q}(t), t \in T_i\};$$

and, finally,

$$V_k^+(\tau, x, \mu[1, k+1])$$

$$= \max_v \min_u \{V_k^+(\tau_k, x(\tau_k), \mu[1, k+1]) \,|x(\tau) \in \mathcal{B}_{\mu_{k+1}}(x), u(t) \in \mathcal{P}(t), v(t) \in \mathcal{Q}(t), t \in T_{k+1}\}.$$

This time, direct calculation gives

$$V_k^+(\tau, x, \mu) = d(x, X_k^+(\tau, t_0, X^0, \mu)), \tag{37}$$

where

$$X_k^+(\tau, t_0, x^0, \mu) \tag{38}$$

$$= \Bigg(\Bigg(\cdots \Bigg((X^0 + \mathcal{B}_{\mu_1}(0)) \dot{-} \int_{t_0}^{\tau_1} (-C(s)) \mathcal{Q}(s) ds \Bigg) + \int_{t_0}^{\tau_1} B(s) \mathcal{P}(s) ds + \mathcal{B}_{\mu_2}(0) \Bigg) \dot{-} \cdots$$

$$\dot{-} \int_{\tau_{i-1}}^{\tau_i} (-C(s)) \mathcal{Q}(s) ds \Bigg) + \int_{\tau_{i-1}}^{\tau_i} B(s) \mathcal{P}(s) ds + \mathcal{B}_{\mu_{i+1}}(0) \Bigg) \dot{-} \cdots$$

$$\dot{-} \int_{\tau_k}^{\tau} (-C(s)) \mathcal{Q}(s) ds \Bigg) + \int_{\tau_k}^{\tau} B(s) \mathcal{P}(s) ds \Bigg).$$

We refer to $X_k^+(\tau, t_0, x^0, \mu)$ as the *maxmin OLRS with k corrections* at points τ_k.

THEOREM 3.5. *The set*

$$X_k^+(\tau, t_0, x^0, \mu[1, k+1]) = \{x : V_k^+(\tau, x, \mu[1, k+1]) \le 0\}$$

is then the minmax OLRS with one correction and is given by formula (38).

Denote

$$V^+(\tau, x, \mu) = V_0^+(\tau, x, \mu);\ V_i^+(\tau, x, \mu[1, i+1]) = V_i^+(\tau, x, \mu[1, i+1] | V_i^+(t_0, \cdot, 0)),$$

assuming $V_0^+(t_0, x, \mu) = d(x, X^0)$ and, further, taking $V_i^+(t_0, x, 0) = d(x, X^0)$ for all i. Under the assumptions and notation of Theorem 3.3, the last results may be summarized in the following theorem.

THEOREM 3.6. (i) *For any fixed values* τ, x *one has*

$$V_0^+(\tau, x, \mu_1) \ge \cdots \ge V_i^+(\tau, x, \mu[1, i+1]) \ge V_{i+1}^+(\tau, x, \mu[1, i+2]) \\ \ge \cdots \ge V_k^+(\tau, x, \mu[1, k+1]). \tag{39}$$

(ii) *For any fixed* τ, x, *and index* $i \in [1, k]$, *one has*

$$V_i^+(\tau, x, \mu_1) \le V_i^+(\tau, x, \mu_2), \tag{40}$$

provided $\mu_1 \le \mu_2$.

(iii) *The following inclusions are true for* $i \in [1, \dots, k], \mu \geq 0$*:*

$$X^+_{i-1}(\tau, t_0, X^0, \mu[i-1]) \subseteq X^+_i(\tau, t_0, X^0, \mu[1, i]). \tag{41}$$

(iv) *The following superpositions will also be true:*

$$V^+_k(\tau_i, x, \mu[1, i]|V^+_k(t_0, \cdot, 0)) = V^+_k(\tau_i, x, \mu[j+1, i]|V^+_k(\tau_j, \cdot, \mu[1, j]|V^+_k(t_0, \cdot, 0))),$$

provided $k + 1 \geq i \geq j \geq 1$.

In this section, we have considered problems with a finite number of possible corrections and additional information coming at fixed instants of time, having presented a hierarchy of piecewise OLRSs of the anticipative (maxmin) or of the nonanticipative type. These were presented as level sets for value functions which are superpositions of "one-stage" value functions calculated in section 2. A semigroup-type property (34) for these value functions was indicated which is true only for the points of correction Remark 3.1. In the continuous case, however, we shall need this property to be true *for any points*. Then it would be possible to formulate the principle of optimality under uncertainty for our class of problems.

We shall therefore investigate some limit transitions with a number of corrections tending to infinity. This will allow a further possibility of continuous corrections of the control under unknown disturbances.

4. The alternated integrals and the value functions. We observed above that the OLRSs of both types (maxmin and minmax) are described as the level sets of some value functions, namely,[6]

$$\begin{aligned} X^-_k(\tau, t_0, X^0, \mu(\cdot)) &= \{x : V^-_k(\tau, x, \mu(\cdot)) \leq 0\},\ X^+_k(\tau, t_0, X^0, \mu(\cdot)) \\ &= \{x : V^+_k(\tau, x, \mu(\cdot)) \leq 0\}. \end{aligned}$$

We now propagate this approach, based on using value functions, to systems with continuous measurements of the state to allow continuous corrections of the control.

First, note that inequality

$$V^-_i(\tau, x, \mu(\cdot)) \leq V^-_i(\tau, x, 0) - \mu$$

is always true with equality attained, for example, under the following assumption.

Assumption 4.1. There exists a scalar function $\epsilon(t) > 0$ such that

$$B(t)\mathcal{P}(t) \dot{-} (C(t)\mathcal{Q}(t) + \epsilon(t)\mathcal{B}_1(0)) \neq \emptyset$$

for all $t \in [t_0, \tau]$.

In order to simplify further explanations, we shall further deal in this section with the case when $\mu = 0$, omitting the last symbol 0 in the notation for V^-, V^+.[7]

Now note that Lemmas 3.1 and 3.2 indicate that each of the functions

$$V^-_k(\tau, x, 0\,|V^-_k(t_0, \cdot, 0)),\ V^+_k(\tau, x, 0\,|V^+_k(t_0, \cdot, 0))$$

[6]Here, without abuse of notation for V^-_k, X^-_k, V^+, X^+_k, we shall use the symbol $\mu(\cdot)$ rather than the earlier $\mu[1, k+1]$, emphasizing the function $\mu(t)$, $\mu(\tau) - \mu(t_0) = \mu$ used in the respective constructions.

[7]The case when $\mu(\cdot) \neq 0$ would add to the length of the expressions but not to the essence of the scheme. This case could be treated similarly, with obvious complements.

may be determined through a sequential procedure

$$V_k^-(\tau, x\,|V_k^-(t_0,\cdot)) = V_k^-(\tau, x\,|V_k^-(\tau-\sigma_k,\cdot\,|\,\ldots\,|V_k^-(t_0+\sigma_1,\cdot\,|V_k^-(t_0,\cdot)\ldots) \tag{42}$$

for V_k^- and a similar one for V_k^+. How could one express this procedure in terms of set-valued representations?

For a given partition Σ_k, we have $(j \le i)$

$$\left\{x : V_k^-\left(t_0+\sum_{l=1}^{i}\sigma_l, x\,|V_k^-\left(t_0+\sum_{l=1}^{j}\sigma_l,\cdot\right)\right)\le 0\right\} =$$

$$= X_k^-\left(t_0+\sum_{l=1}^{i}\sigma_l, t_0+\sum_{l=1}^{j}\sigma_l, \mathcal{M}_j^-\right),$$

where $\mathcal{M}_j^- = \{x : V_k^-(t_0+\sum_{l=1}^{j}\sigma_l,\cdot)\le 0\}$. Then, in view of the previous relations (see (27)–(29)), we may formulate a set-valued analogy of Lemma 3.1.

LEMMA 4.1. *The following relations are true:*

$$X_k^-(\tau, t_0, X^0) \tag{43}$$

$$= X_k^-(\tau, \tau-\sigma_{k+1}, X_k^-(\tau-\sigma_{k+1}, \tau-\sigma_{k+1}-\sigma_k, \ldots X_k^-(t_0+\sigma_2, t_0+\sigma_1, X_k^-(t_0+\sigma_1, t_0, X^0)\ldots).$$

In terms of set-valued integrals, (43) *is precisely the equivalent of* (29).

Moreover,

$$V_k^-\left(t_0+\sum_{l=1}^{i}\sigma_l, x|V_k^-\left(t_0+\sum_{l=1}^{j}\sigma_l,\cdot\right)\right) \tag{44}$$

$$= \max_v\min_u\ldots\max_v\min_u\left\{d\left(x\left(t_0+\sum_{l=1}^{j}\sigma_l\right), \mathcal{M}_j^-\right)|x\left(t_0+\sum_{l=1}^{i}\sigma_l\right) = x;\right.$$

$$\left. u(t)\in\mathcal{P}(t), v(t)\in\mathcal{Q}(t), t\in T_j;\ldots;u(t)\in\mathcal{P}(t), v(t)\in\mathcal{Q}(t), t\in T_i\right\}.$$

Similarly, for the sequential minmax, we have

$$V_k^+(\tau, x|V_k^+(t_0,\cdot)) = V_k^+(\tau, x|V_k^+(\tau-\sigma_{k+1},\cdot|\ldots|V_k^+(t_0+\sigma_1,\cdot|V_k^+(t_0,\cdot)\ldots). \tag{45}$$

Using notation identical to (42) and (43), but with minus changed to plus in the symbols for V_k^-, X_k^-, we have Lemma 4.2.

LEMMA 4.2. *The following relations are true:*

$$X_k^+(\tau, t_0, X^0) = X_k^+(\tau, \tau-\sigma_{k+1}, X_k^+(\tau-\sigma_{k+1}, \tau-\sigma_{k+1}-\sigma_k, \ldots, \tag{46}$$

$$X_k^+(t_0+\sigma_2, t_0+\sigma_1, X_k^+(t_0+\sigma_1, t_0, X^0)\ldots).$$

In terms of set-valued integrals, formula (46) *is precisely the equivalent of* (38), *provided* $\mu(t) \equiv 0$.[8]

Moreover,

$$V_k^+\left(t_0+\sum_{l=1}^{i}\sigma_l, x|V_k^+\left(t_0+\sum_{l=1}^{j}\sigma_l,\cdot\right)\right) \tag{47}$$

$$= \min_u \max_v \ldots \min_u \max_v \left\{ d\left(x\left(t_0+\sum_{l=1}^{j}\sigma_l\right), \mathcal{M}_j^+ \middle| x\left(t_0+\sum_{l=1}^{i}\sigma_l\right) = x;\right.\right.$$

$$\left.\left. u(t)\in\mathcal{P}(t), v(t)\in\mathcal{Q}(t), t\in T_j, ;\ldots; u(t)\in\mathcal{P}(t), v(t)\in\mathcal{Q}(t), t\in T_i\right\},\right.$$

where $\mathcal{M}_j^+ = \{x : V_k^+(t_0+\sum_{l=1}^{j}\sigma_l,\cdot)\le 0\}$.

It is important to emphasize that until now all the relations were derived *for a fixed partition*

$$\Sigma_k = \{t_0=\tau_0,\tau_1,\ldots,\tau_k,\tau=\tau_{k+1}\};\ \tau_i-\tau_{i-1}=\sigma_i;\ i=1,\ldots,k+1.$$

What would happen, however, if k increases to infinity with

$$\max\{\sigma_i\ :\ i=1,\ldots,k+1\}\to 0,\ k\to\infty, \sum_{i=1}^{k+1}\sigma_i = \tau - t_0, \tag{48}$$

and would the result depend on the type of partition?

Our further discussion will require an important *nondegeneracy assumption*.

Assumption 4.2. There exist continuous vector functions $\beta_1(t),\ \beta_2(t)\in\mathbb{R}^n, t\in[t_0,t_1]$, and a number $\epsilon>0$ such that

$$\text{(a)}\quad \beta_1(\tau_j)+\epsilon\mathcal{B}(0)\subseteq X_j^-(\tau_j,t_0,X^0) \tag{49}$$

for all of the sets

$$X_j^-(\tau_j,t_0,X^0)$$

$$= X_j^-(\tau_j,\tau_{j-1},X_j^-(\tau_{j-1},\tau_{j-2},\ldots,X_j^-(\tau_1,t_0,X^0)\ldots)$$

and

$$\text{(b)}\quad \beta_2(\tau_j)+\epsilon\mathcal{B}(0)\subseteq X_j^+(\tau_j,t_0,X^0) \tag{50}$$

for all of the sets

[8] Also note that, under Assumption 4.1, with X^0 single-valued, one may treat the sets $X_k^+(\tau,x,0)$ as the Hausdorff limits $X_k^+(\tau,x,0)=\lim_{\mu\to+0}X_k^+(\tau,x,\mu)$.

$$X_j^+(\tau_j, t_0, X^0) \tag{51}$$

$$= X_j^+(\tau_j, \tau_{j-1}, X_j^+(\tau_{j-1}, \tau_{j-2}, \ldots, X_j^+(\tau_1, t_0, X^0)\ldots)$$

with $j = 1, \ldots, k+1$, whatever the partition Σ_k is.

This last assumption is further taken to be true *without further notice.*[9]

Observing that (29) and (38) have the form of certain set-valued integral sums ("the alternated sums"), we introduce the additional notation

$$X_k^-(\tau, t_0, X^0) = \mathcal{I}^-(\tau, t_0, X^0, \Sigma_k); \;\; X_k^+(\tau, t_0, X^0) = \mathcal{I}^+(\tau, t_0, X^0, \Sigma_k).$$

Let us now proceed with the limit operation. Take a monotone sequence of partitions Σ_k, $k \to \infty$. Due to inclusions (33) and the boundedness of the sequence $X_k^-(\tau, t_0, X^0)$ from below by any of the sets $X_i^+(\tau, t_0, X^0)$, $i \le k$, the sequence $\mathcal{I}^-(\tau, t_0, X^0, \Sigma_k)$ has a set-valued limit. Similarly, the inclusions (40) and the boundedness of the sequence $X_k^+(\tau, t_0, X^0, \Sigma_k)$ from above ensure that it also has a set-valued limit. A more detailed investigation of this scheme along the lines of [23] would indicate that, under Assumption 4.2 (a) and (b), these set-valued limits *do not depend on the type of partition* Σ_k. This leads to Theorem 4.1.

THEOREM 4.1. *There exist Hausdorff limits* $\mathcal{I}^-(\tau, t_0, X^0) = X^-(\tau, t_0, X^0)$, $\mathcal{I}^+(\tau, t_0, X^0) = X^+(\tau, t_0, X^0)$*:*

$$\lim h(\mathcal{I}^-(\tau, t_0, X^0, \Sigma_k), \mathcal{I}^-(\tau, t_0, X^0)) = 0,$$

$$\lim h(\mathcal{I}^+(\tau, t_0, X^0, \Sigma_k), \mathcal{I}^+(\tau, t_0, X^0)) = 0,$$

with

$$\max\{\sigma_i \;:\; i = 1, \ldots, k+1\} \to 0, \; k \to \infty, \sum_{i=1}^{k+1} \sigma_i = \tau - t_0.$$

These limits do not depend on the type of partition Σ_k.

Moreover,

$$\mathcal{I}^-(\tau, t_0, X^0) = \mathcal{I}^+(\tau, t_0, X^0) = \mathcal{I}(\tau, t_0, X^0) \tag{52}$$

so that

$$X_k^-(\tau, t_0, X^0) = X_k^+(\tau, t_0, X^0) = X(\tau, t_0, X^0).$$

We refer to $\mathcal{I}(\tau, t_0, X^0) = X(\tau, t_0, X^0)$ as the *alternated reach set.*[10]

The proofs of the convergence of the alternated integral sums to their Hausdorff limits and of the equalities (52) are not given here. They follow the lines of those given in detail in [15] for problems on sequential maxmin and minmax considered in backward time (see also [23], [9], [14]).

Let us now study the behavior of the function $V_i^-(\tau, x | V_i^-(t_0, \cdot))$ under condition (48). According to (38) and (31), the sequence $V_i^-(\tau, x)$ is increasing in i with $i \to \infty$.

[9] If at some stage this assumption is not fulfilled, it may be applied to sets of type $X_j^-(\tau_j, t_0, X^0, \mu(\cdot)), X_j^+(\tau_j, t_0, X^0, \mu(\cdot))$ with $\mu(\cdot)$ sufficiently large.

[10] A maxmin construction of the indicated type had been introduced in detail in [23], where it was constructed in backward time, becoming known as the *alternated integral of Pontryagin.*

This sequence is pointwise bounded in x by any solution of Problem (II_k) and therefore has a pointwise limit. Due to (29), Theorem 4.1, and the continuity of the distance function $d(x,\mathcal{M})$ in x, $\mathcal{M}\in conv\mathbb{R}^n$, we have, with $k\to\infty$,

$$\lim d(x,\mathcal{I}_k^-)=d(x,\lim\mathcal{I}_k^-)=d(x,\mathcal{I}^-),$$

and therefore we may conclude that

$$V_k^-(\tau,x)\to d(x,\mathcal{I}^-(\tau,t_0,X^0))=\mathcal{V}^-(\tau,x)$$

under condition (48). This yields Theorem 4.2.

THEOREM 4.2. *Under condition* (48)*, there exists a pointwise limit*

$$\lim_{k\to\infty}V_k^-(\tau,x)=\mathcal{V}^-(t,x)=d(x,X^-(\tau,t_0,X^0)),\tag{53}$$

where $X^-(\tau,t_0,X^0)=\mathcal{I}^-(\tau,t_0,X^0)$*. This limit does not depend on the type of partition* Σ_k*.*

The alternated integral is the level set of the function $\mathcal{V}^-(\tau,x)$*,*

$$\mathcal{I}^-(\tau,t_0,X^0)=\{x:\mathcal{V}^-(\tau,x)\le 0\}.$$

Since $\mathcal{V}^-(t,x)$ does not depend on the partition Σ_k and due to the properties of minmax, we also come to the following conclusion.

THEOREM 4.3. *The function* $\mathcal{V}^-(\tau,x)$ *satisfies the semigroup property*

$$\mathcal{V}^-(\tau,x|\mathcal{V}^-(t_0,\cdot))=\mathcal{V}^-(\tau,x|\mathcal{V}^-(t,\cdot|\mathcal{V}^-(t_0,\cdot)))\tag{54}$$

for $t\in[t_0,\tau]$*. The following inequality is true:*

$$\mathcal{V}^-(t,x)\ge\left\{\max_v\min_u\mathcal{V}^-(t-\sigma,x(t-\sigma))|x(t)=x\right\},\quad\sigma>0.\tag{55}$$

Similarly, for the decreasing sequence of functions $V_k^+(\tau,x)$, we have Theorem 4.4.

THEOREM 4.4. (i) *Under condition* (48) *there exists a pointwise limit*

$$\lim_{k\to\infty}V_k^+(\tau,x)=\mathcal{V}^+(t,x)=d(x,X^+(\tau,t_0,X^0)),\tag{56}$$

where $X^+(\tau,t_0,X^0)=\mathcal{I}^+(\tau,t_0,X^0)$*. This limit does not depend on the type of partition* Σ_k*.*

(ii) *The alternated integral is the level set of the function* $\mathcal{V}^+(\tau,x)$*,*

$$\mathcal{I}^+(\tau,t_0,X^0)=\{x:\mathcal{V}^+(\tau,x)\le 0\}.$$

(iii) *The function* $\mathcal{V}^+(\tau,x)$ *satisfies the semigroup property*

$$\mathcal{V}^+(\tau,x|\mathcal{V}^+(t_0,\cdot))=\mathcal{V}^+(\tau,x|\mathcal{V}^+(t,\cdot|\mathcal{V}^+(t_0,\cdot)))\tag{57}$$

for $t\in[t_0,\tau]$*.*

(iv) *The following inequality is true:*

$$\mathcal{V}^+(t,x)\le\left\{\min_u\max_v\mathcal{V}^+(t-\sigma,x(t-\sigma))|x(t)=x\right\},\quad\sigma>0.\tag{58}$$

A consequence of (52) is the basic assertion Theorem 4.5.

THEOREM 4.5. *With the initial condition* $\mathcal{V}^-(t_0,x) = \mathcal{V}^+(t_0,x) = d(x,X^0) = \mathcal{V}(t_0,x)$, *the following equality is true:*

$$\mathcal{V}^+(\tau,x|\mathcal{V}^+(t_0,\cdot)) = \mathcal{V}^-(\tau,x|\mathcal{V}^-(t_0,\cdot)) = \mathcal{V}(\tau,x|\mathcal{V}(t_0,\cdot)) = d(x,X(\tau,t_0,X^0)). \tag{59}$$

The function $\mathcal{V}(\tau,x)$ *satisfies the semigroup property*

$$\mathcal{V}(\tau,x|\mathcal{V}(t_0,\cdot)) = \mathcal{V}(\tau,x|\mathcal{V}(t,\cdot|\mathcal{V}(t_0,\cdot))). \tag{60}$$

The last relation follows from (59), (54), (57).

Thus, under the nondegeneracy Assumption 4.2, the two forward alternated integrals $\mathcal{I}^+,\mathcal{I}^-$ coincide, and so do the value functions $\mathcal{V}^-,\mathcal{V}^+$.

Relations (55), (58), and (59) allow us to construct a partial differential equation for the function $\mathcal{V}(t,x)$—the so-called HJBI *equation*.

We now investigate the existence of the total derivative $d\mathcal{V}(t,x)/dt$ along the trajectories of system (10). Due to (59) and (13), we have

$$\mathcal{V}(t,x) = d(x,X(t,t_0,X^0)) = \max\{(l,x) - \rho(l|X(t,t_0,X^0))|(l,l) \le 1\}.$$

Observing that for $d(x,X(t,t_0,X^0)) > 0$ the maximizer $l^0(t,x)$ of (61) is unique and taking $l^0(t,x) = 0$ if $d(x,X(t,t_0,X^0)) = 0$, we may apply the rules for differentiating a "maximum"-type function [6] to get

$$d\mathcal{V}(t,x)/dt = \partial\mathcal{V}/\partial t + (\partial\mathcal{V}/\partial x,\dot{x}) = (l^0,\dot{x}) - \partial\rho(l^0|X(t,t_0,X^0))/\partial t.$$

Direct calculations indicate that the respective partials exist and are continuous in the domain $\mathcal{D}\cup\mathrm{int}\mathcal{D}_0$, where $\mathcal{D} = \{x : d(x,X(t,t_0,X^0)) > 0\}, \mathcal{D}_0 = \{x : d(x,X(t,t_0,X^0)) = 0\}$ and $\mathrm{int}\mathcal{D}_0$ stands for the interior of the respective set.

To find the value of the total derivative, take inequalities (58) and (55), which may be rewritten as

$$0 \le \min_u \max_v \{V^+(t-\sigma,x(t-\sigma)) - V^+(t,x)|x(t) = x\} \tag{61}$$

and

$$0 \ge \max_v \min_u \{V^-(t-\sigma,x(t-\sigma)) - V^-(t,x)|x(t) = x\}. \tag{62}$$

Dividing both relations by $\sigma > 0$ and passing to the limit with $\sigma \to 0$, we get

$$\max_u \min_v d\mathcal{V}^+(t,x)/dt \le 0,\ \min_v \max_u d\mathcal{V}^-(t,x)/dt \ge 0. \tag{63}$$

Since in Theorem 4.5 we had $\mathcal{V}^+(t,x) = \mathcal{V}^-(t,x) = \mathcal{V}(t,x)$, for the linear system (10) we have

$$\max_u \min_v d\mathcal{V}(t,x)/dt = \min_v \max_u d\mathcal{V}(t,x)/dt, \quad u\in\mathcal{P}(t), \quad v\in\mathcal{Q}(t),$$

which results in the next proposition.

THEOREM 4.6. *In the domain* $\mathcal{D}\cup\mathrm{int}\mathcal{D}_0$, *the value function* $\mathcal{V}(t,x)$ *satisfies the "forward" equation*

$$\partial\mathcal{V}/\partial t + \max_u \min_v (\partial\mathcal{V}/\partial x, B(t)u + C(t)v) = 0 \tag{64}$$

over $u \in \mathcal{P}(t), v \in \mathcal{Q}(t)$ *with boundary condition*

$$\mathcal{V}(t_0, x) = d(x, X^0). \tag{65}$$

Equation (63) may be rewritten as

$$\partial\mathcal{V}/\partial t + \rho(\partial\mathcal{V}/\partial x|B(t)\mathcal{P}(t)) - \rho(\partial\mathcal{V}/\partial x|(-C(t))\mathcal{Q}(t)) = 0. \tag{66}$$

The last theorem indicates that the HJBI equation (63) is satisfied everywhere in the open domain $\mathcal{D} \cup \mathrm{int}\mathcal{D}_0$. However, the continuity of the partials $\partial\mathcal{V}/\partial x, \partial\mathcal{V}/\partial t$ on the boundary of the domains $\mathcal{D}, \mathcal{D}_0$ was not investigated and in fact may not hold. But it is not difficult to check that with boundary condition (65) the function $\mathcal{V}(t, x)$ will be a *minmax solution* to (66) in the sense of [26], which is equivalent to the statement that $\mathcal{V}(t, x)$ is a *viscosity solution* (see [3], [21]) to (66), (67). This particularly follows from the fact that function $\mathcal{V}(t, x)$ is convex in x, being a pointwise limit of convex in x functions $\mathcal{V}_k^-(t, x)$ (see [8]).

Let us note here that the problem under discussion may be treated not only as above but also *within the notion of classical solutions* to (66) and (65). Indeed, although all the results above were proved for the criterion $d(x(t_0, X^0))$ in the respective problems, the following assertion is also true.

Assertion 4.1. *Theorems* 3.1–3.6 *and* 4.1–4.6 *are all true with the criterion* $d(x(t_0, X^0))$ *in the respective problems substituted by* $d^2(x(t_0, X^0))$.

This assertion follows from direct calculations, as in paper [14], with formula (11) substituted by

$$d^2(x, \mathcal{G}) = \max\{(l, x) - \rho(l|\mathcal{G}) - (1/4)(l, l)^{1/2}\}.$$

The respective value function similar to $\mathcal{V}(t, x)$, denoted further as $\mathcal{V}_1(t, x)$, will now be a solution to (66) with boundary condition

$$\mathcal{V}_1(t_0, x) = d^2(x, X^0). \tag{67}$$

Moreover, $\mathcal{V}_1(t, x)$, together with its first partials, turns out to be continuous in $t, x \in \mathcal{D} \cup \mathcal{D}_0$. Thus we come to the following theorem.

Theorem 4.7. *The function* $\mathcal{V}_1(t, x)$*—a classical solution to* (66), (67)*—satisfies the relations*

$$\{x : \mathcal{V}_1(t, x) \le 0\} = X(t, t_0, X^0) = \mathcal{I}(t, t_0, X^0). \tag{68}$$

We have constructed the set $X(t, t_0, X^0)$ as the limit of the OLRS and the level set of function $\mathcal{V}(t, x)$, (or function $\mathcal{V}_1(t, x)$)—the sequential maxmin or minmax of function $d(t, X^0)$ (or function $d^2(t, X^0)$) under restriction $x(t) = x$. It remains to show that $X(t, t_0, X^0)$ is precisely the set of points that may be reached from X^0 with a certain feedback control strategy $\mathcal{U}(t, x)$, whatever the function $v(t)$ is.

Prior to the next section, we wish to note the following. Function $\mathcal{V}(t, x) = \mathcal{V}(t, x|\mathcal{V}(t_0, \cdot))$ may be interpreted as the value function for the following problem.

Problem (IV). Find the *value function*

$$\mathcal{V}(\tau, x) = \min_{\mathcal{U}} \max_{x(\cdot)} \{d(x(t_0), X^0)|\ x(\tau) = x), \mathcal{U} \in U_{\mathcal{C}}, x(\cdot) \in \mathcal{X}_{\mathcal{U}}(\cdot)\},$$

where $\mathcal{U} = \mathcal{U}(t, x) \in U_{\mathcal{C}}$ is a CLC (see section 1) and $\mathcal{X}_{\mathcal{U}}(\cdot)$ is the set of all solutions to the differential inclusion

$$\dot{x} \in B(t)\mathcal{U}(t, x) + C(t)\mathcal{Q}(t), \quad x(\tau) = x, \tag{69}$$

generated by $x(\tau) = x$, $\mathcal{U}(t,x)$, and taken within the interval $t \in [t_0, \tau]$.

Its level set

$$\mathcal{X}_\mu(\tau) = \{x : \mathcal{V}(\tau, x) \leq \mu\}$$

is precisely the closed-loop reach set. It is the set of such points $x \in \mathbb{R}^n$ for which there exists a strategy $\mathcal{U} \in U_\mathcal{C}$ which for any solution $x(t)$ of (69), $x(\tau) = x, t \in [t_0, \tau]$, ensures the inequality $d(x(t_0), X^0) \leq \mu$. Due to the structure of (69) ($A(t) \equiv 0$), this is equivalent to the following *definition of closed-loop reachability sets.*

DEFINITION 4.1. *A closed-loop reachability set $\mathcal{X}_\mu(\tau)$ is the set of such points $x \in \mathbb{R}^n$ for each of which there exists a strategy $\mathcal{U} \in U_\mathcal{C}$ that for every $v(\cdot) \in V_\mathcal{O}$ assigns a point $x^0 \in X^0$, such that every solution $x[t]$ of the differential inclusion*

$$\dot{x} \in B(t)\mathcal{U}(t,x) + C(t)v(t),\ x(t_0) = x^0, \quad t_0 \leq t \leq \tau,$$

satisfies the inequality $d(x[\tau], x) \leq \mu$.

Once the principle of optimality (60) is true, it may also be used directly to derive (64)—the HJBI equation for the function $\mathcal{V}(t,x)$. Therefore, set $\mathcal{X}_\mu(\tau)$ (if nonempty) will be nothing else than the set $X(\tau, t_0, X^0)$ defined earlier as the limit of OLRSs.

5. Closed-loop reachability under uncertainty. We shall now show that each point of $X(t, t_0, X^0)$ may be reached from X^0 with a certain feedback control strategy $\mathcal{U}(t,x)$, whatever the function $v(t)$ is.

In order to do this, we shall need the notion of the *solvability set* (or, in other terms, "the backward reachability set"—see [12], [27], [16])—a set similar to $X(t, t_0, X^0)$ but constructed in backward time. We first recall from [14] some properties of these sets. Consider the following problem.

Problem (V). Find the *value function*

$$\mathcal{V}_*(t,x) \ = \ \min_{\mathcal{U}} \max_{x(\cdot)} \{d^2(x[t_1], \mathcal{M}) | \mathcal{U} \in U_\mathcal{C}, x(\cdot) \in \mathcal{X}_\mathcal{U}\}, \tag{70}$$

where $\mathcal{M}$ is a given convex compact set ($\mathcal{M} \in conv\mathbb{R}^n$) and $\mathcal{X}_\mathcal{U}$ is the variety of all trajectories $x(\cdot)$ of the differential inclusion (69), $x(\tau) = x,\ t \in [t_0, t_1]$, generated by a given strategy $\mathcal{U} \in U_\mathcal{C}$.

The formal HJBI equation for the value $\mathcal{V}_*(t,x)$ is

$$\frac{\partial \mathcal{V}_*}{\partial t} \ + \ \min_u \max_v \left(\frac{\partial \mathcal{V}_*}{\partial x}, B(t)u + C(t)v \right) = 0, \quad u \in \mathcal{P}(t), \quad v \in \mathcal{Q}(t), \tag{71}$$

with boundary condition

$$\mathcal{V}_*(t_1, x) \ = \ d^2(x, \mathcal{M}). \tag{72}$$

Equation (71) may be rewritten as

$$\frac{\partial \mathcal{V}_*}{\partial t} \ - \ \rho\left(\frac{\partial \mathcal{V}_*}{\partial x} | - B(t)\mathcal{P}(t) \right) + \rho\left(\frac{\partial \mathcal{V}_*}{\partial x} | C(t)\mathcal{Q}(t) \right) = 0. \tag{73}$$

An important feature is that function $\mathcal{V}_*(t,x)$ may be interpreted as a sequential maxmin similar to the one in section 3. Namely, taking the interval $\tau \leq t \leq t_1$, introduce a partition $\Sigma_k = \{\tau = \tau_0, \tau_1, \ldots, \tau_k, \tau_{k+1} = t_1\}$, $h_1 = \tau_{k+1} - \tau_k, \ldots, h_{i+1} =$

$\tau_{k+i+1} - \tau_{k+i}, \dots, h_{k+1} = \tau_1 - \tau_0$, similar to that of section 3. For the given partition, consider the recurrence relations

$$V^-_{*k}(t_1 - h_1, x)$$

$$= \left\{ \max_v \min_u d^2(x(t_1), \mathcal{M}) |\ t_1 - h_1 \le t \le t_1\ , x(t_1 - h_1) = x \right\},$$

$$V^-_{*k}(t_1 - h_1 - h_2, x)$$

$$= \left\{ \max_v \min_u V^-_{*k}(t_1 - h_1, x(t_1 - h_1)) |\ t_1 - h_1 - h_2 \le t \le t_1 - h_1\ , x(t_1 - h_1 - h_2) = x \right\},$$

$$V^-_{*k}(\tau, x) = \left\{ \max_v \min_u V^-_{*k}(\tau + h_{k+1}, x(\tau + h_{k+1})) |\ \tau \le t \le \tau + h_{k+1},\ x(\tau) = x \right\},$$

where $v(t) \in \mathcal{Q}(t),\ u(t) \in \mathcal{P}(t)$ almost everywhere in the respective intervals.

LEMMA 5.1 (see [14]). *With*

$$\max\{h_i : i = 1, \dots, k+1\} \to 0,\ k \to \infty,\ \Sigma_{i=1}^{k+1} h_i = t_1 - \tau, \tag{74}$$

there exists a pointwise limit

$$\mathcal{V}^-_*(\tau, x) = \lim_{k \to \infty} V^-_{*k}(\tau, x)$$

that does not depend upon the type of partition Σ_k.

The function $\mathcal{V}^-_*(\tau, x)$ *coincides with* $\mathcal{V}_*(\tau, x)$.

We shall refer to $V^-_*(\tau, x) = \mathcal{V}_*(\tau, x)$ as the *sequential maxmin*. This function enjoys properties similar to those of its "forward time" counterpart, the function $\mathcal{V}^-(\tau, x)$ of section 3. A similar construction is possible for a "backward" version of the sequential minmax.

The level set

$$\mathcal{W}(t, t_1, \mathcal{M}) = \{x : \mathcal{V}_*(t, x) \le 0\}$$

is referred to as the *closed-loop solvability set* CLSS at time $\tau = t$, from set $\mathcal{M}$. It may be presented as an alternated integral of Pontryagin—the Hausdorff limit of the sequence

$$\mathcal{I}_*(t, t_1, \mathcal{M}, \Sigma_k) \tag{75}$$

$$= \left(\dots \left(\mathcal{M} + \int_{t_1 - \sigma_1}^{t_1} B(\tau)\mathcal{P}(\tau) d\tau \right) \dot{-} \int_{t_1 - \sigma_1}^{t_1} C(\tau)\mathcal{Q}(\tau) d\tau \right) \dots$$

$$\dot{-} \int_t^{t + \sigma_k} C(\tau)\mathcal{Q}(\tau) d\tau,$$

under conditions (74). Also presumed is a nondegeneracy assumption similar to Assumption 4.2.

Assumption 5.1. For a given set $\mathcal{M} \in conv\mathbb{R}^n$, there exists a continuous function $\beta_3(t) \in \mathbb{R}^n$ and a number $\epsilon > 0$ such that

$$\beta_3(\tau_i) + \epsilon\mathcal{B}(0) \subseteq \mathcal{I}_*(\tau_i, t_1, \mathcal{M}, \Sigma_k) \tag{76}$$

for any $i = 1, \ldots, k+1$, whatever the partition Σ_k is.

This assumption is presumed in the next lemma.

LEMMA 5.2. *Under condition* (76) *there exists a Hausdorff limit* $\mathcal{I}_*(t, t_1, \mathcal{M})$*:*

$$\lim h(\mathcal{I}_*(t, t_1, \mathcal{M}, \Sigma_k)\ ,\ \mathcal{I}_*(t, t_1, \mathcal{M})) \ =\ 0.$$

This limit does not depend on the type of partition Σ_k *and coincides with the CLSS,* $\mathcal{W}(t, t_1, \mathcal{M})$*:*

$$\mathcal{I}_*(t, t_1, \mathcal{M}) = \mathcal{W}(t, t_1, \mathcal{M}). \tag{77}$$

From the theory of control under uncertainty and differential games, it is known that if a certain point $x^* \in \mathcal{W}(t, t_1, \mathcal{M})$, there exists a feedback strategy $\mathcal{U}(t, x) \in U_{\mathcal{C}}$ that steers system (10) from position $\{t, x^*\}$ $(x(t) = x^*)$ to set $\mathcal{M}$ *whatever the unknown disturbance* $v(\cdot)$ is [12], [29], [16]. Therefore, assuming $X(t_1, t, x^*) \neq \emptyset$ (which is true under further assumptions), we just have to prove the inclusion

$$x^* \in \mathcal{W}(t, t_1, X(t_1, t, x^*))$$

or, in view of the properties of $\mathcal{V}(t, x), \mathcal{V}_*(t, x)$, that

$$x^* \in \{x : \mathcal{V}_*(t, x|t_1, \mathcal{V}(t_1, x)) \leq 0\}.$$

Here $\mathcal{V}_*(t, x|t_1, \mathcal{V}(t_1, x)) = \mathcal{V}_*(t, x)$ is the solution to (71) with boundary condition

$$\mathcal{V}_*(t_1, x) = \mathcal{V}(t_1, x). \tag{78}$$

(Recall that $\mathcal{V}(t_1, x) = d^2(x, X(t_1, t, X^*))$.)

Due to the definition of the geometrical difference and of the integral $\mathcal{I}_-(t_1, t, x^*)$, one may check that

$$\mathcal{I}_-(t_1, t, x^*) = \mathcal{I}_-(t_1, t, 0) + x^*.$$

We thus have to prove the inclusion

$$0 \in \mathcal{I}_*(t, t_1, \mathcal{I}_-(t_1, t, 0)).$$

Under Assumptions 4.2 (a) taken for $X^0 = \{0\}$ and 5.1 for $\mathcal{M} = \{0\}$, or under Assumption 4.1, it is possible to observe, through direct calculation, using the properties of integrals $\mathcal{I}_*, \mathcal{I}_-$ (see formulas (29),(75)), that the following hold: $X(t_1, t, x^*) \neq \emptyset$ and

$$\mathcal{I}_*(t, t_1, \mathcal{I}_-(t_1, t, 0)) \supseteq \mathcal{I}_-(t_1, t, 0) + \mathcal{I}_*(t, t_1, 0) = \mathcal{R}(t, t_1),$$

where

$$0 \in \mathcal{R}(t, t_1),$$

and we arrive at Lemma 5.3.

LEMMA 5.3. *Under Assumptions* 4.2 (a) *taken for* $X^0 = \{0\}$ *and* 5.1 *for* $\mathcal{M} = \{0\}$, *or under Assumption* 4.1, *the following inclusion is true:*

$$x^* \in \mathcal{W}(t, t_1, X(t_1, t, x^*)); \tag{79}$$

moreover,

$$X(s, t, x^*) \subseteq \mathcal{W}(s, t_1, X(t_1, t, x^*)) \quad \forall s \in [t, t_1].$$

Inclusion (79) implies the existence of a feedback strategy $\mathcal{U}_*(t, x)$ that brings system (10) from $x^* = x(t)$ to $x(t_1) \in X(t_1, t, x^*)$.

THEOREM 5.1. *Under Assumptions* 4.2 (b), $X^0 = \{0\}$, *and* 5.1, $\mathcal{M} = \{0\}$, *or under Assumption* 4.1, *there exists a closed-loop strategy* $\mathcal{U}_*(t, x) \subseteq U_{\mathcal{C}}$ *that steers system* (10) *from any position* $\{t, x^*\}$ $(x^* = x(t))$ *to* $X(t_1, t, x^*)$.

The strategy $\mathcal{U}_*(t, x)$ *may be found through the solution* $\mathcal{V}(t, x)$ *of* (71), *with boundary condition* (78), *as*

$$\mathcal{U}_*(t, x) = \arg\min\{(\partial \mathcal{V}_*(t, x)/\partial x, u) | u \in \mathcal{P}(t)\} \tag{80}$$

(if the gradient $\partial \mathcal{V}_*(t, x)/\partial x$ *does exist at* $\{t, x\}$*), or, more generally, as*

$$\mathcal{U}_*(t, x) = \left\{u : \max_v \{dd^2(x, \mathcal{W}^*[t])/dt | v \in \mathcal{Q}(t)\} \leq 0\right\}, \tag{81}$$

where $\mathcal{W}^*[t] = \{x : \mathcal{V}_*(t, x) \leq 0\}$.

This is verified by differentiating $\mathcal{V}(t, x)$ with respect to t and checking that almost everywhere

$$\frac{d\mathcal{V}}{dt}|_{u=\mathcal{U}_*(t,x)} \leq 0 \quad \forall v(t) \in \mathcal{Q}(t)$$

(see [11], [16]).

The previous theorem ensures merely that *some* point of $X(t_1, t, x^*)$ may be reached from x^*. In order to demonstrate that *any point* $x^\star \in X(t_1, t, x^*)$ may be reached from position $\{t, x^*\}$, we have to prove the inclusion

$$x^* \in \mathcal{W}(t, t_1, x^\star) \tag{82}$$

for any $x^\star \in X(t_1, t, x^*)$ or

$$x^* \in \{x : \mathcal{V}_\star(t, x | \mathcal{V}_\star(t_0, x)) \leq 0\}, \tag{83}$$

provided $\mathcal{V}_\star(t_1, x^\star) \leq 0$. Here $\mathcal{V}_\star(t, x)$ is a solution to (66) with boundary condition

$$\mathcal{V}_\star(t_0, x) = d^2(x, x^\star), \tag{84}$$

where $x^\star \in X(t_1, t, x^*)$.

However, inclusions (82) and (83) again follow from the properties of $\mathcal{I}_-(t_1, t, 0), \mathcal{I}_*(t, t_1, x^*)$, assuming that both of these set-valued integrals are nonempty. The latter, in its turn, is again ensured by either Assumptions 4.2 (a), $X^0 = 0$, and 5.1, $\mathcal{M} = 0$, or Assumption 4.1. This leads to Theorem 5.2.

THEOREM 5.2. *Under either Assumptions* 4.1 (a), $X^0 = 0$, *and* 5.1, $\mathcal{M} = 0$, *or* 4.1 *there exists a closed-loop strategy* $\mathcal{U}_\star(t, x) \subseteq U_{\mathcal{C}}$ *that steers system* (10) *from any position* $\{t, x^*\}$ $(x^* = x(t))$ *to point* $x^\star \in X(t_1, t, x^*)$.

The strategy $\mathcal{U}_\star(t,x)$ *may be found through the solution* $\mathcal{V}_\star(t,x)$ *of* (71), *with boundary condition* (84), *as*

$$\mathcal{U}_\star(t,x) = \arg\min\{(\partial\mathcal{V}_\star(t,x)/\partial x, u) | u \in \mathcal{P}(t)\} \tag{85}$$

(if the gradient $\partial\mathcal{V}_\star(t,x)/\partial x$ *does exist at* $\{t,x\}$*) or, more generally, as*

$$\mathcal{U}_\star(t,x) = \left\{u : \max_v\{dd^2(x,\mathcal{W}^\star[t])/dt | v \in \mathcal{Q}(t)\} \leq 0\right\}, \tag{86}$$

where $\mathcal{W}^\star[t] = \{x : \mathcal{V}_\star(t,x) \leq 0\}$.

Remark 5.1. Assumptions 4.1 (a), $X^0 = 0$, and 5.1, $\mathcal{M} = 0$, are ensured by Assumption 4.1. If this does not hold, it is possible to go through all the procedures taking *μ-neighborhoods* of sets $X(\cdot), W(\cdot)$ rather than the sets themselves. Then one has to look for the $\mu(\cdot)$-reach sets $X(t,t_0,x^*,\mu(\cdot))$ and μ-solvability sets $W(t,t_1,x^\star,\mu(\cdot))$ with μ sufficiently large so that $X(t,t_0,X^0,\mu(\cdot)), W(t,t_1,x^\star,\mu(\cdot))$ would surely be nonempty.

Remark 5.2. The emphasis of this paper is to discuss the issue of reachability under uncertainty governed by unknown but bounded disturbances. This topic was studied here through a reduction to the calculation of value functions for a successive problem on sequential minmax and maxmin of certain *distance functions* or their squares. The latter problems were dealt with via techniques of convex analysis and set-valued calculus. However, the solution schemes of this paper naturally allow a more general situation, which is to substitute the distance function $d(x,\mathcal{M})$ by *any proper convex function* $\phi(x)$, for example, with similar results passing through. The more general problems then reduce to those of this paper.

Thus, given terminal cost function $\phi(x)$, it may readily generate a terminal set $\mathcal{M}$ as a level set $\mathcal{M} = \{x : \phi(x) \leq \alpha\}$ for some α, with support function [25]

$$\rho(l|\mathcal{M}) = \inf\{\lambda(\phi^*(l/\lambda) + \alpha) | \lambda > 0\}.$$

The given formalisms for describing reachability are not the only ones available. We further indicate yet another formal scheme.

6. Reachability and the funnel equations. In this section, we briefly indicate some connections between the previous results and those that can be obtained through evolution equations of the "funnel type" [2], [16].

Consider the evolution equations

$$\lim_{\sigma\to\infty} \sigma^{-1} h_+(\mathcal{X}^-(t+\sigma), (\mathcal{X}^-(t) + \sigma B(t)\mathcal{P}(t)) \dot{-} \sigma(-C(t)\mathcal{Q}(t))) = 0, \tag{87}$$

with initial condition

$$\mathcal{X}^-(t_0) = X^0$$

and

$$\lim_{\sigma\to\infty} \sigma^{-1} h_+(\mathcal{X}^+(t+\sigma), (\mathcal{X}^-(t) \dot{-} \sigma(-C(t)\mathcal{Q}(t))) + \sigma B(t)\mathcal{P}(t)) = 0, \tag{88}$$

with

$$\mathcal{X}^+(t_0) = X^0.$$

Under some regularity assumptions (similar to Assumption 4.1) which ensure that all the sets that appear in (87), (88) are nonempty, these equations have solutions which turn out to be *set-valued*. The solutions $\mathcal{X}^-(t), \mathcal{X}^+(t)$ satisfy (87), (88) almost everywhere. But they need not be unique. However, the property of uniqueness may be restored if we presume that $\mathcal{X}^-(t), \mathcal{X}^+(t)$ are the *(inclusion) maximal* solutions (see[16, sections 1.3, 1.7]). (A solution $\mathcal{X}_0(t)$ to a funnel equation of type (87), (88) is maximal if it satisfies the inclusion $\mathcal{X}_0(t) \supseteq \mathcal{X}(t)$ for any other solution $\mathcal{X}(t)$ to the respective equation with the same initial condition.)

Equations (87), (88) may be interpreted as some limit form of the recurrence equations

$$\mathcal{X}^-(t+\sigma) = (\mathcal{X}^-(t) + \sigma B(t)\mathcal{P}(t)) \dot{-} \sigma(-C(t)\mathcal{Q}(t)),\ X^-(t_0) = X^0 \tag{89}$$

and

$$\mathcal{X}^+(t+\sigma) = (\mathcal{X}^+(t) \dot{-} \sigma(-C(t)\mathcal{Q}(t))) + \sigma B(t)\mathcal{P}(t), \tag{90}$$

$$\mathcal{X}^+(t_0) = X^0 + r\sigma\mathcal{B}_1(0),\ r\mathcal{B}_1(0) \dot{-} \sigma(-C(t)\mathcal{Q}(t)) \neq \emptyset.$$

Indeed, taking, for example, $\sigma = (\tau - t_0)/k$ and solving the recurrence equation (89) for values of time $t_0 = 0, t_0 + \sigma = 1, \ldots, \tau - \sigma, \tau = k$, from $\mathcal{X}^-(t_0) = X^0 = X^-_\sigma(0|\tau)$ to $\mathcal{X}^-(\tau) = X^-_\sigma(k|\tau)$, we observe that $\mathcal{X}^-_\sigma(k|\tau)$ is similar to $\mathcal{I}^-(\tau, t_0, X^0, \Sigma_k) = X^-_k(\tau, t_0, X^0)$, provided Σ_k is selected with constant $\sigma_i = \sigma = (\tau - t_0)/k$. Namely, formula

$$\mathcal{X}^-_\sigma(k) = (\ldots(X^0 + B(\sigma)\mathcal{P}(\sigma)) \dot{-} (-C(\sigma)\mathcal{Q}(s)) + \cdots$$

$$+B(\tau-\sigma)\mathcal{P}(\tau-\sigma) \dot{-} (-C(\tau-\sigma)\mathcal{Q}(\tau-\sigma)) + \cdots + B(\tau)\mathcal{P}(\tau)) \dot{-} (-C(\tau)\mathcal{Q}(\tau))$$

is similar to (29)(when $\mu = 0$) and to (43).

Under Assumtion 4.1, a direct calculation leads to the next conclusions.

LEMMA 6.1. *The following relations are true with* $k \to \infty, (\sigma(k) \to 0)$*:*

(i) $\lim h(\mathcal{X}^-_\sigma(k|\tau), X^-_k(\tau, t_0, X^0)) = 0.$

(ii) $\lim h(\mathcal{X}^-_\sigma(k|\tau), \mathcal{X}^-(\tau)) = 0.$

(iii) *Function* $\mathcal{I}^-[\tau] = \mathcal{I}^-(\tau, t_0, X^0) = \lim \mathcal{I}^-(\tau, t_0, X^0, \Sigma_k) = \mathcal{X}^-(\tau)$ *is a maximal solution to* (87) *with* $\mathcal{X}^-(t_0) = X^0$.

Therefore, the closed-loop reach set $\mathcal{X}(\tau, t_0, X^0)$ may also be calculated through the funnel equation (87), which therefore also describes *the dynamics of the level sets of the value function* $\mathcal{V}(\tau, x)$*—the solution to the forward HJBI equation* (66).

Remark 6.1. As we have seen, (87) describes the evolution of the alternated integral $\mathcal{I}^-(\tau, t_0, X^0)$. Similarly to that, (88) describes the evolution of the alternated integral $\mathcal{I}^+(\tau, t_0, X^0)$. The recurrence equations (89), (90) may then serve to be the basis of numerical schemes for calculating the reach sets.

7. Example. Consider the system

$$\dot{x_1} = x_2 + v, \tag{91}$$

$$\dot{x_2} = u,$$

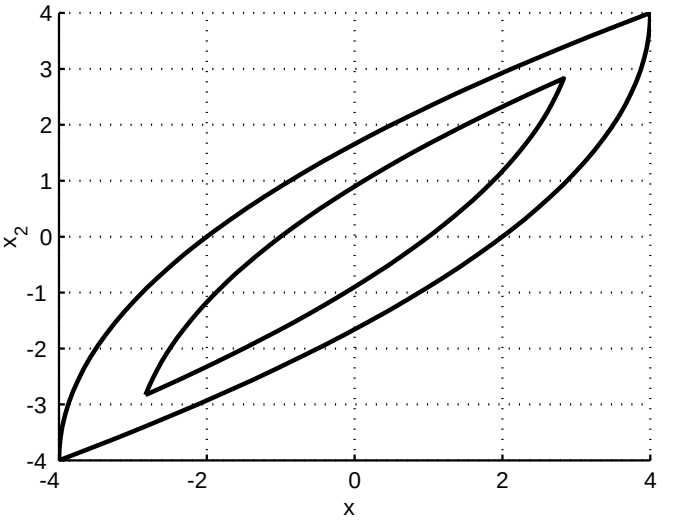

FIG. 1.

defined on the interval $[0, \tau]$, with hard bounds

$$|u| \le r_1,\ |v| \le r_2,\ r_1 > 0,\ r_2 > 0,$$

on the control u and the uncertain disturbance v.

As is known (see, for example, [17]), a parametric representation of the boundary of the reach set $X(\tau, t_0, x^0 | \mathcal{P}(\cdot), \{0\})$ of system (91) without uncertainty ($v(t) \equiv 0$) is given by two curves (see the *external* set in Figure 1, generated for $x^0 = 0, \tau = 2, r_1 = 2, r_2 = 0$):

$$x_1(t) = x_1^0 + x_2^0 t \pm r_1(t^2/2 - \sigma^2),$$

$$x_2(t) = x_2^0 \pm r_1(2\sigma + t),$$

and where $\sigma \le 0$ is the parameter (the values $\sigma > 0$ correspond to the vertices of $X(\tau, t_0, x^0 | \mathcal{P}(\cdot), \{0\})$).

Similarly, the reach set $X(\tau, t_0, X^0 | \{0\}, \mathcal{Q}(\cdot))$ in the variable v is given by the curves

$$x_1(t) = x_1^0 \pm x_2^0 t \pm r_2 t,$$

$$x_2(t) = x_2^0.$$

According to (7) , the set

$$X^-(\tau, 0, x^0, 0) = X(\tau, t_0, x^0 | \mathcal{P}(\cdot), \{0\}) \dot{-} X(\tau, t_0, 0 | \{0\}, \mathcal{Q}(\cdot)),$$

which leads to a parametrization of the boundary of this set in the form

$$x_1(t) = x_1^0 + x_2^0 t \pm r_1(t^2/2 - \sigma^2) \pm r_2 t,$$

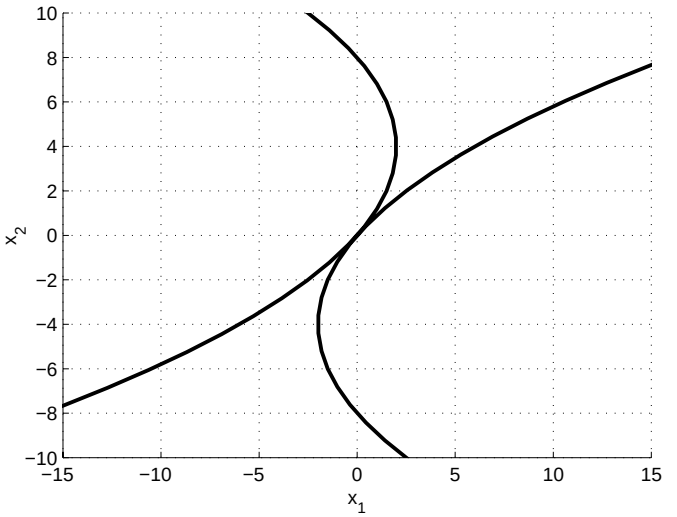

FIG. 2.

$$x_2(t) = x^0 - 2 \pm r_1(2\sigma + t)$$

(see the *internal set* in Figure 1, generated for $X^0 = 0, \tau = 2, r_1 = 2, r_2 = 1$). Clearly,

$$X^-(\tau, 0, x^0, 0) \subset X(\tau, 0, x^0 | \mathcal{P}(\cdot), \{0\})$$

so that the OLRS $X^-(\tau, 0, x^0, 0)$ under uncertainty is smaller than $X(\tau, 0, x^0 | \mathcal{P}(\cdot), \{0\})$—the reach set without uncertainty.

Let us now look for the OLRS $X^-(\tau, 0, x^0, 0)$ with one correction at time $t = \tau_1$. Taking $\tau = 2, \tau_1 = 1, x^0 = 0, r_1 = 1, r_2 = 1/2$, one may figure out that set $X^-(\tau_1, 0, 0, 0)$ has to be bounded by two curves (Figure 2)

$$x_1(t) = \pm(1/2 - 2\sigma^2),$$

$$x_2(t) = \pm 2(2\sigma + 1),$$

which gives $X^-(\tau_1, 0, 0, 0) = \{0\}$. Then for $r_2 > 1/2$ we have $X^-(\tau_1, 0, 0, 0) = \emptyset$, and for $r_2 < 1/2$ we come to $\mathrm{int} X^-(\tau_1, 0, 0, 0) \neq \emptyset$.

Continuing with $r_2 = 1/2$, we have

$$X^-(2, 1, X^-(1, 0, 0, 0), 0) = \{0\} \in X^-(2, 0, 0, 0).$$

We also observe that with $r_2 > 1/2$ we have $X^-(\tau_1, 0, 0, \mu) = \{0\} \neq \emptyset$ if $\mu > 0$ is sufficiently large.

As indicated above, sets $X^+(\tau, t_0, x^0, \mu)$ turn out to be empty unless μ is sufficiently large. Continuing our example further, for $\tau = 2, \tau_1 = 1, x^0 = 0, r_1 = 2, r_2 = 1$, we have

$$X^-(2, 0, 0, \mu) = (\mathcal{B}_\mu(0) + X(2, 0, 0 | \mathcal{P}(\cdot), \{0\})) \dot{-} X(2, 0, 0 | \{0\}, \mathcal{Q}(\cdot)),$$

and

$$X^+(2, 0, 0, \mu) = (\mathcal{B}_\mu(0) \dot{-} X(2, 0, 0 | \{0\}, \mathcal{Q}(\cdot))) + X(2, 0, 0, | \mathcal{P}(\cdot), \{0\}).$$

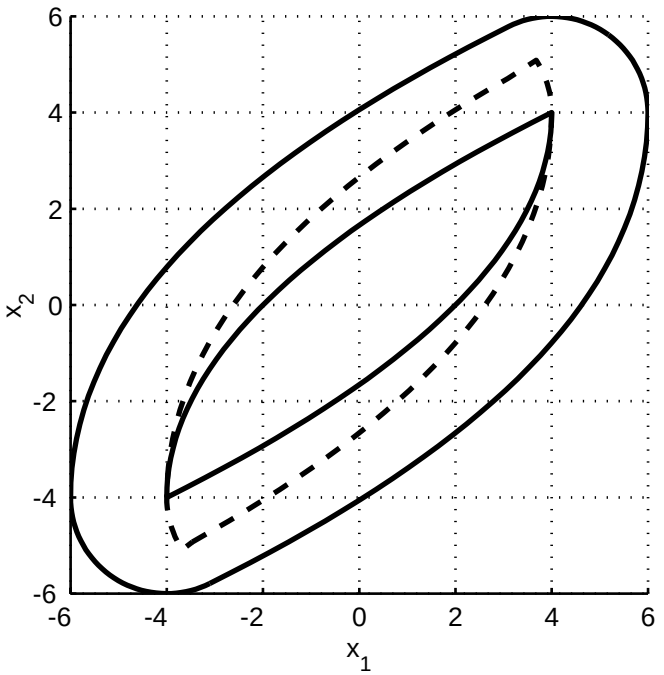

FIG. 3.

The last set is nonvoid if μ is such that $\mathcal{B}_\mu(0) \dot{-} X(2,0,0,|\{0\},\mathcal{Q}(\cdot)) = \mathcal{X}^+[\mu] \neq \emptyset$. The smallest value μ^0 of all such μ ensures $\mathcal{X}^+[\mu^0] = \{0\}$.

For all $\mu \geq \mu^0$ it is then possible to compare sets $X^-(2,0,0,\mu)$ and $X^+(2,0,0,\mu)$, observing that the latter is smaller than the former (see Figure 3, where $X^-(2,0,0,0)$ is shown by the *internal continuous curve*, $X^-(2,0,0,1)$ by the *external continuous curve,* and $X^+(2,0,0,1)$ by the dashed curve).

8. Conclusion. In this paper, we deal with one of the recent problems in reachability analysis which is to specify the sets of points that can be reached by a controlled system *despite the unknown but bounded disturbances in the system inputs.* The paper gives a description of several notions of such reachability and indicates schemes to calculate various types of reach sets. We consider systems with linear structure and closed-loop controls that are generally nonlinear. In particular, we emphasize the difference between reachability under open-loop and closed-loop controls. We distinguish open-loop controls of the anticipative type, which presume the disturbances to be known in advance, and of the nonanticipative type, which presume no such knowledge. The nonanticipative OLRSs is smaller than the one for anticipative open-loop controls, and the closed-loop reach set (which is always nonanticipative) lies in between. Intermediate reach sets are those generated by piecewise closed-loop controls that allow on-line measurements of the state space variable at isolated instants of time—the points of correction. Increasing the number of corrections to infinity and keeping them dense within the interval under consideration, we came to the case of continuous corrections—the solution to the problem of reachability under closed-loop (feedback) control.

The various types of reach sets introduced here *were calculated* through two alternative presentations, namely, *either through operations on set-valued integrals or as level sets for value functions* in sequential problems on maxmin or minmax for certain distance functions.

For the closed-loop reachability problem the corresponding value function defines a mapping that satisfies *the semigroup property.* This property allowed us to formulate *the principle of optimality under uncertainty* for the class of problems considered here. The last principle allowed us to demonstrate that the closed-loop reach set under uncertainty is the level set for the solution to a *forward* HJBI equation. On the other hand, the feedback control strategy that steers a point to its closed-loop reach set (whatever the disturbance is) may be found from the solution to a *backward* HJBI equation whose boundary condition is taken from the solution of the earlier mentioned forward HJBI equation.

This paper leaves many issues for further investigation. For example, there is a strong demand from many applied areas to calculate reach sets under uncertainty. However, the given solutions to the problem are not simple to calculate. Among the nearest issues may be the calculation of the reach sets of this paper through ellipsoidal approximations along the schemes of [16], [17]. Then, of course, comes the propagation of the results to nonlinear systems. Here the application of the HJBI technique seems to allow some progress. Needless to say, similar problems could also be posed for systems with uncertainty in its parameters or in the model itself as well as for other types of controlled transition systems.

Acknowledgment. We thank Oleg Botchkarev for the figures.

CONTROL OF POLLING IN PRESENCE OF VACATIONS IN HEAVY TRAFFIC WITH APPLICATIONS TO SATELLITE AND MOBILE RADIO SYSTEMS*

EITAN ALTMAN† AND HAROLD J. KUSHNER‡

Abstract. Consider a queueing system with many queues, each with its own input stream, but with only one server. The server must allocate its time among the queues to minimize or nearly minimize some cost criterion. The allocation of time among the queues is often called polling and is the subject of a large literature. Usually, it is assumed that the queues are always available, and the server can allocate at will. We consider the case where the queues are not always available due to disruption of the connection between them and the server. Such occurrences are common in wireless communications, where any of the mobile sources might become unavailable to the server from time to time due to obstacles, atmospheric or other effects. The possibility of such "vacations" complicates the polling problem enormously. Due to the complexity of the basic problem we analyze it in the heavy traffic regime where the server has little idle time over the average requirements. It is shown that the suitable scaled total workloads converge to a controlled limit diffusion process with jumps. The jumps are due to the effects of the vacations. The control enters the dynamics only via its value just before a vacation begins; hence it is only via the jump value that the control affects the dynamics. This type of model has not received much attention. The individual queued workloads and job numbers can be recovered (asymptotically) from the limit scaled workload. This state space collapse is critical for the effective numerical and analytical work, since the limit process is one dimensional. It is also shown, under appropriate conditions, that the arrival process during a vacation can be approximated by the scaled "fluid" process. With a suitable nonlinear discounted cost rate, it is shown that the optimal costs for the physical problems converge to that for the limit problem as the traffic intensity approaches its heavy traffic limit. Explicit solutions are obtained in some simple but important cases, and the $c\mu$-rule is asymptotically optimal if there are no vacations. The stability of the queues is analyzed via a perturbed Liapunov function method, under quite general conditions on the data. Finally, we extend the results to unreliable channels where the data might be received with errors and need to be retransmitted.

Key words. heavy traffic analysis, queueing networks, scheduling queues, communication networks, wireless communications, mobile communications, polling, optimal stochastic control

1. Introduction.

Consider a queueing system with several queues and a single server. The problem of assigning service among the competing queues in an optimal way has been studied extensively in the last half of the century, starting with [9, pp. 84–85]. The assignment is often called "polling." For linear holding costs, the fixed-priority policy known as the $c\mu$-rule (and other rules closely related to it) has been shown to be an optimal policy under a variety of statistical assumptions and cost structures (see, e.g., [1, 3, 4, 9] and references therein). Due to Little's rule, this policy turns out to minimize also the overall average expected waiting time in the system. The problem can be considered to be one in optimal stochastic control.

We are concerned with this assignment or polling problem when the connections between each queue and the server are broken at random times and for random durations. Such intervals during which a queue is not available to the server (even if it wished to poll it) are often called vacations in the queueing literature. The possibility of such vacations complicates the control problem considerably, since the possibility that any queue might not be available to the server at any future time needs to be accounted for in choosing the current server allocation.

This problem is of considerable importance in contemporary wireless communications, where the queues are in the mobile sources which generate data to be transmitted and the server is the channel or antenna of the base station. At each time, one assigns the channel to one of the sources (i.e., points the antenna in the direction of that source). In more complex cases with so-called smart antennas, the channel can be shared among the sources in a controlled way, but that possibility will not be considered here.

Recently, Tassiulas and Ephremides [28] have considered this problem of how to assign service to competing queues in the presence of random connectivity. The motivation concerned the dynamic assignment of transmission access to a channel between mobile terminals, any of which might be unavailable from time to time due to physical obstacles or to propagation problems (atmospheric attenuation, interference, noise, fading, etc.). In the context of satellite communications, a survey of such problems can be found in [11].

The classical $c\mu$-rule turns to be not only far from optimal for this system, but in fact the system may be unstable when any fixed priority policy is used. Tassiulas and Ephremides [28] and Tassiulas and Papavassiliou [29] considered the problem of obtaining a dynamic assignment policy that maximizes the throughput. The solution methodology is based on stability analysis using Liapunov functions; first a necessary condition for stability is identified, which holds under any policy. Then a particular policy is identified for which a sufficient stability condition coincides with the above necessary stability condition. It then turns out that this policy stabilizes the system under the largest range of input rates and is thus shown to maximize the throughput that the system can handle. Such a policy has a very simple form [28]: assign a transmission opportunity to the longest connected queue.

It turns out that there is a very large class of policies other than the one above which also achieve that maximum stability region and maximum throughput. (For example, if we first multiply the length of each queue by some [queue dependent] positive constant and then assign transmission to the queue with longest *weighted* length, still an optimal throughput is achieved; this is suggested by our stability analysis in section 6.) The aim of this paper is thus to consider control and optimal control under more sensitive cost criteria, which can not only maximize the throughput but can also minimize some expected holding costs (or in particular, discounted mean values of a broad class of functions of the queue lengths or expected workload in the system).

Due to the complexity of the system and the generality of the statistical assumptions, we consider the optimal control problem only in an asymptotic sense; i.e., the one obtained by an appropriate scaling, corresponding to the heavy traffic regime, where the server has little spare capacity over the mean requirements. As usual with heavy traffic analysis, the limit system is substantially simpler than the original physical system. The aim is to use the limit model to get nearly optimal controls and approximations to the optimal value functions for the actual physical system under heavy traffic conditions. For some large class of policies, we establish the convergence

of the total workload processes to a one dimensional diffusion process with jumps, where the jumps are due to the possibility that the server will have no work to do during part of a vacation of some source. The individual workloads and queue lengths can be approximated in terms of this limit process; hence there is a substantial reduction in dimension from that of the original problem to unity. This limit result is then used to obtain a closed form solution for the asymptotic problem for several types of cost functions. In particular, a closed form solution is obtained for the case when the cost corresponds to the total workload in the system.

A problem related to the one we solve here has been treated in [8] and references therein. There too, optimal scheduling of service opportunities is considered. However, the problem of random (unpredictable) disconnectivity is not considered there; instead, there are predictable instances in which service opportunities appear. These correspond to transmission opportunities between adjacent satellites which use intersatellite links within a satellite constellation. As in [28], the criterion is to maximize the throughput. Several policies are proposed there and their performance is compared.

The structure of the paper is as follows. Section 2 describes the problem and lists the assumptions which are needed to get the weak convergence results of section 3. Jobs (batches of data) arrive at the queues of the individual sources at random times, and in random amounts. It is assumed that the vacations are relatively "rare" and that the ratio of the vacation intervals to the intervacation intervals is small. Nevertheless they have a very important effect on the performance. For notational simplicity, only two sources are considered in the details. However, all of the results hold irrespective of the number of sources, and we comment on the extensions. The analysis contains results which are of broader interest. Examples are the proof that the arrival (and, indeed, the [suitably time scaled] workload and queue processes) process *during a vacation* can be well approximated by a "fluid" process under heavy traffic and that the individual queue sizes can be approximated by linear functions of the individual queued workloads. The policy affects the limit process only via the magnitude of the jumps. In particular, the jumps depend only on the "control" values just before a vacation begins. If we restrict the policy to being a member of a large class of piecewise continuous feedback policies, then Theorem 3.2 shows that the individual workloads can be well approximated by linear functions of the total workload, under heavy traffic.

The discounted cost function is introduced in section 4. The limit control problem appears to be nonstandard, owing to the special way that the control appears in the dynamics, even though it appears in the cost function in a standard way. To get weak convergence of the cost or optimal cost values, one needs a uniform integrability condition as well as weak convergence, and this is dealt with as well.

The optimal control is computed under some assumptions on the costs in section 5. In section 6 we establish the stability conditions for a large class of policies. We extend our model and results in section 7, where we consider the case of unreliable channels which may require retransmissions of erroneous information.

2. The problem formulation. [1] There are two sources with inputs which generate data in some random way. Any number of sources can be used, but we stick to two for notational simplicity. The results for the general case will be apparent

[1] The book by H. Kushner, *Heavy Traffic Analysis of Controlled Queueing and Communication Networks*, Vol. 2, Springer, New York, 2001, has much information on related problems.

from the results for the two source case. The data (or jobs) created by each source are queued there, and the server alternates service (i.e., polling) between them in some way to be determined later. There is no switchover time in going from one source to another. Each of the sources will become unavailable to the server from time to time. The periods of unavailability are called vacations, in accordance with current terminology. Strictly speaking, it is the connection from the source to the server which is "on vacation," but we simply say that the source itself is on vacation. A source that is on vacation cannot be polled, but the data or job inputs which it creates still arrive to its queue. In that case, the content of the unavailable queue grows, but the server can only work on the available queue. Service is nonpreemptive, and first-come-first-served (FCFS): i.e., a job once started is completed, assuming that there is no intervening vacation. Also, the system is assumed to be "work conserving" in that the server will not idle if there is work to do on an available queue. Suppose that a vacation starts in the middle of a job. We suppose *either* (a) that the job is allowed to be completed, or (b) that it is stopped, but when that source is next served the job needs only its residual time, or (c) that the entire job needs to be redone. Because of the "rarity" of vacations under the assumptions (A2.3) and (A2.4) to be introduced below, the results will be the same for all cases. For specificity, and without loss of generality in the results, we suppose that both sources are available at time 0.

Our approach is that of heavy traffic analysis, where the "spare capacity" of the system is small. As usual in heavy traffic analysis, the problem is embedded in a sequence of problems, indexed by n. As $n \to \infty$, the spare capacity of the server goes to zero, and this is quantified in (A2.2). Let $\{\Delta_{i,l}^{a,n}, l < \infty\}$ denote the interarrival times for jobs at source $i = 1, 2$, and let $\{\Delta_{i,l}^{d,n}, l < \infty\}$ denote the corresponding work (real time) requirements.

Comment on weak convergence. Let $\mathbb{R}^r$ denote r-dimensional Euclidean space. The path space for all of the processes will be $D(\mathbb{R}^r; 0, \infty)$, the space of $\mathbb{R}^r$-valued functions which are right continuous and have left-hand limits, for the appropriate values of r. If $r = 1$, we write simply $D(\mathbb{R}; 0, \infty)$. The Skorohod topology will be used on this space. All of the concepts concerning weak convergence which will be used can be found in the standard references [5, 12]. Summaries with applications to stochastic systems can be found in [17, 19]. The following is a convenient criterion for tightness in $D(\mathbb{R}; 0, \infty)$. It will be used implicitly, without specific mention. Let $Y^n(\cdot)$ be a sequence of processes with paths in $D(\mathbb{R}; 0, \infty)$. Let $\mathcal{T}^n(t)$ denote the stopping times with respect to the filtration engendered by $Y^n(\cdot)$ and which are no larger than t. If, for each t,

$$\lim_{\delta \to 0} \sup_n \sup_{\tau \in \mathcal{T}^n(t)} E\left(1 \wedge |Y^n(\tau + \delta) - Y^n(\tau)|\right) = 0 \tag{2.1a}$$

and

$$\{Y^n(s) : n < \infty, s \le t\} \text{ is tight in } \mathbb{R}, \tag{2.1b}$$

then $\{Y^n(\cdot)\}$ is tight [12].

Notation and assumptions. For some centering constants $\bar{\Delta}_i^{\alpha,n}, \alpha = a, d$, whose properties will be specified below, define the processes

$$w_i^{\alpha,n}(t) = \frac{1}{\sqrt{n}} \sum_{l=1}^{nt} \left[1 - \frac{\Delta_{i,l}^{\alpha,n}}{\bar{\Delta}_i^{\alpha,n}}\right], \ t \ge 0, \ \alpha = a, d, i = 1, 2. \tag{2.2}$$

When an index of summation is nt we mean the *integer* part $[nt]$. Let $x_i^n(t)$ denote $1/\sqrt{n}$ times the number of jobs in queue i at *real time* nt, including the one in service, if any. Let $WL_i^n(t)$ (called the workload at queue i) denote $1/\sqrt{n}$ times the real time that the server must work to complete all of the jobs which are in queue i at *real time* nt. Thus, time is scaled by $1/n$ and the state by $1/\sqrt{n}$. Define the *total workload* $WL^n(t) = \sum_i WL_i^n(t)$. By *scaled work* we mean $1/\sqrt{n}$ times the actual physical work in question. The expression *scaled time* of some event always refers to the real time of that event divided by n.

Define the index of a job at queue i as one plus the number of jobs that arrived or were there before it, starting with the ordered $\sqrt{n}x_i^n(0)$ jobs which are in that queue at time zero. Let $L_i^n(t) \geq 0$ denote the index of the last customer to enter service in queue i at or before real time nt. For future use, note that $x_i^n(\cdot)$ and $WL_i^n(\cdot)$ are related by

$$WL_i^n(t) \in \left[\frac{1}{\sqrt{n}} \sum_{l=L_i^n(t)}^{L_i^n(t)+\sqrt{n}x_i^n(t)-1} \Delta_{i,l}^{d,n}, \frac{1}{\sqrt{n}} \sum_{l=L_i^n(t)+1}^{L_i^n(t)+\sqrt{n}x_i^n(t)-1} \Delta_{i,l}^{d,n} \right]. \tag{2.3}$$

We will use the following conditions. By "driving random variables," we mean the set of initial conditions, the arrival times and service requirements, and the starting and stopping times of the vacations.

A2.0. *For each n, $x_i^n(0), WL_i^n(0), i = 1, 2$, are independent of all of the "future" driving random variables. None of the sources is on vacation at $t = 0$.* (The last sentence is used only to simplify the notation.)

A2.1. *For $\alpha = a, d; i = 1, 2$, there are constants $\bar{\Delta}_i^\alpha$ such that*

$$\bar{\Delta}_i^{\alpha,n} \to \bar{\Delta}_i^\alpha.$$

As $n \to \infty$, the sequences $w_i^{\alpha,n}(\cdot), n < \infty, \alpha = a, d; i = 1, 2$, converge weakly to mutually independent Wiener processes $w_i^\alpha(\cdot), \alpha = a, d, i = 1, 2$, with variance parameters $\sigma_{\alpha,i}^2$, respectively.

Define $\bar{\lambda}_i^{\alpha,n} = 1/\bar{\Delta}_i^{\alpha,n}$, which will be used interchangeably, and similarly for $\bar{\lambda}_i^\alpha = 1/\bar{\Delta}_i^\alpha$. Define the traffic intensities

$$\rho_i^n = \bar{\Delta}_i^{d,n}/\bar{\Delta}_i^{a,n} = \bar{\Delta}_i^{d,n}\bar{\lambda}_i^{a,n}, \quad \rho_i = \bar{\Delta}_i^d/\bar{\Delta}_i^a = \bar{\Delta}_i^d\bar{\lambda}_i^a.$$

A2.2. *There is a real number b such that*

$$\lim_n \sqrt{n}\left[\sum_i \rho_i^n - 1\right] = b.$$

Note that (A2.2) implies that $\sum_i \rho_i = 1$.

A2.3. *For each n, i, the intervals between the end of the lth vacation and the start of the next one for source i are denoted by $n\tau_{i,l}^{s,n}, l = 1, \ldots$. They are mutually independent, exponentially distributed, independent of all the other "driving" random variables and have rate $\bar{\lambda}_i^{s,n}/n$, where $\bar{\lambda}_i^{s,n}$ converges to $\bar{\lambda}_i^s > 0$ as $n \to \infty$. The intervals for the different sources are mutually independent.*

A2.4. *For each n, i, there are mutually independent and identically distributed random variables $\tau_{i,l}^{v,n}, l = 1, \ldots$, such that the duration of the lth vacation interval for source i is $\sqrt{n}\tau_{i,l}^{v,n}$. Also, $\tau_{i,l}^{v,n}$ converges weakly to a random variable τ_i^v as $n \to \infty$.*

For each i, the $\tau_{i,l}^{v,n}, l = 1, \ldots,$ are independent of all other "driving" random variables. The intervals for the different sources are mutually independent. $\sup_{i,n} E\tau_{i,l}^{v,n} < \infty$. *Define* $\tau_{i,0}^{v,n} = 0$.

The convergence to the Wiener process in A2.1 is a convenient way of covering many common models, the simplest being the independent and identically distributed cases. The extension of A2.4 which covers correlated (between the sources) vacation intervals is discussed at the end of section 3. The added difficulties are only algebraic. We can work with different information structures, in that the server controller can know either the numbers queued or the work queued. We will confine ourselves to the first case, but it will be seen that the results are asymptotically (as $n \to \infty$) equivalent in that the minimum costs are the same and a good policy for one is equivalent to a good policy for the other. This holds since (Theorem 3.1) the scaled number queued and scaled work queued are (asymptotically) linearly related except on an arbitrarily small (scaled) time interval. Thus, unless mentioned otherwise, the server does not know the work in the queues, only the number of jobs in each queue. It also knows the entire past history, which is the set of past polling decisions, the work done for each job already served and the timing, as well as the starting and ending times of the vacations to date, for each source. The *admissible control* (or polling) policy is defined in the following way.

A2.5. *The server can select the queue served in any nonanticipative way at all, provided that it does not switch while a job is being processed. By nonanticipative we mean the following. Suppose that a job has been completed at real time nt and both sources are available. Then, the next source to be polled is determined by the value* (0 *or* 1) *of a measurable function of the initial queue sizes, all arrival and service data, and the record of vacation starts and completions up to real time nt for each queue.*

Later we will also deal with the set of policies which satisfy either of the following special but important conditions.

A2.6a. (In terms of queued numbers.) *There is a real-valued function $\phi(\cdot)$, which is continuous and nondecreasing, such that between vacations the server polls source* 1 *at real time nt if $x_2^n(t) < \phi(x_1^n(t))$, and polls source* 2 *otherwise. The server does not switch while a job is being processed.*

A2.6b. (In terms of queued workload, a less restrictive function.) *There is a real-valued function $\theta(\cdot)$ which is continuous at all but a finite number of values such that between vacations the server polls source* 1 *if $WL_1^n(t) \geq \theta(WL^n(t))$, and polls source* 2 *otherwise. The server does not switch while a job is being processed.*

3. Weak convergence of the workload and content processes: Arbitrary controls. For $l > 0$, define

$$\nu_{i,l}^n = \sum_{k=1}^{l} \left[\tau_{i,k}^{s,n} + \tau_{i,k-1}^{v,n}/\sqrt{n}\right],$$

which is $1/n$ times the real time of the start of the lth vacation at source i. That is, it is the *scaled* time of the start of the lth vacation at source i. The (scaled) lth vacation interval for source i is the half open (scaled) interval $[\nu_{i,l}^n, \nu_{i,l}^n + \tau_{i,l}^{v,n}/\sqrt{n})$.

Discussion of the control problem. The weak convergence result will be in terms of the total workload (rather than in terms of the workload in each queue), which will be seen to be enough to get the desired results. In fact, except under special policies such as A2.6, in general there is no weak convergence result for the $(WL_i^n(\cdot), i = 1, 2)$ or $(x_i^n(\cdot), i = 1, 2)$. Also, the use of $WL(\cdot)$ yields a one dimensional

limit control problem, a considerable advantage. Next, we introduce some needed notation, and set the problem up and discuss some of its features in a way that facilitates the proof of Theorem 3.1.

Let $S_i^{a,n}(t)$ (resp., $S_i^{d,n}(t)$) denote $1/n$ times the number of jobs that arrived to (resp., were completely served at) queue i by real time nt. Let $Z^n(t)$ denote $1/\sqrt{n}$ times the total real time that both queues are empty *and* neither source is on vacation up to real time nt. Let $T^{v,n}(t)$ denote $1/\sqrt{n}$ times the total time up to real time nt that the server could not work due to a vacation (i.e., where the contents of the available queue, if any, is zero, or where there are no available queues). Then we can write (remaining work = arrived work − work done)

$$WL^n(t) = WL^n(0) + \frac{1}{\sqrt{n}} \sum_i \sum_{l=1}^{nS_i^{a,n}(t)} \Delta_{i,l}^{d,n} - \frac{1}{\sqrt{n}} \left[\text{real time of all service by real time } nt\right], \tag{3.1}$$

where the last term on the right is

$$-\left[\sqrt{n}t - Z^n(t) - T^{v,n}(t)\right]. \tag{3.2}$$

The effect of the vacations: A heuristic discussion. We need to examine $T^{v,n}(t)$ more carefully, since (as will be seen) it is through this term that the control affects the paths of the process in the limit. By A2.4, in scaled time the vacations last $\tau_{i,l}^{v,n}/\sqrt{n}$ units of time, an amount which vanishes as $n \to \infty$.

By A2.3, the intervacation times are $\tau_{i,l}^{v,n}$ in scaled time. Owing to the mutual independence of the intervacation times for the same queue and for the different queues, for any $T > 0$ the probability that vacations will overlap at some point on the scaled time interval $[0, T]$ is of the order of $1/\sqrt{n}$. Since weak convergence on the time interval $[0, \infty)$ is implied by weak convergence on all intervals $[0, T]$, the possibility of overlapping can be ignored in the weak convergence proofs. Thus, in the following discussion, which evaluates the effects of the vacations on the paths for arbitrarily large n, we will suppose (without loss of generality) that only one source can be on vacation at a time. More particularly, if one or more vacations overlap, ignore all but the first. Since this modification alters the paths on each interval $[0, T]$ with a probability of the order $O(1/\sqrt{n})$, it does not affect the distribution of the limit quantities. While the possibility of overlapping vacations is not important for the purely weak convergence aspects in this section, it will have to be taken into account when dealing with the convergence of the costs in section 4. This is because the convergence of the costs (which are not bounded functions) requires both weak convergence of the processes and uniform integrability of the cost functions, so that events of small probability cannot necessarily be neglected. Define $u^n(t) = WL_1^n(t)$. Hence, $WL_2^n(t) = WL^n(t) - u^n(t)$. It will turn out that $u^n(\cdot)$ has the effect of a control. Its value will be seen to be the mechanism for controlling the values of the jumps.

Consider the lth vacation of source i. It starts at (scaled) time $\nu_{i,l}^n$, and the total workload just before that is $WL^n(\nu_{i,l}^n-)$. Define $\bar{A}_{i,l}^{j,n}$ to be $1/\sqrt{n}$ times the work arriving at queue i during the lth vacation of source j. Define

$$\bar{A}_{i,l}^{j,n}(t) = \frac{1}{\sqrt{n}} \sum_{l=nS_i^{a,n}(\nu_{j,l}^n-)+1}^{nS_i^{a,n}((\nu_{j,l}^n+(\tau_{j,l}^{v,n}\wedge t)/\sqrt{n})-)} \Delta_{i,l}^{d,n}. \tag{3.3}$$

The minuses $(-)$ in the lower and upper limits of summation in (3.3) are due to the fact that (recall that the interval is half open) we count $\nu^n_{1,l}$ as part of the (scaled) vacation period, but not $\nu^n_{1,l} + \tau^{v,n}_{1,l}/\sqrt{n}$, for specificity, although the exact accounting procedure used at the end-points is asymptotically (as $n \to \infty$) irrelevant.

The time scale used in (3.3) will be called the *local fluid scale*. In this scale, t denotes an interval of real time of length $\sqrt{n}t$, or, equivalently, an interval in scaled time of length $t/\sqrt{n}$.

Until further notice, for notational simplicity in the motivational discussion, let us fix our attention on the lth vacation of source 1. Thus, $\bar{A}^{1,n}_{i,l} = \bar{A}^{1,n}_{i,l}(\infty)$, the scaled arriving work at queue i during this vacation. Also, $\bar{A}^{1,n}_{i,l}(t)$ is $1/\sqrt{n}$ times the work arriving at queue i in the *real* time interval $[n\nu^n_{1,l}, n\nu^n_{1,l} + \sqrt{n}t)$ for $t < \tau^{v,n}_{1,l}$.

Let $\xi^{v,n}_{i,l}$ denote the change in the *total workload* during the lth vacation of source i. If

$$\tau^{v,n}_{1,l} < WL^n_2(\nu^n_{1,l}-) + \bar{A}^{1,n}_{2,l} = WL^n(\nu^n_{1,l}-) - u^n(\nu^n_{1,l}-) + \bar{A}^{1,n}_{2,l}, \tag{3.4a}$$

then the vacation ends before queue 2 is emptied, and the vacation would not seem to have an immediate effect on the total idle time and workload and (asymptotically, as $n \to \infty$) $\xi^{v,n}_{1,l} = 0$. This is not quite obvious, and the point is both important and subtle, since it is possible that the scaled work that arrives during a vacation all arrives close to the end in which case there might be idle time. However, as seen from Theorem 3.1, it turns out that (asymptotically, as $n \to \infty$ and in the local fluid time scale) the scaled work can be supposed to arrive "continuously" and at the mean rate during the vacation, analogously to a "fluid." This implies that, asymptotically, as $n \to \infty$ and under (3.4a), the vacation has no effect on the total workload.

On the other hand, if

$$\tau^{v,n}_{1,l} > WL^n(\nu^n_{1,l}-) - u^n(\nu^n_{1,l}-) + \bar{A}^{1,n}_{2,l} \equiv \hat{\tau}^{v,n}_{1,l}, \tag{3.4b}$$

then queue 2 is emptied before the vacation ends. The proof of Theorem 3.1 allows us to suppose that (asymptotically, as $n \to \infty$, and in the local fluid time scale) the scaled work arrives continuously, as a fluid, at the mean rate as noted above. However, the heavy traffic condition A2.2 implies that the service rate is so much faster than the arrival rate of work at queue 2, that (asymptotically, as $n \to \infty$) the workload in queue 2 is zero for a nonvanishing fraction of the vacation time. Thus, there is (asymptotically) forced idle time and an increase in the total workload due to the vacation. This increase will depend on the value of the workload at queue 2 at the time that the vacation at queue 1 starts. In turn, that value depends on the control policy. This is the *only* way that the control policy affects the workload: via the sizes of the jumps due to the vacations, which (in turn) is determined by the distribution of the total workload just before the vacation starts. It will be seen that the difference between the scaled work that arrives at queue j during this lth vacation of source 1 and $\bar{\lambda}^a_j \bar{\Delta}^d_j \tau^{v,n}_{1,l} = \rho_j \tau^{v,n}_{1,l}$ converges weakly to zero. Obviously, one can reverse sources 1 and 2 in the above discussion. From the above discussion, we see that the control can be viewed as the division of the total workload among the two queues.

Suppose, formally, that n indexes a weakly convergent subsequence of

$$\left(\tau^{v,n}_{1,l}, u^n(\nu^n_{1,l}-), WL^n(\nu^n_{1,l}-)\right),$$

use the same notation (dropping the n superscript) for the weak sense limits, and formally use the asymptotic fluid approximation to (3.3). This fluid approximation

simply replaces the terms in (3.3) by their asymptotic mean value and is $\rho_i[\tau^v_{1,l} \wedge t]$. We see, formally, that (in the limit) the increase in $T^{v,n}(\cdot)$ (equivalently, in the total workload) during the lth vacation of source 1 can be written as

$$\xi^v_{1,l} = \left[(1-\rho_2)\,\tau^v_{1,l} - [WL(\nu_{1,l}-) - u(\nu_{1,l}-)]\right]^+$$

which equals

$$\left[\rho_1\tau^v_{1,l} - [WL(\nu_{1,l}-) - u(\nu_{1,l}-)]\right]^+. \tag{3.5a}$$

The analogue for the lth vacation of source 2 is

$$\xi^v_{2,l} = \left[\rho_2\tau^v_{2,l} - u(\nu_{2,l}-)\right]^+. \tag{3.5b}$$

Here, $u(t) \le WL(t)$ can be considered to be the control function for the limit system (3.7), (3.8a). It appears only via the discrete values: $u(\nu_{i,l}-), l < \infty, i = 1, 2$. The notation in (3.5) can be misleading since the use of the symbol $u(t-)$ suggests either left continuity or that the left-hand limit exists at t, or that (some subsequence of) $u^n(\cdot)$ converges weakly. *We do not make these claims for general polling policies,* but the sequence $u^n(\nu^n_{i,l}-)$ will always be tight in n. If the control policy is of the type in (A2.6), then roughly speaking (see Theorem 3.2) the "intervacation sections" of $u^n(\cdot)$ will be tight and have continuous weak sense limits.

The intervacation sections. Let $\bar\nu^n_l$ and ν^n_l denote, respectively, the (scaled) time of the beginning and end (respectively) of the lth intervacation interval, irrespective of the source. Thus, by our conventions, $\bar\nu^n_l$ is $1/n$ times the real time of the beginning of the lth vacation. By our convention, no source is on vacation at the initial time, so that $\bar\nu^n_1 = 0$. Define the *intervacation sections* as the functions

$$WL^n\left((\bar\nu^n_l + t) \wedge \nu^n_l\right),\ t \ge 0. \tag{3.6}$$

It is constant for $t \ge \nu^n_l - \bar\nu^n_l$.

State space collapse. The physical dimension of the original problem is the number of sources. Mathematically, the dimension is even higher since the set of queue lengths is not Markovian. Theorem 3.1 is an example of what is called state space collapse [7, 24, 25, 26, 32] in the heavy traffic literature. The dimension of the approximating problem is unity and the original $x^n_i(\cdot)$ (which do not necessarily converge weakly) can be asymptotically approximated by a constant (depending on i) times the total workload process $WL^n(\cdot)$ (which does converge weakly in the sense described in the theorem). Such state space collapse is obviously very helpful in the control problem and for numerical procedures.

Comment on tightness and Theorem 3.1. During a vacation, $WL^n(\cdot)$ changes in steps of size $O(1/\sqrt{n})$ over an interval of scaled size $O(1/\sqrt{n})$. While the effect of the vacation is (asymptotically) a jump in a well-defined sense, because of the way that the jump is realized, $WL^n(\cdot)$ is not tight in the Skorohod topology. Since the parts of the path between vacations are well behaved, it is convenient to work with the effects of the vacations and the intervacation parts separately. Suppose that the set in (3.6) is tight for each l. It is easy to show this (Theorem 3.1) for $l = 1$. Then the set of its "terminal" conditions $WL^n(\nu^n_1-)$ is also tight, as is $u^n(\nu^n_l-)$. Thus the set (3.5a) or (3.5b) for the first vacation is also tight (Theorem 3.1). Then, the set of initial conditions $WL^n(\bar\nu_2)$ for the next intervacation interval is tight. Then repeat, as for the first section, etc. In this way, taking an appropriate subsequence and working

section by section, one constructs a "limit" process $WL(\cdot)$. We call this procedure "concatenation." A primary aim is showing the convergence of the discounted cost functions (4.3b) to (4.3a) for a well-defined "limit" process $WL(\cdot)$. One does not need full weak convergence of $WL^n(\cdot)$ for this and the piecewise or concatenation approach is adequate. The various conclusions of the theorem are denoted by (a), (b), etc.

As indicated above, in the proof of the theorem one works step by step. After some preliminary details concerning convergence of the $S_i^{a,n}(\cdot)$ and representations of the workload process, it is shown that the sequence of sections up to the time of the first vacation is tight and its limit is characterized. Thus, the sequence of states at the time at which the first vacation starts is tight. Then we deal with the first vacation and characterize its limits. Now, we have that the sequence of states at the end of the first vacation is tight, so we can analyze the paths between the end of the first vacation and the beginning of the second, just as the path up to the first vacation was handled, etc. In this way, we can see that there is nothing special about the first intervacation interval or the first vacation. Thus, all of the intervacation sections and vacation jumps can be dealt with. The appropriate limit process puts these together in sequence. This type of convergence is sufficient to get the convergence result for the discounted cost function later on. The procedure is analogous to a common method of constructing the solution to a jump-diffusion process.

THEOREM 3.1. *Assume* A2.0–A2.5*, and suppose that* $(x_i^n(0), i = 1, 2)$ *converges weakly to* $(x_i(0), i = 1, 2)$. (a) *Then* $WL^n(0)$ *converges weakly to* $\sum_i \bar{\Delta}_i^d x_i(0)$. (b) *For* $i = 1, 2$, *the set*

$$\Psi^n = \Big(WL^n(\nu_{i,l}^n-), u^n(\nu_{i,l}^n-), \tau_{i,l}^{v,n}, \tau_{i,l}^{s,n}, \xi_{i,l}^{v,n}, i = 1, 2, l < \infty\Big)$$

is tight in n. (c) *The sequence of intervacation sections of* $WL^n(\cdot)$ *defined by* (3.6) *and of* $Z^n(\cdot)$ *are tight for each* i *and* l, *the weak sense limit of any weakly convergent subsequence has continuous paths.*

Fix a weakly convergent subsequence of the set Ψ^n *and the set of intervacation sections of* $WL^n(\cdot)$ *and* $Z^n(\cdot)$, *and index it by* n *also* (*abusing terminology*). *The weak sense limits are denoted by dropping the* n *superscript.* (d) *Then* $(\tau_{i,l}^{s,n}, l < \infty)$ *converges weakly to* $(\tau_{i,l}^s, l < \infty)$, *where the* $\tau_{i,l}^s$ *are exponentially distributed with rate* $\bar{\lambda}_i^s$. (e) *The differences* $WL_i^n(\cdot) - \bar{\Delta}_i^{d,n} x_i^n(\cdot)$ *converge weakly to the "zero" process.* (f) *Define* $WL(\cdot)$ *by concatenating the weak sense limits of the successive intervacation sections of* $WL^n(\cdot)$. *The weak sense limits of any weakly convergent subsequence are related by*

$$WL(t) = WL(0) + bt + w(t) + \sum_i J_i(t) + Z(t), \tag{3.7}$$

where

$$J_i(t) = \sum_{l:\nu_{i,l} \le t} \xi_{i,l}^v, \quad \nu_{i,l} = \sum_{k=1}^{l} \tau_{i,k}^s. \tag{3.8a}$$

In (3.7) *the process* $WL(\cdot)$ *between its* $(l-1)$*st and* l*th jump is the value of the weak sense limit of the process defined by* (3.6) *on the interval* $[0, \nu_l^n - \bar{\nu}_l^n)$. (g) *Also*

$$\big(WL(0), w(\cdot), \tau_{i,l}^v, \tau_{i,l}^s; i = 1, 2, l < \infty\big) \tag{3.8b}$$

are mutually independent, and $w(\cdot)$ is a Wiener process with variance parameter

$$\sigma^2 = \sum_i \left[\rho_i \sigma_{a,i}^2 + \sigma_{d,i}^2\right], \tag{3.9}$$

which we assume to be positive. (h) *$Z(\cdot)$ is the reflection term. It is continuous, nondecreasing, can increase only at t, where $WL(t) = 0$ and satisfies $Z(0) = 0$.* (i) *The $\xi_{i,l}^v$ have the representation* (3.5). (j) *Define the Poisson processes $N_i(\cdot), i = 1, 2$, to be the process with a unit jump at $\nu_{i,l}, l \geq 1$. For each t,*

$$w(t+\cdot) - w(t), N_i(t+\cdot) - N_i(t),\ i = 1, 2, \tag{3.10}$$

is independent of

$$\begin{aligned} &w(s), N_i(s), s \leq t; s \leq t; i = 1, 2, \\ &\quad \left(u(\nu_{i,l}-) I_{\{\nu_{i,l} \leq t\}}, \xi_{i,l}^v I_{\{\nu_{i,l} \leq t\}}, i = 1, 2, l < \infty\right). \end{aligned} \tag{3.11}$$

(k) *The process* (3.3) *converges weakly to the process with values $\rho_i(t \wedge \tau_{j,l}^v)$.*

Comment on the control $u(\nu_{i,l}-)$. Under the general conditions that are used in this theorem to get the weak convergence, we cannot get convergence of the random processes $u^n(\cdot)$, only of the random variables which are the values at selected points. However, in the next section the class of polling policies will be restricted to be in some very reasonable class, and for this class there will be tightness of $u^n(\cdot)$ in an appropriate sense. Then, the weak sense limits will be well-defined admissible control functions for the weak sense limit $WL(\cdot)$ process.

Proof. As noted below (3.2), without loss of generality we can suppose that at most one source is on vacation at a time. Given the current real time nt, the real time since the current service started or has to go, or the real time since or until the next arrival are called *residual times*. We define a *residual time error term* to be a random process (to be denoted by $\epsilon^n(\cdot)$) which is bounded by [constant/$\sqrt{n}$] times a [finite sum of such residual time terms plus a constant]. Successive uses of $\epsilon^n(\cdot)$ might refer to different residual time error terms. Assumption A2.1 implies that the $\epsilon^n(\cdot)$ converge weakly to the "zero" process, since the continuity of the limit there implies that the maximum of the first $[nt]$ summands, divided by $\sqrt{n}$, goes to zero in probability as $n \to \infty$.

The difference between the terms in (2.3) is a residual time error term, thus the process defined by the difference converges weakly to the "zero" process. The proof that $WL^n(0)$ converges as asserted follows from A2.1 and the representation (2.3), where $t = 0$.

For specificity, we will suppose that the preempt-resume discipline holds for any job which is being served when a vacation of its source starts. Assumption A2.3 implies that, for any t, the number of vacations on any real time interval $[0, nt]$ is bounded in probability, uniformly in n. Due to this and the fact that (by A2.1) the maximum of the first $[nt]$ workloads divided by $\sqrt{n}$ goes to zero in probability as $n \to \infty$, any of the disciplines cited in section 2 will yield the same result.

We next prove the weak convergence of $S_i^{a,n}(\cdot)$ to the process with constant values $\bar{\lambda}_i^a t$. Define $\mathcal{T}_i^{a,n}(t) = \sum_{l=1}^{nt} \Delta_{i,l}^{a,n}/n$. By A2.1, $\mathcal{T}_i^{a,n}(\cdot)$ converges weakly to the process with values $\bar{\Delta}_i^a t = t/\bar{\lambda}_i^a$. Also, possibly modulo a residual time error term,

$$\begin{aligned} S_i^{a,n}(\mathcal{T}_i^{a,n}(t)) &= t, \\ \mathcal{T}_i^{a,n}(S_i^{a,n}(t)) &= t. \end{aligned}$$

This and the weak convergence of $\mathcal{T}_i^{a,n}(\cdot)$ imply the asserted weak convergence of $S_i^{a,n}(\cdot)$.

The next step is to show the tightness and asymptotic continuity of $WL^n(\cdot)$ *when there are no vacations.* In the absence of vacations, we can write

$$WL^n(t) = WL^n(0) + \frac{1}{\sqrt{n}} \sum_i \sum_{l=1}^{nS_i^{a,n}(t)} \Delta_{i,l}^{d,n} - t\sqrt{n} + Z^n(t). \tag{3.12}$$

The term $T^{v,n}(t)$ of (3.2) is not included since, in this part of the proof, we have assumed that there are no vacations. For each i, expand the inner sum in (3.12) as

$$\frac{1}{\sqrt{n}} \sum_{l=1}^{nS_i^{a,n}(t)} \left[\Delta_{i,l}^{d,n} - \bar{\Delta}_i^{d,n}\right] + \frac{1}{\sqrt{n}} \sum_{l=1}^{nS_i^{a,n}(t)} \bar{\Delta}_i^{d,n}. \tag{3.13}$$

The first term of (3.13) is $-\bar{\Delta}_i^{d,n} w_i^{d,n}(S_i^{a,n}(t))$. Expand the last term in (3.13) as

$$\frac{1}{\sqrt{n}} \bar{\Delta}_i^{d,n} \sum_{l=1}^{nS_i^{a,n}(t)} \left[1 - \frac{\Delta_{i,l}^{a,n}}{\bar{\Delta}_i^{a,n}}\right] + \frac{1}{\sqrt{n}} \frac{\bar{\Delta}_i^{d,n}}{\bar{\Delta}_i^{a,n}} \sum_{l=1}^{nS_i^{a,n}(t)} \Delta_{i,l}^{a,n}. \tag{3.14}$$

The right-hand *sum* in (3.14) equals nt minus the time between nt and the last arrival at or before real time nt. Hence, the right-hand term equals $\rho_i^n \sqrt{n} t$ plus a residual time error term.

Summarizing,

$$\begin{aligned} WL^n(t) = WL^n(0) &+ \sum_i \bar{\Delta}_i^{d,n} \left[w_i^{a,n}(S_i^{a,n}(t)) - w_i^{d,n}(S_i^{a,n}(t))\right] \\ &+ \sqrt{n}\left[\sum_i \rho_i^n - 1\right] t + Z^n(t) + \epsilon^n(t). \end{aligned} \tag{3.15}$$

The hypotheses and the weak convergence of $S_i^{a,n}(\cdot)$ imply the weak convergence of the processes on the right of (3.15) to those of (3.7), except possibly that of $Z^n(\cdot)$, with the given definitions of $w(\cdot)$ and b, but without the jump term. If $\{Z^n(\cdot), n < \infty\}$ were not tight and have continuous weak sense limits, then we would have a contradiction to the facts that $Z^n(\cdot)$ can increase only when $WL^n(t) = 0$ and has jumps of size $1/\sqrt{n}$ only. Thus, by taking a further subsequence if necessary, we can suppose that $Z^n(\cdot)$ converges to the reflection term $Z(\cdot)$ in (3.7). The sequence of processes defined by (3.15) converges weakly and the limit satisfies (3.7) without the jump term.

Now, return to the *original problem, where there are vacations,* and recall that ν_1^n is the scaled time of the start of the first vacation. For the remainder of this proof, continue using the assumption that the vacations do not overlap. As noted below (3.2), this is accomplished by ignoring all but the first if there are overlaps. The alteration does not change the distribution of the limit processes, since the probability of such a change on any finite interval goes to zero as $n \to \infty$.

By A2.3 and A2.4, the various sequences of times $\tau_{i,l}^{s,n}, \tau_{i,l}^{v,n}, i = 1, 2, l = 1, \ldots,$ converge weakly and $\bar{\nu}_{l+1}^n - \nu_l^n = \tau_{i,l}^{v,n}/\sqrt{n}$ converges weakly to zero. By A2.3 and the weak convergence of the sequence of processes defined by (3.15), $WL^n(\nu_1^n -)$ also converges weakly. Denote the weak sense limits by dropping the superscript n. By A2.3,

the $(\tau^s_{i,l}, l = 1, \ldots, i = 1, 2)$ are mutually independent, and exponentially distributed, with rate $\bar\lambda^s_i$ for $\tau^s_{i,l}$. By A2.4, $(\tau^v_{i,l}, l = 1, \ldots, i = 1, 2)$ are mutually independent. By A2.0, A2.1, A2.3, and A2.4, the

$$WL(0), w^a_i(\cdot), w^d_i(\cdot), \tau^v_{i,l}, \tau^s_{i,l}, i = 1, 2,\ l = 1, \ldots, \tag{3.16}$$

are mutually independent. For each l, ν^n_l converges weakly and $\nu^n_{l+1} - \nu^n_l$ converges weakly to an exponentially distributed random variable, with rate $\sum_i \bar\lambda^s_i$, and the limits are mutually independent and are independent of the random variables in (3.16) other than $\{\tau^s_{i,l}; i, l\}$.

Suppose for the moment that the jumps $\xi^{v,n}_{i,l}$ are tight for each i, l. Abusing notation, let n index a further subsequence along which all of the $\xi^{v,n}_{i,l}, i = 1, 2, l = 1, \ldots,$ also converge weakly, and denote the weak sense limits by dropping the superscript n. Then, by repeating the analysis which led to (3.15) on each successive intervacation interval, we are led to (3.7) with $J_i(\cdot)$ defined by (3.8a) and the independence in (3.8b). Equation (3.7) represents the limit of $WL^n(\cdot)$ in the particular sense that its interjump sections are the weak sense limits of the intervacation sections (3.6) and its jumps are the limits of the $WL^n(\bar\nu^n_{l+1}) - WL^n(\nu^n_l-)$ (for the chosen subsequence).

By taking a further subsequence, if necessary, we can also suppose that, together with the other convergences, $u^n(\nu^n_{i,l}-), i = 1, 2, l = 1, \ldots,$ converges weakly to random variables which we call $u(\nu_{i,l}-), i = 1, 2, l = 1, \ldots$. From the weak convergence of the $u^n(\nu^n_{i,l}-), \nu^n_{i,l}, i = 1, 2, l = 1, \ldots,$ we have the weak convergence of the $u^n(\nu^n_l-), l = 1, \ldots$.

We will next show that $\xi^{v,n}_{i,l}$ is tight for each i and l and that (3.5) characterizes the weak sense limits. To simplify the notation, we will start with the first vacation and let the first vacation be that of source 1. With this simplifying assumption, we can write $\tau^{s,n}_{1,1} = \nu^n_{1,1} = \nu^n_1$, and we will use these variables (and their weak sense limits) interchangably. By the weak convergence of $WL^n(\cdot)$ (with the weak sense limit of $WL^n(\cdot)$ being continuous) when there are no vacations and the weak convergence of $\tau^{s,n}_{1,1}$, $WL^n_1(\tau^{s,n}_{1,1}-) = WL^n_1(\nu^n_1-) = u^n_1(\nu^n_1-)$ converges weakly to the random variable which we denote by $u(\nu^s_{1,1}-)$. We will show that, under (3.4a),

$$WL^n(\nu^n_{1,1} + \tau^{v,n}_{1,1}/\sqrt{n}) - WL^n(\nu^n_{1,1}) \Rightarrow 0, \tag{3.17}$$

and under (3.4b),

$$WL^n_2(\nu^n_{1,1} + \tau^{v,n}_{1,1}/\sqrt{n}) \Rightarrow 0, \tag{3.18}$$

$$WL^n_1(\nu^n_{1,1} + \tau^{v,n}_{1,1}/\sqrt{n}) - WL^n_1(\nu^n_{1,1}) \text{ is tight}, \tag{3.19}$$

and the weak sense limit (along the selected weakly convergent subsequence) of (3.19) is defined by (3.5). Since the (scaled) vacation interval in question is $[\nu^n_{1,1}, \nu^n_{1,1} + \tau^{v,n}_{1,1}/\sqrt{n})$, strictly speaking, the arguments in the functions in (3.19) should be $(\nu^n_{1,1} + \tau^{v,n}_{1,1}/\sqrt{n})-$, and analogously for (3.17) and (3.18). However, since the processes defined by $WL^n(t) - WL^n(t-)$ and $u^n(t) - u^n(t-)$ converge weakly to the "zero" process, one can always replace $t-$ by t without changing any of the weak sense limits. We will do this to simplify the notation.

Since source 2 is being polled during this vacation, for $t \le \tau^{v,n}_{1,1}$ we can write

$$WL^n_2(\nu^n_{1,1} + t/\sqrt{n}) = \left[WL^n(\nu^n_{1,1}) - u^n(\nu^n_{1,1})\right] - t + T^{v,n}(\nu^n_{1,1} + t/\sqrt{n}) + \bar A^{1,n}_{2,1}(t). \tag{3.20}$$

We will next show that the process defined by

$$\bar{A}_{i,1}^{1,n}(t \wedge \tau_{1,1}^{v,n}) - \rho_i^n(t \wedge \tau_{1,1}^{v,n})$$

converges weakly to the "zero" process. This is what was meant by the statement below (3.4a) to the effect that work can be assumed to arrive continuously during a vacation and it is the last assertion (k) of the theorem. Note that the local fluid time scale defined below (3.3) is used in (3.20), so that t denotes an interval of length $\sqrt{n}t$ in real time or $t/\sqrt{n}$ in scaled time.

Use the representation (3.3) (dropping the $-$ in the indices of summation without changing the end result) to write $\bar{A}_{i,1}^{1,n}(t)$ as

$$\begin{aligned}\frac{1}{\sqrt{n}} \sum_{l=nS_i^{a,n}(\nu_{1,1}^n)+1}^{nS_i^{a,n}(\nu_{1,1}^n+(t\wedge\tau_{1,1}^{v,n})/\sqrt{n})} \left[\Delta_{i,l}^{d,n} - \bar{\Delta}_i^{d,n}\right] \\ + \frac{1}{\sqrt{n}} \sum_{l=nS_i^{a,n}(\nu_{1,1}^n)+1}^{nS_i^{a,n}(\nu_{1,l}^n+(t\wedge\tau_{1,1}^{v,n})/\sqrt{n})} \bar{\Delta}_i^{d,n}.\end{aligned} \tag{3.21}$$

The first term in (3.21) goes weakly to zero by the tightness of $\nu_{i,l}^n, \tau_{i,l}^{v,n}$ in n, the weak convergence of $S_i^{a,n}(\cdot)$, and condition A2.1. We need to characterize the right-hand term of (3.21). Write it as

$$\begin{aligned}\frac{\bar{\Delta}_i^{d,n}}{\sqrt{n}} \sum_{l=nS_i^{a,n}(\nu_{1,1}^n)+1}^{nS_i^{a,n}(\nu_{1,1}^n+(t\wedge\tau_{1,1}^{v,n})/\sqrt{n})} \left[1 - \frac{\Delta_{i,l}^{a,n}}{\bar{\Delta}_i^{a,n}}\right] \\ + \frac{\bar{\Delta}_i^{d,n}}{\bar{\Delta}_i^{a,n}\sqrt{n}} \sum_{l=nS_i^{a,n}(\nu_{1,1}^n)+1}^{nS_i^{a,n}(\nu_{1,1}^n+(t\wedge\tau_{1,1}^{v,n})/\sqrt{n})} \Delta_{i,l}^{a,n}.\end{aligned}$$

Just as for the first term in (3.21), the first term in the above expression goes weakly to the "zero" process as $n \to \infty$. The real time difference between the arguments in the upper and lower indices in the last expression is $\sqrt{n}[t \wedge \tau_{1,1}^{v,n}]$. Hence, the sum in the second term times $1/\sqrt{n}$ is $t \wedge \tau_{1,1}^{v,n}$, modulo a residual time error term. Thus, the difference between the second term and

$$\frac{\bar{\Delta}_i^d}{\bar{\Delta}_i^a}\left(t \wedge \tau_{1,1}^{v,n}\right) = \rho_i\left(t \wedge \tau_{1,1}^{v,n}\right) \tag{3.22}$$

converges weakly to the "zero" process.

The above computations concerning the arriving scaled work during the vacation show that the net change $\xi_{1,1}^{v,n}$ in the total workload is tight, and that we can suppose, asymptotically and in the local fluid time scale defined below (3.3), that scaled work arrives at the queues continuously (i.e., as a fluid process) at the mean rate ρ_i during the vacation.

Consider the case (3.4a). By what has just been proved, the scaled work process arriving to queue 1 during the first vacation is arbitrarily well approximated (in the local fluid time scale) by (3.22) for $i = 1$. Similarly, the scaled work that departs queue 2 during that time (local fluid time scale) is (asymptotically) equal to $\tau_{1,1}^{v,n}$ minus the idle time in the local fluid time scale. However, due to the fluid approximation

and the condition (3.4a), this idle time is zero, asymptotically. Thus, by the above computation, the net increase in the workload (input minus output) of queue 2 during the vacation is (asymptotically) equal to $[\rho_2 - 1]\tau_{1,1}^{v,n}$. Thus, by the heavy traffic condition A2.2, adding the changes in the two queues, we see that the net change in the total workload during the vacation converges weakly to zero as $n \to \infty$.

Now, consider the condition (3.4b), continue to use the approximation (3.22), and recall the definition of $\hat{\tau}_{i,l}^{v,n}$ from (3.4b). It is then clear that $\tau_{i,l}^{v,n} - \hat{\tau}_{i,l}^{v,n}$ is the net contribution to $T^{v,n}(\cdot)$ during this vacation interval, and (3.5) follows from this and the results of the last paragraph. Let $\xi_{1,1}^{v}$ denote the weak sense limit of $\xi_{1,1}^{v,n}$. Thus, we have obtained (3.7) and (3.8) and verified (i) up to and including the time of the first vacation.

Now, with $WL_i^n(\nu_{1,1}^n + \tau_{1,1}^{v,n}/\sqrt{n})$ well defined and tight, restart the $WL_i^n(\cdot)$ at scaled time $\nu_{1,1}^n + \tau_{1,1}^{v,n}/\sqrt{n}$ and repeat the above approximation and limit procedure. Then an induction argument yields the asserted limit relations for all of the intervacation sections and jumps. Take a weakly convergent subsequence of Ψ^n in the theorem statement, and obtain (3.7) and (3.8) by concatenating the intervacation sections.

Next, we will prove the (asymptotic) linear relationship (e) between $WL_i^n(\cdot)$ and $x_i^n(\cdot)$. We say that a sequence of real-valued processes $q^n(\cdot)$ is *bounded in probability* if, for each $T > 0$,

$$\lim_{N\to\infty} \limsup_n P\left\{\sup_{t\le T} |q^n(s)| \ge N\right\} = 0. \tag{3.23}$$

It will be seen that the tightness of $WL^n(\cdot)$ implies that $x_i^n(\cdot)$ satisfies (3.23). Let us assume this for the moment. We will use the representation (2.3). Write $\Delta_{i,l}^{d,n} = \bar{\Delta}_{i,l}^{d,n} + [\Delta_{i,l}^{d,n} - \bar{\Delta}_{i,l}^{d,n}]$. With this representation, expand each of the two terms in the brackets in (2.3) into two components, analogous to what was done to get the expression below (3.21). The first component of the expansion of (say) the first term inside the brackets in (2.3) is

$$\bar{\Delta}_i^{d,n} x_i^n(t). \tag{3.24}$$

The second component of (again) the first term inside the brackets of (2.3) is

$$\frac{1}{\sqrt{n}} \sum_{l=L_i^n(t)}^{L_i^n(t)+\sqrt{n}x_i^n(t)-1} \left[\Delta_{i,l}^{d,n} - \bar{\Delta}_{i,l}^{d,n}\right], \tag{3.25}$$

and it converges weakly to the "zero" process by the weak convergence assumption A2.1 on $w_i^{d,n}(\cdot)$ since $x_i^n(\cdot)$ is assumed to satisfy (3.23).

Note that the difference between the two terms inside the brackets of (2.3) is a residual time error term $\epsilon^n(t)$, where $\epsilon^n(\cdot)$ converges weakly to the "zero" process, and this is true irrespective of whether or not (3.23) holds for $x_i^n(\cdot)$.

By the tightness of the sections of $WL^n(\cdot)$ between the $(l-1)$st and lth vacations (for each l) and of the associated set of jumps, (3.23) holds for $WL_i^n(\cdot)$, hence it holds for the process defined by the first term in the brackets in (2.3). Suppose that (3.23) does not necessarily hold for $x_i^n(\cdot)$. The expansion of the first term in (2.3) into (3.24) and (3.25) still holds. By the assumption A2.1 on the $w_i^{d,n}(\cdot)$, the fact that the upper index of summation in (3.25) is no bigger than $nS_i^{a,n}(\cdot) + \sqrt{n}x_i^n(0)$ and the weak convergence of $S_i^{a,n}(\cdot)$ and of $x_i^n(0)$, the process defined by (3.25) satisfies (3.23).

Then, since the sum of (3.24) and (3.25) is the first term in (2.3), which satisfies (3.23), so must the process defined by (3.24). Hence $x_i^n(\cdot)$ satisfies (3.23). The fact that (3.23) holds for $x_i^n(\cdot)$ and the assumption A2.1 imply that (3.25) converges weakly to the "zero" process. Hence, $WL_i^n(\cdot)$ is asymptotically equivalent to $\bar{\Delta}_i^{d,n} x_i^n(\cdot)$.

Only the nonanticipativity (j) needs to be proved. But this is a consequence of the independence in (3.16) □

More than 2 sources. Suppose that there is an arbitrary number of sources, with the natural extensions of the assumptions A2.0–A2.5 and the notation holding. Then, on any (scaled) interval $[0, T]$, with a probability that goes to one as $n \to \infty$, there is still only a finite number of vacations and at most one source can be on vacation at a time. Because of this, the analogues of (3.4) and (3.5) can easily be written.

Consider the lth vacation of source i. If

$$\tau_{i,l}^{v,n} < \left[WL^n(\nu_{i,l}^n-) - WL_i^n(\nu_{i,l}^n-)\right] + \sum_{j\neq i} \bar{A}_{j,l}^{i,n},$$

then the method of Theorem 3.1 can be used to show that (asymptotically) the vacation at source i ends before the other queues are emptied, and the vacation has no immediate effect on the total workload. On the other hand, if

$$\tau_{i,l}^{v,n} > \left[WL^n(\nu_{i,l}^n-) - WL_i^n(\nu_{i,l}^n-)\right] + \sum_{j\neq i} \bar{A}_{j,l}^{i,n} \equiv \hat{\tau}_{i,l}^{v,n},$$

then there is (asymptotically) a forced idle time during the vacation. Dropping the n superscripts, the increase in scaled work during the lth vacation of source i has the asymptotic form

$$\xi_{i,l}^v = \left[\tau_{i,l}^v - [WL(\nu_{i,l}-) - WL_i(\nu_{i,l}-)] - \tau_{i,l}^v \sum_{j\neq i} \rho_j\right]^+$$

which equals

$$\left[\rho_i \tau_{i,l}^v - [WL(\nu_{i,l}-) - WL_i(\nu_{i,l}-)]\right]^+,$$

where $WL_i(\nu_{i,l}-)$ is the weak sense limit of (a suitable weakly convergent subsequence of) $WL_i^n(\nu_{i,l}^n-)$. This is the only change in Theorem 3.1.

The control form A2.6a. The control form specified by A2.6a seeks to force the relationship (asymptotic) $x_2^n(t) \sim \phi(x_1^n(t))$, at least when possible between vacations, when both sources are available. The control, in practice, might be based on either the queue sizes or on the workloads, depending on what information is available to the controller at the server. Theorem 3.1 implies that we can do either, due to the asymptotic equivalence $WL_i^n(\cdot) \sim \bar{\Delta}_i^{d,n} x_i^n(\cdot)$. To a control represented by the function $\phi(\cdot)$ in A2.6a, there is one in terms of the workload in the sense of asymptotic equivalence. We will now see that A2.6a is asymptotically equivalent to the existence of a continuous and nondecreasing function $\theta(\cdot)$ such that we poll source 1 if $WL_1^n(t) \geq \theta(WL^n(t))$ and poll source 2 otherwise, provided that the source is available.

To get $\theta(\cdot)$, we use the asymptotic equivalence $x_2^n(t) \sim \phi(WL_1^n(t)/\bar{\Delta}_1^d)$ and

$$WL_2^n(t) \sim \bar{\Delta}_2^d \phi(WL_1^n(t)/\bar{\Delta}_1^d).$$

Since, asymptotically, using the policy $\phi(\cdot)$ between vacations,

$$WL^n(t) \sim \sum_i WL_i^n(t) = WL_1^n(t) + \bar{\Delta}_2^d \phi(WL_1^n(t)/\bar{\Delta}_1^d),$$

we can define an "asymptotic inverse" $\theta(\cdot)$ to the function $\phi(\cdot)$ in that (between vacations) we poll source 1 if $WL_1^n(t) \geq \theta(WL^n(t))$ and poll source 2 otherwise. The inverse is obtained from

$$WL - WL_1 = \bar{\Delta}_2^d \phi(WL_1/\bar{\Delta}_1^d).$$

Note that we could have started with $\theta(\cdot)$ and derived $\phi(\cdot)$ from it: i.e., suppose that we are given a nonnegative, continuous, and nondecreasing function $\theta(\cdot)$ satisfying $\theta(WL) \leq WL$, and use the following rule: between vacations, poll source 1 if $WL_1^n(t) \geq \theta(WL^n(t))$ and poll source 2 otherwise. This can be turned into an (asymptotic) rule based on the $x_i^n(\cdot)$ by polling source 1 if

$$x_1^n(t)\bar{\Delta}_1^d \geq \theta(x_1^n(t)\bar{\Delta}_1^d + x_2^n(t)\bar{\Delta}_2^d)$$

and polling source 2 otherwise.

The function $\phi(\cdot)$ in terms of the numbers queued is often (but certainly not always) the more pertinent in applications. However, the dynamic programming equation will be in terms of the total workload and the system (3.7), since the basic weak convergence result is in terms of the total workload. The total workload formulation is also much more convenient from the computational point of view due to the "state space collapse" for which, no matter how many sources there are, the problem is one dimensional. Thus, it is important to be able to travel back and forth between the queued number and total workload forms.

Note on realizing the relationship $WL_1^n(t) \sim \theta(WL^n(t))$, or its equivalent in terms of the number queued, under A2.6. Suppose that both sources are available at scaled time t, and that we wish to change $WL_1^n(\cdot)$ to the value $WL_1^{*,n} > WL_1^n(t)$ as quickly as possible. In heavy traffic, by polling queue 2, the scaled queue of source 1 increases at a mean rate of $\bar{\lambda}_1^a \bar{\Delta}_1^d \sqrt{n}$ in scaled time. Thus, it takes approximately $[WL_1^{*,n} - WL_1^n(t)]/[\bar{\lambda}_1^a \bar{\Delta}_1^d \sqrt{n}]$ units of scaled time for the transition. Thus, in the heavy traffic limit, with neither source on vacation, any desired change can be realized instantaneously.

The relationship $WL_1^n(t) \sim \theta(WL^n(t))$ cannot be realized arbitrarily well, uniformly (for large n) on the entire interval between vacations. This is because the uncontrollable changes in the $WL_i^n(\cdot)$ during a vacation will cause it to be violated for a short interval just after the vacation ends, while we "catch up." But there are $\epsilon_n \to 0$ as $n \to \infty$ such that the sections of the differences

$$x_1^n(\cdot) - \frac{\theta(WL^n(\cdot))}{\bar{\Delta}_1^d} \tag{3.26a}$$

and

$$x_2^n(\cdot) - \frac{WL^n(\cdot) - \theta(WL^n(\cdot))}{\bar{\Delta}_2^d} \tag{3.26b}$$

starting (scaled time) ϵ_n after a vacation *begins* and stopping at the start of the next vacation converge to the zero process as $n \to \infty$. This will be sufficient for our purposes.

Using the control $\theta(\cdot)$ in A2.6b, we can write the $\xi^v_{i,l}$ of (3.5) as

$$\xi^v_{1,l} \equiv \left[(1-\rho_2)\,\tau^v_{1,l} - [WL(\nu_{1,l}-) - \theta(WL(\nu_{1,l}-))]\right]^+ \tag{3.27a}$$

and

$$\xi^v_{2,l} \equiv \left[(1-\rho_1)\,\tau^v_{i,l} - \theta(WL(\nu_{2,l}-))\right]^+. \tag{3.27b}$$

The following theorem codifies the last part of the above discussion and the proof follows from the computations done in Theorem 3.1. The last sentence of the theorem holds because of the weak convergence of the intervacation sections and the fact that, between vacations, $WL(\cdot)$ behaves like a Wiener process, provided that $\sigma^2_{\alpha,i} > 0$ for some α, i.

THEOREM 3.2. *Assume the conditions of Theorem* 3.1 *and* A2.6a *as well. Then there are positive real numbers* $\epsilon_n \to 0$ *such that* $x^n_2(\cdot) - \phi(x^n_1(\cdot))$ *converges weakly to the "zero" process on each interval* $[\nu^n_{i,l} + \epsilon_n, \nu^n_{i,l+1}]$. *So do* $WL^n_1(\cdot) - \theta(WL^n(\cdot))$ *and the processes defined in* (3.26), *where* $\theta(\cdot)$ *is defined from* $\phi(\cdot)$ *as above the theorem.*

Now assume A2.6b *in lieu of* A2.6a. *Then, excluding an arbitrarily small neighborhood of the times where* $WL^n(t)$ *is a point of discontinuity of* $\theta(\cdot)$, *the last sentence of the previous paragraph holds for* $\theta(\cdot)$. *Assume that at least one of the* $\sigma^2_{\alpha,i}, \alpha = a, d, i = 1, 2$, *is positive. Given* $\epsilon > 0$ *and* $t_1 > 0$, *let* $T^n_\epsilon(t_1)$ *denote the Lebesgue measure of the closure set of time points on* $[0, t_1]$ *at which* $WL^n(t)$ *is within* ϵ *of a point of discontinuity of* $\theta(\cdot)$. *Then, for each* $\delta > 0$ *and* $t_1 > 0$,

$$\lim_{\epsilon \to 0} \limsup_n P\left\{T^n_\epsilon(t_1) \geq \delta\right\} = 0. \tag{3.28}$$

Correlated vacations of the sources. Up to now, we have supposed that the vacation processes of the two sources are independent of each other. This would be the case if they were due to movement in independent environments or to extraneous interference if the sources were far apart. If the vacations were due to extraneous interference which affected the sources in a similar manner, then the vacation intervals would be correlated. The main problem in introducing such correlation is algebraic, in that it complicates the expressions.

Let us first suppose that, in addition to the mutually independent vacations specified by A2.3 and A2.4, there are also simultaneous vacations of the two sources, as defined by the following condition.

A3.1. *For each* n, *the intervals between the end of a simultaneous vacation and the start of the next one are denoted by* $n\tau^{m,n}_l, l = 1, \ldots$. *They are mutually independent, exponentially distributed, independent of all the other "driving" random variables and have rate* $\bar\lambda^{m,n}/n$, *where* $\bar\lambda^{m,n}$ *converges to* $\bar\lambda^m > 0$ *as* $n \to \infty$.

A3.2. *For each* n, *there are mutually independent and identically distributed random variables* $\tau^{mv,n}_l, l = 1, \ldots$, *such that the duration of the* l*th simultaneous vacation interval is* $\sqrt{n}\tau^{mv,n}_{i,l}$. *Also,* $\tau^{mv,n}_l$ *converges weakly to a random variable* τ^{mv}_l *as* $n \to \infty$. *The* $\tau^{mv,n}_l, l = 1, \ldots$, *are independent of all other "driving" random variables.*

If A3.1 and A3.2 are added to the conditions of Theorem 3.1 or Theorem 3.2, then the results would be the same, except for the addition of another (independent) jump process $J^m(\cdot)$. Let $\nu^{m,n}_l$ denote the (scaled) starting times of the successive mutual vacations, and let ν^m_l denote the weak sense limits. The weak sense limit (in the sense used in Theorem 3.1) equation is

$$WL(t) = WL(0) + bt + w(t) + \sum_i J_i(t) + J^m(t) + Z(t), \tag{3.29}$$

where

$$J^m(t) = \sum_{l:\nu_l^m \le t} \xi_l^m, \tag{3.30}$$

where ξ_l^m is the weak sense limit of (see (3.3))

$$\bar{A}_l^{m,n} = \frac{1}{\sqrt{n}} \sum_{l=nS_1^{a,n}(\nu_l^{m,n}-)+1}^{nS_1^{a,n}((\nu_l^{m,n}+\tau_l^{m,n}/\sqrt{n})-)} \Delta_{1,l}^{d,n} + \frac{1}{\sqrt{n}} \sum_{l=nS_2^{a,n}(\nu_l^{m,n}-)+1}^{nS_2^{a,n}((\nu_l^{m,n}+\tau_l^{m,n}/\sqrt{n})-)} \Delta_{2,l}^{d,n}, \tag{3.31}$$

and the limit is just τ_l^m, owing to the analysis done for the $\bar{A}_{i,l}^{j,n}$ in Theorem 3.1 and A2.2.

4. The limit control problem. The limit dynamical model. Theorem 3.1 enables us to write the correct limit control problem. As usual in heavy traffic modeling, the aim is to use the limit control problem to get good controls for the physical problem and approximations to its optimal costs, under heavy traffic. The limit dynamics are defined by (3.7) and (3.8), where the jumps are defined by (3.5), where an admissible control $u(\cdot)$ satisfies $u(t) \le WL(t)$ and is nonanticipative in the sense that it is a measurable process, and, for each t, $u(t)$ is independent of $w(t+\cdot) - w(t), N_i(t+\cdot) - N_i(t-), i = 1, 2$. Since $WL(\cdot)$ is continuous at all t where there are no jumps and has a left-hand limit at t if there is a jump there, $WL(t-)$ is well defined for all t. However, $u(t-)$ is not necessarily defined. If the control for (3.7), (3.8) is defined via a function such as the $\theta(\cdot)$ in A2.6b, then we would have $u(t) = \theta(WL(\cdot))$ and $u(t-)$ is well defined for almost all t, which ensures that $u(\nu_{i,l}-)$ is well defined with probability 1. This is one of the main reasons for our interest in control functions such as $\theta(\cdot)$. Alternatively, we could write the jumps as

$$\xi_{1,l}^v = \left[\rho_1 \tau_{1,l}^v - [WL(\nu_{1,l}-) - u(\nu_{1,l})]\right]^+, \tag{4.1a}$$

$$\xi_{2,l}^v = \left[\rho_2 \tau_{2,l}^v - u(\nu_{2,l})\right]^+, \tag{4.1b}$$

where $u(\cdot)$ is a "predictable" process [15, 23]. All that is important is the nonanticipativity as defined above, so that, for each t, $u(t)$ is independent of any jump that might occur at t.

The cost function. Let $c_i(\cdot)$ be a strictly increasing and continuous real-valued function on $[0, \infty)$ with $c_i(0) = 0$, and satisfying $c_i(x) \le Kx + K$ for some $K < \infty$. We will work with a discounted cost function. The cost rate will depend on whether we are penalizing queued jobs or queued workload. In the latter case, we penalize the workloads individually and simply use the cost rate

$$\sum_i c_i(WL_i^n(\cdot)) = c_1(u^n(\cdot)) + c_2(WL^n(\cdot) - u^n(\cdot)) \equiv c(WL^n(\cdot), u^n(\cdot)).$$

In the former case, we would like to penalize the queue sizes individually, i.e., with a cost rate $\sum_i c_i(x_i^n(t))$. Since, in general, we do not have a weak convergence result for the $x_i^n(\cdot)$ for an arbitrary admissible control policy, we are still forced to work with the workload formulation. Then we asymptotically approximate in terms of workload as

$$\sum_i c_i(x_i^n(t)) \approx c_1\left(\frac{u^n(t)}{\bar{\Delta}_1^{d,n}}\right) + c_2\left(\frac{WL^n(t) - u^n(t)}{\bar{\Delta}_2^{d,n}}\right) \equiv c(WL^n(t), u^n(t)). \tag{4.2}$$

Let $\beta > 0$ be the discount factor. The cost function for the limit system will be

$$W_\beta(WL(0), u(\cdot)) = E \int_0^\infty e^{-\beta t} c(WL(t), u(t)) dt, \tag{4.3a}$$

and for the physical system it will be

$$W_\beta^n(WL^n(0), u^n(\cdot)) = E \int_0^\infty e^{-\beta t} c(WL^n(t), u^n(t)) dt. \tag{4.3b}$$

Define $V_\beta(WL(0)) = \inf_u W_\beta(WL(0), u(\cdot))$ and $V_\beta^n(WL^n(0)) = \inf_{u^n} W_\beta^n(WL(0), u^n(\cdot))$, where the $u^n(\cdot)$ and $u(\cdot)$ are admissible. Under a feedback control $\theta^n(\cdot)$ and associated polling policy satisfying A2.6b, we can write

$$W_\beta^n(WL^n(0), \theta^n(\cdot)) = E \int_0^\infty e^{-\beta t} c(WL^n(t), \theta^n(WL^n(t))) dt. \tag{4.4}$$

A restriction of the class of controls and a redefinition of the inf. As noted, we would like to show that a nearly optimal control for the limit problem is nearly optimal for the physical problem for large n and that

$$V_\beta^n(WL^n(0)) \to V_\beta(WL(0)) \tag{4.5}$$

if $WL^n(0)$ converges weakly to $WL(0)$, analogously to what was done in [2, 20, 21]. This is hard to do, since the control appears in the dynamics (3.7) only via the magnitude of the jumps.

The usual method [2, 20, 21] for showing (4.5) involves writing the control in some form such that the sequence of optimal (or ϵ-optimal) controls for the physical problem is tight, and any weak sense limit of the (state process, control process) is an admissible limit control problem. For example, suppose that we have a problem where the control is a vector-valued function which takes values in a compact set. Then, we would write the controls in relaxed control form [19] with the weak topology on them. Since any sequence of such relaxed controls is tight (in the weak topology which is normally used), there is always a weakly convergent subsequence. One could attempt the same thing here. The sequence of relaxed control representations of the control will be tight. The problem is that our $u(\cdot)$ is the derivative of the relaxed control. This derivative is defined only almost everywhere, and in particular, it is not guaranteed that the weak sense limit of $u^n(\nu_{i,l}^n -)$ would be $u(\nu_{i,l} -)$, where this $u(\cdot)$ is the derivative of the weak sense limit of the relaxed control representations. The problem is that, while the cost rate can be written as a linear function of the relaxed control, the jump distribution depends only on specific values of the $u^n(\cdot)$.

One can circumvent these difficulties. However, in order to apply any control which is nearly optimal for the limit system to the physical system, the form in which $u(\cdot)$ appears in (3.5) essentially implies that it should be a feedback control which is continuous "most of the time." Because of these facts, we will be concerned with the more restricted class of controls of A2.6b defined by the following assumption. It is seen from the examples in section 5 and numerical data (taken without the restriction in A4.1) that A4.1 is not restrictive.

A4.1. *Given an integer M, let Θ denote a class of functions, each member of which satisfies* A2.6b, *has at most M points of discontinuity, and on each finite interval $[0, WL]$, the functions in Θ are equicontinuous between discontinuities. The controls will be restricted to such a class, with the polling policy being as defined in* A2.6b.

Fix the class Θ for some M and modulus of equicontinuity. *Redefine* $V_\beta^n(WL(0))$ and $V_\beta(WL(0))$ to be the infima over controls in the class Θ.

A slight alteration of the proof of Theorem 3.1 yields the following. Assume the conditions of Theorem 3.1 and let $\theta^n(\cdot) \in \Theta$. Choose the weakly convergent subsequence such that $\theta^n(\cdot)$ also converges (in the Skorohod topology) to, say, $\theta(\cdot)$. Then the conclusions of Theorems 3.1 and 3.2 hold. Suppose, in addition, that the function whose expectation is being taken in (4.4) is uniformly (in n) integrable. Then the weak convergence in Theorems 3.1 and 3.2 implies that the expected value in (4.4) converges to the expected value for the controlled limit system. We state this in the following more restrictive way, since that is the way it will be verified. The proof is simpler than those in [2, 20, 21] for other control problems under heavy traffic, owing to the more restricted class of allowed controls. The proof implies that a good control for the limit problem will be good for the physical problem under heavy traffic.

THEOREM 4.1. *Assume* A4.1 *and the conditions of Theorem* 3.1. *Let* $c_i(\cdot)$ *satisfy the conditions imposed at the beginning of this section. Suppose that there is a real* C_1 *such that*

$$\sup_{\theta(\cdot)\in\Theta} E\,|WL^n(t)|^2 \le C_1 t + C_1. \tag{4.6}$$

Then the function whose expectation is being taken in (4.4) *is uniformly integrable and*

$$V_\beta^n(WL^n(0)) \to V_\beta(WL(0)).$$

Comments on the proof. Let $\epsilon > 0$ be small and arbitrary. Let $\theta^{\epsilon,n}(\cdot)$ and $\theta^\epsilon(\cdot)$ be ϵ-optimal controls in Θ for the processes $WL^n(\cdot)$ and $WL(\cdot)$, with the initial conditions $WL^n(0)$ and $WL(0)$, respectively. Condition A4.1 implies that, by choosing a subsequence if necessary, we can suppose that $\theta^{\epsilon,n}(\cdot)$ converges to some $\bar\theta(\cdot) \in \Theta$ in the Skorohod topology. Then

$$\epsilon + V_\beta^n(WL^n(0)) \ge W_\beta^n(WL^n(0), \theta^{\epsilon,n}(\cdot)) \to W_\beta(WL(0), \bar\theta(\cdot)) \ge V_\beta(WL(0)).$$

Thus,

$$\liminf_n V^n(WL^n(0)) \ge V_\beta(WL(0)).$$

Now, apply $\theta^\epsilon(\cdot)$ to $WL^n(\cdot)$ to get

$$V_\beta^n(WL^n(0)) \le W_\beta^n(WL^n(0), \theta^\epsilon(\cdot)) \to W_\beta(WL(0), \theta^\epsilon(\cdot)) \le V_\beta(WL(0)) + \epsilon.$$

These inequalities yield the theorem. □

On the condition (4.6). Condition (4.6) is not a consequence of the other conditions. Write (3.15) for the general case where the vacations are included as

$$WL^n(t) = h^n(t) + Z^n(t).$$

It follows from the estimates given for the general Skorohod problem in [10, Theorem 2.2.] that there is a real C such that

$$WL^n(t) \le C \sup_{s\le t} |h^n(s)| \quad \text{for all } t.$$

Thus, a sufficient condition for (4.6) is that the following inequalities hold.

$$\sup_n E\,|WL^n(0)|^2 < \infty, \tag{4.7}$$

$$E \sup_{s\le t} |w_i^{\alpha,n}(S_i^{a,n}(s))|^2 = O(t),\ \alpha = a,d, i = 1,2, \tag{4.8}$$

$$\bar{J}^n(t) = \sum_j E \left| \sum_{k:\nu_{j,k}^n \le t} \xi_{j,k}^{v,n} \right|^2 = O(t^p) \text{ for some } p > 0. \tag{4.9}$$

Dealing with (4.8) and (4.9) in detail will take us far afield, but they do hold under quite broad conditions. To illustrate one of the possibilities, we will give some of the details under the following condition.

A4.2. *For each n, the random variables $(\Delta_{i,l}^{\alpha,n}, l < \infty)$ are mutually independent and identically distributed for each $i = 1,2, \alpha = a,d$, and the absolute third moments are uniformly bounded. There are $\bar{\Delta}_i^{\alpha,n}$ and $\bar{\Delta}_i^{\alpha}$ such that $E\Delta_{i,l}^{a,n} = \bar{\Delta}_i^{\alpha,n} \to \bar{\Delta}_i^{\alpha}$, $\alpha = a,d$. Also, the second moments of $\tau_{i,l}^{v,n}$ are uniformly bounded.*

THEOREM 4.2. *Assume* A2.3, A2.4, *and* A4.2. *Then* (4.8) *and* (4.9) *hold.*

Proof. First, we consider (4.8). Fix α and i and define $\psi_{i,l}^{\alpha,n} = (1 - \Delta_{i,l}^{\alpha,n}/\bar{\Delta}_i^{\alpha,n})$. Let $\mathcal{F}_{i,l}^{\alpha,n}$ denote the minimal ν-algebra which measures $\{\psi_{i,j}^{\alpha,n}, j \le l\}$, and write $E_{i,l}^{\alpha,n}$ for the associated conditional expectation. The $\psi_{i,l}^{\alpha,n}$ are martingale differences in that $E_{i,l}^{\alpha,n}\psi_{i,l+1}^{\alpha,n} = 0$ with probability one for all l. There is $C_2 < \infty$ such that

$$E_{i,l}^{\alpha,n} \left|\psi_{i,l+1}^{\alpha,n}\right|^2 \le C_2.$$

Define

$$N_i^{\alpha,n}(t) = \frac{1}{n} \times \min\left\{ n : \sum_{l=1}^{n} \Delta_{i,l}^{\alpha,n} \ge nt \right\}.$$

The $S_i^{\alpha,n}(t)$ and $N_i^{\alpha,n}(t)$ will differ by at most $1/n$. The $N_i^{\alpha,n}(t)$ have the advantage that they are stopping times with respect to the filtrations $\mathcal{F}_{i,l}^{\alpha,n}$. In particular, $\{\omega : N_i^{\alpha,n}(t) \ge l\} \in \mathcal{F}_{i,l-1}^{\alpha,n}$. We have

$$E \max_{s\le t} |w_i^{\alpha,n}(S_i^{\alpha,n}(s))|^2 \le E \max_{m \le nN_i^{\alpha,n}(t)} \frac{1}{n} \left| \sum_{l=1}^{m} \psi_{i,l}^{\alpha,n} \right|^2. \tag{4.10}$$

Owing to the martingale properties, the right-hand side of (4.10) is bounded by $C_2 E N_i^{\alpha,n}(t)$. Thus, we need to bound $EN_i^{\alpha,n}(t)$.

For an integer $m > 0$, write

$$\frac{m \wedge nN_i^{a,n}(t)}{n} = \frac{1}{n} \sum_{l=1}^{m\wedge(nN_i^{a,n}(t))} 1 = \frac{1}{n} \sum_{l=1}^{m\wedge(nN_i^{a,n}(t))} \psi_{i,l}^{a,n} + \frac{1}{n\bar{\Delta}_i^{a,n}} \sum_{l=1}^{m\wedge(nN_i^{a,n}(t))} \Delta_{i,l}^{a,n}. \tag{4.11}$$

The expectation of the first term on the right is zero. Dropping that term and letting $m \to \infty$ yields

(4.12)
$$EN_i^{a,n}(t) = \frac{t}{\bar{\Delta}_i^{a,n}} + \frac{1}{n} E\left[(\text{first time of arrival to source } i \text{ at or after } nt - nt)\right].$$

Thus

$$EN_i^{a,n}(t) = \frac{t}{\bar{\Delta}_i^{a,n}} + \delta_n,$$

where $\lim_n \delta_n = 0$ and (4.8) holds. (The proof of the renewal theorem for the "excess life" in [13, pp. 192–193] implies that $\delta_n \to 0$.)

Now turn to the proof of (4.9). To bound (4.9), we can use the expression

$$E\left|\xi_{j,k}^{v,n}\right|^2 \le \sum_i \frac{1}{n} E \left| \sum_{l=nS_i^{a,n}(\nu_{j,k}^n)+1}^{nS_i^{a,n}(\nu_{j,k}^n+\tau_{j,k}^{v,n}/\sqrt{n})} \Delta_{i,l}^{d,n} \right|^2. \tag{4.13}$$

Writing $\Delta_{i,l}^{d,n} = [\Delta_{i,l}^{d,n} - \bar{\Delta}_i^{d,n}] + \bar{\Delta}_i^{d,n}$ in (4.13) and splitting the upper bound in (4.13) into the two corresponding parts yields a bound on $E|\xi_{j,k}^{v,n}|^2$ as (twice) the sum of

$$\sum_i \left[\bar{\Delta}_i^{d,n}\right]^2 E\left|w_i^{d,n}(\nu_{j,k}^n + \tau_{j,k}^{v,n}/\sqrt{n}) - w_i^{d,n}(\nu_{j,k}^n)\right|^2 \le C_2 \sum_i \left[\bar{\Delta}_i^{d,n}\right]^2 E\tau_{j,k}^{v,n}/\sqrt{n}$$

and

$$\sum_i \frac{[\bar{\Delta}_i^{d,n}]^2}{n} E\left[\#\text{arrivals at queue } i \text{ in real time } \left[n\nu_{j,k}^n, n\nu_{j,k}^n + \sqrt{n}\tau_{j,k}^{v,n}\right]\right]^2.$$

The first expression is $O(1/\sqrt{n})$. Following the idea in the expansion (4.11), for the second expression we get the bound, for some real C_3,

$$C_3 E\left[\tau_{j,k}^{v,n}\right]^2 + C_3 E\left[\text{a residual time term}\right]^2/n.$$

However, by the cited proof of the renewal theorem for the "excess life" in [13, pp. 192–193], and the third moment condition in A4.2, the mean square value of the residual time term is bounded, uniformly in all indices.

We have obtained a bound for the mean square value of each of the jumps. To complete the proof, we need to average over the number of vacations on real time $[0, nt]$. We do this by ignoring the vacation durations in computing the distribution of the number of vacations on any real time interval $[0, nt]$, which gives an upper bound. Then the number has a Poisson distribution for each n, with the rate parameter being bounded in n, and the number is independent of the jump sizes. If there are L vacations on $[0, nt]$, then (4.9) is bounded by L^2 times the bound on the mean square value of each jump. Finally, using the Poisson distribution, average over L to get (4.9) for $p = 2$. □

The Bellman equation for the limit system. Let $\mathcal{L}$ denote the differential generator of the pure diffusion part of (3.7): i.e., for smooth real-valued $f(\cdot)$, $\mathcal{L}f(WL) = \sigma^2 f_{ww}(WL)/2 + bf_w(WL)$. Write the control in feedback form $u(t) =$

$\theta(WL(t)) \le WL(t)$ for some measurable function $\theta(\cdot)$. The jump part of the differential operator acting on a measurable real-valued function $f(\cdot)$ is

$$\sum_i \bar{\lambda}_i^s E\left[f(WL + \xi_i^v) - f(WL)\right], \tag{4.14}$$

where ξ_i^v is the jump due to a vacation of source i, and E denotes the expectation of the jump given the WL and the control just before the start of the jump. The boundary condition is $f_w(0) = 0$.

Define $\bar{V}_\beta(WL)$ to be the inf of the cost over all admissible controls, not only those of the form in (A4.1). Define the function

$$H(\bar{V}_\beta, WL) = \min_{\theta(WL) \le WL} \left\{ c(WL, \theta(WL)) + \sum_i \bar{\lambda}_i^s E\left[\bar{V}_\beta(WL + \xi_i^v) - V_\beta(WL)\right] \right\}. \tag{4.15}$$

The formal Bellman equation is the partial differential integral equation

$$\mathcal{L}\bar{V}_\beta(WL) - \beta \bar{V}_\beta(WL) + H(\bar{V}_\beta, WL) = 0, \tag{4.16}$$

with the boundary condition $\bar{V}_{\beta,WL}(0) = 0$. The subscript WL denotes the derivative.

Conjecture and assumption. We have not been able to find anything in the literature concerning the PDE (4.16), where the jump magnitudes are controlled. To fully justify the restriction A4.1, it is necessary to show both that (4.16) has a unique (either classical or viscosity sense) solution which is the minimal cost and that the minimizing $\theta(\cdot)$ in (4.15) is of the type in A2.6b. This seems to be a very reasonable expectation, although we have not been able to demonstrate it. As noted in the next section, it is essentially obvious in certain special cases, e.g., where $c_i(x) = x_i$, and we expect that it holds under broad conditions on $c(\cdot)$. Note that this is not an impulse control problem. The jump times are those of a Poisson process.

Thus, we assume that our conjecture is true, namely, that the minimum cost satisfies (4.16) and that the optimal control, given by the minimizer in (4.15), satisfies A2.6b. Under this assumption, an optimal control for the limit problem is nearly optimal for the physical problem under heavy traffic if the controls for the physical problem are restricted to a large enough class of the type in A4.1.

5. Extensions and comments. In special cases, the weak convergence results and the form of the limit problem suggest nearly optimal strategies for the physical problem, without much additional analysis. A case of current interest will be discussed.

Minimizing the total expected workload. Suppose that the cost rates $c_i(\cdot)$, written in terms of workload, satisfy $c_i(WL_i) = WL_i$. Then $c(WL, \theta(WL)) = WL$ and the control problem is the minimization of the expectation of the integral of the discounted total workload. The mean total workload $EWL(t)$ for the limit problem is minimized, uniformly in t, by using the policy $\theta(\cdot)$ that minimizes the mean jump, namely,

$$Q := \bar{\lambda}_1^s E\left[\rho_1 \tau_1^v - [WL - \theta(WL)]\right]^+ + \bar{\lambda}_2^s E\left[\rho_2 \tau_2^v - \theta(WL)\right]^+. \tag{5.1}$$

Example: The case of exponentially distributed vacation intervals. As an example, assume that τ_i^v is exponentially distributed with parameter v_i. Note that for any real

number y and any random variable τ, exponentially distributed with parameter w, we have

$$E(\tau - y)^+ = w \int_y^\infty e^{-wx}(x-y)dx = w \int_0^\infty e^{-w(y+z)} z dz = \frac{e^{-wy}}{w}.$$

Denote for $i = 1, 2$, $j = 1, 2$, $j \neq i$,

$$w_i = \frac{v_i}{1 - \bar{\lambda}_j^a / \bar{\lambda}_j^d}.$$

Then we obtain

$$Q = \frac{\bar{\lambda}_1^s e^{-w_1(WL-\theta)}}{w_1} + \frac{\bar{\lambda}_2^s e^{-w_2\theta}}{w_2}.$$

Thus, for each WL, Q is convex with respect to θ, and its minimum is obtained at θ for which $dQ(\theta)/d\theta = 0$, provided that this solution satisfies $\theta \in (0, WL)$. If it does not, then the minimum over $\theta \in [0, WL]$ is obtained on one of the boundaries. Differentiating with respect to θ yields

$$\bar{\lambda}_1^s e^{-w_1(WL-\theta)} - \bar{\lambda}_2^s e^{-w_2\theta} = 0.$$

Solving this equation yields

$$\theta(WL) = \frac{\log(\bar{\lambda}_2^s / \bar{\lambda}_1^s)}{w_1 + w_2} + \frac{w_1}{w_1 + w_2} WL.$$

A nearly optimal policy $\theta(\cdot)$ for the limit problem should be defined by

$$\theta^*(WL) = \Big(\min \Big(WL, \frac{\log(\bar{\lambda}_2^s / \bar{\lambda}_1^s)}{w_1 + w_2} + \frac{w_1}{w_1 + w_2} WL \Big) \Big)^+,$$

and this is borne out by numerical solutions.

Example: The symmetrical case. In the special case where the two sources have the same rates, it is obvious that $\theta(WL) = WL/2$. Thus, under the conditions of Theorem 3.1 and the uniform integrability conditions of Theorem 4.1, the minimization of (5.1) yields a nearly optimal strategy for large n.

No vacations. The asymptotic optimality of the $c\mu$-rule. Suppose that there are no vacations and the basic desired cost rate is $\bar{c}_1 x_1^n + \bar{c}_2 x_2^n$, where $\bar{c}_i > 0$. Write the limit form of the cost rate in terms of the workload as

$$\bar{\lambda}_1^d \bar{c}_1 \theta(WL) + \bar{\lambda}_2^d \bar{c}_2 [WL - \theta(WL)]. \tag{5.2}$$

The minimizer of (5.2) is just the $c\mu$-rule. Namely, poll source 1 if $\bar{\lambda}_1^d \bar{c}_1 > \bar{\lambda}_2^d \bar{c}_2$ and there are jobs there, and conversely for source 2. Under the conditions of Theorem 3.1 and the uniform integrability conditions, such a rule would be asymptotically optimal for the physical system. In this case, the limit workload does not depend on the polling policy, only the cost rate does. This is an asymptotic form of the well-known $c\mu$-rule [31]. The asymptotic optimality of this rule under heavy traffic was given in [30].

The $c\mu$-rule gives priority to one of the queues, and this might lead to unacceptably long waits in the nonpriority queue. This can be alleviated with a nonlinear

weighting. For example, queue 1 might have a smaller cost rate than queue 2 for moderate queue lengths. But to discourage the complete priority of queue 1, we might use a nonlinear cost rate for queue 2.

Remark. Note that the optimal policies in all the examples in this section indeed satisfy assumption A4.1, which is required in Theorem 4.1. Thus the class of policies described by A4.1 is rich enough to contain an optimal policy within it for these asymptotic problems.

6. Stability.

DEFINITION: STABILITY, UNIFORMLY IN $\boldsymbol{n}$ FOR LARGE $\boldsymbol{n}$. Suppose that there are real n_0 and $\bar{W}$ such that

$$E\big[\text{time for } WL^n(t), t \geq t_0, \text{ to return to the value } WL^n(t) \leq \bar{W} \big| \text{ data to real time } nt_0, WL^n(t_0) = q\big] \leq F(q)$$

for all $n \geq n_0, t_0, q$, where $F(q)$ is bounded on each bounded q-set. Then we say that $WL^n(\cdot)$ is *stable, uniformly in* n.

DEFINITION: STABILITY FOR FIXED $\boldsymbol{n}$. Fix n, and suppose that the above conditional mean return time property holds for all q and t_0. Then, for that value of n, the queue is said to be *stable.*

We will use the following assumption, a modification of A2.2.

A6.1. *There is a real* $b_0 < 0$*:* $\sqrt{n}\left[\sum_i \rho_i^n - 1\right] \leq b_0$ *for all* n.

Comments on stability. Under A6.1, it is trivial to prove the stability of the weak sense limit system (3.7) using classical stochastic Liapunov function methods, as in [14, 16, 17]. Stability is one of the most important properties of physical systems, and should be proved under broad conditions. It is essentially an assertion on the robustness of the system, and should hold under reasonable perturbations of the basic data. Stability of the physical system is not automatically guaranteed by stability of the weak sense limit. The technique to be employed is versatile and gets the desired stability property, uniformly in reasonable perturbations of the basic data, in the sense that the function $F(q)$ will not depend on the exact form of the data, under a reasonable mixing-type condition. The first definition above concerns large n. It will be seen that if there are no vacations then we can set $n_0 = 1$ in that definition, under broad conditions on the data.

Under the conditions of Theorem 3.1, the ratio of time on vacation to total time goes to zero as $n \to \infty$. If n is fixed and small, then it is conceivable that this ratio would be large enough so that the accumulation of data during the vacations will not be offset by the processing between vacations, as is necessary for stability. However, from the point of view of stability with vacations, there is an equivalence between large n and small $\bar{\lambda}_i^s$. This explains the last assertion of Theorem 6.2.

First, we will provide the motivation for the perturbed Liapunov function approach. Then it is used for the problem without vacations and stability uniformly in n (not just in large n) is proved. Then vacations are added. We will simplify the algebra by supposing that arrivals to the queues can occur only at multiples of (real time) $\delta > 0$, which can be as small as desired. Otherwise, we would use integrals in lieu of sums, but the results would be the same. Also, again for notational simplicity and with little loss of generality, we also suppose that vacations start and stop only at integral multiples of δ, and modify the assumptions A2.3 and A2.4 appropriately.

We will also use A2.5 plus other (weak) conditions to be imposed below. Let $E^n_{k\delta}$ denote the expectation, given all of the system data up to and including *real time* $k\delta$. Let $I^{a,n}_{i,k\delta}$ be the indicator function of an arrival at real time $k\delta$ from source i, and let $\Delta^{d,n}_{i,k\delta}$ be the associated work, if there is an arrival.

Motivation and background: Perturbed Liapunov functions. A perturbed Liapunov function method will be used [6, 17, 18, 22]. The classical Liapunov function method is quite limited for problems such as ours, since there is not usually a "contraction" at each step to yield the local supermartingale property of a classical Liapunov function. The perturbed Liapunov function method is a powerful extension of the classical method. In the perturbed Liapunov function method, one adds a small perturbation to the original Liapunov function. As will be seen, when this perturbation can be well defined it provides an "averaging" which is needed to get the local supermartingale property.

The primary Liapunov function will be simply $WL(\cdot)$. The final Liapunov function will be of the form $W^n(\cdot) = WL^n(\cdot) + \delta W^n(\cdot)$, where $\delta W^n(\cdot)$ is bounded. Suppose that there is no vacation at real time $k\delta$. Then, for $WL^n(k\delta/n) \geq \delta$, we can write

$$E^n_{k\delta} WL^n(k\delta/n + \delta/n) - WL^n(k\delta/n) = -\frac{\delta}{\sqrt{n}} + \frac{1}{\sqrt{n}} \sum_i E^n_{k\delta} I^{a,n}_{i,k\delta+\delta} \Delta^{d,n}_{i,k\delta+\delta}. \tag{6.1}$$

The right-hand term needs to be "averaged," and this is done with the use of a perturbation function $\delta W^n(\cdot)$.

Motivation using a simpler problem. Before defining the actual perturbation which will be used, for motivation we will discuss the general principle with a simpler form when there are no vacations. Even for this problem, stability of the physical queues is not guaranteed by stability of the limit system. Let $\bar{\Delta}^{a,n}_i = 1/\bar{\lambda}^{a,n}_i$ and $\bar{\Delta}^{d,n}_i$ be centering constants such that the corresponding ρ^n_i satisfy A6.1 for some $b_0 < 0$. More will be said about them later.

Proceeding formally until further notice, define the first suggested perturbation:

$$\delta\tilde{W}^n(k\delta/n) = \frac{1}{\sqrt{n}} \sum_i \sum_{j=k+1}^{\infty} E^n_{k\delta} \left[I^{a,n}_{i,j\delta} \Delta^{d,n}_{i,j\delta} - \delta\bar{\lambda}^{a,n}_i \bar{\Delta}^{d,n}_i \right]. \tag{6.2}$$

Clearly, the centering constants must be such that the sum is well defined, and we return to this point below. If $WL^n(k\delta/n) \geq \delta$, then we get

$$\begin{aligned} &E^n_{k\delta}\delta\tilde{W}^n(k\delta/n + \delta/n) - \delta\tilde{W}^n(k\delta/n) \\ &\qquad = -\frac{1}{\sqrt{n}} \sum_i E^n_{k\delta} \left[I^{a,n}_{i,k\delta+\delta} \Delta^{d,n}_{i,k\delta+\delta} - \delta\bar{\lambda}^{a,n}_i \bar{\Delta}^{d,n}_i \right]. \end{aligned}$$

Define $\tilde{W}^n(k\delta/n) = WL^n(k\delta/n) + \delta W^n(k\delta/n)$. Then (6.1) and the last expression yield

$$E^n_{k\delta}\tilde{W}^n(k\delta/n + \delta/n) - \tilde{W}^n(k\delta/n) = -\frac{\delta}{\sqrt{n}} + \frac{1}{\sqrt{n}} \sum_i \left[\delta\bar{\lambda}^{a,n}_i \bar{\Delta}^{d,n}_i \right].$$

By the condition A6.1, the right side of the last expression is asymptotically $\leq b_0\delta/n$. Thus, it is less than the negative constant b_0 times the scaled time interval δ/n. Hence, when $WL^n(t) \geq \delta$, $\tilde{W}^n(k\delta/n)$ has the supermartingale property and we can use this to get the desired (uniform in n) stability if $\tilde{W}^n(\cdot)$ is "well defined and bounded."

Let us examine the sum in (6.2) more closely to see why it is well defined and bounded under broad mixing conditions. Since $\bar{\Delta}_i^{d,n}$ and $\bar{\lambda}_i^{a,n}$ are merely *centering* constants for the *entire* sequence, the actual mean values or rates can vary with time (say, being periodic, etc.). Fix k and let $\mu_{i,1}\delta$ and $\mu_{i,2}\delta$ be the real times of the first two arrivals to queue i after real time $k\delta$. Formally, consider the part of the inner sum in (6.2) given by

$$E_{k\delta}^n \sum_{j=\mu_{i,1}+1}^{\mu_{i,2}} \left[I_{i,j\delta}^{a,n} \Delta_{i,j\delta}^{d,n} - \delta \bar{\lambda}_i^{a,n} \bar{\Delta}_i^{d,n} \right].$$

This equals

$$E_{k\delta}^n \left[\Delta_{i,\mu_{i,2}\delta}^{d,n} - (\mu_{i,2} - \mu_{i,1})\delta \bar{\lambda}_i^{a,n} \bar{\Delta}_i^{d,n} \right]. \tag{6.3}$$

Next, suppose that the interarrival times and workloads are mutually independent, with the members of each set being mutually independent and identically distributed, with finite second moments, and means $\bar{\Delta}_i^{a,n}, \bar{\Delta}_i^{d,n}$. Then (6.3) equals zero, since $E_{k\delta}^n(\mu_{i,2} - \mu_{i,1})\delta = \bar{\Delta}_i^{a,n}$. Obviously, for any integer m, $\mu_{i,1}, \mu_{i,2}$ can be the mth and $(m+1)$st arrival times with the same result. Thus, under the independence assumptions, (6.2) is just

$$E_{k\delta}^n \left[\Delta_{i,\mu_{i,1}\delta}^{d,n} - \delta(\mu_{i,1} - k)\bar{\lambda}_i^{a,n} \bar{\Delta}_i^{d,n} \right] = \bar{\Delta}_i^{d,n} E_{k\delta}^n \left[1 - \frac{\delta(\mu_{i,1} - k)}{\bar{\Delta}_i^{a,n}} \right],$$

where $E_{k\delta}^n(\mu_{i,1} - k)\delta$ is just the conditional expectation of the mean time to the next arrival after $k\delta$, given the data to time $k\delta$. For use below, keep in mind that this quantity is bounded uniformly in k, under the above assumptions on the independence and the moments. Hence, formally, $\delta\tilde{W}^n(t)$ is of the order of $1/\sqrt{n}$, uniformly in all variables.

Now, suppose that the interarrival times are as in the last paragraph, but the service times are correlated, still with centering constant $\bar{\Delta}_i^{d,n}$. Let $\mu_{i,j}, j = 1, \ldots,$ denote the sequence of arrival times after $k\delta$. Then (6.3) equals

$$E_{k\delta}^n \left[\Delta_{i,\mu_{i,2}\delta}^{d,n} - \bar{\Delta}_i^{d,n} \right]. \tag{6.4}$$

Then, grouping terms and formally speaking, we see that the sum (6.2) is just (6.3)$/\sqrt{n}$, plus a series

$$\frac{1}{\sqrt{n}} \sum_i \sum_{l=\mu_{i,2}}^{\infty} E_{k\delta}^n \left[\Delta_{i,l}^{d,n} - \bar{\Delta}_{i,l}^{d,n} \right].$$

Clearly, the inner sum is bounded under quite broad mixing conditions. All that is needed is that $E_{k\delta}^n[\Delta_{i,l}^{d,n} - \bar{\Delta}_{i,l}^{d,n}] \to 0$ is a summable way as $l - k \to \infty$. A similar computation can be done if the $\Delta_{i,l}^{a,n}$ are correlated.

If the inner sum in (6.2) is well defined and bounded (uniformly in n, k, ω), then Theorem 6.1, which summarizes the above discussion, proves stability, uniformly in (all) n and the discounting which is used there is not needed. While the inner sums of (6.2) are well defined under broad conditions, there are interesting examples where they are not. For example, consider the case where $\Delta_{i,l}^{a,n} = H\delta = 1/\bar{\lambda}_i^{a,n}$, where H is

an integer and the work in all jobs is just the constant $\bar{\Delta}_i^{d,n}$. Then the inner sum, taken from $k+1$ to m, oscillates between zero and $-(H-1)\delta\bar{\lambda}_i^{a,n}\bar{\Delta}_i^{d,n}/\sqrt{n}$ as $m \to \infty$. The most convenient way of circumventing this problem is to suitably discount the defining sums [22, 27]. Thus, for some small $\beta > 0$, consider the alternative "discounted" perturbation

$$\delta W_\beta^n(k\delta/n) = \frac{1}{\sqrt{n}} \sum_i \sum_{j=k+1}^{\infty} E_{k\delta}^n e^{-(j-k-1)\beta\delta/n} \left[I_{i,j\delta}^{a,n} \Delta_{i,j\delta}^{d,n} - \delta\bar{\lambda}_i^{a,n}\bar{\Delta}_i^{d,n} \right]. \tag{6.5}$$

The sum (6.5) is well defined if $E|\Delta_{i,l}^{d,n}|$ is uniformly bounded, and then the conditional expectation can be taken either inside or outside of the summation.

Stability without vacations. We now proceed to prove the stability results. It is simpler to start with the assumption that there are no vacations. The following additional assumption will be used. The above discussion shows that the assumption covers many cases of interest.

A6.2. *There is real B such that w,p.1 $|\delta W_\beta^n(k\delta/n)| \le B/\sqrt{n}$ for all $\beta > 0$ and all n, k, where $\delta W_\beta^n(\cdot)$ is defined by* (6.5).

Define the final perturbed Liapunov function

$$W_\beta^n(k\delta/n) = WL^n(k\delta/n) + \delta W_\beta^n(k\delta/n). \tag{6.6}$$

THEOREM 6.1. *Let $WL^n(0)$ be tight, suppose that there are no vacations, and assume* A2.5, A6.1, *and* A6.2. *Then the process $WL^n(\cdot)$ is stable, uniformly in n.*

Proof. We have

$$\begin{aligned} &E_{k\delta}^n \delta W_\beta^n(k\delta/n + \delta/n) - \delta W_\beta^n(k\delta/n) \\ &\quad = -\frac{1}{\sqrt{n}} \sum_i E_{k\delta}^n \left[I_{i,k\delta+\delta}^{a,n} \Delta_{i,k\delta+\delta}^{d,n} - \delta\bar{\lambda}_i^{a,n}\bar{\Delta}_i^{d,n} \right] + \epsilon_k^n, \end{aligned} \tag{6.7}$$

where

$$\epsilon_k^n = E_{k\delta}^n \left[1 - e^{-\beta\delta/n} \right] \delta W_\beta^n(k\delta/n + \delta/n). \tag{6.8}$$

Thus, adding (6.1) and (6.7),

$$E_{k\delta}^n W_\beta^n(k\delta/n + \delta/n) - W_\beta^n(k\delta/n) = -\frac{\delta}{\sqrt{n}} + \frac{1}{\sqrt{n}} \sum_i \left[\delta\bar{\lambda}_i^{a,n}\bar{\Delta}_i^{d,n} \right] + \epsilon_k^n. \tag{6.9}$$

By the condition A6.1, the right side of (6.9) is asymptotically no greater than

$$\frac{b_0\delta}{n} + \epsilon_k^n. \tag{6.10}$$

Assumption A6.2 implies that $|\epsilon_k^n| = B[\beta\delta/n]\gamma^n$, where $\gamma^n \to 0$. Thus, for small β

$$E_{k\delta}^n W_\beta^n(k\delta/n + \delta/n) - W_\beta^n(k\delta/n) \le \frac{b_0\delta}{2n}, \quad \text{for } WL^n(k\delta/n) \ge \delta. \tag{6.11}$$

Inequality (6.11) implies that $W_\beta^n(k\delta/n)$ has the supermartingale property when $WL^n(k\delta/n) \ge \delta$. Suppose that $W_\beta^n(k\delta/n) = B_2 > B + \delta$ and let $B_2 > B_1 > B + \delta$. Then, by standard stability arguments [16, 17], the mean number of steps (of real

time length δ and conditioned on the data to real time $k\delta$) for $W_\beta^n(j\delta/n), j \geq k$, to return to the set where $W_\beta^n(j\delta/n) \leq B_1$ is bounded by

$$\frac{W_\beta^n(k\delta/n)}{[-b_0\delta/2n]} \leq \frac{B + WL^n(k\delta/n)}{[-b_0\delta/2n]}.$$

Since $|\delta W_\beta^n(t)| \leq B/\sqrt{n}$, the return time estimate also holds for $WL^n(\cdot)$. Thus, in the time scale which is used to define $WL^n(\cdot)$, where time is compressed by a factor of n, the conditional mean return time is asymptotically bounded by $2[B + WL^n(t)]/[-b_0]$. Hence, we have stability, uniformly in n. □

Stability, with vacations. Now, we add the vacations. Again, to simplify the notation, suppose a preempt-resume discipline, so that we do not have to concern ourselves with redoing all of an interrupted job. The analysis for the latter case follows similar lines.

The polling policy is subject only to the unrestrictive condition A6.3. The condition is motivated by the fact that the $\xi_{i,l}^v$ defined by (3.5) go to zero as the individual workloads go to infinity, since the larger the work remaining in the nonvacationing sources, the less likely it is that the server will have idle time during a vacation. If A6.3 does not hold, then there might not be stability for *each* $b < 0$, uniformly in large n. For example, suppose that the polling policy is to give source 1 priority. Then $WL_1^n(t)$ will be arbitrarily close to zero, except possibly during and for a short interval just after a vacation of that source. Consequently, the mean or conditional mean jump in the total workload during a vacation of source 2 which starts at scaled time t will not go to zero as $WL^n(t)$ goes to infinity. The condition A6.3 excludes exhaustive polling (but only when the workload is very large), where a source is polled until its queue is empty, unless a vacation of that source intervenes. However, when the total workload is large, we might not want to use exhaustive polling anyway. While we work with two sources for notational simplicity, the idea is the same no matter what the number of sources. By our convention, for a vacation that starts at real time $k\delta$, the real time vacation interval is the half open interval $[k\delta + \delta, k\delta + \delta + \sqrt{n}\tau_{i,k\delta}^{v,n})$.

A6.3. *The polling policy is unrestricted, except for the following. There are constants $\bar{W}_a \ll \bar{W}_b$, which will be as large as we wish. If $WL^n(t) \leq \bar{W}_b$, then there are no restrictions. If $WL^n(t) > \bar{W}_b$, then the only restriction is that if*

$$WL_i^n(t) \geq \bar{W}_a \tag{6.12}$$

is not satisfied for some i and the other source is not on vacation, then we poll the other source.

A6.4. *For each $\epsilon > 0$, there is $\bar{W} < \infty$ such that for $i, j : i \neq j$,*

$$E\left[\xi_{i,l}^{v,n} \middle| \text{data to scaled time } \nu_{i,l}^n, WL_j^n(\nu_{i,l}^n-) \geq \bar{W}\right] \leq \epsilon.$$

The assumption A6.4 holds under the conditions of Theorem 4.2 if A6.3 holds. The inequality (6.12) (when $WL^n(t) > \bar{W}_b$) cannot be guaranteed for all time. It will sometimes not hold during a vacation or for a vanishingly short (in scaled time) interval after. The real time interval between vacations is $O(n)$. Let $\alpha(\cdot)$ be a real-valued function on $[0, \infty)$ such that $\alpha(n)/\sqrt{n} \to \infty$ and $\alpha(n)/n \to 0$. Suppose that a vacation ends at real time t_0 and the next one begins at real time t_1, with $t_1 - t_0 = O(n)$. Then with a probability (conditioned on the data up to t_0) that goes to unity as $n \to \infty$, one can poll such that (6.12) is guaranteed on $[t_0 + \alpha(n), t_1)$ when

$WL^n(t_0) > \bar{W}_b$. The excluded interval is just $\alpha(n)/n$ in scaled time. Condition A6.3 works since the probability that two successive vacations will be within $\alpha(n)$ in real time is $O(\alpha(n)/n)$.

THEOREM 6.2. *Let* $\{WL^n(0)\}$ *be tight and assume* A2.3–A2.5 *and* A6.1–A6.4. *Then the process* $WL^n(\cdot)$ *is stable, uniformly in* n. *Fix* n. *Then for small enough* $\bar{\lambda}_i^s, i = 1, 2$, $WL^n(\cdot)$ *is stable.*

Note on the stability of the limit problem (3.7). Let $\mathcal{L}$ denote the differential generator of (3.7) when $WL > 0$. Then

$$\mathcal{L}WL(t) = b + \sum_i \bar{\lambda}_i^s E_{WL(t-),u(t-)}\xi_i^v.$$

Since, for the limit problem, the condition (6.12) can always be guaranteed for $WL(t) > \bar{W}_b$ (except at the jump instants) if $\bar{W}_b \gg \bar{W}_a$ are as large as we wish, it can always be assured that the sum in the above expression is arbitrarily small for large $WL^n(t)$. Then, since $b < 0$, $WL(\cdot)$ is stable. The proof below attempts to duplicate this idea.

Proof. In this proof, it is more convenient to work in scaled time. Thus, let $E_t^{s,n}$ denote the expectation conditioned on all data to scaled time t. All scaled times are integral multiples of δ/n. Suppose that no source is on vacation at scaled time t and a vacation of some source starts at scaled time $t + \delta/n$. Then, let $\tau_t^{v,n}/\sqrt{n}$ denote the scaled time which passes until *no* source is on vacation, and let $\xi_t^{v,n}$ denote the total jump in the workload due to all vacations which start at scaled time $t + \delta/n$ and end at scaled time $t + \delta/n + \tau_t^{v,n}/\sqrt{n}$. Thus, it might cover a single vacation, or several overlapping or abutting vacations.

Define $\sigma_k^n, k \geq 0$, recursively as follows. Start with $\sigma_0^n = 0$. Given σ_k^n, if no vacation starts at scaled time $\sigma_k^n + \delta/n$, then set $\sigma_{k+1}^n = \sigma_k^n + \delta/n$. If a vacation starts at scaled time $\sigma_k^n + \delta/n$, then set $\sigma_{k+1}^n = \sigma_k^n + \delta/n + \tau_{\sigma_k^n}^{v,n}/\sqrt{n}$. Thus, the σ_k^n are the sequence of scaled times $k\delta/n$, but with the instants where some source is on vacation skipped. To prove the stability it is sufficient to work with $WL^n(\sigma_k^n)$ and $WL^n(\sigma_k^n) \geq \bar{W}_a$ only.

Until further notice, suppose that the condition A6.3 holds at the start of each vacation. The event that this is not the case is very rare for large n and will be accounted for later. Recall the definition of $W_\beta^n(\cdot)$ in (6.6). Let $E_t^{v,n}$ denote the expectation, conditioned on all data to scaled time t and the event that a vacation starts at scaled time $t + \delta/n$. By the computations in Theorem 6.1, we have (whether or not (6.12) holds)

(6.13)
$$E_{\sigma_k^n}^{s,n} W_\beta^n(\sigma_{k+1}^n) - W_\beta^n(\sigma_k^n) \leq \prod_i \left(1 - \frac{\bar{\lambda}_i^{s,n}}{n} + o\left(\frac{\bar{\lambda}_i^{s,n}}{n}\right)\right) \frac{b_0\delta}{2n} + \left[\sum_i \frac{\delta}{n}\bar{\lambda}_i^{s,n} + o\left(\frac{\delta\sum_i \bar{\lambda}_i^{s,n}}{n}\right)\right] E_{\sigma_k^n}^{v,n}\xi_{\sigma_k^n}^{v,n}.$$

The $o(\cdot)$ will be ignored henceforth. Now, by A6.4 the term $E_{\sigma_k^n}^{v,n}\xi_{\sigma_k^n}^{v,n}$ in (6.13) goes to zero as $WL^n(\sigma_k^n)$ goes to infinity, which yields the stability, uniformly in n for large n.

Next let us consider the possibility that we might not always have $WL_i^n(t) \geq \bar{W}_a, i = 1, 2$, at the start of a vacation, when $WL^n(t) \geq \bar{W}_b$, for $\bar{W}_b \gg \bar{W}_a$, both being sufficiently large. Let $I_{t+\delta/n}^{v,n}$ denote the event that a vacation starts at scaled time $t + \delta/n$, with $WL_i^n(t) \leq \bar{W}_a$ for some i and $WL^n(t) \geq \bar{W}_b$. Let μ_l^n denote the scaled time of the lth occurrence of this event. We exploit the fact that this event is "rare"

for large n, by introducing another perturbation to the Liapunov function. We need to add the term

$$E^{s,n}_{\sigma^n_k} I^{v,n}_{\sigma^n_k+\delta/n} \tau^{v,n}_{\sigma^n_k} \tag{6.14}$$

to the right side of (6.13) (and multiply the current right-hand term there by $(1 - I^{v,n}_{\sigma^n_k+\delta/n})$, which leaves the estimates for that term unchanged. By A2.4, (6.14) is bounded by $C_1 E^{s,n}_{\sigma^n_k} I^{v,n}_{\sigma^n_k+\delta/n}$ for some constant C_1. Introduce the additional perturbation to the Liapunov function:

$$\delta \bar{W}^n_\beta(k\delta/n) = C_1 \sum_{l=k+1}^{\infty} e^{-(l-k-1)\beta\delta/n} E^{s,n}_{k\delta/n} I^{v,n}_{l\delta/n}. \tag{6.15}$$

This equals (dropping $o(\delta/n)$ terms for simplicity)

$$C_1 \frac{\delta \sum_i \bar{\lambda}^{s,n}_i}{n} \sum_{l:\mu^n_l > k\delta/n} E^{s,n}_{k\delta/n} e^{-\beta(\mu^n_l - k\delta/n - \delta/n)}. \tag{6.16}$$

Write the sum as $K^n_\beta(k)$. Then, for each $\beta > 0$, there is $n(\beta) < \infty$ such that $K^n_\beta(k) \le 2$ for $n \ge n(\beta)$ and all k.

Note the difference of the conditional expectations:

$$E^{s,n}_{\sigma^n_k} \delta \bar{W}^n_\beta(\sigma^n_{k+1}) - \delta \bar{W}^n_\beta(\sigma^n_k) = -C_1 E^{s,n}_{\sigma^n_k} I^{v,n}_{\sigma^n_k+\delta/n} + \epsilon^{v,n}_k, \tag{6.17}$$

where

$$\epsilon^{v,n}_k = C_1 \left[1 - e^{-\beta\delta/n}\right] \sum_{l=k+1}^{\infty} e^{-(l-k-2)\beta\delta/n} E^{s,n}_{k\delta/n} I^{v,n}_{l\delta/n}. \tag{6.18}$$

For $n \ge n(\beta)$,

$$\epsilon^{v,n}_k \le 2C_1 \beta \sum_i \frac{\bar{\lambda}^{s,n}_i}{n}.$$

Now, use the new perturbed Liapunov function defined by $W^n_\beta(k\delta/n) + \delta \bar{W}^n_\beta(k\delta/n)$. The conditional difference (6.17) cancels (6.14), modulo the error $\epsilon^{v,n}_k$, which is $O(\delta\beta/n)$ and β can be made as small as desired for large enough n. The proof is then completed as in Theorem 6.1 □

7. Unreliable channels. Up to now, it was supposed that any data sent from any source to the server arrived without error. In this section, we suppose that an error during transmission (as distinct from a vacation) is possible. Suppose that the server time is divided into "slots," of duration $\delta > 0$. That is, the work in each arrival is an integral multiple of δ, and each δ-interval is devoted to either a job from one of the sources, or to idling if there is no work present at the beginning of the slot. If a vacation starts during a slot, it is assumed that the data in that slot (if any) is retransmitted later. However, this has no effect on the heavy traffic limit. In case of an error in transmission, the data in the slot must be retransmitted. A variety of such situations can be readily incorporated into our general model.

If the sequence of errors is mutually independent in time, or if it does not depend on the source, then the modeling and analytical problem is relatively simple. The

errors would not depend on the source if the corrupting noise were at the server/base station, or was due to, say, a general atmospheric condition which affects all sources in the same way. On the other hand, if the errors are correlated (say, channels with bursty noise) and are *source dependent* as well, then the modeling problem is complicated by the fact that the server is allowed to poll the sources in a rather arbitrary way. For example, suppose that the noise is bursty for the channel connecting to one of the sources but that the channel connecting to the other is noise-free. Then, depending on how the sources are sequenced, the correlation between the errors can take many forms. Thus, it is hard to know the relation between the sequencing of the polling of the sources and the channel noise. One could try to poll taking into account the correlation. But, even if this were feasible, it is beyond our goals. For these reasons, we will assume that the disturbing noise does not depend on the source, despite the importance of the general problem.

The error model. Let $I_l^{e,n}$ denote the indicator function of the event that the data transmitted in the lth time slot was not acceptable and needed to be retransmitted. Let $S_i^{e,n}(t)$ (resp., $S^{e,n}(t)$) denote $1/n$ times the number of slots transmitted (successfully or not) from source i (resp., from both sources) by real time nt. Let $I_l^{a,n}$ denote the indicator function of the event that there is available data to be transmitted in time slot l from any source not on vacation. The (scaled) work that must be retransmitted by real time nt is

$$L^n(t) = \frac{\delta}{\sqrt{n}} \sum_{l=1}^{nt/\delta} I_l^{e,n} I_l^{a,n}. \tag{7.1}$$

For some centering constant $p^{e,n}$, write $L^n(t)$ as

$$L^n(t) = \frac{\delta}{\sqrt{n}} \sum_{l=1}^{nt/\delta} \left[I_l^{e,n} - p^{e,n}\right] I_l^{a,n} + \sqrt{n} p^{e,n} S^{e,n}(t)\delta. \tag{7.2}$$

The last term on the right of (7.2) is (see (3.2))

$$p^{e,n}\left[\sqrt{n}t - T^{v,n}(t) - Z^n(t)\right]. \tag{7.3}$$

Define

$$w^{e,n}(t) = \frac{\delta}{\sqrt{n}} \sum_{l=1}^{nt/\delta} \left[I_l^{e,n} - p^{e,n}\right] I_l^{a,n}. \tag{7.4}$$

We will use the following assumptions.

A7.1. *The error process is independent of all of the other driving processes. Also, $p^{e,n}$ converges to the constant p^e as $n \to \infty$ and $w^{e,n}(\cdot)$ converges weakly to a Wiener process, which will be denoted by $w^e(\cdot)$, and whose variance is $\delta\sigma_e^2$.*

A7.2. (The new heavy traffic condition.) *There is a constant b such that*

$$\lim_n \sqrt{n}\left[\sum_i \rho_i^n + p^{e,n} - 1\right] = b.$$

A7.1 is an assumption on the channel and will be returned to below. By adding

the work to be retransmitted, (3.15) becomes

$$WL^n(t) = WL^n(0) + \sum_i \bar{\Delta}_i^{d,n}\left[w_i^{a,n}(S_i^{a,n}(t)) - w_i^{d,n}(S_i^{a,n}(t))\right] + w^{e,n}(t)$$
$$+\sqrt{n}\left[\sum_i \rho_i^n + p^{e,n} - 1\right]t + (1-p^{e,n})\left[Z^n(t) + T^{v,n}(t)\right] + \epsilon^n(t), \tag{7.5}$$

where $\epsilon^n(\cdot)$ is a residual time error process.

Under the conditions of Theorem 3.1, with A7.1 added and the new heavy traffic condition A7.2 used, Theorem 3.1 continues to hold, with the following changes. The process $w^e(\cdot)$ is added to $w(\cdot)$. The jumps are computed by first showing that (in the local fluid time scale) the processes of completed work *during a vacation* can be asymptotically approximated by a fluid process with slope $1-p^e$, and they are

$$\begin{aligned}\xi_{1,l}^v &= \left[((1-p^e)-\rho_2)\,\tau_{1,l}^v - [WL(\nu_{1,l}-) - u(\nu_{1,l}-)]\right]^+ \\ &= \left[\rho_1 - [WL(\nu_{1,l}-) - u(\nu_{1,l}-)]\right]^+,\end{aligned} \tag{7.6a}$$

$$\xi_{2,l}^v = \left[((1-p^e)-\rho_1)\,\tau_{2,l}^v - u(\nu_{2,l}-)\right]^+ = \left[\rho_2\tau_{2,l}^v - u(\nu_{2,l}-)\right]^+. \tag{7.6b}$$

Also, $w^e(\cdot)$ is independent of $w(\cdot)$. With these changes, Theorem 3.2 also holds. Theorem 4.2 will continue to hold with these changes, provided that $E|w^{e,n}(t)|^2 = O(t)$. Similarly, the analogues of the stability results hold.

Remark. It is not possible to account for the retransmissions by simply enlarging the work in each job by an amount that has the same distribution as the retransmitted work does. This is because the controls are based on either the current queued work or queued numbers, and not what might be expected due to future errors and retransmissions.

Comments concerning $w^{e,n}(\cdot)$. First, suppose that the errors are independent from slot to slot with $P\{I_l^{e,n} = 1\} = p^{e,n}$. Then Donsker's theorem [12] implies that $w^{e,n}(\cdot)$ is tight and converges weakly to a Wiener process with variance $\delta p^e(1-p^e)$.

Now, turn to the correlated error problem. The error process concerns the channel, and is defined whether or not there is something to be transmitted. Suppose that the error process is Markov and doesn't depend on n, for notational simplicity. In particular, assume that

$$P\{I_{l+1}^{e,n} = 1 | I_l^{e,n} = 0\} = p,\ P\{I_{l+1}^{e,n} = 0 | I_l^{e,n} = 1\} = q,$$

where p and q are in $(0,1)$. Then $p^e = p/(p+q)$. Let I_l^e denote the stationary error process. Again, it is not hard to verify that $w^{e,n}(\cdot)$ converges weakly to a Wiener process with variance

$$\delta E\left[I_l^e - p^\epsilon\right]^2 + 2\delta E\sum_{l=1}^{\infty}\left[I_l^e - p^\epsilon\right]\left[I_0^e - p^\epsilon\right]$$

[12, 17].

We have $I_l^{a,n} = 0$ if both sources are on vacation, both queues are empty, or one source is on vacation and the other queue is empty at real time $l\delta$. These possibilities have negligible effect asymptotically.

Lévy processes. Many other models are possible for the error process (7.1) and a couple of other possibilities will be outlined. One approach, which does not require

the addition of A7.1 and uses (3.5) for the jumps, is to simply suppose that $L^n(\cdot)$ converges weakly to a general Lévy jump process. For example, suppose that the noise occurs in occasional bursts, where the rate at which the bursts occur (in real time) is $\bar{\lambda}^{e,n}/n$ and the duration (in real time) is $\sqrt{n}\tau_l^{e,n}$, where the durations (and the process of starting) are mutually independent and independent of the other "driving" random variables in the system. In this model the bursts are rare, and occur at a rate which is of the order of that of the vacations. But $\bar{\lambda}^{e,n}$ might be much larger than $\bar{\lambda}^{s,n}$ and the $\tau_l^{e,n}$ much smaller than $\tau_{i,l}^{v,n}$.

The scheme in the last paragraph supposed a finite rate $\bar{\lambda}^{e,n}$ for the bursts. The rate could depend on the duration, so that shorter durations have higher rates, with the rate going to infinity as the duration goes to zero, but in such a way that there is a limit Lévy process.

DUALITY IN $\mathbf{H}^\infty$ CONE OPTIMIZATION*

ANDREY GHULCHAK† AND ANDERS RANTZER†

Abstract. Positive real cones in the space $\mathbf{H}^\infty$ appear naturally in many optimization problems of control theory and signal processing. Although such problems can be solved by finite-dimensional approximations (e.g., Ritz projection), all such approximations are conservative, providing one-sided bounds for the optimal value. In order to obtain both upper and lower bounds of the optimal value, a dual problem approach is developed in this paper. A finite-dimensional approximation of the dual problem gives the opposite bound for the optimal value. Thus, by combining the primal and dual problems, a suboptimal solution to the original problem can be found with any required accuracy.

Key words. quasi-convex optimization, $\mathbf{H}^\infty$ space, convex duality

1. Introduction.

Many analysis and synthesis problems of control theory have recently been stated in terms of convex optimization [3, 18, 22, 24]. This often gives great benefit for both theoretical analysis and practical computation. However, when an optimization problem is infinite-dimensional, a reduction to finite-dimensional form (like Ritz projection, Galerkin finite element scheme, grid methods, etc.) is needed [3]. Such an approximation introduces conservatism to the problem. The gap between the true optimal value and its finite-dimensional counterpart can be arbitrarily large. To overcome this difficulty and to estimate the conservatism, convex duality has been widely used [3, 4, 8, 11, 12, 16, 17, 24]. Once the dual problem is stated, a similar finite-dimensional scheme can be applied to obtain an opposite bound for the optimal value. Provided that there is no duality gap, a suboptimal solution with any degree of accuracy can be computed by increasing the dimension of the approximations.

In this paper, we consider a cone optimization in the Hardy space $\mathbf{H}^\infty$, by which we mean the optimization of a quasi-convex functional on $\mathbf{H}^\infty$ whose level sets are positive real cones $\{h \in \mathbf{H}^\infty : \mathrm{Re}\,(g^T h) > 0,\ g \in \mathbf{H}^\infty\}$, or the intersection of such cones. Problems of this type appear often in controller design—for example, in $\mathbf{H}^\infty$ control, in robust stabilization under parametric uncertainty, in output error identification, etc. The strong practical aspect has become the main motivation of our work.

The main contribution of the paper is a theoretical development of the duality relation for this cone optimization. An analytical expression of the infinite-dimensional dual problem is obtained. Similarly to the primal problem, it takes the form of quasi-convex optimization. A cornerstone of our approach is convex duality, namely, Ky Fan's min-max theorem [25]. It is shown that there is no duality gap, and the primal-dual method can be used to obtain a suboptimal solution with any predefined level of optimality.

The paper is organized as follows. Section 2 introduces all major notation used throughout the paper. In section 3, the cone optimization problem in $\mathbf{H}^\infty$ is described. Several examples of interesting control problems that can be reduced to such a cone

optimization are gathered in section 4. The main result, which is the dual form of the problem, is presented in section 5, followed by a discussion of some particular cases in section 6. Section 7 compares the main result with duality by Megretski and Rantzer [17]. A brief discussion on possible numerical realizations of the primal-dual method is presented in section 8. Finally, a numerical example is given in section 9, where the primal-dual method is applied to a nonstandard $\mathbf{H}^\infty$ optimization problem. All proofs are moved to the appendices.

2. Notation. By $\mathbb{R}$ (or $\mathbb{C}$) we denote the field of real (or complex) numbers. The subset of $\mathbb{R}$ of nonnegative numbers is denoted by $\mathbb{R}_+$. The unit circle and the open unit disc in $\mathbb{C}$ are denoted by $\mathbb{T}$ and $\mathbb{D}$, respectively:

$$\mathbb{T} = \{z \in \mathbb{C} \;\big|\; |z| = 1\}, \quad \mathbb{D} = \{z \in \mathbb{C} \;\big|\; |z| < 1\}.$$

For every measurable $Y \subset \mathbb{C}^n$, the notation $\mathbf{L}^p(Y)$ stands for the standard Lebesgue space of functions $f\colon \mathbb{T} \to Y$ equipped with the norm

$$\|f\|_p = \begin{cases} \left(\int_{\mathbb{T}} |f(z)|^p \, dm(z)\right)^{1/p}, & 1 \le p < +\infty, \\ \operatorname{ess\,sup}_{z\in\mathbb{T}} |f(z)|, & p = +\infty, \end{cases}$$

where, by $|\cdot|$, we denote the usual Hölder 2-norm in $\mathbb{C}^n$

$$|f| = \sqrt{|f_1|^2 + |f_2|^2 + \cdots + |f_n|^2}.$$

$\mathbf{H}^p(Y)$ denotes the Hardy space of functions in $\mathbf{L}^p(Y)$ that have an analytical continuation inside the unit disc. $\mathbf{H}^p_0(Y)$ denotes the shifted $\mathbf{H}^p(Y)$; that is,

$$\mathbf{H}^p_0(Y) = z\mathbf{H}^p(Y) = \{f \in \mathbf{H}^p(Y) \;\big|\; f(0) = 0\}.$$

We use the notation $\mathbf{RH}^\infty(Y)$ for the set of all functions from $\mathbf{H}^\infty(Y)$ that are rational with real coefficients. The space of all continuous functions $f\colon \mathbb{T} \to Y$ is denoted by $C(Y)$. The notation $\mathbf{A}(Y)$ stands for the Banach disc algebra $\mathbf{H}^\infty(Y) \cap C(Y)$.

The short notations $\mathbf{L}^p$, $\mathbf{H}^p$, etc. will be used if $Y = \mathbb{C}^n$ and the dimension n is clear from context or makes no difference for presentation.

The orthogonal projection from L^2 to H^2 is denoted by P_+, and $P_- = I - P_+$. The prefix $\mathcal{B}$ denotes the unit ball in the corresponding space, and $\mathcal{S}$ is the unit sphere. The superscript ^{T} stands for transposition. Re is the real part of a complex number. A bar over a function denotes the complex conjugate. For two sets A and B,

$$A \setminus B = \{a \in A \;\big|\; a \notin B\}.$$

3. Preliminaries. Let $F \in \mathbf{A}(\mathbb{C}^{1\times n})$ and $G \in \mathbf{A}(\mathbb{C}^{m\times n})$. Denote

$$\Phi_\delta := F + \delta^T G, \tag{3.1}$$

$$J_\delta(h, z) := \operatorname{Re} \Phi_\delta(z) h(z). \tag{3.2}$$

A number of control design problems (see examples in section 4) can be stated as a convex specification

$$J_\delta(h, z) > 0 \quad \forall z \in \mathbb{T}, \ \forall \delta \in \Delta, \tag{3.3}$$

where the function $h \in \mathbf{RH}^\infty(\mathbb{C}^{n\times 1})$ is the design parameter (in control applications, it is usually the free parameter from the Youla parameterization of all stabilizing

controllers), and the set $\Delta \subset \mathbb{C}^m$ is the uncertainty region. The cone optimization problem is to find a (δ-independent) function $h \in \mathbf{RH}^\infty$ that satisfies the condition (3.3) for as large a region Δ as possible.

The condition (3.3) is a linear inequality with respect to δ. This implies that, if it holds for some set Δ, then it holds for the convex hull of the set. Therefore, without loss of generality, it is sufficient to consider the convex Δ's only. In addition, we assume Δ to be compact.

Assumption. The region Δ is assumed to be a compact convex set in $\mathbb{C}^m$.

To define how "large" or "small" the region is, we assume that the regions are described by a monotone family $\{\Delta_\nu\}$ so that the "size" ν is assigned to each set Δ_ν of the family. The monotonicity means that the larger set has the larger size; i.e., if $\nu_1 \le \nu_2$, then $\Delta_{\nu_1} \subset \Delta_{\nu_2}$. A common particular case of the monotonic family is the linear homotopy $\Delta_\nu = \nu\Delta$ of a set $\Delta \subset \mathbb{C}^m$ containing the origin.

Thus the problem is to maximize the size ν as follows:

$$\nu_{opt} = \sup\{\nu \mid \exists h \in \mathbf{RH}^\infty \colon J_\delta(h, z) > 0 \quad \forall z \in \mathbb{T},\ \forall \delta \in \Delta_\nu\}. \tag{3.4}$$

It is called the cone optimization problem since the set

$$K_\nu = \{h \in \mathbf{RH}^\infty \mid J_\delta(h, z) > 0 \quad \forall z \in \mathbb{T},\ \forall \delta \in \Delta_\nu\} \tag{3.5}$$

is a convex cone in $\mathbf{H}^\infty$. Thus, for a given ν, we have a cone programming (feasibility) problem which is related to robust linear programming [4] in the following sense: the linear inequality (3.3) should be satisfied *robustly* with respect to Δ.

4. Examples of $\mathbf{H}^\infty$ cone optimization problems. In this section, we gather several problems in control theory that can be reduced to the cone optimization in $\mathbf{H}^\infty$.

In all examples, the homotopy has the form $\Delta_\nu = \nu\Delta$ for a convex compact set $\Delta \subset \mathbb{C}^m$ containing the origin.

The following theorem is useful for reducing a problem to the cone optimization. It is a slightly modified version of [22, Theorem 1].

THEOREM 4.1. *Let $g \in C(\mathbb{C}^{m\times 1})$, and $\Delta \ni 0$ is a convex set in $\mathbb{C}^m$. The following statements are equivalent:*

1. $1 + \delta^T g(z) \ne 0$ *for all* $z \in \mathbb{T}$ *and* $\delta \in \Delta$.
2. *There exists a function* $\alpha \in \mathbf{RH}^\infty$ *such that*

$$\operatorname{Re}(1 + \delta^T g(z))\alpha(z) > 0 \quad \forall z \in \mathbb{T},\ \delta \in \Delta.$$

Example 1: $\mathbf{H}^\infty$ optimization. Given a $(N_z + N_y) \times (N_w + N_u)$ plant P

$$\begin{pmatrix} z \\ y \end{pmatrix} = P \begin{pmatrix} w \\ u \end{pmatrix},$$

the problem is to find a stabilizing controller $u = Ky$ that minimizes the $\mathbf{H}^\infty$-norm of the closed-loop transfer function T_{zw}. If the disturbance w is scalar ($N_w = 1$), then the Youla parameterization of all admissible closed-loop transfer functions (see, for example, [6]) has the form

$$T_{zw} = T_1 + T_2 Q, \tag{4.1}$$

where $T_1 \in \mathbf{A}(\mathbb{C}^{N_z})$ and $T_2 \in \mathbf{A}(\mathbb{C}^{N_z \times N_u})$ are defined by the plant P, and Q is any function in $\mathbf{RH}^\infty(\mathbb{C}^{N_u})$. With this parameterization, the problem can be rewritten as

$$\min_{Q \in \mathbf{RH}^\infty} \|T_1 + T_2 Q\|_\infty.$$

Equivalently, the problem is to maximize ν such that at all frequencies

$$|T_1(z) + T_2(z)Q(z)| < \nu^{-1} \quad \forall z \in \mathbb{T}. \tag{4.2}$$

For real-rational plants P, the well-developed theory [6] can be applied to solve the problem. However, in some important cases where P is not rational (e.g., systems with delays), there is no analytical solution to the problem in general.

The inequality (4.2) can be rewritten as

$$1 + \delta^T(T_1 + T_2 Q) \neq 0 \quad \forall z \in \mathbb{T},\ \delta \in \nu\Delta,$$

where $\Delta = \mathcal{B}\mathbb{C}^{N_z}$, and Theorem 4.1 reduces it to

$$\operatorname{Re}\left(1 + \delta^T(T_1(z) + T_2(z)Q(z))\right)\alpha(z) > 0 \quad \forall z \in \mathbb{T},\ \delta \in \nu\Delta. \tag{4.3}$$

It takes the form (3.3) with

$$\begin{aligned} F &= \begin{pmatrix} 1 & 0 & \dots & 0 \end{pmatrix} \in \mathbb{R}^{N_u+1}, \\ G &= \begin{pmatrix} T_1 & T_2 \end{pmatrix} \in \mathbf{A}, \\ h &= \begin{pmatrix} \alpha \\ Q\alpha \end{pmatrix} \in \mathbf{RH}^\infty. \end{aligned} \tag{4.4}$$

Setting $\delta = 0$ in (4.3) gives $\operatorname{Re}\alpha > 0$. Therefore, $1/\alpha \in \mathbf{RH}^\infty$, and the solution $Q \in \mathbf{RH}^\infty$ can be reconstructed from h as

$$Q = \frac{1}{h_1} \begin{pmatrix} h_2 \\ h_3 \\ \vdots \\ h_{N_u+1} \end{pmatrix}. \tag{4.5}$$

Example 2: Robust stabilization. Given a $(N_z + N_y) \times (N_w + N_u)$ uncertain plant P

$$\begin{pmatrix} y \\ z \end{pmatrix} = P \begin{pmatrix} w \\ u \end{pmatrix},$$
$$w = \delta^T z,$$

where $\delta \in \nu\Delta$ for some convex compact $\Delta \subset \mathbb{R}^{N_z}$ with $0 \in \Delta$, the problem is to find a controller $u = Ky$ that robustly stabilizes the plant for as large a ν as possible.

In the case where $N_w = 1$, the same Youla parameterization (4.1) gives the following equivalent problem: Find a function $Q \in \mathbf{RH}^\infty(\mathbb{C}^{N_u})$ that maximizes ν subject to

$$1 + \delta^T(T_1(s) + T_2(s)Q(s)) \neq 0 \quad \forall s\colon \operatorname{Re} s \geq 0,\ \forall \delta \in \nu\Delta.$$

Again by Theorem 4.1, this problem can be reduced to the form (3.3), with F and G defined in (4.4). The function Q can be reconstructed from h as in (4.5).

Example 3: Adaptive output error identification. Given a set of stable scalar polynomials

$$\mathcal{P}_\nu = \{z^m + p_1 z^{m-1} + \cdots + p_m \mid |p_i - p_i^0| \le \nu\epsilon_i\},$$

find a rational function b such that $1/b \in \mathbf{RH}^\infty$ and

$$\operatorname{Re}\frac{p(z)}{b(z)} > 0 \quad \forall z \in \mathbb{T},\ \forall p \in \mathcal{P}_\nu,$$

for as large a ν as possible.

The problem appears when a gradient algorithm is applied to output error identification of a plant transfer function with denominator polynomial $p(z)$. To ensure exponential convergence of the identification algorithm, certain signals are supposed to be filtered by a transfer function $1/b$, where p/b is strictly positive real [1].

The problem takes the form (3.3) if we denote $h = 1/b$, $F = p^0(z)$, $G = (z^{m-1}, z^{m-2}, \dots, 1)^T$, and

$$\Delta = \{\delta \in \mathbb{R}^m \mid \delta_i \in [-\epsilon_i, \epsilon_i]\}.$$

5. The problem and the main result. The problem (3.4) is a problem of quasi-convex optimization; for a given ν, the cone K_ν from (3.5) is convex. We will refer to the problem of finding $h \in K_\nu$ as the *primal problem*.

Primal problem. Given $F \in \mathbf{A}(\mathbb{C}^{1\times n})$, $G \in \mathbf{A}(\mathbb{C}^{m\times n})$, and a convex compact set $\Delta_\nu \subset \mathbb{C}^m$, find a function $h \in \mathbf{RH}^\infty(\mathbb{C}^{n\times 1})$ such that

$$J_\delta(h,z) := \operatorname{Re}\,(F(z) + \delta^T G(z))h(z) > 0 \quad \forall z \in \mathbb{T},\ \forall \delta \in \Delta_\nu. \tag{5.1}$$

Since Δ_ν and $\mathbb{T}$ are compact and all functions in (5.1) are continuous, the primal problem takes an equivalent form given by the following proposition.

PROPOSITION 5.1. *Given $\nu \in \mathbb{R}_+$, the following statements are equivalent:*

1. *The primal problem has a solution, i.e., $\nu < \nu_{opt}$ with ν_{opt} defined in* (3.4).
2. $$\gamma_{opt}(\nu) := \sup_{h\in\mathcal{B}\mathbf{A}} \inf_{z\in\mathbb{T}} \inf_{\delta\in\Delta_\nu} J_\delta(h,z) > 0. \tag{5.2}$$

Proof. See Appendix A. □

Remark 1. Note that $\gamma_{opt}(\nu) \ge 0$ even if $\nu \ge \nu_{opt}$. To see this, put $h = 0$.

Remark 2. The choice of the unit ball in $\mathbf{A}$ as an optimization set in (5.2) is not essential. Due to linear dependence of J_δ on h, any bounded set with the closure that absorbs $\mathbf{A}$ could be chosen. However, the unit ball has better relations to and easier interpretations from the classical results, such as the Banach duality, for example, than any other set (see Appendix B).

To obtain a dual representation of (5.2), we have to slightly modify the problem. The following lemma states that γ_{opt} can be calculated via optimization over the larger set $\mathcal{B}\mathbf{H}^\infty$. This is a very useful property for our technique, since $\mathbf{H}^\infty$ is dual to a "nice" space. This will play a central role in the dual presentation.

LEMMA 5.2.

$$\gamma_{opt}(\nu) = \sup_{h\in\mathcal{B}\mathbf{H}^\infty} \operatorname*{ess\,inf}_{z\in\mathbb{T}} \inf_{\delta\in\Delta_\nu} J_\delta(h,z). \tag{5.3}$$

Proof. See Appendix A. ∎

Now we are in a position to present the main result on duality.

THEOREM 5.3 (duality). *Let $F \in \mathbf{H}^\infty(\mathbb{C}^{1\times n})$, $G \in \mathbf{H}^\infty(\mathbb{C}^{m\times n})$, and let $\Delta_\nu \subset \mathbb{C}^m$ be a convex compact set. Denote Φ_δ as in* (3.1). *Then the following equality holds:*

(5.4)
$$\sup_{h\in\mathcal{B}\mathbf{H}^\infty(\mathbb{C}^{n\times 1})} \operatorname*{ess\,inf}_{z\in\mathbb{T}} \inf_{\delta\in\Delta_\nu} \operatorname{Re}\Phi_\delta(z)h(z) = \inf_{\delta\in\mathbf{L}^\infty(\Delta_\nu)} \inf_{w\in\mathcal{S}\mathbf{L}^1(\mathbb{R}_+)} \inf_{p\in\mathbf{H}_0^1(\mathbb{C}^{1\times n})} \|\Phi_\delta w - p\|_1.$$

Proof. See Appendix B. ∎

Remark 1. The left-hand side of the equality is $\gamma_{opt}(\nu)$ from (5.3). Theorem 5.3 gives the dual representation of the quantity as the minimization problem. The problem provides an upper bound on $\gamma_{opt}(\nu)$ by which we can determine the case when $\gamma_{opt}(\nu) = 0$.

Remark 2. The dual condition (5.4) can be rewritten in a convex way by setting a new variable $x = \delta w$:

$$\begin{aligned}\gamma_{opt}(\nu) = \inf\{\|Fw + x^TG - p\|_1 \;\big|\; p \in \mathbf{H}_0^1,\ \|w\|_1 = 1,\\ w \geq 0,\ x(z) \in w(z)\Delta_\nu \quad \forall z \in \mathbb{T}\}.\end{aligned} \tag{5.5}$$

Using Theorem 5.3, we state the *dual problem* to (5.1) as follows.

Dual problem. Given $F \in \mathbf{A}(\mathbb{C}^{1\times n})$, $G \in \mathbf{A}(\mathbb{C}^{m\times n})$, and a convex compact set $\Delta_\nu \subset \mathbb{C}^m$, find a sequence of functions $\{(w_i, \delta_i, p_i)\}_{i=0}^{+\infty}$ such that $w_i \in \mathcal{S}\mathbf{L}^1(\mathbb{R}_+)$, $\delta_i \in \mathbf{L}^\infty(\Delta_\nu)$, $p_i \in \mathbf{H}_0^1(\mathbb{C}^{1\times n})$, and

$$\|(F + \delta_i^TG)w_i - p_i\|_1 \to 0, \quad i \to +\infty. \tag{5.6}$$

We can draw two obvious conclusions from Theorem 5.3.

COROLLARY 5.4. *A number ν is an upper bound on ν_{opt} if and only if the dual problem has a solution.*

Proof. By Theorem 5.3, the dual problem has a solution if and only if $\gamma_{opt}(\nu) = 0$, which is equivalent to $\nu \geq \nu_{opt}$ by Proposition 5.1. ∎

COROLLARY 5.5. *If there exist $w \in \mathbf{L}^1(\mathbb{R}_+) \setminus 0$ and $\delta \in \mathbf{L}^\infty(\Delta_\nu)$ such that $\Phi_\delta w \in \mathbf{H}_0^1$, then $\nu \geq \nu_{opt}$.*

Proof. Scale by $\|w\|_1$, and apply Theorem 5.3 to conclude that $\gamma_{opt}(\nu) = 0$. ∎

Let us point out the main idea behind the equality (5.4). We will see that, if $\Phi_\delta w \in \mathbf{H}_0^1$ for some $w \in \mathbf{L}^1(\mathbb{R}_+)\setminus 0$ and $\delta \in \mathbf{L}^\infty(\Delta_\nu)$, then, in fact, $\gamma_{opt}(\nu) = 0$. For a function $h \in \mathbf{H}^\infty$, we have $f := \Phi_\delta wh \in \mathbf{H}_0^1$, so the mean value property for harmonic functions [27] gives

$$\int_{\mathbb{T}} \operatorname{Re}\left[(F(z) + \delta(z)^TG(z))h(z)\right]w(z)\,dm(z) = \operatorname{Re} f(0) = 0.$$

Therefore, since $w \geq 0$ and $w \not\equiv 0$, there must exist $z \in \mathbb{T}$ such that $\operatorname{Re}(F(z) + \delta(z)^TG(z))h(z) \leq 0$, which contradicts the condition (5.1).

The dual problem in the form (5.6) is complicated because it is stated in terms of *sequences* of functions. The problem would be much simpler if it were possible to replace the sequences with their limit points. The main difficulty here is a limit point for $\{w_i\}$. It may not exist as an element of $\mathcal{S}\mathbf{L}^1(R_+)$. However, the limit point for $\{w_i\}$ exists either as a regular function in $\mathcal{S}L^1(\mathbb{R}_+)$ or as Dirac's δ-function. Based on this, the dual problem can be naturally split into two parts—one regular

and one singular, with no functional sequences left in any of them. The regular part has already been covered by Corollary 5.5. The simplification of the dual problem is completed by the singular part in the next theorem.

THEOREM 5.6. *The optimal value ν_{opt} of the cone optimization problem* (3.4) *has the dual representation*

$$\nu_{opt} = \min\{\, \nu_{opt|s},\ \nu_{opt|c}\,\}, \tag{5.7}$$

where

$$\nu_{opt|s} = \inf\{\nu \;\big|\; \exists z \in \mathbb{T},\ \exists \delta \in \Delta_\nu, : \Phi_\delta(z) = 0\}, \tag{5.8}$$

$$\nu_{opt|c} = \inf\{\nu \;\big|\; \exists w \in \mathbf{L}^1(\mathbb{R}_+) \setminus 0,\ \exists \delta \in \mathbf{L}^\infty(\Delta_\nu) \colon \Phi_\delta w \in \mathbf{H}^1_0\}. \tag{5.9}$$

Proof. See Appendix C. □

Remark 1. It can be seen that $\nu_{opt|s}$ is the optimal value of the problem (3.4) *without* an analyticity condition on h, i.e., when we replace the space $\mathbf{H}^\infty$ with $\mathbf{L}^\infty$.

COROLLARY 5.7. *The bound $\nu_{opt|c}$ can be alternatively represented as*

$$\nu_{opt|c} = \inf\{\nu \;\big|\; \exists g \in (\mathbf{H}^2)^\perp \setminus 0,\ \exists \delta \in \mathbf{L}^\infty(\Delta_\nu) \colon P_-(\Phi_\delta g) = 0\}. \tag{5.10}$$

Proof. The proof follows easily from the factorization $w = f^* f$ with the outer factor $f \in \mathbf{H}^2$, dividing both sides of $\Phi_\delta w \in \mathbf{H}^1_0$ by f and setting $g(z) = f^*(z)/z$. □

The number $\nu_{opt|s}$ is relatively easy to evaluate:

$$\nu_{opt|s} = \inf_{z \in \mathbb{T}} \nu_s(z), \tag{5.11}$$

where

$$\nu_s(z) = \inf\{\nu \;\big|\; \delta \in \Delta_\nu,\ F(z) + \delta^T G(z) = 0\}; \tag{5.12}$$

that is, (5.8) is the convex problem at every $z \in \mathbb{T}$.

Dealing with $\nu_{opt|c}$ is a bit more complicated because it requires optimization on one more infinite-dimensional parameter in $\mathbf{H}^1_0$. Denoting $x(z) = w(z)\delta(z)$, we have

$$\delta(z) \in \Delta_\nu \quad \Leftrightarrow \quad x(z) \in w(z)\Delta_\nu;$$

hence (5.9) becomes

$$\nu_{opt|c} = \inf\{\nu \;\big|\; \exists w \in \mathbf{L}^1(\mathbb{R}_+) \setminus 0,\ \exists x \colon x(z) \in w(z)\Delta_\nu,\ wF + x^T G \in \mathbf{H}^1_0\}. \tag{5.13}$$

This is a quasi-convex optimization problem. It can be used to obtain an upper bound on $\nu_{opt|c}$ in the following way.

LEMMA 5.8. *The number $\nu \in \mathbb{R}_+$ is the upper bound on $\nu_{opt|c}$ if and only if there exists a solution $(x, w, p) \in \mathbf{L}^1(\mathbb{C}^m) \times \mathbf{L}^1(\mathbb{R}_+) \times \mathbf{H}^1_0(\mathbb{C}^n)$ to the problem*

$$\begin{array}{rcl} p(z) & = & w(z)F(z) + x(z)^T G(z), \\ x(z) & \in & w(z)\Delta_\nu, \\ \|w\|_1 & > & 0. \end{array} \tag{5.14}$$

Proof. The proof follows immediately from (5.13). □

Remark. The last condition $\|w\|_1 > 0$ is needed only to avoid the trivial solution $(x, w, p) = 0$. It can be replaced with $\|w\|_1 = 1$.

The condition (5.14) is linear in (w, p) and convex in x.

To conclude the section, let us give an explicit explanation of how the optimization in (3.4) can be done by using the dual problem. First, it is relatively easy to estimate $\nu_{opt|s}$ from (5.11) by sweeping the unit circle and solving the convex problem (5.12). When it is done, the search for ν_{opt} can be organized as a bisection of $[0, \nu_{opt|s}]$, using the duality result to choose the right part of the interval; namely, for a given $\nu \in [0, \nu_{opt|s}]$, one and only one problem of (5.1) and (5.14) has a solution.

6. The primal and dual problems for some particular sets $\boldsymbol{\Delta}$. To get better insight into the cone optimization problem, we consider in detail several typical cases. We assume, for simplicity, that the family Δ_ν is the linear homotopy of a convex compact set $\Delta \ni 0$, i.e., $\Delta_\nu = \nu\Delta$.

Case 1. $\Delta = 0$.

The primal problem (5.1) is to find a function $h \in \mathbf{RH}^\infty(\mathbb{C}^{n\times 1})$ such that

$$\operatorname{Re} F(z)h(z) > 0 \quad \forall z \in \mathbb{T},$$

for given $F \in \mathbf{A}(\mathbb{C}^{1\times n})$. The dual representation for γ_{opt} in Theorem 5.3 simplifies to

$$\gamma_{opt} := \sup_{h\in\mathcal{B}\mathbf{H}^\infty} \operatorname*{ess\,inf}_{z\in\mathbb{T}} \operatorname{Re} F(z)h(z) = \inf_{w\in\mathcal{S}\mathbf{L}^1(\mathbb{R}_+)} \inf_{p\in\mathbf{H}^1_0} \|Fw - p\|_1,$$

and the duality result in Theorem 5.6 claims that the primal problem has no solution if and only if

1. $\exists w \in \mathbf{L}^1(\mathbb{R}_+) \setminus 0$ such that $Fw \in \mathbf{H}^1_0$, or
2. $\exists z \in \mathbb{T}$ such that $|F(z)| = 0$.

The second condition is the absence of zeros of F on the unit circle. The following proposition shows that the first one is related to that in the open unit disc.

PROPOSITION 6.1. *Let $F \in \mathbf{A}(\mathbb{C}^{1\times n})$. The following conditions are equivalent:*

1. $\exists\lambda \in \mathbb{D}$ *such that* $|F(\lambda)| = 0$.
2. $\exists w \in \mathbf{L}^1(\mathbb{R}_+) \setminus 0$ *such that* $Fw \in \mathbf{H}^1_0(\mathbb{C}^{1\times n})$.

Proof. See Appendix D. □

Note that the existence of $h \in \mathbf{A}$ such that $\operatorname{Re} F(z)h(z) > 0$ for all $z \in \mathbb{T}$ is equivalent to the existence of $g \in \mathbf{A}$ such that $Fg = 1$ (if we just set $g = h(Fh)^{-1}$). Thus the duality theorem in the particular case when $\Delta = 0$ gives the well-known result [27] concerning Gelfand's theory of maximal ideals in disc algebra $\mathbf{A}$:

$$\exists g \in \mathbf{A}\colon Fg = 1 \quad \Leftrightarrow \quad \inf_{\lambda\in\mathbb{D}} |F(\lambda)| > 0.$$

Let us now give some interpretation to the primal and dual problems in the case when $\Delta = 0$. Since the uncertainty set is zero, the primal problem can be interpreted as a nominal stabilization problem. For example, in the scalar case, a controller $K = \beta/\alpha$ stabilizes a plant $P = b/a$ if and only if the characteristic polynomial of the closed-loop system $\chi(s) = a(s)\alpha(s) - b(s)\beta(s)$ is stable. Equivalently, there exists $h \in \mathbf{A}(\mathbb{C}^{2\times 1})$ such that

$$\operatorname{Re} \begin{pmatrix} a(z) & -b(z) \end{pmatrix} h(z) > 0 \quad \forall z \in \mathbb{T}. \tag{6.1}$$

Indeed, one possible choice of h is $(\alpha\ \beta)^T/\chi$.

The dual problem gives a stabilizability criterion as $|F(\lambda)| \neq 0$ for all $\lambda \in \mathbb{D}$. In our scalar case example (6.1), the stabilizability criterion gives the following well-known condition: a plant $P = b/a$ is stabilizable if and only if the polynomials a and b have no common unstable zeros.

Case 2. $\Delta = \mathcal{B}\mathbb{C}^m$.

We will show that this case is reduced to the standard $\mathbf{H}^\infty$ optimization. The first step in this direction is the following proposition.

PROPOSITION 6.2. *Let $F \in \mathbf{A}(\mathbb{C}^{1\times n})$, $G \in \mathbf{A}(\mathbb{C}^{m\times n})$, and $\Delta = \mathcal{B}C^m$. Then the following statements are equivalent:*

1. *$\exists h \in \mathbf{A}(\mathbb{C}^{n\times 1})$ such that*

$$\operatorname{Re}\,(F(z) + \delta^T G(z))h(z) > 0 \quad \forall z \in \mathbb{T}, \quad \forall \delta \in \nu\Delta. \tag{6.2}$$

2. *$\exists g \in \mathbf{A}(\mathbb{C}^{n\times 1})$ such that $Fg = 1$ and $\|Gg\|_\infty < \nu^{-1}$.*

Proof. See Appendix D. □

Proposition 6.2 reduces the cone optimization problem (3.4) to the convex optimization problem

$$\nu_{opt}^{-1} = \inf_{g\in\mathbf{A}} \{\, \|Gg\|_\infty \;\big|\; Fg = 1\}. \tag{6.3}$$

To obtain the standard $\mathbf{H}^\infty$ optimization problem from (6.3), we need to perform the parameterization of all solutions to $Fg = 1$ (known as the Youla parameterization in control theory). If $g_0 \in \mathbf{A}$ is a particular solution to the equation $Fg = 1$ and $M \in \mathbf{A}(\mathbb{C}^{n\times(n-1)})$ is a basis of the kernel of F (i.e., $FM = 0$), then all solutions can be parameterized as

$$g = g_0 + Mq, \quad q \in \mathbf{A}(\mathbb{C}^{(n-1)\times 1}),$$

which gives the standard $\mathbf{H}^\infty$ setting

$$\nu_{opt}^{-1} = \inf_{q\in\mathbf{A}} \|Gg_0 + GMq\|_\infty = \inf_{q\in\mathbf{RH}^\infty} \|T_1 + T_2 q\|_\infty \tag{6.4}$$

with given $T_1, T_2 \in \mathbf{A}$. To go back to the form (6.2), one can put, for example,

$$F = \begin{pmatrix} 1 & 0 & \dots & 0 \end{pmatrix}, \quad G = \begin{pmatrix} T_1 & T_2 \end{pmatrix}. \tag{6.5}$$

Let us now have a look at the dual problem to (6.2). Since the case $\Delta = \mathcal{B}\mathbb{C}^m$ can be reduced to the standard $\mathbf{H}^\infty$ optimization problem (6.4), and the latter has the well-known dual (see Theorem B.1, for instance), it seems interesting to compare our dual formulation with the standard one. As we will see, there are some similarities between these two problems, although they are different.

We assume, for simplicity, that the functions T_1 and T_2 in (6.4) are scalar. By (6.5), the problem (6.4) takes the primal form (3.4) as

$$\nu_{opt} = \sup\{\nu \;\big|\; \exists h \in \mathbf{RH}^\infty \colon \operatorname{Re}\,[\begin{pmatrix} 1 - \delta T_1(z) & -\delta T_2 \end{pmatrix} h(z)] > 0 \quad \forall z \in \mathbb{T} \quad \forall |\delta| \le \nu\}.$$

Applying Theorem 5.6, we obtain the dual problem as $\nu_{opt} = \min\{\nu_{opt|c}, \nu_{opt|s}\}$, where

$$\begin{aligned} \nu_{opt|c} &= \inf\{\|\delta\|_\infty \;\big|\; \exists w \in \mathbf{L}^1(\mathbb{R}_+) \setminus 0 \colon \begin{pmatrix} 1 - \delta T_1 & -\delta T_2 \end{pmatrix} w \in \mathbf{H}_0^1\}, \\ \nu_{opt|s} &= \inf\{|\delta| \;\big|\; \exists z \in \mathbb{T} \colon \begin{pmatrix} 1 - \delta T_1(z) & -\delta T_2(z) \end{pmatrix} = 0\}. \end{aligned}$$

Let us interpret first the singular part of the dual problem. Obviously, the equations $\delta T_1(z) = 1$, $\delta T_2(z) = 0$ have a solution δ if and only if $T_2(z) = 0$, in which case

$$\nu_{opt|s} = \min_{z\in\mathbb{T}}\{|T_1(z)|^{-1} \mid T_2(z) = 0\}.$$

This upper bound has a trivial interpretation. In fact, for all $q \in \mathbf{RH}^\infty$ (even for all $q \in \mathbf{L}^\infty$; see Remark 1 after Theorem 5.6), it holds that

$$\|T_1 + T_2 q\|_\infty = \sup_{z\in\mathbb{T}} |T_1(z) + T_2(z)q(z)| \geq |T_1(z)| \quad \forall z \in \mathbb{T}\colon T_2(z) = 0,$$

which gives $\nu_{opt}^{-1} \geq \nu_{opt|s}^{-1}$. Thus, if we assume that $T_2(z) \neq 0$ on $\mathbb{T}$, then $\nu_{opt|s} = +\infty$; i.e., there is no singular part. This brings some dual understanding as to why the $\mathbf{H}^\infty$ control problem under assumption $T_2 \neq 0$ on $\mathbb{T}$ (or full rank conditions on matrices T_2, T_3 in the four-block case) is easier to solve: the dual problem has only the regular part.

Let us now interpret the regular part of the dual problem. Because all zeros of $T_2(z)$ on $\mathbb{T}$ are under the responsibility of the singular part, we assume without loss of generality that $T_2(z) \neq 0$ on $\mathbb{T}$ to deal with $\nu_{opt} = \nu_{opt|c}$. In this case, the inner-outer factorization $T_2 = T_{2i}T_{2o}$ satisfies $T_{2o}^{-1} \in \mathbf{A}$, and hence the problem (6.4) can be equivalently represented as [6]

$$\nu_{opt}^{-1} = \inf_{Q\in\mathbf{RH}^\infty} \|R - Q\|_\infty \tag{6.6}$$

with $R = T_{2i}^* T_1 \in C(\mathbb{T})$. This convex optimization problem has the well-known dual problem given by the Nehari theorem [6]

$$\nu_{opt}^{-1} = \sup_{f\in\mathbf{H}^2} \frac{\|P_-(Rf)\|_2}{\|f\|_2} \quad \Leftrightarrow \quad \nu_{opt} = \inf_{f\in\mathbf{H}^2} \frac{\|f\|_2}{\|P_-(Rf)\|_2}. \tag{6.7}$$

Equivalently, the distance from the function $R \in C(\mathbb{T})$ to $\mathbf{H}^\infty$ is equal to the norm of Hankel operator $H_R = P_- R$. We show that our regular part of the dual problem is closely connected to (6.7). By Corollary 5.7, we have

$$\nu_{opt|c} = \inf\{\|\delta\|_\infty \mid \exists g \in (\mathbf{H}^2)^\perp \setminus 0\colon P_- \begin{pmatrix} 1 - \delta T_1 & -\delta T_2 \end{pmatrix} g = 0\}.$$

Put $f := \delta T_{2i} g$. We have $P_-(T_{2o} f) = P_-(\delta T_2 g) = 0$, which gives $T_{2o} f \in \mathbf{H}^2$ and hence $f \in \mathbf{H}^2$. Furthermore, $g = P_-(\delta T_1 g) = P_-(Rf)$. Finally $\delta = T_{2i}^* f/g$, so

$$\|\delta\|_\infty = \left\| \frac{f}{g} \right\|_\infty = \left\| \frac{f}{P_-(Rf)} \right\|_\infty,$$

and we obtain the following formula for ν_{opt}:

$$\nu_{opt} = \nu_{opt|c} = \inf_{f\in\mathbf{H}^2} \left\| \frac{f}{P_-(Rf)} \right\|_\infty. \tag{6.8}$$

This is rather similar to (6.7) yet different. Note that, in general for $f \in \mathbf{H}^2$,

$$\frac{\|f\|_2}{\|P_-(Rf)\|_2} \leq \left\| \frac{f}{P_-(Rf)} \right\|_\infty, \tag{6.9}$$

so the duality condition (6.8) appears to be stronger than (6.7). This is a question of more delicate analysis to show that for $R \in C(\mathbb{T})$ the Hankel operator is compact, and then there exists a maximizing vector $f \in \mathbf{H}^2$; i.e., $\|P_-(Rf)\|_2 = \nu_{opt}^{-1}\|f\|_2$. Moreover, for such a vector f, the function $P_-(Rf)/f$ is inner (or all-pass), i.e.,

$$\frac{P_-(Rf)(z)}{f(z)} \equiv \nu_{opt}^{-1} \quad \forall z \in \mathbb{T},$$

and the optimal function Q_{opt} in (6.6) can be found as $R - Q_{opt} = P_-(Rf)/f$ (see, for instance, [6]). These extra properties of $f/P_-(Rf)$ explain the equality in (6.9) for the optimal f.

Case 3. Δ is a convex polytope in $\mathbb{C}^m$.

In this case, both the primal and the dual problems are reduced to linear programming which can be stated explicitly in terms of vertices of Δ.

Denote the vertices of Δ by $\{\delta_k\}_{k=1}^K$, $\delta_k \in \mathbb{C}^m$. By the Krein–Milman theorem [26], the polytope Δ is the convex hull of its vertices

$$\Delta = \operatorname{co}\{\delta_1, \delta_2, \dots, \delta_K\}.$$

This means that the primal problem (5.1) is reduced to the *finite* number of linear inequalities at each point $z \in \mathbb{T}$

$$\operatorname{Re}(\nu^{-1}F(z) + \delta_k^T G(z))h(z) > 0 \quad \forall z \in \mathbb{T},\ 1 \le k \le K, \tag{6.10}$$

and the primal algorithm can be implemented as linear programming as follows.

Consider the power series decomposition of $h \in \mathbf{RH}^\infty(\mathbb{C}^{n\times 1})$

$$h(z) = \sum_{m=0}^{+\infty} h_m z^m = \begin{pmatrix} 1\cdot I & z\cdot I & z^2\cdot I & \dots \end{pmatrix} \begin{pmatrix} h_0 \\ h_1 \\ \vdots \end{pmatrix}.$$

Denoting

$$\phi(z) = \begin{pmatrix} 1 & z & z^2 & \dots \end{pmatrix},$$
$$H = \begin{pmatrix} h_0 \\ h_1 \\ \vdots \end{pmatrix},$$

the decomposition takes the short form $h(z) = [\phi(z) \otimes I]H$, with Kronecker's product $\otimes$ defined as

$$A \otimes B = \begin{pmatrix} A_{11}B & A_{12}B & \dots \\ A_{21}B & A_{22}B & \dots \\ \vdots & \vdots & \ddots \end{pmatrix}.$$

Substituting this representation for h into the primal inequality (6.10), we get

$$\operatorname{Re}(\nu^{-1}F(z) + \delta_k^T G(z))(\phi(z)\otimes I)H = \operatorname{Re}\begin{pmatrix} \nu^{-1} & \delta_k^T \end{pmatrix}\left[\phi(z) \otimes \begin{pmatrix} F(z) \\ G(z) \end{pmatrix}\right] H > 0.$$

Denote

$$R(z) = \begin{pmatrix} F(z) \\ G(z) \end{pmatrix}, \quad D_\nu = \begin{pmatrix} \nu^{-1} & \nu^{-1} & \dots & \nu^{-1} \\ \delta_1 & \delta_2 & \dots & \delta_K \end{pmatrix} \tag{6.11}$$

to end up with the explicit linear inequality form of (6.10) with respect to H

$$\mathrm{Re}\,[\phi(z) \otimes D_\nu^T R(z)]H \succ 0 \quad \forall z \in \mathbb{T}. \tag{6.12}$$

Now we will show that the dual problem also takes the form of linear programming. Since the linear homotopy $\Delta_\nu = \nu\Delta$ is considered, we have by convexity that

$$\delta \in \Delta_\nu \quad \Leftrightarrow \quad \delta = \sum_{k=1}^{K} \mu_k \delta_k, \quad \mu_k \geq 0, \ \sum_{k=1}^{K} \mu_k = \nu,$$

and the pointwise singular part of the upper bound (5.12) becomes

$$\nu_s(z) = \inf \left\{ \sum_{k=1}^{K} \mu_k \;\middle|\; \mu_k \geq 0, \ F(z) + \sum_{k=1}^{K} \mu_k \delta_k^T G(z) = 0 \right\}. \tag{6.13}$$

Similarly, the condition $x(z) \in w(z)\Delta_\nu$ in (5.14) can be rewritten as

$$x(z) = \sum_{k=1}^{K} \mu_k(z)\delta_k, \quad \mu_k(z) \geq 0, \ \sum_{k=1}^{K} \mu_k(z) = \nu w(z),$$

and the regular part of the dual problem takes the form

$$\begin{aligned} w(z)F(z) + \sum_{k=1}^{K} \mu_k(z)\delta_k^T G(z) &= p(z), \\ \sum_{k=1}^{K} \mu_k(z) &= \nu w(z), \\ \mu_k(z) &\geq 0, \\ \int_{\mathbb{T}} w(z)\, dm(z) &> 0. \end{aligned}$$

The function w can be found from the second equation, and the number of variables is reduced:

$$\begin{aligned} \sum_{k=1}^{K} \mu_k(z)(\nu^{-1}F(z) + \delta_k^T G(z)) &= p(z), \\ \mu_k(z) &\geq 0, \\ \int_{\mathbb{T}} \sum_{k=1}^{K} \mu_k(z)\, dm(z) &> 0. \end{aligned} \tag{6.14}$$

Using the notation above for ϕ, R, and D_ν together with $\mu(z) = (\mu_1(z), \dots, \mu_K(z))^T$,

$$p(z) = \sum_{m=1}^{+\infty} p_m z^m = ([z\phi(z) \otimes I]P)^T,$$

the problem can be written as

$$\begin{aligned} \begin{pmatrix} -[z\phi(z) \otimes I] & R(z)^T D_\nu \end{pmatrix} \begin{pmatrix} P \\ \mu(z) \end{pmatrix} &= 0, \\ \mu(z) &\succeq 0, \\ E_K \int_{\mathbb{T}} \mu(z)\, dm(z) &= 1, \end{aligned} \tag{6.15}$$

where $E_K = \begin{pmatrix} 1 & \dots & 1 \end{pmatrix}$ is the K-dimensional row vector of ones.

Thus both the primal and the dual problems take the form of linear feasibility programming. The feasibility problem (6.12) can be solved in the same manner as (5.2). The condition $\|h\|_\infty \le 1$ cannot be represented as a linear condition on the coefficients H, so calculation of γ_{opt} is not linear programming. However, all we need is to check if $\gamma_{opt} > 0$. Let us choose a polyhedral set instead of the unit ball in the problem (5.2) to add the necessary linearity to the problem. For example, with

$$\mathcal{H} = \left\{ H \;\Big|\; \sum_{m=0}^{+\infty} |H_m| \le 1 \right\},$$

we have the linear programming to solve the primal problem

$$\gamma_{opt}^{LP} = \max_{H \in \mathcal{H}} \{\gamma \;|\; \mathrm{Re}\,[\phi(z) \otimes D_\nu^T R(z)] H \succeq \gamma \quad \forall z \in \mathbb{T}\}. \tag{6.16}$$

According to Remark 2 after Proposition 5.1, the conditions $\gamma_{opt} > 0$ and $\gamma_{opt}^{LP} > 0$ are equivalent.

For the dual feasibility problem (6.15), we can do a similar trick,

(6.17)
$$\epsilon_{opt} = \max_P \left\{ \epsilon \;\Big|\; R(z)^T D_\nu \mu(z) = [z\phi(z) \otimes I]P,\ \mu(z) \succeq \epsilon,\ E_K \int_{\mathbb{T}} \mu(z)\, dm(z) = 1 \right\},$$

in order to move the corresponding δ out of boundary inward Δ_ν to obtain certain "robustness" of the inclusion $\delta \in \Delta_\nu$. So the dual linear feasibility problem has a solution if and only if $\epsilon_{opt} \ge 0$.

7. Comparison with the previous result. In this section, we compare the duality result with that obtained by Megretski and Rantzer. The following generalized uniform interpolation problem was considered in [17].

Given $\Omega(z) \subset \mathbb{C}^k$, find $h \in \mathbf{RH}^\infty$ such that

$$h(z) \in \Omega(z) \quad \forall z \in \mathbb{T}. \tag{7.1}$$

Our primal problem (5.1) is recovered with

$$\Omega(z) = \{\omega \in \mathbb{C}^{n+1} \;|\; \mathrm{Re}\,(F(z) + \delta^T G(z))\omega > 0 \quad \forall \delta \in \Delta_\nu\}.$$

The authors of [17] presented the dual to the interpolation problem, which is restated below. Denote

$$\langle f, g \rangle := \mathrm{Re} \int_{\mathbb{T}} f(z)^T g(z)\, dm(z) = \frac{1}{2\pi} \mathrm{Re} \int_{-\pi}^{\pi} f(e^{i\theta})^T g(e^{i\theta})\, d\theta. \tag{7.2}$$

The dual problem is the following integral interpolation problem:

Find a function $f \in \mathbf{RH}_0^1$ such that

$$\langle f, g \rangle < 0 \tag{7.3}$$

for all measurable and bounded functions g satisfying $g(z) \in \Omega(z)$ for all $z \in \mathbb{T}$.

This duality is related to the fact that $\mathbf{H}_0^1$ is an annihilator of $\mathbf{H}^\infty$; i.e., $\langle f, h \rangle = 0$ for all $f \in \mathbf{H}_0^1$ and all $h \in \mathbf{H}^\infty$.

It was also shown in [17] that, under additional assumptions on Ω, namely, *convexity*, *continuity*, and *compactness*, there is no duality gap between the two problems. However, these additional assumptions are very restrictive and are almost never satisfied. To meet them, one has to perform a certain "regularization" procedure. Essentially one has to remove neighborhoods of zero and infinity from the cone Ω, replace the condition in the primal with $h(z) \in \Omega_\epsilon(z)$, and modify the dual integral interpolation problem with

$$\sup\{\langle f, g\rangle \mid g(z) \in \Omega_\epsilon(z) \quad \forall z \in \mathbb{T}\} < 0, \tag{7.4}$$

where

$$\Omega_\epsilon(z) = \{\omega \in \mathcal{B}C^{n+1} \mid J_\delta(\omega, z) \geq \epsilon \quad \forall \delta \in \Delta_\nu\}.$$

Since the primal problem in (5.1) is a special case of (7.1), there must be a relation between the dual (7.4) and that in Theorem 5.3.

The purpose of this section is to trace this relation. The following is a formal brief description of the idea of how to relate the two problems, using the Lagrange multiplier method (Kuhn–Tucker theorem [25]), to the optimization problem in (7.4).

$$\begin{aligned}
0 > \sup_{g(z)\in\Omega_\epsilon(z)} \langle f, g\rangle &= \sup_{\inf_{\delta\in\Delta_\nu} \operatorname{Re}\Phi_\delta(z)g(z)\geq\epsilon} \langle f, g\rangle \\
&= \inf_{\tau(z)\geq 0} \sup_{g\in\mathcal{B}\mathbf{L}^\infty} \inf_{\delta(z)\in\Delta_\nu} \big(\langle f, g\rangle + \langle \tau, \Phi_\delta g - \epsilon\rangle\big) \\
&= \inf_{\tau(z)\geq 0} \inf_{\delta(z)\in\Delta_\nu} \sup_{g\in\mathcal{B}\mathbf{L}^\infty} \big(\langle f + \tau\Phi_\delta^T, g\rangle - \langle \tau, \epsilon\rangle\big) \\
&= \inf_{\delta(z)\in\Delta_\nu} \inf_{\tau(z)\geq 0} \int_{\mathbb{T}} (|f + \tau\Phi_\delta^T| - \epsilon\tau)\, dm.
\end{aligned}$$

Hence a function $f \in \mathbf{H}_0^1$ is a solution to (7.3) if and only if there exist functions $\delta \in \mathbf{L}^\infty(\Delta_\nu)$ and $\tau \in \mathbf{L}^1(\mathbb{R}_+)$ such that

$$\|f + \tau\Phi_\delta^T\|_1 < \epsilon\|\tau\|_1.$$

Denoting $w = \tau/\|\tau\|_1$, $p = -f^T/\|\tau\|_1$, we get the similar condition to (5.6) because $\epsilon > 0$ can be chosen arbitrarily small in the regularization Ω_ϵ.

8. Toward an implementation of the primal-dual method. Although efficiency of a primal-dual method depends on a numerical implementation, we do not provide any *particular* numerical scheme and do not discuss *details* of corresponding numerical issues for the following reason. Once the dual pair (5.1), (5.14) is obtained, one can approach it in many different ways—either directly or via finite-dimensional approximations. The latter has a large variety of forms and methods: among others, there are Galerkin-type finite-element schemes, the method of ellipsoids and other cutting plane methods, the analytic center cutting plane (ACCP), path-following, potential reduction, and other barrier-based interior-point methods [20], and, in some cases, semidefinite programming and linear matrix inequalities (LMIs), etc. Each of them has certain advantages and disadvantages, and we cannot prescribe any of them as a cure for all cases. What we do briefly discuss in this section is a general idea of how to bridge the gap between the infinite-dimensional convex condition and a possible numerical implementation of it, taking into account some specific features of the problem.

The main difficulty is that the convex problems (5.1) and (5.14), and even their linear counterparts (6.12) and (6.15), have infinitely many decision variables and equalities/inequalities. To overcome this difficulty, an approximation should be done. The analytical property of the functions h and p make a pointwise representation useless, so the best we can do for the approximation is to introduce a Schauder basis of the space $\mathbf{RH}^\infty$ and $\mathbf{H}_0^1$. A right choice of basis is very important for fast convergence yet unclear a priori in general, so an adaptive adjustment of the basis (especially of the pole location of basis elements) may be useful. Some insight for the adjustment can be obtained by solving an auxiliary simple problem. For example, the approximation of Δ by a ball in $\mathbb{C}^m$ gives the equivalent $\mathbf{H}^\infty$ optimization problem that can be solved effectively, and the pole location of the optimal solution may be used for the first choice of the basis in $\mathbf{RH}^\infty$. Another possibility is to choose a basis and run the algorithm to find a solution most probably of a very high dimension. If the choice of basis is bad, the solution will have many close pole-zero cancellations, and what is left may be used for the basis adjustment.

In any case, by choosing any basis of $\mathbf{RH}^\infty$, for example, the polynomial basis $\{1, z, z^2, \dots\}$, we know that the solution *can* be found since polynomials are uniformly dense in $\mathbf{A}$. This means that we can consider an equivalent problem with a *finite* (although unknown a priori) number of decision variables. Since the number of inequalities is still the continuum, we get a semi-infinite programming that can be solved in many ways. One is by taking a grid on the unit circle $\mathbb{T}$ (see discretization methods for semi-infinite programming in [10, 23]), which has been realized and discussed in [8, 9]. Another is to use a cutting plane algorithm and, in particular, the ACCP method [2, 19] that usually performs better than the method of ellipsoids. A variation of the ACCP method for cone feasibility problems (our primal problem (5.1) is conic) appears in [21]. Other barrier function methods applied to similar problems can be found in [13, 14, 15].

9. Numerical example: A nonconvex $\mathbf{H}^\infty$ optimization problem. In this section, a nonconvex $\mathbf{H}^\infty$ optimization problem is solved numerically by the primal-dual method derived above. By the $\mathbf{H}^\infty$ optimization, we mean a problem in the form

$$\inf_{Q \in \mathbf{RH}^\infty} \{\gamma \mid T_1(z) + T_2(z)Q(z) \in \gamma\Omega \quad \forall z \in \mathbb{D}\}, \tag{9.1}$$

where Ω is the neighborhood of the origin in $\mathbb{C}$ and T_1, $T_2 \in \mathbf{A}$. If $\Omega = \mathbb{D}$, we have the standard $\mathbf{H}^\infty$ optimization [6] since

$$T_1(z) + T_2(z)Q(z) \in \gamma\mathbb{D} \quad \forall z \in \mathbb{D} \quad \Leftrightarrow \quad \|T_1 + T_2Q\|_\infty \le \gamma.$$

If Ω is a convex set, the problem (9.1) is convex.

In this section, we consider the $\mathbf{H}^\infty$ optimization problem (9.1) with the *nonconvex* set

$$\Omega = \{re^{i\phi} \in \mathbb{C} \mid 0 \le r < |\cos(\phi)| + |\sin(\phi)|\}. \tag{9.2}$$

The shape of Ω is shown in Figure 9.1. This set appears, for example, in the optimization of the stability radius for a linear system (see Example 2 in section 4) with the "diamond" type of uncertainty in feedback

$$\Delta = \{x + iy \in \mathbb{C} \mid |x| + |y| \le 1\}.$$

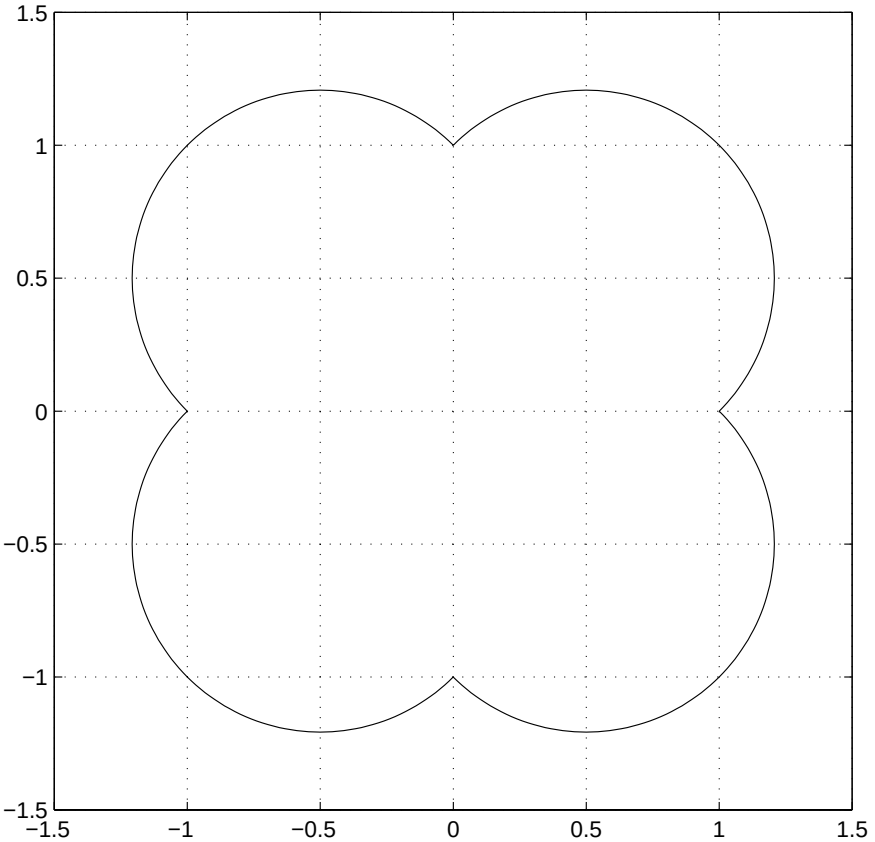

FIG. 9.1. *The set* Ω *from* (9.2).

The problem can be reduced to the cone optimization. First note that $\Omega = \mathbb{C} \setminus \Delta^{-1}$. Then, for $g = T_1 + T_2 Q$, we can rewrite the condition $g(z) \in \nu\Omega$ as

$$\nu^{-1} g(z) \notin \Delta^{-1} \quad \Leftrightarrow \quad 0 \notin 1 + \nu \Delta g(z).$$

Theorem 4.1 implies that there exists a function $\alpha \in \mathbf{RH}^\infty$ such that $\mathrm{Re}\,(1 + \nu\Delta g(z))\alpha(z) > 0$. Thus the problem takes the cone optimization form (5.1) with $F = (1\ 0)$, $G = (T_1\ T_2)$, and $h = \mathrm{col}(\alpha, Q\alpha)$.

The set Δ is a polytope; hence we can use linear programming as described in section 6, Case 3. To approximate it by finite-dimensional problems, we choose a simple idea of discretization. Taking into account only the finite grid $\{z_k\}_{k=1}^K$, representing the upper half of $\mathbb{T}$, and the first N coefficients of the function h, the inequality (6.12) gives the finite-dimensional linear program

$$A_{KN} H_N \succ 0, \tag{9.3}$$

where the matrix A_{KN} is of the size $4K \times 2N$. We solve this feasibility problem as explained in (6.16) except that we choose another set $\mathcal{H}$, namely,

$$\max\{\epsilon \;\big|\; A_{KN} H_N \succeq \epsilon,\ -1 \preceq H_N \preceq 1\}. \tag{9.4}$$

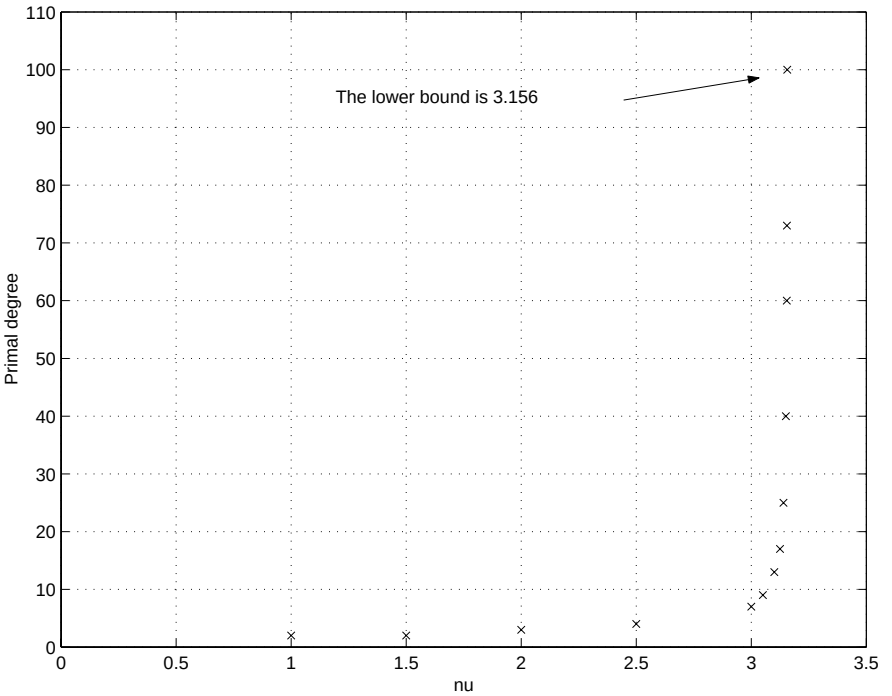

FIG. 9.2. *The primal algorithm produces lower bounds on* ν_{opt}.

The dual problem (6.15) is approximated precisely in the same manner to get the finite-dimensional linear program

$$\begin{array}{rcl} A_{12}X & = & 0, \\ A_{22}X & \succeq & 0, \\ A_{32}X & = & 1, \end{array} \tag{9.5}$$

where the $(2N+4K)$-dimensional vector X absorbs N coefficients of the function $p \in \mathbf{H}_0^1$ and K values of the coordinate functions μ from (6.15). Since the discretization can have difficulties dealing with equalities, we slightly modify the problem (9.5) as

$$\min\{\gamma \mid -\gamma \preceq A_{12}X \preceq \gamma,\ A_{22}X \succeq 0,\ A_{32}X = 1\}. \tag{9.6}$$

This is almost the discretization of (5.6). The difference is that we replace the integral norm with the uniform one (which is approved by Lemma 5.8). The dual algorithm finds a solution if γ is zero. The details of the algorithms can be found in [8, 9].

Take the following functions:

$$T_1(z) = \frac{z^5 + 3z^4 + 2z^3 + 4z^2 + 5z + 3}{z^3 - z^2 - 4z + 12}, \quad T_2(z) = z^2 + \frac{1}{2}.$$

Since $T_1/T_2 \notin \mathbf{H}^\infty$, the solution to the optimization problem is not trivial.

We run the primal algorithm in the linear programming form (9.4) for different values of ν. For small enough ν, it finds a solution, and we increase the value. We stop the optimization at $\nu_{low} = 3.156$ when the degree of approximation N has reached 100. It becomes hard for the linear solver to find an approximation of higher degree because

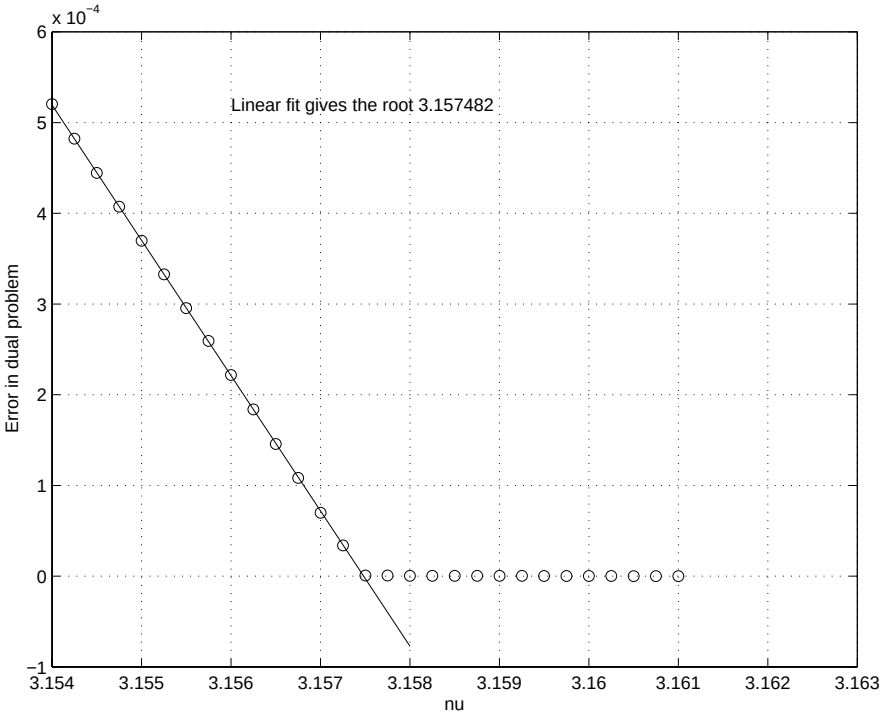

FIG. 9.3. *The dual algorithm gives the opposite side bounds on* ν_{opt}.

the dimension of the linear program (9.4) at this step is already of size 1200×200. The plot of N versus ν is shown in Figure 9.2.

To estimate how far the lower bound ν_{low} is from the optimal value, we use the dual problem in the form (9.6). If $\nu > \nu_{opt}$, the error γ may be minimized to zero. The upper bound ν_{upp} obtained by the dual algorithm is 3.1575. Hence the primal solution for ν_{low} has a good level of suboptimality (about 0.05%). The value of γ as a function of ν is depicted in Figure 9.3.

It happens that the error γ in our example exhibits the linear dependence on ν for $\nu < \nu_{opt}$, which can be also used to find ν_{opt} as a solution to $\gamma(\nu) = 0$.

10. Conclusion. There is a number of design problems in control theory which can be stated as the quasiconvex optimization (3.4). Given a level of suboptimality, the corresponding convex problem can be solved by finite-dimensional approximations. However, these approximations give only one-sided bounds on the optimal value. In this paper, the dual representation (5.7) to this quasiconvex optimization problem has been derived using convex duality arguments in a Banach space setting. Opposite bounds for the optimal value can be obtained by solving the quasiconvex problems (5.8), (5.9). Hence the quasiconvex optimization problem (3.4) can be solved by a primal-dual method followed by a line search on ν.

Appendix A. Proofs of Proposition 5.1 and Lemma 5.2.

PROPOSITION A.1. *Let* $\Delta \subset \mathbb{C}^n$ *be a compact set, and* $g \in C(\mathbb{C}^n)$. *Then*

$$G = \inf_{\delta \in \Delta} \operatorname{Re} \delta^T g \in C.$$

Proof. Let $z_k \to z_0$ as $k \to +\infty$. We have to prove that $G(z_k) \to G(z_0)$. Obviously, for all $\delta \in \Delta$, it holds that $G(z_k) \le \operatorname{Re} \delta^T g(z_k)$, and hence

$$\limsup_{k \to +\infty} G(z_k) \le G(z_0).$$

To prove the opposite inequality, let us consider a subsequence $\{z_{k_n}\}$ of $\{z_k\}$ such that $G(z_{k_n})$ has a limit. The set Δ is compact, and the function $\operatorname{Re} \delta^T g(z_{k_n})$ is continuous (linear) with respect to δ. Hence there exists $\delta_n \in \Delta$ such that $G(z_{k_n}) = \operatorname{Re} \delta_n^T g(z_{k_n})$. The sequence $\{\delta_n\}$ is compact, and then there exists a limit point $\delta_0 \in \Delta$. Moreover,

$$G(z_{k_n}) \to \operatorname{Re} \delta_0^T g(z_0) \ge G(z_0).$$

Since the subsequence $\{z_{k_n}\}$ is arbitrary, we conclude that

$$\liminf_{k \to +\infty} G(z_k) \ge G(z_0).$$

The proposition is proved. ∎

PROPOSITION A.2.

1. *The function*

$$\Gamma(h) := \inf_{z \in \mathbb{T}} \inf_{\delta \in \Delta_\nu} J_\delta(h, z) \tag{A.1}$$

is concave, continuous in the uniform topology of $\mathbf{A}$*, and positively homogeneous:*

$$\Gamma(\lambda h) = \lambda \Gamma(h) \quad \forall h \in \mathbf{A},\ \lambda \in \mathbb{R}_+.$$

Proof. Recall that $J_\delta(h, z) = \operatorname{Re}\,(F(z) + \delta^T G(z))h(z)$. The function Γ is concave and positively homogeneous as an infimum of linear functions.

To prove that the function Γ is continuous with respect to the topology of uniform convergence in $\mathbf{A}$, consider the identity

$$\operatorname{Re} \Phi_\delta h_1 = \operatorname{Re} \Phi_\delta h_2 + \operatorname{Re} \Phi_\delta (h_1 - h_2).$$

Taking the infimum over $\mathbb{T}$ and Δ_ν of both sides yields

$$\Gamma(h_1) \ge \Gamma(h_2) + \inf_{z \in \mathbb{T}} \inf_{\delta \in \Delta_\nu} \operatorname{Re} \Phi_\delta(z)(h_1(z) - h_2(z)).$$

Since h_1 and h_2 are arbitrary functions in $\mathbf{A}$ and can be interchanged, we get

$$\begin{aligned} |\Gamma(h_2) - \Gamma(h_1)| &\le \sup_{z \in \mathbb{T}} \sup_{\delta \in \Delta_\nu} |\operatorname{Re} \Phi_\delta(z)(h_2(z) - h_1(z))| \\ &\le \left(\|F\|_\infty + \sup_{\delta \in \Delta_\nu} |\delta|\, \|G\|_\infty \right) \|h_2 - h_1\|_\infty. \end{aligned}$$

Thus the function Γ is continuous (in fact, even Lipschitz). The proposition is proved. ∎

Proof of Proposition 5.1. (2) $\Rightarrow$ (1) Since the set $\mathbf{RH}^\infty$ is uniformly dense in $\mathbf{A}$ and, by Proposition A.2, Γ is continuous in the uniform topology of $\mathbf{A}$, we have

$$\gamma_{opt} = \sup_{h \in \mathcal{B}\mathbf{RH}^\infty} \inf_{z \in \mathbb{T}} \inf_{\delta \in \Delta_\nu} J_\delta(h, z).$$

Hence $\gamma_{opt} > 0$ obviously implies (5.1).

(1) $\Rightarrow$ (2) Let $h_0 \in \mathbf{RH}^\infty$ be such that (5.1) holds. The function $J_\delta(h_0, z)$ is continuous on (z, δ), and the set $\mathbb{T} \times \Delta$ is compact. Then there exists (z_0, δ_0) such that

$$\Gamma(h_0) = \inf_{z\in\mathbb{T}} \inf_{\delta\in\Delta_\nu} J_\delta(h_0, z) = J_{\delta_0}(h_0, z_0) > 0.$$

Finally,

$$\gamma_{opt} \geq \sup_{h\in\mathcal{B}\mathbf{RH}^\infty} \Gamma(h) \geq \Gamma\left(\frac{h_0}{\|h_0\|_\infty}\right) = \frac{\Gamma(h_0)}{\|h_0\|_\infty} = \frac{J_{\delta_0}(h_0, z_0)}{\|h_0\|_\infty} > 0. \qquad \square$$

Proof of Lemma 5.2. Recall the notation from (3.1) and (3.2),

$$\Phi_\delta = F + \delta^T G, \quad J_\delta(h, z) = \operatorname{Re} \Phi_\delta(z) h(z),$$

and denote

$$\gamma_{\mathbf{H}^\infty} = \sup_{h\in\mathcal{B}\mathbf{H}^\infty} \operatorname*{ess\,inf}_{z\in\mathbb{T}} \inf_{\delta\in\Delta_\nu} J_\delta(h, z).$$

It is obvious that $\gamma_{\mathbf{H}^\infty} \geq \gamma_{opt}$. We have to prove the opposite inequality.

By definition, for any $\epsilon > 0$, there is a function $h \in \mathcal{B}\mathbf{H}^\infty$ such that

$$J_\delta(h, z) \geq \gamma_{\mathbf{H}^\infty} - \epsilon$$

for all $\delta \in \Delta_\nu$ and almost all $z \in \mathbb{T}$. The function J_δ is harmonic as the real part of analytical function. Hence, by the mean value theorem,

$$J_\delta(h, rz) \geq \operatorname*{ess\,inf}_{z\in\mathbb{T}} J_\delta(h, z) \geq \gamma_{\mathbf{H}^\infty} - \epsilon$$

for all $\delta \in \Delta$, $z \in \mathbb{T}$, and $0 \leq r < 1$.

Denote $h_r(z) = h(rz)$ for $0 \leq r < 1$. It holds that $h_r \in \mathbf{A}$ and $\|h_r\|_\infty \leq \|h\|_\infty$; hence $h_r \in \mathcal{B}\mathbf{A}$. Denote similarly $F_r(z) = F(rz)$ and $G_r(z) = G(rz)$. We then obtain

$$\begin{aligned} J_\delta(h_r, z) &= \operatorname{Re} \Phi_\delta(z) h_r(z) = J_\delta(h, rz) + \operatorname{Re} (\Phi_\delta(z) - \Phi(rz)) h_r(z) \\ &\geq \gamma_{\mathbf{H}^\infty} - \epsilon - \sup_{z\in\mathbb{T}} |\Phi_\delta(rz) - \Phi_\delta(z)| \\ &\geq \gamma_{\mathbf{H}^\infty} - \epsilon - \|F - F_r\|_\infty - |\delta| \|G - G_r\|_\infty. \end{aligned}$$

Therefore,

$$\Gamma(h_r) = \inf_{\delta\in\Delta_\nu} \inf_{z\in\mathbb{T}} J_\delta(h_r, z) \geq \gamma_{\mathbf{H}^\infty} - \epsilon - \|F - F_r\|_\infty - \sup_{\delta\in\Delta_\nu} |\delta| \, \|G - G_r\|_\infty.$$

The functions F and G are continuous, and the Fatou theorem [7] implies that $\|F - F_r\|_\infty \to 0$ and $\|G - G_r\|_\infty \to 0$ as $r \to 1$. The constant $\sup_{\delta\in\Delta_\nu} |\delta|$ is bounded. Thus

$$\gamma_{opt} \geq \lim_{r\to 1} \Gamma(h_r) \geq \gamma_{\mathbf{H}^\infty} - \epsilon$$

for all $\epsilon > 0$. Hence $\gamma_{opt} \geq \gamma_{\mathbf{H}^\infty}$. $\square$

Appendix B. Proof of Theorem 5.3. We cite first the classical result which gives the basic Banach duality relation [7, 16]. Recall the notation (7.2)

$$\langle f, g \rangle = \operatorname{Re} \int_{\mathbb{T}} f(z)^T g(z) \, dm(z).$$

THEOREM B.1. *Let $1 \le p \le +\infty$, $1/p + 1/q = 1$, and $f \in \mathbf{L}^p$. Then the distance from the f to $\mathbf{H}^p$ is*

$$\operatorname{dist}_{\mathbf{L}^p}(f, \mathbf{H}^p) = \sup_{h \in \mathcal{B}\mathbf{H}_0^q} \langle f, h \rangle.$$

There exists a function $f_{opt} \in \mathbf{H}^p$ such that $\operatorname{dist}_{\mathbf{L}^p}(f, \mathbf{H}^p) = \|f - f_{opt}\|_p$. The function f_{opt} is unique if $p \neq +\infty$.

COROLLARY B.2. *Under the same conditions as in Theorem* B.1*, it holds that*

$$\operatorname{dist}_{\mathbf{L}^p}(f, \mathbf{H}_0^p) = \sup_{h \in \mathcal{B}\mathbf{H}^q} \langle f, h \rangle.$$

Proof. Consider a function $f(z)/z \in \mathbf{L}^p$, and apply Theorem B.1. ∎

Now we prove the following lemma.

LEMMA B.3. *Let a measurable function $\phi\colon \mathbb{C}^n \times \mathbb{C} \to \mathbb{R}$ be concave and continuous in the first argument. Denote $\phi_h(z) = \phi(h(z), z)$. Then*

$$\sup_{h \in \mathcal{B}\mathbf{H}^\infty(\mathbb{C}^n)} \operatorname*{ess\,inf}_{z \in \mathbb{T}} \phi_h(z) = \inf_{w \in \mathcal{S}\mathbf{L}^1(\mathbb{R}_+)} \sup_{h \in \mathcal{B}\mathbf{H}^\infty(\mathbb{C}^n)} \langle \phi_h, w \rangle. \tag{B.1}$$

Proof. Note that

$$\operatorname*{ess\,inf}_{z \in \mathbb{T}} \phi_h(z) = \inf_{w \in \mathcal{S}\mathbf{L}^1(\mathbb{R}_+)} \langle \phi_h, w \rangle.$$

The set $\mathcal{B}\mathbf{H}^\infty$ is convex and *weak compact, the set $\mathcal{S}\mathbf{L}^1(\mathbb{R}_+)$ is convex, and the function $\langle \phi_h, w \rangle$ is *weak continuous and concave on h and continuous and convex on w (even linear). Hence, by Ky Fan's min-max theorem [5], the order of sup and inf can be interchanged. ∎

Proof of Theorem 5.3. Denote

$$\mathcal{J}_\nu(h, z) = \inf_{\delta \in \Delta_\nu} J_\delta(h, z).$$

This function is concave in h. By Proposition A.1, it is also continuous in h. Using Lemma B.3, the min-max theorem [5], and Theorem B.1, we have

$$\begin{aligned}
&\sup_{h \in \mathcal{B}\mathbf{H}^\infty} \operatorname*{ess\,inf}_{z \in \mathbb{T}} \mathcal{J}_\nu(h, z) = \inf_{w \in \mathcal{S}\mathbf{L}^1(\mathbb{R}_+)} \sup_{h \in \mathcal{B}\mathbf{H}^\infty} \langle \mathcal{J}_\nu(h, \cdot), w \rangle \\
&= \inf_{w \in \mathcal{S}\mathbf{L}^1(\mathbb{R}_+)} \sup_{h \in \mathcal{B}\mathbf{H}^\infty} \inf_{\delta(z) \in \Delta_\nu} \langle \operatorname{Re} \Phi_\delta h, w \rangle = \inf_{w \in \mathcal{S}\mathbf{L}^1(\mathbb{R}_+)} \inf_{\delta(z) \in \Delta_\nu} \sup_{h \in \mathcal{B}\mathbf{H}^\infty} \langle \Phi_\delta^T w, h \rangle \\
&= \operatorname{dist}_{\mathbf{L}^1}([F + \mathbf{L}^\infty(\Delta_\nu)^T G] \mathcal{S}\mathbf{L}^1(\mathbb{R}_+), \mathbf{H}_0^1). \qquad \blacksquare
\end{aligned}$$

Appendix C. Proof of Theorem 5.6. To begin with, we prove the following lemma. All details about Borel measures and Lebesgue decomposition can be found in [27].

LEMMA C.1. *Let $\Phi \in C$, $g \in \mathbf{L}^1$, and w be the density function of a real Borel measure μ on $\mathbb{T}$. Then*

$$\|\Phi w + g\|_1 = \|\Phi w_c + g\|_1 + \int_{\mathbb{T}} |\Phi| \, d\mu_s, \tag{C.1}$$

where $\mu = w_c \, dm + \mu_s$ is the Lebesgue decomposition to absolutely continuous and singular parts.

Proof. Due to the triangular inequality, it is obvious that

$$\|\Phi w + g\|_1 \le \|\Phi w_c + g\|_1 + \int_{\mathbb{T}} |\Phi|\, d\mu_s.$$

Since $m(\operatorname{supp}(\mu_s)) = 0$, for any $\epsilon > 0$, there is an open set $T_\epsilon \subset \mathbb{T}$ such that $\operatorname{supp}(\mu_s) \subset T_\epsilon$ and $m(T_\epsilon) \le \epsilon$. Then the following inequality holds:

$$\begin{aligned}
\|\Phi w + g\|_1 &= \|\Phi w_s + \Phi w_c + g\|_1 = \int_{\mathbb{T}\setminus T_\epsilon} |\Phi w_c + g|\, dm + \int_{T_\epsilon} |\Phi w_s + \Phi w_c + g|\, dm \\
&\ge \int_{\mathbb{T}\setminus T_\epsilon} |\Phi w_c + g|\, dm + \int_{T_\epsilon} |\Phi|\, d\mu_s - \int_{T_\epsilon} |\Phi w_c + g|\, dm \\
&\xrightarrow{\epsilon\to 0} \|\Phi w_c + g\|_1 + \int_{\operatorname{supp}(\mu_s)} |\Phi|\, d\mu_s = \|\Phi w_c + g\|_1 + \int_{\mathbb{T}} |\Phi|\, d\mu_s.
\end{aligned}$$

This proves the lemma. □

Proof of Theorem 5.6. Denote

$$\gamma_{min} = \inf_{\delta(z)\in\Delta_\nu} \inf_{h\in\mathbf{H}_0^1} \inf_{\|w\|_1=1} \|\Phi_\delta w - h\|_1,$$

and let $\delta_i \in \mathbf{L}^\infty(\Delta_\nu)$ and $w_j \in \mathcal{S}\mathbf{L}^1(\mathbb{R}_+)$ be such that

$$\inf_{h\in\mathbf{H}_0^1} \|\Phi_{\delta_i} w_j - h\|_1 \to \gamma_{min}, \quad i, j \to +\infty.$$

Without loss of generality, we assume that $\delta_i \in C$ because the set $\mathbf{L}^\infty(\Delta_\nu) \cap C$ is *weakly dense in $\mathbf{L}^\infty(\Delta_\nu)$. The functions F and G belong to $\mathbf{A}$; therefore,

$$\Phi_{\delta_i} = F + \delta_i^T G \in C.$$

Embed the set $\mathcal{S}\mathbf{L}^1(\mathbb{R}_+)$ in the unit sphere of real Borel measures on $\mathbb{T}$ as $w \hookrightarrow \mu$,

$$\mu(\Omega) = \int_\Omega w(z)\, dm(z).$$

The latter set is *weakly compact, so there exists a *weak limit point μ_{opt} of the sequence $\{\mu_j\}_{j=1}^{+\infty}$. The measure μ_{opt} can be decomposed to the absolutely continuous μ_c and singular parts μ_s as $\mu_{opt} = \mu_c + \mu_s$. This corresponds to the decomposition of a generalized density w_{opt} as $w_{opt} = w_c + w_s$, where w_c is a regular function in $\Re\mathbf{L}_+^1$ and w_s is a generalized function which is equal to zero on $\mathbb{T} \setminus E$ and $m(E) = 0$.

We claim that w_{opt} can be chosen in such a way that either w_c or w_s is zero. Indeed, let $\lambda_0 = \|w_c\|_1$. Then

$$w_{opt} = \lambda_0 \widetilde{w}_c + (1 - \lambda_0)\widetilde{w}_s,$$

where $\widetilde{w}_c$ and $\widetilde{w}_s$ are normalized densities. In the case when $\lambda_0 = 0$, the claim is proved. So assume that $\lambda_0 > 0$. Using Lemma C.1, we have a decomposition

$$\|\Phi w_{opt} - h\|_1 = \lambda_0 \left\| \Phi\widetilde{w}_c - \frac{h}{\lambda_0} \right\|_1 + (1 - \lambda_0) \int_E |\Phi|\, d\widetilde{\mu}_s$$

whenever $h \in \mathbf{H}_0^1$ and $\Phi \in C$. This implies that

$$\begin{aligned}\inf_{h\in\mathbf{H}_0^1} \|\Phi w_{opt} - h\|_1 &= \lambda_0 \inf_{h\in\mathbf{H}_0^1} \|\Phi \widetilde{w}_c - h\|_1 + (1-\lambda_0)\int_E |\Phi|\, d\widetilde{\mu}_s \\ &= \inf_{\lambda\in[0,1]} \left(\lambda \inf_{h\in\mathbf{H}_0^1} \|\Phi \widetilde{w}_c - h\|_1 + (1-\lambda)\int_E |\Phi|\, d\widetilde{\mu}_s\right).\end{aligned}$$

The function is linear with respect to λ. Hence 0 or 1 is always the optimal value. Moreover, if the optimal λ is 0, then the similar argument proves that the singular part $\widetilde{w}_s$ of the optimal density w_{opt} can be chosen as a Dirac δ-function at one of the points $z_0 = \arg\min_{z\in\mathbb{T}} |\Phi(z)|$.

Thus we have proved that, for any $\Phi \in C$, there exists $\widetilde{w}_c \in \mathcal{S}\Re\mathbf{L}_+^1$ such that

$$\inf_{h\in\mathbf{H}_0^1} \inf_{\|w\|_1=1} \|\Phi w - h\|_1 = \min\left\{\inf_{h\in\mathbf{H}_0^1} \|\Phi\widetilde{w}_c - h\|_1,\ \min_{z\in\mathbb{T}} |\Phi(z)|\right\}.$$

Hence, denoting δ_{opt} a *weak limit point of the sequence $\{\delta_i\}_{i=1}^{+\infty}$, we get

$$\begin{aligned}\gamma_{min} &= \inf_{\delta(z)\in\Delta_\nu} \min\left\{\inf_{h\in\mathbf{H}_0^1} \|\Phi_\delta \widetilde{w}_c - h\|_1,\ \min_{z\in\mathbb{T}} |\Phi_\delta(z)|\right\} \\ &= \min\left\{\inf_{h\in\mathbf{H}_0^1} \|\Phi_{\delta_{opt}} \widetilde{w}_c - h\|_1,\ \operatorname*{ess\,inf}_{z\in\mathbb{T}} |\Phi_{\delta_{opt}}(z)|\right\}.\end{aligned}$$

To complete the proof, we use Theorem B.1 to conclude that there exists the optimal function h_{opt} such that

$$\inf_{h\in\mathbf{H}_0^1} \|\Phi_{\delta_{opt}} \widetilde{w}_c - h\|_1 = \|\Phi_{\delta_{opt}} \widetilde{w}_c - h_{opt}\|_1.$$

Now the condition $\gamma_{min} = 0$ can be easily transformed to that stated in Theorem 5.6. The proof is finished. ∎

Appendix D. Proofs of Propositions in section 6.

Proof of Proposition 6.1. (1) ⇒ (2) Denote by w_λ the Poisson kernel at the point $\lambda \in \mathbb{D}$:

$$w_\lambda(z) = \frac{1-|\lambda|^2}{|z-\lambda|^2}.$$

It is clear that $w_\lambda \in \mathbf{L}^1(\mathbb{R}_+)$ and $\|w_\lambda\|_1 = 1$. Since

$$F(\lambda) = \int_{\mathbb{T}} F(z) w_\lambda(z)\, dm(z) = \int_{\mathbb{T}} (F(z)w_\lambda(z) - p(z))\, dm(z)$$

for all $p \in \mathbf{H}_0^1$, we have the inequality

$$|F(\lambda)| \le \inf_{p\in\mathbf{H}_0^1} \|Fw_\lambda - p\|_1. \tag{D.1}$$

The infimum can be calculated by the minimum norm theorem (see Corollary B.2):

$$\begin{aligned}|F(\lambda)| &\le \inf_{p\in\mathbf{H}_0^1} \|Fw_\lambda - p\|_1 = \sup_{h\in\mathcal{B}\mathbf{H}^\infty} \int_{\mathbb{T}} \operatorname{Re}\left(F(z)h(z)\right) w_\lambda(z)\, dm(z) \\ &= \sup_{h\in\mathcal{B}\mathbf{H}^\infty} \operatorname{Re} F(\lambda)h(\lambda) = |F(\lambda)|.\end{aligned}$$

Hence (D.1) is the equality

$$|F(\lambda)| = \inf_{p \in \mathbf{H}_0^1} \|Fw_\lambda - p\|_1 = \|Fw_\lambda - p_0\|_1,$$

where the existence of p_0 is guaranteed by the same minimum norm theorem.

Thus $|F(\lambda)| = 0$ implies that $Fw_\lambda \in \mathbf{H}_0^1$.

(2) $\Rightarrow$ (1) Denote the entries of F by F_k, and suppose that there exists a $w \in \mathbf{L}^1(\mathbb{R}_+) \setminus 0$ such that

$$F_k(z)w(z) = zp_k(z), \quad p_k \in \mathbf{H}^1. \tag{D.2}$$

For all k, the function $zp_k(z)/F_k(z)$ is analytical everywhere in $\mathbb{D}$ except the zeros of F_k. However, these functions are the same function w from (D.2); hence w is the analytical function everywhere in $\mathbb{D}$ except the common zeros of F_k, which are the zeros of $|F|$.

Assume that there are no zeros of $|F|$ in $\mathbb{D}$, and so $w \in \mathbf{H}^1$. The only analytical functions that take real values on $\mathbb{T}$ are constants. Hence w is the constant function. Furthermore, $w(0) = 0$ by (D.2). Then $w = 0$, which contradicts the assumption that $w \neq 0$. Therefore, there must exist a zero of $|F|$ in $\mathbb{D}$. ∎

Proof of Proposition 6.2. (1) $\Rightarrow$ (2) The inequality (6.2) implies that $\operatorname{Re}(F(\lambda) + \delta^T G(\lambda))h(\lambda) > 0$ for all $\lambda \in \mathbb{D}$. Then

$$(Fh + \delta^T Gh)^{-1} \in \mathbf{A} \quad \forall \delta \in \nu\Delta. \tag{D.3}$$

In particular, it gives $(Fh)^{-1} \in \mathbf{A}$. The function $g = h(Fh)^{-1} \in \mathbf{A}$ satisfies $Fg = 1$, and (D.3) becomes

$$(1 + \delta^T Gg)^{-1} = (Fh)^{-1}(Fh + \delta^T Gh)^{-1} \in \mathbf{A} \quad \forall \delta \in \nu\Delta. \tag{D.4}$$

Since, for each $z \in \mathbb{T}$, one can choose

$$\delta = \alpha\overline{G(z)g(z)}/|G(z)g(z)|, \quad \alpha \in [0, \nu],$$

(D.4) implies that $|G(z)g(z)| \notin [\nu^{-1}, +\infty)$. Hence $\|Gg\|_\infty < \nu^{-1}$.

(2) $\Rightarrow$ (1) By Rouché's theorem [27], we get (D.4). Thus

$$1 + \delta^T G(z)g(z) \neq 0 \quad \forall z \in \mathbb{T},\ \delta \in \nu\Delta.$$

By Theorem 4.1, there exists a function $\alpha \in \mathbf{A}$ such that

$$\operatorname{Re}(1 + \delta^T G(z)g(z))\alpha(z) > 0 \quad \forall z \in \mathbb{T},\ \delta \in \nu\Delta.$$

Finally, for $h = g\alpha \in \mathbf{A}$, we have

$$\operatorname{Re}(F(z) + \delta^T G(z))h(z) = \operatorname{Re}(1 + \delta^T G(z)g(z))\alpha(z) > 0. \qquad ∎$$

WORST CASE DESIGN FOR ROBUST COMPENSATION*

SHAUL GUTMAN† AND EYTAN PALDI‡

Abstract. We consider the problem

$$\operatorname*{Max}_{F} \quad \operatorname*{Min}_{c(p,F)=0} \quad h(p,F),$$

where $F \in \mathcal{R}^r$, $p \in \mathcal{R}^m$, and where $c(\cdot)$ and $h(\cdot)$ are C^1. Let $\phi(F) = \operatorname{Min}_{c(p,F)=0} h(p,F)$. We show, by means of simple examples, that $\phi(\cdot)$ is, in general, discontinuous. We develop in this paper necessary conditions for the case where $\phi(\cdot)$ is continuous (but not necessarily differentiable). In an alternative approach (which is computationally inferior), we treat the discontinuous case as well. We apply the results to robust control in linear systems where p stands for the (structured) real parameter uncertainty vector and F stands for the control parameters vector. We demonstrate the results by means of examples.

Key words. robust control, min-max

1. Introduction.

Robust control has attracted the attention of researchers for more than three decades. Basically, we consider a linear time invariant plant with (constant) real parameters whose values are known to lie in some prescribed (ellipsoidal) uncertainty set. The uncertainty structure, however, is arbitrary. We seek a fixed (dynamic) compensator in closed loop such that the closed loop spectrum lies in a prescribed set in the complex plane (relative stability) for all values in the uncertainty set. The compensator has any desired structure, like reduced order, or zeros in the left half plane (LHP). Among infinitely many possible robust controllers, we identify a controller with a clear geometrical meaning, one that maximizes the stability margin. In other words, we seek a controller so that we can increase the uncertainty radius to the maximum while maintaining (relative) stability. It turns out that such a controller leads to a max-min problem as pointed out in [1]. The cost in such a max-min problem is the (ellipsoidal) distance, and the constraint is the stability boundary described by the critical polynomial [2].

While problems of max-min nature are discussed in the literature [3, 4, 5], we treat the robust control problem independently since it possesses some exclusive properties. As explained in [5], max-min creates a differentiability problem, since, after the first operation (minimization), the cost may no longer be smooth. Moreover, as will be demonstrated in section 7, at a global max-min point, a small variation in the outer variables (max) may cause a jump in $\phi(\cdot)$. It turns out that, while the largest ellipsoid may cause a jump, a robust compensator associated with a fixed uncertainty ellipsoid never creates a jump. In mathematical terms, the fixed uncertain ellipsoid is associated with $\operatorname{Max}_F \operatorname{Min}_{p\in P} h(p,F)$, where the set P depends only on p (and not on F). On the other hand, the maximum uncertain ellipsoid is associated with

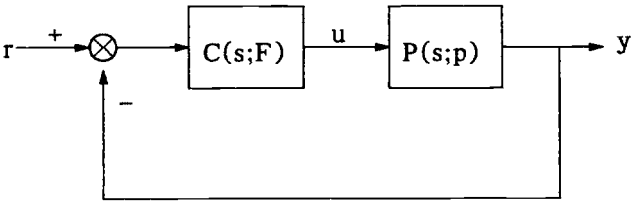

FIG. 1.

$\text{Max}_F \ \text{Min}_{c(p,F)=0} h(p,F)$, where the coupling of p and F in the inner operation is evident. To find necessary conditions for max-min, articles [3, 4, 5] use the directional derivative, which in turn requires that $\phi(\cdot)$ is continuous.

In this paper, we use the Lagrange multiplier method for the inner operation. As for the outer operation, we show that, under mild conditions, at extremum, the number of tangent points needed is related to the (reduced) number of control parameters. It shows, in turn, that the necessary conditions presented in [1] form a special case of our approach. We also present an alternative approach, which is capable of treating jumps. However, computationally this approach is inferior to the first approach. The necessary conditions presented here have the form of a set of polynomial equations. The solutions of these equations are candidates for robust compensation. To find all real solutions, we suggest using a probability one homotopy method like HOMPACK [6]. Finally, we apply to each real solution a robust analysis like [7] and select a robust compensator.

The paper is organized as follows. In section 2, we recall results from root clustering and parameter space, in particular, the critical polynomial, and state our objective. In section 3, we present a max-min formulation associated with the largest ellipsoid contained in the parameter space. Likewise, we present a max-min formulation associated with a fixed uncertainty ellipsoid. In sections 4 and 5, we find necessary conditions for the largest ellipsoid under the assumption that $\phi(\cdot)$ is continuous, while, in section 6, we discuss a more general case using an alternative approach. In section 7, we present necessary conditions for a fixed ellipsoid. Finally, in section 8, we demonstrate some of the results by means of examples.

2. Parameter space and problem statement. We consider a linear time invariant plant P and a linear time invariant controller C connected in a feedback form. We denote the plant's and the controller's transfer functions by $P(s;p)$ and $C(s;F)$, respectively, where $s \in \mathbb{C}$ is the usual complex variable, $p \in \Omega \subset \mathcal{R}^m$ is the plant's uncertainty parameter vector, Ω is the uncertainty set, and $F \in \mathcal{R}^r$ is the controller's design parameter vector. Let $\Delta(s;p,F)$ be the closed loop characteristic polynomial, and let $\sigma(\Delta)$ be the closed loop spectrum. As an illustration, consider the unit feedback configuration as depicted in Figure 1.

Let

$$P(s;p) = D_p^{-1}(s;p)N_p(s;p),$$
$$C(s;F) = N_c(s;F)D_c^{-1}(s;F). \tag{1}$$

Then the characteristic equation $|I + P(s;p)C(s;F)| = 0$ leads to the characteristic polynomial

$$\Delta(s;p,F) = |D_p(s;p)D_c(s;F) + N_p(s;p)N_c(s;F)|. \tag{2}$$

To discuss the matrix version, consider a strictly proper plant with realization

$$\begin{aligned} \dot{x}_p &= A_p(p)x_p + B_p(p)u, \\ y &= C_p(p)x_p. \end{aligned} \tag{3}$$

We seek a stabilizing compensator of fixed order of the form

$$\begin{aligned} \dot{x}_c &= A_c x_c + B_c(r-y), \\ u &= C_c x_c + D_c(r-y), \end{aligned} \tag{4}$$

where r is a reference signal. Combining (3) and (4) in closed loop, we obtain for $r=0$ and for $x=[x_p' \;\; x_c']'$

$$\dot{x} = A(p,F)x, \tag{5}$$

where

$$A(p,F) = A(p) - B(p)FC(p), \tag{6}$$

$$A(p) = \begin{bmatrix} A_p(p) & 0 \\ 0 & 0 \end{bmatrix}, \quad B(p) = \begin{bmatrix} B_p(p) & 0 \\ 0 & I \end{bmatrix},$$

$$C(p) = \begin{bmatrix} C_p(p) & 0 \\ 0 & I \end{bmatrix}, \quad F = \begin{bmatrix} D_c & C_c \\ B_c & A_c \end{bmatrix}. \tag{7}$$

Design objective. Given an uncertain plant P and a region $\aleph \subset \mathbb{C}$ in the complex plane, select F such that $\sigma[\Delta(s;p,F)] \subset \aleph$ or $\sigma[A(p,F] \subset \aleph$ for all $p \in \Omega$. Such a controller is called *robust*.

The root clustering $\aleph$ may represent asymptotic stability, like the left half plane and unit disk, or relative stability like the left hyperbola. Moreover, in some applications, we require a controller of fixed structure (including fixed order) or some other properties like stable controllers. These requirements are included in the above design objective. As mentioned in the introduction, we achieve our objective using the concept of worst case design in the parameter space. To this end, we need an important instrument, known as the *critical polynomial* $c(p,F)$ in the parameter space. This polynomial vanishes at the (relative) stability boundary and is positive in the interior. As early as 1929, it was recognized [8] that the Hurwitz determinant is a critical polynomial for the left half plane, and, in 1963, the unit disk counterpart was constructed [9]. Recently [2, 10], as a part of a general root clustering theory, a critical polynomial for an arbitrary region was constructed. Consider a region $\aleph \subset \mathbb{C}$ in the complex plane

$$\aleph = \left\{ x + jy : f(x,y) = \sum_{i,j} f_{ij} x^i y^j < 0 \right\}, \tag{8}$$

where $f(x,y)$ is a given polynomial in the two real variables x and y. Define the coefficients ϕ_{ik} in the following way:

$$\phi(\alpha,\beta) = f\left(\frac{\alpha+\beta}{2}, \frac{\alpha-\beta}{2j}\right) = \sum \phi_{ik}\alpha^i\beta^k. \tag{9}$$

Then $\Phi = [\phi_{ik}]$ is Hermitian and

$$\aleph = \{s \in \mathbb{C} : \phi(s, \bar{s}) < 0\}. \tag{10}$$

By construction, if $s = x + jy \in \partial\aleph$, the boundary of $\aleph$, then $\phi(s, \bar{s}) = 0$. In 1983, it was recognized [11] that, in parameter space analysis, a region $\aleph$ should be *regular* in the following sense.

DEFINITION 2.1. *$\phi(\alpha, \beta)$, defined above, is* regular *if α, $\beta \in \aleph \Rightarrow \phi(\alpha, \beta) \neq 0$. We say that $\aleph$ is regular if $\phi(\alpha, \beta)$ is regular.*

Note that, in previous articles, we have used the term H-transformability to describe regularity. Following [2, 12], we define the critical polynomial $c(p, F)$ by a double resultant operator as follows:

$$c(p, F) = \mathrm{Res}_\lambda[\Delta(\lambda; p, F), \mathrm{Res}_s[\bar{\Delta}(s; p, F), -\phi(\lambda, s)]], \tag{11}$$

where "Res" is the resultant of two polynomials, $\Delta(\cdot)$ is the (possibly complex) characteristic polynomial, and $\bar{\Delta}(\cdot)$ is the conjugate complex of $\Delta(\cdot)$. Likewise, given a matrix $A(p, F) \in \mathbb{C}^{n \times n}$,

$$c(p, F) = (-1)^n \det\left[\sum \phi_{ik} A^i \otimes \bar{A}^k\right] \tag{12}$$

where $\otimes$ is the Kronecker product of two matrices.

In this matrix version, we will feel free to replace the vector F by an appropriate matrix F. Now consider the image $\hat{\aleph}$ of $\aleph$ in the parameter space.

$$(i) \quad \hat{\aleph} = \{(p, F) \in \mathcal{R}^{m+r} : \sigma(A(p, F)) \subset \aleph\},$$

and in the polynomial setting,

$$\text{(ii)} \quad \hat{\aleph} = \{(p, F) \in \mathcal{R}^{m+r} : \sigma(\Delta(s; p, F)) \subset \aleph\}. \tag{13}$$

It is known [2] that

$$\begin{aligned} &\text{(i)} \quad \hat{\aleph} \subset \{(p, F) \in \mathcal{R}^{m+r} : c(p, F) \geq 0\} \text{ always,} \\ &\text{(ii)} \quad \hat{\aleph} \subset \{(p, F) \in \mathcal{R}^{m+r} : c(p, F) > 0\} \text{ for regular regions,} \\ &\text{(iii)} \quad \partial\hat{\aleph} \subset \{(p, F) \in \mathcal{R}^{m+r} : c(p, F) = 0\} \text{ always.} \end{aligned} \tag{14}$$

3. Robust control: Max-min approach. We first assume that the compensator's parameter vector F is fixed, and we discuss robust *analysis*. In particular, let the system characteristic polynomial be

$$\Delta(\lambda; p) = \sum_{i=0}^{n} a_i(p) \lambda^i, \tag{15}$$

where $p \in \mathcal{R}^m$ is the uncertainty vector associated with the plant and is restricted by

$$p \in \Omega \subset \mathcal{R}^m; \quad \Omega = \left\{ p \in \mathcal{R}^m : \sum_{i=1}^{m} \nu_i^2 p_i^2 - \gamma^2 \leq 0 \right\}. \tag{16}$$

The following theorem is straightforward.

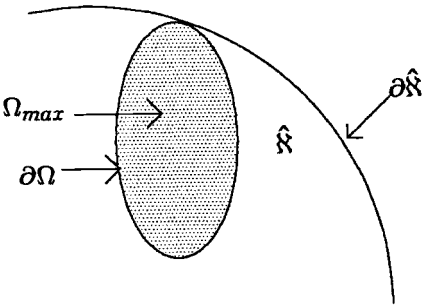

FIG. 2.

THEOREM 3.1. *Consider the uncertain polynomial* (15)*, and suppose that the nominal polynomial* $\Delta(\lambda;0)$ *has all of its roots inside a regular region* $\aleph$*. Then for all* $p \in \text{int}(\Omega)$*,* $\sigma(\Delta(\lambda;p)) \subset \aleph$ *if and only if for all* $p \in \text{int}(\Omega)$*,* $c(p) > 0$*.*

Instead of discussing the positivity $c(p)$ in Ω directly, we pose an optimization problem whose solution identifies the maximum uncertainty radius allowed. Consider

$$\text{Min} \sum_{i=1}^{m} \nu_i^2 p_i^2 \text{ subject to (s.t.) } c(p) = 0. \tag{17}$$

The general meaning of this optimization is depicted in Figure 2.

If we are interested in a fixed radius rather than the maximum radius, we pose the following problem:

$$\text{Min} \sum_{i=1}^{m} \nu_i^2 p_i^2 \text{ s.t. } c(p) - \rho^2 = 0. \tag{18}$$

Here we have to solve (18) for different values of ρ until the corresponding value of $\sum_{i=1}^{m} \nu_i^2 p_i^2$ takes the required value γ^2. However, in light of (14), we can reverse the role of the cost and the constraint to obtain a direct representation for a fixed uncertainty radius as follows:

$$\text{Min } c(p) \text{ s.t.} \sum_{i=1}^{m} \nu_i^2 p_i^2 - \gamma^2 \leq 0. \tag{19}$$

Note that (19) is equivalent in $\hat{\aleph}$ to $\text{Max}[-\ln c(p)]$. Thus we may write

$$\text{Max}[-\ln c(p)] \text{ s.t.} \sum_{i=1}^{m} \nu_i^2 p_i^2 - \gamma^2 \leq 0. \tag{20}$$

The geometry of (19) and (20) is depicted in Figure 3.

We now present a matrix version. Let $A(p) \in \mathcal{R}^{n\times n}$ be a system matrix, where $A(0)$, the nominal matrix, is stable with respect to $\aleph$. With $A(p)$ and $\aleph$ we associate the matrix equation

$$\sum_{i,k} \phi_{ik} A^i(p) P A'^k(p) = -Q, \tag{21}$$

where $(\cdot)'$ is a matrix transposition, $\phi(\cdot)$ defined by (9) is M-transformable [2], and $Q = Q' > 0$.

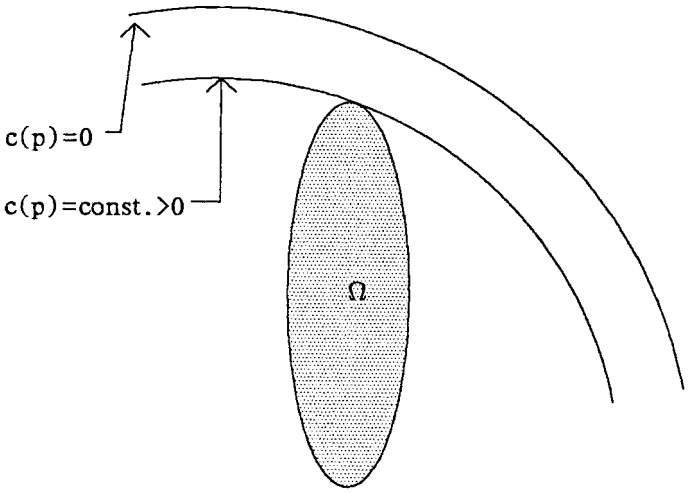

FIG. 3.

According to the theory of composite matrices, the solution to (21) has the form

$$\phi(A(p) \otimes A(p))\hat{p} = -\hat{q}, \tag{22}$$

where $\hat{p}$ and $\hat{q}$ are the stacking operators of matrices P and Q. Recalling the critical polynomial (12), we see that matrix P has a unique solution if and only if $c(p) \neq 0$. We conclude

$$\begin{aligned} &\operatorname{tr}(P) > 0 \quad \forall\, p \in \hat{\aleph}, \\ &\operatorname{tr}(P) \to \infty \text{ as } (p \in \hat{\aleph}) \to \partial\hat{\aleph}, \end{aligned} \tag{23}$$

where $\operatorname{tr}(P)$ is the trace of P. Thus (20) can be replaced by the matrix version

$$\begin{aligned} &\text{Max } \operatorname{tr}(P) \text{ s.t.} \sum_{i,k} \phi_{ik} A^i(p) P A'^k(p) + Q = 0, \\ &\sum_{i=1}^{m} \nu_i^2 p_i^2 - \gamma^2 \leq 0. \end{aligned} \tag{24}$$

So far we have seen that robust stability can be associated with an optimization problem. However, robust stability is the *analysis* part in the design process. Now we discuss the *synthesis*; namely, we construct a compensator such that closed loop relative stability (with respect to $\aleph$) is preserved in the entire uncertainty set Ω. In moving from analysis to synthesis, the optimization problem moves from minimization to a conflict between the uncertainty and the controller. In other words, minimization becomes max-min operation. This operation reflects our deterministic approach to robust compensators. That is, we seek a single compensator F such that

$$\sigma(\Delta(\lambda; p, F)) \subset \aleph \quad \forall\, p \in \Omega, \tag{25}$$

where now $\Delta(\lambda; p, F)$ is the closed loop characteristic polynomial.

To this end, we free the compensator F and seek a value that maximizes the uncertainty radius. Using (17), we obtain the following max-min problem:

$$\underset{F}{\text{Max}}\ \underset{p}{\text{Min}}\ \sum_{i=1}^{m}\nu_i^2 p_i^2 \quad \text{s.t. } c(p,F)=0. \tag{26}$$

Likewise, (18) becomes

$$\underset{F}{\text{Max}}\ \underset{p}{\text{Min}}\ \sum_{i=1}^{m}\nu_i^2 p_i^2 \quad \text{s.t. } c(p,F)-\rho^2=0, \tag{27}$$

while, for fixed uncertainty radius, (19) implies

$$\underset{F}{\text{Max}}\ \underset{p}{\text{Min}}\ c(p,F) \quad \text{s.t.} \sum_{i=1}^{m}\nu_i^2 p_i^2-\gamma^2\le 0. \tag{28}$$

For the inverse critical polynomial (20), we have

$$\underset{F}{\text{Min}}\ \underset{p}{\text{Max}}\ [-\ln c(p,F)] \quad \text{s.t.} \sum_{i=1}^{m}\nu_i^2 p_i^2-\gamma^2\le 0. \tag{29}$$

Finally, the matrix version (24) now becomes

$$\underset{F}{\text{Min}}\ \underset{p}{\text{Max}}\ \ \text{tr}(P) \quad \text{s.t.} \sum_{i,k}\phi_{ik}A^i(p,F)PA'^k(p,f)+Q=0,$$

$$\sum_{i=1}^{m}\nu_i^2 p_i^2-\gamma^2\le 0. \tag{30}$$

It should be emphasized that in a max-min or min-max operation, we first take the inner operation with respect to p and then the outer operation with respect to F. While the first operation always leads to a finite point (Ω is compact), the second operation (with respect to F) may lead to a point at infinity. This is so since F is not restricted to lie in a compact set. Furthermore, the number of solutions to the above problems may be infinity. We leave the discussion of these difficulties to a later section. Finally, note that we do not suppose that a real conflict between the uncertainty and the controller takes place. Rather, we associate with the robust compensator problem a max-min formulation, the solution of which leads to a robust compensator. This compensator is, of course, not unique.

4. Tangency points. Consider the max-min problem (26)

$$\underset{F}{\text{Max}}\ \underset{p}{\text{Min}}\ \sum_{i=1}^{m}\nu_i p_i^2 := p'Dp \quad \text{s.t. } c(p,F)=0. \tag{31}$$

ASSUMPTION 4.1. *The nominal system is stabilizable with respect to* $\aleph$*; that is,* $\{F:(0,F)\in\hat{\aleph}\}\neq\phi$.

We define the robustness radius $\gamma(F)$ by

$$\gamma^2(F):=\underset{c(p,F)=0}{\text{Min}}\ \sum_{i=1}^{m}\nu_i^2 p_i^2 \ \text{ if } \ (0,F)\in\hat{\aleph};\ \ \text{otherwise},\gamma(F):=0. \tag{32}$$

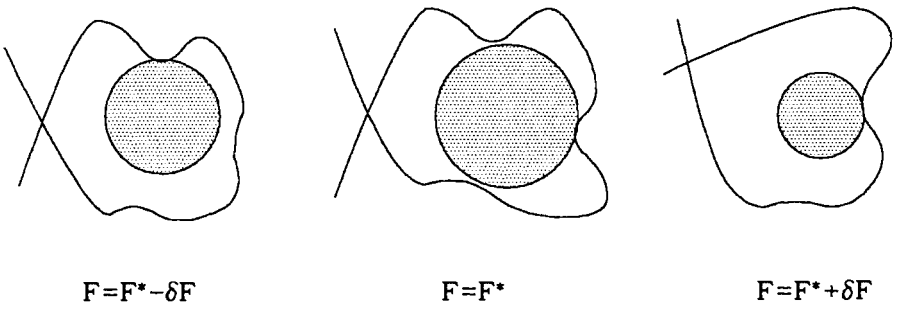

FIG. 4.

In the case of a jump in $\gamma(F)$, we can add the notion of a *practical robustness radius.* Thus the optimal robust controller F^* in the max-min sense is given by

$$\gamma^* := \operatorname*{Sup}_F \gamma(F) = \gamma^*(F^*) \geq \gamma(F^*), \tag{33}$$

where the inequality in (33) becomes an equality if and only if F^* is not a jump point. The minimization in (32) takes place at *contact points* of the critical constraint and the uncertain ellipsoid. Such points are depicted in Figure 4.

Suppose that, at each F with $\gamma(F) > 0$, the contact takes place at $p = p^{(k)}(F)$. These are the local maxima of problem (32). We say that points $p^{(k)}(F)$ are *regular* points of the critical surface $\{p : c(p, F) = 0\}$ if the gradient of $c(p, F)$ at the surface with respect to p does not vanish at these points. In other words,

$$c(p^{(k)}, F) = 0, \quad \gamma^2(F) = \sum_{i=1}^{m} \nu_i^2 p^{(k)2} \Rightarrow c_p(p^{(k)}, F) \neq 0. \tag{34}$$

At this point, it is worth noting that the critical polynomial $c(p, F)$ must be in a reduced form. In particular, let $\{\lambda_i\}$ be the roots of $\Delta(\cdot; p, F) = 0$. Then [2]

$$c(p, F) = \prod_{i,j=1}^{n} (-\phi(\lambda_i, \bar{\lambda}_j)) = (-1)^n \tilde{c}^2(p, F) \prod_{i=1}^{n} \phi(\lambda_i, \bar{\lambda}_i), \tag{35}$$

where

$$\tilde{c}(p, F) = \prod_{i<j} |\phi(\lambda_i, \bar{\lambda}_j)|. \tag{36}$$

Thus $c_p(p, F) \equiv 0$ for every real (p, F) on the critical surface. To overcome this difficulty, we have to replace $c(p, F)$ by the reduced form

$$\hat{c}(p, F) = (-1)^n \tilde{c}(p, F) \prod_{i=1}^{n} \phi(\lambda_i, \bar{\lambda}_i). \tag{37}$$

In the case of complex polynomials, this factorization is impossible. However, for the *real* case, we have the following result:

(i) Given a real characteristic polynomial $\Delta(s;p,F)$,

$$c(p,F) = \mathrm{Res}[\Delta(s;p,F), -\phi(s,s)] \left(\frac{\mathrm{Res}[\Delta(\lambda;p,F), \mathrm{Res}[\Delta(s;p,F), -\phi(\lambda,s)]]}{\mathrm{Res}[\Delta(s;p,F), -\phi(s,s)]} \right)^{\frac{1}{2}}. \tag{38}$$

(ii) Given a real matrix $A(p,F)$,

$$c(p,F) = \det\left[\sum_i f_{i0} A^i(p,F)\right] \det[-\phi(A(p,F) \odot A(p,F))], \tag{39}$$

where $\odot$ is the bialternate produce [2]. In what follows, by $c(p,F)$ we mean the reduced form. It should be noted that, for computational simplicity, we remove from $c(\cdot)$ factors using $\hat{c} = c/gcd(c, \frac{\partial c}{\partial p_1}, \ldots, \frac{\partial c}{\partial p_m})$.

Let us first assume that a max-min point is regular. Let $p^{(i)}, i = 1,2,\ldots,l$, be points of tangency of the critical constraint and the ellipsoid. Using the Lagrange multiplier method, we may write

$$\begin{aligned} &\text{(i)} \quad c_p(p^{(i)},F) = \lambda^{(i)} p^{(i)\prime} D, \quad D = \mathrm{diag}[\nu_k^2]_{k=1}^m, \\ &\text{(ii)} \quad c(p^{(i)},F) = 0, \qquad i-1,2,\ldots,l. \end{aligned} \tag{40}$$

Here

$$c_p(p,F) = \left[\frac{\partial c}{\partial p_1} \cdots \frac{\partial c}{\partial p_m}\right], \tag{41}$$

and λ is the (inverse) Lagrange multiplier.

DEFINITION 4.1. *Given a compensator F satisfying $(0,F) \in \hat{\aleph}$, we say that $p \in \mathcal{R}^m$ is a* contact point *for F if the minimum* (32) *is attained. Given F, we say that $p \in \mathcal{R}^m$ is a* tangency point *if, for some real λ,*

$$c(p,F) = 0, \quad c_p(p,F) = \lambda p' D \neq 0. \tag{42}$$

Note that every contact point for F for which $c_p \neq 0$ is a tangency point (but not necessarily the opposite).

DEFINITION 4.2. *If, for some F^*, there exist a tangency point p^* and a corresponding λ^*, we say that p^* has a* regular multiplicity *k if there exist a neighborhood N_{F^*} of F^* and $C^1(N_{F^*})$ functions $p^{(i)}(F)$, $\lambda^{(i)}(F), i = 1,2,\ldots,k$, satisfying* (42) *for every $F \in N_{F^*}$ and $p^{(i)}(F^*) = p^*$, $\lambda^{(i)}(F^*) = \lambda^*$, such that k is the maximal possible number of such $\{p^{(i)}(F), \lambda^{(i)}(F)\}$ pairs. If $k = 1$, we say that p^* has a* simple regular multiplicity. *If, in addition, $p^{(1)}(F)$ and $\lambda^{(1)}(F)$ are the unique solutions in the neighborhoods of p^*, λ^*, for every $F \in N_{F^*}$, we say that p^* is* simple regular.

We open by characterizing simple regular points. If, for some F^*, there exist a simple regular tangency point p^* and a corresponding λ^*, then there exist a neighborhood N_{F^*} of F^* and functions $p(F)$, $\lambda(F) \in C^1(N_{F^*})$ satisfying (42) for every $F \in N_{F^*}$ with initial conditions $p(F^*) = p^*$, $\lambda(F^*) = \lambda^*$. Thus, taking $p = p(F)$, $\lambda = \lambda(F)$, we obtain from (42)

$$\begin{bmatrix} c_{pp} - \lambda D & -Dp \\ c_p & 0 \end{bmatrix} \begin{bmatrix} dp \\ d\lambda \end{bmatrix} = \begin{bmatrix} -c_{pF} \\ -c_F \end{bmatrix} dF, \quad \text{where } c_{pF} := \left[\frac{\partial^2 c}{\partial p_i \partial F_j}\right]. \tag{43}$$

DEFINITION 4.3. *We define the two matrices*

$$J = \begin{bmatrix} c_{pp} - \lambda D & -Dp \\ c_p & 0 \end{bmatrix}, \qquad J_1 = \begin{bmatrix} c_{pp} - \lambda D & -Dp & -c_{pF} \\ c_p & 0 & -c_F \end{bmatrix}, \tag{44}$$

where $p \in \mathcal{R}^m$, $F \in \mathcal{R}^r$, J *is* $(m+1) \times (m+1)$, *and* J_1 *is* $(m+1) \times (m+r+1)$.

ASSUMPTION 4.2. *If* $p \in \mathcal{R}^m$, $\lambda \in \mathcal{R}$, $F \in \mathcal{R}^r$ *satisfy* (42), *then* J_1 *is of full rank; that is,*

$$c(p,F) = 0, \quad c_p(p,F) = \lambda p' D \Rightarrow \operatorname{rank}(J_1) = m+1. \tag{45}$$

Suppose that, contrary to the assumption, $\operatorname{rank}(J_1) = m$. Then choose m independent rows in J_1, and express the remaining one as a linear combination of these m rows, using m combination coefficients. In that case, we obtain (together with (42)) $2m + r + 2$ equations in $2m + r + 1$ unknowns. If these equations are independent, then the extra equation restricts the nominal plant. Thus the assumption holds for almost every nominal plant.

THEOREM 4.1. *Let* p^* *be a tangent point for* F^* *with a corresponding* λ^*. *Suppose that Assumptions* 4.1 *and* 4.2 *are satisfied. Then* p^* *is simple regular if and only if*

$$|J(F^*, p^*, \lambda^*)| \neq 0. \tag{46}$$

Proof. Let Assumption 4.1 be satisfied at (p^*, F^*, λ^*). Then the implicit function theorem implies that (46) is sufficient for (42) to have, in some neighborhood N_{F^*} of F^*, a unique solution $p(F) \in N_{p^*}$, $\lambda(F) \in N_{\lambda^*}$. Moreover, $p(F), \lambda(F) \in C^1(N_{F^*})$ and satisfy the differential equation

$$\frac{d}{dF}\begin{bmatrix} p \\ \lambda \end{bmatrix} = J^{-1}(p, F, \lambda) \begin{bmatrix} -c_{pF} \\ -c_F \end{bmatrix}, \quad \text{where } \frac{dp}{dF} := \left[\frac{dp_i}{dF_j}\right]. \tag{47}$$

The uniqueness implies the initial conditions $p(F^*) = p^*$, $\lambda(F^*) = \lambda^*$, and, according to Definition 4.2, p^* is simple regular.

To prove necessity, suppose that the above assumptions are satisfied and that p^* is simple regular. Then, in some neighborhood N_{F^*}, system (42) has a solution $p(F)$, $\lambda(F) \in C^1(N_{F^*})$ for which $p(F^*) = p^*$, $\lambda(F^*) = \lambda^*$. For sufficiently small $\|\Delta F\|$, let $F = F^* + \Delta F$, $\Delta p = p(F) - p^*$, $\Delta\lambda = \lambda(F) - \lambda^*$. Then, from (42), we obtain

$$J(p^*, F^*, \lambda^*)\begin{bmatrix} \Delta p \\ \Delta\lambda \end{bmatrix} + O(\|\Delta p\|^2 + |\Delta\lambda|^2) = \begin{bmatrix} -c_{pF} \\ -c_F \end{bmatrix}\Delta F + O(\|\Delta F\|^2). \tag{48}$$

Since $p(F)$, $\lambda(F) \in C^1(N_{F^*})$, it follows that, for sufficiently small $\|\Delta F\|$,

$$(\|\Delta p\|, |\Delta\lambda|) = O(\|\Delta F\|). \tag{49}$$

If (46) does not hold, then there exists $\mu \in \mathcal{R}^{m+1}$ with $\|\mu\| = 1$ such that

$$\mu' J(p^*, F^*, \lambda^*) = 0. \tag{50}$$

Denote $J_2 := \left[\begin{smallmatrix} -c_{pF} \\ -c_F \end{smallmatrix}\right]$. Then, multiplying (48) by μ' and using (49)–(50), we obtain

$$\mu' J_2 \Delta F = O(\|\Delta F\|^2). \tag{51}$$

However, by Assumption 4.2, we have $0 \neq \mu' J_1 = [\mu' J \ \mu' J_2] = [0 \ \mu' J_2]$. Thus $\nu' := \mu' J_2 \neq 0$.

Choosing ΔF in the direction of ν, we obtain from (51) $\|\nu\| \, \|\Delta F\| = |\nu' \Delta F| = O(\|\Delta F\|^2)$ or $\|\Delta F\|^{-1} = O(1)$, which is impossible for sufficiently small ΔF. This contradiction implies that (46) is satisfied. □

Remark. Using the above proof, we find that, under the same assumptions, if (46) does not hold, every solution (p, F, λ) in some neighborhood of (p^*, F^*, λ^*) satisfies $\|\Delta F\| = O(\|\Delta p\|^2 + |\Delta\lambda|^2)$. Since $p^* \neq 0$, it follows that $|\Delta\lambda| = O(\|\Delta p\|)$ and that there exists a positive constant c such that $\|\Delta p\| \geq c\|\Delta F\|^{\frac{1}{2}}$. In particular, there exists no Lipschitzian solution $p(F)$ in the neighborhood of (p^*, F^*). In fact, under Assumptions 4.1 and 4.2, there are only two possibilities. Either a Lipschitzian solution passes through the point and is unique, or every solution that passes through the point is not Lipschitzian. We conclude that every regular point must be simple regular.

COROLLARY 4.1. *Suppose that Assumptions* 4.1 *and* 4.2 *are satisfied. Then every jump point F^* is a member of the closed algebraic set S_1 given by*

$$S_1 := \{F \in \mathcal{R}^r : (\exists p \in \mathcal{R}^m, \lambda \in \mathcal{R}), c(p, F) = 0, c_p = \lambda p' D, |J(p, F, \lambda)| = 0\}.$$

ASSUMPTION 4.3. *The set S_1 does not span the entire space; that is, $S_1 \neq \mathcal{R}^r$.*

This assumption is equivalent to the claim that the elimination of p, λ from the $m+2$ equations defining S_1 results in a nonidentity polynomial equation. As a result, $\dim(S_1) < r$, and S_1 has zero Lebesgue measure in $\mathcal{R}^r$.

5. Necessary conditions for max-min: The largest uncertainty possible. Next we turn to the necessary conditions for max-min points. Let F^* be optimal in the sense of (33) with l tangent points, all simple regular (see Definition 4.2), denoted by $p^{(i)}(F^*), i = 1, 2, \ldots, l$, and Lagrange multipliers $\lambda^{(i)}(F^*)$. Suppose Assumption 4.1 is satisfied. Then, at each tangent point, the functions

$$\gamma^{(i)2}(F) := p^{(i)'}(F) D p^{(i)}(F) \text{ are in } C^1(N_{F^*}). \tag{52}$$

Define the Jacobian

$$J_3(F) = \frac{1}{2}\left[\frac{\partial \gamma^{(i)2}}{\partial F_k}\right] \in \mathcal{R}^{l \times r}, \tag{53}$$

and denote $r(J_3) = \text{rank} J_3(F^*)$.

Using $\gamma^{(i)2} = p' D p$, we have $d(\gamma^{(i)2}) = 2p' D dp$. Multiplying by λ, we have $\lambda d(\gamma^{(i)2}) = 2\lambda p' D dp$. But by (42), $c_p = \lambda p' D$. Thus $\lambda d(\gamma^{(i)2}) = 2c_p dp$. On the other hand, $c(p, F) = 0$ implies $c_p dp + c_F dF = 0$. Thus $\lambda d(\gamma^{(i)2}) = -2c_F dF$ or $\frac{\partial(\gamma^{(i)2})}{\partial F} = -2\lambda^{-1} c_F$.

Thus

$$J_3(F) = \frac{1}{2}\left[\frac{\partial \gamma^{(i)2}}{\partial F_k}\right]_{i,k} = \begin{bmatrix} \cdot \\ -(\lambda^{(i)})^{-1} c_F(p^{(i)}, F) \\ \cdot \end{bmatrix} \overset{\text{rank}}{=} \begin{bmatrix} \cdot \\ c_F(p^{(i)}, F) \\ \cdot \end{bmatrix}$$

$$\overset{\text{rank}}{=} \left[\frac{\partial c(p^{(i)}, F)}{\partial F_k}\right]_{i,k}.$$

Clearly, at $F = F^*$,

$$\gamma^{(i)2} = p^{(i)'} D p^{(i)}, \quad i = 1, \ldots, l. \tag{54}$$

Here we have l equations, and (42),

$$c(p^{(i)}, F^*) = 0, \quad c_p(p^{(i)}, F^*) = \lambda^{(i)} p^{(i)'} D, \quad i = 1, \dots, l, \tag{55}$$

yield another $l(m+1)$ equations for l tangent points. Thus we have $l(m+2)$ equations in $l(m+1)+r+1$ unknowns. We conclude that, if the equations are independent, we obtain a finite number of solutions, provided $l \geq r+1$. To cover all possibilities, we present the following cases.

Case 1. $l \geq r+1$. In this case, it suffices to consider $l = r+1$. Note that, in (54), the vectors $p^{(i)}, i = 1, \dots, r+1$, must be distinct. For more details, see the example in section 8. The set of equations takes the following form:

$$\boxed{\begin{aligned} &\gamma^{*2} = p^{(i)'} D p^{(i)}, \\ &c(p^{(i)}, F^*) = 0, \\ &c_p(p^{(i)}, F^*) = \lambda^{(i)} p^{(i)'} D, \quad i = 1, \dots, r+1. \end{aligned}} \tag{56}$$

Case 2. $r(J_3) = 0$, $1 \leq l \leq r$. In this case, $J_3(F^*) = 0$; that is, $c_F(p^{(i)}, F^*) = 0$. Note that $J_3(F^*) = 0$ defines lr equations, (42) defines $l(m+1)$ equations, and (54) defines another l equations. Thus we have $l(m+r+2)$ equations in $l(m+1)+r+1$ unknowns. We conclude that, for $l = 1$, we obtain $m+r+2$ equations in $m+r+2$ unknowns. For $l \geq 2$, we obtain more equations than unknowns, and, provided these equations are independent, we conclude that the solution set is empty for almost every nominal plant. In other words, we have a single simple regular tangent point ($l = 1$) for almost all nominal plants. We conclude that $c_F = 0$ and obtain

$$\left.\begin{array}{|l|l|}\hline c(p, F^*) = 0 & (1 \text{ equation}) \\ c_p(p, F^*) = \lambda p' D & (m \text{ equations}) \\ c_F(p, F^*) = 0 & (r \text{ equations}) \\ \hline \end{array}\right\} \begin{array}{l} (m+r+1) \text{ equations in} \\ (m+r+1) \text{ unknowns.} \end{array} \tag{57}$$

Remark. This is the classical case in which $\gamma(F) \in C^1(N_{F^*})$.

Case 3. $1 \leq r(J_3) \leq l \leq r$. In this case, J_3 has $r(J_3)$ independent rows. Without loss of generality, we may assume that rows $i = 1, \dots, r(J_3)$, are independent and that the rest are their linear combinations. Using $\Delta F := F - F^*$, we have

$$\begin{bmatrix} \gamma^{(1)2}(F) \\ \vdots \\ \gamma^{(l)2}(F) \end{bmatrix} - \begin{bmatrix} \gamma^{(1)2}(F^*) \\ \vdots \\ \gamma^{(l)2}(F^*) \end{bmatrix} = J_3(F^*)\Delta F + o(\|\Delta F\|), \quad F \in N_{F^*}. \tag{58}$$

We first prove that $r(J_3) = l$ is impossible. If $r(J_3) = l$, $J_3(F^*)$ has l independent columns. Thus there exists $v \in \mathcal{R}^r$ such that $J_3(F^*)v = \mathrm{col}[1 \cdots 1]$. For sufficiently small $\varepsilon > 0$, we choose $\Delta F = \varepsilon v$ and obtain

$$\begin{bmatrix} \gamma^{(1)2}(F) \\ \vdots \\ \gamma^{(l)2}(F) \end{bmatrix} - \begin{bmatrix} \gamma^{(1)2}(F^*) \\ \vdots \\ \gamma^{(l)2}(F^*) \end{bmatrix} = \begin{bmatrix} \varepsilon \\ \vdots \\ \varepsilon \end{bmatrix} + 0(\varepsilon) > 0. \tag{59}$$

That is $\gamma^{(i)}(F) > \gamma^{(i)}(F^*) := \gamma(F^*), i = 1, \dots, l$. Consequently (see the appendix for discussion), $\gamma(F) = \min_{1 \leq i \leq l} \gamma^{(i)}(F) > \gamma(F^*)$, contradicting the optimality of $\gamma(F^*)$.

We conclude that $1 \le r(J_3) < l \le r$, which also implies $r \ge 2$. Now we express the rows $i = r(J_3)+1, \dots, l$, in $J_3(F^*)$ as $[l - r(J_3)]$ linear combinations of the first $r(J_3)$ rows. This generates $(l-r(J_3))r$ equations in $(l-r(J_3))r(J_3)$ coefficients. In addition, we have (55). Thus we have a total of $(l-r(J_3))r + l + l(m+1) = l(m+r+2) - rr(J_3)$ equations in $(l-r(J_3))r(J_3)+l(m+1)+r+1$ unknowns. A simple calculation shows that the number of equations is bigger than the number of unknowns by $(l - r(J_3) - 1)(r - r(J_3) + 1)$. Thus the number of equations equals the number of unknowns only if $l = r(J_3) + 1$. Note that, in all other cases, $r(J_3) + 2 \le l \le r$, in which $l - r(J_3) - 1 \ge 1$ and $r - r(J_3) + 1 \ge 3$. In these cases, we find at least three extra equations. We conclude that, if the equations are independent, if $l \ge r(J_3) + 2$, the solution set is empty for almost every nominal plant, and it suffices to consider $l = r(J_3) + 1$, in which $l \le r(J_3) \le r - 1$ and $r \ge 2$. Thus

$$\boxed{\begin{array}{l} \text{for each } r(J_3) = 1, \dots, r-1, \\ \left.\begin{array}{l} \gamma^{*2} = p^{(i)'} D p^{(i)}, \\ c(p^{(i)}, F^*) = 0, \\ c_p(p^{(i)}, F^*) = \lambda^{(i)} p^{(i)'} D, \end{array}\right\} i = 1, \dots, r(J_3)+1, \\ c_F(p^{(i)}, F^*)|_{i=r(J_3)+1} = \displaystyle\sum_{i=1}^{r(J_3)} \mu_i c_F(p^{(i)}, F^*). \end{array}} \tag{60}$$

That is, for each $r(J_3) = 1, \dots, r-1$, we obtain $r + (m+2)(r(J_3)+1)$ equations in the same number of unknowns. We summarize our results as follows.

THEOREM 5.1. *Consider max-min problem* (26) *or* (31)*, with Assumptions* 4.1*. Suppose that, at a max-min point (optimum), all tangent points are simple regular. Then an optimal compensator satisfies at least one of the following sets of equations:* (56), (57), (60).

Remark. Theorem 4.1 characterizes simple regular points. However, we do not use it in Theorem 5.1.

COROLLARY 5.1. *The results in Theorem* 5.1 *remain unchanged if the constraint in* (31) *is a* C^1 *function not necessarily a polynomial. If the cost* $\gamma^2 = p'Dp$ *is replaced by a more general* C^1 *function, say,* $h(p, F)$*, we replace, in* (57) *and in* (60)*,* $[c_F]$ *by* $[c_F - \lambda h_F]$*. Likewise,* $c_p = \lambda p'D$ *is replaced by* $c_p = \lambda h_p$*.*

6. An alternative approach. Consider the max-min problem (26) or (31)

$$\operatorname*{Max}_{F} \operatorname*{Min}_{p} \gamma^2 = \sum_{i=1}^{m} \nu_i^2 p_i^2 := p'Dp \quad \text{s.t. } c(p, F) = 0. \tag{61}$$

Assuming that the critical polynomial $c(\cdot)$ does not vanish with its gradient, we first perform the minimization part. Define the Lagrangian

$$\mathcal{L} = p'Dp + \lambda c(p, F). \tag{62}$$

Then necessary conditions for the minimum are

$$\begin{aligned} &\mathcal{L}_p := \nabla_p \mathcal{L}(p, F) = 2p'D + \lambda c_p = 0, \\ &\mathcal{L}_\lambda = c(p, F) = 0. \end{aligned} \tag{63}$$

In order to perform the second operation, namely, the maximization with respect to F, we must, in principle, solve (63) for (p, λ), substitute p in γ^2, and maximize with respect to F. To do so, we set the system of polynomial equations

$$\begin{aligned} &\gamma^2 - p'Dp = 0, \\ &2p'D + \lambda c_p(p, F) = 0, \\ &c(p, F) = 0. \end{aligned} \tag{64}$$

Using the Grobner bases [13] to eliminate (p, λ), we obtain the polynomial equation

$$\varphi(\gamma^2, F) = 0. \tag{65}$$

The implicit function $\varphi(\cdot)$ is a polynomial in γ^2 whose coefficients are polynomials in F. To solve

$$\operatorname*{Max}_{F} \ \gamma^2 \quad \text{s.t. } \varphi(\gamma^2, F) = 0, \tag{66}$$

we recall that, while the zeros γ^2 of $\varphi(\cdot, F)$ are continuous functions of F, the function $\gamma^2(F)$ obtained from $\varphi(\gamma^2, F) = 0$ is not single-valued. Thus the Lagrange multiplier method does not apply to (66) directly. To see this, define the Lagrangian (with a "new" multiplier λ) as

$$\mathcal{L} = \gamma^2 + \lambda\varphi(\gamma^2, F). \tag{67}$$

Denote $\varphi' := \frac{\partial\varphi}{\partial(\gamma^2)}$; we have the following necessary conditions for maximum:

$$\begin{aligned} &\frac{\partial\mathcal{L}}{\partial(\gamma^2)} = 1 + \lambda\varphi'(\gamma^2, F) = 0, \text{provided } \varphi' \neq 0, \\ &\frac{\partial\mathcal{L}}{\partial F_i} = \lambda\frac{\partial\varphi}{\partial F_i} = 0. \end{aligned}$$

In other words

$$\boxed{\begin{aligned} &\varphi(\gamma^2, F) = 0, \\ &\frac{\partial\varphi}{\partial F_i} = 0, \quad i = 1, \ldots, r. \end{aligned}} \tag{68}$$

However, at F^*, a max-min point, $\varphi = 0$ and $\varphi' = 0$ may hold simultaneously. Thus we consider the following set of possibilities. Denote $\varphi^{(i)} := (\frac{\partial}{\partial(\gamma^2)})^i\varphi(\gamma^2, F)$, and consider, for $k = 1, \ldots, r-1$,

$$\operatorname*{Max}_{F} \ \gamma^2 \quad \text{s.t. } \varphi^{(i)} = 0, \quad i = 0, 1, \ldots, k. \tag{69}$$

We assume here that, at F^*, $\varphi^{(k+1)} \neq 0$. Define the Lagrangian

$$\mathcal{L} = \gamma^2 + \sum_{i=0}^{k} \lambda_i\varphi^{(i)}. \tag{70}$$

Then

(71)
$$\boxed{\begin{aligned}&\text{For each } k = 1, \dots, r-1,\\ &\frac{\partial \mathcal{L}}{\partial \lambda_i} = \varphi^{(i)} = 0, \qquad i = 0, 1, \dots, k,\\ &\frac{\partial \mathcal{L}}{\partial F_j} = \sum_{i=0}^{k} \lambda_i \frac{\partial \varphi^{(i)}}{\partial F_j} = 0, \quad j = 1, \dots, r.\end{aligned}}$$

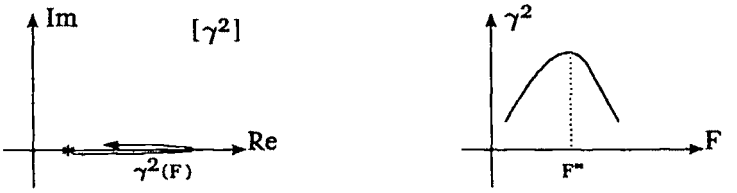
In the case when $k = r$ in (69), the constraints define F^*. In that case, we have the following conditions:

(72)
$$\boxed{\varphi^{(i)} = 0, \quad i = 0, 1, \dots, r.}$$

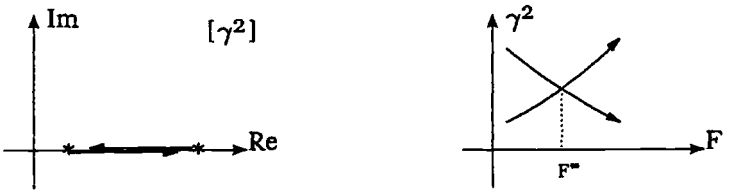
THEOREM 6.1. *Consider max-min problem* (61). *Suppose that Assumption* 4.1 *is satisfied and that* F *is in reduced form. Then necessary conditions for max-min are either* (68) *or* (71) *or* (72).

At this point, we wish to use the so-called root locus to illustrate both regular and singular max-min points. Recall that $\phi(\gamma^2, F)$ is a polynomial in γ^2 whose coefficients are functions of F. Denote by $\gamma^2(F)$ the roots γ^2 of $\varphi(\gamma^2, F) = 0$ as a function of F. Consider three basic cases.

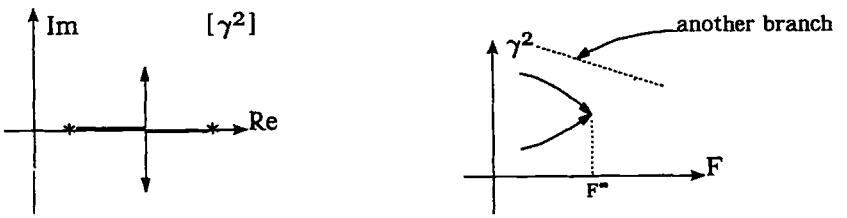
Case 1. A single root moves (as a function of F) in the positive direction, and backward.



Case 2. A positive real pair of roots move "head on" and pass each other.



Case 3. A positive real pair of roots move "head on" and split into a complex pair.



7. Necessary conditions for max-min: The uncertainty region is given. In the previous section, we have discussed the largest ellipsoid contained in the stability region. To discuss a given uncertainty region, consider max-min formulation (27):

$$\underset{F}{\text{Max}}\ \underset{p}{\text{Min}}\ \sum_{i=1}^{m} \nu_i^2 p_i^2 \quad \text{s.t. } c(p,F) - \rho^2 = 0. \tag{73}$$

We now solve a series of max-min problems (73) by increasing ρ^2 from zero. At each step, we calculate the measure $\gamma^{*2} = \sum_{i=1}^{m} \nu_i^2 p_i^2$. The process is stopped at the first time when γ^* becomes the given uncertainty radius.

To present a direct approach, we assume that there exists a robust controller F and recall (28):

$$\underset{F}{\text{Max}}\ \underset{p}{\text{Min}}\ c(p,F) \ \text{ s.t. } \sum_{i=1}^{m} \nu_i^2 p_i^2 - \gamma^2 \le 0. \tag{74}$$

Note that this problem can be handled using the results presented in [3, 4]. For additional comments, see section 9.

To solve (74) using our previous results, we first address the inner operation; namely, we fix F and solve

$$\underset{p}{\text{Min}}\ c(p;F) \ \text{ s.t. } \sum_{i=1}^{m} \nu_i^2 p_i^2 - \gamma^2 \le 0. \tag{75}$$

Since the *constraint qualification* holds for this problem, we can use Kuhn–Tucker conditions as necessary conditions. In particular, there exists a Lagrange multiplier λ such that

$$\begin{aligned} &\text{(i)} \quad c_p(p,F) + 2\lambda p' D = 0, \\ &\text{(ii)} \quad \lambda(p' D p - \gamma^2) = 0. \end{aligned} \tag{76}$$

We remind the reader that the inner operation in problem (31), namely $\gamma(F)$, may result in a discontinuous function. In the present formulation, the inner operation is always continuous. The reason lies in the facts that Ω is a connected set and $c(p,F)$ is continuous. In contrast to the present situation, in (31), we search for the largest ellipsoid contained in the stability region. Since the stability region may be disconnected, it follows that $\gamma(F)$ may be discontinuous. We conclude that our present formulation is *regular*. We now proceed as in section 4. In particular, we replace (56) by

$$\boxed{\begin{aligned} &c_p(p^{(i)},F) + 2\lambda^{(i)} p^{(i)\prime} D = 0, \qquad i = 1,2,\dots r+1, \\ &\lambda^{(i)}(p^{(i)\prime} D p^{(i)} - \gamma^2) = 0, \qquad i = 1,2,\dots,r+1, \\ &c(p^{(i)},F) = c(p^{(1)},F), \qquad i = 2,3,\dots,r+1. \end{aligned}} \tag{77}$$

Likewise, we replace (57) and (60) by proper sets of equations. Note that some $\lambda^{(i)}$ may vanish at optimum (interior point). Before closing this section, we wish to comment on the construction of a fixed order compensator for a nominal plant (with

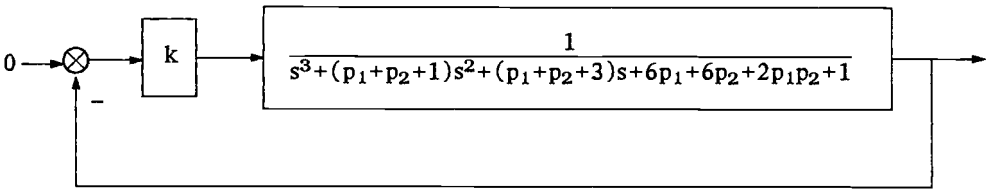


FIG. 5.

no uncertainty). Suppose our objective is to find a compensator F_0 so as to maximize the "distance" to the stability boundary. Then we may write

$$\max_{F_0} \min_{F} \ (F - F_0)' D (F - F_0) \quad \text{s.t. } c(F) = 0. \tag{78}$$

Remarks.

1. Since $c(\cdot)$ is a function of F alone, a jump never occurs.
2. We may interpret the formulation (78) as the "maximum stability margin" possible.
3. Case 2 given by (57) is impossible for (78) since a single contact point ($l = 1$) is impossible.
4. From a practical point of view, we require F to be bounded. In particular, suppose that we require $c_1(F) := F' D_1 F - \rho^2 \leq 0$. Then, in order to achieve bounded control parameters (especially in the case when $\hat{\aleph}$ is unbounded), we replace the constraint $c(F) = 0$ by $c(F)c_1(F) = 0$.

8. Illustrative examples.

Example 1. Consider the unit feedback system (a feedback version of [14]) pictured in Figure 5.

The closed loop characteristic polynomial is

$$\Delta_c(s; p, F) = s^3 + (p_1 + p_2 + 1)s^2 + (p_1 + p_2 + 3)s + (6p_1 + 6p_2 + 2p_1p_2 + 1 + k).$$

Recall that the critical polynomial can be generated from the Hurwitz matrix as follows:

$$c(p, F) = |H_n(p, F)| = a_0(p, F)|H_{n-1}(p, F)|,$$

where $c(p, F) = 0$ contains the stability boundary and, in particular,

(i) $a_0(p, F) = 0$ contains the real root boundary (r.r.b.),

(ii) $|H_{n-1}(p, F)| = 0$ contains the complex root boundary (c.r.b.).

In the present example,

(i) $a_0(p, F) = 6p_1 + 6p_2 + 2p_1p_2 + 1 + k$,

(ii) $|H_2(p, F)| = (p_1 - 1)^2 + (p_2 - 1)^2 - k$.

The stability region is defined by $a_0 > 0$, $a_2 > 0$, and $|H_2| = a_1a_2 - a_0 > 0$ and is depicted in Figure 6.

Our objective is to select the control gain k so as to maximize the robustness radius with respect to the origin. First, note that, as k increases, the circle approaches the origin, while the hyperbola diverges from the origin. Thus max-min takes place at equal distances. Note that, since the circle radius is $\sqrt{k}$, the circle is feasible only for $0 < k < 2$. Also note that the stability interval for the nominal system is $-1 < k < 2$.

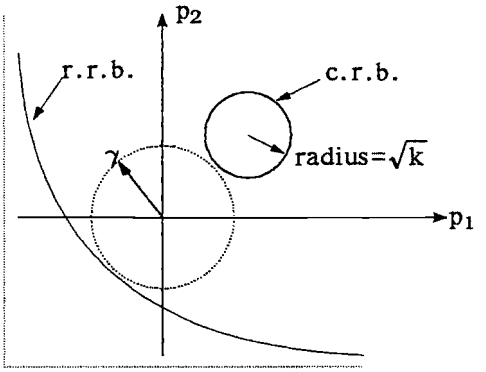

FIG. 6.

From symmetry, it is clear that the robustness circle is tangent to the hyperbola at $p_1 = p_2 < 0$. Indeed, $c_p + \lambda p' = 0$ yields, after solving for λ, $p_2 \frac{\partial c}{\partial p_1} - p_1 \frac{\partial c}{\partial p_2} = 0$. A detailed calculation yields $(p_2 - p_1)(p_1 + p_2 + 3) = 0$, which means $p_1 = p_2 := p$. The hyperbola now yields $p^2 + 6p + \frac{1+k}{2} = 0$. The solution becomes $p = -3 + \sqrt{9 - \frac{k+1}{2}}$. Equating the distances from the origin to the circle and to the hyperbola, we obtain $-(-3 + \sqrt{9 - \frac{1+k}{2}})\sqrt{2} = \sqrt{2} - \sqrt{k}$. The two sides of this equation are depicted in Figure 7. Simple algebra yields $4k^2 - 68k + 81 = 0$. The optimal gain becomes $k^* = 1.29$, and the robustness radius is $\gamma^* = \sqrt{2} - \sqrt{k^*} = 0.27$. Finally, note that, for our example, a complete set of necessary conditions is given by (56). In particular, since $r = 1$, we have $l = 2$. Denote $p^{(1)} = (x, y)$, $p^{(2)} = (v, w)$, and $g = \gamma^2$. Then, eliminating λ, set (56) takes the form

(1) $g - x^2 - y^2 = 0$,
(2) $g - v^2 - w^2 = 0$,
(3) $(6x + 6y + 2xy + 1 + k)((x-1)^2 + (y-1)^2 - k) = 0$,
(4) $(6v + 6w + 2vw + 1 + k)((v-2)^2 + (w-1)^2 - k) = 0$,
(5) $y[(6 + 2y)((x-1)^2 + (y-1)^2 - k) + 2(x-1)(6x + 6y + 2xy + 1 + k)]$
$-x[(6 + 2x)((x-1)^2 + (y-1)^2 - k) + 2(y-1)(6x + 6y + 2xy + 1 + k)] = 0$,
(6) $w[(6 + 2w)((v-1)^2 + (w-1)^2 - k) + 2(v-1)(6v + 6w + 2vw + 1 + k)]$
$-v[(6 + 2v)((v-1)^2 + (w-1)^2 - k) + 2(w-1)(6v + 6w + 2vw + 1 + k)] = 0$.

Using the Grobner package in Maple V, we find that a Grobner basis is formed of 64 (yes, sixty four!) reduced sets of polynomial equations. In principle, we have to test each of them. To save space, we present the two relevant sets

(a) $x + w = 0$, $v - w = 0$, $2g - 16w + 3 = 0$, $2k - 8w - 1 = 0$, $y + w = 0$, $4w^2 - 16w + 3 = 0$,
(b) $x + w = 0$, $v - w = 0$, $2g + 16w + 3 = 0$, $2k + 8w - 1 = 0$, $y + w = 0$, $4w^2 + 16w + 3 = 0$.

Each of these sets yields $k^* = 1.3$.

Finally, we wish to present a solution based on the alternative approach of section 5. Once more, using the Grobner package in Maple V, we obtain from (64)–(65)

$$\varphi(\gamma^2, F) = \prod_{i=1}^{4} \varphi_i(\gamma^2, F),$$

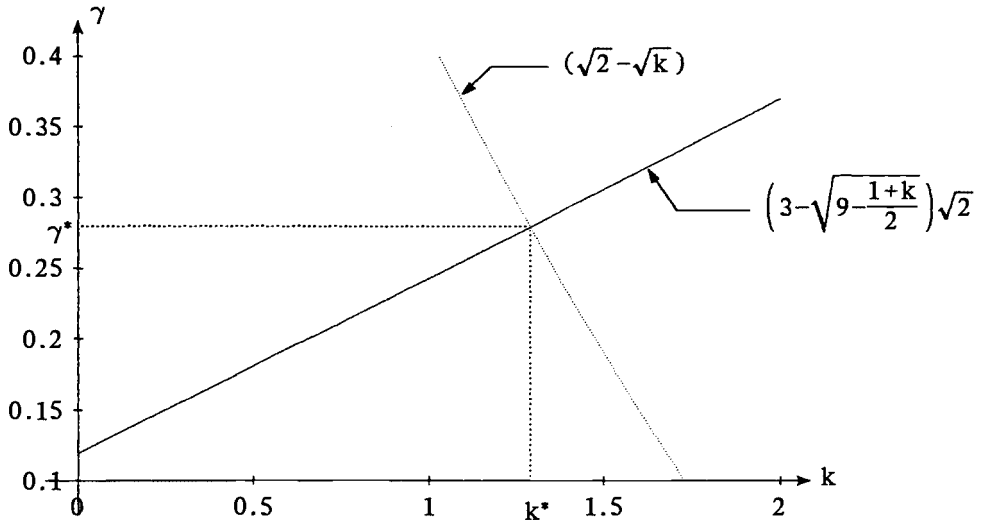

FIG. 7.

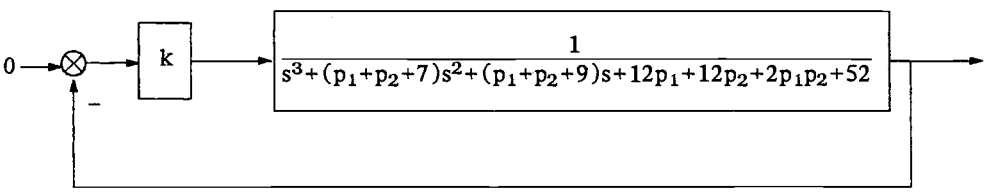

FIG. 8.

where

$$\varphi_1(\gamma^2, F) = (\gamma^2 + k + 1)^2 - 72\gamma^2, \quad \varphi_2(\gamma^2, F) = (\gamma^2 - k + 2)^2 - 8\gamma^2,$$
$$\varphi_3(\gamma^2, F) = \gamma^2 - k + 4, \quad \varphi_4(\gamma^2, F) = \gamma^2 - k + 8.$$

Using (72), we find that $\varphi(\gamma^2, F) = 0$ and $\varphi'(\gamma^2, F) = 0$ are satisfied (among other points) at $\varphi_1 = \varphi_2 = 0$. This yields $k^2 - 17k + 20.25 = 0$ or $k^* = 1.3$.

Example 2. Consider the unit feedback system described by Figure 8. Note that this example is obtained from Example 1 by a simple shift on the parameters:

$$(p_i)_o = (p_i)_n + 3, (k)_o = (k)_n + 3, \text{where } \ o = \text{old and } n = \text{new}.$$

The closed loop characteristic polynomial is

$$\Delta_c(s; p, F) = s^3 + (p_1 + p_2 + 7)s^2 + (p_1 + p_2 + 9)s + (12p_1 + 12p_2 + 2p_1p_2 + 52 + k).$$

The critical polynomial becomes

$$c(p, F) = (12p_1 + 12p_2 + 2p_1p_2 + 52 + k)((p_1 + 2)^2 + (p_2 + 2)^2 + 3 - k).$$

As a result, the stability boundary is formed of two branches—a circle and a hyperbola; see Figure 9. The circle (c.r.b.) disappears as k reaches the value 3. If we calculate the distance from each branch to the origin, we find the description of Figure 10.

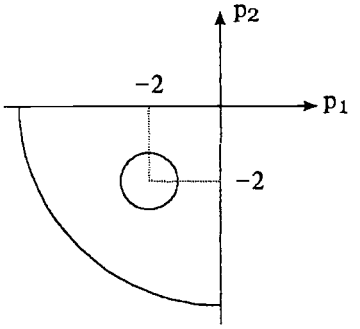

FIG. 9.

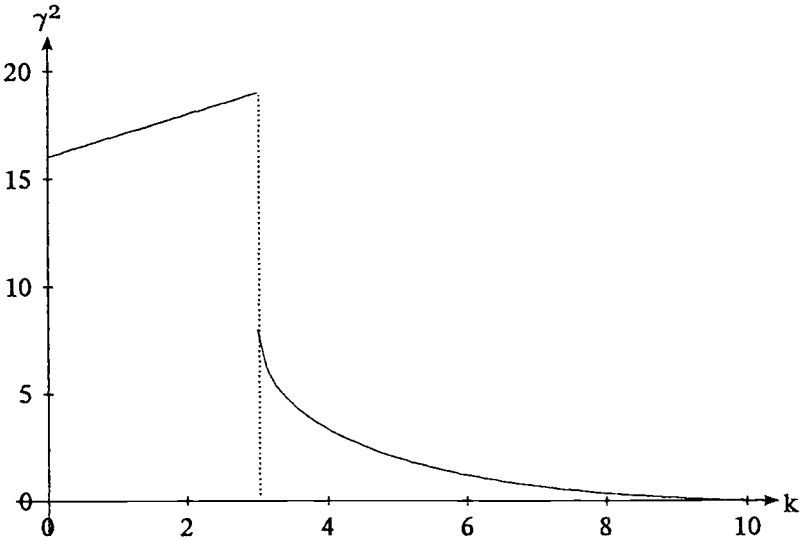

FIG. 10.

The graph illustrates that the robustness radius has a jump at $k = 3$. From an algebraic point of view, using the Grobner package in Maple 6, we obtain from (64)–(65)

$$\varphi(\gamma^2, F) = \prod_{i=1}^{5} \varphi_i(\gamma^2, F), \quad \text{where}$$

$$\varphi_1 = (\gamma^2)^2 + (2k - 184)\gamma^2 + k^2 + 2704 + 104k,$$

$$\varphi_2 = (\gamma^2)^2 - (2k + 10)\gamma^2 + k^2 - 22k + 121,$$

$$\varphi_3 = k - \gamma^2 + 16, \varphi_4 = k - \gamma^2 + 17, \varphi_5 = k - \gamma^2 + 25.$$

Using (72), we find that $\varphi(\gamma^2, F) = 0$ and $\varphi'(\gamma^2, F) = 0$ are satisfied (among other points) at $\varphi_2 = \varphi_2' = 0$. This yields $k = 3$ as expected. Clearly, this example belongs to Case 3, a singular case. It is singular in the sense that, at a max-min point, the stability radius γ has a jump, as shown in Figure 10. In fact, a closer look at

$\varphi_2 = \varphi_2' = 0$ reveals that the roots $\gamma^2(F)$ described by Figure 10 satisfy

$$\gamma^2(F) = \begin{cases} k + 16 & \text{for } -16 < k < 3, \\ k + 5 - 4\sqrt{2k-6} & \text{for } 3 < k < 11. \end{cases}$$

In closing this example, we note that, while the detection of the jump is simple, it illustrates a possible numerical difficulty. The circle tangent to the hyperbola is very close to the hyperbola along a large portion of the hyperbola.

Example 3. According to Theorem 5.1, one has to find all the solutions of the sets of equations (56), (57), and (60). In previous examples, the optimal solution belongs to set (56). The geometric reason is $l = r + 1$, where $l = 2$ is the number of tangent points and $r = 1$ is the number of control parameters. In the present example, $l = r = 2$. In particular, consider the uncertain system $\dot{x} = A(\alpha, \beta)x + B(\alpha, \beta)u$,

$$A = \begin{bmatrix} 0 & \alpha - 1 \\ \beta & 0 \end{bmatrix}, \quad B = \begin{bmatrix} \alpha \\ 1 - \beta \end{bmatrix},$$

where the uncertain parameters α and β lie in the set

$$\{(\alpha, \beta) : (\alpha - 0.5)^2 + (\beta - 0.5)^2 \leq \rho^2\}.$$

First, we transform (α, β) into (p_1, p_2) so that the nominal values $\alpha = 0.5$, $\beta = 0.5$ correspond to the origin $p_1 = 0$, $p_2 = 0$. To this end, let $p_1 = \alpha - 0.5$, $p_2 = \beta - 0.5$. Then

$$A = \begin{bmatrix} 0 & p_1 - 0.5 \\ p_2 + 0.5 & 0 \end{bmatrix}, \quad B = \begin{bmatrix} p_1 + 0.5 \\ 0.5 - p_2 \end{bmatrix},$$

where the uncertainty set takes the form

$$\Omega = \{(p_1, p_2) : p_1^2 + p_2^2 \leq \gamma^2\}.$$

Our objective is to stabilize the above uncertain system using state feedback $u = Fx$, $F = [f_1 \ f_2]$ for all $(p_1, p_2) \in \Omega$ so as to maximize the robustness radius γ. To apply Theorem 5.1, we calculate the closed loop characteristic polynomial

$$\begin{aligned} \Delta_c(s; p, F) = s^2 &- [(p_1 + 0.5)f_1 + (0.5 - p_2)f_2]s \\ &- [(p_1 - 0.5)(p_2 + 0.5) + (p_1 - 0.5)(0.5 - p_2)f_1 \\ &+ (p_1 + 0.5)(p_2 + 0.5)f_2]. \end{aligned}$$

The stability constraints are

$$\begin{aligned} c_1 &= -[(p_1 + 0.5)f_1 + (0.5 - p_2)f_2] > 0 && \text{(r.r.b.)}, \\ c_2 &= -[(p_1 - 0.5)(p_2 + 0.5) + (p_1 - 0.5)(0.5 - p_2)f_1 \\ &\quad + (p_1 + 0.5)(p_2 + 0.5)f_2] > 0 && \text{(c.r.b.)}. \end{aligned}$$

Note that the open loop satisfies $s^2 = (p_1 - 0.5)(p_2 + 0.5)$. Thus, in the region $\{(p_1, p_2) : |p_i| \leq 0.5\}$, the roots of the characteristic polynomial are all located in the interval $[-1, 1]$ on the imaginary axis. Now we wish to study the effect of feedback control on the stability. To simplify the discussion, let $F = [0 \ \ f_2]$. In this case,

$$\begin{aligned} 2c_1 &= -(1 - 2p_2)f_2 > 0, \\ 4c_2 &= -(1 + 2p_2)(-1 + 2p_1 + f_2 + 2p_1 f_2) > 0. \end{aligned}$$

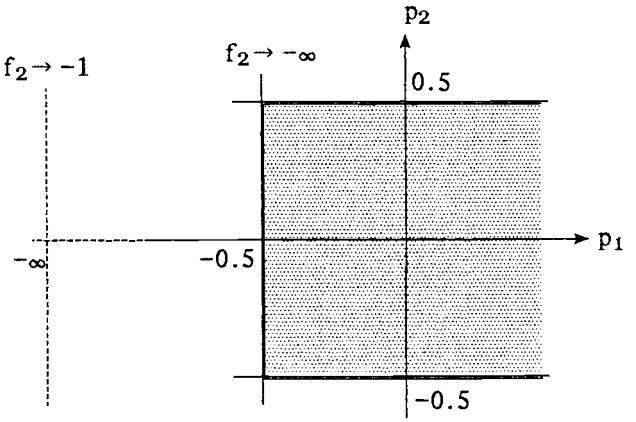

FIG. 11.

Thus the critical polynomial $c = c_1 c_2$ defines the following robust stability boundaries:

$$\{(p_1, p_2) : p_2 = 0.5\}, \quad \{(p_1, p_2) : p_2 = -0.5\}, \quad \{(p_1, p_2) : p_1 = 0.5(1 - f_2)/(1 + f_2)\}.$$

The stability region is depicted in Figure 11. The stabilizing gain is $f_2 \in (-\infty, -1)$. In other words, the use of f_2 in this interval assures stability in the shaded region.

Since the robustness radius ($\gamma^* = 0.5$) is invariant with respect to $f_2 \in (-\infty, -1)$, the optimization process does not detect any optimal point. Since the open loop is marginally stable for all $|p_i| \leq 0.5$, we modify our original objective as follows: Find $u = Fx$ such that the closed loop is stable relative to $\mathrm{Re}(s) < -0.1$. We continue with the control structure $F = [0 \;\; f_2]$. The modified characteristic polynomial becomes

$$\begin{aligned}\Delta(s - 0.1) = s^2 &- [0.2 + (0.5 - p_2)f_2]s \\ &+ [0.26 - 0.2f_2 - 0.6p_2 f_2 - p_1 p_2 - 0.5p_1 + 0.5p_2 - p_1 p_2 f_2 - 0.5p_1 f_2].\end{aligned}$$

The (relative) stability constraints are now

$$\begin{aligned}c_1 &= -0.2 - (0.5 - p_2)f_2 > 0, \\ c_2 &= 0.26 - 0.2f_2 - 0.6p_2 f_2 - p_1 p_2 - 0.5p_1 + 0.5p_2 - p_1 p_2 f_2 - 0.5p_1 f_2 > 0.\end{aligned}$$

Clearly, given f_2, $c_1 = 0$ describes a straight line, while $c_2 = 0$ describes a hyperbola. We suppose that, at the maximum robustness radius, there are two tangent points—one on the line and one on the hyperbola. The distance from the origin to the line is $0.5 + 0.2/f_2$. Let $(p_1, p_2) = (x, y)$ be the tangent point with the hyperbola. Then

$$(1) \quad x^2 + y^2 = (0.5 + 0.2/f_2)^2.$$

The tangency condition at (x, y) is

$$(2) \quad x(0.5 - x - xf_2 - 0.6f_2) - y(-0.5 - y - yf_2 - 0.5f_2) = 0,$$

and the hyperbola satisfies

$$(3) \quad c_2(x, y, f_2) = 0.$$

Solving these equations, we obtain $x = -0.02$ and $y = -0.39$, and the optimal gain is $f_2 = -1.83$. The maximum robustness radius is $\gamma^* = 0.39$.

Now we proceed to the general case where $F = [f_1 \quad f_2]$. As before, we are interested in stability with respect to $\mathrm{Re}(s) < -0.1$. Since we do not have a priori information about the number of tangent points, we assume, as before, two tangent points—one on the line and one on the hyperbola. However, in order to use the simple set of equations (56), we assume three tangent points so that $l = r + 1$ and solve (56) numerically. If our hypothesis concerning two tangent points is correct, two points must be identical. Let the point on the line be (x_1, x_2) and on the hyperbola (x_3, x_4), (x_5, x_6). Then (56) becomes

(1) $-0.8 - 4x_1f_1 - 2f_1 - 2f_2 + 4x_2f_2 = 0$,

(2) $1.04 - 1.6x_3f_1 + 1.2f_1 - 0.8f_2 - 2.4x_4f_2 - 4x_3x_4 - 2x_3 + 2x_4 + 4x_3x_4f_1 - 2x_4f_1 - 4x_3x_4f_2 - 2x_3f_2 = 0$,

(3) $1.04 - 1.6x_5f_1 + 1.2f_1 - 0.8f_2 - 2.4x_6f_2 - 4x_5x_6 - 2x_5 + 2x_6 + 4x_5x_6f_1 - 2x_6f_1 - 4x_5x_6f_2 - 2x_5f_2 = 0$,

(4) $x_1f_2 + x_2f_1 = 0$,

(5) $x_3(-2.4f_2 - 4x_3 + 2 + 4x_3f_1 - 2f_1 - 4x_3f_2) - x_4(-1.6f_1 - 4x_4 - 2 + 4x_4f_1 - 4x_4f_2 - 2f_2) = 0$,

(6) $x_5(-2.4f_2 - 4x_5 + 2 + 4x_5f_1 - 2f_1 - 4x_5f_2) - x_6(-1.6f_1 - 4x_6 - 2 + 4x_6f_1 - 4x_6f_2 - 2f_2) = 0$,

(7) $x_1^2 + x_2^2 - x_3^2 - x_4^2 = 0$,

(8) $x_1^2 + x_2^2 - x_5^2 - x_6^2 = 0$.

Solving numerically this set of equations using Maple 6, we find three real solutions:

$$
\begin{array}{lll}
(x_1, x_2) = (0.052, 0.433), & (0.044, 0.426), & (0.027, 0.412), \\
(x_3, x_4) = (0.027, -0.435), & (0.013, -0.l428), & (-0.006, -0.413), \\
(x_5, x_6) = (0.027, -0.435), & (0.013, -0.428), & (-0.006, -0.413), \\
(f_1, f_2) = (23.91, -199.9), & (1.102, -10.76), & (0.247, -3.749).
\end{array}
$$

Note, of course, that there are more real solutions to this set of equations. The first solution $(f_1, f_2) = (24, -200)$ induces a robustness radius $\gamma^* = 0.44$. This is a 12.5% increase with respect to the previous $(f_1, f_2) = (0, -1.83)$ with $\gamma^* = 0.39$. The fact that there are two identical tangent points implies that neither (56) nor (60) can be used directly. Indeed, these sets of equations are based on the assumption (which may not be necessary) of simple roots. Moreover, Maple solves the above set of equations using a gradient method, starting at some initial point. In other words, the solution containing a multiple root is approached approximately. On the other hand, the use of a homotopy method cannot detect a multiple root since homotopy curves are not allowed to intersect. Still, it is possible to use the homotopy approach indirectly by first approximating the above set of equations and then decreasing the approximation parameter.

9. Conclusions. The most important consequence of this paper is the fact that max-min completely characterizes the largest (or a fixed) ellipsoid contained in the (relative) stability region in the parameter space. As a result, we have a nonconservative approach to feedback compensation in the presence of a real parameter uncertainty. Since in max-min the inner operation results in a nondifferential function, we cannot use for the outer operation the Lagrange multiplier method. Instead, we have found that, under mild conditions, the number of extreme points is related to the (reduced) number of the controller parameters. Moreover, the largest uncertain

ellipsoid might result in a jump. In such a case, the performance of the "robust" controller is sensitive to (small) changes in control parameters. This *singular* situation can be handled using our alternative approach; however, due to elimination, it is numerically expensive. On the other hand, in the case of a fixed uncertain ellipsoid, a jump never occurs. It is worth noting that the largest uncertain ellipsoid and the fixed uncertain ellipsoid are related via limiting processes. In particular, solving (73) and increasing ρ^2 from zero, we can approach the required fixed radius. On the other hand, solving $\mathrm{Max}_F\ \mathrm{Min}_{p'Dp=r^2} c(p,F)$ by increasing r from zero, we can approach the maximum radius. The limiting process, however, requires, in principle, the solution of an infinite number of max-min problems. To achieve performance, we use relative rather than asymptotic stability. Our approach can handle both polynomial and matrix versions—the latter can be transformed into the former. The resulting necessary conditions have the form of a set of nonlinear equations. We suggest the use of a probability one homotopy method (HOMPACK [6]) for solving these equations (see also [15, 16, 17]). In the application to control theory, the functions $h(\cdot)$ and $c(\cdot)$ are usually polynomials. In this important case, the necessary conditions have the form of a set of polynomial equations, the total degree is simple to calculate, and the use of HOMPACK is simple. Moreover, in the polynomial case, the use of Grobner bases simplifies these equations and enables us to solve nontrivial control problems. Finally, the singular case needs more study. This is left for future research.

Appendix. In section 5, Case 3, we use the following result.

LEMMA A.1. *The following is satisfied in some neighborhood of F^*:*

$$\gamma(F) = \min_{1 \le i \le l} \gamma^{(i)}(F).$$

Proof. We have to show that at least one of the points $p^{(i)}(F)$ is indeed a contact point and not just one satisfying the tangency condition (42). Let

$$\|p\|_D := (p'Dp)^{1/2} = \|D^{1/2}p\|.$$

Since D is a positive definite (p.d.) matrix, it follows that $\|p\|_D$ can be used as a norm of p. Note that, if p, F, λ satisfy (42) and $p \neq 0$, then λ is uniquely determined by

$$\lambda(p,F) = \frac{c_p p}{p'Dp} = \frac{c_p p}{\|p\|_D^2}.$$

From Assumption 4.1 it follows that $\gamma^* := \gamma(F^*) = \mathrm{Max}_F \gamma(F)$. Thus F^* is a stabilizing controller for the nominal system; that is, $(0,F^*) \in \hat{\aleph}$, and, in particular, $c(0,F^*) > 0$.

Denote $S(F) := \{p^{(i)}(F)\colon\ i = 1,\dots,l\}$ in some neighborhood of F^*. By construction, $S(F^*)$ is the set of all contact points for F^*, all simple regular. Thus there exists an open set U containing $S(F^*)$ such that, for each F in some neighborhood of F^*, if p, F, λ, satisfy (42) with $p \in U$, then $p \in S(F)$. Denote $B := \{p \in \mathcal{R}^m : \|p\|_D \le \gamma^*\}$. By construction, $S(F^*) \subset U$. Thus $p \in B\backslash U$ implies $p \notin S(F^*)$, and $p \in B\backslash U \Longrightarrow c(p,F^*) \neq 0$. We conclude that the compactness of $B\backslash U$ and the continuity of $c(p,F)$ imply that there exists an open set V containing $B\backslash U$ such that, for each F in some neighborhood of F^*, $p \in V \Rightarrow c(p,F) \neq 0$.

Now denote $W = U \cup V$. Then W^c, the complement of W, is a closed set (nonempty, since we may assume that W is bounded). Thus we may denote $\gamma_+ :=$

$\mathrm{Min}_{p\in W^c}\|p\|_D$. Since $B\backslash U \subset V$, it follows that $B \subset W$; thus $p \in W^c \Rightarrow p \notin B \Rightarrow \|p\|_D > \gamma^*$, and $\gamma_+ > \gamma^*$.

Since F^* stabilizes the nominal system, and since the zeros of $\Delta(\cdot; 0, F)$ vary continuously with F, it follows that, for each F in some neighborhood of F^*, $(0, F) \in \hat{\aleph}$. Since $\|p^{(1)}(F^*)\|_D = \gamma^* < \gamma_+$, it follows from the continuity of $p^{(1)}(F)$ at F^* that there exists a neighborhood U_{F^*} of F^* for which $\gamma(F) = \mathrm{Min}_{c(p,F)=0}\|p\|_D \leq \|p^{(1)}(F)\|_D < \gamma_+$, $F \in U_{F^*}$. Thus, if $F \in U_{F^*}$ with a contact point $p(F)$, it follows that $\|p(F)\|_D = \gamma(F) < \gamma_+ = \mathrm{Min}_{p\in W^c}\|p\|_D$; thus $p(F) \notin W^c$; that is, $p(F) \in W = U \cup V$.

Now, if $p(F) \in V$, it follows from the definition of V (with U_{F^*} sufficiently small) that $c(p(F), F) \neq 0$, contradicting the fact that $p(F)$ is a contact point for F. We thus conclude that $p(F) \in U\backslash V$. Since $p(F)$ satisfies (42), it follows from the definition of U (with U_{F^*} sufficiently small) that $p(F) \in S(F)$. Thus $\gamma(F) = \|p(F)\|_D > \mathrm{Min}_{p\in S(F)}\|p\|_D$. On the other hand, $\gamma(F) = \mathrm{Min}_{c(p,F)=0}\|p\|_D \leq \mathrm{Min}_{p\in S(F)}\|p\|_D$. Thus we finally conclude:

$$\gamma(F) = \min_{p\,\in\, S(F)} \|p\|_D = \min_{1\,\leq\, i\,\leq\, l} \|p^{(i)}(F)\|_D, F \in U_{F^*}. \qquad \square$$

POLE PLACEMENT BY STATIC OUTPUT FEEDBACK FOR GENERIC LINEAR SYSTEMS*

A. EREMENKO† AND A. GABRIELOV†

Abstract. We consider linear systems with m inputs, p outputs, and McMillan degree n such that $n = mp$. If both m and p are even, we show that there is a nonempty open (in the usual topology) subset U of such systems, where the real pole placement map is not surjective. It follows that, for each system in U, there exists an open set of pole configurations, symmetric with respect to the real line, which cannot be assigned by any real static output feedback.

Key words. linear systems, static output control feedback, pole placement

1. Introduction.

We consider *linear systems* $S = (A, B, C)$ described by the equations

$$\begin{aligned} \dot{x} &= Ax + Bu, \\ y &= Cx. \end{aligned} \tag{1.1}$$

Here the state x, the input u, and the output y are functions of a real variable t (time), with values in $\mathbf{R}^n$, $\mathbf{R}^m$, and $\mathbf{R}^p$, respectively, the dot denotes the derivative with respect to t, and A, B, C are real matrices of sizes $n \times n$, $n \times m$, and $p \times n$, respectively.

Assuming zero initial conditions and applying the Laplace transform, we obtain

$$Y(s) = C(sI - A)^{-1} B\, U(s),$$

so the behavior of our linear system is described by a rational matrix-function $C(sI - A)^{-1}B$ of size $p \times m$ of a complex variable s, which is called the (open loop) *transfer function* of S. It is clear that $G(\infty) = 0$. The poles of the transfer function are the eigenvalues of the matrix A.

For a given $p \times m$ matrix function G with the property $G(\infty) = 0$, there exist infinitely many representations of G in the form $G(s) = C(sI - A)^{-1}B$. The smallest integer n over all such representations is called the *McMillan degree* of G.

We consider the possibility of controlling a given system S by attaching a feedback. This means that the output is sent to the input after a preliminary linear transformation, called a *compensator*. The compensator may be another system of the form (1.1) (dynamic output feedback) or just a constant matrix (static output feedback). In this paper, we consider only static output feedback, referring for the recent results on dynamic output feedback to [14, 11].

A static output feedback is described by the equation

$$u = Ky, \tag{1.2}$$

where K is an $m \times p$ matrix which is usually called a *gain* matrix. Eliminating u and y gives

$$\dot{x} = (A + BKC)x,$$

whose characteristic polynomial is

$$\varphi_K(s) = \det(sI - A - BKC). \tag{1.3}$$

It is called the *closed loop characteristic polynomial.*

The pole placement problem is formulated as follows.

Given a system $S = (A, B, C)$ and a set of points $\{s_1, \dots, s_n\}$ in $\mathbf{C}$ (listed with multiplicities) symmetric with respect to the real axis, find a real matrix K such that the zeros of φ_K are exactly $s_1, \dots, s_n$.

For a fixed system S, we define the (real) *pole placement map*

$$\chi_S : \mathrm{Mat}_{\mathbf{R}}(m \times p) \to \mathrm{Poly}_{\mathbf{R}}(n), \quad \chi_S(K) = \varphi_K, \tag{1.4}$$

where $\mathrm{Mat}_{\mathbf{R}}(m \times p)$ is the set of all real matrices of size $m \times p$, $\mathrm{Poly}_{\mathbf{R}}(n)$ is the set of all real monic polynomials of degree n, and the polynomial φ_K is defined in (1.3). Thus to say that, for a system S, an arbitrary symmetric set of poles can be assigned by a real gain matrix is the same as saying that the real pole placement map χ_S is surjective. Extending the domain to complex matrices K and the range to complex monic polynomials gives the *complex pole placement map*

$$\mathrm{Mat}_{\mathbf{C}}(m \times p) \to \mathrm{Poly}_{\mathbf{C}}(n),$$

defined by the same formula as the real one.

It is easy to see that, for every m, n, p, there are systems for which the pole placement map is not surjective. For example, one can take $B = 0$ or $C = 0$. A necessary condition of surjectivity proved in [13] is that S is observable and controllable. This is equivalent to saying that the McMillan degree of the transfer function is equal to n, the dimension of the state space. Notice that this property is *generic:* it holds for an open dense subset of the set

$$\mathfrak{A} = \mathrm{Mat}_{\mathbf{R}}(n \times n) \times \mathrm{Mat}_{\mathbf{R}}(n \times m) \times \mathrm{Mat}_{\mathbf{R}}(p \times n)$$

of all triples (A, B, C). All topological terms in this paper refer to the usual topology.

In this paper, we consider the following problem: *for a given triple of integers (m, n, p), does there exist an open dense subset $V \subset \mathfrak{A}$ such that the real pole placement map χ_S is surjective for $S \in V$?* If this is the case, we say that the real pole placement map is *generically surjective* for these m, n, and p.

We briefly recall the history of the problem, referring to a comprehensive survey [2]. The pole placement map defined by (1.3) and (1.4) is a regular map of affine algebraic varieties. Comparing the dimensions of its domain and range, we conclude that $n \leq mp$ is a necessary condition for generic surjectivity of the pole placement map, real or complex. In the complex case, this condition is also sufficient [7]. To show this, one extends the pole placement map to a regular map between compact algebraic manifolds and verifies that its Jacobi matrix is of full rank. In the case when $n = mp$, we have the following precise result.

THEOREM A (see [1]). *For $n = mp$, the complex pole placement map is generically surjective. Moreover, it extends to a finite regular map between projective varieties and has degree*

$$d(m,p) = \frac{1!2!\dots(p-1)!\,(mp)!}{m!(m+1)!\dots(m+p-1)!}.$$

It follows that, for a generic system (A,B,C) with $n = mp$ and a generic monic complex polynomial φ of degree mp, there are $d(m,p)$ complex matrices K such that $\varphi_K = \varphi$.

The numbers $d(m,p)$ occur as the solution of the following problem of enumerative geometry: how many m-subspaces intersect mp given p-subspaces in $\mathbf{C}^{m+p}$ in a general position? The answer $d(m,p)$ was obtained by Schubert in 1886 (see, for example, [9]).

The real pole placement map is harder to study. For a survey of early results, we refer to [2, 12]. Wang [16] proved that $n < mp$ is sufficient for generic surjectivity of a real (or complex) pole placement map. A simplified proof of this result can be found in [17, 12].

From now on, we discuss only the so-called critical case; that is, we assume that

$$n = mp$$

in the rest of the paper. In addition, we may assume, without loss of generality, that $p \le m$, in view of the symmetry of our problem with respect to the interchange of m and p (see, for example, [15, Theorem 3.3]).

One corollary from Theorem A is that the real pole placement map is generically surjective if $d(m,p)$ is odd. This number is odd if and only if one of the following conditions is satisfied [2]: (a) $\min\{m,p\} = 1$ or (b) $\min\{m,p\} = 2$, and $\max\{m,p\}+1$ is an integral power of 2.

In the opposite direction, Willems and Hesselink [18] found by explicit computation that the real pole placement map is not generically surjective for $(m,p) = (2,2)$. A closely related fact, that the problem of enumerative geometry mentioned above may have no real solutions for the case $(m,p) = (2,2)$, even when the given 2-subspaces are real, is mentioned in [8].

In [13], Rosenthal and Sottile found with a rigorous computer-assisted proof that the real pole placement map is not generically surjective in the case $(m,p) = (4,2)$, thus disproving a conjecture of Kim that $(2,2)$ is the only exceptional case.

In [6], we showed that the real pole placement map is not generically surjective when $p = 2$ and m is even, thus extending the negative results for the cases $(2,2)$ and $(4,2)$ stated above.

In the present paper, we extend this result to all cases when both m and p are even.

THEOREM 1.1. *If $n = mp$ and m and p are both even, then the real pole placement map is not generically surjective.*

Our proof of Theorem 1.1 explicitly gives a system $S_0 \in \mathfrak{A}$ and a polynomial element $u(s) = s(s^2+1)^{mp/2-1}$ such that, for any S' in a neighborhood of S_0, the real pole placement map $\chi_{S'}$ omits a neighborhood of u.

Our proofs in [6] depend on a hard analytic result from [5], related to the so-called B. and M. Shapiro conjecture, which is stated below in section 2. The proofs in the present paper are new, even in the case $\min\{m,p\} = 2$, and they are elementary.

We conclude the introduction with an unsolved problem.

A system S is called stabilizable (by real static output feedback) if there exists a gain matrix $K \in \mathrm{Mat}_{\mathbf{R}}(m \times p)$ such that all zeros of the closed loop characteristic polynomial φ_K belong to the left half-plane. From the positive results on pole placement stated above, it follows that generic systems with m inputs, p outputs, and state of dimension n are stabilizable if $n < mp$ or if $n = mp$ and $m + p$ is odd. We ask whether generic systems with $n = mp$ and even m and p are stabilizable. The answer is known to be negative in the case $(m, p) = (2, 2)$ [3]. For complex output feedback, with static or dynamic compensators, the problem of generic stabilizability was solved in [10].

2. A class of linear systems. We begin with a well-known transformation of the closed loop characteristic polynomial (1.3). The open loop transfer function of a system of McMillan degree n, equal to the dimension of the state space, can be factorized as

$$C(sI - A)^{-1}B = D(s)^{-1}N(s), \quad \det D(s) = \det(sI - A), \tag{2.1}$$

where D and N are polynomial matrix-functions of sizes $p \times p$ and $p \times m$, respectively. For the possibility of such factorization for systems (1.1) of McMillan degree n, we refer to [4, Assertion 22.6]. Using (2.1) and the identity $\det(I - PQ) = \det(I - QP)$, which is true for all rectangular matrices of appropriate dimensions, we write

$$\begin{aligned}\varphi_K(s) &= \det(sI - A - BKC) = \det(sI - A)\det(I - (sI - A)^{-1}BKC)\\ &= \det(sI - A)\det(I - C(sI - A)^{-1}BK)\\ &= \det D(s)\det(I - D(s)^{-1}N(s)K) = \det(D(s) - N(s)K).\end{aligned}$$

This can be rewritten as

$$\varphi_K(s) = \det\left([D(s), N(s)]\begin{bmatrix} I \\ -K \end{bmatrix}\right). \tag{2.2}$$

Now we extend $\chi_S : K \mapsto \varphi_K$ to a map between compact manifolds. For this purpose, we allow an arbitrary $(m + p) \times p$ complex matrix L of rank p in (2.2) instead of

$$\begin{bmatrix} I \\ -K \end{bmatrix}, \tag{2.3}$$

and we define

$$\varphi_L(s) = \det\left([D(s), N(s)]\ L\right). \tag{2.4}$$

A system S represented by $[D(s), N(s)]$ is called *nondegenerate* if $\varphi_L \not\equiv 0$ for every $(m + p) \times p$ matrix L of rank p. Such matrices are called equivalent; $L_1 \sim L_2$ if $L_1 = L_2U$, where $U \in GL_p(\mathbf{C})$. The set of equivalence classes is the Grassmannian $G_{\mathbf{C}}(p, m + p)$, which is a compact algebraic manifold of dimension mp. If $L_1 \sim L_2$, we have $\varphi_{L_1} = c\varphi_{L_2}$, where $c \neq 0$ is a constant. The space of all nonzero polynomials of degree at most mp, modulo proportionality, is identified with the projective space $\mathbf{CP}^{mp}$, coefficients of the polynomials serving as homogeneous coordinates. Monic polynomials represent the points of an open dense subset of $\mathbf{CP}^{mp}$, a so-called *big cell,* which consists of polynomials of degree mp. This construction extends the complex pole placement map of a nondegenerate system to a regular map of compact algebraic manifolds

$$\chi_S : G_{\mathbf{C}}(p, m + p) \to \mathbf{CP}^{mp}, \tag{2.5}$$

where $\chi_S(L)$ is the proportionality class of the polynomial φ_L in (2.4), and L is a matrix of rank p representing a point in $G_{\mathbf{C}}(p, m+p)$. The set $\mathfrak{B}$ of all nondegenerate systems is open and dense in the set $\mathfrak{A}$ of all systems, and the map

$$X \times G_{\mathbf{C}}(p, m+p) \to \mathbf{CP}^{mp}, \quad (S, L) \mapsto \chi_S(L) \tag{2.6}$$

is continuous. Notice that the subset of $G_{\mathbf{R}}(p, m+p)$ consisting of points which can be represented by matrices L of the form (2.3) is open and dense. It corresponds via χ_S to the big cell in $\mathbf{CP}^{mp}$ consisting of polynomials of degree mp.

We consider a system $S_0 = (A_0, B_0, C_0)$ represented by the polynomial matrix $[D(s), N(s)]$

$$= \begin{bmatrix} 1 & s & \dots & s^{m+p-2} & s^{m+p-1} \\ 0 & 1 & \dots & (m+p-2)s^{m+p-3} & (m+p-1)s^{m+p-2} \\ \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & \dots & (m+1)\dots(m+p-1)s^m \end{bmatrix}. \tag{2.7}$$

The first row of $[D(s), N(s)]$ consists of monic monomials, and the kth row is the $(k-1)$st derivative of the first for $2 \le k \le p$. This system S_0 has McMillan degree mp, and the matrices A_0, B_0, C_0 can be recovered from $[D, N]$ by [4, Theorem 22.18]. Let $L = (a_{i,j})$. Introducing polynomials

$$f_j(s) = a_{1,j} + a_{2,j}s + \dots + a_{m+p-1,j}s^{m+p-2} + a_{m+p,j}s^{m+p-1} \tag{2.8}$$

for $1 \le j \le p$, we can write (2.4) as

$$\varphi_L = W(f_1, \dots, f_p) = \begin{vmatrix} f_1 & \dots & f_p \\ f_1' & \dots & f_p' \\ \dots & \dots & \dots \\ f_1^{(p-1)} & \dots & f_p^{(p-1)} \end{vmatrix}.$$

Thus, for our system (A_0, B_0, C_0), the pole placement map becomes the *Wronski map,* which sends a p-vector of polynomials into their Wronski determinant. We say that two p-vectors of polynomials are equivalent, $(f_1, \dots, f_p) \sim (g_1, \dots, g_p)$, if $(g_1, \dots, g_p) = (f_1, \dots, f_p)U$, where $U \in GL_p(\mathbf{C})$. Equivalent p-vectors have proportional Wronski determinants. Equivalence classes of p-vectors of linearly independent polynomials of degree at most $m+p-1$ parametrize the Grassmannian $G_{\mathbf{C}}(p, m+p)$. A p-vector of complex polynomials will be called *real* if it is equivalent to a p-vector of real polynomials. The system represented by (2.7) is nondegenerate. This is a consequence of the well-known fact that the Wronski determinant of p polynomials is zero if and only if the polynomials are linearly dependent.

To prove Theorem 1.1, we use the following general result (compare [13, Theorem 3.1]).

PROPOSITION 2.1. *If, for some (m, n, p), there exists a real nondegenerate system $S_0 = (A_0, B_0, C_0)$ such that the real pole placement map χ_{S_0} in (2.5) is not surjective, then, for these (m, n, p), the real pole placement map is not generically surjective.*

Indeed, if χ_{S_0} omits one point u, it omits a neighborhood of u, because the image of a compact space under a continuous map is compact. Using continuity of the map (2.6), we conclude that, for all S in a neighborhood of S_0, the maps χ_S omit a neighborhood of u. □

In view of Proposition 2.1, to prove Theorem 1.1, it is enough to find a nonzero real polynomial of degree at most mp which cannot be represented as the Wronski

determinant of p real polynomials of degree at most $m+p-1$. Thus Theorem 1.1 follows from Proposition 2.1 and the following proposition.

PROPOSITION 2.2. *If $m \geq p \geq 2$ are even integers, then the polynomial $u(s) = s(s^2+1)^{mp/2-1}$ is not proportional to the Wronski determinant of any p real polynomials of degree at most $m+p-1$.*

Proposition 2.2 is motivated by a conjecture of B. and M. Shapiro (see, for example, [15]), which says: *If the Wronskian determinant of a polynomial p-vector has only real roots, then this p-vector is real.* In [5], we proved this conjecture for $p=2$ and used this result in [6] to derive the case $p=2$ of Theorem 1.1. In the present paper, we prove a result, Proposition 3.1 in section 3, which is a very special case of the B. and M. Shapiro conjecture, but it still permits us to derive Proposition 2.2.

3. The Wronski map. A p-vector of linearly independent polynomials of degree at most $m+p-1$ can be represented by an $(m+p)\times p$ matrix L of rank p, whose columns are composed of the coefficients of the polynomials as in (2.8).

The group $GL_p(\mathbf{C})$ acts on such matrices by multiplication from the right. This action is equivalent to the usual column operations on matrices: interchanging two columns, multiplying a column by a nonzero constant, and adding to a column a multiple of another column. For each column j of L, we introduce two integers $1 \leq e_j \leq d_j \leq m+p$, which are the positions of the first and last nonzero elements of this column, counted from above. Thus $\deg f_j = d_j - 1$, and the order of a root of f_j at zero is $e_j - 1$. It is easy to see that, by column operations, every $(m+p)\times p$ matrix $L = (a_{i,j})$ of rank p can be reduced to the following *canonical form:*

(i) $d_1 > d_2 > \cdots > d_p$,

(ii) $a_{e_j,j} = 1$ for every $j \in [1,p]$,

(iii) $a_{e_k,j} = 0$ for $1 \leq j < k \leq p$.

The elements $a_{e_j,j} = 1$, $1 \leq j \leq p$, of the canonical form will be called the *pivot* elements. It follows from (iii) that all numbers e_j are distinct.

PROPOSITION 3.1. *Suppose that mp is even. Then every polynomial p-vector $(f_1,\dots,f_p)$ of degree at most $m+p-1$ in canonical form, which satisfies*

$$W(f_1,\dots,f_p) = \lambda w, \quad \text{where} \quad w(s) = s^{mp/2+1} - s^{mp/2-1}, \quad \lambda \in \mathbf{C}^*, \tag{3.1}$$

has only real entries.

COROLLARY. *All polynomial p-vectors of degree at most $m+p-1$ satisfying* (3.1) *are real.*

This corollary confirms a special case of the B. and M. Shapiro conjecture, when the Wronskian determinant of a polynomial p-vector is $w(s) = s^{mp/2+1} - s^{mp/2-1}$, which is a polynomial with real roots $0, \pm 1$.

The properties of the Wronskian determinants used here are well known and easy to prove.

LEMMA. *The Wronski map $(f_1,\dots,f_p) \mapsto W(f_1,\dots,f_p)$ is linear with respect to each f_j, and*

$$W(s^{n_1},\dots,s^{n_p}) = V(n_1,\dots,n_p)s^{n_1+\cdots+n_p-p(p-1)/2},$$

where

$$V(n_1,\dots,n_p) = \prod_{k<j}(n_j - n_k)$$

is the Vandermonde determinant. □

Using this lemma, we compute the Wronskian determinant of a polynomial p-vector in canonical form and conclude that

$$\deg W(f_1, \dots, f_p) = d_1 + \cdots + d_p - p(p+1)/2 \tag{3.2}$$

and

$$\operatorname{ord} W(f_1, \dots, f_p) = e_1 + \cdots + e_p - p(p+1)/2, \tag{3.3}$$

where ord denotes the multiplicity of a root at zero.

Proof of Proposition 3.1. According to (3.1), $\deg w = mp/2 + 1$, and $\operatorname{ord} w = mp/2 - 1$. So (3.2) and (3.3) imply

$$\begin{aligned} d_1 + \cdots + d_p &= p(p+1)/2 + mp/2 + 1, \\ e_1 + \cdots + e_p &= p(p+1)/2 + mp/2 - 1. \end{aligned}$$

Subtracting the second equation from the first, we get

$$\sum_{j=1}^{p} (d_j - e_j) = 2.$$

As all the summands are nonnegative, there are two possibilities.

Case 1. In all columns but one, all elements, except the pivot elements, are equal to zero, and, for the exceptional column j, $d_j - e_j = 2$. Computing the Wronskian and comparing it with (3.1), we obtain

$$\begin{aligned} & V(\dots, e_j - 1, \dots) s^{mp/2-1} \\ + \quad & V(\dots, e_j, \dots) a_{e_j+1,j} s^{mp/2} \\ + \quad & V(\dots, e_j + 1, \dots) a_{e_j+2,j} s^{mp/2+1} \\ = \quad & -\lambda s^{mp/2-1} + \lambda s^{mp/2+1}. \end{aligned}$$

Here and in what follows, the notation $V(\dots, e_j + m, \dots)$ means the Vandermonde determinant of p arguments, whose kth argument is $e_k - 1$ for $k \neq j$ and whose jth argument is $e_j + m$.

Comparing the terms with $s^{mp/2-1}$, we conclude that λ is real. Comparing the terms with $s^{mp/2+1}$, we conclude that $V(\dots, e_j + 1, \dots) \neq 0$, and thus $a_{e_j+2,j}$ is real. Now we consider the middle term in the expansion of the Wronskian determinant. If $V(\dots, e_j, \dots) = 0$, then $e_k = e_j + 1$ for some k. As $d_k = e_k$ and $d_j = e_j + 2$, we conclude that $d_k = d_j - 1$, so $k > j$ by (i) in the definition of the canonical form. Now (iii) from the definition of the canonical form implies that $a_{e_j+1,j} = 0$. If $V(\dots, e_j, \dots) \neq 0$, we also conclude that $a_{e_j+1,j} = 0$. Thus all entries of L are real.

Case 2. In all columns but two, all nonpivot elements are equal to zero, and the two exceptional columns contain one extra nonzero element each. Let $j < k$ be the positions of the exceptional columns, and let $a = a_{e_j+1,j}$ and $b = a_{e_k+1,k}$ be the nonzero, nonpivot elements of these columns. Computing the Wronskian and comparing it with (3.1), we obtain

$$\begin{aligned} & V(\dots, e_j - 1, \dots) s^{mp/2-1} \\ + \quad & \left(aV(\dots, e_j, \dots) + bV(\dots, e_k, \dots)\right) s^{mp/2} \\ + \quad & abV(\dots, e_j, \dots, e_k, \dots) s^{mp/2+1} \\ = \quad & -\lambda s^{mp/2-1} + \lambda s^{mp/2+1}, \end{aligned} \tag{3.4}$$

where $V(\dots, e_j, \dots, e_k \dots)$ denotes the Vandermonde determinant of p arguments, whose jth argument is e_j and whose kth argument is e_k, and, for all other indices $l \notin \{j, k\}$, the lth argument is $e_l - 1$.

Our first conclusions are

$$V(\dots, e_j - 1, \dots) = -\lambda \tag{3.5}$$

and

$$V(\dots, e_j, \dots, e_k, \dots) \neq 0. \tag{3.6}$$

It follows from (3.5) that λ is real. If exactly one of the numbers $V(\dots, e_j, \dots)$ and $V(\dots, e_k, \dots)$ is zero, then (3.4) implies that at least one of the numbers a or b is zero. Then the third term in the expansion of the Wronskian is zero, which contradicts (3.4). If both $V(\dots, e_j, \dots)$ and $V(\dots, e_k, \dots)$ are zero, then $V(\dots, e_j, \dots, e_k, \dots) = 0$, and this contradicts (3.6). So both $V(\dots, e_j, \dots)$ and $V(\dots, e_k, \dots)$ are nonzero. This means that there are no pivot elements in the rows $e_j + 1$ and $e_k + 1$. Using (3.6), we conclude that $V(\dots, e_j - 1, \dots)$, $V(\dots, e_j, \dots)$, $V(\dots, e_k, \dots)$, and $V(\dots, e_j, \dots, e_k, \dots)$ have the same sign, and, by (3.5), all these numbers have the sign of $-\lambda$. As $V(\dots, e_j, \dots)$ and $V(\dots, e_k, \dots)$ are of the same sign, (3.4) implies that $a = -cb$, where $c > 0$, and from the equations

$$V(\dots, e_j, \dots, e_k, \dots)ab = \lambda$$

and (3.5) we conclude that a and b are real. □

The group $\mathrm{Aut}(\mathbf{CP}^1)$ of fractional-linear transformations acts on the space $\mathbf{CP}^k$ of proportionality classes of nonzero polynomials of degree at most k by the following rule: Let

$$\ell(s) = \frac{as + b}{cs + d}, \quad ad - bc \neq 0,$$

represent a fractional-linear transformation. For a polynomial $r(s)$, we put

$$\ell r(s) = (-cs + a)^k r \circ \ell^{-1}(s).$$

That this is indeed a group action can be verified as follows. The space of proportionality classes of nonzero polynomials of degree at most k can be canonically identified with the symmetric power $\mathrm{Sym}^k(\mathbf{CP}^1)$, which is the set of unordered k-tuples of points in $\mathbf{CP}^1$. To each polynomial r, one puts into correspondence its roots, counted with multiplicity, and the point ∞ with multiplicity $k - \deg r$. Then the action of $\ell \in \mathrm{Aut}(\mathbf{CP}^1)$ on such a k-tuple is simply

$$(s_1, \dots, s_k) \mapsto (\ell(s_1), \dots, \ell(s_k)).$$

It is easy to verify that this action of $\mathrm{Aut}(\mathbf{CP}^1)$ extends to the space $G_{\mathbf{C}}(p, m+p)$ of equivalence classes of polynomial p-vectors of degree at most $m+p-1$. Furthermore, this extended action is respected by the Wronski map:

$$W(\ell g_1, \dots, \ell g_p) = \ell W(g_1, \dots, g_p). \tag{3.7}$$

Of course, in the left-hand side of this equality, the group $\mathrm{Aut}(\mathbf{CP}^1)$ acts on $\mathrm{Sym}^{m+p-1}(\mathbf{CP}^1)$, while, in the right-hand side, it acts on $\mathrm{Sym}^{mp}(\mathbf{CP}^1)$. Equation (3.7) permits us to simplify the polynomial equation

$$W(g_1, \dots, g_p) = v, \quad v(s) \sim s(s^2 - 1)^{mp/2-1}, \tag{3.8}$$

which will be used to prove Proposition 2.2.

Consider the fractional-linear transformation

$$\ell(s) = \ell^{-1}(s) = \frac{1-s}{1+s}. \tag{3.9}$$

We have $\ell : (0, 1, \infty, -1) \mapsto (1, 0, -1, \infty)$, and $\ell(\overline{\mathbf{R}}) = \overline{\mathbf{R}}$.

Using (3.8) and (3.9), we obtain

$$\ell v(s) = (s+1)^{mp} v \circ \ell^{-1}(s) \sim s^{mp/2+1} - s^{mp/2-1} = w(s),$$

where "$\sim$" means "proportional." Thus, with $f_j = \ell g_j$, (3.8) is equivalent to the equation

$$W(f_1, \dots, f_p) = w, \quad w(s) \sim s^{mp/2+1} - s^{mp/2-1}, \tag{3.10}$$

which we solved in Proposition 3.1. The conclusion is that

(3.11) all solutions of (3.8) in canonical form have real coefficients.

Proof of Proposition 2.2. Suppose that $(f_1, \dots, f_p)$ is a real polynomial p-vector in canonical form satisfying

$$W(f_1, \dots, f_p) = u, \quad u(s) = \lambda s(s^2+1)^{mp/2-1}, \quad \lambda \neq 0. \tag{3.12}$$

Then (3.3) implies

$$e_1 + \cdots + e_p = 1 + p(p+1)/2.$$

As $(e_j)_{j=1}^p$ are distinct positive integers, the only possibility is that

$$\{e_1, \dots, e_p\} = \{1, 2 \dots, p-1, p+1\}. \tag{3.13}$$

Similarly, (3.2) implies

$$d_1 + \cdots + d_p = mp + p(p+1)/2 - 1.$$

As $(d_j)_{j=1}^p$ are distinct integers in the interval $[1, m+p]$, the only possibility is that

$$\{d_1, \dots, d_p\} = \{m, m+2, m+3, \dots, m+p\}. \tag{3.14}$$

Notice that the sequence (3.13) contains $p/2+1$ odd numbers and $p/2-1$ even numbers. On the other hand, the sequence (3.14) contains $p/2-1$ odd numbers and $p/2+1$ even numbers. This implies that, at least for one j,

$$d_j - e_j \quad \text{is odd.} \tag{3.15}$$

This means that the polynomial f_j contains both even and odd powers of s with nonzero coefficients. So the polynomial $g_j(s) = f_j(is)$, $i = \sqrt{-1}$, is not proportional to any polynomial with real coefficients. On the other hand, the polynomial p-tuple $(g_1, \dots, g_p)$, where $g_j(s) = \epsilon_j f_j(is)$ with appropriate $\epsilon_j \in \{\pm 1, \pm i\}$, is a solution of (3.8) in canonical form, and we know from (3.11) that all such solutions have real coefficients. This contradiction completes the proof of Proposition 2.2. ∎

Acknowledgment. We thank the referees of this paper for their helpful comments.

FILTERING FOR LINEAR SYSTEMS DRIVEN BY FRACTIONAL BROWNIAN MOTION*

N. U. AHMED† AND C. D. CHARALAMBOUS‡

Abstract. In this paper we study continuous time filtering for linear multidimensional systems driven by fractional Brownian motion processes. We present the derivation of the optimum linear filter equations which involve a pair of functional-differential equations giving the optimum error covariance (matrix-valued) functions and the optimum filter. These equations are the appropriate substitutes of the matrix-Riccati differential equation arising in classical Kalman filtering. However, the optimum filter has the classical appearance, and, as usual, it is driven by the increments of the observed process.

Key words. linear filtering, fractional Brownian motion

1. Introduction.

In recent years, there has been renewed interest in fractional Brownian motion, originally introduced by Mandelbrot and Van Ness [1], to model phenomena that exhibit so-called self-similarity, which is a form of time invariance of the fundamental structure of the process (fractal), and long range dependence. The long range dependence, which is absent in regular Brownian motion or, more precisely, its (distributional) derivative, the white noise, is historically observed in the study of water accumulation in hydrology [1], ethernet and ATM traffic in telecommunication systems [7, 8], and stock prices in mathematical finance.

A natural question which arises regards the filtering of stochastic dynamical systems driven by fractional Brownian motion, when the measurements are linear in the unobservable variable in additive fractional Brownian motion. Many problems in engineering and science are of this nature, and therefore it is natural to generalize the linear filtering theory to cover the case in which the standard Brownian motion is replaced by fractional Brownian motion. However, unlike the classical Kalman filtering problem, the optimal filter for linear systems perturbed by fractional Brownian motion is not straightforward. This is easily verified by consulting the results described in [14, 11, 13, 16], where the authors treat various versions of filtering and prediction for fractional processes. In particular, it is easily seen in [14] that even the linear prediction problem of fractional Brownian motion based on its past history leads to complicated expressions, and similarly for the rest of these references, which treat the scalar case.

In this paper, we derive the best linear filter for the multidimensional case, when the state is described by a linear stochastic differential equation driven by fractional Brownian motion and the observations are linear in the state process and subject to additive fractional Brownian motion noise. We show that the methodology of variational methods, extensively discussed in [4, 5, 6] for deriving the best linear filter

when the noises are standard Brownian motions, also apply to the current set-up, although the resulting equations are more complicated. In particular, the gain of the filter is shown to satisfy two coupled functional integro-differential matrix equations. In the limit as the fractional Brownian motion in the dynamics or observations, which have different Hurst parameters, converges to the standard Brownian motion (through the convergence of either of the Hurst parameters to 1/2), we also obtain special forms of the coupled functional equations, which include the well-known Riccati equation of the error covariance of the Kalman filter, when both Hurst parameters converge to 1/2. Thus, our results give as a special case the solution to the linear filtering problem when one of the noises is a fractional Brownian motion while the other is a standard Brownian motion. We also propose a numerical technique for computing the solution of the coupled functional equations, which merits further investigation.

The key properties of fractional Brownian motion are by now well known and documented [9, 10, 11, 12, 13, 14, 15, 16, 17; 2, 3]. We shall attempt to summarize only those results which are important in subsequent developments, while referring to these references for the proofs.

Let $(\Omega, \mathcal{F}, P)$ be a probability space and $H \in (0,1)$. A parameterized family of random process $\{B_{H_1}(t), t \geq 0\}$ based on this probability space is said to be a fractional Brownian motion if

(i) $P\{B_H(0) = 0\} = 1$;

(ii) for each $t \in R_+ \equiv [0, \infty)$, $B_H(t)$ is an $\mathcal{F}$-measurable random variable having Gaussian distribution with $E\{B_H(t)\} = 0$;

(iii) for $t, s \in R_+$, $E\{B_H(t)B_H(s)\} = (1/2)\{t^{2H} + s^{2H} - |t-s|^{2H}\}$.

It follows from (iii) and the well-known Kolmogorov's criterion for continuity that, for $H > (1/2)$,

(iv) the sample paths of B_H are continuous with probability one but nowhere differentiable.

Further, it follows from (iii) again that the variance of $B_H(t)$ is t^{2H}, and for $H = 1/2$, $E\{B_{1/2}(t)B_{1/2}(s)\} = t \wedge s$. That is, $B_{1/2}$ is the standard Brownian motion.

In fact, fractional Brownian motion can be constructed from classical Brownian motion by a linear transformation of the form

$$B_H(t) \equiv \int_0^t K_H(t,s)dB(s), \tag{1.1}$$

where the process $\{B(t), t \geq 0\}$ is the classical Brownian motion and K_H is a kernel dependent on the parameter H, known as the Hurst parameter. Assuming (i), one may choose (see [10])

$$K_H(t,s) = \frac{(t-s)^{H-\frac{1}{2}}}{\Gamma(H+\frac{1}{2})} F\left(\frac{1}{2} - H, H - \frac{1}{2}, H + \frac{1}{2}, 1 - \frac{t}{s}\right) \mathbf{1}_{(0,t)}(s) \tag{1.2}$$

(F is the hypergeometric function), which implies that for $H = (1/2)$, $B_{(1/2)}(t) = B(t)$ is the standard Brownian motion.

It follows from this construction that

(v) B_H is self-similar in the sense that, for any $\alpha > 0$, the probability laws of $\{B_H(\alpha t)\}$ and $\{\alpha^H B_H(t)\}$ coincide.

For other choices and more general fractional Brownian motions and their properties, see Mandlebrot [1], as well as [9, 10, 11, 12, 13, 14, 15] and [2, 3]. It is reported in these papers that random processes arising from hydrological and economic time

series exhibit long range interdependence and self-similarity. Since fractional Brownian motion does have these properties, it is reasonable to use fractional Brownian motion to model such processes.

A function that plays an important role in the construction of stochastic integrals based on fractional Brownian motion is given by

$$\varphi_H(t) \equiv H(2H-1)|t|^{2H-2}, \qquad t \in R. \tag{1.3}$$

It can easily be shown (see, for example, [13, 14, 3]) that, for all $t, s \in R_+$, we have

$$E\{B_H(t)B_H(s)\} = \int_0^t \int_0^s \varphi_H(\tau - \theta)d\theta d\tau. \tag{1.4}$$

One can introduce (see [12, 14, 3]) the class of functions $L^2_\varphi(R_+)$ which consist of all Borel measurable real-valued functions $\{f\}$ defined on R_+ satisfying

$$\| f \|^2_\varphi \equiv \int_0^\infty \int_0^\infty \varphi_H(t-s)f(s)f(t)dsdt < \infty. \tag{1.5}$$

With respect to the scalar product

$$(f,g)_\varphi \equiv \int_0^\infty \int_0^\infty \varphi_H(t-s)f(s)g(t)dsdt, \tag{1.6}$$

$L^2_\varphi(R_+)$ is a Hilbert space. Stochastic integrals, with respect to the fractional Brownian motion B_H, of deterministic integrands from the class L^2_φ are well defined. More precisely, for each $f \in L^2_\varphi$, the element X given by

$$X \equiv \int_0^\infty f(t)dB_H(t) \tag{1.7}$$

is a well-defined random variable (real-valued $\mathcal{F}$-measurable). Since f is deterministic and B_H is Gaussian, the random variable X is also Gaussian, and it is easy to see that

$$\text{(a) } E\{X\} = 0 \qquad \text{and} \qquad \text{(b) } E|X|^2 = \| f \|^2_\varphi . \tag{1.8}$$

Since we are interested in the filtering problem for multidimensional processes, we modify the preceding results to suit this requirement. Again we use $(\Omega, \mathcal{F}, P)$ to denote the basic probability space on which all the random processes to be defined below are supported. For any integer n one may construct the fractional Brownian by the following expression:

$$B_H(t) \equiv \int_0^t K_H(t,\theta)dB(\theta), \tag{1.9}$$

where B is an n dimensional Brownian motion with covariance, say $Q \in M_s^+(n \times n)$. Here $M_s^+(n \times n)$ denotes the class of real symmetric positive definite matrices, and K_H is the scalar kernel as introduced above. In view of the previous results, B_H is an R^n-valued Gaussian random process having mean and covariance given by (see, for example, [3])

(B1) $E\{B_H(t)\} = 0$,

(B2) $E\{(B_H(t),\xi)(B_H(s),\eta)\} = \int_0^t \int_0^s \varphi_H(\tau - \theta)(Q\xi,\eta)d\tau d\theta$ for all $\xi, \eta \in R^n$.

Clearly it follows from (B2) that

$$E\{(B_H(t),\xi)^2\} = t^{2H}(Q\xi,\xi), \qquad \xi \in R^n, t \in R_+. \tag{1.10}$$

Now we can define stochastic Wiener integrals with respect to the FBM (fractional Brownian motion). For simplicity we consider finite intervals $I \equiv [0,T]$, $T < \infty$. Let $M(k \times n)$ denote the vector space of $k \times n$ matrices with real entries. For any $H \in (0,1)$, let $L^2_H(I, M(k \times n))$ denote the Hilbert space with the scalar product defined by

$$(\sigma,\beta)_H \equiv \int_I \int_I \varphi_H(u-v) Tr\{\sigma(u) Q \beta^{'}(v)\} du dv \qquad \text{for } \sigma,\beta \in L^2_H(I, M(k\times n)) \tag{1.11}$$

and the norm by

$$\| \sigma \|_H \equiv \left(\int_I \int_I \varphi_H(u-v) Tr\{\sigma(u) Q \sigma^{'}(v)\} du dv \right)^{1/2} \qquad \text{for } \sigma \in L^2_H(I, M(k\times n)). \tag{1.12}$$

Clearly this Hilbert space is related to the FBM B_H.

For $\sigma \in L^2_H(I, M(k \times n))$, define

$$Z \equiv \int_I \sigma(t) dB_H(t) \equiv L(\sigma). \tag{1.13}$$

This is a well-defined random variable with values in R^k. The following result is useful in what follows.

LEMMA 1.1. *For each $\sigma \in L^2_H(I, M(k \times n))$, the element Z given by* (1.13) *is a well-defined Gaussian random variable with values in R^k satisfying the following properties:*

(p1) $EZ = 0$;

(p2) $E(Z,\xi)^2 = \int_I \int_I \varphi_H(u-v)(Q\sigma^{'}(u)\xi, \sigma^{'}(v)\xi) du dv$ *for each* $\xi \in R^k$;

(p3) $E\{\| Z \|^2\} = \int_I \int_I \varphi_H(u-v) Tr\{\sigma(u) Q \sigma^{'}(v)\} du dv$.

Further,

(p4) *for* $H \geq 1/2$, $L^2(I, M(k \times n)) \hookrightarrow L^2_H(I, M(k \times n))$.

Proof. The first statement is obvious. It follows from the fact that a linear transformation of a Gaussian random process is Gaussian. Since σ is deterministic, (p1) follows from the property of B_H given by (B1), and (p2) follows from the property (B2). Let $\{e_i, i = 1,2,\dots,k\}$ be any basis of the space R^k. Replacing ξ by e_i in (p2) and summing over the indices, one obtains (p3). For (p4), let $H \geq 1/2$ and take any $\sigma \in L^2(I, M(k \times n))$. We must verify that it belongs to $L^2_H(I, M(k \times n))$. By definition (1.12),

$$\| \sigma \|^2_H = \int_I \int_I \varphi_H(u-v) Tr\{\sigma(u) Q \sigma^{'}(v)\} du dv.$$

Since φ_H is symmetric positive and Q is a positive symmetric matrix, we have

$$\begin{aligned} \| \sigma \|^2_H &\leq Tr(Q) \int_I \int_I \varphi_H(u-v) \| \sigma(u) \| \| \sigma(v) \| du dv \\ &\leq Tr(Q) \sqrt{\int_{I\times I} \varphi_H(u-v) \| \sigma(u) \|^2 du dv} \sqrt{\int_{I\times I} \varphi_H(u-v) \| \sigma(v) \|^2 du dv} \\ &\leq Tr(Q) \int_I \| \sigma(u) \|^2 \left(\int_I \varphi_H(u-v) dv \right) du. \end{aligned} \tag{1.14}$$

Now we note that

$$\int_I \varphi_H(u-v)dv = H\{u^{2H-1} + (T-u)^{2H-1}\}. \tag{1.15}$$

It follows from (1.14) and (1.15) that, for $H = 1/2$, we have

$$\| \sigma \|_H^2 \;\leq\; Tr(Q) \;\| \sigma \|^2_{L^2(I,M(k\times n))}, \tag{1.16}$$

and for $H > 1/2$ we have

$$\| \sigma \|_H^2 \leq 2HT^{2H-1}\; Tr(Q) \;\| \sigma \|^2_{L^2(I,M(k\times n))}. \tag{1.17}$$

This proves that for $H \geq 1/2$ the Hilbert space $L^2(I, M(k \times n))$ is continuously embedded in $L^2_H(I, M(k \times n))$, proving (p4). This completes the proof. □

It is clear from the above result that the operator L defined by (1.13) is a bounded linear transformation from $L^2_H(I, M(k \times n))$ to $L^2(\Omega, \mathcal{F}, P; R^k)$.

Remark. It is not clear to us at this time whether the following embedding is true: for $0 < H < 1/2$

$$L^2_H(I, M(k \times n)) \hookrightarrow L^2(I, M(k \times n)).$$

Remark. For $T = \infty$, the embedding (p4) does not hold.

2. System and measurement dynamics and the filtering problem. Since long term interdependence is encountered only for Hurst parameters greater than 1/2, from now on we consider only this case. In what follows we shall introduce two FBMs $\{B_{H_1}(t), V_{H_2}(t), t \geq 0\}$, with $H_1 > \frac{1}{2}, H_2 > \frac{1}{2}$, to represent the noise in the system's dynamics and observations. The system is governed by the following linear stochastic differential equation:

$$\begin{aligned} dx(t) &= A(t)x(t)dt + \sigma(t)dB_{H_1}(t), \\ x(0) &= x_0. \end{aligned} \tag{2.1}$$

Simplified versions of model (2.1) have been used in the literature to describe traffic in Internet applications, such as packetized video data.

The measurement dynamics is given by

$$\begin{aligned} dy(t) &= H(t)x(t)dt + \sigma_0(t)dV_{H_2}(t), \qquad t \geq 0, \\ y(0) &= 0. \end{aligned} \tag{2.2}$$

Often, measurements of traffic data consist of an aggregation of various sources from other users in addition to a linear combination of traffic modeled by x. Under such a scenario, one can justify the use of FBM in the measurements, in view of the experimental evidence suggesting that aggregated traffic in Internet applications shows evidence of self-similarity and long range dependence. We caution the reader that the matrix $H(t)$ appearing in (2.2) is part of the sensor model and is not to be confused with the Hurst parameter discussed in the previous section.

Throughout, we consider the processes $\{x, y\}$ taking values from R^n and R^m, respectively. The noise processes $\{B_{H_1}(t), V_{H_2}(t), t \geq 0\}$ are FBMs taking values from R^d and R^m, respectively. For compatibility, it is clear that the matrices $\{A, \sigma, H, \sigma_0\}$, which are deterministic, must take values from $M(n\times n), M(n\times d), M(m\times n), M(m\times m)$, respectively. Let $\mathcal{F}^y_t,\ t \geq 0$, be an increasing family of subsigma algebras of the sigma algebra $\mathcal{F}$ induced by the random process $\{y(t), t \geq 0\}$. In other words, this is the filtration associated with the process y. The basic filtering problem is to find a process z so that for each $t \geq 0$, $z(t)$ is $\mathcal{F}^y_t$-adapted (measurable) satisfying

(1) $E\{z(t)\} = E\{x(t)\}, t \geq 0$,
(2) $E \parallel x(t) - z(t) \parallel^2 \longrightarrow$ is minimum for $t \geq 0$.

That is, we want an unbiased minimum variance filter. This is given by

$$\hat{x}(t) \equiv E\{x(t)|\mathcal{F}_t^y\}. \tag{2.3}$$

However, this is a very difficult problem; therefore our objective here is to find the best (unbiased-minimum variance = UMV) linear filter driven by the observed process y, as described by the following stochastic differential equation:

$$\begin{aligned} dz(t) &= B(t)z(t)dt + \Gamma(t)dy(t), \qquad t \geq 0, \\ z(0) &= \hat{x}_0 \equiv Ex_0, \end{aligned} \tag{2.4}$$

where B and Γ are suitable matrix-valued functions to be determined. Clearly, by substituting the observed processes into (2.4), the FBM appears in the observations, and conditions similar to the previous discussion on Γ should be introduced for the stochastic integral to be well-defined. These conditions are made explicit in subsequent sections where the function spaces associated with B, Γ are identified. Specifically, we shall require that B be locally integrable and $\Gamma \in L^\infty(R_+, M(n \times m))$, and therefore $\Gamma\sigma_0 \in L^2_{H_2}(I, M(n \times m))$, implying that the stochastic integral is well-defined, and consistent with the definitions of the previous section.

3. Reformulation of the filtering problem as a control problem. We introduce the following basic assumptions:

(A1) There exist matrices $Q \in M_s^+(d \times d)$ and $Q_0 \in M_s^+(m \times m)$ such that

$$E\{(B_{H_1}(t), \xi)(B_{H_1}(s), \eta)\} = \int_0^t \int_0^s \varphi_{H_1}(\theta - \tau)(Q\xi, \eta)d\tau d\theta, \quad \xi, \eta \in R^d,$$
$$E\{(V_{H_2}(t), \xi)(V_{H_2}(s), \eta)\} = \int_0^t \int_0^s \varphi_{H_2}(\theta - \tau)(Q_0\xi, \eta)d\tau d\theta, \quad \xi, \eta \in R^m,$$

where $\varphi_{H_i}, i = 1, 2$, are given by (1.3).

(A2) The matrices A and H are locally integrable, while $\sigma \in L^2_{H_1}(R_+, M(n \times d))$ and $\sigma_0 \in L^2_{H_2}(R_+, M(m \times m))$.

(A3) The random elements $\{x_0, B_{H_1}(t), V_{H_2}(t), t \geq 0\}$ are mutually statistically independent.

Recall that we want our filter to have the structure given by (2.4). Define

$$e(t) \equiv x(t) - z(t), \qquad t \geq 0, \tag{3.1}$$

where x is the solution of (2.1), and z is the solution of (2.4) corresponding to any choice of B which is locally integrable and $\Gamma \in L^\infty(R_+, M(n \times m))$. It follows from these equations that e must satisfy the stochastic differential equation

$$\begin{aligned} de &= (A - \Gamma H)e(t)dt + (A - \Gamma H - B)zdt + \sigma dB_{H_1} - \Gamma\sigma_0 dV_{H_2}, \\ e(0) &= e_0 \equiv x_0 - \hat{x}_0, \end{aligned} \tag{3.2}$$

where, for compactness of notation, we have suppressed the time variable. In fact, all the matrices appearing in (3.2) are functions of time. For an unbiased estimate, it follows from this that B must satisfy the identity $B = A - \Gamma H$. Clearly, for this choice of B, the filter equation (2.4) becomes

$$\begin{aligned} dz(t) &= (A(t) - \Gamma(t)H(t))z(t)dt + \Gamma(t)dy(t), \qquad t \geq 0, \\ z(0) &= \hat{x}_0, \end{aligned} \tag{3.3}$$

and the error equation (3.2) reduces to

$$\begin{aligned} de &= (A - \Gamma H)e(t)dt + \sigma dB_{H_1} - \Gamma\sigma_0 dV_{H_2}, \\ e(0) &= e_0. \end{aligned} \tag{3.4}$$

For any $\Gamma \in L^\infty(R_+, M(n \times m))$, let $\Phi_\Gamma(t,s), 0 \le s \le t < \infty$, denote the transition operator corresponding to $A_\Gamma(t) \equiv A(t) - \Gamma(t)H(t)$. Using this transition operator, we can write the solution of (3.4) as

$$e(t) = \Phi_\Gamma(t,0)e_0 + \int_0^t \Phi_\Gamma(t,\theta)\sigma(\theta)dB_{H_1}(\theta) - \int_0^t \Phi_\Gamma(t,\theta)\Gamma(\theta)\sigma_0(\theta)dV_{H_2}(\theta). \tag{3.5}$$

The error covariance K is defined by

$$(K(t)\xi,\eta) \equiv E\{(e(t),\xi)(e(t),\eta)\}, \qquad \xi,\eta \in R^n,\ t \ge 0. \tag{3.6}$$

From here on, we shall consider only the finite time interval $I \equiv [0,T], T < \infty$, unless stated otherwise. We shall need the following result.

LEMMA 3.1. *Suppose that assumptions* (A1)–(A3) *hold. Then, for each* $\Gamma \in L^\infty(I, M(n\times m))$, *the error covariance* K *satisfies the following functional differential equation:*

$$\begin{aligned} \dot K(t) &= A_\Gamma(t)K + KA_\Gamma'(t) + \int_0^t \varphi_{H_1}(t-s)\big\{\Phi_\Gamma(t,s)\tilde Q(s,t) + \tilde Q'(s,t)\Phi_\Gamma'(t,s)\big\}ds \\ &\quad + \int_0^t \varphi_{H_2}(t-s)\big\{\Phi_\Gamma(t,s)\Gamma(s)\tilde Q_0(s,t)\Gamma'(t) \\ &\qquad + \Gamma(t)\tilde Q_0'(s,t)\Gamma'(s)\Phi_\Gamma'(t,s)\big\}ds, \qquad t \in I, \\ K(0) &= K_0, \end{aligned} \tag{3.7}$$

where $A_\Gamma(t) = A(t) - \Gamma(t)H(t)$ *and* $\tilde Q(s,t) \equiv \sigma(s)Q\sigma'(t), \tilde Q_0(s,t) \equiv \sigma_0(s)Q_0\sigma_0'(t)$.

Proof. For $\Gamma \in L^\infty(I, M(n \times m))$, it follows from assumption (A2) that A_Γ is locally integrable, and hence the transition operator is well defined and

$$\sup\{\| \Phi_\Gamma(t,s) \|, s,t \in I\} < \infty.$$

Hence for each fixed but arbitrary $t \in I$ the functions $s \longrightarrow \Phi_\Gamma(t,s)\sigma(s)$ and $s \longrightarrow \Phi_\Gamma(t,s)\Gamma(s)\sigma_0(s)$ belong to $L^2_{H_1}(I, M(n \times d))$ and $L^2_{H_2}(I, M(n \times m))$, respectively. Hence the fractional integrals appearing in the expression (3.5) are well defined and, by virtue of the property (p1) of Lemma 1.1, their expectations vanish. Clearly the expectation of the first term of (3.5) is zero. Hence the filter is unbiased. Further, by virtue of our assumption (A3), all three terms in (3.5) are mutually statistically independent, and hence for each pair of $\xi, \eta \in R^n$ we have

$$\begin{aligned} (K(t)\xi,\eta) &\equiv E\{(e(t),\xi)(e(t),\eta)\} = \big(\Phi_\Gamma(t,0)K_0\Phi_\Gamma'(t,0)\xi,\eta\big) \\ &\quad + \int_0^t\int_0^t \varphi_{H_1}(s-\tau)(\Phi_\Gamma(t,\tau)\tilde Q(\tau,s)\Phi_\Gamma'(t,s)\xi,\eta)dsd\tau \\ &\quad + \int_0^t\int_0^t \varphi_{H_2}(s-\tau)(\Phi_\Gamma(t,\tau)\Gamma(\tau)\tilde Q_0(\tau,s)\Gamma'(s)\Phi_\Gamma'(t,s)\xi,\eta)dsd\tau, \end{aligned} \tag{3.8}$$

where K_0 is the covariance of the random variable x_0. Differentiating this term by term, recalling that $\varphi_{H_i}, i = 1, 2$, are symmetric, and adding all the terms, we find that

$$
\begin{aligned}
(\dot{K}(t)\xi,\eta) &= (A_\Gamma(t)K(t)\xi,\eta) + (K(t)A_\Gamma^{'}(t)\xi,\eta) \\
&\quad + \int_0^t \varphi_{H_1}(t-s)([\Phi_\Gamma(t,s)\tilde{Q}(s,t) + \tilde{Q}^{'}(s,t)\Phi_\Gamma^{'}(t,s)]\xi,\eta)ds \\
&\quad + \int_0^t \varphi_{H_2}(t-s)([\Phi_\Gamma(t,s)\Gamma(s)\tilde{Q}_0(s,t)\Gamma^{'}(t) \\
&\qquad\qquad + \Gamma(t)\tilde{Q}_0(s,t)\Gamma^{'}(s)\Phi_\Gamma^{'}(t,s)]\xi,\eta)ds.
\end{aligned} \tag{3.9}
$$

Here we have used the basic properties of the transition operator Φ_Γ, such as

$$
\begin{aligned}
&(\partial/\partial t)\Phi_\Gamma(t,s) = A_\Gamma(t)\Phi_\Gamma(t,s) \equiv (A(t) - \Gamma(t)H(t))\Phi_\Gamma(t,s), \qquad 0 \le s \le t, \\
&\text{and} \quad \Phi_\Gamma(t,t) = I_d, \qquad t \ge 0.
\end{aligned}
$$

Since $\xi, \eta \in R^n$ are arbitrary, (3.7) follows from (3.9) and the definitions of $\tilde{Q}(s,t)$ and $\tilde{Q}_0(s,t)$. This completes the proof. □

Now we are prepared to formulate the filtering problem as a control problem. First we recall that (3.3), with Γ to be determined, gives an unbiased estimate of x. For a minimum variance estimate, we must now choose Γ so that $TrK(t)$ is minimum. We consider a more general problem which covers the filtering problem. Let T be any arbitrary but finite time with $I \equiv [0,T]$, and Σ any real positive definite symmetric matrix-valued function—for example, $\Sigma \in L^1(I, M_s^+(n \times n))$. Define

$$
J(\Gamma) = \int_0^T Tr(\Sigma(t)K(t))dt. \tag{3.10}
$$

For compactness of notation, set $\mathcal{G} \equiv L^\infty(I, M(n \times m))$. Then the optimum filtering problem is equivalent to the problem: find $\Gamma \in \mathcal{G}$ that imparts a minimum to the functional J subject to the dynamic constraint (3.7).

The first question that must be settled is whether the problem, as stated, has a solution. This is answered in the following corollary.

THEOREM 3.2. *Suppose that assumptions* (A1)–(A3) *hold and* $\Sigma \in L^1(I, M_s^+((n \times n))$. *Then, the optimal control problem as stated above has a solution.*

Proof. First assume that $\Sigma = I_d$, meaning that $J(\Gamma) = \int_I TrK(t)dt$. Using (3.8) and computing the $TrK(t)$ with respect to any basis, say $\{e_i, i = 1, 2, 3, \ldots, n\}$, because of the fourth right-hand-side term of (3.9), which involves $\Gamma(s), \Gamma(t)$, one finds that $J(\Gamma) \longrightarrow \infty$ as $\| \Gamma \|_{L^\infty(I, M(n \times m))} \longrightarrow \infty$. Further, for any fixed $\Gamma \in \mathcal{G}$, $J(\Gamma) < \infty$ and $J(\Gamma) \ge 0$. Define

$$
\mu \equiv \inf\{J(\Gamma), \Gamma \in \mathcal{G}\}.
$$

Clearly, it follows from the above comments that the infimum exists. Let $\{\Gamma_n\}$ be a minimizing sequence. Clearly this is a bounded sequence, and hence there exists a subsequence, relabeled as such, and an element $\Gamma_o \in \mathcal{G}$ such that $\Gamma_n \to \Gamma_o$ in the weak-star topology of $L^\infty(I, M(n \times m))$. This implies that $\Phi_{\Gamma_n}(t,s) \longrightarrow \Phi_{\Gamma_o}(t,s)$ pointwise on the triangle $0 \le s \le t \le T$ (see [6, Theorem 2.3.7]). This fact is proved using the generalized Gronwall inequality. Let K_n denote the solution of (3.7) corresponding to Γ_n, and K_o that corresponding to Γ_o. Using the weak-star convergence and the

pointwise convergence stated above, it follows from Lebesgue dominated convergence theorem that

$$Tr(K_o(t)) \leq \liminf_{n\to\infty} Tr(K_n(t)), \qquad \text{a.e. } t \in I.$$

Then by Fatou's lemma we obtain

$$\int_0^T Tr(K_o(t))\ dt \leq \liminf_{n\to\infty} \int_0^T Tr(K_n(t))dt.$$

This is equivalent to

$$J(\Gamma_o) \leq \liminf_{n\to\infty} J(\Gamma_n).$$

Hence $\mu = J(\Gamma_o)$. In other words, the infimum is attained. This proves that the optimization problem has a solution, given that Σ is an identity matrix. Note that $K \in C(I, M_s^+(n\times n)) \subset L^\infty(I, M_s^+(n\times n))$, and hence the functional (3.10) is well-defined. Thus, for a general symmetric positive definite matrix-valued function Σ, the result follows from orthogonal transformation. This completes the proof. □

Remark. The existence result given above also holds if the set $\mathcal{G}$ is a closed bounded convex subset of $L^\infty(I, M(n\times m))$. This follows from the facts that J is weak-star lower semicontinuous, as demonstrated above, and that $\mathcal{G}$ is weak-star compact.

4. Optimal filter. We have seen in the preceding section that an optimum linear filter exists and that it can be determined by solving the control problem

$$J(\Gamma) = \int_0^T Tr(\Sigma(t)K(t))dt \longrightarrow \min. \tag{4.1}$$

subject to the dynamic constraint

$$\begin{aligned}\dot{K}(t) = {} & A_\Gamma(t)K + KA_\Gamma'(t) + \int_0^t \varphi_{H_1}(t-s)\big\{\Phi_\Gamma(t,s)\tilde{Q}(s,t) + \tilde{Q}'(s,t)\Phi_\Gamma'(t,s)\big\}ds \\ & + \int_0^t \varphi_{H_2}(t-s)\big\{\Phi_\Gamma(t,s)\Gamma(s)\tilde{Q}_0(s,t)\Gamma'(t) \\ & \qquad + \Gamma(t)\tilde{Q}_0'(s,t)\Gamma'(s)\Phi_\Gamma'(t,s)\big\}ds, \qquad t \in I, \\ K(0) = {} & K_0,\end{aligned} \tag{4.2}$$

with $\Gamma \in \mathcal{G}$.

To obtain the necessary conditions of optimality and finally the optimum filter, we use the variational technique as in [4, 5]. For this we shall need the Gateaux differential of K with respect to Γ on $\mathcal{G}$. In general we may assume that $\mathcal{G}$ is any closed convex subset of $L^\infty(I, M(n\times m))$. Let $\Gamma_o \in \mathcal{G}$ be the optimal control, and $\Gamma \in \mathcal{G}$ any other arbitrary element. We show that the Gateaux differential of K at Γ_o in the direction $(\Gamma - \Gamma_o)$ is given by a functional differential equation. For this we must show that the transition operator Φ_Γ is Gateaux differentiable. This is stated in the following result.

LEMMA 4.1. *The Gateaux differential of the map* $\Gamma \longrightarrow \Phi_\Gamma$ *at* Γ_o *in the direction* $\Gamma - \Gamma_o$, *denoted by* $\tilde{\Phi}$, *is given by*

$$\tilde{\Phi}(t,\theta) = -\int_\theta^t ds\ \Phi_{\Gamma_o}(t,s)(\Gamma(s) - \Gamma_o(s))H(s)\Phi_{\Gamma_o}(s,\theta), \tag{4.3}$$

which satisfies the following differential equation:

$$(\partial/\partial t)\tilde{\Phi}(t,\theta) = (A(t) - \Gamma_o(t)H(t))\tilde{\Phi}(t,\theta) - (\Gamma(t) - \Gamma_o(t))H(t)\Phi_{\Gamma_o}(t,\theta), \quad 0 \le \theta \le t,$$
$$\tilde{\Phi}(\theta,\theta) = 0, \quad \theta \ge 0.$$

Further, as $\Gamma \to \Gamma_o$, $\tilde{\Phi}(t,\theta) \to 0$ *uniformly on* $I \times I$.

Proof. The proof follows directly from straightforward computation. □

LEMMA 4.2. *Let* $\mathcal{G}$ *be any closed convex subset of* $L^\infty(I, M(n\times m))$. *Then, for each pair of* $\Gamma_o, \Gamma \in \mathcal{G}$, *the Gateaux differential of* K *at* $\Gamma_o \in \mathcal{G}$ *in the direction* $\Gamma - \Gamma_o$, *denoted by* $\tilde{K}$, *is the solution of the functional differential equation*

$$\begin{aligned}
\dot{\tilde{K}}(t) &= A_{\Gamma o}(t)\tilde{K}(t) + \tilde{K}(t)A_{\Gamma o}^{'}(t) - (\Gamma(t) - \Gamma_o(t))H(t)K_o(t) \\
&\quad - K_o(t)H^{'}(t)(\Gamma(t) - \Gamma_o(t))^{'} \\
&\quad + \int_0^t \varphi_{H_1}(t-s)\big\{\tilde{\Phi}(t,s)\tilde{Q}(s,t) + \tilde{Q}^{'}(s,t)\tilde{\Phi}^{'}(t,s)\big\}ds \\
&\quad + \int_0^t \varphi_{H_2}(t-s)\big\{\tilde{\Phi}(t,s)\Gamma_o(s)\tilde{Q}_0(s,t)\Gamma_o^{'}(t) + \Gamma_o(t)\tilde{Q}_0^{'}(s,t)\Gamma_o^{'}(s)\tilde{\Phi}^{'}(t,s)\big\}ds \\
&\quad + \int_0^t \varphi_{H_2}(t-s)\big\{\Phi_{\Gamma_o}(t,s)(\Gamma - \Gamma_o)(s)\tilde{Q}_0(s,t)\Gamma_o^{'}(t) \\
&\qquad\qquad + \Gamma_o(t)\tilde{Q}_0^{'}(s,t)(\Gamma - \Gamma_o)^{'}(s)\Phi_{\Gamma_o}^{'}(t,s)\big\}ds \\
&\quad + \int_0^t \varphi_{H_2}(t-s)\big\{\Phi_{\Gamma_o}(t,s)\Gamma_o(s)\tilde{Q}_0(s,t)(\Gamma - \Gamma_o)^{'}(t) \\
&\qquad\qquad + (\Gamma - \Gamma_o)(t)\tilde{Q}_0^{'}(s,t)\Gamma_o^{'}(s)\Phi_{\Gamma_o}^{'}(t,s)\big\}ds,
\end{aligned} \tag{4.4}$$
$$\tilde{K}(0) = 0.$$

Proof. The proof is lengthy but straightforward. We give the basic outline. Let $\Gamma_o, \Gamma \in \mathcal{G}$ and $\varepsilon \in [0,1]$, and define $\Gamma_\varepsilon = \Gamma_o + \varepsilon(\Gamma - \Gamma_o)$. Since $\mathcal{G}$ is a closed convex set, $\Gamma_\varepsilon \in \mathcal{G}$. Let K_ε and K_o denote the solutions of (4.2) corresponding to Γ_ε and Γ_o, respectively. Using Lemma 4.1 and the continuous dependence of solutions $\Gamma \longrightarrow K$, one can verify that the limit

$$\lim_{\varepsilon \downarrow 0}(1/\varepsilon)\{K_\varepsilon - K_o\}$$

exists, and that this limit is the solution of (4.4). □

Now we are prepared to present the optimal filter equations. Define the following functionals:

$$\begin{aligned}
F_1(t,K,\Gamma) &\equiv A_\Gamma K + KA_\Gamma^{'} + \int_0^t \varphi_{H_1}(t-s)\big\{\Phi_\Gamma(t,s)\tilde{Q}(s,t) + \tilde{Q}^{'}(s,t)\Phi_\Gamma^{'}(t,s)\big\}ds \\
&\quad + \int_0^t \varphi_{H_2}(t-s)\big\{\Phi_\Gamma(t,s)\Gamma(s)\tilde{Q}_0(s,t)\Gamma^{'}(t) + \Gamma(t)\tilde{Q}_0^{'}(s,t)\Gamma^{'}(s)\Phi_\Gamma^{'}(t,s)\big\}ds
\end{aligned} \tag{4.5}$$

and

$$F_2(t,K,\Gamma) \equiv \int_0^t \varphi_{H_2}(t-s)\{\tilde{Q}_0(s,t)\Gamma'(t) + \tilde{Q}_0'(s,t)\Gamma'(s)\Phi_\Gamma'(t,s) - C_\Gamma(t,s)\Gamma(s)\tilde{Q}_0(s,t)\Gamma'(t)\}ds - \int_0^t \varphi_{H_1}(t-s)C_\Gamma(t,s)\tilde{Q}(s,t)ds - HK, \tag{4.6}$$

where C_Γ is given by

$$C_\Gamma(t,s) \equiv \int_s^t H(\theta)\Phi_\Gamma(\theta,s)d\theta. \tag{4.7}$$

THEOREM 4.3. *Suppose that the assumptions of Theorem* 3.2 *hold. Then, the optimum linear filter is given by the stochastic differential equation*

$$\begin{aligned} dz &= (A - \Gamma_o H)zdt + \Gamma_o dy, \\ z(0) &= \hat{x}_0, \end{aligned} \tag{4.8}$$

where the pair $\{\Gamma_o, K_o\}$ *satisfies the following functional differential equations:*

$$\begin{aligned} \dot{K}_o &= F_1(t,K_o,\Gamma_o), \quad K_o(0) = K_0, \qquad t \in I, \\ 0 &= F_2(t,K_o,\Gamma_o), \qquad t \in I. \end{aligned} \tag{4.9}$$

Proof. Suppose that $\Gamma_o \in \mathcal{G}$ minimizes the functional $J(\Gamma)$ as defined by (3.10). Let Γ be any element of $\mathcal{G}$, and define $\Gamma_\varepsilon \equiv \Gamma_o + \varepsilon(\Gamma - \Gamma_o)$ for $\varepsilon \in [0,1]$. Since $\mathcal{G}$ is a closed convex set, $\Gamma_\varepsilon \in \mathcal{G}$. Clearly, by the optimality of Γ_o,

$$J(\Gamma_\varepsilon) - J(\Gamma_o) \geq 0 \qquad \text{for all } \varepsilon \in [0,1].$$

Since by Lemma 4.2 the map $\Gamma \longrightarrow K$ is Gateaux differentiable, and its Gateaux derivative at Γ_o in the direction $\Gamma - \Gamma_o$ is given by the solution $\tilde{K}$ of (4.4), J is also Gateaux differentiable at Γ_o in the direction $\Gamma - \Gamma_o$, and hence

$$dJ(\Gamma_o, \Gamma - \Gamma_o) = \int_0^T Tr\{\Sigma\tilde{K}\}dt \geq 0 \qquad \text{for all } \Gamma \in \mathcal{G}. \tag{4.10}$$

Here we consider only the case $\mathcal{G} = L^\infty(I, M(n \times m))$, which is much easier. We shall have some comments later for the constrained case. In the unconstrained case the inequality reduces to the identity

$$dJ(\Gamma_o, \Gamma - \Gamma_o) = \int_0^T Tr\{\Sigma\tilde{K}\}dt = 0 \qquad \text{for all } \Gamma \in \mathcal{G}. \tag{4.11}$$

Since $\Sigma \in L^1(I, M_s^+(n \times n))$ is arbitrary and positive definite and T is any finite positive number, this identity can hold if and only if $\tilde{K}$ is identically zero. Since $\tilde{K}$ is the solution of the variational equation (4.4) with initial condition $\tilde{K}(0) = 0$, and the right-hand expression, from the third term through the last term, is a linear functional of the difference $(\Gamma - \Gamma_o)$, this is possible if and only if this nonhomogeneous term

vanishes identically for all $\Gamma \in \mathcal{G}$. Thus it is necessary that the following identity hold for all $\Gamma \in \mathcal{G}$:

$$
\begin{aligned}
0 = &- (\Gamma(t) - \Gamma_o(t))H(t)K_o(t) - K_o(t)H^{'}(t)(\Gamma(t) - \Gamma_o(t))^{'} \\
&+ \int_0^t \varphi_{H_1}(t-s)\big\{\tilde{\Phi}(t,s)\tilde{Q}(s,t) + \tilde{Q}^{'}(s,t)\tilde{\Phi}^{'}(t,s)\big\}ds \\
&+ \int_0^t \varphi_{H_2}(t-s)\big\{\tilde{\Phi}(t,s)\Gamma_o(s)\tilde{Q}_0(s,t)\Gamma_o^{'}(t) + \Gamma_o(t)\tilde{Q}_0^{'}(s,t)\Gamma_o^{'}(s)\tilde{\Phi}^{'}(t,s)\big\}ds \\
&+ \int_0^t \varphi_{H_2}(t-s)\big\{\Phi_{\Gamma_o}(t,s)(\Gamma - \Gamma_o)(s)\tilde{Q}_0(s,t)\Gamma_o^{'}(t) \\
&\qquad + \Gamma_o(t)\tilde{Q}_0^{'}(s,t)(\Gamma - \Gamma_o)^{'}(s)\Phi_{\Gamma_o}^{'}(t,s)\big\}ds \\
&+ \int_0^t \varphi_{H_2}(t-s)\big\{\Phi_{\Gamma_o}(t,s)\Gamma_o(s)\tilde{Q}_0(s,t)(\Gamma - \Gamma_o)^{'}(t) \\
&\qquad + (\Gamma - \Gamma_o)(t)\tilde{Q}_0^{'}(s,t)\Gamma_o^{'}(s)\Phi_{\Gamma_o}^{'}(t,s)\big\}ds
\end{aligned}
\tag{4.12}
$$

for all $t \in I$. For simplicity of presentation we denote the members on the right-hand side of (4.12) as follows:

$$
\alpha_1 \equiv -(\Gamma(t) - \Gamma_o(t))H(t)K_o(t) - K_o(t)H^{'}(t)(\Gamma(t) - \Gamma_o(t))^{'}, \tag{4.13}
$$

$$
\alpha_2 \equiv \int_0^t \varphi_{H_1}(t-s)\big\{\tilde{\Phi}(t,s)\tilde{Q}(s,t) + \tilde{Q}^{'}(s,t)\tilde{\Phi}^{'}(t,s)\big\}ds, \tag{4.14}
$$

$$
\alpha_3 \equiv \int_0^t \varphi_{H_2}(t-s)\big\{\tilde{\Phi}(t,s)\Gamma_o(s)\tilde{Q}_0(s,t)\Gamma_o^{'}(t) + \Gamma_o(t)\tilde{Q}_0^{'}(s,t)\Gamma_o^{'}(s)\tilde{\Phi}^{'}(t,s)\big\}ds, \tag{4.15}
$$

$$
\begin{aligned}
\alpha_4 \equiv \int_0^t \varphi_{H_2}(t-s)\big\{&\Phi_{\Gamma_o}(t,s)(\Gamma - \Gamma_o)(s)\tilde{Q}_0(s,t)\Gamma_o^{'}(t) \\
&+ \Gamma_o(t)\tilde{Q}_0^{'}(s,t)(\Gamma - \Gamma_o)^{'}(s)\Phi_{\Gamma_o}^{'}(t,s)\big\}ds,
\end{aligned}
\tag{4.16}
$$

$$
\begin{aligned}
\alpha_5 \equiv \int_0^t \varphi_{H_2}(t-s)\big\{&\Phi_{\Gamma_o}(t,s)\Gamma_o(s)\tilde{Q}_0(s,t)(\Gamma - \Gamma_o)^{'}(t) \\
&+ (\Gamma - \Gamma_o)(t)\tilde{Q}_0^{'}(s,t)\Gamma_o^{'}(s)\Phi_{\Gamma_o}^{'}(t,s)\big\}ds.
\end{aligned}
\tag{4.17}
$$

According to (4.12), the sum

$$
\alpha \equiv \alpha_1 + \alpha_2 + \alpha_3 + \alpha_4 + \alpha_5 = 0 \qquad \text{for all } \ \Gamma \in \mathcal{G} \text{ and all } \ t \in I. \tag{4.18}
$$

Since this identity must hold for all $\Gamma \in \mathcal{G}$, it must also hold for any Γ of the form

$$
\Gamma(s) = \Gamma_o(s) + X_o(s)D \tag{4.19}
$$

for all constant matrices $D \in M(n \times m)$, where X_o is the fundamental solution of the equation

$$
\dot{X}_o(t) = (A(t) - \Gamma_o(t)H(t))X_0(t), \quad X(0) = I_d, \tag{4.20}
$$

with $I_d \in M(n \times n)$ being the identity matrix. This gives

$$\alpha_1 \equiv -X_o(t)DH(t)K_o(t) - K_o(t)H^{'}(t)(X_0(t)D)^{'}. \tag{4.21}$$

Denote

$$C_o(t,s) \equiv C_{\Gamma_o}(t,s) = \int_s^t H(\theta)\Phi_{\Gamma_o}(\theta,s)d\theta, \tag{4.22}$$

and note that for Γ given by (4.19), $\tilde{\Phi}$ of (4.3) takes the form

$$\begin{aligned}\tilde{\Phi}(t,\theta) &= -X_o(t)D\bigg(\int_\theta^t ds\ H(s)\Phi_{\Gamma_o}(s,\theta)\bigg)\\ &= -X_o(t)DC_o(t,\theta).\end{aligned} \tag{4.23}$$

Using these, we obtain

$$\begin{aligned}\alpha_2 =& -X_o(t)D\bigg\{\int_0^t \varphi_{H_1}(t-s)C_o(t,s)\tilde{Q}(s,t)ds\bigg\}\\ &-\bigg\{\int_0^t \varphi_{H_1}(t-s)\tilde{Q}^{'}(s,t)C_o^{'}(t,s)ds\bigg\}D^{'}X_o^{'}(t),\end{aligned} \tag{4.24}$$

$$\begin{aligned}\alpha_3 =& -X_o(t)D\bigg\{\int_0^t \varphi_{H_2}(t-s)C_o(t,s)\Gamma_o(s)\tilde{Q}_0(s,t)\Gamma_o^{'}(t)ds\bigg\}\\ &-\bigg\{\int_0^t \varphi_{H_2}(t-s)\Gamma_o(t)\tilde{Q}_0^{'}(s,t)\Gamma_o^{'}(s)C_o^{'}(t,s)ds\bigg\}D^{'}X_o^{'}(t),\end{aligned} \tag{4.25}$$

$$\begin{aligned}\alpha_4 =& X_o(t)D\bigg\{\int_0^t \varphi_{H_2}(t-s)\tilde{Q}_0(s,t)\Gamma_o^{'}(t)ds\bigg\}\\ &+\bigg\{\int_0^t \varphi_{H_2}(t-s)\Gamma_o(t)\tilde{Q}_0^{'}(s,t)ds\bigg\}D^{'}X_o^{'}(t),\end{aligned} \tag{4.26}$$

and

$$\begin{aligned}\alpha_5 =& X_o(t)D\bigg\{\int_0^t \varphi_{H_2}(t-s)\tilde{Q}_0^{'}(s,t)\Gamma_o^{'}(s)\Phi_{\Gamma_o}^{'}(t,s)ds\bigg\}\\ &+\bigg\{\int_0^t \varphi_{H_2}(t-s)\Phi_{\Gamma_o}(t,s)\Gamma_o(s)\tilde{Q}_0(s,t)ds\bigg\}D^{'}X_o^{'}(t).\end{aligned} \tag{4.27}$$

Adding all the α's, we arrive at an expression of the form

$$\alpha = X_o(t)DM(t) + M^{'}(t)D^{'}X_o^{'}(t), \tag{4.28}$$

where

$$\begin{aligned}M(t) \equiv& -H(t)K_o(t) + \int_0^t \varphi_{H_2}(t-s)\bigg\{-C_o(t,s)\Gamma_o(s)\tilde{Q}_0(s,t)\Gamma_o^{'}(t)\\ &+\tilde{Q}_0(s,t)\Gamma_o^{'}(t) + \tilde{Q}_0^{'}(s,t)\Gamma_o^{'}(s)\Phi_{\Gamma_o}^{'}(t,s)\bigg\}ds\\ &-\int_0^t \varphi_{H_1}(t-s)C_o(t,s)\tilde{Q}(s,t)ds.\end{aligned}$$

By virtue of (4.18) and (4.28), we have

$$\alpha = X_o(t)DM(t) + M^{'}(t)D^{'}X_o^{'}(t) = 0 \qquad \text{for all } D \in M(n \times m),\ t \in I. \tag{4.29}$$

Thus

$$Tr\{X_o(t)DM(t)\} = 0 \qquad \text{for all } D \in M(n \times m),\ t \in I. \tag{4.30}$$

Since $X_o(t)$ is always nonsingular, this implies that $M(t) \equiv 0$, and hence

$$\begin{aligned} F_2(t, K_o, \Gamma_o) \equiv -H(t)K_o(t) + \int_0^t \varphi_{H_2}(t-s)\Big\{ & \tilde{Q}_0(s,t)\Gamma_o^{'}(t) + \tilde{Q}_0^{'}(s,t)\Gamma_o^{'}(s)\Phi_{\Gamma_o}^{'}(t,s) \\ & - C_o(t,s)\Gamma_o(s)\tilde{Q}_0(s,t)\Gamma_o^{'}(t)\Big\}ds \\ - \int_0^t \varphi_{H_1}(t-s)C_o(t,s)\tilde{Q}(s,t)ds = 0. & \end{aligned} \tag{4.31}$$

Thus it follows from (3.7), (4.5), and (4.31) that the optimal pair must satisfy the functional differential equation (4.9), and consequently the optimum filter must be given by (4.8), with the pair $\{\Gamma_o, K_o\}$ being the solution of (4.9). This completes the proof. □

Remark. When $\mathcal{G}$ is a closed convex, possibly bounded, (proper) subset of $L^\infty(I, M(n \times m))$, the necessary conditions of optimality involve an additional equation, the adjoint equation associated with the (state) functional equation (4.2). Readers interested in constrained filtering may see [4, 5].

Remark. If $\sigma_0(t)$ is nonsingular, the filter equation (4.8) can be rewritten as

$$dz = A(t)zdt + \Gamma_o\ \sigma_0\ d\nu_H(t),$$

where ν_H, given by

$$\nu_H(t) = \int_0^t \sigma_0^{-1}(s)\{dy(s) - H(s)z(s)ds\}, \qquad t \geq 0,$$

is an $\mathcal{F}_t^y$-measurable Gaussian process. However, according to [16], ν_H is not the innovation process, and thus, it is not an FBM with the same Hurst parameter.

Some special cases. Here we adapt the results derived for the special cases, when either of the two FBMs are replaced by standard Brownian motions, and we further show that the convergence methodology yields the Kalman filter equations when both noises are standard Brownian motions. Since the difference between the FBM and the standard Brownian motion is captured through the function $\varphi_{H_j}, j = 1, 2$, we shall show that as the Hurst parameters tend to $1/2$, φ_{H_j} converges to a delta function. Once this result is derived, it can be used in the previous general filter equations to study special cases.

(C1) We show here that if the Hurst parameters $H_i \to (1/2), i = 1, 2$, our filter equations reduce to the classical Kalman filter equations. We need the following lemma.

LEMMA 4.4. *As* $H_i \to (1/2)$, $\varphi_{H_i}(t) \to (1/2)\delta(t), i = 1, 2$.

Proof. Let $H = H_i = (1/2) + \varepsilon$, $i = 1, 2$, $\varepsilon > 0$. Define $\psi_\varepsilon(t) = \varphi_{(1/2)+\varepsilon}(t)$. Let $C_0^\infty[0, \infty)$ denote the class of C^∞ functions with compact supports, and take $\xi \in C_0^\infty[0, \infty)$. Consider the functional

$$f_\varepsilon(\xi) \equiv \int_0^\infty \xi(t)\psi_\varepsilon(t)dt.$$

Then it follows from our definition of φ_H (1.3) that

$$\begin{aligned} f_\varepsilon(\xi) &\equiv \varepsilon(1+2\varepsilon)\int_0^\infty \xi(t)|t|^{2\varepsilon-1}dt \\ &= \varepsilon(1+2\varepsilon)\int_0^\infty \xi(t)\ t^{2\varepsilon-1}dt \\ &= \frac{(1+2\varepsilon)}{2}\int_0^\infty \xi(t^{1/2\varepsilon})dt. \end{aligned}$$

We split the integral as

$$\begin{aligned} f_\varepsilon(\xi) &= \frac{(1+2\varepsilon)}{2}\int_0^\infty \xi(t^{1/2\varepsilon})\ dt \\ &= \frac{(1+2\varepsilon)}{2}\left\{\int_0^{1-0} \xi(t^{1/2\varepsilon})\ dt + \int_{1+0}^\infty \xi(t^{1/2\varepsilon})\ dt\right\}. \end{aligned}$$

Since ξ has compact support on $[0,\infty)$ and is C^∞, one can easily justify that

$$\lim_{\varepsilon\downarrow 0}\frac{(1+2\varepsilon)}{2}\int_0^{1-0} \xi(t^{1/2\varepsilon})\ dt = (1/2)\xi(0)$$

and

$$\lim_{\varepsilon\downarrow 0}\frac{(1+2\varepsilon)}{2}\int_{1+0}^\infty \xi(t^{1/2\varepsilon})\ dt = 0.$$

Using these facts, we arrive at the following identity:

$$\lim_{\varepsilon\downarrow 0} f_\varepsilon(\xi) = \left(\frac{1}{2}\right)\xi(0) \qquad \text{for every } \xi \in C_0^\infty[0,\infty). \tag{4.32}$$

In fact, it follows from the same arguments that, for any $\xi \in C_0^\infty(R)$,

$$\lim_{\varepsilon\downarrow 0} f_\varepsilon(\xi) = \xi(0) \qquad \text{for every } \xi \in C_0^\infty(R). \tag{4.33}$$

In other words, as $H_i \downarrow (1/2)$, $\varphi_{H_i}, i = 1,2$, converge to the Dirac measures concentrated at the origin. This proves the assertion. □

Now we are prepared to derive the classical Kalman filter from our main result given in Theorem 4.3. For given σ and σ_0, define, for each $t \geq 0$, the (auto) covariance matrices:

$$\begin{aligned} Q(t) &\equiv \tilde{Q}(t,t) = \sigma(t)Q\sigma'(t), \\ Q_0(t) &\equiv \tilde{Q}_0(t,t) = \sigma_0(t)Q_0\sigma_0'(t). \end{aligned} \tag{4.34}$$

COROLLARY 4.5. *Suppose that $Q_0(t)$, as defined by* (4.34)*, is nonsingular. Then the Kalman filter is given by the error covariance equation,*

$$\begin{aligned} &\dot{K}_o(t) = A(t)K_o(t) + K_o(t)A'(t) + Q(t) - K_o(t)H'(t)Q_0^{-1}(t)H(t)K_o(t), \\ &K(0) = K_0, \end{aligned} \tag{4.35}$$

and the filter equation,

$$\begin{aligned} &dz(t) = A(t)z(t)dt + K_o(t)H'(t)Q_0^{-1}(t)(dy(t) - H(t)z(t)dt), \\ &z(0) = \hat{x}_0. \end{aligned} \tag{4.36}$$

Proof. By virtue of Lemma 4.4, letting $H_i \downarrow (1/2), i = 1, 2$, it follows from the expressions (4.5) and (4.6) that

$$\begin{aligned} F_1(t, K, \Gamma) &= A_\Gamma(t)K(t) + K(t)A_\Gamma^{'}(t) + Q(t) + \Gamma Q_0(t)\Gamma^{'}(t), \\ F_2(t, K, \Gamma) &= Q_0(t)\Gamma^{'}(t) - H(t)K(t). \end{aligned} \tag{4.37}$$

For optimality, it follows from Theorem 4.3 that both the equations of (4.9) must be satisfied. The second equation of (4.9) requires that

$$F_2(t, K_0, \Gamma_o) = Q_0(t)\Gamma_o^{'}(t) - H(t)K_o(t) = 0.$$

Taking its transpose and using the assumption that $Q_0(t)$ is invertible, we obtain the optimal Kalman gain

$$\Gamma_o(t) = K_o(t)H^{'}(t)Q_0(t)^{-1}. \tag{4.38}$$

Substituting this into F_1 given by (4.37), we obtain

$$F_1(t, K_o, \Gamma_o) = A(t)K_o(t) + K_o(t)A^{'}(t) + Q(t) - K_o(t)H^{'}(t)Q_0^{-1}(t)H(t)K_o(t).$$

Using this expression in the first equation of (4.9), we obtain the classical matrix Riccati differential equation (4.35). Substituting the expression for Γ_o from (4.38) into (4.8), we obtain the filter equation (4.36). Hence the Kalman filter follows from our Theorem 4.3. This completes the proof. □

Remark. Note that if $Q_0(t)$ is not invertible, we do not have the Kalman filter, or more precisely, there are many Kalman filter solutions. To choose a unique solution, one can consider minimizing the norm of K_o subject to the constraint (4.9).

Two other special cases, in which only one of the two Brownian motions is fractional, are given in the following corollary.

COROLLARY 4.6. *Suppose that the following conditions hold:*

(C2) *The signal process $\{x\}$ is perturbed by Q-Brownian motion, and the measurement process $\{y\}$ is driven by Q_0-fractional Brownian motion.*

(C3) *The signal process $\{x\}$ is perturbed by Q-fractional Brownian motion, and the measurement process $\{y\}$ is driven by Q_0-Brownian motion.*

Then the filter equations for these cases are given by (4.8)*, while the covariance equations are given by*

$$\begin{aligned} \dot{K} = A_\Gamma K + KA_\Gamma^{'} + Q(t) + \int_0^t \varphi_{H_2}(t-s)\Big\{ &\Phi_\Gamma(t,s)\Gamma(s)\tilde{Q}_0(s,t)\Gamma^{'}(t) \\ &+ \Gamma(t)\tilde{Q}_0^{'}(s,t)\Gamma^{'}(s)\Phi_\Gamma^{'}(t,s)\Big\}ds, \\ 0 = \int_0^t \varphi_{H_2}(t-s)\Big\{ &\tilde{Q}_0(s,t)\Gamma^{'}(t) + \tilde{Q}_0^{'}(s,t)\Gamma^{'}(s)\Phi_\Gamma^{'}(t,s) \\ &- C_\Gamma(t,s)\Gamma(s)\tilde{Q}_0(s,t)\Gamma^{'}(t)\Big\}ds - H(t)K(t) \end{aligned} \tag{4.39}$$

for (C2)*, and by*

$$\begin{aligned} \dot{K} = A_\Gamma K + KA_\Gamma^{'} + \int_0^t \varphi_{H_1}(t-s)\Big\{ &\Phi_\Gamma(t,s)\tilde{Q}(s,t) + \tilde{Q}^{'}(s,t)\Phi_\Gamma^{'}(t,s)\Big\}ds \\ &+ \Gamma(t)Q_0(t)\Gamma^{'}(t), \\ 0 = Q_0(t)\Gamma^{'}(t) - \int_0^t \varphi_{H_1}(t-s)C_\Gamma(t,s)\tilde{Q}(s,t)ds &- H(t)K(t) \end{aligned} \tag{4.40}$$

for (C3).

Proof. The proof is a straightforward application of Theorem 4.3, with $\varphi_{H_i}, i = 1, 2$, replaced by the Dirac measures in the appropriate sections of (4.5) and (4.6). □

5. Optimal filter for dynamically coupled systems. Here the signal and the observed processes are governed by the following set of stochastic differential equations:

$$\begin{aligned} dx(t) &= A(t)x(t)dt + B(t)y(t)dt + \sigma(t)dB_{H_1}(t), \quad x(0) = x_0, \\ dy(t) &= H(t)x(t)dt + C(t)y(t)dt + \sigma_0(t)dV_{H_2}(t), \quad y(0) = 0, \end{aligned} \tag{5.1}$$

where B and C are the coupling matrices taking values from $M(n\times m)$ and $M(m\times m)$, respectively. In this case we have the following result.

THEOREM 5.1. *Suppose that the assumptions of Theorem* 4.3 *hold and, further, that B and C are locally integrable. Then the optimum linear filter for the system* (5.1) *is given by*

$$\begin{aligned} dz &= (A - \Gamma_o H)zdt + (B - \Gamma_o C)ydt + \Gamma_o dy, \\ z(0) &= \hat{x}_0, \end{aligned} \tag{5.2}$$

where the optimum gain Γ_o is given by the solutions of (4.9).

Proof. Since the proof is very similar to the previous case, we give only an outline of the proof. Consider the following linear structure for the optimum filter:

$$\begin{aligned} dz &= Fzdt + Gydt + \Gamma dy, \\ z(0) &= \hat{x}_0, \end{aligned} \tag{5.3}$$

where the matrix-valued functions $\{F, G, \Gamma\}$ must be chosen to give an unbiased minimum variance filter. Define $e = x - z$, and note that e satisfies the stochastic differential equation

$$\begin{aligned} de = (A - \Gamma H)edt + (A - \Gamma H - F)zdt + (B - G - \Gamma C)ydt \\ + \sigma dB_{H_1} - \Gamma\sigma_0 dV_{H_2}, \\ e(0) = e_0 \equiv x_0 - \hat{x}_0. \end{aligned} \tag{5.4}$$

One can show that for the unbiased filter we must have $F = A - \Gamma H$ and $G = B - \Gamma C$. This reduces the error equation to (3.4), and consequently the error covariance equation remains unchanged. This means that the optimum Γ must be determined by the solution of (4.9) as in Theorem 4.3. Once this is done, we obtain the optimum filter (5.2). This completes the outline of our proof. □

6. An algorithm for computation. Here we briefly present a conceptual algorithm for computing the optimum filter gain. We do this by using the result of Theorem 4.3. Suppose that the nth stage of iteration has been reached and Γ^n has been determined.

Step 1: Use $\Gamma = \Gamma^n$ to solve for K^n using the first equation of (4.9).

Step 2: Use K^n in the second equation of (4.9). If $F_2(t, K^n, \Gamma^n) \neq 0$, solve the corresponding functional equation given by $F_2(t, K^n, \Gamma) = 0$, and call the solution Γ^{n+1}.

Step 3: Use a suitable metric, for example, the metric induced by the standard L^∞ norm, to compute

$$d(\Gamma^{n+1}, \Gamma^n) \equiv \| \Gamma^{n+1} - \Gamma^n \|_{L^\infty(I, M(n\times m))},$$

and stop if a predetermined level of accuracy has been met, and print; if not, go to step 1.

As discussed before, the nonuniqueness of solutions can be addressed by further minimizing the norm of Γ, subject to the constraint $0 = F_2(t, K, \Gamma)$, which will result in a unique solution of the filtering problem (see [4, 5]).

It may be interesting to investigate whether the functional equation (4.9) can be solved by the use of singular perturbation techniques. An interesting point raised by the referee is the investigation of the robustness properties of the filter with respect to the Hurst parameters. In principle, this problem is tractable through the computation of the norm of the difference between two Γ's corresponding to different Hurst parameters.

Acknowledgment. The authors wish to express their thanks to the referee for his valuable comments.

ON A CONSTRAINED DIRICHLET PROBLEM*

ARRIGO CELLINA†

Abstract. We consider a Dirichlet minimum problem with a pointwise constraint on the gradient, i.e., $\|\nabla u(x)\| \leq 1$ a.e., or, equivalently, an unconstrained minimum problem with an extended-valued integrand. Since the subdifferential of this integrand is defined on the whole effective domain, the problem of the validity of the Euler–Lagrange equation (or, equivalently, of the Pontryagin maximum principle) for a solution w can be posed. To show that this equation is verified along a solution, the equivalence of the problem considered here and of a problem with obstacles is proved, and a generalization of Stampacchia's bounded slope condition result is presented.

Key words. Euler–Lagrange equation, Pontryagin maximum principle, constraint on the gradient

Introduction. The author has been interested in the following specific problem: consider a *constrained* Dirichlet problem consisting of minimizing $\int_{S_R} \frac{1}{2}\|\nabla u\|^2$ over those functions u satisfying the boundary condition $u|_{\partial S_R} = u^0|_{\partial S_R}$ and, in addition, the constraint $\|\nabla u(x)\| \leq 1$ a.e. in S_R. Here $S_R \subset \Re^2$ is the planar sector obtained as the intersection of the disk of radius R and of the first orthant. The boundary datum u^0 is defined to be $u^0(x,y) = 1 - \frac{1}{R}\sqrt{x^2+y^2}$. When $R < 1$, there are no Lipschitzian functions satisfying at once the boundary conditions and the constraint on the gradient, and so the problem is of interest for $R \geq 1$. A computation shows that the bounded slope condition of constant 1 is satisfied when $R \geq \sqrt{2}$. In this case, since the solution to the Dirichlet problem is regular, Stampacchia's original theorem [6] proves that the solution w to the unconstrained Dirichlet problem satisfies $\|\nabla w(x)\| \leq 1$, i.e., that the constrained Dirichlet problem is actually equivalent to the unconstrained problem; hence, in this case, the solution to the constrained problem inherits all the regularity of the standard unconstrained problem. The motivation for the present paper was the desire of understanding what happens for $1 \leq R < \sqrt{2}$. In particular, it is our purpose to show that, for all $R \geq 1$, the Euler–Lagrange equation holds for the solution to this problem. To be more precise, consider the following *unconstrained* equivalent formulation to the minimization problem presented above:

$$(DP) \qquad \text{minimize} \int_{S_R} \left(\frac{1}{2}\|\nabla u(x)\|^2\right)^\infty dx \quad \text{on } u - u^0 \in H_0^1(S_R),$$

where $(\frac{1}{2}\|\xi\|^2)^\infty$ denotes the map

$$\xi \to \begin{cases} \frac{1}{2}\|\xi\|^2 & \text{if } \|\xi\| \leq 1, \\ +\infty & \text{otherwise.} \end{cases}$$

The (extended-valued) function $(\frac{1}{2}\|\xi\|^2)^\infty$ is convex, lower semicontinuous, and coercive: solutions to this minimization problem exist. Although the integrand is not

†Dipartimento di Matematica e Applicazioni, Università di Milano Bicocca, Via Bicocca degli Arcimboldi 8, 20126 Milano, Italy (cellina@matapp.unimib.it).

everywhere differentiable, its subdifferential is defined on the whole effective domain of the integrand itself: given one solution w, $\partial((\frac{1}{2}\|\nabla w(x)\|^2)^\infty)$ is defined a.e. We wish to prove the existence of an integrable function $p(.)$, a selection from the map $x \to \partial((\frac{1}{2}\|\nabla w(x)\|^2)^\infty)$, such that, for every $\phi \in H_0^1(S_R)$, one has

$$\int_{S_R} \langle p(x), \nabla\phi(x)\rangle \, dx = 0.$$

Equivalently, we wish to prove the existence of p, a weak solution to the system of equations

$$p(x) \in \partial\left(\left(\frac{1}{2}\|\nabla w(x)\|^2\right)^\infty\right), \quad \text{div } p(x) = 0.$$

Alternatively, from a control theory point of view, the above problem can be seen as the problem of minimizing

$$\int_{S_R} \left(\frac{1}{2}\|v\|^2\right) dx$$

for $u \in u^0 + W_0^\infty(S_R)$, subject to the Hamilton–Jacobi control equation

$$\nabla u(x) = v, \qquad v \in B,$$

where B is the Euclidean unit ball of $\Re^2$. Denote by H the map $H(p,v) = -\frac{1}{2}\|v\|^2 + \langle p, v\rangle$, and notice that $H(p,v) = \max_{z\in B} H(p,z)$ iff $p \in \partial(\frac{1}{2}\|\nabla v\|^2)^\infty$. Hence proving the validity of the Euler–Lagrange equation in the sense specified above amounts to proving the existence of p satisfying the equations

$$\nabla u(x) = \nabla H_p(p(x), v(x)), \qquad \text{div} p(x) = -\frac{\partial H}{\partial u}$$

such that a.e.

$$H(p(x), v(x)) = \max_{z\in B} H(p(x), z),$$

i.e., to proving that the solution w to the optimum control problem satisfies Pontryagin's maximum principle. The same control formulation, for a different minimum problem, was already considered in [4].

Problems like the one we consider here, i.e., the problem of minimizing $\int_\Omega f(\nabla u(x))dx$ on a set $\mathbf{K}$ of functions instead of on a linear space, are not new in the literature: these and similar problems have been treated from the point of view of variational inequalities. In that context, one wishes to show that a solution w is such that

$$\int_\Omega \langle \nabla f(\nabla w(x)), \nabla\phi(x)\rangle \, dx \geq 0$$

whenever $\phi \in C_c^\infty(\Omega)$ is admissible, i.e., such that $w + \phi$ is in $\mathbf{K}$. This kind of condition is *not* equivalent to the answer we seek here. Consider, for instance, the very degenerate problem arising when the boundary conditions are such that there is only one function in the space $W^{1,1}$ satisfying at once the boundary condition and the constraint on the gradient, as in the case considered here when $R = 1$. Then the boundary datum itself is the solution to this problem. However, the relevant

information on this solution that we gain from the validity of a variational inequality is nil since the only admissible variation ϕ is $\phi = 0$. On the other hand, the Euler–Lagrange equation holds on a linear space of test functions ϕ, independent of whether or not the test functions are admissible, and this fact should provide useful information on the solution w even in a degenerate case like this one.

The interest for the special region and boundary condition we examine here arises from the following considerations: it is known that a key to the understanding of problems with a constraint on the gradient comes from proving the equivalence of the given problem with an obstacle problem, as in Brézis and Sibony [1] and in Treu and Vornicescu [5]. When the constraint is $\|\nabla u(x)\| \leq K$, one is lead to consider the Natural Obstacles: the lower obstacle $N_K^-(x) = \sup_{\xi\in\partial S_R} \quad (u^0(\xi) - K\|x-\xi\|)$ and the upper obstacle $N_K^+(x) = \inf_{\xi\in\partial S_R} \quad (u^0(\xi) + K\|x-\xi\|)$: simply, any function u satisfying at once the boundary conditions and the constraint $\|\nabla u(x)\| \leq K$ must lie between the lower and the upper Natural Obstacle function. However computations show that for the region S_R and the boundary condition u^0 described above, these Natural Obstacles are not only not smooth but fail to have those reasonable properties that one can hopefully use to prove regularity of the solutions. Hence this region and boundary conditions provide possibly the simplest non-trivial example that illustrates the needs of more precise techniques to handle the problem.

In order to define the Effective Obstacle functions, that we will use instead of the Natural Obstacles, let us recall the definition of the Bounded Slope Condition [6].

DEFINITION ($(BSC)_K$). *Let K be a positive real, Ω a bounded convex set. The boundary datum u^0 satisfies $(BSC)_K$ if for every $x^0 \in \partial\Omega$ there exist vectors $k^+ = k^+(x^0)$ and $k^- = k^-(x^0)$, $\|k^+\| \leq K, \|k^-\| \leq K$, such that for every $x \in \partial\Omega$, we have*

$$C_+ \qquad u^0(x) - u^0(x^0) \leq \langle k^+, x - x^0\rangle$$

and

$$C_- \qquad u^0(x) - u^0(x^0) \geq \langle k^-, x - x^0\rangle.$$

The next definition presents a lower and an upper obstacle for the solutions, different from the Natural Obstacles.

DEFINITION (effective obstacles). *Let $V_K^+ = \{x^0 \in \partial\Omega$: there exist no $k^+, \|k^+\| \leq K$ satisfying C_+ for every $x \in \partial\Omega\}$; let $V_K^- = \{x^0 \in \partial\Omega$: there exist no $k^-, \|k^-\| \leq K$ satisfying C_- for every $x \in \partial\Omega\}$. Let $\Phi_K^+(x)$ be identically $+\infty$ when $V_K^+ = \emptyset$ and $\inf_{\xi\in V_K^+}(u^0(\xi) + K\|x-\xi\|)$ otherwise. Let $\Phi_K^-(x)$ be identically $-\infty$ when $V_K^- = \emptyset$ and $\sup_{\xi\in V_K^-}(u^0(\xi) - K\|x-\xi\|)$ otherwise.*

Comparing the definition of the natural obstacles with the definition above, one can see that the consideration of a smaller set of points (V_K^+ and V_K^- instead of $\partial\Omega$) gives rise to a larger and smoother upper bound and to a smaller and smoother lower bound for the solution and hence to a lesser constrained problem. Consider the (trivial) one-dimensional problem, where Ω is the interval $(0,1)$ and $u^0(0) = a, u^0(1) = b$. In this case, either $|b-a| > K$ and no solution exists, or $|b-a| \leq K$: in this second case, V_K^+ and V_K^- are empty, and, from our theorems below, the constrained problem is equivalent to the unconstrained problem, as it has to be, since its solutions are affine functions with the absolute value of the slope $= |b-a| \leq K$. The purpose of section 1 is to prove, under general assumptions on the region of integration Ω and the integrand f, that the two minimum problems, the problem with the constraint on the gradient $\|\nabla u(x)\| \leq 1$ and the problem constrained by the effective obstacles

(a less constrained problem than the analogous problem with the natural obstacles), are actually equivalent; this fact, that we can indeed work with a less constrained problem, possessing smoother solutions, will be the key to our proof of the validity of the Euler–Lagrange equation for the constrained Dirichlet problem to be presented in section 2.

From another point of view, our Theorem 1 below can be seen as a generalization of Stampacchia's theorem on the bounded slope condition [6]: in fact, the peculiarity of Theorem 1 is that the obstacles in its statement disappear (i.e., become, respectively, $+\infty$ and $-\infty$) when the bounded slope condition is satisfied.

1. The equivalence of variational problems. Theorem 2 of section 2 will provide suitable regularity for solutions to the problem with obstacles, assuming regularity of the obstacles. To check that the required assumptions are satisfied by the specific problem on S_R we have in mind, let us first explicitly discuss the effective obstacles for this problem: when $R \geq \sqrt{2}, \Phi_1^+(x,y) = +\infty$ and $\Phi_1^-(x,y) = -\infty$; for $1 \leq R < \sqrt{2}$, after some computations we obtain

$$\Phi_1^-(x,y) = \begin{cases} 1 - \frac{1}{R}y - \frac{\sqrt{R^2-1}}{R}x & \text{on } S_R^3 = S_R \cap \{y \geq x\frac{1}{\sqrt{R^2-1}}\}, \\ 1 - \sqrt{x^2+y^2} & \text{on } S_R^2 = S_R \cap \{\sqrt{R^2-1}\,x \leq y \leq x\frac{1}{\sqrt{R^2-1}}\}, \\ 1 - \frac{1}{R}x - \frac{\sqrt{R^2-1}}{R}y & \text{on } S_R^1 = S_R \cap \{0 \leq y \leq \sqrt{R^2-1}\,x\}. \end{cases}$$

Hence

$$\nabla\Phi_1^-(x,y) = \begin{cases} \left(-\frac{\sqrt{R^2-1}}{R}, -\frac{1}{R}\right) & \text{on } S_R^3, \\ \left(-\frac{x}{\sqrt{x^2+y^2}}, -\frac{y}{\sqrt{x^2+y^2}}\right) & \text{on } S_R^2, \\ \left(-\frac{1}{R}, -\frac{\sqrt{R^2-1}}{R}\right) & \text{on } S_R^1, \end{cases}$$

and

$$\Delta\Phi_1^-(x,y) = \begin{cases} 0 & \text{on } S_R^3, \\ -\frac{1}{\sqrt{x^2+y^2}} & \text{on } S_R^2, \\ 0 & \text{on } S_R^1. \end{cases}$$

Moreover,

$$\Phi_1^+(x,y) = +\infty.$$

Hence, in this example, when finite, the obstacle is smooth: the map $x, y \to \nabla\Phi_1^-(x,y)$ is locally Lipschitzian.

Let us also consider, for this special problem, a change of variables τ that will be of use in the proof of the validity of the Euler–Lagrange equation. Let θ^* be such that $\cos\theta^* = \frac{1}{R}$, $\sin\theta^* = \frac{\sqrt{R^2-1}}{R}$; let $\theta^{**} = \frac{\pi}{2} - \theta^*$ and $\theta^{***} = \theta^{**} - \theta^*$. Consider the regions $\Sigma^1 = \{(\xi,\eta) : \xi^2+\eta^2 < R^2; -\tan\theta^*\xi \leq \eta \leq 0\}$; $\Sigma^2 = \{(\xi,\eta) : 0 < \xi < R; 0 \leq \eta \leq \theta^{***}\}$; $\Sigma^3 = \{(\xi,\eta) : \xi^2+\eta^2 < R^2; \theta^{***} \leq \eta \leq \theta^{***} + \tan\theta^{**}\xi\}$. Set $\Sigma_R = \Sigma^1 \cup \Sigma^2 \cup \Sigma^3$,

and define the piecewise smooth transformation $\tau : \Sigma_R \subset \Re^2 \to S_R$ by

$$\begin{pmatrix} x \\ y \end{pmatrix} = \tau(\xi,\eta) = \begin{cases} \begin{pmatrix} \cos\theta^{**} & -\sin\theta^{**} \\ \sin\theta^{**} & \cos\theta^{**} \end{pmatrix} \begin{pmatrix} \xi \\ \eta - \theta^{***} \end{pmatrix} \text{ on } \Sigma^3, \\ \begin{pmatrix} \xi\cos(\eta+\theta^*) \\ \xi\sin(\eta+\theta^*) \end{pmatrix} \text{ on } \Sigma^2, \\ \begin{pmatrix} \cos\theta^* & -\sin\theta^* \\ \sin\theta^* & \cos\theta^* \end{pmatrix} \begin{pmatrix} \xi \\ \eta \end{pmatrix} \text{ on } \Sigma^1. \end{cases}$$

One can verify that $\Phi_1^-(\tau(\xi,\eta))$ is (the restriction to Σ_R of) the affine function $1-\xi$ so that

$$\frac{\partial}{\partial\xi}\Phi_1^-(\tau(\xi,\eta)) \equiv -1; \quad \frac{\partial}{\partial\eta}\Phi_1^-(\tau(\xi,\eta)) \equiv 0.$$

The properties of τ that will be of later use are: (i) τ is orthogonal, i.e. $x_\xi x_\eta + y_\xi y_\eta = 0$, (ii) $\frac{\partial\tau}{\partial\xi}(\xi,\eta) = -(\nabla\Phi_1^-)(\tau(\xi,\eta))$, and hence, in particular, $\|\frac{\partial\tau}{\partial\xi}\| = \|(x_\xi, y_\xi)\| \equiv 1$, and (iii) for every fixed η, the map $\xi \to x_\eta^2 + y_\eta^2$ is nondecreasing. The unit vector $\frac{1}{\sqrt{x_\eta^2+y_\eta^2}}(x_\eta, y_\eta)$ inherits the regularity of $\frac{\partial\tau}{\partial\xi}(\xi,\eta)$.

The following properties of the natural obstacle functions will be of use.

PROPOSITION 1. *When u^0 is continuous and $\Phi_K^- \not\equiv -\infty$, Φ_K^- is Lipschitzian of constant K; whenever $\nabla\Phi_K^-$ exists, we have $\|\nabla\Phi_K^-\| = K$ and a similar case for Φ_K^+.*

The following theorem, on the equivalence of variational problems, is also a generalization of Stampacchia's theorem on the bounded slope condition [6] and of its generalization in [3].

THEOREM 1. *Let Ω be open and bounded; let f be a (possibly extended-valued) strictly convex function. Let K be positive real, let u^0 be in $C(\overline{\Omega}) \cap W^{1,1}(\Omega)$, and let the effective obstacles $\Phi_K^-(x)$, $\Phi_K^+(x)$ be defined as above. Moreover, assume that w, a solution to*

$$(P_{\Phi_K}) \qquad \textit{minimize} \int_\Omega f(\nabla u(x))\,dx,\ u - u^0 \in W_0^{1,1}(\Omega), \Phi_K^-(x) \le u(x) \le \Phi_K^+(x),$$

is in $C(\Omega)$. Then w is Lipschitzian of Lipschitz constant K, and it is a solution to

$$(P)_K \qquad \textit{minimize} \int_\Omega f(\nabla u(x))\,dx,\ u - u^0 \in W_0^{1,1}(\Omega), \|\nabla u(x)\| \le K.$$

Notice that the result is false if we assume f to be convex but not strictly convex: consider the problem of minimizing

$$\int_{-1}^{1} f(|x'(t)|)dt, \quad x(-1) = x(1) = 0,$$

subject to the constraint $|x'(t)| \le \frac{1}{2}$, where $f : \Re^+ \to \Re^+$ is the indicator function of the interval $[0,1]$. Then the bounded slope condition (of constant $\frac{1}{2}$) is verified both at $t=-1$ and at $t=+1$; i.e., the effective obstacles are $+\infty$ and $-\infty$, but it is not true that all solutions to the (unconstrained) resulting problem of minimizing $\int_{-1}^{1} f(|x'(t)|)dt, x(-1) = x(1) = 0$, are Lipschitzian with Lipschitz constant $\frac{1}{2}$: it is enough to consider $x(t) = -1 - t$ for $t \le 0$ and $= -1 + t$ for $t > 0$.

The following corollary to Theorem 1 is Theorem 2 of [3].

COROLLARY 1. *Let Ω be open, convex and bounded; let f be a (possibly extended-valued) strictly convex function. Let K be positive real, let u^0 be in $C(\overline{\Omega}) \cap W^{1,1}(\Omega)$, and let it satisfy $(BSC)_K$. Let w, a solution to*

$$\text{minimize} \int_\Omega f(\nabla u(x))\, dx,\ u - u^0 \in W_0^{1,1}(\Omega),$$

be in $C(\Omega)$. Then w is Lipschitzian of Lipschitz constant K, and it is a solution to

$$\text{minimize} \int_\Omega f(\nabla u(x))\, dx,\ u - u^0 \in W_0^{1,1}(\Omega), \|\nabla u(x)\| \le K.$$

Proof of Theorem 1. (a) The proof follows the same steps as the proof of Theorem 2 of [3]. Any function u satisfying the constraints of problem (P_K) must satisfy those of problem (P_{Φ_K}); hence $\inf(P_K) \ge \inf(P_{\Phi_K})$. Let $I(w)$ be $\int_\Omega f(\nabla w(x))\, dx$; if we show that a continuous solution w to (P_{Φ_K}) satisfies $\|\nabla w(x)\| \le K$, we have $\inf(P_K) \le I(w) = \inf(P_{\Phi_K})$. It is enough to show that there cannot exist a unit vector $\mathbf{v}$, a scalar $M > K$, and a set $E \subset \Omega$ with $\mu(E) > 0$ such that, for x in E, the derivative of the map $t \to w(x + tv)$ at $t = 0$ exists, equals $\langle \nabla w(x), \mathbf{v} \rangle$, and is $> M$. Let us assume that $M, \mathbf{v}, E$ exist. As in [3], the key consists in proving the following claim.

Claim. Let x^{**} be a point in Ω such that $t \to w(x^{**} + t\mathbf{v})$ is differentiable in $t = 0$ with derivative $D^{**} > M$, and let $h^{**} > 0$ be such that, for every $0 < h < h^{**}$, $x^{**} - h\mathbf{v} \in \Omega$, and

$$w(x^{**} + h\mathbf{v}) - w(x^{**}) - Mh > 0.$$

Then w is affine on $[x^{**}, x^{**} + h^{**}\mathbf{v}]$ with derivative D^{**}.

Proof of the claim. Fix $h > 0$. Consider $\Omega_h = \{\Omega \cap (\Omega - h\mathbf{v})\}$ and the set $E_h^+ = \{x \in \Omega_h; w(x + h\mathbf{v}) > w(x) + hM\}$. E_h^+ is open and nonempty since it contains x^{**}. For $x \in E_h^+$, we have that $y = x + h\mathbf{v}$ is such that $y - h\mathbf{v}$ is in Ω and $w(y - h\mathbf{v}) < w(y) - hM$. The set $E_h^- = \{y \in \Omega_{-h}; w(y - h\mathbf{v}) < w(y) - hM\}$ is a translation of E_h^+: $E_h^- - h\mathbf{v} = E_h^+$, and it contains $x^{**} + h\mathbf{v}$. The proof is based on taking variations $\phi_h^+(x) = \max\{w(x + h\mathbf{v}) - w(x) - hM, 0\}$ on Ω_h and $\phi_h^-(x) = \min\{w(x - h\mathbf{v}) - w(x) + hM, 0\}$ on Ω_{-h}. However in the present situation, these variations need not yield admissible functions: for $\lambda > 0$, $w(x) + \lambda\phi_h^+(x) > w(x)$ on E_h^+, but every admissible function has to be bounded above by Φ_K^+ and analogously for $w(x) + \lambda\phi_h^-(x)$. Let us show (for ϕ_h^-) that this is not the case. Let x be in E_h^-. Since the map $\Phi_K^-(x)$ is Lipschitzian with constant K, one has

$$\Phi_K^-(x) - hK \le \Phi_K^-(x - h\mathbf{v}) \le w(x - h\mathbf{v}) < w(x) - hM = \Phi_K^-(x) - hM + (w - \Phi_K^-)(x);$$

i.e., $(w - \Phi_K^-)(x) > h(M - K)$. Again, since Φ_K^- and Φ_K^- are Lipschitzian, $|w|$ is uniformly bounded, and so is $|\phi_h^-|$. Let $\lambda^0 \ge 0$ be so small that $|\lambda^0 \phi_h^-| \le h(M - K)$. Then, for all $0 \le \lambda \le \lambda^0$, we have

$$\Phi_K^-(x) = w(x) - (w(x) - \Phi_K^-(x)) < w(x) - h(M - K) \le w(x) + \lambda\phi_h^-(x) \le w(x) \le \Phi_K^+(x);$$

i.e., the variation $\lambda\phi_h^-(x)$ is admissible. A similar case holds for $\lambda\phi_h^+(x)$. Since w is a minimum, we must have that, for all λ sufficiently small,

$$\int_\Omega f(\nabla w(x) + \lambda \nabla \phi_h^+(x))\, dx \ge \int_\Omega f(\nabla w(x))\, dx,$$

$$\int_\Omega f(\nabla w(x) + \lambda \nabla \phi_h^-(x))\, dx \geq \int_\Omega f(\nabla w(x))\, dx.$$

The above inequalities yield

$$\int_{E_h^+} \{f(\nabla w(x) + \lambda[\nabla w(x + h\mathbf{v}) - \nabla w(x)]) - f(\nabla w(x))\}\, dx \geq 0,$$

$$\int_{E_h^-} \{f(\nabla w(x) + \lambda[\nabla w(x - h\mathbf{v}) - \nabla w(x)]) - f(\nabla w(x))\}\, dx \geq 0.$$

Making the change of variables $y = x + h\mathbf{v}$ and adding the two inequalities, we obtain

$$\int_{E_h^+} \{f(\nabla w(x) + \lambda[\nabla w(x + h\mathbf{v}) - \nabla w(x)]) - f(\nabla w(x)) + f(\nabla w(x + h\mathbf{v})$$

$$-\lambda[\nabla w(x + h\mathbf{v}) - \nabla w(x)]) - f(\nabla w(x + h\mathbf{v}))\}\, dx \geq 0.$$

Reasoning as in [3], we obtain that, a.e. in E_h^+, $\nabla w(x) = \nabla w(x + h\mathbf{v})$. As a consequence, we have that there exists $\Lambda > 0$ such that the map $t \to w(x^* + t\mathbf{v})$ is affine on $[0, \Lambda]$ with derivative $M + \zeta$, $\zeta > 0$, and, in addition, that $x^* + \Lambda\mathbf{v}$ is in $\partial\Omega$. Set x^{**} to be $x^* + \Lambda\mathbf{v}$ (hence, $\Lambda = \|x^{**} - x^*\|$). We have obtained that $w(x^*) = w(x^{**} - \Lambda\mathbf{v}) = w(x^{**}) - \Lambda(M + \zeta)$.

When $x^{**} \in \partial\Omega \setminus V_K^-$, i.e., the bounded slope condition is verified at x^{**}, there exists $k^-, \|k^-\| \leq K$ such that, for every $x \in \partial\Omega$, we have $u^0(x) - u^0(x^{**}) \geq \langle k^-, x - x^{**}\rangle$, or, equivalently, for every $x \in \partial\Omega$, $u^0(x) \geq u^0(x^{**}) + \langle k^-, x - x^{**}\rangle$. Hence Theorem 3 of [3] applies with $\ell(x) = u^0(x^{**}) + \langle k^-, x - x^{**}\rangle$, and we infer that the solution w satisfies the inequality

$$w(x^*) \geq u^0(x^{**}) + \langle k^-, x^* - x^{**}\rangle \geq w(x^{**}) + \langle k^-, x^* - x^{**}\rangle \geq w(x^{**}) - K\Lambda,$$

contradicting $w(x^*) = w(x^{**}) - \Lambda(M + \zeta)$.

On the other hand, when x^{**} belongs to V_K^-, from the very definition of $\Phi_K^-(x^*)$, we have

$$w(x^*) \geq \Phi_K^-(x^*) \geq w(x^{**}) - K\Lambda,$$

again contradicting $w(x^*) = w(x^{**}) - \Lambda(M + \zeta)$.

The assumption that M, $\mathbf{v}$, and E exist leads to a contradiction. □

COROLLARY 2. *Under the same assumptions on f, Ω, and u^0, problems (P_K) and (P_{Φ_K}) coincide in the sense that they have the same solutions.*

2. Regularity of the solutions and the validity of the Euler–Lagrange equation. Our purpose is to apply the results of the previous section to prove the validity of the Euler–Lagrange equation to the minimization problem described in the introduction. To do so, we shall need further regularity of the solution. Notice that, for the specific example we have in mind, the lower obstacle function, as computed in section 1, is not in $W^{2,2}(S_R)$, but it is in $W^{2,2}(\Omega^*)$ for every $\Omega^* \subset\subset S_R$. Theorem 2, in particular, can be applied to the case $\Omega = S_R$ and $f = \Phi_1^-$; in this case, Ω^* is any smooth subset of S_R bounded away from $(0, 0)$.

We recall that $u^0 \geq f$ on $\partial\Omega$ in the sense of $W^{2,2}(\Omega)$ iff $(u^0 - f)^- \in W_0^{2,2}(\Omega)$.

THEOREM 2. *Let Ω be an open and bounded set with Lipschitzian boundary, let $\Omega^* \subset \Omega$ be open with smooth boundary, and let $f \in W^{1,2}(\Omega) \cap W^{2,2}(\Omega^*)$. Let $u^0 \in W^{1,2}(\Omega)$ be such that $u^0 \geq f$ on $\partial\Omega$ in the sense of $W^{1,2}(\Omega)$. Let w be a solution to problem (P):*

$$(P) \qquad \text{minimize} \int_\Omega \|\nabla u(x)\|^2 dx, \quad u(x) \geq f(x) \text{ a.e.}, \quad u - u^0 \in W^{1,1}(\Omega);$$

then w is in $W^{2,2}(\Omega^*)$.

Proof. (a) Since $(w^0 - f)^- = 0$ a.e. in Ω^*, $w^0 \geq f$ on Ω^* in the sense of $W^{1,2}(\Omega^*)$. Hence [7, p. 82] there exists a sequence of smooth maps, $\left(w_n^0\right)$, converging to w in $W^{1,2}(\Omega^*)$ such that $w_n^0 \geq f$ on $\partial\Omega^*$.

Consider the minimization problem:

$$(P^*) \qquad \text{minimize} \int_{\Omega^*} \|\nabla u(x)\|^2 dx, \quad u(x) \geq f(x) \text{ a.e.}, \quad u - w_n^0 \in W^{1,2}(\Omega^*),$$

and let w_n be a solution.

(b) Following the technique of Brézis–Stampacchia [2], we will approximate w_n by smoother maps. For positive ε, let w_n^ε be a solution to the following minimum problem:

$$(P_n) \qquad \text{minimize} \quad \int_{\Omega^*} \varepsilon \|\nabla v - \nabla f\|^2 + (v - w_n)^2 \quad \text{on } w_n^0 + W^{1,2}(\Omega^*).$$

Claim. $w_n^\varepsilon(x) \geq f(x)$ a.e. on Ω^*.

Proof of the claim. The functional to be minimized is convex and coercive; hence a solution w_n^ε in $W^{1,2}(\Omega^*)$ exists; from known results, it satisfies the following Euler–Lagrange equation: for every η in $W_0^{1,2}(\Omega^*)$,

$$\int_{\Omega^*} \varepsilon \langle \nabla w_n^\varepsilon - \nabla f, \nabla \eta \rangle + [w_n^\varepsilon - w_n]\eta = 0.$$

Let $\eta^- = (w_n^\varepsilon - f)^-$, and assume it is not zero a.e. Since

$$0 \geq (w_n^\varepsilon - f)^- \geq (w_n^\varepsilon - w_n^0)^- + (w_n^0 - f)^-,$$

we have $\eta^- \in W_0^{1,2}(\Omega^*)$, and, from the Euler–Lagrange equation, we obtain

$$\int_{\{w_n^\varepsilon < f\}} \varepsilon \langle \nabla w_n^\varepsilon - \nabla f, \nabla w_n^\varepsilon - \nabla f \rangle + (w_n^\varepsilon - w)(w_n^\varepsilon - f) = 0.$$

Since, on the set $\{w_n^\varepsilon < f\}$, we have $w_n \geq f > w_n^\varepsilon$, we obtain $(w_n - w_n^\varepsilon)(f - w_n^\varepsilon) > 0$ and hence a contradiction. Thus $w_n^\varepsilon(x) \geq f(x)$ a.e. on Ω^*.

Moreover, by the regularity results for linear equations, $w_n^\varepsilon \in W^{2,2}(\Omega^*)$, and w_n^ε is a solution of the equation $-\varepsilon\Delta w_n^\varepsilon + (w_n^\varepsilon - w_n) + \varepsilon\Delta f = 0$.

(c) Notice that, for every η in $W_0^{1,2}(\Omega^*)$ admissible, i.e., such that $w_n + \eta \geq f$, one has

$$\int_{\Omega^*} \langle \nabla w_n(x), \nabla \eta(x) \rangle dx \geq 0;$$

we have obtained in (b) that $\eta = w_n^\varepsilon - w_n$ is an admissible variation on Ω^*; hence

$$0 \leq \int_{\Omega^*} \langle \nabla w_n, \nabla \eta \rangle = \int_{\Omega^*} \langle \nabla w_n, \nabla w_n^\varepsilon - \nabla w_n \rangle \leq \int_{\Omega^*} \langle \nabla w_n^\varepsilon, \nabla w_n^\varepsilon - \nabla w_n \rangle.$$

From

$$\int_{\Omega^*} \langle \nabla w_n^\varepsilon, \nabla w_n^\varepsilon - \nabla w_n \rangle = \int_{\Omega^*} (-\Delta w_n^\varepsilon)(w_n^\varepsilon - w) = \varepsilon \int_{\Omega^*} (-\Delta w_n^\varepsilon)(\Delta w_n^\varepsilon - \Delta f),$$

we obtain

$$\varepsilon \int_{\Omega^*} |\Delta w_n^\varepsilon|^2 \le \varepsilon \left(\int_{\Omega^*} |\Delta w_n^\varepsilon|^2 \right)^{\frac{1}{2}} \left(\int_{\Omega^*} |\Delta f|^2 \right)^{\frac{1}{2}};$$

i.e.,

$$\left(\int_{\Omega^*} |\Delta w_n^\varepsilon|^2 \right)^{\frac{1}{2}} \le \left(\int_{\Omega^*} |\Delta f|^2 \right)^{\frac{1}{2}}.$$

As a consequence, from (b) we infer

$$\|w_n^\varepsilon - w_n\|_2 \le \varepsilon 2 \|\Delta f\|_2$$

and also

$$\int_{\Omega^*} -\Delta w_n^\varepsilon (w_n^\varepsilon - w_n) \to 0$$

as $\varepsilon \to 0$. Hence $\int_{\Omega^*} \nabla w_n^\varepsilon (\nabla w_n^\varepsilon - \nabla w_n)$ and $\int_{\Omega^*} \nabla w_n (\nabla w_n^\varepsilon - \nabla w_n) \to 0$ so that $\|\nabla w - \nabla w_n^\varepsilon\|_2 \to 0$ as $\varepsilon \to 0$.

(d) Fix any $\phi \in C_c^\infty(\Omega^*)$. Then

$$\left| \int_{\Omega^*} \langle \nabla w_n, \nabla \phi \rangle \right| = \lim_{\varepsilon \to 0} \left| \int_{\Omega^*} \langle \nabla w_n^\varepsilon, \nabla \phi \rangle \right| \le K \|\phi\|_2$$

(K independent of n) so that $\|\Delta w_n\|_2 \le K$. The sequence (w_n) is weakly precompact in $W^{1,2}(\Omega^*)$.

(e) A subsequence (still called (w_n)) converges weakly in $W^{1,2}(\Omega^*)$ to w^*. We claim that $w^* - u^0 \in W_0^{1,2}(\Omega^*)$. To begin with, we have

$$d((w_n - u^0), W_0^{1,2}(\Omega^*)) \le \|(w_n - u^0) - [(w_n - w_n^0) + (w - u^0)]\|_{1,2} = \|w_n^0 - w\|_{1,2} \to 0.$$

Let (y_n) be a sequence of convex combinations converging to w in $W^{1,2}(\Omega^*)$: more precisely, for every n, there are $\nu(n)$ indices $j_1(n), \dots, j_\nu(n)$ such that $j_1(n) < \cdots < j_\nu(n)$ and $\lim_{n\to\infty} j_1(n) = \infty$ and coefficients $\alpha_{j_1(n)}, \dots, \alpha_{j_\nu(n)}$ such that $\alpha_{j_1(n)} + \cdots + \alpha_{j_\nu(n)} = 1$ and $\alpha_{j_i(n)} \ge 0$ such that

$$y_n = \sum_{j_1(n),\dots,j_\nu(n)} \alpha_j w_j \to w \text{ as } n \to \infty.$$

Also, let $v_n \in W_0^{1,2}(\Omega^*)$ be such that $\|(w_n - u^0) - v_n\| \le 2d((w_n - u^0), W_0^{1,2}(\Omega^*))$. Then

$$d((y_n - u^0), W_0^{1,2}(\Omega^*)) \le \|(y_n - u^0) - v_n\| \le \sum_{j_1(n),\dots,j_{\nu(n)}(n)} \alpha_j \|(w_j - u^0) - v_n\|$$

$$\le 2 \sup_{j \in \{j_1(n),\dots,j_{\nu(n)}(n)\}} d(w_j - u^0, W_0^{1,2}(\Omega^*)) \to 0 \text{ as } n \to \infty$$

so that $w^* - u^0 \in W_0^{1,2}(\Omega^*)$.

(f) We claim that w^* is the restriction to Ω^* of w. Let $I(u)$ be $\int_{\Omega^*} \|\nabla u(x)\|^2 dx$; then, since the restriction of w to Ω^* is a minimum for P^*, $I(w) \le I(w^*)$. Assume there exists $\sigma > 0$ such that $I(w) \le I(w^*) - \sigma$. By the weak lower semicontinuity of the functional to be minimized, for all n sufficiently large, $I(w^*) \le I(w_n) + \frac{\sigma}{2}$. In problems (P_n), compute the integral on w_n^0 to obtain

$$I(w_n) \le I(w_n^0) \le I(w_n^0 - w) + I(w) \le I(w_n^0 - w) + I(w_n) - \frac{\sigma}{2},$$

which is a contradiction since $I(w_n^0 - w) \to 0$. So w^* is a solution to problem (P^*). By the strict convexity of the functional, the solutions are unique. So w^* is the restriction to Ω^* of w, and the whole sequence (w_n) converges weakly to w.

(g) Consider again y^n. Fix any $\phi \in C_c^\infty(\Omega^*)$. Then

$$\left| \int \langle \nabla w, \nabla \phi \rangle \right| = \lim_{n\to\infty} \left| \int \langle \nabla y^n, \nabla \phi \rangle \right| \le K \|\phi\|_2.$$

Hence $w \in W^{2,2}(\Omega^*)$. □

COROLLARY 3. *Let $u^0(x,y) = 1 - \frac{1}{R}\sqrt{x^2+y^2}$; let $\Phi_1^-(z)$ be the natural obstacle for problem (DP) as computed in section 1. Then problems*

$$\text{minimize} \int_{S_R} \frac{1}{2} \|\nabla u(z)\|^2 dz : \quad u - u^0 \in W^{1,1}(S_R), \quad \Phi_1^-(z) \le u(z)$$

and

$$\text{minimize} \int_{S_R} \frac{1}{2} \|\nabla u(z)\|^2 dz : \quad u - u^0 \in W^{1,1}(S_R), \quad \|\nabla u(z)\| \le 1$$

are equivalent in the sense that they have the same solutions.

Proof. Solutions to the obstacle problem are continuous on S_R by the previous theorem. □

The following theorem presents the construction of p.

THEOREM 3. *Let $\Omega \subset \Re$ be a bounded convex region. Let w be a solution to the constrained Dirichlet problem (DP) on S. Let $K = 1$ and $\Phi_1^+(x)$ and $\Phi_1^-(x)$ be the effective obstacles. Assume that $\Phi_1^+(x) = \infty$ and that $\Phi_1^- \in W^{2,2}(\Omega^*)$ on any $\Omega^* \subset\subset \Omega$. Assume that there exists a Lipschitzian one-to-one transformation $\tau : \Sigma \to \Omega$ such that*

(i) *τ is orthogonal;*

(ii) *$\frac{\partial \tau}{\partial \xi}(\xi,\eta) = -(\nabla \Phi_1^-)(\tau(\xi,\eta))$;*

(iii) *for every η, the map $\xi \to x_\eta^2 + y_\eta^2$ is nondecreasing;*

(iv) *τ is piecewise C^2 on Σ.*

Then there exists $p(.)$, a selection from $z \to \partial((\frac{1}{2}\|\nabla w(z)\|^2)^\infty)$, such that, for every $\phi \in W_0^{1,2}(\Omega)$, one has

$$\int_\Omega \langle p(z), \nabla \phi(z) \rangle \, dz = 0.$$

Proof. (a) Apply the previous theorem to infer that w is continuous on Ω. Let $E = \{z \in \Omega : w(z) = \Phi_1^-(z)\}$: E is closed (in Ω). We notice that, on the open set $\Omega \setminus E$, w is a solution to the (unconstrained) minimization problem

$$\text{minimize} \int_{\Omega\setminus E} \|\nabla u(z)\|^2 \, dz;$$

hence w is harmonic in $\Omega \setminus E$.

(b) Consider the transformation τ, and set $\mathbf{\Phi}(\xi,\eta) = \Phi_1^-(\tau(\xi,\eta))$. We have

$$\mathbf{\Phi}_\xi = \Phi_1^-{}_x x_\xi + \Phi_1^-{}_y y_\xi = -\|\nabla\Phi_1^-\|^2 = -1, \qquad \mathbf{\Phi}_\eta = 0.$$

Set $\mathbf{E} = \tau^{-1}(E), \omega(\xi,\eta) = w(\tau(\xi,\eta))$. On $\mathbf{E}$, $\nabla\omega = \nabla\mathbf{\Phi} = (-1,0)$. From the regularity of w and hence of ω, on a.e. line $\eta = \text{const}$, the map $\xi \to \nabla\omega(\xi,\eta)$ is absolutely continuous. Let $\eta = \eta^*$ be one such line. Let (ξ^*,η^*) be in $\mathbf{E}$, so that $\omega(\xi^*,\eta^*) = \mathbf{\Phi}(\xi^*,\eta^*)$. Then, when $0 < \xi \le \xi^*$, $(\xi,\eta^*) \in \mathbf{E}$. In fact, assume there exists ξ^{**} such that $\omega(\xi^{**},\eta^*) > \mathbf{\Phi}(\xi^{**},\eta^*)$. Since $\Phi_\xi \equiv 1$ and $\omega_\xi = w_x x_\xi + w_y y_\xi$ with $\|(x_\xi, y_\xi)\| = 1$, on $\{\eta = \eta^*\} \cap \mathbf{E}$ we would have points where the gradient of w is in norm larger than 1. Hence there exist $\xi^E = \xi^E(\eta^*)$ such that $\{\eta = \eta^*\} \cap \mathbf{E}$ equals either $\{(\xi,\eta^*) : 0 < \xi \le \xi^E\}$ or $\{(\xi,\eta^*) : 0 < \xi < \xi^E\}$ according to whether ξ^E belongs to $\tau^{-1}(\Omega)$ or to $\partial(\tau^{-1}(\Omega))$.

(c) We wish to show that there exists $\alpha(z)$, $\alpha = 1$, when $\|\nabla w(z)\| < 1, \alpha \ge 1$, when $\|\nabla w(z)\| = 1$ such that, for every $\phi \in C_c^\infty(\Omega)$, one has

$$\int_\Omega \alpha(z)\langle\nabla w(z), \nabla\phi(z)\rangle\, dz = 0.$$

If this is the case, the map $\alpha(.)\nabla w(.)$ is $p(.)$, the required selection from the map $z \to \partial((\frac{1}{2}\|\nabla w(z)\|^2)^\infty)$. The computation will be performed in the variables (ξ,η). Let $\Xi(\eta) = \sqrt{(x_\eta^2 + y_\eta^2)}(\xi^E(\eta),\eta)$, and define $A(\xi,\eta) = \frac{1}{\sqrt{(x_\eta^2+y_\eta^2)(\xi,\eta)}}\Xi(\eta)$ for $\xi \le \xi^E(\eta)$, i.e., for (ξ,η) in E, and $= 1$ otherwise. Then, by assumption (iii), $(\xi,\eta) \in E$ implies $A(\xi,\eta) \ge 1$. We will show that

$$\int_{\tau^{-1}(\Omega)} A(\xi,\eta)[\langle\nabla w, \nabla\phi\rangle(\tau(\xi,\eta))]J(\xi,\eta)\, d(\xi,\eta) = 0.$$

Then $\alpha(z) = A(\tau^{-1}(z))$ will be the sought-for function α.

Fix ϕ. Let $P(\xi,\eta) = \phi(\tau(\xi,\eta))$; let s_P be the interior of $\text{supp}(P)$. Recalling that τ is an orthogonal transformation and that $(x_\xi^2 + y_\xi^2) = 1$, we obtain

$$\langle\nabla w, \nabla\phi\rangle(\tau(\xi,\eta)) = \left[\omega_\xi P_\xi + \frac{\omega_\eta P_\eta}{(J)^2}\right].$$

Setting $B(\xi,\eta) = \Xi(\eta)$ for $\xi \ge \xi^E(\eta)$ and $= J(\xi,\eta)$ otherwise, the integral above becomes

$$\int_{s_P} B(\xi,\eta)\left[\omega_\xi P_\xi + \frac{\omega_\eta P_\eta}{(J)^2}\right] d(\xi,\eta).$$

We will compute separately

$$I_1 = \int_{s_P} B(\xi,\eta)[\omega_\xi P_\xi]\, d(\xi,\eta)$$

and

$$I_2 = \int_{s_P} B(\xi,\eta)\left[\omega_\eta P_\eta \frac{1}{(x_\eta^2 + y_\eta^2)}\right] d(\xi,\eta).$$

(d) From the regularity provided by Theorem 2, on a.e. line $\eta = \eta^*$, the maps $\xi \to \nabla\omega(\xi,\eta)$ and $\xi \to \sqrt{(x_\eta^2 + y_\eta^2)}\omega_\xi P(\xi,\eta)$ are absolutely continuous. Consider

$$I_1 = \int \left(\int_{\{\eta=\eta^*\}\cap \mathbf{E}} \Xi(\eta^*)[\omega_\xi P_\xi]\, d\xi \right) d\eta^*$$

$$+ \int \left(\int_{\{\eta=\eta^*\}\cap(\Sigma\setminus\mathbf{E})} \sqrt{(x_\eta^2 + y_\eta^2)}[\omega_\xi P_\xi]\, d\xi \right) d\eta^*.$$

On $\mathbf{E}$, $\omega_\xi = -1$; at ∂s_P, $P = 0$, and we obtain

$$I_1 = \int \left(\int_0^{\xi^E} \Xi(\eta^*)[-P_\xi]\, d\xi \right) d\eta^* + \int \left(\int_{\xi^E}^{\xi^\partial} \sqrt{(x_\eta^2 + y_\eta^2)}[\omega_\xi P_\xi]\, d\xi \right) d\eta^*$$

$$= \int \Xi(\eta^*)[-P(\xi^E(\eta^*),\eta^*)] d\eta^* + \int \left(\int_{\xi^E}^{\xi^\partial} \sqrt{(x_\eta^2 + y_\eta^2)}[\omega_\xi P_\xi]\, d\xi \right) d\eta^*.$$

To compute the second integral above, since

$$\left(\sqrt{(x_\eta^2 + y_\eta^2)}\omega_\xi P\right)(\xi^\partial,\eta^*) - \left(\sqrt{(x_\eta^2 + y_\eta^2)}\omega_\xi P\right)(\xi^E,\eta^*)$$

$$= \int_{\xi^E}^{\xi^\partial} \left(\sqrt{(x_\eta^2 + y_\eta^2)}\omega_\xi P_\xi + P\frac{d}{d\xi}\left(\sqrt{(x_\eta^2 + y_\eta^2)}\omega_\xi\right)\right) d\xi,$$

$\omega_\xi(\xi^E,\eta^*) = -1$ (the continuity of ω_ξ is used here), and $P(\xi^\partial,\eta^*) = 0$, we obtain

$$\int \left(\int_{\xi^E}^{\xi^\partial} \sqrt{(x_\eta^2 + y_\eta^2)}[\omega_\xi P_\xi]\, d\xi \right) d\eta^*$$

$$= \int \left(-\left(\sqrt{(x_\eta^2 + y_\eta^2)}P\right)(\xi^E,\eta^*) - \int_{\xi^E}^{\xi^\partial} P\frac{d}{d\xi}\left(\sqrt{(x_\eta^2 + y_\eta^2)}\omega_\xi\right) d\xi \right) d\eta^*.$$

Hence

$$I_1 = \int \left(-\int_{\xi^E}^{\xi^\partial} P\frac{d}{d\xi}\left(\sqrt{(x_\eta^2 + y_\eta^2)}\omega_\xi\right) d\xi \right) d\eta^*$$

$$= \int_{s_P\setminus E} -\frac{d}{d\xi}\left(\sqrt{(x_\eta^2 + y_\eta^2)}\omega_\xi\right) P\, d(\xi,\eta).$$

(e) Consider

$$I_2 = \int_{s_P} B(\xi,\eta)\left[\omega_\eta P_\eta \frac{1}{(x_\eta^2 + y_\eta^2)}\right] d(\xi,\eta).$$

For a.e. ξ, the map $\eta \to \omega_\eta \frac{1}{\sqrt{(x_\eta^2+y_\eta^2)}} P$ is absolutely continuous. Fix one such ξ^*; the intersection of the line $\xi = \xi^*$ with the open set $s_P \setminus \mathbf{E}$ is the union of (at most countably many) open intervals $((\xi^*, \alpha_i(\xi^*)), (\xi^*, \beta_i(\xi^*)))$, and we obtain

$$\int_{s_P} B(\xi,\eta) \left[\omega_\eta P_\eta \frac{1}{(x_\eta^2+y_\eta^2)}\right] d(\xi,\eta)$$

$$= \int \left(\int_{\Sigma \cap \{\xi = \xi^*\}} B(\xi,\eta) \left[\omega_\eta P_\eta \frac{1}{(x_\eta^2+y_\eta^2)}\right] d\eta \right) d\xi^*$$

$$= \int \left(\int_{\cup((\xi^*,\alpha_i(\xi^*)),(\xi^*,\beta_i(\xi^*)))} \left[\omega_\eta P_\eta \frac{1}{\sqrt{(x_\eta^2+y_\eta^2)}}\right] d\eta \right) d\xi^*$$

$$+ \int \left(\int_{\mathbf{E} \cap \{\xi = \xi^*\}} \Xi(\eta) \left[\omega_\eta P_\eta \frac{1}{(x_\eta^2+y_\eta^2)}\right] d\eta \right) d\xi^*.$$

The last integral is 0 since, on $\mathbf{E}$, $\omega_\eta = 0$. Consider one interval $((\xi^*, \alpha_i(\xi^*)), (\xi^*, \beta_i(\xi^*)))$: by the absolute continuity of $\eta \to \omega_\eta \frac{1}{\sqrt{(x_\eta^2+y_\eta^2)}} P$, we have

$$\omega_\eta \frac{1}{\sqrt{(x_\eta^2+y_\eta^2)}} P|_{\alpha_i}^{\beta_i} = \int_{\alpha_i}^{\beta_i} \left[P \frac{d}{d\eta} \left(\omega_\theta \frac{1}{\sqrt{(x_\eta^2+y_\eta^2)}} \right) + \left(\omega_\eta \frac{1}{\sqrt{(x_\eta^2+y_\eta^2)}} \right) P_\eta \right] d\eta.$$

The points $(\xi^*, \alpha_i(\xi^*))$ and $(\xi^*, \beta_i(\xi^*))$ are either at ∂s_P, so that $P = 0$, or on $\mathbf{E}$, and, in this case, by the regularity of $\omega_\eta \frac{1}{\sqrt{(x_\eta^2+y_\eta^2)}}$, we have $\omega_\eta \frac{1}{\sqrt{(x_\eta^2+y_\eta^2)}} = 0$. Hence

$$I_2 = -\sum_i \int \left(\int_{\alpha_i}^{\beta_i} \left[P \frac{d}{d\eta} \left(\omega_\eta \frac{1}{\sqrt{(x_\eta^2+y_\eta^2)}} \right) \right] d\eta \right) d\xi^*$$

$$= \int_{s_P \setminus \mathbf{E}} \left[\frac{d}{d\eta} \left(\omega_\eta \frac{1}{\sqrt{(x_\eta^2+y_\eta^2)}} \right) \right] P \, d(\xi,\eta).$$

Adding the results of (d) and of (e), we obtain

$$\int_\Omega \alpha(z) \langle \nabla w(z), \nabla \phi(z) \rangle \, dz = I_1 + I_2$$

$$= \int_{s_P \setminus \mathbf{E}} \left[\frac{d}{d\eta} \left(\omega_\eta \frac{1}{\sqrt{(x_\eta^2+y_\eta^2)}} \right) + \frac{d}{d\xi} \sqrt{(x_\eta^2+y_\eta^2)} \omega_\xi \right] P \, d(\xi,\eta)$$

$$= \int_{s_P \setminus \mathbf{E}} \left[\omega_{\eta\eta} \frac{1}{J^2} - \omega_\eta \frac{J_\eta}{J^3} + \omega_\xi \frac{J_\xi}{J} + \omega_{\xi\xi} \right] PJ \, d(\xi,\eta).$$

(f) Expressing the Laplacian of w at the point $\tau(\xi,\eta)$ in terms of ω, for a generic τ twice differentiable at the point (ξ,η), one obtains

$$J^2\Delta(w(\tau(\xi,\eta))) = \omega_{\xi\xi}(y_\eta^2+x_\eta^2)+\omega_{\eta\eta}(x_\xi^2+y_\xi^2)-2\omega_{\xi\eta}(x_\xi x_\eta+y_\xi y_\eta)$$

$$+\omega_\xi\left(x_\eta x_{\eta\xi}-x_\xi x_{\eta\eta}+y_\eta y_{\eta\xi}-y_\xi y_{\eta\eta}-x_\eta^2\frac{J_\xi}{J}-y_\eta^2\frac{J_\xi}{J}+x_\eta x_\xi\frac{J_\eta}{J}+y_\eta y_\xi\frac{J_\eta}{J}\right)$$

$$+\omega_\eta\left(x_\xi x_{\xi\eta}+y_\xi y_{\xi\eta}-x_\eta x_{\xi\xi}-y_\eta y_{\xi\xi}-x_\xi^2\frac{J_\eta}{J}-y_\xi^2\frac{J_\eta}{J}+x_\xi x_\eta\frac{J_\xi}{J}+y_\xi y_\eta\frac{J_\xi}{J}\right).$$

This equality, for a transformation τ with properties (i) and (ii), becomes

$$J^2\Delta(w(\tau(\xi,\eta))) = \omega_{\xi\xi}(y_\eta^2+x_\eta^2)+\omega_{\eta\eta}+\omega_\xi(JJ_\xi)+\omega_\eta\left(-\frac{J_\eta}{J}\right).$$

Since w is harmonic on $\Omega\setminus E$, its Laplacian computed at $\tau(\xi,\eta)$ for every $(\xi,\eta)\in\Omega\setminus E$ is 0; by the change of variables formula, one obtains then that the integral in (e) is zero.

This ends the proof. □

Remark. In the case when $\Omega = S_R$ with $R=1$ and $u^0 = 1-\sqrt{x^2+y^2}$, the previous construction yields an explicit definition of α: in fact, in this case, we have that $(\xi^E(\eta),\eta)=(1,\eta)$, $\Xi(\eta)=1$, and $A(\xi,\eta)=\frac{1}{\sqrt{(x_\eta^2+y_\eta^2)(\xi,\eta)}}\Xi(\eta)=\frac{1}{\xi}$. Hence we obtain that, setting $z=(x,y)$, $\alpha(z)\nabla w(z)=\frac{1}{\sqrt{x^2+y^2}}(\frac{x}{\sqrt{x^2+y^2}},\frac{y}{\sqrt{x^2+y^2}})$ is $p(z)$, the required selection from the map $z\to\partial((\frac{1}{2}\|\nabla w(z)\|^2)^\infty)$ having the property that, for any $\phi\in C_c^\infty(S_1)$,

$$\int_{S_1}\langle p(x),\nabla\phi(x)\rangle\,dx = 0.$$

In this case, p turns out to be the gradient of the harmonic function $\log\sqrt{x^2+y^2}$.

Summarizing the results of Corollary 2 and Theorem 3, we obtain the following corollary.

COROLLARY 4. *For every $R\geq 1$ and $u^0(x,y)=1-\frac{1}{R}\sqrt{x^2+y^2}$, a solution w to problem (DP) on S_R satisfies the Euler–Lagrange equation.*

NOTIONS OF OBSERVABILITY FOR UNCERTAIN LINEAR SYSTEMS WITH STRUCTURED UNCERTAINTY*

IAN R. PETERSEN†

Abstract. This paper introduces a notion of observability for a class of uncertain linear systems with structured uncertainty. In the uncertain systems under consideration, the uncertainty is described by averaged integral quadratic constraints. In order to define a notion of observability for uncertain linear systems, the paper introduces a robust observability function which extends the usual definition of the observability Gramian to the case of uncertain systems. Using this observability function, a corresponding unobservable cone is defined, and an uncertain system is said to be robustly observable if this cone contains only the origin. The paper presents an algorithm for finding the robust observability function and corresponding unobservable cone. This algorithm involves solving a parameterized Riccati differential equation.

Key words. uncertain systems, observability, Riccati equation, integral quadratic constraints, structured uncertainty

1. Introduction.

An important aspect of control theory is the insight it gives the control engineer into the control system design problem at hand. Recent research in robust control theory has resulted in a number of powerful techniques for the synthesis of robust control systems; see, e.g., [19, 3, 9]. However, there remains a need for new results on robust control theory which give additional insight into a given robust control problem. For example, it is extremely helpful for the control system designer to know what factors are currently limiting the performance of the control system design and what might be done to the system in order to achieve an improved level of performance.

One approach to providing the control system designer with additional insight into the control problem under consideration is the current research into "fundamental limitations" in control systems; see, e.g., [15]. In this approach, bounds on achievable performance are given in terms of plant transfer function properties such as poles and zeros. Although this approach is very useful in many applications, it does not fit directly in the uncertain systems approach to robust control system design. Also, in multivariable control systems, it would be useful to have some insight into the performance limitations imposed by the structure of the uncertain dynamics. This fact has motivated us to look at extending the modern control theory notion of observability to the case of uncertain systems. Naturally, it would also be of interest to look at the dual notion of controllability for uncertain systems. However, this question is beyond the scope of the current paper.

The notion of observability is one of the fundamental properties of a linear system; see, e.g., [4]. Together with controllability, the notion of observability can be used to determine if a given linear system can be stabilized via feedback control. Also, it can be used to determine if the unobserved states of a system can be estimated via

a state estimator. However, in considering practical control system and filter design problems, it was found that the notion of observability offered little real insight to the designer. To some extent, this fact can be traced to the lack of concern with robustness issues in the standard definition of observability. For example, the fact that a given plant model is controllable and observable gives the designer very little insight into whether a controller can be designed to achieve adequate performance in the face of model uncertainties. Also, a plant model which fails to be observable can usually be recognized as deficient from physical principles without the need for the concept of observability.

The fact that many of the limitations on achievable control system performance arise from the presence of model uncertainty leads us to think that the notion of observability may provide considerably more insight into a particular controller or state estimator design problem if extended to classes of uncertain systems. Thus the aim of this paper is to introduce a notion of observability for uncertain systems which will provide insight into the structure of uncertain systems and the limitations on achievable performance which arise.

The notion of observability for uncertain systems has previously been considered by a number of authors. In particular, the notion of observability considered in the papers [5, 6] is most closely related to the notion of observability considered here. In these papers, the notion of observability introduced is motivated by a certain set valued state estimation problem. In particular, it is assumed that the state of the uncertain system is initially completely unknown. Then the uncertain system is said to be observable if the set of possible initial states consistent with output measurements over a finite time interval is bounded. This definition of observability for uncertain systems fits in quite well with problems of set valued state estimation such as those considered in [6, 8]. However, it cannot be easily extended to the case of uncertain systems with structured uncertainty. Furthermore, it does not naturally lead to a notion extending the idea of the unobservable subspace, which arises in linear systems theory; see, e.g., [17].

The notion of observability introduced in this paper involves extending the definition of the observability Gramian to the case of uncertain systems; see also [2], where this notion is extended to the case of nonlinear systems. The observability Gramian can be defined in terms of the energy in the output signal resulting from a given initial condition. In our definition, we define the robust observability function as the minimum possible energy in the output signal for the given initial condition and for any admissible uncertainties. Thus, in our definition of observability, we think of the uncertainty as attempting to prevent the energy in the initial condition from being reflected in the output signal. This approach to defining a robust observability function for an uncertain system naturally leads to an extension of the notion of unobservable subspace. That is, we consider the set of all states for which the robust observability function is zero. This set is no longer a subspace but rather a cone in the state space. It is hoped that consideration of this cone will give new insight into the structure of uncertain systems.

As in the papers [5, 6], the uncertain systems considered in this paper will use an integral quadratic constraint (IQC) uncertainty description. However, in [5, 6], only one IQC is considered. Thus, in these papers, the uncertainty is unstructured. The notion of observability introduced in this paper allows for the case of structured uncertainty in a straightforward way, in particular, using the averaged IQC uncertainty description used in [12, 13]. This uncertainty description allows us to exploit a

certain S-procedure theorem in order to calculate the observability function in terms of a certain parameter dependent optimal control problem. A similar result could have been achieved using stochastic IQC uncertainty descriptions such as in [7, 16]. However, in this paper, we used the averaged IQC approach for the sake of simplicity.

2. Problem formulation. We consider the following time-varying uncertain system defined on the finite time interval $[0, T]$:

$$\begin{aligned}
\dot{x}(t) &= A(t)x(t) + \sum_{s=1}^{k} B_s(t)\xi_s(t),\\
y(t) &= C(t)x(t) + \sum_{s=1}^{k} D_s(t)\xi_s(t),\\
z_1(t) &= K_1(t)x(t),\\
z_2(t) &= K_2(t)x(t),\\
&\vdots\\
z_k(t) &= K_k(t)x(t),
\end{aligned} \tag{2.1}$$

where $x(t) \in \mathbf{R}^n$ is the *state*, $y(t) \in \mathbf{R}^l$ is the *measured output*, $z_1(t) \in \mathbf{R}^{h_1}$, $z_2(t) \in \mathbf{R}^{h_2}, \ldots, z_k(t) \in \mathbf{R}^{h_k}$ are the *uncertainty outputs*, $\xi_1(t) \in \mathbf{R}^{r_1}$, $\xi_2(t) \in \mathbf{R}^{r_2}, \ldots, \xi_k(t) \in \mathbf{R}^{r_k}$ are the *uncertainty inputs*, and $A(\cdot)$, $B_1(\cdot), \ldots, B_k(\cdot)$, $C(\cdot)$, $K_1(\cdot)$, $K_2(\cdot)$, $\ldots$, $K_k(\cdot)$ are bounded piecewise continuous matrix functions defined on $[0, T]$. The uncertainty inputs can be thought of as the outputs of uncertainty blocks as shown in Figure 2.1. Also, the uncertainty outputs can be thought of as the inputs to these uncertainty blocks. The bounds on the uncertainties are described below.

System uncertainty. The uncertainty inputs and outputs may be collected together into two vectors. That is, we define

$$\xi(t) \triangleq [\xi_1(t)'\ \xi_2(t)'\ \ldots\ \xi_k(t)'\ ]'$$

and

$$z(t) \triangleq [z_1(t)'\ z_2(t)'\ \ldots\ z_k(t)'\ ]'.$$

The uncertainty is required to satisfy a certain averaged IQC. That is, we consider finite collections of uncertainty inputs such that the following constraint is satisfied.

Averaged IQC. Let $d_1 > 0, d_2 > 0, \ldots, d_k > 0$ be given positive constants associated with the system (2.1). We will consider collections of uncertainty inputs $\mathcal{S} = \{\xi^1(\cdot), \xi^2(\cdot), \ldots \xi^q(\cdot)\}$. The number of elements q in any such collection is arbitrary. A collection of uncertainty functions of the form $\mathcal{S} = \{\xi^1(\cdot), \xi^2(\cdot), \ldots \xi^q(\cdot)\} \subset \mathbf{L}_2[0, T]$ is an *admissible uncertainty collection* for the system (2.1) if the following conditions hold: Given any $\xi^i(\cdot) \in \mathcal{S}$ and any corresponding solution $\{x^i(\cdot), \xi^i(\cdot), z^i(\cdot)\}$ to (2.1) defined on $[0, T]$, we have

$$\begin{aligned}
\frac{1}{q}\sum_{i=1}^{q}\int_0^T \left(\|\xi_1^i(t)\|^2 - \|z_1^i(t)\|^2\right) dt \le d_1,\\
\frac{1}{q}\sum_{i=1}^{q}\int_0^T \left(\|\xi_2^i(t)\|^2 - \|z_2^i(t)\|^2\right) dt \le d_2,
\end{aligned}$$

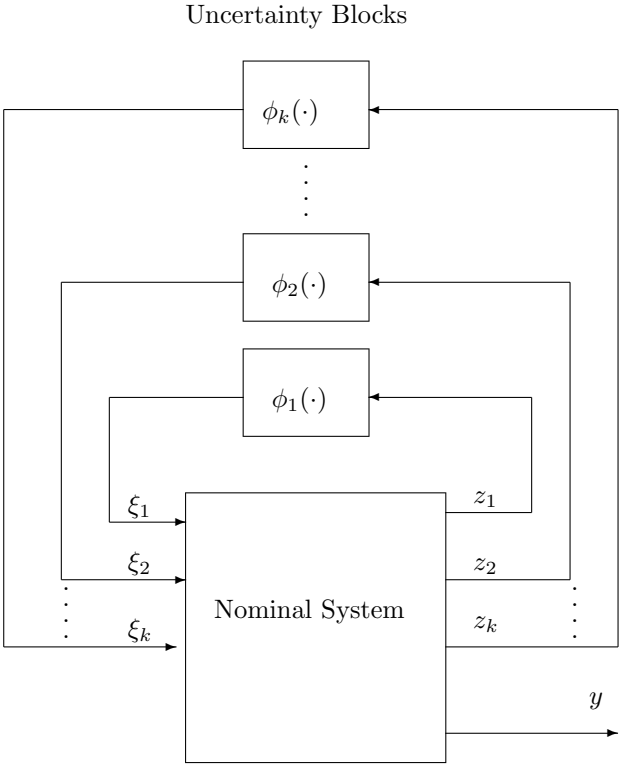

FIG. 2.1. *An uncertain system with structured feedback uncertainty.*

$$\vdots \qquad \vdots$$

$$\frac{1}{q}\sum_{i=1}^{q}\int_0^T \left(\|\xi_k^i(t)\|^2 - \|z_k^i(t)\|^2\right) dt \le d_k. \tag{2.2}$$

Here $\mathbf{L}_2[0,T]$ denotes the set of square integrable vector functions defined on the set $[0,T]$, and $\|\cdot\|$ denotes the standard Euclidean norm. The class of all such admissible uncertainty collections is denoted $\mathbf{\Xi}$. One way in which such uncertainty could be generated is via structured feedback uncertainty, as shown in the block diagram in Figure 2.1.

Remarks. The above definition extends the definition of the IQC given in [18, 10, 11]. In these papers, only individual uncertainty inputs are considered rather than collections of uncertainty inputs. One interpretation of the uncertainty class described above is a probabilistic one. That is, given any admissible uncertainty collection $\mathcal{S} \in \mathbf{\Xi}$, each uncertainty input $\xi^i(\cdot) \in \mathcal{S}$ is assigned an equal probability. Then condition (2.2) amounts to a bound on the expected value of the "measure of mismatch" between given uncertainty inputs $\xi_s(\cdot)$ and the following $\mathbf{L}_2[0,T]$ induced norm bound condition:

$$\int_0^T \left(\|\xi_s(t)\|^2 - \|z_s(t)\|^2\right) dt \le 0;$$

see also, e.g., [10] and [11]. It should be noted that the IQC on the uncertainty allows for nonlinear time-varying dynamic uncertainty. Indeed, the average measure

of mismatch bound d_s can be regarded as a bound on the average size of the initial condition for the uncertainty dynamics.

DEFINITION 2.1. *The* robust observability function *for the uncertain system* (2.1), (2.2) *is defined as*

$$L_o(x_0; d_1, \ldots, d_k; T) \triangleq \inf_{\mathcal{S}\in\Xi} \frac{1}{q} \sum_{i=1}^{q} \int_0^T \|y(t)\|^2 dt, \tag{2.3}$$

where $x(0) = x_0$ *in* (2.1).

This definition extends the standard definition of the observability Gramian for linear systems. In our robust observability function, we consider the worst case observability in which the uncertainty is trying to force the output of the system to zero for the given initial condition.

DEFINITION 2.2. *A state* $x_0 \in \mathbf{R}^n$ *is said to be* unobservable *for the uncertain system* (2.1), (2.2) *if*

$$L_o(x_0; d_1, \ldots, d_k; T) = 0$$

for all constants $d_1 > 0$, $d_2 > 0$,$\ldots d_k > 0$ *in* (2.2). *The set of all unobservable states for the uncertain system* (2.1), (2.2) *is referred to as the* unobservable cone $\mathcal{U}$*; i.e.,*

$$\mathcal{U} \triangleq \{x \in \mathbf{R}^n : L_o(x; d_1, \ldots, d_k; T) = 0 \ \ \forall d_1 > 0, d_2 > 0, \ldots, d_k > 0\}.$$

Also, the uncertain system (2.1), (2.2) *is said to be* robustly observable *if* $\mathcal{U} = \{0\}$*, i.e., if the origin is the only unobservable state.*

The above definition of the unobservable cone extends the standard definition of the unobservable subspace for a linear system (see [17]) to the case of uncertain systems. The aim of this paper is to find a means of constructing the observability function $L_o(x; d_1, \ldots, d_k; T)$ and the unobservable cone $\mathcal{U}$.

Note that the above definition will depend on the time horizon T. Roughly speaking, the observability of a state x_0 may depend on the time horizon T since, as the time horizon is lengthened, more information is obtained from the measurement y, but also more uncertainty may be allowed by the averaged IQC (2.2).

3. The main result. The robust observability function $L_o(x; d_1, \ldots, d_k; T)$ defined in (2.3) is defined as the value function for a constrained optimization problem. In order to solve this constrained optimization problem, we will use a version of the S-procedure theorem to convert the constrained optimization problem into an unconstrained optimization problem dependent on a set of Lagrange multiplier parameters.

3.1. The unconstrained optimization problem. For the uncertain system (2.1), (2.2), we define a function $V_\tau(x_0)$ as follows:

$$V_\tau(x_0) \triangleq \inf_{\xi(\cdot)\in\mathbf{L}_2[0,T]} \int_0^T \left(\|y(t)\|^2 + \sum_{s=1}^{k} \tau_s \|\xi_s(t)\|^2 - \sum_{s=1}^{k} \tau_s \|z_s(t)\|^2 \right) dt. \tag{3.1}$$

Here $\tau_1 \geq 0$, $\tau_2 \geq 0$,$\ldots$,$\tau_k \geq 0$ are given constants. For a given vector of Lagrange multiplier parameters $\tau = [\tau_1 \ \tau_2 \ \ldots \ \tau_k]$, the quantity $V_\tau(x_0)$ can be calculated as the solution to a standard linear quadratic optimal control problem. The solution to this optimal control problem, which will be given below, is given in terms of a Riccati differential equation dependent on the vector τ. Subsequently, we will show, using an

S-procedure theorem, that the robust observability function $L_o(x_0; d_1, \ldots, d_k; T)$ can be calculated in terms of $V_\tau(x_0)$.

In order to calculate $V_\tau(x_0)$, we first introduce some notation. Given $\tau = [\tau_1 \ \tau_2 \ \ldots \ \tau_k]$, let

$$\begin{aligned} B(t) &= [B_1(t) \ B_2(t) \ \ldots \ B_k(t)], \\ D(t) &= [D_1(t) \ D_2(t) \ \ldots \ D_k(t)], \\ K_\tau(t) &= \sum_{s=1}^{k} \tau_s K_s(t)' K_s(t), \\ \Lambda_\tau &= \begin{bmatrix} \tau_1 I & & 0 \\ & \ddots & \\ 0 & & \tau_k I \end{bmatrix}. \end{aligned}$$

Using this notation, it follows that the system (2.1) can be rewritten as

$$\dot{x}(t) = A(t)x(t) + B(t)\xi(t), \quad x(0) = x_0. \tag{3.2}$$

Also, the function $V_\tau(x_0)$ can be rewritten as

$$V_\tau(x_0) = \inf_{\xi(\cdot) \in \mathbf{L}_2[0,T]} J_\tau(\xi(\cdot)), \tag{3.3}$$

where

$$\begin{aligned} J_\tau(\xi(\cdot)) &= \int_0^T \begin{bmatrix} (C(t)x(t) + D(t)\xi(t))'(C(t)x(t) + D(t)\xi(t)) \\ +\xi(t)\Lambda_\tau\xi(t) - x(t)'K_\tau(t)x(t) \end{bmatrix} dt \\ &= \int_0^T \begin{pmatrix} x(t)[C(t)'C(t) - K_\tau(t)]x(t) \\ +2x(t)'C(t)'D(t)\xi(t) + \xi(t)'\Lambda_\tau\xi(t) + \xi(t)'D'D\xi(t) \end{pmatrix} dt. \end{aligned} \tag{3.4}$$

If $\tau = [\tau_1 \ \tau_2 \ \ldots \ \tau_k]$ is such that $\tau_1 > 0$, $\tau_2 > 0, \ldots, \tau_k > 0$, then the optimization problem (3.3) can be solved in terms of the following Riccati differential equation:

$$\begin{aligned} -\dot{P} &= A'P + PA - (PB + C'D)[\Lambda_\tau + D'D]^{-1}(D'C + B'P) + C'C - K_\tau, \\ P(T) &= 0. \end{aligned} \tag{3.5}$$

LEMMA 3.1. *Let $\tau = [\tau_1 \ \tau_2 \ \ldots \ \tau_k]$ be given such that $\tau_1 > 0$, $\tau_2 > 0, \ldots, \tau_k > 0$, and consider the corresponding system* (3.2) *and cost functional* (3.4). *Then the optimal control problem* (3.3) *is such that*

$$V_\tau(x_0) > -\infty$$

if and only if the Riccati differential equation (3.5) *has a solution $P_\tau(t)$ defined on $[0, T]$. In this case,*

$$V_\tau(x_0) = x_0' P_\tau(0) x_0. \tag{3.6}$$

Proof. This lemma follows directly from a standard result on the linear quadratic regulator problem; see, e.g., page 55 of [1]. ∎

3.2. An S-procedure result. In order to use the formula (3.6) to calculate the robust observability function (2.3), we will use the following S-procedure result. Indeed, consider a set of functionals

$$F_0(\xi(\cdot)),\ F_1(\xi(\cdot)),\dots,F_k(\xi(\cdot))$$

defined for the system (3.2).

LEMMA 3.2. *Suppose that, for any collection of input functions* $\{\xi^1(\cdot),\ \xi^2(\cdot),\dots,\xi^q(\cdot)\}$ *such that* $\xi^i(\cdot)\in\mathbf{L}_2[0,T]$ *for all* i *and*

$$\begin{aligned}
&\sum_{i=1}^{q} F_1(\xi^i(\cdot))\geq 0,\\
&\sum_{i=1}^{q} F_2(\xi^i(\cdot))\geq 0,\\
&\qquad\vdots\\
&\sum_{i=1}^{q} F_k(\xi^i(\cdot))\geq 0,
\end{aligned}\tag{3.7}$$

we have

$$\sum_{i=1}^{q} F_0(\xi^i(\cdot))\geq 0.\tag{3.8}$$

Then there exist constants $\tau_0\geq 0$, $\tau_1\geq 0$, $\dots$,$\tau_k\geq 0$ *such that* $\sum_{i=0}^{k}\tau_i>0$ *and*

$$\tau_0 F_0(\xi(\cdot))\geq\sum_{i=1}^{k}\tau_i F_k(\xi(\cdot))\tag{3.9}$$

for all inputs $\xi(\cdot)\in\mathbf{L}_2[0,T]$.

Proof. We first define the set

$$\mathcal{P}\triangleq\{[F_0(\xi(\cdot)),F_1(\xi(\cdot)),\dots,F_k(\xi(\cdot))]'\,:\,\xi(\cdot)\in\mathbf{L}_2[0,T]\}\subset\mathbf{R}^{k+1}.$$

Then condition (3.7), (3.8) implies that this set satisfies the assumptions of Theorem 3.1 of [14]. From this theorem, (3.9) follows. □

OBSERVATION 1. *If there exists an input* $\xi(\cdot)\in\mathbf{L}_2[0,T]$ *such that* $F_1(\xi(\cdot))>0,\ F_2(\xi(\cdot))>0,\dots,F_k(\xi(\cdot))>0$, *and the assumptions of the above lemma hold, then* τ_0 *may be chosen as* $\tau_0=1$ *in* (3.9)*; see Observation* 3.1 *in* [14].

3.3. A formula for the robust observability function. In order to present our main result, which is a formula for the robust observability function $L_o(x;d_1,\dots,d_k;T)$, we first introduce the following notation:

$$\Gamma\triangleq\{\tau=[\tau_1\ \tau_2\ \dots\ \tau_k]:\tau_1>0\ \tau_2>0\ \dots\ \tau_k>0\text{ and }V_\tau(x_0)>-\infty\}.$$

Also,

$$\bar{\Gamma}\triangleq\{\tau=[\tau_1\ \tau_2\ \dots\ \tau_k]:\tau_1\geq 0\ \tau_2\geq 0\ \dots\ \tau_k\geq 0\text{ and }V_\tau(x_0)>-\infty\}.$$

THEOREM 3.3. *Consider the uncertain system* (2.1), (2.2) *and the corresponding robust observability function* (2.3). *Then, for any initial condition* $x(0) = x_0$,

$$L_o(x_0; d_1, \ldots, d_k; T) = \max_{\tau \in \bar{\Gamma}} \left\{ V_\tau(x_0) - \sum_{s=1}^{k} \tau_s d_s \right\}. \tag{3.10}$$

Proof. Given any admissible uncertainty input collection $\mathcal{S} \in \Xi$ for the uncertain system (2.1), (2.2) with initial condition $x(0) = x_0$ and vector $\tau \in \bar{\Gamma}$, we claim

$$\frac{1}{q} \sum_{i=1}^{q} \int_0^T \|y^i(t)\|^2 dt \geq V_\tau(x_0) - \sum_{s=1}^{k} \tau_s d_s. \tag{3.11}$$

To establish this claim, we first note that it follows from the definition of $V_\tau(x_0)$ (3.1) that

$$\int_0^T \left(\|y(t)\|^2 + \sum_{s=1}^{k} \tau_s \|\xi_s(t)\|^2 - \sum_{s=1}^{k} \tau_s \|z_s(t)\|^2 \right) dt \geq V_\tau(x_0)$$

for all $\xi(\cdot) \in \mathbf{L}_2[0, T]$. In particular, this inequality holds for every element in the given collection $\mathcal{S}$. Hence

$$\begin{aligned} &\frac{1}{q} \sum_{i=1}^{q} \int_0^T \left(\|y^i(t)\|^2 + \sum_{s=1}^{k} \tau_s \|\xi_s^i(t)\|^2 - \sum_{s=1}^{k} \tau_s \|z_s^i(t)\|^2 \right) dt \\ &\geq \frac{1}{q} \sum_{i=1}^{q} V_\tau(x_0) \\ &= V_\tau(x_0). \end{aligned} \tag{3.12}$$

However, $\mathcal{S} \in \Xi$ implies that (2.2) is satisfied, and hence from (3.12) we obtain

$$\frac{1}{q} \sum_{i=1}^{q} \int_0^T \|y^i(t)\|^2 dt + \sum_{s=1}^{k} \tau_s d_s \geq V_\tau(x_0).$$

Thus (3.11) holds.

Now, since (3.11) holds for any $\mathcal{S} \in \Xi$, we have

$$\inf_{\mathcal{S} \in \Xi} \frac{1}{q} \sum_{i=1}^{q} \int_0^T \|y^i(t)\|^2 dt \geq V_\tau(x_0) - \sum_{s=1}^{k} \tau_s d_s \tag{3.13}$$

for all $\tau \in \bar{\Gamma}$. We now claim that there exists a $\tau \in \bar{\Gamma}$ such that

$$\inf_{\mathcal{S} \in \Xi} \frac{1}{q} \sum_{i=1}^{q} \int_0^T \|y^i(t)\|^2 dt \leq V_\tau(x_0) - \sum_{s=1}^{k} \tau_s d_s. \tag{3.14}$$

To establish this claim, we let

$$c \triangleq \inf_{\mathcal{S} \in \Xi} \frac{1}{q} \sum_{i=1}^{q} \int_0^T \|y^i(t)\|^2 dt. \tag{3.15}$$

Also, we define the functionals in Lemma 3.1 as follows:

$$\begin{aligned}
F_0(\xi(\cdot)) &\triangleq \int_0^T \|y(t)\|^2 dt - c,\\
F_1(\xi(\cdot)) &\triangleq \int_0^T \left(\|z_1(t)\|^2 - \|\xi_1(t)\|^2\right) dt + d_1,\\
F_2(\xi(\cdot)) &\triangleq \int_0^T \left(\|z_2(t)\|^2 - \|\xi_2(t)\|^2\right) dt + d_2,\\
&\vdots\\
F_k(\xi(\cdot)) &\triangleq \int_0^T \left(\|z_k(t)\|^2 - \|\xi_k(t)\|^2\right) dt + d_k.
\end{aligned}$$

Now, for any uncertainty input collection $\mathcal{S}$ such that

$$\frac{1}{q}\sum_{i=1}^{q} F_1(\xi^i(\cdot)) \geq 0,\ \frac{1}{q}\sum_{i=1}^{q} F_2(\xi^i(\cdot)) \geq 0, \ldots, \frac{1}{q}\sum_{i=1}^{q} F_k(\xi^i(\cdot)) \geq 0,$$

the averaged IQCs (2.2) are satisfied, and hence $\mathcal{S} \in \Xi$. Then it follows from (3.15) that

$$\frac{1}{q}\sum_{i=1}^{q} F_0(\xi^i(\cdot)) \geq 0.$$

Thus the conditions of the S-procedure result, Lemma 3.2, are satisfied. Also, note that, since $d_1 > 0,\ d_2 > 0, \ldots, d_k > 0$, then $F_1(0) > 0,\ F_2(0) > 0, \ldots, F_k(0) > 0$. Thus it follows from Lemma 3.2 and Observation 1 that there exist constants $\tau_1 \geq 0$, $\tau_2 \geq 0, \ldots, \tau_k \geq 0$ such that

$$F_0(\xi(\cdot)) \geq \sum_{s=1}^{k} \tau_s F_s(\xi(\cdot))$$

for all $\xi(\cdot) \in \mathbf{L}_2[0,T]$. That is,

$$\int_0^T \|y(t)\|^2 dt - c \geq \sum_{s=1}^{k} \tau_s \left[\int_0^T \left(\|z_s(t)\|^2 - \|\xi_s(t)\|^2\right) dt + d_s\right]$$

for all $\xi(\cdot) \in \mathbf{L}_2[0,T]$. Hence

$$\inf_{\xi(\cdot)\in\mathbf{L}_2[0,T]} \int_0^T \left(\|y(t)\|^2 + \sum_{s=1}^{k} \tau_s \|\xi_s(t)\|^2 - \sum_{s=1}^{k} \tau_s \|z_s(t)\|^2\right) dt \geq c + \sum_{s=1}^{k} \tau_s d_s.$$

Then, using (3.1) and (3.15), we have

$$V_\tau(x_0) \geq \inf_{\mathcal{S}\in\Xi} \frac{1}{q}\sum_{i=1}^{q} \int_0^T \|y(t)\|^2 dt + \sum_{s=1}^{k} \tau_s d_s \geq 0.$$

That is, (3.14) is satisfied. Furthermore, since $V_\tau(x_0) \geq 0$, then $\tau = [\tau_1\ \tau_2\ \ldots\ \tau_k]' \in \bar{\Gamma}$. Combining (3.13) and (3.14) now leads to (3.10). This completes the proof of the theorem. □

COROLLARY 3.4. *Consider the uncertain system* (2.1), (2.2) *and the corresponding robust observability function* (2.3). *Then, for any initial condition* $x(0) = x_0$,

$$L_o(x_0; d_1, \ldots, d_k; T) = \sup_{\tau \in \Gamma} \left\{ x_0' P_\tau(0) x_0 - \sum_{s=1}^{k} \tau_s d_s \right\}. \tag{3.16}$$

Proof. It is straightforward to verify that

$$\max_{\tau \in \bar{\Gamma}} \left\{ V_\tau(x_0) - \sum_{s=1}^{k} \tau_s d_s \right\} = \sup_{\tau \in \Gamma} \left\{ V_\tau(x_0) - \sum_{s=1}^{k} \tau_s d_s \right\}.$$

Hence, using Lemma 3.1, (3.16) follows. □

COROLLARY 3.5. *Consider the uncertain system* (2.1), (2.2). *Then a state* $x_0 \in \mathbf{R}^n$ *is unobservable if and only if*

$$x_0' P_\tau(0) x_0 \leq 0$$

for all $\tau \in \Gamma$.

Proof. If x_0 is unobservable, then $L_o(x_0; d_1, \ldots, d_k; T) = 0$ for all $d_1 > 0,\ d_2 > 0, \ldots, d_k$. Hence, using Corollary 3.4,

$$x_0' P_\tau(0) x_0 - \sum_{s=1}^{k} \tau_s d_s \leq 0$$

for all $d_1 > 0,\ d_2 > 0, \ldots, d_k > 0$, and $\tau \in \Gamma$. Thus

$$x_0' P_\tau(0) x_0 \leq 0$$

for all $\tau \in \Gamma$.

Conversely, if

$$x_0' P_\tau(0) x_0 \leq 0$$

for all $\tau \in \Gamma$, then

$$x_0' P_\tau(0) x_0 - \sum_{s=1}^{k} \tau_s d_s \leq 0$$

for all $d_1 > 0,\ d_2 > 0, \ldots, d_k > 0$, and $\tau \in \Gamma$. Thus, using Corollary 3.4,

$$L_o(x_0; d_1, \ldots, d_k; T) = \sup_{\tau \in \Gamma} \left\{ x_0' P_\tau(0) x_0 - \sum_{s=1}^{k} \tau_s d_s \right\} \leq 0$$

for all $d_1 > 0,\ d_2 > 0, \ldots, d_k > 0$. However, it follows from the definition of the observability function that $L_o(x_0; d_1, \ldots, d_k; T) \geq 0$. Thus

$$L_o(x_0; d_1, \ldots, d_k; T) = 0$$

for all $d_1 > 0,\ d_2 > 0, \ldots, d_k$. That is, x_0 is unobservable. □

OBSERVATION 2. *From the above corollary, it follows immediately that the unobservable cone* $\mathcal{U}$ *can be written in the form*

$$\mathcal{U} = \{x \in \mathbf{R}^n : x_0' P_\tau(0) x_0 \leq 0 \ \ \forall \tau \in \Gamma\}.$$

Also, it follows that the uncertain system (2.1), (2.2) *is robustly observable if and only if, for all* $x_0 \in \mathbf{R}^n : x_0 \neq 0$, *there exists a* $\tau \in \Gamma$ *such that*

$$x_0' P_\tau(0) x_0 > 0.$$

4. An alternative definition of robust observability. In this section, we compare the notion of robust observability defined above with the notion of robust observability considered in the paper [6]. This paper considers a class of uncertain systems in which the uncertainty is described by a single IQC. Hence the uncertainty in the system is unstructured. Also, in [6] there was no need to use averaged IQCs.

The notion of observability considered in [6] relates to a certain set valued state estimation problem. The result of [6] shows that the uncertain system under consideration has the property of robust observability if and only if the solution to a certain Riccati differential equation is positive-definite at time zero. The main result of this section shows that the definition of robust observability given in [6] is, in fact, equivalent to our definition of robust observability given in section 2.

The uncertain system considered in [6] can be considered as a special case of the uncertain system (2.1), (2.2), where $k = 1$,

$$\begin{aligned} \xi_1(t) &= \begin{bmatrix} w(t) \\ v(t) \end{bmatrix}, \\ A(t) &= A(t); \quad B_1(t) = [B_1(t)\ 0], \\ K_1(t) &= K(t); \quad C(t) = C(t); \quad D_1(t) = [0\ I]. \end{aligned} \tag{4.1}$$

Also, the uncertainty is assumed to satisfy the IQC

$$\int_0^T \left(\|w(t)\|^2 + \|v(t)\|^2 - \|z(t)\|^2 \right) dt \leq d_1. \tag{4.2}$$

This IQC can be considered as a special case of the averaged IQCs (2.2) when we restrict our attention to uncertainty input collections with one element. Also, note that we have assumed that, in [6], $R(t) \equiv I$, $Q \equiv I$.

According to the definition given in [6], an uncertain system is robustly observable if the set of all possible states at time $t = 0$, consistent with the uncertain system model and given output measurements on $[0,\ T]$, is bounded (for all $d_1 > 0$). The main result of [6] on robust observability gives a characterization of robust observability in terms of the Riccati differential equation:

$$\begin{aligned} -\dot{Y}(t) = {} & Y(t)A(t) + A(t)'Y(t) - Y(t)B_1(t)B_1(t)'Y(t) \\ & -K(t)'K(t) + C(t)'C(t), \quad Y(T) = 0. \end{aligned} \tag{4.3}$$

Indeed, it is shown in [6] that the uncertain system under consideration is robustly observable (in the sense of [6]) if and only if (4.3) has a solution on $[0,\ T]$ and $Y(0) > 0$.

In order to compare our definition of robust observability with the definition given in [6], we first observe that the Riccati differential equation (4.3) can be given an optimal control interpretation. Indeed, if we consider the system (2.1), (4.1) with initial condition $x(0) = x_0$ and the Riccati differential equation (4.3), then

$$x_0'Y(0)x_0 = \inf_{w(\cdot)\in \mathbf{L}_2[0,T]} \int_0^T \left(\|C(t)x(t)\|^2 - \|z_1(t)\|^2 + \|w(t)\|^2 \right) dt. \tag{4.4}$$

Now consider the quantity (3.1) for the uncertain system (2.1), (4.1), (4.2). This quantity can be calculated as follows:

$$\begin{aligned} V_\tau(x_0) &= \inf_{\xi(\cdot)\in \mathbf{L}_2[0,T]} \int_0^T \left(\|y(t)\|^2 - \tau\|z(t)\|^2 + \tau\|w(t)\|^2 + \tau\|v(t)\|^2 \right) dt \\ &= \inf_{w(\cdot)\in \mathbf{L}_2[0,T]} \inf_{v(\cdot)\in \mathbf{L}_2[0,T]} \int_0^T \begin{pmatrix} \|C(t)x(t) + v(t)\|^2 - \tau\|z(t)\|^2 \\ +\tau\|w(t)\|^2 + \tau\|v(t)\|^2 \end{pmatrix} dt. \end{aligned}$$

However,

$$\begin{aligned}
&\inf_{v(\cdot)\in\mathbf{L}_2[0,T]} \int_0^T \left(x(t)'C(t)'C(t)x(t) + 2x(t)'C(t)v(t) + v(t)'v(t) + \tau\|v(t)\|^2\right) dt \\
&= \inf_{v(\cdot)\in\mathbf{L}_2[0,T]} \int_0^T \left(\begin{array}{l} [\frac{1}{\sqrt{1+\tau}}C(t)x(t) + \sqrt{1+\tau}v(t)]'[\frac{1}{\sqrt{1+\tau}}C(t)x(t) + \sqrt{1+\tau}v(t)] \\ -\frac{1}{1+\tau}x(t)'C(t)'C(t)x(t) + x(t)'C(t)'C(t)x(t) \end{array} \right) dt \\
&= \int_0^T \frac{\tau}{1+\tau}x(t)'C(t)'C(t)x(t)dt.
\end{aligned}$$

Thus

$$V_\tau(x_0) = \tau \inf_{w(\cdot)\in\mathbf{L}_2[0,T]} \int_0^T \left(\frac{1}{1+\tau}x(t)'C(t)'C(t)x(t) - \|z(t)\|^2 + \|w(t)\|^2\right) dt.$$

Now observe that, for any $\tau > 0$, $V_\tau(x_0) \leq 0$ if and only if $\bar{V}_\tau(x_0) \leq 0$, where

$$\bar{V}_\tau(x_0) = \inf_{w(\cdot)\in\mathbf{L}_2[0,T]} \int_0^T \left(\frac{1}{1+\tau}x(t)'C(t)'C(t)x(t) - \|z(t)\|^2 + \|w(t)\|^2\right) dt. \tag{4.5}$$

Also note that it follows from (4.5) that, for any $x_0 \in \mathbf{R}^n$, $\bar{V}_\tau(x_0)$ is monotone increasing as $\tau \to 0$. Hence it follows from Theorem 3.3 that a state $x_0 \in \mathbf{R}^n$ is unobservable for the uncertain system (2.1), (4.1), (4.2) if and only if

$$\inf_{w(\cdot)\in\mathbf{L}_2[0,T]} \int_0^T \left(x(t)'C(t)'C(t)x(t) - \|z(t)\|^2 + \|w(t)\|^2\right) dt \leq 0.$$

Therefore, it follows from (4.4) that the system has no nonzero unobservable state if and only if

$$Y(0) > 0.$$

That is, our robust observability condition is equivalent to the robust observability condition of [6] for uncertain systems of the form (2.1), (4.1), (4.2). However, in contrast to the robust observability condition of [6], our robust observability condition can be applied to systems with structured uncertainty. Also, our robust observability condition leads naturally to a notion of an unobservable cone.

5. Illustrative examples. In this section, we consider two examples which illustrate our notions of robust observability and the unobservable cone for an uncertain system.

Example 1. We consider an uncertain system of the form (2.1), (2.2), where $k = 1$, $T = 10$,

$$\begin{gathered}
A(t) \equiv \begin{bmatrix} -2 & 0 \\ 0 & -1 \end{bmatrix}, \quad B_1(t) \equiv \begin{bmatrix} 2 \\ 0 \end{bmatrix}, \\
K_1(t) \equiv [1 \;\; 0], \quad C(t) \equiv [1 \;\; 1], \quad D_1(t) \equiv 0.
\end{gathered}$$

In order to characterize the unobservable cone for this uncertain system, we will apply Observation 2. This involves solving the Riccati differential equation (3.5) for different values of the parameter $\tau > 0$. For each value of $\tau > 0$, we form the set

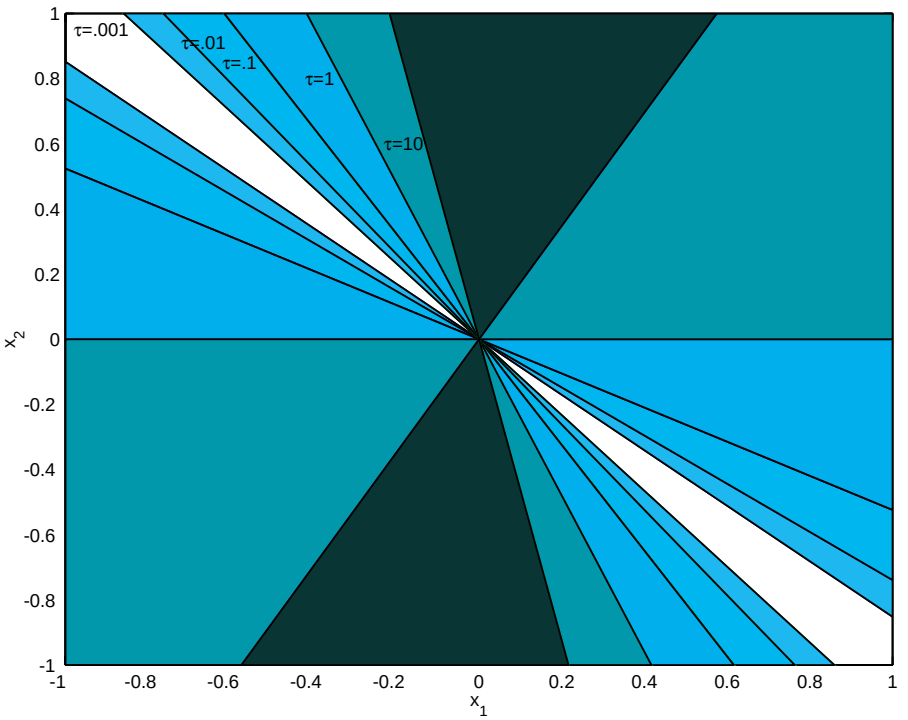

FIG. 5.1. *Unobservable cone for Example* 1.

$\{x \in \mathbf{R}^n : x_0' P_\tau(0) x_0 \leq 0\}$. Then the unobservable cone is the intersection of all of these sets. This process is illustrated in Figure 5.1.

In this figure, the unshaded region corresponds to the states such that $x_0' P_\tau(0) x_0 \leq 0$. As more and more values of τ are considered, the remaining unshaded region becomes smaller and smaller. Indeed, the unobservable cone in this example consists of a single line passing through the origin. This can be seen as follows: For each $\tau > 0$, the set $\{x \in \mathbf{R}^n : x_0' P_\tau(0) x_0 \leq 0\}$ is bounded by two lines which pass through the origin. Furthermore, it is straightforward to verify that, as $\tau \to 0$, both slopes converge to -1; see also Figure 5.2, in which we plot the slope of these lines as a function of τ. From this figure, we can conclude that, in this example, the unobservable cone is

$$\mathcal{U} = \{x = [x_1 \ x_2]' : x_2 = -x_1\}.$$

To further understand this result, note that, for this example, the averaged IQC (2.2) allows for norm bounded uncertainties of the form $w(t) = \delta(t) z(t)$, where $\delta(t)$ is a norm bounded uncertain parameter satisfying the bound $|\delta(t)| \leq 1$. In this case, the uncertain system can be rewritten as

$$\begin{aligned} \dot{x} &= \begin{bmatrix} -2 + 2\delta(t) & 0 \\ 0 & -1 \end{bmatrix} x, \\ y &= [1 \quad 1] x. \end{aligned}$$

In particular, if $\delta(t) \equiv 0.5$, this system becomes

$$\dot{x} = \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix} x,$$

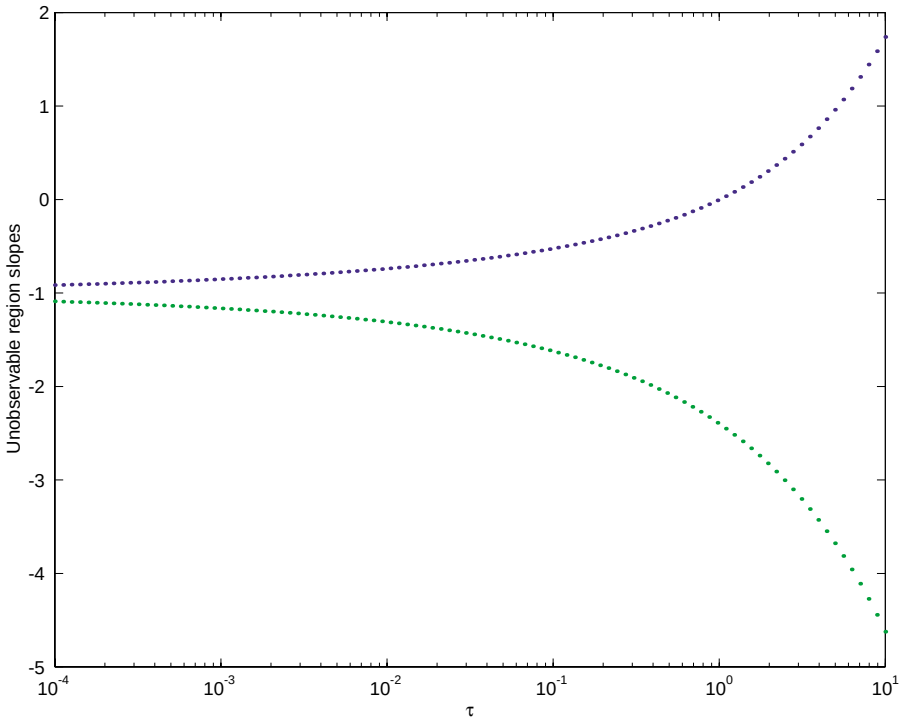

FIG. 5.2. *Bounding slopes vs* τ.

$$y = [1 \quad 1]x,$$

which is an unobservable linear system with unobservable subspace

$$\{x = [x_1 \ x_2]' : x_2 = -x_1\}.$$

This is the same as the unobservable cone for the uncertain system calculated above.

Note that, for this example, we have $D_1(t) \equiv 0$. That is, we have no uncertainty in the "C matrix." In this situation, it is straightforward to verify that the unobservable cone must lie in this null space of the matrix C. Hence, in a two dimensional system such as this one, any nontrivial unobservable cone must be a linear space. In the next example, we allow for uncertainty in the "C matrix" and show that this can lead to an unobservable cone which is not a linear space.

Example 2. We now consider another uncertain system of the form (2.1), (2.2), where $k = 1$, $T = 10$,

$$A(t) \equiv \begin{bmatrix} 0 & 1 \\ -1 & -5 \end{bmatrix}, \quad B_1(t) \equiv \begin{bmatrix} 1 \\ 0 \end{bmatrix},$$
$$K_1(t) \equiv [0 \quad 0.7], \quad C(t) \equiv [1 \quad 0], \quad D_1(t) \equiv 1.$$

As above, we characterize the unobservable cone for this system using Observation 2. This leads to the results illustrated in Figure 5.3.

As in Example 1, the unshaded region in this figure corresponds to the states such that $x_0' P_\tau(0) x_0 \leq 0$ for various values of τ. As more and more values of τ are

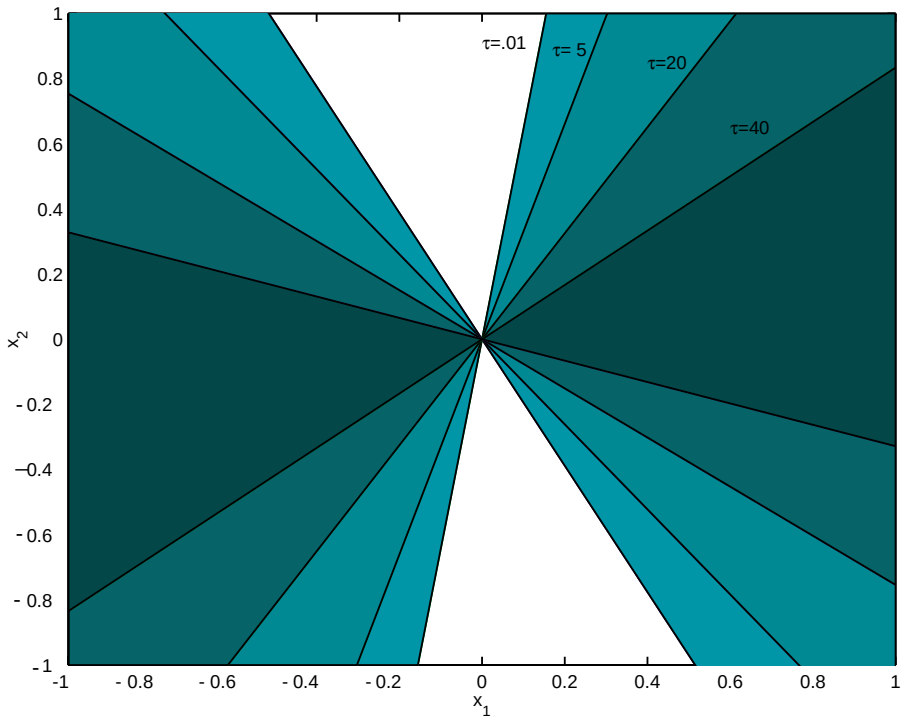

FIG. 5.3. *Unobservable cone for Example* 2.

considered, the remaining unshaded region becomes smaller and smaller. Also, as in Example 1, the regions $x_0' P_\tau(0) x_0 \leq 0$ are bounded by two straight lines passing through the origin. By considering the range of values of these slopes, we conclude that the unobservable cone for this uncertain system is a region in the state space bounded between the lines $\{x_2 = -1.94x_1\}$ and $\{x_2 = 6.47x_1\}$; see, e.g., Figure 5.4, in which we plot the slopes of these lines as a function of τ. Note that we consider only $\tau < 54.4$ since, for τ greater than this value, $P_\tau(0)$ is negative-definite.

For this uncertain system, the corresponding uncertain system with constant norm bounded uncertainty is described by the state equations

$$\dot{x} = \begin{bmatrix} 0 & 1 + 0.7\delta_1 \\ -1 & -5 \end{bmatrix} x,$$
$$y = [1 \quad 0.7\delta_2] x,$$

where $\delta_1^2 + \delta_2^2 \leq 1$. For this system, the corresponding observability matrix is given by

$$\begin{bmatrix} 1 & 0.7\delta_2 \\ -0.7\delta_2 & 1 + 0.7\delta_1 - 3.5\delta_2 \end{bmatrix}.$$

This matrix is nonsingular for some values of δ_1, δ_2 such that $\delta_1^2 + \delta_2^2 \leq 1$. This is consistent with the fact that the original uncertain system considered in this example has a nontrivial unobservable cone.

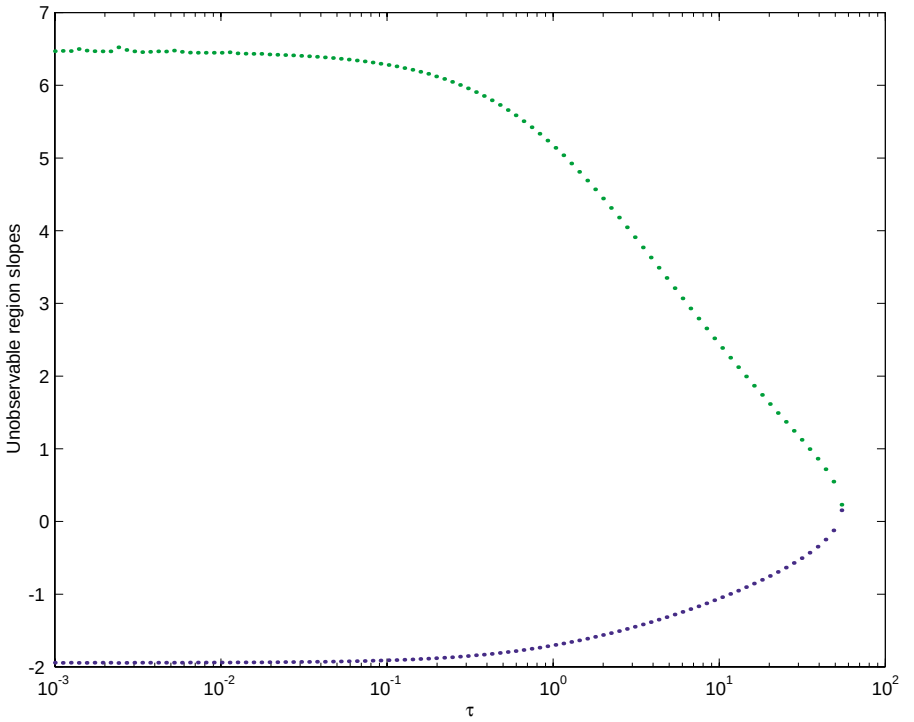

FIG. 5.4. *Bounding slopes vs* τ.

6. Conclusions. In this paper, we have introduced a new notion of robust observability for a class of uncertain systems. We also presented some results which show how this condition can be tested. A feature of this notion of robust observability is that it applies to uncertain systems with structured uncertainty. Furthermore, it also leads naturally to a notion of the unobservable cone for an uncertain system. The paper shows that the notion of robust observability introduced here is equivalent to an earlier notion of robust observability which was only applicable to uncertain systems with unstructured uncertainty. Also, the earlier notion of robust observability did not lead to a corresponding unobservable cone.

The paper presents two simple examples which illustrate the notion of robust observability and the calculation of the unobservable cone. These examples also illustrate the relation between the notion of robust observability and corresponding observability ideas for uncertain systems with constant norm bounded uncertainty.

One of the main areas of future research arising from this paper concerns the computation of the unobservable cone. The results presented in this paper allow the unobservable cone to be found by performing a search over the vector of Lagrange multiplier parameters τ. Future research is required to determine if efficient means can be found to perform this search, e.g., linear matrix inequality methods, etc.

A STUDY ON THE OPTIMAL COST FOR THE H_∞ PROBLEM OF DISCRETE LINEAR PERIODICALLY TIME-VARYING SYSTEMS*

SHUNJI TANAKA†, TOMOMICHI HAGIWARA†, AND MITUHIKO ARAKI†

Abstract. In this paper, we propose a new method to obtain the optimal cost (the infimum of the achievable H_∞ norm of a closed-loop system) for discrete linear periodically time-varying (LPTV) systems. This method reduces via the lifting technique the original problem to the H_∞ problems of linear time-invariant (LTI) systems without the causality constraint, and therefore the optimal cost can be easily calculated. It is one of the primary advantages over other existing methods. We also show, by applying our method to LTI systems, that the optimal cost for the H_∞ problem of discrete LTI systems cannot be improved even if we use a class of noncausal controllers. An intriguing implication of this fact is further shown in the context of causal controllers.

Key words. H_∞ problem, discrete linear periodically time-varying system, causality constraint, lifting technique, optimal cost

1. Introduction.

This paper is devoted to the study of the H_∞ problem of discrete linear periodically time-varying (LPTV) systems. Up to now, several methods of solution have been proposed for this problem, which can be categorized, roughly speaking, into the following two approaches:

(1) time-varying approach,
(2) time-invariant (lifting) approach.

In the time-varying approach, the problem of LPTV systems is directly solved in the framework of general discrete linear time-varying (LTV) systems. As for the H_∞ problem of general discrete LTV systems, Feintuch and Francis [4] first derived a complete solution in 1985. It was based on function space analysis, and the solution was not given in such a form that engineers could easily apply it to their practical problems. In fact, the optimal cost, i.e., the infimum of the achievable H_∞ norm of the closed-loop system, was given in terms of an infinite number of operators in the function space. After the research of Feintuch and Francis [4], not much was reported on this topic for a while. Recently, however, new advances have emerged, inspired by the developments in the H_∞ theory of time-invariant systems. Actually, Dragan, Halanay, and Ionescu [3], Katayama and Ichikawa [7], and Scherpen and Verhaegen [18] gave similar expressions of the solution in terms of algebraic Riccati equations (AREs), while their approaches were mutually different. Although numerical algorithms to solve time-varying AREs are still under development, we can, in principle, obtain the solution numerically by applying these results.

In the time-invariant approach, the solution for linear time-invariant (LTI) systems is directly utilized to solve the problem of LPTV systems. Here, the lifting technique [11, 8] plays a key role. This technique associates a class of LPTV systems with an equivalent class of LTI systems. More specifically, the class of m-input,

†Graduate School of Engineering, Kyoto University, Yoshida-Honmachi, Sakyo-ku, Kyoto 606-8501, Japan (tanaka@kuee.kyoto-u.ac.jp, hagiwara@kuee.kyoto-u.ac.jp, araki@kuee.kyoto-u.ac.jp).

p-output, discrete, linear, N-periodic systems can be shown to be equivalent to the class of mN-input, pN-output discrete LTI systems with the transfer matrix $P(\lambda)$ satisfying the condition that $P(0)$ be block lower triangular. Note that $P(0)$ gives the throughput term in the state space expression, and the above condition corresponds to the causality requirement. For this reason, the above condition on $P(0)$ is referred to as the "causality constraint." This lifting technique enables us to translate the solution of time-invariant systems to that of periodic systems and reduces the difficulties in dealing with time-varying systems to one point: "how to secure the causality constraint, i.e., how to make the controller $K(\lambda)$ satisfy the condition that $K(0)$ be block lower triangular." The methods belonging to this "time-invariant (lifting) approach" category can be classified into several subcategories according to the ways of coping with this causality constraint.

Feintuch, Khargonekar, and Tannenbaum [5] solved a sensitivity minimization problem of periodic systems based on the result in [4]. Georgiou and Khargonekar [6] proposed a constructive algorithm. Voulgaris, Dahleh, and Valavani [19] showed another algorithm for both H_∞ and H_2 problems of general multirate systems including LPTV systems. However, these three methods focus on the so-called one-block H_∞ problem, and it is not easy to extend them to the four-block H_∞ problem.

A method to solve the general four-block H_∞ problem was proposed by Chen and Qiu [2, 13]. They treated the problem in the framework of multirate sampled-data systems and introduced the notion of "nest operators." Sågfors, Toivonen, and Lennartson [15, 16] also proposed another method using the game theoretic approach and formulated the solution in terms of AREs.

In this paper, we propose an alternative way to solve the four-block H_∞ problem of discrete LPTV systems, which can be categorized into the time-invariant approach.

Our method is based on the result in [4] and thus bears a certain similarity to the results in [5, 6] in that the optimal cost for the N-periodic H_∞ problem is given in terms of the maximum of "N values." Here, even though the "N values" in the method in [5, 6] are the norms of N infinite dimensional matrices, our method gives such values as the optimal costs for the N time-invariant H_∞ problems without the causality constraint. Hence our method is more advantageous than other methods in that the optimal cost is given by solving the ordinary (in the sense that no causality constraint is imposed on them) LTI H_∞ problems.

Another important advantage of our method is that it enables us to show an interesting property of the discrete LTI H_∞ problem. More specifically, we can show that the optimal cost for the H_∞ problem of discrete LTI systems cannot be improved even if we extend the class of controllers to a certain class of noncausal systems. Although the practical meaning of this property might be unclear since noncausal controllers cannot be implemented, it certainly lays a fundamental theoretical basis for practical problems. In fact, in section 5, we study a discrete H_∞ problem in the context of sampled-data control (with a causal controller) and show, with this property, the performance limitation that arises if the sampler has a periodic delay.

The outline of this paper is as follows. In section 2, we explain some notation and definitions used in this paper, and, in section 3, we formulate the discrete LPTV H_∞ problem and convert it into a four-block model matching problem. Then, in section 4, we state our main result, which gives the optimal cost for this H_∞ problem based on the result in [4]. In section 5, we show the properties that can be obtained by applying our result to LTI systems. Finally, section 6 summarizes the results obtained in this paper.

2. Preliminaries. In this section, we introduce the notation and definitions used in this paper.

2.1. Spaces and norms. The space of complex $n \times 1$ vector valued sequences $x = \{x_k : k \geq 0\}$ is denoted by s^n or simply s. The subspace of s^n of square-summable sequences is denoted by l_2^n or simply l_2.

The norm on l_2, denoted by $\|\cdot\|_{l_2}$, is defined as

$$\|x\|_{l_2} = \left(\sum_{k=0}^{\infty} x_k^* x_k \right)^{1/2}, \tag{1}$$

where * denotes complex conjugate transpose.

The space of bounded linear operators from l_2^n to l_2^m is denoted by $\mathcal{B}^{m\times n}$ or just $\mathcal{B}$. The norm on $\mathcal{B}$, denoted by $\|\cdot\|$, is defined as

$$\|F\| = \sup_{x\in l_2} \frac{\|Fx\|_{l_2}}{\|x\|_{l_2}}. \tag{2}$$

Any operator F in $\mathcal{B}$ can be expressed by the matrix representation

$$\begin{bmatrix} F_{00} & F_{01} & F_{02} & \cdots \\ F_{10} & F_{11} & F_{12} & \cdots \\ F_{20} & F_{21} & F_{22} & \cdots \\ \vdots & \vdots & \vdots & \end{bmatrix}. \tag{3}$$

The subspace of $\mathcal{B}^{m\times n}$ of causal operators is denoted by $\mathcal{C}^{m\times n}$, or simply $\mathcal{C}$, and the matrix representation of such an operator has a block lower triangular form. The subspace of $\mathcal{B}^{m\times n}$ of time-invariant operators is denoted by $\mathcal{T}^{m\times n}$, or just $\mathcal{T}$, and the matrix representation of such an operator has a block Toeplitz form.

The space of essentially bounded, matrix valued functions defined on the unit circle is denoted by L_∞. The norm on L_∞, denoted by $\|\cdot\|_\infty$, is defined as

$$\|f\|_\infty = \operatorname*{ess\,sup}_{\theta\in[0,2\pi]} \overline{\sigma}(f(e^{j\theta})), \tag{4}$$

where $\overline{\sigma}(\cdot)$ denotes the maximum singular value. The subspace of L_∞, whose element has analytic continuation into the open unit disc, is denoted by H_∞.

Let F be a time-invariant operator in $\mathcal{T}$. From its matrix representation

$$\begin{bmatrix} F_0 & F_{-1} & F_{-2} & \cdots \\ F_1 & F_0 & F_{-1} & \cdots \\ F_2 & F_1 & F_0 & \cdots \\ \vdots & \vdots & \vdots & \end{bmatrix}, \tag{5}$$

define the transfer function $\widehat{F}(\lambda)$ of F by

$$\widehat{F}(\lambda) = \sum_{k=-\infty}^{\infty} F_k \lambda^k. \tag{6}$$

Then $\widehat{F}(e^{j\theta}) \in L_\infty$, and $\|F\| = \|\widehat{F}\|_\infty$. If $F \in \mathcal{C} \cap \mathcal{T}$,

$$\widehat{F}(\lambda) = \sum_{k=0}^{\infty} F_k \lambda^k, \tag{7}$$

and $\widehat{F}(e^{j\theta}) \in H_\infty$.

2.2. Shift operator and truncation operator. The kth shift operator Λ_k is defined by

$$\begin{aligned}\Lambda_k :\ & \{x_0, x_1, \ldots\} \\ & \to \begin{cases} \{\underbrace{0, \ldots, 0}_{k \text{ times}}, x_0, x_1, \ldots\} & \text{if} \quad k \geq 0, \\ \{x_{-k}, x_{-k+1}, \ldots\} & \text{if} \quad k < 0. \end{cases}\end{aligned} \tag{8}$$

For any F from s to s, the kth input/output-shift operator $S_k(F)$ $(k = 0, 1, \ldots)$ is defined by

$$S_k(F) = \Lambda_{-k} F \Lambda_k. \tag{9}$$

The kth truncation operator Π_k $(k = -1, 0, \ldots)$ is defined by

$$\begin{aligned}\Pi_k :\ & \{x_0, x_1, \ldots\} \\ & \to \begin{cases} \{0, 0, \ldots\} & \text{if} \quad k = -1, \\ \{x_0, x_1, \ldots, x_k, 0, \ldots\} & \text{if} \quad k \geq 0. \end{cases}\end{aligned} \tag{10}$$

2.3. Periodic operator and lifting operator. Periodic operators are defined as follows via the input/output-shift operator.

DEFINITION 2.1. *The operator F is called N-periodic if*

$$F = S_N(F) = \Lambda_{-N} F \Lambda_N. \tag{11}$$

The subspace consisting of N-periodic operators in $\mathcal{B}^{m\times n}$ is denoted by $\mathcal{P}_N^{m\times n}$ or just $\mathcal{P}_N$.

Let Ξ_N be the isomorphism defined by

$$\begin{aligned}\Xi_N :\ & \{x_0, x_1, \ldots\} \in s^n \\ & \to \left\{ \begin{bmatrix} x_0 \\ x_1 \\ \vdots \\ x_{N-1} \end{bmatrix}, \begin{bmatrix} x_N \\ x_{N+1} \\ \vdots \\ x_{2N-1} \end{bmatrix}, \ldots \right\} \in s^{nN},\end{aligned} \tag{12}$$

and let $L_N(\cdot)$ be the lifting operator defined by

$$L_N(F) = \Xi_N F \Xi_N^{-1}, \quad F : s^n \to s^m. \tag{13}$$

Then, for any F in $\mathcal{C}^{m\times n} \cap \mathcal{P}_N^{m\times n}$, $L_N(F)$ belongs to $\mathcal{C}^{mN\times nN} \cap \mathcal{T}^{mN\times nN}$, and

$$\|L_N(F)\| = \|F\|. \tag{14}$$

However, the converse is not true in that for an operator F^L in $\mathcal{C}^{mN\times nN} \cap \mathcal{T}^{mN\times nN}$, it might not be expressed as $F^L = L_N(F)$ for any $F \in \mathcal{C}^{m\times n} \cap \mathcal{P}_N^{m\times n}$ because of the *causality constraint*. Namely, for $L_N^{-1}(F^L)$ to belong to $\mathcal{C}^{m\times n} \cap \mathcal{P}_N^{m\times n}$, the transfer function $\widehat{F}^L$ of F^L should have such a structure that the throughput term $\widehat{F}^L(0)$ is block lower triangular. Hence, for convenience hereafter, we define the subspace $\mathcal{W}_N$ of $\mathcal{C}^{mN\times nN} \cap \mathcal{T}^{mN\times nN}$ by

$$\mathcal{W}_N = \{F^L : L_N^{-1}(F^L) \in \mathcal{C}^{m\times n} \cap \mathcal{P}_N^{m\times n}\}. \tag{15}$$

Then any function in $\mathcal{W}_N$ can be associated with a function in $\mathcal{C}^{m\times n} \cap \mathcal{P}_N^{m\times n}$ via $L_N(\cdot)$ and $L_N^{-1}(\cdot)$. We also define the subspace $\hat{\mathcal{W}}_N$ of H_∞, the space of transfer functions $\widehat{F}^L$ whose throughput term $\widehat{F}^L(0)$ is block lower triangular. $\hat{\mathcal{W}}_N$ in H_∞ corresponds to $\mathcal{W}_N$ in $\mathcal{T}$.

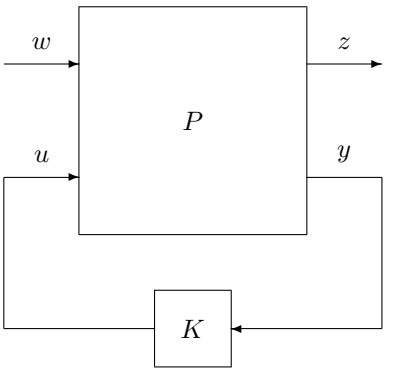

FIG. 1. *The block diagram of the discrete-time system.*

3. The discrete LPTV H_∞ problem. In this section, we formulate the discrete LPTV H_∞ problem and convert it into a model matching problem.

Consider the discrete system shown in Figure 1. In Figure 1, w is the exogenous input, u is the control input, z is the controlled output, and y is the measurement output. P denotes a discrete, linear, N-periodic, causal, finite-dimensional generalized plant that can be partitioned according to w, u, z, y into

$$P = \begin{bmatrix} P_{11} & P_{12} \\ P_{21} & P_{22} \end{bmatrix}. \tag{16}$$

K denotes a discrete linear causal controller.

Let us denote by $\mathcal{F}_l(P, K)$ the linear fractional transformation (LFT) of K on P; namely,

$$\mathcal{F}_l(P, K) = P_{11} + P_{12}K(I - P_{22}K)^{-1}P_{21}. \tag{17}$$

The discrete LPTV H_∞ problem of P is to find K such that

- the closed-loop system is internally stable,
- the norm of $\mathcal{F}_l(P, K)$ (the operator from w to z) is minimized.

In other words, this H_∞ problem is the following optimization problem:

$$\nu = \inf_{K:\text{causal}} \|\mathcal{F}_l(P, K)\|. \tag{18}$$

Let us assume that P_{22} admits a doubly coprime factorization and that the following assumption holds.

ASSUMPTION 3.1. *$\widehat{S}^L(\lambda)$ and $\widehat{T}^{L\sim}(\lambda) = \widehat{T}^{L^T}(\lambda^{-1})$ are injective for every λ on the unit circle.*

Then (18) can be transformed into a model matching problem of the form (see Appendix A)

$$\nu = \inf_{Q \in \mathcal{C} \cap \mathcal{P}_N} \left\| \begin{bmatrix} X - Q & Y \\ Z & U \end{bmatrix} \right\|, \tag{19}$$

where X, Y, Z, and U belong to $\mathcal{P}_N$.

In the next section, we will present our result, which gives the solution to this problem.

4. Main result: A new method to obtain the optimal cost for the discrete LPTV H_∞ problem. In this section, we give a new type of method to obtain the optimal cost for the discrete LPTV H_∞ problem: a method to calculate ν in (19). In the following, we will show three versions of our result, which gives the optimal cost ν in terms of the optimal costs for ordinary LTI H_∞ problems.

Our main result is summarized in the following theorem.

THEOREM 4.1. *For $k = 0, 1, \ldots, N-1$ let us define*

$$X_k^L = L_N(S_k(X)), \quad Y_k^L = L_N(S_k(Y)), \tag{20}$$

$$Z_k^L = L_N(S_k(Z)), \quad U_k^L = L_N(S_k(U)), \tag{21}$$

and

$$\nu_k = \inf_{Q_k^L \in \mathcal{C}\cap\mathcal{T}} \left\| \begin{bmatrix} X_k^L - Q_k^L & Y_k^L \\ Z_k^L & U_k^L \end{bmatrix} \right\|. \tag{22}$$

Then

$$\nu = \max(\nu_0,\ \nu_1, \ldots,\ \nu_{N-1}). \tag{23}$$

The proof of this theorem is given in Appendix B.

The importance of Theorem 4.1 lies in showing the fact that ν can be obtained by solving N model matching problems. It should also be noted that the infimum in (22) is not taken over $\mathcal{W}_N$ but over the larger class $\mathcal{C} \cap \mathcal{T}$. Hence it is easy to check that the model matching problem (22) is equivalent to the discrete LTI H_∞ problem

$$\nu_k = \inf_{K_k^L:\text{causal}} \|\mathcal{F}_l(P_k^L, K_k^L)\|, \tag{24}$$

where P_k^L is defined by

$$\begin{aligned} P_k^L &= \begin{bmatrix} P_{k11}^L & P_{k12}^L \\ P_{k21}^L & P_{k22}^L \end{bmatrix} \\ &= \begin{bmatrix} L_N(S_k(P_{11})) & L_N(S_k(P_{12})) \\ L_N(S_k(P_{21})) & L_N(S_k(P_{22})) \end{bmatrix}. \end{aligned} \tag{25}$$

Thus we are led to the following corollary, in which the advantage of our main result is exploited more explicitly.

COROLLARY 4.1. *The optimal cost ν is given by*

$$\nu = \max(\nu_0,\ \nu_1, \ldots,\ \nu_{N-1}), \tag{26}$$

where ν_k $(k = 0, 1, \ldots, N-1)$ is

$$\nu_k = \inf_{K_k^L:\text{causal}} \|\mathcal{F}_l(P_k^L, K_k^L)\|. \tag{27}$$

Although Corollary 4.1 holds even for the general four-block H_∞ problem, it is difficult to calculate the optimal cost for such problems analytically. For this reason, in many practical situations, we consider the suboptimal H_∞ problem to find controllers that make $\mathcal{F}_l(P, K) < \gamma$ for a given γ. Thus we will rewrite Corollary 4.1 to meet such situations.

COROLLARY 4.2. *There exists a stabilizing controller K such that*

$$\|\mathcal{F}_l(P,K)\| < \gamma, \quad K : \text{causal}, \tag{28}$$

if and only if there exists K_k^L $(k = 0, 1, \ldots, N-1)$ such that

$$\|\mathcal{F}_l(P_k^L, K_k^L)\| < \gamma, \quad K_k^L : \text{causal}. \tag{29}$$

REMARK 4.1. *Note that this corollary holds* without *Assumption* 3.1. *This is because Assumption* 3.1 *corresponds to the conditions of invariant zeros on the unit circle in the standard H_∞ problem, and therefore it can be avoided in the case of a suboptimal problem as* (28) *by using a similar method to those used in* [17, 10, 12].

Since the H_∞ problem (27) or (29) is of the LTI system P_k^L and no causality constraint is imposed on it, it can be solved by existing algorithms for the LTI H_∞ problem. Therefore, the optimal cost ν (or its upper bound γ) for the original problem can be easily calculated. As mentioned in the introduction, this point is the primary advantage of our result and the difference from the results in [5] and [6], though our method gives only the optimal cost for the LPTV H_∞ problem and therefore does not give any explicit knowledge of the structure of optimal controllers.

The following example is meant to illustrate the usefulness of our main result.

Example. Consider the 2-periodic system P whose state space realization is given by

$$P = \left[\begin{array}{c|cc} A(\cdot) & B_1(\cdot) & B_2(\cdot) \\ \hline C_1(\cdot) & D_{11}(\cdot) & D_{12}(\cdot) \\ C_2(\cdot) & D_{21}(\cdot) & 0 \end{array}\right], \tag{30}$$

where

$$\begin{aligned} &\left[\begin{array}{c|cc} A(2l+m) & B_1(2l+m) & B_2(2l+m) \\ \hline C_1(2l+m) & D_{11}(2l+m) & D_{12}(2l+m) \\ C_2(2l+m) & D_{21}(2l+m) & 0 \end{array}\right] \\ &\quad = \left[\begin{array}{c|cc} 2(m+1) & 1 & 1 \\ \hline 1 & 1 & m+1 \\ -m-1 & m+2 & 0 \end{array}\right] \quad \forall\ l,\ m = 0, 1. \end{aligned} \tag{31}$$

In view of (25), let us define

$$P_k = \left[\begin{array}{cc} S_k(P_{11}) & S_k(P_{12}) \\ S_k(P_{21}) & S_k(P_{22}) \end{array}\right], \quad k = 0, 1. \tag{32}$$

Then we have $P_0 = P$, and P_1 is given by

$$P_1 = \left[\begin{array}{c|cc} A'(\cdot) & B_1'(\cdot) & B_2'(\cdot) \\ \hline C_1'(\cdot) & D_{11}'(\cdot) & D_{12}'(\cdot) \\ C_2'(\cdot) & D_{21}'(\cdot) & 0 \end{array}\right], \tag{33}$$

where

$$\begin{aligned} &\left[\begin{array}{c|cc} A'(2l+m) & B_1'(2l+m) & B_2'(2l+m) \\ \hline C_1'(2l+m) & D_{11}'(2l+m) & D_{12}'(2l+m) \\ C_2'(2l+m) & D_{21}'(2l+m) & 0 \end{array}\right] \\ &\quad = \left[\begin{array}{c|cc} A(2l+m+1) & B_1(2l+m+1) & B_2(2l+m+1) \\ \hline C_1(2l+m+1) & D_{11}(2l+m+1) & D_{12}(2l+m+1) \\ C_2(2l+m+1) & D_{21}(2l+m+1) & 0 \end{array}\right]. \end{aligned} \tag{34}$$

Compare this with $P_0 = P$ given in (31) to see the role of the input/output-shift operator.

Now, computing the transformations given in (25) (namely, applying the lifting technique), we obtain the state space realizations of P_0^L and P_1^L as

$$P_0^L = \left[\begin{array}{c|cc:cc} 8 & 4 & 1 & 4 & 1 \\ \hline 1 & 1 & 0 & 1 & 0 \\ 2 & 1 & 1 & 1 & 2 \\ \hdashline -1 & 2 & 0 & 0 & 0 \\ -4 & -2 & 3 & -2 & 0 \end{array}\right], \quad P_1^L = \left[\begin{array}{c|cc:cc} 8 & 2 & 1 & 2 & 1 \\ \hline 1 & 1 & 0 & 2 & 0 \\ 4 & 1 & 1 & 1 & 1 \\ \hdashline -2 & 3 & 0 & 0 & 0 \\ -4 & -1 & 2 & -1 & 0 \end{array}\right]. \tag{35}$$

Since the optimal costs for the H_∞ problems of P_0^L and P_1^L, which are easily calculated, are 6.83 and 14.68, respectively, $\gamma_{\min}$ for the H_∞ problem of P is 14.68.

5. Application to LTI systems: The performance limitation with noncausal controllers. In the preceding section, we showed Theorem 4.1 (or, its explicit forms Corollaries 4.1 and 4.2), which gives the optimal cost for the discrete LPTV H_∞ problem in terms of the optimal costs for discrete LTI H_∞ problems. Although these results are primarily for the discrete LPTV H_∞ problem, they can be used to show a property in regard to the optimal cost for the discrete H_∞ problem of LTI systems when we use noncausal controllers. In this section, we show such a property and give an example of how we can apply it to practical situations.

If P is an LTI system, we can take any positive integer N and regard P as N-periodic. Then P_k^L defined by (25) satisfies

$$P_0^L = P_1^L = \cdots = P_{N-1}^L = P^L, \tag{36}$$

where P^L is

$$P^L = \begin{bmatrix} L_N(P_{11}) & L_N(P_{12}) \\ L_N(P_{21}) & L_N(P_{22}) \end{bmatrix}. \tag{37}$$

Hence, by applying Corollary 4.1 to P, we obtain

$$\nu = \inf_{K:\text{causal}} \|\mathcal{F}_l(P,K)\| = \inf_{K^L:\text{causal}} \|\mathcal{F}_l(P^L,K^L)\|. \tag{38}$$

The claim of (38) is summarized as follows.

COROLLARY 5.1. *The optimal cost for the LTI H_∞ problem of P and that for the LTI H_∞ problem of P^L, the lifted system of P, are identical. In other words, the optimal cost cannot be improved even if we use any* possibly noncausal *N-periodic controller K* such that the lifted system K^L of K is causal.

It is shown in [4, 9, 20] that we cannot improve the optimal cost even if we consider causal time-varying controllers in the case of the LTI H_∞ problem. Thus it is a matter of course that *causal* N-periodic controllers do not improve the optimal cost. However, Corollary 5.1 claims more than that: even if we use such controllers that belong to the class of *noncausal* N-periodic systems *whose lifted systems are causal*, the optimal cost cannot be improved. In spite of the facts that N can be taken arbitrarily large and that the above class gets larger as N gets larger (by an integer multiple), this does not lead to the conclusion that no noncausal controller improves the optimal cost, however. Indeed, in most cases, the optimal cost improves with such noncausal controllers that can use information of one step in the future, but such controllers never belong to the above class since every controller in that class is

incapable of using future information at $t = Nk - 1$. Although there is no qualitative explanation about the difference between these two types of noncausal controllers yet, we can show an interesting property on the H_∞ problem of a certain system by using Corollary 5.1.

Consider a discrete LTI system P, and let us consider the following two situations:

(a) The measurement output is periodically delayed by one step. That is, for some N and for some fixed q $(0 \le q \le N-1)$, the measurement output y at $t = Np + q$ $(p = 0, 1, \ldots)$ is not available by the controller until the next step $t = Np + q + 1$ because of, for example, a periodic delay in the circuit of the sampler. More specifically, we consider a sampler whose input sequence is the sequence of the (ideal) measurement output $y_0, y_1, \ldots$, and whose output sequence is

$$y_0, \ldots, y_{q-1}, \phi, \begin{bmatrix} y_q \\ y_{q+1} \end{bmatrix}, y_{q+2}, \ldots, y_{N+q-1}, \phi, \begin{bmatrix} y_{N+q} \\ y_{N+q+1} \end{bmatrix}, \ldots, \tag{39}$$

where ϕ denotes the empty set.

(b) The measurement output is always delayed by one step. In other words, we consider a sampler whose input sequence is the sequence of the (ideal) measurement output $y_0, y_1, \ldots$, and whose output sequence is

$$\phi, y_0, y_1, \ldots. \tag{40}$$

In these two situations, we are to solve the H_∞ problems and compare the optimal costs.

Intuitively, the optimal cost ν_a in (a) seems smaller than the optimal cost ν_b in (b) because, at any time instant, more information is available by controllers in (a) than in (b). However, in reality, the optimal costs in both situations are identical. It can be shown by applying Corollary 5.1, as we do in the following.

First, we consider the situation (b). Since P, together with the sampler (40), is modeled as

$$P' = \begin{bmatrix} P'_{11} & P'_{12} \\ P'_{21} & P'_{22} \end{bmatrix} = \begin{bmatrix} P_{11} & P_{12} \\ \Lambda_1 P_{21} & \Lambda_1 P_{22} \end{bmatrix}, \tag{41}$$

our problem here can be converted into the LTI H_∞ problem to find $K' = K\Lambda_1^{-1}$ for P'. Therefore, in the lifted space, we are to consider the problem to find $K'^L = L_N(K') = L_N(K\Lambda_1^{-1})$ for $P'^L = L_N(P')$ such that $\widehat{K}'^L(0)$ satisfies the causality constraint; i.e., $\widehat{K}'^L(0)$ has the block lower triangular form

$$\widehat{K}'^L(0) = \begin{bmatrix} k'_{00} & 0 & & & \\ k'_{10} & k'_{11} & & \mathbf{0} & \\ \vdots & \vdots & \ddots & \ddots & \\ k'_{N-2,0} & k'_{N-2,1} & \cdots & k'_{N-2,N-2} & 0 \\ k'_{N-1,0} & k'_{N-1,1} & \cdots & k'_{N-1,N-2} & k'_{N-1,N-1} \end{bmatrix}. \tag{42}$$

Namely, we have

$$\nu_b = \inf_{K':\text{causal}} \|\mathcal{F}_l(P', K')\| = \inf_{\substack{K'^L:\text{causal and} \\ \text{satisfying (42)}}} \|\mathcal{F}_l(P'^L, K'^L)\|. \tag{43}$$

From Corollary 5.1,

$$\nu_b = \inf_{K':\text{causal}} \|\mathcal{F}_l(P', K')\| = \inf_{K'^L:\text{causal}} \|\mathcal{F}_l(P'^L, K'^L)\|, \tag{44}$$

and hence by (43) we have

$$\inf_{\substack{K'^L:\text{causal and}\\ \text{satisfying (42)}}} \|\mathcal{F}_l(P'^L, K'^L)\| = \inf_{K'^L:\text{causal}} \|\mathcal{F}_l(P'^L, K'^L)\|. \tag{45}$$

Next we consider the situation (a). If, as in (b), we treat P together with the sampler (39) as a plant, it becomes an N-periodic system. Therefore, we can assume without loss of generality that $q = N - 1$ from Lemma B.2, and, as mentioned in the preceding section, we can restrict the class of the controllers to that of N-periodic systems. On the other hand, if we treat the delay of the measurement output as a constraint on the controller, we are to consider K such that the elements K_{ij} $(i, j = 0, 1, 2, \ldots)$ of its matrix representation satisfy

$$K_{ij} = 0, \quad i < j \text{ or } i = j = Np + q. \tag{46}$$

As a consequence, the problem that we should consider here is to find $K^L = L_N(K)$ for $P^L = L_N(P)$ such that the throughput term $\widehat{K}^L(0)$ of the transfer function of K^L has the form

$$\widehat{K}^L(0) = \begin{bmatrix} k_{00} & 0 & & \multicolumn{2}{c}{\multirow{2}{*}{0}} \\ k_{10} & k_{11} & & \\ \vdots & \vdots & \ddots & & \\ k_{N-2,0} & k_{N-2,1} & \cdots & k_{N-2,N-2} & 0 \\ k_{N-1,0} & k_{N-1,1} & \cdots & k_{N-1,N-2} & 0 \end{bmatrix}. \tag{47}$$

By using P' given by (41) and $P'^L = L_N(P')$, this problem can be further converted into the problem to find $K'^L = L_N(K\Lambda_1^{-1})$ for P'^L such that the throughput term $\widehat{K}'^L(0)$ of the transfer function of K'^L has the form

$$\widehat{K}'^L(0) = \begin{bmatrix} k'_{00} & k'_{01} & & \multicolumn{2}{c}{\multirow{2}{*}{0}} \\ k'_{10} & k'_{11} & k'_{12} & & \\ \vdots & \vdots & & \ddots & \\ k'_{N-2,0} & k'_{N-2,1} & \cdots & k'_{N-2,N-2} \\ k'_{N-1,0} & k'_{N-1,1} & \cdots & k'_{N-1,N-1} \end{bmatrix}. \tag{48}$$

Namely,

$$\nu_a = \inf_{\substack{K'^L:\text{causal and}\\ \text{satisfying (48)}}} \|\mathcal{F}_l(P'^L, K'^L)\|. \tag{49}$$

Since, as a matter of course,

$$\begin{aligned} &\{K'^L|\ \text{causal and satisfying (42)}\} \\ &\quad \subset \{K'^L|\ \text{causal and satisfying (48)}\} \\ &\quad \subset \{K'^L|\ \text{causal}\}, \end{aligned} \tag{50}$$

it follows from (45) and (49) that $\nu_a = \nu_b$. This implies that the optimal costs in both situations (a) and (b) are identical.

This example shows that when we consider the H_∞ problem of LTI systems, there is no advantage in trying to use the available current output if there exists even a *single* sequence of the measurement output $y_p,\ y_{N+p}, \ldots$ that is delayed by one step. What is worse, trying to do so rather becomes a disadvantage compared with the case that *all* the measurement output is delayed by one step, since in such a case we can restrict the class of controllers to that of LTI controllers and do not need to take time-varying controllers into account.

6. Conclusion. In this paper, we proposed a new method to obtain the optimal cost for the discrete LPTV H_∞ problem. Our method reduces the original LPTV H_∞ problem to the ordinary LTI H_∞ problems in the sense that no causality constraint is imposed. This point is the primary advantage of our method over other existing methods of solving the same problem. Another advantage is that by applying our method to LTI systems, not to LPTV systems, it can be shown that we cannot improve the H_∞ performance of LTI systems even if we use a class of noncausal controllers. We demonstrated by an example that we can apply this result in order to discuss the performance limitation of practical problems.

Appendix A. Derivation of (19). In [14], it is shown that a doubly coprime factorization of an N-periodic operator F can be obtained by a doubly coprime factorization of the LTI system $L_N(F)$ and that each factor which appears in the doubly coprime factorization of $L_N(F)$ satisfies the causality constraint. By applying this result to P_{22} in our problem, we obtain

$$P_{22} = N_r D_r^{-1} = D_l^{-1} N_l, \tag{A1}$$

$$\begin{bmatrix} X_l & -Y_l \\ -N_l & D_l \end{bmatrix} \begin{bmatrix} D_r & Y_r \\ N_r & X_r \end{bmatrix} = I, \tag{A2}$$

where N_r, D_r, X_r, Y_r, N_l, D_l, X_l, and Y_l all belong to $\mathcal{C} \cap \mathcal{P}_N$. From (A2), all controllers that internally stabilize the closed-loop system are parametrized by

$$\begin{aligned} K &= (Y_r - D_r Q)(X_r - N_r Q)^{-1} \\ &= (X_l - Q N_l)^{-1}(Y_l - Q D_l), \end{aligned} \tag{A3}$$

where $Q \in \mathcal{C}$. Substituting (A3) into (17), we obtain

$$\mathcal{F}_l(P, K) = R - SQT, \tag{A4}$$

where

$$R = P_{11} + P_{12} D_r Y_l P_{21} \in \mathcal{C} \cap \mathcal{P}_N, \tag{A5}$$

$$S = P_{12} D_r \in \mathcal{C} \cap \mathcal{P}_N, \tag{A6}$$

$$T = D_l P_{21} \in \mathcal{C} \cap \mathcal{P}_N. \tag{A7}$$

Therefore, our problem is equivalent to [4, 19]

$$\nu = \inf_{Q \in \mathcal{C}} \|R - SQT\|, \quad R, S, T \in \mathcal{C} \cap \mathcal{P}_N, \tag{A8}$$

where $Q \in \mathcal{C}$ is a free parameter in the parametrization of stabilizing controllers. Furthermore, in [1, 19] it is shown that if R, S, and T are N-periodic, the infimum in the right-hand side of (A8) remains the same if Q is restricted to $\mathcal{C} \cap \mathcal{P}_N$. Namely,

$$\begin{aligned} \nu &= \inf_{Q \in \mathcal{C}} \|R - SQT\| \\ &= \inf_{Q \in \mathcal{C} \cap \mathcal{P}_N} \|R - SQT\|. \end{aligned} \tag{A9}$$

Thus, by applying the lifting technique to (A9), we obtain

$$\nu = \inf_{Q^L \in \mathcal{W}_N} \|R^L - S^L Q^L T^L\|, \tag{A10}$$

$$R^L = L_N(R) \in \mathcal{W}_N,\ S^L = L_N(S) \in \mathcal{W}_N,\ T^L = L_N(T) \in \mathcal{W}_N \tag{A11}$$

or, equivalently,

$$\nu = \inf_{\widehat{Q}^L(\lambda) \in \hat{\mathcal{W}}_N} \|\widehat{R}^L(\lambda) - \widehat{S}^L(\lambda)\widehat{Q}^L(\lambda)\widehat{T}^L(\lambda)\|_\infty, \tag{A12}$$

$$\widehat{R}^L(\lambda),\ \widehat{S}^L(\lambda),\ \widehat{T}^L(\lambda) \in \hat{\mathcal{W}}_N, \tag{A13}$$

where $\widehat{R}^L(\lambda)$, $\widehat{S}^L(\lambda)$, and $\widehat{T}^L(\lambda)$ denote the transfer functions of R^L, S^L, and T^L, respectively.

Under Assumption 3.1, there exist inner-outer factorizations of $\widehat{S}^L(\lambda)$ and $\widehat{T}^L(\lambda)$ in (A12). Therefore, $\widehat{S}^L(\lambda)$ and $\widehat{T}^L(\lambda)$ can be factorized as follows:

$$\widehat{S}^L(\lambda) = \widehat{S}_i^L(\lambda)\widehat{S}_o^L(\lambda), \tag{A14}$$

$$\widehat{T}^L(\lambda) = \widehat{T}_o^L(\lambda)\widehat{T}_i^L(\lambda), \tag{A15}$$

$$\widehat{S}_i^L(\lambda) \in H_\infty, \quad \widehat{S}_i^{L\sim}(\lambda)\widehat{S}_i^L(\lambda) = I, \tag{A16}$$

$$\widehat{T}_i^L(\lambda) \in H_\infty, \quad \widehat{T}_i^L(\lambda)\widehat{T}_i^{L\sim}(\lambda) = I, \tag{A17}$$

$$\widehat{S}_o^L(\lambda),\ \widehat{S}_o^{L^{-1}}(\lambda),\ \widehat{T}_o^L(\lambda),\ \widehat{T}_o^{L^{-1}}(\lambda) \in H_\infty. \tag{A18}$$

In [2], it is shown that $\widehat{S}_o^L(\lambda)$, $\widehat{T}_o^L(\lambda)$ can always be chosen so as to belong to $\hat{\mathcal{W}}_N$. In this case, the mapping from $\widehat{Q}^L(\lambda)$ to $\widehat{S}_o^L(\lambda)\widehat{Q}^L(\lambda)\widehat{T}_o^L(\lambda)$ is surjective on $\hat{\mathcal{W}}_N$. Therefore, (A12) becomes

$$\nu = \inf_{\widehat{Q}^L(\lambda) \in \hat{\mathcal{W}}_N} \|\widehat{R}^L(\lambda) - \widehat{S}_i^L(\lambda)\widehat{Q}^L(\lambda)\widehat{T}_i^L(\lambda)\|_\infty. \tag{A19}$$

By multiplying

$$\begin{bmatrix} \widehat{S}_i^{L\sim}(\lambda) \\ I - \widehat{S}_i^L(\lambda)\widehat{S}_i^{L\sim}(\lambda) \end{bmatrix} \tag{A20}$$

from the left and

$$\left[\widehat{T}_i^{L\sim}(\lambda) \quad I - \widehat{T}_i^{L\sim}(\lambda)\widehat{T}_i^{L}(\lambda)\right] \tag{A21}$$

from the right of (A19), we obtain

$$\|\widehat{R}^L(\lambda) - \widehat{S}_i^L(\lambda)\widehat{Q}^L(\lambda)\widehat{T}_i^L(\lambda)\|_\infty = \left\| \begin{bmatrix} \widehat{X}^L(\lambda) - \widehat{Q}^L(\lambda) & \widehat{Y}^L(\lambda) \\ \widehat{Z}^L(\lambda) & \widehat{U}^L(\lambda) \end{bmatrix} \right\|_\infty, \tag{A22}$$

where $\widehat{X}^L(\lambda)$, $\widehat{Y}^L(\lambda)$, $\widehat{Z}^L(\lambda)$, and $\widehat{U}^L(\lambda)$ are defined by

$$\begin{aligned} &\begin{bmatrix} \widehat{X}^L(\lambda) & \widehat{Y}^L(\lambda) \\ \widehat{Z}^L(\lambda) & \widehat{U}^L(\lambda) \end{bmatrix} \\ &\quad = \begin{bmatrix} \widehat{S}_i^{L\sim}(\lambda) \\ I - \widehat{S}_i^L\widehat{S}_i^{L\sim}(\lambda) \end{bmatrix} R^L(\lambda) \ \left[\widehat{T}_i^{L\sim}(\lambda) \quad I - \widehat{T}_i^{L\sim}(\lambda)\widehat{T}_i^L(\lambda)\right]. \end{aligned} \tag{A23}$$

Thus our problem (A12) can be rewritten as

$$\nu = \inf_{\widehat{Q}^L(\lambda)\in\widehat{\mathcal{W}}_N} \left\| \begin{bmatrix} \widehat{X}^L(\lambda) - \widehat{Q}^L(\lambda) & \widehat{Y}^L(\lambda) \\ \widehat{Z}^L(\lambda) & \widehat{U}^L(\lambda) \end{bmatrix} \right\|_\infty \tag{A24}$$

or

$$\nu = \inf_{Q^L\in\mathcal{W}_N} \left\| \begin{bmatrix} X^L - Q^L & Y^L \\ Z^L & U^L \end{bmatrix} \right\|. \tag{A25}$$

Let

$$\begin{aligned} X = L_N^{-1}(X^L), \quad Y = L_N^{-1}(Y^L), \\ Z = L_N^{-1}(Z^L), \quad U = L_N^{-1}(U^L). \end{aligned} \tag{A26}$$

Then $X, Y, Z, U \in \mathcal{P}_N$, and (19) is obtained.

Appendix B. Proof of Theorem 4.1. To prove Theorem 4.1, we use the following lemmas.

LEMMA B.1 (see [4]). *Suppose that X, Y, Z, and U belong to $\mathcal{B}$ and that μ is given by*

$$\mu = \inf_{Q\in\mathcal{C}} \left\| \begin{bmatrix} X - Q & Y \\ Z & U \end{bmatrix} \right\|. \tag{B1}$$

Then

$$\mu = \sup_{k\geq -1} \|\Gamma_k\|, \tag{B2}$$

where

$$\Gamma_k = \begin{bmatrix} \Pi_k & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} X & Y \\ Z & U \end{bmatrix} \begin{bmatrix} I - \Pi_k & 0 \\ 0 & I \end{bmatrix}. \tag{B3}$$

REMARK B.1. *The reader may think that this lemma cannot be applied directly to* (19)*, because Q in* (19) *is taken over $\mathcal{C}\cap\mathcal{P}_N$, while Q in* (B1) *is taken over $\mathcal{C}$.*

However, as mentioned before, the right-hand side of (B1) *remains the same even if* Q *is restricted to* $\mathcal{C}\cap\mathcal{P}_N$ *provided that* X, Y, Z, *and* U *belong to* $\mathcal{P}_N$. *Therefore, the above lemma implies that* ν *in* (19) *is given by the right-hand side of* (B2):

$$\nu = \sup_{k\geq -1} \|\Gamma_k\|. \tag{B4}$$

LEMMA B.2. *Assume that* X, Y, Z, *and* U *belong to* $\mathcal{P}_N$. *Then, for any* $i, j = 0, 1, \ldots, N-1$,

$$\inf_{Q\in\mathcal{C}\cap\mathcal{P}_N} \left\| \begin{bmatrix} S_i(X)-Q & S_i(Y) \\ S_i(Z) & S_i(U) \end{bmatrix} \right\| = \inf_{Q\in\mathcal{C}\cap\mathcal{P}_N} \left\| \begin{bmatrix} S_j(X)-Q & S_j(Y) \\ S_j(Z) & S_j(U) \end{bmatrix} \right\|. \tag{B5}$$

Proof of Lemma B.2. Without loss of generality, we assume that $i > j$. Since the mapping $S_k(\cdot)$ is bijective on $\mathcal{C}\cap\mathcal{P}_N$,

$$\begin{aligned} &\inf_{Q\in\mathcal{C}\cap\mathcal{P}_N} \left\| \begin{bmatrix} S_k(X)-Q & S_k(Y) \\ S_k(Z) & S_k(U) \end{bmatrix} \right\| \\ &\quad = \inf_{Q\in\mathcal{C}\cap\mathcal{P}_N} \left\| \begin{bmatrix} S_k(X)-S_k(Q) & S_k(Y) \\ S_k(Z) & S_k(U) \end{bmatrix} \right\| \\ &\quad = \inf_{Q\in\mathcal{C}\cap\mathcal{P}_N} \left\| \begin{bmatrix} S_k(X-Q) & S_k(Y) \\ S_k(Z) & S_k(U) \end{bmatrix} \right\|. \end{aligned} \tag{B6}$$

Therefore, it suffices to show that

$$\|S_i(F)\| = \|S_j(F)\| \quad \forall\ F\in\mathcal{P}_N, \tag{B7}$$

for all $i, j = 0, 1, \ldots, N-1$. From the definition of $S_k(\cdot)$,

$$\begin{aligned} \|S_i(F)\| &= \|S_{i-j}(S_j(F))\| \\ &= \|\Lambda_{-i+j} S_j(F) \Lambda_{i-j}\| \\ &\leq \|S_j(F)\Lambda_{i-j}\| \\ &\leq \|S_j(F)\|. \end{aligned} \tag{B8}$$

Since (B8) is also true for $S_j(F)$ and $S_{N+i}(F)$,

$$\|S_j(F)\| \leq \|S_{N+i}(F)\| = \|S_i(F)\|. \tag{B9}$$

This completes the proof. □

Now we are in a position to prove Theorem 4.1.

Proof of Theorem 4.1. For simplicity, we consider only the 2-periodic case ($N = 2$); that is, we are to prove that

$$\nu = \max(\nu_0,\ \nu_1), \tag{B10}$$

where

$$\begin{aligned} \nu_0 &= \inf_{Q_0^L\in\mathcal{C}\cap\mathcal{T}} \left\| \begin{bmatrix} X_0^L - Q_0^L & Y_0^L \\ Z_0^L & U_0^L \end{bmatrix} \right\| \\ &= \inf_{Q^L\in\mathcal{C}\cap\mathcal{T}} \left\| \begin{bmatrix} X^L - Q^L & Y^L \\ Z^L & U^L \end{bmatrix} \right\|, \end{aligned} \tag{B11}$$

$$\nu_1 = \inf_{Q_1^L \in \mathcal{C} \cap \mathcal{T}} \left\| \begin{bmatrix} X_1^L - Q_1^L & Y_1^L \\ Z_1^L & U_1^L \end{bmatrix} \right\|. \tag{B12}$$

It would be evident that the following arguments can be extended to the general case.

Applying Lemma B.1 to (B11), ν_0 is given by

$$\nu_0 = \sup_{k \geq -1} \|\Gamma_k^L\|, \tag{B13}$$

where

$$\Gamma_k^L = \begin{bmatrix} \Pi_k & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} X^L & Y^L \\ Z^L & U^L \end{bmatrix} \begin{bmatrix} I - \Pi_k & 0 \\ 0 & I \end{bmatrix}. \tag{B14}$$

From (A26) and (B3), $\|\Gamma_k^L\|$ can be expressed in terms of Γ_k as

$$\|\Gamma_k^L\| = \|\Gamma_{2k+1}\|. \tag{B15}$$

Thus, from (B13) and (B15),

$$\nu_0 = \sup_{k=-1,1,\ldots} \|\Gamma_k\|. \tag{B16}$$

Similarly,

$$\nu_1 = \sup_{k=-1,1,\ldots} \|\Gamma_k'\|, \tag{B17}$$

where

$$\Gamma_k' = \begin{bmatrix} \Pi_k & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} S_1(X) & S_1(Y) \\ S_1(Z) & S_1(U) \end{bmatrix} \begin{bmatrix} I - \Pi_k & 0 \\ 0 & I \end{bmatrix}. \tag{B18}$$

Let the matrix representation of

$$\begin{bmatrix} X & Y \\ Z & U \end{bmatrix} \tag{B19}$$

be

$$\left[\begin{array}{ccccc|ccccc} X_{00} & X_{1,-1} & X_{0,-2} & X_{1,-3} & \cdots & Y_{00} & Y_{1,-1} & Y_{0,-2} & Y_{1,-3} & \cdots \\ X_{01} & X_{10} & X_{0,-1} & X_{1,-2} & \cdots & Y_{01} & Y_{10} & Y_{0,-1} & Y_{1,-2} & \cdots \\ X_{02} & X_{11} & X_{00} & X_{1,-1} & \cdots & Y_{02} & Y_{11} & Y_{00} & Y_{1,-1} & \cdots \\ X_{03} & X_{12} & X_{01} & X_{10} & \cdots & Y_{03} & Y_{12} & Y_{01} & Y_{10} & \cdots \\ \vdots & \vdots & \vdots & \vdots & & \vdots & \vdots & \vdots & \vdots & \\ \hline Z_{00} & Z_{1,-1} & Z_{0,-2} & Z_{1,-3} & \cdots & U_{00} & U_{1,-1} & U_{0,-2} & U_{1,-3} & \cdots \\ Z_{01} & Z_{10} & Z_{0,-1} & Z_{1,-2} & \cdots & U_{01} & U_{10} & U_{0,-1} & U_{1,-2} & \cdots \\ Z_{02} & Z_{11} & Z_{00} & Z_{1,-1} & \cdots & U_{02} & U_{11} & U_{00} & U_{1,-1} & \cdots \\ Z_{03} & Z_{12} & Z_{01} & Z_{10} & \cdots & U_{03} & U_{12} & U_{01} & U_{10} & \cdots \\ \vdots & \vdots & \vdots & \vdots & & \vdots & \vdots & \vdots & \vdots & \end{array}\right]. \tag{B20}$$

Then the matrix representation of Γ_k $(k = 1, 3, \ldots)$ is

$$\left[\begin{array}{c|ccc||ccc} & X_{0,-k-1} & X_{1,-k-2} & \cdots & Y_{00} & \cdots & Y_{0,-k-1} & \cdots \\ 0 & \vdots & \vdots & & \vdots & & \vdots & \\ & X_{0,-1} & X_{1,-2} & \cdots & Y_{0k} & \cdots & Y_{0,-1} & \cdots \\ \hline 0 & \multicolumn{3}{c||}{0} & \multicolumn{3}{c}{0} \\ \hline & Z_{0,-k-1} & Z_{1,-k-2} & \cdots & U_{00} & \cdots & U_{0,-k-1} & \cdots \\ & \vdots & \vdots & & \vdots & & \vdots & \\ 0 & Z_{0,-1} & Z_{1,-2} & \cdots & U_{0k} & \cdots & U_{0,-1} & \cdots \\ & \vdots & \vdots & & \vdots & & \vdots & \end{array}\right] \tag{B21}$$

Also, the matrix representation of Γ'_k $(k = 1, 3, \ldots)$ is

$$\left[\begin{array}{c|ccc||ccc} & X_{1,-k-1} & X_{0,-k-2} & \cdots & Y_{10} & \cdots & Y_{1,-k-1} & \cdots \\ 0 & \vdots & \vdots & & \vdots & & \vdots & \\ & X_{1,-1} & X_{0,-2} & \cdots & Y_{1k} & \cdots & Y_{1,-1} & \cdots \\ \hline 0 & \multicolumn{3}{c||}{0} & \multicolumn{3}{c}{0} \\ \hline & Z_{1,-k-1} & Z_{0,-k-2} & \cdots & U_{10} & \cdots & U_{1,-k-1} & \cdots \\ & \vdots & \vdots & & \vdots & & \vdots & \\ 0 & Z_{1,-1} & Z_{0,-2} & \cdots & U_{1k} & \cdots & U_{1,-1} & \cdots \\ & \vdots & \vdots & & \vdots & & \vdots & \end{array}\right] \tag{B22}$$

Since the matrix representation of Γ_{k-1} $(k = 1, 3, \ldots)$ is

$$\left[\begin{array}{c|ccc||ccc} & X_{1,-k} & X_{0,-k-1} & \cdots & Y_{00} & \cdots & Y_{1,-k} & \cdots \\ 0 & \vdots & \vdots & & \vdots & & \vdots & \\ & X_{1,-1} & X_{0,-2} & \cdots & Y_{0,k-1} & \cdots & Y_{1,-1} & \cdots \\ \hline 0 & \multicolumn{3}{c||}{0} & \multicolumn{3}{c}{0} \\ \hline & Z_{1,-k} & Z_{0,-k-1} & \cdots & U_{00} & \cdots & U_{1,-k} & \cdots \\ & \vdots & \vdots & & \vdots & & \vdots & \\ 0 & Z_{1,-1} & Z_{0,-2} & \cdots & U_{0,k-1} & \cdots & U_{1,-1} & \cdots \\ & \vdots & \vdots & & \vdots & & \vdots & \end{array}\right], \tag{B23}$$

Γ_{k-1} can be expressed by

$$\Gamma_{k-1} = \begin{bmatrix} \Lambda_{-1} & 0 \\ 0 & \Lambda_{-1} \end{bmatrix} \Gamma'_k \begin{bmatrix} \Lambda_1 & 0 \\ 0 & \Lambda_1 \end{bmatrix}. \tag{B24}$$

Therefore,

$$\|\Gamma'_k\| \geq \|\Gamma_{k-1}\| \quad \forall\ k = 1, 3, \ldots, \tag{B25}$$

and hence

$$\begin{aligned}\nu &= \max\left(\sup_{k=-1,1,\ldots}\|\Gamma_k\|,\ \sup_{k=0,2,\ldots}\|\Gamma_k\|\right)\\ &\le \max\left(\sup_{k=-1,1,\ldots}\|\Gamma_k\|,\ \sup_{k=-1,1,\ldots}\|\Gamma'_k\|\right)\\ &= \max(\nu_0,\ \nu_1)\end{aligned}\tag{B26}$$

by (B4), (B16), and (B17). Furthermore, from Lemmas B.1 and B.2 and (B18),

$$\begin{aligned}\nu &= \inf_{Q\in\mathcal{C}\cap\mathcal{P}_2}\left\|\begin{bmatrix} X-Q & Y\\ Z & U\end{bmatrix}\right\|\\ &= \inf_{Q\in\mathcal{C}\cap\mathcal{P}_2}\left\|\begin{bmatrix} S_1(X)-Q & S_1(Y)\\ S_1(Z) & S_1(U)\end{bmatrix}\right\|\\ &= \sup_{k\ge -1}\|\Gamma'_k\|\\ &\ge \sup_{k=-1,1,\ldots}\|\Gamma'_k\| = \nu_1.\end{aligned}\tag{B27}$$

Since $\nu \ge \nu_0$ by (B4) and (B16), this, together with (B26), implies that

$$\nu = \max(\nu_0,\ \nu_1). \qquad \square \tag{B28}$$

SECOND ORDER SUFFICIENT CONDITIONS FOR OPTIMAL CONTROL PROBLEMS WITH FREE FINAL TIME: THE RICCATI APPROACH*

HELMUT MAURER† AND HANS JOACHIM OBERLE‡

Abstract. Second order sufficient conditions (SSC) for control problems with control-state constraints and free final time are presented. Instead of deriving such SSC from first principles, we transform the control problem with free final time into an augmented control problem with fixed final time for which well-known SSC exist. SSC are then expressed as a condition on the positive definiteness of the second variation. A convenient numerical tool for verifying this condition is based on the Riccati approach, where one has to find a bounded solution of an associated Riccati equation satisfying specific boundary conditions. The augmented Riccati equations for the augmented control problem are derived, and their modifications on the boundary of the control-state constraint are discussed. Two numerical examples, (1) the classical Earth-Mars orbit transfer in minimal time and (2) the Rayleigh problem in electrical engineering, demonstrate that the Riccati equation approach provides a viable numerical test of SSC.

Key words. optimal control, control-state constraints, free final time, second order sufficient conditions, Riccati equation, Earth-Mars orbit transfer, Rayleigh problem

1. Introduction.

In the last three decades, one can find an extensive literature on second order sufficient conditions (SSC) for optimal control problems with control and state constraints; cf. [2, 4, 6, 7, 8, 9, 10, 20, 25, 26, 31, 32, 35] and further literature cited in these papers. SSC have shown to be of fundamental importance for stability and sensitivity analysis of parametric optimal control problems; cf., e.g., [2, 5, 9, 10, 18, 19, 21, 23, 24, 33, 34].

SSC are usually expressed in terms of the positiveness of a quadratic form on a certain critical cone which is obtained through linearization of equality and inequality constraints. In general, such conditions are far too abstract to lend themselves to numerical verification. A practical test for SSC can be devised on the basis of a matrix-valued Riccati equation [23, 25, 37]. The main ideas underlying this approach are already exposed in the book of Bryson and Ho [1] for unconstrained control problems. This test requires the construction of a bounded solution to a Riccati equation which has to satisfy additional boundary conditions. An inherent difficulty arises from the fact that the coefficients of the Riccati equation depend on the accurate solution for state, control, and adjoint variables.

Most of the cited papers deal with control problems on a *fixed* time interval. Extensions of the results to problems with *free* final time or with nonfixed time intervals have been discussed in [1, 4, 12, 26, 31, 32]. The method in Bryson and Ho [1, Chapter 6] uses heuristic arguments and also suffers from the drawback that, e.g.,

time-optimal control problems are not tractable via this approach. More precisely, the function α defined in (6.6.13) of [1] is identically zero, and hence the quantity in (6.6.16) is not defined. A rigorous proof of the SSC in [1] may be found in Chamberland and Zeidan [4], where extensions of the results to control problems with mixed control-state constraints are also given. Again, however, the time-optimal case is not covered by these conditions. A remedy for this deficiency has been proposed in Hull [12] for unconstrained control problems. These conditions have been tested in a numerically unchallenging situation. We emphasize that a general approach for SSC on nonfixed time intervals has been developed by Osmolovskii [26, 31, 32], but the author does not offer any practical device to test his conditions numerically.

The aim of the present paper is to develop verifiable SCC for control problems with free final time and mixed control-state constraints. Our approach is rather straightforward in the sense that it uses the well-known idea (cf., e.g., [11]) of reducing the *free* final time case to the *fixed* final time case by treating the free final time as an *augmented* state variable. It is not surprising that this procedure will lead to an augmented set of Riccati equations and boundary conditions. For unconstrained control problems, this derivation has already been described in [22].

The organization of the paper is as follows. In section 2, we recall known SSC for control problems with fixed final time [25, 37]. Section 3 describes the effect of the time transformation on the augmented variables and functions of the problem. A straightforward calculation shows that the Riccati equation for the augmented problem splits into three separate parts. A salient feature of the approach is that it suffices to solve a reduced form of the Riccati equation on the boundary of the control-state constraint. The boundary conditions for the Riccati equation are worked out in some cases of practical interest. In particular, we derive additional sign conditions of the Riccati solution at the initial and final time which turn out to be crucial in the numerical test.

In sections 4 and 5, we apply the numerical methodology to two practical and challenging examples. A highly accurate numerical solution to both examples is obtained via the multiple shooting method [3, 29]. The classical problem of a planar Earth-Mars orbit transfer in minimal time [14, 16, 17] is treated in section 4. The augmented Riccati equation test succeeds in confirming the optimality of the numerical solution. Section 5 presents a modification of the Rayleigh problem, which has been solved in [13, 23, 36] on fixed time intervals. Surprisingly, when no control constraints are imposed, the free final time problem has several local minima and one local maximum. The augmented Riccati test is capable of proving optimality for both local minima. Then the Rayleigh problem, subject to control constraints, is studied. We derive the reduced Riccati equations on the boundary of the constraint and compute a bounded solution which satisfies the extra boundary condition.

Let us mention two further applications and extensions. First, on the basis of SSC, it is rather straightforward to perform a computational *sensitivity analysis* for both examples. The numerical techniques in [21, 24, 23, 33, 34] indicate that sensitivity differentials of optimal solutions with respect to parameters can be obtained through the solution of an additional linear boundary value problem (BVP). The second extension concerns optimal control problems with *pure* state constraints to which the techniques of this paper apply as well.

2. Second order conditions for control problems with fixed final time. We consider the following autonomous control problem (CP) subject to mixed control-state constraints: for a given final time $T > 0$, determine a control

function $u \in L^\infty(0,T;\mathbb{R}^m)$ and a state function $x \in W^{1,\infty}(0,T;\mathbb{R}^n)$ that minimize the
functional

$$F(x,u) = g(x(0),x(T)) + \int_0^T L(x(t),u(t))dt \tag{2.1}$$

subject to

$$\dot{x}(t) = f(x(t),u(t)) \quad \text{for a.e. } t \in [0,T]\,, \tag{2.2}$$

$$\varphi(x(0),x(T)) = 0\,, \tag{2.3}$$

$$C(x(t),u(t)) \le 0 \quad \text{for a.e. } t \in [0,T]\,. \tag{2.4}$$

It is assumed that the functions $g : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}$, $L : \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}$, $f : \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}^n$, $\varphi : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}^r$, $0 \le r \le 2n$, and $C : \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}^k$ are C^2-functions on appropriate open sets. In this section, the *final time* T is supposed to be specified. Further, we assume that there exists a feasible pair of functions $(x_0,u_0) \in W^{1,\infty}(0,T;\mathbb{R}^n) \times L^\infty(0,T;\mathbb{R}^m)$ satisfying the constraints (2.2)–(2.4).

The first order necessary conditions for an optimal pair (x_0,u_0) are well known in the literature [11, 28]. The *unconstrained* Hamiltonian function H^0, respectively, the *augmented* Hamiltonian H, are defined as

$$H^0(x,u,\lambda) = L(x,u) + \lambda^* f(x,u)\,, \quad H(x,u,\lambda,\mu) = H^0(x,u,\lambda) + \mu^* C(x,u), \tag{2.5}$$

where $\lambda \in \mathbb{R}^n$ denotes the adjoint variable and $\mu \in \mathbb{R}^k$ is the multiplier associated with the control-state constraint (2.4); the asterisk denotes the transpose. Henceforth, partial derivatives will often be denoted by subscripts. In the following, we shall make the hypothesis that first order conditions are satisfied in *normal form* with a nonzero cost multiplier. Hence we assume that there exist Lagrange multipliers (for convenience, we shall drop the lower subscript zero)

$$(\lambda,\mu,\rho) \in W^{1,\infty}(0,T;\mathbb{R}^n) \times L^\infty(0,T;\mathbb{R}^k) \times \mathbb{R}^r$$

such that the following first order necessary conditions hold for a.e. $t \in [0,T]$:

$$\dot{\lambda}(t) = -H_x(x_0(t),u_0(t),\lambda(t),\mu(t))^*\,, \tag{2.6}$$

$$(-\lambda(0),\lambda(T)) = \nabla_{(x(0),x(T))}\,(g + \rho^*\varphi)(x_0(0),x_0(T))\,, \tag{2.7}$$

$$H_u(x_0(t),u_0(t),\lambda(t),\mu(t)) = 0, \tag{2.8}$$

$$\mu(t) \ge 0 \quad \text{and} \quad \mu(t)^* C(x_0(t),u_0(t)) = 0, \tag{2.9}$$

$$H^0(x_0(t),u_0(t),\lambda(t)) \equiv \text{const.} \tag{2.10}$$

We shall use the notation $[t]$ to denote arguments of functions at the reference solution $x_0(t),u_0(t),\lambda(t),\mu(t)$. To introduce regularity assumptions, we consider for $\beta \ge 0$ the set of β-active constraints

$$I_\beta(t) := \{i \in \{1,\dots,k\} \mid C^i[t] \ge -\beta\}\,,$$

where C^i denotes the ith component of the vector C. In particular, for $\beta = 0$, we obtain the set of active indices

$$I_0(t) = \{i \in \{1,\dots,k\} \mid C^i[t] = 0\}\,.$$

The following regularity assumption concerns the *linear independence* of gradients for active constraints; cf. [18, 19, 21, 25, 37].

(A1) For some $\beta > 0$, the gradients $C_u^i[t]$ are uniformly linear independent for all $i \in I_\beta(t)$ a.e. on $[0,T]$.

Further, we consider a margin $\delta \geq 0$ and define the set of indices

$$J_\delta(t) := \{i \in \{1,\dots,k\} \mid \mu_i(t) > \delta\}, \quad j_\delta(t) := \operatorname{card}(J_\delta(t)),$$

where μ_i denotes the ith component of the multiplier μ. It is obvious that $J_\delta(t) \subset I_0(t)$ holds for all $\delta \geq 0$. In particular, the *strict complementarity condition* $\mu^i(t) > 0$ is valid for all indices $i \in J_\delta(t)$. It will be convenient to introduce the notation

$$C^\delta[t] = (C^i[t])_{\,i \in J_\delta(t)}\,.$$

We assume that the following *modified strict Legendre–Clebsch condition* [18, 19, 21, 25, 37] is satisfied, where $|\,.\,|$ denotes the euclidean norm.

(A2) For some $\delta > 0$, there exists $c > 0$ such that, for all $t \in [0,T]$, the estimate $v^* H_{uu}[t] v \geq c|v|^2$ holds for all $v \in \mathbb{R}^m$ satisfying $C_u^\delta[t]v = 0$.

SSC can now be derived by studying the behavior of the second variation on the variational system associated with (2.2)–(2.4). In what follows, we shall use the abbreviation $\varphi[\,0,T] = \varphi(x_0(0), x_0(T))$ and similar notation. The *variational system* of equations (2.2)–(2.4) is the set of functions $(y,v) \in W^{1,2}(0,T;\mathbb{R}^n) \times L^2(0,T;\mathbb{R}^m)$ satisfying

$$\dot y(t) = f_x[t]y(t) + f_u[t]v(t), \quad \text{a.e. } t \in [0,T]\,, \tag{2.11}$$

$$D_{x(0)}\varphi[0,T]y(0) + D_{x(T)}\varphi[0,T]y(T) = 0\,, \tag{2.12}$$

$$C_x^i[t]y(t) + C_u^i[t]v(t) = 0 \quad \forall\ i \in J_\delta(t)\,, \text{ a.e. } t \in [0,T]\,. \tag{2.13}$$

Moreover, we introduce the function

$$G(x(0),x(T)) := g(x(0),x(T)) + \rho^*\,\varphi(x(0),x(T))$$

and define the $(2n,2n)$-matrix

$$\Gamma[0,T] := D^2_{(x(0),x(T))}\,G(x_0(0),x_0(T)) = \begin{pmatrix} G_{00}[0,T] & G_{0T}[0,T] \\ G_{T0}[0,T] & G_{TT}[0,T] \end{pmatrix} \tag{2.14}$$

with obvious notation $G_{00}[0,T] = D^2_{(x(0),x(0))}G[0,T]$, $G_{0T}[0,T] = D^2_{((x(0),x(T))}G[0,T]$, etc. Then the so-called *second variation* is given by the quadratic form

$$\begin{aligned} J^2(y,v) = \frac{1}{2}\int_0^T (y(t)^*, v(t)^*) \begin{pmatrix} H_{xx}[t] & H_{xu}[t] \\ H_{ux}[t] & H_{uu}[t] \end{pmatrix} \begin{pmatrix} y(t) \\ v(t) \end{pmatrix} dt \\ + \frac{1}{2}\,(y(0)^*, y(T)^*)\Gamma[0,T] \begin{pmatrix} y(0) \\ y(T) \end{pmatrix}. \end{aligned} \tag{2.15}$$

The next theorem summarizes the SSC for a weak local minimum which are to be found in [21, 25, 35, 37].

THEOREM 2.1 (SSC for control problems with fixed final time). *Let (x_0,u_0) be admissible for problem* (CP). *Suppose that there exist multipliers $(\lambda,\mu,\rho) \in W^{1,\infty}(0,T;\mathbb{R}^n) \times L^\infty(0,T;\mathbb{R}^k) \times \mathbb{R}^r$ such that the following conditions hold:*

(1) *the necessary conditions* (2.6)–(2.10) *are satisfied;*
(2) *assumptions* (A1) *and* (A2) *hold;*
(3) *there exist* $\gamma_0 > 0$ *such that the quadratic form in* (2.15) *can be estimated from below as*

$$J^2(y,v) \geq \gamma_0 \left(||y||^2_{1,2} + ||v||^2_2 \right) \tag{2.16}$$

for all variations $(y,v) \in W^{1,2}(0,T;\mathbb{R}^n) \times L^2(0,T;\mathbb{R}^m)$ *satisfying the variational system* (2.11)–(2.13);
(4) *if* u_0 *is continuous, then one may choose* $\beta = 0$ *and* $\delta = 0$ *in assumptions* (A1) *and* (A2) *and in condition* (3).

Then for all constants $0 < \gamma < \gamma_0$ *with* γ_0 *as in* (2.16) *there exists* $\alpha > 0$ *such that*

$$F(x,u) \geq F(x_0,u_0) + \gamma \left(||x - x_0||^2_{1,2} + ||u - u_0||^2_2 \right)$$

holds for all admissible (x,u) *with* $||x - x_0||_{1,\infty} + ||u - u_0||_\infty \leq \alpha$. *In particular,* (x_0,u_0) *provides a strict weak local minimum for problem* (CP).

The SSC in the previous theorem usually are not suitable for a *direct numerical verification* in practical control problems. Let us mention that, for a *discretized* version of the control problem (CP), optimization techniques have been developed that allow us to check the positiveness condition by computing the reduced Hessian; cf. [2]. In order to obtain *verifiable sufficient conditions* for the control problem in function spaces, the SSC in Theorem 2.1 are strengthened in the following way.

Consider a symmetric matrix function $Q \in W^{1,\infty}(0,T;M_{n\times n})$. For every variation $y(t)$ satisfying the linearized state equation (2.11), we have $y(t)^*Q(t)(\dot{y}(t) - f_x[t]y(t) - f_u[t]v(t)) \equiv 0$. Adding the last identity to the second variation $J^2(y,v)$ in (2.15) and performing a partial integration, we find that the definiteness condition (2.16) in Theorem 2.1 holds if the following two conditions (a) and (b) are satisfied.

Condition (a). There exist a symmetric matrix $Q \in W^{1,\infty}(0,T;M_{n\times n})$ and $\gamma > 0$ such that

$$\begin{aligned}(y^*, v^*) &\begin{pmatrix} \dot{Q}(t) + Q(t)f_x[t] + f_x[t]^*Q(t) + H_{xx}[t] & H_{xu}[t] + Q(t)f_u[t] \\ H_{ux}[t] + f_u[t]^*Q(t) & H_{uu}[t] \end{pmatrix} \begin{pmatrix} y \\ v \end{pmatrix} \\ &\geq \gamma\, |(y,v)|^2 \end{aligned} \tag{2.17}$$

holds *uniformly* in $t \in [0,T]$ for all vectors $(y,v) \in \mathbb{R}^n \times \mathbb{R}^m$ with

$$C^i_x[t]y + C^i_u[t]v = 0 \quad \forall\, i \in J_\delta(t)\,. \tag{2.18}$$

Condition (b). The boundary condition

$$(\xi_0^*, \xi_1^*) \begin{pmatrix} G_{00}[0,T] + Q(0) & G_{0T}[0,T] \\ G_{T0}[0,T] & G_{TT}[0,T] - Q(T) \end{pmatrix} \begin{pmatrix} \xi_0 \\ \xi_1 \end{pmatrix} > 0 \tag{2.19}$$

is valid for all $(\xi_0,\xi_1) \in \mathbb{R}^n \times \mathbb{R}^n \setminus \{0\}$ satisfying

$$D_{x(0)}\varphi[0,T]\xi_0 + D_{x(T)}\varphi[0,T]\xi_1 = 0\,. \tag{2.20}$$

A first consequence is that the definiteness condition (2.16) holds if the matrix in (2.17) is positive definite on the *whole* space $\mathbb{R}^n \times \mathbb{R}^m$ and if conditions (2.19)

and (2.20) are satisfied. First, this leads to the requirement that the strict Legendre–Clebsch condition

$$H_{uu}[t] \geq c \cdot I_m \quad \forall\, t \in [0,T]\,, \quad c > 0,$$

is valid on the *whole* interval $[0,T]$. Second, by evaluating the Schur complement of this matrix and using the continuous dependence of ODEs on system data, the estimate (2.16) follows from the following assumption: there exists a solution of the Riccati equation

$$\dot{Q} = -Qf_x[t] - f_x[t]^*Q - H_{xx}[t] + (H_{xu}[t] + Qf_u[t])H_{uu}[t]^{-1}(H_{xu}[t] + Qf_u[t])^*, \tag{2.21}$$

for a.e. $t \in [0,T]$ such that the matrix function $Q(t)$ is *bounded* on $[0,T]$ and satisfies the boundary conditions (2.19) and (2.20); cf. [25, Theorem 5.2].

However, in some applications, these conditions are too strong since the Riccati equation (2.21) may fail to have a *bounded* solution; cf. the Rayleigh problem in [23]. A weaker condition can be obtained by introducing the following *modified* or *reduced* Riccati equation. For $\delta \geq 0$, recall the definition of the vector

$$C^\delta[t] = (C^i[t])_{i \in J_\delta(t)}\,, \quad j_\delta(t) = ca\ rd(J_\delta(t))\,.$$

Then the matrix $C_u^\delta[t]$ of partial derivatives has dimension $j_\delta(t) \times m$. For simplicity, the time argument will be omitted in what follows. The *pseudoinverse* of the matrix C_u^δ is given by the $(m \times j_\delta)$-matrix

$$(C_u^\delta)^+ := (C_u^\delta)^*\,(C_u^\delta (C_u^\delta)^*)^{-1},$$

which exists in view of the linear independence assumption (A1). Furthermore, let $(C_u^\delta)^\perp$ denote an $(m \times (m - j_\delta))$-matrix whose column vectors form an orthogonal basis of the kernel $\mathrm{Ker}(C_u^\delta)$. Consider then the following matrices (cf. [9, 10, 25, 37]):

$$D^\delta := -(C_u^\delta)^+ C_x^\delta\,, \quad P^\delta := (C_u^\delta)^\perp, \quad A^\delta := f_x + f_u D^\delta, \tag{2.22}$$

$$\mathcal{H}_{xx}^\delta := H_{xx} + H_{xu}D^\delta + (D^\delta)^* H_{ux} + (D^\delta)^* H_{uu} D^\delta, \tag{2.23}$$

$$\mathcal{H}_{xu}^\delta := H_{xu} + (D^\delta)^* H_{uu}\,, \tag{2.24}$$

$$(\mathcal{H}_{uu}^\delta)^{(-1)} := P^\delta(\,(P^\delta)^*\, H_{uu} P^\delta\,)^{-1}(P^\delta)^*\,. \tag{2.25}$$

Note that the $(m \times m)$-matrix $(\mathcal{H}_{uu}^\delta)^{(-1)}$ in (2.25) is well defined by virtue of assumption (A2). It follows that the estimate (2.16) holds if there exists a symmetric matrix function $Q(t)$ that solves the Riccati equation

$$\dot{Q} = -QA^\delta - (A^\delta)^* Q - \mathcal{H}_{xx}^\delta + (\mathcal{H}_{xu}^\delta + Qf_u)(\mathcal{H}_{uu}^\delta)^{(-1)}(\mathcal{H}_{xu}^\delta + Qf_u)^* \tag{2.26}$$

for a.e. $t \in [0,T]$ such that $Q(t)$ is *bounded* on $[0,T]$ and satisfies the boundary conditions (2.19), (2.20).

In general, it is rather tedious to elaborate this Riccati equation explicitly. To facilitate the numerical treatment in practical applications, we discuss special cases in more detail. On *interior arcs* with $C[t] < 0$, we have $j_\delta(t) = 0$, and thus the Riccati equation (2.26) reduces to the one introduced in (2.21). Consider now a *boundary arc* with $j_\delta(t) = m$, where we have as many control components as active constraints. Due to assumption (A1), the pseudoinverse is given by $(C_u^\delta)^+ = (C_u^\delta)^{-1}$, and hence

the matrix $P^\delta = (C_u^\delta)^\perp = 0$ in (2.22) vanishes. Then the matrices in (2.22)–(2.25) become

$$D^\delta = -(C_u^\delta)^{-1} C_x^\delta, \quad A^\delta = f_x - f_u (C_u^\delta)^{-1} C_x^\delta, \quad (\mathcal{H}_{uu}^\delta)^{(-1)} = 0, \tag{2.27}$$

$$\mathcal{H}_{xx}^\delta = H_{xx} - H_{xu}(C_u^\delta)^{-1} C_x^\delta + [(C_u^\delta)^{-1} C_x^\delta]^* [H_{uu}(C_u^\delta)^{-1} C_x^\delta - H_{ux}], \tag{2.28}$$

and thus the Riccati equation (2.26) reduces to the *linear* ODE

$$\dot{Q} = -QA^\delta - (A^\delta)^* Q - \mathcal{H}_{xx}^\delta . \tag{2.29}$$

Another special case arises for *pure control* constraints where we have $C_x \equiv 0$. Then (2.28) and (2.29) simplify to the linear ODE

$$\dot{Q} = -Qf_x - f_x^* Q - H_{xx} . \tag{2.30}$$

The Rayleigh problem in [23] provided an illustrative application of this approach.

Let us also evaluate the boundary conditions (2.19) and (2.20) in a special case of practical interest. Suppose that the boundary conditions are separated and that some components for the initial and final state are fixed according to

$$x_k(0) = a_k \ \text{ for } \ k \in K_0 \subset \{1, \dots, n\}, \quad x_k(T) = b_k \ \text{ for } \ k \in K_T \subset \{1, \dots, n\}, \tag{2.31}$$

whereas the other components are free. Denote the complements of the index sets by $K_0^c = \{1, \dots, n\} \setminus K_0$, $K_T^c = \{1, \dots, n\} \setminus K_T$. Then it is easy to see that the boundary conditions (2.19), (2.20) are satisfied if the following submatrices are positive definite:

$$[\, Q(0) \,]_{(i,j) \in K_0^c \times K_0^c} > 0, \quad [\, -Q(T) \,]_{(i,j) \in K_T^c \times K_T^c} > 0 . \tag{2.32}$$

By virtue of the continuous dependence of solutions to ODEs on systems data, one of these definiteness conditions can be relaxed. For example, it suffices to require only positive semidefiniteness

$$[\, Q(0) \,]_{(i,j) \in K_0^c \times K_0^c} \geq 0 .$$

This relaxation will be convenient for the numerical verification of SSC applied to the examples in sections 4 and 5.

3. SSC for control problems with free final time. We consider again the control problem (CP) in (2.1)–(2.4), but in this section the final time will *not* be specified. It will always be assumed that the final time $T > 0$ is positive. The first order necessary conditions for problem (CP) with free final time are well known [11, 28] and extend those given in the last section.

Let H be the Hamiltonian defined in (2.5). Then it is assumed that there exist multipliers in normal form,

$$(\lambda, \mu, \rho) \in W^{1,\infty}(0, T; \mathbb{R}^n) \times L^\infty(0, T; \mathbb{R}^k) \times \mathbb{R}^r,$$

which satisfy (2.6)–(2.10). In addition, the following transversality condition associated with the free final time T holds:

$$H[T] = 0, \quad \text{i.e.,} \quad H[t] \equiv 0 \quad \forall\, t \in [0, T] . \tag{3.1}$$

These conditions can be obtained by transforming problem (CP) with *free* final time T into a problem ($\widetilde{\text{CP}}$) with *fixed* final time $\tilde{T} = 1$. The transformation proceeds by

augmenting the state dimension and by introducing the free final time as an additional state variable. Indeed, it is this transformation that will allow us to develop SSC for the free final time case on the basis of the SSC in Theorem 2.1 for fixed final time. Now define the *new time variable* $\tau \in [0,1]$ by

$$t = \tau \cdot T\,, \quad 0 \le \tau \le 1\,. \tag{3.2}$$

We shall use the same notation $x(\tau) := x(\tau \cdot T)$ and $u(\tau) := u(\tau \cdot T)$ for the state and the control variable with respect to the new time variable τ. The *augmented* state

$$\tilde{x} := \begin{pmatrix} x \\ x_{n+1} \end{pmatrix} \in \mathbb{R}^{n+1}, \quad x_{n+1} := T\,,$$

satisfies the differential equations

$$dx/d\tau = T \cdot f(x(\tau), u(\tau))\,, \qquad dx_{n+1}/d\tau \equiv 0\,. \tag{3.3}$$

As a result of this time transformation, we consider the following augmented control problem ($\widetilde{\text{CP}}$) on the fixed time interval $[0,1]$: minimize the functional

$$F(\tilde{x}, u) = F(x, T, u) = \tilde{g}(\tilde{x}(0), \tilde{x}(1)) + \int_0^1 \tilde{L}(\tilde{x}(\tau), u(\tau))\, d\tau \tag{3.4}$$

subject to

$$d\tilde{x}/d\tau = \tilde{f}(\tilde{x}(\tau), u(\tau)), \quad \text{a.e. } \tau \in [0,1]\,, \tag{3.5}$$

$$\tilde{\varphi}(\tilde{x}(0), \tilde{x}(1)) = 0\,, \tag{3.6}$$

$$\tilde{C}(\tilde{x}(\tau), u(\tau)) \le 0, \quad \text{a.e. } \tau \in [0,1]\,. \tag{3.7}$$

The functions herein are given by

$$\tilde{g}(\tilde{x}(0), \tilde{x}(1)) := g(x(0), x(1))\,, \quad \tilde{L}(\tilde{x}, u) := T \cdot L(x, u)\,, \tag{3.8}$$

$$\tilde{f}(\tilde{x}, u) := \begin{pmatrix} T \cdot f(x, u) \\ 0 \end{pmatrix}, \tag{3.9}$$

$$\tilde{\varphi}(\tilde{x}(0), \tilde{x}(1)) := \varphi(x(0), x(1))\,, \quad \tilde{C}(\tilde{x}, u) := C(x, u)\,. \tag{3.10}$$

The transformed problem ($\widetilde{\text{CP}}$) on the fixed time interval $[0,1]$ falls into the category of control problems treated in the preceding section. Thus we are able to obtain SSC for the transformed problem ($\widetilde{\text{CP}}$) by evaluating the SSC in Theorem 2.1 for the augmented state variable $\tilde{x} = (x, T)$.

First we relate the multipliers for problem ($\widetilde{\text{CP}}$) to those of problem (CP) on the time interval $[0, T]$. The Hamiltonian for problem ($\widetilde{\text{CP}}$) becomes

$$\begin{aligned} \tilde{H}(\tilde{x}, u, \tilde{\lambda}, \tilde{\mu}) &= \tilde{L}(\tilde{x}, u) + \tilde{\lambda}^* \tilde{f}(\tilde{x}, u) + \tilde{\mu}^* \tilde{C}(\tilde{x}, u) \\ &= T \cdot [\, L(x, u) + \lambda^* f(x, u)\,] + \tilde{\mu}^* C(x, u), \end{aligned} \tag{3.11}$$

where $\tilde{\lambda}^* = (\lambda^*, \lambda_{n+1}) \in \mathbb{R}^{n+1}$ denotes the augmented adjoint variable and $\tilde{\mu} \in \mathbb{R}^k$ is the multiplier for the constraint (3.7). Introducing the scaled multiplier $\mu := \tilde{\mu}/T$, the Hamiltonian $\tilde{H}$ is related to the Hamiltonian H in (2.5) as follows:

$$\tilde{H}(\tilde{x}, u, \tilde{\lambda}, \tilde{\mu}) = T \cdot [\, L(x, u) + \lambda^* f(x, u) + \mu^* C(x, u)\,] = T \cdot H(x, u, \lambda, \mu)\,. \tag{3.12}$$

According to (2.6)–(2.10), the multipliers for problem ($\widetilde{\text{CP}}$),

$$(\tilde\lambda, \tilde\mu, \rho) \in W^{1,\infty}(0,1;\mathbb{R}^{n+1}) \times L^\infty(0,1;\mathbb{R}^k) \times \mathbb{R}^r\,, \quad \tilde\lambda = \begin{pmatrix} \lambda \\ \lambda_{n+1} \end{pmatrix},$$

satisfy the following necessary conditions for a.e. $\tau \in [0,1]$:

$$d\lambda/d\tau = -\tilde H_x[\tau]^* = -T \cdot H_x[\tau]^*\,, \quad d\lambda_{n+1}/d\tau = -\tilde H_T[\tau] = -H[\tau]\,, \tag{3.13}$$

$$(-\lambda(0), \lambda(1)) = \nabla_{(x(0),x(1))}(g + \rho^*\varphi)(x_0(0), x_0(1))\,, \tag{3.14}$$

$$\lambda_{n+1}(0) = \lambda_{n+1}(1) = 0\,, \tag{3.15}$$

$$\tilde H_u[\tau] = 0\,, \tag{3.16}$$

$$\tilde\mu(\tau) \ge 0 \quad \text{and} \quad \tilde\mu(\tau)^* C[\tau] = 0, \tag{3.17}$$

$$\tilde H[\tau] \equiv \text{const.} \quad \forall\, \tau \in [0,1]. \tag{3.18}$$

Relations (3.13), (3.15), and (3.18) immediately yield

$$0 = \tilde H[1] = T \cdot H[1]\,, \tag{3.19}$$

which proves the transversality condition (3.1). To check the Legendre–Clebsch condition in assumption (A2), one has to observe the scaling

$$\tilde H_{uu}[\tau] = T \cdot H_{uu}[\tau]\,. \tag{3.20}$$

In order to apply the SSC in Theorem 2.1 to problem ($\widetilde{\text{CP}}$), we have to evaluate all terms in relations (2.11)–(2.32) for the tilde quantities defined in (3.8)–(3.10). Recalling the scaled multiplier $\mu_0 = \tilde\mu_0/T$ in (3.12), we obtain the transformed quantities

$$\tilde f_{\tilde x} = \begin{pmatrix} T \cdot f_x & f \\ 0 & 0 \end{pmatrix}, \quad \tilde f_u = \begin{pmatrix} T \cdot f_u \\ 0 \end{pmatrix}, \quad \tilde C_{\tilde x} = (C_x, 0)\,, \quad \tilde C_u = C_u\,, \tag{3.21}$$

$$\tilde H_{\tilde x \tilde x} = \begin{pmatrix} T \cdot H_{xx} & (H^0_x)^* \\ H^0_x & 0 \end{pmatrix}, \quad \tilde H_{xu} = \begin{pmatrix} T \cdot H_{xu} \\ H^0_u \end{pmatrix}, \quad \tilde H_{uu} = T \cdot H_{uu}\,. \tag{3.22}$$

Observe that the last relations make use of the identity $\tilde H_T = H^0$, which can be seen from (3.11) with H^0 denoting the unconstrained Hamiltonian. The preceding considerations lead to the following SSC for problem ($\widetilde{\text{CP}}$) with free final time.

THEOREM 3.1 (SSC for control problems with free final time). *Let (x_0, T_0, u_0) with $T_0 > 0$ be admissible for problem ($\widetilde{\text{CP}}$). Suppose that there exist multipliers $(\lambda, \mu, \rho) \in W^{1,\infty}(0,1;\mathbb{R}^n) \times L^\infty(0,1;\mathbb{R}^k) \times \mathbb{R}^r$ such that the following conditions hold:*

1. *the necessary conditions* (3.13)–(3.19) *are satisfied;*
2. *assumptions* (A1) *and* (A2) *hold with respect to the time interval* $[0,1]$;
3. *there exists $\gamma_0 > 0$ such that the quadratic form* (2.15) *expressed in terms of the transformed functions* (3.21), (3.22) *can be estimated from below as*

$$J^2(\tilde y, \tilde v) \ge \gamma_0 \left(||\tilde y||^2_{1,2} + ||\tilde v||^2_2 \right)$$

for all variations $(\tilde y, \tilde v) \in W^{1,2}(0,1;\mathbb{R}^{n+1}) \times L^2(0,1;\mathbb{R}^m)$ which satisfy the variational system (2.11)–(2.13) *on the time interval* $[0,1]$.

(4) *if* u_0 *is continuous, then one may choose* $\beta = 0$ *and* $\delta = 0$ *in assumptions* (A1) *and* (A2) *and in condition* (3).

Then for all constants $0 < \gamma < \gamma_0$ *there exists* $\alpha > 0$ *such that*

$$F(x,T,u) \geq F(x_0,T_0,u_0) + \gamma\,(\,||x-x_0||_{1,2}^2 + |T-T_0|^2 + ||u-u_0||_2^2\,)$$

holds for all admissible (x,T,u) *with* $||x-x_0||_{1,\infty} + |T-T_0| + ||u-u_0||_\infty \leq \alpha$. *In particular,* (x_0,T_0,u_0) *provides a strict weak local minimum for problem* $(\widetilde{\mathrm{CP}})$.

Note that this theorem immediately yields SSC for the original problem (CP) since we have identified the pair of state and control functions $(x(t),u(t)) = (x(\tau\cdot T), u(\tau\cdot T))$ on the interval $[0,T]$ with the pair $(x(\tau),u(\tau))$ on the interval $[0,1]$. It is apparent that these conditions are not very handy in practical applications. Again, we may resort to the Riccati equations and boundary conditions developed in (2.21)–(2.32).

Now we consider the augmented $(n+1,n+1)$-matrix

$$\tilde{Q} = \begin{pmatrix} Q & R \\ R^* & q_T \end{pmatrix}, \tag{3.23}$$

where Q is a symmetric $(n\times n)$-matrix, R is an n-vector, and q_T is a scalar. Inserting the transformed quantities (3.21) and (3.22) into the Riccati equation (2.21) for the matrix $\tilde{Q}$, we obtain a Riccati equation for Q, a linear equation for R, and a direct integration for q_T on the interval $[0,1]$; the argument τ is omitted for simplicity:

$$dQ/d\tau = T\cdot[\,-Qf_x - f_x^*Q - H_{xx} + (H_{xu}+Qf_u)(H_{uu})^{-1}(H_{xu}+Qf_u)^*\,], \tag{3.24}$$

$$dR/d\tau = -Qf - Tf_x^*R - (H_x^0)^* + (H_{xu}+Qf_u)(H_{uu})^{-1}(H_u^0 + Tf_u^*R)^*, \tag{3.25}$$

$$dq_T/d\tau = -2R^*f + \frac{1}{T}\cdot(H_u^0 + Tf_u^*R)(H_{uu})^{-1}(H_u^0+Tf_u^*R)^*\,. \tag{3.26}$$

Clearly, the Riccati equation (3.24) evaluated on the interval $[0,1]$ agrees with the Riccati equation (2.21) on the interval $[0,T]$. Note again that $H_u^0 \equiv 0$ holds on totally interior arcs with $C[t] < 0$. We wish to draw attention to the fact that (3.25) and (3.26) are *not* identical to corresponding equations in Bryson and Ho [1, sections 6.6, 6.7] and Chamberland and Zeidan [4, formulae (28)–(30)], or Hull [12].

The *modified* Riccati equation (2.26) can be worked out on the time interval $[0,1]$ in a similar way using the transformed quantities (3.21) and (3.22). However, since this procedure is quite cumbersome, we restrict the discussion to the special case $m = j_\delta(t)$, which was considered already in (2.27)–(2.29). Upon computing the matrices in (2.27) and (2.28),

$$A^\delta = f_x - f_u(C_u^\delta)^{-1}C_x^\delta\,,$$
$$\mathcal{H}_{xx}^\delta = H_{xx} - H_{xu}(C_u^\delta)^{-1}C_x^\delta + [(C_u^\delta)^{-1}C_x^\delta]^*[H_{uu}(C_u^\delta)^{-1}C_x^\delta - H_{ux}]\,,$$

for the tilde quantities (3.21), (3.22), we recognize that the Riccati equation (2.29) splits into the following three equations:

$$dQ/d\tau = T\cdot[\,-QA^\delta - (A^\delta)^*Q - \mathcal{H}_{xx}^\delta\,], \tag{3.27}$$

$$dR/d\tau = -Qf - T\cdot(A^\delta)^*R - (H_x^0)^* - [H_u^0(C_u^\delta)^{-1}C_x^\delta]^*, \tag{3.28}$$

$$dq_T/d\tau = -2R^*f\,. \tag{3.29}$$

These formulas simplify considerably if $C_x \equiv 0$ holds, i.e., if the constraint is a *pure control* constraint. Then we get $A^\delta = f_x$, and the last equations yield

$$\begin{aligned} &dQ/d\tau = T \cdot [\, -Qf_x - f_x^* Q - H_{xx}\,], \quad dR/d\tau = -Qf - T \cdot f_x^* R - (H_x^0)^*\,, \\ &dq_T/d\tau = -2R^* f\,. \end{aligned} \tag{3.30}$$

These equations will provide a convenient test for SSC when applied to the Rayleigh problem in section 5.

It is rather tedious to write out the boundary conditions (2.19) and (2.20) in the general case. We shall only discuss the important case in which the initial and final states are fixed; i.e., $x(0) = x_0$ and $x(1) = x_1$ hold with prescribed $x_0, x_1 \in \mathbb{R}^n$. In this situation, the positive definiteness condition (2.32) evaluated for the augmented matrix $\tilde{Q}$ reduces to the following boundary conditions:

$$q_T(0) > 0 \quad \text{and} \quad q_T(1) < 0\,. \tag{3.31}$$

These conditions constitute extra conditions for the free final time case and will turn out to be crucial for the numerical examples discussed in the next two sections. Note that we may relax one of these conditions, e.g., the initial condition, to $q_T(0) \geq 0$ by virtue of the continuous dependence of ODE solutions on initial data.

4. Planar Earth-Mars transfer with minimal flight time. Rocket flights in an inverse square law field have been studied extensively in the literature; see, e.g., Kelley [14, 15], Kenneth and McGill [16], Lawden [17], Moyer and Pinkham [27], and Oberle and Taubert [30]. We consider the classical Earth-Mars orbit transfer with minimal transfer time. The state variables are r: distance of the vehicle to the sun; w: radial component of the velocity; v: horizontal component of the velocity; m: mass of the vehicle. The control variable is ψ: angle of the thrust vector with respect to local horizon. The thrust is always at its maximal value $\beta_{\max}$ since the final time is minimized. All variables are scaled according to the dynamic model treated in Oberle and Taubert [30].

The optimal control problem is to minimize the final time

$$F(x, T, u) = T = \int_0^T 1\, dt \tag{4.1}$$

subject to the equations of motion,

$$\begin{aligned} dr/dt &= w, \\ dw/dt &= \frac{v^2}{r} - \frac{1}{r^2} + \beta_{\max} \frac{c}{m} \sin\psi, \\ dv/dt &= -\frac{w\,v}{r} + \beta_{\max} \frac{c}{m} \cos\psi, \\ dm/dt &= -\beta_{\max}\,, \end{aligned} \tag{4.2}$$

and the boundary conditions for the initial and final state

$$\begin{aligned} &r(0) = 1.0, \qquad w(0) = 0.0, \quad v(0) = 1.0, \qquad m(0) = 1.0, \\ &r(T) = 1.525, \quad w(T) = 0.0, \quad v(T) = 1.0/\sqrt{r(T)}. \end{aligned} \tag{4.3}$$

The constants are given by $c = 1.872$ and $\beta_{\max} = 0.075$. The underlying physical data of the vehicle are given as follows: the initial mass is $m_0 = 679.78$ kg; the (maximal) thrust = 0.56493 N; and the (constant) equivalent exit velocity is $v_c = 55809$ m/s.

4.1. The BVP. Recall now the time transformation $t = \tau \cdot T$ introduced in (3.2). Since there is no control constraint in this problem, the Hamiltonian (3.12) is given by

$$\tilde{H} \;=\; T \cdot \left[1 \;+\; \lambda_r \, w \;+\; \lambda_w \left(\frac{v^2}{r} \;-\; \frac{1}{r^2} \;+\; \beta_{\max} \, \frac{c}{m} \, \sin\psi \right) \right. \\ \left. +\; \lambda_v \left(-\; \frac{w\,v}{r} \;+\; \beta_{\max} \, \frac{c}{m} \, \cos\psi \right) \;-\; \lambda_m \, \beta_{\max} \right]. \tag{4.4}$$

Let us evaluate the first order optimality conditions (3.13)–(3.16) and omit for convenience the subscript zero referring to the optimal solution. The *optimal control* ψ is derived from condition (3.16) and the assumed Legendre–Clebsch condition (A2) as

$$\sin\psi \;=\; -\,\frac{\lambda_w}{\sqrt{\lambda_w^2 \;+\; \lambda_v^2}} \;, \qquad \cos\psi \;=\; -\,\frac{\lambda_v}{\sqrt{\lambda_w^2 \;+\; \lambda_v^2}} \,. \tag{4.5}$$

The *adjoint equations* (3.13) on the normalized time interval $[0,1]$ are given by

$$\begin{aligned} d\lambda_r/d\tau &= T \cdot \left[\lambda_w \left(\frac{v^2}{r^2} \;-\; \frac{2}{r^3} \right) \;-\; \lambda_v \frac{wv}{r^2} \right] , \\ d\lambda_w/d\tau &= T \cdot \left[-\,\lambda_r \;+\; \lambda_v \, \frac{v}{r} \right] , \\ d\lambda_v/d\tau &= T \cdot \left[-\,\lambda_w \, \frac{2v}{r} \;+\; \lambda_v \, \frac{w}{r} \right] , \\ d\lambda_m/d\tau &= T \cdot \left[-\,\frac{\beta_{\max}\, c}{m^2} \, \sqrt{\lambda_w^2 \;+\; \lambda_v^2} \right] . \end{aligned} \tag{4.6}$$

The transversality conditions (3.14) and (3.19) yield

$$\begin{aligned} \lambda_m(1) &= 0, \\ H[1] &= 1 \;-\; \frac{\beta_{\max}\, c}{m(1)} \, \sqrt{\lambda_w(1)^2 \;+\; \lambda_v(1)^2} \;=\; 0 \,. \end{aligned} \tag{4.7}$$

After transforming the state equations (4.2) to the normalized time interval $[0,1]$ according to (3.3), we obtain a two-point BVP consisting of (4.2)–(4.8). This BVP can be further simplified by eliminating the variables $m(\tau)$ and $\lambda_m(\tau)$. The variable $m(\tau)$ is substituted according to

$$m(\tau) \;=\; 1.0 \;-\; \beta_{\max}\, T \cdot \tau, \tag{4.8}$$

and the variable λ_m can be dropped since it does not enter into the first three equations in (4.6). The reduced BVP then comprises the six ODEs with respect to the variables r, w, v, λ_r, λ_w, and λ_v on the fixed time interval $[0,1]$ and the trivial equation $dT/d\tau \equiv 0$ in view of (3.3). The corresponding boundary conditions are the six boundary conditions (4.3) with respect to r, w, and v and the Hamiltonian boundary condition in (4.7).

Once a solution of this BVP has been determined, the adjoint variable λ_m can be obtained through an integration of the last equation in (4.6):

$$\lambda_m(\tau) \;=\; T \cdot \int_\tau^1 \frac{\beta_{\max}\, c}{m(\tau)^2} \, \sqrt{\lambda_w(\tau)^2 \;+\; \lambda_v(\tau)^2} \, d\tau \,.$$

Alternatively, λ_m can be eliminated from the condition $H \equiv 0$.

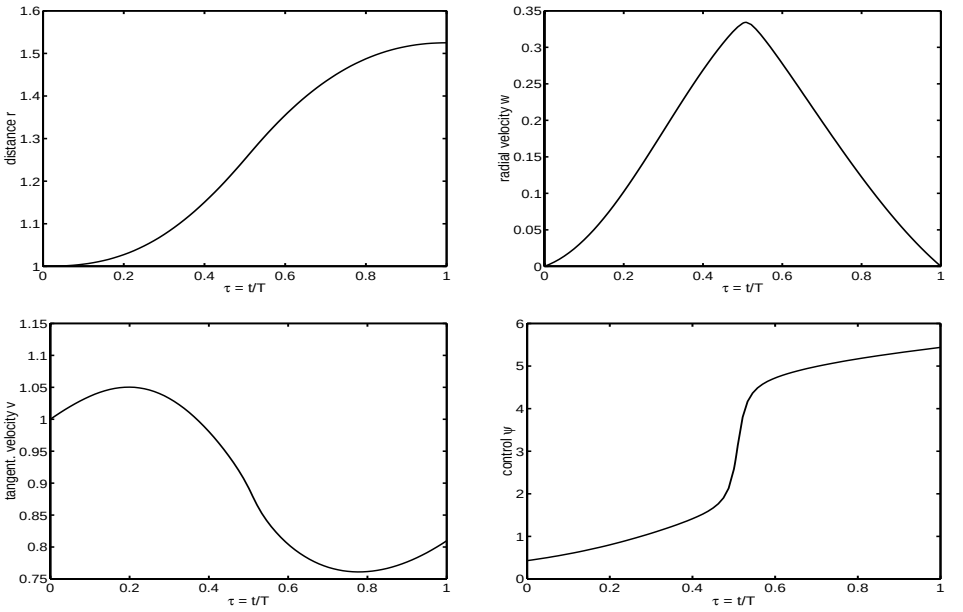

FIG. 4.1. *Earth-Mars transfer: State variables r, w, v and control variable ψ.*

The code BNDSCO in Oberle and Grimm [29] provides the following initial and final values for the adjoint variables and the final time:

$$\begin{aligned} \lambda_r(0) &= -0.52729\,67236 \times 10^1, \quad \lambda_r(1) = -0.37511\,95452 \times 10^1, \\ \lambda_w(0) &= -0.26088\,76037 \times 10^1, \quad \lambda_w(1) = 0.40004\,02548 \times 10^1, \\ \lambda_v(0) &= -0.56884\,53434 \times 10^1, \quad \lambda_v(1) = -0.35509\,23985 \times 10^1, \\ T &= 0.33199\,21219 \times 10^1. \end{aligned} \tag{4.9}$$

Figure 4.1 displays the corresponding state variables r, w, v and the control variable ψ, while Figure 4.2 shows the adjoint variables.

4.2. SSC. Let us first check the strict Legendre–Clebsch condition in assumption (A2), taking into account the scaling $\tilde{H}_{\psi\,\psi}[\tau] = T \cdot H_{\psi\,\psi}[\tau]$ in (3.20). We obtain

$$H_{\psi\,\psi} = \frac{\beta_{\max}\, c}{m} \sqrt{\lambda_w^2 + \lambda_v^2}$$

and find

$$\min\,\{\tilde{H}_{\psi\,\psi}[\tau] \mid \tau \in [\,0,1\,]\,\} = \tilde{H}_{\psi\,\psi}[\tau_0] = 0.07390\,1871 > 0, \quad \tau_0 = 0.50935\,25818\,,$$

which verifies the strict Legendre–Clebsch condition (A2). To prove the SSC in Theorem 3.1, it remains to show that the Riccati equations (3.24)–(3.26) possess a bounded solution such that the sign conditions (3.31) hold.

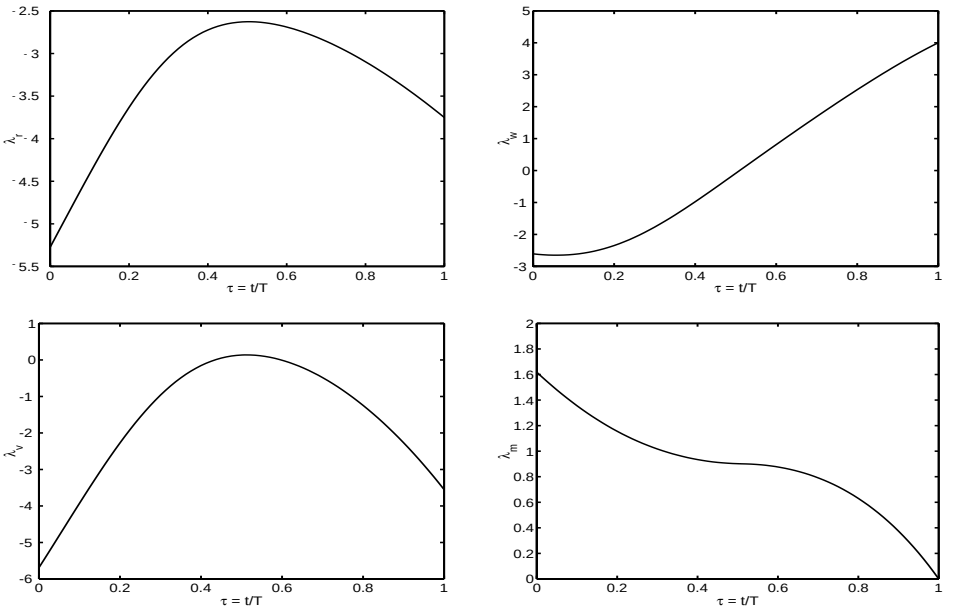

FIG. 4.2. *Earth-Mars transfer: Adjoint variables* λ_r, λ_w, λ_v, λ_m.

The reader is reminded that we have eliminated the state variable m so that the remaining state variables r, w, v have fixed final values. The symmetric Riccati matrix $\tilde{Q}$ in (3.23) is given in the form

$$\tilde{Q} = \begin{pmatrix} Q & R \\ R^* & q \end{pmatrix} = \left(\begin{array}{ccc|c} q_{11} & q_{12} & q_{13} & r_1 \\ q_{12} & q_{22} & q_{23} & r_2 \\ q_{13} & q_{23} & q_{33} & r_3 \\ \hline r_1 & r_2 & r_3 & q_T \end{array}\right).$$

We refrain from writing down the Riccati equations (3.24)–(3.26) explicitly. The evaluation is rather tedious but can be simplified with the help of symbolic computations offered, for example, in the package MAPLE. It should be noted that the coefficients of the Riccati equation are functions of the nominal trajectory characterized by (4.9). We merely indicate how to find appropriate initial values for $\tilde{Q}(0)$ such that the sign conditions (3.31) hold:

$$q_T(0) > 0, \quad q_T(1) < 0.$$

We succeeded using a rather heuristic optimization technique. Starting with initial estimates for $Q(0)$ which allowed the integration of (3.24)–(3.26) on $[0, 1]$, we changed iteratively one component of $Q(0)$ in order to minimize $q_T(1)$. Changing the indices of components in a cyclic way, we got the following initial values:

$$\begin{array}{rcrrcrrcr} q_{11}(0) & = & 1.0, & q_{12}(0) & = & 2.0, & q_{13}(0) & = & 1.0, \\ q_{22}(0) & = & -50.0, & q_{23}(0) & = & -10.0, & q_{33}(0) & = & -100.0, \\ r_1(0) & = & 80.0, & r_2(0) & = & 40.0, & r_3(0) & = & 100.0, \\ q_T(0) & = & 10.0 > 0. & & & & & & \end{array}$$

For these data, a solution of the Riccati equations was found to exist on the whole interval $[0, 1]$ with final value $q_T(1) = -18.090\,44002 < 0$. Hence all assumptions for

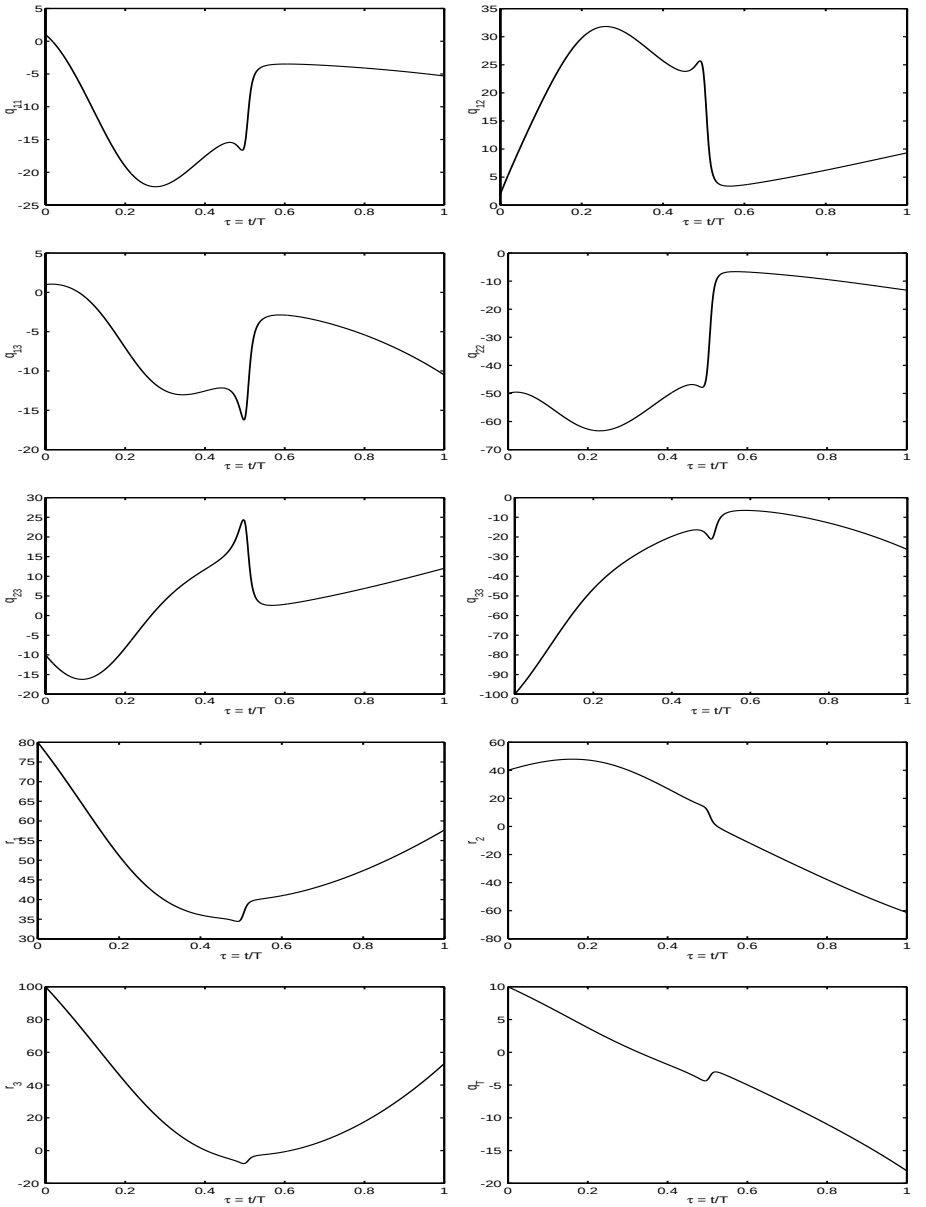

FIG. 4.3. *Solutions of the Riccati equations* (3.24)–(3.26).

Theorem 3.1 are verified, and we draw the conclusion that the trajectory characterized by (4.9) provides a weak local minimum for problem (4.1)–(4.3). The component functions of $\tilde{Q}[\tau]$ are shown in Figure 4.3.

5. Control of current in a tunnel-diode oscillator: Rayleigh problem with control constraints. The following Rayleigh problem has been treated in [13, 36] as a *fixed* final time control problem. SSC and sensitivity analysis for this model have been discussed in Maurer and Augustin [23]. In this section, we investigate a slightly modified problem with *free* final time. Figure 5.1 displays an electric circuit

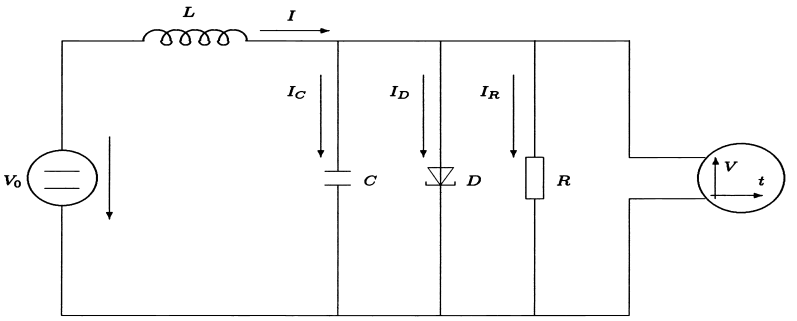

FIG. 5.1. *Tunnel-diode oscillator,* $x_1(t) = I(t)$.

(tunnel-diode oscillator), where L denotes inductivity, C denotes capacity, R denotes resistance, I denotes electric current, and D is a diode. The state variables are the electric current $x_1(t) = I(t)$ at time $t \in [\,0, T\,]$ and $x_2(t) := \dot{x}_1(t)$. The control $u(t)$ is a suitable transformation of the voltage V_0 at the generator.

With an additional parameter $c \geq 0$, the Rayleigh problem with *free* final time is defined as follows: minimize the functional

$$F_c(x, T, u) = c \cdot T + \int_0^T (\, u(t)^2 + x_1(t)^2 \,)\, dt \;=\; \int_0^T (\, c + u(t)^2 + x_1(t)^2 \,)\, dt \tag{5.1}$$

subject to

$$\dot{x}_1(t) = x_2(t)\,,\ \dot{x}_2(t) = -x_1(t) + x_2(t)\,(\,1.4 - 0.14\,x_2(t)^2\,) + 4\,u(t)\,, \tag{5.2}$$

$$x_1(0) = x_2(0) = -5\,, \quad x_1(T) = x_2(T) = 0\,, \tag{5.3}$$

$$|\,u(t)\,| \leq 1 \quad \text{for } t \in [0, T\,]\,. \tag{5.4}$$

The solution of this problem with final time $T = 4.5$ specified and $c = 0$ may be found in [23]. In the following, we denote by $F_c(T)$ the optimal value of the control problem (5.1)–(5.4) for *fixed* final time T. The behavior of this function gives insight into the behavior of optimal solutions for *free* final time.

5.1. Unconstrained optimal solutions. We consider the unconstrained problem with control constraint (5.4) deleted. After applying the time transformation (3.2), the unconstrained Hamiltonian in (3.12) becomes

$$\tilde{H}^0(\tilde{x}, u, \tilde{\lambda}) = T \cdot [\, c + u^2 + x_1^2 + \lambda_1 x_2 + \lambda_2\,(-x_1 + x_2\,(1.4 - 0.14 x_2^2) + 4u)\,]. \tag{5.5}$$

Henceforth, we omit the lower index zero to denote the optimal solution. The control is computed from the equation $\tilde{H}_u^0[\tau] = 0$, which yields

$$u(\tau) = -2\lambda_2(\tau)\,.$$

The transformed state equations (3.3) and adjoint equations (3.13) lead to the following ODEs in $[0, 1]$:

$$\begin{aligned} dx_1/d\tau &= T \cdot x_2, \\ dx_2/d\tau &= T \cdot (-x_1 + 1.4x_2 - 0.14x_2^3 - 8\lambda_2), \\ d\lambda_1/d\tau &= T \cdot (-2x_1 + \lambda_2), \\ d\lambda_2/d\tau &= T \cdot (-\lambda_1 - 1.4\lambda_2 + 0.42x_2^2\lambda_2). \end{aligned} \tag{5.6}$$

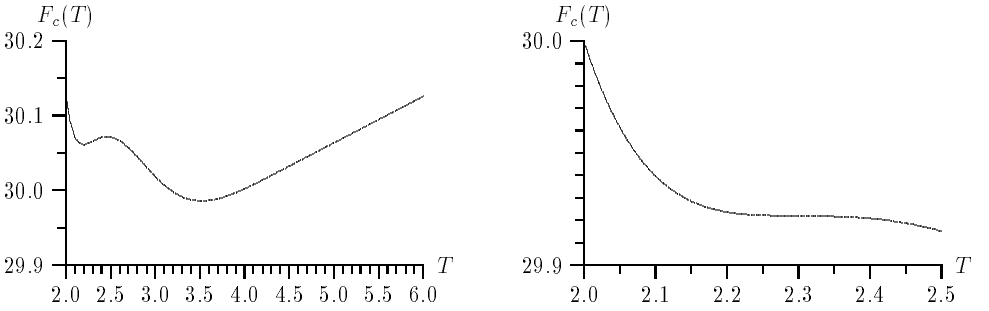

FIG. 5.2. *Graph of* $F_c(T)$ *for* $c = 1/16$ *and* $c = 0$.

To compute the optimal solution of the control problem with *fixed* final time, we resolve the BVP which comprises (5.6) and the boundary conditions

$$x_1(0) = x_2(0) = -5, \quad x_1(1) = x_2(1) = 0\,. \tag{5.7}$$

The BVP is solvable only for final times $T > T^* > 0$, where T^* is a suitable final time. The optimal value function $F_c(T)$ is shown in Figure 5.2 for $T > T^* = 2$ and two different values $c = 1/16$ and $c = 0$. Observe that, for $c = 1/16$, the graph of $F_c(T)$ in Figure 5.2 depicts two local minima and one local maximum with respect to the final time T, whereas no clear minimum can be discerned for $c = 0$.

For *free* final time T, the transversality condition (3.19) and the boundary conditions (5.7) yield $0 = \tilde{H}^0[1] = T \cdot (c + u(1)^2 + 4\lambda_2(1)u(1)) = T \cdot (c - 4\lambda_2(1)^2)$, from which we get the boundary condition

$$\lambda_2(1)^2 = c/4\,. \tag{5.8}$$

Now we solve the BVP (5.6)–(5.8) for the cases $c = 1/16$ and $c = 0$, using again the code BNDSCO in [29].

Case $c = 1/16$. We find three solutions:

Solution 1:	T	=	2.19460 79912,	$F_c(T)$	=	30.06097 62322,
	$\lambda_1(0)$	=	−9.01234 54748,	$\lambda_1(1)$	=	0.97693 36044,
	$\lambda_2(0)$	=	−2.67606 29500,	$\lambda_2(1)$	=	0.125.
Solution 2:	T	=	2.46029 38602,	$F_c(T)$	=	30.07173 02593,
	$\lambda_1(0)$	=	−9.01228 20002,	$\lambda_1(1)$	=	0.95904 74639,
	$\lambda_2(0)$	=	−2.67605 43511,	$\lambda_2(1)$	=	−0.125.
Solution 3:	T	=	3.51535 36980,	$F_c(T)$	=	29.98534 49252,
	$\lambda_1(0)$	=	−9.01085 93855,	$\lambda_1(1)$	=	0.15146 20116,
	$\lambda_2(0)$	=	−2.67586 16249,	$\lambda_2(1)$	=	−0.125.

It is obvious that these three solutions correspond to the two local minima and one local maximum shown in Figure 5.2. Note that $\lambda_2(1)$ changes sign when passing from solution 1 to solutions 2 and 3.

Now let us show that solution 3 indeed provides a local minimum. The respective optimal control, state, and adjoint variables are displayed in Figure 5.3. The

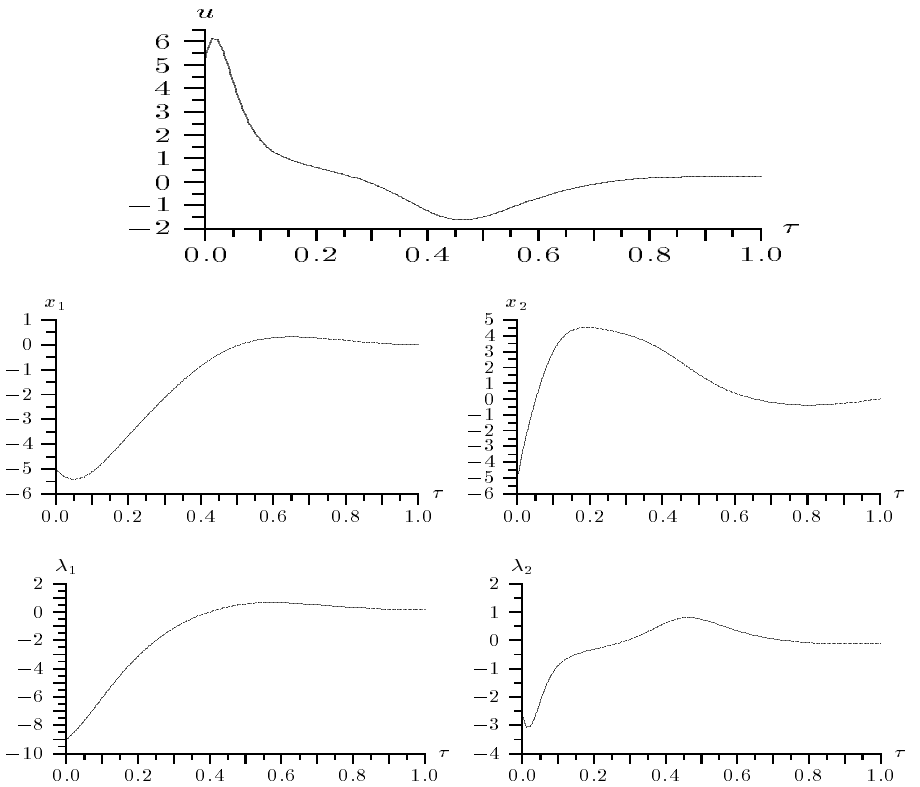

FIG. 5.3. *Optimal control, state, and adjoint variables for* $c = 1/16$ *and* $T = 3.5153536980$.

Legendre–Clebsch condition (A2) trivially holds in view of $\tilde{H}^0_{uu}[\tau] \equiv 2 \cdot T > 0$. Next we verify that the Riccati equations (3.24)–(3.26) have a bounded solution such that the boundary conditions (3.31) hold in the relaxed forms $q_T(0) \geq 0$ and $q_T(1) < 0$. The matrix (3.23) becomes

$$\widetilde{Q} = \begin{pmatrix} Q & R \\ R^* & q \end{pmatrix} =: \left(\begin{array}{cc|c} q_1 & q_2 & r_1 \\ q_2 & q_4 & r_2 \\ \hline r_1 & r_2 & q_T \end{array}\right), \tag{5.9}$$

for which we evaluate the Riccati equations (3.24)–(3.26) as

$$\begin{aligned}
dq_1/d\tau &= T \cdot [\, 2q_2 - 2 + 8q_2^2 \,], \\
dq_2/d\tau &= T \cdot [\, -q_1 - (1.4 - 0.42x_2^2)q_2 + q_4 + 8q_2q_4 \,], \\
dq_4/d\tau &= T \cdot [\, -2(q_2 + (1.4 - 0.42x_2^2)q_4) + 0.84x_2\lambda_2 + 8q_4^2 \,], \\
dr_1/d\tau &= -q_1x_2 - q_2(-x_1 + 1.4x_2 - 0.14x_2^3 - 8\lambda_2) + Tr_2 \\
&\quad -2x_1 + \lambda_2 + 8Tq_2r_2\,, \\
dr_2/d\tau &= -q_2x_2 - q_4(-x_1 + 1.4x_2 - 0.14x_2^3 - 8\lambda_2) - Tr_1 \\
&\quad -T \cdot (1.4 - 0.42x_2^2)r_2 - \lambda_1 - \lambda_2(1.4 - 0.42x_2^2) + 8Tq_4r_2\,, \\
dq_T/d\tau &= -2[\, r_1x_2 + r_2(-x_1 + 1.4x_2 - 0.14x_2^3 - 8\lambda_2) \,] + 8Tr_2^2\,.
\end{aligned} \tag{5.10}$$

It suffices to find a bounded solution of these Riccati equations satisfying $q_T(0) = 0$. After several trials, we were successful with the initial values

$$\begin{array}{lll} q_1(0) = 2.00684\,76891, & q_2(0) = 0.47018\,97048, & q_4(0) = -0.35197\,44265, \\ r_1(0) = 0, & r_2(0) = 0, & q_T(0) = 0, \end{array}$$

for which we get the final values,

$$\begin{array}{lll} q_1(1) = 0, & q_2(1) = 0, & q_4(1) = 0, \\ r_1(1) = -0.125 = \lambda_2(1), & r_2(1) = 0.02353\,79884, & q_T(1) = -r_2(1) < 0, \end{array}$$

and the bound $||\widetilde{Q}(\tau)||_\infty \leq 3$ for all $\tau \in [0,1]$. Hence Theorem 3.1 asserts that solution 3 is indeed a weak local minimum. We mention that the sufficient conditions in Hull [12] can also be checked numerically for solution 3.

In a similar way, we can test the optimality of solution 1 with $T = 2.1946\,079912$. We obtain a bounded solution of the Riccati equation for initial values

$$\begin{array}{lll} q_1(0) = 1.59068\,73787, & q_2(0) = 0.33016\,84322, & q_4(0) = -0.39917\,54076, \\ r_1(0) = 0, & r_2(0) = 0, & q_T(0) = 0 \end{array}$$

and final values

$$\begin{array}{lll} q_1(1) = 0, & q_2(1) = 0, & q_4(1) = 0, \\ r_1(1) = 0.125 = \lambda_2(1), & r_2(1) = -1.15193\,36046, & q_T(1) = r_2(1) < 0. \end{array}$$

These values yield the bound $||\widetilde{Q}(\tau)||_\infty \leq 5$ for all $\tau \in [0,1]$.

The situation is different for solution 2, which provides a *local maximum* with respect to the final time T. All initial values $q_T(0) \geq 0$ that we tested produce a solution of the Riccati equation with $q_T(1) \geq 0$. Though this test does not exclude optimality of the solution, it is a rather strong indication of nonoptimality. Thus we may draw the conclusion that solution 2 behaves like a *saddle point solution*, which is a local minimum with respect to control for every fixed time but a local maximum with respect to final time.

Case $c = 0$. Here the situation is more complicated since Figure 5.2 does not indicate a distinctive local minimum. The code BNDSCO of [29] provides, e.g., the following two solutions:

$$\begin{array}{lrcrrcr} \text{Solution 1:} & T & = & 2.29903\,95815, & F_c(T) & = & 29.9218\,12616, \\ & \lambda_1(0) & = & -9.00409\,78999, & \lambda_1(1) & = & 1.00813\,43679, \\ & \lambda_2(0) & = & -2.67325\,14651, & \lambda_2(1) & = & 0. \end{array}$$

$$\begin{array}{lrcrrcr} \text{Solution 2:} & T & = & 4.50237\,87337, & F_c(T) & = & 29.75107\,51464, \\ & \lambda_1(0) & = & -9.00247\,06599, & \lambda_1(1) & = & -0.0044561\,06307, \\ & \lambda_2(0) & = & -2.67303\,08344, & \lambda_2(1) & = & 0. \end{array}$$

Solving the Riccati equation (5.10), e.g., for the final time $T = 2.2990\ 395815$, we find that the initial value $q_T(0) = 0$ produces the final value $q_T(1) = 0$ in all tested cases. Thus the sign conditions (3.29) cannot be verified, and the Riccati test is not able to detect whether solution 1 is a local minimum.

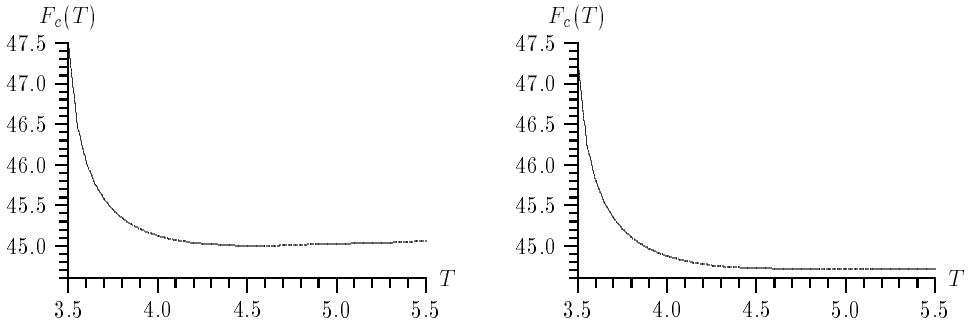

FIG. 5.4. *Graph of* $F_c(T)$ *for control constraint* $|u| \le 1$: *Cases* $c = 1/16$ *and* $c = 0$.

5.2. Constrained optimal solutions. Now we consider solutions satisfying, in addition, the control constraint (5.4),

$$-1 \le u(\tau) \le 1 \quad \forall\ \tau \in [0,1]\,.$$

The augmented Hamiltonian (3.12) becomes, in view of (5.5),

$$\begin{aligned}(5.11)\quad \tilde{H}(\tilde{x},u,\tilde{\lambda},\tilde{\mu}) &= \tilde{H}^0(\tilde{x},u,\tilde{\lambda}) + \tilde{\mu}_1(-u-1) + \tilde{\mu}_2(u-1)\\ &= T\cdot\left[\, c + u^2 + x_1^2 + \lambda_1 x_2 + \lambda_2\left(-x_1 + x_2\,(1.4 - 0.14x_2^2) + 4u\right)\right.\\ &\qquad \left. + \mu_1(-u-1) + \mu_2(u-1)\,\right],\end{aligned}$$

where $\mu_i := \tilde{\mu}/T$, $i = 1,2$, are the scaled multipliers. The state and adjoint equations agree with those given in (5.6). Again, we get the control law $u(\tau) = -2\lambda_2(\tau)$ on interior arcs $|u(\tau)| < 1$. The *unconstrained* control $u(\tau)$ depicted in Figure 5.3 suggests that the *constrained* control has one boundary arc with $u(\tau) \equiv 1$ and one boundary arc with $u(\tau) \equiv -1$. Thus we may assume the following solution structure of the optimal control:

$$(5.12)\qquad u(\tau) = \left\{\begin{array}{rl} 1, & 0 \le \tau \le \tau_1\\ -2\lambda_2(\tau), & \tau_1 \le \tau \le \tau_2\\ -1, & \tau_2 \le \tau \le \tau_3\\ -2\lambda_2(\tau), & \tau_3 \le \tau \le 1\end{array}\right\}.$$

The junction points τ_1, τ_2, τ_3 are implicitly determined through the conditions that the control is *continuous* at these points. This leads to the junction conditions

$$(5.13)\qquad \lambda_2(\tau_1) = -0.5, \quad \lambda_2(\tau_2) = 0.5, \quad \lambda_2(\tau_3) = -0.5\,.$$

Hence, on the interval $[0,1]$, we have to solve the multipoint BVP, which is composed by the state and adjoint equations (5.6) with control substituted from (5.12) as well as the boundary and junction conditions (5.7) and (5.13).

The optimal value function $\tilde{F}_c(T)$ for the constrained problem is depicted in Figure 5.4 for the values $c = 1/16$ and $c = 0$. A distinctive minimum can only be detected in case $c = 1/16$.

Case $c = 1/16$. Again we use the code BNDSCO in [29] and obtain

$$\begin{array}{rclrcl} T &=& 4.54230\,98018, & \tau_1 &=& 0.22932\,06694,\\ \tau_2 &=& 0.37589\,55717, & \tau_3 &=& 0.63465\,63122,\\ \lambda_1(0) &=& -12.70813\,77440, & \lambda_1(1) &=& 0.02860\,41331,\\ \lambda_2(0) &=& -4.59503\,53190, & \lambda_2(1) &=& -0.125,\\ F_c(T) &=& 44.71797\,06589. & & & \end{array}$$

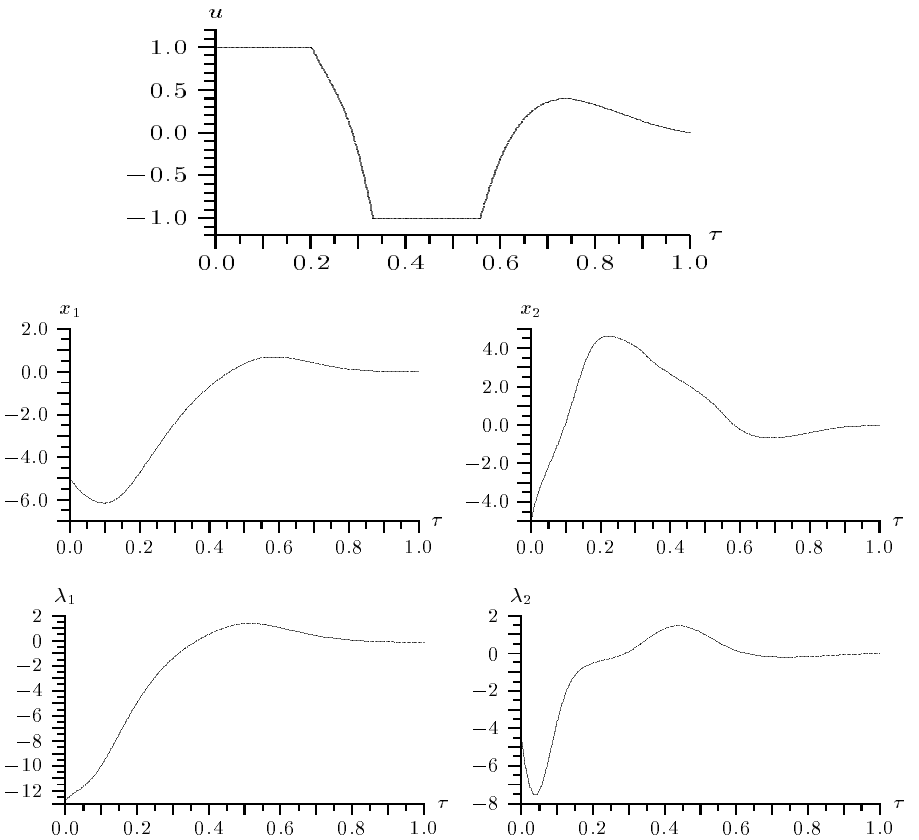

FIG. 5.5. *Optimal control, state, and adjoint variables for* $c = 1/16$ *and* $T = 4.54230\ 98018$.

The corresponding optimal control, state, and adjoint variables are shown in Figure 5.5. In order to check the sufficient conditions in Theorem 3.1, we try to find a *bounded* solution of the Riccati equations (5.10) on the *interior arcs* $[\tau_1, \tau_2]$ and $[\tau_3, 1]$ and the *modified* Riccati equations (3.30) on the *boundary arcs* $[0, \tau_1]$ and $[\tau_2, \tau_3]$. The modified Riccati equations yield the following *linear* equations:

$$
\begin{aligned}
dq_1/d\tau &= T \cdot 2(q_2 - 1)\,, \\
dq_2/d\tau &= T \cdot [\,-q_1 - (1.4 - 0.42x_2^2)q_2 + q_4\,]\,, \\
dq_4/d\tau &= T \cdot [\,-2(q_2 + (1.4 - 0.42x_2^2)q_4) + 0.84x_2\lambda_2\,]\,, \\
dr_1/d\tau &= -q_1x_2 - q_2(-x_1 + 1.4x_2 - 0.14x_2^3 + 4u) + Tr_2 - 2x_1 + \lambda_2\,, \\
dr_2/d\tau &= -q_2x_2 - q_4(-x_1 + 1.4x_2 - 0.14x_2^3 + 4u) - Tr_1 \\
&\quad -T \cdot (1.4 - 0.42x_2^2)r_2 - \lambda_1 - \lambda_2(1.4 - 0.42x_2^2)\,, \\
dq_T/d\tau &= -2\,[\,r_1x_2 + r_2(-x_1 + 1.4x_2 - 0.14x_2^3 + 4u)\,]\,.
\end{aligned}
\tag{5.14}
$$

We wish to find a solution satisfying the terminal values $q_1(1) = q_2(1) = q_4(1) = 0$. A bounded solution of the Riccati equations then is obtained for the initial values

$$
\begin{aligned}
&q_1(0) = 2.39837121, \quad q_2(0) = 0.89021498, \quad q_4(0) = -1.26573031, \\
&r_1(0) = 0, \qquad\qquad r_2(0) = 0, \qquad\qquad q_T(0) = 0,
\end{aligned}
$$

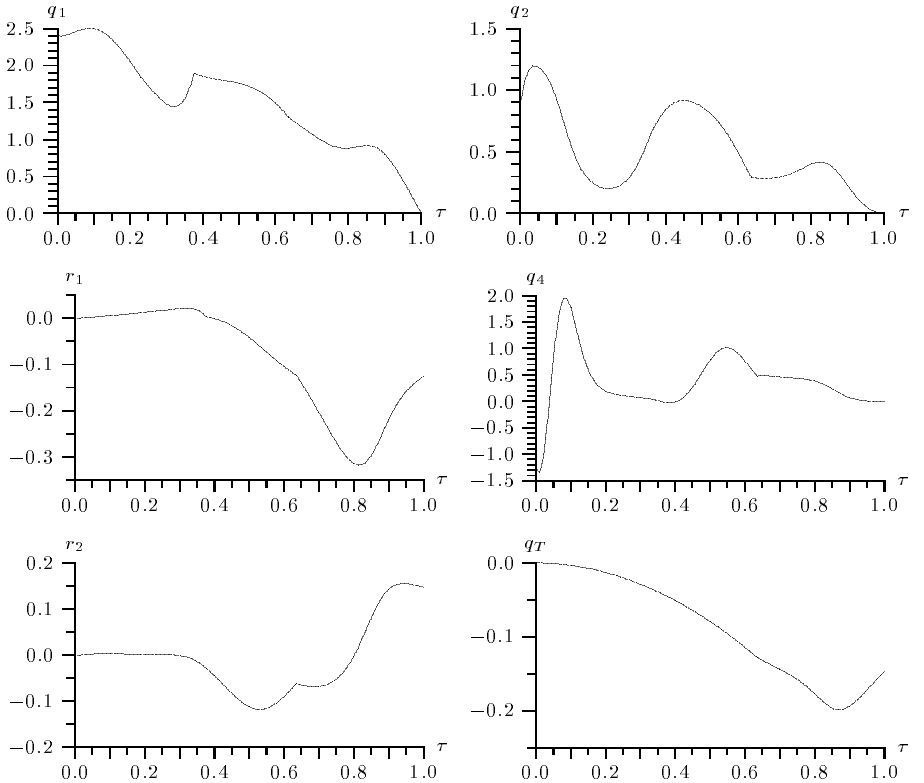

FIG. 5.6. *Solutions* $q_1, q_2, q_4, r_1, r_2, q_T$ *of Riccati equations* (5.10) *and* (5.14) *for* $c = 1/16$ *and* $T = 4.54230\ 98018$.

which produce the desired terminal values for q_1, q_2, q_4 and

$$r_1(1) = -0.125 = \lambda_2(1), \quad r_2(1) = 0.146395866, \quad q_T(1) = -r_2(1) < 0\,.$$

For these values, we get the bound $||\widetilde{Q}(\tau)||_\infty \leq 4$ for all $\tau \in [0,1]$, which can be seen in Figure 5.6. It is interesting to note that it was not possible to obtain a *bounded solution* of the Riccati equation (5.10) on the *whole interval*. Thus the Riccati test developed in section 3 in its weaker form considerably facilitates the numerical check of SSC.

Case $c = 0$. The code BNDSCO yields the solution

$$\begin{aligned}
T &= 5.15173\,31990, & \tau_1 &= 0.20192\,87957,\\
\tau_2 &= 0.33186\,51046, & \tau_3 &= 0.55797\,03824,\\
\lambda_1(0) &= -12.70087\,48310, & \lambda_1(1) &= 0.09649\,19382,\\
\lambda_2(0) &= -4.58996\,79054, & \lambda_2(1) &= 0,\\
\tilde{F}_{c=0}(T) &= 44.70866\,79043.
\end{aligned}$$

Evaluating the Riccati equations (5.10) and (5.14) along this specific solution, we were not able to find a bounded solution satisfying the sign conditions $q_T(0) \geq 0$ and $q_T(1) < 0$. This fact confirms our impression gained from Figure 5.4 that no local minimum can be identified for $c = 0$.

Acknowledgments. We are indebted to D. Augustin, Ch. Beckmann, and J. Strade for numerical assistance with the examples. We would like to thank an anonymous reviewer for helpful remarks.

STOCHASTIC TARGET PROBLEMS, DYNAMIC PROGRAMMING, AND VISCOSITY SOLUTIONS*

H. METE SONER† AND NIZAR TOUZI‡

Abstract. In this paper, we define and study a new class of optimal stochastic control problems which is closely related to the theory of backward SDEs and forward-backward SDEs. The controlled process (X^ν, Y^ν) takes values in $\mathbb{R}^d \times \mathbb{R}$ and a given initial data for $X^\nu(0)$. Then the control problem is to find the minimal initial data for Y^ν so that it reaches a stochastic target at a specified terminal time T. The main application is from financial mathematics, in which the process X^ν is related to stock price, Y^ν is the wealth process, and ν is the portfolio.

We introduce a new dynamic programming principle and prove that the value function of the stochastic target problem is a discontinuous viscosity solution of the associated dynamic programming equation. The boundary conditions are also shown to solve a first order variational inequality in the discontinuous viscosity sense. This provides a unique characterization of the value function which is the minimal initial data for Y^ν.

Key words. stochastic control, dynamic programming, discontinuous viscosity solutions, forward-backward SDEs

1. Introduction.

Let $(\Omega, \mathcal{F}, P)$ be a probability space, $T > 0$, and let $\{W(t), 0 \le t \le T\}$ be a d-dimensional Brownian motion whose P-completed natural filtration is denoted by $\mathbb{F}$. Given a control process $\nu = \{\nu(t),\ 0 \le t \le T\}$ with values in the control set $\mathcal{U}$, we consider the controlled process $Z_y^\nu = (X_y^\nu, Y_y^\nu) \in \mathbb{R}^d \times \mathbb{R}$ satisfying

$$dZ(t) = \alpha\left(t, Z(t), \nu(t)\right)\, dt + \beta\left(t, Z(t), \nu(t)\right)\, dW(t), \qquad 0 \le t < T, \tag{1.1}$$

together with the initial data $Z^\nu(0) = (X(0), y)$.

For a given real-valued function g, the stochastic target control problem is to minimize the initial data y while satisfying the random constraint $Y_y^\nu(T) \ge g(X_y^\nu(T))$ with probability one, i.e.,

$$v(0, X(0)) := \inf\left\{y \in \mathbb{R} \ :\ \exists\, \nu \in \mathcal{U},\ \ Y_y^\nu(T) \ge\ g\left(X_y^\nu(T)\right) \quad P - \text{a.s.}\right\},$$

which we call the stochastic target problem.

The chief goal of this paper is to obtain a characterization of the value function v as a discontinuous viscosity solution of an associated Hamilton–Jacobi–Bellman (HJB) second order PDE with suitable boundary conditions. We do not address the important uniqueness issue associated to the HJB equation in this paper. We simply refer to Crandall, Ishii, and Lions [5] for some general uniqueness results.

The main step in the derivation of the above-mentioned PDE characterization is a nonclassical dynamic programming principle. To the best of our knowledge, this

dynamic programming is new; it was only partially used by the authors in a previous paper [23].

This dynamic programming principle is closely related to the theory of viscosity solutions. In the derivation of the supersolution property of the HJB equation, the notion of viscosity solutions is only used to handle the lack of a priori regularity of the value function. However, the use of the notion of viscosity solutions seems necessary in order to derive the subsolution property from our dynamic programming principle, even if the value function were known to be smooth.

This study is mainly motivated by applications to financial mathematics. Indeed, a special specification of the coefficients α and β (see section 6) leads to the so-called superreplication problem; see, e.g., El Karoui and Quenez [11], Cvitanić and Karatzas [6], Broadie, Cvitanić, and Soner [4], Cvitanić, Pham, and Touzi [9], and Cvitanić and Ma [8].

In the financial mathematics literature, the superreplication problem is usually solved via convex duality. In this approach, a classical optimal control problem is derived by first applying the duality; see Jouini and Kallal [15], El Karoui and Quenez [11], Cvitanić and Karatzas [6], and Föllmer and Kramkov [13]. Then, one may use classical dynamic programming to obtain the PDE characterization of the value function v. However, this method cannot be applied to the general stochastic target problem because of the presence of the control ν in the diffusion part of the state process X^ν. The methodology developed in this paper precisely allows us to avoid this step and to obtain the PDE characterization directly from the initial (nonclassical) formulation of the problem without using the duality.

The stochastic target problem is also closely related to the theory of backward SDEs and forward-backward SDEs; see Antonelli [1], Cvitanić, Karatzas, and Soner [7], Hu and Peng [16], Ma, Protter, and Yong [18], Ma and Yong [19], Pardoux [20], and Pardoux and Tang [21]. Indeed, an alternative formulation of the problem is this: find a triple of $\mathbb{F}$-adapted processes (X, Y, ν) satisfying

$$(1.2)\quad (X,Y)\ \text{ solves }\ (1.1)\ \text{ with }\ \nu \in \mathcal{U}, X(0)\ \text{ fixed, }\ Y(T) + A(T) = g(X(T))$$

for some nondecreasing $\mathbb{F}$-adapted process A with $A(0) = 0$ as well as the minimality condition

$$(\tilde{X}, \tilde{Y}, \tilde{\nu}, \tilde{A})\ \text{ satisfies }\ (1.2) \Longrightarrow Y(.)\ \le\ \tilde{Y}(.) \quad P - \text{a.s.}$$

Notice that the nondecreasing process A is involved in the above definition to account for possible constraints on the control ν; see [7]. In financial applications, this connection has been observed by Cvitanić and Ma [8] and El Karoui, Peng, and Quenez [12].

The paper is organized as follows: the definition of the stochastic target problem is formulated in section 2. In section 3, we state the dynamic programming principle. Section 4 studies the HJB equation satisfied by the value function v in the discontinuous viscosity sense. In section 5, the terminal condition of the problem is characterized by a first order variational inequality again in the discontinuous viscosity sense. Finally, in section 6, we apply our results to the problem of superreplication under portfolio constraints in a large investor financial market.

2. Stochastic target problem. In this section, we define a nonstandard stochastic control problem.

Let $T > 0$ be the finite time horizon, and let $W = \{W(t),\ 0 \le t \le T\}$ be a d-dimensional Brownian motion defined on a complete probability space $(\Omega, \mathcal{F}, P)$.

We denote by $\mathbb{F} = \{\mathcal{F}(t),\, 0 \le t \le T\}$ the P-augmentation of the filtration generated by W.

We assume that the control set U is a convex compact subset of $\mathbb{R}^d$ with a nonempty interior, and we denote by $\mathcal{U}$ the set of all progressively measurable processes $\nu = \{\nu(t),\, 0 \le t \le T\}$ with values in U.

The state process is defined as follows: given the initial datum $z = (x, y) \in \mathbb{R}^d \times \mathbb{R}$, an initial time $t \in [0, T]$, and a control process $\nu \in \mathcal{U}$, let the controlled process $Z^\nu_{t,z} = (X^\nu_{t,x}, Y^\nu_{t,z})$ be the solution of the SDE

$$dX^\nu_{t,x}(u) \;=\; \mu\left(u, X^\nu_{t,x}(u), \nu(u)\right) du + \sigma^*\left(u, X^\nu_{t,x}(u), \nu(u)\right) dW(u), \qquad u \in (t, T),$$

$$dY^\nu_{t,x,y}(u) \;=\; b\left(u, Z^\nu_{t,z}(u), \nu(u)\right) du + a^*\left(u, Z^\nu_{t,z}(u), \nu(u)\right) dW(u), \qquad u \in (t, T),$$

with initial data

$$X^\nu_{t,x}(t) \;=\; x, \qquad\qquad Y^\nu_{t,x,y}(t) \;=\; y,$$

where M^* denotes the transpose of the matrix M, and μ, σ, b, a are bounded functions on $[0, T] \times \mathbb{R}^k \times U$ ($k = d$ or $d + 1$) satisfying the usual conditions in order for the process $Z^\nu_{t,z}$ to be well defined.

Throughout the paper, we assume that the matrix $\sigma(t, x, r)$ is invertible and the function

$$r \mapsto \sigma^{-1}(t, x, r) a(t, x, y, r)$$

is one to one for all (t, x, y). Let ψ be its inverse; i.e.,

$$\sigma^{-1}(t, x, r) a(t, x, y, r) \;=\; p \quad \Longleftrightarrow \quad r \;=\; \psi(t, x, y, p). \tag{2.1}$$

This is a crucial assumption which enables us to match the stochastic parts of the X and the Y processes by a judicial choice of the control process ν. Similar assumptions were also utilized in the backward-forward SDEs. See also Remark 2.2.

Now we are in a position to define the "stochastic target" control problem. Let g be a real-valued measurable function defined on $\mathbb{R}^d$. We shall denote by $\mathcal{E}pi(g) := \{(x, y) \in \mathbb{R}^d \times \mathbb{R} :\, y \ge g(x)\}$ the epigraph of g. Let

$$v(t, x) := \inf\left\{y \in \mathbb{R} \;:\; \exists\, \nu \in \mathcal{U}\,,\; Z^\nu_{t,x,y}(T) \;\in\; \mathcal{E}pi(g) \;\; P - \text{a.s.}\right\}. \tag{2.2}$$

In some cases, it is possible to find initial datum and a control so that $Y^\nu_{t,x,y}(T) = g(X^\nu_{t,x}(T))$. In that case, this problem is equivalent to a backward-forward SDE; see the discussion in our introduction. In particular, when $U = \mathbb{R}^d$, the corresponding backward-forward SDE has a solution (see, e.g., [21]), and it is equal to v. However, when the control set U is bounded, in general there is no solution of the backward-forward equation, and v is the natural generalization of the backward-forward SDE. An alternative generalization can be obtained by involving a nondecreasing process, as discussed in the introduction; see [7].

We conclude this section by introducing several sets to simplify the notation. Let

$$\mathcal{A}(t, x, y) := \left\{\nu \in \mathcal{U} \;:\; Z^\nu_{t,x,y}(T) \;\in\; \mathcal{E}pi(g) \;\; P - \text{a.s.}\right\}.$$

Note that $\mathcal{A}(t, x, y)$ may be empty for some initial datum (t, x, y). Next we define

$$\mathcal{Y}(t, x) := \left\{y \in \mathbb{R} \;:\; \mathcal{A}(t, x, y) \neq \emptyset\right\}.$$

Then the stochastic target problem can be written as

$$v(t,x) \;=\; \inf \mathcal{Y}(t,x) = \inf \left\{ y \in \mathbb{R} \;:\; \; y \in \mathcal{Y}(t,x) \right\}.$$

Remark 2.1. The set $\mathcal{Y}(t,x)$ satisfies the following important property:

$$\text{for all } \; y \in \mathbb{R}, \;\; y \in \mathcal{Y}(t,x) \implies [y,\infty) \subset \mathcal{Y}(t,x).$$

This follows from the facts that $X^{\nu}_{t,x}$ is independent of y and $Y^{\nu}_{t,x,y}(T)$ is nondecreasing in y.

Remark 2.2. A more general formulation of this problem, as discussed in our accompanying paper [24], is obtained by defining the *reachability set* of the deterministic target $\mathcal{E}pi(g)$:

$$V(t) := \left\{ z \in \mathbb{R}^{d+1} \;:\; Z^{\nu}_{t,z}(T) \in \mathcal{E}pi(g) \; P-\text{a.s. for some } \nu \in \mathcal{A} \right\}.$$

From the previous remark, the set $V(t)$ is "essentially" characterized as the epigraph of the scalar function $v(t,.)$. A standing assumption in [24] is

$$\mathcal{N}(t,z,p) := \left\{ \nu \in \mathbb{R}^d \;:\; [\sigma|a](t,z,\nu) \begin{bmatrix} p \\ -1 \end{bmatrix} = 0 \right\} \neq \emptyset;$$

i.e., since we wish to hit the deterministic target $\mathcal{E}pi(g)$ with probability one, the diffusion process has to degenerate along certain directions captured by the kernel $\mathcal{N}$. This degeneracy assumption is directly related to our condition (2.1).

3. Dynamic programming. In this section, we introduce a new dynamic programming equation for the stochastic target problem. This will allow us to characterize the value function of the stochastic target problem as a viscosity solution of a nonlinear PDE. For the classical stochastic control problem, this connection between the dynamic programming principle and the PDEs is well known (see, e.g., [14]). The chief goal of this paper is to develop the same tools for this nonstandard target control problem. Namely, we will formulate an appropriate dynamic programming principle and then derive the corresponding nonlinear PDE as a consequence of it.

A discussion of general dynamic programming of this type is the subject of an accompanying paper by the authors [24].

THEOREM 3.1. *Let* $(t,x) \in [0,T] \times \mathbb{R}^d$.

(DP1) *For any* $y \in \mathbb{R}$, *set* $z := (x,y)$. *Suppose that* $\mathcal{A}(t,z) \neq \emptyset$. *Then, for all* $\nu \in \mathcal{A}(t,z)$ *and a* $[t,T]$*-valued stopping time* θ,

$$Y^{\nu}_{t,x,y}(\theta) \geq v\left(\theta, X^{\nu}_{t,x}(\theta)\right) \qquad P-a.s.$$

(DP2) *Set* $y^* := v(t,x)$. *Let* θ *be an arbitrary* $[t,T]$*-valued stopping time. Then, for all* $\nu \in \mathcal{U}$ *and* $\eta > 0$,

$$P\left[Y^{\nu}_{t,x,y^*-\eta}(\theta) \;>\; v\left(\theta, X^{\nu}_{t,x}(\theta)\right) \right] < 1.$$

Proof. We provide only the main idea of the proof. We refer to [24] for the complete argument. Let $z = (x,y)$ and ν be as in the statement of (DP1). By the definition of $\mathcal{A}(t,z)$, $Z^{\nu}_{t,z}(T) \in \mathcal{E}pi(g)$. Since $Z^{\nu}_{t,z}(T) = Z^{\nu}_{\theta, Z^{\nu}_{t,z}(\theta)}(T)$, it follows that

$$\nu(\cdot) \in \mathcal{A}\left(\theta(w), Z^{\nu}_{t,z}(t+\theta(w))\right) \qquad \text{for } P \text{ almost every } w \in \Omega\,.$$

Then, again for P almost every $w \in \Omega$, $Y^\nu_{t,z}(\theta(w)) \in \mathcal{Y}\big(\theta(w), X^\nu_{t,x}(\theta(w))\big)$, and, by the definition of the value function, $v\big(\theta(w), X^\nu_{t,x}(\theta(w))\big) \le Y^\nu_{t,z}(\theta(w))$.

We prove (DP2) by contraposition. So, toward a contradiction, suppose that there exists a $[t,T)$-valued stopping time θ such that

$$Y^\nu_{t,x,y^*-\eta}(\theta) \;>\; v\big(\theta, X^\nu_{t,x}(\theta)\big) \qquad P-\text{a.s.}$$

In view of Remark 2.1, this proves that $Y^\nu_{t,x,y^*-\eta}(\theta) \in \mathcal{Y}\big(\theta, X^\nu_{t,x}(\theta)\big)$. Then there exists a control $\hat\nu \in \mathcal{U}$ such that

$$Y^{\hat\nu}_{\theta, Z^\nu_{t,x,y^*-\eta}(\theta)}(T) \ge g\big(X^{\hat\nu}_{\theta, X^\nu_{t,x}(\theta)}(T)\big) \qquad P-\text{a.s.}$$

Since the process $(X^{\hat\nu}_{\theta,X^\nu_{t,x}(\theta)}, Y^{\hat\nu}_{\theta,Z^\nu_{t,x,y^*-\eta}(\theta)})$ depends on $\hat\nu$ only through its realizations in the stochastic interval $[t,\theta]$, we may chose $\hat\nu$ so that $\hat\nu = \nu$ on $[t,\theta]$. (This is the difficult part of this proof.) Then $Z^{\hat\nu}_{\theta,Z^\nu_{t,x,y^*-\eta}(\theta)}(T) = Z^{\hat\nu}_{t,x,y^*-\eta}(T)$, and therefore $y^*-\eta \in \mathcal{Y}(t,x)$; hence $y^*-\eta \le v(t,x)$. Recall that, by definition, $y^* = v(t,x)$ and $\eta > 0$. □

The dynamic programming principle stated in Theorem 3.1 does not require all of the assumptions made in the first section. Namely, the control set U does not need to be convex or compact, and the function $\sigma^{-1}(t,x,r)a(t,x,y,r)$ is not required to be one to one in the r variable.

For completeness, we mention that the statement of Theorem 3.1 is equivalent to the following, apparently stronger but more natural, dynamic programming principle.

COROLLARY 3.1. *For all $(t,x) \in [0,T)\times\mathbb{R}^d$ and a $[t,T]$-valued stopping time θ, we have*

$$v(t,x) = \inf\big\{y\in\mathbb{R} \;:\; \exists\,\nu\in\mathcal{U},\; Y^\nu_{t,x,y}(\theta) \;\ge\; v\big(\theta, X^\nu_{t,x}(\theta)\big)\;\; P-a.s.\big\}.$$

4. Viscosity property. In this section, we use the dynamic programming principle stated in Theorem 3.1 to prove that the value function of the stochastic target control problem (2.2) is a discontinuous viscosity solution to the corresponding dynamic programming equation.

Following the convention in the viscosity literature, let v_* (resp., v^*) be the lower (resp., upper) semicontinuous envelope of v; i.e.,

$$v_*(t,x) \;:=\; \liminf_{(t',x')\to(t,x)} v(t',x') \quad\text{and}\quad v^*(t,x) \;:=\; \limsup_{(t',x')\to(t,x)} v(t',x').$$

Let δ_U be the support function of the closed convex set U:

$$\delta_U(\zeta) := \sup_{\nu\in U}(\nu^*\zeta), \qquad \zeta\in\mathbb{R}^d.$$

We shall denote by $\tilde U$ the effective domain of δ_U and by $\tilde U_1$ the restriction of $\tilde U$ to the unit circle:

$$\tilde U \;=\; \big\{\zeta\in\mathbb{R}^d \;:\; \delta_U(\zeta)\in\mathbb{R}\big\} \text{ and } \tilde U_1 \;=\; \big\{\zeta\in\tilde U \;:\; |\zeta|=1\big\}$$

so that $\tilde U$ is the closed cone generated by $\tilde U_1$. Under our assumptions, since U is a bounded subset of $\mathbb{R}^d$,

$$\tilde U \;=\; \mathbb{R}^d \text{ and } \tilde U_1 \;=\; \big\{\zeta\in\mathbb{R}^d \;:\; |\zeta|=1\big\}.$$

Remark 4.1. The compactness of U is only needed in order to establish some results which require us to extract convergent subsequences from sequences in U. Therefore, many results contained in this paper hold for a general closed convex subset U. For this reason, we shall keep using the notation $\tilde{U}$ and $\tilde{U}_1$.

Remark 4.2. For later reference, note that the closed convex set U can be characterized in terms of $\tilde{U}$ (see, e.g., [22]):

$$\begin{aligned}\nu \in U \text{ iff } \inf_{\zeta\in\tilde{U}} (\delta_U(\zeta) - \zeta^*\nu) \ &\geq\ 0,\\ \text{iff } \inf_{\zeta\in\tilde{U}_1} (\delta_U(\zeta) - \zeta^*\nu) \ &\geq\ 0;\end{aligned}$$

the second characterization follows from the facts that $\tilde{U}$ is the closed cone generated by $\tilde{U}_1$ and δ_U is positively homogeneous.

Remark 4.3. We shall also use the following characterization of $\mathrm{int}(U)$ in terms of $\tilde{U}_1$:

$$\nu \in \mathrm{int}(U) \text{ iff } \inf_{\zeta\in\tilde{U}_1} (\delta_U(\zeta) - \zeta^*\nu) \ >\ 0.$$

To see this, suppose that the right-hand side infimum is zero. Then, for all $\varepsilon > 0$, there exists some $\zeta_0 \in \tilde{U}_1$ such that $0 \leq \delta_U(\zeta_0) - \zeta_0^*\nu \leq \varepsilon/2$. Then $\delta_U(\zeta_0) - \zeta_0^*(\nu + \varepsilon\zeta_0) < 0$, and therefore $\nu + \varepsilon\zeta_0 \notin U$ by the previous remark. Since $\varepsilon > 0$ is arbitrary, this proves that $\nu \notin \mathrm{int}(U)$. Conversely, suppose that $\ell := \inf_{\zeta\in\tilde{U}_1} (\delta_U(\zeta) - \zeta^*\nu) > 0$. Then, by the Cauchy–Schwarz inequality and the characterization of the previous remark, it is easily checked that the ball around ν with radius ℓ is included in U.

Remark 4.4. Let f be the function defined on $\mathbb{R}^d$ by

$$f(\nu) := \inf_{\zeta\in\tilde{U}_1} (\delta_U(\zeta) - \zeta^*\nu)\,.$$

Then f is continuous. Indeed, since $\tilde{U}_1$ is a compact subset of $\mathbb{R}^d$, the infimum in the above definition of $f(\nu)$ is attained, say, at $\hat{\zeta}(\nu) \in \tilde{U}_1$. Then, for all $\nu, \nu' \in \mathbb{R}^d$,

$$f(\nu') \leq \delta_U(\hat{\zeta}(\nu)) - \hat{\zeta}(\nu)^*\nu + \hat{\zeta}(\nu)^*(\nu - \nu') \ =\ f(\nu) + \hat{\zeta}(\nu)^*(\nu - \nu') \ \leq\ f(\nu) + |\nu - \nu'|$$

by the Cauchy–Schwarz inequality. By symmetry, this proves that f is a contracting mapping.

Finally, we introduce the Dynkin second order differential operator associated to the process X^ν:

$$\mathcal{L}^\nu u(t,x) := \frac{\partial u}{\partial t}(t,x) + \mu(t,x,\nu)^* Du(t,x) + \frac{1}{2}\mathrm{Trace}\left(D^2u(t,x)\sigma^*(t,x,\nu)\sigma(t,x,\nu)\right),$$

where Du and D^2u denote, respectively, the gradient and the Hessian matrix of u with respect to the x variable.

THEOREM 4.1. *Assume that μ, σ, a, b are all bounded and satisfy the usual Lipschitz conditions and that v^*, v_* are finite everywhere. Further assume* (2.1) *and that U has a nonempty interior. Then the value function v of the stochastic target problem is a discontinuous viscosity solution of the equation on $[0,T) \times \mathbb{R}^d$,*

$$\min\left\{-\mathcal{L}^{\nu_0}u(t,x) + b\left(t,x,u(t,x),\nu_0\right);\ H(t,x,u(t,x),Du(t,x))\right\} = 0, \tag{4.1}$$

where

$$\nu_0(t,x) := \psi\left(t,x,u(t,x),Du(t,x)\right), \tag{4.2}$$

$$H(t,x,u(t,x),Du(t,x)) = \inf_{\zeta\in\tilde{U}_1}\left(\delta_U(\zeta) - \zeta^*\nu_0(t,x)\right); \tag{4.3}$$

i.e., v_* and v^* are, respectively, viscosity supersolution and subsolution of (4.1).

Remark 4.5. In view of Remark 4.2, $H \geq 0$ iff $\nu_0 \in U$. Since U has a nonempty interior, it follows from Remark 4.3 that $H > 0$ iff $\nu_0 \in \text{int}(U)$.

The proof of Theorem 4.1 will be completed in the following two subsections. The supersolution part of the claim follows from (DP1) and a classical argument in the viscosity theory which is due to P.-L. Lions. We shall take advantage of the fact that the inequality in (DP1) is in the a.s. sense. This allows for suitable change of measure before taking expectations. The subsolution part is obtained from (DP2) by means of a contraposition argument.

The above result will be completed in Theorem 5.1 by the description of the boundary condition. The reader who is not interested in the technical proof of Theorem 4.1 can go directly to section 5.

4.1. Proof of the viscosity supersolution property. Fix $(t_0,x_0) \in [0,T)\times\mathbb{R}^d$, and let φ be a $C^2([0,T]\times\mathbb{R}^d)$ function satisfying

$$0 \;=\; (v_*-\varphi)(t_0,x_0) = \min_{(t,x)\in[0,T)\times\mathbb{R}^d}(v_*-\varphi)\,.$$

Observe that $v \geq v_* \geq \varphi$ on $[0,T)\times\mathbb{R}^d$.

Step 1. Let $(t_n,x_n)_{n\geq 1}$ be a sequence in $[0,T)\times\mathbb{R}^d$ such that

$$(t_n,x_n) \;\to\; (t_0,x_0) \text{ and } v(t_n,x_n) \;\to\; v_*(t_0,x_0).$$

Set $y_n := v(t_n,x_n)+(1/n)$ and $z_n := (x_n,y_n)$. Then, by the definition of the stochastic target control problem, the set $\mathcal{A}(t_n,z_n)$ is not empty. Let ν_n be any element of $\mathcal{A}(t_n,z_n)$.

For any $[0,T-t_n)$-valued stopping time θ_n (to be chosen later), (DP1) yields

$$Y^{\nu_n}_{t_n,z_n}(t_n+\theta_n) \geq v\left(t_n+\theta_n, X_{t_n,x_n}(t_n+\theta_n)\right) \qquad P-\text{a.s.}$$

Set $\beta_n := y_n - \varphi(t_n,x_n)$. Since, as n tends to infinity, $y_n \to v_*(t_0,x_0)$ and $\varphi(t_n,x_n) \to \varphi(t_0,x_0) = v_*(t_0,x_0)$,

$$\beta_n \to 0\,.$$

Further, since $v \geq v_* \geq \varphi$, we have $v\left(t_n+\theta_n, X_{t_n,x_n}(t_n+\theta_n)\right) \geq \varphi(t_n+\theta_n, X_{t_n,x_n}(t_n+\theta_n))$ P-a.s. Then

$$\beta_n + \left[Y^{\nu_n}_{t_n,z_n}(t_n+\theta_n) - y_n\right] - \left[\varphi\left(t_n+\theta_n, X_{t_n,x_n}(t_n+\theta_n)\right) - \varphi(t_n,x_n)\right] \geq 0 \qquad P-\text{a.s.}$$

By Itô's lemma,

$$\begin{aligned} 0 \leq \beta_n \;+\; & \int_{t_n}^{t_n+\theta_n}\left[b\left(s,Z^{\nu_n}_{t_n,z_n}(s),\nu_n(s)\right) - \mathcal{L}^{\nu_n(s)}\varphi\left(s,X^{\nu_n}_{t_n,x_n}(s)\right)\right]ds \\ & + \int_{t_n}^{t_n+\theta_n}\Big[a\left(s,Z^{\nu_n}_{t_n,z_n}(s),\nu_n(s)\right) \\ & \qquad - \sigma\left(s,X^{\nu_n}_{t_n,x_n}(s),\nu_n(s)\right)D\varphi\left(s,X^{\nu_n}_{t_n,x_n}(s)\right)\Big]^* dW(s). \end{aligned} \tag{4.4}$$

Step 2. For some large constant C, set

$$\theta_n := \inf\left\{s > t_n \ : \ |X^{\nu_n}_{t_n,x_n}(s)| \geq C\right\}.$$

Since U is bounded in $\mathbb{R}^d$ and $(t_n, x_n) \longrightarrow (t_0, x_0)$, one can easily show that

$$\liminf_{n\to\infty} t \wedge \theta_n \ > \ t_0 \text{ for all } t > t_0. \tag{4.5}$$

For $\xi \in \mathbb{R}$, we introduce the probability measure P^ξ_n equivalent to P defined by the density process

$$M^\xi_n(t) := \mathcal{E}\left(-\xi \int_{t_n}^{t\wedge\theta_n} (a - \sigma D\varphi)\left(s, Z^{\nu_n}_{t_n,z_n}(s), \nu_n(s)\right) dW(s)\right), \quad t \geq t_n \ ,$$

where $\mathcal{E}(.)$ is the Doléans–Dade exponential operator. We shall denote by E^ξ_n the conditional expectation with respect to $\mathcal{F}_{t_n}$ under P^ξ_n.

We take the conditional expectation with respect to $\mathcal{F}_{t_n}$ under P^ξ_n in (4.4). The result is

$$\begin{aligned} 0 \leq \beta_n + E^\xi_n \left[\int_{t_n}^{t_n+h\wedge\theta_n} \left(b\left(s, Z^{\nu_n}_{t_n,z_n}(s), \nu_n(s)\right) - \mathcal{L}^{\nu_n(s)}\varphi\left(s, X^{\nu_n}_{t_n,x_n}(s)\right)\right) ds\right] \\ - \xi\, E^\xi_n \left[\int_{t_n}^{t_n+h\wedge\theta_n} \Big|a\left(s, Z^{\nu_n}_{t_n,z_n}(s), \nu_n(s)\right) \right. \\ \left. - \sigma\left(s, X^{\nu_n}_{t_n,x_n}(s), \nu_n(s)\right) D\varphi\left(s, X^{\nu_n}_{t_n,x_n}(s)\right)\Big|^2 ds\right] \end{aligned}$$

for all $h > 0$. We now consider two cases:

- Suppose that the set $\{n \geq 1 : \beta_n = 0\}$ is finite. Then there exists a subsequence, renamed $(\beta_n)_{n\geq 1}$, such that $\beta_n \neq 0$ for all $n \geq 1$. Set $h_n = \sqrt{|\beta_n|}$ and $k_n := \theta_n \wedge (t_n + h_n)$.
- If the set $\{n \geq 1 : \beta_n = 0\}$ is not finite, then there exists a subsequence, renamed $(\beta_n)_{n\geq 1}$, such that $\beta_n = 0$ for all $n \geq 1$. Set $h_n := n^{-1}$ and $k_n := \theta_n \wedge (t_n + h_n)$.

The final inequality still holds if we replace $t \wedge \theta_n$ with k_n. We then divide this inequality by h_n and send n to infinity by using (4.5), the dominated convergence theorem, and the right continuity of the filtration. The result is

$$\begin{aligned} 0 \leq \liminf_{n\to\infty} \frac{1}{h_n} \int_{t_n}^{t_n+h_n} \big[b\left(s, Z^{\nu_n}_{t_n,z_n}(s), \nu_n(s)\right) - \mathcal{L}^{\nu_n(s)}\varphi\left(s, X^{\nu_n}_{t_n,x_n}(s)\right) \\ - \xi\left|a\left(s, Z^{\nu_n}_{t_n,z_n}(s), \nu_n(s)\right) - \sigma\left(s, X^{\nu_n}_{t_n,x_n}(s), \nu_n(s)\right) D\varphi\left(s, X^{\nu_n}_{t_n,x_n}(s)\right)\right|^2\big] ds. \end{aligned}$$

We continue by using the following result, whose proof is given after the proof of the supersolution property.

LEMMA 4.1. *Let $\psi : [0,T] \times \mathbb{R}^{d+1} \times U \to \mathbb{R}$ be locally Lipschitz in (t,z) uniformly in r. Then*

$$\frac{1}{h_n} \int_{t_n}^{t_n+h_n} \left[\psi\left(s, Z^{\nu_n}_{t_n,z_n}(s), \nu_n(s)\right) - \psi\left(t_0, z_0, \nu_n(s)\right)\right] ds \to 0 \qquad P - a.s.$$

along some subsequence.

In view of this lemma,

$$0 \le \liminf_{n\to\infty} \frac{1}{h_n}\int_{t_n}^{t_n+h_n} \big[b\left(t_0,z_0,\nu_n(s)\right) - \mathcal{L}^{\nu_n(s)}\varphi\left(t_0,x_0\right) \\ - \xi\left|a\left(t_0,z_0,\nu_n(s)\right) - \sigma\left(t_0,x_0,\nu_n(s)\right)D\varphi\left(t_0,x_0\right)\right|^2\big]ds.$$

Then, since $h_n^{-1}\int_{t_n}^{t_n+h_n} ds = 1$,

$$\frac{1}{h_n}\int_{t_n}^{t_n+h_n} \big[b\left(t_0,z_0,\nu_n(s)\right) - \mathcal{L}^{\nu_n(s)}\varphi\left(t_0,x_0\right) \\ - \xi\left|a\left(t_0,z_0,\nu_n(s)\right) - \sigma\left(t_0,x_0,\nu_n(s)\right)D\varphi\left(t_0,x_0\right)\right|^2\big]ds \in \bar{\mathrm{co}}\mathcal{V}(t_0,z_0), \tag{4.6}$$

where $\bar{\mathrm{co}}\mathcal{V}(t_0,z_0)$ is the closed convex hull of the set $\mathcal{V}(t_0,z_0)$ defined by

$$\mathcal{V}(t_0,z_0) := \big\{b(t_0,z_0,\nu) - \mathcal{L}^{\nu}\varphi(t_0,x_0) - \xi\left|a(t_0,z_0,\nu) - \sigma(t_0,x_0,\nu)D\varphi(t_0,x_0)\right|^2 \ : \ \nu\in U\big\}.$$

Therefore, it follows from (4.6) that

$$\begin{aligned} 0 &\le \sup_{\phi\in\bar{\mathrm{co}}\mathcal{V}} \phi \\ &= \sup_{\nu\in U}\big\{\xi\left|-a(t_0,z_0,\nu) + \sigma(t_0,x_0,\nu)D\varphi(t_0,x_0)\right|^2 - \mathcal{L}^{\nu}\varphi(t_0,x_0) + b(t_0,z_0,\nu)\big\} \end{aligned} \tag{4.7}$$

for all $\xi\in\mathbb{R}$.

Step 3. For a large positive integer n, set $\xi = -n$. Since U is compact, the supremum in (4.7) is attained at some $\hat{\nu}_n \in U$, and

$$-n\left|a(t_0,z_0,\hat{\nu}_n) - \sigma(t_0,x_0,\hat{\nu}_n)D\varphi(t_0,x_0)\right|^2 - \mathcal{L}^{\hat{\nu}_n}\varphi(t_0,x_0) + b(t_0,z_0,\hat{\nu}_n) \ge 0.$$

By passing to a subsequence, we may assume that there exists $\hat{\nu}\in U$ such that $\hat{\nu}_n \to \nu_0$. Now let n to infinity in the last inequality to prove that

$$\left|a(t_0,z_0,\hat{\nu}_n) - \sigma(t_0,x_0,\hat{\nu}_n)D\varphi(t_0,x_0)\right|^2 \ \to \ 0 \tag{4.8}$$

and

$$-\mathcal{L}^{\nu_0}\varphi(t_0,x_0) + b(t_0,z_0,\nu_0) \ge 0. \tag{4.9}$$

In view of (4.8), we conclude that

$$\nu_0 = \psi\left(t_0,z_0,D\varphi(t_0,x_0)\right). \tag{4.10}$$

Since $\nu_0\in U$, it follows from Remark 4.2 that

$$\inf_{\zeta\in\tilde{U}_1}\left(\delta_U(\zeta) - \zeta^*\nu_0\right) \ge 0. \tag{4.11}$$

The supersolution property now follows from (4.9), (4.10), and (4.11). □

Proof of Lemma 4.1. Since $\psi(t,z,r)$ is locally Lipschitz in (t,z) uniformly in r,

$$\begin{aligned} &\frac{1}{h_n}\int_{t_n}^{t_n+h_n}\left[\psi\left(s,Z^{\nu_n}_{t_n,z_n}(s),\nu_n(s)\right) - \psi\left(t_0,z_0,\nu_n(s)\right)\right]ds \\ &\quad\le K\ \frac{1}{h_n}\int_{t_n}^{t_n+h_n}\left(|s-t_0| + \left|Z^{\nu_n}_{t_n,z_n}(s) - z_0\right|\right)ds \\ &\quad\le K\ \left(h_n + |t_n - t_0| + \sup_{t_n\le s\le t_n+h_n}\left|Z^{\nu_n}_{t_n,z_n}(s) - z_0\right|\right) \end{aligned}$$

for some constant K. Thus, to complete the proof of this lemma, it suffices to show

$$\sup_{t_n \le s \le t_n + h_n} \left| Z^{\nu_n}_{t_n, z_n}(s) - z_0 \right| \longrightarrow 0 \qquad P - \text{a.s.}$$

along a subsequence. Set

$$\gamma(t,x,y,r) := \begin{pmatrix} \mu(t,x,r) \\ b(t,x,y,r) \end{pmatrix} \text{ and } \alpha(t,x,y,r) := \begin{pmatrix} \sigma^*(t,x,r) \\ a^*(t,x,y,r) \end{pmatrix}.$$

Functions α and γ inherit the pointwise bounds from μ, b, σ, and a. We directly calculate that, for $t_n \le s \le t_n + h_n$,

$$Z^{\nu_n}_{t_n, z_n}(s) - z_0 \le |z_n - z_0| + \|\gamma\|_\infty h_n + \left| \int_{t_n}^{s} \alpha\left(s, Z^{\nu_n}_{t_n, z_n}(s), \nu_n(s)\right) dW(s) \right|,$$

and, therefore,

$$\begin{aligned} \sup_{t_n \le s \le t_n + h_n} \left| Z^{\nu_n}_{t_n, z_n}(s) - z_0 \right| \le |z_n - z_0| + \|\gamma\|_\infty h_n \\ + \sup_{t_n \le s \le t_n + h_n} \left| \int_{t_n}^{s} \alpha\left(s, Z^{\nu_n}_{t_n, z_n}(s), \nu_n(s)\right) dW(s) \right|. \end{aligned}$$

The first two terms on the right-hand side converge to zero. We estimate the third term by Doob's maximal inequality for submartingales.

The result is

$$\begin{aligned} E\left[\left(\sup_{t_n \le s \le t_n + h_n} \left| \int_{t_n}^{s} \alpha\left(s, Z^{\nu_n}_{t_n, z_n}(s), \nu_n(s)\right) dW(s) \right| \right)^2 \right] \\ \le 4\, E\left[\int_{t_n}^{t_n + h_n} \alpha\left(s, Z^{\nu_n}_{t_n, z_n}(s), \nu_n(s)\right)^2 ds \right] \\ \le 4\, \|\alpha\|^2_\infty h_n. \end{aligned}$$

This proves that

$$\sup_{t_n \le s \le t_n + h_n} \left| Z^{\nu_n}_{t_n, z_n}(s) - z_0 \right| \to 0 \quad \text{ in } L^2(P),$$

and, therefore, it also converges P-a.s. along some subsequence. □

4.2. Subsolution property. We start with a technical lemma which will be used both in the proof of the subsolution property and also in the next section on the characterization of the terminal data. We first introduce some notation. Given a smooth function $\varphi(t,x)$, we define the open subset of $[0,T] \times \mathbb{R}^d$:

$$\begin{aligned} \mathcal{M}_0(\varphi) := \Big\{ (t,x) \ : \ \inf_{\zeta \in \tilde{U}_1} \left(\delta_U(\zeta) - \zeta^* \nu_0(t,x) \right) > 0 \text{ and} \\ -\mathcal{L}^{\nu_0(t,x)} \varphi(t,x) + b\left(t,x,\varphi(t,x),\nu_0(t,x)\right) > 0 \Big\}, \\ = \{ (t,x) \ : \ \nu_0(t,x) \in \text{int}(U) \text{ and } - \mathcal{L}^{\nu_0(t,x)} \varphi(t,x) \\ + b\left(t,x,\varphi(t,x),\nu_0(t,x)\right) > 0 \}, \\ \text{where} \quad \nu_0(t,x) = \psi\left(t,x,\varphi(t,x),D\varphi(t,x)\right). \end{aligned}$$

LEMMA 4.2. *Let φ be a smooth test function, and let $B = B_R(x_0)$ be the open ball around x_0 with radius $R > 0$. Suppose that there are $t_1 < t_2 \le T$ such that*

$$\mathrm{cl}(\mathcal{M}) \subset \mathcal{M}_0(\varphi), \text{ where } \mathcal{M} := (t_1, t_2) \times B.$$

Then

$$\sup_{\partial_p \mathcal{M}} (v - \varphi) = \max_{\mathrm{cl}(\mathcal{M})} (v^* - \varphi),$$

where $\partial_p \mathcal{M}$ is the parabolic boundary of $\mathcal{M}$; i.e., $\partial_p \mathcal{M} = ([t_1, t_2] \times \partial B) \cup \big(\{t_2\} \times \bar{B}\big)$.

Proof. We shall denote $\overline{\mathcal{M}} := \mathrm{cl}(\mathcal{M})$. Suppose, to the contrary, that

$$\max_{\overline{\mathcal{M}}} (v^* - \varphi) - \sup_{\partial_p \mathcal{M}} (v - \varphi) := 2\beta > 0,$$

and let us work toward a contradiction of (DP2).

Choose $(t_0, x_0) \in \mathcal{M}$ so that $(v - \varphi)(t_0, x_0) \ge -\beta + \max_{\overline{\mathcal{M}}}(v^* - \varphi)$, and

$$(v - \varphi)(t_0, x_0) \ge \beta + \sup_{\partial_p \mathcal{M}} (v - \varphi). \tag{4.12}$$

Step 1. In view of Remark 4.5, $\inf_{\zeta \in \tilde{U}_1} (\delta_U(\zeta) - \zeta^* \nu_0) > 0$ is equivalent to $\nu_0 \in \mathrm{int}(U)$. Set

$$\mathcal{N} := \big\{(t, x, y) \ : \ \hat{\nu}(t, x, y) \in \mathrm{int}(U) \ \text{ and } \ -\mathcal{L}^{\hat{\nu}(t,x,y)} \varphi(t, x) + b\,(t, x, y, \hat{\nu}(t, x, y)) > 0\big\},$$

where $\hat{\nu}(t, x, y) = \psi(t, x, y, D\varphi(t, x))$, and, for $\eta \ge 0$,

$$\mathcal{M}_\eta := \{\ (t, x) \ : \ \ (t, x, \varphi(t, x) - \eta) \in \mathcal{N}\ \}.$$

Note that this definition of $\mathcal{M}_0 := \mathcal{M}_0(\varphi)$ agrees with the previous definition. Moreover, in view of our hypothesis, for all sufficiently small η, $\overline{\mathcal{M}} \subset \mathcal{M}_\eta$. Fix $\eta \le \beta$ satisfying this inclusion.

Step 2. Let η be as in the previous step. Let (X_η, Y_η) be the solution of the state equation with initial data $X_\eta(t_0) = x_0$, $Y_\eta(t_0) = \varphi(t_0, x_0) - \eta$ and the control ν given in the feedback form

$$\nu(t, x) = \psi(t, x, \varphi(t, x) - \eta, D\varphi(t, x)).$$

Set

$$\nu(t) := \nu(t, X_\eta(t))$$

so that

$$(X_\eta, Y_\eta) = Z^\nu_{t_0, x_0, v(t_0,x_0) - \eta} \ = \ \big(X^\nu_{t_0,x_0}, Y^\nu_{t_0,x_0,v(t_0,x_0)-\eta}\big).$$

Set

$$\hat{Y}_\eta(t) := \varphi(t, X_\eta(t)) - \eta + (v - \varphi)(t_0, x_0),$$

and observe that $Y_\eta(0) = \hat{Y}_\eta(0) = v(t_0, x_0) - \eta$. In the next step, we will compare the processes Y_η and $\hat{Y}_\eta$.

Step 3. By Itô's rule,

$$d\hat{Y}_\eta(t) = \mathcal{L}^{\nu(t)}\varphi(t, X_\eta(t))dt + D\varphi(t, X_\eta(t)) \cdot \sigma^*(t, X_\eta(t), \nu(t))dW(t).$$

In view of (2.1) and the definition of $\nu(t)$,

$$D\varphi(t, X_\eta(t)) \cdot \sigma^*(t, X_\eta(t), \nu(t)) = a^*(t, X_\eta(t), \hat{Y}_\eta(t), \nu(t)).$$

Hence

$$d\hat{Y}_\eta(t) = \hat{b}(t)dt + a^*(t, X_\eta(t), \hat{Y}_\eta(t), \nu(t))dW(t),$$

where

$$\hat{b}(t) := \mathcal{L}^{\nu(t)}\varphi(t, X_\eta(t)).$$

Recall that Y_η solves the same SDE with a different drift term:

$$dY_\eta(t) = b(t)dt + a^*(t, X_\eta(t), Y_\eta(t), \nu(t))dW(t),$$

where $b(t) := b(t, X_\eta(t), Y_\eta(t), \nu(t))$.

Let θ be the stopping time

$$\theta := \inf\ \{\ s > 0\ :\ \ (t_0 + s, X_\eta(t_0 + s)) \notin \mathcal{M}\ \}.$$

Since $\mathcal{M}$ is an open set containing (t_0, x_0), the stopping time θ is positive a.s.

Now, from the definition of η, we have $\mathcal{M} \subset \mathcal{M}_\eta$. It follows that, for $t \in [t_0, t_0+\theta)$, $(t, X_\eta(t)) \in \mathcal{M}_\eta$ a.s.; i.e., $(t, X_\eta(t), \hat{Y}_\eta(t)) \in \mathcal{N}$ a.s. by definition of $\mathcal{M}_\eta$. Hence

$$b(t) > \mathcal{L}^{\nu(t)}\varphi(t, X_\eta(t))\ =\ \hat{b}(t), \qquad t \in [t_0, t_0 + \theta), \quad P - \text{a.s.}$$

Since $Y_\eta(0) = \hat{Y}_\eta(0) = v(t_0, x_0) - \eta$, it follows from stochastic comparison that

$$\hat{Y}_\eta(t) \le Y_\eta(t), \qquad t \in [t_0, t_0 + \theta), \quad P - \text{a.s.}$$

Step 4. We now proceed to contradict (DP2). First, observe that, by continuity of the process X_η, $(t_0 + \theta, X_\eta(t_0 + \theta)) \in \partial_p\mathcal{M}$. Also, from inequality (4.12), we have $v \le \varphi - \beta + (v - \varphi)(t_0, x_0)$ on $\partial_p\mathcal{M}$. Therefore,

$$\begin{aligned} Y_\eta(t_0 + \theta) - v(t_0 + \theta, X_\eta(t_0 + \theta)) &\ge \beta + Y_\eta(t_0 + \theta) - \varphi(t_0 + \theta, X_\eta(t_0 + \theta)) \\ &\qquad + (v - \varphi)(t_0, x_0) \\ &= (\beta - \eta) + Y_\eta(t_0 + \theta) - \hat{Y}_\eta(t_0 + \theta) \\ &\ge \beta - \eta\ \ge\ 0 \end{aligned}$$

from step 3. By (4.12) and the definition of (X_η, Y_η), we have $Y_\eta = Y^\nu_{t_0,x_0,v(t_0,x_0)-\eta}$ and $X_\eta = X^\nu_{t_0,x_0}$. Then the previous inequality contradicts (DP2). □

Proof of the subsolution property. Fix $(t_0, x_0) \in [0, T) \times \mathbb{R}^d$, and let φ be a $C^2([0, T] \times \mathbb{R}^d)$ function satisfying

$$(v^* - \varphi)(t_0, x_0) = (\text{strict}) \max_{(t,x)\in[0,T)\times\mathbb{R}^d} (v^* - \varphi).$$

Set $z_0 := (x_0, \varphi(t_0, x_0))$. Let $\mathcal{M}_0 := \mathcal{M}_0(\varphi)$ be as in the previous lemma. Since (t_0, x_0) is a *strict* maximizer of $(v^* - \varphi)$ and since $\mathcal{M}_0$ is an open set, by the previous lemma we conclude that $(x_0, y_0) \notin \mathcal{M}_0$. Then, by the definition of $\mathcal{M}_0$,

$$\min\left\{ \inf_{\zeta\in\tilde{U}_1} \left(\delta_U(\zeta) - \zeta^*\hat{\nu}(t_0, z_0)\right),\ -\mathcal{L}^{\hat{\nu}(t_0,z_0)}\varphi(t_0, x_0) + b\left(t_0, z_0, \hat{\nu}(t_0, z_0)\right) \right\} \le 0,$$

and therefore v^* is a viscosity subsolution. □

5. Terminal condition. To characterize the value function as the unique solution of the dynamic programming equation, we need to specify the terminal data. The definition of the value function implies that

$$v(T,x) = g(x), \qquad x \in \mathbb{R}. \tag{5.1}$$

However, it is known that

$$\underline{G}(x) := \liminf_{t\uparrow T,\ x'\to x} v(t,x')$$

may be strictly larger than $g(x)$ (see, for instance, [4] and Lemma 5.1 below).

In this section, we will characterize $\underline{G}$ as the viscosity supersolution of a first order PDE. We will also study

$$\overline{G}(x) := \limsup_{t\uparrow T,\ x'\to x} v(t,x')$$

and prove that $\overline{G}$ is a viscosity subsolution of the same equation. More precisely, we have the following theorem.

THEOREM 5.1. *Let the assumptions of Theorem* 4.1 *hold, and assume that* $\underline{G}$ *and* $\overline{G}$ *are finite for every* $x \in \mathbb{R}^d$. *Suppose, further, that* $(g_*)^* \geq g$. *Then* $\overline{G}$ *and* $\underline{G}$, *respectively, are viscosity super- and subsolutions of the following equations on* $\mathbb{R}^d$:

$$\min\{\underline{G}(x) - g_*(x);\ H\,(T,x,\underline{G}(x), D\underline{G}(x))\} \geq 0,$$
$$\min\{\overline{G}(x) - g^*(x);\ H\,\big(T,x,\overline{G}(x), D\overline{G}(x)\big)\} \leq 0.$$

In most cases, since a subsolution is not greater than a supersolution, this characterization implies that $\overline{G} \leq \underline{G}$ and therefore that $\overline{G} = \underline{G}$. In the next section, we provide examples for which this holds, and we will also compute $G := \overline{G} = \underline{G}$ explicitly in those examples.

The rest of this section is devoted to the proof of Theorem 5.1.

Remark 5.1. In the definition of $\overline{G}$, we may replace v by v^*:

$$\overline{G}(x) = \limsup_{t\uparrow T,\ x'\to x} v^*(t,x').$$

Similarly,

$$\underline{G}(x) := \liminf_{t\uparrow T,\ x'\to x} v_*(t,x').$$

We start with the following lemma.

LEMMA 5.1. *Suppose that* $\underline{G}(x)$ *and* $\overline{G}(x)$ *are finite for every* $x \in \mathbb{R}^d$. *Then*

$$\underline{G}(x) \ \geq\ g_*(x) \text{ for all } \ x \in \mathbb{R}^d.$$

Proof. Take a sequence $(x_n,t_n) \to (x,T)$ with $t_n < T$. Set $y_n := v(t_n,x_n)+(1/n)$. For each n, there exists a control $\nu_n \in \mathcal{U}$ satisfying

$$Y^{\nu_n}_{t_n,x_n,y_n}(T) \geq g\left(X^{\nu_n}_{t_n,x_n}(T)\right) \qquad \mathrm{P}-\text{a.s.}$$

Since a and b are bounded,

$$E\left[\ Y^{\nu_n}_{t_n,x_n,y_n}(T)\ \right] \leq y_n + \|b\|_\infty(T-t_n) \ =\ v(t_n,x_n) + \frac{1}{n} + \|b\|_\infty(T-t_n).$$

We continue by using the following claim, whose proof will be provided later:

$$\left\{Y^{\nu_n}_{t_n,x_n,y_n}(T)\ ,\ \ n\geq 0\right\} \text{ is uniformly integrable.} \tag{5.2}$$

Then

$$\begin{aligned}\liminf_{n\to\infty} v(t_n,x_n) &\geq \liminf_{n\to\infty} E\left[\ Y^{\nu_n}_{t_n,x_n,y_n}(T)\ \right]\\ &= E\left[\ \liminf_{n\to\infty} Y^{\nu_n}_{t_n,x_n,y_n}(T)\ \right]\\ &\geq E\left[\ \liminf_{n\to\infty} g\left(X^{\nu_n}_{t_n,x_n}(T)\right)\ \right].\end{aligned}$$

Since U is compact and (t_n,x_n) converges to (T,x), $X^{\nu_n}_{t_n,x_n}(T)$ approaches x as n tends to infinity. The required result then follows from the definition of the lower semicontinuous envelope g_* of g.

It remains to prove claim (5.2). Since b is bounded,

$$\begin{aligned}\left|Y^{\nu_n}_{t_n,x_n,y_n}(T)\right| &\leq |y_n| + (T-t_n)\|b\|_\infty + \left|\int_{t_n}^T a\left(u, Z^{\nu_n}_{t_n,x_n,y_n}(u),\nu_n(u)\right)^* dW(u)\right|\\ &\leq T\|b\|_\infty + |v(t_n,x_n)| + \left|\int_{t_n}^T a\left(u, Z^{\nu_n}_{t_n,x_n,y_n}(u),\nu_n(u)\right)^* dW(u)\right|.\end{aligned}$$

Now observe that $\limsup v(t_n,x_n) \leq \limsup v^*(t_n,x_n) \leq \overline{G}(x)$ and $\liminf v(t_n,x_n) \geq \liminf v_*(t_n,x_n) \geq \underline{G}(x)$. This proves that the sequence $v(t_n,x_n)$ is bounded. In order to complete the proof, it suffices to show that the sequence

$$\left\{U_n := \int_{t_n}^T a\left(u, Z^{\nu_n}_{t_n,x_n,y_n}(u),\nu_n(u)\right)^* dW(u),\ n\geq 0\right\}$$

is uniformly integrable. Since a is bounded,

$$\sup_{n\geq 0} E\left[U_n^2\right] \leq \sup_{n\geq 0}(T-t_n)\|a^*a\|_\infty\ \leq\ T\|a^*a\|_\infty.$$

Hence $\{U_n,\ n\geq 0\}$ is bounded in L^2, and, therefore, it is uniformly integrable. □

Next, we will show that $\underline{G}$ is a viscosity supersolution of $H\geq 0$, where H is as in (4.3).

LEMMA 5.2. *Suppose that $\underline{G}(x)$ is finite for every $x\in\mathbb{R}^d$. Then $\underline{G}$ is a viscosity supersolution of*

$$H(T,x,\underline{G}(x),D\underline{G}(x))\geq 0.$$

Proof. By definition, $\underline{G}$ is lower semicontinuous. Let f be a $C^2(\mathbb{R}^d)$ function satisfying

$$0\ =\ (\underline{G}-f)(x_0) = \min_{x\in\mathbb{R}^d}(\underline{G}-f)$$

at some $x_0\in\mathbb{R}^d$. Observe that $\underline{G}\geq f$ on $\mathbb{R}^d$.

Step 1. In view of Remark 5.1, there exists a sequence (s_n,ξ_n) converging to (T,x_0) such that $s_n<T$ and

$$\lim_{n\to\infty}\ v_*(s_n,\xi_n) = \underline{G}(x_0).$$

For a positive integer n, consider the auxiliary test function

$$\varphi_n(t,x) := f(x) - \frac{1}{2}|x-x_0|^2 + \frac{T-t}{(T-s_n)^2}.$$

Let $B := B_1(x_0)$ be the unit open ball in $\mathbb{R}^d$ centered at x_0. Choose $(t_n, x_n) \in [s_n, T] \times \bar{B}$, which minimizes the difference $v_* - \varphi_n$ on $[s_n, T] \times \bar{B}$.

Step 2. We claim that, for sufficiently large n, $t_n < T$, and x_n converges to x_0. Indeed, for sufficiently large n,

$$(v_* - \varphi_n)(s_n, \xi_n) \le -\frac{1}{2(T-s_n)}.$$

On the other hand, for any $x \in \bar{B}$,

$$(v_* - \varphi_n)(T,x) = \underline{G}(x) - f(x) + \frac{1}{2}|x-x_0|^2 \ge \underline{G}(x) - f(x) \ge 0.$$

Comparing the two inequalities leads us to conclude that $t_n < T$ for large n. Suppose that, on a subsequence, x_n converges to x^*. Since $t_n \ge s_n$ and (t_n, x_n) minimizes the difference $(v_* - \varphi_n)$,

$$\begin{aligned}
(\underline{G} - f)(x^*) - (\underline{G} - f)(x_0) &\\
&\le \liminf_{n\to\infty} (v_* - \varphi_n)(t_n, x_n) - (v_* - \varphi_n)(s_n, \xi_n) - \frac{1}{2}|x_n - x_0|^2 \\
&\le \limsup_{n\to\infty} (v_* - \varphi_n)(t_n, x_n) - (v_* - \varphi_n)(s_n, \xi_n) - \frac{1}{2}|x_n - x_0|^2 \\
&\le -\frac{1}{2}|x^* - x_0|^2.
\end{aligned}$$

Since x_0 minimizes the difference $\underline{G} - f$,

$$0 \le (\underline{G} - f)(x^*) - (\underline{G} - f)(x_0) \le -\frac{1}{2}|x^* - x_0|^2.$$

Hence $x^* = x_0$. The above argument also proves that

$$\begin{aligned}
0 &= \lim_{n\to\infty} (v_* - \varphi_n)(t_n, x_n) - (v_* - \varphi_n)(s_n, \xi_n) \\
&= -\underline{G}(x_0) + \lim_{n\to\infty} v_*(t_n, x_n) + \frac{(T-s_n) - (T-t_n)}{(T-s_n)^2} \\
&\ge -\underline{G}(x_0) + \limsup_{n\to\infty} v_*(t_n, x_n).
\end{aligned}$$

This proves that $\limsup_{n\to\infty} v_*(t_n, x_n) \le \underline{G}(x_0)$. Since $\limsup v_*(t_n, x_n) \ge \liminf v_*(t_n, x_n) \ge \underline{G}(x_0)$, by definition of $\underline{G}$, this proves that

$$\lim_{n\to\infty} v_*(t_n, x_n) = \underline{G}(x_0). \tag{5.3}$$

This implies that, for all sufficiently large n, (t_n, x_n) is a local minimizer of the difference $(v_* - \varphi_n)$. In view of the general theory of viscosity solutions (see, for instance, Fleming and Soner [14]), the viscosity property of v_* holds at (t_n, x_n).

Step 3. We now use the viscosity property of v_* in $[0,T) \times \mathbb{R}^d$: for every n,

$$H(t_n, x_n, v_*(t_n, x_n), D\varphi_n(x_n, t_n)) \ge 0.$$

Note that $D\varphi_n(x_n,t_n) = Df(x_n,t_n) - (x_n - x_0)$, and recall that H is continuous; see Remark 4.4. Since (t_n,x_n) tends to (T,x_0), (5.3) implies that

$$H(T,x_0,\underline{G}(x_0),Df(x_0)) \geq 0. \qquad \square$$

These results imply that $\underline{G}$ is a viscosity supersolution of

$$\min\ \{\underline{G}(x) - g_*(x);\ H(T,x,\underline{G}(x),D\underline{G}(x))\} \geq 0, \tag{5.4}$$

proving the first part of Theorem 5.1. The following result concludes the proof of the theorem.

LEMMA 5.3. *Suppose that $\underline{G}(x)$ and $\overline{G}(x)$ are finite for every $x \in \mathbb{R}^d$ and that $(g_*)^* \geq g$. Then $\overline{G}$ is a viscosity subsolution on $\mathbb{R}^d$ of*

$$\min\ \left\{\overline{G}(x) - g^*(x);\ H(T,x,\overline{G}(x),D\overline{G}(x))\right\} \leq 0.$$

Proof. By definition, $\overline{G}$ is upper semicontinuous. Let $x_0 \in \mathbb{R}^d$ and $f \in C^2(\mathbb{R}^d)$ satisfy

$$0 \ = \ (\overline{G} - f)(x_0) = \max_{x\in\mathbb{R}^d}(\overline{G} - f).$$

We need to show that, if $\overline{G}(x_0) > g^*(x_0)$, then

$$H(T,x_0,\overline{G}(x_0),D\overline{G}(x_0)) \leq 0. \tag{5.5}$$

So we assume that

$$\overline{G}(x_0) > g^*(x_0). \tag{5.6}$$

For a positive integer n, set

$$s_n := T - \frac{1}{n^2},$$

and consider the auxiliary test function

$$\varphi_n(t,x) := f(x) + \frac{1}{2}|x - x_0|^2 + n(T-t), \qquad (t,x) \in [s_n,T] \times \mathbb{R}^d.$$

In order to obtain the required result, we shall first prove that the test function φ_n does not satisfy the condition of Lemma 4.2 on $[s_n,T] \times B_R(x_0)$ for some $R > 0$, and then we shall pass to the limit as $n \to \infty$.

Step 1. By definition, $\overline{G} \geq \underline{G}$. From Lemma 5.1, this provides $\overline{G} \geq g_*$ and then $\overline{G} \geq (g_*)^*$ by upper semicontinuity of $\overline{G}$. Hence, by assumption of the lemma,

$$\overline{G} \geq g. \tag{5.7}$$

This proves that $(v - \varphi_n)(T,x) = (g - f)(x) - |x - x_0|^2/2 \leq (\overline{G} - f)(x) \leq 0$ by definition of the test function f. Then, for all $R > 0$,

$$\sup_{B_R(x_0)} (v - \varphi_n)(T,.) \leq 0.$$

Now suppose that there exists a subsequence of (φ_n), still denoted (φ_n), such that

$$\lim_{n\to\infty} \sup_{B_R(x_0)} (v - \varphi_n)(T,.) = 0,$$

and let us work toward a contradiction. For each n, let $(x_n^k)_k$ be a maximizing sequence of $(v-\varphi_n)(T,.)$ on $B_R(x_0)$; i.e.,

$$\lim_{n\to\infty}\lim_{k\to\infty}(v-\varphi_n)(T,x_n^k)=0.$$

Then it follows from (5.7) that $(v-\varphi_n)(T,x_n^k)\le -|x_n^k-x_0|^2/2$, which provides

$$\lim_{n\to\infty}\lim_{k\to\infty}x_n^k=x_0.$$

Therefore,

$$\begin{aligned}0 \;&=\; \lim_{n\to\infty}\lim_{k\to\infty}(v-\varphi_n)(T,x_n^k) \;=\; \lim_{n\to\infty}\lim_{k\to\infty}g(x_n^k)-f(x_0)\\ &\le\; \limsup_{x\to x_0}g(x)-f(x_0) \;=\; (g^*-f)(x_0) \;<\; (G-f)(x_0)\end{aligned}$$

by (5.6). Since $(G-f)(x_0)=0$, this cannot happen since $(G-f)(x_0)=0$. The consequence of this is

$$\limsup_{n\to\infty}\sup_{B_R(x_0)}(v-\varphi_n)(T,.)<0 \qquad \text{for all } R>0. \tag{5.8}$$

Step 2. Let $(t_n,x_n)_n$ be a maximizing sequence of $(v^*-\varphi_n)$ on $[s_n,T]\times\partial B_R(x_0)$. Then, since $T-t_n\le T-s_n=n^{-2}$,

$$\limsup_{n\to\infty}\sup_{[s_n,T]\times\partial B_R(x_0)}(v^*-\varphi_n)\le\limsup_{n\to\infty}(v^*(t_n,x_n)-f(x_n))-\frac{1}{2}R^2.$$

Since $t_n\longrightarrow T$ and, after passing to a subsequence, $x_n\longrightarrow x^*$ for some $x^*\in\partial B_R(x_0)$, we get

$$\limsup_{n\to\infty}\sup_{[s_n,T]\times\partial B_R(x_0)}(v^*-\varphi_n)\le(\overline{G}-f)(x^*)-\frac{1}{2}R^2\;\le\;-\frac{1}{2}R^2.$$

This, together with (5.8), implies that, for all $R>0$, there exists $n(R)$ such that, for all $n>n(R)$,

$$\max\{\;(v-\varphi_n)\;:\;\partial_p\left((s_n,T)\times B_R(x_0)\right)\;\}<0\;=\;(v^*-\varphi_n)(T,x_0).$$

Hence it follows from Lemma 4.2 that

$$(s_n,T)\times B_R(x_0)\text{ is not a subset of }\mathcal{M}_0(\varphi_n)\quad\text{for all }\;n>n(R). \tag{5.9}$$

Step 3. Observe that, for all $\nu\in U$ and (t,x,y),

$$-\mathcal{L}^\nu\varphi_n(t,x)\;=\;n-\mathcal{L}^\nu f(x)-\mu(t,x,\nu)^*(x-x_0)-\frac{1}{2}\mathrm{Trace}[\sigma^*\sigma](t,x,\nu)>b(t,x,y,\nu),$$

provided that n is sufficiently large. Then, for large n,

$$\begin{aligned}&\mathcal{M}_0(\varphi_n)\cap((s_n,T)\times B_R(x_0))\\ &\qquad=\{\;(t,x)\in(s_n,T)\times B_R(x_0)\;:\;H(t,x,\varphi_n(t,x),D\varphi_n(t,x))>0\;\}.\end{aligned}$$

In view of this, it follows from (5.9) that there is a sequence (t_n,x_n) converging to (T,x_0) such that

$$H(t_n,x_n,\varphi_n(t_n,x_n),D\varphi_n(t_n,x_n))\le 0.$$

We now let n tend to infinity to obtain (5.5). □

6. Application: Superreplication problem in finance. Consider a financial market consisting of

- a nonrisky asset with price process $\tilde{X}^0$ normalized to unity,
- a risky asset $\tilde{X}$ defined by a positive price process with dynamics described by an SDE.

A trading strategy is an $\mathbb{F}$-adapted process $\nu = \{\nu(t),\, 0 \le t \le T\}$ valued in the closed interval $[-\ell, u]$ with $\ell, u \in [0, \infty)$ and $\ell + u > 0$. At each time $t \in [0, T]$, $\nu(t)$ represents the proportion of wealth invested in the risky asset $\tilde{X}$. The set of all trading strategies is denoted by $\mathcal{U}$.

Given an initial capital $\tilde{y} > 0$ and a trading strategy ν, the wealth process $\tilde{Y}$ is defined by

$$\tilde{Y}_{\tilde{y}}^{\nu}(0) \;=\; \tilde{y} \text{ and } d\tilde{Y}_{\tilde{y}}^{\nu}(t) \;=\; \tilde{Y}_{\tilde{y}}^{\nu}(t)\nu(t)\,\frac{d\tilde{X}(t)}{\tilde{X}(t)}.$$

We shall consider a "large investor" model in which the dynamics of the risky asset price process may be affected by trading strategies. Namely, given a trading strategy $\nu \in \mathcal{U}$,

$$\begin{aligned} \tilde{X}^{\nu}(0) = e^{X^{\nu}(0)} \;&=\; e^{X(0)}, \quad \tilde{X}^{\nu}(t) \;=\; e^{X^{\nu}(t)}, \\ dX^{\nu}(t) &= \mu\left(t, X^{\nu}(t), \nu(t)\right) dt + \sigma\left(t, X^{\nu}(t), \nu(t)\right) dW(t), \end{aligned}$$

where W is a one-dimensional Brownian motion. Define the log-wealth process:

$$Y_y^{\nu}(0) \;=\; y \;:=\; \ln(\tilde{y}) \text{ and } Y_y^{\nu}(t) \;=\; \ln\left(\tilde{Y}_{\tilde{y}}^{\nu}(t)\right).$$

Then a direct application of Itô's lemma provides

$$dY_y^{\nu}(t) = b\left(t, X^{\nu}(t), \nu(t)\right) dt + \nu(t)\sigma\left(t, X^{\nu}(t), \nu(t)\right) dW(t),$$

where

$$b(t,x,r) = r\left(\mu + \frac{1}{2}\sigma^2\right)(t,x,r) - \frac{1}{2}r^2\sigma^2(t,x,r).$$

Let f be a positive function defined on $[0, \infty)$. The superreplication problem is defined by

$$\tilde{v}(0, X(0)) := \inf\left\{\tilde{y} > 0 \;:\; \exists\, \nu \in \mathcal{U},\; \tilde{Y}_{\tilde{y}}^{\nu}(T) \ge f\left(X^{\nu}(T)\right) \quad P - \text{a.s.}\right\}.$$

Here $f\left(X^{\nu}(T)\right)$ is a contingent claim. The value function of the above superreplication problem is then the minimal initial capital which allows the seller of the contingent claim to face the promised payoff $f\left(X^{\nu}(T)\right)$ through some trading strategy $\nu \in \mathcal{U}$.

To see that the superreplication problem belongs to the general class of stochastic target problems studied in the previous sections, we introduce

$$v(0, X(0)) \;:=\; \ln \tilde{v}(0, X(0)) \text{ and } g \;:=\; \ln f.$$

Then

$$v(0, X(0)) := \inf\left\{y \in \mathbb{R} \;:\; \exists\, \nu \in \mathcal{U},\; Y_y^{\nu}(T) \ge g\left(X^{\nu}(T)\right) \quad P - \text{a.s.}\right\}.$$

Remark 6.1. Assume that function g is bounded. Then the value function v is bounded. Using the notation of previous sections, we also have that v_*, v^*, $\underline{G}$, and $\overline{G}$ are bounded functions.

Let us introduce the support function of the interval $[-\ell^{-1}, u^{-1}]$:

$$h(p) := u^{-1}p^+ \ + \ \ell^{-1}p^-,$$

with the convention $1/0 = +\infty$, and the usual notation $p^+ := p \vee 0$ and $p^- := (-p)^+$. Observe that h is a mapping from $\mathbb{R}$ into $\mathbb{R} \cup \{+\infty\}$. We also denote by $\overline{F}$ and $\underline{F}$ the functions

$$\overline{F} \ := \ e^{\overline{G}} \ = \ \limsup_{t\uparrow T, x' \to x} \tilde{v}(t,x') \text{ and } \underline{F} \ := \ e^{\underline{G}} \ = \ \liminf_{t\uparrow T, x' \to x} \tilde{v}(t,x').$$

Applying Theorems 4.1 and 5.1, we obtain the following characterization of the superreplication problem $\tilde{v}$ by a change of variable.

THEOREM 6.1. *Let μ and σ be bounded Lipschitz functions uniformly in the t variable, and $\sigma > 0$. Suppose further that g is bounded and satisfies $(g_*)^* \geq g$. Then*

(i) *$\tilde{v}$ is a discontinuous viscosity solution of*

$$\min\left\{ -\tilde{v}_t(t,x) - \frac{1}{2}\sigma^2\left(t,x,\tilde{v}_x(t,x)\right)\tilde{v}_{xx}(t,x) \ ; \ \tilde{v}(t,x) - h\left(\tilde{v}_x(t,x)\right) \right\} = 0$$
$$\text{on} \quad [0,T) \times \mathbb{R} \, .$$

(ii) *The terminal value functions $\underline{F}$ and $\overline{F}$ satisfy in the viscosity sense*

$$\min\{ \ \underline{F} - f_* ; \ \underline{F} - h(\underline{F}_x) \ \} \geq 0,$$
$$\min\{ \ \overline{F} - f^* ; \ \overline{F} - h(\overline{F}_x) \ \} \leq 0 \qquad \text{on} \quad \mathbb{R}.$$

The rest of this section is devoted to the characterization of the terminal functions $\overline{F}$ and $\underline{F}$. It is known that the first order variational inequality appearing in part (ii) of the above theorem could fail to have a unique bounded discontinuous viscosity solution: under our condition $(f_*)^* \geq f$, all viscosity discontinuous bounded solutions have the same lower semicontinuous envelope; see Barles [3]. Therefore, we do not have much to say in the case where the payoff function f is not continuous.

We provide a characterization of the terminal condition of the superreplication problem in the case of Lipschitz payoff function f.

PROPOSITION 6.1. *Let the conditions of Theorem* 6.1 *hold. Assume, further, that the payoff function f is Lipschitz on $\mathbb{R}$. Then*

$$\overline{F}(x) \ = \ \underline{F}(x) = \hat{f}(x) \ := \ \sup_{y \in \mathbb{R}} f(x+y)e^{-\delta(y)},$$

where $\delta := \delta_U$ is the support function of the interval $U = [-\ell, u]$.

Proof. From Theorem 6.1, functions $\overline{F}$ and $\underline{F}$ are, respectively, upper and lower semicontinuous viscosity sub- and supersolutions of

$$\text{(VI)} \qquad \min\left\{u - f \ ; \ u - h(u_x)\right\} = 0 \quad \text{on} \quad \mathbb{R}.$$

In order to obtain the required result, we shall first prove that $\hat{f}$ is a (continuous) viscosity supersolution of (VI) (step 1). Then we will prove that $\underline{F} \geq \hat{f}$ (step 2). The proof is then concluded by means of a comparison theorem (Barles [2, Theorem 4.3, p. 93]); since f is Lipschitz, conditions (H1), (H4), and (H11) of this theorem are easily seen to hold. Since $\overline{F} \geq \underline{F}$ by definition, the above claims provide $\hat{f} \geq \overline{F} \geq \underline{F} \geq \hat{f}$.

Step 1. Let us prove that $\hat{f}$ is a continuous viscosity supersolution of (VI).

(i) $\hat{f}$ is a Lipschitz function. To see this, observe that, since δ is a sublinear function, it follows that $\hat{\hat{f}} = \hat{f}$, where $\hat{\hat{f}}$ is defined by the same formula as $\hat{f}$ with $\hat{f}$ substituted to f. Then, since $\hat{f}$ and δ are nonnegative,

$$\begin{aligned}\hat{f}(x+y) - \hat{f}(x) &\le \hat{f}(x+y)(1-e^{-\delta(y)}) \quad \text{for all } \ y \in \mathbb{R} \\ &\le \hat{f}(x+y)\delta(y) \ \le \ \|f\|_\infty \max(u,\ell)|y|.\end{aligned}$$

(ii) $\hat{f}$ is a supersolution of (VI). To see this, let $x_0 \in \mathbb{R}$ and $\varphi \in C^1(\mathbb{R})$ be such that $0 = (\hat{f} - \varphi)(x_0) = \min(\hat{f} - \varphi)$. Observe that $\hat{f} \ge \varphi$. Since $\hat{f} > 0$, we can assume without loss of generality that $\varphi > 0$. By definition, we have $\hat{f}(x_0) \ge f(x_0)$.

It remains to prove that $(\varphi'/\varphi)(x_0) \in [-\ell, u]$. Since $\hat{\hat{f}} = \hat{f}$, we have

$$\varphi(x_0) \ = \ \hat{f}(x_0) \ge \hat{f}(x_0+h)e^{-\delta(h)} \ \ge \ \varphi(x_0+h)e^{-\delta(h)}$$

for all $h \in \mathbb{R}$. Now let h be an arbitrary positive constant. Then

$$\frac{\varphi(x_0+h) - \varphi(x_0)}{h} \le \varphi(x_0+h)\frac{1-e^{-uh}}{h},$$

and, by sending h to zero, we get $\varphi'(x_0) \le u\varphi(x_0)$. Similarly, by considering an arbitrary constant $h < 0$, we see that $\varphi'(x_0) \ge -\ell\varphi(x_0)$.

Step 2. We now prove that $\underline{F} \ge \hat{f}$. From the supersolution property of $\underline{F}$, we have that $\underline{F} \ge f$, and, for all $y \in \mathbb{R}$, $\underline{F}$ satisfies in the viscosity sense

$$\delta(y)\underline{F} - y\underline{F}_x \ge 0.$$

By an easy change of variable, we see that $\underline{G} = \ln \underline{F}$ satisfies in the viscosity sense

$$\delta(y) - y\underline{G}_x \ge 0.$$

This proves that the function $x \longmapsto \delta(y)x - y\underline{G}(x)$ is nondecreasing (see, e.g., Cvitanić, Pham, and Touzi [9]), and therefore

$$\begin{aligned}\delta(y)(x+y) - y\underline{G}(x+y) &\ge \delta(y)x - y\underline{G}(x) \quad \text{for all } \ y > 0, \\ \delta(y)(x+y) - y\underline{G}(x+y) &\le \delta(y)x - y\underline{G}(x) \quad \text{for all } \ y < 0.\end{aligned}$$

Recalling that $\underline{F} \ge f$, this provides

$$\underline{F}(x) \ge \sup_{y\in\mathbb{R}} \underline{F}(x+y)e^{-\delta(y)} \ \ge \ \sup_{y\in\mathbb{R}} f(x+y)e^{-\delta(y)} \ = \ \hat{f}(x). \qquad \square$$

BOUNDARY-VALUE PROBLEMS FOR SYSTEMS OF HAMILTON–JACOBI–BELLMAN INCLUSIONS WITH CONSTRAINTS*

JEAN-PIERRE AUBIN†

Abstract. We study in this paper boundary-value problems for *systems of Hamilton–Jacobi–Bellman* first-order partial differential equations and variational inequalities, the solutions of which are constrained to obey viability constraints. They are motivated by some control problems (such as impulse control) and financial mathematics. We shall prove the *existence and uniqueness of such solutions in the class of closed set-valued maps* by giving a precise meaning to what a solution means in this case. We shall also provide *explicit formulas* for this problem. When we deal with Hamilton–Jacobi–Bellman equations, we obtain the existence and uniqueness of Frankowska contingent episolutions. We shall deduce these results from the fact that the graph of the solution is the viable-capture basin of the graph of the boundary conditions under an auxiliary system and then from their properties and their characterizations proved in [J.-P. Aubin, *SIAM J. Control Optim.*, 40 (2001), pp. 853–881].

Key words. partial differential inclusion, systems of Hamilton–Jacobi–Bellman equations, viability, capture basins, method of characteristics, shocks, impulse control, contingent cone, Marchaud map

Introduction. It is well known that value functions of optimal control problems are solutions to Hamilton–Jacobi partial differential equations of the form

$$-\frac{\partial}{\partial t}v(t,x) + \inf_{u\in P(x,v(t,x))}\left(\frac{\partial}{\partial x}v(t,x)f(x,v(t,x),u) - g(x,v(t,x),u)\right) \;=\; 0$$

with adequate boundary conditions.

Observe, nevertheless, that, in this equation, the infimum hides two inequalities:

1. there exists $u \in P(x,v(t,x))$ such that

$$-\frac{\partial}{\partial t}v(t,x) + \frac{\partial}{\partial x}v(t,x)f(x,v(t,x),u) - g(x,v(t,x),u) \;\leq\; 0;$$

2. for all $u \in P(x,v(t,x))$,

$$\frac{\partial}{\partial t}v(t,x) - \frac{\partial}{\partial x}v(t,x)f(x,v(t,x),u) + g(x,v(t,x),u) \;\leq\; 0.$$

However, several other problems of control theory lead to the study of *controlled systems* of first-order partial differential equations (or systems of first-order *partial differential inclusions*): Let $P : X \times Y \rightsquigarrow \mathcal{U}$ be a set-valued map associating with any pair (x,y) a feasible set $P(x,y)$ of controls, and let f and g be single-valued maps from $X \times Y \times \mathcal{U}$ to finite dimensional vector spaces X and Y, respectively.

The problem is to find a set-valued map $V : \mathbf{R}_+ \times X \rightsquigarrow Y$ satisfying the following:

†Réseau de Recherche Viabilité, Jeux, Contrôle 14, rue Domat, F-75005 Paris, France (J.P.Aubin@wanadoo.fr).

1. there exists $u \in P(x, V(t,x))$ such that

$$(1) \quad 0 \in \text{“} - \frac{\partial}{\partial t} V(t,x) + \frac{\partial}{\partial x} V(t,x) f(x, V(t,x), u)\text{”} - g(x, V(t,x), u);$$

2. for all $u \in P(x, v(t,x))$,

$$(2) \qquad 0 \in \text{“} \frac{\partial}{\partial t} V(t,x) - \frac{\partial}{\partial x} V(t,x) f(x, V(t,x), u)\text{”} + g(x, V(t,x), u),$$

where we shall give a meaning to the derivative

$$\text{“} \frac{\partial}{\partial t} V(t,x) - \frac{\partial}{\partial x} V(t,x) f(x, V(t,x), u)\text{”}$$

in Theorem 3.1 below. Indeed, even in the absence of controls, it is well known that such solutions may have shocks, i.e., can be set-valued, and, when they happen to be single-valued, are not even necessarily differentiable in the usual sense.

The definition of solution shall be taken in a generalized sense—the Frankowska solution[1] that we shall define later in the paper.

In order to obtain uniqueness, we have to impose boundary conditions. Furthermore, problems arising in economics, finance, and other fields lead us to *introduce constraints* bearing on both the state and the solution. We shall describe these boundary conditions and constraints by introducing two set-valued maps $\Phi : \mathbf{R}_+ \times X \rightsquigarrow Y$ and $\Psi : \mathbf{R}_+ \times X \rightsquigarrow Y$ such that $\Phi \subset \Psi$. The first one encompasses initial and/or boundary-value conditions, or other conditions as we shall see, and the second one encompasses viability constraints both on the state variables x, which must remain in the domain of Ψ, and on the solution $V(t,x)$.

We shall prove that *there exists a unique* “solution” $(t,x) \rightsquigarrow V(t,x)$ to this general problem (1,2) satisfying the conditions

$$\forall\, (t,x) \in \mathbf{R}_+ \times X, \quad \Phi(t,x) \subset V(t,x) \subset \Psi(t,x)$$

in the class of closed set-valued maps (i.e., set-valued maps with closed graph) that depends continuously of the data Φ (in the “graphical sense,” mapping graphical limits to graphical limits, as is explained later).

Even more, we shall provide an explicit formula when $f(x,u)$ and $P(x)$ do not depend on the variable y and when

$$g(x,y,u) := -M(x,u)y - L(x,u)$$

is affine with respect to y, where

[1] Hélène Frankowska proved that the epigraph of the value function of an optimal control problem—assumed to be only lower semicontinuous—is semipermeable (i.e., invariant and backward viable) under a (natural) auxiliary system. Furthermore, when it is continuous, she proved that its epigraph is viable and its hypograph invariant [43, 44, 46]. By duality, she proved that the latter property is equivalent to the fact that the value function is a viscosity solution of the associated Hamilton–Jacobi equation in the sense of Crandall and Lions. See also [32, 31] for more details. We refer also to [39, 40] for the study of these equations through the characteristics method using the contingent derivative (and not epi- and hypo- derivatives). Such concepts have been extended to solutions of systems of first-order partial differential equations without boundary conditions by Hélène Frankowska and the author (see [19, 20, 21, 22, 23, 24] and chapter 8 of [2] and [7]). See also [16, 17]. This point of view is used here in the case of boundary value problems.

1. M is a continuous matrix-valued function

$$M : (x,u) \in X \times \mathcal{U} \mapsto M(x,u) \in \mathcal{L}(X,Y),$$

2. L is a continuous "vector-Lagrangian"

$$L : (x,u) \in X \times \mathcal{U} \mapsto L(x,u) \in Y.$$

Let us denote by $\mathcal{C} : x \in X \rightsquigarrow \mathcal{C}(x) \subset \mathcal{C}(0,\infty;X) \times L^1(0,\infty;\mathcal{U})$ the set-valued map associating with $x \in X$ the set $\mathcal{C}(x)$ of the pairs $(x(\cdot),u(\cdot))$ of solutions to the control system

$$\left\{ \begin{array}{ll} \text{(i)} & x'(t) \ = \ f(x(t),u(t)), \\ \text{(ii)} & u(t) \ \in \ P(x(t)), \end{array} \right.$$

starting at x at $t = 0$.

In the absence of constraints ($\Psi(t,x) := Y$), we shall prove that, setting

$$\left\{ \begin{array}{l} J_\Phi(t;(x(\cdot),u(\cdot)))(T,x) \\ \\ := \ e^{\int_0^t M(x(s),u(s))ds}\Phi(T-t,x(t)) + \displaystyle\int_0^t e^{\int_0^\tau M(x(s),u(s))ds} L(x(\tau),u(\tau))d\tau, \end{array} \right.$$

the set-valued solution V is defined by

$$V(\Phi)(T,x) \ := \ \bigcup_{(x(\cdot),u(\cdot))\in\mathcal{C}(x)} \ \bigcup_{t\in[0,T]} J_\Phi(t;(x(\cdot),u(\cdot)))(T,x).$$

With an adequate choice of the set-valued map Ψ associated with the set-valued map Φ, we find as a solution the set-valued map defined by

$$W(\Phi)(T,x) \ := \ \bigcup_{(x(\cdot),u(\cdot))\in\mathcal{C}(x)} \ \bigcap_{t\in[0,T]} J_\Phi(t;(x(\cdot),u(\cdot)))(T,x).$$

We shall find as many formulas as pairs (Ψ,Φ) of set-valued maps (see formula (24) of Theorem 5.1 below).

We can read this type of result the other way around: For instance, the set-valued map $V(\Phi)$ defined by

$$\left\{ \begin{array}{l} V(\Phi)(T,x) \ := \ \bigcup_{(x(\cdot),u(\cdot))\in\mathcal{C}(x)} \bigcup_{t\in[0,T]} \\ \left(e^{\int_0^t M(x(s),u(s))ds}\Phi(T-t,x(t)) + \displaystyle\int_0^t e^{\int_0^\tau M(x(s),u(s))ds} L(x(\tau),u(\tau))d\tau \right) \end{array} \right.$$

is the unique "solution" to the Hamilton–Jacobi partial differential inclusion (1,2) satisfying the initial condition

$$V(0,x) \ = \ \Phi(0,x)$$

and

$$\forall\, t \geq 0,\ x \in X, \ \ \Phi(t,x) \ \subset \ V(t,x).$$

They define set-valued analogue of optimal control problems, where the "$\cup$" operation replaces the "inf" operation and the "$\cap$" operation replaces the "sup" operation. Actually, when $Y := \mathbf{R}$ and when we associate with two extended functions $\mathbf{c} : \mathbf{R}_+ \times X \rightsquigarrow \mathbf{R} \cup \{+\infty\}$ and $\mathbf{b} : \mathbf{R}_+ \times X \rightsquigarrow \mathbf{R} \cup \{+\infty\}$ the set-valued maps

$$\left\{ \begin{array}{ll} \text{(i)} & \Phi(t,x) := \mathbf{c}(t,x) + \mathbf{R}_+, \\ \text{(ii)} & \Psi(t,x) := \mathbf{b}(t,x) + \mathbf{R}_+, \end{array} \right.$$

we find problems of dynamic valuation and management of portfolios in mathematical finance, used, in particular, for valuating options as in [55, 30, 56]. For instance, we deduce that

$$\left\{ \begin{array}{l} \inf_{y \in V(\Phi)(T,x)} y \ = \ \inf_{(x(\cdot),u(\cdot)) \in \mathcal{C}(x)} \inf_{t \in [0,T]} \\ \left(e^{\int_0^t M(x(s),u(s))ds} \mathbf{c}(T-t, x(t)) + \displaystyle\int_0^t e^{\int_0^\tau M(x(s),u(s))ds} L(x(\tau), u(\tau)) d\tau \right) \end{array} \right.$$

is the *valuation function* of a stopping time problem (see section 5 below).

These two explicit formulas are given by the *caliber* $V : \mathbf{R}_+ \times X \rightsquigarrow Y$ defined in the following way: y belongs to $V(T,x)$ if there exist a control $t \in [0,T] \mapsto u(t)$ and a time $T^* \in [0,T]$ such that the solution $(x(\cdot), u(\cdot), y(\cdot))$ to the control system

$$\left\{ \begin{array}{lll} \text{(i)} & x'(t) & = f(x(t), y(t), u(t)), \\ \text{(ii)} & y'(t) & = g(x(t), y(t), u(t)), \\ \text{(iii)} & u(t) & \in P(x(t), y(t)) \end{array} \right.$$

starting at $x(0) = x$, $y(0) = y$ satisfies

$$\left\{ \begin{array}{ll} \text{(i)} & \forall\, t \in [0, T^*], \ \ y(t) \in \Psi(T-t, x(t)), \\ \\ \text{(ii)} & y(T^*) \in \Phi(T - T^*, x(T^*)). \end{array} \right.$$

Observe that taking $\Phi(t,x) = \emptyset$ whenever $t > 0$ guarantees that $T^* = T$.

We shall prove that this set-valued map is the unique solution to our problem (1,2). Actually, this is a reformulation dictated by problems arising in dynamic economic theory, finance mathematics, and control theory of the celebrated "method of characteristics."

We shall revisit this method using the tools of set-valued analysis and viability theory which go back to the early 1980's.[2] They find here an unexpected relevance to assert the existence and the uniqueness of the solution to this problem since such solutions may have shocks, i.e., can be set-valued, and even when they happen to be single-valued, they are not differentiable in the usual sense. The tools forged by set-valued analysis and viability theory happen to allow us to prove existence and uniqueness in the class of set-valued maps with closed graph only instead of classes of vector-distributions.[3]

[2] See [18, 2, 60], etc., for instance.

[3] The strong requirement of pointwise convergence of differential quotients can be weakened in (at least) two ways, with each way sacrificing different groups of properties of the usual derivatives:

- *Distributional derivatives.* Fix the direction v, and take the limit of the function $x \mapsto \nabla_h f(x)(v)$ in the weaker sense of distributions. The limit $D_v f$ may then be a distribution and no longer a single-value map. However, it coincides with the usual limit when f is Gâteaux differentiable. Moreover, one can define difference quotients of distributions, take their limit, and thus differentiate distributions.

The basic concept useful in our framework is the concept of the *viable-capture basin* of a "target" $C \subset K$ viable in a constrained subset $K \subset X$ under a differential inclusion $x' \in F(x)$: It is the subset $\mathrm{Capt}_F^K(C)$ of initial states $x_0 \in K$ such that C is reached in finite time before possibly leaving K by at least one solution $x(\cdot) \in \mathcal{S}(x_0)$, where $\mathcal{S}(x_0)$ denotes[4] the set of solutions to the differential inclusion $x' \in F(x)$ starting at x_0.

Then we shall prove that *the graph of the solution* $(t,x) \rightsquigarrow V(t,x)$ *to the above boundary value problem is the viable-capture basin of the graph of the set-valued map* Φ *viable in the graph of the set-valued map* Ψ under the auxiliary differential inclusion

$$\begin{cases} \text{(i)} & \tau'(t) \;=\; -1, \\ \text{(ii)} & x'(t) \;=\; f(x(t),y(t),u(t)), \\ \text{(iii)} & y'(t) \;=\; g(x(t),y(t),u(t)), \\ \text{(iv)} & u(t) \;\in\; P(x(t),y(t)) \end{cases}$$

and that this solution is *unique* among the solutions with closed graph to this boundary value problem.

In some instances, this viable-capture basin can be computed analytically, and we obtain in this case an explicit formula of the solution to the above boundary value problem.

In all cases, the Viability/Capturability Algorithm designed by Patrick Saint-Pierre provides numerically the viable-capture basins and thus the solutions to systems of Hamilton–Jacobi–Bellman equations, bypassing finite-difference methods. (See

---

Distributions are no longer functions or maps defined on $\mathbf{R}^n$, so they lose the pointwise character of functions and maps but retain the linearity of the operator $f \mapsto D_v f$, which is mandatory for using the theory of the linear operator for solving partial differential equations.

- *Graphical derivatives.* Fix the direction x, and take the limit of the function $v \mapsto \nabla_h f(x)(v)$ in the weaker sense of "graphical convergence." (The graph of the graphical limit is the Painlevé–Kuratowski upper limit of the graphs.) The limit $Df(x)$ may then be a set-valued map and no longer a single-value map. However, it coincides with the usual limit when f is Gâteaux differentiable. Moreover, one can define difference quotients of set-valued maps, take their limit, and thus differentiate set-valued maps. These graphical derivatives keep the pointwise character of functions and maps, which is mandatory for implementing the Fermat rule, proving inverse function theorems under constraints or using Lyapunov functions, for instance, but they lose the linearity of the map $f \mapsto Df(x)$.

In both cases, the approaches are similar: They use (different) convergences *weaker than the pointwise convergence* for increasing the possibility for the difference-quotients to converge. But the price to pay is the loss of some properties by passing to these weaker limits (the pointwise character for distributional derivatives, the linearity of the differential operator for graphical derivatives).

[4]When we are studying the viable-capture basins of targets under differential inclusions, we observe that they are not specific to differential inclusions. They involve only a few properties of the solution map $\mathcal{S}$, associating with any initial state x the set $\mathcal{S}(x)$ of solutions $t \mapsto x(t)$ that are solutions to the above differential inclusion starting at x at initial time 0. These properties (translation and concatenation properties as well as continuity properties) of the solution map $x \rightsquigarrow \mathcal{S}(x)$ are common to other control problems, such as

1. control problems with memory (see the contributions of [50, 51, 52], some of them being presented in [2]), before known under the name of functional control problems and now called "path dependent control systems";
2. parabolic (diffusion-reaction) type partial differential inclusions (see the contributions of [64, 65, 66, 67], some of them being presented in [2]), also known as distributed control systems;
3. "mutational equations" governing the evolution in metric spaces, including "morphological equations" governing the evolution of sets (see [4], for instance).

[61, 38, 55, 56] for solutions of Hamilton–Jacobi–Bellman equations derived from mathematical finance.)

This existence and uniqueness result follows from the following three steps:

1. From a characterization proved in [15] stating the viable-capture basin $\mathrm{Capt}^K(C)$ is the *unique* closed subset D between C and K satisfying

$$\text{(3)} \qquad \begin{cases} \text{(i)} & \mathrm{Capt}^D(C) \;=\; D, \\ \text{(ii)} & \mathrm{Capt}^K(D) \;=\; D. \end{cases}$$

2. From a characterization stated below of the viable-capture basin of a target C viable in a closed subset K under a differential inclusion $x' \in F(x)$ proved in [12] (see also [57, 58, 59]): Let us recall that
   (a) $K\backslash C$ is a repeller, meaning that all solutions $x(\cdot) \in \mathcal{S}(x)$ starting from $x \in K\backslash C$ reach C or leave K in finite time;
   (b) the subset $D\backslash C$ is said to be *locally viable* under $\mathcal{S}$ if from any initial state $x \in D\backslash C$ starts at least one solution viable in $D\backslash C$ on a nonempty interval;
   (c) a subset $D \subset K$ is *locally backward invariant relatively to* K under $\mathcal{S}$ if, for every $x \in D$, all backward solutions starting from x and viable in K on an interval $[0, T]$ are viable in D on $[0, T]$.

   THEOREM 0.1. *Let us assume that F is Marchaud*[5] *and that a closed subset $C \subset K$ satisfies the property*

$$\text{(4)} \qquad K\backslash C \;\; \textit{is a repeller under } F.$$

   Then the viable-capture basin $\mathrm{Capt}^K(C)$ *is the* unique *closed subset D satisfying $C \subset D \subset K$ and*

$$\text{(5)} \qquad \begin{cases} \text{(i)} & D\backslash C \textit{ is} \text{ locally viable } \textit{under } \mathcal{S}, \\ \text{(ii)} & D \textit{ is} \text{ locally backward invariant relatively to } K \textit{ under } \mathcal{S}. \end{cases}$$

3. From the viability and invariance theorems that translate the necessary and sufficient conditions (5) in terms of tangential conditions. We recall that the *contingent cone* to a subset K at a point $x \in K$, introduced in the early 1930's independently by Bouligand and Severi, adapts to any subset the concept of tangent space to manifolds: A direction $v \in X$ belongs to $T_K(x)$ if there exist sequences $h_n > 0$ and $v_n \in X$ converging to 0 and v, respectively, such that

$$\forall\, n \geq 0, \;\; x + h_n v_n \;\in\; K.$$

   This means that the contingent cone is the Painlevé–Kuratowski upper limit of the subsets $\frac{K-x}{h}$ when h converges to 0 (see, for instance, [18, 60] for more details).

   We shall use the following statements of [12].

   THEOREM 0.2. *Let us assume that F is Marchaud, that $C \subset K$ and K are closed, and that $K\backslash C$ is a repeller. Then the viable-capture basin* $\mathrm{Capt}_F^K(C)$ *is*

[5] F is a *Marchaud map* if

$$\begin{cases} \text{(i)} & \text{the graph and the domain of } F \text{ are nonempty and closed,} \\ \text{(ii)} & \text{the values } F(x) \text{ of } F \text{ are convex,} \\ \text{(iii)} & \text{the growth of F is linear:} \\ & \exists\, c > 0 \mid \forall\, x \in X, \;\; \|F(x)\| := \sup_{v \in F(x)} \|v\| \;\leq\; c(\|x\| + 1). \end{cases}$$

(a) *the* largest *closed subset D satisfying $C \subset D \subset K$ and*

$$\forall\, x \in D\backslash C,\ \ F(x) \cap T_D(x) \neq \emptyset; \tag{6}$$

(b) *if, furthermore, F is Lipschitz, the* unique *closed subset D satisfying $C \subset D \subset K$ and the* Frankowska properties

$$\begin{cases} \text{(i)} & \forall\, x \in D\backslash C,\ \ F(x) \cap T_D(x) \neq \emptyset, \\ \text{(ii)} & \forall\, x \in D \cap \mathrm{Int}(K),\ \ -F(x) \subset T_D(x), \\ \text{(iii)} & \forall\, x \in D \cap \partial K,\ \ -F(x) \subset T_D(x) \cup T_{X\backslash K}(x). \end{cases} \tag{7}$$

4. From the property

$$T_{\mathrm{Graph}(V)}(t,x,y) = \mathrm{Graph}(DV(t,x,y))$$

of the contingent derivative $DV(t,x,y)$ of the set-valued map $V : (t,x) \rightsquigarrow V(t,x)$ at the point (t,x,y) of its graph introduced in [1]: The graph of the set-valued map $DV(t,x,y)$ from $\mathbf{R} \times X$ to Y is equal to the contingent cone to the graph of V at (t,x,y) (see [1]). This is how Fermat in 1637 defined the derivative of a function as the slope of the tangent to its graph. Leibniz and Newton provided the characterization in terms of limits of difference quotients. Here, too, *the contingent derivative $DV(t,x,y)$ is the upper graphical limit of the difference quotients*, the graph of which being by definition the upper limit of the graphs of the difference quotients $\nabla_h V(t,x,y)$ of V at $(t,x,y) \in \mathrm{Graph}(V)$ defined by

$$(\lambda, f) \mapsto \nabla_h V(t,x,y)(\lambda,f) := \frac{V(t+\lambda h, x+hf) - y}{h}.$$

Indeed, we observe that

$$\mathrm{Graph}(\nabla_h V(t,x,y)) = \frac{\mathrm{Graph}(V) - (t,x,y)}{h}$$

so that the contingent cone to the graph of V, being the upper limit of the graphs of the difference quotients, is equal by definition to the graph of the upper graphical limit of the difference quotients. Consequently, to say that $g \in Y$ belongs to the contingent derivative $DV(t,x,y)\,(\pm 1, f)$ of V at (t,x,y) in the direction $(\pm 1, f) \in \mathbf{R} \times X$ means that

$$\liminf_{h \to 0+,\ f' \to f} \left\| \frac{V(t \pm h, x + hf') - y}{h} - g \right\| = 0.$$

Since the contingent cone is a closed subset, the graph of a contingent derivative is always closed and positively homogenous. (This is what remains of the required linearity of the derivative in classical analysis, but, fortunately, we can survive pretty well without linearity.)

When $u : \mathbf{R} \times X \mapsto Y$ is single-valued, we set $Du(t,x) := Du(t,x,u(t,x))$. We see at once that $Du(t,x)(\pm 1, f) = \pm \frac{\partial u(t,x)}{\partial t} + \frac{\partial u(t,x)}{\partial x} \cdot f$ whenever u is differentiable at (t,x). When u is Lipschitz on a neighborhood of (t,x) and when the dimension of X is finite, the domain of $Du(t,x)$ is not empty. Furthermore, the Rademacher theorem stating that a locally Lipschitz single-valued map is almost everywhere differentiable implies that $x \rightsquigarrow Du(t,x)$ is almost everywhere single-valued.

However, in this case, equality $Du(t,x)(-1,-f) = -Du(t,x)(1,f)$ is not true in general. We refer to [18, 60] for more details.

The above results—which are interesting by themselves for other mathematical models of evolutionary economics (see [3]), population dynamics, dynamical games (see [11]), and epidemiology—can be applied to many other problems. Dealing with subsets, they can be applied to graphs of single-valued maps as well as set-valued maps, to epigraphs and hypographs of (extended) real-valued functions for solving Hamilton–Jacobi–Bellman equations, to graph of "impulse" maps (which take empty values except in discrete sets, useful in the study of hybrid systems or inventory management), etc. (See, for instance, [5, 10, 6, 8, 9, 25, 26, 27, 28, 29, 34, 53, 54, 62, 63] and their bibliographical references.)

Outline. We begin in section 1 with two nonstandard motivations arising in macroeconomic problems faced by central banks (filtering informations on the economy from past informations and future expectations) and in the study of impulse and hybrid systems, leading to systems of Hamilton–Jacobi–Bellman inclusions. This section (which states the problems without solving them, as this task is done in specific articles) can be skipped by true believers in mathematics. We define in section 2 the "caliber" of a pair of set-valued maps (Φ, Ψ) under a control system that appears naturally in some control problems and in economic and financial mathematics. We next prove in section 3 that the caliber is the unique solution to the system of Hamilton–Jacobi–Bellman inclusions satisfying the imposed conditions. In section 4, we provide a useful stability result, stating roughly that the caliber of graphical limits is the graphical limit of calibers. Section 5 deals with the explicit formula of the caliber when the control system is structured and the exosystem is affine with respect to the second variable. We also prove that, in this case, the caliber is the unique solution to a system of "fixed-set equations" and provide interesting "barrier properties" of the boundary of the caliber. We derive in section 6 the usual characterization theorems of the valuation functions of a large class of control and stopping time problems as Frankowska episolutions to the scalar Hamilton–Jacobi–Bellman equations that justify the usefulness of the results they are derived from, and we extend this scalar situation in section 7 to the case of "dynamical vector optimization," where we look for intertemporal Pareto minima. □

1. Motivations. We shall provide two motivations coming from recent issues arising

1. in macroeconomics (filtering informations on the economy from past informations and future expectations), and
2. in hybrid systems and impulse control,

leading to systems of Hamilton–Jacobi–Bellman partial differential inclusions.

We refer to specific articles for more details, since they use the basic theorems of this paper to solve the Hamilton–Jacobi–Bellman partial differential inclusions that appear in those articles.

Further applications to the value functions of optimal control and stopping time problems are given in section 6, and applications to dynamic vector optimization are given in section 7.

1.1. Selector through past informations and future expectations. As a first motivation, we present a problem originating in a research program under current investigation by Noël Bonneuil, Halim Doss, Georges Haddad, Henri Pages, Dominique Pujal, Patrick Saint-Pierre, and the author on macroeconomic problems faced by central banks.

We quote excerpts of the introduction of [68]: *It is a truism that monetary policy*

operates under considerable uncertainty about the state of the economy and the size and nature of the disturbances that hit the economy...But in a more realistic case where important variables are forward-looking [and not only backward-looking] variables, the problem of efficient signal-extraction is inherently more complicated...In the real world, many important indicator variables are forward-looking variables [routinely watched by central banks].

We suggest taking up this issue by using nonlinear continuous evolutionary models controlled by instruments such as interest rates. We keep the problem of extracting the "real evolution," knowing only backward-looking measurements and forward-looking expectations that we shall describe by "expectation tubes."

The use of the Kalman filter for extracting information is replaced by the recent concept of the detector introduced in [13] and [27] in the case of "impulse and hybrid control systems." We adapt this concept of the detector in the case of both backward-looking and forward-looking informations and expectations.

For that purpose, we introduce three time variables for describing the evolution of the system: the current (or present) time T, the past time $t \in [0, T]$, and a prediction time or forward-looking time $s \geq T$, where $a := s - T \in \mathbf{R}_+$ is the prediction horizon used to take into account anticipations and expectations (or make predictions) in the future.

At each past date, the state is measured, or informations on the state are gathered: This is mathematically described by a *detectability tube* (as in [13])

$$t \in \mathbf{R}_+ \rightsquigarrow I(t) \ \subset \ X := \mathbf{R}^n$$

that provides the limited amount of information about the states at time t. We take $I(t) := X$ when no information is recorded at time t. Hence "discrete" measurements are obtained when $I(t) \neq X$ only for a discrete number of instants t_n.

An example of detectability tubes is given by $I(t) := h^{-1}(y(t))$, where $h : X \mapsto Y$ is an observation map (or measurement map) and where $t \mapsto y(t)$ is the evolution of the observed output:

$$\forall\, t \in [0, T], \ \ y(t) \ = \ h(x(t)).$$

The same framework also houses the case when the observation map is set-valued: We set $I(t) := H^{-1}(y(t))$, and the above viability condition reads

$$\forall\, t \in [0, T], \ \ y(t) \ \in \ H(x(t)),$$

so that "tychastic" uncertainties (by opposition to stochastic uncertainties) on the measurements can be incorporated in this framework.

In order to take into account expectations made at each instant t for future dates $s := t + a$, $a \geq 0$, we describe them mathematically by an *expectation tube* $(t, a) \in \mathbf{R}^2_+ \mapsto I(t, a) \subset X$, where we set $I(t, 0) := I(t)$ for obtaining the detectability tube.

We may assume that, if $a_1 \leq a_2$, then $I(t, a_2) \subset I(t, a_1) \subset I(t, 0) =: I(t)$, since the predictions made at time t up to time $s_2 := t+a_2$ are valid up to time $s_1 := t+a_1 \leq s_2$.

Therefore, we associate with any current time T, any horizon $s \geq t$, and any backward-looking time $t \in [0, T]$ the set $I(t, s - t)$ of states measured at time t that depend upon the duration $a := s - t$ of the expectation interval between t and the horizon s.

Hence the information/expectation constraint can be summarized by

$$\forall\, T \geq 0,\ \forall\, s \geq T,\ \forall\, t \in [0,T],\ x(t) \in I(t, s-t). \tag{8}$$

Let $\mathcal{U}$ be a space of controls, regulees, prices, interest-rate instruments, etc. The dynamics of the state are described by a map $f : (t,a,x,u) \in \mathbf{R}^2_+ \times X \times \mathcal{U} \mapsto X$ and by a set-valued map $P : \mathbf{R}_+ \times X \rightsquigarrow \mathcal{U}$ depicting the state-dependent constraints on the controls $u \in P(a,x)$.

For any current time T and horizon $s \geq T$, we assume that the evolution of the state of the system is governed by the control system

$$\forall\, t \in [0,T], \begin{cases} \text{(i)} & x'(t) = f(t, s-t, x(t), u(t)), \\ \text{(ii)} & u(t) \in P(s-t, x(t)). \end{cases} \tag{9}$$

In other words, at each time $t \in [0,T]$, the velocity $x'(t)$ depends upon the time t, the time $s-t$ left to the horizon s, and a control $u(t)$ subjected to constraints depending upon both the expected time $s-t$ left to the horizon and the state $x(t)$ at time t.

We also introduce a set-valued map $a \in \mathbf{R}_+ \rightsquigarrow C(a)$ specifying another constraint on the subsets $C(a)$ of initial states that may depend upon the term $a \geq 0$ satisfying

$$\forall\, a \geq 0,\ C(a) \subset I(0,a).$$

DEFINITION 1.1. *Let us consider a control system (f,P), an expectation tube $I : \mathbf{R}^2_+ \rightsquigarrow X$, and a tube $C : \mathbf{R}_+ \rightsquigarrow X$ satisfying, for all $a \geq 0$, $C(a) \subset I(0,a)$.*

The selector *is the set-valued map $\mathbf{S}_{(I,C)} : \mathbf{R}^2_+ \rightsquigarrow X$ that associates with any current time T and any expectation $a := s-T$ the (possibly empty) subset $\mathbf{S}_{(I,C)}(t,a)$ of states $x \in I(t,a)$ such that there exists a solution $x(\cdot) \in \mathcal{S}(t,a,x)$ to the system*

$$\begin{cases} & \forall\, t \in [0,T],\ \forall\, s := T + a \geq 0, \\ \text{(i)} & x'(t) = f(t, s-t, x(t), u(t)), \\ \text{(ii)} & u(t) \in P(s-t, x(t)) \end{cases} \tag{10}$$

such that

$$\begin{cases} \text{(i)} & x(0) \in C(s), \\ \text{(ii)} & \forall\, t \in [0,T],\ x(t) \in I(t, s-t), \\ \text{(iii)} & x(T) = x. \end{cases}$$

In other words, both the dynamics and the constraints depend upon horizon $s \geq T$ and take into account the informations gathered at any preceding time $t \in [0,T]$ and expectations at time $s-t$ left to the horizon s. The selector is thus a tube associating with any horizon $s \geq T$ the set of states x such that there exists a control $u(\cdot)$ governing the evolution $x(\cdot)$ through control system (9):

$$\forall\, t \in [0,T], \begin{cases} \text{(i)} & x'(t) = f(t, s-t, x(t), u(t)), \\ \text{(ii)} & u(t) \in P(s-t, x(t)), \end{cases}$$

which satisfies for all anterior time $t \in [0,T]$ the expected constraints made at that time t for the future time $s-t$.

We can easily check the following lemma.

LEMMA 1.2. *The graph of the selector $\mathbf{S}_{(I,C)}$ is the capture basin of $\{0\} \times \mathrm{Graph}(C)$ viable in the graph of the tube I under the auxiliary system*

$$\begin{cases} \text{(i)} & \tau'(t) = -1, \\ \text{(ii)} & \alpha'(t) = +1, \\ \text{(iii)} & x'(t) = -f(\tau(t), \alpha(t), x(t)). \end{cases}$$

Proof. Indeed, to say that (T, a, x) belongs to the viable-capture basin of $\{0\} \times \text{Graph}(C)$ viable in $\text{Graph}(I)$ means that there exist an evolution $\widehat{x}(\cdot)$ to $\widehat{x}'(t) \in -f(T-t, a+t, \widehat{x}(t), \widetilde{u}(t))$ starting at $\widehat{x}(0) := x$ and a time $t^* \geq 0$ such that

$$\left\{ \begin{array}{lll} \text{(i)} & \forall\, t \in [0, t^*], & (T-t, a+t, \widehat{x}(t)) \in \text{Graph}(I), \\ \text{(ii)} & & (T-t^*, a+t^*, \widehat{x}(t^*)) \in \{0\} \times \text{Graph}(C). \end{array} \right.$$

The second condition means that $t^* = T$ and that $\widehat{x}(T)$ belongs to $C(a+T)$. The first one means that for every $t \in [0, T]$, $\widehat{x}(t) \in I(T-t, a+t)$. This amounts to saying that the evolution $x(\cdot) := \widehat{x}(T - \cdot)$ is a solution to the control system

$$x'(t) \;=\; f(t, a+T-t, x(t), u(t))$$

starting at $x(0) := \widehat{x}(T) \in C(T+a)$, satisfying $x(T) = x$, and

$$\forall\, t \in [0, T],\ \forall\, a \geq 0,\ \ x(t) \in I(t, a+T-t).$$

This means that $x \in \mathbf{S}_{(I,C)}(T, a)$. □

We shall therefore characterize the selector as a solution to a system of Hamilton–Jacobi–Bellman partial differential inclusions

$$\forall\, x \in V(t,a),\ \exists\, u \in P(a,x) \quad \text{such that} \quad -\frac{\partial V(t,a,x)}{\partial t} + \frac{\partial V(t,a,x)}{\partial a} + f(t,a,x,u) \;=\; 0$$

satisfying the initial condition

$$\forall\, a \geq 0,\ \ V(0,a) \;=\; C(a)$$

and the viability constraints

$$\forall\, (t,a) \in \mathbf{R}^2_+,\ \ V(t,a) \;\subset\; I(t,a).$$

We deduce from the knowledge of the derivatives of the selector the *regulation map* $R : \mathbf{R}^2_+ \times X \rightsquigarrow \mathcal{U}$ providing the controls (or regulees, prices, or interest-rate instruments) that at each time t, for any future date a and any state x, answer the detection/prediction problems. The regulation map associates with any triple (t, a, x) the set $R(t, a, x)$ of controls $u \in P(a, x)$ such that the solutions to the new control system

$$\left\{ \begin{array}{ll} & \forall\, t \in [0, T],\ \forall\, s \geq T, \\ \text{(i)} & x'(t) \;=\; f(t, s-t, x(t), u(t)), \\ \text{(ii)} & u(t) \;\in\; R(t, s-t, x(t)) \end{array} \right. \tag{11}$$

satisfy the constraints

$$\left\{ \begin{array}{ll} \text{(i)} & x(0) \;\in\; C(s), \\ \text{(ii)} & \forall\, t \in [0, T],\ \ x(t) \;\in\; I(t, s-t), \\ \text{(iii)} & x(T) \;=\; x. \end{array} \right.$$

Finally, the Capture Basin Algorithm allows us to compute the selector and the regulation map.

1.2. The substratum of an impulse differential inclusion. *Impulse differential inclusions* are described by two set-valued maps, F—the right-hand side of the differential inclusion $x' \in F(x)$ governing the continuous evolution of an impulse system—and Φ, describing the *reset map* reinitializing the system when required and a constrained set K inside which the evolution of the impulse differential equation must remain. We denote by $\mathcal{S}(x)$ the set of solutions $x(\cdot)$ to the differential inclusion starting at x.

Let us set $x(^-t) := \lim_{\tau \mapsto t-} x(\tau)$ when $x(\cdot)$ is defined on some interval $[t-\eta, t[$, where $\eta > 0$, and, for consistency, $x(s) = x(^-t)$ if $s = t$.

An evolution of the impulse differential inclusion, called a "run" or an "execution" in the hybrid system community, is a finite or infinite sequence $x(\cdot) := \{(\tau_n, x_n, x_n(\cdot))\}_{n \geq 0}$ made of triples of

1. nonnegative *cadences* $\tau_n \in [0, +\infty[$,
2. a sequence of *reinitialized states* x_n,
3. a sequence of *motives* $x_n(\cdot) \in \mathcal{S}(x_n)$ satisfying the end-point condition $x_n(\tau_n) \in \Phi^{-1}(x_{n+1})$,

defining the sequence of impulse times $t_{n+1} := t_n + \tau_n$ and, on each interval $[t_n, t_{n+1}[$,

$$\forall\, t \in [t_n, t_{n+1}[, \;\; x(t) \;:=\; x_n(t - t_n). \tag{12}$$

If the sequence is finite and stops at τ_N, we set $\tau_{N+1} := +\infty$ and take $x_N(\cdot) \in \mathcal{S}(x_N)$. (This definition is taken from [25, 26].)

We say that a run $x(\cdot)$ is viable in K if, for any $t \geq 0$, $x(t) \in K$.

At this stage, a run $x(\cdot)$ can just be a (discrete) sequence of states $x_{n+1} \in \Phi(x_n)$ at a fixed time, or just a (continuous) solution $x(\cdot)$ to the differential inclusion $x' \in F(x)$, or a hybrid of these two modes, the discrete and the continuous.

We just define the concept of a *substratum* of an impulse differential inclusion introduced in [9], which summarizes the salient features of a run, by considering only its sequences of cadences τ_n and of reinitialized states x_n. Knowing them, we can reconstruct the motives of the run by taking solutions $x_n(\cdot) \in \mathcal{S}(x_n)$ satisfying the end-point condition $x_n(\tau_n) \in \Phi^{-1}(x_{n+1})$. The question that arises is to provide an algorithm that provides these sequences of cadences τ_n and of reinitialized states x_n without solving the impulse differential inclusion, but only through such an algorithm. The substratum just does that.

Definition 1.3. *We associate with the dynamics (F, Φ) of the impulse differential inclusion its* substratum $\Gamma : \mathbf{R}_+ \times K \rightsquigarrow K$*, that is the set-valued map associating with any $(T, x) \in \mathbf{R}_+ \times K$ the subset*

$$\Gamma(T, x) \;:=\; \bigcup_{x(\cdot) \in \mathcal{S}_F^K(x)} \Phi(x(T))$$

of the elements $y \in \Phi(x(T))$, where $x(\cdot) \in \mathcal{S}_F^K(x)$ is a solution to the differential inclusion $x' \in F(x)$ starting at x and viable in K until it reaches $x(T) \in C := K \cap \Phi^{-1}(K)$ at time T.

We associate with the substratum Γ

1. *the* cadence map

$$\mathbf{C}(x) \;:=\; \{t \geq 0 \quad \textit{such that} \;\; \Gamma(t, x) \;\neq\; \emptyset\} \;\; \textit{and}$$

2. *the* initialization map $\mathbf{I} : K \rightsquigarrow X$*,*

$$\mathbf{I}(x) \;=\; \bigcup_{t \in \mathbf{C}(x)} \Gamma(t, x).$$

Knowing the substratum Γ of (K, F, Φ) and thus the cadence map $\mathbf{C}$ and the initialization map $\mathbf{I}$, we can *reconstruct* a viable run of the impulse differential inclusion (F, Φ) through the following algorithm: Given the cadence τ_n and the initial state x_n, we take

$$(13)\quad \begin{cases} \text{(i)} & \text{the next cadence } \tau_{n+1} \in \mathbf{C}_{(F,\Phi)}(x_n), \\ \text{(ii)} & \text{the next reinitialized state } x_{n+1} \in \Gamma_{(F,\Phi)}(\tau_{n+1}, x_n) \subset \mathbf{I}(x_n), \\ \text{(iii)} & \text{the next motive } x_n(\cdot) := x(\cdot + t_n), \text{ a solution to } x' \in F(x) \text{ satisfying} \\ & x_n(0) \;=\; x_n \;\text{ and }\; x_n(\tau_{n+1}) \;\in\; \Phi^{-1}(x_{n+1}). \end{cases}$$

Assume for a while that the impulse differential inclusion is actually an impulse differential equation (f, φ), where the maps f and φ are single-valued, and that the substratum is single-valued and differentiable. We define

$$\Phi(t,x) \;:=\; \begin{cases} \varphi(x) & \text{if} \quad x \in C := K \cap \varphi^{-1}(K), \\ \emptyset & \text{if} \quad x \notin C \end{cases}$$

and

$$\Psi(t,x) \;:=\; \begin{cases} K & \text{if} \quad x \in K, \\ \emptyset & \text{if} \quad x \notin K. \end{cases}$$

Then we shall prove that the substratum is a "solution" $v(t,x)$ to the system of first-order partial differential inclusions

$$\forall\, i = 1, \dots n, \quad -\frac{\partial v_i(t,x)}{\partial t} + \sum_{j=1}^{n} \frac{\partial v_i(t,x)}{\partial x_j} f_j(x) \;=\; 0$$

satisfying the "condition"

$$\forall\, x \in C := K \cap \varphi^{-1}(K), \;\; v(0,x) \;=\; \varphi(x),$$

which either is single-valued or takes empty values—and thus is a set-valued map.

Actually, we shall extend this result to general impulse differential inclusions by characterizing the substratum as a generalized (set-valued) solution—a Frankowska solution—to the system of first-order partial differential inclusions

$$\begin{cases} \text{(i)} & -\dfrac{\partial}{\partial t} V(t,x) + \dfrac{\partial V(t,x)}{\partial x} \cdot u \;=\; 0, \\ \\ \text{(ii)} & u \;\in\; F(x) \end{cases}$$

satisfying the "condition"

$$\forall\, x \in C := K \cap \Phi^{-1}(K), \;\; V(0,x) \;=\; \Phi(x)$$

and the constraints $V(t,x) \subset K$.

Indeed, the substratum is a particular case of a caliber with $f(x,y,u) := u$, $g(x,y,u) := 0$, $P(x,y) := F(x)$, $\Phi(0,x) := \Phi(x)$ if $x \in K$, $\Phi(0,x) := \emptyset$ if $x \notin K$, $\Phi(t,x) := \emptyset$ if $t > 0$, $\Psi(t,x) := K$ if $x \in K$, and $\Psi(t,x) := \emptyset$ otherwise.

2. The caliber of dynamical constraints and objective. The purpose of this section is to show how "viability techniques" may be efficient for solving systems of first-order partial differential inclusions arising in different fields of control theory and hybrid systems.

We denote by $L^1(0,\infty;\mathcal{U})$ the set of measurable functions from $[0,+\infty[$ to a vector space $\mathcal{U}$, the *control space*.

We consider a control system of the form

$$\left\{\begin{array}{ll} \text{(i)} & x'(t) \;=\; f(x(t),y(t),u(t)),\\ \text{(ii)} & y'(t) \;=\; g(x(t),y(t),u(t)),\\ \text{(iii)} & u(t) \;\in\; P(x(t),y(t)).\end{array}\right.$$

We denote by $\mathcal{B}(x,y)$ the set of solutions $(x(\cdot),y(\cdot),u(\cdot)) \in \mathcal{C}(0,\infty;X\times Y)\times L^1(0,\infty;\mathcal{U})$ to the above system starting at (x,y) at time 0.

Definition 2.1. *We say that the* control system *is*

1. Marchaud *if the set-valued map $P : X \times Y \rightsquigarrow \mathcal{U}$ is Marchaud and if $f : X \times Y \times \mathcal{U} \mapsto X$ and $g : X \times Y \times \mathcal{U} \mapsto Y$ are continuous and affine,*[6]
2. Lipschitz *if the set-valued map $P : X \rightsquigarrow \mathcal{U}$ is Lipschitz and if $f : X\times Y\times\mathcal{U} \mapsto X$ and $g : X \times Y \times \mathcal{U} \mapsto Y$ are Lipschitz.*

We associate the set-valued map $G : \mathbf{R}_+ \times X \times Y \rightsquigarrow \mathbf{R}_+ \times X \times Y$ defined by

$$G(T,x,y) \;:=\; \{\{-1\}\times\{f(x,y,u)\}\times\{g(x,y,u)\}\}_{u\in P(x,y)}\,, \tag{14}$$

and we denote by $\mathcal{R}$ the set-valued map defined by the formula

$$\mathcal{R}(T,x,y) \;=\; \{(T-\cdot,x(\cdot),y(\cdot),u(\cdot))\}_{(x(\cdot),y(\cdot),u(\cdot))\in\mathcal{B}(x,y)}.$$

We infer that *the set-valued map G is a Marchaud (resp., Lipschitz) map whenever the control system is Marchaud (resp., Lipschitz).*

We introduce now dynamical constraints and objectives defined by

1. a set-valued map $\Phi : \mathbf{R}_+ \times X \rightsquigarrow Y$ defining an *objective*, regarded as an obstacle in problems of unilateral mechanics, for instance;
2. a set-valued map $\Psi : \mathbf{R}_+ \times X \rightsquigarrow Y$ defining dynamical constraints. *State constraints* are involved in the domain

$$\mathrm{Dom}(\Psi) \;:=\; \{(t,x)\in\mathbf{R}_+\times X \mid \Psi(t,x) \;\neq\; \emptyset\}$$

of the set-valued map Ψ.

We shall assume that

$$\left\{\begin{array}{ll} \text{(i)} & \forall\,(t,x)\in\mathbf{R}_+\times X,\quad \Phi(t,x) \;\subset\; \Psi(t,x),\\ \\ \text{(ii)} & \forall\,t<0,\ \forall\,x\in X,\quad \Psi(t,x) \;:=\; \emptyset.\end{array}\right.$$

Definition 2.2. *The two constraint and objective set-valued maps being given, the* caliber $(T,x) \rightsquigarrow V_\Psi(\Phi)(T,x)$ of the pair (Ψ,Φ) under the controlled system *is the set-valued map associating with the pair (T,x) made of the horizon T and the initial state x the set of initial observations y such that there exist a control $t\in[0,T]\mapsto u(t)$*

[6] We actually need only that the values $\{(f(x,y,u),g(x,y,u))\}_{u\in P(x,y)}$ are closed and convex.

and a time $T^* \in [0,T]$ *such that a solution* $(x(\cdot),u(\cdot),y(\cdot)) \in \mathcal{B}(x,y)$ *starting at* $x(0)=x$, $y(0)=y$ *satisfies*

$$\text{(15)} \qquad \begin{cases} \text{(i)} & \forall\, t \in [0,T^*],\ \ y(t) \in \Psi(T-t,x(t)), \\ \text{(ii)} & y(T^*) \in \Phi(T-T^*,x(T^*)). \end{cases}$$

We observe at once the following property: *The caliber satisfies the initial condition*

$$\forall\, x \in X,\ \ V_\Psi(\Phi)(0,x) \ = \ \Phi(0,x).$$

Indeed, condition (15) (ii) with $T=0$ means that $y \in V_\Psi(\Phi)(0,x)$, implying that $T^*=0$ and $(0,x,y) \in \mathrm{Graph}(\Phi)$, i.e., $y \in \Phi(0,x)$. Hence $V_\Psi(\Phi)(0,x) \subset \Phi(0,x) \subset V_\Psi(\Phi)(0,x)$. □

What is the connection between this problem and the basic viability theorems? The answer is simple: The graph of the caliber is the capture basin of the graph of the set-valued map Φ viable in the graph of Ψ under the auxiliary control system G.

Proposition 2.3. *The graph of the caliber* $V_\Psi(\Phi)$ *is equal to the viable-capture basin of* $\mathrm{Graph}(\Phi)$ *viable in* $\mathrm{Graph}(\Psi)$ *under the auxiliary system* $\mathcal{R}$*:*

$$\mathrm{Graph}(V_\Psi(\Phi))) \ = \ \mathrm{Capt}_{\mathcal{R}}^{\mathrm{Graph}(\Psi)}(\mathrm{Graph}(\Phi)).$$

Proof. It is enough to translate conditions (15) in the form

$$\text{(16)} \qquad \begin{cases} \text{(i)} & \forall\, t \in [0,T^*],\ \ (T-t,x(t),y(t)) \in \mathrm{Graph}(\Psi), \\ \text{(ii)} & (T-T^*,x(T^*),y(T^*)) \in \mathrm{Graph}(\Phi) \end{cases}$$

to recognize that

$$\mathrm{Graph}(V_\Psi(\Phi)) \ = \ \mathrm{Capt}_{\mathcal{R}}^{\mathrm{Graph}(\Psi)}(\mathrm{Graph}(\Phi)). \qquad \square$$

This being checked, it will be sufficient to translate the properties of capture basins in terms of caliber.

3. Set-valued solutions to systems of Hamilton–Jacobi–Bellman inclusions. In the case of controlled systems, we shall relate the caliber with the set-valued solution to the controlled Hamilton–Jacobi–Bellman partial differential equations:

1. there exists $u \in P(x,V(t,x))$ such that

$$0 \ \in \ \text{“} - \frac{\partial}{\partial t}V(t,x) + \frac{\partial}{\partial x}V(t,x)f(x,V(t,x),u)\text{”} - g(x,V(t,x),u);$$

2. for all $u \in P(x,v(t,x))$,

$$0 \ \in \ \text{“}\frac{\partial}{\partial t}V(t,x) - \frac{\partial}{\partial x}V(t,x)f(x,V(t,x),u)\text{”} + g(x,V(t,x),u),$$

satisfying the initial condition

$$V(0,x) \ = \ \Phi(0,x)$$

and the constraints

$$\forall\, t \geq 0,\ x \in\ X,\ \ \Phi(t,x) \ \subset\ V(t,x) \ \subset\ \Psi(t,x)$$

in a sense that we make precise in the following theorem.

Theorem 3.1. *Let us assume that the system is Marchaud.*

1. *Then the caliber* $V_\Psi(\Phi)$ *of* (Ψ, Φ) *is the* largest *closed set-valued map* $V : \mathbf{R}_+ \times X \rightsquigarrow Y$ *satisfying*

$$\forall\, (t,x) \in \mathbf{R}_+ \times X,\ \ \Phi(t,x)\ \subset\ V(t,x)\ \subset\ \Psi(t,x) \tag{17}$$

and

$$\begin{cases} \forall\, y \in V(t,x)\backslash\Phi(t,x),\ \exists\, u \in P(x,y) \\ \textit{such that} \\ 0\ \in\ DV(-1, f(x,y,u)) - g(x,y,u). \end{cases} \tag{18}$$

2. *Let us set*

$$\mathbf{R}(t,x,y)\ :=\ \{u \in P(x,y) \mid 0\ \in\ DV_\Psi(\Phi)(t,x,y)(-1, f(x,y,u)) - g(x,y,u)\}.$$

Knowing the caliber, any solution satisfying the constraints (15) (i) *and reaching the objective* (15) (ii) *in finite time is obtained in the following way: Starting from* (x_0, y_0) *such that* $y_0 \in V_\Psi(\Phi)(T, x_0)\backslash\Phi(T, x_0)$*, any solution* $(x(\cdot), y(\cdot), u(\cdot))$ *to the control system: for almost all* $t \in [0,T]$*,*

$$\begin{cases} \text{(i)} & x'(t)\ =\ f(x(t), y(t), u(t)), \\ \text{(ii)} & y'(t)\ =\ g(x(t), y(t), u(t)), \\ \text{(iii)} & u(t)\ \in\ \mathbf{R}(T-t, x(t), y(t)), \end{cases} \tag{19}$$

starting at (x,y) *is a solution satisfying*

$$y(t)\ \in\ V_\Psi(\Phi)(T-t, x(t))$$

until the first time $t^* \in]0,T]$ *when*

$$y(t^*)\ \in\ \Phi(T-t^*, x(t^*)).$$

3. *If we assume, furthermore, that the system is Lipschitz, then the caliber* $V_\Psi(\Phi)$ *of* (Ψ, Φ) *is the* unique *closed set-valued map* $V : \mathbf{R}_+ \times X \rightsquigarrow Y$ *satisfying* (17), (18)*, and*

$$\begin{cases} \forall\, y \in V(t,x) \cap \Psi^\circ(t,x),\ \forall\ u \in P(x,y), \\ 0\ \in\ DV(1, -f(x,y,u)) + g(x,y,u) \\ \textit{and} \\ \forall\, y \in V(t,x) \cap \Psi^\partial(t,x),\ \forall\ u \in P(x,y), \\ 0\ \in\ DV(1, -f(x,y,u)) \cup D\Psi^c(+1, -f(x,y,u)) + g(x,y,u), \end{cases} \tag{20}$$

where $\mathrm{Graph}(\Psi^\circ) := \mathrm{Int}(\mathrm{Graph}(\Psi))$, $\mathrm{Graph}(\Psi^\partial) := \partial\mathrm{Graph}(\Psi)$*, and* $\mathrm{Graph}(\Psi^c) := X\backslash\mathrm{Graph}(\Psi)$*.*

Proof.

1. The graph of the caliber $V_\Psi(\Phi)$ being equal to the capture basin $\mathrm{Capt}_G^{\mathrm{Graph}(\Psi)}(\mathrm{Graph}(\Phi))$ by Proposition 2.3, we can apply the first part of Theorem 0.1 since $\mathrm{Graph}(\Psi) \subset \mathbf{R}_+ \times X \times Y$ is a repeller under G. Hence it is the largest graph of a set-valued map $V : X \rightsquigarrow Y$ between $\mathrm{Graph}(\Phi)$ and $\mathrm{Graph}(\Psi)$ such that, for any $(t,x,y) \in \mathrm{Graph}(V)\backslash\mathrm{Graph}(\Phi))$, i.e., whenever $y \in V(t,x)\backslash\Phi(t,x)$, there exists a control $u \in P(x)$ such that

$$(-1, f(x,y,u), -g(x,y,u))\ \in\ T_{\mathrm{Graph}(V)}(t,x,y). \tag{21}$$

In other words, it is the graph of the largest closed set-valued map V satisfying

$$\Phi(t,x) \ \subset \ V(t,x) \ \subset \ \Psi(t,x)$$

and, whenever $y \in V(t,x)\backslash\Phi(t,x)$, there exists $u \in P(x,y)$ such that

$$0 \ \in \ DV(-1, f(x,y,u)) - g(x,y,u).$$

2. The solutions $(T-\cdot, x(\cdot), y(\cdot))$ viable in the graph of Ψ until they reach the graph of Ψ satisfy: for almost all $t \geq 0$,

$$\left\{ \begin{array}{l} u(t) \ \in \ P(x(t),y(t)) \\ \text{and} \\ (-1, f(x(t),y(t),u(t)), g(x(t),y(t),u(t))) \ \in \ T_{\mathrm{Graph}(V)}(T-t, x(t), y(t)). \end{array} \right.$$

This condition can be rewritten as follows:

$$\text{for almost all } t \geq 0, \ \ u(t) \ \in \ R(T-t, x(t), y(t)).$$

3. Under the Lipschitz conditions, Theorem 0.2 states that the graph of $V_{_\Psi}(\Phi)$ is the unique closed subset $\mathrm{Graph}(V)$ satisfying the Frankowska properties:

$$\left\{ \begin{array}{ll} \text{(i)} & \forall\ (t,x,y) \in \mathrm{Graph}(V)\backslash\mathrm{Graph}(\Phi), \\ & \exists\ u \in P(x,y) \mid (-1, f(x,y,u), g(x,y,u)) \in T_{\mathrm{Graph}(V)}(t,x,y), \\ \text{(ii)} & \forall\ (t,x,y) \in \mathrm{Graph}(V) \cap \mathrm{Int}(\mathrm{Graph}(\Psi)), \forall\ u \in P(x,y), \\ & (1, -f(x,y,u), -g(x,y,u)) \ \in \ T_{\mathrm{Graph}(V)}(t,x,y), \\ \text{(iii)} & \forall\ (t,x,y) \in \mathrm{Graph}(V) \cap \partial(\mathrm{Graph}(\Psi)), \forall\ u \in P(x,y), \\ & (1, -f(x,y,u), -g(x,y,u)) \ \in \ T_{\mathrm{Graph}(V)}(t,x,y) \cup T_{X\backslash\mathrm{Graph}(\Psi)}(t,x,y). \end{array} \right.$$

Using the fact that $\mathrm{Graph}(DV)(t,x,y) = T_{\mathrm{Graph}(V)}(t,x,y)$, we infer the third part of the theorem. □

4. Stability properties. We state the following theorem of [12].

THEOREM 4.1. *Let us consider a sequence of closed subsets C_n satisfying* $\mathrm{Viab}(K) \subset C_n \subset K$ *and*

$$\mathrm{Lim}_{n\to+\infty} C_n \ := \ \mathrm{Limsup}_{n\to+\infty} C_n \ = \ \mathrm{Liminf}_{n\to+\infty} C_n.$$

If the set-valued map F is Marchaud and Lipschitz and if K is closed and backward invariant under F, then

$$\mathrm{Lim}_{n\to+\infty} \mathrm{Capt}^K(C_n) \ = \ \mathrm{Capt}^K(\mathrm{Lim}_{n\to+\infty} C_n). \tag{22}$$

Theorem 4.1 implies "continuity properties" of the caliber regarded as a map $\Phi \mapsto V_\Psi(\Phi)$.

For that purpose, let us recall the following definitions of graphical convergence (see [18] and/or [60], for instance):

1. the upper limit of the graphs

$$\mathrm{Limsup}_{n\to+\infty} \mathrm{Graph}(\Phi_n) \ =: \ \mathrm{Graph}(\mathrm{Lim}^\sharp{}_{n\to+\infty} \Phi_n)$$

is the graph of the *graphical upper limit* $\mathrm{Lim}^\sharp{}_{n\to+\infty}\Phi_n$ defined by

$$(\mathrm{Lim}^\sharp{}_{n\to+\infty}\Phi_n)(T,x) \ = \ \liminf_{n\to+\infty,\ s\to t,\ y\to x} V(\Phi_n)(s,y);$$

2. the lower limit of the graphs

$$\text{Liminf}_{n\to+\infty}\text{Graph}(\Phi_n) \;=:\; \text{Graph}(\text{Lim}^{\flat}{}_{n\to+\infty}\Phi_n)$$

is the graph of the *graphical lower limit*.

Then we derive the following "continuity" properties of the calibers.

THEOREM 4.2. *Let us consider a sequence of nontrivial set-valued maps* $\Psi_n : \mathbf{R}_+ \times X \rightsquigarrow Y \cup \{+\infty\}$ *and* $\Phi_n : \mathbf{R}_+ \times X \rightsquigarrow Y \cup \{+\infty\}$ *such that*

$$\forall\, (T,x) \in \mathbf{R}_+ \times X, \;\; \Phi_n(T,x) \;\subset\; \Psi_n(T,x).$$

The calibers also satisfy the following properties:

1. *Let us assume that the auxiliary control system* F *is Marchaud. Then*

$$\lim^{\sharp}{}_{n\to+\infty} V_{\Psi_n}(\Phi_n)(T,x) \;\subset\; V_{\lim^{\sharp}{}_{n\to+\infty}\Psi_n}(\lim^{\sharp}{}_{n\to+\infty}\Phi_n)(T,x).$$

2. *Let us assume that the auxiliary control system* F *is Marchaud and Lipschitz. Then*

$$\begin{cases} V(\lim^{\flat}{}_{n\to+\infty}\Phi_n)(T,x) \;\subset\; \lim^{\flat}{}_{n\to+\infty} V(\Phi_n)(T,x) \\ \subset\; \lim^{\sharp}{}_{n\to+\infty} V(\Phi_n)(T,x) \;\subset\; V(\lim^{\sharp}{}_{n\to+\infty}\Phi_n)(T,x). \end{cases}$$

Therefore, if the sequence of set-valued maps Φ_n *converges graphically to* Φ*, the caliber of the graphical limit is the graphical limit of the calibers.*

Proof. If the system is Marchaud, Theorem 4.1 implies that

$$\begin{aligned} &\text{Limsup}_{n\to+\infty}\text{Capt}_{\mathcal{R}}^{\text{Graph}(\Psi_n)}(\text{Graph}(\Phi_n)) \\ &\subset\; \text{Capt}_{\mathcal{R}}^{\text{Limsup}_{n\to+\infty}\text{Graph}(\Psi_n)}(\text{Limsup}_{n\to+\infty}\text{Graph}(\Phi_n)). \end{aligned}$$

Hence we deduce from Proposition 2.3, characterizing the graph of the caliber as a viable-capture basin, and from the definitions of graphical limits that

$$\lim^{\sharp}{}_{n\to+\infty} V_{\Psi_n}(\Phi_n)(T,x) \;\subset\; V_{\lim^{\sharp}{}_{n\to+\infty}\Psi_n}(\lim^{\sharp}{}_{n\to+\infty}\Phi_n)(T,x).$$

Under Lipschitz conditions of G, Theorem 4.1 implies that

$$\text{Capt}_{\mathcal{R}}(\text{Liminf}_{n\to+\infty}\text{Graph}(\Phi_n)) \;\subset\; \text{Liminf}_{n\to+\infty}\text{Capt}_{\mathcal{R}}(\text{Graph}(\Phi_n)).$$

Hence we deduce that

$$V(\lim^{\flat}{}_{n\to+\infty}\Phi_n)(T,x) \;\subset\; \lim^{\flat}{}_{n\to+\infty} V(\Phi_n)(T,x).$$

This completes the proof. □

5. Caliber of structured problems with linear exosystems. Of special interest is the particular case when the first differential equation does not depend upon the variable y and when the set-valued map $P : X \rightsquigarrow \mathcal{U}$ does not depend on the observation variable y: We thus obtain a *structured system*—as *age structured systems* in demography, when x plays the role of the age variable—of the form

$$\begin{cases} \text{(i)} & x'(t) \;=\; f(x(t),u(t)), \\ \text{(ii)} & y'(t) \;=\; g(x(t),y(t),u(t)), \\ \text{(iii)} & u(t) \;\in\; P(x(t)), \end{cases}$$

where $y(\cdot)$ is often regarded as an *observation* of the state (see, for instance, [14]). In control theory, the second controlled equation is called the *exosystem*.

We denote by $\mathcal{C} : x \in X \rightsquigarrow \mathcal{C}(x) \in \mathcal{C}(0,\infty;X) \times L^1(0,\infty;\mathcal{U})$ the set-valued map associating with $x \in X$ the set $\mathcal{C}(x)$ of the pairs $(x(\cdot),u(\cdot))$ of solutions to the control system

$$\begin{cases} \text{(i)} & x'(t) \ = \ f(x(t),u(t)), \\ \text{(ii)} & u(t) \ \in \ P(x(t)), \end{cases}$$

starting at x at $t = 0$.

We shall also set $g(x,y,u) := -M(x,u)y - L(x,u)$, where

1. M is a bounded continuous matrix-valued function

$$M : (x,u) \in X \times \mathcal{U} \mapsto M(x,u) \in \mathcal{L}(X,Y), \ \text{ and}$$

2. L is a continuous[7] "vector-Lagrangian"

$$L : (x,u) \in X \times \mathcal{U} \mapsto L(x,u) \in Y$$

with linear growth.

We introduce the map $(y;(x(\cdot),u(\cdot))) \rightsquigarrow \mathcal{S}(y;(x(\cdot),u(\cdot)))$ associating the subset of evolutions

$$y(t) \ = \ e^{-\int_0^t M(x(s),u(s))ds}\left(y - \int_0^t e^{\int_0^\tau M(x(s),u(s))ds} L(x(\tau),u(\tau))d\tau\right) \tag{23}$$

to the linear dynamical system

$$y'(t) \ = \ -M(x(t),u(t))y(t) - L(x(t),u(t))$$

starting at $y \in Y$.

We already know that the caliber is the unique Frankowska solution to the following:

1. there exists $u \in P(x,V(t,x))$ such that

$$0 \ \in \ \text{“} - \frac{\partial}{\partial t}V(t,x) + \frac{\partial}{\partial x}V(t,x)f(x,V(t,x),u)\text{”} - M(x,u)V(t,x) - L(x,u);$$

2. for all $u \in P(x,v(t,x))$;

$$0 \ \in \ \text{“}\frac{\partial}{\partial t}V(t,x) - \frac{\partial}{\partial x}V(t,x)f(x,V(t,x),u)\text{”} + M(x,u)V(t,x) + L(x,u),$$

satisfying the viability constraints

$$\forall\, t \geq 0,\ x \in \ X, \ \ \Phi(t,x) \ \subset \ V(t,x) \ \subset \ \Psi(t,x)$$

and the initial condition

$$V(0,x) \ = \ \Phi(0,x).$$

[7] We could take L to be set-valued map, but we restrict our attention to the single-valued case for simplicity.

In summary, we now deal with a *structured problem* where the exosystem is linear with respect to the observations. In this case, we shall be able to provide an explicit formula of the caliber V.

For that purpose, we introduce the subset

$$\left\{\begin{array}{l} J_\Phi(t;(x(\cdot),u(\cdot)))(T,x) \\ \\ := \ e^{\int_0^t M(x(s),u(s))ds}\Phi(T-t,x(t)) + \displaystyle\int_0^t e^{\int_0^\tau M(x(s),u(s))ds}L(x(\tau),u(\tau))d\tau \end{array}\right.$$

(where t ranges over $[0,T]$). The controls—most often prices or other regulees in economics and portfolios in finance—appear *both* in the matrix M and in the Lagrangian L.

We associate with Ψ the set-valued map J_Ψ defined by

$$\left\{\begin{array}{l} J_\Psi(t;(x(\cdot),u(\cdot)))(T,x) \\ \\ := \ e^{\int_0^t M(x(s),u(s))ds}\Psi(T-t,x(t)) + \displaystyle\int_0^t e^{\int_0^\tau M(x(s),u(s))ds}L(x(\tau),u(\tau))d\tau \end{array}\right.$$

and

$$K_\Psi(t,x;(x(\cdot),u(\cdot))) \ := \ \bigcap_{s\in[0,t]} J_\Psi(s,x;(x(\cdot),u(\cdot))).$$

We next introduce

$$L^\Phi_\Psi(t;(x(\cdot),u(\cdot)))(T,x) \ := \ K_\Psi(t,x;(x(\cdot),u(\cdot))) \cap J_\Phi(t;(x(\cdot),u(\cdot)))(T,x).$$

5.1. Explicit formula of the caliber. We shall prove now that the caliber V of the pair (Ψ,Φ) under $\mathcal{B}$ is equal to the set-valued map $V_\Psi(\Phi)$ defined by

$$V_\Psi(\Phi)(T,x) \ := \bigcup_{(x(\cdot),u(\cdot))\in\mathcal{C}(x)} \ \bigcup_{t\in[0,T]} L^\Phi_\Psi(t;(x(\cdot),u(\cdot)))(T,x). \tag{24}$$

Note that if $\Psi_1 \subset \Psi_2$ and $\Phi_1 \subset \Phi_2$, then $V_{\Psi_1}(\Phi_1) \subset V_{\Psi_2}(\Phi_2)$ and

$$\forall\, t \geq 0, \forall\, x \in X, \ \ \Phi(t,x) \ \subset \ V_\Psi(\Phi)(t,x) \ \subset \ \Psi(t,x).$$

We shall use the fact that its graph is the viable-capture basin of the graph of the cost function Φ viable under the graph of Ψ under the auxiliary system $\mathcal{R}$.

THEOREM 5.1. *Let us assume that the set-valued maps Ψ and Φ are nontrivial. Then the caliber of the pair (Ψ,Φ) is equal to the set-valued map $V_\Psi(\Phi)$ defined by* (24).

Furthermore, the caliber is the unique solution *V to the two following "fixed set equations":*

$$\left\{\begin{array}{rcl} V_V(\Phi)(T,x) & := & \bigcup_{(x(\cdot),u(\cdot))\in\mathcal{C}(x)} \bigcup_{t\in[0,T]} L^\Phi_V(t,x;(x(\cdot),u(\cdot))) \\ = & & V(T,x) \\ = & & V_\Psi(V)(T,x) \ := \ \bigcup_{(x(\cdot),u(\cdot))\in\mathcal{C}(x)} \bigcup_{t\in[0,T]} L^V_\Psi(t,x;(x(\cdot),u(\cdot))). \end{array}\right. \tag{25}$$

Moreover, when F is Marchaud and the set-valued maps Φ and Ψ are closed, the graph of the caliber $V_\Psi(\Phi)$ is closed.

5.2. Examples.

1. We see that the set-valued map defined by

$$V(\Phi)(T,x) \;:=\; \bigcup_{(x(\cdot),u(\cdot))\in\mathcal{C}(x)} \bigcup_{t\in[0,T]} J_\Phi(t;(x(\cdot),u(\cdot)))(T,x) \;=\; V_{\mathbf{Y}}(\Phi)$$

is the caliber of (Ψ,Φ), where the set-valued map $\Psi=\mathbf{Y}$ is defined by

$$\mathbf{Y}(t,x) \;:=\; \begin{cases} Y & \text{if} \quad t\geq 0,\\ \emptyset & \text{if} \quad t<0. \end{cases}$$

Indeed, we observe that, taking $\Psi=\mathbf{Y}$,

$$K_{\mathbf{Y}}(t,x;(x(\cdot),u(\cdot))) \;=\; J_{\mathbf{Y}}(t,x;(x(\cdot),u(\cdot))) \;=\; Y$$

so that, for any set-valued map Φ, we have $L^\Phi_{\mathbf{Y}}=J_\Phi$ and thus $V(\Phi)=V_{\mathbf{Y}}(\Phi)$.

2. We also observe that the set-valued map

$$W(\Psi)(T,x) \;:=\; \bigcup_{(x(\cdot),u(\cdot))\in\mathcal{C}(x)} \bigcap_{t\in[0,T]} J_\Psi(t;(x(\cdot),u(\cdot)))(T,x) \;=\; V_\Psi(\Psi_\emptyset)$$

is the caliber of (Ψ,Φ), where we take $\Phi:=\Psi_\emptyset:\mathbf{R}_+\times X\rightsquigarrow Y$ defined by

$$\Psi_\emptyset(t,x) \;:=\; \begin{cases} \Psi(0,x) & \text{if} \quad t=0,\\ \emptyset & \text{if} \quad t\neq 0. \end{cases}$$

Indeed, we see that $J_{\Psi_\emptyset}(t,x;(x(\cdot),u(\cdot)))=\emptyset$ if $t<T$ and $J_{\Psi_\emptyset}(T,x;(x(\cdot),u(\cdot)))=J_\Psi(T,x;(x(\cdot),u(\cdot)))$. Therefore,

$$L^{\Psi_\emptyset}_\Psi(t,x;(x(\cdot),u(\cdot))) \;:=\; \begin{cases} K_\Psi(T,x;(x(\cdot),u(\cdot))) & \text{if} \quad t=T,\\ \emptyset & \text{if} \quad t<T, \end{cases}$$

and thus $W(\Psi)=V_\Psi(\Psi_\emptyset)$.

3. Let us introduce a time-independent set-valued map $U:X\rightsquigarrow X$. We shall associate with three pairs (Ψ,Φ) of set-valued maps associated with U the three following calibers:

   (a) Taking $\Phi:=U_\emptyset$ and $\Psi=\mathbf{Y}$, we obtain

$$\bigcup_{(x(\cdot),u(\cdot))\in\mathcal{C}(x)} \Bigg(e^{\int_0^T M(x(s),u(s))ds} U(x(T)) + \int_0^T e^{\int_0^\tau M(x(s),u(s))ds} L(x(\tau),u(\tau))d\tau \Bigg).$$

   When $M=0$, the above problem boils down to the set-valued equivalent of the *Bolza map*

$$\bigcup_{(x(\cdot),u(\cdot))\in\mathcal{C}(x)} \Bigg(U(x(T)) + \int_0^T L(x(\tau),u(\tau))d\tau \Bigg)$$

   and the *Mayer map*

$$\bigcup_{(x(\cdot),u(\cdot))\in\mathcal{C}(x)} U(x(T))$$

   when, furthermore, $L=0$. This is the case of the substratum of an impulse differential inclusion defined above (see also [9]).

(b) Taking $\Phi := U_\emptyset$ and $\Psi := U$, we obtain

$$\bigcup_{(x(\cdot),u(\cdot))\in\mathcal{C}(x)} \bigcap_{t\in[0,T]} \left(e^{\int_0^t M(x(s),u(s))ds} U(x(t)) + \int_0^t e^{\int_0^\tau M(x(s),u(s))ds} L(x(\tau),u(\tau))d\tau \right).$$

(c) Taking $\Phi := U$ and $\Psi := \mathbf{Y}$, we obtain

$$\bigcup_{(x(\cdot),u(\cdot))\in\mathcal{C}(x)} \bigcup_{t\in[0,T]} \left(e^{\int_0^t M(x(s),u(s))ds} U(x(t)) + \int_0^t e^{\int_0^\tau M(x(s),u(s))ds} L(x(\tau),u(\tau))d\tau \right).$$

When $M = 0$, we find

$$V(U)(T,x) := \bigcup_{(x(\cdot),u(\cdot))\in\mathcal{C}(x)} \bigcup_{t\in[0,T]} \left(U(x(t)) + \int_0^t L(x(\tau),u(\tau))d\tau \right).$$

This map—the set-valued analogue of the valuation function of "obstacle problems"—involves "max-plus" operations and is the set-valued equivalent of the *mathematical fear or faith* with respect to a Maslov measure introduced in dynamical optimization by Pierre Bernhard (see [35, 36, 37]).

Regarding the caliber as a transform $\Phi \mapsto V(\Phi)$ mapping closed set-valued maps to closed set-valued map, we observe that the caliber satisfies

$$V\left(\bigcup_{i=1,\dots,n} \Phi_i\right) = \bigcup_{i=1,\dots,n} V(\Phi_i),$$

the *extensivity* property, $\Phi \subset V(\Phi)$, and the *monotonicity* property: if $\Phi_1 \subset \Phi_2$, then $V(\Phi_1) \subset V(\Phi_2)$.

We recall that Theorem 4.2 implies that the value transform is also "upper continuous" in the sense that

$$\text{Limsup}_{n\to+\infty,\, s\to t,\, y\to x} V(\Phi_n)(s,y) \subset V\left(\text{Limsup}_{n\to+\infty,\, s\to t,\, y\to x} \Phi_n(s,y)\right)(t,x)$$

and actually, under stronger assumptions, "continuous" in the sense that the caliber of a graphical limit is the graphical limit of calibers.

5.3. Proof of the explicit formula. First, to say that a pair (T,x,y) belongs to the viable-capture basin

$$\text{Graph}(V) := \text{Capt}_{\mathcal{R}}^{\text{Graph}(\Psi)}(\text{Graph}(\Phi) \subset \text{Graph}(\Psi)$$

means that there exist a solution $(T-\cdot, \widetilde{x}(\cdot), \widetilde{u}(\cdot), y(\cdot)) \in \mathcal{R}(T,x,y)$ to the auxiliary control problem and some $t^* \geq 0$ such that

$$\begin{cases} \text{(i)} \quad \forall\, t \in [0,t^*], \ (T-t, \widetilde{x}(t), y(t)) \in \text{Graph}(\Psi), \\ \text{(ii)} \quad (T-t^*, \widetilde{x}(t^*), y(t^*)) \in \text{Graph}(\Phi) \end{cases}$$

or, equivalently, such that

$$\begin{cases} \text{(i)} & \forall\, t \in [0,t^*],\ \ y(t) \ \in\ \Psi(T-t,\widetilde{x}(t)), \\ \text{(ii)} & y(t^*) \ \in\ \Psi(T-t^*,\widetilde{x}(t^*). \end{cases}$$

By the very definition of $\mathcal{R}(T,x,y)$ and by the definition (23) of the auxiliary system that its component $y(\cdot)$ satisfies

$$y(t) \ =\ e^{-\int_0^t M(\widetilde{x}(s),\widetilde{u}(s))ds}\left(y-\int_0^t e^{\int_0^\tau M(\widetilde{x}(s),\widetilde{u}(s))ds}L(\widetilde{x}(\tau),\widetilde{u}(\tau))d\tau\right),$$

this implies that (T,x,y) belongs to $\mathrm{Capt}_{\mathcal{R}}^{\mathrm{Graph}(\Psi)}(\mathrm{Graph}(\Phi)$ if and only if there exists a solution $(\widetilde{x}(\cdot),\widetilde{u}(\cdot))\in\mathcal{C}(x)$ satisfying, for almost all $t\in[0,\overline{t}]$,

$$\begin{cases} \text{(i)} & y \in e^{\int_0^t M(\widetilde{x}(s),\widetilde{u}(s))ds}\Psi(T-t,\widetilde{x}(t),\widetilde{u}(t))+\displaystyle\int_0^t e^{\int_0^\tau M(\widetilde{x}(s),\widetilde{u}(s))ds}L(\widetilde{x}(\tau),\widetilde{u}(\tau))d\tau, \\ \text{(ii)} & y \in e^{\int_0^{t^*} M(\widetilde{x}(s),\widetilde{u}(s))ds}\Phi(T-t^*,\widetilde{x}(t^*))+\displaystyle\int_0^{t^*} e^{\int_0^\tau M(\widetilde{x}(s),\widetilde{u}(s))ds}L(\widetilde{x}(\tau),\widetilde{u}(\tau))d\tau. \end{cases}$$

(26)

Since we set

$$K_\Psi(t,x;(\widetilde{x}(\cdot),\widetilde{u}(\cdot)))\ :=\ \bigcap_{s\in[0,t]} J_\Psi(s,x;(\widetilde{x}(\cdot),\widetilde{u}(\cdot)))$$

and

$$L_\Psi^\Phi(t,x;(\widetilde{x}(\cdot),\widetilde{u}(\cdot)))\ :=\ K_\Psi(t,x;(\widetilde{x}(\cdot),\widetilde{u}(\cdot)))\cap J_\Phi(t,x;(\widetilde{x}(\cdot),\widetilde{u}(\cdot))),$$

this is equivalent to state that y belongs to $V_\Psi(\Phi)(T,x)$.

Formula (3) of [15] and the first part of this theorem implies that the caliber is the unique solution to the system (25).

Finally, the closedness of the graph of the caliber is an immediate consequence of Theorem 0.1 because $\mathrm{Graph}(\Psi)\subset\mathbf{R}_+\times X\times Y$ is a repeller under G, which is Marchaud, and the viable-capture basin $\mathrm{Graph}(V_\Psi)(\Phi))\ :=\ \mathrm{Capt}_{\mathcal{R}}^{\mathrm{Graph}(\Psi)}(\mathrm{Graph}(\Phi))$ is closed. □

5.4. The barrier property of the caliber. We begin with a first form of the *barrier property.*

Proposition 5.2. *Let us consider $y_T\in\partial_{\Psi(T,x)}V_\Psi(\Phi)(T,x)$. Then, any solution $(x(\cdot),u(\cdot))\in\mathcal{C}(x)$ starting from x satisfying the following inclusion: for every $t\in[0,t^*]$,*

$$y_T\ \in\ L_\Psi^\Phi(t;(x(\cdot),u(\cdot)))(T,x) \tag{27}$$

until the first time t^* when

$$y_T\in\Phi(T-t^*,x(t^*)$$

actually satisfies the following: for every $t\in[0,t^*]$,

$$\forall\, y_T\ \in\ \partial L_\Psi^\Phi(t;(x(\cdot),u(\cdot)))(T,x).$$

Proof. Since y_T belongs to $V_\Psi(\Phi)(T,x)$, there exists a solution $(x^*(\cdot),u^*(\cdot))$ and a time $t^* \in [0,T]$ such that

$$y_T \ \in \ L^\Phi_\Psi(t^*,x;(x^*(\cdot),u^*(\cdot))).$$

Since y_T belongs to $\partial_{\Psi(T,x)}V_\Psi(\Phi)(T,x)$, it can be approximated by elements $y_n \in \Psi(T,x)\backslash V_\Psi(\Phi)(T,x)$. We know that, for every t and any solution $(x(\cdot),u(\cdot))$, either y_n does not belong to $K_\Psi(t,x;(x(\cdot),u(\cdot)))$ or it belongs to $K_\Psi(t,x;(x(\cdot),u(\cdot)))\backslash V(T,x)$.

We claim that

$$\left\{\begin{array}{l} \forall\ (x(\cdot),u(\cdot)) \in \mathcal{C}(x),\ \forall\ t \in [0,T], \\ \\ K_\Psi(t,x;(x(\cdot),u(\cdot)))\backslash V(T,x) \ \subset \ X\backslash J_V(t,x;(x(\cdot),u(\cdot))). \end{array}\right. \tag{28}$$

Indeed, take y in $K_\Psi(t,x;(x(\cdot),u(\cdot)))\backslash V(T,x)$. This means that, for every $s \in [0,t]$, y belongs to $J_\Psi(s,x;(x(\cdot),u(\cdot)))$ or, equivalently,

$$\forall\ s \in [0,t],\ \ (T-s,x(s),y(s)) \ \in \ \mathrm{Graph}(\Psi),$$

where

$$y(t) \ := \ e^{-\int_0^t M(x(s),u(s))ds}\left(y - \int_0^t e^{\int_0^\tau M(x(s),u(s))ds}L(x(\tau),u(\tau))d\tau\right).$$

Since (T,x,y) does not belong to the viable capture basin, we infer that every solution in $\mathcal{R}(T,x,y)$ starting at (T,x,y) is viable in the graph $\mathrm{Graph}(\Psi)$ of Ψ before hitting the graph $\mathrm{Graph}(V)$ of V: Therefore, if

$$\forall\ s \in [0,t],\ \ y(s) \ \in \ \Psi(T-s,x(s),u(s)),$$

we have

$$y(t) \ \in \ X\backslash V(T-t,x(t)) \ \subset \ X\backslash\Phi(T-t,x(t)),$$

which can be written in the form

$$y \ \in \ X\backslash J_V(t,x;(x(\cdot),u(\cdot))) \ \subset \ X\backslash J_\Phi(t,x;(x(\cdot),u(\cdot))).$$

Therefore, inclusion (28) holds true, and thus y_n does not belong to $J_V(t,x;(x(\cdot),u(\cdot)))$. Consequently, for any $t \in [0,T]$ and for any $n \geq 0$,

$$y_n \ \in \ X\backslash L^V_\Psi(t,x;(x(\cdot),u(\cdot))) \ \subset \ X\backslash L^\Phi_\Psi(t,x;(x(\cdot),u(\cdot))).$$

This is particularly true for the solution $(x^*(\cdot),u^*(\cdot))$ and for any $t \in [0,t^*]$. Hence, letting y_n converge to y_T, we deduce the conclusion of the proposition. □

We can strengthen this result and prove the following "barrier property." Let us recall that $J_{V_\Psi(\Phi)}(0,x;(x(\cdot),u(\cdot))) = V_\Psi(\Phi)(T,x)$. We shall prove that the boundary condition

$$y_T \ \in \partial V_\Psi(\Phi)(T,x) \ = \ \partial J_{V_\Psi(\Phi)}(0,x;(x(\cdot),u(\cdot)))$$

propagates as long as y_T remains in the interior of $K_\Psi(t,x;(x(\cdot),u(\cdot)))$.

THEOREM 5.3. *Let us consider $y_T \in \partial V_\Psi(\Phi)(T,x) \cap \mathrm{Int}(\Psi(T,x))$. Then, any solution $(x(\cdot),u(\cdot)) \in \mathcal{C}(x)$ starting from x satisfying the inclusion*

$$y_T \ \in \ J_{V_\Psi(\Phi)}(t,x;(x(\cdot),u(\cdot))) \tag{29}$$

until the first time $\overline{t}$ *when*

$$y_T \notin \mathrm{Int}(K_\Psi(\overline{t}, x; (x(\cdot), u(\cdot))))$$

actually satisfies

$$\forall\, t \in [0, \overline{t}],\ \ y \in \partial J_{V_\Psi(\Phi)}(t; (x(\cdot), u(\cdot)))(T, x). \tag{30}$$

Proof. Since y_T belongs to $\partial V_\Psi(\Phi)(T, x)$, it can be approximated by elements $y_n \in \Psi(T, x) \backslash V_\Psi(\Phi)(T, x)$. By assumption, for any $t < \overline{t}$, there exists δ_t such that

$$B(y_T, \delta_t) \subset K_\Psi(t; (x(\cdot), u(\cdot)))(T, x),$$

and thus there exists some N_t such that, for any $n \geq N_t$, y_n belongs to $B(y^T, \delta_t)$, and thus

$$y_n \in K_\Psi(t; (x(\cdot), u(\cdot)))(T, x) \backslash V_\Psi(\Phi)(T, x).$$

However, by (28), we know that, in this case, y_n does not belong to $J_{V_\Psi(\Phi)}(t; (x(\cdot), u(\cdot)))(T, x)$. □

6. Frankowska contingent episolutions to Hamilton–Jacobi–Bellman equations. When $Y := \mathbf{R}$, we can associate with two extended functions $\mathbf{c} : \mathbf{R}_+ \times X \rightsquigarrow \mathbf{R} \cup \{+\infty\}$ and $\mathbf{b} : \mathbf{R}_+ \times X \rightsquigarrow \mathbf{R} \cup \{+\infty\}$ such that

$$\forall\, (t, x) \in \mathbf{R}_+ \times X,\ \ 0 \leq \mathbf{b}(t, x) \leq \mathbf{c}(t, x)$$

the set-valued maps Φ and Ψ defined by

$$\begin{cases} \text{(i)} & \Phi(t, x) := \mathbf{c}(t, x) + \mathbf{R}_+, \\ \text{(ii)} & \Psi(t, x) := \mathbf{b}(t, x) + \mathbf{R}_+ \end{cases}$$

by setting $\Phi(t, x) := \emptyset$ whenever $\mathbf{c}(t, x) = +\infty$. We observe that $\mathrm{Graph}(\Phi) = \mathcal{E}p(\mathbf{c})$ and that

$$D\Phi(t, x, \mathbf{c}(t, x))(\pm 1, v) = D_\uparrow \mathbf{c}(t, x)(\pm 1, v) + \mathbf{R}_+,$$

where $D_\uparrow \mathbf{c}(t, x)$ is the *contingent epiderivative* of $\mathbf{c}$ at (t, x) in the direction $(\pm 1, v)$, defined by

$$D_\uparrow \mathbf{c}(t, x)(\pm 1, v) = \liminf_{h \to 0+, v' \mapsto v} \frac{\mathbf{c}(t \pm h, x + hv') - \mathbf{c}(t, x)}{h}.$$

We set

$$\begin{cases} J_{\mathbf{c}}(t; (x(\cdot), u(\cdot)))(T, x) \\ \\ := e^{\int_0^t M(x(s), u(s))ds} \mathbf{c}(T - t, x(t)) + \displaystyle\int_0^t e^{\int_0^\tau M(x(s), u(s))ds} L(x(\tau), u(\tau))d\tau, \end{cases}$$

and then

$$K_{\mathbf{b}}(t, x; (x(\cdot), u(\cdot))) := \sup_{s \in [0, t]} J_{\mathbf{b}}(s, x; (x(\cdot), u(\cdot))).$$

We next integrate this cumulated cost together with the former cost $J_{\mathbf{c}}(t,x;(x(s),u(s)))$ by introducing the new cost function

$$L^{\mathbf{c}}_{\mathbf{b}}(t;(x(\cdot),u(\cdot)))(T,x) \;:=\; \max(K_{\mathbf{b}}(t,x;(x(\cdot),u(\cdot))),J_{\mathbf{c}}(t;(x(\cdot),u(\cdot)))(T,x).$$

We shall deduce from Theorem 5.1 the following consequence.

THEOREM 6.1. *Let us assume that the extended functions* $\mathbf{b}$ *and* $\mathbf{c}$ *are nontrivial and nonnegative. The viable-capture basin* $\mathrm{Capt}^{\mathcal{E}p(\mathbf{b})}_{\mathcal{R}}(\mathcal{E}p(\mathbf{c}))$ *of* $\mathcal{E}p(\mathbf{c})$ *under* $\mathcal{R}$ *is the epigraph of the valuation function* $V_{\mathbf{b}}(\mathbf{c})$ *defined by*

$$V_{\mathbf{b}}(\mathbf{c})(T,x) \;:=\; \inf_{(x(\cdot),u(\cdot))\in\mathcal{C}(x)}\ \inf_{t\in[0,T]} L^{\mathbf{c}}_{\mathbf{b}}(t;(x(\cdot),u(\cdot)))(T,x).$$

Furthermore, any solution $(x(\cdot),u(\cdot))\in\mathcal{C}(x)$ *starting from* $x\in X$ *satisfying the following inequality: for every* $t\in[0,t^*]$

$$(31)\quad \left\{\begin{array}{l} V_{\mathbf{b}}(\mathbf{c})(T,x) \\ \geq\; e^{\int_0^t M(x(s),u(s))ds}V_{\mathbf{b}}(\mathbf{c})(T-t,x(t)) + \displaystyle\int_0^t e^{\int_0^\tau M(x(s),u(s))ds}L(x(\tau),u(\tau))d\tau \end{array}\right.$$

until the first time t^* *when*

$$V_{\mathbf{b}}(\mathbf{c})(T-t^*,x(t^*)) = \mathbf{c}(T-t^*,x(t^*))$$

is an optimal solution for the optimal time t^*.

Finally, the valuation function is a solution $\mathbf{v}$ *to the two following functional equations stating that the functions* $L^{\mathbf{v}}_{\mathbf{b}}$ *and* $L^{\mathbf{c}}_{\mathbf{v}}$ *have the same infimum as* $L^{\mathbf{c}}_{\mathbf{b}}$:

$$(32)\quad \left\{\begin{array}{l} \inf_{(x(\cdot),u(\cdot))\in\mathcal{C}(x)}\inf_{t\in[0,T]} L^{\mathbf{c}}_{\mathbf{v}}(t,x;(x(\cdot),u(\cdot))) \\ =\; \mathbf{v}(T,x) \\ =\; \inf_{(x(\cdot),u(\cdot))\in\mathcal{C}(x)}\inf_{t\in[0,T]} L^{\mathbf{v}}_{\mathbf{b}}(t,x;(x(\cdot),u(\cdot))). \end{array}\right.$$

Proof. It is enough—and easy—to check that

$$L^{\Phi}_{\Psi}(t;(x(\cdot),u(\cdot)))(T,x) \;=\; L^{\mathbf{c}}_{\mathbf{b}}(t;(x(\cdot),u(\cdot)))(T,x) + \mathbf{R}_+$$

and thus that

$$\inf_{y\in V^{\Phi}_{\Psi}(t,x)} y \;=\; V^{\mathbf{c}}_{\mathbf{b}}(t,x)$$

since $\inf\left(\bigcup_{i\in I}[a_i,\infty[\right) = \inf_{i\in I} a_i$. □

Theorem 5.3 implies the following form of the optimality principle.

THEOREM 6.2. *Let us assume that* $V_{\mathbf{b}}(\mathbf{c})(T,x) > \mathbf{b}(T,x)$. *Then any solution* $(x(\cdot),u(\cdot))\in\mathcal{C}(x)$ *starting from* $x\in\mathrm{Dom}(V_{\mathbf{b}}(\mathbf{c}))$ *satisfying inequalities*

$$(33)\quad \left\{\begin{array}{l} V_{\mathbf{b}}(\mathbf{c})(T,x) \\ \geq\; e^{\int_0^t M(x(s),u(s))ds}V_{\mathbf{b}}(\mathbf{c})(T-t,x(t)) + \displaystyle\int_0^t e^{\int_0^\tau M(x(s),u(s))ds}L(x(\tau),u(\tau))d\tau \end{array}\right.$$

until the first time $t^*\in[0,T]$ *when*

$$V_{\mathbf{b}}(\mathbf{c})(T-t^*,x(t^*) = \mathbf{b}(T-t^*,x(t^*))$$

actually satisfies equality

$$\left\{\begin{array}{l} \forall\, t \in [0,t^*],\ V_{\mathbf{b}}(\mathbf{c})(T,x) \\ \\ =\ e^{\int_0^t M(x(s),u(s))ds} V_{\mathbf{b}}(\mathbf{c})(T-t,x(t)) + \displaystyle\int_0^t e^{\int_0^\tau M(x(s),u(s))ds} L(x(\tau),u(\tau))d\tau. \end{array}\right. \tag{34}$$

The first statement of Theorem 3.1 implies that the valuation function is a Frankowska contingent episolution to Hamilton–Jacobi–Bellman equations.

THEOREM 6.3 (Frankowska). *Let us assume that the control system* (P,f,L,M) *is Marchaud and that the functions* $\mathbf{b}$ *and* $\mathbf{c}$ *are nontrivial, nonnegative, and lower semicontinuous.*

Then the valuation function $V_{\mathbf{b}}(\mathbf{c})$ *is characterized as the smallest of the nonnegative lower semicontinuous functions* $\mathbf{v} : \mathbf{R}_+ \times X \mapsto \mathbf{R}_+ \cup \{+\infty\}$ *satisfying, for every* $(t,x) \in]0,\infty[\times X$*,*

$$\left\{\begin{array}{ll} \text{(i)} & \mathbf{b}(t,x) \ \le\ \mathbf{v}(t,x) \ \le\ \mathbf{c}(t,x), \\ \text{(ii)} & \textit{if } (t,x) \in \Omega(\mathbf{v}), \\ & \inf_{u\in P(x)} \left(D_\uparrow \mathbf{v}(t,x)(-1,f(x,u)) + L(x,u) + M(x,u)\mathbf{v}(t,x)\right) \ \le\ 0. \end{array}\right.$$

Let us set

$$\mathbf{R}(t,x) \ :=\ \{u \in P(x) \mid D_\uparrow V_{\mathbf{b}}(\mathbf{c})(t,x)(-1,f(x,u)) + L(x,u) + M(x,u)V_{\mathbf{b}}(\mathbf{c})(t,x) \le 0\}.$$

Knowing the valuation function, an optimal solution is obtained in the following way: Starting from x_0 *such that* $V_{\mathbf{b}}(\mathbf{c})(T,x_0) < \mathbf{c}(T,x_0)$*, any optimal solution* $(x(\cdot),u(\cdot))$ *is a solution to the control system*

$$\left\{\begin{array}{ll} \text{(i)} & x'(t) \ =\ f(x(t),u(t)), \\ \text{(ii)} & u(t) \ \in\ \mathbf{R}(T-t,x(t)) \end{array}\right. \tag{35}$$

until the first time $t^* \ge 0$ *when*

$$V_{\mathbf{b}}(\mathbf{c})(T-t^*,x(t^*)) \ =\ \mathbf{c}(T-t^*,x(t^*)).$$

The second part of Theorem 3.1 implies the following existence and uniqueness result:

THEOREM 6.4 (Frankowska). *Let us assume that the control system* (P,f,L,M) *is Marchaud and Lipschitz and that* $\mathbf{b}$ *and* $\mathbf{c}$ *are nontrivial, nonnegative, and lower semicontinuous.*

Then the valuation function $V_{\mathbf{b}}(\mathbf{c})$ *is the unique lower semicontinuous* episolution $\mathbf{v}$ *to the following system of differential inequalities: for every* $(t,x) \in \mathrm{Dom}(\mathbf{v})$*,*

$$\left\{\begin{array}{ll} \text{(i)} & \mathbf{b}(t,x) \ \le\ \mathbf{v}(t,x) \ \le\ \mathbf{c}(t,x), \\ \text{(ii)} & \textit{if } \mathbf{v}(t,x) < \mathbf{c}(t,x), \\ & \inf_{u\in P(x)} \left(D_\uparrow \mathbf{v}(t,x)(-1,f(x,u)) + L(x,u) + M(x,u)\mathbf{v}(t,x)\right) \ \le\ 0, \\ \text{(iii)} & \textit{if } \mathbf{v}(t,x) > \mathbf{b}(t,x), \\ & \sup_{u\in P(x)} (D_\uparrow \mathbf{v}(t,x)(1,-f(x,u)) - L(x,u) - M(x,u)\mathbf{v}(t,x)) \ \le\ 0, \\ \text{(iv)} & \textit{if } \mathbf{v}(t,x) = \mathbf{b}(t,x), \\ & \sup_{u\in P(x)} [\min(D_\uparrow \mathbf{v}(t,x)(1,-f(x,u)), D_\downarrow \mathbf{b}(t,x)(1,-f(x,u))) \\ & -L(x,u) - M(x,u)\mathbf{v}(t,x)] \ \le\ 0. \end{array}\right. \tag{36}$$

Remark. Condition (36) (iv) is automatically satisfied whenever

$$\sup_{u\in P(x)} (D_\downarrow \mathbf{b}(t,x)(1,-f(x,u)) - L(x,u) - M(x,u)\mathbf{v}(t,x)) \ \leq\ 0.$$

We refer to the papers [43, 41, 42, 44, 45, 46, 47] for other differential properties of the value function obtained using the tools of the epigraphical approach and, in particular, by duality, the links with viscosity solutions and lower semicontinuous bilateral solutions also introduced in [32, 33] by PDE methods.

7. Vector optimal control problems. When $Y := \mathbf{R}^n$ is supplied with the natural order relation $\leq$ associated with the positive orthant $\mathbf{R}^n_+$, we can associate with two maps $\vec{\mathbf{c}} : \mathbf{R}_+ \times X \rightsquigarrow \mathbf{R}^n_+$ and $\vec{\mathbf{b}} : \mathbf{R}_+ \times X \rightsquigarrow \mathbf{R}^n_+$ such that

$$\forall\ (t,x) \in \mathbf{R}_+ \times X,\ \ 0 \ \leq\ \vec{\mathbf{b}}(t,x) \ \leq\ \vec{\mathbf{c}}(t,x)$$

the set-valued maps Φ and Ψ defined by

$$\begin{cases} \text{(i)} & \Phi(t,x) \ := \ \vec{\mathbf{c}}(t,x) + \mathbf{R}^n_+, \\ \text{(ii)} & \Psi(t,x) \ := \ \vec{\mathbf{b}}(t,x) + \mathbf{R}^n_+. \end{cases}$$

In the following formulas, the supremums and the infimums are taken component by component. We set

$$\begin{cases} J_{\vec{\mathbf{c}}}(t;(x(\cdot),u(\cdot)))(T,x) \\ \\ := \ e^{\int_0^t M(x(s),u(s))ds}\vec{\mathbf{c}}(T-t,x(t)) + \displaystyle\int_0^t e^{\int_0^\tau M(x(s),u(s))ds} L(x(\tau),u(\tau))d\tau, \end{cases}$$

and then

$$K_{\vec{\mathbf{b}}}(t,x;(x(\cdot),u(\cdot))) \ := \ \sup_{s\in[0,t]} J_{\vec{\mathbf{b}}}(s,x;(x(\cdot),u(\cdot))).$$

We next integrate this cumulated cost together with the former cost $J_{\vec{\mathbf{c}}}(t,x;(x(s),u(s)))$ by introducing the new cost function

$$L^{\vec{\mathbf{c}}}_{\vec{\mathbf{b}}}(t;(x(\cdot),u(\cdot)))(T,x) \ := \ \max(K_{\vec{\mathbf{b}}}(t,x;(x(\cdot),u(\cdot))), J_{\vec{\mathbf{c}}}(t;(x(\cdot),u(\cdot)))(T,x)$$

and the subset

$$V_{\vec{\mathbf{b}}}(\vec{\mathbf{c}})(T,x) \ := \bigcup_{(x(\cdot),u(\cdot))\in\mathcal{C}(x)} \ \bigcup_{t\in[0,T]} L^{\vec{\mathbf{c}}}_{\vec{\mathbf{b}}}(t;(x(\cdot),u(\cdot)))(T,x).$$

We shall deduce from Theorem 5.1 the following consequence.

THEOREM 7.1. *Let us assume that, for any $(x,u) \in X \times \mathcal{U}$ and for any $y \in \mathbf{R}^n_+$, whenever $y_i = 0$, then $(M(x,u)y)_i = 0$.*

Then

$$\forall\ T \geq 0, x \in X,\ \ V_\Psi(\Phi)(T,x) \ = \ V_{\vec{\mathbf{b}}}(\vec{\mathbf{c}})(T,x) + \mathbf{R}^n_+.$$

Proof. It is enough to check that

$$L^\Phi_\Psi(t;(x(\cdot),u(\cdot)))(T,x) \ = \ L^{\vec{\mathbf{c}}}_{\vec{\mathbf{b}}}(t;(x(\cdot),u(\cdot)))(T,x) + \mathbf{R}^n_+.$$

By assumption, the cone $\mathbf{R}^n_+$ is forward and backward invariant under the differential equation $y'(t) = M(x(t), u(t))y(t)$ so that

$$\forall\, y \in \mathbf{R}^n_+,\ \ e^{\pm \int_0^t M(x(\tau),u(\tau))d\tau} y \ \in\ \mathbf{R}^n_+.$$

Therefore, since $\vec{\mathbf{c}}(t,x) \in \mathbf{R}^n_+$, we infer that

$$J_\Phi(t;(x(\cdot),u(\cdot)))(T,x) \ =\ J_{\vec{\mathbf{c}}}(t;(x(\cdot),u(\cdot)))(T,x) + \mathbf{R}^n_+.$$

Next we observe that, if $a_i \in \mathbf{R}^n$,

$$\bigcap_{i\in I}(a_i + \mathbf{R}^n_+) \ =\ \sup_{i\in I} a_i + \mathbf{R}^n_+,$$

and thus

$$K_\Psi(t;(x(\cdot),u(\cdot)))(T,x) \ =\ L_{\vec{\mathbf{b}}}(t;(x(\cdot),u(\cdot)))(T,x) + \mathbf{R}^n_+$$

and

$$L^\Phi_\Psi(t;(x(\cdot),u(\cdot)))(T,x) \ =\ L^{\vec{\mathbf{c}}}_{\vec{\mathbf{b}}}(t;(x(\cdot),u(\cdot)))(T,x) + \mathbf{R}^n_+.$$

Finally, we note that

$$\left\{\begin{array}{l} V_\Psi(\Phi)(T,x) \\ \ =\ \bigcup_{(x(\cdot),u(\cdot))\in\mathcal{C}(x)} \bigcup_{t\in[0,T]} \left[L^{\vec{\mathbf{c}}}_{\vec{\mathbf{b}}}(t;(x(\cdot),u(\cdot)))(T,x) + \mathbf{R}^n_+\right] \\ \ =\ V_{\vec{\mathbf{b}}}(\vec{\mathbf{c}})(T,x) + \mathbf{R}^n_+. \qquad \square \end{array}\right.$$

Recall that, for a closed subset $A \subset \mathbf{R}^n$ satisfying $A = A + \mathbf{R}^n_+$, the interior of A is equal to

$$\mathrm{Int}(A) \ =\ A + \overset{\circ}{\mathbf{R}}{}^n_+,$$

and thus the boundary of A is equal to the set of (weak) Pareto optima of A: Indeed, $y \in \partial A$ if and only if, for any $z \in A$, there exists at least $i \in \{1,\dots,n\}$ such that $y_i \le z_i$. We say that $z >> y$ if, for any $i \in \{1,\dots,n\}$, $z_i > y_i$.

Hence we deduce the following consequence of Theorem 5.3.

THEOREM 7.2. *Let us consider $y_T >> \vec{\mathbf{b}}(T,x))$ to be a Pareto minimum of the set $J_{V_{\vec{\mathbf{b}}}(\vec{\mathbf{c}})}(T,x)$. Consider any solution $(x(\cdot),u(\cdot)) \in \mathcal{C}(x)$ starting from $x \in \mathrm{Dom}(V_{\mathbf{b}}(\mathbf{c}))$ satisfying*

$$y_T \ \ge\ J_{V_{\vec{\mathbf{b}}}(\vec{\mathbf{c}})}(t,x;(x(\cdot),u(\cdot))) \tag{37}$$

until the first time t^* when, for at least one component $i = 1,\dots,n$,

$$y_{T_i} \ \le\ K_{\vec{\mathbf{b}}_i}(t^*,x;(x(\cdot),u(\cdot))).$$

Then y_T actually remains a Pareto minimum of the sets $J_{V_{\vec{\mathbf{b}}}(\vec{\mathbf{c}})}(t;(x(\cdot),u(\cdot)))(T,x)$ whenever $t \in [0,t^*]$.

NUMERICAL APPROXIMATIONS FOR STOCHASTIC DIFFERENTIAL GAMES*

HAROLD J. KUSHNER†

Abstract. The Markov chain approximation method is a widely used, robust, relatively easy to use, and efficient family of methods for the bulk of stochastic control problems in continuous time for reflected-jump-diffusion-type models. It has been shown to converge under broad conditions, and there are good algorithms for solving the numerical problems if the dimension is not too high. Versions of these methods have been used in applications to various two-player differential and stochastic dynamic games for a long time, and proofs of convergence are available for some cases, mainly using PDE-type techniques. In this paper, purely probabilistic proofs of convergence are given for a broad class of such problems, where the controls for the two players are separated in the dynamics and cost function, and which cover a substantial class not dealt with in previous works. Discounted and stopping time cost functions are considered. Finite horizon problems and problems where the process is stopped on first hitting an a priori given boundary can be dealt with by adapting the methods of [H. J. Kushner and P. Dupuis, *Numerical Methods for Stochastic Control Problems, in Continuous Time,* 2nd ed., Springer-Verlag, Berlin, New York, 2001] as done in this paper for the treated problems. The essential conditions are the weak-sense existence and uniqueness of solutions, an "almost everywhere" continuity condition, and that a weak local consistency condition holds "almost everywhere" for the numerical approximations, just as for the control problem. There are extensions to problems with controlled variance and jumps.

Key words. stochastic differential games, numerical methods, Markov chain approximations

1. Introduction.

The Markov chain approximation method of [25, 26, 32] is an effective and widely used method for the numerical solution of virtually all of the standard forms of stochastic control problems with reflected-jump-diffusion models. It is robust and can be shown to converge under very broad conditions. In this paper, the basic ideas will be extended to two-player stochastic dynamic games with the same systems model, but where the controls for the two players are separated in the dynamics and cost functions, and for certain classes of stopping time problems. Such "separated" models occur, for example, in pursuit-evasion games, where each player controls its own dynamics, risk-sensitive and robust control [2, 3, 8, 18, 36], Lagrangian formulation of optimization under side constraints, and controlled large deviation problems [12]. When the robust control is for controlled queues in heavy traffic, with or without finite buffers, or for its fluid limits, then the state is confined to some convex polyhedron by boundary reflection [28]. See section 8 for a few illustrations. The minimizing and maximizing players will be called, respectively, players 1 and 2.

Early results concerning algorithms and convergence for stochastic games for finite-state Markov chain models are in [30, 31], and a survey is in [37]. The performance of all of these algorithms can be improved with the use of multigrid, Gauss–Seidel, and various accelerated versions. See [32] for additional references and more

detail concerning such accelerated algorithms.

Partial results for the convergence problem for approximations of various forms of continuous state and time dynamic games have appeared, but there does not seem to be a complete development for the fully stochastic problem for reflected-jump-diffusion models. The upper value for a deterministic game (an ODE model) was treated by the Markov chain approximation method in [34, 35]. Results for various deterministic problems are in [4, 5, 6, 7, 40, 41]. The actual numerical methods which are used in the computations tend to be of the Markov chain approximation type, although the proofs are sometimes based on subsequent PDE techniques.

In this paper, we will use purely probabilistic methods of proof. Such methods have the advantage of providing intuition concerning numerical approximations, they cover many of the problem formulations to date, and they converge under quite general conditions. The essential conditions are *weak-sense* existence and uniqueness of the solution to the controlled equations, "almost everywhere" continuity of the dynamical and cost rate terms, and a natural "local consistency" condition: The local consistency and continuity need hold only almost everywhere with respect to the measure of the basic model; hence discontinuities and severe singularities in the dynamics and cost function can be treated under appropriate conditions (see, in particular, Theorems 4.7 and 7.1 and the treatment of discontinuities and complex variational problems with singularities in [32]). Furthermore, the numerical approximations are represented as processes which are close to the original, which gives additional intuitive and practical meaning to the method. Indeed, the Markov chain approximation method seems to provide the intuition for many of the actual numerical methods which are used, no matter what the method of proof of convergence.

We will treat only a selection of problems. The basic controlled process $x(\cdot)$ is defined by (2.2) or, equivalently, (2.4). We concentrate on discounted and stopping time cost functions. Others, such as finite horizon problems and problems where the process is stopped on first hitting an a priori given boundary, can be dealt with by adapting the methods of [32] as done in this paper for the treated problems.

In many applications, the state of the actual physical problem is confined to a bounded set, and the reflection term in (2.2) ensures the correct boundary behavior. One example is the heavy traffic limit of controlled queueing networks with finite buffers [1, 28] or robust control of such systems as in [2, 3], where the set is a hyperrectangle. Then robust control or the optimization under side constraints would lead to a game problem with a hyperrectangular state space. Another example would be the control of large deviations for such problems, along the lines of [12]. If the system state is not a priori confined to a bounded set, then, for numerical purposes, it is commonly necessary to bound the state space artificially and then experiment with the bounds. Such problems which are bounded for numerical purposes often involve reflecting boundaries. For this reason, our basic model is confined to a state space G that is a convex polyhedron, and it is confined by a "reflection" on the boundary. In [32], the boundary of the state space was determined by a set of smooth curved surfaces. We restrict our attention to the simpler polyhedral case, since that is the one most widely used, and it avoids details which distract from the general development. However, the approximations of the more general boundaries that were used in [32] can be carried over without change to the problem of this paper. Similarly, for simplicity, we drop the jump term (which is treated in [32]) since including it for the game involves no new issues. See also [27] for a setup where the jumps themselves are controlled. Again, for simplicity, we do not allow the variance to be controlled.

However, if (see (2.2)) $w(\cdot) = (w_1(\cdot), w_2(\cdot))$, where the $w_i(\cdot), i = 1, 2$, are mutually independent, and we have the separated form $\sigma(x, u)dw = \sigma_1(x, u_1)dw_1 + \sigma_2(x, u_2)dw_2$, then the methods in [32, Chapter 13] or [26] can be adapted.

The methods to be used are based on the theory of weak convergence [10, 14] as they are applied in [32]. For any process with values in a complete and separable metric space S, let $D(S; 0, \infty)$ denote the space of S-valued paths on the time interval $[0, \infty)$ which are right continuous and have left-hand limits, and with the Skorohod topology used. The path space for the state process $x(\cdot)$ is $D(G; 0, \infty)$, where $G \subset \mathbb{R}^r$, r-dimensional Euclidean space. The tightness criterion to be used implicitly is Theorem 2.7b of [24], which is restated as [32, Theorem 9.2.1].

The development involves various concepts from stochastic control and game theory, weak-sense solutions, the Skorohod problem, and numerical methods for stochastic control, not all of which will be familiar to many readers. Because of this, to make the material as accessible as possible as well as to minimize detail, the development has been structured to take advantage of the results in [32] whenever possible. The analysis for the game problem is more difficult than that for the pure control problem, since we must work with strategies and not simply controls, the strategies of the two players might be dependent, and they need to be approximated in various ways for purposes of the analysis.

Sections 2 and 3 give the basic systems model and describe the numerical method. They also contain necessary background material. The dynamical model is the reflected SDE (2.2) or (2.4), also called the *Skorohod problem* [11, 32, 28]. (See also the beginning of section 4.) The conditions on the boundary of the state space are A2.1–A2.2. Condition A2.1 covers the great majority of cases of current interest, including those that arise from queueing and communications networks, as noted in section 2. The condition is trivial to verify for the special case where the state space is a hyperrectangle, with reflection directions being the interior normals. As is common in control theory when limits of a sequence of controls are involved, much of the analysis uses the notion of relaxed control, and the necessary definitions are given. The definitions of the upper and lower value of the game requires a precise definition of the class of allowed strategies. These are given in section 2. Later, we will define various subclasses of these sets which are needed in the approximation and limit proofs. The bulk of the paper works with weak-sense solutions. This allows the greatest generality, including the possibility of using Girsanov transformation methods for constructing solutions, hence the possibility of discontinuous dynamics. However, it comes at a price since the notation is more complicated than what would be required if Lipschitz conditions (hence strong-sense solutions) were used.

The numerical method, which is the Markov chain approximation procedure, is discussed in section 3. The actual ways of approximating the original problem to get the approximating chain and associated cost function are the same as in [32] for the pure control problem since it is the process for arbitrary controls that is approximated. The basic and natural *local consistency conditions* are stated. The approximation to the original process $x(\cdot)$ is a continuous time interpolation of the chain, and this interpolation $\psi^h(\cdot)$ is defined, and a useful representation is given. The upper and lower values for the game for the chain are defined.

The actual proof of convergence of the numerical method in Theorem 7.1 is not long. However, it depends on many approximations and estimates as well as on the fact that the original game has a value. These issues are dealt with in sections 4–6. Under a Lipschitz condition, Theorem 4.3 shows that the costs are well approximated

(in a uniform sense) if the controls are, and Theorem 4.4 proves similar facts when there is only a weak-sense solution. Then it is shown that a fine discretization of any of the controls in space and time, and even slightly delaying the actions of any of the controls, changes the costs only slightly, again uniformly in the controls. Loosely speaking, the costs are continuous in the controls of either player and uniform in the control of the other. Theorem 4.7 shows, under appropriate conditions, how to get similar results when the dynamical and cost rate functions are discontinuous. These approximations are fundamental to the proof of the existence of the value of the game in section 5 since they imply that slight delays in any of the controls have little effect on the results, which in turn implies that "who goes first" is not too important.

Section 6 contains the final "auxiliary" result. In the proof of convergence of the numerical method, one needs to use ϵ-optimal strategies for the player who goes first. These strategies are for theoretical purposes only and *do not have any use in practice.* The construction of these strategies is much more complicated than what is required for the pure control problem, and it is done in Theorem 6.1.

The convergence of the numerical method is given in section 7. In the pure control problem of [32], the numerical approximations are controlled Markov chains, and one needs to show that the sequence of approximations to the optimal value function converges as the approximation parameter goes to zero. Here, the numerical approximations are games for Markov chains. They might or might not have a value, depending on the form of the approximation. However, one needs to show at least that the upper and lower values converge to the value of the original game as the approximation parameter goes to its limit. This is more difficult than the proof of convergence for the control problem, and one needs to keep careful track of the information available to the individual players.

Section 8 contains a brief discussion of some examples and extensions. The treatment of the ergodic cost case uses quite different methods and is in [29].

2. The system model.

Assumptions on the state space G. It is assumed that the system state $x(t)$ is confined to the set G by boundary reflections. Conditions A2.1 and A2.2 are common in treatments of SDEs with reflections and piecewise smooth boundaries [11, 32, 28].

A2.1. *G is a bounded convex polyhedron in r-dimensional Euclidean space $\mathbb{R}^r$ with an interior and a finite number of faces. Let d_i denote the direction of reflection to the interior of the ith face, assumed constant there. On any edge or corner, the reflection direction can be any nonnegative linear combination of the directions on the adjoining faces. Let $d(x)$ denote the set of reflection directions at $x \in \partial G$, the boundary of G. For an arbitrary corner or edge of ∂G, let $\bar{d}_i$ and $\bar{n}_i$ denote the direction of reflection and the interior normal, respectively, on the ith adjoining face. Then there are constants $a_i > 0$ (depending on the edge or corner) such that*

$$a_i \langle \bar{n}_i, \bar{d}_i \rangle > \sum_{j:j\neq i} a_j \left| \langle \bar{n}_i, \bar{d}_j \rangle \right| \quad \text{for all } i. \tag{2.1}$$

A2.2. *There is a neighborhood $N(\partial G)$ and an extension of $d(\cdot)$ to $\overline{N(\partial G)}$ such that the following holds: For each $\epsilon > 0$, there is $\mu > 0$ which goes to zero as $\epsilon \to 0$ and such that if $x \in \overline{N(\partial G)} - \partial G$ and distance$(x, \partial G) \leq \mu$, then $d(x)$ is in the convex hull of $\{d(v); v \in \partial G, \text{distance}(x, v) \leq \epsilon\}$.*

In A2.3, the real variables c_i are the coefficients in the cost rate term $c'dy$, $c = \{c_i\}$, in (2.5), and U_i is the space of values for the control $u_i(t)$ of player i in (2.2).

A2.3. *$U_i, i = 1, 2$, are compact subsets of some Euclidean space, and $c_i \geq 0$.*

A2.4. *The functions $k_i(\cdot)$ and $b_i(\cdot)$ are real-valued (resp., $\mathbb{R}^r$-valued) and continuous on $G \times U_i$. Let $\sigma(\cdot)$ be a Lipschitz continuous matrix-valued function on G, with r rows and with the number of columns being the dimension of the Wiener process in* (2.2). *The $b_i(\cdot, \alpha_i)$ are Lipschitz continuous, uniformly in α_i.*

Later, the continuity and Lipschitz conditions in A2.4 will be replaced by A2.5 and either A2.6 or A2.7, and then we will be concerned with weak-sense solutions.

Comments on A2.1 and A2.2. Condition A2.2 is unrestrictive since one can always construct the extension. That A2.1 is quite natural can be seen from the following comments. First, suppose that the state space is being bounded for purely numerical reasons. Then the reflections are introduced merely to give a compact set G, which should be large enough so that the effects on the solution in the region of main interest are small. Then one often uses a hyperrectangle with normal reflection directions, in which case the right side of (2.1) is zero. Next, consider a heavy traffic queueing network model [22, 28, 39] where the state space is the nonnegative orthant, and the probability that an output of the ith processor goes to the queue for the jth processor is q_{ij}. Define the routing matrix $Q = \{q_{ij}; i, j\}$. If the spectral radius of Q is less than unity, then all customers will eventually leave the system, with probability one. The model is a special case of (2.2), and we can write $z(t) = [I - Q']y(t)$, where $y_i(\cdot)$ is nondecreasing, continuous, and can increase only at t, where $x_i(t) = 0$. In this case, A2.1 implies (see [11, 28]) the so-called completely S condition [22, 28, 38], which is essential to ensure important properties of the representation (2.2); for example, that $z(\cdot)$ has bounded variation with probability one. Also, A2.1 implies the Lipschitz condition and bound in Theorem 4.2.

The system model. Let $w(\cdot)$ be a standard vector-valued Wiener process with respect to a filtration $\{\mathcal{F}_t, t < \infty\}$, which might depend on the control. Let $u_i(\cdot), i = 1, 2$, be U_i-valued, measurable, and $\mathcal{F}_t$-adapted processes. Such processes are to be called *admissible controls.*[1] Keep in mind that the mere fact that $u_i(\cdot), i = 1, 2$, are admissible does not imply that they are acceptable controls for the game since the two players will have different information available depending on who "goes first." Furthermore, controls for the game are defined in terms of "strategies," as discussed at the end of this section. Nevertheless, for any controls with the correct information dependencies, there will be a filtration with respect to which $w(\cdot)$ is a standard vector-valued Wiener process, and to which the controls are adapted. The concept of admissibility will be used in getting useful approximations and bounds.

The dynamical model for the game process is the reflected SDE

$$x(t) = x(0) + \sum_{i=1}^{2} \int_0^t b_i(x(s), u_i(s))ds + \int_0^t \sigma(x(s))dw(s) + z(t), \tag{2.2}$$

where $u_i(\cdot)$ is the control for player i, $i = 1, 2$. The process $z(\cdot)$ is due to the boundary reflections and ensures that $x(t) \in G$. It has the representation

$$z(t) = \sum_i d_i y_i(t), \tag{2.3}$$

where $y(0) = 0$ and the $y_i(\cdot)$ are continuous, nondecreasing, and can increase only at t, where $x(t)$ is on the ith face of ∂G. The condition (2.1) implies that the set of reflection directions on any set of intersecting boundary faces are linearly independent.

[1] They will sometimes be referred to as admissible ordinary controls to distinguish them from relaxed controls.

This implies that the representation (2.3) is unique. See [28, Chapter 3] or [11, 21, 32] for a discussion of equations such as (2.2).

Relaxed controls $r_i(\cdot)$. Suppose that, for some filtration $\{\mathcal{F}_t, t < \infty\}$ and some standard vector-valued $\mathcal{F}_t$-Wiener process $w(\cdot)$, each $r_i(\cdot), i = 1, 2$, is a measure on the Borel sets of $U_i \times [0, \infty)$ such that $r_i(U_i \times [0, t]) = t$ and $r_i(A \times [0, t])$ is $\mathcal{F}_t$-measurable for each Borel set $A \subset U_i$. Then $r_i(\cdot)$ is said to be an *admissible relaxed control* for player i, with respect to $w(\cdot)$. If the Wiener process and filtration have been given or are obvious or unimportant, we simply say that $r_i(\cdot)$ is an admissible relaxed control for player i [15, 32]. For Borel sets $A \subset U_i$, we will write $r_i(A \times [0, t]) = r_i(A, t)$.

For almost all (ω, t) and each Borel set $A \subset U_i$, one can define the derivative

$$r_{i,t}(A) = \lim_{\delta \to 0} \frac{r_i(t, A) - r_i(t - \delta, A)}{\delta}.$$

Without loss of generality, we can suppose that the limit exists for all (ω, t). Then, for all (ω, t), $r_{i,t}(\cdot)$ is a probability measure on the Borel sets of U_i, and, for any bounded Borel set B in $U_i \times [0, \infty)$,

$$r_i(B) = \int_0^\infty \int_{U_i} I_{\{(\alpha_i, t) \in B\}} r_{i,t}(d\alpha_i) dt.$$

An ordinary control $u_i(\cdot)$ can be represented in terms of the relaxed control $r_i(\cdot)$, defined by its derivative $r_{i,t}(A) = I_A(u_i(t))$, where $I_A(u_i)$ is unity if $u_i \in A$ and is zero otherwise. The weak topology [32] will be used on the space of admissible relaxed controls. Relaxed controls are commonly used in control theory to prove existence theorems since any sequence of relaxed controls has a convergent subsequence.

Define the relaxed control $r(\cdot) = (r_1(\cdot) \times r_2(\cdot))$, with derivative $r_t(\cdot) = r_{1,t}(\cdot) \times r_{2,t}(\cdot)$. The $r(\cdot)$ is a measure on the Borel sets of $(U_1 \times U_2) \times [0, \infty)$, with marginals $r_i(\cdot), i = 1, 2$. Sometimes we will just write $r(\cdot) = (r_1(\cdot), r_2(\cdot))$ without ambiguity. The pair $(w(\cdot), r(\cdot))$ is called an *admissible pair* if each of the $r_i(\cdot)$ is admissible with respect to $w(\cdot)$.

In relaxed control terminology, (2.2) is written as

$$x(t) = x(0) + \sum_{i=1}^{2} \int_0^t \int_{U_i} b_i(x(s), \alpha_i) r_{i,s}(d\alpha_i) ds + \int_0^t \sigma(x(s)) dw(s) + z(t). \tag{2.4}$$

The existence and uniqueness of solutions to (2.4) will be discussed in the next section. Until section 8, for $x(0) = x$ and $\beta > 0$, the cost function is

$$W(x, r_1, r_2) = E \int_0^\infty e^{-\beta t} \left[\sum_{i=1}^{2} \int_{U_i} k_i(x(s), \alpha_i) r_{i,t}(d\alpha_i) dt + c' dy(t) \right]. \tag{2.5}$$

Define $\alpha = (\alpha_1, \alpha_2)$, $u = (u_1, u_2)$, and $b(x, \alpha) = b_1(x, \alpha_1) + b_2(x, \alpha_2)$, and define $k(\cdot)$ analogously.

Weak-sense solution. Suppose that $(w(\cdot), r(\cdot))$ is admissible with respect to some filtration $\{\mathcal{F}_t, t < \infty\}$ on some probability space. If there is a probability space on which are defined a filtration $\{\tilde{\mathcal{F}}_t, t < \infty\}$ and an $\tilde{\mathcal{F}}_t$-adapted triple $(\tilde{x}(\cdot), \tilde{w}(\cdot), \tilde{r}(\cdot))$, where $(\tilde{w}(\cdot), \tilde{r}(\cdot))$ is admissible and has the same probability law as $(w(\cdot), r(\cdot))$, and the triple satisfies (2.4), then it is said that there is a *weak-sense* solution to (2.4) for $(w(\cdot), r(\cdot))$. (The associated reflection process $\tilde{z}(\cdot)$ is determined by $(\tilde{x}(\cdot), \tilde{w}(\cdot), \tilde{r}(\cdot))$.)

Unique weak-sense solution. Suppose that we are given two probability spaces (indexed by $i = 1, 2$) with filtrations $\{\mathcal{F}_t^i, t < \infty\}$ and on which are defined processes $(x^i(\cdot), w^i(\cdot), r^i(\cdot))$, where $w^i(\cdot)$ is a standard vector-valued $\mathcal{F}_t^i$-Wiener process, $(w^i(\cdot), r^i(\cdot))$ is an admissible pair, and $(x^i(\cdot), w^i(\cdot), r^i(\cdot))$ solves (2.4). If equality of the probability laws of $(w^i(\cdot), r^i(\cdot))$, $i = 1, 2$, implies equality of the probability laws of $(x^i(\cdot), w^i(\cdot), r^i(\cdot))$, $i = 1, 2$, then we say that there is a *unique weak-sense solution* to (2.4) for the admissible pair $(w^i(\cdot), r^i(\cdot))$.

When working with weak-sense solutions, condition A2.5 and either A2.6 or A2.7 will replace A2.4.

A2.5. *The functions $\sigma(\cdot), b_i(\cdot), k_i(\cdot), i = 1, 2$, are bounded and measurable. Equation* (2.4) *has a unique weak-sense solution for each admissible pair $(w(\cdot), r(\cdot))$ and each initial condition.*

A2.6. *The functions $\sigma(\cdot), b_i(\cdot)$, and $k_i(\cdot), i = 1, 2$, are continuous.*

In A2.7, let $(w(\cdot), r(\cdot))$ be an arbitrary admissible pair, and let $x(\cdot)$ be the corresponding solution. Condition A2.7 differs from A2.6 in that the dynamics can be discontinuous, provided that not much time is spent in a small neighborhood of the set of discontinuity. A "threshold" control example where A2.7 holds is where $\sigma(x)\sigma'(x)$ is uniformly positive definite in G, $b(x, \alpha) = \bar{b}(x, \alpha) + b_0(x)$, where $\bar{b}(\cdot) = \sum_i \bar{b}_i(\cdot)$ and $k_i(\cdot), \bar{b}_i(\cdot)$, and $\sigma(\cdot)$ are continuous, and $b_0(x)$ takes one of two values, depending on which side of a hyperplane x lies.

A2.7. *There is a Borel set $D_d \subset G$ such that $\sigma(\cdot), b_i(\cdot)$, and $k_i(\cdot), i = 1, 2$, are continuous when $x \notin D_d$, and, for each $\epsilon > 0$, there is $t_\epsilon > 0$, which goes to zero as $\epsilon \to 0$, and such that, for any real T,*

$$\limsup_{\epsilon \to 0} \sup_{x(0)} \sup_{admis.\ r(\cdot)} \sup_{t_\epsilon \le t \le T} P\{x(t) \in N_\epsilon(D_d)\} = 0,$$

where $N_\epsilon(D_d)$ is an ϵ-neighborhood of D_d.

Comment on the Girsanov transformation method for defining solutions. When there is not a uniform Lipschitz condition (i.e., A2.3 does not hold), a common and useful approach to modeling uses the Girsanov transformation method [9, 23, 28, 32]. Here one starts with either a unique strong- or weak-sense solution and then introduces the control by a change of measure. Under appropriate conditions, the transformation is used to "shift" the drift term so that it includes the desired control. This procedure does not change the filtration or the probability space, but it does change the Wiener process. The new solution will also be weak-sense unique. See the references for more detail.

Classes of controls and strategies. Definitions. Let $\{\mathcal{F}_t, t < \infty\}$ be a filtration, and let $w(\cdot)$ be a standard vector-valued $\mathcal{F}_t$-Wiener process. Let $\mathcal{U}_i$ denote the set of controls $u_i(\cdot)$ for player i that are admissible with respect to $w(\cdot)$. For $\Delta > 0$, let $\mathcal{U}_i(\Delta) \subset \mathcal{U}_i$ denote the subset of admissible controls $u_i(\cdot)$ that are constant on the intervals $[k\Delta, k\Delta + \Delta)$, $k = 0, 1, \dots$, and where $u_i(k\Delta)$ is $\mathcal{F}_{k\Delta}$-measurable. Let B be a Borel subset of U_1. Let $\mathcal{L}_1(\Delta)$ denote the set of such piecewise constant controls for player 1 that are represented by functions $Q_{1k}(B; \cdot), k = 0, 1, \dots$, of the conditional probability type

$$\begin{aligned} P\left\{u_1(k\Delta) \in B \middle| w(s), u_2(s), s < k\Delta; u_1(l\Delta), l < k\right\} \\ = Q_{1k}\left(B; w(s), u(s), s < k\Delta\right), \end{aligned} \tag{2.6}$$

where $Q_{1k}(B; \cdot)$ is a measurable function for each Borel set B. Controls determined by (2.6) can be called strategies, owing to their explicit dependence on the past actions of both players.

If a rule for player 1 is given by the form (2.6), then, in the arguments of the cost functions, it will sometimes be written as $u_1(u_2)$ to emphasize its dependence on $u_2(\cdot)$. Although there is also dependence on $w(\cdot)$, that dependence is suppressed in the notation. Define $\mathcal{L}_2(\Delta)$ and the associated rules $u_2(u_1)$ for player 2 analogously. The same terminology will be used for relaxed controls. Thus $r_i(\cdot) \in \mathcal{U}_i$ means that $r_i(\cdot)$ is admissible, $r_i(\cdot) \in \mathcal{U}_i(\Delta)$ means that $r_i(\cdot)$ is admissible, the derivative $r_{i,t}(\cdot)$ is constant on the intervals $[k\Delta, k\Delta + \Delta)$, and $r_{i,t}(\cdot)$ is $\mathcal{F}_{k\Delta}$-measurable. Thus the difference between $\mathcal{L}_i(\Delta)$ and $\mathcal{U}_i(\Delta)$ is that, in the former case, the control is determined by a conditional probability law such as (2.6). However, the uniqueness condition A2.5 implies that it is only the probability law of $(w(\cdot), u_1(\cdot), u_2(\cdot))$ (or, more generally, of $(w(\cdot), r_1(\cdot), r_2(\cdot))$) that determines the law of the solution and hence the value of the cost. Thus we can always suppose that if the control for, say, player 1 is determined by a form such as (2.6), then (in relaxed control terminology) the law for $(w(\cdot), r_2(\cdot))$ is determined recursively by a conditional probability law

$$P\left\{\{w(s), r_2(s), k\Delta \le s \le k\Delta + \Delta\} \in \cdot \middle| w(s), r_2(s), u_1(s), s < k\Delta\right\}.$$

Theorems 4.5–4.7 imply that the values defined by (2.7) and (2.8) would not change if admissible relaxed controls were used in lieu of admissible ordinary controls.

Upper and lower values. For initial condition $x(0) = x$, define the upper and lower values for the game as

$$V^+(x) = \lim_{\Delta \to 0} \inf_{u_1 \in \mathcal{L}_1(\Delta)} \sup_{u_2 \in \mathcal{U}_2} W(x, u_1(u_2), u_2), \tag{2.7}$$

$$V^-(x) = \lim_{\Delta \to 0} \sup_{u_2 \in \mathcal{L}_2(\Delta)} \inf_{u_1 \in \mathcal{U}_1} W(x, u_1, u_2(u_1)). \tag{2.8}$$

Discussion of (2.7), (2.8). Let us interpret (2.7). For fixed $\Delta > 0$, consider the right side of (2.7). For each k, at time $k\Delta$, player 1 uses a rule of the form (2.6) to decide on the constant action that it will take on $[k\Delta, k\Delta + \Delta)$. That is, it "goes first." Player 2 can decide on its action at $t \in [k\Delta, k\Delta + \Delta)$ at the actual time that it is to be applied. (Its choice for the discrete instants $k\Delta$ is irrelevant.) Thus player 2 "goes last." Player 2 selects its strategy simply to be admissible. This operation yields admissible $u(\cdot) = (u_1(\cdot), u_2(\cdot))$. Under the Lipschitz condition A2.4, there is clearly a unique solution to (2.4). Alternatively, under the weak-sense existence and uniqueness assumption A2.5, there is a probability space on which are defined $(\tilde{w}(\cdot), \tilde{u}(\cdot))$ (with the same distribution as $(w(\cdot), u(\cdot))$) and on which is defined a solution to (2.4). The distribution of the set (solution, Wiener process, control) does not depend on the probability space. Thus, either way, the $\sup_{u_2 \in \mathcal{U}_2}$ is well defined for each rule for player 1. As $\Delta \to 0$, the inf sup is monotonically decreasing since player 1 can make decisions more often. Similar monotonicity was discussed in [20]. The analogous comments hold for (2.8). In section 4, it will be seen that the infs and sups could be taken over the relaxed controls without changing the results. Under our conditions, Theorem 5.1 says that there is a saddle point in that

$$V^+(x) = V^-(x) = V(x) \quad \text{for all } x \in G. \tag{2.9}$$

The use of limits of discrete strategies to define the upper and lower values goes back to [16, 17, 20], where discrete time games were used to approximate continuous time games. The Elliott–Kalton definition [13] does not require discretization and admits the widest class of strategies. However, various approaches based on discretized strategies are shown to yield the same values as those given by the Elliott–Kalton definition (see, for example, [19]). The references [4, 5, 6] all use various discrete time approximations in defining value, similar to (2.7) and (2.8). The numerical approximations converge to the value given by the definition (2.7)–(2.9).

3. The numerical procedure: The Markov chain approximation method.

The Markov chain approximation. Since some facts concerning the Markov chain approximation method of [25, 26, 32] will be needed when dealing with the convergence of the numerical approximation, let us recall the basic numerical procedure for the control problem where there is only one player. Loosely speaking, the method consists of two steps. The first step is the determination of a finite-state controlled Markov chain that has a continuous time interpolation that is an "approximation" of the process $x(\cdot)$. The second step solves the optimization problem for the chain and a cost function that approximates the one used for $x(\cdot)$. Let h denote the approximation parameter. Under a natural "local consistency" condition, the minimal cost function $V^h(x)$ for the controlled approximating chain converges to the minimal cost function for the original problem. The optimal control for the original problem is also approximated. The method is a robust and effective method for solving optimal control problems for reflected-jump-diffusions under very general conditions. The approximating chain and local consistency conditions are the same for the game problems of this paper. There are many methods for getting suitable approximating chains, and the references contain a comprehensive discussion. An advantage of the approach is that the approximations "stay close" to the physical model and can be adjusted to exploit local features. Our main aim is the proof of convergence for the game problem, so only the essential details of the numerical approximations will be given, and the reader is referred to the references for more information.

To construct the approximation, start by defining S_h, a discretization of $\mathbb{R}^r$. This can be done in many ways. For example, S_h might be a regular grid with the distance between points in any coordinate direction being h. The precise requirements, as spelled out below, are quite general. It is only the points in G and their immediate neighbors that will be of interest. The next step is to define the approximating controlled Markov chain ξ_n^h and its state space, which will be a subset of S_h. The state space for the chain is usually divided into two parts. The first part is $G_h = G \cap S_h$, on which the chain approximates the diffusion part of (2.4). If the chain tries to leave G_h, then it is returned immediately, consistently with the local reflection direction. Thus define ∂G_h^+ to be the set of points not in G_h to which the chain might move in one step from some point in G_h. The set ∂G_h^+ is an approximation to the reflecting boundary. This two-step procedure on the boundary simplifies both coding and analysis. In particular, it allows us to introduce a reflection process $z^h(\cdot)$ that is analogous to $z(\cdot)$. This "approximating" reflection process is needed to get the correct form for the limits of the approximating chain and for the components of the cost function that are due to the boundary reflection.

Local consistency on G_h. First, we define local consistency at $x \in G_h$. Let $u_n^h = (u_{1,n}^h, u_{2,n}^h)$ denote the controls used at step n for the approximating chain ξ_n^h. Let $E_{x,n}^{h,\alpha}$ (resp., $\text{covar}_{x,n}^{h,\alpha}$) denote the expectation (resp., the covariance), given all of the data to step n, when $\xi_n^h = x, u_n^h = \alpha$. Then the chain satisfies the following

condition: There is a function $\Delta t^h(x,\alpha) > 0$ such that

$$\begin{gathered} E^{h,\alpha}_{x,n}\left[\xi^h_{n+1} - x\right] = b(x,\alpha)\Delta t^h(x,\alpha) + o(\Delta t^h(x,\alpha)), \\ \operatorname{covar}^{h,\alpha}_{x,n}\left[\xi^h_{n+1} - x\right] = a(x)\Delta t^h(x,\alpha) + o(\Delta t^h(x,\alpha)),\ a(x) = \sigma(x)\sigma'(x), \\ \lim_{h\to 0}\sup_{x,\alpha} \Delta t^h(x,\alpha) = 0, \\ \|\xi^h_{n+1} - \xi^n_h\| \le K_1 h \end{gathered} \tag{3.1}$$

for some real K_1. With the straightforward methods in [32], $\Delta t^h(\cdot)$ is obtained automatically as a byproduct of getting the transition probabilities, and it will be used as an interpolation interval. Thus, in G, the conditional mean first two moments of $\xi^h_{n+1} - \xi^h_n$ are very close to those of the "differences" of the $x(\cdot)$ of (2.4). The interpolation interval $\Delta t^h(x,\alpha)$ can always be selected so that it does not depend on the control α (or even on the state x), and this is often the choice since it simplifies both the coding and numerical computations.

Remark concerning discontinuous dynamical and cost terms. The consistency condition (3.1) need not hold at all points. For example, consider a case where A2.7 holds: Let $k(\cdot), \sigma(\cdot)$ be continuous, and let $b(\cdot)$ have the form $b(x,\alpha) = b_0(x) + \bar{b}(x,\alpha)$, where $\bar{b}(\cdot)$ is continuous but $b_0(\cdot)$ is discontinuous at $D_d \subset G$. If A2.7 holds for D_d, then we do not need local consistency there. A2.7 would hold if the "noise" $\sigma(x)dw$ "drives" the process away from the set D_d, no matter what the control. See [32, discussion in section 5.5 and Theorem 10.5.3, and also the discussion concerning discontinuous dynamics in section 10.2] for examples and more detail.

Local consistency on the reflecting boundary ∂G^+_h. From points in ∂G^+_h, the transitions of the chain are such that they move to G_h, with the conditional mean direction being a reflection direction at x. More precisely,

$$\lim_{h\to 0}\sup_{x\in\partial G^+_h} \text{distance}(x, G_h) = 0, \tag{3.2}$$

and there are $\theta_1 > 0$ and $\theta_2(h) \to 0$ as $h \to 0$ such that, for all $x \in \partial G^+_h$,

$$\begin{gathered} E^{h,\alpha}_{x,n}\left[\xi^h_{n+1} - x\right] \in \{a\gamma :\ \gamma \in d(x), \theta_2(h) \ge a \ge \theta_1 h\}, \\ \Delta t^h(x,\alpha) = 0 \ \text{ for } x \in \partial G^+_h. \end{gathered} \tag{3.3}$$

The last line of (3.3) says that the reflection from states on ∂G^+_h is instantaneous. Reference [32] has an extensive discussion of straightforward methods of obtaining useful approximations, which can also be used for the game problem.

A cost function. Define $\Delta t^h_n = \Delta t^h(\xi^h_n, u^h_n)$ and $t^h_n = \sum_{l=0}^{n-1} \Delta t^h_l$. When $\xi^h_n \in \partial G^+_h$, we can write (modulo an asymptotically negligible term) $\xi^h_{n+1} - \xi^h_n = \sum_i d_i \delta y^h_{i,n}$, where $\delta y^h_{i,n} \ge 0$ and represents the increments in the direction d_i. The $\delta y^h_{i,n} = 0$ for $\xi^h_n \notin \partial G^+_h$. See also the representation of $z^h(\cdot)$ above (3.9). One choice of discounted cost function for the approximating chain and initial condition $x = x(0)$ is

$$W^h(x,u^h) = E\sum_{n=0}^{\infty} e^{-\beta t^h_n}\left[k(\xi^h_n, u^h_n)\Delta t^h_n I_{\{\xi^h_n \in G_h\}} + c'\delta y^h_n\right]. \tag{3.4}$$

Admissible controls and the values. Let $p^h(x,y|u)$ denote the transition probability of the chain for $u = (u_1, u_2)$, $u_1 \in U_1, u_2 \in U_2$. We will define the strategies

for the game analogously to what was done in (2.6). If player i goes first, its strategy is defined by a conditional probability law of the type

$$P\left\{u_{i,n}^n \in \cdot \middle| \xi_l^h, l \le n;\, u_l^h, l < n\right\}.$$

The class of such rules is called $\mathcal{U}_i^h(1)$. If player i goes last, then its strategy is defined by a conditional probability law of the type

$$P\left\{u_{i,n}^n \in \cdot \middle| \xi_l^h, l \le n, u_l^h, l < n;\, u_{j,n}^h, j \ne i\right\}.$$

The class of such strategies is called $\mathcal{U}_i^h(2)$. Let $\{\delta\tilde{w}_n^h, n < \infty\}$ be mutually independent random variables and such that $\delta\tilde{w}_n^h$ is independent of the "past" $\{\xi_l^h, l \le n, u_l^h, l < n\}$. For technical reasons, in section 7, the conditioning data might be augmented by $\{\delta\tilde{w}_l^h, l \le n\}$, but the Markov property

$$P\left\{\xi_{n+1}^h = x \middle| \xi_l^h, u_l^h, l \le n\right\} = p^h\left(\xi_n^h, x \middle| u_n^h\right)$$

will always hold.

The same notation $\mathcal{U}_i^h(k)$ is used for the admissible relaxed controls. Define the upper values, respectively, as

$$V^{+,h}(x) = \inf_{u_1 \in \mathcal{U}_1^h(1)} \sup_{u_2 \in \mathcal{U}_2^h(2)} W^h(x, u_1, u_2), \tag{3.5}$$

$$V^{-,h}(x) = \sup_{u_2 \in \mathcal{U}_2^h(1)} \inf_{u_1 \in \mathcal{U}_1^h(2)} W^h(x, u_1, u_2). \tag{3.6}$$

In interpreting the cost function and the interpolations to be defined below, keep in mind that $\Delta t^h(x, \alpha) = 0$ for $x \in \partial G_h^+$. For $x \in G_h$, the dynamic programming equation for the upper value is ($\alpha = (\alpha_1, \alpha_2)$)

$$V^{+,h}(x) = \min_{\alpha_1 \in U_1}\{\max_{\alpha_2 \in U_2} E_x^\alpha[e^{-\beta\Delta t^h(x,\alpha)}V^{+,h}(\xi_1^h) + k(x,\alpha)\Delta t^h(x,\alpha)]\}, \tag{3.7}$$

and, for $x \in \partial G_h^+$, it is

$$V^{+,h}(x) = E_x\left[V^{+,h}(\xi_1^h) + c'\delta y_1^h\right]. \tag{3.8}$$

Here E_x^α denotes the expectation, given initial state x, with control pair α used, and E_x is the expectation, given initial state x (the reflection direction is not controlled). The equations are analogous for the lower value. Owing to the contraction implied by the discounting, there is a unique solution to (3.7) [35]. If desired, the transition probabilities could be constructed so that $\Delta t^h(\cdot)$ does not depend on α, and we have the separated form[2]

$$p^h(x, y|\alpha) = \bar{p}_1(x, y|\alpha_1) + \bar{p}_2(x, y|\alpha_2).$$

Such a form is useful for establishing the existence of a value for the game for the chain [31, 30], but it is not needed for the convergence of the numerical method.

Continuous time interpolation. The chain ξ_n^h is defined in discrete time, but $x(\cdot)$ is defined in continuous time. Only the chain is needed for the numerical

[2]For example, for the latter use, the splitting method of [32, subsection 5.3.2].

computations. However, for the proofs of convergence, the chain must be interpolated into a continuous time process which approximates $x(\cdot)$. The interpolation intervals are suggested by the $\Delta t^h(\cdot)$ in (3.1). We will use a Markovian interpolation, called $\psi^h(\cdot)$. Let $\{\Delta\tau_n^h, n < \infty\}$ be conditionally mutually independent and "exponential" random variables in that

$$P_{x,n}^{h,\alpha}\left\{\Delta\tau_n^h \geq t\right\} = e^{-t/\Delta t^h(x,\alpha)}.$$

Note that $\Delta\tau_n^h = 0$ if ξ_n^h is on the reflecting boundary ∂G_h^+. Define $\tau_0^h = 0$, and, for $n > 0$, set $\tau_n^h = \sum_{i=0}^{n-1} \Delta\tau_i^h$. The τ_n^h will be the jump times of $\psi^h(\cdot)$. Now define $\psi^h(\cdot)$ and the interpolated reflection processes by

$$\psi^h(t) = x(0) + \sum_{\tau_{i+1}^h \leq t} [\xi_{i+1}^h - \xi_i^h],$$

$$Z^h(t) = \sum_{\tau_{i+1}^h \leq t} [\xi_{i+1}^h - \xi_i^h] I_{\{\xi_i^h \in \partial G_h^+\}},$$

$$z^h(t) = \sum_{\tau_{i+1}^h \leq t} E_i^h[\xi_{i+1}^h - \xi_i^h] I_{\{\xi_i^h \in \partial G_h^+\}}.$$

Define the continuous time interpolations $u_i^h(\cdot)$ of the controls analogously. Let $r_i^h(\cdot)$ denote the relaxed control representation of $u_i^h(\cdot)$. The process $\psi^h(\cdot)$ is a continuous time Markov chain. When the state is x and control pair is α, the jump rate out of $x \in G_h$ is $1/\Delta t^h(x,\alpha)$. So the conditional mean interpolation interval is $\Delta t^h(x,\alpha)$; i.e., $E_{x,n}^{h,\alpha}[\tau_{n+1}^h - \tau_n^h] = \Delta t^h(x,\alpha)$.

Define $\tilde{z}^h(\cdot)$ by $Z^h(t) = z^h(t) + \tilde{z}^h(t)$. Note that this representation splits the effects of the reflection into two parts. The first is composed of the "conditional mean" parts $E_i^h[\xi_{i+1}^h - \xi_i^h] I_{\{\xi_i^h \in \partial G_h^+\}}$, and the second is composed of the perturbations about these conditional means [32, section 5.7.9]. The process $z^h(\cdot)$ is a reflection term of the classical type. Both components can change only at t, where $\psi^h(t)$ can leave G_h. Suppose that at some time t, $Z^h(t) - Z^h(t-) \neq 0$, with $\psi^h(t-) = x \in G_h$. Then by (3.3), $z^h(t) - z^h(t-)$ points in a direction in $d(N_h(x))$, where $N_h(x)$ is a neighborhood with radius that goes to zero as $h \to 0$. The process $\tilde{z}^h(\cdot)$ is the "error" due to the centering of the increments of the reflection term about their conditional means and has bounded (uniformly in x, h) second moments, and it converges to zero, as will be seen in Theorem 3.1. By A2.1, A2.2, and the local consistency condition (3.3), we can write (modulo an asymptotically negligible term)

$$z^h(t) = \sum_i d_i y_i^h(t),$$

where $y_i^h(0) = 0$ and $y_i^h(\cdot)$ is nondecreasing and can increase only when $\psi^h(t)$ is arbitrarily close (as $h \to 0$) to the ith face of ∂G.

The interpolated cost criterion. The cost criterion (3.4) can be written (modulo an asymptotically negligible error), where we use relaxed control terminology, $x(0) = x$, and $r_i^h(\cdot)$ is the relaxed control representation of $u_i^h(\cdot)$, as

$$W^h(x, r^h) = E\int_0^\infty e^{-\beta t}\left[\sum_{i=1}^2 \int_{U_i} k_i(\psi^h(s), \alpha_i) r_{i,t}^h(d\alpha_i)dt + c'dy^h(t)\right]. \tag{3.9}$$

In the numerical computations, the controls are ordinary and not relaxed, but it will be convenient to use the relaxed control terminology when taking limits. The proof of Theorem 7.1 implies that there is $\rho^h \to 0$ as $h \to 0$ such that

$$V^{+,h}(x) \leq V^{-,h}(x) + \rho^h. \tag{3.10}$$

This implies that either the upper or lower numerical game gives an approximation to the original game.

A representation for $\psi^h(\cdot)$. The process $\psi^h(\cdot)$ has a representation which makes it appear close to (2.4) and which is useful in the convergence proofs. Let $\xi_0^h = x$. If $a(\cdot)$ is not uniformly positive definite, then augment the probability space by adding a standard vector-valued Wiener process $\tilde{w}(\cdot)$, where, for each n, $\delta\tilde{w}_{n+1}^h = \tilde{w}(\tau_n^h + \cdot) - \tilde{w}(\tau_n^h)$ is independent of the "past" $\{\psi^h(s), u^h(s), \tilde{w}(s), s \leq \tau_n^h\}$. Then, by [32, sections 5.7.3 and 10.4.1], we can write

$$\begin{aligned} \psi^h(t) = x &+ \int_0^t b(\psi^h(s), u^h(s))ds \\ &+ \int_0^t \sigma(\psi^h(s))dw^h(s) + Z^h(s) + \epsilon^h(s), \end{aligned} \tag{3.11}$$

where $\psi^h(t) \in G$. The process $\epsilon^h(\cdot)$ is due to the $o(\cdot)$ terms in (3.1) and is asymptotically unimportant in that, for any T, $\lim_h \sup_{x,r^h} \sup_{s\leq T} E|\epsilon^h(s)|^2 = 0$. The process $w^h(\cdot)$ is a martingale with respect to the filtration induced by $(\psi^h(\cdot), u^h(\cdot), w^h(\cdot))$ and converges weakly to a standard (vector-valued) Wiener process. The $w^h(t)$ is obtained from $\{\psi^h(s), \tilde{w}(s), s \leq t\}$. All of the processes in (3.11) are constant on the intervals $[\tau_n^h, \tau_{n+1}^h)$.

Let $|z^h|(T)$ denote the variation of the process $z^h(\cdot)$ on the time interval $[0, T]$. Then we have the following theorem from [32].

THEOREM 3.1 (Theorem 11.1.3 and (5.7.5) [32]). *Assume* A2.1, A2.2, *and the local consistency conditions, and let $b(\cdot)$ and $\sigma(\cdot)$ be bounded and measurable. Then, for any $T < \infty$, there are $K_2 < \infty$ and δ_h, where $\delta_h \to 0$ as $h \to 0$, and which do not depend on the controls or initial condition, such that*

$$E\left|z^h\right|^2(T) \leq K_2, \tag{3.12}$$

$$E \sup_{s\leq T} \left|\tilde{z}^h(s)\right|^2 = \delta_h E\left|z^h\right|(T). \tag{3.13}$$

The inequalities hold for $y^h(\cdot)$ replacing $z^h(\cdot)$.

4. Auxiliary results: Bounds and approximations. This section is concerned with various estimates and approximations of the solution to (2.4) which are uniform in the control. The proofs of convergence of any numerical approximations involve approximations of the underlying process, especially when control is involved, and the results of this section will be used in section 6 to obtain nearly optimal strategies of a particular type that will play a fundamental role in the convergence proofs of the numerical algorithms. Furthermore, the approximations will be used in section 5 to show that the game has a value. This is critical in showing that the numerical approximations actually converge to the desired value. The approximations imply, among other things, that slight delays in the controls of any of the players affect the

costs only slightly. Delaying the control of the second player is equivalent to that player "going first" since its actual applied control at any time will depend on "old" information. This idea will be used in the next section to prove that the game has a value. The first part of the following theorem is [11, Theorem 2.2]. The inequality (4.3) is [32, Theorem 11.1.1].

DEFINITION 4.1 (the Skorohod problem). *Assume* A2.1 *and* A2.2*, and let the components of the $\mathbb{R}^r$-valued function $\psi(\cdot)$ be right continuous and have left-hand limits. Consider the equation $\bar{x}(t) = \psi(t) + \bar{z}(t)$, $x(t) \in G$. Then $\bar{x}(\cdot)$ is said to solve the Skorohod problem* [11, 32] *if the following holds. The components of $\bar{z}(\cdot)$ are right continuous with $\bar{z}(0) = 0$, and $\bar{z}(\cdot)$ is constant on the time intervals where $\bar{x}(t)$ is in the interior of G. The variation $|\bar{z}|(t)$ of $\bar{z}(\cdot)$ on each $[0,t]$ is finite. There is measurable $\gamma(\cdot)$ with values $\gamma(t) \in d(\bar{x}(t))$, the set of reflection directions at $\bar{x}(t)$, such that $\bar{z}(t) = \int_0^t \gamma(s) d|\bar{z}|(s)$. Thus $\bar{z}(\cdot)$ can change only when $\bar{x}(t)$ is on the boundary of G, and then its "increment" is in a reflection direction at $\bar{x}(t)$.*

THEOREM 4.2. *Assume* A2.1 *and* A2.2*. Let $\psi(\cdot) \in D(\mathbb{R}^r; 0, \infty)$, and consider the Skorohod problem $\bar{x}(t) = \psi(t) + \bar{z}(t)$, $x(t) \in G$. Then there is a unique solution $(\bar{x}(\cdot), \bar{z}(\cdot))$ in $D(\mathbb{R}^{2r}; 0, \infty)$. There is $K < \infty$ depending only on the $\{d_i\}$ such that*

$$|\bar{x}(t)| + |\bar{z}(t)| \le K \sup_{s \le t} |\psi(s)|, \tag{4.1}$$

and, for any $\psi^i(\cdot) \in D(\mathbb{R}^r; 0, \infty), i = 1, 2$, and corresponding solutions $(\bar{x}^i(\cdot), \bar{z}^i(\cdot))$,

$$|\bar{x}_1(t) - \bar{x}_2(t)| + |\bar{z}_1(t) - \bar{z}_2(t)| \le K \sup_{s \le t} |\psi_1(s) - \psi_2(s)|. \tag{4.2}$$

Consider (2.4)*, where $b(\cdot)$ and $\sigma(\cdot)$ are bounded and measurable, and use the representation* (2.3) *for the reflection process $z(\cdot)$. Then, for any $T < \infty$, there is a constant K_1 which does not depend on the initial condition or controls and such that*

$$\sup_{x \in G} E\,|y(1)|^2 \le K_1. \tag{4.3}$$

Approximations under the Lipschitz condition A2.4. Suppose that the Lipschitz and continuity condition A2.4 holds. Then the bound (4.1) and Lipschitz condition (4.2) ensure a unique strong-sense solution to the SDE (2.2) or (2.4) for any admissible controls. The proofs of the convergence of the numerical methods and of the existence of the value depend on our ability to approximate the controls. This is simplest under the Lipschitz condition A2.4, and we start with that case. Then the same approximations will be shown to hold if A2.5 and either A2.6 or A2.7 replace A2.4.

For each admissible relaxed control $r(\cdot)$, let $r^\epsilon(\cdot)$ be admissible relaxed controls with respect to the same filtration and Wiener process $w(\cdot)$ and that satisfy

$$\lim_{\epsilon \to 0} \sup_{r_i \in \mathcal{U}_i} E \sup_{t \le T} \left| \int_0^t \int_{U_i} \phi_i(\alpha_i) \left[r_{i,s}(d\alpha_i) - r^\epsilon_{i,s}(d\alpha_i) \right] ds \right| = 0, \quad i = 1, 2, \tag{4.4}$$

for each bounded and continuous real-valued nonrandom function $\phi_i(\cdot)$ and each $T < \infty$. For future use, note that if (4.4) holds, then it also holds for functions $\phi_i(\cdot)$ of (t, α_i) that are continuous except when t takes some value in a finite set $\{t_i\}$. Let $x(\cdot)$ and $x^\epsilon(\cdot)$ denote the solutions to (2.4) corresponding to $r(\cdot)$ and $r^\epsilon(\cdot)$, respectively, with the same Wiener process used. In particular,

$$x^\epsilon(t) = x(0) + \int_0^t \int_{U_1 \times U_2} b(x^\epsilon(s), \alpha) r^\epsilon_s(d\alpha) ds + \int_0^t \sigma(x^\epsilon(s)) dw(s) + z^\epsilon(t). \tag{4.5}$$

Define

$$\rho^\epsilon(t) = \int_0^t \int_{U_1\times U_2} b(x(s),\alpha)\left[r_s(d\alpha) - r_s^\epsilon(d\alpha)\right] ds.$$

The processes $x(\cdot), x^\epsilon(\cdot)$, and $\rho^\epsilon(\cdot)$ depend on $r(\cdot)$, but this dependence is suppressed in the notation. The next theorem shows that the set $\{x(\cdot)\}$ over all admissible controls is equicontinuous in probability in the sense that (4.6) holds, and that the costs corresponding to $r(\cdot)$ and $r^\epsilon(\cdot)$ are arbitrarily close for small ϵ, uniformly in $r(\cdot)$.

THEOREM 4.3. *Assume* A2.1 *and* A2.2*, and let $b(\cdot), \sigma(\cdot)$ be bounded and measurable. Then, for each real $\lambda > 0$,*

$$\lim_{\Delta\to 0} \sup_{x(0)} \sup_{t} \sup_{r_1\in\mathcal{U}_1} \sup_{r_2\in\mathcal{U}_2} P\left\{\sup_{s\le\Delta} |x(t+s) - x(t)| \ge \lambda\right\} = 0. \tag{4.6}$$

Now add the assumptions A2.3 *and* A2.4*, and let $(r(\cdot), r^\epsilon(\cdot))$ satisfy* (4.4) *for each bounded and continuous $\phi_i(\cdot), i = 1, 2$, and $T < \infty$. Define $\Delta^\epsilon(t) = \sup_{s\le t} |x(s) - x^\epsilon(s)|^2$. Then, for each t,*

$$\lim_{\epsilon\to 0} \sup_{x(0)} \sup_{r_1\in\mathcal{U}_1} \sup_{r_2\in\mathcal{U}_2} E\left|\sup_{s\le t} \rho^\epsilon(s)\right|^2 = 0, \tag{4.7}$$

$$\lim_{\epsilon\to 0} \sup_{x(0)} \sup_{r_1\in\mathcal{U}_1} \sup_{r_2\in\mathcal{U}_2} \left[E\Delta^\epsilon(t) + E\sup_{s\le t} |z(s) - z^\epsilon(s)|^2\right] = 0, \tag{4.8}$$

$$\lim_{\epsilon\to 0} \sup_{x} \sup_{r_1\in\mathcal{U}_1} \sup_{r_2\in\mathcal{U}_2} |W(x,r) - W(x,r^\epsilon)| = 0. \tag{4.9}$$

Proof. Assume the conditions in the first sentence of the theorem. Define $\psi(\cdot)$ by

$$\psi(t) = \int_0^t \int_{U_1\times U_2} b(x(s),\alpha) r_s(d\alpha) ds + \int_0^t \sigma(x(s)) dw(s).$$

Then

$$x(t+\delta) - x(t) = [\psi(t+\delta) - \psi(t)] + [z(t+\delta) - z(t)].$$

By Theorem 4.2, there is $K < \infty$ which does not depend on the control or initial condition and such that

$$\sup_{s\le\delta} |x(t+s) - x(t)| + \sup_{s\le\delta} |z(t+s) - z(t)| \le K \sup_{s\le\delta} [\psi(t+s) - \psi(t)].$$

Now using standard estimates for SDEs to evaluate the fourth moments of the right side of the last inequality yields, for some $K_1 < \infty$,

$$\sup_{x(0),t} \sup_{r_1\in\mathcal{U}_1} \sup_{r_2\in\mathcal{U}_2} E\sup_{s\le\delta} |x(t+s) - x(t)|^4 \le K_1\delta^2, \tag{4.10}$$

which implies Kolmogorov's criterion for equicontinuity in probability, which is (4.6) [33, Proposition III.5.3]. Write

$$\begin{aligned} x(t) - x^\epsilon(t) \;=\; & \int_0^t \int_{U_1\times U_2} [b(x(s),\alpha) - b(x^\epsilon(s),\alpha)]\, r_s^\epsilon(d\alpha) ds + \rho^\epsilon(t) \\ & + \int_0^t [\sigma(x(s)) - \sigma(x^\epsilon(s))]\, dw(s) + z(t) - z^\epsilon(t). \end{aligned}$$

Now assume the Lipschitz condition A2.4. Then the Lipshitz condition (4.2) together with standard estimates for SDEs, imply that there is a constant K not depending on $(r(\cdot), r^\epsilon(\cdot))$ or on the initial condition $x(0)$ and such that

(4.11)
$$E\Delta^\epsilon(t) \le K\left[E\sup_{s\le t}|\rho^\epsilon(s)|^2 + (t+1)\int_0^t E\Delta^\epsilon(s)ds + E\sup_{s\le t}|z(s)-z^\epsilon(s)|^2\right],$$
$$E\sup_{s\le t}|z(s)-z^\epsilon(s)|^2 \le K\left[E\sup_{s\le t}|\rho^\epsilon(s)|^2 + (t+1)\int_0^t E\Delta^\epsilon(s)ds\right].$$

Suppose that, in the definition of $\rho^\epsilon(\cdot)$, the function $b(x(t),\alpha)$ was replaced by a bounded nonrandom function $\phi(t,\alpha)$, which is continuous except when t takes values in some finite set $\{t_i\}$. Then (4.7) and (4.8) would hold by (4.4) and the use of Gronwall's inequality on the first line of (4.11), after the second line is substituted in to eliminate $z(\cdot)-z^\epsilon(\cdot)$. The equicontinuity in probability (4.6) and the boundedness and continuity of $b(\cdot)$ imply that $b(x(t),\alpha)$ can be approximated arbitrarily well by replacing $x(t)$ by $x(k\mu)$ for $t\in[k\mu,k\mu+\mu), k=0,1,\dots$, where μ can be chosen independently of $r(\cdot)$. Doing this approximation and using (4.4) imply (4.7) and (4.8).

Now we turn our attention to (4.9). By (4.7), (4.8), and the discounting, the parts of $W(x,r^\epsilon)$ that involve $k(\cdot)$ converge to the corresponding parts of $W(x,r)$. As noted below (2.3), the linear independence of the reflection directions on any set of intersecting boundary faces which is implied by (2.1) implies that $z(\cdot)$ uniquely determines $y(\cdot)$ with probability one. Thus $y^\epsilon(\cdot)$ converges to $y(\cdot)$ with probability one. This convergence, the uniform integrability of the set $\{|y^\epsilon(t+1)-y^\epsilon(t)|;\ t<\infty,\ \text{all } r(\cdot),\epsilon>0\}$ (which is implied by (4.3) and the compactness of G), and the discounting imply that the component of $W(x,r^\epsilon)$ involving $y^\epsilon(\cdot)$ converges to the component of $W(x(0),r)$ involving $y(\cdot)$. □

Weak-sense solutions. The next theorem uses only weak-sense solutions and does not require the Lipschitz condition A2.4. Except for the uniformity assertion, it is a slight variation of [32, Theorem 10.1.2] or, equivalently, of [26, Theorem 3.5.2]. The method of proof, using specially selected probability spaces, is very useful in general when dealing with sequences of solutions that are defined in the weak sense.

THEOREM 4.4. *Assume* A2.1–A2.3, A2.5, *and* A2.6. *Let* $r(\cdot)$ *and* $r^\epsilon(\cdot)$, $\epsilon>0$, *be admissible with respect to some Wiener process* $w^r(\cdot)$ *and satisfy* (4.4). *For each* $\epsilon>0$, *there is a probability space with an admissible pair* $(\tilde w^{r,\epsilon}(\cdot),\tilde r^\epsilon(\cdot))$ *which has the same probability law as* $(w^r(\cdot),r^\epsilon(\cdot))$ *and on which is defined a solution* $(\tilde x^{r,\epsilon}(\cdot),\tilde y^{r,\epsilon}(\cdot))$ *to* (2.4). *Let* $x^r(\cdot)$ *denote the solution to* (2.4), *corresponding to* $(w^r(\cdot),r(\cdot))$, *and let* $z^r(\cdot)=\sum_i d_i y_i^r(\cdot)$ *denote the associated reflection process. Let* $F(\cdot)$ *be a bounded and continuous real-valued function on the path space of the canonical set* $(x(\cdot),y(\cdot),r(\cdot))$. *Then the approximation of the solutions by using* $r^\epsilon(\cdot)$ *is uniform in that*

$$\lim_{\epsilon\to0}\sup_{x(0)}\sup_{r_1\in\mathcal{U}_1}\sup_{r_2\in\mathcal{U}_2}\left|EF(\tilde x^{r,\epsilon}(\cdot),\tilde y^{r,\epsilon}(\cdot),\tilde r^\epsilon(\cdot)) - EF(x^r(\cdot),y^r(\cdot),r(\cdot))\right| = 0. \tag{4.12}$$

Now let $F(\cdot)$ *be only continuous with probability one with respect to the measure of any solution set* $(x(\cdot),y(\cdot),r(\cdot))$. *Then, if* $(x^n(\cdot),y^n(\cdot),r^n(\cdot))$ *converges weakly to* $(x(\cdot),y(\cdot),r(\cdot))$, $F(x^n(\cdot),y^n(\cdot),r^n(\cdot))$ *converges weakly to* $F(x(\cdot),y(\cdot),r(\cdot))$. *Also,* (4.12) *continues to hold.*

Proof. Let $F(\cdot)$ be bounded and continuous. Let $(w^r(\cdot),r(\cdot))$ be an admissible pair on some probability space, with associated solution process $x^r(\cdot)$ and re-

flection process $z^r(\cdot) = \sum_i d_i y_i^r(\cdot)$. Since $(w^r(\cdot), r^\epsilon(\cdot))$ is an admissible pair, by the existence part of A2.5, there is a probability space on which are defined processes $(\tilde{x}^{r,\epsilon}(\cdot), \tilde{y}^{r,\epsilon}(\cdot), \tilde{w}^{r,\epsilon}(\cdot), \tilde{r}^\epsilon(\cdot))$, where the last two members are an admissible pair with the same law as $(w^r(\cdot), r^\epsilon(\cdot))$, and $\tilde{x}^{r,\epsilon}(\cdot)$ is the associated weak-sense solution to (2.4), with reflection process $\tilde{z}^{r,\epsilon}(\cdot) = \sum_i d_i \tilde{y}^{r,\epsilon}(\cdot)$. Any weak-sense limit (as $\epsilon \to 0$) $(\tilde{x}^r(\cdot), \tilde{y}^r(\cdot), \tilde{w}^r(\cdot), \tilde{r}(\cdot))$ of the quadruple must solve (2.4), and $\tilde{w}^r(\cdot)$ is a standard vector-valued Wiener process with respect to the filtration generated by $(\tilde{x}^r(\cdot), \tilde{w}^r(\cdot), \tilde{r}(\cdot))$. For a proof of such a characterization of a related limit, see [32, Theorem 11.1.2].

By (4.4) and the weak convergence, $(\tilde{w}^r(\cdot), \tilde{r}(\cdot))$ has the probability law of $(w^r(\cdot), r(\cdot))$. Thus by the uniqueness part of A2.5, $(\tilde{x}^r(\cdot), \tilde{y}^r(\cdot), \tilde{w}^r(\cdot), \tilde{r}(\cdot))$ has the probability law of $(x^r(\cdot), y^r(\cdot), w^r(\cdot), r(\cdot))$. This yields convergence (as $\epsilon \to 0$) in (4.12) for each pair $(w^r(\cdot), r(\cdot))$ and initial condition $x(0)$.

Suppose that the uniformity (in $r(\cdot)$ and $x(0)$) of the convergence in (4.12) does not hold. Then there are $x(0), x_n \to x(0)$, all in G, $\rho > 0$, $\epsilon_n \to 0$, bounded and continuous $F(\cdot)$, and for each n there is a probability space on which are defined an admissible pair $(w^n(\cdot), r^n(\cdot))$, an associated solution $(x^n(\cdot), y^n(\cdot))$, and approximations $r_i^{n,\epsilon_n}(\cdot)$ to $r_i^n(\cdot), i = 1, 2$, satisfying

$$\lim_{n\to\infty} E \sup_{t\le T} \left| \int_0^t \int_{U_i} \phi_i(\alpha_i) \left[r_{i,s}^n(d\alpha_i) - r_{i,s}^{n,\epsilon_n}(d\alpha_i) \right] ds \right| = 0, \quad i = 1, 2, \tag{4.13}$$

for each bounded and continuous real-valued nonrandom function $\phi_i(\cdot)$ and each $T < \infty$, and with the following additional properties. For each n, there is a probability space on which are defined an admissible pair $(\tilde{w}^{n,\epsilon}(\cdot), \tilde{r}^{n,\epsilon_n}(\cdot))$, which has the law of $(w^n(\cdot), r^{n,\epsilon_n}(\cdot))$, and associated solution $(\tilde{x}^{n,\epsilon_n}(\cdot), \tilde{y}^{n,\epsilon_n}(\cdot))$ with initial conditions $\tilde{x}^{n,\epsilon_n}(0) = x_n$ such that

$$\liminf_n \left| EF(x^n(\cdot), y^n(\cdot), r^n(\cdot)) - EF(\tilde{x}^{n,\epsilon_n}(\cdot), \tilde{y}^{n,\epsilon_n}(\cdot), \tilde{r}^{n,\epsilon_n}(\cdot)) \right| \ge \rho. \tag{4.14}$$

Equation (4.13) is implied by (4.4).

Now take a weakly convergent subsequence of $\{\tilde{x}^{n,\epsilon_n}(\cdot), \tilde{y}^{n,\epsilon_n}(\cdot), \tilde{w}^{n,\epsilon_n}(\cdot), \tilde{r}^{n,\epsilon_n}(\cdot)\}$, with limit $(\tilde{x}(\cdot), \tilde{y}(\cdot), \tilde{w}(\cdot), \tilde{r}(\cdot))$. Take a weakly convergent subsequence of $\{x^n(\cdot), y^n(\cdot), w^n(\cdot), r^n(\cdot), r^{n,\epsilon_n}(\cdot)\}$ with limit $(x(\cdot), y(\cdot), w(\cdot), r(\cdot), \hat{r}(\cdot))$. By (4.13), $r(\cdot) = \hat{r}(\cdot)$. Also, $(x(\cdot), y(\cdot), w(\cdot), r(\cdot))$ and $(\tilde{x}(\cdot), \tilde{y}(\cdot), \tilde{w}(\cdot), \tilde{r}(\cdot))$ both solve (2.4) with initial condition $x(0)$. Since $(w(\cdot), r(\cdot))$ has the same law as $(w(\cdot), \hat{r}(\cdot))$, hence as $(\tilde{w}(\cdot), \tilde{r}(\cdot))$, the quadruples in the last sentence must be identical in law, which (together with the weak convergence) contradicts (4.14). Thus (4.12) holds.

Now let $F(\cdot)$ be merely bounded and measurable. The first assertion of the last paragraph of the theorem follows from [14, Theorem 3.1(f), Chapter 3]. With this in hand, the uniformity of the convergence in (4.12) is treated as for the case of continuous $F(\cdot)$. □

Finite-valued and piecewise constant approximations $r^\epsilon(\cdot)$ in (4.4): Definitions. Now some approximations of subsequent interest will be defined. They are just piecewise constant and finite-valued ordinary controls. Consider the following discretization of the U_i. Given $\mu > 0$, partition U_i into a finite number of disjoint subsets $C_i^l, l \le p_i$, each with diameter no greater than $\mu/2$. Choose a point $\alpha_i^l \in C_i^l$. Henceforth let p_i be some given function of μ.

Now, given admissible $(r_1(\cdot), r_2(\cdot))$, define the approximating admissible relaxed control $r_i^\mu(\cdot)$ on the control value space $\{\alpha_i^l, l \le p_i\}$ by its derivative as $r_{i,t}^\mu(\alpha_i^l) =$

$r_{i,t}(C_i^l)$. Denote the set of such controls over all $\{C_i^l, \alpha_i^l, l \le p_i\}$ by $\mathcal{U}_i(\mu)$. Let $\mathcal{U}_i(\mu,\delta)$ denote the subset of $\mathcal{U}_i(\mu)$ that are ordinary controls and constant on the intervals $[l\delta, l\delta+\delta), l = 0, 1, \ldots$. Another subclass $\mathcal{U}_i(\mu,\delta,\Delta)$ will be defined above Theorem 4.6.

Finite-valued controls. The proof that (4.4) holds in the next two theorems is straightforward and the details are left to the reader. Under the Lipschitz conditions in A2.4, (4.9) follows from Theorem 4.3, and this implies (4.17). Under A2.5 and A2.6, use Theorem 4.4 to get (4.17).

THEOREM 4.5. *Assume* A2.1–A2.3, A2.5, A2.6*, and the above approximation of* $r_i(\cdot)$ *by* $r_i^\mu(\cdot) \in \mathcal{U}_i(\mu), i = 1, 2$. *Then* (4.4) *and* (4.9) *hold for* μ *replacing* ϵ*, no matter what the* $\{C_i^l, \alpha_i^l\}$. *The same result holds if we approximate only one of the* $r_i(\cdot)$.

Finite-valued, piecewise-constant, and "delayed" approximations. The proof that the game has a value in section 6 depends on showing that the cost changes little if the controls of any player are "delayed" since that implies that the order in which the players act is not important. Let $r_i^\mu(\cdot) \in \mathcal{U}_i(\mu)$, where the control-space values are $\{\alpha_i^l,\ l \le p_i\}$. Let $\Delta > 0$. Define the "backward" differences $\Delta_{i,k}^l = r_i^\mu(\alpha_i^l, k\Delta) - r_i^\mu(\alpha_i^l, k\Delta - \Delta), l \le p_i, k = 1, \ldots$. Define the piecewise constant ordinary controls $u_i^{\mu,\Delta}(\cdot) \in \mathcal{U}_i(\mu,\Delta)$ on the interval $[k\Delta, k\Delta+\Delta)$ by

$$u_i^{\mu,\Delta}(t) = \alpha_i^l \ \text{ for } \ t \in \left[k\Delta + \sum_{\nu=1}^{l-1} \Delta_{i,k}^\nu,\ k\Delta + \sum_{\nu=1}^{l} \Delta_{i,k}^\nu\right). \tag{4.15}$$

Note that, on $[k\Delta, k\Delta+\Delta)$, $u^{\mu,\Delta}(\cdot)$ takes the value α_i^l on a time interval of length $\Delta_{i,k}^l$. Note also that the $u_i^{\mu,\Delta}(\cdot)$ are "delayed" in that the values of $r_i(\cdot)$ on $[k\Delta - \Delta, k\Delta)$ determine the values of $u_i^{\mu,\Delta}(\cdot)$ on $[k\Delta, k\Delta+\Delta)$. Thus $u_i^{\mu,\Delta}(\cdot)$ is $\mathcal{F}_{k\Delta-}$-measurable. This delay will play an important role in the next two sections. Let $r_i^{\mu,\Delta}(\cdot)$ denote the relaxed control representation of $u_i^{\mu,\Delta}(\cdot)$.

The intervals $\Delta_{i,k}^l$ in (4.15) are just real numbers. For use in section 6, it is important to have them be some multiple of some small $\delta > 0$, where Δ/δ is an integer. Consider one method of doing this. Divide $[k\Delta, k\Delta+\Delta)$ into Δ/δ subintervals of length δ each. To each value α_i^l first assign (the integer part) $[\Delta_{i,k}^l/\delta]$ subintervals of length δ. Then assign the remaining unassigned subintervals to the values α_i^l at random with probabilities proportional to the residual (unassigned) lengths $\Delta_{i,k}^l - [\Delta_{i,k}^l/\delta]\delta$, $i \le p_i$. Call the resulting control $u_i^{\mu,\delta,\Delta}(\cdot)$, with relaxed control representation $r_i^{\mu,\delta,\Delta}(\cdot)$. Let $\mathcal{U}_i(\mu,\delta,\Delta)$ denote the set of such controls. If $u_i^{\mu,\delta,\Delta}(\cdot)$ is obtained from $r_i(\cdot)$ in this way, then we will henceforth write it as $u_i^{\mu,\delta,\Delta}(\cdot|r_i)$ to emphasize that fact. Similarly, if $u_i^{\mu,\Delta}(\cdot)$ is obtained from $r_i(\cdot)$, then it will be written as $u_i^{\mu,\Delta}(\cdot|r_i)$. Let $r_{i,t}^{\mu,\Delta}(\cdot|r_i)$ denote the time derivative of $r_i^{\mu,\Delta}(\cdot|r_i)$. As stated in the next theorem, for fixed μ and small δ, $u_i^{\mu,\delta,\Delta}(\cdot|r_i)$ well approximates $u_i^{\mu,\Delta}(\cdot|r_i)$ uniformly in $r_i(\cdot)$ and $\{\alpha_i^l\}$ in that (4.4) holds in the sense that, for each $\mu > 0$ $\Delta > 0$ and bounded and continuous $\phi_i(\cdot)$,

$$\lim_{\delta\to 0} \sup_{r_i \in \mathcal{U}_i} E \sup_{t \le T} \left| \int_0^t \int_{U_i} \phi_i(\alpha_i)[r_{i,s}^{\mu,\Delta}(d\alpha_i|r_i) - r_{i,s}^{\mu,\delta,\Delta}(d\alpha_i|r_i)]ds \right| = 0,\ i = 1, 2. \tag{4.16}$$

THEOREM 4.6. *Assume* A2.1–A2.3, A2.5*, and* A2.6. *For* $r_i(\cdot) \in \mathcal{U}_i$*, approximate as above the theorem to get* $r_i^{\mu,\Delta}(\cdot|r_i) \in \mathcal{U}_i(\mu,\Delta)$ *and* $r_i^{\mu,\delta,\Delta}(\cdot|r_i) \in \mathcal{U}_i(\mu,\delta,\Delta)$. *Then* (4.4) *holds for* $r_i^{\mu,\Delta}(\cdot|r_i)$ *and* (μ,Δ) *replacing* $r_i^\epsilon(\cdot)$ *and* ϵ*, respectively. Also,* (4.16)

holds and

$$\lim_{\Delta\to 0}\lim_{\delta\to 0}\sup_{x}\sup_{r_1\in\mathcal{U}_1}\sup_{r_2\in\mathcal{U}_2}|W(x,r_1,r_2)-W(x,r_1,u_2^{\mu,\delta,\Delta}(\cdot|r_2))|=0. \tag{4.17}$$

For each $\epsilon>0$, there are $\mu_\epsilon>0$ and $\delta_\epsilon>0$ such that, for $\mu\le\mu_\epsilon$ and $\delta\le\delta_\epsilon$ and $r_i(\cdot)\in\mathcal{U}_i, i=1,2$, there are $u_i^{\mu,\delta}(\cdot)\in\mathcal{U}_i(\mu,\delta)$ such that (4.4) holds for $u_i^{\mu,\delta}(\cdot)$ and (μ,δ) replacing $r_i^\epsilon(\cdot)$ and ϵ, respectively, and

$$\sup_{x}\sup_{r_1\in\mathcal{U}_1}\sup_{r_2\in\mathcal{U}_2}|W(x,r_1,r_2)-W(x,r_1,u_2^{\mu,\delta})|\le\epsilon. \tag{4.18}$$

The expressions (4.17) and (4.18) hold with the indices 1 and 2 interchanged.

THEOREM 4.7. *If* A2.7 *replaces* A2.6 *in Theorems* 4.4–4.6*, then their conclusions continue to hold.*

Proof. Only a few details will be given. The last part of Theorem 4.4 will be used, and we need only identify the $F(\cdot)$ for the present case. Theorem 4.2 and (4.6) required only measurability and boundedness of $b(\cdot)$ and $\sigma(\cdot)$. Also, the tightness of any solution sequence $\{x^\epsilon(\cdot),y^\epsilon(\cdot),w^\epsilon(\cdot),r^\epsilon(\cdot)\}$ requires only the measurability and boundedness of $b(\cdot)$ and $\sigma(\cdot)$.

For each $t>0$, define the bounded real-valued function $F(\phi(\cdot),m(\cdot))$ on the product path space of $x(\cdot)$ and $r(\cdot)$ by

$$F(\phi(\cdot),m(\cdot))=\int_0^t\int_{U_1\times U_2}b(\phi(s),\alpha)m_s(d\alpha)ds.$$

Under A2.7, $F(\phi(\cdot),m(\cdot))$ is continuous with probability one with respect to the measure induced by any pair $(x(\cdot),r(\cdot))$ solving (2.4). Let $(x^\epsilon(\cdot),y^\epsilon(\cdot),w^\epsilon(\cdot),r^\epsilon(\cdot))$ satisfy

$$x^\epsilon(t)=x(0)+\int_0^t\int_{U_1\times U_2}b(x^\epsilon(s),\alpha)r^\epsilon(d\alpha)ds+\int_0^t\sigma(x^\epsilon(s))dw^\epsilon(s)+z^\epsilon(t) \tag{4.19}$$

and converge weakly to $(x(\cdot),y(\cdot),w(\cdot),r(\cdot))$ as $\epsilon\to 0$.

For the sake of simplicity and without loss of generality, suppose that the Skorohod representation is used so that all processes are defined on the same probability space and the weak convergence is equivalent to convergence with probability one [14, Theorem 1.8, Chapter 3]. First, suppose that $\sigma(\cdot)$ is continuous but $b(\cdot)$ is not. By the asserted almost everywhere continuity of $F(\cdot)$ and the weak convergence and Skorohod representation, the integral in (4.19) involving $b(\cdot)$ converges to

$$\int_0^t\int_{U_1\times U_2}b(x(s),\alpha)r_s(d\alpha)ds$$

with probability one. Discontinuous $k(\cdot)$ is treated in the same way. Also, the stochastic integral and reflection term converge to those for the limit. The proof for the convergence of the stochastic integral uses a finite sum approximation $\sum_{l\gamma\le t}\sigma(x^\epsilon(l\gamma))\cdot[w^\epsilon(l\gamma+\gamma)-w^\epsilon(l\gamma)]$ and a standard estimate of the errors in this approximation. The proof for the reflection direction is similar to that in [32, Theorem 11.1.2]. The uniformity in $r(\cdot)$ of the approximations, as asserted in (4.9), (4.12), (4.17), and (4.18) in Theorems 4.4–4.6, is shown by a contradiction argument as in Theorem 4.4.

Now, suppose that $\sigma(\cdot)$ is discontinuous but that A2.7 holds. For $\rho>0$, define the real-valued function $f^\rho(\cdot)$ by

$$f^\rho(x)=\begin{cases}1 & \text{for } \operatorname{dist}(x,D_d)\ge\rho,\\ \operatorname{dist}(x,D_d)/\rho & \text{otherwise.}\end{cases}$$

The function $\sigma(\cdot)f^\rho(\cdot)$ is continuous, and, for each $T < \infty$, A2.7 implies that

$$\lim_{\rho\to 0} \sup_{x(0),r} \sup_{\epsilon} E \sup_{t\le T} \left| \int_0^t \sigma(x^\epsilon(s))\,[1 - f^\rho(x^\epsilon(s))]\,dw^\epsilon(s) \right|^2 = 0. \tag{4.20}$$

Now approximate $\sigma(\cdot)$ by $\sigma(\cdot)f^\rho(\cdot)$, and use (4.20) to get the convergence of the stochastic integrals

$$\int_0^t \sigma(x^\epsilon(s))dw^\epsilon(s) \to \int_0^t \sigma(x(s))dw(s). \qquad \square$$

5. Existence of the value of the game.

Motivating the proof that the value exists, i.e., that (2.9) holds. Let player 1 go first, and have a control that is constant on intervals of length Δ_1. Theorems 4.5–4.7 imply that, if the control for player 2 is delayed by more than Δ_1 and discretized in time, then the costs change little for small Δ_1. This delay will mean that player 1 will know player 2's actions before it selects its own. This, in turn, is equivalent to player 2 going first, which (together with the fact that the costs change little) essentially implies that the upper and lower values are as close as we wish. The proof formalizes this idea.

THEOREM 5.1. *Assume* A2.1–A2.3, A2.5, *and either* A2.6 *or* A2.7. *Then the game has a value in that* (2.9) *holds.*

Proof. Let $\Delta_1 > 0$. Let $\Delta, \delta, \mu, \epsilon$ be positive with Δ/δ being an integer. By Theorems 4.5–4.7, for small enough μ, δ, Δ, and large Δ/δ,

$$|W(x, u_1(r_2), r_2) - W(x, u_1(r_2), u_2^{\mu,\delta,\Delta}(\cdot|r_2))| \le \epsilon \tag{5.1}$$

for all $u_1(\cdot) \in \mathcal{L}_1(\Delta_1)$ and $r_2(\cdot) \in \mathcal{U}_2$. Also, for all $\Delta_1 > 0$,

$$\left| \inf_{u_1\in\mathcal{L}_1(\Delta_1)} \sup_{r_2\in\mathcal{U}_2} W(x, u_1(r_2), r_2) - \inf_{u_1\in\mathcal{L}_1(\Delta_1)} \sup_{r_2\in\mathcal{U}_2} W(x, u_1(r_2), u_2^{\mu,\delta,\Delta}(\cdot|r_2)) \right| \le \epsilon. \tag{5.2}$$

The results analogous to (5.1)–(5.2) hold if player 1 goes last. It follows that, in computing the upper or lower values, we can use either relaxed or ordinary controls for the player that goes last.

By the definition (2.7), for each $\Delta_1 > 0$,

$$V^+(x) \le \inf_{u_1\in\mathcal{L}_1(\Delta_1)} \sup_{r_2\in\mathcal{U}_2} W(x, u_1(r_2), r_2). \tag{5.3}$$

Let $\epsilon > 0$. By (5.2), there is $\Delta_\epsilon > 0$ such that, for $\Delta \le \Delta_\epsilon$, there are $\mu > 0$ and $\delta > 0$ such that, for all $\Delta_1 > 0$,

$$\begin{aligned} &\inf_{u_1\in\mathcal{L}_1(\Delta_1)} \sup_{r_2\in\mathcal{U}_2} W(x, u_1(r_2), r_2) \\ &\quad\le \inf_{u_1\in\mathcal{L}_1(\Delta_1)} \sup_{r_2\in\mathcal{U}_2} W(x, u_1(r_2), u_2^{\mu,\delta,\Delta}(\cdot|r_2)) + \epsilon \\ &\quad\le \inf_{u_1\in\mathcal{L}_1(\Delta_1)} \sup_{r_2\in\mathcal{U}_2} W(x, u_1(u_2^{\mu,\delta,\Delta}(\cdot|r_2)), u_2^{\mu,\delta,\Delta}(\cdot|r_2)) + \epsilon. \end{aligned} \tag{5.4}$$

Now let $\Delta_1 < \Delta$ with Δ/Δ_1 being an integer. Recall that the process $u_2^{\mu,\delta,\Delta}(\cdot|r_2)$ is constant on the intervals $[l\delta, l\delta+\delta), l = 0, 1, \dots$, and that $u_2^{\mu,\delta,\Delta}(t|r_2)$ is $\mathcal{F}_{q\Delta}$-measurable for $t \in [q\Delta, q\Delta+\Delta)$. Thus, for integers k and q such that $k\Delta_1 \in [q\Delta, q\Delta+\Delta)$, the inf sup and the use of $u_2^{\mu,\delta,\Delta}(\cdot|r_2)$ on the right of (5.4) can be interpreted to mean that, at each such time $k\Delta_1$, player 1 knows all of player 2's actions on the entire interval $[k\Delta_1, q\Delta+\Delta)$ as well as the data on the "past" up to $k\Delta_1$. Thus one computes the value of the main term on the right side of (5.4) as if player 2 goes first: For $k\Delta_1 \in [q\Delta, q\Delta+\Delta)$, player 1 uses a rule which can be represented in the form

$$P\{u_1(k\Delta_1) \in \cdot \big| u_1(l\Delta_1), l < k;\ u_2^{\mu,\delta,\Delta}(l\delta|r_2), l\delta < q\Delta+\Delta;\ w(s), s < k\Delta_1\}. \tag{5.5}$$

Since it is only the joint probability law that matters, it can be supposed that the value of $u_2(t) = u_2^{\mu,\delta,\Delta}(t|r_2)$ which is actually applied on $[q\Delta, q\Delta+\Delta)$ is determined by a conditional probability law which can be represented in the form

$$P\left\{(u_2(q\Delta+l\delta), l\delta < \Delta) \in \cdot \big| u_2(l\delta), l\delta < q\Delta;\ u_1(s),\ w(s), s < q\Delta\right\}, \tag{5.6}$$

where the $u_2(l\delta)$ take values in a μ-discretization of U_2. Let $\mathcal{L}_2(\mu,\delta,\Delta)$ denote the set of such rules for player 2. The main term on the right side of (5.4) involves arbitrary strategies for player 2 but which are discretized in space and time and delayed. By this fact and the use of the form (5.5), the $u_2^{\mu,\delta,\Delta}(\cdot|r_2)$ can be replaced by a control $u_2(\cdot)$ in $\mathcal{L}_2(\mu,\delta,\Delta)$, and we can write

$$\begin{aligned}
&\inf_{u_1\in\mathcal{L}_1(\Delta_1)} \sup_{r_2\in\mathcal{U}_2} W(x, u_1(u_2^{\mu,\delta,\Delta}(\cdot|r_2)), u_2^{\mu,\delta,\Delta}(\cdot|r_2)) \\
&\quad = \inf_{u_1\in\mathcal{L}_1(\Delta_1)} \sup_{u_2\in\mathcal{L}_2(\mu,\delta,\Delta)} W(x, u_1(u_2), u_2) \\
&\quad = \inf_{u_1\in\mathcal{U}_1(\Delta_1)} \sup_{u_2\in\mathcal{L}_2(\mu,\delta,\Delta)} W(x, u_1(u_2), u_2).
\end{aligned}$$

Now, since player 2 can be considered to "go first," we can write

$$\begin{aligned}
&\inf_{u_1\in\mathcal{U}_1(\Delta_1)} \sup_{u_2\in\mathcal{L}_2(\mu,\delta,\Delta)} W(x, u_1(u_2), u_2) \\
&\quad = \sup_{u_2\in\mathcal{L}_2(\mu,\delta,\Delta)} \inf_{u_1\in\mathcal{U}_1(\Delta_1)} W(x, u_1, u_2(u_1)).
\end{aligned} \tag{5.7}$$

By (5.3), (5.4), and (5.6),

$$V^+(x) \le \sup_{u_2\in\mathcal{L}_2(\mu,\delta,\Delta)} \inf_{u_1\in\mathcal{U}_1(\Delta_1)} W(x, u_1, u_2(u_1)) + \epsilon. \tag{5.8}$$

For small Δ_1 and large Δ/Δ_1,

$$\begin{aligned}
&\left| \sup_{u_2\in\mathcal{L}_2(\mu,\delta,\Delta)} \inf_{u_1\in\mathcal{U}_1(\Delta_1)} W(x, u_1, u_2(u_1)) - \sup_{u_2\in\mathcal{L}_2(\mu,\delta,\Delta)} \inf_{u_1\in\mathcal{U}_1} W(x, u_1, u_2(u_1)) \right| \\
&\qquad \le \epsilon.
\end{aligned}$$

It now follows from this, (5.8), and the definition of $V^-(x)$ that, for small Δ and μ and large Δ/δ and Δ/Δ_1,

$$\begin{aligned}
V^+(x) &\le \sup_{u_2\in\mathcal{L}_2(\mu,\delta,\Delta)} \inf_{u_1\in\mathcal{U}_1(\Delta_1)} W(x, u_1, u_2(u_1)) + \epsilon \\
&\le \sup_{u_2\in\mathcal{L}_2(\mu,\delta,\Delta)} \inf_{u_1\in\mathcal{U}_1} W(x, u_1, u_2(u_1)) + \epsilon \\
&\le \sup_{u_2\in\mathcal{U}_2(\delta)} \inf_{u_1\in\mathcal{U}_1} W(x, u_1, u_2(u_1)) + \epsilon \le V^-(x) + 2\epsilon.
\end{aligned} \tag{5.9}$$

Since ϵ is arbitrary and $V^+(x) \ge V^-(x)$, the theorem is proved. □

6. An auxiliary result: Nearly optimal policies. The proof of convergence of the numerical method in the next section will require the use of particular ϵ-optimal minimizing (resp., maximizing) strategies for player 1 when it goes first (resp., for player 2 when it goes first). Such strategies will be constructed in this section. They are for mathematical purposes only and do not have any practical value otherwise.

In order to motivate the construction, we will first recall the method of proof used for the pure control problem (where there is only a minimizing player) in [32, Chapters 10 and 11]. Let $r^h(\cdot)$ denote the continuous time interpolation of the relaxed control representation of the optimal control for the approximating chain ξ_n^h. Thus the optimal cost $V^h(x)$ equals $W^h(x, r^h)$. The corresponding set $\{\psi^h(\cdot), z^h(\cdot), w^h(\cdot), r^h(\cdot)\}$ was shown to be tight. The limit $(x(\cdot), z(\cdot), w(\cdot), r(\cdot))$ of any weakly convergent subsequence was shown to satisfy the (one-player form of) (2.4). Hence it cannot be better than an optimal solution for (2.4). This implies that $\liminf_h V^h(x) \geq V(x)$, the minimal value of the cost for (2.4).

To finish the convergence proof in [32], we had to show that $\limsup_h V^h(x) \leq V(x)$. This was done in the following way. Given arbitrary $\epsilon > 0$, a special ϵ-optimal control for (2.4) was constructed. This special control was such that it could be adapted for use on the approximating chain, and for small h the interpolated chain well approximated the limit process under that control. In more detail, let $r^\epsilon(\cdot)$ denote the relaxed control form of this special ϵ-optimal control for (2.4), with Wiener process $w^\epsilon(\cdot)$ and associated solution and reflection process $(x^\epsilon(\cdot), z^\epsilon(\cdot))$. Let $r^{\epsilon,h}(\cdot)$ denote the relaxed control form of the adaptation of this special control for use on the chain ξ_n^h, interpolated to continuous time, and let $(\psi^{\epsilon,h}(\cdot), z^{\epsilon,h}(\cdot), w^{\epsilon,h}(\cdot))$ denote the continuous time interpolation of the corresponding solution, reflection process and "pre-Wiener" process in the representation (3.11). Since $r^{\epsilon,h}(\cdot)$ is no better than the optimal control for the chain, $V^h(x) \leq W^h(x, r^{\epsilon,h})$. By the method of construction of $r^{\epsilon,h}(\cdot)$, the set $(\psi^{\epsilon,h}(\cdot), z^{\epsilon,h}(\cdot), w^{\epsilon,h}(\cdot), r^{\epsilon,h}(\cdot))$ converged weakly to the set $(x^\epsilon(\cdot), z^\epsilon(\cdot), w^\epsilon(\cdot), r^\epsilon(\cdot))$, with ϵ-optimal cost $W(x, r^\epsilon)$. Since ϵ is arbitrary, we have $\limsup_h V^h(x) \leq V(x)$, which completes the proof that $V^h(x) \to V(x)$. See the references for full details.

Such an ϵ-optimal control for (2.4) (whether minimizing or maximizing) for the player that goes first plays a similar role for the game problem of this paper. The construction follows the general lines of what was done in [32, Theorem 10.3.1], but there are some very important differences since we must work with strategies, where the two controls depend on each other, which is not the case for the pure (i.e., one-player) control problem. The construction is done as it is since we know little about nearly optimal policies in general. For example, we do know whether there are smooth ϵ-optimal feedback controls for either player, in general.

THEOREM 6.1. *Assume* A2.1–A2.3, A2.5, *and either* A2.6 *or* A2.7. *Let player* 1 *go first. Then, for each* $\epsilon > 0$, *there is an* ϵ*-optimal minimizing control law for player* 1 *with the following properties. For positive* Δ, δ, *and* ρ, *let* δ/ρ *and* Δ/δ *be integers. The control is constant on the intervals* $[k\Delta, k\Delta + \Delta)$, $k = 0, 1, \ldots$, *finite-valued, the value at* $k\Delta$ *is* $\mathcal{F}_{k\Delta}$*-measurable, and, for small* $\lambda > 0$, *it is defined by the conditional probability law* (*which defines the function* $q_{i,k}(\cdot)$)

$$
\begin{aligned}
& P\left\{u_1(k\Delta) = \gamma \middle| u_1(l\Delta), l < k;\ w(s), r_2(s), s < k\Delta\right\} \\
& = P\{u_1(k\Delta) = \gamma \big| w(l\lambda), l\lambda < k\Delta;\ u_1(l\Delta), l < k;\ u_2^{\mu,\rho,\delta}(l\rho|r_2), l\rho < k\Delta\} \\
& = q_{1,k}(\gamma;\ w(l\lambda), l\lambda < k\Delta;\ u_1(l\Delta), l < k;\ u_2^{\mu,\rho,\delta}(l\rho|r_2), l\rho < k\Delta).
\end{aligned} \tag{6.1}
$$

The function $q_{1k}(\cdot)$ *is continuous in the* w*-arguments for each value of the others. Since the rule* (6.1) *depends on* $r_2(\cdot)$ *only via* $u_2^{\mu,\rho,\delta}(\cdot|r_2)$ (*which is defined above*

Theorem 4.6), *we write the rule as* $\bar{u}_1^\epsilon(u_2^{\mu,\rho,\delta}(\cdot|r_2))$. *In particular, for small* λ, μ, Δ *and large* δ/ρ *and* Δ/δ, *it satisfies the inequality*

$$\sup_{r_2 \in \mathcal{U}_2} W(x, \bar{u}_1^\epsilon(u_2^{\mu,\rho,\delta}(\cdot|r_2)), r_2) \le V(x) + \epsilon. \tag{6.2}$$

Also, if $r_2^n(\cdot)$ *is a sequence which converges weakly to some* $r_2(\cdot)$, *then*

$$\limsup_n W(x, \bar{u}_1^\epsilon(u_2^{\mu,\rho,\delta}(\cdot|r_2^n)), r_2^n) \le V(x) + \epsilon. \tag{6.3}$$

For each $r_2(\cdot)$ *and* $l = 0, 1, \dots$, *let* $\tilde{u}_2^{\mu,\rho,\delta}(l\rho|r_2)$ *be a control that differs from* $u_2^{\mu,\rho,\delta}(l\rho|r_2)$ *by at most* μ *in absolute value. Then* (6.2) *and* (6.3) *hold for the perturbation* $\tilde{u}_2^{\mu,\rho,\delta}(\cdot|r_2)$ *replacing* $u_2^{\mu,\rho,\delta}(\cdot|r_2)$.

Similarly, if player 2 *goes first, then there is an* ϵ*-optimal control rule of the same type: In particular, and with the analogous terminology,*

$$\inf_{r_1 \in \mathcal{U}_1} W(x, r_1, \bar{u}_2^\epsilon(u_1^{\mu,\rho,\delta}(\cdot|r_1))) \ge V(x) - \epsilon, \tag{6.4}$$

and (6.4) *continues to hold with the perturbation* $\tilde{u}_1^{\mu,\rho,\delta}(\cdot|r_1)$ *replacing* $u_1^{\mu,\rho,\delta}(\cdot|r_1)$.

Proof. Recall the approximation of the U_i given above Theorem 4.5: Given $\mu_1 > 0$, U_i was partitioned into a finite number of disjoint subsets $C_i^l, l \le p_i$, each with diameter no greater than $\mu_1/2$. A point α_i^l in each C_i^l was chosen. These are the values of γ in (6.1). Let player 1 go first. Given $\epsilon > 0$, there are $\Delta > 0, \mu_1 > 0$, and an $\epsilon/8$-optimal rule for player 1 which can be represented in the "conditional probability" form

$$P\left\{u_1(k\Delta) = \gamma \middle| u_1(l\Delta), l < k;\, w(s), r_2(s), s \le k\Delta\right\}. \tag{6.5}$$

Call the rule $u_1^\epsilon(r_2)$. Then, by the $\epsilon/8$-optimality, for all $r_2(\cdot)$, we have

$$W(x, u_1^\epsilon(r_2), r_2) \le V^+(x) + \epsilon/8. \tag{6.6}$$

The rule (6.5) needs to be approximated so that it depends only on selected samples of the data.

Whatever $r_2(\cdot)$, $u_2^{\mu,\rho,\delta}(\cdot|r_2)$ is also an admissible control. Hence, by (6.6), for all $r_2(\cdot) \in \mathcal{U}_2$,

$$W(x, u_1^\epsilon(u_2^{\mu,\rho,\delta}(\cdot|r_2)), u_2^{\mu,\rho,\delta}(\cdot|r_2)) \le V^+(x) + \epsilon/8. \tag{6.7}$$

Indeed, (6.7) holds for all $u_2^{\mu,\rho,\delta}(\cdot|r_2)$, irrespective of $r_2(\cdot)$. Let μ, ρ, and δ be positive numbers with Δ/δ and δ/ρ being integers. For small μ and δ and large δ/ρ, Theorems 4.5–4.7 imply that

$$W(x, u_1^\epsilon(u_2^{\mu,\rho,\delta}(\cdot|r_2)), r_2) \le W(x, u_1^\epsilon(u_2^{\mu,\rho,\delta}(\cdot|r_2)), u_2^{\mu,\rho,\delta}(\cdot|r_2)) + \epsilon/8 \tag{6.8}$$

for all $r_2(\cdot) \in \mathcal{U}_2$. The control law $u_1^\epsilon(u_2^{\mu,\rho,\delta}(\cdot|r_2))$ can be represented in the form

$$\begin{aligned} &P\{u_1(k\Delta) = \gamma \big| u_1(l\Delta), l < k;\, r_2(s), w(s), s < k\Delta\} \\ &= P\{u_1(k\Delta) = \gamma \big| w(s), s < k\Delta\ \ u_1(l\Delta); l < k;\, u_2^{\mu,\rho,\delta}(l\rho|r_2), l\rho < k\Delta\}. \end{aligned} \tag{6.9}$$

Let $r_2^n(\cdot)$ converge to $r_2(\cdot)$ as $n \to \infty$. Then the discrete approximations $u_2^{\mu,\rho,\delta}(\cdot|r_2^n)$ do not necessarily converge to $u_2^{\mu,\rho,\delta}(\cdot|r_2)$ as $n \to \infty$. They will converge if the limit

"mass" on the boundaries of the sets $\{C_2^m, m \le p_2\}$ into which U_2 is subdivided is zero—more particularly, if

$$r_2(l\delta + \delta, \partial C_2^m) - r_2(l\delta, \partial C_2^m) = 0$$

for all m, l [14, Chapter 3, Theorem 3.1(f)]. Such convergence is hard to ensure for arbitrary $r_2(\cdot)$. The problem is due to the fact that the sets C_2^n are not all closed so that part of the boundary of some set will actually be in a neighboring set. Owing to our use of a μ-discretization of the U_i, the worst that can happen is that $u_2^{\mu,\rho,\delta}(l\rho|r_2^n)$ will differ from $u_2^{\mu,\rho,\delta}(l\rho|r_2)$ by at most μ for each l in the limit as $n \to \infty$. For each $r_2(\cdot)$, let $\tilde{u}_2^{\mu,\rho,\delta}(\cdot|r_2)$ be any admissible control satisfying

$$\sup_l |u_2^{\mu,\rho,\delta}(l\rho|r_2) - \tilde{u}_2^{\mu,\rho,\delta}(l\rho|r_2)| \le \mu.$$

Then, as $n \to \infty$ and $r_2^n(\cdot) \to r_2(\cdot)$, we will have $u_1^\epsilon(u_2^{\mu,\rho,\delta}(\cdot|r_2^n)) \to u_1^\epsilon(\tilde{u}_2^{\mu,\rho,\delta}(\cdot|r_2))$ for some perturbation $\tilde{u}_2^{\mu,\rho,\delta}(\cdot|r_2)$ that differs from $\tilde{u}_2^{\mu,\rho,\delta}(\cdot|r_2)$ by a most μ at each time point. For small μ and large δ/ρ, it will be seen that inequality (6.12) holds, and that is all that will be needed.

For small μ and δ and large δ/ρ, (6.8) yields

$$W(x, u_1^\epsilon(\tilde{u}_2^{\mu,\rho,\delta}(\cdot|r_2)), r_2) \le W(x, u_1^\epsilon(\tilde{u}_2^{\mu,\rho,\delta}(\cdot|r_2)), \tilde{u}_2^{\mu,\rho,\delta}(\cdot|r_2)) + \epsilon/8 \tag{6.10}$$

for all $r_2(\cdot) \in \mathcal{U}_2$. Inequalities (6.10) and (6.6) (with all $r_2(\cdot)$ replaced by $\tilde{u}_2^{\mu,\rho,\delta}(\cdot|r_2)$) imply that, for all $r_2(\cdot)$ and all such perturbations $\tilde{u}_2^{\mu,\rho,\delta}(\cdot|r_2)$,

$$W(x, u_1^\epsilon(\tilde{u}_2^{\mu,\rho,\delta}(\cdot|r_2)), r_2) \le V^+(x) + 2\epsilon/8. \tag{6.11}$$

Hence, for small μ and δ and large δ/ρ, the rule (6.9), but with any perturbation $\tilde{u}_2^{\mu,\rho,\delta}(\cdot|r_2)$ used in lieu of $u_2^{\mu,\rho,\delta}(\cdot|r_2)$, still yields a $2\epsilon/8$-optimal rule for player 1 if it goes first. Furthermore, if $r_2^n(\cdot)$ converges to $r_2(\cdot)$, then

$$\limsup_n W(x, u_1^\epsilon(u_2^{\mu,\rho,\delta}(\cdot|r_2^n)), r_2^n) = W(x, u_1^\epsilon(\tilde{u}_2^{\mu,\rho,\delta}(\cdot|r_2)), r_2) \le V^+(x) + 2\epsilon/8 \tag{6.12}$$

for some perturbation $\tilde{u}_2^{\mu,\rho,\delta}(\cdot|r_2)$.

The next step is to approximate the right side of (6.9) so that it depends only on samples of the $w(\cdot)$. Other than the $w(\cdot)$-variables, owing to the discretizations of time and control value, the conditioning data in (6.9) takes only a finite number of values. By the martingale convergence theorem, as $\lambda \to 0$, the function defined by

$$\begin{aligned} &q_{1,k}^\lambda(\gamma;\, w(l\lambda), l\lambda < k\Delta;\, u_1(l\Delta), l < k;\, u_2^{\mu,\rho,\delta}(l\rho|r_2), l\rho < k\Delta) \\ &\quad \equiv P\{u_1(k\Delta) = \gamma \big| w(l\lambda), l\lambda < k\Delta;\, u_1(l\Delta), l < k;\, u_2^{\mu,\rho,\delta}(l\rho|r_2), l\rho < k\Delta\} \end{aligned} \tag{6.13}$$

converges to

$$P\{u_1(k\Delta) = \gamma \big| w(s), s < k\Delta;\, u_1(l\Delta), l < k; u_2^{\mu,\rho,\delta}(l\rho|r_2), l\rho < k\Delta\}$$

for almost all $w(\cdot)$, for each value of the other conditioning variables. Thus, for small enough λ, the rule (6.9) can be approximated by (6.13). If the new rule is called $\hat{u}_1^{\epsilon,\lambda}(u_2^{\mu,\rho,\delta}(\cdot|r_2))$, then, for small λ,

$$W(x, \hat{u}_1^{\epsilon,\lambda}(u_2^{\mu,\rho,\delta}(\cdot|r_2)), r_2) \le V^+(x) + 6\epsilon/8,$$

and for small λ, μ, ρ, and δ and large Δ/δ and δ/ρ, the same inequality holds if the perturbation $\tilde{u}_2^{\mu,\rho,\delta}(\cdot|r_2)$ replaces $u_2^{\mu,\rho,\delta}(\cdot|r_2)$. We can suppose, without loss of generality, that Δ/λ is an integer.

There is one more approximation since we will require that the function $q_{1,k}(\cdot)$ in (6.1) be continuous in the $w(l\lambda)$-variables for each value of the others. Fix k, and let m denote the dimension of $w(1)$. Let $n = [k\Delta/\lambda] - 1$. Let $\bar{\alpha}$ denote the canonical value of the entire set $\{u_1(l\Delta), l < k\}$, and let $\bar{\beta}$ denote the canonical value of the entire set $\{u_2(l\rho), l\rho < k\Delta\}$. Let $w_\nu, v_\nu, \nu \le n$, be vectors in $\mathbb{R}^m$. For $\kappa > 0$, define the smoothed function

$$
\begin{aligned}
&q_{1,k}^{\lambda,\kappa}\left(\gamma\middle|\bar{\alpha},\bar{\beta};\, w_\nu, \nu \le n\right) \\
&= \frac{1}{[2\pi\kappa]^{nm/2}} \int \cdots \int e^{-|w_\nu - v_\nu|^2/[2\kappa]} q_{1,k}^{\lambda}\left(\gamma\middle|\bar{\alpha},\bar{\beta};\, v_\nu, \nu \le n\right) dv_1 \cdots dv_n.
\end{aligned} \tag{6.14}
$$

The smoothed function defined by (6.14) is continuous in $\{w_\nu, \nu \le n\}$ for each value of $\bar{\alpha}, \bar{\beta}, \gamma$. As $\kappa \to 0$, for each $\bar{\alpha}, \bar{\beta}, \gamma$, it converges to $q_{1,k}^{\lambda}\left(\gamma\middle|\bar{\alpha},\bar{\beta};\, w_\nu, \nu \le n\right)$ for almost all (Lebesgue measure) $\{w_\nu, \nu \le n\}$. Since the measure of $\{w(l\lambda), l\lambda < k\Delta\}$ is absolutely continuous with respect to Lebesgue measure, the convergence is for almost all $w(\cdot)$. Finally, defining the function $q_{1,k}(\cdot)$ in (6.1) by $q_{1,k}^{\lambda,\kappa}(\cdot)$ for small enough λ and κ and calling the resulting control law $\bar{u}_1^{\epsilon}(u_2^{\mu,\rho,\delta}(\cdot|r_2))$, we have (6.1) and (6.3), and $q_{1,k}(\cdot)$ is continuous in the w-variables for each value of the others.

If players 1 and 2 are interchanged in all of the above arguments, then we get an ϵ-optimal (maximizing) rule analogous to the form (6.1) for player 2, and (6.4) holds. □

7. Convergence of the numerical solutions. The next theorem establishes the convergence of the numerical procedure. It supposes the local consistency condition (3.1)–(3.3) everywhere, but recall the remarks concerning discontinuous dynamical and cost terms below (3.1). We do not show the convergence of the controls. In numerical examples, the sequence of optimal feedback controls for the chain does converge as well, and, in all examples of which we are aware, it is of a form that can be shown to be optimal. This would be the case if the optimal feedback controls $\bar{u}_i^h(\cdot)$ for the chain converged to feedback controls $\bar{u}_i(\cdot)$, where the convergence is uniform and the limits are continuous outside of an arbitrarily small neighborhood of a set D_d satisfying A2.7, and the process (2.4) under the $\bar{u}_i(\cdot)$ is unique in the weak sense. Then $W(x, \bar{u}_1, \bar{u}_2) = V(x)$.

THEOREM 7.1. *Assume the local consistency conditions* (3.1)–(3.3), A2.1–A2.3, A2.5, *and either* A2.6 *or* A2.7. *Then* $V^{\pm,h}(x) \to V(x)$ *as* $h \to 0$.

Proof. Let player 1 go first. Given $\epsilon > 0$, let us adapt the ϵ-optimal (minimizing) rule $\bar{u}_1^{\epsilon}(u_2^{\mu,\rho,\delta}(\cdot|r_2))$ for (2.4) that is defined by (6.1) for use on the chain. With player 1 using this rule for the Markov chain model, for each integer k player 1 uses a constant control value on the interpolated time interval $[k\Delta, k\Delta + \Delta)$. The continuous time interpolation of the relaxed control representation of the control processes which are used for the two players will be written as $r^h(\cdot) = (r_1^h(\cdot), r_2^h(\cdot))$. Thus, for some small positive μ, ρ, δ, and λ, the adaptation of the rule (6.1) for player 1 for the chain can be represented by the form, where $w^h(\cdot)$ is the "pre-Wiener" process in (3.11),

$$
\begin{aligned}
&P\left\{u_1^h(k\Delta) = \gamma\middle|u_1^h(l\Delta), l < k;, r_2^h(s), w^h(s), s \le t\right\} \\
&= P\{u_1^h(k\Delta) = \gamma\middle|u_1^h(l\Delta), l < k;\, u_2^{\mu,\rho,\delta}(l\rho|r_2^h), l\rho < k\Delta;\, w^h(l\lambda), l\lambda < k\Delta\} \\
&= q_{1,k}(\gamma\middle|u_1^h(l\Delta), l < k;\, u_2^{\mu,\rho,\delta}(l\rho|r_2^h), l\rho < k\Delta;\, w^h(l\lambda), l\lambda < k\Delta).
\end{aligned} \tag{7.1}
$$

Given the rule (7.1) for player 1, player 2 selects a maximizing control at each state transition. Let $u_2^h(\cdot)$ denote player 2's optimal choice. Then $r_2^h(\cdot)$ is its relaxed control representation, and $r_1^h(\cdot)$ is the relaxed control representation of the realization of player 1's actions which are determined by (7.1).

Choose a weakly convergent subsequence of $\{\psi^h(\cdot), r^h(\cdot), w^h(\cdot), y^h(\cdot)\}$ (abusing terminology, for simplicity this subsequence is also indexed by h). This converges weakly to a solution $(x(\cdot), r(\cdot), w(\cdot), y(\cdot))$ of (2.4) and $W^h(x, r^h) \to W(x, r)$. The proofs of these facts are the same as for the pure control problem in [32, Theorems 11.1.2 and 11.1.5]. Let us use the Skorohod representation [14, Theorem 1.8, Chapter 3] so that all processes are defined on the same probability space, and weak convergence becomes convergence with probability one. If

$$r_2(l\delta + \delta, \partial C_2^m) - r_2(l\delta, \partial C_2^m) = 0$$

for all m, l, then, using the continuity of $q_{1k}(\cdot)$ in the w-variables,

$$\begin{aligned} &q_{1,k}(\gamma\big|u_1^h(l\Delta), l < k;\, u_2^{\mu,\rho,\delta}(l\rho|r_2^h), l\rho < k\Delta;\, w^h(l\lambda), l\lambda < k\Delta) \\ &\quad \to q_{1,k}(\gamma\big|u_1(l\Delta), l < k;\, u_2^{\mu,\rho,\delta}(l\rho|r_2), l\rho < k\Delta;\, w(l\lambda), l\lambda < k\Delta) \end{aligned} \tag{7.2}$$

with probability one,

$$W^h(x, \bar{u}_1^\epsilon(u_2^{\mu,\rho,\delta}(\cdot|r_2^h)), r_2^h) \to W(x, \bar{u}_1^\epsilon(u_2^{\mu,\rho,\delta}(\cdot|r_2)), r_2), \tag{7.3}$$

and (6.2) holds. In any case, as noted in the paragraph below (6.9),

$$W^h(x, \bar{u}_1^\epsilon(u_2^{\mu,\rho,\delta}(\cdot|r_2^h)), r_2^h) \to W(x, \bar{u}_1^\epsilon(\tilde{u}^{\mu,\rho,\delta}(\cdot|r_2)), r_2), \tag{7.4}$$

where $\tilde{u}^{\mu,\rho,\delta}(\cdot|r_2)$ is a perturbation of the type defined in Theorem 6.1. We have, where $\tilde{r}_i(\cdot)$ is the relaxed control representations of the canonical $\tilde{u}_i(\cdot)$,

$$\begin{aligned} V^{+,h}(x) &= \inf_{\tilde{u}_1 \in \mathcal{U}_1^h(1)} \sup_{\tilde{u}_2 \in \mathcal{U}_2^h(2)} W^h(x, \tilde{u}_1, \tilde{u}_2) \le \sup_{\tilde{u}_2 \in \mathcal{U}^h(2)} W^h(x, \bar{u}_1^\epsilon(u_2^{\mu,\rho,\delta}(\cdot|\tilde{r}_2)), \tilde{r}_2) \\ &= W^h(x, \bar{u}_1^\epsilon(u_2^{\mu,\rho,\delta}(\cdot|r_2^h)), r_2^h) \to W(x, \bar{u}_1^\epsilon(\tilde{u}_2^{\mu,\rho,\delta}(\cdot|r_2)), r_2). \end{aligned} \tag{7.5}$$

This and the inequality (6.3) imply that, for any $\epsilon > 0$,

$$\limsup_h V^{+,h}(x) \le V(x) + \epsilon. \tag{7.6}$$

Now repeat the procedure, but with player 2 going first. Use the analogue of the ϵ-optimal rule (6.1) for player 2. Then, given that rule for player 2, let player 1 optimize (minimize). Writing $r^h(\cdot)$ for the actual control process, we have the analogue of (7.5), namely,

$$\begin{aligned} V^{-,h}(x) &= \sup_{\tilde{u}_2 \in \mathcal{U}_2^h(1)} \inf_{\tilde{u}_1 \in \mathcal{U}_1^h(2)} W^h(x, \tilde{u}_1, \tilde{u}_2) \ge \inf_{\tilde{u}_1 \in \mathcal{U}_1^h(2)} W^h(x, \tilde{r}_1, \bar{u}_2^\epsilon(u_1^{\mu,\rho,\delta}(\cdot|\tilde{r}_1))) \\ &= W^h(x, r_1^h, \bar{u}_2^\epsilon(u_1^{\mu,\rho,\delta}(\cdot|r_1^h))) \to W(x, r_1, r_2) = W(x, r_1, \bar{u}_2^\epsilon(\tilde{u}_1^{\mu,\rho,\delta}(\cdot|r_1))), \end{aligned}$$

where $\tilde{u}_1^{\mu,\rho,\delta}(\cdot|r_1)$ is a perturbation of $u_1^{\mu,\rho,\delta}(\cdot|r_1)$. Using this and (6.4) yields

$$\liminf_h V^{-,h}(x) \ge V(x) - \epsilon. \tag{7.7}$$

Finally, (7.5) and (7.7) yield

$$\limsup_h V^{+,h}(x) - \liminf_h V^{-,h}(x) \le 2\epsilon,$$

and the proof is concluded since $\epsilon > 0$ is arbitrary. □

8. Comments and extensions.

8.1. Examples with separated dynamics. Only a few comments will be made since the interest is in reminding the reader of the connection between risk-sensitive, robust, constrained, and large deviations control and differential games.

Risk-sensitive control. Let $\epsilon > 0$, and consider the problem of minimizing

$$\Lambda^{\epsilon}(u_1) = \lim_{T\to\infty} \frac{1}{T} \log E_x \exp\left[\frac{1}{\epsilon}\int_0^T L(x(s), u_1(s))ds\right]$$

for bounded and continuous $L(\cdot)$ with dynamics given by

$$dx = b(x, u_1)dt + \left[\frac{\epsilon}{2\gamma}\right]^{1/2} \sigma(x)dw + dz,$$

where $u_1(t) \in U_1$, a compact set. This is part of the subject of risk-sensitive control [18]. Under appropriate conditions, the solution reduces to that of a differential game with separated dynamics. Let $\bar{\Lambda}^{\epsilon} = \inf_{u_1} \Lambda^{\epsilon}(u_1)$, and define $a(x) = \sigma(x)\sigma'(x)$, assumed positive definite for each x. For x in the interior of G, the Isaacs equation is [18]

$$\bar{\Lambda}^{\epsilon} = \frac{\epsilon}{4\gamma^2}\sum_{i,j} V_{x_i x_j}(x)a_{ij}(x) + \max_{u_2}[V_x'(x)u_2 - \gamma^2 |u_2|^2] + \min_{u_1}\left[V_x'(x)b(x, u_1) + L(x, u_1)\right].$$

This corresponds to a two-person game with cost rate $k(x, u) = L(x, u_1) - \gamma^2|u_2|^2$. Only u_1 appears in the dynamical equation.

In applications, the set U_1 is often unbounded. Effective approaches to dealing with unbounded sets for the control problem are in the chapters concerning the variational problems in [32], and they can be adapted to the game problem under appropriate conditions.

Constrained optimization via the Lagrangian method. Consider the model (2.4), but with only one control $u_1(\cdot)$. Let $q_i(\cdot), i \le p$, be bounded, continuous, and continuously differentiable real-valued functions on G, and consider the minimization of

$$E\int_0^{\infty} e^{-\beta t} k_1(x(t), u_1(t))dt$$

for a bounded and continuous function subject to the constraints $Eq_i(x(t)) \le 0$ for almost all t, $i = 1, \dots, \mu$. The problem can be formulated as a game, via the introduction of Lagrange multipliers $u_{2,i}(t) \ge 0, i = 1, \dots, p$. Define

$$W(x, u_1, u_2) = E\int_0^{\infty} e^{-\beta t}\left[k_1(x(t), u_1(t)) + u_2'(t)q(x(t))\right]dt.$$

Then the solution is obtained from the game with upper (and lower as well, since the game has a value) value

$$\lim_{\Delta\to 0} \inf_{u\in\mathcal{U}_1(\Delta)} \sup_{u_2\in\mathcal{U}_2} W(x, u_1(u_2), u_2).$$

Here the set U_2 is $[0,\infty)$. However, for numerical purposes, one bounds the interval and then experiments with the bound until the desired solution is obtained.

Controlled large deviations problems. Consider the problem in controlled large deviations where one wishes to minimize (over choice of a control) the large deviations estimate of the probability of an event, say the probability that a set will be exited over some time interval. The mathematical formulation of such problems for diffusion-type models often reduces to that of a game, where the dynamics and cost function are separated, analogously to the forms of $b(\cdot)$ and $k(\cdot)$ in (2.4) and (2.5). See for example, the development in [12].

8.2. Stopping time problems and pursuit-evasion games.

Stopping cost not depending on who stops first. Suppose that player i now has a choice of an $\mathcal{F}_t$-stopping time τ_i as well as of the controls. Define $\tau = \min\{\tau_1, \tau_2\}$. For a continuous function $g(\cdot)$, replace (2.5) by

$$W(x,r,\tau) = E\int_0^\tau e^{-\beta t}\left[\int_{U_i}\sum_{i=1}^{2} k_i(x(t),\alpha_i)r_{i,t}(d\alpha_i)dt + c'dy(t)\right] + Ee^{-\beta\tau}g(x(\tau)). \tag{8.1}$$

Thus, in this model, the stopping cost $g(x(\tau))$ does not depend on who selects the stopping time.

The control spaces such as $\mathcal{U}_i$, $\mathcal{U}_i(\Delta), \mathcal{L}_i(\Delta)$, and $\mathcal{U}_i(\mu,\delta,\Delta)$, etc. need to be extended so that they include the stopping times. Let $\overline{\mathcal{U}}_i$ be the set of pairs $(u_i(\cdot),\tau)$, where $u_i(\cdot)\in\mathcal{U}_i$ and τ is an $\mathcal{F}_t$-stopping time. Let $\overline{\mathcal{U}}_i(\Delta)$ denote the subset where $u_i(\cdot)\in\mathcal{U}_i(\Delta)$ and τ takes values $k\Delta, k=0,1\ldots$, where the set $\{\omega:\tau=k\Delta\}$ is $\mathcal{F}_{k\Delta}$-measurable. Similarly, $\overline{\mathcal{U}}_i(\mu,\delta,\Delta)$ denotes the subset of $\overline{\mathcal{U}}_i(\Delta)$, where $u_i(\cdot)\in\mathcal{U}_i(\mu,\delta,\Delta)$. Let $\overline{\mathcal{L}}_1(\Delta)$ denote the set of controls in $\overline{\mathcal{U}}_1(\Delta)$ for player 1 which can be represented in the form

$$\begin{aligned} &P\left\{\tau_1 > k\Delta \middle| w(s), u_2(s), s<t; u_1(l\Delta), l<k, \tau_1\ge k\Delta\right\},\\ &P\left\{u_1(k\Delta)\in\cdot\middle| w(s), u_2(s), s<t; u_1(l\Delta), l<k;\ \tau_1 > k\Delta\right\}. \end{aligned} \tag{8.2}$$

Define $\mathcal{L}_2(\Delta)$ analogously for player 2.

The definitions of the upper and lower values in (2.6) are replaced by, respectively,

$$\begin{aligned} V^+(x) &= \lim_{\Delta\to 0}\inf_{u_1,\tau_1\in\overline{\mathcal{L}}_1(\Delta)}\sup_{(u_2,\tau_2)\in\overline{\mathcal{U}}_2} W(x,u_1,u_2,\tau),\\ V^-(x) &= \lim_{\Delta\to 0}\sup_{(u_2,\tau_2)\in\overline{\mathcal{L}}_2(\Delta)}\inf_{(u_1,\tau_1)\in\overline{\mathcal{U}}_1} W(x,u_1,u_2,\tau). \end{aligned} \tag{8.3}$$

The first line of (8.3) is to be understood as follows. Suppose that the game has not stopped by time $k\Delta$. Then, at $k\Delta$, player 1 goes first and decides whether to stop based on data to time $k\Delta-$. If it stops, the game is over. If not, it selects the control value $u_1(k\Delta)$ (which it will use until $(k\Delta+\Delta)-$ or until player 2 stops, whichever comes first) based on data to time $k\Delta-$. If the game is not stopped at $k\Delta$ by player 1, then player 2 has the opportunity to stop at any time on $[k\Delta, k\Delta+\Delta)$, with the decision to stop at any time being based on all data to that time. Until it stops (if it does), it chooses admissible control values $u_2(\cdot)$. The procedure is then repeated at time $k\Delta+\Delta$, and so forth. With these changes and minor (mostly notational) modifications, the previous theorems continue to hold. In particular, Theorem 7.1 holds.

Stopping cost depends on who stops first. Now let the cost be

$$W(x,r,\tau_1,\tau_2) = E\int_0^{\tau} e^{-\beta t}\left[\int_{U_i}\sum_{i=1}^{2} k_i(x(t),\alpha_i)r_{i,t}(d\alpha_i)dt + c'dy(t)\right] + Ee^{-\beta\tau_1}g_1(x(\tau_1))I_{\{\tau_1<\tau_2\}} + Ee^{-\beta\tau_2}g_2(x(\tau_2))I_{\{\tau_2\le\tau_1\}}, \tag{8.4}$$

where $\tau = \min\{\tau_1,\tau_2\}$ and the $g_i(\cdot)$ are bounded and continuous. The proof in Theorem 5.1 that the game has a value does not carry over to the present case, since the stopping cost depends on who stops first. However, if the game has a value, then Theorem 7.1 holds.

Consider the approximating Markov chain. Let player 1 go first, and let I_1 denote the indicator of the event that player 1 stops at the current step. Then the Bellman equation for the (for example) upper value is

$$\begin{aligned} V^{+,h}(x) = \min_{I_1,\alpha_1}\{&g_1(x)I_1, \\ &(1-I_1)\max[\max_{\alpha_2}(E_x^{\alpha}e^{-\beta\Delta t^h(x,\alpha)}V^{+,h}(\xi_1^h) + k(x,\alpha)\Delta t^h(x,\alpha)), g_2(x)]\}. \end{aligned} \tag{8.5}$$

Acknowledgments. The author greatly appreciates the many helpful suggestions of Paul Dupuis and Wendell Fleming.

CONSISTENT APPROXIMATIONS AND APPROXIMATE FUNCTIONS AND GRADIENTS IN OPTIMAL CONTROL*

OLIVIER PIRONNEAU† AND ELIJAH POLAK‡

Abstract. Because of the unavoidable use of numerical integration methods, such as Runge–Kutta or finite elements, the numerical solution of optimal control problems, with either ODE or PDE dynamics, is governed by a discretization parameter such as the integration mesh-size. Usually, when explicit integration techniques are used, function and derivative values can be computed exactly for the discretized problems. Recently, we have come across some examples where function and derivative values of the explicitly discretized problems had to be approximated by the outcome of N iterations of a solver. Consequently, the discretization of these problems is controlled by *two* parameters: the mesh-size and the number of iterations of the solver.

Referring to [E. Polak, *Optimization: Algorithms and Consistent Approximations*, Springer-Verlag, 1997], we find a theory for solving optimization problems that require discretization. It deals with two situations. In the first, which is referred to as that of *consistent approximations*, it is assumed that an infinite dimensional optimization problem can be suitably approximated by a family of progressively higher dimensional optimization problems. In this case, strategies, in the form of algorithm models, are presented for "diagonalizing" the solution process. In the second situation, it is assumed that numerical solution of the dynamic equations does not result in a family of finite dimensional consistent approximations (e.g., when implicit integration methods are used). For this case, the theory provides models for the implementation of *conceptual* algorithms. Unfortunately, neither of these situations envisions the possibility of two discretization parameters.

In this paper, we present new algorithm models that can be used with two discretization parameters. The first one controls the mesh-size of an explicit integration scheme, and the second one controls the precision with which functions and gradients associated with a fixed mesh-size are computed. The result can be seen as a framework of *quasi-consistent approximations*.

We implemented these new algorithm models using an approximate steepest descent method for the solution of two problems: a two-point boundary value problem in which the discretized linear ODE dynamics are solved approximately using the Gauss–Seidel method and a distributed control problem in which the discretized dynamics are solved using a domain decomposition algorithm which can be implemented on parallelized computers. Our numerical results show that these new algorithms perform quite well and are fairly insensitive to the selection of user-set parameters. Also, they appear to be superior to some alternative, ad hoc schemes.

1. Introduction.

Many classes of optimization problems, such as semi-infinite optimization problems, continuous optimal control problems with ODE dynamics, and optimal control problems with PDE dynamics, cannot be solved numerically without resorting to a discretization strategy. The simplest but least efficient approach is to discretize the problem with desired precision and to solve the discretized problem using finite dimensional optimization algorithms. It is much more efficient to start out with low discretization precision and to increase the precision progressively as the computation proceeds. Referring to [21], we see that there are essentially two distinct approaches to "dynamic" discretization. The first and oldest is that of *algorithm*

implementation; see, e.g., [1, 3, 4, 5, 7, 8, 9, 10, 11, 12, 19, 18, 23]. In this approach, first one develops a *conceptual* algorithm for the original problem and then a *numerical implementation* of this algorithm. In each iteration, the numerical implementation adjusts the precision with which the function and derivative values used by the conceptual algorithm are approximated so as to ensure convergence to a stationary point of the original problem. When far from a solution, the approximate algorithms perform well at low precision, but, as a solution is approached, the demand for increased precision progressively increases.

The second and more recent approach to dynamic discretization uses sequences of finite dimensional approximating problems. It was formalized in [20, 21] in the form of a theory of consistent approximations. Applications to optimal control are described in [24, 26], and a software package for optimal control, based on consistent approximations, can be obtained from [25]. Within this approach, an infinite dimensional problem, $\mathbf{P}$, such as an optimal control problem with either ODE or PDE dynamics, is replaced by an infinite sequence of "nested," epi-converging finite dimensional problems $\{\mathbf{P}_k\}$. Epi-convergence ensures that the *global* optimal solutions of the approximating problems $\{\mathbf{P}_k\}$ converge to *global* optimal solutions of the infinite dimensional problem $\mathbf{P}$. Problem $\mathbf{P}$ is then solved by a recursive scheme which consists of applying a nonlinear programming algorithm to problem $\mathbf{P}_k$ until a test is satisfied, at which point one proceeds to solve problem $\mathbf{P}_{k+1}$, using the last point obtained for $\mathbf{P}_k$ as the initial point for the new calculation. In [21], we find a number of Algorithm Models for organizing such a calculation. These range from simple schemes that ensure the convergence of the subsequence of points, at which discretization has been increased, to a stationary point, to quite complex schemes that ensure the convergence of the entire sequence, constructed by the master algorithm, to a stationary point, with rate of convergence determined by the nonlinear programming algorithms being used. The advantages of the consistent approximations approach over the algorithm implementation approach are that (i) there is a much richer set of possibilities for constructing precision refinement tests, and hence for devising one that enhances computational efficiency, and (ii) one can use unmodified nonlinear programming code libraries as subroutines; see [24, 25].

In this paper, we deal with a situation that has not been considered before: the case where it is either impossible or uneconomical to compute with high precision the values and gradients of functions appearing in the finite dimensional consistent approximating problems $\mathbf{P}_k$, introduced above. We develop a two-tier algorithm, which, in the first tier, constructs an infinite sequence of epi-converging finite dimensional approximating problems $\{\mathbf{P}_k\}$ and, in the second tier, uses an algorithm implementation strategy in solving each $\mathbf{P}_k$. The main task that we had to address was that of constructing efficient tests for dynamically adjusting *two* precision parameters, k and N, where N determines the precision used in the implementation strategy. The end result can be viewed as a *quasi-consistent approximations* approach. As we will see in section 3, our new algorithm performs considerably better than an ad hoc algorithm implementation scheme on the problems tested.

2. Basic definitions and a motivational example. To make this paper reasonably self-contained, we begin with a definition.

DEFINITION 1. *Let S be a normed space, let $\{S_h\}_{h=\alpha}^{0}$ be a sequence of finite dimensional subspaces of S such that $\cup S_h$ is dense in S, and consider the problems*

$$(\mathbf{P}) \qquad \min_{v \in V} f(v), \tag{1}$$

where V is a subset of S and $f : S \to \mathbb{R}$ is continuous, together with the approximating problems

$$(\mathbf{P}_h) \qquad \min_{v_h \in V_h} f_h(v_h), \tag{2}$$

where V_h is a subset of S_h and $f_h : S_h \to \mathbb{R}$ is continuous.

(a) *We say that the problems $\mathbf{P}_h$* epi-converge[1] *to $\mathbf{P}$ if* (i) *for every $v \in V$, there exists a sequence $\{v_h\}$, with $v_h \in V_h$, such that $v_h \to v$, and $\limsup f_h(v_h) \le f(v)$; and* (ii) *for every infinite sequence $\{v_h\}$, such that $v_h \in V_h$ and $v_h \to v$, $v \in V$, and $\liminf f_h(v_h) \ge f(v)$.*

(b) *We say that upper-semicontinuous, nonpositive-valued functions $\theta_h : V_h \to \mathbb{R}$ ($\theta : V \to \mathbb{R}$) are optimality functions for $\mathbf{P}_h$ ($\mathbf{P}$) if they vanish at local minimizers of $\mathbf{P}_h$ ($\mathbf{P}$).*[2]

(c) *We say that the problem-optimality function pairs $\{\mathbf{P}_h, \theta_h\}$ are* consistent approximations *to the problem-optimality function pair $\{\mathbf{P}, \theta\}$ if the $\mathbf{P}_h$ epi-converge to $\mathbf{P}$, and, for every infinite sequence $\{v_h\}$, such that $v_h \in V_h$ and $v_h \to v \in V$, $\limsup \theta_h(v_h) \le \theta(v)$.*[3]

The reason for introducing optimality functions into the definition of consistency of approximation is that it enables us to ensure that not only *global* optimal solutions of the problems $\mathbf{P}_h$ converge to *global* optimal solutions of $\mathbf{P}$, but also *local* optimal solutions converge to either local solutions or stationary points.

The motivation for this work stems from the fact that, while attempting to solve some optimal control problems with distributed dynamics (see Lions [13]), using the consistent approximations framework, we came across a new difficulty, caused by the fact that even the discretized state equation cannot be solved with adequate precision in reasonable time. In such problems, there are *two* precision parameters to control: the mesh-size h, which defines the approximating problem, and the number of iterations N used by a "solver" in solving the discretized state equations. Since the parameter N seriously impacts the behavior of optimization algorithms as well as the total work needed to solve a problem, it is desirable to control the two precision parameters individually.

For example, consider an optimization problem of the form

$$(\mathbf{P}) \qquad \min_{v \in V} f(v), \tag{3}$$

where $V = L^2(0,1)$,

$$f(v) = J(u(v), v) = \int_0^2 |u(v) - u_d|^2 dx, \tag{4}$$

and $u(v)$ is the solution of an equation of the form

$$Cu = Bv \tag{5}$$

[1]The epigraphs of f_h, restricted to V_h, converge to the epigraph of f, restricted to V, in the Painlevé–Kuratowski sense (see [22]).

[2]When optimality functions are properly constructed, their zeros are standard stationary points; for examples, see [21].

[3]Note that this property ensures that the limit point of a converging sequence of approximate stationary points for the $\mathbf{P}_h$ must be a stationary point for $\mathbf{P}$.

such as

$$-u''(x) = v(x)I_{(0,1)} \quad \forall x \in (0,2), \quad u(0) = u(2) = 0, \tag{6}$$

where u_d is given and I_D is the characteristic function of a set D.

This problem can be approximated by a finite dimensional problem of the form

$$(\mathbf{P}_h) \qquad \min_{v_h \in V_h} f_h(v_h), \tag{7}$$

where V_h is the space of piecewise constant functions defined on a mesh for $(0,1)$, $h > 0$ is the mesh-size,

$$f_h(v_h) = J(u_h(v_h), v_h), \tag{8}$$

and $u_h(v_h)$ is the solution of a discretized equation of the form

$$C_h u_h = B_h v_h, \tag{9}$$

arising from a centered finite difference approximation to (6).

It is not difficult to show that the problems $\mathbf{P}_h$ epi-converge to the problem $\mathbf{P}$ as $h \to 0$, and, if $\{v_h\}$ is a sequence of points such that $v_h \in V_h$, $h \to 0$, and $v_h \to v$ as $h \to 0$, then $\mathrm{grad} f_h(v_h) \to \mathrm{grad} f(v)$ as $h \to 0$. These facts show that the pairs $(\mathbf{P}_h, -\|\mathrm{grad} f_h(\cdot)\|)$ form a family of *consistent approximations* for the pair $(\mathbf{P}, -\|\mathrm{grad} f(\cdot)\|)$. Hence any accumulation point of global optimizers of the problems $\mathbf{P}_h$ is a global optimizer of the problem $\mathbf{P}$, and, if $\{v_h\}$ is a sequence of points such that $v_h \in V_h$, $h \to 0$, $v_h \to v$, and $\mathrm{grad} f_h(v_h) \to 0$, then $\mathrm{grad} f(v) = 0$ also.

The fact that the approximating pairs $(\mathbf{P}_h, -\|\mathrm{grad} f_h(\cdot)\|)$ are a family of consistent approximations for the pair $(\mathbf{P}, -\|\mathrm{grad} f(\cdot)\|)$ lays a basis for the solution of $\mathbf{P}$ by the type of algorithm outlined in section 3.3 of [21]. Unfortunately, for small h, C_h is a large sparse matrix, and it is quite possible that all efficient methods for solving the linear system for $u_h(v_h)$ are iterative, and, realistically, only a reasonable number of iterations of an iterative "solver" can be contemplated. Similar facts apply to the computation of $f_h(v_h)$ and $\mathrm{grad} f_h(v_h)$. Thus let $u_{h,N}(v_h)$ denote the result of N iterations of an iterative "solver" applied to the linear system (9), and let $f_{h,N}(v_h)$ denote the associated approximation to $f_h(v_h)$. Similarly, let $\mathrm{grad}_N f_h(v_h)$ denote the result of N iterations of an iterative "solver" applied to the defining equations for $\mathrm{grad} f_h(v_h)$. For instance, if the Gauss–Seidel relaxation algorithm is used to solve (9), then $u_{h,N}(v_h)$ is the Nth iterate of the recursion

$$L_h u^p = B_h v_h - U_h u^{p-1}, \quad p = 1, \ldots, N, \quad u^0 \text{ given}, \tag{10}$$

where L_h is the lower diagonal part of C_h and U_h its upper part.

Thus we see that, in this case, the "discretized" functions $f_h(v_h)$ are not computable exactly, and, for obvious reasons, neither are their gradients. We will see later that this is also the case when domain decomposition is used to solve discretized PDEs. A quick reference to section 3.3 of [21] shows that the Master Algorithm Models outlined there are not applicable to these cases, because there are no standard nonlinear programming algorithms that use approximate function and gradient values, necessitating the development of a new computational scheme, which we will present in the next section. At this point, we drop the subscript h on the "controls" v_h since it will be clear from the context as to which subspace V_h a control v is in.

3. An algorithm model. We will construct a new algorithm model for solving problems of the form **P** that uses only approximations $f_{h,N}(v)$ and $\mathrm{grad}_N f_h(v)$ to the cost function $f_h(v)$ and its gradient $\mathrm{grad} f_h(v)$ by making use of some existing results in [21]. The relevant results are as follows: First, on page 406 in [21], we find the following Algorithm Model 3.3.17 for solving problems of the form **P**, in (4) above, which uses an iteration function $A_h : V_h \to V_h$, $h \in (0, h^{-1}]$, which can be of the form

$$A_h(v) = v - \lambda(v)\mathrm{grad} f_h(v), \tag{11}$$

where $\lambda(v) > 0$ is a step-size.

Algorithm Model 1: Solves problem **P**.

Parameters. $\omega \in (0,1)$, $\sigma > 0$.

Data. $h^{-1} \in \mathbb{R}_+$, and $v^0 \in V_{h^{-1}}$.

Step 0. Set $i = 0$.

Step 1. Compute the largest h^i, of the form $h^{i-1}/2^k$, $k \in \mathcal{N} := \{0, 1, 2, 3, \ldots\}$, and v^{i+1}, such that $h^i \leq h^{i-1}$ and

$$v^{i+1} = A_{h^i}(v^i), \tag{12}$$

and

$$f_{h^i}(v^{i+1}) \; - \; f_{h^i}(v^i) \leq -\sigma(h^i)^\omega. \tag{13}$$

Step 2. Replace i by $i \; + \; 1$, and go to **Step 1**.

Unfortunately, as we have explained in the preceding section, we may not have explicit formulas for computing $f_h(v)$ and $\mathrm{grad} f_h(v)$, and hence we may be forced to use the limited precision results of N iterations of an iterative solver for computing these quantities. Defining, as before, $u_{h,N}(v)$ to be the result of N iterations of a solver applied to the defining equation (9), we define

$$f_{h,N}(v) := J(u_{h,N}(v), v). \tag{14}$$

As we will see later, $\mathrm{grad} f_h(v)$ is usually determined as a solution of an adjoint equation. Hence $\mathrm{grad}_N f_h(v)$ is defined as the result of N iterations of a solver applied to the adjoint equation. This leads to an approximation $A_{h,N}(v)$ to the ideal iteration map $A_h(v)$. For example, the ideal iteration map $A_h(v)$ defined in (11) has to be replaced by

$$A_{h,N}(v) = v - \lambda \mathrm{grad}_N f_h(v), \tag{15}$$

where the step-size λ is determined either by a modified Armijo rule or by one dimensional minimization.

There are obviously any number of ways of making the parameter N a function of h, or even a function of h and v, which results in a new approximation to the cost function

$$\hat{f}_h(v) := f_{h,N(h,v)}(v) \tag{16}$$

and iteration map

$$\hat{A}_h(v) := A_{h,N(h,v)}(v), \tag{17}$$

which, hopefully, can be used within the structure of Algorithm Model 1. One can classify the rules for making N a function of h (or h and v) as *open-loop* or *closed-loop*.

An example of an open-loop rule is to set $N = \text{int}(1/h)$, the integer part of $1/h$. A closed-loop rule can be made more subtle and can be designed to produce as small a parameter N as is compatible with the convergence of the overall solution scheme in the form of an algorithm model. An example of a closed-loop (feedback) rule can be found in Algorithm Model 1.2.36 in [21].

The integer $N^0 > 0$ and an increment integer $K > 0$ are fixed parameters: given h and v, $N(h, v) := N^0 + kK$, where $k \geq 0$ is the smallest integer such that, for $N = N^0 + kK$,

$$f_{h,N}(A_{h,N}(v)) \; - \; f_{h,N}(v) \leq -\frac{\sigma}{N^\omega}, \tag{18}$$

where σ and ω are as in Algorithm Model 1, say.

Proceeding formally from this point on, we assume that, for every $h > 0$, we can construct an iteration map $A_{h,N} : V_h \to V_h$. In our analysis, we will depend on the following assumption.

ASSUMPTION 1. *We will assume the following:*

(i) *The function $f(\cdot)$ is continuous and bounded from below, and, for all $h \in (0, h_{max}]$, the functions $f_h(\cdot)$ are continuous and bounded from below.*

(ii) *For every bounded set $B \subset V$, there exist $\kappa < \infty$, a function $N^* : \mathbb{R}_+ \to \mathcal{N}$ (the set of positive integers), and functions $\varphi : \mathbb{R}_+ \times \mathcal{N} \to \mathbb{R}_+$, $\Delta : \mathbb{R}_+ \to \mathbb{R}_+$ with the properties*

$$\lim_{h \to 0} N^*(h) = \infty, \tag{19}$$

$$\lim_{N \to \infty} \varphi(h, N) = 0 \quad \forall h > 0, \tag{20}$$

$$\lim_{h \to 0} \varphi(h, N_h) = 0 \quad \forall N_h \geq N^*(h), \tag{21}$$

$$\lim_{h \to 0} \Delta(h) = 0, \tag{22}$$

such that, for all $h \in (0, h_{max}]$, $v \in V_h \cap B$,

$$|f_h(v) - f(v)| \leq \kappa \Delta(h), \tag{23}$$

and, for all $h \in (0, h_{max}]$, $N \in \mathcal{N}$, $v \in V_h \cap B$,

$$|f_{h,N}(v) - f_h(v)| \leq \kappa \varphi(h, N). \tag{24}$$

(iii) *For every $v^* \in V$ such that $\text{grad} f(v^*) \neq 0$, there exist $\rho^* > 0$, $\delta^* > 0$, $h^* > 0$, and $N^{**} < \infty$, such that*

$$f_{h,N}(A_{h,N}(v)) - f_{h,N}(v) \leq -\delta^* \;\; \forall v \in V_h \cap B(v^*, \rho^*), \;\; \forall h \leq h^*, \;\; \forall N \geq N^{**}. \tag{25}$$

Algorithm Model 2: Solves problem **P**.
Parameters. $\omega \in (0, 1)$, $\gamma > 0$, $n, K \in \mathcal{N}$, $N^*(\cdot)$, $\Delta(\cdot)$, $\varphi(\cdot, \cdot)$ verifying (19), (20), (21), (22).
Data. $h^0 \in (0, h_{max}]$, $v^0 \in V_{h^0}$.
Begin Outer Loop
Step 0. Set $i = 0$.
Begin Inner Loop (Computes $\hat{f}_h(v^i)$, $\hat{A}_{h^i}(v^i)$), and $\hat{\Delta}(h^i, v^i)$).
Step 1. Set $N^i = N^*(h^i)$.

Step 2. Compute a point $v^* = A_{h^i,N^i}(v^i)$.
Step 3. If $N^i < nN^*(h^i)$ and

$$f_{h^i,N^i}(v^*) - f_{h^i,N^i}(v^i) > -\varphi(h^i, N^i)^\omega, \tag{26}$$

replace N^i by $N^i + K$ and go to **Step 2.**
Else, set

$$N(h^i, v^i) := N^i, \tag{27}$$

$$\hat{f}_{h^i}(v^i) := f_{h^i,N(h^i,v^i)}(v^i), \tag{28}$$

$$\hat{A}_{h^i}(v^i) := A_{h^i,N(h^i,v^i)}(v^i), \tag{29}$$

and

$$\hat{\Delta}(h^i, v^i) = \Delta(h^i) + \varphi(h^i, N(h^i, v^i)). \tag{30}$$

End Inner Loop
Step 4. If

$$\hat{f}_{h^i}(v^*) - \hat{f}_{h^i}(v^i) > -\gamma\hat{\Delta}(h^i, v^i)^\omega, \tag{31}$$

replace the mesh-size h^i by $h^i/2$ and go to **Step 1**.
Else, set

$$v^{i+1} = \hat{A}_{h^i}(v^i), \tag{32}$$

replace i by $i + 1$, and go to **Step 2**.
End Outer Loop

Remark 1.

1. The main function of the test (26) is to increase N over the initial value of $N = N^*(h^i)$ if that is necessary. It gets reset to $N = N^*(h^i)$ whenever h^i is halved.
2. Note that the faster $\varphi(h, N) \to 0$ as $N \to \infty$, the easier it is to satisfy the test (26) at a particular value of N. Thus, when the solver is fast, the precision parameter N will be increased more slowly than when it is slow. A similar argument applies to the reduction of the mesh-size, h^i, on the basis of the test in (31). In the context of dynamics defined by differential equations, the integration mesh-size will be refined much faster when the Euler method is used for integration than when a Runge–Kutta method is used for integration.
3. Note that the test (31) effectively requires the computation of v^{i+2}. In an efficient implementation, this fact must be taken into account so as to avoid unnecessary duplication of computations.
4. It would be mathematically less elegant, but computationally more efficient, to replace the test (31) by

$$f_{h^i,N^i}(v^*) - \hat{f}_{h^i}(v^i) > -\hat{\Delta}(h^i, v^i)^\omega. \tag{33}$$

The proof of convergence of the resulting algorithm would, if anything, be slightly simpler.

We define the problems

$$(\hat{\mathbf{P}}_h) \qquad \inf_{v \in V_h} \hat{f}_h(v), \tag{34}$$

where $\hat{f}_h(v)$ is defined as in (28) for every $h \in (0, h_{max}]$ and $v \in V_h$.

For every $h > 0$, $N \in \mathcal{N}$, and $v \in V_h \cap B$, let $\mathrm{grad}_N f_h(v)$ denote the approximation to $\mathrm{grad} f_h(v)$ obtained by means of N iterations of a solver, and let $N(h, v)$ be defined by (27), in the Inner Loop of Algorithm Model 2. Finally, let

$$\mathrm{grd}\hat{f}_h(v) := \mathrm{grad}_{N(h,v)} f_h(v). \tag{35}$$

Although the functions $-\|\mathrm{grd}\hat{f}_h(v)\|$ are not the negatives of norms of gradients of the functions $\hat{f}_h(v)$ and hence not optimality functions for the problems $\hat{\mathbf{P}}_h$, it will become clear, under the following assumption, that the pairs $\{\hat{\mathbf{P}}_h, -\|\mathrm{grd}\hat{f}_h)\|\}$ are *pseudo*consistent approximations to $\{\mathbf{P}, -\|\mathrm{grad} f\|\}$, in the sense that the problems $\hat{\mathbf{P}}_h$ epi-converge to $\mathbf{P}$, and, for any sequences $\{h^i\}$, $h^i \to 0$, $\{v^i\}$, $v^i \in V_{h^i}$, $v^i \to v \in V$, $\|\mathrm{grd}\hat{f}_{h^i}(v^i)\| \to \|\mathrm{grad} f(v)\|$. We found this observation helpful in constructing the proof of convergence of Algorithm Model 2.

ASSUMPTION 2. *For every $h > 0$, $N \in \mathcal{N}$, and $v \in V_h \cap B$, let $\mathrm{grad}_N f_h(v)$ denote the approximation to $\mathrm{grad} f_h(v)$ obtained by means of N iterations of a solver. We will assume that, for all $h \in (0, h_{max}]$, $v \in V_h \cap B$,*

$$\|\mathrm{grad} f_h(v) - \mathrm{grad} f(v)\| \leq \kappa \Delta(h), \tag{36}$$

and, for all $h \in (0, h_{max}]$, $N \in \mathcal{N}$, $v \in V_h \cap B$,

$$\|\mathrm{grad}_N f_h(v) - \mathrm{grad} f_h(v)\| \leq \kappa \varphi(h, N), \tag{37}$$

where κ, $\Delta(\cdot)$, and $\varphi(\cdot, \cdot)$ are as in Assumption 1.

In order to establish the fact that the pairs $\{\hat{\mathbf{P}}_h, -\|\mathrm{grd}\hat{f}_h)\|\}$ are pseudoconsistent approximations to $\{\mathbf{P}, -\|\mathrm{grad} f\|\}$ and to establish the convergence of Algorithm Model 2, we need the following result.

LEMMA 2. *Let $h^0 > 0$ be as in the Data of Algorithm Model 2, and, for any $h \in (0, h^0]$ and $v \in V_h$, let $N(h, v)$, $\hat{f}_h(v)$, $\hat{A}_h(v)$, and $\hat{\Delta}(h, v)$ be defined as in the Inner Loop of Algorithm Model 2, i.e., by (27), (28), (29), (30), respectively. Then the following hold.*

(a) *For every bounded set $B \subset V$, $\hat{\Delta}(h, v) \to 0$ as $h \to 0$, uniformly in $v \in B$, and there exists a $\kappa < \infty$, such that, for all $h \in (0, h^0]$, $v \in V_h \cap B$,*

$$|\hat{f}_h(v) - f(v)| \leq \kappa \hat{\Delta}(h, v), \tag{38}$$

and

$$\|\mathrm{grd}\hat{f}_h(v) - \mathrm{grad} f(v)\| \leq \kappa \hat{\Delta}(h, v). \tag{39}$$

(b) *For every $\hat{v} \in V$ such that $\mathrm{grad} f(\hat{v}) \neq 0$, there exist $\hat{\rho} > 0$, $\hat{\delta} > 0$, $\hat{h} \in (0, h^0]$ such that*

$$\hat{f}_h(\hat{A}_h(v)) - \hat{f}_h(v) \leq -\hat{\delta} \quad \forall v \in V_h \cap B(\hat{v}, \hat{\rho}), \quad \forall h \leq \hat{h}, \tag{40}$$

where $\hat{A}_h(v)$ is defined by (29).

Proof. (a) It follows from (23) and (24) that, for all $h \in (0, h_{max}]$, $v \in V_h$, and $N \in \mathcal{N}$,

$$\begin{aligned} |f_{h,N}(v) - f(v)| &\leq |f_{h,N}(v) - f_h(v)| + |f_h(v) - f(v)| \\ &\leq \kappa\varphi(h,N) + \kappa\Delta(h). \end{aligned} \tag{41}$$

Hence we have that

$$|\hat{f}_h(v) - f(v)| = |f_{h,N_h(v)}(v) - f(v)| \leq \kappa(\varphi(h, N(h,v)) + \Delta(h)) \equiv \kappa\hat{\Delta}(h,v). \tag{42}$$

Since

$$\hat{\Delta}(h,v) = \varphi(h, N(h,v)) + \Delta(h) \tag{43}$$

and $N(h,v) \geq N^*(h)$, it follows that $\hat{\Delta}(h,v) \to 0$ as $h \to 0$, uniformly in $v \in V \cap B$.

The fact that (39) holds follows by similar arguments, and hence we omit its proof.

(b) Suppose that $v^* \in V$ is such that $\mathrm{grad} f(v^*) \neq 0$. Then, by Assumption 2 (iii), there exist $\rho^* > 0$, $\delta^* > 0$, $h^* \in (0, h^0]$, and $N^{**} < \infty$ such that (25) holds. Let $\hat{h} \in (0, h^*]$ be such that $N^*(h) \geq N^{**}$ for all $h \in (0, \hat{h}]$. Let $h \in (0, \hat{h}]$ and $v \in V_h \cap B(v^*, \rho^*)$ be arbitrary, and let $v' = \hat{A}_h(v)$. Then, because, for any $v \in V_h$, $N(h,v) \geq N^*(h)$ by construction, it follows from (23), (24), and (25) that

$$\begin{aligned} \hat{f}_h(v') - \hat{f}_h(v) &= f_{h,N(h,v')}(v') - f_{h,N(h,v)}(v) \\ &= [f_{h,N(h,v')}(v') - f_{h,N(h,v)}(v')] + [f_{h,N(h,v)}(v') - f_{h,N(h,v)}(v)] \\ &\leq [f_{h,N(h,v')}(v') - f_{h,N(h,v)}(v')] - \delta^* \\ &= [f_{h,N(h,v')}(v') - f(v')] + [f(v') - f_{h,N(h,v)}(v')] - \delta^* \\ &\leq \kappa[\varphi(h, N(h,v')) + \varphi(h, N(h,v)) + 2\Delta(h)] - \delta^* \\ &\leq -\frac{1}{2}\delta^*, \end{aligned} \tag{44}$$

provided that $h^* > 0$ is taken sufficiently small. This completes our proof. ∎

The following corollary follows directly from Lemma 2(a).

Corollary 3. *Suppose that Assumptions* 1 *and* 2 *are satisfied. Then the problems* $\{\hat{\mathbf{P}}_h\}$ *epi-converge to the problem* $\mathbf{P}$*, and, for any sequences* $\{h^i\}$*,* $h_i \to 0$*,* $\{v^i\}$*,* $v^i \in V_{h^i}$*,* $v^i \to v \in V$*,* $\|\mathrm{grd}\hat{f}_{h^i}(v^i)\| \to \|\mathrm{grad} f(v)\|$*; i.e., the pairs* $\{\hat{\mathbf{P}}_h, -\|\mathrm{grd}\hat{f}_h\|\}$ *are pseudoconsistent approximations to* $\{\mathbf{P}, -\|\mathrm{grad} f\|\}$.

Lemma 4. *Suppose that Assumption* 1 *is satisfied.*

(a) *If* $v^i \in V$ *is such that* $\mathrm{grad} f(v^i) \neq 0$*, then there exists an* $h^i > 0$ *such that* (31) *fails.*

(b) *If Algorithm Model* 2 *constructs an infinite sequence* $\{v^i\}_{i=0}^{\infty}$ *that has at least one accumulation point, then* $h^i \to 0$ *as* $i \to \infty$.

Proof. (a) Suppose that $v^i \in V$ is such that $\mathrm{grad} f(v^i) \neq 0$. Then, by Lemma 2(b), there exists an $\hat{h} > 0$ such that, for all $h \leq \hat{h}$,

$$\hat{f}_h(\hat{A}_h(v^i)) - \hat{f}_h(v^i) \leq -\hat{\delta} \leq -\hat{\Delta}(h, v^i)^{\omega}, \tag{45}$$

which shows that there exists an $h^i > 0$ such that (31) fails.

(b) For the sake of contradiction, suppose that the monotone decreasing sequence $\{h^i\}_{i=0}^{\infty}$ is bounded from below by $b > 0$. Then there exists an i_0 such that $h^i = h^{i_0} = h* > 0$ for all $i \geq i_0$. Hence it follows from the fact that (31) fails, at each $i \geq i_0$, that $\hat{f}_{h*}(v^i) \to -\infty$ as $i \to \infty$. It now follows from (38) that $f(v^i) \to -\infty$ as $i \to \infty$. However, by assumption, there exist an infinite subsequence $\{v^{i_j}\}$ and a $v* \in V_{h*}$, such that $v^{i_j} \to v*$ as $j \to \infty$. Since $f(\cdot)$ is continuous, by assumption, we conclude that $f(v^{i_j}) \to f(v*)$ as $j \to \infty$, which is a contradiction and completes our proof. ∎

THEOREM 5. *Suppose that Assumption* 1 *is satisfied.*

(a) *If* $\{v^i\}_{i=0}^{\infty}$ *is a sequence constructed by Algorithm Model* 2 *in solving the problem* $\mathbf{P}$*, then every accumulation point* $v*$ *of* $\{v^i\}_{i=0}^{\infty}$ *satisfies* $\mathrm{grad} f(v*) = 0$.

(b) *If* $f(\cdot)$ *is strictly convex, with bounded level sets, and* $\{v^i\}_{i=0}^{\infty}$ *is a sequence constructed by Algorithm Model* 2 *in solving the problem* $\mathbf{P}$*, then* $\{v^i\}_{i=0}^{\infty}$ *converges to the unique solution of* $\mathbf{P}$.

Proof. (a) Suppose that $\{v^i\}_{i=0}^{\infty}$ is a sequence constructed by Algorithm Model 2 and that $\{v^{i_j}\}_{j=0}^{\infty}$ is a subsequence converging to a point $\hat{v}$ and that $\mathrm{grad} f(\hat{v}) \neq 0$. ∎

Now, by Lemma 4, $h^i \to 0$ as $i \to \infty$, and, by Lemma 2(b), there exist $\hat{\rho} > 0$, $\hat{\delta} > 0$, $\hat{h} > 0$, such that

$$\hat{f}_{h^i}(\hat{A}_h(v^i)) - \hat{f}_{h^i}(v^i) \leq -\hat{\delta} \quad \forall v^i \in B(\hat{v}, \hat{\rho}), \quad \forall h^i \leq \hat{h}. \tag{46}$$

Let i_0 be such that, for all $i_j \geq i_0$, $v^{i_j} \in B(\hat{v}, \hat{\rho})$, and

$$2\kappa\hat{\Delta}(h^{i_j}, v^{i_j}) \leq \frac{1}{2}\hat{\delta}, \tag{47}$$

$$2\kappa\hat{\Delta}(h^{i_j}, v^{i_j})^{1-\omega} \leq \gamma. \tag{48}$$

Finally, let $i_1 \geq i_0$ be such that $h^i \leq \hat{h}$ for all $i \geq i_1$. Then, for the subsequence $\{v^{i_j}\}_{j=0}^{\infty}$, with $i_j \geq i_1$,

$$f(v^{i_j+1}) - f(v^{i_j}) \leq -\hat{\delta} + 2\kappa\hat{\Delta}(h^{i_j}, v^{i_j}) \leq -\frac{1}{2}\hat{\delta}, \tag{49}$$

and, in addition, in view of Lemma 2 and the test (31), for all $i \geq i_1$,

$$\begin{aligned} f(v^{i+1}) - f(v^i) &\leq 2\kappa\hat{\Delta}(h^i, v^i) - \gamma\hat{\Delta}(h^i, v^i)^{\omega} \\ &= -\hat{\Delta}(h^i, v^i)^{\omega}[\gamma - 2\kappa\hat{\Delta}(h^i, v^i)^{1-\omega}] \leq 0. \end{aligned} \tag{50}$$

Hence we see that the sequence $\{f(v^i)\}_{i=i_1}^{\infty}$ is monotone decreasing, and, therefore, because $f(\cdot)$ is continuous, it must converge to $f(\hat{v})$. Since this is contradicted by (48), our proof is complete.

(b) Since a strictly convex function, with bounded level sets, has exactly one stationary point, the desired result follows from (a) and the fact that $\{f(v^i)\}_{i=i_1}^{\infty}$ is monotone decreasing.

Remark 2. The following Algorithm Model differs from Algorithm Model 2 in two respects: first, the integer N is never reset and hence increases monotonically, and second, the test for reducing h is based on the magnitude of the norm of the approximate cost-gradient. As a result, the proof of its convergence is substantially simpler than that for Algorithm Model 2. However, convergence can be established only for the diagonal subsequence $\{v^{i_j}\}_j$ at which h is halved.

Algorithm Model 3: Solves problem **P**.
Parameters. $\omega \in (0,1)$, $\epsilon^0 > 0$, $K \in \mathcal{N}$, $N^*(\cdot)$, $\varphi(\cdot,\cdot)$ verifying (19), (20), (21).
Data. $h^0 > 0$, $v^0 \in V_{h^0}$.
Begin Outer Loop
Step 0. Set $i = 0$, $j = 0$, $N^0 = N^*(h^0)$.
Begin Inner Loop
Step 1. Compute a point $v^* = A_{h^i,N^i}(v^i)$.
Step 2. If

$$f_{h^i,N^i}(v^*) - f_{h^i,N^i}(v^i) > -\varphi(h^i,N^i)^\omega, \tag{51}$$

replace N^i by $N^i + K$, and go to **Step 1**.
Else, set $v^{i+1} = v^*$, and go to **Step 3**.
End Inner Loop
Step 3. If

$$\|\mathrm{grad}_{N^i} f_{h^i}(v^{i+1})\| \le \epsilon^i \text{ and } N^i \ge N^*(h^i), \tag{52}$$

set $v_*^{j+1} = v^{i+1}$, $N_*^{j+1} = N^i$, $h_*^{j+1} = h^i$, replace j by $j+1$, h^i by $h^i/2$, ϵ^i by $\epsilon^i/2$, i by $i+1$, and go to **Step 1**.
Else, replace i by $i+1$, and go to **Step 1**.
End Outer Loop

THEOREM 6. *Suppose that Assumptions* 1 *and* 2 *are satisfied and that* $\{v_*^j\}$ *is a sequence constructed by Algorithm Model* 3 *in solving the problem* **P**.

(a) *If* $\{v_*^j\}$ *is finite, then the sequence* $\{v^i\}_{i=0}^\infty$ *has no accumulation points.*

(b) *If* $\{v_*^j\}$ *is infinite, then every accumulation point* $v*$ *of* $\{v_*^j\}_{j=0}^\infty$ *satisfies* $\mathrm{grad} f(v*) = 0$.

(c) *If* $f(\cdot)$ *is strictly convex, with bounded level sets, and* $\{v_*^j\}_{j=0}^\infty$ *is a bounded sequence constructed by Algorithm Model* 3 *in solving the problem* **P**, *then it converges to the unique solution of* **P**.

Proof. (a) Suppose that the sequence $\{v_*^j\}$ is finite and that the sequence $\{v^i\}_{i=0}^\infty$ has an accumulation point $v*$. Then there exist an i_0, an $h* > 0$, and an $\epsilon* > 0$, such that, for all $i \ge i_0$, $h^i = h*$, $\epsilon^i = \epsilon*$, and $\|\mathrm{grad}_{N^i} f_{h^i}(v^i)\| > \epsilon*$. But, in this case, for $i \ge i_0$, the Inner Loop of Algorithm Model 2 is recognized as being of the form of Master Algorithm Model 1.2.36 in [21]. It now follows from Theorem 1.2.37 in [21] that $N^i \to \infty$ as $i \to \infty$ and that $\mathrm{grad} f_{h*}(v*) = 0$. It now follows from (20) in Assumption 1 and from Assumption 2 that, for some infinite subsequence $\{v^{i_j}\}$, $\mathrm{grad}_{N^{i_j}} f_{h*}(v^{i_j}) \to \mathrm{grad} f_{h*}(v*) = 0$, which shows that (52) cannot be violated an infinite number of times, which is a contradiction.

(b) When the sequence $\{v_*^j\}$ is infinite, it follows directly from Assumptions 1 and 2 and the test (52) that, if $v*$ is an accumulation point of $\{v_*^j\}$, then $\mathrm{grad} f(v*) = 0$.

(c) When the function $f(\cdot)$ is strictly convex, with bounded level sets, it has a unique minimizer $v*$, which is the only point in V satisfying $\mathrm{grad} f(v*) = 0$. Hence the desired result follows from (b). ∎

4. A two-point boundary value control problem. Consider again the two-point boundary value control problem first stated in section 2:

$$(\mathbf{P_1}) \qquad \left| \begin{array}{l} \min\limits_{v \in L^2(0,1)} f(v) := J(u(v)) := \displaystyle\int_0^2 |u - u_d|^2 dx \quad \text{subject to} \\ \qquad\qquad -u''(x) = v(x) I_{(0,1)} \quad \forall x \in (0,2), \quad u(0) = u(2) = 0. \end{array} \right. \tag{53}$$

The gradient of $f(\cdot)$ with respect to v can be expressed in terms of p, the solution of the adjoint equation

$$-p'' = 2(u - u_d), \quad p(0) = p(2) = 0. \tag{54}$$

Thus

$$\delta f = 2\int_0^2 (u - u_d)\delta u = -\int_0^2 p''\delta u = -\int_0^2 p\delta u'' = \int_0^1 p\delta v, \tag{55}$$

which shows that $\mathrm{grad} f(v) = p$ on (0,1).

To approximate the problem $\mathbf{P}_1$, we use a finite difference method with uniform mesh of size $h = 1/M$ to solve the differential equation (54). This results in the approximating problems

$$(\mathbf{P}_{1h}) \quad \left| \begin{array}{c} \min_{v\in V_h} f_h(v) := \sum_1^{2M-1} |u_j - u_d(jh)|^2 \quad \text{subject to} \\ -\frac{1}{h^2}(u_{j+1} - 2u_j + u_{j-1}) = v_j I_{j\le M}, \quad j = 1,\dots,2M-1, \\ u_0 = u_{2M} = 0, \end{array} \right. \tag{56}$$

where V_h is the set of piecewise constant functions on the intervals $(jh,(j+1)h]$, $j = 1,\dots,M$. Note that the coefficients u_j define a piecewise constant function $u(\cdot)$ on $[0,2]$.

As in the continuous case

$$\delta f = \sum_1^{2M-1} 2(u_j - u_d(jh))\delta u_j \tag{57}$$

and if

$$-\frac{p_{j+1} - 2p_j + p_{j-1}}{h^2} = 2(u_j - u_d(jh)), \quad j = 1,\dots,2M-1, \quad p_0 = p_{2M} = 0, \tag{58}$$

then

$$\begin{aligned} \sum_1^{2M-1} 2(u_j - u_d(jh))\delta u_j &= -\sum_1^{2M-1} \frac{p_{j+1} - 2p_j + p_{j-1}}{h^2}\delta u_j \\ &= -\sum_1^{2M-1} \frac{\delta u_{j+1} - 2\delta u_j + \delta u_{j-1}}{h^2} p_j. \end{aligned} \tag{59}$$

Therefore,

$$\delta f = \sum_1^M p_j \delta v_j, \tag{60}$$

and hence the gradient $\mathrm{grad} f_h(v)$ is the piecewise constant function $p_h(\cdot)$, on $(h, 1+h]$, defined by the coefficients $p_0, p_1, \dots, p_M$.

To illustrate the theory, the difference equations in (56), (58) will be solved by the Gauss–Seidel method, and the optimization problem will be solved by the method of steepest descent.

4.1. Verification of the hypotheses. Algorithm Model 2 depends on Assumption 1 to be satisfied and, in particular, on the existence of three appropriate functions $\varphi(h, N)$, $N^*(h)$, and $\Delta(h)$ and of an appropriate iteration map $A_{h,N}(\cdot)$.

We begin by showing that parts (i) and (ii) of Assumption 1 are satisfied. When the ODE for u is multiplied by u and integrated in x, we obtain, after integrating by parts, that

$$-\int_0^2 (uu'') = \int_0^1 uv = \int_0^2 (u'^2). \tag{61}$$

Applying the Schwarz inequality to the middle integral leads to $\|u'\|_0 \leq \|v\|_0$. It follows from the Poincaré inequality that $\|u\|_0 \leq C\|u'\|_0$ for some $C < \infty$. Hence we conclude that u is continuous with respect to v in L^2:

$$\|u\|_0 \leq C\|v\|_0. \tag{62}$$

Now the function $u \to J(u)$ is obviously continuous in u, and hence $f(\cdot)$ is continuous in v.

Using similar arguments, we find that p is continuous in v, and hence $\operatorname{grad} f(\cdot)$ exists and is continuous.

For the discrete problem, we note that $(u_1, u_2, \ldots, u_{2M-1})^T$ is the solution of a linear system with right-hand side $(v_1, \ldots, v_M, 0.., 0)^T$, and the matrix of the linear system is tridiagonal with $2/h^2$ on the main diagonal and $-1/h^2$ on the diagonals below and above the main one. This is a positive definite matrix, and hence u is continuous with respect to v. Similarly, p is continuous with respect to u and with respect to v by transitivity.

Next, it follows from the error analysis for the finite difference scheme that, for some $C < \infty$,

$$\|u_h - u\|_0 < Ch^2, \quad |J_h(u, v) - J(u, v)| < Ch^2, \tag{63}$$

which implies that

$$|f_h(v_h) - f(v)| < Ch^2. \tag{64}$$

Now the Gauss–Seidel algorithm is linearly convergent, but the constant of convergence is proportional to the condition number of the linear system. In particular, for some $C, c < \infty$,

$$\|u_{h,N} - u_h\| \leq C(1 - ch^2)^N \quad \forall N \in \mathcal{N}. \tag{65}$$

By inspection, a bound function φ is $\varphi(h, N) = C'(1 - ch^2)^N$ with any $C' \geq C$. However, it contains an unknown constant. We have the choice of either guessing this constant or replacing the function φ with a conservative estimate, such as $\varphi(h, N) = (1 - h^{2+\epsilon})^N$, with $\epsilon < 1$, small; i.e., we replace c with h^ϵ. In either event, and to satisfy the hypothesis, we may take

$$N^*(h) = \frac{C}{h^{2+2\epsilon}}, \tag{66}$$

with C a generic constant. Indeed,

$$(1 - h^{2+\epsilon})^{\frac{C}{h^{2+2\epsilon}}} = \exp \frac{C \log(1 - h^{2+\epsilon})}{h^{2+2\epsilon}} \approx e^{-\frac{C}{h^\epsilon}} \to 0 \text{ as } h \to 0. \tag{67}$$

We have thus shown that parts (i) and (ii) of Assumption 1 are satisfied.

To conclude, we must show that part (iii) of Assumption 1 is satisfied. We will derive the iteration map $A_{h,N}(\cdot)$ from the standard steepest descent algorithm with exact step-size. We recall that, for the problems $\mathbf{P}_{1h}$, this algorithm is defined by the following iteration function:

$$A_h(v) := v - \lambda(v)\text{grad}f_h(v), \tag{68}$$

where

$$\lambda(v) := \arg\min_{\lambda} f_h(v - \lambda\text{grad}f_h(v)). \tag{69}$$

Note that, for our problem, $\lambda(v)$ can be computed exactly because $f_h(v-\lambda\text{grad}f_h(v))$ is a quadratic function of λ.

Next, we define $A_{h,N}$ as follows:

$$A_{h,N}(v) := v - \lambda_N(v)\text{grad}_N f_h(v), \tag{70}$$

with

$$\lambda_N(v) := \arg\min_{\lambda} f_{h,N}(v - \lambda\text{grad}_N f_h(v)), \tag{71}$$

where $f_{h,N}(v)$ and $\text{grad}_N f_h(v)$ are computed using N iterations of the Gauss–Seidel algorithm on the difference equation in (56) and the adjoint equation (58), respectively.

Now, it follows from the properties of the method of steepest descent that, given any $v^* \in V = L^2(0,1)$ such that $\text{grad}f(v^*) \neq 0$, there exist $\rho^* > 0$, $\delta^* > 0$, λ^*, and $h^* > 0$, such that, for all $v \in V \cap B(v^*, \rho)$, (i) $\text{grad}f_h(v) \neq 0$ and (ii)

$$f(v - \lambda(v)\text{grad}f(v)) - f(v) \leq f(v - \lambda^*\text{grad}f(v)) - f(v) \leq -\delta^*, \tag{72}$$

where $\lambda(v)$ is the exact step-size computed by the Steepest Descent Algorithm. It now follows from (20), (21), (23), (24) that there exist an $h^* > 0$ and an $N^{**} < \infty$, such that, for all $h \leq h^*$, $N \geq N^{**}$, and $v \in V_h \cap B(v^*, \rho)$,

$$\begin{aligned} f_{h,N}(v - \lambda_N(v)\text{grad}_N f_h(v)) - f_{h,N}(v) &\leq f_{h,N}(v - \lambda(v)\text{grad}_N f_h(v)) \\ &\quad - f_{h,N}(v) \leq -\delta^*/2, \end{aligned} \tag{73}$$

which shows that part (iii) of Assumption 1 is satisfied.

4.2. Implementation of Algorithm Model 2. For any positive real number α, we define $\texttt{ceil}[\alpha]$ to be the smallest integer larger than α. Then, making use of the maps defined in the preceding subsection, we now obtain from Algorithm Model 2 the following.

Algorithm 1.

Data. $C_1 > 0$, $C_2 > 0$, $C_3 > 0$, $\epsilon > 0$, $h > 0$, $K \in \mathcal{N}$, $v_0 \in V_h$.

Step 0. Set $i = 0$.

Step 1. Set $M = 1/h$, $N = \texttt{ceil}(\frac{C_1}{h^{2+2\epsilon}})$.

Step 2. Compute $\{u_j^i\}$ using N Gauss–Seidel iterations.

Step 3. Compute $\{p_j^i\}$ using N Gauss–Seidel iterations.

Step 4. Compute $\lambda^i = \text{argmin}_\lambda f_{h,N}(v^i - \lambda p^i)$ using N Gauss–Seidel iterations.

Step 5. Set $v_j^{i+1} = v_j^i - \lambda^i p_j^i, \quad j = 1, \ldots, M.$

Step 6. **If** $f_{h,N}(v^{i+1}) - f_{h,N}(v^i) > -C_2(1 - C_4h^{2+\epsilon})^N$, replace N by $N+K$, and go to **Step 2**.
Else, go to **Step 7**.

Step 7. **If** $f_{h,N}(v^{i+1}) - f_{h,N}(v^i) > -C_3[h^2 + (1 - C_4h^{2+\epsilon})^N]$, replace h by $h/2$, and go to **Step 1**.
Else, replace i by $i+1$, and go to **Step 2**.

PROPOSITION 7. *There exists C^* such that, if $C_2 \geq C^*, C_3 \leq C^*$, and $\{v^i\}$ is a sequence of piecewise constant functions constructed by Algorithm* 1*, then $\{v^i\}$ converges to the solution of $\mathbf{P}_1$ as $i \to \infty$.*

Proof. This is Algorithm Model 2 with N^*,φ, and Δ multiplied by constants, and so, if the last two are smaller than the theoretical constants in (64), (65), then the method converges in the sense that any accumulation point satisfies the optimality conditions of the problem. Since the control problem is linear-quadratic, any solution of the optimality conditions is the solution of the problem. ∎

4.3. Numerical results. Problem (53) was solved with $u_d = \sin(\pi x)$ starting from $v = 0$, first using the standard steepest descent method, with a fixed mesh of 256 points, and solving the linear system using 500 Gauss–Seidel iterations. Then it was solved using Algorithm 1 (see Figures 1 and 2).

In the second case, the initial mesh had 8 points, and the final mesh had 512. The algorithm constants were

$$C_1 = 1, \quad C_2 = 0.1, \quad C_3 = 2\ 10^{-4}, \quad C_4 = 5, \quad \epsilon = 0.1, \quad K = 20.$$

These constants were chosen using trial and error to obtain good efficiency, but, as shown in Figure 3, the results are not very sensitive to these choices as long as the order of magnitude is right.

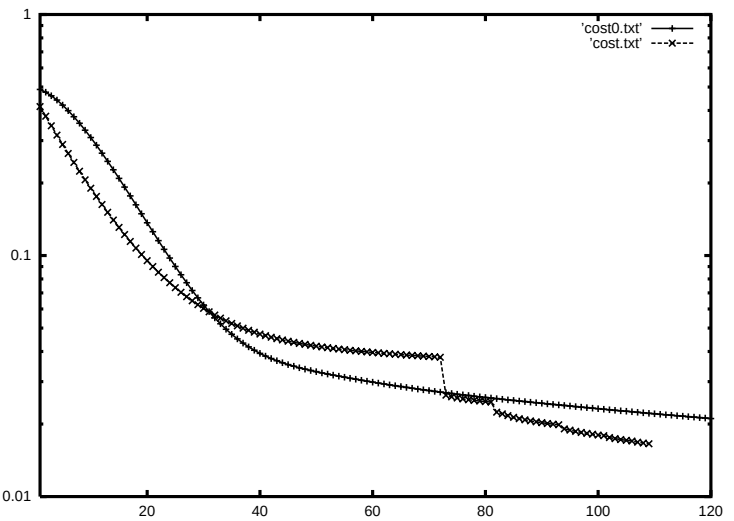

FIG. 1. *Cost function versus iteration number with and without mesh adaptation for problem P_1. The smooth curve (–+–) corresponds to standard steepest descent on the finest mesh with* 500 *Gauss–Seidel iterations for the linear systems. The broken curve (–×–) shows cost function decrease with Algorithm* 1*. Although the two curves are similar, there is an order of magnitude decrease in computing time using Algorithm* 1*.*

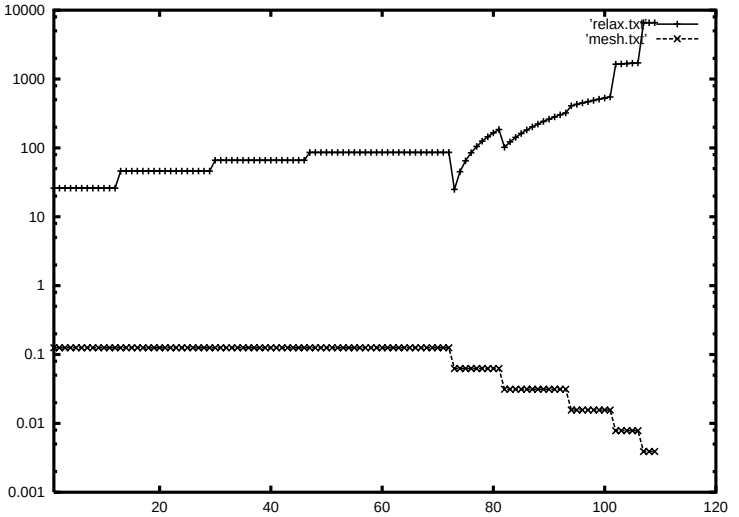

FIG. 2. *Mesh-size and number of Gauss–Seidel iterations versus iteration number for problem* P_1 *solved using Algorithm* 1. *The top curve is the history of Gauss–Seidel iterations count, and the lower one is the history of the mesh-size.*

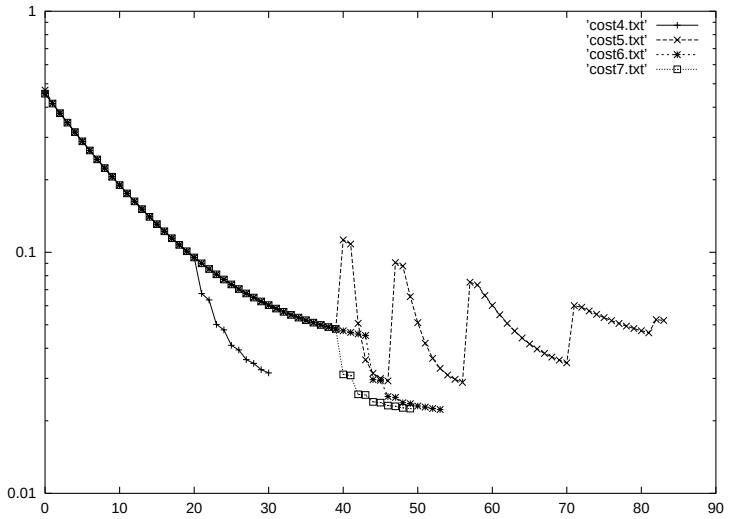

FIG. 3. *Cost function for other values of* C_i. *The behavior of Algorithm* 1 *on problem* P_1 *is shown for different values of the implementation constants:* C_1 *divided by* 10 ($-+-$), C_2 *divided by* 10 ($-\times-$), C_3 *divided by* 10 ($-*-$), *and* C_4 *divided by* 10 ($-\diamond-$).

Figure 1 shows the convergence history of the cost function for both tests. Figure 2 shows the history of the number of Gauss–Seidel iterations for the second case.

Figure 3 shows the behavior resulting from replacing each constant C_i by $C_i/10$, $i = 1, 2, 3, 4$ (one at a time).

In Figure 4, Algorithm 1 is compared with three other methods:

- *Implementation of steepest descent.* Use any approximation of the continuous gradient combined with a mesh refinement/Gauss–Seidel iteration increase based on when the approximate gradient is no longer an approximate feasible descent direction; for instance,

  (74)
  $$\text{if } f_{h,N}(v^{i+1}) - f_{h,N}(v^i) > -\varepsilon, \text{ then replace } (N, h, \varepsilon) \text{ by } (2N, h/2, \varepsilon/2).$$

  However, in Figure 4, we see that such a strategy is too crude, especially because the relationship between the change of h and N is linear.
- *Open-loop mesh refinement*: In Algorithm 1, we replace Step 7 with the rule that the mesh should be refined every 20 steps.
- *Implementation of Algorithm Model* 3: Finally, we compare Algorithm 1 with Algorithm Model 3, where mesh refinement is based on the norm of the gradient rather than on cost function decrease.

We have also tested a number of other parameter values and other functions $N^*(h, v)$, $\varphi(h, N)$ in Algorithm 1. Most of the time, similar computational behavior to that described here was obtained. However, sometimes the mesh was refined too quickly, and sometimes the number of Gauss–Seidel iterations became too large too soon, etc.

It is clear that the common strategy of simply discretizing a problem is easily modified to conform to Algorithm Model 2 or 3. The computing time will always be smaller when dynamic precision adjustment is used, and, for reasonable values of

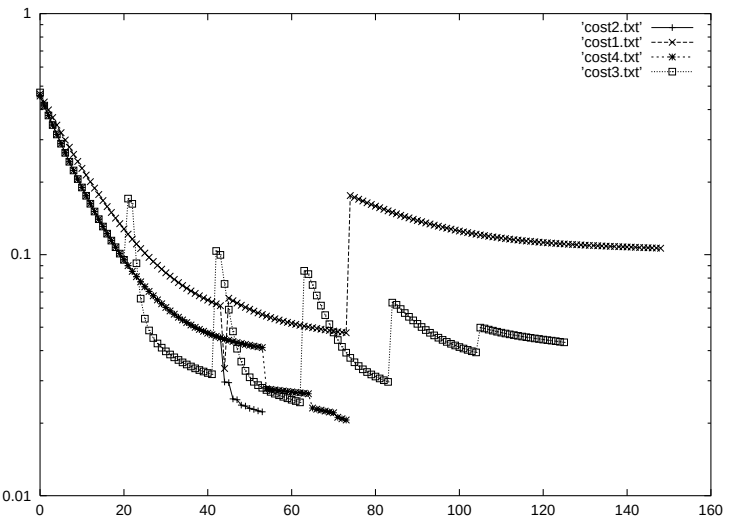

FIG. 4. *Comparison with other methods. Algorithm* 1 (−+−) *is compared to three other methods:* (i) *Implementation of Algorithm Model* 3 (−∗−), (ii) *Heuristic precision refinement* (75) (−×−), (iii) *Algorithm* 1 *with the test on mesh refinement replaced by a division by two every* 20 *iterations* (−◇−).

algorithm parameters, the computing time will be of an order of magnitude smaller than in the case where dynamic precision adjustment is not used.

5. A distributed control problem. Let S be a given subset of the boundary Γ of an open bounded subset Ω of $\mathbb{R}^d$; let ξ be a given function on S (added to this academic problem only to make it nontrivial (see (81), (91))), and consider the boundary control problem

$$(\mathbf{P}_2) \qquad \left| \begin{array}{l} \min\limits_{v\in L^2(S)} f(v) = \dfrac{1}{2}\displaystyle\int_\Omega [(u-u_d)^2 + |\nabla(u-u_d)|^2] \quad \text{subject to} \\ \qquad u - \Delta u = 0 \text{ in } \Omega, \quad \dfrac{\partial u}{\partial n}|_S = \xi v, \quad u_{\Gamma - S} = u_d. \end{array} \right. \tag{75}$$

The gradient of $f(\cdot)$ can be obtained by making use of the fact that

$$\delta f = \int_\Omega ((u-u_d)\delta u + \nabla(u-u_d)\cdot\nabla\delta u) + o(|v|) = \int_S \xi(u-u_d)\delta v, \tag{76}$$

which follows from the fact that the PDE in variational form is: find $u \in H^1(\Omega)$, the Sobolev space of order 1, such that $u - u_d \in H^1_{0_{\Gamma-S}}(\Omega) := \{u \in H^1(\Omega) \ : \ v|_{\Gamma-S} = 0\}$ and

$$\int_\Omega (uw + \nabla u\cdot\nabla w) = \int_S \xi v w \quad \forall w \in H^1_{0_{\Gamma-S}}(\Omega). \tag{77}$$

So, by inspection of (76), we see that the gradient of $f(\cdot)$ with respect to the $L^2(S)$ norm is

$$\operatorname{grad}_v f(v) = \xi(u-u_d)|_S. \tag{78}$$

To approximate the problem (75), we used a finite element method with $u \in V_h$, continuous, and piecewise linear on the triangles of a triangulation of Ω. This results in the discretized, finite dimensional optimization problem

$$(\mathbf{P}_{2h}) \qquad \left| \begin{array}{l} \min\limits_{v\in V_h} f_h(v) = \dfrac{1}{2}\displaystyle\int_\Omega [(u-u_{dh})^2 + |\nabla(u-u_{dh})|^2] \quad \text{subject to} \\ \qquad \displaystyle\int_\Omega (uw + \nabla u\cdot\nabla w) = \int_S \xi v w \quad \forall w \in V_h^0, \end{array} \right. \tag{79}$$

where V_h^0 is the approximation of $H^1_{0_{\Gamma-S}}(\Omega)$ consisting of continuous piecewise linear functions on the triangulation, which are zero on $\Gamma - S$.

The gradient of the discrete cost function $f_h(\cdot)$ can be obtained exactly as in the continuous case

$$\delta f_h = \int_S \xi(u-u_{dh})\delta v. \tag{80}$$

Therefore,

$$\operatorname{grad}_v f_h(v) = \mathcal{P}_h(\xi(u-u_{dh}))|_S, \tag{81}$$

where $\mathcal{P}_h$ is the projection operator from $L^2(S)$ into $V_h \cap L^2(S)$.

Strictly speaking, (81) holds only if Ω is a polygonal domain, but this is a standard technical problem with the finite element method which can be dealt with easily.

5.1. The Schwarz algorithm. Now, for some reason (parallel computing, for instance), suppose that we want to solve the discrete PDE (i.e., its equivalent sparse linear system) by a domain decomposition method (see [14, 15, 16, 17]).

Let $\Omega = \Omega_1 \cup \Omega_2$ with $\Omega_1 \cap \Omega_2 \neq \emptyset$; let $\Gamma = \partial\Omega$, and let $\Gamma_{ij} = \partial\Omega_i \cap \Omega_j$. To compute u, the solution of

$$u - \Delta u = f \text{ in } \Omega, \quad u|_{\Gamma - S} = u_\Gamma, \quad \frac{\partial u}{\partial n}|_S = \xi v, \tag{82}$$

the multiplicative Schwarz algorithm starts from a guess u_1^0, u_2^0 and computes $u_j = u|_{\Omega_j}$ as the limit when $n \to \infty$, of the sequence $u_j^n, j = 1, 2$, defined by

$$\left.\begin{aligned} & u_1^n - \Delta u_1^n = f \text{ in } \Omega_1, \\ & u_1^n|_{\Gamma \cap \bar{\Omega}_1 - S} = u_\Gamma, \quad u_1^n|_{\Gamma_{12}} = u_2^{n-1}, \quad \frac{\partial u_1^n}{\partial n}|_{S \cap \bar{\Omega}_1} = \xi v, \\ & u_2^n - \Delta u_2^n = f \text{ in } \Omega_2, \\ & u_2^n|_{\Gamma \cap \bar{\Omega}_2 - S} = u_\Gamma, \quad u_2^n|_{\Gamma_{21}} = u_1^{n-1}, \quad \frac{\partial u_2^n}{\partial n}|_{S \cap \bar{\Omega}_2} = \xi v, \end{aligned}\right\} \tag{83}$$

and

$$u^n = u_1^n \text{ on } \Omega_1 \cap \Omega_2^c,\ u^n = u_2^n \text{ on } \Omega_2 \cap \Omega_1^c,\ u^n = \frac{1}{2}(u_1^n + u_2^n) \text{ on } \Omega_1 \cap \Omega_2. \tag{84}$$

5.2. The doubly discretized problem. The introduction of the Schwarz algorithm leads to a doubly discretized problem, as follows. Let $\mathcal{T}_h$ be a triangulation of Ω of average edge size h such that, by removing triangles, we also obtain proper triangulations $\{\mathcal{T}_{jh}\}_{j=1,2}$ of Ω_1 and Ω_2.

Let V_{1h} and V_{2h} be the finite element spaces of continuous piecewise affine functions on $\{\mathcal{T}_{jh}\}_{j=1,2}$. Let V_{jh}^0 be the subspaces of continuous piecewise linear functions which are zero on the Dirichlet boundaries Γ_{ij}, $j = 1, 2$.

Then the doubly discretized problem is

(85)

$$(\mathbf{P}_{2h,N}) \left| \begin{array}{c} \min_{v \in V_h} f_{h,N}(v) = \|u^N - u_d\|_\Omega^2 : \quad u_j^0 = 0, \quad n = 1, \ldots, N, \\ u_j^n \in V_{jh} \ : \ u_j^n|_{\Gamma_{ij}} = u_i^{n-1}, \quad \displaystyle\int_{\Omega_j} [u_j^n w + \nabla u_j^n \nabla w] = \int_S \xi v w \quad \forall w \in V_{jh}^0, \\ j = 1, 2, \quad i = (j+1) \bmod 2, \\ u^N = u_1^N \text{ on } \Omega_1 \cap \Omega_2^c,\ u^N = u_2^N \text{ on } \Omega_2 \cap \Omega_1^c,\ u^N = \dfrac{1}{2}(u_1^N + u_2^N) \text{ on } \Omega_1 \cap \Omega_2. \end{array} \right.$$

So N is the number of Schwarz iterations applied to the discretized PDE in (79).

Consider the mapping from $V_{1h} \times V_{2h}$ onto itself which defines u^n from u^{n-1} by (84) and

$$\int_{\Omega_j} [u_j^n w + \nabla u_j^n \nabla w] = \int_S \xi v w \ \ \forall w \in V_{jh}^0, \quad u_j^n \in V_{jh}, \ \ u_j^n|_{\partial\Omega_{ij}} = u_i^{n-1}, \tag{86}$$

for $j = 1, 2$, $i = j \bmod 2$, $n = 1, \ldots, N$. Let $\{A, B, C\}$ be the finite element matrices associated with this operation. In matrix form, (86) is

$$AU^n = BU^{n-1} + CV, \tag{87}$$

where U denotes the vector of values of u_1 at the vertices of $\mathcal{T}_{1h}$ and of u_2 at the vertices of $\mathcal{T}_{2h}$, and V is the vector of values of v at the vertices of S.

For simplicity, we choose $U^0 = 0$. The doubly discretized problem (85) can now be rewritten as

(88)
$$\min_v \left\{ (U^N - U_d)^T G (U^N - U_d) : \begin{pmatrix} A & 0 & 0 & ... & 0 & 0 \\ -B & A & 0 & ... & 0 & 0 \\ 0 & -B & A & .. & 0 & 0. \\ ... & & & & & ... \\ ... & & & & -B & A \end{pmatrix} \begin{pmatrix} U^1 \\ U^2 \\ U^3 \\ ... \\ U^N \end{pmatrix} = \begin{pmatrix} CV \\ CV \\ CV \\ CV \\ CV \end{pmatrix} \right\},$$

where G is the finite element mass matrix (see Ciarlet [6] for more details).

We can express the exact gradient $\operatorname{grad} f_{h,N}(v)$ of $f_{h,N}(v)$ in terms of the solution of the adjoint equation

(89)
$$\begin{pmatrix} A & -B^T & 0 & ... & 0 & 0 \\ 0 & A & -B^T & ... & 0 & 0 \\ 0 & 0 & A & .. & 0 & 0. \\ ... & & & & ... & -B^T \\ ... & & & & 0 & A \end{pmatrix} \begin{pmatrix} P^1 \\ P^2 \\ P^3 \\ ... \\ P^N \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 2G(U^N - U_d) \end{pmatrix}$$

by making use of the fact that $\delta f_{h,N} = \left(\sum_1^N P^n\right)^T C \delta V$. Thus we see that $\operatorname{grad} f_{h,N}(v) = C^T \sum_1^N P^n$.

The interpretation is that P, like U, is the set of values at vertices of the Schwarz system

$$p^N - \Delta p^N = 2(u^N - u_d), \quad p^{N-1} - \Delta p^{N-1} = 0, \quad p^{N-1}_{\Gamma_{ij}} = p^N. \tag{90}$$

These equations are difficult to implement because, in principle, we must store all intermediate functions generated by the Schwarz algorithm and integrate the system for p^n in reverse order, although here it is not necessary because the problem is linear. Hence we will use approximations to the gradients $\operatorname{grad} f_{h,N}(v)$ defined by

$$\operatorname{grad}_N f_h(v) := \Pi_h(\xi(u_{h,N}(v) - u_d))|_S, \tag{91}$$

where Π_h is the interpolation operator ($\Pi_h g$ is the piecewise linear function which coincides with g at the vertices of S) and $u_{h,N}$ is computed by N iterations of the Schwarz algorithm with the convention that on $\Omega_1 \cap \Omega_2$, $u_{h,N} = \frac{1}{2}(u_{1h,N} + u_{2h,N})$.

5.3. Verification of the hypotheses. We proceed exactly as in the one dimensional case to show that Assumption 1 is satisfied.

(i) Continuity of $f(\cdot)$ with respect to the control is established in Lions [13]. Continuity of $f_h(\cdot)$ with respect to the control is obvious from (89).

(ii) It follows from the finite element error estimates given in [6] that the error analysis (63), (64) holds for this case as well. Hence we can set $\Delta(h) = h^2$.

(iii) The Schwarz algorithm converges linearly with rate $(1 - d/D)$, where d is the diameter of $\Omega_1 \cap \Omega_2$ and D is the diameter of $\Omega_1 \cup \Omega_2$; so, instead of (65), we have the bound

$$\|u_{h,N} - u_h\| \leq C \left(1 - \frac{d}{D}\right)^N \quad \forall N \in \mathcal{N}, \tag{92}$$

for some $C \in (0, \infty)$, which implies that we can set $\varphi(h, N) = (1 - \frac{d}{D})^N$. Note that, in this case, $\varphi(h, N)$ is actually independent of h. In view of this, we can take $N^*(h) = \texttt{ceil}(C/h)$, where $C > 0$ is arbitrary.

(iv) The relation (72) obviously holds for this case as well. To show that the relation (73) also holds, we make use of the facts that (a)

(93)
$$\text{grad} f_h(v) = \mathcal{P}_h(\xi(u_h(v) - u_{dh}))|_S, \quad \text{grad}_N f_h(v) = \Pi_h(\xi(u_{h,N}(v) - u_d))|_S,$$

(b) both $\mathcal{P}_h$ and Π_h tend to the identity operator at the rate $O(h)$ at least, and (c) the bound functions $\Delta(h)$, $\varphi(h, N)$, and $N^*(h)$ have the required properties.

5.4. A numerical example. In this example, Ω_1 is the unit circle centered at the origin, and Ω_2 is the rectangle $(0, 1) \times (0, 1)$ minus the unit triangle with vertices (0,0),(0,1),(1,0) and minus a disk of boundary S. The control boundary is S.

The function which is to be recovered by the optimization process is $u_d = e^{-x\sqrt{2}} \sin(y)$ over the whole domain Ω. The weight on the control has been deliberately chosen to have oscillations $\xi = \sin(30 * (x - 1.15)) + \sin(30 * (y - 0.5))$. We have used an automatic mesh generator controlled by a parameter n, the number of vertices on the boundaries, so, for practical reasons, we initialized $h = 1/(8n)$. The number of Schwarz iterations was initialized at 1.

The tests (26) (in Algorithm Model 2) and (51) (in Algorithm Model 3) for increasing the number of Schwarz iterations were determined by setting $\varphi(h, N) = (0.8)^N$ and $C_1 = 0.1$. The mesh refinement test (31) in Algorithm Model 2 was implemented with the right-hand side set to $-0.001[10^{-4}h^2 + (0.8)^{1/(8h)}]$, which corresponds to $N^*(h) = 0.1/(8h)$, $\varphi(h, N) = 0.8^N$, $\Delta(h) = h^2$. Naturally other choices of coefficients and bound functions are possible.

The mesh refinement test (52) in Algorithm Model 3 was implemented by setting $\epsilon(n) = 10^{-n}$, where $n = 1/8h$.

We have used the code freefem+ [2], which is a matlab-like environment for PDEs developed for the purpose of testing parallel algorithms, among other things.

In Figure 5, we plot the values of the cost function $f(\cdot)$ versus the iteration number for two cases. The first corresponds to optimization using a fixed mesh and a fixed number of Schwarz iterations, i.e., without adaptive precision refinement (curve "criter0"), and the second one was obtained using adaptive refinement based either on the norm of the gradient (case (i), curve "criter1"), or on the decrease of the cost function (case (ii), curve "criter").

Figure 6 shows the number of Schwarz iterations N and the mesh parameter n versus the iteration number for case (i). After 30 iterations, the gradient is 10^{-6} times its initial value, while, without mesh refinement, it is only 10^{-2} times its initial value (multilevel effect).

The solution and the precision are shown in Figures 7 and 8, respectively.

6. Conclusion. We have developed algorithm models based on the consistent approximations approach for solving infinite dimensional problems with two independent precision parameters. We have applied it to two optimal control problems with ODE and PDE dynamics each having two precision parameters: the step-size and an iteration loop count in the solvers. Our numerical results show that the algorithms are effective. The numerical study was done using the method of steepest descent, but the models and the proofs are general and can probably be used with Newton's

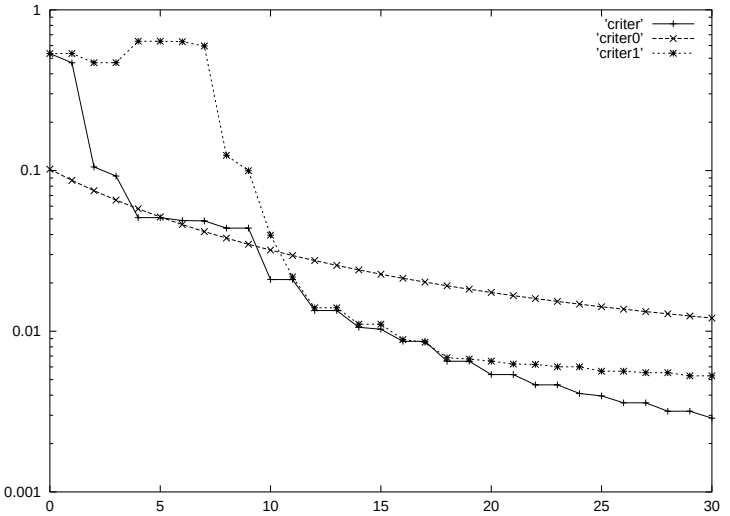

FIG. 5. *Cost function versus iterations for without* $(-\times-)$ *and with mesh adaptation with Algorithm Model* 1 $(-+-)$ *and* 3 $(-*-)$ *for problem* P_2. *Here again, although the general behavior is similar, there is an order of magnitude decrease in the computing time with mesh adaptation because the first fifteen iterations are essentially instantaneous in this case.*

method, conjugate gradient methods, etc. Other applications are under way, in cooperation with G. Lemarchand and Y. Achdou, using the conjugate gradient method for two problems:

- Optimal shape design of wing profiles with mesh adaptation and for which the iteration number for the solvers of the Euler or compressible Navier–Stokes equations was determined in the same way as the number of Schwarz iterations was determined in this paper.
- Volatility smile in financial modeling of option pricing, where one parameter function (the volatility) in the Black–Scholes PDE is adjusted by least square/optimal control to fit the market observations; there, incomplete gradients are due to short cycles in the solvers, and mesh adaptation is used.

In these two important applications, we have reduced the computing time by an order of magnitude, as compared to the times with fixed discretization parameters, and we had no stability problems even though we had much less information as to the rate of convergence of the solvers to guide the choice of the various parameters of our algorithm models.

INDIRECT BOUNDARY STABILIZATION OF WEAKLY COUPLED HYPERBOLIC SYSTEMS*

FATIHA ALABAU-BOUSSOUIRA†

Abstract. This work is concerned with the boundary stabilization of an abstract system of two coupled second order evolution equations wherein only one of the equations is stabilized (indirect damping; see, e.g., *J. Math. Anal. Appl.*, 173 (1993), pp. 339–358). We show that, under a condition on the operators of each equation and on the boundary feedback operator, the energy of smooth solutions of this system decays polynomially at ∞. We then apply this abstract result to several systems of partial differential equations (wave-wave systems, Kirchhoff–Petrowsky systems, and wave-Petrowsky systems).

Key words. boundary stabilization, indirect damping, hyperbolic systems, abstract linear evolution equations

PII. S0363012901385368

1. Introduction. Motivations. It is well known that the energy of the solutions of the wave equation in a bounded open domain $\Omega \subset \mathbb{R}^N$,

$$\begin{cases} u_{tt} - \Delta u = 0 & \text{in } \Omega \times (0,\infty), \\ u(.,0) = u_0(.), u_t(.,0) = u_1(.) & \text{in } \Omega, \end{cases} \tag{1}$$

is dissipated when a boundary feedback of the form

$$\frac{\partial u}{\partial \nu} + au + lu_t = 0 \quad \text{on} \quad \Sigma_1 = \Gamma_1 \times (0,\infty) \tag{2}$$

is applied on a part Γ_1 of the boundary Γ of Ω that satisfies certain geometric conditions (see [5], [27], [18]), whereas no feedback is applied on the other part of the boundary, i.e.,

$$u = 0 \quad \text{on} \quad \Sigma_0 = (\Gamma - \Gamma_1) \times (0,\infty). \tag{3}$$

Here Δ stands for the Laplacian with respect to the spatial variables, and the subscript t stands for the partial derivative with respect to the t-variable. We recall that the energy of a solution u of the wave equation is defined by

$$E(u(t)) = \frac{1}{2}\int_\Omega (|u_t|^2 + |\nabla u|^2)\, dx,$$

and that, formally, the dissipation of energy is given by the relation

$$E'(u(t)) = -\int_{\Gamma_1} \ell |u_t|^2 \, d\gamma \le 0 \quad \text{for } \ell \ge 0 \text{ on } \Gamma_1.$$

Moreover, if the feedback coefficients a and l are suitably chosen (see, e.g., [18] and the references therein), the dissipation of the energy through the part Γ_1 of the boundary

†MMAS, Université de Metz and CNRS (FRE 2344), 57045 Metz, France (alabau@poncelet.univ-metz.fr).

is sufficient to lead to exponential decay of the solutions; i.e., there exist positive constants M and ω such that

$$E(u(t)) \leq M \exp(-\omega t) E(u(0))$$

for all initial data (u_0, u_1) of finite energy. On the other hand, when no feedback is applied on the boundary, i.e., when

$$u = 0 \quad \text{on} \quad \Sigma = \Gamma \times (0, \infty), \tag{4}$$

then the energy of the solutions is conserved, that is, $E(u(t)) = E(u(0))$ for all $t \geq 0$.

One question of interest then is *how the stability properties are affected if we couple the exponentially stable wave equations* (1)–(3) *to the conservative wave equations* (1) and (4). That is, we wonder how these properties are affected if we consider the following system:

$$\begin{cases} u_{1,tt} - \Delta u_1 + \alpha u_2 = 0 & \text{in } \Omega \times (0, \infty), \\ u_{2,tt} - \Delta u_2 + \alpha u_1 = 0 & \text{in } \Omega \times (0, \infty), \\ \dfrac{\partial u_1}{\partial \nu} + a u_1 + l u_{1,t} = 0 & \text{on } \Sigma_1 = \Gamma_1 \times (0, \infty), \\ u_1 = 0 \quad \text{on } \Sigma_0 = \Gamma_0 \times (0, \infty), \qquad u_2 = 0 \quad \text{on } \Sigma = \Gamma \times (0, \infty), \\ u_i(0) = u_{i0}, u_i'(0) = u_{i1}, \end{cases} \tag{5}$$

where α is a coupling parameter. For this model problem, one can remark that a boundary feedback is applied directly to the first component of the solution, whereas no direct feedback is applied to the second component. Also of interest is the question *is it possible to obtain a somehow general result for abstract systems of second order evolution equations coupling a conservative equation to an exponentially stable one*? The abstract model that we refer to in this paper is

$$\begin{cases} u_1'' + A_1 u_1 + B u_1' + \alpha P u_2 = 0 \quad \text{in } V_1', \\ u_2'' + A_2 u_2 + \alpha P^\star u_1 = 0 \quad \text{in } V_2', \\ (u_1, u_1')(0) = (u_1^0, u_1^1) = U_1^0 \in V_1 \times H, \\ (u_2, u_2')(0) = (u_2^0, u_2^1) = U_2^0 \in V_2 \times H, \end{cases} \tag{6}$$

where H, $V_1 \subset H$ and $V_2 \subset H$ are separable Hilbert spaces; A_1, A_2 are coercive self-adjoint unbounded operators in H; B is unbounded symmetric in H, whereas the coupling operator P is assumed to be bounded in H; $P^\star$ is the adjoint operator of P; and α is a coupling parameter. The total energy of a solution (u_1, u_2) is defined by

$$E(u_1(t), u_2(t)) = \frac{1}{2}\left(||u_1'(t)||_H^2 + ||u_2'(t)||_H^2 + ||A_1^{1/2} u_1(t)||_H^2 + ||A_2^{1/2} u_2(t)||_H^2 \right) + \alpha (u_1, P u_2)_H,$$

where $||\cdot||_H$ and $(\cdot)_H$ denote, respectively, the norm and scalar product in H, and $A_i^{1/2}$, $i \in \{1, 2\}$, denotes the usual fractional power of a coercive self-adjoint operator A_i in H (see [29]).

Now the questions of interest are *is the full above system stable and, if so, at which rate*? We can first remark that if $\alpha = 0$, then the solutions of both the above

model problem and the abstract one are not even strongly stable. Hence, the results we are looking for cannot be obtained by a perturbation argument with respect to the case $\alpha = 0$. Moreover, in [2] we have studied the above abstract system in the case of bounded feedback operators B (internal stabilization case). Using a general result of [2, section 1] concerning systems of first evolution equations coupling a conservative equation to a nonconservative one (the coupling operator in the conservative equation being compact in the product space), we can deduce that our abstract system (6) is never exponentially stable. Hence if stability holds for such systems, it must be a weaker stability criterion than the exponential one. Indeed, our main result (see Theorem 3.3 in section 3 below) shows that if $|\alpha|$ is sufficiently small (but not equal to 0), the total energy of the smooth solutions of (6) decays polynomially at ∞, provided mainly that the semigroup generated by A_1 is exponentially stable (see hypothesis $(H1)$), and the two operators A_0 (where A_0 is defined from A_1 in section 2) and A_2 satisfy a compatibility condition (see $(H3)$). From this result, we deduce, thanks to the density of the domains of powers of the generator of the associated first order evolution equation and to the contractivity of the corresponding semigroup, that any solution of (6) is strongly stable. The main requirement for proving the above result is to obtain a generalized integral inequality of the form

$$\int_S^T E(u_1(t), u_2(t))dt \le c \sum_{p=0}^{k} E(u_1^{(p)}(S), u_2^{(p)}(S)) \quad \forall 0 \le S \le T$$

for smooth initial data, where $k = 2$ in our case and where E stands for the total energy of the system. Then a general lemma (introduced in [1] and valid for arbitrary nonzero integer k) shows that if in addition E is a nonincreasing function, it has to decay polynomially at ∞. The main technical point is then to prove this generalized inequality. This is done by the use of appropriate multipliers, one of the obvious difficulties being that, with the second equation not directly stabilized, we miss some information that we must get back from the system.

We then apply our abstract result to several systems of partial differential equations. In particular, we obtain a polynomial decay rate for the energy of smooth solutions of (5) under classical (multiplier-type) geometric conditions on the boundary where the feedback is active. Similar results can be obtained for a Kirchhoff–Petrowsky system. For these two examples, the operators A_0 and A_2 coincide. We further give two examples for which these two operators do not coincide, namely, the case of two coupled wave equations with different speeds of propagation, and a wave-Petrowsky coupling. In these two latter cases, we have to restrict our analysis to the situation in which the spatial domain is an n-dimensional interval.

These results can also be interpreted in the framework of indirect stabilization, which, as far as we know, was introduced by Russell [32]. Indeed, since strong stability holds for abstract systems of the form (6), the first equation of this system can be viewed as an *indirect* stabilizer for the second equation.

We will now give some references to the existing literature on this subject, referring the reader to those papers for further references. A large number of papers (see, e.g., [10], [28], [26], [24], [3], [30]) concern the stabilization of hyperbolic-parabolic coupled systems, such as thermoelasticity, thermoplates, etc. For such systems, the main goal is to determine whether the dissipation induced by the heat-type equation is sufficient for stabilizing the full system obtained by coupling it to a hyperbolic-type equation. Exponential stability results for coupled hyperbolic-hyperbolic systems via two feedback operators (i.e., each equation of the system is directly stabilized if the

coupling parameter is set equal to 0; this is the *direct* stabilization case) can be found in [17], [20], [23]. In the case of coupled wave-wave systems subjected to only one internal feedback operator (this is the *indirect* internal stabilization situation), positive and negative exponential stability results have been obtained in [16], [4]. In [2] we have proved polynomial decay estimates in the indirect internal stabilization case. These results were extended to several cases (wave-wave, Petrowsky-Petrowsky coupling) for locally distributed indirect stabilization in [8]. In the one-dimensional case, another approach, based on the use of a Riesz basis, leads to stability results with an optimal decay rate (see, e.g., [31], [14]). This technique is based on determination of precise asymptotic estimates of the eigenvalues of the involved operators for large frequencies. Such precise estimates can be obtained only in the one-dimensional case and require a careful analysis of the associated spectral problems. Moreover, this analysis has to be performed for each new system under consideration. The main advantage of the method presented in our paper is that it is valid in any dimension and for a wide class of weakly coupled systems, without requiring the performance of all computations for each new system. However, the stability results obtained by this method are probably not optimal, in contrast to the one-dimensional results derived by the use of the Riesz basis.

Complete and partial observability (respectively, controllability) results for coupled systems of either hyperbolic-hyperbolic type or of hyperbolic-parabolic type can be found in [27]. These results assume that the coupling parameter is sufficiently small. They have been extended in [19] to the cases of arbitrary coupling parameters (assuming bounded coupling operators). For both references, the multiplier method was the main requirement for obtaining the desired estimates. Complete observability (respectively, controllability) results have also been obtained in [25] for systems of coupled second order hyperbolic equations containing first order terms in both the original and the coupled unknowns. These results are based on Carleman estimates.

The paper is organized as follows. In section 2, we give the abstract framework for system (6) and establish the well-posedness of both the uncoupled and coupled abstract systems. In section 3, we establish a polynomial decay lemma for a nonincreasing nonnegative functional satisfying a generalized integral inequality. We then prove our main stability result and some useful corollaries. Finally, in section 4 we give several applications of our main results to systems of partial differential equations.

2. Abstract coupled model.

2.1. Introduction. Let V_i, $i = 1, 2$, and H be separable real Hilbert spaces such that the injections $V_i \subset H$ are dense, compact, and continuous for $i = 1, 2$, and the injection $V_2 \subset V_1$ is continuous.

In all of what follows we identify H with its dual space, so that the injections $V_i \subset H \subset V_i'$ hold and are continuous, dense, and compact. The scalar products on V_i, $i = 1, 2$, and H are respectively denoted by $(,)_{V_i}$ and $(,)_H$, whereas the corresponding norms are respectively denoted by $||\ ||_{V_i}$ and $||\ ||_H$. Moreover, we denote by $\langle , \rangle_{V_i', V_i}$ the duality product, and by A_i, $i = 1, 2$, the duality mapping from V_i to V_i' defined by

$$\langle A_i w, z\rangle_{V_i', V_i} = (w, z)_{V_i} \qquad \forall w, z \in V_i.$$

It will also be useful (see subsection 3.2) to assume that V_1 contains a closed subspace V_0, equipped with the norm and scalar product induced by those of V_1. Then denoting by i the canonical injection from V_0 in V_1, and by P_0 the operator of

projection from V_1 on V_0, we recall that for any $u_1 \in V_1$, $P_0 u_1$ is characterized by

$$\begin{cases} \langle A_1 i(P_0 u_1), i(\phi)\rangle_{V_1',V_1} = \langle A_1 u_1, i(\phi)\rangle_{V_1',V_1} \quad \forall\ \phi \in V_0,\ u_1 \in V_1, \\ P_0 u_1 \in V_0. \end{cases} \tag{7}$$

We define an operator A_0 from V_0 to V_0' by

$$\langle A_0\phi, \psi\rangle_{V_0',V_0} = \langle A_1 i(\phi), i(\psi)\rangle_{V_1',V_1} \quad \forall\ \phi, \psi \in V_0. \tag{8}$$

Note that A_0 is, indeed, the duality mapping from V_0 to V_0'.

Let B be a given linear continuous operator from V_1 to V_1' (it will serve as the abstract formulation of the boundary conditions), which further satisfies

$$\langle Bu, u\rangle_{V_1',V_1} \geq 0, \quad \langle Bu, z\rangle_{V_1',V_1} = \langle Bz, u\rangle_{V_1',V_1} \quad \forall u, z \in V_1. \tag{9}$$

Moreover, let P be a given linear continuous operator on H, and α be a given nonzero parameter. For the sake of clarity we will assume that α is positive; nevertheless, the results in this paper are valid for negative α as well. We consider the following weakly coupled system:

$$\begin{cases} u_1'' + A_1 u_1 + Bu_1' + \alpha P u_2 = 0 \quad \text{in } V_1', \\ u_2'' + A_2 u_2 + \alpha P^\star u_1 = 0 \quad \text{in } V_2', \\ (u_1, u_1')(0) = (u_1^0, u_1^1) = U_1^0 \in V_1 \times H, \\ (u_2, u_2')(0) = (u_2^0, u_2^1) = U_2^0 \in V_2 \times H. \end{cases} \tag{10}$$

In order to study this coupled system, we need to establish basic results on the decoupled system obtained when $\alpha = 0$.

2.2. The decoupled system. We consider the decoupled system

$$\begin{cases} u_1'' + A_1 u_1 + Bu_1' = 0 \quad \text{in } V_1', \\ (u_1, u_1')(0) = U_1^0 \in V_1 \times H, \end{cases} \tag{11}$$

and

$$\begin{cases} u_2'' + A_2 u_2 = 0 \quad \text{in } V_2', \\ (u_2, u_2')(0) = U_2^0 \in V_2 \times H. \end{cases} \tag{12}$$

We set $\mathcal{H}_i = V_i \times H$ for $i = 1, 2$. This space is equipped with the scalar product

$$((u_i, v_i), (\tilde{u_i}, \tilde{v_i}))_{\mathcal{H}_i} = (u_i, \tilde{u_i})_{V_i} + (v_i, \tilde{v_i})_H \qquad \forall (u_i, v_i), (\tilde{u_i}, \tilde{v_i}) \in \mathcal{H}_i$$

and the corresponding norm $||\ ||_{\mathcal{H}_i}$. We define two linear unbounded operators $\mathcal{A}_i$ on $\mathcal{H}_i$ for $i = 1, 2$ by

$$\mathcal{A}_1(u_1, v_1) = (-v_1, A_1 u_1 + Bv_1), \quad D(\mathcal{A}_1) = \{(u_1, v_1)\ \in V_1 \times V_1,\ A_1 u_1 + Bv_1\ \in H\},$$

$$\mathcal{A}_2(u_2, v_2) = (-v_2, A_2 u_2), \quad D(\mathcal{A}_2) = \{(u_2, v_2)\ \in V_2 \times V_2,\ A_2 u_2\ \in H\}.$$

Then the decoupled system (11)–(12) can be reformulated as

$$\begin{cases} (u_i, v_i)' + \mathcal{A}_i(u_i, v_i) = 0, \quad i = 1, 2, \\ (u_i, v_i)(0) = U_i^0\ \in \mathcal{H}_i, \quad i = 1, 2. \end{cases} \tag{13}$$

PROPOSITION 2.1. *We assume the above hypotheses on V_i, H, A_i, and B. Then $\mathcal{A}_i$ is a maximal monotone operator on $\mathcal{H}_i$ for $i = 1, 2$, so that for every $U_i^0 = (u_i^0, u_i^1) \in \mathcal{H}_i$ problem (13) has a unique solution $(u_i, v_i) \in \mathcal{C}([0, +\infty); \mathcal{H}_i)$, $i = 1, 2$. Moreover, the energy of the solution, defined by*

$$e_i(t) = \frac{1}{2} \, ||(u_i, v_i)||^2_{\mathcal{H}_i}, \tag{14}$$

is locally absolutely continuous for $i = 1, 2$, and e_1 is nonincreasing, whereas e_2 is conserved through time. If, in addition, $U_i^0 \in D(\mathcal{A}_i^k)$ for $k \in \mathbb{N}^\star$, then the solution is in $\mathcal{C}^{k-j}([0, +\infty); D(\mathcal{A}_i^j))$ for $j = 0, \ldots, k$ and $i = 1, 2$.

Proof. For $(u_1, v_1) \in D(\mathcal{A}_1)$ we have

$$(\mathcal{A}_1(u_1, v_1), (u_1, v_1))_{\mathcal{H}_1} = (-v_1, u_1)_{V_1} + (A_1 u_1 + B v_1, v_1)_H = \langle B v_1, v_1 \rangle_{V_1', V_1} \geq 0,$$

since B satisfies (9). In the same way, for $(u_2, v_2) \in D(\mathcal{A}_2)$ we obtain $(\mathcal{A}_2(u_2, v_2), (u_2, v_2))_{\mathcal{H}_2} = 0$. Hence $\mathcal{A}_i$ is a monotone operator for $i = 1, 2$. We now prove that $\mathcal{A}_i$ is onto. For this, it is sufficient to prove that $I + A_1 + B$ and $I + A_2$ are onto. Let $h_1 \in V_1'$ be given arbitrarily. We consider, as usual (see, e.g., [18]), the map F_1 defined from V_1 on $\mathbb{R}$ by

$$F_1(u_1) = \frac{1}{2}||u_1||^2_H + \frac{1}{2}||u_1||^2_{V_1} + \frac{1}{2}\langle B u_1, u_1 \rangle_{V_1', \, V_1} - \langle h_1, u_1 \rangle_{V_1', \, V_1}.$$

Then F_1 is continuously differentiable and

$$F_1'(u_1) \cdot \phi_1 = \langle (I + A_1 + B) u_1 - h_1, \phi_1 \rangle_{V_1', V_1} \quad \forall u_1, \phi_1 \in V_1.$$

Moreover, F_1 is convex and coercive, i.e, $F_1(u_1) \to +\infty$ if $||u_1||_{V_1} \to +\infty$. Therefore, F_1 attains its minimum at some point $u_1 \in V_1$ for which $F_1'(u_1) = 0$. Hence we have $(I + A_1 + B)u_1 = h_1$. We then deduce easily that $I + \mathcal{A}_1$ is onto on $\mathcal{H}_1$. In a similar way, we prove that $I + \mathcal{A}_2$ is onto on $\mathcal{H}_2$. Hence the operators $\mathcal{A}_i$, $i = 1, 2$, are maximal monotone. We easily conclude, using well-known properties of maximal monotone linear operators (see, e.g., [7]).

2.3. Abstract formulation of the coupled system. We now turn back to the weakly coupled system (10). We set $V = V_1 \times V_2$. This space is equipped with the usual scalar product $(u, \tilde{u})_V = (u_1, \tilde{u_1})_{V_1} + (u_2, \tilde{u_2})_{V_2}$ and the corresponding norm $|| \, ||_V$, where $u = (u_1, u_2) \in V$ and $\tilde{u} = (\tilde{u_1}, \tilde{u_2}) \in V$. We have $V \subset H \times H \subset V'$ with continuous, dense, and compact injections. We also define a linear continuous operator A_α from V on V' by

$$A_\alpha u = (A_1 u_1 + \alpha P u_2, A_2 u_2 + \alpha P^\star u_1), \qquad u = (u_1, u_2) \in V.$$

Moreover, we consider on V the continuous bilinear form

$$(u, \tilde{u})_\alpha = (u, \tilde{u})_V + \alpha(P u_2, \tilde{u_1})_H + \alpha(P^\star u_1, \tilde{u_2})_H, \qquad u = (u_1, u_2), \tilde{u} = (\tilde{u_1}, \tilde{u_2}) \in V.$$

PROPOSITION 2.2. *Assume the hypotheses of Proposition* 2.1. *Then there exists $\alpha_0 > 0$ such that for all $0 \leq |\alpha| < \alpha_0$ there exist constants $c_1(\alpha) > 0$ and $c_2(\alpha) > 0$ such that*

$$c_1(\alpha)||u||_V \leq ((u, u)_\alpha)^{1/2} \leq c_2(\alpha)||u||_V \quad \forall \; u \in V.$$

Hence, for all $0 \leq |\alpha| < \alpha_0$, *the application*

$$u \in V \mapsto ||u||_\alpha = ((u,u)_\alpha)^{1/2}$$

defines a norm on V *which is equivalent to the norm* $||\ ||_V$. *Moreover, for all* $0 \leq |\alpha| < \alpha_0$, A_α *is the duality mapping from* V *on* V' *when* V *is equipped with the scalar product* $(,)_\alpha$.

Proof. Let us denote by β_i, $i = 1, 2$, the smallest positive constants such that

$$||u_i||_H \leq \beta_i ||u_i||_{V_i} \quad \forall\ u_i \in V_i.$$

Then we have

$$(u,u)_\alpha \geq ||u_1||^2_{V_1} + ||u_2||^2_{V_2} - 2\alpha||P||\beta_1\beta_2||u_1||_{V_1}||u_2||_{V_2} \geq ||u||^2_V(1 - \alpha||P||\beta_1\beta_2).$$

Hence, setting

$$\alpha_0 = (||P||\beta_1\beta_2)^{-1}, \qquad c_1(\alpha) = \sqrt{1 - \alpha||P||\beta_1\beta_2},$$

we have

$$\sqrt{(u,u)_\alpha} \geq c_1(\alpha)||u||_V \quad \forall\ u \in V.$$

In a similar way, we have

$$\sqrt{(u,u)_\alpha} \leq c_2(\alpha)||u||_V \quad \forall\ u \in V,$$

where

$$c_2(\alpha) = \sqrt{1 + \alpha||P||\beta_1\beta_2}.$$

We now prove that A_α is the duality mapping for the scalar product $(,)_\alpha$. For $u = (u_1, u_2)$ and $u = (\tilde{u}_1, \tilde{u}_2)$ given in V we have

$$\langle A_\alpha u, \tilde{u}\rangle_{V',V} = (u,\tilde{u})_V + \alpha\langle Pu_2, \tilde{u_1}\rangle_{V_1',V_1} + \alpha\langle P^\star u_1, \tilde{u_2}\rangle_{V_2',V_2}.$$

Now, since $Pu_2 \in H$ and $\tilde{u_1} \in V_1$, we have

$$\langle Pu_2, \tilde{u_1}\rangle_{V_1',V_1} = (Pu_2, \tilde{u_1})_H.$$

In a similar way, we have

$$\langle P^\star u_1, \tilde{u_2}\rangle_{V_2',V_2} = (P^\star u_1, \tilde{u_2})_H.$$

Hence

$$\langle A_\alpha u, \tilde{u}\rangle_{V',V} = (u,\tilde{u})_\alpha. \qquad \square$$

We now set $\mathcal{H} = V \times H^2$. This space is equipped with the scalar product

$$(U,\tilde{U})_{\mathcal{H}} = (u,\tilde{u})_\alpha + (v,\tilde{v})_{H\times H}$$

and the corresponding norm

$$||U||_{\mathcal{H}} = (||u||^2_\alpha + ||v||^2_{H\times H})^{1/2},$$

where $U = (u, v) \in \mathcal{H}$, with $u = (u_1, u_2)$, $v = (v_1, v_2)$. We also define the unbounded linear operator $\mathcal{A}_\alpha$ on $\mathcal{H}$ by

$$\mathcal{A}_\alpha U = (-v, A_\alpha u + (Bv_1, 0)),$$

$$D(\mathcal{A}_\alpha) = \{U = (u, v) = ((u_1, u_2), (v_1, v_2)) \in V \times V,\ A_\alpha u + (Bv_1, 0) \in H \times H\}.$$

One can easily prove that

$$U = ((u_1, u_2), (v_1, v_2)) \in D(\mathcal{A}_\alpha) \Longleftrightarrow (u_1, v_1) \in D(\mathcal{A}_1), (u_2, v_2) \in D(\mathcal{A}_2).$$

We can now reformulate the system (10) as the abstract first order equation

$$\begin{cases} U' + \mathcal{A}_\alpha U = 0, \\ U(0) = U^0 \in \mathcal{H}. \end{cases} \tag{15}$$

PROPOSITION 2.3. *Assume the hypotheses of Proposition* 2.1*, and let* α_0 *be given as in Proposition* 2.2*. Then, for all* $0 \leq |\alpha| < \alpha_0$*,* $\mathcal{A}_\alpha$ *is a maximal monotone linear operator on* $\mathcal{H}$*, so that for every* $U^0 \in \mathcal{H}$ *problem* (15) *has a unique solution* $U = (u, v) \in \mathcal{C}([0, +\infty); \mathcal{H})$*. If, in addition,* $U^0 \in D({\mathcal{A}_\alpha}^k)$ *for* $k \in \mathbb{N}^\star$*, then the solution is in* $\mathcal{C}^{k-j}([0, +\infty); D(\mathcal{A}_\alpha^j))$ *for* $j = 0, \ldots, k$*. Moreover, the energy of the solution defined by*

$$E(U(t)) = \frac{1}{2}\ ||U||^2_{\mathcal{H}} \tag{16}$$

is locally absolutely continuous, and for strong solutions, i.e., when $U^0 \in D(\mathcal{A}_\alpha)$*, we have*

$$E'(U(t)) = -\langle Bu_1', u_1' \rangle_{V_1', V_1}; \tag{17}$$

here $'$ *denotes the derivative with respect to time* t*. Hence the energy of any solution of* (15) *is a nonincreasing function of time.*

Proof. The proof is similar to that of Proposition 2.1 and is left to the reader.

Remark. The well-posedness of problem (15) holds true for any α, since $\mathcal{A}_\alpha$ is a compact perturbation of the corresponding decoupled operator (obtained by setting $\alpha = 0$). Of course, in this case V should be equipped with the norm $||\ ||_V$, and $\mathcal{H}$ with the scalar product $(U, \tilde{U}) = (u, \tilde{u})_V + (v, \tilde{v})_{H \times H}$ and the corresponding norm.

For what follows, we will also need the following result whose (easy) proof is left to the reader.

PROPOSITION 2.4. *Assume the hypotheses of Proposition* 2.1*, and let* α_0 *be given as in Proposition* 2.2*. Then, for all* $0 \leq |\alpha| < \alpha_0$*, there exist constants* $c_3(\alpha) > 0$ *and* $c_4(\alpha) > 0$ *such that for all* $U = (u_1, u_2, v_1, v_2) \in \mathcal{H}$ *we have*

$$\begin{aligned} \frac{c_3(\alpha)}{2}\ (||(u_1, v_1)||^2_{\mathcal{H}_1} + ||(u_2, v_2)||^2_{\mathcal{H}_2}) &\leq ||U||^2_{\mathcal{H}} \\ &\leq \frac{c_4(\alpha)}{2}(||(u_1, v_1)||^2_{\mathcal{H}_1} + ||(u_2, v_2)||^2_{\mathcal{H}_2}). \end{aligned} \tag{18}$$

3. Main results.

3.1. A generalized integral inequality. We prove below a generalized integral inequality that will be useful in what follows for obtaining polynomial decay rates for smooth solutions of coupled equations when only one of the equations is stabilized. Let A be the infinitesimal generator of a continuous semigroup $\exp(tA)$ on a Hilbert space $\mathcal{H}$, and $D(A)$ its domain. For U^0 in $\mathcal{H}$ we set $U(t) = \exp(tA)U^0$ in all of what follows.

THEOREM 3.1. *Assume that there exists a functional E defined on $C([0,+\infty),\mathcal{H})$ such that for every U^0 in $\mathcal{H}$, $E(\exp(.A))$ is a nonincreasing, locally absolutely continuous function from $[0,+\infty)$ on $[0,+\infty)$. Assume, moreover, that there exist an integer $k \in \mathbb{N}^\star$ and nonnegative constants c_p for $p = 0,\dots,k$ such that*

$$\int_S^T E(U(t))\ dt \le \sum_{p=0}^{k} c_p E(U^{(p)}(S)) \qquad \forall\ 0 \le S \le T,\ U^0 \in D(A^k). \tag{19}$$

Then the following inequalities hold for every U^0 in $D(A^{kn})$, where n is any positive integer:

$$\int_S^T E(U(\tau))\frac{(\tau - S)^{n-1}}{(n-1)!}\ d\tau \le c\sum_{p=0}^{kn} E(U^{(p)}(S)) \qquad \forall\, 0 \le S \le T,\ U^0 \in D(A^{kn}), \tag{20}$$

and

$$E(U(t)) \le c\sum_{p=0}^{kn} E(U^{(p)}(0))t^{-n} \qquad \forall t > 0,\ U^0 \in D(A^{kn}),$$

where c is a constant that depends on n.

Proof. We first prove (20) by induction on n. For $n = 1$, it reduces to the hypothesis (19). Assume now that (20) holds for n, and let U^0 be given in $D(A^{k(n+1)})$. Then we have

$$\int_S^T \int_t^T E(U(\tau))\frac{(\tau - t)^{n-1}}{(n-1)!}\ d\tau\ dt \le c\sum_{p=0}^{kn}\int_S^T E(U^{(p)}(t))\ dt$$

$$\forall 0 \le S \le T,\ U^0 \in D(A^{kn}).$$

Since U^0 is in $D(A^{k(n+1)})$, we deduce that $U^{(p)}(0) = A^p U^0$ is in $D(A^k)$ for $p \in \{0,\dots,kn\}$. Hence we can apply assumption (19) to the initial data $U^{(p)}(0)$. This, together with Fubini's theorem applied on the left-hand side of the above inequality, gives (20) for $n+1$. Using the property that $E(U(t))$ is nonincreasing in (20), we easily obtain the last desired inequality. ∎

In all of what follows, we write U instead of $U(t)$ in the expressions involving the energy, and S will denote a nonnegative real number.

3.2. Polynomial decay of weakly coupled systems. Let us first prove that, under the hypotheses of Proposition 2.1, the semigroup generated by the operator $-\mathcal{A}_\alpha$ is not exponentially stable.

PROPOSITION 3.2. *We assume the hypotheses of Proposition* 2.1 *and that the space* $V_2 \times H$ *is infinite-dimensional. Then the semigroup generated by the operator* $-\mathcal{A}_\alpha$ *is not exponentially stable.*

Proof. We recall that $\mathcal{H}_i = V_i \times H$ and $\mathcal{H} = V_1 \times V_2 \times H^2$, and we define the operators $\mathcal{A}_i$ for $i = 1, 2$ and their domains as in section 2. Now let U_0 be given in $\mathcal{H}$, and $U = ((u_1, u_2), (v_1, v_2))$ be the solution of (15). Setting $w_1 = (u_1, v_1)$ and $w_2 = (u_2, v_2)$, we can reformulate the system (15) in the following form:

$$\text{(21)} \qquad \begin{cases} w_1'(t) = L_1 w_1(t) + K_1 w_2(t), \\ w_2'(t) = L_2 w_2(t) + K_2 w_1(t), \\ w_1(0) = (u_1^0, u_1^1) = U_1^0 \in \mathcal{H}_1, \\ w_2(0) = (u_2^0, u_2^1) = U_2^0 \in \mathcal{H}_2, \end{cases}$$

where the operators L_i are unbounded operators in $\mathcal{H}_i$ for $i = 1, 2$ and are defined by $L_i = -\mathcal{A}_i$, $D(L_i) = D(\mathcal{A}_i)$ for $i = 1, 2$. In contrast, the operators K_1 and K_2 are the bounded linear operators acting, respectively, from $\mathcal{H}_2$ on $\mathcal{H}_1$ and $\mathcal{H}_1$ on $\mathcal{H}_2$ defined by $K_1 = (0, -\alpha P)$ and $K_2 = (0, -\alpha P^\star)$. Now, from our hypotheses and thanks to Proposition 2.1, we know that L_i generates a strongly continuous semigroup of bounded linear operators $\exp(tL_i)$ on $\mathcal{H}_i$ for $i = 1, 2$, and that $||\exp(tL_2)w|| = ||w||$ for all $w \in \mathcal{H}_2$, where $||\cdot||$ denotes the norm on $\mathcal{H}_2$. Moreover, one can easily notice that, thanks to the compact imbedding of V_2 in H, K_2 is a compact operator. Hence if $V_2 \times H$ is infinite-dimensional, we can apply the results of [2, section 1], so that the semigroup generated by $-\mathcal{A}_\alpha$ is not exponentially stable. □

Hence if the system (15) is stable, it must be stable in a weaker sense than the exponential one. Indeed, we now want to prove that, under additional hypotheses on the operators $(\mathcal{A}_1, \mathcal{A}_2)$, the operator $-\mathcal{A}_\alpha$ generates a polynomially decaying semigroup.

We first assume that the operator $\mathcal{A}_1$ satisfies the following hypotheses (H1)–(H2):

$$\text{(H1)} \begin{cases} \exists \gamma_i > 0,\ i = 1, 2, 3, \text{ such that } \forall f_1 \in \mathcal{C}^1([0, +\infty); H) \text{ and } 0 \le S \le T, \\ \text{the solution } (u_1, v_1) \text{ of} \\ \quad (u_1, v_1)' + \mathcal{A}_1(u_1, v_1) = (0, f_1), \\ \quad (u_1, v_1) = (u_1^0, v_1^0) \in D(\mathcal{A}_1) \\ \text{satisfies} \\ \int_S^T e_1(t)\, dt \le \gamma_1(e_1(S) + e_1(T)) + \gamma_2 \int_S^T ||f_1(t)||_H^2\, dt + \gamma_3 \int_S^T \langle Bv_1, v_1\rangle_{V_1', V_1}\, dt; \end{cases}$$

and

$$\text{(H2)} \begin{cases} \langle Bu_1, i(\phi)\rangle_{V_1', V_1} = 0 \quad \forall\ \phi \in V_0,\ u_1 \in V_1, \\ \text{and} \\ \exists \beta > 0, \qquad ||u_1 - P_0 u_1||_H^2 \le \beta\ \langle Bu_1, u_1\rangle_{V_1', V_1} \quad \forall u_1 \in V_1. \end{cases}$$

Remarks. The assumption (H1) implies, in particular, that $-\mathcal{A}_1$ generates an exponentially stable semigroup, since for $f_1 = 0$ we deduce that e_1, which is locally absolutely continuous and nonincreasing (see Proposition 2.1), satisfies the classical integral inequality

$$\text{(22)} \qquad \int_S^T e_1(t)\ dt \le (2\gamma_1 + \gamma_3) e_1(S) \quad \forall\ 0 \le S \le T,$$

so that $-\mathcal{A}_1$ generates an exponentially stable semigroup (see [15], [18]). As will be seen later (in section 4), this property is satisfied for most systems (e.g., wave, Kirchhoff, etc.).

The hypothesis (H2) implies that B satisfies a "weak" coercivity property (since the norm on the left-hand side of the second inequality in (H2) is the weaker H-norm) in the subspace orthogonal to the closed subspace V_0. As will be seen later (in section 4), this property is satisfied for most systems (e.g., wave, Kirchhoff, etc.).

We now state the next hypothesis, which gives the "authorized" couplings in the abstract system (10). For the sake of simplicity, we still denote by A_i the unbounded operator on H defined by the restriction of A_i to $D(A_i) = \{\phi \in V_i,\ A_i\phi \in H\}$ for $i = 0$ and $i = 2$. We now assume the following properties on the coupling:

$$\text{(H3)} \begin{cases} V_2 \subset V_0 \text{ with continuous imbedding and} \\ \exists \text{ a bounded operator } C \text{ on } H \text{ such that} \\ CV_2 \subset V_0, CD(A_2) \subset D(A_0), \text{ and } A_0 C u_2 = C A_2 u_2 \quad \forall u_2 \in D(A_2). \end{cases}$$

Furthermore, we assume that

$$\text{(H4)} \qquad \exists \gamma > 0 \text{ such that } (Pu_2, Cu_2)_H \geq \gamma ||u_2||_H^2 \quad \forall u_2 \in H.$$

We now state the main result of this paper.

THEOREM 3.3. *Assume that A_1, A_2, and B satisfy the hypotheses of section* 2 *and assumptions* (H1)–(H4). *Then there exists an $\alpha_1 \in (0, \alpha_0]$ such that for all $0 < |\alpha| < \alpha_1$ the solution $U(t) = \exp(-\mathcal{A}_\alpha t)U^0$ of* (10) *satisfies*

$$E(U(t)) \leq \frac{c}{t^n} \sum_{p=0}^{2n} E(U^{(p)}(0)) \qquad \forall\ t > 0,\ U^0 \in D(\mathcal{A}_\alpha^{2n}),$$

where c is a constant depending on α and n. Moreover, if $U^0 \in \mathcal{H}$, then $E(U(t))$ converges to zero as t goes to infinity (this is strong stability).

As will be seen in what follows (in section 4), assumptions (H1) and (H2) will be satisfied for many operators $\mathcal{A}_1$. Assumption (H3), which concerns the coupling between the two operators involved in the full system, is more restrictive. We give below two abstract examples for which assumption (H3) is satisfied.

Example 1. Case $A_0 = A_2$. We give a first example for which assumption (H3) is trivially satisfied.

PROPOSITION 3.4. *Assume that*

$$\begin{aligned} &\text{(H3)}' \quad V_0 = V_2, \quad A_0 = A_2, \quad D(A_0) = D(A_2), \\ &\text{(H4)}' \quad \exists \gamma > 0,\ (Pu_2, u_2)_H \geq \gamma ||u_2||_H^2 \quad \forall\ u_2 \in H, \end{aligned}$$

where the equality between Banach spaces E and F has to be understood as E and F are isomorphic. Then assumptions (H3)–(H4) *are trivially satisfied with $C = \mathrm{Id}_H$.*

Therefore, from Theorem 3.3 and Proposition 3.4, we easily deduce the following corollary.

COROLLARY 3.5. *Assume that A_1, A_2, A_0, and B satisfy the hypotheses of section* 2, *and take assumptions* (H1)–(H2) *together with* (H3)′ *and* (H4)′. *Then there exists $\alpha_1 \in (0, \alpha_0]$ such that for all $0 < |\alpha| < \alpha_1$ the solution $U(t) = \exp(-\mathcal{A}_\alpha t)U^0$ of* (10) *satisfies*

$$E(U(t)) \leq \frac{c}{t^n} \sum_{p=0}^{2n} E(U^{(p)}(0)) \qquad \forall\ t > 0,\ U^0 \in D(\mathcal{A}_\alpha^{2n}).$$

Moreover, if $U^0 \in \mathcal{H}$, then $E(U(t))$ converges to zero as t goes to infinity.

Example 2. Case $A_0 \neq A_2$. The second example allows us a more general situation, even though it is still restrictive. We define the spaces H, V_1, V_2, V_0 and the unbounded operators $A_0 : D(A_0) \subset H \mapsto H$, $A_2 : D(A_2) \subset H \mapsto H$ as in section 2, where $D(A_i) = \{u \in V_i, A_i u \in H\}$ for $i = 0, 2$.

LEMMA 3.6. *Assume that $V_2 \subset V_0$ and that there exists a common orthonormal basis $\{e_k\}_{k=1}^{\infty}$ of eigenfunctions of the operators A_i in H, for $i = 0, 2$, with*

$$A_i e_k = \lambda_{i,k} e_k, \qquad k = 1, \dots, \ i = 0, 2.$$

Assume, moreover, that the following hypothesis holds:

$$\text{(H5)} \left\{ \begin{array}{l} \exists r : \mathbb{N}^\star \mapsto \mathbb{N}^\star, \ \textit{one-to-one, such that} \\ \lambda_{2,k} = \lambda_{0,r(k)} \quad \forall k \in \mathbb{N}^\star. \end{array} \right.$$

Then, there exists a bounded linear operator C in H that satisfies assumption (H3) *and $||Cu||_H = ||u||_H$ for all $u \in H$.*

Proof. Assume that there exists an application r as above. For $u \in H$, u has a unique orthonormal expansion $u = \sum_{k=1}^{\infty} u_k e_k$, where $\sum_{k=1}^{\infty} |u_k|^2 < +\infty$. In the remainder of the proof, we will assume that $u \in H$ is written under this form. Moreover, we recall that for $i = 0$ or $i = 2$, $u \in V_i$ if and only if

$$\sum_{k=1}^{\infty} \lambda_{i,k} |u_k|^2 < +\infty,$$

whereas $u \in D(A_i)$ if and only if

$$\sum_{k=1}^{\infty} |\lambda_{i,k}|^2 |u_k|^2 < +\infty.$$

We define C as follows:

$$Cu = \sum_{k=1}^{\infty} u_k e_{r(k)}.$$

Hence, we have $Cu = \sum_{l=1}^{\infty} v_\ell e_\ell$, where $v_\ell = u_k$ if $k \in \{1, \dots, \infty\}$ exists such that $\ell = r(k)$, and $v_\ell = 0$ otherwise. This implies that $||Cu||_H = ||u||_H$ for all $u \in H$. We now check that this operator C satisfies assumption (H3). Let u be given in V_2. Then, thanks to the assumption on r, we have

$$\sum_{k=1}^{\infty} \lambda_{0,r(k)} |u_k|^2 < +\infty.$$

Defining v_ℓ as above, we deduce that

$$\sum_{\ell=1}^{\infty} \lambda_{0,\ell} |v_\ell|^2 = \sum_{k=1}^{\infty} \lambda_{0,r(k)} |u_k|^2 < +\infty.$$

Hence, we have $Cu \in V_0$, and thanks to the assumption on r, $||Cu||_{V_0} = ||u||_{V_2}$ holds.

Now let u be given in $D(A_2)$, and define v_ℓ as above. Then, thanks to the assumption on r, we prove, as above, that

$$\sum_{\ell=1}^{\infty} |\lambda_{0,\ell}|^2 |v_\ell|^2 = \sum_{k=1}^{\infty} |\lambda_{0,r(k)}|^2 |u_k|^2 < +\infty.$$

Hence, we have $Cu \in D(A_0)$. Finally, let u be given in $D(A_2)$. Then

$$A_2 u = \sum_{k=1}^{\infty} \lambda_{2,k} u_k e_k,$$

so that, thanks to the assumption on r,

$$CA_2 u = \sum_{k=1}^{\infty} \lambda_{0,r(k)} u_k e_{r(k)}.$$

On the other hand, we have

$$A_0 Cu = \sum_{\ell=1}^{\infty} \lambda_{0,\ell} v_l e_\ell = CA_2 u,$$

thanks to the above definition of v_ℓ. □

Thanks to Theorem 3.3 and to Lemma 3.6, we also deduce the following corollary of our main result.

COROLLARY 3.7. *Assume that A_1, A_2, A_0, and B satisfy the hypotheses of section* 2. *Moreover, assume that* (H1)–(H2), (H4), *and the assumptions of Lemma* 3.6 *hold. Then there exists $\alpha_1 \in (0, \alpha_0]$ such that for all $0 < |\alpha| < \alpha_1$ the solution $U(t) = \exp(-\mathcal{A}_\alpha t)U^0$ of* (10) *satisfies*

$$E(U(t)) \le \frac{c}{t^n} \sum_{p=0}^{2n} E(U^{(p)}(0)) \qquad \forall\ t > 0,\ U^0 \in D(\mathcal{A}_\alpha^{2n}).$$

Moreover, if $U^0 \in \mathcal{H}$, then $E(U(t))$ converges to zero as t goes to infinity.

Proof of the main result. We now turn to the proof of Theorem 3.3. However, we first need to prove the following lemmas.

LEMMA 3.8. *Assume the hypotheses of Theorem* 3.3. *Then for all $0 < |\alpha| < \alpha_0$ and all $U^0 = (u_1^0, u_2^0, u_1^1, u_2^1) \in D(\mathcal{A}_\alpha)$ the solution $U(t) = \exp(-t\mathcal{A}_\alpha)U^0 = (u_1, u_2, v_1, v_2)$ of* (10) *satisfies*

$$\frac{\alpha\gamma}{2} \int_S^T ||u_2||_H^2\ dt \le \alpha\ c \int_S^T ||u_1||_H^2\ dt + c(E(U'(S)) + E(U(S))) \quad \forall\ 0 \le S \le T,$$

where c is a constant depending on α.

Proof. Assume first that $U^0 \in D(\mathcal{A}_\alpha^2)$; then we know that the solution $U(t) = \exp(-t\mathcal{A}_\alpha)U^0 = (u_1, u_2, v_1, v_2)$ of (10) is in $\mathcal{C}([0, +\infty); D(\mathcal{A}_\alpha^2)) \cap \mathcal{C}^1([0, +\infty); D(\mathcal{A}_\alpha)) \cap \mathcal{C}^2([0, +\infty); \mathcal{H})$. Hence $U = (u_1, u_2, v_1, v_2)$ satisfies

$$\begin{cases} v_1 = u_1', \quad v_2 = u_2', \\ u_1'' + A_1 u_1 + B u_1' + \alpha P u_2 = 0 \quad \text{in } H, \\ u_2'' + A_2 u_2 + \alpha P^\star u_1 = 0 \quad \text{in } H. \end{cases} \tag{23}$$

We now evaluate the term

$$\begin{aligned} K = \int_S^T & (u_1'' + A_1 u_1 + B u_1' + \alpha P u_2,\ Cu_2)_H \\ & - (Cu_2'' + CA_2 u_2 + \alpha C P^\star u_1,\ P_0 u_1)_H\ dt = 0. \end{aligned} \tag{24}$$

Then we have $K = K_1 + K_2 + K_3$, where

$$K_1 = \int_S^T (u_1'', Cu_2)_H - (P_0u_1, Cu_2'')_H \ dt,$$
$$K_2 = \int_S^T (A_1u_1 + Bu_1', Cu_2)_H - (CA_2u_2, P_0u_1)_H \ dt,$$
$$K_3 = \alpha \int_S^T (Pu_2, Cu_2)_H - (CP^\star u_1, P_0u_1)_H \ dt.$$

We first consider the term K_1.

Thanks to the regularity of the solution, we have that $u_i \in \mathcal{C}^2([0,+\infty); V_i)$ for $i = 1, 2$. Hence, $P_0(u_1'') = (P_0u_1)''$, so that we can rewrite K_1 as

$$K_1 = \int_S^T (u_1'' - P_0u_1'', Cu_2)_H \ dt + [(P_0u_1', Cu_2)_H - (P_0u_1, Cu_2')_H]_S^T.$$

Hence we have for all $\varepsilon > 0$

$$|K_1| \leq \frac{1}{2\varepsilon} \int_S^T ||u_1'' - P_0u_1''||_H^2 \ dt + \frac{\varepsilon}{2} \int_S^T ||Cu_2||_H^2 \ dt$$
$$+ c \sum_{i=1,2} (||u_i'(T)||_H^2 + ||u_i(T)||_H^2) + c \sum_{i=1,2} (||u_i'(S)||_H^2 + ||u_i(S)||_H^2).$$

On the other hand, since we have

$$||u_i'||_H^2 + ||u_i||_H^2 \leq ||u_i'||_H^2 + \beta_i^2 ||u_i||_{V_i}^2,$$

we deduce, also using Proposition 2.2, that

$$\sum_{i=1,2} (||u_i'(\cdot)||_H^2 + ||u_i(\cdot)||_H^2) \leq 2 \max\left(1, \frac{\max(\beta_1^2, \beta_2^2)}{c_1^2(\alpha)}\right) E(U(\cdot)),$$

where the constant $c_1(\alpha)$ is defined as in Proposition 2.2. Together with hypothesis (H2), this implies that for all $\varepsilon > 0$

$$|K_1| \leq \frac{\beta}{2\varepsilon} \int_S^T \langle Bu_1'', u_1'' \rangle_{V_1', V_1} \ dt + \frac{\varepsilon}{2} \int_S^T ||Cu_2||_H^2 \ dt + c(E(U(T)) + E(U(S))). \tag{25}$$

On the other side, we know from Proposition 2.3 that

$$E'(U(t)) = -\langle Bu_1', u_1' \rangle_{V_1', V_1}$$

for all $U^0 \in D(\mathcal{A}_\alpha)$, so that we have

$$E'(U'(t)) = -\langle Bu_1'', u_1'' \rangle_{V_1', V_1}$$

for all $U^0 \in D(\mathcal{A}_\alpha^2)$. Hence, using this last relation in (25), together with the fact that $E(U(\cdot))$ and $E(U'(\cdot))$ are nonnegative and nonincreasing, we obtain

$$|K_1| \leq \frac{\beta}{2\varepsilon} E(U'(S)) + \frac{\varepsilon}{2} \int_S^T ||Cu_2||_H^2 \ dt + cE(U(S)). \tag{26}$$

We now consider the term K_2. Since $U^0 \in D(\mathcal{A}_\alpha^2)$, and thanks to the hypothesis (H3), we have $u_2 \in D(A_2) \subset V_0$ and $Cu_2 \in D(A_0)$. Therefore, since (H2) holds, we have

$$(A_1u_1 + Bu_1', Cu_2)_H = \langle A_1u_1 + Bu_1', i(Cu_2)\rangle_{V_1',V_1} = \langle A_1u_1, i(Cu_2)\rangle_{V_1',V_1}.$$

On the other hand, by definition of P_0 and A_0, we have

$$\begin{aligned}\langle A_1u_1, i(Cu_2)\rangle_{V_1',V_1} &= \langle A_1 i(P_0u_1), i(Cu_2)\rangle_{V_1',V_1} \\ &= \langle A_0P_0u_1, Cu_2\rangle_{V_0',V_0} = \langle A_0Cu_2, P_0u_1\rangle_{V_0',V_0}.\end{aligned}$$

Moreover, since $Cu_2 \in D(A_0)$, we have $A_0Cu_2 \in H$. Hence

$$\langle A_0Cu_2, P_0u_1\rangle_{V_0',V_0} = (A_0Cu_2, P_0u_1)_H,$$

so that

$$(A_1u_1 + Bu_1', Cu_2)_H = (A_0Cu_2, P_0u_1)_H.$$

Hence, thanks once again to assumption (H3), we have finally

$$K_2 = 0. \tag{27}$$

We now turn to the term K_3. Thanks to assumption (H4), we have

$$K_3 \geq \alpha\gamma \int_S^T ||u_2||_H^2 \, dt - \alpha c \int_S^T ||u_1||_H^2 \, dt. \tag{28}$$

Using (26)–(28) in (24), we obtain for all $\varepsilon > 0$

$$\begin{aligned}\alpha\gamma \int_S^T ||u_2||_H^2 \, dt \leq \alpha c \int_S^T ||u_1||_H^2 \, dt + \frac{\beta}{2\varepsilon} E(U'(S)) \\ + \frac{\varepsilon ||C||^2}{2} \int_S^T ||u_2||_H^2 \, dt + cE(U(S)).\end{aligned}$$

Choosing $\varepsilon = \alpha\gamma/||C||^2$ and using assumption (H4), we obtain

$$\begin{aligned}&\frac{\alpha\gamma}{2} \int_S^T ||u_2||_H^2 \, dt \leq \alpha c \int_S^T ||u_1||_H^2 \, dt + c(E(U'(S)) + E(U(S))) \\ &\quad \forall\ 0 \leq S \leq T,\ U^0 \in D(\mathcal{A}_\alpha^2),\end{aligned} \tag{29}$$

where c is a constant depending on α. By a density argument, we deduce that (29) holds for every $U^0 \in D(\mathcal{A}_\alpha)$. □

From now on, for $U(t) = \exp(-t\mathcal{A}_\alpha)U^0 = (u_1, u_2, v_1, v_2)$ a solution of (10), we set $e_i((u_i, v_i)(t)) = e_i(t)$ for $i = 1, 2$, where $e_i(t)$ is defined by (14).

LEMMA 3.9. *Assume the hypotheses of Theorem* 3.3. *Then there exists* $\alpha_1 \in (0, \alpha_0]$ *such that for all* $0 < |\alpha| < \alpha_1$ *and all* $U^0 = (u_1^0, u_2^0, u_1^1, u_2^1) \in D(\mathcal{A}_\alpha)$ *the solution* $U(t) = \exp(-t\mathcal{A}_\alpha)U^0 = (u_1, u_2, v_1, v_2)$ *of* (10) *satisfies*

$$\int_S^T e_1((u_1, v_1)(t)) \, dt \leq c(\alpha)(E(U(S)) + E(U'(S))) \quad \forall\ 0 \leq S \leq T.$$

Proof. Assume that $U^0 \in D(\mathcal{A}_\alpha)$; then we know that the solution $U(t)$ of (10) is in $\mathcal{C}([0,+\infty);D(\mathcal{A}_\alpha)) \cap \mathcal{C}^1([0,+\infty);\mathcal{H})$. Hence $U=(u_1,u_2,v_1,v_2)$ satisfies

$$\begin{cases} (u_1,v_1)' + \mathcal{A}_1(u_1,v_1) = -\alpha(0,Pu_2), \\ (u_1,v_1)(0) = (u_1^0,u_1^1) \in \mathcal{A}_1. \end{cases}$$

Moreover, we have, in particular, that $Pu_2 \in \mathcal{C}^1([0,+\infty);H)$. Hence, thanks to assumption (H1), we have

$$\begin{aligned} \int_S^T e_1((u_1,v_1)(t))\ dt &\le \gamma_1(e_1((u_1,v_1)(S)) + e_1((u_1,v_1)(T))) \\ &\quad + \alpha^2\gamma_2||P||^2 \int_S^T ||u_2||_H^2\ dt + \gamma_3 \int_S^T \langle Bv_1,v_1\rangle_{V_1',V_1}\ dt. \end{aligned} \tag{30}$$

Using (29) and (17) in this last relation, we obtain

$$\begin{aligned} &\int_S^T e_1((u_1,v_1)(t))\ dt \\ &\quad \le \gamma_1(e_1((u_1,v_1)(S)) + e_1((u_1,v_1)(T))) + \gamma_3(E(U(S)) - E(U(T))) \\ &\quad + \frac{2\alpha\gamma_2||P||^2}{\gamma}\left(\alpha\ c\ \int_S^T ||u_1||_H^2\ dt + cE(U'(S)) + cE(U(S))\right) \quad \forall\ 0 \le S \le T, \end{aligned} \tag{31}$$

so that for

$$0 < |\alpha| < \min\left(\alpha_0, \sqrt{\frac{\gamma}{4\gamma_2 c\beta_1^2||P||^2}}\right) = \alpha_1$$

we have

$$\begin{aligned} 0 &\le \left(1 - \frac{4\gamma_2\alpha^2 c\beta_1^2||P||^2}{\gamma}\right)\int_S^T e_1(u_1,v_1)(t))\ dt \\ &\le \gamma_1(e_1((u_1,v_1)(S)) + e_1((u_1,v_1)(T))) \\ &\quad + c(\alpha)(E(U'(S)) + E(U(S))) \quad \forall\ 0 \le S \le T. \end{aligned}$$

Hence, thanks to Proposition 2.4, we have

$$\int_S^T e_1((u_1,v_1)(t))\ dt \le c(\alpha)(E(U(S)) + E(U'(S))) \quad \forall\ 0 \le S \le T, \tag{32}$$

where $c(\alpha)$ is a constant that depends on α but is bounded with respect to it for any $\alpha \in [r_1,r_2]$, for any $0 < r_1 < r_2 < \alpha_1$. In all of what follows, we will denote by $c(\alpha)$ a generic constant verifying these properties. ∎

LEMMA 3.10. *Assume the hypotheses of Theorem* 3.3. *Then for all* $0 < |\alpha| < \alpha_0$ *and all* $U^0 = (u_1^0,u_2^0,u_1^1,u_2^1) \in D(\mathcal{A}_\alpha^2)$ *the solution* $U(t) = \exp(-t\mathcal{A}_\alpha)U^0 = (u_1,u_2,v_1,v_2)$ *of* (10) *satisfies*

$$\int_S^T e_2((u_2,v_2)(t))\ dt \le c(\alpha)(E(U(S)) + E(U'(S)) + E(U''(S))) \quad \forall\ 0 \le S \le T.$$

Proof. Since (29) holds for every $U^0 \in D(\mathcal{A}_\alpha)$, we deduce that for any $U^0 \in D(\mathcal{A}_\alpha^2)$ we have

$$\begin{aligned} \frac{\alpha\gamma}{2}\int_S^T ||u_2'||_H^2\ dt &\le \alpha c \int_S^T ||u_1'||_H^2\ dt + c(E(U'(S)) + E(U''(S))) \\ &\quad \forall\ 0 \le S \le T,\ U^0 \in D(\mathcal{A}_\alpha^2). \end{aligned} \tag{33}$$

On the other hand, thanks to the third relation in (23), we have

$$\int_S^T (u_2'' + A_2 u_2 + \alpha P^\star u_1, u_2)_H \; dt = 0,$$

so that we have

$$\int_S^T e_2((u_2, v_2)(t)) \; dt = \int_S^T ||u_2'||_H^2 \; dt - \frac{1}{2}[(u_2', u_2)_H]_S^T - \frac{\alpha}{2} \int_S^T (u_1, Pu_2)_H \; dt.$$

Hence, using (32) and (33) in this last relation, we obtain

$$\int_S^T e_2((u_2, v_2)(t)) \; dt \le c(\alpha) \; (E(U(S)) + E(U'(S)) + E(U''(S))) \quad \forall \; 0 \le S \le T. \tag{34}$$

□

Proof of Theorem 3.3. Combining (32) and (33) with the inequality of Proposition 2.4, we finally obtain for $0 < |\alpha| < \alpha_1$

$$\int_S^T E(U(t))\, dt \le c(\alpha)(E(U(S)) + E(U'(S)) + E(U''(S))) \quad \forall\, 0 \le S \le T, \; U^0 \in D(\mathcal{A}_\alpha^2).$$

Now applying Theorem 3.1 with $k = 2$, we deduce that

$$E(U(t)) \le \frac{c(\alpha)}{t^n} \left(\sum_{p=0}^{2n} E(U^{(p)}(0)) \right) \quad \forall \; t > 0, \; U^0 \in D(\mathcal{A}_\alpha^{2n}).$$

The strong stability result follows easily, thanks to the above inequality for $n = 1$ and since $\exp(-t\mathcal{A}_\alpha)$ is a contraction semigroup on $\mathcal{H}$, and $D(\mathcal{A}_\alpha^2)$ is dense in $\mathcal{H}$. □

4. Applications.

4.1. The case $A_0 = A_2$. In all of what follows, Ω is a nonempty bounded open set in $\mathbb{R}^N$ having a boundary Γ of class C^2, $\{\Gamma_0, \Gamma_1\}$ is a partition of Γ such that $\overline{\Gamma}_0 \cap \overline{\Gamma}_1 = \emptyset$, and x_0 is a point in $\mathbb{R}^N$ such that $m \cdot \nu \le 0$ on Γ_0 and $m \cdot \nu \ge \beta > 0$ on Γ_1, where $m(x) = x - x_0$. We set $\sup_\Omega ||m|| = R$. Moreover, we set $H^p_{\Gamma_0}(\Omega) = \{u \in H^p(\Omega), u = \cdots = \frac{\partial^p u}{\partial \nu^p} = 0 \text{ on } \Gamma_0\}$.

Coupled wave equations with the same speed of propagation. We consider the system

$$\begin{cases} u_{1,tt} - \Delta u_1 + \alpha u_2 = 0 \quad \text{in} \quad \Omega \times (0, \infty), \\ u_{2,tt} - \Delta u_2 + \alpha u_1 = 0 \quad \text{in} \quad \Omega \times (0, \infty), \\ u_1 = u_2 = 0 \quad \text{on} \quad \Sigma_0 = \Gamma_0 \times (0, \infty), \\ \dfrac{\partial u_1}{\partial \nu} + a u_1 + \ell u_{1,t} = 0, u_2 = 0 \quad \text{on} \quad \Sigma_1 = \Gamma_1 \times (0, \infty), \\ (u_1, u_{1,t})(0) = (u_1^0, u_1^1), (u_2, u_{2,t})(0) = (u_2^0, u_2^1) \quad \text{on} \quad \Omega, \end{cases} \tag{35}$$

where

$$a = (N-1)m \cdot \frac{\nu}{2R^2}, \qquad l = m \cdot \frac{\nu}{R}. \tag{36}$$

For clarity, we will assume that $a \neq 0$ or $\text{meas}(\Gamma_0) > 0$, where the measure stands for the Lebesgue measure. We set $H = L^2(\Omega)$ and $V_1 = H^1_{\Gamma_0}(\Omega)$, equipped, respectively, with the L^2 scalar product and the scalar product $(u,z)_{V_1} = \int_\Omega \nabla u \cdot \nabla z + \int_{\Gamma_1} auz$ and the corresponding norms. Moreover, we set $V_2 = H^1_0(\Omega)$, equipped with the scalar product $(u,z)_{V_2} = \int_\Omega \nabla u \cdot \nabla z$ and the associated norm. We define the duality mappings A_1 and A_2 as in section 2. Moreover, we define a continuous linear operator B from V_1 to V_1' by

$$\langle Bu,\ z\rangle_{V_1',V_1} = \int_{\Gamma_1} \ell uz \, d\gamma.$$

Then B satisfies (9). We also set $P = P^\star = \text{Id}_H$. Then system (35) can be rewritten under the form (10) with the above notation. The energy of a solution $U = (u_1, u_2, v_1, v_2)$ is then given by

$$E(U(t)) = \frac{1}{2}(||u_1||^2_{V_1} + ||u_2||^2_{V_2} + ||u_{1,t}||^2_H + ||u_{2,t}||^2_H) + \alpha(u_1,u_2)_H. \tag{37}$$

To prove polynomial decay of the solutions, we need only to check that the assumptions of Corollary 3.5 are satisfied. For the sake of simplicity we will assume that $N \geq 3$. We begin with assumption (H1). Let (u_1, v_1) be a solution of the system considered in hypothesis (H1); then u_1 satisfies

$$\begin{cases} u_{1,tt} - \Delta u_1 = f_1 \quad \text{in} \quad \Omega \times (0,\infty), \\ u_1 = 0 \quad \text{on} \quad \Sigma_0 = \Gamma_0 \times (0,\infty), \\ \dfrac{\partial u_1}{\partial \nu} + au_1 + \ell u_{1,t} = 0 \quad \text{on} \quad \Sigma_1 = \Gamma_1 \times (0,\infty), \\ (u_1, u_{1,t})(0) = (u_1^0, u_1^1) \in \mathcal{H}_1 \quad \text{on} \quad \Omega. \end{cases} \tag{38}$$

Then, proceeding as in [18, Theorem 8.6], we use the multiplier $Mu_1 = m \cdot \nabla u_1 + \frac{(N-1)}{2} u_1$ in the first equation of (38). We obtain the identity

$$\begin{aligned} &\int_S^T e_1((u_1,v_1)(t))\, dt \\ &\quad = \int_S^T (f_1, Mu_1)_H \, dt + [(u_{1,t}, Mu_1)_H]_T^S + \frac{1}{2}\int_S^T \int_{\Gamma_0} m \cdot \nu \left|\frac{\partial u_1}{\partial \nu}\right|^2 d\gamma \, dt \\ &\quad + \int_S^T \int_{\Gamma_1} \frac{m\cdot\nu}{2}(|u_{1,t}|^2 - |\nabla u_1|^2 + bu_1^2 - 2(bu_1 + ku_{1,t})Mu_1)\, d\gamma \, dt. \end{aligned} \tag{39}$$

Now, recalling that the following three inequalities hold for all $t \geq 0$ (see [18, pp. 106–108]),

$$\begin{aligned} |(u_{1,t}, Mu_1)_H| &\leq e_1((u_1,v_1)(t)), \\ |u_{1,t}|^2 - |\nabla u_1|^2 + bu_1^2 - 2(bu_1 + ku_{1,t})Mu_1 &\leq 2|u_{1,t}|^2 \text{ on } \Gamma_1, \\ ||Mu_1||^2_H &\leq 2R^2 e_1((u_1,v_1)(t)), \end{aligned}$$

and using them in (39), we deduce that for all $\varepsilon > 0$ we have

$$\int_S^T e_1((u_1,v_1),t)\,dt \le \frac{R}{1-\varepsilon R^2}(e_1((u_1,v_1)(S)) + e_1((u_1,v_1)(T))) + \frac{1}{2\varepsilon(1-\varepsilon R^2)}\int_S^T ||f_1||_H^2\,dt + \frac{R}{1-\varepsilon R^2}\int_S^T \langle Bu_{1,t}, u_{1,t}\rangle_{V_1',V_1}\,dt. \tag{40}$$

Now choosing $\varepsilon = 1/R^2$, we deduce that the hypothesis (H1) is satisfied with $\gamma_1 = \gamma_3 = 2R$ and $\gamma_2 = 1/2R^2$.

We now check hypothesis (H2). We set $V_0 = V_2$. For the sake of clarity, we identify $i(\phi)$ with ϕ for $\phi \in V_0$ (where i is the canonical injection from V_0 in V_1). We remark that the first equality in assumption (H2) is trivially satisfied, thanks to the definition of B and V_0. We define P_0 and A_0 as in section 2. Then P_0u_1 is the weak solution of

$$\begin{cases} -\Delta P_0 u_1 = -\Delta u_1 \quad \text{in} \quad \Omega, \\ P_0 u_1 \in V_0, \end{cases}$$

and A_0 is defined by

$$\langle A_0\phi, \psi\rangle_{V_0',V_0} = \int_\Omega \nabla\phi\cdot\nabla\psi\,dx \qquad \forall\psi,\ \phi\in V_0. \tag{41}$$

We now check the second relation in (H2). For this, we set $z = u_1 - P_0u_1$. Therefore, z is the weak solution of

$$\begin{cases} -\Delta z = 0 \quad \text{in} \quad \Omega, \\ z = u_1 \quad \text{on} \quad \Gamma. \end{cases}$$

Notice that this function has been introduced by [9] in a different framework. By classical results on elliptic theory, we deduce that there exists a constant $c > 0$ such that

$$||z||_H \le c||u_{1|\Gamma_1}||_{L^2(\Gamma_1)},$$

so that, since $m\cdot\nu \ge \delta > 0$ and $\ell = \frac{m\cdot\nu}{R}$ on Γ_1, there exists $\beta > 0$ such that

$$||z||_H^2 \le \beta\ \langle Bu_1, u_1\rangle_{V_1',V_1} \qquad \forall u_1 \in V_1.$$

On the other hand, since $V_0 = V_2$ and (41) holds, we deduce that assumption (H3)$'$ is satisfied. In addition, since $P = \mathrm{Id}_H$, assumption (H4)$'$ is verified with $\gamma = 1$. Now applying Corollary 3.5, we deduce the following result.

THEOREM 4.1. *There exists an $\alpha_1 \in (0,\alpha_0]$ such that for all $0 < |\alpha| < \alpha_1$ the solution $U(t) = \exp(-\mathcal{A}_\alpha t)U^0$ of (35) satisfies*

$$E(U(t)) \le \frac{c}{t^n}\sum_{p=0}^{2n} E(U^{(p)}(0)) \qquad \forall\ t > 0,\ U^0 \in D(\mathcal{A}_\alpha^{2n}).$$

Moreover, strong stability holds in the energy space $\mathcal{H} = V_1 \times V_2 \times H^2$.

Coupled Kirchhoff–Petrowsky plates. Let $N = 2$, and assume that Ω is a nonempty bounded open set in $\mathbb{R}^N$ having a boundary Γ of class C^4. We assume as before that

$\{\Gamma_0, \Gamma_1\}$ is a partition of Γ such that $\overline{\Gamma}_0 \cap \overline{\Gamma}_1 = \emptyset$, and x_0 is a point in $\mathbb{R}^N$ such that $m \cdot \nu \leq 0$ on Γ_0 and $m \cdot \nu \geq \beta > 0$ on Γ_1, where $m(x) = x - x_0$. We set $\sup_\Omega ||m|| = R$.

We consider the system

$$
\left\{
\begin{array}{l}
u_{1,tt} + \Delta^2 u_1 + \alpha u_2 = 0 \quad \text{in} \quad \Omega \times (0, +\infty), \\
u_{2,tt} + \Delta^2 u_2 + \alpha u_1 = 0 \quad \text{in} \quad \Omega \times (0, +\infty), \\
u_1 = u_2 = 0 = \dfrac{\partial u_1}{\partial \nu} = \dfrac{\partial u_2}{\partial \nu} \quad \text{on} \quad \Sigma_0 = \Gamma_0 \times (0, +\infty), \\
\Delta u_1 + (1-\mu) B_1 u_1 = -km \cdot \nu \dfrac{\partial u_{1,t}}{\partial \nu}, \qquad u_2 = 0 = \dfrac{\partial u_2}{\partial \nu} \quad \text{on} \quad \Sigma_1, \\
\dfrac{\partial \Delta u_1}{\partial \nu} + (1-\mu) \dfrac{\partial B_2 u_1}{\partial \tau} = \ell m \cdot \nu u_{1,t} \quad \text{on} \quad \Sigma_1, \\
(u_1, u_{1,t})(0) = (u_1^0, u_1^1), \quad (u_2, u_{2,t})(0) = (u_2^0, u_2^1) \quad \text{on} \quad \Omega.
\end{array}
\right. \tag{42}
$$

We assume that $\text{meas}(\Gamma_0) > 0$, that the functions k and ℓ are continuous functions on Γ_1, and that there exist constants k_0, k_1 ℓ_0, and ℓ_1 such that

$$k_1 \geq k \geq k_0 > 0, \quad \ell_1 \geq \ell \geq \ell_0 > 0 \quad \text{on} \quad \Gamma_1.$$

We refer the reader to [22] for more details on this model. The constant $\mu \in (0, 1/2)$ is the Poisson coefficient, and the boundary operators B_1 and B_2 are defined by

$$
\begin{aligned}
B_1 v &= 2\nu_1 \nu_2 v_{xy} - \nu_1^2 v_{yy} - \nu_2^2 v_{xx}, \\
B_2 v &= (\nu_1^2 - \nu_2^2) v_{xy} + \nu_1 \nu_2 (v_{xx} - v_{yy}),
\end{aligned}
$$

where the subscripts x and y denote the partial derivatives with respect to the first and second components of the space variable. We set $H = L^2(\Omega)$ (equipped with the usual norm and scalar product) and $V_1 = H^2_{\Gamma_0}(\Omega)$, equipped with the scalar product

$$(u, z)_{V_1} = \int_\Omega (u_{xx} z_{xx} + u_{yy} z_{yy} + \mu(u_{xx} z_{yy} + u_{yy} z_{xx}) + 2(1-\mu) u_{xy} z_{xy})\, dx\, dy$$

and the associated norm. Moreover, we set $V_2 = H_0^2(\Omega)$, equipped with the scalar product

$$(u, z)_{V_2} = \int_\Omega \Delta u \Delta z \, dx \, dy$$

and the associated norm. We define the duality mappings A_1, A_2 as in section 2. Moreover, we define a linear continuous operator B from V_1 to V_1' by

$$\langle Bu, z \rangle_{V_1', V_1} = \int_{\Gamma_1} m \cdot \nu \left(\ell \, uz + k \, \frac{\partial u}{\partial \nu} \frac{\partial z}{\partial \nu} \right) d\gamma.$$

Then B satisfies (9). We also set $P = P^\star = \text{Id}_H$. Then the system (42) can be rewritten under the form (10) with the above notation. The energy of a solution $U = (u_1, u_2, v_1, v_2)$ is then defined as in (37). We now check the assumptions of Corollary 3.5. We begin with assumption (H1). Let (u_1, v_1) be a solution of the system considered in hypothesis (H1); then u_1 satisfies

$$
\left\{
\begin{array}{l}
u_{1,tt} + \Delta^2 u_1 = f_1 \quad \text{in} \quad \Omega \times (0, \infty), \\
u_1 = \dfrac{\partial u_1}{\partial \nu} = 0 \quad \text{on} \quad \Sigma_0 = \Gamma_0 \times (0, \infty), \\
\Delta u_1 + (1-\mu) B_1 u_1 = -km \cdot \nu \dfrac{\partial u_{1,t}}{\partial \nu} \quad \text{on} \quad \Sigma_1, \\
\dfrac{\partial \Delta u_1}{\partial \nu} + (1-\mu) \dfrac{\partial B_2 u_1}{\partial \tau} = \ell m \cdot \nu u_{1,t} \quad \text{on} \quad \Sigma_1, \\
(u_1, u_{1,t})(0) = (u_1^0, u_1^1) \quad \text{on} \quad \Omega.
\end{array}
\right. \tag{43}
$$

We then proceed as in [22]. Consider the relation

$$\int_S^T (u_{1,tt} + \Delta^2 u_1, m \cdot \nabla u_1)_H \, dt = \int_S^T (f_1, m \cdot \nabla u_1)_H \, dt. \tag{44}$$

This leads to the inequality (see [22])

$$\begin{aligned} 2 \int_S^T & e_1((u_1, v_1)(t)) \, dt \\ &= \int_S^T (f_1, m \cdot \nabla u_1)_H \, dt + [(u_{1,t}, m \cdot \nabla u_1)_H]_T^S + \frac{1}{2} \int_S^T \int_{\Gamma_0} m \cdot \nu (\Delta u_1)^2 \, d\gamma \, dt \\ &\quad + \frac{1}{2} \int_S^T \int_{\Gamma_1} m \cdot \nu |u_{1,t}|^2 \, d\gamma \, dt \\ &\quad - \int_S^T \int_{\Gamma_1} m \cdot \nu \left(\ell u_{1,t} m \cdot \nabla u_1 + k \frac{\partial u_{1,t}}{\partial \nu} \frac{\partial m \cdot \nabla u_1}{\partial \nu} \right) d\gamma \, dt \\ &\quad - \frac{1}{2} \int_S^T \int_{\Gamma_1} m \cdot \nu (u_{1xx}^2 + u_{1yy}^2 + 2\mu u_{1xx} u_{1yy} + 2(1-\mu) u_{1xy}^2) \, d\gamma \, dt. \end{aligned} \tag{45}$$

We now estimate the terms on the right-hand side of the above inequality. We first denote by λ_0 the smallest positive constant such that

$$||\nabla u||_H^2 \le \lambda_0^2 ||u||_{V_1}^2 \qquad \forall u \in H_{\Gamma_0}^2(\Omega), \tag{46}$$

and by μ_0 the smallest positive constant such that

$$\int_{\Gamma_1} |\nabla u|^2 \, d\gamma \le \mu_0^2 ||u||_{V_1}^2 \qquad \forall u \in H_{\Gamma_0}^2(\Omega). \tag{47}$$

Now, using (46) and for all $\varepsilon > 0$, we estimate the first term of (45) as follows:

$$\begin{aligned} \int_S^T (f_1, m \cdot \nabla u_1)_H \, dt &\le \frac{1}{2\varepsilon} \int_S^T ||f_1||_H^2 \, dt + \frac{\varepsilon R^2}{2} \int_S^T ||\nabla u_1||_H^2 \, dt \\ &\le \frac{1}{2\varepsilon} \int_S^T ||f_1||_H^2 \, dt + \varepsilon R^2 \lambda_0^2 \int_S^T e_1((u_1, v_1)(t)) \, dt. \end{aligned} \tag{48}$$

We now consider the second term of (45). Using (46) once again, we deduce that

$$|[(u_{1,t}, m \cdot \nabla u_1)_H]_T^S| \le R\lambda_0 (e_1((u_1, v_1)(S)) + e_1((u_1, v_1)(T))). \tag{49}$$

Since $m \cdot \nu \le 0$ on Γ_0, we estimate the third term of (45) as follows:

$$\frac{1}{2} \int_S^T \int_{\Gamma_0} m \cdot \nu (\Delta u_1)^2 \, d\gamma \, dt \le 0. \tag{50}$$

We now consider the fourth term in (45). We have, thanks to our assumptions on ℓ and k,

$$\begin{aligned} \frac{1}{2} \int_S^T \int_{\Gamma_1} m \cdot \nu |u_{1,t}|^2 \, d\gamma \, dt &\le \frac{1}{2\ell_0} \int_S^T \int_{\Gamma_1} m \cdot \nu \left(\ell |u_{1,t}|^2 + k \left| \frac{\partial u_{1,t}}{\partial \nu} \right|^2 \right) d\gamma \, dt \\ &= \frac{1}{2\ell_0} \int_S^T \langle B u_{1,t}, u_{1,t} \rangle_{V_1', V_1} \, dt. \end{aligned} \tag{51}$$

We now turn to the fifth term in (45). Using well-known estimates (see [22]), we obtain that for all $\delta > 0$

$$\begin{aligned}
&\left| \int_S^T \int_{\Gamma_1} m \cdot \nu \left(\ell u_{1,t} m \cdot \nabla u_1 + k \frac{\partial u_{1,t}}{\partial \nu} \frac{\partial m \cdot \nabla u_1}{\partial \nu} \right) d\gamma \ dt \right| \\
&\quad \leq \frac{1}{2\delta} \int_S^T \langle B u_{1,t}, u_{1,t} \rangle_{V_1',V_1} \ dt + \frac{\delta}{2} \int_S^T \int_{\Gamma_1} m \cdot \nu (R^2 \ell + 2k) |\nabla u_1|^2 \ d\gamma \ dt \\
&\quad + \frac{\delta R^2}{1-\mu} \int_S^T \int_{\Gamma_1} k m \cdot \nu (u_{1xx}^2 + u_{1yy}^2 + 2\mu u_{1xx} u_{1yy} + 2(1-\mu) u_{1xy}^2) d\gamma \ dt \qquad (52) \\
&\quad \leq \frac{1}{2\delta} \int_S^T \langle B u_{1,t}, u_{1,t} \rangle_{V_1',V_1} \ dt \ + \frac{\delta}{2} (R^2 \ell_1 + 2k_1) R \mu_0^2 \int_S^T ||u_1||_{V_1}^2 \ dt \\
&\quad + \frac{\delta R^2 k_1}{1-\mu} \int_S^T \int_{\Gamma_1} m \cdot \nu \left(u_{1xx}^2 + u_{1yy}^2 + 2\mu u_{1xx} u_{1yy} + 2(1-\mu) u_{1xy}^2 \right) d\gamma \ dt.
\end{aligned}$$

Using the estimates (48)–(52) in (45), we obtain for all $\varepsilon > 0$ and all $\delta > 0$

(53)

$$\begin{aligned}
&(2 - \varepsilon R^2 \lambda_0^2 - \delta (R^2 \ell_1 + 2k_1) R \mu_0^2) \int_S^T e_1((u_1, v_1), t) \ dt \leq \frac{1}{2\varepsilon} \int_S^T ||f_1||_H^2 \ dt \\
&\quad + R \lambda_0 (e_1((u_1, v_1)(S)) + e_1((u_1, v_1)(T))) + \left(\frac{1}{2\ell_0} + \frac{1}{2\delta} \right) \int_S^T \langle B u_{1,t}, u_{1,t} \rangle_{V_1',V_1} \ dt \\
&\quad + \left(\frac{\delta R^2 k_1}{1-\mu} - \frac{1}{2} \right) \int_S^T \int_{\Gamma_1} m \cdot \nu (u_{1xx}^2 + u_{1yy}^2 + 2\mu u_{1xx} u_{1yy} + 2(1-\mu) u_{1xy}^2) \ d\gamma \ dt.
\end{aligned}$$

Now choosing any δ such that

$$0 < \delta < \min \left(\frac{1-\mu}{2R^2 k_1}, \frac{2}{R \mu_0^2 (R^2 \ell_1 + 2k_1)} \right)$$

and then

$$0 < \varepsilon < \frac{2 - \delta R \mu_0^2 (R^2 \ell_1 + 2k_1)}{R^2 \lambda_0^2},$$

we prove that the desired inequality in assumption (H1) is satisfied with the corresponding γ_i, for $i = 1, 2, 3$. We now check assumption (H2). We set $V_0 = V_2$, and for the sake of clarity, we identify, as before, $i(\phi)$ with ϕ for any $\phi \in V_0$. Thanks to the definition of B and V_0, the first relation of (H2) is trivially satisfied. On the other hand, since the set of $\mathcal{C}^\infty$-functions on Ω with compact support in Ω is dense in V_0, we deduce that

$$\langle A_1 u, z \rangle_{V_1',V_1} = \int_\Omega \Delta u \Delta z \ dx \ dy \qquad \forall z \in V_0. \qquad (54)$$

Hence, for every $u_1 \in V_1$, $P_0 u_1$ is the weak solution of

$$\begin{cases} \Delta^2 (P_0 u_1) = \Delta^2 (u_1), \\ P_0 u_1 \in H_0^2(\Omega). \end{cases}$$

We set $z = u_1 - P_0 u_1$; then z is the weak solution of

$$\begin{cases} \Delta^2 z = 0, \\ z = u_1, \quad \dfrac{\partial z}{\partial \nu} = \dfrac{\partial u_1}{\partial \nu} \quad \text{on } \Gamma. \end{cases}$$

From classical results, based on elliptic theory, we know that there exists a constant $c > 0$ such that, for every $u_1 \in V_1$, we have

$$||z||_H^2 \le c \int_{\Gamma_1} \left(|u_1|^2 + \left| \frac{\partial u_1}{\partial \nu} \right|^2 \right) \, d\gamma.$$

Since $m \cdot \nu \ge \delta > 0$, $\ell \ge \ell_0 > 0$, and $k \ge k_0 > 0$ on Γ_1, we deduce that

$$||z||_H^2 \le C \langle Bu_1, u_1 \rangle_{V_1', V_1},$$

so that the second relation in (H2) is satisfied. Moreover, thanks to (54) and since $V_0 = V_2$ holds, assumption (H3)$'$ is satisfied. Finally, since $P = \mathrm{Id}_H$, assumption (H4)$'$ is trivially satisfied with $\gamma = 1$. Hence, we can apply Corollary 3.5. We deduce the following result.

THEOREM 4.2. *There exists an $\alpha_1 \in (0, \alpha_0]$ such that for all $0 < |\alpha| < \alpha_1$ the solution $U(t) = \exp(-\mathcal{A}_\alpha t) U^0$ of (42) satisfies*

$$E(U(t)) \le \frac{c}{t^n} \sum_{p=0}^{2n} E(U^{(p)}(0)) \qquad \forall\ t > 0,\ U^0 \in D(\mathcal{A}_\alpha^{2n}).$$

Moreover, strong stability holds in the energy space $\mathcal{H} = V_1 \times V_2 \times H^2$.

4.2. Case of different operators A_0 and A_2. In order to avoid loss of regularity of the solutions, we assume in this subsection that $\Gamma_0 = \emptyset$. Hence we do not treat the case of mixed boundary conditions. Nevertheless, the results are still valid for a more general situation (see [11, 12, 13]).

Coupled wave equations with different speed of propagation. We consider the following system:

$$\begin{cases} u_{1,tt} - c_1 \Delta u_1 + \alpha P u_2 = 0 \quad \text{in} \quad \Omega \times (0, \infty), \\ u_{2,tt} - c_2 \Delta u_2 + \alpha P^\star u_1 = 0 \quad \text{in} \quad \Omega \times (0, \infty), \\ \dfrac{\partial u_1}{\partial \nu} + a u_1 + \ell u_{1,t} = 0, \quad u_2 = 0 \quad \text{on} \quad \Sigma = \Gamma \times (0, \infty), \\ (u_1, u_{1,t})(0) = (u_1^0, u_1^1), \quad (u_2, u_{2,t})(0) = (u_2^0, u_2^1) \quad \text{on} \quad \Omega, \end{cases} \tag{55}$$

where $c_i > 0$, $i = 1, 2$, and

$$a = (N-1) m \cdot \frac{\nu}{2R^2}, \qquad l = \frac{m \cdot \nu}{R\sqrt{c_1}}. \tag{56}$$

We mainly keep the notation of section 4.1. We set $H = L^2(\Omega)$ and $V_1 = H^1(\Omega)$, equipped, respectively, with the L^2 scalar product and the scalar product $(u, z)_{V_1} = c_1 \int_\Omega \nabla u \cdot \nabla z + c_1 \int_\Gamma auz$ and the corresponding norms. Moreover, we set $V_2 = H_0^1(\Omega)$, equipped with the scalar product $(u, z)_{V_2} = c_2 \int_\Omega \nabla u \cdot \nabla z$ and the associated norm.

We define the duality mappings A_1 and A_2 as in section 2. Moreover, we define a continuous linear operator B from V_1 to V_1' by

$$\langle Bu,\ z\rangle_{V_1',V_1} = c_1 \int_\Gamma \ell u z \ d\gamma.$$

Then B satisfies (9). We assume for the moment that P is a given bounded operator in H. Then the system (55) can be rewritten under the form (10) with the above notation. The energy of a solution $U = (u_1, u_2, v_1, v_2)$ is then given by

$$E(U(t)) = \frac{1}{2}(||u_1||^2_{V_1} + ||u_2||^2_{V_2} + ||u_{1,t}||^2_H + ||u_{2,t}||^2_H) + \alpha(u_1, u_2)_H. \tag{57}$$

To prove polynomial decay of the solutions, we need to check only that the assumptions of Lemma 3.6 are satisfied. We begin with assumption (H1). Let (u_1, v_1) be a solution of the system considered in hypothesis (H1); then u_1 satisfies

$$\begin{cases} u_{1,tt} - c_1\Delta u_1 = f_1 \quad \text{in} \quad \Omega \times (0,\infty), \\ \dfrac{\partial u_1}{\partial \nu} + a u_1 + \ell u_{1,t} = 0 \quad \text{on} \quad \Sigma = \Gamma \times (0,\infty), \\ (u_1, u_{1,t})(0) = (u_1^0, u_1^1) \in \mathcal{H}_1 \quad \text{on} \quad \Omega. \end{cases} \tag{58}$$

Then, making the change of time variable $s = \sqrt{c_1}t$, we obtain a system similar to system (38), where f_1 is replaced by f_1/c_1, and ℓ is replaced by $\sqrt{c_1}\ell$. However, as will be seen later, hypothesis (H3) can be checked only for domains Ω which are N-dimensional intervals $\prod_{i=1}^N (a_i, b_i)$, where $a_i < b_i$, $i = 1, \dots, N$, and $N \le 3$. Of course, for such domains the boundary is no longer of class $\mathcal{C}^2$. Therefore we need to check that all the computations performed earlier are still valid in this case. For this, we make the following statement.

Important Remark. We recall that when Ω is a convex polygon (case $N = 2$) or polyhedron (case $N = 3$), Grisvard's results (see [11], [12], and also [6]) on the solution of the Poisson equation

$$-\Delta u = f \in L^2(\Omega) \quad \text{in } \Omega,$$

subjected to either Dirichlet, Neumann, or oblique boundary conditions in such domains, say that these solutions are in $H^2(\Omega)$. Moreover, thanks to the above regularity result, all the classical results for the wave equation, subjected to either Dirichlet, Neumann, or oblique boundary conditions (in particular, the well-known multiplier identity, which leads to the required estimate in our hypothesis (H1)), are still valid for convex polygons or polyhedra. Hence our hypothesis (H1) is verified when Ω is an N-dimensional interval $\prod_{i=1}^N (a_i, b_i)$, where $a_i < b_i$, $i = 1, \dots, N$, with $N \le 3$. (Let us remark that in that case the angles between corners as defined in Grisvard's results are all equal to $\pi/2$.)

We now check hypothesis (H2), assuming as before that Ω is an N-dimensional interval $\prod_{i=1}^N (a_i, b_i)$, where $a_i < b_i$, $i = 1, \dots, N$, and $N \le 3$. We set $V_0 = V_2$. For the sake of clarity, we identify $i(\phi)$ with ϕ for $\phi \in V_0$ (where i is the canonical injection from V_0 in V_1). We remark that the first equality in assumption (H2) is trivially satisfied, thanks to the definition of B and V_0. We define P_0 and A_0 as in section 2. Then $P_0 u_1$ is the weak solution of

$$\begin{cases} -\Delta P_0 u_1 = -\Delta u_1 \quad \text{in} \quad \Omega, \\ P_0 u_1 \in V_0. \end{cases}$$

We now check that the second relation in (H2) holds. We set $z = u_1 - P_0 u_1$. Then, thanks to the above important remark on the regularity of solutions of the Poisson equation subjected to oblique boundary conditions in convex polygons or polyhedra, we know that $u_1(t)$ is in $H^2(\Omega)$ for any positive t. On the other hand, thanks to similar results (the Dirichlet case), we know that $P_0 u_1$ is also in $H^2(\Omega)$. Therefore, $z(\cdot)$ is in $H^2(\Omega)$ for any positive t. Moreover, z is a strong solution of

$$\begin{cases} -\Delta z = 0 \quad \text{in} \quad \Omega, \\ z = u_1 \quad \text{on} \quad \Gamma. \end{cases}$$

In order to establish the second relation in (H2), we introduce the solution of the following Poisson equation:

$$\begin{cases} -\Delta w = z \quad \text{in} \quad \Omega, \\ w = 0 \quad \text{on} \quad \Gamma. \end{cases}$$

Then since $z \in L^2(\Omega)$ and thanks to Grisvard's results, we have that w is in $H^2(\Omega)$, so that the trace of the normal derivative of w on Γ is well defined as a function of $H^{1/2}(\Gamma)$. Moreover, we have

$$||w||_{V_1} \leq c||z||_H. \tag{59}$$

Multiplying the above equation by z, integrating by parts, and using the relation $\Delta z = 0$ in Ω and $z = u_1$ on Γ, we obtain the following equality:

$$\int_\Omega z^2 dx = \int_\Gamma u_1 \frac{\partial w}{\partial \nu} d\gamma. \tag{60}$$

Now using the classical multiplier $Mw = m \cdot \nabla w + \frac{N-1}{2} w$ and integrating by parts the expression

$$-\int_\Omega \Delta w M w dx,$$

we obtain that

$$\int_\Gamma m \cdot \nu \left| \frac{\partial w}{\partial \nu} \right|^2 d\gamma = \int_\Omega |\nabla w|^2 dx + 2 \int_\Omega z M w dx.$$

Using (59) in the above equality and since $m \cdot \nu \geq \beta > 0$ on Γ, we deduce that there exists a positive constant c such that

$$\int_\Gamma \left| \frac{\partial w}{\partial \nu} \right|^2 d\gamma \leq c||z||_H^2.$$

Using this last inequality in (60), we obtain

$$||z||_H \leq c||u_1||_{L^2(\Gamma)}.$$

Hence the second relation of (H2) is satisfied.

We now want to check assumption (H3). For this, we will use Lemma 3.6. As will be seen below, we can check this restrictive hypothesis only when Ω is an N-dimensional interval $\prod_{i=1}^N (a_i, b_i)$, where $a_i < b_i$, $i = 1, \ldots, N$, with $N \leq 3$.

We first note that we have, thanks to Grisvard's regularity results,

$$A_0 = -c_1\Delta, \qquad D(A_0) = H^2(\Omega) \cap H_0^1(\Omega),$$
$$A_2 = -c_2\Delta, \qquad D(A_2) = H^2(\Omega) \cap H_0^1(\Omega).$$

We denote by $A = -\Delta$ the unbounded operator in H with domain $D(A) = H^2(\Omega) \cap H_0^1(\Omega)$. Then, it is well known that there exists an orthonormal basis in H of eigenfunctions e_k of A associated to the eigenvalues $\lambda_k > 0$, for $k = 1, \dots$. Moreover, λ_k and e_k are such that

$$\begin{cases} -\Delta e_k = \lambda_k e_k & \text{in } \Omega, \\ e_k \in H_0^1(\Omega) \cap \mathcal{C}^\infty(\Omega). \end{cases}$$

Then, $\{e_k\}_{k=1}^\infty$ also forms an orthonormal basis of the unbounded operators A_0 and A_2, respectively. We denote by $\lambda_{i,k}$ the eigenvalue of the operator A_i associated to the eigenfunction e_k for $i = 0, 2$. When Ω is an N-dimensional interval, it is more convenient, as will be seen below, to consider $k = (k_1, \dots, k_N) \in (\mathbb{N}^\star)^N$. This notation will be used in all of what follows. We have the following result.

THEOREM 4.3. *Assume now that Ω is an N-dimensional interval $\prod_{i=1}^N (a_i, b_i)$, where $a_i < b_i$, $i = 1, \dots, N$, with $N \le 3$, and that there exists a positive integer k_0 such that $c_2 = k_0^2 c_1$. Moreover, assume that for $u = \sum_{k \in (N^\star)^N} u_k e_k$ in H, Pu is defined by*

$$Pu = \sum_{k \in (N^\star)^N} \delta_k u_k e_{k_0 k},$$

where the sequence of real numbers $(\delta_k)_k$ is such that there exist $\gamma > 0$ and δ with $0 < \gamma \le \delta_k \le \delta$. Then there exists an $\alpha_1 \in (0, \alpha_0]$ such that for all $0 < |\alpha| < \alpha_1$ the solution $U(t) = \exp(-\mathcal{A}_\alpha t)U^0$ of (55) satisfies

$$E(U(t)) \le \frac{c}{t^n} \sum_{p=0}^{2n} E(U^{(p)}(0)) \qquad \forall\ t > 0,\ U^0 \in D(\mathcal{A}_\alpha^{2n}).$$

Moreover, strong stability holds in the energy space $\mathcal{H} = V_1 \times V_2 \times H^2$.

Proof. Since Ω is an N-dimensional interval, we have for all $k = (k_1, \dots, k_N) \in (\mathbb{N}^\star)^N$

$$e_k(x_1, \dots, x_N) = \prod_{i=1}^N \sin\left(\frac{k_i \pi (x_i - a_i)}{b_i - a_i}\right),$$

whereas

$$\lambda_{i,k} = c_i \pi^2 \left(\sum_{i=1}^N \frac{k_i^2}{(b_i - a_i)^2}\right).$$

Thanks to the relation $c_2 = k_0^2 c_1$, we deduce that $\lambda_{2,k} = \lambda_{0,k_0 k}$ for all $k \in (N^\star)^N$, where $k_0 k = (k_0 k_1, \dots, k_0 k_N)$. Hence the assumptions of Lemma 3.6 are satisfied, and, in particular, assumption (H5), with the one-to-one application r defined on $(\mathbb{N}^\star)^N$ by $r(k) = k_0 k$ for k in $(\mathbb{N}^\star)^N$. We define C as in the proof of Lemma 3.6, that is

$$Cu = \sum_{k \in (N^\star)^N} u_k e_{r(k)}.$$

Then, thanks to the assumption on the sequence δ_k, we deduce that P satisfies (H4). Now applying Corollary 3.7, we conclude the proof. □

Remark. If the condition on the ratio of the two speeds of propagation is violated, one can show that, in some situations, the total energy does not decay to 0 at infinity. Indeed, assume that there exists a bounded operator C such that (H3) holds, but that C is not one-to-one, so that the assumption (H4) is not verified. This situation occurs, for instance, in the above example of two coupled wave equations, when $c_2/c_1 = p_0^2/q_0^2$, where $p_0 \in \mathbb{N}^\star$ and $q_0 > 1$ are integers with no common divisors. In this case, one can take the operator C defined by

$$Cu = \sum_{n \in (N^\star)^N} u_{nq_0} e_{np_0} \qquad \forall\ u = \sum_{k \in (N^\star)^N} u_k e_k \in H.$$

If P is any bounded operator on H that is not one-to-one (for instance, one can take $P = C$), then, setting $u_1 = 0$ and choosing any smooth function u_2 with values in the kernel of P such that

$$u_2'' + A_2 u_2 = 0,$$

the couple (u_1, u_2) is a solution of the full coupled system (10). Its energy is conserved, so it does not decay to zero at ∞ unless the initial conditions on u_2 and its first time derivative are zero. With the above choice of C, one can take, for instance, $u_2 = y(t)e_{(p_0,\dots,p_0)}$, where y satisfies the ordinary differential equation

$$y'' + \lambda_{2,(p_0,\dots,p_0)} y = 0$$

with nonzero initial data.

Coupled wave-Petrowsky equations. We consider the following system:

$$\text{(61)} \qquad \begin{cases} u_{1,tt} - \Delta u_1 + \alpha P u_2 = 0 \quad \text{in} \quad \Omega \times (0,\infty), \\ u_{2,tt} + \Delta^2 u_2 + \alpha P^\star u_1 = 0 \quad \text{in} \quad \Omega \times (0,\infty), \\ \dfrac{\partial u_1}{\partial \nu} + a u_1 + \ell u_{1,t} = 0, \quad u_2 = \Delta u_2 = 0 \quad \text{on} \quad \Sigma = \Gamma \times (0,\infty), \\ (u_1, u_{1,t})(0) = (u_1^0, u_1^1), \quad (u_2, u_{2,t})(0) = (u_2^0, u_2^1) \quad \text{on} \quad \Omega, \end{cases}$$

where

$$\text{(62)} \qquad a = (N-1)m \cdot \frac{\nu}{2R^2}, \qquad \ell = \frac{m \cdot \nu}{R}.$$

We mainly keep the notation of section 4.1. We set $H = L^2(\Omega)$ and $V_1 = H^1(\Omega)$, equipped, respectively, with the L^2 scalar product and the scalar product $(u,z)_{V_1} = \int_\Omega \nabla u \cdot \nabla z + \int_\Gamma auz$ and the corresponding norms. Moreover, we set $V_2 = H^2(\Omega) \cap H_0^1(\Omega)$, equipped with the scalar product $(u,z)_{V_2} = \int_\Omega \Delta u \cdot \Delta z$ and the associated norm. We define the duality mappings A_1 and A_2 as in section 2. Moreover, we define a continuous linear operator B from V_1 to V_1' by

$$\langle Bu,\ z\rangle_{V_1',V_1} = \int_\Gamma \ell u z \, d\gamma.$$

Then B satisfies (9). We assume for the moment that P is a given bounded operator in H. Then the system (61) can be rewritten under the form (10) with the above notation. The energy of a solution $U = (u_1, u_2, v_1, v_2)$ is then given by

$$\text{(63)} \qquad E(U(t)) = \frac{1}{2}(||u_1||_{V_1}^2 + ||u_2||_{V_2}^2 + ||u_{1,t}||_H^2 + ||u_{2,t}||_H^2) + \alpha(u_1, u_2)_H.$$

To prove polynomial decay of the solutions, we need to check only that the assumptions of Lemma 3.6 are satisfied. We first need to characterize the domain of the operator $A_2 = \Delta^2$, viewed as an unbounded operator in H. Now let u be given in $D(A_2)$. Then $u \in V_2$ and there exists a $f \in L^2(\Omega)$ such that

$$\int_\Omega \Delta u \Delta v dx = \int_\Omega f v dx \qquad \forall v \in V_2. \tag{64}$$

We set $w = \Delta u$. Since $u \in V_2$, we have $w \in L^2(\Omega)$. Moreover, thanks to (64), we have

$$\int_\Omega w \Delta v dx = \int_\Omega f v dx \qquad \forall v \in V_2. \tag{65}$$

Hence, since the space of $\mathcal{C}^\infty$-functions on Ω with compact support in Ω is continuously imbedded in V_2, we deduce that $\Delta w = f$ almost everywhere in Ω, so that $\Delta w \in L^2(\Omega)$. We cannot conclude directly because we have to prove that $w \in H_0^1(\Omega)$. For that, we proceed as follows.

We introduce the variational solution $\Theta \in H_0^1(\Omega)$ of

$$\Delta \Theta = f \quad \text{ in } \Omega.$$

Then, thanks to the above-mentioned Grisvard's results, we know that $\Theta \in V_2$. Using (65) and the definition of Θ, we easily deduce that

$$\int_\Omega w \Delta v dx = -\int_\Omega \nabla \Theta \cdot \nabla v dx = \int_\Omega \Theta \Delta v dx \qquad \forall v \in V_2, \tag{66}$$

so that we have

$$\int_\Omega (w - \Theta) \Delta v dx = 0 \qquad \forall v \in V_2. \tag{67}$$

We now choose as a test function v, the variational solution $v \in H_0^1(\Omega)$ of

$$\Delta v = w - \Theta \quad \text{ in } \Omega.$$

Then, thanks to the above-mentioned Grisvard's results, we know that $v \in V_2$. Now using (67) with this specially chosen v, we obtain that

$$\int_\Omega |w - \Theta|^2 dx = 0. \tag{68}$$

Hence we have $w = \Theta$ almost everywhere on Ω, so that $w = 0$ on Γ. Hence, thanks again to Grisvard's regularity results for the Poisson equation subjected to homogeneous Dirichlet boundary conditions, we have $w \in H^2(\Omega) \cap H_0^1(\Omega)$. Hence, we have proved that when $u \in D(A_2)$, then $u \in V_2$ satisfies

$$\Delta u = w \in H^2(\Omega) \cap H_0^1(\Omega) \quad \text{ in } \Omega.$$

Then, thanks to Grisvard's results (see, for instance, [12, section 2.7]) for convex polygons or polyhedra, we know that u is indeed in $H^3(\Omega)$, since the involved angles in an N-dimensional interval are all equal to $\pi/2$. Hence the traces of all second derivatives of u on Γ are well defined, and, moreover, we have

$$\Delta u = w = 0 \quad \text{ on } \Gamma. \tag{69}$$

We will now prove that u is indeed in $H^4(\Omega)$. We proceed as follows. Let us, for instance, assume that $N = 3$, and let us choose one of the six faces, denoted by Γ_3, of the surface Γ, the normal to which is along the x_3-direction. Then the tangential directions to Γ_3 are in the x_i-directions for $i = 1, 2$ on Γ_3. Since $u = 0$ on Γ, we deduce that

$$\frac{\partial^2 u}{\partial x_i^2} = 0 \quad \text{on } \Gamma_3 \quad \text{for } i = 1, 2.$$

Then, thanks to (69), we deduce that

$$\frac{\partial^2 u}{\partial x_3^2} = 0 \quad \text{on } \Gamma_3.$$

For each other face of Γ–Γ_3, the normal to it is either in the x_1- or x_2-directions; hence x_3 is always a tangential direction to it. Since $u = 0$ on Γ, we deduce that

$$\frac{\partial^2 u}{\partial x_3^2} = 0 \quad \text{on } \Gamma - \Gamma_3.$$

Now we set $z = \partial^2 u/\partial x_3^2$. Then z is the solution of

$$\Delta z = \frac{\partial^2 w}{\partial x_3^2} \in L^2(\Omega) \quad \text{in } \Omega,$$

with homogeneous boundary conditions on Γ. Hence from Grisvard's regularity results we deduce that z is in $H^2(\Omega)$. We proceed in a similar way for the other fourth order derivatives of u and show in this way that u is in $H^4(\Omega)$. Hence we have proved that $D(A_2) = \{u \in H^4(\Omega) \cap H_0^1(\Omega),\ \Delta u = 0 \text{ on } \Gamma\}$. Hence all the integrations by parts required for the definition of weak solutions of the above coupled wave-Petrowsky system are justified for data in the domain of the operator.

For the sake of clarity, we identify $i(\phi)$ with ϕ for $\phi \in V_0$ (where i is the canonical injection from V_0 in V_1). We define P_0 and A_0 as in section 2. From the former example on wave-wave equations with different speeds of propagation in an N-dimensional interval, with $N \leq 3$, we already know that the hypotheses (H1) and (H2) are satisfied. We now want to check assumption (H3). For this, we will use Lemma 3.6. We first note that we have

$$\begin{aligned} &A_0 = -\Delta, \quad D(A_0) = H^2(\Omega) \cap H_0^1(\Omega), \\ &A_2 = \Delta^2, \quad D(A_2) = \{u \in H^4(\Omega),\ u = \Delta u = 0 \text{ on } \Gamma\}. \end{aligned}$$

We have already remarked that there exists an orthonormal basis in H of eigenfunctions e_k of A_0 associated to the eigenvalues $\lambda_{0,k} > 0$, for $k \in (N^\star)^N$. Moreover, $\lambda_{0,k} > 0$ and e_k are such that

$$\begin{cases} -\Delta e_k = \lambda_{0,k} e_k & \text{in } \Omega, \\ e_k \in H_0^1(\Omega) \cap \mathcal{C}^\infty(\Omega). \end{cases}$$

Then $\{e_k\}_{k \in (N^\star)^N}$ also forms an orthonormal basis of the unbounded operator A_2, with the corresponding eigenvalues $\lambda_{2,k} = \lambda_{0,k}^2$. Then assumption (H5) of Lemma 3.6 is satisfied if and only if there exists a one-to-one application r on $(\mathbb{N}^\star)^N$ such that,

for all $k \in (\mathbb{N}^\star)^N$, $\lambda_{0,k}^2 = \lambda_{0,r(k)}$. In the case of N-dimensional intervals, we know explicitly the functions e_k, and thus we can prove the following result.

THEOREM 4.4. *Let Ω be an N-dimensional interval $\prod_{i=1}^N (a_i, b_i)$, where $a_i < b_i$, $i = 1, \dots, N$, with $N \leq 3$. Assume, moreover, that there exists a $d > 0$ for which $b_i - a_i = d$ for all $i = 1, \dots, N$ and such that $\frac{\pi}{d\sqrt{N}} \in N^\star$. In addition, assume that for $u = \sum_{k \in (N^\star)^N} u_k e_k$ in H, Pu is defined by*

$$Pu = \sum_{k \in (N^\star)^N} \delta_k u_k e_{r(k)},$$

where the sequence of real numbers $(\delta_k)_k$ is such that there exist $\gamma > 0$ and δ with $0 < \gamma \leq \delta_k \leq \delta$, and where r is the one-to-one application defined by $r(k) = (\ell, \dots, \ell)$ for $k \in (N^\star)^N$, where $\ell = \frac{\pi}{d\sqrt{N}} \sum_{i=1}^N k_i^2$. Then there exists an $\alpha_1 \in (0, \alpha_0]$ such that for all $0 < |\alpha| < \alpha_1$ the solution $U(t) = \exp(-\mathcal{A}_\alpha t) U^0$ of (61) satisfies

$$E(U(t)) \leq \frac{c}{t^n} \sum_{p=0}^{2n} E(U^{(p)}(0)) \qquad \forall\ t > 0,\ U^0 \in D(\mathcal{A}_\alpha^{2n}).$$

Moreover, strong stability holds in the energy space $\mathcal{H} = V_1 \times V_2 \times H^2$.

Proof. Since Ω is an N-dimensional interval, we have for all $k \in (\mathbb{N}^\star)^N$

$$e_k(x_1, \dots, x_N) = \prod_{i=1}^N \sin\left(\frac{k_i \pi (x_i - a_i)}{b_i - a_i}\right),$$

whereas

$$\lambda_{0,k} = (d^{-1}\pi)^2 \sum_{i=1}^N k_i^2.$$

Since, by hypothesis, $\pi d^{-1} N^{-1/2} \in \mathbb{N}^\star$, we deduce that $\lambda_{2,k} = \lambda_{0,r(k)}$ for all $k \in (\mathbb{N}^\star)^N$. Hence the assumptions of Lemma 3.6 are satisfied, and in particular assumption (H5), with the application r defined above. We define C as in the proof of Lemma 3.6, that is,

$$Cu = \sum_{k \in (\mathbb{N}^\star)^N} u_k e_{r(k)}.$$

Then, thanks to the assumption on the sequence δ_k, we deduce that P satisfies the assumption (H4). Now applying Corollary 3.7, we conclude the proof. ∎

Acknowledgments. The author is very grateful to the referees and the associate editor for their valuable comments and suggestions.

AVERAGING AND VIBRATIONAL CONTROL OF MECHANICAL SYSTEMS*

FRANCESCO BULLO†

Abstract. This paper investigates averaging theory and oscillatory control for a large class of mechanical systems. A link between averaging and controllability theory is presented by relating the key concepts of averaged potential and symmetric product. Both analysis and synthesis results are presented within a coordinate-free framework based on the theory of affine connections.

The analysis focuses on characterizing the behavior of mechanical systems forced by high amplitude high frequency inputs. The averaged system is shown to be an affine connection system subject to an appropriate forcing term. If the input codistribution is integrable, the subclass of systems with Hamiltonian equal to "kinetic plus potential energy" is closed under the operation of averaging. This result precisely characterizes when the notion of averaged potential arises and how it is related to the symmetric product of control vector fields. Finally, a notion of vibrational stabilization for mechanical systems is introduced, and sufficient conditions are provided in the form of linear matrix equality and inequality tests.

Key words. mechanical system, averaging, vibrational stabilization, nonlinear controllability

1. Introduction.

This paper investigates the open loop response of nonlinear mechanical control systems. This topic is studied in different ways by the classic disciplines of averaging and controllability. Relying on tools from both fields, this work characterizes the response of a large class of mechanical systems to high amplitude high frequency forcing. The class of mechanical control systems we consider includes systems with integrable inputs (Hamiltonian systems with conservative forces) as well as systems with more general types of forces and nonholonomic constraints.

Averaging and vibrational stabilization techniques find useful applications in various areas. Within the context of mechanical systems, much recent interest has focused on the control of underactuated robotic manipulators and on the analysis and design of robotic locomotion devices. Underactuated robotic manipulators have fewer control inputs than their degrees of freedom due to either design or failure. In both cases, the objective is to control the system despite the lack of control authority. Examples of works in this area are [37, 25], where the authors investigate the control via oscillatory inputs for some two and three degrees of freedom planar manipulators.

Robotic locomotion studies the movement patterns that biological systems and mechanical robots undergo during locomotion; see [24]. Typically, cyclic motion in certain internal variables generates displacement in Euclidean space; consider the example of how a snake changes its shape to locomote. Computing the feasible trajectories of a locomotion system is an analytically untractable problem for any nontrivial example. Averaging provides a means of tackling such problems; see, for example,

the contributions on motion planning and trajectory generation documented in [17, 6] and the references therein.

Finally, averaging analysis seems well suited to tackle novel applications in the field of microelectromechanical systems, and vibrational control is being investigated within the context of active control of fluids and separation control. Examples include [7] on the scale dependence in oscillatory control and [43] on unsteady flow control using oscillatory blowing. In these settings, vibrational stabilization schemes appear advantageous since they require no expensive or complicated sensing.

Literature review. Averaging theory is discussed in a number of textbooks [13, 42, 19]. The control relevance of averaging ideas was underlined in the work on vibrational control by Bellman, Bentsman, and Meerkov [9, 10] and by Bentsman [11]. These works introduce vibrational stabilization techniques under various types of input forcing (e.g., vector additive, linear, and nonlinear multiplicative forcing). The later work by Baillieul [3, 4, 5] and Baillieul and Lehman [6] extends these techniques to the context of mechanical systems described by specific Lagrangian and Hamiltonian models. In particular, the work in [3] presents two treatments of averaging for mechanical control systems. The first approach relies on a coordinate transformation to bring the system to standard averaging form. The second approach is based on directly averaging the Hamiltonian function and gives rise to the notion of *averaged potential*. Some assumptions restrict how applicable the latter approach is. For example, the control system is assumed to have a cyclic variable and to be single-input with the control input applied to the cyclic variable. Nonetheless, the notion of averaged potential has proven very successful in treating a number of important cases; see, for example, [50, 51, 7].

Another set of relevant results includes the work on small-time local controllability for mechanical systems. The main references are the original work in Lewis and Murray [32] and the advances in [31]. These works introduce the notion of configuration and equilibrium controllability and provide sufficient conditions to characterize them. The main technical tool is the notion of *symmetric product* as a way to represent certain Lie brackets. Control algorithms that exploit motions along the "symmetric product directions" are presented in [17].

Statement of contributions. This paper contains a number of novel results both on averaging analysis as well as on control design. One key technical contribution is the understanding of the relationship between the symmetric product [32] and the averaged potential [3]. We describe the contributions in the next three paragraphs.

We start by studying the behavior of a large class of mechanical systems forced by high amplitude high frequency inputs. We rely on the notion of a *system described by an affine connection* as a generalized way of describing mechanical control systems with simple Hamiltonian, generic nonintegrable (nonconservative) forces and nonholonomic constraints. Under mild assumptions, we show how the averaged system is again a system described by an affine connection and subject to an appropriate forcing. Since this forcing term is a certain symmetric product, the result illustrates an instructive connection between controllability and averaging. The averaging analysis relies on a careful application of the variation of constants formula and of the homogeneity property of mechanical systems. The theorem statement and proof are presented in a coordinate-free manner.

We then consider the set of simple mechanical systems, that is, systems with Hamiltonian equal to "kinetic plus potential," and we investigate when this subclass is closed under the operation of averaging. A sufficient condition is that the input

codistribution be integrable, or in other words, that the control forces be described by conservative fields. Under this assumption, the Hamiltonian function of the average system includes a generalized averaged potential. This result shows how the notion of averaged potential is applicable to a wider set of systems than those considered by Baillieul [3]. The proof relies on the observation that the averaged potential is related to a certain symmetric product of functions; see [20].

Finally, we focus on the design of open and closed loop controllers based on high amplitude high frequency forcing. We introduce an appropriate notion of vibrational stabilization for mechanical systems, where only the configuration variables are considered. We consider simple systems with integrable forces and assume that the control system is underactuated (i.e., fewer control inputs are available than degrees of freedom). We consider the point stabilization problem and design control Lyapunov functions via the "potential shaping" technique; see the original [46] and a modern account in [47]. Here the closed loop potential energy reflects the presence of both a proportional action as well an oscillatory action. We provide sufficient conditions for stabilizability in the form of a linear matrix equality and inequality test. We illustrate the control design by applying it to an underactuated two-link manipulator.

Organization. The paper is organized as follows. We present a quick summary of averaging and introduce some tools from chronological calculus in section 2. In section 3, we introduce a useful classification of mechanical systems and study their common homogeneous structure. Section 4 contains the averaging analysis. In section 5, we present the vibrational stabilization results and work out the example.

2. Averaging and the variation of constants formula. In this section, we present some basic results on averaging theory and their coordinate-free interpretation. The averaging results are taken from Sanders and Verhulst [42] and from Guckenheimer and Holmes [22].

Let x, y, x_0 belong to an open subset $D \subset \mathbb{R}^n$, let $t \in \mathbb{R}_+ = [0, \infty)$, and let the parameter ϵ vary in the range $(0, \epsilon_0]$ with $\epsilon_0 \ll 1$. Let $f, g : \mathbb{R}_+ \times D \to \mathbb{R}^n$ be smooth time-varying vector fields. Consider the initial value problem in *standard form*:

$$\frac{dx}{dt} = \epsilon f(t, x), \qquad x(0) = x_0. \tag{2.1}$$

If $f(t, x)$ is a T-periodic function in its first argument, we let *the averaged system* be the initial value problem

$$\frac{dy}{dt} = \epsilon f^0(y), \qquad y(0) = x_0, \tag{2.2}$$

$$f^0(y) = \frac{1}{T} \int_0^T f(t, y) dt.$$

We say that an estimate is *on the time scale* $\delta^{-1}(\epsilon)$ if the estimate holds for all times t such that $0 < \delta(\epsilon)t < L$ with L a constant independent of ϵ. From pages 39 and 71 in [42] and from page 168 in [22], we summarize as follows.

THEOREM 2.1 (first order periodic averaging). *There exists a positive* ϵ_0 *such that, for all* $0 < \epsilon \leq \epsilon_0$,

(i) $x(t) - y(t) = O(\epsilon)$ *as* $\epsilon \to 0$ *on the time scale* $1/\epsilon$, *and*

(ii) *if the origin is a hyperbolically stable critical point for* f^0, *then* $x(t) - y(t) = O(\epsilon)$ *as* $\epsilon \to 0$ *for all* $t \in \mathbb{R}_+$, *and the differential equation* (2.1) *possesses a unique periodic orbit which is hyperbolically stable and belongs to an* $O(\epsilon)$ *neighborhood of the origin.*

Next, consider the initial value problem

$$\frac{dx}{dt} = f\left(t/\epsilon, x\right), \qquad x(0) = x_0, \tag{2.3}$$

where $f(t,x)$ is a T-periodic function in its first argument. A time scaling argument shows that the averaged version of this problem is the same as in (2.2). Accordingly, Theorem 2.1 implies that $x(t) - y(t) = O(\epsilon)$ as $\epsilon \to 0$ *only* on the time scale 1 unless $y = 0$ is a hyperbolically stable point of f^0.

2.1. Variation of constants formula in coordinate-free terms. The variation of constants formula is a means to bring various systems into the standard form in (2.1). This tool originates in Lagrange's work (see [42, page 183]) and is presented here in a coordinate-free setting.

Given a diffeomorphism ϕ and a vector field g, the *pull-back of g along ϕ*, denoted $\phi^* g$, is the vector field

$$(\phi^* g)(x) \triangleq \left(\frac{\partial \phi^{-1}}{\partial x} \circ g \circ \phi\right)(x),$$

where the order of composition of functions is $(\varphi \circ \phi)(x) = \varphi(\phi(x))$. A useful diffeomorphism is the flow map $y(t) = \Phi^g_{0,T}(y_0)$ describing the solution at time T to the initial value problem

$$\dot{y} = g(t,y), \quad y(0) = y_0.$$

Next, consider the initial value problem

$$\dot{x}(t) = f(x,t) + g(x,t), \qquad x(0) = x_0. \tag{2.4}$$

We regard f as a perturbation to the vector field g, and we seek to characterize the flow map of $f+g$ in terms of the nominal flow map of g. The answer is provided by the *variation of constants* formula:

$$\Phi^{f+g}_{0,t} = \Phi^g_{0,t} \circ \Phi^{(\Phi^g_{0,t})^* f}_{0,t}. \tag{2.5}$$

In other words, if $z(t)$ is the solution to the initial value problem

$$\dot{z}(t) = \left((\Phi^g_{0,t})^* f\right)(z), \qquad z(0) = x_0, \tag{2.6}$$

the solution $x(t)$ to the initial value problem (2.4) satisfies

$$\dot{x}(t) = g(t,x), \qquad x(0) = z(t). \tag{2.7}$$

We illustrate the formula in Figure 2.1 and provide a self-contained proof in the appendix.

2.2. Formal expansions for the pull-back of a flow map. Here we study in more detail the differential geometry of the initial value problem (2.6). Such a system is referred to as the "pulled back" or the "adjoint" system; e.g., see [23].

If f and g are time-invariant vector fields, the infinitesimal Campbell–Baker–Hausdorff formula (see [26]) provides a means of computing the pull-back

$$(\Phi^g_{0,t})^* f(x) = \sum_{k=0}^{\infty} \mathrm{ad}^k_g f \, \frac{t^k}{k!},$$

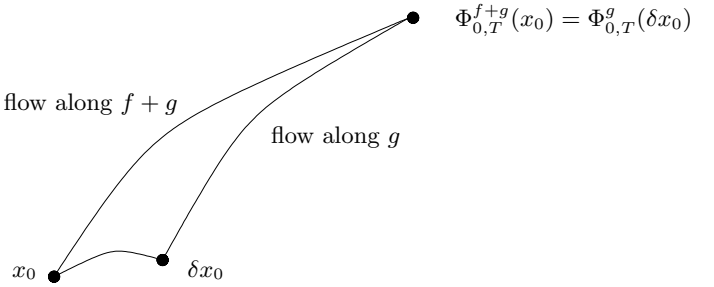

FIG. 2.1. *The flow along $f+g$ with initial condition x_0 equals the flow along g with initial condition δx_0. The variation δx_0 is computed via the variation of constants formula as the flow along $(\Phi^g_{0,t})^* f$ for time $[0,T]$ with initial condition x_0.*

where $\mathrm{ad}_g f(x) = [g,f](x)$ is the Lie bracket between g and f and $\mathrm{ad}^k_g f = \mathrm{ad}^{k-1}_g \mathrm{ad}_g f$.

If, instead, f is the time-invariant vector field and g is the time-varying vector field, we invoke a result from the chronological calculus formalism by Agrachev and Gamkrelidze [2]. It turns out that

$$((\Phi^g_{0,t})^* f)(t,x) = f(x) + \sum_{k=1}^{\infty} \int_0^t \dots \int_0^{s_{k-1}} \left(\mathrm{ad}_{g(s_k,x)} \dots \mathrm{ad}_{g(s_1,x)} f(x)\right) ds_k \dots ds_1. \tag{2.8}$$

The convergence properties for the series expansion in (2.8) are difficult to characterize; see, for example, a related discussion in [49] on the Campbell–Baker–Hausdorff formula. Nonetheless, sufficient conditions for local convergence are given in [2, Propositions 2.1 and 3.1]. For our analysis, the following simple statement suffices: if the terms $\mathrm{ad}_{g(s_k)} \dots \mathrm{ad}_{g(s_1)} f$ vanish for all k greater than a given N, then the series in (2.8) becomes a finite sum.

2.3. Averaging under high magnitude high frequency forcing. We return to the description of averaging results, and we focus on a setting of interest in vibrational stabilization problems [9, 10, 11]. Consider the initial value problem

$$\frac{dx}{dt} = f(x) + (1/\epsilon) g\left(t/\epsilon\,, x\right), \qquad x(0) = x_0, \tag{2.9}$$

where we assume that $g(t,x)$ is a T-periodic function in its first argument. Let $\Phi^g_{0,t}$ denote the flow map along $g(t,x)$, and define

$$F(t,x) = \left((\Phi^g_{0,t})^* f\right)(x), \tag{2.10}$$

$$F^0(x) = \frac{1}{T} \int_0^T F(\tau, x) d\tau. \tag{2.11}$$

Finally, let z and y be solutions to the initial value problems

$$\dot z = F(t/\epsilon, z), \quad z(0) = x_0, \tag{2.12}$$

$$\dot y = F^0(y), \quad y(0) = x_0. \tag{2.13}$$

LEMMA 2.2. *Let F be a T-periodic function in its first argument. For $t \in \mathbb{R}_+$, we have*

$$x(t) = \Phi^g_{0,t/\epsilon}(z(t)).$$

As $\epsilon \to 0$ on the time scale 1, we have

$$z(t) - y(t) = O(\epsilon).$$

If the origin is a hyperbolically stable critical point for F^0, then $z(t) - y(t) = O(\epsilon)$ as $\epsilon \to 0$ for all $t \in \mathbb{R}_+$, and the differential equation (2.12) possesses a unique periodic orbit which is hyperbolically stable and belongs to an $O(\epsilon)$ neighborhood of the origin.

Proof. As a first step, we change the time scale by setting $\tau = t/\epsilon$. Equation (2.9) becomes

$$\frac{d}{d\tau}x = \epsilon f(x) + g(\tau, x), \quad x(0) = x_0.$$

As a second step, we apply the variation of constants formula

$$\begin{aligned}\frac{d}{d\tau}x &= g(\tau, x), \quad x(0) = z(\tau),\\ \frac{d}{d\tau}z &= \epsilon F(\tau, z), \quad z(0) = x_0,\end{aligned}$$

where F is defined according to (2.10). As a third step, we average the initial value problem in z to obtain

$$\frac{d}{d\tau}y = \epsilon F^0(y), \quad y(0) = x_0,$$

where F^0 is defined according to (2.11) and F is assumed to be a T-periodic function. The averaged curve y approximates z over the time scale $\tau = 1/\epsilon$ and over all time according to Theorem 2.1. As a fourth step, we change the time scale back to $t = \epsilon\tau$ and compute

$$\begin{aligned}\frac{d}{dt}x &= (1/\epsilon)g(t/\epsilon, x), \quad x(0) = z(t),\\ \frac{d}{dt}z &= F(t/\epsilon, z), \quad z(0) = x_0,\\ \frac{d}{dt}y &= F^0(y), \quad y(0) = x_0.\end{aligned}$$

These are the definitions of z and y in (2.12) and (2.13). Finally, the equality in $x(t)$ follows by noting that the flow along $(1/\epsilon)g\,(t/\epsilon\,, x)$ for time 1 is equivalent to the flow along $g\,(t, x)$ for time $1/\epsilon$. □

This concludes our geometric presentation of averaging in systems with high magnitude high frequency inputs. These results on averaging and the variation of constants formula are known (see [10, Section III]), and they play a key role in the study of vibrational stabilization problems; see also [9, 11]. The presentation of these results in a coordinate-free fashion is novel: for a large class of mechanical control systems, an explicit expression will be provided for the infinite series describing the variation of constants formula.

3. Mechanical control systems and their homogeneous structure. In this section, we present three different types of mechanical systems and a geometric formalism that leads to a unified modeling framework. We also present some results on the Lie algebraic structure common to these systems and to generic second order control systems, where the input is an acceleration (alternatively, a force). To present

an accessible treatment, we assume the configuration space to be $Q = \mathbb{R}^n$. However, Remark 3.1 and section 3.1 provide the key ideas necessary to develop a coordinate-free treatment over manifolds.

Let $q = (q^1, \dots, q^n) \in \mathbb{R}^n$ be the configuration of the mechanical system. We consider the control system

$$\ddot{q}^i + \Gamma^i_{jk}(q)\dot{q}^j\dot{q}^k = Y^i_0(q) + Y^i_a(q)u^a(t) + R^i_j(q)\dot{q}^j, \tag{3.1}$$

where the summation convention is in place here and in what follows, the indices j, k run from 1 to n, the index a runs from 1 to m (the number of input fields), and where the following hold.

(i) The Γ^i_{jk} are $n^2(n+1)/2$ arbitrary scalar functions on $\mathbb{R}^n$ called the Christoffel symbols. (They satisfy the symmetric relationship $\Gamma^i_{jk} = \Gamma^i_{kj}$.)

(ii) $q \mapsto Y_a(q)$ for $a = 1, \dots, m$ are vector fields characterizing configuration-dependent forces applied to the system. Y_0, for example, might include the effect of a conservative force such as gravity.

(iii) The functions $t \mapsto u^a(t)$ are integrable and describe the control magnitude applied along the input Y_a. The ith component of Y_a is Y^i_a. We also let

$$Y(q,t) = Y_a(q)u^a(t).$$

(iv) $R(q)\dot{q}$ describes a generic force linearly proportional to velocity.

All quantities are assumed to be smooth functions of their arguments.

Equation (3.1) describes a large class of mechanical systems with Hamiltonian equal to kinetic plus potential energy, with symmetries and with nonholonomic constraints. A slightly loose but instructive classification follows.

Simple systems with integrable forces. These systems have Hamiltonian equal to "kinetic plus potential energy" and are subject to integrable (conservative) input forces. For example, should the mechanical system be a robotic manipulator with motors at joints, then the appropriate Christoffel symbols are computed via a well-known combination of partial derivatives of the inertia tensor; see the definition of the Coriolis matrix in [36], for example. Only for this kind of system can one write a Hamiltonian function that includes the effect of forces; the treatment in Chapter 14 of [38] relies on this assumption.

Simple systems with nonintegrable forces. This class is a superset of the previous class, where, however, *nonintegrable* input forces are allowed. For example, the force applied by a thruster of a satellite, hovercraft, or underwater vehicle is in general a nonintegrable force. Simplified equations of motion can be written if the system has symmetries, i.e., if the system's configuration belongs to the group of rigid displacements (or one of its subgroups) and its Hamiltonian is independent of the configuration.

Systems with nonholonomic constraints. This set includes systems from the previous two subclasses and is additionally subject to nonholonomic constraints. Two very interesting locomotion devices called snakeboard and roller racer are described in recent papers [40] and [29]. Two methodologies for writing the equations of motions for these systems into form (3.1) are discussed in [30, 31, 12]. While the description "nonholonomic" is commonly used to refer to wheeled robots and while such systems are usually driftless,[1] we consider here nonholonomic systems with drift.

[1] Driftless control systems have the characterizing property that $u_i = 0$ implies $\dot{x} = 0$, where x is the state and u_i are the inputs.

Three remarks are appropriate. First, the model relies on no specific structure on the Γ^i_{jk} functions. In the classic Hamiltonian system case, these functions are readily computed from the inertia matrix. By leaving these functions unspecified, our analysis includes systems with nonholonomic constraints. We refer to [12, 31] for a thorough treatment of this point.

Second, the distinctions between these three sets of mechanical systems have various instructive implications. For example, the notion of "actuated degree of freedom" is well defined only in systems subject to integrable forces. This simple fact is neglected even in recent literature on mechanical control systems.

Third, more complete definitions of the various quantities above should include transformation rules under changes of coordinates. For example, the Christoffel symbols $\{\Gamma^i_{jk}, i, j, k = 1, \dots, n\}$ obey relatively surprising transformation rules if the correct equations of motion are to be computed. If $\overline{q} = (\overline{q}^1, \dots, \overline{q}^n) \in \mathbb{R}^n$ are the transformed coordinates, the transformation rule for the Γ^i_{jk} is

$$\overline{\Gamma}^k_{ij} = \frac{\partial q^p}{\partial \overline{q}^i} \frac{\partial q^m}{\partial \overline{q}^j} \frac{\partial \overline{q}^k}{\partial q^r} \Gamma^r_{pm} + \frac{\partial \overline{q}^k}{\partial q^l} \frac{\partial^2 q^l}{\partial \overline{q}^i \partial \overline{q}^j}. \tag{3.2}$$

We refer to [35, section 7.5] for a more complete discussion.

3.1. Control systems described by an affine connection. Equations (3.1) are the Euler–Lagrange equations for a simple mechanical system. Numerous methodologies are available for writing these equations in vector or in abstract formats. The theory of affine connections is a convenient formalism that formalizes the Euler–Lagrange equations as well as more general second order control systems (including systems with nonholonomic constraints).

An easily accessible treatment of the theory of affine connections is given by Do Carmo [21]. An early reference on mechanical control systems on Riemannian manifolds is the work by Crouch [20]. The use of Riemannian concepts is encountering increasing success as testified by the contributions on modeling [12], decompositions [33], controllability [32], stabilization [28], tracking [18], interpolation [39], and (static and dynamic) feedback linearization [8, 41].

A smooth affine connection ∇ is a collection of n^3 smooth functions Γ^i_{jk} that satisfy the transformation rule in (3.2). An affine connection induces an operation between vector fields as follows. Let the vector fields X and Y have components

$$X(q) = X^i(q) \frac{\partial}{\partial q^i} \qquad \text{and} \qquad Y(q) = Y^i(q) \frac{\partial}{\partial q^i}.$$

The covariant derivative of Y along X is the vector field $\nabla_X Y$ defined by

$$\nabla_X Y = \left(\frac{\partial Y^i}{\partial q^j} X^j + \Gamma^i_{jk} X^j Y^k \right) \frac{\partial}{\partial q^i}.$$

Similarly, an affine connection induces an operation between a curve $\gamma : [0, 1] \mapsto \mathbb{R}^n$ and a vector field Y. The covariant derivative of Y along γ is a vector field along γ defined by

$$\nabla_{\dot\gamma} Y = \left(\frac{dY^i(\gamma(t))}{dt} + \Gamma^i_{jk} \dot\gamma^j Y^k \right) \frac{\partial}{\partial q^i}.$$

Whenever the reference curve is uniquely determined, we let $\nabla_{\dot\gamma} Y = \frac{DY}{dt}$. The two definitions of covariant derivative have similarities; however, $\frac{DY}{dt}$ is not a vector field

over $\mathbb{R}^n$, but it is only defined on the trajectory $\gamma : [0,1] \mapsto \mathbb{R}^n$. We refer to [21] for a more complete treatment of affine connections and of manifolds.

We are finally ready to rewrite (3.1) in a coordinate-free fashion. According to the definition of covariant derivative along a curve, the generalized Euler–Lagrange equations are

$$\frac{D\,\dot{q}}{dt} = Y_0(q) + R(q)\dot{q} + Y_a(q)u^a(t), \tag{3.3}$$

where the covariant derivative of $\dot{q}$ is computed along the curve $q(t)$, i.e., $D\dot{q}/dt = \nabla_{\dot{q}}\dot{q}$.

3.2. Lie algebraic structure. The fundamental structure of the control system in (3.1) (and, accordingly, (3.3)) is the polynomial dependence of the various vector fields on the velocity variable $\dot{q}$. This structure affects the Lie bracket computations involving input and drift vector fields; see related ideas in [32, 45]. We start by rewriting the system (3.1) as a first order differential equation. We write

$$\frac{d}{dt}\begin{bmatrix} q \\ \dot{q} \end{bmatrix} = \begin{bmatrix} \dot{q} \\ -\Gamma(q,\dot{q}) + Y_0(q) + R(q)\dot{q} \end{bmatrix} + \begin{bmatrix} 0 \\ Y_a \end{bmatrix} u^a(t),$$

where $\Gamma(q,\dot{q})$ is the vector with ith component $\Gamma^i_{jk}(q)\dot{q}^j\dot{q}^k$. Also, we let $x = (q,\dot{q})$,

$$Z_g(x) = \begin{bmatrix} \dot{q} \\ -\Gamma(q,\dot{q}) \end{bmatrix}, \quad Y_a^{\text{lift}}(x) \triangleq \begin{bmatrix} 0 \\ Y_a(q) \end{bmatrix}, \quad \text{and} \quad R^{\text{lift}}(x) \triangleq \begin{bmatrix} 0 \\ R(q)\dot{q} \end{bmatrix}$$

so that the control system is rewritten as

$$\dot{x} = Z_g(x) + Y_0^{\text{lift}}(x) + R^{\text{lift}}(x) + Y_a^{\text{lift}}(x)u^a(t).$$

Let $h_i(q,\dot{q})$ be the set of scalar functions on $\mathbb{R}^{2n}$, which are arbitrary functions of q and homogeneous polynomials in $\{\dot{q}^1,\dots,\dot{q}^n\}$ of degree i. Let $\mathcal{P}_i$ be the set of vector fields on $\mathbb{R}^{2n}$ whose first n components belong to h_i and whose second n components belong to h_{i+1}. It is easily seen that

$$Z_g \in \mathcal{P}_1, \quad R^{\text{lift}} \in \mathcal{P}_0, \quad \text{and} \quad Y_a^{\text{lift}} \in \mathcal{P}_{-1}.$$

Direct computations show that the sets $\{\mathcal{P}_i\}$ have the following properties:

(i) $[\mathcal{P}_i, \mathcal{P}_j] \subset \mathcal{P}_{i+j}$, i.e., the Lie bracket between a vector field in $\mathcal{P}_i$ and a vector field in $\mathcal{P}_j$ belongs to $\mathcal{P}_{i+j}$.
(ii) $\mathcal{P}_k = \{0\}$ for all $k \le -2$.
(iii) if $k \ge 1$, then $X(q,0) = 0$ for all $X(q,\dot{q}) \in \mathcal{P}_k$.

Given these properties, we investigate the Lie brackets between the vector fields Z_g and Y_a^{lift}. A few useful brackets are

$$[Z_g, Y_a^{\text{lift}}] \in \mathcal{P}_0, \qquad [Y_a^{\text{lift}}, Y_b^{\text{lift}}] = 0,$$
$$[Y_b^{\text{lift}}, [Z_g, Y_a^{\text{lift}}]] \in \mathcal{P}_{-1}.$$

Of particular interest is the Lie bracket $[Y_b^{\text{lift}}, [Z_g, Y_a^{\text{lift}}]]$. Since this vector field belongs to $\mathcal{P}_{-1}$, there must exist a vector field on $\mathbb{R}^n$, which we denote $\langle Y_a : Y_b \rangle$, such that

$$\langle Y_a : Y_b \rangle^{\text{lift}} = [Y_b^{\text{lift}}, [Z_g, Y_a^{\text{lift}}]].$$

We call this vector field the *symmetric product* between Y_b and Y_a. Some straightforward computations in coordinates show that $\langle Y_a : Y_b\rangle = \langle Y_b : Y_a\rangle$ and that

$$\langle Y_b : Y_a\rangle^i = \frac{\partial Y_a^i}{\partial q^j} Y_b^j + \frac{\partial Y_b^i}{\partial q^j} Y_a^j + \Gamma^i_{jk}(Y_a^j Y_b^k + Y_a^k Y_b^j),$$
$$\langle Y_b : Y_a\rangle = \nabla_{Y_a} Y_b + \nabla_{Y_b} Y_a.$$

REMARK 3.1. *While the results in this section are presented in coordinates, it is possible to turn them into coordinate-free statements on manifolds. The enabling concepts are the operation of vertical lift and symmetric product between vector fields (see* [32]*), the notion of geometric homogeneity (see* [27]*), and the intrinsic definition of the Liouville vector field (see* [34, page 64]*).*

4. Averaging for mechanical systems under high amplitude high frequency forcing. This section contains the main result of the paper. We consider systems described by an affine connection and subject to high amplitude high frequency forcing. We show how the average system is again described by the same affine connection subject to an appropriate forcing term. Additionally, we show how the subclass of systems subject to integrable forces and without nonholonomic constraints is also closed under the operation of averaging.

The approach we take differs substantially from the classic averaging of Hamiltonian systems; see Chapter 4 in [22]. In that setting, the Hamiltonian system is integrable, and the variation of constants formula is applied by treating the ϵ size forcing as perturbation. In our setting, it is the Hamiltonian dynamics that plays the role of the perturbation to the dominant high amplitude high frequency forcing. Finally, it is important to note that, while the accelerations driving the systems are high amplitude, the generated displacements are typically small in magnitude.

4.1. Systems described by affine connections. Consider a control system described by an affine connection as in (3.3):

$$\begin{aligned} &\frac{D\,\dot q}{dt} = Y_0(q) + R(q)\dot q \;+\; Y_a(q)(1/\epsilon)v^a(t/\epsilon),\\ &q(0) = q_0, \quad \dot q(0) = v_0, \end{aligned} \tag{4.1}$$

where $u^a(t) = v^a(t/\epsilon)/\epsilon$, and $\{v^1, \dots, v^m\}$ are T-periodic functions that satisfy

$$\int_0^T v^a(s_1)ds_1 = 0, \tag{4.2}$$

$$\int_0^T \int_0^{s_2} v^a(s_1)ds_1 ds_2 = 0. \tag{4.3}$$

Also, let $v(t) = [v^1(t), \dots, v^m(t)]'$ and define the matrix Λ according to

$$\Lambda = \frac{1}{2T}\int_0^T \left(\int_0^{s_1} v(s_2)ds_2\right)\left(\int_0^{s_1} v(s_2)ds_2\right)' ds_1. \tag{4.4}$$

Finally, define the time-varying vector field as

$$\Xi(t,q) = \left(\int_0^t v^a(s)ds\right) Y_a(q)$$

and the curve as

$$z(t) = \big(q(t),\ \dot{q}(t) - \Xi\big(t/\epsilon, q(t)\big)\big)\,. \tag{4.5}$$

THEOREM 4.1. *Let $q(t)$ be the solution to the initial value problem in* (4.1)*, and let $r(t)$ be the solution to*

$$\begin{aligned} \frac{D\,\dot{r}}{dt} &= Y_0(r) + R(r)\dot{r} - \sum_{a,b=1}^{m} \Lambda_{ab}\,\langle Y_a : Y_b\rangle\,(r), \\ r(0) &= q_0, \quad \dot{r}(0) = v_0. \end{aligned} \tag{4.6}$$

There exists a positive ϵ_0 such that, for all $0 < \epsilon \leq \epsilon_0$,

$$\begin{aligned} q(t) &= r(t) + O(\epsilon), \\ \dot{q}(t) &= \dot{r}(t) + \Xi(t/\epsilon, q(t)) + O(\epsilon) \end{aligned} \tag{4.7}$$

as $\epsilon \to 0$ on the time scale 1*.*

Furthermore, let $(r, \dot{r}) = (q_1, 0)$ be a hyperbolically stable critical point for (4.6)*, and let its region of attraction contain the initial condition (q_0, v_0). Then the approximations in* (4.7) *are valid for all $t \in \mathbb{R}_+$, and the curve $z(t)$ is the solution to an initial value problem which possesses a unique, hyperbolically stable, periodic orbit belonging to an $O(\epsilon)$ neighborhood of $(q_1, 0)$.*

Justified by the approximations in (4.7), we call the initial value problem in (4.6) the *averaged mechanical system* of the initial value problem in (4.1).

Proof. The proof brings together the analysis in subsections 2.3 and 3.2. As a first step, we translate the second order (4.1) into the first order format in (2.9). We let $x = (q, \dot{q})$ and

$$\begin{aligned} f(x) &= Z_g(x) + Y_0^{\text{lift}}(x) + R^{\text{lift}}(x), \\ g(t,x) &= \sum_{a=1}^{m} Y_a^{\text{lift}}(x) v^a(t). \end{aligned}$$

Next, we compute the vector field F according to (2.10):

$$F(t,y) = \big((\Phi_{0,t}^g)^* f\big)\,(y) = \Big(\Phi_{0,t}^{\sum Y_a^{\text{lift}}(y) v^a(t)}\Big)^* \,(Z_g(y) + Y_0^{\text{lift}}(y) + R^{\text{lift}}(y)).$$

We study its expression according to the series expansion in section 2.2:

$$(\Phi_{0,t}^g)^* f = f + \sum_{k=1}^{\infty} \int_0^t \dots \int_0^{s_{k-1}} \left(\mathrm{ad}_{g(s_k)} \dots \mathrm{ad}_{g(s_1)}\, f\right)\, ds_k \dots ds_1.$$

The Lie algebraic structure unveiled in section 3.2 leads to remarkable simplifications:

$$\begin{aligned} \mathrm{ad}^k_{Y_a^{\text{lift}}}(Z_g(y) + Y_0^{\text{lift}}(y) + R^{\text{lift}}(y)) &= 0 \qquad \forall\ k \geq 3, \\ \mathrm{ad}_{Y_b^{\text{lift}}}\, \mathrm{ad}_{Y_a^{\text{lift}}}(Z_g(y) + Y_0^{\text{lift}}(y) + R^{\text{lift}}(y)) &= -\,\langle Y_a : Y_b\rangle^{\text{lift}}\,. \end{aligned}$$

With a little bookkeeping, we exploit these equalities and compute

$$\begin{aligned}
&\left(\Phi_{0,t}^{\sum Y_a^{\text{lift}}(y)v^a(t)}\right)^* \left(Z_g(y)+Y_0^{\text{lift}}(y)+R^{\text{lift}}(y)\right)\\
&\qquad=\left(Z_g+Y_0^{\text{lift}}+R^{\text{lift}}\right)+\sum_{a=1}^{m}\left(\int_0^t v^a(s_1)ds_1\right)\left[Y_a^{\text{lift}},\left(Z_g+Y_0^{\text{lift}}+R^{\text{lift}}\right)\right]\\
&\qquad\quad+\sum_{a,b=1}^{m}\left(\int_0^t\int_0^{s_b} v^b(s_b)v^a(s_a)ds_ads_b\right)\left[Y_b^{\text{lift}},\left[Y_a^{\text{lift}},\left(Z_g+Y_0^{\text{lift}}+R^{\text{lift}}\right)\right]\right]\\
&\qquad=\left(Z_g+Y_0^{\text{lift}}+R^{\text{lift}}\right)+\sum_{a=1}^{m}\left(\int_0^t v^a(s_1)ds_1\right)\left[Y_a^{\text{lift}},\left(Z_g+R^{\text{lift}}\right)\right]\\
&\qquad\qquad-\sum_{a,b=1}^{m}\left(\int_0^t\int_0^{s_b} v^b(s_b)v^a(s_a)ds_ads_b\right)\langle Y_a:Y_b\rangle^{\text{lift}}.
\end{aligned}$$

An integration by parts and the symmetry of the symmetric product lead to

$$\begin{aligned}
&\sum_{a,b=1}^{m}\left(\int_0^t\int_0^{s_b} v^b(s_b)v^a(s_a)ds_ads_b\right)\langle Y_a:Y_b\rangle\\
&\qquad=\frac{1}{2}\sum_{a,b=1}^{m}\left(\int_0^t v^b(s_b)ds_b\int_0^t v^a(s_a)ds_a\right)\langle Y_a:Y_b\rangle
\end{aligned}$$

so that we have

(4.8)

$$\begin{aligned}
F(t,y)=&\left(Z_g+Y_0^{\text{lift}}+R^{\text{lift}}\right)+\sum_{a=1}^{m}\left(\int_0^t v^a(s_1)ds_1\right)\left[Y_a^{\text{lift}},\left(Z_g+R^{\text{lift}}\right)\right]\\
&-\frac{1}{2}\sum_{a,b=1}^{m}\left(\int_0^t v^b(s_b)ds_b\int_0^t v^a(s_a)ds_a\right)\langle Y_a:Y_b\rangle^{\text{lift}}.
\end{aligned}$$

Assumption (4.2) implies that the function F is T-periodic so that we can compute its average F^0 according to (2.11). Given the assumption on v^a in (4.3) and the definition of Λ in (4.4), we have

$$F^0(y)=\left(Z_g+Y_0^{\text{lift}}+R^{\text{lift}}\right)-\sum_{a,b=1}^{m}\Lambda_{ab}\langle Y_a:Y_b\rangle^{\text{lift}}.$$

This is precisely the vector field that describes the evolution of $(r,\dot r)$. This proves that $y=(r,\dot r)$. Let $\widehat z=(p,\dot p)$ be the flow of the vector field F starting from (q_0,v_0). Lemma 2.2 implies that, over the appropriate time scale,

$$\begin{aligned}
x(t)&=\Phi^g_{0,t/\epsilon}(\widehat z(t)),\\
\widehat z(t)&=y(t)+O(\epsilon),
\end{aligned}$$

and, should $(q_1,0)$ be a hyperbolically stable critical point for F^0, the vector field F possesses a unique, hyperbolically stable, periodic orbit in an $O(\epsilon)$ neighborhood of $(q_1,0)$.

Finally, we verify that the curve $\widehat{z}$ defined via the equality $x(t) = \Phi^g_{0,t/\epsilon}(\widehat{z}(t))$ is equal to the curve z defined in (4.5). In coordinates, we have

$$\frac{d}{ds}\begin{bmatrix} q(s) \\ \dot{q}(s) \end{bmatrix} = \begin{bmatrix} 0 \\ Y_a(q(s))v^a(s) \end{bmatrix}, \qquad \big(q(0), \dot{q}(0)\big) = \Phi^g_{0,t/\epsilon}\big(p(t), \dot{p}(t)\big)$$

so that, at final time $s = t/\epsilon$, we compute $q(t) = q(0) = p(t)$ and

$$\dot{q}(t) = Y_a(q(0)) \int_0^{t/\epsilon} v^a(s)ds + \dot{q}(0) = \Xi(t/\epsilon, q(t)) + \dot{p}(t). \qquad \square$$

The coordinate-free treatment and the use of the Lie algebraic structure underline the connection between these results on averaging and the treatment on controllability in [32] and on motion planning in [17]. To quickly recall the first of these references, consider the control system in (3.3), where $Y_0 = R = 0$. If the family of vector fields $\{Y_a, \langle Y_a : Y_b\rangle, a, b = 1, \dots, m\}$ is full rank in a neighborhood of q_0, then the control system (3.3) is small-time locally accessible from $(q_0, 0)$. Similar in these works is the key observation that a mechanical control system subject to a force Y moves approximately in the direction spanned by $\langle Y : Y\rangle$.

The novel proof methodology should facilitate further research into higher order averaging. Indeed, the work in [16] indicates that the exact solution of a mechanical control system can be written as a series expansion with terms including iterated symmetric products and time integrals.

4.2. Averaged potential for simple systems with integrable inputs. The textbook [22] presents the classic result that "the average of a Hamiltonian system forced by a bounded high frequency perturbation can be computed by averaging its Hamiltonian." For the case of high magnitude high frequency forces, the various insightful works by Baillieul [3, 4] and Baillieul and Lehman [6] introduce the notion of *averaged potential*[2] as a means to characterize the average behavior.

In this section, we assume that the original forced system is "simple," i.e., that no nonholonomic constraints are present, and we answer the questions "when is the averaged system again simple?" and "what assumptions lead to the definition of an averaged potential?" Incidentally, the answer to these questions involves the relationships between various definitions of symmetric product that go back to the early treatment by Crouch [20].

We quickly review some basic concepts in simple mechanical control systems and refer to the textbooks [21, 35] for a more detailed presentation. In a mechanical system without constraints, the total energy is defined as the sum of potential $V(q)$ and kinetic $\frac{1}{2}\langle\langle \dot{q}\,,\, \dot{q}\rangle\rangle = \frac{1}{2}\dot{q}^T M(q)\dot{q}$, where we denote with both $\langle\langle \cdot\,,\, \cdot\rangle\rangle$ and M the metric associated with the kinetic energy. The tensor R is weakly dissipative if $\langle\langle \dot{q}\,,\, R\dot{q}\rangle\rangle \leq 0$; it is strictly quadratically dissipative if there exists a positive constant β such that

$$\langle\langle \dot{q}\,,\, R\dot{q}\rangle\rangle \leq -\beta\langle\langle \dot{q}\,,\, \dot{q}\rangle\rangle. \tag{4.9}$$

If integrable forces are present, they are written as $Y_a(q) = \operatorname{grad}\varphi_a(q)$ for $a = 1, \dots, m$, where a gradient vector field reads, in coordinates, as

$$(\operatorname{grad}\varphi_a)^i = M^{ij}\frac{\partial \varphi_a}{\partial q_j}.$$

[2]More precisely, in Baillieul's work, the inputs are assumed to be high frequency bounded magnitude velocities. It is therefore very similar to our setting with high magnitude high frequency accelerations.

According to the treatment in [38, Chapter 12], the controlled Hamiltonian is

$$H(q,p,u) = V(q) + \frac{1}{2}p' M(q)^{-1} p - \sum_{a=1}^{m} \varphi_a(q) u^a, \tag{4.10}$$

where the momentum $p = M(q)\dot{q}$. The affine connection is the Levi–Civita connection of the metric M. The Christoffel symbols are computed according to the usual

$$\Gamma_{ij}^k = \frac{1}{2} M^{mk} \left(\frac{\partial M_{mj}}{\partial q^i} + \frac{\partial M_{mi}}{\partial q^j} - \frac{\partial M_{ij}}{\partial q^m} \right).$$

The equations of motion (4.6) take the specific form

$$\frac{D\,\dot{q}}{dt} = -\operatorname{grad} V(q) + R(q)\dot{q} + \operatorname{grad} \varphi_a(q)\, u^a(t). \tag{4.11}$$

Next we present a useful result on the symmetric product of gradient vector fields.

LEMMA 4.2 (symmetric products of functions). *Let φ_1, φ_2 be two smooth scalar functions. The symmetric product $\langle \operatorname{grad}\varphi_1 : \operatorname{grad}\varphi_2 \rangle$ is again a gradient vector field. Additionally, if one defines a symmetric product of functions according to*

$$\langle \varphi_i : \varphi_j \rangle \triangleq \frac{\partial \varphi_i}{\partial q} M^{-1} \frac{\partial \varphi_j}{\partial q} = \langle\!\langle \operatorname{grad}\varphi_i \,,\, \operatorname{grad}\varphi_j \rangle\!\rangle, \tag{4.12}$$

then

$$\langle \operatorname{grad}\varphi_1 : \operatorname{grad}\varphi_2 \rangle = \operatorname{grad} \langle \varphi_1 : \varphi_2 \rangle .$$

This result was originally proven by Crouch in [20], where this symmetric product of functions was presented under the name of the Beltrami bracket. It is interesting to note how, in contrast to the treatment in [20], this symmetric operation is relevant here in a Hamiltonian system context.

Finally, we are ready to apply Theorem 4.1 to the setting of simple systems.

THEOREM 4.3. *Consider the simple mechanical control system in* (4.11) *with Hamiltonian in* (4.10). *Let $u^a(t) = v^a(t/\epsilon)/\epsilon$, and let the functions v^a satisfy the condition in* (4.3). *It follows that the averaged system is a simple mechanical system subject to no force and with Hamiltonian*

$$H_{\text{averaged}}(q,p) = V_{\text{averaged}}(q) + \frac{1}{2} p' M(q)^{-1} p,$$

where the averaged potential *is defined as*

$$V_{\text{averaged}}(q) \triangleq V(q) + \sum_{a,b=1}^{m} \Lambda_{ab} \langle \varphi_a : \varphi_b \rangle (q). \tag{4.13}$$

Accordingly, the equations of motion for the averaged system are

$$\frac{D\,\dot{q}}{dt} = -\operatorname{grad}(V_{\text{averaged}}) + R(q)\dot{q}.$$

The result follows directly from Lemma 4.2 and Theorem 4.1. Theorem 4.3 can be used as follows. In order to stabilize a mechanical control system, we design oscillatory inputs that render V_{averaged} positive definite about the desired equilibrium point. The next section presents this idea in detail.

5. Vibrational stabilization of mechanical systems. In this section, we apply the averaging results to stabilization problems. We focus on simple mechanical systems, consider the point stabilization problem via oscillatory inputs, and rely on the averaged Hamiltonian as a candidate control Lyapunov function; see [44].

We start by presenting the notion of vibrational stabilization according to the treatments in [9, 10, 11]. Consider the control system

$$\frac{dx}{dt} = f(x) + g_a(x)u^a(t). \tag{5.1}$$

A critical point x_1 of f is said to be *vibrationally stabilizable*[3] if, for any $\delta > 0$, there exist almost-periodic zero-average inputs $u^a(t)$ such that the system in (5.1) has an asymptotically stable almost periodic solution $x^*(t)$ characterized by

$$\|\overline{x}^* - x_1\| \leq \delta, \qquad \overline{x}^* = \lim_{T\to\infty} \frac{1}{T} \int_0^T x^*(s)ds.$$

REMARK 5.1. *We refer to* [9, 10, 11] *for the vibrational stabilization theory for systems controlled by vector additive, linear, and nonlinear multiplicative forcing. Adopting these definitions, the vibrational stabilization problem we consider corresponds to a nonlinear multiplicative setting; see* [11]. *In that paper, the ith component of the vibrational forcing depends only on the ith state variable. This requirement is removed here, and the structure of the nonlinearities we consider is more general.*

5.1. Stabilization in systems with integrable inputs. Once more, consider the control system in (4.11):

$$\frac{D\,\dot{q}}{dt} = -\operatorname{grad} V(q) + R(q)\dot{q} \;+\; \operatorname{grad} \varphi_a(q)u^a(t). \tag{5.2}$$

We present a notion of vibrational stabilization tailored to mechanical systems. A configuration q_1 is said to be *vibrationally stabilizable* if, for any $\delta > 0$, there exist almost-periodic zero-average inputs $u^a(t)$ such that the system in (5.2) has an asymptotically stable almost-periodic solution $q^*(t)$ characterized by

$$\|\overline{q}^* - q_1\| \leq \delta, \qquad \overline{q}^* = \lim_{T\to\infty} \frac{1}{T} \int_0^T q^*(s)ds. \tag{5.3}$$

This definition is weaker than the general one above since no requirement is imposed on the behavior of the velocity variables $\dot{q}$.

Next, we design vibrationally stabilizing control laws. The following useful lemma focuses on "inverting" the definition of $\Lambda = \Lambda(v^1, \ldots, v^m)$ in (4.4).

LEMMA 5.2 (design of vibrations). *Let $t \in [0, T]$, and define a vector-valued function of time $v(t) = [v^1(t), \ldots, v^m(t)]'$ that satisfies* (4.2) *and* (4.3). *Any matrix Λ computed according to* (4.4) *is symmetric and positive semidefinite. Vice versa, given any symmetric positive semidefinite matrix Λ, there exists a vector-valued function of time v that satisfies* (4.2), (4.3), *and* (4.4).

Proof. Obviously, Λ is symmetric, and, for any vector $x \in \mathbb{R}^m$, one has

$$x'\Lambda x = \int_0^T \left(\int_0^{s_1} \big(x'v(s_2)\big) ds_2 \right)^2 ds_1 \geq 0.$$

[3] Baillieul and Lehman [6] assume both the inputs and the asymptotically stable solution x^* to be T-periodic.

Given any symmetric positive semidefinite Λ, we design inputs that satisfy (4.2), (4.3), and (4.4). First, we introduce the T-periodic base functions

$$\psi_i(t) = \frac{4\pi i}{T} \cos\left(\frac{2\pi\, i}{T} t\right), \quad i \in \mathbb{N}.$$

Any linear combination of the $\{\psi_i\}$ satisfies (4.2), (4.3), and

$$\frac{1}{2T} \int_0^T \left(\int_0^{s_1} \psi_i(s_2) ds_2 \right) \left(\int_0^{s_1} \psi_j(s_2) ds_2 \right) ds_1 = \delta_{ij},$$

where δ_{ij} is the Kronecker delta. Next, we diagonalize Λ via an orthogonal similarity transformation W. Assuming the rank of Λ is $p \leq m$, we have

$$\Lambda = W \operatorname{diag}([\lambda_1, \ldots, \lambda_p, 0, \ldots, 0])\, W' = \sum_{i=1}^{p} (\sqrt{\lambda_i} W e_i)(\sqrt{\lambda_i} W e_i)',$$

where $\operatorname{diag}([\lambda_1, \ldots, \lambda_p, 0, \ldots, 0])$ is the diagonal matrix with nonvanishing elements $\{\lambda_1, \ldots, \lambda_p\}$, and where $\{e_i, \ldots, e_n\}$ is the usual basis for $\mathbb{R}^n$. Since the vectors $(\sqrt{\lambda_i} W e_i)$ are uniquely determined by Λ, we define

$$w(t, \Lambda) = \sum_{i=1}^{p} (\sqrt{\lambda_i} W e_i)\, \psi_i(t). \tag{5.4}$$

By construction, $v(t) = w(t, \Lambda)$ satisfies (4.2), (4.3), and (4.4). □

Introduce the control gains $k_1 \in \mathbb{R}^m$, $K_2, K_3 \in \mathbb{R}^{m \times m}$, subject to $K_2 = K_2' \geq 0$ and $K_3 = K_3' \geq 0$. To simplify notation, let $\varphi = [\varphi^1, \ldots, \varphi^m]$, and let the $m \times m$ matrix $\langle \varphi : \varphi \rangle (q)$ have (a, b) component $\langle \varphi_a : \varphi_b \rangle (q)$. Let the control input be the sum of open (feedforward) and closed loop (feedback) terms

$$u(t, \epsilon) = -k_1 - K_2 \varphi + (1/\epsilon) w(t/\epsilon, K_3), \tag{5.5}$$

where w is as defined in (5.4). According to Theorem 4.3 and to Lemma 5.2, the averaged controlled system is Hamiltonian with potential energy given by

$$V_{\text{control}}(q) = V(q) + k_1' \varphi(q) + \frac{1}{2} \varphi(q)' K_2 \varphi(q) + \operatorname{Trace}\big(K_3 \langle \varphi : \varphi \rangle\big), \tag{5.6}$$

where the Trace operation is equivalent to the summation in (4.13). It is useful to note that V_{control} depends linearly on the control gains k_1, K_2, K_3.

Existence and stability of equilibrium points are analyzed according to the classic potential energy criterion. The configuration q_1 is an equilibrium point if it is a critical point for the averaged controlled potential energy V_{control}; it is locally/globally stable if V_{control} has a local/global minimum at q_1. Of course, the point is stable only in the average approximation. We make this point precise in the following theorem.

THEOREM 5.3 (vibrational stabilization of configurations). *Consider the control system in* (5.2)*, and assume the tensor R is strictly quadratically dissipative. Let $q_1 \in \mathbb{R}^n$, and consider the following set of linear matrix equality and inequalities in the free variables k_1, K_2, K_3:*

$$\begin{aligned} K_2 = K_2' \geq 0, \qquad & K_3 = K_3' \geq 0, \\ \frac{\partial V_{\text{control}}}{\partial q}(q_1) = 0, \qquad & \frac{\partial^2 V_{\text{control}}}{\partial q^2}(q_1) > 0. \end{aligned} \tag{5.7}$$

If the convex problem (5.7) *is feasible, the configuration* q_1 *is vibrationally stabilizable, and there exists an* $\epsilon_0 > 0$ *such that stabilizing controls are computed according to* (5.5)*, with* $0 < \epsilon \leq \epsilon_0$ *and with* k_1, K_2, K_3 *solutions to the system of equations* (5.7)*.*

Proof. As a first step, we prove that $(q_1, 0)$ is a locally exponentially stable point for the averaged controlled system. We follow a well-known procedure (see [47]) and rely on Theorem 4.3 and Lemma 5.2. At $q = q_1$, the function V_{control} in (5.6) and its gradient vanish, while its Hessian is positive definite. The total energy $H_{\text{control}}(q, \dot{q}) \triangleq V_{\text{control}}(q) + \frac{1}{2}\dot{q}' M \dot{q}$ is therefore positive definite about $(q_1, 0)$. Because R is strictly quadratically dissipative, there exists a $\beta > 0$ such that, along the solutions of the averaged controlled system,

$$\dot{H}_{\text{control}} = -\beta \langle\!\langle \dot{q}\,,\, \dot{q} \rangle\!\rangle.$$

The function H_{control} is a Lyapunov function for the averaged controlled system, and $(q_1, 0)$ is a stable equilibrium point. Asymptotic stability follows from an application of LaSalle's lemma; exponential stability follows from a linearization argument.

As a second step, we prove that the controlled system has a unique periodic exponentially stable solution $q(t)$ in a neighborhood of q_1. We follow a well-known procedure (see [10]) and rely on Theorem 4.1. Since the averaged system has an exponentially stable point, the curve $z(t)$ is a solution to a differential equation which possesses a unique periodic orbit, say, $z^\star(t)$, which is exponentially stable and belongs to an $O(\epsilon)$ neighborhood of $(q_1, 0)$. The same statement can be made for the first component of $z(t)$, that is, the curve $q(t)$. We call this periodic orbit $q^\star(t)$ and its average $\overline{q}^\star$, as defined in (5.3). Since $q^\star(t)$ lives in a $O(\epsilon)$ neighborhood of q_1, so does $\overline{q}^\star$. Therefore, there must exist ϵ_0 such that $\|\overline{q}^* - q_1\| \leq \delta$ for any $\delta > 0$. □

The stability result relies on the open loop system having full rank dissipation; i.e., the tensor R is required to be strictly quadratically dissipative. This requirement can be weakened by augmenting the control input with a "derivative action" (a term negatively proportional to the velocity). Asymptotic stability is then guaranteed under a linear-controllability–like condition; see [47, 15].

The location of the poles of the linearized model about q_1 affects the behavior of the controlled system. Given that a large oscillatory signal is superimposed, better performance is achieved when these poles are far to the left of the imaginary axis. This and related performance requirements can be addressed within the linear matrix equality and inequality formulation; see the surveys in [48, 14].

5.2. Vibrational stabilization of an underactuated two-link manipulator. We present a simple example of vibrational stabilization. We consider a planar two-link manipulator as depicted in Figure 5.1: no potential energy is present. We assume the manipulator is subject to damping forces at both angles.

The configuration of the system is described by the pair (θ_1, θ_2), where θ_1 is the angle between the first link and the horizontal axis and θ_2 is the relative angle between the two links. Both angles are measured counterclockwise. The links' physical parameters are length ℓ, mass m, and moment of inertia I. We let $\ell_1 = 3, \ell_2 = 4$, $m_1 = I_1 = \ell_1^2$, and $m_2 = I_2 = \ell_2^2$. A known procedure provides the inertia matrix:

$$M(q) = \begin{bmatrix} \frac{1013}{4} + 192\cos(\theta_2) & 16(5 + 6\cos(\theta_2)) \\ 16(5 + 6\cos(\theta_2)) & 80 \end{bmatrix}.$$

We assume the system is subject to the damping force $(-.2\dot{\theta}_1, -.2\dot{\theta}_2)$ and to a single control input, i.e., a torque τ applied at the first joint. Accordingly, the force can

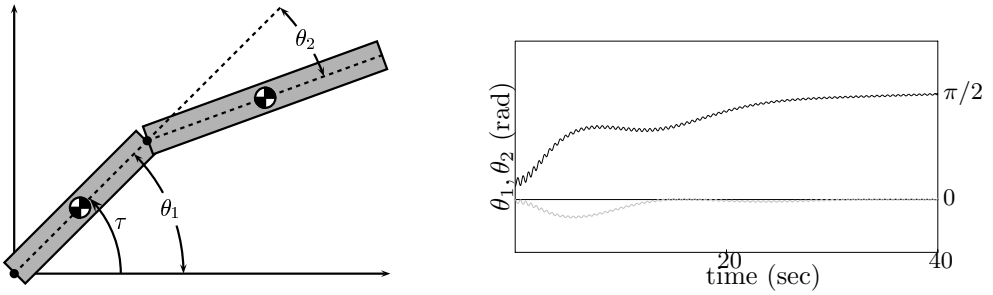

FIG. 5.1. *Two-link manipulator: θ_1 and θ_2 are measured counterclockwise. In the right figure, the gray line is θ_1, and the black line is θ_2. Despite the superimposed oscillatory behavior, the variables (θ_1, θ_2) converge to the global minimum of the averaged controlled potential energy.*

be described by the function $\varphi(q) = \theta_1$. The symmetric product is easily computed according to Lemma 4.2:

$$\langle \varphi : \varphi \rangle (q) = \frac{20}{2313 - 1152\cos(2\theta_2)}.$$

We adopt the control law in (5.5) and compute the averaged controlled potential according to (5.6):

$$V_{\text{control}}(q) = k_1\theta_1 + \frac{1}{2}k_2\theta_1^2 + k_3\frac{20}{2313 - 1152\cos(2\theta_2)}.$$

At $k_1 = 0$ and for any positive k_2 and k_3, the function V_{control} has two global minima at $(\theta_1, \theta_2) = (0, \pm\pi/2)$.

We run the simulation as follows. We design the control law parameters as $\epsilon = .5$, $T = 1$, $k_2 = 15$, and $k_3 = 150$. At initial time, the manipulator is at rest with angles $(\theta_1(0), \theta_2(0)) = (0, \pi/16)$. This initial condition is in the domain of attraction of the minimum $(\theta_1, \theta_2) = (0, \pi/2)$. The differential equation solver `NDSolve` within Mathematica generated the simulation results reported in Figure 5.1.

We conclude the example with a final remark. The stabilization result is not surprising, and it intuitively agrees with the classic example in [6], where the controlled variable is the speed of the joint connected to the second link and where the joint itself is constrained to move vertically.

6. Conclusions. This paper provides a systematic study of high magnitude high frequency averaging for mechanical systems. The averaging extends the results of earlier works in two directions. First, the analysis applies to the multi-input setting where controls are not necessarily applied to cyclic variables. Instead, forces are described as generic one-forms. Additionally, our analysis applies to the case of mechanical systems with nonholonomic constraints. From a control design viewpoint, the improved analysis leads to sufficient tests for an appropriate notion of vibrational stabilization.

At the heart of the proposed approach is a detailed analysis of the Lie algebraic structure of mechanical systems (with or without constraints, with or without non-integrable forces). It is this structure that enables closed form expressions for the averaging analysis. Furthermore, it is this same structure that underlies the controllability analysis in [32]. Our analysis provides a missing link between the notions of averaged potential [3] and symmetric product [32].

Numerous extensions appear promising. First, one could pursue generalizations to high order averaging and applications in the field of robotic motion planning; see [17, 16]. Second, the setting of distributed parameter systems with Lagrangian structure might provide a number of interesting applications and further theoretical challenges. Finally, the tools developed here might shed new light on the problem of existence and stability of limit cycles in the study of animal and robotics locomotion.

Appendix. The variations of constants formula in geometric terms.

LEMMA A.1. *Let f, g be smooth time-varying vector fields on $\mathbb{R}^n$. Let $x_0 \in \mathbb{R}^n$, and let $T \in \mathbb{R}^n$ be small enough so that the flow map $\Phi^g_{0,T}$ is a local diffeomorphism in a neighborhood of x_0. The final value $x(T) = \Phi^{f+g}_{0,T}(x_0)$ can be written as*

$$x(T) = \Phi^g_{0,T}(z(T)), \tag{A.1}$$

$$\dot{z}(t) = ((\Phi^g_{0,t})^* f)(z), \quad z(0) = x_0. \tag{A.2}$$

Additionally, we have the formal equality

$$((\Phi^g_{0,t})^* f)(t,x) = f(x) + \sum_{k=1}^{\infty} \int_0^t \dots \int_0^{s_{k-1}} \left(\mathrm{ad}_{g(s_k,x)} \dots \mathrm{ad}_{g(s_1,x)} f(x)\right) ds_k \dots ds_1. \tag{A.3}$$

Proof. Let $x(T) = \Phi^{f+g}_{0,T}(x_0)$, and let $y(T) = \Phi^g_{0,T}(z(T))$, where $z(t)$ is computed via (A.2). We compute

$$\begin{aligned} \dot{z} &= ((\Phi^g_{0,t})^* f)(z) = (T_z(\Phi^g_{0,t})^{-1} \circ f \circ \Phi^g_{0,t})(z) \\ &= \left(T_z \Phi^g_{0,t}\right)^{-1} \circ f(y(t),t) \end{aligned}$$

so that

$$\begin{aligned} \dot{y}(t) &= \frac{d}{dt}\left(\Phi^g_{0,t}(z(t))\right) = g\left(\Phi^g_{0,t}(z(t)),t\right) + \left(T_z \Phi^g_{0,t}(z(t))\right) \dot{z} \\ &= g\left(y(t),t\right) + \left(T_z \Phi^g_{0,t}(z(t))\right) \dot{z} = g\left(y(t),t\right) + f(y(t),t). \end{aligned}$$

Therefore, $y(t)$ obeys the same differential equation as $x(t)$. Since it is also clear that $x(0) = y(0)$, the curves x and y must be equal.

Next, we investigate the pull-back of f along the flow of g. We assume f to be time-invariant and g time-varying. The following statement is proved in [1, Theorem 4.2.31] and in [2, equation (3.3)]:

$$\frac{d}{dt}((\Phi^g_{0,t})^* f)(t,x) = (\Phi^g_{0,t})^*[g(t,x), f(x)],$$

where the Lie bracket between g and f is computed at t fixed. At fixed $x \in \mathbb{R}^n$, we integrate the previous equation from time 0 to t to obtain

$$((\Phi^g_{0,t})^* f)(t,x) = f(x) + \int_0^t (\Phi^g_{0,s})^*[g(s,x), f(x)] ds.$$

The formal expansion in (A.3) follows from iteratively applying the previous equality. ∎

EXTENSION OF THE PERRON–FROBENIUS THEOREM TO HOMOGENEOUS SYSTEMS*

DIRK AEYELS† AND PATRICK DE LEENHEER‡

Abstract. This paper deals with a particular class of positive systems. The state components of a positive system are positive or zero for all positive times. These systems are often encountered in applied areas such as chemical engineering or biology. It is shown that for this particular class the first orthant contains an invariant ray in its interior. An invariant ray generalizes the concept of an eigenvector of linear systems to nonlinear homogeneous systems. Then sufficient conditions for uniqueness of this ray are given. The main result states that the vector field on an invariant ray determines the stability properties of the zero solution with respect to initial conditions in the first orthant. The asymptotic behavior of the solutions is examined. Finally, we compare our results to the Perron–Frobenius theorem, which gives a detailed picture of the dynamical behavior of positive linear systems.

Key words. positive systems, cooperative systems, homogeneous systems, monotone flows, global asymptotic stability

1. Introduction.

A dynamical system is said to be *positive* if it leaves the first orthant of $\mathbb{R}^n$ invariant for future times when initiated in this orthant. Examples of these systems abound in a variety of applied areas such as biology, chemistry, economics, and sociology [6], [14], [9]. In a biological system, for example, a state component will typically be the number of individuals of a certain species in a population of interacting species. State components in a chemical system are typically concentrations or amounts of chemical substances. Important issues arising in the study of positive systems are the boundedness of solutions, permanence or persistence, and the (asymptotic) stability of equilibrium points. In this paper the stability properties of the zero solution of a class of positive systems is considered. At first glance, it might be surprising that we are interested in the zero solution, because in most applications this solution is not very interesting. For example, it corresponds to death of all species in a biological context, or to washout of all chemicals in chemical engineering. In the context of positive systems, nontrivial equilibrium points are of much more interest. However, these equilibrium points arise in models where some type of control action is already present in the model, although implicitly.

As an illustration, consider the simplest example of the well-known predator-prey model proposed by Volterra (see [6]) to explain the observed oscillations in the biomass of prey species (denoted by x) and predator species (denoted by y):

$$\dot{x} = -axy + bx,$$
$$\dot{y} = cxy - dy,$$

where a, b, c, and d are positive constants. The term bx is the growth rate of the prey species and suggests the availability of a feeding source. The abundance of the food is represented by the parameter b, which can be interpreted as the implicit control action hinted at before. If there is no food ($b = 0$), then the only equilibrium point of the system is the trivial one. If there is food available ($b > 0$), then there is a nontrivial equilibrium point. It might not come as a surprise that the stability behavior of the zero solution of the simpler system with $b = 0$ determines to some extent the behavior of the system with $b > 0$. (Bifurcation theory might serve as a tool here.) This motivates the study of the zero solution for the case in which $b = 0$.

We provide another example of a chemical reactor at the end of section 5.

Therefore, the study of the stability behavior of the zero solution is not only interesting in its own right, but also important for control purposes.

Homogeneous systems on $\mathbb{R}^n$ (see, e.g., [3]) are a particular class of nonlinear systems. *Invariant rays*—when they exist—play an important role in the study of the stability behavior of the zero solution of a homogeneous system. An invariant ray is a particular curve that is invariant for the flow of the system. It can be interpreted as the generalization of the concept of the linear space spanned by an eigenvector of a real eigenvalue, in the context of *linear* systems, to the context of *homogeneous*—and thus generally nonlinear—systems. Suppose that a homogeneous system possesses a number of invariant rays. A necessary condition for global asymptotic stability (GAS) of the zero solution is that the vector field on all invariant rays points towards the origin. Although this condition is not sufficient in general for GAS, we introduce a particular class of homogeneous systems for which invariant rays determine the stability behavior.

Within the class of positive systems, cooperative and irreducible systems are well examined [5], [13]. In this paper a class of positive systems is introduced, characterized by *homogeneous* cooperative and irreducible vector fields. It is shown that these systems enjoy a fairly simple dynamical behavior. This may come as a surprise, since it is well known that the behavior of homogeneous systems is in principle as involved as the behavior of general nonlinear systems.

Next, to describe our results in some detail, we digress to discuss positive *linear* systems, known to model a number of important physical systems; see, e.g., [9]. A necessary and sufficient condition for a linear system $\dot{x} = Ax$ to be positive is that A be a Metzler matrix (i.e., have nonnegative off-diagonal entries) or equivalently that the system be cooperative. The principal tool for the analysis of the (stability) behavior of a positive linear system is the Perron–Frobenius theorem. It is natural to ask whether it is possible to generalize this to classes of positive *nonlinear* systems. The purpose of this paper is to show that this is indeed the case for homogeneous cooperative and irreducible systems.

First of all it is shown that these systems *always* possess an invariant ray in the interior of the first orthant. If the order of the homogeneous vector field is equal to zero, then this ray is unique in the first orthant; if the order of the vector field is strictly greater than zero, then the ray is unique in the first orthant if the vector field on this ray does not point away from the origin. In both cases the stability behavior of the zero solution of the system is determined by the behavior of the system on this unique invariant ray.

Several invariant rays may exist if the order of the homogeneous vector field is strictly greater than zero and if the vector field on every invariant ray points away from the origin. In this case the stability behavior of the zero solution of the system

is also determined by the behavior of the system on the invariant rays.

This paper is organized as follows. Basic definitions are given in section 2. In section 3, results on homogeneous systems are reviewed. A class of positive homogeneous systems is introduced in section 4, leading to a criterion for GAS of the zero solution with respect to the initial conditions in $\mathbb{R}^n_+$ (section 5). The asymptotic behavior of solutions of this class of systems is examined in section 6. The paper is concluded in section 7 with a discussion; in particular, the classical Perron–Frobenius theorem for linear differential equations (see [1] or [13]) is compared to the results of this paper.

2. Preliminaries. Let $\mathbb{R}$ be the set of real numbers, and $\mathbb{R}^n$ the set of n-tuples with all components belonging to $\mathbb{R}$. For $x \in \mathbb{R}^n$, $|x|$ is the Euclidean norm of x. $\mathbb{R}^+ := [0, +\infty)$, $\mathbb{R}^+_0 := (0, +\infty)$, and $\mathbb{R}^n_+$ $(\mathrm{int}(\mathbb{R}^n_+))$ is the set of n-tuples with all components belonging to $\mathbb{R}^+$ $(\mathbb{R}^+_0)$. Finally, $\mathrm{bd}(\mathbb{R}^n_+) := \mathbb{R}^n_+ \setminus \mathrm{int}(\mathbb{R}^n_+)$ is the boundary of $\mathbb{R}^n_+$.

Let $x, y \in \mathbb{R}^n_+$; then $x \leq y$ means $x_i \leq y_i$ $\forall i = 1, \ldots, n$. Furthermore, $x < y$ if and only if $x \leq y$ and $x \neq y$, while $x \ll y$ if and only if $x_i < y_i$ $\forall i = 1, \ldots, n$. For subsets U and V of $\mathbb{R}^n_+$, we denote $U \leq (<, \ll) V$ if $x \leq (<, \ll) y$ $\forall x \in U$ and $y \in V$.

For $x \in \mathbb{R}^n$, $\mathrm{diag}(x)$ stands for an $n \times n$ diagonal matrix, where the ith diagonal entry is equal to x_i, the ith component of the vector x. A real $n \times n$ matrix $A = (a_{ij})$ is *Metzler* if and only if its off-diagonal entries a_{ij}, $\forall i \neq j$, belong to $\mathbb{R}^+$.

A real $n \times n$ matrix $A = (a_{ij})$ is *reducible* if and only if the index set $N := \{1, 2, \ldots, n\}$ can be split into two sets J and K, with $J \cup K = N$ and $J \cap K = \emptyset$ such that $a_{jk} = 0$ $\forall j \in J$ and $k \in K$.

It is clear that A is reducible if and only if there exists a permutation matrix P such that

$$PAP^T = \begin{pmatrix} B & 0 \\ C & D \end{pmatrix},$$

where B and D are square matrices.

The *standard basis* of the vector space $\mathbb{R}^n$ is given by $\{e_i | i \in N\}$, where the ith entry of e_i is equal to 1, while the other entries are equal to 0. An m-dimensional *coordinate subspace* of $\mathbb{R}^n$ is a subspace of $\mathbb{R}^n$ with a basis $\{e_{k_1}, e_{k_2}, \ldots, e_{k_m}\}$, with $1 \leq k_1 < k_2 < \cdots < k_m$.

The matrix A is reducible if and only if the linear operator, associated to the matrix A and the standard basis, has an m-dimensional invariant coordinate subspace with $1 \leq m < n$.

When A is not reducible, it is *irreducible*.

Consider the system

$$\dot{x} = f(x), \tag{1}$$

where $x \in \mathbb{R}^n$ and $f(x)$ is a continuous vector field on $\mathbb{R}^n$, continuously differentiable (of class C^1) on $\mathbb{R}^n \setminus \{0\}$, and such that $f(0) = 0$. Later we give conditions such that the uniqueness of solutions for system (1) is guaranteed. The *forward solution* of system (1) with initial condition $x_0 \in \mathbb{R}^n$ at $t = 0$ is denoted as $x(t, x_0)$, $t \in \mathcal{I}_{x_0} := [0, T_{\max}(x_0))$, where $\mathcal{I}_{x_0}$ is the *maximal forward interval of existence*. A set $D \subset \mathbb{R}^n$ is *forward invariant* for system (1) if and only if $\forall x_0 \in D$, $x(t, x_0) \in D$ $\forall t \in \mathcal{I}_{x_0}$. System (1) is *positive* if and only if $\mathbb{R}^n_+$ is forward invariant.

Suppose that $D \subset \mathbb{R}^n$ is a forward invariant set for system (1). The flow of system (1) is *monotone in* D if and only if $\forall x_0$, $y_0 \in D$ with $x_0 \leq (<, \ll) y_0$ it holds that $x(t, x_0) \leq (<, \ll) x(t, y_0)$ $\forall t \in (\mathcal{I}_{x_0} \cap \mathcal{I}_{y_0})$.

The flow of system (1) is *strongly monotone in D* if and only if it is monotone in D and $\forall x_0, y_0 \in D$ with $x_0 < y_0$ it holds that $x(t, x_0) \ll x(t, y_0)\ \forall t \in (\mathcal{I}_{x_0} \cap \mathcal{I}_{y_0}) \setminus \{0\}$.

A point $p \in \mathbb{R}^n$ is an *omega limit point* of x_0 if there exists an increasing sequence of time instances $\{t_k\}$, with $t_k \to +\infty$ when $k \to +\infty$, such that $\lim_{t_k \to +\infty} x(t_k, x_0) = p$. The set of all omega limit points of x_0 is the *omega limit set* of x_0 and is denoted by $\omega(x_0)$. Notice that the *omega limit set* of x_0 may be the empty set, for instance if the solution starting in x_0 diverges. If $T_{\max(x_0)} = +\infty$, then the set $\mathcal{O}(x_0) := \{x(t, x_0) | t \in \mathbb{R}^+\}$ is the *forward orbit* of the forward solution $x(t, x_0)$. It follows from classical results on the theory of ordinary differential equations that if $\mathrm{cl}(\mathcal{O}(x_0))$, the closure of the forward orbit $\mathcal{O}(x_0)$, is compact, then $\omega(x_0)$ is nonempty and compact and $d(\omega(x_0), x(t, x_0)) \to 0$ when $t \to +\infty$ (where $d(A, z) := \inf_{y \in A} d(y, z)$ and $d(y, z)$ is the Euclidean distance between y and z).

3. Homogeneous systems. In this section we review the concept of a homogeneous system and discuss some of its properties. Many of these results are known, and no originality is claimed here. However, we have chosen to include the proofs to make the paper self-contained.

3.1. Definition and Euler's formula. We first introduce the concept of a homogeneous vector field [12].

DEFINITION 3.1. *A vector field $f(x)$, $x \in \mathbb{R}^n$, is* homogeneous *of order $\tau \in \mathbb{R}$ with respect to the dilation map $\delta^r_\lambda(x) : \mathbb{R}^n \to \mathbb{R}^n$ with $\delta^r_\lambda(x) = (\lambda^{r_1} x_1, \lambda^{r_2} x_2, \ldots, \lambda^{r_n} x_n)$, where $r := (r_1, r_2, \ldots, r_n)$ is a fixed n-tuple$(r_i \in \mathbb{R}^+_0 \forall i \in N)$, and $\forall \lambda \in \mathbb{R}^+_0$ if and only if*

$$\forall x \in \mathbb{R}^n, \lambda \in \mathbb{R}^+_0 \qquad f(\delta^r_\lambda(x)) = \lambda^\tau \delta^r_\lambda(f(x)). \tag{2}$$

To every n-tuple of positive real numbers, one can associate a dilation map $\delta^r_\lambda(x)$. When $r = (1, 1, \ldots, 1)$, then $\delta^r_\lambda(x)$ is the *standard dilation map*.

System (1) is *homogeneous* if $f(x)$ is homogeneous.

We introduce the following hypothesis:

($\mathcal{H}1$) $f(x)$ is a homogeneous vector field of order $\tau \in \mathbb{R}^+$ with respect to a dilation map $\delta^r_\lambda(x)$.

Notice that if ($\mathcal{H}1$) holds, then $f(0) = 0$ (by continuity of f on $\mathbb{R}^n$), and thus $x = 0$ is an equilibrium point of system (1). Since $f(x)$ is C^1 on $\mathbb{R}^n \setminus \{0\}$, solutions starting in $\mathbb{R}^n \setminus \{0\}$ exist and are unique. On the other hand, the vector field $f(x)$ is only continuous at $x = 0$. This implies that a solution starting in $x = 0$ exists (the zero solution satisfies the differential equation) but might not be unique. The additional hypothesis ($\mathcal{H}1$) excludes the possibility that there are multiple solutions starting in $x = 0$ as proved in [10].

Let U be an open subset of $\mathbb{R}^n$, and suppose that $f(x)$ is a homogeneous vector field of order τ with respect to the dilation map $\delta^r_\lambda(x)$ and of class C^1 on $\mathbb{R}^n$. For future reference we recall Euler's formula:

$$\forall x \in U \qquad \frac{\partial f}{\partial x}(x) \mathrm{diag}(r) x = \mathrm{diag}(r + \tau^*) f(x),$$

where $\tau^* := (\tau, \ldots, \tau)$. This formula is easily proved by first taking the derivative with respect to λ on both sides of (2) and then evaluating the resulting equation for $\lambda = 1$.

3.2. Invariant rays. For $x \in \mathbb{R}^n \setminus \{0\}$ and a fixed but arbitrary dilation map $\delta^r_\lambda(x)$, $R_x := \{\delta^r_\lambda(x) | \lambda \in \mathbb{R}^+_0\}$ is the *ray through x*.

The ω limit sets of points on a ray are related as follows.

LEMMA 3.2. *If system* (1) *satisfies* ($\mathcal{H}1$) *and if* $p \in \omega(x_0)$, *then* $\delta_\lambda^r(p) \in \omega(\delta_\lambda^r(x_0))$.

This follows immediately from the scaling property [7] of solutions of homogeneous differential equations. By the scaling property we mean the following: Suppose that $x(t, x_0)$, $t \in [0, T_{\max}(x_0))$, is a solution of system (1). Then $\forall \lambda \in \mathbb{R}_0^+$ the term $\delta_\lambda^r(x(\lambda^\tau t, x_0))$, $t \in [0, \frac{T_{\max}(x_0)}{\lambda^\tau})$, is also a solution of system (1).

LEMMA 3.3. *If system* (1) *satisfies* ($\mathcal{H}1$) *and if there exists a point* $\bar{x} \in \mathbb{R}^n \setminus \{0\}$ *such that*

$$f(\bar{x}) = \gamma_{\bar{x}} \mathrm{diag}(r) \bar{x} \tag{3}$$

for some $\gamma_{\bar{x}} \in \mathbb{R}$, *then the vector field* $f(x)$ *is tangent to* $R_{\bar{x}}$ *at each point of* $R_{\bar{x}}$.

Proof. Indeed, $\frac{d}{d\lambda}(\delta_\lambda^r(\bar{x}))|_{\lambda=1} = \mathrm{diag}(r)\bar{x}$. This and (3) imply that the vector field $f(x)$ is tangent to $R_{\bar{x}}$ at the point $\bar{x}$. Moreover, $\forall \lambda \in \mathbb{R}_0^+$

$$f(\delta_\lambda^r(\bar{x})) = (\gamma_{\bar{x}} \lambda^\tau) \mathrm{diag}(r) \delta_\lambda^r(\bar{x}), \tag{4}$$

and thus the vector field $f(x)$ is tangent to $R_{\bar{x}}$ in *every* point of $R_{\bar{x}}$, which proves the lemma. Notice that (4) implies that $\forall \lambda \in \mathbb{R}_0^+$

$$\gamma_{\delta_\lambda^r(\bar{x})} = \gamma_{\bar{x}} \lambda^\tau. \qquad \square \tag{5}$$

Suppose that there exists a point $\bar{x} \in \mathbb{R}^n \setminus \{0\}$ such that (3) holds. Then it follows from Lemma 3.3 that the forward (and backward) solution of system (1), starting in an arbitrary point of $R_{\bar{x}}$, stays on this ray for all future (and past) times for which this solution is defined. Such a ray is an *invariant ray* for system (1).

An invariant ray R_y is *asymptotically stable*, *stable*, or *unstable* if and only if $\gamma_x < 0$, $\gamma_x \leq 0$, respectively, $\gamma_x > 0$ for some $x \in R_y$ and by (5) for any $x \in R_y$.

An easy calculation shows that solutions starting on an invariant ray $R_{\bar{x}}$ satisfy the set of decoupled differential equations

$$\dot{x}_k = \left(\gamma_z r_k z_k^{-\frac{\tau}{r_k}}\right) x_k^{1+\frac{\tau}{r_k}} \qquad \forall k \in N \tag{6}$$

for some $z \in R_{\bar{x}}$, and thus $f(z) = \gamma_z \mathrm{diag}(r) z$ for some $\gamma_z \in \mathbb{R}$. Notice that invariant rays do not always exist for homogeneous systems. The linear harmonic oscillator, for example, is homogeneous of order zero with respect to the standard dilation map but does not possess an invariant ray.

3.3. Projection of a homogeneous system. We next introduce the concept of a homogeneous norm.

DEFINITION 3.4. *A* homogeneous norm *associated to the dilation map* $\delta_\lambda^r(x)$ *is a function* $\rho : \mathbb{R}^n \to \mathbb{R}^+$ *satisfying the following:*

1. $\rho(x)$ *is continuous on* $\mathbb{R}^n$ *and of class* C^1 *on* $\mathbb{R}^n \setminus \{0\}$.
2. $\rho(x) = 0$ *only if* $x = 0$.
3. $\forall x \in \mathbb{R}^n$ *and* $\forall \lambda \in \mathbb{R}_0^+$, $\rho(\delta_\lambda^r(x)) = \lambda \rho(x)$.

For example, the function

$$\left(\sum_{i=1}^n |x_i|^{\frac{p}{r_i}} \right)^{\frac{1}{p}}, \tag{7}$$

with $p > \max_{i=1,\ldots,n}(r_i)$, is a homogeneous norm.

Pick an arbitrary homogeneous norm $\rho(x)$. Then the *ρ-homogeneous unit $(n-1)$-sphere* is defined as $S_\rho := \{x \in \mathbb{R}^n | \rho(x) = 1\}$.

LEMMA 3.5. *Suppose that system* (1) *satisfies* ($\mathcal{H}1$). *Consider the system*

$$\dot{x} = g(x) := \begin{cases} \frac{1}{(\rho(x))^\tau} f(x) & \text{for } x \in \mathbb{R}^n_+ \setminus \{0\}, \\ 0 & \text{for } x = 0. \end{cases} \tag{8}$$

Then $g(x)$ is a continuous vector field on $\mathbb{R}^n$, of class C^1 on $\mathbb{R}^n \setminus \{0\}$, and homogeneous of order zero with respect to $\delta^r_\lambda(x)$.

Proof. Indeed, it is clear that $g(x)$ is continuous on $\mathbb{R}^n \setminus \{0\}$, so it only has to be shown that $g(x)$ is continuous at $x = 0$. Pick a sequence $\{x_k\} \to 0$ when $k \to +\infty$. Associated to this sequence is the sequence $\{x'_k\} \subset S_\rho$ with

$$x_k = \delta^r_{\lambda_k}(x'_k) \tag{9}$$

for suitable $\lambda_k \in \mathbb{R}^+_0$ and such that $\{\lambda_k\} \to 0$ when $k \to +\infty$. Then

$$\begin{aligned} \lim_{k \to +\infty} \frac{1}{(\rho(x_k))^\tau} f(x_k) &= \lim_{\lambda_k \to 0} \frac{1}{(\rho(\delta^r_{\lambda_k}(x'_k)))^\tau} f(\delta^r_{\lambda_k}(x'_k)) \\ &= \lim_{\lambda_k \to 0} \frac{1}{\lambda_k^\tau (\rho(x'_k))^\tau} \lambda_k^\tau \delta^r_{\lambda_k}(f(x'_k)) \text{ by homogeneity of } f(x) \text{ and of } \rho(x) \\ &= \lim_{\lambda_k \to 0} \delta^r_{\lambda_k}(f(x'_k)) \qquad \text{because } \rho(x'_k) = 1 \text{ as } \{x'_k\} \subset S_\rho \\ &= 0. \end{aligned}$$

Since $f(x)$ and $\rho(x)$ are of class C^1 on $\mathbb{R}^n \setminus \{0\}$, and since $\rho(x) > 0 \ \forall x \in \mathbb{R}^n \setminus \{0\}$, it follows that $g(x)$ is of class C^1 on $\mathbb{R}^n \setminus \{0\}$. It is also easily verified that $g(x)$ is homogeneous of order *zero* with respect to $\delta^r_\lambda(x)$. ∎

Uniqueness of the solutions for system (8) is guaranteed. A proof of this assertion proceeds along the same lines of the proof of the uniqueness of solutions of system (1). In addition, system (8) is topologically equivalent to system (1). Indeed, the direction of both the vectors $f(x)$ and $g(x)$ is the same $\forall x \in \mathbb{R}^n$. This implies that the solutions of system (1) are transformed to solutions of system (8) by a change in time scale. In particular, a ray is invariant for system (8) if and only if it is invariant for system (1), and system (8) is positive if and only if system (1) is positive.

With system (8) we now associate a system defined on S_ρ as follows. Consider the projection map $\pi : \mathbb{R}^n \setminus \{0\} \to S_\rho$ with $\pi(x) := \delta^r_{1/\rho(x)}(x)$. Notice that

$$\pi = \pi \circ \delta^r_\lambda \tag{10}$$

$\forall \lambda \in \mathbb{R}^+_0$. This means that the image of a ray under π is a unique point of S_ρ. Geometrically, $\pi(x)$ is the intersection of the ray through x and S_ρ.

Now pick a point $m \in \mathbb{R}^n \setminus \{0\}$ and consider R_m. It will now be shown that *for all points m'* of the ray R_m, the tangent mapping of π maps the vector $g(m')$ to the *same* vector at $\pi(m)$. More precisely, it will be shown that

$$T_m \pi(g(m)) = T_{m'} \pi(g(m')) \tag{11}$$

$\forall m' \in R_m$, where $T_m \pi$ is the derivative of π at m.

For $m' \in R_m$ there exists by the definition of R_m a $\tilde{\lambda} \in \mathbb{R}^+_0$ such that

$$m' = \delta^r_{\tilde{\lambda}}(m). \tag{12}$$

Then

$$\begin{aligned} T_m\pi(g(m)) &= T_m(\pi \circ \delta^r_{\tilde{\lambda}})(g(m)) && \text{by (10)} \\ &= T_{\delta^r_{\tilde{\lambda}}(m)}\pi \circ T_m\delta^r_{\tilde{\lambda}}(g(m)) && \text{by the chain rule} \\ &= T_{m'}\pi \circ T_m\delta^r_{\tilde{\lambda}}(g(m)) && \text{by (12)} \\ &= T_{m'}\pi \circ \delta^r_{\tilde{\lambda}}(g(m)) && \text{by linearity of the dilation map} \\ &= T_{m'}\pi(g(m')) && \text{by homogeneity of } g \text{ of order zero and (12).} \end{aligned}$$

Since the preimage of a point $y \in S_\rho$, $\pi^{-1}(y)$ is equal to the ray through y, R_y, and by (11), it follows that $\forall y \in S_\rho$ a unique tangent vector $h(y) \in T_yS_\rho$ can be defined as follows:

$$h(y) = T_m\pi(g(m)) \qquad \forall m \in R_y. \tag{13}$$

It remains to be shown that h defines a vector field of class C^1 on S_ρ. This is done by showing that for every C^∞ function $\tilde{f} : S_\rho \to \mathbb{R}$ the function $h(\tilde{f}) : S_\rho \to \mathbb{R}$ is of class C^1 on S_ρ.

For all $m \in \mathbb{R}^n \setminus \{0\}$ it holds that

$$\begin{aligned} h(\pi(m))(\tilde{f}) &= T_m\pi(g(m))(\tilde{f}) && \text{by (13)} \\ &= g(m)(\tilde{f} \circ \pi) && \text{by definition of the tangent mapping.} \end{aligned}$$

This implies that

$$h(\tilde{f}) \circ \pi|_m = g(\tilde{f} \circ \pi)|_m \tag{14}$$

$\forall m \in \mathbb{R}^n \setminus \{0\}$, and thus $h(\tilde{f}) \circ \pi = g(\tilde{f} \circ \pi)$. Denoting the canonical injection by $j : S_\rho \to \mathbb{R}^n \setminus \{0\}$, we obtain that

$$h(\tilde{f}) \circ \pi \circ j = g(\tilde{f} \circ \pi) \circ j. \tag{15}$$

Since $\pi \circ j$ is the identity mapping on S_ρ, it follows that $h(\tilde{f}) = g(\tilde{f} \circ \pi) \circ j$, which is clearly of class C^1 on S_ρ.

Thus the following system can be considered:

$$\dot{y} = h(y), \tag{16}$$

where $y \in S_\rho$ and h is the vector field of class C^1 defined above.

We conclude this section with the following claim.

PROPOSITION 3.6. *Suppose that $y_0 \in S_\rho$ is an equilibrium point for system* (16). *Then R_{y_0} is an invariant ray for system* (8).

Proof. Since $h(y_0) = 0$, it follows by (13) that

$$T_m\pi(g(m)) = 0 \qquad \forall m \in R_{y_0}. \tag{17}$$

By the chain rule, we have that the tangent mapping of the mapping $j \circ \pi : \mathbb{R}^n \setminus \{0\} \to \mathbb{R}^n \setminus \{0\}$ equals

$$T_m(j \circ \pi) = T_{\pi(m)}j \circ T_m\pi. \tag{18}$$

We obtain from (17) and (18) that $\forall m \in R_{y_0}$

$$(T_m(j \circ \pi))(g(m)) = 0. \tag{19}$$

In local coordinates we have that $j \circ \pi(x) = (\frac{1}{\rho^{r_1}(x)} x_1, \ldots, \frac{1}{\rho^{r_n}(x)} x_n)$, and this implies that

$$g(m) = \frac{1}{\rho(x)} \left(\sum_{i=1}^{n} \frac{\partial \rho}{\partial x_i}(m) g_i(m) \right) \operatorname{diag}(r) m \tag{20}$$

$\forall m \in R_{y_0}$, and therefore R_{y_0} is an invariant ray for system (8). □

4. A class of positive homogeneous systems. We call on the concept of a cooperative vector field, which has been widely studied [5], [13].

DEFINITION 4.1. *A vector field $f(x)$, $x \in \mathbb{R}^n$, is* cooperative in $W \subset \mathbb{R}^n$ *if the Jacobian matrix $\frac{\partial f}{\partial x}$ is Metzler $\forall x \in W$.*

System (1) is called *cooperative* if the following hypothesis holds.

($\mathcal{H}2$) $f(x)$ is cooperative in $\mathbb{R}^n_+ \setminus \{0\}$.

THEOREM 4.2. *If system* (1) *satisfies* ($\mathcal{H}1$) *and* ($\mathcal{H}2$), *then $\mathbb{R}^n_+$ is a forward invariant set for system* (1).

Proof. Since $\tau \geq 0$ and $f(x)$ is cooperative in $\mathbb{R}^n_+ \setminus \{0\}$, it follows from Euler's formula that $f_i(x) \geq 0 \; \forall x \in \mathbb{R}^n_+ \setminus \{0\} : x_i = 0$. Also $f(0) = 0$ and the uniqueness of solutions for system (1) are guaranteed, as has been shown in the previous section. Then forward solutions cannot leave $\mathbb{R}^n_+$, proving Theorem 4.2. □

For future reference we apply Kamke's theorem to obtain the following.

PROPOSITION 4.3. *If system* (1) *satisfies* ($\mathcal{H}1$) *and* ($\mathcal{H}2$), *then the flow of system* (1) *is monotone in $\mathbb{R}^n_+$.*

Proof. This follows from Kamke's theorem [13, Remark 1.4, p. 34] if the following conditions hold:

1. $f(x)$ is of *type K* on $\operatorname{int}(\mathbb{R}^n_+)$, i.e., $\forall x, y \in \operatorname{int}(\mathbb{R}^n_+)$ with $x \leq y$ it holds that $f_i(x) \leq f_i(y) \; \forall i : x_i = y_i$. It is easily checked that $f(x)$ is of type K on $\operatorname{int}(\mathbb{R}^n_+)$ since ($\mathcal{H}2$) holds (see [13, Remark 1.1, p. 33]).
2. $\mathbb{R}^n_+$ is a forward invariant set for system (1). This follows from Theorem 4.2.
3. $\forall x, y \in \mathbb{R}^n_+$ with $x < y$ there exist sequences $\{x_n\}, \{y_n\} \subset \operatorname{int}(\mathbb{R}^n_+)$ such that $x_n < y_n \; \forall n$ and $x_n \to x$, $y_n \to y$ when $n \to +\infty$. It is easily checked that this condition holds.
4. $f(x)$ is continuously differentiable on some neighborhood of $\mathbb{R}^n_+$. This condition is not necessarily satisfied here. Indeed, it may happen that $\frac{\partial f}{\partial x}$ is not defined at $x = 0$. A closer look at the proof of Kamke's theorem as stated in [13] indicates that only the continuity of solutions with respect to initial conditions is needed. Since we have shown that with ($\mathcal{H}1$) the solutions of system (1) are unique, it follows that solutions of system (1) are continuous with respect to initial conditions [4, Theorem 2.1, p. 94].

This concludes the proof. □

THEOREM 4.4. *If system* (1) *satisfies* ($\mathcal{H}1$) *and* ($\mathcal{H}2$), *then there exists at least one invariant ray in $\mathbb{R}^n_+$ for system* (1).

Proof. Since, by Theorem 4.2, $\mathbb{R}^n_+$ is a forward invariant set for system (1), $\mathbb{R}^n_+$ is also a forward invariant set for system (8). It follows that the set $S_{\rho,+} := \mathbb{R}^n_+ \cap S_\rho$ is a forward invariant set for system (16). If not, there exists a forward solution $y(t, y_0)$, $y_0 \in S_{\rho,+}$ and $t \in \mathcal{I}_{y_0}$, for system (16) and a $T \in \mathcal{I}_{y_0}$ such that $y(T, y_0) \in S_\rho \setminus S_{\rho,+}$. But then the forward solution of system (8) starting in y_0 at $t = 0$, $z(t, y_0)$, is such that $z(T, y_0) \in \mathbb{R}^n \setminus \mathbb{R}^n_+$, and thus we obtain a contradiction.

Since $S_{\rho,+}$ is compact, system (16), restricted to $S_{\rho,+}$, is forward complete; i.e., forward solutions are defined $\forall t \in \mathbb{R}^+$. For each $t \in \mathbb{R}^+$ consider the mapping

$\psi_t : S_{\rho,+} \to S_{\rho,+}$ of system (16), mapping $y_0 \to \psi_t(y_0) := y(t, y_0)$. Since $S_{\rho,+}$ is compact and since it is a retract of the $(n-1)$-dimensional unit disk $D^{n-1} := \{x \in \mathbb{R}^{n-1} | \, |x| \leq 1\}$, it follows from a generalization of Brouwer's fixed point theorem (see, e.g., [2, p. 171]) that each (continuous) mapping ψ_t, $t \in \mathbb{R}^+$, has a fixed point x_t^*.

Pick an arbitrary $T^* \in \mathbb{R}_0^+$ and consider the sequence of times $\{\frac{T^*}{n}\}$ with $n \geq 1$ integer and $n \to +\infty$. Then $\forall n$ the map $\psi_{\frac{T^*}{n}}$ has at least one fixed point x_n^*. Since the elements of the sequence $\{x_n^*\}$, $n \to +\infty$, belong to the compact set $S_{\rho,+}$, there exists a convergent subsequence $\{x_{n_k}^*\}$ with $n_k \to +\infty$ when $k \to +\infty$. The limit of this subsequence is denoted as x^*. We will prove that $\psi_t(x^*) = x^* \ \forall t \in \mathbb{R}_0^+$ and thus that x^* is an equilibrium point for system (16).

Pick an arbitrary $t \in \mathbb{R}_0^+$. We can find a sequence of nonnegative integers $\{l_k\}$ and a sequence of real numbers $\{d_k\}$ with $0 \leq d_k < \frac{T^*}{n_k}$ and $d_k \to 0$ when $k \to +\infty$ and such that $t = l_k \frac{T^*}{n_k} + d_k$. It follows that

$$\begin{aligned}
\psi_t(x^*) &= \lim_{k \to +\infty} \psi_t(x_{n_k}^*) \\
&= \lim_{k \to +\infty} \psi_{d_k}(\psi_{l_k \frac{T^*}{n_k}}(x_{n_k}^*)) && \text{because } t = l_k \tfrac{T^*}{n_k} + d_k \\
&= \lim_{k \to +\infty} \psi_{d_k}(x_{n_k}^*) && \text{because } x_{n_k}^* \text{ is a fixed point of } \psi_{l_k \frac{T^*}{n_k}} \\
&= \lim_{k \to +\infty} y(d_k, x_{n_k}^*) && \text{by definition of } \psi_{d_k} \\
&= x^*.
\end{aligned}$$

In the above, the third equality is valid since if x_n^* is a fixed point of $\psi_{\frac{T^*}{n}}$, then x^* is also a fixed point of $\psi_{k\frac{T^*}{n}}$ $\forall$ nonnegative integers k; the fifth equality is valid since $y(t, x_0)$ is continuous on $\mathbb{R}^+ \times S_{\rho,+}$. Since $t \in \mathbb{R}_0^+$ was arbitrary, we have proved that $\psi_t(x^*) = x^* \ \forall t \in \mathbb{R}_0^+$, and thus x^* is an equilibrium point of system (16).

Then by Proposition 3.6, R_{x^*} is an invariant ray for system (8) and thus also for system (1). □

We introduce the following hypothesis:

($\mathcal{H}3$) For $x \in \text{int}(\mathbb{R}_+^n)$, $\frac{\partial f}{\partial x}$ is irreducible. For $x \in \text{bd}(\mathbb{R}_+^n) \setminus \{0\}$, either $\frac{\partial f}{\partial x}(x)$ is irreducible or $f_i(x) > 0 \ \forall i : x_i = 0$.

System (1) is called *irreducible* if ($\mathcal{H}3$) holds.

PROPOSITION 4.5. *If system* (1) *satisfies* ($\mathcal{H}1$), ($\mathcal{H}2$), *and* ($\mathcal{H}3$), *then the flow of system* (1) *is strongly monotone in* $\mathbb{R}_+^n$.

Proof. The flow of system (1) is monotone by Proposition 4.3.

It will now be shown that $\forall x_0, y_0 \in \mathbb{R}_+^n$ with $x_0 < y_0$ it holds that

$$x(t, x_0) \ll x(t, y_0) \qquad \forall t \in (\mathcal{I}_{x_0} \cap \mathcal{I}_{y_0}) \setminus \{0\}. \tag{21}$$

Case 1. $y_0 \in \text{int}(\mathbb{R}_+^n)$.

1. If $x_0 = 0$, then $x_0 \ll y_0$, and thus (21) follows from Proposition 4.3.
2. If $x_0 \neq 0$, then (21) follows from the generalized Kamke theorem in [13, Remark 1.1, p. 58].

Case 2. $y_0 \in \text{bd}(\mathbb{R}_+^n) \setminus \{0\}$. Notice that in this case x_0 belongs to $\text{bd}(\mathbb{R}_+^n)$ since $x_0 < y_0$. We distinguish two cases:

1. $x_0 = 0$. We distinguish two subcases:
   (a) $f_i(y_0) > 0 \ \forall i : (y_0)_i = 0$. It is clear that for t small enough and strictly positive,

   $$0 = x(t, x_0) \ll x(t, y_0). \tag{22}$$

   Then it follows by Proposition 4.3 that (22) holds $\forall t \in \mathcal{I}_{y_0} \setminus \{0\}$, which proves (21).

(b) $\frac{\partial f}{\partial x}(y_0)$ is irreducible. It follows from Proposition 4.3 that $x(t, y_0) > 0$ $\forall t \in \mathcal{I}_{y_0} \setminus \{0\}$. Suppose that (21) does not hold; then there exists some $i \in N$ such that $x_i(t, y_0) = 0$ $\forall t \in [0, t']$, where t' is some strictly positive real number.
On the other hand, since $\frac{\partial f}{\partial x}(y_0)$ is irreducible, it follows from Euler's formula that there exists some $j \in N$ such that $f_j(y_0) > 0$, implying that for small and strictly positive t, $x_j(t, y_0) > 0$.
If $j = i$, then we have reached a contradiction. If $j \neq i$, then we can pick $0 < t_1 < t'$ and consider $x(t_1, y_0) \in \mathrm{bd}(\mathbb{R}^n_+) \setminus \{0\}$.
If $\frac{\partial f}{\partial x}(x(t_1, y_0))$ is reducible, then it follows from $(\mathcal{H}3)$ that $f_k(x(t_1, y_0)) > 0$ $\forall k : x_k(t_1, y_0) = 0$ (and thus, in particular, for $k = i$), yielding a contradiction.
If $\frac{\partial f}{\partial x}(x(t_1, y_0))$ is irreducible, then there exists a $j' \in N$ with $j' \neq j$ such that $x_{j'}(t, y_0) > 0$ for small $t > t_1$. This argument is repeated and ends in a finite number of steps, leading to a contradiction.

2. $x_0 \neq 0$. It follows from Case 2.1 that both solution $x(t, x_0)$ and $y(t, y_0)$ belong to $\mathrm{int}(\mathbb{R}^n_+)$ for $t \in \mathcal{I}_{x_0} \setminus \{0\}$, respectively, $t \in \mathcal{I}_{y_0} \setminus \{0\}$.
On the other hand, it follows from Proposition 4.3 that $x(t, x_0) < y(t, y_0)$ $\forall t \in (\mathcal{I}_{x_0} \cap \mathcal{I}_{y_0}) \setminus \{0\}$. Suppose that (21) does not hold; then there exists some $l \in N$ such that $x_l(t, x_0) = x_l(t, y_0)$ $\forall t \in [0, t'']$, where t'' is some strictly positive real number. This contradicts that the flow on $\mathrm{int}(\mathbb{R}^n_+)$ is strongly monotone, which follows from the generalized Kamke theorem in [13]. ∎

It follows from Theorem 4.4 that if system (1) satisfies $(\mathcal{H}1)$ and $(\mathcal{H}2)$, there exists at least one invariant ray in $\mathbb{R}^n_+$ for system (1). Adding hypothesis $(\mathcal{H}3)$ allows us to draw more conclusions regarding the location of these invariant rays in $\mathbb{R}^n_+$ and their possible uniqueness, by means of the strong monotonicity property of the flow of system (1) as expressed in Proposition 4.5.

THEOREM 4.6. *If system* (1) *satisfies* $(\mathcal{H}1)$, $(\mathcal{H}2)$, *and* $(\mathcal{H}3)$, *then the invariant rays for system* (1) *in* $\mathbb{R}^n_+$ *belong to* $\mathrm{int}(\mathbb{R}^n_+)$.

If the order τ *of the homogeneous vector field* $f(x)$ *is equal to zero, then there exists a* unique *invariant ray for system* (1) *in* $\mathrm{int}(\mathbb{R}^n_+)$.

If the order τ *of the homogeneous vector field* $f(x)$ *is greater than zero and if there exists a stable invariant ray for system* (1) *in* $\mathrm{int}(\mathbb{R}^n_+)$, *then this invariant ray is unique in* $\mathrm{int}(\mathbb{R}^n_+)$.

If the order τ *of the homogeneous vector field* $f(x)$ *is greater than zero and if there exists an unstable invariant ray for system* (1) *in* $\mathrm{int}(\mathbb{R}^n_+)$, *then this invariant ray is not necessarily unique in* $\mathrm{int}(\mathbb{R}^n_+)$. *There may be multiple invariant rays for system* (1) *in* $\mathrm{int}(\mathbb{R}^n_+)$, *all of them unstable.*

Proof. Let $R_{x^*} \subset \mathbb{R}^n_+$ be an invariant ray for system (1); then

$$f(x^*) = \gamma_{x^*} \mathrm{diag}(r) x^* \tag{23}$$

for some $\gamma_{x^*} \in \mathbb{R}$.

First it is shown that $R_{x^*} \subset \mathrm{int}(\mathbb{R}^n_+)$. Suppose not; then $R_{x^*} \subset \mathrm{bd}(\mathbb{R}^n_+)$. According to $(\mathcal{H}3)$, two cases can be distinguished: $\frac{\partial f}{\partial x}(x^*)$ is irreducible or $f_i(x^*) > 0$ $\forall i : x^*_i = 0$.

Case 1. $\frac{\partial f}{\partial x}(x^*)$ is irreducible. From Euler's formula and (23),

$$(\mathrm{diag}(r + \tau^*))^{-1} \frac{\partial f}{\partial x}(x^*) \mathrm{diag}(r) x^* = \gamma_{x^*} \mathrm{diag}(r) x^*. \tag{24}$$

Since $r \in \operatorname{int}(\mathbb{R}^n_+)$, $\tau \in \mathbb{R}^n_+$, and $\frac{\partial f}{\partial x}(x^*)$ is Metzler and irreducible, $(\operatorname{diag}(r+\tau^*))^{-1}\frac{\partial f}{\partial x}(x^*)$ is also Metzler and irreducible. In addition, $\operatorname{diag}(r)x^* \in \operatorname{bd}(\mathbb{R}^n_+) \setminus \{0\}$. However, an irreducible Metzler matrix has no nonzero eigenvector belonging to $\operatorname{bd}(\mathbb{R}^n_+)$ [1]. Thus we obtain a contradiction.

Case 2. $f_i(x^*) > 0\ \forall i : x_i^* = 0$. Since $x^* \in \operatorname{bd}(\mathbb{R}^n_+)$ and with (23), there exists $i \in N$ such that $x_i^* = 0$ and $f_i(x^*) = 0$, yielding a contradiction.

Next it is shown that an invariant ray for system (1) is unique.

Suppose that there are two invariant rays $R_1, R_2 \subset \operatorname{int}(\mathbb{R}^n_+)$ $(R_1 \neq R_2)$ for system (1). Pick an arbitrary point $\bar{x} \in R_1$. There exist two points $p, q \in R_2$ such that $p < \bar{x} < q$ and $p_i = \bar{x}_i$, $q_j = \bar{x}_j$ for some $i \neq j$, $i, j \in N$. Indeed, pick an arbitrary $y \in R_2$. Since $R_2 \subset \operatorname{int}(\mathbb{R}^n_+)$, it follows that $y \gg 0$, and thus the following positive real numbers can be defined:

$$\lambda_1 = \min_{k \in N} \left(\left(\frac{\bar{x}_k}{y_k} \right)^{\frac{1}{r_k}} \right), \tag{25}$$

$$\lambda_2 = \max_{k \in N} \left(\left(\frac{\bar{x}_k}{y_k} \right)^{\frac{1}{r_k}} \right). \tag{26}$$

Since $R_1 \neq R_2$, it follows that $\lambda_1 \neq \lambda_2$. Then there exist $i, j \in N$ with $i \neq j$ such that $\lambda_1 = (\frac{\bar{x}_i}{y_i})^{\frac{1}{r_i}}$ and $\lambda_2 = (\frac{\bar{x}_j}{y_j})^{\frac{1}{r_j}}$. This implies that $p := \delta^r_{\lambda_1}(y)$ and $q := \delta^r_{\lambda_2}(y)$ satisfy the desired properties.

Solutions of system (1) starting on R_1, respectively on R_2, satisfy (6). Since p, $q \in R_2$, there exists a $\tilde{\lambda} \in \mathbb{R}^+_0$ such that $q = \delta^r_{\tilde{\lambda}}(p)$ and $\gamma_q = \tilde{\lambda}^\tau \gamma_p$ (see (5)). It follows from Proposition 4.5 that

$$x(t,p) \ll x(t,\bar{x}) \ll x(t,q), \tag{27}$$

where the first inequality holds $\forall t \in (\mathcal{I}_{\bar{x}} \cap \mathcal{I}_p) \setminus \{0\}$, and the second inequality $\forall t \in (\mathcal{I}_{\bar{x}} \cap \mathcal{I}_q) \setminus \{0\}$. We obtain from (6), (27) and since $p_i = \bar{x}_i$ and $\bar{x}_j = q_j$ that

$$\left(\gamma_p r_i p_i^{-\frac{\tau}{r_i}} \right) p_i^{1+\frac{\tau}{r_i}} < \left(\gamma_{\bar{x}} r_i \bar{x}_i^{-\frac{\tau}{r_i}} \right) \bar{x}_i^{1+\frac{\tau}{r_i}}, \tag{28}$$

$$\left(\gamma_{\bar{x}} r_j \bar{x}_j^{-\frac{\tau}{r_j}} \right) \bar{x}_j^{1+\frac{\tau}{r_j}} < \left(\gamma_q r_j q_j^{-\frac{\tau}{r_j}} \right) q_j^{1+\frac{\tau}{r_j}}, \tag{29}$$

or

$$\gamma_p < \gamma_{\bar{x}} < \gamma_q. \tag{30}$$

Two cases can be distinguished: $\tau = 0$ and $\tau > 0$.

Case 1. $\tau = 0$. If $\tau = 0$, then $\gamma_p = \tilde{\lambda}^0 \gamma_q = \gamma_q$, contradicting (30).

Case 2. $\tau > 0$. We introduce the sign function $\operatorname{sign} : \mathbb{R} \to \mathbb{R}$ as

$$\operatorname{sign}(x) = \begin{cases} -1 & \text{for } x < 0, \\ 0 & \text{for } x = 0, \\ +1 & \text{for } x > 0. \end{cases} \tag{31}$$

From $\gamma_q = \tilde{\lambda}^\tau \gamma_p$ it follows that $\operatorname{sign}(\gamma_p) = \operatorname{sign}(\gamma_q)$.

Case 2(a). $\operatorname{sign}(\gamma_{\bar{x}}) \neq \operatorname{sign}(\gamma_p)$. Since $\operatorname{sign}(\gamma_p) = \operatorname{sign}(\gamma_q)$, it follows from (30) that $\operatorname{sign}(\gamma_{\bar{x}}) = \operatorname{sign}(\gamma_p) = \operatorname{sign}(\gamma_q)$, which is impossible because $\operatorname{sign}(\gamma_{\bar{x}}) \neq \operatorname{sign}(\gamma_p)$.

Case 2(b). $\operatorname{sign}(\gamma_{\bar{x}}) = \operatorname{sign}(\gamma_p)$. Two cases can be distinguished: $\operatorname{sign}(\gamma_{\bar{x}}) = 0$ and $\operatorname{sign}(\gamma_{\bar{x}}) = -1$.

1. $\text{sign}(\gamma_{\bar{x}}) = \text{sign}(\gamma_p) = 0$. This is impossible since, from (30), $\gamma_p < \gamma_{\bar{x}}$.
2. $\text{sign}(\gamma_{\bar{x}}) = \text{sign}(\gamma_p) = -1$. From (30),

$$\gamma_p < \gamma_q. \tag{32}$$

On the other hand, since $p < \bar{x} < q$ and $q = \delta^r_{\tilde{\lambda}}(p)$, it follows that $\tilde{\lambda} > 1$. Furthermore, $\gamma_q = \tilde{\lambda}^\tau \gamma_p$. But since $\text{sign}(\gamma_p) = \text{sign}(\gamma_q) = -1$, $\tau > 0$, and $\tilde{\lambda} > 1$, it follows that $\gamma_q \leq \gamma_p$, contradicting (32). ∎

Notice that Theorem 4.6 does not exclude the possibility of several invariant rays in $\text{int}(\mathbb{R}^n_+)$ for system (1). This can happen only if $\tau > 0$ and if all invariant rays are unstable. This situation can indeed occur; in particular, we will give an example of a planar cooperative irreducible and homogeneous system of order $\tau = 1$ possessing infinitely many unstable invariant rays in $\text{int}(\mathbb{R}^n_+)$.

Example. Consider the following system:

$$\dot{x} = f_1(x) := (x_1 + x_2)x, \tag{33}$$

where $x := (x_1, x_2)^T \in \mathbb{R}^2$. This system is homogeneous of order $\tau = 1$ with respect to the standard dilation map. In addition, $f_1(x)$ is cooperative in $\mathbb{R}^2_+$, and $\frac{\partial f_1}{\partial x}$ is irreducible $\forall x \in \text{int}(\mathbb{R}^2_+)$. Notice that $(\mathcal{H}3)$ is not satisfied.

Next consider the following system:

$$\dot{x} = f_2(x) := \begin{pmatrix} x_1^2 + x_1x_2 + x_2^2 \\ x_1^2 + x_1x_2 + x_2^2 \end{pmatrix}. \tag{34}$$

This system is also homogeneous of order $\tau = 1$ with respect to the standard dilation map. In addition, $f_2(x)$ is cooperative in $\mathbb{R}^2_+$, and $\frac{\partial f_2}{\partial x}$ is irreducible $\forall x \in \mathbb{R}^2_+ \setminus \{0\}$. In particular, $\frac{\partial f_2}{\partial x}$ is irreducible when $x \in \text{bd}(\mathbb{R}^2_+)\setminus\{0\}$.

Based on systems (33) and (34), we would like to construct a system with infinitely many unstable invariant rays in $\text{int}(\mathbb{R}^2_+)$. Before doing so, partition $\mathbb{R}^2_+$ into five conic parts:

$$\mathbb{R}^2_+ := \bigcup_{i=1}^{5} C_i, \tag{35}$$

where $C_1 := \{x \in \mathbb{R}^2_+ | x_2 - \frac{1}{2}x_1 \geq 0, x_1 - \frac{1}{2}x_2 \geq 0\}$, $C_2 := \{x \in \mathbb{R}^2_+ | x_2 - \frac{1}{4}x_1 \leq 0\}$, $C_3 := \{x \in \mathbb{R}^2_+ | x_2 - \frac{1}{2}x_1 < 0, x_2 - \frac{1}{4}x_1 > 0\}$, $C_4 := \{x \in \mathbb{R}^2_+ | x_1 - \frac{1}{4}x_2 \leq 0\}$, and $C_5 := \{x \in \mathbb{R}^2_+ | x_1 - \frac{1}{4}x_2 > 0, x_1 - \frac{1}{2}x_2 < 0\}$.

Now define the system

$$\dot{x} = f(x) := \begin{cases} f_1(x) & \text{for } x \in C_1, \\ f_2(x) & \text{for } x \in C_2, C_4, \\ f_1(x) + g_1(\theta)p(x) & \text{for } x \in C_3, \\ f_1(x) + g_2(\theta)p(x) & \text{for } x \in C_5, \end{cases} \tag{36}$$

where $\theta := \frac{x_2}{x_1}$, $p(x) := (x_2^2, x_1^2)^T$, and $g_1(\theta)$ ($g_2(\theta)$) is a continuously differentiable function defined on $[\theta_2, \theta_1] := [\frac{1}{4}, \frac{1}{2}]$ ($[\theta_3, \theta_4] := [2, 4]$) to be specified hereafter. The aim is to construct $g_1(\theta)$ and $g_2(\theta)$ such that $f(x)$ is continuously differentiable on $\mathbb{R}^2_+$, homogeneous of order $\tau = 1$ with respect to the standard dilation map, cooperative

on $\mathbb{R}^2_+$, and such that $\frac{\partial f}{\partial x}$ is irreducible when $x \in \mathbb{R}^2_+ \setminus \{0\}$. First $g_1(\theta)$ is constructed. Notice that $f_1(x) + g_1(\theta)p(x)$ is homogeneous of order $\tau = 1$ with respect to the standard dilation map since $p(x)$ is homogeneous of order $\tau = 1$ with respect to the standard dilation map and since g_1 is constant along any ray in C_3. For $f(x)$ to be continuous on $\cup_{i=1}^3 C_i$, it suffices that the following hold: $g_1(\theta)$ is continuous on $[\theta_2, \theta_1]$, $g_1(\theta_1) = 0$, and $g_1(\theta_2) = 1$. Consider the Jacobian of $f_1(x) + g_1(\theta)p(x)$ on C_3:

$$\frac{\partial f_1}{\partial x} + g_1(\theta) \begin{pmatrix} 0 & 2x_2 \\ 2x_1 & 0 \end{pmatrix} + \frac{\partial g_1}{\partial \theta} \begin{pmatrix} -\frac{x_2^3}{x_1^2} & \frac{x_2^2}{x_1} \\ -x_2 & x_1 \end{pmatrix}. \tag{37}$$

For $f(x)$ to be continuously differentiable on $\cup_{i=1}^3 C_i$, it suffices that the following hold: $g_1(\theta)$ is continuously differentiable on $[\theta_2, \theta_1]$ and $\frac{\partial g_1}{\partial \theta}(\theta_1) = \frac{\partial g_1}{\partial \theta}(\theta_2) = 0$. Finally, $f(x)$ is cooperative in $\cup_{i=1}^3 C_i$ and irreducible in $(\cup_{i=1}^3 C_i) \setminus \{0\}$ if and only if the off-diagonal elements of the Jacobian (37) are strictly positive when $x \in C_3$. This is the case when the following two conditions are satisfied:

I. $x_1(1 + \theta(2g_1(\theta) + \theta\frac{\partial g_1}{\partial \theta})) > 0$ when $\theta \in [\theta_2, \theta_1]$ and $x \in C_3$.

II. $x_2 + 2g_1(\theta)x_1 - \frac{\partial g_1}{\partial \theta}x_2 > 0$ when $\theta \in [\theta_2, \theta_1]$ and $x \in C_3$.

Condition II is satisfied if $g_1(\theta)$ is chosen such that $g_1(\theta) \geq 0$ and $\frac{\partial g_1}{\partial \theta} \leq 0$ when $\theta \in [\theta_2, \theta_1]$. Summarizing, we are looking for $g_1(\theta) : [\theta_2, \theta_1] \to \mathbb{R}$ such that the following conditions are satisfied:

($\mathcal{C}1$) $g_1(\theta)$ is continuously differentiable in $[\theta_2, \theta_1]$.

($\mathcal{C}2$) $g_1(\theta) \geq 0$ in $[\theta_2, \theta_1]$ and $g_1(\theta_1) = 0$, $g_1(\theta_2) = 1$.

($\mathcal{C}3$) $\frac{\partial g_1}{\partial \theta} \leq 0$ in $[\theta_2, \theta_1]$ and $\frac{\partial g_1}{\partial \theta}(\theta_1) = \frac{\partial g_1}{\partial \theta}(\theta_2) = 0$.

($\mathcal{C}4$) $x_1(1 + \theta(2g_1(\theta) + \theta\frac{\partial g_1}{\partial \theta})) > 0$ when $\theta \in [\theta_2, \theta_1]$ and $x \in C_3$.

From this we propose that $g_1(\theta)$ is a third order polynomial in θ:

$$g_1(\theta) = a\left(\frac{\theta^3}{3} - \frac{\theta_1 + \theta_2}{2}\theta^2 + \theta_1\theta_2\theta + c\right), \tag{38}$$

where a and c are real numbers that we will determine hereafter. It is clear that ($\mathcal{C}1$) and ($\mathcal{C}3$) are satisfied if $a > 0$. From ($\mathcal{C}2$) we find that $c = -\frac{1}{96}$ and $a = 384$, fixing the function $g_1(\theta)$. We have to check whether ($\mathcal{C}4$) holds. This amounts to the following question:

$$h(\theta) := 640\theta^4 - 576\theta^3 + 144\theta^2 - 8\theta + 1 > 0 \qquad \forall\theta \in [\theta_2, \theta_1]? \tag{39}$$

It is easily verified by means of Cardano's formula for finding the roots of a third order polynomial that $\frac{\partial h}{\partial \theta} = 2560(\theta - \theta')(\theta - \theta'')(\theta - \theta^*)$, where $\theta', \theta'' < \theta_2$ and $\theta^* \in (\theta_2, \theta_1)$. In addition, $\frac{\partial^2 h}{\partial \theta^2}(\theta^*) > 0$, and thus $h(\theta)$ reaches a global minimum in $[\theta_2, \theta_1]$. Finally, $h(\theta^*) > 0$, and this implies that $h(\theta) > 0$ $\forall\theta \in [\theta_2, \theta_1]$.

We are left with finding an appropriate $g_2(\theta) : [\theta_3, \theta_4] \to \mathbb{R}$. Because of the symmetry of both $f_1(x)$ and $f_2(x)$ and because $\frac{1}{\theta_3} = \theta_1$ and $\frac{1}{\theta_4} = \theta_2$, we can set $g_2(\theta) := g_1(\frac{1}{\theta})$ $\forall\theta \in [\theta_3, \theta_4]$.

In conclusion, system (36) is homogeneous of order $\tau = 1$ with respect to the dilation map, $f(x)$ is cooperative in $\mathbb{R}^2_+$, and $\frac{\partial f}{\partial x}$ is irreducible for $x \in \mathbb{R}^2_+ \setminus \{0\}$. There are an infinite number of unstable invariant rays for system (36) in $\text{int}(\mathbb{R}^2_+)$. Indeed, *every* ray in C_1 is invariant and unstable for system (36). □

5. Main result. Suppose that system (1) satisfies ($\mathcal{H}1$), ($\mathcal{H}2$), and ($\mathcal{H}3$), and assume that initial conditions for system (1) belong to $\mathbb{R}^n_+$. From Theorem 4.6 it

follows that there exists at least one invariant ray in $\mathbb{R}^n_+$ for system (1) and that this invariant ray belongs to $\text{int}(\mathbb{R}^n_+)$.

If $\tau = 0$, then there exists a unique invariant ray in $\text{int}(\mathbb{R}^n_+)$.

If $\tau > 0$ and if there exists a stable invariant ray in $\text{int}(\mathbb{R}^n_+)$, then this invariant ray is unique.

Consider the flow $\phi_t : \mathbb{R}^n_+ \to \mathbb{R}^n$ of system (1) mapping x_0 to $\phi_t(x_0) := x(t, x_0)$. $\forall x_0 \in \mathbb{R}^n_+$, $\phi_t(x_0)$ exists when $t \in \mathcal{I}_{x_0}$. In the following lemma, we provide sufficient conditions guaranteeing that ϕ_t is defined $\forall t \in \mathbb{R}^+$ when restricting initial conditions to $\mathbb{R}^n_+$.

LEMMA 5.1. *If system* (1) *satisfies* ($\mathcal{H}1$) *and if* $\tau = 0$, *then* $\phi_t : \mathbb{R}^n_+ \to \mathbb{R}^n_+$ *is defined* $\forall t \in \mathbb{R}^+$.

If system (1) *satisfies* ($\mathcal{H}1$), ($\mathcal{H}2$), *and* ($\mathcal{H}3$); *if* $\tau > 0$; *and if there exists a stable (and thus unique) invariant ray for system* (1) *in* $\text{int}(\mathbb{R}^n_+)$, *then* $\phi_t : \mathbb{R}^n_+ \to \mathbb{R}^n_+$ *is defined for all* $t \in \mathbb{R}^+$.

Proof. Case 1. $\tau = 0$. First it will be shown that every forward solution of system (1) remains in a compact set in finite time intervals. Therefore we consider the dynamics of a homogeneous norm:

$$\begin{aligned} \dot{\rho} &= \left(\frac{1}{\rho} \frac{\partial \rho}{\partial x} f \right) \rho \\ &= k(x)\rho. \end{aligned} \tag{40}$$

It is easily verified that

$$k(\delta^r_\lambda(x)) = k(x) \tag{41}$$

$\forall x \in \mathbb{R}^n \setminus \{0\}$ and $\lambda \in \mathbb{R}^+_0$. The function $k(x)$ takes a maximal value M on the compact set $\{z \in \mathbb{R}^n | \rho(z) = 1\}$. In fact, by (41), M is the maximum of $k(x)$ in $\mathbb{R}^n \setminus \{0\}$. Then $\dot{\rho} \leq M\rho$, and thus

$$\rho(x(t, x_0)) \leq e^{Mt}\rho(x_0). \tag{42}$$

This implies that $x(t, x_0)$, $t \in \mathcal{I}_{x_0}$, belongs to the compact set $K := \{z \in \mathbb{R}^n | \rho(z) \leq e^{MT_{\max}(x_0)\rho(x_0)}\}$.

Now suppose that $\mathcal{I}_{x_0} = [0, T_{\max}(x_0))$, with $T_{\max}(x_0) < +\infty$. Pick a sequence $\{x_{t_n}\} \subset x(t, x_0)$ with $t_n \to T_{\max}(x_0)$ when $n \to +\infty$. Since $|f(x)|$ is continuous, it attains a maximum M' on K. Then $\forall t_n$ and t_m

$$\begin{aligned} |x_{t_n} - x_{t_m}| &\leq \int_{t_m}^{t_n} |f(x(t, x_0))| dt \\ &\leq M' |t_n - t_m|. \end{aligned}$$

This implies that $|x_{t_n} - x_{t_m}| \to 0$ when n and $m \to +\infty$. Therefore $\{x_{t_n}\}$ is a Cauchy sequence and thus converges.

Every sequence on $x(t, x_0)$ converges to the same point $p \in K$. Indeed, if this were not the case, then there would exist two Cauchy sequences on $x(t, x_0)$, converging to different points p_1 and $p_2 \in K$. Then there would exist a sequence on $x(t, x_0)$ with *two* limit points p_1 and p_2. This is impossible since, as we have shown, every sequence on $x(t, x_0)$ is a Cauchy sequence and therefore converges.

Since every sequence on $x(t, x_0)$ converges to p, it follows that $\lim_{t \to T_{\max}(x_0)} x(t, x_0) = p$. The solution $x(t, x_0)$ can then be extended by concatenating it with the solution starting in p. This implies that the maximal forward interval of existence of the

solution starting at $t = 0$ in x_0 contains $\mathcal{I}_{x_0}$ as a proper subset, contradicting the assumption that $\mathcal{I}_{x_0}$ is the maximal forward interval of existence. Thus $\forall x_0 \in \mathbb{R}^n_+$, $T_{\max}(x_0) = +\infty$, implying that ϕ_t is defined $\forall t \in \mathbb{R}^+$.

Case 2. $\tau > 0$. Let R_{x^*} be the unique stable invariant ray for system (1) in $\operatorname{int}(\mathbb{R}^n_+)$. For each $x_0 \in \mathbb{R}^n_+$ we can find $y_0 \in R_{x^*}$ such that $x_0 < y_0$. Since $x(t, y_0)$ satisfies (6) with $z = x^*$ and $\gamma_{x^*} \le 0$, we obtain that $\mathcal{I}_{y_0} = [0, +\infty)$. This implies that $x(t, x_0)$ belongs to the compact hypercube $C := \{z \in \mathbb{R}^n_+ | 0 \le z \le x(T_{\max}(x_0), y_0)\}$.

The rest of the proof follows the same lines as the proof of Case 1. The role of the compact set K is now played by the compact set C. □

We are ready to state the main theorem.

THEOREM 5.2 (Main Theorem). *Assume that system* (1) *satisfies* ($\mathcal{H}1$), ($\mathcal{H}2$), *and* ($\mathcal{H}3$), *and assume that initial conditions for system* (1) *belong to* $\mathbb{R}^n_+$. *Then there exists at least one invariant ray* $R_{x^*} \subset \operatorname{int}(\mathbb{R}^n_+)$.

If $\tau = 0$, *then* R_{x^*} *is unique in* $\operatorname{int}(\mathbb{R}^n_+)$. *If* $\tau > 0$ *and if* R_{x^*} *is stable, then* R_{x^*} *is unique. If* $\tau > 0$ *and if* R_{x^*} *is unstable, then* R_{x^*} *is not necessarily unique. If there are several invariant rays, all of them are unstable.*

The zero solution of system (1) *is*

- *unstable if and only if* R_{x^*} *is unstable,*
- *stable if and only if* R_{x^*} *is stable,*
- *globally asymptotically stable if and only if* R_{x^*} *is asymptotically stable.*

Proof. Sufficiency.

1. R_{x^*} is unstable. $\forall x_0 \in R_{x^*}$, the forward solution of system (1) starting at $t = 0$ in x_0 satisfies (6) with $z = x^*$. Since R_{x^*} is unstable, $\gamma_{x^*} > 0$, and thus $x(t, x_0)$ diverges when $t \to T_{\max}(x_0)$. Then the zero solution of system (1) is unstable.
2. R_{x^*} is stable. $\forall x_0 \in R_{x^*}$, the forward solution of system (1) starting at $t = 0$ in x_0 satisfies (6) with $z = x^*$. Since R_{x^*} is stable, $\gamma_{x^*} \le 0$, and thus $x(t, x_0) \le x_0 \ \forall t \in \mathbb{R}^+$.
   It follows that $\forall x_0 \in R_{x^*}$ the hypercube $C_{x_0} := \{y_0 \in \mathbb{R}^n_+ | 0 \le y_0 \le x_0\}$ is a forward invariant set for system (1). Indeed, if $y_0 = x_0$, then $x(t, y_0) \in C_{x_0}$ $\forall t \in \mathbb{R}^+$, since $x(t, x_0) \le x_0 \ \forall t \in \mathbb{R}^+$. If $y_0 < x_0$ with $y_0 \in C_{x_0}$, then from Proposition 4.5 and Lemma 5.1, $x(t, y_0) \ll x(t, x_0) \le x_0 \ \forall t \in \mathbb{R}^+$, and thus $x(t, x_0) \in C_{x_0} \ \forall t \in \mathbb{R}^+$.
   Since x_0 can be chosen arbitrarily close to the origin, the zero solution of system (1) is stable.
3. R_{x^*} is asymptotically stable. $\forall x_0 \in R_{x^*}$, the forward solution of system (1) starting at $t = 0$ in x_0 satisfies (6) with $z = x^*$. Since R_{x^*} is asymptotically stable, $\gamma_{x^*} < 0$, and thus $\lim_{t \to +\infty} x(t, x_0) = 0$. Also all forward solutions starting outside R_{x^*} converge to the origin. Indeed, $\forall y_0 \notin R_{x^*}$ there exists $p \in R_{x^*}$ such that $y_0 < p$ since $R_{x^*} \subset \operatorname{int}(\mathbb{R}^n_+)$. Then it follows from Proposition 4.5 and Lemma 5.1 that $x(t, y_0) \ll x(t, p) \ \forall t \in \mathbb{R}^+$. From $\lim_{t \to +\infty} x(t, p) = 0$ it follows that $\lim_{t \to +\infty} x(t, y_0) = 0$.
   It has been shown that all forward solutions converge to the origin. Stability of the zero solution follows from the proof of item 2 above. Thus the zero solution of system (1) is globally asymptotically stable.

Necessity.

1. System (1) is unstable. This follows from the contrapositive statement of the statement proved in item 2 of the sufficiency part of this theorem.
2. System (1) is stable. This follows from the contrapositive statement of the statement proved in item 1 of the sufficiency part of this theorem.

3. System (1) is asymptotically stable. Suppose that R_{x^*} is not asymptotically stable. Then $\gamma_{x^*} \geq 0$, implying that no forward solution starting on R_{x^*} converges to the origin and contradicting the assumption that system (1) is asymptotically stable. □

Example. Consider a reversible chemical reaction at a given, constant temperature:

$$A \leftrightarrows B, \tag{43}$$

where A and B are chemical components. Denote the concentrations of A and B, respectively, by x_1 and x_2. We assume that this reaction takes place in a *closed* chemical reactor and thus there is no exchange of material with the environment. The rate constant of reaction $A \to B$ is denoted by $k_1 \in \mathbb{R}^+$, and the rate constant of reaction $B \to A$ by $k_2 \in \mathbb{R}_+$. Supposing that the dynamics of both reactions is dictated by the *mass action principle* [11] and that both reactions are of second order, we obtain that the concentrations satisfy the following differential equations:

$$\begin{pmatrix} \dot{x}_1 \\ \dot{x}_2 \end{pmatrix} = \begin{pmatrix} -k_1 x_1^2 + k_2 x_2^2 \\ k_1 x_1^2 - k_2 x_2^2 \end{pmatrix}. \tag{44}$$

System (44) is homogeneous of order $\tau = 1$ with respect to the standard dilation map, cooperative in $\mathbb{R}^2_+$, and $(\mathcal{H}3)$ holds. Therefore Theorem 5.2 can be applied. It is easily verified that R_{x^*} with $x^* = (\sqrt{k}_2 \ \sqrt{k}_1)$ is the unique invariant ray in $\mathbb{R}^2_+$ that belongs to $\text{int}(\mathbb{R}^2_+)$ and that this ray is stable. We conclude that the zero solution of system (44) is also stable but not asymptotically stable.

One of the basic assumptions in model (44) is that the chemical reactor is closed, which is usually not satisfied. Indeed, in most models of chemical reactors there is exchange of chemicals with the environment, and a more realistic model would be (see [14])

$$\begin{pmatrix} \dot{x}_1 \\ \dot{x}_2 \end{pmatrix} = \begin{pmatrix} -k_1 x_1^2 + k_2 x_2^2 + (p_1(x_1,\, x_2) - q_1(x_1,\, x_2)) \\ k_1 x_1^2 - k_2 x_2^2 + (p_2(x_1,\, x_2) - q_2(x_1,\, x_2)) \end{pmatrix}, \tag{45}$$

where the functions $p_i \geq 0$, respectively $q_i \geq 0$, model the inflow, respectively outflow, of the chemicals. We show in [8] that the stability behavior of the trivial solution of the (simpler) system (44) plays an important role in determining the behavior of system (45) and that this can be extended to more general chemical reactors (in particular, to reactors containing more than two chemicals, in which several reactions take place).

6. Asymptotic behavior. Assume that system (1) satisfies $(\mathcal{H}1)$, $(\mathcal{H}2)$, and $(\mathcal{H}3)$, that the initial conditions of (1) belong to $\mathbb{R}^n_+$, and that $\tau = 0$. We recall from Theorem 4.6 that system (1) possesses a unique invariant ray R_{x^*} in $\mathbb{R}^n_+$, which belongs to $\text{int}(\mathbb{R}^n_+)$, such that

$$f(x^*) = \gamma \text{diag}(r) x^* \tag{46}$$

for some $\gamma \in \mathbb{R}$. The sign of γ then determines the stability properties of the zero solution of system (1). In this section the limiting behavior of solutions of systems satisfying these conditions will be described in more detail.

Introduce the following variable:

$$z(t, x_0) := (\text{diag}(e^{\gamma r t}))^{-1} \phi_t(x_0), \tag{47}$$

where $e^{\gamma r t} := (e^{\gamma r_1 t}, e^{\gamma r_2 t}, \dots, e^{\gamma r_n t})$.

Since $f(x)$ is homogeneous of order $\tau = 0$ with respect to $\delta_\lambda^r(x)$, it is easily verified that $z(t, x_0)$ satisfies

$$\dot{z} = -\gamma \mathrm{diag}(r) z + f(z), \tag{48}$$

where $z \in \mathbb{R}_+^n$ and $z(0, x_0) = x_0$.

System (48) satisfies $(\mathcal{H}1)$ with $\tau = 0$, $(\mathcal{H}2)$, and $(\mathcal{H}3)$, and therefore Theorem 4.6 can be applied to system (48). In particular, there exists a unique invariant ray for system (48) in $\mathrm{int}(\mathbb{R}_+^n)$. It is easy to see that this invariant ray is R_{x^*}, the unique invariant ray of system (1). For system (48) this ray consists of equilibrium points. It follows from Theorem 4.2 that system (48) is positive. Restricting initial conditions for system (48) to $\mathbb{R}_+^n$, it is possible to define the flow $\Phi_t : \mathbb{R}_+^n \to \mathbb{R}^n$ of system (48) (which is defined $\forall t \in \mathbb{R}^+$ by Lemma 5.1), mapping $\mathbb{R}_+^n$ *into* $\mathbb{R}_+^n$.

We recall the following results (see [13, Theorem 2.3, p. 5, and Theorem 3.7, p. 8]).

LEMMA 6.1. *If the forward flow of a system is strongly monotone, then a limit set cannot contain two limit points x and y with $x < y$.*

LEMMA 6.2. *If the forward flow of a system is strongly monotone, if $z_1 < z_2$, and if $\omega(z_1)$ and $\omega(z_2)$ are nonempty, then $\omega(z_1) \le \omega(z_2)$.*

It follows from Proposition 4.5 that the forward flow of system (48) is strongly monotone since system (48) satisfies $(\mathcal{H}1)$ with $\tau = 0$, $(\mathcal{H}2)$, and $(\mathcal{H}3)$. This implies that Lemmas 6.1 and 6.2 apply to system (48).

THEOREM 6.3. *If system* (1) *satisfies* $(\mathcal{H}1)$ *with* $\tau = 0$, $(\mathcal{H}2)$, *and* $(\mathcal{H}3)$, *then* $\forall x_0 \in \mathbb{R}_+^n$ *there exists a* $p_{x_0} \in R_{x^*} \cup \{0\}$ *such that* $\lim_{t \to +\infty} (\mathrm{diag}(e^{\gamma r t}))^{-1} \phi_t(x_0) = p_{x_0}$.

Proof. The forward solutions of system (48) are bounded. Indeed, for each $x_0 \in \mathbb{R}_+^n$ there exists a $y \in R_{x^*}$ such that $x_0 < y$. From Proposition 4.5 it follows that $z(t, x_0) \ll z(t, y) \equiv y \ \forall t \in \mathbb{R}^+$, since y is an equilibrium point of system (48). Thus all forward solutions of system (48) are bounded, implying that the omega limit set of every forward solution is nonempty.

The proof of the theorem proceeds in two steps:

1. The omega limit set of every forward solution of system (48) is a subset of $R_{x^*} \cup \{0\}$.
2. The omega limit set of every forward solution of system (48) consists of a single equilibrium point.

First a proof of item 1 is given. Suppose that there exists a $x_0 \in \mathbb{R}_+^n$ such that $\omega(x_0) \not\subset R_{x^*} \cup \{0\}$. Then there exist at least two points p and $q \in \omega(x_0)$ with $p \neq q$ and $p \notin R_{x^*} \cup \{0\}$. Indeed, the existence of $p \in \omega(x_0)$ with $p \notin R_{x^*} \cup \{0\}$ follows immediately from the assumption that $\omega(x_0) \not\subset R_{x^*} \cup \{0\}$. Now suppose that p is the only element in $\omega(x_0)$. Then p is an equilibrium point of system (48) and thus belongs to $R_{x^*} \cup \{0\}$, since omega limit sets are (forward) invariant sets. This contradicts the fact that $p \notin R_{x^*} \cup \{0\}$. Therefore there exists a second element $q \in \omega(x_0)$ with $p \neq q$.

Three cases can occur: $p \le q$, $q \le p$, or p and q are not related by $\le$.

Case 1. $p \le q$. Now $\delta_\lambda^r(x_0) < x_0 \ \forall \lambda \in (0, 1)$, and using Lemmas 3.2 and 6.2, this implies in particular that $\forall \lambda \in (0, 1)$

$$\delta_\lambda^r(q) \le p. \tag{49}$$

On the other hand, it follows from $p \le q$ and $p \neq q$ that $p < q$. This means that there exist two subsets J and K of N, where J is a subset of N and K can be empty such

that $N = J \cup K$ and

$$\begin{aligned} p_j &< q_j \qquad \forall j \in J, \\ p_k &= q_k \qquad \forall k \in K. \end{aligned}$$

This implies that there exists a $\lambda^* \in (0,1)$ close to 1 such that

$$\begin{aligned} p_j &< (\delta^r_{\lambda^*}(q))_j \qquad \forall j \in J, \\ (\delta^r_{\lambda^*}(q))_k &\leq p_k \qquad \forall k \in K. \end{aligned}$$

This implies that $p < \delta^r_{\lambda^*}(q)$ or that p and $\delta^r_{\lambda^*}(q)$ are not related by $\leq$, contradicting (49).

Case 2. $q \leq p$. If $q < p$, then a contradiction is obtained using an argument similar to that of Case 1.

Case 3. p and q are not related by $\leq$. We have $\delta^r_\lambda(x_0) < x_0$ $\forall \lambda \in (0,1)$, and using Lemmas 3.2 and 6.2, this implies in particular that $\forall \lambda \in (0,1)$

$$\delta^r_\lambda(p) \leq q. \tag{50}$$

On the other hand, since p and q, $p \neq q$, are not related by $\leq$, there exist $i, j \in N$ with $i \neq j$ such that

$$\begin{aligned} p_i &< q_i, \\ p_j &> q_j. \end{aligned}$$

This implies that there exists a $\tilde{\lambda} \in (0,1)$ close to 1 such that

$$\begin{aligned} (\delta^r_{\tilde{\lambda}}(p))_i &< q_i, \\ (\delta^r_{\tilde{\lambda}}(p))_j &> q_j. \end{aligned}$$

This implies that $\delta^r_{\tilde{\lambda}}(p)$ and q are not related by $\leq$, contradicting (50). This concludes the proof of item 1.

Next a proof of item 2 is given. Suppose that there exists a $x_0 \in \mathbb{R}^n_+$ such that $\omega(x_0) \subset R_{x^*} \cup \{0\}$ contains two points p and q with $p \neq q$. Since both p and q belong to $R_{x^*} \cup \{0\}$ and since $R_{x^*} \subset \operatorname{int}(\mathbb{R}^n_+)$, we may assume that $p \ll q$. However, it follows from Lemma 6.1 that p and q cannot be related by $<$. Thus a contradiction is obtained, and this proves item 2. □

7. Discussion of the results. In this paper a particular class of *positive* homogeneous systems has been introduced for which the stability behavior with respect to initial conditions in $\mathbb{R}^n_+$ can be characterized by means of a simple criterion expressed in Theorem 5.2. This contrasts with the case of homogeneous systems on $\mathbb{R}^n$, where in general no criteria for (asymptotic) stability are available.

In the following we will review the Perron–Frobenius theorem. Although this theorem normally refers to *discrete*-time systems, we consider its linear continuous-time version.

Consider the linear system

$$\dot{x} = Ax, \tag{51}$$

where A is an irreducible Metzler matrix and $x \in \mathbb{R}^n$. This system is cooperative and irreducible in $\mathbb{R}^n_+$ (in fact, also in $\mathbb{R}^n$) and homogeneous of order $\tau = 0$ with respect

to the standard dilation map. Since $(Ax)_i \geq 0$ when $x_i = 0$, $\mathbb{R}^n_+$ is a forward invariant set for system (51). Thus system (51) is a positive system.

For this class of systems the Perron–Frobenius theorem states that there exists a unique eigenvector z in $\mathbb{R}^n_+$ (up to multiplication with positive scalars) and such that $z \in \text{int}(\mathbb{R}^n_+)$. Also, the eigenvalue γ associated with z is real and simple and has the property that if γ' is an eigenvalue of A and $\gamma' \neq \gamma$, then $\text{Re}(\gamma') < \gamma$, where $\text{Re}(\gamma')$ stands for the real part of γ'. The sign of γ then determines the stability behavior of the zero solution of system (51): It is unstable if $\gamma > 0$, stable if $\gamma \leq 0$, and GAS if $\gamma < 0$. Furthermore, $\forall x_0 \in \mathbb{R}^n_+$ there exists a c_{x_0} such that $\lim_{t\to+\infty} e^{At}x_0/e^{\gamma t} = c_{x_0}z$.

Theorems 4.6 and 5.2 generalize the Perron–Frobenius theorem for *linear* cooperative and irreducible systems to the class of *homogeneous* cooperative and irreducible systems and therefore to a nonlinear context. We distinguish two cases.

Case 1. $\tau = 0$. If the order of the homogeneous vector field equals zero, then according to Theorem 4.6 there exists a unique invariant ray in $\mathbb{R}^n_+$, and it belongs to $\text{int}(\mathbb{R}^n_+)$. This ray plays the role of the unique eigenvector associated to the dominating eigenvalue featured in the Perron–Frobenius theorem for linear cooperative and irreducible systems.

According to Theorem 5.2, the stability behavior of the zero solution with respect to the initial conditions in $\mathbb{R}^n_+$ is completely determined by the flow on the unique invariant ray. This is reminiscent of the Perron–Frobenius theorem for linear cooperative and irreducible systems, where the sign of the eigenvalue associated to the unique eigenvector determines the stability behavior of the system. The only difference is that the stability behavior in the linear case holds with respect to initial conditions in $\mathbb{R}^n$ and not just in $\mathbb{R}^n_+$.

It follows from Theorem 6.3 that the properties of the asymptotic behavior of solutions of homogeneous order zero, systems which are cooperative and irreducible, are similar to those of solutions of system (51).

Therefore the conclusions of the Perron–Frobenius theorem for linear cooperative and irreducible systems remain valid for the class of homogeneous *order zero* cooperative and irreducible systems, provided one restricts initial conditions to $\mathbb{R}^n_+$.

Case 2. $\tau > 0$. If the order of the homogeneous vector field is strictly positive, then according to Theorem 4.4 there is at least one invariant ray in $\mathbb{R}^n_+$. It follows from Theorem 4.6 that every invariant ray in $\mathbb{R}^n_+$ belongs to $\text{int}(\mathbb{R}^n_+)$.

1. An invariant ray is unique in $\mathbb{R}^n_+$ if it is stable or asymptotically stable. The stability behavior of the zero solution with respect to the initial conditions in $\mathbb{R}^n_+$ is completely determined by the flow on this unique invariant ray. Therefore the conclusions of the Perron–Frobenius theorem remain valid for the class of homogeneous systems of *positive order*, which are cooperative and irreducible, if the invariant ray is stable or asymptotically stable, provided one restricts initial conditions to $\mathbb{R}^n_+$.
2. If an invariant ray is unstable, then it is not necessarily unique. In case there are several invariant rays in $\mathbb{R}^n_+$, all of them belong to $\text{int}(\mathbb{R}^n_+)$, and they are all unstable. The zero solution is then unstable. This is in contrast with the Perron–Frobenius theorem for linear cooperative and irreducible systems, where the eigenvector associated with the dominating eigenvalue is always unique.

OPTIMAL CONTROLS OF 3-DIMENSIONAL NAVIER–STOKES EQUATIONS WITH STATE CONSTRAINTS*

GENGSHENG WANG†

Abstract. This work is concerned with the maximum principles for optimal control problems governed by 3-dimensional Navier–Stokes equations. Some types of state constraints (time variables) are considered.

Key words. optimal control, Navier–Stokes equation, state constraint, maximum principle

AMS subject classifications. 93C05, 93B50, 93C35

1. Introduction.

In this paper, we shall study the optimal control problems governed by 3-dimensional Navier–Stokes equations

$$\begin{cases} \frac{\partial y}{\partial t} - \gamma \Delta y + y \cdot \nabla y + \nabla p = D_0 u + f_0 \ \text{ in } \Omega \times (0,T), \\ \nabla \cdot y = \operatorname{div} y = 0 \ \text{ in } \Omega \times (0,T); \ \ y = 0 \ \text{ in } \partial\Omega \times (0,T) \end{cases} \tag{1.1}$$

with some types of state constraints, which we shall state later. Here and throughout this paper, we shall omit (x,t) in all functions of (x,t) if there is no ambiguity. In (1.1), Ω is a bounded and open subset of R^3 with smooth boundary $\partial\Omega$, $T > 0$ is a given constant, $\gamma > 0$ is the viscosity constant, $f_0 \in L^2(0,T;L^2(\Omega))$ is a source field, $y(x,t) = (y_1(x,t), y_2(x,t), y_3(x,t))$ is the velocity vector, $\nabla \cdot y$ is the divergence of y, p stands for the pressure, and $u \in L^2(0,T;U)$ is input; here we have denoted by U a real Hilbert space and by D_0 a linear bounded operator from U to $(L^2(\Omega))^3$.

Let us introduce some functional spaces to represent the Navier–Stokes equation (1.1) as infinite dimensional differential equations. For the details, we refer the reader to [7] and [18].

Let V be the divergence free subspace of $(H_0^1(\Omega))^3$; i.e.,

$$V = \{y \in (H_0^1(\Omega))^3 : \nabla \cdot y = 0 \ \text{ in } \Omega\}$$

and

$$H = \{y \in (L^2(\Omega))^3 : \nabla \cdot y = 0 \ \text{ in } \Omega; \ \ n \cdot y = 0 \ \text{ on } \partial\Omega\}.$$

The space H is endowed with the usual $(L^2(\Omega))^3$-norm denoted by $|\cdot|$ and V with the norm $\|\cdot\|$ defined by

$$\|y\|^2 = \sum_{1 \le i \le 3} \int_\Omega |\nabla y_i|^2 dx, \quad y = (y_1, y_2, y_3).$$

We shall denote by $\langle\cdot,\cdot\rangle$ the scalar product of H and the pairing between V and its dual V^* with the norm $\|\cdot\|_*$. Let $A \in L(V,V^*)$ and $b : V\times V\times V \to R$ be defined by

$$\langle Ay, z\rangle = \sum_{1\le i,j\le 3}\int_\Omega \nabla y_i\cdot\nabla z_i dx \quad \forall\ y,z\in V \tag{1.2}$$

and

$$b(y,z,w) = \sum_{1\le i,j\le 3}\int_\Omega y_i D_i z_j w_j dx \quad \forall\ y,z,w\in V, \tag{1.3}$$

respectively, where $D_i = \frac{\partial}{\partial x_i}$. We define $B : V\to V^*$ by

$$\langle B(y), w\rangle = b(y,y,w) \quad \forall\ y,w\in V. \tag{1.4}$$

Let $f(t) = Pf_0(t)$ and $D\in L(U,H)$ be given by $D = PD_0$, where $P : (L^2(\Omega))^3 \to H$ is the projection on H. Then we may rewrite the state system (1.1) as

$$y'(t) + \gamma Ay(t) + By(t) = Du(t) + f(t) \quad \text{a.e. in } (0,T). \tag{1.5}$$

The general functional framework which will be in effect throughout this paper is explained in the following hypotheses.

(H_1) V and H are two real Hilbert spaces with the norms $\|\cdot\|$, $|\cdot|$ and the scalar products $\langle\cdot,\cdot\rangle_V$ and $\langle\cdot,\cdot\rangle$. Moreover, $V\subset H\subset V^*$ algebraically and topologically with compact injection, where we identify H with its own dual and denote by V^* the dual space of V, with norm denoted by $\|\cdot\|_*$. Denote again by $\langle\cdot,\cdot\rangle$ the pairing between V and V^*.

(H_2) $\gamma > 0$ is a constant. $A\in L(V,V^*)$ is symmetric and coercive, satisfying that $\langle Ay, y\rangle = \|y\|^2$ for all $y\in V$. We set $D(A) = \{y\in V : Ay\in H\}$ and denote by A again the restriction of A to H. Then, as we know (cf. [3]), A is a positive, self-adjoint operator, and $D(A^{\frac12}) = V$.

(H_3) The operator $B : V\to V^*$ is defined by (1.4), where $b : V\times V\times V\to R$ is a trilinear continuous functional satisfying

$$b(y,z,w) = -b(y,w,z) \quad \forall\ y,z,w\in V, \tag{1.6}$$

$$|b(y,z,w)| \le C\cdot\begin{cases} |y|^{\frac12}\|y\|^{\frac12}\|z\|\|w\|, \\ \|y\|\|z\|\|w\|^{\frac12}|w|^{\frac12} \end{cases} \quad \forall\ y,z,w\in V, \tag{1.7}$$

$$|b(y,z,w)| \le C\cdot\begin{cases} \|y\|^{\frac12}|Ay|^{\frac12}\|z\||w| & \forall\ y\in D(A), z\in V, w\in H, \\ \|y\|\|z\|^{\frac12}|Az|^{\frac12}|w| & \forall\ y\in V, z\in D(A), w\in H, \\ |y|\|z\|\|w\|^{\frac12}|Aw|^{\frac12} & \forall\ y\in H, v\in V, w\in D(A), \end{cases} \tag{1.8}$$

where C denotes several positive constants.

(H_4) $D\in L(U,H)$, $f\in L^2(0,T;H)$, where U is a real Hilbert space with the norm denoted by $|\cdot|_U$ and the scalar product $\langle\cdot,\cdot\rangle_U$.

Recall that assumption (H_3) is satisfied for b given by (1.3) (see [18]). We shall denote by Y the space $W^{1,2}([0,T];H)\cap L^2(0,T;D(A))$, where $W^{1,2}([0,T];H)$ is the space of all absolutely continuous functionals $y : [0,T]\to H$ such that $y' = \frac{dy}{dt}\in L^2(0,T;H)$. We have (cf. [3]) that $Y\subset C([0,T];V)$. We shall denote by $W(0,T)$ the space $\{y : y\in L^2(0,T;V), y'\in L^2(0,T;V^*)\}$ endowed with the norm $\|y\|_{W(0,T)} = [\int_0^T\|y\|^2dt + \int_0^T\|y'\|_*dt]^{\frac12}$. We have (cf. [12, Chapter 4]) that $W(0,T)\subset C([0,T];H)$.

The cost functional we shall study in this paper is as follows:

$$L(y,u)=\int_0^T [g(t,y(t))+h(u(t))]dt, \tag{1.9}$$

where we assume the following.

(H_5) $g:[0,T]\times V\to R^+$ is measurable in the first variable, $g(t,0)\in L^\infty(0,T)$, and for every $r>0$, there exists an $L_r>0$ independent of t such that

$$|g(t,y_1)-g(t,y_2)|\le L_r\|y_1-y_2\| \quad \forall\, t\in[0,T], \|y_1\|+\|y_2\|\le r. \tag{1.10}$$

$h:U\to \bar{R}\equiv(-\infty,\infty]$ is convex and lower semicontinuous. Moreover, there exist $c_1>0$ and $c_2\in R$ such that

$$h(u)\ge c_1|u|_U^2-c_2 \quad \forall\, u\in U. \tag{1.11}$$

In section 4, we shall give some explicit forms of the integrand $g(t,y)$, such as $|\operatorname{curl} y|^2$, which physically motivate the results.

In this paper, we shall derive the Pontryagin maximum principle for optimal control governed by system (1.5) with three types of state constraints, including a type of integral, a type of two point boundary (time variable), and a periodic type. The periodic type is a special case of a type of two point boundary. However, in the maximum principle for optimality of the two point boundary case, obtained in this paper (Theorem 2.4), we do not know if the multiplier is nonzero, i.e., if the maximum principle is qualified for the two point boundary case. Even for the periodic case, we cannot get a qualified maximum principle by the same methods as those used in getting the maximum principle for the two point boundary case. Such difficulty exists also for the optimal control governed by a semilinear parabolic equation with a two point boundary state constraint (cf. [16], [17], and [20]). This stimulates us to investigate, in particular, the periodic case to derive a qualified maximum principle. Now we formulate our problems as follows.

The first optimal control problem (P_1) we shall study in this paper is as follows.

(P_1) $\inf L(y,u)$ over all $(y,u)\in Y\times L^2(0,T;U)$ subject to

$$\begin{cases} y'+\gamma Ay+By=Du+f \quad \text{a.e. in } (0,T),\\ y(0)=y_0, \end{cases} \tag{1.12}$$

with

$$F(y)\in W, \tag{1.13}$$

where $y_0\in V$ and we assume the following.

(H_6) $F:L^2(0,T;V)\to X$ is continuously Frechet differentiable, where X is a Banach space with the dual X^* strictly convex, and $W\subset X$ is a closed and convex subset.

The second problem (P_2) we shall study is as follows.

(P_2) $\inf L(y,u)$ over all $(y,u)\in Y\times L^2(0,T;U)$ subject to (1.5) and

$$(y(0),y(T))\in S, \tag{1.14}$$

where we assume the following.

(H_7) $S\subset H\times H$ is a closed and convex subset.

The third problem (P_3) we shall study is as follows.

(P_3) $\inf L(y,u) = \int_0^T [g(t,y) + h(u)]dt$ over all $(y,u) \in Y \times L^2(0,T;U)$ subject to (1.5) and

$$y(0) = y(T). \tag{1.15}$$

In (P_3), we modify the assumption on the functional g as follows.

(H_8) $g : [0,T] \times H \to R^+$ is measurable in the first variable, $g(t,0) \in L^\infty(0,T)$, and for each $r > 0$, there exists an $L_r > 0$ independent of t such that

$$|g(t,y_1) - g(t,y_2)| \le L_r|y_1 - y_2| \quad \forall\, t \in [0,T]; |y_1| + |y_2| \le r.$$

For both physical and mathematical reasons, we consider the space Y as the state space in our problems. Physically, one needs the optimal state to have some smoothness, and, mathematically, because of the complexity of operator B, it is very difficult to analyze the linearized system corresponding to (1.12) around a state y, which is a weak solution to (1.12); i.e., $y \in L^2(0,T;V)$ and $y' \in L^1(0,T;V^*)$, even though such a weak solution exists for each $u \in L^2(0,T;U)$ (cf. [7] and [18]). However, as we know (cf. [7] and [18]), for each $y_0 \in V$, $u \in L^2(0,T;U)$, there exists $T^* \equiv T^*(y_0,u)$ such that (1.12) has a unique solution in $W^{1,2}([0,T_1];H) \cap L^2(0,T_1;D(A))$ for all $T_1 < T^*$. Thus, for $T > 0$ given, (1.7) may have no solution in $W^{1,2}([0,T];H) \cap L^2(0,T;D(A))$ for each $u \in L^2(0,T;U)$ and $y_0 \in V$. So problems (P_1), (P_2), and (P_3) are non-well-posed optimal control problems.

One of the main difficulties is that system (1.2) may have no solution in Y for each $u \in L^2(0,T;U)$, and the estimates on the operator B defined in (1.4) are weaker than those for the 2-dimensional Navier–Stokes equation. This makes us unable to apply the general techniques in, for instance, [3], [8], [17], and [19] to study the variations of the state with respect to the controls and to study the adjoint system and linearized system corresponding to (1.5). We overcome such difficulty by thinking of system (1.5) as a constraint mixed by the state and the control and then by introducing kinds of penalty functionals so that we may transfer the original non-well-posed control problems into optimization problems, where the variables y and u are independent. Thus we do not need to analyze the variations of the state with respect to the control. Instead, we use some special way involving the generic solvability theorem for linear parabolic evolution systems to construct the adjoint state. We believe that there are other ways to approach such problems. For instance, we may consider the local optimal control problem governed by (1.5), which means that the control set is taken as $U_{ad} = \{u \in L^2(0,T;U) : \|u\|_{L^2(0,T;U)} \le r\}$ for some small $r > 0$ depending on T. In such a way, system (1.12) has a unique solution $y \in Y$ corresponding to each $u \in U_{ad}$. However, we believe the methods deployed in this paper are more constructive.

Another difficulty is caused by the involvement of state constraints (1.13) and (1.14) and the integrand $g(t,y)$, which is allowed to be from $R^+ \times V$ to R (instead of from $R^+ \times H$ to R). This makes the analyses of the linearized system and the adjoint system of (1.5) more complicated.

For other literature on optimal control problems governed by Navier–Stokes equations and related to this paper, we cite [3], [4], [5], [6], [8], [9], [11], [12], and [13].

The outline of this paper is as follows. In section 2, we give and prove the necessary conditions for optimalities of problems (P_1) and (P_2). In section 3, we get the first order necessary conditions of optimality for problem (P_3) in terms of the Euler–Lagrange system. In section 4, we give some examples covered by the form of cost functionals (1.9) and the form of state constraints (1.13) and (1.14).

2. Optimal control with state constraint of integral type. Let (y^*, u^*) be optimal for problem (P_1). In this section, we shall state and prove the necessary conditions for (y^*, u^*). First we recall approximations g^ε of g and h_ε of h as follows. For the details, we refer the reader to [1, Chapter 1]. Let $g^\varepsilon : [0,T] \times V \to R^+$ be defined by

$$g^\varepsilon(t,y) = \int_{R^m} g(t, P_m y - \varepsilon \Lambda_m \tau)\rho_m(\tau)d\tau \quad \forall\ y \in V, \tag{2.1}$$

where $m = [\varepsilon^{-1}]$, ρ_m is a mollifier on R^m, $P_m : V \to X_m$ is the projection operator from H to X_m, which is the finite dimensional space generated by $\{e_i\}_{i=1}^m$, where $\{e_i\}_{i=1}^\infty$ is an orthonormal basis in V, and $\Lambda_m : R^m \to X_m$ is defined by $\Lambda_m(\tau) = \sum_{i=1}^m \tau_i e_i$, $\tau = (\tau_1, \dots, \tau_m)$. Let $h_\varepsilon : U \to R$ be defined by

$$h_\varepsilon(u) = \inf\{|u - v|_U^2/(2\varepsilon) + h(v) : v \in U\}. \tag{2.2}$$

Now, for each $\varepsilon > 0$, we define a penalty functional $L_\varepsilon : Y \times L^2(0,T;U) \to R$ by

$$\begin{aligned} L_\varepsilon(y,u) = {} & \int_0^T [g^\varepsilon(t,y) + h_\varepsilon(u)]dt + \frac{1}{4}\int_0^T \|y - y^*\|^4 dt + \frac{1}{2}\int_0^T |u - u^*|^2 dt \\ & + \frac{1}{2\varepsilon}\int_0^T |y' + \gamma Ay + By - Du - f|^2 dt + \frac{1}{2\varepsilon}[\varepsilon + d_W(F(y))]^2. \end{aligned} \tag{2.3}$$

Since $y \in Y \subset C([0,T];V)$, L_ε is well defined, and we may define $Y_0 = \{y \in Y : y(0) = y_0\}$. Consider the approximation problem $(P_{1\varepsilon})$ as follows.

$(P_{1\varepsilon})$ $\inf L_\varepsilon(y,u)$ over all $(y,u) \in Y_0 \times L^2(0,T;U)$.

We have the following existence and approximation results for problem $(P_{1\varepsilon})$.

LEMMA 2.1. *For each $\varepsilon > 0$, problem $(P_{1\varepsilon})$ has at least one solution.*

Proof. It is clear that $\inf(P_{1\varepsilon}) > -\infty$. Let $(y_n, u_n) \in Y_0 \times L^2(0,T;U)$ be such that

$$\inf(P_{1\varepsilon}) \le L_\varepsilon(y_n, u_n) \le \inf(P_{1\varepsilon}) + \frac{1}{n}, \quad n = 1, 2, \dots. \tag{2.4}$$

By (2.3) and (2.4), we imply that

$$\|u_n\|_{L^2(0,T;U)} \le C \tag{2.5}$$

and

$$\|y_n\|_{L^4(0,T;V)} \le C; \tag{2.6}$$

here and throughout the proof of Lemma 2.1, we shall denote by C several positive constants independent of n. By (2.3) and (2.4) again, there exist $v_n \in L^2(0,T;H)$, $n = 1, 2, \dots$, such that

$$\|v_n\|_{L^2(0,T;H)} \le C \tag{2.7}$$

and

$$\begin{cases} y_n' + \gamma A y_n + B y_n = D u_n + v_n \quad \text{a.e. in } (0,T), \\ y_n(0) = y_0. \end{cases} \tag{2.8}$$

Multiplying (2.8) by y_n, integrating on $(0,t)$, using Gronwall's inequality, and noting that $\langle By_n, y_n\rangle = 0$, which is from (1.6), we get that

$$|y_n(t)|^2 + \int_0^T \|y_n(t)\|^2 dt \le C \quad \forall\, t \in [0,T]. \tag{2.9}$$

It follows from (1.8) that

$$\begin{aligned}\int_0^t |\langle By_n, Ay_n\rangle| ds &\le C\int_0^t \|y_n\|^{\frac{3}{2}} |Ay_n|^{\frac{3}{2}} ds \\ &\le \frac{\gamma}{4}\int_0^t |Ay_n|^2 ds + C_\gamma \int_0^t \|y_n\|^6 ds;\end{aligned} \tag{2.10}$$

here and throughout what follows, C_γ denotes several positive constants independent of n but dependent on γ.

Multiplying (2.8) by Ay_n and integrating on $(0,t)$, by (2.10), (2.5), and (2.7) we get that

$$\|y_n(t)\|^2 + \gamma\int_0^T |Ay_n(t)|^2 dt \le C_\gamma \left(1 + \int_0^t \|y_n(s)\|^4 \|y_n(s)\|^2 ds\right).$$

Then, by (2.6) and by Gronwall's inequality, we obtain that

$$\|y_n(t)\|^2 + \gamma\int_0^T |Ay_n(t)|^2 dt \le C \quad \forall\, t \in [0,T]. \tag{2.11}$$

Now it follows from (1.8) and (2.11) that, for each $w \in H$,

$$|\langle By_n, w\rangle| = |b(y_n, y_n, w)| \le C\|y_n\|^{\frac{3}{2}} |Ay_n|^{\frac{1}{2}} |w| \le C|Ay_n|^{\frac{1}{2}} |w|,$$

which implies that

$$\int_0^T |By_n|^2 ds \le C. \tag{2.12}$$

By (2.11), (2.12), and (2.8), we obtain that

$$\|y_n'\|_{L^2(0,T;H)} \le C. \tag{2.13}$$

Thus by (2.5), (2.6), (2.11), (2.13), the Arezala–Ascoli theorem, and the Aubin compactness theorem, we conclude that there exist $(\tilde{y}, \tilde{u}) \in Y \times L^2(0,T;U)$ and subsequences of $\{y_n\}$ and $\{u_n\}$, still denoted by themselves, such that, as $n \to \infty$,

$$\begin{aligned} y_n &\to \tilde{y} \quad \text{strongly in } C([0,T];H) \cap L^2(0,T;V), \\ &\quad\ \text{weakly in } L^2(0,T;D(A)) \cap L^4(0,T;V), \end{aligned} \tag{2.14}$$

$$y_n' \to \tilde{y}' \ \text{ weakly in } L^2(0,T;H), \tag{2.15}$$

$$u_n \to \tilde{u} \ \text{ weakly in } L^2(0,T;U). \tag{2.16}$$

Next we claim that

$$By_n \to B\tilde{y} \ \text{ strongly in } L^2(0,T;H) \ \text{ as } n \to \infty. \tag{2.17}$$

To this end, we observe first that

$$\begin{aligned}|\langle By_n - B\tilde{y}, w\rangle| &\le |b(y_n - \tilde{y}, y_n, w)| + |b(y_n, y_n - \tilde{y}, w)| \\ &\le C[\|y_n - \tilde{y}\|^{\frac{1}{2}}|A(y_n - \tilde{y})|^{\frac{1}{2}}\|y_n\| + \|y_n\|^{\frac{1}{2}}|Ay_n|^{\frac{1}{2}}\|y_n - \tilde{y}\|]|w| \\ &\le C[\|y_n - \tilde{y}\|^{\frac{1}{2}}|A(y_n - \tilde{y})|^{\frac{1}{2}} + |Ay_n|^{\frac{1}{2}}\|y_n - \tilde{y}\|]|w|\end{aligned}$$

for each $w \in H$. Since $\|y_n - \tilde{y}\|_{C([0,T];V)} \le C$, which is from (2.11), the above inequality implies that

$$\begin{aligned}\int_0^T |By_n - B\tilde{y}|^2 dt &\le C\int_0^T [\|y_n - \tilde{y}\||A(y_n - \tilde{y})| + |Ay_n|\|y_n - \tilde{y}\|^2]dt \\ &\le C\left\{\left[\int_0^T \|y_n - \tilde{y}\|^2 dt\right]^{\frac{1}{2}}\left[\int_0^T |A(y_n - \tilde{y})|^2 dt\right]^{\frac{1}{2}}\right. \\ &\qquad \left. + \|y_n - \tilde{y}\|_{C([0,T];V)}\left[\int_0^T |Ay_n|^2 dt\right]^{\frac{1}{2}}\left[\int_0^T \|y_n - \tilde{y}\|^2 dt\right]^{\frac{1}{2}}\right\} \\ &\to 0 \ \text{ as } n \to \infty.\end{aligned}$$

By (2.14), (2.15), (2.16), and (2.17), we infer that

$$\underline{\lim}_{n\to\infty}\int_0^T \|y_n - y^*\|^4 dt \ge \int_0^T \|\tilde{y} - y^*\|^4 dt \tag{2.18}$$

and

$$\underline{\lim}_{n\to\infty}\int_0^T |y_n' + \gamma Ay_n + By_n - Du_n - f|^2 dt \ge \int_0^T |\tilde{y}' + \gamma A\tilde{y} + B\tilde{y} - D\tilde{u} - f|^2 dt. \tag{2.19}$$

By (1.10), (2.1), (2.11), and (2.14), we imply that

$$\int_0^T |g^\varepsilon(t, y_n) - g^\varepsilon(t, \tilde{y})|dt \le L\int_0^T \|y_n - \tilde{y}\|dt \to 0 \ \text{ as } n \to \infty, \tag{2.20}$$

where $L > 0$ is independent of n. Since h_ε is convex and continuous, it follows from (2.16) that

$$\underline{\lim}_{n\to\infty}\int_0^T h_\varepsilon(u_n)dt \ge \int_0^T h_\varepsilon(\tilde{u})dt. \tag{2.21}$$

By (2.14) and (H_6), $F(y_n) \to F(\tilde{y})$ as $n \to \infty$. Thus we have that

$$\frac{1}{2\varepsilon}(\varepsilon + d_W(F(y_n)))^2 \to \frac{1}{\varepsilon}(\varepsilon + d_W(F(\tilde{y})))^2 \ \text{ as } n \to \infty. \tag{2.22}$$

On the other hand, since $y_n(0) = y_0$ and $y_n(0) \to \tilde{y}(0)$ strongly in H, we have that $\tilde{y}(0) = y_0$, which shows that $\tilde{y} \in Y_0$. Thus it follows immediately from (2.4) and (2.18)–(2.22) that $(\tilde{y}, \tilde{u})$ is optimal for problem $(P_{1\varepsilon})$. This completes the proof.

LEMMA 2.2. *Let $(y_\varepsilon, u_\varepsilon)$ be optimal for problem $(P_{1\varepsilon})$. Then there exists a generalized subsequence of $(y_\varepsilon, u_\varepsilon)$, still denoted by itself, such that*

$$u_\varepsilon \to u^* \ \textit{strongly in } L^2(0,T;U), \quad y_\varepsilon \to y^* \ \textit{strongly in } Y \ \textit{ as } \varepsilon \to 0.$$

Remark. We say $y_\varepsilon \to y^*$ strongly in Y as $\varepsilon \to 0$ if $y_\varepsilon \to y^*$ strongly in $L^2(0,T;D(A)) \cap C([0,T];V)$ and $dy_\varepsilon/dt \to dy^*/dt$ strongly in $L^2(0,T;H)$ as $\varepsilon \to 0$.

Proof. Since $(y_\varepsilon, u_\varepsilon)$ is optimal for $(P_{1\varepsilon})$, it follows from (2.3) that

$$L_\varepsilon(y_\varepsilon, u_\varepsilon) \le L_\varepsilon(y^*, u^*) = \int_0^T [g^\varepsilon(t, y^*) + h_\varepsilon(u^*)]dt + \frac{\varepsilon}{2}. \tag{2.23}$$

By (2.1) and by the same argument as in [1, Chapter 3], we get that

$$|g^\varepsilon(t, y^*) - g(t, y^*)| \le L(\|y^* - P_m y^*\| + \varepsilon), \tag{2.24}$$

where $L > 0$ is a constant independent of ε, and the projection operator P_m was given in (2.1). By (2.23), (2.24), and the same argument as in [17], we get that

$$\overline{\lim}_{\varepsilon \to 0} L(y_\varepsilon, u_\varepsilon) \le L(y^*, u^*). \tag{2.25}$$

On the other hand, it follows from (2.3) and (2.25) that

$$\|y_\varepsilon\|_{L^4(0,T,V)} + \|u_\varepsilon\|_{L^2(0,T;U)} \le C, \tag{2.26}$$

$$\int_0^T |y'_\varepsilon + \gamma A y_\varepsilon + B y_\varepsilon - D u_\varepsilon - f|^2 dt \le 2C\varepsilon, \tag{2.27}$$

and

$$[\varepsilon + d_W(F(y_\varepsilon))]^2 \le 2C\varepsilon. \tag{2.28}$$

Here and throughout the proof of Lemma 2.2, we shall denote by C several positive constants independent of ε.

By (2.27), there exists a $v_\varepsilon \in L^2(0,T;H)$ for each $\varepsilon > 0$ such that $\|v_\varepsilon\|_{L^2(0,T;H)} \to 0$ as $\varepsilon \to 0$, and

$$\begin{cases} y'_\varepsilon + \gamma A y_\varepsilon + B y_\varepsilon = D u_\varepsilon + v_\varepsilon + f \quad \text{a.e. in } (0,T), \\ y_\varepsilon(0) = y_0. \end{cases} \tag{2.29}$$

By (2.26) and (2.29), using the same argument as in the proof of Lemma 2.1, we obtain that there exist $\tilde{y} \in Y$, $\tilde{u} \in L^2(0,T;U)$, and subsequences of $\{y_\varepsilon\}$ and $\{u_\varepsilon\}$, still denoted by themselves, such that, as $\varepsilon \to 0$,

$$y_\varepsilon \to \tilde{y} \quad \begin{array}{l} \text{strongly in } C([0,T];H) \cap L^2(0,T;V), \\ \text{weakly in } L^2(0,T;D(A)), \end{array} \tag{2.30}$$

$$\|y_\varepsilon\|_{C([0,T];V)} \le C, \tag{2.31}$$

$$y'_\varepsilon \to \tilde{y}' \ \text{ weakly in } L^2(0,T;H), \tag{2.32}$$

and

$$u_\varepsilon \to \tilde{u} \ \text{ weakly in } L^2(0,T;U). \tag{2.33}$$

By (2.30) and (2.31) and by the same argument as in the proof of Lemma 2.1, we deduce that

$$B y_\varepsilon \to B y^* \ \text{ strongly in } L^2(0,T;H) \ \text{ as } \varepsilon \to 0. \tag{2.34}$$

Thus, by (2.30)–(2.34), we may pass to the limit for $\varepsilon \to 0$ in (2.29) to derive that

$$\begin{cases} \tilde{y}' + \gamma A\tilde{y} + B\tilde{y} = D\tilde{u} + f \quad \text{a.e. in } (0,T), \\ \tilde{y}(0) = y_0. \end{cases} \tag{2.35}$$

It follows from (2.30) and (H_6) that

$$F(y_\varepsilon) \to F(\tilde{y}) \ \text{ strongly in } X \ \text{ as } \varepsilon \to 0. \tag{2.36}$$

However, by (2.28), we have that $d_W(F(y_\varepsilon)) \to 0$ as $\varepsilon \to 0$, which, combined with (2.36), indicates that

$$F(\tilde{y}) \in W, \tag{2.37}$$

since W is closed. Thus, by (2.35) and (2.37), we infer that

$$L(y^*, u^*) \le L(\tilde{y}, \tilde{u}) \tag{2.38}$$

because (y^*, u^*) is optimal for (P).

Now by (2.1), (1.10), and (2.31), one can get that

$$|g^\varepsilon(t, y_\varepsilon) - g^\varepsilon(t, \tilde{y})| \le L\|y_\varepsilon - \tilde{y}\|, \tag{2.39}$$

$$\lim_{\varepsilon \to 0} g^\varepsilon(t, \tilde{y}(t)) = g(t, \tilde{y}(t)) \quad \forall\, t \in [0,T], \tag{2.40}$$

$$|g^\varepsilon(t, \tilde{y}(t)) - g(t, \tilde{y}(t))| \le L(\|\tilde{y} - P_m\tilde{y}\| + \varepsilon), \tag{2.41}$$

where $L > 0$ is independent of ε, and P_m was given in (2.1). Then, by (2.39), (2.40), (2.41), and the Lebesgue dominated convergence theorem, we get that

$$\begin{aligned} \int_0^T |g^\varepsilon(t, y_\varepsilon) - g(t, \tilde{y})|dt &\le \int_0^T [|g^\varepsilon(t, y_\varepsilon) - g^\varepsilon(t, \tilde{y})| + |g^\varepsilon(t, \tilde{y}) - g(t, \tilde{y})|]dt \\ &\le \int_0^T [L\|y_\varepsilon(t) - \tilde{y}(t)\| + |g^\varepsilon(t, \tilde{y}) - g(t, \tilde{y})|]dt \\ &\to 0 \ \text{ as } \varepsilon \to 0. \end{aligned} \tag{2.42}$$

By the same argument as in [1, Chapter 5], we deduce that

$$\underline{\lim}_{\varepsilon \to 0} \int_0^T \left[h_\varepsilon(u_\varepsilon) + \frac{1}{2}|u_\varepsilon - u^*|^2 \right] dt \ge \int_0^T \left[h(\tilde{u}) + \frac{1}{2}|\tilde{u} - u^*|^2 \right] dt. \tag{2.43}$$

Now it follows from (2.38), (2.42), and (2.43) that

$$\underline{\lim}_{\varepsilon \to 0} L_\varepsilon(y_\varepsilon, u_\varepsilon) \ge L(\tilde{y}, \tilde{u}) \ge L(y^*, u^*). \tag{2.44}$$

Thus, by (2.25) and (2.44), we infer that $\tilde{u} = u^*$, $\tilde{y} = y^*$,

$$u_\varepsilon \to u^* \ \text{ strongly in } L^2(0,T;U) \ \text{ as } \varepsilon \to 0, \tag{2.45}$$

and

$$y_\varepsilon \to y^* \ \text{ strongly in } L^4(0,T;V) \ \text{ as } \varepsilon \to 0. \tag{2.46}$$

Finally, we shall prove that $y_\varepsilon \to y^*$ strongly in Y as $\varepsilon \to 0$. To this end, we first observe that

$$\begin{cases} (y_\varepsilon - y^*)' + \gamma A(y_\varepsilon - y^*) + By_\varepsilon - By^* = D(u_\varepsilon - u^*) + v_\varepsilon \quad \text{a.e. in } (0,T), \\ (y_\varepsilon - y^*)(0) = 0. \end{cases} \tag{2.47}$$

Multiplying (2.47) by $A(y_\varepsilon - y^*)$ and integrating on $(0,t)$, we get

$$\begin{aligned} &\frac{1}{2}\|y_\varepsilon(t) - y^*(t)\|^2 + \gamma \int_0^T |A(y_\varepsilon - y^*)|^2 dt \\ &\quad \le \frac{\gamma}{2}\int_0^T |A(y_\varepsilon - y^*)|^2 dt + C_\delta \left\{ \int_0^T |By_\varepsilon - By^*|^2 dt + \int_0^T [|D(u_\varepsilon - u^*)|_U^2 + |v_\varepsilon|^2] dt \right\}. \end{aligned}$$

This together with (2.34) and (2.47) yields that

$$y'_\varepsilon \to (y^*)' \text{ strongly in } L^2(0,T;H) \text{ as } \varepsilon \to 0.$$

Hence $y_\varepsilon \to y^*$ strongly in Y as $\varepsilon \to 0$. This completes the proof.

Now we are in a position to state and prove the necessary conditions for (y^*, u^*). Let y_ε be a solution to problem $(P_{1\varepsilon})$, $\varepsilon > 0$, and define the operator $B'(y_\varepsilon(t)) : V \to V^*$ for each $t \in [0,T]$ by

$$\langle B'(y_\varepsilon(t))z, w\rangle = b(z, y_\varepsilon(t), w) + b(y_\varepsilon(t), z, w) \quad \forall\, z, w \in V. \tag{2.48}$$

It is clear that $B'(y_\varepsilon(t)) \in L(V, V^*)$ for each $t \in [0,T]$. The adjoint operator of $B'(y_\varepsilon(t))$, $[B'(y_\varepsilon(t))]^*$ is given by

$$\langle [B'(y_\varepsilon(t))]^* q, w\rangle = b(w, y_\varepsilon(t), q) + b(y_\varepsilon(t), w, q). \tag{2.49}$$

Because $\{y_\varepsilon\}$ is bounded in $C([0,T];V)$, it follows from (1.7), (2.48), and (2.49) that

$$\|B'(y_\varepsilon(t))\varphi\|_* \le C\|y_\varepsilon\|\|\varphi\| \le C\|\varphi\| \quad \forall\, \varphi \in V, \tag{2.50}$$

$$\|[B'(y_\varepsilon(t))]^*\varphi\|_* \le C\|y_\varepsilon\|\|\varphi\| \le C\|\varphi\| \quad \forall\, \varphi \in V, \tag{2.51}$$

$$|\langle B'(y_\varepsilon(t))\varphi, \varphi\rangle| \le C\|y_\varepsilon\||\varphi|^{\frac{1}{2}}\|\varphi\|^{\frac{3}{2}} \le \frac{\gamma}{2}\|\varphi\|^2 + C_\gamma|\varphi|^2 \quad \forall\, \varphi \in V, \tag{2.52}$$

and

$$|\langle [B'(y_\varepsilon)]^*\varphi, \varphi\rangle| \le \frac{\gamma}{2}\|\varphi\|^2 + C_\gamma|\varphi|^2 \quad \forall\, \varphi \in V. \tag{2.53}$$

By (2.50)–(2.53), using a standard existence result for linear evolution equations (cf. [12, Theorem 1.2, Chapter 3]), the Cauchy problems

$$\begin{cases} \varphi' + \gamma A\varphi + B'(y_\varepsilon)\varphi = g \quad \text{a.e. in } (0,T), \\ \varphi(0) = x \end{cases} \tag{2.54}$$

and

$$\begin{cases} -\psi' + \gamma A\psi + [B'(y_\varepsilon)]^*\psi = g \quad \text{a.e. in } (0,T), \\ \psi(T) = x \end{cases} \tag{2.55}$$

have unique solutions φ and ψ in $W(0,T)$ for each $g \in L^2(0,T;V^*)$ and $x \in H$, respectively. Moreover,

$$\|\varphi'\|^2_{L^2(0,T;V^*)} + \|\varphi\|^2_{L^2(0,T;V)} \le C(\|g\|^2_{L^2(0,T;V^*)} + |x|^2), \tag{2.56}$$

and

$$\|\psi'\|^2_{L^2(0,T;V^*)} + \|\psi\|^2_{L^2(0,T;V)} \le C(\|g\|^2_{L^2(0,T;V^*)} + |x|^2). \tag{2.57}$$

If $g \in L^2(0,T;H)$ and $x \in V$, then $\varphi, \psi \in Y$ (cf. [1]).

Similar to (2.48), we may define operator $B'(y^*(t)) : V \to V^*$ and obtain similar estimates to (2.56) and (2.57).

In order to get the necessary conditions for (y^*, u^*), we need one more assumption, as follows.

(H_9) The set $F'(y^*)R_r - W$ has finite codimensionality in X for some $r > 0$, where

$$M(0,r) = \{v \in L^2(0,T;U) : \|v\|_{L^2(0,T;U)} \le r\} \tag{2.58}$$

and

$$\begin{aligned} R_r = \{z \in Y : z' + \gamma Az + B'(y^*)z = Dv \quad \text{a.e. in } (0,T) \\ \text{and } z(0) = 0 \quad \text{for some } v \in M(0,r)\}. \end{aligned} \tag{2.59}$$

For the definition of a set to be finite codimensional in X and for related results, we refer the reader to [14]. Throughout what follows, we shall denote by $\partial g(t, y^*)$ the generalized derivative of g to the second variable at y^* and by $\partial h(u^*)$ the subdifferential of h at u^*. For the details, we refer the reader to [1]. We denote by $\langle \cdot, \cdot \rangle_{X^*,X}$ the pairing between X^* and X and by $[F'(y^*)]^*$ and D^* the adjoint operators of $F'(y^*)$ and D, respectively.

THEOREM 2.3. *Suppose that (H_1)–(H_6) hold. Let (y^*, u^*) be optimal for problem (P_1). Suppose further that (H_7) holds. Then there exists a triplet $(\lambda_0, \varphi, \xi_0) \in R \times L^2(0,T;V) \cap W(0,T) \times X^*$ with $(\lambda_0, \xi_0) \ne 0$ such that*

$$\begin{cases} -p' + \gamma Ap + [B'(y^*)]^*p + [F'(y^*)]^*\xi_0 \in -\lambda_0 \partial g(t, y^*) & \text{a.e. in } (0,T), \\ p(T) = 0, \end{cases} \tag{2.60}$$

$$\langle \xi_0, w - F(y^*) \rangle_{X^*,X} \le 0 \quad \forall\, w \in W, \tag{2.61}$$

and

$$D^*p(t) \in \lambda_0 \partial h(u^*(t)) \quad \text{a.e. in } (0,T). \tag{2.62}$$

Moreover, if $F'(y^*)$ is injective, then $(\lambda_0, p) \ne 0$.

Proof. Let $Z = \{y \in Y : y(0) = 0\}$. For $z \in Z$, $v \in L^2(0,T;U)$, we set $y^\rho_\varepsilon = y_\varepsilon + \rho z$, $u^\rho_\varepsilon = u_\varepsilon + \rho v$, where $(y_\varepsilon, u_\varepsilon)$ is optimal for problem $(P_{1\varepsilon})$. It is clear that $y^\rho_\varepsilon \in Y_0$, $u^\rho_\varepsilon \in L^2(0,T;U)$,

$$y^\rho_\varepsilon \to y_\varepsilon \ \text{ strongly in } Y \ \text{ as } \rho \to 0,$$

and

$$u^\rho_\varepsilon \to u_\varepsilon \ \text{ strongly in } L^2(0,T;U) \ \text{ as } \rho \to 0.$$

One can easily check that

$$(By^\rho_\varepsilon - By_\varepsilon)/\rho = B'(y_\varepsilon)z + \rho B(y_\varepsilon). \tag{2.63}$$

Hence

$$(By_\varepsilon^\rho - By_\varepsilon)/\rho \to B'(y_\varepsilon)z \text{ strongly in } L^2(0,T;H) \text{ as } \rho \to 0. \tag{2.64}$$

It follows from (2.64) that

$$\begin{aligned}\frac{1}{2\varepsilon\rho}\int_0^T [|(y_\varepsilon^\rho)' + \gamma A y_\varepsilon^\rho + By_\varepsilon^\rho - Du_\varepsilon^\rho - f|^2 - |y_\varepsilon' + \gamma A y_\varepsilon + By_\varepsilon - Du_\varepsilon - f|^2]dt \\ \to \int_0^T \langle q_\varepsilon, z' + \gamma Az + B'(y_\varepsilon)z - Dv\rangle dt \text{ as } \rho \to 0,\end{aligned} \tag{2.65}$$

where $q_\varepsilon = \frac{1}{\varepsilon}[y_\varepsilon' + \gamma A y_\varepsilon + By_\varepsilon - Du_\varepsilon - f]$. Since $\langle Ay, z\rangle = \langle y, z\rangle_V$ for all $y \in D(A), z \in V$, we infer that

$$\begin{aligned}\lim_{\rho\to 0}\frac{1}{4\rho}\int_0^T [\|y_\varepsilon^\rho - y^*\|^4 - \|y_\varepsilon - y^*\|^4]dt &= \int_0^T \|y_\varepsilon - y^*\|^2\langle y_\varepsilon - y^*, z\rangle_V dt \\ &= \int_0^T \|y_\varepsilon - y^*\|^2\langle A(y_\varepsilon - y^*), z\rangle dt.\end{aligned} \tag{2.66}$$

By the same argument as in [1, Chapter 5], we see that

$$\lim_{\rho\to 0}\frac{1}{\rho}\int_0^T [g^\varepsilon(t, y_\varepsilon^\rho) - g^\varepsilon(t, y_\varepsilon)]dt = \int_0^T \langle \nabla g^\varepsilon(t, y_\varepsilon), z\rangle dt \tag{2.67}$$

and

$$\begin{aligned}\lim_{\rho\to 0}\frac{1}{\rho}\int_0^T \left\{[h_\varepsilon(u_\varepsilon^\rho) - h_\varepsilon(u_\varepsilon)] + \frac{1}{2}[\|u_\varepsilon^\rho - u^*\|^2 - \|u_\varepsilon - u^*\|^2]\right\} dt \\ = \int_0^T \langle \nabla h_\varepsilon(u_\varepsilon) + u_\varepsilon - u^*, u\rangle_U dt.\end{aligned} \tag{2.68}$$

By the same argument as in [21], we get that

$$\begin{aligned}\lim_{\rho\to 0}[(\varepsilon + d_W(F(y_\varepsilon^\rho)))^2 - (\varepsilon + d_W(F(y_\varepsilon)))^2] \\ = \frac{\varepsilon + d_W(F(y_\varepsilon))}{\varepsilon}\langle \xi_\varepsilon, F'(y_\varepsilon)z\rangle_{X^*,X},\end{aligned} \tag{2.69}$$

where $\nabla g^\varepsilon(t, y_\varepsilon)$ denotes the gradient of g^ε to the second variable at y_ε and $\nabla h_\varepsilon(u_\varepsilon)$ denotes the gradient of h_ε at u_ε, while $\xi_\varepsilon \in \partial d_W(F(y_\varepsilon))$. Moreover,

$$\|\xi_\varepsilon\|_{X^*} = \begin{cases} 1 & \text{if } F(y_\varepsilon) \notin W, \\ 0 & \text{if } F(y_\varepsilon) \in W, \end{cases} \tag{2.70}$$

because W is convex and closed and X^* is strictly convex (cf. [15, Chapter 5]).

Since $(L_\varepsilon(y_\varepsilon^\rho, u_\varepsilon^\rho) - L_\varepsilon(y_\varepsilon, u_\varepsilon))/\rho \geq 0$ for all $\rho > 0$, it follows from (2.3) and (2.65)–(2.69) that

$$\begin{aligned}0 \leq \lambda_\varepsilon \int_0^T [&\langle \nabla g^\varepsilon(t, y_\varepsilon), z\rangle + \langle \nabla h_\varepsilon(u_\varepsilon), v\rangle_U \\ &+ \|y_\varepsilon - y^*\|^2\langle A(y_\varepsilon - y^*), z\rangle + \langle u_\varepsilon - u^*, v\rangle_U]dt \\ &+ \int_0^T \langle p_\varepsilon, z' + \gamma Az + B'(y_\varepsilon)z - Dv\rangle dt \\ &+ \int_0^T \langle [F'(y_\varepsilon)]^*\xi_\varepsilon, z\rangle dt \quad \forall\, z \in Z, v \in L^2(0,T;U),\end{aligned} \tag{2.71}$$

where

$$\lambda_\varepsilon = \frac{\varepsilon}{\varepsilon + d_W(F(y_\varepsilon))}, \quad p_\varepsilon = \lambda_\varepsilon q_\varepsilon \in L^2(0,T;H). \tag{2.72}$$

By taking $z = 0$ in (2.71), we obtain that

$$D^* p_\varepsilon = \lambda_\varepsilon \nabla h_\varepsilon(u_\varepsilon) + \lambda_\varepsilon(u_\varepsilon - u^*) \quad \text{a.e. in } (0,T), \tag{2.73}$$

while, by taking $v = 0$ in (2.71), we get that

$$\begin{aligned} 0 = &\int_0^T \langle \lambda_\varepsilon \nabla g^\varepsilon(t, y_\varepsilon) + [F'(y_\varepsilon)]^* \xi_\varepsilon + \lambda_\varepsilon \|y_\varepsilon - y^*\|^2 A(y_\varepsilon - y^*), z\rangle dt \\ &+ \int_0^T \langle p_\varepsilon, z' + \gamma A z + B'(y_\varepsilon) z\rangle dt \quad \forall\ z \in Z. \end{aligned} \tag{2.74}$$

We may regard (2.73) and (2.74) as the necessary conditions for $(y_\varepsilon, u_\varepsilon)$. Now we are in a position to pass to the limit for $\varepsilon \to 0$ in (2.73) and (2.74) to derive (2.62) and (2.60), respectively.

First we deal with (2.73). Note that $\alpha_\varepsilon \equiv \lambda_\varepsilon \nabla g^\varepsilon(t, y_\varepsilon) + [F'(y_\varepsilon)]^* \xi_\varepsilon + \lambda_\varepsilon \|y_\varepsilon - y^*\|^2 A(y_\varepsilon - y^*) \in L^2(0,T;V^*)$ and $\{\alpha_\varepsilon\}_{\varepsilon>0}$ is bounded in $L^2(0,T;V^*)$.

By (2.55), we may let $p_{\varepsilon 1} \in W(0,T)$ be the solution to

$$\begin{cases} -p'_{\varepsilon 1} + \gamma A p_{\varepsilon 1} + [B'(y_\varepsilon)]^* p_{\varepsilon 1} = -\alpha_\varepsilon \quad \text{a.e. in } (0,T), \\ p_{\varepsilon 1}(T) = 0. \end{cases} \tag{2.75}$$

Multiplying (2.75) by z and integrating on $(0,t)$, we get that

$$\int_0^T \langle p_{\varepsilon 1}, z' + \gamma A z + B'(y_\varepsilon) z\rangle dt = -\int_0^T \langle \alpha_\varepsilon, z\rangle dt.$$

This together with (2.74) implies that

$$\int_0^T \langle p_\varepsilon - p_{\varepsilon 1}, z' + \gamma A z + B'(y_\varepsilon) z\rangle dt = 0 \quad \forall\ z \in Z. \tag{2.76}$$

By (2.54), for each $g \in L^2(0,T;H)$, there exists $z \in Z$ such that $z' + \gamma A z + B'(y_\varepsilon) z = g$ in $(0,T)$. Thus it follows from (2.76) that $p_\varepsilon(t) = p_{\varepsilon 1}(t)$ a.e. in $(0,T)$. So $p_\varepsilon \in W(0,T)$ and satisfies

$$\|p'_\varepsilon\|^2_{L^2(0,T;V^*)} + \|p_\varepsilon\|^2_{L^2(0,T;V)} \le C\|\alpha_\varepsilon\|^2_{L^2(0,T;V^*)} \le C. \tag{2.77}$$

By the Aubin compactness theorem and the trace theorem (cf. [13, Theorem 3.1 of Chapter 1]), there exist $p \in W(0,T)$ and a subsequence of p_ε, still denoted by itself, such that

$$\begin{aligned} &p_\varepsilon \to p \ \text{ strongly in } L^2(0,T;H) \ \text{ weakly in } L^2(0,T;V) \ \text{ as } \varepsilon \to 0, \\ &p'_\varepsilon \to p' \ \text{ weakly in } L^2(0,T;V^*) \ \text{ as } \varepsilon \to 0, \\ &p_\varepsilon(0) \to p(0) \ \text{ weakly in } H \ \text{ as } \varepsilon \to 0. \end{aligned} \tag{2.78}$$

By (2.70) and (2.72), we have that

$$1 \le \lambda_\varepsilon + \|\xi_\varepsilon\|_{X^*} \le 2 \quad \forall\ \varepsilon > 0. \tag{2.79}$$

Thus there exist generalized subsequences of λ_ε and ξ_ε such that

$$\lambda_\varepsilon \to \lambda_0 \ \text{ as } \varepsilon \to 0, \tag{2.80}$$

and

$$\xi_\varepsilon \to \xi_0 \ \text{ weakly star in } X^* \ \text{ as } \varepsilon \to 0. \tag{2.81}$$

By Lemma 2.2 and (2.78), using the same argument as in [2, (1)], we may pass to the limit for $\varepsilon \to 0$ in (2.73) to derive (2.62).

Next we deal with (2.74), i.e., pass to the limit for $\varepsilon \to 0$ in (2.74).

By Lemma 2.2 and by the same argument as in [1, Chapter 5], we infer that

$$\nabla g^\varepsilon(t, y_\varepsilon) \to \beta \ \text{ weakly in } L^2(0,T;V^*) \ \text{ and } \ \beta(t) \in \partial g(t, y^*(t)) \ \text{ a.e. in } (0,T). \tag{2.82}$$

By (H_6), Lemma 2.2, and (2.81), we obtain that

$$[F'(y_\varepsilon)]^* \xi_\varepsilon \to [F'(y^*)]^* \xi_0 \ \text{ weakly in } L^2(0,T;V^*) \ \text{ as } \varepsilon \to 0. \tag{2.83}$$

By Lemma 2.2 again, we get that

$$\|y_\varepsilon - y^*\|^2 A(y_\varepsilon - y^*) \to 0 \ \text{ strongly in } L^2(0,T;H). \tag{2.84}$$

Now we claim that

$$[B'(y_\varepsilon)]^* p_\varepsilon \to [B'(y^*)]^* p \ \text{ weakly star in } L^2(0,T;V^*) \ \text{ as } \varepsilon \to 0. \tag{2.85}$$

Here is the argument. For any $w \in L^2(0,T;V)$, we have from (1.7) and (2.49) that

(2.86)

$$\begin{aligned}
&\int_0^T |\langle [B'(y_\varepsilon)]^* p_\varepsilon - [B'(y^*)]^* p, w\rangle| dt \\
&\quad = \int_0^T |b(w, y_\varepsilon, p_\varepsilon) + b(y_\varepsilon, w, p_\varepsilon) - b(w, y^*, p) - b(y^*, w, p)| dt \\
&\quad \le \int_0^T |b(w, y_\varepsilon - y^*, p_\varepsilon)| dt + \int_0^T |b(w, y^*, p_\varepsilon - p)| dt \\
&\qquad + \int_0^T |b(y_\varepsilon - y^*, w, p_\varepsilon)| dt + \int_0^T |b(y^*, w, p_\varepsilon - p)| dt \\
&\quad \le C \left[\int_0^T \|w\| \|p_\varepsilon\| \|y_\varepsilon - y^*\|^{\frac{1}{2}} |y_\varepsilon - y^*|^{\frac{1}{2}} dt + \int_0^T \|w\| \|y^*\| \|p_\varepsilon - p\|^{\frac{1}{2}} |p_\varepsilon - p|^{\frac{1}{2}} \right] \\
&\quad \le C \left[\|y_\varepsilon - y^*\|^{\frac{1}{2}}_{C([0,T];V)} \|y_\varepsilon - y^*\|^{\frac{1}{2}}_{C([0,T];H)} \left[\int_0^T \|w\|^2 dt \right]^{\frac{1}{2}} \left[\int_0^T \|p_\varepsilon\|^2 dt \right]^{\frac{1}{2}} \right. \\
&\qquad \left. + \|y^*\|_{C([0,T];V)} \left[\int_0^T \|w\|^2 dt \right]^{\frac{1}{2}} \left[\int_0^T \|p_\varepsilon - p\|^2 dt \right]^{\frac{1}{4}} \left[\int_0^T |p_\varepsilon - p|^2 dt \right]^{\frac{1}{4}} \right].
\end{aligned}$$

By (2.78), (2.86), and Lemma 2.2, we obtain (2.85) as claimed.

Thus, by (2.78), (2.80), and (2.82)–(2.85), we may pass to the limit for $\varepsilon \to 0$ in (2.75) to obtain that $p \in W(0,T)$ and satisfies (2.60).

On the other hand, since $\xi_\varepsilon \in \partial d_W(F(y_\varepsilon))$, we must have that

$$\langle \xi_\varepsilon, w - F(y_\varepsilon)\rangle_{X^*,X} \le 0 \quad \forall\, w \in W.$$

This implies that

$$\langle \xi_\varepsilon, w - F(y^*)\rangle_{X^*,X} \le \langle \xi_\varepsilon, F(y_\varepsilon) - F(y^*)\rangle_{X^*,X}. \tag{2.87}$$

Then, by Lemma 2.2, (H_6), and (2.81), we may pass to the limit for $\varepsilon \to 0$ in (2.87) to get (2.61).

We have proved (2.60), (2.61), and (2.62). Now we are in a position to show that $(\lambda_0, \xi_0) \neq 0$. To this end, we suppose that $\lambda_0 = 0$. Then, by (2.79) and (2.80), there exist $\varepsilon_1 > 0$ and $\delta > 0$ such that

$$2 \ge \|\xi_\varepsilon\|_{X^*} \ge \delta > 0 \quad \forall\, \varepsilon < \varepsilon_1. \tag{2.88}$$

It follows from (2.71) and (2.87) that

$$\begin{aligned} -\eta_\varepsilon(z,v) \le{}& \langle \xi_\varepsilon, F'(y^*)z - w + F(y^*)\rangle_{X^*,X} \\ &+ \int_0^T \langle p_\varepsilon, z' + \gamma Az + B'(y^*)z - Dv\rangle dt \end{aligned} \tag{2.89}$$

for all $(z,v) \in Z \times L^2(0,T;U)$ and $w \in W$, where

$$\begin{aligned} \eta_\varepsilon(z,v) = \lambda_\varepsilon &\left\{ \int_0^T [\langle \nabla g^\varepsilon(t, y_\varepsilon), z\rangle + \langle \nabla h_\varepsilon(u_\varepsilon), v\rangle_U] dt \right. \\ &+ \int_0^T \langle \|y_\varepsilon - y^*\|^2 A(y_\varepsilon - y^*), z\rangle dt \\ &\left. + \int_0^T \langle u_\varepsilon - u^*, v\rangle_U dt \right\} + \int_0^T \langle p_\varepsilon, [B'(y_\varepsilon) - B'(y^*)]z\rangle dt \\ &+ \langle \xi_\varepsilon, [F'(y_\varepsilon) - F'(y^*)]z + F(y_\varepsilon) - F(y^*)\rangle_{X^*,X}. \end{aligned} \tag{2.90}$$

For each $\varepsilon > 0$ and $v \in M(0,r)$, where $M(0,r)$ was given in (2.58) and $r > 0$ was given in (H_9), let $z_\varepsilon(v)$ be the solution to (2.54) with $g = Dv$ and $x = 0$; then $z_\varepsilon(v) \in Z$, and

$$\|z_\varepsilon(v)\|^2_{L^2(0,T;D(A))} + \|z'_\varepsilon(v)\|^2_{L^2(0,T;H)} \le C \quad \forall\, v \in M(0,r), \tag{2.91}$$

where $C > 0$ is independent of ε and v. Here we have used the estimate

$$|\langle B'(y_\varepsilon)z_\varepsilon, Az_\varepsilon\rangle| \le C\|z_\varepsilon\|^{\frac{1}{2}} \|y_\varepsilon\| |Az_\varepsilon|^{\frac{3}{2}} \le \frac{\gamma}{4}|Az_\varepsilon|^2 + C_\gamma \|z_\varepsilon\|^2,$$

which is from (1.8), (2.48), and Lemma 2.2.

It follows from (1.8) and (2.48) that

$$\begin{aligned} &\int_0^T |\langle p_\varepsilon, [B'(y_\varepsilon) - B'(y^*)]z_\varepsilon(v)\rangle| dt \\ &\quad \le C\int_0^T [|b(z_\varepsilon(v), y_\varepsilon - y^*, p_\varepsilon)| + |b(y_\varepsilon - y^*, z_\varepsilon(v), p_\varepsilon)|] dt \\ &\quad \le C\int_0^T \|z_\varepsilon(v)\| \|p_\varepsilon\| \|y_\varepsilon - y^*\|^{\frac{1}{2}} |y_\varepsilon - y^*|^{\frac{1}{2}} dt \\ &\quad \le C\|y_\varepsilon - y^*\|^{\frac{1}{2}}_{C([0,T];V)} \|y_\varepsilon - y^*\|^{\frac{1}{2}}_{C([0,T];H)} \|z_\varepsilon(v)\|_{L^2(0,T;V)} \|p_\varepsilon\|_{L^2(0,T;V)}. \end{aligned} \tag{2.92}$$

By (2.90), (2.91), (2.92), and Lemma 2.2, one can easily check that

$$\eta_\varepsilon(z_\varepsilon(v), v) \to 0 \ \text{ as } \varepsilon \to 0 \ \text{ uniformly in } v \in M(0,r). \tag{2.93}$$

Thus it follows from (2.89), (2.9), and (2.59) that

$$\langle \xi_\varepsilon, F'(y^*)z - w + F(y^*)\rangle_{X^*,X} \geq -\eta_\varepsilon \quad \forall\ z \in R_r, w \in W, \tag{2.94}$$

where $\eta_\varepsilon \to 0$ as $\varepsilon \to 0$. By (H_9), $F'(y^*)R_r - W$ has finite codimensionality in X, and so does $F'(y^*)R_r - W + F(y^*)$. Thanks to [14, Lemma 3.6], we conclude from (2.88), (2.93), and (2.94) that $(\lambda_0, \xi_0) \neq 0$.

Finally, if $F'(y^*)$ is injective and $(\lambda_0, p) \neq 0$, then it follows from (2.60) that $[F'(y^*)]^*\xi_0 = 0$, which implies that $\xi_0 = 0$. This contradiction leads $(\lambda_0, p) \neq 0$ and completes the proof.

Now we turn to present the maximum principle for problem (P_2). Let (y^*, u^*) be optimal for problem (P_2). We set

$$Q_{r_1,r_2} = \left\{ (z_0, z_T) \in V \times V : \begin{array}{l} \exists\ z \in Y \ \text{ with } \|z\|_Y \leq r_1 \ \text{ such that} \\ \mathcal{A}z \in D(M(0,r_2)) \ \text{ and } z(0) = z_0, z(T) = z_T \end{array} \right\}, \tag{2.95}$$

where $\mathcal{A}$ is the operator from Y to $L^2(0,T;H)$ defined by

$$\mathcal{A}z = z' + \gamma Az + B'(y^*)z, \tag{2.96}$$

$M(0,r_2)$ was defined in (2.58), and $D(M(0,r_2)) = \{Dv : v \in M(0,r_2)\}$. Then we assume the following.

(H_{10}) The set $Q_{r_1,r_2} - S$ has finite codimensionality in $H \times H$ for some $r_1, r_2 > 0$.

The main result for problem (P_2) will be as follows.

THEOREM 2.4. *Suppose that (H_1)–(H_5) and (H_7) hold. Let (y^*, u^*) be optimal for problem (P_2). Suppose further that (H_{10}) holds. Then there exists $(\lambda_0, p) \in R \times W(0,T)$ with $(\lambda_0, p) \neq 0$ such that*

$$\begin{aligned} -p' + \gamma Ap + [B'(y^*)]^*p &\in -\lambda_0 g(t, y^*) \quad \text{a.e. in } (0,T), \\ \langle p(0), x_0 - y^*(0)\rangle - \langle p(T), x_1 - y^*(T)\rangle &\leq 0 \quad \forall\ (x_0, x_1) \in S, \\ D^*p(t) &\in \lambda_0 \partial h(u^*(t)) \quad \text{a.e. in } (0,T). \end{aligned}$$

In this case, we introduce the penalty functional

$$\begin{aligned} L_\varepsilon(y,u) = &\int_0^T [g^\varepsilon(t,y) + h_\varepsilon(u)]dt + \frac{1}{2}\int_0^T |u - u^*|_U^2 dt + \frac{1}{2}\|y(0) - y^*(0)\|^2 \\ &+ \frac{1}{4}\int_0^T \|y - y^*\|^4 dt + \frac{1}{2\varepsilon}[\varepsilon + d_S(y(0), y(T))]^2 \\ &+ \frac{1}{2\varepsilon}\int_0^T |y' + \gamma Ay + By - Du - f|^2 dt, \end{aligned}$$

where $d_S(\cdot,\cdot)$ denotes the distance of $(\cdot,\cdot)$ to S in $H \times H$, and we consider the following approximation problem.

$(P_{2\varepsilon})$ $\inf L_\varepsilon(y,u)$ over all $(y,u) \in Y \times L^2(0,T;U)$.

Since the main ideas and steps in the proof of Theorem 2.4 are similar to those in the proof of Theorem 2.3, we omit the proof of Theorem 2.4 here.

3. Optimal control with periodic inputs. The form of state constraint (1.14) covers the periodic case; we will see this in Example 4.7 in section 4. However, in Theorem 2.4, we cannot get $\lambda_0 \neq 0$. In this section, we shall derive the qualified maximum principle for the periodic case (i.e., $\lambda_0 \neq 0$) by a different method.

Let $X = \{y \in Y : y(0) = y(T)\}$. Then X is dense in $L^2(0,T;H)$ (cf. [3]). Suppose that (H_8) holds and $g^\varepsilon : [0,T] \times H \to R^+$ is defined in the similar way as in (2.1), where we replace V by H, and h_ε is defined by (2.2). We introduce $L_\varepsilon : Y \times L^2(0,T;U) \to R$ by

$$\begin{aligned} L_\varepsilon(y,u) = &\int_0^T [g^\varepsilon(t,y) + h_\varepsilon(u)]dt + \frac{1}{4}\int_0^T \|y - y^*\|^4 dt \\ &+ \frac{1}{2}\int_0^T |u - u^*|_U^2 dt + \frac{1}{2\varepsilon}\int_0^T |y' + \gamma Ay + By - Du - f|^2 dt \end{aligned} \tag{3.1}$$

and consider the following approximation problem $(P_{3\varepsilon})$.

$(P_{3\varepsilon})$ $\inf L_\varepsilon(y,u)$ over all $(y,u) \in X \times L^2(0,T;U)$.

Similar to Lemmas 2.1 and 2.2, we may have the following existence and approximation results for problem $(P_{3\varepsilon})$. We omit the proofs here.

LEMMA 3.1. *For each $\varepsilon > 0$, problem $(P_{3\varepsilon})$ has at least one solution.*

LEMMA 3.2. *Let $(y_\varepsilon, u_\varepsilon) \in X \times L^2(0,T;U)$ be optimal for problem $(P_{3\varepsilon})$. Then*

$$\begin{aligned} &y_\varepsilon \to y^* \ \text{ strongly in } Y \ \text{ as } \varepsilon \to 0, \\ &u_\varepsilon \to u^* \ \text{ strongly in } L^2(0,T;U) \ \text{ as } \varepsilon \to 0. \end{aligned}$$

In the space $L^2(0,T;H)$, we define the operators

$$\mathcal{A}_\varepsilon \varphi = \varphi' + \gamma A\varphi + B'(y_\varepsilon)\varphi \quad \forall\ \varphi \in D(\mathcal{A}_\varepsilon) = X \tag{3.2}$$

and

$$\mathcal{A}_\varepsilon{}^*\varphi = -\varphi' + \gamma A\varphi + [B'(y_\varepsilon)]^*\varphi \quad \forall\ \varphi \in X, \tag{3.3}$$

where $B'(y_\varepsilon)$ and $[B'(y_\varepsilon)]^*$ were defined in (2.48) *and* (2.49), *respectively. It is readily seen that*

$$\int_0^T \langle \mathcal{A}_\varepsilon{}^* q, \varphi\rangle dt = \int_0^T \langle \mathcal{A}_\varepsilon \varphi, q\rangle dt \quad \forall\ \varphi, q \in D(\mathcal{A}_\varepsilon) = D(\mathcal{A}_\varepsilon{}^*) = X. \tag{3.4}$$

The operators $\mathcal{A}$ and $\mathcal{A}^*$ are defined by the same formulae (3.2) *and* (3.3), *where $y_\varepsilon = y^*$.*

LEMMA 3.3. *The operators $\mathcal{A}_\varepsilon$, $\mathcal{A}_\varepsilon{}^*$, $\mathcal{A}$, and $\mathcal{A}^*$ are closed, densely defined, and have closed ranges in $L^2(0,T;H)$. Moreover, $\dim N(\mathcal{A}_\varepsilon)$, $\dim N(\mathcal{A}_\varepsilon{}^*) \le n_0$, independent of ε, $\mathcal{A}_\varepsilon{}^*$ is the adjoint operator of $\mathcal{A}_\varepsilon$, and the following estimates hold:*

$$\|\mathcal{A}_\varepsilon{}^{-1} g\|_{L^2(0,T;D(A))\cap W^{1,2}([0,T];H)} \le C\|g\|_{L^2(0,T;H)} \quad \forall\ g \in R(\mathcal{A}_\varepsilon), \tag{3.5}$$

$$\|(\mathcal{A}_\varepsilon{}^*)^{-1} g\|_{L^2(0,T;D(A))\cap W^{1,2}([0,T];H)} \le C\|g\|_{L^2(0,T;H)} \quad \forall\ g \in R(\mathcal{A}_\varepsilon{}^*). \tag{3.6}$$

Similarly, the operator $\mathcal{A}^*$ and $\mathcal{A}$ are mutually adjoint and estimates (3.5) *and* (3.6) *remain true for $\mathcal{A}$ and $\mathcal{A}^*$. Here we have used the symbols N and R to denote the null space and the range of the corresponding operators.*

Remark. Lemma 3.3 was obtained by Barbu (cf. [3, Lemma 2]) for 2-dimensional Navier–Stokes equations. We observe that it works for 3-dimensional Navier–Stokes equations, and the proof is similar to that in [3].

Proof of Lemma 3.3. Consider the linear evolution equation

$$\begin{cases} \varphi' + \gamma A\varphi + B'(y_\varepsilon)\varphi = g \quad \text{a.e. in } (0,T), \\ \varphi(0) = x. \end{cases} \tag{3.7}$$

By (2.50) and (2.52), system (3.7) has a unique solution $\varphi \equiv \varphi_\varepsilon(t;x,g) \in W(0,T)$ for each $x \in H$, $g \in L^2(0,T;H)$, satisfying the estimate (2.56) with $\|g\|_{L^2(0,T;V^*)}$ replaced by $\|g\|_{L^2(0,T;H)}$. Moreover, if $x \in V$, then it follows that $\varphi \in Y \subset C([0,T];V)$.

In the latter case, if we multiply (3.7) by $tA\varphi(t)$, integrate on $(0,t)$, and observe that (by (1.8) and (2.48))

$$\begin{aligned} |\langle B'(y_\varepsilon)\varphi, A\varphi\rangle| &\le |b(\varphi, y_\varepsilon, A\varphi)| + |b(y_\varepsilon, \varphi, A\varphi)| \\ &\le C[\|\varphi\|^{\frac12}|A\varphi|^{\frac12}\|y_\varepsilon\| + \|y_\varepsilon\|\|\varphi\|^{\frac12}|A\varphi|^{\frac12}]|A\varphi| \\ &\le C\|\varphi\|^{\frac12}|A\varphi|^{\frac32} \\ &\le \frac{\gamma}{4}|A\varphi|^2 + C_\gamma\|\varphi\|^2, \end{aligned}$$

we get that

$$\begin{aligned} &\frac12 t\|\varphi(t)\|^2 + \gamma\int_0^t s|A\varphi(s)|^2 ds \\ &\quad\le \frac{\gamma}{4}\int_0^t s|A\varphi(s)|^2 ds + C_\gamma\int_0^T |g(t)|^2 dt + \frac{\gamma}{4}\int_0^t s|A\varphi(s)|^2 ds + C_\gamma\int_0^T \|\varphi\|^2 dt, \end{aligned}$$

which, together with (2.56), implies that

$$t\|\varphi(t)\|^2 \le C[|x|^2 + \|g\|^2_{L^2(0,T;H)}] \quad \forall\, t \in [0,T].$$

This estimate extends to all solutions to (3.7), where $x \in H$, and we have, therefore, that

$$\varphi_\varepsilon(T;x,g) \in V; \quad \|\varphi_\varepsilon(T;x,g)\|^2 \le C[|x|^2 + \|g\|^2_{L^2(0,T;H)}] \quad \forall\, \varepsilon > 0, \tag{3.8}$$

where $C > 0$ is independent of ε.

We define $G_\varepsilon : L^2(0,T;U) \to H$ by $G_\varepsilon(g) = \varphi_\varepsilon(T;0,g)$ and define $\Gamma_\varepsilon : H \to H$ by $\Gamma_\varepsilon x = \varphi_\varepsilon(T;x,0)$. It is clear that

$$\varphi_\varepsilon(T;x,g) = \Gamma_\varepsilon x + G_\varepsilon g, \tag{3.9}$$

and estimate (3.8) yields that

$$\|\Gamma_\varepsilon\|_{L(H,V)} + \|G_\varepsilon\|_{L(L^2(0,T;H),V)} \le C \quad \forall\, \varepsilon > 0. \tag{3.10}$$

Since the injection of V into H is compact, we infer that Γ_ε is completely continuous. Let $(y,g) \in \mathcal{A}_\varepsilon$; i.e., $\mathcal{A}_\varepsilon y = g$. We have, therefore, that $y(t) = \varphi_\varepsilon(t;x,g)$, where $(I - \Gamma_\varepsilon)x = G_\varepsilon g$. By the Fredholm–Riesz theory (cf. [22, Chapter X]), we know that $R(I - \Gamma_\varepsilon)$ is closed and $\dim N(I - \Gamma_\varepsilon) < \infty$. Hence $R(\mathcal{A}_\varepsilon)$ is closed in $L^2(0,T;H)$, and $N(\mathcal{A}_\varepsilon)$ is finite dimensional. Moreover, if $(\varphi_n, g_n) \in \mathcal{A}_\varepsilon$ and $\varphi_n \to \varphi$, $g_n \to g$ strongly in $L^2(0,T;H)$, then we have

$$\varphi_n' + \gamma A\varphi_n + B'(y_\varepsilon)\varphi_n = g_n \quad \text{a.e. in } (0,T). \tag{3.11}$$

Multiplying (3.11) by $t\varphi_n(t)$ and integrating on $(0,t)$, by (2.52) we get that

$$t|\varphi_n(t)|^2 + \gamma\int_0^t s\|\varphi_n(s)\|^2 ds \le C_\gamma\left[1 + \int_0^t s|\varphi_n(s)|^2 ds\right].$$

By Gronwall's inequality, we get that $t|\varphi_n(t)|^2 \le C$ for all $t \in [0,T]$. This implies that $|\varphi_n(T)| \le C$, and so $|\varphi_n(0)| \le C$. Then it follows from (3.8) that $\{\varphi_n(0)\}$ is bounded in V, and, as seen earlier, this implies that $\{\varphi_n\}$ is bounded in Y.

Hence, on a subsequence, still denoted by φ_n,

$$\varphi_n \to \varphi \ \text{ strongly in } L^2(0,T;V)\cap C([0,T];H) \ \text{ as } \varepsilon \to 0,$$

which, combined with (1.8) and Lemma 3.2, indicates that

$$\begin{aligned}\int_0^T |B'(y_\varepsilon)\varphi_n - B'(y_\varepsilon)\varphi|^2 dt &\le C\int_0^T \|\varphi_n - \varphi\|\|A\varphi_n - A\varphi\|\|y_\varepsilon\| dt\\ &\le C\left[\int_0^T \|\varphi_n - \varphi\|^2\right]^{\frac12}\left[\int_0^T \|A\varphi_n - A\varphi\|^2 dt\right]^{\frac12}\\ &\to 0 \ \text{ as } \varepsilon \to 0.\end{aligned}$$

Hence we may pass to the limit for $n \to \infty$ in (3.11) to get that $(\varphi, g) \in \mathcal{A}_\varepsilon$, i.e., $\mathcal{A}_\varepsilon$ is closed.

Now let $\Gamma \in L(H,H)$ be defined by $\Gamma x = \varphi(T;x,0)$, where φ is the solution to

$$\begin{cases}\varphi' + \gamma A\varphi + B'(y^*)\varphi = g \quad \text{a.e. in } (0,T),\\ \varphi(0) = x.\end{cases}$$

As seen earlier, $\Gamma \in L(H,V)$, and so Γ is completely continuous from H into itself. Moreover, by Lemma 3.2 and the estimate (3.10), it follows that

$$\Gamma_\varepsilon \to \Gamma \ \text{ in } L(H,H) \ \text{ as } \varepsilon \to 0.$$

Since $\dim N(I-\Gamma) < \infty$, the latter implies that there exists $n_0 > 0$ such that $\dim N(I-\Gamma_\varepsilon) \le n_0$ for all $\varepsilon > 0$. Hence $\dim N(\mathcal{A}_\varepsilon) \le n_0$ for all $\varepsilon > 0$ as claimed. Moreover, we have that

$$|(I-\Gamma_\varepsilon)^{-1}g_0| \le C|g_0| \quad \forall\ g_0 \in R(I-\Gamma_\varepsilon). \tag{3.12}$$

Indeed, otherwise there exist $x_\varepsilon \in R((I-\Gamma_\varepsilon)^*)$, $f_\varepsilon \in R(I-\Gamma_\varepsilon)$ such that $(I-\Gamma_\varepsilon)x_\varepsilon = f_\varepsilon$ and $|f_\varepsilon| = 1$, $|x_\varepsilon| \to \infty$. Let $\tilde{x}_\varepsilon = \frac{x_\varepsilon}{|x_\varepsilon|}$ and $\tilde{f}_\varepsilon = \frac{f_\varepsilon}{|x_\varepsilon|}$. Then $\tilde{f}_\varepsilon \to 0$ and $(I-\Gamma_\varepsilon)\tilde{x}_\varepsilon = \tilde{f}_\varepsilon$. We have that $\Gamma_\varepsilon\tilde{x}_\varepsilon = \varphi(T;\tilde{x}_\varepsilon,0)$. It follows from (3.8) that $\|\Gamma_\varepsilon\tilde{x}_\varepsilon\| \le C|\tilde{x}_\varepsilon| \le C$. This implies that $\{\Gamma_\varepsilon\tilde{x}_\varepsilon\}$ has a subsequence which converges in H. Since $\tilde{x}_\varepsilon = \Gamma_\varepsilon\tilde{x}_\varepsilon + \tilde{f}_\varepsilon$, we infer that there exists a subsequence of $\{\tilde{x}_\varepsilon\}$, still denoted by itself, such that $\tilde{x_\varepsilon} \to x_0$ in H and $|x_0| = 1$. We have that $x_0 \in R((I-\Gamma)^*)$ and $(I-\Gamma)x_0 = 0$, which contradicts the fact that

$$R((I-\Gamma)^*) \oplus N(I-\Gamma) = H.$$

Recall that $\varphi = \varphi_\varepsilon(t;x,g)$, where $(I-\Gamma_\varepsilon)x = G_\varepsilon g$ is a solution to $\mathcal{A}_\varepsilon\varphi_\varepsilon = g$. It follows from (3.12) that

$$|\varphi_\varepsilon(0)| \le |(I-\Gamma_\varepsilon)^{-1}(G_\varepsilon g)| \le C|G_\varepsilon g|. \tag{3.13}$$

Then, as seen above, we have that

$$\|\varphi_\varepsilon\|_{W^{1,2}([0,T];H)} + \|\varphi_\varepsilon\|_{L^2(0,T;D(A))} \le C\|g\|_{L^2(0,T;H)} \quad \forall\, g \in R(\mathcal{A}_\varepsilon),$$

which implies (3.5).

The corresponding properties of the operator ${\mathcal{A}_\varepsilon}^*$ follow from the previous arguments because, in this case, (3.7) is replaced by

$$\varphi' + \gamma A\varphi + [B'(y_\varepsilon)]^*\varphi = g, \quad \varphi(0) = x,$$

and so the previous estimates remain valid. In particular, it follows that the operator ${\mathcal{A}_\varepsilon}^*$ is closed, and so we conclude from (3.4) that its adjoint is precisely $\mathcal{A}_\varepsilon$.

Similarly, we may prove the corresponding results for the operators $\mathcal{A}$ and $\mathcal{A}^*$. This completes the proof.

THEOREM 3.4. *Let (H_1)–(H_4) and (H_8) hold. Suppose that (y^*, u^*) is optimal for problem (P_3). Then there exists $p \in X$ such that*

$$p' - \gamma Ap - [B'(y^*)]^*p \in \partial g(t, y^*) \quad \text{a.e. in } (0,T), \tag{3.14}$$

and

$$D^*p(t) \in \partial h(u^*(t)) \quad \text{a.e. in } (0,T). \tag{3.15}$$

Proof. Let $(y_\varepsilon, u_\varepsilon)$ be optimal for $(P_{3\varepsilon})$. For any $z \in X$, $v \in L^2(0,T;U)$ fixed, we set $y_\varepsilon^\rho = y_\varepsilon + \rho z$ and $u_\varepsilon^\rho = u_\varepsilon + \rho v$. Then $(y_\varepsilon^\rho, u_\varepsilon^\rho) \in X \times L^2(0,T;U)$. By the same argument as in the proof of Theorem 2.3, we have that

$$\begin{aligned} 0 \le &\int_0^T [\langle \nabla g^\varepsilon(t, y_\varepsilon), z\rangle + \langle \nabla h_\varepsilon(u_\varepsilon), v\rangle_U]dt \\ &+ \int_0^T \langle \|y_\varepsilon - y^*\|^2 A(y_\varepsilon - y^*), z\rangle dt \\ &+ \int_0^T \langle u_\varepsilon - u^*, v\rangle_U dt + \int_0^T \langle p_\varepsilon, z' + \gamma Az + B'(y_\varepsilon)z - Dv\rangle dt \end{aligned} \tag{3.16}$$

for all $z \in X$ and $v \in L^2(0,T;U)$, where $p_\varepsilon = \frac{1}{\varepsilon}[y_\varepsilon' + \gamma Ay_\varepsilon + By_\varepsilon - Du_\varepsilon - f]$.

By taking $v = 0$ in (3.17), we get that

$$\begin{aligned} &\int_0^T \langle \nabla g^\varepsilon(t, y_\varepsilon) + \|y_\varepsilon - y^*\|^2 A(y_\varepsilon - y^*), z\rangle dt \\ &\qquad + \int_0^T \langle p_\varepsilon, \mathcal{A}_\varepsilon z\rangle dt = 0 \quad \forall\, z \in Z. \end{aligned} \tag{3.17}$$

Hence $p_\varepsilon \in D({\mathcal{A}_\varepsilon}^*) = X$, and

$${\mathcal{A}_\varepsilon}^* p_\varepsilon = -\nabla g^\varepsilon(t, y_\varepsilon) - \|y_\varepsilon - y^*\|^2 A(y_\varepsilon - y^*). \tag{3.18}$$

By taking $z = 0$ in (3.16), we deduce that

$$\int_0^T [\langle \nabla h_\varepsilon(u_\varepsilon), v\rangle_U - \langle D^*p_\varepsilon, v\rangle_U + \langle u_\varepsilon - u^*, v\rangle_U]dt \ge 0 \quad \forall\, v \in L^2(0,T;U).$$

This yields that

$$D^*p_\varepsilon(t) = \nabla h_\varepsilon(u_\varepsilon(t)) + u_\varepsilon(t) - u^*(t) \quad \text{a.e. in } (0,T). \tag{3.19}$$

By (3.19) and Lemma 3.2 and using the same argument as in [2, Chapter 1], we have

$$\|D^*p_\varepsilon\|_{L^2(0,T;H)} \le C \quad \forall\, \varepsilon > 0. \tag{3.20}$$

Now, by Lemma 3.3 and the closed range theorem (cf. [20, p. 205]), we may write

$$p_\varepsilon = p_\varepsilon^1 + p_\varepsilon^2,$$

where $p_\varepsilon^1 \in R(\mathcal{A}_\varepsilon)$ and $p_\varepsilon^2 \in N(\mathcal{A}_\varepsilon{}^*)$. By Lemma 3.3 again, we get that

$$\|p_\varepsilon^1\|_{L^2(0,T;D(A))\cap W^{1,2}([0,T];H)} \le C \quad \forall\, \varepsilon > 0. \tag{3.21}$$

On the other hand, since the space $N(\mathcal{A}_\varepsilon{}^*)$ is finite dimensional, we infer that the restriction of D to $N(\mathcal{A}_\varepsilon{}^*)$, still denoted by D, has closed range. Then by the closed range theorem again, we deduce that

$$p_\varepsilon^2 = p_\varepsilon^3 + p_\varepsilon^4,$$

where $p_\varepsilon^3 \in R(D)$ and $p_\varepsilon^4 = N(D^*)$. Then, by (3.20), we see that $\{p_\varepsilon^3\}$ is bounded in $L^2(0,T;H)$. Since $\{p_\varepsilon^3\} \subset N(\mathcal{A}_\varepsilon{}^*)$ and $\dim(\mathcal{A}_\varepsilon{}^*) \le n_0$, there exist $p^3 \in L^2(0,T;H)$ and a subsequence of p_ε^3, still denoted by itself, such that

$$p_\varepsilon^3 \to p^3 \ \text{ strongly in } L^2(0,T;H) \ \text{ as } \varepsilon \to 0. \tag{3.22}$$

By (3.21), we may assume that (without loss of generality)

$$p_\varepsilon^1 \to p^1 \ \text{ strongly in } L^2(0,T;H) \ \text{ as } \varepsilon \to 0. \tag{3.23}$$

By Lemma 3.2, one can easily check that

$$\mathcal{A}_\varepsilon z \to \mathcal{A}z \ \text{ weakly in } L^2(0,T;H) \quad \forall\, z \in X. \tag{3.24}$$

Since $p_\varepsilon^2 = p_\varepsilon^3 + p_\varepsilon^4 \in N(\mathcal{A}_\varepsilon)$, we may rewrite (3.18) as

$$\mathcal{A}_\varepsilon{}^*(p_\varepsilon^1 + p_\varepsilon^3) = -\nabla g^\varepsilon(t, y_\varepsilon) - \|y_\varepsilon - y^*\|^2 A(y_\varepsilon - y^*),$$

which is equivalent to

$$\begin{aligned} &\int_0^T \langle \nabla g^\varepsilon(t, y_\varepsilon) + \|y_\varepsilon - y^*\|^2 A(y_\varepsilon - y^*), z\rangle dt \\ &\qquad + \int_0^T \langle p_\varepsilon^1 + p_\varepsilon^3, \mathcal{A}_\varepsilon z\rangle dt = 0 \end{aligned} \tag{3.25}$$

for all $z \in X$.

By Lemma 3.2 and by the same argument as in [1, Chapter 5], we have that

$$\nabla g^\varepsilon(t, y_\varepsilon) \to \beta \ \text{ weakly in } \ L^2(0,T;H) \ \text{ and } \beta \in \partial g(t, y^*) \quad \text{a.e. in } (0,T). \tag{3.26}$$

Now by (3.22), (3.23), (3.24), (3.26), and Lemma 3.2, we may pass to the limit for $\varepsilon \to 0$ in (3.25) to get

$$\int_0^T \langle \beta, z\rangle dt + \int_0^T \langle p^1 + p^3, \mathcal{A}z\rangle dt = 0 \quad \forall\ z \in Z.$$

This shows that $p^1 + p^3 \in D(\mathcal{A}^*)$ and

$$\mathcal{A}(p^1 + p^3) = \beta. \tag{3.27}$$

By (3.22), (3.23), (3.26), and Lemma 3.2, we may pass to the limit for $\varepsilon \to 0$ in (3.19) to get that

$$D^*(p^1 + p^3) \in \partial h(u^*) \quad \text{a.e. in } (0,T). \tag{3.28}$$

Let $p = p^1 + p^3 \in X$. Then $p \in X$. By (3.27) and (3.28), we derive (3.14) and (3.15). This completes the proof.

4. Applications. In this section, we shall point out some special cases of cost functionals and state constraints covered by (1.9), (1.13), and (1.14).

Example 4.1. Let $g(t,y) = \frac{1}{2}[|y - y^0(t)|^2 + |\nabla \times y|^2]$, where $y^0 \in L^\infty(0,T;H)$ stands for reference velocity and $\nabla \times y = \operatorname{curl} y$, and let $h(u) = \frac{1}{2}|u|_U^2$.

One can check that $g : [0,T] \times V \to R^+$ and $h : U \to R$ satisfy all conditions in (H_5). In this case, our objective is to determine the control u in such a way that the velocity vector is as close as possible, in the sense of (P_1) (or (P_2)), to the desired velocity y^0, and the turbulence is minimal.

Example 4.2. In (H_6), we take $X = L^2(0,T;V)$, $F \equiv I$, the identity operator on $L^2(0,T;V)$, and $W = \{y \in L^2(0,T;V) : \|y\|_{L^2(0,T;V)} \le \rho\}$.

It is clear that W is closed and convex and has finite codimensionality in $L^2(0,T;V)$. In this case, (1.13) is equivalent to $\int_0^T \|y\|^2 dt \le \rho$, which is equivalent to (cf. [5]) $\int_0^T |\nabla \times y|^2 dt \le \rho^2$. Thus the state constraint (1.13) in this case means that the average of the turbulence in $[0,T]$ is governed by ρ^2.

Example 4.3. In (H_6), we may take $X = R$, $F(y) = \int_0^T |y|^2 dt$, and $W = (-\infty, \rho^2]$.

It is clear that W is convex and closed in $X = R$ with the codimension zero (cf. [6] and [10]) and $F'(y)$ injective for all $y \in L^2(0,T;V)$. In this case, (1.13) is equivalent to $\int_0^T |y|^2 dt \le \rho^2$. Thus the state constraint (1.13) means that the average of the energy in $[0,T]$ is governed by ρ^2.

Example 4.4. In (H_6), we may take $X = R$, $F(y) = \int_0^T [|\nabla \times y|^2 - c|y|^2] dt$, where $c \ge 0$ and $W = (-\infty, \rho^2]$.

One can easily check that F is class of C^1 and $F'(y)$ is injective (for c small enough), and W is closed and convex with the codimension zero. In this case, (1.13) is equivalent to $\int_0^T [|\nabla \times y|^2 - c|y|^2] dt \le \rho^2$ or $\int_0^T |\nabla \times y|^2 dt \le c\int_0^T |y|^2 dt + \rho^2$. Thus the state constraint (1.13) in this case means that the average of the turbulence is governed by the average of the energy and ρ^2.

Recall that the enstrophy set (cf. [6] and [10]) $K = \{y_0 \in V : |\nabla \times y_0|^2 \le \varphi(|y_0|^2) + \rho^2\}$ plays an important role in fluid mechanics. We may regard $\tilde{K}$ as a special generalized enstrophy set, where $\tilde{K} = \{y \in L^2(0,T;V) : \int_0^T |\nabla \times y|^2 dt \le c\int_0^T |y|^2 dt + \rho^2\}$. Thus (1.13) in this case means that $y \in \tilde{K}$.

Example 4.5. In (H_6), we may take $X = R$, $W = (-\infty, \rho^2]$, and $F(y) = \int_0^T \langle y, \nabla \times y\rangle^2 dt + \lambda^2 \int_0^T \|y\|^2 dt$.

One can easily check that F is class of C^1 and $F'(y)$ is injective. In this case, (1.13) is equivalent to $\int_0^T \langle y, \nabla \times y\rangle^2 dt + \lambda^2 \int_0^T \|y\|^2 dt \le \rho^2$.

Recall that the helicity set $K_1 = \{y_0 \in V : \langle y_0, \nabla \times y_0\rangle^2 + \lambda^2 \|y_0\|^2 \le \rho^2\}$ plays an important role in fluid mechanics, and, in particular, it is an invariant set of Euler's equation (cf. [9]). We may regard $\tilde{K_1}$ as a generalized helicity set, where

$$\tilde{K_1} = \left\{ y \in L^2(0,T;V) : \int_0^T \langle y, \nabla \times y\rangle^2 dt + \lambda^2 \int_0^T \|y\|^2 dt \le \rho^2 \right\}.$$

The state constraint (1.13) in this case means that $y \in \tilde{K_1}$.

Example 4.6. In (H_7), let $S = \{y_0\} \times S_1$, where $y_0 \in V$ and $S_1 \subset H$ is convex and closed. Furthermore, we assume the following.

$(H_{10,1})$ S_1 has finite codimensionality in H.

We claim that $(H_{10,1})$ implies (H_{10}). To this end, let $\Gamma : H \to H$ and $G : L^2(0,T;U) \to H$ be defined by $\Gamma x = \varphi(T;x,0)$ and $Gu = \varphi(T;0,u)$, where $\varphi(t;x,u)$ is the solution to

$$\begin{cases} \varphi' + \gamma A\varphi + B'(y^*)\varphi = Du \quad \text{a.e. in } (0,T), \\ \varphi(0) = x. \end{cases} \tag{4.1}$$

Notice that (4.1) has a unique solution $\varphi(t;x,u) \in W(0,T)$ for each $x \in H$ and $u \in L^2(0,T;U)$. Moreover, $\varphi(t;x,u) \in Y$ if $x \in V$ and $u \in L^2(0,T;U)$.

Let $M(0,r)$ be defined by (2.58), let Q_{r_1,r_2} be defined in (3.2), and let $E(0,r)$ be defined by $E(0,r) = \{z_0 \in V : \|z_0\| \le r\}$. Consider the set $\{(z_0, \Gamma z_0 + Gu) : z_0 \in E(0,r), u \in M(0,r)\}$. It is clear that $E(0,r)$ has finite codimensionality in H for each $r > 0$. Thus by $(H_{10,1})$ and by [14, Proposition 4], we deduce that $\{(z_0, \Gamma z_0 + Gu) : z_0 \in E(0,r), u \in M(0,r)\} - \{y_0\} \times S_1$ has finite codimensionality in $H \times H$.

However, for all $z_0 \in E(0,r)$ and $u \in M(0,r)$, $\Gamma z_0 + Gu = \varphi(T;z_0,u) \in V$ and $|\varphi(t;z_0,u| \le r_0$ for some $r_0 > 0$ independent of z_0 and u. Hence $Q_{r_0,r} \supset \{(z_0, \Gamma z_0 + Gu) : z_0 \in E(0,r), u \in M(0,r)\}$. So $Q_{r_0,r} - S$ has finite codimensionality. This means $(H_{10,1})$ implies (H_{10}).

Example 4.7. Let Γ, G, $M(0,r)$, and $E(0,r)$ be defined in Example 4.6.

Let $Q = \{x_1 - \Gamma x_0 : (x_0, x_1) \in S\}$, $\mathcal{R}_r = GM(0,r) = \{Gu : u \in M(0,r)\}$, and $\tilde{\mathcal{R}}_r = \{(z_0, z_T) \in H \times H : z_0 \in E(0,r), z_T = \Gamma z_0 + Gu, u \in M(0,r)\}$. We assume the following.

$(H_{10,2})$ $\mathcal{R}_r - Q$ has finite codimensionality in H.

We recall the following proposition; for its proof, we refer the reader to [20, Lemma 2.5].

PROPOSITION 4.8. *$\mathcal{R}_r - Q$ is finite codimensional in H if and only if $\tilde{\mathcal{R}}_r - S$ is so in $H \times H$.*

By the same argument as in Example 4.6, we have that $\tilde{\mathcal{R}}_r \subset Q_{r_0,r}$ for some $r_0 > 0$. Thus $(H_{10,2})$ implies (H_{10}).

Next we shall show that Theorem 2.4 works for the periodic case, i.e., the case where $S = \{(x,x,) : x \in H\}$ without assumption (H_{10}). Indeed, in this case, $Q = \{(I - \Gamma)x : x \in H\}$. By the previous discussion (cf. the proof of Lemma 3.3 in section 3), $R(I-\Gamma)^*$ is closed, $\dim N(I-\Gamma) < \infty$, and $H = R((I-\Gamma)^*) \oplus N(I-\Gamma)$. Thus Q has finite codimensionality in H. So does $\mathcal{R}_r - Q$ (cf. [14, Proposition 4 of Chapter 4]). Then it follows from Proposition 4.8 that $Q_{r_0,r}$ has finite codimensionality.

Notice that, in this case, we cannot get $\lambda_0 = 0$; i.e., the maximum principle we obtain is not qualified.

ON THE BOUNDARY CONTROL OF SYSTEMS OF CONSERVATION LAWS*

ALBERTO BRESSAN† AND GIUSEPPE MARIA COCLITE†

Abstract. This paper is concerned with the boundary controllability of entropy weak solutions to hyperbolic systems of conservation laws. We prove a general result on the asymptotic stabilization of a system near a constant state. On the other hand, we give an example showing that exact controllability in finite time cannot be achieved, in general.

Key words. boundary control, hyperbolic system, conservation laws

1. Introduction.

Consider an $n \times n$ system of conservation laws on a bounded interval:

$$u_t + f(u)_x = 0, \qquad t \geq 0, \quad x \in]a, b[. \tag{1.1}$$

The system is assumed to be strictly hyperbolic, each characteristic field being either linearly degenerate or genuinely nonlinear in the sense of Lax [8]. We shall also assume that all characteristic speeds are bounded away from zero. More precisely, let $f : \Omega \mapsto \mathbb{R}^n$ be a smooth map defined on an open set $\Omega \subseteq \mathbb{R}^n$. For each $u \in \Omega$, call $\lambda_1(u) < \cdots < \lambda_n(u)$ the eigenvalues of the Jacobian matrix $Df(u)$. We assume that there exist a minimum speed $c_0 > 0$ and an integer $p \in \{1, \ldots, n\}$ such that

$$\begin{cases} \lambda_i(u) < 0 & \text{if} \quad i \leq p, \\ \lambda_i(u) > 0 & \text{if} \quad i > p, \end{cases} \tag{1.2}$$

$$\big|\lambda_i(u)\big| \geq c_0 > 0, \qquad u \in \Omega. \tag{1.3}$$

By (1.2), for a solution defined on the strip $t \geq 0,\ x \in]a, b[$, there will be $n - p$ characteristics entering at the boundary point $x = a$ and p characteristics entering at $x = b$. The initial-boundary value problem is thus well posed if we prescribe $n - p$ scalar conditions at $x = a$ and p scalar conditions at $x = b$ [11]. See also [1, 2] for the case of general entropy weak solutions taking values in the space BV of functions with bounded variation.

In the present paper, we study the effect of boundary conditions on the solution of (1.1) from the point of view of control theory. Namely, given an initial condition

$$u(0, x) = \phi(x), \qquad x \in]a, b[, \tag{1.4}$$

with small total variation, we regard the boundary data as *control functions*, and we study the family of configurations

$$\mathcal{R}(T) \doteq \big\{u(T, \cdot)\big\} \subset \mathbf{L}^1\big([a, b]\,;\, \mathbb{R}^n\big), \tag{1.5}$$

which can be reached by the system at a given time $T > 0$.

†S.I.S.S.A., Via Beirut 4, Trieste 34014, Italy (bressan@sissa.it, coclite@sissa.it).

Beginning with the simplest case, consider a strictly hyperbolic system with constant coefficients:

$$u_t + Au_x = 0, \tag{1.6}$$

where A is an $n \times n$ constant matrix, with real distinct eigenvalues

$$\lambda_1 < \cdots < \lambda_p < 0 < \lambda_{p+1} < \cdots < \lambda_n.$$

Call

$$\tau \doteq \max_i \frac{b-a}{|\lambda_i|}$$

the maximum time taken by waves to cross the interval $[a, b]$. In this case, it is easy to see that the reachable set in (1.5) is the entire space: $\mathcal{R}(T) = \mathbf{L}^1$ for all $T \geq \tau$. In other words, the system is completely controllable after time τ. Indeed, for any $T \geq \tau$ and initial and terminal data $\phi, \psi \in \mathbf{L}^1\big([a, b]; \mathbb{R}^n\big)$, one can always find a solution of (1.4), defined on the rectangle $[0, T] \times [a, b]$, such that

$$u(0, x) = \phi(x), \qquad u(T, x) = \psi(x), \qquad x \in [a, b].$$

Such a solution can be constructed as follows. Let $l_1, \ldots, l_n$ and $r_1, \ldots, r_n$ be dual bases of right and left eigenvectors of A so that $l_i \cdot r_j = \delta_{ij}$. For $i = 1, \ldots, n$, let $u_i(t, x)$ be a solution to the scalar Cauchy problem

$$u_{i,t} + \lambda_i u_{i,x} = 0,$$

$$u_i(0, x) = \begin{cases} l_i \cdot \phi(x) & \text{if} \quad x \in [a, b], \\ l_i \cdot \psi(x + \lambda_i T) & \text{if} \quad x \in [a - \lambda_i T,\ b - \lambda_i T], \\ 0 & \text{otherwise.} \end{cases}$$

Then the restriction of

$$u(t, x) = \sum_i u_i(t, x) r_i$$

to the interval $[0, T] \times [a, b]$ satisfies (1.6) and takes the required initial and terminal values. Of course, this corresponds to the solution of an initial-boundary value problem, determined by the n boundary conditions

$$\begin{cases} l_i \cdot u(t, a) = u_i(t, a), & i = p + 1, \ldots, n, \\ l_i \cdot u(t, b) = u_i(t, b), & i = 1, \ldots, p. \end{cases}$$

This result on exact boundary controllability has been extended in [9, 10] to the case of general quasi-linear systems of the form

$$u_t + A(u)u_x = 0.$$

In this case, the existence of a solution taking the prescribed initial and terminal values is obtained for all sufficiently small data $\phi, \psi \in \mathcal{C}^1$.

The aim of the present paper is to study analogous controllability properties within the context of entropy weak solutions $t \mapsto u(t, \cdot) \in BV$. For the definitions

and basic properties of weak solutions, we refer to [4]. For general nonlinear systems, it is clear that a complete controllability result within the space BV cannot hold. Indeed, already for a scalar conservation law, it was proved in [3] that the profiles $\psi \in BV$ which can be attained at a fixed time $T > 0$ are only those which satisfy the Oleinik-type conditions

$$\psi'(x) \leq \frac{f'\big(\psi(x)\big)}{(x-a)f''\big(\psi(x)\big)} \qquad \text{for almost every } x \in [a,b].$$

For general $n \times n$ systems, a complete characterization of the reachable set $\mathcal{R}(T)$ does not seem possible, due to the complexity of repeated wave-front interactions.

Our first result is concerned with stabilization near a constant state. Assuming that all characteristic speeds are bounded away from zero, we show that the system can be asymptotically stabilized to any state $u^* \in \Omega$, with quadratic rate of convergence.

THEOREM 1. *Let K be a compact, connected subset of the open domain $\Omega \subset \mathbb{R}^n$. Then there exist constants $C_0, \delta, \kappa > 0$ such that the following holds. For every constant state $u^* \in K$ and every initial data $u(0) = \phi : [a,b] \mapsto K$ with* Tot.Var.$\{\phi\} < \delta$, *there exists an entropy weak solution $u = u(t,x)$ of (1.1) such that, for all $t > 0$,*

$$\text{Tot.Var.}\big\{u(t)\big\} \leq C_0\, e^{-2^{\kappa t}}, \tag{1.7}$$

$$\big\|u(t,x) - u^*\big\|_{L^\infty} \leq C_0\, e^{-2^{\kappa t}}. \tag{1.8}$$

The proof will be given in section 2. An interesting question is whether the constant state u^* can be exactly reached in a finite time T. By the results in [9], this is indeed the case if the initial data has a small $\mathcal{C}^1$ norm. On the contrary, in the final part of this paper, we show that exact controllability in finite time cannot be attained, in general, if the initial data is only assumed to have small total variation.

Our counterexample is concerned with a class of strictly hyperbolic, genuinely nonlinear 2×2 systems of the form (1.1). More precisely, we assume the following.

(H) The eigenvalues $\lambda_i(u)$ of the Jacobian matrix $A(u) = Df(u)$ satisfy

$$-\lambda^* < \lambda_1(u) < -\lambda_* \ < 0 \ < \lambda_* < \lambda_2(u) < \lambda^*. \tag{1.9}$$

Moreover, the right eigenvectors $r_1(u)$, $r_2(u)$ satisfy the inequalities

$$D\lambda_1 \cdot r_1 > 0, \qquad D\lambda_2 \cdot r_2 > 0, \tag{1.10}$$

$$r_1 \wedge r_2 < 0, \qquad r_1 \wedge (Dr_1 \cdot r_1) < 0, \qquad r_2 \wedge (Dr_2 \cdot r_2) < 0. \tag{1.11}$$

Here $D\lambda_i$, Dr_i denote the differentials of the functions $\lambda_i(u)$, $r_i(u)$, while $\wedge$ is the wedge product: if $v = (v_1, v_2)$, $w = (w_1, w_2)$, we define

$$v \wedge w \doteq v_1 w_2 - v_2 w_1.$$

A particular system which satisfies the above assumptions is the one studied by DiPerna [7]:

$$\begin{cases} \rho_t + (u\rho)_x = 0, \\ u_t + \left(\dfrac{u^2}{2} + \dfrac{K^2}{\gamma - 1}\rho^{\gamma-1}\right)_x = 0, \end{cases}$$

with $1 < \gamma < 3$. Here $\rho > 0$ and u denote the density and the velocity of a gas, respectively.

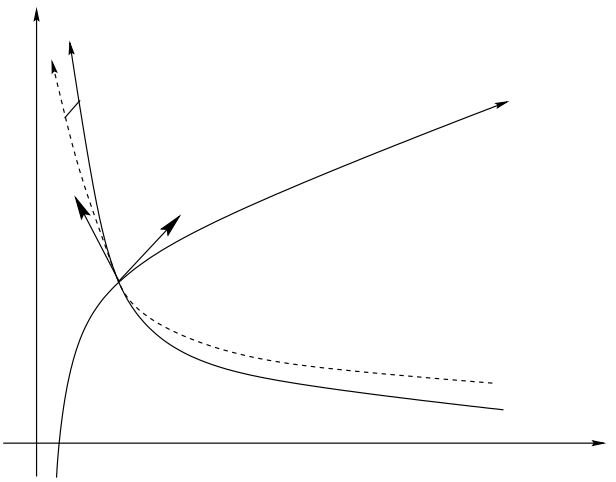

FIG. 1.

The last two inequalities in (1.11) imply that the rarefaction curves (i.e., the integral curves of the vector fields (r_1, r_2) in the (u_1, u_2) plane) turn clockwise (Figure 1). In such a case, the interaction of two shocks of the same family generates a shock in the other family.

THEOREM 2. *Consider a* 2×2 *system satisfying the assumption* (H). *Then there exist initial data* $\phi : [a, b] \mapsto \mathbb{R}^2$ *having arbitrarily small total bounded variation for which the following holds. For every entropy weak solution* u *of* (1.1), (1.4), *with* Tot.Var.$\{u(t, \cdot)\}$ *remaining small for all* t, *the set of shocks in* $u(t, \cdot)$ *is dense on* $[a, b]$ *for each* $t > 0$. *In particular,* $u(t, \cdot)$ *cannot be constant.*

As a preliminary, in section 3, we establish an Oleinik-type estimate on the decay of positive waves. This bound is of independent interest and sharpens the results in [5] for systems satisfying the additional conditions (H).

As a consequence, this implies that positive waves are "weak" and cannot completely cancel a shock within finite time. The proof of Theorem 2 is then achieved by an induction argument. We show that, if the set of 1-shocks is dense on $[0, T] \times [a, b]$, then the set of points $P_j = (t_j, x_j)$, where two 1-shocks interact and create a new 2-shock, is also dense on the same domain. Therefore, new shocks are constantly generated, and the solution can never be reduced to a constant. Details of the proof will be given in section 4.

As in [9], all of the above results refer to the case where total control on the boundary values is available. As a consequence, the problem is reduced to proving the existence (or nonexistence) of an entropy weak solution defined on the open strip $t > 0$, $x \in]a, b[$, satisfying the required conditions. This is a first step toward the analysis of more general controllability problems, where the control acts only on some of the boundary conditions. We thus leave open the case where a subset of indices $I \subset \{1, \dots, n\}$ is given, and one requires

$$l_i \cdot u(t, a) = \begin{cases} \alpha_i(t) & \text{if} \quad i \in I, \\ 0 & \text{if} \quad i \notin I, \end{cases} \qquad i = p+1, \dots, n,$$

$$l_i \cdot u(t, b) = \begin{cases} \alpha_i(t) & \text{if} \quad i \in I, \\ 0 & \text{if} \quad i \notin I, \end{cases} \qquad i = 1, \dots, p,$$

for some control functions α_i acting only on the components $i \in I$.

Throughout the following, we denote by $r_i(u), l_i(u)$ the right and left i-eigenvectors of the Jacobian matrix $A(u) \doteq Df(u)$. As in [4], we write $\sigma \mapsto R_i(\sigma)(u_0)$ for the parametrized i-rarefaction curve through the state u_0 so that

$$\frac{d}{d\sigma} R_i(\sigma) = r_i\big(R_i(\sigma)\big), \qquad R_i(0) = u_0.$$

The i-shock curve through u_0 is denoted by $\sigma \mapsto S_i(\sigma)(u_0)$. It satisfies the Rankine–Hugoniot equations

$$f\big(S_i(\sigma)\big) - f(u_0) = \lambda_i(\sigma)\,\big(S_i(\sigma) - u_0\big)$$

for some shock speed λ_i. We recall (see [4, Chap. 5]) that the general Riemann problem is solved in terms of the composite curves

$$\Psi_i(u_0)(\sigma) = \begin{cases} R_i(u_0)(\sigma) & \text{if } \ \sigma \geq 0, \\ S_i(u_0)(\sigma) & \text{if } \ \sigma < 0. \end{cases} \tag{1.12}$$

2. Proof of Theorem 1. The proof relies on the following two lemmas.

LEMMA 1. *In the setting of Theorem* 1*, there exists a time* $T > 0$ *such that the following holds. For every pair of states* $\omega, \omega' \in K$*, there exists an entropic solution* $u = u(t,x)$ *of* (1.1) *such that*

$$u(0,x) \equiv \omega, \qquad u(T,x) \equiv \omega' \qquad \textit{for all } x \in [a,b]. \tag{2.1}$$

Proof. Consider the function

$$\Phi(\sigma_1, \ldots, \sigma_n\,;\ v,\, v') \doteq \Psi_n(\sigma_n) \circ \cdots \circ \Psi_{p+1}(\sigma_{p+1})(v') - \Psi_p(\sigma_p) \circ \cdots \circ \Psi_1(\sigma_1)(v). \tag{2.2}$$

Observe that, whenever $v = v'$, the $n \times n$ Jacobian matrix $\partial\Phi/\partial\sigma_1 \cdots \sigma_n$ computed at $\sigma_1 = \sigma_2 = \cdots = \sigma_n = 0$ has full rank. Indeed, the columns of this matrix are given by the linearly independent vectors $-r_1(v), \ldots, -r_p(v)$, $r_{p+1}(v), \ldots, r_n(v)$. By the implicit function theorem and a compactness argument, we can find $\delta > 0$ such that the following holds. For every $v, v' \in K$, with $|v - v'| \leq \delta$, there exist unique values $\sigma_1, \ldots, \sigma_n$ such that

$$v'' \doteq \Psi_n(\sigma_n) \circ \cdots \circ \Psi_{p+1}(\sigma_{p+1})(v') = \Psi_p(\sigma_p) \circ \cdots \circ \Psi_1(\sigma_1)(v). \tag{2.3}$$

Defining the time as

$$\tau \doteq \max_{1 \leq i \leq n} \sup_{u \in \Omega} \frac{b-a}{\big|\lambda_i(u)\big|}, \tag{2.4}$$

we claim that there exists an entropy weak solution $u : [0, 2\tau] \times [a,b] \mapsto \Omega$ such that

$$u(0,x) \equiv v, \qquad u(2\tau, x) \equiv v'. \tag{2.5}$$

The function u is constructed as follows (see Figure 2). For $t \in [0, \tau]$, we let u be the solution of the Riemann problem

$$u(0,x) = \begin{cases} v & \text{if } \ x < b, \\ v'' & \text{if } \ x > b. \end{cases} \tag{2.6}$$

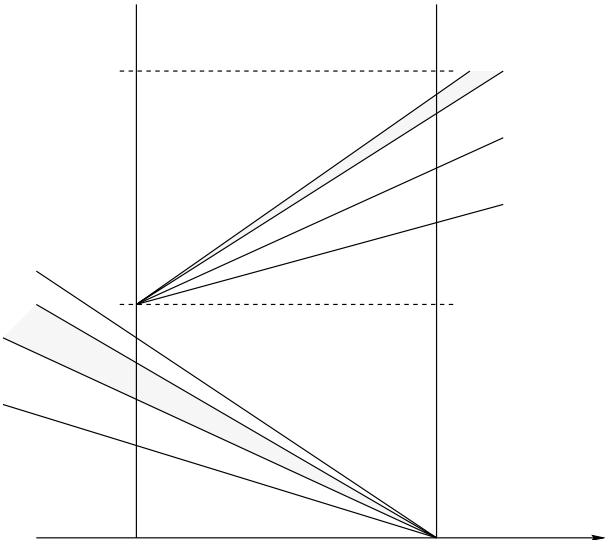

FIG. 2.

Moreover, for $t \in [\tau,\ 2\tau]$, we define u as the solution of the Riemann problem

$$u(\tau, x) = \begin{cases} v' & \text{if} \quad x < a, \\ v'' & \text{if} \quad x > a. \end{cases} \tag{2.7}$$

It is now clear that the restriction of u to the domain $[0,\ 2\tau] \times [a, b]$ satisfies the conditions in (2.5). Indeed, by (2.3), on $[0, \tau]$ the solution u contains only waves of families $\leq p$, originating at the point $(0, b)$. By (2.4), these waves cross the whole interval $[a, b]$ and exit from the boundary point a before time τ. Hence $u(\tau, x) \equiv v''$. Similarly, still by (2.3), for $t \in [\tau,\ 2\tau]$, the function u contains only waves of families $\geq p+1$, originating at the point (τ, a). By (2.4), these waves cross the whole interval $[a, b]$ and exit from the boundary point b before time 2τ. Hence $u(2\tau, x) \equiv v'$.

Next, given any two states $\omega, \omega' \in K$, by the connectedness assumption, we can find a chain of points $\omega_0 = \omega, \omega_1, \ldots, \omega_N = \omega'$ in K such that $|\omega_i - \omega_{i-1}| < \delta$ for every $i = 1, \ldots, N$. Repeating the previous construction in connection with each pair of states (ω_{i-1}, ω_i), we thus obtain an entropy weak solution $u : [0,\ 2N\tau] \times [a, b] \mapsto \Omega$ that satisfies the conclusion of the lemma, with $T = 2N\tau$. □

In the following, we shall construct the desired solution $u = u(t, x)$ as the limit of a sequence of front tracking approximations. Roughly speaking, an ε-approximate front tracking solution is a piecewise constant function u^ε, having jumps along a finite set of straight lines in the t-x plane, say, $x = x_\alpha(t)$, which approximately satisfies the Rankine–Hugoniot equations:

$$\sum_\alpha \left| f\big(u(t, x_\alpha+)\big) - f(u(t, x_\alpha-)\big) - \dot{x}_\alpha \left(u(t, x_\alpha+) - u(t, x_\alpha-)\right)\right| < \varepsilon$$

for all $t > 0$. For details, see [4, p. 125].

LEMMA 2. *In the setting of Theorem* 1*, for every state* $u^* \in \Omega$*, there exist constants* $C, \delta_0 > 0$ *for which the following holds. For any* $\varepsilon > 0$ *and every piecewise constant function* $\bar{u} : [a, b] \mapsto \Omega$ *such that*

$$\rho \doteq \sup_{x \in [a,b]} \left|\bar{u}(x) - u^*\right| \leq \delta_0, \qquad \delta \doteq \text{Tot.Var.}\{\bar{u}\} \leq \delta_0, \tag{2.8}$$

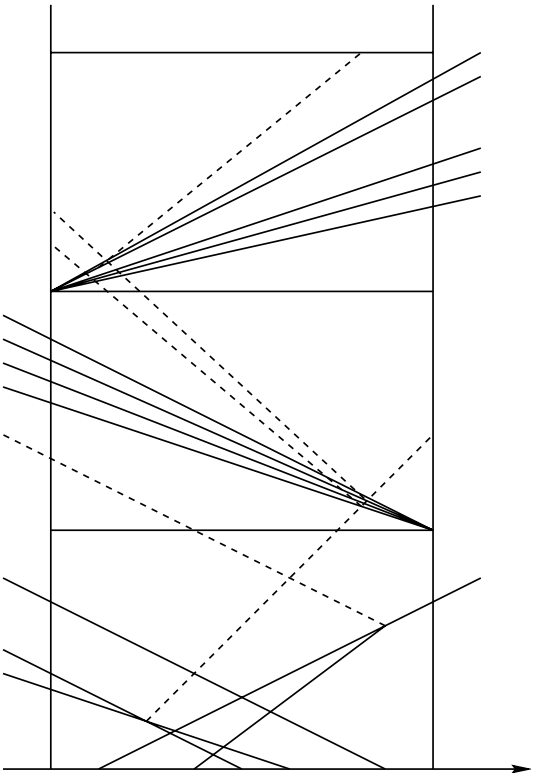

FIG. 3.

there exists an ε-approximate front tracking solution $u = u(t,x)$ of (1.1), with $u(0,x) = \bar{u}(x)$, such that

$$\sup_{x\in[a,b]} \big|u(3\tau,\, x) - u^*\big| \leq C\delta^2, \qquad \text{Tot.Var.}\big\{u(3\tau)\big\} \leq C\delta^2. \tag{2.9}$$

Proof. On the domain $(t,x) \in [0,\tau] \times [a,b]$, we construct u as an ε-approximate front tracking solution in such a way that, whenever a front hits one of the boundaries $x = a$ or $x = b$, no reflected front is ever created (see Figure 3). Since all fronts emerging from the initial data $\bar{u}$ at time $t = 0$ exit from $[a,b]$ within time τ, it is clear that $u(\tau)$ can contain only fronts of second or higher generation order. In other words, the only fronts that can be present in $u(\tau,\cdot)$ are the new ones, generated by interactions at times $t > 0$ (the dotted lines in Figure 3). Therefore, using the interaction estimate (7.69) in [4], we obtain

$$\sup_{x\in[a,b]} \big|u(\tau,\, x) - u^*\big| = \mathcal{O}(1)\cdot(\rho+\delta), \qquad \text{Tot.Var.}\big\{u(\tau)\big\} = \mathcal{O}(1)\cdot\delta^2. \tag{2.10}$$

We now apply a similar procedure as in the proof of Lemma 1 and construct a solution on the interval $[\tau,\ 3\tau]$ in such a way that $u(3\tau) \approx u^*$. More precisely, to construct u on the domain $[\tau,\ 2\tau] \times [a,b]$, consider the state v'' implicitly defined by (2.2), with $v \doteq u(\tau, b-)$, $v' \doteq u^*$. On a forward neighborhood of the point (τ,b), we let u coincide with (a front tracking approximation of) the solution to the Riemann problem

$$u(\tau,x) = \begin{cases} u(\tau,b-) & \text{if} \quad x < b, \\ v'' & \text{if} \quad x > b. \end{cases}$$

This procedure will introduce at the point (τ, b) a family of wave-fronts of families $i = 1, \dots, p$, whose total strength is $\mathcal{O}(1) \cdot (\rho + \delta)$. Because of (2.4), all of these fronts will exit from the boundary $x = a$ within time 2τ. Of course, they can interact with the other fronts present in $u(\tau, \cdot)$. In any case, the total strength of fronts in $u(2\tau, \cdot)$ is still estimated as

$$\text{Tot.Var.}\big\{u(2\tau)\big\} = \mathcal{O}(1) \cdot \delta^2. \tag{2.11}$$

Next, to define u for $t \in [2\tau,\, 3\tau]$, consider the state v''' implicitly defined by

$$\begin{cases} u(2\tau, a+) = \Psi_n(\sigma_n) \circ \cdots \circ \Psi_{p+1}(\sigma_{p+1})(v'''), \\ \qquad u^* = \Psi_p(\sigma_p) \circ \cdots \circ \Psi_1(\sigma_1)(v'''). \end{cases} \tag{2.12}$$

On a forward neighborhood of the point $(2\tau, a)$, we let u coincide with (a front tracking approximation of) the solution to the Riemann problem

$$u(2\tau, x) = \begin{cases} u(2\tau,\, a+) & \text{if} \quad x > a, \\ v''' & \text{if} \quad x < a. \end{cases}$$

This procedure introduces at the point $(2\tau,\, a)$ a family of wave-fronts of families $i = p+1, \dots, n$, whose total strength is $\mathcal{O}(1) \cdot (\rho + \delta)$. Because of (2.4), all of these fronts will exit from the boundary $x = b$ within time 3τ. Of course, they can interact with the other fronts present in $u(2\tau, \cdot)$. In any case, the total strength of fronts in $u(3\tau, \cdot)$ is still estimated as

$$\text{Tot.Var.}\big\{u(3\tau)\big\} = \mathcal{O}(1) \cdot \delta^2. \tag{2.13}$$

Moreover, the difference between the values $u(3\tau, x)$ and u^* will be of the same order of the total strength of waves in $u(\tau, \cdot)$ so that the first inequality in (2.9) will also hold. □

Proof of Theorem 1. Using the same arguments as in the proof of Lemma 1, for every $\varepsilon > 0$, we can construct an ε-approximate front tracking solution $u = u(t, x)$ on $[0,\, 2N\tau] \times [a, b]$ such that

$$\sup_{x \in [a,b]} \big|u(2N\tau, x) - u^*\big| = \mathcal{O}(1) \cdot \delta, \qquad \text{Tot.Var.}\big\{u(2N\tau)\big\} = \mathcal{O}(1) \cdot \delta. \tag{2.14}$$

Choosing $\delta > 0$ sufficiently small, we can assume that, in (2.14), $\mathcal{O}(1) \cdot \delta < \delta_0 < 1/C$, the constant in Lemma 2. Calling $T \doteq 2N\tau$, we can now repeat the construction described in Lemma 2 on each interval $\big[T + 3k\tau,\ T + 3(k+1)\tau\big]$. This yields

$$\sup_{x \in [a,b]} \big|u(T + 3k\tau,\, x) - u^*\big| \leq \delta_k, \qquad \text{Tot.Var.}\big\{u(T + 3k\tau)\big\} \leq \delta_k, \tag{2.15}$$

where the constants δ_k satisfy the inductive relations

$$\delta_{k+1} \leq C\delta_k^2. \tag{2.16}$$

Choosing a sequence of ε-approximate front tracking solutions u_ε satisfying (2.15)–(2.16) and taking the limit as $\varepsilon \to 0$, we obtain an entropy weak solution u which still satisfies the same estimates. The bounds (1.7)–(1.8) are now a consequence of (2.15)–(2.16), with a suitable choice of the constants C_0, κ. □

3. Decay of positive waves. Throughout the following, we consider a 2×2 system of conservation laws

$$u_t + f(u)_x = 0, \tag{3.1}$$

satisfying the assumptions (H). Following [6, p. 128], we construct a set of Riemann coordinates (w_1, w_2). One can then choose the right eigenvectors of $Df(u)$ so that

$$r_i(u) = \frac{\partial u}{\partial w_i}, \qquad \frac{\partial \lambda_i}{\partial w_i} = D\lambda_i \cdot r_i > 0, \qquad i = 1, 2. \tag{3.2}$$

It will be convenient to perform most of the analysis on a special class of solutions: piecewise Lipschitz functions with finitely many shocks and no compression waves. Due to the geometric structure of the system, this set of functions turns out to be positively invariant for the flow generated by the hyperbolic system. We first derive several a priori estimates concerning these solutions, in particular on the strength and location of the shocks. We then observe that any BV solution can be obtained as a limit of a sequence of piecewise Lipschitz solutions in our special class. Our estimates can thus be extended to general BV solutions.

DEFINITION 1. *We call $\mathcal{U}$ the set of all piecewise Lipschitz functions $u : \mathbb{R} \mapsto \mathbb{R}^2$ with finitely many jumps such that*

(i) *at every jump, the corresponding Riemann problem is solved only in terms of shocks (no centered rarefactions);*
(ii) *no compression waves are present; i.e., $w_{i,x}(x) \geq 0$ at almost every $x \in \mathbb{R}$, $i = 1, 2$.*

The next lemma establishes the forward invariance of the set $\mathcal{U}$.

LEMMA 3. *Consider the 2×2 system of conservation laws* (3.1) *satisfying the assumptions* (H). *Let $u = u(t, x) >$ be the solution to a Cauchy problem, with small total variation, satisfying $u(0, \cdot) \in \mathcal{U}$. Then*

$$u(t, \cdot) \in \mathcal{U} \qquad \text{for all } \ t \geq 0. \tag{3.3}$$

Proof. We have to show that, as time progresses, the total number of shocks does not increase and no compression wave is ever formed. This will be the case provided that the following hold:

(i) The interaction of two shocks of the same family produces an outgoing shock in the other family.
(ii) The interaction of a shock with an infinitesimal rarefaction wave of the same family produces a rarefaction wave in the other family.

Both of the above conditions can be easily checked by analyzing the relative positions of shocks and rarefaction curves. We will do this for the first family, leaving the verification of the other case to the reader.

Call $\sigma \mapsto R_1(\sigma)$ the rarefaction curve through a state u_0, parametrized so that

$$\lambda_1\big(R_1(\sigma)\big) = \lambda_1(u_0) + \sigma.$$

It is well known that the shock curve through u_0 has a second order tangency with this rarefaction curve. Hence there exists a smooth function $c_1(\sigma)$ such that the point

$$S_1(\sigma) \doteq R_1(\sigma) + c_1(\sigma)\frac{\sigma^3}{6} r_2(u_0)$$

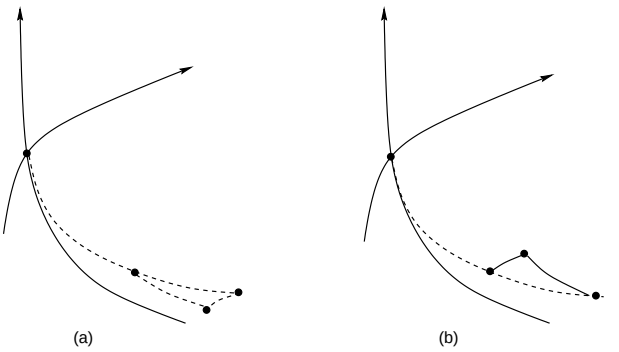

FIG. 4.

lies on this shock curve for all σ in a neighborhood of zero. From the Rankine–Hugoniot equations, it now follows that

$$\chi(\sigma) \doteq \big(f\big(R_1(\sigma)+c_1(\sigma)(\sigma^3/6)\, r_2(u_0)\big)-f(u_0)\big)\wedge\big(R_1(\sigma)+c_1(\sigma)(\sigma^3/6)\, r_2(u_0)-u_0\big) = 0. \tag{3.4}$$

Differentiating the wedge product (3.4) four times at $\sigma = 0$ and denoting derivatives with upper dots, we obtain

$$\begin{aligned}\frac{d^4\chi}{d\sigma^4}(0) &= 4\big[\lambda_1(u_0)\,\dddot{R}_1\,(0) + 2\ddot{R}_1(0) + \lambda_2(u_0)\, c_1(0) r_2(u_0)\big] \wedge \dot{R}_1(0)\\ &\quad + 6\big[\lambda_1(u_0)\ddot{R}_1(0) + \dot{R}_1(0)\big] \wedge \ddot{R}_1(0) + 4\lambda_1(u_0)\dot{R}_1(0) \wedge \big[\,\dddot{R}_1\,(0) + c(0) r_2(u_0)\big]\\ &= 4\big(\lambda_2(u_0) - \lambda_1(u_0)\big)c_1(0)\, r_2(u_0) \wedge r_1(u_0) + 2(Dr_1 \cdot r_1)(u_0) \wedge r_1(u_0)\\ &= 0.\end{aligned}$$

Hence

$$c_1(0) = \frac{(Dr_1 \cdot r_1) \wedge r_1}{2(\lambda_2 - \lambda_1)(r_1 \wedge r_2)} < 0. \tag{3.5}$$

By (3.5), the relative position of 1-shock and 1-rarefaction curves is as depicted in Figure 1. By the geometry of wave curves, the properties (i) and (ii) are now clear. Figure 4a illustrates the interaction of two 1-shocks, while Figure 4b shows the interaction between a 1-shock and a 1-rarefaction. By u_l, u_m, u_r we denote the left, middle, and right states before the interaction, while u'_m is the middle state after the interaction. In the two cases, the solution of the Riemann problem contains a 2-shock and a 2-rarefaction, respectively. □

The next lemma shows the decay of positive waves for solutions with small total variation, taking values inside $\mathcal{U}$.

LEMMA 4. *Let $u = u(t,x)$ be a solution of the Cauchy problem for the 2×2 system* (3.1) *satisfying* (H). *Assume that*

$$u(t,\cdot) \in \mathcal{U}, \qquad t \geq 0. \tag{3.6}$$

Then there exist $\kappa, \delta > 0$ such that, if Tot.Var.$(u(t,\cdot)) < \delta$ *for all t, then its Riemann coordinates (w_1, w_2) satisfy*

$$0 \leq w_{i,x}(t,x) \leq \frac{\kappa}{t}, \qquad t > 0, \quad i = 1,2. \tag{3.7}$$

Proof. We consider the case $i = 1$. Fix any point $(\bar t,\ \bar x)$. Since centered rarefaction waves are not present, there exists a unique 1-characteristic through this point, which we denote as $t \mapsto x_1(t;\ \bar t,\ \bar x)$. It is the solution of the Cauchy problem

$$\dot x(t) = \lambda_1\big(u(t, x(t))\big), \qquad x(\bar t) = \bar x. \tag{3.8}$$

The evolution of $w_{1,x}$ along this characteristic is described by

$$\frac{d}{dt} w_{1,x}\big(t, x_1(t)\big) = w_{1,xt} + \lambda_1 w_{1,xx} = -(\lambda_1 w_{1,x})_x + \lambda_1 w_{1,xx} = -\frac{\partial \lambda_1}{\partial w_1} w_{1,x}^2 - \frac{\partial \lambda_1}{\partial \omega_2} w_{1,x} w_{2,x}.$$

Since the system is genuinely nonlinear, there exists $k_1 > 0$ such that $\partial\lambda_1/\partial w_1 \geq k_1 > 0$, and hence

$$\frac{d}{dt} w_{1,x}\big(t, x_1(t)\big) \leq -k_1 w_{1,x}^2 + \mathcal{O}(1) \cdot w_{1,x} w_{2,x}. \tag{3.9}$$

Moreover, at each time t_α where the characteristic crosses a 2-shock of strength $|\sigma_\alpha|$, we have the estimate

$$w_{1,x}(t_\alpha+) \leq \big(1 + \mathcal{O}(1) \cdot |\sigma_\alpha|\big) w_{1,x}(t_\alpha-). \tag{3.10}$$

Let $Q(t)$ be the total interaction potential at time t (see, for example, [4, p. 202]), and let $V_2(t)$ be the total amount of 2-waves approaching our 1-wave located at $x_1(t)$. Repeating the arguments in [4, p. 139], we can find a constant $C_0 > 0$ such that the quantity

$$\Upsilon(t) \doteq V_1(t) + C_0\, Q(t), \qquad t > 0,$$

is nonincreasing. Moreover, for almost every t, one has

$$\dot\Upsilon(t) \leq -\big|\lambda_2 - \lambda_1\big| |w_{2,x}|\big(t, x_1(t)\big),$$

while, at times t_α, where x_1 crosses a 2-shock of strength $|\sigma_\alpha|$, there holds

$$\Upsilon(t_\alpha-) \leq \Upsilon(t_\alpha+) - |\sigma_\alpha|.$$

Call $W(t) \doteq w_{1,x}\big(t, x_1(t)\big)$. By the previous estimates, from (3.9) and (3.10), it follows that

$$\begin{aligned} \dot W(t) &\leq -k_1 W^2(t) - C\, \dot\Upsilon(t) W(t), \\ W(t_\alpha+) - W(t_\alpha-) &\leq C\big[\Upsilon(t_\alpha+) - \Upsilon(t_\alpha-)\big] W(t_\alpha-) \end{aligned} \tag{3.11}$$

for a suitable constant C. We now observe that

$$y(t) \doteq \frac{e^{-C\Upsilon(t)}}{\int_0^t k_1 e^{-C\Upsilon(s)} ds}$$

is a distributional solution of the equation

$$\dot y = -k_1 y^2 - C\, \dot\Upsilon(t) y,$$

with $y(t) \to \infty$ as $t \to 0+$. A comparison argument now yields $W(t) \leq y(t)$. Since Υ is positive and decreasing, we have

$$W(t) \leq \frac{1}{k_1} \frac{1}{\int_0^t e^{-C\Upsilon(s)} ds} \leq \frac{e^{C\Upsilon(0)}}{k_1 t}$$

for all $t > 0$. This establishes (3.7) for $i = 1$, with $\kappa \doteq e^{C\Upsilon(0)}/k_1$. The case $i = 2$ is identical. □

We conclude this section by proving a decay estimate for positive waves, valid for general BV solutions of the system (3.1). For this purpose, we need to recall some definitions introduced in [5]. See also [4, p. 201].

Let $u : \mathbb{R} \mapsto \mathbb{R}^2$ have bounded variation. By possibly changing the values of u at countably many points, we can assume that u is right continuous. The distributional derivative $\mu \doteq D_x u$ is a vector measure, which can be decomposed into a continuous and an atomic part: $\mu = \mu_c + \mu_a$. For $i = 1, 2$, the scalar measures $\mu^i = \mu^i_c + \mu^i_a$ are defined as follows. The continuous part of μ^i is the Radon measure μ^i_c such that

$$\int \phi \, d\mu^i_c = \int \phi \, l_i(u) \cdot d\mu_c \tag{3.12}$$

for every scalar continuous function ϕ with compact support. The atomic part of μ^i is the measure μ^i_a concentrated on the countable set $\{x_\alpha;\ \alpha = 1, 2, \ldots\}$, where u has a jump, such that

$$\mu^i_a\big(\{x_\alpha\}\big) = \sigma_{\alpha,i} \doteq E_i\big(u(x_\alpha-),\ u(x_\alpha+)\big) \tag{3.13}$$

is the size of the ith wave in the solution of the corresponding Riemann problem with data $u(x_\alpha\pm)$. We regard μ^i as the *measure of i-waves* in the solution u. It can be decomposed in a positive and a negative part so that

$$\mu^i = \mu^{i+} - \mu^{i-}, \qquad |\mu^i| = \mu^{i+} + \mu^{i-}. \tag{3.14}$$

The decay estimate in (3.7) can now be extended to general BV solutions. Indeed, we show that the density of positive i-waves decays as κ/t. By meas(J) we denote here the Lebesgue measure of a set J.

LEMMA 5. *Let $u = u(t, x)$ be a solution of the Cauchy problem for the 2×2 system* (3.1) *satisfying* (H). *Then there exist $\kappa, \delta > 0$ such that, if* Tot.Var.$(u(t, \cdot)) < \delta$ *for all t, then the measures μ^{1+}_t, μ^{2+}_t of positive waves in $u(t, \cdot)$ satisfy*

$$\mu^{i+}_t(J) \le \frac{\kappa}{t}\text{meas}(J) \tag{3.15}$$

for every Borel set $J \subset \mathbb{R}$ and every $t > 0$, $i = 1, 2$.

Proof. For every BV solution u of (3.1), we can construct a sequence of solutions u_ν with $u_\nu \to u$ as $\nu \to \infty$ and such that $u_\nu(t, \cdot) \in \mathcal{U}$ for all t. Calling (w^ν_1, w^ν_2) the Riemann coordinates of u_ν, by Lemma 4 we have

$$0 \le w^\nu_{i,x}(t, x) \le \frac{\kappa}{t}, \qquad t > 0, \quad i = 1, 2, \quad \nu \ge 1. \tag{3.16}$$

For a fixed $t > 0$, observe that the map $x \mapsto w^\nu_1(t, x)$ has upward jumps precisely at the points x_α where $u(t, \cdot)$ has a 2-shock. Define $\tilde\mu_\nu$ as the positive, purely atomic measure, concentrated on the finitely many points x_α where $u(t, \cdot)$ has a 2-shock, such that

$$\tilde\mu_\nu\big(\{x_\alpha\}\big) = w^\nu_1(t,\, x_\alpha+) - w^\nu_1(t,\, x_\alpha-) \le C\,|\sigma_\alpha|^3 \tag{3.17}$$

for some constant C. By possibly taking a subsequence, we can assume the existence of a weak limit $\tilde\mu_\nu \rightharpoonup \tilde\mu$. Because of the estimate in (3.17), the measure $\tilde\mu$ is purely

atomic and is concentrated on the set of points x_β, which are limits as $\nu \to \infty$ of a sequence of points x^ν_α, where $u_\nu(t,\cdot)$ has a 2-shock of uniformly positive strength $|\sigma_\nu| \geq \delta > 0$. Therefore, $\tilde\mu$ is concentrated on the set of points where the limit solution $u(t,\cdot)$ has a 2-shock and makes no contribution to the positive part of μ_t^{1+}. We thus conclude that the positive part of μ_t^{1+} is absolutely continuous with respect to Lebesgue measure, with density $\leq \kappa/t$. An analogous argument holds for μ_t^{2+}. □

COROLLARY 1. *Let $u = u(t,x)$ be a solution of the 2×2 system (1.1). Let the assumptions* (H) *hold. Fix $\varepsilon > 0$, and consider the subinterval $[a',b'] \doteq [a+\varepsilon,\ b-\varepsilon]$. Assume that, at time $t = 0$, the measures μ^{1+}, μ^{2+} of positive waves in $u(0,\cdot)$ on $[a,b]$ vanish identically. Then, for every $t > 0$, one has*

$$\mu_t^{i+}(J) \leq \frac{\kappa\lambda^*}{\varepsilon}\mathrm{meas}(J) \tag{3.18}$$

for every Borel set $J \subset [a',b']$ and every $t > 0$, $i = 1,2$.

Indeed, recalling (1.9), the values of $u(t,\cdot)$ restricted to the interval $[a',b']$ can be obtained by solving a Cauchy problem, with initial data assigned on the whole interval $[a,b]$ at time $t - \varepsilon/\lambda^*$.

4. Proof of Theorem 2.

LEMMA 6. *In the same setting as Lemma 4, assume that there exists $\kappa' > 0$ such that*

$$0 \leq w_{i,x}(t,x) \leq \kappa', \qquad t \in [0,T], \quad i = 1,2. \tag{4.1}$$

Let $t \mapsto x(t)$ be the location of a shock, with strength $\big|\sigma(t)\big|$. There exists a constant $0 < c < 1$ such that

$$\big|\sigma(t)\big| \geq c\big|\sigma(s)\big|, \qquad 0 \leq s < t \leq T. \tag{4.2}$$

Proof. To fix the ideas, let $u(t,\cdot)$ have a 1-shock located at $x(t)$, with strength $\big|\sigma(t)\big|$. Outside points of interaction with other shocks, the strength satisfies an inequality of the form

$$\frac{d}{dt}\big|\sigma(t)\big| \geq -C\cdot\big(w_{1,x}\big(t,x(t)+\big)+w_{1,x}\big(t,x(t)-\big)w_{2,x}\big(t,x(t)+\big)+w_{2,x}\big(t,x(t)-\big)\big)\big|\sigma(t)\big|. \tag{4.3}$$

At times where our 1-shock interacts with other 1-shocks, its strength increases. Moreover, at each time t_α where our 1-shock interacts with a 2-shock, say, of strength $|\sigma_\alpha|$, one has

$$\big|\sigma(t_\alpha+)\big| \geq \big|\sigma(t_\alpha-)\big|\,\big(1 - C'|\sigma_\alpha|\big) \tag{4.4}$$

for some constant C'. Assuming that the total variation remains small, the total number of 2-shocks which cross any given 1-shock is uniformly small. Hence (4.3)–(4.4) together imply (4.2). □

LEMMA 7. *Let $t \mapsto u(t,\cdot) \in \mathcal{U}$ be a solution of the Cauchy problem for a genuinely nonlinear 2×2 system satisfying (1.11). Assume that there exists $\kappa' > 0$ such that*

$$w_{i,x}(t,x) \leq \kappa', \qquad t \in [0,T], \quad i = 1,2. \tag{4.5}$$

Since no centered rarefactions are present, any two i-characteristics, say, $x(t) < y(t)$, can uniquely be traced backward up to time $t = 0$. There exists a constant $L > 0$ such that

$$y(t) - x(t) \leq L\big(y(s) - x(s)\big), \qquad 0 \leq s < t \leq T. \tag{4.6}$$

Proof. Consider the case when $i = 2$. By definition, the characteristics are solutions of

$$\dot{x}(t) = \lambda_2\big(u(t, x(t))\big), \qquad \dot{y}(t) = \lambda_2\big(u(t, y(t))\big).$$

Since the characteristic speed λ_2 decreases across 2-shocks, we can write

$$\dot{y}(t) - \dot{x}(t) \leq C \int_{x(t)}^{y(t)} \big|w_{1,x}(t,\xi)\big| + \big|w_{2,x}(t,\xi)\big|\, d\xi + C \sum_{\alpha \in \mathcal{S}_1[x,y]} \big|\sigma_\alpha(t)\big|, \tag{4.7}$$

where $\mathcal{S}_1[x, y]$ denotes the set of all 1-shocks located inside the interval $\big[x(t),\ y(t)\big]$. Introduce the function

$$\phi(t,x) \doteq \begin{cases} 0 & \text{if} \quad x \leq x(t), \\ \frac{x - x(t)}{y(t) - x(t)} & \text{if} \quad x(t) < x < y(t), \\ 1 & \text{if} \quad x \geq y(t). \end{cases}$$

Moreover, define the functional

$$\Phi(t) \doteq \sum_{\alpha \in \mathcal{S}_1} \phi\big(t, x_\alpha(t)\big)\, \big|\sigma_\alpha(t)\big| + C_0\, Q(t),$$

where the summation now refers to all 1-shocks in $u(t, \cdot)$ and Q is the usual interaction potential. Observe that the map $t \mapsto \Phi(t)$ is nonincreasing. By (4.5) and (4.7), we can now write

$$\dot{y}(t) - \dot{x}(t) \leq C'\big(1 - \dot{\Phi}(t)\big)\big(y(t) - x(t)\big)$$

for some constant C'. This implies (4.6) with $L = \exp\big\{C'T + C'\Phi(0)\big\}$. ∎

The next result is the key ingredient toward the proof of Theorem 2. It provides the density of the set of interaction points where new shocks are generated.

LEMMA 8. *Fix $\varepsilon > 0$, and define $a'' = a + 2\varepsilon$, $b'' = b - 2\varepsilon$. Consider a 2×2 system of the form* (1.1)*, satisfying* (H)*. Let u be an entropy weak solution defined on $[0, \tau] \times [a, b]$, with $\tau \doteq \varepsilon/4\lambda^*$. Let* (3.18) *hold for all $t \in [0, \tau]$, and assume that $u(0, \cdot)$ has a dense set of 1-shocks on the interval $[a'',\ b'']$. Then, for $0 \leq t \leq \tau$, the solution $u(t, \cdot)$ has a set of 1-shocks which is dense on $[a'',\ b' - \lambda^* t]$ and a set of 2-shocks which is dense on $[a'',\ b'']$.*

Proof. By the assumptions of the lemma, there exists a sequence of piecewise Lipschitz solutions $t \mapsto u_\nu(t) \in \mathcal{U}$ such that $u_\nu \to u$ in $\mathbf{L}^1$,

$$0 \leq w^\nu_{i,x}(t,x) \leq \frac{2\kappa\lambda^*}{\varepsilon}, \qquad i = 1, 2, \quad \nu \geq 1,$$

and, moreover, the following holds. For every $\rho > 0$, there exists $\delta > 0$ such that each $u_\nu(0, \cdot)$ (with ν large enough) contains at least one 1-shock of strength $\big|\sigma_\nu(0)\big| \geq \delta$ on every subinterval $J \subset [a'',\ b'']$ having length $\geq \rho$.

To prove the first statement in Lemma 8, fix $t \in [0, \tau]$, and consider any nontrivial interval $[p, q] \subseteq [a'',\ b'' - t\lambda^*]$. Call $s \mapsto p_\nu(s)$, $s \mapsto q_\nu(s)$ the backward characteristics through these points, relative to the solution u_ν. We thus have

$$\begin{cases} \dot{p}_\nu(s) = \lambda_1\big(u_\nu(s,\, p_\nu(s))\big), \\ \dot{q}_\nu(s) = \lambda_1\big(u_\nu(s,\, q_\nu(s))\big), \end{cases} \qquad \begin{cases} p_\nu(t) = p, \\ q_\nu(t) = q. \end{cases}$$

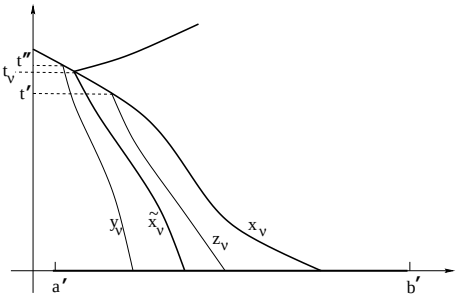

FIG. 5.

By Lemma 7, $q_\nu(0) - p_\nu(0) \geq \rho$ for some $\rho > 0$ independent of ν. Hence, each solution u_ν contains a shock of strength $\big|\sigma_\nu(s)\big| \geq \delta$ located inside the interval $\big[p_\nu(0),\ q_\nu(0)\big]$. Lemma 5 now yields $\big|\sigma_\nu(t)\big| \geq c\delta$. By possibly taking a subsequence, we conclude that the limit solution $u(t,\cdot)$ contains a 1-shock of positive strength at the point $x(t) = \lim x_\nu(t) \in [p,q]$.

To prove the second statement, we will show that the set of points where two 1-shocks in u interact and produce a new 2-shock is dense on the triangle

$$\Delta \doteq \big\{(t,x)\,;\quad t \in [0,\tau],\quad a'' < x < b'' - \lambda^* t\big\}.$$

Indeed, let $t \in [0,\tau]$ and $p < q$ be as before. For each ν sufficiently large, let $t \mapsto x_\nu(t)$ be the location of a 1-shock in u_ν, with strength $\big|\sigma_\nu(t)\big| \geq \delta > 0$. Assume $x_\nu(\cdot) \to x(\cdot)$ as $\nu \to \infty$, and $x_\nu(t) \in [p,q]$, so that $x(t)$ is the location of a 1-shock of the limit solution u, say, with strength $\big|\sigma(t)\big| > 0$.

We claim that the set of times $\hat{t}$ where some other 1-shock σ' impinges on σ and generates a new 2-shock is dense on $[0,t]$. To see this, fix $0 < t' < t'' < t$. For each ν sufficiently large, consider the backward 1-characteristics $y_\nu,\ z_\nu$ impinging from the left on the shock x_ν at times t'', t', respectively (see Figure 5). These provide solutions to the Cauchy problems

$$\begin{aligned} \dot{y}_\nu(t) &= \lambda_1\big(u_\nu\big(t, y_\nu(t)\big)\big), \qquad & y_\nu(t'') &= x_\nu(t''), \\ \dot{z}_\nu(t) &= \lambda_1\big(u_\nu(t, z_\nu(t))\big), \qquad & z_\nu(t') &= x_\nu(t'), \end{aligned}$$

respectively. Observe that

$$z_\nu(0) - y_\nu(0) \geq \rho$$

for some $\rho > 0$ independent of ν. Indeed, the genuine nonlinearity of the system implies

$$\lambda_1\big(u_\nu(t, x_\nu(t)-)\big) - \dot{x}_\nu(t) \geq \kappa\Big|u_\nu\big(t,\ x_\nu(t)+\big) - u_\nu\big(t,\ x_\nu(t)-\big)\Big| \geq \kappa\delta.$$

Therefore,

$$x_\nu(t') - y_\nu(t') \geq \rho' > 0$$

for some constant $\rho' > 0$ independent of ν. By Lemma 6, the interval $\big[y_\nu(0),\ z_\nu(0)\big]$ has uniformly positive length. Hence it contains a 1-shock of $u_\nu(0,\cdot)$ with uniformly

positive strength $\big|\sigma_\nu(0)\big| \geq \delta > 0$. By Lemma 5, every u_ν has a 1-shock with strength $\big|\sigma_\nu(t)\big| \geq c\delta$ located along some curve $t \mapsto \tilde{x}_\nu(t)$ with

$$y_\nu(t) < \tilde{x}_\nu(t) < z_\nu(t), \qquad t \in [0, t'].$$

Clearly, this second 1-shock impinges on the shock x_ν at some time $t_\nu \in [t', t'']$, creating a new 2-shock with uniformly large strength. Letting $\nu \to \infty$, we obtain the result. □

Proof of Theorem 2. Let $\delta_0 > 0$ be given. We can then construct an initial condition $u(0, \cdot) = \phi$, with Tot.Var.$\{\phi\} < \delta_0$, having a dense set of 1-shocks on the interval $[a, b]$ and no other waves. As a consequence, for any $\varepsilon > 0$, by Corollary 1, we have the estimate (3.18) on the density of positive waves away from the boundary.

Fix $\tau = \varepsilon/4\lambda^*$, and consider again the subinterval $[a'',\ b''] = [a + 2\varepsilon,\ b - 2\varepsilon]$. We can apply Lemma 8 first on the time interval $[0, \tau]$, obtaining the density of 2-shocks on the region $[0, \tau] \times [a'',\ b'']$. Then, by induction on m, the same argument is repeated on each time interval $t \in \big[m\tau,\ (m+1)\tau\big]$, proving the theorem. □

NECESSARY SUBOPTIMALITY AND OPTIMALITY CONDITIONS VIA VARIATIONAL PRINCIPLES*

BORIS S. MORDUKHOVICH† AND BINGWU WANG†

Abstract. The paper aims to develop some basic principles and tools of nonconvex variational analysis with applications to necessary suboptimality and optimality conditions for constrained optimization problems in infinite dimensions. We establish a certain subdifferential variational principle as a new characterization of Asplund spaces. This result is different from conventional support forms of variational principles and appears to be convenient for applications to nonsmooth optimization. Based on the subdifferential variational principle, we obtain new necessary conditions for suboptimal solutions in general nonsmooth optimization problems with equality, inequality, and set constraints in Asplund spaces. In this way we establish the so-called sequential normal compactness properties of constraint sets that play an essential role in infinite-dimensional variational analysis and its applications. As a by-product of our approach, we derive various forms of necessary optimality conditions for nonsmooth constrained problems in infinite dimensions, which extend known results in that direction.

Key words. variational analysis, variational principles, nonsmooth optimization, Banach and Asplund spaces, generalized differentiation, suboptimality, necessary optimality conditions

1. Introduction.

This paper is devoted to variational analysis in infinite dimensions and its applications to optimization problems. The main topic is related to *variational principles* that play a crucial role in nonlinear analysis and its various applications in infinite-dimensional spaces; cf. Ekeland [7], Borwein and Preiss [2], and Deville, Godefroy, and Zizler [6].

In this paper we consider the framework of *Asplund spaces* that were originally defined as Banach spaces on which every convex continuous function is generically Fréchet differentiable. This class is sufficiently broad and convenient for the theory and applications. It includes all Banach spaces with Fréchet smooth renorms or bump functions—in particular, every reflexive space. On the other hand, there are Asplund spaces that fail to have even a Gâteaux smooth renorm. The class of Asplund spaces admits many nice geometric characterizations; see, e.g., [6] and [24].

The first result of this paper gives a new *variational characterization* of Asplund spaces that we call the *subdifferential variational principle*. The major difference between this result and variational principles in the conventional support form is that, instead of a supporting/minimization condition for the given lower semicontinuous function $f\colon X \to (-\infty, \infty]$, the subdifferential variational principle provides a dual-space condition involving the Fréchet subdifferential of f. If the space in question admits a Fréchet smooth renorm (bump function), the subdifferential variational principle implies a *smooth* variational principle in the conventional support form of Borwein–Preiss (resp., Deville–Godefroy–Zizler). Fabian and Mordukhovich [9] recently proved that the mentioned smooth renorm/bump function assumption on X

is not only sufficient but also *necessary* for the validity of the corresponding smooth variational principle. In contrast, the subdifferential variational principle turns out to be a *characterization* of Asplund spaces and may be treated as an appropriate variational principle for this general class of Banach spaces. In fact, we show that the subdifferential variational principle is equivalent to the *extremal principle* established in Mordukhovich and Shao [19] as another characterization of Asplund spaces. The latter result can be viewed as a variational analogue of the convex separation principle in the case of nonconvex sets.

Next we give applications of the subdifferential variational principle to *suboptimality* conditions for problems of mathematical programming in infinite dimensions. This means that we do *not* assume the *existence* of optimal solutions and obtain conditions held for suboptimal (ε-optimal) solutions, which always exist. The latter is particularly important for infinite-dimensional problems of optimization and optimal control, where the existence of optimal solutions requires quite restrictive assumptions. As pointed out by Young [30], any theory of necessary optimality conditions is "naive" until the existence of optimal solutions is clarified. This was the primary motivation for developing theories of generalized curves/relaxed controls in problems of the calculus of variations and optimal control to automatically ensure the existence of optimal solutions. For the general optimization theory in infinite dimensions, an alternative route to avoiding trouble with the existence of optimal solutions is to find "suboptimal solutions," which are "almost" optimal and which "almost" satisfy necessary conditions for optimality.

Necessary conditions for suboptimal solutions were first obtained by Ekeland [7] for classical problems of nonlinear programming with smooth equality and inequality constraints and unconstrained optimal control. More recent developments for nondifferentiable programming are given by Loridan [16], Bustos [5], and Hamel [11] that are based mostly on Ekeland's variational principle and the usage of Clarke's generalized gradients for locally Lipschitzian functions. Suboptimality conditions for various problems of optimal control can be found in Gabasov, Kirillova, and Mordukhovich [12], Mordukhovich [17], Moussaoui and Seeger [22], Sumin [27], and their references.

In this paper we establish, based on the subdifferential variational principle, necessary conditions for suboptimal solutions in a sufficiently broad class of optimization problems, with equality and inequality constraints given by locally Lipschitzian functions, as well as geometric constraints given by closed sets. The main results are expressed in terms of our basic (limiting) normal cone and subdifferential, which may be much smaller than Clarke's counterparts even in finite dimensions and enjoy *full calculus* under general qualification conditions and the so-called *sequential normal compactness* assumptions. The latter assumptions, which are automatic in finite dimensions, are crucial to perform limiting procedures and prove the required calculus rules. As an essential part of our approach, we obtain new subdifferential conditions ensuring the sequential normal compactness of constraint sets given by Lipschitzian equalities and inequalities. We also establish a weak form of suboptimality conditions for problems with non-Lipschitzian data that do not require constraint qualifications. As a by-product of our approach, we prove necessary *optimality* conditions for the mentioned problems in strong and weak forms. In particular, the weak form of these results extends to the case of Asplund spaces the necessary optimality conditions for problems with non-Lipschitzian data recently obtained by Borwein, Treiman, and Zhu [4] in reflexive spaces.

The rest of the paper is organized as follows. Section 2 contains preliminary

results and notation used in the paper. Section 3 is devoted to the subdifferential variational principle and its relation to other basic principles of variational analysis. In section 4 we present and discuss necessary suboptimality and optimality conditions for a general constrained problem of nondifferentiable programming in Asplund spaces. Proofs of these conditions are given in section 5, where we also establish sequential normal compactness of the constraint sets, which is crucial for the proof of the main results and is certainly of independent interest.

2. Preliminaries. Our notation is basically standard and can be found in [20] with most of the definitions and results presented in this section. Finite-dimensional versions of these constructions and results are given in [17] and [26], while [29] contains recent applications to optimal control.

For any Banach space X we denote its norm by $\|\cdot\|$ and the dual space by X^* with the canonical pairing $\langle\cdot,\cdot\rangle$; $\mathbb{B}$ and $\mathbb{B}^*$ stand for the closed unit balls in the space and dual space in question. We use $\mathbb{R}^+$ to denote the interval $[0,\infty)$, $\overline{\mathbb{R}}$ the interval $(-\infty,\infty]$, and $\mathbb{R}^+\Omega := \{\alpha x |\, \alpha \ge 0,\ x \in \Omega\}$ for a given subset Ω of X.

Let $\bar{x} \in \Omega$ and $\varepsilon \ge 0$. Then

$$\widehat{N}_\varepsilon(\bar{x};\Omega) := \left\{ x^* \in X^* \,\middle|\, \limsup_{x \xrightarrow{\Omega} \bar{x}} \frac{\langle x^*, x-\bar{x}\rangle}{\|x-\bar{x}\|} \le \varepsilon \right\} \tag{2.1}$$

is the set of *ε-normals* to Ω at $\bar{x}$, where $x \xrightarrow{\Omega} \bar{x}$ means that $x \to \bar{x}$ with $x \in \Omega$. In particular, $\widehat{N}_0(\bar{x};\Omega)$ is a cone that is called the *prenormal cone* or the *Fréchet normal cone* to Ω at $\bar{x}$ and is denoted by $\widehat{N}(\bar{x};\Omega)$ for simplicity. When Ω is convex, $\widehat{N}(\bar{x};\Omega)$ reduces to the normal cone of convex analysis.

Given a multifunction $F\colon X \rightrightarrows X^*$, the expression

$$\begin{aligned}\operatorname*{Lim\,sup}_{x\to\bar{x}} F(x) := \{x^* \in X^* |\, &\exists \text{ sequences } x_k \to \bar{x} \text{ and } x_k^* \xrightarrow{w^*} x^* \\ &\text{with } x_k^* \in F(x_k) \text{ for all } k \in \mathbb{N}\}\end{aligned}$$

signifies the *sequential* Painlevé–Kuratowski upper (outer) limit with respect to the norm topology in X and the weak* topology w^* in X^*.

Now we define the (basic, limiting) *normal cone* to Ω at $\bar{x} \in \Omega$ by

$$N(\bar{x};\Omega) := \operatorname*{Lim\,sup}_{x \xrightarrow{\Omega} \bar{x}, \varepsilon \downarrow 0} \widehat{N}_\varepsilon(x;\Omega). \tag{2.2}$$

If X is Asplund, this is equivalent to

$$N(\bar{x};\Omega) = \operatorname*{Lim\,sup}_{x \xrightarrow{\Omega} \bar{x}} \widehat{N}(x;\Omega). \tag{2.3}$$

For an extended-real-valued lower semicontinuous (l.s.c.) function $f\colon X \to \overline{\mathbb{R}}$, the *Fréchet subdifferential* $\widehat{\partial} f(\bar{x})$ at $\bar{x} \in \operatorname{dom} f$ is given by

$$\widehat{\partial} f(\bar{x}) := \left\{ x^* \in X^* \,\middle|\, \liminf_{x\to\bar{x}} \frac{f(x) - f(\bar{x}) - \langle x^*, x-\bar{x}\rangle}{\|x-\bar{x}\|} \ge 0 \right\}$$

or, equivalently, by

$$\widehat{\partial} f(\bar{x}) = \left\{ x^* \in X^* \,\middle|\, (x^*,-1) \in \widehat{N}((\bar{x}, f(\bar{x})); \operatorname{epi} f) \right\}, \tag{2.4}$$

where $\operatorname{epi} f$ denotes the epigraph of f. For any $\bar{x} \in \operatorname{dom} f$, the sets

$$\partial f(\bar{x}) := \{x^* \in X^* \,|\, (x^*, -1) \in N((\bar{x}, f(\bar{x})); \operatorname{epi} f)\}, \tag{2.5}$$

$$\partial^\infty f(\bar{x}) := \{x^* \in X^* \,|\, (x^*, 0) \in N((\bar{x}, f(\bar{x})); \operatorname{epi} f)\} \tag{2.6}$$

are called, respectively, the *basic subdifferential* and the *singular subdifferential* of f at $\bar{x}$. We have $\partial^\infty f(\bar{x}) = \{0\}$ when f is Lipschitz continuous around $\bar{x}$. If X is Asplund, the following relations hold for any l.s.c. function f:

$$\partial f(\bar{x}) = \operatorname*{Lim\,sup}_{x \xrightarrow{f} \bar{x}} \widehat{\partial} f(x) \quad \text{and} \quad \partial^\infty f(\bar{x}) = \operatorname*{Lim\,sup}_{x \xrightarrow{f} \bar{x}, \lambda \downarrow 0} \lambda \widehat{\partial} f(x), \tag{2.7}$$

where $x \xrightarrow{f} \bar{x}$ means that $x \to \bar{x}$ with $f(x) \to f(\bar{x})$. Note that, due to (2.4)–(2.6), one has

$$\widehat{N}(\bar{x}; \Omega) = \widehat{\partial} \delta(\bar{x}; \Omega) \quad \text{and} \quad N(\bar{x}; \Omega) = \partial \delta(\bar{x}; \Omega) = \partial^\infty \delta(\bar{x}; \Omega)$$

for any $\Omega \subset X$ and $\bar{x} \in \Omega$, where $\delta(x; \Omega)$ is the indicator function of Ω.

Recall [21] that Ω is *sequentially normally compact* at $\bar{x} \in \Omega$ if for any sequences $x_k \xrightarrow{\Omega} \bar{x}$ and $x_k^* \in \widehat{N}(x_k; \Omega)$ with $x_k^* \xrightarrow{w^*} 0$ one has $\|x_k^*\| \to 0$. It always holds when Ω is compactly epi-Lipschitzian at $\bar{x}$ in the sense of [3] (see also [15] for a dual counterpart of the latter property), in particular, if either $X = \mathbb{R}^n$ or Ω is epi-Lipschitzian at $\bar{x}$ in the sense of [25]. A function $f \colon X \to \overline{\mathbb{R}}$ is *sequentially normally epi-compact* at $\bar{x} \in \operatorname{dom} f$ if $\operatorname{epi} f$ is sequentially normally compact at $(\bar{x}, f(\bar{x}))$. Note that f is sequentially normally epi-compact at $\bar{x}$ if it is Lipschitz continuous around this point.

The following basic calculus result for subdifferentials and its corollary for normal cones were proved in [20] by using the extremal principle; see below.

PROPOSITION 2.1. *Let X be an Asplund space and let $f_i \colon X \to \overline{\mathbb{R}}$, $i = 1, \dots, n$, be l.s.c. functions. Assume that all but one of these functions are sequentially normally epi-compact at a common point $\bar{x}$ of their domains. Suppose that the following qualification condition holds:*

$$\left[x_i^* \in \partial^\infty f_i(\bar{x}) \ (1 \le i \le n) \text{ and } \sum_{i=1}^n x_i^* = 0 \right] \Longrightarrow x_1^* = \dots = x_n^* = 0.$$

Then one has the subdifferential sum rule

$$\partial(f_1 + \dots + f_n)(\bar{x}) \subset \partial f_1(\bar{x}) + \dots + \partial f_n(\bar{x}).$$

In particular, if Ω_1 and Ω_2 are closed subsets of X such that one of them is sequentially normally compact at $\bar{x} \in \Omega_1 \cap \Omega_2$ and $N(\bar{x}; \Omega_1) \cap (-N(\bar{x}; \Omega_2)) = \{0\}$, then $N(\bar{x}; \Omega_1 \cap \Omega_2) \subset N(\bar{x}; \Omega_1) + N(\bar{x}; \Omega_2)$.

The next result follows from Proposition 2.1 and provides useful subdifferential representations of the basic normal cone to functional constraint sets given by equalities and inequalities.

PROPOSITION 2.2. *The following assertions hold in any Asplund space X.*

(a) *Let $\Omega := \{x \in X | \, f(x) \le 0\}$, where $f \colon X \to \overline{\mathbb{R}}$ is l.s.c. around $\bar{x} \in \Omega$. Suppose that there is no $\alpha \ne 0$ with $(0, \alpha) \in N((\bar{x}, 0); \operatorname{epi} f)$. Then*

$$N(\bar{x}; \Omega) \subset \{x^* \in X^* | \, (x^*, -\alpha) \in N((\bar{x}, 0); \operatorname{epi} f) \text{ for some } \alpha \ge 0\}, \tag{2.8}$$

which is equivalent to $N(\bar{x};\Omega) \subset \partial^\infty f(\bar{x}) \cup \mathbb{R}^+\partial f(\bar{x})$ *if* $f(\bar{x}) = 0$. *If, in addition,* f *is locally Lipschitzian around* $\bar{x}$ *with* $f(\bar{x}) = 0$, *then*

$$N(\bar{x};\Omega) \subset \bigcup_{\alpha\geq 0} \alpha\partial f(\bar{x}).$$

(b) *Let* $\Omega := \{x \in X |\, f(x) = 0\}$, *where* $f\colon X \to \mathbb{R}$ *is continuous around* $\bar{x} \in \Omega$. *Then*

$$N(\bar{x};\Omega) \subset \partial^\infty f(\bar{x}) \cup \partial^\infty(-f)(\bar{x}) \cup \mathbb{R}^+\partial f(\bar{x}) \cup \mathbb{R}^+\partial(-f)(\bar{x}) \tag{2.9}$$

if $0 \notin \partial f(\bar{x}) \cup \partial(-f)(\bar{x})$. *In particular, if* f *is locally Lipschitzian around* $\bar{x}$, *then*

$$N(\bar{x};\Omega) \subset \bigcup_{\alpha\geq 0} \alpha\Big(\partial f(\bar{x}) \cup \partial(-f)(\bar{x})\Big).$$

The main tool of our analysis in this paper is the *extremal principle*, which provides necessary conditions for set extremality in terms of a generalized Euler equation and can be treated as a local variational extension of the classical convex separation to systems of nonconvex sets. We refer the reader to [19] and the recent survey [18] for more information about the extremal principle and its various applications. The version of the extremal principle that we need in what follows is formulated in Theorem 3.1 of the next section, where it is used to derive the subdifferential variational principle. Now we recall that, given two subsets Ω_1 and Ω_2 of a Banach space X, a point $\bar{x} \in \Omega_1 \cap \Omega_2$ is *locally extremal* for the system $\{\Omega_1, \Omega_2\}$, named in this case an "extremal system," if there are sequences $a_{1k} \to 0$ and $a_{2k} \to 0$ in X and a neighborhood U of $\bar{x}$ such that

$$(\Omega_1 - a_{1k}) \cap (\Omega_2 - a_{2k}) \cap U = \emptyset \qquad \text{for all } k \in \mathbb{N}.$$

Various examples of extremal systems in variational analysis, optimization, and related topics can be found in [18] and in the rest of this paper.

3. Variational principles. In this section we establish the subdifferential variational principle as a characterization of Asplund spaces. In the next theorem we derive the subdifferential variational principle from a version of the extremal principle formulated below, and then we discuss its relationships with smooth variational principles in conventional support forms.

THEOREM 3.1. *Let* X *be a Banach space. Then the following assertions are equivalent:*

(a) (Extremal principle) *For every locally extremal point* $\bar{x}$ *of a closed set system* $\{\Omega_1, \Omega_2\}$ *in* X *and any* $\varepsilon > 0$ *there exist* $x_i \in \Omega_i \cap (\bar{x} + \varepsilon\mathbb{B})$ *and* $x_i^* \in \widehat{N}(x_i;\Omega_i) + \varepsilon\mathbb{B}^*$ $(i = 1, 2)$ *such that*

$$\|x_1^*\| + \|x_2^*\| = 1, \qquad x_1^* + x_2^* = 0.$$

(b) (Subdifferential variational principle) *For any l.s.c. function* $f\colon X \to \overline{\mathbb{R}}$ *bounded from below and every* $\varepsilon > 0$, $\lambda > 0$, *and* $\bar{x} \in \operatorname{dom} f$ *with* $f(\bar{x}) < \inf_X f + \varepsilon$ *there exist* $\widehat{x} \in X$ *and* $\widehat{x}^* \in \widehat{\partial} f(\widehat{x})$ *such that*

(i) $\|\widehat{x} - \bar{x}\| < \lambda$,

(ii) $f(\widehat{x}) < \inf_X f + \varepsilon$,

(iii) $\|\widehat{x}^*\| < \varepsilon/\lambda$.

(c) *X is an Asplund space.*

Proof. Implication (c)⇒(a) was first proved in [19]; another proof is given in [10]. Let us justify the remaining parts of the theorem. We begin with (b)⇒(c), and then derive (a)⇒(b), which is the main part.

(b)⇒(c). It is well known and easy to prove that a function $f\colon X \to \mathbb{R}$ is Fréchet differentiable at x if and only if the sets $\widehat{\partial} f(x)$ and $\widehat{\partial}(-f)(x)$ are nonempty simultaneously. Take an arbitrary convex continuous function $f\colon X \to \mathbb{R}$. Then $\widehat{\partial} f(x)$ agrees with the subdifferential of convex analysis and is nonempty at every $x \in X$. To establish the Asplund property of X, it is sufficient to show, due to [24, Proposition 1.25], that there is a dense subset $S \subset X$ such that $\widehat{\partial}(-f)(x) \neq \emptyset$ for every $x \in S$.

Denote $g(x) := -f(x)$ and fix $\bar{x} \in X$ and $\varepsilon > 0$. Since g is continuous, there exists a positive number $\widetilde{\varepsilon} < \varepsilon$ such that $g(x) > g(\bar{x}) - \varepsilon$ whenever $\|x - \bar{x}\| \le \widetilde{\varepsilon}$. Thus we have $h(\bar{x}) < \inf_X h(x) + 2\varepsilon$ for all $x \in X$, where $h(x) := g(x) + \delta(x; \bar{x} + \widetilde{\varepsilon}\mathbb{B})$ is obviously l.s.c. on X. Applying the subdifferential variational principle to the latter function, we find a point $\widehat{x} \in X$ with $\|\widehat{x} - \bar{x}\| < \widetilde{\varepsilon}$ such that $\widehat{\partial} h(\widehat{x}) \neq \emptyset$. This clearly implies that $\widehat{\partial} g(\widehat{x}) \neq \emptyset$, i.e., the set of points $x \in X$ with $\widehat{\partial}(-f)(x) \neq \emptyset$ is dense in X. Hence X must be Asplund.

(a)⇒(b). First we choose $\varepsilon_1 > 0$ such that $f(\bar{x}) < \inf_X f + \varepsilon - \varepsilon_1$ and let $\lambda_1 := (2\varepsilon)^{-1}(2\varepsilon - \varepsilon_1)\lambda$. Applying Ekeland's variational principle, we find $\widetilde{x} \in X$ satisfying $\|\widetilde{x} - \bar{x}\| < \lambda_1$, $f(\widetilde{x}) \le \inf_X f + \varepsilon - \varepsilon_1$, and

$$f(\widetilde{x}) < f(x) + \lambda_1^{-1}(\varepsilon - \varepsilon_1)\|x - \widetilde{x}\| \qquad \text{for all } \ x \in X \backslash \{\widetilde{x}\}. \tag{3.1}$$

Define two closed subsets of $X \times \mathbb{R}$ by

$$\Omega_1 := \operatorname{epi} f, \qquad \Omega_2 := \big\{(x, \mu) \in X \times \mathbb{R} \big| \, \mu \le f(\widetilde{x}) - \lambda_1^{-1}(\varepsilon - \varepsilon_1)\|x - \widetilde{x}\|\big\}.$$

It is easy to conclude from (3.1) that $(\widetilde{x}, f(\widetilde{x}))$ is a locally extremal point of the set system $\{\Omega_1, \Omega_2\}$; thus we can use the extremal principle.

Consider the norm $\|(x, \mu)\| := \|x\| + |\mu|$ on $X \times \mathbb{R}$ and observe that the corresponding dual norm on $X^* \times \mathbb{R}$ is given by $\|(x^*, \mu^*)\| = \max\{\|x^*\|, |\mu^*|\}$. Applying the extremal principle to the above system, for any $\varepsilon_2 > 0$ we find $(x_i, \mu_i) \in \Omega_i$ and $(x_i^*, \mu_i^*) \in \widehat{N}((x_i, \mu_i); \Omega_i)$, $i = 1, 2$, satisfying

$$\|x_i - \widetilde{x}\| + |\mu_i - f(\widetilde{x})| < \varepsilon_2, \quad i = 1, 2, \tag{3.2}$$

$$\frac{1}{2} - \varepsilon_2 < \max\{\|x_i^*\|, |\mu_i^*|\} < \frac{1}{2} + \varepsilon_2, \quad i = 1, 2, \tag{3.3}$$

$$\max\{\|x_1^* + x_2^*\|, |\mu_1^* + \mu_2^*|\} < \varepsilon_2. \tag{3.4}$$

Observe that $(x_2^*, \mu_2^*) \neq 0$ when ε_2 is sufficiently small. It follows from the structure of Ω_2 that $\mu_2 = f(\widetilde{x}) - \lambda_1^{-1}(\varepsilon - \varepsilon_1)\|x_2 - \widetilde{x}\|$, which yields $\mu_2^* > 0$ and thus implies that

$$\frac{x_2^*}{\mu_2^*} \in \widehat{\partial}\left(\lambda_1^{-1}(\varepsilon - \varepsilon_1)\|\cdot - \widetilde{x}\|\right)(x_2) \quad \text{and} \quad \frac{\|x_2^*\|}{\mu_2^*} \le \lambda_1^{-1}(\varepsilon - \varepsilon_1).$$

Taking (3.3) into account, the latter gives the estimate

$$\mu_2^* \ge \min\left\{\frac{(1 - 2\varepsilon_2)\lambda_1}{2(\varepsilon - \varepsilon_1)}, \frac{1}{2} - \varepsilon_2\right\}, \tag{3.5}$$

which ensures by (3.4) that $\mu_1^* < 0$ when ε_2 is sufficiently small. This allows us to show that $\mu_1 = f(x_1)$, since the opposite implies $\mu_1^* = 0$ due to $(x_1^*, \mu_1^*) \in \widehat{N}((x_1, \mu_1); \Omega_1)$ and the definition of Fréchet normals. Consequently, $-x_1^*/\mu_1^* \in \widehat{\partial} f(x_1)$.

It follows from (3.5) that $\varepsilon_2/\mu_2^* \to 0$ as $\varepsilon_2 \downarrow 0$. Putting all the above together, we conclude that

$$\frac{\|x_1^*\|}{|\mu_1^*|} < \frac{\|x_2^*\| + \varepsilon_2}{\mu_2^* - \varepsilon_2} = \left(\frac{\frac{\|x_2^*\|}{\mu_2^*} + \frac{\varepsilon_2}{\mu_2^*}}{1 - \frac{\varepsilon_2}{\mu_2^*}} \right) < \frac{\varepsilon}{\lambda}$$

when ε_2 is sufficiently small. On the other hand, it follows from (3.2) and the choice of λ_1 that

$$\|x_1 - \bar{x}\| < \lambda_1 + \varepsilon_2 \quad \text{and} \quad f(x_1) = \mu_1 < \inf_X f + \varepsilon - \varepsilon_1 + \varepsilon_2.$$

Finally, letting $\widehat{x} := x_1$ and $\widehat{x}^* := -x_1^*/\mu_1^*$, we get all the conclusions (i)–(iii) in (b) and finish the proof of the theorem. □

Remark 3.1. If f is smooth (Fréchet differentiable on its domain), then relation (iii) of the subdifferential variational principle reduces to $\|f'(\widehat{x})\| \le \varepsilon/\lambda$, which can be viewed as an approximate version of Fermat's stationary principle for suboptimal solutions in unconstrained optimization and was first obtained by Ekeland [7] in arbitrary Banach spaces. The next step was made by Rockafellar [25], who established, employing the sum rule for Clarke's generalized gradients, the corresponding generalized gradient version of assertion (b) in Theorem 3.1 for l.s.c. functions on Banach spaces. The same device, invoking the sum rule for two functions in Proposition 2.1, one of which is Lipschitz continuous, leads to the counterpart of Theorem 3.1(b) in terms of basic subgradients (2.5) in Asplund spaces; cf. [26, Proposition 10.44] in finite dimensions. Such a proof does not work for Fréchet subgradients in infinite dimensions; however, one can get the required conclusions of (b) in Asplund spaces by employing the "strong fuzzy sum rule" of Fabian [8, Theorem 3], which is actually equivalent to the extremal principle; see [19].

Remark 3.2. If X admits a Fréchet smooth renorm, conclusions (b) of Theorem 3.1 follow from the Borwein–Preiss smooth variational principle [2], which is equivalent, in this case, to the extremal principle by [1, Theorem 3.1]. Note that the *smooth renorm* assumption is not only sufficient but also *necessary* for the fulfillment of the smooth variational principle; see [9, Theorem 4.2]. On the other hand, the subdifferential variational principle is proved to be a characterization of Asplund spaces, and thus it can be viewed as an appropriate variational principle for this class of Banach spaces with no smoothness assumptions.

Remark 3.3. It follows from Theorem 4.6 in Fabian and Mordukhovich [9] that the subdifferential variational principle (b) in Theorem 3.1 directly implies *enhanced versions* of smooth variational principles in conventional support forms if the Asplund space X in question satisfies certain smoothness assumptions related to the existence of either smooth renorms or smooth bump functions of several types; see [9] for more details. Note that the combination of Theorem 3.1(b) and [9, Theorem 4.6] ensures the fulfillment of smooth variational principles that provide some additional information on supporting functions in comparison with the classical results of Borwein–Preiss and Deville–Godefroy–Zizler.

4. Necessary suboptimality and optimality conditions. Let us consider a general optimization problem of mathematical programming with equality, inequality,

and set constraints:

$$\text{(P)} \qquad \begin{cases} \text{minimize } f_0(x) \\ \text{subject to} \\ x \in \Delta \subset X, \\ f_i(x) \le 0, & i = 1, \dots, p, \\ f_i(x) = 0, & i = p+1, \dots, p+q, \end{cases}$$

where $f_i \colon X \to \overline{\mathbb{R}}$ are functions on a Banach space X. The main objective of this section is to present and discuss necessary conditions for *suboptimal solutions* to problem (P), proofs of which are given in the next section. In these results we do *not* assume the *existence of optimal solutions* that is an underlying assumption in the theory of necessary optimality conditions. The latter assumption is rather restrictive for problems of infinite-dimensional optimization and optimal control, while suboptimal solutions always exist. Based on the subdifferential variational principle, we find suboptimal solutions to (P) that *approximately* satisfy necessary conditions for optimality in problems with nonsmooth data. As a by-product of our approach, we derive refined necessary conditions for *optimal solutions* to (P), provided that they exist.

We obtain two types of results in this direction. Results of the first type justify "strong" necessary suboptimality and optimality conditions in both qualified and nonqualified forms for problems with Lipschitzian functions in terms of the basic normals and subgradients discussed in section 2. Proofs of these results essentially exploit the calculus rules and representations given in Propositions 2.1 and 2.2, as well as new subdifferential conditions for the sequential normal compactness of constraint sets derived in section 5. Independent results of the second type provide a "weak" form of necessary suboptimality and optimality conditions in terms of Fréchet normals and subgradients for problems with non-Lipschitzian data.

Let us consider the constraint sets

$$\Omega_i := \{x \in X | \, f_i(x) \le 0\}, \quad i = 1, \dots, p, \tag{4.1}$$

$$\Omega_i := \{x \in X | \, f_i(x) = 0\}, \quad i = p+1, \dots, p+q, \tag{4.2}$$

and denote by

$$\mathfrak{C} := \bigcap_{i=1}^{p+q} \Omega_i \cap \Delta, \qquad I(x) := \{i = 1, \dots, p+q | \, f_i(x) = 0\}$$

the sets of *feasible solutions* to (P) and *active constraint indices*, respectively. We always assume that $\mathfrak{C} \ne \emptyset$. To compress the statements of necessary suboptimality and optimality conditions formulated below, it is convenient to introduce the following sets of *generalized multipliers*.

DEFINITION 4.1. *Let $x \in \mathfrak{C}$ and $\mu \in \{0, 1\}$ be given. Then*

(a) *$M_\mu(x)$ denotes the collection of all tuples*

$$(x_0^*, \dots, x_{p+q}^*, x_\Delta^*, \alpha_1, \dots, \alpha_{p+q}) \in (X^*)^{2+p+q} \times [0, \infty)^{p+q} \tag{4.3}$$

satisfying the conditions

$$\begin{aligned} & x_0^* \in \partial f_0(x), \qquad x_\Delta^* \in N(x; \Delta), \\ & x_i^* \in \partial f_i(x) \quad \textit{for} \quad i \in \{1, \dots, p\} \cap I(x), \\ & x_i^* \in \partial f_i(x) \cup \partial(-f_i)(x) \quad \textit{for} \quad i = p+1, \dots, p+q, \\ & \alpha_i = 0 \quad \textit{for} \quad i \notin I(x), \end{aligned} \tag{4.4}$$

and

$$\mu x_0^* + \sum_{i\in I(x)} \alpha_i x_i^* + x_\Delta^* = 0. \tag{4.5}$$

(b) $M_\mu^\infty(x)$ *denotes the collection of all tuples* (4.3) *for which* (4.4) *and* (4.5) *hold, except that the inclusion required for* x_0^* *in* (4.4) *is replaced by* $x_0^* \in \partial^\infty f_0(x)$.

(c) *Given* $r > 0$, *let* $M_\mu(x; r)$ *denote the set of all tuples* (4.3) *obeying* (4.4) *and*

$$\left\| \mu x_0^* + \sum_{i\in I(x)} \alpha_i x_i^* + x_\Delta^* \right\| \le r, \qquad \mu + \sum_{i\in I(x)} \alpha_i \ge 1. \tag{4.6}$$

The next theorem gives *strong* necessary *suboptimality* conditions in both *nonqualified* (Fritz John) and *qualified* (Kuhn–Tucker) forms.

THEOREM 4.2. *Let* X *be an Asplund space. Assume that* Δ *is closed, that all of* $f_1, \dots, f_{p+q}$ *are locally Lipschitzian around each point of* $\mathfrak{C}$, *and that* $\inf_{\mathfrak{C}} f_0 > -\infty$. *Given an arbitrary* $\varepsilon > 0$, *let* $\bar{x} \in \mathfrak{C}$ *be an* ε*-optimal solution to* (P), *i.e.,* $f_0(\bar{x}) < \inf_{\mathfrak{C}} f_0 + \varepsilon$. *The following three assertions hold:*

(a) *Suppose that* f_0 *is also locally Lipschitzian around each point of* $\mathfrak{C}$. *Then for every* $\lambda > 0$ *there are* $\widehat{x} \in \mathfrak{C} \cap (\bar{x} + \lambda\mathbb{B})$ *and* $\mu \in \{0, 1\}$ *such that* $f_0(\widehat{x}) \le \inf_{\mathfrak{C}} f_0 + \varepsilon$ *and* $M_\mu(\widehat{x}; \varepsilon/\lambda) \ne \emptyset$.

(b) *Suppose that* f_0 *is l.s.c. on* $\mathfrak{C}$ *and that each* $x \in \mathfrak{C}$ *obeys both conditions* (i) *and* (ii):

  (i) *the basic qualification condition, namely, for every tuple of form* (4.3) *in* $M_1^\infty(x)$ *one has* $x_0^* = 0$, $x_\Delta^* = 0$, *and* $\alpha_i = 0$ *for all* $i \in I(x)$;

  (ii) *either* f_0 *is sequentially normally epi-compact at* x *or* Δ *is sequentially normally compact at* x *(in particular,* $\Delta = X$*).*

  Then for every $\lambda > 0$ *there is* $\widehat{x} \in \mathfrak{C} \cap (\bar{x} + \lambda\mathbb{B})$ *such that* $f_0(\widehat{x}) \le \inf_{\mathfrak{C}} f_0 + \varepsilon$ *and* $M_1(\widehat{x}; \varepsilon/\lambda) \ne \emptyset$.

(c) *Conversely, if the suboptimality conditions in* (b) *hold for any problem* (P) *with* $\mathfrak{C} = X$ *and an l.s.c. function* $f_0 \colon X \to \overline{\mathbb{R}}$ *concave on its domain, then* X *must be Asplund.*

Remark 4.1. If f_0 is locally Lipschitzian around every $x \in \mathfrak{C}$, then $\partial^\infty f_0(x) = \{0\}$ and the basic qualification condition in (i) is a *constraint qualification*. Moreover, if $\Delta = X$ and all f_i are *strictly differentiable* at x, then (i) is equivalent to the classical *Mangasarian–Fromovitz constraint qualification*:

(1) $f'_{p+1}(x), \dots, f'_{p+q}(x)$ are linearly independent.

(2) There exists $z \in X$ such that

$$\begin{aligned} &\langle f_i'(x), z\rangle < 0 \quad \text{for all} \quad i \in \{1, \dots, p\} \cap I(x), \\ &\langle f_i'(x), z\rangle = 0 \quad \text{for all} \quad i = p+1, \dots, p+q. \end{aligned}$$

In this smooth case, the suboptimality conditions of Theorem 4.2(b) reduce to those obtained by Ekeland [7] under a more restrictive constraint qualification. Namely, it was assumed in [7, Theorem 3.1] that *all* $\{f_i'(x) |\ i \in I(x)\}$ are linearly independent for each $x \in \mathfrak{C}$.

Next we present *necessary optimality* conditions in (P), which can be viewed as the limiting case of Theorem 4.2 as $\varepsilon = 0$. Note that $M_1(x; 0) = M_1(x)$.

THEOREM 4.3. *Let* X *be an Asplund space, and let* $\bar{x}$ *be an optimal solution to* (P). *Suppose that the corresponding assumptions in* (a) *and* (b) *of Theorem* 4.2 *are*

imposed only at $x = \bar{x}$. Then the conclusions of these assertions hold with $\varepsilon = 0$ for $\widehat{x} = \bar{x}$.

The last theorem of this section contains both necessary suboptimality and optimality conditions in problems (P) with *no* Lipschitzian, qualification, and/or sequential normal compactness assumptions. We obtain results in a *weak* approximate form of nonsmooth Lagrange multipliers with the replacement of relations (4.4)–(4.6) by their weaker counterparts.

To compress the statements of weak necessary suboptimality and optimality conditions in (P), it is convenient to introduce the following set. Given $\varepsilon > 0$, a weak* neighborhood V^* of the origin in X^*, and $x \in \mathfrak{C}$, we denote by $W_{\varepsilon,V^*}(x)$ the collection of all tuples

$$\begin{aligned} w &:= (x_0, \dots, x_{p+q}, x_\Delta, x_0^*, \dots, x_{p+q}^*, x_\Delta^*, \alpha_0, \dots, \alpha_{p+q}) \\ &\in X^{2+p+q} \times (X^*)^{2+p+q} \times [0,\infty)^{1+p+q} \end{aligned}$$

satisfying the conditions

$$\begin{aligned} &x_\Delta \in \Delta \cap (x + \varepsilon\mathbb{B}), \\ &f_0(x_0) - f_0(x)| \le \varepsilon, \quad \|x_i - x\| \le \varepsilon \quad \text{for } i = 0, \dots, p+q, \\ &x_\Delta^* \in \widehat{N}(x_\Delta;\Delta), \quad x_i^* \in \widehat{\partial} f_i(x_i) \quad \text{for } i = 0, \dots, p, \\ &x_i^* \in \widehat{\partial} f_i(x_i) \cup \widehat{\partial}(-f_i)(x_i) \quad \text{for } i = p+1, \dots, p+q, \end{aligned} \tag{4.7}$$

and

$$0 \in \sum_{i=0}^{p+q} \alpha_i x_i^* + x_\Delta^* + V^*, \qquad \sum_{i=0}^{p+q} \alpha_i = 1. \tag{4.8}$$

THEOREM 4.4. *Let X be an Asplund space, and let V^* be an arbitrary weak* neighborhood of the origin in X^*. The following assertions hold for problem* (P):

(a) *Assume that Δ is closed, that $f_0, \dots, f_p$ are l.s.c., and that $f_{p+1}, \dots, f_{p+q}$ are continuous around each $x \in \mathfrak{C}$. Suppose also that $\inf_{\mathfrak{C}} f_0 > -\infty$. Then there is a number $\bar{\varepsilon} > 0$ such that for every $0 < \varepsilon < \bar{\varepsilon}$ and every $\bar{x} \in \mathfrak{C}$ with $f_0(\bar{x}) < \inf_{\mathfrak{C}} f_0 + \varepsilon^2$ one has $W_{\varepsilon,V^*}(\bar{x}) \ne \emptyset$.*

(b) *Let $\bar{x}$ be an optimal solution to* (P). *Suppose that the assumptions in* (a) *are satisfied locally around $\bar{x}$. Then for every $\varepsilon > 0$ there is a $w \in W_{\varepsilon,V^*}(\bar{x})$, which obeys in addition the estimates*

$$|f_i(x_i) - f_i(\bar{x})| \le \varepsilon, \quad i = 1, \dots, p+q, \tag{4.9}$$

for the corresponding vectors x_i.

In the case of reflexive Banach spaces X, necessary optimality conditions in Theorem 4.4(b) reduce the main result of Borwein, Treiman, and Zhu [4, Theorem 2.1], obtained by a different technique based on "fuzzy" representations of the Fréchet normal cone, to the constraint sets (4.1) and (4.2). Recently these results were extended to the case of Asplund spaces by Ngai and Théra [23], who independently derived a version of Theorem 4.4(b) using Treiman's approach in [28] and a fuzzy chain rule for Fréchet subgradients. Furthermore, the result of [23] claims that all multipliers $\alpha_0, \dots, \alpha_{p+q}$ are nonzero, but it is actually equivalent to the statement of Theorem 4.4(b), since we can always cause them to be nonzero by small perturbations.

5. Proofs and auxiliary results. In this section we give proofs of the suboptimality and optimality results presented in section 4. These proofs apply the subdifferential variational principle of Theorem 3.1. Beyond that principle and the calculus rules given in section 2, our arguments strongly involve the following theorem ensuring the sequential normal compactness of the constraint sets (4.1) and (4.2). The proof of this theorem is based on the extremal principle.

THEOREM 5.1. *Let X be an Asplund space, and let $f\colon X \to \mathbb{R}$ be a function Lipschitz continuous around a given point $\bar{x} \in X$. Then the following assertions hold:*

(a) *The set $\Omega := \{x \in X | \, f(x) \le 0\}$ is sequentially normally compact at $\bar{x}$, provided that $f(\bar{x}) = 0$ and $0 \notin \partial f(\bar{x})$.*

(b) *The set $\Omega := \{x \in X | \, f(x) = 0\}$ is sequentially normally compact at $\bar{x}$, provided that $0 \notin \partial f(\bar{x}) \cup \partial(-f)(\bar{x})$.*

Proof. We prove both assertions (a) and (b) in a parallel way. In what follows, the set $\Theta \subset X \times \mathbb{R}$ stands for either $\operatorname{epi} f$ in (a) or $\operatorname{gph} f$ in (b). Choose arbitrary sequences $(x_k, x_k^*) \in X \times X^*$ such that $x_k \in \Omega$, $x_k^* \in \widehat{N}(x_k; \Omega)$ for all $k \in \mathbb{N}$, and $x_k \to \bar{x}$, $x_k^* \overset{w^*}{\to} 0$ as $k \to \infty$. It is required to prove that $\|x_k^*\| \to 0$ as $k \to \infty$. We are going to show that there exists a subsequence of $\{x_k^*\}$ with $\|x_k^*\| \to 0$. Since this result can be applied to any subsequence of $\{x_k^*\}$, it ensures the required convergence of the whole sequence.

Fix a sequence $\varepsilon_k \downarrow 0$ as $k \to \infty$. By the definition of $\widehat{N}(x_k; \Omega)$, we find a neighborhood U_k of x_k such that

$$\langle x_k^*, x - x_k \rangle - \varepsilon_k \|x - x_k\| \le 0 \qquad \text{for all } x \in U_k \cap \Omega. \tag{5.1}$$

Consider the sets

$$\begin{aligned} \Lambda_{1k} &:= \{(x, 0, \gamma) \in X \times \mathbb{R} \times \mathbb{R} | \, \gamma \ge 0\}, \\ \Lambda_{2k} &:= \{(x, \mu, \gamma) \in X \times \mathbb{R} \times \mathbb{R} | \, (x, \mu) \in \Theta, \\ &\qquad \gamma \le \langle x_k^*, x - x_k \rangle - \varepsilon_k (\|x - x_k\| + |\mu|)\}. \end{aligned}$$

Obviously these sets are closed in $X \times \mathbb{R} \times \mathbb{R}$ and $(x_k, 0, 0) \in \Lambda_{1k} \cap \Lambda_{2k}$. It follows from (5.1) that

$$\Lambda_{1k} \cap (\Lambda_{2k} - (0, 0, \nu)) \cap (U_k \times \mathbb{R} \times \mathbb{R}) = \emptyset \qquad \text{for all } \nu > 0.$$

This means that $(x_k, 0, 0)$ is a locally extremal point of the system $\{\Lambda_{1k}, \Lambda_{2k}\}$. Since X is an Asplund space, so is the product space $X \times \mathbb{R} \times \mathbb{R}$; see [24]. Thus we can apply the *extremal principle* in Theorem 3.1(a). Using this result, we find $(x_{ik}, \mu_{ik}, \gamma_{ik}) \in \Lambda_{ik}$ and

$$(x_{ik}^*, \mu_{ik}^*, \gamma_{ik}^*) \in \widehat{N}((x_{ik}, \mu_{ik}, \gamma_{ik}); \Lambda_{ik}) \quad \text{for } \ i = 1, 2, \tag{5.2}$$

satisfying the relations

$$\|x_{ik} - x_k\| + |\mu_{ik}| + |\gamma_{ik}| \le \varepsilon_k, \quad i = 1, 2, \tag{5.3}$$

$$\frac{1}{2} - \varepsilon_k \le \max\{\|x_{ik}^*\|, |\mu_{ik}^*|, |\gamma_{ik}^*|\} \le \frac{1}{2} + \varepsilon_k, \quad i = 1, 2, \tag{5.4}$$

$$\max\{\|x_{1k}^* + x_{2k}^*\|, |\mu_{1k}^* + \mu_{2k}^*|, |\gamma_{1k}^* + \gamma_{2k}^*|\} \le \varepsilon_k. \tag{5.5}$$

It easily follows from (5.2) as $i = 1$ that $x_{1k}^* = 0$ and $\gamma_{1k}^* \le 0$. Then (5.5) implies $\|x_{2k}^*\| \le \varepsilon_k$. Let us show that there exists a constant $c > 0$ such that

$$(x_{2k}^* + \gamma_{2k}^* x_k^*, \mu_{2k}^*) \in \widehat{N}_{c\varepsilon_k}((x_{2k}, \mu_{2k}); \Theta). \tag{5.6}$$

Using (5.2) with $i=2$ and the definition of $\widehat{N}$, we have

$$\limsup_{(x,\mu,\gamma)\overset{\Lambda_{2k}}{\to}(x_{2k},\mu_{2k},\gamma_{2k})} \frac{\langle x_{2k}^*, x-x_{2k}\rangle + \mu_{2k}^*(\mu-\mu_{2k}) + \gamma_{2k}^*(\gamma-\gamma_{2k})}{\|x-x_{2k}\|+|\mu-\mu_{2k}|+|\gamma-\gamma_{2k}|} \le 0, \tag{5.7}$$

where

$$\gamma_{2k} \le \langle x_k^*, x_{2k}-x_k\rangle - \varepsilon_k(\|x_{2k}-x_k\|+|\mu_{2k}|)$$

due to the construction of Λ_{2k}. If this inequality is strict, (5.7) implies that $\gamma_{2k}^*=0$ by letting $x=x_{2k}$, $\mu=\mu_{2k}$ and passing to the limit as $\gamma\to\gamma_{2k}$. Furthermore, setting $\gamma=\gamma_{2k}$ in (5.7), we get $(x_{2k}^*,\mu_{2k}^*)\in\widehat{N}((x_{2k},\mu_{2k});\Theta)$, which ensures (5.6) in this case. The other case of

$$\gamma_{2k} = \langle x_k^*, x_{2k}-x_k\rangle - \varepsilon_k(\|x_{2k}-x_k\|+|\mu_{2k}|)$$

is more difficult and can be handled as follows. We substitute

$$\gamma := \langle x_k^*, x-x_k\rangle - \varepsilon_k(\|x-x_k\|+|\mu|)$$

into (5.7) and find a neighborhood V_k of (x_{2k},μ_{2k}) such that

$$\frac{\langle x_{2k}^*, x-x_{2k}\rangle + \mu_{2k}^*(\mu-\mu_{2k}) + \gamma_{2k}^*(\gamma-\gamma_{2k})}{\|x-x_{2k}\|+|\mu-\mu_{2k}|+|\gamma-\gamma_{2k}|} \le \varepsilon_k \tag{5.8}$$

for all $(x,\mu)\in\Theta\cap V_k$. In this case

$$\begin{aligned}
&|\gamma-\gamma_{2k}-\langle x_k^*, x-x_{2k}\rangle| \\
&\quad = |-\varepsilon_k(\|x-x_k\|+|\mu|)+\varepsilon_k(\|x_{2k}-x_k\|+|\mu_{2k}|)| \\
&\quad \le \varepsilon_k(\|x-x_{2k}\|+|\mu-\mu_{2k}|), \\
&|\gamma-\gamma_{2k}| \le (1+\|x_k^*\|)(\|x-x_{2k}\|+|\mu-\mu_{2k}|).
\end{aligned}$$

Then (5.8) gives the estimate

$$\frac{\langle x_{2k}^*+\gamma_{2k}^*x_k^*, x-x_{2k}\rangle + \mu_{2k}^*(\mu-\mu_{2k})}{\|x-x_{2k}\|+|\mu-\mu_{2k}|} \le (2+|\gamma_{2k}^*|+\|x_k^*\|)\varepsilon_k \le c\varepsilon_k \tag{5.9}$$

for all $(x,\mu)\in\Theta\cap V_k$ and $c:=\sup_k\{2+|\gamma_{2k}^*|+\|x_k^*\|\}$. Note that $c<\infty$, since the sequence $\{x_k^*\}$ is w^*-convergent, and hence it is bounded due to the classical uniform boundedness theorem. Thus we get (5.6) from (5.9) and definition (2.1).

Note that the sequences of real numbers $\{\mu_{ik}^*\}$ and $\{\gamma_{ik}^*\}$, $i=1,2$, are bounded due to (5.4); hence we may assume that each of them converges. Due to (5.5) we have

$$-\lim_{k\to\infty}\mu_{1k}^* = \lim_{k\to\infty}\mu_{2k}^* := \bar{\mu}^*, \qquad -\lim_{k\to\infty}\gamma_{1k}^* = \lim_{k\to\infty}\gamma_{2k}^* := \bar{\gamma}^* \ge 0.$$

Let us show that $\bar{\mu}^*=0$ under the assumptions made. Indeed, assume the contrary and pass to the limit in (5.6) as $k\to\infty$. Taking into account definition (2.2) and also that $x_{2k}\to\bar{x}$ and $\mu_{2k}\to 0=f(\bar{x})$ by (5.3), we get $(0,\bar{\mu}^*)\in N((\bar{x},f(\bar{x}));\Theta)$ due to $x_k^*\overset{w^*}{\to}0$. This implies that $0\in\partial f(\bar{x})$ when $\Theta=\operatorname{epi} f$, and $0\in\partial f(\bar{x})\cup\partial(-f)(\bar{x})$ when $\Theta=\operatorname{gph} f$. Each of these conclusions contradicts the assumptions made in (a) and (b), respectively. Thus $\bar{\mu}^*=0$. Consequently, (5.4) and $x_{1k}^*=0$, $\|x_{2k}^*\|\le\varepsilon_k$ imply

that $\bar{\gamma}^* \neq 0$ and thus $\bar{\gamma}^* > 0$. Without loss of generality we assume that $\gamma^*_{2k} \geq d > 0$ for some constant d and all $k \in \mathbb{N}$.

To finish the proof, let us consider the following two cases for each $k \in \mathbb{N}$. (Only case (i) applies when $\Theta = \operatorname{gph} f$.)

Case (i). $\mu_{2k} = f(x_{2k})$. Substituting $\mu = f(x)$ and $\mu_{2k} = f(x_{2k})$ into (5.9), we get the estimates:

$$\begin{aligned}\frac{|\langle x^*_k, x - x_{2k}\rangle|}{\|x - x_{2k}\|} &\leq \frac{|\langle x^*_{2k}, x - x_{2k}\rangle|}{\gamma^*_{2k}\|x - x_{2k}\|} + \frac{|\mu^*_{2k}| \cdot |f(x) - f(x_{2k})|}{\gamma^*_{2k}\|x - x_{2k}\|}\\ &\quad + \frac{c\varepsilon_k}{\gamma^*_{2k}}\left(1 + \frac{|f(x) - f(x_{2k})|}{\|x - x_{2k}\|}\right)\\ &\leq \frac{\|x^*_{2k}\|}{d} + \frac{|\mu^*_{2k}|L}{d} + \frac{c\varepsilon_k}{d}(1 + L)\end{aligned}$$

for all x in a neighborhood of x_{2k}, where L is a Lipschitz modulus of f around $\bar{x}$. The latter yields

$$\|x^*_k\| \leq \frac{\|x^*_{2k}\|}{d} + \frac{|\mu^*_{2k}|L}{d} + \frac{c\varepsilon_k}{d}(1 + L). \tag{5.10}$$

Case (ii). $\mu_{2k} > f(x_{2k})$. (This only applies when $\Theta = \operatorname{epi} f$.) In this case $(x, \mu_{2k}) \in \Theta \cap V_k$ when x is near x_{2k}. Substituting $\mu = \mu_{2k}$ into (5.9), we get $\|x^*_{2k} + \gamma^*_{2k}x^*_k\| \leq c\varepsilon_k$. This implies the estimate

$$\|x^*_k\| \leq \frac{c\varepsilon_k}{d} + \frac{\|x^*_{2k}\|}{d}. \tag{5.11}$$

Summarizing both cases (i) and (ii), we see that for each $k \in \mathbb{N}$ either (5.10) or (5.11) holds. This finally implies that $\|x^*_k\| \to 0$ as $k \to \infty$, since $\|x^*_{2k}\| \leq \varepsilon_k$ for all $k \in \mathbb{N}$. The proof of the theorem is complete. □

Remark 5.1. The assumptions $0 \notin \partial f(\bar{x})$ and $0 \notin \partial f(\bar{x}) \cup \partial(-f)(\bar{x})$ are essential in Theorem 5.1. A corresponding counterexample is provided by the function $f(x) = \|x\|^2$ at $\bar{x} = 0$ for assertion (a) and by the function $f(x) = -\|x\|$ at the same point for assertion (b).

Remark 5.2. It is proved by Rockafellar [25] that if $0 \notin \overline{\partial} f(\bar{x})$, where $\overline{\partial}$ denotes the Clarke subdifferential, then the set $\Omega = \{x |\, f(x) \leq 0\}$ is epi-Lipschitzian at $\bar{x}$, provided that $f(\bar{x}) = 0$ and f is Lipschitz continuous around $\bar{x}$. It is well known that

$$\overline{\partial} f(\bar{x}) = \operatorname{cl}^* \operatorname{co} \partial f(\bar{x})$$

for locally Lipschitz functions in Asplund spaces; see [20, Theorem 8.11]. Thus, can we expect Ω to be epi-Lipschitzian at $\bar{x}$ under the weaker condition $0 \notin \partial f(\bar{x})$ ensuring the sequential normal compactness property of this set due to Theorem 5.1(a)? The answer is *negative* even in finite dimensions. A counterexample is provided by the function $f\colon \mathbb{R}^2 \to \mathbb{R}$ defined by $f(x_1, x_2) := |x_1| - |x_2|$. One can check that

$$0 \notin \partial f(0,0) = \Big\{(x_1, x_2) \in \mathbb{R}^2 |\, |x_1| \leq 1 \text{ and either } x_2 = 1 \text{ or } x_2 = -1\Big\},$$

while the set $\{(x_1, x_2) \in \mathbb{R}^2 |\, |x_1| \leq |x_2|\}$ is obviously not epi-Lipschitzian at $(0, 0)$.

Proof of Theorem 4.2. Let us first prove assertion (b). Define an l.s.c. function f by

$$f(x) := f_0(x) + \delta(x; \mathfrak{C}) \qquad \text{for all } x \in X, \tag{5.12}$$

which is obviously bounded from below on X. Since $\inf_X f = \inf_{\mathfrak{C}} f_0$, we have $f(\bar{x}) < \inf_X f + \varepsilon$ for any $\bar{x}$ and $\varepsilon > 0$ given in the theorem. Applying the subdifferential variational principle of Theorem 3.1(b) to the function f in (5.12) with the given $\lambda > 0$, we find $\widehat{x} \in \mathfrak{C}$ and $\widehat{x}^* \in \partial f(\widehat{x})$ such that

$$\|\widehat{x} - \bar{x}\| < \lambda, \qquad f_0(\widehat{x}) = f(\widehat{x}) < \inf_X f + \varepsilon = \inf_{\mathfrak{C}} f_0 + \varepsilon, \qquad \|\widehat{x}^*\| < \varepsilon/\lambda. \tag{5.13}$$

Due to the structure of the feasible set $\mathfrak{C}$ in (P), we get from (5.12) that

$$\partial f(\widehat{x}) = \partial \left(f_0 + \sum_{i \in I(\mathbb{b})} \delta(\cdot; \Omega_i) + \delta(\cdot; \Delta) \right)(\widehat{x}), \tag{5.14}$$

with the sets Ω_i defined in (4.1) and (4.2). Now let us apply to (5.14) the basic calculus rules of Proposition 2.1 as well as the subdifferential conditions for the sequential normal compactness of the sets Ω_i obtained in Theorem 5.1. In this way, using assumptions (i) and (ii) and the normal cone representations of Proposition 2.2, we ensure that $M_1(\widehat{x}; \varepsilon/\lambda) \neq \emptyset$), which proves (b).

Next let us justify (a). By the proof of (b) we get $\widehat{x}$ and $\widehat{x}^* \in \partial f(\widehat{x})$ satisfying (5.13) and (5.14). If the basic qualification condition in (i) holds at $\widehat{x}$, then (a) follows, with $\mu = 1$, from the subsequent proof of (b). Suppose that (i) does not hold at $\bar{x}$. This means that there are numbers $\alpha_i \geq 0$ for $i \in I(\widehat{x})$, not all zero, and vectors $x^*_\Delta \in N(\widehat{x}; \Delta)$, $\widehat{x}^*_i \in \partial f_i(\widehat{x})$ for $i \in \{1, \ldots, p\} \cap I(\widehat{x})$, and $\widehat{x}^*_i \in \partial f_i(\widehat{x}) \cup \partial(-f_i)(\widehat{x})$ for $i = p+1, \ldots, p+q$ satisfying

$$\sum_{i \in I(\mathbb{b})} \alpha_i \widehat{x}^*_i + x^*_\Delta = 0.$$

Dividing the latter equality by $\alpha := \sum_{i \in I(\mathbb{b})} \alpha_i > 0$, we arrive at the conclusions of (a) with $\mu = 0$.

It remains to prove (c). Let X be a Banach space, and let $f \colon X \to \mathbb{R}$ be an arbitrary concave continuous function. Due to the continuity of f, for any $\bar{x} \in X$ and $\varepsilon > 0$ there is $0 < \varepsilon_1 < \varepsilon$ such that $f(\bar{x}) < f(x) + 2\varepsilon$ for all $x \in \bar{x} + \varepsilon_1 \mathbb{B}$. Consider the following unconstrained optimization problem of type (P):

$$\text{minimize} \quad f_0(x) \quad \text{on} \quad X, \quad \text{with} \quad f_0(x) := f(x) + \delta(x; \bar{x} + \varepsilon_1 \mathbb{B}), \tag{5.15}$$

where $f_0 \colon X \to \overline{\mathbb{R}}$ obviously satisfies the assumptions in (c). Applying to (5.15) the suboptimality conditions in (b), we find $\widehat{x} \in \bar{x} + \frac{\varepsilon_1}{2}\mathbb{B}$ such that $\partial f_0(\widehat{x}) = \partial f(\widehat{x}) \neq \emptyset$. It is well known (see [20]) that the basic subdifferential (2.5) admits the representation

$$\partial f(\widehat{x}) = \operatorname*{Lim\,sup}_{x \to \mathbb{b}, \gamma \downarrow 0} \widehat{\partial}_\gamma f(x)$$

for any continuous function f on a Banach space X, where

$$\widehat{\partial}_\gamma f(\bar{x}) := \left\{ x^* \in X^* \,\middle|\, \liminf_{x \to \bar{x}} \frac{f(x) - f(\bar{x}) - \langle x^*, x - \bar{x} \rangle}{\|x - \bar{x}\|} \geq -\gamma \right\}.$$

So for every $\gamma > 0$ there is a $x_\gamma \in \bar{x} + \varepsilon \mathbb{B}$ with $\widehat{\partial}_\gamma f(x_\gamma) \neq \emptyset$. This implies that, for any concave continuous function $f \colon X \to \mathbb{R}$ and any $\gamma > 0$, the set $\{x \in X |\ \widehat{\partial}_\gamma f(x) \neq \emptyset\}$

is dense in X. Now the Asplund property of X follows from [13, Proposition 1]. This ends the proof of the theorem. □

Proof of Theorem 4.3. Obviously $\bar{x}$ is an optimal solution to the problem of unconstrained minimization of the function $f\colon X \to \overline{\mathbb{R}}$ defined in (5.12). Due to Fermat's stationary principle in terms of the basic subdifferential (2.5), we have $0 \in \partial f(\bar{x})$. Let us first consider the case in which the assumptions of Theorem 4.2(b) hold around $\bar{x}$. Then, by Theorem 5.1, each of the sets $\Omega_1, \ldots, \Omega_{p+q}$ defined in (4.1) and (4.2) is sequentially normally compact at $\bar{x}$. Now employing Propositions 2.1 and 2.2, we get necessary optimality conditions of the form $M_1(\bar{x}; 0) \neq \emptyset$. Similarly to the proof of Theorem 4.2(a), these conditions imply the nonqualified form of $M_\mu(\bar{x}; 0) \neq \emptyset$ with $\mu \in \{0, 1\}$ when the basic qualification condition is not imposed. □

Proof of Theorem 4.4. First let us justify the weak necessary suboptimality conditions in (a). For any $z \in X$ and $\gamma > 0$ we consider a family of the w^*-neighborhoods

$$V^*(z; \gamma) := \big\{x^* \in X^* |\ |\langle x^*, z\rangle| < \gamma\big\}$$

of the origin in X^* that form a basis of the weak* topology. Taking an arbitrary w^*-neighborhood V^* in the theorem, we find constants $\bar{\gamma} > 0$, $l \in \mathbb{N}$ and vectors $z_j \in X$ with $\|z_j\| = 1,\ 1 \le j \le l$, such that

$$\bigcap_{j=1}^{l} V^*(z_j; 2\bar{\gamma}) \subset V^*.$$

Let us show that the conclusions of the theorem hold for every ε satisfying

$$0 < \varepsilon < \bar{\varepsilon} := \min\{\bar{\gamma}, 1\}.$$

Indeed, take any $\bar{x} \in \mathfrak{C}$ with $f_0(\bar{x}) < \inf_{\mathfrak{C}} f_0 + \varepsilon^2$, and find $\nu \in (0, \varepsilon)$ such that

$$f_0(\bar{x}) < \inf_{\mathfrak{C}} f_0 + (\varepsilon - \nu)^2.$$

Then for the function $f : X \to \overline{\mathbb{R}}$ defined in (5.12) one has

$$f(\bar{x}) < \inf_{X} f + (\varepsilon - \nu)^2.$$

Applying the subdifferential variational principle of Theorem 3.1(b), we find $\widehat{x} \in \mathfrak{C}$ and $\widehat{x}^* \in \widehat{\partial} f(\widehat{x})$ such that

$$\|\widehat{x} - \bar{x}\| < \varepsilon - \nu, \quad \|\widehat{x}^*\| < \varepsilon - \nu < \bar{\gamma}, \quad \text{and}$$

$$f_0(\widehat{x}) < \inf_{\mathfrak{C}} f_0 + (\varepsilon - \nu)^2 < \inf_{\mathfrak{C}} f_0 + \varepsilon - \nu.$$

The latter implies that

$$|f_0(\widehat{x}) - f_0(\bar{x})| < \varepsilon - \nu.$$

Now let us take $\gamma := \bar{\gamma}/(p + q + 1)$ and consider the w^*-neighborhood

$$\widehat{V}^* := \bigcap_{j=1}^{l} V^*(z_j; \gamma).$$

Given $\widehat{V}^*$ and ν, we employ the "weak fuzzy sum rule" of [8, Theorem 2] to $\widehat{x}^* \in \widehat{\partial} f(\widehat{x})$ and find

$$\begin{gathered} x_\Delta \in \Delta, \quad x_0 \in X, \quad y_i \in X \ \text{ for } \ i = 1, \dots, p+q, \\ \widehat{x}^*_\Delta \in \widehat{\partial}\delta(x_\Delta; \Delta) = \widehat{N}(x_\Delta; \Delta), \quad x^*_0 \in \widehat{\partial} f_0(x_0), \\ y^*_i \in \widehat{\partial}\delta(y_i; \Omega_i) = \widehat{N}(y_i; \Omega_i) \ \text{ for } \ i = 1, \dots, p+q \end{gathered}$$

satisfying the relations

$$\begin{gathered} \|x_0 - \widehat{x}\| < \nu, \quad |f_0(x_0) - f_0(\widehat{x})| < \nu, \quad \|x_\Delta - \widehat{x}\| < \nu, \\ \|y_i - \widehat{x}\| < \nu/2 \ \text{ for } \ i = 1, \dots, p+q, \quad \text{and} \\ \widehat{x}^* \in x^*_0 + \sum_{i=1}^{p+q} y^*_i + \widehat{x}^*_\Delta + \widehat{V}^*. \end{gathered}$$

To finish the proof, we need to consider the following two cases.

Case (1). There exist either $i \in \{1, \dots, p\}$ and $\alpha \neq 0$ satisfying $(0, \alpha) \in N((y_i, 0); \operatorname{epi} f_i)$ or $i \in \{p+1, \dots, p+q\}$ satisfying $0 \in \partial f_i(y_i) \cup \partial(-f_i)(y_i)$. If this happens for some $i \in \{1, \dots, p\}$, we use the basic normal cone representation (2.3) and find elements $(x_i, \mu_i) \in \operatorname{epi} f_i$ and $(x^*_i, -\mu^*_i) \in \widehat{N}((x_i, \mu_i); \operatorname{epi} f_i)$ with

$$\|x_i - y_i\| < \nu/2, \qquad \mu^*_i > 0, \qquad \text{and } x^*_i \in \mu^*_i V^*.$$

It is easy to check that $\widehat{N}((x_i, \mu_i); \operatorname{epi} f_i) \subset \widehat{N}((x_i, f_i(x_i)); \operatorname{epi} f_i)$, since $\mu_i \geq f_i(x_i)$. So we have $(x^*_i, -\mu^*_i) \in \widehat{N}((x_i, f_i(x_i)); \operatorname{epi} f_i)$, and hence

$$x^*_i/\mu^*_i \in \widehat{\partial} f_i(x_i) \quad \text{with} \quad x^*_i/\mu^*_i \in V^*.$$

If $i \in \{p+1, \dots, p+q\}$, we use the basic subdifferential representation (2.7) for continuous functions and find $x_i \in X$ and $x^*_i \in \widehat{\partial} f_i(x_i) \cup \widehat{\partial}(-f_i)(x_i)$ such that

$$\|x_i - y_i\| < \nu/2 \quad \text{and} \quad x^*_i \in V^*.$$

So in both situations of case (i) we get all the required relations of the theorem with $\alpha_i = 1$ (the other α_i are 0) and $x^*_\Delta = 0$.

Case (2). Otherwise. In this case we can use the normal cone representations (2.8) and (2.9), since the qualification assumptions of Proposition 2.2 hold. Employing (2.9) and then (2.7) for the equality constraints at y_i, we find

$$x_i \in X, \quad x^*_i \in \widehat{\partial} f_i(x_i) \cup \widehat{\partial}(-f_i)(x_i), \quad \text{and } \ \beta_i \geq 0$$

for $i = p+1, \dots, p+q$ satisfying

$$\|x_i - y_i\| < \nu/2 \quad \text{and} \quad \beta_i x^*_i \in y^*_i + \widehat{V}^*, \qquad 1 \leq i \leq p+q.$$

Now let us consider the inequality constraints and use representation (2.8) of the basic normal cone for each $i = 1, \dots, p$. Taking (y_i, y^*_i) above, we find $\mu^*_i \geq 0$ such that $(y^*_i, -\mu^*_i) \in N((y_i, 0); \operatorname{epi} f_i)$. Then using the limiting representation (2.3) of the basic normal cone in Asplund spaces, we approximate $(y^*_i, -\mu^*_i)$ in the weak* topology of $X^* \times \mathbb{R}$ by elements $(z^*_i, -r^*_i) \in \widehat{N}((z_i, r_i); \operatorname{epi} f_i)$, with (z_i, r_i) sufficiently close to $(y_i, 0)$. Without loss of generality we may assume that $r_i = f_i(z_i)$; cf. case (1). If

$r_i^* \neq 0$, we set $\beta_i := r_i^*$, $x_i := z_i$, and $x_i^* := z_i^*/\beta_i \in \widehat{\partial} f_i(x_i)$ to get the required relations. If $r_i^* = 0$, then, using the techniques developed in [14, proof of Theorem 4], we find an X^*-norm approximation $\beta_i x_i^*$ of z_i^* with some $\beta_i \geq 0$, and an X-norm approximation x_i of z_i such that $(x_i^*, -1) \in \widehat{N}((x_i, f_i(x_i)); \operatorname{epi} f_i)$, which means $x_i^* \in \widehat{\partial} f_i(x_i)$.

Combining all of the above relationships and taking into account that $\nu < \varepsilon < \bar{\gamma}$, we get

$$
\begin{gathered}
|f_0(x_0) - f_0(\bar{x})| < \varepsilon, \\
\|x_\Delta - \bar{x}\| < \varepsilon, \quad \|x_i - \bar{x}\| < \varepsilon \ \text{ for } \ i = 0, \dots, p+q, \\
0 \in x_0^* + \sum_{i=1}^{p+q} \beta_i x_i^* + \widehat{x}_\Delta^* + V^*.
\end{gathered}
$$

Finally, setting $\beta := 1/(1 + \sum_{i=1}^{p+q} \beta_i)$ and noting that $\beta V^* \subset V^*$, we arrive at (4.7) and (4.8) with

$$
x_\Delta^* := \beta \widehat{x}_\Delta^*, \quad \alpha_0 := \beta, \quad \text{and } \alpha_i := \beta\beta_i \qquad \text{for } \ i = 1, \dots, p+q.
$$

This justifies assertion (a) of the theorem.

It remains to prove the weak necessary optimality conditions in (b). Since $\bar{x}$ provides a local minimum to the function f in (5.12), we have $0 \in \widehat{\partial} f(\bar{x})$. Now following the (simplified) scheme in the proof of assertion (a), we arrive at all the conclusions of (b) except estimates (4.9) for $i = 1, \dots, p$. If $f_i(\bar{x}) = 0$ for some $i \in \{1, \dots, p\}$, then (4.9) follows directly from the lower semicontinuity of f_i at $\bar{x}$. Otherwise, if $f_i(\bar{x}) < 0$ for some $i \in \{1, \dots, p\}$, we substitute this constraint by $g_i(x) := f_i(x) - f_i(\bar{x}) \leq 0$ and observe that $\bar{x}$ is an optimal solution to the new problem with $g_i(\bar{x}) = 0$ and $\widehat{\partial} g_i(\bar{x}) = \widehat{\partial} f_i(\bar{x})$. Thus we get the desired necessary optimality conditions under the general assumptions of the theorem. □

SINGULARLY PERTURBED CONTROL SYSTEMS WITH ONE-DIMENSIONAL FAST DYNAMICS*

ZVI ARTSTEIN† AND ARIE LEIZAROWITZ‡

Abstract. The order reduction approach to singularly perturbed control systems suggests employing as a variational limit the differential algebraic system obtained when the small parameter is set to be zero. It is known that the method is valid only under restrictive convergence conditions on the fast dynamics. We verify in this paper that, when the fast state variable is one-dimensional, the order reduction method is valid in general. This is true, however, when appropriate relaxation is allowed in the reduced-order system. We also indicate how to extract near optimal solutions to the original system from optimal solutions of the order reduction one along the traditional reasoning of separating time scales. Examples are displayed, showing that, without allowing the relaxation, the order reduction may not provide the correct limit.

Key words. singular perturbations, order reduction, slow and fast motions, relaxed controls

1. Introduction.

Consider the optimal control problem with singularly perturbed fast dynamics as follows:

$$\text{minimize} \quad \int_0^1 c(x(t), y(t), u(t))dt \tag{1.1}$$

subject to

$$\begin{aligned} \frac{dx}{dt} &= f(x, y, u), \\ \varepsilon \frac{dy}{dt} &= g(x, y, u), \end{aligned} \tag{1.2}$$

with initial conditions

$$x(0) = x_0, \quad y(0) = y_0, \tag{1.3}$$

where $x \in R^n$, $y \in R^m$, and $u \in R^k$ (see Remark 8.1 for extensions). The understanding is that the parameter ε multiplying the derivative of the y variable is small. Hence y is referred to as the fast variable. One is interested, in fact, in the limit behavior of the value and of the solutions to the problem as $\varepsilon \to 0$. This limit structure may be drawn from a limit problem. Hence we may try to identify an optimal control problem whose optimal value and solutions are limits, as $\varepsilon \to 0$, of the value and optimal solutions to the original system. Such a limit system is referred to as a variational limit.

The order reduction approach offers a candidate for a variational limit for the singularly perturbed system. It asserts that the behavior, when the small parameter tends to zero, is captured by the system arrived at when the parameter is set to be zero, namely, when (1.2) is replaced by

$$\begin{aligned} \frac{dx}{dt} &= f(x, y, u), \\ 0 &= g(x, y, u). \end{aligned} \tag{1.4}$$

The initial condition of the fast variable may not be compatible with the algebraic equation in (1.4); then a boundary layer is permitted.

The order reduction method yields suitable variational limits for a broad variety of situations, extending beyond optimal control problems. For the theory and many important applications, consult Kokotovic, Khalil, and O'Reilly [14]. See also Kokotovic and Khalil [13] and O'Malley [15]. However, for the order reduction method to apply, the optimal solutions have to satisfy quite restrictive conditions. In particular, on the fast scale, the dynamics has to converge to a stationary point. Many systems fail to have this property, and there are examples demonstrating that (1.4) may not be an appropriate variational limit for (1.2). Examples for this phenomenon, and alternative variational limits, were offered in Artstein [2], Artstein and Gaitsgory [3], [4], Gaitsgory [10], [11], and Vigodner [16].

In this paper, we establish, under mild conditions, that, for a one-dimensional fast variable y, namely a scalar, the system (1.4) is an appropriate variational limit for (1.2), provided that an appropriate relaxation of the order reduction system is allowed. No restrictions are put on the dimensions of the slow variable and the control variable. The relaxation is needed, however, for both the control variable and the stationary limit of the fast variable and the control. Indeed, the stationary solution of the reduced-order system serves as a control on the slow time scale; hence it may be subject to relaxation. In the particular case where the slow dynamics is not present, it is enough to employ relaxed controls, and, moreover, a stationary solution exists. A similar observation concerning a one-dimensional fast variable holds and is easy to verify for the uncontrolled version (see Remark 8.2). The result for the optimal control problem, even without slow dynamics, is not that apparent. Indeed, we provide examples (see Examples 8.3 and 8.4) demonstrating that, without allowing relaxed controls, the order reduction may not be a suitable variational limit.

Once an optimal solution to the relaxed version of the order reduction is detected, one can construct a near optimal solution to the original problem (1.1)–(1.3). This can be carried out along the traditional reasoning of separating the slow and fast components in the order reduction method. Consult Kokotovic, Khalil, and O'Reilly [14].

The paper is organized as follows. In the next section, we display some terminology and the technical assumptions. The interpretation of relaxed solutions for the order reduction problem is displayed in section 3, where the main general result is given. In section 4, we state the main result concerning the special case where there is no slow dynamics in the optimization process. The information we get in this case is sharper than in the general case. Two auxiliary lemmas are stated and verified in section 5. They are independent of optimality considerations. They capture and reveal, however, the role of the condition that y is a scalar variable. The proofs of the two main results, the special case with no slow dynamics and the general coupled

dynamics, are given in sections 6 and 7, respectively. In the closing section, we display some comments, extensions, and examples. In particular, counterexamples are given (Examples 8.5 and 8.7), showing that the relaxation of the fast stationary limit must be allowed, and results are exhibited (Proposition 8.9 and Example 8.10), addressing the situation where there is no need to use such a relaxation.

2. The setting. In this section, we set the terminology and display the conditions under which the main result is verified.

The control functions which are admissible for the optimal control system (1.1)–(1.3) are functions $u(\cdot) : [0,1] \to R^k$ which are Lebesgue measurable. We assume that, if there exists a solution to (1.2)–(1.3) when an admissible control $u(\cdot)$ is applied, this solution is unique. We denote by $\text{cost}_\varepsilon(u(\cdot))$ the cost of applying the admissible control function, namely, the outcome of the integral in (1.1) evaluated with the control function and with the resulting trajectories satisfying (1.2) and (1.3) for a given value of ε. We denote by $\text{val}(\varepsilon)$ the infimum of $\text{cost}_\varepsilon(u(\cdot))$ over all admissible controls.

Assumption 2.1.

(i) Continuity: The functions $f(x,y,u)$, $g(x,y,u)$, and $c(x,y,u)$ are continuous in their respective domains.

(ii) Uniqueness: Plugging a bounded and measurable control function $u(\cdot)$ in (1.2) with any initial conditions yields a unique solution $(x_\varepsilon(\cdot), y_\varepsilon(\cdot))$ on $[0,1]$.

(iii) Controllability of the fast flow: Consider the controlled equation $\frac{dy}{ds} = g(x,y,u)$ for x fixed and for $s \in [0,\infty)$. Any initial fast state y_1 can be steered to any other state y_2 by an admissible bounded control on some interval $[0,S]$.

(iv) Boundedness: There exists a uniformly bounded family of admissible controls $u_\varepsilon(\cdot)$, parameterized by ε, such that the resulting trajectories $(x_\varepsilon(\cdot), y_\varepsilon(\cdot))$ are also uniformly bounded, and such that $\text{val}(\varepsilon) - \text{cost}_\varepsilon(u_\varepsilon(\cdot))$ tends to zero as $\varepsilon \to 0$.

Conditions (i) and (ii) of Assumption 2.1 are standard. Condition (iii) is a simple one when y is scalar, as it assumes, roughly, that, for x and y fixed, the function $g(x,y,u)$ takes both positive and negative values. Condition (iv) can be derived from growth conditions on the cost function. It holds in broad classes of optimal control problems, let alone in practically all of the applications.

The term "near optimal control" is used throughout the paper, meaning that the near optimal control in question, which depends typically on a parameter, yields an arbitrarily good approximation to the optimal cost as the parameter tends to its limit.

3. The general result. In this section, we clarify how the order reduction system is solved and state the main result.

As mentioned already, the main result assumes that relaxed controls may be used. Relaxed controls were originated by Warga and are heavily employed in optimal control theory. For the theory, background, and applications of relaxed controls, consult Warga [17], Young [18], or Berkovitz [7]. Here we recall some essential facts. A relaxed control is a function which at each point t takes as a value a probability measure, say, μ, on the control space. We shall need two types of relaxation—one on the original control space and the second on the limit stationary fast dynamics, when considered as a control for the slow dynamics.

Consider first relaxed controls with values being probability measures on R^k, namely, the relaxation in the control space. The effect of the probability measure on

the right-hand side of (1.2) and on the cost function in (1.1) is via averaging. Namely, when the relaxed control μ is applied, these functions take the values

$$\int_{R^k} f(x,y,u)\mu(du), \quad \int_{R^k} g(x,y,u)\mu(du), \quad \text{and} \quad \int_{R^k} c(x,y,u)\mu(du),$$

which are denoted, respectively, by $f(x,y,\mu)$, $g(x,y,\mu)$, and $c(x,y,\mu)$. It is clear that a control value u can be regarded as the relaxed control measure supported on the singleton $\{u\}$. (As commented on in Remarks 6.3 and 7.3, for a one-dimensional y, it will be enough to consider relaxed controls whose values are supported at any given time on either 3 points or on $(n+3)^2$ points, depending on the problem.)

An admissible relaxed control is a measurable mapping $\mu(\cdot)$ defined on $[0,1]$ and with values in the space of probability measures on R^k. We denote this space by $\mathcal{P}(R^k)$. The space $\mathcal{P}(R^k)$ is endowed with the metric of weak convergence of measures (see, e.g., Billingsley [8]), namely, μ_i converge as $i \to \infty$ to μ_0 if

$$\int_{R^k} h(u)\mu_i(du) \to \int_{R^k} h(u)\mu_0(du),$$

as $i \to \infty$, holds for every bounded and continuous real valued function $h(\cdot)$. Convergence of relaxed controls is taken in the sense of weak convergence of measures over $[0,1] \times R^k$ (see Warga [17]). In particular, the relaxed controls $\mu_i(\cdot)$ converge as $i \to \infty$ to the relaxed control $\mu_0(\cdot)$ if the convergence

$$\int_0^1 \int_{R^k} h(t,u)\mu_i(t)(du)dt \to \int_0^1 \int_{R^k} h(t,u)\mu_0(t)(du)dt,$$

as $i \to \infty$, holds for every bounded and continuous real valued function $h(\cdot,\cdot)$.

The order reduction variational limit of (1.1)–(1.3), with relaxed controls, is as follows:

$$\text{minimize} \quad \int_0^1 c(x(t),y(t),\mu(t))dt \tag{3.1}$$

subject to

$$\begin{aligned} \frac{dx}{dt} &= f(x,y,\mu), \\ 0 &= g(x,y,\mu), \end{aligned} \tag{3.2}$$

with initial condition

$$x(0) = x_0. \tag{3.3}$$

We wish to emphasize the difference between (1.4) and (3.2); namely, in (3.2), relaxed controls are employed. Notice that the initial condition for the fast variable does not appear in the limit problem. Indeed, as in the standard order reduction case, the near optimal trajectories of the perturbed system may exhibit a boundary layer near $t = 0$.

In order to explain our interpretation of the order reduction system, we now display an equivalent formulation as follows.

We view the pairs (y, μ), which solve the algebraic equation in (3.2), as admissible controls for the differential equation in (3.2). To this end, we define

$$V(x) = \{(y, \mu) : 0 = g(x, y, \mu)\}. \tag{3.4}$$

It is clear from the continuity assumption that the sets $V(x)$ are closed and the set valued map $x \to V(x)$ has a closed graph. Using the notation v for the pair (y, μ), the order reduction problem can now be rephrased as follows:

$$\text{minimize} \quad \int_0^1 c(x(t), v(t))dt \tag{3.5}$$

subject to

$$\begin{aligned} \frac{dx}{dt} &= f(x, v), \\ v &\in V(x), \end{aligned} \tag{3.6}$$

with the initial condition (3.3).

An admissible trajectory of (3.2)–(3.3) (equivalently, of (3.6), (3.3)), is a triplet of functions, $(x(\cdot), y(\cdot), \mu(\cdot))$, from $[0, 1]$ to $(R^n \times R^m \times \mathcal{P}(R^k))$ (the space $\mathcal{P}(R^k)$ was described earlier) such that $x(0) = x_0$ and such that both the differential and the algebraic equations in (3.2) are satisfied (equivalently, (3.6) is satisfied). (See Remark 8.6.)

As in the standard optimal control theory, relaxed controls may be needed for solving (3.5)–(3.6). Recall that here the controls are pairs $v = (y, \mu)$ of solutions of the algebraic equation, and include, in particular, stationary points of the fast variable. Hence the relaxation amounts to employing probability measures, say, ν, on the set $V(x)$ (the effect being the convexification of this set). The meaning of $c(x, \nu)$ and $f(x, \nu)$ for the relaxation of the order reduction is drawn in the usual manner, namely,

$$c(x, \nu) = \int_{V(x)} c(x, y, \mu)\nu(dy \times d\mu), \quad f(x, \nu) = \int_{V(x)} f(x, y, \mu)\nu(dy \times d\mu). \tag{3.7}$$

With a relaxed control ν over $V(x)$, namely, over pairs (y, μ), we associate its effective distribution, say, $N(\nu)$ over $R^m \times R^k$. Namely, the probability measure $N(\nu)$ is given by

$$N(\nu)(C \times D) = \int_{C \times M} \mu(D)\nu(dy \times d\mu) \tag{3.8}$$

with M being the family of probability measures on R^k. It is clear that $c(x, \nu) = c(x, N(\nu))$ and $f(x, \nu) = f(x, N(\nu))$, which justifies the term "effective distribution."

An admissible relaxed trajectory of (3.5)–(3.6) is now a pair $(x(\cdot), \nu(\cdot))$ of measurable functions from $[0, 1]$ into the product of R^n and the collection of probability measures over the pairs (y, μ) which belong to $V(x(t))$; this is true for almost every t and such that (3.2) is satisfied with ν replacing (y, μ). (Equivalently, when in (3.6), $V(x)$ is replaced by its convex hull.)

The cost of an admissible trajectory $(x(\cdot), \nu(\cdot))$ is $\int_0^1 c(x(t), \nu(t))dt$, employing the term $c(x, \nu)$ given in (3.7) (compare with (3.1)). In view of the boundedness

assumption, Assumption 2.1(iv), we consider only relaxed trajectories with uniformly bounded supports. (In particular, $x(\cdot)$ is bounded and absolutely continuous.) The cost of the trajectory is denoted by $\text{cost}_R(x(\cdot), \nu(\cdot))$ (or by $\text{cost}_R(x(\cdot), y(\cdot), \mu(\cdot))$ if the trajectory is not a relaxed one). The subscript R stands for reduction.

As is customary, the infimum of all admissible costs is the value of the optimization problem. We need two notions. We denote by val(OR) the infimum over all admissible trajectories which use relaxation only in the control, and we denote by val(ROR) the infimum of the costs over all admissible relaxed trajectories. (Here OR and ROR stand for order reduction and relaxed-order reduction, respectively.)

In general, val(ROR) may be strictly less than val(OR). This is demonstrated in Example 8.7. In our application, it is val(ROR) which plays the key role (see also Remark 8.8). We display in Proposition 8.9 conditions under which the two values coincide.

We now state our main general result.

THEOREM 3.1. *Let Assumption* 2.1 *hold, and suppose that the fast variable y is a scalar. Then the following hold:*

(i) *The values val(ε) converge to val(ROR) as $\varepsilon \to 0$.*

(ii) *An optimal admissible relaxed trajectory of the order reduction problem exists.*

(iii) *For any admissible relaxed trajectory $(\bar{x}(\cdot), \bar{\nu}(\cdot))$, there exists a sequence $u_\varepsilon(\cdot)$ of control functions such that $\text{cost}_\varepsilon(u_\varepsilon(\cdot))$ converges to $\text{cost}_R(\bar{x}(\cdot), \bar{\nu}(\cdot))$ as $\varepsilon \to 0$, and the triplets $(x_\varepsilon(\cdot), y_\varepsilon(\cdot), u_\varepsilon(\cdot))$, resulting from the solution of* (1.2)–(1.3), *converge to $(\bar{x}(\cdot), \bar{\nu}(\cdot))$ as follows. The convergence of the slow dynamics component is uniform on $[0, 1]$. The pairs $(y_\varepsilon(\cdot), u_\varepsilon(\cdot))$ converge, in the sense of relaxed control, to the probability measure valued function $N(\bar{\nu}(\cdot))$. In particular, if the admissible relaxed solution $(x(\cdot), \nu(\cdot))$ is optimal for the order reduction system, then the controls $u_\varepsilon(\cdot)$ are near optimal for the original system when ε is small.*

4. The case of fast dynamics. As explained in the introduction, the results are sharper in the case where the slow variable x is absent from the control problem. This case is examined in the present section.

For completeness, we restate the optimal control problem without the slow variable. The problem then is as follows:

$$\text{minimize} \quad \int_0^1 c(y(t), u(t))dt \tag{4.1}$$

subject to

$$\varepsilon \frac{dy}{dt} = g(y, u), \tag{4.2}$$

with initial condition

$$y(0) = y_0. \tag{4.3}$$

The main result in this case takes a particular form as follows. Since the control problem is time-independent and the x variable, which acts as a parameter for the fast dynamics in the full problem, is absent, it is clear that the order reduction problem (4.1)–(4.3) reduces (see, however, Remark 6.2 and Examples 8.3 and 8.4) to the following optimization problem:

$$\text{minimize} \quad c(y, \mu) \tag{4.4}$$

subject to

$$0 = g(y, \mu), \tag{4.5}$$

where μ is a relaxed control. Notice that, again, the initial condition for the fast variable does not appear in the limit problem.

As in the full problem, we denote by val(ε) the optimal value of the problem (4.1)–(4.3), and we denote by val(OR) the optimal value of the problem (4.4)–(4.5). (In the present case, there is no need to use the relaxation of the fast variable; hence we do not refer to val(ROR).) The functions cost_ε and cost_R have the same meaning as in the full problem. When we refer to Assumption 2.1 in the present case, we interpret it with the absence of the x variable.

THEOREM 4.1. *Consider the optimal control problem* (4.1)–(4.3) *and the order reduction limit* (4.4)–(4.5), *both under Assumption* 2.1, *and when the fast variable y is one-dimensional. Then the following hold:*

(i) *val(ε) converges to val(OR) as $\varepsilon \to 0$.*

(ii) *An optimal solution $(\bar{y}, \bar{\mu})$ of the order reduction system exists.*

(iii) *For any solution $(\bar{y}, \bar{\mu})$ of the order reduction equation* (4.5), *there exists a bounded sequence $u_\varepsilon(\cdot)$ of control functions such that $\text{cost}_\varepsilon(u_\varepsilon(\cdot))$ converges to $\text{cost}_R(\bar{y}, \bar{\mu})$ as $\varepsilon \to 0$, and the pairs $(y_\varepsilon(\cdot), u_\varepsilon(\cdot))$, resulting from the solution of* (4.2)–(4.3), *converge to the constant function $(\bar{y}, \bar{\mu})$ as follows. The convergence of the y-component is uniform on any subinterval $[\delta, 1]$ with $\delta > 0$. The control functions $u_\varepsilon(\cdot)$ converge to $\bar{\mu}$ in the sense of relaxed controls. In particular, if $(\bar{y}, \bar{\mu})$ is an optimal solution of* (4.4)–(4.5), *then the control $u_\varepsilon(\cdot)$ forms a near optimal control for the original problem* (4.1)–(4.3) *when ε is small.*

5. Two key lemmas. In this section, we display two auxiliary results which hold the key to the main results of the paper, as they capture the role played by y being one-dimensional. The results are similar and have similar proofs, yet it is easier to provide independent proofs than to reduce one case to the other. The two results are independent of the optimality considerations of the singularly perturbed problem.

We start with a construction as follows. Let $(y_i(\cdot), u_i(\cdot))$ be a uniformly bounded family of functions from $[0, 1]$ into $R^m \times R^k$. (Indeed, we think of them as the fast trajectories and controls of a singularly perturbed system.) For each i, let P_i be the distribution of the mapping $(y_i(\cdot), u_i(\cdot))$ in $R^m \times R^k$. Namely, P_i is the probability measure given by

$$P_i(B) = \lambda(\{t : (y_i(t), u_i(t)) \in B\}) \tag{5.1}$$

for every Borel set B and where λ is the Lebesgue measure on the unit interval. Assume that the measures P_i converge in the sense of weak convergence of probability measures. Let the limit probability measure of P_i on $R^m \times R^k$ be denoted by P.

Let P^1 be the marginal measure of P on the fast coordinate space R^m; namely,

$$P^1(C) = P(C \times R^k) \tag{5.2}$$

for all Borel sets $C \subseteq R^m$. The superscript 1 indicates that the marginal is taken on the first coordinate, but also recall that we assume that, and later use, $m = 1$.

It is clear that P^1 is a probability measure on R^m. Let $\mu(\cdot)$ be the disintegration of P with respect to P^1. Namely, for P^1-almost every y, the measure $\mu(y)$ is a

probability measure on R^k, which depends measurably on y, and such that, for Borel subsets C of R^m and D of R^k,

$$P(C \times D) = \int_C \mu(y)(D) P^1(dy). \tag{5.3}$$

The construction is a standard one; see, e.g., Ash [6]. It is valid for any finite-dimensional fast dynamics. The following result depends on y being one-dimensional.

LEMMA 5.1. *Suppose that the variable y is scalar, and suppose that, for every i, the pair $(y_i(\cdot), u_i(\cdot))$ satisfies the differential equation*

$$\varepsilon_i \frac{dy}{dt} = g(y, u) \tag{5.4}$$

with $\varepsilon_i \to 0$ and with $g(\cdot, \cdot)$ continuous. Then $g(y, \mu(y)) = 0$ for P^1-almost every y.

Proof. The condition $g(y, \mu(y)) = 0$ means that

$$\int_{R^k} g(y, u) \mu(y)(du) = 0. \tag{5.5}$$

Clearly, it is enough to prove that

$$\int_{y_1}^{y_2} \int_{R^k} g(y, u) \mu(y)(du) P^1(dy) = 0 \tag{5.6}$$

whenever $[y_1, y_2]$ is an interval in the one-dimensional space, and such that y_1 and y_2 are not atoms of the marginal measure P^1. Equivalently, it is enough to verify that

$$\int_{[y_1, y_2] \times R^k} g(y, u) P(dy \times du) = 0 \tag{5.7}$$

for such intervals. Denote

$$J_i = \{t : (y_{\varepsilon_i}(t), u_{\varepsilon_i}(t)) \in [y_1, y_2] \times R^k\}. \tag{5.8}$$

The definition of P as the limit of the distributions P_i and the continuity of the function $g(y, u)$ together with the boundedness assumption on the controls and trajectories imply that the left-hand side of (5.7) is the limit, as $i \to \infty$, of

$$\int_{J_i} g(y_i(t), u_i(t)) dt. \tag{5.9}$$

For a fixed i, we divide the set J_i into three parts and perform the integration in (5.9) on each part separately.

Let $J_{i,1}$ be the subset of points t in J_i which do not belong to an interval, say, $[t_1, t_2]$, included in J_i. Then, for $t \in J_{i,1}$ (except possibly for $t = 0$ and $t = 1$), the derivative of $y_i(\cdot)$ at t, if it exists, must be equal to 0. Otherwise, on one side at least, the trajectory would enter the interval $[y_1, y_2]$. Since $(y_i(\cdot), u_i(\cdot))$ is a solution of the ordinary differential equation, this derivative exists λ-almost everywhere, and, since the differential equation is (5.4), it follows that $g(y_i(t), u_i(t)) = 0$ for λ-almost every t in $J_{i,1}$. Hence, when the integration (5.9) is performed on $J_{i,1}$, the value is 0.

Consider now a maximal interval $[t_1, t_2]$ included in J_i. Then $y_i(t_1)$ and $y_i(t_2)$ take as values either y_1 or y_2. Consider the case where $y_i(t_1) = y_i(t_2)$, say, where they both are equal to y_1. From (5.4) we deduce that

$$\int_{t_1}^{t_2} g(y_i(t), u_i(t))dt = \varepsilon_i y_1 - \varepsilon_i y_1 = 0 \tag{5.10}$$

and likewise when the common value is y_2. Let $J_{i,2}$ denote the union of such intervals in J_i. Then, when the integration (5.9) is performed on $J_{i,2}$, the value is again 0.

The rest of the set J_i (call it $J_{i,3}$) consists of intervals $[t_{1,j}, t_{2,j}]$ such that $y_i(t_{1,j}) \neq y_i(t_{2,j})$. In particular, there are only a finite number, say, r, of such intervals, and, moreover, if the index j signifies the order of these intervals, it follows that $y_i(t_{2,j}) = y_i(t_{1,j+1})$. In particular, when the integration (5.9) is performed on $J_{i,3}$, employing the differential equation (5.4), we get

$$\int_{J_{i,3}} g(y_i(t), u_i(t))dt = \sum_j \varepsilon_i(y_i(t_{2,j}) - y_i(t_{1,j})) = \varepsilon_i y_i(t_{2,r}) - \varepsilon_i y_i(t_{1,1}). \tag{5.11}$$

All in all, the integral (5.9) is the sum of the integrals on $J_{i,1}$, $J_{i,2}$, and $J_{i,3}$; namely, it is equal to the value exhibited in (5.11). Since the trajectories are uniformly bounded, it follows that, as $\varepsilon_i \to 0$, the integral (5.9) tends to zero. By the construction of J_i, the desired equality (5.7) is verified, and the proof is complete. ∎

Remark 5.2. The proof, specifically the arguments leading to (5.10) and (5.11), relies heavily on y being one-dimensional. The result does not hold in higher dimensions, as, e.g., Example 7.4 in [5], Example 10.2 in [3], or Example 10.1 in [4] show. A weaker result, however, does hold in higher dimensions, namely, that integrating $g(y, u)$ against P is equal to zero. This was established (in a slightly different context) in Artstein [1, (4.2)].

For the second auxiliary result, we need the following construction. We start again with a uniformly bounded family of functions $(y_i(\cdot), u_i(\cdot))$ from $[0, 1]$ into $R^m \times R^k$. We assume now that the functions converge in the sense of relaxed controls; namely, there exists a measure valued function $\eta(\cdot)$ on $[0, 1]$, with each value $\eta(t)$ being a probability measure on $R^m \times R^k$ such that

$$\int_0^1 h(t, y_i(t), u_i(t))dt \to \int_0^1 \int_{R^m \times R^k} h(t, y, u)\eta(t)(dy \times du)dt, \tag{5.12}$$

as $i \to \infty$, holds for every bounded and continuous real valued function $h(\cdot, \cdot, \cdot)$.

For a fixed t, we construct the marginals as in the preceding construction; namely, let $\eta^1(t)$ be the marginal of $\eta(t)$ on R^m, and let $\mu(t, \cdot)$ be the disintegration of $\eta(t)$ with respect to $\eta^1(t)$. (At this point, it is not clear how to get the measurable dependence of $\mu(\cdot, y)$, but, as we shall see, it will follow from the derivations.)

LEMMA 5.3. *Suppose that the variable y is scalar, and suppose that, for every i, the pair $(y_i(\cdot), u_i(\cdot))$ satisfies a differential equation*

$$\varepsilon_i \frac{dy}{dt} = g(x_i(t), y, u) \tag{5.13}$$

with $\varepsilon_i \to 0$, with $x_i(\cdot) : [0, 1] \to R^n$ being a uniformly converging prescribed sequence (say, the limit is $x_0(\cdot)$), and with $g(\cdot, \cdot, \cdot)$ continuous. Then, for λ-almost every t, the equality $g(x_0(t), y, \mu(t, y)) = 0$ holds for $\eta^1(t)$-almost every y.

Proof. We start as in the previous proof. Verifying $g(x_0(t), y, \mu(t, y)) = 0$ for t fixed amounts to

$$\int_{R^k} g(x_0(t), y, u)\mu(t, y)(du) = 0. \tag{5.14}$$

Clearly, it is enough to prove that

$$\int_{y_1}^{y_2} \int_{R^k} g(x_0(t), y, u)\mu(t, y)(du)\eta^1(t)(dy) = 0 \tag{5.15}$$

for intervals $[y_1, y_2]$ with a dense family of end points in the one-dimensional space. Equivalently, it is enough to verify that

$$\int_{[y_1,y_2]\times R^k} g(x_0(t), y, u)\eta(t)(dy \times du) = 0 \tag{5.16}$$

for such intervals. Since $\eta(\cdot)$ is measurable (and by this we overcome the difficulty of establishing that $\mu(\cdot, y)$ is measurable), it follows that, in order to verify the equality (5.16) for λ-almost every t, it is enough to verify that

$$\frac{1}{2\delta} \int_{t-\delta}^{t+\delta} \int_{[y_1,y_2]\times R^k} g(x_0(t), y, u)\eta(s)(dy \times du)ds \tag{5.17}$$

converges to 0 as $\delta \to 0$. The continuity of $g(\cdot, \cdot, \cdot)$ and the continuity of $x_0(\cdot)$ imply that it is enough to establish the convergence to 0 of the integration in (5.17) when the constant $x_0(t)$ is replaced by the function $x_0(\cdot)$. For convenience, we display the formula with this change:

$$\frac{1}{2\delta} \int_{t-\delta}^{t+\delta} \int_{[y_1,y_2]\times R^k} g(x_0(s), y, u)\eta(s)(dy \times du)ds. \tag{5.18}$$

Since the function $\eta(\cdot)$ is the relaxed control limit of the distributions of $(y_i(\cdot), u_i(\cdot))$, it follows from (5.12) and from Theorem 2.1(v) in Billingsley [8] that, if we assume that the points y_1, y_2 are such that the integral over $[t - \delta, t + \delta]$ of the η-measure of $\{y_1\} \times R^k$ is zero and likewise with y_2, we get that (5.18) is the limit as $i \to \infty$ of

$$\frac{1}{2\delta} \int_{J_i} g(x_0(s), y_i(s), u_i(s))ds \tag{5.19}$$

with

$$J_i = \{s \in [t - \delta, t + \delta] : (y_i(s), u_i(s)) \in [y_1, y_2] \times R^k\}. \tag{5.20}$$

It is clear that there exists a dense sequence of points in R with the properties demanded of y_1 and y_2. Since the function g is continuous, the convergence of $x_i(\cdot)$ to $x_0(\cdot)$ implies that the integral in (5.19) shares the same limit, as $i \to \infty$, with

$$\frac{1}{2\delta} \int_{J_i} g(x_i(s), y_i(s), u_i(s))ds. \tag{5.21}$$

We now show that the quantity (5.21) converges to 0 as $i \to \infty$. This, in view of the chain of arguments, would complete the proof.

To this end, we proceed in a way similar to the proof of the preceding lemma. Since the arguments are delicate, we provide the details as follows.

For a fixed i, we divide the set J_i into three parts and perform the integration in (5.21) on each part separately.

Let $J_{i,1}$ be the subset of points s in J_i which do not belong to an interval, say, $[s_1, s_2]$, included in J_i. Then, if the derivative $\frac{dy_i}{ds}(\cdot)$ exists at $s \in J_{i,1}$, it must be equal to 0 (except possibly for $s = t - \delta$ and $s = t + \delta$). Otherwise, on one side at least, the trajectory would enter the interval $[y_1, y_2]$. Since $(y_i(\cdot), u_i(\cdot))$ solves the differential equation (5.13), it follows that the derivative exists λ-almost everywhere, and then $g(x_i(s), y_i(s), u_i(s)) = 0$. Hence, when the integration (5.21) is performed on $J_{i,1}$, the value is 0.

Consider now a maximal interval $[s_1, s_2]$ included in J_i. Then $y_i(s_1)$ and $y_i(s_2)$ take as values either y_1 or y_2. Consider the case where $y_i(s_1) = y_i(s_2)$, say, where both are equal to y_1. From (5.13), we deduce that

$$\frac{1}{2\delta}\int_{s_1}^{s_2} g(x_i(s), y_i(s), u_i(s))ds = \varepsilon_i y_1 - \varepsilon_i y_1 = 0 \tag{5.22}$$

and likewise when the common value is y_2. Let $J_{i,2}$ denote the union of such intervals in J_i. Then, when the integration (5.21) is performed on $J_{i,2}$, the value is again 0.

The rest of the set J_i (call it $J_{i,3}$) consists of intervals $[s_{1,j}, s_{2,j}]$ such that $y_i(s_{1,j}) \neq y_i(s_{2,j})$. In particular, there are only a finite number, say, r, of such intervals in $[t - \delta, t + \delta]$, and, moreover, if the index j signifies the order of these intervals, it follows that $y_i(s_{2,j}) = y_i(s_{1,j+1})$. In particular, when the integration (5.21) is performed on $J_{i,3}$, employing the differential equation (5.13), we get

$$\begin{aligned}\frac{1}{2\delta}\int_{J_{i,3}} g(x_i(s), y_i(s), u_i(s))ds &= \sum_j \varepsilon_i(y_i(s_{2,j}) - y_i(s_{1,j})) \\ &= \varepsilon_i y_i(s_{2,r}) - \varepsilon_i y_i(s_{1,1}).\end{aligned} \tag{5.23}$$

All in all, the integral (5.21) is the sum of the integrals on $J_{i,1}$, $J_{i,2}$, and $J_{i,3}$; namely, it is equal to the value exhibited in (5.23). Since the trajectories are uniformly bounded, it follows that, as $i \to 0$, the integral (5.21) tends to zero. This verifies the desired convergence, and the proof is complete. □

6. Proof of Theorem 4.1. Let $u_\varepsilon(\cdot)$ be the uniformly bounded family of near optimal controls for ε small, guaranteed by Assumption 2.1(iv). Let $y_\varepsilon(\cdot)$ be the resulting trajectories of the fast variable. The assumption implies, in particular, that the pairs $(y_\varepsilon(\cdot), u_\varepsilon(\cdot))$ are uniformly bounded. We fix a subsequence ε_i such that

$$\liminf_{\varepsilon \to 0} \quad \text{val}(\varepsilon) = \lim_{\varepsilon_i \to 0} \quad \text{val}(\varepsilon_i). \tag{6.1}$$

We refer now to the construction in section 5 with $(y_i(\cdot), u_i(\cdot))$ being $(y_{\varepsilon_i}(\cdot), u_{\varepsilon_i}(\cdot))$. We may also choose the sequence such that the distributions P_i, as defined in (5.1), converge, say, to P. The continuity of the cost functional together with Assumption 2.1(iv) and (6.1) imply that

$$\liminf_{\varepsilon \to 0} \quad \text{val}(\varepsilon) = \int_{R \times R^k} c(y, u)P(dy \times du). \tag{6.2}$$

Let P^1 be the marginal of P on R, and let $\mu(\cdot)$ be the disintegration of P with respect to P^1, as was described at the beginning of section 5. Then

$$\int_{R\times R^k} c(y,u)P(dy\times du) = \int_R \int_{R^k} c(y,u)\mu(y)(du)P^1(dy). \tag{6.3}$$

The right-hand side of (6.3) can be written as $\int_R c(y,\mu(y))P^1(dy)$. Since, by Lemma 5.1, each pair $(y,\mu(y))$ in the latter integral satisfies $g(y,\mu(y))=0$, namely, it solves (4.5), it follows that

$$\liminf_{\varepsilon\to 0} \quad \mathrm{val}(\varepsilon) \geq \mathrm{val}(OR). \tag{6.4}$$

This verifies one direction of claim (i) in Theorem 4.1.

All of the values of $(y_\varepsilon(\cdot), u_\varepsilon(\cdot))$ are in one compact set, say, $\bar{B}$. Since the function $g(y,u)$ is continuous, it follows that the family of admissible pairs $(y,\mu(y))$ supported in $\bar{B}$ is compact. The continuity of $c(y,u)$ implies, therefore, that, among these pairs, a minimizer of $c(y,\mu)$ exists. Let $(\bar{y},\bar{\mu}(\bar{y}))$ be this minimizer. We show later that this minimizer is an optimal solution of the reduced-order problem (4.4)–(4.5).

At this point, we ignore the optimality property of $(\bar{y},\bar{\mu}(\bar{y}))$ and the fact that it is supported on $\bar{B}$ and regard it as a general admissible solution of (4.5). We now construct the family $u_\varepsilon(\cdot)$ promised in claim (iii) of the theorem. The controllability assumption, Assumption 2.1(iii), implies the existence of a bounded control function, say, $w(\cdot)$, defined on, say, the interval $[0,S]$, such that the solution of $\frac{dy}{ds} = g(y,w(s))$ with $y(0)=y_0$ satisfies $y(S)=\bar{y}$. We define $u_\varepsilon(t) = w(\varepsilon^{-1}t)$. It is clear then that the solution $y_\varepsilon(\cdot)$ of (4.2)–(4.3), resulting by applying this control function, satisfies $y_\varepsilon(\varepsilon S)=\bar{y}$. If relaxed controls were permissible on $[\varepsilon S,1]$, we could use $\bar{\mu}(\bar{y})$ on this interval, and claim (iii) of the theorem would be satisfied. However, since such relaxed controls are not allowed, we have to resort to the classical approximation of a relaxed control by ordinary controls (see, e.g., Warga [17]). In fact, given a fixed ε, for an arbitrary desired approximation, there exists an ordinary control function $u_\varepsilon(\cdot)$ on $[\varepsilon S,1]$ such that the resulting trajectory $y_\varepsilon(\cdot)$ stays close to $\bar{y}$ during $[\varepsilon S,1]$ and such that $u_\varepsilon(\cdot)$ approximates, as relaxed controls, the constant relaxed control $\bar{\mu}(\bar{y})$. The continuity of $c(y,u)$ implies then that $\mathrm{cost}_\varepsilon(u_\varepsilon(\cdot))$ approximates $\mathrm{cost}_R(\bar{y},\bar{\mu})$. This verifies the construction required by claim (iii) of the theorem.

The preceding construction implies, in particular, that

$$\limsup_{\varepsilon\to 0} \quad \mathrm{val}(\varepsilon) \leq \mathrm{val}(OR), \tag{6.5}$$

and, together with (6.4), claim (i) of the theorem is complete.

Recall that the specific pair $(\bar{y},\bar{\mu}(\bar{y}))$ was optimal only among those admissible relaxed controls supported on $\bar{B}$. However, the construction verifying claim (iii) of the theorem together with (6.2) imply that $\mathrm{cost}_R(\bar{y},\bar{\mu}(\bar{y}))$ is less than or equal to $\mathrm{val}(OR)$. In particular, the pair $(\bar{y},\bar{\mu}(\bar{y}))$ is actually optimal for the order reduction problem (4.4)–(4.5). Hence claim (ii) of the theorem is verified as well. This completes the proof of Theorem 4.1. □

Remark 6.1. In retrospect, (6.2) and (6.3) imply that, when the disintegration P_1 is carried out, P_1-almost every pair $(y,\mu(y))$ is an optimal solution of the order reduction problem (4.4)–(4.5). Indeed, the integral of their costs is equal to the infimal value of the cost.

Remark 6.2. The result of this section establishes the existence of an optimal solution to the order reduction problem (4.4)–(4.5) which is constant over $[0,1]$. The

case may be, however, that the minimization problem has more than one solution. In such a case, any measurable function $(y(t), \mu(t))$ which solves (4.4)–(4.5) pointwise can be regarded as a solution to the order reduction problem. In turn, such a solution would, in a manner similar to the above construction, yield near optimal solutions, which are not nearly constant, to the original singular perturbations problem.

Remark 6.3. The probability measure in the optimal pair $(\bar{y}, \bar{\mu}(\bar{y}))$ as established in the proof may be a general one. However, since it needs only to satisfy the two scalar equalities $g(\bar{y}, \bar{\mu}(\bar{y})) = 0$ and $c(\bar{y}, \bar{\mu}(\bar{y})) = \mathrm{val}(OR)$, it follows from standard arguments (see, e.g., Berkovitz [7]) that, for the same fast state $\bar{y}$, there exists an optimal probability measure which is supported on three points in R^k.

7. Proof of Theorem 3.1. We proceed along the reasoning of the proof of Theorem 4.1 in the preceding section but with the appropriate modifications.

Let $u_\varepsilon(\cdot)$ be the uniformly bounded family of near optimal controls for ε small guaranteed by Assumption 2.1(iv). Let $(x_\varepsilon(\cdot), y_\varepsilon(\cdot))$ be the resulting trajectories of the slow and fast variables. The assumption implies, in particular, that the pairs $(y_\varepsilon(\cdot), u_\varepsilon(\cdot))$ are uniformly bounded. We fix a subsequence ε_i such that

$$\liminf_{\varepsilon \to 0} \quad \mathrm{val}(\varepsilon) = \lim_{\varepsilon_i \to 0} \quad \mathrm{val}(\varepsilon_i). \tag{7.1}$$

We refer now to the construction preceding Lemma 5.3 in section 5, with $(y_i(\cdot), u_i(\cdot))$ being $(y_{\varepsilon_i}(\cdot), u_{\varepsilon_i}(\cdot))$. We may also choose the sequence such that the sequence $x_{\varepsilon_i}(\cdot)$ converges uniformly on $[0, 1]$, say, to $x_0(\cdot)$, and that $(y_i(\cdot), u_i(\cdot))$ converges in the sense of relaxed controls, say, to $\eta(\cdot)$, as defined in (5.12). The limit $(x_0(\cdot), \eta(\cdot))$ constitutes an admissible relaxed trajectory as described in section 3. The continuity of the cost functional together with Assumption 2.1(iv) and (7.1) imply that

$$\liminf_{\varepsilon \to 0} \quad \mathrm{val}(\varepsilon) = \int_0^1 \int_{R \times R^k} c(x_0(t), y, u) \eta(t)(dy \times du) dt. \tag{7.2}$$

Let $\eta^1(t)$ be the marginal of $\eta(t)$ on R, and let $\mu(t, \cdot)$ be the disintegration of $\eta(t)$ with respect to $\eta^1(t)$, as was described in section 5. Then, for every fixed t,

$$\int_{R \times R^k} c(x_0(t), y, u) \eta(t)(dy \times du) = \int_R \int_{R^k} c(x_0(t), y, u) \mu(t, y)(du) \eta^1(t)(dy). \tag{7.3}$$

The right-hand side of (7.3) can be written as $\int_R c(x_0(t), y, \mu(t, y)) \eta^1(t)(dy)$. In view of Lemma 5.3, each triplet $(x_0(t), y, \mu(t, y))$ in the latter integral satisfies $g(x_0(t), y, \mu(t, y)) = 0$; namely, it solves the algebraic equation in (3.2) for $\eta^1(t)$-almost every y. In particular, the measure $\eta^1(t)$ can be interpreted as a measure on the graph of the pairs $(y, \mu(y))$, and, as such, it constitutes a relaxation of admissible controls in $V(x_0(t))$; see (3.4). The equalities in (7.1), (7.2), and (7.3) imply now that

$$\liminf_{\varepsilon \to 0} \quad \mathrm{val}(\varepsilon) \geq \mathrm{val}(ROR). \tag{7.4}$$

This verifies one direction of claim (i) in Theorem 3.1. (Notice that we verified (7.4) with the value ROR only; this is unlike the case in Theorem 4.1, where equality with the value OR was established. Example 8.7 shows that (7.4) may not hold with $\mathrm{val}(OR)$.)

All of the values of $(x_\varepsilon(\cdot), y_\varepsilon(\cdot), u_\varepsilon(\cdot))$ are in one compact set, say, $\bar{D}$, and the trajectories $x_\varepsilon(\cdot)$ form a compact family. Since the function $g(x, y, u)$ is continuous, it

follows that the family of admissible pairs $\{(x,v) : v \in V(x)\}$, which are supported in the natural sense in $\bar{D}$, is compact. The continuity of $c(x,y,u)$ implies, therefore, that, among the admissible relaxed solutions $(x(\cdot),\nu(\cdot))$, there exists a minimizer of the cost functional. Let $(\bar{x}(\cdot),\bar{\nu}(\cdot))$ be this minimizer. We show later that this minimizer is an optimal solution of the reduced-order problem (3.1)–(3.3), with the relaxation as described in section 3.

At this point, we ignore the optimality property of $(\bar{x}(\cdot),\bar{\nu}(\cdot))$ and the fact that it is supported on $\bar{D}$, and we regard it as a general admissible relaxed solution. We now construct the family $u_\varepsilon(\cdot)$ promised in claim (iii) of the theorem.

Each $\bar{\nu}(t)$ is a probability measure on pairs $(y,\mu(y))$, which satisfy $g((\bar{x}(t),y,\mu(y))) = 0$. Recall the notion of the effective distribution of such probability measures, namely, $N(\nu)$ as defined in (3.8).

Consider for t fixed the differential equation

$$\frac{dy}{ds} = g(\bar{x}(t),y,u). \tag{7.5}$$

Claim 7.1. *The distribution $N(\bar{\nu}(t))$ can be approximated up to an arbitrarily desired approximation by the distribution of solutions $(y(\cdot),u(\cdot))$ to the differential equation* (7.5) *on some interval* $[0,S]$.

The proof provided here follows standard considerations (see, e.g., Warga [17]), employing the controllability in Assumption 2.1(iii) and the fact that $\bar{\nu}(t)$ is a probability measure on pairs which make the right-hand side of (7.5) equal to 0. (Without this property, the construction may not be possible; see Remark 7.2.) We can first approximate $\bar{\nu}(t)$ by a probability measure supported on a finite number of points, say, $(y_1,\mu_1),\dots,(y_r,\mu_r)$, with weights $p_1,\dots,p_r$ (see also Remark 7.3). Then on subsequent intervals we use the following strategy. At the beginning of the jth interval, we use the controllability to steer the trajectory to y_j. Then, for most of the interval, we use an arbitrarily close control approximation to the relaxed control $\mu_j(y_j)$. The fact that $g(\bar{x}(t),y_j,\mu_j) = 0$ implies that the solution $y(\cdot)$ will stay close to y_j on the rest of the interval. Now we take the lengths of these intervals in proportion to the weights p_j, and the claim is proved □

Notice that if, instead of (7.5), we use the original singularly perturbed equation in (3.2) and set the initial time to be t, the preceding construction will take place on the interval $[t,t+\varepsilon S]$. If t is chosen as a Lebesgue point of $N(\nu(\cdot))$, we get an approximation of the latter on a small interval. Given the relaxed trajectory $(\bar{x}(\cdot),\bar{\nu}(\cdot))$ and using the fact that the measure valued component is measurable (hence almost all its points are Lebesgue points), we can construct a piecewise approximation to the effective distribution $N(\bar{\nu}(t))$. Since the functions f and c are continuous and the measures have uniformly bounded support, the continuous dependence with respect to relaxed controls implies that the resulting slow trajectories will be uniformly close to $\bar{x}(\cdot)$. This verifies claim (iii) in Theorem 3.1.

The preceding construction implies, in particular, that

$$\limsup \quad \mathrm{val}(\varepsilon) \le \mathrm{val}(ROR), \tag{7.6}$$

and, together with (7.4), claim (i) of the theorem is complete.

Recall that the specific trajectory $(\bar{x}(\cdot),\bar{\nu}(\cdot))$ was optimal only among those admissible relaxed controls supported on $\bar{D}$. However, the construction verifying claim (iii) of the theorem together with (7.2) imply that $\mathrm{cost}_R(\bar{x}(\cdot),\bar{\nu}(\cdot))$ is less than or equal to $\mathrm{val}(ROR)$. In particular, the pair $(\bar{x}(\cdot),\bar{\nu}(\cdot))$ is actually optimal for the order

reduction problem (3.1)–(3.3). Hence claim (ii) of the theorem is verified as well. This completes the proof of Theorem 3.1 □

Remark 7.2. The approximation claimed in Claim 7.1 depends on the fact that the pairs $(y, \mu(y))$ satisfy the algebraic equation in the order reduction system. Controllability itself does not imply existence of an approximation to a given relaxed control, as the fast variable will not stay close to a constant on the long interval.

Remark 7.3. Along the reasoning of the argument in Remark 6.3, we note that the effective probability measure in the optimal admissible relaxed solution $(\bar{x}(\cdot), \bar{\nu}(\cdot))$, as established in the proof, may be a general one. However, since at each t only the values $g(\bar{x}(t), \bar{\nu}(t))$, $c(\bar{x}(t), \bar{\nu}(t))$, and $f(\bar{x}(t), \bar{\nu}(t))$ count, it follows from standard arguments (see, e.g., Berkovitz [7]) that an optimal relaxed control $\bar{\nu}(t)$ exists which, for each t, is supported on $n + 3$ points. These points are of the form (y, μ), where μ is a probability measure on R^k. For each y in the $n + 3$ points in the support, the values of $g(\bar{x}(t), y, \mu)$, $c(\bar{x}(t), y, \mu)$, and $f(\bar{x}(t), y, \mu)$ can be generated by $n + 3$ points in R^k. All in all, an optimal relaxed control can be found which, for each t, is supported on $(n + 3)^2$ points in R^k.

8. Extensions, examples, and remarks. In this section, we collect some remarks and examples concerning possible and impossible extensions of the main results.

Remark 8.1. It is clear that the choice of $[0, 1]$ as the integration domain in the problem is for convenience only, as any finite time interval will do. The restriction to a time-invariant equation is also done for convenience. If the cost and the right-hand side of (1.2) were also functions of t, we could add the time variable to the slow dynamics via the standard equation $\frac{dt}{dt} = 1$ and reduce the problem to a time-invariant one. Since no restrictions were put on the dimensionality of the slow variable, the results follow. The linear structure of the space R^k of controls is not used. It is enough to assume that $u \in U$, where U is a locally compact metric space (e.g., a closed, not necessarily convex, subset of R^k). A bounded set in U is then a set with a compact closure.

Remark 8.2. A particular case is where the dynamics does not depend on the u variable. Our result implies then that, when the variable y is one-dimensional, replacing the differential equation for the fast variable by the algebraic equation depicts the limit behavior of the solutions as $\varepsilon \to 0$. This particular observation follows easily from the approach displayed in Artstein and Vigodner [5]. In fact, what is proved there is that bounded fast solutions converge, as $\varepsilon \to 0$, to invariant measures of the fast equation (for a fixed slow state). It is easy to see that invariant measures of a one-dimensional equation are supported on equilibria.

Example 8.3. Arguments for using relaxed controls in the order reduction problem can be displayed along the reasoning of the traditional justification of relaxation. For instance, suppose that, in (4.1)–(4.3), $c(y, u) = y^2 + (1 - |u|)^2$, $g(y, u) = u$, and $y(0) = 0$. Then, already for the original singularly perturbed equation, the only optimal solution is a relaxed one, namely, the constant measure equally distributed over $\{-1, 1\}$. The next example is more telling.

Example 8.4. We display here an example where ordinary solutions for the perturbed equations exist, but their limit is not easily captured by the order reduction method. (Yet it can be interpreted along other methods suggested in the literature.) Furthermore, without relaxing the controls, the order reduction does not provide a solution at all. We also point out the solution yielded by the order reduction equation

with relaxation.

Consider the problem (4.1)–(4.3) with $c(y,u) = 0$ when $y \in [-2,2]$ and $|u| = 1$, and $c(y,u) > 0$ otherwise. Also, let $g(y,u) = u$ and $y(0) = 0$. It is easy to figure out an optimal control for each fixed ε. Indeed, the control function $u_\varepsilon(\cdot)$ should alternate between the values $+1$ and -1, with the switching occurring when the function $y_\varepsilon(\cdot)$ (which is the integral of $\varepsilon^{-1}u_\varepsilon(\cdot)$) reaches the values $+2$ and -2, respectively. The limit, as $\varepsilon \to 0$, of these solutions can be described in the language of invariant measures and limit occupational measures, as developed in Artstein [2], Artstein and Gaitsgory [3], [4], Gaitsgory and Leizarowitz [12], and Vigodner [16]. Indeed, the limit of the trajectories $(y_\varepsilon(\cdot), u_\varepsilon(\cdot))$ is an appropriate measure over $[-2,2] \times \{-1,1\}$. No single element in the support of this measure satisfies the algebraic equation in the order reduction system. In particular, this solution cannot be captured by the order reduction method. The present paper guarantees, however, that there exists a relaxed optimal solution of the order reduction system, for instance, the probability measure distributed equally on $\{-1,1\}$ applied to any stationary fast state in $[-2,2]$.

Example 8.5. The need for relaxation of the stationary fast dynamics in (1.1)–(1.3) in order to obtain an optimal solution can be derived from standard arguments. For instance, consider the problem with scalar variables, where the cost is $c(x,y,u) = x^2 + (|y|-1)^2$, and the equations are determined by $f(x,y,u) = y$ and $g(x,y,u) = u$. It is clear that an optimal solution to the reduced-order problem employs the measure on the y variable which is distributed equally on $y = 1$ and $y = -1$. This example does not demonstrate the need of relaxation in depicting the limit of the values, as here $\mathrm{val}(OR) = \mathrm{val}(ROR)$. This need is demonstrated later.

Remark 8.6. Notice that, unlike in the differential equations (1.2), the control (be it ordinary or relaxed) in the order reduction may not determine the dynamics; namely, given μ, the algebraic equation in (3.2) may have more than one solution. In particular, in the approximation, one has to specify how to drive the solution to the desired equilibrium or how to generate the chattering needed (e.g., in the preceding example) for the relaxed control approximation. In many applications, however, fixing the control determines the limit stationary state. See Kokotovic, Khalil, and O'Reilly [14]. One example for such a phenomenon is when $g(x,y,u) = -\alpha(x)y + h(x,u)$ with $\alpha(x)$ positive.

Example 8.7. We provide an example for $\mathrm{val}(ROR)$ strictly less than $\mathrm{val}(OR)$. It is a variant of known examples where using relaxed controls may strictly lower the cost. Consider the system with scalar variables where the cost is given by $c(x,y,u) = x^2 + (|y|-1)^2 + u^2$, the equations are determined by $\frac{dx}{dt} = y$ and $\varepsilon\frac{dy}{dt} = x + h(u)$ with initial conditions $x(0) = 0$, $y(0) = 0$, and where $h(u)$ is defined by $h(u) = 0$ for $u \in [-10,10]$, $h(u) = u - 10$ for $u > 10$, and $h(u) = u + 10$ for $u < 10$. The reduced equation (which in this example is independent of y) is $0 = x + h(u)$. A direct inspection reveals the optimal relaxed solution of the order reduction form. Indeed, the pairs $(y,u) = (1,0)$ and $(y,u) = (-1,0)$ are both admissible solutions of the algebraic equation, and relaxing these states with equal probabilities yields a trajectory with $x(t) = 0$ for every t and zero cost. In particular, $\mathrm{val}(ROR) = 0$. The conditions of the main result hold, and hence this relaxed optimal trajectory can be approximated by near optimal solutions of the original system.

If, however, we consider first trajectories generated by the solutions (y,μ) of the algebraic equation $0 = x + h(u)$, we see that, for $x \neq 0$, the only way to get a solution is to apply controls with absolute value greater than or equal to 10. Since, without

the relaxation of the stationary limits of the fast dynamics, the state $x = 0$ is not a solution, we deduce that val$(OR) \geq 100$.

Remark 8.8. We wish to point out that the relaxation of the order reduction system plays a role beyond guaranteeing existence of an optimal solution. Indeed, when val(OR) is strictly greater than val(ROR), there is no way to generate near optimal solutions to the perturbed system with the aid of nonrelaxed solutions of the order reduction system. As in the previous example, ordinary trajectories of the order reduction system cannot approximate optimal relaxed solutions. It is interesting to note that ordinary solutions of the perturbed system are able to approximate optimal relaxed solutions of the order reduction system.

The discrepancy between val(OR) and val(ROR) stems from the fact that the relaxation of the differential inclusion (3.6), which is determined by the set valued map with values $V(x)$, yields strictly lower values. Standard conditions are available in the literature, ensuring that this discrepancy does not occur. Since the case where one may operate with the order reduction problem (3.1)–(3.3) without alluding to relaxation may be of interest, we display conditions which guarantee that. To this end, consider the set valued map in the extended space as follows:

$$\hat{V}(x) = \{(c(x,v), f(x,v)) : v \in V(x)\}. \tag{8.1}$$

For a positive number b, let $\hat{V}_b(x)$ be the set of pairs $(c(x,v), f(x,v))$ in $\hat{V}(x)$ such that v is supported on the b-ball in $R^m \times R^k$. Distance between sets is taken as the Hausdorff distance.

PROPOSITION 8.9. *Let b be a bound on the sequence of near optimal trajectories guaranteed in Assumption* 2.1(iv). *Suppose that the mapping $x \to \hat{V}_b(x)$ is a Lipschitz function of x. Then val(OR)=val(ROR). Furthermore, if the sets $\hat{V}_b(x)$ are all convex sets, then an optimal solution to the order reduction problem can be found which does not use relaxation of the fast state variable.*

Proof. As is evident from the structure, the result alludes only to the structure of the differential inclusion. Hence the arguments go back to the fundamental observations of Filippov [9]. See Berkovitz [7, III.4 and IV.4]. □

Example 8.10. Conditions for the fulfillment of the properties listed in the previous result, thus guaranteeing that the order reduction system can be analyzed without the relaxation of the fast variable, can be demonstrated for large classes of equations. For instance, it is easy to verify that the Lipschitz property is satisfied when all of the functions involved are Lipschitz, and the equation for the fast variable is of the form $g(x,y,u) = h(x,y) + \beta(x)u$, with $\beta(x)$ not equal to 0. Indeed, the pairs (y,u) participating in the generation of $\hat{V}(x)$ are related by a Lipschitz factor. In the particular case where $g(x,y,u) = a(x)y + \beta(x)u$, with $a(x) \neq 0$ and $\beta(x) \neq 0$ (here u and $\beta(x)$ may be k-dimensional), the set valued function $\hat{V}(x)$ can be computed directly. Indeed, $\hat{V}(x) = \{(c(x, \frac{-1}{a(x)}\beta(x)\mu, \mu), f(x, \frac{-1}{a(x)}\beta(x)\mu, \mu)) : \mu \text{ is a relaxed control}\}$. Since $\hat{V}_b(x)$ is generated by controls in a bounded set, it is easy to see that, in this particular case, if the functions f, c, β, and a (note that a is continuous and $a(x) \neq 0$) are Lipschitz, then $\hat{V}_b(x)$ is Lipschitz continuous.

SEMICONCAVE CONTROL-LYAPUNOV FUNCTIONS AND STABILIZING FEEDBACKS*

LUDOVIC RIFFORD†

Abstract. We study the general problem of stabilization of globally asymptotically controllable systems. We construct discontinuous feedback laws, and particularly we make it possible to choose these continuous outside a small set (closed with measure zero) of discontinuity in the case of control systems which are affine in the control; moreover this set of singularities is shown to be repulsive for the Carathéodory solutions of the closed-loop system under an additional assumption.

Key words. asymptotic controllability, control-Lyapunov function, feedback stabilization, nonsmooth analysis

1. Introduction.

In a previous paper [23] we considered the stabilization problem for standard control systems. In particular, we proved that if a control system is globally asymptotically controllable, then one can associate to it a control-Lyapunov function which is semiconcave outside the origin. The goal of this article is to show the utility of the semiconcavity of such functions in the construction of stabilizing feedbacks.

We consider a standard control system of the general form $\dot{x} = f(x,u)$ which is globally asymptotically controllable, our objective being to design a feedback law $u : \mathbb{R}^n \to U$ such that the origin of the closed-loop system $\dot{x} = f(x,u(x))$ is globally asymptotically stable. Unfortunately, as pointed out by Sontag and Sussmann [28] and by Brockett [7], a continuous stabilizing feedback fails to exist in general. In addition to that, a smooth Lyapunov function may not exist either. As a matter of fact, although smooth Lyapunov-like techniques have been successfully used in many problems in control theory, it was shown by many authors (see Artstein [5] for the affine case, and more recently Clarke, Ledyaev, and Stern [11] for the general case) that there is no hope of obtaining a smooth Lyapunov function in the general case of globally asymptotically controllable systems. (The existence of such a function is indeed equivalent to that of a robust stabilizing feedback; see [17, 21].) These facts lead us to consider nonsmooth control-Lyapunov functions and particularly semiconcave control-Lyapunov functions; we proved the existence of such a function in our previous article [23]. This article builds on this result to derive a useful and direct construction of stabilizing feedbacks. In fact, the semiconcavity of the control-Lyapunov function allows us to give an explicit formula for the design of the stabilizing feedbacks. More particularly, this formula can be used in the context of control systems which are affine in the control to extend Sontag's formula [26] to the case of discontinuous feedback laws. Furthermore, the main result of this paper asserts that when the control system is affine in the control, we can design a feedback which is continuous on an open dense set and which stabilizes the closed-loop system in the sense of Carathéodory solutions. Surprisingly, we show that in this case, under an additional assumption on

†Institut Girard Desargues, Université Lyon I, 43 Bd du 11 Novembre 1918, 69622 Villeurbanne Cedex, France (rifford@igd.univ-lyon1.fr).

the control-Lyapunov function, all the trajectories of the closed-loop system remain in the set of continuity for positive times; in other words, the set of singularities of the stabilized system is repulsive, and hence the feedback law is continuous (even locally Lipschitz) along the trajectories for $t > 0$.

Our paper is organized as follows: In section 2 we describe our main results. In section 3 we present some basic facts about nonsmooth analysis, semiconcavity, and discontinuous stabilizing feedbacks. In sections 4 and 5, we give the proofs of different results. Finally, the main theorems are proved in sections 6 and 7.

Throughout this paper, $\mathbb{R}_{\geq 0}$ denotes the nonnegative reals, $\|\cdot\|$ a norm on $\mathbb{R}^n$, B the open ball $B(0,1) := \{x : \|x\| < 1\}$ in $\mathbb{R}^n$, and $\overline{B}$ the closure of B.

2. Definitions and statements of the results.

2.1. General control systems. We study systems of the general form

$$\dot{x}(t) = f(x(t), u(t)), \tag{2.1}$$

where the state $x(t)$ takes values in a Euclidean space $\mathbb{R}^n$, the control $u(t)$ takes values in a given compact metric space U, and f is locally Lipschitz in x uniformly in u. We distinguish a special element "0" in U and assume that the state $x = 0$ is an equilibrium point (i.e., $f(0,0) = 0$). We are interested in globally asymptotically controllable systems, which we proceed to define.

DEFINITION 2.1. *The system* (2.1) *is globally asymptotically controllable (GAC) if there exists a nondecreasing function*

$$\tilde{\theta} : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$$

such that $\lim_{r \to 0^+} \tilde{\theta}(r) = 0$, *with the property that, for each* $\xi \in \mathbb{R}^n$, *there exist a control* $u : R_{\geq 0} \to U$ *and a corresponding trajectory* $x(\cdot) : \mathbb{R}_{\geq 0} \to \mathbb{R}^n$ *such that* $x(0) = \xi$,

$$x(t) \to 0 \text{ as } t \to \infty,$$

and

$$\sup\{\|x(t)\| : 0 \leq t < \infty\} \leq \tilde{\theta}(|\xi|).$$

This definition of global asymptotic controllability is appropriate under the assumption of compactness of the control set U. When this set is not compact, we must add some conditions on the open-loop controls which stabilize the initial states; we refer to the papers of Sontag and Sussmann [29, 30] for a generalization of this definition to the general case on a noncompact control set.

REMARK 2.2. *This definition seems weaker than the one given initially in* [23]. *However, as explained by Sontag and Sussmann in* [29, 30], *a routine argument involving continuity of trajectories with respect to initial states shows that our different definitions are indeed equivalent.*

Our objective is to design a feedback law $u : \mathbb{R}^n \to U$ such that the origin of the closed-loop system (2.1) is globally asymptotically stable; that is, such that the new system

$$\dot{x}(t) = f(x(t), u(x(t))) \tag{2.2}$$

is globally asymptotically stable. Our method relies on nonsmooth Lyapunov functions, which we proceed to define; we refer to the next section for the definition of the proximal subdifferential $\partial_P V(\cdot)$.

DEFINITION 2.3. *A control-Lyapunov function for the system* (2.1) *is a continuous function* $V : \mathbb{R}^n \to \mathbb{R}$ *which is positive definite (i.e.,* $V(0) = 0$ *and* $V(x) > 0$ *for* $x \neq 0$*), proper (i.e.,* $V(x) \to \infty$ *when* $\|x\| \to \infty$*), and such that there exists a positive definite continuous function* $W : \mathbb{R}^n \longrightarrow \mathbb{R}$ *with the property that, for each* $x \in \mathbb{R}^n \setminus \{0\}$*, we have*

$$\forall \zeta \in \partial_P V(x), \quad \min_{u \in U} \langle \zeta, f(x,u) \rangle \leq -W(x). \tag{2.3}$$

The present article is based on the following theorem, which is a refinement of a result proved in [23]. The regularity of our control-Lyapunov function will be crucial for the construction of discontinuous stabilizing feedbacks.

THEOREM 2.4. *If the system* (2.1) *is GAC, then there exists a control-Lyapunov function* V *which is semiconcave on* $\mathbb{R}^n \setminus \{0\}$ *and such that*

$$\forall x \in \mathbb{R}^n \setminus \{0\}, \ \forall \zeta \in \partial_P V(x), \quad \min_{u \in U} \langle \zeta, f(x,u) \rangle \leq -V(x). \tag{2.4}$$

This theorem differs from the one given in our previous article [23] in the decrease condition (2.4). Here, we assert that we can take V as the function W of Definition 2.3. This special form of the infinitesimal decrease condition (2.4) will allow us to obtain exponential decrease for $V(x(t))$ and will make it possible to give closed-form estimates (in terms of V) on the rate of stabilization.

Now, using the concept of π-trajectories and of Euler trajectories which will be defined in the next section, we give a general result on the existence of stabilizing feedbacks; this result was announced in [25].

THEOREM 2.5. *Assume that the system* (2.1) *is GAC. Then there exists a feedback* $u : \mathbb{R}^n \to U$ *for which the system* $\dot{x} = f(x, u(x))$ *is globally asymptotically stabilizable in the sense of* π*-trajectories and in the Euler sense.*

Moreover, if we consider a control-Lyapunov function V *for the given system, then the stabilizing feedback can be designed as follows:*

- *We set* $u(0) = 0$.
- *For each* $x \in \mathbb{R}^n \setminus \{0\}$*, we choose arbitrarily* $\zeta \in \partial_L V(x)$ *and we set*

$$u := u(x) \in U, \ \textit{where } u(x) \textit{ is any point in } U \textit{ such that } \langle \zeta, f(x,u) \rangle \leq -W(x).$$

Furthermore, if the control-Lyapunov function V *is the one given by Theorem* 2.4 *(i.e., if* $W = V$*), then we have*

$$V(x(t)) \leq e^{-t} V(x_0) \tag{2.5}$$

for any Euler trajectory starting at $x_0 \in \mathbb{R}^n$.

The existence of a discontinuous feedback which is stabilizing in the sense of the π-trajectories is not new; it appeared initially in the article of Clarke et al. [10]. We refer also to Ancona and Bressan [4], who proved a slightly stronger result in the sense that their feedback stabilizes the closed-loop system in the sense of Carathéodory; their proof does not use nonsmooth control-Lyapunov functions. However, here the consideration of a semiconcave control-Lyapunov function leads to a simple proof and allows us to give an explicit formula for the design of the feedback. Moreover, we are able to design some stabilizing feedbacks which are rather regular in the case of affine systems.

2.2. Affine control systems. Let us assume now that the control system is affine in the control, that is,

$$f(x,u) = f_0(x) + \sum_{i=1}^{m} u_i f_i(x) \quad \forall (x,u) \in \mathbb{R}^n \times U, \tag{2.6}$$

where the $f_0, \dots, f_m$ are locally Lipschitz functions from $\mathbb{R}^n$ into $\mathbb{R}^n$ and where U is a strictly convex and compact set of $\mathbb{R}^m$.

REMARK 2.6. *Instead of assuming the control set U to be strictly convex, we could make a weaker assumption of convexity. As a matter of fact, if the control set is supposed to be convex, we can define a subset of it which is strictly convex and for which the control system* (2.6) *keeps the same properties of controllability. Consequently all our results hold in the case of a convex compact control set.*

First of all, assuming the knowledge of a control-Lyapunov function, we are able to give an explicit feedback law; it reduces to Sontag's formula [26] in the smooth case.

THEOREM 2.7. *Assume that V is a control-Lyapunov function for* (2.6) *and consider any selection $\zeta_V(\cdot)$ of $\partial_L V(\cdot)$. Then the feedback control defined by*

$$u_i(x) := -\phi\left(\langle f_0(x), \zeta_V(x)\rangle, \sum_{i=1}^{m} \langle f_i(x), \zeta_V(x)\rangle^2\right) \langle f_i(x), \zeta_V(x)\rangle,$$

where

$$\phi(a,b) = \begin{cases} \frac{a+\sqrt{a^2+b^2}}{b} & \text{if } b \neq 0, \\ 0 & \text{if } b = 0, \end{cases}$$

(globally asymptotically) stabilizes the control system (2.6) *in the sense of π-trajectories and in the Euler sense.*

REMARK 2.8. *The feedback given in Theorem* 2.7 *may not be with values in the control set U. However, we can project the values $u(x)$ on the unit ball $\bar{B}$ to get a stabilizing feedback which is locally bounded.*

Furthermore, we can exploit the semiconcavity property more strongly to derive some regularity properties on the feedback in the case of affine control systems. We are going to obtain continuity of our discontinuous feedback outside a set of singularity which will be proved small on account of semiconcavity.

THEOREM 2.9. *If the control affine system* (2.6) *is GAC, then there exists a subset $\mathcal{D} \subset \mathbb{R}^n$ which verifies the following properties:*

(i) *The set $\mathcal{D}$ is an open dense set.*
(ii) *The complement S of $\mathcal{D}$ has Hausdorff dimension no greater than $n-1$.*
(iii) *There exists a feedback $u : \mathbb{R}^n \to U$ which is continuous on $\mathcal{D}$ for which the closed-loop system* (2.6) *is globally asymptotically stable in the sense of Carathéodory; in particular, the Euler trajectories are solutions in the sense of Carathéodory.*

REMARK 2.10. *As in the paper of Artstein* [5, Theorem 5.2]*, if the system verifies the small-control property, then the feedback can be chosen to be continuous at the origin. More precisely, if we assume that there exists a semiconcave control-Lyapunov function such that for all $\epsilon > 0$, there exists $\delta > 0$ such that $\|x\| \leq \delta$ implies the existence of $u \in U$ with $\|u\| < \epsilon$ and satisfying* (2.4)*, then the feedback given by the previous theorem can be taken to be continuous at the origin.*

We recognize this time in Theorem 2.9 the result of Ancona and Bressan [4] in the case of control affine systems. As in their case, it turns out from the proof that the function $t \mapsto f(x(t), u(x(t))$ is left-continuous. Let us also remark that we get from the upper bound on the Hausdorff dimension of S that this set has Lebesgue measure zero. We refer to Morgan [19] for a survey of the notions of Hausdorff measure and Hausdorff dimension.

Actually, if we consider a control-Lyapunov function given by Theorem 2.4 we will see in the proof of Theorem 2.9 that the construction of the set $\mathcal{D}$ is based on the function

$$\Psi_V(x) := \min_{u \in U} \max_{\zeta \in \partial V(x)} \langle \zeta, f(x,u) \rangle, \tag{2.7}$$

where ∂V denotes the Clarke's generalized gradient of V; see section 3.1 for the definition. This function is upper semicontinuous on $\mathbb{R}^n \setminus \{0\}$; hence if we consider a continuous function $\delta : \mathbb{R}^n \to \mathbb{R}$, the set

$$\mathcal{D}_V^\delta := \{x \in \mathbb{R}^n \setminus \{0\} : \Psi_V(x) < -\delta(x)\}$$

is open. In particular, if the control-Lyapunov function V satisfies an additional assumption concerning the set $\mathcal{D}_V^\delta$ and the function Ψ_V, then we can provide a stabilizing feedback which is invariant with respect to $\mathcal{D}_V^\delta$. Let us state the result.

THEOREM 2.11. *Let there be given a GAC control system and a control-Lyapunov function V as in Theorem* 2.4. *If there exists a continuous and positive definite function*

$$\delta : \mathbb{R}^n \to \mathbb{R}$$

such that

$$\forall x \in \mathbb{R}^n \setminus \{0\}, \quad \delta(x) < V(x), \tag{2.8}$$

and

$$\forall x \in \mathbb{R}^n \setminus \{0\}, \quad \Psi_V(x) \leq -\delta(x) \Longrightarrow x \in \mathcal{D}_V^\delta, \tag{2.9}$$

then we have the following:

(i) *The set $\mathcal{D}_V^\delta$ is an open dense set and $\mathcal{D}_V^\delta \cup \{0\}$ is path-connected.*

(ii) *The complement S_V of $\mathcal{D}_V^\delta$ has Hausdorff dimension no greater than $n-1$.*

(iii) *There exists a feedback $u : \mathbb{R}^n \to U$ which is smooth on $\mathcal{D}_V^\delta$ for which the closed-loop system* (2.6) *is globally asymptotically stable in the sense of Carathéodory. Moreover, for any Carathéodory solution $x(\cdot)$ of this system, we have*

$$x(t) \in \mathcal{D}_V^\delta \quad \forall t > 0. \tag{2.10}$$

In particular, the Euler trajectories are solutions in the sense of Carathéodory.

REMARK 2.12. *Let us note that if there exists a positive definite and continuous function δ such that*

$$\forall x \in \mathbb{R}^n, \quad \Psi_V(x) < 0 \Longrightarrow \Psi_V(x) \leq -\delta(x),$$

then the function $\frac{\delta}{2}$ satisfies (2.8) *and* (2.9).

We stress that the property (2.10) implies the following facts: For each state $x_0 \in \mathbb{R}^n$, for any Carathéodory solution of the closed-loop system starting at x_0, the following hold:

- If $x_0 = 0$, then $x(t) = 0$ for all $t \geq 0$.
- If $x_0 \in \mathcal{D}_V^\delta$, then $x(t) \in \mathcal{D}_V^\delta \cup \{0\}$ for all $t \geq 0$; and consequently
$$\dot{x}(t) = f(x(t), u(x(t))) \quad \forall t \geq 0 \quad \text{such that (s.t.) } x(t) \neq 0.$$
- If $x_0 \notin \mathcal{D}_V^\delta \cup \{0\}$, then $x(t) \in \mathcal{D}_V^\delta \cup \{0\}$ for all $t > 0$; and consequently
$$\dot{x}(t) = f(x(t), u(x(t))) \quad \forall t > 0 \quad \text{s.t. } x(t) \neq 0.$$

To summarize our results, we have shown that under the additional assumptions (2.8) and (2.9), there exists a feedback which stabilizes our closed-loop system in the sense of Carathéodory, and moreover its Carathéodory trajectories are solutions in the classical sense for positive times whenever $x(t) \neq 0$. Let's also emphasize that the conclusions of Theorem 2.11 imply some topological properties for the set $\mathcal{D}_V^\delta$. As a matter of fact, the set $\mathcal{D}_V^\delta \cup \{0\}$ is invariant with respect to a locally Lipschitz vector field (since the functions $f_0, f_1, \ldots, f_m$ are locally Lipschitz), which is asymptotically stabilizing to the origin; therefore it is contractible.

We present in the two following sections two simple examples where the hypotheses (2.8) and (2.9) of Theorem 2.11 are fulfilled.

2.3. One-dimensional systems. Let us assume that the control system is of the form

$$\dot{x} = ug(x), \tag{2.11}$$

where the control u belongs to the interval $[a, b]$ and g is a locally Lipschitz vector field on $\mathbb{R}^n$. In this case, the condition (2.9) is always ensured. Let us consider a semiconcave control-Lyapunov V for the system (2.11) and set

$$\mathcal{D}_V := \{x \in \mathbb{R}^n \setminus \{0\} : \Psi_V(x) < 0\},$$

where

$$\forall x \in R^n, \quad \Psi_V(x) := \min_{u \in U} \max_{\zeta \in \partial V(x)} \langle \zeta, f(x, u) \rangle.$$

We have the following.

LEMMA 2.13. *For any $x \in \mathcal{D}_V$,*

$$\Psi_V(x) \leq -V(x).$$

Proof. Let $x \in \mathcal{D}_V$. Thus $\Psi_V(x) < 0$, and there exists $u \in [a, b]$ such that

$$\forall \zeta \in \partial V(x), \quad u\langle \zeta, g(x) \rangle < 0. \tag{2.12}$$

Without loss of generality we treat the case where $u > 0$.

We know by assumption on V that for each $\zeta \in \partial_L V(x)$, there exists $u(\zeta) \in [a, b]$ such that

$$u(\zeta)\langle \zeta, g(x) \rangle \leq -V(x).$$

Since $\partial_L V(x) \subset \partial V(x)$, we deduce immediately from (2.12) that $u(\zeta) > 0$ and that $\Psi(x) \leq -V(x)$. ∎

From this lemma and Remark 2.12 we deduce that the conclusions of Theorem 2.11 apply in the case of one-dimensional systems. We add that we will clearly define the shape of the set of singularities (i.e., S_V the complement of $\mathcal{D}_V$) in the forthcoming paper [22].

REMARK 2.14. *Actually, it is not difficult to see that the system* (2.11) *is GAC and locally stabilizable by a continuous feedback if and only if it is globally stabilizable by a smooth feedback.*

2.4. The nonholonomic integrator. The nonholonomic integrator control system

$$\begin{aligned} \dot{x}_1 &= u_1, \\ \dot{x}_2 &= u_2, \\ \dot{x}_3 &= x_1 u_2 - x_2 u_1 \end{aligned} \tag{2.13}$$

appeared in [7] as an example of a nonlinear control system which does not satisfy Brockett's condition and cannot be stabilized with continuous feedback. It was shown in [16] that the nonsmooth function

$$V = \max\left\{\sqrt{x_1^2 + x_2^2}, |x_3| - \sqrt{x_1^2 + x_2^2}\right\} \tag{2.14}$$

is a control-Lyapunov function for the nonholonomic integrator system (2.13). As before,

$$\Psi_V(x) := \min_{u \in U} \max_{\zeta \in \partial V(x)} \langle \zeta, (u_1, u_2, x_1 u_2 - x_2 u_1)^t \rangle,$$

and we remark that $\Psi_V(x) = 0$ on the set

$$S := \left\{ x \in \mathbb{R}^n : x_1^2 + x_2^2 = 0 \right\}.$$

In addition, the function V is differentiable outside S, and thus by the results given in [16] we get that for any $x \in \mathcal{D}_V$,

$$\Psi_V(x) \leq -\frac{V(x)}{\sqrt{4 + V(x)^2}} =: \delta(x).$$

Theorem 2.11 and Remark 2.12 now imply the existence of a stabilizing feedback satisfying the properties given in its statement.

2.5. A counterexample. We give in this section for every Euclidean space $\mathbb{R}^n$ with $n \geq 2$ an example of a control affine system which is GAC and which does not verify the conditions (2.8) and (2.9) for any control-Lyapunov function V and any continuous positive definite function δ, and for which the conclusions of Theorem 2.11 do not hold.

Let $n \geq 2$ and $x_0 \in R^n \setminus 3\overline{B}$ be fixed. There exists a locally Lipschitz vector field on $\mathbb{R}^n$ such that

$$f_0(x) = \begin{cases} -x & \text{if } x \in \overline{B}, \\ x - x_0 & \text{if } \frac{1}{4} \leq \|x - x_0\| \leq \frac{1}{2}. \end{cases}$$

Let us also define two auxiliary functions g_0 and g_1. We set for any $x \in \mathbb{R}^n$,

$$g_0(x) := \max\{0, 1 - d_{K_1}(x)\},$$

where $d_{K_1}(\cdot)$ denotes the distance function corresponding to the set

$$K_1 := \overline{B} \bigcup \left(x_0 + \frac{1}{2}\overline{B} \right) \setminus \left(x_0 + \frac{1}{4}\overline{B} \right).$$

Then we set for any $x \in \mathbb{R}^n, g_1(x) := d_{K_2}(x)$ with

$$K_2 := \frac{1}{2}\overline{B} \bigcup \mathcal{A} \subset K_1,$$

where $\mathcal{A}$ denotes the annulus $\mathcal{A} = \left(x_0 + \frac{7}{16}\overline{B}\right) \setminus \left(x_0 + \frac{5}{16}\overline{B}\right)$.

We now present the dynamics which will form our counterexample; we consider the following control system:

$$\dot{x} = f(x,u) := g_0(x)f_0(x) + g_1(x)u, \quad (x,u) \in \mathbb{R}^n \times \overline{B}. \tag{2.15}$$

Let us notice the following facts:

$$f(x,u) = f_0(x) \quad \text{if } (x,u) \in K_2 \times \overline{B}$$

and

$$f(x,u) = g_1(x)u \quad \text{if } (x,u) \in \left(\mathbb{R}^n \setminus (K_1 + \overline{B})\right) \times \overline{B}.$$
