4. Estimating the condition number λ_1/λ_n. We now apply the results of the previous section and Theorem 4.2 of [9] to estimate the condition number of a matrix. Since $\hat{\xi}_k = \hat{\xi}(A, b, k)$ and $\xi_k = \xi(A, b, k)$ are the Lanczos approximations to the largest and to the smallest eigenvalues of A correspondingly, we estimate the condition number cond A by $\kappa_k = \hat{\xi}_k/\xi_k$, $\kappa_k \leq$ cond A. Clearly, the quality of this estimation depends on the starting vector b. We now give a lower bound on the measure of the set of vectors b for which cond $A \leq \alpha\kappa_k$ for $\alpha > 1$. Let

$$Z_k = \{b \in S_n : \text{cond } A \leq \alpha\kappa_k\}.$$

Then we have the following theorem.

THEOREM 5. *Let A be a symmetric positive definite matrix A and let m denote the number of distinct eigenvalues of A. Then*

$$\mu(Z_k) = 1 \quad \text{for } k \geq m,$$

for any k and any $\alpha > 1$

$$\mu(Z_k) \geq 1 - 1.648\sqrt{n} \inf_{0 < t < \frac{1-1/\alpha}{\kappa_k}} \phi(t),$$

where

$$\phi(t) = e^{-(2k-1)\sqrt{1-t\kappa_k-1/\alpha}} + e^{-(2k-1)\sqrt{t}}.$$

Proof. The proof for $k \geq m$ follows immediately from the corresponding parts of Theorem 4.2 in [9] and Theorem 2. Assume now that k is any integer. Consider the sets

$$W = \{b \in S_n : \lambda_1 \leq \hat{\xi}_k/(1-\varepsilon_1)\}$$

and

$$\hat{Y} = \{b \in S_n : \lambda_n \geq \xi_k - \varepsilon_2 \lambda_1\}$$

for any $\varepsilon_1, \varepsilon_2 \in (0,1)$. From Theorem 4.2 of [9] it follows that

$$\mu(W) > 1 - \phi_1(\varepsilon_1) = 1 - 1.648\sqrt{n}\, e^{-\sqrt{\varepsilon_1}(2k-1)},$$

while from Theorem 2 we have

$$\mu(\hat{Y}) > 1 - \phi_2(\varepsilon_2) = 1 - 1.648\sqrt{n}\, e^{-(2k-1)\sqrt{\varepsilon_2}}.$$

Let

$$Y = \left\{ b \in S_n : \lambda_n \geq \xi_k - \varepsilon_2 \frac{\hat{\xi}_k}{1-\varepsilon_1} \right\}$$

for ε_1 and ε_2 such that $\xi_k - \varepsilon_2 \frac{\hat{\xi}_k}{1-\varepsilon_1} > 0$. Then $W \cap \hat{Y} \subset Y$ ($W \cap \hat{Y} \subset W \cap Y$) and

$$\mu(W \cap Y) \geq \mu(W \cap \hat{Y}) = \mu(W) + \mu(\hat{Y}) - \mu(W \cup \hat{Y})$$

$$> 1 - \phi_1(\varepsilon_1) + 1 - \phi_2(\varepsilon_2) - 1 = 1 - (\phi_1(\varepsilon_1) + \phi_2(\varepsilon_2)).$$

Thus, since $\xi_k - \varepsilon_2 \frac{\hat{\xi}_k}{1-\varepsilon_1} > 0$, we have

$$\mu\left\{ b \in S_n : \operatorname{cond} A \leq \frac{1}{1 - \varepsilon_1 - \varepsilon_2 \kappa_k} \kappa_k \right\} > 1 - (\phi_1(\varepsilon_1) + \phi_2(\varepsilon_2)).$$

Maximizing the right-hand side of the last inequality under constraints

$$0 < \varepsilon_1 < 1, \quad 0 < \varepsilon_2 < 1, \quad 0 < \varepsilon_2/(1-\varepsilon_1) < 1/\kappa_k, \quad 1 - \varepsilon_1 - \varepsilon_2\kappa_k = 1/\alpha,$$

we complete the proof by taking $\varepsilon_2 = t$ and $\varepsilon_1 = 1 - 1/\alpha - t\kappa_k$. □

The first part of Theorem 5 states that the Lanczos algorithm at the mth step recovers the condition number of a matrix with probability one. This confirms our intuition that for sufficiently large k the Lanczos algorithm may fail only on a set of measure zero.

The second part of Theorem 5 gives a lower bound on the probability that the condition number of a matrix is not greater than $\alpha\kappa_k$ for $\alpha > 1$. It may happen that this bound is negative, especially when κ_k grows too rapidly with respect to k (see Table 1 where the approximated minimum of the function ϕ is shown) or for α close to one or n huge. However, for $k \geq n$, $\kappa_k = \operatorname{cond} A$ with probability one no matter what was happening with κ_k for $k < n$.

It is difficult to calculate the exact value of the infimum of the function ϕ in the interval $(0, (1 - 1/\alpha)/\kappa_k)$ (note that k, α, and κ_k are known), but it is quite easy to find a satisfactory approximation of it numerically. Indeed, having calculated κ_k we can perform a few steps of the bisection method applied to the first derivative ϕ' on the interval $(0, (1 - 1/\alpha)/\kappa_k)$. Table 1 displays an approximation of the minimum of the function ϕ for $\alpha = 10$ for some values of k and κ_k. The first column contains values of k. The next four columns show an approximation of the minimum of $\phi, \phi_{\min}(k, \kappa_k)$ for $\kappa_k = \sqrt{k}$, $\kappa_k = k$, $\kappa_k = k^2$, and $\kappa_k = k^3$, respectively.

TABLE 1

k	$\phi_{\min}(k, \sqrt{k})$	$\phi_{\min}(k, k)$	$\phi_{\min}(k, k^2)$	$\phi_{\min}(k, k^3)$
10	0.00025	0.00612	0.184	0.585
20	0.0000002	0.00039	0.163	0.667
30	0	0.00005	0.158	0.714
40	0	0.000009	0.156	0.745
50	0	0.000002	0.154	0.768
60	0	0.0000006	0.153	0.785
70	0	0.0000002	0.153	0.799
80	0	0.0000001	0.152	0.810

To apply Theorem 5 for $\mu(Z_k)$ we have to compute κ_k. It is possible to estimate $\mu(Z_k)$ without computing κ_k. It can be done by combining Theorems 3 and 4. Indeed, observe that for $\alpha = \theta/\eta$, we have $L_k \cap M_k \subseteq Z_k$, and

$$\mu(Z_k) \geq \mu(L_k \cap M_k) = \mu(L_k) + \mu(M_k) - \mu(L_k \cup M_k) \geq \mu(L_k) + \mu(M_k) - 1.$$

Thus, to find a lower bound on $\mu(Z_k)$, we need to find lower bounds on $\mu(L_k)$ and $\mu(M_k)$. Applying Theorems 3 and 4 we get the following theorem.

THEOREM 6. *For any symmetric positive definite matrix A let m denote the number of distinct eigenvalues. Let α be any number, $\alpha > 1$. Then for any numbers θ and η such that $\theta > 1$, $0 < \eta < 1$ and $\alpha = \theta/\eta$, we have*

$$\mu(Z_k) = 1 \quad \text{for } k \geq m \quad \text{or} \quad (\theta \geq \operatorname{cond} A \quad \text{and} \quad \eta \leq 1/\operatorname{cond} A)$$

and

$$\mu(Z_k) \geq 1 - \frac{2\Gamma((n-j)/2+1)}{\sqrt{\pi}\,\Gamma((n-j+1)/2)\,\sqrt{\theta-1}\,U_{2(k-1)}(\sqrt{\theta})} - \frac{2\Gamma(i/2)}{\sqrt{\pi}\,\Gamma((i-1)/2)} \sqrt{\frac{\eta \operatorname{cond} A - 1}{1-\eta}}\, U^{-1}_{2(k-1)}\left(\sqrt{1+(1-\eta)/(\eta \operatorname{cond} A - 1)}\right),$$

where $\theta < \operatorname{cond} A$ or $\eta > 1/\operatorname{cond} A$ and j and i satisfy:

$$\lambda_j \leq \lambda_1/\theta < \lambda_{j-1}, \quad 2 \leq j \leq n \quad \text{and} \quad \lambda_n/\lambda_{i-1} < \eta \leq \lambda_n/\lambda_i, \quad 2 \leq i \leq n.$$

Theorem 6 yields a bound on the measure of the set Z_k that depends on the indices i and j as well as $\operatorname{cond} A$. Usually they are unknown. However, the indices i, j can be replaced by n, and $\operatorname{cond} A$ can be replaced by an upper bound M. Using the second inequality of Theorem 3 and Corollary 1, we then get the following theorem.

THEOREM 7. *Let A be any symmetric positive definite matrix of the size $n \geq 8$ such that $\operatorname{cond} A \leq M$. Then under assumptions of Theorem 6, we have*

$$\mu(Z_k) = 1 \quad \text{for } k \geq m \quad \text{or} \quad (\theta \geq M \quad \text{and} \quad \eta \leq 1/M)$$

and

$$\begin{aligned}\mu(Z_k) &\geq 1 - \frac{2\Gamma(n/2)}{\sqrt{\pi}\,\Gamma((n-1)/2)} \left((\theta-1)^{-1/2} U^{-1}_{2(k-1)}(\sqrt{\theta}) + \sqrt{\frac{M\eta-1}{1-\eta}}\, U^{-1}_{2(k-1)}\left(\sqrt{1+(1-\eta)/(M\eta-1)}\right)\right) \\ &\geq 1 - 0.824\sqrt{n}\left((\theta-1)^{-1/2} U^{-1}_{2(k-1)}(\sqrt{\theta}) + \sqrt{z}\, U^{-1}_{2(k-1)}(\sqrt{1+1/z}\,)\right)\end{aligned}$$

for $1 < \theta < M$ *or* $1/M < \eta < 1$, *where* $z = (M\eta - 1)/(1 - \eta)$.

Note that the better bound M on $\operatorname{cond} A$ is given, and the better bound on the measure of the set Z_k is obtained.

Obviously, any number $\alpha > 1$ can be decomposed as $\alpha = \theta/\eta$, $M > \theta > 1$, $1/M < \eta < 1$ in many ways. To get the best probability bound one can maximize it over θ and η under the constrains $\alpha = \theta/\eta$, $M > \theta > 1$, $1/M < \eta < 1$. It can easily be done numerically.

5. Numerical results. We tested several matrices with many pseudorandom starting vectors b. Without loss of generality [9] we restricted ourselves only to diagonal matrices. Vectors b were generated in the same way as in [9]. The tests were performed on XT and 486 personal computers with the round-off unit of order 10^{-7}. All calculations were done in the single precision. The diagonal form of matrices reduced the effect of round-off errors.

The purpose of the numerical tests was, in particular, to verify the sharpness of the bound of Theorem 1 and to check the quality of the bounds of Theorems 5 and 7. We first report our results for the matrix of dimension $n = 250$ with eigenvalues

$$\lambda_k = 1 + \cos\frac{(2k-1)\pi}{2n}, \qquad k = 1, \ldots, 250.$$

Hence, λ_k's are the shifted zeros of the Chebyshev polynomial of the first kind of degree 250. This distribution of eigenvalues is difficult for the Lanczos algorithm [15]. We have selected several values of ε and ten pseudorandom vectors b and for each of them we run the Lanczos algorithm for $k = 1, \ldots, k^*$, where k^* was the minimal k for which the relative error $e(A, b, k)$ was no greater than ε. We compared the relative error with k^{-2}. For each b and k we observed

$$0.20 \le e(A, b, k)\, k^2 \le 1.23.$$

In Table 2 we report the average errors achieved after $(k-1)$ steps of the Lanczos algorithm for some values of k displayed in the first column. The second column shows the average errors defined as

$$\varepsilon^{\text{ave}} = \frac{1}{10}\sum_{i=1}^{10} e(A, b_i, k),$$

where b_i is the ith pseudorandom vector. The third column contains upper bounds on the Lanczos errors from Theorem 1, i.e.,

$$\varepsilon^{up} = 0.103\left(\frac{\ln(n(k-1)^4)}{k-1}\right)^2.$$

The fourth column shows the ratio $r_1 = \varepsilon^{\text{up}}/\varepsilon^{\text{ave}}$, while the last column displays how r_1 is related to the (probably unnecessary) factor $r_2 = r_1/\ln^2(n(k-1)^4)$ in the theoretical bound.

TABLE 2

$k-1$	ε^{ave}	ε^{up}	r_1	r_2
10	0.005276	0.2235	42.36	0.195
20	0.001379	0.0789	57.22	0.187
30	0.000688	0.0419	60.87	0.166
40	0.000387	0.0265	68.53	0.167
50	0.000244	0.0185	75.76	0.184
60	0.000165	0.0137	83.23	0.174
70	0.000145	0.0107	73.95	0.146

Small changes in the last column of Table 2 may suggest that the error of the Lanczos algorithm for the matrix with Chebyshevian distribution of eigenvalues behaves like k^{-2} and the factor roughly $\ln^2(n(k-1)^4)$ is probably an overestimate in the upper bound.

Table 3 shows for five values of ε how many steps were needed to achieve the relative error no greater than ε. The first row contains the values of ε, the second row the average number k^{ave} of performed steps with $k^{\text{ave}} = \sum_{i=1}^{10} k(A, b_i)/10$, where $k(A, b_i)$ was the number of steps needed for the pseudorandom vector b_i. The third row indicates the minimal $k = k^{\text{up}}$ such that

$$0.103 \left(\frac{\ln(n(k-1)^4)}{k-1} \right)^2 \leq \varepsilon,$$

which is one of the two theoretical bounds of Theorem 1 for the Lanczos algorithm. The fourth row presents the ratio $r = k^{\text{up}}/k^{\text{ave}}$.

TABLE 3

ε	$1_{10}-3$	$7.5_{10}-4$	$5_{10}-4$	$2.5_{10}-4$	$2.0_{10}-4$
k^{ave}	35.5	41	49.9	65.5	69.2
k^{up}	287	339	429	638	724
r	8.08	8.27	8.6	9.74	10.46

Note that the theoretical bound exceeds the actual value by a factor of at most 11. Observe also that all k^{up}'s are greater than $n = 250$ and the second bound of Theorem 1 gives a better estimate.

We also tested matrices of dimension 250 with other distributions of eigenvalues in the interval $(0, 2)$. The following distributions were tested:

- the quadratic, $\lambda_i = 2\,(1 - i/251)^2$ and $\lambda_i = 2\,(1 - (i/251)^2)$;
- the uniform, $\lambda_i = 2\,(1 - i/251)$;
- the logarithmic, $\lambda_i = 2\,\log(252 - i)/\log 252$;
- the expotential, $\lambda_i = 2\,e^{-\sqrt[3]{i}}, \lambda_i = 1 + e^{-i}, i = 1, \ldots, 250$.

For all these matrices we have observed faster convergence to the smallest eigenvalue than for the matrix with Chebyshevian distribution. For some matrices the difference was significant.

We were also interested in checking the quality of the bound on the condition number presented in Theorems 5 and 7. As before, for each matrix we selected several pseudorandom vectors b and ran the Lanczos algorithm both for the smallest and for the largest eigenvalues with $k = 1, 2, \ldots, k^*$, where k^* was the minimal k for which this algorithm gave approximations with a prescribed accuracy. In all tests, i.e., for all matrices, all starting vectors and all k, the number α was fixed to be equal to 10. We now describe some tests on the bound of Theorem 5. The infimum of the function ϕ from Theorem 5 was computed numerically. The matrices most intensively tested were the matrices that arise as discretizations of a two-dimensional Laplace operator. We first report some results for the matrix A of the size 256 (16 points in each direction). The condition number of this matrix is $116.461\ldots$. Table 4 shows some results obtained for ten pseudorandom vectors $b_i, i = 1, 2, \ldots, 10$. The first column contains twelve values of k. The next one indicates the average of the condition numbers obtained for vectors b_i, i.e.,

$$\text{cond}^{\text{ave}} = \frac{1}{10} \sum_{i=1}^{10} \hat{\xi}(A, b_i, k)/\xi(A, b_i, k),$$

while the third one shows the standard deviation $\sigma_{10}^{\text{cond}}$ of the empirical condition number. The last two columns concern the bound on the probability given in Theorem 5, namely, the average, prob^{ave}, and the standard deviation, $\sigma_{10}^{\text{prob}}$, of the bound of probability for the vectors b_i.

TABLE 4

$k-1$	cond^{ave}	$\sigma_{10}^{\text{cond}}$	prob^{ave}	$\sigma_{10}^{\text{prob}}$
5	21.533	5.997	−2.692	0.913
10	57.481	19.465	−1.178	0.885
15	85.442	21.391	−0.230	0.448
20	102.793	19.770	0.349	0.199
25	111.690	12.074	0.701	0.062
30	116.163	0.782	0.866	0.002
35	116.451	0.018	0.944	0
40	116.457	0.0017	0.977	0
45	116.457	0.0017	0.990	0
50	116.457	0.0017	0.996	0
55	116.457	0.0017	0.998	0
60	116.457	0.0017	0.999	0

Observe that the first three elements of the fourth and fifth columns should be replaced by zeros, but we think it is interesting to see how the bound of Theorem 5 increases with k.

Table 4 shows that the average bound on the probability is close to 1 for k larger than 30. Note that for these k's, the average condition number is nearly equal to the exact condition number of this matrix. We stress that the corresponding standard deviations are very small. For k smaller than 20, the average bound of the probability was quite small (or even negative) although for $k \geq 7$ and all pseudorandom vectors b_i, the computed condition number, $\hat{\xi}_k/\xi_k$ satisfied: $\hat{\xi}_k/\xi_k \leq \text{cond}\, A \leq 10\,\hat{\xi}_k/\xi_k$.

For the matrix A of the size 1024 (32 points in each direction) the corresponding table is (the condition number of this matrix is 440.6886...).

TABLE 5

$k-1$	cond^{ave}	$\sigma_{10}^{\text{cond}}$	prob^{ave}	$\sigma_{10}^{\text{prob}}$
5	24.195	1.625	−7.338	0.496
10	66.358	8.380	−4.223	0.743
15	123.881	30.943	−3.053	1.256
20	181.720	56.008	−2.115	1.312
25	233.467	71.980	−1.347	1.093
30	279.179	80.741	−0.752	0.834
35	321.968	82.043	−0.314	0.588
40	375.354	62.747	−0.049	0.316
45	420.228	32.238	0.191	0.120
50	434.603	11.736	0.452	0.033
55	439.324	2.548	0.643	0.005
60	440.310	0.684	0.771	0.001
65	440.556	0.156	0.854	0
70	440.622	0.042	0.907	0

Note that for $k > 8$ and all pseudorandom vectors b_i, the computed condition number, $\hat{\xi}_k/\xi_k$ satisfied: $\hat{\xi}_k/\xi_k \leq \text{cond}\, A \leq 10\,\hat{\xi}_k/\xi_k$, while the corresponding probability is positive for $k > 42$. This suggests that the lower bound on the probability given in Theorem 5 is rather poor for this matix.

We have also tested matrices with distributions of eigenvalues described earlier. For instance, for Chebyshevian distribution the bound on the probability was negative (usually between -7 and -3). Note that for this matrix the approximations $\hat{\xi}_k/\xi_k$ of the condition number satisfying: $\hat{\xi}_k/\xi_k \leq \text{cond}\, A = 101371 \leq 10\,\hat{\xi}_k/\xi_k$ were observed

(on average) for k larger than 70. Let us stress that for all pseudorandom vectors b_i, the numbers k^* were smaller than 80. Similar results were observed for the quadratic distribution of eigenvalues $\lambda_i = 2(1 - i/251)^2$, $i = 1, \ldots, 250$ (for this matrix the condition number is equal to 62500).

For other distributions we obtained better results. Note that the condition numbers were much smaller than the condition number for the Chebyshevian distribution. For instance, for the logarithmic distribution the bound on the probability was on average greater than 0.9 for k larger than 9. The condition number of this matrix is 7.9715 and for each k we got the empirical condition number $\hat{\xi}_k/\xi_k$ satisfying $\hat{\xi}_k/\xi_k \leq \operatorname{cond} A = 7.9715 \leq 10\,\hat{\xi}_k/\xi_k$.

We now turn to the bounds for the condition number of a matrix given by Theorem 7. As before, the number α was fixed to 10 and θ and η were chosen to maximize (numerically) the second bound of Theorem 7. Table 6 shows some results for the matrix A of the size 256 that arises as a discretization of a two-dimensional Laplace operator and for ten pseudorandom vectors $b_i, i = 1, \ldots, 10$ (compare with Table 4). The first three columns contain values defined in the description of Table 4. The last two columns display the bound on the probability given in Theorem 7 with $M = \operatorname{cond} A$ (prob(1)) and $M = 100 \operatorname{cond} A$ (prob(100)), respectively. To speed our tests, for $k-1 \geq 75$ we did not compute approximations to the extreme eigenvalues. Instead, we use bounds on $\mu(Z_k)$ from Theorem 7 with κ_{69}. Thus, we slightly decreased the actual bound on $\mu(Z_k)$ and this is denoted by "$\geq$" in the second column and by "$\leq$" in the third column.

TABLE 6

$k-1$	cond^{ave}	$\sigma_{10}^{\text{cond}}$	prob(1)	prob(100)
5	21.307	6.444	−1.401	−45.042
10	55.979	19.397	0.800	−21.575
15	84.451	20.874	0.984	−13.191

45	116.456	0.013	1	−1.198
50	116.456	0.013	1	−0.661
55	116.456	0.013	1	−0.256
60	116.456	0.013	1	−0.050
65	116.456	0.013	1	0.2390
70	116.456	0.013	1	0.4236
75	$\geq$ 116.456	$\leq$ 0.013	1	0.5869
80	$\geq$ 116.456	$\leq$ 0.013	1	0.6871
85	$\geq$ 116.456	$\leq$ 0.013	1	0.7627
90	$\geq$ 116.456	$\leq$ 0.013	1	0.8202
95	$\geq$ 116.456	$\leq$ 0.013	1	0.8636
100	$\geq$ 116.456	$\leq$ 0.013	1	0.8968
110	$\geq$ 116.456	$\leq$ 0.013	1	0.9407
120	$\geq$ 116.456	$\leq$ 0.013	1	0.9660
130	$\geq$ 116.456	$\leq$ 0.013	1	0.9804
140	$\geq$ 116.456	$\leq$ 0.013	1	0.9888
150	$\geq$ 116.456	$\leq$ 0.013	1	0.9935

We observed that the probability bound of Theorem 7 with $M = \operatorname{cond} A$ is larger than 0.9 for $k \geq 12$. The fact that relatively early we can be almost sure that the Lanczos algorithm produces a good approximation to the condition number of this matrix is due to the fact that we have used a perfect bound for the condition number, namely, the condition number itself. To contrast this, we see that the probability

bound gets much worse (the fifth column) if we use Theorem 7 with $M = 100 \operatorname{cond} A$. Let us stress that for all $k \geq 7$, the approximations $\kappa_k = \hat{\xi}_k/\xi_k$ to the condition number satisfied

$$\kappa_k \leq \operatorname{cond} A \leq 10\kappa_k.$$

For the matrix A of the size 1024 (32 points in each direction) the corresponding table (Table 7) is as follows (compare with Table 5).

TABLE 7

$k-1$	$\operatorname{cond}^{\text{ave}}$	$\sigma_{10}^{\text{cond}}$	prob(1)	prob(100)
10	66.358	8.380	−2.695	−88.952
20	181.720	56.008	0.758	−42.527
30	279.179	80.741	0.984	−26.218
40	375.354	62.747	0.999	−17.680

We now briefly report some results for other matrices. The size of the matrices was chosen to be equal to 250. For the quadratic distribution of eigenvalues $\lambda_i = 2(1-i/251)^2$, $i = 1, \ldots, 250$ in the interval $(0, 2)$ we obtained much worse probability bounds. For $M = \operatorname{cond} A$, the bounds were negative up to the 140th step and they reached 0.786 at the 201st step. For $M = 100 \operatorname{cond} A$, the bounds were all negative and at the 201st step they reached −25.02. Note that for all $k > 71$, the approximated condition numbers κ_k satisfy

$$\kappa_k \leq \operatorname{cond} A = 62500 \leq 10\kappa_k.$$

Slightly worse results were obtained for the shifted Chebyshev distribution of the eigenvalues. Better results were obtained for matrices with the quadratic distribution of eigenvalues

$$\lambda_i = 2(1 - (i/251)^2), \qquad i = 1, ..., 250.$$

The condition number of this matrix is equal to 125.749. Only five steps were needed to get the desired approximations to the condition number of this matrix. The probability bounds for $M = \operatorname{cond} A$ and $M = 100 \operatorname{cond} A$ were positive after 9 and 62 steps. They were greater than 0.5 after 11 and 76 steps, and greater than 0.9 after 15 and 106 steps, respectively.

6. Final remarks. *Remark* 1. We now report a result for the average relative error with respect to the smallest eigenvalue. That is, define

$$e^{\text{avg}}_{\min}(A,k) = \int_{S_n} \frac{\xi(A,b,k) - \lambda_n}{\lambda_n}\, \mu(db).$$

We will show that this error is unbounded in the class of all symmetric positive definite matrices. Indeed, using the same notation as in the proof of Theorem 3, we get

$$e^{\text{avg}}_{\min}(A,k) = \frac{1}{c_n\,\lambda_n} \int_{B_n} \inf_{P\in\mathcal{P}_k} \frac{\sum_{i=1}^{n-1}(\lambda_i - \lambda_n) b_i^2 P^2(\lambda_i)}{\sum_{i=1}^{n} b_i^2 P^2(\lambda_i)}\, db.$$

Assume that the matrix A has n distinct eigenvalues and let $\lambda_i - \lambda_n \geq \delta > 0$ for $i = 1,\ldots,n-1$. Then we have

$$e^{\text{avg}}_{\min}(A,k) \geq \frac{\delta}{c_n\,\lambda_n} \int_{B_n} \left(1 - \sup_{P\in\mathcal{P}_k} \frac{b_n^2 P^2(\lambda_n)}{\sum_{i=1}^{n} b_i^2 P^2(\lambda_i)}\right) db = \frac{\delta}{c_n\,\lambda_n}\, \phi(A,k),$$

where

$$\phi(A,k) = \int_{B_n} \left(1 - \sup_{P\in\mathcal{P}_k} \frac{b_n^2 P^2(\lambda_n)}{\sum_{i=1}^{n} b_i^2 P^2(\lambda_i)}\right) db.$$

Note that the function ϕ is shift invariant, i.e., $\phi(A+\alpha I,k) = \phi(A,k)$ for all $\alpha \in \mathcal{R}$, and $\phi(A,k) > 0$ for $k \leq n-1$. Take now the matrix $A - \alpha I$, where $\alpha < \lambda_n$. Then for $\alpha \to \lambda_n$, we have

$$e^{\text{avg}}_{\min}(A-\alpha I,k) \geq \frac{\delta}{c_n(\lambda_n - \alpha)}\, \phi(A,k) \to +\infty.$$

Thus for any k no greater than $n-1$ and any positive number M there exists a symmetric positive definite matrix A such that

$$e^{\text{avg}}_{\min}(A,k) > M.$$

Remark 2. We now consider a gap ratio as the error criterion instead of the relative error with respect to the largest eigenvalue, i.e., we want to find ξ such that

$$\frac{\xi - \lambda_n(A)}{\lambda_1(A) - \lambda_n(A)} < \varepsilon.$$

Note that the gap ratio for the Lanczos algorithm approximating the smallest eigenvalue is shift invariant, i.e.,

$$\frac{\xi(A+\alpha I,b,k) - \lambda_n(A+\alpha I)}{\lambda_1(A+\alpha I) - \lambda_n(A+\alpha I)} = \frac{\xi(A,b,k) - \lambda_n(A)}{\lambda_1(A) - \lambda_n(A)}.$$

Using a continuity argument, we can conclude that the bounds given in Theorems 1 and 2 hold, since

$$\frac{\xi(A) - \lambda_n(A)}{\lambda_1(A) - \lambda_n(A)} = \frac{\xi(B) - \lambda_n(B)}{\lambda_1(B) - \lambda_n(B)},$$

where $B = A - \lambda_n I$, $B = B^T \geq 0$ with $\lambda_n(B) = 0$.

Acknowledgments. We thank A. Kiełbasiński, J. F. Traub, and A. G. Werschulz for their valuable comments.

AN ERROR MODEL FOR SWARZTRAUBER'S PARALLEL TRIDIAGONAL EQUATION SOLVER*

NAI-KUAN TSAO†

Abstract. Error models for two algorithms based on Cramer's rule are given for tridiagonal systems. The results show that if the exact x_i of the solution vector x is expressed as det p/ det q where p and q are matrices formed from the original coefficient matrix and the right-hand side vector, then the computed x_i can be expressed as det $\hat{p}$/ det $\hat{q}$, where det $\hat{p}$ and det $\hat{q}$ are perturbed det p and det q, respectively, using either the parallel or the sequential algorithm. The relative error of each product in the determinantal expansion of det $\hat{p}$ and det $\hat{q}$ can also be bounded easily.

Key words. tridiagonal matrix, determinant, parallel algorithms, linear equations, error analysis

1. Introduction.

In [1], Swarztrauber described a parallel algorithm that is based on an efficient implementation of Cramer's rule for solving general tridiagonal equations. His basic algorithm can be described as follows. For a given tridiagonal system

$$Ax = y, \quad A = \begin{bmatrix} b_1 & c_1 & & & & \\ a_2 & b_2 & c_2 & & & \\ & \cdot & \cdot & \cdot & & \\ & & \cdot & \cdot & \cdot & \\ & & & \cdot & \cdot & c_{n-1} \\ & & & & a_n & b_n \end{bmatrix} \equiv [\, a_j \quad b_j \quad c_j \,], \quad a_1 = c_n = 0,$$

$$x = [\, x_1 \quad x_2 \quad \dots \quad x_n \,]^T, \qquad y = [\, y_1 \quad y_2 \quad \dots \quad y_n \,]^T,$$

let us denote by d_i the determinant of the leading i by i submatrix of A, f_i the determinant of the trailing $(n-i+1)$ by $(n-i+1)$ submatrix of A, t_i the determinant of the leading i by i submatrix of A with column i replaced by the first i components of y, and u_i the determinant of the trailing $(n-i+1)$ by $(n-i+1)$ submatrix of A with column i replaced by the last $(n-i+1)$ components of y. Then the following theorem can be proved [1].

THEOREM 1.1. *Given the sequences d_i, f_i, t_i, and u_i defined above, then the solution x_i is given by*

$$x_1 = u_1/d_n, \quad x_i = (d_{i-1}u_i - a_i f_{i+1} t_{i-1})/d_n, \quad 1 < i < n, \quad x_n = t_n/d_n,$$

where

$$d_i = b_i d_{i-1} - a_i c_{i-1} d_{i-2}, \quad d_0 = 1, \; d_1 = b_1, \quad i > 1,$$

$$t_i = -a_i t_{i-1} + d_{i-1} y_i, \quad t_1 = y_1, \quad i > 1,$$

$$f_i = b_i f_{i+1} - a_{i+1} c_i f_{i+2}, \quad f_{n+1} = 1, \quad f_n = b_n, \quad i < n,$$

*Received by the editors April 15, 1992; accepted for publication (in revised form) November 10, 1992.

$$u_i = -c_i u_{i+1} + f_{i+1} y_i, \quad u_n = y_n, \quad i < n.$$

A sequential algorithm based on the above theorem is given below.

ALGORITHM Sw1
$d_1 = b_1$; $e_1 = c_1$
for $i = 2$ to n do
  $d_i = fl(b_i d_{i-1} - a_i e_{i-1})$; $e_i = fl(c_i d_{i-1})$
$f_n = b_n$; $g_n = a_n$
for $i = n - 1$ downto 1 do
  $f_i = fl(b_i f_{i+1} - c_i g_{i+1})$; $g_i = fl(a_i f_{i+1})$
$t_1 = y_1$
for $i = 2$ to n do
  $t_i = fl(-a_i t_{i-1} + d_{i-1} y_i)$
$u_n = y_n$
for $i = n - 1$ downto 1 do
  $u_i = fl(-c_i u_{i+1} + f_{i+1} y_i)$
$x_1 = fl(u_1/d_n)$; $x_n = fl(t_n/d_n)$
for $i = 2$ to $n - 1$ do
  $x_i = fl((-g_i t_{i-1} + d_{i-1} u_i)/d_n)$

where $fl(.)$ is used to denote the computed result of the enclosed argument.

For $n = 2^k$, $k > 0$, Stone's recursive doubling technique [2] can be used to parallelize the calculation of the vectors d, e, f, g, t, and u using the following algorithm.

ALGORITHM Sw2
for $i = 1$ to n do {in parallel}
  $\alpha_i^{(i)} = -a_i$; $\gamma_i^{(i)} = -c_i$; $Q_i^{(i)} = \begin{bmatrix} b_i & c_i \\ -a_i & 0 \end{bmatrix}$
for $j = 1$ to k do
  $l = 2^{j-1}$
  for $i = 0$ to $n - 2^j$ step 2^j do {in parallel}
    $\alpha_{i+1}^{(i+2l)} = fl\left(\alpha_{i+1}^{(i+l)} \alpha_{i+l+1}^{(i+2l)}\right)$; $\gamma_{i+1}^{(i+2l)} = fl\left(\gamma_{i+1}^{(i+l)} \gamma_{i+l+1}^{(i+2l)}\right)$
    $Q_{i+1}^{(i+2l)} = fl\left(Q_{i+1}^{(i+l)} Q_{i+l+1}^{(i+2l)}\right)$
for $j = 0$ to k do {in parallel}
  $l = 2^j$; $[d_l \; e_l] = [1 \; 0] Q_1^{(l)}$; $\begin{bmatrix} f_{n-l+1} \\ g_{n-l+1} \end{bmatrix} = Q_{n-l+1}^{(n)} \begin{bmatrix} 1 \\ 0 \end{bmatrix}$
for $j = k - 1$ downto 1 do
  $l = 2^{j-1}$
  for $i = 2^j$ to $n - 2^j$ step 2^j do {in parallel}
    $[d_{i+l} \; e_{i+l}] = fl\left([d_i \; e_i] Q_{i+1}^{(i+l)}\right)$; $\begin{bmatrix} f_{i-l+1} \\ g_{i-l+1} \end{bmatrix} = fl\left(Q_{i-l+1}^{(i)} \begin{bmatrix} f_{i+1} \\ g_{i+1} \end{bmatrix}\right)$
$d_0 = 1$; $f_{n+1} = 1$
for $i = 1$ to n do {in parallel}
  $t_i^{(i)} = fl(d_{i-1} y_i)$; $u_i^{(i)} = fl(f_{i+1} y_i)$
for $j = 1$ to k do
  $l = 2^{j-1}$
  for $i = 0$ to $n - 2^j$ step 2^j do {in parallel}
    $t_{i+1}^{(i+2l)} = fl\left(t_{i+l+1}^{(i+2l)} + \alpha_{i+l+1}^{(i+2l)} t_{i+1}^{(i+l)}\right)$; $u_{i+1}^{(i+2l)} = fl\left(u_{i+1}^{(i+l)} + \gamma_{i+1}^{(i+l)} u_{i+l+1}^{(i+2l)}\right)$
for $j = k - 1$ downto 1 do

$l = 2^{j-1}$
for $i = 2^j$ to $n - 2^j$ step 2^j do {in parallel}
$t_1^{(i+l)} = fl\left(t_{i+1}^{(i+l)} + \alpha_{i+1}^{(i+l)} t_1^{(i)}\right)$; $u_{i-l+1}^{(n)} = fl\left(u_{i-l+1}^{(i)} + \gamma_{i-l+1}^{(i)} u_{i+1}^{(n)}\right)$
$x_1 = fl\left(u_1^{(n)}/d_n\right)$; $x_n = fl\left(t_1^{(n)}/d_n\right)$
for $i = 2$ to $n - 1$ do {in parallel}
$x_i = fl\left(\left(g_i t_1^{(i-1)} + d_{i-1} u_i^{(n)}\right)/d_n\right)$

Note the required t_i and u_i in Algorithm Sw1 are given as $t_1^{(i)}$ and $u_i^{(n)}$, respectively, in Algorithm Sw2.

The experimental numerical equivalence of Algorithm Sw2 and the usual Gaussian elimination method has been demonstrated in [1]. In this paper we carry out the error analysis of the above two algorithms and show that if the exact x_i of the solution vector x is expressed as $\det p/\det q$ where p and q are matrices formed from the original coefficient matrix and the right-hand side vector, then the computed x_i can be expressed as $\det \hat{p}/\det \hat{q}$, where $\det \hat{p}$ and $\det \hat{q}$ are perturbed $\det p$ and $\det q$, respectively, using either the parallel or the sequential algorithm. The relative error of each product in the determinantal expansion of $\det \hat{p}$ and $\det \hat{q}$ can also be bounded easily. Some preliminary results are given in § 2. The error analysis of Algorithms Sw1 and Sw2 are presented in §§ 3 and 4.

2. Some preliminary results. For convenience, determinants will be used to express the various computed results from Algorithms Sw1 and Sw2. To this end, let

$$D_{\delta_1,\delta_2,\ldots,\delta_k}^{\beta_1,\beta_2,\ldots,\beta_k}$$

be used to denote the determinant of a submatrix formed by the common elements of rows $\beta_1, \beta_2, \ldots, \beta_k$ and columns $\delta_1, \delta_2, \ldots, \delta_k$ of the matrix A. For contiguous rows or columns, they are denoted by

$$\beta_i : \beta_j = \beta_i, \beta_i + 1, \ldots, \beta_j - 1, \beta_j$$

or

$$\delta_i : \delta_j = \delta_i, \delta_i + 1, \ldots, \delta_j - 1, \delta_j, \qquad i \le j.$$

If row indices are the same as the column indices, then only the column indices will be used. Thus $D_{1:2,4}$ is the same as $D_{1:2,4}^{1:2,4}$. We shall also use $D_{i:j}(k)$ for $i \le k \le j$ to denote $D_{i:j}^{i:j}$ with column k, $i \le k \le j$, replaced by a column formed by $y_i, y_{i+1}, \ldots, y_j$. As an example, let $n = 4$. Then we have

$$D_{1,2} = \begin{vmatrix} b_1 & c_1 \\ a_2 & b_2 \end{vmatrix}, \quad D_{2,5}^{3,4} = \begin{vmatrix} a_3 & 0 \\ 0 & c_4 \end{vmatrix}, \quad D_{2:4}(3) = \begin{vmatrix} b_2 & y_2 & \\ a_3 & y_3 & c_3 \\ & y_4 & b_4 \end{vmatrix}.$$

We have the following lemmas.

LEMMA 2.1. *If exact computations were possible, then*

$$D_{i:j} = D_{i:k} D_{k+1:j} - D_{i:k-1,k+1}^{i:k} D_{k,k+2:j}^{k+1:j}, \quad i < j, \quad i \le k, \quad k \le j.$$

Furthermore, for $1 < i < j < n$,

$$D_{i:j-1,j+1}^{i:j} = c_j D_{i:j-1}, \qquad D_{i-1,i+1:j}^{i:j} = a_i D_{i+1:j},$$

$$D^{i:j}_{i-1,i+1:j-1,j+1} = c_j D^{i:j-1}_{i-1,i+1:j-1} = a_i D^{i+1:j}_{i+1:j-1,j+1} = a_i c_j D_{i+1:j-1}.$$

Proof. The second part of the lemma is easily obtained by definition. For the first part we have

$$D_{i:j} = \begin{vmatrix} b_i & c_i & & & & & & \\ a_{i+1} & b_{i+1} & c_{i+1} & & & & & \\ & \ddots & \ddots & \ddots & & & & \\ & & a_k & b_k & c_k & & & \\ & & & a_{k+1} & b_{k+1} & c_{k+1} & & \\ & & & & a_{k+2} & \ddots & \ddots & \\ & & & & & \ddots & b_{j-1} & c_{j-1} \\ & & & & & & a_j & b_j \end{vmatrix}.$$

Now partition the matrix in the above expression into two parts: one formed by the first $k-i+1$ rows and the other formed by the last $j-k$ rows. Let H_{k-i+1}, and H_{j-k} be used to denote the determinant of any submatrix formed by choosing $k-i+1$ columns of the first part, and the corresponding complementary set of columns (there are $j-k$ of them) of the second part, respectively. Now $D_{i:j}$ can be expressed as a sum of $H_{k-i+1}H_{j-k}$ (with appropriate signs) over all possible ways that $k-i+1$ columns can be chosen from $j-i+1$ columns of the first part as long as $H_{k-i+1}H_{j-k} \neq 0$. In this case there are only two choices: selecting from the first group $k-i+1$ columns so that $H_{k-i+1} = D_{i:k}$, $H_{j-k} = D_{k+1:j}$ and the sign is positive; and selecting from the first group the first $k-i$ plus the $k-i$+2-nd column so that $H_{k-i+1} = D^{i:k}_{i:k-1,k+1}$, $H_{j-k} = D^{k+1:j}_{k,k+2:j}$ and the sign is negative. The sum of these two products is then $D_{i:j}$. Thus the lemma is proved. □

LEMMA 2.2. *If exact computations were possible, then the computed results of Algorithm* Sw2 *are such that*

$$Q^{(i+2l)}_{i+1} = \begin{bmatrix} D_{i+1:i+2l} & D^{i+1:i+2l}_{i+1:i+2l-1,i+2l+1} \\ -D^{i+1:i+2l}_{i,i+2:i+2l} & -D^{i+1:i+2l}_{i,i+2:i+2l-1,i+2l+1} \end{bmatrix},$$

where

$$l = 2^{j-1}, \quad i = 0, 1(2^j), 2(2^j), \ldots, n-2^j, \quad n = 2^k, \quad j = 1, 2, \ldots, k.$$

Proof. We prove by substitution. By definition

$$Q^{(i+2l)}_{i+1} \equiv \begin{bmatrix} q_{11} & q_{12} \\ q_{21} & q_{22} \end{bmatrix} = Q^{(i+l)}_{i+1} Q^{(i+2l)}_{i+l+1}. \tag{2.1}$$

Since

$$Q_{i+1}^{(i+l)} = \begin{bmatrix} D_{i+1:i+l} & D_{i+1:i+l-1,i+l+1}^{i+1:i+l} \\ -D_{i,i+2:i+l}^{i+1:i+l} & -D_{i,i+2:i+l-1,i+l+1}^{i+1:i+l} \end{bmatrix},$$

$$Q_{i+l+1}^{(i+2l)} = \begin{bmatrix} D_{i+l+1:i+2l} & D_{i+l+1:i+2l-1,i+2l+1}^{i+l+1:i+2l} \\ -D_{i+l,i+l+2:i+2l}^{i+l+1:i+2l} & -D_{i+l,i+l+2:i+2l-1,i+2l+1}^{i+l+1:i+2l} \end{bmatrix}.$$

Equating both sides of (2.1) then gives us

$$q_{11} = D_{i+1:i+l}D_{i+l+1:i+2l} - D_{i+1:i+l-1,i+l+1}^{i+1:i+l} D_{i+l,i+l+2:i+2l}^{i+l+1:i+2l} = D_{i+1:i+2l}$$

by Lemma 2.1. Similarly, Lemma 2.1 can be used again to give

$$\begin{aligned} q_{12} &= D_{i+1:i+l}D_{i+l+1:i+2l-1,i+2l+1}^{i+l+1:i+2l} - D_{i+1:i+l-1,i+l+1}^{i+1:i+l} D_{i+l,i+l+2:i+2l}^{i+l+1:i+2l} \\ &= c_{i+2l}\left(D_{i+1:i+l}D_{i+l+1:i+2l-1} - D_{i+1:i+l-1,i+l+1}^{i+1:i+l} D_{i+l,i+l+2:i+2l-1}^{i+l+1:i+2l-1}\right) \\ &= c_{i+2l}D_{i+l:i+2l-1} = D_{i+l:i+2l-1,i+2l+1}^{i+1:i+2l}. \end{aligned}$$

The remaining identities can be verified similarly. This completes our proof. □

3. Error analysis of Algorithm Sw1. Given a normalized floating-point system with a τ-digit base β mantissa, the following equations can be assumed to facilitate the error analysis of general arithmetic expressions using only $+, -, *,$ or $/$ operations [3]

$$fl(x\#y) = (x\#y)\Delta, \qquad \# \in \{+, -, *, /\}, \tag{3.1}$$

where x and y are given machine floating-point numbers and $fl(.)$ is used to denote the computed floating-point result of the given argument, and

$$\Delta = 1 + \epsilon, \qquad |\epsilon| \le u = \begin{cases} \beta^{1-\tau}/2 & \text{for rounded operations,} \\ \beta^{1-\tau} & \text{for chopped operations.} \end{cases}$$

We call Δ the unit Δ-factor. For simplicity, we assume that the given matrix A and right-hand side vector y are exact.

We first look at the computation of d_i and e_i. The basic equations are the following:

$$d_0 = 1, \quad d_1 = b_1, \quad e_1 = c_1, \quad d_i = fl(b_i d_{i-1} - a_i e_{i-1}), \quad e_i = fl(c_i d_{i-1}), \quad i \ge 2.$$

By applying (3.1) to the above equations, we obtain $d_0 = 1$, $d_1 = b_1$, $e_1 = c_1$,

$$d_2 = b_2 d_1 \Delta_2\Delta_3 - a_2 e_1 \Delta_1\Delta_3 = \begin{vmatrix} b_1 & c_1 \\ a_2\Delta_1\Delta_3 & b_2\Delta_2\Delta_3 \end{vmatrix},$$

$$e_2 = c_2 b_1 \Delta_4 = \begin{vmatrix} b_1 & \\ a_2\Delta_1\Delta_3 & c_2\Delta_4 \end{vmatrix}.$$

Note the added $\Delta_1\Delta_3$ factor to a_2 in the expression for e_2. Since usually the various Δ-factors are unknown, the generic form Δ^k is used to denote a product of possible k different Δ-factors. Thus we have

$$d_2 = \begin{vmatrix} b_1 & c_1 \\ a_2\Delta^2 & b_2\Delta^2 \end{vmatrix}, \qquad e_2 = \begin{vmatrix} b_1 & \\ a_2\Delta^2 & c_2\Delta \end{vmatrix}. \tag{3.2a}$$

Similarly,

$$d_3 = b_3d_2\Delta^2 - a_3e_2\Delta^2 = \begin{vmatrix} d_2 & e_2 \\ a_3\Delta^2 & b_3\Delta^2 \end{vmatrix} = \begin{vmatrix} b_1 & c_1 & \\ a_2\Delta^2 & b_2\Delta^2 & c_2\Delta \\ & a_3\Delta^2 & b_3\Delta^2 \end{vmatrix}, \tag{3.2b}$$

$$e_3 = c_3d_2\Delta = \begin{vmatrix} b_1 & c_1 & \\ a_2\Delta^2 & b_2\Delta^2 & \\ & a_3\Delta^2 & c_3\Delta \end{vmatrix}. \tag{3.2c}$$

By induction we then obtain the following theorem.

THEOREM 3.1. *The computed d_i and e_i using Algorithm* Sw1 *satisfy* (3.2) *for $i = 2, 3$. And generally for $3 < i \leq n$ they are such that*

$$d_i = \begin{vmatrix} b_1 & c_1 & & & & \\ a_2\Delta^2 & b_2\Delta^2 & c_2\Delta & & & \\ & \ddots & \ddots & \ddots & & \\ & & a_{i-1}\Delta^2 & b_{i-1}\Delta^2 & c_{i-1}\Delta & \\ & & & a_i\Delta^2 & b_i\Delta^2 & \end{vmatrix},$$

$$e_i = \begin{vmatrix} b_1 & c_1 & & & & \\ a_2\Delta^2 & b_2\Delta^2 & c_2\Delta & & & \\ & \ddots & \ddots & \ddots & & \\ & & a_{i-2}\Delta^2 & b_{i-2}\Delta^2 & c_{i-2}\Delta & \\ & & & a_{i-1}\Delta^2 & b_{i-1}\Delta^2 & \\ & & & & a_i\Delta^2 & c_i\Delta \end{vmatrix}.$$

By similar reasonings, one can obtain the following theorem.

THEOREM 3.2. *The computed f_i and g_i using Algorithm* Sw1 *are such that*

$$f_i = \begin{vmatrix} b_i\Delta^2 & c_i\Delta^2 & & & \\ a_{i+1}\Delta & b_{i+1}\Delta^2 & c_{i+1}\Delta^2 & & \\ & \ddots & \ddots & \ddots & \\ & & a_{n-1}\Delta & b_{n-1}\Delta^2 & c_{n-1}\Delta^2 \\ & & & a_n & b_n \end{vmatrix}, \qquad 1 \le i \le n-1,$$

$$g_{n-1} = \begin{vmatrix} a_{n-1}\Delta & c_{n-1}\Delta^2 \\ & b_n \end{vmatrix}, \qquad g_{n-2} = \begin{vmatrix} a_{n-2}\Delta & c_{n-2}\Delta^2 & \\ & b_{n-1}\Delta^2 & c_{n-1}\Delta^2 \\ & a_n & b_n \end{vmatrix},$$

$$g_i = \begin{vmatrix} a_i\Delta & c_i\Delta^2 & & & & \\ & b_{i+1}\Delta^2 & c_{i+1}\Delta^2 & & & \\ & a_{i+2}\Delta & b_{i+2}\Delta^2 & c_{i+2}\Delta^2 & & \\ & & \ddots & \ddots & \ddots & \\ & & & a_{n-1}\Delta & b_{n-1}\Delta^2 & c_{n-1}\Delta^2 \\ & & & & a_n & b_n \end{vmatrix}, \qquad 1 \le i < n-2.$$

The computation of t_i and u_j are more complicated. For t_2, we have

$$t_2 = fl(-a_2t_1 + d_1y_2) = -a_2t_1\Delta^2 + d_1y_2\Delta^2 = \begin{vmatrix} b_1 & y_1 \\ a_2\Delta^2 & y_2\Delta^2 \end{vmatrix}. \tag{3.3a}$$

Similarly for t_3, we have

$$t_3 = \begin{vmatrix} d_2 & t_2 \\ a_3\Delta^2 & y_3\Delta^2 \end{vmatrix}.$$

Now

$$d_2 = \begin{vmatrix} b_1 & c_1 \\ a_2\Delta^2 & b_2\Delta^2 \end{vmatrix}.$$

Although the expressions for d_2 and t_2 share the same $a_2\Delta^2$ in the above equations, they are most likely different because d_2 and t_2 are computed in separate occasions. Thus strictly speaking, one cannot write the equality

$$t_3 = \begin{vmatrix} b_1 & c_1 & y_1 \\ a_2\Delta^2 & b_2\Delta^2 & y_2\Delta^2 \\ & a_3\Delta^2 & y_3\Delta^2 \end{vmatrix}. \tag{3.3b}$$

However, the above equality is valid if the right-hand side is interpreted as a compact representation of the sum of products contained in the expansion of the determinant. Because then $a_2\Delta^2$ can be part of many different products and one can assign different values for Δ^2 if necessary. Henceforth the above interpretation of equality will be used in our discussions. Note that the new interpretation does not affect the validity of Theorems 3.1 and 3.2.

For u_{n-1} and u_{n-2}, we have

$$(3.3c)\qquad u_{n-1} = \begin{vmatrix} y_{n-1}\Delta^2 & c_{n-1}\Delta^2 \\ y_n & b_n \end{vmatrix}, \qquad u_{n-2} = \begin{vmatrix} y_{n-2}\Delta^2 & c_{n-2}\Delta^2 & \\ y_{n-1}\Delta^2 & b_{n-1}\Delta^2 & c_{n-1}\Delta^2 \\ y_n & a_n & b_n \end{vmatrix}.$$

In general, we have the following theorem.

THEOREM 3.3. *The computed t_i and u_j using Algorithm* Sw1 *are such that t_2, t_3, u_{n-1}, and u_{n-2} satisfy* (3.3) *and for $3 < i \le n$ and $1 \le j < n-2$,*

$$(3.4)\qquad t_i = \begin{vmatrix} b_1 & c_1 & & & & y_1 \\ a_2\Delta^2 & b_2\Delta^2 & c_2\Delta & & & y_2\Delta^2 \\ & \ddots & \ddots & \ddots & & \vdots \\ & & a_{i-2}\Delta^2 & b_{i-2}\Delta^2 & c_{i-2}\Delta & y_{i-2}\Delta^2 \\ & & & a_{i-1}\Delta^2 & b_{i-1}\Delta^2 & y_{i-1}\Delta^2 \\ & & & & a_i\Delta^2 & y_i\Delta^2 \end{vmatrix},$$

$$u_j = \begin{vmatrix} y_j\Delta^2 & c_j\Delta^2 & & & & \\ y_{j+1}\Delta^2 & b_{j+1}\Delta^2 & c_{j+1}\Delta^2 & & & \\ y_{j+2}\Delta^2 & a_{j+2}\Delta & b_{j+2}\Delta^2 & c_{j+2}\Delta^2 & & \\ \vdots & & \ddots & \ddots & \ddots & \\ y_{n-1}\Delta^2 & & & a_{n-1}\Delta & b_{n-1}\Delta^2 & c_{n-1}\Delta^2 \\ y_n & & & & a_n & b_n \end{vmatrix}.$$

Proof. By construction we have

$$t_i = fl(-a_i t_{i-1} + d_{i-1}y_i) = -a_i t_{i-1}\Delta^2 + d_{i-1}y_i\Delta^2.$$

Now the structure of d_{i-1} is given in Theorem 3.1. If we assume that Theorem 3.3 is true for t_{i-1}, then the above expression is exactly equivalent to the expression obtained when expanding the right-hand side determinant of (3.4) by its last row. Hence (3.4) is valid. Similar reasonings can also be used to verify the expression for u_j. This time

the expansion of its right-hand side determinant is by its first row. This completes our proof. □

From Theorems 3.1, 3.2, and 3.3 one can obtain the following theorem.

THEOREM 3.4. *The computed x_i for $1 \le i \le n$ are such that*

$$x_1 = \frac{u_1\Delta}{d_n} = \frac{\hat{u}_1}{d_n}, \qquad \hat{u}_1 = \begin{vmatrix} y_1\Delta^3 & c_1\Delta^2 & & & & \\ y_2\Delta^3 & b_2\Delta^2 & c_2\Delta^2 & & & \\ y_3\Delta^3 & a_3\Delta & b_3\Delta^2 & c_3\Delta^2 & & \\ \vdots & & \ddots & \ddots & \ddots & \\ y_{n-1}\Delta^3 & & & a_{n-1}\Delta & b_{n-1}\Delta^2 & c_{n-1}\Delta^2 \\ y_n\Delta & & & & a_n & b_n \end{vmatrix},$$

$$x_n = \frac{t_n\Delta}{d_n} = \frac{\hat{t}_n}{d_n}, \qquad \hat{t}_n = \begin{vmatrix} b_1 & c_1 & & & & y_1\Delta \\ a_2\Delta^2 & b_2\Delta^2 & c_2\Delta & & & y_2\Delta^3 \\ & \ddots & \ddots & \ddots & & \vdots \\ & & a_{n-2}\Delta^2 & b_{n-2}\Delta^2 & c_{n-2}\Delta & y_{n-2}\Delta^3 \\ & & & a_{n-1}\Delta^2 & b_{n-1}\Delta^2 & y_{n-1}\Delta^3 \\ & & & & a_n\Delta^2 & y_n\Delta^3 \end{vmatrix},$$

$$x_i = \frac{\begin{vmatrix} d_{i-1} & t_{i-1}\Delta^3 \\ g_i & u_i\Delta^3 \end{vmatrix}}{d_n} = \frac{\xi_i}{d_n},$$

where

$$\xi_i = \begin{vmatrix} b_1 & c_1 & & & & y_1\Delta^3 & & & & \\ a_2\Delta^2 & b_2\Delta^2 & c_2\Delta & & & y_2\Delta^5 & & & & \\ & \cdots & \cdots & & & \cdots & & & & \\ & a_{i-2}\Delta^2 & b_{i-2}\Delta^2 & c_{i-2}\Delta & & y_{i-2}\Delta^5 & & & & \\ & & a_{i-1}\Delta^2 & b_{i-1}\Delta^2 & & y_{i-1}\Delta^5 & & & & \\ & & & a_i\Delta & & y_i\Delta^5 & c_i\Delta^2 & & & \\ & & & & & y_{i+1}\Delta^5 & b_{i+1}\Delta^2 & c_{i+1}\Delta^2 & & \\ & & & & & y_{i+2}\Delta^5 & a_{i+2}\Delta & b_{i+2}\Delta^2 & c_{i+2}\Delta^2 & \\ & & & & & \cdots & & \cdots & \cdots & \\ & & & & & y_{n-1}\Delta^5 & & a_{n-1}\Delta & b_{n-1}\Delta^2 & c_{n-1}\Delta^2 \\ & & & & & y_n\Delta^3 & & & a_n & b_n \end{vmatrix}.$$

Proof. Results for x_1 and x_n are straightforward by using Theorem 3.3. For x_i, one can expand ξ_i using a similar approach as described in the proof of Lemma 2.1 to show that

$$\xi_i = d_{i-1}u_i\Delta^3 - t_{i-1}g_i\Delta^3 = \begin{vmatrix} d_{i-1} & t_{i-1}\Delta^3 \\ g_i & u_i\Delta^3 \end{vmatrix}.$$

This completes our proof. □

4. Error analysis of Algorithm Sw2. To give consistent and compact expressions similar to Theorems 3.1–3.4 for Algorithm Sw2, we introduce the relation $\preceq$ as follows: If for a certain matrix B, we have

$$p^* = \det B = \sum_{j=1}^{\lambda(\det B)} p_j^*,$$

where p_j^*'s are exact products of error-free data and $\lambda(\det B)$ is the total number of such products in $\det B$, then

$$p = fl(\det B) = \sum_{j=1}^{\lambda(\det B)} p_j^*\Delta^{\gamma_j^*} \preceq \sum_{j=1}^{\lambda(\det B)} p_j^*\Delta^{\gamma_j} = \det \tilde{B} \quad \text{if} \quad \gamma_j^* \le \gamma_j \quad \text{for all } j.$$

In other words, γ_j is an upper bound of γ_j^*. Thus, for example,

$$\begin{vmatrix} b_1 & c_1 \\ a_2\Delta^2 & b_2\Delta^2 \end{vmatrix} \preceq \begin{vmatrix} b_1\Delta & c_1 \\ a_2\Delta^2 & b_2\Delta^2 \end{vmatrix} \preceq \begin{vmatrix} b_1\Delta & c_1\Delta \\ a_2\Delta^2 & b_2\Delta^2 \end{vmatrix}.$$

Furthermore, we use the following model in evaluating a general 2×2 determinant:

$$fl\left(\begin{vmatrix} x & y \\ z & w \end{vmatrix}\right) = \begin{vmatrix} x\Delta & y\Delta \\ z\Delta & w\Delta \end{vmatrix}.$$

For simplicity, the same $D_{\delta_1,\delta_2,\ldots,\delta_k}^{\beta_1,\beta_2,\ldots,\beta_k}$ is used to denote the computed determinant of a submatrix formed by the common elements of rows $\beta_1, \beta_2, \ldots, \beta_k$ and columns $\delta_1, \delta_2, \ldots, \delta_k$ of the matrix A.

Consider the computation of $Q_{i+1}^{(i+2l)}$ for $n = 8$ first. It proceeds as follows: stage 1, the computation of $Q_1^{(2)}, Q_3^{(4)}, Q_5^{(6)}, Q_7^{(8)}$; stage 2, the computation of $Q_1^{(4)}, Q_5^{(8)}$; stage 3, the computation of $Q_1^{(8)}$. We give the computed $Q_1^{(2)}, Q_3^{(4)}$, and $Q_1^{(4)}$ first.

$$Q_1^{(2)} = \begin{bmatrix} D_{1:2} & D_{1,3}^{1:2} \\ 0 & 0 \end{bmatrix}, \quad Q_3^{(4)} = \begin{bmatrix} D_{3:4} & D_{3,5}^{3:4} \\ -D_{2,4}^{3:4} & -D_{2,5}^{3:4} \end{bmatrix}, \quad Q_1^{(4)} = \begin{bmatrix} D_{1:4} & D_{1:3,5}^{1:4} \\ 0 & 0 \end{bmatrix},$$

where

$$D_{1:2} = \begin{vmatrix} b_1\Delta & c_1\Delta \\ a_2\Delta & b_2\Delta \end{vmatrix}, \quad D_{3:4} = \begin{vmatrix} b_3\Delta & c_3\Delta \\ a_4\Delta & b_4\Delta \end{vmatrix}, \quad D_{1,3}^{1:2} = \begin{vmatrix} b_1 & 0 \\ a_2\Delta & c_2\Delta \end{vmatrix} \preceq \begin{vmatrix} b_1\Delta & 0 \\ a_2\Delta & c_2\Delta \end{vmatrix},$$

$$D_{3,5}^{3:4} \preceq \begin{vmatrix} b_3\Delta & 0 \\ a_4\Delta & c_4\Delta \end{vmatrix}, \quad D_{2,4}^{3:4} \preceq \begin{vmatrix} a_3\Delta & c_3\Delta \\ 0 & b_4\Delta \end{vmatrix}, \quad D_{2,5}^{3:4} = \begin{vmatrix} a_3 & 0 \\ 0 & c_4\Delta \end{vmatrix} \preceq \begin{vmatrix} a_3\Delta & 0 \\ 0 & c_4\Delta \end{vmatrix},$$

and

$$D_{1:4} = D_{1:2}D_{3:4}\Delta^2 - D_{1,3}^{1:2}D_{2,4}^{3:4}\Delta^2 = (D_{1:2}\Delta)(D_{3:4}\Delta) - (D_{1,3}^{1:2}\Delta)(D_{2,4}^{3:4}\Delta)$$

$$\preceq \begin{vmatrix} b_1\Delta & c_1\Delta \\ a_2\Delta^2 & b_2\Delta^2 \end{vmatrix} \begin{vmatrix} b_3\Delta^2 & c_3\Delta^2 \\ a_4\Delta & b_4\Delta \end{vmatrix} - \begin{vmatrix} b_1\Delta & 0 \\ a_2\Delta^2 & c_2\Delta^2 \end{vmatrix} \begin{vmatrix} a_3\Delta^2 & c_3\Delta^2 \\ 0 & b_4\Delta \end{vmatrix}$$

$$\preceq \begin{vmatrix} b_1\Delta & c_1\Delta & & \\ a_2\Delta^2 & b_2\Delta^2 & c_2\Delta^2 & \\ & a_3\Delta^2 & b_3\Delta^2 & c_3\Delta^2 \\ & & a_4\Delta & b_4\Delta \end{vmatrix},$$

$$D_{1:3,5}^{1:4} = D_{1:2}D_{3,5}^{3:4}\Delta^2 - D_{1,3}^{1:2}D_{2,5}^{3:4}\Delta^2 \preceq \begin{vmatrix} b_1\Delta & c_1\Delta & & \\ a_2\Delta^2 & b_2\Delta^2 & c_2\Delta^2 & \\ & a_3\Delta^2 & b_3\Delta^2 & \\ & & a_4\Delta & c_4\Delta \end{vmatrix}.$$

Similar expressions can also be obtained for $Q_5^{(6)}$ and $Q_7^{(6)}$. We show only the computed $Q_5^{(8)}$ and $Q_1^{(8)}$:

$$Q_5^{(8)} = \begin{bmatrix} D_{5:8} & 0 \\ -D_{4,6:8}^{5:8} & 0 \end{bmatrix}, \qquad Q_1^{(8)} = \begin{bmatrix} D_{1:8} & 0 \\ 0 & 0 \end{bmatrix},$$

where

$$D_{5:8} \preceq \begin{vmatrix} b_5\Delta & c_5\Delta & & \\ a_6\Delta^2 & b_6\Delta^2 & c_6\Delta^2 & \\ & a_7\Delta^2 & b_7\Delta^2 & c_7\Delta^2 \\ & & a_8\Delta & b_8\Delta \end{vmatrix}, \qquad D_{4,6:8}^{5:8} \preceq \begin{vmatrix} a_5\Delta & c_5\Delta & & \\ & b_6\Delta^2 & c_6\Delta^2 & \\ & a_7\Delta^2 & b_7\Delta^2 & c_7\Delta^2 \\ & & a_8\Delta & b_8\Delta \end{vmatrix},$$

$$D_{1:8} \preceq \begin{vmatrix} b_1\Delta & c_1\Delta & & & & & & \\ a_2\Delta^2 & b_2\Delta^2 & c_2\Delta^2 & & & & & \\ & a_3\Delta^2 & b_3\Delta^2 & c_3\Delta^2 & & & & \\ & & a_4\Delta^2 & b_4\Delta^2 & c_4\Delta^2 & & & \\ & & & a_5\Delta^2 & b_5\Delta^2 & c_5\Delta^2 & & \\ & & & & a_6\Delta^2 & b_6\Delta^2 & c_6\Delta^2 & \\ & & & & & a_7\Delta^2 & b_7\Delta^2 & c_7\Delta^2 \\ & & & & & & a_8\Delta & b_8\Delta \end{vmatrix}.$$

In general, the following theorem can be obtained easily by induction.

THEOREM 4.1. *The computed* $Q_{i+1}^{(i+2l)}$ *are such that for*

$$l = 2^{j-1}, \quad i = 0, 1(2^j), 2(2^j), \ldots, n - 2^j, \quad n = 2^k, \quad j = 1, 2, \ldots, k,$$

$$Q_{i+1}^{(i+2l)} = \begin{bmatrix} D_{i+1:i+2l}^{i+1:i+2l} & D_{i+1:i+2l-1,i+2l+1}^{i+1:i+2l} \\ -D_{i,i+2:i+2l}^{i+1:i+2l} & -D_{i,i+2:i+2l-1,i+2l+1}^{i+1:i+2l} \end{bmatrix},$$

where

$$D_{i+1,i+2} = \begin{vmatrix} b_{i+1}\Delta & c_{i+1}\Delta \\ a_{i+2}\Delta & b_{i+2}\Delta \end{vmatrix}, \qquad D_{i+1,i+3}^{i+1,i+2} \preceq \begin{vmatrix} b_{i+1}\Delta & 0 \\ a_{i+2}\Delta & c_{i+2}\Delta \end{vmatrix},$$

$$D_{i,i+2}^{i+1,i+2} \preceq \begin{vmatrix} a_{i+1}\Delta & c_{i+1}\Delta \\ 0 & b_{i+2}\Delta \end{vmatrix}, \qquad D_{i,i+3}^{i+1,i+2} \preceq \begin{vmatrix} a_{i+1}\Delta & 0 \\ 0 & c_{i+2}\Delta \end{vmatrix},$$

$$D_{i+1:i+2l} \preceq \hat{D}_{i+1:i+2l} = \begin{vmatrix} b_{i+1}\Delta & c_{i+1}\Delta & & & \\ a_{i+2}\Delta^2 & b_{i+2}\Delta^2 & c_{i+2}\Delta^2 & & \\ & \ddots & \ddots & \ddots & \\ & & a_{i+2l-1}\Delta^2 & b_{i+2l-1}\Delta^2 & c_{i+2l-1}\Delta^2 \\ & & & a_{i+2l}\Delta & b_{i+2l}\Delta \end{vmatrix},$$

$$D^{i+1:i+2t}_{i+1:i+2l-1,i+2l+1} \preceq \hat{D}^{i+1:i+2l}_{i+1:i+2l-1,i+2l+1}$$

$$= \begin{vmatrix} b_{i+1}\Delta & c_{i+1}\Delta & & & & & \\ a_{i+2}\Delta^2 & b_{i+2}\Delta^2 & c_{i+2}\Delta^2 & & & & \\ & \ddots & \ddots & \ddots & & & \\ & & a_{i+2l-2}\Delta^2 & b_{i+2l-2}\Delta^2 & c_{i+2l-2}\Delta^2 & & \\ & & & a_{i+2l-1}\Delta^2 & b_{i+2l-1}\Delta^2 & & \\ & & & & a_{i+2l}\Delta & c_{i+2l}\Delta \end{vmatrix},$$

$$D^{i+1:i+2l}_{i,i+2:i+2l} \preceq \hat{D}^{i+1:i+2l}_{i,i+2:i+2l}$$

$$= \begin{vmatrix} a_{i+1}\Delta & c_{i+1}\Delta & & & & \\ & b_{i+2}\Delta^2 & c_{i+2}\Delta^2 & & & \\ & a_{i+3}\Delta^2 & b_{i+3}\Delta^2 & c_{i+3}\Delta^2 & & \\ & & \ddots & \ddots & \ddots & \\ & & & a_{i+2l-1}\Delta^2 & b_{i+2l-1}\Delta^2 & c_{i+2l-1}\Delta^2 \\ & & & & a_{i+2l}\Delta & b_{i+2l}\Delta \end{vmatrix},$$

$$D^{i+1:i+2l}_{i,i+2:i+2l-1,i+2l+1} \preceq \hat{D}^{i+1:i+2l}_{i,i+2:i+2l-1,i+2l+1}$$

$$= \begin{vmatrix} a_{i+1}\Delta & c_{i+1}\Delta & & & & & \\ & b_{i+2}\Delta^2 & c_{i+2}\Delta^2 & & & & \\ & a_{i+3}\Delta^2 & b_{i+3}\Delta^2 & c_{i+3}\Delta^2 & & & \\ & & \ddots & \ddots & \ddots & & \\ & & & a_{i+2l-2}\Delta^2 & b_{i+2l-2}\Delta^2 & c_{i+2l-2}\Delta^2 & \\ & & & & a_{i+2l-1}\Delta^2 & b_{i+2l-1}\Delta^2 & \\ & & & & & a_{i+2l}\Delta & c_{i+2l}\Delta \end{vmatrix}.$$

Before we turn our attention to other parts of Algorithm Sw2, we need to define some additional terms. For any positive integer i, let i be expressed in powers of 2 as follows:

$$i = 2^{s_1} + 2^{s_2} + \cdots + 2^{s_j}, \quad 0 \le s_1 < s_2 < \cdots < s_j, \quad 1 \le j.$$

Then we can define the following vectors:

$$e^{(2^{s_l})} = \sum_{p=1}^{2^{s_l}} e_p^{(2^{s_l})}, \qquad q^{(i)} = \begin{bmatrix} q_1^{(i)} \\ q_2^{(i)} \\ \vdots \\ q_i^{(i)} \end{bmatrix} = \begin{bmatrix} q^{(2^{s_1})} + e^{(2^{s_1})} \\ q^{(2^{s_2})} + e_1^{(2^{s_2})} + e^{(2^{s_2})} \\ \vdots \\ q^{(2^{s_{j-1}})} + e_1^{(2^{s_{j-1}})} + e^{(2^{s_{j-1}})} \\ q^{(2^{s_j})} + e_1^{(2^{s_j})} \end{bmatrix},$$

where each $q^{(2^{s_l})}$ is a 2^{s_l}-vector, $e_p^{(2^{s_l})}$ is the pth column of a 2^{s_l} by 2^{s_l} identity matrix, and

$$q^{(2^0)} = [0], \quad q^{(2^1)} = \begin{bmatrix} 1 \\ 1 \end{bmatrix}, \quad q^{(2^{s_j})} = \begin{bmatrix} q^{(2^{s_j-1})} + e^{(2^{s_j-1})} \\ q^{(2^{s_j-1})} \end{bmatrix} \quad \text{for } s_j \geq 2.$$

One can also easily establish the following bounds:

$$1 \leq q_j^{(i)} \leq \lceil \log_2 n \rceil, \qquad 1 \leq j \leq i. \tag{4.1}$$

As an example, let $i = 7 = 2^0 + 2^1 + 2^2$, then

$$q^{(7)} = \begin{bmatrix} q^{(1)} + e^{(1)} \\ q^{(2)} + e_1^{(1)} + e^{(1)} \\ q^{(4)} + e^{(4)} \end{bmatrix} = [1, 3, 2, 3, 3, 2, 2]^T.$$

We have the following theorems.

THEOREM 4.2. *The computed* $\alpha_{i+1}^{(i+2l)}$, $\gamma_{i+1}^{(i+2l)}$, $t_{i+1}^{(i+2l)}$, *and* $u_{i+1}^{(i+2l)}$ *are such that for*

$$l = 2^{j-1}, \quad i = 0, 1(2^j), 2(2^j), \ldots, n - 2^j, \quad n = 2^k, \quad j = 1, 2, \ldots, k,$$

$$\alpha_{i+1}^{(i+2l)} \preceq \hat{\alpha}_{i+1}^{(i+2l)}$$

$$= \begin{vmatrix} a_{i+1}\Delta & b_{i+1}\Delta & c_{i+1}\Delta & & & & \\ & a_{i+2}\Delta^2 & b_{i+2}\Delta^2 & c_{i+2}\Delta^2 & & & \\ & & \ddots & \ddots & \ddots & & \\ & & & a_{i+2l-2}\Delta^2 & b_{i+2l-2}\Delta^2 & c_{i+2l-2}\Delta^2 & \\ & & & & a_{i+2l-1}\Delta & b_{i+2l-1}\Delta & \\ & & & & & a_{i+2l}\Delta & \end{vmatrix},$$

$$\gamma_{i+1}^{(i+2l)} \preceq \hat{\gamma}_{i+1}^{(i+2l)}$$

$$= \begin{vmatrix} c_{i+1}\Delta & & & & & & \\ b_{i+2}\Delta & c_{i+2}\Delta & & & & & \\ a_{i+3}\Delta^2 & b_{i+3}\Delta^2 & c_{i+3}\Delta^2 & & & & \\ & \ddots & \ddots & \ddots & & & \\ & & a_{i+2l-1}\Delta^2 & b_{i+2l-1}\Delta^2 & c_{i+2l-1}\Delta^2 & & \\ & & & a_{i+2l}\Delta & b_{i+2l}\Delta & c_{i+2l}\Delta \end{vmatrix},$$

where $\alpha_{i+1}^{(i+2l)}$ *and* $\gamma_{i+1}^{(i+2l)}$ *are expressed as the determinant of an upper and lower triangular matrix, respectively. Also,*

$$t_{i+1}^{(i+2l)} \preceq \hat{t}_{i+1}^{(i+2l)}$$

$$= \begin{vmatrix} b_1\Delta & c_1\Delta & & & & & \\ a_2\Delta^2 & b_2\Delta^2 & c_2\Delta^2 & & & & \\ & \ddots & \ddots & \ddots & & & y_{i+1}\Delta^{q_{2l}^{(2l)}} \\ & & \ddots & \ddots & \ddots & & \vdots \\ & & & a_{i+2l-2}\Delta^2 & b_{i+2l-2}\Delta^2 & c_{i+2l-2}\Delta^2 & y_{i+2l-2}\Delta^{q_3^{(2l)}} \\ & & & & a_{i+2l-1}\Delta^2 & b_{i+2l-1}\Delta^2 & y_{i+2l-1}\Delta^{q_2^{(2l)}} \\ & & & & & a_{i+2l}\Delta & y_{i+2l}\Delta^{q_1^{(2l)}} \end{vmatrix},$$

$$u_{i+1}^{(i+2l)} \preceq \hat{u}_{i+1}^{(i+2l)}$$

$$= \begin{vmatrix} y_{i+1}\Delta^{q_1^{(2l)}} & c_{i+1}\Delta & & & & & \\ y_{i+2}\Delta^{q_2^{(2l)}} & b_{i+2}\Delta^2 & c_{i+2}\Delta^2 & & & & \\ y_{i+3}\Delta^{q_3^{(2l)}} & a_{i+3}\Delta^2 & b_{i+3}\Delta^2 & c_{i+3}\Delta^2 & & & \\ \vdots & & \ddots & \ddots & \ddots & & \\ y_{i+2l}\Delta^{q_{2l}^{(2l)}} & & & \ddots & \ddots & \ddots & \\ & & & & a_{n-1}\Delta^2 & b_{n-1}\Delta^2 & c_{n-1}\Delta^2 \\ & & & & & a_n\Delta & b_n\Delta \end{vmatrix}.$$

Proof. We prove by substitution. For $\alpha_{i+1}^{(i+2l)}$, we have

$$\alpha_{i+1}^{(i+2l)} = fl\left(\alpha_{i+1}^{(i+l)}\alpha_{i+l+1}^{(i+2l)}\right) = \alpha_{i+1}^{(i+l)}\alpha_{i+l+1}^{(i+2l)}\Delta \preceq \hat{\alpha}_{i+1}^{(i+l)}\hat{\alpha}_{i+l+1}^{(i+2l)}\Delta.$$

Now

$$\hat{\alpha}_{i+1}^{(i+l)} \preceq \begin{vmatrix} a_{i+1}\Delta & b_{i+1}\Delta & c_{i+1}\Delta & & & & \\ & a_{i+2}\Delta^2 & b_{i+2}\Delta^2 & c_{i+2}\Delta^2 & & & \\ & & \ddots & \ddots & \ddots & & \\ & & & a_{i+l-2}\Delta^2 & b_{i+l-2}\Delta^2 & c_{i+l-2}\Delta^2 & \\ & & & & a_{i+l-1}\Delta^2 & b_{i+l-1}\Delta^2 & \\ & & & & & a_{i+l}\Delta^2 & \end{vmatrix}$$

because the right-hand side expression in the above equation is a modified $\hat{\alpha}_{i+1}^{(i+l)}$ with its last two rows multiplied by Δ. Similarly,

$$\hat{\alpha}_{i+l+1}^{(i+2l)}\Delta \preceq \begin{vmatrix} a_{i+l+1}\Delta^2 & b_{i+l+1}\Delta^2 & c_{i+l+1}\Delta^2 & & & & \\ & a_{i+l+2}\Delta^2 & b_{i+l+2}\Delta^2 & c_{i+l+2}\Delta^2 & & & \\ & & \ddots & \ddots & \ddots & & \\ & & & a_{i+2l-2}\Delta^2 & b_{i+2l-2}\Delta^2 & c_{i+2l-2}\Delta^2 & \\ & & & & a_{i+2l-1}\Delta & b_{i+2l-1}\Delta & \\ & & & & & a_{i+2l}\Delta & \end{vmatrix}.$$

Hence

$$\alpha_{i+1}^{(i+2l)} \preceq \hat{\alpha}_{i+1}^{(i+l)}\hat{\alpha}_{i+l+1}^{(i+2l)}\Delta \preceq \hat{\alpha}_{i+1}^{(i+2l)}.$$

For $t_{i+1}^{(i+2l)}$, we have

$$\begin{aligned} t_{i+1}^{(i+2l)} &= fl\left(t_{i+l+1}^{(i+2l)} + \alpha_{i+l+1}^{(i+2l)}t_{i+1}^{(i+l)}\right) = t_{i+l+1}^{(i+2l)}\Delta + \alpha_{i+l+1}^{(i+2l)}t_{i+1}^{(i+l)}\Delta^2 \\ &\preceq \hat{t}_{i+l+1}^{(i+2l)}\Delta + \hat{\alpha}_{i+l+1}^{(i+2l)}\Delta^2\hat{t}_{i+1}^{(i+l)}. \end{aligned}$$

Now

$$\hat{t}_{i+1}^{(i+l)} = \begin{vmatrix} b_1\Delta & c_1\Delta & & & & \\ a_2\Delta^2 & b_2\Delta^2 & c_2\Delta^2 & & & \\ & \ddots & \ddots & \ddots & & y_{i+1}\Delta^{q_l^{(l)}} \\ & & \ddots & \ddots & \ddots & \vdots \\ & & & a_{i+l-2}\Delta^2 & b_{i+l-2}\Delta^2 & c_{i+l-2}\Delta^2 & y_{i+l-2}\Delta^{q_3^{(l)}} \\ & & & & a_{i+l-1}\Delta^2 & b_{i+l-1}\Delta^2 & y_{i+l-1}\Delta^{q_2^{(l)}} \\ & & & & & a_{i+l}\Delta & y_{i+l}\Delta^{q_1^{(l)}} \end{vmatrix},$$

and in $\hat{\alpha}_{i+l+1}^{(i+2l)}\Delta^2$ one can multiply one of the Δ-factor to the first row of $\hat{\alpha}_{i+l+1}^{(i+2l)}$ and the other one to the next to the last row and obtain

$$\hat{\alpha}_{i+l+1}^{(i+2l)}\Delta^2 = \begin{vmatrix} a_{i+l+1}\Delta^2 & b_{i+l+1}\Delta^2 & c_{i+l+1}\Delta^2 & & & \\ & \ddots & \ddots & \ddots & & \\ & & a_{i+2l-2}\Delta^2 & b_{i+2l-2}\Delta^2 & c_{i+2l-2}\Delta^2 & \\ & & & a_{i+2l-1}\Delta^2 & b_{i+2l-1}\Delta^2 & \\ & & & & a_{i+2l}\Delta & \end{vmatrix}.$$

Furthermore, the Δ-factor in $\hat{t}_{i+l+1}^{(i+2l)}\Delta$ can be multiplied to the last column of $\hat{t}_{i+l+1}^{(i+2l)}$ to obtain

$\hat{t}_{i+l+1}^{(i+2l)}\Delta =$

$$\begin{vmatrix} b_1\Delta & c_1\Delta & & & & & \\ a_2\Delta^2 & b_2\Delta^2 & c_2\Delta^2 & & & & \\ & \ddots & \ddots & \ddots & & & \\ & & a_{i+l+1}\Delta^2 & b_{i+l+1}\Delta^2 & c_{i+l+1}\Delta^2 & & y_{i+l+1}\Delta^{q_l^{(l)}+1} \\ & & & \ddots & \ddots & \ddots & \vdots \\ & & & & a_{i+2l-2}\Delta^2 & b_{i+2l-2}\Delta^2 & c_{i+2l-2}\Delta^2 & y_{i+2l-2}\Delta^{q_3^{(l)}+1} \\ & & & & & a_{i+2l-1}\Delta^2 & b_{i+2l-1}\Delta^2 & y_{i+2l-1}\Delta^{q_2^{(l)}+1} \\ & & & & & & a_{i+2l}\Delta & y_{i+2l}\Delta^{q_1^{(l)}+1} \end{vmatrix}.$$

Now

$$\hat{t}_{i+l+1}^{(i+2l)}\Delta + \hat{\alpha}_{i+l+1}^{(i+2l)}\Delta^2\hat{t}_{i+1}^{(i+l)} =$$

$$\begin{vmatrix} b_1\Delta & c_1\Delta & & & & & \\ a_2\Delta^2 & b_2\Delta^2 & c_2\Delta^2 & & & & \\ & \ddots & \ddots & \ddots & & & y_{i+1}\Delta^{q_l^{(l)}} \\ & & \ddots & \ddots & \ddots & & \vdots \\ & & & a_{i+l}\Delta^2 & b_{i+l}\Delta^2 & c_{i+l}\Delta^2 & y_{i+l}\Delta^{q_1^{(l)}} \\ & & & & \ddots & \ddots & \ddots & y_{i+l+1}\Delta^{q_l^{(l)}+1} \\ & & & & & a_{i+2l-1}\Delta^2 & b_{i+2l-1}\Delta^2 & \vdots \\ & & & & & & a_{i+2l}\Delta & y_{i+2l}\Delta^{q_1^{(l)}+1} \end{vmatrix}$$

since one can expand the above determinant by splitting the last column into two parts with nontrivial parts formed by the vectors

$$\begin{bmatrix} y_{i+1}\Delta^{q_l^{(l)}} \\ \vdots \\ y_{i+l}\Delta^{q_1^{(l)}} \end{bmatrix}, \quad \begin{bmatrix} y_{i+l+1}\Delta^{q_l^{(l)}+1} \\ \vdots \\ y_{i+2l}\Delta^{q_1^{(l)}+1} \end{bmatrix},$$

and their sum is precisely $\hat{t}_{i+l+1}^{(i+2l)}\Delta + \hat{\alpha}_{i+l+1}^{(i+2l)}\Delta^2\hat{t}_{i+1}^{(i+l)}$. Furthermore, by using the recursive definition

$$q^{(2^j)} = \begin{bmatrix} q^{(2^{j-1})} + e^{(2^{j-1})} \\ q^{(2^{j-1})} \end{bmatrix},$$

the nontrivial parts of the last column can be expressed as

$$\begin{bmatrix} y_{i+1}\Delta^{q_{2l}^{(2l)}} & \cdots & y_{i+l}\Delta^{q_{l+1}^{(2l)}} & y_{i+l+1}\Delta^{q_l^{(2l)}} & \cdots & y_{i+2l}\Delta^{q_1^{(2l)}} \end{bmatrix}^T.$$

Thus

$$\hat{t}_{i+l+1}^{(i+2l)}\Delta + \hat{\alpha}_{i+l+1}^{(i+2l)}\Delta^2\hat{t}_{i+1}^{(i+l)} = \hat{t}_{i+1}^{i+2l}.$$

The validity of the expressions for γ_{i+1}^{i+2l} and u_{i+1}^{i+2l} can also be proved using similar reasonings. This completes our proof. □

The following theorems can also be proved easily by induction.

THEOREM 4.3. *The computed d_i, e_i, and $t_1^{(i)}$ for $n \geq i \geq 2$ are such that*

$$d_i \preceq \hat{d}_i = \begin{vmatrix} b_1\Delta & c_1\Delta & & & & \\ a_2\Delta^2 & b_2\Delta^2 & c_2\Delta^2 & & & \\ & \ddots & \ddots & \ddots & & \\ & & a_{i-1}\Delta^2 & b_{i-1}\Delta^2 & c_{i-1}\Delta^2 & \\ & & & a_i\Delta & b_i\Delta & \end{vmatrix},$$

$$e_i \preceq \hat{e}_i = \begin{vmatrix} b_1\Delta & c_1\Delta & & & & \\ a_2\Delta^2 & b_2\Delta^2 & c_2\Delta^2 & & & \\ & \ddots & \ddots & \ddots & & \\ & & a_{i-2}\Delta^2 & b_{i-2}\Delta^2 & c_{i-2}\Delta^2 & \\ & & & a_{i-1}\Delta^2 & b_{i-1}\Delta^2 & \\ & & & & a_i\Delta & c_i\Delta \end{vmatrix},$$

$$t_1^{(i)} \preceq \hat{t}_1^{(i)} = \begin{vmatrix} b_1\Delta & c_1\Delta & & & & y_1\Delta^{q_i^{(i)}} \\ a_2\Delta^2 & b_2\Delta^2 & c_2\Delta^2 & & & y_2\Delta^{q_{i-1}^{(i)}} \\ & \ddots & \ddots & \ddots & & \vdots \\ & & a_{i-2}\Delta^2 & b_{i-2}\Delta^2 & c_{i-2}\Delta^2 & y_{i-2}\Delta^{q_3^{(i)}} \\ & & & a_{i-1}\Delta^2 & b_{i-1}\Delta^2 & y_{i-1}\Delta^{q_2^{(i)}} \\ & & & & a_i\Delta & y_i\Delta^{q_1^{(i)}} \end{vmatrix}.$$

THEOREM 4.4. *The computed f_i, g_i, and $u_i^{(n)}$ for $n-1 \geq i \geq 1$ are such that*

$$f_i \preceq \hat{f}_i = \begin{vmatrix} b_i\Delta & c_i\Delta & & & \\ a_{i+1}\Delta^2 & b_{i+1}\Delta^2 & c_{i+1}\Delta^2 & & \\ & \ddots & \ddots & \ddots & \\ & & a_{n-1}\Delta^2 & b_{n-1}\Delta^2 & c_{n-1}\Delta^2 \\ & & & a_n\Delta & b_n\Delta \end{vmatrix},$$

$$g_i \preceq \hat{g}_i = \begin{vmatrix} a_i\Delta & c_i\Delta & & & \\ & b_{i+1}\Delta^2 & c_{i+1}\Delta^2 & & \\ & a_{i+2}\Delta^2 & b_{i+2}\Delta^2 & c_{i+2}\Delta^2 & \\ & & \ddots & \ddots & \ddots \\ & & & a_{n-1}\Delta^2 & b_{n-1}\Delta^2 & c_{n-1}\Delta^2 \\ & & & & a_n\Delta & b_n\Delta \end{vmatrix},$$

$$u_i^{(n)} \preceq \hat{u}_i^{(n)} = \begin{vmatrix} y_i\Delta^{q_1^{(n-i+1)}} & c_i\Delta & & & & \\ y_{i+1}\Delta^{q_2^{(n-i+1)}} & b_{i+1}\Delta^2 & c_{i+1}\Delta^2 & & & \\ y_{i+2}\Delta^{q_3^{(n-i+1)}} & a_{i+2}\Delta^2 & b_{i+2}\Delta^2 & c_{i+2}\Delta^2 & & \\ \vdots & & \ddots & \ddots & \ddots & \\ y_{n-1}\Delta^{q_{n-i}^{(n-i+1)}} & & & a_{n-1}\Delta^2 & b_{n-1}\Delta^2 & c_{n-1}\Delta^2 \\ y_n\Delta^{q_{n-i+1}^{(n-i+1)}} & & & & a_n\Delta & b_n\Delta \end{vmatrix}.$$

From Theorems 4.1–4.4 one can easily obtain the following theorem.

THEOREM 4.5. *The computed x_i for $1 \le i \le n$ are such that*

$$x_1 = \frac{u_1^{(n)}\Delta}{d_n},$$
$$x_n = \frac{t_1^{(n)}\Delta}{d_n},$$

where

$$u_1^{(n)}\Delta \preceq \hat{u}_1^{(n)} = \begin{vmatrix} y_1\Delta^{1+q_1^{(n)}} & c_1\Delta & & & & \\ y_2\Delta^{1+q_2^{(n)}} & b_2\Delta^2 & c_2\Delta^2 & & & \\ y_3\Delta^{1+q_3^{(n)}} & a_3\Delta^2 & b_3\Delta^2 & c_3\Delta^2 & & \\ \vdots & & \ddots & \ddots & \ddots & \\ y_{n-1}\Delta^{1+q_{n-1}^{(n)}} & & & a_{n-1}\Delta^2 & b_{n-1}\Delta^2 & c_{n-1}\Delta^2 \\ y_n\Delta^{1+q_n^{(n)}} & & & & a_n\Delta & b_n\Delta \end{vmatrix},$$

$$t_1^{(n)}\Delta \preceq \hat{t}_1^{(n)} = \begin{vmatrix} b_1\Delta & c_1\Delta & & & & y_1\Delta^{1+q_n^{(n)}} \\ a_2\Delta^2 & b_2\Delta^2 & c_2\Delta^2 & & & y_2\Delta^{1+q_{n-1}^{(n)}} \\ & \ddots & \ddots & \ddots & & \vdots \\ & & a_{n-2}\Delta^2 & b_{n-2}\Delta^2 & c_{n-2}\Delta^2 & y_{n-2}\Delta^{1+q_3^{(n)}} \\ & & & a_{n-1}\Delta^2 & b_{n-1}\Delta^2 & y_{n-1}\Delta^{1+q_2^{(n)}} \\ & & & & a_n\Delta & y_n\Delta^{1+q_1^{(n)}} \end{vmatrix},$$

and

$$x_i = \frac{\begin{vmatrix} d_{i-1} & t_1^{(i-1)}\Delta^3 \\ g_i & u_i^{(n)}\Delta^3 \end{vmatrix}}{d_n} = \frac{\xi_i}{d_n},$$

where

$\xi_i \preceq \hat{\xi}_i =$

$$\begin{vmatrix}
b_1\Delta & c_1\Delta & & & y_1\Delta^{3+q_{i-1}^{(i-1)}} & & & & \\
a_2\Delta^2 & b_2\Delta^2 & c_2\Delta^2 & & y_2\Delta^{3+q_{i-2}^{(i-1)}} & & & & \\
& \ddots & \ddots & & \vdots & & & & \\
& & a_{i-1}\Delta & b_{i-1}\Delta & y_{i-1}\Delta^{3+q_1^{(i-1)}} & & & & \\
& & & a_i\Delta & y_i\Delta^{3+q_1^{(n-i+1)}} & c_i\Delta & & & \\
& & & & y_{i+1}\Delta^{3+q_2^{(n-i+1)}} & b_{i+1}\Delta^2 & c_{i+1}\Delta^2 & & \\
& & & & \vdots & & \ddots & \ddots & \\
& & & & y_{n-1}\Delta^{3+q_{n-i}^{(n-i+1)}} & & a_{n-1}\Delta^2 & b_{n-1}\Delta^2 & c_{n-1}\Delta^2 \\
& & & & y_n\Delta^{3+q_{n-i+1}^{(n-i+1)}} & & & a_n\Delta & b_n\Delta
\end{vmatrix}.$$

5. Concluding remarks. From Theorems 3.4 and 4.5 we see that although the computed solution component x_i cannot be expressed as the exact answer of a neighboring system of the original matrix A and the right-hand side vector y, nevertheless the computed solution component is of the form $\frac{p}{q}$ where p and q are sums of products of the perturbed input data. Furthermore, if the exact solution component x_i is expressed as

$$x_i = \frac{\sum_{j=1}^{\lambda(D_{1:n}(i))} p_j}{\sum_{k=1}^{\lambda(D_{1:n})} q_k},$$

then

$$x_i|_{Sw1} = \frac{\sum_{j=1}^{\lambda(D_{1:n}(i))} \bar{p}_j}{\sum_{k=1}^{\lambda(D_{1:n})} \bar{q}_k}, \qquad x_i|_{Sw2} = \frac{\sum_{j=1}^{\lambda(D_{1:n}(i))} \hat{p}_j}{\sum_{k=1}^{\lambda(D_{1:n})} \hat{q}_k},$$

where

$$\sum_{k=1}^{\lambda(D_{1:n})} \bar{q}_k = d_n|_{Sw1}, \qquad \sum_{j=1}^{\lambda(D_{1:n}(i))} \bar{p}_j = \begin{cases} \hat{u}_1|_{Sw1} \text{ if } i = 1, \\ \xi_i|_{Sw1} \text{ for } 2 \le i \le n-1, \\ \hat{t}_n|_{Sw1} \text{ if } i = n, \end{cases}$$

$$\sum_{k=1}^{\lambda(D_{1:n})} \hat{q}_k \preceq \hat{d}_n|_{Sw2}, \qquad \sum_{j=1}^{\lambda(D_{1:n}(i))} \hat{p}_j \preceq \begin{cases} \hat{u}_1|_{Sw2}^{(n)} \text{ if } i = 1, \\ \hat{\xi}_i|_{Sw2} \text{ for } 2 \le i \le n-1, \\ \hat{t}_1|_{Sw2}^{(n)} \text{ if } i = n. \end{cases}$$

By using Theorems 3.4, 4.5, and (4.1), one can easily bound the relative error of p_j or q_k as follows:

$$\frac{|\bar{p}_j - p_j|}{|p_j|} \le |\Delta^{2n+1} - 1| \le (2n+1)u + O(u^2),$$

$$\frac{|\hat{p}_j - p_j|}{|p_j|} \leq |\Delta^{2n+q_1^{(n)}} - 1| \leq (2n + \lceil \log_2 n \rceil)u + O(u^2),$$

$$\frac{|\bar{q}_k - q_k|}{|q_k|} \leq |\Delta^{2(n-1)} - 1| \leq 2(n-1)u + O(u^2),$$

$$\frac{|\hat{q}_k - q_k|}{|q_k|} \leq |\Delta^{2(n-1)} - 1| \leq 2(n-1)u + O(u^2).$$

The above first-order bounds can thus be used to assess the relative importance of errors caused by the computation versus those caused by the inherent data error.

SENSITIVITY OF THE STATIONARY DISTRIBUTION OF A MARKOV CHAIN*

CARL D. MEYER†

Abstract. It is well known that if the transition matrix of an irreducible Markov chain of moderate size has a subdominant eigenvalue which is close to 1, then the chain is ill conditioned in the sense that there are stationary probabilities which are sensitive to perturbations in the transition probabilities. However, the converse of this statement has heretofore been unresolved. The purpose of this article is to address this issue by establishing upper and lower bounds on the condition number of the chain such that the bounding terms are functions of the eigenvalues of the transition matrix. Furthermore, it is demonstrated how to obtain estimates for the condition number of an irreducible chain with little or no extra computational effort over that required to compute the stationary probabilities by means of an LU or QR factorization.

Key words. Markov chains, stationary distribution, stochastic matrix, sensitivity analysis, perturbation theory, character of a Markov chain, condition numbers

1. Introduction.

The problem under consideration is that of analyzing the effects of small perturbations to the transition probabilities of a finite, irreducible, homogeneous Markov chain. More precisely, if $\mathbf{P}_{n\times n}$ is the transition probability matrix for such a chain, and if $\boldsymbol{\pi}^T = (\pi_1, \pi_2, \ldots, \pi_n)$ is the stationary distribution vector satisfying $\boldsymbol{\pi}^T\mathbf{P} = \boldsymbol{\pi}^T$ and $\sum_{i=1}^n \pi_i = 1$, the goal is to describe the effect on $\boldsymbol{\pi}^T$ when $\mathbf{P}$ is perturbed by a matrix $\mathbf{E}$ such that $\tilde{\mathbf{P}} = \mathbf{P} + \mathbf{E}$ is the transition probability matrix of another irreducible Markov chain.

Schweitzer (1968) provided the first perturbation analysis in terms of Kemeny and Snell's "fundamental matrix" $\mathbf{Z} = (\mathbf{A} + \mathbf{e}\boldsymbol{\pi}^T)^{-1}$ in which $\mathbf{A} = \mathbf{I} - \mathbf{P}$ and $\mathbf{e}$ is a column of 1's. If $\mathbf{A}^{\#}$ denotes the group inverse of $\mathbf{A}$ [Meyer (1975) or Campbell and Meyer (1991)], then

$$\mathbf{Z} = (\mathbf{A} + \mathbf{e}\boldsymbol{\pi}^T)^{-1} = \mathbf{A}^{\#} + \mathbf{e}\boldsymbol{\pi}^T.$$

But in virtually all applications involving $\mathbf{Z}$, the term $\mathbf{e}\boldsymbol{\pi}^T$ is redundant; i.e., all relevant information is contained in $\mathbf{A}^{\#}$. In particular, if $\tilde{\boldsymbol{\pi}}^T = (\tilde{\pi}_1, \tilde{\pi}_2, \ldots, \tilde{\pi}_n)$ is the stationary distribution for $\tilde{\mathbf{P}} = \mathbf{P} + \mathbf{E}$, then

$$\tilde{\boldsymbol{\pi}}^T = \boldsymbol{\pi}^T \left(\mathbf{I} + \mathbf{E}\mathbf{A}^{\#}\right)^{-1} \tag{1.1}$$

and

$$\left\|\boldsymbol{\pi}^T - \tilde{\boldsymbol{\pi}}^T\right\| \leq \|\mathbf{E}\| \left\|\mathbf{A}^{\#}\right\| \tag{1.2}$$

in which $\|\star\|$ can be either the 1-, 2-, or ∞-norm. If the jth column and the (i,j)-entry of $\mathbf{A}^{\#}$ are denoted by $\mathbf{A}^{\#}_{*j}$ and $a^{\#}_{ij}$, respectively, then

$$|\pi_j - \tilde{\pi}_j| \leq \|\mathbf{E}\| \left\|\mathbf{A}^{\#}_{*j}\right\| \tag{1.3}$$

and

$$\max_j |\pi_j - \tilde{\pi}_j| \leq \|\mathbf{E}\|_\infty \max_{i,j} |a_{ij}^{\#}|. \tag{1.4}$$

This bound is about as good as possible—see Ipsen and Meyer (1994) for a discussion of optimal bounds. Moreover, if the transition probabilities are analytic functions of a parameter t so that $\mathbf{P} = \mathbf{P}(t)$, then

$$\frac{d\boldsymbol{\pi}^T}{dt} = \boldsymbol{\pi}^T \frac{d\mathbf{P}}{dt}\mathbf{A}^{\#} \quad \text{and} \quad \frac{d\pi_j}{dt} = \boldsymbol{\pi}^T \frac{d\mathbf{P}}{dt}\mathbf{A}^{\#}_{*j}. \tag{1.5}$$

The results (1.1) and (1.2) are due to Meyer (1980), and (1.3) appears in Golub and Meyer (1986). The inequality (1.4) was given by Funderlic and Meyer (1986), and the formulas (1.5) are derived in Golub and Meyer (1986) and Meyer and Stewart (1988). Seneta (1991) established an inequality similar to (1.2) using the coefficient of ergodicity $\tau_1(\mathbf{A}^{\#})$ in place of $\left\|\mathbf{A}^{\#}\right\|$.

These facts make it absolutely clear that the entries in $\mathbf{A}^{\#}$ determine the extent to which $\boldsymbol{\pi}^T$ is sensitive to small changes in $\mathbf{P}$, so, on the basis of (1.4), it is natural to adopt the following definition of Funderlic and Meyer (1986).

DEFINITION 1.1. The *condition* of a Markov chain with a transition matrix $\mathbf{P}$ is measured by the size of its *condition number,* which is defined to be

$$\kappa = \max_{i,j} |a_{ij}^{\#}|$$

where $a_{ij}^{\#}$ is the (i,j)-entry in the group inverse $\mathbf{A}^{\#}$ of $\mathbf{A} = \mathbf{I} - \mathbf{P}$. It is an elementary fact that κ is invariant under permutations of the states of the chain.

For chains of moderate size, it is not difficult to show (see the proof of Theorem 2.1 given in §4) that if there exists a subdominant eigenvalue of $\mathbf{P}$ which is close to 1, then κ must be large. However, the converse of this statement has heretofore been unresolved, and our purpose is to focus on this issue. More precisely, we address the following question.

> *If the subdominant eigenvalues of an irreducible Markov chain are well separated from* 1, *can we be sure that the chain is well conditioned? In other words, do the subdominant eigenvalues of* $\mathbf{P}$ (*or equivalently, the nonzero eigenvalues of* $\mathbf{A}$) *somehow provide complete information about the sensitivity of the chain—or do we really need to know something about the singular values of* $\mathbf{A}$?

The conjecture that $\kappa = \max_{i,j} |a_{ij}^{\#}|$ is somehow controlled by the nonzero eigenvalues of $\mathbf{A}$ is contrary to what is generally true—a standard example is the triangular matrix

(1.6)

$$\mathbf{T}_{n\times n} = \begin{pmatrix} 1 & -2 & 0 & \cdots & 0 & 0 \\ 0 & 1 & -2 & \cdots & 0 & 0 \\ 0 & 0 & 1 & \ddots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 & -2 \\ 0 & 0 & 0 & \cdots & 0 & 1 \end{pmatrix}, \quad \mathbf{T}^{-1} = \begin{pmatrix} 1 & 2 & 4 & \cdots & 2^{n-2} & 2^{n-1} \\ 0 & 1 & 2 & \cdots & 2^{n-3} & 2^{n-2} \\ 0 & 0 & 1 & \ddots & 2^{n-4} & 2^{n-3} \\ \vdots & \vdots & \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 & 2 \\ 0 & 0 & 0 & \cdots & 0 & 1 \end{pmatrix}$$

for which $\max_{i,j}[\mathbf{T}^{-1}]_{ij}$ is immense for even moderate values of n, but the eigenvalues of $\mathbf{T}$ provide no clue whatsoever that this occurs. The fact that the eigenvalues are repeated or that $\mathbf{T}$ is nonsingular is irrelevant—consider a small perturbation of $\mathbf{T}$ or the matrices

$$\tilde{\mathbf{T}} = \begin{pmatrix} 0 & 0 \\ 0 & \mathbf{T} \end{pmatrix} \quad \text{and} \quad \tilde{\mathbf{T}}^{\#} = \begin{pmatrix} 0 & 0 \\ 0 & \mathbf{T}^{-1} \end{pmatrix}.$$

We will prove that, unlike the situation illustrated above, irreducible stochastic matrices $\mathbf{P}$ possess enough structure to guarantee that growth of the entries in $\mathbf{A}^{\#}$ is controlled by the nonzero eigenvalues of $\mathbf{A} = \mathbf{I} - \mathbf{P}$. As a consequence, it will follow that the sensitivity of an irreducible Markov chain is governed by the location of its subdominant eigenvalues.

2. The main result. In the sequel, it is convenient to adopt the following terminology and notation.

DEFINITION 2.1. Let $\mathbf{P}$ be the transition probability matrix of an n-state irreducible Markov chain, and let

$$\sigma(\mathbf{P}) = \{1, \lambda_2, \lambda_3, \ldots, \lambda_n\}$$

denote the eigenvalues of $\mathbf{P}$. The *character*[1] of the chain is defined to be the (necessarily real) number

$$\chi = (1 - \lambda_2)(1 - \lambda_3)\cdots(1 - \lambda_n).$$

It will follow from later developments that

$$0 < \chi \leq n. \tag{2.1}$$

A chain is said to be of "weak character" when χ is close to 0, and the chain is said to have a "strong character" when χ is significantly larger than 0.

If

$$\mathbf{P} = \mathbf{T}^{-1}\begin{pmatrix} 1 & 0 \\ 0 & \mathbf{C} \end{pmatrix}\mathbf{T}$$

(e.g., this may be the reduction to Jordan form) where the spectral radius of $\mathbf{C}$ is less than 1, then

$$\mathbf{A} = \mathbf{T}^{-1}\begin{pmatrix} 0 & 0 \\ 0 & \mathbf{I} - \mathbf{C} \end{pmatrix}\mathbf{T} \quad \text{and} \quad \mathbf{A}^{\#} = \mathbf{T}^{-1}\begin{pmatrix} 0 & 0 \\ 0 & (\mathbf{I} - \mathbf{C})^{-1} \end{pmatrix}\mathbf{T}$$

[Campbell and Meyer (1991)], so

$$\chi = \det(\mathbf{I} - \mathbf{C}) \quad \text{and} \quad \chi^{-1} = \det(\mathbf{I} - \mathbf{C})^{-1}.$$

In other words, χ and χ^{-1} are the respective determinants of the nonsingular parts of $\mathbf{A}$ and $\mathbf{A}^{\#}$ in the sense that

$$\chi = \det\left(\mathbf{A}_{/\mathcal{R}(\mathbf{A})}\right) \quad \text{and} \quad \chi^{-1} = \det\left(\mathbf{A}^{\#}_{/\mathcal{R}(\mathbf{A})}\right)$$

where $\mathbf{A}_{/\mathcal{R}(\mathbf{A})}$ denotes the linear operator defined by restricting $\mathbf{A}$ to $R(\mathbf{A})$. It is also true that $\chi^{-1} = \det(\mathbf{Z})$ where $\mathbf{Z}$ is Kemeny and Snell's "fundamental matrix."

The main result of this paper is the following theorem which establishes the connection between the condition of an irreducible chain and its character.

---

[1] The character was defined by Meyer (1993) to be $\chi = n^{-1}(1 - \lambda_2)(1 - \lambda_3)\cdots(1 - \lambda_n)$, which is the normalization of the definition given here.

THEOREM 2.1. *For an irreducible stochastic matrix* $\mathbf{P}_{n\times n}$, *let* $\mathbf{A} = \mathbf{I} - \mathbf{P}$, *and for* $i \neq j$, *let* $\delta_{ij}(\mathbf{A})$ *denote the deleted product of diagonal entries*

$$\delta_{ij}(\mathbf{A}) = \prod_{k\neq i,j} a_{kk} = \prod_{k\neq i,j} (1 - p_{kk}).$$

If $\delta = \max_{i,j} \delta_{ij}(\mathbf{A})$ (*the product of all but the two smallest diagonal entries*), *then the condition number* κ *is bounded by*

$$\frac{1}{n \min\limits_{\lambda_i \neq 1} |1 - \lambda_i|} \leq \kappa < \frac{2\delta(n-1)}{\chi} \leq \frac{2(n-1)}{\chi}. \tag{2.2}$$

The proof of this theorem depends on exploiting the rich structure of $\mathbf{A}$, some of which is apparent, and some of which requires illumination. Before giving a formal argument, it is necessary to detail the various components of this structure, so the important facets are first laid out in §3 as a sequence of lemmas. After the necessary framework is in place, it will be a simple matter to connect the lemmas together in order to construct a proof; this is contained in §4.

By combining Theorem 2.1 with (1.4) and the other facts listed in §1, we arrive at the following conclusion.

THEOREM 2.2. *The condition of an irreducible Markov chain is primarily governed by how close the subdominant eigenvalues of the chain are to* 1. *More precisely, if an irreducible chain is well conditioned, then all subdominant eigenvalues must be well separated from* 1, *and if all subdominant eigenvalues are well separated from* 1 *in the sense that the chain has a strong character, then it must be well conditioned.*

It is a corollary of Theorem 2.1 that if $\max_{\lambda_i\neq 1} |\lambda_i| << 1$, then the chain is not overly sensitive, but it is important to underscore the point that the issue of sensitivity is not equivalent to the question of how close $\max_{\lambda_i\neq 1} |\lambda_i|$ is to 1. Knowing that some $|\lambda_i| \approx 1$ is not sufficient to guarantee that the chain is sensitive; e.g., consider the well-conditioned periodic chain (or any small perturbation thereof) for which

$$\mathbf{P} = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix} \quad \text{and} \quad \mathbf{A}^{\#} = \frac{1}{3}\begin{pmatrix} 1 & -1 & 0 \\ 0 & 1 & -1 \\ -1 & 0 & 1 \end{pmatrix}.$$

3. The underlying structure. The purpose of this section is to organize relevant properties of $\mathbf{A} = \mathbf{I} - \mathbf{P}$ into a sequence of lemmas from which the formal proof of Theorem 2.1 can be constructed. Some of the more transparent or well-known features of $\mathbf{A}$ are stated in the first lemma.

LEMMA 3.1. *If* $\mathbf{A} = \mathbf{I} - \mathbf{P}$ *where* $\mathbf{P}_{n\times n}$ *is an irreducible stochastic matrix, then the following statements are true.*

(3.1) $\mathbf{A}$ *as well as each principal submatrix of* $\mathbf{A}$ *has strictly positive diagonal entries, and the off-diagonal entries are nonpositive.*

(3.2) $\mathbf{A}$ *is a singular M-matrix of rank* $n - 1$.

(3.3) *If* $\mathbf{B}_{k\times k}$ $(k < n)$ *is a principal submatrix of* $\mathbf{A}$, *then each of the following statements is true.*

- (a) $\mathbf{B}$ *is a nonsingular M-matrix.*
- (b) $\mathbf{B}^{-1} \geq 0$.
- (c) $\det(\mathbf{B}) > 0$.
- (d) $\mathbf{B}$ *is diagonally dominant.*
- (e) $\det(\mathbf{B}) \leq b_{11}b_{22}\cdots b_{kk} \leq 1$.

Proof. These facts are either self-evident, or they are direct consequences of well-known results—see Berman and Plemmons (1979) or Horn and Johnson (1991). □

Part of the less transparent structure of $\mathbf{A}$ is illuminated in the following sequence of lemmas.

LEMMA 3.2. *If $\mathbf{P}_{n\times n}$ is an irreducible stochastic matrix, and if $\mathbf{A}_i$ denotes the principal submatrix of $\mathbf{A} = \mathbf{I} - \mathbf{P}$ obtained by deleting the ith row and column from $\mathbf{A}$, then*

$$\chi = \sum_{i=1}^{n} \det(\mathbf{A}_i).$$

Proof. Suppose that the eigenvalues of $\mathbf{A}$ are denoted by $\{\mu_1, \mu_2, \ldots, \mu_n\}$, and write the characteristic equation for $\mathbf{A}$ as

$$x^n + \alpha_{n-1}x^{n-1} + \cdots + \alpha_1 x + \alpha_0 = 0.$$

Each coefficient α_{n-k} is given by $(-1)^k$ times the sum of the product of the eigenvalues of $\mathbf{A}$ taken k at a time. That is,

$$\alpha_{n-k} = (-1)^k \sum_{1\le i_1<\cdots<i_k\le n} \mu_{i_1}\mu_{i_2}\cdots\mu_{i_k}. \tag{3.4}$$

But it is also a standard result from elementary matrix theory that each coefficient α_{n-k} can be described as

$$\alpha_{n-k} = (-1)^k \sum(\text{all } k\times k \text{ principal minors of } \mathbf{A}).$$

Since 0 is a simple eigenvalue for $\mathbf{A}$, there is only one nonzero term in the sum (3.4) when $k = n-1$, and hence

$$\begin{aligned}\alpha_1 &= (-1)^{n-1}\mu_2\mu_3\cdots\mu_n = (-1)^{n-1}(1-\lambda_2)(1-\lambda_3)\cdots(1-\lambda_n)\\ &= (-1)^{n-1}\sum_{i=1}^{n}\det(\mathbf{A}_i).\end{aligned}$$

Therefore,

$$\sum_{i=1}^{n}\det(\mathbf{A}_i) = \prod_{k=2}^{n}(1-\lambda_k) = \chi. \qquad \square$$

LEMMA 3.3. *If $\mathbf{A}_i$ denotes the principal submatrix of $\mathbf{A} = \mathbf{I} - \mathbf{P}$ obtained by deleting the ith row and column from $\mathbf{A}$, and if π_i is the ith stationary probability, then the character of the chain is given by*

$$\chi = \frac{\det(\mathbf{A}_i)}{\pi_i}.$$

Proof. This result follows directly from Lemma 3.2 and the fact that the stationary distribution $\boldsymbol{\pi}^T$ is given by the formula

$$\boldsymbol{\pi}^T = \frac{1}{\sum_{i=1}^{n}\det(\mathbf{A}_i)}\Big(\det(\mathbf{A}_1), \det(\mathbf{A}_2), \ldots, \det(\mathbf{A}_n)\Big)$$

[Golub and Meyer (1986) or Iosifescu (1980), p. 123]. □

The mean return time for the kth state is $R_k = 1/\pi_k$ [Kemeny and Snell (1960)], and, since not all of the π_k's can be less than $1/n$, there must exist a state such that $R_k \le n$. By combining this with (3.3c) and (3.3e), an interesting corollary—which proves (2.1)—is produced.

COROLLARY 3.1. *If R_k denotes the mean return time for the kth state then*

$$0 < \det(\mathbf{A}_i) < \chi \leq \min_k R_k \leq n \quad \textit{for each } i = 1, 2, \ldots, n.$$

LEMMA 3.4. *If $\mathbf{A} = \mathbf{I} - \mathbf{P}$ where $\mathbf{P}_{n\times n}$ is an irreducible stochastic matrix, and if $\mathbf{B}_{k\times k}$ $(k < n)$ is a principal submatrix of $\mathbf{A}$, then the largest entry in each column of $\mathbf{B}^{-1}$ is the diagonal entry. That is, for $j = 1, 2, \ldots, k$, it must be the case that*

$$[\mathbf{B}^{-1}]_{jj} \geq [\mathbf{B}^{-1}]_{ij} \quad \textit{for each } i \neq j.$$

At least two different proofs are possible, and we shall give both because each is instructive in its own right. The first argument is shorter and more probabilistic, but it rests on a result which requires a proof of its own. The second argument involves more algebraic details, but it is entirely self-contained and depends only on elementary concepts.

Probabilistic proof. Without loss of generality, assume that $\mathbf{B}$ is the leading $k \times k$ principal submatrix of $\mathbf{A}$ so that $\mathbf{P}$ has the form

$$\mathbf{P} = \begin{pmatrix} \mathbf{I} - \mathbf{B} & \star \\ \star & \star \end{pmatrix}.$$

Consider any pair of states i and j in the set $\mathcal{S} = \{1, 2, \ldots, k\}$, and let N_j denote the number of times the process is in state j before first hitting a state in the complement $\overline{\mathcal{S}} = \{k+1, k+2, \ldots, n\}$. If X_n denotes the state of the process after n steps, and if

$$h_{ij} = P(\text{hitting state } j \text{ before entering } \overline{\mathcal{S}} \mid X_0 = i),$$

then

$$E[N_j \mid X_0 = i] = d_{ij} + h_{ij} E[N_j \mid X_0 = j] \quad \text{where} \quad d_{ij} = \begin{cases} 1 & \text{if } i = j, \\ 0 & \text{if } i \neq j. \end{cases} \tag{3.5}$$

This statement (which appears without proof on p. 62 in Kemeny and Snell (1960)) is intuitive, but it is not trivial. The theory of absorbing chains says that

$$[\mathbf{B}^{-1}]_{ij} = E[N_j \mid X_0 = i],$$

so for $i \neq j$ we have $[\mathbf{B}^{-1}]_{ij} = h_{ij}[\mathbf{B}^{-1}]_{jj} \leq [\mathbf{B}^{-1}]_{jj}$. □

Algebraic proof. Assume that $\mathbf{B}$ is the leading $k \times k$ principal submatrix of $\mathbf{A}$, and suppose the states have been arranged so that the jth state is listed first and the ith state is listed second. The goal is to prove that $[\mathbf{B}^{-1}]_{11} \geq [\mathbf{B}^{-1}]_{21}$. Because

$$[\mathbf{B}^{-1}]_{11} = \frac{\det(\mathbf{B}_{11})}{\det(\mathbf{B})} \quad \text{and} \quad [\mathbf{B}^{-1}]_{21} = \frac{-\det(\mathbf{B}_{12})}{\det(\mathbf{B})}$$

where $\mathbf{B}_{ij}$ denotes the submatrix of $\mathbf{B}$ obtained by deleting the ith row and jth column from $\mathbf{B}$ and because Lemma 3.1 guarantees that $\det(\mathbf{B}) > 0$, it suffices to prove that

$$\det(\mathbf{B}_{11}) + \det(\mathbf{B}_{12}) \geq 0.$$

Denote the first unit vector by $\mathbf{e}_1^T = (1, 0, \ldots, 0)$, and partition $\mathbf{B}$ as

(3.6)
$$\mathbf{B} = \begin{pmatrix} 1-p_{11} & -p_{12} & \cdots & -p_{1k} \\ -p_{21} & 1-p_{22} & \cdots & -p_{2k} \\ \vdots & \vdots & \ddots & \vdots \\ -p_{k1} & -p_{k2} & \cdots & 1-p_{kk} \end{pmatrix} = \left(\begin{array}{c|c|c|c} 1-p_{11} & -p_{12} & \cdots & -p_{1k} \\ \hline \mathbf{b}_1 & \mathbf{b}_2 & \cdots & \mathbf{b}_k \end{array}\right).$$

In terms of these quantities, $\det(\mathbf{B}_{11}) + \det(\mathbf{B}_{12})$ is given by

$$\begin{aligned} \det(\mathbf{B}_{11}) + \det(\mathbf{B}_{12}) &= \det(\mathbf{b}_2 \,|\, \mathbf{b}_3 \,|\, \cdots \,|\, \mathbf{b}_k) + \det(\mathbf{b}_1 \,|\, \mathbf{b}_3 \,|\, \cdots \,|\, \mathbf{b}_k) \\ &= \det(\mathbf{b}_2 + \mathbf{b}_1 \,|\, \mathbf{b}_3 \,|\, \cdots \,|\, \mathbf{b}_k) \\ &= \det(\mathbf{B}_{11} + \mathbf{b}_1 \mathbf{e}_1^T) \\ &= \det(\mathbf{B}_{11})\,(1 + \mathbf{e}_1^T \mathbf{B}_{11}^{-1} \mathbf{b}_1). \end{aligned}$$

Lemma 3.1 also insures that $\det(\mathbf{B}_{11}) > 0$, so the proof can be completed by arguing that

$$1 + \mathbf{e}_1^T \mathbf{B}_{11}^{-1} \mathbf{b}_1 \geq 0.$$

To do so, modify the chain by making state 1 as well as states $k+1, k+2, \ldots, n$ absorbing states so that the transition matrix has the form

$$\tilde{\mathbf{P}} = \left(\begin{array}{c|ccc|c|ccc} 1 & 0 & 0 & \cdots & 0 & 0 & \cdots & 0 \\ \hline p_{21} & p_{22} & p_{23} & \cdots & p_{2k} & p_{2,k+1} & \cdots & p_{2n} \\ p_{31} & p_{32} & p_{33} & \cdots & p_{3k} & p_{3,k+1} & \cdots & p_{3n} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & & \vdots \\ p_{k1} & p_{k2} & p_{k3} & \cdots & p_{kk} & p_{k,k+1} & \cdots & p_{kn} \\ \hline 0 & 0 & 0 & \cdots & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 0 & 0 & \cdots & 1 \end{array}\right)$$

$$= \left(\begin{array}{c|c|c} 1 & \mathbf{0} & \mathbf{0} \\ \hline -\mathbf{b}_1 & \mathbf{Q} & \mathbf{R} \\ \hline \mathbf{0} & \mathbf{0} & \mathbf{I}_{n-k} \end{array}\right).$$

It follows from the elementary theory of absorbing chains that the entries in the matrix

$$(\mathbf{I} - \mathbf{Q})^{-1}(-\mathbf{b}_1 \,|\, \mathbf{R}) = \mathbf{B}_{11}^{-1}(-\mathbf{b}_1 \,|\, \mathbf{R})$$

represent the various absorption probabilities, and consequently all entries in $-\mathbf{B}_{11}^{-1}\mathbf{b}_1$ are between 0 and 1 so that

$$0 \leq 1 + \mathbf{e}_1^T \mathbf{B}_{11}^{-1} \mathbf{b}_1 \leq 1. \qquad \square$$

Note. Although it may not be of optimal efficiency, the algebraic argument given above is also a proof of the statement (3.5).

LEMMA 3.5. *If* $\mathbf{A} = \mathbf{I} - \mathbf{P}$ *where* $\mathbf{P}_{n\times n}$ *is an irreducible stochastic matrix, and if* $\mathbf{B}_{k\times k}$ $(k < n)$ *is a principal submatrix of* $\mathbf{A}$, *then*

$$0 < \det(\mathbf{B}) \leq \frac{\max_i \delta_i(\mathbf{B})}{\max_{i,j} [\mathbf{B}^{-1}]_{ij}} \leq \frac{1}{\max_{i,j} [\mathbf{B}^{-1}]_{ij}}$$

where $\delta_r(\mathbf{B})$ *denotes the deleted product* $\delta_r(\mathbf{B}) = b_{11}b_{22}\cdots b_{kk}/b_{rr}$.

Proof. Lemma 3.4 insures that there is some diagonal entry $[\mathbf{B}^{-1}]_{rr}$ of $\mathbf{B}^{-1}$ such that

$$[\mathbf{B}^{-1}]_{rr} = \max_{i,j} [\mathbf{B}^{-1}]_{ij}. \tag{3.7}$$

If $\mathbf{B}_{rr}$ is the principal submatrix of $\mathbf{B}$ obtained by deleting the rth row and column from $\mathbf{B}$, then (3.3e) together with (3.7) produces

$$\begin{aligned}\det(\mathbf{B}) = \frac{\det(\mathbf{B}_{rr})}{[\mathbf{B}^{-1}]_{rr}} &\leq \frac{\delta_r(\mathbf{B})}{[\mathbf{B}^{-1}]_{rr}} = \frac{\delta_r(\mathbf{B})}{\max_{i,j}[\mathbf{B}^{-1}]_{ij}} \\ &\leq \frac{\max_i \delta_i(\mathbf{B})}{\max_{i,j}[\mathbf{B}^{-1}]_{ij}} \leq \frac{1}{\max_{i,j}[\mathbf{B}^{-1}]_{ij}}. \qquad \square\end{aligned}$$

LEMMA 3.6. *For an irreducible stochastic matrix* $\mathbf{P}_{n\times n}$, *let* $\mathbf{A}_j$ *be the principal submatrix of* $\mathbf{A} = \mathbf{I} - \mathbf{P}$ *obtained by deleting the* j*th row and column from* $\mathbf{A}$, *and let* $\mathbf{Q}$ *be the permutation matrix such that*

$$\mathbf{Q}^T\mathbf{A}\mathbf{Q} = \begin{pmatrix} \mathbf{A}_j & \mathbf{c}_j \\ \mathbf{d}_j^T & a_{jj} \end{pmatrix}.$$

If the stationary distribution for $\mathbf{Q}^T\mathbf{P}\mathbf{Q}$ *is written as* $\boldsymbol{\psi}^T = \boldsymbol{\pi}^T\mathbf{Q} = (\overline{\boldsymbol{\pi}}^T, \pi_j)$, *then the group inverse of* $\mathbf{A}$ *is given by*

$$\mathbf{A}^{\#} = \mathbf{Q}\begin{pmatrix} (\mathbf{I} - \mathbf{e}\overline{\boldsymbol{\pi}}^T)\mathbf{A}_j^{-1}(\mathbf{I} - \mathbf{e}\overline{\boldsymbol{\pi}}^T) & -\pi_j(\mathbf{I} - \mathbf{e}\overline{\boldsymbol{\pi}}^T)\mathbf{A}_j^{-1}\mathbf{e} \\ -\overline{\boldsymbol{\pi}}^T\mathbf{A}_j^{-1}(\mathbf{I} - \mathbf{e}\overline{\boldsymbol{\pi}}^T) & \pi_j\,\overline{\boldsymbol{\pi}}^T\mathbf{A}_j^{-1}\mathbf{e} \end{pmatrix}\mathbf{Q}^T$$

where $\mathbf{e}$ *is a column of* 1*'s whose size is determined by the context in which it appears.*

Proof. The group inverse possesses the property that $(\mathbf{T}^{-1}\mathbf{A}\mathbf{T})^{\#} = \mathbf{T}^{-1}\mathbf{A}^{\#}\mathbf{T}$ for all nonsingular matrices $\mathbf{T}$ [Campbell and Meyer (1991)], so

$$\mathbf{A}^{\#} = \mathbf{Q}\begin{pmatrix} \mathbf{A}_j & \mathbf{c}_j \\ \mathbf{d}_j^T & a_{jj} \end{pmatrix}^{\#}\mathbf{Q}^T.$$

Since $\operatorname{rank}(\mathbf{Q}^T\mathbf{A}\mathbf{Q}) = n - 1$, it follows that $a_{jj} - \mathbf{d}_j^T\mathbf{A}_j^{-1}\mathbf{c}_j = 0$, and this is used to verify that

$$\begin{aligned}\begin{pmatrix} \mathbf{A}_j & \mathbf{c}_j \\ \mathbf{d}_j^T & a_{jj} \end{pmatrix}^{\#} &= (\mathbf{I} - \mathbf{e}\boldsymbol{\psi}^T)\begin{pmatrix} \mathbf{A}_j^{-1} & \mathbf{0} \\ \mathbf{0} & 0 \end{pmatrix}(\mathbf{I} - \mathbf{e}\boldsymbol{\psi}^T) \\ &= \begin{pmatrix} (\mathbf{I} - \mathbf{e}\overline{\boldsymbol{\pi}}^T)\mathbf{A}_j^{-1}(\mathbf{I} - \mathbf{e}\overline{\boldsymbol{\pi}}^T) & -\pi_j(\mathbf{I} - \mathbf{e}\overline{\boldsymbol{\pi}}^T)\mathbf{A}_j^{-1}\mathbf{e} \\ -\overline{\boldsymbol{\pi}}^T\mathbf{A}_j^{-1}(\mathbf{I} - \mathbf{e}\overline{\boldsymbol{\pi}}^T) & \pi_j\,\overline{\boldsymbol{\pi}}^T\mathbf{A}_j^{-1}\mathbf{e} \end{pmatrix}. \qquad \square\end{aligned}$$

4. Proof of the main theorem. The preceding sequence of lemmas are now connected together to prove the primary results stated in Theorem 2.1.

The upper bound. To derive the inequalities

$$\max_{i,j} |a_{ij}^{\#}| < \frac{2\delta(n-1)}{\chi} \leq \frac{2(n-1)}{\chi}, \tag{4.1}$$

begin by letting $\mathbf{Q}$ be the permutation matrix given in Lemma 3.6 so that for $i \neq j$, the (i,j)-entry of $\mathbf{A}^{\#}$ is the (k,n)-entry of $\mathbf{Q}^T\mathbf{A}^{\#}\mathbf{Q}$ where $k \neq n$. In succession, use the formula of Lemma 3.6 and Hölder's inequality followed by the results of Lemmas 3.5 and 3.3 to write

$$\begin{aligned}
|a_{ij}^{\#}| &= \pi_j |\mathbf{e}_k^T(\mathbf{I} - \mathbf{e}\overline{\boldsymbol{\pi}}^T)\mathbf{A}_j^{-1}\mathbf{e}| \leq \pi_j \|\mathbf{e}_k - \overline{\boldsymbol{\pi}}\|_1 \left\|\mathbf{A}_j^{-1}\mathbf{e}\right\|_\infty \\
&< 2\pi_j \left\|\mathbf{A}_j^{-1}\right\|_\infty \leq 2\pi_j(n-1)\max_{r,s}\left[\mathbf{A}_j^{-1}\right]_{rs} \\
&\leq \frac{2\pi_j(n-1)\max_i \delta_i(\mathbf{A}_j)}{\det(\mathbf{A}_j)} \leq \frac{2\pi_j(n-1)\delta}{\det(\mathbf{A}_j)} \\
&= \frac{2\delta(n-1)}{\chi} \leq \frac{2(n-1)}{\chi}.
\end{aligned}$$

Now consider the diagonal elements. The (j,j)-entry of $\mathbf{A}^{\#}$ is the (n,n)-entry of $\mathbf{Q}^T\mathbf{A}^{\#}\mathbf{Q}$, so proceeding in a manner similar to that above produces

$$\begin{aligned}
|a_{jj}^{\#}| &= \pi_j |\overline{\boldsymbol{\pi}}^T\mathbf{A}_j^{-1}\mathbf{e}| \leq \pi_j \|\overline{\boldsymbol{\pi}}\|_1 \left\|\mathbf{A}_j^{-1}\mathbf{e}\right\|_\infty \\
&< \pi_j \left\|\mathbf{A}_j^{-1}\right\|_\infty \leq \pi_j(n-1)\max_{r,s}\left[\mathbf{A}_j^{-1}\right]_{rs} \\
&\leq \frac{\pi_j(n-1)\max_i \delta_i(\mathbf{A}_j)}{\det(\mathbf{A}_j)} \leq \frac{\pi_j(n-1)\delta}{\det(\mathbf{A}_j)} \\
&= \frac{\delta(n-1)}{\chi} \leq \frac{(n-1)}{\chi},
\end{aligned}$$

thus proving (4.1).

The lower bound. To establish that

$$\frac{1}{n\min_{\lambda_i \neq 1}|1-\lambda_i|} \leq \max_{i,j}|a_{ij}^{\#}|, \tag{4.2}$$

make use of the fact that if $\mathbf{Ax} = \mu\mathbf{x}$ for $\mu \neq 0$, then $\mathbf{A}^{\#}\mathbf{x} = \mu^{-1}\mathbf{x}$ [Campbell and Meyer (1991), p. 129]. In particular, if $\lambda \neq 1$ is an eigenvalue of $\mathbf{P}$, and if $\mathbf{x}$ is a corresponding eigenvector, then $\mathbf{Ax} = (1-\lambda)\mathbf{x}$ implies that $\mathbf{A}^{\#}\mathbf{x} = (1-\lambda)^{-1}\mathbf{x}$, so

$$\frac{1}{1-\lambda} \leq \left\|\mathbf{A}^{\#}\right\|_\infty \leq n\max_{i,j}|a_{ij}^{\#}|. \qquad \square$$

5. Using an LU factorization. Except for chains which are too large to fit into a computer's main memory, the stationary distribution $\boldsymbol{\pi}^T$ is generally computed by direct methods; i.e., either an LU or QR factorization of $\mathbf{A} = \mathbf{I} - \mathbf{P}$ (or $\mathbf{A}^T$) is computed [Harrod and Plemmons (1984); Grassmann et al. (1985); Funderlic and Meyer (1986); Golub and Meyer (1986); Barlow (1993)]. Even for very large chains which are nearly uncoupled, direct methods are usually involved—they can be the basis of the main algorithm [Stewart and Zhang (1991)], or they can be used to solve the aggregated and coupling chains in iterative aggregation/disaggregation algorithms [Chatelin and Miranker (1982), Haviv (1987)]. In the conclusion of their paper, Golub and Meyer (1986) make the following observation.

> *Computational experience suggests that when a triangular factorization of* $\mathbf{A}_{n\times n}$ *is used to solve an irreducible chain, the condition of the chain seems to be a function of the size of the nonzero pivots, and this means that it should be possible to estimate* κ *with little or no extra cost beyond that incurred in computing* $\boldsymbol{\pi}^T$. *For large chains, this can be a significant savings over the* $O(n^2)$ *operations demanded by traditional condition estimators.*

Of course, this is contrary to the situation which exists for general nonsingular matrices because the absence of small pivots (or the existence of a large determinant) is not a guarantee of a well-conditioned matrix—consider the matrix in (1.6). A mathematical formulation and proof (or even an intuitive explanation) of Golub and Meyer's observation has heretofore not been given, but the results of §2 and §3 now make it possible to give a more precise statement and a rigorous proof of the Golub–Meyer observation. The arguments hinge on the fact that whenever $\boldsymbol{\pi}^T$ is computed by means of a triangular factorization of $\mathbf{A}$ (or $\mathbf{A}^T$), the character of the chain is always an immediate by-product. The results for an LU factorization are given below, and the analogous theory for a QR factorization is given in the next section.

Suppose that the LU factorization [2] of $\mathbf{A} = \mathbf{I} - \mathbf{P}$ is computed to be

$$\mathbf{A} = \mathbf{LU} = \begin{pmatrix} \mathbf{L}_n & \mathbf{0} \\ \mathbf{r}^T & 1 \end{pmatrix} \begin{pmatrix} \mathbf{U}_n & \mathbf{c} \\ \mathbf{0} & 0 \end{pmatrix}.$$

If $\mathbf{A}_n$ is the principal submatrix of $\mathbf{A}$ obtained by deleting the last row and column from $\mathbf{A}$, then $\mathbf{A}_n$ is a nonsingular M-matrix, and its LU factorization is $\mathbf{A}_n = \mathbf{L}_n\mathbf{U}_n$. Since the LU factors of a nonsingular M-matrix are also nonsingular M-matrices [Berman and Plemmons (1979), Horn and Johnson (1991)], it follows that $\mathbf{L}_n$ and $\mathbf{U}_n$ are nonsingular M-matrices, and hence $\mathbf{L}_n^{-1} \geq \mathbf{0}$ and $\mathbf{U}_n^{-1} \geq \mathbf{0}$. Consequently, $\mathbf{r}^T \leq \mathbf{0}$, so the solution (obtained by a simple substitution process with no divisions) of the nonsingular triangular system $\mathbf{x}^T\mathbf{L}_n = -\mathbf{r}^T$ is nonnegative. This together with the result of Lemma 3.3 and Theorem 2.1 produces the following conclusion.

THEOREM 5.1. *For an irreducible Markov chain whose transition matrix is* $\mathbf{P}$, *let the* LU *factorization of* $\mathbf{A} = \mathbf{I} - \mathbf{P}$ *be given by*

$$\mathbf{A} = \mathbf{LU} = \begin{pmatrix} \mathbf{L}_n & \mathbf{0} \\ \mathbf{r}^T & 1 \end{pmatrix} \begin{pmatrix} \mathbf{U}_n & \mathbf{c} \\ \mathbf{0} & 0 \end{pmatrix}.$$

---

[2] Regardless of whether $\mathbf{A}$ or $\mathbf{A}^T$ is used, Gaussian elimination with finite-precision arithmetic can prematurely produce a zero (or even a negative) pivot, and this can happen for well-conditioned chains. Practical implementation demands a strategy to deal with this situation, and Funderlic and Meyer (1986) and Stewart and Zhang (1991) discuss this problem along with possible remedies. Practical algorithms involve reordering schemes which introduce permutation matrices, but these permutations are not important in the context of this section, so they are suppressed.

If $\mathbf{x}^T$ *is the solution of* $\mathbf{x}^T\mathbf{L}_n = -\mathbf{r}^T$, *then each of the following statements is true. The stationary distribution of the chain is*

$$\boldsymbol{\pi}^T = \frac{1}{1+\|\mathbf{x}\|_1}(\mathbf{x}^T, 1). \tag{5.1}$$

The character of the chain is

$$\chi = \frac{\det(\mathbf{U}_n)}{\pi_n} = (1+\|\mathbf{x}\|_1)\det(\mathbf{U}_n). \tag{5.2}$$

The condition number for the chain is bounded above by

$$\kappa < \frac{2\delta(n-1)\pi_n}{\det(\mathbf{U}_n)} = \frac{2\delta(n-1)}{(1+\|\mathbf{x}\|_1)\det(\mathbf{U}_n)} \leq \frac{2(n-1)}{(1+\|\mathbf{x}\|_1)\det(\mathbf{U}_n)}. \tag{5.3}$$

The condition number for the chain is bounded below by

$$\pi_n \sum_{i=1}^{n-1} \frac{\pi_i}{u_{ii}} = \frac{1}{(1+\|\mathbf{x}\|_1)^2} \sum_{i=1}^{n-1} \frac{x_i}{u_{ii}} \leq \kappa \tag{5.4}$$

where u_{ii} *is the ith pivot in* $\mathbf{U}_n$.

Proof. Statements (5.1), (5.2), and (5.3) are straightforward consequences of the previous discussion. To establish (5.4), first recall from Lemma 3.6 that

$$a_{nn}^{\#} = \pi_n \overline{\boldsymbol{\pi}}^T \mathbf{A}_n^{-1}\mathbf{e} = \pi_n \overline{\boldsymbol{\pi}}^T \mathbf{U}_n^{-1}\mathbf{L}_n^{-1}\mathbf{e} > 0.$$

Since $\mathbf{U}_n^{-1} \geq \mathbf{0}$ and $\mathbf{L}_n^{-1} \geq \mathbf{0}$, it follows that $\overline{\boldsymbol{\pi}}^T\mathbf{U}_n^{-1}$ and $\mathbf{L}_n^{-1}\mathbf{e}$ can be written as

$$\overline{\boldsymbol{\pi}}^T\mathbf{U}_n^{-1} = \left(\frac{\pi_1}{u_{11}}, \frac{\pi_2}{u_{22}} + \alpha_2, \ldots, \frac{\pi_{n-1}}{u_{n-1,n-1}} + \alpha_{n-1}\right),$$

$$\mathbf{L}_n^{-1}\mathbf{e} = (1,\ 1+\beta_2, \ldots, 1+\beta_{n-1})^T$$

where each α_i and β_i is nonnegative, and consequently (setting $\alpha_0 = \beta_0 = 0$)

$$\overline{\boldsymbol{\pi}}^T\mathbf{A}_n^{-1}\mathbf{e} = \overline{\boldsymbol{\pi}}^T\mathbf{U}_n^{-1}\mathbf{L}_n^{-1}\mathbf{e} = \sum_{i=1}^{n-1} \frac{(\pi_i+\alpha_i)(1+\beta_i)}{u_{ii}} \geq \sum_{i=1}^{n-1} \frac{\pi_i}{u_{ii}}.$$

Therefore,

$$\kappa \geq a_{nn}^{\#} = \pi_n \overline{\boldsymbol{\pi}}^T\mathbf{U}_n^{-1}\mathbf{L}_n^{-1}\mathbf{e} \geq \pi_n \sum_{i=1}^{n-1} \frac{\pi_i}{u_{ii}} = \frac{1}{(1+\|\mathbf{x}\|_1)^2} \sum_{i=1}^{n-1} \frac{x_i}{u_{ii}}. \qquad \square$$

As mentioned before, the pivots or the determinant need not be indicators of the condition of a general nonsingular matrix. In particular, the absence of small pivots (or the existence of a large determinant) is not a guarantee of a well-conditioned matrix. However, for our special matrices $\mathbf{A} = \mathbf{I} - \mathbf{P}$, the bounds in Theorem 5.1 allow the pivots to be used as condition estimators.

COROLLARY 5.1. *For an irreducible Markov chain whose transition matrix is* $\mathbf{P}$, *suppose that the* LU *factorization of* $\mathbf{A} = \mathbf{I} - \mathbf{P}$ *and the stationary distribution* $\boldsymbol{\pi}^T$ *have been computed as described in Theorem* 5.1. *If the pivots* u_{ii} *are large relative to* π_n *in the sense that* $\pi_n / \det(\mathbf{U}_n)$ *is not too small, then the chain is well conditioned. If there are pivots* u_{ii} *which are small relative to* $\pi_n \pi_i$ *in the sense that*

$$\pi_n \sum_{i=1}^{n-1} \pi_i / u_{ii}$$

is large, then the chain is ill conditioned.

6. Using a QR factorization. The utility of orthogonal triangularization is well documented in the vast literature on matrix computations, and the use of a QR factorization to solve and analyze Markov chains is discussed by Golub and Meyer (1986). The following theorem shows that the character of an irreducible chain can be directly obtained from the diagonal entries of $\mathbf{R}$ and the last column of $\mathbf{Q}$, and this will establish an upper bound using a QR factorization which is analogous to that in Theorem 5.1 for an LU factorization. A lower bound analogous to the one in Theorem 5.1 is not readily available.

THEOREM 6.1. *For an irreducible Markov chain whose transition matrix is* $\mathbf{P}$, *the QR factorization of* $\mathbf{A} = \mathbf{I} - \mathbf{P}$ *is given by*

$$\mathbf{A} = \mathbf{QR} = \begin{pmatrix} \mathbf{Q}_n & \mathbf{c} \\ \mathbf{d}^T & q_{nn} \end{pmatrix} \begin{pmatrix} \mathbf{R}_n & -\mathbf{R}_n \mathbf{e} \\ \mathbf{0} & 0 \end{pmatrix} = \begin{pmatrix} \mathbf{Q}_n \mathbf{R}_n & -\mathbf{Q}_n \mathbf{R}_n \mathbf{e} \\ \mathbf{d}^T \mathbf{R}_n & -\mathbf{d}^T \mathbf{R}_n \mathbf{e} \end{pmatrix}.$$

If $\mathbf{q}$ *denotes the last column of* $\mathbf{Q}$, *then each of the following statements are true. The stationary distribution of the chain is*

$$\boldsymbol{\pi}^T = \frac{\mathbf{q}^T}{\sum_{i=1}^{n} q_{in}}. \tag{6.1}$$

The character of the chain is

$$\chi = \|\mathbf{q}\|_1 \det(\mathbf{R}_n). \tag{6.2}$$

The condition number for the chain is bounded above by

$$\kappa < \frac{2\delta(n-1)}{\|\mathbf{q}\|_1 \det(\mathbf{R}_n)} \leq \frac{2(n-1)}{\|\mathbf{q}\|_1 \det(\mathbf{R}_n)}. \tag{6.3}$$

Proof. The formula (6.1) for $\boldsymbol{\pi}^T$ is derived in Golub and Meyer (1986). To prove (6.2), first recall the result of Lemma 3.3, and observe that

$$\chi^2 = \left(\frac{\det \mathbf{A}_n}{\pi_n} \right)^2 = \frac{(\det \mathbf{Q}_n \mathbf{R}_n)^2}{\pi_n^2} = \frac{(\det \mathbf{Q}_n)^2 (\det \mathbf{R}_n)^2}{q_{nn}^2 / \|\mathbf{q}\|_1^2}.$$

Use the fact that $\mathbf{QQ}^T = \mathbf{I}$ implies $\mathbf{Q}_n \mathbf{Q}_n^T + \mathbf{cc}^T = \mathbf{I}$ to obtain

$$(\det \mathbf{Q})^2 = \det\left(\mathbf{Q}_n \mathbf{Q}_n^T\right) = \det\left(\mathbf{I} - \mathbf{cc}^T\right) = 1 - \mathbf{c}^T \mathbf{c} = q_{nn}^2,$$

and substitute this into the previous expression to obtain (6.2). The bound (6.3) is now a consequence of the result of Theorem 2.1. □

7. Concluding remarks. It has been argued that the sensitivity of an irreducible chain is primarily governed by how close the subdominant eigenvalues are to 1 in the sense that the condition number of the chain is bounded by

$$\frac{1}{n \min\limits_{\lambda_i \neq 1} |1 - \lambda_i|} \leq \kappa < \frac{2\delta(n-1)}{\chi}. \tag{7.1}$$

Although the upper bound explicitly involves n, it is generally not the case that $2\delta(n-1)/\chi$ grows in proportion to n. Except in the special case when the diagonal entries of $\mathbf{P}$ are 0, the term δ somewhat mitigates the presence of n because as n becomes larger, δ becomes smaller.

Computational experience suggests that $2\delta(n-1)/\chi$ is usually a rather conservative estimate of κ, and the term δ/χ by itself, although not always an upper bound for κ, is often of the same order of magnitude as κ. However, there exist pathological cases for which even δ/χ severely overestimates κ. This seems to occur for chains which are not too badly conditioned and no single eigenvalue is extremely close to 1, but enough eigenvalues are within range of 1 to force χ^{-1} to be too large. This suggests that for the purposes of bounding κ above, perhaps not all of the subdominant eigenvalues need to be taken into account. In a forthcoming article, Seneta (1993) addresses this issue by an analysis involving coefficients of ergodicity.

When direct methods are used to solve an irreducible chain, standard condition estimators can be used to produce reliable estimates for κ, but the cost of doing so is $O(n^2)$ operations beyond the solution process. The results of Theorems 5.1 and 6.1 make it possible to estimate κ with the same computations which produce $\boldsymbol{\pi}^T$. Although the bounds for κ produced by Theorem 5.1 are sometimes rather loose, they are nevertheless virtually free. One must balance the cost of obtaining condition estimates against the information one desires to obtain from these estimates.

8. Acknowledgments. The exposition of this article was enhanced by suggestions provided by Dianne O'Leary, Guy Latouche, and Paul Schweitzer.

STRONGLY INERTIA-PRESERVING MATRICES *

ABRAHAM BERMAN† AND DAFNA SHASHA†

Abstract. It is shown that a matrix can be strongly inertia preserving without being diagonally stable.

Key words. inertia-preserving matrices, strongly inertia-preserving matrices, diagonally stable and semistable matrices

AMS subject classifications. 15A18, 15A99, 93D05

1. Introduction.

All matrices in this note are real. For a square matrix A let $i_+(A)$ be the number of eigenvalues with a positive real part, $i_0(A)$ the number of pure imaginary eigenvalues, and $i_-(A)$ the number of eigenvalues with a negative real part. As usual, the triple

$$\text{In } A = \{i_+(A), i_0(A), i_-(A)\}$$

is the *inertia* of A. We further denote by $B_0(A)$ the class of all positive semidefinite matrices B with

$$(BA)_{ii} = 0, \qquad i = 1, \ldots, n,$$

and let

$$r_A = \min\{\text{rank } B; 0 \neq B \in B_0(A)\} \quad \text{if } B_0(A) \neq \{0\},$$

where

$$r_A = \infty \quad \text{if } B_0(A) = \{0\}.$$

An $n \times n$ matrix A is (*positive*) *stable* if $i_+(A) = n$. Motivated by the classical Lyapunov theorem, which says that A is stable if and only if there exists a positive definite matrix X such that $AX + XA^T$ is positive definite, we say that A is *Lyapunov diagonally stable* if there exists a positive diagonal matrix D such that $AD + DA^T$ is positive definite. Furthermore, A is *Lyapunov diagonally semistable* if there exists a positive diagonal matrix D such that $AD+DA^T$ is positive semidefinite, and A is *Lyapunov diagonally near stable* if it is Lyapunov diagonally semistable but not Lyapunov diagonally stable. For applications of these classes of matrices see [3] and [5].

We say that a matrix A is *inertia preserving* if $\text{In } AG = \text{In } G$ for every invertible diagonal matrix G and *strongly inertia preserving* if $\text{In } AG = \text{In } G$ for every (possibly singular) diagonal matrix G.

Observe that A is strongly inertia preserving if and only if every principal submatrix of A is inertia preserving.

In [2] it is shown that every Lyapunov diagonally stable matrix is strongly inertia preserving. Using an example given in [5], we show that the converse is not true by proving that a Lyapunov diagonally near stable matrix with $r_A \geq 3$ is strongly inertia preserving. We conjecture that Lyapunov diagonally semistable matrices are strongly inertia preserving if and only if $r_A \geq 3$.

2. Lyapunov diagonally semistable matrices with $r_A \geq 3$. We use the following result.

THEOREM 1 ([2, Corollary 5.4]). *A Lyapunov diagonally semistable matrix A is inertia preserving if and only if for every $B \in B_0(A)$ of rank not exceeding 2 and for every diagonal invertible G, the matrix BAG is skew symmetric only when $B = 0$.*

We start with a lemma in which A need not be Lyapunov diagonally semistable.

LEMMA 1. *Let $A[\alpha]$ be the principal submatrix of a square matrix A based on the indices in α. Then*

$$r_{A[\alpha]} \geq r_A.$$

Proof. If $B_0(A[\alpha]) = \{0\}$, then $r_{A[\alpha]} = \infty$. Otherwise, let $0 \neq C \in B_0(A[\alpha])$ be of minimal rank. Let B be a matrix of the same order as A such that $B[\alpha] = C$ and all other entries of B are zeros. Then, $B \in B_0(A)$ and $r_A \leq \text{rank } B = \text{rank } B[\alpha] = r_{A[\alpha]}$. □

THEOREM 2. *If A is Lyapunov diagonally semistable and $r_A \geq 3$, then A is strongly inertia preserving.*

Proof. If $r_A \geq 3$, then the only matrix of rank ≤ 2 in $B_0(A)$ is the zero matrix, so by Theorem 1, A is inertia preserving. By Lemma 2 and Theorem 1 all principal submatrices of A are inertia preserving, so A is strongly inertia preserving. □

By Theorem 3.4 of [6] or Theorem 3.1 of [4], a Lyapunov diagonally semistable matrix is Lyapunov diagonally stable if and only if $r_A = \infty$ ($B_0(A) = \{0\}$). In [5] it is shown that the matrix

$$A = \begin{bmatrix} 10 & 0 & 1 & 0 & 5 & 8 \\ -4 & 5 & 10 & 0 & -3 & -2 \\ 6 & -6 & 4 & -4 & 5 & -4 \\ 8 & 4 & 4 & 4 & 6 & 4 \\ -2 & 7 & -1 & -2 & 2 & 14 \\ 0 & 5 & 6 & 2 & -3 & 4 \end{bmatrix}$$

is Lyapunov diagonally semistable with $r_A = 3$. Thus, it is an example of a strongly inertia-preserving matrix that is not Lyapunov diagonally stable.

3. Lyapunov diagonally semistable matrices with $r_A \leq 2$. We start with a proposition where it is not assumed that A is Lyapunov diagonally semistable.

PROPOSITION 1. *A matrix A has a singular principal submatrix if and only if $r_A = 1$.*

Proof. Suppose $r_A = 1$. Then there exists a nonzero vector $\mathbf{x}$ such that $(\mathbf{x}\mathbf{x}^T A)_{ii} = 0$, for all i. Let α be the support of $\mathbf{x}$, that is, $\alpha = \{i; \mathbf{x}_i \neq 0\}$. Then $A[\alpha]$, the principal submatrix of A based on the indices in α, is singular.

Conversely, suppose $A[\alpha]$ is a singular principal submatrix of A. Let $\mathbf{x} \in \mathbb{R}^n$ be a nonzero vector such that

$$x[\{1, 2, \ldots, n\} - \alpha] = 0 \quad \text{and} \quad x[\alpha]^T A[\alpha] = 0.$$

Then $\mathbf{x}\mathbf{x}^T A = 0$, so $\mathbf{x}\mathbf{x}^T \in B_0(A)$ and $r_A = 1$. □

For Lyapunov diagonally semistable matrices, we suggest the following.

CONJECTURE 1. *Let A be Lyapunov diagonally semistable. Then A is strongly inertia preserving if and only if $r_A \geq 3$.*

To prove the conjecture, it suffices by the previous section and the above proposition to show that if $r_A = 2$, then A cannot be strongly inertia preserving.

A partial result in this direction is as follows.

PROPOSITION 2. *If $A \in \mathbb{R}^{3\times 3}$ is Lyapunov diagonally semistable and if $r_A = 2$, then A is not inertia preserving.*

Proof. We shall prove that there exists a nonzero matrix $B \in B_0(A)$ and an invertible diagonal matrix G such that BAG is skew symmetric; so, by Theorem 1, A is not inertia preserving.

Let B be a rank 2 matrix in $B_0(A)$. Then

$$BA = \begin{bmatrix} 0 & a & b \\ c & 0 & d \\ e & h & 0 \end{bmatrix}.$$

We show that there exists an invertible diagonal matrix $G = \operatorname{diag}\{g_1, g_2, g_3\}$ such that

$$BAG + GA^TB = 0.$$

Indeed, the system

$$\begin{aligned} cg_1 + ag_2 &= 0, \\ eg_1 + bg_3 &= 0, \\ fg_2 + dg_3 &= 0 \end{aligned}$$

has a nontrivial solution g_1, g_2, g_3, since

$$\det \begin{bmatrix} c & a & 0 \\ e & 0 & b \\ 0 & f & d \end{bmatrix} = -\det \begin{bmatrix} 0 & a & b \\ c & 0 & d \\ e & f & 0 \end{bmatrix} = \det BA,$$

and $\det BA = 0$ as rank $B = 2$.

To show that g_1, g_2, g_3, are nonzero, it is enough, without loss of generality, to prove the impossibility of the following two cases:

(a) $g_1 = 0, \quad g_2 \neq 0, \quad g_3 \neq 0.$

(b) $g_1 = g_2 = 0, \quad g_3 \neq 0.$

In the first case

$$\begin{aligned} ag_2 &= 0, \\ bg_3 &= 0, \\ fg_2 + dg_3 &= 0, \end{aligned}$$

where g_2 and g_3 are nonzero. Consequently, $a = b = 0$, so

$$BA = \begin{bmatrix} 0 & 0 & 0 \\ c & 0 & d \\ e & f & 0 \end{bmatrix}.$$

Thus, $B_1A = 0$, where B_1 denotes the first row of B.

By Proposition 1, A is nonsingular; hence $B_1 = 0$, so

$$B = \begin{bmatrix} 0 & 0 & 0 \\ 0 & b_{22} & b_{23} \\ 0 & b_{23} & b_{33} \end{bmatrix}.$$

Since the 3×3 matrix A has no singular principal submatrices and since a Lyapunov diagonally semistable matrix is Lyapunov diagonally stable if and only if it has no singular principal submatrices (see [1]), the matrix $A[2,3]$ is Lyapunov diagonally stable. This implies that $B[2,3] = 0$ in contradiction to rank $B = 2$.

In case (b),

$$\begin{aligned} bg_3 &= 0, \\ dg_3 &= 0, \end{aligned}$$

where g_3 is nonzero. Thus,

$$BA = \begin{bmatrix} 0 & a & 0 \\ c & 0 & 0 \\ e & f & 0 \end{bmatrix}.$$

We now use the fact that A is Lyapunov diagonally semistable, so $AD + DA^T$ is positive semidefinite for a positive diagonal matrix D, which implies (see [4], [6]) that

$$B(AD + DA^T) = 0. \tag{1}$$

Since the third columns of BA and BAD equal zero, it follows by (1) that the third column of BDA^T also vanishes, so the third column and row of AD lie in the one dimensional null space of B. Observe that by Proposition 1, a_{33} is nonzero, so the third column and the third row of AD are equal. Let

$$AD = \begin{bmatrix} k & l & m \\ n & p & q \\ m & q & t \end{bmatrix}.$$

Then

$$AD + DA^T = \begin{bmatrix} 2k & 1+n & 2m \\ 1+n & 2p & 2q \\ 2m & 2q & 2t \end{bmatrix}.$$

Thus, $AD[2,3] = \frac{1}{2}(AD + DA^T)[2,3]$. But, by (1), rank $(AD + DA^T) = 1$, so $(AD + DA^T)[2,3]$ is singular. This implies that $AD[2,3]$ and $A[2,3]$ are singular, in contradiction to the assumption that $r_A = 2$. □

DYNAMICAL SYSTEMS THAT COMPUTE BALANCED REALIZATIONS AND THE SINGULAR VALUE DECOMPOSITION*

U. HELMKE†, J. B. MOORE‡, AND J. E. PERKINS‡

Abstract. The tasks of finding balanced realizations in systems theory and the singular value decomposition (SVD) of matrix theory are accomplished by finding the limiting solutions of differential equations. Several alternative sets of equations and their convergence properties are investigated. The dynamical systems for these tasks generate flows on the space of realizations that leave the transfer functions invariant. They are termed isodynamical flows. Isodynamical flows are generalizations of isospectral flows on matrices. These flows evolve on the actual system matrices and thus remove the need for considering coordinate transformation matrices. The methods are motivated by the power of parallel processing and the ability of a differential equations approach to tackle time-varying or adaptive tasks.

1. Introduction.

In current practice, the problems of finding a balanced realization for a linear control system, as well as achieving an SVD of a matrix are solved using algebraic matrix manipulations, implemented in standard computer programs. Balanced realizations are a useful tool in systems theory to increase numerical robustness, and they allow a sensible model order reduction to be performed. This operation has been widely studied [10], [11] and computation methods have been described. Certainly, these methods are widely used, reliable, and well understood. On the other hand, recent advances in neural network theory and associative memories have shown that gradient-type algorithms can lead to effective and fast methods for algebraic tasks such as principle component analysis. This latter task is equivalent to the SVD. It follows that gradient flows can be an effective tool for SVD, although the full possibilities and limitations of this approach are not yet fully clear.

Brockett [1], again motivated by the renewed interest in neural networks, parallel processing, and analog computing, has also shown that other linear algebra and combinatorial problems can be solved in terms of the limiting solutions of ordinary differential equations (ODEs) that are gradient flows on orthogonal matrices. In [2] a systematic approach to balanced realizations of linear systems was developed, which treats balanced realizations as the global minima of objective functions, defined on the set of all realizations of a given transfer function. Aspects of this work are generalized in [3] for the task of finding an SVD using gradient flows on unitary matrices. In an earlier paper [4], it is shown how certain types of balancing problems can be solved using gradient flows on positive definite matrices with an exponential rate of convergence. Such algorithms are possibly suitable for application to time-varying systems [5].

In this paper, a systematic attempt is made to construct and analyze dynamical systems that are capable of achieving balancing or the SVD. Based on the cost

function approach developed in [2], we propose several different gradient flows that solve the problem of finding a balanced realization, given an initial system realization. Each of these equations has an exponential rate of convergence and we compare their respective rates. It is envisaged that for particular applications there will be one gradient flow that will give a better convergence rate than other algorithms. First we review the linear and quadratic gradient flows of [4] that evolve on $P = T'T > 0$, where T is the state space transformation matrix that gives the balanced realization. The next solution method we consider are differential equations that evolve on the actual transformation matrix T. This solution method is of interest because it circumvents the need to find T given $P = T'T$.

Next we propose alternative ODEs that solve the balanced realization problem. These differential equations, termed isodynamical flows, evolve on the actual system matrices (A, B, C) rather than having the intermediate step of transformation matrices. They have the obvious advantage of immediacy as well as giving a clearer indication as to how the system is evolving. This is the first time a *direct* method to compute balanced realizations, without computing any balancing transformations, has been given. The class of all isodynamical flows can be viewed as a generalization of the isospectral flows, studied in matrix theory, as in [1], [3], [6], [7], [9], and their references.

In §2 gradient flows that give the transformation matrices for balanced realizations are studied, and in §3 related ODEs are developed for a direct evolution of the system matrices. In §4 flows achieving the SVD of a matrix are studied, and in §5 conclusions are drawn. The Appendix summarizes important results about gradient flows on manifolds.

2. Gradient flows for balancing transformations. In this section we consider the problem of computing balancing coordinate transformations via differential equations. While a part of this problem has been already considered in [4], we review some of the material developed in [4] and emphasize some new points as well.

We consider linear dynamical systems in continuous or discrete time

$$\left\{ \begin{array}{l} \dot{x}(t) = Ax(t) + Bu(t) \\ y(t) = Cx(t) \end{array} \right\} \quad \text{or} \quad \left\{ \begin{array}{c} x_{k+1} = Ax_k + Bu_k \\ y_k = Cx_k \end{array} \right\}$$

defined by the system matrices $(A, B, C) \in \Re^{n\times n} \times \Re^{n\times m} \times \Re^{p\times n}$. Such a system is called asymptotically stable if the eigenvalues of A are in the open complex left half-plane or in the open unit disc, respectively. For any asymptotically stable system (A,B,C), the controllability and observability gramians W_c and W_o are, respectively, defined in discrete time and continuous time by the symmetric matrices

$$W_c = \sum_{k=0}^{\infty} A^k BB'A'^k, \qquad W_o = \sum_{k=0}^{\infty} A'^k C'CA^k, \tag{2.1a}$$

$$W_c = \int_0^{\infty} e^{At} BB' e^{tA'} \mathrm{dt}, \qquad W_o = \int_0^{\infty} e^{tA'} C'Ce^{At} \mathrm{dt}. \tag{2.1b}$$

For unstable systems the controllability and observability gramians are likewise defined by finite sums or integrals rather than by the above infinite sums or integrals. In the following we will assume asymptotic stability of A; however, all results hold mutatis mutandis in the unstable case using finite gramians. To emphasize the dependence of the gramians on (A, B, C), we also write $W_c(A, B)$ and $W_o(A, C)$ for the controllability and observability gramians of (A, B, C).

In the sequel we fix an initial asymptotically stable controllable and observable realization $(A, B, C) \in \Re^{n\times n} \times \Re^{n\times m} \times \Re^{p\times n}$ of a given transfer function $G(s) = C(sI - A)^{-1}B \in \Re(s)^{p\times m}$. Thus, by Kalman's realization theorem, see, e.g., Kailath [8], all other minimal realizations of $G(s)$ are of the form (TAT^{-1}, TB, CT^{-1}) for a uniquely determined invertible coordinate transformation T.

Any linear change of coordinates in the state space $\Re^n$ by an invertible transformation $T \in GL(n, \Re)$ changes the realization according to $(A, B, C) \mapsto (TAT^{-1}, TB, CT^{-1})$ and thus transforms the gramians via

$$W_c \mapsto TW_cT', \qquad W_o \mapsto (T')^{-1}W_oT^{-1}. \tag{2.2}$$

We call a state space representation (A, B, C) of the transfer function *balanced* if $W_c = W_o$. This is more general than the usual definition of balanced realizations, (see Moore [10]), which requires that $W_c = W_o = diagonal$. In this case we refer to (A, B, C) as a *diagonal balanced realization*, which is thus one particular realization of our class of balanced realizations.

To obtain a quantitative measure of how the gramians change for the various realizations of a transfer function, we consider the function

$$\begin{aligned} \Phi(T) &= \operatorname{tr}(W_c(TAT^{-1}, TB) + W_o(TAT^{-1}, CT^{-1})) \\ &= \operatorname{tr}(TW_cT' + (T')^{-1}W_oT^{-1}) \\ &= \operatorname{tr}(W_cT'T + W_o(T'T)^{-1}) \\ &= \operatorname{tr}(W_cP + W_oP^{-1}) \end{aligned} \tag{2.3}$$

with

$$P = T'T. \tag{2.4}$$

Note that $\Phi(T)$ is the sum of the eigenvalues of the controllability and observability gramians of (TAT^{-1}, TB, CT^{-1}) and is thus a crude numerical measure for the controllability and observability of (TAT^{-1}, TB, CT^{-1}).

2.1. Balancing flows of positive definite matrices. Let $\mathcal{P}(n)$ denote the set of positive definite real symmetric $n\times n$ matrices $P = P' > 0$. $\mathcal{P}(n)$ is an open, convex subset of the set of all symmetric $n \times n$ matrices and is diffeomorphic to Euclidean space $\Re^{(1/2)n(n+1)}$. By (2.3) we are led to study the function

$$\phi : \mathcal{P}(n) \to \Re, \qquad \phi(P) = \operatorname{tr}(W_cP + W_oP^{-1}). \tag{2.5}$$

For a proof of the following results we refer to [4] and [9].

LEMMA 2.1 ([4], [9]). *Let W_c, W_o be the controllability and observability gramians* (2.1) *of an asymptotically stable minimal realization (A, B, C). Then the function $\phi : \mathcal{P}(n) \to \Re, \phi(P) = \operatorname{tr}(W_cP + W_oP^{-1})$, defined on the set $\mathcal{P}(n)$ of positive definite symmetric matrices, has compact sublevel sets, i.e., for all $a \in \Re$ then $\{P \in \mathcal{P}(n) \mid \operatorname{tr}(W_cP + W_oP^{-1}) \le a\}$ is a compact subset of $\mathcal{P}(n)$. In particular, there exists a minimizing $P = P' > 0$ for the function $\phi : \mathcal{P}(n) \to \Re$ defined by* (2.5).

While Lemma 2.1 establishes the existence of a minimizing $P_\infty = P'_\infty > 0$ for the function (2.5), Theorem 2.2 provides a more constructive approach towards finding the minimum by showing that it is the global attractor for the gradient flow on $\mathcal{P}(n)$.

THEOREM 2.2. *Linear index gradient flow* ([4]). *Let W_c, W_o denote the controllability and observability gramians* (2.1) *of an asymptotically stable, controllable, and observable realization (A, B, C).*

(a) *There exists a unique* $P_\infty = P'_\infty > 0$, *which minimizes* $\phi : \mathcal{P}(n) \to \Re, \phi(P) = \operatorname{tr}(W_c P + W_o P^{-1})$, *and* $T_\infty = P_\infty^{1/2}$ *is a balancing transformation for* (A, B, C). *This minimum is given by*

$$P_\infty = W_c^{-1/2}(W_c^{1/2} W_o W_c^{1/2})^{1/2} W_c^{-1/2}.$$

(b) *The gradient flow* $\dot{P}(t) = -\nabla \phi(P(t))$ *of* $\phi : \mathcal{P}(n) \to \Re$ *is given by*

$$\dot{P} = P^{-1} W_o P^{-1} - W_c. \tag{2.6}$$

For every initial condition $P_o = P'_o > 0$, $P(t)$ *exists for all* $t \geq 0$ *and converges exponentially fast to* P_∞ *as* $t \to \infty$ *with a lower bound for the rate of exponential convergence given by*

$$\rho \geq 2 \frac{\lambda_{\min}(W_c)^{3/2}}{\lambda_{\max}(W_o)^{1/2}}, \tag{2.7}$$

where $\lambda_{\min}(A)$ *respectively* $\lambda_{\max}(A)$ *denote the smallest, respectively largest, eigenvalue of* A.

In the sequel we refer to (2.6) as the *linear index gradient flow.* Instead of minimizing $\phi(P)$, we might as well consider the minimization problem for the quadratic index function

$$\Psi(P) = \operatorname{tr}((W_c P)^2 + (W_o P^{-1})^2) \tag{2.8}$$

over all positive definite symmetric matrices $P = P' > 0$.

Since, for $P = T'T$, $\Psi(P)$ is equal to $\operatorname{tr}[(TW_cT')^2 + ((T')^{-1}W_oT^{-1})^2]$, the minimization problem for (2.8) is equivalent to minimizing $\operatorname{tr}[(W_c(TAT^{-1}, TB))^2 + (W_o(TAT^{-1}, CT^{-1}))^2]$ over the set of all realizations (TAT^{-1}, TB, CT^{-1}) of a given transfer function $G(s) = C(sI - A)^{-1}B$. Thus $\Psi(P)$ is the sum of the squared eigenvalues of the controllability and observability gramians of (TAT^{-1}, TB, CT^{-1}). Note also that

$$tr[(TW_cT')^2 + ((T')^{-1}W_oT^{-1})^2] = \|TW_cT' - (T')^{-1}W_oT^{-1}\|^2 + 2tr[W_cW_o].$$

Thus minimizing this quadratic index function is equivalent to minimizing the least square distance $\|TW_cT' - (T')^{-1}W_oT^{-1}\|^2$.

THEOREM 2.3. *Quadratic index gradient flow* ([4]). *Under the same hypotheses as for Theorem* 2.2, *we have:*

(a)

$$P_\infty = W_c^{-1/2}(W_c^{1/2} W_o W_c^{1/2})^{1/2} W_c^{-1/2}$$

is the uniquely determined $P \in \mathcal{P}(n)$ *which minimizes* $\Psi : \mathcal{P}(n) \to \Re$ *and* $T_\infty = P_\infty^{1/2}$ *is a balancing transformation for* (A, B, C).

(b) *The gradient flow* $\dot{P}(t) = -\nabla \Psi(P(t))$ *on* $\mathcal{P}(n)$ *is*

$$\dot{P} = 2P^{-1}W_oP^{-1}W_oP^{-1} - 2W_cPW_c. \tag{2.9}$$

For all initial conditions $P_o = P'_o > 0$, *the solution* $P(t)$ *of* (2.9) *exists for all* $t \geq 0$ *and converges exponentially to* P_∞. *A lower bound on the rate of exponential convergence is*

$$\rho > 4\lambda_{\min}(W_c)^2. \tag{2.10}$$

We refer to (2.9) as *quadratic index gradient flow.* The above results show that both algorithms converge exponentially fast to P_∞. Both algorithms are rather slow if the smallest singular value of W_c is near to zero, i.e., if the system is nearly uncontrollable. In contrast to this behaviour, (2.7) shows that the convergence of the linear index flow becomes relatively fast if $\lambda_{\max}(W_o)$; that is, the 2-norm $\|W_o\|_2$ of the observability gramian is small. Similarly, the bound (2.10) for the rate of convergence of the quadratic index flow is independent of W_o and therefore we expect a certain amount of robustness of our algorithms in the case where the observability properties of the system are poor.

In general, the quadratic index flow seems to behave better than the linear index flow, at least if the smallest singular value of the associated Hankel operator of (A, B, C) is greater than $\frac{1}{2}$, i.e., if $\lambda_{\min}(W_o W_c) > \frac{1}{4}$. This is supported by the following simulations.

Simulations. The following simulations show the exponential convergence of the diagonal elements of P towards the solution matrix P_∞ and illustrate what might affect the convergence rate. In Figs. 1(a)–(c) we have

$$W_o = W_3 = \begin{bmatrix} 7 & 4 & 4 & 3 \\ 4 & 4 & 2 & 2 \\ 4 & 2 & 4 & 1 \\ 3 & 2 & 1 & 5 \end{bmatrix} \quad \text{and} \quad W_c = W_4 = \begin{bmatrix} 5 & 2 & 0 & 3 \\ 2 & 7 & -1 & -1 \\ 0 & -1 & 5 & 2 \\ 3 & -1 & 2 & 6 \end{bmatrix},$$

so that $\lambda_{\min}(W_o W_c) \approx 1.7142 > \frac{1}{4}$. Figure 1(a) concerns the linear index flow, while Fig. 1(b) shows the evolution of the quadratic index flow, both using $P(0) = P_1$, where

$$P(0) = P_1 = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \qquad P(0) = P_2 = \begin{bmatrix} 2 & 1 & 0 & 0 \\ 1 & 2 & 1 & 0 \\ 0 & 1 & 2 & 1 \\ 0 & 0 & 1 & 2 \end{bmatrix}.$$

Figure 1(c) shows the evolution of both algorithms with a starting value of $P(0) = P_2$. These three simulations demonstrate that the quadratic algorithm converges more rapidly than the linear algorithm when $\lambda_{\min}(W_o W_c) > \frac{1}{4}$. This rapid convergence rate is achieved at the expense of twice the number of matrix multiplications in calculating the gradient.

In Fig. 1(d),

$$W_o = W_1 = \begin{bmatrix} 7 & 4 & 4 & 3 \\ 4 & 4 & 2 & 2 \\ 4 & 2 & 4 & 1 \\ 3 & 2 & 1 & 3 \end{bmatrix} \quad \text{and} \quad W_c = W_2 = \begin{bmatrix} 5 & 4 & 0 & 3 \\ 4 & 7 & -1 & -1 \\ 0 & -1 & 5 & 2 \\ 3 & -1 & 2 & 6 \end{bmatrix},$$

so that $\lambda_{\min}(W_o W_c) \approx 0.207 < \frac{1}{4}$. Figure 1(d) compares the linear index flow behaviour with that of the quadratic index flow for $P(0) = P_1$. This simulation demonstrates that the linear algorithm does not necessarily converge more rapidly than the quadratic algorithm when $\lambda_{\min}(W_o W_c) < \frac{1}{4}$, because the bounds on convergence rates are conservative.

2.2. Gradient flows for balancing transformations. In the previous section we studied gradient flows that converged to $P_\infty = T_\infty^2$, where T_∞ is the unique symmetric positive definite balancing transformation for a given asymptotically stable

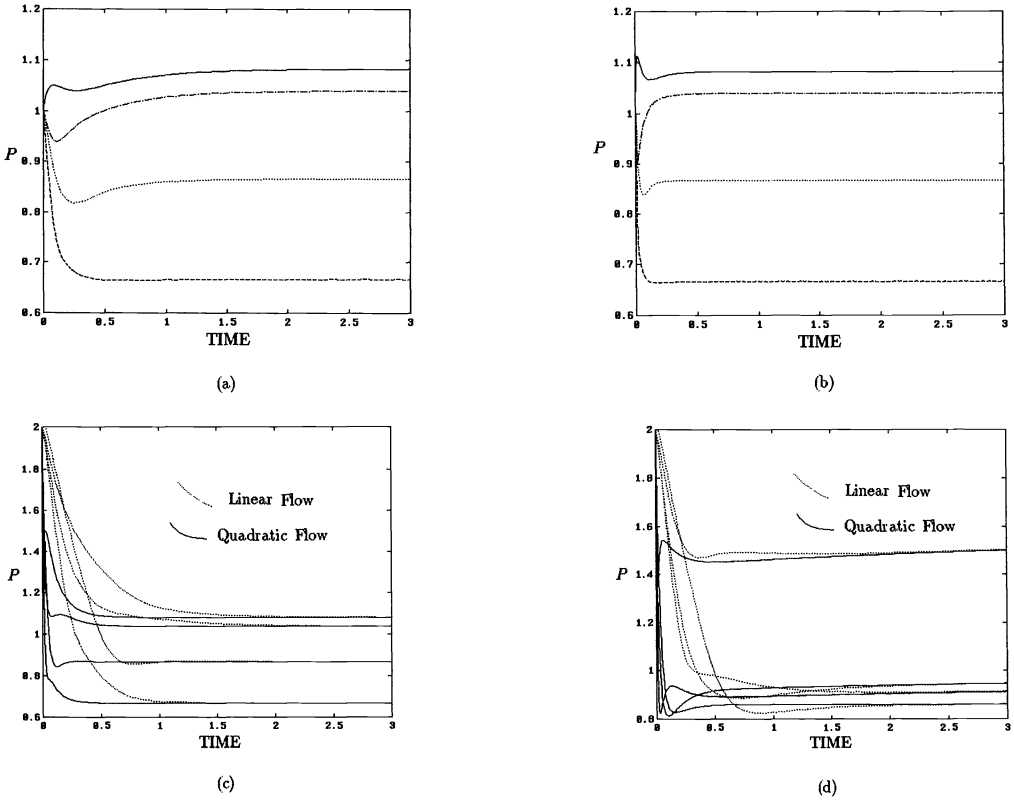

FIG. 1. *Comparison of linear and quadratic flows on $P(t)$.* (a) *Linear index flow when* $\lambda_{\min}(W_oW_c) > \frac{1}{4}$. (b) *Quadratic index flows when* $\lambda_{\min}(W_oW_c) > \frac{1}{4}$. (c) *Linear and quadratic flows when* $\lambda_{\min}(W_oW_c) > \frac{1}{4}$. (d) *Linear and quadratic flows when* $\lambda_{\min}(W_oW_c) < \frac{1}{4}$.

system (A, B, C). T_∞ is then obtained as the unique symmetric positive definite square root of P_∞. In this section we address the general problem of determining *all* balancing transformations $T \in GL(n, \Re)$ for a given asymptotically stable system (A, B, C), using a suitable gradient flow on the set $GL(n, \Re)$ of all invertible $n \times n$-matrices. This allows us to compute balancing transformations without squaring down an operator; cf. [11].

Thus for $T \in GL(n, \Re)$, we consider the cost function $\Phi : GL(n, \Re) \to \Re$ defined by

$$\Phi(T) = \operatorname{tr}(TW_cT' + (T')^{-1}W_oT^{-1}) \tag{2.11}$$

and the associated gradient flow $\dot{T} = -\nabla \Phi(T)$ on $GL(n, \Re)$. Of course, to define the gradient of a function, we must specify a Riemannian metric with respect to which the gradient is defined; see the Appendix. Here, as in the previous section, we endow $GL(n, \Re)$ with its standard Riemannian metric

$$\langle A, B \rangle = 2\operatorname{tr}(A'B), \tag{2.12}$$

i.e., with the constant Frobenius inner product (2.12) defined on the tangent spaces of $GL(n, \Re)$.

THEOREM 2.4. *Let W_c and W_o denote the controllability and observability gramians of the asymptotically stable, controllable and observable realization (A, B, C).*

(a) *The gradient flow* $\dot{T} = -\nabla \Phi(T)$ *of* $\Phi : GL(n, \Re) \to \Re$ *is*

$$\dot{T} = (T')^{-1} W_o (T'T)^{-1} - TW_c, \tag{2.13}$$

and for any initial condition $T_0 \in GL(n, \Re)$, *the solution* $T(t)$ *of* (2.13), $T(0) = T_0$ *exists in* $GL(n, \Re)$ *for all* $t \geq 0$.

(b) *For any initial condition* $T_0 \in GL(n, \Re)$, *the solution* $T(t)$ *of* (2.13) *converges to a balancing transformation* $T_\infty \in GL(n, \Re)$, *and all balancing transformations can be obtained in this way for suitable initial conditions* $T_0 \in GL(n, \Re)$.

(c) *Let* T_∞ *be a balancing transformation and let* $\mathrm{In}(T_\infty)$ *denote the set of all* $T_0 \in GL(n, \Re)$, *such that the solution* $T(t)$ *of* (2.13) *with* $T(0) = T_0$ *converges to* T_∞ *as* $t \to \infty$. *Then* $\mathrm{In}(T_\infty)$ *is an immersed invariant submanifold of* $GL(n, \Re)$ *of dimension* $n(n+1)/2$ *and every solution* $T(t) \in \mathrm{In}(T_\infty)$ *converges exponentially fast in* $\mathrm{In}(T_\infty)$ *to* T_∞.

Proof. $GL(n, \Re)$ is an open subset of $\Re^{n \times n}$ and therefore the tangent space of $GL(n, \Re)$ at T can be identified with the $\Re$-vectorspace of all real $n \times n$ matrices $\xi \in \Re^{n \times n}$. The Fréchet derivative of $\Phi : GL(n, \Re) \to \Re$, at T is the linear operator on the tangent space of $GL(n, \Re)$ at T defined by

$$D\Phi|_T(\xi) = 2\mathrm{tr}[(W_c T' - T^{-1}(T')^{-1} W_o T^{-1})\xi] = 2\mathrm{tr}[(TW_c - (T')^{-1} W_o (T'T)^{-1})'\xi]$$

for all $\xi \in \Re^{n \times n}$. Thus the gradient of Φ with respect to the Riemannian metric (2.12) is

$$\nabla \Phi(T) = TW_c - (T')^{-1} W_o (T'T)^{-1}.$$

To prove that the gradient flow (2.13) is complete, i.e., that the solutions $T(t)$ exist for all $t \geq 0$, it suffices to show that $\Phi : GL(n, \Re) \to \Re_+$ is proper, i.e., that the pre-image $\Phi^{-1}(K)$ of any compact subset $K \subset \Re_+$ is compact in $GL(n, \Re)$. More generally, a continuous map $f : X \to Y$ between topological Hausdorff spaces is called proper if the inverse image of $f^{-1}(K)$ of any compact subset $K \subset Y$ is compact. Let $\mathcal{P}(n) = \{P \in GL(n, \Re) | P = P' > 0\}$. By Lemma 2.1, $P \mapsto \mathrm{tr}(W_c P + W_o P^{-1})$ is a proper function on $\mathcal{P}(n)$. By the polar decomposition, the set of invertible matrices T corresponding to a fixed matrix $T'T$ is compact. More generally, we conclude that the map $GL(n, \Re) \to \mathcal{P}(n), T \mapsto T'T$ is proper. Thus Φ is the composition of proper maps and therefore it is also proper. This shows (a). To prove (b), we note that by (a) and a well-known property of gradient flows, any solution $T(t)$ converges to an equilibrium point T_∞ of (2.13).

$$(T'_\infty)^{-1} W_o (T'_\infty T_\infty)^{-1} = T_\infty W_c \iff (T'_\infty)^{-1} W_o T_\infty^{-1} = T_\infty W_c T'_\infty$$

and hence T_∞ is balancing. This shows (b).

To prove (c), we use the following lemma, where

$$E := \{T_\infty \in GL(n, \Re) | (T'_\infty T_\infty) W_c (T'_\infty T_\infty) = W_o\} \tag{2.14}$$

denotes the set of equilibria points of (2.13).

LEMMA 2.5. *The tangent space of* E *at* $T_\infty \in E$ *is*

$$T_{T_\infty} E = \{S \in \Re^{n \times n} | S' T_\infty + T'_\infty S = 0\}. \tag{2.15}$$

Proof. Let P_∞ denote the unique symmetric positive definite solution of $PW_cP = W_o$. Thus $E = \{T | T'T = P_\infty\}$ and therefore $T_{T_\infty}E$ is the kernel of the derivative of $T \mapsto T'T - P_\infty$ at T_∞. Thus $S \in T_{T_\infty}E$ if and only if $S'T_\infty + T'_\infty S = 0$. □

Let

$$\phi(P) = \operatorname{tr}(W_cP + W_oP^{-1})$$

and

$$\lambda(T) = T'T.$$

Thus $\Phi(T) = \phi(\lambda(T))$. By Theorem 2.2, see also [4] and [2],

(i) $D\phi|_{P_\infty} = 0$.

(ii) $D^2\phi|_{P_\infty} > 0$.

Let X denote the matrix representing the linear operator $D\lambda|_{T_\infty}(S) = T'_\infty S + S'T_\infty$. Using the chain rule, we obtain

$$D^2\Phi|_{T_\infty} = X' \cdot D^2\phi|_{P_\infty} \cdot X \tag{2.16}$$

for all $T_\infty \in E$. By (ii) and (2.16), $D^2\Phi|_{T_\infty} \geq 0$ and $D^2\Phi|T_\infty$ degenerates exactly on the kernel of X, i.e., on the tangent space $T_{T_\infty}E$. Thus Φ is a Morse–Bott function; see the Appendix. Thus Proposition A.3 implies that every solution $T(t)$ of (2.13) converges to an equilibrium point. Moreover, the equilibrium set E is normally hyperbolic.

It follows from the theory of stable manifolds (see, e.g., Irwin [12]) that $\operatorname{In}(T_\infty)$ is the stable manifold of (2.13) at T_∞ and thus is an immersed invariant submanifold of $GL(n, \Re)$ of dimension $\dim GL(n, \Re) - \dim E = n^2 - n(n-1)/2 = n(n+1)/2$. Since the convergence is always exponential on stable manifolds, this completes the proof of (c). □

Now consider the following quadratic version of our objective function Φ. For $T \in GL(n, \Re)$, let $\Psi : GL(n, \Re) \to \Re$ be defined by

$$\Psi(T) := \operatorname{tr}((TW_cT')^2 + ((T')^{-1}W_oT^{-1})^2). \tag{2.17}$$

The gradient flow $\dot{T} = -\nabla \Psi(T)$ on $GL(n, \Re)$ is easily computed to be

$$\dot{T} = (T')^{-1}W_o(T'T)^{-1}W_o(T'T)^{-1} - TW_cT'TW_c. \tag{2.18}$$

The same arguments as for Theorem 2.4 show that for all initial conditions $T_o \in GL(n, \Re)$, the solution $T(t) \in GL(n, \Re)$ of (2.18) exists for all $t \geq 0$ and converges to a balancing transformation for (A, B, C). Thus we can also use (2.18) or suitable discretized versions to compute balancing transformations for a given asymptotically stable minimal realization (A, B, C). We illustrate the behaviour of the gradient flows (2.13) and (2.18) by means of the following simulation experiments.

In Fig. 2 the diagonal entries of $T(t)$ are plotted. Figure 2(a) uses $W_o = W_1$, $W_c = W_2$ and a starting value of $T_0 = P_1$, in (2.13). Figure 2(b) has the same value for the gramians, but has a starting value of

$$T_0 = \begin{bmatrix} 1 & 3 & 4 & 2 \\ 4 & 3 & 2 & 5 \\ 3 & 2 & 4 & 1 \\ 2 & 4 & 3 & 4 \end{bmatrix}.$$

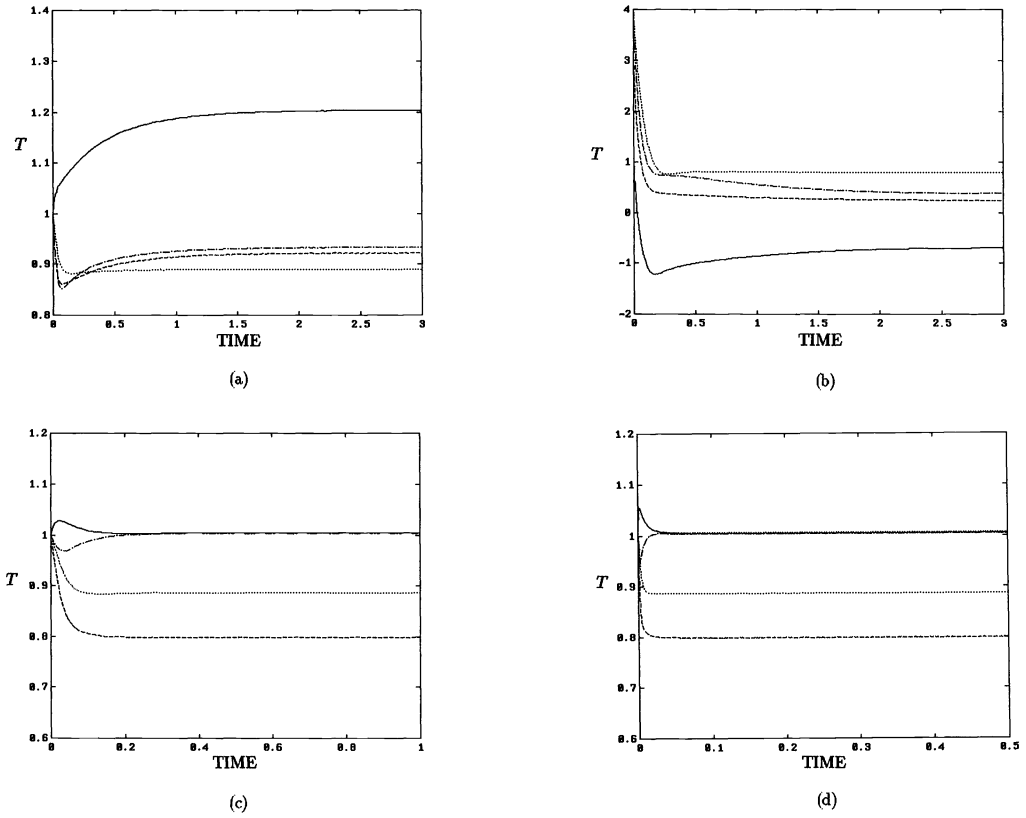

FIG. 2. *Comparison of linear and quadratic index flows on* $GL(n, \Re)$. (a) *Linear flow on* T *when* $\lambda_{\min}(W_o W_c) < \frac{1}{4}$. (b) *Quadratic flow on* T *when* $\lambda_{\min}(W_o W_c) < \frac{1}{4}$. (c) *Linear flow on* T *when* $\lambda_{\min}(W_o W_c) > \frac{1}{4}$. (d) *Quadratic flow on* T *when* $\lambda_{\min}(W_o W_c) > \frac{1}{4}$.

It can be observed that these T_0 values give different final solutions, both of which are generalized balancing transformations. Figures 2(c)–(d) use $W_o = W_3$, $W_c = W_4$ and a starting value of $T_0 = P_1$. Figure 2(c) uses (2.13) while Fig. 2(d) uses (2.18). Note that in this case, (2.18) converges more rapidly than (2.13).

2.3. Diagonal balancing transformations. Here we address the related issue of computing diagonal balancing transformations T for a given asymptotically stable minimal realization, i.e., T satisfies

$$TW_cT' = (T')^{-1}W_oT^{-1} = \text{diagonal}.$$

Any such diagonal balancing transformation T is of the form $T = \Theta \cdot T_\infty$, where $T_\infty = P_\infty^{1/2}$ is the uniquely determined positive definite symmetric balancing transformation whose existence is guaranteed by Theorem 2.1 and where Θ is an orthogonal matrix that diagonalizes $T_\infty W_c T_\infty' = (T_\infty')^{-1} W_o T_\infty^{-1}$.

Let us consider a fixed diagonal positive definite matrix $N = \operatorname{diag}(\lambda_1, \ldots, \lambda_n)$ with distinct eigenvalues $\lambda_1 > \cdots > \lambda_n > 0$. Using N, a weighted cost function for balancing is defined by

$$\Phi_N(T) = \operatorname{tr}(NTW_cT' + N(T')^{-1}W_oT^{-1}). \tag{2.19}$$

The following lemma characterizes the diagonal balancing transformations as the critical points of the weighted cost function Φ_N on $GL(n,\Re)$.

LEMMA 2.6. *Let* $N = \operatorname{diag}(\lambda_1,\dots,\lambda_n)$ *with* $\lambda_1 > \cdots > \lambda_n > 0$ *and let* W_c, W_o *denote the controllability and observability gramians of an asymptotically stable minimal realization* (A,B,C). *Then*

(a) $T \in GL(n,\Re)$ *is a critical point of* $\Phi_N : GL(n,\Re) \to \Re$, $\Phi_N(T) = \operatorname{tr}(NTW_cT' + N(T')^{-1}W_oT^{-1})$, *if and only if* T *is a diagonal balancing transformation, i.e.,*

$$TW_cT' = (T')^{-1}W_oT^{-1} = \text{diagonal}.$$

(b) $\Phi_N : GL(n,\Re) \to \Re$ *has compact sublevel sets. In particular, a global minimum* $T_{\min} \in GL(n,\Re)$ *of* $\Phi_N : GL(n,\Re) \to \Re$ *exists.*

Proof. The Fréchet derivative of $\Phi_N : GL(n,\Re) \to \Re$ at T is the linear map defined by

$$\begin{aligned} D\Phi_N|_T(\xi) &= 2\operatorname{tr}(N\xi W_cT' - N(T')^{-1}W_oT^{-1}\xi T^{-1}) \\ &= 2\operatorname{tr}[(NTW_c - (T')^{-1}W_oT^{-1}N(T')^{-1})'\xi], \end{aligned} \tag{2.20}$$

and therefore the gradient of $\Phi_N(T)$ with respect to the Riemannian metric (2.12) on $GL(n,\Re)$ is

$$\nabla\,\Phi_N(T) = NTW_c - (T')^{-1}W_oT^{-1}N(T')^{-1}. \tag{2.21}$$

It follows that $T \in GL(n,\Re)$ is a critical point of Φ_N if and only if $\nabla\Phi_N(T) = 0$, i.e., if and only if

$$NTW_cT' = (T')^{-1}W_oT^{-1}\cdot N. \tag{2.22}$$

By symmetry of TW_cT' and $(T')^{-1}W_oT^{-1}$, we obtain from (2.22) that

$$N^2TW_cT' = TW_cT'N^2, \tag{2.23a}$$

$$N^2(T')^{-1}W_oT^{-1} = (T')^{-1}W_oT^{-1}N^2. \tag{2.23b}$$

Any symmetric matrix that commutes with N^2 must be diagonal, since N^2 has distinct eigenvalues. Thus we see that (2.22) is equivalent to $TW_cT' = (T')^{-1}W_oT^{-1} =$ diagonal. This proves (a). For (b) note that $\Phi_N(T) \le a$ implies

$$||N^{1/2}TW_c^{1/2}||^2 \le a, \qquad ||W_o^{1/2}T^{-1}N^{1/2}||^2 \le a$$

for the Frobenius norm $||X||^2 = \operatorname{tr}(XX')$. Hence $||T|| \le c_1, ||T^{-1}|| \le c_2$ for positive constants c_1, c_2 that depend only on N, W_c, W_o and a. Thus $\{T \in GL(n,\Re) \mid \Phi_N(T) \le a\}$ is a closed subset of the compact set $\{T \in GL(n,\Re) \mid ||T|| \le c_1,\ ||T^{-1}|| \le c_2\}$ and therefore also compact. This shows that $\Phi_N : GL(n,\Re) \to \Re$ has compact sublevel sets. But any continuous function $f : GL(n,\Re) \to \Re_+$ with compact sublevel sets has a minimizing $T \in GL(n,\Re)$. This completes the proof of Lemma 2.6. □

From Lemma 2.6 and by (2.20), similar arguments as for Theorem 2.4(a) and (b) show the following theorem.

THEOREM 2.7. *Let* W_c, W_o *be the controllability and observability gramians of the asymptotically stable, controllable, and observable realization* (A,B,C) *and let* $N = \operatorname{diag}(\lambda_1,\dots,\lambda_n)$ *with* $\lambda_1 > \cdots > \lambda_n > 0$. *Then*

(a) *gradient flow* $\dot{T} = -\nabla \Phi_N(T)$ *of the weighted cost function* Φ_N: $GL(n, \Re) \to \Re$ *is*

$$\dot{T} = (T')^{-1} W_o T^{-1} N (T')^{-1} - NTW_c. \tag{2.24}$$

For all initial conditions $T(0) \in GL(n, \Re)$, *the solution* $T(t) \in GL(n, \Re)$ *of* (2.24) *exists for all* $t \geq 0$.

(b) *For any initial condition* $T(0) \in GL(n, \Re)$, *the solution* $T(t)$ *of* (2.24) *converges to a diagonal balancing transformation* T_∞ *of* (A, B, C).

(c) *Suppose that the singular values* $0 < d_1 < \cdots < d_n$ *of the Hankel operator of* (A, B, C) *are distinct. Then the stable equilibrium of* (2.24) *are characterized by* $(T'_\infty)^{-1} W_o T_\infty^{-1} = T_\infty W_c T'_\infty = D$, *where* $D = diag(d_1, \ldots, d_n)$ *is diagonal and the diagonal entries are in reverse ordering to those of* N. *Moreover, the gradient flow* (2.24) *converges exponentially fast to the* 2^n *stable equilibria with a convergence rate lower bounded by*

$$\lambda_{\min}((T_\infty T'_\infty)^{-1}) \min_{i<j} [(d_i - d_j)(\lambda_j - \lambda_i), 4 d_i \lambda_i].$$

All other equilibria are unstable.

Proof. Parts (a) and (b) follow easily from Lemma 2.6, using similar arguments as for Theorem 2.4. To prove (c), consider the linearization of (2.24) at an equilibrium point T_∞; that is, where $(T'_\infty)^{-1} W_o T_\infty^{-1} = T_\infty W_c T'_\infty = D$ and

$$\begin{aligned} \dot{\eta} = &-N\eta T_\infty^{-1} D (T'_\infty)^{-1} - D\eta T_\infty^{-1} N (T'_\infty)^{-1} \\ &- (T'_\infty)^{-1} \eta' D N (T'_\infty)^{-1} - D N (T'_\infty)^{-1} \eta' (T'_\infty)^{-1}. \end{aligned}$$

Let $\zeta = \eta T_\infty^{-1}$, then

$$\dot{\zeta}(T_\infty T'_\infty) = -N\zeta D - D\zeta N - \zeta' D N - D N \zeta'$$

and thus, using Kronecker products and the vec notation, and recalling that $\mathrm{vec}(ABC) = (C' \otimes A)\mathrm{vec}(B)$, then

$$[(T_\infty T'_\infty) \otimes I]\mathrm{vec}(\dot{\zeta}) = -[D \otimes N + N \otimes D]\mathrm{vec}(\zeta) - [DN \otimes I + I \otimes DN]\mathrm{vec}(\zeta').$$

Consider first the special case when $T_\infty T'_\infty = I$, and ζ is denoted ζ^*:

$$\mathrm{vec}(\dot{\zeta}^*) = -[D \otimes N + N \otimes D]\mathrm{vec}(\zeta^*) - [DN \otimes I + I \otimes DN]\mathrm{vec}(\zeta^{*\prime}). \tag{2.25}$$

Then for $i < j$,

$$\begin{bmatrix} \dot{\zeta}^*_{ij} \\ \dot{\zeta}^*_{ji} \end{bmatrix} = - \begin{bmatrix} d_i\lambda_j + \lambda_i d_j & d_j\lambda_j + d_i\lambda_i \\ d_i\lambda_i + d_j\lambda_j & d_i\lambda_j + \lambda_i d_j \end{bmatrix} \begin{bmatrix} \zeta^*_{ij} \\ \zeta^*_{ji} \end{bmatrix},$$

and for all i,

$$\dot{\zeta}^*_{ii} = -4 d_i \lambda_i \zeta^*_{ii}.$$

By assumption, $\lambda_i > 0$, and $d_i > 0$ for all i. Thus (2.25) is exponentially stable if and only if $(d_i - d_j)(\lambda_j - \lambda_i) > 0$ for all $i, j, i < j$, or equivalently, if and only if the diagonal entries of D are distinct and in reverse ordering to those of N. In this case, (2.25) is equivalent to (2.26)

$$\mathrm{vec}(\dot{\zeta}^*) = -\mathcal{F}\mathrm{vec}(\zeta^*) \tag{2.26}$$

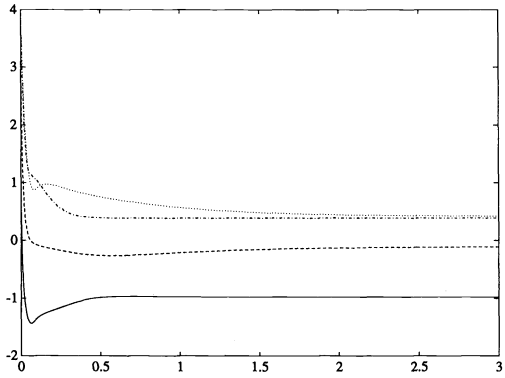

FIG. 3. *Evolution of the diagonalizing transformation T.*

with a symmetric positive definite matrix $\mathcal{F} = \mathcal{F}' > 0$.

Consequently, there is exponential convergence with a rate given by $\lambda_{\min}(\mathcal{F})$ as follows:

$$\begin{aligned}\lambda_{\min}(\mathcal{F}) &= \min\left(\min_{i<j}\left[\lambda_{\min}\left(\begin{bmatrix} d_i\lambda_j + \lambda_i d_j & d_j\lambda_j + d_i\lambda_i \\ d_i\lambda_i + d_j\lambda_j & d_i\lambda_j + \lambda_i d_j \end{bmatrix}\right)\right], \min_i[4d_i\lambda_i]\right) \\ &= \min(\min_{i<j}[d_i\lambda_j + \lambda_i d_j - d_j\lambda_j - d_i\lambda_i], \min_i[4d_i\lambda_i]) \\ &= \min(\min_{i<j}[(d_i - d_j)(\lambda_j - \lambda_i)], \min_i[4d_i\lambda_i]).\end{aligned}$$

Relaxing the assumption $T_\infty T_\infty' = I$ is possible since $T_\infty T_\infty'$ is positive definite so that $(T_\infty T_\infty' \otimes I)$ is positive definite. Thus exponential stability of (2.26) assures exponential stability of

$$[(T_\infty T_\infty') \otimes I]\mathrm{vec}(\dot{\zeta}) = -\mathcal{F}\mathrm{vec}(\zeta).$$

The rate of exponential convergence is given by $\lambda_{\min}[((T_\infty T_\infty')^{-1} \otimes I)\mathcal{F}]$. Now since $A = A' > 0, B = B' > 0$ implies $\lambda_{\min}(AB) \geq \lambda_{\min}(A)\lambda_{\min}(B)$, a lower bound on the convergence rate is given from

$$\begin{aligned}&\lambda_{\min}[((T_\infty T_\infty')^{-1} \otimes I)\mathcal{F}] \geq \lambda_{\min}[(T_\infty T_\infty')^{-1} \otimes I]\lambda_{\min}(\mathcal{F}) \\ &= \lambda_{\min}[(T_\infty T_\infty')^{-1}] \min(\min_{i<j}[(d_i - d_j)(\lambda_j - \lambda_i)], \min_i[4d_i\lambda_i])\end{aligned}$$

as claimed. □

Simulation. In Fig. 3 the diagonal elements of $T(t)$ are plotted. The flow (2.24) is allowed to evolve with $W_o = W_1, W_c = W_2$, $N = \mathrm{diag}(5, 4, 3, 2)$, and initial matrix T_0 as before. At $t = 3$,

$$T(t) = \begin{bmatrix} -0.9788 & 0.6595 & -0.1033 & 0.6623 \\ -0.0807 & -0.1124 & -0.7002 & 0.5847 \\ 0.1079 & -0.4691 & 0.4256 & 0.1943 \\ 0.7586 & 0.5177 & 0.4245 & 0.3909 \end{bmatrix}$$

and this transformation gives

$$W_c = \begin{bmatrix} 0.4554 & 0.0017 & 0.0006 & -0.0005 \\ 0.0017 & 2.7493 & 0.0034 & -0.0000 \\ 0.0006 & 0.0034 & 3.3641 & -0.0034 \\ -0.0005 & -0.0000 & -0.0034 & 11.3114 \end{bmatrix},$$

$$W_o = \begin{bmatrix} 0.4553 & 0.0021 & 0.0009 & 0.0014 \\ 0.0021 & 2.7496 & 0.0042 & 0.0007 \\ 0.0009 & 0.0042 & 3.3625 & 0.0081 \\ 0.0014 & 0.0007 & 0.0081 & 11.3090 \end{bmatrix}.$$

Notice that although convergence has not been completed, the gramians are diagonally dominant with increasing elements.

3. Differential equations for balanced realizations. In this section we construct certain ordinary differential equations

$$\begin{aligned} \dot{A} &= f(A,B,C) \\ \dot{B} &= g(A,B,C) \\ \dot{C} &= h(A,B,C) \end{aligned}$$

evolving on the space of all realizations (A,B,C) of a given transfer function $G(s)$, with the property that their solutions $(A(t),B(t),C(t))$ all converge for $t \to \infty$ to balanced realizations $(\bar{A},\bar{B},\bar{C})$ of $G(s)$.

Let $G(s) \in \Re(s)^{p\times m}$ denote an asymptotically stable strictly proper real rational transfer function of McMillan degree n. Thus $G(s)$ has its poles either in the open left half-plane or in the open unit disc, respectively. We denote by $(A,B,C) \in \Re^{n\times(n+m+p)}$ an asymptotically stable, controllable, and observable realization of $G(s)$, i.e., $G(s) = C(sI-A)^{-1}B$.

Let

$$\mathcal{R}_G = \{(A,B,C) \in \Re^{n\times(n+m+p)} \mid G(s) = C(sI-A)^{-1}B\} \tag{3.1}$$

denote the set of all minimal state space realizations of the transfer function $G(s)$. By Kalman's realization theorem, [8]

$$\mathcal{R}_G = \{(TAT^{-1},TB,CT^{-1}) \in \Re^{n\times(n+m+p)} \mid T \in GL(n,\Re)\} \tag{3.2}$$

for any fixed initial realization $(A,B,C) \in \mathcal{R}_G$. Thus $\mathcal{R}_G$ is an orbit of the $GL(n,\Re)$-similarity action $(A,B,C) \mapsto (TAT^{-1},TB,CT^{-1})$ on $\Re^{n\times(n+m+p)}$.

We consider the function

$$\Phi: \ \mathcal{R}_G \to \Re$$

defined by

$$\Phi(A,B,C) = \operatorname{tr}(W_c(A,B) + W_o(A,C)), \tag{3.3}$$

i.e., by the sum of the eigenvalues of the controllability and observability gramians of (A,B,C). The following proposition summarizes some important properties of $\mathcal{R}_G$ and $\Phi: \mathcal{R}_G \to \Re$.

PROPOSITION 3.1. *It holds that*

(a) *$\mathcal{R}_G$ is a smooth, closed submanifold of $\Re^{n\times(n+m+p)}$. The tangent space of $\mathcal{R}_G$ at $(A,B,C) \in \mathcal{R}_G$ is*

$$T_{(A,B,C)}\mathcal{R}_G = \{(XA - AX, XB, -CX) \mid X \in \Re^{n\times n}\}. \tag{3.4}$$

(b) *The function $\Phi : \mathcal{R}_G \to \Re$ defined by* (3.3) *is smooth and has compact sublevel sets.*

Proof. $\mathcal{R}_G$ is an orbit of the $GL(n,\Re)$-similarity action

$$\begin{aligned}\sigma : GL(n,\Re) \times \Re^{n\times(n+m+p)} &\to \Re^{n\times(n+m+p)}\\ (T,(A,B,C)) &\mapsto (TAT^{-1}, TB, CT^{-1})\end{aligned}$$

and thus, by a general result about algebraic Lie group actions (see, e.g., Appendix C in [9]) is a smooth submanifold of the Euclidean space $\Re^{n\times(n+m+p)}$. By Lemma 3.3 [2], $\mathcal{R}_G$ is a closed subset of $\Re^{n(n+m+p)}$ if (A,B,C) is controllable and observable. Explicitly, by realization theory, $\mathcal{R}_G$ is a fiber of the continuous map

$$\begin{aligned}f : \Re^{n(n+m+p)} &\to \prod_{i=0}^{\infty} \Re^{p\times m}\\ (F,G,H) &\mapsto (HF^iG \mid i \in \mathbb{N}_o)\end{aligned} \tag{3.5}$$

and therefore closed.

To prove (b) and (3.4), we consider the diffeomorphism

$$\begin{aligned}\sigma : GL(n,\Re) &\to \mathcal{R}_G\\ T &\mapsto (TAT^{-1}, TB, CT^{-1})\end{aligned} \tag{3.6}$$

(this requires that (A,B,C) is minimal). The derivative of σ at the identity matrix is the linear map $X \mapsto (XA - AX, XB, -CX)$, which maps $\Re^{n\times n}$ onto $T_{(A,B,C)}\mathcal{R}_G$. This proves (3.4). Furthermore, with $P = T'T$,

$$\begin{aligned}\Phi(\sigma(T)) &= \operatorname{tr}(TW_c(A,B)T' + (T')^{-1}W_o(A,C)T^{-1})\\ &= \operatorname{tr}(W_cP + W_oP^{-1}),\end{aligned}$$

and the result now follows from Lemma 2.1, i.e., that the function $P \mapsto \operatorname{tr}(W_cP + W_oP^{-1})$ on the set of positive definite symmetric matrices has compact sublevel sets. □

We now address the issue of finding gradient flows for the objective function $\Phi : \mathcal{R}_G \to \Re$ relative to some Riemannian metric on $\mathcal{R}_G$. While there are several possible choices for a Riemannian metric on the realization space $\mathcal{R}_G$, the following one leads to a particularly simple expression for the gradient.

In the sequel, we use the Lie bracket notation

$$[A,B] = AB - BA \tag{3.7}$$

for $n \times n$ matrices A, B.

Given two tangent vectors $([X_1,A], X_1B, -CX_1)$ and $([X_2,A], X_2B, -CX_2) \in T_{(A,B,C)}\mathcal{R}_G$ we define

$$\langle\langle([X_1,A], X_1B, -CX_1), \quad ([X_2,A], X_2B, -CX_2)\rangle\rangle := \operatorname{tr}(X_1'X_2). \tag{3.8}$$

To prove that (3.8) defines an inner product on $T_{(A,B,C)}\mathcal{R}_G$, we need the following lemma.

LEMMA 3.2. *Let (A,B,C) be controllable or observable. Then $([X,A],XB,-CX) = (0,0,0)$ implies $X=0$.*

Proof. If $XB=0$ and $AX=XA$, then $X(B,AB,\dots,A^{n-1}B)=0$. Thus controllability implies $X=0$. This is also true for observability. □

It is now easily seen, using Lemma 3.2, that (3.8) defines a nondegenerate symmetric bilinear form on each tangent space $T_{(A,B,C)}\mathcal{R}_G$ and in fact a Riemannian metric on $\mathcal{R}_G$. We refer to this as the *normal Riemannian metric* on $\mathcal{R}_G$.

To determine the gradient flow of $\Phi : \mathcal{R}_G \to \Re$ with respect to the normal Riemannian metric, we need a lemma.

LEMMA 3.3. *Let $N \in \Re^{n\times n}$ be a real symmetric $n\times n$ matrix and let $\Phi_N : \mathcal{R}_G \to \Re$ be defined by $\Phi_N(A,B,C) = \operatorname{tr}(NW_c(A,B) + NW_o(A,C))$ for all $(A,B,C) \in \mathcal{R}_G$. Then the Fréchet derivative of Φ_N at $(A,B,C) \in \mathcal{R}_G$ is the linear map $D\Phi_N(A,B,C) : T_{(A,B,C)}\mathcal{R}_G \to \Re$ defined by*

$$D\Phi_N(A,B,C)([X,A],XB,-CX) = 2\operatorname{tr}[(W_c(A,B)N - NW_o(A,C))X] \tag{3.9}$$

for $X \in \Re^{n\times n}$.

Proof. Let $\sigma : GL(n,\Re) \to \mathcal{R}_G$ be the diffeomorphism defined by $\sigma(T) = (TAT^{-1}, TB, CT^{-1})$. The derivative of σ at the identity matrix I_n is the linear map $X \mapsto ([X,A],XB,-CX)$ on $\Re^{n\times n}$. By the chain rule for the composed map $\Phi_N \circ \sigma$ defined by

$$\Phi_N(\sigma(T)) = \operatorname{tr}(NTW_c(A,B)T' + N(T')^{-1}W_o(A,C)T^{-1}),$$

we have

$$\begin{aligned} D\Phi_N(\sigma(I_n))([X,A],-XB,CX) &= D(\Phi_N \circ \sigma)(I_n)X \\ &= 2\operatorname{tr}(NXW_c(A,B) - NW_o(A,C)X) \\ &= 2\operatorname{tr}[(W_c(A,B)N - NW_o(A,C))X] \end{aligned}$$

for all $X \in \Re^{n\times n}$. The result follows. □

THEOREM 3.4. *Let $\Phi : \mathcal{R}_G \to \Re$ be the objective function defined by $\Phi(A,B,C) = \frac{1}{2}\operatorname{tr}(W_c(A,B) + W_o(A,C))$.*

(a) *The gradient flow $(\dot{A} = -\operatorname{grad}_A\Phi(A,B,C), \dot{B} = -\operatorname{grad}_B\Phi(A,B,C), \dot{C} = -\operatorname{grad}_A\Phi(A,B,C))$ of Φ for the normal Riemannian metric on $\mathcal{R}_G$ is*

$$\begin{aligned} \dot{A} &= [A, W_o(A,C) - W_c(A,B)] \\ \dot{B} &= (W_o(A,C) - W_c(A,B))B \\ \dot{C} &= C(W_c(A,B) - W_o(A,C)). \end{aligned} \tag{3.10}$$

For every initial condition $(A(0),B(0),C(0)) \in \mathcal{R}_G$, the solution $(A(t),B(t),C(t)) \in \mathcal{R}_G$ of (3.10) exists for all $t \geq 0$ and converges for $t \to +\infty$ to a balanced realization $(\bar{A},\bar{B},\bar{C})$ of $G(s)$:

$$W_c(\bar{A},\bar{B}) = W_o(\bar{A},\bar{C}).$$

(b) *Convergence to the class of balanced realizations is exponentially fast.*

(c) *The transfer function of any solution $(A(t),B(t),C(t))$ of (3.10) is independent of t.*

Proof. By definition of a gradient,

$$\text{grad}\Phi(A,B,C) = (\text{grad}_A\Phi(A,B,C), \text{grad}_B\Phi(A,B,C), \text{grad}_C\Phi(A,B,C))$$

is characterized by the properties (see the Appendix)

$$\text{(3.11a)} \qquad \text{grad}\Phi(A,B,C) \in T_{(A,B,C)}\mathcal{R}_G,$$

and

$$\text{(3.11b)} \quad D\Phi(A,B,C)([X,A],XB,-CX) = \langle\langle \text{grad}\Phi(A,B,C), ([X,A],XB,-CX)\rangle\rangle$$

for all $X \in \Re^{n\times n}$. By Proposition 3.1 and Lemma 3.2,

$$\text{(3.12)} \qquad \text{grad}\Phi(A,B,C) = ([A,\Lambda],\Lambda B,-C\Lambda)$$

for a uniquely determined $\Lambda \in \Re^{n\times n}$. Applying Lemma 3.3 for $N = \frac{1}{2}I_n$, we see that (3.11b) is equivalent to

$$\begin{aligned}\text{tr}[(W_c(A,B) - W_o(A,C))X] &= \langle\langle([A,\Lambda],\Lambda B,-C\Lambda),\ ([A,X],XB,-CX)\rangle\rangle \\ &= \text{tr}(\Lambda' X)\end{aligned}$$

for all $X \in \Re^{n\times n}$. Thus

$$\Lambda = W_c(A,B) - W_o(A,C)$$

and $\text{grad}\Phi(A,B,C) = ([A,\Lambda],\Lambda B,-C\Lambda)$. This proves (3.10). Since (3.10) is minus the gradient flow of Φ, $\Phi(A(t),B(t),C(t))$ decreases on any solution of (3.10). By Proposition 3.1(b), $\{(A,B,C) \in \mathcal{R}_G \mid \Phi(A,B,C) \le \Phi(A(0),B(0),C(0))\}$ is a compact subset of $\mathcal{R}_G$, which is invariant under the flow of (3.10). Therefore $(A(t),B(t),C(t))$ stays in that compact subset and thus exists for all $t \ge 0$. The equilibria of (3.10) are characterized by $W_c(A,B) = W_o(A,C)$, i.e., by the balanced realizations. This proves (a), except that we have not yet established convergence to an equilibrium point.

To prove (b), we consider the diffeomorphism $\sigma : GL(n,\Re) \to \mathcal{R}_G$ defined by $\sigma(T) = (TAT^{-1}, TB, CT^{-1})$ for any $(A,B,C) \in \mathcal{R}_G$. At each critical point, (A,B,C) of $\Phi : \mathcal{R}_G \to \Re$, σ induces an invertible congruence transformation between the Hessian of $\Phi : \mathcal{R}_G \to \Re$ at (A,B,C) and the Hessian of $\Phi \circ \sigma$ at I_n. By (2.16) and the proof of Theorem 2.4(c), the Hessian of $\Phi \circ \sigma$ at I_n is positive semidefinite and degenerates exactly on the tangent space (at I_n) of the set of balancing transformations. Therefore the Hessian of Φ at a balanced realization (A,B,C) is positive semidefinite and degenerates exactly on the tangent space of the set of balanced realizations at (A,B,C). (N.B. By Lemma 2.5, the set of balanced realizations of $G(s)$ can be shown to be a smooth submanifold of $\mathcal{R}_G$.) This proves (b). As $\Phi : \mathcal{R}_G \to \Re$ is now seen as a Morse–Bott function, we can apply Proposition A.3 to conclude that $(A(t),B(t),C(t))$ converges to an equilibrium point.

Part (c) is obvious, as the flow evolves on $\mathcal{R}_G$. □

We emphasize that Theorem 3.4 gives, for the first time, a *direct* method to compute balanced realizations, without computing any balancing transformations. We regard this as one of the really new insights that can be obtained by our ODE methods.

Remark. As is shown in the above proof, any flow on symmetric matrices

$$\begin{aligned}\dot{A} &= -[A,\Lambda(A,B,C)] \\ \dot{B} &= -\Lambda(A,B,C)B \\ \dot{C} &= +C\Lambda(A,B,C),\end{aligned}$$

where $\Lambda(A,B,C) \in \Re^{n\times n}$ is an arbitrary matrix valued function of (A,B,C), leaves the transfer function

$$G(t,s) = C(t)(sI_n - A(t))^{-1}B(t) = C(0)(sI_n - A(0))^{-1}B(0)$$

of the system invariant. We therefore term these flows *isodynamical* and a more systematic analysis of such flows is given in [9]. Obviously, these flows leave the eigenvalues of $A(t)$ invariant and in fact generalize the class of isospectral flows on matrices, obtained by letting $B = 0, C = 0$; see, e.g., [1], [3], and the references therein.

Simulations. Figures 4(a)–(c) show the evolution of the system matrices (A,B,C) using this algorithm. In this example, the starting matrices are chosen to be

$$A = \begin{bmatrix} -3 & 0 & 0 \\ 0 & -2 & 0 \\ 0 & 0 & -1 \end{bmatrix}, \quad B = \begin{bmatrix} 2 \\ 3 \\ 1 \end{bmatrix}, \quad C' = \begin{bmatrix} 2 \\ 1 \\ 3 \end{bmatrix}, \tag{3.13}$$

and after ten "time intervals" the gramians are equal to three significant figures.

A similar "isodynamical flow approach" works also for obtaining diagonal balanced realizations. Here we consider the weighted cost function

$$\Phi_N : \mathcal{R}_G \to \Re,$$

$$\Phi_N(A,B,C) = \frac{1}{2}\mathrm{tr}[N(W_c(A,B) + W_o(A,C))] \tag{3.14}$$

for a real diagonal matrix N.

THEOREM 3.5. *Let $\Phi_N : \mathcal{R}_G \to \Re$ be the objective function defined by* (3.14) *for $N = \frac{1}{2}\mathrm{diag}(\lambda_1,\dots,\lambda_n), \lambda_1 > \cdots > \lambda_n > 0$.*

(a) *The gradient flow*

$$(\dot{A} = -\mathrm{grad}_A\Phi_N(A,B,C), \dot{B} = -\mathrm{grad}_B\Phi_N(A,B,C), \dot{C} = -\mathrm{grad}_C\Phi_N(A,B,C))$$

of Φ_N with respect to the normal Riemannian metric on $\mathcal{R}_G$ is

$$\begin{aligned} \dot{A} &= [A, NW_o(A,C) - W_c(A,B)N] \\ \dot{B} &= (NW_o(A,C) - W_c(A,B)N)B \\ \dot{C} &= C(W_c(A,B)N - NW_o(A,C)). \end{aligned} \tag{3.15}$$

For every initial condition $(A(0),B(0),C(0)) \in \mathcal{R}_G$, the solution $(A(t),B(t),C(t)) \in \mathcal{R}_G$ of (3.15) *exists for all $t \geq 0$ and converges for $t \to +\infty$ to a diagonal balanced realization $(\bar{A},\bar{B},\bar{C})$ of $G(s)$, i.e., $W_c(\bar{A},\bar{B}) = W_o(\bar{A},\bar{C}) =$* diagonal.

(b) *Suppose that the singular values of the Hankel of (A,B,C) are distinct. Then* (3.15) *has exactly 2^n locally asymptotically stable equilibrium points $(\bar{A},\bar{B},\bar{C})$, characterized by $W_c(\bar{A},\bar{B}) = W_o(\bar{A},\bar{C})$=diagonal, with the diagonal elements in the reverse order to that of N. All other equilibria are unstable.*

(c) *The transfer function of every solution $(A(t),B(t),C(t))$ of* (3.15) *is independent of t.*

Proof. The proof runs similarly to that of Theorem 3.4, now applying Lemma 3.3 for $N = \frac{1}{2}\mathrm{diag}(\lambda_1,\dots,\lambda_n)$ and using Proposition A.3. The only points we must check are that the equilibria of (3.15) are just the diagonal balanced realizations and

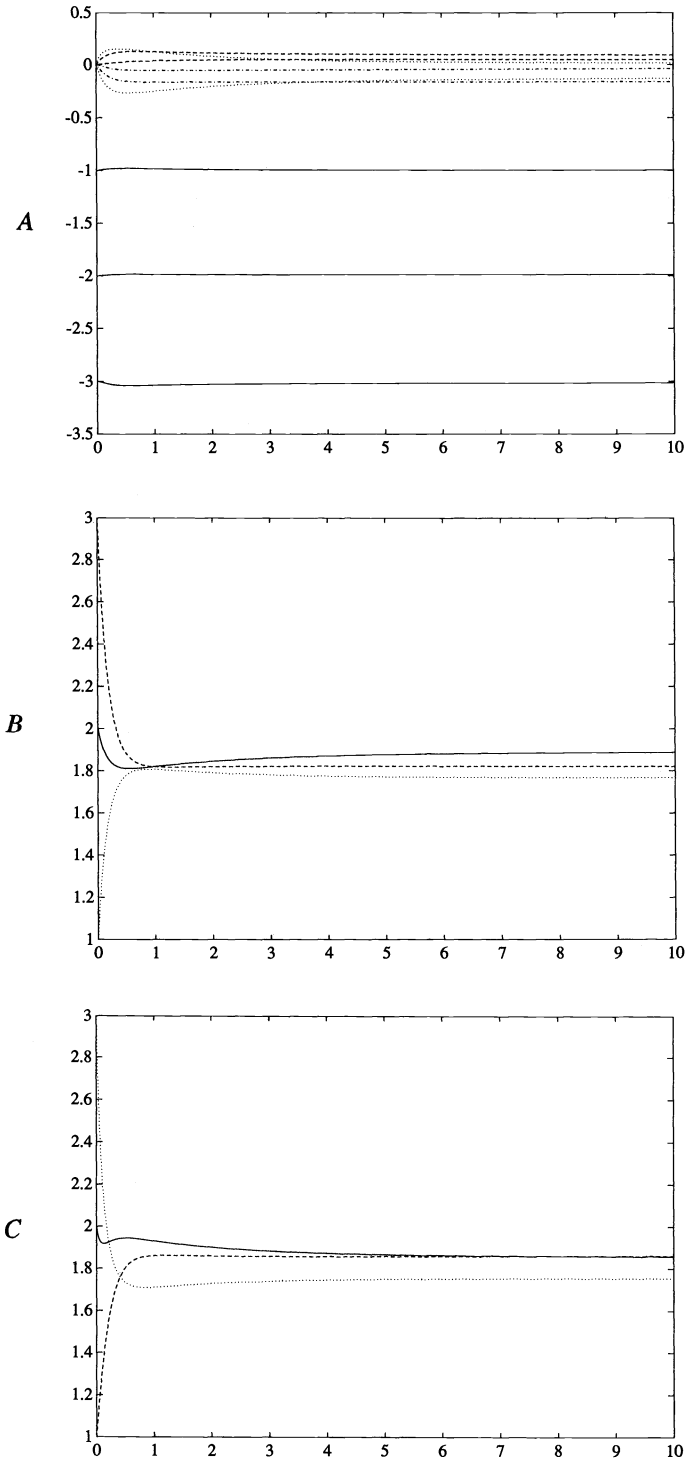

FIG. 4. *Evolution of the system matrices* (A, B, C).

their stability. But the equilibria of (3.15) are the critical points of $\Phi_N : \mathcal{R}_G \to \Re$ and hence correspond to those of $\Phi_N \circ \sigma : GL(n, \Re) \to \Re$. The result now follows from Lemma 2.6, and Theorem 2.7. □

Simulations. Figure 5 shows the evolution of the matrices (A, B, C) for (3.15), with starting condition given in (3.13), and $N = \text{diag}(3, 2, 1)$. After 30 "time intervals" the solution gives

$$W_o = \begin{bmatrix} 2.7720 & 0 & 0 \\ 0 & 0.1367 & 0.0214 \\ 0 & 0.0214 & 0.0048 \end{bmatrix}, \qquad W_c = \begin{bmatrix} 2.7750 & 0 & 0 \\ 0 & 0.1367 & 0.0212 \\ 0 & 0.0212 & 0.0067 \end{bmatrix}$$

as opposed to the true balanced solution $W_o = W_c = \text{diag}(0.0021, 0.1401, 2.7744)$. The convergence in this case can be expected to be slow because the smallest Hankel singular value is near zero.

4. Application to SVD. The common linear algebra problem of SVD can be solved using differential equations. Gradient flow solutions for SVD have been studied in [3], [4], [6], and [7]. Here we consider SVD to be a special case of the balanced realization task.

THEOREM 4.1. *Given an $m \times n$ matrix H of rank r with distinct singular values $\sigma_1 > \cdots > \sigma_r$. Let N be an $r \times r$ diagonal matrix with distinct positive diagonal entries. Let $X_0 \in \Re^{m \times r}$ and $Y_0 \in \Re^{r \times n}$ be matrices of full rank r such that $H = X_0 Y_0$. Then the solution $(X(t), Y(t))$ of*

$$\dot{X} = X(NYY' - X'XN), \qquad X(0) = X_0, \tag{4.1a}$$

$$\dot{Y} = (X'XN - NYY')Y, \qquad Y(0) = Y_0 \tag{4.1b}$$

exists for all $t \geq 0$ and satisfies $H = X(t)Y(t)$ for all $t \geq 0$. The solution $(X(t), Y(t))$ converges to (X_∞, Y_∞) such that $H = X_\infty Y_\infty$ and $X'_\infty X_\infty = Y_\infty Y'_\infty = D = $ diagonal. Moreover, there are 2^r stable equilibria that have the diagonal elements of D in reverse order to those of N. All other equilibrium points are unstable.

Furthermore, this factorization yields $H = USV$, where $U = X_\infty D^{-1/2}$, $S = D$, $V = D^{-1/2} Y_\infty$, $U'U = I$, $VV' = I$.

Proof. In Theorem 3.5, set $A = 0$ and let B, C be full rank matrices. Clearly, (A, B, C) is controllable and observable. Then $W_c = B'B, W_o = CC'$ and (3.15) is equivalent to

$$\dot{B} = -(CC'N - NB'B)B, \qquad \dot{C} = C(CC'N - NB'B). \tag{4.2}$$

The equilibria of (4.2) are characterized by $B'B = CC' =$ diagonal, and the stable equilibria are such that $B'B$ is in reverse order to N.

As (4.2) preserves the transfer function, CB is constant. Hence (4.1) with $X = C$ and $Y = B$ converges to a diagonal balanced matrix factorization $H = X_\infty Y_\infty$. By choosing $U = X_\infty D^{-1/2}, S = D, V = D^{-1/2} Y_\infty$, then

$$USV = X_\infty D^{-1/2} D D^{-1/2} Y_\infty = X_\infty Y_\infty = H, \qquad U'U = D^{-1/2} X'_\infty X_\infty D^{-1/2} = I,$$

and $VV' = D^{-1/2} Y_\infty Y'_\infty D^{-1/2} = I$. The full singular value decomposition can be obtained by extending U and V to make them orthogonal. □

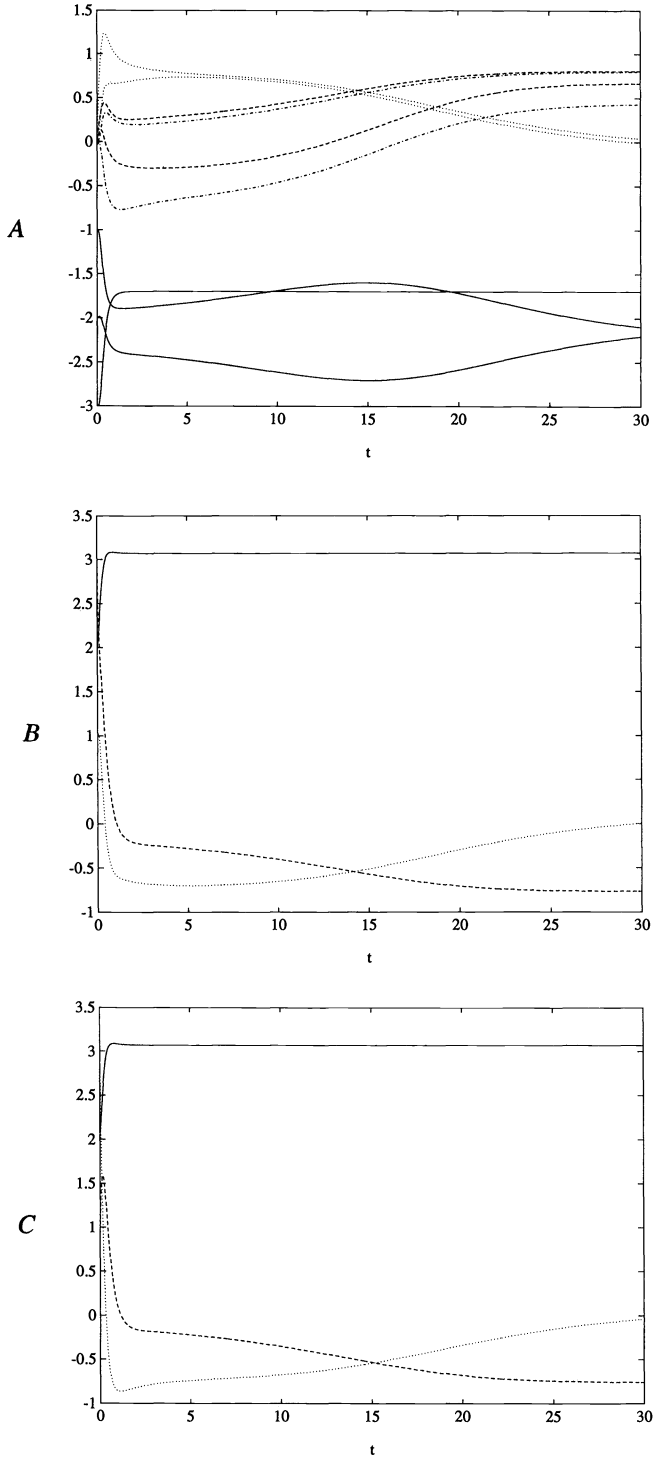

FIG. 5. *Evolution of the diagonalizing system matrices* (A, B, C).

5. Conclusions. There are a number of distinct ODEs that evolve to give the solution to the task of finding a balanced realization of a system or to the task of finding the SVD of a matrix. Each differential equation has distinct transient behaviour but all have exponential convergence rates of the factors. The dynamical systems for balancing gramains that were investigated evolve on either spaces of state coordinate transformation matrices T, its square $P = T'T$, or on manifolds of the actual system matrices (A, B, C). Similar equations for SVD are studied and are a special case of the balancing equations. Different convergence properties make some algorithms more attractive in certain problem settings. These solution methods may be useful when using analog or parallel computers.

Appendix. Riemannian metrics and gradient flows. Let M be a smooth manifold and let TM and T^*M denote its tangent and cotangent bundle, respectively. A Riemannian metric on M is a family of nondegenerate inner products $<,>_x$, defined on each tangent space T_xM, such that $<,>_x$ depends smoothly on $x \in M$. Any (nondegenerate) inner product on $\Re^n$ also defines a Riemannian metric on $\Re^n$ (but not conversely) and thus induces a Riemannian metric on every submanifold M of $\Re^n$.

Let $\Phi : M \to \Re$ be a smooth function defined on the manifold M and let $D\Phi : M \to T^*M$ denote the differential, i.e., a section of the cotangent bundle T^*M. To define the gradient vector field of Φ, we fix a Riemannian metric $<,>$ on M. The gradient $\bigtriangledown\Phi$ of Φ is then characterized by the following properties:

Compatibility condition (a). $D\Phi(x)\xi = \langle \bigtriangledown\Phi(x), \xi \rangle$ for all $\xi \in T_xM$.

Tangency condition (b). $\bigtriangledown\Phi(x) \in T_xM$ for all $x \in M$.

The following result is well known.

PROPOSITION A.1. *There exists a uniquely determined vector field* $\bigtriangledown\Phi$ *on* M *such that* (a) *and* (b) *hold.* $\bigtriangledown\Phi$ *is called the gradient vector field of* Φ.

Note that the gradient vector field depends on the choice of the Riemannian metric; changing the metric will also change the gradient.

It follows immediately from the definition of $\bigtriangledown\Phi$ that the equilibria of the differential equation

$$\dot{x}(t) = - \bigtriangledown \Phi(x(t)) \tag{A.1}$$

are precisely the critical points of Φ. Moreover, the linearization of the gradient flow (A.1) around each equilibrium point is given by the Hessian of Φ and thus has only real eigenvalues.

For any solution of (A.1),

$$\frac{d}{dt}\Phi(x(t)) = -|| \bigtriangledown \Phi(x(t))||^2$$

and therefore $\Phi(x(t))$ is monotonically decreasing. The following standard result is often used in this paper.

PROPOSITION A.2. *Let* $\Phi : M \to \Re$ *be a smooth function on a Riemannian manifold with compact sublevel sets, i.e., for all* $c \in \Re$ *the sublevel set* $\{x \in M \mid \Phi(x) \leq c\}$ *is a compact subset of* M. *Then every solution* $x(t) \in M$ *of the gradient flow* (A.1) *on* M *exists for all* $t \geq 0$. *Furthermore,* $x(t)$ *converges to a connected component of the set of critical points of* Φ *as* $t \to +\infty$.

Note that the condition of the proposition is automatically satisfied if M is compact. Moreover, in suitable local coordinates of M, the linearization of the gradient flow (A.1) around each equilibrium point has only real eigenvalues.

Let M be a smooth manifold and let $\Phi : M \to \Re$ be a smooth function. Let $C(\Phi) \subset M$ denote the set of all critical points of Φ. We say Φ is a *Morse–Bott* function provided the following three conditions (i), (ii), (iii) are satisfied.

(i) $\Phi : M \to \Re$ has compact sublevel sets.

(ii) $C(\Phi) = \bigcup_{j=1}^{k} N_j$ with N_j disjoint, closed, and connected submanifolds of M, such that Φ is constant on $N_j, j = 1, \ldots, k$.

(iii) $\mathrm{Ker}(\mathrm{Hess}\Phi)_x = T_x N_j$ for all $x \in N_j, j = 1, \ldots, k$.

Actually, the original definition of a Morse–Bott function also includes a global topological condition on the negative eigenspace bundle defined by the Hessian, but this condition is not relevant to us.

Recall that the *ω-limit set* $L_\omega(x)$ of a point $x \in M$ for a vector field X on M is the set of points of the form $\lim_{n\to\infty} \phi_{t_n}(x)$, where (ϕ_t) is the flow of X and $t_n \to +\infty$. Similarly, the *α-limit set* $L_\alpha(x)$ is defined by letting $t_n \to -\infty$ instead of $+\infty$.

PROPOSITION A.3.

(a) *Suppose $\Phi : M \to \Re$ has isolated critical points. Then $L_\omega(x), x \in M$, consists of a single critical point. Therefore every solution of the gradient flow* (A.1) *converges for $t \to +\infty$ to a critical point of Φ.*

(b) *Let $\Phi : M \to \Re$ be a Morse–Bott function on a Riemannian manifold M. Then the ω-limit set $L_\omega(x)$, $x \in M$, for the gradient flow* (A.1) *is a single critical point of Φ. Every solution of the gradient flow* (A.1) *converges as $t \to +\infty$ to an equilibrium point.*

TRUST REGION PROBLEMS AND NONSYMMETRIC EIGENVALUE PERTURBATIONS*

RONALD J. STERN† AND HENRY WOLKOWICZ‡

Abstract. A characterization is given for the spectrum of a symmetric matrix to remain real after a nonsymmetric sign-restricted border perturbation, including the case where the perturbation is skew-symmetric. The characterization is in terms of the stationary points of a quadratic function on the unit sphere. This yields interlacing relationships between the eigenvalues of the original matrix and those of the perturbed matrix. As a result of the linkage between the perturbation and stationarity problems, new theoretical insights are gained for each. Applications of the main results include a characterization of those matrices that are exponentially nonnegative with respect to the n-dimensional ice-cream cone, which in turn leads to a decomposition theorem for such matrices. In addition, results are obtained for nonsymmetric matrices regarding interlacing and majorization.

Key words. trust region problems, nonsymmetric perturbation, secular function, secular antiderivative, eigenvalues, interlacing, exponential nonnegativity, majorization, inverse eigenvalue problems

AMS subject classification. 15A18

1. Introduction.

Suppose that B is a real symmetric $(n-1)\times(n-1)$ matrix. Then the classical Rayleigh Principle and Courant–Fischer Minimax Theorem relate the eigenvalues of B to the stationary points of the quadratic function

$$\nu(x) = x^t B x$$

with respect to the constraint set

$$S_{n-1} = \{x \in R^{n-1} : x^t x = 1\}.$$

In particular, if we introduce the *Lagrangian function*

$$L(x,\lambda) = \nu(x) - \lambda(x^t x - 1), \tag{1.1}$$

then the *Lagrange equation*

$$\partial_x L(x,\lambda) = 0 \tag{1.2}$$

becomes

$$Bx - \lambda x = 0. \tag{1.3}$$

If x and λ satisfy the Lagrange equation and $x \in S_{n-1}$, then we shall say that λ and x are a *Lagrange multiplier* and an associated *stationary point* of $\nu(\cdot)$ with respect to S_{n-1}, respectively. Thus there is a one-to-one correspondence between the eigenvalues of B and the Lagrange multipliers. Furthermore, the stationary points, including the maximum and minimum points, can be found by determining the unit eigenvectors of

B. The lack of convexity in the constraint does not cause difficulties in locating the constrained maxima and minima, since such points correspond to the maximum and minimum eigenvalues, respectively.

The eigenvalues of symmetric border perturbations of B have well-known properties. In particular, the eigenvalues $\delta_1 \geq \delta_2 \cdots \geq \delta_n$ of the $n \times n$ matrix

$$A = \begin{pmatrix} B & \eta \\ \eta^t & t \end{pmatrix} \tag{1.4}$$

interlace the eigenvalues of B, which we denote $\gamma_1 \geq \gamma_2 \geq \cdots \geq \gamma_{n-1}$. That is,

$$\delta_1 \geq \gamma_1 \geq \delta_2 \geq \gamma_2 \geq \cdots \geq \gamma_{n-1} \geq \delta_n. \tag{1.5}$$

(See, e.g., pp. 94–97 in Wilkinson [24].)

Nonsymmetric border perturbations of B are not as well understood. For example, the $n \times n$ matrix

$$A = \begin{pmatrix} B & -\alpha \\ \alpha^t & t \end{pmatrix}, \tag{1.6}$$

which is a skew-symmetric perturbation for $t = 0$, may possess either a complex or real spectrum, and may be either diagonalizable or derogatory.

On the other hand, the important problem of finding the Lagrange multipliers and stationary points of the general quadratic function

$$\mu(x) = x^t B x - 2\eta^t x \tag{1.7}$$

on S_{n-1} has been extensively studied in the literature. In particular, we shall consider the "trust region" problems

$$P^{\mu}_{\min}: \quad \min\{\mu(x) \ : \ x \in S_{n-1}\}$$

and

$$P^{\mu}_{\max}: \quad \max\{\mu(x) \ : \ x \in S_{n-1}\}.$$

Such problems arise during the calculation of the step between iterates in an important class of minimization algorithms called "trust region methods." (The step in trust region algorithms is actually calculated with a constraint of the form $\| Gy \| \leq \psi$, for some nonsingular matrix G and $\psi > 0$. However, complementary slackness and the change of variables $x = (1/\psi)Gy$ lead to the form of our trust region problems.) The theory has been discussed in Forsythe and Golub [5], Golub [9], Gander [6], Sorensen [21], Fletcher [4] and Gander, Golub, and von Matt [7]. Furthermore, numerical techniques for solving trust region problems are given in [21], Moré and Sorensen [18], [4], Coleman and Hempel [3], [7], and Golub and von Matt [10].

In the present work, we establish new connections between spectral properties of a nonsymmetrically perturbed symmetric matrix and the stationarity properties of a specific trust region problem. We provide explicit criteria for the spectrum of the perturbed matrix to remain real, as well as eigenvalue interlacing properties. We shall consider certain sign-restricted nonsymmetric border perturbations, including the case (1.6). Our approach, in essence, is to regard the perturbation of a matrix as a linear perturbation of a purely quadratic form. As a result of the interplay between

the trust region and perturbation problems, new theoretical insights are gained for each.

In the next section we summarize required known facts concerning trust region problems, some of which involve the so-called *secular function* associated with $\mu(\cdot)$. In addition, we shall make use of the *secular antiderivative function* associated with $\mu(\cdot)$. This is a key tool which we employ to relate results on trust region problems to perturbation theory. The main results are then given in §3, including interlacing relationships for a nonsymmetrically perturbed matrix.

Section 4 contains applications of our main results. These include a characterization of matrices which are exponentially nonnegative with respect to the n-dimensional ice-cream cone, which leads to a decomposition theorem for such matrices. In addition, results are given for nonsymmetric matrices regarding interlacing and majorization.

2. Trust region problems.

2.1. Some known results. For the real symmetric $(n-1)\times(n-1)$ matrix B and the real $(n-1)$-vector η, consider the quadratic function $\mu(\cdot)$ given by (1.7) on S_{n-1}. Then the Lagrangian function is

$$L(x,\lambda) = x^tBx - 2\eta^tx - \lambda(x^tx-1). \tag{2.1}$$

In all that follows, our terminology regarding Lagrange multipliers and stationary points is as in §1, with the appropriate Lagrange equation replacing (1.3). Presently, the Lagrange equation is

$$(B-\lambda I)x - \eta = 0, \tag{2.2}$$

The set of Lagrange multipliers of $\mu(\cdot)$ with respect to S_{n-1} will be denoted by Λ, and for $\lambda\in\Lambda$, the associated set of stationary points will be denoted by $S_\mu(\lambda)$.

Useful properties concerning trust region problems are summarized in the following theorem.

THEOREM 2.1. *Part* 1. *The vector* $x\in R^{n-1}$, *with* $x^tx=1$, *is a minimum (maximum) point of* $\mu(\cdot)$ *over* S_{n-1} *if and only if there exists a scalar* λ *such that* x *and* λ *together satisfy the Lagrange equation* (2.2), *with the matrix* $B-\lambda I$ *being positive (negative) semidefinite.*

Part 2. *The set* Λ *of Lagrange multipliers of* $\mu(\cdot)$ *with respect to* S_{n-1} *is finite. Let* Λ *be given by*

$$\lambda_1 > \lambda_2 > \cdots > \lambda_k,$$

and let $x^{\lambda_i}\in S_\mu(\lambda_i)$, $i=1,2,\ldots,k$. *Then*

$$\mu(x^{\lambda_1}) > \mu(x^{\lambda_2}) > \cdots > \mu(x^{\lambda_k}).$$

In particular, the minimum (maximum) of $\mu(\cdot)$ *over* S_{n-1} *is attained at any stationary point associated with* λ_k (λ_1).

Part 1 of the above theorem is due to Sorensen [21]; see also pages 101–102 in Fletcher [4]. Part 2 is due to Forsythe and Golub [5]; also see the discussion of Case b below.

Again denoting the spectrum of B by $\gamma_1\geq\gamma_2\geq\cdots\geq\gamma_{n-1}$, let P be an orthogonal matrix such that

$$P^tBP = D = \operatorname{diag}(\gamma_1,\gamma_2,\ldots,\gamma_{n-1}), \tag{2.3}$$

the diagonal matrix with diagonal elements $\gamma_1, \gamma_2, \ldots, \gamma_{n-1}$. Then the Lagrange equation (2.2) becomes

$$(D - \lambda I)\hat{x} = \hat{\eta}, \tag{2.4}$$

where

$$\hat{x} = P^t x, \quad \hat{\eta} = P^t \eta.$$

The set of Lagrange multipliers Λ is not changed by this transformation of the Lagrange equation, and for every $x \in R^{n-1}$, we have

$$\hat{\mu}(\hat{x}) := \hat{x}^t D\hat{x} - 2\hat{\eta}^t\hat{x} = \mu(x). \tag{2.5}$$

We now introduce the condition

$$\hat{\eta}_i \neq 0 \quad \forall i = 1, 2, \ldots, n-1, \tag{2.6}$$

or equivalently,

$$\textit{no column of } P \textit{ is orthogonal to } \eta. \tag{2.7}$$

There are two cases to consider.

Case a. Condition (2.6) holds. Then (2.4) implies that if $\lambda \in \Lambda$, it must be the case that $D - \lambda I$ and $B - \lambda I$ are invertible. Also, the sets $S_\mu(\lambda)$ and $S_{\hat{\mu}}(\lambda)$ are then the singletons

$$x^\lambda = (B - \lambda I)^{-1}\eta \tag{2.8}$$

and

$$\hat{x}^\lambda = (D - \lambda I)^{-1}\hat{\eta} = P^t x^\lambda, \tag{2.9}$$

respectively. Furthermore, in the present case, Λ is the set of solutions to the *implicit secular equation*

$$1 - \eta^t (B - \lambda I)^{-2}\eta = 0, \tag{2.10}$$

which has the same solution set as the *explicit secular equation*

$$f_\mu(\lambda) := 1 - \sum_{i=1}^{n-1} \left(\frac{\hat{\eta}_i}{\gamma_i - \lambda}\right)^2 = 0. \tag{2.11}$$

Continuing to utilize the terminology of [7], we shall call $f_\mu(\cdot)$ the *secular function* associated with $\mu(\cdot)$.

In Case a, unique solutions to $P^\mu_{\min}$ and $P^\mu_{\max}$ are given by x^{λ_k} and x^{λ_1}, respectively, from formula (2.8). Furthermore, in view of Part 1 of Theorem 2.1, the invertibility of $B - \lambda_k I$ implies

$$\lambda_k < \gamma_{n-1}, \tag{2.12}$$

while the invertibility of $B - \lambda_1 I$ implies

$$\lambda_1 > \gamma_1. \tag{2.13}$$

Case b. Condition (2.6) does not hold. In [5] it was proven that in this case, $\Lambda = \tilde{\Lambda} \cup \Gamma$, with $\tilde{\Lambda}$ being the solution set of the explicit secular equation, and where

$$\Gamma = \{\gamma_i \ : \ f_\mu(\gamma_i) > 0\},$$

where we adopt the convention $0/0 = 0$ in defining $f_\mu(\cdot)$. For each $\lambda \in \tilde{\Lambda}$, $B - \lambda I$ is invertible and $S_\mu(\lambda)$ is the singleton x^λ given by formula (2.8). For each $\gamma_i \in \Gamma$, the set $S_\mu(\gamma_i)$ is an $(m_{\gamma_i} - 1)$-dimensional manifold, where m_{γ_i} is the multiplicity of the eigenvalue γ_i.

In Case b, it is possible that $\gamma_1 = \lambda_1$, implying that λ_1 occurs strictly to the right of the maximal root of $f_\mu(\cdot)$. Note that this can happen only if

$$\gamma_i = \lambda_1 \Longrightarrow \hat{\eta}_i = 0.$$

Furthermore, then $f_\mu(\lambda_1) > 0$, implying that $S_\mu(\lambda_{n-1})$, the set of solutions to the trust region problem $P^\mu_{\max}$, is not a singleton. Likewise, it is possible that $\gamma_{n-1} = \lambda_k$, implying that λ_k occurs strictly to the left of the minimal root of $f_\mu(\cdot)$. This is possible only if

$$\gamma_i = \lambda_k \Longrightarrow \hat{\eta}_i = 0.$$

It may then happen that $f_\mu(\lambda_k) > 0$, implying that $S_\mu(\lambda_k)$, the set of solutions to the trust region problem $P^\mu_{\min}$, is not a singleton.

2.2. The secular antiderivative. For the general quadratic function $\mu(\cdot)$ given by (1.7), consider the function

$$g_\mu(\lambda) = \lambda - \sum_{i=1}^{n-1} \left(\frac{\hat{\eta}_i^2}{\gamma_i - \lambda} \right), \tag{2.14}$$

with the convention $0/0 = 0$. Then the singularities of $g_\mu(\cdot)$ are the same as those of the secular function $f_\mu(\cdot)$, and what is more,

$$g'_\mu(\lambda) = f_\mu(\lambda) \tag{2.15}$$

at every nonsingularity λ. We shall call $g_\mu(\cdot)$ the *secular antiderivative function* associated with $\mu(\cdot)$.

The following lemma will be used in the next section to establish connections between trust region problems and perturbation theory. The lemma asserts that in Case a, the secular antiderivative's values on the Lagrange multiplier set Λ are precisely the values of $\mu(\cdot)$ on the corresponding set of stationary points, as given by (2.8). A variant of this result may be found in §2 of Forsythe and Golub [5], where it is used in proving Part 2 of Theorem 2.1 above.

LEMMA 2.1. *Assume that condition* (2.7) *holds* (*i.e., Case* a), *and let* $\lambda \in \Lambda$. *Then*

$$g_\mu(\lambda) = \mu(x^\lambda), \tag{2.16}$$

where $x^\lambda = (B - \lambda I)^{-1}\eta$.

Proof. Using the fact that $(\hat{x}^\lambda)^t \hat{x}^\lambda = 1$, we obtain

$$g_\mu(\lambda) = \sum_{i=1}^{n-1} \left[\lambda \left(\frac{\hat{\eta}_i}{\gamma_i - \lambda} \right)^2 - \frac{\hat{\eta}_i^2}{(\gamma_i - \lambda)} \right]$$

$$= \sum_{i=1}^{n-1} (2\lambda - \gamma_i) \left(\frac{\hat{\eta}_i}{\gamma_i - \lambda} \right)^2$$
$$= \sum_{i=1}^{n-1} \gamma_i \left(\frac{\hat{\eta}_i}{\gamma_i - \lambda} \right)^2 - 2 \sum_{i=1}^{n-1} \left(\frac{\hat{\eta}_i^2}{\gamma_i - \lambda} \right)$$
$$= \hat{\mu}(\hat{x}^\lambda) = \mu(x^\lambda). \qquad \square$$

At this point it will be useful to discuss the graph of the function $g_\mu(\cdot)$ in Case a. Clearly $g_\mu(\cdot)$ possesses a singularity at each eigenvalue γ_i, $i = 1, 2, \ldots, n-1$. Also, $g_\mu(\lambda) \to \infty$ as $\lambda \downarrow \gamma_i$, while $g_\mu(\lambda) \to -\infty$ as $\lambda \uparrow \gamma_i$, for each $i = 1, 2, \ldots, n-1$. Let i be such that $\gamma_{i+1} < \gamma_i$. Then there is at least one root of $g_\mu(\cdot)$ in (γ_{i+1}, γ_i). It is readily checked that $g_\mu'''(\lambda) < 0$, and consequently $g_\mu''(\lambda)$ is monotone decreasing in this interval. It follows that $g_\mu(\cdot)$ has at most one point of inflection on (γ_{i+1}, γ_i), which is possibly also a critical point. Should there be a point of inflection in (γ_{i+1}, γ_i), then on that interval $g_\mu(\cdot)$ is strictly convex to the left of this point, and strictly concave to the right of it. Hence $g_\mu(\cdot)$ has either zero, one, or two critical points on (γ_{i+1}, γ_i), with the possibility of only one critical point being accounted for by the existence of an inflection which is also critical. By again considering $g_\mu''(\cdot)$, we find that $g_\mu(\cdot)$ is strictly convex on the semi-infinite interval (γ_1, ∞), while we have strict concavity on the other semi-infinite interval, namely $(-\infty, \gamma_{n-1})$. Now, since $g_\mu(\lambda) \to \infty$ as $\lambda \downarrow \gamma_1$ and as $\lambda \to \infty$, we conclude that $g_\mu(\cdot)$ has a unique critical point, namely, λ_1 on (γ_1, ∞). Similarly, since $g_\mu(\lambda) \to -\infty$ as $\lambda \uparrow \gamma_{n-1}$ and as $\lambda \to -\infty$, we see that $g_\mu(\cdot)$ has a unique critical point, namely, λ_k on $(-\infty, \gamma_{n-1})$. (Note that this agrees with (2.12) and (2.13).)

In Case a, it is clear that the set of critical points of the secular antiderivative function $g_\mu(\cdot)$ is Λ. Furthermore, in view of our previous discussion, we then have

$$\mu_1 = g_\mu(\lambda_1) > \mu_2 = g_\mu(\lambda_2) > \cdots > \mu_k = g_\mu(\lambda_k), \tag{2.17}$$

where we have adopted the notation

$$\mu_i = \mu(x^{\lambda_i}), \qquad i = 1, 2, \ldots, k$$

for the *stationary values* of $\mu(\cdot)$ on S_{n-1}.

The preceeding discussion is summarized in Fig. 1, which illustrates the graph of a typical secular antiderivative function when (2.7) holds and the γ_i are distinct.

3. Main results. In what follows, we will be considering the border perturbation of the real symmetric $(n-1) \times (n-1)$ matrix B given by

$$A = \begin{pmatrix} B & -\alpha \\ \beta^t & t \end{pmatrix}, \tag{3.1}$$

where α and β are real $(n-1)$-vectors and $t \in R$. Letting P be an orthogonal matrix which diagonalizes B as in (2.3), we define

$$\hat{P} = \begin{pmatrix} P & 0 \\ 0 & 1 \end{pmatrix}. \tag{3.2}$$

Then

$$\hat{A} := \hat{P}^t A \hat{P} = \begin{pmatrix} D & -\hat{\alpha} \\ \hat{\beta}^t & t \end{pmatrix}, \tag{3.3}$$

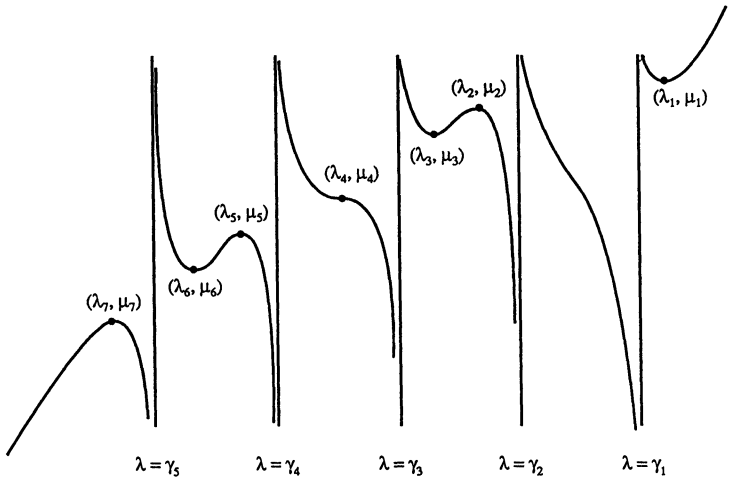

FIG. 1.

where

$$\hat{\alpha} = P^t \alpha, \qquad \hat{\beta} = P^t \beta.$$

Let us assume that

$$\hat{\alpha}_i \hat{\beta}_i \geq 0 \quad \forall i = 1, 2, \ldots, n-1. \tag{3.4}$$

Since a permutation can be built into P, we can without loss of generality assume that

$$\hat{A} = \begin{pmatrix} \tilde{D} & 0 & -\tilde{\alpha} \\ 0 & \bar{D} & -\bar{\alpha} \\ \tilde{\beta}^t & \bar{\beta}^t & t \end{pmatrix}, \tag{3.5}$$

where

$$\begin{aligned} \tilde{D} &= \operatorname{diag}(\tilde{\gamma}_1, \tilde{\gamma}_2, \ldots, \tilde{\gamma}_{\tilde{n}}), \\ \bar{D} &= \operatorname{diag}(\bar{\gamma}_1, \bar{\gamma}_2, \ldots, \bar{\gamma}_{\bar{n}}), \\ \tilde{\alpha}_i \tilde{\beta}_i &= 0 \quad \forall i = 1, 2, \ldots, \tilde{n}, \\ \bar{\alpha}_i \bar{\beta}_i &> 0 \quad \forall i = 1, 2, \ldots, \bar{n}, \end{aligned}$$

and

$$\tilde{n} + \bar{n} = n - 1.$$

Furthermore, we can assume the ordering

$$\bar{\gamma}_1 \geq \bar{\gamma}_2 \geq \cdots \geq \bar{\gamma}_{\bar{n}}.$$

Remark 3.1. (i) Note that condition (3.4) holds if $\alpha = \beta$; that is, when A is given by (1.6).

(ii) It is possible, of course, that either $\tilde{n}$ or $\bar{n}$ may be zero. It is readily shown that

$$\tilde{n} = 0 \iff \textit{no eigenvector of } B \textit{ is orthogonal to } \alpha \textit{ or } \beta. \tag{3.6}$$

Consider the submatrix of $\hat{A}$ given by

$$\bar{A} = \begin{pmatrix} \bar{D} & -\bar{\alpha} \\ \bar{\beta}^t & t \end{pmatrix}. \tag{3.7}$$

We associate with $\bar{A}$ the quadratic function

$$\bar{\mu}(\bar{x}) = \bar{x}^t \bar{D} \bar{x} - 2 \sum_{i=1}^{\bar{n}} (\bar{\alpha}_i \bar{\beta}_i)^{1/2} \bar{x}_i. \tag{3.8}$$

The secular antiderivative function associated with $\bar{\mu}(\cdot)$ is then

$$g_{\bar{\mu}}(\lambda) = \lambda - \sum_{i=1}^{\bar{n}} \left(\frac{\bar{\alpha}_i \bar{\beta}_i}{\bar{\gamma}_i - \lambda} \right). \tag{3.9}$$

From the structure of $\hat{A}$, we see that the characteristic polynomial of A is

$$p(\lambda) = \bar{p}(\lambda) \prod_{i=1}^{\tilde{n}} (\tilde{\gamma}_i - \lambda), \tag{3.10}$$

where

$$\bar{p}(\lambda) = \det(\bar{A} - \lambda \bar{I}). \tag{3.11}$$

In view of (3.10), it is clear that each of the $\tilde{n}$ diagonal entries of $\tilde{D}$ is an eigenvalue of A. Therefore to completely determine the spectrum of A, it is necessary only to determine the spectrum of $\bar{A}$. The following key lemma describes this spectrum in terms of the secular antiderivative function associated with $\bar{\mu}(\cdot)$, and is the basis of our linkage between trust region problems and perturbation theory.

LEMMA 3.1. *The real eigenvalues of $\bar{A}$ that differ from the $\bar{n}$ values $\bar{\gamma}_i$ are the solutions of*

$$g_{\bar{\mu}}(\lambda) = t. \tag{3.12}$$

Proof. Let $\lambda \in R$ where $\lambda \neq \bar{\gamma}_i$ for all $i = 1, 2, \ldots, \bar{n}$. From the Schur complement formula (see [12], p. 22), we then obtain

$$\det(\bar{A} - \lambda I) = \det(\bar{D} - \lambda I)[t - \lambda + \bar{\beta}^t (\bar{D} - \lambda I)^{-1} \bar{\alpha}], \tag{3.13}$$

from which it follows that the real eigenvalues of $\bar{A}$ differing from the $\bar{n}$ numbers $\bar{\gamma}_i$ are the solutions of

$$t - \lambda + \sum_{i=1}^{\bar{n}} \left(\frac{\bar{\alpha}_i \bar{\beta}_i}{\bar{\gamma}_i - \lambda} \right) = 0. \tag{3.14}$$

In view of (3.9), this is equivalent to (3.12). □

Let us denote the set of Lagrange multipliers of $\bar{\mu}(\cdot)$ with respect to $S_{\bar{n}}$ by $\bar{\Lambda}$, and let this set be given by

$$\bar{\lambda}_1 > \bar{\lambda}_2 > \cdots > \bar{\lambda}_m.$$

Since condition (2.6) holds for $\bar{\mu}(\cdot)$, we are presently in Case a. Therefore the set of critical points of $g_{\bar{\mu}}(\cdot)$ is $\bar{\Lambda}$, and moreover, in view of (2.17), we have

$$\bar{\mu}_1 = g_{\bar{\mu}}(\bar{\lambda}_1) > \bar{\mu}_2 = g_{\bar{\mu}}(\bar{\lambda}_2) > \cdots > \bar{\mu}_m = g_{\bar{\mu}}(\bar{\lambda}_m), \tag{3.15}$$

where the stationary values of $\bar{\mu}(\cdot)$ on $S_{\bar{n}}$ are denoted

$$\bar{\mu}_i = \bar{\mu}(\bar{x}^{\bar{\lambda}_i}), \qquad i = 1, 2, \ldots, m.$$

Here

$$\bar{x}^{\bar{\lambda}_i} = (\bar{D} - \bar{\lambda}_i \bar{I})^{-1} \bar{\eta}, \qquad i = 1, 2, \ldots, m,$$

with $\bar{\eta}$ being the $\bar{n}$-vector whose ith component is $(\bar{\alpha}_i \bar{\beta}_i)^{1/2}$.

The next theorem provides a qualitative description of the eigenstructure of the matrix A given by (3.1), when condition (3.4) holds. Realness of the spectrum of A is characterized in terms of the graph of $g_{\bar{\mu}}(\cdot)$, and in particular, in terms of the stationary values of the quadratic function $\bar{\mu}(\cdot)$. Should the spectrum be real, the interlacing relationships between the eigenvalues of A and B are described. Prior to stating the result, we require some further terminology and notation.

Let $\bar{\lambda} \in \bar{\Lambda}$. We shall say that $\bar{\lambda}$ is a *type*-1 *critical point* of $g_{\bar{\mu}}(\cdot)$ if it is a critical point that is also an inflection. Otherwise, we call $\bar{\lambda}$ a *type*-2 *critical point* of $g_{\bar{\mu}}(\cdot)$. From the discussion of the secular antiderivative function given in §2.2, it is clear that the number of type-2 critical points is even, since these points occur pairwise upon the particular bounded intervals $(\bar{\gamma}_{i+1}, \bar{\gamma}_i)$ where they exist, and in addition, there is a single type-2 critical point in each of the semi-infinite intervals $(-\infty, \bar{\gamma}_{\bar{n}})$ and $(\bar{\gamma}_1, \infty)$; these are $\bar{\lambda}_{\bar{n}}$ and $\bar{\lambda}_1$, respectively. Let us denote the sets of type-1 and type-2 critical points of $g_{\bar{\mu}}(\cdot)$ by $\bar{\Lambda}'$ and $\bar{\Lambda}''$, respectively. Then

$$\bar{\Lambda} = \bar{\Lambda}' \cup \bar{\Lambda}''.$$

We shall write the set $\bar{\Lambda}'$ as

$$\bar{\lambda}'_1 > \bar{\lambda}'_2 > \cdots > \bar{\lambda}'_w,$$

while the set $\bar{\Lambda}''$ will be written as

$$\bar{\lambda}_1 > \bar{\lambda}''_1 > \bar{\lambda}''_2 > \cdots > \bar{\lambda}''_{2v} > \bar{\lambda}_{\bar{n}}.$$

Here

$$w + 2v + 2 = m,$$

with w or v possibly being zero. We denote the set of stationary values corresponding to $\bar{\Lambda}'$ as $\{\bar{\mu}'_i\}_{i=1}^{w}$, while the set of stationary values corresponding to $\bar{\Lambda}''$ is written as

$$\{\bar{\mu}_1\} \cup \{\bar{\mu}_m\} \cup \left\{ \bigcup_{i=1}^{2v} \bar{\mu}''_i \right\}.$$

It will be convenient to define the following closed intervals:

$$I_1 = [\bar{\mu}_1, \infty).$$
$$I_m = (-\infty, \bar{\mu}_m].$$
$$I_i'' = [\bar{\mu}_{2i}'', \bar{\mu}_{2i-1}''],\ i = 1, 2, \ldots, v.$$

It is important to note that, in view of (3.15), the intervals defined above are mutually disjoint.

THEOREM 3.1. *Let B be an $(n-1) \times (n-1)$ real symmetric matrix, and let A be the perturbation of B given by* (3.1). *Assume that condition* (3.4) *holds, and that $\hat{A}$ is of the form* (3.5). *Let $\bar{\mu}(\cdot)$ be given by* (3.8). *Then the following hold:*

1. *There exist $n-2$ real eigenvalues $\{\delta_i\}_{i=1}^{n-2}$ of A, including all the eigenvalues of $\tilde{D}$ and $\bar{n}-1$ eigenvalues of $\bar{A}$, which interlace the $n-1$ ordered eigenvalues $\{\gamma_i\}_{i=1}^{n-1}$ of B; that is,*

$$\gamma_1 \geq \delta_1 \geq \gamma_2 \geq \cdots \geq \gamma_{n-2} \geq \delta_{n-2} \geq \gamma_{n-1}. \tag{3.16}$$

2. *The remaining two eigenvalues of A (which are eigenvalues of $\bar{A}$), say $\bar{\delta}_a$ and $\bar{\delta}_b$, are real if and only if*

$$t \in \{\bar{\Lambda}'\} \cup \{I_1\} \cup \{I_m\} \cup \left\{ \bigcup_{i=1}^{v} I_i'' \right\}. \tag{3.17}$$

3. *Furthermore, $\bar{\delta}_a$ and $\bar{\delta}_b$ are real and distinct if and only if t is in the interior of one of the $v+2$ intervals in* (3.17). *In this case, the $\bar{n}+1$ eigenvalues of $\bar{A}$ are real and distinct.*

4. *If* (3.17) *holds, we have the following relations involving $\bar{\delta}_a$ and $\bar{\delta}_b$, where we assume $\bar{\delta}_a \leq \bar{\delta}_b$:*

(a) $t > \bar{\mu}_1 \Longrightarrow \bar{\gamma}_1 < \bar{\delta}_a < \bar{\lambda}_1 < \bar{\delta}_b \leq t.$
(b) $t = \bar{\mu}_1 \Longrightarrow \bar{\gamma}_1 < \bar{\delta}_a = \bar{\lambda}_1 = \bar{\delta}_b \leq t.$
(c) $t = \bar{\mu}_{2i-1}'' \Longrightarrow \bar{\lambda}_{2i}'' < \bar{\delta}_a = \bar{\lambda}_{2i-1}'' = \bar{\delta}_b.$
(d) $t \in (\bar{\mu}_{2i}'', \bar{\mu}_{2i-1}'') \Longrightarrow \bar{\lambda}_{2i}'' < \bar{\delta}_a < \bar{\lambda}_{2i-1}'' < \bar{\delta}_b$ *or* $\bar{\delta}_a < \bar{\lambda}_{2i}'' < \bar{\delta}_b < \bar{\lambda}_{2i-1}''.$
(e) $t = \bar{\mu}_{2i}'' \Longrightarrow \bar{\lambda}_{2i}'' = \bar{\delta}_a = \bar{\lambda}_{2i}'' = \bar{\delta}_b < \bar{\lambda}_{2i-1}''.$
(f) $t = \bar{\mu}_i' \Longrightarrow \bar{\delta}_a = \bar{\mu}_i' = \bar{\delta}_b.$
(g) $t = \bar{\mu}_m \Longrightarrow t \leq \bar{\delta}_a = \bar{\lambda}_m = \bar{\delta}_b < \bar{\gamma}_{\bar{n}}.$
(h) $t < \bar{\mu}_m \Longrightarrow t \leq \bar{\delta}_a < \bar{\lambda}_m < \bar{\delta}_b < \bar{\gamma}_{\bar{n}}.$

Furthermore, in each of the statements (c)–(f), *all values on the right-hand side of $\Longrightarrow$ are contained in a single interval of the form $(\bar{\gamma}_{j+1}, \bar{\gamma}_j)$.*

Proof. Consider the graph of $g_{\bar{\mu}}(\cdot)$, a typical example of which is given in Fig. 2. We see that if $\bar{\gamma}_{i+1} < \bar{\gamma}_i$, then (3.12) has at least one solution $\bar{\delta}_i$ in $(\bar{\gamma}_{i+1}, \bar{\gamma}_i)$, which, in view of Lemma 3.1, is an eigenvalue of $\bar{A}$. Furthermore, since the characteristic equation of $\bar{A}$ is given by

$$\det(\bar{A} - \lambda I) = \prod_{i=1}^{\bar{n}} (\bar{\gamma}_i - \lambda) \left[t - \lambda + \sum_{i=1}^{\bar{n}} \left(\frac{\bar{\alpha}_i \bar{\beta}_i}{\bar{\gamma}_i - \lambda} \right) \right] = 0,$$

it follows that if $\bar{\gamma}_i$ has multiplicity k_i as an eigenvalue of $\bar{D}$, then $\bar{\gamma}_i$ is an eigenvalue of $\bar{A}$ with multiplicity $k_i - 1$. Hence

$$\bar{\gamma}_1 \geq \bar{\delta}_1 \geq \bar{\gamma}_2 \geq \cdots \geq \bar{\gamma}_{\bar{n}-1} \geq \bar{\delta}_{\bar{n}-1} \geq \bar{\gamma}_{\bar{n}}, \tag{3.18}$$

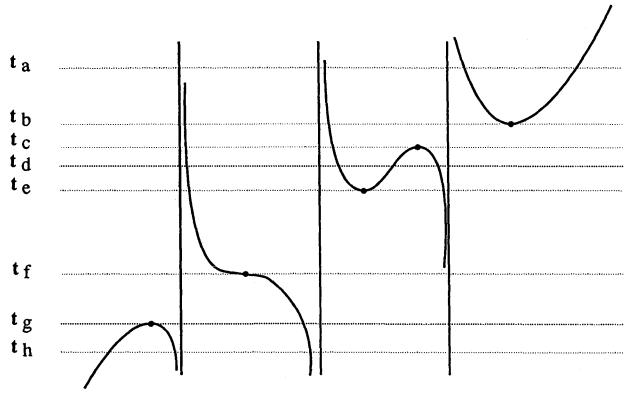

FIG. 2.

where the $\bar{n}-1$ numbers $\bar{\delta}_i$, are eigenvalues of $\bar{A}$. Part 1 of the theorem now follows readily. Parts 2 and 3 are consequences of part 4, which follows directly from consideration of the graph of $g_{\bar{\mu}}(\cdot)$, as in Fig. 2. There the relevant values of t are indicated, with the subscripts on t corresponding to (a)–(h) above. (Note that there are two possibilities for (d).) That $\bar{\delta}_b \leq t$ in (a) and (b) follows from the graph and the fact that the trace of $\bar{A}$ is the sum of the eigenvalues of $\bar{A}$, as does the inequality $t \leq \bar{\delta}_a$ occurring in (g) and (h). □

Remark 3.2. In Theorem 3.1, we can replace $\bar{\mu}(\cdot)$ with any quadratic function of the form

$$\bar{x}^t \bar{D} \bar{x} - 2 \sum_{i=1}^{\bar{n}} \psi_i (\bar{\alpha}_i \bar{\beta}_i)^{1/2} \bar{x}_i,$$

where $\psi_i = \pm 1$, since this change does not alter the Lagrange multipliers or critical values of $\bar{\mu}(\cdot)$ with respect to $S_{\bar{n}}$.

Theorem 3.1 gives a detailed description of the eigenstructure of the perturbation A under assumption (3.4), and in particular, a complete characterization of when the spectrum of A is real. However, to apply the result, one requires an orthogonal diagonalization of B, and this may not be readily available. In the following corollary, sufficient conditions for realness of the spectrum of A are given, without reliance on an orthogonal diagonalization, in case A is given by (1.6); that is, when $\alpha = \beta$.

COROLLARY 3.1. *Let B be an $(n-1) \times (n-1)$ real symmetric matrix, and consider the perturbation of B given by*

$$A = \begin{pmatrix} B & -\alpha \\ \alpha^t & t \end{pmatrix}, \tag{3.19}$$

where α is a real $(n-1)$-vector. Define

$$\mu(x) = x^t B x - 2\alpha^t x. \tag{3.20}$$

Let

$$\mu_1 = \max\{\mu(x) \ : \ x^t x = 1\} \tag{3.21}$$

and

$$\mu_k = \min\{\mu(x) \ : \ x^t x = 1\}. \tag{3.22}$$

Then either of the conditions

$$t \geq \mu_1 \tag{3.23}$$

or

$$t \leq \mu_k \tag{3.24}$$

are sufficient for the spectrum of A to be real.

Proof. As was noted in Remark 3.1, condition (3.4) holds for the present perturbation. Now observe that $\mu(\cdot)$ and $\bar{\mu}(\cdot)$ have the same secular function and secular antiderivative, where $\bar{\mu}(\cdot)$ is given by (3.8) with $\bar{\alpha}_i = \bar{\beta}_i$ for $i = 1, 2, \ldots, \bar{n}$. Since the roots of the secular function $f_\mu(\cdot)$ are the critical points of the secular antiderivative $g_\mu(\cdot)$, the discussion of Cases a and b in §2.1 tells us that

$$\lambda_1 \geq \bar{\lambda}_1$$

and

$$\lambda_k \leq \bar{\lambda}_m.$$

From Part 2 of Theorem 2.1, we then have

$$\mu_1 \geq \bar{\mu}_1$$

and

$$\mu_k \leq \bar{\mu}_m.$$

(The last two inequalities can also be deduced directly from the definitions of the functions $\mu(\cdot)$ and $\bar{\mu}(\cdot)$.) The result now follows from Theorem 3.1, and in particular, from part 4, (a), (b), (g), and (h). □

The values μ_1 and μ_k in Corollary 3.1, which are the optimal objective function values of the trust region problems $P^{\mu}_{\max}$ and $P^{\mu}_{\min}$, respectively, may be efficiently determined numerically by the method of Moré and Sorensen [18].

In Corollary 3.2, we give a Gersgorin-like sufficient condition for realness of the spectrum of A given by (3.19). We use the notation $\| \cdot \|$ for both the euclidean norm of an $(n-1)$-vector and the spectral norm of an $(n-1) \times (n-1)$ matrix.

COROLLARY 3.2. *Let B and A be as in Corollary* 3.1. *Then a sufficient condition for the spectrum of A to be real is*

$$\| B \| + 2 \| \alpha \| \leq |t|. \tag{3.25}$$

Proof. This follows from the fact that (3.25) implies that either (3.23) or (3.24) hold, and Corollary 3.1. □

We conclude this section with another result regarding the perturbation (3.19). This elementary result is independent of Theorem 3.1, and yields further connections between trust region problems and nonsymmetric perturbations.

THEOREM 3.2. *Let B, A, and $\mu(\cdot)$ be as in Corollary* 3.1. *Then $\lambda \in \Lambda$ (that is, λ is a Lagrange multiplier of $\mu(\cdot)$ with respect to S_{n-1}) with $x \in S_\mu(\lambda)$, if and only if λ is an eigenvalue of A with associated eigenvector*

$$\begin{pmatrix} x \\ 1 \end{pmatrix},$$

in which case $||x|| = 1$ and $t = \mu(x)$.

Proof. Upon premultiplying the Lagrange equation

$$Bx - \alpha - \lambda x = 0 \tag{3.26}$$

by x^t and using the fact that $x^t x = 1$, we obtain

$$\mu(x) + \alpha^t x - \lambda = 0, \tag{3.27}$$

i.e., the following eigenvalue-eigenvector equation holds

$$\begin{pmatrix} B - \lambda I & -\alpha \\ \alpha^t & t - \lambda \end{pmatrix} \begin{pmatrix} x \\ 1 \end{pmatrix} = 0. \tag{3.28}$$

Conversely, suppose that the above eigenvalue-eigenvector equation holds, with $t = \mu(x)$. Then the Lagrange equation (3.26) and (3.27) clearly hold. Premultiplying by x^t again and substituting for λ yields $x^t Bx - \alpha^t x - (\mu(x) + \alpha^t x)x^t x = 0$, which implies that $x^t x = 1$. □

4. Applications.

4.1. Exponential nonnegativity. In this subsection it will be seen that the main results of §3 can be applied to characterize those matrices that are exponentially nonnegative with respect to the n-dimensional ice-cream cone and to provide a decomposition theorem for such matrices.

Let us denote the *n-dimensional ice-cream cone* by

$$K_n = \left\{ y \in R^n \ : \ \sum_{i=1}^{n-1} y_i^2 \leq y_n^2, \ y_n \geq 0 \right\}.$$

Equivalently,

$$K_n = \{ y \in R^n \ : \ y^t Q_n y \leq 0, \ y_n \geq 0 \},$$

where $Q_n = \operatorname{diag}(1, 1, \ldots, 1, -1)$. We shall denote the matrix exponential by

$$e^{tA} = \sum_{j=0}^{\infty} (tA)^j / j!,$$

and the boundary of K_n by ∂K_n. The following further notation and terminology will be utilized:

$$\begin{aligned} \Pi(K_n) &= \{ A : AK_n \subset K_n \}. \\ e(K_n) &= \{ A : e^{tA} \subset \Pi(K_n) \ \ \forall t \geq 0 \}. \\ e(\partial K_n) &= \{ A : e^{tA}(\partial K_n) \subset \partial K_n \forall t \geq 0 \}. \end{aligned}$$

These sets will be referred to as the *K_n-nonnegative matrices*, *exponentially K_n-nonnegative matrices*, and *exponentially ∂K_n-invariant matrices*, respectively. It is readily verified that both $\Pi(K_n)$ and $e(\partial K_n)$ are subsets of $e(K_n)$. Although our discussion will be essentially self-contained, the reader is referred to Berman and Plemmons [2] and Berman, Neumann, and Stern [1] for general facts concerning these sets of matrices.

Notice that $A \in e(K_n)$ if and only if for any initial point $y_o \in K_n$, the solution $y(t) = e^{tA}y_o$ of the initial value problem

$$\frac{d}{dt}y(t) = Ay(t); \qquad t \geq 0,$$
$$y(0) = y_o$$

satisfies $y(t) \in K_n$ for all $at \geq 0$. Similarly, $A \in e(\partial K_n)$ means that $y(t) \in \partial K_n$ for all $y_o = y(0) \in \partial K_n$.

We require the following lemma of Stern and Wolkowicz [22], in which $e(K_n)$ and $e(\partial K_n)$ are characterized in terms of tangency-like properties of the vector field $\{Ay\}$ relative to the surface

$$\partial K_n = \{y \in R^n \ : \ y^tQ_ny = 0, \ y_n \geq 0\}.$$

LEMMA 4.1. *Let A be a real $n \times n$ matrix. Then the following hold:* 1. *A necessary and sufficient condition for $A \in e(K_n)$ is*

$$y^tQ_nAy \leq 0 \quad \forall y \in \partial K_n. \tag{4.1}$$

2. *A necessary and sufficient condition for $A \in e(\partial K_n)$ is*

$$y^tQ_nAy = 0 \quad \forall y \in \partial K_n, \tag{4.2}$$

which is in turn equivalent to A being of the form

$$A = \begin{pmatrix} G + aI & g \\ g^t & a \end{pmatrix}, \tag{4.3}$$

for some real $(n-1)$-vector g and real number a, where the $(n-1) \times (n-1)$ matrix G is skew-symmetric.

We next use Corollary 3.1 to characterize $e(K_n)$ in terms of the maximal critical value of a specific trust region problem, as well as in terms of the realness of the spectrum of a certain matrix.

Suppose that $A \in e(K_n)$, or equivalently, that (4.1) holds. Let us partition A as

$$\begin{pmatrix} A_1 & c \\ d^t & a_{nn} \end{pmatrix}. \tag{4.4}$$

Then condition (4.1) becomes

$$x^tA_1x + (c^t - d^t)x - a_{nn} \leq 0 \quad \forall x \in S_{n-1}. \tag{4.5}$$

Let us define

$$B = \frac{A_1 + A_1^t}{2}. \tag{4.6}$$

From (4.5) it follows that (4.1) is equivalent to

$$\mu(x) := x^t Bx - 2\alpha^t x \leq a_{nn} \quad \forall x \in S_{n-1}, \tag{4.7}$$

where

$$\alpha = \frac{d-c}{2}. \tag{4.8}$$

Defining

$$\mu_1 = \max\{\mu(x) \ : \ x^t x = 1\}$$

as in (3.21), we see that (4.7) becomes

$$\mu_1 \leq a_{nn}. \tag{4.9}$$

Now, in view of Corollary 3.1, (4.9) implies that the spectrum of the matrix

$$A_r = \begin{pmatrix} B & (c-d)/2 \\ (d^t - c^t)/2 & a_{nn} \end{pmatrix} \tag{4.10}$$

is real. We shall call A_r the *regularization* of A.

The preceding discussion is summarized in the following result.

THEOREM 4.1. *Let A be a real $n \times n$ matrix. Then the following hold:* 1. *A is exponentially K_n-nonnegative if and only if* (4.9) *holds.*

2. *A necessary condition for A to be exponentially K_n-nonnegative is that the spectrum of A_r be real.*

Example 4.1. In this example,

$$A = \begin{pmatrix} -1 & 1 & 1 \\ 4 & 2 & 3 \\ 0 & 1 & a_{33} \end{pmatrix}.$$

We wish to determine those values of a_{33} for which $A \in e(K_n)$. The regularization of A becomes

$$A_r = \begin{pmatrix} -1 & \frac{5}{2} & -\frac{1}{2} \\ \frac{5}{2} & 2 & -1 \\ \frac{1}{2} & 1 & a_{33} \end{pmatrix}.$$

Therefore

$$\mu(x) = -x_1^2 + 2x_2^2 + 5x_1x_2 - x_1 - 2x_2. \tag{4.11}$$

At this point, one could employ the algorithm of Moré and Sorensen [18] to compute μ_1. Alternatively, one can find an orthogonal diagonalization of B with MATLAB, and then generate the graph of $g_\mu(\cdot)$. The eigenvalues of B are thusly found to be $\lambda_1 = 3.4155$ and $\lambda_2 = -2.4155$, while an orthogonal matrix that diagonalizes B is

$$P = \begin{pmatrix} .8702 & .4927 \\ -.4927 & .8702 \end{pmatrix}.$$

Then

$$P\alpha = P \begin{pmatrix} \frac{1}{2} \\ 1 \end{pmatrix} = \begin{pmatrix} -.0576 \\ 1.1166 \end{pmatrix}.$$

It follows that

$$g_\mu(\lambda) = \lambda - \frac{.0576^2}{(-2.4155 - \lambda)} - \frac{1.1166^2}{(3.4155 - \lambda)}. \tag{4.12}$$

Note that the present example is Case a (since no component of $P^t\alpha$ is zero). We used MATLAB to graphically determine $\mu_1 = 5.67$.

Hence

$$A \in e(K_n) \Longleftrightarrow a_{33} \geq 5.67.$$

Furthermore, if a_{33} satisfies this inequality, then the spectrum of A_r is guaranteed to be real.

Our main objective in the remainder of this subsection is to prove that every exponentially K_n-nonnegative matrix may be (nonuniquely) represented as the sum of a K_n-nonnegative matrix and an exponentially ∂K_n-invariant matrix. Formally, this decomposition result is stated as follows.

THEOREM 4.2. *One has*

$$e(K_n) = \Pi(K_n) + e(\partial K_n). \tag{4.13}$$

In proving this theorem, we make use of Theorem 4.1. We also require the following result, which provides characterizations of $\Pi(K_n)$ and $e(K_n)$ in terms of definiteness conditions. (For a real symmetric matrix C, the notation $C \leq 0$ indicates that C is negative semidefinite.)

THEOREM 4.3. *Let A be a real $n \times n$ matrix.* 1. *Assume that* $\operatorname{rank}(A) > 1$. *Then a necessary and sufficient condition for*

$$A \in \Pi(K_n) \cup \{-\Pi(K_n)\}$$

is the existence of $\mu \geq 0$ such that

$$A^t Q_n A - \mu Q_n \leq 0. \tag{4.14}$$

2. *A necessary and sufficient condition for $A \in e(K_n)$ is the existence of $\gamma \in R$ such that*

$$Q_n A + A^t Q_n - \gamma Q_n \leq 0. \tag{4.15}$$

Part 1 of Theorem 4.3 is due to Loewy and Schneider [14], while part 2 is due to Stern and Wolkowicz [22].

We now shall prove the decomposition theorem.

Proof of Theorem 4.2. Let $A \in e(K_n)$. By part 2 of Theorem 4.1, we know that the spectrum of A_r is real, and we can choose $\delta > 0$ such that all eigenvalues of

$$\tilde{A} = A_r + \delta I$$

are positive. Let Γ be an open disk in the open right-half complex plane, centered at $\psi > 0$, such that the entire spectrum of $\tilde{A}$ lies within Γ. Inside Γ, one can express a branch of the function $f(\lambda) = \lambda^{1/2}$ as

$$f(\lambda) = \sum_{i=0}^{\infty} c_i(\lambda - \psi)^i, \tag{4.16}$$

where the coefficients c_i are all real. According to the theory of matrix functions (see, e.g., [8]), $\tilde{A}$ has a real square root given by

$$\tilde{A}^{1/2} = \sum_{i=0}^{\infty} c_i (\tilde{A} - \psi I)^i. \tag{4.17}$$

Let us write

$$A = \tilde{A} + C, \tag{4.18}$$

where

$$C = \frac{1}{2} \begin{pmatrix} A_1 - A_1^t & c + d \\ c^t + d^t & 0 \end{pmatrix}. \tag{4.19}$$

Then $C \in e(\partial K_n)$, and, in view of Lemma 4.1, it follows that $\tilde{A}$ and A_r are exponentially K_n-nonnegative.

Since $Q_n A_r$ is symmetric, so is $Q_n \tilde{A}$. Then part 2 of Theorem 4.3 implies the existence of $\tilde{\gamma}$ such that

$$Q_n \tilde{A} - \tilde{\gamma} Q_n \leq 0. \tag{4.20}$$

From the fact that the spectrum of $\tilde{A}^{1/2}$ is real and positive, it follows that

$$(\tilde{A}^{1/2})^t [Q_n \tilde{A} - \tilde{\gamma} Q_n] \tilde{A}^{1/2} \leq 0. \tag{4.21}$$

Now, (4.17) implies that the matrix $Q_n \tilde{A}^{1/2}$ is symmetric, and therefore (4.21) yields

$$Q_n \tilde{A}^2 - \tilde{\gamma} Q_n \tilde{A} \leq 0. \tag{4.22}$$

Again using the symmetry of $Q_n \tilde{A}$, it follows that

$$\tilde{A}^t Q_n \tilde{A} - \tilde{\gamma} Q_n \tilde{A} \leq 0. \tag{4.23}$$

We can assume without loss of generality that $\tilde{\gamma} \geq 0$, since δ can be increased, if necessary. Then upon combining (4.20) and (4.23), we arrive at

$$\tilde{A}^t Q_n \tilde{A} - \tilde{\gamma}^2 Q_n \leq 0. \tag{4.24}$$

Since rank($\tilde{\mathrm{A}}$) = n, part 1 of Theorem 4.3 implies

$$\tilde{A} \in \Pi(K_n) \cup \{-\Pi(K_n)\}. \tag{4.25}$$

Then (4.25) yields

$$\tilde{A} e^n \in K_n \cup \{-K_n\},$$

where $e^n = (0, 0, \ldots, 0, 1)^t$. We can assume that δ has been chosen sufficiently large to ensure that

$$\tilde{a}_{nn} = a_{nn} + \delta \geq 0. \tag{4.26}$$

Hence (4.25) and (4.26) imply that $Ae^n \in K_n$. We conclude that

$$\tilde{A} = A - C \in \Pi(K_n). \tag{4.27}$$

Since $C \in e(\partial K_n)$, it follows that

$$A \in \Pi(K_n) + e(\partial K_n). \tag{4.28}$$

This completes the proof. □

Example 4.2. Let

$$A = \begin{pmatrix} -1 & 0 & 0 \\ 0 & -2 & 2 \\ 0 & 0 & 0 \end{pmatrix}.$$

Here

$$\langle Ay, Q_3 y \rangle = -(y_2 - 1)^2 \leq 0 \quad \forall y \in K_3,$$

and therefore A is exponentially K_3-nonnegative. Then

$$A_r = \begin{pmatrix} -1 & 0 & 0 \\ 0 & -2 & 1 \\ 0 & -1 & 0 \end{pmatrix},$$

and following the proof of Theorem 4.2, $\tilde{A} = A_r + \delta I \in \Pi(K_3)$ provided that δ is chosen sufficiently large. Indeed, if we take $\delta = 2$, then

$$\tilde{A} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & -1 & 2 \end{pmatrix}.$$

It is readily checked that $\langle \tilde{A}y, Q_3 \tilde{A}y \rangle = -2(y_2 - 1)^2 \leq 0$ and $(\tilde{A}y)_3 \geq 0$ for all $y \in K_3$. Hence $\tilde{A} \in \Pi(K_3)$, and therefore $A \in \Pi(K_3) + e(\partial K_3)$.

Remark 4.1. Given an $n \times n$ exponentially K_n-nonnegative matrix in the regularized form A_r, define

$$\delta^* = \min\{\delta \in R : A_r + \delta I \in \Pi(K_n)\}.$$

Let us denote the eigenvalues of A_r by $\lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_n$. It is conjectured that

$$\delta^* = -\frac{(\lambda_1 + \lambda_n)}{2}.$$

This is precisely the minimal value of δ that will ensure that the spectral radius of the matrix $A_r + \delta I$ is in its spectrum. Therefore this conjecture relates to the result of Vandergraft in [23], which asserts that a matrix leaves a proper cone invariant only if its spectral radius is an eigenvalue. (The cone K is said to be *proper* provided that it is closed, convex, possesses nonempty interior, and $K \cap \{-K\} = \{0\}$.) Note that δ^* is generally less than the "sufficiently large" value of δ used in the proof of Theorem 4.2 to ensure various properties, including the existence of a real square root $\tilde{A}^{1/2} = (A_r + \delta I)^{1/2}$. As an illustration, consider the matrix A_r in Example 4.2. The spectrum of A_r is $\{-1, -1, -1\}$, and therefore $\delta^* = 1$. Then

$$A_r + \delta^* I = \begin{pmatrix} 0 & 0 & 0 \\ 0 & -1 & 1 \\ 0 & -1 & 1 \end{pmatrix} \in \Pi(K_3),$$

but this matrix does not possess a real square root.

Remark 4.2. An interesting open problem is to determine whether the decomposition (4.13) holds for any proper cone $K \subset R^n$; that is

$$e(K) = \Pi(K) + e(\partial K). \tag{4.29}$$

It is not difficult to verify (4.29) for the class of ellipsoidal cones; these are the linear homeomorphisms of K_n. Also, results in Schneider and Vidyasagar [19] may be applied to verify (4.29) for the class of polyhedral proper cones, and to show that for a general proper cone K, we have

$$e(K) = \overline{\Pi(K) + e(\partial K)}, \tag{4.30}$$

where the bar denotes closure. Hence (4.30) implies that conjecture (4.29) is equivalent to closedness of $\Pi(K)+e(\partial K)$. The sets $\Pi(K)$ and $e(\partial K)$ can be shown to be a proper cone and a subspace, respectively, in the space of $n \times n$ matrices. Such a sum is not necessarily closed, and the conjecture therefore remains unsettled.

4.2. Interlacing and majorization. Given two real n-vectors x and y with component orderings

$$x_1 \geq x_2 \geq \cdots \geq x_n \tag{4.31}$$

and

$$y_1 \geq y_2 \geq \cdots \geq y_n, \tag{4.32}$$

we say that x is *majorized* by y (notationally, $x \prec y$) provided that

$$\begin{aligned} x_1 &\leq y_1, \\ x_1 + x_2 &\leq y_1 + y_2, \\ &\vdots \\ x_1 + x_2 + \cdots + x_{n-1} &\leq y_1 + y_2 + \cdots + y_{n-1}, \\ x_1 + x_2 + \cdots + x_n &= y_1 + y_2 + \cdots + y_n. \end{aligned}$$

The following is a classical theorem of Schur [20].

THEOREM 4.4. *Let A be a real symmetric $n \times n$ matrix with diagonal elements*

$$a_{11} \geq a_{22} \geq \cdots \geq a_{nn}$$

and eigenvalues

$$\delta_1 \geq \delta_2 \geq \cdots \geq \delta_n.$$

Then

$$(a_{11}, a_{22}, \ldots, a_{nn}) \prec (\delta_1, \delta_2, \ldots, \delta_n). \tag{4.33}$$

One proof of Schur's theorem appearing in Mirsky [16], and attributed there to Schneider, makes use of the interlacing (1.5) obtained upon writing A in the form (1.4). (See also Theorem 9.B.1 in Marshall and Olkin [15] or Theorem 4.3.26 in Horn and Johnson [12].) We next give an analogous "near-majorization" result and proof

for (nonsymmetric) matrices of the form (3.1) satisfying condition (3.4), by applying the "near-interlacing" provided by Theorem 3.1. We first introduce some further terminology and notation.

Given real n-vectors x and y satisfying the orderings (4.31) and (4.32), we say that x is *near-majorized* by y (notationally, $x \tilde{\prec} y$) provided that

$$\begin{aligned} x_2 &\le y_2, \\ x_2 + x_3 &\le y_2 + y_3, \\ &\vdots \\ x_2 + x_3 + \cdots + x_n &\le y_2 + y_3 + \cdots + y_n, \\ x_1 + x_2 + \cdots + x_n &= y_1 + y_2 + \cdots + y_n. \end{aligned}$$

Note that $x \tilde{\prec} y$ implies $x_1 \ge y_1$.

THEOREM 4.5. *Assume that the hypotheses of Theorem* 3.1 *hold, and consider the matrix* $\bar{A}$ *given by* (3.7).

1. *Assume that* $t \ge \bar{\mu}_1$. *Then the spectrum of* $\bar{A}$ *is real,* $t \ge \bar{\gamma}_1$, *and*

$$(t, \bar{\gamma}_1, \bar{\gamma}_2, \ldots, \bar{\gamma}_{\bar{n}}) \tilde{\prec} v,$$

where v *denotes the vector of eigenvalues of* $\bar{A}$ *listed in nonincreasing order.*

2. *Assume that* $t \le \bar{\mu}_m$. *Then the spectrum of* $\bar{A}$ *is real,* $t \le \bar{\gamma}_{\bar{n}}$, *and*

$$-(\bar{\gamma}_1, \bar{\gamma}_2, \ldots, \bar{\gamma}_{\bar{n}}, t) \tilde{\prec} -v.$$

Proof. We only prove part 1 of the theorem. The proof of part 2 is similar and is left to the reader.

In view of Theorem 3.1 (part 4(a) and 4(b)), the eigenvalues of $\bar{A}$ are all real and the ordered spectrum of $\bar{A}$ is given by

$$\bar{\delta}_{\bar{n}-1} \le \bar{\delta}_{\bar{n}-2} \le \cdots \le \bar{\delta}_1 \le \bar{\delta}_a \le \bar{\delta}_b, \tag{4.34}$$

and we have

$$\bar{\gamma}_{\bar{n}} \le \bar{\delta}_{\bar{n}-1} \le \bar{\gamma}_{\bar{n}-1} \le \cdots \le \bar{\delta}_1 \le \bar{\gamma}_1 \le \bar{\delta}_a \le \bar{\delta}_b \le t. \tag{4.35}$$

This yields the system of inequalities

$$\begin{aligned} \bar{\gamma}_1 &\le \bar{\delta}_a, \\ \bar{\gamma}_1 + \bar{\gamma}_2 &\le \bar{\delta}_a + \bar{\delta}_1, \\ &\vdots \\ \bar{\gamma}_1 + \bar{\gamma}_2 + \cdots + \bar{\gamma}_{\bar{n}} &\le \bar{\delta}_a + \bar{\delta}_1 + \cdots + \bar{\delta}_{\bar{n}-1}. \end{aligned}$$

The result now follows from the fact that

$$\begin{aligned} \operatorname{trace}(\bar{A}) &= t + \bar{\gamma}_1 + \bar{\gamma}_2 + \cdots + \bar{\gamma}_{\bar{n}} \\ &= \bar{\delta}_b + \bar{\delta}_a + \bar{\delta}_1 + \cdots + \bar{\delta}_{\bar{n}-1}. \end{aligned}$$

□

In the following corollary to Theorem 4.5, we obtain a near-majorization result for matrices of the form (1.6).

COROLLARY 4.1. *Let B, A, $\mu(\cdot)$, μ_1 and μ_k be as in Corollary* 3.1, *where the diagonal of B is assumed to have the ordering*

$$b_{11} \geq b_{22} \geq \cdots \geq b_{(n-1)(n-1)}. \tag{4.36}$$

In addition, assume that no eigenvector of B is orthogonal to α.

1. *If condition* (3.23) *holds (that is, $t \geq \mu_1$), then the spectrum of A is real, $t \geq b_{11}$, and*

$$(t, b_{11}, b_{22}, \ldots, b_{(n-1)(n-1)}) \tilde{\prec} v,$$

where v is vector of eigenvalues of A listed in nonincreasing order.

2. *If condition* (3.24) *holds (that is, $t \leq \mu_k$), then the spectrum of A is real, $t \leq b_{(n-1)(n-1)}$, and*

$$-(b_{11}, b_{22}, \ldots, b_{(n-1)(n-1)}, t) \tilde{\prec} -v.$$

Proof. We will only prove part 1, with the proof of part 2 being left to the reader.

Since condition (3.6) holds, we have $\hat{A} = \bar{A}$, where $\hat{A}$ and $\bar{A}$ are given by (3.5) and (3.7), respectively. From the proof of Corollary 3.1, we see that the eigenvalues of A are all real, and that the entire ordered spectrum of A is given by (4.34) with $\bar{n} = n - 1$. Upon applying Schur's majorization theorem to B, we obtain

$$\begin{aligned} b_{11} &\leq \bar{\gamma}_1, \\ b_{11} + b_{22} &\leq \bar{\gamma}_1 + \bar{\gamma}_2, \\ &\vdots \\ b_{11} + b_{22} + \cdots + b_{(n-1)(n-1)} &\leq \bar{\gamma}_1 + \bar{\gamma}_2 + \cdots + \bar{\gamma}_{n-1}, \end{aligned}$$

and making use of (4.35) as in the proof of Theorem 4.5, we have that

$$\begin{aligned} \bar{\gamma}_1 &\leq \bar{\delta}_a, \\ \bar{\gamma}_1 + \bar{\gamma}_2 &\leq \bar{\delta}_a + \bar{\delta}_1, \\ &\vdots \\ \bar{\gamma}_1 + \bar{\gamma}_2 + \cdots + \bar{\gamma}_{n-1} &\leq \bar{\delta}_a + \bar{\delta}_1 + \bar{\delta}_2 + \cdots + \bar{\delta}_{n-2}. \end{aligned}$$

The result now follows from the facts that $t \geq \bar{\gamma}_1 \geq b_{11}$ and

$$\begin{aligned} \text{trace(A)} &= t + b_{11} + b_{22} + \cdots + b_{(n-1)(n-1)} \\ &= \bar{\delta}_b + \bar{\delta}_a + \bar{\delta}_1 + \bar{\delta}_2 + \cdots + \bar{\delta}_{n-2}. \end{aligned}$$

□

Notice that the ordering of the diagonal (4.36) can be assumed to hold without loss of generality in Corollary 4.1, since it can always be attained via a permutational similarity.

The following inverse eigenvalue theorem is due to Mirsky [17]; see also Theorem 9.3.B in [15].

THEOREM 4.6. *Suppose we are given real numbers $\gamma_1, \gamma_2, \ldots, \gamma_{n-1}$ and $\delta_1, \delta_2, \ldots, \delta_n$, which satisfy the interlacing property* (1.5); *that is*

$$\delta_1 \geq \gamma_1 \geq \delta_2 \geq \gamma_2 \geq \cdots \geq \gamma_{n-1} \geq \delta_n.$$

Then there exists a real symmetric $n \times n$ matrix of the form

$$A = \begin{pmatrix} D & \eta \\ \eta^t & t \end{pmatrix} \tag{4.37}$$

with $D = \operatorname{diag}(\gamma_1, \gamma_2, \ldots, \gamma_{n-1})$, *such that the spectrum of* A *is* $\{\delta_1, \delta_2, \ldots, \delta_n\}$.

We will now show that an analogous inverse eigenvalue theorem holds when the interlacing (1.5) is replaced by the types of near-interlacing occurring in Theorem 3.1. The proof closely follows Mirsky, but we include it nevertheless for the sake of completeness. (See also Theorem 7 in [13].)

THEOREM 4.7. *Suppose we are given real numbers* $\gamma_1, \gamma_2, \ldots, \gamma_{n-1}$, $\delta_1, \delta_2, \ldots, \delta_{n-2}$, *and* δ_b, δ_a, *which satisfy*

$$\gamma_1 \geq \delta_1 \geq \gamma_2 \geq \delta_2 \geq \cdots \geq \delta_{n-2} \geq \gamma_{n-1}. \tag{4.38}$$

Assume that one of the following three cases holds:

1. $\delta_b \geq \delta_a \geq \gamma_1$;
2. $\gamma_{n-1} \geq \delta_b \geq \delta_a$;
3. $\gamma_j \geq \delta_j \geq \delta_b \geq \delta_a \geq \gamma_{j+1}$ *for some* j, $1 \geq j \geq n-2$.

Then there exists a real $n \times n$ *matrix of the form*

$$A = \begin{bmatrix} D & \eta \\ -\eta^t & t \end{bmatrix},$$

such that $D = \operatorname{diag}(\gamma_1, \gamma_2, \ldots, \gamma_{n-1})$ *and such that the spectrum of* A *is* $\{\delta_1, \ldots, \delta_{n-1}\} \cup \{\delta_b, \delta_a\}$.

Proof. The characteristic equation of A is given by

$$\det(\lambda I - A) = \prod_{i=1}^{n-1} (\lambda - \gamma_i) \left[\lambda - t + \sum_{j=1}^{n-1} \left(\frac{\eta_j^2}{\lambda - \gamma_j} \right) \right] = 0. \tag{4.39}$$

We need to choose η and t so that the numbers δ_i, $i = 1, \ldots, n$, are the roots of (4.39), where with some abuse of notation, we refer to δ_b, δ_a as δ_{n-1}, δ_n. First suppose that the δ_i are distinct. Let

$$f(\lambda) = \prod_{i=1}^{n} (\lambda - \delta_i), \qquad g(\lambda) = \prod_{i=1}^{n-1} (\lambda - \gamma_i).$$

By direct verification, or by Lagrange's interpolation formula, we have

$$\frac{f(\lambda)}{g(\lambda)} = \lambda - \left(\sum_{i=1}^{n} \delta_i - \sum_{i=1}^{n-1} \gamma_i \right) + \sum_{k=1}^{n-1} \frac{f(\gamma_k)}{g'(\gamma_k)} \frac{1}{(\lambda - \gamma_k)}. \tag{4.40}$$

Due to the near-interlacing in case 1, that is, when $\delta_b \geq \delta_a \geq \gamma_1$ (or $\delta_{n-1} \geq \delta_n \geq \gamma_1$), we have

$$\begin{aligned} f(\gamma_k) &= \prod_{i=n-1}^{n} (\gamma_k - \delta_i) \prod_{i=1}^{k-1} (\gamma_k - \delta_i) \prod_{i=k}^{n-2} (\gamma_k - \delta_i) \\ &= (-1)^2 \prod_{i=n-1}^{n} |\gamma_k - \delta_i| (-1)^{k-1} \prod_{i=1}^{k-1} |\gamma_k - \delta_i| \prod_{i=k}^{n-2} (\gamma_k - \delta_i) \\ &= (-1)^{k-1} \prod_{i=1}^{n} |\gamma_k - \delta_i| \end{aligned}$$

and

$$g'(\gamma_k) = (-1)^{k-1} \prod_{\substack{i=1 \\ i \neq k}}^{n-1} |\gamma_k - \gamma_i|.$$

It follows that

$$\frac{f(\gamma_k)}{g(\gamma_k)} \geq 0, \quad k = 1, 2, \ldots, n-1.$$

Similarly, this can be shown to hold in the other two cases as well.

Now choose

$$\eta_k^2 = \frac{f(\gamma_k)}{g'(\gamma_k)}, \qquad k = 1, 2, \ldots, n$$

and

$$t = \sum_{i=1}^{n} \delta_i - \sum_{i=1}^{n-1} \gamma_i.$$

Then the eigenvalues of A are the roots of $f(\cdot)$, which are the n values δ_i. (A modification of the proof yields the case of nondistinct δ_i.) □

Remark 4.3. In [11], A. Horn proved the following inverse eigenvalue result, which may be viewed as a converse to Theorem 4.4.

If we are given real numbers

$$a_{11} \geq a_{22} \geq \cdots \geq a_{nn}$$

and

$$\delta_1 \geq \delta_2 \geq \cdots \geq \delta_n,$$

such that the majorization (4.33) holds, then there exists an $n \times n$ real symmetric matrix A with diagonal elements $a_{11}, a_{22}, \ldots, a_{nn}$ and with eigenvalues $\delta_1, \delta_2, \ldots, \delta_n$.

One proof of Horn's theorem is due to Mirsky [17], and relies on Theorem 4.6. (See also Theorem 9.B.2 in [15].) Hence it seems apppropriate to ask whether one can obtain analogous converses to Theorem 4.5 or Corollary 4.1 by utilizing Theorem 4.7. At the present time, this remains an open problem.

Remark 4.4. In this subsection we have seen that known results for symmetric matrices regarding interlacing and majorization can be extended, under certain conditions, to "near-symmetric" matrices, i.e., matrices of the form (3.19). This was possible because these extensions depended more on the realness of the spectrum than on symmetry per se. Other results in the literature regarding symmetric matrices can also be extended to the near-symmetric case by employing the present work; e.g., results on eigenvalue bounds appearing in Wolkowicz and Styan [25].

Acknowledgment. The authors wish to thank Q. Ye for pointing out reference [13].

THE GENERALIZED ORDER LINEAR COMPLEMENTARITY PROBLEM*

M. SEETHARAMA GOWDA† AND ROMAN SZNAJDER†

Abstract. The generalized order linear complementarity problem (in the setting of a finite dimensional vector lattice) is the problem of finding a solution to the piecewise-linear system

$$x \wedge (M_1 x + q_1) \wedge (M_2 x + q_2) \wedge \cdots \wedge (M_k x + q_k) = 0,$$

where M_i's are linear transformations and q_i's are vectors. This problem is equivalent to the generalized linear complementarity problem considered by Cottle and Dantzig [*J. Combin. Theory*, 8 (1970), pp. 79–90.]. Using degree theory, a comprehensive analysis of existence, uniqueness, and stability aspects of this problem is presented.

Key words. order complementarity problem, piecewise-linear function, block transformations, type

AMS subject classifications. 90C33, 47H11, 46A40

1. Introduction.

For a given matrix $M \in R^{n\times n}$ and a vector $q \in R^n$, the (classical) linear complementarity problem, LCP(M, q), is to find a vector $x \in R^n$ such that

$$x \geq 0, \quad Mx + q \geq 0, \quad \text{and} \quad x^T (Mx + q) = 0. \tag{1}$$

The importance of this problem is well documented in the literature (see, e.g., [40] and [5]).

The above formulation of the LCP deals with the nonnegative orthant R^n_+ and the usual inner product. A generalization of the above problem, appropriately called the topological complementarity problem in [2], deals with a Hilbert space and a closed convex cone. This generalized problem has been well studied in the literature (see, e.g., [1], [7], [28]).

LCP(M, q) can be formulated equivalently as an equation: find x such that

$$x \wedge (Mx + q) = 0, \tag{2}$$

where $x \wedge (Mx + q) = (\min \{x_i, (Mx + q)_i\})$. This is an instance of an order complementarity problem (OCP). Since topology plays no role in this formulation, it is possible to define a generalization of this problem in the setting of a vector lattice. To define this generalization, consider a vector lattice X; that is, X is an ordered vector space in which for any two elements x and y, $x \wedge y = \min \{x, y\}$ and $x \vee y = \max \{x, y\}$ are defined [44]. Corresponding to any function $f : X \to X$, the OCP(f) is to find a vector x in X such that

$$x \wedge f(x) = 0. \tag{3}$$

Interesting results have been obtained in this general setting [1], [2], [18], and [19]. However, it is the mixing of topological and order structures that has yielded more (and perhaps better) results [7], [39], [46].

The subject matter of our article is concerned with OCP(f) when f is a minimum of a finite number of affine functions. To be specific, let k be any natural number. Given k linear transformations $M_1, M_2, \ldots, M_k$ from X into itself and k vectors $q_1, q_2, \ldots, q_k$ in X, we write,

$$\mathbf{M} = (M_1, M_2, \ldots, M_k) \quad \text{and} \quad \mathbf{q} = (q_1, q_2, \ldots, q_k). \tag{4}$$

Then the generalized order linear complementarity problem GOLCP($\mathbf{M}, \mathbf{q}$) is to find a vector x in X such that

$$x \wedge (M_1 x + q_1) \wedge (M_2 x + q_2) \wedge \cdots \wedge (M_k x + q_k) = 0. \tag{5}$$

For $k = 1$, this problem was methodically analyzed by Borwein and Dempster [2]. Relying heavily on the order structure, they were able to get many existence results. They showed by an infinite dimensional example why uniqueness (of solution) for every solvable $\mathbf{q}$ does not assert the solvability of all $\mathbf{q}$'s. We show in this article that when X is finite dimensional, as in the classical situation, uniqueness for every solvable $\mathbf{q}$ implies the solvability of every $\mathbf{q}$. In fact, as in the classical situation, we tie this property to certain $\mathbf{P}$-matrices.

Of special importance is when X is the Euclidean space R^n with the usual ordering. It is shown in §6 that the above GOLCP is equivalent to the generalized linear complementarity problem (henceforth called the vertical linear complementarity problem (VLCP), as in [5]) considered by Cottle and Dantzig [4], who established basic existence results via (a modification of) Lemke's algorithm. The uniqueness aspect for the VLCP was considered by Szanc [53]. In recent times, a number of articles dealing with GOLCP (and equivalently, VLCP) have been written [14], [15], [17], [31].

Working still in the Euclidean space R^n with the usual order, we obtain a general problem when x appearing at the beginning of the expression (5) is replaced by an affine function. The resulting piecewise-linear system is an extended GOLCP: find $x \in R^n$ such that

$$(M_0 x + q_0) \wedge (M_1 x + q_1) \wedge (M_2 x + q_2) \wedge \cdots \wedge (M_k x + q_k) = 0. \tag{6}$$

It is clear that if M_0 is invertible, then (6) can be formulated as a GOLCP. This system occurs in certain nonlinear networks [20], [21] and in control theory [50], [51]. Eaves [10] gives a complementary pivoting algorithm to solve the piecewise-linear system (6), and Pang [43] studies this system by formulating it as an implicit complementarity problem. The general problem was also studied by Mangasarian [37], who established the equivalence of this to a certain linear programming problem. A sufficient condition for uniqueness in the extended GOLCP was provided by Isac and Goeleven [31]. We say more about the extended GOLCP in §7.

Our main object in this article is to give a comprehensive analysis of existence, uniqueness, and stability issues connected with the GOLCP. Traditionally, the existence results in the LCP theory are derived via the basic theorem of complementarity [25]. This basic theorem itself is obtained via the theorem of Hartman–Stampacchia on variational inequalities. It is not clear to the authors whether GOLCP can be formulated as a variational inequality problem. As we see, the degree theory approach allows us to prove existence results directly and under relaxed assumptions. Degree theory plays an important role in stability results as well. Some of the results proved in this paper are new even in the LCP setting.

Here is a brief description of various sections. In §3, we introduce block transformations of various types and prove existence results in a general setting. Section

4 deals with the corresponding uniqueness results. Section 5 deals with the stability aspects. In §6, we deal with the usual ordering on R^n and show the equivalence of the GOLCP with the generalized LCP of Cottle and Dantzig. Furthermore, in various subsections of §6, we show how to recover the results of Cottle–Dantzig, Szanc, Ebiefung–Kostreva, and others. Finally, in §7, we deal with the extended GOLCP and completely characterize uniqueness in such problems.

2. Preliminaries. Throughout this paper, we assume that X is a finite dimensional vector lattice. This means that there is a closed convex cone K that induces the order on X: for any two elements x and y, $x \leq y$ if and only if $y - x \in K$ and $x \vee y := \max\{x, y\}$ and $x \wedge y := \min\{x, y\}$ exist in X. Although X is isomorphic to R^n with the usual ordering (cf. [44, Prop., p. 9]), to simplify the notation (and with possible generalizations to infinite dimensional spaces in mind), we work with X and its ordering. The reader can refer to [44] or [36] for properties of order and lattice on a vector space. Let $\mathbf{Y}$ denote the Cartesian product of k copies of X, that is, $\mathbf{Y} = \prod_1^k X$. Because X and $\mathbf{Y}$ are finite dimensional, we may suppose that they have norms defined on them; we denote both norms by the same symbol $\|\cdot\|$. Let $\mathcal{B}$ denote the open unit ball in X. Since $x = x^+ - x^-$ where $x^+ = \max\{x, 0\}$ and $x^- = \max\{-x, 0\}$, we see that $X = K - K$, and so by convex analysis [49], the interior of K is nonempty. To indicate that an element d of X belongs to the interior of K, we use the notation $d \succ 0$. (While dealing with the usual ordering, we use the standard notation $d > 0$ instead of $d \succ 0$. Note, however, that the notation $d > 0$ in the context of a general vector lattice means that $d \geq 0$ and $d \neq 0$ [44].) For a $\mathbf{d} = (d_1, d_2, \ldots, d_k) \in \mathbf{Y}$, we write $\mathbf{d} \succ \mathbf{0}$ when $d_i \succ 0$ for all i and write $\mathbf{d} \geq 0$ when $d_i \geq 0$ for all i. In what follows, $\mathbf{M}$ and $\mathbf{q}$ are given by (4). For brevity, we write

$$x \wedge (\mathbf{M}x + \mathbf{q}) := x \wedge (M_1 x + q_1) \wedge (M_2 x + q_2) \wedge \cdots \wedge (M_k x + q_k),$$

$$x \wedge \mathbf{M}x := x \wedge M_1 x \wedge M_2 x \wedge \cdots \wedge M_k x \quad \text{and} \quad x \vee \mathbf{M}x := x \vee M_1 x \vee M_2 x \vee \cdots \vee M_k x.$$

We use the notation $\mathbf{M}x + \mathbf{q} \geq 0$ ($\succ 0$) to mean $M_i x + q_i \geq 0$ (respectively, $\succ 0$) for all $i = 1, 2, \ldots, k$. A vector x with $x \geq 0, \mathbf{M}x + \mathbf{q} \geq 0$ ($\succ 0$) is called a *feasible* (respectively, *strictly feasible*) vector for GOLCP$(\mathbf{M}, \mathbf{q})$. If there is such a vector, we say that GOLCP$(\mathbf{M}, \mathbf{q})$ is feasible (respectively, strictly feasible). Let

$$\mathcal{F}(\mathbf{M}) = \{\mathbf{q} : \mathbf{M}x + \mathbf{q} \geq 0 \text{ for some } x \geq 0\} \quad \text{and} \quad \mathcal{K}(\mathbf{M}) = \{\mathbf{q} : \mathrm{SOL}(\mathbf{M}, \mathbf{q}) \neq \emptyset\},$$

where SOL$(\mathbf{M}, \mathbf{q})$ denotes the solution set of GOLCP$(\mathbf{M}, \mathbf{q})$.

Borrowing the terminology from the LCP theory, we say that these sets are, respectively (when $\mathbf{M}$ is fixed), the set of all "feasible" $\mathbf{q}$'s and "solvable" $\mathbf{q}$'s. Note that $\mathcal{F}(\mathbf{M})$ is closed, convex, and

$$\operatorname{int} \mathcal{F}(\mathbf{M}) = \{\mathbf{q} : \mathbf{M}x + \mathbf{q} \succ 0 \text{ for some } x \geq 0\}.$$

3. Existence results. As in the LCP theory, our existence results deal with classes of (block) transformations $\mathbf{M}$. Motivated by the LCP theory, we introduce the following definition.

DEFINITION 1. *We say that* $\mathbf{M}$ *is of*

1. type $\mathbf{R}_0$ *if* $x \wedge \mathbf{M}x = 0 \Longrightarrow x = 0$;
2. type $\mathbf{G}$ *if for some* $\mathbf{d} \succ \mathbf{0}, \mathrm{SOL}(\mathbf{M}, \mathbf{d}) = \{0\}$;
3. type $\mathbf{R}$ *if it is of* type $\mathbf{R}_0$ *and* type $\mathbf{G}$;
4. type $\mathbf{E}$ *if* $x \geq 0, x \wedge \mathbf{M}x \leq 0 \Longrightarrow x = 0$;

5. type $\mathbf{P}$ *if* $x \wedge \mathbf{M}x \leq 0 \leq x \vee \mathbf{M}x \Longrightarrow x = 0$;
6. type $\mathbf{Q}$ *if for every* $\mathbf{q}$, GOLCP($\mathbf{M}$, $\mathbf{q}$) *has a solution*;
7. type $\mathbf{Q}_0$ *if* $\mathcal{F}(\mathbf{M}) \subseteq \mathcal{K}(\mathbf{M})$.

Remarks. We use the same symbol to denote the class of $\mathbf{M}$'s of a given type. For example, type $\mathbf{Q}$ denotes the set of all $\mathbf{M}$'s which are of type $\mathbf{Q}$. When X is R^n with the usual ordering and $k = 1$, the definitions 1, 2, 3, 6, and 7, reduce, respectively, to those of $\mathbf{R}_0$-matrices, $\mathbf{G}$-matrices, $\mathbf{R}$-matrices, $\mathbf{Q}$-matrices, and $\mathbf{Q}_0$-matrices [5]; definitions 4 and 5 reduce to those of strictly semimonotone and $\mathbf{P}$-matrices, respectively (see Theorems 3 and 4 below).

To illustrate the above definitions, we give two examples dealing with R^2 and the usual ordering. More examples are given in §6.

Example 1. Let $\mathbf{M} = (M_1, M_2)$ where

$$M_1 = \begin{bmatrix} 0 & 1 \\ 1 & 1 \end{bmatrix}, \qquad M_2 = \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix}.$$

It is easily verified that $\mathbf{M}$ is of type $\mathbf{R}_0$. Note that neither M_1 nor M_2 is an $\mathbf{R}_0$-matrix.

Example 2. Let $\mathbf{M} = (M_1, M_2)$ where

$$M_1 = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}, \qquad M_2 = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}.$$

It is easily verified that $\mathbf{M}$ is of type $\mathbf{E}$ and hence of types $\mathbf{R}$ and $\mathbf{R}_0$ by Proposition 1 below.

PROPOSITION 1. type $\mathbf{P} \subseteq$ type $\mathbf{E} \subseteq$ type $\mathbf{R} \subseteq$ type $\mathbf{R}_0$.

Proof. If $x \geq 0$, then for any vector $y, 0 \leq x \vee y$. This observation shows that type $\mathbf{P} \subseteq$ type $\mathbf{E}$. Since $x \geq 0$ and $x \wedge \mathbf{M}x \leq 0$ when $x \wedge (\mathbf{M}x + t\mathbf{d}) = 0, t \in R_+, \mathbf{d} \succ 0$, we have the inclusion type $\mathbf{E} \subseteq$ type $\mathbf{R}$. The last inclusion type $\mathbf{R} \subseteq$ type $\mathbf{R}_0$ follows from the definition. □

Corresponding to the problem GOLCP($\mathbf{M}, \mathbf{q}$), we define two functions $F_{(\mathbf{M},\mathbf{q})}$ and $F_{\mathbf{M}}$ by

$$F_{(\mathbf{M},\mathbf{q})}(x) = x \wedge (\mathbf{M}x + \mathbf{q}) \quad \text{and} \quad F_{\mathbf{M}}(x) = x \wedge \mathbf{M}x.$$

We see that the problem GOLCP($\mathbf{M}, \mathbf{q}$) can be formulated as an equation $F_{(\mathbf{M},\mathbf{q})}(x) = 0$. It is now possible to study the GOLCP using degree theory. Suppose that $\mathbf{M}$ is of type $\mathbf{R}_0$ so that the zero vector is the only solution of $F_{\mathbf{M}}(x) = 0$. Let Ω be any bounded open set in X containing the zero vector. Then the integer $\deg(F_{\mathbf{M}}, \Omega, 0)$ (the degree of $F_{\mathbf{M}}$ over Ω relative to zero) is defined [35]. Furthermore, this is independent of the bounded open set Ω. We call this integer the GOLCP-degree of $\mathbf{M}$ and denote it by GOLCP-deg $\mathbf{M}$.

We remark that in the context of the (classical) LCP, the GOLCP-degree (simply called the LCP-degree) of an $\mathbf{R}_0$-matrix M can also be computed by using the mapping $x \mapsto x^+ - Mx^-$ [5, Chap. 6], [12].

Before stating our first existence result, we give a necessary and sufficient condition for boundedness of SOL ($\mathbf{M}, \mathbf{q}$) for all $\mathbf{q}$. We omit the proof as it is identical to the one in the classical case. Note that the solution set SOL ($\mathbf{M}, \mathbf{q}$) may be empty for some particular $\mathbf{q}$.

PROPOSITION 2. $\mathbf{M}$ *is of* type $\mathbf{R}_0$ *if and only if for all* $\mathbf{q}$, SOL ($\mathbf{M}$, $\mathbf{q}$) *is bounded.*

Remark. When $\mathbf{M}$ is of type $\mathbf{R}_0$, it is easily seen that the solution sets of GOLCP($\mathbf{M}, \mathbf{q}$) are uniformly bounded as $\mathbf{q}$ varies over a bounded set in $\mathbf{Y}$.

Here is our first existence result.

THEOREM 1. *Suppose that* $\mathbf{M}$ *is of* type $\mathbf{R}_0$ *and* GOLCP-degree *of* $\mathbf{M}$ *is nonzero. Then* $\mathbf{M}$ *is of type* $\mathbf{Q}$.

Proof. Let $\mathbf{q}$ be arbitrary. For any t in the interval [0, 1], consider

$$F_{(\mathbf{M},t\mathbf{q})}(x) = x \wedge (\mathbf{M}x + t\mathbf{q}).$$

In view of the remark above, the set $\{x : F_{(\mathbf{M},t\mathbf{q})}(x) = 0 \text{ for some } t \in [0,1]\}$ is bounded in X and hence contained in some bounded open set, say, Ω. Note that $F_{(\mathbf{M},t\mathbf{q})}$ is a homotopy connecting the mappings $F_{(\mathbf{M},\mathbf{q})}$ and $F_{\mathbf{M}}$. Using the homotopy invariance property of the degree [35, Thm. 2.1.2], we see that $\deg(F_{(\mathbf{M},\mathbf{q})}, \Omega, 0) = \deg(F_{\mathbf{M}}, \Omega, 0) =$ GOLCP-deg$\mathbf{M}$. Since this last integer is assumed to be nonzero, by the well-known property of the degree [35, Thm. 2.1.1], the equation $F_{(\mathbf{M},\mathbf{q})}(x) = 0$ has a solution in Ω, i.e., GOLCP$(\mathbf{M}, \mathbf{q})$ has a solution. Since $\mathbf{q}$ is arbitrary, the result follows. □

Our next result is the GOLCP analog of Karamardian's result [33] for regular matrices. Karamardian based his proof on an existence theorem of Hartman–Stampacchia on variational inequalities, which in turn is based on the Brouwer fixed point theorem. The proof of our result below is based on degree theory.

THEOREM 2. *Suppose that* $\mathbf{M}$ *is of* type $\mathbf{R}$. *Then its* GOLCP-degree *is one and hence it is of* type $\mathbf{Q}$. *In particular, if* $\mathbf{M}$ *is of* type $\mathbf{P}$ *or of* type $\mathbf{E}$, *then it is of* type $\mathbf{Q}$.

Proof. For t in the interval [0, 1], consider

$$F_{(\mathbf{M},t\mathbf{d})}(x) = x \wedge (\mathbf{M}x + t\mathbf{d}),$$

where $\mathbf{d}$ is as in the definition of the class type $\mathbf{R}$. As in the proof of the previous theorem, we have GOLCP-deg $\mathbf{M} = \deg(F_{\mathbf{M}}, \Omega, 0) = \deg(F_{(\mathbf{M},\mathbf{d})}, \Omega, 0)$, where Ω is any bounded open set containing zero. Since $\mathbf{d} \succ 0$, we have for all x near zero, $\mathbf{M}x + \mathbf{d} \succ 0$ and $F_{(\mathbf{M},\mathbf{d})}(x) = x$. This implies that $\deg(F_{\mathbf{M}}, \Omega, 0) = 1$; cf. [35, Thm. 1.1.4]. Now Theorem 1 completes the proof. □

4. Uniqueness results. The following theorem characterizes uniqueness in GOLCPs. Another equivalent characterization using $\mathbf{P}$-matrices is given in §6.

THEOREM 3. *The following statements are equivalent*:

(a) $\mathbf{M}$ *is of* type $\mathbf{P}$;

(b) *for every* $\mathbf{q}$, GOLCP$(\mathbf{M}, \mathbf{q})$ *has at most one solution*;

(c) *for every* $\mathbf{q}$, GOLCP$(\mathbf{M}, \mathbf{q})$ *has exactly one solution*;

Proof. The proof of the equivalence (a) $\iff$ (b) is standard (see, e.g., [2, Thm. 2.14]); for the sake of completeness, we include a proof. Assume (a). If x and y are two solutions of GOLCP$(\mathbf{M}, \mathbf{q})$, then with $z = x - y$, we easily verify that

$$z \wedge \mathbf{M}z \leq 0 \leq z \vee \mathbf{M}z, \tag{7}$$

which, in view of (a) gives $z = 0$. Hence, (a) $\Longrightarrow$ (b). Now suppose that (a) fails to hold. Let $z \neq 0$ satisfy (7). Define $\mathbf{q}$ by $q_j = (M_j z)^+ - M_j(z^+)$ $(j = 1, 2, \ldots, k)$ and note that $q_j = (M_j z)^- - M_j(z^-)$ $(j = 1, 2, \ldots, k)$. Since (7) is equivalent to $z^+ \wedge (M_1 z)^+ \wedge \cdots \wedge (M_k z)^+ = 0 = z^- \wedge (M_1 z)^- \wedge \cdots \wedge (M_k z)^- = 0$, we see that z^+ and z^- are two (distinct) solutions of GOLCP$(\mathbf{M}, \mathbf{q})$ contradicting (b). Hence, (b) $\Longrightarrow$ (a). Clearly, (c) $\Longrightarrow$ (b) $\Longrightarrow$ (a). From the implication (a) $\Longrightarrow$ (b) and Theorem 2, we get (a) $\Longrightarrow$ (c). This completes the proof. □

Remarks. As pointed out in the proof, the implication (a) $\Longrightarrow$ (b) was proved by Borwein and Dempster. They also give an example to show that in the infinite dimensional setting, the converse (b) $\Longrightarrow$ (a) is false.

THEOREM 4. *The following statements are equivalent:*

(a) $\mathbf{M}$ *is of* type $\mathbf{E}$;

(b) *For every* $\mathbf{q} \geq \mathbf{0}$, *the zero vector is the only solution* GOLCP$(\mathbf{M}, \mathbf{q})$.

Proof. Suppose (a) holds and x is a solution of GOLCP$(\mathbf{M}, \mathbf{q})$ where $\mathbf{q} \geq \mathbf{0}$. It follows that $x \geq 0$ and $x \wedge (\mathbf{M}x) \leq x \wedge (\mathbf{M}x + \mathbf{q}) = 0$. We see that $x = 0$. On the other hand, suppose (b) holds and let z be a solution of the system $z \geq 0, z \wedge \mathbf{M}z \leq 0$. Then z is a solution of GOLCP$(\mathbf{M}, \mathbf{q})$ where $\mathbf{q}$ is defined by $q_j = (M_j z)^+ - (M_j z)$ $(j = 1, 2, \ldots, k)$. Since $\mathbf{q} \geq \mathbf{0}$, we get $z = 0$. □

In the classical LCP theory, statement (b) in Theorem 4 describes strictly semimonotone matrices (defined by the condition: for all $0 \neq x \geq 0$, there is an index i such that $x_i(Mx)_i > 0$). Analogous to the classes of semimonotone matrices and $\mathbf{P}_0$-matrices, we introduce two classes of block transformations $\mathbf{M}$. Let I denote the identity mapping on X and let

$$\mathbf{M} + \varepsilon\mathbf{I} := (M_1 + \varepsilon I, M_2 + \varepsilon I, \ldots, M_k + \varepsilon I).$$

We say that $\mathbf{M}$ is of type $\mathbf{E}_0$ ($\mathbf{P}_0$) if $\mathbf{M} + \varepsilon\mathbf{I}$ is of type $\mathbf{E}$ (respectively, type $\mathbf{P}$) for every $\varepsilon > 0$. It is clear from Theorems 3 and 4 that type $\mathbf{P}_0 \subseteq$ type $\mathbf{E}_0$. We have the following theorem.

THEOREM 5. *Consider the statements:*

(a) $\mathbf{M}$ *is of* type $\mathbf{E}_0$;

(b) *for every* $\mathbf{q} \succ \mathbf{0}$, *the zero vector is the only solution of* GOLCP$(\mathbf{M},\mathbf{q})$.

Then (a) $\Longrightarrow$ (b).

Remark. We show in §6.3 that the reverse implication (b) $\Longrightarrow$ (a) holds when X is R^n with the usual ordering. Isomorphism considerations then allow us to get the reverse implication in the general case as well.

Proof. Suppose $\mathbf{q} \succ \mathbf{0}$ and $x \wedge (\mathbf{M}x + \mathbf{q}) = 0$. Let $\mathbf{x} := (x, x, \ldots, x)$ and $\varepsilon > 0$ be small so that $\mathbf{q} - \varepsilon\mathbf{x} \succ \mathbf{0}$. Then $x \geq 0$ and $x \wedge (\mathbf{M}x + \varepsilon x) \leq x \wedge (\mathbf{M}x + \mathbf{q}) = 0$, which implies that $x = 0$ in view of (a). □

Remark. The above theorem shows that type $\mathbf{E}_0 \subseteq$ type $\mathbf{G}$ and therefore type $\mathbf{E}_0 \cap$ type $\mathbf{R}_0 \subseteq$ type $\mathbf{R}$.

5. Stability. In the stability aspect of GOLCP, we are interested in the solution behavior as the data changes. First, we deal with the behavior of the entire solution set. In the definition below, $\|\mathbf{M}\|$ refers to the norm of $\mathbf{M}$ as a linear operator from $\mathbf{Y}$ into itself; however, we can use any norm.

DEFINITION 2. *The problem* GOLCP$(\mathbf{M}, \mathbf{q})$ *is said to be stable if for every* $\varepsilon > 0$ *there exists a* $\delta > 0$ *such that*

$$\mathrm{SOL}\,(\mathbf{M}', \mathbf{q}') \cap (\mathrm{SOL}(\mathbf{M}, \mathbf{q}) + \varepsilon\mathcal{B}) \neq \emptyset$$

for all $(\mathbf{M}', \mathbf{q}')$ *with* $\|\mathbf{M}' - \mathbf{M}\| + \|\mathbf{q}' - \mathbf{q}\| < \delta$.

The following theorem is the basis of our stability analysis.

THEOREM 6. *Suppose that* SOL$(\mathbf{M}, \mathbf{q})$ *is nonempty and bounded. Suppose that for some open set* Ω *containing* SOL$(\mathbf{M}, \mathbf{q})$, $\deg(F_{(\mathbf{M},\mathbf{q})}, \Omega, 0)$ *is nonzero. Then* GOLCP$(\mathbf{M}, \mathbf{q})$ *is stable.*

Proof. For any given ε, we consider the open set $\mathcal{D} = \mathrm{SOL}(\mathbf{M}, \mathbf{q}) + \varepsilon\mathcal{B}$. Without loss of generality, we can assume that $\mathcal{D} \subset \Omega$. Since there are no solutions of

$F_{(\mathbf{M},\mathbf{q})}(x) = 0$ in $\Omega \setminus \mathcal{D}$, by the excision property of the degree, we have deg $(F_{(\mathbf{M},\mathbf{q})}, \mathcal{D}, 0) = \deg\,(F_{(\mathbf{M},\mathbf{q})}, \Omega, 0) \neq 0$. Now for a suitable $\delta > 0$, we have

$$\sup_{\mathcal{D}} \left\| F_{(\mathbf{M},\mathbf{q})}\,(x) - F_{(\mathbf{M}',\mathbf{q}')}\,(x) \right\| < \operatorname{dist}\left(0, F_{(\mathbf{M},\mathbf{q})}\,(\partial D)\right)$$

for all $(\mathbf{M}', \mathbf{q}')$ with $\|\mathbf{M}' - \mathbf{M}\| + \|\mathbf{q}' - \mathbf{q}\| < \delta$. By the nearness property of the degree [35, Thm. 2.1.2], $\deg(F_{(\mathbf{M}',\mathbf{q}')}, \mathcal{D}, 0) = \deg(F_{(\mathbf{M},\mathbf{q})}, \mathcal{D}, 0) \neq 0$. Hence, the equation $F_{(\mathbf{M}',\mathbf{q}')}(x) = 0$ has a solution in $\mathcal{D}$. The stated conclusion follows. □

To illustrate the above theorem as well as for future reference, we formulate a definition. We say that $\mathbf{M}$ is of type $\mathbf{D}$ if there is a $\mathbf{d}$ such that (a) $\mathrm{SOL}(\mathbf{M}, \mathbf{d})$ is nonempty and bounded, and (b) $\deg(F_{(\mathbf{M},\mathbf{d})}, \Omega, 0) \neq 0$, where Ω is some bounded open set containing $\mathrm{SOL}(\mathbf{M}, \mathbf{d})$.

Note that these two conditions imply the stability of $\mathrm{GOLCP}(\mathbf{M}, \mathbf{d})$. In particular, when $\mathbf{M}$ is of type $\mathbf{D}$, the vector $\mathbf{d}$ that appears in the definition of $\mathbf{D}$ is necessarily in the interior of $\mathcal{F}(\mathbf{M})$. Now recall that $\mathbf{M}$ is of type $\mathbf{G}$ if there is a $\mathbf{d} \succ 0$ such that $\mathrm{SOL}(\mathbf{M}, \mathbf{d}) = \{0\}$. It follows that for such an $\mathbf{M}, F_{(\mathbf{M},\mathbf{d})}(x) = x$ for all x near the zero vector. So, $\deg(F_{(\mathbf{M},\mathbf{d})}, \Omega, 0) = 1$ where Ω is any bounded open set containing the zero vector in R^n. This establishes the inclusion type $\mathbf{G} \subseteq$ type $\mathbf{D}$.

The theorem given below is new even in the classical LCP theory. For positive semidefinite matrices, this result was proved in the LCP setting by Robinson [47] via generalized equations and maximal monotone multifunctions. Using degree theory, Gowda and Pang presented various generalizations of Robinson's result for the affine variational inequality problem [27]. As we see below, the Gowda–Pang analysis goes through even for GOLCP.

THEOREM 7. *Let* $\mathbf{M}$ *be of* type $\mathbf{P}_0$ *and* $\mathrm{SOL}(\mathbf{M}, \mathbf{q})$ *be nonempty and bounded. Then* $\mathrm{GOLCP}(\mathbf{M}, \mathbf{q})$ *is stable.*

Proof. Let Ω be a bounded open set in X containing $\mathrm{SOL}(\mathbf{M}, \mathbf{q})$. Let $x^* \in \mathrm{SOL}(\mathbf{M}, \mathbf{q})$. For any t with $0 \leq t \leq 1$, define $(\mathbf{M}_t, \mathbf{q}_t)$ by

$$\mathbf{M}_t = \mathbf{M} + t\mathbf{I}, \qquad \mathbf{q}_t = \mathbf{q} - t\mathbf{x}^*,$$

where $\mathbf{x}^* := (x^*, x^*, \ldots, x^*)$. Then for $t > 0, x^* \in \mathrm{SOL}(\mathbf{M}_t, \mathbf{q}_t)$ and $\mathbf{M}_t$ is of type $\mathbf{P}$. Therefore, $\mathrm{SOL}(\mathbf{M}_t, \mathbf{q}_t) = \{x^*\}$ for all $t > 0$. Clearly, we have a homotopy between $(\mathbf{M}, \mathbf{q})$ and $(\mathbf{M}_1, \mathbf{q}_1)$. Hence, $\deg(F_{(\mathbf{M},\mathbf{q})}, \Omega, 0) = \deg(F_{(\mathbf{M}_1,\mathbf{q}_1)}, \Omega, 0)$. Since $\mathbf{M}_1$ is of type $\mathbf{P}$, it is of type $\mathbf{R}$ by Proposition 1. By Theorem 2, its GOLCP-degree is one. By following the proof of Theorem 1, we see that $\deg(F_{(\mathbf{M}_1,\mathbf{q}_1)}, \Omega, 0) = 1$. Therefore, $\deg(F_{(\mathbf{M},\mathbf{q})}, \Omega, 0) \neq 0$. Now the stability follows from the previous theorem. □

We now formulate the definition of stability at a solution point.

DEFINITION 3. *Let* x^* *be a solution of* $\mathrm{GOLCP}(\mathbf{M}, \mathbf{q})$. *The problem* $\mathrm{GOLCP}(\mathbf{M}, \mathbf{q})$ *is said to be stable at* x^* *if* x^* *is an isolated solution of* $\mathrm{GOLCP}(\mathbf{M}, \mathbf{q})$ *and for every* $\varepsilon > 0$ *there exists a* $\delta > 0$ *such that*

$$\mathrm{SOL}\,(\mathbf{M}', \mathbf{q}') \cap (x^* + \varepsilon\mathcal{B}) \neq \emptyset$$

for all $(\mathbf{M}', \mathbf{q}')$ *with* $\|\mathbf{M}' - \mathbf{M}\| + \|\mathbf{q}' - \mathbf{q}\| < \delta$.

In the case of the classical LCP, the stability at a solution point is fairly well understood [23]–[26], [29], [30]. Here, we present a result for GOLCP. By modifying the proofs of Theorems 6 and 7, we are led to the following. We omit the details.

THEOREM 8. *Suppose that* x^* *is an isolated solution of* $\mathrm{GOLCP}(\mathbf{M}, \mathbf{q})$. *Suppose that there is a bounded open set* Ω *containing only one solution of* $\mathrm{GOLCP}(\mathbf{M}, \mathbf{q})$, *namely,* x^* *and* $\deg(F_{(\mathbf{M},\mathbf{q})}, \Omega, 0)$ *is nonzero. Then* $\mathrm{GOLCP}(\mathbf{M}, \mathbf{q})$ *is stable at* x^*.

THEOREM 9. *Let* $\mathbf{M}$ *be of type* $\mathbf{P}_0$ *and let* x^* *be an isolated solution of* GOLCP$(\mathbf{M}, \mathbf{q})$. *Then* GOLCP$(\mathbf{M}, \mathbf{q})$ *is stable at* x^*.

An interesting consequence can be obtained from the above theorem. Suppose that $\mathbf{M}$ is of type $\mathbf{P}_0$ and there are two isolated solutions, say, x^* and y^* for GOLCP$(\mathbf{M}, \mathbf{q})$. From the above theorem, GOLCP$(\mathbf{M}, \mathbf{q})$ is stable at both the solutions. But if $\mathbf{M}$ is perturbed to $\mathbf{M}'$, which is of type $\mathbf{P}$, then the problem GOLCP$(\mathbf{M}', \mathbf{q})$ must have solutions near x^* as well as y^*. This clearly contradicts the uniqueness property of $\mathbf{M}'$. We conclude that for GOLCP$(\mathbf{M}, \mathbf{q})$, there can be at most one isolated solution. This means that *when* $\mathbf{M}$ *is of type* $\mathbf{P}_0$ *and* $\mathbf{q}$ *is arbitrary,* SOL$(\mathbf{M}, \mathbf{q})$ *either is empty, or a singleton set, or an infinite set.*

In the LCP setting, Theorem 9 reduces to a result of Gowda [23]. In [26], Gowda and Pang generalize this LCP result by imposing a condition only on a submatrix of the given matrix. Such a detailed analysis is certainly possible for GOLCP and is dealt with elsewhere.

6. Results for R^n with the usual ordering. In this section, we assume that X is R^n with the usual order. In this setting, we prove existence, uniqueness, and stability results. We think of vectors in R^n as column vectors. For $x \in R^n, x_i$ denotes the ith component. For $x, y \in R^n$, the Hadamard product $x * y$ is the vector whose ith component is $x_i y_i$. We recall that the (standard) notation $r > 0$ means that the vector r is positive ($r \succ 0$).

6.1. The VLCP. In this subsection, we describe the vertical LCP [5] and show that it is equivalent to GOLCP.

Consider a rectangular matrix N of order $m \times n$ with $m \geq n$, and let p be an m-vector. Suppose that N and p are partitioned in the form

$$N = \begin{bmatrix} N_1 \\ N_2 \\ \vdots \\ N_n \end{bmatrix}, \qquad p = \begin{bmatrix} p_1 \\ p_2 \\ \vdots \\ p_n \end{bmatrix}, \tag{8}$$

where each $N_i \in R^{m_i \times n}$ and $p_i \in R^{m_i}$ with $\sum_{i=1}^{n} m_i = m$. Then VLCP(N, p) is to find a vector $z \in R^n$ such that

$$z \geq 0,\ Nz + p \geq 0, \quad \text{and} \quad z_i \prod_{j=1}^{m_i} (N_i z + p_i)_j = 0 \qquad i = 1, 2, \ldots, n. \tag{9}$$

We show that this problem can be formulated as a GOLCP. Let $k = \max\{m_i : i = 1, \ldots, n\}$. Let N_i^j denote the jth row of the matrix N_i. We define matrices $\tilde{N}_1, \tilde{N}_2, \ldots, \tilde{N}_n$ each of size $k \times n$ in the following way. For any i, the jth row of $\tilde{N}_i$ is N_i^j if $j \leq m_i$ and N_i^1 (the first row of N_i) if $j > m_i$. Correspondingly, we define vectors $\tilde{p}_1, \tilde{p}_2, \ldots, \tilde{p}_n$ each of size $k \times 1$. This construction leads to the rectangular (block) matrix $\tilde{N}$ and the vector $\tilde{p}$. It is clear that VLCP$(\tilde{N}, \tilde{p})$ is equivalent to the VLCP(N, p). Now let M_i be the matrix of size $n \times n$ whose jth row is the ith row in the matrix $\tilde{N}_j$. (For example, M_1 is formed by considering the first row in each of the matrices $\tilde{N}_1, \tilde{N}_2, \ldots, \tilde{N}_n$.) Similarly, let q_i be the vector of size $1 \times n$ whose jth component is the ith component in the vector $\tilde{p}_j$. It is easily verified that the VLCP$(\tilde{N}, \tilde{p})$ is equivalent to GOLCP$(\mathbf{M}, \mathbf{q})$.

To see that every GOLCP can be formulated as a VLCP, consider GOLCP$(\mathbf{M}, \mathbf{q})$. Let N_i be the $k \times n$-matrix whose jth row is the ith row of the matrix M_j. (For example,

N_1 is formed by considering the first row in each of the matrices $M_1, M_2, \ldots, M_k$.) Correspondingly, we define the $k \times n$ vector p_i. This construction leads to the pair (N, p), and the corresponding VLCP is easily seen to be equivalent to GOLCP$(\mathbf{M}, \mathbf{q})$.

6.2. Representative matrices. Let $(\mathbf{M}, \mathbf{q})$ be given by (4) where each M_i is an $n \times n$ real matrix and q_i is an $n \times n$ vector. We say that the pair $(A, a) \in R^{n \times n} \times R^n$ is a *representative* of $(\mathbf{M}, \mathbf{q})$ if for each $j = 1, 2, \ldots, n$, the jth row of A is the jth row of some M_i and jth component of a is the jth component of the corresponding q_i. In other words, $A^j \in \{M_1^j, M_2^j, \ldots, M_k^j\}$, where the superscript refers to the corresponding row vector, and so on. We say that matrix A is a *representative matrix* of $\mathbf{M}$ and a is a representative vector of $\mathbf{q}$.

It is immediate that $x \in \mathrm{SOL}(\mathbf{M}, \mathbf{q})$ if and only if x is a feasible vector for GOLCP$(\mathbf{M}, \mathbf{q})$ and $x \in \mathrm{SOL}(A, a)$ for some representative (A, a) of $(\mathbf{M}, \mathbf{q})$. We record this formally in the following proposition.

PROPOSITION 3. *It holds that*

$$\mathrm{SOL}\,(\mathbf{M}, \mathbf{q}) = \mathcal{N}\,(\mathbf{M}, \mathbf{q}) \cap (\cup\ \mathrm{SOL}\,(A, a))\,, \tag{10}$$

where

$$\mathcal{N}\,(\mathbf{M}, \mathbf{q}) = \{x\ :\ x \geq 0,\ \mathbf{M}x + \mathbf{q} \geq 0\}$$

and the union is over all representatives (A, a) *of* $(\mathbf{M}, \mathbf{q})$.

Proposition 3 leads to three important observations. First, the set $\mathrm{SOL}(\mathbf{M}, \mathbf{q})$ is a union of finite number of polyhedral (convex) sets. Second, $\mathcal{K}(\mathbf{M})$ is closed. (This follows from the facts that for any given $\mathbf{M}$, the set of all $\mathbf{q}$'s with $\mathcal{N}(\mathbf{M}, \mathbf{q}) \neq \emptyset$ is closed and in the case of classical LCP, for any given matrix A, the set of all a's with $\mathrm{SOL}(A, a) \neq \emptyset$ is closed.) Third, the graph of the mapping $\mathbf{\Phi} : \mathbf{q} \mapsto \mathrm{SOL}(\mathbf{M}, \mathbf{q})$ is a union of finite number of polyhedral sets, i.e., $\mathbf{\Phi}$ is a polyhedral multifunction [48]. This third observation leads to the following proposition.

PROPOSITION 4. *For any given* $\mathbf{M}$, *consider the mapping* $\mathbf{\Phi}(\mathbf{q}) := \mathrm{SOL}(\mathbf{M}, \mathbf{q})$. *Let* $\mathcal{E}$ *be a compact subset of* $\prod_1^k R^n$. *If* $\mathbf{\Phi}(\mathbf{q})$ *is bounded for each* $\mathbf{q} \in \mathcal{E}$, *then* $\mathbf{\Phi}$ *is (uniformly) bounded on* $\mathcal{E}$, *i.e., the set* $\bigcup_{\mathbf{q} \in \mathcal{E}} \mathbf{\Phi}(\mathbf{q})$ *is bounded.*

Proof. It follows from Robinson's locally upper Lipschitzian property of $\mathbf{\Phi}$ [48] that the mapping $\mathbf{\Phi}$ is upper semicontinuous at any $\mathbf{q}$, i.e., given any $\mathbf{q}$ and $\varepsilon > 0$, there exists a neighborhood $\mathbf{V}$ of $\mathbf{q}$ such that

$$\Phi\,(\mathbf{q}') \subseteq \Phi\,(\mathbf{q}) + \varepsilon \mathcal{B}$$

for all $\mathbf{q}'$ in $\mathbf{V}$ where $\mathcal{B}$ is the open unit ball in R^n. Since we are assuming that $\mathbf{\Phi}(\mathbf{q})$ is bounded for each $\mathbf{q} \in \mathcal{E}$, a standard argument, involving the compactness and upper semicontinuity notions, gives the desired result. □

We say that $\mathbf{M}$ has the $\mathbf{T}$-*property* if every representative matrix of $\mathbf{M}$ is a $\mathbf{T}$-matrix where $\mathbf{T}$ denotes a class of matrices. For example, $\mathbf{M}$ has the $\mathbf{P}$-property if every representative matrix of $\mathbf{M}$ is a $\mathbf{P}$-matrix. (Recall that a square matrix A is a $\mathbf{P}$-matrix if every principal minor of A is positive; equivalently [5], $z * Az \leq 0 \Longrightarrow z = 0$.) The standard classes in the LCP theory are the classes of copositive matrices, $\mathbf{R}_0$-matrices, $\mathbf{R}$-matrices, copositive-plus matrices, $\mathbf{E}_1$-matrices, and so on. We refer the reader to [5] for detailed information on these classes.

PROPOSITION 5. *If* $\mathbf{M}$ *has the* $\mathbf{R}_0$*-property, then it is of* type $\mathbf{R}_0$.

Proof. Suppose that $\mathbf{M}$ has the $\mathbf{R}_0$-property and let x be a vector such that $x \wedge \mathbf{M}x = 0$. Since the ordering is the usual ordering, this leads to $x_i \wedge (M_1 x)_i \wedge$

$(M_2x)_i \cdots \wedge (M_kx)_i = 0$ for each $i = 1, 2, \ldots, n$. Corresponding to say i, let $l(i)$ be an index such that $(M_{l(i)}x)_i = (M_1x)_i \wedge (M_2x)_i \cdots \wedge (M_kx)_i$. Let A be the representative matrix of $\mathbf{M}$ whose ith row is $M^i_{l(i)}$. Clearly, $x \wedge Ax = 0$. By assumption, A is an $\mathbf{R}_0$-matrix and so $x = 0$. Thus, $\mathbf{M}$ is of type $\mathbf{R}_0$. □

Remarks. Example 1 shows that the converse statement in the above proposition may not hold. There does not seem to be any connection between type $\mathbf{R}$ and the $\mathbf{R}$-property (see example below). However, suppose there is a positive vector e in R^n such that for every representative matrix A of $\mathbf{M}$ and for every $t \geq 0, \mathrm{SOL}(A, te) = \{0\}$. Then it is easily verified that $\mathbf{M}$ is of type $\mathbf{R}$. In particular, if $\mathbf{M}$ has the $\mathbf{E}_0$-property and the $\mathbf{R}_0$-property, then it is of type $\mathbf{R}$.

Before moving on to the uniqueness aspect, we present two important examples.

Example 3. Let $\mathbf{M} = (M_1, M_2)$ where

$$M_1 = \begin{bmatrix} 1 & -1 \\ 1 & -1 \end{bmatrix}, \quad M_2 = \begin{bmatrix} 1 & -2 \\ 1 & 1 \end{bmatrix}, \quad \text{and} \quad e = \begin{bmatrix} 1 \\ 1 \end{bmatrix}.$$

It is easily verified that $\mathrm{SOL}(\mathbf{M}, t\mathbf{e}) = \{0\}$, where t is any nonnegative real number and $\mathbf{e} = (e, e)$. (While verifying this, we have used the fact that the matrix

$$A = \begin{bmatrix} 1 & -2 \\ 1 & -1 \end{bmatrix}$$

is an $\mathbf{R}$-matrix [5, p. 194].) This means that $\mathbf{M}$ is of type $\mathbf{R}$ and hence of type $\mathbf{Q}$ by Theorem 2. However, M_1 is neither an $\mathbf{R}_0$-matrix nor a $\mathbf{Q}$-matrix, i.e., $\mathbf{M}$ has neither the $\mathbf{R}$-property nor the $\mathbf{Q}$-property.

Example 4. Let $\mathbf{M} = (M_1, M_2)$ and $\mathbf{q} = (q_1, q_2)$, where

$$M_1 = \begin{bmatrix} 2 & -3 \\ 1 & -1 \end{bmatrix}, \quad M_2 = \begin{bmatrix} -\frac{1}{2} & 1 \\ 2 & -1 \end{bmatrix}, \quad q_1 = \begin{bmatrix} 6 \\ 3 \end{bmatrix}, \quad \text{and} \quad q_2 = \begin{bmatrix} -1 \\ 3 \end{bmatrix}.$$

By employing complementary cones [5], it can be verified that $\mathbf{M}$ has the $\mathbf{Q}$-property but that $\mathrm{GOLCP}(\mathbf{M}, \mathbf{q})$ has no solution, i.e., $\mathbf{M}$ is not of type $\mathbf{Q}$. Note also that $\mathbf{M}$ has the $\mathbf{R}_0$-property.

6.3. Uniqueness.

THEOREM 10. $\mathbf{M}$ *has the* $\mathbf{P}$*-property if and only if it is of* type $\mathbf{P}$.

Proof. Suppose that $\mathbf{M}$ is of type $\mathbf{P}$ and let A be a representative matrix of $\mathbf{M}$. To show that A is a $\mathbf{P}$-matrix, we start with a vector x such that $x_i(Ax)_i \leq 0$ for all i and show that $x = 0$. If $x_i > 0$, then $A^ix \leq 0$ and hence $(x \wedge \mathbf{M}x)_i \leq 0 \leq (x \vee \mathbf{M}x)_i$. If $x_i < 0$, then $A^ix \geq 0$ and hence $(x \wedge \mathbf{M}x)_i \leq 0 \leq (x \vee \mathbf{M}x)_i$. Finally, if $x_i = 0$, then $(x \wedge \mathbf{M}x)_i \leq 0 \leq (x \vee \mathbf{M}x)_i$. Therefore, $x \wedge \mathbf{M}x \leq 0 \leq x \vee \mathbf{M}x$. Since $\mathbf{M}$ is of type $\mathbf{P}, x = 0$. We have shown that each representative of $\mathbf{M}$ is a $\mathbf{P}$-matrix and so $\mathbf{M}$ has the $\mathbf{P}$-property.

To see the converse, assume that $\mathbf{M}$ has the $\mathbf{P}$-property. Let x be a vector such that $x \wedge \mathbf{M}x \leq 0 \leq x \vee \mathbf{M}x$. We construct a representative matrix A as follows. For any index j, let A^j be a vector in the set $\{M_1^j, M_2^j, \ldots, M_k^j\}$ such that $A^jx \leq 0$ if $x_j > 0$ and $A^jx \geq 0$ if $x_j \leq 0$. Since A is a $\mathbf{P}$-matrix (by assumption) and $x*(Ax) \leq 0$, we see that $x = 0$. Therefore $\mathbf{M}$ is of type $\mathbf{P}$. □

Remarks. Combining Theorems 3 and 10 we see that $\mathrm{GOLCP}(\mathbf{M}, \mathbf{q})$ *has a unique solution for all* $\mathbf{q}$ *if and only if every representative matrix of* $\mathbf{M}$ *is a* $\mathbf{P}$*-matrix.* This result for VLCPs was proved earlier by Cottle and Dantzig [4], who proved the existence of solution when $\mathbf{M}$ has the $\mathbf{P}$-property, and by Szanc [53], who proved that

$\mathbf{M}$ has the $\mathbf{P}$-property if and only if every VLCP corresponding to $\mathbf{M}$ has at most one solution.

By slightly modifying the proof of the above theorem, we can show that $\mathbf{M}$ is of type $\mathbf{E}$ (type $\mathbf{E}_0$, type $\mathbf{P}_0$) if and only if $\mathbf{M}$ has the $\mathbf{E}$-property (respectively, $\mathbf{E}_0$-property, $\mathbf{P}_0$-property). We omit the details.

We end this subsection by proving the reverse implication (b) $\Longrightarrow$ (a) in Theorem 5. Because of the previous remarks, we need to show that if (b) holds, then every representative matrix of $\mathbf{M}$ is an $\mathbf{E}_0$-matrix. Without loss of generality, consider the matrix M_1 in $\mathbf{M}$. Let $q_1 > 0$ in R^n. If the problem LCP(M_1, q_1) has two solutions, say, x and y, then we can take $r > 0$ and define $q_i = (-M_i x) \vee (-M_i y) \vee r$ for $i = 2, 3, \ldots, k$. Clearly, $\mathbf{q} \succ 0$ and GOLCP$(\mathbf{M}, \mathbf{q})$ has two solutions. So, if (b) holds, then LCP(M_1, q_1) has a unique solution for all $q_1 > 0$, that is, M_1 is an $\mathbf{E}_0$-matrix.

6.4. The $\mathbf{E}_1$-property. Our next two sections deal with existence results not covered by Theorems 1 and 2. As in the classical LCP, we deal with the classes of $\mathbf{E}_1$-matrices (also called $\mathbf{L}_2$-matrices) and copositive matrices. Recall that a matrix A is an $\mathbf{E}_1$-matrix if for each nonzero solution $v \in \mathrm{SOL}(A, 0)$, there exist two nonnegative diagonal matrices Γ and Λ such that $\Gamma v \neq 0$ and $A^T(\Gamma v) + \Lambda A v = 0$. In [4], Cottle and Dantzig show via a modification of Lemke's algorithm that when $\mathbf{M}$ has the copositive-plus property, feasibility of the VLCP implies its solvability. The extension of this result given below deals with an $\mathbf{M}$ that has the $\mathbf{E}_1$-property. In the classical setting, results for $\mathbf{E}_1$-matrices are proved using either the Lemke algorithm (as in Eaves [10] and [39]) or using the basic theorem of complementarity (as in [25] and [5]). As we see below, degree theory allows us to deal with the $\mathbf{E}_1$-property in a comprehensive way, even allowing a generalization of the classical LCP result of Moré [39].

THEOREM 11. *Suppose that* $\mathbf{M}$ *has the* $\mathbf{E}_1$*-property and is of* type $\mathbf{D}$. *Suppose further that* GOLCP$(\mathbf{M}, \mathbf{q})$ *is strictly feasible. Then* SOL$(\mathbf{M}, \mathbf{q})$ *is nonempty and bounded.*

Proof. We first show that for any $\mathbf{p} \in \mathrm{int}\, \mathcal{F}(\mathbf{M})$, SOL$(\mathbf{M}, \mathbf{p})$ is bounded. Assume the contrary. By Proposition 3, there exists a representative pair (A, a) of $(\mathbf{M}, \mathbf{p})$ such that $\mathcal{N}(\mathbf{M}, \mathbf{p}) \cap \mathrm{SOL}(A, a)$ is unbounded. Hence, there exists an $x \in \mathrm{SOL}(A, a)$ and a direction $v \neq 0$ such that $x + \lambda v \in \mathrm{SOL}(A, a)$ for all $\lambda \geq 0$, i.e., $(x + \lambda v) \wedge \{A(x + \lambda v) + a\} = 0$ for all $\lambda \geq 0$. It is easily verified that $v \wedge Av = 0, x * Av = 0$, and $v * (Ax + a) = 0$. Since $\mathbf{M}$ has the $\mathbf{E}_1$-property, A is an $\mathbf{E}_1$-matrix and so there exists two nonnegative diagonal matrices Λ and Γ such that $\Gamma v \neq 0$ and $A^T(\Gamma v) + \Lambda A v = 0$. It follows from $v * (Ax + a) = 0$ that $(\Gamma v)^T (Ax + a) = 0$. Since $\mathbf{M}s + \mathbf{p} \succ 0$ for some $s \geq 0$, we can write $a = r - As$ with $r > 0$. We now have

$$0 = -(\Lambda A v)^T x + (\Gamma v)^T r + (\Lambda A v)^T s.$$

In view of $x * Av = 0$, the first term in the above equality is zero. Since Av and Λ are nonnegative, the third term is nonnegative. Since $\Gamma v \neq 0$ and $r > 0$, we reach a contradiction. Hence, SOL$(\mathbf{M}, \mathbf{p})$ is bounded.

To show that SOL$(\mathbf{M}, \mathbf{q})$ is nonempty, we consider the homotopy defined by $\mathbf{q}_t := (1 - t)\mathbf{d} + t\mathbf{q}$, where $\mathbf{d}$ is the vector that corresponds to $\mathbf{M}$ in the definition of $\mathbf{D}$. It is clear that $\mathbf{q}_t \in \mathrm{int}\, \mathcal{F}(\mathbf{M})$ for all t and (by the above argument) SOL$(\mathbf{M}, \mathbf{q}_t)$ is bounded for each t. By Proposition 4, SOL$(\mathbf{M}, \mathbf{q}_t)$ is uniformly bounded, say, by an open set Ω' that includes the open set Ω appearing in the definition of $\mathbf{d}$. By the homotopy invariance and the excision properties of the degree, $\deg(F_{(\mathbf{M},\mathbf{q})}, \Omega', 0) =$

$\deg(F_{(\mathbf{M},\mathbf{d})}, \Omega, 0) \neq 0$. This means that the equation $F_{(\mathbf{M},\mathbf{q})}(x) = 0$ has a solution in Ω', i.e., GOLCP$(\mathbf{M}, \mathbf{q})$ has a solution. This completes the proof. □

THEOREM 12. *Suppose that* $\mathbf{M}$ *has the* $\mathbf{E}_1$*-property and is of* type $\mathbf{D}$. *Then* $\mathbf{M}$ *is of* type $\mathbf{Q}_0$, *i.e., for all* $\mathbf{q} \in \mathcal{F}(\mathbf{M}), \mathrm{SOL}(\mathbf{M}, \mathbf{q})$ *is nonempty. Moreover, the following are equivalent for any* $\mathbf{q}$:

(a) GOLCP$(\mathbf{M}, \mathbf{q})$ *is stable*;

(b) $\mathbf{q} \in \text{int } \mathcal{F}(\mathbf{M})$, *i.e.*, GOLCP$(\mathbf{M}, \mathbf{q})$ *is strictly feasible*;

(c) SOL$(\mathbf{M}, \mathbf{q})$ *is nonempty and bounded.*

Proof. It was observed earlier that $\mathcal{K}(\mathbf{M})$ is closed and $\mathcal{K}(\mathbf{M}) \subseteq \mathcal{F}(\mathbf{M})$. The previous theorem says that int $\mathcal{F}(\mathbf{M}) \subseteq \mathcal{K}(\mathbf{M})$. Since $\mathcal{F}(\mathbf{M})$ is a closed convex set, it follows that $\mathcal{K}(\mathbf{M}) = \mathcal{F}(\mathbf{M})$. Therefore, $\mathbf{M}$ is of type $\mathbf{Q}_0$. The implication (a) $\Longrightarrow$ (b) follows from the definition of stability. The implication (b) $\Longrightarrow$ (c) follows from the previous theorem. Now suppose that $\mathrm{SOL}(\mathbf{M}, \mathbf{q})$ is nonempty and bounded. Let $\mathbf{d}$ be the vector that appears in the definition of $\mathbf{D}$. Consider the homotopy joining $(\mathbf{M}, \mathbf{q})$ and $(\mathbf{M}, \mathbf{d})$ defined by $\mathbf{q}_t := (1-t)\mathbf{d} + t\mathbf{q}$. Since $\mathbf{q} \in \mathcal{F}(\mathbf{M})$, we have $\mathbf{q}_t \in \text{int } \mathcal{F}(\mathbf{M})$ for all $t \in [0, 1)$. $\mathrm{SOL}(\mathbf{M}, \mathbf{q}_t)$ is bounded for all t; for $t < 1$ by the previous theorem and for $t = 1$ by the assumption. We proceed as in the proof of the previous theorem to conclude that GOLCP$(\mathbf{M}, \mathbf{q})$ is stable. This gives the implication (c) $\Longrightarrow$ (a). □

Remarks. It is clear that in the above theorem, $\mathbf{q}$ is in the boundary of $\mathcal{F}(\mathbf{M}, \mathbf{q})$ if and only if $\mathrm{SOL}(\mathbf{M}, \mathbf{q})$ is unbounded (which is equivalent to saying that there is a solution ray for GOLCP$(\mathbf{M}, \mathbf{q})$).

Note that the conclusions of Theorems 11 and 12 hold if we assume (instead of the $\mathbf{E}_1$-property) that for every $p \in \text{int } \mathcal{F}(\mathbf{M}), \mathrm{SOL}(\mathbf{M}, \mathbf{p})$ is bounded.

When $k = 1$, Theorem 12 covers various known results. For example, when M is in the class $\mathbf{G} \cap \mathbf{E}_1$, the implication (c) $\Longrightarrow$ (a) (which holds since type $\mathbf{G} \subseteq$ type $\mathbf{D}$) is a result of Doverspike [8]. For M in the same class, the equivalence (b) $\Longleftrightarrow$ (c), when stated in terms of boundary of $\mathcal{F}(\mathbf{M})$ and solution rays, reduces to the result of Eagambaram and Mohan [9]. See [3], [38], and [5] for related results.

Interestingly enough, Theorem 12 covers (when $k = 1$) matrices outside of the class $\mathbf{G}$. To see this, consider a matrix M for which there is a vector d that is nondegenerate with respect to M (i.e., $x + Mx + d > 0$ for all $x \in \mathrm{SOL}(M, d)$) and $\sum \text{sgn det } M_{\alpha\alpha} \neq 0$, where $M_{\alpha\alpha}$ is the submatrix of M corresponding to the nonzero indexes of a solution x of LCP(M, d) and the summation is over all solutions x of LCP(M, d). (This sum is precisely the local degree of M at d [5]. This sum is nonzero, for example, when LCP(M, d) consists of odd number of solutions.) If M is also in the class $\mathbf{E}_1$, then Theorem 12 applies.

6.5. The $\mathbf{G}^{\#}$-property. In the classical LCP theory, copositive matrices have interesting LCP properties. In this subsection, we see how degree theory can be employed to get a generalization of the celebrated result of Lemke [34].

We say that $\mathbf{M}$ has the *sharp property* if every representative of $\mathbf{M}$ has the sharp property, i.e., for any representative A of $\mathbf{M}$,

$$x \in \mathrm{SOL}\,(A, 0) \Rightarrow \left(A + A^T\right) x \geq 0. \tag{11}$$

We note that when $k = 1$, this condition is shared by copositive matrices, $\mathbf{R}_0$-matrices, and symmetric matrices (see [5], p. 695). Now consider an $\mathbf{M}$ having the sharp property (11). Let

$$\mathcal{C}\,(\mathbf{M}) := \left\{\mathbf{q} : a \in (\mathrm{SOL}(A, 0))^* \text{ for all representatives } (A, a) \text{ of } (\mathbf{M}, \mathbf{q})\right\},$$

where for any set S in R^n, $S^* = \{x : x^T s \geq 0 \text{ for all } s \in S\}$ is the dual cone of S.

We note that $\mathcal{C}(\mathbf{M})$ is convex and every $\mathbf{d} \succ 0$ is in $\mathcal{C}(\mathbf{M})$. We claim that for any $\mathbf{q} \in \text{int } \mathcal{C}(\mathbf{M})$, SOL($\mathbf{M}$, $\mathbf{q}$) is bounded. If not, we proceed as in the proof of Theorem 11 to get a representative (A, a) of $(\mathbf{M}, \mathbf{q})$, solution x and a direction v such that $(x + \lambda v)^T(Ax + \lambda Ax + a) = 0$ for all $\lambda \geq 0$. This leads to $x^T a + (A + A^T)x = 0$. In view of the sharp property, $x^T a \leq 0$. We reach a contradiction to $\mathbf{q} \in \text{int } \mathcal{C}(\mathbf{M})$.

THEOREM 13. *Let* $\mathbf{M}$ *have the sharp property* (11) *and suppose that for some* $\mathbf{d} \in \text{int } \mathcal{C}(\mathbf{M})$ *and for some bounded open set* Ω *containing* SOL($\mathbf{M}, \mathbf{d}$), $\deg(F_{(\mathbf{M},\mathbf{d})}, \Omega, 0) \neq 0$. *Then for all* $\mathbf{q} \in \text{int } \mathcal{C}(\mathbf{M})$, GOLCP($\mathbf{M}, \mathbf{q}$) *is stable. Moreover, for all* $\mathbf{q} \in \mathcal{C}(\mathbf{M})$, GOLCP($\mathbf{M}, \mathbf{q}$) *has a solution.*

Proof. We fix a $\mathbf{q} \in \text{int } \mathcal{C}(\mathbf{M})$ and consider the homotopy joining $(\mathbf{M}, \mathbf{d})$ and $(\mathbf{M}, \mathbf{q})$ defined by $\mathbf{q}_t := (1 - t)\mathbf{d} + t\mathbf{q}$. Since int $\mathcal{C}(\mathbf{M})$ is convex, $\mathbf{q}_t \in \text{int } \mathcal{C}(\mathbf{M})$ and SOL($\mathbf{M}, \mathbf{q}_t$) is bounded for each t. By Proposition 4, SOL($\mathbf{M}, \mathbf{q}_t$) is uniformly bounded for all t. We proceed as in the second part of the proof of Theorem 11 and get the stability of GOLCP($\mathbf{M}, \mathbf{q}$). Since $\mathcal{K}(\mathbf{M})$ is closed, the inclusion int $\mathcal{C}(\mathbf{M}) \subseteq \mathcal{K}(\mathbf{M})$ shows that $\mathcal{C}(\mathbf{M}) \subseteq \mathcal{K}(\mathbf{M})$. The second part of the theorem follows. □

By definition, $\mathbf{M}$ has the $\mathbf{G}^{\#}$-property if it has both the sharp property and the $\mathbf{G}$-property. The following result is immediate.

COROLLARY 1. *Suppose that* $\mathbf{M}$ *has the* $\mathbf{G}^{\#}$*-property. Then for all* $\mathbf{q} \in \text{int } \mathcal{C}(\mathbf{M})$, GOLCP($\mathbf{M}, \mathbf{q}$) *is stable. Moreover, for all* $\mathbf{q} \in \mathcal{C}(\mathbf{M})$, GOLCP($\mathbf{M}, \mathbf{q}$) *has a solution.*

Remarks. It is easily seen that $\mathbf{M}$ has the $\mathbf{G}^{\#}$-property if $\mathbf{M}$ has the copositive-plus property, and so Corollary 1 is applicable. When $k = 1$, the first part in the above corollary covers Theorem 7.5.8 and Exercise 7.6.6 in [5]. Furthermore, for $k = 1$, the second part in the above corollary was proved in [25] using the basic theorem of complementarity of Eaves. Note that this second part, for copositive matrices, is precisely the result of Lemke [34]. The above corollary can further be specialized to copositive plus matrices to obtain well-known results of Mangasarian [38] and Cottle [3]. We omit the details.

7. The extended GOLCP. In this section, we indicate how to analyze the extended GOLCP (EGOLCP). Given

$$\mathbf{B} = (B_0, B_1, B_2, \ldots, B_k) \quad \text{and} \quad \mathbf{b} = (b_0, b_1, b_2, \ldots, b_k), \tag{12}$$

where each B_j is an $n \times n$ matrix and b_j is an n-vector, the EGOLCP($\mathbf{B}, \mathbf{b}$) is to find $x \in R^n$ such that

$$F_{(\mathbf{B},\mathbf{b})}(x) := (B_0 x + b_0) \wedge (B_1 x + b_1) \wedge (B_2 x + b_2) \wedge \cdots \wedge (B_k x + b_k) = 0. \tag{13}$$

We write $F_{\mathbf{B}}(x) := F_{(\mathbf{B},\mathbf{0})}(x)$. If $F_{\mathbf{B}}(x) = 0$ implies that $x = 0$, then $\deg(F_{\mathbf{B}}, \Omega, 0)$ is defined and is independent of Ω, where Ω is any bounded open set containing the origin in R^n. We call this number the EGOLCP-degree of $\mathbf{B}$. The result below is similar to Theorem 1. We omit the proof.

THEOREM 14. *Suppose that* $F_{\mathbf{B}}(x) = 0$ *only when* $x = 0$, *and* EGOLCP-degree *of* $\mathbf{B}$ *is nonzero. Then for all* $\mathbf{b}$, *the* EGOLCP($\mathbf{B}, \mathbf{b}$) *has a solution.*

As in §6.2, we say that an $n \times n$ matrix B is a *representative* matrix of $\mathbf{B}$ if the ith row $(i = 1, 2, \ldots, k)$ of B comes from the set $\{B_0^i, B_1^i, \ldots, B_k^i\}$ where, of course, the superscript refers to the corresponding row. We note immediately that if every representative matrix of $\mathbf{B}$ is nonsingular, then the implication $F_{\mathbf{B}}(x) = 0 \Longrightarrow x = 0$ holds.

The next two results address the question of calculating the EGOLCP-degree of $\mathbf{B}$.

THEOREM 15. *Suppose that* $F_{\mathbf{B}}(x) = 0$ *only when* $x = 0$ *and that* B_0 *is nonsingular. Let* $M_i = B_i(B_0)^{-1}$ *for* $i = 1, \ldots, k$. *Then* $\mathbf{M}$ *given by* (4) *is of* type $\mathbf{R}_0$ *and*

$$\text{EGOLCP-deg } \mathbf{B} = \text{sgn det } (B_0)\, \text{GOLCP-deg } \mathbf{M}.$$

Proof. The first part of the conclusion follows immediately from the relation $F_{\mathbf{B}}(B_0^{-1}x) = F_{\mathbf{M}}(x)$. The second part follows from the equality $\deg(F_{\mathbf{M}}, \Omega, 0) = \text{sgn det } (B_0) \deg(F_{\mathbf{B}}, \Omega, 0)$, which is a consequence of the multiplication property of the degree [35, Thm. 2.3.1]. □

THEOREM 16. *Suppose that* $F_{\mathbf{B}}(x) = 0$ *only when* $x = 0$. *Then for all* $\tilde{\mathbf{B}} = (\tilde{B}_0, \tilde{B}_1, \ldots, \tilde{B}_k)$ *sufficiently close to* $\mathbf{B}$ *with* $\tilde{B}_0$ *invertible, we have*

$$\text{EGOLCP-deg } \mathbf{B} = \text{sgn det } \left(\tilde{B}_0\right) \text{GOLCP-deg } \tilde{\mathbf{M}},$$

where $\tilde{\mathbf{M}} = (\tilde{M}_1, \tilde{M}_2, \ldots, \tilde{M}_k)$ *and* $\tilde{M}_i = \tilde{B}_i(\tilde{B}_0)^{-1}$ $(i = 1, 2, \ldots, k)$.

Proof. As in the proof of Theorem 6, we can appeal to the nearness property of the degree and conclude that EGOLCP-deg $\mathbf{B}$ =EGOLCP-deg $\tilde{\mathbf{B}}$ whenever $\tilde{\mathbf{B}}$ is sufficiently close to $\mathbf{B}$. When $\tilde{B}_0$ is invertible, we can use the previous theorem to get the desired conclusion. □

As an illustration of the above result, we state the following corollary.

COROLLARY 2. *Suppose that* (i) $F_{\mathbf{B}}(x) = 0$ *only when* $x = 0$, *and* (ii) *for some* $\mathbf{b}^*$ *with* $b_0^* = 0$ *and* $b_i^* > 0, i = 1, 2, \ldots, k$, *the zero vector is the only solution of* EGOLCP$(\mathbf{B}, \mathbf{b}^*)$. *Then for every* $\mathbf{b}$, EGOLCP$(\mathbf{B}, \mathbf{b})$ *has a solution.*

Proof. To see this, first observe (by the usual normalization arguments) that the above two conditions hold if $\mathbf{B}$ is perturbed (slightly) to $\tilde{\mathbf{B}}$ for which Theorem 16 is applicable. The resulting $\tilde{\mathbf{M}}$ is of type $\mathbf{R}$, and so, by Theorem 2, EGOLCP-deg $\mathbf{B}$ is nonzero. Now applying Theorem 14 we get the desired result. □

We now turn to the uniqueness issue. The result below completely characterizes the uniqueness in EGOLCPs.

THEOREM 17. *Let* $\mathbf{B}$ *be given by* (12) *and when* B_0 *is invertible, let* $\mathbf{M}$ *be given by* (4), *where* $M_i = B_i(B_0)^{-1}, i = 1, 2, \ldots, k$. *Then the following conditions are equivalent.*

1. *For every* $\mathbf{b}$, EGOLCP$(\mathbf{B}, \mathbf{b})$ *has a unique solution.*
2. *The implication* $B_0x \wedge B_1x \wedge \cdots \wedge B_kx \leq 0 \leq B_0x \vee B_1x \vee \cdots \vee B_kx \Longrightarrow x = 0$ *holds.*
3. *For every* $\mathbf{b}$, EGOLCP$(\mathbf{B}, \mathbf{b})$ *has at most one solution.*
4. B_0 *is invertible and* $\mathbf{M}$ *has the* $\mathbf{P}$*-property.*
5. *All representative matrices of* $\mathbf{B}$ *have the same (nonzero) determinantal sign.*

Proof. 1 $\Longrightarrow$ 2: Similar to the proof of the implication (b) $\Longrightarrow$ (a) in Theorem 3.

2 $\Longrightarrow$ 3: Similar to the proof of the implication (a) $\Longrightarrow$ (b) in Theorem 3.

3 $\Longrightarrow$ 4: Suppose that $B_0x = 0$. Define $\mathbf{b}$ by $b_0 = -B_0x^+$ $(= -B_0x^-)$, $b_i = (-B_ix^+) \vee (-B_ix^-)$ for $i = 1, 2, \ldots, k$. Then x^+ and x^- are solutions of EGOLCP$(\mathbf{B}, \mathbf{b})$. From condition 3, $x = 0$, and hence B_0 is invertible. Now for any $\mathbf{q}$ given by (4), u is a solution of GOLCP$(\mathbf{M}, \mathbf{q})$ if and only if $v = B_0^{-1}u$ is a solution of EGOLCP$(\mathbf{B}, \mathbf{b})$, where $b_0 = 0$ and $b_i = q_i$ for $i = 1, 2, \ldots, k$. Hence, we see from Condition 3 that GOLCP$(\mathbf{M}, \mathbf{q})$ as at most one solution for every $\mathbf{q}$. The $\mathbf{P}$-property of $\mathbf{M}$ follows from Theorems 3 and 10.

4 $\Longrightarrow$ 1: Clearly, x is a solution of EGOLCP$(\mathbf{B}, \mathbf{b})$ if and only if $y = B_0x + b_0$ is a solution of GOLCP$(\mathbf{M}, \mathbf{q})$, where $\mathbf{q}$ is given by (4) with $q_i = b_i - M_ib_0, i = 1, 2, \ldots, k$. Now the desired implication follows from Theorem 3.

4 $\iff$ 5: It is easily seen that for any $n \times n$ matrix C, any representative matrix of

$$\mathbf{B}C := (B_0C, B_1C, \ldots, B_kC)$$

looks like BC where B is a representative matrix of $\mathbf{B}$. Hence, when C is nonsingular, all representative matrices of $\mathbf{B}C$ will have the same nonzero determinantal sign if and only if all representative matrices of $\mathbf{B}$ have the same nonzero determinantal sign. The equivalence of Conditions 4 and 5 is seen by taking $C = B_0^{-1}$ and observing that $\mathbf{M}$ has the $\mathbf{P}$-property if and only if all representative matrices of $(I, M_1, M_2, \ldots, M_k)$ have the same positive determinantal sign. □

Remarks. In some practical situations, for example, in nonlinear network theory [20], it is essential to know when a piecewise-linear function on R^n is a homeomorphism. Many researchers, including Kuhn and Löwen, Rheinboldt and Vandergraft, Kojima and Saigal, and Schramm, studied this problem (see the recent paper of Ralph [45] for precise references). We now show that condition 5 in Theorem 17 (which is typical in the above works) implies that for each $\mathbf{b}$, the piecewise-linear function $F_{(\mathbf{B},\mathbf{b})}$, given by (13), is a homeomorphism of R^n. This can be seen easily by observing that the equation $F_{(\mathbf{B},\mathbf{b})}(x) = y$ is equivalent to EGOLCP$(\mathbf{B}, \mathbf{b} - \mathbf{y})$, where $\mathbf{y} := (y, y, \ldots, y)$, and by appealing to the Invariance of Domain Theorem.

In some important practical problems involving the EGOLCP, one encounters [50], [51], [41], via discretization procedures, $\mathbf{Z}$-matrices. (Recall that these are matrices having nonpositive off-diagonal entries.) The following corollary deals with these matrices.

COROLLARY 3. *Consider a* $\mathbf{B}$ *given by* (12) *in which each* B_i *is a* $\mathbf{Z}$*-matrix. Suppose that one of the following conditions holds.*

(a) *Each* B_i *has positive diagonal and is strictly diagonally dominant.*

(b) *There exists a positive vector* e *in* R^n *such that* $B_ie > 0$ *for all* $i = 0, 1, \ldots, k$.

Then for all $\mathbf{b}$, EGOLCP$(\mathbf{B}, \mathbf{b})$ *has a unique solution.*

Proof. Let B be any representative matrix of $\mathbf{B}$. Obviously, B is a $\mathbf{Z}$-matrix. Moreover, under (a), B will have positive diagonal entries and is strictly diagonally dominant, and when (b) holds, $Be > 0$. In either situation, B is a $\mathbf{P}$-matrix [5], and hence the determinant of B is positive. The equivalence of Conditions 1 and 5 in Theorem 17 gives the desired result. □

Remarks. The conditions (a) and (b) of Corollary 3 were considered, in the context of EGOLCP, by Isac and Goeleven [31] and Goeleven [22], respectively. They showed that for each $\mathbf{b}$, EGOLCP$(\mathbf{B}, \mathbf{b})$ has at most one solution but they did not prove the existence of solutions.

Concluding remarks. In this paper, we have presented an analysis of existence, uniqueness, and stability aspects of the GOLCP and its extension, the EGOLCP. This analysis, which is based on degree theory, is by no means complete. For example, we have not treated $\mathbf{Z}$-matrices, row (column) sufficient matrices, and their counterparts in the general theory. Note, however, that there are results for such matrices and their generalizations [5], [2], [15]. Although our study is rather limited, we believe that, on the whole, the GOLCP theory is very similar to the classical LCP theory.

Acknowledgment. We thank one of the referees for pointing out an error in an earlier version of Theorem 15 and for indicating the given simplified proof in the present version.

A MATRIX APPROACH TO FINDING A SET OF GENERATORS AND FINDING THE POLAR (DUAL) OF A CLASS OF POLYHEDRAL CONES *

CAROLYN PILLERS DOBLER†

Abstract. A set of generators for a polyhedral cone is found by using a new representation for the polar (dual) cone. Examples from order-restricted statistical inference are chosen to illustrate this method.

Key words. polyhedral cone, generators, polar cone, dual cone, order-restricted statistical inference

AMS subject classifications. primary 52B99; secondary 15A39

1. Introduction. Mathematical quantities or objects can often be expressed by more than one representation. The object of interest in this paper is a polyhedral cone or a "cone which is a polyhedron" [1, p. 55]. A polyhedral cone is a special type of closed, convex cone and has at least two representations. It can be expressed as the solution set of a system of homogeneous linear inequalities:

$$C = \{\mathbf{x} \in \Re^k : \mathbf{a}_i'\mathbf{x} \leq 0, \quad i = 1, 2, \ldots, m\} = \{\mathbf{x} \in \Re^k : A'\mathbf{x} \leq \mathbf{0}\}, \tag{1}$$

where $\mathbf{a}_i'$ is the ith row of A'. Note that for any given system of homogeneous linear inequalities, the matrix A is not unique. Another representation of a polyhedral cone is the set of all nonnegative linear combinations of a finite set of generating vectors [1, Thm. of Minkowski]:

$$\begin{aligned} C &= \left\{ \mathbf{x} \in \Re^k : \mathbf{x} = \sum_{i=1}^{p} \lambda_i \mathbf{g}_i, \quad \forall \lambda_i \geq 0, \quad i = 1, 2, \ldots, p \right\} \\ &= \{\mathbf{x} \in \Re^k : \mathbf{x} = G\boldsymbol{\lambda} \quad \forall \boldsymbol{\lambda} \geq \mathbf{0}\}, \end{aligned} \tag{2}$$

where $\mathbf{g}_i$ is the ith column of G. The columns of G are a set of generators for C. Note that we say "a" set of generators rather that "the" set of generators, because a set of generators is not unique. Also note any set of generators in scale invariant, that is, if $\{\mathbf{g}_1, \mathbf{g}_2, \ldots, \mathbf{g}_p\}$ is a set of generators for C and α is any positive scalar, then $\{\alpha\mathbf{g}_1, \alpha\mathbf{g}_2, \ldots, \alpha\mathbf{g}_p\}$ is also.

Polyhedral cones arise in many practical problems, particularly in order-restricted statistical inference (wherein constraints on a set of parameters are often defined by polyhedral cones) and in linear programming. In some of these problems, a homogeneous system of linear inequalities, as in (1), is specified, but one needs to find a set of generators, as in (2). In this paper, we discuss a matrix approach for finding a set of generators for a particular class of polyhedral cones. That is, we provide an answer to

the question: If a matrix A in (1) is specified, how can we find a matrix G to satisfy (2)? In fact, the answer to this question also provides the answer to another question: How can we find the polar (dual) of a polyhedral cone?

2. Motivation and examples. Why is the identification of a set of generators of a polyhedral cone important? A set of generators is useful for determining order-preserving functions [2]. In order-restricted statistical inference, a set of generators can be used to verify one of the conditions that the isotonic regression must satisfy [3, Example 1.3.2]. An important use of a set of generators is in the creation of contrast statistics for hypothesis testing problems involving order restrictions [3, §§4.2 and 4.3], [4], and [5]. In minimization and maximization problems, one often needs to find the closest point in a polyhedral cone to a specified point $\mathbf{x} \in \Re^k$; this closest point is called the projection of $\mathbf{x}$ onto C. There are many algorithms available for computing the projection. In [6], an algorithm is presented where C is expressed in representation (2), and thus one can compute the projection from a set of generators. For certain polyhedral cones, this algorithm may be more efficient than existing algorithms because the algorithm converges in finitely many linear steps.

An example of a polyhedral cone using both representations (1) and (2) is provided by the "simple tree" polyhedral cone [3, Example 1.3.2]. The simple tree polyhedral cone is the set of all vectors in $\Re^k$ satisfying the simple tree partial order, that is, $x_1 \leq x_i, i = 2, 3, \ldots, k$. Expressing the simple tree cone in representation (1), the matrix A is a $k \times (k-1)$ matrix with (i,j)th entry: $a_{ij} = 1$ if $i = 1, a_{ij} = -1$ if $i = j+1$, and $a_{ij} = 0$ otherwise. The matrix G in representation (2) is a $k \times (k+1)$ matrix with ith column $\mathbf{g}_i$: for $i = 1, 2, \ldots, k-1, g_{i,i+1} = 1$ and $g_{ij} = 0$ for $j \neq i+1$; $\mathbf{g}_k = \mathbf{1}'$ (the vector of ones), and $\mathbf{g}_{k+1} = -\mathbf{g}_k$. We see that for any vector $\mathbf{x}$ that follows the simple tree order, $\mathbf{x}$ can be written as $\mathbf{x} = G\boldsymbol{\lambda} = \sum_{i=1}^{k+1} \lambda_i \mathbf{g}_i$ for some $\lambda_i \geq 0, i = 1, 2, \ldots, k+1$. In particular, $\lambda_i = x_i - x_1 \geq 0$ for $i = 1, 2, \ldots, k-1$, and if $x_1 < 0, \lambda_k = 0$ and $\lambda_{k+1} = -x_1 > 0$, whereas if $x_1 \geq 0, \lambda_k = x_1 \geq 0$ and $\lambda_{k+1} = 0$.

Several examples of polyhedral cones appearing in the literature are the simple linear order [3, §1.2] and [4], the star-shaped order [3, §5.3], the unimodal (umbrella) order [3, §5.5], the positive orthant [7, Chap. 14, §C], and the positive orthant restricted to the linear subspace where the sum of the components of the vector is zero [7, Chap. 14, §C].

3. Background. The standard reference for polyhedral cones is [1, Chap. 2]. A discussion of polyhedral cones in the context of order-restricted statistical inference appears in [3, §2.7].

Define a weighted inner product as $\langle \mathbf{x}, \mathbf{y} \rangle_W = \mathbf{x}' W \mathbf{y}$, for $\mathbf{x}, \mathbf{y} \in \Re^k$, where W is a $k \times k$ positive definite weight matrix. (Note that since W is positive definite, it must also be symmetric.) In a statistical context, the weight matrix W is often the variance–covariance matrix, or it may be a diagonal matrix, with diagonal entries being the sample sizes or reciprocals of the sample sizes. The notation $\mathbf{x} \leq \mathbf{y}$ denotes component-wise inequality, that is, $x_i \leq y_i, i = 1, 2, \ldots, k$.

The question of interest is: Given a polyhedral cone in its inequality representation, (1), with a matrix A specified, how can we find a matrix G in (2) so we can identify a set of generators of the cone? When A is $k \times k$ and full rank, a set of generators is given by the columns of $-A^{-1}$ [2], but a more general solution does not exist in the literature. Many of the examples in the literature simply provide a set of generators and then show that any vector in the polyhedral cone can be written as a nonnegative linear combination of these generators, but it is not indicated *how* these generators are obtained. This process appears to be largely trial and error. We now

discuss a more systematic way of finding a set of generators for a class of polyhedral cones.

The key to the relationship between A in (1) and G in (2) is provided by the polar, or dual, cone. The polar cone of a polyhedral cone C is

$$(3) \qquad C^P = \{\mathbf{y} \in \Re^k : \langle \mathbf{x},\ \mathbf{y}\rangle_W \leq 0 \quad \forall \mathbf{x} \in C\} = \{y \in \Re^k : \mathbf{x}'W\mathbf{y} \leq 0 \quad \forall \mathbf{x} \in C\}.$$

Geometrically, the polar (dual) cone is the set of all vectors in $\Re^k$ that make an obtuse angle with every vector in C. The polar, C^P, is also a polyhedral cone, and $C^{PP} = C$ [1].

For any C expressed in representation (1), an alternative representation for the polar is

$$(4) \qquad C^P = \{\mathbf{y} \in \Re^k : \mathbf{y} = W^{-1}A\boldsymbol{\lambda}, \quad \forall \boldsymbol{\lambda} \geq \mathbf{0}\}$$

[1, p. 55]. From this representation, it is obvious that the columns of $W^{-1}A$ are a set of generators for C^P.

Since C^P is a polyhedral cone, it can be written in an inequality representation, that is, $C^P = \{\mathbf{y} \in \Re^k : G'\mathbf{y} \leq \mathbf{0}\}$. By (1), (4), and the fact that $C^{PP} = C$, we see that $C = \{\mathbf{x} \in \Re^k : \mathbf{x} = W^{-1}G\boldsymbol{\alpha}$, for all $\boldsymbol{\alpha} \geq \mathbf{0}\}$, and a set of generators for C are the columns of $W^{-1}G$. To reach our goal of finding a set of generators for C, we express C^P in its inequality representation, (1), where the matrix G defining the inequalities of C^P is somehow related to A, a specified matrix defining the inequalities of C.

To facilitate reaching our goal, let us rewrite C and C^P in a slightly different form. Note that any polyhedral cone is determined by either linear inequalities, linear equalities, or both. Separating the inequalities and equalities, an alternative form of (1) is

$$(5) \qquad C = \{\mathbf{x} \in \Re^k : A'\mathbf{x} \leq \mathbf{0} \quad \text{and} \quad B'\mathbf{x} = \mathbf{0}\},$$

where A is $k \times m_1$ and B is $k \times m_2$.

An alternative form of C^P corresponding to (4) is

$$(6) \qquad C^P = \{\mathbf{y} \in \Re^k : \mathbf{y} = W^{-1}(A\boldsymbol{\lambda} + B\mathbf{r}), \quad \forall \boldsymbol{\lambda} \geq \mathbf{0}, \quad \mathbf{r} \in \Re^{m_2}\}.$$

DEFINITION 3.1. *A polyhedral cone in the form of* (5) *is in* full rank *form if* rank $(A) = m_1$ *and* rank $(B) = m_2$.

Note that for a polyhedral cone to be in full rank form, the rows of $A'(B')$ must be linearly independent and the number of inequality (equality) constraints, m_1 (m_2), must be less than or equal to the dimension of the space, k. Not all polyhedral cones can be written in full rank form. When trying to express a polyhedral cone in full rank form, it is often helpful to first eliminate all redundant constraints. Let the columns of A (B) be expressed as a set of m_1 (m_2) vectors $\{\mathbf{a}_1, \mathbf{a}_2, \ldots, \mathbf{a}_{m_1}\}$ $(\{\mathbf{b}_1, \mathbf{b}_2, \ldots, \mathbf{b}_{m_2}\})$. A vector $\mathbf{a}_l$ is redundant if

$$\{\mathbf{x} \in \Re^k : \mathbf{a}_i'\mathbf{x} \leq 0,\ i \in \{1, 2, \ldots, m_1\} \text{ and } \mathbf{b}_j'\mathbf{x} = 0,\ j \in \{1, 2, \ldots, m_2\}\}$$
$$= \{\mathbf{x} \in \Re^k : \mathbf{a}_i'\mathbf{x} \leq 0,\ i \in \{1, 2, \ldots, m_1\} - \{l\} \text{ and } \mathbf{b}_j'\mathbf{x} = 0,\ j \in \{1, 2, \ldots, m_2\}\}.$$

A vector $\mathbf{b}_l$ is redundant by a similar definition. Hence, a constraint (either $\mathbf{a}_l'\mathbf{x} \leq 0$ or $\mathbf{b}_l'\mathbf{x} = 0$) is redundant if the vector $\mathbf{a}_l$ $(\mathbf{b}_l)$ is redundant. An algorithm for removing redundant constraints is found in [8].

DEFINITION 3.2. *A polyhedral cone in form* (5) *is in* nonredundant *form if all redundant constraints have been removed.*

An example of a polyhedral cone that cannot be written in full rank form is the simple loop order [3, p. 84] when $k = 4$: $C = \{\mathbf{x} \in \Re^4 : x_1 \leq x_2 \leq x_4 \text{ and } x_1 \leq x_3 \leq x_4\}$. Then

$$A = \begin{bmatrix} 1 & 1 & 0 & 0 \\ -1 & 0 & 1 & 0 \\ 0 & -1 & 0 & 1 \\ 0 & 0 & -1 & -1 \end{bmatrix},$$

which contains no redundant columns. Since rank $(A) = 3 \neq 4 = m_1$, the simple loop polyhedral cone does not have a full rank form. We discuss the nonfull rank case more fully in §6.

The set of all polyhedral cones that can be written in full rank form is called the class of full rank polyhedral cones. The main result in the next section provides a relationship between C and C^P, both in representation (5), for the class of full rank polyhedral cones that satisfy one additional condition.

4. The main result. In the following, I_m is the $m \times m$ identity matrix and $0_{m_1 \times m_2}$ is an $m_1 \times m_2$ matrix of zeros. Also recall that W is a positive definite weight matrix that defines the weighted inner product. The following lemma provides the existence of a matrix needed in the theorem.

LEMMA 4.1. *Let A be a $k \times m$ matrix,* rank $(A) = m$. *Then there exists a matrix G_A such that $G_A A = I_m$.*

Proof. Note that G_A' is the solution to $A'G_A' = I_m$. Its existence can be seen by considering the m sets of simultaneous equations $A'\mathbf{g}_{A_i} = \mathbf{e}_i$, where $\mathbf{g}_{A_i}$ is the ith column of G_A' and $\mathbf{e}_i$ is the column vector with ith component one, all other components zero. Since rank (A') = rank $(A) = m, A'\mathbf{g}_{A_i} = \mathbf{e}_i$ has a solution [9, Thm. 7.2.4]. Hence, $A'G_A' = I_m$ has a solution. The solution is unique if and only if $k =$ rank (A') = rank (A) [9, Cor. 7.3.1.4]. Thus, a unique G_A exists if and only if A is a $k \times k$ full rank matrix. □

THEOREM 4.2. *Let C be a full-rank polyhedral cone in representation* (5), *with G_A and G_B any matrices satisfying $G_A A = I_{m_1}$ and $G_B B = I_{m_2}$. If, in addition, $G_A B = 0_{m_1 \times m_2}$, then*

$$(7) \qquad C^P = \{\mathbf{y} \in \Re^k : -G_A W\mathbf{y} \leq \mathbf{0} \quad \textit{and} \quad (I - AG_A - BG_B)\,W\mathbf{y} = \mathbf{0}\}.$$

Furthermore, if $G_B A = 0_{m_2 \times m_1}$ and $m_1 + m_2 = k$, then $C^P = \{\mathbf{y} \in \Re^k : -G_A W\mathbf{y} \leq \mathbf{0}\}$.

Proof. We know that G_A and G_B exist from Lemma 4.1. Recall from (3) and (6) that $C^P = \{\mathbf{y} \in \Re^k : \mathbf{x}'W\mathbf{y} \leq 0 \text{ for all } \mathbf{x} \in C\} = \{\mathbf{y} \in \Re^k : \mathbf{y} = W^{-1}[A \quad B]\begin{bmatrix}\boldsymbol{\lambda} \\ \mathbf{r}\end{bmatrix} \text{ for all } \boldsymbol{\lambda} \geq \mathbf{0}, \mathbf{r} \in \Re^{m_2}\}$. Let C^* be as in (7), and we want to show that $C^* = C^P$. First, note if $G_B A = 0_{m_2 \times m_1}$, then $AG_A + BG_B$ is idempotent. Furthermore, if $m_1 + m_2 = k$, then rank $(AG_A + BG_B) = k$ and hence $AG_A + BG_B = I_k$.

Consider $\mathbf{y} \in C^*$. If $m_1 + m_2 = k$ and $G_B A = 0_{m_2 \times m_1}$, then for all $\mathbf{x} \in C$,

$$\mathbf{x}'W\mathbf{y} = \mathbf{x}'\,(AG_A + BG_B)\,W\mathbf{y} = \mathbf{x}'AG_AW\mathbf{y} + \mathbf{x}'BG_BW\mathbf{y} \leq 0,$$

because $\mathbf{x}'A \leq \mathbf{0}', G_AW\mathbf{y} \geq \mathbf{0}$, and $\mathbf{x}'B = \mathbf{0}'$. If $m_1 + m_2 \neq k$, then $\mathbf{y} = W^{-1}(AG_A + BG_B)W\mathbf{y}$. For all $\mathbf{x} \in C$, $\mathbf{x}'W\mathbf{y} = \mathbf{x}'WW^{-1}(AG_A + BG_B)W\mathbf{y} = \mathbf{x}'AG_AW\mathbf{y} + \mathbf{x}'BG_BW\mathbf{y} \leq 0$. Hence, $\mathbf{y} \in C^P$, so $C^* \subset C^P$.

Consider $\mathbf{y} \in C^P$. Then $\mathbf{y} = W^{-1}A\boldsymbol{\lambda} + W^{-1}B\mathbf{r}$ for some $\boldsymbol{\lambda} \geq \mathbf{0}$ and $\mathbf{r} \in \Re^{m_2}$. Now, $G_AW\mathbf{y} = G_AWW^{-1}A\boldsymbol{\lambda}+G_AWW^{-1}B\mathbf{r} = \boldsymbol{\lambda} \geq \mathbf{0}$ or $-G_AW\mathbf{y} \leq \mathbf{0}$. If $m_1+m_2 = k$ and $G_BA = 0_{m_2\times m_1}$, then $AG_A + BG_B = I_k$, so that $(I - AG_A - BG_B)W\mathbf{y} = \mathbf{0}$, and hence $\mathbf{y} \in C^*$. If $m_1 + m_2 \neq k$, then we know that $\mathbf{y} = W^{-1}A\boldsymbol{\lambda} + W^{-1}B\mathbf{r}$ has a solution, implying $W\mathbf{y} = A\boldsymbol{\lambda} + B\mathbf{r}$ has a solution. The solution must satisfy

$$[A \quad B]\begin{bmatrix} G_A \\ G_B \end{bmatrix} W\mathbf{y} = W\mathbf{y}$$

[9, Thm. 7.2.3]. Therefore, $(I - AG_A - BG_B)W\mathbf{y} = \mathbf{0}$ and $\mathbf{y} \in C^*$, so $C^P \subset C^*$. Hence, $C^* = C^P$. □

To use the theorem to find a set of generators for C: (i) Solve the system of equations $G_AA = I, G_BB = I$, and $G_AB = 0$. The system of equations may not have a unique solution. Often, G_A (or G_B) is of a simple form such as $(A'A)^{-1}A'$ or $(A'DA)^{-1}A'D$, for some $k \times k$ full rank matrix D. Although G_B always exists, there may not be a matrix G_A to satisfy the system of equations defined by $G_AA = I$ and $G_AB = 0$. (Note that if $m_1 + m_2 = k$, we solve the system $G_AA = I, G_AB = 0, G_BB = I$, and $G_BA = 0$.)

(ii) Define a set of generators by the unduplicated rows of the matrices $-G_A, I - AG_A - BG_B$, and $-(I - AG_A - BG_B)$.

To see that a set of generators arises from this process, we simply use the form of C^P in (7) to obtain a set of generators for C as the columns of $-W^{-1}(G_AW)'$ and $\pm W^{-1}((I - AG_A - BG_B)W)'$. But since W is positive definite and symmetric, a set of generators is given by the columns of $-G_A^{'}$ and $\pm(I - AG_A - BG_B)'$ or the rows of their transposes.

Note that if $A = 0$, then C is a linear subspace. C^P is the orthogonal complement of C, and the rows of $(I - BG_B)$ are a set of spanning vectors for C. Since $G_B = (B'B)^{-1}B'$ satisfies the condition of the theorem, a set of spanning vectors is provided by the rows of $(I - B(B'B)^{-1}B')$.

Also note that if $B = 0$, then C consists entirely of inequality constraints, and the only condition for C to satisfy is that the inequality constraints are independent and the number of inequality constraints (m_1) is less than the dimension of the space (k).

Although our aim was to find a set of generators for a polyhedral cone, we see that Theorem 4.2 also provides the solution to finding the polar (dual) cone. This situation is of interest in its own right, because an optimization problem involving a polyhedral cone may be easier to solve in terms of the dual cone [3, §1.7], [10], and [11]. Examples of this use of Theorem 4.2 are given in the next section.

Theorem 4.2 also provides a vehicle for expressing C in its inequality representation (1) if a set of generators are known. When a set of generators for C are known, then we can express C^P in its inequality/equality representation (7). Now, just apply Theorem 4.2, with C^P playing the role of C. Since $C^{PP} = C$, the polar of C^P in representation (7) is just C! An example of this procedure is also given in the next section.

5. Special cases and examples. We now consider special cases in which the computation of G_A and G_B is relatively straightforward. In the examples in this section, unless otherwise specified, $k = 3$ for ease of computation and of presentation, although all the examples easily extend when $k > 3$. We also assume that W is an arbitrary positive definite weight matrix, unless otherwise stated.

If $m_1 = k, B = 0$, then $G_A = A^{-1}$, and the rows of $-A^{-1}$ are a set of generators for C. This is the situation discussed in [3].

If $m_1 < k, B = 0$, then $G_A = (A'A)^{-1}A'$, the Moore–Penrose inverse of A, is a solution to $G_A A = I$. The rows of $-(A'A)^{-1}A'$ and $\pm(I - A(A'A)^{-1}A')$ are a set of generators for C. For example, consider the simple tree ordering from the example in §2 when $k = 3$. Then $C = \{\mathbf{x} \in \Re^3 : x_1 \leq x_2 \text{ and } x_1 \leq x_3\}$ and

$$A = \begin{bmatrix} 1 & 1 \\ -1 & 0 \\ 0 & -1 \end{bmatrix}, \quad G_A = \left(\frac{1}{3}\right)\begin{bmatrix} -1 & 2 & -1 \\ -1 & -1 & 2 \end{bmatrix}, \quad \text{and} \quad I - AG_A = \left(\frac{1}{3}\right)\mathbf{1}\mathbf{1}'.$$

Since a set of generators is scale invariant, a set of generators for C are $\mathbf{g}_1 = [-1, 2, -1]', \mathbf{g}_2 = [-1, -1, 2]', \mathbf{g}_3 = [1, 1, 1]'$, and $\mathbf{g}_4 = [-1, -1, -1]'$. Note that this set of generators is different than the one in the example in §2. Since $\mathbf{x} = \sum_{i=1}^{4} \lambda_i \mathbf{g}_i$ for all $\mathbf{x} \in C, \lambda_1 = (x_2 - x_1)/3 \geq 0, \lambda_2 = (x_3 - x_1)/3 \geq 0$, and if $x_1 < 0, \lambda_3 = (x_2 + x_3 - 2x_1)/3 \geq 0$ and $\lambda_4 = -x_1 \geq 0$, whereas if $x_1 \geq 0, \lambda_3 = (x_1 + x_2 + x_3)/3 \geq 0$ and $\lambda_4 = 0$. This illustrates that a set of generators need not be unique. In addition, Theorem 4.2 provides the polar of C. If $W = I, C^P = (\mathbf{y} \in \Re^3 : y_1 + y_3 - 2y_2 \geq 0, y_1 + y_2 - 2y_3 \geq 0, y_1 + y_2 + y_3 = 0) = (\mathbf{y} \in \Re^3 : y_2 \leq 0, y_3 \leq 0, y_1 + y_2 + y_3 = 0)$. Now, suppose we only know a set of generators of C, $(\mathbf{g}_1, \ldots, \mathbf{g}_4)$, as given above. Since $C^P = (\mathbf{y} \in \Re^3 : y_2 \leq 0, y_3 \leq 0, y_1 + y_2 + y_3 = 0)$,

$$A = \begin{bmatrix} 0 & 0 \\ 1 & 0 \\ 0 & 1 \end{bmatrix}$$

and $B = \mathbf{1}'$. Since $m_1 = 2$ and $m_2 = 1$, so that $m_1 + m_2 = 3$, we solve the system of equations $G_A A = I, G_A B = 0, G_B B = I$, and $G_B A = 0$. The unique solution is

$$G_A = \begin{bmatrix} -1 & 1 & 0 \\ -1 & 0 & 1 \end{bmatrix},$$

and $G_B = [1 \quad 0 \quad 0]$, so $C = C^{PP} = \{\mathbf{x} \in \Re^3 : -G_A \mathbf{x} \leq \mathbf{0}\} = \{\mathbf{x} \in \Re^3 : x_1 \leq x_2 \text{ and } x_1 \leq x_3\}$, which is the simple tree cone.

The next two examples illustrate polyhedral cones with both inequality and equality constraints. First, suppose $m_1 < k$ and $B = W\mathbf{1}$, where again W is an arbitrary positive definite weight matrix. In this context, B represents a vector of weights, and we are restricting our original polyhedral cone to a linear subspace where the weighted sum of the components of the vectors is zero. An example of this situation appears in [5], where a multiple contrast statistic is defined for the treatments versus control hypothesis testing situation. In this problem, any contrast vector must satisfy the simple tree order, and the weighted sum of its components must be zero. If $A'\mathbf{1} = \mathbf{0}$, then $G_A = (A'W^{-1}A)^{-1}A'W^{-1}$ and $G_B = (\mathbf{1}'W\mathbf{1})^{-1}\mathbf{1}'$. A set of generators are the rows of $-G_A$ and $\pm[I - A(A'W^{-1}A)^{-1}A'W^{-1} - W\mathbf{1}(\mathbf{1}'W\mathbf{1})^{-1}\mathbf{1}']$.

A second example involves the umbrella order constrained to the "symmetry" subspace, that is, $C = \{\mathbf{x} \in \Re^3 : x_1 \leq x_2 \leq x_3, \text{ and } x_1 = x_3\}$, as in [12]. If we let

$$A' = \begin{bmatrix} 1 & -1 & 0 \\ 0 & -1 & 1 \end{bmatrix},$$

and $B' = [-1 \quad 0 \quad 1]$, then C is in full rank form, but it contains redundant constraints. Furthermore, the system of equations $G_A A = I$ and $G_A B = 0$ does not have

a solution because the rows of A' and B' are linearly dependent. Since $x_1 = x_3$, the constraint defined by the second row of A' is redundant and can be ignored. Letting $A' = [1 \quad -1 \quad 0]$, and $B' = [-1 \quad 0 \quad 1]$, then a solution to $G_A A = I, G_A B = 0$, and $G_B B = 1$ is $G_A = [0 \quad -1 \quad 0]$ and $G_B = [0 \quad 0 \quad 1]$. Then $-G_A = [0 \quad 1 \quad 0]$ and

$$I - AG_A - BG_B = \begin{bmatrix} 1 & 1 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix},$$

and a set of generators is $\mathbf{g}_1 = [0,1,0]', \mathbf{g}_2 = [1,1,1]'$, and $\mathbf{g}_3 = -\mathbf{g}_2$. For any $\mathbf{x} \in C, \mathbf{x} = \sum_{i=1}^{3} \lambda_i \mathbf{g}_i$, where $\lambda_1 = x_2 - x_1 \geq 0$, and if $x_2 \geq 0$, then $\lambda_2 = x_2 \geq 0$ and $\lambda_3 = x_2 - x_1 \geq 0$, whereas if $x_2 < 0$, then $x_1 < 0$ so that $\lambda_2 = 0$ and $\lambda_3 = -x_1 > 0$. Further, $C^P = \{\mathbf{y} \in \Re^k : -G_A \mathbf{y} \leq 0 \text{ and } (I - AG_A - BG_B)\mathbf{y} = \mathbf{0}\} = \{\mathbf{y} \in \Re^3 : y_2 \leq 0 \text{ and } y_1 + y_2 + y_3 = 0\}$. This example illustrates the importance of eliminating all redundant constraints from A and B before trying to apply the theorem.

6. Nonfull rank case. The main problem with Theorem 4.2 is its restriction to full rank cones. Although most practical problems involve full rank cones, situations may arise when the cone is not full rank, as illustrated by the simple loop order discussed in §3. The following algorithm, suggested by a referee, can be used to find a set of generators for a nonfull rank cone.

ALGORITHM 6.1. Assume that C is expressed in representation (1) and that all constraints are nonredundant. Furthermore, rank $(A) > m$.

Step 1. Find, if possible, a subspace $S \subset C$, where S has codimension r. Let $\mathbf{a}_i^* = P(\mathbf{a}_i | S^\perp), i = 1,2,\ldots,m$, that is, project $\mathbf{a}_i$ onto $S^\perp$, the orthogonal complement of S.

Step 2. Let K_j be a subset of $\{\mathbf{a}_1^*, \mathbf{a}_2^*, \ldots, \mathbf{a}_m^*\}$ of size $r-1$, where $j = 1,2,\ldots, \binom{m}{r-1}$. Find a vector $\mathbf{b}_j$ such that $\mathbf{b}_j' \mathbf{c}_i = 0$ for all $\mathbf{c}_i \in K_j$ and $\mathbf{b}_j' \mathbf{d} = 0$ for all $\mathbf{d} \in S$. The set

$$\left\{\mathbf{b}_1 \mathbf{b}_2, \ldots, \mathbf{b}_{\binom{m}{r-1}}, -\mathbf{b}_1, -\mathbf{b}_2, \ldots, -\mathbf{b}_{\binom{m}{r-1}}\right\}$$

contains a set of generators for C.

Step 3. For each vector $\mathbf{b}_j, j = 1,2,\ldots,\binom{m}{r-1}$, compute $\mathbf{b}_j' \mathbf{a}_i$ for $i = 1,2,\ldots,m$. If $\mathbf{b}_j' \mathbf{a}_i < 0$ for all $\mathbf{a}_i^* \notin K_j$, then $\mathbf{b}_j$ is a generator of C. If $\mathbf{b}_j' \mathbf{a}_i > 0$ for all $\mathbf{a}_i^* \notin K_j$, then $-\mathbf{b}_j$ is a generator of C. If $\mathbf{b}_j' \mathbf{a}_i > 0$ for some $\mathbf{a}_i^* \notin K_j$ and $\mathbf{b}_j' \mathbf{a}_{i'} < 0$ for some $\mathbf{a}_{i'}^* \notin K_j$, then $\mathbf{b}_j$ is not a generator of C.

If the constraints of C are written "in order," then one need not search all subsets K_j.

For example, consider the simple loop order when $k = 4$. Then $\mathbf{a}_1 = (1 \quad -1 \quad 0 \quad 0), \mathbf{a}_2 = (1 \quad 0 \quad -1 \quad 0), \mathbf{a}_3 = (0 \quad 1 \quad 0 \quad -1)$, and $\mathbf{a}_4 = (0 \quad 0 \quad 1 \quad -1)$. Now $S = (\mathbf{x} \in \Re^4 : \sum_{i=1}^{4} x_i = 0)$, which is generated by $(1 \quad 1 \quad 1 \quad 1)$ and codim $(S) = 3$. Furthermore, $S^\perp = \{\mathbf{y} \in \Re^4 : y_1 + y_2 + y_3 + y_4 = 0\}$, so $\mathbf{a}_i \in S^\perp$ and hence $\mathbf{a}_i^* = \mathbf{a}_i$. Rather than consider all subsets of $\{\mathbf{a}_i\}$ of size $r - 1 = 2$, note that dim $(C^P) = 3$ and the faces of C^P are two dimensional, generated by pairs of $\{\mathbf{a}_i\}$. The pairs generating these faces are $\{\mathbf{a}_1, \mathbf{a}_2\}, \{\mathbf{a}_2, \mathbf{a}_3\}, \{\mathbf{a}_3, \mathbf{a}_4\}$, and $\{\mathbf{a}_4, \mathbf{a}_1\}$, so we only need to consider these four pairs in Step 2 of Algorithm 6.1 rather than all six pairs. It is easy to see that $\mathbf{b}_1 = (-1,-1,-1,3), \mathbf{b}_2 = (-1,1,-1,1), \mathbf{b}_3 = (-3,1,1,1)$, and $\mathbf{b}_4 = (-1,-1,1,1)$ are a set of generators of the simple loop order.

7. Summary. Theorem 4.2 provides an alternative representation for the polar (dual) of a polyhedral cone. This representation serves three purposes: (i) finding a set

of generators for a polyhedral cone, (ii) finding the polar (dual) of a polyhedral cone, and (iii) expressing a polyhedral cone in its inequality form when a set of generators is known. To use the theorem, the polyhedral cone must be in full-rank form. As seen by the "simple loop" example, not all polyhedral cones in applications can be written in full rank form. In addition, it is important to remove all redundant constraints before attempting to use this method. The examples in §5 illustrate how Theorem 4.2 can be applied to many polyhedral cones arising in practical situations, particularly in order-restricted statistical inference.

A UNIFORM APPROACH FOR THE FAST COMPUTATION OF MATRIX-TYPE PADÉ APPROXIMANTS *

BERNHARD BECKERMANN† AND GEORGE LABAHN‡

Abstract. Recently, a uniform approach was given by B. Beckermann and G. Labahn [*Numer. Algorithms*, 3 (1992), pp. 45–54] for different concepts of matrix-type Padé approximants, such as descriptions of vector and matrix Padé approximants along with generalizations of simultaneous and Hermite Padé approximants. The considerations in this paper are based on this generalized form of the classical scalar Hermite Padé approximation problem, *power Hermite Padé approximation.* In particular, this paper studies the problem of computing these new approximants.

A recurrence relation is presented for the computation of a basis for the corresponding linear solution space of these approximants. This recurrence also provides bases for particular subproblems. This generalizes previous work by Van Barel and Bultheel and, in a more general form, by Beckermann. The computation of the bases has complexity $\mathcal{O}(\sigma^2)$, where σ is the order of the desired approximant and requires no conditions on the input data. A second algorithm using the same recurrence relation along with divide-and-conquer methods is also presented. When the coefficient field allows for fast polynomial multiplication, this second algorithm computes a basis in the superfast complexity $\mathcal{O}(\sigma \log^2 \sigma)$. In both cases the algorithms are reliable in exact arithmetic. That is, they never break down, and the complexity depends neither on any normality assumptions nor on the singular structure of the corresponding solution table. As a further application, these methods result in fast (and superfast) reliable algorithms for the inversion of striped Hankel, layered Hankel, and (rectangular) block-Hankel matrices.

Key words. vector Padé approximant, Hermite Padé approximant, simultaneous Padé approximant, matrix Padé approximant, Hankel matrices

1. Introduction.

Let $\mathbf{F} = (f_1, \ldots, f_m)^T$ (with $m \geq 2$) be an m-tuple of formal power series with coefficients from a field $\mathbb{K}$ (typically a subfield of either the real or complex numbers) and $\mathbf{n} = (n_1, \ldots, n_m)$ an m-tuple of integers, $n_l \geq -1$. A *Hermite Padé approximant* for $\mathbf{F}$ of type $\mathbf{n}$ is a nontrivial tuple $\mathbf{P} = (P_1, \ldots, P_m)$ of polynomials P_l over $\mathbb{K}$ having degrees bounded by the n_l such that

$$\mathbf{P}(z) \cdot \mathbf{F}(z) = P_1(z)f_1(z) + \cdots + P_m(z)f_m(z) = c_N z^N + c_{N+1} z^{N+1} + \cdots, \tag{1}$$

with $N = n_1 + \cdots + n_m + m - 1$.

The *Hermite Padé approximation problem* was introduced in 1873 by Hermite and has been studied widely by several authors (for a bibliography, see, e.g. [2]–[4] or [25]). Note that when $m = 2, \mathbf{F} = (f, -1)^T$, Eq. (1) is the same as

$$P_1(z)f(z) - P_2(z) = O\left(z^{n_1+n_2+1}\right),$$

and hence as a special case we have the classical Padé approximation problem for a power series f. Hermite Padé approximation also includes other classical approximation problems such as algebraic approximants ($\mathbf{F} = (1, f, f^2, \ldots, f^{m-1})^T$) (e.g. [23] for the special case $m = 2$) and G^3J approximants ($m = 3, \mathbf{F} = (f', f, 1)^T$). We refer the reader to [1, pp. 32–40] for additional examples. More generally, there is the

M-Padé approximation problem that requires that $\mathbf{P} \cdot \mathbf{F}$ vanishes at a given set of knots $z_0, z_1, \ldots, z_{N-1}$, counting multiplicities ([2]–[4], [20], [21]). The case where all the z_i are equal to 0 is just the Hermite Padé problem.

Hermite also defined a second type of approximant to a vector of power series, the so-called *simultaneous Padé approximants* and used them in his proof of the transcendence of e. Close connections between these two approximation problems have been pointed out in [7], [14], [16], [17], [21].

In recent years, several vector and matrix generalizations of these approximation problems have been given (see §2). The aim of this paper is to study a uniform approach not only to Hermite Padé and simultaneous Padé approximants but also to their matrix-type generalizations. To this end, we consider the following generalized scalar Hermite Padé approximation problem [5].

DEFINITION 1.1. *Let* $\sigma \geq 0, s > 0, n_1, \ldots, n_m$ *be integers,* $n_l \geq -1$ *and* $\mathbf{n} = (n_1, \ldots, n_m)$. *Then a* power Hermite Padé approximant *(PHPA)* $\mathbf{P} = (P_1, \ldots, P_m)$ *of type* $(\mathbf{n}, \sigma, s)$ *consists of scalar polynomials* P_l *having degrees bounded by the* n_l *with*

$$(2)\quad R(z) = \mathbf{P}(z^s) \cdot \mathbf{F}(z) = P_1(z^s) f_1(z) + \cdots + P_m(z^s) f_m(z) = c_\sigma z^\sigma + c_{\sigma+1} z^{\sigma+1} + \cdots,$$

that is, has order σ. *The power series* R *is referred to as the* s-residual.

The power s appearing in Definition 1.1 provides a method of converting a vector problem into a scalar problem (see §2). By defining these approximants in a similar way to Hermite Padé approximants we can borrow from the (successful) computational techniques for the Hermite Padé problem used in [2], [4], [25]. Of course the classical Hermite Padé approximation problem is included by setting $s = 1$ and $\sigma = \|\mathbf{n}\| - 1$, where the norm of multiindices $\mathbf{n} = (n_1, \ldots, n_m) \in (\mathbb{N}_0 \cup \{-1\})^m$ is defined by $\|\mathbf{n}\| := (n_1 + 1) + \cdots + (n_m + 1)$. Note that, by equating coefficients, (2) results in a system of homogeneous linear equations. By comparing the number of unknowns to equations, one can conclude that there exists at least $\|\mathbf{n}\| - \sigma$ PHPAs of type $(\mathbf{n}, \sigma, s)$ that are linearly independent over $\mathbb{K}$.

Section 2 gives examples of matrix-type generalizations of existing approximation problems. These are shown to be special cases of the PHPA problem for various values of s and σ. In §3 we provide a recursive algorithm to efficiently and reliably solve the PHPA problem in exact arithmetic. Some interesting properties of our algorithm along with a cost analysis are given in §4. It is shown that the algorithm is at least as fast or faster than existing methods for special cases. Thus, our results provide a uniform method of computing matrix-type generalizations of Padé approximation problems. Section 5 gives an example of the use of this algorithm in the context of square-matrix Padé approximants. Section 6 considers a modification of our algorithm that combines divide-and-conquer techniques along with the recurrence relation of §3. When the field $\mathbb{K}$ allows fast polynomial multiplication, the resulting new algorithm solves the PHPA problem with superfast complexity. Finally, the paper closes with a discussion of a number of research directions that follow from our work.

For purposes of presentation, we adopt the following notations. Let $\mathcal{S}$ be a space with scalars from $\mathbb{K}$, for instance, $\mathcal{S} = \mathbb{K}^{(p \times q)}$, the space of $p \times q$ matrices over $\mathbb{K}$. Then $\mathcal{S}[z]$ denotes the set of polynomials in z with coefficients from $\mathcal{S}$, whereas $\mathcal{S}[[z]]$ represents the set of formal power series in z with coefficients from $\mathcal{S}$. Multiindices and PHPAs are denoted in boldface letters; they are both $(1 \times m)$ row vectors. Also, throughout this paper the parameter s and the multiindex $\mathbf{n}$ are fixed. The algorithm of §3 follows along an m-dimensional "diagonal" path $(\mathbf{n}(\delta))_{\delta \in \mathbb{Z}}$ induced by $\mathbf{n}$, which

is defined as follows:

$$(3)\quad \delta \in \mathbb{Z}, \mathbf{n} = (n_1, \ldots, n_m) : \mathbf{n}(\delta) = \left(n_1', \ldots, n_m'\right) \quad \text{with } n_l' = \max\{-1, n_l + \delta\}.$$

This notion allows us to discuss not only one approximation problem corresponding to $\mathbf{n} = \mathbf{n}(0)$ but also simultaneously all subproblems associated with $\mathbf{n}(\delta), \delta < 0$ (cf. Table 3). Finally, the set of all PHPAs of type $(\mathbf{n}(\delta), \sigma, s)$ is denoted as $\mathcal{L}_\delta^\sigma$; it is a finite-dimensional space over $\mathbb{K}$.

Parallel to and independent of [5] and our present work, another uniforming approach was proposed in [26] by Van Barel and Bultheel based on the concept of vector M-Padé approximation. Their approach does not reduce to a simple scalar concept as does the notion of our PHPAs. However, their approach does have the advantage of handling matrix rational interpolation and is seen as complementary to this paper.

2. Matrix-type Padé approximants as special PHPAs. In this section we give examples of a number of matrix-type generalizations of classical Padé approximation problems. Let A be a $p \times q$ matrix of power series over $\mathbb{K}$ and suppose that $r \in \mathbb{N}$ and $M, N \in \mathbb{N}_0$.

Example 2.1 (Right-hand square and rectangular Matrix-Padé forms). Find $P \in \mathbb{K}^{(p\times r)}[z], Q \in \mathbb{K}^{(q\times r)}[z]$, with $\deg P \le M$, $\deg Q \le N$, and the columns of Q being linearly independent over $\mathbb{K}$ such that

$$A(z) \cdot Q(z) - P(z) = z^{M+N+1} \cdot R(z),$$

with $R \in \mathbb{K}^{(p\times r)}[[z]]$.

Example 2.2 (Left-hand square and rectangular Matrix-Padé forms). Find $P \in \mathbb{K}^{(r\times q)}[z], Q \in \mathbb{K}^{(r\times p)}[z]$, with $\deg P \le M$, $\deg Q \le N$, and the rows of Q being linearly independent over $\mathbb{K}$ such that

$$Q(z) \cdot A(z) - P(z) = z^{M+N+1} \cdot R(z),$$

with $R \in \mathbb{K}^{(r\times q)}[[z]]$.

When $p = q = r = 1$ this is the classical scalar Padé approximation problem. When $p = q = r > 1$ these are square right-hand or left-hand matrix Padé approximants [19]. In the rectangular ($p \neq q$) case, two natural matrix Padé approximations occur when either $p = r$ or $q = r$. Both of these rectangular-matrix types of Padé forms are used, for example, to compute the inverse of matrices partitioned into a rectangular-block Hankel structure [18].

We remark that, in the examples where $Q(z)$ is square, it is of special interest to determine those cases where we can form a Padé fraction $P(z)\cdot Q(z)^{-1}$ or $Q(z)^{-1}\cdot P(z)$ as an approximant to $A(z)$. In both cases we are therefore interested in necessary and sufficient conditions under which $Q(z)$ is nonsingular.

Motivated by the well-known connections between left-hand and right-hand square matrix Padé forms and by inversion formulas of block Hankel-like matrices, one of the authors [17] introduced for $p, \mu \in \mathbb{N}$ and $\rho_0, \ldots, \rho_\mu \ge 0, \rho = \rho_0 + \cdots + \rho_\mu, A_0, \ldots, A_\mu \in \mathbb{K}^{p\times p}[[z]]$.

Example 2.3 (Matrix Hermite Padé form). Find polynomials $P_0, \ldots, P_\mu \in \mathbb{K}^{p\times p}[z]$ with $\deg P_l \le \rho_l - 1, 0 \le l \le \mu$, and

$$A_0(z)P_0(z) + \cdots + A_\mu(z)P_\mu(z) = z^{\rho-1} \cdot R(z),$$

$R \in \mathbb{K}^{p\times p}[[z]]$ such that the matrix $[P_0, \ldots, P_\mu] \in \mathbb{K}^{p\times(\mu+1)p}[z]$ has full rank over $\mathbb{K}$.

Example 2.4 (Matrix simultaneous Padé form). Find polynomials $Q_0, \ldots, Q_\mu \in \mathbb{K}^{p\times p}[z]$ with $\deg Q_l \le \rho - \rho_l, 0 \le 1 \le \mu$, and

$$Q_0(z)A_l(z) - Q_l(z)A_0(z) = z^{\rho+1} \cdot R_l(z),$$

$1 \le l \le \mu, R_l \in \mathbb{K}^{p\times p}[[z]]$ such that the matrix $[Q_0, \ldots, Q_\mu] \in \mathbb{K}^{p\times(\mu+1)p}[z]$ has full rank over $\mathbb{K}$.

Beside the classical scalar simultaneous Padé approximants ($p = 1, A_0(z) = 1$), Example 2.4 also includes the *simultaneous partial Padé approximation problem* where we have prescribed poles and zeros for the approximants [8]. Following [22], the question of irreducible Hermite Padé forms is of special interest, i.e., we also require that $[P_0(0), \ldots, P_\mu(0)] \in \mathbb{K}^{p\times(\mu+1)p}$ is different from zero (or moreover has full rank over $\mathbb{K}$). Similarly, in Example 2.4 we are interested in approximants where $Q_0(0)$ is a nonsingular matrix.

We remark that the order conditions in Examples 2.1–2.4 are all such that at least one solution exists for each approximation problem. In addition, the so-called *weak matrix Hermite Padé* and *weak matrix simultaneous Padé forms* are connected to Examples 2.3 and 2.4 (see [17]). In this case the order conditions are weakened to allow for more linearly independent solutions. Other examples of matrix-type generalizations of Padé approximants include Hermite Padé [11] and simultaneous Padé systems [12], [17]. These, however, only exist in certain cases.

Note that the matrix simultaneous Padé form is closely connected to a rectangular matrix Hermite Padé form if the interpolation conditions are written as follows:

$$\begin{bmatrix} A_1^T(z) \\ A_2^T(z) \\ A_3^T(z) \\ \vdots \\ A_\mu^T(z) \end{bmatrix} \cdot Q_0^T(z) + \begin{bmatrix} -A_0^T(z) \\ 0 \\ 0 \\ \vdots \\ 0 \end{bmatrix} \cdot Q_1^T(z) + \cdots + \begin{bmatrix} 0 \\ 0 \\ 0 \\ \vdots \\ -A_0^T(z) \end{bmatrix} \cdot Q_\mu^T(z) = z^{\rho+1} \cdot \begin{bmatrix} R_1^T(z) \\ R_2^T(z) \\ R_3^T(z) \\ \vdots \\ R_\mu^T(z) \end{bmatrix}.$$

All examples given here are special cases of so-called vector Hermite Padé approximants.

Example 2.5 (vector Hermite Padé approximant). Let $m, s, \tau \in \mathbb{N}_0$, $m, s \ge 2, G_1, \ldots, G_m \in \mathbb{K}^{s\times 1}[[z]]$ and let $\mathbf{n}$ be a multiindex. Find linearly independent polynomial tuples $(P_1, \ldots, P_m), P_l \in \mathbb{K}[z]$ with $\deg P_l \le n_l, 1 \le l \le m$ such that

$$G_1(z)P_1(z) + \cdots + G_m(z)P_m(z) = z^\tau \cdot R(z),$$

with $R \in \mathbb{K}^{s\times 1}[[z]]$.

By setting

$$\text{for } 1 \le l \le m: \quad f_l(z) = (1, z, z^2, \ldots, z^{s-1}) \cdot G_l(z^s), \tag{4}$$

we see that computing vector Hermite Padé approximants of type $(\mathbf{n}, \tau)$ and dimension s is equivalent to the determination of PHPAs of type $(\mathbf{n}, \tau s, s)$, i.e. of the solution set $\mathcal{L}_0^{\tau s}$. Indeed, the above technique of converting a vector problem to a scalar problem via the raising of z to the sth power provides the motivation for Definition 1.1.

In Table 1, we list the particular choices of $m, \mathbf{n}, s, \sigma, \mathbf{F}$ with respect to Examples 2.1, 2.2, and 2.3. Instead of Example 2.4, we consider the special case of scalar simultaneous Padé approximation.

* Number of PHPA solutions required to construct the corresponding matrix-type Padé approximant.

3. Recursive computation of PHPA bases. In this section, we construct systems of m PHPAs by recurrence on σ. This allows us to describe all the PHPAs of type $(\mathbf{n}(\delta), \sigma, s), \delta \le 0$, when a fixed $s, \mathbf{F}$, and $\mathbf{n}$ are given. Therefore, we not only solve the Hermite Padé approximation problem of type $\mathbf{n}$ or the corresponding matrix-type Padé approximation problem (see §2) but also all subproblems of type $\mathbf{n}(\delta), \delta \le 0$ (cf. (3)) belonging to a "diagonal path" in the solution table. The recurrence formula and the resulting algorithm do not require any assumptions on the input data $\mathbf{F}$. Moreover, the algorithm is fast, i.e. it always has a complexity of $\mathcal{O}(\|\mathbf{n}\|^2)$ arithmetic operations, whereas the classical Gaussian algorithm, applied on the corresponding system of linear equations, has complexity $\mathcal{O}(\|\mathbf{n}\|^3)$ because it does not take into account the special structure of the matrix of coefficients. Finally, our method is also reliable, which in this context means that it also recognizes insoluble problems or gives representations if the solution sets of type $\mathbf{n}(\delta), \delta < 0$ are multidimensional (assuming that exact arithmetic is available). We remark that our algorithm does not consider the case of floating point arithmetic and hence does not consider the issue of numerical stability in the presence of roundoff errors.

Several fast algorithms for special cases of PHPAs are well known, but most of them require a normal or perfect solution table (i.e., PHPAs of different type are distinct). As far as we know, only the methods proposed in [19] for square matrix Padé approximation and the Jacobi–Perron continued fraction algorithms of [6] for simultaneous Padé approximation and [2], [4], [11], [12], [25] for scalar Hermite Padé approximation are also reliable. All of them still require slight assumptions on the input data ($A(0)$ regular, $\mathbf{F}(0)$ nontrivial); moreover, the algorithms of [11], [12], [19] might reach a complexity $\mathcal{O}(\|\mathbf{n}\|^3)$ if none of the subproblems of type $\mathbf{n}(\delta), \delta < 0$ has a unique solution.

For the special case $s = 1$ (i.e., scalar Hermite Padé approximation), the recurrence formula of our new algorithm is similar to that used in [2], [4], [25]. The *fast Gaussian algorithm* [2, §5] is motivated by the close connections to the factorization of the corresponding matrix of coefficients via the Gaussian algorithm with partial pivoting; a "special rule" reduces the complexity to $\mathcal{O}(\|\mathbf{n}\|^2)$. It provides solutions

to all subproblems on the diagonal path $(\mathbf{n}(\delta))_{\delta \le 0}$. The methods of [2], [4] both are developed for the more general M-Padé approximation problem (arbitrary interpolation knots); moreover, by the algorithm given in [4] we can compute solutions by recurrence on "arbitrary paths" or "staircases" $(\mathbf{n}_k)$ where the multiindex $\mathbf{n}_{k+1}$ differs from $\mathbf{n}_k$ by increasing one component (also the decreasing of a second component is allowed). Parallel to [2], [4], Van Barel and Bultheel proposed a fast, reliable method for computing Hermite Padé approximants on diagonal paths [25]. Their version is similar to [2] but notationally less complicated. The ideas developed in [26] for a recursive computation of vector M-Padé approximants have close connections to [4], [25]. The authors propose three alternative "basic steps" that include considerable freedom in solving certain subproblems.

There seems to be no connection between the methods described above and the reliable Jacobi–Perron continued fraction algorithm of [6] for simultaneous Padé approximation. For this approximation problem, using our formalism we obtain a more compact method with at most the same complexity; in addition, we get more information about singular cases.

Before describing bases for PHPA solution sets let us introduce the following definition.

DEFINITION 3.1 (defect, order). *The defect of a* $\mathbf{P} = (P_1, \dots, P_m) \in \mathbb{K}^m[z]$ *(with respect to the fixed multiindex* $\mathbf{n} = (n_1, \dots, n_m)$*) is*

$$\operatorname{dct} \mathbf{P} := \min_l \{n_l + 1 - \deg P_l\},$$

where the zero polynomial has degree $-\infty$*. The order of* $\mathbf{P}$ *(with respect to* $s \in \mathbb{N}$ *and* $\mathbf{F}$*) is defined by*

$$\operatorname{ord} \mathbf{P} := \sup \{\sigma \in \mathbb{N}_0 : \mathbf{P}(z^s) \cdot \mathbf{F}(z) = z^\sigma \cdot R(z) \quad \text{with } R \in \mathbb{K}[[z]]\}.$$

The definition of the defect is a natural extension of that found in the case of the M-Padé problem (cf. [3], [4]) and its special case of rational interpolation (some authors use a slightly different definition). The defect is also closely connected to the τ-degree of [25].

Using Definition 3.1, we get an equivalent characterization for PHPA solution sets:

$$\text{(5)} \quad \text{For } \sigma \in \mathbb{N}_0, \quad \delta \in \mathbb{Z} \cup \{+\infty\} : \mathcal{L}_\delta^\sigma = \{\mathbf{P} \in \mathbb{K}^m[z] : \operatorname{dct} \mathbf{P} > -\delta, \operatorname{ord} \mathbf{P} \ge \sigma\}.$$

Now we are able to describe so-called σ-bases of PHPAs.

DEFINITION 3.2 (σ-bases). *Let* $\sigma \in \mathbb{N}_0$*. The system* $\mathbf{P}_1, \dots, \mathbf{P}_m \in \mathbb{K}^m[z]$ *is called a* σ*-basis if and only if*:

(a) $\mathbf{P}_1, \dots, \mathbf{P}_m \in \mathcal{L}_{+\infty}^\sigma$, *i.e.*, $\operatorname{ord} \mathbf{P}_l \ge \sigma$.

(b) *For each* $\delta \in \mathbb{Z} \cup \{+\infty\}$ *and for each* $\mathbf{Q} \in \mathcal{L}_\delta^\sigma$ *there exists one and only one tuple of polynomials* $(\alpha_1, \dots, \alpha_m), \deg \alpha_l < \operatorname{dct} \mathbf{P}_l + \delta$ *such that* $\mathbf{Q} = \alpha_1 \cdot \mathbf{P}_1 + \dots + \alpha_m \cdot \mathbf{P}_m$.

Note that, as a consequence of Definition 3.2, a σ-basis $\mathbf{P}_1, \dots, \mathbf{P}_m$ must be linearly independent with respect to polynomial coefficients. Moreover, we have

$$\text{(6)} \quad \mathcal{L}_\delta^\sigma = \operatorname{span}\left\{z^j \cdot \mathbf{P}_l : 1 \le l \le m, 0 \le j < \operatorname{dct} \mathbf{P}_l + \delta\right\},$$

$$\text{(7)} \quad \dim \mathcal{L}_\delta^\sigma = \max\{\operatorname{dct} \mathbf{P}_1 + \delta, 0\} + \dots + \max\{\operatorname{dct} \mathbf{P}_m + \delta, 0\}.$$

The existence of σ-bases for the case $s = 1$ was given in [2]–[4], [25] and for the case $s > 1$ in [5]. Before giving an algorithm for their computation, let us state some simple rules for the defect and order of linear combinations of PHPAs.

LEMMA 3.3. *For* $\mathbf{P}, \mathbf{Q} \in \mathbb{K}^m[z], c \in \mathbb{K} \setminus \{0\}$:

(8)

$$\operatorname{dct}(c \cdot \mathbf{P}) = \operatorname{dct} \mathbf{P}, \quad \operatorname{dct}(\mathbf{P} + \mathbf{Q}) \geq \min\{\operatorname{dct} \mathbf{P}, \operatorname{dct} \mathbf{Q}\} \quad \operatorname{dct}(z \cdot \mathbf{P}) = \operatorname{dct} \mathbf{P} - 1,$$

(9)

$$\operatorname{ord}(c \cdot \mathbf{P}) = \operatorname{ord} \mathbf{P}, \quad \operatorname{ord}(\mathbf{P} + \mathbf{Q}) \geq \min\{\operatorname{ord} \mathbf{P}, \operatorname{ord} \mathbf{Q}\}, \quad \operatorname{ord}(z \cdot \mathbf{P}) = \operatorname{ord} \mathbf{P} + s.$$

Proof. The proof is left to the reader. □

From the characterization (5), it is clear that $\mathcal{L}_\delta^\sigma \subset \mathcal{L}_{\delta+1}^\sigma$ and $\mathcal{L}_\delta^{\sigma+1} \subset \mathcal{L}_\delta^\sigma$. In addition, if $\mathbf{P} \in \mathcal{L}_\delta^\sigma \setminus \mathcal{L}_\delta^{\sigma+1}$, i.e. $\operatorname{ord} \mathbf{P} = \sigma$, then from (8), (9) it is easy to see that for each $\mathbf{Q} \in \mathcal{L}_\delta^\sigma$ there exists a $c \in \mathbb{K}$ such that $\mathbf{Q} - c \cdot \mathbf{P} \in \mathcal{L}_\delta^{\sigma+1}$. This proves the statement

$$\mathcal{L}_\delta^{\sigma+1} \subset \mathcal{L}_\delta^\sigma, \qquad \dim \mathcal{L}_\delta^{\sigma+1} \geq \dim \mathcal{L}_\delta^\sigma - 1 \tag{10}$$

and already gives an idea about the computation of σ-bases by recurrence on the order as proposed in the procedure FPHPS (*fast power Hermite Padé solver*) below. We show in Theorem 3.4 that this method is both correct and produces the desired σ-bases.

FPHPS ALGORITHM

INPUT: $m \geq 2, s \in \mathbb{N}, \mathbf{F} = (f_1, \ldots f_m)^T$, multiindex $\mathbf{n} = (n_1, \ldots, n_m)$

INITIALIZATION: Let for $\sigma = 0, l = 1, \ldots, m$:
$d_{l,0} = n_l, \mathbf{P}_{l,0} = (0, \ldots, 0, 1, 0, \ldots, 0)$($l$th unit vector)

RECURSIVE STEP: For $\sigma = 0, 1, 2, \ldots$:
Let for $l = 1, \ldots, m$: $c_{l,\sigma} = z^{-\sigma} \cdot \mathbf{P}_{l,\sigma}(z^s) \cdot \mathbf{F}(z)|_{z=0}$ and $\Lambda_\sigma = \{l \ : \ c_{l,\sigma} \neq 0\}$
CASE $\Lambda_\sigma = \{\}$, then for $l = 1, \ldots, m$:
$\mathbf{P}_{l,\sigma+1} = \mathbf{P}_{l,\sigma}, d_{l,\sigma+1} = d_{l,\sigma}$
CASE $\Lambda_\sigma \neq \{\}$, then let $\pi = \pi_\sigma \in \Lambda_\sigma$ be defined by
$d_{\pi,\sigma} = \max\{d_{l,\sigma} \ : \ l \in \Lambda_\sigma\}$
and compute for $l = 1, \ldots, m$:
$l \in \Lambda_\sigma, l \neq \pi$: $\mathbf{P}_{l,\sigma+1} = \mathbf{P}_{l,\sigma} - \frac{c_{l,\sigma}}{c_{\pi,\sigma}} \cdot \mathbf{P}_{\pi,\sigma}, d_{l,\sigma+1} = d_{l,\sigma}$
$l \notin \Lambda_\sigma$: $\mathbf{P}_{l,\sigma+1} = \mathbf{P}_{l,\sigma}, d_{l,\sigma+1} = d_{l,\sigma}$
$l = \pi$: $\mathbf{P}_{\pi,\sigma+1} = z \cdot \mathbf{P}_{\pi,\sigma}, d_{\pi,\sigma+1} = d_{\pi,\sigma} - 1$

OUTPUT: For $\sigma = 0, 1, 2, \ldots$:
σ-bases $\mathbf{P}_{1,\sigma}, \ldots, \mathbf{P}_{m,\sigma}$ with $\operatorname{dct} \mathbf{P}_{l,\sigma} = d_{l,\sigma} + 1, l = 1, \ldots, m$, i.e.
for all δ: $\mathcal{L}_\delta^\sigma = \{\alpha_1 \cdot \mathbf{P}_{1,\sigma} + \cdots + \alpha_m \cdot \mathbf{P}_{m,\sigma} \ : \ \deg \alpha_l \leq d_{l,\sigma} + \delta\}$.

THEOREM 3.4 (Feasibility of method FPHPS). *Method* FPHPS *is well defined and gives the specified results.*

Proof. We show the assertion by induction on σ for a fixed δ.

The case $\sigma = 0$ follows immediately from the definition of $\mathcal{L}_\delta^0$. Hence, suppose $\sigma \geq 0$ and that the algorithm is correct for σ. We show that the algorithm produces the correct output for $\sigma + 1$. Note that by assumption $\operatorname{ord} \mathbf{P}_{l,\sigma} \leq \sigma$, i.e., its s-residual takes the form

$$\mathbf{P}_{l,\sigma}(z^s) \cdot \mathbf{F}(z) = z^\sigma \cdot R_l(z) \quad \text{with } R_l \in \mathbb{K}[[z]].$$

Hence, $c_{l,\sigma} = R_l(0)$ and the recurrence step is well defined. By construction we have

$$\operatorname{ord} \mathbf{P}_{l,\sigma+1} \geq \sigma + 1 \quad \text{and} \quad \operatorname{dct} \mathbf{P}_{l,\sigma+1} \geq d_{l,\sigma+1} + 1.$$

Moreover, it is easy to see that with $\mathbf{P}_{1,\sigma},\dots,\mathbf{P}_{m,\sigma}$ also $\mathbf{P}_{1,\sigma+1},\dots,\mathbf{P}_{m,\sigma+1}$ are linearly independent with respect to polynomial coefficients.

Consider first the case when $\mathcal{L}_\delta^\sigma = \mathcal{L}_\delta^{\sigma+1}$. By assumption, each $\mathbf{Q} \in \mathcal{L}_\delta^{\sigma+1}$ then has a representation

$$\mathbf{Q} = \alpha_1 \cdot \mathbf{P}_{1,\sigma} + \cdots + \alpha_m \cdot \mathbf{P}_{m,\sigma}, \quad \deg\ \alpha_l < \operatorname{dct} \mathbf{P}_{l,\sigma} + \delta.$$

This is already a suitable linear combination of $\mathbf{P}_{1,\sigma+1},\dots,\mathbf{P}_{m,\sigma+1}$. To see this, note that with $\alpha_l \neq 0$, we get $\operatorname{dct} \mathbf{P}_{l,\sigma} + \delta > 0$ and $\mathbf{P}_{l,\sigma} \in \mathcal{L}_\delta^\sigma = \mathcal{L}_\delta^{\sigma+1}$; hence, $c_{l,\sigma} = 0$ and $\mathbf{P}_{l,\sigma+1} = \mathbf{P}_{l,\sigma}$.

The case where $\mathcal{L}_\delta^\sigma \neq \mathcal{L}_\delta^{\sigma+1}$ is also easy to handle. Let

$$\mathcal{L}_\delta := \{\alpha_1 \cdot \mathbf{P}_{1,\sigma+1} + \cdots + \alpha_m \cdot \mathbf{P}_{m,\sigma+1} : \deg\ \alpha_l < \operatorname{dct} \mathbf{P}_{l,\sigma+1} + \delta\},$$

so that in view of Lemma 3.3 we have $\mathcal{L}_\delta \subset \mathcal{L}_\delta^{\sigma+1}$. On the other hand, the dimension of $\mathcal{L}_\delta$ can be estimated as follows:

$$\begin{aligned}
\dim\ L_\delta &= \max\ \{\operatorname{dct} \mathbf{P}_{1,\sigma+1} + \delta, 0\} + \cdots + \max\ \{\operatorname{dct} \mathbf{P}_{m,\sigma+1} + \delta, 0\}, \\
&\geq \max\ \{d_{1,\sigma+1} + 1 + \delta, 0\} + \cdots + \max\ \{d_{m,\sigma+1} + 1 + \delta, 0\}, \\
&\geq \max\ \{d_{1,\sigma} + 1 + \delta, 0\} + \cdots + \max\ \{d_{m,\sigma} + 1 + \delta, 0\} - 1, \\
&= \dim\ \mathcal{L}_\delta^\sigma - 1 = \dim\ \mathcal{L}_\delta^{\sigma+1},
\end{aligned}$$

where for the last two equalities we have applied (7) and (10). Consequently, $\mathcal{L}_\delta = \mathcal{L}_\delta^{\sigma+1}$, and we have equality in the estimation above. For all $\Delta \geq \delta$ we also have that $\mathcal{L}_\Delta^{\sigma+1} \neq \mathcal{L}_\Delta^\sigma$, since by definition $\emptyset \neq \mathcal{L}_\delta^\sigma \setminus \mathcal{L}_\delta^{\sigma+1} \subset \mathcal{L}_\Delta^\sigma \setminus \mathcal{L}_\Delta^{\sigma+1}$. Therefore, the above equations are also valid if we replace δ by $\Delta \geq \delta$. Choosing Δ sufficiently large, we can conclude that $\operatorname{dct} \mathbf{P}_{l,\sigma+1} = d_{l,\sigma+1} + 1$ for $l = 1,\dots,m$ which proves the theorem. □

4. Some properties of the FPHPS algorithm. In this section, we discuss some properties of the σ-bases obtained by the procedure FPHPS. In particular, we are interested in simple conditions describing whether some PHPAs are irreducible and whether given PHPAs $\mathbf{P}_1,\dots,\mathbf{P}_\lambda$ (and its values at zero) are linearly independent with respect to polynomial coefficients (and constant coefficients, respectively)—questions that as explained in §2 naturally arise in the context of matrix Padé approximation. In addition, for multidimensional solution sets, we classify PHPAs having "best" approximation properties, i.e., maximal order and/or minimal degree. The complexity of method FPHPS is determined at the end of this section.

Let Λ_σ and π_σ (for a given σ) be defined as in the FPHPS algorithm. As given in all applications of Table 1, in the sequel we only discuss the case $s \leq m$ and $\Lambda_0 \neq \{\ \},\dots,\Lambda_{s-1} \neq \{\ \}$. This is equivalent to the fact that the matrix $(\mathbf{F}(0), \mathbf{F}'(0),\dots,\mathbf{F}^{(s-1)}(0))$ has full rank. In Theorem 4.1, we summarize some facts about reducible PHPAs. These results are generalizations of ideas appearing in [25].

THEOREM 4.1. (a) *For all $\sigma \geq s$, we have* $\operatorname{card} \Lambda_\sigma \geq 1$, *more precisely*

$$\begin{aligned}
&\pi_{\sigma-s} \in \Lambda_\sigma \subset L_\sigma \cup \{\pi_{\sigma-s}\}, \\
&\text{where } L_\sigma := \{1,\dots,m\} \setminus \{\pi_{\sigma-s}, \pi_{\sigma-s+1},\dots,\pi_{\sigma-1}\}.
\end{aligned} \tag{11}$$

(b) *Let U denote the $(m-s)$ dimensional subspace of vectors that are orthogonal to all $\mathbf{F}(0), \mathbf{F}'(0),\dots,\mathbf{F}^{(s-1)}(0)$. Then for $\sigma \geq s$*

$$\operatorname{span}\ \{\mathbf{P}_{l,\sigma}(0) : l \in L_\sigma\} = U \quad \text{and for all } l \notin L_\sigma : \mathbf{P}_{l,\sigma}(0) = 0. \tag{12}$$

Proof. Note that in the FPHPS algorithm we always have ord $\mathbf{P}_{\pi_\sigma,\sigma+1} = \sigma + s$. Therefore, $\pi_\sigma \in \Lambda_{\sigma+s} \neq \{\ \}$ but $\pi_\sigma \notin \Lambda_{\sigma+1}, \ldots, \pi_\sigma \notin \Lambda_{\sigma+s-1}$. This proves (a). The second part of (b) follows directly from the fact that $\mathbf{P}_{l,\sigma+1} = \mathbf{P}_{l,\sigma}$ for all $l \notin L_{\sigma+1} \cup L_\sigma$, and $\mathbf{P}_{l,\sigma+1}(0) = 0$ for $l = \pi_\sigma$. The first assertion of (b) can be shown by a simple recurrence argument on $\sigma \geq s$. Let

$$U_\sigma := \text{span}\,\{\mathbf{P}_{l,\sigma}(0) : l \in L_\sigma\}.$$

Then $U_\sigma \subset U$ since we have ord $\mathbf{P}_{l,\sigma} \geq s$. With $\mathbf{P}_{l,\sigma}(0), l \in L_\sigma$, also the vectors $\mathbf{P}_{l,\sigma+1}(0), l \in L_\sigma \bigcap L_{\sigma+1}$, together with $\mathbf{P}_{\pi_\sigma,\sigma}(0)$ are linearly independent. From the recurrence relations we know that $\mathbf{P}_{\pi_{\sigma-s},\sigma}(0) = 0$ and $\mathbf{P}_{\pi_{\sigma-s},\sigma+1}(0) = c \cdot \mathbf{P}_{\pi_\sigma,\sigma}(0)$ with $c \neq 0$. Consequently, $\mathbf{P}_{l,\sigma+1}(0), l \in L_{\sigma+1}$, are linearly independent that proves part (b). □

Supposing that the vector $\mathbf{F}$ contains only polynomial entries, we expect that the solution set $\mathcal{L}_\delta^\sigma$ becomes stationary for sufficiently large σ. In contrast, due to Theorem 4.1(a) the σ-bases will always change if σ is increased. In fact, we observe that for large σ, the nonconstant part of the σ-basis described by the sets Λ_σ consists only of approximants with defect smaller than $-\delta$ and that, for sufficiently large σ, for the representation (6) of the solution set $\mathcal{L}_\delta^\sigma$ we need at most $(m - s)$ elements of the σ-basis.

Theorem 4.1(b) yields a simple criterion determining whether the solution set $\mathcal{L}_\delta^\sigma$ contains an irreducible element. By definition, the components of an element of the σ-basis can only have a common factor that vanishes at zero. Hence, there exists an element $\mathbf{P}$ of $\mathcal{L}_\delta^\sigma$ being irreducible, i.e., $\mathbf{P}(0) \neq 0$, if and only if there is an $l \in L_\sigma$ with $d_{l,\sigma} \geq -\delta$. Moreover, we immediately get the following corollary.

COROLLARY 4.2. (a) *$\mathcal{L}_\delta^\sigma$ contains $\lambda \leq m$ elements $\mathbf{P}_1, \ldots, \mathbf{P}_\lambda$ being linearly independent over $\mathbb{K}[z]$ if and only if there are distinct $l_1, \ldots, l_\lambda \in \{1, \ldots, m\}$ with $d_{l_j,\sigma} \geq -\delta$.*

(b) *$\mathcal{L}_\delta^\sigma$ contains $\lambda \leq m - s$ elements $\mathbf{P}_1, \ldots, \mathbf{P}_\lambda$ such that $\mathbf{P}_1(0), \ldots, \mathbf{P}_\lambda(0)$ are linearly independent over $\mathbb{K}$ if and only if there are distinct $l_1, \ldots, l_\lambda \in L_\sigma$ with $d_{l_j,\sigma} \geq -\delta$.*

(c) *In both cases linearly independent approximants from $\mathcal{L}_\delta^\sigma$ are given by $\mathbf{P}_j = \mathbf{P}_{l_j,\sigma}, j = 1, \ldots, \lambda$.*

In most applications, the first s components of $\mathbf{F}$ take the simple form $f_j(z) = z^{j-1}$. Here we consider the first s components $\mathbf{p}$ and the last $(m - s)$ components $\mathbf{q}$ of a PHPA $\mathbf{P} = (\mathbf{p}, \mathbf{q})$ separately and ask for approximants $\mathbf{P}_1, \ldots, \mathbf{P}_\lambda \in \mathcal{L}_\delta^\sigma$ with $\mathbf{q}_1, \ldots, \mathbf{q}_\lambda$ (or $\mathbf{q}_1(0), \ldots, \mathbf{q}_\lambda(0)$) being linearly independent. Here also the criteria given in Corollary 4.2.(a) and (b) can be applied as long as we can guarantee there is no $\mathbf{P} = (\mathbf{p}, \mathbf{q}) \in \mathcal{L}_\delta^\sigma$ with $\mathbf{p} \neq 0$ and $\mathbf{q} = 0$ ($\mathbf{p}(0) \neq 0$ and $\mathbf{q}(0) = 0$, respectively). But due to the simple form of $\mathbf{F}$ it can be easily verified that $\mathbf{P} = (\mathbf{p}, \mathbf{q}) \in \mathcal{L}_\delta^\sigma$ with $\mathbf{q}(0) = 0$ and $\sigma \geq s$ also implies that $\mathbf{p}(0) = 0$. Similarly, if $s \cdot (n_j + \delta) + j \leq \sigma$ for $j = 1, \ldots, s$ (which for the most interesting PHPA cases of §2 is true) and $\mathbf{P} = (P_1, \ldots, P_m) = (\mathbf{p}, 0) \in \mathcal{L}_\delta^\sigma$, then $\mathbf{p}$ must also be identical zero since ord $\mathbf{P} \leq \max\{s \cdot \deg P_j + j - 1 : j = 1, \ldots, s\}$.

If the solution set is multidimensional, we are interested in classifying particular solutions that have certain uniqueness properties. The concept of approximants with correct degree satisfying "best possible" order conditions is discussed in Corollary 4.3.

COROLLARY 4.3. *Let each $\mathbf{P} \in \mathbb{K}^m[z]$ have finite order and let $\delta + \min\{n_1, \ldots, n_m\} \geq 0$. Consider the problem of finding "optimal" PHPAs $\mathbf{P}_1, \ldots, \mathbf{P}_\lambda, \lambda \leq m - s$ with*

(i) $\mathbf{P}_1(0), \ldots, \mathbf{P}_\lambda(0)$ *are linearly independent,*
(ii) $\operatorname{dct} \mathbf{P}_1 > -\delta, \ldots, \operatorname{dct} \mathbf{P}_\lambda > -\delta$,
(iii) *the number* $(\operatorname{ord} \mathbf{P}_1 + \cdots + \operatorname{ord} \mathbf{P}_\lambda)$ *is maximal,*
(iv) $\operatorname{ord} \mathbf{P}_1 =: \sigma(1) > \operatorname{ord} \mathbf{P}_2 =: \sigma(2) > \cdots > \operatorname{ord} \mathbf{P}_\lambda =: \sigma(\lambda)$

(*it is easy to see that condition* (iv) *only implies a particular ordering for the* PHPAs *determined by* (i), (ii), (iii)). *A solution for this problem is given by*

$$\sigma(j) := \max\{\sigma : \operatorname{card}\ \{l \in L_\sigma\ :\ d_{l,\sigma} \geq -\delta\} \geq j\}$$

and $\mathbf{P}_j = \mathbf{P}_{\pi_{\sigma(j)},\sigma(j)}, j = 1, \ldots, \lambda$.

Corollary 4.3 is a canonical generalization of the optimal Hermite Padé form of type $\mathbf{n}(\delta)$ of [22] ($s = \lambda = 1$). Paszkowski [22] speaks of nonexistent optimal Hermite Padé forms if $\mathbf{P}_1$ is not unique, i.e., if there is a further (necessarily reducible) PHPA $\mathbf{P}_0$ with $\operatorname{dct} \mathbf{P}_0 > -\delta$ and $\operatorname{ord} \mathbf{P}_0 > \operatorname{ord} \mathbf{P}_1$. For $\lambda = m - s = 1$, for example, scalar simultaneous (partial) Padé approximation, our approach is closely connected to a concept proposed by de Bruin [8] for nonnormal solution tables. Note that although in view of Corollary 4.2.(b), the numbers $\sigma(1), \ldots, \sigma(\lambda)$ are unique, we might get several tuples of optimal PHPAs being essentially different. The significance of the integer $\sigma(\lambda)$ for matrix Padé approximation is discussed at the end of §5.

Following Corollary 4.3, we always find irreducible approximants with correct degree, but the order condition might be weakened. In contrast, Van Barel and Bultheel [24], [26] look for irreducible approximants with correct order and a type of minimal degree. More precisely, instead of (ii)–(iv), the conditions

(v) $\operatorname{ord} \mathbf{P}_1 \geq \sigma, \ldots, \operatorname{ord} \mathbf{P}_\lambda \geq \sigma$,
(vi) the number $(\operatorname{dct} \mathbf{P}_1 + \cdots + \operatorname{dct} \mathbf{P}_\lambda)$ is maximal

are imposed. As above, this problem will not generally have a unique solution. However, the method FPHPS also gives a solution for this problem: due to Corollary 4.2(b) we can take those λ approximants $\mathbf{P}_{l,\sigma}, l \in L_\sigma$ with maximal defect.

The problem of uniqueness for both concepts is illustrated in Example 4.4.

Example 4.4. Let

$$m = 4, \qquad s = 2, \qquad \mathbf{n} = (2,2,2,2), \qquad \delta = 0,$$
$$\mathbf{F}(z) = \left(1, z, \frac{z}{1-z^4} + z^{10}, \frac{z}{1+z^4} + z^{12}\right)^T + \mathcal{O}\left(z^{16}\right).$$

An application of FPHPS gives the values $\pi_0, \pi_1, \ldots, \pi_{13} = 1,2,1,2,1,3,1,3,1,4,2,4,3,4$. In particular, we obtain a σ-basis for $\sigma = 10$ (output in matrix form with the rows $\mathbf{P}_{1,10}, \mathbf{P}_{2,10}, \mathbf{P}_{3,10}$, and $\mathbf{P}_{4,10}$ as the basis elements) as

$$\mathbf{P}_{10}(z) = \begin{bmatrix} z^5 & 0 & 0 & 0 \\ 0 & z^2 & -\frac{1}{2} & \frac{1}{2} \\ 0 & 1-z^2 & -\frac{1}{2}+z^2 & -\frac{1}{2} \\ 0 & -2z & z & z \end{bmatrix},$$

with s-residuals

$$\mathbf{P}_{10}(z^2) \cdot \mathbf{F}(z) = \begin{bmatrix} z^{10} + \mathcal{O}\left(z^{26}\right) \\ -\frac{z^{10}}{2} + \frac{z^{12}}{2} - z^{13} + \mathcal{O}\left(z^{16}\right) \\ -\frac{z^{10}}{2} - \frac{z^{12}}{2} + z^{13} + z^{14} + \mathcal{O}\left(z^{16}\right) \\ 2z^{11} + z^{12} + z^{14} + \mathcal{O}\left(z^{18}\right) \end{bmatrix}.$$

The defects for this basis are $-2, 1, 1$ and 2, respectively. Hence, $\mathcal{L}_0^{10}$ does not have dimension 2 (as expected from comparing the number of equations and unknowns) but 4. For $\lambda = 1$, a particular solution with "minimal degree" (satisfying conditions (i), (v), and (vi) above) is given by $a \cdot \mathbf{P}_{2,10} + b \cdot \mathbf{P}_{3,10} + (cz + d) \cdot \mathbf{P}_{4,10}$ with arbitrary constants $a, b, c, d, |a| + |b| \neq 0$. A particular solution with "maximal order" $\sigma(1) = 12$ (satisfying conditions (i), (ii), (iii), and (iv) above) is given by $a \cdot \mathbf{P}_{3,12} + b \cdot \mathbf{P}_{4,12} = a \cdot (\mathbf{P}_{3,10} - \mathbf{P}_{2,10}) + b \cdot z \cdot \mathbf{P}_{4,10}$ with arbitrary constants $a, b, a \neq 0$ (the solution proposed in Corollary 4.3 equals $\mathbf{P}_{3,12}$).

Consider now the problem of determining the complexity of the FPHPS algorithm. For simplicity, we still impose the conditions before Theorem 4.1 (otherwise, the complexity will be still smaller). As seen in §2, in most applications one must determine σ-bases of PHPAs for $\sigma \approx \|\mathbf{n}\|$. To determine the number of arithmetic operations (AO) required for the computation of a $\|\mathbf{n}\|$-basis, we essentially only have to take into account the computation of $c_{1,\sigma}, \ldots, c_{m,\sigma}$ and of $\mathbf{P}_{1,\sigma+1}, \ldots, \mathbf{P}_{m,\sigma+1}, 0 \leq \sigma < \|\mathbf{n}\|$. Here the complexity strongly depends on the parameters $\mathbf{F}$ and s.

THEOREM 4.5 (Complexity). *The* FPHPS *algorithm for computing* PHPAs *of order* $\sigma = 0, 1, \ldots, \|\mathbf{n}\|$ *has a complexity of at most*

$$4(m - s) \cdot \|\mathbf{n}\|^2 + \mathcal{O}\left(m^2 \cdot \|\mathbf{n}\|\right) \text{ AO}, \tag{13}$$

roughly half additions and half multiplications plus $\mathcal{O}(m \cdot \|\mathbf{n}\|)$ *divisions. At least for the case* $\mathbf{n} = (n, \ldots, n)$, *we obtain the sharper bound*

$$\left(1 - \frac{s}{m}\right) \cdot (2m - \text{card } L) \cdot \|\mathbf{n}\|^2 + \mathcal{O}\left(m^2 \cdot \|\mathbf{n}\|\right) \text{ AO}, \tag{14}$$

where $L = \{l : f_l(z) = z^j \text{ with a } j \in \mathbb{N}_0\}$.

Proof. Since $c_{\pi_{\sigma-s},\sigma} = c_{\pi_{\sigma-s},\sigma-s}$ and $P_{\pi_\sigma,\sigma+1}$ can be easily determined by shifting some coefficients, for the complexity it remains to consider the computation of at most $c_{l,\sigma}$ and $\mathbf{P}_{l,\sigma+1}$ for $l \in L_{\sigma+1}$. In addition, we are not interested in PHPAs with dct $\mathbf{P}_{l,\sigma} \leq 0$, since they do not occur in the solution sets $\mathcal{L}_\delta^\sigma, \delta \leq 0$ (cf. (6)). Therefore, the degree of the λth component of $\mathbf{P}_{l,\sigma}$ is bounded by $n_\lambda - d_{l,\sigma} \leq n_\lambda$ and we require for loop number σ the number of at most $2 \cdot \sum_{l \in L_{\sigma+1}} \sum_{\lambda=1}^{m} (n_\lambda + 1) + \mathcal{O}(m^2) = 2(m-s) \cdot \|\mathbf{n}\| + \mathcal{O}(m^2)$ additions/subtractions and the same number of multiplications that totally gives a complexity as stated in (13). For the case $\mathbf{n} = (n, \ldots, n)$, we can apply the relation

$$2 \cdot \sum_{\sigma=0}^{\|\mathbf{n}\|-1} \sum_{l \in L_{\sigma+1}} (d_{l,\sigma} + 1) \geq \cdots \geq \|\mathbf{n}\|^2 - 2 \cdot s \cdot \sum_{l=1}^{m} \sum_{j=0}^{n+1} j,$$

which by using similar arguments leads to (14). □

TABLE 2
Complexity for solving matrix-type Padé approximation problems.

Example	Complexity via (13)	Via (14), special case
Classical Hermite Padé	$4(m-1)\cdot\|\mathbf{n}\|^2+\mathcal{O}(m^2\cdot\|\mathbf{n}\|)$	for $n_1=\cdots=n_m$: $2(m-1)\cdot\|\mathbf{n}\|^2+\mathcal{O}(m^2\cdot\|\mathbf{n}\|)$
2.1	$4q[p(M+1)+q(N+1)]^2$ $+\mathcal{O}((p+q)^2\cdot(M+N))$	for $M=N$: $q(2q+p)(p+q)(M+1)^2$ $+\mathcal{O}((p+q)^2\cdot M)$
2.2	$4p[q(M+1)+p(N+1)]^2$ $+\mathcal{O}((p+q)^2\cdot(M+N))$	for $M=N$: $p(2p+q)(p+q)(M+1)^2$ $+\mathcal{O}((p+q)^2\cdot M)$
2.3	$4\mu p^3\rho^2+\mathcal{O}(\mu^2p^4\rho)$	for $\rho_0=\cdots=\rho_\mu$: $2\mu p^3\rho^2+\mathcal{O}(\mu^2p^4\rho)$
2.4 with $p=1, A_0=1$	$4\mu^2\rho^2+\mathcal{O}(\mu^4\rho)$	for $\rho_0=\cdots=\rho_\mu$: $\frac{\mu+2}{\mu+1}\mu^2\rho^2+\mathcal{O}(\mu^4\rho)$

It should be mentioned that our algorithm can be implemented very efficiently on a vector or on a parallel processor (with, e.g., m or $\|\mathbf{n}\|$ processors). The complexity of our algorithm for the examples of §2 is given in Table 2, whereas in Table 3 some solved subproblems and their corresponding PHPA solution space are listed.

5. An example of matrix Padé approximation. In this section, we give an example of a matrix Padé approximation problem computed using the FPHPS algorithm. Let

$$A(z)=\begin{bmatrix}1+z^2+2z^4-z^5+z^6+\mathcal{O}\left(z^8\right) & z^7+\mathcal{O}\left(z^8\right)\\ -z^5+\mathcal{O}\left(z^8\right) & 1+z^2+z^4+z^7+\mathcal{O}\left(z^8\right)\end{bmatrix}$$

and consider the problem of determining a (2, 3) right-hand matrix Padé form for $A(z)$. Thus, we are looking for 2×2 matrix polynomials P and Q of degree at most 2 and 3, respectively, such that

$$A(z)\cdot Q(z)-P(z)=z^6\cdot R(z)$$

for some matrix power series R. The suitable choice of the parameters is stated in Table 1, row 2. Note that, for any PHPA (P_1,P_2,P_3,P_4) of type $(M,M,N,N),2(M+N+1),2)$, the components P_1 and P_2 correspond to a column of an (M,N) right-hand matrix Padé numerator, whereas P_3,P_4 correspond to a column of the denominator (cf. Table 3, for left-hand matrix Padé approximation, P_1,P_2 and P_3,P_4 correspond to rows of numerator and denominator, respectively).

Setting $s=2,\mathbf{n}=(2,2,3,3)$ and

$$\begin{aligned}\mathbf{F}^T(z)&=[1,z]\cdot\left[\mathbf{I},\,-A\left(z^2\right)\right]\\&=\left[1,z,-1-z^4-2z^8+z^{10}+z^{11}-z^{12}+\mathcal{O}\left(z^{16}\right),\right.\\&\qquad\left.-z-z^5-z^9-z^{14}-z^{15}+\mathcal{O}\left(z^{16}\right)\right]\end{aligned}$$

and using the FPHPS algorithm gives a σ-basis for $\sigma=12$ (output in matrix form with the rows as the basis elements) as

$$\begin{bmatrix}-z-z^2+z^3 & 0 & -z-z^2+2z^3+z^4 & 0\\ 1+z-z^2 & z^3 & 1+z-2z^2-z^3 & z^3\\ -z^2 & 0 & -z^2+z^4 & 0\\ 0 & -1 & 0 & -1+z^2\end{bmatrix}.$$

TABLE 3
Some matrix-type Padé subproblems solved by FPHPS *and their corresponding* PHPA *solution spaces, parameters* $m, \mathbf{n}, s, \sigma, \mathbf{F}$ *as in Table* 1.

Example	Type of subproblem	PHPA solution space
Classical Hermite Padé	$(n_1 - j, \ldots, n_m - j), j \leq \min\{n_l + 1\}$	$\mathcal{L}_{-j}^{\sigma - j \cdot m}$
2.1	$(M - j, N - j), j \leq \min\{M + 1, N + 1\}$	$\mathcal{L}_{-j}^{\sigma - 2 \cdot j \cdot s}$ contains rows of (P^T, Q^T)
2.2	$(M - j, N - j), j \leq \min\{M + 1, N + 1\}$	$\mathcal{L}_{-j}^{\sigma - 2 \cdot j \cdot s}$ contains rows of (P, Q)
2.3	$(\rho_0 - j, \ldots, \rho_\mu - j), j \leq \min\{\rho_l\}$	$\mathcal{L}_{-j}^{\sigma - j \cdot m}$ contains rows of $(P_0, \ldots, P_\mu)$
2.4 with $p = 1, A_0 = 1$	$(\rho_0 - j, \ldots, \rho_\mu - j), j \leq \min\{\rho_l\}$	$\mathcal{L}_{-j \cdot s}^{\sigma - j \cdot s \cdot m}$

The defects for this basis are 0, 0, 0, and 2, respectively. Therefore, a basis for the solution space $\mathcal{L}_0^{12}$, as a finite-dimensional space over $\mathbb{K}$, is given by $(a + b \cdot z) \cdot \mathbf{P}_{4,12} = (a + b \cdot z) \cdot [0, -1, 0, -1 + z^2]$, with a and b being arbitrary constants. Translating the solution space basis into matrix form implies that the columns of P and Q are generated by

$$(a + bz) \cdot \begin{bmatrix} 0 \\ -1 \end{bmatrix} \quad \text{and} \quad (a + bz) \cdot \begin{bmatrix} 0 \\ -1 + z^2 \end{bmatrix},$$

respectively. This gives a right matrix Padé form of type (2, 3) for $A(z)$ as

$$P(z) = \begin{bmatrix} 0 & 0 \\ -1 & -z \end{bmatrix} \quad \text{and} \quad Q(z) = \begin{bmatrix} 0 & 0 \\ -1 + z^2 & -z + z^3 \end{bmatrix}.$$

In this case, such a matrix Padé form is unique up to multiplication on the right by a nonsingular 2×2 matrix. In particular, note that it is not possible to construct a right matrix Padé fraction of type (2, 3) in this instance.

The left matrix Padé forms of type (2, 3) for $A(z)$ can also be computed by the FPHPS procedure. Setting $s = 2, \mathbf{n} = (2, 2, 3, 3)$ and

$$\mathbf{F}(z) = \begin{bmatrix} \mathbf{I} \\ -A\left(z^2\right) \end{bmatrix} \cdot \begin{bmatrix} 1 \\ z \end{bmatrix} = \begin{bmatrix} 1 \\ z \\ -1 - z^4 - 2z^8 + z^{10} + \mathcal{O}\left(z^{12}\right) \\ -z - z^5 - z^9 + z^{10} + \mathcal{O}\left(z^{12}\right) \end{bmatrix},$$

and computing the σ-basis for $\sigma = 12$ gives

$$\begin{bmatrix} -1 + z^2 & 1 & -1 + 2z^2 & 1 - z^2 \\ 0 & z^4 & 0 & z^4 \\ -z & -1 & -z + z^3 & -1 + z^2 \\ 0 & -z & 0 & -z + z^3 \end{bmatrix}.$$

In this case the defects are $1, -1, 1$, and 1, respectively, so the solution space $\mathcal{L}_0^{12}$ is of the form $a \cdot \mathbf{P}_{1,12} + b \cdot \mathbf{P}_{3,12} + c \cdot \mathbf{P}_{4,12}$ with a, b, and c arbitrary constants. Again translating the basis information to matrix form implies that the rows of P and Q are generated by

$$a \cdot \left[-1 + z^2, 1\right] + b \cdot [-z, -1] + c \cdot [0, -z]$$

and

$$a \cdot \left[-1+2z^2, 1-z^2\right] + b \cdot \left[-z+z^3, -1+z^2\right] + c \cdot \left[0, -z+z^3\right],$$

respectively. Unlike the previous example, there is not one Padé form that is unique up to left multiplication by a nonsingular matrix of scalars. One possibility for a left matrix Padé form in this case is

$$P(z) = \begin{bmatrix} -z & -1 \\ -1+z^2 & 1 \end{bmatrix} \quad \text{and} \quad Q(z) = \begin{bmatrix} -z+z^3 & -1+z^2 \\ -1+2z^2 & 1-z^2 \end{bmatrix}.$$

Note that the denominator has a nonzero determinant, indeed that $Q(0)$ is nonsingular. Therefore, unlike the case for approximants on the right, one can always form the rational expression $Q(z)^{-1} \cdot P(z)$.

Using the FPHPS algorithm in the above example also determines, at no added cost, the σ-basis for $\mathcal{L}^4_{-2}$ and $\mathcal{L}^8_{-1}$. Hence, the right matrix Padé forms of type (0, 1)

$$P(z) = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \qquad Q(z) = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$$

and (1, 2)

$$P(z) = \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix}, \qquad Q(z) = \begin{bmatrix} -1+z^2 & 0 \\ 0 & -1+z^2 \end{bmatrix}$$

(determined uniquely up to matrix multiplication on the right in both cases) are byproducts of the previous computation. In addition, one can continue the computation to determine the matrix Padé form of type (3, 4) since the σ-basis for $\mathcal{L}^{12}_0$ can be used to determine the σ-basis for $\mathcal{L}^{16}_1$. In the case of the right matrix Padé form of type (3, 4) this gives (again unique up to matrix multiplication on the right)

$$P(z) = \begin{bmatrix} 0 & 1+z/5+11/5z^2+4/5z^3 \\ -z^2 & 1/5-2/5z+z^3 \end{bmatrix},$$

$$Q(z) = \begin{bmatrix} 0 & 1+z/5+6/5z^2+3/5z^3-16/5z^4 \\ -z^2+z^4 & -1/5-2/5z+1/5z^2+7/5z^3 \end{bmatrix},$$

an example where the denominator matrix polynomial Q is nonsingular but has a singular leading term $Q(0)$.

Our example shows that, in general, the matrix Padé approximation problem does not have a unique rational solution as in the scalar case. Moreover, there are three distinct and possible forms of a denominator matrix polynomial Q. First, the case occurs when $Q(z)$ is singular for all z and hence no matrix rational form exists; this type of degeneracy is not found in the scalar case. Second, it is possible that $Q(0)$ is nonsingular (cf. Corollary 4.2(a) and (b) and the following remarks). Here we can form $P(z) \cdot Q(z)^{-1}$ and its matrix power series agrees with $A(z)$ to the full order condition. Finally, if $Q(z)$ is nonsingular for some z, but $Q(0)$ is singular, we can cancel P and Q by a common matrix polynomial factor on the right. Here, similarly to the degenerate case found in scalar Padé approximation, the resulting matrix rational form $P(z) \cdot Q(z)^{-1}$ does not agree anymore with $A(z)$ to the full order condition.

Note that the concept as proposed in Corollary 4.3 ($2\lambda = 2s = m$) always leads to a matrix Padé-like form with correct degree and maximal order $[\sigma(s)/s]$ (perhaps less than $(M+N+1)$ as required for matrix Padé approximants) where by forming the rational function $P(z) \cdot Q(z)^{-1}$ we do not obtain an additional order deflation. In fact one can show that there is no other rational function of the form $P(z) \cdot Q(z)^{-1}$ satisfying the degree constraints and having an order greater than $[\sigma(s)/s]$.

6. A superfast PHPA solver. In §4 we have shown that the FPHPS algorithm computes a σ-basis with quadratic complexity. This is better than using methods such as Gaussian elimination and is optimal in special cases for arbitrary fields $\mathbb{K}$. However, when the field $\mathbb{K}$ allows for fast polynomial multiplication via the use of the FFT (cf. [15]), then there are faster methods in special cases. For example, when $s = 1$ and $m = 2$ (i.e., the case of Padé approximation) the algorithms of Brent, Gustavson, and Yun [9] and Cabay and Choi [10] compute these approximants with the superfast complexity $\mathcal{O}(\sigma \log^2 \sigma)$. Similarly, a recent algorithm of Cabay and Labahn [12] also solves the Hermite Padé and simultaneous Padé problems with superfast complexity. In this section we describe a second algorithm that takes advantage of fast polynomial multiplication when solving the PHPA problem. The new algorithm has the advantage of always being superfast—the algorithm of [12] sometimes slows down to quadratic or even cubic complexity (if most of the subproblems of type $\mathbf{n}(\delta), \delta < 0$ do not have a unique solution), although in practical problems this is rare.

The FPHPS algorithm of §3 provides a σ-basis $\mathbf{P}_1, \ldots, \mathbf{P}_m$ with respect to given $\mathbf{F}$, $\mathbf{n}$, and σ (and a fixed parameter s). For convenience, we arrange the $\mathbf{P}_l = (P_{l,1}, \ldots, P_{l,m})$ in a matrix

$$\mathbf{P} = (P_{l,\lambda})_{l=1,\ldots,m}^{\lambda=1,\ldots,m}.$$

Then with $\mathbf{d} := (d_1, \ldots, d_m), d_l := \operatorname{dct} \mathbf{P}_l - 1$, we can symbolize the procedure as follows

$$(\mathbf{P}, \mathbf{d}) \leftarrow \text{FPHPS } (\mathbf{F}, \sigma, \mathbf{n}).$$

Note that, in general, the choice of π_σ and therefore the output of FPHPS is not unique, but uniqueness could be easily obtained, for instance, by the additional restriction that π_σ must be as small as possible.

The basic step of a divide-and-conquer version is described in Theorem 6.1.

THEOREM 6.1. *Let ρ, σ be integers with $0 \le \rho \le \sigma$. Suppose that we have iterated $\rho \le \sigma$ times the recursive step of* FPHPS

$$(\mathbf{P}^{(1)}, \mathbf{d}^{(1)}) \leftarrow \text{FPHPS } (\mathbf{F}, \rho, \mathbf{n}),$$

and then continue iterating

$$(\mathbf{P}^{(3)}, \mathbf{d}^{(3)}) \leftarrow \text{FPHPS } (\mathbf{F}, \sigma, \mathbf{n}).$$

Suppose further that we restart the procedure with new initializations

$$\left(\mathbf{P}^{(2)}, \mathbf{d}^{(2)}\right) \leftarrow \text{FPHPS } \left(\mathbf{F}^{(1)}, \sigma - \rho, \mathbf{d}^{(1)}\right), \quad \textit{where } \mathbf{F}^{(1)}(z) := z^{-\rho} \cdot \mathbf{P}^{(1)}(z^s) \cdot \mathbf{F}(z),$$

where we always use the above uniqueness condition for the values π_σ. Then

$$\mathbf{P}^{(3)} = \mathbf{P}^{(2)} \cdot \mathbf{P}^{(1)} \quad \textit{and} \quad \mathbf{d}^{(3)} = \mathbf{d}^{(2)}.$$

Proof. We show Theorem 6.1 by induction on $(\sigma - \rho)$. Extending our notation slightly, set

$$\left(\mathbf{P}_{\rho}^{(1)}, \mathbf{d}_{\rho}^{(1)}\right) = \left(\mathbf{P}^{(1)}, \mathbf{d}^{(1)}\right), \qquad \left(\mathbf{P}_{\sigma}^{(3)}, \mathbf{d}_{\sigma}^{(3)}\right) = \left(\mathbf{P}^{(3)}, \mathbf{d}^{(3)}\right),$$
$$\left(\mathbf{P}_{\sigma-\rho}^{(2)}, \mathbf{d}_{\sigma-\rho}^{(2)}\right) = \left(\mathbf{P}^{(2)}, \mathbf{d}^{(2)}\right).$$

Note that Theorem 6.1 is trivially true for $\sigma - \rho = 0$. Assume now that the result is true for $\sigma - \rho \geq 0$. Then

$$\mathbf{P}_{\sigma}^{(3)} = \mathbf{P}_{\sigma-\rho}^{(2)} \cdot \mathbf{P}_{\rho}^{(1)} \quad \text{and} \quad \mathbf{d}_{\sigma}^{(3)} = \mathbf{d}_{\sigma-\rho}^{(2)}. \tag{15}$$

Consequently, the corresponding s-residuals

$$\mathbf{R}_{\sigma}^{(3)}(z) = z^{-\sigma} \cdot \mathbf{P}_{\sigma}^{(3)}(z^s) \cdot \mathbf{F}(z) \quad \text{and} \quad \mathbf{R}_{\sigma-\rho}^{(2)}(z) = z^{-\sigma+\rho} \cdot \mathbf{P}_{\sigma-\rho}^{(2)}(z^s) \cdot \mathbf{F}^{(1)}(z)$$

are equal. Hence, in both cases we must take the same value π and the assertion (15) with σ replaced by $(\sigma + 1)$ follows. □

The basic step of a divide-and-conquer version (15) yields the *superfast power Hermite Padé solver* (SPHPS), a reliable algorithm for computing a σ-basis of PHPAs with complexity $\mathcal{O}(\sigma \cdot \log^2 \sigma)$. The reason for the improvement in complexity results from the use of fast Fourier transform (FFT) techniques for fast polynomial multiplication. Such techniques consist of converting to a new coordinate representation via polynomial evaluation at roots of unity, computing the arithmetic operations in these new coordinates and transfering the results back to the original computation domain via polynomial interpolation. For purposes of efficiency we describe our superfast algorithm in both coordinate representations. Hence, we require some FFT details needed for our implementation. Additional details of the FFT procedure can be found in many texts (cf. [15]).

Let ω_κ be the principal κth root of unity (e.g., if $\mathbb{K}$ is the complex numbers, then $\omega_\kappa := \cos(2\pi/\kappa) + i \cdot \sin(2\pi/\kappa)$) and let

$$(\xi_j)_{j=0,\ldots,2\kappa-1} \leftarrow \mathrm{DFT}_{2\kappa}(p(z))$$

denote the evaluation of $\xi_j := p(\omega_{2\kappa}^j), j = 0, \ldots, 2\kappa - 1$. Then for the classical discrete FFT algorithm, we split p into its even and odd part $p(z) = p_e(z^2) + z \cdot p_o(z^2)$ and use the fact that for $j = 0, \ldots, \kappa - 1$ we have

$$\xi_j = \xi_j^{(e)} + \omega_{2\kappa}^j \cdot \xi_j^{(o)} \quad \text{and} \quad \xi_{\kappa+j} = \xi_j^{(e)} - \omega_{2\kappa}^j \cdot \xi_j^{(o)},$$

where $(\xi_j^{(e)})_{j=0,\ldots,\kappa-1} \leftarrow \mathrm{DFT}_\kappa(p_e(z))$ and $(\xi_j^{(o)})_{j=0,\ldots,\kappa-1} \leftarrow \mathrm{DFT}_\kappa(p_o(z))$. The "inverse" polynomial interpolation computation of

$$p(z) \leftarrow \mathrm{IDFT}_\kappa\left((\xi_j)_{j=0,\ldots,\kappa-1}\right),$$

i.e. of the uniquely defined polynomial p of degree less than κ with $\xi_j := p(\omega_\kappa^j), j = 0, \ldots, \kappa - 1$, is done by

$$\hat{p}(z) := \sum_{j=0}^{\kappa-1} \xi_j z^{n-j}, (\hat{\xi}_j)_{j=0,\ldots,\kappa-1} \leftarrow \mathrm{DFT}_\kappa(\hat{p}(z)), \qquad \text{then } p(z) = \frac{1}{\kappa} \cdot \sum_{j=0}^{\kappa-1} \hat{\xi}_j z^j.$$

Polynomials are multiplied componentwise in the new coordinates, that is, if

$$\left(\xi_j^{(1)}\right)_{j=0,\ldots,\kappa-1} \leftarrow \mathrm{DFT}_\kappa\left(p_1(z)\right),$$
$$\left(\xi_j^{(2)}\right)_{j=0,\ldots,\kappa-1} \leftarrow \mathrm{DFT}_\kappa\left(p_2(z)\right), \quad \text{and}$$
$$p^{(3)}(z) \leftarrow \mathrm{IDFT}_\kappa\left(\left(\xi_j^{(1)} \cdot \xi_j^{(2)}\right)_{j=0,\ldots,\kappa-1}\right),$$

and if c denotes the leading coefficient of $p_1(z) \cdot p_2(z)$, then

$$\begin{aligned} p^{(3)}(z) &= p^{(1)}(z) \cdot p^{(2)}(z) \bmod z^\kappa, \\ &= p^{(1)}(z) \cdot p^{(2)}(z) + \begin{cases} 0 & \text{if } \deg\left(p^{(1)} \cdot p^{(2)}\right) < \kappa, \\ -c \cdot z^\kappa + c & \text{if } \deg\left(p^{(1)} \cdot p^{(2)}\right) = \kappa. \end{cases} \end{aligned}$$

For κ a power of two, the complexity of converting to the new coordinate representation and back again (via either DFT_κ or IDFT_κ) is at most $\frac{1}{2} \cdot \kappa \cdot \log \kappa + \mathcal{O}(\kappa)$ multiplications and $\kappa \cdot \log \kappa + \mathcal{O}(\kappa)$ additions (the logarithm taken with respect to the basis 2). Therefore, the polynomial multiplication is of complexity $\mathcal{O}(\kappa \cdot \log \kappa)$.

In the SPHPS algorithm, we use the notations $\mathbf{e}_l$ is the lth unit vector, $\mathbf{I}$ the unit matrix of size $(m \times m)$, and $\{\sum_{j=0}^{\infty} c_j z^j\}_\kappa := \sum_{j=0}^{\kappa-1} c_j z^j$ denotes a truncated power series.

SPHPS Algorithm $(\mathbf{F}, \sigma, \kappa, \mathbf{n})$
Input: $\sigma, \kappa \in \mathbb{N}_0$, with $\sigma \le \kappa = 2^k$ for a $k \in \mathbb{N}_0$,
$\mathbf{n} = (n_1, \ldots, n_m)$, vector of integers,
$\mathbf{F} = (f_1, \ldots, f_m)^T$ vector of truncated power series,
i.e., of polynomials of degree less than κ,
Let $\mathbf{G} \in \mathbb{K}^{m \times s}[z]$ be defined by $\mathbf{F}(z) = \mathbf{G}(z^s) \cdot (1, z, \ldots, z^{s-1})^T$

Output: $\mathbf{P}, \xi$, and $\mathbf{d}$ where:
$\mathbf{d} = (d_1, \ldots, d_m)$, vector of integers,
$\mathbf{P} = (P_{l,\lambda})_{l=1,\ldots,m}^{\lambda=1,\ldots,m}$, consisting of rows
$\mathbf{P}_l = (P_{l,1}, \ldots, P_{l,m})$ with $\mathrm{dct}\ \mathbf{P}_l = d_l + 1$,
$\deg P_{l,l} \le \kappa$ and for $l \ne \lambda : \deg P_{l,\lambda} < \kappa$,
for all $\delta \in \mathbb{Z} : \mathcal{L}_\delta^\sigma = \{\alpha_1 \mathbf{P}_1 + \cdots + \alpha_m \mathbf{P}_m : \deg \alpha_l \le d_l + \delta\}$
$\xi = (\xi_j)_{j=0,\ldots,2\kappa-1}$, each ξ_j an m by m matrix,
$(\xi_j)_{j=0,\ldots,2\kappa-1} \longleftarrow \mathrm{DFT}_{2\kappa}(\mathbf{P}(z))$

The Recursion
Case ($\sigma = 0$ and $\kappa \ge 1$) or ($\sigma = \kappa = 1$ and $f_1(0) = \cdots = f_m(0) = 0$):
Return $(\mathbf{P}, \xi, \mathbf{d}) = (\mathbf{I}, \underbrace{(\mathbf{I}, \ldots, \mathbf{I})}_{2\kappa}, \mathbf{n})$

Case $\sigma = \kappa = 1, f_\pi(0) \ne 0$ and for all l with $n_l > n_\pi$: $f_l(0) = 0$:

$$P \leftarrow \begin{bmatrix} 1 & & & -f_1(0)/f_\pi(0) & & \\ & \ddots & & \vdots & & \\ & & 1 & -f_{\pi-1}(0)/f_\pi(0) & & \\ & & & z & & \\ & & & -f_{\pi+1}(0)/f_\pi(0) & 1 & \\ & & & \vdots & & \ddots \\ & & & -f_m(0)/f_\pi(0) & & 1 \end{bmatrix}$$

RETURN $(\mathbf{P}, \xi, \mathbf{d}) = (\mathbf{P}, (\mathbf{P}(1), \mathbf{P}(-1)), \mathbf{n} - \mathbf{e}_\pi)$

CASE $\sigma \geq 1$ and $\kappa > 1$: (Divide-and-conquer step)

Compute basis to order $\kappa/2$:

$\overline{\kappa} \longleftarrow \kappa/2, \overline{\sigma} \longleftarrow \min\{\sigma, \overline{\kappa}\}; \mathbf{F}^{(1)}(z) \longleftarrow \{\mathbf{F}(z)\}_{\overline{\kappa}}$

$(\mathbf{P}^{(1)}, \xi^{(1)}, \mathbf{d}^{(1)}) \longleftarrow$ SPHPS $(\mathbf{F}^{(1)}, \overline{\sigma}, \overline{\kappa}, \mathbf{n})$

Compute basis to order κ:

$(\eta_j)_{j=0,\ldots,\kappa-1} \longleftarrow \mathrm{DFT}_\kappa(\mathbf{G}(z))$

$\mathbf{G}^{(2)}(z) \longleftarrow \mathrm{IDFT}_\kappa((\xi_j^{(1)} \cdot \eta_j)_{j=0,\ldots,\kappa-1})$

$\mathbf{F}^{(2)}(z) \longleftarrow \{z^{-\overline{\kappa}} \cdot \mathbf{G}^{(2)}(z^s) \cdot (1, z, \ldots, z^{s-1})^T\}_{\overline{\kappa}}$

$(\mathbf{P}^{(2)}, \xi^{(2)}, \mathbf{d}^{(2)}) \longleftarrow$ SPHPS $(\mathbf{F}^{(2)}, \sigma - \overline{\sigma}, \overline{\kappa}, \mathbf{d}^{(1)})$

Combine both parts:

$\xi_{2j}^{(3)} \longleftarrow \xi_j^{(2)} \cdot \xi_j^{(1)}$ for $j = 0, 1, \ldots, \kappa - 1$

$\mathbf{P}^{(3)}(z) \longleftarrow \mathrm{IDFT}_\kappa((\xi_{2j}^{(3)})_{j=0,\ldots,\kappa-1})$

If $\deg P_{l,l}^{(1)} = \deg P_{l,l}^{(2)} = \overline{\kappa}$, then $P_{l,l}^{(3)}(z) \longleftarrow P_{l,l}^{(3)}(z) - 1 + z^\kappa$

$(\xi_{2j+1}^{(3)})_{j=0,1,\ldots,\kappa-1} \longleftarrow \mathrm{DFT}_\kappa(\mathbf{P}^{(3)}(\omega_{2\kappa} \cdot z))$

RETURN $(\mathbf{P}, \xi, \mathbf{d}) = (\mathbf{P}^{(3)}, \xi^{(3)}, \mathbf{d}^{(2)})$

Consider now the problem of determining the complexity of the SPHPS algorithm. For simplicity, we still impose the conditions before Theorem 4.1 (otherwise, the complexity will be still smaller). As in §2, in most applications one must determine σ-bases of PHPAs for $\sigma \approx \|\mathbf{n}\|$.

THEOREM 6.2 (Complexity). *The* SPHPS *algorithm for computing* PHPAs *of order σ has a complexity of at most*

$$\frac{3}{2} \cdot (m+s) \cdot m \cdot \sigma \cdot \log^2 \sigma + \mathcal{O}(\sigma \cdot \log \sigma)\,\mathrm{AO}, \tag{16}$$

roughly half multiplications as additions.

Proof. Let $\Phi_A(\kappa)$ and $\Phi_M(\kappa)$ denote the number of additions/subtractions and multiplications/divisions required for the SPHPS algorithm with parameter κ, respectively. We easily obtain $\Phi_A(1) \leq 1$ and $\Phi_M(1) \leq m - 1$. Moreover, in the last case we call the subroutines DFT_κ or IDFT_κ at most $2(m+s)m$ times; hence,

$$\Phi_A(\kappa) \leq 2 \cdot \Phi_A(\kappa/2) + 2 \cdot (m+s) \cdot m \cdot \kappa \cdot \log \kappa + \mathcal{O}(\kappa)$$

and

$$\Phi_M(\kappa) \leq 2 \cdot \Phi_M(\kappa/2) + (m+s) \cdot m \cdot \kappa \cdot \log \kappa + \mathcal{O}(\kappa).$$

This gives the complexity result. □

We remark that, as was the case with method FPHPS, the complexity will be even less for some special cases. For example, for simultaneous Padé approximation, this number will be smaller if one carefully checks whether some entries of the matrix $\mathbf{G}$ always equal zero or 1.

7. Conclusions. In this paper we have studied the concept of a power Hermite Padé approximant. These approximants are shown to generalize a number of Padé approximation problems, including, for example, the classical Hermite Padé and simultaneous Padé approximation problems as well as matrix-type generalizations of common Padé approximation problems. A fast (and also a superfast), reliable algorithm to compute these approximants is given. In this way our work provides a

uniform method of both describing and computing a wide variety of Padé and matrix-Padé approximation problems. As an immediate application, our work results in new and faster algorithms for a number of problems that rely on matrix-type Padé computation. For example, our algorithms, used in conjunction with the results of [17], gives faster algorithms for the inversion of striped or layered block Hankel (or Toeplitz) matrices. Similarly, the same algorithms combined with the results of [18] give similar improvements for the inversion of rectangular-block Hankel (or Toeplitz) matrices.

There are a number of directions for new research in this area. Our algorithm follows an m-dimensional "diagonal" path. In special cases, however, fast, reliable algorithms are given (cf. [4]) that can succeed on arbitrary staircase paths in m-dimensional space. The methods of [4] could also be extended to compute the more general PHPAs on arbitrary staircase paths, leading to a method with smaller complexity (cf. [26]).

Our algorithm does not consider the problem of stability when the computations are to be done with floating point numbers. Recently, Cabay and Meleshko [13] presented a (weakly) stable algorithm for the case $s = 1$ and $m = 2$. We conjecture that such an algorithm is also possible for the PHPA problem with arbitrary s and m, though not necessarily using the same approach as used in this paper. Our algorithm assumes exact arithmetic and has been implemented in the Maple computer algebra system. However, it does not consider the problem of exponential growth of the coefficients resulting in our computations. It would be interesting to extend our algorithm to this case. This would be done by restricting $\mathbb{K}$ to be an integral domain rather than a field and perhaps using fraction-free methods similar to those used for solving polynomial greatest common divisor (gcd) problems (cf. [15]).

Finally, the concept of a PHPA is a scalar generalization of a Hermite Padé approximant used to solve matrix-like Padé approximation problems. For example, as shown in [5] this concept also allows for a description of the structures in a singular PHPA solution table by adapting the scalar techniques of [3]. For matrix-like rational interpolation problems (with arbitrary knots), a common framework is given by the vector M-Padé approximation as a canonical extension of Example 2.5 (see [26]). In contrast, we are interested in a scalar generalization of the M-Padé approximant that can be used for simple, fast, and efficient algorithms and that, following [3], [5], might also be helpful for obtaining results about the structure of the singular matrix rational interpolation table.

A BLOCK-PARALLEL NEWTON METHOD VIA OVERLAPPING EPSILON DECOMPOSITIONS *

A. I. ZEČEVIĆ† AND D. D. ŠILJAK‡

Abstract. The purpose of this paper is to present a block-parallel Newton method for solving large nonlinear systems. A graph-theoretic decomposition algorithm is first used to partition the Jacobian into weakly coupled, possibly overlapping blocks. It is then shown that it suffices to invert only the diagonal blocks to carry out the Newton iterates. A rigorous justification of this practice is provided by using a convergence result of Kantorovich in the expanded space of the iterates, where overlapping blocks appear as disjoint. The individual blocks, or a group of blocks, can be inverted by a dedicated processor, making the new block-diagonal Newton method ideally suited for parallel processing. Applications to the power flow problem are presented and parallelization issues are discussed.

Key words. nonlinear equations, block-iterative solutions, weak coupling, overlapping decompositions, bigraphs, power systems, load-flow problem

AMS subject classification. 65

1. Introduction.

Due to steadily increasing demands for speedups and reliability in solving large systems of nonlinear equations, there has been a concerted effort to develop new methods for parallel computation via multiprocessor architectures. A common obstacle in this context has been excessive requirements for communication between the processors that can slow down the convergence of the solution process, if not destroy it altogether. For this reason, a good deal of research has been devoted to formulations of effective partitioning algorithms for mapping of large problems onto multiprocessor architectures, which result in minimal communication requirements [8].

The objective of this paper is to propose a block-parallel Newton method for solving large systems of nonlinear equations. The principal part of the method is the partitioning algorithm based on overlapping epsilon decompositions [21] with which we decompose the corresponding Jacobian matrix into weakly coupled diagonal blocks. By assigning a block per processor and ignoring the coupling between the blocks, we can significantly reduce the communication between the processors during the solution process. Most importantly, we extend the results of Kantorovich [12] to rigorously establish the convergence of the corresponding block-Newton iterates containing overlapping blocks.

The proposed block-parallel method is ideally suited for solving the load-flow problem in electric power systems, e.g., [25]. A whole range of epsilon decompositions is available that allows for tradeoffs in balancing the size of the blocks and the strength of coupling. This translates into a desired balance between the load across processors and the amount of communication between processors. Furthermore, the graph-theoretic algorithm underlying the decompositions is linear in complexity, thus making the proposed solution procedure more attractive with increasing size of the system.

Finally, since epsilon decompositions are inherently nested, there is a real potential in building hierarchical multiprocessor-multirate schemes with rate and granularity at each level being determined by the level of coupling between the corresponding parts of the system.

2. Epsilon decomposition. Our objective is to compute a solution x^* of the system

$$\mathcal{S} : f(x) = 0 \tag{2.1}$$

using the simplified Newton method

$$\mathcal{N} : x_{k+1} = x_k - A(x_0)^{-1} f(x_k), \qquad k = 0, 1, 2, \ldots, \tag{2.2}$$

where $A(x_0) = f'(x_0)$ is the Jacobian of nonlinear mapping $f : \Omega \subset \mathbf{R}^n \to \mathbf{R}^n$, which is computed at initial point x_0. A nonstandard feature of our solution procedure is a partitioning of Jacobian $A(x_0)$ into weakly coupled blocks, so that the inversion $A(x_0)^{-1}$ can be reduced to an inversion of the diagonal blocks of $A(x_0)$. A justification of the block-diagonal inversion in the context of Newton's iterative process $\mathcal{N}$ is provided in the next section. Our immediate interest, however, is to illustrate the decomposition solution procedure by a simple example.

Example (2.3). Let us consider a system

$$\begin{aligned} \mathcal{S} : f_1(x) &\equiv e^{x_1} e^{x_2/5} \cos \frac{x_3}{5} - 1.85 = 0, \\ f_2(x) &\equiv x_2 e^{x_3/3} \cos \frac{x_1}{3} - 2.9 = 0, \\ f_3(x) &\equiv e^{x_2/2} \cos \frac{1}{10}(x_3 + 1) - 4.3 = 0, \end{aligned} \tag{2.4}$$

with the Jacobian computed as

(2.5)

$$A(x) = \begin{bmatrix} e^{x_1} e^{x_2/5} \cos \frac{x_3}{5} & \frac{1}{5} e^{x_1} e^{x_2/5} \cos \frac{x_3}{5} & -\frac{1}{5} e^{x_1} e^{x_2/5} \sin \frac{x_3}{5} \\ -\frac{1}{3} x_2 e^{x_3/3} \sin \frac{x_1}{3} & e^{x_3/3} \cos \frac{x_1}{3} & \frac{1}{3} x_2 e^{x_3/3} \cos \frac{x_1}{3} \\ 0 & \frac{1}{2} e^{x_2/2} \cos \frac{1}{10}(x_3 + 1) & -\frac{1}{10} e^{x_2/2} \sin \frac{1}{10}(x_3 + 1) \end{bmatrix}.$$

Choosing initial approximation $x_0 = (0.1, 3, 0)^T$, we get

$$A(x_0) = \begin{bmatrix} 2.014 & 0.403 & 0 \\ -0.333 & 0.999 & 0.999 \\ 0 & 2.23 & -0.045 \end{bmatrix}. \tag{2.6}$$

To decompose this matrix into weakly coupled blocks, we denote by ε all nonzero elements of the matrix with absolute value less than or equal to 0.05 and by $*$ all other nonzero elements. Then, a symbolic representation of $A = A(x_0)$ is

$$A = \begin{bmatrix} * & * & 0 \\ \varepsilon & * & * \\ 0 & * & \varepsilon \end{bmatrix}. \tag{2.7}$$

Since there is a column of stars in A, no permutation of rows and columns can produce an epsilon decomposition of A; that is, a decomposition such that all off-diagonal blocks of A consist of epsilon elements only. However, matrix A has an *overlapping decomposition* [21]. By expanding the underlying space $\mathbf{R}^3$ using the transformation matrices,

$$V = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \qquad \tilde{V} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix}, \tag{2.8}$$

we get the expanded Jacobian

$$\tilde{A} = \left[\begin{array}{cc:cc} * & * & 0 & 0 \\ 0 & * & \varepsilon & 0 \\ \hdashline \varepsilon & 0 & * & * \\ 0 & 0 & \varepsilon & * \end{array}\right], \tag{2.9}$$

which is defined by

$$VA = \tilde{A}\tilde{V}. \tag{2.10}$$

Matrix $\tilde{A}$ now has an epsilon decomposition indicated by dashed lines in (2.9).

We can take advantage of the weak coupling in (2.9) and consider Newton iterates

$$\tilde{\mathcal{N}} : \tilde{x}_{k+1} = \tilde{x}_k - \tilde{A}^{-1}\tilde{f}(\tilde{x}_k), \qquad k = 0, 1, 2, \ldots \tag{2.11}$$

in the expanded space $\mathbf{R}^4$ to solve the system of equations

$$\begin{aligned} \tilde{\mathcal{S}} : \tilde{f}_1(\tilde{x}) &\equiv e^{\tilde{x}_1} e^{\tilde{x}_2/5} \cos \frac{\tilde{x}_3}{5} - 1.85 = 0, \\ \tilde{f}_2(\tilde{x}) &\equiv e^{\tilde{x}_2/2} \cos \frac{1}{10}(\tilde{x}_3 + 1) - 4.3 = 0, \\ \tilde{f}_3(\tilde{x}) &\equiv \tilde{x}_4 e^{\tilde{x}_3/3} \cos \frac{\tilde{x}_1}{3} - 2.9 = 0, \\ \tilde{f}_4(\tilde{x}) &\equiv e^{\tilde{x}_4/2} \cos \frac{1}{10}(\tilde{x}_3 + 1) - 4.3 = 0 \end{aligned} \tag{2.12}$$

with initial approximation $\tilde{x}_0 = \tilde{V}x_0 = (0.1, 3, 0, 3)^T$. A description of the method used to construct such an expanded function $\tilde{f}$ is presented in §4.

The matrix $\tilde{A}(\tilde{x}_0)$ is Jacobian $\tilde{f}'(\tilde{x}_0)$ of mapping $\tilde{f}(\tilde{x})$, which is defined by $\tilde{f}(\tilde{V}x) = Vf(x)$. The significance of expansion is that Jacobian $\tilde{A}$ has a weak coupling structure indicated in (2.9), which provides an epsilon decomposition

$$\tilde{A} = \tilde{A}_D + \varepsilon \tilde{A}_C, \tag{2.13}$$

where

$$\tilde{A}_D = \left[\begin{array}{cc:cc} 2.014 & 0.403 & & \\ 0 & 2.23 & \multicolumn{2}{c}{\odot} \\ \hdashline & & 0.999 & 0.999 \\ \multicolumn{2}{c:}{\odot} & -0.045 & 2.23 \end{array}\right],$$

(2.14)

$$\tilde{A}_C = \left[\begin{array}{cc:cc} & & 0 & 0 \\ \multicolumn{2}{c:}{\odot} & -0.9 & 0 \\ \hdashline -0.66 & 0 & \multicolumn{2}{c}{\odot} \\ 0 & 0 & & \end{array}\right].$$

A crucial step in the solution process is to take advantage of the weak coupling term $\varepsilon\tilde{A}_c$ and replace $\tilde{A}^{-1}$ in Newton iterates (2.11) by $\tilde{A}_D^{-1}$ computed as

$$\tilde{A}_D^{-1} = \left[\begin{array}{cc:cc} 0.4965 & -0.09 & & \\ 0 & 0.4485 & \multicolumn{2}{c}{\odot} \\ \hdashline & & 0.981 & -0.4395 \\ \multicolumn{2}{c:}{\odot} & 0.0198 & 0.4395 \end{array}\right], \tag{2.15}$$

which amounts to inverting only the diagonal 2×2 blocks of $\tilde{A}$. This fact allows for the construction of parallel schemes that can provide significant computational speedups in large systems.

After several iterations, the *block-diagonal Newton iterates*

$$\tilde{\mathcal{N}}_D : \tilde{x}_{k+1} = \tilde{x}_k - \tilde{A}_D^{-1}\tilde{f}(\tilde{x}_k), \qquad k = 0, 1, 2, \ldots \tag{2.16}$$

produce a solution of $\tilde{\mathcal{S}}$

$$\tilde{x}^* = (0.029859,\ 2.926705,\ -0.027351,\ 2.926705)^T. \tag{2.17}$$

A straightforward elimination of the repeated components in $\tilde{x}^*$ using transformation

$$\tilde{x}^* = \tilde{V}x^* \tag{2.18}$$

provides the solution

$$x^* = (0.029859,\ 2.926705,\ -0.027351)^T \tag{2.19}$$

of the original system $\mathcal{S}$.

Remark (2.20). Although in Example (2.3) the overlapping epsilon decomposition was necessary, most of the time a disjoint decomposition would suffice [20], [23]. Disjoint decompositions result in less computation and they are easier to obtain. As in Example (2.3), however, a disjoint decomposition may not exist for a given epsilon and more general overlapping decompositions are required.

3. The main result. We now provide a justification of the procedure proposed in Example (2.3). The full generality of our development is based on a result of Kantorovich, which was established for a weak perturbation of the Jacobian matrix. What makes our result interesting is that it concerns weak perturbations of a *block-diagonal* Jacobian and that the blocks are *overlapping*. The latter feature requires use of the inclusion principle [23] in the context of Newton iterates, as well as an extension of Kantorovich's result to the expansion-contraction process involving the underlying space of the iterates.

We consider the system of nonlinear equations

$$\mathcal{S} : f(x) = 0, \tag{3.1}$$

where $f : \Omega \subset \mathbf{R}^n \to \mathbf{R}^n$ is a twice differentiable mapping on a domain Ω, and x_0 is an initial approximation of the solution x^* of $\mathcal{S}$. Our crucial assumption is that there exist two $\tilde{n} \times n$ matrices V and $\tilde{V}$ with full column rank and $\tilde{n} \geq n$, such that Jacobian $A = f'(x_0)$, satisfying the condition

$$VA = \tilde{A}\tilde{V} \tag{3.2}$$

has an epsilon decomposition in the expanded space,

$$\tilde{A} = \tilde{A}_D + \varepsilon \tilde{A}_C, \tag{3.3}$$

where $\varepsilon > 0$ is a sufficiently small number, and $\tilde{A}_D$ is a block-diagonal matrix

$$\tilde{A}_D = \operatorname{diag}\left\{\tilde{A}_1, \tilde{A}_2, \ldots, \tilde{A}_N\right\} \tag{3.4}$$

with invertible blocks.

The expanded matrix $\tilde{A}(\tilde{x}_0)$ is the Jacobian $\tilde{f}'(\tilde{x}_0)$ of the mapping $\tilde{f} : \tilde{\Omega} \subset \mathbf{R}^{\tilde{n}} \to \mathbf{R}^{\tilde{n}}$ defined by

$$V f(x) = \tilde{f}\left(\tilde{V}x\right) \quad \forall x \in \mathbf{R}^n. \tag{3.5}$$

How epsilon decompositions (3.3) of $\tilde{A}$ are generated from a matrix A by choosing different values for ε and how each decomposition produces (automatically) the expanded mapping $\tilde{f}(\tilde{x})$ is explained in the next section. Here we want to establish rigorously that when we use linear transformation

$$\tilde{x} = \tilde{V}x, \tag{3.6}$$

which is obtained as a by-product of epsilon decomposition, and get the expanded system

$$\tilde{\mathcal{S}} : \tilde{f}(\tilde{x}) = 0, \tag{3.7}$$

we can then solve $\tilde{\mathcal{S}}$ instead of $\mathcal{S}$, as illustrated by Example (2.3) in §2.

We start by applying the inclusion principle to iterative processes $\mathcal{N}$ and $\tilde{\mathcal{N}}$ of (2.2) and (2.11), which are discrete dynamic systems that generate sequences $x(k; x_0)$ and $\tilde{x}(k; \tilde{x}_0)$ starting at x_0 and $\tilde{x}_0 = \tilde{V}x_0$.

DEFINITION (3.8). *An iterative process $\tilde{\mathcal{N}}$ is said to include process $\mathcal{N}$ if there exists an $\tilde{n} \times n$ matrix $\tilde{V}$ with $\tilde{n} \geq n$ and full column rank, such that*

$$\tilde{x}\left(k; \tilde{V}x_0\right) = \tilde{V}x\left(k; x_0\right) \quad \forall x_0 \in \mathbf{R}^n. \tag{3.9}$$

The reason for this definition is obvious: if sequence $\tilde{x}(k; \tilde{x}_0)$ converges to a solution $\tilde{x}^*$ of $\tilde{\mathcal{S}}$, then the corresponding solution x^* of $\mathcal{S}$ can be extracted from $\tilde{x}^*$ by using matrix $\tilde{V}$. We recall [23] that when $\tilde{\mathcal{N}}$ includes $\mathcal{N}$, we say that $\tilde{\mathcal{N}}$ is an expansion of $\mathcal{N}$, or that $\mathcal{N}$ is a contraction of $\tilde{\mathcal{N}}$.

To provide conditions for inclusion (3.9), we prove the following.

LEMMA (3.10). *Let us assume that $\tilde{\mathcal{N}}$ is obtained by expanding $A(\underline{x}_0)$ at a fixed $\underline{x}_0$, and that* (3.2) *and* (3.5) *hold. Then, $\tilde{\mathcal{N}}$ includes $\mathcal{N}$.*

Proof. Let x_0 be an arbitrary initial approximation for $\mathcal{N}$ and consider $\tilde{\mathcal{N}}$ with $\tilde{x}_0 = \tilde{V}x_0$. We note that (3.2) implies

$$\tilde{A}^{-1}V = \tilde{V}A^{-1} \tag{3.11}$$

and the proof follows by induction. Denoting $x(k) = x(k; x_0)$ and $\tilde{x}(k) = \tilde{x}(k; \tilde{V}x_0)$, and assuming $\tilde{x}(k) = \tilde{V}x(k)$, we conclude, using (3.5) and (3.11), that

$$\begin{aligned} \tilde{x}\left(k+1\right) &= \tilde{x}\left(k\right) - \tilde{A}^{-1}\tilde{f}\left[\tilde{x}\left(k\right)\right], \\ &= \tilde{V}x\left(k\right) - \tilde{A}^{-1}Vf\left[x\left(k\right)\right], \\ &= \tilde{V}\left\{x\left(k\right) - A^{-1}f\left[x\left(k\right)\right]\right\}, \\ &= \tilde{V}x\left(k+1\right) \quad \forall k > 0. \end{aligned} \tag{3.12}$$

□

Remark (3.13). It is interesting to note that inclusion (3.9) holds for all x_0 and $\tilde{x}_0 = \tilde{V}x_0$, even though Jacobian $A(x) = f'(x)$ is computed at a fixed $\underline{x}_0 \neq x_0$, as long as $\tilde{A}(\tilde{V}\underline{x}_0)$ is used in $\tilde{\mathcal{N}}$. This is clear from (3.12). We should note, however, that even though inclusion (3.9) holds for all $x_0 \in \mathbf{R}^n$, process $\tilde{\mathcal{N}}$, and thus $\mathcal{N}$, may not converge.

To establish convergence of $\tilde{\mathcal{N}}_D$, when we use $\tilde{A}_D$ instead of $\tilde{A}$, we first define a region

$$\tilde{\Omega}_0 = \{\tilde{x} \in \mathbf{R}^{\tilde{n}} : \|\tilde{x} - \tilde{x}_0\| \leq \rho\} \tag{3.14}$$

for some $\rho > 0$. Here, and throughout the paper, we use l_∞ norm $\|x\|_\infty = \max_{i \in \mathbf{N}} \{|x_i|\}$ in $\mathbf{R}^n$, and the corresponding operator norm $L(\mathbf{R}^n), \|A\|_\infty = \max_{i \in \mathbf{N}} \{\sum_{j=1}^{n} |a_{ij}|\}$, where $\mathbf{N} = \{1, 2, \ldots, n\}$. We state our main result.

THEOREM (3.15). *Let us assume that mapping $f(x)$ and its expansion $\tilde{f}(\tilde{x})$ satisfy* (3.2) *through* (3.5) *and that the following bounds hold:*

$$\left\|\tilde{A}_D^{-1}\tilde{f}\left(\tilde{x}_0\right)\right\| \leq \alpha, \tag{3.16}$$

$$\left\|\tilde{A}_D^{-1}\tilde{A}_C\right\| \leq \beta, \tag{3.17}$$

$$\left\|\tilde{A}_D^{-1}\tilde{f}''\left(\tilde{x}\right)\right\| \leq \gamma, \tag{3.18}$$

for some positive numbers α, β, γ, and for all $\tilde{x} \in \tilde{\Omega}_0$. Furthermore, we assume that

$$\varepsilon\beta < 1, \tag{3.19}$$

$$\delta = \frac{\alpha\gamma}{(1-\varepsilon\beta)^2} < \frac{1}{2}, \tag{3.20}$$

$$\underline{\rho} \leq \rho < \bar{\rho}, \tag{3.21}$$

where

$$\underline{\rho} = \frac{1-\sqrt{1-2\delta}}{\delta}\frac{\alpha}{1-\varepsilon\beta}, \qquad \bar{\rho} = \frac{1+\sqrt{1-2\delta}}{\delta}\frac{\alpha}{1-\varepsilon\beta}. \tag{3.22}$$

Then,

(i) The system $\tilde{S}$ of (3.7) has a solution $\tilde{x}^* \in \tilde{\Omega}_0$, and block-diagonal iterative process $\tilde{\mathcal{N}}_D$ converges to this solution.

(ii) Solution $\tilde{x}^*$ is unique in $\tilde{\Omega}_0$.

(iii) Iterative process $\tilde{\mathcal{N}}_D$ converges to $\tilde{x}^*$ as

$$\|\tilde{x}^* - \tilde{x}_k\| \leq \frac{\alpha}{\delta(1-\varepsilon\beta)^2}\left[1-(1-\varepsilon\beta)\sqrt{1-2\delta}\right]^{k+1}. \tag{3.23}$$

(iv) Define a manifold

$$\tilde{M} = \left\{\tilde{x} \in \mathbf{R}^{\tilde{n}} : \tilde{x} = \tilde{V}x, x \in \mathbf{R}^n\right\}. \tag{3.24}$$

Then, $\tilde{x}^* \in \tilde{M}$, and the system $\mathcal{S}$ has a unique solution x^* in the region

$$\Omega_0 = \{x \in \mathbf{R}^n : \|x - x_0\| \leq \rho\}, \tag{3.25}$$

which is related to $\tilde{x}^*$ by

$$\tilde{V}x^* = \tilde{x}^*. \tag{3.26}$$

The proof of Theorem (3.15) is provided in the Appendix.

4. The algorithm. Efficiency of the proposed block-diagonal Newton scheme hinges on our ability to systematically generate overlapping decompositions of the Jacobian matrix $A(x_0)$ and produce the transformation matrices V and $\tilde{V}$. With these matrices at hand, we can proceed to construct the function $\tilde{f}(\tilde{x})$ and use it to solve the expanded Newton iterates $\tilde{\mathcal{N}}_D$ of (2.16). Since our main task is to describe the construction of $\tilde{f}(\tilde{x})$, the epsilon decomposition algorithm will be outlined only to the extent needed for understanding the construction of $\tilde{f}(\tilde{x})$. A detailed presentation of the algorithm is provided in [21].

Given an $n \times n$ matrix $A = (a_{ij})$ and a number $\varepsilon > 0$, we say that A has an epsilon decomposition if there exist $\tilde{n} \times n$ ($\tilde{n} \geq n$) permutation matrices V and $\tilde{V}$ having full rank, such that

$$\tilde{A} = \tilde{A}_D + \varepsilon\tilde{A}_C, \tag{4.1}$$

where

$$VA = \tilde{A}\tilde{V} \tag{4.2}$$

and $\tilde{A}_D$ is a nonsingular block diagonal matrix,

$$\tilde{A}_D = \operatorname{diag}\left\{\tilde{A}_1, \tilde{A}_2, \ldots, \tilde{A}_N\right\}. \tag{4.3}$$

In the case of singular blocks, another decomposition with a different ε should be attempted. When $\tilde{n} > n$ and $N > 1$, (4.1) represents an overlapping decomposition of A.

To generate an overlapping decomposition of a nonsingular matrix A, we associate with A a bigraph $\mathbf{B}(\mathcal{X}, \mathcal{Y}; \mathcal{E})$ such that $|\mathcal{X}| = |\mathcal{Y}| = n$ and $(x_j, y_i) \in \mathcal{E}$ if and only if $a_{ij} \neq 0, i, j, = 1, 2, \ldots, n$. We assume that bigraph $\mathbf{B}$ has a *perfect matching* $\mathbf{M}^*$, which is consistent with generic nonsingularity of A. This is equivalent to assuming that A can be permuted into a matrix with nonzero diagonal elements, e.g., [21].

For example, with a matrix

$$A = \begin{bmatrix} \otimes & * & 0 \\ \varepsilon & * & \otimes \\ 0 & \otimes & \varepsilon \end{bmatrix}, \tag{4.4}$$

which is that of (2.7) in Example (2.3), we associate bigraph $\mathbf{B}$ of Fig. 1(a). A perfect matching, which is denoted by $\otimes$ in A, is shown in Fig. 1(a) by heavy lines. By removing the edges of $\mathbf{B}$ that correspond to epsilon elements of A, we get subgraph $\mathbf{B}^\varepsilon = (\mathcal{X}, \mathcal{Y}; \mathcal{E}^\varepsilon)$ shown in Fig. 1(b). It is $\mathbf{B}^\varepsilon$ that we decompose into two overlapping components. Before doing that, however, we note that $\mathbf{B}^\varepsilon$ has retained the perfect matching of $\mathbf{B}$. If this were not true, the decomposition algorithm would terminate prematurely. In this case ε should be decreased to $\varepsilon_1 < \varepsilon$ and the algorithm restarted with a new $\mathbf{B}^{\varepsilon_1}$, which has more edges than $\mathbf{B}^\varepsilon$. The algorithm recursively determines (component by component) a perfect matching of a given bigraph and, thus, the *generic rank* of the corresponding matrix. This is performed *simultaneously* with the partitioning of bigraph $\mathbf{B}^\varepsilon$ into overlapping components.

The basic idea of the algorithm is to rearrange and often split vertices of $\mathbf{B}^\varepsilon$ to obtain a new bigraph $\tilde{\mathbf{B}}^\varepsilon = (\tilde{\mathcal{X}}, \tilde{\mathcal{Y}}; \tilde{\mathcal{E}}^\varepsilon)$ consisting of several (disjoint) components. These components define the blocks $\tilde{A}_i$ of the diagonal matrix $\tilde{A}_D$ in (4.3). By reconnecting the epsilon edges of the original bigraph $\mathbf{B}$, we subsequently obtain an expanded bigraph $\tilde{\mathbf{B}}$ that identifies the matrix $\tilde{A}$ of (4.1) having the desired epsilon decomposition [21]. We provide the code in C for a simplified algorithm of the epsilon decomposition, which is sufficient for our objective in this paper. A new version of the complete algorithm is in a refinement stage and will appear elsewhere.

ALGORITHM (4.5).

```
main( )
{
  int tst1, tst2;
  initialization( );
/* Set column node x1 ∈ X as the current column xc */
  A: horiz_edges( );
/* Link xc with its matching. This matching becomes the current row yc ∈ Y */
  other_edges( );
```

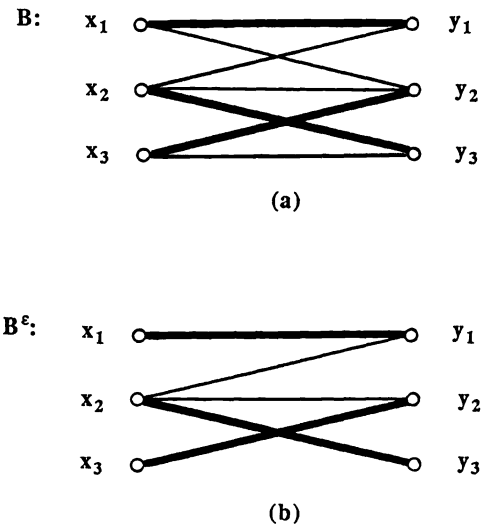

FIG. 1. *System bigraphs.*

```
/* Link y_c with all columns other than x_c that have an element > ε in row y_c. Add any
   such vertices of X to the current component if they are not there already */
     tst1 = next_x( );
/* Check if there are some unexamined x-vertices in the current component. If yes, set
   next one as x_c */
     if (tst1)
/* There exist unexamined x-vertices in current component */
        goto A;
     else{
/* All x-vertices in current component have been examined */
        tst2 = end_of_block( );
/* Check if there are any unused x-vertices left */
        if(tst2){
/* Unused x-vertices exist */
           new_block ( );
/* Initiate new block and set next unused x-vertex as x_c */
           goto A;
        }
        else
/* All x-vertices have been used—the graph is complete */
           final( );
     }
  }
```

This algorithm produces an expansion $\tilde{\mathbf{B}}$ of the original bigraph $\mathbf{B}$, which defines the expanded matrix $\tilde{A}$, as well as the transformation matrices V and $\tilde{V}$ relating $\tilde{A}$ to the original matrix A. Once the matrices V and $\tilde{V}$ are identified, the corresponding

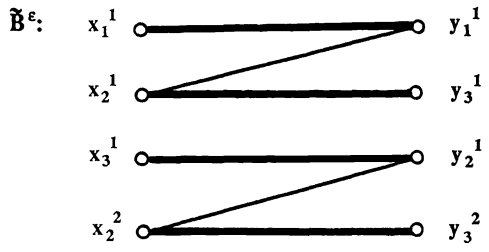

FIG. 2. *Expanded bigraph.*

function $\tilde{f}(\tilde{x})$ defined as

$$\tilde{f}'\left(\tilde{V}x_0\right) = \tilde{A}, \qquad \tilde{f}\left(\tilde{V}x\right) = Vf(x) \quad \forall x \in \mathbf{R}^n \tag{4.6}$$

is obtained by a straightforward bookkeeping procedure. The procedure is best described by reconsidering Example (2.3).

We start with the expanded bigraph $\tilde{\mathbf{B}}^{\epsilon}$ in Fig. 2, which was obtained from $\mathbf{B}^{\epsilon}$ of Fig. 1(b) by using Algorithm (4.5). In $\tilde{\mathbf{B}}^{\epsilon}$, x_j^r and y_j^r represent the rth appearance of the vertices x_j and y_j. This notation will help us track the vertex ordering in $\tilde{\mathbf{B}}^{\epsilon}$ in forming V and $\tilde{V}$.

The ordering of y-vertices in $\tilde{\mathbf{B}}^{\epsilon}$ uniquely determines the matrix V together with a correspondence relating the components $f_i : \mathbf{R}^n \to \mathbf{R}$ of $f(x)$ with the components $\tilde{f}_i : \mathbf{R}^{\tilde{n}} \to \mathbf{R}$ of the expanded function $\tilde{f}(\tilde{x})$ as follows:

$$V = \begin{array}{c} \\ y_1^1 \\ y_3^1 \\ y_2^1 \\ y_3^2 \end{array} \begin{array}{c} \begin{array}{ccc} 1 & 2 & 3 \end{array} \\ \left[\begin{array}{ccc} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{array}\right] \end{array} \begin{array}{l} \\ f_1 \to \tilde{f}_1, \\ f_3 \to \tilde{f}_2, \\ f_2 \to \tilde{f}_3, \\ f_3 \to \tilde{f}_4. \end{array} \tag{4.7}$$

The arrows indicate the defining implications and the dashed line indicates the two components induced by the overlapping decomposition.

The ordering of x-vertices in $\tilde{\mathbf{B}}^{\epsilon}$ uniquely determines matrix $\tilde{V}$ as well as the correspondence between the original n variables x_i and the $\tilde{n}$ variables $\tilde{x}_i$ of the expansion:

$$\tilde{V} = \begin{array}{c} \\ x_1^1 \\ x_2^1 \\ x_3^1 \\ x_2^2 \end{array} \begin{array}{c} \begin{array}{ccc} 1 & 2 & 3 \end{array} \\ \left[\begin{array}{ccc} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{array}\right] \end{array} \begin{array}{l} \\ x_1 \to \tilde{x}_1, \\ x_2 \to \tilde{x}_2, \\ x_3 \to \tilde{x}_3, \\ x_2 \to \tilde{x}_4. \end{array} \tag{4.8}$$

It should be pointed out that, in general, any original variable x_i can have multiple representations x_i^r in $\mathbf{R}^{\tilde{n}}$. In (4.8), only x_2 exhibits this property with $r = 1, 2$.

Based on the established correspondences, each component $\tilde{f}_i(\tilde{x})$ is now constructed by identifying function $f_j \to \tilde{f}_i$ and then by replacing each variable $x_k, k = 1, 2, \ldots, n$, in $f_j(x_1, \ldots, x_k, \ldots, x_n)$ by one of its representations in the expanded space. We note that once the components $\tilde{f}_i$ of $\tilde{f}$ are identified with the kth block of V as in (4.7), the variables $\tilde{x}_i$ associated with the same kth block of $\tilde{V}$, as in (4.8), are the *endogenous* (subsystem) variables. They will replace their original variables in all

components $\tilde{f}_i$ comprising the kth block. On the other hand, an original variable, which is represented only by *exogenous* (interconnection) variables to the kth block, can be replaced by any one of its representations. Referring to (4.7) and (4.8), we have

Block 1:

$$\begin{aligned} &x_1 \to \tilde{x}_1 \quad \text{endogenous}, \\ &x_2 \to \tilde{x}_2 \quad \text{endogenous}, \\ &x_3 \to \tilde{x}_3 \quad \text{exogenous}, \\ &\tilde{f}_1(\tilde{x}) = f_1(\tilde{x}_1, \tilde{x}_2, \tilde{x}_3), \\ &\tilde{f}_2(\tilde{x}) = f_3(\tilde{x}_1, \tilde{x}_2, \tilde{x}_3). \end{aligned} \tag{4.9}$$

Block 2:

$$\begin{aligned} &x_1 \to \tilde{x}_1 \quad \text{exogenous}, \\ &x_2 \to \tilde{x}_4 \quad \text{endogenous}, \\ &x_3 \to \tilde{x}_3 \quad \text{endogenous}, \\ &\tilde{f}_3(\tilde{x}) = f_2(\tilde{x}_1, \tilde{x}_4, \tilde{x}_3), \\ &\tilde{f}_4(\tilde{x}) = f_3(\tilde{x}_1, \tilde{x}_4, \tilde{x}_3). \end{aligned} \tag{4.10}$$

It is obvious that functions (4.9) and (4.10) are those of (2.12).

5. Power systems: the load-flow problem. To determine the static operating condition of an electric power transmission system, commonly known as the load-flow problem [24], [25], one must solve a large system of nonlinear algebraic equations

$$f(x; P, Q) = 0. \tag{5.1}$$

Typically, there are several thousand equations that need to be solved for a variety of input vectors P and Q. Since it is crucial to obtain solutions as efficiently as possible, preferably on-line, parallel computations via multiprocessor architectures have become a central research topic.

Since the initial studies of parallel solutions to load-flow problems [9], it has been recognized that the key step in mapping a problem on a multiprocessor system is an efficient partitioning algorithm. Schemes for partitioning power systems have been based on a wide variety of principles, such as sparsity [7]; coherency [16], [19]; diakoptics [10], [13]; decoupling and time scales [17], [3], [15]; and overlapping subsystems [22], [11], [26], [2]. Recent studies [4], [6], [1] have indicated that the most efficient parallel configurations are those that happen to group the tightly coupled variables together. These are precisely the configurations that the overlapping epsilon decomposition [21] is designed to produce. Most importantly, the epsilon decomposition algorithm is linear in complexity; it is binary, recursive and exhaustive, and does not rely on heuristic or intuitive reasoning. That epsilon partitions are conducive to convergence of the corresponding Newton's iterates is confirmed by (3.19), (3.20), and (3.23) of our main result, Theorem (3.15), where the effect of ε is apparent.

An n-bus electric power system consists of n *nodes,* each representing either a generator or a load. If any two nodes i and k are connected by a *line,* the corresponding complex line admittance is denoted as

$$Y_{ik} = G_{ik} + jB_{ik}. \tag{5.2}$$

In addition, with each node we associate its self-admittance

$$Y_{ii} = G_{ii} + jB_{ii}, \tag{5.3}$$

where

$$G_{ii} \cong -\sum_{k \neq i} G_{ik}, \qquad B_{ii} \cong -\sum_{k \neq i} B_{ik}. \tag{5.4}$$

The load-flow problem now amounts to computing the complex voltage $E_i = V_i e^{j\theta_i}$ for all nodes, given the injected powers

$$S_i = P_i + jQ_i. \tag{5.5}$$

Since all quantities are complex, an n-bus power system generally results in a $2n \times 2n$ system of nonlinear equations

$$f_i(x_1, x_2, \ldots, x_n; P_i, Q_i) = 0, \quad i = 1, 2, \ldots, n, \tag{5.6}$$

where

$$f_i = (F_{P_i}, F_{Q_i})^T, \qquad x_i = (\theta_i, V_i)^T \tag{5.7}$$

and

$$\begin{aligned} F_{P_i} &= \bar{P}_i - V_i \sum_k \left[\bar{G}_{ik} \cos(\theta_i - \theta_k) + \bar{B}_{ik} \sin(\theta_i - \theta_k)\right] V_k, \\ F_{Q_i} &= \bar{Q}_i - V_i \sum_k \left[\bar{G}_{ik} \sin(\theta_i - \theta_k) - \bar{B}_{ik} \cos(\theta_i - \theta_k)\right] V_k, \end{aligned} \tag{5.8}$$

The overbar denotes scaling by B_{ii}.

At some nodes, the voltage magnitude V_i may be regulated at a preassigned value V_i^R, and only P_i is known. Such nodes are referred to as PV nodes. The nodes at which both P_i and Q_i are available are termed PQ nodes. With this distinction, we reformulate (5.7) as

$$f_i = \begin{cases} (F_{P_i}, F_{Q_i})^T, & i \in PQ, \\ F_{P_i}, & i \in PV. \end{cases} \tag{5.9}$$

To solve (5.6) by the Newton method, we assume the initial approximation x_0 to be

$$\theta_i^0 = 0, \qquad V_i^0 = \begin{cases} 1, & i \in PQ, \\ V_i^R & i \in PV, \end{cases} \tag{5.10}$$

which is known as "flat voltage start." In practice, this approximation is usually improved by one or two iterations on a linearization of (5.6).

To apply overlapping epsilon decompositions to the load-flow problem, we should first note that the Jacobian computed at x_0 involves both $\bar{G}_{ik}$ and $\bar{B}_{ik}$. However, since in power systems typically $\bar{B}_{ik} \gg \bar{G}_{ik}$, it suffices to perform an epsilon decomposition on the $n \times n$ matrix $\bar{B} = (\bar{B}_{ik})$, which automatically induces the corresponding decomposition of the $2n \times 2n$ Jacobian. This reduces the dimension of the decomposition problem a priori by a factor of two.

FIG. 4. *Expanded matrix* $\tilde{B}$.

As an illustration of the proposed solution procedure, we consider the IEEE 14-bus system [25] with matrix $\bar{B}$ shown in Fig. 3. This matrix has a variety of epsilon decompositions, one of which is presented in Fig. 4 for $\varepsilon = 0.4$. The expanded and original solutions $\tilde{x}^*$ and x^* that are obtained by the block-diagonal Newton method, are shown in Tables 1 and 2, respectively.

For a complete assessment of the proposed Newton method, we also discuss a number of parallelization issues that came up during experimentation with the IEEE

118-bus system using the Intel iPSC/860 parallel processing system. We begin by recalling that, in general, execution of the original Newton method for an $n \times n$ system requires inversion of the Jacobian that amounts to solving an $n \times n$ system of linear equations in each iteration. Although typical power systems do not require many iterations, for large n the computational effort may still be prohibitively large.

Consider now a partition of the Jacobian into N diagonal blocks of dimension n_i with $n_m = \max_i n_i$. In a parallelization based on inverting only the diagonal blocks, the execution would effectively be reduced to solving an $n_m \times n_m$ system in each iteration. Nevertheless, this advantage in itself is not enough because the number of iterations I is seen to vary significantly with different choices of partitions and termination criteria; for some choices the iterations may not converge at all. To resolve this problem, we first point out that given N processors, only *balanced* partitions (i.e., those satisfying $n_m \approx n/N$) should be considered for parallel implementation. This is due to the fact that such partitions provide adequate load balancing and at the same time require minimal execution time T_i per iteration. Our experiments have confirmed that with a fixed number of processors, time T_i is indeed approximately equal for a variety of balanced partitions. Consequently, in the class of such partitions I becomes the dominant measure for the efficiency of the iterative algorithm.

In view of the above discussion, given N processors and a preassigned termination criterion, optimal parallelization of the solution process amounts to choosing a balanced partition that provides the minimal I. Expectedly, experimental studies have indicated that the partition resulting in the optimal I is indeed an epsilon decomposition. To demonstrate this optimality, in Table 3 we present a comparison of three different partitionings that map the 118-bus system onto eight processors, with a mismatch at 0.001 per unit as the termination criterion in all cases. Partitions denoted Heuristic1 and Heuristic2 represent two common ways of partitioning power systems based on the geography and node numbering of the network, respectively. The choice of ε is induced by the preassigned number of processors and I_0 represents the number of iterations corresponding to the epsilon decomposition.

It should be pointed out that the block-parallel algorithm normally requires more iterations than the original Newton method. However, by virtue of the reduction of dimensionality, the parallel algorithm based on epsilon decompositions can result in significant computational savings. Our experiments on the IEEE 118-bus system confirmed our expectations even for this relatively small system, in which a parallel solution was seen to be up to 40% faster than when using a single processor. This is explicitly demonstrated in Table 4, where we present a comparison of computation times needed for solving the load flow equations for the IEEE 118-bus system with one, two, four, and eight processors. An improved initial approximation and the usual termination criterion (0.001 p.u. mismatch) were used.

In computations with a *single* processor, the *standard modified Newton method* of (2.2) was used and a suboptimal ordering scheme for minimizing fill in was applied in the LU factorization of the complete (unpartitioned) Jacobian. The same ordering scheme was also utilized for factorizing the individual blocks in parallel computations. When interpreting the results of Table 4 it is also important to note that such an ordering algorithm shows full efficiency only when the blocks are sufficiently large, so an upper limit should be imposed on the number of processors to be used on a given system. In particular, results presented in Table 4 indicate that the 118-bus system is

not sufficiently large to be efficiently mapped onto more than four processors (although results using eight processors are still better than those using a single processor).

6. Conclusions. We have shown how overlapping epsilon decompositions can help in solving large systems of nonlinear algebraic equations on parallel computers. By partitioning the Jacobian into overlapping weakly coupled blocks, we can take advantage of the special structural features of the system and invert only diagonal blocks of the Jacobian in a Newton interative scheme. Each block can be assigned to a dedicated processor to speed up the solution process without excessive communication among individual processors.

The proposed method has been applied to the load-flow problem of an 118-bus power system. A pleasing fact in this context is the ability of the method to exploit sparsity of the system, thus allowing a whole host of powerful sparse techniques to be developed in the new framework. Other applications are considered in transient stability analysis of power systems [4], VLSI circuit simulations along the lines suggested in [21], as well as parallel computations in control system design [5], [20], [23].

Appendix.

Proof of Theorem (3.15). Parts (i)–(iii) follow from various results of Kantorovich [12], and will be established with a minimum of derivation. Define a mapping $\tilde{g} : \tilde{\Omega}_0 \subset \mathbf{R}^{\tilde{n}} \to \mathbf{R}^{\tilde{n}}$ as

$$\tilde{g}(\tilde{x}) = \tilde{x} - \tilde{A}_D^{-1} \tilde{f}(\tilde{x}) \tag{A.1}$$

and a scalar function

$$\varphi(t) = \frac{1}{2}\gamma t^2 + \varepsilon\beta t + \alpha. \tag{A.2}$$

(i) First, from (3.16), we conclude that

$$\|\tilde{g}(\tilde{x}_0) - \tilde{x}_0\| \leq \varphi(0). \tag{A.3}$$

Second, we set $\Delta\tilde{x} = \tilde{x} - \tilde{x}_0$ and assume $\|\Delta\tilde{x}\| \leq t, t \in [0, \rho]$. Then,

$$\begin{aligned} \|\tilde{g}'(\tilde{x})\| &= \left\| I - \tilde{A}_D^{-1} \tilde{f}'(\tilde{x}) \right\| \\ &\leq \left\| I - \tilde{A}_D^{-1} \tilde{f}'(\tilde{x}_0) \right\| + \left\| \tilde{A}_D^{-1} \left[\tilde{f}'(\tilde{x}_0) - \tilde{f}'(\tilde{x}) \right] \right\|. \end{aligned} \tag{A.4}$$

TABLE 3

Heuristic2	15, 15, 15, 15, 15, 14, 14, 14	2.26

TABLE 4
Computation time.

Number of processors	Number of iterations	Computation time (s)	Communication time(s)	Total execution time (s)
Single processor	2	0.103	0	0.103
2	10	0.062	0.001	0.063
4	19	0.053	0.008	0.061
8	39	0.072	0.013	0.085

From (3.17) and (3.18), we can provide a bound

$$\|\tilde{g}'(\tilde{x})\| \leq \gamma t + \varepsilon\beta \equiv \varphi'(t) \tag{A.5}$$

for all $\|\tilde{x} - \tilde{x}_0\| \leq t, t \in [0, \rho]$.

Now, let us introduce a modification $\psi(t) = \varphi(t) - t$ of $\varphi(t)$,

$$\psi(t) = \frac{1}{2}\gamma t^2 - (1 - \varepsilon\beta)\, t + \alpha, \tag{A.6}$$

which has the zeros $\underline{t} = \underline{\rho}$ and $\bar{t} = \bar{\rho}$ defined in (3.22). Since $\varphi(t)$ is a nondecreasing function on $[0, \rho]$, we can show that the sequence

$$t_{k+1} = \varphi(t_k), \qquad k = 0, 1, 2, \ldots, \tag{A.7}$$

for $t_0 = 0$, converges to $\underline{t}$.

Next, by using inequalities (A.4) and (A.5), we can prove by induction on k that

$$\|\tilde{x}_{k+1} - \tilde{x}_k\| \leq t_{k+1} - t_k, \tag{A.8}$$

for all $k \geq 0$, and that $\tilde{x}_k \in \tilde{\Omega}_0$. Finally, from convergence of (A.7), compactness of $\tilde{\Omega}_0$, continuity of $\tilde{g}(\tilde{x})$, and inequality (A.8), it follows that, in fact, the sequence $\{\tilde{x}_k\}$ converges to $\tilde{x}^* \in \tilde{\Omega}_0$, which is a stationary solution of the iterative process $\tilde{\mathcal{N}}_D$, that is, $\tilde{x}^* = \tilde{g}(\tilde{x}^*)$.

(ii) To establish uniqueness of $\tilde{x}^*$ in $\tilde{\Omega}_0$, we rely on the properties of function $\varphi(t)$. We consider a sequence

$$\tau_{k+1} = \varphi(\tau_k), \qquad k = 0, 1, 2, \ldots, \tag{A.9}$$

for $\tau_0 = \rho$, and show that the sequence $\{\tau_k\}$ converges to some $\tau^* \in [\underline{t}, \rho]$. From condition (3.21) of the theorem, we have $\underline{t} \leq \rho < \bar{t}$, and $\varphi(\rho) \leq \rho$. Continuity of $\varphi(t)$ implies $\tau^* = \varphi(\tau^*)$, and because $\bar{t} > \rho$, $\underline{t}$ is the only solution of (A.9) in $[\underline{t}, \rho]$.

Now, to show uniqueness of $\tilde{x}^*$, we take an arbitrary initial element $\tilde{y}_0 \in \tilde{\Omega}_0$ of the sequence

$$\tilde{y}_{k+1} = g(\tilde{y}_k), \qquad k = 0, 1, 2, \ldots, \tag{A.10}$$

and prove, similarly as in (i) above, that

$$\|\tilde{y}_k - \tilde{x}_k\| \leq \tau_k - t_k, \qquad k = 1, 2, \ldots, \tag{A.11}$$

and $\tilde{y}_k \in \tilde{\Omega}_0$. Finally, since $\lim_{k\to\infty} \tau_k = \underline{t}$, from (A.11) it follows that $\lim_{k\to\infty} \tilde{y}_k = \lim_{k\to\infty} \tilde{x}_k = \tilde{x}^* \in \tilde{\Omega}_0$.

(iii) To estimate the convergence rate, we note that from part (i) of the proof, we have

$$\|\tilde{x}^* - \tilde{x}_k\| \leq \underline{t} - t_k \tag{A.12}$$

for all $k \geq 0$. Furthermore,

$$\underline{t} - t_k = \varphi(\underline{t}) - \varphi(t_{k-1}) = \varphi'(t')(\underline{t} - t_{k-1}), \tag{A.13}$$

where $t' \in [t_{k-1}, \underline{t}]$. Since $\varphi'(t') = \gamma t' + \varepsilon\beta \leq \gamma\underline{t} + \varepsilon\beta = 1 - (1 - \varepsilon\beta)\sqrt{1 - 2\delta}$, we have

$$\underline{t} - t_k \leq \left[1 - (1 - \varepsilon\beta)\sqrt{1 - 2\delta}\right](\underline{t} - t_{k-1}). \tag{A.15}$$

Proceeding recursively, we obtain

$$\underline{t} - t_k \leq \left[1 - (1 - \varepsilon\beta)\sqrt{1 - 2\delta}\right]^k (\underline{t} - t_0), \tag{A.16}$$

where $t_0 = 0$, and the estimate (3.23) follows.

(iv) We first establish that conditions (3.16) through (3.22) also guarantee that the Newton iterative process

$$\tilde{\mathcal{N}} : \tilde{x}_{k+1} = \tilde{x}_k - \tilde{A}^{-1}\tilde{f}(\tilde{x}_k), \qquad \tilde{x}_0 = \tilde{V}x_0 \tag{A.17}$$

converges to $\tilde{x}^*$. Let us define operator U as

$$U = \left(\tilde{A}_D^{-1}\tilde{A}\right)^{-1} = \left(I + \varepsilon\tilde{A}_D^{-1}\tilde{A}_C\right)^{-1}. \tag{A.18}$$

By (3.17) and (3.19) it follows that U exists and

$$\|U\| \leq \frac{1}{1 - \varepsilon\beta}. \tag{A.19}$$

Definition (A.18) now implies

$$U\tilde{A}_D^{-1} = \tilde{A}^{-1}, \tag{A.20}$$

and, consequently, by (3.16) and (3.18) we get

$$\left\|\tilde{A}^{-1}\tilde{f}(\tilde{x}_0)\right\| \leq \|U\| \left\|\tilde{A}_D^{-1}\tilde{f}(\tilde{x}_0)\right\| \leq \frac{\alpha}{1 - \varepsilon\beta}, \tag{A.21}$$

$$\left\|\tilde{A}^{-1}\tilde{f}''(\tilde{x})\right\| \leq \|U\| \left\|\tilde{A}_D^{-1}\tilde{f}''(\tilde{x})\right\| \leq \frac{\gamma}{1 - \varepsilon\beta} \tag{A.22}$$

for all $\tilde{x} \in \tilde{\Omega}_0$.

We now define operator

$$\tilde{h}(\tilde{x}) = \tilde{x} - \tilde{A}^{-1}\tilde{f}(\tilde{x}) \tag{A.23}$$

and auxiliary function

$$\varphi_1(t) = \frac{\gamma}{1-\varepsilon\beta} \cdot \frac{t^2}{2} + \frac{\alpha}{1-\varepsilon\beta}. \tag{A.24}$$

It should be pointed out that the modification $\psi_1(t) \equiv \varphi_1(t) - t$, that is,

$$\psi_1(t) = \frac{\gamma}{1-\varepsilon\beta}\frac{t^2}{2} - t + \frac{\alpha}{1-\varepsilon\beta} \tag{A.25}$$

has the same roots $\underline{t} = \underline{\rho}$ and $\bar{t} = \bar{\rho}$ defined in (3.22). Furthermore,

$$\left\|\tilde{h}(\tilde{x}_0) - \tilde{x}_0\right\| \leq \varphi_1(0) \tag{A.26}$$

and

$$\begin{aligned} \left\|\tilde{h}'(\tilde{x})\right\| &\leq \left\|\tilde{A}^{-1}\left(\tilde{f}'(\tilde{x}_0) - \tilde{f}'(\tilde{x})\right)\right\| \\ &\leq \frac{\gamma}{1-\varepsilon\beta}\, t = \varphi_1'(t) \end{aligned} \tag{A.27}$$

for all $\|\tilde{x} - \tilde{x}_0\| \leq t, t \in [0, \rho]$. Proceeding as in part (i), we readily conclude that $\tilde{\mathcal{N}}$ converges to the same $\tilde{x}^*$ as $\tilde{\mathcal{N}}_D$.

Since (3.2) and (3.5) hold by assumption from Lemma (3.10), it follows that $\tilde{\mathcal{N}}$ is an expansion of $\mathcal{N}$. Consequently, since $\tilde{x}_0 = \tilde{V}x_0$,

$$\tilde{x}_k = \tilde{V}x_k \in \tilde{M}, \qquad k = 0, 1, 2, \ldots. \tag{A.28}$$

Furthermore, it is easily established that manifold $\tilde{M}$ is closed, implying $\tilde{x}^* = \tilde{V}x^*$ for some $x^* \in \mathbf{R}^n$. It now only remains to show that x^* is the unique solution of $\mathcal{S}$ in Ω_0.

From (3.1), it follows that

$$0 = \tilde{f}(\tilde{x}^*) = \tilde{f}\left(\tilde{V}x^*\right) = Vf(x^*). \tag{A.29}$$

Since V and $\tilde{V}$ are permutation matrices of full rank, we have

$$f(x^*) = 0 \tag{A.30}$$

and, in addition,

$$\|x^* - x_0\| = \left\|\tilde{V}x^* - \tilde{V}x_0\right\| = \|\tilde{x}^* - \tilde{x}_0\| \leq \rho \tag{A.31}$$

since $\tilde{x}^* \in \tilde{\Omega}_0$. Consequently, $x^* \in \Omega_0$, where Ω_0 is defined in (3.25).

Assume now that there exists some $y^* \in \Omega_0, y^* \neq x^*$, which is another solution of $\mathcal{S}$. Then,

$$0 = Vf(y^*) = \tilde{f}\left(\tilde{V}y^*\right) \tag{A.32}$$

is a solution of $\tilde{\mathcal{S}}$. Furthermore, since $y^* \in \Omega_0$,

$$\|\tilde{y}^* - \tilde{x}_0\| = \left\|\tilde{V}y^* - \tilde{V}x_0\right\| = \|y^* - x_0\| \leq \rho \tag{A.33}$$

and, therefore, $\tilde{y}^* \in \tilde{\Omega}_0$. From the fact that $\tilde{V}$ has full rank, it follows that $y^* \neq x^*$ implies $\tilde{y}^* \neq \tilde{x}^*$. This contradicts the uniqueness of $\tilde{x}^*$ in $\tilde{\Omega}_0$. □

Acknowledgments. The authors are grateful to M. Amano, Hitachi Research Laboratory, Ibaraki-ken, Japan, for his useful comments on the paper and experimental results obtained by applying the epsilon decompositions to parallelization of load-flow equations.

FACTORIZATION OF MATRIX POLYNOMIALS WITH SYMMETRIES *

A. C. M. RAN† AND L. RODMAN‡

Abstract. An $n \times n$ matrix polynomial $L(\lambda)$ (with real or complex coefficients) is called selfadjoint if $L(\lambda) = (L(\bar{\lambda}))^*$ and symmetric if $L(\lambda) = (L(\pm\lambda))^T$. Factorizations of selfadjoint and symmetric matrix polynomials of the form $L(\lambda) = (M(\bar{\lambda}))^* DM(\lambda)$ or $L(\lambda) = (M(\pm\lambda))^T DM(\lambda)$ are studied, where D is a constant matrix and $M(\lambda)$ is a matrix polynomial. In particular, the minimal possible size of D is described in terms of the elementary divisors of $L(\lambda)$ and (sometimes) signature of the Hermitian values of $L(\lambda)$.

Key words. matrix polynomials, symmetries, factorization

AMS subject classifications. 15A22, 15A54, 15A23

1. Introduction.

Let $L(\lambda) = \sum_{j=0}^{l} \lambda^j A_j$ be a matrix polynomial, where $A_j (j = 0, \ldots, l)$ are complex $n \times n$ matrices and λ is a complex parameter. The polynomial $L(\lambda)$ is called *selfadjoint* if $L(\lambda) = (L(\bar{\lambda}))^*$ for all $\lambda \in \mathbb{C}$.

Factorizations of the form

$$L(\lambda) = \left(M\left(\bar{\lambda}\right)\right)^* DM(\lambda), \tag{1.1}$$

where $D = D^*$ is a constant matrix (not necessarily of the same size as $L(\lambda)$) and $M(\lambda)$ is a matrix polynomial, have been studied in the literature under various additional hypotheses (see [Ja], [Co], [GLR1], [GLR2]). The study of factorizations (1.1) is motivated by several applied problems, such as filtering [AM, Chap. 9]. Factorizations of a matrix polynomial $L(\lambda)$ having other types of symmetries, such as $L(\lambda) = (L(-\lambda))^T$ or $L(\lambda) = (L(\lambda))^T$, have been studied in the literature as well (see, e.g., [Lyu1], [Lyu2]). For such polynomials, it is natural to seek factorizations of type

$$L(\lambda) = (M(\varepsilon\lambda))^T DM(\lambda), \tag{1.2}$$

where $D = D^T$ is a constant matrix (not necessarily of the same size as $L(\lambda)$), $M(\lambda)$ is a matrix polynomial, and $\varepsilon = 1$ or $\varepsilon = -1$, as appropriate.

In this paper we identify the minimal possible size of the matrix D in factorizations of types (1.1) and (1.2), where $L(\lambda)$ has the appropriate symmetry. The cases when $L(\lambda)$ has complex coefficients or real coefficients are studied (if $L(\lambda)$ is assumed to be real, then in (1.1) and (1.2) $M(\lambda)$ and D are assumed to be real as well). Our result concerning the factorization (1.1) is a generalization of the main result of [GLR2], where only the case of constant signature was considered under the additional hypothesis that $\det L(\lambda) \not\equiv 0$.

---

In §2, we also present general factorization results in an abstract framework for matrix polynomials over a field having suitable symmetries. These results, although independently interesting, play an auxiliary role in this paper, serving as essential ingredients in the proofs of the main results given in §§3–6.

The following notation is used throughout the paper. $\mathbb{R}(\mathbb{C})$ denotes the real (complex) field, and I_k is the $k \times k$ unit matrix. A^T (respectively, A^*) stands for the transpose (respectively, conjugate transpose) of a matrix A, and $(A^T)^{-1}$ (respectively, $(A^*)^{-1}$) is abbreviated as A^{-T} (respectively, A^{-*}). A block diagonal matrix with blocks $Z_1, \ldots, Z_m$ on the main diagonal will be denoted $Z_1 \oplus \cdots \oplus Z_m$ or diag $(Z_1, \ldots, Z_m)$. For a Hermitian $n \times n$ matrix X, let $\nu_+(X)$ (respectively, $\nu_-(X)$, or $\nu_0(X)$) be the number of positive (respectively, negative, or zero) eigenvalues of X counted with multiplicities. Thus,

$$\nu_+(X) + \nu_-(X) + \nu_0(X) = n.$$

Given a matrix polynomial $L(\lambda)$ over $\mathbb{C}$, its *general rank* $r(L)$ is defined by

$$r(L) = \max_{\lambda_0 \in \mathbb{C}} \{\text{rank } L(\lambda_0)\}.$$

This coincides (when $F = \mathbb{C}$) with the notion of general rank introduced and used in §2 for a matrix polynomial over a field F. The points $\lambda_0 \in \mathbb{C}$ for which rank $L(\lambda_0) = r(L)$ are called *regular points* of $L(\lambda)$; all other points $\lambda_0 \in \mathbb{C}$ are called *singular points* of $L(\lambda)$. Clearly, the set of singular points is finite (or possibly empty). An $n \times n$ matrix polynomial $L(\lambda)$ is called *regular* if $r(L) = n$, or, equivalently, if $\det L(\lambda) \not\equiv 0$.

2. Symmetric matrix polynomials over a general field. Let F be a (commutative) field, and let $F[\lambda]$ be the ring of polynomials over F in one variable λ. Matrices $L(\lambda)$ with entries in $F[\lambda]$ are called *matrix polynomials* (over F). It is well known (see, e.g., [M]) that every $m \times n$ matrix polynomial $L(\lambda)$ admits a representation (called the *Smith form*)

$$L(\lambda) = E(\lambda) \text{ diag } (d_1(\lambda), d_2(\lambda), \ldots, d_r(\lambda), 0, \ldots, 0) F(\lambda), \tag{2.1}$$

where $E(\lambda)$ and $F(\lambda)$ are matrix polynomials with sizes $m \times m$ and $n \times n$, respectively, and having constant nonzero determinants, and $d_1(\lambda), \ldots, d_r(\lambda)$ are monic scalar polynomials (over F) such that $d_i(\lambda)$ divides $d_{i+1}(\lambda)$ $(i = 1, \ldots, r-1)$. The polynomials $d_i(\lambda)$ are called *invariant polynomials* of $L(\lambda)$; these polynomials, as well as their number r, are uniquely determined by $L(\lambda)$: $r \times r$ is the maximal size of a square submatrix in $L(\lambda)$ with determinant not identically zero and, for $i = 1, \ldots, r$ the product $d_1(\lambda) \cdots d_i(\lambda)$ is the greatest common divisor of the determinants of all $i \times i$ submatrices in $L(\lambda)$.

The number r coincides with the *general rank* of $L(\lambda)$.

In this section we study factorizations of symmetric matrix polynomials using the Smith form as our main tool.

From now on we assume that the characteristic of F is different from two. For a given automorphism σ of F such that $\sigma^2 = \text{identity}$, and for fixed $\varepsilon = \pm 1$ consider the following transformation: for $a(\lambda) = \sum a_j \lambda^j \in F[\lambda]$, let

$$a_*(\lambda) = \sum \sigma(a_j)(\varepsilon\lambda)^j = \sum \sigma(a_j)\varepsilon^j \lambda^j \in F[\lambda]. \tag{2.2}$$

For an $m \times n$ matrix polynomial

$$X(\lambda) = [x_{ij}(\lambda)]_{i=1,j=1}^{m,n} \text{ over } F, \quad \text{define } X_*(\lambda) = [\tilde{x}_{ij}(\lambda)]_{i=1,j=1}^{n,m},$$

where $\tilde{x}_{ij}(\lambda) = [x_{ji}(\lambda)]_*$. We have

(i) $[X(\lambda)Y(\lambda)]_* = Y(\lambda)_* X(\lambda)_*$,

(ii) $[X(\lambda)]_{**} = X(\lambda)$,

(iii) $[x(\lambda)X(\lambda) + y(\lambda)Y(\lambda)]_* = x_* X_* + y_* Y_*$ for scalar polynomials $x(\lambda)$ and $y(\lambda)$.

(iv) If $\det X(\lambda) \equiv \text{const.} \neq 0$, then $[X_*(\lambda)]^{-1} = ([X(\lambda)]^{-1})_*$.

These rules are used often in the sequel.

An $m \times n$ matrix polynomial $L(\lambda)$ is called *generally invertible* if all its invariant polynomials are constant one. The terminology is justified by the fact that $L(\lambda)$ is generally invertible if and only if $L(\lambda)$ has a generalized inverse, i.e., a matrix polynomial $N(\lambda)$ such that $N(\lambda)L(\lambda)N(\lambda) = N(\lambda)$ and $L(\lambda)N(\lambda)L(\lambda) = L(\lambda)$ (this fact is easily proved using the Smith form). A matrix polynomial $L(\lambda)$ is called *right* (respectively, *left*) *invertible* if there exists a matrix polynomial $N(\lambda)$ such that $L(\lambda)N(\lambda) \equiv I$ (respectively, $N(\lambda)L(\lambda) \equiv I$).

We now state one of the main factorization results of this section.

THEOREM 2.1. *Let $L(\lambda)$ be an $n \times n$ generally invertible matrix polynomial such that*

$$L(\lambda) = L_*(\lambda), \tag{2.3}$$

and let r be the general rank of $L(\lambda)$. Then $L(\lambda)$ can be factorized in the form

$$L(\lambda) = M_*(\lambda) D M(\lambda), \tag{2.4}$$

where $M(\lambda)$ is an $r \times n$ right invertible matrix polynomial and D is an $r \times r$ constant matrix such that $D = D_*$.

Conversely, if (2.4) *holds for an $r \times n$ right invertible matrix polynomial $M(\lambda)$ and a constant matrix $D = D_*$, then $L(\lambda)$ satisfies* (2.3), *is generally invertible, and has general rank r.*

Proof. The converse statement is easy. Indeed, if

$$M(\lambda) = \tilde{E}(\lambda)[I \quad 0]\tilde{F}(\lambda)$$

is the Smith form for $M(\lambda)$, then

$$\begin{aligned} L(\lambda) &= \tilde{F}_*(\lambda)\begin{bmatrix} I \\ 0 \end{bmatrix}\tilde{E}_*(\lambda) D \tilde{E}(\lambda)[I \quad 0]\tilde{F}(\lambda) \\ &= \tilde{F}_*(\lambda)\begin{bmatrix} \tilde{E}_*(\lambda) & 0 \\ 0 & I \end{bmatrix}\begin{bmatrix} D & 0 \\ 0 & 0 \end{bmatrix}\begin{bmatrix} \tilde{E}(\lambda) & 0 \\ 0 & I \end{bmatrix}\tilde{F}(\lambda). \end{aligned}$$

So by uniqueness of the Smith form, $L(\lambda)$ is generally invertible and has general rank r. The verification of (2.3) is trivial.

We now prove the direct statement.

Observe that the proof is easily reduced to the case when $r = n$, i.e., $\det L(\lambda) \equiv \text{const.} \neq 0$. Indeed, let $L(\lambda) = E(\lambda)D(\lambda)F(\lambda)$ be the Smith form of $L(\lambda)$, and let $\tilde{L}(\lambda) = (F_*(\lambda))^{-1}L(\lambda)F(\lambda)^{-1}$. Clearly, $\tilde{L}(\lambda)$ is a matrix polynomial $\tilde{L}(\lambda) = \tilde{L}_*(\lambda)$, and because of the equality $\tilde{L}(\lambda) = (F_*(\lambda))^{-1}E(\lambda)D(\lambda)$ the last $n - r$ rows and columns of $\tilde{L}(\lambda)$ are zeros. Obviously, it suffices to prove the direct statement for the

$r \times r$ matrix polynomial $N(\lambda)$ formed by the first r rows and columns of $\tilde{L}(\lambda)$. As $\det N(\lambda) \equiv \text{const.} \neq 0$, the required reduction is accomplished.

We assume from now on that $\det L(\lambda) \equiv \text{const.} \neq 0$. In this case the direct statement follows from Theorem 3 in [Lyu1] (see also [Lyu2]). We outline an alternative procedure developed in [Co]. As in [Co] or [GLR2] (§4), we prove that there exists an $n \times n$ matrix polynomial $X(\lambda)$ with $\det X(\lambda) \equiv \text{const.} \neq 0$ such that for the matrix polynomial

$$A(\lambda) := X_*(\lambda) L(\lambda) X(\lambda) = [\alpha_{ij}(\lambda)]_{i,j=1}^{n}$$

either $\alpha_{11} \equiv 0$ or $A(\lambda)$ is diagonally dominant (i.e., for $j = 1, \dots, n$, the degree of $\alpha_{jj}(\lambda)$ is bigger than the degrees of all nonzero entries in the jth row and the jth column in $A(\lambda)$). Because of this fact, without loss of generality we can assume that either $L(\lambda)$ is diagonally dominant or the (1, 1) entry in $L(\lambda)$ is identically zero. If $L(\lambda)$ is diagonally dominant, then it must be constant, and we are done. So let

$$L = \begin{bmatrix} 0 & a_* \\ a & A_1 \end{bmatrix}, \qquad L^{-1} = \begin{bmatrix} \gamma & c_* \\ c & C_1 \end{bmatrix},$$

where $A_1 = A_{1*}$ and $C_1 = C_{1*}$ are $(n-1) \times (n-1)$ matrix polynomials. Now put

$$y = \frac{1}{2}(1 - c_* A_1 c), \quad x = -A_1 c - a y, \quad \text{and} \quad Y = \begin{bmatrix} y & x_* \\ c & I \end{bmatrix}.$$

A calculation shows that

$$\begin{bmatrix} 1 & -x_* \\ 0 & I \end{bmatrix} Y \begin{bmatrix} 1 & 0 \\ -c & I \end{bmatrix} \equiv I,$$

and so $\det Y = 1$. Another straightforward calculation shows that

$$Y_* L Y = \begin{bmatrix} 1 & 0 \\ 0 & L_0 \end{bmatrix},$$

where $L_0(\lambda)$ is an $(n-1) \times (n-1)$ matrix polynomial. Thus, we have reduced the size of L by one and can complete the proof by induction on n. □

As the proof of Theorem 2.1 shows, the constant matrix D can be taken to be diagonal.

If $L(\lambda)$ is not generally invertible, then easy examples show that the representation (2.4) (with D having the size equal to the general rank of $L(\lambda)$) is not always possible, even if we omit the requirement that $M(\lambda)$ is right invertible. We can, however, obtain a factorization result for not generally invertible $L(\lambda)$ if we allow D to be a polynomial (with special properties). To state and prove this result we need the concept of elementary divisors. Let $L(\lambda)$ be an $m \times n$ matrix polynomial with invariant polynomials $d_1(\lambda), \dots, d_r(\lambda)$, where $d_s(\lambda), d_{s+1}(\lambda), \dots, d_r(\lambda)$ are nonconstant (if $L(\lambda)$ is generally invertible, then we say that $L(\lambda)$ has no elementary divisors). Factor

$$d_i(\lambda) = (f_{i1}(\lambda))^{\alpha_{i1}} (f_{i2}(\lambda))^{\alpha_{i2}} \cdots (f_{ik_i}(\lambda))^{\alpha_{ik_i}}; \qquad i = s, s+1, \dots, r \tag{2.5}$$

where $f_{i1}(\lambda), \dots, f_{i,k_i}(\lambda)$ are irreducible and pairwise relatively prime nonconstant monic scalar polynomials (over F). The collection of factors $(f_{ij}(\lambda))^{\alpha_{ij}} (j = 1, \dots, k_i; i = s, s+1, \dots, r)$, where each factor is repeated as many times as it occurs in (2.5), is called the *elementary divisors* of $L(\lambda)$, and the positive integer α_{ij} is called the

order of the elementary divisor $(f_{ij}(\lambda))^{\alpha_{ij}}$. Because of the divisibility relations among invariant polynomials, the collection of elementary divisors of $L(\lambda)$ determines the invariant polynomials uniquely, and therefore is invariant under the transformations $L(\lambda) \to E(\lambda)L(\lambda)F(\lambda)$, where

$$\det E(\lambda) \equiv \text{const.} \neq 0, \qquad \det F(\lambda) \equiv \text{const.} \neq 0.$$

THEOREM 2.2. *Let $L(\lambda)$ be an $n \times n$ matrix polynomial such that*

$$L(\lambda) = L_*(\lambda),$$

and let r be the general rank of $L(\lambda)$. Furthermore, let $\{f_1(\lambda)^{\alpha_1}, \dots, f_q(\lambda)^{\alpha_q}\}$ be the collection of elementary divisors of $L(\lambda)$. Then $L(\lambda)$ admits a factorization

$$L(\lambda) = M_*(\lambda)\, D(\lambda)\, M(\lambda),$$

where $M(\lambda)$ is an $r \times n$ matrix polynomial and $D(\lambda) = D_*(\lambda)$ is an $r \times r$ matrix polynomial. Moreover, the collection of elementary divisors of $D(\lambda)$ is $\{f_j(\lambda) : j \in J\}$, where the subset J of $\{1, 2, \dots, q\}$ consists precisely of those indices j for which $f_j = \varepsilon^{\text{degree } f_j} f_{j^*}$ and α_j is odd.

Recall that $\varepsilon = \pm 1$ is taken from (2.2).

Proof. As in the proof of Theorem 2.1, we can assume that $r = n$. Let $L(\lambda) = E(\lambda)D_1(\lambda)F(\lambda)$ be the Smith form $L(\lambda)$, where the invariant polynomials $d_1(\lambda), \dots, d_r(\lambda)$ are on the main diagonal of $D_1(\lambda)$. Because $L = L_*$, and by the uniqueness of invariant polynomials, we have in fact $d_{i^*} = \varepsilon^{\text{degree } d_i} d_i$ $(i = 1, \dots, r)$. The factor $\varepsilon^{\text{degree } d_i}$ appears because d_i is monic (this is part of the definition of invariant polynomials) while the leading coefficient of d_{i^*} is $\varepsilon^{\text{degree } d_i}$. In the sequel it is convenient to denote $f_+ = \varepsilon^{\text{degree } f} f_*$ for a scalar polynomial f. Thus, $d_{i+} = d_i$. Observe that f_+ is monic if f is monic and that $(f_1 f_2)_+ = f_{1+} f_{2+}$ for all pairs of polynomials f_1, f_2.

Replacing L by $F_*^{-1} L F^{-1}$, we can further assume without loss of generality that the ith column of L is divisible by $d_i(\lambda)$ $(i = 1, \dots, n)$. By symmetry, the ith row of L is divisible by $d_{i^*}(\lambda)$. Let the nonconstant invariant polynomials of $L(\lambda)$ be $d_s(\lambda), \dots, d_r(\lambda)$ and factor them as in (2.5). Then

$$d_i = \prod_{j=1}^{k_i} (f_{ij})^{\alpha_{ij}} = \prod_{j=1}^{k_i} (f_{ij+})^{\alpha_{ij}} \qquad (i = s, s+1, \dots, r),$$

and by the uniqueness of the decomposition (2.5), we see that the set $\{f_{i1}, \dots, f_{ik_i}\}$ must consist of selfsymmetric polynomials $(f_{ij} = f_{ij+})$ and/or of pairs of mutually symmetric polynomials $f_{ij_1} = f_{ij_2+}$; in this case necessarily $\alpha_{ij_1} = \alpha_{ij_2}$. Say, $f_{i1}, \dots, f_{i,p_i}$ are selfsymmetric and

$$f_{i,p_i+1} = (f_{i,p_i+2})_+, \dots, f_{i,p_i+2q_i-1} = (f_{i,p_i+2q_i})_+;$$

here $p_i + 2q_i = k_i$. Let i_0 be the smallest index such that $\alpha_{i_0 j} > 1$ for some $j \in \{1, \dots, p_i\}$; say, $\alpha_{i_0 1} > 1$ (if no such i_0 exists, we put

$$h_i = \prod_{j=1}^{q_i} (f_{i,p_i+2j})^{\alpha_{i,p_i+2j}} \qquad (i = s, s+1, \dots, r).$$

Define

$$h_i = \prod_{j=1}^{q_i} (f_{i,p_i+2j})^{\alpha_{i,p_i+2j}} \qquad i = s, s+1, \ldots, i_0 - 1,$$

$$h_i = f_{i1} \prod_{j=1}^{q_i} (f_{i,p_i+2j})^{\alpha_{i,p_i+2j}} \qquad i = i_0, i_0+1, \ldots, r,$$

where we assume that the elementary divisors are numbered so that $f_{i1} = f_{i_0 1}$ for $i = i_0 + 1, \ldots, r$. To make the subsequent formulas more uniform, we define also $h_i \equiv 1$ for $i = 1, \ldots, s-1$. The divisibility relations among the d_i's imply that whenever $f_{i_1 j_1} = f_{i_2 j_2}$, where $i_1 < i_2$, then $\alpha_{i_1 j_1} \leq \alpha_{i_2 j_2}$. It follows that h_i divides h_{i+1} $(i = 1, \ldots, r-1)$.

The formulas (2.5) lead to the factorization

$$d_i = h_{i^*} g_i h_i \qquad (i = 1, \ldots, r), \tag{2.6}$$

where $g_i \equiv 1$ for $i = 1, \ldots, s-1$;

$$g_i = \pm \prod_{j=1}^{p_i} (f_{ij})^{\alpha_{ij}} \quad \text{for } i = s, \ldots, i_0 - 1,$$

$$g_i = \pm f_{i1}^{\alpha_{ij}-2} \prod_{j=2}^{p_i} (f_{ij})^{\alpha_{ij}} \quad \text{for } i = i_0, i_0+1, \ldots, r,$$

(the sign $+$ or $-$ in g_i is chosen so that g_i is monic). Clearly, g_i divides g_{i+1} for $i = 1, \ldots, r-1$.

In view of (2.6) we now have a factorization

$$L(\lambda) = \operatorname{diag}\ (1, \ldots, 1, h_{s^*}(\lambda), \ldots, h_{r^*}(\lambda))\, \tilde{L}(\lambda)\ \operatorname{diag}\ (1, \ldots, 1, h_s(\lambda), \ldots, h_r(\lambda)) \tag{2.7}$$

for some matrix polynomial $\tilde{L} = \tilde{L}_*$. Denote by $\tilde{d}_1(\lambda), \ldots, \tilde{d}_r(\lambda)$ the invariant polynomials of $\tilde{L}(\lambda)$. Equality (2.7), together with the Binet–Cauchy formula for determinants of submatrices in the product of several matrices implies the following. The determinant of every $j \times j$ submatrix in $L(\lambda)$ is a linear combination (with polynomial coefficients) of determinants of $j \times j$ submatrices in $\tilde{L}(\lambda)$ when the determinants are multiplied by $\prod_{i=1}^{j} (h_{i^*}(\lambda) h_i(\lambda))$. It follows that $d_1(\lambda) \cdots d_j(\lambda)$ divides $\tilde{d}_1(\lambda) \cdots \tilde{d}_j(\lambda) \prod_{i=1}^{j} (h_{i^*}(\lambda) h_i(\lambda))$ for $j = 1, \ldots, r$. The equality (2.6) now shows that $g_1(\lambda) \cdots g_j(\lambda)$ divides $\tilde{d}_1(\lambda) \cdots \tilde{d}_j(\lambda)$. On the other hand, for the (i,j)th entries $\tilde{p}_{ij}$ of $\tilde{L}$ and p_{ij} of L, respectively, we obtain

$$\tilde{p}_{ij} = h_{i^*}^{-1} p_{ij} h_j^{-1} = h_{i^*}^{-1} p_{ij} d_i^{-1} h_{j^*} g_j,$$

and since (assuming $i \leq j$) both $p_{ij} d_i^{-1}$ and $h_{i^*}^{-1} h_{j^*}$ are polynomials, $\tilde{p}_{ij}$ is divisible by g_j. Also, $\tilde{p}_{ij}$ is divisible by g_i (because g_i divides g_j if $i \leq j$). By the symmetry of $\tilde{L}$, we see that $\tilde{p}_{ij}$ is divisible by $g_{\max(i,j)}$. Therefore, the determinant of every $j \times j$ submatrix of $\tilde{L}$ is divisible by $g_1 \cdots g_j$. Consequently, $\tilde{d}_1 \cdots \tilde{d}_j$ divides $g_1 \cdots g_j$. Comparing this result with the previously obtained opposite divisibility relation, we conclude that $g_1, \ldots, g_r$ are the invariant polynomials of $\tilde{L}$.

We repeat the procedure given above with L replaced by $\tilde{L}$, and so on, until (after a finite number of steps) we obtain a matrix polynomial $D(\lambda)$ with the properties required in Theorem 2.2. □

3. Factorization of selfadjoint matrix polynomials on the real axis. In this section we consider matrix polynomials $L(\lambda)$ over $\mathbb{C}$ with the following property:

$$L(\lambda) = \left(L\left(\bar{\lambda}\right)\right)^*, \qquad \lambda \in \mathbb{C}.$$

Such polynomials are called *selfadjoint.*

THEOREM 3.1. *Let $L(\lambda)$ be a selfadjoint $n \times n$ matrix polynomial. Then $L(\lambda)$ admits a factorization*

$$L(\lambda) = \left(M\left(\bar{\lambda}\right)\right)^* D\, M(\lambda), \tag{3.1}$$

where D is an $m \times m$ constant Hermitian matrix and $M(\lambda)$ an $m \times n$ matrix polynomial, if and only if

$$m \geq m_0, \tag{3.2}$$

where

$$m_0 = \max_{\lambda \in \mathbb{R}} \nu_+(L(\lambda)) + \max_{\lambda \in \mathbb{R}} \nu_-(L(\lambda)). \tag{3.3}$$

Moreover, in all factorizations (3.1) *having the minimal size $m_0 \times m_0$ of D, the matrix D is uniquely determined up to congruence: D has* $\max \nu_+(L(\lambda))$ *positive eigenvalues and* $\max \nu_-(L(\lambda))$ *negative eigenvalues (multiplicities counted).*

We can say more about the spectral properties of the factor $M(\lambda)$ in (3.1). A set Λ of nonreal numbers is called a *c-set* (with respect to a selfadjoint matrix polynomial $L(\lambda)$) if Λ is a maximal (by inclusion) set of nonreal singular points of $L(\lambda)$ with the property that $\lambda_0 \in \Lambda \Longrightarrow \bar{\lambda}_0 \notin \Lambda$. (The case when a c-set is empty is not excluded.) The concept of c-set was introduced and used in [GLR1] and [GLR3]. It turns out that, given $L(\lambda)$ as in Theorem 3.1, and given a c-set Λ, there exists a factorization (3.1), where D is $m_0 \times m_0$ and where the set of nonreal singular points of $M(\lambda)$ coincides with Λ. This statement follows as a by-product of the proof of Theorem 3.1.

Theorem 3.1 admits an alternative formulation. An $n \times n$ matrix polynomial $M(\lambda)$ will be called *elementary* if $r(M) = 1$ and $M(\lambda)$ is positive semidefinite for all real λ. It is not difficult to see (this fact is actually a particular case of Theorem 3.1) that $M(\lambda)$ is elementary if and only if $M(\lambda)$ is of the form $M(\lambda) = x(\lambda)(x(\bar{\lambda}))^*$, where $x(\lambda) \not\equiv 0$ is an $n \times 1$ column polynomial. One can consider elementary matrix polynomials as building blocks for selfadjoint matrix polynomials in the same spirit in which the constant rank-1 positive semidefinite matrices are building blocks for constant Hermitian matrices.

THEOREM 3.2. *Any selfadjoint $n \times n$ matrix polynomial $L(\lambda)$ admits a representation*

$$L(\lambda) = \sum_{j=1}^{m} \varepsilon_j M_j(\lambda), \tag{3.4}$$

where $\varepsilon_j = \pm 1$ and $M_j(\lambda)$ are elementary matrix polynomials. The number m of terms in (3.4) *is greater than or equal to m_0, where m_0 is given by* (3.3); *if $m = m_0$,*

then exactly $\max \nu_+(L(\lambda))$ *of the* ε_j*'s are equal to* $+1$ *and exactly* $\max \nu_-(L(\lambda))$ *of the* ε_j*'s are equal to* -1.

To obtain Theorem 3.2 from Theorem 3.1, assume (without loss of generality) that D in (3.1) is a diagonal matrix with ± 1's on the main diagonal. Then let $M_j(\lambda) = (x_j(\bar{\lambda}))^* x_j(\lambda)$, where $x_j(\lambda)$ is the jth row of $M(\lambda)$, to produce the formula (3.4).

COROLLARY 3.3. *Any selfadjoint* $n \times n$ *matrix polynomial admits a factorization* (3.1), *or a representation* (3.4), *where* $m \leq 2n$.

There are selfadjoint matrix polynomials, for example, $L(\lambda) = \lambda I$, for which there do not exist representations (3.1) or (3.4) with $m < 2n$.

The rest of this section is devoted to the proof of Theorem 3.1.

We start with the easy direction. Let a factorization (3.1) be given, and let λ_0 be a real point for which

$$\nu_+(L(\lambda_0)) = \max_{\lambda \in \mathbb{R}} \nu_+(L(\lambda)).$$

As $L(\lambda_0) = Y^* D Y$, where $Y = M(\lambda_0)$, the Hermitian matrix D must have at least $\nu_+(L(\lambda_0))$ positive eigenvalues. Analogously, D must have at least $\nu_-(L(\lambda_1))$ negative eigenvalues, where $\lambda_1 \in \mathbb{R}$ is chosen so that

$$\nu_-(L(\lambda_1)) = \max_{\lambda \in \mathbb{R}} \nu_-(L(\lambda)).$$

We obtain therefore the inequality (3.2). It is also clear that in any factorization (3.1), where D is $m_0 \times m_0$, the Hermitian matrix D is unique up to congruence.

It remains to show that a given selfadjoint matrix polynomial $L(\lambda)$ admits a factorization (3.1) with $m_0 \times m_0$ the size of D. This is the difficult part and we need some preliminaries. Note that $L(\lambda)$ is selfadjoint if and only if $L = L_*$, where the transformation $a \to a_*$ is defined as in §2, with $F = \mathbb{C}, \sigma(x) = \bar{x}$ $(x \in \mathbb{C})$, and $\varepsilon = 1$. Nevertheless, here the general results of §2 are not used because the preliminary results we need (such as Proposition 3.4 below) are already available in the literature. It should be noted, however, that the result of Theorem 2.2 plays an essential role in the proof of Proposition 3.4.

First observe that there exists an $n \times n$ matrix polynomial $N(\lambda)$ with constant nonzero determinant such that

$$L(\lambda) = \left(N(\bar{\lambda})\right)^* \begin{bmatrix} L_0(\lambda) & 0 \\ 0 & 0 \end{bmatrix} N(\lambda), \tag{3.5}$$

where $L_0(\lambda)$ is a selfadjoint $k \times k$ matrix polynomial, $k = r(L)$. For example, see Theorem 32.4 in [M], where (3.5) is proved for symmetric matrices over principal ideal rings with $(N(\bar{\lambda}))^*$ replaced by $N(\lambda)^T$; the same proof works to produce (3.5). Also, (3.5) can be obtained without difficulties from the Smith form of $L(\lambda)$ (see §2). Because of (3.5) we can (and do) assume from the very beginning, that the general rank of L is equal to n, i.e., $\det L(\lambda) \not\equiv 0$.

Our next observation is that the result of Theorem 3.1 is known in the case where $L(\lambda)$ has *constant signature*, i.e., $\nu_+(L(\lambda))$, and therefore also $\nu_-(L(\lambda))$ and $\nu_0(L(\lambda))$, is constant for all real regular points λ.

PROPOSITION 3.4 ([GLR2]). *Let* $L(\lambda)$ *be a selfadjoint* $n \times n$ *matrix polynomial such that*

$$\max_{\lambda \in \mathbb{R}} \nu_+(L(\lambda)) + \max_{\lambda \in \mathbb{R}} \nu_-(L(\lambda)) = n$$

(*necessarily* $\det L(\lambda) \not\equiv 0$). *Then* $L(\lambda)$ *admits a factorization* (3.1) *in which* D *is* $n \times n$.

We now prove the following lemma.

LEMMA 3.5. *Let* $L(\lambda)$ *be a selfadjoint* $n \times n$ *matrix polynomial with* $\det L(\lambda) \not\equiv 0$, *and let* $m_0 \geq n$ *be defined by* (2.3). *Then there exists an* $m_0 \times m_0$ *selfadjoint matrix polynomial* $\tilde{L}(\lambda)$ *such that*

$$\tilde{L}(\lambda) = \begin{bmatrix} L(\lambda) & 0 \\ 0 & * \end{bmatrix}$$

and such that

$$\max_{\lambda \in \mathbb{R}} \nu_+(\tilde{L}(\lambda)) + \max_{\lambda \in \mathbb{R}} \nu_-(\tilde{L}(\lambda)) = m_0, \tag{3.6}$$

or, equivalently, $\tilde{L}$ *is regular and has constant signature.*

Proof. By Rellich's theorem [R] (see also [GLR3]) the eigenvalues $\mu_1(\lambda), \dots, \mu_n(\lambda)$ of $L(\lambda)$ for λ real can be enumerated so that $\mu_1(\lambda), \dots, \mu_n(\lambda)$ are real analytic functions of the real variable λ. Clearly, $\lambda_0 \in \mathbb{R}$ is a singular point of $L(\lambda)$ if and only if λ_0 is a zero of at least one of the analytic functions $\mu_1(\lambda), \dots, \mu_n(\lambda)$. Let $\lambda_0 \in \mathbb{R}$ be a singular point of $L(\lambda)$, and let

$$\Omega(\lambda_0) = \{1 \leq j \leq n | \mu_j(\lambda_0) = 0\}.$$

For every $j \in \Omega(\lambda_0)$, let m_j be the multiplicity of λ_0 as a zero of $\mu_j(\lambda)$, and let ε_j be the sign of the nonzero real number $[\mu_j^{(m_j)}(\lambda)]|_{\lambda=\lambda_0}$. (We suppress the dependence of m_j and ε_j on λ_0 in the notation.) Define the integer $q(\lambda_0)$ by

$$\begin{aligned} q(\lambda_0) = &\{\text{number of indices } j \in \Omega(\lambda_0) \text{ such that } m_j \text{ is odd and } \varepsilon_j = 1\} \\ &- \{\text{number of indices } j \in \Omega(\lambda_0) \text{ such that } m_j \text{ is odd and } \varepsilon_j = -1\}. \end{aligned}$$

From the definition of $q(\lambda_0)$ it is clear that

$$\nu_+(L(\lambda_0 + \varepsilon)) - \nu_+(L(\lambda_0 - \varepsilon)) = q(\lambda_0) \tag{3.7}$$

for all sufficiently small $\varepsilon > 0$. It is easy to see that

$$m_0 := \max_{\lambda \in \mathbb{R}} \nu_+(L(\lambda)) + \max_{\lambda \in \mathbb{R}} \nu_-(L(\lambda)) = n + \max |\nu_+(L(\lambda_1)) - \nu_+(L(\lambda_2))|, \tag{3.8}$$

where the maximum is taken over all regular real points λ_1 and λ_2. Also, it follows from (3.7) that

$$\max |\nu_+(L(\lambda_1)) - \nu_+(L(\lambda_2))| = \max_{\lambda_1 < \lambda_2} \left| \sum_{\lambda_1 < \lambda_0 < \lambda_2} q(\lambda_0) \right|, \tag{3.9}$$

where the summation in the right-hand side of (3.9) is over all singular points λ_0 of $L(\lambda)$ in the interval $\lambda_1 < \lambda_0 < \lambda_2$.

Denote the right-hand side of (3.9) by p. We now construct p scalar real polynomials $r_1(\lambda), \dots, r_p(\lambda)$ with the following properties:

Property 1. all zeros of $r_j(\lambda)$ $(j = 1, \dots, p)$ are real and simple and belong to the set S of real singular points λ_0 of $L(\lambda)$ for which $q(\lambda_0) \neq 0$;

Property 2. for every $\lambda \in S$ exactly $|q(\lambda_0)|$ polynomials among $r_1(\lambda), \dots, r_p(\lambda)$ have λ_0 as their zeros, and for each $r_j(\lambda)$ such that $r_j(\lambda_0) = 0$ we have $q(\lambda_0) r_j'(\lambda_0) < 0$.

The definition of p ensures that such polynomials $r_1(\lambda), \ldots, r_p(\lambda)$ can indeed be constructed. Let

$$\tilde{L}(\lambda) = \operatorname{diag}\left(L(\lambda), r_1(\lambda), \ldots, r_p(\lambda)\right).$$

By Property 1, and in view of (3.8) and (3.9), it is easy to see that the number of positive eigenvalues of $\tilde{L}(\lambda)$ is constant for every real λ that is a regular point for $L(\lambda)$. The assertion in (3.6) therefore follows. □

Now we can easily finish the proof of Theorem 3.1. Indeed, given a selfadjoint matrix polynomial $L(\lambda)$ with $\det L(\lambda) \not\equiv 0$, construct $\tilde{L}(\lambda)$ as in Lemma 3.5 and apply Proposition 3.4 to $\tilde{L}(\lambda)$:

$$\tilde{L}(\lambda) = \left(N(\bar{\lambda})\right)^* D N(\lambda),$$

where D is a constant $m_0 \times m_0$ Hermitian matrix. Then (3.1) holds for $M(\lambda)$ formed by first n columns of $N(\lambda)$.

4. Factorization of real symmetric matrix polynomials. Let $L(\lambda) = \sum_{j=0}^{l} \lambda^j A_j$ be a *real symmetric* matrix polynomial, i.e., A_j $(j = 0, \ldots, l)$ are real symmetric $n \times n$ matrices. For such polynomials $L(\lambda)$ we consider factorizations

$$L(\lambda) = (M(\lambda))^T D M(\lambda), \tag{4.1}$$

where D is a constant real symmetric $m \times m$ matrix and $M(\lambda)$ is a matrix polynomial with real coefficients.

It is convenient to state the next theorem in terms of elementary divisors (see §2 for definitions of the concepts related to elementary divisors).

THEOREM 4.1. *Let $L(\lambda)$ be a real symmetric $n \times n$ matrix polynomial and assume that the elementary divisors of $L(\lambda)$ that are powers of irreducible quadratic polynomials (over $\mathbb{R}$) all have even orders. Then $L(\lambda)$ admits a factorization* (4.1) *if and only if $m \geq m_0$, where m_0 is defined by* (3.3). *Moreover, in factorization* (4.1) *with the minimal possible size of D, the matrix D is uniquely determined up to congruence and has exactly $\max_{\lambda \in \mathbb{R}} \nu_+(L(\lambda))$ positive eigenvalues and exactly $\max_{\lambda \in \mathbb{R}} \nu_-(L(\lambda))$ negative eigenvalues, multiplicities counted. Alternatively, $L(\lambda)$ admits a representation*

$$L(\lambda) = \sum_{j=1}^{m} \varepsilon_j M_j(\lambda), \tag{4.2}$$

where $M_j(\lambda)$ are real elementary matrices and $\varepsilon_j = \pm 1$, if and only if $m \geq m_0$. In case $m = m_0$, the number of $+1$'s (respectively, -1's) among the $\varepsilon_1, \ldots, \varepsilon_m$ is exactly $\max_{\lambda \in \mathbb{R}} \nu_+(L(\lambda))$ (respectively, $\max_{\lambda \in \mathbb{R}} \nu_-(L(\lambda))$).

In particular, Theorem 4.1 applies if all singular points of $L(\lambda)$ are real.

Proof. The only if part (easy direction) is proved as in the proof of Theorem 3.1. Also, we can easily reduce the proof to the case in which $\det L(\lambda) \not\equiv 0$. Using Theorem 2.2 (with $F = \mathbb{R}, \sigma = \text{identity}, \varepsilon = 1$), we can further assume that all elementary divisors of $L(\lambda)$ are first degree polynomials (necessarily with real roots). From now on the proof proceeds in the same way as that of Theorem 3.1. The role of Proposition 3.4 is played by Proposition 4.2 below. □

PROPOSITION 4.2. *Let $L(\lambda)$ be a real symmetric $n \times n$ matrix polynomial, all of whose elementary divisors are first degree polynomials. Assume further that*

$$\max_{\lambda \in \mathbb{R}} \nu_+(L(\lambda)) + \max_{\lambda \in \mathbb{R}} \nu_-(L(\lambda)) = n.$$

Then $L(\lambda)$ admits a factorization (4.1) *in which D is $n \times n$.*

Proposition 4.2 can be proved by repeating the arguments leading to the proof of Theorem 1 in [GLR2]. We omit the details.

If the hypothesis on the orders of elementary divisors of $L(\lambda)$ is omitted in Theorem 4.1, easy scalar examples (for example, $L(\lambda) = \lambda^2 + 1$) show that the result of Theorem 4.1 is not generally valid. Scalar examples show also that, in this case, the matrices D of minimal size in factorizations (4.1) are not necessarily congruent to each other:

$$\lambda^2 + 1 = [\lambda \quad 1] \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \lambda \\ 1 \end{bmatrix} = \left[\tfrac{1}{2}(\lambda^2+2), \tfrac{1}{2}\lambda^2\right] \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \begin{bmatrix} \frac{1}{2}(\lambda^2+2) \\ \frac{1}{2}\lambda^2 \end{bmatrix}.$$

We have, however, an upper bound on the minimal size of D.

THEOREM 4.3. *Let $L(\lambda)$ be a real symmetric $n \times n$ matrix polynomial, and let m_0 be defined by* (3.3). *Then for every $m \geq 2 \min(m_0, n)$ $L(\lambda)$ admits a factorization* (4.1).

Proof. Assume first that $m_0 \leq n$. By Theorem 3.1, we have

$$L(\lambda) = \left(M(\bar{\lambda})\right)^* D M(\lambda), \tag{4.3}$$

where D is an $m_0 \times m_0$ constant Hermitian matrix (which can be chosen to be real without loss of generality), and $M(\lambda)$ is a complex matrix polynomial. Write $M(\lambda) = M_1(\lambda) + iM_2(\lambda)$, where $M_1(\lambda)$ and $M_2(\lambda)$ are real matrix polynomials. Then, separating the real part in (4.3), we obtain

$$L(\lambda) = \left[M_1(\lambda)^T \quad M_2(\lambda)^T\right] \begin{bmatrix} D & 0 \\ 0 & D \end{bmatrix} \begin{bmatrix} M_1(\lambda) \\ M_2(\lambda) \end{bmatrix},$$

which is the desired factorization (with $m = 2m_0$).

If $m_0 > n$, use the simple identity:

$$4L(\lambda) = [L(\lambda) + I \quad L(\lambda) - I] \begin{bmatrix} I & 0 \\ 0 & -I \end{bmatrix} \begin{bmatrix} L(\lambda) + I \\ L(\lambda) - I \end{bmatrix}. \qquad \square$$

5. Factorization of symmetric real polynomials on the imaginary axis. In this section we consider the case of $n \times n$ matrix polynomials $L(\lambda)$ such that $L(\lambda) = (L(-\lambda))^T$ and $L(\lambda)$ is real for real λ. Note that such a polynomial is selfadjoint on the imaginary axis, i.e., $L(\lambda) = (L(\lambda))^*$ for $\lambda \in i\mathbb{R}$. An immediate consequence of Theorem 3.1 (applied to $L(i\lambda)$) is that such a matrix polynomial admits a factorization

$$L(\lambda) = (M(-\lambda))^T D M(\lambda) \tag{5.1}$$

for a complex $m \times m$ Hermitian matrix D and a complex $m \times n$ matrix polynomial $M(\lambda)$ if and only if

$$m \geq \max_{\lambda \in i\mathbb{R}} \nu_+(L(\lambda)) + \max_{\lambda \in i\mathbb{R}} \nu_-(L(\lambda)).$$

We show in this section that D and $M(\lambda)$ can be taken to be real. Note that there is a contrast here with the situation of §4, where an analogous factorization of a real symmetric matrix polynomial having real factors is not always possible.

First we deal with the case in which $L(\lambda)$ is regular and has constant signature (on the imaginary axis), after which the general case is reduced to the case of constant signature.

In view of Theorem 2.2 (with $F = \mathbb{R}, \sigma = \text{identity}, \varepsilon = -1$), we can restrict our attention to matrix polynomials having only elementary divisors of the form λ or $\lambda^2 + \lambda_0^2$ where λ_0 is real and nonzero. Next, we deal with the case in which L is regular and has constant signature.

THEOREM 5.1. *Suppose that $L(\lambda)$ is a real regular $n \times n$ matrix polynomial satisfying $L(\lambda) = L(-\lambda)^T$ and having constant signature on the imaginary axis: $\nu_+(L(\lambda))$ is constant for all regular points $\lambda \in i\mathbb{R}$. Then L admits a factorization*

$$L(\lambda) = (M(-\lambda))^T D M(\lambda),$$

where M is an $n \times n$ matrix polynomial with real coefficients and D is an $n \times n$ constant real matrix.

Proof. Again by Theorem 2.2 we may assume that $L(\lambda)$ has only pure imaginary eigenvalues and all elementary divisors are linear (in the sense of $\mathbb{C}$). First we deal with the case in which $\lambda^2 + \lambda_0^2, \lambda_0 \in \mathbb{R} \setminus \{0\}$ is an elementary divisor of $L(\lambda)$. Using the Smith form of $L(\lambda)$, write

$$L(\lambda) = E(\lambda) \text{ diag } ((\lambda^2 + \lambda_0^2) p_1(\lambda), \ldots, (\lambda^2 + \lambda_0^2) p_q(\lambda), p_{q+1}(\lambda), \ldots, p_n(\lambda)) F(\lambda),$$

where $p_j(\lambda)$ $(j = 1, \ldots, n)$ are real monic scalar polynomials and $E(\lambda), F(\lambda)$ are real $n \times n$ matrix polynomials with $\det E(\lambda) \equiv \text{const.} \neq 0, \det F(\lambda) \equiv \text{const.} \neq 0$. Then we have for

$$\begin{aligned} &\hat{L}(\lambda) := F(-\lambda)^{-T} L(\lambda) F(\lambda)^{-1}: \\ &\hat{L}(\lambda) = \begin{bmatrix} (\lambda^2 + \lambda_0^2) \hat{B}_{11}(\lambda) & (\lambda^2 + \lambda_0^2) \hat{B}_{12}(\lambda) \\ (\lambda^2 + \lambda_0^2) \hat{B}_{21}(\lambda) & \hat{A}_{22}(\lambda) \end{bmatrix}, \end{aligned} \tag{5.2}$$

where $\hat{B}_{11}$ is a $q \times q$ matrix polynomial. Moreover, $\hat{B}_{11}(\pm i\lambda_0)$ must be invertible, as otherwise $\det \hat{L}(\lambda)$ and hence also $\det L(\lambda)$ would be divisible by $(\lambda^2 + \lambda_0^2)^{q+1}$. Note: If L has constant signature, so has $\hat{L}$, which means $\hat{L}(i\lambda)$ for $\lambda \in \mathbb{R}$ is a Hermitian matrix having constant signature for all real λ except for a finite number of points. Using Rellich's theorem [R], we can write

$$\hat{L}(i\lambda) = (U(\lambda))^* \text{ diag } (\mu_1(\lambda), \ldots, \mu_n(\lambda)) U(\lambda), \qquad \lambda \in \mathbb{R},$$

where $U(\lambda)$ is unitary-valued and analytic and $\mu_j(\lambda)$ is analytic and real. The functions $\mu_j(\lambda)$ have only simple zeros as $\hat{L}$ has only linear elementary divisors (over $\mathbb{C}$). Without loss of generality we may assume that $\mu_1(\lambda_0) = \cdots = \mu_q(\lambda_0) = 0$. By Lemma 6 in [GLR2] we see that q is even, and exactly half of the numbers $\mu_j'(\lambda_0)$ $(j = 1, \ldots, q)$ are positive; the other half are negative. Let u_j be the jth column of $(U(\lambda_0))^*$. Then one calculates

$$\langle \hat{L}'(i\lambda_0) u_j, u_i \rangle = \langle D'(\lambda_0) e_j, e_i \rangle,$$

where $D(\lambda) = \text{diag } (\mu_1(\lambda), \ldots, \mu_n(\lambda))$. Note that $u_1, \ldots, u_q$ span $\ker L(i\lambda_0)$. On $\ker L(i\lambda_0)$, the quadratic form given by $\hat{L}'(i\lambda_0)$ has, therefore, $q/2$ positive squares and $q/2$ negative squares. Now by (5.2) $\ker L(i\lambda_0)$ is span $\{e_1, \ldots, e_q\}$, and for $x, y \in \ker L(i\lambda_0)$, we have

$$\frac{d}{d\lambda} \langle L(i\lambda) x, y \rangle \big|_{\lambda = \lambda_0} = -2\lambda_0 \langle \hat{B}_{11}(i\lambda_0) x, y \rangle.$$

Therefore we conclude that there is an invertible matrix V such that

$$\hat{B}_{11}(i\lambda_0) = V^* \left\{ \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \oplus \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \oplus \cdots \oplus \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \right\} V, \tag{5.3}$$

where the block $\left[\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right]$ is repeated $q/2$ times. Moreover, a simple argument shows that V can be taken to have a real determinant.

Now we state and prove a lemma, after which we return to the proof of Theorem 5.1.

LEMMA 5.2. *Let W be a complex invertible $n \times n$ matrix with real determinant, and let λ_0 be a nonzero real number. Then there exists a real $n \times n$ matrix polynomial $M(\lambda)$ with constant determinant such that $M(i\lambda_0) = W$.*

Proof. We can decompose W as a product of elementary matrices:

$$W = W_1 \cdot W_2 \cdot \cdots W_k, \tag{5.4}$$

where each W_j is either triangular with ones on the diagonal and exactly one nonzero off-diagonal entry, or W_j is a diagonal invertible matrix. Multiplying each diagonal W_j by a suitable complex number α_j so that $\det(\alpha_j W_j)$ is real, we can assume without loss of generality that $\det W_j$ is real ($j = 1, \ldots, k$); here we use the hypothesis that $\det W$ is real. Furthermore, by writing

$$\begin{aligned} W_j = \operatorname{diag}(c_{j1}, \ldots, c_{jn}) = \operatorname{diag}(c_{j1}, \bar{c}_{j1}, 1, \ldots, 1) \\ \cdot \operatorname{diag}\left(1, c_{j2}\bar{c}_{j1}^{-1}, \bar{c}_{j2}c_{j1}^{-1}, 1, \ldots, 1\right) \cdot \operatorname{diag}(1, 1, \ldots, p_{jn}, c_{jn}) \end{aligned}$$

(here $p_{jn} \in \mathbb{C} - \{0\}$), we can assume that every diagonal matrix W_j in (5.4) has real nonzero determinant and at most two diagonal entries different from one (located in adjacent positions). Clearly, it suffices to construct a polynomial $M(\lambda)$ as required such that $M(i\lambda_0) = W_j$ (for a fixed j). If W_j is triangular, let

$$M(\lambda) = \frac{1}{2}\left(W_j + \bar{W}_j\right) + \frac{\lambda}{2\lambda_0} \cdot \frac{1}{i}\left(W_j - \bar{W}_j\right).$$

If $W_j = \operatorname{diag}(1, \ldots, 1, d_1, d_2, 1, \ldots, 1)$ with d_1, d_2 real, then the constant $M(\lambda) \equiv W_j$ will do. Finally, if $W_j = \operatorname{diag}(1, \ldots, 1, d_1, d_2, 1, \ldots, 1)$ with $d_1 d_2 \in \mathbb{R}$, but $d_1 \notin \mathbb{R}$, then put

$$M(\lambda) = \operatorname{diag}\left(1, \ldots, 1, \begin{bmatrix} p(\lambda) & (\lambda^2 + \lambda_0^2) r \\ \lambda^2 + \lambda_0^2 & q(\lambda) \end{bmatrix}, 1, \ldots, 1\right). \tag{5.5}$$

Here

$$\begin{aligned} p(\lambda) &= d_{1R} + \lambda\lambda_0^{-1} d_{1I}, \qquad r = -d_1 d_2 \left(\lambda_0^2 + \left(\lambda_0 d_{1R} d_{1I}^{-1}\right)^2\right)^{-2}, \\ q(\lambda) &= p(\lambda)^{-1}\left[r\lambda^4 + 2r\lambda^2\lambda_0^2 + r\lambda_0^4 + d_1 d_2\right], \end{aligned}$$

where d_{1R} (respectively, d_{1I}) stands for the real (respectively, imaginary) part of d_1. The 2×2 block

$$\begin{bmatrix} p(\lambda) & (\lambda^2 + \lambda_0^2) r \\ \lambda^2 + \lambda_0^2 & q(\lambda) \end{bmatrix}$$

is in the same position in $M(\lambda)$ as

$$\begin{bmatrix} d_1 & 0 \\ 0 & d_2 \end{bmatrix}$$

is in W_j. It is easy to verify that $q(\lambda)$ is a real polynomial, $M(\lambda)$ (defined by (5.5)) is a real matrix polynomial with constant nonzero determinant, and $M(i\lambda_0) = W_j$. □

Now let us return to the proof of Theorem 5.1. Let V be as in (5.3), and choose $M(\lambda)$, a real $q \times q$ polynomial with constant nonzero determinant such that $M(i\lambda_0) = V$. This is possible by Lemma 5.2 (recall $\det V$ is real). Now we may replace $\hat{L}(\lambda)$ by

$$\tilde{L}(\lambda) = \begin{bmatrix} M(-\lambda)^{-T} & 0 \\ 0 & I \end{bmatrix} \hat{L}(\lambda) \begin{bmatrix} M(\lambda)^{-1} & 0 \\ 0 & I \end{bmatrix}.$$

Because M has constant nonzero determinant, $\hat{L}$ is a matrix polynomial, and we may write

$$\tilde{L}(\lambda) = \begin{bmatrix} (\lambda^2 + \lambda_0^2) B_{11}(\lambda) & (\lambda^2 + \lambda_0^2) B_{12}(\lambda) \\ (\lambda^2 + \lambda_0^2) B_{21}(\lambda) & A_{22}(\lambda) \end{bmatrix},$$

where

$$B_{11}(i\lambda_0) = \operatorname{diag}(1, -1, \ldots, 1, -1).$$

Now put

$$K(\lambda) = \begin{bmatrix} \lambda & -\lambda_0 \\ \lambda_0 & \lambda \end{bmatrix} \oplus \cdots \oplus \begin{bmatrix} \lambda & -\lambda_0 \\ \lambda_0 & \lambda \end{bmatrix} \oplus I_{n-q},$$

where the leading block is repeated $q/2$ times.

We shall show that $N(\lambda) = K(-\lambda)^{-T} \tilde{L}(\lambda) K(\lambda)^{-1}$ is a matrix polynomial. Note that $N(\lambda)$ may have a pole only at $\pm i\lambda_0$, and it suffices to show it has no pole at either one of these points. Moreover, any pole of $N(\lambda)$ must appear in its leading $q \times q$ block. This leading $q \times q$ block equals

$$(\lambda^2 + \lambda_0^2)^{-1} \left(\begin{bmatrix} -\lambda & -\lambda_0 \\ \lambda_0 & -\lambda \end{bmatrix} \oplus \cdots \oplus \begin{bmatrix} -\lambda & -\lambda_0 \\ \lambda_0 & -\lambda \end{bmatrix} \right) B_{11}(\lambda) \left(\begin{bmatrix} \lambda & \lambda_0 \\ -\lambda_0 & \lambda \end{bmatrix} \oplus \cdots \oplus \begin{bmatrix} \lambda & \lambda_0 \\ -\lambda_0 & \lambda \end{bmatrix} \right)$$

as an easy computation shows. Now at $\lambda = i\lambda_0$, we have

$$\begin{bmatrix} -i\lambda_0 & -\lambda_0 \\ \lambda_0 & -i\lambda_0 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \begin{bmatrix} i\lambda_0 & \lambda_0 \\ -\lambda_0 & i\lambda_0 \end{bmatrix} = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}.$$

Recalling that

$$B_{11}(i\lambda_0) = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \oplus \cdots \oplus \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix},$$

we see that $N(\lambda)$ is a matrix polynomial. Taking determinants we see that $N(\lambda)$ has no eigenvalue at $\pm i\lambda_0$. Applying the same argument at each nonzero, singular point of $L(\lambda)$, we reduce the proof of Theorem 5.1 to the case in which zero is the only possible singular point of $L(\lambda)$. However, for that case a similar argument shows that $L(\lambda)$ admits a representation $L(\lambda) = (K(-\lambda))^T N(\lambda) K(\lambda)$ with $K(\lambda)$ a real matrix polynomial and $N(\lambda)$ a real matrix polynomial without singular points (cf. the proof of Proposition 3.4 given in [GLR2]).

We have finally reduced to the case where L has no singular points. In this case the result follows from Theorem 2.1. □

Next we state the main result of this section.

THEOREM 5.3. *Let $L(\lambda) = (L(-\lambda))^T$ be an $n \times n$ matrix polynomial with real coefficients. Then there is a real $m \times m$ matrix $D = D^T$ and an $m \times n$ matrix polynomial $M(\lambda)$ with real coefficients such that*

$$L(\lambda) = (M(-\lambda))^T D M(\lambda) \tag{5.6}$$

if and only if

$$m \geq m_0 := \max_{\lambda \in i\mathbb{R}} \nu_+(L(\lambda)) + \max_{\lambda \in i\mathbb{R}} \nu_-(L(\lambda)). \tag{5.7}$$

Moreover, when $m = m_0$, the matrix D is unique up to congruence by a real orthogonal matrix.

Analogous to the situation in Theorem 3.1, the matrix polynomial $M(\lambda)$ in Theorem 5.3 can be chosen with additional spectral properties. Given a polynomial $L(\lambda)$ as in Theorem 5.3, a set Λ of numbers with nonzero real parts is called a *d-set* (with respect to $L(\lambda)$) if Λ is a maximal set of singular points of $L(\lambda)$ with nonzero real parts having the property that $\lambda \in \Lambda \Longrightarrow \bar{\lambda} \in \Lambda, -\bar{\lambda} \notin \Lambda$. (A d-set may be empty.) It turns out that under the hypotheses of Theorem 5.3, for every given d-set Λ, there exists a factorization (5.6) where $D = D^T$ is $m_0 \times m_0$ and where the set of nonreal singular points of $M(\lambda)$ coincides with Λ. This follows as a by-product of the proof of Theorem 5.3 (including Theorem 5.1 and Theorem 2.2 with $F = \mathbb{R}, \sigma = \text{identity}, \varepsilon = -1$).

Proof. The uniqueness of D is verified as in the proof of Theorem 3.1. The fact that $m \geq m_0$ is necessary for the existence of real $D = D^T$ and $M(\lambda)$ such that (5.6) is satisfied is seen as in the proof of Theorem 3.1. It remains to prove sufficiency. We may reduce to the regular case again as in §3. In case $L(\lambda)$ has constant signature we are finished, using Theorem 5.1. In case $L(\lambda)$ does not have constant signature on the imaginary axis, it is shown that there exists a real $m_0 \times m_0$ matrix polynomial $\tilde{L}(\lambda)$ such that $\tilde{L}(\lambda) = \tilde{L}(-\lambda)^T$ and

$$\tilde{L}(\lambda) = \begin{bmatrix} L(\lambda) & 0 \\ 0 & * \end{bmatrix},$$

while $\tilde{L}$ is regular and has constant signature on the imaginary axis. Indeed, as $L(i\lambda)$ is selfadjoint for real λ, we can write (using Rellich's theorem [R]; also [GLR3])

$$L(i\lambda) = (U(\lambda))^* \operatorname{diag}(\mu_1(\lambda), \ldots, \mu_n(\lambda)) U(\lambda),$$

where $\mu_j(\lambda)$ is analytic and real valued and $U(\lambda)$ is analytic and unitary. Since $L(i\lambda) = \overline{L(-i\lambda)}, \lambda \in \mathbb{R}$, the matrices $L(i\lambda)$ and $L(-i\lambda)$ have the same eigenvalues, and therefore for every point $\lambda_0 \in \mathbb{R}$ there is a permutation σ on $\{1, \ldots, n\}$ such that

$$\mu_i(-\lambda) = \mu_{\sigma(i)}(\lambda) \quad (i = 1, \ldots, n) \tag{5.8}$$

in a neighborhood of λ_0.

Let $\lambda_0 \in \mathbb{R}$ be such that $\pm i\lambda_0$ are singular points of $L(\lambda)$. Define $\Omega(\lambda_0)$ and $q(\lambda_0)$ as in the proof of Lemma 3.5. It follows from (5.8) that $q(\lambda_0) = -q(-\lambda_0)$; in particular, $q(0) = 0$ (if $\lambda_0 = 0$ is a singular point of $L(\lambda)$). Furthermore (analogous to (3.8) and (3.9))

$$\begin{aligned} m_0 &= \max_{\lambda > 0} \nu_+(L(i\lambda)) + \max_{\lambda > 0} \nu_-(L(i\lambda)) \\ &= n + \max |\nu_+(L(i\lambda_1)) - \nu_+(L(i\lambda_2))| \end{aligned}$$

and

$$\max |\nu_+(L(i\lambda_1)) - \nu_+(L(i\lambda_2))| = \max_{\lambda_1 < \lambda_2} \left| \sum_{\lambda_1 < \lambda_0 < \lambda_2} q(\lambda_0) \right|, \tag{5.9}$$

where the summation is over all $\lambda_0 \in (\lambda_1, \lambda_2)$ such that $i\lambda_0$ is a singular point of L. (Here the real numbers λ_1 and λ_2 are such that $i\lambda_1$ and $i\lambda_2$ are regular points of L.) Denote the number (5.9) by p, as in the proof of Lemma 3.5. Now construct p polynomials $r_1(\lambda), \dots, r_p(\lambda)$ with real coefficients having the following properties:

(i) $r_j(\lambda) = r_j(-\lambda)$ is real for $\lambda \in \mathbb{R}$;

(ii) all zeros of r_j are pure imaginary, nonzero numbers and belong to the set S of pure imaginary singular points λ_0 of L for which $q(\lambda_0) \neq 0$;

(iii) for every $\lambda_0 \in S$ exactly $|q(\lambda_0)|$ polynomials among $r_1, \dots, r_p$ have λ_0 as a zero and for each r_j having λ_0 as a zero we have

$$q(\lambda_0) \frac{d}{d\lambda} r_j(i\lambda)\Big|_{\lambda=\lambda_0} < 0.$$

(Note that because of (i) and $q(-\lambda_0) = -q(\lambda_0)$, condition (iii) is satisfied at $-\lambda_0$ if it is satisfied at λ_0.) Put

$$\tilde{L}(\lambda) = L(\lambda) \oplus \operatorname{diag}(r_1(\lambda), \dots, r_p(\lambda)).$$

Then $\tilde{L}(\lambda)$ is regular and has constant signature on the imaginary axis, as desired. Thus, by Theorem 5.1, $\tilde{L}(\lambda)$ admits a factorization

$$\tilde{L}(\lambda) = (N(-\lambda))^T D N(\lambda)$$

with D an $m_0 \times m_0$ real matrix and $N(\lambda)$ an $m_0 \times n$ real matrix polynomial. Taking for $M(\lambda)$ the matrix polynomial formed by the first n columns of N now finishes the proof. □

Analogous to Theorem 3.2, the result of Theorem 5.3 can be put in terms of additive representations of $L(\lambda)$ via elementary matrix polynomials. Here, a real $n \times n$ matrix polynomial $M(\lambda)$ will be called *elementary* if $r(M) = 1$ and $M(\lambda)$ is positive semidefinite Hermitian for all $\lambda \in i\mathbb{R}$.

THEOREM 5.4. *Let $L(\lambda)$ be as in Theorem 5.3. Then $L(\lambda)$ admits a representation*

$$L(\lambda) = \sum_{j=1}^{q} \varepsilon_j M_j(\lambda), \tag{5.10}$$

where $\varepsilon_j = \pm 1$ and $M_j(\lambda)$ are elementary matrix polynomials, if and only if $q \geq m_0$, where m_0 is defined by (5.7). *Moreover, when $q = m_0$, exactly $\max_{\lambda_0 \in i\mathbb{R}} \nu_+(L(\lambda_0))$ of the ε_j's in* (5.10) *are equal to $+1$, and exactly $\max_{\lambda \in i\mathbb{R}} \nu_-(L(\lambda))$ of them are equal to -1.*

We omit the easy derivation of Theorem 5.4 from Theorem 5.3.

6. Factorization of complex symmetric polynomials. In this section we consider $n \times n$ matrix polynomials $L(\lambda)$ with complex coefficients having the symmetry

$$L(\lambda) = (L(\varepsilon\lambda))^T, \tag{6.1}$$

where $\varepsilon = \pm 1$ is fixed, and their factorizations of the form

$$L(\lambda) = (M(\varepsilon\lambda))^T D M(\lambda), \tag{6.2}$$

where $M(\lambda)$ is an $m \times n$ matrix polynomial (over $\mathbb{C}$), and D is a constant complex symmetric matrix. Observe that every $m \times m$ complex symmetric matrix D can be factored as $D = V^T V$ for some complex matrix V (see, e.g., Corollary 4.4.6 in [HJ]). Therefore, we may assume that $D = I$ in (6.2).

Here (in contrast with §§3–5) signatures of Hermitian matrices do not play a role.

We start with the case where $\varepsilon = -1$.

THEOREM 6.1. *Let $L(\lambda)$ be an $n \times n$ matrix polynomial satisfying* (6.1), *where $\varepsilon = -1$. Then the minimal size m for which $L(\lambda)$ admits a factorization*

$$L(\lambda) = (M(-\lambda))^T M(\lambda) \tag{6.3}$$

with an $m \times n$ matrix polynomial $M(\lambda)$ is equal to the general rank r of $L(\lambda)$.

Proof. We use the same ideas as in the proofs of results in the previous sections. Therefore, the proof of Theorem 6.1 is presented with less detail.

Clearly, a factorization (6.3) is impossible if $m < r$. Therefore we have to prove only that such a factorization exists for $m = r$. We can (and do) assume that $n = r$, i.e., $\det L(\lambda) \not\equiv 0$.

Apply Theorem 2.2 with $F = \mathbb{C}, \sigma = \text{identity}, \varepsilon = -1$. Since the only irreducible monic complex polynomial f satisfying $f = \varepsilon^{\text{degree } f} f_*$ is $f(\lambda) = \lambda$, by Theorem 2.2 we can assume (replacing $L(\lambda)$ by $D(\lambda)$) that the elementary divisors of $L(\lambda)$ are $\lambda, \lambda, \ldots, \lambda$ (k times). Here k is necessarily even. Indeed, the property $L(\lambda) = (L(-\lambda))^T$ ensures that $\det L(\lambda) = (\text{const.})\lambda^k$ is an even function.

If $k = 0$, i.e., $\det L(\lambda) \equiv \text{const.} \neq 0$, an application of Theorem 2.1 gives the desired result. Suppose therefore that $k > 0$. Using the Smith form of $L(\lambda)$, write

$$L(\lambda) = E(\lambda) \begin{bmatrix} \lambda I_k & 0 \\ 0 & I_{n-k} \end{bmatrix} F(\lambda),$$

where $E(\lambda)$ and $F(\lambda)$ are $n \times n$ matrix polynomials with constant nonzero determinants. Replacing $L(\lambda)$ by $(F(-\lambda))^{-T} L(\lambda) F(\lambda)^{-1}$, we can assume that the first k columns (and, by symmetry, also the first k rows) of $L(\lambda)$ are divisible by λ. Thus

$$L(\lambda) = \begin{bmatrix} \lambda L_1(\lambda) & \lambda L_2(\lambda) \\ -\lambda (L_2(-\lambda))^T & L_3(\lambda) \end{bmatrix},$$

where the matrix polynomials L_1, L_2, and L_3 are $k \times k, k \times (n-k)$, and $(n-k) \times (n-k)$, respectively. Moreover, $-L_1(-\lambda) = (L_1(\lambda))^T$ and $L_3(-\lambda) = (L_3(\lambda))^T$. We claim that $L_1(0)$ is invertible. Indeed, if $L_1(0)$ were not invertible, then

$$\det \begin{bmatrix} L_1(\lambda) & L_2(\lambda) \\ -\lambda (L_2(-\lambda))^T & L_3(\lambda) \end{bmatrix}$$

would be divisible by λ, and consequently

$$\det L(\lambda) = \lambda^k \det \begin{bmatrix} L_1(\lambda) & L_2(\lambda) \\ -\lambda (L_2(-\lambda))^T & L_3(\lambda) \end{bmatrix}$$

would be divisible by λ^{k+1}, which is an impossibility. Now $L_1(0)$ is skew-symmetric and therefore admits a factorization

$$L_1(0) = Q^T \left(\begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} \oplus \cdots \oplus \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} \right) Q$$

for some invertible matrix Q. Let

$$M_1(\lambda) = \left(\begin{bmatrix} -\lambda & 0 \\ 0 & 1 \end{bmatrix} \oplus \cdots \oplus \begin{bmatrix} -\lambda & 0 \\ 0 & 1 \end{bmatrix} \oplus I_{n-k}\right) \begin{bmatrix} Q & 0 \\ 0 & I_{n-k} \end{bmatrix} \tag{6.4}$$

(the summand $\left[\begin{smallmatrix} -\lambda & 0 \\ 0 & 1 \end{smallmatrix}\right]$ is repeated $k/2$ times). Then

$$L(\lambda) = (M_1(-\lambda))^T \tilde{L}(\lambda) M_1(\lambda)$$

for some matrix polynomial $\tilde{L}(\lambda)$ such that $\tilde{L}(-\lambda) = (\tilde{L}(\lambda))^T$ and $\det \tilde{L}(\lambda) \equiv \text{const.} \neq 0$. The only thing not immediate here is the claim that $\tilde{L}(\lambda)$ is indeed a polynomial. But the only point in $\mathbb{C}$ where $\tilde{L}(\lambda)$ could have a pole is $\lambda_0 = 0$. We have

$$\begin{aligned} Z(\lambda) &:= (M_1(-\lambda))^{-T} L(\lambda) M_1(\lambda)^{-1} \\ &= \left(\begin{bmatrix} \lambda^{-1} & 0 \\ 0 & 1 \end{bmatrix} \oplus \cdots \oplus \begin{bmatrix} \lambda^{-1} & 0 \\ 0 & 1 \end{bmatrix} \oplus I_{n-k}\right) \begin{bmatrix} Q^{-T} & 0 \\ 0 & I_{n-k} \end{bmatrix} \\ &\quad \cdot \begin{bmatrix} \lambda L_1(\lambda) & \lambda L_2(\lambda) \\ -\lambda (L_2(-\lambda))^T & L_3(\lambda) \end{bmatrix} \begin{bmatrix} Q^{-1} & 0 \\ 0 & I_{n-k} \end{bmatrix} \\ &\quad \cdot \left(\begin{bmatrix} -\lambda^{-1} & 0 \\ 0 & 1 \end{bmatrix} \oplus \cdots \oplus \begin{bmatrix} -\lambda^{-1} & 0 \\ 0 & 1 \end{bmatrix} \oplus I_{n-k}\right). \end{aligned}$$

Clearly, $\lambda Z(\lambda)$ is analytic at $\lambda_0 = 0$, and the coefficient of λ^{-1} in the Laurent series of $Z(\lambda)$ in a neighborhood of $\lambda_0 = 0$ is

$$\begin{aligned} &\left(\begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \oplus \cdots \oplus \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \oplus 0\right) \begin{bmatrix} Q^{-T} & 0 \\ 0 & I_{n-k} \end{bmatrix} \begin{bmatrix} L_1(0) & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} Q^{-1} & 0 \\ 0 & I_{n-k} \end{bmatrix} \\ &\quad \cdot \left(\begin{bmatrix} -1 & 0 \\ 0 & 0 \end{bmatrix} \oplus \cdots \oplus \begin{bmatrix} -1 & 0 \\ 0 & 0 \end{bmatrix} \oplus 0\right) \\ &\qquad = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} \begin{bmatrix} -1 & 0 \\ 0 & 0 \end{bmatrix} \oplus \cdots \oplus \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} \begin{bmatrix} -1 & 0 \\ 0 & 0 \end{bmatrix} \oplus 0 = 0. \end{aligned}$$

To finish the proof, apply Theorem 2.1 to $Z(\lambda)$. □

Finally, we consider matrix polynomials $L(\lambda)$ having the symmetry (6.1) with $\varepsilon = 1$.

THEOREM 6.2. *Let $L(\lambda) = L(\lambda)^T$ be an $n \times n$ matrix polynomial over $\mathbb{C}$, and let r be the general rank of $L(\lambda)$. If the product of the invariant polynomials of $L(\lambda)$ is a square of a complex polynomial, then $L(\lambda)$ admits a factorization*

$$L(\lambda) = (M(\lambda))^T M(\lambda) \tag{6.5}$$

for some $m \times n$ matrix polynomial $M(\lambda)$ if and only if $m \geq r$. If the product of invariant polynomials of $L(\lambda)$ is not a square of any complex polynomial, then $L(\lambda)$ admits a factorization (6.5) *if and only if $m \geq r + 1$.*

Proof. Again, we omit many details here. We assume that $r = n$. If $L(\lambda)$ admits a factorization (6.5) with $M(\lambda)$ $n \times n$, then $\det L(\lambda) = (\det M(\lambda))^2$, and so the product of invariant polynomials of $L(\lambda)$ must be a square as well. This implies the only if part.

To prove the if part, first observe that it suffices to consider only the case in which $\det L(\lambda)$ is the square of a polynomial (if it is not, replace $L(\lambda)$ by $\left[\begin{smallmatrix} L(\lambda) & 0 \\ 0 & f(\lambda) \end{smallmatrix}\right]$, where

$f(\lambda)$ is a scalar polynomial chosen so that $f(\lambda)$ det $L(\lambda)$ is a square). By Theorem 2.2 we may assume that all elementary divisors of $L(\lambda)$ are first-degree polynomials. Since det $L(\lambda)$ is a square, the number $k = k(a)$ of elementary divisors $\lambda - a, \ldots, \lambda - a$ of $L(\lambda)$ (where $a \in \mathbb{C}$ is fixed) is even. As in the proof of Theorem 6.1, we can further assume that

$$L(\lambda) = \begin{bmatrix} (\lambda - a) L_1(\lambda) & (\lambda - a) L_2(\lambda) \\ (\lambda - a) (L_2(\lambda))^T & L_3(\lambda) \end{bmatrix}$$

for some matrix polynomials $L_1(\lambda) = L_1(\lambda)^T, L_2(\lambda)$, and $L_3(\lambda) = L_3(\lambda)^T$ of sizes $k \times k, k \times (n-k)$, and $(n-k) \times (n-k)$, respectively. Moreover, $L_1(a)$ is invertible and symmetric, and therefore

$$L_1(a) = Q^T \left(\begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \oplus \cdots \oplus \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \right) Q$$

for some invertible matrix Q (the direct summand $\left[\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right]$ is repeated here $k/2$ times). As in the proof of Theorem 6.1, we verify that

$$L(\lambda) = (M_1(\lambda - a))^T \tilde{L}(\lambda) M_1(\lambda - a),$$

where $M_1(\lambda)$ is defined by (6.4), and $\tilde{L}(\lambda)$ is a matrix polynomial such that $\tilde{L}(\lambda) = (\tilde{L}(\lambda))^T$ and $\tilde{L}(\lambda)$ has no elementary divisors of the form $\lambda - a$. Apply the above procedure to $\tilde{L}(\lambda)$ in place of $L(\lambda)$, using elementary divisors $\lambda - b, \ldots, \lambda - b$ of $\tilde{L}(\lambda)$ for some $b \in \mathbb{C}$, and so on, until a matrix polynomial $L_1(\lambda) = (L_1(\lambda))^T$ with det $L_1(\lambda) \equiv$ const. $\neq 0$ is obtained. Now apply Theorem 2.1 to get the desired factorization of $L_1(\lambda)$. □

Theorems 6.1 and 6.2 can be recast in terms of elementary matrices (analogous to Theorem 3.2). An $n \times n$ matrix polynomial $M(\lambda)$ (over $\mathbb{C}$) is called ε-elementary if

$$M(\lambda) = (x(\varepsilon\lambda))^t x(\lambda)$$

for some $1 \times n$ row polynomial $x(\lambda) \neq 0$ (here $\varepsilon = \pm 1$ is fixed).

THEOREM 6.3. *Let $L(\lambda)$ be an $n \times n$ matrix polynomial satisfying* (6.1), *and let r be the general rank of $L(\lambda)$. Then $L(\lambda)$ can be written as a sum of r ε-elementary matrix polynomials, unless $\varepsilon = 1$ and the product of the elementary divisors of $L(\lambda)$ is not a square of polynomial. In this latter case, $L(\lambda)$ can be written as a sum of $r+1$ 1-elementary matrix polynomials, and it cannot be represented as a sum of any r 1-elementary matrix polynomials.*

Acknowledgment. The problem of finding the minimal possible size of D in factorization (1.1) for complex selfadjoint matrix polynomials has been posed by Professor I. Gohberg.

DECOMPOSABILITY AND QUOTIENT SUBSPACES FOR THE PENCIL $sL - M$*

V. L. SYRMOS† AND F. L. LEWIS‡

Abstract. This paper introduces the notion of *decomposability* of the domain and the codomain relative to the generalized nonsquare matrix pencil $\Pi(s) = sL - M$. Its importance is justified rigorously and it is demonstrated that a special case of these new results is the familiar notion of decomposability for the pencil $sI - M$. This definition is motivated by the concepts of strict equivalence and quotient subspaces. By decomposing both the domain and the codomain of L and M the close relation between decomposability and the Kronecker invariants of the pencil $sL - M$ is shown. Finally, an application of the notion of decomposabilty in controls design is presented.

Key words. matrix pencil theory, decomposability, generalized Sylvester equations

AMS subject classifications. 15A04, 15A06, 15A22

1. Introduction.

The notion of decomposability of the domain, which actually is precisely the same as the codomain, for the map $sI - M$ was presented in [6], [19] from two different perspectives. In [6] it was presented in the spirit of revealing how the finite elementary divisors of the pencil $sI - M$ are related to the concept of decomposability. On the other hand, in [19] the main motive was to show how this property can be exploited to develop some geometric controls design techniques. Although the motives were different the goal was the same, that is, to exhibit the significance of decomposability to the matrix pencil theory as well as to control theory.

In this paper we present the notion of decomposabilty of both the *domain* and the *codomain* of the map $sL - M$. The introduced geometric theory extends the concept of decomposability to the general nonsquare pencil $sL - M$. Moreover, it finds applications to the Kronecker structure of the map $sL - M$ and to control system theory.

Motivated by the work in [6], [19] for decomposability and the matrix pencil theory [1], [6], [7], [17], in this paper we introduce the notion of decomposability of the domain and the codomain of the map $\Pi(s) = sL - M$, where $sL - M$ is generally nonsquare. The first major difference between the traditional case where $\Pi(s) = sI - M$ and the proposed one is that the domain and the codomain are not the same. As a result, the notion of similarity (e.g., $T(sI - M)T^{-1}$) is replaced by the notion of strict equivalence (e.g., $U(sL - M)V$). Our first result exhibits the direct relationship between the concepts of strict equivalence and quotient subspaces.

The definition of decomposability for $(sL - M)$ requires a nontraditional decomposition of both the domain and the codomain. This leads us to the key theorem of the paper, which presents necessary and sufficient conditions for decomposabilty. Moreover, further elaboration of these conditions results in two *generalized Sylvester* equations. It has been recently shown in the literature that the generalized Sylvester

equations proposed in this paper can be solved in a computationally stable manner using generalized Schur methods with condition estimators [8]. Throughout our exploration we show that the results of [6], [19] may be recovered as a special case of our results. Finally, we present a relation of decomposabilty to the Kronecker structure of the pencil $sL - M$.

The above remarks demonstrate the significance of decomposability for the pencil $sL - M$, but they do not exhibit its application to control theory. In order to show how the proposed notion of decomposability can find applications to control theory we will refer to the importance of singular systems, which have attracted the interest of researchers in control theory [3], [15]. Singular systems involve the study of the generalized pencil $sL - M$. Therefore, the decomposability condition is a useful tool in design for singular systems. Specifically, in [12] a sufficient condition is presented for the solution of the problem of proportional feedback, which under thorough consideration is seen to be a sufficient condition of decomposability. Moreover, as in the state-variable case, for the output-regulation problem decomposability was of primary importance [19]; it is also expected that decomposability will be of great importance for the same problem in singular systems.

Finally, in order to further demonstrate the usefulness of decomposability of generalized pencils, we refer to the fact that state-variable systems can always be transformed to an equivalent nonsquare system [7], which is easier to study. In order to show the importance of decomposability in control applications, in §4 we explore the closed-loop eigenstructure problem with state feedback in a computationally stable fashion, under the setting of nonsquare descriptions. In addition, in the proposed technique we show how the reduced-order nonsquare system implies more computationally stable algorithms. Consequently, classical design problems that have already been solved can be reconsidered under the notion of nonsquare systems. In that case the decomposability condition will certainly find applications that will exploit its most general form.

2. The notion of decomposability for the pencil $sL - M$. Consider the pencil

$$\Pi(s) = [sL - M], \tag{2.1}$$

where $sL - M \in \Re^{l\times n}[s]$ is generally nonsquare and not necessarily of full rank. We shall represent the domain $\Re^n$ of $(sL - M)$ by $\mathcal{X}$ and its codomain $\Re^l$ by $\mathcal{Z}$. If the pencil (2.1) is square and

$$\Delta(s) = \det(sL - M) \not\equiv 0 \quad \text{for some } s, \tag{2.2}$$

then it will be called *regular*. In any other case it will be called *singular*. If $(sL - M)$ is regular, those isolated values of s where (2.2) fails to hold will be said to comprise the *spectrum* of $(sL - M)$, denoted $\sigma(L, M)$. The usual spectrum of $(sI - M)$ will be denoted $\sigma(M)$. Note that $\sigma(L, M)$ may contain finite and infinite values of s.

Define two pencils $sL - M$ and $s\tilde{L} - \tilde{M}$ of dimension $l \times n$ to be *strictly equivalent* [6], [17], [18] when there exist nonsingular constant matrices U and V of orders l and n respectively such that

$$U(sL - M)V = s\tilde{L} - \tilde{M}. \tag{2.3}$$

If $\mathcal{S} \subset \mathcal{X}$, $x \in \mathcal{X}$, define the equivalence class $\bar{x} = \{y \in \mathcal{X} : x - y \in \mathcal{S}\}$ and the *quotient* space $\mathcal{X}/\mathcal{S}$ as the set of all $\bar{x}$. Then the *canonical* projection $P : \mathcal{X} \to \mathcal{X}/\mathcal{S}$ is defined by $Px = \bar{x}$. We may also write $\bar{x}$ as $x + \mathcal{S}$. See [19].

In the next result, we are motivated by the fact that the equivalence of matrix pencils is defined in terms of two constant nonsingular maps, one acting on the domain and one acting on the codomain. This is in contrast to the case of a single matrix operator, where similarity is defined in terms of the same matrix in both the domain and the codomain (e.g., $T(sI - M)T^{-1}$).

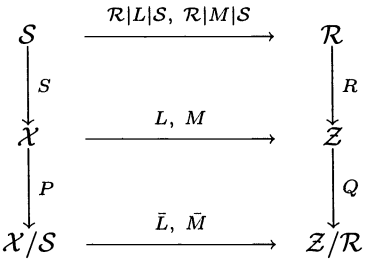
The result is that for $sL - M$ the domain $\mathcal{X}$ and the codomain $\mathcal{Z}$ must be considered as separate spaces. The definition of strict equivalence motivates the next lemma, which is key for the theory presented in this paper. As will be shown, this lemma relates the algebraic condition for equivalence of pencils ($P[sL - M]Q = [s\tilde{L} - \tilde{M}]$) to the geometric approach.

LEMMA 2.1. *Let $\mathcal{S} \subset \mathcal{X}$ and $\mathcal{R} \subset \mathcal{Z}$, such that $L\mathcal{S} + M\mathcal{S} \subset \mathcal{R}$ where $L, M : \mathcal{X} \to \mathcal{Z}$ and $sL - M \in \mathfrak{R}^{l\times n}[s]$ is not necessarily regular. Let P and Q be the canonical projections $P : \mathcal{X} \to \mathcal{X}/\mathcal{S}$ and $Q : \mathcal{Z} \to \mathcal{Z}/\mathcal{R}$. Then there exist unique maps $\bar{L}$ and $\bar{M}$ such that*

$$\bar{L}P = QL, \tag{2.4}$$

$$\bar{M}P = QM. \tag{2.5}$$

That is, the following diagram commutes



where R and S are the insertion maps of $\mathcal{R}$ in $\mathcal{X}$ and $\mathcal{S}$ in $\mathcal{Z}$ respectively.

Proof. Let $\mathcal{T}$ be any complement of $\mathcal{S}$ in $\mathcal{X}$ so that $\mathcal{X} = \mathcal{T} \oplus \mathcal{S}$. Choose $\{t_i\}_{i=1}^{\tau}$ to be a basis for $\mathcal{T}$. Then, if $\bar{t}_i = Pt_i$, a basis for $\mathcal{X}/\mathcal{S}$ is $\{\bar{t}_i\}_{i=1}^{\tau}$, where $\tau = \dim \mathcal{T}$. Define $\bar{L}$ and $\bar{M}$ by

$$\bar{L}\bar{t}_i = QLt_i, \tag{2.6}$$

$$\bar{M}\bar{t}_i = QMt_i. \tag{2.7}$$

To show that $\bar{L}$ is well defined, suppose $\bar{x}_1, \bar{x}_2 \in \mathcal{X}/\mathcal{S}$ with $\bar{x}_1 = \bar{x}_2$. Then $\bar{x}_1 = x_1 + \mathcal{S}$ and $\bar{x}_2 = x_2 + \mathcal{S}$ for some $x_i \in \mathcal{T}$, and $x_1 + \mathcal{S} = x_2 + \mathcal{S}$, or $x_1 - x_2 \in \mathcal{S}$. Thus $QL(x_1 - x_2) \in QL\mathcal{S} \subset Q\mathcal{R} = 0$. Therefore $QLx_1 = QLx_2$.

Now let $x \in \mathcal{X}/\mathcal{S}$ and $x = t + s$ with $t \in \mathcal{T}$, $s \in \mathcal{S}$. Then $QLx = QL(t + s)$. But $QL\mathcal{S} \in Q\mathcal{R} = 0$, therefore by (2.16) $QLx = QLt = \bar{L}\bar{t} = \bar{L}\bar{P}(t + s)$, which verifies (2.6). Similarly we can prove that $\bar{M}$ is well defined. Compare this proof with that in [13]. □

At this point we introduce some notation that we will use later. The induced maps will be denoted as $L_1 = \bar{L} : \mathcal{X}/\mathcal{S} \to \mathcal{Z}/\mathcal{R}$ and $M_1 = \bar{M} : \mathcal{X}/\mathcal{S} \to \mathcal{Z}/\mathcal{R}$. We will denote as $L_2 = \mathcal{R}|L|\mathcal{S}$, $M_2 = \mathcal{R}|M|\mathcal{S}$, Also $\dim\mathcal{X} = n$, $\dim\mathcal{Z} = l$, $\dim\mathcal{S} = \sigma$, $\dim\mathcal{X}/\mathcal{S} = n - \sigma = s$, $\dim\mathcal{R} = \rho$, and $\dim\mathcal{Z}/\mathcal{R} = l - \rho = r$. In a suitable basis representation for $\mathcal{S}$ and $\mathcal{R}$, the matrices L and M can be written

$$\begin{pmatrix} L_1^{r\times s} & 0^{r\times\sigma} \\ L_3^{\rho\times s} & L_2^{\rho\times\sigma} \end{pmatrix}, \qquad \begin{pmatrix} M_1^{r\times s} & 0^{r\times\sigma} \\ M_3^{\rho\times s} & M_2^{\rho\times\sigma} \end{pmatrix}. \tag{2.8}$$

Note that in the case where the matrices L and M are square and $L = I$ then Lemma 2.1 boils down to the well-known theory in [19].

DEFINITION 2.2. *Let $\mathcal{S} \subset \mathcal{X}$, $\mathcal{R} \subset \mathcal{Z}$ and $L\mathcal{S} + M\mathcal{S} \subset \mathcal{R}$. If there exists a subspace $\mathcal{T}$ such that $L\mathcal{T} + M\mathcal{T} \subset \mathcal{V}$, $\mathcal{X} = \mathcal{S} \oplus \mathcal{T}$, and $\mathcal{Z} = \mathcal{R} \oplus \mathcal{V}$, then $\mathcal{S}$, $\mathcal{R}$ decompose $\mathcal{X}$, $\mathcal{Z}$ relative to L, M.*

Definition 2.2 means that there are coordinate system transformations such that L_3 and M_3 are zero. It is rather interesting to see how this definition is expressed in some special cases. Assume that $\mathcal{S}$ is an (L, M)–invariant subspace, that is, $L\mathcal{S} \subset M\mathcal{S}$. Then the decomposability condition takes the following form. Let $L\mathcal{S} \subset M\mathcal{S} \subset \mathcal{R}$; if there exist subspaces $\mathcal{T}$ and $\mathcal{V}$ such that $L\mathcal{T} \subset M\mathcal{T} \subset \mathcal{V}$, $\mathcal{X} = \mathcal{S} \oplus \mathcal{T}$, and $\mathcal{Z} = \mathcal{R} \oplus \mathcal{V}$, then $\mathcal{S}$, $\mathcal{R}$ decompose $\mathcal{X}$, $\mathcal{Z}$ relative to L, M.

Assuming in addition that the pencil is regular and $L = I$ gives the same results as those in [19]. Indeed, for the case where $L = I$, the condition $L\mathcal{S} + M\mathcal{S} \subset \mathcal{R}$ in Definition 2.2 becomes $\mathcal{S} + M\mathcal{S} \subset \mathcal{R}$. This last relation implies $\mathcal{S} \subset \mathcal{R}$. As a result there exists a subspace $\mathcal{S}_1$ such that $\mathcal{R} = \mathcal{S} \oplus \mathcal{S}_1$. Similarly, there exists a subspace $\mathcal{T}_1$ such that $\mathcal{V} = \mathcal{T} \oplus \mathcal{T}_1$. By adding these two equations and taking into consideration the fact that in this case the domain is the same as the codomain, that is, $\mathcal{X} = \mathcal{R} \oplus \mathcal{V} = \mathcal{S} \oplus \mathcal{T}$, it follows that $\mathcal{S} = \mathcal{R}$ and $\mathcal{T} = \mathcal{V}$. Finally under this argument the conditions $L\mathcal{S} + M\mathcal{S} \subset \mathcal{R}$ and $L\mathcal{T} + M\mathcal{T} \subset \mathcal{V}$ boil down to the conditions $M\mathcal{S} \subset \mathcal{S}$ and $M\mathcal{T} \subset \mathcal{T}$, so the definition of decomposability coincides with that presented in [19].

We now close this small digression of special cases and return to our general discussion. The definition of decomposability simply states that selecting $\mathcal{T}$, $\mathcal{V}$ as the complements for $\mathcal{S}$, $\mathcal{R}$, we have that $L_1 = \mathcal{V}|L|\mathcal{T}$ and $M_1 = \mathcal{V}|M|\mathcal{T}$. It is natural now to draw connections between Lemma 2.1 and Definition 2.2 relative to the pencil $sL - M$. These connections are presented through the proof of the next theorem along with an algebraic interpretation of the decomposability property presented in Definition 2.2.

THEOREM 2.3. *Consider $\mathcal{S} \subset \mathcal{X}$, $\mathcal{R} \subset \mathcal{Z}$, and $L\mathcal{S} + M\mathcal{S} \subset \mathcal{R}$. Let $S : \mathcal{S} \to \mathcal{X}$ and $R : \mathcal{R} \to \mathcal{Z}$ be the insertion maps of $\mathcal{S}$ in $\mathcal{X}$ and of $\mathcal{R}$ in $\mathcal{Z}$ respectively. Then $\mathcal{S}$, $\mathcal{R}$ decompose $\mathcal{X}$, $\mathcal{Z}$ relative to L, M if and only if there exist maps $S^+ : \mathcal{X} \to \mathcal{S}$ and $R^+ : \mathcal{Z} \to \mathcal{R}$ such that*

$$R^+R = I_\rho, \tag{2.9}$$

$$S^+S = I_\sigma, \tag{2.10}$$

$$R^+L = L_2S^+, \tag{2.11}$$

$$R^+M = M_2S^+, \tag{2.12}$$

where I_σ and I_ρ are the identity maps on $\mathcal{S}$ and $\mathcal{R}$ respectively.

Proof. If (2.9)–(2.12) hold, set $\mathcal{T} = \operatorname{Ker} S^+$ and $\mathcal{V} = \operatorname{Ker} R^+$. Then if $x \in \mathcal{X}$ and $z \in \mathcal{Z}$

$$x = SS^+x + (I_\sigma - SS^+)x, \tag{2.13}$$

$$z = RR^+z + (I_\rho - RR^+)z. \tag{2.14}$$

Since $S^+(I - SS^+)x = 0$ and $R^+(I - RR^+)z = 0$, we have that $x \in \mathcal{S} + \mathcal{T}$, so that $\mathcal{X} = \mathcal{S} + \mathcal{T}$ and $z \in \mathcal{R} + \mathcal{V}$, so that $\mathcal{Z} = \mathcal{R} + \mathcal{V}$. Also $x \in \mathcal{S} \cap \mathcal{T}$ and $z \in \mathcal{R} \cap \mathcal{V}$ imply that $x = Ss$ and $z = Rr$, say, and $S^+x = 0$ and $R^+z = 0$. Thus $0 = S^+Ss = s$ and

$0 = R^+Rr = r$, therefore $x = 0$ and $z = 0$. Hence $\mathcal{S} \cap \mathcal{T} = 0$ and $\mathcal{R} \cap \mathcal{V} = 0$. Finally $S^+x = 0$ and $R^+z = 0$ implies that

$$L_2S^+x = R^+Lx, \tag{2.15}$$

$$M_2S^+x = R^+Mx. \tag{2.16}$$

Hence $L\mathcal{T} + M\mathcal{T} \subset \mathcal{V}$ and $\mathcal{R} \oplus \mathcal{V} = \mathcal{Z}$.

Conversely if $L\mathcal{S} + M\mathcal{S} \subset \mathcal{R}$, $L\mathcal{T} + M\mathcal{T} \subset \mathcal{V}$ with $\mathcal{S} \oplus \mathcal{T} = \mathcal{X}$ and $\mathcal{R} \oplus \mathcal{V} = \mathcal{Z}$, let S^+ and R^+ be the natural projections $S^+ : \mathcal{S} \oplus \mathcal{T} \to \mathcal{S}$ and $R^+ : \mathcal{R} \oplus \mathcal{V} \to \mathcal{R}$ and using Lemma 2.1 the proof follows. □

Equations (2.9)–(2.12) can take a simpler and more useful form. We will show how (2.9)–(2.12) can be represented by two equivalent equations. Let $\tilde{\mathcal{T}} \oplus \mathcal{S} = \mathcal{X}$ and $\tilde{\mathcal{V}} \oplus \mathcal{R} = \mathcal{Z}$ be arbitrary complements of $\mathcal{S}$ and $\mathcal{R}$, respectively. In a compatible basis L, M, $\mathcal{S}$, and $\mathcal{R}$ have the following matrix representation:

$$\begin{pmatrix} L_1^{r\times s} & 0^{r\times\sigma} \\ L_3^{\rho\times s} & L_2^{\rho\times\sigma} \end{pmatrix}, \qquad \begin{pmatrix} M_1^{r\times s} & 0^{r\times\sigma} \\ M_3^{\rho\times s} & M_2^{\rho\times\sigma} \end{pmatrix},$$

$$R = \begin{pmatrix} 0 \\ I_\rho \end{pmatrix}, \qquad S = \begin{pmatrix} 0 \\ I_\sigma \end{pmatrix}.$$

Then

$$R^+ = [R_2 \;\; I_\rho], \tag{2.17}$$

$$S^+ = [S_2 \;\; I_\sigma] \tag{2.18}$$

for arbitrary R_2, S_2. Then using this in (2.9)–(2.12) yields

$$L_2S_2 - R_2L_1 = L_3, \tag{2.19}$$

$$M_2S_2 - R_2M_1 = M_3. \tag{2.20}$$

Equations (2.19) and (2.20) will be called the *generalized Sylvester* equations. Thus to check whether $\mathcal{S}$ and $\mathcal{R}$ decompose $\mathcal{X}$ and $\mathcal{Z}$ relative to L and M, it is enough to verify that these two equations have a solution S_2, R_2. It has been recently shown in the literature that the solution of these two generalized bilateral Sylvester equations can be achieved in a computationally stable manner by utilizing the generalized Schur methods with condition estimators [8].

For purposes of comparison it is interesting to see how (2.9)–(2.12) and (2.19)–(2.20) are transformed in the special case where the pencil $sL - M$ is regular and $L = I$. Notice that in this case the domain and the codomain are precisely the same. Consequently in this case $R = S$ and $R^+ = S^+$. By observing now (2.9)–(2.10), we see that the first two equations merge to one equation, while the third states a trivial equality. Specifically these four equations under the above concepts can take the form

$$S^+S = I_\sigma, \tag{2.21}$$

$$R^+M = M_2S^+, \tag{2.22}$$

which are precisely the equations presented in [19] for the notion of decomposability. Finally, we end this digression by considering how the two generalized Sylvester

equations transformed in this special case. It is clear that (2.19) is a trivial equality ($0 = 0$), while (2.20) takes the well-known form

$$M_2 S_2 - S_2 M_1 = M_3, \tag{2.23}$$

which constitutes the decomposability criterion for the pencil $sI - M$ [19].

3. Relation of decomposability to Kronecker invariants. The next step in our exploration of decomposability for the pencil $sL - M$ is to reveal the important role that the Kronecker invariants of this pencil play in the concept of decomposability. Specifically, we desire to find a condition that guarantees decomposabilty, as presented in Definition 2.2, in terms of the Kronecker invariants [6], [7], [17] of the pencil $sL - M$. The next proposition reveals this condition.

THEOREM 3.1. *$\mathcal{S}$ and $\mathcal{R}$ decompose $\mathcal{X}$ and $\mathcal{Z}$ relative to L and M if and only if the Kronecker invariants of the pencil $sL_1 - M_1$ together with those of the pencil $sL_2 - M_2$ (see (2.8)), give all the Kronecker invariants of the pencil $sL - M$.*

Proof. Assume that $\mathcal{S}$ and $\mathcal{R}$ decompose $\mathcal{X}$ and $\mathcal{Z}$ relative to L and M, then (2.9)–(2.12) hold true. Let P and Q be the canonical projections $P : \mathcal{X} \to \mathcal{X}/\mathcal{S}$ and $Q : \mathcal{Z} \to \mathcal{Z}/\mathcal{R}$. Select $P = [P_1 \;\; 0]$, $Q = [Q_1 \;\; 0]$, $S^+ = [S_2 \;\; I_\sigma]$, $R^+ = [R_2 \;\; I_\rho]$, $S = [0 \;\; I_\sigma]^T$, and $R = [0 \;\; I_\rho]^T$. As a result the matrices

$$\begin{pmatrix} P \\ S^+ \end{pmatrix}, \qquad \begin{pmatrix} Q \\ R^+ \end{pmatrix} \tag{3.1}$$

are full rank. Now by using Lemma 2.1 and (2.11) and (2.12), the following equations hold true

$$Q(sL - M) = (sL_1 - M_1)P, \tag{3.2}$$

$$R^+(sL - M) = (sL_2 - M_2)S^+. \tag{3.3}$$

Then by combining (3.2) and (3.3) in one equation, we get

$$\begin{pmatrix} P \\ S^+ \end{pmatrix} (sL - M) = \begin{pmatrix} sL_1 - M_1 & 0 \\ 0 & sL_2 - M_2 \end{pmatrix} \begin{pmatrix} Q \\ R^+ \end{pmatrix}, \tag{3.4}$$

where $(Q^T \;\; R^{+^T})^T$ and $(P^T \;\; S^{+^T})^T$ are full rank matrices of dimensions $l \times l$ and $n \times n$, respectively. Hence (3.4) can be written in the form

$$\tilde{P}(sL - M)\tilde{Q} = \begin{pmatrix} sL_1 - M_1 & 0 \\ 0 & sL_2 - M_2 \end{pmatrix}. \tag{3.5}$$

But we know that strictly equivalence property preserves the Kronecker structure of the pencil [6], [7], [17]. Hence the Kronecker invariants of the pencil $sL_1 - M_1$, together with those of the pencil $sL_2 - M_2$, give all the Kronecker invariants of the pencil $sL - M$.

Conversely, if the pencils $sL_1 - M_1$ and $sL_2 - M_2$ contain all the Kronecker invariants of the pencil $sL - M$, then there exist $\tilde{P}$ and $\tilde{Q}$ such that (3.5) holds true. To see this, follow the procedure of elimination proposed in [17]. Then partition $\tilde{Q}$ and $\tilde{P}$ as in (3.4). Hence (3.2) and (3.3) hold true, and consequently from (3.3), (2.11) and (2.12) follow immediately. Moreover since R^+ and S^+ are full row rank there exist

R and S such that (2.9) and (2.10) hold true. As a result, there exist $\mathcal{S}$ and $\mathcal{R}$ that decompose $\mathcal{X}$ and $\mathcal{Z}$ relative to L and M. □

If the pencil $sL - M$ is regular, that is, (2.2) holds true, then a sufficient condition for the decomposability is that the spectra of the pencils $sL_1 - M_1$ and $sL_2 - M_2$ are disjoint. This is a fairly good assumption in practice and has been used for the solution of generalized Lyapunov equations in the pole-placement problem using proportional feedback in singular systems [12].

This sufficient condition can also be used for the characterization of a semiregular system in the sense of [5]. In particular, by solving the proposed generalized equations under the assumption of disjoint spectra, we compute in a computationally stable fashion a partition as defined in [5, Lemma 4.1]. Moreover, the solvability of these two equations is a sufficient criterion for semiregular systems. Therefore, under these considerations, decomposabilty may find an application to the disturbance decoupling problem in singular systems from the computational point of view.

In the case where the pencil is regular and $L = I$, Theorem 3.1 reduces to the following corollary.

COROLLARY 3.2. : *$\mathcal{S}$ decomposes $\mathcal{X}$ relative to M if and only if the finite elementary divisors of the pencil $sI - M_1$ together with those of the pencil $sI - M_2$, give all the finite elementary divisors of the pencil $sI - M$.*

Moreover, a sufficient condition for decomposability in this case is that the spectra of M_1 and M_2 are disjoint, that is, $\sigma(M_1) \cap \sigma(M_2) = 0$. These results, not surprisingly, are the same as those presented in [19].

It is worthwhile pointing out some remarks as far as the partition of the spectrum is concerned, for both the cases of pencils of the form $sI - M$ and regular pencils of the form $sL - M$. In the case of the pencil $sI - M$ the partition of the spectrum implies a decomposition of the matrix M defined as in (2.8) (note that $L = I$). This decomposition does not imply that we can decompose the domain according to the matrices M_1 and M_2. However, if we can define row and column operations Q on M_1 and M_2 such that $M_1Q - QM_2 = M_3$, that is, we can eliminate M_3, then the partition of the spectrum implies the decomposition of the domain [19]. Similarly, in the case of a regular pencil $sL - M$, the partition of the spectrum does not imply the decomposition of the domain and the codomain through L_1, L_2, M_1 and M_2. However, if there exist row operations (codomain) and column operations (domain) such that (2.19) and (2.20) hold, then the partition of the spectrum implies the decomposition of the domain and the codomain.

An application of Theorem 3.1 to the Kronecker decomposition of the pencil $sL - M$ is presented next. The Kronecker decomposition of the pencil $sL - M$, as it is known [6], [7], [17], imposes a decomposition of the domain. Specifically, let $\mathcal{S}_r$, $\mathcal{S}_c$, $\mathcal{S}_\alpha$ and $\mathcal{S}_\infty$ be the subspaces of the row minimal indices (rmi), the column minimal indices (cmi), the finite elementary divisors (fed), and the infinite elementary divisors (ied), respectively, of the pencil $sL - M$ [7]. Then this implies a decomposition of the domain as

$$\mathcal{S} = \mathcal{S}_r \oplus \mathcal{S}_\infty \oplus \mathcal{S}_\alpha \oplus \mathcal{S}_c. \tag{3.6}$$

The next result shows that a similar decomposition is imposed on the codomain. The properties and relationships between these subspaces and their corresponding Kronecker invariants are extensively discussed in [14].

THEOREM 3.3. *Consider*

$$\mathcal{R}_r = L\mathcal{S}_r + M\mathcal{S}_r, \tag{3.7}$$

$$\mathcal{R}_c = L\mathcal{S}_c + M\mathcal{S}_c, \tag{3.8}$$

$$\mathcal{R}_\alpha = L\mathcal{S}_\alpha + M\mathcal{S}_\alpha, \tag{3.9}$$

$$\mathcal{R}_\infty = L\mathcal{S}_\infty + M\mathcal{S}_\infty, \tag{3.10}$$

where $\mathcal{R}_r$, $\mathcal{R}_c$, $\mathcal{R}_\alpha$ *and* $\mathcal{R}_\infty$ *will be called the* rmi, cmi, fed, *and* ied *subspaces of the codomain. Then*

$$\mathcal{R} = \mathcal{R}_r \oplus \mathcal{R}_\infty \oplus \mathcal{R}_\alpha \oplus \mathcal{R}_c. \tag{3.11}$$

Proof. We know [7] that the Kronecker decomposition of the pencil $sL - M$ imposes a decomposition on the domain. Consider now P and Q such that $P(sL-M)Q$ is in its Kronecker canonical form. Then Q can be partitioned as $Q = [\, Q_r |\, Q_c |\, Q_\infty |\, Q_\alpha]$ where the columns of Q_r, Q_c, Q_∞, Q_α span $\mathcal{S}_r$, $\mathcal{S}_c$, $\mathcal{S}_\infty$, $\mathcal{S}_\alpha$ respectively. Then we have

$$P[(sL - M)Q_r|(sL - M)Q_c|(sL - M)Q_\infty|(sL - M)Q_\alpha]. \tag{3.12}$$

Note that (3.12) using (3.7)–(3.10) can be written as $[P\mathcal{R}_r|P\mathcal{R}_c|P\mathcal{R}_\infty|P\mathcal{R}_\alpha]$. Keeping in mind the Kronecker canonical form and that P is a full rank matrix, (3.11) follows immediately. □

The following corollary is an application of Theorem 3.1 and reveals how closely related the Kronecker form of the pencil $sL - M$ and the concept of decomposabilty relative to the maps L and M are. The proof of this corollary is based on a process of *sequential decomposition* of the generalized pencil $sL - M$. This corollary is not presented for computational purposes, but for revealing the relation between the Kronecker invariants and decomposability conditions. Efficient computation techniques for finding the Kronecker invariants have been proposed in [17], [9].

COROLLARY 3.4. *Consider the decomposition of the domain defined in* (3.6) *and the decomposition of the codomain as defined in* (3.11). *Then there exist matrices* P *and* Q *that can be constructed using* (2.9)–(2.12) *such that the pencil* $P(sL - M)Q$ *is in its Kronecker canonical form.*

Remark. The geometric interpretation of this corollary is shown in Fig. 3.1.

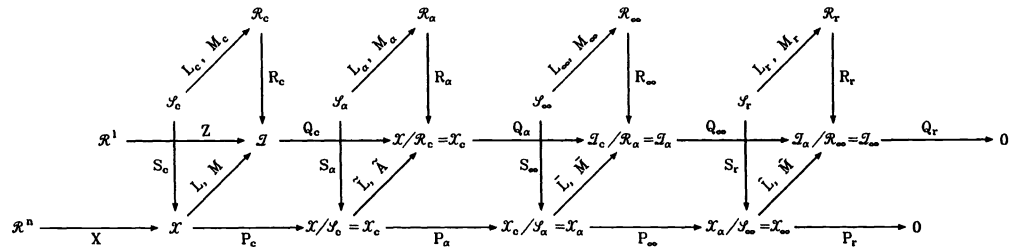


FIG. 3.1

Proof. The proof of this corollary is constructive and based on Theorem 3.1. Define

$$P_c : \mathcal{X} \to \mathcal{X}_c = \mathcal{X}/\mathcal{S}_c, \qquad Q_c : \mathcal{Z} \to \mathcal{Z}_c = \mathcal{Z}/\mathcal{R}_c, \tag{3.13}$$

$$P_\alpha : \mathcal{X}_c \to \mathcal{X}_\alpha = \mathcal{X}_c/\mathcal{S}_\alpha, \qquad Q_\alpha : \mathcal{Z}_c \to \mathcal{Z}_\alpha = \mathcal{Z}_c/\mathcal{R}_\alpha, \tag{3.14}$$

$$P_\infty : \mathcal{X}_\alpha \to \mathcal{X}_\infty = \mathcal{X}_\alpha/\mathcal{S}_\infty, \qquad Q_\infty : \mathcal{Z}_\alpha \to \mathcal{Z}_\infty = \mathcal{Z}_\alpha/\mathcal{R}_\infty, \tag{3.15}$$

$$S_c : \mathcal{S}_c \to \mathcal{X}, \qquad S_c^+ : \mathcal{X} \to \mathcal{S}_c \tag{3.16}$$

$$S_\alpha : \mathcal{S}_\alpha \to \mathcal{X}_c, \qquad S_\alpha^+ : \mathcal{X}_c \to \mathcal{S}_\alpha, \tag{3.17}$$

$$S_\infty : \mathcal{S}_\infty \to \mathcal{X}_\alpha, \qquad S_\infty^+ : \mathcal{X}_\alpha \to \mathcal{S}_\infty, \tag{3.18}$$

$$S_r : \mathcal{S}_r \to \mathcal{X}_\infty, \qquad S_r^+ : \mathcal{X}_\infty \to \mathcal{S}_r, \tag{3.19}$$

$$R_c : \mathcal{R}_c \to \mathcal{Z}, \qquad R_c^+ : \mathcal{Z} \to \mathcal{R}_c, \tag{3.20}$$

$$R_\alpha : \mathcal{R}_\alpha \to \mathcal{Z}_c, \qquad R_\alpha^+ : \mathcal{Z}_c \to \mathcal{R}_\alpha, \tag{3.21}$$

$$R_\infty : \mathcal{R}_\infty \to \mathcal{Z}_\alpha, \qquad R_\infty^+ : \mathcal{Z}_\alpha \to \mathcal{R}_\infty, \tag{3.22}$$

$$R_r : \mathcal{R}_r \to \mathcal{Z}_\infty, \qquad R_r^+ : \mathcal{Z}_\infty \to \mathcal{R}_r. \tag{3.23}$$

Define also $\dim \mathcal{S}_\psi = \sigma_\psi$ where $\psi \in \{c, r, \alpha, \infty\}$. Similarly define $\dim \mathcal{R}_\psi = \rho_\psi$ where $\psi \in \{c, r, \alpha, \infty\}$. Having defined these maps and using Theorem 2.3, the following equations hold true. (Variables above and beside matrices denote dimensions.)

$$\begin{matrix} & l & \\ q_c & \begin{pmatrix} Q_c \\ R_c^+ \end{pmatrix} & (sL - M) = \end{matrix} \begin{pmatrix} s\tilde{L} - \tilde{M} & 0 \\ 0 & sL_c - M_c \end{pmatrix} \begin{matrix} & n & \\ & \begin{pmatrix} P_c \\ S_c^+ \end{pmatrix} & \begin{matrix} p_c \\ \sigma_c \end{matrix} \end{matrix}, \tag{3.24}$$

$$\begin{matrix} & q_c & \\ q_\alpha & \begin{pmatrix} Q_\alpha \\ R_\alpha^+ \end{pmatrix} & (s\tilde{L} - \tilde{M}) = \end{matrix} \begin{pmatrix} s\bar{L} - \bar{M} & 0 \\ 0 & sL_\alpha - M_\alpha \end{pmatrix} \begin{matrix} & p_c & \\ & \begin{pmatrix} P_\alpha \\ S_\alpha^+ \end{pmatrix} & \begin{matrix} p_\alpha \\ \sigma_\alpha \end{matrix} \end{matrix}, \tag{3.25}$$

$$\begin{matrix} & q_\alpha & \\ q_\infty & \begin{pmatrix} Q_\infty \\ R_\infty^+ \end{pmatrix} & (s\bar{L} - \bar{M}) = \end{matrix} \begin{pmatrix} s\hat{L} - \hat{M} & 0 \\ 0 & sL_\infty - M_\infty \end{pmatrix} \begin{matrix} & p_\alpha & \\ & \begin{pmatrix} P_\infty \\ S_\infty^+ \end{pmatrix} & \begin{matrix} p_\infty \\ \sigma_\infty \end{matrix} \end{matrix}, \tag{3.26}$$

$$\begin{matrix} & q_r & \\ \rho_r & R_r^+ \, (s\hat{L} - \hat{L}) = & \end{matrix} \begin{matrix} & p_r & \\ (sL_r - M_r) & S_r^+ & \sigma_r \, . \end{matrix} \tag{3.27}$$

By combining (3.24)–(3.27) into one equation we get

$$\begin{pmatrix} R_r & 0 & 0 & 0 \\ 0 & I_{\rho_\infty} & 0 & 0 \\ 0 & 0 & I_{\rho_\alpha} & 0 \\ 0 & 0 & 0 & I_{\rho_c} \end{pmatrix} \begin{pmatrix} \begin{pmatrix} Q_\infty \\ R_\infty^+ \end{pmatrix} & 0 & 0 \\ 0 & I_{\rho_\alpha} & 0 \\ 0 & 0 & I_{\rho_c} \end{pmatrix} \begin{pmatrix} \begin{pmatrix} Q_\alpha \\ R_\alpha^+ \end{pmatrix} & 0 \\ 0 & I_{\rho_c} \end{pmatrix} \begin{pmatrix} Q_c \\ R_c^+ \end{pmatrix},$$

$$(sL - M) = \begin{pmatrix} sL_r - M_r & 0 & 0 & 0 \\ 0 & sL_\infty - M_\infty & 0 & 0 \\ 0 & 0 & sL_\alpha - M_\alpha & 0 \\ 0 & 0 & 0 & sL_c - M_c \end{pmatrix},$$

$$\begin{pmatrix} S_r & 0 & 0 & 0 \\ 0 & I_{\sigma_\infty} & 0 & 0 \\ 0 & 0 & I_{\sigma_\alpha} & 0 \\ 0 & 0 & 0 & I_{\sigma_c} \end{pmatrix} \begin{pmatrix} \begin{pmatrix} P_\infty \\ S_\infty^+ \end{pmatrix} & 0 & 0 \\ 0 & I_{\sigma_\alpha} & 0 \\ 0 & 0 & I_{\sigma_c} \end{pmatrix} \begin{pmatrix} \begin{pmatrix} P_\alpha \\ S_\alpha^+ \end{pmatrix} & 0 \\ 0 & I_{\sigma_c} \end{pmatrix} \begin{pmatrix} P_c \\ S_c^+ \end{pmatrix}.$$

Hence there exist matrices P and Q that can be constructed using (2.7)–(2.9) such that the pencil $P(sL - M)Q$ is in its Kronecker canonical form. That is

$$P(sL - M)Q = \begin{pmatrix} sL_r - M_r & 0 & 0 & 0 \\ 0 & sL_\infty - M_\infty & 0 & 0 \\ 0 & 0 & sL_\alpha - M_\alpha & 0 \\ 0 & 0 & 0 & sL_c - M_c \end{pmatrix},$$

which concludes the proof. □

4. An application of decomposability to controls design. Consider the linear time-invariant system described by

$$\dot{x} = Ax + Bu, \tag{4.1}$$

where $x \in \mathcal{X}$, $u \in \mathcal{U}$, $A \in \Re^{n\times n}$, $B \in \Re^{n\times m}$. We assume that B has full column rank $m < n$, and denote by N and B^+ a left annihilator and a left inverse of B, respectively (i.e., $NB = 0$, $B^+B = I_m$).

Consider the system

$$N\dot{x} = NAx, \tag{4.2a}$$

$$u = B^+(\dot{x} - Ax). \tag{4.2b}$$

Systems (4.1) and (4.2) are related in the following sense. For given $u(t)$, a solution $x(t)$ of (4.1) is also a solution of (4.2a). For a given $x(t)$ satisfying (4.2a), there exists a control $u(t)$ such that $x(t)$ is also a solution of (4.1), namely, the control given by (4.2b).

Since (4.2a) is not affected by any feedback of the form $u = Kx$, it is termed the *feedback-free representation* of the state-variable system (4.1). A subspace $\mathcal{V}$ is an (A, B)-*invariant* [19] subspace if

$$A\mathcal{V} \subset \mathcal{V} + \mathrm{Im}B, \tag{4.3}$$

or equivalently if there exists a map $K : \mathcal{X} \to \mathcal{U}$ such that

$$(A + BK)\mathcal{V} \subset \mathcal{V}. \tag{4.4}$$

We let $\mathcal{K}(\mathcal{V})$ denote the set of all K satisfying (4.4). Selecting V as a basis for $\mathcal{V}$, (4.3) can be written as

$$AV = VF - BG \tag{4.5}$$

for some F and G. Equation (4.5) is a *Sylvester* equation. Equivalently, (4.5) can be written as

$$(A + BK)V = VF$$

for some K where $KV = G$

The *controllability* pencil of (4.1) is defined as

$$C(s) = [sI - A \quad B]. \tag{4.6}$$

Similarly the *controllability pencil* of the nonsquare system (4.2) is defined as

$$\Gamma(s) = [sN - NA]. \tag{4.7}$$

It has been traditional to use $C(s)$ for pole-placement feedback design. Our contention, on the other hand, is that the pole placement problem is more conveniently solved using $\Gamma(s)$, which is a nonsquare pencil of lower order than $(sI - A)$.

The structure and the properties of these two pencils have been extensively studied in [7]. The aim of this section is to find computationally stable methods that

relate these two pencils, and then use the reduced-order pencil for the closed-loop eigenstructure assignment problem. Therefore we seek a pair $(N,\ B^+)$ such that (4.7) follows from (4.6) by only performing row and column eliminations.

Performing the algorithm proposed in [17], [18], which is based on orthogonal transformations, the controllability pencil (4.6) can be written as

$$[sI - U^TAU \quad U^TB] = \begin{array}{c} \\ r_f \\ r_c \end{array} \begin{array}{c} \begin{array}{ccc} r_f & r_c & m \end{array} \\ \begin{pmatrix} sI_f - A_f & 0 & 0 \\ -\bar{A} & sI_c - A_c & B_c \end{pmatrix} \end{array}, \tag{4.8}$$

where the pencil $sI_f - A_f$ contains all the uncontrollable modes of (4.1), while the pencil $[sI_c - A_c \ \ B]$ is full row rank for every s. Moreover, A_f may be taken in lower Schur form and A_c, B_c have the following form

$$A_c = \begin{array}{c} \\ t_1 \\ t_2 \\ t_3 \\ \vdots \\ t_{k-1} \\ t_k \end{array} \begin{array}{c} \begin{array}{cccccc} t_1 & t_2 & t_3 & \cdots & t_k \end{array} \\ \begin{pmatrix} A_{11} & A_{12} & 0 & \cdots & 0 \\ A_{22} & A_{22} & A_{23} & \cdots & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ A_{k-1,1} & \cdots & \cdots & A_{k-1,k-1} & A_{k-1,k} \\ A_{k1} & \cdots & \cdots & A_{k,k-1} & A_{kk} \end{pmatrix} \end{array}, \qquad B_c = \begin{array}{c} \\ \\ \\ \\ \\ t_k \end{array} \begin{array}{c} \begin{array}{c} m \end{array} \\ \begin{pmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ B_m \end{pmatrix} \end{array}. \tag{4.9}$$

That is, A_c is in lower block Hessenberg form, where the blocks $A_{j,j+1}$ $j \in \{1, 2, \ldots, k-1\}$ have full row rank t_j. Moreover B_m has full row rank t_k, but from our assumption that B is of full column rank ($t_k = m$) it follows that B_m is a square nonsingular matrix of dimensions $m \times m$. The pencil in (4.9), where A_f is in lower Schur form and A_c in lower block Hessenberg form, will be referred as the Schur–Hessenberg form of the system.

Now choose $(N,\ B^+)$ as follows

$$\begin{pmatrix} N \\ B^+ \end{pmatrix} = \begin{array}{c} \\ r_f \\ t_1 \\ \vdots \\ t_k \\ m \end{array} \begin{array}{c} \begin{array}{ccccc} r_f & t_1 & \cdots & t_k & m \end{array} \\ \begin{pmatrix} I_f & 0 & \ldots & 0 & 0 \\ 0 & I_{t_1} & \ldots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \ldots & I_{t_{k-1}} & 0 \\ 0 & 0 & \ldots & 0 & B_m^{-1} \end{pmatrix} \end{array}. \tag{4.10}$$

Then premultiplication of (4.8) by (4.10) yields

$$\begin{array}{c} \\ n - m \\ m \end{array} \begin{array}{c} \begin{array}{cc} n & m \end{array} \\ \begin{pmatrix} sN - NA & 0 \\ sB^+ - B^+A & I_m \end{pmatrix} \end{array}, \tag{4.11}$$

where $sN - NA$ has the following form

(4.12)

$$\begin{array}{c} \\ sI_f - A_f \\ \\ \\ -A_3 \\ \\ \end{array} \begin{array}{c} \begin{array}{ccccccc} r_f & t_1 & t_2 & t_3 & \cdots & t_k \end{array} \\ \begin{pmatrix} 0 & 0 & 0 & \ldots & 0 \\ sI_{11} - A_{11} & -A_{12} & 0 & \ldots & 0 \\ -A_{22} & sI_{22} - A_{22} & -A_{23} & \ldots & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ -A_{k-1,1} & \ldots & \ldots & sI_{k-1,k-1} - A_{k-1,k-1} & -A_{k-1,k} \end{pmatrix} \end{array}$$

and $sB^+ - B^+A$ has the form

$$(-B_m^{-1}A_{k0} \quad -B_m^{-1}A_{k1} \quad \dots \quad -B_m^{-1}A_{k,k-1} \quad -B_m^{-1}(sI_{kk} - A_{kk})), \tag{4.13}$$

with A_{k0} defined by partitioning $\bar{A}$ in (4.8) as

$$\bar{A} = \begin{pmatrix} A_3 \\ A_{k0} \end{pmatrix}.$$

It is now important to note that we can obtain from the controllability pencil (4.8) the controllability pencil for the nonsquare system by simply *eliminating the last m rows and m columns* of the pencil in (4.11).

Another important remark is that the specific selection of the pair (N, B^+) does not destroy the structure of the identity matrix, the Schur form of A_f, or the Hessenberg form of the matrix A_c in the original controllability pencil (4.8). This property, as we shall show, is very important for the computational aspects of the problem.

Let us denote the pencil (4.12) by

$$sN - NA = \begin{pmatrix} sI_f - A_f & 0 \\ -A_3 & s\tilde{I} - A_2 \end{pmatrix}, \tag{4.14}$$

where $\tilde{I} = [I_l \ \ 0_k]$, ($I_l$ is the identity matrix of dimensions $l \times l$ and $l = n - m - r_f$, 0_m is the zero matrix with dimensions $l \times m$ ($t_k = m$)) and A_2, as can be seen from (4.11) and (4.12), is obtained from A_c by eliminating its m last rows. It is known [7], [19] that the pencil $sI_f - A_f$ in (4.12) contains the finite elementary divisors of the pencil $sN - NA$. Moreover, the pencil $s\tilde{I} - A_2$ contains all the column minimal indices of the pencil $sN - NA$. The next corollary now follows readily from Theorem 3.1 and the above discussion.

COROLLARY 4.1. *The generalized Sylvester equations* (2.19) *and* (2.20) *always have a solution for the pencil as decomposed in* (4.12), (4.14). *That is, for* $sL_1 - M_1 = sI_f - A_f$, $sL_2 - M_2 = s\tilde{I} - A_2$, *and* $sL_3 - M_3 = -A_3$.

Next, we exploit the special form of these two generalized Sylvester equations in order to formulate a computationally stable algorithm that calculates a solution ($X = S_2$, $Y = R_2$) for the decomposition in (4.14) that utilizes the special form of the matrices L and M.

Notice that for the pencil given in (4.14) $L_1 = I_f$, $L_3 = 0$, and $L_2 = \tilde{I}$. As a result (2.19) becomes

$$Y = \tilde{I}X. \tag{4.15}$$

Similarly, by setting $M_1 = A_f$, $L_3 = -A_3$, and $L_2 = A_2$, (2.20) takes the form

$$A_2X - YA_f = -A_3. \tag{4.16}$$

We can partition the matrix X (according to $\tilde{I}$) as follows:

$$X = \begin{matrix} \\ l \\ m \end{matrix} \begin{matrix} r_f \\ \begin{pmatrix} X_1 \\ X_2 \end{pmatrix} \end{matrix}, \qquad l + m = r_c. \tag{4.17}$$

Then (4.15) yields that $Y = X_1$. Also notice that (4.15) is satisfied for arbitrary X_2. Substituting (4.15) into (4.16) we get

$$HX - \tilde{I}XS = C, \tag{4.18}$$

where $H = A_2$, $S = A_f$, $C = -A_3$, and $X = [x_1|x_2|\cdots|x_{r_f}]$. A computationally stable algorithm for solving (4.18) is presented in [15].

If the proportional feedback

$$u = Kx \tag{4.19}$$

is applied to (2.1), the resulting closed-loop system is

$$\dot{x} = (A + BK)x. \tag{4.20}$$

Define the set of *uncontrollable* (i.e., *fixed*) *modes* of (4.1) as

$$\sigma_f(A) = \{\alpha \in \sigma(A) \mid \operatorname{rank}(C(\alpha)) < n\} \tag{4.21a}$$

and the set of the *controllable modes* of (4.1)

$$\sigma_c(A) = \{\alpha \in \sigma(A) \mid \operatorname{rank}(C(\alpha)) = n\}, \tag{4.21b}$$

where $\sigma(A)$ denotes the spectrum of the matrix A.

The next result [15] shows the most that may be achieved using proportional feedback in terms of pole assignment. It is our main result of this section and the proof provides a computationally stable design technique for computing the feedback gain K that assigns the desired closed-loop on $\mathcal{V}$, and relies on the Schur–Hessenberg form of the pencil $[sI - A \quad B]$. It uses the reduced-order nonsquare pencil (4.7), the concept of decomposabilty, and the algorithm proposed in [15].

THEOREM 4.2. *Given a desired closed-loop structure, select a self-conjugate set* Σ *of* $n = \dim \mathcal{V}$ *desired poles of* (4.1) *such that*

$$\sigma_f(A) \subset \Sigma. \tag{4.22}$$

Then there exists a feedback (4.19) *that assigns* Σ *as the closed-loop spectrum of* (4.20) *on an* (A, B)*-invariant subspace* $\mathcal{V}$.

Proof. Restricting (4.11) to $\Re^n$ and proposing a lower triangular form as the basis for $\mathcal{V}$ and a diagonal form for F, (4.5) becomes

$$\begin{pmatrix} A_f & 0 \\ A_3 & A_2 \end{pmatrix} \begin{pmatrix} V_f & 0 \\ V_3 & V_c \end{pmatrix} = \begin{pmatrix} I_f & 0 \\ 0 & \tilde{I} \end{pmatrix} \begin{pmatrix} V_f & 0 \\ V_3 & V_c \end{pmatrix} \begin{pmatrix} F_f & 0 \\ 0 & F_c \end{pmatrix}, \tag{4.23}$$

$$[G_f \; G_c] = -B_m^{-1}\{(A_{k0} \; A_{k1} \ldots A_{kk})V - (0_{k0} \; 0_{k1} \ldots I_{kk})VF\}. \tag{4.24}$$

Notice that in the proposed basis representation the state feedback is

$$[K_f \; K_c] = [G_f \; G_c]V^{-1}.$$

We now consider the three component equations of (4.23), solving them one at a time.

(a) *Uncontrollable modes*: Consider the diagonal term

$$A_f V_f = V_f F_f. \tag{4.25}$$

We select F_f as a matrix such that $\sigma(F_f) = \sigma(A_f)$. Using (4.18), where $\tilde{I} = I_{r_f}$ and $C = 0$, we compute V_f. Note that A_f is in its Schur form, a fact that further simplifies the solution of (4.18).

(b) *Coupling equation*: Now, consider the off-diagonal portion of (4.23),

$$A_2 V_3 - \tilde{I} V_3 F_f = -A_3 V_f. \tag{4.26}$$

Using (4.25), (4.26) can be written as

$$A_2 X - \tilde{I} X A_f = -A_3, \tag{4.27}$$

where $X = V_3 V_f^{-1}$. But (4.27) is exactly the same as (4.18), which, due to the decomposability property has always a solution, that can be easily computed.

(c) *Controllable modes*: The third portion of (4.23) is

$$A_2 V_c = \tilde{I} V_c F_c. \tag{4.28}$$

We select F_c in a lower Schur form such that $\sigma(F_c) = \Sigma - \sigma_f(A)$. The selection F_c is based on the fact that no further transformations will be necessary for the solution of (4.28). That is, we use (4.18), where $C = 0$, $H = A_2$, and $S = F_c$, to compute the solution of (4.28).

(d) *Driving equation*: We call (4.24) the driving equation since it is the one that incorporates the influence of the input $u(t)$ in the pole-placement problem. Equation (4.24) can be written as

$$[K_f \; K_c] = [G_f \; G_c] V^{-1} = -B_m^{-1}\{(A_{k0} \; A_{k1} \ldots A_{kk}) - (0_{k0} \; 0_{k1} \ldots I_{kk}) V F V^{-1}\}. \tag{4.29}$$

□

The proposed technique not only computes the feedback gain for the controllable part of the system (2.1) but also for the uncontrollable one. That is, we extend the feedback to the uncontrollable subspace, showing that the uncontrollable eigenvectors can be selected within limits. This is in contrast with Tsui [16] and Datta [4] where complete controllability is imposed on the system. In addition to that we do not require that the desired closed-loop spectrum and the uncontrollable modes must be disjoint as in [19]. The presented technique is exploiting the ideas presented in [10]. There a similar methodology is used. Specifically, the rows of B are compressed and then robust solutions are derived for (4.5). This is achieved by using the extra freedom that the input matrix B provides for assigning the closed-loop right eigenvectors.

Remarks. Several remarks must be made about the above algorithm [15].

(a) The proposed design technique is based on the reduced-order nonsquare pencil (4.7).

(b) The algorithm is based on unitary transformations that guarantee the computational stability of the technique.

(c) If the spectrum assignability objectives change there is no need to carry out the computations for the uncontrollable part of the sytem. This fact is due to the notion of decomposability. As a result, a considerable amount of computation is avoided.

(d) The design generalized Sylvester equations can be solved easily in a computationally effecient manner due to the specific choice of the pair $(N,\ B^+)$ and the idea of decomposability. Thus, once the controllability pencil has been brought to its Schur–Hessenberg form, the solution of the Sylvester equation can be easily achieved.

(e) The feedback-gain matrix is extended also to the uncontrollable subspace of the system.

(f) The solution V is implicitly dependent on B through N. However, the feedback gain matrix K is explicitly dependent on B.

For more details on the computational aspects of the proposed application and numerical examples see [15]. This application of decomposabilty for the closed-loop eigenstructure problem can be easily extended to the case of singular systems.

5. Conclusion. In this paper we presented the connection between strict equivalence of two pencils and the concept of quotient subspaces. This connection led us to the definition of decomposability for nonsquare pencils of the form $sL - M$. We proposed a set of necessary and sufficient conditions for the decomposability property. Furthermore, we showed that these algebraic conditions are equivalent to two coupled generalized Sylvester equations.

Throughout the paper we showed how the well-known notions for decomposability for the pencil $sI - M$ can be recovered as a special case of our general approach. We related the concept of decomposability to the Kronecker structure of the pencil $sL - M$. We drew connections between the Kronecker invariants and the decomposability property.

Finally we presented an application of the notion of decomposability to the control systems theory. In particular, we showed the advantages that provides for the closed-loop eigenstructure problem with state-feedback, by utilizing nonsquare pencils of reduced order.

Acknowledgments. We would like to thank the reviewers for their critical and incisive comments, which have done much to help improve the quality of this paper. We also want to thank Dr. N. Nichols for her input in the presentation of this work.

NUMERICAL GRADIENT ALGORITHMS FOR EIGENVALUE AND SINGULAR VALUE CALCULATIONS*

J.B. MOORE†, R.E. MAHONY†, AND U. HELMKE‡

Abstract. Recent work has shown that the algebraic question of determining the eigenvalues, or singular values, of a matrix can be answered by solving certain continuous-time gradient flows on matrix manifolds. To obtain computational methods based on this theory, it is reasonable to develop algorithms that iteratively approximate the continuous-time flows. In this paper the authors propose two algorithms, based on a double Lie-bracket equation recently studied by Brockett, that appear to be suitable for implementation in parallel processing environments. The algorithms presented achieve, respectively, the eigenvalue decomposition of a symmetric matrix and the singular value decomposition of an arbitrary matrix. The algorithms have the same equilibria as the continuous-time flows on which they are based and inherit the exponential convergence of the continuous-time solutions.

Key words. eigenvalue decomposition, singular value decomposition, numerical gradient algorithm

AMS subject classifications. 15A18, 65F10

1. Introduction.

A traditional algebraic approach to determining the eigenvalue and eigenvector structure of an arbitrary matrix is the QR-algorithm. In the early 1980s it was observed that the QR-algorithm is closely related to a continuous-time differential equation that has become known through study of the Toda lattice. Symes [13] and Deift, Nanda, and Tomei [6] showed that for tridiagonal real symmetric matrices, the QR-algorithm is a discrete-time sampling of the solution to a continuous-time differential equation. This result was generalised to full complex matrices by Chu [3], and Watkins and Elsner [14] provided further insight in the late 1980s.

Brockett [2] studied dynamic matrix flows generated by the double Lie-bracket equation

$$\dot{H} = [H, [H, N]], \qquad H(0) = H_0$$

for constant symmetric matrices N and H_0, and where we use the Lie-bracket notation $[X, Y] = XY - YX$. We call this differential equation the *double-bracket* equation, and we call solutions of this equation *double-bracket flows.* Similar matrix differential equations in the area of Physics were known and studied prior to the references given above. An example, is the Landau–Lifschitz–Gilbert equation of micromagnetics

$$\frac{d\hat{m}}{dt} = \frac{\gamma}{1+\alpha^2}(\hat{m} \times \overline{H} - \alpha \hat{m} \times (\hat{m} \times \overline{H})) \quad |\hat{m}|^2 = 1,$$

as $\alpha \to \infty$ and $\gamma/\alpha \to k$, a constant. In this equation $\hat{m}, \overline{H} \in \mathbb{R}^3$ and the cross-product is equivalent to a Lie-bracket operation. The relevance of such equations

to traditional linear algebra problems, however, has only recently been studied and discretisations of such flows have not been investigated.

The double-bracket equation is not known to be a continuous-time version of any previously existing linear algebra algorithm; however, it exhibits exponential convergence to an equilibrium point on the manifold of self-equivalent symmetric matrices [2], [5], [9]. Brockett [2] was able to show that this flow could be used to diagonalise real symmetric matrices, and thus, to find their eigenvalues, sort lists, and even to solve linear programming problems. Part of the flexibility and theoretical appeal of the double-bracket equation follows from its dependence on the arbitrary matrix parameter N, which can be varied to control the transient behaviour of the differential equation.

In independent work by Driessel [7], Chu and Driessel [5], Smith [12] and Helmke and Moore [8], a similar gradient flow approach is developed for the task of computing the singular values of a general nonsymmetric, nonsquare matrix. The differential equation obtained in these approaches is almost identical to the double-bracket equation. In [8], it is shown that these flows can also be derived as special cases of the double-bracket equation for a nonsymmetric matrix, suitably augmented to be symmetric.

With the theoretical aspects of these differential equations becoming known, and with applications in the area of balanced realizations [10], [11] along with the more traditional matrix eigenvalue problems, there remains the question of efficiently computing their solutions. No explicit solutions to the differential equations have been obtained and a direct numerical estimate of their integral solutions seems unlikely to be an efficient computational algorithm. Iterative algorithms that approximate the continuous-time flows, however, seem more likely to yield useful numerical methods. Furthermore, discretisations of such isospectral matrix flows are of general theoretical interest in the field of numerical linear algebra. For example, the algorithms proposed in this paper involve adjustable parameters, such as step-size selection schemes and a matrix parameter N, which are not present in traditional algorithms such as the QR-algorithm or the Jacobi method.

In this paper, we propose a new algorithm termed the *Lie-bracket algorithm*, for computing the eigenvalues of an arbitrary symmetric matrix

$$H_{k+1} = e^{-\alpha_k[H_k,N]} H_k e^{\alpha_k[H_k,N]}.$$

For suitably small α_k, termed *time-steps*, the algorithm is an approximation of the solution to the continuous time double-bracket equation. Thus, the algorithm represents an approach to developing new recursive algorithms based on approximating suitable continuous-time flows. We show that for suitable choices of time-steps, the Lie-bracket algorithm inherits the same equilibria as the double-bracket flow. Furthermore, exponential convergence of the algorithm is shown. This paper presents only theoretical results on the Lie-bracket algorithm and does not attempt to compare its performance to that of existing methods for calculating the eigenvalues of a matrix.

Continuous-time gradient flows that compute the singular values of arbitrary nonsymmetric matrices, such as those covered in [5], [8], [9], [12], have a similar form to the double-bracket equation on which the Lie-bracket algorithm was based. We use this similarity to generate a new scheme for computing the singular values of a general matrix termed the *singular value algorithm*. The natural equivalence between the Lie-bracket algorithm and the singular value algorithm is demonstrated and exponential convergence results follow almost directly.

Associated with the main algorithms presented for the computation of the eigenvalues or singular values of matrices are algorithms that compute the full eigenspace decompositions of given matrices. These algorithms are closely related to the Lie-bracket algorithm and also display exponential convergence.

The paper is divided into eight sections including the Introduction and an Appendix. In §2 of this paper, we consider the Lie-bracket algorithm and prove a proposition that ensures the algorithm converges to a fixed point. Section 3 deals with choosing step-size selection schemes and proposes two valid deterministic functions for defining the time-steps. Considering the particular step-size selection schemes presented in §3 we return to the question of stability in §4 and show that the Lie-bracket algorithm has a unique exponentially attractive fixed point, though several of the technical proofs are deferred to the Appendix. This completes the discussion for the symmetric case and §5 considers the nonsymmetric case and the singular value decomposition. Section 6 presents associated algorithms that compute the eigenspace decompositions of given initial conditions. A number of computational issues are briefly mentioned in §7, while §8 provides a conclusion.

2. The Lie-bracket algorithm. In this section, we begin by introducing the least squares potential that underpins the recent gradient flow results and then we describe the double Lie-bracket equation first derived by Brockett [2]. The Lie-bracket recursion is introduced and conditions are given that guarantee convergence of the algorithm.

Let N and H be real symmetric matrices and consider the potential function

$$\begin{aligned} \psi(H) &:= ||H - N||^2 \\ &= ||H||^2 + ||N||^2 - 2\mathrm{tr}(NH), \end{aligned} \tag{1}$$

where the norm used is the Frobenius norm $||X||^2 := \mathrm{tr}(X^T X) = \sum x_{ij}^2$, with x_{ij} the elements of X. Note that $\psi(H)$ measures the least squares difference between the elements of H and the elements of N. Let $M(H_0)$ be the set of orthogonally similar matrices, generated by some symmetric initial condition $H_0 = H_0^T \in \mathbb{R}^{n\times n}$. Then

$$M(H_0) = \{U^T H_0 U \mid U \in O(n)\}, \tag{2}$$

where $O(n)$ denotes the group of all $n \times n$ real orthogonal matrices. It is shown in [9, p. 48] that $M(H_0)$ is a smooth compact Riemannian manifold with explicit forms given for its tangent space and Riemannian metric. Furthermore, in [1], [5] the gradient of $\psi(H)$, with the respect to the normal Riemannian metric on $M(H_0)$ [9, p. 50], is shown to be $\nabla\psi(H) = -[H,[H,N]]$. Consider the gradient flow given by the solution of

$$\begin{aligned} \dot{H} &= -\nabla\psi(H) \\ &= [H,[H,N]], \quad \text{with } H(0) = H_0, \end{aligned} \tag{3}$$

which we call the *double-bracket flow* [2], [5]. Thus, the double-bracket flow is a gradient flow that acts to decrease or minimise the least squares potential ψ on the manifold $M(H_0)$. Note that from (1), this is equivalent to increasing or maximising $\mathrm{tr}(NH)$. We refer to the matrix H_0 as the *initial condition* and the matrix N as the *target matrix*.

The *Lie-bracket algorithm* proposed in this paper is

$$H_{k+1} = e^{-\alpha_k[H_k,N]} H_k e^{\alpha_k[H_k,N]} \tag{4}$$

for arbitrary symmetric $n \times n$ matrices H_0 and N and some suitably small scalars α_k termed *time-steps*. To motivate the Lie-bracket algorithm, consider the curve $H_{k+1}(t) = e^{-t[H_k,N]} H_k e^{t[H_k,N]}$. Thus, $H_{k+1}(0) = H_k$ and $H_{k+1} = H_{k+1}(\alpha_k)$, the $(k+1)$th iteration of (4). Observe that

$$\frac{d}{dt}(e^{-t[H_k,N]} H_k e^{t[H_k,N]})\Big|_{t=0} = [H_k, [H_k, N]],$$

and thus, $e^{-t[H_k,N]} H_k e^{t[H_k,N]}$ is a first approximation of the double-bracket flow at $H_k \in M(H_0)$. It follows that for small α_k, the solution to (3) evaluated at time $t = \alpha_k$ with $H(0) = H_k$ is approximately $H_{k+1} = H_{k+1}(\alpha_k)$.

It is easily seen from above that stationary points of (3) are fixed points of (4). In general, (4) may have more fixed points than just the stationary points of (3), however, Proposition 2.1 shows that this is not the case for a suitable choice of time-step α_k. We use the term *equilibrium point* to mean a fixed point of the algorithm that is also a stationary point of (3).

To implement (4) it is necessary to specify the time-steps α_k. We do this by considering functions $\alpha_N : M(H_0) \to \mathbb{R}_+$ and setting $\alpha_k := \alpha_N(H_k)$. We refer to the function α_N as the *step-size selection scheme*. We require that the step-size selection scheme satisfies the following condition.

CONDITION 2.1. *Let $\alpha_N : M(H_0) \to \mathbb{R}_+$ be a step-size selection scheme for the Lie-bracket algorithm on $M(H_0)$. Then α_N is well defined and continuous on all of $M(H_0)$, except possibly those points $H \in M(H_0)$ where $HN = NH$. Furthermore, there exist real numbers $B, \gamma > 0$, such that $B > \alpha_N(H) \geq \gamma$ for all $H \in M(H_0)$ where α_N is well defined.*

Remark 2.1. We find that the variable step-size selection scheme proposed in this paper, which provides the best simulation results, is discontinuous at all the points $H \in M(H_0)$, such that $[H, N] = 0$.

Remark 2.2. Note that the definition of a step-size selection scheme depends implicitly on the matrix parameter N. Indeed, α_N can be thought of as a function in two matrix variables N and H.

CONDITION 2.2. *Let N be a diagonal $n \times n$ matrix with distinct diagonal entries $\mu_1 > \mu_2 > \ldots > \mu_n$.*

Remark 2.3. This condition on N, along with Condition 2.1 on the step-size selection scheme, is chosen to ensure that the Lie-bracket algorithm converges to a diagonal matrix from which the eigenvalues of H_0 can be directly determined.

Let $\lambda_1 > \lambda_2 > \ldots > \lambda_r$ be the eigenvalues of H_0 with associated algebraic multiplicities $n_1, \ldots, n_r$ satisfying $\sum_{i=1}^{r} n_i = n$. Note that as H_0 is symmetric, the eigenvalues of H_0 are all real. Thus, the diagonalisation of H_0 is

$$\Lambda := \begin{bmatrix} \lambda_1 I_{n_1} & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \lambda_r I_{n_r} \end{bmatrix}, \tag{5}$$

where I_{n_i} is the $n_i \times n_i$ identity matrix. For generic initial conditions and a target matrix N that satisfies Condition 2.2, the continuous-time equation (3) converges exponentially fast to Λ [2], [9]. Thus, the eigenvalues of H_0 are the diagonal entries of the limiting value of the infinite time solution to (3). The Lie-bracket algorithm behaves similarly to (3) for small α_k and, given a suitable step-size selection scheme, should converge to the same equilibrium as the continuous-time equation.

PROPOSITION 2.1. *Let H_0 and N be $n \times n$ real symmetric matrices where N satisfies Condition* 2.2. *Let $\psi(H)$ be given by* (1) *and let $\alpha_N : M(H_0) \to \mathbb{R}_+$ be a step-size selection scheme that satisfies Condition* 2.1. *For $H_k \in M(H_0)$, let $\alpha_k = \alpha_N(H_k)$ and define*

$$\triangle \psi(H_k, \alpha_k) := \psi(H_{k+1}) - \psi(H_k), \tag{6}$$

where H_{k+1} is given by (4). *Suppose*

$$\triangle \psi(H_k, \alpha_k) < 0 \quad \text{when } [H_k, N] \neq 0. \tag{7}$$

Then (a) *The iterative equation* (4) *defines an isospectral (eigenvalue preserving) recursion on the manifold $M(H_0)$.*

(b) *The fixed points of* (4) *are characterised by matrices $H \in M(H_0)$ satisfying*

$$[H, N] = 0. \tag{8}$$

(c) *Every solution H_k, for $k = 1, 2, \ldots$, of* (4), *converges as $k \to \infty$, to some $H_\infty \in M(H_0)$ where $[H_\infty, N] = 0$.*

Proof. To prove part (a), note that the Lie-bracket $[H, N]^T = -[H, N]$ is skew-symmetric. As the exponential of a skew-symmetric matrix is orthogonal, (4) is an orthogonal conjugation of H_k and hence is isospectral.

For part (b) note that if $[H_k, N] = 0$, then by direct substitution into (4) we see $H_{k+1} = H_k$ and thus, $H_{k+l} = H_k$ for $l \geq 1$, and H_k is a fixed point of (4). Conversely if $[H_k, N] \neq 0$, then from (7), $\triangle\psi(H_k, \alpha_k) \neq 0$, and thus $H_{k+1} \neq H_k$. By inspection, points satisfying (8) are stationary points of (3), and indeed are known to be the only stationary points of (3) [9, pg. 50]. Thus, the fixed points of (4) are equilibrium points in the sense that they are all stationary points of (3). To prove part (c) we need the following lemma.

LEMMA 2.2. *Let N satisfy Condition* 2.2 *and α_N satisfy Condition* 2.1 *such that the Lie-bracket algorithm satisfies* (7). *The Lie-bracket algorithm* (4) *has exactly $n!/\prod_{i=1}^{r}(n_i!)$ distinct equilibrium points in $M(H_0)$. These equilibrium points are characterised by the matrices $\pi^T \Lambda \pi$, where π is an $n \times n$ permutation matrix, a rearrangement of the rows of the identity matrix, and Λ is given by* (5).

Proof. Note that part (b) of Proposition 2.1 characterises equilibrium points of (4) as $H \in M(H_0)$ such that $[H, N] = 0$. Evaluating this condition componentwise for $H = \{h_{ij}\}$ gives

$$h_{ij}(\mu_j - \mu_i) = 0,$$

and hence by Condition 2.2, $h_{ij} = 0$ for $i \neq j$. Using the fact that (4) is isospectral, it follows that equilibrium points are diagonal matrices that have the same eigenvalues as H_0. Such matrices are distinct and can be written in the form $\pi^T \Lambda \pi$ for π an $n \times n$ permutation matrix. A simple counting argument yields the number of matrices that satisfy this condition to be $n!/\prod_{i=1}^{r}(n_i!)$. □

Consider for a fixed initial condition H_0, the sequence H_k generated by the Lie-bracket algorithm. Observe that condition (7) implies that $\psi(H_k)$ is strictly monotonic decreasing for all k where $[H_k, N] \neq 0$. Also, since ψ is a continuous function on the compact set $M(H_0)$, then ψ is bounded from below and $\psi(H_k)$ will converge to some nonnegative value ψ_∞. As $\psi(H_k) \to \psi_\infty$ then $\triangle\psi(H_k, \alpha_k) \to 0$.

For an arbitrary positive number ϵ, define the open set $D_\epsilon \subset M(H_0)$, consisting of all points of $M(H_0)$, within an ϵ neighbourhood of some equilibrium point of (4).

The set $M(H_0) - D_\epsilon$ is a closed, compact subset of $M(H_0)$ on which the matrix function $H \mapsto [H, N]$ does not vanish. As a consequence, the difference function (6) is continuous and strictly negative on $M(H_0) - D_\epsilon$, and thus can be over bounded by some strictly negative number $\delta_1 < 0$. Moreover, as $\triangle\psi(H_k, \alpha_k) \to 0$, then there exists a $K = K(\delta_1)$ such that for all $k > K$ then $0 \geq \triangle\psi(H_k, \alpha_k) > \delta_1$. This ensures that $H_k \in D_\epsilon$ for all $k > K$. In other words, H_k is converging to some subset of possible equilibrium points.

Imposing the upper bound B on the step-size selection scheme α_N, Condition 2.2, it follows that $\alpha_N(H_k)[H_k, N] \to 0$ as $k \to \infty$. Thus, $e^{\alpha_N(H_k)[H_k,N]} \to I$, the identity matrix, and hence, $e^{-\alpha_N(H_k)[H_k,N]} H_k e^{\alpha_N(H_k)[H_k,N]} \to H_k$ as $k \to \infty$. As a consequence $||H_{k+1} - H_k|| \to 0$ for $k \to \infty$ and this combined with the distinct nature of the fixed points, Lemma 2.2, and the partial convergence already shown, completes the proof. □

Remark 2.4. In Condition 2.2 it was required that N have distinct diagonal entries. If this condition is not satisfied, the equilibrium condition $[H, N] = 0$ may no longer force H to be diagonal, and thus, though the algorithm will converge, it is unlikely to converge to a diagonal matrix.

3. Step-size selection. The Lie-bracket algorithm (4) requires a suitable step-size selection scheme before it can be implemented. To generate such a scheme, we use the potential (1) as a measure of the convergence of (4) at each iteration. Thus, we aim to choose each time-step to maximise the absolute change in potential $|\triangle\psi|$ of (6), such that $\triangle\psi < 0$. Optimal time-steps can be determined at each step of the iteration by completing a line search to maximise the absolute change in potential as the time-step is increased. Such an approach, however, involves high computational overheads and we aim rather to obtain a step-size selection scheme in the form of a scalar equation depending on known values.

Using the Taylor expansion, we express $\triangle\psi(H_k, \tau)$ for a general time-step τ, as a linear term plus a higher order error term. By estimating the error term we obtain a mathematically simple function $\triangle\psi_U(H_k, \tau)$, which is an upper bound to $\triangle\psi(H_k, \tau)$ for all τ. Then, choosing a suitable time-step α_k based on minimising $\triangle\psi_U$, we guarantee that the actual change in potential, $\triangle\psi(H_k, \alpha_k) \leq \triangle\psi_U(H_k, \alpha_k) < 0$, satisfies (7). Due to the simple nature of the function $\triangle\psi_U$, there is an explicit form for the time-step α_k depending only on H_k and N. We begin by deriving an expression for the error term.

LEMMA 3.1. *For the kth step of the recursion* (4) *the change in potential* $\triangle\psi(H_k, \tau)$ *of* (6), *for a time-step* τ *is*

$$\triangle\psi(H_k, \tau) = -2\tau||[H_k, N]||^2 - 2\tau^2 \mathrm{tr}(N\mathcal{R}_2(\tau)) \tag{9}$$

with

$$\mathcal{R}_2(\tau) := \int_0^1 (1-s) H''_{k+1}(s\tau) ds, \tag{10}$$

where $H''_{k+1}(\tau)$ *is the second derivative of* $H_{k+1}(\tau)$ *with respect to* τ.

Proof. Let $H_{k+1}(\tau)$ be the $(k+1)$th recursive estimate for an arbitrary time-step τ. Thus $H_{k+1}(\tau) = e^{-\tau[H_k,N]} H_k e^{\tau[H_k,N]}$. It is easy to verify that the first and second time derivatives of H_{k+1} are exactly

$$H'_{k+1}(\tau) = [H_{k+1}(\tau), [H_k, N]],$$
$$H''_{k+1}(\tau) = [[H_{k+1}(\tau), [H_k, N]], [H_k, N]].$$

Applying Taylor's theorem, then

$$\begin{aligned} H_{k+1}(\tau) &= H_{k+1}(0) + \tau \frac{d}{d\tau} H_{k+1}(0) + \tau^2 \int_0^1 (1-s) H''_{k+1}(s\tau) ds, \\ &= H_k + \tau [H_k, [H_k, N]] + \tau^2 \mathcal{R}_2(\tau). \end{aligned} \tag{11}$$

Consider the change in the potential $\psi(H)$ between the points H_k and $H_{k+1}(\tau)$,

$$\begin{aligned} \triangle\psi(H_k, \tau) &= \psi(H_{k+1}(\tau)) - \psi(H_k) \\ &= -2\mathrm{tr}(N(H_{k+1}(\tau) - H_k)) \\ &= -2\mathrm{tr}(N(\tau[H_k, [H_k, N]] + \tau^2 \mathcal{R}_2(\tau))) \\ &= -2\tau ||[H_k, N]||^2 - 2\tau^2 \mathrm{tr}(N\mathcal{R}_2(\tau)). \end{aligned} \tag{12}$$

□

Note that for $\tau = 0$, then $\triangle\psi(H_k, 0) = 0$ and also that

$$\frac{d}{d\tau} \triangle\psi(H_k, \tau)\Big|_{\tau=0} = -2||[H_k, N]||^2.$$

Thus, for sufficiently small τ the error term $\tau^2 \mathrm{tr}(N\mathcal{R}_2(\tau))$ becomes negligible and $\triangle\psi(H_k, \tau)$ is strictly negative. Let $\alpha_{\mathrm{opt}} > 0$ be the first time for which

$$\frac{d}{d\tau} \triangle\psi(H_k, \tau)\Big|_{\tau=\alpha_{\mathrm{opt}}} = 0,$$

then $\triangle\psi(H_k, \alpha_{\mathrm{opt}}) < \triangle\psi(H_k, \tau) < 0$ for all strictly positive $\tau < \alpha_{\mathrm{opt}}$. It is not possible, however, to estimate α_{opt} directly from (12) due to the transcendental nature of the error term $\mathcal{R}_2(\tau)$. By considering two separate estimates of the error term, we obtain two step-size selection schemes $\alpha_k \leq \alpha_{\mathrm{opt}}$. The first and constant step-size selection scheme follows from a loose bound of the error, whereas the second variable step-size selection scheme follows from a more sophisticated argument and results in faster convergence of (4).

LEMMA 3.2 (Constant step-size selection scheme). *The constant time-step*

$$\alpha_N^c = \frac{1}{4||H_0|| \cdot ||N||} \tag{13}$$

satisfies Condition 2.1. *Furthermore, the Lie-bracket algorithm, equipped with the step-size selection scheme* α_N^c, *satisfies* (7).

Proof. Recall that for the Frobenius norm $|\mathrm{tr}(XY)| \leq ||X|| \cdot ||Y||$. Then

$$\begin{aligned} \triangle\psi(H_k, \tau) &\leq -2\tau ||[H_k, N]||^2 + 2\tau^2 |\mathrm{tr}(N\mathcal{R}_2(\tau))| \\ &\leq -2\tau ||[H_k, N]||^2 + 2\tau^2 ||N|| \cdot ||\mathcal{R}_2(\tau)|| \\ &\leq -2\tau ||[H_k, N]||^2 + 2\tau^2 ||N|| \cdot \\ &\qquad \int_0^1 (1-s) |||[[H_{k+1}(s\tau), [H_k, N]], [H_k, N]]|| ds \\ &\leq -2\tau ||[H_k, N]||^2 + 4\tau^2 ||N|| \cdot ||H_0|| \cdot |||[H_k, N]||^2 \\ &=: \triangle\psi_U(H_k, \tau). \end{aligned} \tag{14}$$

Thus $\triangle\psi_U(H_k, \tau)$ is an upper bound for $\triangle\psi(H_k, \tau)$ and has the property that for sufficiently small τ, it is strictly negative; see Fig. 1. Due to the quadratic form of

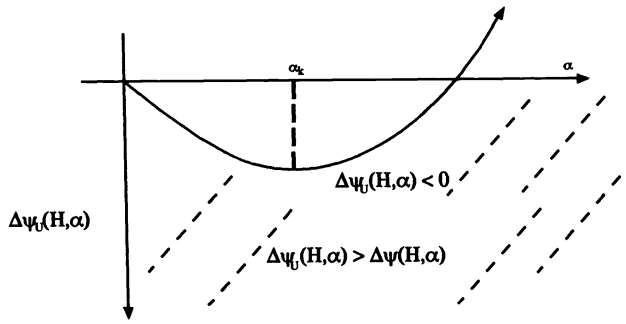

FIG. 1. *The upper bound on* $\triangle\psi(H_k,\alpha)$ *viz* $\triangle\psi_U(H_k,\alpha)$.

$\triangle\psi_U(H_k,\tau)$ in τ, it is immediately clear that $\alpha_k^c = \alpha_N^c(H_k) = 1/(4||H_0||||N||)$ of (13) is the minimum of (14). □

A direct norm bound of the integral error term is not likely to be a tight estimate of the error and the function $\triangle\psi_U$ is a fairly crude bound for $\triangle\psi$. The following more sophisticated estimate results in a step-size selection scheme that causes the Lie-bracket algorithm to converge an order of magnitude faster.

LEMMA 3.3 (An improved bound for $\triangle\psi(H_k,\tau)$). *Note the difference function* $\triangle\psi(H_k,\tau)$ *can be over bounded by*

$$\begin{aligned}\triangle\psi(H_k,\tau) &\le -2\tau||[H_k,N]||^2 \\ &\quad + \frac{||H_0||\cdot|||[N,[H_k,N]]||}{||[H_k,N]||}\left(e^{2\tau||[H_k,N]||}-1-2\tau||[H_k,N]||\right) \\ &=: \triangle\psi_U^*(H_k,\tau).\end{aligned} \tag{15}$$

Proof. Consider the Taylor series expansion of the matrix exponential

$$e^A = I + A + \frac{1}{2}A^2 + \frac{1}{3!}A^3 + \cdots.$$

It is easily verified that

$$\begin{aligned}e^A B e^{-A} &= B + [A,B] + \frac{1}{2!}[A,[A,B]] + \frac{1}{3!}[A,[A,[A,B]]] + \cdots \\ &= \sum_{i=0}^{\infty}\frac{1}{i!}ad_A^i B.\end{aligned} \tag{16}$$

Here $ad_A^i B = ad_A\,(ad_A^{i-1}B)$, $ad_A^0 B = B$, where $ad_A : \mathbb{R}^{n\times n} \to \mathbb{R}^{n\times n}$ is the linear map $X \mapsto AX - XA$. Substituting $-\tau[H_k,N]$ and H_k for A and B in (16) and comparing with (11), gives

$$\tau^2\mathcal{R}_2(\tau) = \sum_{j=2}^{\infty}\frac{1}{j!}ad_{-\tau[H_k,N]}^j(H_k).$$

Considering $|\mathrm{tr}(N\mathcal{R}_2(\tau))|$ and using the readily established identity $\mathrm{tr}(Nad_{-A}^j B) =$

$\mathrm{tr}((ad_A^j N)B)$ gives

$$\begin{aligned}
|\tau^2 \mathrm{tr}(N\mathcal{R}_2(\tau))| &= \left| \sum_{j=2}^{\infty} \frac{1}{j!} \mathrm{tr}\left(ad^j_{\tau[H_k,N]}(N) H_k \right) \right| \\
&\leq \sum_{j=2}^{\infty} \frac{1}{j!} ||ad^j_{\tau[H_k,N]}(N)|| \cdot ||H_0|| \\
&\leq \sum_{j=2}^{\infty} \frac{1}{j!} (2||\tau[H_k,N]||)^{j-1} ||ad_{\tau[H_k,N]}(N)|| \cdot ||H_0|| \\
&= \frac{||H_0|| \cdot ||ad_{\tau[H_k,N]}(N)||}{2\tau||[H_k,N]||} \sum_{j=2}^{\infty} \frac{1}{j!} (2\tau||[H_k,N]||)^j \\
&= \frac{||H_0|| \cdot ||[N,[H_k,N]]||}{2||[H_k,N]||} \left(e^{2\tau||[H_k,N]||} - 1 - 2\tau||[H_k,N]|| \right).
\end{aligned}$$

Thus combining this with the first line of (14) gives (15). □

The variable step-size selection scheme is derived from this estimate of the error term in the same manner the constant step-size selection scheme was derived in Lemma 3.2.

LEMMA 3.4 (Variable step-size selection scheme). *The step-size selection scheme* $\alpha_N^* : M(H_0) \to \mathbb{R}_+$

$$\alpha_N^*(H) = \frac{1}{2||[H,N]||} \log\left(\frac{||[H,N]||^2}{||H_0||\ ||[N,[H,N]]||} + 1 \right), \tag{17}$$

where all norms are Frobenius norms, satisfies Condition 2.1. *Furthermore, the Lie-bracket algorithm, equipped with the step-size selection scheme* α_N^*, *satisfies* (7).

Proof. We first show that α_N^* satisfies the requirements of Condition 2.1. As the Frobenius norm is a continuous function, then α_N^* is well defined and continuous at all points $H \in M(H_0)$ such that $[H,N] \neq 0$. Note that when $[H,N] = 0$, then α_N^* is not well defined. To show that there exists a positive constant γ, such that $\alpha_N^*(H) > \gamma$, consider the following lower bound,

$$\begin{aligned}
\alpha_N^L &:= \frac{1}{2||[H_k,N]||} \log\left(\frac{||[H_k,N]||}{2||[H_0||\ ||N||} + 1 \right) \\
&\leq \frac{1}{2||[H_k,N]||} \log\left(\frac{||[H_k,N]||^2}{2||[H_0||\ ||N||\ ||[H_k,N]||} + 1 \right) \\
&\leq \frac{1}{2||[H_k,N]||} \log\left(\frac{||[H_k,N]||^2}{||[H_0||\ ||[N,[H_k,N]]||} + 1 \right),
\end{aligned} \tag{18}$$

which is just α_N^*. Using L'Hôpital's rule it can be seen that the limit of α_N^L at an equilibrium point, $H \in M(H_0)$ such that $[H,N] = 0$, is $1/(4||H_0|| \cdot ||N||)$. Including these points in the definition of α_N^L, gives that α_N^L is a continuous, strictly positive, well-defined function for all $H \in M(H_0)$. Thus, as $M(H_0)$ is compact, there exists a real number $\gamma > 0$ such that

$$\alpha_N^* \geq \alpha_N^L \geq \gamma > 0$$

on $M(H_0) - \{H_\infty \mid [H_\infty, N] = 0\}$.

To show that there exists a real number $B > 0$, such that $\alpha_N^*(H) < B$, $H \in M(H_0)$, set $[H, N] = X = \{x_{ij}\}$. For N given by Condition 2.2, then $|||[N, X]||| = \sum_{i=j}(\mu_i - \mu_j)^2 x_{ij}^2$, where $x_{ii} = 0$ as $[H, N]$ is skew-symmetric. Observe that

$$\begin{aligned} ||X||/|||[N, X]||| &= \frac{\sum_{i=j} x_{ij}^2}{\sum_{i=j}(\mu_i - \mu_j)^2 x_{ij}^2} \\ &\leq \max_{i=j}(\mu_i - \mu_j)^{-2} =: b \end{aligned}$$

for all choices of $X = -X^T$. It follows that

$$\begin{aligned} \alpha_N^*(H) &= \frac{1}{2||X||} \log\left(\frac{||X||^2}{||H_0||\,|||[N, X]|||} + 1\right) \\ &\leq \frac{1}{2||X||} \log\left(\frac{||X||b}{||H_0||} + 1\right) \\ &\leq \frac{b}{2||H_0||} =: B \end{aligned}$$

since $\log(x + 1) \leq x$ for $x > 0$.

Finally, for a matrix $H_k \in M(H_0)$, $[H_k, N] \neq 0$, the time-step $\alpha_N^*(H_k) = \alpha_k^* > 0$ minimises (15), and from Lemma 3.3 it follows that $0 \geq \triangle\psi_U^*(H_k, \tau) \geq \triangle\psi(H_k, \tau)$. Thus, the Lie-bracket algorithm, equipped with the step-size selection scheme α_N^*, satisfies (7) and the proof is complete. □

4. Stability analysis. In this section we study the stability of equilibria of the Lie-bracket algorithm (4). It is shown that for generic initial conditions and any step-size selection scheme that satisfies Condition 2.1 and (7), the solution H_k of the Lie-bracket algorithm converges to the unique equilibrium point Λ given by (5). Furthermore, we derive local exponential bounds on the rate of convergence. To improve the readability of the paper the proofs of a number of the more technical results have been deferred to an appendix. We begin by showing that Λ is the unique locally asymptotically stable equilibrium point of (4).

LEMMA 4.1. *Let N satisfy Condition* (2.2) *and α_N be some selection scheme that satisfies Condition* 2.1 *and* (7). *The Lie-bracket algorithm* (4) *has a unique locally asymptotically stable equilibrium point Λ given by* (5). *All other equilibrium points of* (4) *are unstable.*

Proof. It is known that Λ is the unique local and global minimum of the potential function ψ on $M(H_0)$ [9]. By assumptions on N and α_N, $\psi(H_k)$ is monotonically decreasing. Thus the domain of attraction of Λ contains an open neighbourhood of Λ, and hence, Λ is a locally asymptotically stable equilibrium point of (4).

All other equilibrium points H_∞ are either saddle points or maxima of ψ [9]. Thus for any neighbourhood D of some equilibrium point $H_\infty \neq \Lambda$, there exists some $H_0 \in D$ such that $\psi(H_0) < \psi(H_\infty)$. It follows that the solution to the Lie-bracket algorithm, with initial condition H_0, will not converge to H_∞ and thus H_∞ is unstable. □

Lemma 4.1 is sufficient to conclude that for generic initial conditions the Lie-bracket algorithm will converge to the unique matrix Λ. It is difficult to characterise the set of initial conditions for which the algorithm converges to some unstable equilibrium point $H_\infty \neq \Lambda$. For the continuous-time double-bracket flow, however, it is

known that the unstable basins of attraction of such points are of zero measure in $M(H_0)$ [9].

LEMMA 4.2. *Let N satisfy Condition* 2.2. *Let $d \in \mathbb{R}_+$ be a constant such that $0 < d < 1/2||H_0||_2||N||_2$ and consider the constant step-size selection scheme, $\alpha_N^d : M(H_0) \to \mathbb{R}_+$,*

$$\alpha_N^d(H) = d.$$

The Lie-bracket algorithm (4) *equipped with the step-size selection scheme α_N^d has a unique locally exponentially asymptotically stable equilibrium point Λ given by* (5).

Proof. Since α_N^d is a constant function, the time-step $\alpha_k^d = \alpha_N^d(H_k) = d$ is constant. Thus, the map

$$H_k \mapsto e^{-d[H_k,N]} H_k e^{d[H_k,N]}$$

is a differentiable map on all $M(H_0)$, and we may consider the linearisation of this map at the equilibrium point Λ given by (5). The linearisation of this recursion expressed in terms of $\Xi_k \in T_\Lambda M(H_0)$ (the tangent space of the equilibrium point Λ) is

$$\Xi_{k+1} = \Xi_k - d[(\Xi_k N - N\Xi_k)\Lambda - \Lambda(\Xi_k N - N\Xi_k)]. \tag{19}$$

Thus for the elements of Ξ_k, we have

$$(\xi_{ij})_{k+1} = [1 - d(\lambda_i - \lambda_j)(\mu_i - \mu_j)](\xi_{ij})_k \quad \text{for } i,j = 1,\dots,n. \tag{20}$$

The tangent space $T_\Lambda M(H_0)$ at Λ consists of those matrices $\Xi = [\Lambda, \Omega]$ where $\Omega \in \mathrm{Skew}(n)$, the class of skew-symmetric matrices [9, p. 53]. Thus, the matrices Ξ are parameterised by their components ξ_{ij}, where $i < j$, and $\lambda_i \neq \lambda_j$. This is a linearly independent parameterisation of $T_\Lambda M(H_0)$ and the eigenvalues of the linearisation (19) can be read directly from (20) as $1 - d(\lambda_{\pi(i)} - \lambda_{\pi(j)})(\mu_i - \mu_j)$, for $i < j$ and $\lambda_i \neq \lambda_j$. Since $\lambda_i \geq \lambda_j$ when $i > j$, then if $d < 1/2||H_0||_2||N||_2$ it follows that

$$|1 - d(\lambda_i - \lambda_j)(\mu_i - \mu_j)| < 1$$

for all $i < j$ with $\lambda_i \neq \lambda_j$. Classical stability theory gives that Λ is a locally exponentially asymptotically stable equilibrium point of the recursion (4) with an exponential rate of convergence of $\max_{i<j,\lambda_i=\lambda_j}\{d(\lambda_i - \lambda_j)(\mu_i - \mu_j)\}$. □

Remark 4.1. As $||N||_2||H_0||_2 < 2||N||||H_0||$, the constant step-size selection scheme α_N^c is an example of such a selection scheme where $c = 1/(4||H_0|| \cdot ||N||)$.

Remark 4.2. Let $\alpha_N : M(H_0) \to \mathbb{R}_+$ be a step-size selection scheme that satisfies Condition 2.1 and (7) and is also continuous on all $M(H_0)$. Let Λ be the locally asymptotically stable equilibrium point given by (5). Set $\alpha_\infty = \alpha_N(\Lambda)$ and observe that the linearisation of the Lie-bracket algorithm will be of the form (19) with d replaced by α_∞. Recall that the α_N^L, scheme defined in (18) is continuous with limit $\alpha_N^L(H_\infty) = 1/(4||H_0|| \cdot ||N||)$. Thus, Λ is an exponentially asymptotically stable equilibrium point for the Lie-bracket recursion equipped with the step-size selection scheme α_N^L.

To show that the Lie-bracket algorithm is exponentially stable at Λ for the α_N^* step-size selection scheme is technically difficult due to the discontinuous nature of α_N^* at equilibrium points. The proof of the following proposition is given in the Appendix.

PROPOSITION 4.3. *Let N satisfy assumption* (2.2) *and α_N^* be the step-size selection scheme given by Lemma* 3.4. *The iterative algorithm* (4), *has a unique exponentially attractive equilibrium point Λ given by* (5).

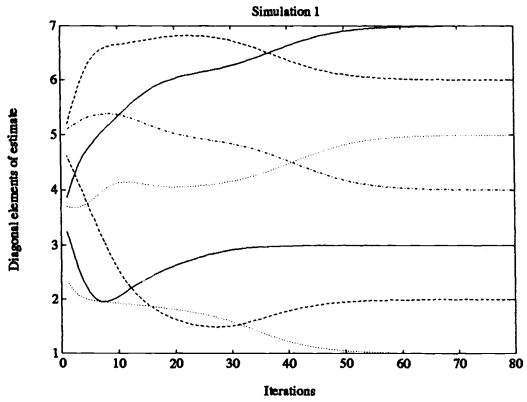

FIG. 2. *A plot of the diagonal elements h_{ii} of each iteration H_k of the Lie-bracket algorithm run on a 7×7 initial condition H_0 with eigenvalues $(1, \ldots, 7)$. The target matrix N was chosen to be* $\operatorname{diag}(1, \ldots, 7)$.

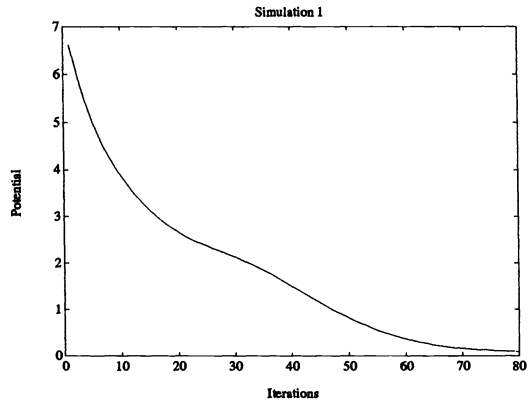

FIG. 3. *The potential $\psi(H_k) = ||H_k - N||^2$ for the Lie-bracket recursion.*

To give an indication of the behaviour of the Lie-bracket algorithm, two plots of a simulation have been included as Figs. 2 and 3. The simulation was run on a random 7×7 symmetric initial value matrix with eigenvalues $1, \ldots, 7$. The target matrix N is chosen as $\operatorname{diag}(1, \ldots, 7)$ and as a consequence the minimum potential is $\psi_\infty = 0$. Figure 2 is a plot of the diagonal entries of the recursive estimate H_k. The off-diagonal entries converge to zero as the diagonal entries converge to the eigenvalues of H_k. Figure 3 is a plot of the potential $||H_k - N||^2$ verses the iteration k. This plot clearly shows the monotonic decreasing nature of the potential at each step of the algorithm.

We summarise the results of §§2–4 in Theorem 4.4.

THEOREM 4.4. *Let $H_0 = H_0^T$ be a real symmetric $n \times n$ matrix with eigenvalues $\lambda_1 \geq \cdots \geq \lambda_n$. Let $N \in \mathbb{R}^{n \times n}$ satisfy Condition 2.2 and let α_N be either the constant step-size selection* (13) *or the variable step-size selection* (17). *The Lie-bracket*

recursion

$$H_{k+1} = e^{-\alpha_k[H_k,N]} H_k e^{\alpha_k[H_k,N]},$$
$$\alpha_k = \alpha_N(H_k),$$

with initial condition H_0, *has the following properties*:

(i) *The recursion is isospectral.*

(ii) *If* H_k *is a solution of the Lie-bracket algorithm, then* $\psi(H_k) = ||H_k - N||^2$ *is strictly monotonically decreasing for every* $k \in \mathbb{N}$, *where* $[H_k, N] \neq 0$.

(iii) *Fixed points of the recursive equation are characterised by matrices* $H \in M(H_0)$ *such that*

$$[H, N] = 0.$$

(iv) *Fixed points of the recursion are exactly the stationary points of the double-bracket equation. These points are termed* equilibrium *points.*

(v) *Let* H_k, $k = 1, 2, \ldots$, *be a solution to the Lie-bracket algorithm, then* H_k *converges to a matrix* $H_\infty \in M(H_0)$, $[H_\infty, N] = 0$, *an equilibrium point of the recursion.*

(vi) *All equilibrium points of the Lie-bracket algorithm are strictly unstable except* $\Lambda = \operatorname{diag}(\lambda_1, \ldots, \lambda_n)$, *which is locally exponentially asymptotically stable.*

5. Singular value computations. In this section we consider discretisations of continuous-time flows to compute the singular values of an arbitrary matrix.

A singular value decomposition of a matrix $H_0 \in \mathbb{R}^{m\times n}$, $m \geq n$ is a matrix decomposition

$$H_0 = V^T \Sigma U, \tag{21}$$

where $V \in O(m)$, $U \in O(n)$ and

$$\Sigma = \begin{pmatrix} \sigma_1 I_{n_1} & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \sigma_r I_{n_r} \\ & 0_{(m-n)\times n} & \end{pmatrix}. \tag{22}$$

Here $\sigma_1 > \sigma_2 > \cdots > \sigma_r \geq 0$ are the distinct singular values of H_0 occurring with multiplicities $n_1, \ldots, n_r$, such that $\sum_{i=1}^r n_i = n$. By convention the singular values of a matrix are chosen to be nonnegative. It should be noted that although such a decomposition always exists and Σ is unique, there is no unique choice of orthogonal matrices V and U. The approach we take is to define an algorithm that converges to Σ and thus computes the singular values of H_0 without directly generating the orthogonal decomposition.

Let $S(H_0)$ be the set of all orthogonally equivalent matrices to H_0,

$$S(H_0) = \{ V^T H_0 U \in \mathbb{R}^{m\times n} \mid V \in O(m),\ U \in O(n)\}. \tag{23}$$

It is shown in [9, p. 89] that $S(H_0)$ is a smooth compact Riemannian manifold with explicit forms given for its tangent space and Riemannian metric. Following [4], [5], [8], [9], and [12] we consider the task of calculating the singular values of a matrix H_0 by minimising the least squares cost function $\psi : S(H_0) \to \mathbb{R}_+$, $\psi(H) = ||H - N||^2$. It is shown in [8] and [9] that ψ achieves a unique local and global minimum at the

point $\Sigma \in S(H_0)$. Moreover, in [8], [9], and [12] the explicit form for the gradient $\nabla\psi$ is calculated. The gradient flow is

$$\begin{aligned} \dot{H} &= -\nabla\psi(H) \\ &= H\{H,N\} - \{H^T,N^T\}H, \end{aligned} \tag{24}$$

with $H(0) = H_0$ the initial condition. Here we have used a generalisation of the Lie-bracket $\{X,Y\} := X^TY - Y^TX = -\{X,Y\}^T$.

To accomplish the task of computing the singular values of a matrix we require N to satisfy the following.

CONDITION 5.1. *Let N be an $m \times n$ matrix*

$$N = \begin{bmatrix} \mu_1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \mu_n \\ & 0_{(m-n)\times n} & \end{bmatrix},$$

where $\mu_1 > \mu_2 > \cdots > \mu_n > 0$ are strictly positive, distinct real numbers.

For generic initial conditions and a target matrix N that satisfies Condition 5.1, it is known that (24) converges exponentially fast to $\Sigma \in S(H_0)$ [8], [12]. A recursive version of this flow follows from an analogous argument to that used in the derivation of the Lie-bracket algorithm. For H_0 and N constant $m \times n$ matrices, the *singular value algorithm* proposed is

$$H_{k+1} = e^{-\alpha_k\{H_k^T,N^T\}}H_k e^{\alpha_k\{H_k,N\}}. \tag{25}$$

The singular value algorithm and the Lie-bracket algorithm are closely linked as is shown in the following lemma.

LEMMA 5.1. *Let H_0, N be $m \times n$ matrices. For any $H \in \mathbb{R}^{m\times n}$ define a map $H \mapsto \widehat{H} \in \mathbb{R}^{(m+n)\times(m+n)}$, where*

$$\widehat{H} = \begin{pmatrix} 0_{m\times m} & H \\ H^T & 0_{n\times n} \end{pmatrix}. \tag{26}$$

For any sequence of real numbers α_k, $k = 1,\ldots,\infty$ the iterations

$$H_{k+1} = e^{-\alpha_k\{H_k^T,N^T\}}H_k e^{\alpha_k\{H_k,N\}} \tag{27}$$

with initial condition H_0 and

$$\widehat{H}_{k+1} = e^{-\alpha_k[\widehat{H}_k,\widehat{N}]}\widehat{H}_k e^{\alpha_k[\widehat{H}_k,\widehat{N}]} \tag{28}$$

with initial condition $\widehat{H}_0$ are equivalent.

Proof. Consider the iterative solution to (28) and evaluate the multiplication in the block form of (26). This gives two equivalent iterative solutions, one the transpose of the other, both of which are equivalent to the iterative solution to (27). □

Remark 5.1. Note that $\widehat{H}_0$ and $\widehat{N}$ are symmetric $(m+n)\times(m+n)$ matrices and that, as a result, the iteration (28) is just the Lie-bracket algorithm.

Remark 5.2. The equivalence given by Lemma 5.1 is complete in every way. In particular, H_∞ is an equilibrium point of (27) if and only if $\widehat{H}_\infty$ is an equilibrium point of (28). Similarly, $H_k \to H_\infty$ if and only if $\widehat{H}_k \to \widehat{H}_\infty$ as $k \to \infty$.

This leads us directly to consider step-size selection schemes for the singular value algorithm induced by selection schemes that we have already considered for the Lie-bracket algorithm. Indeed if $\alpha_{\widehat{N}} : M(\widehat{H_0}) \to \mathbb{R}_+$ is a step-size selection scheme for (4) on $M(\widehat{H}_0)$, and $H_k \in S(H_0)$, then we can define a time-step α_k for the singular value algorithm by

$$\alpha_k = \alpha_{\widehat{N}}(\widehat{H}_k). \tag{29}$$

Thus, if (28) equipped with a step-size selection scheme $\alpha_{\widehat{N}}$ satisfies Condition 2.1 and (7), then from Lemma 5.1, (27) will satisfy similar conditions. For simplicity, we deal only with the step-size selection schemes induced by the constant step-size selection (13) and the variable step-size selection (17). Thus we may state the main convergence theorem for the singular value algorithm.

THEOREM 5.2. *Let H_0, N be $m \times n$ matrices where $m \geq n$ and N satisfies Condition* 5.1. *Let $\alpha_{\widehat{N}} : M(\widehat{H_0}) \to \mathbb{R}_+$ be either the constant step-size selection* (13), *or the variable step-size selection* (17). *The singular value algorithm*

$$\begin{aligned} H_{k+1} &= e^{-\alpha_k\{H_k^T, N^T\}} H_k e^{\alpha_k\{H_k, N\}}, \\ \alpha_k &= \alpha_{\widehat{N}}(\widehat{H}_k), \end{aligned}$$

with initial condition H_0, has the following properties:

(i) *The singular value algorithm is a self-equivalent* (*singular value preserving*) *recursion on the manifold $S(H_0)$.*

(ii) *If H_k is a solution of the singular value algorithm, then $\psi(H_k) = ||H_k - N||^2$ is strictly monotonically decreasing for every $k \in \mathbb{N}$, where $\{H_k, N\} \neq 0$ and $\{H_k^T, N^T\} \neq 0$.*

(iii) *Fixed points of the recursive equation are characterised by matrices $H \in S(H_0)$ such that*

$$\{H_k, N\} = 0 \quad \textit{and} \quad \{H_k^T, N^T\} = 0. \tag{30}$$

Fixed points of the recursion are exactly the stationary points of the singular value gradient flow (24) *and are termed* equilibrium *points.*

(iv) *Let H_k, $k = 1, 2, \ldots$, be a solution to the singular value algorithm, then H_k converges to a matrix $H_\infty \in S(H_0)$, an equilibrium point of the recursion.*

(v) *All equilibrium points of the Lie-bracket algorithm are strictly unstable except Σ given by* (22), *which is locally exponentially asymptotically stable.*

Proof. To prove part (i), note that the generalised Lie-bracket $\{X, Y\} = -\{X, Y\}^T$ is skew-symmetric and thus (25) is an orthogonal conjugation and preserves the singular values of H_k. Also note that the potential $\psi(H_k) = \frac{1}{2}\psi(\widehat{H}_k)$. Moreover, Lemma 5.1 shows that the sequence $\widehat{H}_k$ is a solution to the Lie-bracket algorithm and thus from Proposition 2.1, $\frac{1}{2}\psi(\widehat{H}_k)$ must be monotonically decreasing for all $k \in \mathbb{N}$ such that $[\widehat{H}_k, \widehat{N}] \neq 0$, which is equivalent to (30). This proves part (ii) and part (iii) follows by noting that if $\{H_k^T, N^T\} = 0$ and $\{H_k, N\} = 0$, then $H_{k+l} = H_k$ for $l = 1, 2, \ldots$, and H_k is a fixed point of (25). Moreover, since $\psi(H_k)$ is strictly monotonic decreasing for all $\{H_k, N\} \neq 0$ and $\{H_k^T, N^T\} \neq 0$, then these points can be the only fixed points. It is known that these are the only stationary points of (24) [8], [9], [12].

To prove (iv), we need the following characterisation of equilibria of the singular value algorithm.

LEMMA 5.3. *Let N satisfy Condition 5.1 and $\alpha_{\widehat{N}}$ be either the constant step-size selection (13) or the variable step-size selection (17). The singular value algorithm (25) equipped with time-steps $\alpha_k = \alpha_{\widehat{N}}(\widehat{H}_k)$ has exactly $2^n n!/\prod_{i=1}^r (n_i!)$ distinct equilibrium points in $S(H_0)$. Furthermore, these equilibrium points are characterised by the matrices*

$$\begin{pmatrix} \pi^T & 0_{n\times(m-n)} \\ 0_{(m-n)\times n} & 0_{(m-n)\times(m-n)} \end{pmatrix} \Sigma S \pi,$$

where π is an $n \times n$ permutation matrix and $S = \operatorname{diag}(\pm 1, \ldots, \pm 1)$ a sign matrix.

Proof. Equilibrium points of (25) are characterised by the two conditions (30). For $H = (h_{ij})$, $\{H, N\} = 0$ is equivalent to

$$\mu_j h_{ji} - \mu_i h_{ij} = 0 \quad \text{for } i = 1, \ldots, n, \qquad j = 1, \ldots, n.$$

Similarly, the condition $\{H^T, N^T\} = 0$ is equivalent to

$$\begin{aligned} \mu_j h_{ij} - \mu_i h_{ji} = 0 \quad &\text{for } i = 1, \ldots, n, \qquad j = 1, \ldots, n, \\ h_{ij}\mu_j = 0 \quad &\text{for } i = n+1, \ldots, m, \qquad j = 1, \ldots, n. \end{aligned}$$

By manipulating the relationships, and using the distinct, positive nature of the μ_i, it is easily shown that $h_{ij} = 0$ for $i \neq j$. Using the fact that (25) is self equivalent, the only possible matrices of this form that have the same singular values as H_0 are characterised as above. A simple counting argument shows that the number of distinct equilibrium points is $2^n n!/\prod_{i=1}^r (n_i!)$. □

The proof of Theorem 5.2 part (iv) is now directly analogous to the proof of Proposition 2.1 part (c). It remains only to prove Theorem 5.2 part (v), which involves the stability analysis of the equilibrium points characterised by (30). It is not possible to directly apply the results obtained in §4 to the Lie-bracket recursion $\widehat{H}_k$, since the $\widehat{N}$ does not satisfy Condition 2.2. However, for the constant step-size selection scheme induced by (13), and using analogous arguments to those used in Lemmas 4.1 and 4.2, it follows that Σ is the unique locally exponentially attractive equilibrium point of the singular value algorithm. Thus, for the constant step-size selection scheme, $\widehat{\Sigma}$ is the unique exponentially attractive equilibrium point of the Lie-bracket algorithm on $M(\widehat{H}_0)$, and now the argument from Proposition 4.3 applies directly and $\widehat{\Sigma}$ is exponentially attractive for the variable step-size selection scheme (17). This completes the proof. □

Remark 5.3. Theorem 5.2 holds true for any time-steps $\alpha_k = \alpha_{\widehat{N}}(\widehat{H}_k)$ induced by a step-size selection scheme, $\alpha_{\widehat{N}}$, that satisfies Condition 2.1, such that Theorem 4.4 holds.

Remark 5.4. It is possible that for nongeneric initial conditions, the singular value algorithm may converge to a diagonal matrix with the singular values ordered in a different manner to Σ. However, all simulations run have converged exponentially fast to the unique matrix Σ, and thus it is likely that the attractive basins of the unstable equilibrium points have zero measure. Note that for the continuous-time flows, it is known that the attractive basins of the unstable equilibrium points have zero measure in $S(H_0)$ [9].

6. Associated orthogonal algorithms. In the previous sections we have proposed the Lie-bracket and the singular value algorithms that calculate the eigenvalues and singular values, respectively, of given initial conditions. Associated with these recursions are orthogonal recursions that compute the eigenvectors or singular vectors

of given initial conditions and provide a full spectral decomposition. To simplify the subsequent analysis we impose a genericity condition on the initial condition H_0.

CONDITION 6.1. *If $H_0 = H_0^T \in \mathbb{R}^{n\times n}$ is a real symmetric matrix then assume that H_0 has distinct eigenvalues $\lambda_1 > \cdots > \lambda_n$. If $H_0 \in \mathbb{R}^{m\times n}$, where $m \geq n$, then assume that H_0 has distinct singular values $\sigma_1 > \cdots > \sigma_n > 0$.*

For a sequence of positive real numbers α_k for $k = 1, 2, \ldots$ the *associated orthogonal Lie-bracket algorithm* is

$$U_{k+1} = U_k e^{\alpha_k [U_k^T H_0 U_k, N]}, \qquad U_0 \in O(n), \tag{31}$$

where $H_0 = H_0^T \in \mathbb{R}^{n\times n}$ is symmetric. For an arbitrary initial condition $H_0 \in \mathbb{R}^{m\times n}$ the *associated orthogonal singular value algorithm* is

$$\begin{aligned} V_{k+1} &= V_k e^{\alpha_k \{U_k^T H_0^T V_k, N^T\}}, \qquad V_0 \in O(m) \\ U_{k+1} &= U_k e^{\alpha_k \{V_k^T H_0 U_k, N\}}, \qquad U_0 \in O(n). \end{aligned} \tag{32}$$

Note that in each case the exponents of the exponential terms are skew-symmetric and thus the recursions will remain orthogonal.

Let $H_0 = H_0^T \in \mathbb{R}^{n\times n}$ and consider the map $g : O(n) \to M(H_0)$, $U \mapsto U^T H_0 U$, which is a smooth surjection. If U_k is a solution to (31) it follows that

$$g(U_{k+1}) = e^{-\alpha_k [g(U_k), N]} g(U_k) e^{\alpha_k [g(U_k), N]},$$

which generates the Lie-bracket algorithm (4). Thus, g maps the associated orthogonal Lie-bracket algorithm with initial condition U_0 to the Lie-bracket algorithm with initial condition $U_0^T H_0 U_0$ on $M(U_0^T H_0 U_0) = M(H_0)$.

Remark 6.1. Consider the potential function $\phi : O(n) \to \mathbb{R}_+$, $\phi(U) = ||U^T H_0 U - N||^2$ on the set of orthogonal $n \times n$ matrices. Using the standard induced Riemannian metric from $\mathbb{R}^{n\times n}$ on $O(n)$, the *associated orthogonal gradient flow* is [2], [3], [5], [9]

$$\dot{U} = -\nabla\phi(U) = U[U^T H_0 U, N].$$

THEOREM 6.1. *Let $H_0 = H_0^T$ be a real symmetric $n \times n$ matrix that satisfies Condition* 6.1. *Let $N \in \mathbb{R}^{n\times n}$ satisfy Condition* 2.2, *and let α_N be either the constant step-size selection* (13) *or the variable step-size selection* (17). *The recursion*

$$\begin{aligned} U_{k+1} &= U_k e^{\alpha_k [U_k^T H_0 U_k, N]}, \qquad U_0 \in O(n), \\ \alpha_k &= \alpha_N(H_k) \end{aligned}$$

referred to as the associated orthogonal Lie-bracket algorithm *has the following properties*:

(i) *A solution U_k, $k = 1, 2, \ldots$, to the associated orthogonal Lie-bracket algorithm remains orthogonal.*

(ii) *Let $\phi(U) = ||U^T H_0 U - N||^2$ be a map from $O(n)$ to the set of nonnegative reals $\mathbb{R}_+$. Let U_k, $k = 1, 2, \ldots$, be a solution to the associated orthogonal Lie-bracket algorithm. Then $\phi(U_k)$ is strictly monotonically decreasing for every $k \in \mathbb{N}$ where $[U_k^T H_0 U_k, N] \neq 0$.*

(iii) *Fixed points of the algorithm are characterised by matrices $U \in O(n)$ such that*

$$[U^T H_0 U, N] = 0.$$

There are exactly $2^n n!$ distinct fixed points.

(iv) *Let U_k, $k = 1, 2, \ldots$, be a solution to the associated orthogonal Lie-bracket algorithm, then U_k converges to an orthogonal matrix U_∞, a fixed point of the algorithm.*

(v) *All fixed points of the associated orthogonal Lie-bracket algorithm are strictly unstable except those 2^n points $U_* \in O(n)$ such that*

$$U_*^T H_0 U_* = \Lambda,$$

where $\Lambda = \operatorname{diag}(\lambda_1, \ldots, \lambda_n)$. Such points U_* are locally exponentially asymptotically stable and $H_0 = U_* \Lambda U_*^T$ is an eigenspace decomposition of H_0.

Proof. Part (i) follows directly from the orthogonal nature of $e^{\alpha_k [U_k^T H_0 U_k, N]}$. Note that in part (ii) the definition of ϕ can be expressed in terms of the map $g(U) = U^T H_0 U$ from $O(n)$ to $M(H_0)$ and the Lie-bracket potential $\psi(H) = ||H - N||^2$ of (1), i.e.,

$$\phi(U_k) = \psi(g(U_k)).$$

Observe that $g(U_0) = U_0^T H_0 U_0$ and thus $g(U_k)$ is the solution of the Lie-bracket algorithm with initial condition $U_0^T H_0 U_0$. As the step-size selection scheme α_N is either (13) or (17), then $g(U_k)$ satisfies (7). This ensures that part (ii) holds.

If U_k is a fixed point of the associated orthogonal Lie-bracket algorithm with initial condition $U_0^T H_0 U_0$, then $g(U_k)$ is a fixed point of the Lie-bracket algorithm. Thus, from Proposition 2.1, $[g(U_k), N] = [U_k^T H_0 U_k, N] = 0$. Moreover, if $[U_k^T H_0 U_k, N] = 0$ for some given $k \in \mathbb{N}$, then by inspection $U_{k+l} = U_k$ for $l = 1, 2, \ldots$, and U_k is a fixed point of the associated orthogonal Lie-bracket algorithm. From Lemma 2.2 it follows that if U is a fixed point of the algorithm then $U^T H_0 U = \pi^T \Lambda \pi$ for some permutation matrix π. By inspection any orthogonal matrix $W = SU\pi^T$, where S is a sign matrix $S = \operatorname{diag}(\pm 1, \ldots, \pm 1)$, is also a fixed point of the recursion, and indeed, any two fixed points are related in this manner. A simple counting argument shows that there are exactly $2^n n!$ distinct matrices of this form.

To prove (iv), note that since $g(U_k)$ is a solution to the Lie-bracket algorithm, it converges to a limit point $H_\infty \in M(H_0)$, $[H_\infty, N] = 0$ (Proposition 2.1). Thus U_k must converge to the preimage set of H_∞ via the map g. Condition 6.1 ensures that a set generated by the preimage of H_∞ is a finite distinct set, any two elements U_∞^1 and U_∞^2 of which are related by $U_\infty^1 = U_\infty^2 S$, $S = \operatorname{diag}(\pm 1, \ldots, \pm 1)$. Convergence to a particular element of this preimage follows since $\alpha_k [U_k^T H_0 U_k, N] \to 0$ as in Proposition 2.1.

To prove part (v), observe that the dimension of $O(n)$ is the same as the dimension of $M(H_0)$ due to genericity Condition 6.1. Thus g is locally a diffeomorphism on $O(n)$ that forms an exact equivalence between the Lie-bracket algorithm and the associated orthogonal Lie-bracket algorithm. Restricting g to a local region, the stability structure of equilibria are preserved under the map g^{-1}. Thus, all fixed points of the associated orthogonal Lie-bracket algorithm are locally unstable except those that map via g to the unique locally asymptotically stable equilibrium of the Lie-bracket recursion. Observe that due to the monotonicity of $\phi(U_k)$ a locally unstable equilibrium is also globally unstable. □

THEOREM 6.2. *Let $H_0 \in \mathbb{R}^{m \times n}$ where $m \geq n$ satisfies Condition* 6.1. *Let $N \in \mathbb{R}^{m \times n}$ satisfy Condition* 5.1. *Let the time-step α_k be given by*

$$\alpha_k = \alpha_{\widehat{N}}(\widehat{H}),$$

where $\alpha_{\widehat{N}}$ is either the constant step-size selection (13) *or the variable step-size selection scheme* (17), *on $M(\widehat{H}_0)$. The recursion*

$$V_{k+1} = V_k e^{\alpha_k \{U_k^T H_0^T V_k, N^T\}}, \qquad V_0 \in O(m),$$
$$U_{k+1} = U_k e^{\alpha_k \{V_k^T H_0 U_k, N\}}, \qquad U_0 \in O(n),$$

referred to as the associated orthogonal singular value algorithm, *has the following properties*:

(i) *Let (V_k, U_k) be a solution to the associated orthogonal singular value algorithm, then both V_k and U_k remain orthogonal.*

(ii) *Let $\phi(V,U) = \|V^T H_0 U - N\|^2$ be a map from $O(m) \times O(n)$ to the set of nonnegative reals $\mathbb{R}_+$, then $\phi(V_k, U_k)$ is strictly monotonically decreasing for every $k \in \mathbb{N}$ where $\{V_k^T H_0 U_k, N\} \neq 0$ and $\{U_k^T H_0^T V_k, N^T\} \neq 0$. Moreover, fixed points of the algorithm are characterised by matrix pairs $(V,U) \in O(m) \times O(n)$ such that*

$$\{V^T H_0 U, N\} = 0 \quad \textit{and} \quad \{U^T H_0^T V, N^T\} = 0.$$

(iii) *Let (V_k, U_k), $k = 1, 2, \ldots$, be a solution to the associated orthogonal singular value algorithm, then (V_k, U_k) converges to a pair of orthogonal matrices (V_∞, U_∞), a fixed point of the algorithm.*

(iv) *All fixed points of the associated orthogonal singular value algorithm are strictly unstable except those points $(V_*, U_*) \in O(m) \times O(n)$ such that*

$$V_*^T H_0 U_* = \Sigma,$$

where $\Sigma = \operatorname{diag}(\sigma_1, \ldots, \sigma_n) \in \mathbb{R}^{m \times n}$. Each such point (V_*, U_*) is locally exponentially asymptotically stable and $H_0 = V_* \Sigma U_*^T$ is a singular value decomposition of H_0.

Proof. The proof of this theorem is analogous to the proof of Theorem 6.1. □

7. Computational considerations. There are several issues involved in the implementation of the Lie-bracket algorithm as a numerical tool that have not been dealt with in the body of this paper. Design and implementation of efficient code has not been considered and would depend heavily on the nature of the hardware on which such a recursion would be run. As each iteration requires the calculation of a time-step, an exponential and a $k+1$ estimate, it is likely that it would be best to consider applications in parallel processing environments. Certainly in a standard computational environment the exponential calculation would limit the possible areas of useful application of the algorithms proposed.

It is also possible to consider approximations of the Lie-bracket algorithm that have good computational properties. For example, consider a (1,1) Padé approximation to the matrix exponential

$$e^{\alpha_k [H_k, N]} \approx \frac{2I + \alpha_k [H_k, N]}{2I - \alpha_k [H_k, N]}.$$

Such an approach has the advantage that, as $[H_k, N]$ is skew-symmetric, the Padé approximation will be orthogonal and will preserve the isospectral nature of the Lie-bracket algorithm. Similarly, an (n,n) Padé approximation of the exponential for any n will also be orthogonal. There are difficulties involved in obtaining direct step-size selection schemes based on the Padé approximate Lie-bracket algorithms. To guarantee that the potential ψ is monotonic decreasing for such schemes, direct

estimates of time-step must be chosen prohibitively small. A good heuristic choice of a step-size selection scheme, however, can be made based on the selection schemes given in this paper and simulations indicate that such an approach is viable.

Another approach is to take just the linear term from the Taylor expansion of $H_{k+1}(\alpha_k)$,

$$H_{k+1} \approx H_k + \alpha_k[H_k,[H_k,N]],$$

as an algorithm on $\mathbb{R}^{n\times n}$. An algorithm such as this is similar in form to approximating the curves generated by the Lie-bracket algorithm by straight lines. The approximation will not retain the isospectral nature of the Lie-bracket recursion; however, it is computationally cheap. Furthermore, when the curvature of the manifold $M(H_0)$ is small, then it can be imagined that the linear algorithm would be a good approximation to the Lie-bracket algorithm.

8. Conclusion. In this paper we have proposed two algorithms which, along with their associated orthogonal algorithms, calculate respectively, the eigenvalue decomposition of a symmetric matrix and the singular value decomposition of a general matrix. Moreover, we have presented two suitable step-size selection schemes which ensure that, for generic initial conditions, the algorithms proposed will converge exponentially fast to an asymptotically attractive fixed point.

In future work we hope to improve the theoretical understanding of the step-size selection schemes necessary for the Lie-bracket algorithm as well as to investigate a number of related applications of the double-bracket flow and its discretisation.

9. Appendix. The following discussion is a proof of Proposition 4.3.

Proof. By Lemma 4.1, Λ is the unique locally asymptotically stable equilibrium point and it remains to show that Λ is exponentially attractive. Note that direct linearisation techniques do not apply as the recursion will not necessarily be differentiable at the equilibrium Λ. To proceed we set $c = 1/(4||H_0|| \cdot ||N||)$, the constant time-step, and show that the Lie-bracket algorithm converges faster using the variable step-size selection scheme than it does with the constant time-step c. The proof is divided into a number of lemmas.

LEMMA 9.1. *Let $0 < \beta < \min(1, c)$, where $c = 1/(4||H_0|| \cdot ||N||)$. Then there exists a real number δ_1 such that for $H_k \in M(H_0)$ and $|||[H_k, N]|| < \delta_1$, then*

$$0 > \triangle\psi(H_k,\beta) \geq -3\beta|||[H_k,N]|||^2. \tag{33}$$

Proof. Consider the error term $\tau^2 tr(N\mathcal{R}_2(\tau))$ defined in Lemma 3.1 and recall the estimation argument for Lemma 3.3. Employing a similar argument for $\tau = \beta$ gives

$$|\beta^2 \mathrm{tr}(N\mathcal{R}_2(\beta))| \leq ||H_0|| \cdot ||N|| \cdot \left(e^{2\beta|||[H_k,N]|||} - 1 - 2\beta|||[H_k,N]|||\right).$$

Thus, combining this with (9) it follows that

$$\begin{aligned} \triangle\psi(H_k,\beta) &\geq -2\beta|||[H_k,N]|||^2 - 2\beta^2|tr(N\mathcal{R}_2(\beta))| \\ &\geq -2\beta|||[H_k,N]|||^2 - 2||H_0|| \cdot ||N|| \cdot \\ &\qquad \left(e^{2\beta|||[H_k,N]|||} - 1 - 2\beta|||[H_k,N]|||\right). \end{aligned} \tag{34}$$

It is well known that

$$2(e^y - 1 - y) \sim y^2 \quad \text{for } y \to 0^+,$$

where "$\sim$" indicates that two functions are asymptotically equal. This is equivalent to saying that for any $\epsilon > 0$, there exists $\delta(\epsilon) > 0$, such that for all y, where $\delta(\epsilon) > y > 0$, then $1 - \epsilon < 2(e^y - 1 - y)/y^2 < 1 + \epsilon$. Thus, choosing $\epsilon = \frac{1}{4}$, it follows that for $\delta(\frac{1}{4}) > y > 0$ then $2(e^y - 1 - y) < 2y^2$. Recall that we are restricting $\beta < 1$, and thus, there exists some real number $\delta_1 > 0$ such that if $||[H_k, N]|| < \delta_1$, then $2\beta||[H_k, N]|| < \delta(\frac{1}{4})$, and hence $2(e^{2\beta||[H_k,N]||} - 1 - 2\beta||[H_k, N]||) < 4\beta^2||[H_k, N]||^2$. Substituting this into (34) gives

$$\triangle\psi(H_k, \beta) \geq -2\beta||[H_k, N]||^2 - 4\beta^2||H_0|| \cdot ||N|| \cdot ||[H_k, N]||^2. \tag{35}$$

By additionally requiring that $\beta < c = 1/(4||H_0|| \cdot ||N||)$ the lemma is proved. □

LEMMA 9.2. *Let α_N^* be the step-size selection scheme given by Lemma* 3.4, *and let $\gamma \in \mathbb{R}_+$, such that $\alpha_N^*(H_k) > \gamma > 0$ for all $[H_k, N] \neq 0$. Define $\overline{\gamma} := \min\{\gamma, c\}$ and choose $\beta \in \mathbb{R}_+$ such that*

$$0 < \beta < \min\left\{1, c, \frac{2}{3}(\overline{\gamma} - 2||H_0|| \cdot ||N||\overline{\gamma}^2)\right\}.$$

Then there exists a real number $\delta_2 > 0$ such that for any $H_k \in M(H_0)$ with $||[H_k, N]|| < \delta_2$

$$-3\beta||[H_k, N]||^2 > \triangle\psi_U^*(H_k, \alpha_k^*). \tag{36}$$

Proof. Recall that α_k^* was chosen as the first critical point of the function $\triangle\psi_U^*(H_k, \tau)$. Thus $\triangle\psi_U^*(H_k, \tau)$ is monotonic decreasing on the interval $(0, \alpha_k^*)$. The lower bound $\overline{\gamma} < \gamma$, for α_N^*, must be less than α_k^*, and thus $\triangle\psi_U^*(H_k, \overline{\gamma}) > \triangle\psi_U^*(H_k, \alpha_k^*)$. Substituting $\overline{\gamma}$ into the definition of $\triangle\psi_U^*$ gives

$$\begin{aligned}
\triangle\psi_U^*(H_k, \overline{\gamma}) &= -2\overline{\gamma}||[H_k, N]||^2 \\
&\quad + \frac{||H_0|| \cdot ||[N, [H_k, N]]||}{||[H_k, N]||}\left(e^{2\overline{\gamma}||[H_k,N]||} - 1 - 2\overline{\gamma}||[H_k, N]||\right), \\
&\leq -2\overline{\gamma}||[H_k, N]||^2 \\
&\quad + 2||H_0|| \cdot ||N||\left(e^{2\overline{\gamma}||[H_k,N]||} - 1 - 2\overline{\gamma}||[H_k, N]||\right).
\end{aligned}$$

As shown in Lemma 9.1, there exists $\delta_2 > 0$, such that for any $H_k \in M(H_0)$, where $||[H_k, N]|| < \delta_2$, then $2\left(e^{2\gamma||[H_k,N]||} - 1 - 2\gamma||[H_k, N]||\right) < 4\gamma^2||[H_k, N]||^2$. Using this with the above inequality gives

$$\triangle\psi_U^*(H_k, \overline{\gamma}) \leq 2||[H_k, N]||^2\left(2||H_0|| \cdot ||N||\overline{\gamma}^2 - \overline{\gamma}\right).$$

Note that since $\overline{\gamma} < c$, then the right-hand side of the last inequality is strictly negative. Now as

$$0 < \beta < \frac{2}{3}\left(\overline{\gamma} - 2||H_0|| \cdot ||N||\overline{\gamma}^2\right),$$

then $-3\beta||[H_k, N]||^2 > 2||[H_k, N]||^2\left(2||H_0|| \cdot ||N||\overline{\gamma}^2 - \overline{\gamma}\right)$ and the result follows. □

The proof of Proposition 4.3 now follows by choosing

$$\beta = \min\left\{\begin{array}{l} 1, \\ c, \\ \frac{2}{3}\left(\overline{\gamma} - 2||H_0|| \cdot ||N||\overline{\gamma}^2\right), \end{array}\right. \tag{37}$$

where $\overline{\gamma} = \min(\gamma, c)$. Thus, from Lemmas 9.1 and 9.2, choose δ_1 and δ_2 such that the results hold and set $\delta = \frac{1}{2} \min \{\delta_1, \delta_2\}$. Hence, combining the inequalities (33) and (36) gives

$$\triangle\psi(H_k, \alpha_k^*) < \triangle\psi(H_k, \beta) < 0 \tag{38}$$

for all $H_k \in M(H_0)$ with $|||[H_k, N]||| < \delta$.

Let D_δ be some open set around Λ such that $|||[H_k, N]||| < \delta$. Note that $\beta \leq c$, and thus from Lemma 4.2 the Lie-bracket algorithm equipped with $\alpha_N^\beta = \beta$ as a step-size selection scheme is exponentially stable. Finally, note that within D_δ, and due to (38), $\psi(H_{k+1}(\alpha_k^*))$ will always decrease faster than $\psi(H_{k+1}(\beta))$, regardless of H_k. Since Λ is exponentially attractive for the Lie-bracket algorithm equipped with the selection scheme α_N^β, it follows that Λ must also be exponentially attractive for the same recursion equipped with the selection scheme α_N^*. □

Acknowledgments. The authors would like to thank Kenneth Driessel and Wei-Yong Yan for many useful comments. Also the authors thank an anonymous referee for mentioning the connection of the double-bracket flow to micromagnetics as well as a number of useful comments.

A NOTE ON EXTREME CORRELATION MATRICES*

CHI-KWONG LI† AND BIT-SHUN TAM‡

Abstract. An $n \times n$ complex Hermitian or real symmetric matrix is a correlation matrix if it is positive semidefinite and all its diagonal entries equal one. The collection of all $n \times n$ correlation matrices forms a compact convex set. The extreme points of this convex set are called extreme correlation matrices. In this note, elementary techniques are used to obtain a characterization of extreme correlation matrices and a canonical form for correlation matrices. Using these results, the authors deduce most of the existing results on this topic, simplify a construction of extreme correlation matrices proposed by Grone, Pierce, and Watkins, and derive an efficient algorithm for checking extreme correlation matrices.

Key words. correlation matrix, extreme point, perturbation, rank, linear span

AMS subject classification. 15A48

Let $\mathcal{M} = \mathcal{H}_n$ or $\mathcal{S}_n$, the real linear space of all $n \times n$ Hermitian matrices and the real linear space of all $n \times n$ symmetric matrices, respectively. A positive semidefinite matrix $A = (a_{ij}) \in \mathcal{M}$ with $a_{11} = \cdots = a_{nn} = 1$ is called a *correlation matrix.* The term correlation matrix comes from statistics, where the entries of a real correlation matrix occur as correlations between pairs of random variables. It is easy to see that the collection of $n \times n$ correlation matrices forms a compact convex set, and we are interested in its extreme points. Recall that an element x in a convex set S is an *extreme point* if $x = ty + (1-t)z$ for $y, z \in S$ and $0 < t < 1$ implies $y = z = x$, that is, if x can be a convex combination of points of S in only trivial ways.

We shall call an extreme point of the set of correlation matrices an *extreme correlation matrix.* This concept has been studied in [1], [4], and [2]. In those papers, different approaches were used to determine all possible ranks of extreme correlation matrices, to construct extreme correlation matrices of different ranks, and to give simple characterizations of extreme correlation matrices in low dimensional cases. In this note, we use an elementary approach to prove several results on the subject. Using our results, one can deduce easily all of the main results in the three papers mentioned above. Moreover, we simplify a construction of extreme correlation matrices proposed in [2], derive an efficient algorithm for checking extreme correlation matrices, and compare our condition with the one given in [4]. A question posed in [2] is also discussed.

In the following we shall concentrate mainly on the Hermitian case, the slightly more difficult case. For the real case, we also give some results that have no analogs in the Hermitian case.

1. Basic results. Given an $n \times n$ correlation matrix A, a nonzero Hermitian matrix B is said to be a *perturbation* of A if $A \pm tB$ are correlation matrices for some

*Received by the editors March 22, 1992; accepted for publication (in revised form) November 20, 1992.

(and hence for all sufficiently small) $t > 0$. Clearly, A is not extreme if and only if A has a perturbation. In fact, if $A = (A_1 + A_2)/2$ for two distinct correlation matrices A_1 and A_2, then $B := (A_1 - A_2)/2$ is such that $A \pm B$ are correlation matrices. We give a characterization of perturbations of a given correlation matrix and a characterization of extreme correlation matrices in the following theorem.

THEOREM 1. *Let $A \in \mathcal{H}_n$ be an $n \times n$ correlation matrix of rank r. Suppose that $A = XQX^*$, where $X \in \mathbb{C}^{n\times r}$ and $Q \in \mathcal{H}_r$. Then*

(a) *$B \in \mathcal{H}_n$ is a perturbation of A if and only if all diagonal entries of B equal zero and $B = XRX^*$ for some nonzero $R \in \mathcal{H}_r$, and*

(b) *A is extreme if and only if*

$$\operatorname{span}\{x_j x_j^* : 1 \le j \le n\} = \mathcal{H}_r,$$

where x_j is the jth column of X^*.

Proof. With the notation of the theorem, one sees easily that $\operatorname{rank} X = r$ and Q is positive definite.

(a) Let B be a matrix with all diagonal entries equal to zero and of the form XRX^* for some nonzero $R \in \mathcal{H}_r$. Since X is a matrix of full column rank, we have $\operatorname{rank} XRX^* = \operatorname{rank} R > 0$. Thus B is nonzero. Since Q is positive definite, $Q \pm tR$ is positive semidefinite for all sufficiently small $t > 0$. It follows that B is a perturbation of A. Conversely, suppose B is a perturbation of A. Evidently, all diagonal entries of B equal zero. Append to X an $n \times (n - r)$ matrix Y such that the $n \times n$ matrix $V = (X|Y)$ is nonsingular. Clearly A can be expressed as $V(Q \oplus 0_{n-r})V^*$. Write B as VCV^*, where $C \in \mathcal{H}_n$. Partition C in the same way as $Q \oplus O_{n-r}$. Since B is a perturbation of A, $(Q \oplus O_{n-r}) \pm tC$ is positive semidefinite for some $t > 0$. It follows that except for its $(1,1)$ block, which we denote by R, the blocks of C are all zero. Hence B is of the form XRX^*, with $0 \ne R \in \mathcal{H}_r$.

(b) Since A is not extreme if and only if it has a perturbation, by part (a) one sees that A is extreme if and only if for any $R \in \mathcal{H}_r$, $R = 0$ whenever all diagonal entries of XRX^* equal zero. In terms of the usual inner product on $\mathcal{H}_r$ defined by $\langle X, Y\rangle = tr(XY)$, we can reformulate the last condition as: $R = 0$ whenever $\langle R, x_j x_j^*\rangle = 0$ for all j, $1 \le j \le n$; or equivalently, $\operatorname{span}\{x_j x_j^* : 1 \le j \le n\} = \mathcal{H}_r$. Thus our result follows. □

Notice that for a given rank r positive semidefinite matrix A, there are two standard ways to decompose it as XQX^*. One way is to take Q to be a diagonal matrix whose diagonal entries are all the nonzero eigenvalues of A and form the matrix X whose columns are the corresponding eigenvectors. Another way is to find X such that $A = XX^*$, i.e., to take $Q = I_r$. In both cases, there are standard algorithms and computer programs to do the decomposition.

From Theorem 1 and its real analog, one easily deduces the following result proved in [1] (for the Hermitian case) and [2] (for the real case).

COROLLARY 2. *If A is an $n \times n$ extreme Hermitian (respectively, real symmetric) correlation matrix of rank r, then $r^2 \le n$ (respectively, $r(r+1) \le 2n$).*

In [4] and [2] it is shown that if r satisfies the inequality in the corollary, then there exists a rank r extreme correlation matrix. One can verify the constructions of extreme correlation matrices in those papers using our Theorem 1. We shall suggest a construction after proving Theorem 3. To state the result, we need the following definition and notation. A matrix is a (real) generalized permutation matrix if it is a unitary (respectively, real orthogonal) matrix with exactly one nonzero entry in each row and each column. Denote by $J_{r,s}$ the $r \times s$ matrix all of whose entries equal 1. For simplicity we use J_r to represent $J_{r,r}$.

THEOREM 3. *Let $A \in \mathcal{H}_n$. Then A is a correlation matrix if and only if there exists a generalized permutation matrix P such that $PAP^* = (B_{st})$, a $p \times p$ block matrix with $B_{st} = b_{st} J_{k(s),k(t)}$, $(k(1)+\cdots+k(p) = n)$, where $(b_{st}) \in \mathcal{H}_p$ is a correlation matrix all of whose off-diagonal entries have moduli less than one. Furthermore, we have*

(a) $\operatorname{rank} A = \operatorname{rank} (b_{st})$;

(b) *A is extreme if and only if (b_{st}) is extreme.*

Proof. To prove the "only if" part, express A in the form XX^*, where $X \in \mathbb{C}^{n \times r}$ and $r = \operatorname{rank} A$. Denote the jth column of X^* by x_j. Since each diagonal entry of A is equal to 1, each x_j is a vector of unit length. Now permute the rows of X and then multiply each row with a suitable scalar of absolute value one so that rows of X that differ by unit multiples are grouped together and become equal. The resulting effect on X is equivalent to applying a generalized permutation similarity to A. Since the inner product between any two linearly independent unit vectors always has modulus less than one, A is transformed to the required form. That (b_{st}) is a correlation matrix follows from the observation that it is a principal submatrix of A of the required form.

To prove the "If" part, suppose $A = (B_{st})$ as described in the theorem. It is clear that $A \in \mathcal{H}_n$ and its main diagonal entries are all equal to one. Note that we can write $J_{k(s),k(t)}$ as $\tilde{e}_{k(s)} \tilde{e}_{k(t)}^t$, where $\tilde{e}_j$ denotes the $j \times 1$ vector of all 1's. If $x_j \in \mathbb{C}^{k(j)}$ for $j = 1, \ldots, p$, then by direct calculations, the value of the quadratic form of A at x with $x^* = (x_1^*, \ldots, x_p^*)$ is equal to the value of the quadratic form of $(b_{st}) \in \mathcal{H}_p$ at $\tilde{x} = (\tilde{e}_{k(1)}^t x_1, \ldots, \tilde{e}_{k(p)}^t x_p)^t$ and so is nonnegative.

It is not difficult to show that $\operatorname{rank} A = \operatorname{rank} (b_{st})$. That A is extreme if and only if (b_{st}) is extreme follows readily from Theorem 1. □

Notice that the real analog of Theorem 3 also holds. To obtain the statement and the proof for the real case, one only needs to replace $\mathcal{H}_n$ by $\mathcal{S}_n$, generalized permutation matrices by real generalized permutation matrices, complex scalars by real scalars, etc.

Notice that the matrix (B_{st}) in Theorem 3 is a *block Kronecker product* of the matrices (b_{st}) and $(J_{k(s),k(t)})$. We refer the readers to [3] and its references for the definition and properties of this product.

2. A construction and an algorithm. There are at least two ways that Theorem 3 can help to study extreme correlation matrices. First, it helps to reduce the dimension of a problem under consideration. Second, if one can find an $n \times n$ rank r extreme correlation matrix, then one can use Theorem 3 to construct an $m \times m$ rank r extreme correlation matrices for any $m \geq n$. We illustrate the latter idea by describing a construction of extreme correlation matrices. (Note that this construction is a modification of the one given in [2].)

2.1. Construction of extreme correlation matrices. By the preceding discussion, for a given r it suffices to construct an $n \times n$ rank r extreme correlation matrix for $n = r^2$ in the Hermitian case, and for $n = r(r+1)/2$ in the real case. Then one can get an $m \times m$ rank r extreme correlation matrix for any $m \geq n$. We shall again use e_j to denote the jth column of I_r.

For the Hermitian case, assume $n = r^2$. Set $A = XX^*$ with $X \in \mathbb{C}^{n \times r}$ such that the first r columns of X^* form I_r, the next $r(r-1)/2$ columns consist of vectors of the form $(e_s + e_t)/\sqrt{2}$ with $1 \leq s < t \leq r$, and the rest of the $r(r-1)/2$ columns consist of vectors of the form $(e_s + ie_t)/\sqrt{2}$. Using Theorem 1, one verifies readily that $A \in \mathcal{H}_n$ is an extreme correlation matrix.

For the real case, assume $n = r(r+1)/2$. Let $\tilde{A} = \tilde{X}\tilde{X}^t$ where $\tilde{X}$ is obtained

from X constructed in the Hermitian case by deleting the last $r(r-1)/2$ rows. Again by Theorem 1, one can show easily that $\tilde{A} \in \mathcal{S}_n$ is an extreme correlation matrix.

2.2. An algorithm for checking extreme correlation matrices. By Theorems 1, 3 (and its proof), and Corollary 2, one derives readily the following algorithm to determine whether a given Hermitian correlation matrix is extreme. A similar algorithm also holds for the real case.

Step 1. Express A as XX^*, where $X \in \mathbb{C}^{n\times r}$, $r = \operatorname{rank} A$.

Step 2. Form a matrix Y from the distinct (up to unit multiples) rows of X. Say $Y \in \mathbb{C}^{p\times r}$. (Then YY^* is equal to the matrix (b_{st}) as given in Theorem 3.)

Step 3. Determine $\operatorname{rank} Y$. If $\operatorname{rank} Y = r$ satisfies $r^2 > p$, then A is not extreme. Otherwise, proceed to Step 4.

Step 4. Determine the dimension of $\operatorname{span}\{y_j y_j^* : 1 \le j \le p\}$, where y_j is the jth column of Y^*. It is r^2 if and only if A is extreme.

An efficient way to perform Step 4 is to construct a $p \times r^2$ matrix F as follows. For each j between 1 and p, the first r entries of the jth row of F are $|y_{j1}|^2, |y_{j2}|^2, \dots, |y_{jr}|^2$, arranged in the natural order, and its remaining $r^2 - r$ entries $y_{jk}\overline{y}_{jl}, \overline{y}_{jk}y_{jl}$, $1 \le k < l \le r$ (indexed by ordered pairs (k,l), and with conjugate entries adjacent) are arranged in the usual lexicographic order. Then $\operatorname{rank} F = \dim \operatorname{span}\{y_j y_j^* : 1 \le j \le p\}$.

Explanation. Consider the following real subspace of $\mathbb{C}^{r^2}$:

$$W = \{(t_1, \dots, t_{r^2})^t : t_j \in \mathbb{R}, \quad j = 1, \dots, r; \qquad \text{and}$$
$$t_{r+2m-1} = \overline{t}_{r+2m}, \quad m = 1, \dots, (r^2 - r)/2\}.$$

Note that the real span of the row vectors of F is included in W, and is isomorphic with the subspace of $\mathcal{H}_r$ spanned by $\{y_j y_j^* : 1 \le j \le p\}$. But any set of vectors in W that is linearly independent over $\mathbb{R}$ is also linearly independent over $\mathbb{C}$, so $\operatorname{rank} F = \dim \operatorname{span}\{y_j y_j^* : 1 \le j \le p\}$.

Notice that the equivalent condition in [4] for an extreme correlation matrix can also be deduced readily as follows. Denote by f_j^t the jth row of F. Note that the vectors $f_1, \dots, f_p$ all lie in the (real) hyperplane $\{f = (f_1, \dots, f_{r^2})^t \in W : \sum_{i=1}^{r} f_j = 1\}$ of W (since the row vectors of Y are of unit length, as YY^* is a correlation matrix). But this hyperplane does not contain the zero vector, so we have

$$\begin{aligned}\dim \operatorname{span}\{f_j : 1 \le j \le p\} &= 1 + \dim \operatorname{span}\{f_j - f_p : 1 \le j \le p-1\} \\ &= 1 + \dim \operatorname{span}\{f_j - f_{j+1} : 1 \le j \le p-1\}.\end{aligned}$$

Denote by D_A the $(p-1)\times r^2$ matrix whose jth row is $(f_j - f_{j+1})^t$. Then A is extreme if and only if $r^2 = \dim \operatorname{span}\{f_j : 1 \le j \le p\} (= \operatorname{rank} F)$ if and only if $\operatorname{rank} D_A = r^2 - 1$, which is the condition given in [4]. (In [4] the matrix D_A is obtained from the matrix X instead of from Y. But this does not affect our argument.)

3. Further results. We first consider two results that are valid only for the real case.

COROLLARY 4. *Let $A \in \mathcal{S}_n$ be a rank two correlation matrix. Suppose P is a real generalized permutation matrix such that PAP^t is equal to (B_{st}), a $p \times p$ block matrix that satisfies the conditions as given in Theorem* 3. *Then A is extreme if and only if $p \ge 3$.*

Proof. "Only if" part. Since $\operatorname{rank} A = \operatorname{rank}(b_{st})$, p cannot be 1. If $p = 2$, then (b_{st}) is not extreme since it is nonsingular, and hence A is also not extreme according to Theorem 3.

"If" part. Suppose that A is not extreme. Since $\operatorname{rank} A = 2$, each (relative) boundary point of the face (of the set of $n \times n$ correlation matrices) generated by A is a matrix of rank one. So there exist two rank one correlation matrices A_1, A_2 such that $A = \lambda A_1 + (1-\lambda)A_2$ for some λ with $0 < \lambda < 1$. By applying a generalized permutation similarity to A, we may assume that $A_1 = J_n$ and

$$A_2 = \begin{pmatrix} J_k & -J_{k,n-k} \\ -J_{k,n-k} & J_{n-k} \end{pmatrix}$$

for some k between 1 and $n-1$. But then we have

$$A = \begin{pmatrix} J_k & \alpha J_{k,n-k} \\ \alpha J_{n-k,k} & J_{n-k} \end{pmatrix},$$

where $\alpha = \lambda + (-1)(1-\lambda)$ is of absolute value less than one. So in this case, $p = 2$. □

COROLLARY 5. *A 3×3 real symmetric correlation matrix of rank two is extreme if and only if its off-diagonal entries all have absolute values less than one.*

Two remarks are in order. First, by Corollaries 4 and 5, one sees that a rank two correlation matrix $A \in \mathcal{S}_n$ is extreme if and only if A has a principal submatrix that is an extreme 3×3 correlation matrix.

Second, the "if" parts of Corollaries 4 and 5 are both invalid in the Hermitian case. Indeed, for any $n \geq 2$, if we take A_n to be the matrix $(J_n + uu^*)/2$, where $u = (1, \mu, \ldots, \mu^{n-1})^t$, μ a primitive nth root of unity, then A_n is a nonextreme Hermitian correlation matrix of rank two, all of whose off-diagonal entries have moduli less than one.

By Theorem 1, we have the following observation for rank two correlation matrices in $\mathcal{H}_n$.

OBSERVATION. *Suppose $A = XQX^* \in \mathcal{H}_n$ with $X \in \mathbb{C}^{n\times 2}$ and $Q \in \mathcal{H}_2$ is a rank two correlation matrix. Let S be a 2×2 nonsingular submatrix of X^*. Then A is extreme if and only if there are two column vectors $u = (u_1, u_2)^t$ and $v = (v_1, v_2)^t$ of the matrix $S^{-1}X^*$, such that $\overline{u}_1 u_2$ and $\overline{v}_1 v_2$ are complex numbers that are not nonzero real multiples of each other.*

In the lemma in [2], it was shown that an equivalent condition for a real symmetric correlation matrix to be extreme is that its nullspace is maximal among the nullspaces of all correlation matrices. (The corresponding result for the Hermitian case also holds.) Clearly another equivalent condition is that the range space of the matrix is minimal among the range spaces of all correlation matrices. In [2] the authors also posed the question of determining the structure of the nullspace of a correlation matrix. Below we give an answer to the dual question of characterizing the linear subspaces of $\mathbb{C}^n$ (also $\mathbb{R}^n$) that can be the range space of a correlation matrix.

THEOREM 6. *A subspace of $\mathbb{C}^n$ (or $\mathbb{R}^n$) is the range space of a correlation matrix if and only if it has a basis (or a spanning set) $\{v_1, \ldots, v_r\}$ such that $\sum_{j=1}^r v_j \circ \overline{v}_j = (1, \ldots, 1)^t \in \mathbb{R}^n$, where $\overline{x}$ denotes the complex conjugate of the vector x, and $x \circ y$ denotes the Schur (Hadamard/entrywise) product of x and y.*

Proof. Suppose W is the range space of the correlation matrix A. Let $A = XX^*$ with $X \in \mathbb{C}^{n\times r}$, where $r = \operatorname{rank} A$. Then the columns of X form a basis for W that satisfies the required properties.

Conversely, if W is a subspace that has a spanning set as described in the theorem, then $A = XX^*$, where the columns of $X \in \mathbb{C}^{n\times r}$ are the vectors from the spanning set, is the required correlation matrix. □

COROLLARY 7. *A subspace of* $\mathbb{C}^n$ *(or* $\mathbb{R}^n$*) is the nullspace of a correlation matrix if and only if its orthogonal complement has a spanning set satisfying the condition in Theorem* 6.

Note added in proof. After the paper had been accepted for publication, the authors found that a slight modification of the proof of Theorem 1 yields the following result that covers [1, Thm. 3].

THEOREM 8. *Under the hypotheses and notation of Theorem* 1, *the face of the convex set of* $n \times n$ *correlation matrices generated by* A *is of dimension*

$$r^2 - \dim \operatorname{span} \{x_j x_j^* : 1 \leq j \leq n\}.$$

Proof. It is clear that the dimension of the face generated by A is equal to the dimension of the space generated by the perturbations of A. According to Theorem 1(a) (or its proof), a nonzero matrix is a perturbation of A if and only if it is of the form XRX^*, where X is $n \times r$ and R is $r \times r$ lying in the orthogonal complement of $\operatorname{span}\{x_j x_j^* : 1 \leq j \leq n\}$. Since X has full column rank, the mapping $R \mapsto XRX^*$ is a linear isomorphism. □

Acknowledgment. The authors wish to thank Dr. H.J. Woerdeman for drawing their attention to this subject. Thanks are also due to Dr. R. Horn and the referees for their helpful comments that improved our exposition.

ON PRECONDITIONING FOR FINITE ELEMENT EQUATIONS ON IRREGULAR GRIDS*

ALISON RAMAGE† AND ANDREW J. WATHEN‡

Abstract. Preconditioning methods are widely used in conjunction with the conjugate gradient method for solving large sparse symmetric linear systems arising from the discretisation of selfadjoint linear elliptic partial differential equations. Many different preconditioners have been proposed, and they are generally analysed and compared using model problems: simple discretisations of Laplacian operators on regular computational grids, generally in two space dimensions. For such model problems there are highly competitive multigrid methods, and it is principally for geometrically irregular (nonmodel) problems that the applicability and economy of preconditioned conjugate gradient methods are most useful. This is particularly true for problems on irregular unstructured three-dimensional grids.

This paper is concerned with the comparison of preconditioners for finite element discretisations of three-dimensional selfadjoint elliptic problems on irregular and unstructured computational grids. It is argued that simple preconditioners, which are inferior for regular grid problems in two dimensions, are competitive for irregular grid problems in three dimensions.

Key words. finite elements, irregular grids, preconditioned conjugate gradients

1. Introduction.

When faced with choosing a method for solving a partial differential equation on an irregular domain, one possibility is certainly the finite element method. This is a well established and widely used technique that has many attractive approximation properties, e.g., [20]. As with other numerical methods for solving partial differential equations, using the finite element method involves some form of discretisation of the problem domain. A basic decision must therefore be made: Should this be done in a regular or irregular way? It is true that problems on oddly shaped domains can be tackled by using very fast methods on regular finite element grids that are highly refined near irregular features or perhaps on a series of superimposed regular grids. Nevertheless, practical problems may well be best modelled using unstructured grids: for example, if irregular geometries are fitted exactly they are often easier to deal with in terms of grid visualisation. Furthermore, an irregular discretisation will frequently have the practical advantage of covering the whole domain in a smaller number of elements than will a regular grid. In the light of such observations, here we consider the topic of solving finite element equations with particular reference to unstructured grids.

Applying the Galerkin finite element method to a second order selfadjoint elliptic partial differential equation gives rise to a linear system

$$A\mathbf{x} = \mathbf{b}, \tag{1.1}$$

where the real coefficient matrix A is symmetric, positive definite, and, in most practical applications, large and sparse. As the direct solution of such a system can be

prohibitively expensive, one popular approach is to use the iterative *preconditioned conjugate gradient* (PCG) method (see, e.g., Concus, Golub, and O'Leary [5]).

The construction of appropriate preconditioners for use with this method is a popular topic of current research and a wide range of preconditioners have been developed that work very efficiently on regular grids, particularly in two dimensions (see, e.g., [3], [8]). However, the effect on the performance of a preconditioner of using an irregular finite element grid is one research area that is often neglected. In the literature, the most common comparison of the performance of various preconditioners is on regular grid problems in two dimensions, but results in such cases do not always translate to irregular geometries (or three dimensions). Developing rigorous theory for irregular problems has proved to be much more difficult than for analogous regular grids and, as a result, many aspects of working with irregular finite element geometries are less understood.

In this paper we adopt an algebraic representation of the finite element process that has been used previously by the second author to derive various properties of finite element matrices [25], [26]. Its general nature means that it can be particularly helpful in the analysis of irregular grid problems. We begin by extending the work of the second author to find easily computed eigenvalue bounds for a class of finite element matrices on irregular grids. In addition, we obtain (weak) bounds on the interior eigenvalues of a general finite element matrix. These can be useful for predicting the rate of convergence of the PCG method (see, e.g., [18], [22]). In §3 we discuss asymptotic estimates for the work involved in implementing some preconditioning methods. This introduces different considerations when choosing a preconditioner for problems on three-dimensional irregular grids. Section 4 contains a result concerning the effect of a certain class of element-based preconditioners on the matrix condition number, which is again relevant to the rate of PCG convergence. Finally, we present a numerical comparison of three PCG methods on some highly irregular three-dimensional finite element grids.

2. Eigenvalue bounds. To analyse irregular grids we introduce an algebraic representation of finite element matrices. Suppose that the finite element grid contains elements $e = 1, \ldots, E$ with V_e local unknowns on each element, giving a total of N global unknowns. The Galerkin finite element coefficient matrix A can be written as

$$A = L^T[A_e]L, \tag{2.1}$$

where $[A_e]$ represents an $[E.V_e \times E.V_e]$ block diagonal matrix whose $[V_e \times V_e]$ diagonal blocks are the element-calculated coefficient matrices. L is an $[E.V_e \times N]$ Boolean connectivity matrix that contains all the necessary information about the grid structure [26]. This notation applies to any grid regardless of irregularity and type of element used, as all connectivity information is stored in the Boolean matrix L.

The rate of convergence of the PCG method depends on the eigenvalue distribution of the preconditioned coefficient matrix (see, e.g., [9], [18], [22]), and the standard estimate for the number of iterations required to achieve a certain level of convergence is usually given in terms of the matrix condition number. For a symmetric positive definite matrix, this is the ratio of its largest eigenvalue to smallest eigenvalue. A useful result of Wathen [25], then, is that if $\{B_e\}$ is any set of $[V_e \times V_e]$ symmetric positive definite matrices and a preconditioner B is formed from

$$B = L^T[B_e]L, \tag{2.2}$$

then the eigenvalues of the global matrix $B^{-1}A$ must satisfy

$$\min_e \lambda_{\min}(B_e^{-1}A_e) \leq \lambda(B^{-1}A) \leq \max_e \lambda_{\max}(B_e^{-1}A_e), \tag{2.3}$$

where $\lambda_{\min}$ and $\lambda_{\max}$ are the extreme eigenvalues of the preconditioned element matrix $B_e^{-1}A_e$.

The bounds given by (2.3) apply to any grid regardless of irregularity. The assembly notation (2.1) has been used by the second author to give eigenvalue bounds for diagonal scaling of mass and stiffness matrices using various elements on regular grids in two and three dimensions [24], [25]. Here we extend this analysis to irregular grids using the example of a two-dimensional grid of linear triangles with preconditioner $B = \text{diag}A$. By examining the diagonally scaled element matrices and applying (2.3), we can obtain global eigenvalue bounds for both the finite element mass and stiffness matrices.

For an arbitrary triangle of area S_e with angles θ_i and opposite sides of length s_i ($i = 1, 2$ or 3), respectively, the element mass matrix is

$$M_e = \frac{S_e}{12}\begin{bmatrix} 2 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 2 \end{bmatrix} \tag{2.4}$$

(see, e.g., [3, p. 259]). When diagonal scaling is applied, the eigenvalues of $D_e^{-1}M_e$ (where $D_e = \text{diag}M_e$) are $\frac{1}{2}$, $\frac{1}{2}$, and 2, which means that the eigenvalues of the diagonally scaled global mass matrix all lie in the interval $[\frac{1}{2}, 2]$.

The element stiffness matrix is

$$K_e = \frac{1}{2}\begin{bmatrix} \cot\theta_2 + \cot\theta_3 & -\cot\theta_3 & -\cot\theta_2 \\ -\cot\theta_3 & \cot\theta_1 + \cot\theta_3 & -\cot\theta_1 \\ -\cot\theta_2 & -\cot\theta_1 & \cot\theta_1 + \cot\theta_2 \end{bmatrix} \tag{2.5}$$

(see, e.g., [3, p. 415]). The eigenvalues of $D_e^{-1}K_e$ (where $D_e = \text{diag}K_e$) can be found algebraically to be

$$\begin{Bmatrix} 0 \\ \frac{3}{2} \pm \frac{1}{2}\left\{9 - 8\left[\frac{S_e \sin 2\theta_i}{s_i^2} + \sin^2\theta_i\right]\right\}^{1/2} \end{Bmatrix} \tag{2.6}$$

(see the Appendix). The minimum eigenvalue (and hence the lower bound in (2.3)) will always be zero because the element stiffness matrix is singular. For an upper bound, the maximum value of (2.6) occurs on the triangle in the grid that contains the largest angle. This means that for any finite element grid, a global upper eigenvalue bound can be found from (2.3) by identifying the triangle that contains the largest angle and finding the appropriate element matrix eigenvalues. In the regular grid case this is trivial as all elements (and hence all element matrices) are the same. It is not clear how easy it would be to identify such an element on a very large irregular grid. Note that the minimum value of the maximum eigenvalue in (2.6) occurs when the grid is "most regular"; that is, when all triangles are equilateral (the eigenvalues will be 0, $\frac{3}{2}$, and $\frac{3}{2}$). This result reflects the intuitive view that it is desirable to distort the elements of any grid as little as possible, which is the philosophy behind Delaunay triangularisation (see, e.g., [13]). It is also compatible with the angle condition for triangles given by Strang and Fix [20, p. 106] to guarantee the uniform finite element

approximation of derivatives. Because of the general nature of (2.3), analogous results could be derived for many other element types.

In addition to this estimate of the extreme eigenvalues, we can obtain bounds on the interior eigenvalues of a general finite element matrix using the above notation with the Cauchy Interlace Theorem (see, e.g., [17]). We recall that we have chosen the element matrices B_e to be symmetric and positive definite for $e = 1, \ldots, E$. Since the $[E.V_e \times N]$ matrix L is always of full rank, we can extend L to be an $[E.V_e \times E.V_e]$ nonsingular matrix $[L|J]$ with $L^T[B_e]J = 0$. Thus we can define

$$\widetilde{A} = [L|J]^T[A_e][L|J] = \begin{bmatrix} A & A_1 \\ A_1^T & A_2 \end{bmatrix}, \tag{2.7}$$

where $A_1 = L^T[A_e]J$ and $A_2 = J^T[A_e]J$ and

$$\widetilde{B} = [L|J]^T[B_e][L|J] = \begin{bmatrix} B & 0 \\ 0 & B_2 \end{bmatrix}, \tag{2.8}$$

where $B_2 = J^T[B_e]J$ is symmetric and positive definite.

Now,

$$(\widetilde{A} - \mu\widetilde{B}) \text{ is singular} \Leftrightarrow [L|J]^T([A_e] - \mu[B_e])[L|J] \text{ is singular}, \tag{2.9}$$

which implies that the eigenvalues of $\widetilde{B}^{-1}\widetilde{A}$ are precisely the eigenvalues of the element preconditioned matrices $B_e^{-1}A_e, e = 1, \ldots, E$. That is, the eigenvalues $\mu_1 \leq \cdots \leq \mu_{E.V_e}$ say, of $\widetilde{B}^{-1}\widetilde{A}$ are all obtainable from simple calculations on the elements. Although the number of elements may be large, each calculation will involve finding the eigenvalues of a $V_e \times V_e$ matrix where, in practice, V_e is usually small. Thus the computational complexity of such an operation would be linear in the number of elements. Furthermore, such independent calculations are obviously suited to parallel computation. On a regular grid, all element matrices will be identical so the calculation of the μ_e in this case would be trivial. Now

$$\widetilde{B}^{-1/2}\widetilde{A}\widetilde{B}^{-1/2} = \begin{bmatrix} B^{-1/2}AB^{-1/2} & B^{-1/2}A_1B_2^{-1/2} \\ B_2^{-1/2}A_1^TB^{-1/2} & B_2^{-1/2}A_2B_2^{-1/2} \end{bmatrix} \begin{matrix} \} & N, \\ \} & E.V_e - N, \end{matrix} \tag{2.10}$$

and hence the Cauchy Interlace Theorem [17] can be directly applied to give

$$\mu_i \leq \lambda_i \leq \mu_{i+E.V_e-N} \tag{2.11}$$

for $i = 1, \ldots, N$, where $\lambda_1 \leq \cdots \leq \lambda_N$ are the eigenvalues of $B^{-1}A$.

The eigenvalue bounds (2.11) are usually weak since N is often significantly less than $E.V_e$. Nevertheless, the result has some useful and obvious applications. For example, on an irregular grid with a small number, p say, of "bad" (highly distorted) elements that give rise to p relatively small eigenvalues $\mu_i \ll \mu_{p+1}$ for $i = 1, \ldots, p$, (2.11) implies that there are at most p relatively small eigenvalues of the preconditioned global matrix $B^{-1}A$.

3. Asymptotic work estimates. As stated above, many preconditioners that are used with the PCG method have attractive theoretical convergence estimates for two-dimensional second order elliptic problems [11], [27]. However, extension of these and other methods to three dimensions can involve difficulties with regard to practical

implementation, although theoretical convergence estimates may still be good. On irregular grids in particular, the data structures used by these methods can become increasingly complicated. This and other such considerations when solving very large problems on irregular grids raise an important question: How much work is it practical to do before the gain of accelerated conjugate gradient convergence is outweighed by the amount of work involved in constructing the preconditioner itself?

Consider a second order partial differential equation in three dimensions. By solving such a problem on a regular grid with n nodes in each coordinate direction a distance h apart, giving $N = n^3$ unknowns in total, it is possible to calculate an asymptotic order estimate for the amount of work involved in implementing a certain preconditioner as $N \to \infty$ (or equivalently as $h \to 0$). We note that the condition number of the finite element stiffness matrix with appropriate boundary conditions is $O(h^{-2}) = O(N^{2/3})$ in three dimensions [20]. Given that there are $O(N)$ floating point operations (flops) per PCG iteration and assuming that the total number of iterations required is proportional to the square root of the condition number of the preconditioned matrix [3], using PCG with diagonal scaling (which does not alter the asymptotic order of the condition number) has asymptotic complexity $O(N^{4/3})$. Similarly, any preconditioner that reduces the asymptotic order of the condition number to $O(h^{-1})$ will have complexity $O(N^{7/6})$. For a large problem with, for example, $N = 10^6$ unknowns, $N^{4/3} = 10N^{7/6}$. That is, the more complex preconditioner is even at first glance only ten times better than diagonal scaling. In addition, the constants that are hidden in the order notation in these work estimates can have a significant influence. Thus the effect on these constants of aspects of implementation and architecture, work per iteration, and internal eigenvalue distribution is considerably more pronounced for large three-dimensional problems than for those in lower dimensions.

In practice it is often hard to quantify how difficult it is to implement a particular preconditioner. As stated above, diagonal scaling does not alter the asymptotic order of the condition number. Its benefits lie in the fact that for any particular case it will reduce the condition number by a constant factor [7]. One example of a method that reduces the asymptotic order of the finite element matrix condition number to $O(h^{-1})$ is the popular modified incomplete Cholesky conjugate gradient (MICCG(0)) method of Gustafsson [11]. However, a major drawback of using such a preconditioning for three-dimensional irregular problems is that often the coefficient matrix is not an M-matrix and so existence and stability of the factorisation is not guaranteed [15]. Other sparse factorisation methods such as the Dupont, Kendall, and Rachford (DKR) method [6], the strongly implicit procedure (SIP) [19] and the consistent sparse factorization (CSF) method [4] cannot be used in three dimensions. Many of the attractive vector and parallel capabilities of polynomial preconditioners [1] are lost when using irregular grids. Hierarchical preconditioning gives an asymptotic condition number of $O(\ln N)^2$ for triangular elements in two dimensions [27] and Ong obtains the analogous but less attractive result of $O(N \ln N)$ using tetrahedral elements in three dimensions [16]. She does, however, go on to observe that using such preconditioners in three dimensions is impractical on irregular grids. These observations reinforce the point that standard comparisons of preconditioners that involve only condition number estimates are not always appropriate for large irregular three-dimensional problems.

4. Element-based preconditioners. One common feature of many preconditioners is that they take little or no account of the very specific structure of finite

element matrices. It is natural in a finite element context to look for some sort of preconditoning that can be applied to each individual element. The simplest method that can be considered in this way is diagonal scaling, that is, set

$$B = L^T[\text{diag}A_e]L = \text{diag}A \tag{4.1}$$

(see [26]). Using this preconditioning leaves the asymptotic matrix condition number as $O(h^{-2})$, but has the advantage that it will reduce the condition number by a constant factor and is extremely simple to implement. We now show that it is one of a large class of element-based preconditioners that does not affect the asymptotic order of the condition number.

Suppose we have a preconditioner B of the form (2.2), where all of the eigenvalues of each element matrix B_e are of the same order as the discretisation parameter h tends to zero; that is,

$$c_1 h^p \leq \lambda_{\min}(B_e) \leq c_2 h^p \quad \text{and} \quad c_3 h^p \leq \lambda_{\max}(B_e) \leq c_4 h^p, \tag{4.2}$$

where $p \in \Re$. Throughout the following $c_i, i = 1, 2, \ldots$ represents nonzero positive constants. Result (2.3) can be used to deduce an inequality analogous to (4.2) for the global case, that is,

$$c_5 h^p \leq \lambda(B) \leq c_6 h^p. \tag{4.3}$$

The quantity of interest from our point of view is $\kappa(B^{-1}A)$. Because $B^{-1}A$ is symmetric with respect to the A-inner product, the ratio $\lambda_{\max}(B^{-1}A)/\lambda_{\min}(B^{-1}A)$ gives the A-condition number rather than the usual $(I-)$ condition number [2]. To bound the I-condition number we use the general definition

$$\kappa(B^{-1}A) = \| B^{-1}A \| \| A^{-1}B \| \tag{4.4}$$

to give

$$\kappa(B^{-1}A) \leq \| B^{-1} \| \| A \| \| A^{-1} \| \| B \| = \kappa(A)\kappa(B). \tag{4.5}$$

From (4.3), $\kappa(B)$ must be independent of h so

$$\kappa(B^{-1}A) \leq c_7 \kappa(A). \tag{4.6}$$

Furthermore,

$$\lambda_{\max}(B^{-1}A) = \max_{\mathbf{x}=\mathbf{0}} \frac{\mathbf{x}^T\mathbf{x}}{\mathbf{x}^T B\mathbf{x}} . \frac{\mathbf{x}^T A\mathbf{x}}{\mathbf{x}^T\mathbf{x}} \tag{4.7}$$

and so

$$\lambda_{\max}(B^{-1}A) \geq \frac{\mathbf{v}_{\max}^T\mathbf{v}_{\max}}{\mathbf{v}_{\max}^T B\mathbf{v}_{\max}} \lambda_{\max}(A) = Q_1 \lambda_{\max}(A), \tag{4.8}$$

where $\mathbf{v}_{\max}$ is the eigenvector corresponding to $\lambda_{\max}(A)$. Similarly,

$$\lambda_{\min}(B^{-1}A) \leq \frac{\mathbf{v}_{\min}^T\mathbf{v}_{\min}}{\mathbf{v}_{\min}^T B\mathbf{v}_{\min}} \lambda_{\min}(A) = Q_2 \lambda_{\min}(A), \tag{4.9}$$

where $\mathbf{v}_{\min}$ is the eigenvector corresponding to $\lambda_{\min}(A)$. For any natural matrix norm,

$$| \lambda(M) | \leq \| M \| \tag{4.10}$$

where M is an arbitrary square matrix (e.g., [23, p. 10]) so, from (4.8),

$$Q_1 \lambda_{\max}(A) \leq \| B^{-1}A \| . \tag{4.11}$$

Now, from (4.9),

$$\lambda_{\min}(B^{-1}A) \leq Q_2 \lambda_{\min}(A), \tag{4.12}$$

so

$$\frac{1}{\lambda_{\max}(A^{-1}B)} \leq Q_2 \lambda_{\min}(A). \tag{4.13}$$

Using result (4.10) and inverting both sides gives

$$\| A^{-1}B \| \geq \frac{1}{Q_2 \lambda_{\min}(A)}, \tag{4.14}$$

hence

$$\| B^{-1}A \| \| A^{-1}B \| \geq \frac{\| B^{-1}A \|}{Q_2 \lambda_{\min}(A)}. \tag{4.15}$$

Finally, from (4.11),

$$\| B^{-1}A \| \| A^{-1}B \| \geq \frac{Q_1 \lambda_{\max}(A)}{Q_2 \lambda_{\min}(A)}. \tag{4.16}$$

Again using assumption (4.2) (and the corresponding global result (4.3)) the quotients Q_1 and Q_2 involving B in (4.8) and (4.9) are of the same order as $h \to 0$ and so

$$\kappa(B^{-1}A) \geq c_8 \kappa(A). \tag{4.17}$$

Inequalities (4.6) and (4.17) give rise to the result that if the element matrices B_e satisfy (4.2), then

$$\kappa(B^{-1}A) = c_9 \kappa(A). \tag{4.18}$$

Thus the order of the condition number of the coefficient matrix can never be improved by applying any element-based preconditioner of this form. Note that result (4.18) applies to diagonal scaling and is consistent with what we have already observed, namely, that in such a case the asymptotic order of the condition number of the global finite element stiffness matrix is unchanged by preconditioning.

It is appropriate to mention here the element-by-element (EBE) method of Hughes, Levit, and Winget [12]. Although this method does not fit exactly into the above category, analysis of the condition number indicates that EBE preconditioning is also spectrally equivalent to diagonal scaling [14], [26] and so will not affect the asymptotic condition number estimate. Numerical experiments in the above papers show that in practice the constants in the estimates are significantly better for EBE preconditioning than those for diagonal scaling on regular grids. The performance of the two methods on some irregular grids is compared in §5.

5. Numerical experiments. In the past it has been common practice to use test problems on regular finite element grids as a yardstick for comparing the performance of various preconditioners [1], [10], [16]. However, as stated above, the performance of some preconditioning methods can deteriorate rapidly when the grids are distorted, and so this approach may not always give a fair comparison. Here we compare methods using two types of unstructured grid: the set of grids in Problem 1 have been randomly constructed to be extremely irregular, while the grid in Problem 2 was constructed to model a particular irregular physical geometry in a practical situation.

Problem 1. We look for a solution to Laplace's equation as the steady state of the related parabolic partial differential equation

$$\begin{aligned} \frac{\partial u}{\partial t} - \nabla^2 u = 0 \quad &\text{in } \Omega, \\ \frac{\partial u}{\partial n} = 0 \quad &\text{on } \delta\Omega \end{aligned} \tag{5.1}$$

for domain Ω with boundary $\delta\Omega$ and unit normal n. Using the Galerkin finite element method with fully implicit backward difference timestepping leads to a matrix system

$$\left[\frac{M}{\delta t} + K\right] \mathbf{u}^{n+1} = \frac{M}{\delta t}\mathbf{u}^{n}, \tag{5.2}$$

where M and K are the finite element mass and stiffness matrices and $\mathbf{u}_n$ and $\mathbf{u}_{n+1}$ are vectors of the solution values at timesteps n and $n+1$, respectively. This system has a symmetric positive definite coefficient matrix and was solved using the PCG method with various preconditioners, terminating in each case when the Euclidean norm of the residual vector, $\mathbf{r}_n = \mathbf{b} - A\mathbf{u}_n$, was less than 10^{-4}. All calculations were done in double precision FORTRAN on an ARDENT TITAN machine with unit roundoff of 10^{-15}.

The results in Table 1 come from irregular three-dimensional grids of linear tetrahedra (with four unknowns per element). The coordinates of the global unknowns were generated using a random number generator (with appropriate scaling) and the

convex hull of these points was then tetrahedralised using a FORTRAN grid generation code [21]. Some specifications of these grids are given in Table 2, including the maximum and minimum number of elements round each node (P) and the maximum and minimum number of nonzeros in any one row of the assembled matrix (NZ). The extreme values of the x, y, and z coordinates are also listed. The fact that some nodes in the grid are surrounded by a very large number of elements suggests that the angles in these elements will be extremely small, indicating that the tetrahedra are badly distorted. Tetrahedral elements are in reality not particularly practical, especially from the point of view of element-based preconditioners, as the number of elements is much larger than the number of unknowns. They are used here because it is relatively easy to generate very irregular grids with such elements.

We compare the performance of three preconditioning methods:

- DSCG, diagonal scaling;
- ELCG, element-by-element preconditioning [12];
- SFCG, sparse factorisation based on MICCG(0) [11] but taking the absolute value of the pivot at each stage to ensure stability (as the coefficient matrix is not an M-matrix).

All CPU times quoted are for the iterative solver only and do not include matrix setup times. Results are given for each program in scalar (V OFF) and vector (V ON) mode. As the time scales involved in this type of problem can be large, it was appropriate to use timesteps of variable length in the matrix system (5.2). This, however, introduced an unfair imbalance as the sparse factorisation had to be recalculated at every timestep. To remove this bias, a large timestep was chosen ($\delta t = 10^5$) so that the steady state in the runs of Table 1 was achieved in one time step. The *setup* times (in CPU seconds) do not refer to the time taken to construct the finite element equations; this has been omitted in all cases. Instead they give an indication of the amount of work that must be done once (or once per timestep for a variable δt) before the actual iterative solution can proceed. The setup steps involved for each method are:

- DSCG, setup time negligible;
- ELCG, crout factorisation of element matrices;
- SFCG, sparse factorisation of assembled coefficient matrix.

The *solve* times are the number of CPU seconds taken for the k iterations required to achieve convergence.

For the first four cases shown, the initial condition chosen was $\mathbf{u}_0 = \frac{1}{10}(\mathbf{x}+\mathbf{y}+\mathbf{z})$,

TABLE 3
ARDENT TITAN CPU times: Problem 2.

N		k	V=OFF		V=ON	
			Setup	Solve	Setup	Solve
9422	DSCG	88	–	110.48	–	90.36
	ELCG	102	4.89	523.97	3.59	233.68
	SFCG	15	1737.0	23.37	1768.42	20.76

where $\mathbf{x}$, $\mathbf{y}$, and $\mathbf{z}$ are the coordinates of the node points. To see if this choice of a "smooth" starting vector affected the speed of convergence, the experiments were repeated on the largest grid with a random initial vector. However, the choice of starting vector did not seem to have a significant effect on the overall results.

The results of these numerical experiments give a rough idea of the comparative performance of the three methods. The idea of these tests was to use each method in a straightforward way. In particular, the factorisation time for SFCG may well be improved by using a more sophisticated implementation. It is still, however, true that the overall solution time for SFCG will be dominated by the factorisation step itself. This re-emphasises the point that for large and very irregular three-dimensional problems, implementation plays a very important role.

An equivalent set to the results in Table 1 from a series of regular grid problems would show obvious relationships between the iteration counts and total number of unknowns N (usually expressed in terms of the discretisation parameter h). Such specific conclusions cannot be drawn in the irregular case. Nevertheless, some important observations can be made. In terms of iteration counts, ELCG is the most efficient. This supports the remarks of §4 concerning the relative performance of the EBE method and diagonal scaling, namely, that although the h-dependence in the asymptotic estimates of their convergence rates is the same, that of the latter will contain a smaller constant [26]. Notice, however, the effect of vectorisation, which gives a dramatic improvement in the performance of DSCG. This means that despite taking more iterations, it is faster than ELCG in its vectorised form. In fact, for the largest of these particular problems, it is vectorised diagonal scaling which is the best technique to use in terms of total CPU time.

Problem 2. We look for a solution to Poisson's equation

$$\begin{aligned} \nabla^2 u &= 1 \quad \text{in } \Omega, \\ u &= 0 \quad \text{on } \delta\Omega \end{aligned} \tag{5.3}$$

for domain Ω with boundary $\delta\Omega$. Using the Galerkin finite element method leads to a system with a symmetric positive definite coefficient matrix. This was solved using the PCG method with various preconditioners, this time terminating in each case when the Euclidean norm of the residual vector, $\mathbf{r}_n = \mathbf{b} - A\mathbf{u}_n$, was less than 10^{-6}. All calculations were again done in double precision FORTRAN on an ARDENT TITAN machine.

The results in Table 3 come from the irregular three-dimensional grid of serendipity bricks (with twenty unknowns per element) shown in Fig. 1. This grid was generated for a commercial simulation by the British company Nuclear Electric plc and some of its specifications are given in Table 4.

We compare the performance of the same three preconditioning methods described above, again quoting CPU times for the iterative solver only. The initial condition chosen was $\mathbf{u}_0 = 0$.

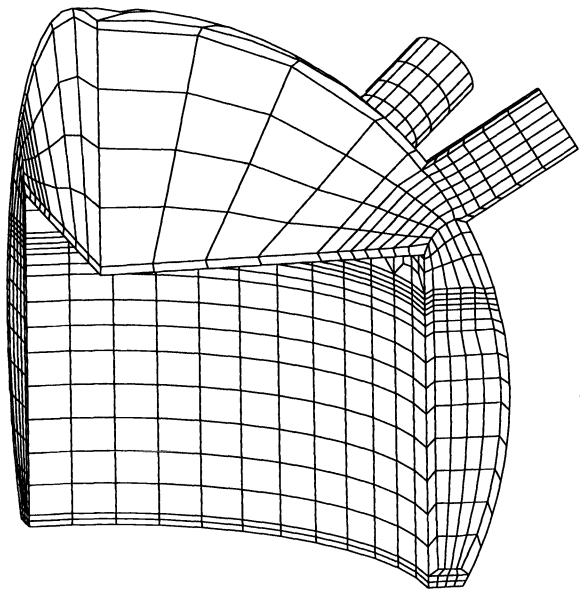

FIG. 1.

The major difference between these results and those from Problem 1 seems to be a deterioration in the performance of ELCG. The reason for this may be related to the fact that the grid contains elements of extreme aspect ratios: the relation between element aspect ratio and the EBE method was studied in [14]. For DSCG and SFCG, however, the same behaviour pattern is seen; that is, although SFCG performs well, the time taken to perform the actual factorisation is prohibitive. Vectorisation, while improving the performance of DSCG, does not have the same marked effect as in Problem 1. This is due to a difference in implementation. In this problem, the value of u is fixed at certain nodes by boundary conditions. This means that the number of unknowns in the matrix system is slightly less than the total number of nodes on the original grid, and so not all the elements have the same number of unknowns. As a result, a different storage strategy has been used for the coefficient matrix which makes some parts of the code less vectorisable.

The above experiments show that it is difficult to make generalisations when dealing with large irregular grids. In practice, the final choice of solution technique in any particular case will depend both on the type of problem to be solved and the hardware to be used in the solution process. It is however important to appreciate that using very large irregular three-dimensional grids may involve a different philosophical approach.

Appendix A. The finite element stiffness matrix of any linear triangle can be expressed entirely in terms of the coordinates of the three node points. To find the eigenvalues for an arbitrary linear triangle, it is sufficient to consider a triangle that has been translated to fix one node at the origin and rotated to fix one side along the y-axis, i.e., a triangle with coordinates $(x_1, y_1),(0, y_2),(0, 0)$.

In this case the stiffness matrix is

$$K_e = \frac{1}{4S_e}\begin{bmatrix} a & -b & b-a \\ -b & c & b-c \\ b-a & b-c & a-2b+c \end{bmatrix}, \tag{A.1}$$

where S_e is the element area, $a = y_2^2$, $b = y_1 y_2$, and $c = x_1^2 + y_1^2$. The eigenvalues of $D_e^{-1}K_e$ (where D_e is the diagonal of K_e) can be found algebraically and the results can be simplified by expressing a, b, and c in terms of the angles θ_i with opposite sides of length s_i ($i = 1, 2$, or 3). This gives precisely the eigenvalues in (2.6), namely,

$$\begin{cases} 0, \\ \dfrac{3}{2} \pm \dfrac{1}{2}\left\{9 - 8\left[\dfrac{S_e \sin 2\theta_i}{s_i^2} + \sin^2\theta_i\right]\right\}^{1/2}. \end{cases} \tag{A.2}$$

It is clear that the maximum and minimum values of (A.2) both occur at the minimum value of

$$\frac{S_e \sin 2\theta_i}{s_i^2} + \sin^2\theta_i. \tag{A.3}$$

As $S_e = \frac{1}{2}s_j s_k \sin\theta_i$ (where $i \neq j \neq k$), using the cosine rule

$$s_j s_k \cos\theta_i = \frac{1}{2}(s_j^2 + s_k^2 - s_i^2) \tag{A.4}$$

reduces (A.3) to

$$\left[\frac{\sin\theta_i}{s_i}\right]^2 (s_i^2 + s_j^2 + s_k^2). \tag{A.5}$$

Note that (from the sine rule) this is independent of the index.

By expressing the area S_e in terms of the semiperimeter $\frac{1}{2}(s_i + s_j + s_k)$, we can substitute for $\sin\theta$ in (A.5) to give

$$\frac{1}{8}(s_i + s_j + s_k)(s_j + s_k - s_i)(s_i + s_k - s_j)(s_i + s_j - s_k)\frac{(s_i^2 + s_j^2 + s_k^2)}{s_i^2 s_j^2 s_k^2}. \tag{A.6}$$

As this formula is symmetric, we arbitrarily choose s_k to be the longest side and write

$$\frac{s_i}{s_k} = \lambda, \qquad \frac{s_j}{s_k} = \mu, \tag{A.7}$$

so (A.6) becomes

$$\frac{1}{8}(\lambda + \mu + 1)(\mu + 1 - \lambda)(\lambda + 1 - \mu)(\lambda + \mu - 1)\frac{(\lambda^2 + \mu^2 + 1)}{\lambda^2\mu^2}. \tag{A.8}$$

From the obvious inequalities

$$\lambda + \mu \geq 1, \quad \mu + 1 \geq \lambda, \quad \lambda + 1 \geq \mu, \tag{A.9}$$

it is clear that (A.8) will have a minimum of zero precisely when one of these holds as an equality; that is, when the triangle involved is a straight line. Thus (A.3) will tend to a minimum as the angle θ_i tends towards π.

Acknowledgments. The authors would like to thank Dr. S. Ashby of Lawrence Livermore National Laboratory for useful comments concerning the proof in §4.

THE REVERSE BORDERING METHOD*

C. BREZINSKI†, M. MORANDI CECCHI‡, AND M. REDIVO-ZAGLIA§

Abstract. The bordering method allows recursive computation of the solution of a system of linear equations by adding one new row and one new column at each step of the procedure. When some of the intermediate systems are nearly singular, it is possible, by the block bordering method, to add several new rows and columns simultaneously. However, in that case, the solutions of some of the intermediate systems are not computed. The reverse bordering method allows computation of the solutions of these systems afterwards. Such a procedure has many applications in numerical analysis, that include orthogonal polynomials, Padé approximation, and the progressive forms of extrapolation processes.

Key words. linear equations, bordering methods, extrapolation, Padé approximants, orthogonal polynomials

AMS subject classifications. 65F05, 65B05

1. Introduction.

The bordering method is a recursive method for computing the solution of a system of linear equations. It consists, at each step, of adding one new row and one new column to the previous matrix and using the previous solution to compute the new one. This method can only be used if some quantity is different from zero at each step. If, at some steps, this quantity is zero (or nearly zero), then it is possible to add several new rows and columns to the matrix simultaneously. However, if this situation occurs, the solutions of the intermediate systems that have been skipped are not computed. This is a drawback of the method since, in some applications, the solutions of all the intermediate systems must be known (if nonsingular). In this paper we propose the reverse bordering method for avoiding this case. The procedure is, after jumping over the near-singular intermediate systems and computing the solution of the first nonnear-singular system, to go back by decreasing the dimension of the matrix (that is, by deleting the last row and the last column) and using the solution of the previous larger system for computing the solutions of the smaller systems that have been skipped. Such a procedure has applications in the recursive computation of orthogonal polynomials, in Padé approximation, and in the implementation of the progressive forms of extrapolation algorithms.

2. Bordering method.

When we must solve a system of linear equations that is obtained by adding one new equation and one new unknown to a given system or, in other words, when the matrix of the system has been bordered by a new row

and a new column, the bordering method can be used to save computational time. This method is well known in numerical analysis and permits us to solve a system recursively by using the solution of the previous system (see, Faddeeva [7]). Let us first explain this method.

Let A_k be a regular square matrix of dimension k and d_k a vector of dimension k. Let z_k be the solution of the system

$$A_k z_k = d_k.$$

Now let u_k be a column vector of dimension k, v_k a row vector of dimension k, and a_k a scalar. We consider the bordered matrix A_{k+1} of dimension $k+1$ given by

$$A_{k+1} = \begin{pmatrix} A_k & u_k \\ v_k & a_k \end{pmatrix}.$$

We have

$$A_{k+1}^{-1} = \begin{pmatrix} A_k^{-1} + A_k^{-1} u_k v_k A_k^{-1}/\beta_k & -A_k^{-1} u_k/\beta_k \\ -v_k A_k^{-1}/\beta_k & 1/\beta_k \end{pmatrix}$$

with $\beta_k = a_k - v_k A_k^{-1} u_k$.

Let f_k be a scalar and z_{k+1} be the solution of the bordered system

$$A_{k+1} z_{k+1} = d_{k+1} = \begin{pmatrix} d_k \\ f_k \end{pmatrix}.$$

Then we have

$$z_{k+1} = \begin{pmatrix} z_k \\ 0 \end{pmatrix} + \frac{f_k - v_k z_k}{\beta_k} \begin{pmatrix} -A_k^{-1} u_k \\ 1 \end{pmatrix}.$$

This formula gives the solution of the bordered system in terms of the solution of the previous system.

To avoid computation and storage of A_k^{-1}, we can set $q_k = -A_k^{-1} u_k$ and compute it recursively by the same bordering method. In such a way, we obtain the following variant of the bordering method that needs the storage of A_k instead of that of A_k^{-1} for the original procedure.

Let $q_k^{(i)}$ be the solution of the system

$$A_i q_k^{(i)} = -u_k^{(i)},$$

where $u_k^{(i)}$ is the vector formed by the first i components of u_k. Thus $u_i^{(i)} = u_i$ and $q_i^{(i)} = q_i$ for all i. A_i is the matrix of dimension i formed by the first i rows and columns of A_k.

We have, since A_1 is a number,

$$q_k^{(1)} = -\frac{u_k^{(1)}}{A_1},$$

$$q_k^{(i+1)} = \begin{pmatrix} q_k^{(i)} \\ 0 \end{pmatrix} - \frac{u_{k,i+1} + v_i q_k^{(i)}}{a_i + v_i q_i^{(i)}} \begin{pmatrix} q_i^{(i)} \\ 1 \end{pmatrix}, \qquad i = 1, \ldots, k-1,$$

where $u_{k,i+1}$ is the $(i+1)$th component of u_k.

Then

$$q_k^{(k)} = q_k = -A_k^{-1} u_k,$$

thus allowing us to use the previous formula for computing z_{k+1} without knowledge of A_k^{-1}; [3] and [4] contain the subroutine BORDER performing this variant of the bordering method.

3. Block bordering method. The bordering method can be applied only if $\beta_k \neq 0$ for all k. When this is not the case, we can use a block bordering procedure (see Brezinski, Redivo-Zaglia, and Sadok [5]).

We now assume the following dimensions for the matrices involved in the process

$$\begin{aligned} A_k &\quad n_k \times n_k, \\ u_k &\quad n_k \times p_k, \\ v_k &\quad p_k \times n_k, \\ a_k &\quad p_k \times p_k, \end{aligned}$$

and finally

$$A_{k+1} \quad n_{k+1} \times n_{k+1}$$

with $n_{k+1} = n_k + p_k$.

We set

$$\beta_k = a_k - v_k A_k^{-1} u_k$$

and we have

$$A_{k+1}^{-1} = \begin{pmatrix} A_k^{-1} + A_k^{-1} u_k \beta_k^{-1} v_k A_k^{-1} & -A_k^{-1} u_k \beta_k^{-1} \\ -\beta_k^{-1} v_k A_k^{-1} & \beta_k^{-1} \end{pmatrix}.$$

f_k is now a vector with p_k components and we obtain

$$z_{k+1} = \begin{pmatrix} z_k \\ 0 \end{pmatrix} + \begin{pmatrix} -A_k^{-1} u_k \\ I_k \end{pmatrix} \beta_k^{-1} \, (f_k - v_k z_k),$$

where I_k is the identity matrix of dimension p_k.

The subroutine BLBORD given in [4] performs this block bordering method.

Remark. We note that the subroutine BLBORD only works if $a_{11} = 1$, which can always be made true. It is also possible to add the instruction A(1,1)=1.0D0/A(1,1) after the instruction Z(1)=D(1)/A(1,1).

Again it is possible to avoid computation and storage of A_k^{-1} by setting $q_k = -A_k^{-1} u_k$ (whose dimension is $n_k \times p_k$) and computing it recursively by the bordering method in the following way.

Let $u_k^{(i)}$ be the $n_i \times p_k$ matrix formed by the first n_i rows of u_k for $i \leq k$, $n_i \leq n_k$. We have $u_i^{(i)} = u_i$. Let $q_k^{(i)}$ be the $n_i \times p_k$ matrix satisfying $A_i q_k^{(i)} = -u_k^{(i)}$ for $i \leq k$. We have $q_i^{(i)} = q_i$.

We set

$$q_k^{(1)} = -A_1^{-1} u_k^{(1)}$$

and then we have

$$q_k^{(i+1)} = \begin{pmatrix} q_k^{(i)} \\ 0 \end{pmatrix} - \begin{pmatrix} q_i^{(i)} \\ I_i \end{pmatrix} \beta_i^{-1} \left(u_{k,i+1} + v_i q_k^{(i)} \right), \qquad i = 1, \ldots, k-1$$

with $\beta_i = a_i + v_i q_i^{(i)}$ and $u_{k,i+1}$ the matrix formed by the rows $n_i + 1, \ldots, n_i + p_i$ of u_k.

Instead of using the block bordering method when β_k is zero for some k, it is possible to use a pivoting strategy. If, for some k, $\beta_k = 0$, then the last row of the matrix can be interchanged with the next one and so on until some $\beta_k \neq 0$ has been obtained. Such a procedure is not adapted when the solutions of the intermediate systems must be computed. It can be used if only the last solution is needed and if the solutions of the intermediate systems are not required.

Obviously, the block bordering method can also be used even if the matrix β_k is nonsingular and thus, at each step, an arbitrary number of new rows and columns can be added. In particular, when some of the intermediate systems are almost singular, such a strategy allows us to jump over them and thus improve the numerical stability and precision of the solutions of the subsequent systems. However, in such a case the solutions of the systems that have been skipped have not been computed. The reverse bordering method that we now present allows us to come back afterwards to these systems by deleting rows and columns one by one and obtain their solutions from the solution of the larger system.

4. Reverse bordering method. Let us now look at the possibility of finding A_k^{-1} from A_{k+1}^{-1}.

We write the inverse matrix A_{k+1}^{-1} of dimension n_{k+1} under the form

$$A_{k+1}^{-1} = \begin{array}{c} \begin{matrix} n'_k & p'_k \end{matrix} \\ \begin{pmatrix} A'_k & u'_k \\ v'_k & a'_k \end{pmatrix} \end{array} \begin{matrix} n'_k \\ p'_k \end{matrix}.$$

The matrix A_{k+1} will also be partitioned by blocks with the same corresponding dimensions. Thus A_k will be the square matrix of dimension $n'_k = n_{k+1} - p'_k$ obtained by suppressing the last p'_k rows and columns of A_{k+1}.

From the block bordering method we know that

$$\begin{aligned} A'_k &= A_k^{-1} + A_k^{-1} u_k \beta_k^{-1} v_k A_k^{-1} \\ u'_k &= -A_k^{-1} u_k \beta_k^{-1}, \qquad v'_k = -\beta_k^{-1} v_k A_k^{-1}, \\ a'_k &= \beta_k^{-1}, \qquad \beta_k = a_k - v_k A_k^{-1} u_k. \end{aligned}$$

Because

$$a_k'^{-1} = \beta_k$$

then

$$u'_k a_k'^{-1} = -A_k^{-1} u_k,$$

and thus

$$u'_k a_k'^{-1} v'_k = A_k^{-1} u_k \beta_k^{-1} v_k A_k^{-1}.$$

Thus using this in the expression of A'_k gives us

$$A_k^{-1} = A'_k - u'_k\, a_k'^{-1}\, v'_k. \tag{1}$$

This formula, which corresponds to the Schur complement, was already given by Duncan in 1944 [6]. The following relations also hold.

$$\det A_k^{-1} = \det A_{k+1}^{-1} / \det a'_k,$$
$$\det A_{k+1} = \det A_k \cdot \det \beta_k.$$

Moreover, from the Sherman–Morrison formula (see [8] for review), we have

$$A'_k = \left(A_k - u_k\, a_k^{-1}\, v_k\right)^{-1},$$

and

$$A_k = \left(A'_k - u'_k\, a_k'^{-1}\, v'_k\right)^{-1} = A_k'^{-1} + A_k'^{-1}\, u'_k\, \beta_k'^{-1}\, v'_k\, A_k'^{-1},$$

with

$$\beta'_k = a'_k - v'_k\, A_k'^{-1}\, u'_k.$$

This is another proof of (1).

From these formulæ, we obtain

$$A_k = A_k'^{-1} + u_k\, a_k^{-1}\, v_k = \left(A'_k - u'_k\, a_k'^{-1}\, v'_k\right)^{-1},$$
$$A'_k = A_k^{-1} + u'_k\, a_k'^{-1}\, v'_k = \left(A_k - u_k\, a_k^{-1}\, v_k\right)^{-1}.$$

Now we want to compute the solution z_k of the previous system

$$A_k z_k = d_k$$

starting from the solution z_{k+1} of the bordered system

$$A_{k+1} z_{k+1} = d_{k+1} = \begin{pmatrix} d_k \\ f_k \end{pmatrix} \begin{matrix} n'_k \\ p'_k \end{matrix}.$$

As previously stated

$$z_{k+1} = \begin{pmatrix} z'_k \\ c_k \end{pmatrix} = \begin{pmatrix} z_k \\ 0 \end{pmatrix} + \begin{pmatrix} -A_k^{-1} u_k \\ I_k \end{pmatrix} \beta_k^{-1}\, (f_k - v_k z_k)$$
$$= \begin{pmatrix} z_k \\ 0 \end{pmatrix} + \begin{pmatrix} u'_k \\ a'_k \end{pmatrix} (f_k - v_k z_k).$$

Thus

$$c_k = a'_k f_k - a'_k v_k z_k,$$

that is,

$$a_k'^{-1} c_k = f_k - v_k z_k \quad \text{or} \quad v_k z_k = f_k - a_k'^{-1} c_k$$

and

$$z'_k = z_k + u'_k\, (f_k - v_k z_k) = z_k + u'_k\, a_k'^{-1}\, c_k.$$

Finally, it holds that

$$z_k = z'_k - u'_k\, a'^{-1}_k\, c_k.$$

Another way of finding z_k is as follows. From (1), we have

$$A_k^{-1} d_k = A'_k d_k - u'_k\, a'^{-1}_k\, v'_k\, d_k.$$

But

$$\begin{pmatrix} z'_k \\ c_k \end{pmatrix} = \begin{pmatrix} A'_k & u'_k \\ v'_k & a'_k \end{pmatrix} \begin{pmatrix} d_k \\ f_k \end{pmatrix} = \begin{pmatrix} A'_k d_k + u'_k f_k \\ v'_k d_k + a'_k f_k \end{pmatrix}.$$

Thus

$$A'_k d_k = z'_k - u'_k f_k \quad \text{and} \quad v'_k d_k = c_k - a'_k f_k$$

and we have

$$\begin{aligned} z_k = A_k^{-1} d_k &= z'_k - u'_k f_k - u'_k a'^{-1}_k\, (c_k - a'_k f_k) \\ &= z'_k - u'_k f_k - u'_k\, a'^{-1}_k\, c_k + u'_k\, a'^{-1}_k\, a'_k\, f_k \\ &= z'_k - u'_k a'^{-1}_k c_k. \end{aligned}$$

5. Variants and particular cases. Instead of bordering the matrix A_k as we did, we can also add the new rows and columns on the top and on the left according to the scheme

$$A_{k+1} = \begin{pmatrix} a_k & v_k \\ u_k & A_k \end{pmatrix}.$$

Thus the inverse matrix becomes

$$A_{k+1}^{-1} = \begin{pmatrix} \beta_k^{-1} & -\beta_k^{-1} v_k A_k^{-1} \\ -A_k^{-1} u_k \beta_k^{-1} & A_k^{-1} + A_k^{-1} u_k \beta_k^{-1} v_k A_k^{-1} \end{pmatrix}.$$

The solution z_{k+1} of the bordered system

$$A_{k+1} z_{k+1} = d_{k+1} = \begin{pmatrix} f_k \\ d_k \end{pmatrix}$$

can be computed by

$$z_{k+1} = \begin{pmatrix} 0 \\ z_k \end{pmatrix} + \begin{pmatrix} I_k \\ -A_k^{-1} u_k \end{pmatrix} \beta_k^{-1}\, (f_k - v_k z_k).$$

Similarly for the reverse bordering method, starting from

$$A_{k+1}^{-1} = \begin{pmatrix} & p'_k & n'_k \\ & a'_k & v'_k \\ & u'_k & A'_k \end{pmatrix} \begin{matrix} \\ p'_k \\ n'_k \end{matrix}$$

we have

$$A_k^{-1} = A'_k - u'_k\, a'^{-1}_k\, v'_k.$$

The solution z_k of the system

$$A_k z_k = d_k$$

can be obtained from the solution z_{k+1} of the bordered system

$$A_{k+1} z_{k+1} = d_{k+1} = \begin{pmatrix} f_k \\ d_k \end{pmatrix} \begin{matrix} p'_k \\ n'_k \end{matrix}.$$

We set

$$z_{k+1} = \begin{pmatrix} c_k \\ z'_k \end{pmatrix} \begin{matrix} p'_k \\ n'_k \end{matrix}$$

and we have

$$z_k = z'_k - u'_k a'^{-1}_k c_k.$$

Thus the block bordering method and the reverse bordering method can be applied in the following two cases.

Case 1.

$$\left(\begin{array}{c|c} A_k & u_k \\ \hline v_k & a_k \end{array}\right) z_{k+1} = \left(\begin{array}{c} d_k \\ \hline f_k \end{array}\right).$$

Case 2.

$$\left(\begin{array}{c|c} a_k & v_k \\ \hline u_k & A_k \end{array}\right) z_{k+1} = \left(\begin{array}{c} f_k \\ \hline d_k \end{array}\right).$$

There are also two other possibilities of bordering that could be investigated.

Case 3.

$$\left(\begin{array}{c|c} u_k & A_k \\ \hline a_k & v_k \end{array}\right) z_{k+1} = \left(\begin{array}{c} d_k \\ \hline f_k \end{array}\right).$$

This case can be treated the same as Case 2 because we can put the last p_k rows of the matrix and the right-hand side on the top and all the formulæ for the methods are the same.

Case 4.

$$\left(\begin{array}{c|c} v_k & a_k \\ \hline A_k & u_k \end{array}\right) z_{k+1} = \left(\begin{array}{c} f_k \\ \hline d_k \end{array}\right).$$

This case can be treated the same as Case 1 for the reason explained in Case 3.

Two particular cases can be interesting since they have many applications.

Let us first consider the case where A_k is a Hankel matrix; that is, when its elements a_{ij} are such that $a_{ij} = c_{i+j}$ where the c_i are given complex numbers. In this case, the reverse bordering method must be applied in its normal formulation because the structure of the inverse matrix does not permit any simplification.

Let us now consider the case of Toeplitz matrices. Let $A_k = (a_{ij})$ be the Hermitian positive definite Toeplitz matrix, built from a sequence of complex numbers $c_0, c_1, c_2, \ldots$. Thus we have $a_{ij} = c_{i-j}$ (for $i, j = 0, \ldots, n_k - 1$), $c_l = \overline{c}_{-l}$, and

$$A_k = T^{(0)}_{n_k} = \begin{pmatrix} c_0 & \overline{c}_1 & \overline{c}_2 & \cdots & \overline{c}_{n_k-1} \\ c_1 & c_0 & \overline{c}_1 & \cdots & \overline{c}_{n_k-2} \\ \vdots & \vdots & \vdots & & \vdots \\ c_{n_k-1} & c_{n_k-2} & c_{n_k-3} & \cdots & c_0 \end{pmatrix}.$$

In this case, A_{k+1} can be obtained from A_k by bordering either at the bottom and on the right or at the top and on the left. In both cases, due to the particular structure of the matrix, we have $v_k = \overline{u}_k^{\mathrm{T}}$.

Thus we can choose between two bordered matrices of dimension $n_{k+1} = n_k + p_k$

$$A_{k+1} = \begin{pmatrix} A_k & u_k \\ \overline{u}_k^{\mathrm{T}} & a_k \end{pmatrix} \quad \text{or} \quad A'_{k+1} = \begin{pmatrix} a_k & \overline{w}_k^{\mathrm{T}} \\ w_k & A_k \end{pmatrix}.$$

Obviously the two possibilities are not equivalent and the systems to be solved are different. However, in both cases, the bordering method can be applied after the simplification due to the special structure of the matrices.

If we consider the reverse unit matrix J (i.e., the unit matrix with its columns in the reverse order) of order n_k and the reverse unit matrix J' of order p_k, we have

$$w_k = J\overline{u}_k J'.$$

6. Numerical examples. When solving a system of linear equations by the bordering method some intermediate systems can be nearly singular. In that case, the block bordering method described in [5] allows us to jump over these near-singularities and the numerical stability of the process is thus improved.

Before giving a numerical example, let us discuss our strategy for deciding when and how far to jump. This strategy is based on the relation

$$\det A_{k+1} = \det A_k \cdot \det \beta_k.$$

Assuming that A_k^{-1} has already been obtained, we first add one new row and one new column to the matrix A_k; that is, we use the formulæ of §2 (or, equivalently, those of §3 with $p_k = 1$). If

$$|\beta_k| \leq \varepsilon$$

for some given $\varepsilon > 0$, we will add one more new row and one more new column to A_k and use the formulæ of §3 with $p_k = 2$. If

$$|\det \beta_k| \leq \varepsilon$$

we again add one new row and one new column to A_k and repeat the process until, after having added p_k new rows and columns, we obtain a matrix β_k such that

$$|\det \beta_k| > \varepsilon.$$

Then A_{k+1}^{-1} and z_{k+1} can be computed by the formulæ of §3. Let us also mention that the determinant of β_k is computed as the product of the pivots in a Gaussian elimination process. Such a strategy avoids the inversion of nearly singular matrices β_k, thus improving the numerical stability of the bordering method as shown by the following examples.

We first consider the system

$$\begin{pmatrix} 1 & 1 & 1 & 1 & -1 & 0 & -1 \\ 1 & 1 & 2 & 0 & 1 & 1 & -1 \\ 1 & 1 & -1 & 0 & 2 & -2 & 0 \\ -1 & 1 & 2 & 0 & -1 & 1 & 2 \\ 0 & 0 & 0 & 0 & 1 & 1 & 2 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & -1 & 0 & 2 \end{pmatrix} \begin{pmatrix} 1 \\ 2 \\ 3 \\ 4 \\ 5 \\ 6 \\ 7 \end{pmatrix} = \begin{pmatrix} -2 \\ 13 \\ -2 \\ 22 \\ 25 \\ 18 \\ 9 \end{pmatrix}.$$

In this system, the subsystems of dimensions 2, 3, and 6 are singular. Thus we add a perturbation η to a_{11} and a_{55}. So that the solution of the system remains the same, we also add η to the first component of the right-hand side and 5η to its fifth component.

Using the bordering and the block bordering methods for solving this system, we obtain the results in Tables 1 and 2 (ε denotes the threshold under which the block bordering method jumps and the numbers in parentheses denote the powers of 10).

However, in some applications, it is necessary to compute the solutions of all the intermediate systems. For example, this is the case in the computation of orthogonal polynomials [9], the Padé approximation, and the implementation of the progressive forms of extrapolation processes where the first step consists of the computation of the first descending diagonal of the triangular array [4]. In such cases, the block bordering method allows us to jump over the near-singular systems and then the reverse bordering method allows us to compute afterwards their solution with an improved numerical stability.

Let us first discuss the strategy used in the reverse bordering method. We assume that A_k^{-1} and A_{k+1}^{-1} are known and we want to compute the solutions of the intermediate systems of dimensions $n_{k+1} - 1, \ldots, n_k + 1$, which were skipped in the block bordering method when climbing to higher dimensions. We begin by deleting the last row and the last column of A_{k+1}^{-1}, that is, we use the formulæ of §4 with $p'_k = 1$ and $n'_k = n_{k+1} - 1$. For that, we must compute $a_k'^{-1}$. If a'_k is nearly singular, we delete the last two rows and the last two columns of A_{k+1}^{-1}; that is, we use the formulæ of §4 with $p'_k = 2$ and $n'_k = n_{k+1} - 2$ and so on until a nonnearly singular matrix a'_k has been obtained. The near singularity of a'_k is tested by computing its determinant (again by Gaussian elimination) and checking to see if $|\det a'_k| \leq \varepsilon'$ or not. However, if, in this test, we take $\varepsilon' \geq \varepsilon$ (where ε is the threshold used in the block bordering method) then a jump will occur from n_{k+1} to n_k and the intermediate systems that were not solved when climbing to higher dimensions will again be skipped. Thus we must choose $\varepsilon' < \varepsilon$.

TABLE 3
Solutions with the block bordering method and the reverse bordering method ($\eta = 10^{-14}, \varepsilon = 10^{-14}, \varepsilon' = 10^{-20}$).

n							
1	−0.2000(1)						
2	−0.1501(16)	0.1501(16)					
3	−0.1001(16)	0.1001(16)	0.5000(1)				
4	−0.4500(1)	0.7500(1)	0.5000(1)	−0.1000(2)			
5	−0.2950(2)	−0.9167(1)	0.1333(2)	0.4833(2)	0.2500(2)		
6	−0.7006(15)	−0.1168(16)	0.9341(15)	0.1635(16)	0.7006(15)	−0.7006(15)	
7	0.1000(1)	0.2000(1)	0.3000(1)	0.4000(1)	0.5000(1)	0.6000(1)	0.7000(1)

Let us now return to our previous example. Table 3 shows this improvement (ε' is the threshold for jumping in the reverse bordering method).

Let us now give an example with the ε-algorithm. This algorithm is an extrapolation process whose theory can be found in [4]. It can be interpreted as solving the system

$$\begin{cases} a_0 S_0 + a_1 S_1 + \cdots + a_k S_k = 1 \\ a_0 S_1 + a_1 S_2 + \cdots + a_k S_{k+1} = 1 \\ \vdots \qquad\qquad\qquad\qquad\qquad \vdots \\ a_0 S_k + a_1 S_{k+1} + \cdots + a_k S_{2k} = 1 \end{cases}$$

and then computing [1]

$$\varepsilon_{2k}^{(0)} = 1 / \sum_{i=0}^{k} a_i.$$

Let us apply the ε-algorithm to the partial sums of the series expansion of

$$f(x) = \frac{1 + b_1 x + \cdots + b_{m-1} x^{m-1} + x^m}{1 + x^m}.$$

Thanks to the theory of the ε-algorithm and its connection with Padé approximants (see the next section), we should have

$$\varepsilon_{2m}^{(0)} = f(x).$$

With $\eta = 0.25, m = 10, x = 2$, and $b_i = i \cdot \eta$, we have $f(x) = 2.998536585365854$. We set $\varepsilon = 10^{-6}$ and $\varepsilon' = 10^{-30}$ for the block bordering and reverse bordering methods and we obtain the following results for $\varepsilon_{2k}^{(0)}$. R means that the corresponding value was obtained by the reverse bordering method.

k	Bordering method	Block and reverse	
0	1.000000000000000	1.000000000000000	
1	0.833333333333333	0.833333333333333	
2	1.500000000000007	1.500000000000007	
3	1.500000000000006	1.500000000000007	R
4	1.500000000000004	1.499999999999987	R
5	1.500000000000004	1.499999999999984	R
6	1.500000000000006	1.500000000000006	R
7	1.500000000000007	1.500000000000006	
8	1.057370161706715	1.061205132114060	
9	5.442384375014805	5.530461077969034	
10	2.965829933964836	2.998536585365856	

Thus, only two exact digits are obtained for $\varepsilon_{10}^{(0)}$ with the bordering method and fifteen exact digits with the block bordering and reverse bordering methods.

Let us now take $\eta = 0.1, m = 10, x = 1, b_i = \eta/i$, and $\varepsilon = 10^{-3}$.

We have $f(x) = 1.141448412698413$ and we obtain

k	Bordering method	Block and reverse	
0	1.000000000000000	1.000000000000000	
1	1.200000000000000	1.200000000000000	
2	1.299999999999898	1.299999999999898	
3	1.366666666630687	1.366666666630683	R
4	1.416666663166007	1.416666665980086	R
5	1.416669182535733	1.416669185348150	R
6	1.370133070676631	1.370133070822927	R
7	1.363779438853716	1.363779438821982	
8	1.299241827763746	1.299241827748625	
9	1.221626694740750	1.221626694709201	
10	1.141448412733146	1.141448412698013	

Again the precision has been improved by the reverse bordering method.

In both examples, the subsystems of dimensions 3, 4, 5, and 6 were nearly singular and their solutions were obtained by the reverse bordering method from the solution of the system of dimension 7.

7. Application to Padé approximants. An important application of the bordering and the reverse bordering methods is the recursive computation of Padé approximants. We now recall the necessary definitions (see [2]).

A Padé approximant is a rational function whose series expansion in ascending powers of the variable agrees with a given power series f up to the term whose degree is the sum of the degrees of its numerator and its denominator. Such a Padé approximant is denoted by $[p/q]_f(x)$, where p is the degree of the numerator and q the degree of the denominator. By definition we have

$$[p/q]_f(x) - f(x) = O(x^{p+q+1}).$$

Let us define the linear functional c on the vector space of polynomials by

$$c\left(x^i\right) = c_i \quad \text{for } i = 0, 1, \ldots.$$

We consider the polynomial P_k of degree k belonging to the family of orthogonal polynomials with respect to c; that is,

$$P_k(x) = b_0 + b_1 x + \cdots + b_k x^k$$

such that

$$c\left(x^i P_k(x)\right) = \sum_{j=0}^{k} c_{i+j}\, b_j = 0 \quad \text{for } i = 0, 1, \ldots, k-1.$$

One of the b_i's is arbitrary and we choose the normalization $b_0 = 1$.

The coefficients $b_1, \ldots, b_k$ are obtained as the solution of a linear system

$$\begin{pmatrix} c_1 & c_2 & \cdots & c_k \\ c_2 & c_3 & \cdots & c_{k+1} \\ \vdots & \vdots & & \vdots \\ c_k & c_{k+1} & \cdots & c_{2k-1} \end{pmatrix} \begin{pmatrix} b_1 \\ b_2 \\ \vdots \\ b_k \end{pmatrix} = - \begin{pmatrix} c_0 \\ c_1 \\ \vdots \\ c_{k-1} \end{pmatrix}.$$

If we denote by A_k the Hankel matrix of the preceding system, by d_k its right-hand side, and by $z_k = (b_1, \ldots, b_k)^{\mathrm{T}}$ its solution, we can solve this system by the block bordering and the reverse bordering methods.

We consider the formal power series

$$f(x) = c_0 + c_1 x + c_2 x^2 + \cdots$$

and the polynomial $\widetilde{P}_k(x)$ given by

$$\widetilde{P}_k(x) = x^k P_k\left(x^{-1}\right) = b_k + b_{k-1} x + \cdots + b_1 x^{k-1} + x^k.$$

From the connections between Padé approximants and orthogonal polynomials, we know that $\widetilde{P}_k(x)$ is the denominator of the Padé approximant $[k-1/k]_f(x)$. If we want to have the normalization $b_k = 1$ one can simply consider the polynomial

$$P_k^*(x) = b_k^{-1} \widetilde{P}_k(x).$$

Thus the block bordering and the reverse bordering methods allow us to compute recursively the coefficients of the denominators of the Padé approximants [0/1], [1/2], [2/3], ...

To control the accuracy and numerical stability of the reverse bordering method, we take f as the power series expansion of a rational function with numerator of degree $k-1$ and denominator of degree k. In that case, the Padé approximant $[k-1/k]_f$ must be identical to f. We set

$$f(x) = \frac{1 + \alpha_1 x + \alpha_2 x^2 + \cdots + \alpha_{k-1} x^{k-1}}{1 + \beta_0 x^k} = c_0 + c_1 x + c_2 x^2 + \cdots.$$

Giving some values to the α_i's and to the β_i's, we compute the c_i's so that $[k-1/k]_f = f$; that is, in order to have

$$P_k^* = 1 + \beta_0 x^k = 1 + \frac{b_0}{b_k} x^k,$$

where $b_0 = 1$, b_k is the coefficient of x^k in the orthogonal polynomial P_k, and all the $b_i, i = 1, \ldots, k-1$ are zero. The α_i's depend on a parameter η and we give to it different values.

We set ε as the threshold under which the block bordering method jumps, and ε' as the threshold under which the reverse bordering method jumps.

In the following examples, we give the residual $r_k = |A_k z_k - d_k|$, where z_k is the vector of the coefficients $b_i, i = 1, \ldots, k$ of the polynomial P_k (the numbers in parenthesis denote again the powers of 10). The coefficients of the polynomial P_k^*, which is the denominator of $[k-1/k] = f$, are also given.

7.1. Example 1. We consider the function

$$f(x) = \frac{1 + \eta x + \eta x^2}{1 - x^3} = 1 + \eta x + \eta x^2 + x^3 + \eta x^4 + \eta x^5 + x^6 + \cdots.$$

We should have $[2/3]_f = f$, that is, $P_3^* = 1 - x^3$.

$\eta = 10^{-5}$							
k	Bordering method no jump			Block and reverse $\varepsilon = 10^{-4}, \varepsilon' = 10^{-10}$

$$P_5^* = 1 + .11 \cdot 10^{-15}x - .22 \cdot 10^{-15}x^2 - .22 \cdot 10^{-15}x^3 - x^5$$

8. Conclusions. In Gaussian elimination, pivotal strategies are often necessary to ensure a better numerical stability. In particular, they avoid division by numbers close to zero (which are possibly due to cancellation errors in the previous steps), thus preventing possible catastrophic errors. The block bordering method provides a similar strategy in a different context for the same drawback. However, with such a strategy, the solutions of the intermediate systems that were skipped when climbing to higher and higher dimensions are not computed. It was the purpose of this paper to propose an algorithm (the reverse bordering method) for obtaining these solutions.

SOME SPECTRAL PROPERTIES OF HERMITIAN TOEPLITZ MATRICES*

WILLIAM F. TRENCH†

Abstract. Necessary conditions are given for the Hermitian Toeplitz matrix $T_n = (t_{r-s})_{r,s=1}^n$ to have a repeated eigenvalue λ with multiplicity $m > 1$ and for an eigenpolynomial of T_n associated with λ to have a given number of zeros off the unit circle $|z| = 1$. It is assumed that $t_r = \frac{1}{2\pi}\int_{-\pi}^{\pi} f(\theta)e^{-ir\theta}\,d\theta$ $(0 \le r \le n-1)$, where f is real-valued and in $L(-\pi,\pi)$. The conditions are given in terms of the number of changes in sign of $f(\theta) - \lambda$.

Key words. Toeplitz, Hermitian, eigenvalue, eigenvector, eigenpolynomial

AMS subject classifications. 15A18, 15A42

1. Introduction.

We consider the Hermitian Toeplitz matrix

$$T_n = (t_{r-s})_{r,s=1}^n,$$

where

$$t_r = \frac{1}{2\pi}\int_{-\pi}^{\pi} f(\theta)e^{-ir\theta}\,d\theta, \qquad r = 0, 1, \ldots, n-1, \tag{1}$$

and f is real-valued and Lebesgue integrable on $(-\pi,\pi)$ and not constant on a set of measure 2π.

Let $\lambda_1 \le \lambda_2 \le \cdots \le \lambda_n$ be the eigenvalues of T_n, with associated orthonormal eigenvectors $x_1, x_2, \ldots, x_n$. Our first main result (Theorem 2.1) presents a necessary condition on f for λ_r to have multiplicity $m > 1$. To describe our second main result we first recall some well-known properties of eigenvectors of Hermitian Toeplitz matrices. If J is the $n \times n$ matrix with ones on the secondary diagonal and zeros elsewhere, then $JT_nJ = \overline{T}_n$. This implies that a vector x_r is a λ_r-eigenvector of T_n if and only if $J\overline{x}_r$ is. It follows that if λ_r has multiplicity one then

$$J\overline{x}_r = \xi x_r, \tag{2}$$

where ξ is a complex constant with modulus one. A stronger result holds if T_n is real and symmetric: Cantoni and Butler [1] have shown that in this case (even if T_n has repeated eigenvalues) R^n has an orthonormal basis consisting of $\lceil n/2 \rceil$ eigenvectors of T_n for which (2) holds with $\xi = 1$ and $\lfloor n/2 \rfloor$ for which (2) holds with $\xi = -1$.

The polynomial

$$X_r(z) = [1, z, \ldots, z^{n-1}]x_r \tag{3}$$

is said to be an *eigenpolynomial of* T_n *associated with* λ_r. The location of the zeros of the eigenpolynomials of Hermitian Toeplitz matrices is of interest in signal processing applications [2]–[5], [7]. If x_r satisfies (2) then

$$X_r(z) = \overline{\xi} z^{n-1}\overline{X_r(1/\overline{z})};$$

* Received by the editors October 19, 1992; accepted for publication (in revised form) February 16, 1993. This work was partially supported by National Science Foundation grants DMS-8907939 and DMS-9108254.

† Trinity University, 715 Stadium Drive, San Antonio, Texas 78212 (wtrench@trinity.edu).

hence, zeros of $X_r(z)$ that are not on the unit circle must occur in pairs ζ and $1/\overline{\zeta}$.

Gueguen proved the following theorem in [5]. (See also [2] and [4].)

THEOREM 1.1. *Let λ_r be an eigenvalue of T_n, but not of T_{n-1}. Then its associated eigenpolynomial $X_r(z)$ has at least $|n-2r+1|$ zeros on the unit circle $|z|=1$.*

Delsarte, Genin, and Kamp proved the following theorem in [3]. (See also [4].)

THEOREM 1.2. *Suppose that the eigenvalue λ_r of T_n has multiplicity m and let s be the largest integer $< n$ such that λ_r is not an eigenvalue of T_s. Then any eigenpolynomial $X(z)$ of T_n corresponding to λ_r has at least $|n-m-2r+2|$ and at most $m+s-1$ zeros on the unit circle $|z|=1$.*

Our second main result (Theorem 3.1) gives a necessary condition on f for an eigenpolynomial of T_n satisfying (2) to have a given number of zeros that are not on the unit circle.

2. A necessary condition for repeated eigenvalues.. Let α and β be the essential upper and lower bounds of f; that is, α is the largest number and β the smallest such that $\alpha \le f(\theta) \le \beta$ almost everywhere on $(-\pi,\pi)$. It is known [6, p. 65] that all the eigenvalues of T are in (α,β). A proof of this is included naturally in the proof of the following theorem.

THEOREM 2.1. *If λ_r is an eigenvalue of T_n with multiplicity m, then $f(\theta)-\lambda_r$ must change sign at least $2m-1$ times in $(-\pi,\pi)$.*

Proof. Associate with each vector $v=[v_1,v_2,\dots,v_n]^t$ in C^n the polynomial

$$V(z)=[1,z,\dots,z^{n-1}]v=\sum_{j=1}^{n} v_j z^{j-1}.$$

If u and v are in C^n then

$$(u,v)=\frac{1}{2\pi}\int_{-\pi}^{\pi} U(z)\overline{V(z)}\,d\theta, \tag{4}$$

where $z=e^{i\theta}$ whenever z appears in an integral. Moreover, (1) implies that

$$(T_n u,v)=\frac{1}{2\pi}\int_{-\pi}^{\pi} f(\theta)U(z)\overline{V(z)}\,d\theta. \tag{5}$$

Now let $\lambda_1 \le \lambda_2 \le \cdots \le \lambda_n$ be the eigenvalues of T_n, with corresponding orthonormal eigenvectors $x_1,x_2,\dots,x_n$, and let

$$X_i(z)=[1,z,\dots,z^{n-1}]x_i, \qquad 1\le i\le n,$$

be the corresponding eigenpolynomials. From (4),

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} X_i(z)\overline{X_j(z)}\,d\theta=\delta_{ij}, \qquad 1\le i,j\le n \tag{6}$$

and from (5),

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} f(\theta)X_i(z)\overline{X_j(z)}\,d\theta=\delta_{ij}\lambda_j, \qquad 1\le i,j\le n. \tag{7}$$

The last two equations with $i=j$ show that the eigenvalues of T_n are in (α,β). Therefore, $f(\theta)-\lambda_r$ must change sign at some point in $(-\pi,\pi)$. This completes the proof if $m=1$.

Now suppose that $m > 1$ and $f(\theta) - \lambda_r$ changes sign only at the points $\theta_1 < \theta_2 < \cdots < \theta_k$ in $(-\pi, \pi)$, where $k \le 2m-2$. We will show that this assumption leads to a contradiction.

Define

$$g(\theta) = \frac{1}{2\pi}\left(f(\theta) - \lambda_r\right). \tag{8}$$

For reference below note that if $k = 2p$ then the function

$$g(\theta)\prod_{j=1}^{2p}\sin\left(\frac{\theta-\theta_j}{2}\right) \tag{9}$$

does not change sign in $(-\pi, \pi)$. This remains true if $k = 2p-1$, if we define $\theta_{2p} = \pi$. Now suppose that λ_r has multiplicity m; that is,

$$\lambda_r = \lambda_{r+1} = \cdots = \lambda_{r+m-1}. \tag{10}$$

From (6), (7), and (10),

$$\int_{-\pi}^{\pi} g(\theta)X_i(z)\overline{X_j(z)}\,d\theta = 0 \qquad (r \le i \le r+m-1,\ 1 \le j \le n).$$

Therefore

$$\int_{-\pi}^{\pi} g(\theta)\left(\sum_{\ell=0}^{m-1} c_\ell X_{r+\ell}(z)\right)\overline{X_j(z)}\,d\theta = 0, \qquad 1 \le j \le n,$$

if $c_0, \ldots, c_{m-1}$ are constants. This implies that

$$\int_{-\pi}^{\pi} g(\theta)\left(\sum_{\ell=0}^{m-1} c_\ell X_{r+\ell}(z)\right)\overline{Q(z)}\,d\theta = 0 \tag{11}$$

if Q is any polynomial of degree $\le n-1$, since any such polynomial can be written as a linear combination of $X_1(z), \ldots, X_n(z)$. In particular, choose $c_0, \ldots, c_{m-1}$—not all zero—so that

$$\sum_{\ell=0}^{m-1} c_\ell X_{r+\ell}(e^{i\theta_j}) = 0, \qquad 1 \le j \le p$$

(this is possible, since $p < m$), and let

$$Q(z) = \left(\sum_{\ell=0}^{m-1} c_\ell X_{r+\ell}(z)\right)\prod_{j=1}^{p}\frac{z - e^{i\theta_{p+j}}}{z - e^{i\theta_j}}.$$

Substituting this into (11) yields

$$\int_{-\pi}^{\pi} g(\theta)\left|\sum_{\ell=0}^{m-1} c_\ell X_{r+\ell}(z)\right|^2 \prod_{j=1}^{p}\frac{\overline{z} - e^{-i\theta_{p+j}}}{\overline{z} - e^{-i\theta_j}}\,d\theta = 0,$$

or, equivalently,

$$\int_{-\pi}^{\pi} g_1(\theta) \prod_{j=1}^{p} (z - e^{i\theta_j})(\overline{z} - e^{-i\theta_{p+j}})\, d\theta = 0, \tag{12}$$

where

$$g_1(\theta) = g(\theta) \left| \frac{\sum_{\ell=0}^{m-1} c_\ell X_{r+\ell}(z)}{\prod_{j=1}^{p} (z - e^{i\theta_j})} \right|^2.$$

If $z = e^{i\theta}$ then

$$(z - e^{i\theta_j})(\overline{z} - e^{-i\theta_{p+j}}) = 4e^{i(\theta_j - \theta_{p+j})/2} \sin\left(\frac{\theta - \theta_j}{2}\right) \sin\left(\frac{\theta - \theta_{p+j}}{2}\right);$$

hence, (12) implies that

$$\int_{-\pi}^{\pi} g_1(\theta) \prod_{j=1}^{2p} \sin\left(\frac{\theta - \theta_j}{2}\right) d\theta = 0,$$

which is impossible because of (8) and our observation that the function in (9) is sign constant on $(-\pi, \pi)$. □

Theorem 2.1 immediately implies the following theorems. Theorem 2.4 was proved in [8].

THEOREM 2.2. *If f is monotonic on $(-\pi, \pi)$ or there is a number ϕ in $(-\pi, \pi)$ such that f is monotonic on $(-\pi, \phi)$ and (ϕ, π), then all eigenvalues of T_n have multiplicity one.*

THEOREM 2.3. *Suppose that $f(-\theta) = f(\theta)$, so that T_n is a real symmetric Toeplitz matrix. If λ_r is an eigenvalue of T_n with multiplicity m, then $f(\theta) - \lambda_r$ must change sign at least m times in $(0, \pi)$*

THEOREM 2.4. *Suppose that $f(-\theta) = f(\theta)$ and f is monotonic on $(0, \pi)$. Then all the eigenvalues of T_n have multiplicity one.*

3. Location of the zeros of eigenpolynomials. The following theorem is the main result of this section.

THEOREM 3.1. *Suppose that the eigenvalue λ_r has an associated eigenvector x_r such that $J\overline{x}_r = \xi x_r$, where ξ is a constant, and the eigenpolynomial $X_r(z)$ defined in (3) has $2m$ zeros ($m \geq 1$) that are not on the unit circle. Then $f(\theta) - \lambda_r$ must change sign at least $2m + 1$ times in $(-\pi, \pi)$.*

Proof. The proof is by contradiction. Suppose $f(\theta) - \lambda_r$ changes sign only at the points $\theta_1 < \cdots < \theta_k$ in $(-\pi, \pi)$, where $1 \leq k \leq 2m$. Then, as in the proof of Theorem 2.1, the function (9) does not change sign in $(-\pi, \pi)$. (Again, $k = 2p$ if k is even, and we define $\theta_{2p} = \pi$ if $k = 2p - 1$.) From among the $2m$ zeros of $X_r(z)$ not on the unit circle choose $2p$ distinct zeros $\zeta_1, \ldots, \zeta_p, 1/\overline{\zeta}_1, \ldots, 1/\overline{\zeta}_p$, and define g as in (8).

From (6) and (7),

$$\int_{-\pi}^{\pi} g(\theta) X_r(z) \overline{X_s(z)}\, d\theta = 0 \, (1 \leq s \leq n),$$

which implies that

$$\int_{-\pi}^{\pi} g(\theta)X_r(z)\overline{Q(z)}\,d\theta = 0 \tag{13}$$

if Q is any polynomial of degree $\le n-1$.

Now define

$$q_j(z) = \frac{(z-e^{i\theta_j})(1-e^{-i\theta_{p+j}}z)}{(z-\zeta_j)(1-\overline{\zeta}_j z)}, \qquad 1 \le j \le p,$$

and let

$$Q(z) = X_r(z)q_1(z)\cdots q_p(z).$$

Then (13) implies that

$$\int_{-\pi}^{\pi} g(\theta)|X_r(z)|^2\overline{q_1(z)}\cdots\overline{q_p(z)}\,d\theta = 0. \tag{14}$$

However, if $z = e^{i\theta}$ then

$$q_j(z) = \frac{4e^{i(\theta_j-\theta_{p+j})/2}}{|1-\overline{\zeta}_j e^{i\theta}|^2}\sin\left(\frac{\theta-\theta_j}{2}\right)\sin\left(\frac{\theta-\theta_{p+j}}{2}\right).$$

This and (14) imply that

$$\int_{-\pi}^{\pi} \frac{g(\theta)|X_r(z)|^2}{\prod_{j=1}^{p}|1-\overline{\zeta}_j e^{i\theta}|^2}\prod_{j=1}^{2p}\sin\left(\frac{\theta-\theta_j}{2}\right)\,d\theta = 0, \tag{15}$$

which is impossible, since the function (9) is sign constant in $(-\pi,\pi)$. □

Theorem 3.1 immediately implies the following theorem.

THEOREM 3.2. *If f satisfies the hypotheses of either Theorem 2.2 or Theorem 2.4, then all zeros of the eigenpolynomials of T_n are on the unit circle $|z| = 1$.*

THEORY OF DECOMPOSITION AND BULGE-CHASING ALGORITHMS FOR THE GENERALIZED EIGENVALUE PROBLEM*

DAVID WATKINS† AND LUDWIG ELSNER‡

Abstract. A generic GZ algorithm for the generalized eigenvalue problem $Ax = \lambda Bx$ is presented. This is actually a large class of algorithms that includes multiple-step QZ and LZ algorithms, as well as QZ-LZ hybrids, as special cases. First the convergence properties of the GZ algorithm are discussed, then a study of implementations is undertaken. The notion of an elimination rule is introduced as a device for studying the QZ, LZ and other algorithms simultaneously. To each elimination rule there corresponds an explicit GZ algorithm. Through a careful study of the steps involved in executing the explicit algorithm, it is discovered how to implement the algorithm implicitly by bulge chasing. The approach taken here was introduced by Miminis and Paige in the context of the QR algorithm for the ordinary eigenvalue problem. It is more involved than the standard approach, but it yields a much clearer picture of the relationship between the implicit and explicit versions of the algorithm. Furthermore, it is more general than the standard approach, as it does not require the use of a theorem of "Implicit-Q" type. Finally a generalization of the implicit GZ algorithm, the generic bulge-chasing algorithm, is introduced. It is proved that the generic bulge-chasing algorithm implicitly performs iterations of the generic GZ algorithm. Thus the convergence theorems that are proved for the generic GZ algorithm hold for the generic bulge-chasing algorithm as well.

1. Introduction.

The standard algorithm for finding the eigenvalues of a dense, indefinite, matrix pencil $A - \lambda B$ with B nonsingular is the QZ algorithm of Moler and Stewart [11]. Related methods are the LZ algorithm of Kaufman [8] and the combination-shift QZ algorithm of Ward [14]. In this paper we introduce and study a generic GZ algorithm, which is actually a large class of algorithms that contains these and many other algorithms as special cases. For example, QZ-LZ hybrids are also included. Our coverage is not restricted to single- or double-step algorithms; we allow multiple steps of arbitrary multiplicity.

The QZ algorithm is an extension of the QR algorithm, which is one of the most widely used algorithms for the standard eigenvalue problem. The QR algorithm has both explicit and implicit versions. The explicit version is useful for introducing the algorithm and discussing theoretical aspects such as convergence theory, but it is usually the implicit version that is actually implemented. The standard approach to the QZ algorithm, as presented in contemporary textbooks [6], [12], mentions only an implicit version, which is interpreted as a way of applying the QR algorithm to the matrix AB^{-1} without actually forming AB^{-1} or even B^{-1}. Earlier approaches [11], [8] started from an explicit version and derived the implicit version therefrom. In every instance the focus was on the matrix AB^{-1}. Our approach also starts with an explicit version, but our explicit QZ algorithm differs from earlier formulations in that it effectively applies the QR algorithm to both AB^{-1} and $B^{-1}A$. The advantage of this approach is that it reveals symmetries in the algorithm that are obscured by the usual approaches. In particular, it puts the "Q" and "Z" transformations on an

equal footing. Of course our discussion is couched in more general terms. We consider a generic GZ algorithm that amounts to the generic GR algorithm [17] applied to the matrices $p(AB^{-1})$ and $p(B^{-1}A)$ simultaneously, where p is a polynomial whose degree is the multiplicity of the step. Our generic GZ algorithm is quite similar to the FGZ algorithm of [16].

The explicit algorithm is not a practical algorithm, because it would be too costly to implement and quite likely unstable as well. However, it is a useful vehicle for both the study of convergence and the introduction of implicit versions of the algorithm. We introduce the generic GZ algorithm in §2. In §3 we study the convergence properties of the algorithm and in §4 we consider questions of implementation. Sections 3 and 4 can be read independently of one another.

The convergence theorem that we prove in §3 is a generalization of a theorem on the convergence of the GR algorithm that we proved in [17]. The theorem says roughly that if the eigenvalues can be separated, and the shifts converge, and the condition numbers of the accumulated transforming matrices remain bounded, then the algorithm converges. We also introduce the generalized Rayleigh quotient shift strategy and discuss its asymptotic convergence properties without proof. Usually the convergence rate is quadratic.

In §4 we consider how to implement the GZ algorithm. Our approach is inspired by Miminis and Paige [10]. They showed that by taking a detailed look at how one would carry out an iteration of the QR algorithm in its explicit form, one can discover how it can be done implicitly. As Miminis and Paige pointed out, this approach is more involved than the usual approach, which invokes the Implicit-Q Theorem [6, p. 367], but it gives a much clearer picture of the relationship between the explicit and implicit versions of the algorithm. Miminis and Paige also stated that their approach is quite general. Our vehicle for introducing the desired generality is the idea of an elimination rule, which allows us to discuss the QZ, LZ, and all related algorithms simultaneously. Each elimination rule gives rise to a specific implementation of the GZ algorithm. Following Miminis and Paige, we take a close look at the steps involved in implementing the GZ algorithm explicitly. By studying the form of the intermediate matrices so produced, we discover how the algorithm can be implemented implicitly, that is, without forming or operating on the matrices $p(AB^{-1})$ or $p(B^{-1}A)$.

Once we have derived the implicit GZ algorithm, we introduce a generalization called the generic bulge-chasing algorithm and prove that each iteration of the generic bulge-chasing algorithm amounts to an iteration of the generic GZ algorithm. The purpose of making this last generalization is to allow additional flexibility in implementing the algorithm. This flexibility can be exploited to build more efficient and stable algorithms. In particular it allows the introduction of variants that do not break down when B happens to be singular. (For the originators of the QZ and LZ algorithms this was an important point.) When it comes to implementing the algorithm in practice, these are the variants that should be used.

In [18] we introduced a generic bulge-chasing algorithm for the standard eigenvalue problem. Our aim there was to lay common foundations for implicit versions of GR algorithms of all types (e.g., QR, LR with or without pivoting, SR, hybrids, etc.). To achieve the desired level of generality, we devised an approach that, like the Miminis–Paige approach, avoids using a theorem of the Implicit-Q type. However, unlike Miminis and Paige, we did not establish a close correspondence between the operations in the implicit and explicit versions of the algorithms. The results of this paper generalize those of [18].

2. The generic GZ algorithm. We consider the generalized eigenvalue problem

$$(A - \lambda B)x = 0,$$

where A and B are square matrices whose entries are complex numbers. Recall that the pencil $A - \lambda B$ is said to be *singular* if its determinant is zero for all λ and *regular* otherwise. We focus here on the regular case. If the given pencil is singular (or not known a priori to be regular), the staircase algorithm of Van Dooren [13] can be used to remove the singular part. (See also Demmel and Kågström [3], [4].) This algorithm also removes the infinite eigenvalue and its associated structure (which may be present if B is singular) and the zero eigenvalue and its associated structure (which may be present if A is singular). What is left is a regular pencil for which both A and B are nonsingular. We assume throughout (with few exceptions, when we explicitly state otherwise) that our pencil has a nonsingular B; we do not need to assume that A is nonsingular.[1]

Recall that the pencils $A - \lambda B$ and $\hat{A} - \lambda \hat{B}$ are said to be *strictly equivalent* if there exist nonsingular matrices G and Z such that

$$\hat{A} = G^{-1}AZ \quad \text{and} \quad \hat{B} = G^{-1}BZ.$$

Strictly equivalent pencils have the same eigenvalues, and the eigenvectors are related in a simple way through the transforming matrices G and Z. The generic GZ algorithm generates a sequence of strictly equivalent pencils $(A_i - \lambda B_i)$ that converges (we hope) to upper triangular or block triangular form, thus exposing the eigenvalues of the pencil. The eigenvectors can be found by a back-substitution process that utilizes the final upper-triangular matrices and the accumulated transforming matrices.

We assume that before we start our iterations of the GZ algorithm, we transform the pencil to some initial form

$$A_0 = G_0^{-1}AZ_0, \qquad B_0 = G_0^{-1}BZ_0.$$

For example, it is possible to make A_0 upper Hessenberg and B_0 upper triangular, as described in [6] and elsewhere. Later on we assume that A_0 and B_0 have this form, but for now we allow them to have any form; for example, we could take $G_0 = Z_0 = I$.

The ith iteration of the GZ algorithm transforms $A_{i-1} - \lambda B_{i-1}$ to $A_i - \lambda B_i$ by transformations obtained from GR decompositions. By a GR decomposition of a square matrix M, we mean any decomposition

$$M = GR$$

in which G is nonsingular and R is upper triangular. Every matrix has many different GR decompositions. To obtain A_i and B_i we first take GR decompositions of $p_i(A_{i-1}B_{i-1}^{-1})$ and $p_i(B_{i-1}^{-1}A_{i-1})$, where p_i is a polynomial. Thus we find nonsingular G_i and Z_i and upper triangular R_i and S_i such that

$$p_i(A_{i-1}B_{i-1}^{-1}) = G_iR_i \quad \text{and} \quad p_i(B_{i-1}^{-1}A_{i-1}) = Z_iS_i.$$

[1] However, if A is known to be nonsingular, one has the possibility of reversing the roles of A and B and considering the pencil $B - \mu A$, where $\mu = 1/\lambda$. If neither A nor B is known to be nonsingular, a prudent course of action is to run the staircase algorithm to determine the fine structure of the pencil.

We then let

$$A_i = G_i^{-1} A_{i-1} Z_i \quad \text{and} \quad B_i = G_i^{-1} B_{i-1} Z_i.$$

In the special case $B_{i-1} = I$, $Z_i = G_i$, $S_i = R_i$, this algorithm reduces to the generic GR algorithm for the standard eigenvalue problem.

The GZ algorithm is really a large class of algorithms. Specific instances are obtained by specifying the exact form of each GR decomposition and how the p_i are to be chosen. For example, variants of the QZ and LZ algorithms are obtained by specifying that each decomposition be a QR or LR decomposition, respectively. The p_i are chosen so that their roots, which we call the *shifts* for the ith iteration, are estimates of eigenvalues. The degree of p_i is called the *multiplicity* of the iteration.

We will see that it is possible to carry out the GZ iterations implicitly without even calculating matrices of the form AB^{-1} or $B^{-1}A$, much less $p(AB^{-1})$ or $p(B^{-1}A)$. Were this not the case, there would be no point in discussing these algorithms at all. First we look at convergence.

3. Convergence of GZ algorithms. An easy computation shows that

$$A_i B_i^{-1} = G_i^{-1} (A_{i-1} B_{i-1}^{-1}) G_i.$$

Since G_i was obtained from the decomposition $p_i(A_{i-1}B_{i-1}^{-1}) = G_i R_i$, we see that the transformation $A_{i-1}B_{i-1}^{-1} \to A_i B_i^{-1}$ is an iteration of the GR algorithm [17]. At the same time we have

$$B_i^{-1} A_i = Z_i^{-1} (B_{i-1}^{-1} A_{i-1}) Z_i,$$

where

$$p_i(B_{i-1}^{-1} A_{i-1}) = Z_i S_i,$$

so the transformation $B_{i-1}^{-1}A_{i-1} \to B_i^{-1}A_i$ is also a GR iteration. It follows from the theorems in [17] that both of the sequences $(A_i B_i^{-1})$ and $(B_i^{-1}A_i)$ converge to (block) upper triangular form, provided that the condition numbers of the accumulated transforming matrices $\hat{G}_i = G_1 \cdots G_i$ and $\hat{Z}_i = Z_1 \cdots Z_i$ remain bounded and the shifts converge, as $i \to \infty$. Preferably the shifts should converge to eigenvalues of the pencil, in which case the convergence of $(A_i B_i^{-1})$ and $(B_i^{-1}A_i)$ is superlinear.

We would like to be able to say something about the convergence of the sequences (A_i) and (B_i) separately, since these are the matrices with which we actually work. To do this we recall some nomenclature. Let $\mathcal{T}_d$ and $\mathcal{T}_r$ be subspaces of $\mathbb{C}^n$ of equal dimension. The pair $(\mathcal{T}_d, \mathcal{T}_r)$ is called a *deflating pair* for the regular pencil $A - \lambda B$ if and only if

$$A\mathcal{T}_d \subseteq \mathcal{T}_r \quad \text{and} \quad B\mathcal{T}_d \subseteq \mathcal{T}_r.$$

The subscripts d and r are mnemonics for domain and range, respectively. Since we are assuming that B is nonsingular, the condition $B\mathcal{T}_d \subseteq \mathcal{T}_r$ implies $B\mathcal{T}_d = \mathcal{T}_r$. Clearly $(\mathcal{T}_d, \mathcal{T}_r)$ is a deflating pair for $A - \lambda B$ if and only if $\mathcal{T}_d$ is invariant under $B^{-1}A$, $\mathcal{T}_r$ is invariant under AB^{-1}, and $B\mathcal{T}_d = \mathcal{T}_r$. The following lemma generalizes Lemma 6.1 of [17]. Here $d(\mathcal{S}, \mathcal{T})$ denotes the usual distance (or gap) between two subspaces and $\kappa_2(G)$ denotes the condition number of G with respect to the spectral norm.

LEMMA 3.1. *Let $A, B \in \mathbb{C}^{n\times n}$ and let $(\mathcal{T}_d, \mathcal{T}_r)$ be a deflating pair of k-dimensional subspaces for the pencil $A-\lambda B$. Let Z, $G \in \mathbb{C}^{n\times n}$ be nonsingular matrices, and let $\mathcal{S}_d$ and $\mathcal{S}_r$ be the spaces spanned by the first k columns of Z and G, respectively. (Think of $\mathcal{S}_d$ and $\mathcal{S}_r$ as approximations to $\mathcal{T}_d$ and $\mathcal{T}_r$, respectively.) Let C denote either A or B, and let $\hat{C} = G^{-1}CZ$. Consider the partition*

$$\hat{C} = \begin{bmatrix} \hat{C}_{11} & \hat{C}_{12} \\ \hat{C}_{21} & \hat{C}_{22} \end{bmatrix},$$

where $\hat{C}_{11} \in \mathbb{C}^{k\times k}$. Then

$$\frac{\|\hat{C}_{21}\|_2}{\|\hat{C}\|_2} \le \sqrt{2}\kappa_2(G)\kappa_2(Z)\left[d(\mathcal{S}_d, \mathcal{T}_d) + d(\mathcal{S}_r, \mathcal{T}_r)\right].$$

Proof. Let $Z = PU$, $G = QR$ be the QR decompositions of Z and G, respectively. Thus P and Q are unitary, and U and R are upper triangular. Partition these decompositions as

$$\begin{bmatrix} Z_1 & Z_2 \end{bmatrix} = \begin{bmatrix} P_1 & P_2 \end{bmatrix} \begin{bmatrix} U_{11} & U_{12} \\ 0 & U_{22} \end{bmatrix},$$

where Z_1 and P_1 are $n \times k$, and similarly for the decomposition $G = QR$. Since $\hat{C} = G^{-1}CZ = R^{-1}Q^*CPU$, we have $\hat{C}_{21} = R_{22}^{-1}Q_2^*CP_1U_{11}$, from which

$$\|\hat{C}_{21}\|_2 \le \|R_{22}^{-1}\|_2 \|Q_2^*CP_1\|_2 \|U_{11}\|_2.$$

Since $\|R_{22}^{-1}\|_2 \le \|R^{-1}\|_2 = \|G^{-1}\|_2$, $\|U_{11}\|_2 \le \|U\|_2 = \|Z\|_2$, and $\|C\|_2 \le \|G\|_2\|\hat{C}\|_2\|Z^{-1}\|_2$, we see that

$$\frac{\|\hat{C}_{21}\|_2}{\|\hat{C}\|_2} \le \kappa_2(G)\kappa_2(Z)\frac{\|Q_2^*CP_1\|_2}{\|C\|_2}. \tag{1}$$

Since $Z_1 = P_1U_{11}$ and $G_1 = Q_1R_{11}$, we have $\mathcal{S}_d = \mathcal{R}(Z_1) = \mathcal{R}(P_1)$ and $\mathcal{S}_r^\perp = \mathcal{R}(G_1)^\perp = \mathcal{R}(Q_1)^\perp = \mathcal{R}(Q_2)$. Therefore, by Lemma 4.1 of [17], there exist $T_1 \in \mathbb{C}^{n\times k}$ and $T_2 \in \mathbb{C}^{n\times n-k}$ with orthonormal columns, such that $\mathcal{T}_d = \mathcal{R}(T_1)$, $\mathcal{T}_r^\perp = \mathcal{R}(T_2)$,

$$\|P_1 - T_1\|_2 \le \sqrt{2}d(\mathcal{S}_d, \mathcal{T}_d)$$

and

$$\|Q_2 - T_2\|_2 \le \sqrt{2}d(\mathcal{S}_r, \mathcal{T}_r).$$

We use here the fact that $d(\mathcal{S}_r, \mathcal{T}_r) = d(\mathcal{S}_r^\perp, \mathcal{T}_r^\perp)$. Now

$$\|Q_2^*CP_1\|_2 \le \|(Q_2 - T_2)^*CP_1\|_2 + \|T_2^*C(P_1 - T_1)\|_2 + \|T_2^*CT_1\|_2.$$

Since $\mathcal{R}(T_1) = \mathcal{T}_d$, $C\mathcal{T}_d \subseteq \mathcal{T}_r$, and $\mathcal{R}(T_2) = \mathcal{T}_r^\perp$, the product $T_2^*CT_1$ is zero. Thus

$$\begin{aligned}\|Q_2^*CP_1\|_2 &\le \|Q_2 - T_2\|_2\|C\|_2\|P_1\|_2 + \|T_2\|_2\|C\|_2\|P_1 - T_1\|_2 \\ &\le \sqrt{2}\,\|C\|_2\left[d(\mathcal{S}_d, \mathcal{T}_d) + d(\mathcal{S}_r, \mathcal{T}_r).\right]\end{aligned}$$

Combining this inequality with (1), we obtain the desired result. ∎

Define the cumulative transforming matrices by

$$\hat{G}_i = G_1 \cdots G_i, \qquad \hat{R}_i = R_i \cdots R_1,$$

$$\hat{Z}_i = Z_1 \cdots Z_i, \qquad \hat{S}_i = S_i \cdots S_1.$$

Then

$$C_i = \hat{G}_i^{-1} C_0 \hat{Z}_i,$$

where C can stand for either A or B. In the following theorem we prove the convergence of the GZ algorithm by applying Lemma 3.1 with the roles of C, G, Z, and $\hat{C}$ played by C_0, $\hat{G}_i$, $\hat{Z}_i$, and C_i, respectively. The symbol $\langle e_1, \ldots, e_k \rangle$ denotes the space spanned by the vectors $e_1, \ldots, e_k$.

THEOREM 3.2. *Let A_0, $B_0 \in \mathbb{C}^{n \times n}$ with B_0 nonsingular, and let p be a polynomial of degree $\leq n$. Let $\lambda_1, \ldots, \lambda_n$ denote the eigenvalues of the pencil $A_0 - \lambda B_0$, ordered so that $|p(\lambda_1)| \geq |p(\lambda_2)| \geq \cdots \geq |p(\lambda_n)|$. Suppose k is a positive integer less than n such that $|p(\lambda_k)| > |p(\lambda_{k+1})|$, and let $\rho = |p(\lambda_{k+1})|/|p(\lambda_k)|$. Let (p_i) be a sequence of polynomials of degree $\leq n$ such that $\lim_{i \to \infty} p_i = p$ and $p_i(\lambda_j) \neq 0$ for $j = 1, \ldots, k$ and all i. Let $(\mathcal{T}_d, \mathcal{T}_r)$ and $(\mathcal{U}_d, \mathcal{U}_r)$ be the deflating subspaces of $A_0 - \lambda B_0$ associated with $\lambda_1, \ldots, \lambda_k$ and $\lambda_{k+1}, \ldots, \lambda_n$, respectively. Suppose $\langle e_1, \ldots, e_k \rangle \cap \mathcal{U}_d = \{0\}$ and $\langle e_1, \ldots, e_k \rangle \cap \mathcal{U}_r = \{0\}$. Let $(A_i - \lambda B_i)$ be the sequence of iterates of the GZ algorithm using the given (p_i), starting from $A_0 - \lambda B_0$. If there is a constant $\hat{\kappa}$ such that the cumulative transforming matrices $\hat{G}_i$ and $\hat{Z}_i$ all satisfy $\kappa_2(\hat{G}_i) \leq \hat{\kappa}$ and $\kappa_2(\hat{Z}_i) \leq \hat{\kappa}$, then $(A_i - \lambda B_i)$ tends to block triangular form in the following sense. Let C_i denote either A_i or B_i, and partition C_i as*

$$C_i = \begin{bmatrix} C_{11}^{(i)} & C_{12}^{(i)} \\ C_{21}^{(i)} & C_{22}^{(i)} \end{bmatrix},$$

where $C_{21}^{(i)} \in \mathbb{C}^{(n-k) \times k}$. Then for every $\hat{\rho}$ satisfying $\rho < \hat{\rho} < 1$ there exists a constant M such that

$$\frac{\| C_{21}^{(i)} \|_2}{\| C_i \|_2} \leq M \hat{\rho}^i \quad \text{for all } i. \tag{2}$$

Remark 1. If A_0 is upper Hessenberg with no zeros on the subdiagonal and B_0 is upper triangular, then the subspace conditions $\langle e_1, \ldots, e_k \rangle \cap \mathcal{U}_d = \{0\}$ and $\langle e_1, \ldots, e_k \rangle \cap \mathcal{U}_r = \{0\}$ are satisfied for all k, as is explained in [17] for the standard eigenvalue problem. The reasoning is no different for the generalized eigenvalue problem.

Remark 2. The conditions $p_i(\lambda_j) \neq 0$ for $j = 1, \ldots, k$ may occasionally be violated, but this is not undesirable. If $p_i(\lambda_j) = 0$, then $p_i(A_i B_i^{-1})$ is singular. Theorem 4.3 shows that in this case the eigenvalue λ_j can be deflated from the problem after the ith iteration.

Remark 3. The conclusion of the theorem implies that the eigenvalues of $A_{11}^{(i)} - \lambda B_{11}^{(i)}$ and $A_{22}^{(i)} - \lambda B_{22}^{(i)}$ converge to $\lambda_1, \ldots, \lambda_k$ and $\lambda_{k+1}, \ldots, \lambda_n$, respectively, as can be shown by standard techniques.

Remark 4. If p has $\lambda_{k+1}, \ldots, \lambda_n$ among its roots, then $\rho = 0$, so (2) holds for all $\hat{\rho} > 0$. Thus the convergence is superlinear.

Remark 5. The hypotheses of the theorem usually hold for many values of k simultaneously, thereby giving a limiting form that is block triangular with many small blocks on the main diagonal. If the conditions hold for all k $(1 \le k \le n-1)$, the limiting form is upper triangular.

Proof. Let $\hat{p}_i = p_i \cdots p_1$, let $\mathcal{S} = \langle e_1, \ldots, e_k \rangle$, $\mathcal{S}_{ri} = \hat{p}_i(A_0 B_0^{-1})\mathcal{S}$, and $\mathcal{S}_{di} = \hat{p}_i(B_0^{-1}A_0)\mathcal{S}$. All of the hypotheses of Theorem 5.4 of [17] are satisfied, with the role of A in that theorem played by either $A_0 B_0^{-1}$ or $B_0^{-1}A_0$. Consequently there exists $\hat{M}$ such that $d(\mathcal{S}_{ri}, \mathcal{T}_r) \le \hat{M}\hat{\rho}^i$ and $d(\mathcal{S}_{di}, \mathcal{T}_d) \le \hat{M}\hat{\rho}^i$. Recall that (as shown in [17] and elsewhere) $\hat{p}_i(A_0 B_0^{-1}) = \hat{G}_i \hat{R}_i$ and $\hat{p}_i(B_0^{-1}A_0) = \hat{Z}_i \hat{S}_i$. Consider the partition $\hat{G}_i = [\hat{G}_1^{(i)} \ \hat{G}_2^{(i)}]$, $\hat{Z}_i = [\hat{Z}_1^{(i)} \ \hat{Z}_2^{(i)}]$, where $\hat{G}_1^{(i)}$, $\hat{Z}_1^{(i)} \in \mathbb{C}^{n \times k}$. Since $\hat{R}_i$ and $\hat{S}_i$ are upper triangular, $\mathcal{S}_{ri} = \mathcal{R}(\hat{G}_1^{(i)})$ and $\mathcal{S}_{di} = \mathcal{R}(\hat{Z}_1^{(i)})$. This is true even if $\hat{p}_i(A_0 B_0^{-1})$ and $\hat{p}_i(B_0^{-1}A_0)$ are singular, as the assumptions $\mathcal{S} \cap \mathcal{U}_d = \{0\}$, $\mathcal{S} \cap \mathcal{U}_r = \{0\}$, and $|p_i(\lambda_j)| > 0$, $j = 1, \ldots, k$ guarantee that $\mathcal{S}$ contains no nontrivial null vectors of $\hat{p}_i(A_0 B_0^{-1})$ or $\hat{p}_i(B_0^{-1}A_0)$. Therefore the spaces $\mathcal{S}_{di}$ and $\mathcal{S}_{ri}$ have dimension k for all i. Applying Lemma 3.1 with the roles of C, G, Z, and $\hat{C}$ played by C_0, $\hat{G}_i$, $\hat{Z}_i$, and C_i, respectively, we conclude that

$$\frac{\| C_{21}^{(i)} \|_2}{\| C_i \|_2} \le 2\sqrt{2}\kappa_2(\hat{G}_i)\kappa_2(\hat{Z}_i)\hat{M}\hat{\rho}^i \le M\hat{\rho}^i,$$

where $M = 2\sqrt{2}\hat{\kappa}^2\hat{M}$. □

3.1. The generalized Rayleigh quotient shift. Suppose we plan to perform GZ iterations of multiplicity m, where $m \ll n$. A natural way of choosing the shift polynomials is to let p_i be the characteristic polynomial of the $m \times m$ lower right-hand corner pencil $A_{22}^{(i)} - \lambda B_{22}^{(i)}$. We call this the *generalized Rayleigh quotient shift* strategy.

In [17] we proved that for the standard eigenvalue problem, the asymptotic convergence rate of the GR algorithm with the generalized Rayleigh quotient shift strategy is quadratic, provided that the eigenvalues of the given matrix are simple. This result also holds for the generalized eigenvalue problem. Specifically, if the GZ algorithm converges under the conditions of Theorem 3.2, and generalized Rayleigh quotient shifts with $m = n - k$ are used, the asymptotic convergence rate will be quadratic, provided $A_0 B_0^{-1}$ is simple. We omit the proof. The details are more tedious than they are for the standard problem, but the ideas are the same.

4. Implementation of GZ algorithms. We assume from now on that the initial transformation

$$A_0 = G_0^{-1} A Z_0, \qquad B_0 = G_0^{-1} B Z_0$$

makes A_0 upper Hessenberg and B_0 upper triangular. We even assume that A_0 is a *proper* upper Hessenberg matrix; that is, all of its subdiagonal entries $a_{i+1,i}^{(0)}$ are nonzero. This implies no loss of generality, for if some of the entries $a_{i+1,i}^{(0)}$ are zero, we can reduce the problem to two or more subproblems, each of which has a properly upper Hessenberg coefficient matrix. Since we are now concerned with the problem of implementing one iteration of the GZ algorithm, we drop the subscripts and consider the single iteration

$$\hat{A} = \hat{G}^{-1} A \hat{Z}, \qquad \hat{B} = \hat{G}^{-1} B \hat{Z}, \tag{3}$$

where

$$p(AB^{-1}) = \hat{G}\hat{R}, \qquad p(B^{-1}A) = \hat{Z}\hat{S}. \tag{4}$$

Here all matrices are in $\mathbb{C}^{n\times n}$. The degree of the polynomial p is m, which is assumed to be less than n. Normally $m \ll n$. Dropping the subscripts allows us to reintroduce subscripts later for a different purpose.

An important relationship that follows directly from (3) and (4) is given in the following lemma, which plays a key role in determining the structure of $\hat{A}$, $\hat{B}$ and intermediate matrices that arise during the execution of a GZ iteration. (It is a generalization of [10, (3.5)].) Although the lemma is used to study structure, it is not itself dependent on any special structure of the matrices involved, except that it is crucial that $\hat{G}$ and $\hat{Z}$ be nonsingular.

LEMMA 4.1. *Suppose A, $\hat{A}$, B, $\hat{B}$, $\hat{R}$, and $\hat{S}$ are any $n \times n$ matrices related by* (3) *and* (4), *where $\hat{G}$ and $\hat{Z}$ are nonsingular matrices, and p is a polynomial. Then*

$$\hat{A}\hat{S} = \hat{R}A \quad \textit{and} \quad \hat{B}\hat{S} = \hat{R}B.$$

Proof. $\hat{A}\hat{S} = \hat{A}\hat{Z}^{-1}p(B^{-1}A) = \hat{G}^{-1}Ap(B^{-1}A) = \hat{G}^{-1}p(AB^{-1})A = \hat{R}A$. The same argument shows that $\hat{B}\hat{S} = \hat{R}B$, since the equation $Bp(B^{-1}A) = p(AB^{-1})B$ also holds. □

As a first application of Lemma 4.1, consider a GZ iteration in which the matrices $p(AB^{-1})$ and $p(B^{-1}A)$ are nonsingular, as is usually the case. Then $\hat{R}$ and $\hat{S}$ are also nonsingular, so the equations in Lemma 4.1 can be rewritten in the form

$$\hat{A} = \hat{R}A\hat{S}^{-1}, \qquad \hat{B} = \hat{R}B\hat{S}^{-1}.$$

Since A is properly upper Hessenberg and B, $\hat{R}$, and $\hat{S}^{-1}$ are all upper triangular, we see immediately that $\hat{A}$ is properly upper Hessenberg and $\hat{B}$ is upper triangular. Thus the special form is preserved from one iteration to the next.

4.1. The singular case. When $p(AB^{-1})$ and $p(B^{-1}A)$ are singular, the upper Hessenberg-triangular form is not preserved, but something even better happens. A small subpencil at the lower right-hand corner of the matrix can be deflated from the pencil after the iteration. The part of the pencil that remains after deflation remains in Hessenberg-triangular form. We consider this case in detail.

The matrices AB^{-1} and $B^{-1}A$ are both properly upper Hessenberg. The proper upper Hessenberg matrix W that appears in the following lemma is taken to be AB^{-1} or $B^{-1}A$ in the application.

If $p(W)$ is singular, then at least one of the shifts (roots of p) is an eigenvalue of W, and conversely. Any shift that is an eigenvalue is called a *perfect* shift.

LEMMA 4.2. *Let W be a proper upper Hessenberg matrix, and let p be a polynomial that has ν roots that are perfect shifts for W. Then*

$$\operatorname{rank}(p(W)) = n - \nu.$$

Furthermore, the leading $n - \nu$ columns of $p(W)$ are linearly independent.

Remark. When we count perfect shifts, we allow repeated shifts, but we count a repeated shift no more times than it appears as a root of the characteristic polynomial of W.

This result is also proved in [10] as part of Theorem 4.1.

Proof. The statement about the rank is just Lemma 4.4 of [18]. To get the other assertion, let $x = p(W)e_1$. Let $K(W,x)$ denote the Krylov matrix

$$K(W,x) = [x, Wx, W^2x, \ldots, W^{n-1}x].$$

Then

$$K(W,x) = p(W)T, \tag{5}$$

where $T = K(W,e_1)$. Since W is properly upper Hessenberg, T is upper triangular and nonsingular. Thus, for any k, the span of the first k columns of $K(W,x)$ is the same as the span of the first k columns of $p(W)$. In particular, $\operatorname{rank}(K(W,x)) = n-\nu$. The form of a Krylov matrix implies that if a given column is a linear combination of previous columns, all subsequent columns will also be linear combinations of the previous columns. Thus the first $n-\nu$ columns of $K(W,x)$, and hence also of $p(W)$, must be linearly independent. □

THEOREM 4.3. *Consider the GZ iteration* (3), (4), *in which ν of the shifts are eigenvalues of $A - \lambda B$. Then*

$$\hat{R} = \begin{bmatrix} \hat{R}_{11} & \hat{R}_{12} \\ 0 & 0 \end{bmatrix}, \qquad \hat{S} = \begin{bmatrix} \hat{S}_{11} & \hat{S}_{12} \\ 0 & 0 \end{bmatrix},$$

$$\hat{A} = \begin{bmatrix} \hat{A}_{11} & \hat{A}_{12} \\ 0 & \hat{A}_{22} \end{bmatrix}, \quad \textit{and} \quad \hat{B} = \begin{bmatrix} \hat{B}_{11} & \hat{B}_{12} \\ 0 & \hat{B}_{22} \end{bmatrix},$$

where $\hat{R}_{11}$, $\hat{S}_{11}$, $\hat{A}_{11}$, $\hat{B}_{11} \in \mathbb{C}^{(n-\nu)\times(n-\nu)}$, $\hat{R}_{11}$ and $\hat{S}_{11}$ are nonsingular, $\hat{A}_{11}$ is properly upper Hessenberg, and $\hat{B}_{11}$ is upper triangular. The eigenvalues of the subpencil $\hat{A}_{22} - \lambda\hat{B}_{22}$ are exactly the ν perfect shifts.

Proof. In light of (4) and Lemma 4.2, the upper triangular matrices $\hat{R}$ and $\hat{S}$ both have rank $n-\nu$ and their first $n-\nu$ columns are linearly independent. This proves that they have the stated form.

Writing the equations of Lemma 4.1 in partitioned form, we have

$$\begin{bmatrix} \hat{C}_{11} & \hat{C}_{12} \\ \hat{C}_{21} & \hat{C}_{22} \end{bmatrix} \begin{bmatrix} \hat{S}_{11} & \hat{S}_{12} \\ 0 & 0 \end{bmatrix} = \begin{bmatrix} \hat{R}_{11} & \hat{R}_{12} \\ 0 & 0 \end{bmatrix} \begin{bmatrix} C_{11} & C_{12} \\ C_{21} & C_{22} \end{bmatrix},$$

where C can denote either A or B. Equating the $(2,1)$ blocks of the partitioned equation, we find that $\hat{C}_{21}\hat{S}_{11} = 0$. Since $\hat{S}_{11}$ is nonsingular, we have $\hat{C}_{21} = 0$. Equating the $(1,1)$ blocks and multiplying on the right by $\hat{S}_{11}^{-1}$, we get

$$\hat{C}_{11} = \hat{R}_{11}C_{11}\hat{S}_{11}^{-1} + \hat{R}_{12}C_{21}\hat{S}_{11}^{-1}.$$

In the case $C = B$, we have $B_{21} = 0$, so $\hat{B}_{11} = \hat{R}_{11}B_{11}\hat{S}_{11}^{-1}$, which shows that $\hat{B}_{11}$ is upper triangular. Now consider the case $C = A$. Since A is upper Hessenberg, $A_{21} = \alpha e_1 e_{n-\nu}^T$, where $\alpha = a_{n-\nu+1,n-\nu}$. Since $\hat{S}_{11}^{-1}$ is upper triangular, we have $\alpha e_{n-\nu}^T\hat{S}_{11}^{-1} = \beta e_{n-\nu}^T$ for some β. Let $x = \hat{R}_{12}e_1$. Then

$$\hat{A}_{11} = \hat{R}_{11}A_{11}\hat{S}_{11}^{-1} + \beta x e_{n-\nu}^T.$$

The first term on the right-hand side is properly upper Hessenberg and the second term has nonzero entries only in the last column. Thus $\hat{A}_{11}$ is a proper upper Hessenberg matrix.

The fact that the eigenvalues of $\hat{A}_{22} - \lambda\hat{B}_{22}$ are just the ν perfect shifts can be deduced in the same way as in the standard eigenvalue problem by considering the form of $\hat{A}\hat{B}^{-1}$. See Theorem 4.5 of [18]. □

Remarks. We have opted for a brief algebraic proof using Lemma 4.1. Alternatively one could prove the form of $\hat{A}$ and $\hat{B}$ geometrically, using the Hessenberg form of A, the relationships between the underlying subspaces (spanned by the leading columns of $\hat{G}$ and $\hat{Z}$), and the fact that the $n-\nu$ dimensional spaces $\mathcal{T}_d = \mathcal{R}(p(B^{-1}A))$ and $\mathcal{T}_r = \mathcal{R}(p(AB^{-1}))$ form a deflating pair for $A - \lambda B$. Such a proof would be lengthier but perhaps more revealing.

Theorem 4.3 generalizes Theorem 4.5 of [18] and some aspects of Theorem 4.1 of Miminis and Paige [10]. However, the Miminis–Paige result addresses certain details that we have chosen to ignore.

Theorem 4.3 shows that if ν of the shifts are perfect, then a $\nu \times \nu$ subpencil can be deflated from the problem after the iteration. The pencil $\hat{A}_{22} - \lambda\hat{B}_{22}$ may not have Hessenberg-triangular form, but it is normally small enough that it can easily be returned to that form and its eigenvalues found. Subsequent iterations can focus on the pencil $\hat{A}_{11} - \lambda\hat{B}_{11}$, which does have Hessenberg-triangular form. Of course this is only a theoretical result. In a GZ step with roundoff errors, $\hat{A}_{21}$ will be not quite zero. Usually it will be far enough from zero to prevent deflation. In that case a subsequent GZ step with the same p will often produce the deflation.

4.2. *GR* decompositions and elimination rules. To introduce specific versions of the GZ algorithm, we need to consider how GR decompositions are carried out in practice. The standard way to perform a GR decomposition of any type is to "reduce the matrix to triangular form" by introducing zeros into the matrix one column at a time. Each column of zeros is obtained by multiplying on the left by a nonsingular matrix of a specified form. Algorithms of this type have the following general structure. A matrix $M \in \mathbb{C}^{n\times n}$ is reduced to upper triangular form in $n-1$ steps. After $i-1$ steps, M has been transformed to a matrix $\hat{R}_{i-1}$ whose first $i-1$ columns have been reduced to upper triangular form. That is,

$$\hat{R}_{i-1} = \begin{bmatrix} T & E \\ 0 & F \end{bmatrix},$$

where $T \in \mathbb{C}^{i-1\times i-1}$ is upper triangular. The ith step transforms $\hat{R}_{i-1}$ to $\hat{R}_i = G_i^{-1}\hat{R}_{i-1}$, where G_i has the form

$$G_i = \begin{bmatrix} I & 0 \\ 0 & \tilde{G}_i \end{bmatrix},$$

and $\tilde{G}_i \in \mathbb{C}^{(n-i+1)\times(n-i+1)}$ is chosen so that $\tilde{G}_i^{-1}x = \alpha e_1$, where x is the first column of F, and α is a scalar. After $n-1$ such steps, M will have been transformed to the upper triangular matrix $\hat{R} = \hat{R}_{n-1}$. Clearly $\hat{R} = G_{n-1}^{-1}\cdots G_1^{-1}M$, or

$$M = \hat{G}\hat{R},$$

where $\hat{G} = G_1 \cdots G_{n-1}$.

Given any vector $x \in \mathbb{C}^m$ (for any $m \geq 2$) we say that a matrix $\tilde{G} \in \mathbb{C}^{m \times m}$ is an *elimination matrix* for x if $\tilde{G}$ is nonsingular and $\tilde{G}^{-1}x = \alpha e_1$ for some scalar α. If $\tilde{G}$ is an elimination matrix for x, then $\tilde{G}$ is an elimination matrix for all nonzero multiples of x.

Usually an elimination matrix $\tilde{G}$ is embedded in a larger matrix G. We also refer to the larger matrix as an elimination matrix.

An *elimination rule* is a map $x \mapsto \tilde{G}$ having the following properties. (i) The domain of the map is a subset of $\bigcup_{i=2}^{\infty} \mathbb{C}^i$. (ii) Each vector x in the domain is mapped to a matrix $\tilde{G}$ that is an elimination matrix for x. (iii) The map is homogeneous, that is, if x is in the domain, so are all nonzero multiples of x, and they are all mapped to the same elimination matrix. (iv) Zero vectors are in the domain, and each is mapped to the identity matrix of the same size. (v) If $x = \begin{bmatrix} y \\ 0 \end{bmatrix} \in \mathbb{C}^n$, where $y \in \mathbb{C}^k$ with $k < n$, then x is in the domain if and only if y is, and x is mapped to the matrix $\tilde{G} = \operatorname{diag}\{\tilde{H}, I_{n-k}\}$, where $\tilde{H}$ is the elimination matrix assigned to y by the map.

A *complete* elimination rule is one whose domain is all of $\bigcup_{i=2}^{\infty} \mathbb{C}^i$. A *partial* elimination rule is one whose domain is a proper subset of $\bigcup_{i=2}^{\infty} \mathbb{C}^i$.

Probably the simplest elimination rule is *Gaussian elimination without pivoting.* It is a partial elimination rule, as it is undefined on those nonzero x that satisfy $x_1 = 0$. An example of a complete elimination rule is Gaussian elimination with pivoting, which interchanges x_1 with the entry in x of largest magnitude before performing the elimination. Another complete elimination rule is *elimination by reflector* (*Householder transformation*). All of these types of elimination are discussed in [6] and [15], for example. One can also build hybrid elimination rules from other rules. For example, one can pick a tolerance τ satisfying $0 < \tau < 1$ and specify that x should be eliminated by Gaussian elimination (without pivoting) if $\max_{2 \leq i \leq k} |x_i| \leq \tau |x_1|$ and by a reflector otherwise. This type of strategy has been used successfully in some of the algorithms in [7]. There are also more exotic types of elimination rules. For example, a symplectic (partial) elimination rule, which gives rise to the SR algorithm, is described in [1].

Every elimination rule induces a rule for carrying out GR decompositions; namely, carry out the "reduction to triangular form" described above using the specified elimination rule. Hence each elimination rule, together with a mechanism for choosing p, induces a GZ algorithm. If the elimination rule is not complete, the algorithm will break down (fail) if at some point it needs to perform an elimination on a vector that is not in the domain of the rule.

4.3. The explicit GZ algorithm. We now assume that we have chosen an elimination rule and will perform all of our eliminations with that rule.[2] Let us examine closely the steps involved in performing a GZ iteration explicitly. First the matrices $p(AB^{-1})$ and $p(B^{-1}A)$ are calculated. Then GR decompositions of both matrices are performed, using our chosen elimination rule. As above, we assume that ν of the shifts are perfect. If $\nu > 0$, then by Theorem 4.3, the resulting upper triangular matrices $\hat{R}$ and $\hat{S}$ have rank $n - \nu$, and their bottom ν rows zero. This

[2] However, everything we do could be cast in greater generality. For example, we could allow a different rule to be used at each step of the decomposition. Another possibility is to prescribe different rules for the two different GR decompositions on which the GZ iteration is based. Such an algorithm was once proposed by Kaufman [9]. In this algorithm all of the "G" transformations are unitary and all of the "Z" transformations are stabilized elementary (i.e., Gaussian elimination) transformations. This is a GZ algorithm in which the decomposition of $p(AB^{-1})$ is a QR decomposition and that of $p(B^{-1}A)$ is an LR decomposition with partial pivoting.

implies that the reductions to triangular form will be completed after $n - \nu$ steps. Thus, letting $\rho = \min\{n - \nu, n - 1\}$, the reductions have the form

$$\hat{R} = G_\rho^{-1} \cdots G_2^{-1} G_1^{-1} p(AB^{-1}),$$

$$\hat{S} = Z_\rho^{-1} \cdots Z_2^{-1} Z_1^{-1} p(B^{-1}A).$$

Therefore

$$p(AB^{-1}) = \hat{G}\hat{R} \quad \text{and} \quad p(B^{-1}A) = \hat{Z}\hat{S},$$

where

$$\hat{G} = G_1 \cdots G_\rho \quad \text{and} \quad \hat{Z} = Z_1 \cdots Z_\rho.$$

We then complete the iteration by performing the equivalence transformations

$$\hat{A} = \hat{G}^{-1} A \hat{Z} \quad \text{and} \quad \hat{B} = \hat{G}^{-1} B \hat{Z}. \tag{6}$$

Remark. In the case of the standard eigenvalue problem ($B = I$), we have $p(AB^{-1}) = p(B^{-1}A) = p(A)$, so $G_i = Z_i$, $i = 1, \ldots, \rho$, $\hat{G} = \hat{Z}$, $\hat{R} = \hat{S}$, $\hat{A} = \hat{G}^{-1} A \hat{G}$, and $\hat{B} = I$. This is one iteration of a GR algorithm [17].

To determine how to do these operations implicitly, we break the transformations (6) down into small steps and study the intermediate results. Let C denote A or B, as before; define $\hat{C}_0 = C$, and

$$\left.\begin{aligned} \hat{C}_{i-1/2} &= G_i^{-1} \hat{C}_{i-1} \\ \hat{C}_i &= \hat{C}_{i-1/2} Z_i \end{aligned}\right\} \quad i = 1, \ldots, \rho. \tag{7}$$

Then $\hat{C} = \hat{C}_\rho$.

We also give names to the intermediate matrices in the GR decompositions. Let $\hat{R}_0 = p(AB^{-1})$, $\hat{S}_0 = p(B^{-1}A)$, and

$$\left.\begin{aligned} \hat{R}_i &= G_i^{-1} \hat{R}_{i-1} \\ \hat{S}_i &= Z_i^{-1} \hat{S}_{i-1} \end{aligned}\right\} \quad i = 1, \ldots, \rho.$$

Then $\hat{R} = \hat{R}_\rho$ and $\hat{S} = \hat{S}_\rho$.

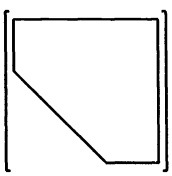
Since AB^{-1} and $B^{-1}A$ are proper upper Hessenberg matrices, $\hat{R}_0$ and $\hat{S}_0$ satisfy

$$\hat{r}^{(0)}_{j+m,j} \neq 0, \quad \hat{s}^{(0)}_{j+m,j} \neq 0, \quad j = 1, \ldots, n - m$$

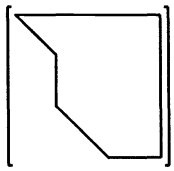
and

$$\hat{r}^{(0)}_{ij} = \hat{s}^{(0)}_{ij} = 0 \quad \text{when } i > j + m,$$

where m is the degree of p. Thus they have the form



where the entries outside of the outlined area are all zero. Since G_1 is the elimination matrix for the first column of $\hat{R}_0$, $G_1 = \text{diag}\{\tilde{G}_1, I\}$, where $\tilde{G}_1 \in \mathbb{C}^{(m+1)\times(m+1)}$ is the elimination matrix of $[\hat{r}_{11}^{(0)}, \ldots, \hat{r}_{m+1,1}^{(0)}]^T$. The form of Z_1 is similar. In general $\hat{R}_{i-1}$ and $\hat{S}_{i-1}$ have the form



for $i = 2, \ldots, n-m$. The first $i-1$ columns are in upper triangular form. The ith column has m nonzeros below the main diagonal. Thus $G_i = \text{diag}\{I_{i-1}, \tilde{G}_i, I\}$ and $Z_i = \text{diag}\{I_{i-1}, \tilde{Z}_i, I\}$, where $\tilde{G}_i$ and $\tilde{Z}_i$ are the elimination matrices of

$$[\hat{r}_{ii}^{(i-1)}, \ldots, \hat{r}_{m+i,i}^{(i-1)}]^T \quad \text{and} \quad [\hat{s}_{ii}^{(i-1)}, \ldots, \hat{s}_{m+i,i}^{(i-1)}]^T,$$

respectively. For $i > n-m$ the transformations have the same form, except that the vectors to be eliminated are shorter because we have reached the bottom of the matrix. We then have $G_i = \text{diag}\{I_{i-1}, \tilde{G}_i\}$, where $\tilde{G}_i$ is the elimination matrix of $[\hat{r}_{ii}^{(i-1)}, \ldots, \hat{r}_{n,i}^{(i-1)}]^T$, and similarly for Z_i.

Let $\hat{G}_i = G_1 \cdots G_i$ and $\hat{Z}_i = Z_1 \cdots Z_i$, $i = 1, \ldots, \rho$. Then for $i < n-m$, $\hat{G}_i$ has the form

$$\hat{G}_i = \begin{bmatrix} \hat{G}_{11}^{(i)} & 0 \\ 0 & I \end{bmatrix},$$

where $\hat{G}_{11}^{(i)}$ is $(m+i) \times (m+i)$. This is clear from the form of the factors. The form of $\hat{Z}_i$ is the same.

The initial pencil $A - \lambda B = \hat{A}_0 - \lambda \hat{B}_0$ is in Hessenberg-triangular form, and so is the final pencil $\hat{A} - \lambda \hat{B} = \hat{A}_\rho - \lambda \hat{B}_\rho$, except possibly for a small subpencil that can be removed by deflation. The intermediate pencils $\hat{A}_{i-1/2} - \lambda \hat{B}_{i-1/2}$ and $\hat{A}_i - \lambda \hat{B}_i$ are not in Hessenberg-triangular form, but, as we shall see, they do not deviate from it by too much. First note that

$$\hat{A}_i = \hat{G}_i^{-1} A \hat{Z}_i \quad \text{and} \quad \hat{B}_i = \hat{G}_i^{-1} B \hat{Z}_i, \tag{8}$$

for $i = 1, \ldots, \rho$. Since also

$$p(AB^{-1}) = \hat{G}_i \hat{R}_i \quad \text{and} \quad p(B^{-1}A) = \hat{Z}_i \hat{S}_i, \tag{9}$$

we see that the pencil $\hat{A}_i - \lambda \hat{B}_i$ is the result of a partial GZ iteration driven by the partial GR decompositions (9). Applying Lemma 4.1 to (8) and (9), we find that also

$$\hat{A}_i \hat{S}_i = \hat{R}_i A \quad \text{and} \quad \hat{B}_i \hat{S}_i = \hat{R}_i B. \tag{10}$$

We use these two equations in Lemmas 4.8 and 4.5, respectively, to help determine the shape of $\hat{A}_i$ and $\hat{B}_i$.

Similarly, we have

$$\hat{A}_{i-1/2} = \hat{G}_i^{-1} A \hat{Z}_{i-1} \quad \text{and} \quad \hat{B}_{i-1/2} = \hat{G}_i^{-1} B \hat{Z}_{i-1}, \tag{11}$$

so the pencil $\hat{A}_{i-1/2} - \lambda\hat{B}_{i-1/2}$ can be viewed as the result of a partial GZ iteration driven by the partial GR decompositions

$$p(AB^{-1}) = \hat{G}_i\hat{R}_i \quad \text{and} \quad p(B^{-1}A) = \hat{Z}_{i-1}\hat{S}_{i-1}. \tag{12}$$

Applying Lemma 4.1 to (11) and (12), we obtain

$$\hat{A}_{i-1/2}\hat{S}_{i-1} = \hat{R}_iA \quad \text{and} \quad \hat{B}_{i-1/2}\hat{S}_{i-1} = \hat{R}_iB. \tag{13}$$

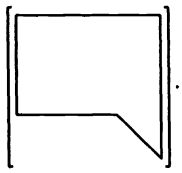
These equations are used to help to determine the shape of $\hat{A}_{i-1/2}$ and $\hat{B}_{i-1/2}$.

We study first the shape of the "B" matrices.

LEMMA 4.4. *For $i = 1, \ldots, n-m-1$, the last $n-m-i$ rows of $\hat{B}_{i-1/2}$ and $\hat{B}_i$ are in upper triangular form. That is,*

$$\hat{b}_{jk}^{(i-1/2)} = \hat{b}_{jk}^{(i)} = 0 \quad \text{if } j > k \quad \text{and} \quad j > i+m.$$

Pictorially, $\hat{B}_{i-1/2}$ and $\hat{B}_i$ have the form



Proof. Writing the transformation $\hat{B}_i = \hat{G}_i{}^{-1}B\hat{Z}_i$ in partitioned form, we have

$$\begin{bmatrix} \hat{B}_{11}^{(i)} & \hat{B}_{12}^{(i)} \\ \hat{B}_{21}^{(i)} & \hat{B}_{22}^{(i)} \end{bmatrix} = \begin{bmatrix} X & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} B_{11} & B_{12} \\ 0 & B_{22} \end{bmatrix} \begin{bmatrix} Y & 0 \\ 0 & I \end{bmatrix},$$

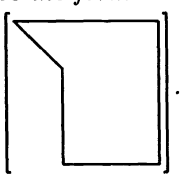
where the $(1,1)$ blocks all have dimension $(m+i) \times (m+i)$. Clearly $\hat{B}_{21}^{(i)} = 0$, and $\hat{B}_{22}^{(i)} = B_{22}$, which is upper triangular. Thus $\hat{B}_i$ has the stated form. To prove that $\hat{B}_{i-1/2}$ also has this form, apply the same partition to the equation $\hat{B}_{i-1/2} = \hat{G}_i^{-1}B\hat{Z}_{i-1}$. □

Lemma 4.4 suggests that $\hat{B}_{n-m-1/2}$ and $\hat{B}_{n-m}$ should be completely filled in. Fortunately the transformations do not only destroy zeros, they create zeros as well, as we see in Lemma 4.5. For the purpose of avoiding distracting complications in the statement of this lemma, we define $\hat{B}_{\rho+1/2} = \hat{B}$.

LEMMA 4.5. *For $i = 1, \ldots, \rho$, the first i columns of $\hat{B}_i$ and $\hat{B}_{i+1/2}$ are in upper triangular form. That is,*

$$\hat{b}_{jk}^{(i)} = \hat{b}_{jk}^{(i+1/2)} = 0 \quad \text{if } j > k \quad \text{and} \quad k \leq i.$$

Pictorially, both $\hat{B}_i$ and $\hat{B}_{i+1/2}$ have the form



Proof. By (10) $\hat{B}_i \hat{S}_i = \hat{R}_i B$. We write this equation in partitioned form as

$$\begin{bmatrix} \hat{B}_{11}^{(i)} & \hat{B}_{12}^{(i)} \\ \hat{B}_{21}^{(i)} & \hat{B}_{22}^{(i)} \end{bmatrix} \begin{bmatrix} S_{11} & S_{12} \\ 0 & S_{22} \end{bmatrix} = \begin{bmatrix} R_{11} & R_{12} \\ 0 & R_{22} \end{bmatrix} \begin{bmatrix} B_{11} & B_{12} \\ 0 & B_{22} \end{bmatrix},$$

where the $(1,1)$ blocks are all $i \times i$. The matrices S_{11}, R_{11}, and B_{11} are upper triangular. We know that the first $n-\nu$ columns of $\hat{S}_i$ are linearly independent, and since $i \leq \rho \leq n-\nu$, S_{11} must be nonsingular. Therefore

$$\begin{bmatrix} \hat{B}_{11}^{(i)} \\ \hat{B}_{21}^{(i)} \end{bmatrix} = \begin{bmatrix} R_{11} \\ 0 \end{bmatrix} B_{11} S_{11}^{-1}.$$

Consequently, $\hat{B}_{11}^{(i)} = R_{11} B_{11} S_{11}^{-1}$ is upper triangular and $\hat{B}_{21}^{(i)} = 0$. This proves that $\hat{B}_i$ has the stated form. To obtain the same result for $\hat{B}_{i+1/2}$, partition the equation $\hat{B}_{i+1/2} \hat{S}_i = \hat{R}_{i+1} B$ (from (13)) exactly as above. □

Remark. In the nonsingular case, or even in the case $\nu = 1$, Lemma 4.5 shows that $\hat{B} = \hat{B}_{n-1}$ is upper triangular. If $\nu \geq 2$, we can conclude that $\hat{B} = \hat{B}_\rho$ has only its first $\rho = n-\nu$ columns upper triangular; it is not guaranteed that the final ν columns get reduced to upper triangular form. But we already know from Theorem 4.3 that this portion of the matrix will be removed by deflation at the end of the iteration.

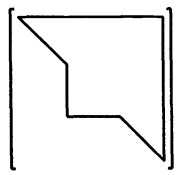
Combining Lemmas 4.4 and 4.5, we have the following result.

THEOREM 4.6. *For* $i = 1, \ldots, \rho$,

$$\hat{b}_{jk}^{(i-1/2)} = 0 \quad \text{if } j > k \text{ and either } j > i+m \text{ or } k \leq i-1,$$

$$\hat{b}_{jk}^{(i)} = 0 \quad \text{if } j > k \text{ and either } j > i+m \text{ or } k \leq i.$$

Thus we see that when $i < n-m$, $\hat{B}_{i-1/2}$ is upper triangular in its first $i-1$ columns and its last $n-i-m$ rows. Its nonzero pattern is



which would be upper triangular, except that it has a bulge. The tip of the bulge is at the $(i+m, i)$ position. We call this an *m-bulge* or a *bulge of order m* because it protrudes m diagonals below the upper triangular part of the matrix. The form of $\hat{B}_i$ is similar, but the tip of its bulge is at the $(i+m, i+1)$ position. This is a bulge of order $m-1$. We see thus that the transformation $\hat{B}_{i-1/2} \to \hat{B}_i$ shrinks the bulge by deleting one column from the left side. On the other hand, the transformation $\hat{B}_i \to \hat{B}_{i+1/2}$ enlarges the bulge by adding one row to the bottom. Thus the bulge is chased downward and to the right as the GZ iteration proceeds. When $i = n-m$, the bulge has reached the bottom of the matrix and begins to be pushed off the edge. If $\nu \leq 1$, the bulge is eventually eliminated completely. If $\nu > 1$, the iteration ends with the last ν columns uncleared.

We now turn our attention to the "A" matrices.

LEMMA 4.7. *For $i = 0, \ldots, n-m-2$, the last $n-i-m-1$ rows of $\hat{A}_i$ and $\hat{A}_{i+1/2}$ have upper Hessenberg form. That is,*

$$\hat{a}_{jk}^{(i)} = \hat{a}_{jk}^{(i+1/2)} = 0 \quad \text{if } j > k+1 \quad \text{and} \quad j > i+m+1.$$

Proof. Write the transformation $\hat{A}_{i+1/2} = \hat{G}_{i+1}^{-1} A \hat{Z}_i$ in the unsymmetric partitioned form

$$\begin{bmatrix} \hat{A}_{11}^{(i+1/2)} & \hat{A}_{12}^{(i+1/2)} \\ \hat{A}_{21}^{(i+1/2)} & \hat{A}_{22}^{(i+1/2)} \end{bmatrix} = \begin{bmatrix} X & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{bmatrix} \begin{bmatrix} Y & 0 \\ 0 & I \end{bmatrix},$$

where $\hat{A}_{11}^{(i+1/2)}$, $A_{11} \in \mathbb{C}^{(i+m+1)\times(i+m)}$, $X \in \mathbb{C}^{(i+m+1)\times(i+m+1)}$, $Y \in \mathbb{C}^{(i+m)\times(i+m)}$. Clearly $\hat{A}_{21}^{(i+1/2)} = 0$, and $\hat{A}_{22}^{(i+1/2)} = A_{22}$, which is the bottom right-hand corner of an upper Hessenberg matrix. Thus $\hat{A}_{i+1/2}$ has the stated form. To prove that $\hat{A}_i$ also has this form, apply the same partition to the equation $\hat{A}_i = \hat{G}_i^{-1} A \hat{Z}_i$. □

Thus it appears that $\hat{A}_{n-m-1}$ is completely filled in. But again it turns out that the transformations are not only destroying zeros, they are creating zeros as well.

LEMMA 4.8. *For $2 \le i \le \rho$, the first $i-1$ columns of $\hat{A}_{i-1/2}$ and $\hat{A}_i$ are in upper Hessenberg form. That is,*

$$\hat{a}_{jk}^{(i-1/2)} = \hat{a}_{jk}^{(i)} = 0 \quad \text{if } j > k+1 \quad \text{and} \quad k \le i-1.$$

Proof. By (13) we know that $\hat{A}_{i-1/2}\hat{S}_{i-1} = \hat{R}_i A$. Consider the unsymmetric partition

$$\begin{bmatrix} \hat{A}_{11}^{(i-1/2)} & \hat{A}_{12}^{(i-1/2)} \\ \hat{A}_{21}^{(i-1/2)} & \hat{A}_{22}^{(i-1/2)} \end{bmatrix} \begin{bmatrix} S_{11} & S_{12} \\ 0 & S_{22} \end{bmatrix} = \begin{bmatrix} R_{11} & R_{12} \\ 0 & R_{22} \end{bmatrix} \begin{bmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{bmatrix},$$

where $\hat{A}_{11}^{(i-1/2)}$, $A_{11} \in \mathbb{C}^{i\times(i-1)}$, $S_{11} \in \mathbb{C}^{(i-1)\times(i-1)}$, and $R_{11} \in \mathbb{C}^{i\times i}$. Both S_{11} and R_{11} are upper triangular and nonsingular. Thus

$$\begin{bmatrix} \hat{A}_{11}^{(i-1/2)} \\ \hat{A}_{21}^{(i-1/2)} \end{bmatrix} = \begin{bmatrix} R_{11} \\ 0 \end{bmatrix} A_{11} S_{11}^{-1}.$$

Therefore $\hat{A}_{21}^{(i-1/2)} = 0$ and $\hat{A}_{11}^{(i-1/2)} = R_{11} A_{11} S_{11}^{-1}$. Since R_{11} and S_{11}^{-1} are upper triangular, and A_{11} satisfies $a_{jk} = 0$ if $j > k+1$, $\hat{A}_{11}^{(i-1/2)}$ must also have this zero pattern. This proves that $\hat{A}_{i-1/2}$ has the stated form. We obtain the same result for $\hat{A}_i$ by partitioning the equation $\hat{A}_i \hat{S}_i = \hat{R}_i A$ in exactly the same way. □

Remark. As long as $\nu \le 1$, Lemma 4.8 shows that both $\hat{A}_{\rho-1/2}$ and $\hat{A}_\rho$ are upper Hessenberg. If $\nu > 1$, Lemma 4.8 states that the first $\rho - 1$ columns of $\hat{A} = \hat{A}_\rho$ are upper Hessenberg. In fact the situation is better than that. From Theorem 4.3 we know that $\hat{A}$ is block triangular; all of the entries in column ρ below the main diagonal are automatically zero. Of course this is a theoretical result that is valid only in the absence of roundoff error.

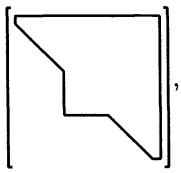
Combining the results of Lemmas 4.7 and 4.8, we have the following theorem.

THEOREM 4.9. *For* $1 \le i \le \rho$,

$$\hat{a}_{jk}^{(i-1/2)} = 0 \quad \text{if } j > k+1 \quad \text{and either } j > i+m \text{ or } k \le i-1,$$

$$\hat{a}_{jk}^{(i)} = 0 \quad \text{if } j > k+1 \text{ and either } j > i+m+1 \text{ or } k \le i-1.$$

For $i = 1, \ldots, n-m-1$, $\hat{A}_{i-1/2}$ has its first $i-1$ columns and its last $n-m-i$ rows in upper Hessenberg form. Thus it has the form



It has a bulge that has its tip at position $(i+m, i)$. We call this a bulge of *order* $m-1$ because it protrudes $m-1$ diagonals below the Hessenberg part of the matrix. $\hat{A}_i$ has its first $i-1$ columns and last $n-m-i-1$ rows upper Hessenberg. That is, it has a bulge whose tip is at $(i+m+1, i)$. This is an m-bulge.

The transformation $\hat{A}_{i-1/2} \to \hat{A}_i$ enlarges the bulge by adding one row to the bottom. On the other hand, the transformation $\hat{A}_i \to \hat{A}_{i+1/2}$ shrinks the bulge by removing one column from the left side. Thus the bulge in $\hat{A}_i$ moves downward and to the right, just as it does in $\hat{B}_i$. When $i = n-m-1$, the bulge has reached the bottom of the matrix and begins to be pushed off the edge.

Now let us consider the effects of the transformations on the A and B matrices together. The transformation $\hat{C}_{i-1/2} \to \hat{C}_i$ enlarges the "A"-bulge while shrinking the "B"-bulge. On the other hand, the transformation $\hat{C}_i \to \hat{C}_{i+1/2}$ shrinks the "A"-bulge while expanding the "B"-bulge. The relative positions of the bulges in $\hat{A}_i$ and $\hat{B}_i$ can be seen by superimposing them on one array.

$$\begin{bmatrix}
b & b & b & b & b & b & b & b \\
a & b & & & & & & b \\
 & a & b & & & & & b \\
 & a & b & & & & & b \\
 & a & b & b & b & & & b \\
 & a & a & a & a & b & & b \\
 & & & & & a & b & b \\
 & & & & & & a & b
\end{bmatrix}.$$

Here we have pictured the case $n = 8$, $m = 3$, $i = 2$. The nonzero part of $\hat{B}_2$ is the area outlined by the letter b. The nonzero part of $\hat{A}_2$ includes the nonzero part of $\hat{B}_2$ and in addition the entries marked with the letter a. This is an m-bulge for $\hat{A}_2$ and an $(m-1)$-bulge for $\hat{B}_2$. After the transformation $\hat{C}_2 \to \hat{C}_{5/2}$, the situation is

as follows.

$$\begin{bmatrix} b & b & b & b & b & b & b & b \\ a & b & & & & & & b \\ & a & b & & & & & b \\ & 0 & b & & & & & b \\ & 0 & b & b & b & & & b \\ & 0 & b & b & b & b & & b \\ & & & & & a & b & b \\ & & & & & & a & b \end{bmatrix}.$$

The "A"-bulge has been shrunk by the elimination of one column from the left (marked by zeros), and the "B"-bulge has been enlarged by the addition of one row at the bottom. Now the bulges coincide perfectly. This is an $m-1$ bulge in $\hat{A}_{5/2}$ and an m bulge in $\hat{B}_{5/2}$.

4.4. The implicit GZ algorithm. Now we are ready to use the information amassed in the previous section to see how to carry out an iteration of the GZ algorithm without actually forming the matrices $\hat{R}_0 = p(AB^{-1})$, $\hat{S}_0 = p(B^{-1}A)$, or any of the derived matrices $\hat{R}_i$, $\hat{S}_i$.

The first step is to find G_1, which is the elimination matrix for the first column of $\hat{R}_0 = p(AB^{-1})$. Thus we need to find $x = p(AB^{-1})e_1$. This can be computed relatively inexpensively if $m \ll n$. Indeed, p is given in the factored form $p(\lambda) = (\lambda - \sigma_1)\cdots(\lambda - \sigma_m)$. Thus x can be calculated by the recursion

$$x^{(j)} = (AB^{-1} - \sigma_j I)x^{(j-1)}, \qquad j = 1, \ldots, m, \tag{14}$$

with $x^{(0)} = e_1$. Then $x = x^{(m)}$. Since it does not matter whether we get x or a multiple of x, in practice we would also rescale at each step to avoid over/underflow. This is inexpensive. Since AB^{-1} is upper Hessenberg, only the first j components of $x^{(j-1)}$ are nonzero. Now consider the jth step. If we let $y^{(j)} = AB^{-1}x^{(j-1)}$, then $x^{(j)} = y^{(j)} - \sigma_j x^{(j-1)}$. We can find $y^{(j)}$ by solving $Bz^{(j)} = x^{(j-1)}$ for $z^{(j)}$ and then calculating $y^{(j)} = Az^{(j)}$. Because only the first j components of $x^{(j-1)}$ are nonzero and B is upper triangular, the system $Bz^{(j)} = x^{(j-1)}$ is in fact only a $j \times j$ upper triangular system, whose solution requires only $O(j^2)$ operations. Only the first j entries of $z^{(j)}$ are nonzero. Thus the product $Az^{(j)}$ involves only the first j columns of A. The nonzero entries in these columns are confined to the first $j+1$ rows, so $y^{(j)}$ can be obtained in $O(j^2)$ operations. The computation $x^{(j)} = y^{(j)} - \sigma_j x^{(j-1)}$ requires only $O(j)$ operations. Thus the total operation count for the jth step is $O(j^2)$. This must be done for $j = 1, \ldots, m$, so the total cost of computing x is $O(m^3)$, which is small if $m \ll n$.[3]

Once we have x, we can let $G_1 = \operatorname{diag}\{\tilde{G}_1, I\}$ be the elimination matrix for x given by the chosen elimination rule and calculate

$$\hat{A}_{1/2} = G_1^{-1}A \quad \text{and} \quad \hat{B}_{1/2} = G_1^{-1}B.$$

Logically the next question would be how to find Z_1. However, we postpone that and ask instead how one finds G_i, $i = 2, 3, \ldots, \rho$, to make the transformations

$$\hat{A}_{i-1/2} = G_i^{-1}\hat{A}_{i-1} \quad \text{and} \quad \hat{B}_{i-1/2} = G_i^{-1}\hat{B}_{i-1},$$

[3] This procedure can be modified in various ways. For example, a more accurate formula for the case $m = 2$ is given in [11]. Also, although we are assuming throughout this paper that B is nonsingular, one might reasonably ask whether this process can be salvaged in case one of $b_{11}, \ldots, b_{mm}$ happens to be zero. Deflation strategies for singular B are discussed in [11], [9], and [6, p. 400].

(see (7)) given that $\hat{A}_{i-1}$ and $\hat{B}_{i-1}$ are available. To deal with the two cases $i \leq n-m$ and $i > n-m$ simultaneously, let $k = \min\{i+m, n\}$. Then G_i has the form $\operatorname{diag}\{I_{i-1}, \tilde{G}_i, I_{n-k}\}$, where $\tilde{G}_i \in \mathbb{C}^{(k-i+1)\times(k-i+1)}$ is the elimination matrix for $[\hat{r}_{i,i}^{(i-1)}, \ldots, \hat{r}_{k,i}^{(i-1)}]^T$. Call this (column) vector y. We need to find y or a multiple of y and we need to do it without knowledge of $\hat{R}_{i-1}$. We know that $\tilde{G}^{-1}y = \alpha e_1$ for some scalar α. The fact that the first ρ columns of $\hat{R}_i$ are linearly independent guarantees that $\alpha \neq 0$.

We know from Theorem 4.9 that the operation

$$G_i^{-1}\hat{A}_{i-1} = \hat{A}_{i-1/2}$$

shrinks the bulge in $\hat{A}_{i-1}$ by removing column $i-1$ from the bulge. All this means is that the entries in positions $(i+1, i-1), \ldots, (k, i-1)$ get set to zero. Let us focus on this column. In transforming $\hat{A}_{i-1}$ to $\hat{A}_{i-1/2}$, the submatrix $\tilde{G}_i^{-1}$ acts only on rows i through k. As far as column $i-1$ is concerned, the action is

$$\tilde{G}_i^{-1}\begin{bmatrix} \hat{a}_{i,i-1}^{(i-1)} \\ \hat{a}_{i+1,i-1}^{(i-1)} \\ \vdots \\ \hat{a}_{k,i-1}^{(i-1)} \end{bmatrix} = \begin{bmatrix} \hat{a}_{i,i-1}^{(i-1/2)} \\ 0 \\ \vdots \\ 0 \end{bmatrix}.$$

In other words, defining $x \in \mathbb{C}^{k-i+1}$ by $x = [\hat{a}_{i,i-1}^{(i-1)}, \hat{a}_{i+1,i-1}^{(i-1)}, \ldots, \hat{a}_{k,i-1}^{(i-1)}]^T$, we have $\tilde{G}_i^{-1}x = \beta e_1$, where $\beta = \hat{a}_{i,i-1}^{(i-1/2)}$. One easily checks that $\beta \neq 0$. Indeed, subsequent transformations do not alter the entry in position $(i, i-1)$. Thus $\beta = \hat{a}_{i,i-1}$, and this is nonzero by Theorem 4.3. The relationship $\tilde{G}_i^{-1}x = \beta e_1$ says that $\tilde{G}_i$ is an elimination matrix for x. Since it is also an elimination matrix for y, x must be a multiple of y. Indeed, $x = \beta\tilde{G}_i e_1 = \beta\alpha^{-1}y$.

This relationship can also be inferred directly from the equation $\hat{A}_{i-1}\hat{S}_{i-1} = \hat{R}_{i-1}A$ by comparing column $i-1$ of the left-hand side product with the same column of the right-hand side, which is analogous to the approach used in [10]. Focusing on rows i through k, and taking into account the zero structure of the various matrices, we find that

$$\begin{bmatrix} \hat{a}_{i,i-1}^{(i-1)} \\ \vdots \\ \hat{a}_{k,i-1}^{(i-1)} \end{bmatrix} \hat{s}_{i-1,i-1}^{(i-1)} = \begin{bmatrix} \hat{r}_{i,i}^{(i-1)} \\ \vdots \\ \hat{r}_{k,i}^{(i-1)} \end{bmatrix} a_{i,i-1}. \tag{15}$$

We know that $a_{i,i-1} \neq 0$ for all i, and $\hat{s}_{i-1,i-1}^{(i-1)} \neq 0$ as long as $i \leq \rho + 1$. Thus x is a multiple of y.

This solves the problem of how to find G_i. We see that we do not need $\hat{R}_{i-1}$, as the required information for building G_i is also present in $\hat{A}_{i-1}$. We summarize our findings as a theorem.

THEOREM 4.10. *Let $2 \leq i \leq \rho$, and let $k = \min\{i+m, n\}$. Then $G_i = \operatorname{diag}\{I_{i-1}, \tilde{G}_i, I_{n-k}\}$, where $\tilde{G}_i$ is the elimination matrix of*

$$[\hat{a}_{i,i-1}^{(i-1)}, \hat{a}_{i+1,i-1}^{(i-1)}, \ldots, \hat{a}_{k,i-1}^{(i-1)}]^T.$$

We now turn to the question of how to compute the transformations Z_i. Given $1 \leq i \leq \rho$, let $k = \max\{i+m, n\}$. We know that $Z_i = \operatorname{diag}\{I_{i-1}, \tilde{Z}_i, I_{n-k}\}$, where $\tilde{Z}_i$

is the elimination matrix for the vector

$$x = [\hat{s}_{i,i}^{(i-1)}, \hat{s}_{i+1,i}^{(i-1)}, \ldots, \hat{s}_{k,i}^{(i-1)}]^T,$$

which is part of the ith column of $\hat{S}_i$. We wish to determine this vector (or a multiple thereof) without computing $\hat{S}_i$. We have $\tilde{Z}_i^{-1}x = \alpha e_1$, where $\alpha \neq 0$.

We know from Theorem 4.6 that the transformation $\hat{B}_{i-1/2}Z_i = \hat{B}_i$ (from (7)) shrinks the bulge in $\hat{B}_{i-1/2}$ by setting the entries in positions $(i+1,i),\ldots,(k,i)$ to zero. To see how Z_i^{-1} acts, we consider the inverse equation $Z_i^{-1}\hat{B}_{i-1/2}^{-1} = \hat{B}_i^{-1}$. We know that $\hat{B}_{i-1/2}$ has the form

$$\hat{B}_{i-1/2} = \begin{bmatrix} B_{11} & B_{12} & B_{13} \\ 0 & B_{22} & B_{23} \\ 0 & 0 & B_{33} \end{bmatrix},$$

where $B_{11} \in \mathbb{C}^{(i-1)\times(i-1)}$, $B_{22} \in \mathbb{C}^{(k-i+1)\times(k-i+1)}$, and $B_{33} \in \mathbb{C}^{(n-k)\times(n-k)}$. B_{11} and B_{33} are upper triangular, but B_{22} is full, as it holds the bulge. Clearly $\hat{B}_{i-1/2}^{-1}$ has exactly the same zero structure; it is upper triangular with a bulge of order $k-i$. $\hat{B}_i$ has the same form as $\hat{B}_{i-1/2}$, except that the first column of B_{22} has been set to upper triangular form. It is upper triangular with a bulge of order $k-i-1$. Its inverse has exactly the same structure. Thus the transformation $Z_i^{-1}\hat{B}_{i-1/2}^{-1} = \hat{B}_i^{-1}$ shrinks the bulge in $\hat{B}_{i-1/2}^{-1}$ by setting the entries in positions $(i+1,i),\ldots,(k,i)$ to zero. The submatrix $\tilde{Z}_i^{-1}$ acts on rows i through k. Within these rows, our interest focuses on column i, the first column of B_{22}^{-1}, as this is where the elimination takes place. Call this column y; that is, $y = B_{22}^{-1}e_1$. Then $\tilde{Z}_i^{-1}y = \beta e_1$, where $\beta \neq 0$ because $\hat{B}_i^{-1}$ is nonsingular. Thus $\tilde{Z}_i$ is an elimination matrix of y. Since it is also an elimination matrix of x, y must be a multiple of x. Indeed $y = \beta\tilde{Z}_i e_1 = \beta\alpha^{-1}x$. Since $y = B_{22}^{-1}e_1$, we can obtain it by solving the small system $B_{22}y = e_1$. We have now proved the following theorem.

THEOREM 4.11. *For $1 \leq i \leq \rho$ let $k = \min\{i+m, n\}$. Let B_{22} denote the principal submatrix of $\hat{B}_{i-1/2}$ consisting of rows and columns i through k. Let y be the unique solution of $B_{22}y = e_1$. Then $Z_i = \operatorname{diag}\{I_{i-1}, \tilde{Z}_i, I_{n-k}\}$, where $\tilde{Z}_i$ is the elimination matrix of y.*

Theorem 4.11 can also be inferred from the equation

$$\hat{B}_{i-1/2}\hat{S}_{i-1} = \hat{R}_i B, \tag{16}$$

which holds by (13). The vector x lies in the ith column of $\hat{S}_{i-1}$, so consider the ith column of (16), partitioned as

$$\begin{bmatrix} B_{11} & B_{12} & B_{13} \\ 0 & B_{22} & B_{23} \\ 0 & 0 & B_{33} \end{bmatrix} \begin{bmatrix} z \\ x \\ 0 \end{bmatrix} = \begin{bmatrix} R_{11} & R_{12} \\ R_{21} & R_{22} \\ 0 & R_{32} \end{bmatrix} \begin{bmatrix} b \\ 0 \end{bmatrix},$$

where $\hat{B}_{i-1/2}$ is partitioned as before, $z \in \mathbb{C}^{i-1}$, $x \in \mathbb{C}^{k-i+1}$, $R_{11} \in \mathbb{C}^{(i-1)\times i}$, $R_{21} \in \mathbb{C}^{(k-i+1)\times i}$, and $b \in \mathbb{C}^i$. Since the first i columns of $\hat{R}_i$ are upper triangular, R_{21} has only one nonzero entry, $\hat{r}_{ii}^{(i)}$, which lies in the upper right-hand corner. Thus $R_{21} = \gamma e_1 e_i^T$, where $\gamma = \hat{r}_{ii}^{(i)} \neq 0$. We seek x. But clearly $B_{22}x = R_{21}b = \gamma e_1 e_i^T b = \delta e_1$, where $\delta = \gamma e_i^T b = \gamma b_{ii} \neq 0$. Thus we can find $y = \delta^{-1}x$ by solving $B_{22}y = e_1$.

Theorems 4.10 and 4.11 justify the implicit GZ algorithm, which is summarized in (17). Notice that the algorithm takes $n-1$ steps, rather than stopping after ρ steps. In practice ρ is usually unknown because ν is unknown. Even if ν is known in principle, it is not well determined in the presence of roundoff error. When it happens that $\nu > 1$, the implicit algorithm differs from the explicit algorithm only in one way. In this case a small subpencil can be deflated from the bottom of the matrix. The implicit algorithm operates on this subpencil, reducing it to Hessenberg-triangular form, whereas the explicit algorithm does not. This further reduction is useful because we need to calculate the eigenvalues of the subpencil anyway.

IMPLICIT GZ ALGORITHM

(17)

```
for i = 1, ..., n - 1
    k ← min{i + m, n}
    if (i = 1) then
        x ← p(AB^{-1})e_1        (See the discussion following (14).)
        y ← first k entries of x
    else
        y ← [a_{i,i-1}, ..., a_{k,i-1}]^T
    end if
    G̃ ← elimination matrix of y                (*)
    G ← diag{I_{i-1}, G̃, I_{n-k}}
    A ← G^{-1}A,   B ← G^{-1}B
    B_22 ← rows, columns i through k of B
    z ← B_22^{-1} e_1
    Z̃ ← elimination matrix of z                (**)
    Z ← diag{I_{i-1}, Z̃, I_{n-k}}
    A ← AZ,   B ← BZ
```

Remarks. For standard eigenvalue problems ($B = I$), we have already noted that $Z_i = G_i$ for $i = 1, \ldots, n-1$. Thus we have $Z = G$ at each step of (17). This special case is the implicit GR algorithm.

In [2] Bunse-Gerstner and Elsner developed a new version of the QZ algorithm for unitary pencils, which are of interest in certain signal-processing applications. Instead of using the Hessenberg-triangular form, they introduced a more condensed block-diagonal form. Since our development is built upon the Hessenberg-triangular form, it does not encompass the algorithm of [2] as a special case. However, the methodology used here can be adapted to that situation and used to derive that algorithm and its generalizations to higher multiplicity. In particular, if A and B are unitary, the equations in Lemma 4.1 are joined by the two related equations

$$\hat{A}^* \hat{R} = \hat{S} A^* \quad \text{and} \quad \hat{B}^* \hat{R} = \hat{S} B^*.$$

Whereas the equations of Lemma 4.1 yield information about zeros below the main diagonal (e.g., upper Hessenberg form is preserved from one iteration to the next), these new equations give information about zeros above the main diagonal. In particular, block diagonal forms are preserved from one iteration to the next. Of course, we must now insist that the G and Z transformations be unitary, so that the pencil stays unitary from one iteration to the next.

4.5. The generic bulge-chasing algorithm. If one compares the implicit GZ algorithm (17) with the standard double-step QZ algorithm, as presented in, for

example, EISPACK [5], one notices an important difference. In (17) the transformation Z_i is designed to clear out one column of the bulge in B. In contrast, the corresponding transformation in the standard code eliminates the entire B bulge before proceeding to the computation of G_{i+1}. The bulge is annihilated row by row, using one elimination matrix for each row. In the case $m = 2$ (as in the EISPACK code) the added cost of doing this is small. However, as m is made larger, the cost difference becomes significant. On the other hand, the standard procedure may be substantially more stable. The reason for this is that the Z_i calculated in (17) is designed so that the transformation $Z_i^{-1}\hat{B}_{i-1/2}^{-1} = \hat{B}_i^{-1}$ will clear out one column in the bulge in the inverse matrix. As a consequence, the transformation $\hat{B}_{i-1/2}Z_i = \hat{B}_i$ will also, in principle, remove one column from the bulge in $\hat{B}_{i-1/2}$. However, these zeros are introduced only incidentally; they are not enforced by the transformation. Therefore, in the presence of roundoff errors these numbers will not be exactly zero. They may sometimes be far enough from zero that they cannot be set to zero without compromising the stability of the algorithm. After all, if the submatrix B_{22} should be ill conditioned at some point, then the solution of $B_{22}z = e_1$ and the resulting Z_i may not be well determined. In contrast, the standard procedure introduces the desired zeros explicitly through the mechanism of eliminating the entire bulge from B. Therefore there is no question of having to set to zero some numbers that should be, but are not quite, zero. We note finally that in the extreme case of singular B, the implicit GZ algorithm (17) breaks down, whereas the standard procedure does not.

It is therefore desirable to broaden our class of algorithms to include procedures of this type. To this end we introduce a *generic bulge-chasing algorithm*, which is exactly algorithm (17), except that at the two steps labelled $(*)$ and $(**)$, where $\tilde{G}$ and $\tilde{Z}$ are chosen, we do not require that they be determined by a specific elimination rule. At $(*)$ we allow any nonsingular $\tilde{G}$ for which $\tilde{G}^{-1}y = \alpha e_1$ for some α, and likewise for $\tilde{Z}$ at $(**)$. That $\tilde{G}^{-1}y = \alpha e_1$ means exactly that (at the ith step) the premultiplication by G^{-1} causes entries $(i+1, i-1), \ldots, (i+k, i-1)$ of the A matrix to be transformed to zero. Similarly, that $\tilde{Z}^{-1}z = \beta e_1$, where $z = B_{22}^{-1}e_1$, means neither more nor less than that (at the ith step) the postmultiplication by Z causes entries $(i+1, i), \ldots, (i+k, i)$ of the B matrix to be transformed to zero. We do not require that the vector z be calculated explicitly, only that the transformations produce the desired zeros. (Indeed this can be done even if B_{22} is singular, in which case z is not well defined.) Thus algorithms that annihilate the entire bulge in B at each step fit into this structure.

It is worth mentioning a class of algorithms that avoids the high cost of eliminating the entire bulge in B at each step by never allowing that bulge to build up in the first place [9, p. 75]. Suppose that after $i-1$ steps of a generic bulge-chasing algorithm we have $\hat{A}_{i-1} - \lambda\hat{B}_{i-1}$, where $\hat{B}_{i-1}$ has no bulge. The next step is to build an elimination matrix G_i such that G_i^{-1} annihilates the entries in positions $(i+1, i-1), \ldots, (i+k, i-1)$ of $\hat{A}_{i-1}$. One can build such a G_i^{-1} as a product of simpler matrices $G_{i,i+1}^{-1} \cdots G_{i,i+k}^{-1}$, where each $G_{i,j}^{-1}$ acts only on rows $j-1$ and j (that is, its nontrivial part is a 2×2 matrix) and annihilates the $(j, i-1)$ entry. One easily checks that the matrix $\hat{B}_{i-1/2} = G_i^{-1}\hat{B}_{i-1}$ fails to be upper triangular only in that the entries in positions $(i+1, i)$, $(i+2, i+1), \ldots, (i+k, i+k-1)$ are nonzero. These can be annihilated by a transformation $\hat{B}_i = \hat{B}_{i-1/2}Z_i$, where $Z_i = Z_{i,i+k} \cdots Z_{i,i+1}$, and each $Z_{i,j}$ acts only on columns $j-1$ and j and annihilates the entry in position $(j, j-1)$. Thus $\hat{B}_i$ is upper triangular. Algorithms of this type conform to the framework of the generic bulge-chasing algorithm.

Our analysis of the generic bulge-chasing algorithm will show that each iteration amounts to an iteration of a generic GZ algorithm. Thus the generic bulge-chasing algorithm lies within the class of algorithms whose convergence properties we studied in §3. To this end we introduce some notation. In fact the notation is identical to notation that we used earlier, but the symbols now carry slightly different meanings. Let G_i and Z_i denote the transformations produced at the ith step of the generic chasing algorithm (as we have already done in the previous paragraph), let $\hat{G}_i = G_1 \cdots G_i$, $\hat{Z}_i = Z_1 \cdots Z_i$, $\hat{A}_i = \hat{G}_i^{-1} A \hat{Z}_i$, $\hat{B}_i = \hat{G}_i^{-1} B \hat{Z}_i$, $\hat{A}_{i-1/2} = \hat{G}_i^{-1} A \hat{Z}_{i-1}$, and $\hat{B}_{i-1/2} = \hat{G}_i^{-1} B \hat{Z}_{i-1}$, $i = 1, \ldots, n-1$. These matrices may be different from those featured in Theorems 4.6 and 4.9, but they have the same bulge structure; it is exactly the function of the generic bulge-chasing algorithm to enforce this structure. Let $\hat{A} = \hat{A}_{n-1}$ and $\hat{B} = \hat{B}_{n-1}$. These are the final products of (one iteration of) the generic bulge-chasing algorithm. $\hat{A}$ is upper Hessenberg, and $\hat{B}$ is upper triangular. Assuming once again that B is nonsingular, let $\hat{R}_0 = p(AB^{-1})$ and $\hat{S}_0 = p(B^{-1}A)$, as before, and let $\hat{R}_i = G_i^{-1} \hat{R}_{i-1}$ and $\hat{S}_i = Z_i^{-1} \hat{S}_{i-1}$ for $i = 1, \ldots, n-1$. Now we are using the matrices G_i and Z_i to define $\hat{R}_i$ and $\hat{S}_i$, whereas in the development of the explicit GZ algorithm we used $\hat{R}_i$ and $\hat{S}_i$ to define G_i and Z_i. It is an immediate consequence of the new definitions that

$$p(AB^{-1}) = \hat{G}_i \hat{R}_i \quad \text{and} \quad p(B^{-1}A) = \hat{Z}_i \hat{S}_i$$

for $i = 1, \ldots, n-1$. The matrices $\hat{R}_i$ and $\hat{S}_i$ defined in connection with the explicit algorithm were partially upper triangular. Whether or not the new $\hat{R}_i$ and $\hat{S}_i$ have that property is not immediately clear from the definition. In fact they do, as the following theorem shows.

THEOREM 4.12. *For $i = 1, \ldots, n-1$, the matrices $\hat{R}_i$ and $\hat{S}_i$ defined in the previous paragraph both have the form*

$$\begin{bmatrix} X_{11} & X_{12} \\ 0 & X_{22} \end{bmatrix}, \tag{18}$$

where $X_{11} \in \mathbb{C}^{i \times i}$ is upper triangular.

Proof. The proof is by induction on i. First let $i = 1$. The transformation G_1 is designed to annihilate $p(AB^{-1})e_1$, the first column of $p(AB^{-1}) = \hat{R}_0$. Since $\hat{R}_1 = G_1^{-1} \hat{R}_0$, $\hat{R}_1$ must have its first column in upper triangular form, as claimed.

Now we show that, for $i = 1, \ldots, n-1$, if $\hat{R}_i$ has the stated form, then so does $\hat{S}_i$. Since $\hat{B}_i = \hat{G}_i^{-1} B \hat{Z}_i$, $p(AB^{-1}) = \hat{G}_i \hat{R}_i$ and $p(B^{-1}A) = \hat{Z}_i \hat{S}_i$, we can apply Lemma 4.1 to obtain $\hat{B}_i \hat{S}_i = \hat{R}_i B$ or, equivalently,

$$\hat{S}_i = \hat{B}_i^{-1} \hat{R}_i B.$$

Each of the three matrices on the right-hand side has the form (18), where $X_{11} \in \mathbb{C}^{i \times i}$, so $\hat{S}_i$ must also have this form.

We complete the induction by showing that for $i = 2, \ldots, n-1$, if $\hat{R}_{i-1}$ and $\hat{S}_{i-1}$ have the stated form, then so does $\hat{R}_i$. Certainly the first $i-1$ columns of $\hat{R}_i$ are in upper triangular form, for this is true of $\hat{R}_{i-1}$, and the transformation $\hat{R}_i = G_i^{-1} \hat{R}_{i-1}$ does not alter these columns, as one easily checks. Thus we can focus on the ith column of $\hat{R}_i$. Since $\hat{A}_{i-1/2} = \hat{G}_i^{-1} A \hat{Z}_{i-1}$, $p(AB^{-1}) = \hat{G}_i \hat{R}_i$ and $p(B^{-1}A) = \hat{Z}_{i-1} \hat{S}_{i-1}$, we can apply Lemma 4.1 to obtain

$$\hat{A}_{i-1/2} \hat{S}_{i-1} = \hat{R}_i A. \tag{19}$$

We wish to pick out the ith column of $\hat{R}_i$. Noting that $a_{i,i-1} \neq 0$, we examine column $i-1$ of (19), partitioned unsymmetrically as

$$\begin{bmatrix} \hat{A}_{11}^{(i-1/2)} & \hat{A}_{12}^{(i-1/2)} \\ 0 & \hat{A}_{22}^{(i-1/2)} \end{bmatrix} \begin{bmatrix} v \\ 0 \end{bmatrix} = \begin{bmatrix} R_{11} & R_{12} \\ R_{21} & R_{22} \end{bmatrix} \begin{bmatrix} w \\ 0 \end{bmatrix}, \tag{20}$$

where $\hat{A}_{11}^{(i-1/2)} \in \mathbb{C}^{i \times i-1}$, $R_{11} \in \mathbb{C}^{i \times i}$, $v \in \mathbb{C}^{i-1}$, and $w \in \mathbb{C}^i$. The last entry in w is $a_{i,i-1}$. We already know that the first $i-1$ columns of $\hat{R}_i$ are upper triangular. This implies that R_{11} is upper triangular, and all but the last column of R_{12} is zero. Thus $R_{12} = xe_i^T$ for some x. If we can show that $x = 0$, we will be finished. Equating second components of (20), we have $0 = R_{21}w = xe_i^T w = xa_{i,i-1}$. Since $a_{i,i-1} \neq 0$, we have $x = 0$. □

Let $\hat{G} = \hat{G}_{n-1}$, $\hat{Z} = \hat{Z}_{n-1}$, $\hat{R} = \hat{R}_{n-1}$, and $\hat{S} = \hat{S}_{n-1}$. Then $\hat{R}$ and $\hat{S}$ are upper triangular by Theorem 4.12 with $i = n-1$, and

$$\hat{A} = \hat{G}^{-1} A \hat{Z} \quad \text{and} \quad \hat{B} = \hat{G}^{-1} B \hat{Z}, \tag{21}$$

where

$$p(AB^{-1}) = \hat{G}\hat{R} \quad \text{and} \quad p(B^{-1}A) = \hat{Z}\hat{S}. \tag{22}$$

We conclude that one iteration of the generic bulge-chasing algorithm amounts to one iteration of the generic GZ algorithm.

THE DIAGONAL TORUS OF A MATRIX UNDER SPECIAL UNITARY EQUIVALENCE*

ROBERT C. THOMPSON†

Abstract. Given a matrix A, a sufficient condition is given for the vector of diagonal elements of UAV to cover a torus with specified base circle radii as U and V run over the special unitary group.

Key words. singular values, subtracted terms, spectral inequalities

AMS subject classification. 15A18

1. Introduction. Let A be an $n \times n$ matrix with complex elements and singular values $s_1 \geqq \cdots \geqq s_n$. Define $\mathcal{U}_n$ to be the $n \times n$ unitary group. Some years ago, the author [3] and Sing [2] (independently) characterized the principal diagonals of the matrices in the $\mathcal{U}_n \otimes \mathcal{U}_n$ orbit of A, under the group action for which $U \otimes V^*$ takes A to UAV, for U and V in $\mathcal{U}_n$. (V^* is the conjugate transpose of V.) The present paper should be viewed as a supplement to [2] and [3], especially [3].

To explain the principal diagonal characterization, let $d_1, \ldots, d_n$ be complex numbers enumerated such that $|d_1| \geqq \cdots \geqq |d_n|$. Then [3], [2] unitary matrices U and V exist such that the principal diagonal of UAV consists of $d_1, \ldots, d_n$ if and only if

$$\sum_{t=1}^{k} |d_t| \leqq \sum_{t=1}^{k} s_t, \qquad k = 1, \ldots, n,$$

$$\sum_{t=1}^{n-1} |d_t| - |d_n| \leqq \sum_{t=1}^{n-1} s_t - s_n.$$

This theorem solved a question posed by Mirsky [1] in 1964.

An unexpected facet of this theorem is the last inequality, each side of which has a subtracted term.

The author, in [3], also investigated the proper orthogonal counterpart of this theorem in which A is a real matrix with given singular values and nonnegative determinant, and the unitary group $\mathcal{U}_n$ is replaced by the real proper orthogonal group $\mathcal{O}_n$. The result was a somewhat similar theorem, except that under certain circumstances the minus term on the left side of the last inequality is replaced with a plus term, with the minus term on the right still being present.

Since the publication of [3], it has been realized that singular values frequently satisfy inequalities with subtracted terms; see [4] and [5].

Motivated by the real proper orthogonal theorem just mentioned, the objective of this paper is to investigate the vectors of principal diagonal elements in the $\mathcal{SU}_n \otimes \mathcal{SU}_n$ orbit of a given matrix A, where $\mathcal{SU}_n$ is the $n \times n$ special unitary group, comprising the unitary matrices with determinant one. While the diagonal vectors may satisfy intricate conditions (see the lemma in §3) a tidy theorem is obtained if attention is

* Received by the editors February 19, 1992; accepted for publication (in revised form) February 8, 1993. The work of this author was supported in part by a National Science Foundation grant.

† Department of Mathematics, University of California, Santa Barbara, California 93106-3080 (thompson@math.ucsb.edu).

focused on diagonals covering a torus (definition below) in n space. Our theorem furnishes a sufficient condition on the radii of the base circles in an n-torus in order that the diagonal vectors of the matrices in the orbit of A will cover it.

We say that a vector $[d_1, \dots, d_n]$ of diagonal elements of a matrix UAV in the $\mathcal{SU}_n \otimes \mathcal{SU}_n$ orbit of A belongs to a torus of diagonal vectors if $[\zeta_1 d_1, \cdots, \zeta_n d_n]$ are diagonal vectors of matrices in the orbit of A for every choice of $\zeta_1, \dots, \zeta_n$ with $|\zeta_1| = \cdots = |\zeta_n| = 1$. The radii of the base circles in the torus are $|d_1|, \dots, |d_n|$.

2. The torus theorem. When studying the diagonal elements $d_1, \dots, d_n$ of a matrix UAV in the orbit of A, no generality is lost if we assume that $|d_1| \geqq \cdots \geqq |d_n|$ since arbitrary rearrangements of the principal diagonal are obtained by passing to $P(UAV)P^*$ for a suitable generalized permutation matrix P with determinant one.

THEOREM. *Let A be a matrix with singular values $s_1 \geqq \cdots \geqq s_n$, and let $d_1, \dots, d_n$ be complex numbers with $|d_1| \geqq \cdots \geqq |d_n|$. If*

$$\sum_{t=1}^{k} |d_t| \leqq \sum_{t=1}^{k} s_t, \qquad k = 1, \dots, n-1, \tag{1}$$

$$\sum_{t=1}^{n} |d_t| \leqq \sum_{t=1}^{n-1} s_t - s_n, \tag{2}$$

then the diagonal vectors of the matrices in the $\mathcal{SU}_n \otimes \mathcal{SU}_n$ orbit of A cover the torus with $|d_1|, \dots, |d_n|$ as the base circle radii.

In the last condition, there is no subtracted term on the left even though there is one on the right.

We speculate that if the diagonal vectors of the matrices in the $\mathcal{SU}_n \otimes \mathcal{SU}_n$ orbit of A cover a torus with base circle radii $|d_1| \geqq \cdots \geqq |d_n|$, then the $|d_i|$ satisfy the just displayed inequalities, of which only the last is conjectural.

In passing, we note that the $\mathcal{SU}_n \otimes \mathcal{SU}_n$ orbit of a matrix A with singular values $s_1 \geqq \cdots \geqq s_n$ contains a unique matrix $\operatorname{diag}(s_1, \dots, s_{n-1}, \zeta s_n)$ where $|\zeta| = 1$. This is the special unitary version of the singular value decomposition.

3. The 2×2 case. The following lemma establishes the theorem and its converse in the 2×2 case.

LEMMA. *Let A be a 2×2 matrix with singular values $s_1 \geqq s_2$. Then the diagonal vectors $[d_1, d_2]$ of the matrices in the $\mathcal{SU}_2 \otimes \mathcal{SU}_2$ orbit of A cover a torus with fixed base circle radii $|d_1|, |d_2|$ if and only if $|d_1| + |d_2| \leqq s_1 - s_2$.*

Proof. Let $\det A = \zeta s_1 s_2$, where $|\zeta| = 1$. We wish to construct a matrix

$$\begin{bmatrix} d_1 & z_1 \\ z_2 & d_2 \end{bmatrix}$$

in the $\mathcal{SU}_2 \otimes \mathcal{SU}_2$ orbit of A, where z_1, z_2 are complex numbers to be determined. This matrix belongs to the orbit if and only if

$$|d_1|^2 + |d_2|^2 + |z_1|^2 + |z_2|^2 = s_1^2 + s_2^2,$$
$$d_1 d_2 - z_1 z_2 = \zeta s_1 s_2.$$

A choice for $\arg(z_1 z_2)$ exists to satisfy the second condition if and only if

$$|z_1||z_2| = |d_1 d_2 - \zeta s_1 s_2|.$$

Thus the existence of the desired matrix requires that the polynomial

$$w^2 - (s_1^2 + s_2^2 - |d_1|^2 - |d_2|^2)w + |d_1 d_2 - \zeta s_1 s_2|^2$$

in w have two nonnegative roots $|z_1|^2$, $|z_2|^2$. An equivalent form of this condition is

$$|d_1 d_2 - \zeta s_1 s_2|^2 \leqq \frac{1}{4}(s_1^2 + s_2^2 - |d_1|^2 - |d_2|^2)^2$$

with

$$s_1^2 + s_2^2 - |d_1|^2 - |d_2|^2 \geqq 0.$$

This inequality pair is the necessary and sufficient condition for the $\mathcal{SU}_2 \otimes \mathcal{SU}_2$ orbit of A to contain a matrix with diagonal d_1, d_2.

We require that when d_1, d_2 satisfy these inequalities, so do $\zeta_1 d_1$ and $\zeta_2 d_2$ for any choice of ζ_1, ζ_2 with modulus one. Choosing ζ_1 and ζ_2 to maximize the left side of the first inequality, and using the second, we obtain this necessary and sufficient condition:

$$(|d_1||d_2| + s_1 s_2) \leqq \frac{1}{2}(s_1^2 + s_2^2 - |d_1|^2 - |d_2|^2).$$

This condition rearranges to become $(|d_1| + |d_2|)^2 \leqq (s_1 - s_2)^2$, and therefore to become $|d_1| + |d_2| \leqq s_1 - s_2$. □

4. The proof. The hypotheses and conclusion of the theorem are valid for a matrix A whenever they are valid for ξA, where ξ is a complex number with $|\xi| = 1$. Choosing ξ appropriately, it may be assumed that $\det A \geqq 0$. Then A is in the $\mathcal{SU}_n \otimes \mathcal{SU}_n$ orbit of $\operatorname{diag}(s_1, \ldots, s_n)$.

The following argument uses the proof of Lemma 1 of [3]. We briefly describe the aspect of this proof that we need. Let complex numbers δ_1, δ_2 and nonnegative real numbers $\sigma_1 \geqq \sigma_2$ satisfy $|\delta_1| + |\delta_2| \leqq \sigma_1 + \sigma_2, |\delta_1| - |\delta_2| \leqq \sigma_1 - \sigma_2, |\delta_2| - |\delta_1| \leqq \sigma_1 - \sigma_2$. Then unitary matrices U, V with determinant 1 exist such that $U\operatorname{diag}(\sigma_1, \sigma_2)V$ has principal diagonal $|\delta_1|, |\delta_2|$. Multiplying from the left by $D = \operatorname{diag}(e^{iarg\delta_1}, e^{iarg\delta_2})$, we obtain unitary matrices DU and V with $(DU)\operatorname{diag}(\sigma_1, \sigma_2)V$ having δ_1, δ_2 as principal diagonal elements, with $\det(DU) = e^{i(arg\delta_1 + arg\delta_2)}$, and with $\det V = 1$.

We now prove the theorem by induction on the matrix size, using techniques similar to those in [3]. Let the matrices be $n \times n$, and let $d_1, \ldots, d_n$ be given with $|d_1| \geqq \cdots \geqq |d_n|$. The $n = 1$ case is trivial (the assumptions imply $d_1 = s_1 = 0$), and the $n = 2$ case is settled by the lemma, so let $n > 2$.

First, suppose that $s_i \geqq |d_1| \geqq s_{i+1}$ for some i with $i \leqq n - 2$. Let $t = s_i + s_{i+1} - |d_1|$. Then $s_i \geqq t \geqq s_{i+1}$, $|d_1| + t \leqq s_i + s_{i+1}$, $|d_1| - t \leqq s_i - s_{i+1}$, $t - |d_1| \leqq s_i - s_{i+1}$. By the remarks above, we can find unitary matrices U and V such that

$$\begin{bmatrix} d_1 & * \\ * & t \end{bmatrix} = U\operatorname{diag}(s_i, s_{i+1})V \text{ with } \det U = e^{iarg d_1} \text{ and } \det V = 1.$$

We also have

$$\begin{aligned}
|d_2| &\leqq s_1, \\
&\cdots\cdots \\
|d_2| + \cdots + |d_i| &\leqq s_1 + \cdots + s_{i-1}, \\
|d_2| + \cdots + |d_{i+1}| &\leqq s_1 + \cdots + s_{i-1} + t, \\
&\cdots\cdots \\
|d_2| + \cdots + |d_n| &\leqq s_1 + \cdots + s_{i-1} + t + s_{i+2} + \cdots + s_{n-1} - s_n.
\end{aligned}$$

Therefore, by induction, we can construct a matrix in the $\mathcal{SU}_{n-1} \otimes \mathcal{SU}_{n-1}$ orbit of $\operatorname{diag}(t, s_1, \ldots, s_{i-1}, s_{i+2}, \ldots, s_n)$ with diagonal elements $\zeta^{-1}d_2, \ldots, \zeta^{-1}d_n$, where $\zeta = e^{-i(\arg d_1)/(n-1)}$. Multiplying by ζ, we get a matrix $A_1 = U_1 \operatorname{diag}(t, s_1, \ldots, s_{i-1}, s_{i+2}, \ldots, s_n)V_1$ with diagonal elements $d_2, \ldots, d_n$, where U_1 and V_1 are unitary with $\det U_1 = \zeta^{n-1}$, $\det V_1 = 1$. And now

$$\begin{bmatrix} 1 & 0 \\ 0 & U_1 \end{bmatrix} \begin{bmatrix} U & 0 \\ 0 & I_{n-2} \end{bmatrix} \operatorname{diag}(s_i, s_{i+1}, s_1, \ldots, s_{i-1}, s_{i+2}, \ldots, s_n) \begin{bmatrix} V & 0 \\ 0 & I_{n-2} \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & V_1 \end{bmatrix}$$

has $d_1, \ldots, d_n$ as its principal diagonal with the left and right unitary factors

$$\begin{bmatrix} 1 & 0 \\ 0 & U_1 \end{bmatrix} \begin{bmatrix} U & 0 \\ 0 & I_{n-2} \end{bmatrix}, \qquad \begin{bmatrix} V & 0 \\ 0 & I_{n-2} \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & V_1 \end{bmatrix}$$

having determinants $\det U_1 \det U = e^{i\arg d_1}\zeta^{n-1} = 1$ and $\det V \det V_1 = 1$. Since $\operatorname{diag}(s_i, s_{i+1}, s_1, \ldots, s_{i-1}, s_{i+2}, \ldots, s_n) = PAQ$ for suitable unitary matrices P, Q with determinant 1, this case is finished.

Now let $|d_1| \leqq s_{n-1}$. We choose a real number t satisfying

$$\left.\begin{matrix} |d_1| - s_{n-1} + s_n \\ 0 \end{matrix}\right\} \leqq t \leqq \begin{cases} s_{n-1} + s_n - |d_1|, \\ s_{n-1} - s_n + |d_1|, \\ s_1 + \cdots + s_{n-2} - |d_2| - \cdots - |d_n|. \end{cases}$$

This number t will exist if and only if the six inequalities comparing the extreme left and right expressions are all satisfied, and this is the case exactly when $|d_2| + \cdots + |d_n| \leqq s_1 + \cdots + s_{n-2}$. Assuming that this holds, we imitate the proof in the previous part with $i = n - 1$.

First, we have

$$\begin{aligned} |d_1| + t &\leqq s_{n-1} + s_n, \\ |d_1| - t &\leqq s_{n-1} - s_n, \\ t - |d_1| &\leqq s_{n-1} - s_n, \end{aligned}$$

implying that $t \leqq s_{n-1}$, and second we have

$$\begin{aligned} |d_2| &\leqq s_1, \\ &\cdots\cdots \\ |d_2| + \cdots + |d_{n-1}| &\leqq s_1 + \cdots + s_{n-2}, \\ |d_2| + \cdots + |d_n| &\leqq s_1 + \ldots s_{n-2} - t. \end{aligned}$$

By the first set of inequalities and the proof of Lemma 1 of [3], unitary matrices U and V exist such that $U\operatorname{diag}(s_{n-1}, s_n)V$ has diagonal elements d_1 and t, with $\det U = e^{i\arg d_1}$ and $\det V = 1$. By the second set of inequalities, and induction, noting that $t \leqq s_{n-1}$, the $\mathcal{SU}_{n-1} \otimes \mathcal{SU}_{n-1}$ orbit of $\operatorname{diag}(t, s_1, \ldots, s_{n-2})$ contains a matrix with diagonal elements $\zeta^{-1}d_2, \ldots, \zeta^{-1}d_n$, where $\zeta = e^{-i(\arg d_1)/(n-1)}$. Multiplying by ζ, we obtain unitary matrices U_1 and V_1 with $\det U_1 = \zeta^{n-1}$ and $\det V_1 = 1$ such that

$$U_1 \operatorname{diag}(t, s_1, \ldots, s_{n-2})V_1$$

has diagonal elements $d_2, \ldots, d_n$. Now complete the argument as in the previous case.

So now assume that

$$|d_2| + \cdots + |d_n| > s_1 + \cdots + s_{n-2}, \qquad |d_1| \leqq s_{n-1}.$$

We choose a number t satisfying

$$|d_1| + |d_n| - s_{n-1} \leqq t \leqq \begin{cases} s_1 + \cdots + s_{n-2} - s_n - |d_2| - \cdots - |d_{n-1}|, \\ s_{n-1} - |d_1| + |d_n|, \\ |d_{n-1}|. \end{cases}$$

The left member does not exceed each of the right members, easily seen using $|d_1| \leqq s_{n-1}$, so a real value for t exists. And $|d_1| + |d_n| - s_{n-1} \geqq 0$ since we have: from $|d_2| + \cdots + |d_n| > s_1 + \cdots + s_{n-2}$, we get $s_1 + \cdots + s_{n-3} + |d_{n-1}| + |d_n| > s_1 + \cdots + s_{n-2}$, and therefore $|d_{n-1}| + |d_n| > s_{n-2}$. This implies that $|d_1| + |d_n| > s_{n-1}$, and therefore t is positive.

Then two sets of conditions are satisfied. The first is

$$\begin{gathered} |d_2| \leqq s_1, \\ \cdots\cdots \\ |d_2| + \cdots + |d_{n-1}| \leqq s_1 + \cdots + s_{n-2}, \\ |d_2| + \ldots |d_{n-1}| + t \leqq s_1 + \cdots + s_{n-2} - s_n, \end{gathered}$$

and the second is

$$\begin{aligned} |d_1| + |d_n| &\leqq t + s_{n-1}, \\ |d_1| - |d_n| &\leqq s_{n-1} - t. \end{aligned}$$

Let ζ satisfy $\zeta^{n-1} e^{i(\arg d_1 + \arg d_n)} = 1$.

Because of the first set of conditions, and by induction, we may find unitary matrices U and V with determinant 1 such that

$$U \operatorname{diag}(s_1, \ldots, s_{n-2}, s_n) V$$

has diagonal elements

$$\zeta^{-1} d_2, \ldots, \zeta^{-1} d_{n-1}, \zeta^{-1} t.$$

Multiplying by ζ, we obtain a matrix

$$(\zeta U) \operatorname{diag}(s_1, \ldots, s_{n-2}, s_n) V$$

with diagonal elements $d_2, \ldots, d_{n-1}, t$ and ζU and V having determinants ζ^{n-1} and 1.

By the second set of conditions, and the proof of Lemma 1 of [3], we may choose unitary matrices U_1 and V_1 such that $U_1 \operatorname{diag}(t, s_{n-1}) V_1$ has diagonal elements d_1, d_n, where U_1 has determinant $e^{i(\arg d_1 + \arg d_n)}$, and $\det V_1 = 1$.

Then

$$\begin{bmatrix} I & 0 \\ 0 & U_1 \end{bmatrix} \begin{bmatrix} \zeta U & 0 \\ 0 & 1 \end{bmatrix} \operatorname{diag}(s_1, \ldots, s_{n-2}, s_n, s_{n-1}) \begin{bmatrix} V & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} I & 0 \\ 0 & V_1 \end{bmatrix}$$

has diagonal elements $d_2, \ldots, d_{n-1}, d_1, d_n$ and the left and right unitary factors have determinant one. □

FAST ESTIMATION OF PRINCIPAL EIGENSPACE USING LANCZOS ALGORITHM*

GUANGHAN XU† AND THOMAS KAILATH‡

Abstract. This paper considers the problem of finding the principal eigenspace and/or eigenpairs of $M \times M$ Hermitian matrices that can be expressed or *approximated* by a low-rank matrix plus a shift, i.e., $\mathbf{A} = \mathbf{B} + \sigma\mathbf{I}$, where $\mathbf{B}$ is a rank d Hermitian matrix and $d \ll M$. Such matrices arise in signal processing, geophysics, dynamic structure analysis, and other fields. The proposed problem can be solved by a full $O(M^3)$ eigendecomposition, or by several more efficient alternatives, e.g., the power, subspace iteration, and Lanczos algorithms. This paper shows that the Lanczos algorithm can exploit the inherent structure and is generally more efficient than other alternatives. More specifically, if $\mathbf{A} = \mathbf{B}+\sigma\mathbf{I}$, the Lanczos algorithm can be used to *exactly* determine the principal eigenspace span$\{\mathbf{B}\}$ and σ with a *finite* amount of computation. If $\mathbf{A}$ is *close* to $\mathbf{B}+\sigma\mathbf{I}$, the Lanczos algorithm can estimate the principal eigenvectors and eigenvalues in $O(M^2d)$ flops. It is shown that the errors in the estimates of the kth principal eigenvalue λ_k and eigenvector $\mathbf{e}_k$ decay at the rate of $\varepsilon^2/(\lambda_k - \sigma)^2$ and $\varepsilon/(\lambda_k - \sigma)$, respectively, where ε is a measure of the mismatch between $\mathbf{A}$ and $\mathbf{B} + \sigma\mathbf{I}$.

1. Introduction.

In the fields of signal processing, geophysics, and image compression, we often encounter the problem of estimating the principal eigenvalues and eigenvectors, or often just the principal eigenspace, of an $M \times M$ matrix that can be either *exactly expressed* or *approximated* by a low-rank matrix plus a shift, say

$$\mathbf{A} = \mathbf{B} + \sigma\mathbf{I}, \tag{1}$$

where $\mathbf{B}$ is a rank $d(\ll M)$ positive semidefinite Hermitian matrix and σ is a real number. The eigenvalues of such an $\mathbf{A}$ can be arranged as $\lambda_1 \geq \lambda_2 \geq \cdots \lambda_d > \lambda_{d+1} = \cdots = \lambda_M = \sigma$. We can also easily verify that span$\{\mathbf{B}\}$ = span$\{\mathbf{e}_1, \ldots, \mathbf{e}_d\}$, where $\mathbf{e}_1, \ldots, \mathbf{e}_d$ are the eigenvalues corresponding to the eigenvalues $\lambda_1, \ldots, \lambda_d$, respectively. These will be called the principal eigenvalues and eigenvectors whose span is the principal eigenspace.

1.1. Applications in signal processing.

Such matrix structure arises in several signal processing problems (see, e.g., [14], [15]) where the data vectors $\mathbf{x}(\cdot)$ can be decomposed into a signal part $\mathbf{s}(\cdot)$ and additive noise part $\mathbf{n}(\cdot)$, where $\mathbf{s}(\cdot)$ is confined to a low-dimensional subspace, called the *signal subspace*, while the noise is not so

restricted. Given such data samples, the goal is to determine the signal subspace. Assuming that the signal and noise are uncorrelated, as is often the case, the ideal data covariance matrix of $\mathbf{x}(\cdot)$ can be expressed as the sum of the signal covariance $\mathbf{B}$ and the noise covariance $\sigma\mathbf{I}$, where σ is the intensity of the white noise,

$$\mathbf{A} = E\{\mathbf{x}(\cdot)\mathbf{x}^H(\cdot)\} = E\{\mathbf{s}(\cdot)\mathbf{s}^H(\cdot)\} + E\{\mathbf{n}(\cdot)\mathbf{n}(\cdot)\} = \mathbf{B} + \sigma\mathbf{I}. \tag{2}$$

Since $\mathbf{s}(\cdot)$ lies in the d-dimensional signal subspace, its covariance also has rank d, and span$\{\mathbf{B}\}$ will be the signal subspace. Then, as mentioned above, span$\{\mathbf{B}\}$ = span$\{\mathbf{e}_1, \ldots, \mathbf{e}_d\}$.

In reality, however, the ideal covariance matrix (obtained from an *infinite* amount of data samples) is often not available. Instead, one has the so-called *sample* covariance matrix $\hat{\mathbf{A}}$ that is estimated based upon a finite number (N) data samples. Nevertheless, for a reasonably large N, the estimation error is of order $O(1/\sqrt{N})$ (see, e.g., [2]), i.e.,

$$\hat{\mathbf{A}} = \mathbf{A} + O(1/\sqrt{N}), \tag{3}$$

and for the eigenvalues and eigenvectors, we have

$$\hat{\mathbf{e}}_i = \mathbf{e}_i + O(1/\sqrt{N}), \quad i = 1, \ldots, d, \quad \hat{\lambda}_i = \lambda_i + O(1/\sqrt{N}), \quad i = 1, \ldots, M, \tag{4}$$

where $(\hat{\lambda}_i, \hat{\mathbf{e}}_i)$ denotes the ith eigenpair of $\hat{\mathbf{A}}$. By (4) $\hat{\lambda}_{d+1} \approx \cdots \approx \hat{\lambda}_M \approx \sigma$ and they are confined in a small region of size $O(1/\sqrt{N})$ about σ. In [4], it was shown that the maximum likelihood (optimal) estimate of the signal subspace is span$\{\hat{\mathbf{e}}_1, \ldots, \hat{\mathbf{e}}_d\}$, which has the $O(1/\sqrt{N})$ estimation error by (4).

1.2. Other applications. In dynamic structural analysis and image compression, among others, the matrix under consideration $\mathbf{A}$ ($M \times M$) has a few dominant eigenvalues and many much smaller ones, i.e., $\lambda_1 \geq \cdots \geq \lambda_d \gg \lambda_{d+1} \geq \cdots \geq \lambda_M$. The objective is to find a small number of dominant modes, i.e., the principal eigenvalues and eigenvectors $\{\lambda_i, \mathbf{e}_i\}_{i=1}^d$, so that the original large matrix $\mathbf{A}$ can be approximated by a rank-d matrix $\hat{\mathbf{A}} = \sum_{k=1}^d \mathbf{e}_k \lambda_k \mathbf{e}_k^H$. According to the Eckart–Young theorem, such an approximation $\hat{\mathbf{A}}$ is optimal since it yields the minimum error $\mathbf{A} - \hat{\mathbf{A}}$ in the Frobenius norm sense among all possible rank-d matrices. If all the nonprincipal eigenvalues are relatively small and can be bounded by a small quantity ε, i.e., $\lambda_k < \varepsilon$ for $d + 1 \leq k \leq M$, then the approximation error is of the order of ε, i.e.,

$$\|\mathbf{A} - \hat{\mathbf{A}}\|_F = \sqrt{\lambda_{d+1}^2 + \cdots + \lambda_M^2} = O(\varepsilon). \tag{5}$$

1.3. Problem statement and conventional approaches. Summarizing the above potential applications, we can make the following problem statement.

Given a Hermitian matrix $\mathbf{A} = \mathbf{B} + \sigma\mathbf{I} + O(\varepsilon)$, *where* $\mathbf{B}$ *is a* rank-d *matrix,* $d \ll M$ *and* $\varepsilon < \|\mathbf{B}\|_F$ *is a small quantity, find its principal eigenspace, i.e.,* span$\{\mathbf{B}\}$ *or its principal eigenvalues and eigenvectors.*

Obviously, the proposed problem can be solved by a full eigendecomposition, which is computationally intensive ($O(M^3)$ flops) and difficult to implement in very large scale integrated (VLSI) hardware. There are several more efficient alternatives, e.g., the power method, subspace iteration, and the use of the Lanczos algorithm [6]. In this paper, it is shown that the Lanczos algorithm can nicely exploit the inherent structure of the matrices of interest and is more efficient in solving the stated problem

than the other alternatives. More specifically, we will show that the Lanczos algorithm requires only $O(M^2 d)$ flops to estimate the principal eigenpairs. Performance analysis is also presented to show that after d Lanczos steps, the estimation errors of the kth principal eigenvalue and eigenvector decay exponentially at the rates $\varepsilon^2/(\lambda_k - \sigma)^2$ and $\varepsilon/(\lambda_k - \sigma)$, respectively. Since the *optimal* solution (complete eigendecomposition) to the above problems is only an $O(\varepsilon)$ approximation, the analysis results show that the estimates obtained via the Lanczos algorithm achieve the same first-order approximation as those derived from the more costly full eigendecomposition.

We remark that if $\varepsilon = 0$, i.e., $\mathbf{A} = \mathbf{B} + \sigma\mathbf{I}$, then via the Lanczos algorithm, we can obtain the principal eigenspace (and also σ) exactly in a finite number of steps. This may seem surprising at first glance, but note that we are not finding the principal eigenpairs; the fact that a single repeated eigenvalue can always, in principle, be found in a finite number of steps. In other words, the task of finding the span$\{\mathbf{B}\}$ if $\varepsilon = 0$, is clearly not a conventional eigenproblem.

This paper is organized as follows. We briefly outline the *finite-step* procedure for computing the principal eigenspace of an exactly structured matrix ($\varepsilon = 0$) in the following section. This provides the motivation for a more realistic procedure given in §3, along with the appropriate analysis. Some numerical examples are given in §4.

2. Matrices with exact structure. First, we introduce the Krylov subspace

$$\mathcal{K}^m(\mathbf{A}, \mathbf{f}) = \text{span}\{\mathbf{f}, \mathbf{A}\mathbf{f}, \ldots, \mathbf{A}^{m-1}\mathbf{f}\}, \tag{6}$$

where $\mathbf{f}$ is a vector to be specified later. The important property that $\mathcal{K}^m(\mathbf{A}, \mathbf{f}) = \mathcal{K}^m(\mathbf{A} - \rho\mathbf{I}, \mathbf{f})$, for any scalar ρ, shows that (using (1))

$$\mathcal{K}^m(\mathbf{A}, \mathbf{f}) = \mathcal{K}^m(\mathbf{A} - \sigma\mathbf{I}, \mathbf{f}) = \mathcal{K}^m(\mathbf{A}, \mathbf{f}), \tag{7}$$

which we note has dimension at most $d + 1$, where $d = \text{rank } \mathbf{B}$. Suppose that $\mathbf{f}$ is not orthogonal to any of the d principal eigenvectors and to at least one of the nonprincipal eigenvectors,[1] and that the d principal eigenvalues are distinct. Then, it is not difficult to show that $\dim(\mathcal{K}^{d+1}(\mathbf{A}, \mathbf{f})) = d + 1$ [18], [19]. The Lanczos method is an efficient way of finding an orthonormal basis $\mathbf{Q}_m = [\mathbf{q}_1, \ldots, \mathbf{q}_m]$ for $\mathcal{K}^m(\mathbf{A}, \mathbf{f})$ as follows:

Given $\mathbf{A}$ (Hermitian); $\mathbf{r}_0 = \mathbf{q}_1$ (unit-norm); $j = 0$
while $\beta_j \neq 0$
$\mathbf{q}_{j+1} = \mathbf{r}_j/\beta_j$; $j := j + 1$; $\alpha_j = \mathbf{q}_j^H \mathbf{A}\mathbf{q}_j$
$\mathbf{r}_j = \mathbf{A}\mathbf{q}_j - \alpha_j\mathbf{q}_j - \beta_{j-1}\mathbf{q}_{j-1}$; $\beta_j = \|\mathbf{r}_j\|$
end

Since $\dim(\mathcal{K}^{d+1}(\mathbf{A}, \mathbf{f})) = d + 1$, it turns out that the Lanczos algorithm will terminate at the $(d+1)$th Lanczos step, i.e., β_{d+1} will be zero. This early termination determines d. Furthermore, we can show that the $(d+1) \times (d+1)$ (tridiagonal) matrix $\mathbf{T}_{d+1} = \mathbf{Q}_{d+1}^H \mathbf{A}\mathbf{Q}_{d+1}$ has the eigenvalues $\{\lambda_1, \ldots, \lambda_d, \sigma\}$, where $\{\lambda_1, \ldots, \lambda_d\}$ are the principal eigenvalues of $\mathbf{A}$. Therefore, if an eigendecomposition is performed on this matrix, we can exactly obtain the principal eigenvalues $\{\lambda_i\}$ and $\mathbf{Q}_{d+1}\mathbf{s}_1, \ldots, \mathbf{Q}_{d+1}\mathbf{s}_d$ will be the principal eigenvectors of $\mathbf{A}$, where $\{\mathbf{s}_k\}$ are the eigenvectors of $\mathbf{T}_{d+1}$.

Now, an exact eigendecomposition requires an infinite amount of computation. But in our special case, it is possible to exactly find the principal eigenspace in a finite

[1] If $\mathbf{f}$ is randomly selected, it satisfies this condition with probability one.

number of steps. One way of seeing this is to note that since

$$\text{(8)} \qquad \mathrm{Tr}(\mathbf{A}) = \sum_{k=1}^{M} \lambda_k = \sum_{k=1}^{d} \lambda_k + (M-d)\sigma, \qquad \mathrm{Tr}(\mathbf{T}_{d+1}) = \sum_{k=1}^{d} \lambda_k + \sigma,$$

thus

$$\text{(9)} \qquad \sigma = \frac{\mathrm{Tr}(\mathbf{A}) - \mathrm{Tr}(\mathbf{T}_{d+1})}{M-d-1}.$$

Knowing σ, the principal eigenspace will be the range space of any d independent columns of $\mathbf{A} - \sigma\mathbf{I} = \mathbf{B}$. However, an orthonormal basis can also be easily obtained. Since σ is an eigenvalue of $\mathbf{T}_{d+1}$, we can solve $(\mathbf{T}_{d+1} - \sigma\mathbf{I})\mathbf{s} = \mathbf{0}$ and find the unit-norm vector $\mathbf{s}$. Then $\mathbf{Qs}$ is orthogonal to the principal eigenspace. Let us form a Householder matrix $\mathbf{H}$ that transforms $\mathbf{s}$ to $\mathbf{l}_{d+1}$, where $\mathbf{l}_{d+1}$ has zero elements everywhere except the last one, which is one. Then the first d column of $\mathbf{QH}$ is orthogonal to $\mathbf{Qs}$ and forms an orthonormal basis of $\mathbf{B}$.

However, if some principal eigenvalues are repeated, the Lanczos algorithm terminates before $d+1$ steps and (9) is no longer valid. So we must work a little harder to find σ. Suppose that the Lanczos algorithm stops at the mth step ($m < d+1$), yielding $\mathbf{AQ}_m = \mathbf{Q}_m\mathbf{T}_m$, where m is the number of distinct eigenvalues of $\mathbf{A}$. In this case, $\mathbf{T}_m$ no longer contains all the principal eigenvalues. To handle this, we can select another initial vector $\mathbf{f}_1$ that is orthogonal to $\mathbf{Q}_m$ and apply the Lanczos algorithm to the deflated matrix $\mathbf{A} - \mathbf{Q}_m\mathbf{T}_m\mathbf{Q}_m^H$. Proceeding in this way, we get orthogonal $\mathbf{Q}_{m_1}^{(1)}$, $\mathbf{Q}_{m_2}^{(2)}, \ldots$ to block tridiagonalize $\mathbf{A}$, i.e.,

$$\text{(10)} \qquad \cdots \mathbf{Q}_{m_2}^{(2)}\mathbf{Q}_{m_1}^{(1)}\mathbf{A}\mathbf{Q}_{m_1}^{(1)H}\mathbf{Q}_{m_2}^{(2)H}\cdots = \begin{bmatrix} \mathbf{T}_{m_1} & 0 & \cdots \\ 0 & \mathbf{T}_{m_2} & \cdots \\ \vdots & \vdots & \ddots \end{bmatrix},$$

where each $\mathbf{T}_{m_i}$ is a tridiagonal matrix of size m_i equal to the number of steps in the ith application of the Lanczos algorithm. We can proceed with the above deflation till a certain $\mathbf{T}_{m_i}$ is of block size one. Then we have exhausted all the principal eigenvalues of $\mathbf{A}$ and the only element of $\mathbf{T}_{m_i}$ must be σ. Knowing σ, we can easily find a basis of the principal eigenspace from $\mathbf{A} - \sigma\mathbf{I}$. In this case, the total number of Lanczos steps is less than $d + d'$, requiring less than $O(M^2(d+d'))$ flops, where $d'(\leq d)$ is the maximum multiplicity among all the principal eigenvalues.

3. Performance analysis of the Lanczos algorithm. In reality, the matrices under consideration do not have *exactly* repeated eigenvalues, so that a more practical problem is to estimate the eigenpairs of a matrix of the form

$$\text{(11)} \qquad \mathbf{A} = \mathbf{B} + \sigma\mathbf{I} + O(\varepsilon).$$

We can still apply the Lanczos approach given in §2 to estimate the principal eigenspace. However, as is made clear in the following, though the corresponding estimation error is of the same order as for the approximation error of an exact eigendecomposition, it may have a larger first-order coefficient. However, if we modify the above algorithm and adopt the well-known Rayleigh–Ritz (RR) approximation [12], we show that the error between the kth RR value and eigenvalue λ_k is $O((\varepsilon/(\lambda_k - \sigma))^{2(m-d)})$, while the error between the kth RR vector and eigenvector

$\mathbf{e}_k$ is $O((\varepsilon/(\lambda_k - \sigma))^{m-d})$, where $k = 1, \ldots, d$ and $m(> d)$ is the number of Lanczos steps. If $m = d + 2$, we can see that the errors are $O(\varepsilon)$, and the Lanczos algorithm achieves the same first-order approximation as an exact eigendecomposition. If $m(\geq d+2)$ Lanczos steps are executed, we can achieve the same $(m-d-1)$th order approximation as the eigendecomposition.

3.1. Existing error bounds.

DEFINITION 3.1. *For the matrix* $\mathbf{A}$ *and its Krylov subspace* $\mathcal{K}^m(\mathbf{A}, \mathbf{f})$ *the* RR *values* θ_i *and vectors* $\mathbf{y}_i$ *are defined such that*

$$\mathbf{A}\mathbf{y}_i - \theta_i \mathbf{y}_i \perp \mathcal{K}^m(\mathbf{A}, \mathbf{f}). \tag{12}$$

In general, it is very difficult to estimate the errors between the eigenpairs and the corresponding RR pairs. The only existing error bounds are stated below [12].

Saad bound: *For* $j = 1, \ldots, m$,

$$|\theta_j - \lambda_j| \leq |\lambda_M - \lambda_j| \left[\frac{\sin\_(\mathbf{f}, \mathcal{E}^j)}{\cos\_(\mathbf{f}, \mathbf{e}_j)} \cdot \frac{\prod_{l=1}^{j-1} \left(\frac{\theta_l - \lambda_M}{\theta_l - \lambda_j} \right)}{T_{m-j}(1 + 2\gamma_{j,j+1,M})} \right]^2 \tag{13}$$

and

$$\tan\_(\mathbf{e}_j, \mathcal{K}^m(\mathbf{A}, \mathbf{f})) \leq \frac{\sin\_(\mathbf{f}, \mathcal{E}^j)}{\cos\_(\mathbf{f}, \mathbf{e}_j)} \cdot \frac{\prod_{l=1}^{j-1} \left(\frac{\lambda_l - \lambda_M}{\lambda_l - \lambda_j} \right)}{T_{m-j}(1 + 2\gamma_{j,j+1,M})}, \tag{14}$$

where $\gamma_{j,j+1,M} = (\lambda_j - \lambda_{j+1})/(\lambda_{j+1} - \lambda_M)$, $\mathcal{E}^j = \operatorname{span}\{\mathbf{e}_1, \mathbf{e}_2, \ldots, \mathbf{e}_j\}$, *and* $T_{m-j}(\cdot)$ *is the Chebyshev polynomial.*

Kaniel bound: *For* $j = 1, \ldots, m$,

$$|\theta_j - \lambda_j| \leq |\lambda_M - \lambda_j| \left[\frac{\sin\_(\mathbf{f}, \mathcal{E}^j)}{\cos\_(\mathbf{f}, \mathbf{e}_j)} \cdot \frac{\prod_{l=1}^{j-1} \left(\frac{\lambda_l - \lambda_M}{\lambda_l - \lambda_j} \right)}{T_{m-j}(1 + 2\gamma_{j,j+1,M})} \right]^2 + \sum_{l=1}^{j-1} (\lambda_M - \lambda_l) \sin^2\_(\mathbf{y}_l, \mathbf{e}_l), \tag{15}$$

and

$$\sin^2\_(\mathbf{y}_l, \mathbf{e}_l) \leq \left[(\theta_l - \lambda_l) + \sum_{s=1}^{l-1} (\lambda_{l+1} - \lambda_s) \sin^2\_(\mathbf{y}_s, \mathbf{e}_s) \right] / (\lambda_{l+1} - \lambda_l). \tag{16}$$

However, these bounds are not good enough for our purposes. For one thing, they require knowledge of *both* the eigenpairs $\{\lambda_k, \mathbf{e}_k\}$ and the RR pairs $\{\theta_k, \mathbf{s}_k\}$. Second, the bounds are not tight enough. For example, when $\varepsilon = 0$, we know from §2 that the error is zero, while the bounds are obviously nonzero.

It is very difficult to derive a tighter error bound since, as is revealed in the following, the relationship between RR values and the eigenvalues are highly nonlinear. Now, it is known (see [12]) that by exploiting more knowledge of the eigenvalue distribution, one can get a tighter error bound.

The improved bound: If there are significant gaps between $\{\lambda_1, \ldots, \lambda_{k-1}\}$ *and* $\{\lambda_k, \ldots, \lambda_l\}$ *and between* $\{\lambda_k, \ldots, \lambda_l\}$ *and* $\{\lambda_{l+1} \ldots \lambda_M\}$, *then* $T_{m-j}(1 + 2\gamma_{j,j+1,M})$ *in the Kaniel and Saad bounds can be replaced by*

$$\prod_{\mu=j+1}^{k-1} \left(\frac{\lambda_\mu - \lambda_j}{\lambda_l - \lambda_\mu}\right) \prod_{\nu=l+1}^{M} \left(\frac{\lambda_\nu - \lambda_j}{\lambda_\nu - \lambda_k}\right) T_{M-j-(l-k)}(1 + 2\gamma_{jkl}), \tag{17}$$

where $j < k < l$ *and* $\gamma_{jkl} \triangleq (\lambda_j - \lambda_k)/(\lambda_k - \lambda_l)$.

For the matrix of interest in this paper, there is a gap between $\{\lambda_1, \ldots, \lambda_d\}$ and $\{\lambda_{d+1}, \ldots, \lambda_M\}$. In this case, $k = d + 1$, $l = M$, and for $j \leq d$, $\gamma_{jkl} = (\lambda_j - \lambda_{d+1})/(\lambda_{d+1} - \lambda_M)$. We know that $|\lambda_{d+1} - \lambda_M|$ is significantly smaller than $(\lambda_j - \lambda_{d+1})$. Therefore, the gap ratio γ_{jkl} is much larger than its counterparts in the Kaniel and Saad bounds; hence the improved bound for this special matrix is tighter than the Kaniel and Saad bounds. However, it is still difficult to know how tight the error bound is. As with the Kaniel and Saad bounds, the improved error bound is also a function of the *unknown* RR values $\{\theta_k\}$ and it is difficult to gain more insight from the fairly complicated expression (e.g., Chebychev polynomial).

In the following, we introduce a *new* approach to obtain a tighter and more useful error estimate of the RR approximation that also determines the speed of convergence. Although such an error estimate is not a strict bound, it shows the order of the error (in terms of ε), which can be important in, for example, determining the asymptotic performance of certain signal processing algorithms [17].

3.2. Convergence analysis and error estimate.

THEOREM 3.2. *Let* $\lambda_1 > \lambda_2 > \cdots > \lambda_M$ *be the eigenvalues of a Hermitian matrix* $\mathbf{A}$. *Suppose that the* $M - d$ *smaller eigenvalues cluster in a small region with center* $\sigma = (\lambda_{d+1} + \lambda_M)/2$, *while the principal eigenvalues are reasonably far away from* σ, *i.e.,*

$$\lambda_d - \sigma > \varepsilon, \qquad \lambda_{d+1} - \lambda_M < \varepsilon. \tag{18}$$

Let $(\theta_i, \mathbf{y}_i)$ *be the* RR *pairs from* $\mathcal{K}^m(\mathbf{A}, \mathbf{f})$, *arranged in descending order according to* θ_i, $i = 1, 2, \ldots, m$, *and* $m \geq d + 1$. *Then the error of the* k*th* RR *approximation is of the order* $O((\varepsilon/(\lambda_k - \sigma))^{2(m-d)})$, *for* $1 \leq k \leq d$, *More specifically, for* $k = 1, 2, \ldots, d$,

$$\frac{\lambda_k - \theta_k}{\lambda_k - \sigma} \sim \left\{ \frac{\sin^2 \angle(\mathcal{E}^d, \mathbf{f})}{\cos^2 \angle(\mathbf{e}_k, \mathbf{f})} \prod_{\substack{i=1 \\ i \neq k}}^{d} \frac{(\lambda_i - \sigma)^2}{(\lambda_i - \lambda_k)^2} \right\} \cdot \left(\frac{\varepsilon}{\lambda_k - \sigma}\right)^{2(m-d)}, \tag{19}$$

$$\sin^2 \angle(\mathbf{y}_k, \mathbf{e}_k) \sim \left\{ \frac{\sin^2 \angle(\mathcal{E}^d, \mathbf{f})}{\cos^2 \angle(\mathbf{e}_k, \mathbf{f})} \prod_{\substack{i=1 \\ i \neq k}}^{d} \frac{(\lambda_i - \sigma)^2}{(\lambda_i - \lambda_k)^2} \right\} \cdot \left(\frac{\varepsilon}{\lambda_k - \sigma}\right)^{2(m-d)}, \tag{20}$$

where $\mathcal{E}^d = \operatorname{span}\{\mathbf{e}_1, \mathbf{e}_2, \ldots, \mathbf{e}_d\}$.

First, we need to clarify the meaning of the symbol $\sim$ introduced in (19) and (20). By $a \sim b$, we mean (i) $a, b = O(\varepsilon^k)$; (ii) $\lim_{\varepsilon \to 0} a\varepsilon^{-k} \leq \lim_{\varepsilon \to 0} b\varepsilon^{-k}$. In other words, $a \sim b$ means that the term in a with the highest power of ε is no larger than its counterpart in b.

The proof of Theorem 3.2 is quite complicated and is described in Appendix A. Its main ideas can be summarized as follows. First, by definition, the RR pairs obey (see [12]) $\mathbf{A}\mathbf{y}_i - \theta_i \mathbf{y}_i \perp \mathcal{K}^m(\mathbf{A}, \mathbf{f}) = \mathcal{K}^m(\mathbf{A} - \sigma\mathbf{I})$ or, equivalently,

$$(\mathbf{A}_\mathbf{s}^j \mathbf{f})^H (\mathbf{A}_\mathbf{s}\mathbf{y}_i - \rho_i \mathbf{y}_i) = \mathbf{0}, \qquad j = 1, 2, \ldots, m, \tag{21}$$

where $\mathbf{A}_\mathbf{s} = \mathbf{A} - \sigma\mathbf{I}$ and $\rho_i = \theta_i - \sigma$. Using the fact that $\mathbf{y}_i = \pi_k(\mathbf{A}_\mathbf{s})\mathbf{f} / \|\pi_k(\mathbf{A}_\mathbf{s})\mathbf{f}\|$ (by a corollary in [12, p. 240]), we can obtain m independent equations for $\theta_1, \ldots, \theta_m$, where the polynomial

$$\pi_k(x) = \prod_{\substack{i=1 \\ i=k}}^{m} (x - \theta_i).$$

By the Cauchy interlace theorem [12], for $k \geq d+1$, θ_k lies between λ_{d+1} and λ_M, or by (18) $\theta_k - \sigma \sim \varepsilon$ for $k \geq d+1$. Then, let us keep the terms with the lowest power of ε and drop all the higher power terms. After some algebra, we end up with a set of Vandermonde equations from which we can recursively find the explicit expressions of $\lambda_1 - \theta_1$, $\lambda_2 - \theta_2, \ldots$. Based on this and the relationship between eigenvalues and eigenvectors, we obtain the error estimate of the principal eigenvectors (20).

A referee suggested an alternative method of proof that is listed in Appendix B. Extending the results in this proof, we can also obtain the following result, where we have strict upper bounds. For our further arguments, Theorem 3.2 is more useful, but Theorem 3.3 has independent value.

THEOREM 3.3. *For the same conditions and notation as defined in Theorem* 3.2, *we claim*

$$\lambda_k - \theta_k < \left\{ \frac{\sum_{j=d+1}^{M} \cos^2\angle(\mathbf{e}_j, \mathbf{f})(\lambda_k - \lambda_j) \prod_{\substack{i=1 \\ i=k}}^{d} (\lambda_j - \lambda_i)^2}{\cos^2\angle(\mathbf{e}_k, \mathbf{f}) \prod_{i=1}^{k-1} (\lambda_k - \theta_i)^2 \cdot \prod_{i=k}^{d} (\lambda_i - \lambda_k)^2} \right\} \cdot \left(\frac{\varepsilon}{\lambda_k - \sigma} \right)^{2(m-d)}, \tag{22}$$

$$\sin^2\angle(\mathbf{y}_k, \mathbf{e}_k) < \frac{\sum_{\substack{j=1 \\ j=k}}^{M} \cos^2\angle(\mathbf{e}_j, \mathbf{f}) \prod_{\substack{i=1 \\ i=k}}^{m} (\lambda_j - \theta_i)^2}{\cos^2\angle(\mathbf{e}_k, \mathbf{f}) \prod_{i=1}^{k-1} (\theta_i - \lambda_k)^2 \prod_{i=k+1}^{d} (\lambda_k - \lambda_i)^2}. \tag{23}$$

3.3. Other relevant results. We can use the same approach to derive the following results, whose proof is omitted.

COROLLARY 3.4. *It holds that*

$$\sin^2\angle(\mathcal{E}^d, \mathbf{y}_k) \sim \left\{ \frac{\sin^2\angle(\mathcal{E}^d, \mathbf{f})}{\cos^2\angle(\mathbf{e}_k, \mathbf{f})} \prod_{\substack{j=1 \\ j=k}}^{d} \frac{(\lambda_j - \sigma)^2}{(\lambda_k - \lambda_j)^2} \right\} \cdot \left(\frac{\varepsilon}{\lambda_k - \sigma} \right)^{2(m-d)}, \tag{24}$$

$$\gamma_k = \|\mathbf{A}\mathbf{y}_k - \theta_k \mathbf{y}_k\|^2$$

$$(25) \qquad \sim (\lambda_k - \sigma)^2 \left\{ \frac{\sin^2 \angle(\mathcal{E}^d, \mathbf{f})}{\cos^2 \angle(\mathbf{e}_k, \mathbf{f})} \prod_{\substack{j=1 \\ j \neq k}}^{d} \frac{(\lambda_j - \sigma)^2}{(\lambda_k - \lambda_j)^2} \right\} \cdot \left(\frac{\varepsilon}{\lambda_k - \sigma} \right)^{2(m-d)},$$

$$\prod_{k=d+1}^{m} \beta_k^2 \sim \sin^2 \angle(\mathcal{E}^d, \mathbf{f}) \cdot \prod_{k=1}^{d} (\lambda_k - \sigma)^2 \cdot \sum_{k=1}^{d} \left(\frac{(\lambda_k - \sigma)^{d-1}}{\prod_{\substack{j=1 \\ j \neq k}}^{d} (\lambda_k - \lambda_j)} \right)^2 \cdot \prod_{k=1}^{d} \beta_k^{-2} \cdot \varepsilon^{2(m-d)},$$

where $d+1 \leq m \leq M$, $k = 1, 2, \ldots, d$ $\mathbf{P}_{\mathcal{K}^m}^{\perp}$ *is a projection matrix that projects a vector onto the orthogonal subspace of* $\mathcal{K}^m(\mathbf{A}, \mathbf{f})$. In the exact repeated eigenvalue case, i.e., $\varepsilon = 0$, Corollary 3.4 yields $\beta_{d+1} = 0$, which is consistent with the results in §2. It is also interesting to note that the error of the RR approximation decays exponentially at the rate ε, while β_m seems to stay at the $O(\varepsilon)$ level when $m \geq d+1$. The possible reason is that $\mathbf{q}_k$ is normalized by β_k at each step.

3.4. Significance of Theorem 3.2. By Theorem 3.2, we can see that all the quantities associated with the estimation error of the eigenvalues and eigenvectors in (19), (20), (24), and (25) decay *uniformly* and *exponentially* after d Lanczos steps at the rate of $\varepsilon/(\lambda_k - \sigma)$. Note that here ε is not the smallest eigenvalue of $\mathbf{A}$ but the maximum difference between the smaller eigenvalues of $\mathbf{A}$, which is usually small for the structured matrices defined in (11). For the structured sample covariance matrix, $\varepsilon = O(1/\sqrt{N})$, where N is the number of data samples. After the $(d+2)$th Lanczos step, the errors between the RR vectors and the corresponding eigenvectors of the sample covariance matrix are $O(1/N)$ or $O(1/\sqrt{N})$. Since in this case, the principal eigenvectors are $O(1/\sqrt{N})$ approximation of the *true* basis vectors of the signal subspace, the RR vectors achieve the same first order approximation as the principal eigenvectors. In other words, $\operatorname{span}\{\mathbf{e}_1, \ldots, \mathbf{e}_d\}$ and $\operatorname{span}\{\mathbf{y}_1, \ldots, \mathbf{y}_d\}$ are *asymptotically equivalent* estimates of the signal subspace (see [18], [17] for more details).

3.5. Selection of the initial vector f. From (19)–(20) in Theorem 3.2, we see that the initial vector $\mathbf{f}$ plays an important role to achieve fast convergence. First, if $\mathbf{f}$ is orthogonal to some eigenvector, then this eigenvector will not appear in the Krylov subspace $\mathcal{K}^m(\mathbf{A}, \mathbf{f})$. However, this is not the generic case. If $\mathbf{f} \in \mathcal{E}^d$, then $\sin \angle(\mathbf{f}, \mathcal{E}^d) = 0$. In this case, after d Lanczos steps, all the errors will be zero, according to (19), (20), (24), and (25). If $\mathbf{f}$ is chosen to be very close to the principal subspace, i.e., $\sin \angle(\mathbf{f}, \mathcal{E}^d)$ is very small, the initial error will be small as well. In this case, the total error can be made small enough in a very small number of Lanczos steps.

According to (19), (20), (24), and (25), the accuracy of the kth eigenvalue and eigenvector is also related to $\cos^2 \angle(\mathbf{e}_k, \mathbf{f})$. If $\mathbf{f}$ is chosen to be close to $\mathbf{e}_k$, then $\cos^2 \angle(\mathbf{e}_k, \mathbf{f})$ is large and the error associated with the kth eigenpair estimation tends to be small. Note that $\sum_{i=1}^{d} \cos^2 \angle(\mathbf{e}_k, \mathbf{f}) = 1 - \sin^2 \angle(\mathcal{E}^d, \mathbf{f}) \leq 1$ and $\cos \angle(\mathbf{e}_i, \mathbf{f})$, $i \neq k$ can be very small. Then, the error associated with other eigenpairs can be large and require more Lanczos steps.

If we have any rough a priori information on the principal eigenpairs, we can take advantage of this information to choose an appropriate $\mathbf{f}$ to achieve a well-balanced convergence in terms of the estimation of the whole principal eigenspace in the smallest number of steps [19]. In many applications, we do have such a priori information. In

target tracking problems, the sample covariance matrix at the current time sector is close to the one at the previous time sector, whose principal eigenpairs have been estimated. These eigenpairs can be used as the a priori information to find a good initial vector $\mathbf{f}$.

3.6. Estimation of the principal eigenspace dimension. Detection schemes for estimating the dimension of the principal eigenspace are problem dependent and are very difficult to unify into a common framework. In fact, several papers [1], [3], [13], [16] appeared in various special problems, e.g., direction finding, harmonic retrieval, autoregressive moving averaging (ARMA) estimation, etc. Most of the techniques used in these papers (such as the so-called minimum description length (MDL) and an information theoretic criterion (AIC) schemes [16]) require all the M eigenvalues, which are not available at any intermediate Lanczos step. Therefore, *new* detection schemes based on the accessible information at certain Lanczos steps need to be developed. In the following, we just give a general discussion on the kind of information that can be exploited to design a proper detection scheme.

In the exact repeated eigenvalue case, $\beta_m \doteq 0$ is the criterion for estimating d. By Corollary 3.4, β_{d+1} falls below the $O(\varepsilon)$ level at the $(d+1)$th Lanczos step. Therefore, the fundamental difference between the value of β_m for $m < d+1$ and $m = d+1$ can be used as one criterion to estimate the dimension of the principal eigenspace. One approach is to compare β_m with a predetermined threshold δ_β; once $\beta_m < \delta_\beta$, $d = m-1$. In this case, the RR approximation is carried out only at the last Lanczos step, but not at the intermediate steps.

A more reliable scheme relies on the RR values at each Lanczos step. Since the smallest $M-d$ eigenvalues of $\mathbf{A}$, viz., $\lambda_{d+1}, \ldots, \lambda_M$, are close to each other, their quadratic mean and arithmetic mean should be also approximately the same. Hence the ratio of these two means should be close to one or

$$\varphi_d = \log \left(\frac{\sqrt{\frac{1}{M-d} \sum_{k=d+1}^{M} \lambda_k^2}}{\frac{1}{M-d} \sum_{k=d+1}^{M} \lambda_k} \right) \approx 0. \tag{26}$$

Clearly, if $\hat{d} < d$ or the hypothesis is wrong, $\varphi_{\hat{d}}$ is significantly larger than φ_d. Based on this fact, we can design a detection scheme by checking $\varphi_{\hat{d}} \lessgtr \gamma_{\hat{d}}$ where $\gamma_{\hat{d}}$ is a properly predetermined threshold. Now the problem is how to compute $\varphi_{\hat{d}}$ without knowing these $M - \hat{d}$ smallest eigenvalues. The trick to circumvent this difficulty is to properly use the available information, i.e., RR values, $\mathrm{Tr}(\mathbf{A})$ (Trace of $\mathbf{A}$), $\|\mathbf{A}\|_F$ (F-norm of $\mathbf{A}$). It is well known that

$$\mathrm{Tr}(\mathbf{A}) = \sum_{k=1}^{M} \lambda_k, \qquad \|\mathbf{A}\|_F^2 = \sum_{k=1}^{M} \lambda_k^2. \tag{27}$$

Since by Theorem 3.2, the d principal eigenvalues can be well approximated (to order $O(\varepsilon^{m-d})$) by their corresponding RR values from the mth Lanczos step, if $\hat{d} \leq d$,

$m \geq d+1$,

$$\varphi_{\hat{d}} \approx \log \left(\frac{\sqrt{\frac{1}{M-\hat{d}} \left(\|\mathbf{A}\|^2 - \sum_{k=1}^{\hat{d}} \theta_k^2 \right)}}{\frac{1}{M-\hat{d}} \left(\mathrm{Tr}(\mathbf{A}) - \sum_{k=1}^{\hat{d}} \theta_k \right)} \right). \tag{28}$$

It can be shown that $\varphi_{\hat{d}} = O(1)$, for $\hat{d} < d$ and $\varphi_{\hat{d}} = O(\varepsilon^2)$, when $\hat{d} = d$. To avoid any possible numerical problems, it is recommended to use only the well-converged RR values in (28) instead of all the m RR values. We can summarize the new detection scheme for the mth Lanczos step below.

NEW DETECTION SCHEME

1. Set $\hat{d} = 1$.
2. Set null hypothesis $\mathrm{H}_0 : d = \hat{d}$.
3. Evaluate $\varphi_{\hat{d}}$ using the converged RR values.
4. If $\varphi_{\hat{d}} \leq \gamma_{\hat{d}}$ accept H_0 and stop.
5. Otherwise, reject H_0; if $\hat{d} < l$, $\hat{d} := \hat{d}+1$, return to 2, where l is the number of the converged RR values. Otherwise, $m := m+1$, continue the mth Lanczos step.

As we know, the computation of $\mathrm{Tr}(\mathbf{A})$ and $\|\mathbf{A}\|_F^2$ requires about M and $M^2/2$ flops. According to [12], it takes approximately $9m^2$ flops to find the RR values (not the RR vectors) of an $m \times m$ tridiagonal matrix. Therefore, the computational complexity involved in the above detection scheme is marginal.

The last issue is how to choose the threshold $\gamma_{\hat{d}}$. It all depends on the a priori information on $\varphi_{\hat{d}}$ and the answer to this question varies from problem to problem. For example, if $\mathbf{A}$ is a sample covariance matrix as in many signal processing problems, we can show that $N(M-d)\varphi_d$ is asymptotically Chi-square ($\mathcal{X}^2$) distributed with $\frac{1}{2}(M-d)(M-d+1)-1$ degrees of freedom, where N is the length of data samples. Therefore, $\gamma_{\hat{d}}$ can be chosen based on the tail area of the $\mathcal{X}^2$ distribution function. In this case, we can also show that the above detection scheme is *strongly consistent* [17], [19].

3.7. A basic algorithm. According to (19), (20), and (25), the errors regarding the RR values and vectors, i.e., $\theta_k - \lambda_k$ and $\sin^2 \angle(\mathbf{y}_k, \mathbf{e}_k)$, converge at the same rate. Since it only takes about $9m^2$ flops to find the RR values at the mth Lanczos step versus $O(m^3)$ flops for computing the RR vectors, one can save a reasonable amount of computation by using only the RR values to check convergence at intermediate Lanczos steps. The RR vectors will be computed at the last Lanczos step after convergence is achieved.

Now, we can present a basic algorithm.

THE BASIC ALGORITHM

1. Start with a nondegenerate initial vector $\mathbf{f}$.
2. Carry out the mth Lanczos step, i.e., Steps 1–6 of the Lanczos algorithm.
3. Compute the RR values and vectors $(\theta_i^{(m)}, \mathbf{y}_i^{(m)}, \ i = 1, 2, \ldots, m)$.
4. Check the convergence of the RR values: $|\theta_k^{(m)} - \theta_k^{(m-1)}| \lesssim \delta_\theta$. If yes, store them in the set of the converged RR values.

5. Perform an appropriate detection scheme based on the converged RR values. If d is determined, then go to Step 7. Otherwise, return to Step 2 and execute the $(m+1)$th Lanczos step.
6. Compute the RR vectors and stop.

In the above algorithm, δ_θ is the threshold for θ. We present this basic algorithm only to show the basic ideas of the proposed approach. Interested readers can modify it to their problems. Obviously, if d is known, Step 6 can be skipped.

3.8. Numerical issues. According to Paige [10]–[12], when β_m and $\gamma_k^{(m)} = \|\mathbf{A}\mathbf{y}_k^{(m)} - \theta_k^{(m)}\mathbf{y}_k^{(m)}\|$ are too small at the mth Lanczos step, numerical problems may arise because the $\mathbf{q}_m$ may not be orthogonal to $\mathbf{q}_j$, $j \leq m-1$. By Corollary 3.4, for $1 \leq m \leq d$, β_m and $\gamma_k^{(m)}$ are not necessarily small until $m \geq d+1$, in which case, $\beta_{d+1}\cdots\beta_m \sim O(\varepsilon^{m-d})$ and $\gamma_k^{(m)} \sim O(\varepsilon^{m-d})$. If the initial vector does not lie too close to one specific eigenvector, the errors in all the *principal* eigenvalue and eigenvector estimates are $O(\varepsilon^{2(m-d)})$ and $O(\varepsilon^{m-d})$, respectively, at the mth Lanczos step. Therefore, once β_m and $\gamma_k^{(m)}$ become really small, the estimation of these principal eigenpairs becomes accurate enough and the algorithm should be terminated. Nevertheless, if $\mathbf{f}$ is selected improperly to be very close to one eigenvector, e.g., $\cos\angle(\mathbf{f}, \mathbf{e}_i)$ is close to one, but $\cos\angle(\mathbf{f}, \mathbf{e}_k)$ close to zero, for $k \neq i$, then by Theorem 3.2, $\gamma_i^{(m)}$ is very small but $\gamma_k^{(m)}$, $k \neq i$ is large. As discussed above, if we have some a priori information about the principal eigenvalues and eigenvectors, we can find a good initial $\mathbf{f}$ so that the convergence is well balanced and the algorithm is numerically better. At any rate, even if β_m or $\gamma_k^{(m)}$ is small but the estimation error is still above the tolerance level for various reasons, we can always alleviate the numerical problems by adopting selective reorthogonalization [12] or even complete reorthogonalization. Since $d \ll M$, there will not be a significant increase of computation load. In short, the numerical problem is not that serious in the proposed algorithm, because the algorithm usually terminates before β_k becomes very small and $d \ll M$. A large number of computer simulations also verified this point.

3.9. Computational complexity and parallel implementation. To insure the required precision of the results, we may need to carry out a few more Lanczos steps than in the repeated eigenvalue case. Nevertheless, since the error for the kth principal eigenvalues decays exponentially at the rate of $(\varepsilon/(\lambda_k - \sigma))$, there is not any significant increase of computational load compared to the finite-step algorithm in §2. Another small increase of computation arises from the calculation of the RR values for some Lanczos steps and the calculation of the RR vectors at the final step. The total cost for the RR approximations is no more than $O(\log M d + d^3)$ multiplications. Since we only calculate the RR vectors in the final step and $d \ll M$, the total computational load is essentially the same as that in the exact repeated eigenvalue case, i.e., $O(M^2 d)$ flops.

Of course, if the matrix has more structure, e.g., Toeplitz, Hankel, quasi-Toeplitz, or sparse, another order of computation reduction may be achieved. Since the covariance matrix of a stationary process is Toeplitz, Toeplitz matrices may often arise in detection and estimation problems. Due to the fact that the Toeplitz/Hankel and related matrices have a so-called displacement structure [5], the matrix-vector product can be accomplished via a fast convolution that only takes $O(M \log M)$ flops instead of $O(M^2)$. Therefore, only $O(Md \log M)$ flops in total are required for the displacement structured matrices if the proposed algorithm is employed.

Obviously, the most computational intensive operation in our approach is the matrix-vector product ($O(M^2)$ flops), which is very easy to implement in parallel. If we have M or M^2 multipliers or array processors, we can reduce the computational time to $O(Md)$ or $O(d^3)$ accordingly. Moreover, the computation of the RR values and RR vectors can also be done in parallel with the calculation of $\mathbf{q}_m$.

4. Numerical examples. To give some intuitive ideas of how the Lanczos algorithm achieves fast convergence via exploitation of the matrix structure, we applied it to the following two numerical examples. For comparison, we also tried the power method and the subspace iteration method for the same matrices. In the first example, we have a 20×20 matrix with exact repeated eigenvalues. The matrix in the second example is a perturbed version of the first one. The eigenvalues of both matrices are listed below.

Matrix with repeated eigenvalues.

$\{\lambda_i\}$ = {11.2115, 9.2050, 9.0024, 7.8380, $\vdots$ 5.0000, 5.0000, 5.0000, 5.0000, 5.0000, 5.0000, 5.0000, 5.0000, 5.0000, 5.0000, 5.0000, 5.0000, 5.0000, 5.0000, 5.0000, 5.0000}.

Matrix with near-repeated eigenvalues.

$\{\lambda_i\}$ = {11.1178, 9.1882, 9.0093, 7.7430, $\vdots$ 5.4246, 5.4103, 5.3240, 5.2159, 5.1959, 5.1501, 5.1130, 5.0707, 5.0470, 5.0034, 4.9937, 4.9190, 4.8851, 4.8705, 4.8424, 4.7789}.

Obviously, according to the eigenvalue distribution, $d = 4$. To simplify the comparison, let us assume that we know the principal eigenspace dimension and set the convergence threshold to be 10^{-2}. We begin with the matrix with repeated eigenvalues. It took 19, 37, 19, 13 iterations for the power method to converge to the corresponding four principal eigenvectors. Similarly, the subspace iteration method required 14 iterations. Since each iteration of the subspace iteration requires four matrix-vector multiplications, reorthogonalization, and RR approximation, the total cost is more than $14 \times 4 = 56$ equivalent power iterations. Therefore, the total computational load for the power method and subspace iteration methods exceed M^3 flops and these methods may not gain much advantage over a conventional eigendecomposition. Nevertheless, as was shown in §2, the error of the Lanczos algorithm became exactly zero at the fifth or $(d+1)$th Lanczos step.

Now let us consider the perturbed matrix. For the power method, the iteration numbers were similar to those in the previous case, i.e., 21, 23, 21, 14. The subspace iteration method also required 14 iterations. In this case, we notice that the distances among these 16 eigenvalues are clustered together, i.e., $|\lambda_i - \lambda_j| \leq 5.4246 - 4.7789 =$

TABLE 2

0.6457. The Lanczos algorithm was used to exploit this property. The errors $\lambda_k - \theta_k$ and $\sin^2 \angle(\mathbf{y}_k, \mathbf{e}_k)$ estimated according to (19), (20) are listed in Table 1, while the actual estimation errors are in Tables 2 and 3. By Table 1, the error estimates of Theorem 3.2 became below 10^{-4} (threshold) at the ninth step. However, the actual errors were below 10^{-6} at the eighth step. Therefore, only a few more Lanczos steps are required to remedy the perturbation according to the analytic error bound and the actual error illustrated in Tables 1, 2, and 3. In fact, this example should be a difficult case for the Lanczos algorithm since there are two close principal eigenvalues, 9.1882 and 9.0093, whose difference is even much smaller than $\epsilon = 0.6457$. Nevertheless, as shown in these tables, this difficulty could be easily overcome by three more Lanczos steps. Therefore, in most cases, the closely spaced principal eigenvalues do not pose a very serious problem since there are many more near (almost) repeated nonprincipal eigenvalues. Of course, if the principal eigenvalues are reasonably far apart, then more rapid convergence is expected.

In the following, we give more practical examples in array signal processing. Here, a 15-element uniform linear array was used to estimate the direction-of-arrival (DOA) of two uncorrelated sources from 35° and 45°, respectively. In this case, the sample covariance matrix estimated based on 500 data samples should be close to a rank-2 matrix plus shift. Standard eigendecomposition and the Lanczos-based algorithms were used to estimate the principal eigenspace. Since d was unknown, the aforementioned AIC and MDL techniques were used to detect d based on all 15 eigenvalues. Alternatively, the suggested Lanczos-based algorithm plus a new detection scheme was also carried out for comparison. The ESPRIT algorithm [14] was utilized to estimate the DOAs based on the principal eigenspace estimates from both eigendecomposition

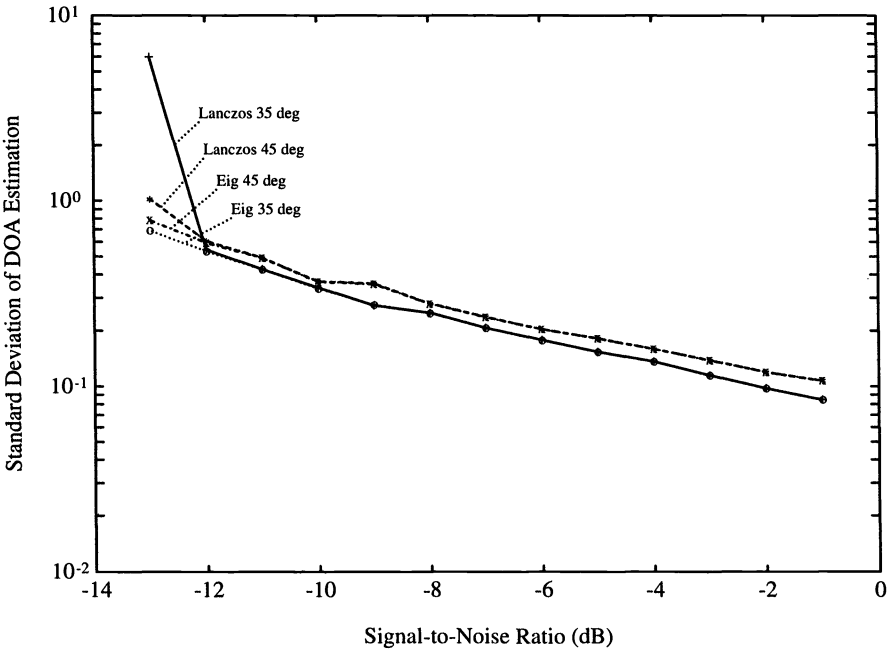

FIG. 1. *Comparison of the* MDL, AIC, *and Lanczos-based detection schemes.*

and Lanczos (with random **f**). The quality of the detection is characterized by the probability of detection based on 500 independent trials for each case, while the accuracy of the signal subspace estimation is measured by the standard deviation of the DOA estimates based on the same number of trials. Here, the signal-to-noise-ratio (SNR) varied from -20 dB to 0 dB, and the results are shown in Figs. 1 and 2. From Fig. 1, it is clear that the AIC scheme is not strongly consistent since it stays at 90% even if the SNR increases. As shown in [16] and [17], MDL and the new scheme are strongly consistent. Hence, their probability of correct detection approaches to one after SNR ≥ -14 dB, as illustrated in Fig. 1. It is interesting to note that the new schemes work a little better in the low SNR case. When SNR ≥ -14 dB, typical eigenvalue distribution of the sample covariance matrix is illustrated below:

{76.00, 65.67 ⋮ 49.91, 47.10, 45.89, 44.50, 42.50, 40.78, 39.85, 38.46, 38.40, 36.68, 34.56, 32.30, 30.10}

Therefore, the gap between the principal and nonprincipal eigenvalues is not very large and the proposed fast method still works reasonably well. For the cases where the correct detection is made, i.e., SNR ≥ -14 dB, the DOA estimates are given in Fig. 2, from which we can tell that there is no significant difference between these two methods except when SNR $= 14$ dB. However, the flop counts were also recorded and the fast approach achieves a factor of 10 computational savings on average, which is quite significant.

5. Concluding remarks. In this paper, we studied the problem of estimating the principal eigenspace or eigenpairs of certain structured matrices that can be expressed as a low-rank matrix plus a shift. Though this problem can be solved by a full eigendecomposition and several other faster alternatives, we observed that the Lanczos algorithm can exploit the inherent matrix structure and is more efficient than

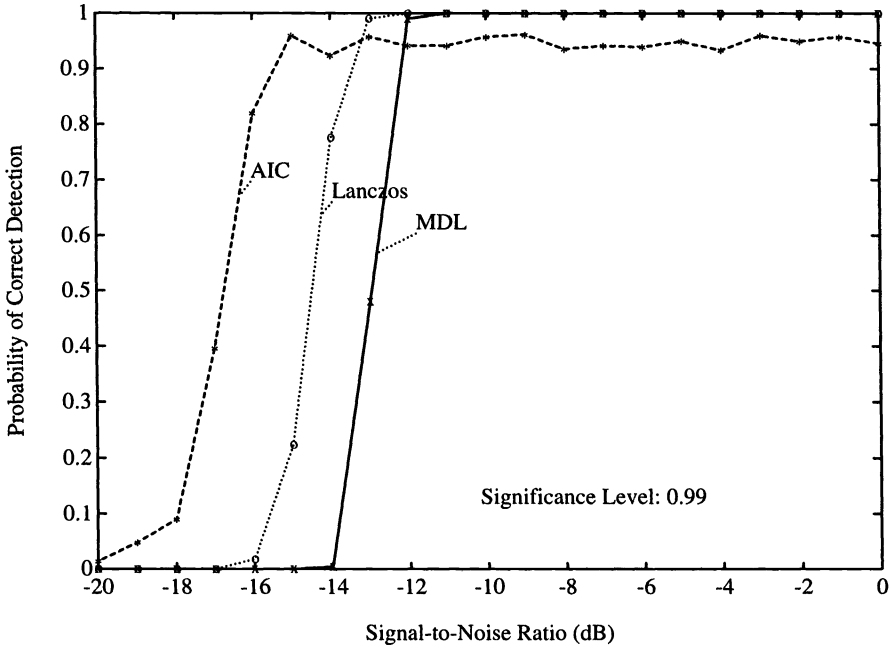

FIG. 2. *Comparison of the* DOA *estimation of eigendecomposition and Lanczos.*

most of the other existing algorithms. We first briefly described a finite-step Lanczos based algorithm to find the principal eigenspace of an exact low-rank-plus-shift matrix. A new analytic error estimate of the RR approximation for the structured matrix was then presented, which is more useful and accurate than the existing error bounds. Such an analysis also showed that the estimation error of the RR approximation decreases exponentially at a small rate as the Lanczos algorithm proceeds. We discussed several important implementation issues such as parallel computation, estimation of the dimension of the principal eigenspace, and exploitation of other matrix structure. Numerical examples were given to demonstrate the superior performance of the Lanczos-based algorithm over its alternatives.

Appendix A. Proof of Theorem 3.2. By definition, $\mathbf{A}\mathbf{y}_k - \theta_k \mathbf{y}_k \perp \mathcal{K}^m(\mathbf{A}, \mathbf{f})$. It is well known that Krylov subspace is invariant of shift, i.e., $\mathcal{K}^m(\mathbf{A}, \mathbf{f}) = \mathcal{K}^m(\mathbf{A} - \sigma\mathbf{I}, \mathbf{f})$ (see, e.g., [12]). Let $\mu_i = \lambda_i - \sigma$ and $\rho_i = \theta_i - \sigma$, where $\sigma = (\lambda_{d+1} + \lambda_M)/2$. Clearly $|\mu_i - \mu_j| = |\lambda_i - \lambda_j| < \epsilon$ and $\mu_i < \epsilon$ for $d+1 \le i, j \le M$. Also, $\mathbf{A}\mathbf{y}_k - \theta_k \mathbf{y}_k = (\mathbf{A} - \sigma\mathbf{I})\mathbf{y}_k - \rho_k \mathbf{y}_k$. Hence, it is equivalent to study the problem with $\mathbf{A}_\mathbf{s} = \mathbf{A} - \sigma\mathbf{I}$ instead of $\mathbf{A}$ (except for a shift in the eigenvalues). Starting again from the definition of the RR pair, viz., $\mathbf{A}_\mathbf{s}\mathbf{y}_k - \theta_k \mathbf{y}_k \perp \mathcal{K}^m(\mathbf{A}_\mathbf{s}, \mathbf{f})$, we obtain

$$(\mathbf{A}_\mathbf{s}^j \mathbf{f})^H (\mathbf{A}_\mathbf{s}\mathbf{y}_k - \rho_k \mathbf{y}_k) = 0, \qquad j = 0, 1, \ldots, m-1. \tag{A.1}$$

By a corollary in [12, p. 142], $\mathbf{y}_k = \pi_k(\mathbf{A}_\mathbf{s})\mathbf{f} / \|\pi_k(\mathbf{A}_\mathbf{s})\mathbf{f}\|$. Substituting into (A.1) and recalling that $\pi(\mathbf{A}_\mathbf{s}) = \pi_k(\mathbf{A}_\mathbf{s})(\mathbf{A}_\mathbf{s} - \rho_k \mathbf{I})$, gives

$$\mathbf{f}^H \mathbf{A}_\mathbf{s}^j \pi(\mathbf{A}_\mathbf{s})\mathbf{f} = \mathbf{f}^H \mathbf{A}_\mathbf{s}^j (\mathbf{A}_\mathbf{s} - \rho_k \mathbf{I}) \pi_k(\mathbf{A}_\mathbf{s})\mathbf{f} = 0. \tag{A.2}$$

Obviously, the eigendecomposition of $\mathbf{A}_\mathbf{s}$ is $\mathbf{E}\mathbf{\Lambda}_\mathbf{s}\mathbf{E}^H$, where $\mathbf{E} = [\mathbf{e}_1, \mathbf{e}_2, \ldots, \mathbf{e}_M]$ and $\mathbf{\Lambda}_\mathbf{s} = \operatorname{diag}(\mu_1, \mu_2, \ldots, \mu_M)$. Let us define f_k to be $|\mathbf{e}_k^H \mathbf{f}| = \|\mathbf{f}\| \cos \angle(\mathbf{e}_i, \mathbf{f})$. Then (A.2)

becomes

$$(\mathbf{E}^H\mathbf{f})^H\mathbf{\Lambda}_\mathbf{s}^j\pi(\mathbf{\Lambda}_\mathbf{s})\mathbf{E}^H\mathbf{f}=0$$

or

$$\sum_{k=1}^{M}\mu_k^j f_k^2\pi(\mu_k)=0. \tag{A.3}$$

Write out all d equations for $m-d\le j\le m-1$ and move the terms containing $\pi(\mu_i)$, $i\ge d+1$ to the right-hand side. Then

(A.4)
$$\begin{aligned}\mu_1^{m-d}f_1^2\pi(\mu_1)+\cdots+\mu_d^{m-d}f_d^2\pi(\mu_d)&=-\mu_{d+1}^{m-d}f_{d+1}^2\pi(\mu_{d+1})-\cdots-\mu_M f_M^2\pi(\mu_M),\\ \mu_1^{m-1}f_1^2\pi(\mu_1)+\cdots+\mu_d^{m-1}f_d^2\pi(\mu_d)&=-\mu_{d+1}^{m-1}f_{d+1}^2\pi(\mu_{d+1})-\cdots-\mu_M^{m-1}f_M^2\pi(\mu_M).\end{aligned}$$

Let $x_k=f_k\mu_k^{m-d}\pi(\mu_k)$, $k=1,2,\ldots,d$. Then (A.4) becomes a set of d linear equations. Now let us examine the quantities on the right-hand side of (A.4). For $k\ge d+1$, $\pi(\mu_k)=\prod_{i=1}^{d}(\mu_k-\rho_i)\prod_{i=d+1}^{m}(\mu_k-\rho_i)$. We know that the RR values ρ_i, $1\le i\le m$ are the eigenvalues of $\mathbf{Q}^H\mathbf{A}_\mathbf{s}\mathbf{Q}$. Then, according to the Cauchy interlace theorem, we have $\mu_{M-m+i}\le\rho_i\le\mu_i$. For $i\ge d+1$, $M-m+1>d+1$. Therefore $|\rho_i-\mu_k|<\max(|\mu_i-\mu_k|,|\mu_{i+M-m}-\mu_k|)<\epsilon$, $k\ge m+1\ge d+1$ by assumption. So $\pi(\mu_k)\sim o(\epsilon^{m-d})$. Also note that $|\mu_k|<\epsilon$. For $k>d$, $\mu_k^j\pi(\mu_k)\sim o(\epsilon^{m-d+j})$. Clearly, the dominant term on the right-hand side is the one with the lowest power of ϵ, i.e., $\epsilon^{2(m-d)}$, when $j=m-d$. Let us neglect the higher power terms of ϵ and write (A.4) in matrix form

$$\begin{bmatrix}1&1&\cdots&1\\ \mu_1&\mu_2&\cdots&\mu_d\\ \vdots&\vdots&\ddots&\vdots\\ \mu_1^{d-1}&\mu_2^{d-1}&\cdots&\mu_d^{d-1}\end{bmatrix}\begin{bmatrix}f_1^2\mu_1^{m-d}\pi(\mu_1)\\ f_2^2\mu_2^{m-d}\pi(\mu_2)\\ \vdots\\ f_d^2\mu_d^{m-d}\pi(\mu_d)\end{bmatrix}=\begin{bmatrix}-\sum_{i=d+1}^{M}\mu_i^{m-d}f_i^2\pi(\mu_i)\\ 0\\ \vdots\\ 0\end{bmatrix}.$$

The matrix on the left-hand side of the above equation is a Vandermonde matrix. Hence, there is a closed form solution for this set of linear equations, namely,

$$f_k^2\mu_k^{m-d}\pi(\mu_k)=-\prod_{\substack{i=1\\ i=k}}^{d}\left(\frac{\mu_i}{\mu_i-\mu_k}\right)\sum_{i=d+1}^{M}\mu_i^{m-d}f_i^2\pi(\mu_i), \tag{A.5}$$

where $k=1,2,\ldots,d$. Let us start with $k=1$. In this case, by the Cauchy interlace theorem, $\rho_i\le\mu_i$ for $i=1,2,\ldots,m$. Since $\mu_1>\mu_i$, $\mu_1-\rho_i>\mu_1-\mu_i$, for $i\ge 2$. Hence

$$\mu_1-\rho_1\le(-1)^d\frac{1}{\mu_1^{m-d}}\prod_{i=2}^{d}\frac{\mu_i}{(\mu_i-\mu_1)^2}\prod_{i=d+1}^{m}\frac{1}{\mu_1-\rho_i}\sum_{i=d+1}^{M}\mu_i^{m-d}f_i^2\pi(\mu_i). \tag{A.6}$$

Since $|\mu_i-\mu_j|<\epsilon$ for $d+1\le i,j\le M$,

$$\left|-\sum_{i=d+1}^{M}\mu_i^{m-d}f_i^2\pi(\mu_i)\right|\le\sum_{i=d+1}^{M}f_i^2\prod_{i=1}^{d}\rho_i\epsilon^{2(m-d)}\le\sum_{i=d+1}^{M}f_i^2\prod_{i=1}^{d}\mu_i\epsilon^{2(m-d)}. \tag{A.7}$$

Also, we know $\mu_1 - \rho_i = \mu_1 + O(\epsilon)$, for $d+1 \le i \le m$. Thus,

$$\text{(A.8)} \qquad \prod_{i=d+1}^{m} \frac{1}{\mu_1 - \rho_i} \left| \sum_{i=d+1}^{M} \mu_i^{m-d} f_i^2 \pi(\mu_i) \right| \sim \mu_1^{-(m-d)} \sum_{i=d+1}^{M} f_i^2 \prod_{i=1}^{d} \mu_i \epsilon^{2(m-d)}.$$

Hence,

$$\text{(A.9)} \qquad \frac{\mu_1 - \rho_1}{\mu_1} \sim \frac{\sum_{i=d+1}^{M} f_i^2}{f_1^2} \prod_{i=2}^{d} \frac{\mu_i^2}{(\mu_1 - \mu_i)^2} \left(\frac{\epsilon}{\mu_1} \right)^{2(m-d)}.$$

Let us try $k = 2$. Using the Cauchy interlace theorem again, we can still replace ρ_i by μ_i for $i > 2$. Hence,

$$\text{(A.10)} \qquad |(\mu_2 - \rho_1)(\mu_2 - \rho_2)| \sim \mu_2(\mu_2 - \mu_1) \frac{\sum_{i=d+1}^{M} f_i^2}{f_2^2} \prod_{\substack{i=1 \\ i=2}}^{m} \frac{\mu_i^2}{(\mu_2 - \mu_i)^2} \left(\frac{\epsilon}{\mu_2} \right)^{2(m-d)}.$$

From (A.9), $\mu_1 - \rho_1 = O(\epsilon/\mu_1)$ for $m \ge d+1$. Therefore, $\mu_2 - \rho_1 = (\mu_2 - \mu_1) + (\mu_1 - \rho_1) = (\mu_2 - \mu_1) + O(\epsilon/\mu_1)$ and we can replace $\mu_2 - \rho_1$ by $\mu_2 - \mu_1$ and maintain the same approximation order $((\epsilon/\mu_2)^{2(m-d)})$.

$$\text{(A.11)} \qquad \frac{\mu_2 - \rho_2}{\mu_2} \sim \frac{\sum_{i=d+1}^{M} f_i^2}{f_2^2} \prod_{\substack{i=1 \\ i=2}}^{d} \frac{\mu_i^2}{(\mu_2 - \mu_i)^2} \left(\frac{\epsilon}{\mu_2} \right)^{2(m-d)}.$$

Similarly, trying $k = 1, 2, \ldots, d$, we will be able to obtain

$$\text{(A.12)} \qquad \frac{\mu_k - \rho_k}{\mu_k} \sim \frac{\sum_{i=d+1}^{M} f_i^2}{f_k^2} \prod_{\substack{i=1 \\ i=k}}^{d} \frac{\mu_i^2}{(\mu_k - \mu_i)^2} \left(\frac{\epsilon}{\mu_k} \right)^{2(m-d)}.$$

Since $\mu_k = \lambda_k - \sigma$, $\rho_k = \theta_k - \sigma$, $f_k^2 = \|\mathbf{f}\|^2 \cos^2 \angle(\mathbf{e}_k, \mathbf{f})$, $\sum_{i=d+1}^{M} f_i^2 = \|\mathbf{f}\|^2 - \sum_{i=1}^{d} f_i^2 = \|\mathbf{f}\|^2(1 - \cos^2 \angle(\mathcal{E}^d, \mathbf{f})) = \|\mathbf{f}\|^2 \sin^2 \angle(\mathcal{E}^d, \mathbf{f})$

$$\text{(A.13)} \qquad \frac{\lambda_k - \theta_k}{\lambda_k - \sigma} \sim \left\{ \frac{\sin^2 \angle(\mathcal{E}^d, \mathbf{f})}{\cos^2 \angle(\mathbf{e}_k, \mathbf{f})} \prod_{\substack{i=1 \\ i=k}}^{d} \frac{(\lambda_i - \sigma)^2}{(\lambda_k - \lambda_i)^2} \right\} \cdot \left(\frac{\epsilon}{\lambda_k - \sigma} \right)^{2(m-d)}.$$

Now let us evaluate the error between the eigenvectors and RR vectors, i.e., the angle between the $\mathbf{e}_k$ and $\mathbf{y}_k$, $k = 1, 2, \ldots, d$

$$\text{(A.14)} \qquad \cos^2 \angle(\mathbf{e}_k, \mathbf{y}_k) = |\mathbf{e}_k^H \mathbf{y}_k|^2 = \frac{|\mathbf{e}_k^H \pi_k(\mathbf{A_s})\mathbf{f}|^2}{\|\pi_k(\mathbf{A_s})\mathbf{f}\|^2}.$$

Since $\mathbf{e}_k^H \mathbf{A_s} = \mu_k \mathbf{e}_k^H$, it is easy to see that

$$\|\mathbf{e}_k^H \pi_k(\mathbf{A_s})\mathbf{f}\|^2 = \|\mathbf{e}_k^H \pi_k(\mu_k)\mathbf{f}\|^2 = \pi_k(\mu_k)^2 f_k^2.$$

Write $\mathbf{A_s}$ in terms of its eigenvalues and eigenvectors, i.e., $\mathbf{A_s} = \mathbf{E}\Lambda_\mathbf{s}\mathbf{E}^H$. Then, $\pi_k(\mathbf{A_s})\mathbf{f} = \mathbf{E}\pi_k(\Lambda_\mathbf{s})\mathbf{E}^H\mathbf{f}$. Thus,

$$\|\pi_k(\mathbf{A_s})\mathbf{f}\|^2 = \sum_{i=1}^{M} \pi_k(\mu_i)^2 f_i^2,$$

$$\text{(A.15)}\quad \sin^2{}_-(\mathbf{e}_k, \mathbf{y}_k) = 1 - \cos^2{}_-(\mathbf{e}_k, \mathbf{y}_k) = 1 - \frac{\pi_k^2(\mu_k) f_k^2}{\sum_{i=1}^{M} \pi_k^2(\mu_i) f_i^2} = \frac{\sum_{\substack{i=1 \\ i=k}}^{M} \pi_k^2(\mu_i) f_i^2}{\sum_{i=1}^{M} \pi_k^2(\mu_i) f_i^2}.$$

Let us examine $\pi_k^2(\lambda_i)$ in three cases: (i) $i \le d$, $i \ne k$; (ii) $i = k$; (iii) $i \ge d+1$. Starting with case (i), by (A.5), we have

(A.16)

$$\pi_k^2(\mu_i) f_i^2 = \frac{\pi^2(\mu_i)}{(\mu_i - \rho_k)^2} f_i^2 = \prod_{\substack{j=1 \\ j=i}}^{d} \frac{\mu_j^2}{(\mu_j - \mu_i)^2} \cdot \left(\sum_{j=d+1}^{M} f_j^2 \pi(\mu_j) \frac{\mu_j^{m-d}}{\mu_i^{m-d}} \right)^2 f_i^{-2} (\mu_i - \rho_k)^{-2}$$

$$\sim \frac{\left(\sum_{j=d+1}^{M} f_j^2 \right)^2 \mu_i^{2(m-d)}}{f_i^2 (\mu_k - \mu_i)^2} \prod_{\substack{j=1 \\ j=i}}^{d} \frac{\mu_j^4}{(\mu_j - \mu_i)^2} \cdot \left(\frac{\epsilon}{\mu_i} \right)^{4(m-d)}.$$

In case (ii), i.e., $i = k$.

$$\text{(A.17)}\qquad \pi_k^2(\mu_k) f_k^2 = \prod_{\substack{j=1 \\ j=k}}^{m} (\mu_k - \rho_j)^2 f_k^2 \sim \mu_k^{2(m-d)} f_k^2 \prod_{\substack{j=1 \\ j=k}}^{d} (\mu_k - \mu_j)^2.$$

In case (iii), viz., $i \ge d+1$, since $\mu_i = O(\epsilon)$ and $\rho_j = \mu_j + O(\epsilon)$, for $1 \le j \le d$, thus

$$\pi_k^2(\mu_i) f_i^2 = \prod_{\substack{j=1 \\ j=k}}^{m} (\mu_i - \rho_j)^2 f_i^2 = f_i^2 \prod_{\substack{j=1 \\ j=k}}^{d} (\mu_i - \rho_j)^2 \prod_{j=d+1}^{m} (\mu_i - \rho_j)^2$$

(A.18)

$$\sim f_i^2 \mu_k^{2(m-d)} \left(\prod_{\substack{j=1 \\ j=k}}^{d} \mu_j^2 \right) \cdot \left(\frac{\epsilon}{\mu_k} \right)^{2(m-d)}.$$

Hence, the term in case (ii) is the dominant term of the sum $\sum_{i=1}^{M} \pi_k^2(\mu_i) f_i^2$, i.e.,

$$\text{(A.19)}\qquad \sum_{i=1}^{M} \pi_k^2(\mu_i) f_i^2 \sim \mu_k^{2(m-d)} f_k^2 \prod_{\substack{j=1 \\ j=k}}^{d} (\mu_k - \mu_j)^2.$$

Nevertheless, since the numerator of (A.15) does not have this term (A.17), its smallest power of ϵ is then $2(m-d)$ corresponding to case (iii). Hence,

$$\sum_{\substack{i=1\\ i=k}}^{M} \pi_k^2(\mu_i) f_i^2 \sim \sum_{i=d+1}^{M} f_i^2 \left(\prod_{\substack{j=1\\ j=k}}^{d} \mu_j^2 \right) \mu_k^{2(m-d)} \cdot \left(\frac{\epsilon}{\mu_k} \right)^{2(m-d)}. \tag{A.20}$$

Therefore, by (A.15), we obtain

$$\sin^2\_(\mathbf{e}_k, \mathbf{y}_k) \sim \frac{\sum_{i=d+1}^{M} f_i^2}{f_k^2} \prod_{\substack{j=1\\ j=k}}^{d} \frac{\mu_j^2}{(\mu_k - \mu_j)^2} \cdot \left(\frac{\epsilon}{\mu_k} \right)^{2(m-d)}. \tag{A.21}$$

Since $\sum_{i=d+1}^{M} f_i^2 = \|\mathbf{f}\|^2 \sin^2\_(\mathcal{E}^d, \mathbf{f})$ and $f_k^2 = \|\mathbf{f}\|^2 \cos^2\_(\mathbf{e}_k, \mathbf{f})$,

$$\sin^2\_(\mathbf{e}_k, \mathbf{y}_k) \sim \left\{ \frac{\sin^2\_(\mathcal{E}^d, \mathbf{f})}{\cos^2\_(\mathbf{e}_k, \mathbf{f})} \prod_{\substack{j=1\\ j=k}}^{d} \frac{(\lambda_j - \sigma)^2}{(\lambda_k - \lambda_j)^2} \right\} \cdot \left(\frac{\epsilon}{\lambda_k - \sigma} \right)^{2(m-d)}. \tag{A.22}$$

□

Appendix B. Another proof of Theorem 3.2. For $m \geq d+1$, let us create the $(m-1)$th order polynomials $p_k(x)$, $1 \leq k \leq d$:

$$p_k(x) = \prod_{j=1}^{k-1} (x - \theta_j) \prod_{j=k+1}^{d} (x - \lambda_j) \cdot (x - \sigma)^{m-d}. \tag{B.23}$$

It is clear that $p_k(\mathbf{A})\mathbf{f} \in \mathcal{K}^m(\mathbf{A}, \mathbf{f})$. Since $\{\theta_j\}_{j=1}^{k-1}$ are roots of $p_k(x)$, then as shown in [12], $\mathbf{t}_k = p_k(\mathbf{A})\mathbf{f} \perp \mathbf{y}_1, \ldots, \mathbf{y}_{k-1}$. Clearly, $(\theta_i, \mathbf{y}_i)$, $1 \leq i \leq m$ are the eigenpairs corresponding the projection of $\mathbf{A}$ onto $\mathcal{K}^m(\mathbf{A}, \mathbf{f})$. Since $\mathbf{t}_k \in \mathcal{K}^m(\mathbf{A}, \mathbf{f})$ and $\mathbf{t}_k \perp \mathbf{y}_1, \ldots, \mathbf{y}_{k-1}$, it is not difficult to show that the Rayleigh quotient $\rho(\mathbf{A}, \mathbf{t}_k) = \mathbf{t}_k^H \mathbf{A} \mathbf{t}_k / \|\mathbf{t}_k\|^2 < \theta_k$ (see e.g., [12]). Then,

$$\lambda_k - \theta_k < \lambda_k - \rho(\mathbf{A}, \mathbf{t}_k) = \rho(\lambda_k \mathbf{I} - \mathbf{A}, \mathbf{t}_k). \tag{B.24}$$

Let us write $\mathbf{A} = \sum_{i=1}^{M} \lambda_i \mathbf{e}_i \mathbf{e}_i^H$ and define $f_i = |\mathbf{e}_i^H \mathbf{f}| = \cos\_(\mathbf{e}_i, \mathbf{f})$. It is not difficult to show that

$$\|\mathbf{t}_k\|^2 = \sum_{i=1}^{M} p_k^2(\lambda_i) f_i^2, \qquad \mathbf{t}_k^H (\lambda_k \mathbf{I} - \mathbf{A}) \mathbf{t}_k = \sum_{i=1}^{M} p_k^2(\lambda_i)(\lambda_k - \lambda_i) f_i^2, \tag{B.25}$$

and

$$\rho(\lambda_k \mathbf{I} - \mathbf{A}, \mathbf{t}_k) = \frac{\sum_{i=1}^{M} p_k^2(\lambda_i)(\lambda_k - \lambda_i) f_i^2}{\sum_{i=1}^{M} p_k^2(\lambda_i) f_i^2} \leq \frac{\sum_{i=k+1}^{M} p_k^2(\lambda_i)(\lambda_k - \lambda_i) f_i^2}{p_k^2(\lambda_k) f_k^2} \tag{B.26}$$

$$= \frac{\sum_{i=d+1}^{M} p_k^2(\lambda_i)(\lambda_k - \lambda_i) f_i^2}{p_k^2(\lambda_k) f_k^2}. \tag{B.27}$$

The inequality in (B.26) is due to the fact that $\lambda_k - \lambda_i \leq 0$ for $i < k$ and $p_k^2(\lambda_i) f_i^2 \geq 0$. The equality from (B.26) to (B.27) results from the fact that $p_k(\lambda_i) = 0$ for $k+1 \leq i \leq d$, as these λ_i's are the roots of $p_k(x)$ according to (B.23).

Let us start with $k = 1$. Combining (B.24)–(B.27), we obtain

$$\text{(B.28)}\quad \lambda_1 - \theta_1 < \frac{\sum_{i=d+1}^{M} f_i^2 (\lambda_1 - \lambda_i) \cdot (\lambda_i - \lambda_2)^2 \cdots (\lambda_i - \lambda_d)^2 (\lambda_i - \sigma)^{2(m-d)}}{f_1^2 (\lambda_1 - \lambda_2)^2 \cdots (\lambda_1 - \lambda_d)^2 (\lambda_1 - \sigma)^{2(m-d)}}$$

$$\text{(B.29)}\quad < \frac{\sum_{i=d+1}^{M} f_i^2 (\lambda_i - \lambda_1) \cdot (\lambda_i - \lambda_2)^2 \cdots (\lambda_i - \lambda_d)^2}{f_1^2 (\lambda_1 - \lambda_2)^2 \cdots (\lambda_1 - \lambda_d)^2} \cdot \left(\frac{\varepsilon}{\lambda_1 - \sigma} \right)^{2(m-d)}.$$

The inequality in (B.29) holds because $|\lambda_i - \sigma| < \varepsilon$, $d+1 \leq i \leq M$. For the same reason, we can replace the λ_i in (B.29) by σ without affecting the order $\varepsilon^{2(m-d)}$ term. Realizing that $f_i^2 = \cos^2 \angle(\mathbf{e}_i, \mathbf{f})$ and $\sum_{i=d+1}^{M} f_i^2 = \sin^2 \angle(\mathbf{f}, \mathcal{E}^d)$, we can easily obtain (19) for $k = 1$. Let us consider the case: $k = 2$. Then (B.27) yields

(B.30)

$$\lambda_2 - \theta_2 < \frac{\sum_{i=d+1}^{M} f_i^2 (\lambda_i - \theta_1)^2 (\lambda_2 - \lambda_i)(\lambda_i - \lambda_3)^2 \cdots (\lambda_i - \lambda_d)^2}{f_2^2 (\lambda_2 - \theta_1)^2 (\lambda_2 - \lambda_3)^2 \cdots (\lambda_2 - \lambda_d)^2} \cdot \left(\frac{\varepsilon}{\lambda_2 - \sigma} \right)^{2(m-d)}$$

$$< \frac{\sum_{i=d+1}^{M} f_i^2 (\lambda_i - \lambda_1)^2 (\lambda_2 - \lambda_i)(\lambda_i - \lambda_3)^2 \cdots (\lambda_i - \lambda_d)^2}{f_2^2 (\lambda_2 - \theta_1)^2 (\lambda_2 - \lambda_3)^2 \cdots (\lambda_2 - \lambda_d)^2} \cdot \left(\frac{\varepsilon}{\lambda_2 - \sigma} \right)^{2(m-d)}.$$

Since, by (B.29) $\theta_1 = \lambda_1 + O(\varepsilon^{2(m-d)})$, θ_1 in (B.30) can be replaced by λ_1 without affecting the most significant term (i.e., the $\varepsilon^{2(m-d)}$ term) on the right-hand side. (19) can be obtained for $k = 2$. Following the similar procedure, we can show (19) for $k = 2, \ldots, d$. With (19) and the relationship between eigenvalues and eigenvectors, (20) can be shown as in Appendix A. □

Although this simpler proof and the one in Appendix A seem to give the same results, they are significantly different in several respects. Since the simpler one starts with a particular trial polynomials $\{p_k(x)\}$, it is an ad hoc approach and does not indicate how tight the bound is. In other words, we do not know whether $\varepsilon^{2(m-d)}$ is the largest order of the eigenvalue error after the mth Lanczos step, while the other one (in Appendix A) starts with the exact equations on θ_k's and obtain the final error estimates by sequentially removing the higher order error terms and keeping the dominating terms. Knowing that $\theta_i - \sigma = O(\varepsilon)$, it indicates that the best possible order of error in terms of ε is $2(m-d)$ for the principal eigenvalues and $m-d$ for the principal eigenvectors.

There are also some differences between this proof and the proof of the improved bound in [12]. Although the improved bound is a strict bound and Theorem 3.2 is an error estimate, the improved bound is not as tight as the intermediate results of this proof, e.g., (B.29) for $k = 1$ and (B.30) for $k = 2$, which are also strict bounds. The reason is that the improved bound [12] is derived with certain unnecessary enlargement such as

$$\text{(B.31)}\quad \|p_k(\mathbf{A})\mathbf{h}\| < \|(\mathbf{A} - \theta_1 \mathbf{I}) \cdots (\mathbf{A} - \theta_{k-1})\mathbf{I}\| \cdot \|\tilde{p}_k(\mathbf{A})\mathbf{h}\|,$$

where $\tilde{p}_k(x) = p_k(x) / ((x - \theta_1) \cdots (x - \theta_{k-1}))$ and $\mathbf{h}$ is the projection of $\mathbf{f}$ onto the orthogonal subspace of $\mathcal{E}^k = \text{span}\{\mathbf{e}_1, \ldots, \mathbf{e}_k\}$.

Acknowledgments. The authors would like to express their gratitude to Prof. B. N. Parlett of the University of California at Berkeley for his reading of this paper and constructive comments. We also thank the anonymous referees for their useful comments, especially the detailed suggestions on a simpler proof of Theorem 3.2 and a clearer presentation of certain results.

LCP DEGREE THEORY AND ORIENTED MATROIDS*

WALTER D. MORRIS, JR.†

Abstract. It is shown that the degree of a square-oriented matroid $\mathcal{M}$ can be defined in terms of the number of solutions to the oriented matroid complementarity problem defined by a point extension of $\mathcal{M}$, and that this definition is independent of the point extension. If $\mathcal{M}$ is represented by a matrix $[I, -M]$, then this degree is the same as the degree of the LCP mapping defined by M. The average value of the degree is determined. A new characterization of P-matrices in terms of degree theory is given. A negative result concerning Q-matrices defining maps of degree zero is presented.

Key words. linear complementarity problem, degree theory, oriented matroids

AMS subject classification. 90C33

1. Introduction. In [23] and [24], Todd developed a framework for using oriented matroid theory for studying the linear complementarity problem (LCP). One of the main results of that work was the development of an algorithm for oriented matroid programming that both preserved feasibility and avoided cycling. This was a major discovery for oriented matroid theory. A great deal of LCP theory that had been developed to consider more general instances of LCPs than those considered in the papers by Todd was shown in [11] to be derived in a unified way by considering the degree of a mapping, given in [4], defined by the matrix of an LCP. In particular, degree theory can be used in many instances to show that the number of solutions of a certain type to an LCP is the same for all nondegenerate choices of the right-hand side. LCP degree theory has been applied in several papers [8], [9] recently to study the stability of solutions to LCPs. LCP degree theory is also central to the study of the class of Q-matrices (matrices that define LCPs that have solutions for any right-hand side).

We show that one can also incorporate the theory of the degree of an LCP mapping into Todd's oriented matroid LCP framework. The LCP mapping itself has no direct analog in oriented matroid theory, but the calculation of its degree is made by examining the circuits of the oriented matroid represented by the matrix of the LCP. Thus LCP degree theory gives a new integer valued function on the set of oriented matroids, and we investigate some properties of this function. Readers familiar with LCP degree theory know that many results are proved by theorems involving homotopies. The analogous process of changing one oriented matroid into another by changing the orientation of one basis at a time has received much attention, and it is known that in some cases it is not possible. Therefore, we cannot use arguments of this type. However, we show that such analytical tools are unnecessary and derive all our results combinatorially.

The mapping of an LCP is determined by its matrix, and the degree is calculated using the right-hand side. It is proved in [11] that under certain nondegeneracy assumptions, the number calculated is independent of the right-hand side at which

it is calculated. We develop an analogous result for oriented matroids, showing that the degree of a square oriented matroid, calculated with an extension of the oriented matroid, does not depend on the extension chosen. Once this is accomplished, we determine that the average value of the degree of a square oriented matroid on $2n$ elements is 2^{-n}. This is proved using results on the degrees of oriented matroids obtained from each other by reorientations. We will also derive a characterization of P-oriented matroids (generalizations of P-matrices) in terms of their "reorientation vectors."

For matrices, this implies that the average degree of the LCP mapping defined by a matrix chosen "at random" is 2^{-n}, and that a matrix is a P-matrix if and only if the degrees of the mappings defined by it and the matrices obtained by changing the signs of its rows and columns follow a certain pattern.

The Q-matrix problem, finding necessary and sufficient conditions on a matrix M so that an LCP defined by it always has a solution, is one of the main problems of LCP theory. The discovery of Q-matrices representing maps of degree zero, in [12], put limits on the extent to which oriented matroid theory could aid in the investigation of the Q-matrix problem. On the other hand, it is as yet unknown how large the set of such matrices is. We show that the degree zero Q-matrix given by Howe [10] represents a Q-oriented matroid; that is, every oriented matroid complementarity problem defined by an extension of the oriented matroid represented by this matrix has a solution.

2. Definitions. Oriented matroid theory was developed independently by various researchers. The papers of Bland and Las Vergnas [2] and Folkman and Lawrence [5] are two of the earliest papers on the subject. Todd [23] introduced the study of complementarity in oriented matroids. A simplified development of Todd's theory in a more general setting is found in a recent paper by Fukuda and Terlaky [6]. As in [23], we mostly use the notation found in [2]. The oriented matroid axioms that we have found most convenient to use are from [16]. Our definition of lexicographic extensions becomes simpler using these axioms. Apart from these considerations, the definitions and facts from this section follow those in [23] directly.

Let M be in $\mathbf{R}^{n\times n}$ and q in $\mathbf{R}^n$. The *linear complementarity problem* defined by M and q (the LCP(M,q)) is to find vectors y and x in $\mathbf{R}^n$ satisfying $y - Mx = q$, $y^T x = 0$, $y \geq 0, x \geq 0$. Background on the linear complementarity problem, as well as definitions of matrix classes used in this paper, can be found in [3]. The LCP can be seen as the search for a vector in the nullspace of the matrix $[I, -M, -q]$ having a prescribed sign pattern. We can think of such sign patterns as combinatorial objects that can be manipulated according to certain rules. This leads us to oriented matroids.

Let E be a finite set. A *signed set* on E is a pair $X = (X^+, X^-)$ of disjoint subsets of E. The set $\underline{X} = X^+ \cup X^-$ is called the set *underlying* X and $-X = (X^-, X^+)$ is called the *opposite* of X. An *oriented matroid* $\mathcal{M}$ on E is a pair $(E, \mathcal{K})$, where E is a finite set and $\mathcal{K}$ is a collection of signed sets on E satisfying the following:

(K1) $(\emptyset, \emptyset) \in \mathcal{K}$, and $K \in \mathcal{K}$ implies that $-K \in \mathcal{K}$.

(K2) If $K_1, K_2 \in \mathcal{K}$, then $K_3 = (K_1^+ \cup (K_2^+ \setminus K_1^-), K_1^- \cup (K_2^- \setminus K_1^+)) \in \mathcal{K}$.

(K3) If $K_1, K_2, \in \mathcal{K}, e \in (K_1^+ \cap K_2^-) \cup (K_1^- \cap K_2^+)$, there exists $K_3 \in \mathcal{K}$ with $e \notin \underline{K}_3, ((K_1^+ \setminus K_2^-) \cup (K_2^+ \setminus K_1^-)) \subseteq K_3^+, ((K_1^- \setminus K_2^+) \cup (K_2^- \setminus K_1^+)) \subseteq K_3^-, \underline{K}_3 \subseteq \underline{K}_1 \cup \underline{K}_2$.

The signed set K_3 obtained in $(K2)$ is said to be the *composition* of K_1 and K_2, written $K_3 = K_1 \circ K_2$. A signed set K_3 obtained as in $(K3)$ is said to be obtained by *eliminating* e between K_1 and K_2. The nonzero members of $\mathcal{K}$ with minimal underlying sets are called *circuits* of $\mathcal{M}$. We write $\mathcal{K} = \mathcal{K}(\mathcal{M})$. A fundamental

result of [2] is that members of $\mathcal{K}$ can be *conformally decomposed* into circuits of $\mathcal{M}$; that is, for any $K \in \mathcal{K}(\mathcal{M})$ there exist circuits $C_1, C_2, \ldots, C_k$ of $\mathcal{K}(\mathcal{M})$ so that $K^+ = C_1^+ \cup C_2^+ \cup \cdots \cup C_k^+$, $K^- = C_1^- \cup C_2^- \cup \cdots \cup C_k^-$.

An oriented matroid $\mathcal{M}$ on a set $E = \{e_1, e_2, \ldots, e_n\}$ is said to be *represented* by an $m \times n$ matrix A if $\mathcal{K}(\mathcal{M})$ is the collection of signed sets $(\{e_i : x_i > 0\}, \{e_i : x_i < 0\})$ for x satisfying $Ax = 0$.

A maximal subset of E that does not contain the underlying set of any circuit of $\mathcal{M}$ is called a *base* of $\mathcal{M}$. All bases of $\mathcal{M}$ have the same cardinality, called the *rank* of $\mathcal{M}$. Let $B(\mathcal{M})$ be the set of bases of $\mathcal{M}$, and let $\beta(\mathcal{M})$ be the set of ordered bases of $\mathcal{M}$. Las Vergnas showed (see [15]) that there is a map $\varepsilon : \beta(\mathcal{M}) \to \{-1, 1\}$ satisfying the following:

(E1) If β_1, β_2 are two orderings of a base B, then $\varepsilon(\beta_1) = \varepsilon(\beta_2)$ if β_2 can be obtained from β_1 by an even permutation.

(E2) If β_1 is an ordering of B_1, β_2 is an ordering of B_2, and β_1, β_2 agree in all but one position, then $\varepsilon(\beta_1) = \varepsilon(\beta_2)$ if each circuit C of M with $\underline{C} \subseteq B_1 \cup B_2$ has $B_1 \setminus B_2 \subseteq C^+$ and $B_2 \setminus B_1 \subseteq C^-$ or vice versa.

Furthermore, if $\varepsilon_1, \varepsilon_2$ satisfy the above, then $\varepsilon_1 = \pm\varepsilon_2$. A map ε satisfying (E1) and (E2) will be called a consistent assignment of signs to the bases of $\mathcal{M}$. We may drop the word consistent. In the case in which $\mathcal{M}$ of rank m is represented by an $m \times n$ matrix A, the bases of $\mathcal{M}$ correspond to nonsingular $m \times m$ submatrices of A, and one of the assignments of signs to bases of $\mathcal{M}$ assigns to each base the sign of the determinant of the corresponding $m \times m$ submatrix of A.

If B is a base of $\mathcal{M}$ and $f \in E \backslash B$, there is a unique circuit $C = C(B, f)$ with $\underline{C} \subseteq B \cup f$ and $f \in C^+$. This is called the fundamental circuit associated with B and f.

If F, G are disjoint subsets of E, define an oriented matroid $\mathcal{M}\backslash F/G$ on $E\backslash(F \cup G)$ by $\mathcal{K}(\mathcal{M}\backslash F/G) = \{(K^+\backslash G, K^-\backslash G) : K \in \mathcal{K}, \underline{K} \cap F = \emptyset\}$. We say that $\mathcal{M}\backslash F/G$ is obtained from $\mathcal{M}$ by *deleting* F and *contracting* G. We will write $\mathcal{M}\backslash q$ as an abbreviation for $\mathcal{M}\backslash\{q\}/\emptyset$.

A *point extension* of an oriented matroid $\mathcal{M}$ on a set E is an oriented matroid $\hat{\mathcal{M}}$ on $E \cup q$ so that $\hat{\mathcal{M}}\backslash q = \mathcal{M}$. We say then that q extends $\mathcal{M}$ to $\hat{\mathcal{M}}$. All of the point extensions $\hat{\mathcal{M}}$ considered in this paper are of the same rank as $\mathcal{M}$. Of particular importance to us are the *lexicographic extensions*, originally defined in [14]. Let $\mathcal{M}$ be an oriented matroid on a set E, and let $F = (f_1, f_2, \ldots, f_k)$ be a nonempty subset of E that does not contain the set underlying any circuit of $\mathcal{M}$. For every base B of $\mathcal{M}$ and every $i = 1, \ldots, k$ define $\check{C}(B, f_i) = (\emptyset, f_i)$ if $f_i \in B$, $\check{C}(B, f_i) = (C(B, f_i)^+\backslash f_i, C(B, f_i)^-)$ if $f_i \notin B$. Then define $C(B, q)$ to be the signed set $(q, \emptyset) \circ \check{C}(B, f_1) \circ \cdots \circ \check{C}(B, f_k)$. From [23] we get that the set $\mathcal{C} = \{C : C \text{ is a circuit of } \mathcal{M}\} \cup \{C(B, q) : B \text{ is a base of } \mathcal{M}\} \cup \{-C(B, q) : B \text{ is a base of } \mathcal{M}\}$ is the set of circuits of a point extension $\hat{\mathcal{M}}$ of $\mathcal{M}$, in which case we say $q = \text{lex}(f_1, f_2, \ldots, f_k)$ extends $\mathcal{M}$ to $\hat{\mathcal{M}}$. Todd showed that every circuit of $\hat{\mathcal{M}}$ containing q will then have at least $k + 1$ elements in its underlying set.

A *square oriented matroid* $\mathcal{M}$ is an oriented matroid on a set $E = S \cup T$ where $S = \{s_1, s_2, \ldots, s_n\}$, $T = \{t_1, t_2, \ldots, t_n\}$, $S \cap T = \emptyset$ and S is a base of $\mathcal{M}$. Oriented matroids represented by matrices of the form $[I, -M]$, for $M \in \mathbf{R}^{n \times n}$ are square, with the elements $s_1, s_2, \ldots, s_n$ corresponding to the columns of I. A subset A of such a set E is called *complementary* if $|\{s_i, t_i\} \cap A| \leq 1$ for $i = 1, \ldots, n$. If p extends a square oriented matroid $\mathcal{M}$ to $\hat{\mathcal{M}}$, the *oriented matroid complementarity problem* (OMCP) defined by $\hat{\mathcal{M}}$ is to find a circuit C of $\hat{\mathcal{M}}$ so that $C^- = \emptyset$ (C is *positive*), $p \in C^+$, and

$\underline{C}\backslash p$ is complementary.

We will work with three different nondegeneracy assumptions for our square oriented matroids:

(TND) All circuits of $\mathcal{M}$ have $n+1$ elements.

(ND) No circuits of $\mathcal{M}$ are complementary.

(WND) No positive circuits of $\mathcal{M}$ are complementary.

If $\mathcal{M}$ is represented by the $n\times 2n$ matrix $[I,-M]$, then $\mathcal{M}$ satisfies TND (totally nondegenerate) if every $n\times n$ submatrix of $[I,-M]$ is nonsingular, $\mathcal{M}$ satisfies ND (nondegenerate) if there is no nonzero $x\in\mathbf{R}^n$ so that $x_i(Mx)_i=0$ for $i=1,\ldots,n$, or equivalently, all principal minors of M are nonzero. $\mathcal{M}$ satisfies WND (weakly nondegenerate) if there is no nonzero $x\in\mathbf{R}^n$ with $x\geq 0$, $Mx\geq 0$, and $x_i(Mx)_i=0$ for $i=1,\ldots,n$, i.e., M is an R_0-matrix. It should be clear that TND $\Longrightarrow$ ND $\Longrightarrow$ WND.

3. The degree of a square oriented matroid. In this section we show that it is possible to define the degree of a square oriented matroid in terms of the solution set of the OMCP defined by an extension and that this definition is independent of the extension chosen.

DEFINITION 3.1. *Let $\mathcal{M}$ be a square oriented matroid of rank n. Let ε be the assignment of signs to bases of $\mathcal{M}$ that satisfies $\varepsilon(s_1,s_2,\ldots,s_n)=1$. For every complementary base B of $\mathcal{M}$, define the* index *of B,* $\mathrm{ind}(B)$, *to be* $(-1)^{|B\cap T|}\varepsilon(b_1,b_2,\ldots,b_n)$, *where $b_i\in\{s_i,t_i\}$ for $i=1,\ldots,n$.*

DEFINITION 3.2. *Let $\mathcal{M}$ be a square oriented matroid of rank n satisfying* WND. *Let p extend $\mathcal{M}$ to $\hat{\mathcal{M}}$, so that every positive circuit C of $\hat{\mathcal{M}}$ containing p with $\underline{C}\backslash p$ complementary has $n+1$ elements. Then the* degree *of $\mathcal{M}$ is the sum of the values of* $\mathrm{ind}(B)$ *for the bases B of $\mathcal{M}$ for which $C(B,p)$ solves the* OMCP *of $\hat{\mathcal{M}}$.*

To show that the degree is well defined, we pick a particular extension and show that the degree calculated with any other extension gives the same number. For a square oriented matroid $\mathcal{M}$ of rank n represented by a matrix $[I,-M]$, $q=\mathrm{lex}(s_1,s_2,\ldots,s_n)$ extends $\mathcal{M}$ to an oriented matroid represented by $[I,-M,r]$, where $r=(\varepsilon,\varepsilon^2,\ldots,\varepsilon^n)^T$, for all sufficiently small positive ε.

THEOREM 3.1. *Under the assumptions of Definition* 3.2, *the degree of $\mathcal{M}$ is well defined.*

Proof. Let $\mathcal{M}$ and $\hat{\mathcal{M}}$ be as in definition 3.2. Let $q=\mathrm{lex}(s_1,s_2,\ldots,s_n)$ extend $\hat{\mathcal{M}}$ to $\bar{\mathcal{M}}$. Using the ideas of [22] and [23], one can construct a graph for which the vertices correspond to the positive circuits C of $\bar{\mathcal{M}}$ that have $\underline{C}\backslash\{p,q\}$ complementary. Two vertices corresponding to circuits C_1 and C_2 are connected by an edge if $|\underline{C}_1\triangle\underline{C}_2|=2$. This graph turns out (see [23]) to be the union of disjoint paths and cycles, where every vertex corresponding to a circuit containing p and q has two neighbors, and every vertex corresponding to a circuit containing exactly one of p or q has one neighbor. We also have (see [23]) that:

(1) If $C(B_1,p)$ and $C(B_2,p)$ correspond to the two endpoints of a path, or if $C(B_1,q)$ and $C(B_2,q)$ correspond to the two endpoints of a path, then $\mathrm{ind}(B_1)=-\mathrm{ind}(B_2)$.

(2) If $C(B_1,p)$ and $C(B_2,q)$ correspond to the two endpoints of a path, then $\mathrm{ind}(B_1)=\mathrm{ind}(B_2)$.

This implies that if we add up the values of $\mathrm{ind}(B)$ for all B for which $C(B,p)$ solves the OMCP of $\hat{\mathcal{M}}$, we get the same number as when we sum up the values of $\mathrm{ind}(B)$ for all B so that $C(B,q)$ is positive and $\underline{C}(B,q)\backslash q$ is complementary. But these are

the solutions to the OMCP defined by $\check{\mathcal{M}} = \bar{\mathcal{M}}\backslash p$, the same oriented matroid as the extension of $\mathcal{M}$ by $q = \text{lex}(s_1, s_2, \ldots, s_n)$. □

Some ideas of the above proof go back to Lemke [25]. With oriented matroids one must take extra care, since two extensions may not be compatible. If p extends $\mathcal{M}$ to $\hat{\mathcal{M}}$ and q extends $\mathcal{M}$ to $\check{\mathcal{M}}$, there does not necessarily exist an oriented matroid $\bar{\mathcal{M}}$ so that $\bar{\mathcal{M}}\backslash q = \hat{\mathcal{M}}$ and $\bar{\mathcal{M}}\backslash p = \check{\mathcal{M}}$. Fortunately, this lexicographic extension is compatible with any other extension. The lexicographic extension is also useful because it guarantees that all of the circuits corresponding to vertices of the graph contain $n + 1$ elements.

The assumption that $\mathcal{M}$ satisfies WND is sufficient for the graph defined in the proof to have the structure described. When $\mathcal{M}$ does not satisfy WND, things can easily go wrong. For example, if $n = 1$ and $\mathcal{M}$ is represented by the matrix $[1, 0]$, then $\mathcal{M}$ does not satisfy WND as $(t_1, \emptyset)$ is a positive complementary circuit. Calculating the degree using the extension represented by $[1, 0, 1]$ gives 0 as the answer, while calculating it at $[1, 0, -1]$ gives 1. However, the assumption is not strictly necessary. Let $M = \left(\begin{smallmatrix} 0 & 0 \\ 0 & -1 \end{smallmatrix}\right)$. Then the oriented matroid represented by $[I, -M]$ does not satisfy WND, but calculating the degree at any extension as in the definition yields 0. There does not seem to be any obvious simple necessary and sufficient condition for the degree to be well defined, but the assumption WND includes many important cases.

If $\mathcal{M}$ satisfying WND is represented by a matrix $[I, -M]$, then the degree of $\mathcal{M}$ is the same as the degree of the mapping determined by M, as defined in [11]. This mapping sends the standard basis vectors of $\mathbf{R}^n$ to themselves, sends the negative of the ith standard basis vector to the ith column of $-M$, for $i = 1, \ldots, n$ and is linear on each orthant. A consequence of the definition is that the mappings defined by two matrices M_1 and M_2, for which the oriented matroid represented by $[I, -M_1]$ is the same as that represented by $[I, -M_2]$, have the same degree.

Recent work by Stewart [21] (see also [7]) gives a method for calculating the degree of $\mathcal{M}$ with extensions $\hat{\mathcal{M}}$ for which there are solutions to the LCP of $\hat{\mathcal{M}}$ that have less than $n + 1$ elements. Lemma 3.1 gives an indication of how one can deal with extensions for which some of the solutions to the resulting OMCP have less than $n + 1$ elements.

LEMMA 3.1. *Let $\mathcal{M}$ be a square oriented matroid satisfying* WND. *If the degree of $\mathcal{M}$ is nonzero, then the* OMCP *defined by any extension of $\mathcal{M}$ has a solution.*

Proof. Let $\mathcal{M}$ be a square oriented matroid of nonzero degree. Let q extend $\mathcal{M}$ to $\hat{\mathcal{M}}$. If $(q, \emptyset)$ is a circuit of $\hat{\mathcal{M}}$, then this is a solution to the OMCP of $\hat{\mathcal{M}}$. If not, then there is an ordered base F of $\hat{\mathcal{M}}$ containing q in the first position. Let $p = \text{lex}(F)$ extend $\hat{\mathcal{M}}$ to $\bar{\mathcal{M}}$, and let $\check{\mathcal{M}} = \bar{\mathcal{M}}\backslash q$. Then $\check{\mathcal{M}}$ satisfies the conditions of Theorem 3.1, so its OMCP must have a solution. A solution $C(B, p)$ to the OMCP of $\check{\mathcal{M}}$ implies, by the definition of lexicographic extensions, that there is a circuit $C(B, q)$ of $\hat{\mathcal{M}}$ that solves the OMCP of $\hat{\mathcal{M}}$. □

It was observed in [11] that specifying the signs of the principal minors of a matrix M does not determine the degree of the LCP mapping defined by M. On the other hand, from the definition of lexicographic extensions one sees that if $\mathcal{M}$ is represented by $[I, -M]$ and $q = \text{lex}(s_1, s_2, \ldots, s_n)$ extends $\mathcal{M}$ to $\hat{\mathcal{M}}$, then the solutions to the OMCP of $\hat{\mathcal{M}}$, and hence the degree of $\mathcal{M}$, are determined by the circuits of $\mathcal{M}$ of the form $C(B, s_i)$, where B is a complementary base of $\mathcal{M}$ not containing s_i. By (E2) these circuits in turn are determined by the values of $\varepsilon(\beta)$ for orderings β of bases B that are either complementary or contain $\{s_i, t_i\}$ for exactly one subscript i (Here

we assume that $\varepsilon(s_1, s_2, \ldots, s_n) = 1$). In the representable case, these values of ε are determined by the determinants of square submatrices of M that either are principal or are defined by a set of rows I and a set of columns J with $|I \triangle J| = 2$.

4. Reorientation results. All of the square oriented matroids in this section are assumed to satisfy ND. We would like to obtain relationships between the degree of a square oriented matroid $\mathcal{M}$ and the degrees of its minors.

DEFINITION 4.1. *If F is a subset of $E = S \cup T$, then define the oriented matroid $\mathcal{M}_{\bar{F}}$ by $\mathcal{K}(\mathcal{M}_{\bar{F}}) = \{((K^+ \backslash F) \cup (K^- \cap F), (K^- \backslash F) \cup (K^+ \cap F)), K \in \mathcal{K}(\mathcal{M})\}$.*

The oriented matroid $\mathcal{M}_{\bar{F}}$ is said to be obtained from reorienting F. We write $\deg(\mathcal{M})$ for the degree of $\mathcal{M}$. If ε is an assignment of signs to bases of $\mathcal{M}$, then $\varepsilon_{\bar{F}}$ defined by $\varepsilon_{\bar{F}}(\beta) = \varepsilon(\beta)(-1)^{|\beta \cap F|}$ is an assignment of signs to bases of $\mathcal{M}_{\bar{F}}$.

DEFINITION 4.2. *Let $\mathcal{M}$ be a square oriented matroid. Let ε be an assignment of signs to ordered bases of $\mathcal{M}$. Define the assignment signs $\varepsilon \backslash s_i$ of signs to ordered bases of $\mathcal{M} \backslash t_i / s_i$ by $\varepsilon \backslash s_i(\beta) = \varepsilon(\bar{\beta})$, where $\bar{\beta}$ is obtained from β by inserting s_i in the ith position. Similarly, define $\varepsilon \backslash t_i$ for $\mathcal{M} \backslash s_i / t_i$ by $\varepsilon \backslash t_i(\beta) = \varepsilon(\bar{\beta})$, where $\bar{\beta}$ is obtained from β by inserting t_i into the ith position.*

LEMMA 4.1. *Let $\mathcal{M}$ be a square oriented matroid satisfying* ND. *Then*

(1) $\deg(\mathcal{M}) + \deg(\mathcal{M}_{\bar{s}_i}) = \deg(\mathcal{M} \backslash t_i / s_i)$;

(2) $\deg(\mathcal{M}) - \deg(\mathcal{M}_{\bar{t}_i}) = -\deg(\mathcal{M} \backslash s_i / t_i)(\varepsilon(\sigma_i))$

for $i = 1, 2, \ldots, n$, where σ_i is the ordering of $S \backslash s_i \cup t_i$ for which the subscripts are in increasing order and $\varepsilon(s_1, s_2, \ldots, s_n) = 1$.

Proof. We first prove (1). Let F be a complementary ordered base of $\mathcal{M}$ containing t_i in the first position. Let $q = \text{lex}(F)$ extend $\mathcal{M}$ to $\hat{\mathcal{M}}$. Note that if B is a complementary base of $\mathcal{M}$ containing t_i, then in $\hat{\mathcal{M}}$ we must have $t_i \in C(B, q)^-$ by the definition of lexicographic extensions. Thus all complementary bases B that solve the OMCP of $\hat{\mathcal{M}}$ contain s_i. The same is true for all bases B that solve the OMCP of $\hat{\mathcal{M}}_{\bar{s}_i}$, and no base can solve both the OMCP of $\hat{\mathcal{M}}$ and the OMCP of $\hat{\mathcal{M}}_{\bar{s}_i}$. For any base B that solves the OMCP of $\hat{\mathcal{M}}$ or $\hat{\mathcal{M}}_{\bar{s}_i}$, the base $B \backslash s_i$ of $\mathcal{M} \backslash t_i / s_i$ solves the OMCP of $\hat{\mathcal{M}} \backslash t_i / s_i$. If ε is the assignment of signs to ordered bases of $\mathcal{M}$ satisfying $\varepsilon(s_1, s_2, \ldots, s_n) = 1$, and β is a complementary ordered base of $\mathcal{M}$ containing s_i, then $\varepsilon(\beta) = -\varepsilon_{\bar{s}_i}(\beta) = (\varepsilon \backslash s_i)(\beta \backslash s_i)$. But $\varepsilon_{\bar{s}_i}$ is the opposite of the assignment of bases to ordered bases of $\hat{\mathcal{M}}_{\bar{s}_i}$ that assigns 1 to $(s_1, s_2, \ldots, s_n)$. Thus if β is an ordering of B, then the index of B in $\hat{\mathcal{M}}$ is the same as the index of B in $\hat{\mathcal{M}}_{\bar{s}_i}$, and this is the same as the index of $B \backslash s_i$ in $\hat{\mathcal{M}} \backslash t_i / s_i$. Thus (1) follows.

To prove (2), we analogously extend $\mathcal{M}$ to $\hat{\mathcal{M}}$ by $q = \text{lex}(F)$, where F is an ordered base of $\mathcal{M}$ with s_i in the first position. For a complementary ordered base β of $\mathcal{M}$ containing t_i we still have $\varepsilon(\beta) = -\varepsilon_{\bar{t}_i}(\beta)$, but now if ε assigns 1 to $(s_1, s_2, \ldots, s_n)$, so does $\varepsilon_{\bar{t}_i}$. We also have $\varepsilon(\beta) = \varepsilon \backslash t_i(\beta \backslash t_i)$, but here $\varepsilon \backslash t_i$ assigns 1 to $(s_1, s_2, \ldots, s_n) \backslash s_i$ only if $\varepsilon(\sigma_i) = 1$. The index formula counts $|B \cap T|$, so we must multiply by -1 to account for deleting t_i. □

If $\mathcal{M}$ is represented by $[I, -M]$, then: $\mathcal{M}_{\bar{t}_i}$ is represented by $[I, -M_1]$, where M_1 is obtained from M by negating the ith column; $\mathcal{M}_{\bar{s}_i}$ is represented by $[I, -M_2]$, where M_2 is obtained from M by negating the ith row; $\mathcal{M} \backslash t_i / s_i$ is represented by $[I, -M_3]$, where M_3 is obtained from M by deleting the ith row and column; $\mathcal{M} \backslash s_i / t_i$ is represented by $[I, -M_4]$, where M_4 is obtained from M by first pivoting on the ith diagonal element of M and then deleting the ith row and column of the resulting matrix. Finally, $\varepsilon(\sigma_i)$ is the sign of the ith diagonal element of $-M$.

When $n = 1$, there are only two square oriented matroids satisfying ND. These

are the oriented matroids represented by the matrices $[1,1]$ and $[1,-1]$. It is easy to check that if we define the *empty* oriented matroid $\mathcal{M} = (\emptyset, \{(\emptyset,\emptyset)\})$ to have degree 1, then Lemma 4.1 holds in the case $n = 1$.

THEOREM 4.1. *Let $\mathcal{M}$ be a square oriented matroid of rank n satisfying* ND. *Then if $N = \{1,2,\ldots,n\}$*

$$\sum_{I\subseteq N} \deg(\mathcal{M}_{\bar{S}_I}) = 1,$$

where $S_I = \{s_i : i \in I\}$.

Proof. The proof is by induction on n. By the definition of the degree of the empty oriented matroid, the statement is true for $n = 0$. For $n = 1$, the oriented matroid represented by the matrix $[1,-1]$ has degree 1, and the oriented matroid represented by $[1,1]$ has degree 0. If $\mathcal{M}$ is one of these two, then $\mathcal{M}_{\bar{s}_1}$ is the other. Suppose next that the statement is true for all square oriented matroids of rank $n-1$, and let $\mathcal{M}$ be a square oriented matroid of rank n. Then

$$\begin{aligned}\sum_{I\subseteq N} \deg(\mathcal{M}_{\bar{S}_I}) &= \sum_{J\subseteq(N\setminus n)} \deg(\mathcal{M}_{\bar{S}_J}) + \deg(\mathcal{M}_{\overline{S_J\cup s_n}}) \\ &= \sum_{J\subseteq(N\setminus n)} \deg(\mathcal{M}_{\bar{S}_J}\backslash t_n/s_n) = 1.\end{aligned}$$

The last equality is the inductive hypothesis. □

Since there are 2^n subsets of $\{1,2,\ldots,n\}$, it follows that the average value of the degree of a square oriented matroid satisfying ND is 2^{-n}. The implication for the matrix case is stated as a corollary.

COROLLARY 4.1. *Let P be a probability measure on $\mathbf{R}^{n\times n}$ for which* (1) *$P(ND) = 1$, where* ND *is the set of matrices in $\mathbf{R}^{n\times n}$ with all principal minors nonzero.*

(2) *If $G\subseteq\mathbf{R}^{n\times n}$ and H is obtained from G by negating the ith row of each element of G, then $P(G) = P(H)$ for $i = 1,2,\ldots,n$.*

Then the expected value of the degree of the mapping defined by a matrix chosen at random from $\mathbf{R}^{n\times n}$ according to P is 2^{-n}.

Due to the asymmetry of Lemma 4.1, Corollary 4.1 does not remain true when "row" is replaced by "column."

Theorem 4.1 implies that for at least one of the subsets I, the degree of $\mathcal{M}_{\bar{S}_I}$ must be nonzero. Matrices for which the corresponding maps have nonzero degree are known to be Q-matrices. (This also follows from Lemma 3.1.) This justifies the following corollary.

COROLLARY 4.2. *Let P be as in Corollary* 4.1, *and let Q be the set of Q-matrices in $\mathbf{R}^{n\times n}$. Then $P(Q) \geq 2^{-n}$.*

It is plausible that as n approaches infinity, $P(Q)$ goes to zero for P as above. It seems to be difficult to prove this.

One can get various other equations similar to those of Lemma 4.1. For example, we have the following lemma.

LEMMA 4.2. *Let $\mathcal{M}$ be a square oriented matroid of rank n satisfying* ND. *Then*

(1) $\deg(\mathcal{M}_{\bar{t}_i}) + \deg(\mathcal{M}_{\overline{s_i\cup t_i}}) = \deg(\mathcal{M}\backslash t_i/s_i)$,

(2) $\deg(\mathcal{M}_{\bar{s}_i}) - \deg(\mathcal{M}_{\overline{s_i\cup t_i}}) = \deg(\mathcal{M}\backslash s_i/t_i)(\varepsilon(\sigma_i))$, *and*

(3) $\deg(\mathcal{M}) + \deg(\mathcal{M}_{\bar{s}_i}) - \deg(\mathcal{M}_{\bar{t}_i}) - \deg(\mathcal{M}_{\overline{s_i\cup t_i}}) = 0$ *for $i = 1,2,\ldots,n$.*

Parts (1) and (2) are proved similarly to Lemma 4.1 and part (3) is a linear combination of the first parts of Lemmas 4.1 and 4.2, or a combination of their second parts.

The degree of a square oriented matroid is not always determined by those of its minors. For example, if $M_1 = \left(\begin{smallmatrix} -1 & 2 \\ 2 & -1 \end{smallmatrix}\right)$ and $M_2 = \left(\begin{smallmatrix} -1 & -2 \\ -2 & -1 \end{smallmatrix}\right)$, and $\mathcal{M}_1$ is represented by $[I, -M_1]$, $\mathcal{M}_2$ is represented by $[I, -M_2]$, then $\mathcal{M}_1\backslash t_i/s_i = \mathcal{M}_2\backslash t_i/s_i$ and $\mathcal{M}_1\backslash s_i/t_i = \mathcal{M}_2\backslash s_i/t_i$ for $i = 1, 2$. On the other hand, $\deg(\mathcal{M}_1) = -1$ while $\deg(\mathcal{M}_2) = 0$.

We would like to organize the study of equations such as those proved above by introducing the *reorientation vector* of a square oriented matroid. This is a vector with 2^{2n} components, indexed by the subsets of $E = S \cup T$ ordered lexicographically. For a square oriented matroid $\mathcal{M}$ of rank n, the component of the reorientation vector of $\mathcal{M}$ corresponding to a set $I \subseteq E$ is $\deg(\mathcal{M}_{\bar{I}})$. The reorientation vector is not defined if $\mathcal{M}$ does not satisfy ND, because if $\mathcal{M}$ has a complementary circuit, then this circuit is positive for some reorientation of $\mathcal{M}$.

PROBLEM 4.1. Characterize the set of reorientation vectors of square oriented matroids of rank n.

One hope is that a characterization of the set of reorientation vectors would indicate a relationship between this set and other sets of vectors in combinatorial geometry, such as the set of f-vectors of convex polytopes. This search is partly motivated by the fact that the tools from algebra instrumental in proving the upper bounds on the components of the f-vectors were also used by the author in proving special cases of the conjectured bound on the entries of the reorientation vector in [19]. The conjectured bound, given in [18], on the degree of an LCP mapping is

$$\binom{n-1}{\lfloor \frac{n-1}{2} \rfloor}.$$

A trivial observation to make is that for any $I \subseteq E$, we have $\mathcal{M}_{\bar{I}} = \mathcal{M}_{\overline{E\backslash I}}$. This cuts down the dimension of the linear span of the reorientation vectors to 2^{2n-1}. Theorem 4.1 and Lemma 4.2 give us more affine and linear equations satisfied by these vectors.

In the case that $\mathcal{M}$ satisfies TND, we can get help from oriented matroid theory. We first prove the following lemma, which is valid under a weaker nondegeneracy assumption.

LEMMA 4.3. *Let $\mathcal{M}$ be a square oriented matroid satisfying* WND. *If $\mathcal{K}(\mathcal{M})$ does not contain the signed set $(E, \emptyset)$ then* $\deg(\mathcal{M}) = 0$.

Proof. If $\mathcal{K}(\mathcal{M})$ does not contain the signed set $(E, \emptyset)$, then there is an element $e \in E$ so that no positive circuits of $\mathcal{K}(\mathcal{M})$ contain e. Furthermore, e is the first element of some ordered base F. Let $q = \text{lex}(F)$ extend $\mathcal{M}$ to $\hat{\mathcal{M}}$. Then $\hat{\mathcal{M}}$ has no positive circuits containing q. Hence we have that the OMCP of $\hat{\mathcal{M}}$ has no solutions and $\deg(\mathcal{M}) = 0$.

An oriented matroid $\mathcal{M}$ with $(E, \emptyset) \in \mathcal{K}(\mathcal{M})$ is said to be *acyclic*. If $\mathcal{M}$ is represented by $[I, -M]$ with M square and $\mathcal{M}$ is acyclic, then M is an S-matrix.

If $\mathcal{M}$ satisfies TND and $\mathcal{M}$ is square, it follows from [13] that $\mathcal{M}_{\bar{I}}$ is acyclic for exactly half of the subsets $I \subseteq E$. Furthermore, the collection of these subsets of E has the combinatorial structure of a "barely unlopsided set" (see [13]).

COROLLARY 4.3. *If $\mathcal{M}$ of rank greater than zero is square and satisfies* TND, *then at least half of the components of its reorientation vector are zero.*

We close this section by showing that the set of P-oriented matroids is characterized by its reorientation vectors. A square oriented matroid $\mathcal{M}$ is called a P-oriented matroid if for every circuit C of $\mathcal{M}$ there is a subscript i so that $\{s_i, t_i\} \subseteq C^+$ or $\{s_i, t_i\} \subseteq C^-$. See [14] for other equivalent characterizations of these oriented matroids. A matrix M for which $[I, -M]$ represents a P-oriented matroid $\mathcal{M}$ is a P-matrix.

THEOREM 4.2. *A square oriented matroid $\mathcal{M}$ of rank n is a P-oriented matroid if and only if for all subsets J of E we have* $\deg(\mathcal{M}_{\bar{J}}) = 1$ *if* $J = S_I \cup T_I$ *for some* $I \subseteq \{1, 2, \ldots, n\}$, $\deg(\mathcal{M}_{\bar{J}}) = 0$ *otherwise.*

Proof. Suppose first that $\mathcal{M}$ is a P-oriented matroid. From [23] it follows that the OMCP of every extension of $\mathcal{M}$ has a unique solution. In particular, if $q = \text{lex}(s_1, s_2, \ldots, s_n)$ extends $\mathcal{M}$ to $\check{\mathcal{M}}$, then the OMCP defined by $\hat{\mathcal{M}} = \check{\mathcal{M}}_{\bar{q}}$ has as its solution $C(S, q)$. Since $\text{ind}(S) = 1$, $\deg(\mathcal{M}) = 1$. If $J = S_I \cup T_I$ for some I, it is clear that $\mathcal{M}_{\bar{J}}$ is also a P-oriented matroid, hence its degree is also 1. If J is not of the form $S_I \cup T_I$ for any I, assume without loss of generality that $s_i \in J, t_i \notin J$. Let F be an ordered base of $\mathcal{M}$ containing s_i in the first position, and let $q = \text{lex}(F)$ extend $\mathcal{M}_{\bar{J}}$ to $\hat{\mathcal{M}}_{\bar{J}}$. As in the proof of Lemma 4.2, we see that all solutions B to the LCP of $\hat{\mathcal{M}}_{\bar{J}}$ must contain t_i. However, since the only index j for which $\{s_j, t_j\} \subseteq \underline{C}(B, s_i)$ for such a B is i, we must have $t_i \in C(B, s_i)^-$ by the P-oriented matroid property of $\mathcal{M}$. Thus the OMCP of $\hat{\mathcal{M}}_{\bar{J}}$ has no solution and $\deg(\mathcal{M}_{\bar{J}}) = 0$.

The opposite implication will be proved by induction on n, the rank of $\mathcal{M}$. The implication is true for $n = 0$ because we defined the degree of the empty oriented matroid to be 1 and it is a P-oriented matroid. The case $n = 1$ can be quickly checked. Suppose next that $\mathcal{M}$ is of rank $n > 1$, and that for all subsets J of E we have $\deg(\mathcal{M}_{\bar{J}}) = 1$ if J is of the form $S_I \cup T_I$, $\deg(\mathcal{M}_{\bar{J}}) = 0$ otherwise. Let $J = S_I \cup T_I$ for some $I \subseteq (N \backslash n)$. Then by Lemma 4.1, $\deg((\mathcal{M}_{\bar{J}}) \backslash t_n / s_n) = \deg(\mathcal{M}_{\bar{J}}) + \deg(\mathcal{M}_{\overline{J \cup s_n}}) = 1 + 0 = 1$. On the other hand, if J is not of the form $S_I \cup T_I$ for any I, and also $J \cap \{s_n, t_n\} = \emptyset$, then $\deg((\mathcal{M}_{\bar{J}}) \backslash t_n / s_n) = \deg(\mathcal{M}_{\bar{J}}) + \deg(\mathcal{M}_{\overline{J \cup s_n}}) = 0 + 0 = 0$ and $\deg((\mathcal{M}_{\bar{J}}) \backslash s_n / t_n) = \pm(\deg(\mathcal{M}_{\bar{J}}) - \deg(\mathcal{M}_{\overline{J \cup t_n}})) = \pm(0 - 0) = 0$. By induction we can say that $\mathcal{M} \backslash t_n / s_n$ is a P-oriented matroid. If we apply Theorem 4.1 to $(\mathcal{M}_{\bar{T}_I}) \backslash s_n / t_n$ where $I \subseteq (N \backslash n)$, we have that $\deg((\mathcal{M}_{\overline{S_I \cup T_I}}) \backslash s_n / t_n) = 1$. Thus we can also say by induction that $\mathcal{M} \backslash s_n / t_n$ is a P-oriented matroid. Here n was arbitrary, so we can replace n by any $i = 1, 2, \ldots, n$. Finally, if C is a circuit of $\mathcal{M}$, then there must be an element of E that is not in $\underline{C}$, say s_n. Then $C \in \mathcal{K}(\mathcal{M} \backslash s_n / t_n)$, which is a P-oriented matroid. Thus there is a subscript i in $\{1, 2, \ldots, n-1\}$ for which $\{s_i, t_i\} \subseteq C^+$ or $\{s_i, t_i\} \subseteq C^-$. This means that $\mathcal{M}$ is a P-oriented matroid. □

5. A degree zero Q-oriented matroid. A matrix M in $\mathbf{R}^{n \times n}$ is a Q-matrix if the LCP defined by M and a vector q has a solution for all $q \in \mathbf{R}^n$. It is well known that if the degree of the mapping defined by M is nonzero, then M is a Q-matrix. On the other hand, the discovery by Kelly and Watson [12] of a Q-matrix defining a map of degree zero, showed that the Q-matrix property is more difficult to establish than the calculation of the degree. The Kelly and Watson example gave a matrix on the boundary of the set of Q-matrices, showing that the set of Q-matrices is not open in $\mathbf{R}^{n \times n}$. The set of matrices in $\mathbf{R}^{n \times n}$ defining maps of nonzero degree is open. Kelly and Watson go on to ask if there are other interesting open sets of Q-matrices.

Part of the mystique concerning Q-matrices is generated by the fact that the only known method that can guarantee to tell if a matrix is a Q-matrix, due to Gale, requires the solution of n^{2^n} linear programs in the worst case, each with 2^n constraints. Recent work by Naiman and Stone (see [20]) has reduced the amount of work needed to a roughly $O(2^{3n^2})$ algorithm. Compare this to the obvious algorithm for calculating the degree by solving 2^n linear systems for some arbitrary right-hand side. The result is that one can calculate the degree by hand for 4×4 matrices quite easily, whereas showing that a 4×4 matrix is a Q-matrix often involves a "proof by picture" argument as in [12].

For a square oriented matroid $\mathcal{M}$ of rank n satisfying TND, the set of matrices $M \in \mathbf{R}^{n\times n}$ for which $[I, -M]$ represents $\mathcal{M}$ is an open set. (However, for $n \geq 5$, it is not necessarily connected! See [1].) Thus, if we can produce an oriented matroid $\mathcal{M}$ satisfying TND so that for any point extension $\hat{\mathcal{M}}$, the OMCP has a solution, we have an open set of Q-matrices.

DEFINITION 5.1. *A square oriented matroid $\mathcal{M}$ is called a* Q-oriented matroid *if for every point extension $\hat{\mathcal{M}}$ of $\mathcal{M}$ the* OMCP *of $\hat{\mathcal{M}}$ has a solution.*

If a matrix M is a Q-matrix, it is not necessarily true that the oriented matroid $\mathcal{M}$ represented by $[I, -M]$ is a Q-oriented matroid. $\mathcal{M}$ may have nonrepresentable extensions or representable extensions that cannot be represented by adding a column to $[I, -M]$, for which the OMCP has no solutions. An example of a Q-matrix M for which the oriented matroid $\mathcal{M}$ represented by $[I, -M]$ satisfies TND, but is not a Q-oriented matroid, is given in [17]. Thus the boundary of the set of Q-matrices can run through the interior of a set of matrices representing a particular TND oriented matroid of degree zero. It is not a priori clear that there must exist such a set entirely contained within the set of Q-matrices. Theorem 5.1 shows that there is such an example.

THEOREM 5.1. *There exists a Q-oriented matroid of degree zero.*

Proof. Let

$$M = \begin{pmatrix} -4 & 3 & 3 & 5 \\ 3 & -4 & 3 & 5 \\ 3 & 3 & -4 & 5 \\ 5 & 5 & 5 & -4 \end{pmatrix}.$$

Howe [10] showed that the mapping defined by M had degree zero. Howe also showed that M was a Q-matrix. Let $\tilde{\mathcal{M}}$ be the oriented matroid represented by $[I, -M]$. The proof of [10] can be translated into oriented matroidese to show that $\tilde{\mathcal{M}}$ is a Q-oriented matroid. We do this for the benefit of those not conversant with this language.

LEMMA 5.1. *If $\mathcal{M}$ is a square oriented matroid satisfying, for some i,*

(1) *for all $j \neq i$, $s_i \notin C(S, t_j)^-$*

(2) *$\mathcal{M}\backslash t_i/s_i$ is a Q-oriented matroid.*

Then if q extends $\mathcal{M}$ to $\hat{\mathcal{M}}$ with $s_i \notin C(S, q)^-$, the OMCP *of $\hat{\mathcal{M}}$ will have a solution.*

Proof of Lemma 5.1. Let C_i be a solution to the OMCP $\hat{\mathcal{M}}\backslash t_i/s_i$. Then there is a $K \in \mathcal{K}(\mathcal{M})$ with $K\backslash s_i = C_i$. If $s_i \in K^+$, then K is a solution to the OMCP $\hat{\mathcal{M}}$. Suppose that $s_i \in K^-$. If $T \cap \underline{K} = \emptyset$, then $K = C(S, q)$, contradicting $s_i \notin C(S, q)^-$. Otherwise, eliminate t_j for some $t_j \in T \cap K$ between K and $-C(S, t_j)$, obtaining $K' \in \mathcal{K}(\mathcal{M})$ with $s_i \in K'^-, q \in K'^+, |T \cap \underline{K'}| = |T \cap \underline{K}| - 1, K'^- \cap T = \emptyset$. Continue this way until $T \cap \underline{K}$ is empty, obtaining a contradiction. □

Howe also showed that the maps defined by the 3×3 principal minors of M are all of nonzero degree. It follows that the oriented matroids $\tilde{\mathcal{M}}\backslash t_i/s_i$ are Q-oriented matroids for $i = 1, 2, 3, 4$. Lemma 5.1 then shows that there only remains to find a solution to the OMCPs of extensions $\hat{\mathcal{M}}$ of $\tilde{\mathcal{M}}$ with $C(S, q) = (q, S)$. Let $\hat{\mathcal{M}}$ be such an extension. One can calculate that $\mathcal{K}(\tilde{\mathcal{M}})$ contains the positive circuits $(\{s_1, s_4, t_1, t_2, t_3\}, \emptyset), (\{s_2, s_4, t_1, t_2, t_3\}, \emptyset)$, and $(\{s_3, s_4, t_1, t_2, t_3\}, \emptyset)$. For $B = \{t_1, t_2, t_3, s_4\}$, these are the circuits $C(B, s_i)$, for $i = 1, 2, 3$. By successively eliminating s_i between $C(S, q)$ and $C(B, s_i)$ for $i = 1, 2, 3$, as in the proof of Lemma 5.1 above, one gets $C(B, q)$, with $\{t_1, t_2, t_3\} \subseteq C(B, q)^+$. If $s_4 \in C(B, q)^+$, then $C(B, q)$ will solve the OMCP of $\hat{\mathcal{M}}$. Suppose then that $s_4 \in C(B, q)^-$. We can also calculate that $\mathcal{K}(\mathcal{M})$ contains the circuits $C_1 = (\{s_1, s_2, t_3, t_4\}, t_1), C_2 = (\{s_1, s_2, s_4, t_3, t_4\}, \emptyset)$,

and $C_3 = (\{s_1, s_2, t_3, t_4\}, t_2)$. Eliminate t_1 between $C(B, q)$ and C_1 to get $K_1 = (\{s_1, s_2, t_2, t_3, t_4, q\}, s_4)$ of $\mathcal{K}(\hat{\mathcal{M}})$. Then eliminate s_4 between K_1 and C_2 to get $K_2 = (\{s_1, s_2, t_2, t_3, t_4, q\}, \emptyset) \in \mathcal{K}(\hat{\mathcal{M}})$. Finally, eliminate t_2 between K_2 and C_3 to get $(\{s_1, s_2, t_3, t_4, q\}, \emptyset)$, which solves the OMCP. □

The oriented matroid $\tilde{\mathcal{M}}$ did not satisfy TND, so we cannot say that the set of matrices M for which $[I, -M]$ represents $\tilde{\mathcal{M}}$ is an open set. However, one can get a *perturbation* of $\tilde{\mathcal{M}}$ that satisfies TND and that has the relevant properties of $\tilde{\mathcal{M}}$. The idea of perturbations was shown in the proof of Lemma 3.1, where q was replaced by p. Because q was in the first position of F, circuits of $\hat{\mathcal{M}}$ with $n+1$ elements, containing q become circuits of $\tilde{\mathcal{M}}$ with p replacing q. We can start with $\tilde{\mathcal{M}}$ and replace t_i by t_i' this way successively for $i = 1, 2, \ldots, n$. The resulting oriented matroid will satisfy TND. All of the relevant circuits of $\tilde{\mathcal{M}}$ used in the proof contained $n+1 = 5$ elements, hence they will also be circuits of the perturbed oriented matroid. Thus the set of matrices M for which $[I, -M]$ represents this perturbed oriented matroid will be an open set of Q-matrices defining maps of degree zero.

6. Remarks. Theorems 3.1 and 5.1 were written in an earlier version of this paper that was not submitted for publication. Comments of M. J. Todd were very helpful for the improvement of this paper. The anonymous referees also provided very helpful comments.

VARIATION OF THE UNITARY PART OF A MATRIX*

RAJENDRA BHATIA† AND KALYAN MUKHERJEA‡

Abstract. The derivative of the map that takes an invertible matrix A to the unitary factor U in the polar decomposition $A = UP$ is evaluated. The same is done for the map that takes A to the unitary factor Q in the QR decomposition $A = QR$. These results lead to perturbation bounds for these maps. Other applications of the method developed are discussed.

Key words. polar decomposition, QR decomposition, Cholesky factorisation, perturbation, manifold, tangent space, unitarily invariant norm, singular value, Fréchet derivative

AMS subject classifications. 15A45, 65F99

1. Introduction.

Let $\mathbf{M}(n)$ be the space of all $n \times n$ (complex) matrices; let $\mathbf{GL}(n)$ be the group consisting of all invertible matrices and let $\mathbf{U}(n)$ be the subgroup of unitary matrices. Every matrix A has a *polar decomposition* $A = UP$, where $U \in \mathbf{U}(n)$ and P is positive semidefinite. The positive part P, written as $|A|$, is unique and is equal to $(A^*A)^{1/2}$. If $A \in \mathbf{GL}(n)$ then the polar part U is also unique, since $U = AP^{-1}$.

Let $F : \mathbf{GL}(n) \longrightarrow \mathbf{U}(n)$ be the map $F(UP) = U$, which takes an invertible matrix to its polar part. Our first result, Theorem 2.1 below, gives an explicit expression for the Fréchet derivative of this map. As corollaries we obtain the value of the norm of this derivative with respect to any unitarily invariant norm on $\mathbf{M}(n)$, and then a perturbation bound for the polar part.

Another expression for the derivative of F has been obtained by Barrlund [1]. Using this and some results on Hadamard products, Mathias [12] has obtained the perturbation bound (13) derived below. Our coordinate-free approach to these questions is in line with some of our earlier work [3], [6], and [2, Chaps. 4, 5]. This approach has two merits. First, it is adaptable to more general contexts such as the KAK decomposition in semisimple Lie groups. We do not pursue that direction in this paper. Second, it works well for other matrix decompositions like the QR factorisation and the Cholesky factorisation. We illustrate this in later sections of this paper. Results similar to these have been obtained by Stewart [13] and, more recently, by Sun [15]. Here our approach clarifies some of the issues, unifies the work on these different questions, and clearly brings out the similarities and the differences between them.

We will denote by $|||\cdot|||$ any norm on $\mathbf{M}(n)$ that is *unitarily invariant*, i.e., a norm that satisfies the condition $|||UAV||| = |||A|||$ for all $A \in \mathbf{M}(n)$ and $U, V \in \mathbf{U}(n)$. Basic properties of such norms may be found in [2]. The singular values of A will be denoted as $s_1(A) \geq s_2(A) \geq \cdots \geq s_n(A)$. The *operator bound norm*, also called the *spectral norm* in the numerical analysis literature, will be denoted by $||\cdot||$ and the *Frobenius norm* by $||\cdot||_F$. We have

$$||A|| = s_1(A),$$

$$||A||_F = \left[\sum_j s_j^2(A)\right]^{1/2}.$$

If $\mathcal{T}$ is a transformer, i.e., a linear map on the space $\mathbf{M}(n)$, then for any norm $|||\cdot|||$ on $\mathbf{M}(n)$, we define

$$|||\mathcal{T}||| = \sup\{|||\mathcal{T}(X)||| : |||X||| = 1\}.$$

We will use some elementary facts of calculus on manifolds that the reader may find in texts such as [7].

2. Variation of the unitary part. Let $\mathbf{T}_A\mathbf{GL}(n)$ be the tangent space to the manifold $\mathbf{GL}(n)$ at a point A in it. Since $\mathbf{GL}(n)$ is an open subset of $\mathbf{M}(n)$ we have $\mathbf{T}_A\mathbf{GL}(n) = \mathbf{M}(n)$. This is a special instance of the correspondence between a Lie group and its Lie algebra. Here the Lie algebra corresponding to the group $\mathbf{GL}(n)$ is $gl(n) = \mathbf{M}(n)$. The Lie algebra corresponding to the group $\mathbf{U}(n)$ is $u(n)$, the set of all skew-Hermitian matrices. This is the tangent space to $\mathbf{U}(n)$ at the point I. The tangent space to $\mathbf{U}(n)$ at a point U is $\mathbf{T}_U\mathbf{U}(n) = U \cdot u(n) = \{US : S \in u(n)\}$. The derivative of F at a point $A = UP$ of $\mathbf{GL}(n)$, denoted by $DF(UP)$, is a linear map from $\mathbf{M}(n)$ to $U \cdot u(n)$.

Let $h(n)$ denote the space of all Hermitian matrices. We have $h(n) = i \cdot u(n)$. We have a vector space decomposition

$$\mathbf{M}(n) = u(n) + h(n), \tag{1}$$

in which every matrix splits uniquely as

$$X = S + H, \tag{2}$$

where

$$S = \frac{X - X^*}{2}, \qquad H = \frac{X + X^*}{2}. \tag{3}$$

We can now state our first main result.

THEOREM 2.1. *Let $F : \mathbf{GL}(n) \longrightarrow \mathbf{U}(n)$ be the map defined above as $F(UP) = U$. Let X be any element of $\mathbf{M}(n)$ and let $X = S + H$ be its splitting into skew-Hermitian and Hermitian parts. Then the value of the derivative $DF(UP)$ on the tangent vector UX is given by*

$$DF(UP)(UX) = 2U \int_0^\infty e^{-tP} S e^{-tP} dt. \tag{4}$$

Proof. Let $\mathbf{P}(n)$ be the set of all $n \times n$ positive definite matrices. This is an open subset of the real vector space $h(n)$. Hence for every $P \in \mathbf{P}(n)$ the tangent space $\mathbf{T}_P\mathbf{P}(n) = h(n)$.

Let $\Psi : \mathbf{U}(n) \times \mathbf{P}(n) \longrightarrow \mathbf{GL}(n)$ be the map $\Psi(U, P) = UP$ and let Φ be the inverse map $\Phi(UP) = (U, P)$. Then writing $\Phi = (\Phi_1, \Phi_2)$, we have $F = \Phi_1$.

The derivative $D\Psi(U, P)$ is a linear map with domain $\mathbf{T}_U\mathbf{U}(n) + \mathbf{T}_P\mathbf{P}(n) = U \cdot u(n) + h(n)$ and range $\mathbf{M}(n) = U \cdot u(n) + U \cdot h(n)$. By definition, this derivative is evaluated as

$$D\Psi(U, P)(US, H) = \frac{d}{dt}[\Psi(Ue^{tS}, P + tH)]_{t=0} = USP + UH \tag{5}$$

for all $S \in u(n), H \in h(n)$.

Now note that for small values of t, $P+tH$ is positive for any $H \in h(n)$, and hence we have $\Phi_1(UP+tUH) = \Phi_1(UP) = U$. So the kernel of $D\Phi_1(UP)$ contains $U \cdot h(n)$. In fact, $\ker D\Phi_1(UP) = U \cdot h(n)$, since Φ is a diffeomorphism from $\mathbf{GL}(n)$ onto $\mathbf{U}(n) \times \mathbf{P}(n)$ and each of $u(n)$ and $h(n)$ has half the dimension of $\mathbf{M}(n)$. So we need to compute the value of $D\Phi_1(UP)$ only on tangent vectors of the form $US, S \in \mathrm{u}(n)$. Let

$$D\Phi(UP)(US) = (UM, N), \qquad M \in \mathrm{u}(n), N \in h(n). \tag{6}$$

Since $\Phi = \Psi^{-1}$, we have using (5)

$$US = D\Psi(U,P)(UM,N) = UMP + UN. \tag{7}$$

We want to determine M from this equation. So, we must solve the equation

$$MP + N = S.$$

Taking adjoints we have

$$-PM + N = -S.$$

From these two equations we obtain

$$MP + PM = 2S. \tag{8}$$

This is the familiar Lyapunov equation and its solution (see [9], [10]) is

$$M = 2\int_0^\infty e^{-tP} S e^{-tP} dt. \tag{9}$$

Equation (4) now follows from (6) and (9). □

COROLLARY 2.1. *For every unitarily invariant norm* $|||\cdot|||$ *on* $\mathbf{M}(n)$ *we have*

$$|||DF(UP)||| = ||P^{-1}|| = s_n^{-1}(A). \tag{10}$$

Proof. This follows from (4) by a familiar argument that we repeat for the reader's convenience.

Since the norm is unitarily invariant, we have

$$|||DF(UP)(UX)||| \leq 2\int_0^\infty |||e^{-tP} S e^{-tP}|||dt. \tag{11}$$

Then, since $|||BCD||| \leq ||B|| \cdot |||C||| \cdot ||D||$ for all B, C, D, we have

$$\begin{aligned} |||e^{-tP} S e^{-tP}||| &\leq ||e^{-tP}|| \cdot |||S||| \cdot ||e^{-tP}|| \\ &\leq e^{-2ts_n(A)}|||S||| \\ &\leq e^{-2ts_n(A)}|||X||| \end{aligned} \tag{12}$$

using the fact $|||S||| \leq |||X|||$.

From (11) and (12) we obtain

$$|||DF(UP)||| = \sup_{|||X|||=1} |||DF(UP)(UX)||| \leq s_n^{-1}(A).$$

Choosing $X = \imath I/|||I|||$ one sees that this is actually an equality. □

Using the mean value theorem, we obtain from Corollary 2.2.

COROLLARY 2.2. *Let A_0 and A_1 be two elements of $\mathbf{GL}(n)$ with polar parts U_0 and U_1, respectively. Assume that the line segment $A(t) = (1-t)A_0 + tA_1, 0 \leq t \leq 1$, joining A_0 and A_1 lies inside $\mathbf{GL}(n)$. Then for every unitarily invariant norm*

$$|||U_0 - U_1||| \leq \max_{0\leq t\leq 1} ||A(t)^{-1}||.|||A_0 - A_1|||. \tag{13}$$

These statements can be expressed in another language by saying that in any unitarily invariant norm, the *condition* of the function F at any point A of $\mathbf{GL}(n)$ is given by $s_n^{-1}(A)$.

We should remark that the solution of (8) can also be expressed as a Hadamard product [10], [11]; from this we can obtain estimates like ours either directly or by converting this formula to the integral expression (9). We have chosen the integral form of the solution because it might be useful in analysing infinite dimensional problems as well. An effective use of such integrals was made earlier in [5].

3. The QR decomposition. Every square complex matrix A can be written as a product $A = QR$ where Q is unitary and R is upper triangular. If A is invertible then so is R. Furthermore, we can choose the diagonal entries of R to be positive and with this added restriction this product decomposition is unique for every $A \in GL(n)$. This decomposition called the *QR decomposition* is extremely important in numerical analysis. See [14] for details.

We will now analyse the variation of the unitary part in this decomposition in the same way as for the polar decomposition.

Let $\mathbf{B}(n)$ denote the set of all upper triangular matrices with positive diagonal entries and let $b(n)$ be the set of all upper triangular matrices with real diagonal entries. Then $b(n)$ is a real vector space and $\mathbf{B}(n)$ is an open subset of it. So, the tangent space $\mathbf{T}_R\mathbf{B}(n)$ to $\mathbf{B}(n)$ at any point R of it is the space $b(n)$. (One may note here that $\mathbf{B}(n)$ is a Lie group and $b(n)$ is its Lie algebra.)

The QR decomposition associates with every element A of $\mathbf{GL}(n)$ a unique element Q of $\mathbf{U}(n)$ and a unique element R of $\mathbf{B}(n)$. Let $F : \mathbf{GL}(n) \longrightarrow \mathbf{U}(n)$ now be the map $F(QR) = Q$. The derivative of F at $A = QR$ is a linear map from $\mathbf{M}(n)$ to $Q{\cdot}\mathbf{U}(n)$.

The subspaces $u(n)$ and $b(n)$ are complementary to each other in $\mathbf{M}(n)$ and we have a vector space decomposition

$$\mathbf{M}(n) = u(n) + b(n). \tag{14}$$

This decomposition is not as familiar as the one in (1) and it has some different features. If a matrix X splits as

$$X = K + T \tag{15}$$

in the above decomposition then we must have the following relations between the entries of these matrices

$$k_{jj} = \imath \mathrm{Im}\, x_{jj} \quad \text{for all } j, \quad k_{ij} = -\overline{x}_{ji} \quad \text{for } j > i, \quad k_{ij} = x_{ij} \quad \text{for } i > j,$$

$$t_{jj} = \mathrm{Re}\, x_{jj} \quad \text{for all } j, \quad t_{ij} = x_{ij} + \overline{x}_{ji} \quad \text{for } j > i, \quad t_{ij} = 0 \quad \text{for } i > j. \tag{16}$$

Whereas, in the case of the decomposition (1) the projections onto both the components are norm-reducing for every unitarily invariant norm (just use the triangle inequality), this is not the case for the decomposition (14). Instead, we have for the Frobenius norm the following lemma.

LEMMA 3.1. *Let $\mathcal{P}_1$ and $\mathcal{P}_2$ be the complementary projection operators in $\mathbf{M}(n)$ corresponding to the decomposition* (14). *Then*

$$||\mathcal{P}_1||_F = ||\mathcal{P}_2||_F = \sqrt{2}. \tag{17}$$

Proof. From (15) and (16) one can easily see that $||K||_F^2 \leq 2||X||_F^2$ and $||T||_F^2 \leq 2||X||_F^2$. The first inequality becomes an equality when $X = \left(\begin{smallmatrix} 0 & 0 \\ 1 & 0 \end{smallmatrix}\right)$, the second when $X = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. □

Remark 3.1. If instead of the Frobenius norm the operator norm is used then the norms of the projections $\mathcal{P}_1$ and $\mathcal{P}_2$ grow with the dimension n. To see this, note that if X is Hermitian then

$$T = 2\Delta(X) - \operatorname{diag} X, \tag{18}$$

where Δ is the *triangular truncation* operator, i.e., for any matrix $A, \Delta(A)$ is the matrix obtained from A by replacing the entries below the main diagonal by zeros. It is well known that the norm $||\Delta||$ grows as $\log n$. For example, if X is the $n \times n$ Hermitian matrix whose diagonal entries are zero and whose off-diagonal entries are $x_{ij} = \sqrt{-1}/(i-j)$, then $||X|| \leq \pi$ and $||\Delta(X)|| \geq \frac{4}{5}\log n$. (See [8, p. 39].) On the other hand, $||\operatorname{diag} X|| \leq ||X||$. So $||\mathcal{P}_2||$ must grow at least as $\log n$. Hence so must $||\mathcal{P}_1||$.

Returning to the map $F(QR) = Q$, let us see how far an analysis similar to the one in §2 takes us. Now define $\Psi : \mathbf{U}(n) \times \mathbf{B}(n) \longrightarrow \mathbf{GL}(n)$ to be the map $\Psi(Q, R) = QR$ and let Φ be its inverse map $\Phi(QR) = (Q, R)$. If Φ is written as $\Phi = (\Phi_1, \Phi_2)$ then $F = \Phi_1$. The derivative $D\Psi(Q, R)$ is a linear map whose domain is $\mathbf{T}_Q\mathbf{U}(n) + \mathbf{T}_R\mathbf{B}(n) = Q \cdot u(n) + b(n)$, and whose range is $\mathbf{M}(n) = Q \cdot u(n) + Q \cdot b(n)$. The derivative is evaluated as

$$D\Psi(Q, R)(QK, T) = \frac{d}{dt}[\Psi(Qe^{tK}, R + tT)]_{t=0} = QKR + QT \tag{19}$$

for all $K \in u(n), T \in b(n)$.

If $R \in \mathbf{B}(n)$ and $T \in b(n)$ then for small values of t, $R + tT$ is in $\mathbf{B}(n)$. By the uniqueness of the QR factorisation, $\Phi_1(QR + tQT) = \Phi_1(QR) = Q$. Hence the space $Q \cdot b(n)$ is contained in $\ker D\Phi_1(QR)$. But, then counting their dimensions we can conclude that $Q \cdot b(n) = \ker D\Phi_1(QR)$. So we need to compute the values of $D\Phi_1(QR)$ only on tangent vectors of the form $QK, K \in u(n)$. Let

$$D\Phi(QR)(QK) = (QM, Y), \quad \text{where } M \in u(n), \qquad Y \in b(n). \tag{20}$$

Since $\Phi = \Psi^{-1}$, we have from (19) and (20)

$$QK = QMR + QY. \tag{21}$$

To determine M from this we need to solve the equation

$$MR + Y = K. \tag{22}$$

Here the similarity with the analysis in §2 ends. In (3) P and N were selfadjoint, so taking adjoints we could achieve a major simplification by eliminating the redundant variable N. We cannot do that here. However, we can still obtain an expression for M from (22). Rewrite this equation as

$$M + YR^{-1} = KR^{-1}.$$

Note that $M \in \mathrm{u}(n)$ and $YR^{-1} \in b(n)$. So $M = \mathcal{P}_1(KR^{-1})$ in the notation used earlier. We have thus proved the following theorem.

THEOREM 3.1. *Let $F : \mathbf{GL}(n) \longrightarrow \mathbf{U}(n)$ be the map defined as $F(QR) = Q$. Let X be any element of $\mathbf{M}(n)$ and let $X = K + T$ be its splitting in the decomposition $\mathbf{M}(n) = \mathrm{u}(n) + b(n)$. Then the value of the derivative $DF(QR)$ on the tangent vector QX is given by*

$$DF(QR)(QX) = Q\mathcal{P}_1(KR^{-1}), \tag{23}$$

where $\mathcal{P}_1$ is the projection operator in $\mathbf{M}(n)$ projecting onto $\mathrm{u}(n)$ along the complementary space $b(n)$.

Note that the quantities occurring in the above formula can be explicitly computed from the relations (16).

COROLLARY 3.1. *For every matrix $A = QR$ in $\mathbf{GL}(n)$, we have*

$$||DF(QR)||_F \leq \sqrt{2}||R^{-1}|| = \sqrt{2}||A^{-1}||. \tag{24}$$

Proof. Use Theorem 3.1, Lemma 3.1, the unitary invariance of the Frobenius norm, and the inequality $||ST||_F \leq ||S||_F||T||$ that is valid for any two matrices S and T. □

Using the mean value theorem we obtain the following corollary.

COROLLARY 3.2. *Let $A_0 = Q_0R_0$ and $A_1 = Q_1R_1$ be any two elements of $\mathbf{GL}(n)$. Suppose that the line segment $A(t) = (1-t)A_0 + tA_1$, $0 \leq t \leq 1$, joining A_0 and A_1 lies entirely inside $\mathbf{GL}(n)$. Then*

$$||Q_0 - Q_1||_F \leq \sqrt{2} \max_{0\leq t\leq 1} ||A(t)^{-1}|| \ ||A_0 - A_1||_F. \tag{25}$$

We should remark that from (23) we could surely derive some estimates for $|||DF(QR)|||$ for any unitarily invariant norm. These would, however, involve $|||\mathcal{P}_1|||$ and for this we have good estimates only in the case of the Frobenius norm.

4. The Cholesky factorisation. A common feature of our analysis of the polar decomposition and the QR decomposition is that we replaced the study of the map Φ, which takes a matrix to its factors, by that of its inverse map Ψ. This, being a multiplication map, is easier to handle. A similar idea is useful in the perturbation analysis of the Cholesky factorisation.

Every positive definite matrix A has a unique factorisation $A = R^*R$, where R is an upper triangular matrix with positive diagonal entries. This is called the *Cholesky factorisation.*

In our notation, we now have a map $\Phi : \mathbf{P}(n) \longrightarrow \mathbf{B}(n)$ defined as $\Phi(A) = R$, where R is the Cholesky factor of A. The inverse map is $\Psi(R) = R^*R$. The derivative $D\Psi(R)$ is a linear map from the tangent space $\mathbf{T}_R\mathbf{B}(n) = b(n)$ to the tangent space $\mathbf{T}_A\mathbf{P}(n) = h(n)$. This derivative is evaluated as

$$D\Psi(R)(T) = \frac{d}{dt}\ [\Psi(R + tT)]_{t=0} = R^*T + T^*R, \tag{26}$$

for every $T \in b(n)$.

Now, for $H \in h(n)$ let

$$D\Phi(A)(H) = T, \quad \text{where } T \in b(n). \tag{27}$$

Then since $\Phi = \Psi^{-1}$, we must have

$$R^*T + T^*R = H. \tag{28}$$

To estimate $|||D\Phi(A)|||$, we need to estimate T in terms of H and R. Rewrite (28) as

$$TR^{-1} + (TR^{-1})^* = (R^*)^{-1}HR^{-1}. \tag{29}$$

Since $TR^{-1} \in b(n)$, we have from (29)

$$||TR^{-1}||_F \leq \frac{1}{\sqrt{2}}||(R^*)^{-1}HR^{-1}||_F \leq \frac{1}{\sqrt{2}}||R^{-1}||^2||H||_F.$$

Since $||T||_F \leq ||TR^{-1}||_F||R||$, this gives

$$||T||_F \leq \frac{1}{\sqrt{2}}||R||\ ||R^{-1}||^2\ ||H||_F. \tag{30}$$

From (27) and (30), we get

$$||D\Phi(A)||_F \leq \frac{1}{\sqrt{2}}||R||\ ||R^{-1}||^2 = \frac{1}{\sqrt{2}}||A||^{1/2}\ ||A^{-1}||. \tag{31}$$

For the map Ψ, we could write from (26)

$$|||D\Psi(R)||| = \sup_{|||T|||=1} |||R^*T + T^*R||| \leq 2||R||, \tag{32}$$

for every unitarily invariant norm.

Inequalities (31) and (32) can be used to write perturbation bounds for Φ and Ψ as before.

Finally, we remark that from results of §§2 and 3, we can obtain some information about the variation of the positive part P in the polar decomposition and the upper triangular part R in the QR decomposition.

Note. In a sequel to this paper [4], the above analysis has been carried further to obtain perturbation bounds for several other matrix decompositions.

AN UPPER BOUND FOR THE REAL PART OF NONMAXIMAL EIGENVALUES OF NONNEGATIVE IRREDUCIBLE MATRICES*

SHMUEL FRIEDLAND† AND LEONID GURVITS‡

Abstract. Let A be a nonnegative irreducible matrix. In this note an upper bound is given for the real part of an eigenvalue of A that is different from its spectral radius.

Key words. nonnegative matrices, nonmaximal eigenvalues

AMS subject classifications. A18, A42, A48

Introduction. Let $M_n(\mathbf{R})$ denote the algebra of $n \times n$ real valued matrices. Assume that $A = (a_{ij})_1^n \in M_n(\mathbf{R})$ is a nonnegative irreducible matrix. The Perron–Frobenius theorem yields that $\rho(A)$, the spectral radius of A, is an algebraically simple eigenvalue of A with the corresponding positive right and left eigenvectors

$$Au = \rho(A)u, \quad A^T v = \rho(A)v, \quad 0 < u, v \in \mathbf{R}^n. \tag{1}$$

Arrange the eigenvalues of A in the following order

$$\rho(A) = \lambda_n(A) > \Re(\lambda_{n-1}(A)) \geq \cdots \geq \Re(\lambda_1(A)). \tag{2}$$

A is called diagonally symmetric if there exists a diagonal matrix D with positive diagonal entries and a nonnegative irreducible symmetric C so that $A = D^{-1}C$. Note that if A is diagonally symmetric, then all the eigenvalues of A are real and A is diagonable. The results of [Fri, §4] yield that any nonnegative irreducible diagonally symmetric matrix A satisfies

$$\rho(A) - \lambda_{n-1}(A) \geq \frac{1}{2}(\rho(A) - \max_{1 \leq i \leq n} a_{ii})\epsilon(A, u, v)^2. \tag{3}$$

Here

$$\begin{aligned} \epsilon(A, u, v) &= \inf_{\emptyset \neq U \subset \{1,\ldots,n\}, \operatorname{card}(U) \leq \lfloor \frac{n}{2} \rfloor} \frac{\sum_{i \in U, j \in \{1,\ldots,n\} \setminus U} a_{ij} v_i u_j + a_{ji} v_j u_i}{\sum_{i \in U} 2(\rho(A) - a_{ii}) v_i u_i} \\ &= \inf_{\emptyset \neq U \subset \{1,\ldots,n\}, \operatorname{card}(U) \leq \lfloor \frac{n}{2} \rfloor} \frac{\sum_{i \in U, j \in \{1,\ldots,n\} \setminus U} a_{ij} v_i u_j + a_{ji} v_j u_i}{\sum_{i \in U, 1 \leq j = i \leq n} a_{ij} v_i u_j + a_{ji} v_j u_i}. \end{aligned} \tag{4}$$

The aim of this paper to prove the following extension of (3).

THEOREM. *Let $A = (a_{ij})_1^n$ be a nonnegative irreducible matrix with the positive right and left eigenvectors u and v, respectively, satisfying* (1). *Arrange the eigenvalues of A in the order* (2). *Let $\epsilon(A, u, v)$ be defined by* (4). *Then*

$$\rho(A) - \Re(\lambda_{n-1}(A)) \geq \frac{1}{2}(\rho(A) - \max_{1 \leq i \leq n} a_{ii})\epsilon(A, u, v)^2. \tag{5}$$

‡Robotics Research Laboratory, Courant Institute of Mathematical Sciences, New York University, New York, New York 10012. Current address, Learning Systems Dept., Siemens Corporation Research, Princeton, New Jersey 08540 (gurvits@scr.siemens.com).

Assume that A is an irreducible stochastic matrix. Then choose $u = e = (1, \dots, 1)^T$ and $v = \pi = (\pi_1, \dots, \pi_n)^T$ to be the stationary probability vector of the Markov chain corresponding to A. As $\rho(A) = 1$ we get (5) with

$$\epsilon(A, e, \pi) = \inf_{\emptyset \neq U \subset \{1,\dots,n\}, \operatorname{card}(U) \leq \lfloor \frac{n}{2} \rfloor} \frac{\sum_{i \in U, j \in \{1,\dots,n\} \setminus U} a_{ij}\pi_i + a_{ji}\pi_j}{\sum_{i \in U} 2(1 - a_{ii})\pi_i}. \tag{6}$$

Let A be an irreducible permutation matrix, i.e., A has one cycle. Hence, the n eigenvalues of A are the nth roots of unity. In particular, $\Re(\lambda_{n-1}(A)) = \cos \frac{2\pi}{n}$. Note that A is orthogonal and hence a normal matrix. In this case we let $u = v = e$. A straightforward computation shows that $\epsilon(A, e, e) = \frac{1}{n-1}$. Hence the inequality (5) in this case reduces to

$$1 - \cos \frac{2\pi}{n} \geq \frac{1}{2(n-1)^2}, \qquad n \geq 2.$$

In the case where a stochastic matrix A corresponds to a time reversible Markov chain, i.e., A is diagonably symmetric, the inequality (5) is due to Sinclair and Jerrum [S-J, Lemma 3.3].

Proof of the Theorem. Let $D = \operatorname{diag}(d_1, \dots, d_n)$ be a diagonal matrix with positive diagonal entries. Set $\hat{A} = DAD^{-1} = (d_i a_{ij} d_j^{-1})_1^n$. As A and $\hat{A}$ are similar A and $\hat{A}$ have the same spectrum. We next note that

$$\hat{A}\hat{u} = \rho(A)\hat{u}, \quad \hat{A}^T\hat{v} = \rho(A)\hat{v}, \quad \hat{u} = Du, \quad \hat{v} = D^{-1}v.$$

It now follows that $\epsilon(A, u, v) = \epsilon(\hat{A}, \hat{u}, \hat{v})$. Thus, it suffices to prove (5) for $\hat{A}$. Choose the unique D with positive diagonal entries so that $\hat{u} = \hat{v} = w$. Hence, without loss of generality, we may assume that $Aw = A^T w = \rho(A)w$, $w > 0$. Set $B = (A + A^T)/2 = (b_{ij})_1^n$, $b_{ii} = a_{ii}$, $i = 1, \dots, n$. Thus, B is a nonnegative irreducible symmetric matrix. As w is a positive eigenvector of B, we deduce that $\rho(B) = \rho(A)$. Furthermore, it is straightforward to check that $\epsilon(B, w, w) = \epsilon(A, w, w)$. Theorem 4.5 in [Fri] states that

$$\rho(B) - \lambda_{n-1}(B) \geq \frac{1}{2}(\rho(B) - \max_{1 \leq i \leq n} b_{ii})\chi(B, w)^2,$$

where

$$\chi(B, w) = \inf_{\emptyset \neq U \subset \{1,\dots,n\}, \operatorname{card}(U) \leq \lfloor \frac{n}{2} \rfloor} \frac{\sum_{i \in U, j \in \{1,\dots,n\} \setminus U} b_{ij} w_i w_j}{\sum_{i \in U, 1 \leq j = i \leq n} b_{ij} w_i w_j}.$$

As $Bw = \rho(B)w$ and B is symmetric, it is straightforward to show that $\chi(B, w) = \epsilon(B, w, w)$. Thus, to prove (5) it suffices to show that

$$\lambda_{n-1}(B) \geq \Re(\lambda_{n-1}(A)). \tag{7}$$

Let $w^\perp$ be the orthogonal complement of $\operatorname{span}(w)$ in $\mathbf{R}^n$. Thus, $Aw^\perp, A^T w^\perp, Bw^\perp \subset w^\perp$. Choose an orthonormal basis of $\mathbf{R}$ of the form $w_1 = w/\sqrt{w^T w}, w_2, \dots, w_n$. That is $w_2, \dots, w_n$ is an orthonormal basis of $w^\perp$. In the new basis $w_1, \dots, w_n$ the matrices A, B are represented by the matrices $(\rho(A)) \oplus A_1, (\rho(A)) \oplus B_1$ such that the following equalities hold:

$$A_1, B_1 \in M_{n-1}(\mathbf{R}), \quad B_1 = \frac{A_1 + A_1^T}{2}, \quad \lambda_j(A_1) = \lambda_j(A), \quad \lambda_j(B_1) = \lambda_j(B), \quad j = 1, \dots, n-1.$$

Recall that $\nu(A_1) = \{z = x^*A_1x : x \in \mathbf{C}^{n-1}, x^*x = 1\}$ is the numerical range of A_1. It is well known that $\nu(A_1)$ contains all the eigenvalues of A_1. As $\Re(x^*A_1x) = x^*B_1x$ we deduce that $\Re(\nu(A_1)) = \nu(B_1)$. Since B_1 is a real symmetric matrix its numerical range is $[\lambda_1(B_1), \lambda_{n-1}(B_1)]$. In particular, $\Re(\lambda_{n-1}(A_1)) \leq \lambda_{n-1}(B_1)$. The proof of the theorem is completed. □

BLOCK DOWNDATING OF LEAST SQUARES SOLUTIONS*

L. ELDÉN† AND H. PARK‡

Abstract. This paper introduces new algorithms that extend the LINPACK downdating algorithm for a single row downdating, to downdating of a block of rows in an efficient way. The method of the corrected seminormal equations is then applied to the LINPACK-type block downdating algorithm to produce accurate downdated solutions. A sensitivity analysis of the Cholesky block downdating problem is presented. Based on this analysis, a hybrid algorithm is developed that has the advantages of the lower computational cost of the LINPACK-type algorithm and the higher accuracy of the corrected seminormal equation (CSNE) block downdating algorithm. Numerical test results comparing the accuracy of these three new block downdating algorithms for the recursive least squares sliding window method are presented.

AMS subject classifications. 65F20, 65F25

1. Introduction.

In linear least squares problems, we need to solve

$$\min_w \|Xw - s\|_2, \quad X \in \mathbf{R}^{p\times n}, \quad p > n. \tag{1.1}$$

If $\operatorname{rank}(X) = n$ and the QR decomposition of the data matrix $(X\ s)$ is

$$Q^T(X\ s) = \begin{pmatrix} R & u \\ 0 & \rho \\ 0 & 0 \end{pmatrix} \in \mathbf{R}^{p\times(n+1)}, \tag{1.2}$$

where $Q \in \mathbf{R}^{p\times p}$ is orthogonal, then the least squares solution w is obtained from

$$Rw = u, \tag{1.3}$$

and the residual vector r and its norm satisfy

$$r = s - Xw, \qquad \|r\|_2 = |\rho|.$$

Frequently, one knows the factorization in (1.2) and wishes to find the solution to a modified problem

$$\min_w \|\tilde{X}w - \tilde{s}\|_2,$$

where a block of k new observations $(Y\ y) \in \mathbf{R}^{k\times(n+1)}$ is added (*block updating*):

$$\tilde{X} = \begin{pmatrix} X \\ Y \end{pmatrix}, \qquad \tilde{s} = \begin{pmatrix} s \\ y \end{pmatrix},$$

or a block of k old observations $(Z\ z) \in \mathbf{R}^{k\times(n+1)}$ is removed (*block downdating*):

$$X = \begin{pmatrix} Z \\ \tilde{X} \end{pmatrix}, \qquad s = \begin{pmatrix} z \\ \tilde{s} \end{pmatrix}.$$

Throughout this paper, we assume that the data matrices have full rank, i.e.,

$$\operatorname{rank}(X) = \operatorname{rank}(\tilde{X}) = n.$$

Often the modified problem involves both an updating and a downdating. From (1.3) we see that the solution to the modified problem can be obtained by modifying the R factor of the corresponding augmented matrix $(\tilde{X}\ \tilde{s})$. If R and $\tilde{R}$ are the R factors of X and $\tilde{X}$, respectively, then for updating we have

$$\tilde{R}^T\tilde{R} = R^TR + Y^TY$$

and for downdating

$$\tilde{R}^T\tilde{R} = R^TR - Z^TZ.$$

The case when $k = 1$ has been considered in several papers. For information concerning updating, see [13, p. 596]. Downdating for $k = 1$ has been studied, e.g., in [1], [4], [7], [10], [12], [15], [19]. Downdating a block using a variation of the Householder transformation is treated in [5], [6], [16].

In this paper we consider the downdating problem when $k > 1$, which we refer to as *block downdating*. The *block updating* problem is easy in the sense that a backward stable algorithm can be obtained by a straightforward generalization of the algorithm for the case $k = 1$ [16].

The LINPACK downdating algorithm due to Saunders [17] has been analyzed in [19]. A generalization of the LINPACK algorithm to block downdating can be found in [18]. Recently we developed accurate downdating methods for $k = 1$ based on the LINPACK algorithm combined with iterative refinement [4]. In this paper, we introduce generalizations of these methods for block downdating and compare their accuracies and computational complexities. In §2, we discuss some properties of the block downdating problem. In §3, we analyze the sensitivity of the Cholesky block downdating problem. Then we present two algorithms generalizing the LINPACK and CSNE algorithms for single row downdating [4], to handle block downdating in §§4 and 5, respectively. As in the case when only one row is downdated, it is possible to compromise between the LINPACK algorithm that is faster but less accurate when the downdating is ill conditioned, and the CSNE algorithm that has a higher computational complexity but better stability properties. Thus a hybrid method, which is an intermediary between the LINPACK-type algorithm and the CSNE algorithm with some significant virtues of both, is described in §6. Finally in §7, some numerical experiments are presented that show that the hybrid algorithm produces far more accurate solutions than the LINPACK-type algorithm when the problem is ill conditioned, with a modest increase in computational complexity.

2. Block downdating. Assume that the matrix $(X\ \ s) \in \mathbf{R}^{p\times(n+1)}$ has the QR decomposition

$$(X\ \ s) = \begin{pmatrix} Z & z \\ \tilde{X} & \tilde{s} \end{pmatrix} = Q \begin{pmatrix} R & u \\ 0 & \rho \\ 0 & 0 \end{pmatrix}, \tag{2.1}$$

where $(\,Z \quad z\,) \in \mathbf{R}^{k\times(n+1)}$ is the block of k rows to be deleted and

$$p \geq k+n, \qquad n > k.$$

We first show that removing the block $(\,Z \quad z\,)$ is equivalent to updating the QR factorization of

$$(\,E_k \quad X \quad s\,) = \begin{pmatrix} I_k & Z & z \\ 0 & \tilde{X} & \tilde{s} \end{pmatrix},$$

where $E_k = \begin{pmatrix} I_k \\ 0 \end{pmatrix}$ and I_k is the $k \times k$ identity matrix. From (2.1), it follows that

$$Q^T(\,E_k \quad X \quad s\,) = \begin{pmatrix} Q_1 & R & u \\ q^T & 0 & \rho \\ Q_2 & 0 & 0 \end{pmatrix},$$

where $(Q_1^T \; q \; Q_2^T) \in \mathbf{R}^{k\times p}$ denotes the first k rows of Q. We can now determine an orthogonal matrix U that makes $Q^T(\,E_k \quad X \quad s\,)$ upper triangular, i.e.,

$$U^TQ^T(\,E_k \quad X \quad s\,) = U^T\begin{pmatrix} Q_1 & R & u \\ q^T & 0 & \rho \\ Q_2 & 0 & 0 \end{pmatrix} = \begin{pmatrix} I_k & V & f \\ 0 & \tilde{R} & \tilde{u} \\ 0 & 0 & \tilde{\rho} \\ 0 & 0 & 0 \end{pmatrix}, \tag{2.2}$$

for some $V \in \mathbf{R}^{k\times n}$ and $f \in \mathbf{R}^{k\times 1}$. Then we have

$$\hat{Q}^T\begin{pmatrix} I_k & Z & z \\ 0 & \tilde{X} & \tilde{s} \end{pmatrix} = \begin{pmatrix} I_k & V & f \\ 0 & \tilde{R} & \tilde{u} \\ 0 & 0 & \tilde{\rho} \\ 0 & 0 & 0 \end{pmatrix}, \tag{2.3}$$

where $\hat{Q} = QU$. Equating the first k columns on both sides of (2.3), we obtain $\hat{Q}^TE_k = E_k$, so the first k rows in $\hat{Q}$ are equal to those of E_k^T. Hence, $\hat{Q}$ must have the form

$$\begin{pmatrix} I_k & 0 \\ 0 & \tilde{Q} \end{pmatrix},$$

and it follows that $(V \; f) = (Z \; z)$. Dropping the first k rows and columns from (2.3) gives the downdated QR decomposition

$$(\,\tilde{X} \; \tilde{s}\,) = \tilde{Q}\begin{pmatrix} \tilde{R} & \tilde{u} \\ 0 & \tilde{\rho} \\ 0 & 0 \end{pmatrix}.$$

The new algorithms described in this paper are based on the above derivation. An important fact in *downdating the QR decomposition* is that the downdating transformation U is determined based on the first k rows of the square orthogonal factor Q. Thus, the first k rows $(\,Q_1^T \quad q \quad Q_2^T\,)$ of Q must be known or recovered to determine the downdating transformation U in (2.2). We consider only the case when the full orthogonal matrix Q is not available.

3. Sensitivity of the Cholesky block downdating problem. The sensitivity of the Cholesky downdating problem has been treated previously in [19], [14] for the case of a single row downdating ($k = 1$). We now discuss the sensitivity of the Cholesky block downdating problem to perturbations, with the purpose of motivating the hybrid algorithm that we present in §6. A more detailed investigation of sensitivity analysis is presented in [9]. The problem is formulated as that of downdating a Cholesky decomposition

$$\tilde{R}^T\tilde{R} = R^TR - Z^TZ, \tag{3.1}$$

and we first consider perturbations of the type

$$\bar{R}^T\bar{R} = (R+E)^T(R+E) - Z^TZ,$$

where E is the perturbation matrix, satisfying $||E||_2 \leq \epsilon$.

LEMMA 3.1. *Assume that $R^TR - Z^TZ$ is positive definite, and thus the Cholesky decomposition*

$$\tilde{R}^T\tilde{R} = R^TR - Z^TZ$$

exists. Then there is a matrix $\tilde{C} \in \mathbf{R}^{n\times n}$, such that

$$\tilde{R}^T\tilde{R} = R^TR - Z^TZ = R^T\tilde{C}^T\tilde{C}R, \tag{3.2}$$

where the singular values, $\sigma_i(\tilde{C})$, $1 \leq i \leq n$, of $\tilde{C}$ satisfy

$$\begin{aligned}\sigma_i(\tilde{C}) &= 1, \qquad i = 1,\ldots,n-k,\\ 1 \geq \sigma_{n-k+1}(\tilde{C}) &\geq \sigma_{n-k+2}(\tilde{C}) \geq \cdots \geq \sigma_n(\tilde{C}) > 0.\end{aligned}$$

Proof. We have

$$\tilde{R}^T\tilde{R} = R^T(I - Q_1Q_1^T)R,$$

where $Q_1 = R^{-T}Z^T \in \mathbf{R}^{n\times k}$. Since $\tilde{R}^T\tilde{R}$ is assumed to be positive definite, the same must be true of $I - Q_1Q_1^T$ and $\tilde{C}$ can be taken as the Cholesky factor of $I - Q_1Q_1^T$. Since $\tilde{C}^T\tilde{C}$ is a perturbation of the identity matrix of rank at most k, it has at least $n-k$ eigenvalues equal to one and the remaining eigenvalues are one minus the nonzero eigenvalues of $Q_1Q_1^T$. Since the eigenvalues of $Q_1Q_1^T$ are nonnegative, the corresponding eigenvalues of $\tilde{C}$ must lie in the half open interval $(0, 1]$. □

We can now prove a perturbation theorem for the Cholesky block downdating problem.

THEOREM 3.2. *Assume that $R^TR - Z^TZ$ is positive definite, and thus that the Cholesky decomposition $\tilde{R}^T\tilde{R} = R^TR - Z^TZ$ exists. Further assume that for a perturbation matrix E, satisfying $||E||_2 \leq \epsilon$, the Cholesky decomposition*

$$\bar{R}^T\bar{R} = (R+E)^T(R+E) - Z^TZ,$$

exists. Then there is a matrix $\bar{C} \in \mathbf{R}^{n\times n}$, such that

$$\bar{R}^T\bar{R} = R^T\bar{C}^T\bar{C}R,$$

and the eigenvalues of $\bar{C}^T\bar{C}$ satisfy

$$\lambda_i(\bar{C}^T\bar{C}) = \sigma_i^2(\tilde{C}) + \eta_i, \qquad i = 1,\ldots,n,$$

where $\sigma_i(\tilde{C})$ are the singular values of the matrix $\tilde{C}$ defined in (3.2), *the η_i are bounded by*

$$|\eta_i| \le \epsilon \left(\frac{2}{\sigma_n(R)} + \frac{\epsilon}{\sigma_n^2(R)} \right), \qquad i = 1, \ldots, n, \tag{3.3}$$

and $\sigma_n(R)$ is the smallest singular value of R.

Proof. We have

$$\bar{R}^T \bar{R} = (R+E)^T (R+E) - Z^T Z = \tilde{R}^T \tilde{R} + R^T (F^T + F + F^T F) R,$$

where $F = ER^{-1}$. From Lemma 3.1, we have $\tilde{R}^T \tilde{R} = R^T \tilde{C}^T \tilde{C} R$, for some matrix $\tilde{C}$, and $\bar{R}^T \bar{R} = R^T \bar{C}^T \bar{C} R$, where

$$\bar{C}^T \bar{C} = \tilde{C}^T \tilde{C} + F^T + F + F^T F.$$

Using classical perturbation theory for eigenvalues of symmetric matrices [13, p. 411], we get

$$|\lambda_i(\bar{C}^T \bar{C}) - \sigma_i^2(\tilde{C})| \le 2||F||_2 + ||F||_2^2 \le 2\epsilon ||R^{-1}||_2 + \epsilon^2 ||R^{-1}||_2^2.$$

Since $||R^{-1}||_2 = \sigma_n^{-1}$, (3.3) follows. □

The same inequality (3.3) can be obtained for a perturbation in Z using the technique of the above proof and the relations $Q_1 = R^{-T} Z^T$ and $||Q_1||_2 \le 1$; see [9].

The theorem shows the importance of the magnitude of the singular values $\sigma_i(\tilde{C})$, and it implies that $\bar{C}$ and $\tilde{C}$ can deviate in norm by a large amount. This can be seen as follows. Since, for nonnegative x and y, the inequality $x|x-y| \le |x+y||x-y|$ holds, we get from (3.3),

$$|\sigma_i(\bar{C}) - \sigma_i(\tilde{C})| \le \frac{\epsilon}{\sigma_i(\tilde{C})} \left(\frac{2}{\sigma_n} + \frac{\epsilon}{\sigma_n^2} \right).$$

Therefore, since $||\bar{C} - \tilde{C}||_2 \ge \max |\sigma_i(\bar{C}) - \sigma_i(\tilde{C})|$, we see that $||\bar{C} - \tilde{C}||$ can be as large as $\epsilon/\sigma_n(\tilde{C})(2/\sigma_n(R) + \epsilon/\sigma_n^2(R))$. Furthermore, if $\sigma_n(\tilde{C}) \le \sqrt{2/\sigma_n(R) + \epsilon/\sigma_n^2(R)}$, then we can expect that $\sigma_n(\bar{C})$ and $\sigma_n(\tilde{C})$ do not agree to any significant figures.

It is seen that we can take

$$\kappa_{\text{down}} = \max_i \{\sigma_i^{-2}(\tilde{C})\} = 1/\sigma_n^2(\tilde{C}), \tag{3.4}$$

as a measure of the conditioning of the block downdating problem. This is a generalization of the results by Stewart for a single row downdating [19].

The arguments in [19] that we referred to above are concerned with the singular values of $\tilde{R}$ (and not $\tilde{C}$) for the special case of a single row downdating ($k = 1$). It is shown in [19] that if *any* singular value of R is reduced (to a singular value of $\tilde{R}$) by a considerable amount, then the downdating problem is ill conditioned. Therefore, to ascertain the downdating conditioning, all of the singular values of R and $\tilde{R}$ must be examined, and it is inefficient to numerically estimate the conditioning this way.

In contrast, the singular values of $\tilde{C}$ give clear information about the reduction of quantities from R to $\tilde{R}$, i.e., a small $\sigma_i(\tilde{C})$ represents a quantity that has been reduced from one in R, and thus it signals that the downdating problem is ill conditioned. Later, in §6 we demonstrate how downdating condition estimation based on κ_{down} can be implemented efficiently.

If κ_{down} is large, then the downdating problem is ill conditioned. Also, if the condition number of R is large, then the computation of the matrix Q_1 via $R^{-T}Z^T$ is sensitive to errors, and so is the downdating problem. In (3.3), $\sigma_n(R)$ appears in the denominator, and if $\sigma_n(R)$ is small, then the bound in (3.3) for $|\eta_i|$ is large. However, the following example shows that the downdating problem can be ill conditioned, even if $\sigma_n(R)$ is not small.

Example. Let

$$X = \begin{pmatrix} \tau & 0 & 0 \\ 0 & \tau & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

where $\tau >> 1$, and let Z consist of the first two rows of X. Then

$$R = \begin{pmatrix} \sqrt{\tau^2+1} & 0 & 0 \\ 0 & \sqrt{\tau^2+1} & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

and $\sigma_3 = 1$. From

$$Q_1 = \begin{pmatrix} \tau/\sqrt{\tau^2+1} & 0 \\ 0 & \tau/\sqrt{\tau^2+1} \\ 0 & 0 \end{pmatrix},$$

it follows that $c_1 = 1$, $c_2 = c_3 = 1/\sqrt{\tau^2+1}$, and $\kappa_{\text{down}} = \tau^2 + 1$, which indicates that this downdating problem is ill conditioned. In fact, downdating from R to $\tilde{R}$ is here equivalent to computing the diagonal elements in $\tilde{R}$ from the formula

$$\tilde{r} = \sqrt{r^2 - \tau^2}, \qquad r^2 = \tau^2 + 1.$$

Consider the perturbed problem

$$\bar{r} = \sqrt{(r+e)^2 - \tau^2}, \quad |e| \le \epsilon,$$

where ϵ is small. A simple computation shows that

$$\bar{r} \approx \tilde{r}\left(1 + \frac{r}{\tilde{r}^2}\, e\right) \approx \tilde{r}(1 + \tau e),$$

which shows that the problem is ill conditioned. If $\tau > 1/\sqrt{\mu}$, where μ is the unit round-off of the floating point system, then the downdating will fail completely, since $\tilde{R}$ will be computed as

$$\begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

where all information from the first two rows of $\tilde{X}$ is lost.

For the case $k = 1$ we have $\kappa_{\text{down}} = 1/\sigma_1(\tilde{C})^2$, which is the same as $1/(1 - ||q_1||_2^2)$, where q_1 is the vector consisting of the first n elements of the first row of the orthogonal matrix Q, see §2. This is essentially the quantity discussed in [19] and [4] as an indicator of ill-conditioning for the downdating problem in the special case $k = 1$.

4. Generalization of the LINPACK algorithm. In §2, we showed that to downdate the first k rows of the data matrix, we need the first k rows, $(\,Q_1^T \quad q \quad Q_2^T\,) \in \mathbf{R}^{k\times p}$, of the orthogonal matrix Q. From (2.1), we have

$$(\,Z \quad z\,) = (\,Q_1^T \quad q \quad Q_2^T\,)\begin{pmatrix} R & u \\ 0 & \rho \\ 0 & 0 \end{pmatrix} = (\,Q_1^T \quad q\,)\begin{pmatrix} R & u \\ 0 & \rho \end{pmatrix}.$$

It follows that Q_1 and q can be computed by solving the triangular system

$$\begin{pmatrix} R^T & 0 \\ u^T & \rho \end{pmatrix}\begin{pmatrix} Q_1 \\ q^T \end{pmatrix} = \begin{pmatrix} Z^T \\ z^T \end{pmatrix},$$

which gives $Q_1 = R^{-T}Z^T$. Using the relation $u^TQ_1 = u^TR^{-T}Z^T = w^TZ^T$, where w is the solution of the least squares problem (1.1), we obtain

$$q = (z - Zw)/\rho, \qquad (\rho \neq 0). \tag{4.1}$$

If $\rho = 0$ then q cannot be computed from (4.1). However, it is seen below that the computations can be arranged so that the assumption $\rho \neq 0$ is not needed.

Now we need to determine a matrix Q_2 that satisfies

$$Q_1^TQ_1 + qq^T + Q_2^TQ_2 = I_k. \tag{4.2}$$

The orthogonal transformation U in (2.2) can be chosen in such a way that Q_2 is first reduced to upper triangular form without changing R, u, or ρ. Therefore *it is sufficient to determine an upper triangular matrix* $\bar{\Gamma} \in \mathbf{R}^{k\times k}$ *that satisfies*

$$Q_1^TQ_1 + qq^T + \bar{\Gamma}^T\bar{\Gamma} = I_k.$$

This can be done simply by computing a Cholesky decomposition

$$\bar{\Gamma} = \mathrm{chol}(I_k - Q_1^TQ_1 - qq^T),$$

where $\bar{\Gamma}$ is upper triangular and $\bar{\Gamma}^T\bar{\Gamma} = I_k - Q_1^TQ_1 - qq^T$. Next we determine a product of plane rotations U such that

$$U^T\begin{pmatrix} Q_1 & R & u \\ q^T & 0 & \rho \\ \bar{\Gamma} & 0 & 0 \end{pmatrix} = \begin{pmatrix} I_k & Z & z \\ 0 & \tilde{R} & \tilde{u} \\ 0 & 0 & \tilde{\rho} \end{pmatrix}. \tag{4.3}$$

We can initially choose an orthogonal matrix J that affects only rows from $(n+1)$ to $(n+k+1)$ of (4.3)

$$J\begin{pmatrix} q^T & \rho \\ \bar{\Gamma} & 0 \end{pmatrix} = \begin{pmatrix} \Gamma & h \\ 0 & \tilde{\rho} \end{pmatrix}, \tag{4.4}$$

where $\Gamma \in \mathbf{R}^{k\times k}$ is upper triangular. Then, since $\Gamma^T\Gamma = qq^T + \bar{\Gamma}^T\bar{\Gamma}$, we can obtain the upper triangular matrix Γ from

$$\Gamma = \mathrm{chol}(I_k - Q_1^TQ_1). \tag{4.5}$$

From (4.1) and (4.4), we obtain

$$h = \Gamma^{-T}(z - Q_1^Tu), \qquad \tilde{\rho} = (\rho^2 - h^Th)^{1/2}. \tag{4.6}$$

Note that q in (4.1) is not used, so the assumption that $\rho \neq 0$ is not needed. If $I_k - Q_1^T Q_1$ is not positive definite, then the downdating procedure would break down. This is equivalent to the case when $\tilde{X}^T \tilde{X}$ is not positive definite. Consider the Cholesky downdating problem

$$\tilde{R}^T \tilde{R} = R^T R - Z^T Z = R^T (I_n - Q_1 Q_1^T) R,$$

where $Q_1 = R^{-T} Z^T$. The matrix $\tilde{R}^T \tilde{R}$ is positive definite if and only if all the eigenvalues of $I_n - Q_1 Q_1^T$ are positive, in which case all the eigenvalues of $I_k - Q_1^T Q_1$ are also positive (the former matrix has additional $n - k$ eigenvalues that are equal to one). Since we have assumed that $\operatorname{rank}(\tilde{X}) = n$, $I_k - Q_1^T Q_1$ is positive definite and Γ is nonsingular. Thus, under the assumption that $\operatorname{rank}(\tilde{X}) = n$ the algorithm is well defined. Summarizing these results we get the following algorithm.

ALGORITHM BDLIN: LINPACK-type algorithm for block downdating

Given R, u, ρ, w, and $(Z \;\; z)$, the following algorithm computes the downdated quantities $\tilde{R}, \tilde{u}, \tilde{\rho}$ and $\tilde{w}$:

1. (a) Compute Q_1 and Γ from

$$R^T Q_1 = Z^T, \qquad \Gamma := chol(I_k - Q_1^T Q_1).$$

   (b) Compute h from

$$\Gamma^T h = (z - Q_1^T u).$$

2. Apply a product of Givens rotations, $\hat{U}$, such that

$$\begin{pmatrix} I_k & Z & z \\ 0 & \tilde{R} & \tilde{u} \end{pmatrix} := \hat{U}^T \begin{pmatrix} Q_1 & R & u \\ \Gamma & 0 & h \end{pmatrix}.$$

3. Compute the new solution $\tilde{w}$ and the residual norm from

$$\tilde{R}\tilde{w} = \tilde{u}, \qquad \tilde{\rho} := (\rho^2 - h^T h)^{1/2}.$$

In Step 2, we assume that the sequence of Givens rotations in the adjacent planes is generated in the order of annihilating the elements $(n+1,1), (n,1), \ldots, (2,1), (n+2,2), (n+1,2), \ldots, (3,2)$, etc., of $\binom{Q_1}{\Gamma}$. Assuming that $k < n$, this algorithm takes the total of approximately $2.5n^2k$ flops (one flop is taken to be one multiplication and one addition). For $k = 1$, the Saunders LINPACK algorithm requires $3n^2$ flops; thus applying it k times for downdating k rows would require about $3n^2k$ flops. However, by a simple modification of the Saunders LINPACK algorithm for the $k = 1$ case, we can avoid solving a triangular system each time and reduce the complexity of single row downdating to $2.5n^2$. With this modification, the above algorithm has about the same computational complexity as applying LINPACK algorithm for a single row downdating k times.

5. Block downdating using seminormal equations. As in the case of $k = 1$ [4], we can improve the accuracy of the solution vector for the downdated least squares problem by applying the method of CSNE. The seminormal equations (SNE) for solving a least squares problem $\min_w \|Xw - s\|_2$ are defined as

$$R^T R w = X^T s,$$

where R is the upper triangular factor in the QR decomposition of X, which we denote as

$$R = qr(X).$$

Applying one step of iterative refinement on the solution computed from the SNE, we have the method of CSNE

$$\begin{aligned} R^T R w &= X^T s, \qquad r = s - Xw, \\ R^T R \delta w &= X^T r, \quad w^c = w + \delta w, \quad r^c = r - X\delta w. \end{aligned} \tag{5.1}$$

We assume that *all computations* are performed in *single precision.* For details, see [3].

The following theorem shows how the CSNE method can be used to recover the rows in the orthogonal matrix Q more accurately based on which the downdating transformation is determined.

THEOREM 5.1. *Let V be the solution to*

$$\min_V \|E_k - XV\|_F, \qquad E_k = \begin{pmatrix} I_k \\ 0 \end{pmatrix}. \tag{5.2}$$

Then the R factor of $(X\ E_k)$ is

$$\begin{pmatrix} R & Q_1 \\ 0 & \Gamma \end{pmatrix}, \tag{5.3}$$

where the upper triangular matrix $\Gamma \in \mathbf{R}^{k\times k}$ is the same as the upper triangular factor of $qr(E_k - XV)$. The matrix V satisfies the equation $Q_1 = RV$.

Applying the CSNE method to (5.2), we obtain

$$R^T Q_1 = Z^T, \quad RV = Q_1, \quad T = E_k - XV, \tag{5.4}$$

$$R^T \delta Q_1 = X^T T, \qquad Q_1^c = Q_1 + \delta Q_1, \tag{5.5}$$

$$R\delta V = \delta Q_1, \qquad T^c = T - X\delta V \tag{5.6}$$

and more accurate Γ (5.3) can be computed as the R factor in the QR decomposition of T^c. We can also apply the CSNE method to downdate the *augmented* upper triangular factor for solving the least squares problem

$$\min_{Y,f} \|E_k - (X\ s)\begin{pmatrix} Y \\ f^T \end{pmatrix}\|_F. \tag{5.7}$$

In this case, we have

$$\begin{pmatrix} R & u & Q_1 \\ 0 & \rho & q^T \\ 0 & 0 & \bar{\Gamma} \end{pmatrix} = qr((X \quad s \quad E_k)), \tag{5.8}$$

where $u \in \mathbf{R}^{n\times 1}$, $\rho \in \mathbf{R}$, $q \in \mathbf{R}^{k\times 1}$, and $\bar{\Gamma} \in \mathbf{R}^{k\times k}$. First, from (5.7) and (5.8), we obtain

$$\begin{pmatrix} R^T & 0 \\ u^T & \rho \end{pmatrix}\begin{pmatrix} Q_1 \\ q^T \end{pmatrix} = \begin{pmatrix} Z^T \\ z^T \end{pmatrix},$$

which gives

$$Q_1 = R^{-T}Z^T, \qquad q = (z - Q_1^T u)/\rho = (z - Zw)/\rho \tag{5.9}$$

with the assumption that $\rho \neq 0$. This assumption is eliminated in the following. Next we solve

$$\begin{pmatrix} R & u \\ 0 & \rho \end{pmatrix} \begin{pmatrix} Y \\ f^T \end{pmatrix} = \begin{pmatrix} Q_1 \\ q^T \end{pmatrix},$$

which gives

$$f = q/\rho, \qquad Y = R^{-1}(Q_1 - uf^T) = V - wf^T.$$

The residual matrix T_a for the augmented problem (5.7) is

$$T_a = E_k - (X\ s)\begin{pmatrix} Y \\ f^T \end{pmatrix} = E_k - XV - (s - Xw)q^T/\rho = T - (s - Xw)q^T/\rho$$

and

$$\bar{\Gamma} = qr(T_a).$$

The equation

$$\begin{pmatrix} R^T & 0 \\ u^T & \rho \end{pmatrix} \begin{pmatrix} \delta Q_{1a} \\ \delta q^T \end{pmatrix} = \begin{pmatrix} X^T \\ s^T \end{pmatrix} T_a \tag{5.10}$$

is analogous to the first equation in (5.5). Since $X^T(s - Xw) = 0$, we have $X^T T_a = X^T T$, and therefore $\delta Q_{1a} = \delta Q_1$, where δQ_1 is defined by (5.5). From (5.10) we get

$$\delta q = T_a^T(s - Xw)/\rho.$$

Similarly, from

$$\begin{pmatrix} R & u \\ 0 & \rho \end{pmatrix} \begin{pmatrix} \delta Y \\ \delta f^T \end{pmatrix} = \begin{pmatrix} \delta Q_1 \\ \delta q^T \end{pmatrix},$$

which is analogous to the first equation in (5.6), we obtain

$$\delta f = \delta q/\rho, \quad \delta Y = \delta V - w\delta q^T/\rho, \quad T_a^c = T_a - X\delta V - (s - Xw)\delta q^T/\rho.$$

As in the generalization of the LINPACK algorithm for block downdating, we can choose an orthogonal matrix J to make $J\left(\begin{smallmatrix} q^T & \rho \\ \bar{\Gamma} & 0 \end{smallmatrix}\right)$ upper triangular, i.e.,

$$J\begin{pmatrix} q^T & \rho \\ \bar{\Gamma} & 0 \end{pmatrix} = \begin{pmatrix} \Gamma & h \\ 0 & \tilde{\rho} \end{pmatrix}, \tag{5.11}$$

which gives

$$h = \rho\Gamma^{-T}q, \qquad \tilde{\rho}^2 = \rho^2 - h^T h = \rho^2(1 - q^T\Gamma^{-1}\Gamma^{-T}q). \tag{5.12}$$

By applying the Sherman–Morrison formula [13] to

$$qq^T + \bar{\Gamma}^T\bar{\Gamma} = \Gamma^T\Gamma, \tag{5.13}$$

we have

$$q^T\Gamma^{-1}\Gamma^{-T}q = q^T\bar{\Gamma}^{-1}\bar{\Gamma}^{-T}q/(1+q^T\bar{\Gamma}^{-1}\bar{\Gamma}^{-T}q) \tag{5.14}$$

and

$$\tilde{\rho}^2 = \rho^2(1-q^T\Gamma^{-1}\Gamma^{-T}q) = \rho^2/(1+q^T\bar{\Gamma}^{-1}\bar{\Gamma}^{-T}q) = \rho^2||\Gamma^{-T}q||_2^2/||\bar{\Gamma}^{-T}q||_2^2. \tag{5.15}$$

We now summarize the above derivations in the following algorithm.

ALGORITHM BDCSNE: Block downdating using CSNE.

Given R, u, ρ, w, and the data $(X\ s)$ the following algorithm deletes the first k rows $(Z\ z)$ of $(X\ s)$ and computes the downdated quantities $\tilde{R}, \tilde{u}, \tilde{\rho}$ and $\tilde{w}$:

1. Compute Q_1, V, and T from

$$(a)\ R^TQ_1 = Z^T, \quad (b)\ RV = Q_1, \quad (c)\ T := E_k - XV.$$

2. (a) Update Q_1, V, and T:

$$\begin{aligned} R^T\delta Q_1 &= X^TT, & Q_1 &:= Q_1 + \delta Q_1, \\ R\delta V &= \delta Q_1, & T &:= T - X\delta V. \end{aligned}$$

(b) Compute a QR decomposition of T to determine Γ:

$$\Gamma = qr(T).$$

3. Set $h := 0$, $\tilde{\rho} := 0$
   $r = s - Xw$; $\rho = ||r||_2$
   If $fl(1+\rho) \neq 1$,
   (a) compute the normalized residual: $r := (s - Xw)/\rho$,
   (b) modify T: $q := E_k^Tr$, $T := T - rq^T$,
   (c) update q and T: $\delta q := T^Tr$, $q := q + \delta q$, $T := T - r\delta q^T$,
   (d) compute h from $\Gamma^Th = \rho q$,
   (e) compute $\bar{\Gamma} = qr(T)$,
   (f) determine y from $\bar{\Gamma}^Ty = q$, and compute $\tilde{\rho} = ||h||_2/||y||_2$.
4. Determine an orthogonal matrix U^T as a product of Givens rotations such that

$$\begin{pmatrix} I_k & Z & z \\ 0 & \tilde{R} & \tilde{u} \end{pmatrix} := U^T \begin{pmatrix} Q_1 & R & u \\ \Gamma & 0 & h \end{pmatrix}.$$

5. Compute the new solution $\tilde{w}$ from

$$\tilde{R}\tilde{w} = \tilde{u}.$$

Applying the CSNE algorithm for a single row downdating requires approximately $4pn + 4.5n^2$ flops [4]. Thus, if we downdate k rows by applying the CSNE algorithm for a single row downdating k times, the computational complexity becomes about $4kpn + 4.5kn^2$ flops. Assuming that $k < n$ and $n < p$, the above algorithm takes a total of approximately $(3k+1)pn + 4kn^2$ flops. This algorithm is rich in level 3 BLAS [8] operations: solution of triangular systems with k right-hand sides, matrix–matrix multiplications. Therefore, it should execute efficiently on vector and parallel computers.

6. A hybrid algorithm. For a single row downdating, the CSNE algorithm gives much better accuracy than the LINPACK algorithm when the downdating problem is ill conditioned [4], but the computational complexity of the CSNE algorithm is considerably higher than that of the LINPACK algorithm. We have recently developed a hybrid algorithm for a single row downdating [4], and have shown that it produces accurate solutions that are comparable to those of the CSNE algorithm with lower computational cost. In the hybrid algorithm, the CSNE algorithm is used if the downdating is ill conditioned and the LINPACK algorithm is used otherwise. Thus, the hybrid algorithm will be a competitive alternative if a good indication of the conditioning of the downdating problem is available so that the iterative refinement is used only when it is necessary. We now introduce a hybrid algorithm for block downdating that is a combination of the block LINPACK-type algorithm and the block CSNE algorithm we presented in the previous sections.

Before we develop the hybrid algorithm, we state the following two properties of the block downdating that are essential in our hybrid algorithm.

First, from the sensitivity analysis of the block downdating problem presented in §3, we know that if any of the singular values of $\tilde{C}$ is small, where $\tilde{C}$ is the Cholesky factor of $I - Q_1 Q_1^T$, then the downdating problem is ill conditioned. Since Γ, which is the Cholesky factor of $I - Q_1^T Q_1$, has the same singular values as $\tilde{C}$, apart from a number of singular values equal to one, we can determine the downdating conditioning by estimating the singular values of Γ.

Second, since we have

$$X = \begin{pmatrix} Z \\ \tilde{X} \end{pmatrix} = Q \begin{pmatrix} R \\ 0 \end{pmatrix}, \tag{6.1}$$

where $Z \in \mathbf{R}^{k \times n}$, applying a permutation on the first k rows of the matrices X and Q does not change the block downdating problem mathematically. In other words, the result of downdating a block of the first k rows is not affected by a permutation on these k rows. Thus, removing the block $(\, Z \quad z \,)$ is also equivalent to updating the QR decomposition of

$$(\, P_k \quad X \quad s \,) = \begin{pmatrix} \Pi_k & Z & z \\ 0 & \tilde{X} & \tilde{s} \end{pmatrix}, \qquad P_k = \begin{pmatrix} \Pi_k \\ 0 \end{pmatrix},$$

where $\Pi_k \in \mathbf{R}^{k \times k}$ is any permutation matrix. Then from (2.1), it follows that

$$Q^T (\, P_k \quad X \quad s \,) = \begin{pmatrix} Q_1 \Pi_k & R & u \\ q^T \Pi_k & 0 & \rho \\ Q_2 \Pi_k & 0 & 0 \end{pmatrix}.$$

Proceeding as in §2, we find an orthogonal downdating transformation that makes $Q^T (\, P_k \quad X \quad s \,)$ upper triangular.

In our hybrid algorithm, we incorporate a diagonal pivoting strategy when we compute the upper triangular matrix Γ as a Cholesky factor of $I_k - Q_1^T Q_1$ (see Step 1(a) in Algorithm BDLIN): in the first step of the Cholesky decomposition algorithm, we permute the rows and columns of $I_k - Q_1^T Q_1$ so that the largest diagonal element is moved to position (1,1), and similarly in the subsequent steps. This is mathematically (but not numerically) equivalent to computing the matrix R in the QR decomposition with column pivoting, see [13, §5.4]. By using diagonal pivoting, we permute and partition the block $(\, Z \quad z \,)$ into two parts so that we downdate the better conditioned

first block of rows by the less costly algorithm, and apply one step of the iterative refinement to the ill-conditioned block of the rest of the rows to improve the accuracy.

Specifically, assume that after i steps of the Cholesky decomposition procedure on $I_k - Q_1^T Q_1$, we have computed the partial decomposition

$$\Pi^{(i)^T} \cdots \Pi^{(1)^T} (I_k - Q_1^T Q_1) \Pi^{(1)} \cdots \Pi^{(i)} = \begin{pmatrix} \Gamma_{11}^{(i)} & \Gamma_{12}^{(i)} \\ 0 & \Gamma_{22}^{(i)} \end{pmatrix}^T \begin{pmatrix} \Gamma_{11}^{(i)} & \Gamma_{12}^{(i)} \\ 0 & \Gamma_{22}^{(i)} \end{pmatrix},$$

where $\Pi^{(i)}$'s are permutation matrices and $\Gamma_{11}^{(i)} \in \mathbf{R}^{i \times i}$ is upper triangular. The purpose of the pivoting is to find the maximal triangular matrix $\Gamma_{11}^{(i)}$ for which the corresponding block of rows of $(\, Z \quad z \,)$ constitute a well-conditioned downdating problem. We use the incremental condition estimator (ICE) [2] to get an estimate $\hat{\sigma}^{(i)}$ of the smallest singular value of $\Gamma_{11}^{(i)}$ in each step of the Cholesky procedure, and if $\hat{\sigma}^{(i)} > \text{tol}$ for some given tolerance "tol," we conclude that the downdating problem so far is well-conditioned enough to be handled using Algorithm BDLIN. The first time when $\hat{\sigma}^{(i)} > \text{tol}$ and $\hat{\sigma}^{(i+1)} < \text{tol}$, the downdating problem is partitioned into two blocks between rows i and $i+1$, and we apply Algorithm BDLIN to the block of first i rows after the permutation determined from the pivoting and Algorithm BDCSNE to the rest.

ALGORITHM BDHYB: Hybrid block downdating algorithm.

Given R, u, ρ, w, and $(X \; s)$, the following algorithm deletes the first k rows $(Z \; z)$ of $(X \; s)$ and computes the downdated quantities $\tilde{R}, \tilde{u}, \tilde{\rho}$ and $\tilde{w}$:

1. Compute Q_1 from

$$R^T Q_1 = Z^T.$$

2. Compute a Cholesky decomposition with diagonal pivoting of $I_k - Q_1^T Q_1$ until the last index i such that $\hat{\sigma}^{(i)}(\Gamma_{11}) > \text{tol}$ is found, where $\Gamma_{11} \in R^{i \times i}$, $1 \le i \le k$, and

$$\Pi_k^T (I_k - Q_1^T Q_1) \Pi_k = \begin{pmatrix} \Gamma_{11} & \bar{\Gamma}_{12} \\ 0 & \bar{\Gamma}_{22} \end{pmatrix}^T \begin{pmatrix} \Gamma_{11} & \bar{\Gamma}_{12} \\ 0 & \bar{\Gamma}_{22} \end{pmatrix}.$$

Permute the rows of X and s (including Z and z), and the columns of Q_1:

$$X(1:k,:) := \Pi_k^T X(1:k,:); \quad s(1:k) := \Pi_k^T s(1:k), \quad Q_1 := Q_1 \Pi_k$$

3. If $i = k$ (use LINPACK-type algorithm for the whole block),
   Perform Steps 1(b)–3 of Algorithm BDLIN
   else if $i = 0$ (use CSNE algorithm for the whole block),
   Perform Steps 1(b)–5 of Algorithm BDCSNE
   else
   (a) (Separate the data that are needed for downdating the first i rows of $(Z \; z)$.)

$$Q_1 := Q_1(:, 1:i), \quad \Gamma := \Gamma_{11}, \quad z := z(1:i).$$

   (b) (Downdate rows 1 to i of $(Z \; z)$)
   Perform Steps 1(b) – 3 of Algorithm BDLIN, giving downdated $\check{R}$, $\check{u}$, $\check{\rho}$, and $\check{w}$.

(c) (Downdate rows $i+1$ to k of Z)
Take $\check{R}$, $\check{u}$, $\check{\rho}$, and $\check{w}$ from step (b), and rows $i+1$ to k of Z as input and perform Algorithm BDCSNE.

We remark that it is also possible to replace Step 1 in Algorithm BDHYB by Step 1 in Algorithm BDCSNE. Then Γ_{11} can be obtained from a QR decomposition with column pivoting [13, §5.4] of the residual matrix T instead of a Cholesky decomposition with diagonal pivoting of $I_k - Q_1^T Q_1$ in Step 2, since $T^T T = I_k - Q_1^T Q_1$. This variant should have slightly better stability properties than the usual LINPACK-type block downdating algorithm since the data matrix X is used in the computation of T. We do not pursue this here, however, since Algorithm BDHYB performed well in our tests and since it is more efficient.

The computational complexity of Algorithm BDHYB is between $2.5kn^2$ (when the LINPACK-type algorithm is applied for the whole block) and $3kpn + 4kn^2$ (when the CSNE-type algorithm is used for the whole block), and in general, it depends on the index where the block of rows is partitioned. If p is much larger than n, then we can expect the hybrid algorithm to be considerably faster than the CSNE algorithm. The ICE only requires $3i^2/2$ approximately, where i is the number of rows to be downdated by Algorithm BDLIN. Hence its contribution to the overall computational complexity is minimal. The numerical experimental results presented in the next section show that the accuracy of the above algorithm is far superior to that of Algorithm BDLIN and the additional cost is modest.

7. Numerical experiments. In a sliding window method, a least squares solution is computed based on the p latest rows of an observation matrix A, where p is the number of rows in the window matrix [1]. In each step, a new block of k rows of observations, is updated into the QR decomposition, and an existing block of k rows of the data matrix is downdated from the decomposition, on a first in, first out basis.

Numerical tests for the recursive least squares method using the sliding window method have been performed in Pro-Matlab with IEEE double precision floating point arithmetic to compare the accuracy of the block downdating algorithms that have been presented. The solution obtained from the QR decomposition of the window matrix was used as a reference. In each figure, we present the relative error in Euclidean norm in the downdated solution vector produced by algorithms BDLIN, BDCSNE, and BDHYB. A measure of the conditioning of the downdating of the whole block of k rows, $1/\sigma_k^2(\Gamma)$, and the spectral condition number κ_X of the window matrix to be downdated are shown. To illustrate the conditioning of the subproblem that is treated by Algorithm BDLIN in the hybrid algorithm, we give estimates $1/(\hat{\sigma}^{(i)})^2$ (obtained from ICE) of $1/\sigma_i^2(\Gamma_{11}^{(i)})$. The digits in the plot denote the size of the row block that was downdated in the hybrid algorithm using Algorithm BDLIN. We have used the following criterion in the hybrid method: if i is the last index such that $\hat{\sigma}^{(i)} > \text{tol}$, then Algorithm BDCSNE is applied to the part that starts from the row $i+1$. The approximation $\hat{\sigma}^{(i)}$ of the smallest singular values of $\Gamma_{11}^{(i)}$ was computed using ICE [2] and tol was chosen to be 0.5.

The following two test problems are similar to those in [4] and [10], which we used earlier to compare the accuracy of several downdating algorithms when $k = 1$. They were also used in the context of adaptive condition number estimation in [11].

Test I. A random matrix $A \in \mathbf{R}^{210\times 12}$ was constructed with elements taken from a uniform distribution in $(0,1)$. An outlier equal to $6 \cdot 10^3$ was added in position (34,3). The right-hand side vector b was taken to be $b = Ax_0 + b_r$, where b_r has

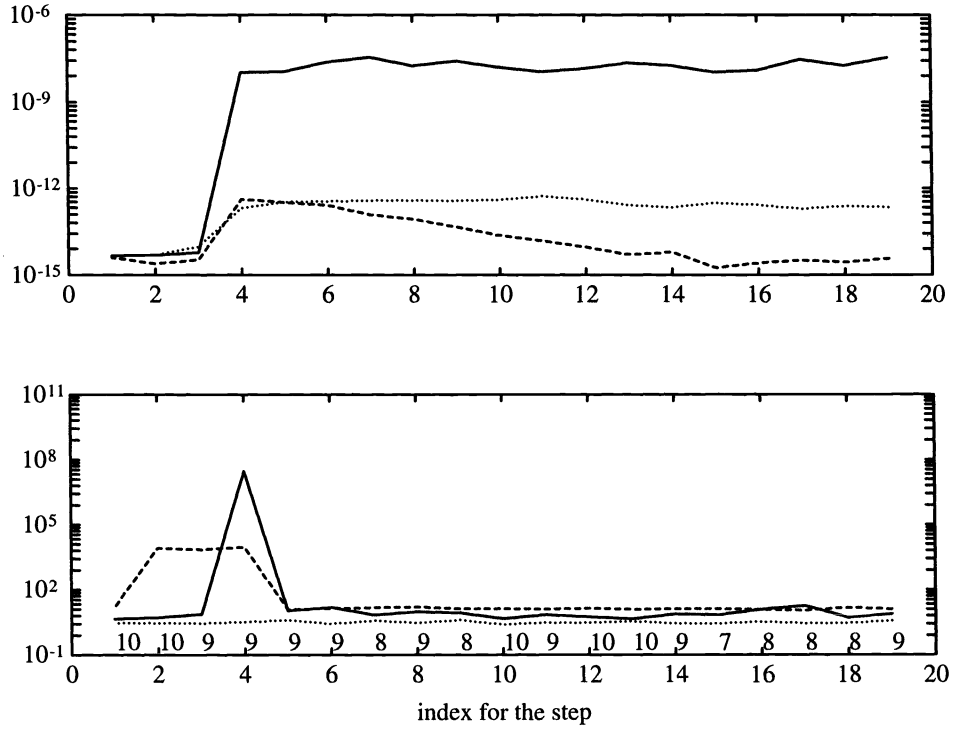

FIG. 7.1. *Test* I. *The upper graph shows the relative error in Euclidean norm in the downdated solution vector by the* BDLIN (*solid line*), BDCSNE (*dashed*), *and* BDHYB (*dotted*) *algorithms. The lower graph shows the condition number* κ_X *of the window matrix to be downdated* (*dashed*), $1/\sigma_k^2(\Gamma)$ (*solid line*), *and the* ICE *estimate* $1/(\hat{\sigma}^{(i)})^2$ (*dotted*). *The digits in the graph show the number of rows* (*in the block of* 10 *rows*) *treated by Algorithm* BDLIN *in the hybrid method.*

random elements uniformly distributed in $(0, 10^{-6})$ and x_0 is 12×1 vector with ones as its components. The window size p is 20 and ten rows are added and deleted each time, i.e., $k = 10$.

The results are shown in Fig. 7.1. It is seen that the relative error in the solution using Algorithm BDLIN is considerably magnified in the ill-conditioned downdating step and that it remains on that high level even if the subsequent downdating problems are well conditioned. The BDCSNE and BDHYB algorithms are much less affected by the ill-conditioned downdating and the errors remain on a low level throughout.

The digits in the plot show that in Algorithm BDHYB the major part of each downdating was performed using Algorithm BDLIN. In fact, over 88% of the total number of rows was downdated using Algorithm BDLIN. This shows that the hybrid algorithm can be much more efficient than Algorithm BDCSNE and can produce solutions that are far more accurate than those from Algorithm BDLIN.

Test II. A 76×6 matrix was constructed by taking a 38×6 Hilbert matrix as the first 38 rows and the same rows in reversed order as the 38 last rows. Then a perturbation from a uniform distribution in $(0, 10^{-5})$ was added to each matrix element. The right-hand side was constructed as in Test I, $p = 8$ and $k = 4$.

The results are shown in Fig. 7.2. Throughout this test, the downdating problem

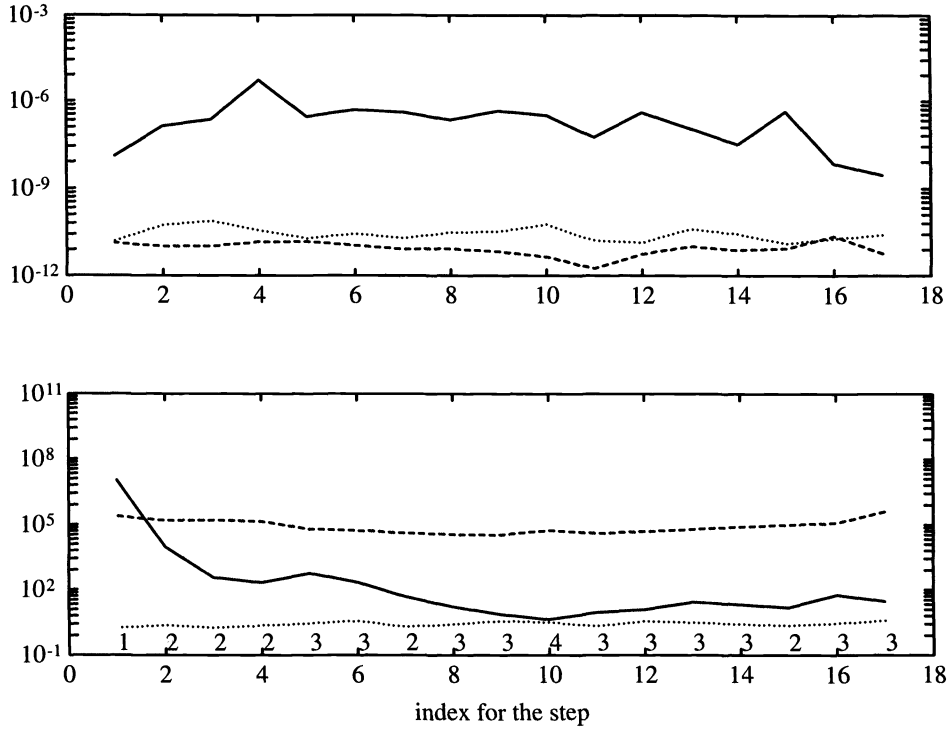

FIG. 7.2. *Test* II. *Modified Hilbert matrix with perturbations from a uniform distribution in* $(0, 10^{-5})$.

is rather ill conditioned, but even so, the CSNE branch of the hybrid algorithm is used only for one third of the total number of rows downdated. It is remarkable that Algorithm BDLIN performs so much worse than the others. This is probably due to the fact that the window matrix is very ill conditioned, which leads to large errors in the computed approximations of Q_1. In Algorithm BDCSNE, this vector is refined and much better accuracy is attained.

8. Conclusion. In this paper, we have considered generalizations of the LINPACK and CSNE algorithms for single row downdating to handle block downdating. The block downdating algorithms are rich in level 3 BLAS operations and this makes them amenable to efficient implementation on vector and parallel computers. The sensitivity of the block downdating problem to perturbations has been analyzed and a method of estimating the conditioning of the downdating problem has been devised. Based on this analysis we have developed a hybrid method in which the more efficient LINPACK-type algorithm is used for the well-conditioned part of the block downdate and the more expensive CSNE algorithm is used for the ill-conditioned part.

Preliminary numerical experiments indicate that the block downdating LINPACK-type and CSNE algorithms have properties that are similar to those of their single row counterparts, i.e., the latter is much more accurate (but considerably more expensive) than the former. The hybrid method has accuracy comparable to that of the CSNE algorithm, and it is almost as fast as the LINPACK-type algorithm. Therefore

it appears to be very promising for applications, where both speed and accuracy are essential.

Acknowledgments. The second author would like to thank the Department of Mathematics, Linköping University, Linköping, Sweden, where part of this work was carried out in August 1992. The first author acknowledges a discussion about block downdating with Adam Bojanczyk at the initial stage of this work. We would also like to thank the referees for their helpful comments.

AN ATTAINABLE LOWER BOUND FOR THE BEST NORMAL APPROXIMATION*

LAJOS LÁSZLÓ†

Abstract. Lower bounds for the distance of a complex $n \times n$ matrix A from the variety of normal matrices are established. The weaker version gives a lower bound of the form $\mathrm{dep}(A)/\sqrt{n}$, where $\mathrm{dep}(A)$ is Henrici's "departure from normality." Recall that $\mathrm{dep}(A)$ itself is an upper bound for the distance at issue. The tighter bound contains n diagonal sums coming from the Schur form, hence its computational cost is larger; however, it is attainable. The main result is showing this property. To this end some lemmas concerning normal and triangular matrices are needed, and a set of triangular and (closest) normal matrices with properties of independent interest is introduced.

Key words. best normal approximation, departure from normality, lower bound, extremal normal matrices, Schur decomposition

AMS subject classifications. 15A60, 15A42

1. Introduction.

Let A be a complex matrix of order n, and denote by $\nu(A)$ its distance from the set of normal matrices, i.e., let

$$\nu(A) = \nu_F(A) = \min \{\|A - N\|_F : \ N \text{ is normal}\}.$$

There exist a number of measures of nonnormality with several inequalities holding between them, e.g.,

(i) the "departure from normality" defined by Henrici [4, p. 27]:

$$\mathrm{dep}(A) = \{\|A\|_F^2 - \sum |\lambda_i|^2\}^{1/2},$$

where $\{\lambda_i\}$ are the eigenvalues of A; or

(ii) the commutator of A and A^*, more precisely,

$$\mathrm{com}(A) = \|A^*A - AA^*\|_F^{1/2}.$$

The latter one is suitable for estimating $\nu(A)$ both from below and above; see (C1), (C3), (C5) in Elsner–Paardekooper [2, p. 111]:

$$\mathrm{com}^2(A) \ / \ (4\|A\|_2) \ \leq \ \nu(A) \ \leq ((n^3 - n)/12)^{1/4}\mathrm{com}(A).$$

However, this is unsatisfactory in some sense as stated by Higham [5, p. 16], "Unfortunately the lower and upper bounds differ by orders of magnitude when $\nu(A)/\|A\|_F$ is small."

In light of this fact, it is remarkable that there exist lower and upper bounds for $\nu(A)$ in terms of $\mathrm{dep}(A)$—without the trouble mentioned:

$$\mathrm{dep}(A)/\sqrt{n} \ \leq \ \nu(A) \ \leq \mathrm{dep}(A). \tag{1}$$

*Received by the editors June 15, 1992; accepted for publication (in revised form) April 21, 1993.

†Department of Numerical Analysis, Eötvös Loránd University, Múzeum krt. 6-8, 1088 Budapest, Hungary (llaszlo@ludens.elte.hu).

The second inequality here is an easy consequence of the Schur decomposition theorem (see, e.g., Elsner–Paardekooper [2, p. 115], or Ruhe [8, p. 587]), while the first one is new, see Theorem 2.

In fact we will obtain a tighter lower bound, which is attainable, i.e., the coefficients involved are optimal.

THEOREM 1. *Let A be $n \times n$ with a Schur decomposition*

$$A = WRW^*$$

and let N be its closest normal matrix in the Frobenius norm. Then

$$\|R. * T\|_F \leq \|A - N\|_F \leq \|R. * E\|_F$$

with . denoting elementwise (Hadamard) product and T and E are upper triangular Toeplitz matrices with first row*

$$t_1 = (0, 1/n, 2/(n+1), \ldots, 1/2)^{1/2} \quad \text{and} \quad (0, 1, 1, \ldots, 1),$$

respectively. No single element of t_1 can be replaced by a larger number.

Remark. Observe that the theorem is formulated in terms of a *fixed* Schur decomposition; hence the lower bound $\|R. * T\|_F$ does not depend on A only, but also on R, the Schur form used. (As an illustrative 3×3 example for the nonunicity of the Schur decomposition, see [6].) However, the following weakened version gives an underestimate, independent on R.

THEOREM 2. *Let A be $n \times n$ with eigenvalues $\{\lambda_i\}$. Then* (1) *holds.*

Remark. Recall that relations between $\mathrm{dep}(A)$ and $\mathrm{com}(A)$ also are available; see (C1),(C2) in [2, p. 111]. We prove Theorems 1 and 2 in §4.

2. Notations. We mention in advance that the subscript F at the matrix norms is omitted since the Frobenius norm is exclusively used. The order of all square matrices occurring through this paper is denoted by n, while $n \geq 2$, respectively, $n \geq 3$ in certain cases. The classes of right triangular, unitary, and normal matrices are denoted by $\mathcal{R}$, $\mathcal{U}$, $\mathcal{N}$, omitting the index n for the sake of simplicity. Matrix elements are referred to with the corresponding lower case and indices if not otherwise stated.

Any $R \in \mathcal{R}$ can be partitioned into the diagonals

$$r(m) = (r_{1,m+1}, r_{2,m+2}, \ldots, r_{n-m,n})^T, \qquad 0 \leq m \leq n-1.$$

In particular, the main diagonal—as the vector of the eigenvalues—is denoted by λ, i.e.,

$$\lambda = r(0).$$

We use four auxiliary matrices in conjunction with elementwise operations (including square rooting). They are defined in §§1 and 3, more precisely: E and T in Theorem 1; S in Lemma 1; M in Lemma 2.

3. Preliminary lemmas. The first two statements of this section are true for arbitrary normal matrices. (We use for them the notation Z instead of N to avoid writing "n_{ij}" for the entries.)

LEMMA 1. *If $Z \in \mathcal{N}$, then*

$$\|Z. * S\|^2 = \|Z. * S^T\|^2,$$

where S is the upper triangular Toeplitz matrix with first row

$$(0, 1, 2, \ldots, n-1)^{1/2}.$$

Proof. The equality of the main diagonal elements in $ZZ^* = Z^*Z$ yields

$$\sum_{j=1}^{n} |z_{ij}|^2 = \sum_{j=1}^{n} |z_{ji}|^2, \qquad 1 \le i \le n.$$

By summation for $1 \le i \le k$ and subtracting the equal terms, we have

$$\sum_{i=1}^{k} \sum_{j=k+1}^{n} |z_{ij}|^2 = \sum_{i=1}^{k} \sum_{j=k+1}^{n} |z_{ji}|^2, \qquad 1 \le k \le n-1.$$

Now we add these equalities for $1 \le k \le n-1$, then we rearrange both sides in accordance with the scheme

$$\sum_{k=1}^{n-1} \sum_{i=1}^{k} \sum_{j=k+1}^{n} p_{ij} = \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} (j-i) p_{ij},$$

and we change the indices on the right to get

$$\sum_{i=1}^{n-1} \sum_{j=i+1}^{n} (j-i)|z_{ij}|^2 = \sum_{j=1}^{n-1} \sum_{i=j+1}^{n} (i-j)|z_{ij}|^2. \qquad \square$$

The normal, *very* nearly triangular matrices play a significant role in the treatment.

DEFINITION 1. $\mathcal{N}_0 = \{ Z \in \mathcal{N} : z_{ij} = 0 \text{ if } i > j \text{ and } (i,j) \ne (n,1) \}$.

For example,

$$Z = \begin{pmatrix} 1 & 4 & 3 \\ 0 & -2 & 4 \\ 5 & 0 & 1 \end{pmatrix} \in \mathcal{N}_0.$$

In Lemma 2 the class $\mathcal{N}_0$ is characterized. We denote elementwise division by $./$, so that $A./B = (a_{ij}/b_{ij})$.

LEMMA 2. $\|Z./M\| \le \|Z\|$ *with equality for* $Z \in \mathcal{N}_0$, *where* M *is the upper triangular Toeplitz matrix with first row*

$$(1, (n-1)/n, (n-1)/(n+1), \ldots, (n-1)/(2n-3), 1/2)^{1/2}.$$

Proof. We have

$$\begin{aligned} \|Z\|^2 - \|Z./M\|^2 &= \sum_{i=1}^{n} \sum_{j=1}^{n} |z_{ij}|^2 - \sum_{i=1}^{n} \sum_{j=i}^{n} (n+j-i-1)/(n-1)\ |z_{ij}|^2 \\ &= \sum_{j=1}^{n-1} \sum_{i=j+1}^{n} |z_{ij}|^2 - \sum_{i=1}^{n} \sum_{j=i}^{n} (j-i)/(n-1)\ |z_{ij}|^2. \end{aligned}$$

Applying Lemma 1 to the second term, we get

$$\|Z\|^2 - \|Z./M\|^2 = \sum_{j=1}^{n-1} \sum_{i=j+1}^{n} (n+j-i-1)/(n-1)\ |z_{ij}|^2.$$

Since here every term is nonnegative, the first statement is true. On the other hand, this double sum contains only terms with indices $i > j$, while the coefficient of $|z_{ij}|^2$ is positive except when $(i,j) = (n,1)$; hence the second statement holds as well. □

The following definition is based on [7, Thm. 4(i)], using the equivalence of the problems

$$\max\{\|\operatorname{diag} UAU^*\|^2 :\ U \in \mathcal{U}\} \tag{2}$$

and

$$\min\{\|A - N\|^2 :\ N \in \mathcal{N}\} \tag{3}$$

as investigated in [1] and [3].

DEFINITION 2. *For $R \in \mathcal{R}$, $Z \in \mathcal{N}$ let*

$$\Delta(R,Z) = \|R - Z\|^2 - \|R. * T\|^2.$$

Remark. Because of the theorem mentioned, this quantity is always nonnegative, since any upper bound "ub" for (2) automatically yields a lower bound "lb" for (3). This can be seen by observing that

$$\|A - U^*DU\|^2 = \|UAU^* - D\|^2 \geq \|UAU^*\|^2 - \|\operatorname{diag} UAU^*\|^2$$

$$\geq \|A\|^2 - \text{ub} = \|R\|^2 - \text{ub} = \text{lb}$$

holds for any diagonal D and unitary U, i.e., for any $N = U^*DU \in \mathcal{N}$; R is an arbitrary but fixed Schur form of A as in Theorem 1. Consequently, by taking the upper bound $\text{ub} = \|R. * M\|^2$ from [7, Thm. 4(i)], we immediately get $\text{lb} = \|R. * T\|^2$ and, at the same time, $\|A - \mathcal{N}\|^2 = \|R - \mathcal{N}\|^2 \geq \text{lb}$.

Remark. Lemma 2 and inequality $\|R. * M\| \leq \|R\|$ can be extended to a chain of inequalities

$$\|Z./M\|^2 \leq \|Z\|^2 \leq \|R. * M\|^2 \leq \|R\|^2,$$

where

(i) the first $\leq$ is true for every $Z \in \mathcal{N}$,

(ii) the third $\leq$ is true for every $R \in \mathcal{R}$,

(iii) the second $\leq$ holds if Z is the best normal approximation to R, since then

$$\|R - Z\|^2 = \|R\|^2 - \|Z\|^2, \quad \|R. * T\|^2 = \|R\|^2 - \|R. * M\|^2, \quad \text{and} \quad \Delta(R,Z) \geq 0.$$

DEFINITION 3. *$R \in \mathcal{R}$ is called* extremal *if there exists $Z \in \mathcal{N}$ such that*

$$\Delta(R,Z) = 0.$$

If, moreover, the restrictions

$$\|r(m)\|^2 \neq 0, \qquad 0 \leq m \leq n-1$$

also hold, then R is perfectly extremal.

Remark. If R is extremal, then Z at issue is *necessarily* its best normal approximation, i.e., the closest normal matrix to R.

Our last preparing lemma yields a useful representation for $\Delta(R, Z)$.

LEMMA 3. $\Delta(R, Z) = \|R. * M - Z./M\|^2 + \|Z\|^2 - \|Z./M\|^2$.

Proof. By Definition 2 we have

$$\begin{aligned}
\Delta(R,Z) &= \sum_{i=1}^{n}\sum_{j=i}^{n}|r_{ij}-z_{ij}|^2 + \sum_{j=1}^{n-1}\sum_{i=j+1}^{n}|z_{ij}|^2 \\
&\quad - \sum_{i=1}^{n}\sum_{j=i}^{n}(j-i)/(n+j-i-1)\;|r_{ij}|^2 \\
&= \sum_{i=1}^{n}\sum_{j=i}^{n}(n-1)/(n+j-i-1)\;|r_{ij}-(n+j-i-1)/(n-1)\;z_{ij}|^2 \\
&\quad + \sum_{j=1}^{n-1}\sum_{i=j+1}^{n}|z_{ij}|^2 - \sum_{i=1}^{n}\sum_{j=i}^{n}(j-i)/(n-1)\;|z_{ij}|^2 \\
&= \Sigma_1 + \Sigma_2 - \Sigma_3,
\end{aligned}$$

where we have applied elementary algebraic transformations. Let

$$\Sigma_0 = \sum_{i=1}^{n}\sum_{j=i}^{n}|z_{ij}|^2,$$

then

$$\begin{aligned}
\Delta(R,Z) &= \Sigma_1 + (\Sigma_2 + \Sigma_0) - (\Sigma_3 + \Sigma_0) \\
&= \|R. * M - Z./M\|^2 + \|Z\|^2 - \|Z./M\|^2,
\end{aligned}$$

and the lemma is proved. □

Remark. By virtue of Lemmas 2 and 3 extremal matrices can be characterized by using the equivalence

$$\Delta(R,Z) = 0 \iff R. * M = Z./M \quad \text{and} \quad Z \in \mathcal{N}_0.$$

4. Perfectly extremal matrices: proof of the main result. Before constructing perfectly extremal matrices of any order n, we distinguish between the cases $n = 2$ and $n \geq 3$.

(i) In case of $n = 2$ every $R \in \mathcal{R}$ is extremal. For, if

$$R = \begin{pmatrix} \lambda_1 & r \\ 0 & \lambda_2 \end{pmatrix} \in \mathcal{R},$$

then

$$R. * M = \begin{pmatrix} \lambda_1 & r/\sqrt{2} \\ 0 & \lambda_2 \end{pmatrix} \in \mathcal{R},$$

and

$$N = \begin{pmatrix} \lambda_1 & r/2 \\ \varepsilon r/2 & \lambda_2 \end{pmatrix} \in \mathcal{N}$$

for a suitable complex ε with $|\varepsilon| = 1$. (If $z = (\lambda_1 - \lambda_2)\bar{r} \neq 0$ then $\varepsilon = z/\bar{z}$; otherwise $\varepsilon = 1$ can be taken). Hence we have

$$\|R - N\|^2 = 1/2\,|r|^2 = \|R\|^2 - \|R. * M\|^2 = \|R. * T\|^2,$$

thus R is extremal.

(ii) In case of $n \geq 3$ one would have a simple way of proving Theorem 1, namely, constructing n extremal $n \times n$ matrices such that

$$\|r(m)\|^2 \neq 0 \quad \text{and} \quad \|r(i)\|^2 = 0, \quad 0 \leq i \leq n-1, \quad i \neq m$$

holds for the mth one. However, this idea is not executable, as the following example /$n = 4, m = 2$/ shows: among the matrices with pattern

$$\begin{pmatrix} 0 & 0 & * & 0 \\ 0 & 0 & 0 & * \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

there is no extremal matrix! Thus, constructing perfectly extremal matrices cannot be avoided.

Proof of Theorem 1. The second inequality is well known: it states that

$$\|A - \mathcal{N}\| = \|R - \mathcal{N}\| \leq \|R - \operatorname{diag} R\|.$$

Since the first inequality is a reformulation of [7, Thm. 4(i), p. 297], it suffices to prove that it can be attained. To this aim we choose $U = I$, i.e., $A = R \in \mathcal{R}$, and assume $n \geq 3$. There will be defined perfectly extremal matrices of

$$k = [(n-1)/2]$$

free parameters, by means of the following "big steps."

I. We give a matrix $R \in \mathcal{R}$ of k free parameters.

II. We give a matrix $Z \in \mathcal{N}_0$ in terms of the above free parameters.

In detail the following instructions should be kept.

I. (R1) R is real;

(R2) R is persymmetric, i.e.,

$$r_{ij} = r_{n-j+1,n-i+1}, \qquad 1 \leq i, j \leq n;$$

(R3) The elements of R "within the upper triangle" are zero, i.e.,

$$r_{ij} = 0, \qquad 1 < i < j < n;$$

(R4) $r_{11} = r_{nn} = n - 2$; $r_{ii} = -2$, $2 \leq i \leq n-1$; $r_{1n} = 2n$;

(R5) $0 \neq r_{1i}$, $2 \leq i \leq k+1$ are free parameters;

(R6) $(n + i - 2)r_{1,n+1-i} = (2n - 1 - i)r_{1i}$, $2 \leq i \leq n-1$.

II. (Z1) Z is real;

(Z2) Z is persymmetric;

(Z3) $z_{ij} = 0$, $1 < i < j < n$, and $Z \in \mathcal{N}_0$;

(Z4) $z_{11} = z_{nn} = n - 2$; $z_{ii} = -2$, $2 \leq i \leq n-1$; $z_{1n} = n$;

(Z5) $z_{1i} = r_{1i}(n-1)/(n+i-2)$, $2 \leq i \leq k+1$;

(Z6) $z_{1,n+1-i} = z_{1i}$, $2 \le i \le n-1$; and $z_{n1} = (\sum_{i=2}^{n} z_{1i}^2)^{1/2}$.

It is easy to check that I and II uniquely determine $R \in \mathcal{R}$ and $Z \in \mathcal{N}_0$ in terms of the parameters (R5), while (Z5) implies that

$$R. * M = Z./M.$$

Hence, from the last remark of the previous section it follows that R is extremal, and owing to (R5), R can be assumed to be perfect. The theorem is proved. □

Proof of Theorem 2. The following chain of (in)equalities yields a lower bound for $\|R. * T\|^2$:

$$\begin{aligned}
\|R. * T\|^2 &= \sum_{m=0}^{n-1} m/(n+m-1)\ \|r(m)\|^2 \\
&= \|R\|^2 - \|\lambda\|^2 - \sum_{m=1}^{n-1} (n-1)/(n+m-1)\ \|r(m)\|^2 \\
&\ge \|R\|^2 - \|\lambda\|^2 - (n-1)/n \sum_{m=1}^{n-1} \|r(m)\|^2 \\
&= \|R\|^2 - \|\lambda\|^2 - (n-1)/n\ (\|R\|^2 - \|\lambda\|^2) \\
&= 1/n\ (\|R\|^2 - |\lambda\|^2) \\
&= 1/n\ (\|A\|^2 - |\lambda\|^2) \\
&= \mathrm{dep}^2(A)\,/\,n,
\end{aligned}$$

using $\lambda = r(0)$ and $\|A\|^2 = \|R\|^2$. Applying the first relation in Theorem 1 gives the first inequality of (1). The second inequality is equivalent to that of Theorem 1, by observing that $\mathrm{dep}(A) = \|R. * E\|$. The proof is complete. □

Remark. Observe that the first inequality of (1) corresponds to the "simple version" [7, Thm. 3(iv)]. Therefore it can be proved also by rewriting that theorem in terms of the best normal approximation, i.e., from (2) into (3), to get

$$\|A - N\|^2 \ge \|A\|^2 - \left(\frac{1}{n} \sum_{i=1}^{n} |\lambda_i|^2 + \frac{(n-1)}{n} \|A\|^2 \right) = \mathrm{dep}^2(A)/n.$$

Example. The following choice of the free parameters yields a quite special "canonical" pair $\{R, Z\}$:

$$r_{1i} = n + i - 2, \quad z_{1i} = n - 1, \quad 2 \le i \le n-1.$$

For illustration, we display the ninth order special extremal triangular and normal matrices R_9 and Z_9. (This case is distinguished by the fact that the left bottom element in Z_9 is integer, too.)

$$R_9 = \begin{pmatrix}
7 & 9 & 10 & 11 & 12 & 13 & 14 & 15 & 18 \\
0 & -2 & 0 & 0 & 0 & 0 & 0 & 0 & 15 \\
0 & 0 & -2 & 0 & 0 & 0 & 0 & 0 & 14 \\
0 & 0 & 0 & -2 & 0 & 0 & 0 & 0 & 13 \\
0 & 0 & 0 & 0 & -2 & 0 & 0 & 0 & 12 \\
0 & 0 & 0 & 0 & 0 & -2 & 0 & 0 & 11 \\
0 & 0 & 0 & 0 & 0 & 0 & -2 & 0 & 10 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & -2 & 9 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 7
\end{pmatrix},$$

$$Z_9 = \begin{pmatrix} 7 & 8 & 8 & 8 & 8 & 8 & 8 & 8 & 9 \\ 0 & -2 & 0 & 0 & 0 & 0 & 0 & 0 & 8 \\ 0 & 0 & -2 & 0 & 0 & 0 & 0 & 0 & 8 \\ 0 & 0 & 0 & -2 & 0 & 0 & 0 & 0 & 8 \\ 0 & 0 & 0 & 0 & -2 & 0 & 0 & 0 & 8 \\ 0 & 0 & 0 & 0 & 0 & -2 & 0 & 0 & 8 \\ 0 & 0 & 0 & 0 & 0 & 0 & -2 & 0 & 8 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & -2 & 8 \\ 23 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 7 \end{pmatrix}.$$

Example. (The case $n = 3$). The matrix $R_3 = R_3(p)$ below is extremal for any real value of the free parameter p; moreover, it is perfect if and only if $p \neq 0$:

$$R_3(p) = \begin{pmatrix} 1 & p & 6 \\ 0 & -2 & p \\ 0 & 0 & 1 \end{pmatrix}.$$

The best normal approximation to $R_3(p)$ is

$$Z_3(p) = \begin{pmatrix} 1 & 2p/3 & 3 \\ 0 & -2 & 2p/3 \\ q & 0 & 1 \end{pmatrix},$$

where $q = (9 + 4p^2/9)^{1/2}$.

Observe that the "canonical" pair $\{R_3,\ Z_3\}$ defined in the above example can be obtained for $p = 3$.

Remark. The matrices constructed in the theorem are real. This makes one think that all matrices involved in the problem of *extremality* can be assumed to be real. However, this conception is fundamentally false: the *optimal* unitary U, corresponding to a perfectly extremal R, is in case of $n \geq 3$ *necessarily complex*!

To see this, we must consider parallel with

$$\nu(A) \ = \ \min\{\|A - N\| : \ N = U\Lambda U^*,\ \Lambda : \text{diag},\ U : \text{unitary}\},$$

also the quantity

$$\nu^{\text{real}}(A) \ = \min\{\|A - N\| : \ N = U\Lambda U^T,\ \Lambda : \text{diag},\ U : \text{real orthogonal}\}.$$

Then we have

$$\|R. * E\|/\sqrt{2} \leq \nu^{\text{real}}(A)$$

for any $A = R \in \mathcal{R}$. (This follows from [7, Remark 3] and [7, Lemma 1(e)], using the equivalence of the problems (2) and (3).) At the same time, if

$$\|r(m)\|^2 \neq 0$$

holds for at least one m, $1 \leq m \leq n - 1$, then obviously

$$\|R. * T\| < \|R. * E\|/\sqrt{2},$$

showing that the lower bound $\|R.*T\|$ cannot be attained for real orthogonal matrices.

We illustrate this phenomenon by the help of 3×3 matrices.

Example. Consider the matrices

$$R = \begin{pmatrix} 1 & 6 & 6 \\ 0 & -2 & 6 \\ 0 & 0 & 1 \end{pmatrix} \in \mathcal{R}, \qquad N = \begin{pmatrix} 1 & 4 & 3 \\ 0 & -2 & 4 \\ 5 & 0 & 1 \end{pmatrix} \in \mathcal{N}_0.$$

Both matrices are real. Furthermore, $\Delta(R, N) = 0$, consequently, R is extremal (in fact, perfectly extremal) and N is its best normal approximation. By the considerations above, the minimum in $\nu^{\text{real}}(R)$ is not attainable for real orthogonal matrices, or equivalently, the eigenvectors of N cannot be pure real. This can also be checked by calculating its characteristic polynomial

$$\det(\lambda I - N) = \lambda^3 - 18\lambda - 108 = (\lambda - 6)\{(\lambda + 3)^2 + 9\}.$$

A PERTURBATION ANALYSIS OF THE GENERALIZED SYLVESTER EQUATION $(AR - LB, DR - LE) = (C, F)^*$

BO KÅGSTRÖM†

Abstract. Perturbation and error bounds for the generalized Sylvester equation $(AR-LB, DR-LE) = (C, F)$ are presented. An explicit expression for the normwise relative backward error associated with an approximate solution of the generalized Sylvester equation is derived and conditions when it can be much greater than the relative residual are given. This analysis is applicable to any method that solves the generalized Sylvester equation. A condition number that reflects the structure of the problem and a normwise forward error bound based on $\mathrm{Dif}^{-1}[(A, D), (B, E)]$ and the residual are derived. The structure-preserving condition number can be arbitrarily smaller than a Dif^{-1}-based condition number. The normwise error bound can be evaluated robustly and at moderate cost by using a reliable Dif^{-1} estimator. A componentwise LAPACK-style forward error bound that can be stronger than the normwise error bound is also presented. A componentwise approximate error bound that can be evaluated to a much lower cost is also proposed. Finally, some computational experiments that validate and evaluate the perturbation and error bounds are presented.

1. Introduction.

In this paper we study the sensitivity of and derive perturbation and error bounds for the generalized Sylvester equation

$$\begin{aligned} AR - LB &= C, \\ DR - LE &= F, \end{aligned} \tag{1}$$

where L and R are unknown $m \times n$ matrices, (A, D), (B, E), and (C, F) are given pairs of $m \times m, n \times n$, and $m \times n$ matrices, respectively, with real (or complex) entries. If we choose D and E to be the identity matrices and F as the zero matrix then (1) reduces to the (standard) Sylvester equation $AR - RB = C$. Using Kronecker products the matrix equation (1) can be written as a $2mn \times 2mn$ linear system of equations [6]

$$\begin{bmatrix} I_n \otimes A & -B^T \otimes I_m \\ I_n \otimes D & -E^T \otimes I_m \end{bmatrix} \begin{bmatrix} \mathrm{col}(R) \\ \mathrm{col}(L) \end{bmatrix} = \begin{bmatrix} \mathrm{col}(C) \\ \mathrm{col}(F) \end{bmatrix}, \tag{2}$$

where the column vector $\mathrm{col}(X)$ denotes an ordered stack of the columns of a matrix X from left to right starting with the first column. We write the system (2) in compact form as

$$Zx = b. \tag{3}$$

The coefficient matrix Z in (2) is $2mn \times 2mn$, which for moderate m and n is already quite a large matrix. So this equivalent formulation is mainly of interest for theoretical purposes.

One important application of the generalized Sylvester equation originates from computing stable eigendecompositions of matrix pencils [6]. It can be formulated in terms of a block-diagonalizing equivalence transformation $P^{-1}(M - \lambda N)Q$, where

$$M - \lambda N \equiv \begin{bmatrix} A & -C \\ 0 & B \end{bmatrix} - \lambda \begin{bmatrix} D & -F \\ 0 & E \end{bmatrix}. \tag{4}$$

We want to find (L, R) such that

$$\begin{bmatrix} I_m & -L \\ 0 & I_n \end{bmatrix} (M - \lambda N) \begin{bmatrix} I_m & R \\ 0 & I_n \end{bmatrix} = \begin{bmatrix} A & 0 \\ 0 & B \end{bmatrix} - \lambda \begin{bmatrix} D & 0 \\ 0 & E \end{bmatrix}. \tag{5}$$

The first m columns of the transformation matrices in (5) (P^{-1} and Q, respectively) span a pair of eigenspaces (deflating subspaces) associated with $\lambda(A, D)$ [21]. By solving for (L, R) in (1) we also get a pair of complementary eigenspaces (deflating subspaces associated with $\lambda(B, E)$) from the last n columns of P^{-1} and Q, respectively. One can show that (1) has a unique solution if and only if the *regular* pencils $A - \lambda D$ and $B - \lambda E$ have disjoint spectra [20]. If these pencils have common spectra or are *singular* (i.e., $\det(A - \lambda D) \equiv 0$ or $\det(B - \lambda E) \equiv 0$ for each λ), the generalized Sylvester equation will not generally be consistent. An important quantity that measures the sensitivity of these eigenspaces is the *separation of the matrix pairs* (A, D) and (B, E) [20], [21],

$$\mathrm{Dif}[(A, D), (B, E)] = \inf_{\|(L,R)\|_F = 1} \|(AR - LB, DR - LE)\|_F. \tag{6}$$

The relationship with the generalized Sylvester equation is that $\mathrm{Dif}[(A, D), (B, E)] > 0$ (Dif for short) if and only if (1) has a unique solution. Furthermore, it can be shown [6] that

$$\mathrm{Dif}^{-1}[(A, D), (B, E)] = \|Z^{-1}\|_2 = \sigma_{\min}(Z)^{-1}, \tag{7}$$

where $\sigma_{\min}(Z)$ is the smallest singular value of Z.

A new direct method for reordering eigenvalues in the generalized real Schur form of a regular matrix pair is based on solving sequences of generalized Sylvester equations where m, n are 1 or 2 [14]. In [16] and [17], algorithms for computing an additive decomposition of a (generalized) transfer matrix are presented. The problem, computing the stable projection with respect to a specified region Γ in the complex plane of a transfer matrix given by its generalized state space realization, comprises both a reordering of eigenvalues and a block-diagonalization as described above.

Recently, Higham [13] presented a perturbation analysis of the standard Sylvester equation $AR - RB = C$. By taking full account of the structure of the Sylvester equation, he derives expressions for the backward error of an approximate solution $\hat{R}$ and a condition number that measures the sensitivity of a solution to perturbations in the data (A, B, C). One important result from [13] is that a small value of the residual $A\hat{R} - \hat{R}B - C$ does not necessarily yield a small backward error. The main purpose of this paper is to generalize these results and extend the analysis to the generalized Sylvester equation.

An alternative form of a generalized Sylvester equation with applications in control theory is

$$AXB^T + CXD^T = E, \tag{8}$$

where A and C are $m \times m$, B and D are $n \times n$, and E and the desired solution X are $m \times n$ [7]. The matrix equation (8) has a unique solution if and only if (A, C) and $(-D, B)$ are regular matrix pairs with disjoint spectra [5]. By introducing $R = XB^T$ and $L = CX$, (8) can be recast in the form (1)

$$\begin{aligned} AR + LD^T &= E, \\ CR - LB^T &= 0. \end{aligned}$$

The solvability condition for (8) (which is similar to the solvability condition for (1)) implies that at least one of B and C must be nonsingular, so X can be resolved from L or R. However, if both B and C are ill conditioned with respect to inversion (or one of them is singular and the other is ill conditioned), it is recommended to solve (8) directly [7].

The rest of the paper is outlined as follows. In §1.1 we collect the notation used. In §2 we briefly review algorithms for solving the generalized Sylvester equation and discuss residual bounds for an approximate solution $(\hat{L}, \hat{R})$. Section 3 is devoted to a normwise backward error analysis. An explicit expression for the normwise relative backward error associated with an approximate solution of (1) is derived and conditions when it can be much greater than the relative residual are given. This analysis is of course applicable to any method that solves the generalized Sylvester equation. In §4 we derive a condition number for the generalized Sylvester equation that reflects the structure of the problem and a normwise forward error bound based on $\mathrm{Dif}^{-1}[(A, D), (B, E)]$ and the residual. The structure-preserving condition number can be arbitrarily smaller than a Dif^{-1}-based condition number. The normwise error bound can be evaluated robustly and at moderate cost by using the Dif^{-1} estimators in [18]. Section 5 presents a componentwise forward error bound that can be stronger than the normwise error bound. This forward error bound can be converted to a LAPACK-style [1] error bound as for the standard Sylvester equation [13]. We also propose a componentwise approximate error bound that can be evaluated to a much lower cost. Finally, in §6 we present and discuss some computational experiments that validate and evaluate the perturbation and error bounds.

1.1. Notation. The following notation is used in the paper. $\lambda(A, B)$ denotes the spectrum of a regular matrix pair (A, B) or pencil $A - \lambda B$. If $B = I$ we only use $\lambda(A)$. $\|A\|_2$ denotes the spectral norm (2-norm) of a matrix A induced by the Euclidean vector norm. $\|A\|_F$ denotes the Frobenius (or Euclidean) matrix norm. $\|A\|_M = \max_{i,j} |a_{ij}|$, i.e., the maximum of the absolute values of the matrix entries. $\kappa(A) = \|A\|_2 \|A^+\|_2$, where A^+ is the pseudoinverse of A, and denotes the condition numbers of a matrix A with respect to the 2-norm. $\sigma(A)$ denotes the set of singular values of a matrix A. Especially, $\sigma_{\max}(A)$ and $\sigma_{\min}(A)$ denote the largest and smallest singular values of A, respectively. For a square matrix A, we have that $\|A\|_2 = \sigma_{\max}(A)$ and $\|A^{-1}\|_2 = \sigma_{\min}(A)^{-1}$. $A \otimes B$ denotes the Kronecker product of two matrices A and B whose (i, j)th block element is $a_{ij}B$. A^T denotes the transpose of A. A^H denotes the conjugate transpose of A. $\overline{A}$ denotes the conjugate of A. $|A|$ and $|x|$ denote the matrix and the vector whose elements are $|a_{ij}|$ and $|x_i|$, respectively. Inequalities such as $|A| \leq |B|, |x| \leq |y|$ are interpreted componentwise. $D = \mathrm{diag}(x)$ denotes a diagonal matrix wih $d_{ii} = x_i$.

2. Algorithms and residual bounds. In [18], algorithms for solving (1) are presented that are generalizations of the Schur method [3] and the Hessenberg–Schur method [8] for solving $AR - RB = C$. Both methods are based on orthogonal equiva-

lence transformations (unitary transformations if the matrix entries are complex) and involve the following four steps.

1. Transform (A, D) and (B, E) to simpler form:

$$(A_1, D_1) := (P^T A Q, P^T D Q),$$
$$(B_1, E_1) := (U^T B V, U^T E V).$$

2. Modify the right-hand sides (C, F):

$$C_1 := P^T C V, \qquad F_1 := P^T F V.$$

3. Solve the transformed system for (L_1, R_1):

$$\begin{aligned} A_1 R_1 - L_1 B_1 &= C_1, \\ D_1 R_1 - L_1 E_1 &= F_1. \end{aligned} \tag{9}$$

4. Transform the solution back to the original system:

$$L := P L_1 U^T, \qquad R := Q R_1 V^T.$$

In the generalized Schur method [18] (A_1, D_1) and (B_1, E_1) are in generalized real Schur form with A_1 and B_1 (upper) quasi triangular and D_1 and E_1 (upper) triangular. A quasi triangular matrix is block triangular with 1×1 and 2×2 diagonal blocks. The 2×2 blocks correspond to pairs of complex conjugate eigenvalues of the associated matrix pencil and the ratios of the 1×1 diagonal blocks are the real eigenvalues. (In the generalized complex Schur form A_1 and B_1 will be (upper) triangular too, which simplifies the discussion below.) Suppose the transformed matrix equation (9) is partitioned according to the diagonal block structure of A_1 and B_1. Let A_{ii} of size $a \times a, a = 1, 2$ and B_{jj} of size $b \times b, b = 1, 2$ denote the diagonal blocks of A_1 and B_1, respectively, and let p, q be the number of diagonal blocks of A_1 and B_1. Then (9) is solved by the GS algorithm that can be written compactly as [18]

$$\begin{aligned} A_{ii} R_{ij} - L_{ij} B_{jj} &= C_{ij} - \left(\textstyle\sum_{k=i+1}^{p} A_{ik} R_{kj} - \sum_{k=1}^{j-1} L_{ik} B_{kj} \right) \equiv G_{ij}, \\ D_{ii} R_{ij} - L_{ij} E_{jj} &= F_{ij} - \left(\textstyle\sum_{k=i+1}^{p} D_{ik} R_{kj} - \sum_{k=1}^{j-1} L_{ik} E_{kj} \right) \equiv H_{ij}, \end{aligned} \tag{10}$$

for $j = 1, 2, \ldots, q$ and $i = p, p-1, \ldots, 1$. In total we solve $p \cdot q$ small subsystems (10). Each of them can be written as a linear system

$$\begin{bmatrix} I_b \otimes A_{ii} & -B_{jj}^T \otimes I_a \\ I_b \otimes D_{ii} & -E_{jj}^T \otimes I_a \end{bmatrix} \begin{bmatrix} \operatorname{col}(R_{ij}) \\ \operatorname{col}(L_{ij}) \end{bmatrix} = \begin{bmatrix} \operatorname{col}(G_{ij}) \\ \operatorname{col}(H_{ij}) \end{bmatrix} \tag{11}$$

of size 2, 4, or 8. Note that even if A_{ii} and B_{jj} are upper triangular, the subsystems (11) cannot generally be transformed to upper triangular form only by permutations. This is in contrast to the Schur method for $AR - RB = C$.

In the generalized Hessenberg–Schur method [18], (A, D) is only transformed to a generalized Hessenberg-triangular form, where A_1 is (upper) Hessenberg and D_1 is (upper) triangular. The solution (L_1, R_1) is computed by solving a sequence of banded linear subsystems.

In both methods we use Gaussian elimination with partial pivoting to solve the generalized Sylvester equation (subsystem (11)) in each step. A rounding error analysis of the generalized Schur method is presented in [18]. The conclusion is that the

method is weakly stable [4], meaning that the relative errors in the computed solution $(\hat{L}, \hat{R})$ are small for well-conditioned problems. More precisely, the relative errors in $(\hat{L}, \hat{R})$ are proportional to a condition number times a smooth function of the relative machine precision. The analysis in [18] applies standard results on backward error analysis for products of orthogonal matrices (steps 1, 2, and 4) and for Gaussian elimination with partial pivoting for solving (9) in step 3 as $Z_1 x_1 = b_1$ (3). Since steps 1, 2, and 4 are backward stable processes, in general, the computed solution $\hat{x}$ of (3) satisfies (e.g., see [9])

$$(Z + \Delta Z)\hat{x} = b, \quad |\Delta Z| \leq 2mnu(3|Z| + 5P^T|\hat{L}_Z|\,|\hat{U}_Z|), \tag{12}$$

where $\hat{L}_Z, \hat{U}_Z$ are the computed LU factors, P the permutation matrix, and u is the unit roundoff (Z is $2mn \times 2mn$). From (12) we can derive the following normwise bounds on the residual of (1) for $\hat{x}$:

$$\begin{aligned} \|C - A\hat{R} + \hat{L}B\|_F &\leq c_{m,n}\rho_{m,n}u\left(\|A\|_F\|\hat{R}\|_F + \|\hat{L}\|_F\|B\|_F\right) \\ &\leq c_{m,n}\rho_{m,n}u\,(\|A\|_F + \|B\|_F)\max(\|\hat{L}\|_F, \|\hat{R}\|_F) \end{aligned} \tag{13}$$

and

$$\begin{aligned} \|F - D\hat{R} + \hat{L}E\|_F &\leq c_{m,n}\rho_{m,n}u\left(\|D\|_F\|\hat{R}\|_F + \|\hat{L}\|_F\|E\|_F\right) \\ &\leq c_{m,n}\rho_{m,n}u\,(\|D\|_F + \|E\|_F)\max(\|\hat{L}\|_F, \|\hat{R}\|_F), \end{aligned} \tag{14}$$

where $c_{m,n}$ is a modest function in the dimensions m and n, $\rho_{m,n}$ is the growth factor in Gaussian elimination. One interpretation of the bounds (13), (14) is that the relative residuals are bounded by a modest multiple of $c_{m,n}\rho_{m,n}u$. The size of the relative residuals is mainly determined by the (maximum) growth factor that measures how large the numbers become during the elimination processes. In practice, $\rho_{m,n}$ is usually of order 10 but it can also be as large as 2^{k-1}, where k is the size of the linear system solved. A similar error analysis can be performed for the generalized Hessenberg–Schur method that also results in residual bounds similar to (13), (14).

A LAPACK-style [1] block algorithm for solving (9) is under development [15]. Gaussian elimination with complete pivoting and tests for underflow and overflow are used to solve the subsystems (11). This will hopefully prohibit a large growth factor (in the residual bounds) despite the fact that examples have been found with growth factors greater than the problem size [10].

3. A normwise backward error analysis. Let $(\hat{L}, \hat{R})$ denote an approximate solution of the generalized Sylvester equation (1). The normwise backward error of $(\hat{L}, \hat{R})$ is defined by

$$\begin{aligned} \eta(\hat{L}, \hat{R}) \equiv \min\{\,\epsilon : &(A + \Delta A)\hat{R} - \hat{L}(B + \Delta B) = C + \Delta C, \\ &(D + \Delta D)\hat{R} - \hat{L}(E + \Delta E) = F + \Delta F, \\ &\|(\Delta A, \Delta D)\|_F \leq \epsilon\alpha, \|(\Delta B, \Delta E)\|_F \leq \epsilon\beta, \|(\Delta C, \Delta F)\|_F \leq \epsilon\gamma\}. \end{aligned} \tag{15}$$

It holds that $\eta(\hat{L}, \hat{R})$ is a measure of the distance to the closest perturbed generalized Sylvester equation that has $(\hat{L}, \hat{R})$ as the exact solution. By choosing $\alpha = \|(A, D)\|_F, \beta = \|(B, E)\|_F, \gamma = \|(C, F)\|_F$, $\eta(\hat{L}, \hat{R})$ corresponds to the normwise relative backward error with respect to the Frobenius norm. The perturbed generalized Sylvester equation in the definition (15) can be written as

$$\begin{aligned} \Delta A\hat{R} - \hat{L}\Delta B - \Delta C &= C - (A\hat{R} - \hat{L}B) \equiv R_1, \\ \Delta D\hat{R} - \hat{L}\Delta E - \Delta F &= F - (D\hat{R} - \hat{L}E) \equiv R_2, \end{aligned} \tag{16}$$

where (R_1, R_2) denotes the residual corresponding to $(\hat{L}, \hat{R})$. From (15) we can bound R_i as

$$\|R_i\|_F \leq (\alpha\|\hat{R}\|_F + \beta\|\hat{L}\|_F + \gamma)\eta(\hat{L}, \hat{R}). \tag{17}$$

Since $\|(R_1, R_2)\|_F = (\|R_1\|_F^2 + \|R_2\|_F^2)^{\frac{1}{2}}$, it follows that a small backward error of the generalized Sylvester equation implies a small relative residual. In the following analysis we show that a small relative residual will not always give a small (relative) backward error $\eta(\hat{L}, \hat{R})$.

We use a similar technique as in [13] and start to rewrite (16) by using Kronecker products:

$$\begin{aligned}(\hat{R}^T \otimes I_m)\mathrm{col}(\Delta A) - (I_n \otimes \hat{L})\mathrm{col}(\Delta B) - \mathrm{col}(\Delta C) &= \mathrm{col}(R_1),\\ (\hat{R}^T \otimes I_m)\mathrm{col}(\Delta D) - (I_n \otimes \hat{L})\mathrm{col}(\Delta E) - \mathrm{col}(\Delta F) &= \mathrm{col}(R_2),\end{aligned}$$

or equivalently

$$\mathcal{H}z = r, \qquad \mathcal{H} \equiv \begin{bmatrix} \hat{H} & 0 \\ 0 & \hat{H} \end{bmatrix}, \tag{18}$$

where

$$\hat{H} = \begin{bmatrix} \alpha(\hat{R}^T \otimes I_m) & -\beta(I_n \otimes \hat{L}) & -\gamma I_{mn} \end{bmatrix}, \tag{19}$$

and

$$z = \begin{bmatrix} \mathrm{col}(\Delta A)/\alpha \\ \mathrm{col}(\Delta B)/\beta \\ \mathrm{col}(\Delta C)/\gamma \\ \mathrm{col}(\Delta D)/\alpha \\ \mathrm{col}(\Delta E)/\beta \\ \mathrm{col}(\Delta F)/\gamma \end{bmatrix}, \qquad r = \begin{bmatrix} \mathrm{col}(R_1) \\ \mathrm{col}(R_2) \end{bmatrix}.$$

The system (18) is underdetermined where $\mathcal{H}$ is of size $2mn \times (2m^2 + 2n^2 + 2mn)$. If $\gamma \neq 0$, $\hat{H}$ is of full (row) rank and (18) has a minimum 2-norm solution

$$z = \mathcal{H}^+ r. \tag{20}$$

It follows from (18), (20) and the definition of $\eta(\hat{L}, \hat{R})$ that

$$\eta(\hat{L}, \hat{R}) \leq \|\mathcal{H}^+ r\|_2. \tag{21}$$

On the other side,

$$\|z\|_2^2 = \frac{\|(\Delta A, \Delta D)\|_F^2}{\alpha^2} + \frac{\|(\Delta B, \Delta E)\|_F^2}{\beta^2} + \frac{\|(\Delta C, \Delta F)\|_F^2}{\gamma^2} \leq 3\epsilon^2.$$

In summary, we have

$$\frac{1}{\sqrt{3}}\|\mathcal{H}^+ r\|_2 \leq \eta(\hat{L}, \hat{R}) \leq \|\mathcal{H}^+ r\|_2 \leq \|\mathcal{H}^+\|_2 \|r\|_2, \tag{22}$$

or in words, the maximum size of the backward error relative to the residual $\|(R_1, R_2)\|_F$ is dependent on $\|\mathcal{H}^+\|_2 = \sigma_{\min}(\hat{H})^{-1}$, where $\hat{H}$ is defined by (19).

Now, let $\hat{R} = U_R \Sigma_R V_R^H$ and $\hat{L} = U_L \Sigma_L V_L^H$ be the singular value decompositions of $\hat{R}$ and $\hat{L}$, respectively, giving

$$\hat{H} = \begin{bmatrix} \alpha(\overline{V}_R \Sigma_R^T U_R^T \otimes I_m) & -\beta(I_n \otimes U_L \Sigma_L V_L^H) & -\gamma I_{mn} \end{bmatrix}. \tag{23}$$

As in [13] we can find unitary transformations

$$Q = V_R^T \otimes U_L^H, \qquad P = \operatorname{diag}\{\overline{U}_R \otimes U_L, \overline{V}_R \otimes V_L, \overline{V}_R \otimes U_L\}$$

such that

$$\tilde{H} = Q\hat{H}P = \begin{bmatrix} \alpha(\Sigma_R^T \otimes I_m) & -\beta(I_n \otimes \Sigma_L) & -\gamma I_{mn} \end{bmatrix}. \tag{24}$$

Since $\hat{H}$ and $\tilde{H}$ are unitarily equivalent they have the same singular values, namely, the square roots of the eigenvalues of the diagonal matrix:

$$\tilde{H}\tilde{H}^H = \alpha^2(\Sigma_R^T \Sigma_R \otimes I_m) + \beta^2(I_n \otimes \Sigma_L \Sigma_L^T) + \gamma^2 I_{mn}. \tag{25}$$

Let $\sigma_i(\hat{R})$ and $\sigma_i(\hat{L})$ for $i = 1, \ldots, \min(m,n)$ denote the singular values of $\hat{R}$ and $\hat{L}$ in decreasing order ($\sigma_i() \geq \sigma_{i+1}()$), respectively, and define $\sigma_i(\hat{R}) = \sigma_i(\hat{L}) = 0$ for $i = \min(m,n) + 1, \ldots, \max(m,n)$. Then, assuming $\hat{H}$ has full (row) rank, we have

$$\|\mathcal{H}^+\|_2 = \|\hat{H}^+\|_2 = (\alpha^2 \sigma_n(\hat{R})^2 + \beta^2 \sigma_m(\hat{L})^2 + \gamma^2)^{-\frac{1}{2}}. \tag{26}$$

Substituting (26) in (22) gives us

$$\eta(\hat{L}, \hat{R}) \leq \mu(\hat{L}, \hat{R}) \frac{\|(R_1, R_2)\|_F}{(\alpha + \beta)\|(\hat{L}, \hat{R})\|_F + \gamma}, \tag{27}$$

where

$$\mu(\hat{L}, \hat{R}) = \frac{(\alpha + \beta)\|(\hat{L}, \hat{R})\|_F + \gamma}{(\alpha^2 \sigma_n(\hat{R})^2 + \beta^2 \sigma_m(\hat{L})^2 + \gamma^2)^{\frac{1}{2}}}. \tag{28}$$

By squaring both sides of (28), we see that $\mu(\hat{L}, \hat{R}) \geq 1$ and as for the standard Sylvester equation [13], $\mu(\hat{L}, \hat{R})$ is a *growth factor* that measures by how much the backward error $\eta(\hat{L}, \hat{R})$, at most, can be greater than the relative residual as defined in (27). It is now interesting to examine the size of $\mu(\hat{L}, \hat{R})$ more closely.

If $D = I_m$, $E = I_n$, and $F = 0$, then (1) reduces to the standard Sylvester equation $AR - RB = C$, and by choosing $\alpha = \|A\|_F, \beta = \|B\|_F, \gamma = \|C\|_F$, $\mu(\hat{L}, \hat{R})$ is at most a factor $\sqrt{2}$ times the growth factor for the standard Sylvester equation [13].

The detailed discussion of the growth factor in [13] can be extended to our case. For clarity, we accomplish some of it here. If $m = n$ then

$$\mu(\hat{L}, \hat{R}) = \frac{(\|(A,D)\|_F + \|(B,E)\|_F)\|(\hat{L}, \hat{R})\|_F + \|(C,F)\|_F}{(\|(A,D)\|_F{}^2 \sigma_{\min}(\hat{R})^2 + \|(B,E)\|_F{}^2 \sigma_{\min}(\hat{L})^2 + \|(C,F)\|_F{}^2)^{\frac{1}{2}}}. \tag{29}$$

The growth factor is large only when

$$\|(\hat{L}, \hat{R})\|_F \gg \sigma_{\min}(\hat{R}), \sigma_{\min}(\hat{L}) \tag{30}$$

and

$$\|(\hat{L}, \hat{R})\|_F \gg \frac{\|(C,F)\|_F}{\|(A,D)\|_F + \|(B,E)\|_F}, \tag{31}$$

i.e., $(\hat{L}, \hat{R})$ is an ill-conditioned, large-normed solution to the generalized Sylvester equation.

If $m \neq n$, one of $\sigma_n(\hat{R})$ and $\sigma_m(\hat{L})$ must be zero and we will have a large growth factor if the data is badly scaled: (A, D) (if $m < n$) or (B, E) (if $m > n$) greatly exceeds the rest of the data in norm. The effect on $\mu(\hat{L}, \hat{R})$ from badly scaled data can be overcome by regarding (A, D) and (B, E) as one set of data and choosing $\alpha = \beta = \|(A, D)\|_F + \|(B, E)\|_F$.

In practice, when solving the generalized Sylvester equation, we typically have (A, D) and (B, E) in generalized Schur form, i.e., A and B are quasi triangular and D and E are triangular. If we wish to restrict the perturbations to have the same structure, this can be done by removing elements in $\mathrm{col}(X), X = \Delta A, \Delta B, \Delta D, \Delta E$ in (18) that correspond to the "zero triangles" of A, B, D, E and deleting the corresponding columns of $\mathcal{H}$. However, removing columns of $\mathcal{H}$ will result in a possibly smaller $\sigma_{\min}$ and potentially a larger backward error.

4. Normwise perturbation and error bounds. Consider the perturbed generalized Sylvester equation

$$\begin{aligned} (A + \delta A)(R + \delta R) - (L + \delta L)(B + \delta B) &= C + \delta C, \\ (D + \delta D)(R + \delta R) - (L + \delta L)(E + \delta E) &= F + \delta F. \end{aligned} \tag{32}$$

By dropping second order terms in (32), we obtain

$$\begin{aligned} A\delta R - \delta L B &= \delta C - \delta A R + L \delta B, \\ D\delta R - \delta L E &= \delta F - \delta D R + L \delta E. \end{aligned} \tag{33}$$

The system (33) can be written

(34)

$$\begin{bmatrix} I_n \otimes A & -B^T \otimes I_m \\ I_n \otimes D & -E^T \otimes I_m \end{bmatrix} \begin{bmatrix} \mathrm{col}(\delta R) \\ \mathrm{col}(\delta L) \end{bmatrix} = - \begin{bmatrix} R^T \otimes I_m & -I_m \otimes L & -I_{mn} & 0 & 0 & 0 \\ 0 & 0 & 0 & R^T \otimes I_m & -I_m \otimes L & -I_{mn} \end{bmatrix} \begin{bmatrix} \mathrm{col}(\delta A) \\ \mathrm{col}(\delta B) \\ \mathrm{col}(\delta C) \\ \mathrm{col}(\delta D) \\ \mathrm{col}(\delta E) \\ \mathrm{col}(\delta F) \end{bmatrix}.$$

If we solve for $(\delta L, \delta R)$ in (34) and measure the perturbations normwise by

$$\epsilon = \max\left(\frac{\|(\delta A, \delta D)\|_F}{\alpha}, \frac{\|(\delta B, \delta E)\|_F}{\beta}, \frac{\|(\delta C, \delta F)\|_F}{\gamma} \right), \tag{35}$$

where $\alpha = \|(A, D)\|_F, \beta = \|(B, E)\|_F, \gamma = \|(C, F)\|_F$, we can derive the following relative perturbation bound.

THEOREM 4.1. *Assume that the unperturbed and perturbed matrix equations* (1) *and* (32), *respectively, are given, and that the perturbations in* (32) *fulfill* (35). *Then*

$$\frac{\|(\delta L, \delta R)\|_F}{\|(L, R)\|_F} \leq \frac{\|Z^{-1}\mathcal{X}\|_2}{\|(L, R)\|_F} \epsilon \sqrt{3}, \tag{36}$$

where Z is the coefficient matrix in (2), (34), *and*

$$\mathcal{X} = \begin{bmatrix} H & 0 \\ 0 & H \end{bmatrix}, \tag{37}$$

with

$$H = \begin{bmatrix} \alpha(R^T \otimes I_m) & -\beta(I_n \otimes L) & -\gamma I_{mn} \end{bmatrix}. \tag{38}$$

Proof. From (34) we obtain

$$\|(\delta L, \delta R)\|_F \leq \|Z^{-1}\mathcal{X}\|_2 \|\mathrm{diag}\{\alpha^{-1}, \beta^{-1}, \gamma^{-1}, \alpha^{-1}, \beta^{-1}, \gamma^{-1}\} \begin{bmatrix} \mathrm{col}(\delta A) \\ \mathrm{col}(\delta B) \\ \mathrm{col}(\delta C) \\ \mathrm{col}(\delta D) \\ \mathrm{col}(\delta E) \\ \mathrm{col}(\delta F) \end{bmatrix} \|_2.$$

The 2-norm of the second term above is equivalent to

$$(\alpha^{-2}\|(\delta A, \delta D)\|_F^2 + \beta^{-2}\|(\delta B, \delta E)\|_F^2 + \gamma^{-2}\|(\delta C, \delta F)\|_F^2)^{\frac{1}{2}},$$

which from (35) is less than or equal to $\epsilon\sqrt{3}$. □

The perturbation bound (36) is sharp to first order in ϵ and

$$\Psi = \frac{\|Z^{-1}\mathcal{X}\|_2}{\|(L, R)\|_F} \tag{39}$$

is the corresponding condition number for the generalized Sylvester equation. From (36) it is possible to derive a (weaker) normwise perturbation bound that relates to $\|Z^{-1}\|_2$.

COROLLARY 4.2. Assumptions from Theorem 4.1. *Then*

$$\frac{\|(\delta L, \delta R)\|_F}{\|(L, R)\|_F} \leq \Phi\epsilon\sqrt{3}, \tag{40}$$

where

$$\Phi = \|Z^{-1}\|_2 \frac{(\alpha + \beta)\|(L, R)\|_F + \gamma}{\|(L, R)\|_F}. \tag{41}$$

Proof. We have $\|Z^{-1}\mathcal{X}\|_2 \leq \|Z^{-1}\|_2\|\mathcal{X}\|_2$ and

$$\begin{aligned} \|\mathcal{X}\|_2 = \|H\|_2 &\leq \alpha\|R^T \otimes I_m\|_2 + \beta\|I_n \otimes L\|_2 + \gamma \\ &= \alpha\|R\|_2 + \beta\|L\|_2 + \gamma \leq (\alpha + \beta)\|(L, R)\|_F + \gamma, \end{aligned}$$

which in (36) gives (40). □

In [18] a similar bound was derived by applying standard perturbation theory for linear systems to (2). If $\|Z^{-1}\|_2(\alpha+\beta)\epsilon < r \leq 1$ then that theory (see, e.g., [9]) gives us the following strict bound for the relative error

$$\frac{\|(\delta L, \delta R)\|_F}{\|(L, R)\|_F} \leq \frac{2}{1 - r}\Phi\epsilon\sqrt{3}. \tag{42}$$

It is of course interesting to know how much the bounds (36) and (42) differ. From definition we know that $\Psi \leq \Phi$. In general the bounds will be of the same magnitude. But there are examples where (36) can be arbitrarily better than (42) (see §6). The reason is that the bound (42) does not take any account to the special structure of the problem. This is in contrast to the bound (36).

We can also show the following (a posteriori) forward error bound for a computed solution.

COROLLARY 4.3. *Let* $(\hat{L}, \hat{R})$ *be a computed solution to* (1) *with residuals*

$$R_1 = A\hat{R} - \hat{L}B - C,$$
$$R_2 = D\hat{R} - \hat{L}E - F.$$

Then

$$\frac{\|(L,R) - (\hat{L},\hat{R})\|_F}{\|(L,R)\|_F} \leq \|Z^{-1}\|_2 \frac{\|(R_1,R_2)\|_F}{\|(L,R)\|_F}. \tag{43}$$

Proof. Let $(\hat{L}, \hat{R}) = (L + \delta L, R + \delta R)$ and set $(\delta A, \delta D) = (0,0), (\delta D, \delta E) = (0,0)$ and $(\delta C, \delta F) = (R_1, R_2)$ in (34) and apply Theorem 4.1. □

The normwise error bound (43) holds in general but can be weaker than one based on componentwise errors that are described in the next section.

5. Componentwise error bounds. We will now derive a LAPACK-style error bound [1] for an approximate solution of the generalized Sylvester equation. In [13] it was shown that such a bound could be derived for the standard Sylvester equation and estimated by the technique used in the LAPACK library for linear systems. For clarity, we outline the technique used for the $Ax = b$ case. Let $\hat{x}$ be an approximate solution and $r = b - A\hat{x}$. Then the following error bound holds:

$$\frac{\|x - \hat{x}\|_\infty}{\|\hat{x}\|_\infty} \leq \frac{\|A^{-1}r\|_\infty}{\|\hat{x}\|_\infty} \leq \frac{\| \, |A^{-1}||r| \, \|_\infty}{\|\hat{x}\|_\infty}. \tag{44}$$

This bound can be interpreted as a componentwise bound since it measures the largest error in the components of the quantities involved. To obtain a strict error bound, we must add a term r_u for rounding errors in forming r (let $d = |r| + |r_u|$):

$$\frac{\|x - \hat{x}\|_\infty}{\|\hat{x}\|_\infty} \leq \frac{\| \, |A^{-1}|d\|_\infty}{\|\hat{x}\|_\infty}. \tag{45}$$

The trick is to write $D = \mathrm{diag}(d)$ and let $e = (1, \ldots, 1)^T$. Then the numerator of the error bound (44) can be written as [2]

$$\| \, |A^{-1}|De\|_\infty = \| \, |A^{-1}D|e\|_\infty = \|A^{-1}D\|_\infty.$$

Let $B = (A^{-1}D)^T$ and $\|B^T\|_\infty$ can now be estimated by the 1-norm estimator described in [11] and [12] (also implemented in LAPACK). It estimates $\|B\|_1$ at the cost of computing a few matrix-vector products involving B and B^T, that is, solving a few linear systems involving A^T and A, respectively.

Now we apply the same technique to the generalized Sylvester equation. The rounding errors in the computed residuals can be expressed as

$$\hat{R}_1 = \mathrm{fl}(C - (A\hat{R} - \hat{L}B)) = R_1 + \Delta R_1,$$
$$\hat{R}_2 = \mathrm{fl}(F - (D\hat{R} - \hat{L}E)) = R_2 + \Delta R_2,$$

where

$$|\Delta R_1| \le u\left(3|C| + (m+3)|A||\hat{R}| + (n+3)|\hat{L}||B|\right) \equiv {R_1}^u,$$
$$|\Delta R_2| \le u\left(3|F| + (m+3)|D||\hat{R}| + (n+3)|\hat{L}||E|\right) \equiv {R_2}^u.$$

Introducing

$$g = |\mathrm{col}(\begin{bmatrix} \hat{R}_1 & \hat{R}_2 \end{bmatrix})| + \mathrm{col}(\begin{bmatrix} {R_1}^u & {R_2}^u \end{bmatrix}),$$

and $G = \mathrm{diag}(g)$, we get the bound

$$\frac{\|(L,R) - (\hat{L},\hat{R})\|_M}{\|(\hat{L},\hat{R})\|_M} \le \frac{\| \, |Z^{-1}|g\|_M}{\|(\hat{L},\hat{R})\|_M} = \frac{\|Z^{-1}G\|_M}{\|(\hat{L},\hat{R})\|_M}. \tag{46}$$

From (46) we see that large elements in the kth column of $|Z^{-1}|$ can be offset by a small kth element of g. This situation can never be reflected in the bound (43) which in these cases is a weaker bound. Accordingly, (46) has better scaling properties than (43) but none of the bounds are invariant under diagonal scalings of the (generalized) Sylvester equation [13]. $Z^T y = c$ is not a transposed generalized Sylvester equation (1) (as in the standard case). However, y can be recovered at the same cost by utilizing that the matrix pairs (A, D) and (B, E) are already in generalized real Schur form [15]. The cost for solving (9) using the GS algorithm is $O(m^2n + mn^2)$ flops (see §2 and [18]).

We would like to compare the strict bound (46) with the following componentwise approximate error bound:

$$\frac{\|(L,R) - (\hat{L},\hat{R})\|_M}{\|(\hat{L},\hat{R})\|_M} \lesssim \frac{\|Z^{-1}r\|_M}{\|(\hat{L},\hat{R})\|_M}, \tag{47}$$

where

$$r = \mathrm{col}(\begin{bmatrix} \hat{R}_1 & \hat{R}_2 \end{bmatrix}) + \mathrm{col}(\begin{bmatrix} {R_1}^u & {R_2}^u \end{bmatrix}).$$

The bound (47) is easy to compute and corresponds to the defect in one step of iterative refinement of (3). To compute $Z^{-1}r$ is equivalent to solving a generalized Sylvester equation (1) with the right-hand sides $(C, F) = (\hat{R}_1 + {R_1}^u, \hat{R}_2 + {R_2}^u)$. The bound (47) has the same appealing properties as (46) and only requires one generalized Sylvester solve. Estimating (46) is an iterative process that typically requires four–six generalized Sylvester solves [15]. In our extensive testing we have only seen once that (47) underestimates the exact error. In this case the error bound was still the same order as the exact error.

6. Some computational experiments. In the following we illustrate the perturbation analysis of the generalized Sylvester equation on some test problems ranging from well-conditioned to extremely ill-conditioned problems.

Examples. The *first* set of test problems illustrates *well-conditioned to (moderately) ill-conditioned* generalized Sylvester equations [18]. In the first example we let $A = J_m(1,-1), D = I_m$ and $B = J_n(1-\alpha, 1), E = I_n$, where $J_k(d,s)$ denotes a Jordan block of size k with d and s as diagonal and superdiagonal elements, respectively, and $\alpha > 0$ is a real parameter. When $\alpha \to 0$, the separation between (A, D) and (B, E) is of order $O(\alpha^{m+n+1})$ [22]. Furthermore, we apply unitary random equivalence transformations to (A, D) and (B, E), respectively, and choose (L, R) randomly,

TABLE 1
Condition numbers for well-conditioned to moderately ill-conditioned problems.

m	n	α	$\|(\hat{L},\hat{R})\|_F$	$\sigma_{\min}(Z)$	Φ	Ψ	Φ/Ψ

2	10		3.77e+00	3.56e−04	2.51e+04	9.48e+03	2.65e+00
8	4		4.61e+00	1.02e−05	8.85e+05	1.69e+05	5.24e+00
10	6		6.47e+00	1.02e−09	1.16e+10	2.70e+09	4.30e+00
10	10		8.46e+00	4.53e−08	3.23e+08	5.37e+07	6.01e+00

which similarly specifies the right-hand sides (C, F). The second example comprises upper triangular random problems. First, two upper triangular $(m+n) \times (m+n)$ matrices M and N are generated with entries chosen randomly (uniform distribution on $[-1, 1]$). Then A, B, C, D, E, F are given from the partitioning (4). Finally, the third example comprises quasi upper triangular random problems, i.e., M is chosen with 2×2 diagonal blocks and N upper triangular as before.

The *second* test problem illustrates *badly scaled* data. The examples chosen are upper triangular random problems (as above) and scaled in the following way: $A = \alpha A, D = \alpha D$ (if $m < n$), and $B = \alpha B, E = \alpha E$ (if $m > n$), where $\alpha = 10^{13}, 10^{16}$, and 10^{19}.

The *third* set of test problems illustrates *ill-conditioned* (generalized) Sylvester equations [13]. In the first example, $A = J_3(0,1), D = I_3, B = J_3(\alpha, 1), E = I_3$, and the entries of C, F are chosen to 1 and 0, respectively ($C_{ij} = 1, F_{ij} = 0$). In the second example, we have

$$A = \begin{bmatrix} 1 & -1 \\ 1 & -1 \end{bmatrix}, \quad B = A - \alpha \begin{bmatrix} 1+\alpha & 0 \\ 0 & -1 \end{bmatrix}, \quad D = E = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}.$$

First we choose $\mathrm{col}(C, F)$ as the right singular vector corresponding to the smallest singular value of Z (3). In the second case, $\mathrm{col}(C)$ is chosen as the left singular vector of the smallest singular value of $I_n \otimes A - B^T \otimes I_m$, the coefficient matrix of the corresponding $Zx = b$ representation of the standard Sylvester equation [13] and $F = 0$.

Test results and discussion. In Tables 1, 4, and 7 quantities that reflect the conditioning of our three sets of test problems are displayed. Besides $\|(\hat{L}, \hat{R})\|_F$ and $\mathrm{Dif}[(A, D), (B, E)] = \sigma_{\min}(Z)$, the Dif-based condition number Φ (41), the new structure preserving condition number Ψ (39) and their ratio Φ/Ψ are shown. In Tables 2, 5, and 8 associated computed residuals and backward error bounds are displayed. More precisely, $\|(R_1, R_2)\|_F$, the relative residual $\|(R_1, R_2)\|_F / ((\alpha + \beta)\|(\hat{L}, \hat{R})\|_F + \gamma)$ the exact backward error $\|\mathcal{H}^+ r\|_2$ (22), an upper bound on the backward error $\eta(\hat{L}, \hat{R})$ (27), and the growth factor $\mu(\hat{L}, \hat{R})$ (28) that measures by how much the backward error, at most, can be greater than the relative residual. Finally, exact (relative) errors (when the exact solution is known) and the forward error bounds (43), (46), and (47) are shown in Tables 3, 6, and 9.

All results presented are computed in the MATLAB environment [19] with unit roundoff $\approx 2.2 \times 10^{-16}$, and $(\hat{L}, \hat{R})$ is obtained by solving the system $Zx = b$ (3)

by Gaussian elimination with partial pivoting. In some cases we would (probably) obtain better results (for example, smaller residuals) if we use the generalized Schur methods [18]. Notice that some of the test problems are standard Sylvester equations that we solve as generalized Sylvester equations. As a consequence we should expect less favourable results compared to the standard case.

The *first* set of test problems have all small-normed solutions and the ratios Φ/Ψ are of size $O(1)$, i.e., the Dif-based and the structure-preserving condition numbers are similar. We also see that the relative residuals and the relative backward errors are both of the size $O(\epsilon)$, where ϵ denotes the relative machine precision, and the growth factors $\mu(\hat{L}, \hat{R})$ are of size $O(1)$. Finally, the normwise and componentwise forward error bounds are similar and quite accurate.

The *badly scaled data* illustrate that the ratio Φ/Ψ can be arbitrarily large and show that these problems are not really ill conditioned (Ψ of size $O(10^2)$). Notice that the relative backward errors are at the machine precision level but are much larger than the relative residuals. The componentwise forward error bounds are in most cases better than the normwise forward error bounds, but this is not always the case $(m = 2, n = 4, \alpha = 10^{16})$.

are characterized by a large-normed solution $(\hat{L},\hat{R})$, a small $\mathrm{Dif}[(A,D),(B,E)]$ (Z is almost singular) and a quite large Ψ. The condition numbers $\kappa(\hat{L}),\kappa(\hat{R})$ of the first example are moderate and, therefore, the computed solutions are nevertheless quite accurate (relative backward errors and componentwise forward error bounds of size $O(10^2\epsilon)$). Note that the componentwise forward error bounds are much smaller than the normwise error bound for this example. However, in the second example $\kappa(\hat{L}),\kappa(\hat{R})$ are large ($(\hat{L},\hat{R})$ are large normed and ill conditioned [13]) and the computed solutions have almost no accuracy at all. It is clear that the last example reflects an extremely ill-conditioned (generalized) Sylvester equation, but it is still an open problem (in general) to identify the exact conditions for an ill-conditioned

UNIFORM STABILITY OF MARKOV CHAINS*

ILSE C. F. IPSEN† AND CARL D. MEYER‡

Abstract. By deriving a new set of tight perturbation bounds, it is shown that all stationary probabilities of a finite irreducible Markov chain react essentially in the same way to perturbations in the transition probabilities. In particular, if at least one stationary probability is insensitive in a relative sense, then all stationary probabilities must be insensitive in an absolute sense. New measures of sensitivity are related to more traditional ones, and it is shown that all relevant condition numbers for the Markov chain problem are small multiples of each other. Finally, the implications of these findings to the computation of stationary probabilities by direct methods are discussed, and the results are applied to stability issues in nearly transient chains.

Key words. Markov chains, stationary distribution, stochastic matrix, sensitivity analysis, perturbation theory, stability of a Markov chain, condition numbers

1. Introduction.

The purpose of this paper is to analyse the sensitivity of individual stationary probabilities to perturbations in the transition probabilities of finite irreducible Markov chains. In addition to providing perturbation bounds that are much sharper than the traditional bounds, our analysis demonstrates that all stationary probabilities in an irreducible chain react in a somewhat uniform manner to perturbations in the transition probabilities. This property of uniform sensitivity markedly distinguishes Markov problems from general linear systems. Examples are presented in §3 to illustrate why a Markov problem should not be treated as just another linear system.

Previous perturbation theory for irreducible chains focused on the derivation of norm-based bounds of the following kind. Let P and $\tilde{P} = P + E$ be transition probability matrices with respective stationary probability vectors π^T and $\tilde{\pi}^T$ satisfying

$$\pi^T P = \pi^T, \quad \tilde{\pi}^T \tilde{P} = \tilde{\pi}^T, \quad \sum_i \pi_i = 1 = \sum_i \tilde{\pi}_i.$$

For suitable vector and matrix norms, it is known that

$$\|\pi^T - \tilde{\pi}^T\| \leq \kappa \|E\|$$

where values for the condition number κ can be derived in various ways. Schweitzer (1968) derives a value for κ from the fundamental matrix of Kemeny and Snell (1960) whereas the group inverse $A^{\#}$ of $A = I - P$ is used by Meyer (1980), Golub and Meyer (1986), Funderlic and Meyer (1986), Meyer (1994), Meyer and Stewart (1988), Barlow (1993), and Stewart (1991). Seneta (1991) suggests using a coefficient of ergodicity for κ.

These norm-based bounds are not satisfying for two reasons. First, there exist irreducible chains for which the bounds are not tight, so the condition number κ may seriously overestimate the sensitivity to perturbations. Secondly, the bounds generally provide little information about the relative error $|\pi_j - \tilde{\pi}_j|/\pi_j$ in individual stationary probabilities. We remedy this situation in §4 by deriving tight perturbation bounds for individual stationary probabilities. On the basis of these bounds, we prove a uniform sensitivity theorem saying that if at least one stationary probability has low relative sensitivity, or if at least one large stationary probability has low absolute sensitivity, then all probabilities have low absolute sensitivity.

In §5 we relate our measure of sensitivity to the traditional condition numbers for the Markov problem, and we prove that all relevant condition numbers for the problem $\pi^T A = 0$ are small multiples of each other. After discussing the ramifications of the perturbation results on direct methods for computing the stationary probabilities, we consider the case of nearly transient chains in §§6 and 7. We show that under special perturbations even small stationary probabilities may have low relative sensitivity. In addition, we give conditions under which a nearly transient chain is absolutely stable under general perturbations.

2. Norms and notation. Throughout the article the infinity-norm is exclusively used for matrices and column vectors, and the one-norm is used for row vectors. Since it will always be clear from the context whether a quantity is a matrix, column, or row, the subscripts on $\| \star \|_\infty$ and $\| \star \|_1$ are suppressed. Row vectors will always be transposed (e.g., π^T), and column vectors will be untransposed. The jth column of the identity matrix I is denoted by e_j and the column of all ones is denoted by e. The matrix P denotes the transition probability matrix of an n-state irreducible Markov chain with stationary distribution π^T whose entries satisfy $\pi_i > 0$ and $\sum_i \pi_i = 1$. We define $A = I - P$ and $A^\#$ denotes the group inverse of A, properties of which can be found in Campbell and Meyer (1991), Meyer (1975), and Meyer (1982). The matrix $\tilde{P} = P + E$ is a perturbation of P that represents the transition matrix of another irreducible chain with stationary distribution $\tilde{\pi}^T$. The perturbation matrix E is not necessarily constrained to be small. We use $E^{(j)}$ to denote the matrix obtained by deleting the jth column of E, and A_j denotes the principal submatrix obtained by deleting the jth row and column from $A = I - P$. Finally, we let N denote the matrix obtained by replacing the last column of A by a column of ones.

3. Absolutely stable chains. The solution of a general ill-conditioned linear system $Ax = b$ need not be uniformly sensitive to small perturbations. Some components of x can be sensitive while others are not. Furthermore, as shown in Chandrasekaran and Ipsen (1992), the sensitivity of the x_i's need not be a result of their size. Our purpose is to demonstrate that this cannot happen for Markov chains, but first it is important to distinguish between absolute sensitivity and relative sensitivity in the Markov chain setting.

Example 3.1. For the three-state chain whose transition matrix is

$$P(\epsilon) = \begin{pmatrix} 0 & 1-\epsilon & \epsilon \\ 1-\epsilon & 0 & \epsilon \\ 1 & 0 & 0 \end{pmatrix},$$

the associated stationary distribution is

$$\pi^T(\epsilon) = \left(\frac{1}{(2-\epsilon)(1+\epsilon)}, \frac{1-\epsilon}{(2-\epsilon)(1+\epsilon)}, \frac{\epsilon}{1+\epsilon} \right).$$

If $P = P(10^{-8})$ is perturbed to become $\tilde{P} = P(10^{-4})$, then the magnitude of the perturbation $E = \tilde{P} - P$ is

$$\|E\| = 2(10^{-4} - 10^{-8}).$$

Consider the change in the respective stationary distributions

$$\pi^T = \pi^T(10^{-8}) \quad \text{and} \quad \tilde{\pi}^T = \pi^T(10^{-4}).$$

The *absolute change* (the change relative to 1) in π_3 is

$$|\pi_3 - \tilde{\pi}_3| = \left| \frac{10^{-8}}{1+10^{-8}} - \frac{10^{-4}}{1+10^{-4}} \right| = \frac{10^{-4} - 10^{-8}}{(1+10^{-4})(1+10^{-8})} \approx 10^{-4} - 10^{-8} = \frac{\|E\|}{2},$$

but the *relative change* (the change relative to the original value) is

$$\left| \frac{\pi_3 - \tilde{\pi}_3}{\pi_3} \right| = \left| 1 - \frac{10^{-4}(1+10^{-8})}{10^{-8}(1+10^{-4})} \right| \approx 10^4.$$

If the change in probabilities is assessed in an absolute sense by comparing it to 1, then π_3 is not at all sensitive to the perturbation because the change of magnitude $\|E\|$ in the transition probabilities produces a change in π_3 of only $\|E\|/2$. We say that π_3 is *absolutely insensitive*. But if the change in probabilities is assessed in a relative sense then the change in π_3 is large, so π_3 is *relatively sensitive*. As for the sensitivity of the other two probabilities π_1 and π_2, if $a_{ij}^{\#}$ is element (i,j) in the group inverse $A^{\#}$ of $A = I - P$, then, as shown by Funderlic and Meyer (1986), the absolute error in the jth stationary probability is bounded by

$$|\pi_j - \tilde{\pi}_j| \leq \kappa_j \|E\|, \qquad \kappa_j = \max_i |a_{ij}^{\#}|.$$

In this example, $\max_{i,j} |a_{ij}^{\#}| < 1$, so all three stationary probabilities are insensitive in the absolute sense. Because π_1 and π_2 are both very close to .5, they are insensitive in the relative sense as well. This example motivates the following definition.

DEFINITION 3.1. *An irreducible chain is said to be* absolutely stable *whenever each π_j is insensitive to perturbations in P in the absolute sense; i.e., whenever there is a small constant κ such that for all perturbations E,*

$$|\pi_j - \tilde{\pi}_j| \leq \kappa \|E\| \quad \textit{for each } 1 \leq j \leq n,$$

where the term "small" is to be interpreted in the context of the underlying application.

Sufficient conditions for absolute stability are well-known. The results in Barlow (1993), Funderlic and Meyer (1986), Golub and Meyer (1986), Meyer (1980), Meyer (1994), Meyer and Stewart (1988), Stewart (1991), for instance, use the fact that a chain is absolutely stable if the group inverse $A^{\#}$ of $A = I - P$ has no large entries (relative to 1). The results of §5 will establish that the converse of this statement is also true.

4. Componentwise analysis. In this section we derive tight upper bounds on the relative change in individual stationary probabilities, and we prove that all stationary probabilities show essentially the same sensitivity to perturbations in the transition probabilities.

We make use of the following properties of M–matrices, details of which can be found in the text by Berman and Plemmons (1979). If P is an irreducible stochastic matrix of order n, then $A = I - P$ is a singular M–matrix of rank $n-1$. Moreover, if A_j is the principal submatrix of A obtained by deleting the jth row and column from A, then A_j is a nonsingular M–matrix. Hence $A_j^{-1} > 0$, and if e is the column vector of all ones, then $\|A_j^{-1}e\| = \|A_j^{-1}\|$. The following theorem demonstrates that the entries in A_j^{-1} determine the relative sensitivity of the jth stationary probability to perturbations in the transition probabilities.

THEOREM 4.1. *If $E^{(j)}$ denotes the matrix obtained by deleting the jth column of E, then*

$$\frac{\pi_j - \tilde{\pi}_j}{\pi_j} = \tilde{\pi}^T E^{(j)} A_j^{-1} e.$$

Furthermore,

$$\left| \frac{\pi_j - \tilde{\pi}_j}{\pi_j} \right| \leq \|E^{(j)}\| \, \|A_j^{-1}\|,$$

and there always exists a perturbation E (dependent on j) for which equality is attained.

Proof. By applying a symmetric permutation to P, the states may be reordered so that a particular stationary probability occurs in the last position of π^T. Thus it suffices to prove the theorem for $j = n$. With the partitioning

$$\pi^T = (\overline{\pi}^T \quad \pi_n), \qquad A = \begin{pmatrix} A_n & b \\ c^T & \delta \end{pmatrix},$$

$\pi^T A = 0^T$ implies $\overline{\pi}^T = -\pi_n c^T A_n^{-1}$. Replacing the last column of A by the vector of all ones produces a nonsingular matrix

$$N = \begin{pmatrix} A_n & e \\ c^T & 1 \end{pmatrix} \quad \text{with inverse} \quad N^{-1} = \begin{pmatrix} A_n^{-1}(I - e\overline{\pi}^T) & -\pi_n A_n^{-1} e \\ \overline{\pi}^T & \pi_n \end{pmatrix}.$$

The stationary distribution of the original chain is the solution of the system

$$\pi^T N = e_n^T \quad \text{where} \quad e_n^T = (0 \quad \cdots \quad 0 \quad 1),$$

and the stationary distribution for the perturbed chain is the solution of

$$\tilde{\pi}^T (N - F) = e_n^T \quad \text{where} \quad F = (E^{(n)} \quad 0).$$

Consequently,

$$\pi^T - \tilde{\pi}^T = -\tilde{\pi}^T F N^{-1}, \tag{4.1}$$

so

$$\pi_n - \tilde{\pi}_n = -\tilde{\pi}^T \begin{pmatrix} E^{(n)} & 0 \end{pmatrix} \begin{pmatrix} -\pi_n A_n^{-1} e \\ \pi_n \end{pmatrix} = \pi_n \left(\tilde{\pi}^T E^{(n)} A_n^{-1} e \right),$$

and therefore

$$\frac{\pi_n - \tilde{\pi}_n}{\pi_n} = \tilde{\pi}^T E^{(n)} A_n^{-1} e.$$

Applying Hölder's inequality and $\|A_n^{-1}e\| = \|A_n^{-1}\|$ yields

$$\left|\frac{\pi_n - \tilde{\pi}_n}{\pi_n}\right| \leq \|\tilde{\pi}\| \, \|E^{(n)} A_n^{-1} e\| \leq \|E^{(n)}\| \, \|A_n^{-1}\|.$$

To see that equality is always attainable, let k be the position where the largest component of $A_n^{-1}e$ occurs so that

$$e_k^T A_n^{-1} e = \|A_n^{-1}e\| = \|A_n^{-1}\|,$$

and let $E = \epsilon e(e_k - e_n)^T$. Then $\tilde{\pi}^T E^{(n)} = \epsilon e_k^T$ and $\|E^{(n)}\| = \epsilon$, so that

$$\frac{\pi_n - \tilde{\pi}_n}{\pi_n} = \tilde{\pi}^T E^{(n)} A_n^{-1} e = \epsilon e_k^T A_n^{-1} e = \epsilon \|A_n^{-1}\| = \|E^{(n)}\| \, \|A_n^{-1}\|. \qquad \square$$

COROLLARY 4.1. *An irreducible chain is absolutely stable if and only if* $\pi_j \|A_j^{-1}\|$ *is small for every* $1 \leq j \leq n$.

The results of Theorem 4.1 and its corollary suggest the following definitions.

DEFINITION 4.1. *Let* A_j *be the principal submatrix obtained by deleting the* j*th row and column from* A, *and let* π_j *denote the* j*th stationary probability. The* relative condition number *for* π_j *is defined to be*

$$\rho_j = \|A_j^{-1}\| \quad \textit{and we set} \quad \rho = \min_j \{\rho_j\}.$$

The absolute condition number *for* π_j *is defined to be*

$$\alpha_j = \pi_j \|A_j^{-1}\| \quad \textit{and we set} \quad \alpha = \max_j \{\alpha_j\}.$$

In terms of this notation, Theorem 4.1 states

$$\left|\frac{\pi_j - \tilde{\pi}_j}{\pi_j}\right| \leq \rho_j \, \|E^{(j)}\|, \quad |\pi_j - \tilde{\pi}_j| \leq \alpha_j \, \|E\|, \quad \text{and} \quad \|\pi - \tilde{\pi}\| \leq \alpha \|E\|,$$

so α is the *absolute condition number for the entire chain.*

Notice that if a stationary probability is relatively well-conditioned, then it is absolutely well-conditioned but not conversely, cf., Example 3.1. It may be of interest to note that the existence of a small ρ_j means that the $(n-1)$st singular value of A is large (Barlow (1993)).

We now arrive at one of our principal conclusions which states that the sensitivity of the stationary distribution is uniform in the sense that all π_j's are absolutely well-conditioned if and only if at least one π_j is relatively well-conditioned.

THEOREM 4.2. *For every* $1 \leq j \leq n$,

$$|\pi_j - \tilde{\pi}_j| \leq \rho \, \|E\|.$$

Consequently, an irreducible chain is absolutely stable if and only if at least one π_j *is relatively well-conditioned.*

Proof. As in the proof of Theorem 4.1, assume that the states have been permuted so the best relatively conditioned stationary probability is in the last position; i.e., $\rho_n = \rho$. If

$$N = \begin{pmatrix} A_n & e \\ c^T & 1 \end{pmatrix}$$

is the matrix obtained by replacing the last column of A by ones then, as in (4.1),

$$\pi^T - \tilde{\pi}^T = -\tilde{\pi}^T F N^{-1}, \quad \text{where} \quad F = \begin{pmatrix} E^{(n)} & 0 \end{pmatrix}.$$

From

$$N^{-1} = \begin{pmatrix} A_n^{-1}(I - e\overline{\pi}^T) & -\pi_n A_n^{-1} e \\ \overline{\pi}^T & \pi_n \end{pmatrix} = \begin{pmatrix} A_n^{-1} & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} I - e\overline{\pi}^T & -\pi_n e \\ \overline{\pi}^T & \pi_n \end{pmatrix}, \tag{4.2}$$

it follows that

$$\pi_j - \tilde{\pi}_j = -\tilde{\pi}^T F N^{-1} e_j = \begin{cases} -\tilde{\pi}^T E^{(n)} A_n^{-1}(e_j - \pi_j e) & \text{if} \quad j < n. \\ -\tilde{\pi}^T E^{(n)} A_n^{-1}(-\pi_j e) & \text{if} \quad j = n. \end{cases}$$

Since $\|e_j - \pi_j e\| = \max\{\pi_j, 1 - \pi_j\} < 1$ and $\|A_n^{-1} e\| = \|A_n^{-1}\| = \rho_n$, we have that

$$|\pi_j - \tilde{\pi}_j| \leq \rho_n \|E^{(n)}\| \leq \rho_n \|E\|, \qquad 1 \leq j \leq n.$$

Therefore, if at least one stationary probability is relatively well-conditioned, then all stationary probabilities are absolutely well-conditioned. The converse follows from Corollary 4.1 because at least one π_j must be greater than or equal to $1/n$. □

The following two statements are direct consequences of Theorem 4.2, but they are important to state because they drive home the extent to which there exists uniform stability in Markov chains.

COROLLARY 4.2. *If any stationary probability is relatively well-conditioned, then all large stationary probabilities are relatively well-conditioned.*

COROLLARY 4.3. *If any large stationary probability is absolutely well-conditioned, then the chain is absolutely stable.*

A natural question arises at this point. We know that the existence of one relatively well-conditioned π_j implies the chain is absolutely stable, but does the existence of one absolutely well-conditioned π_j insure absolute stability? Unfortunately, the answer is "no," and this can be seen by considering

$$P = \begin{pmatrix} 1-\epsilon & \epsilon/2 & \epsilon/2 \\ \epsilon/2 & 1-\epsilon & \epsilon/2 \\ 1/2 & 1/2 & 0 \end{pmatrix}, \qquad \pi^T = \frac{1}{2+\epsilon}\begin{pmatrix} 1 & 1 & \epsilon \end{pmatrix}$$

for small $0 < \epsilon < 1$. The absolute and relative condition numbers are

$$\alpha_1 = \alpha_2 = \frac{1}{2+\epsilon}\left(\frac{2}{3} + \frac{4}{3\epsilon}\right), \quad \alpha_3 = \frac{2}{2+\epsilon}, \quad \rho_1 = \rho_2 = \frac{2}{3} + \frac{4}{3\epsilon}, \quad \text{and} \quad \rho_3 = \frac{2}{\epsilon},$$

so, for small ϵ, π_3 is absolutely well-conditioned, but π_1 and π_2 are not. The chain is not absolutely stable, and no π_j is relatively well-conditioned.

Small stationary probabilities are the ones that appear least likely to be relatively well-conditioned. Therefore it makes sense to try to determine features that may be responsible for the small size. The following theorem shows that those π_j whose associated submatrix A_j is well-conditioned cannot be small. It also shows that a nearly reducible matrix A that is far from being uncoupled produces small π_j.

THEOREM 4.3. *If Q is a permutation matrix such that*

$$Q^T A Q = \begin{pmatrix} A_j & b_j \\ c_j^T & \delta_j \end{pmatrix},$$

then

$$\frac{1}{1+\rho_j} \leq \pi_j \leq \frac{\|b_j\|}{\|c_j^T\| + \|b_j\|}.$$

Proof. Let $\pi^T Q = \psi^T = \begin{pmatrix} \overline{\psi}^T & \pi_j \end{pmatrix}$. Since $\psi^T A = 0$ implies $\overline{\psi}^T = -\pi_j c_j^T A_j^{-1}$, Hölder's inequality gives the lower bound

$$1 - \pi_j = \overline{\psi}^T e = \pi_j |c_j^T A_j^{-1} e| \leq \pi_j \rho_j.$$

To obtain the upper bound, use $\|c_j^T\| = -c_j^T e = \delta_j$ and $\delta_j \pi_j = -\overline{\psi}^T b_j$, and again apply Hölder's inequality,

$$\pi_j \|c_j^T\| = \pi_j \delta_j = -\overline{\psi}^T b_j \leq \|\overline{\psi}^T\| \, \|b_j\| = (1 - \pi_j)\|b_j\|. \qquad \square$$

5. Condition numbers and linear systems. It was demonstrated in the previous section that the sensitivity of the stationary distribution is governed by ρ. We now compare this measure of sensitivity to other condition numbers, and we relate these results to numerical techniques for computing stationary probabilities by solving certain linear systems.

The nonsingular matrix

$$N = \begin{pmatrix} A_n & e \\ c^T & 1 \end{pmatrix} \quad \text{and the associated system} \quad \pi^T N = e_n^T$$

are focal points of the development. The expression (4.2) together with the fact that $\rho_n = \|A_n^{-1}\| \geq 1$ (because $e = -A_n^{-1} b$) produces

$$1 \leq \|N^{-1}\| \leq 2\rho_n. \tag{5.1}$$

This means that if π_n is relatively well-conditioned, then $\pi^T N = e_n^T$ is a well-conditioned nonsingular system and therefore any stable algorithm can accurately solve it. But it is not clear that the solution of $\pi^T N = e_n^T$ should be attempted when ρ_n is large, even if the chain is absolutely stable. Theorem 4.1 insures that some ρ_j must be small, but, as Example 3.1 demonstrates, it need not be ρ_n. Of course, safety can be guaranteed if one is willing to determine a value of k such that $\rho_k = \rho$ because the same logic that produced (5.1) insures that the system $\pi^T \hat{N} = e_k^T$ is well-conditioned where $\hat{N}$ is the nonsingular matrix obtained by replacing the kth column of A by e. But determining ρ (or its position) is prohibitively expensive, and this may be why this approach is dismissed as "naive" by Paige, Styan, and Wachter (1975) and not included in their comparisons.

Surprisingly, it does not matter which column of A is replaced by e. This is a consequence of the next theorem that relates N^{-1} to the group inverse $A^{\#}$.

THEOREM 5.1. *For the numbers* α *and* ρ *given in Definition* 4.1,

$$\frac{\|A^{\#}\|}{2} \leq \|N^{-1}\| \leq 2\,\|A^{\#}\| + 1$$

and

$$\frac{\alpha}{2} \leq \|A^{\#}\| \leq 4\rho.$$

Proof. We derive the upper bounds first. It is easily verified (Meyer (1975)) that

$$\begin{aligned} A^{\#} &= (I - e\pi^T)\begin{pmatrix} A_n^{-1} & 0 \\ 0 & 0 \end{pmatrix}(I - e\pi^T) \\ &= \begin{pmatrix} (I - e\overline{\pi}^T)A_n^{-1}(I - e\overline{\pi}^T) & -\pi_n(I - e\overline{\pi}^T)A_n^{-1}e \\ -\overline{\pi}^T A_n^{-1}(I - e\overline{\pi}^T) & \pi_n \overline{\pi}^T A_n^{-1} e \end{pmatrix}. \end{aligned} \tag{5.2}$$

A symmetric permutation can bring any principal submatrix A_j of A to the upper left-hand corner of $Q^T A Q$. Then $(Q^T A Q)^{\#} = Q^T A^{\#} Q$, and

$$\psi^T = \pi^T Q = \begin{pmatrix} \overline{\psi}^T & \pi_j \end{pmatrix}$$

imply

$$\begin{aligned} Q^T A^{\#} Q &= (I - e\psi^T)\begin{pmatrix} A_j^{-1} & 0 \\ 0 & 0 \end{pmatrix}(I - e\psi^T) \\ &= \begin{pmatrix} (I - e\overline{\psi}^T)A_j^{-1}(I - e\overline{\psi}^T) & -\pi_j(I - e\overline{\psi}^T)A_j^{-1}e \\ -\overline{\psi}^T A_j^{-1}(I - e\overline{\psi}^T) & \pi_j \overline{\psi}^T A_j^{-1} e \end{pmatrix}. \end{aligned}$$

The second upper bound is now immediate because

$$\|A^{\#}\| = \|Q^T A^{\#} Q\| \leq 4\rho_j \quad \text{for all } j.$$

The first upper bound follows from

$$N^{-1} = \begin{pmatrix} I & -e \\ -c^T & -\delta \end{pmatrix} A^{\#} + e_n e_n^T,$$

which can be verified by using (5.2), so that $\|N^{-1}\| \leq 2\|A^{\#}\| + 1$. To establish the lower bounds, use the expressions for $A^{\#}$ and $Q^T A^{\#} Q$ to write

$$A^{\#} = \begin{pmatrix} I - e\overline{\pi}^T & 0 \\ -\overline{\pi}^T & 0 \end{pmatrix} N^{-1} \quad \text{and} \quad \pi_j A_j^{-1} = \begin{pmatrix} I & -e \end{pmatrix} Q^T A^{\#} Q \begin{pmatrix} \pi_j I \\ -\overline{\psi}^T \end{pmatrix}.$$

Hence $\|A^{\#}\| \leq 2\|N^{-1}\|$ and, for every j,

$$\alpha_j = \pi_j \|A_j^{-1}\| \leq 2\|A^{\#}\|. \qquad \square$$

The group inverse is relevant because

$$\pi - \tilde{\pi} = \tilde{\pi} E A^{\#} \quad \text{and} \quad |\pi_j - \tilde{\pi}_j| \leq \|E\|\,\|A^{\#}\|, \tag{5.3}$$

(Meyer (1980)), so if $\|A^{\#}\|$ is small, then the chain is absolutely stable. While conjectured, the converse of this statement has never been proven. However, on the basis of Theorems 4.2 and 5.1, the converse is now evident.

The logic used in proving Theorem 5.1 dictates that replacing *any* column of A by e results in a well-conditioned matrix when the chain is absolutely stable, and when the chain is not absolutely stable, all such matrices are ill-conditioned. Consequently, it does not matter which column of A is replaced by 1's, so the problem addressed by Harrod and Plemmons (1984) and Barlow (1986, 1993) of having to locate a well-conditioned principal submatrix A_j in order to build a well-conditioned system is obviated. Furthermore, since N is nonsingular, standard numerical techniques[1] can be applied to solve $\pi^T N = e_n^T$.

So far we have viewed the stationary distribution π^T as a solution to two different linear systems; the singular system $\pi^T A = 0$ and the nonsingular system $\pi^T N = e_n^T$. There is a yet a third linear system of which π^T is a solution, namely

$$\pi^T M = e_{n+1}^T \quad \text{where} \quad M = (A \quad e). \tag{5.4}$$

The augmented matrix M is of order $n \times (n+1)$ and has full row rank. The perturbed system is $\tilde{\pi}^T(M+E) = e_{n+1}^T$, so

$$\pi^T - \tilde{\pi}^T = \tilde{\pi}^T E M^{\dagger},$$

where $M^{\dagger}$ is the Moore-Penrose pseudo-inverse (Campbell and Meyer (1991)), and

$$|\pi_j - \tilde{\pi}_j| \leq \|\tilde{\pi}\| \, \|E\| \, \|M^{\dagger}\| \quad \text{for each } j.$$

Hence $\|M^{\dagger}\|$ is a condition number for measuring absolute stability. Another such number is $\|Z\|$ where $Z = (A + e\pi^T)^{-1}$ is the Kemeny and Snell (1960) fundamental matrix because $\pi^T - \tilde{\pi}^T = \tilde{\pi}^T E Z$ and $|\pi_j - \tilde{\pi}_j| \leq \|\tilde{\pi}\| \, \|E\| \, \|Z\|$ (Schweitzer (1968)). The following lemma shows that $\|M^{\dagger}\|$ and $\|Z\|$ are small multiples of each other and that they are not significantly different from $\|A^{\#}\|$.

LEMMA 5.1. *For the matrices M and Z defined above,*

$$\frac{\|Z\|}{3} \leq \|M^{\dagger}\| \leq 2\|Z\| \quad \text{and} \quad \|A^{\#}\| - 1 \leq \|Z\| \leq \|A^{\#}\| + 1.$$

Proof. The first set of inequalities follows from the identities

$$Z = \Big((I - e\pi^T) \;\; e\Big) M^{\dagger} \quad \text{and} \quad M^{\dagger} = \begin{pmatrix} I - ee^T/n \\ \pi^T \end{pmatrix} Z,$$

each of which is straightforward to verify. The second set of inequalities is a consequence of the fact that $Z = A^{\#} + e\pi^T$ (Meyer (1975)). □

Combining the results of Lemma 5.1 with those of Theorems 4.2 and 5.1 produces the following complete statement concerning the stability of irreducible Markov chains.

---

[1] Gaussian elimination with exact arithmetic generates positive pivots, but floating-point arithmetic may produce a zero or negative pivot (Funderlic and Mankin (1981)). This can be avoided with diagonal adjustment schemes as discussed by Grassmann, Taksar, and Heyman (1985), Stewart and Zhang (1991), and Barlow (1993).

THEOREM 5.2. *For an n-state irreducible Markov chain, the following statements are equivalent.*

- *At least one stationary probability is relatively well-conditioned.*
- *The chain is absolutely stable.*
- *All entries of the group inverse* $A^{\#}$ *are small.*
- *The matrix* N *and the system* $\pi^T N = e_n^T$ *are well-conditioned.*
- *The matrix* M *and the system* $\pi^T M = e_{n+1}^T$ *are well-conditioned.*
- *All entries in the Kemeny and Snell fundamental matrix* Z *are small.*

6. Sensitivity of nearly transient chains. In this section we examine the sensitivity of stationary probabilities of irreducible chains with nearly transient states; i.e., irreducible chains in which the states can be ordered so that the transition matrix is almost block triangular in the sense that

$$P = \begin{pmatrix} P_{11} & P_{12} \\ P_{21} & P_{22} \end{pmatrix} \quad \text{with} \quad \|P_{21}\| << 1. \tag{6.1}$$

We prove two results, one for structured perturbations and one for more general perturbations.

The first theorem establishes a result similar to the one by Stewart (1992b). It says that *small* stationary probabilities of an absolutely stable chain are *relatively* well-conditioned if only the states corresponding to these probabilities are perturbed and all other states remain unaffected.

THEOREM 6.1. *If* E *can be symmetrically permuted so that*

$$E = \begin{pmatrix} 0 \\ E_2 \end{pmatrix} \quad \textit{with} \quad \|E\| = \epsilon,$$

and if $\pi^T = (\,\pi_1^T \quad \pi_2^T\,)$ *is partitioned conformably, then*

$$\frac{|\pi_j - \tilde{\pi}_j|}{\|\tilde{\pi}_2\|} \leq 4\epsilon\,\rho, \qquad 1 \leq j \leq n.$$

Proof. Combine (5.3) with the fact $\|A^{\#}\| \leq 4\rho$ from Theorem 5.1. □

The second theorem concerns nearly transient chains, but no restriction is placed on the structure of the perturbation matrix.

THEOREM 6.2. *Suppose* P_{11} *in* (6.1) *is* $s \times s$, *and let*

$$A = \begin{pmatrix} A_n & b \\ c^T & \delta \end{pmatrix}, \quad A_n = \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix}, \quad \textit{and} \quad b = \begin{pmatrix} b_1 \\ b_2 \end{pmatrix},$$

where B_{11} *is* $s \times s$, b_1 *is* $s \times 1$, *and* $b_i \neq 0$ *for each* i. *The relative condition of* π_n *is bounded by*

$$\rho_n < \frac{2\max\{\|B_{11}^{-1}\|, \|B_{22}^{-1}\|\}}{1 - \|B_{22}^{-1}B_{21}\|},$$

so the chain is absolutely stable whenever B_{11} *and* B_{22} *have small inverses.*

Proof.

$$A_n = \begin{pmatrix} B_{11} & B_{12} \\ 0 & B_{22} \end{pmatrix} + \begin{pmatrix} 0 & 0 \\ B_{21} & 0 \end{pmatrix} = T + K = T(I + T^{-1}K).$$

If $\|T^{-1}K\| < 1$, then, from results in §2.3.4 in Golub and Van Loan (1989),

$$\rho_n = \|A_n^{-1}\| \le \|T^{-1}\| \, \|(I + T^{-1}K)^{-1}\| \le \frac{\|T^{-1}\|}{1 - \|T^{-1}K\|}.$$

Since A is an M–matrix, $B_{ii}^{-1} > 0$, $B_{ij} \le 0$, and $b \le 0$. Consequently, $Ae = 0$ implies

$$0 \le -B_{11}^{-1}B_{12}e = e + B_{11}^{-1}b_1 \le e.$$

By assumption, $b_1 \ne 0$, so $B_{11}^{-1}b_1 < 0$, and thus

$$\|B_{11}^{-1}B_{12}\| = \|B_{11}^{-1}B_{12}e\| < 1.$$

A similar argument shows that $\|B_{22}^{-1}B_{21}\| < 1$. Since

$$T^{-1} = \begin{pmatrix} B_{11}^{-1} & -B_{11}^{-1}B_{12}B_{22}^{-1} \\ 0 & B_{22}^{-1} \end{pmatrix} = \begin{pmatrix} I & -B_{11}^{-1}B_{12} \\ 0 & I \end{pmatrix} \begin{pmatrix} B_{11}^{-1} & 0 \\ 0 & B_{22}^{-1} \end{pmatrix},$$

we have

$$\|T^{-1}\| \le (1 + \|B_{11}^{-1}B_{12}\|) \max\{\|B_{11}^{-1}\|, \|B_{22}^{-1}\|\} < 2\max\{\|B_{11}^{-1}\|, \|B_{22}^{-1}\|\}.$$

Similarly,

$$T^{-1}K = \begin{pmatrix} -B_{11}^{-1}B_{12}B_{22}^{-1}B_{21} & 0 \\ B_{22}^{-1}B_{21} & 0 \end{pmatrix}$$

implies

$$\|T^{-1}K\| \le \max\{\|B_{11}^{-1}B_{12}B_{22}^{-1}B_{21}\|, \|B_{22}^{-1}B_{21}\|\} < \|B_{22}^{-1}B_{21}\|,$$

so

$$\rho_n \le \frac{\|T^{-1}\|}{1 - \|T^{-1}K\|} < \frac{2\max\{\|B_{11}^{-1}\|, \|B_{22}^{-1}\|\}}{1 - \|B_{22}^{-1}B_{21}\|}. \qquad \square$$

7. Small probabilities in nearly transient chains. Let $\pi^T = (\bar{\pi}_1^T \quad \bar{\pi}_2^T)$ be the stationary distribution of the nearly transient matrix P in (6.1), and set

$$A = I - P = \begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix}, \quad \text{where} \quad \|A_{21}\| = \|P_{21}\| = \epsilon.$$

Since $\bar{\pi}_1^T = -\bar{\pi}_2^T A_{21}A_{11}^{-1}$ implies $\|\bar{\pi}_1^T\| \le \epsilon\|A_{11}^{-1}\|$, we see that the trailing stationary probabilities dominate the leading ones provided $\|A_{11}^{-1}\|$ is not too large. For nearly transient chains with a finer block structure, say

$$(7.1) \qquad A = \begin{pmatrix} A_{11} & A_{12} & A_{13} & \cdots & A_{1k} \\ F_{21} & A_{22} & A_{23} & \cdots & A_{2k} \\ F_{31} & F_{32} & A_{33} & \cdots & A_{3k} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ F_{k1} & F_{k2} & F_{k3} & \cdots & A_{kk} \end{pmatrix}, \quad \pi = \begin{pmatrix} \bar{\pi}_1 \\ \bar{\pi}_2 \\ \bar{\pi}_3 \\ \vdots \\ \bar{\pi}_k \end{pmatrix}, \quad \left\| \begin{pmatrix} F_{j+1,j} \\ F_{j+2,j} \\ F_{j+3,j} \\ \vdots \\ F_{k,j} \end{pmatrix} \right\| = \epsilon_j,$$

$1 \leq j \leq k-1$, the same should be true; i.e., the trailing stationary probabilities tend to be larger than the leading ones. We will quantify this statement by providing bounds in terms of ϵ_j on the probabilities $\bar{\pi}_j$ associated with each block.

The strategy is to proceed inductively by applying the above 2×2 case to successive diagonal blocks. This is accomplished by applying the following lemma that provides a perturbation of size ϵ that essentially uncouples A_{11} from the remaining blocks. In particular, the lemma shows that the remaining probabilities are the exact probabilities of a perturbed problem of the same form (the only difference being that the sum of the probabilities is less than one).

LEMMA 7.1. *Let*

$$A = \begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix}$$

with $\|A_{21}\| \leq \epsilon$. *If*

$$\Delta = \frac{A_{21} e \bar{\pi}_1^T A_{12}}{\bar{\pi}_2^T A_{21} e},$$

then $A_{22} + \Delta$ *is a singular M–matrix such that*

$$\bar{\pi}_2^T (A_{22} + \Delta) = 0, \quad (A_{22} + \Delta)e = 0, \quad \textit{and} \quad \|\Delta\| \leq \epsilon.$$

Proof. We first verify that Δ satisfies the required equations. From $\pi^T A = 0$ and $Ae = 0$ we get $r_1^T = \bar{\pi}_2^T A_{22} = -\bar{\pi}_1^T A_{12}$ and $r_2 = A_{22}e = -A_{21}e$, so one can write

$$\Delta = -\frac{r_2 r_1^T}{\bar{\pi}_2^T r_2}.$$

Since $\bar{\pi}_2^T \Delta = -r_1^T$, it follows that $\bar{\pi}_2^T (A_{22} + \Delta) = 0$, and thus Δ satisfies the first equation. To prove that Δ satisfies the second equation, observe that $\pi^T A = 0$ and $Ae = 0$ imply

$$\bar{\pi}_2^T r_2 = -\bar{\pi}_2^T A_{21} e = \bar{\pi}_1^T A_{11} e = -\bar{\pi}_2^T A_{12} e = r_1^T e.$$

Thus,

$$\Delta = -\frac{r_2 r_1^T}{r_1^T e},$$

so $\Delta e = -r_2$ and $(A_{22} + \Delta)e = 0$. As for the bound on the norm of Δ, notice that r_1 and r_2 both consist entirely of nonnegative elements since A is an M–matrix so Δ consists entirely of nonpositive elements. This means

$$\|\Delta\| = \left\| \frac{r_2 r_1^T}{r_1^T e} e \right\| = \|r_2\| \leq \epsilon.$$

Moreover, since all elements of Δ are nonpositive, the off-diagonal elements in $A_{22}+\Delta$ are more negative than those of A_{22}. This implies with $(A_{22} + \Delta)e = 0$ that the diagonal elements must be nonnegative. From $\pi > 0$ it follows that $A_{22}+\Delta$ must be irreducible, for otherwise a component of $\bar{\pi}_2$ would be zero. According to Corollary 1 in §3.5 of Varga (1962), the signs of the matrix elements and the irreducibility imply that every principal submatrix of $A_{22} + \Delta$ is an M–matrix. Therefore, $A_{22} + \Delta$ is a singular M–matrix. □

Now we can prove the following theorem that says that in a nearly transient chain, the size of the π_i in the jth block is controlled by the smallness of the preceding off-diagonal columns $1, \ldots, j-1$, and by the condition of a perturbed jth diagonal block. The size of this perturbation is again determined by the smallness of the off-diagonal columns $1, \ldots, j-1$. This implies that the trailing solution components tend to be larger than the leading ones.

THEOREM 7.1. *If A is partitioned as indicated in* (7.1), *then* $\|\bar{\pi}_1^T\| \leq \epsilon_1\kappa_1$ *with* $\kappa_1 = \|A_{11}^{-1}\|$. *Furthermore, there exist matrices* $X_{j+1,j+1}$ *such that*

$$\|A_{j+1,j+1} - X_{j+1,j+1}\| \leq \epsilon_1 + \cdots + \epsilon_j, \quad 1 \leq j \leq k-2,$$

and

$$\|\bar{\pi}_{j+1}^T\| \leq (\epsilon_1 + \cdots + \epsilon_{j+1})\kappa_{j+1}, \quad \textit{where} \quad \kappa_{j+1} = \|X_{j+1}^{-1}\|.$$

Proof. The statements for $\bar{\pi}_1$ follow from the 2×2 block partitioning. Now apply the same argument recursively to the matrix

$$\bar{A}_{22} = \begin{pmatrix} A_{22} & * & \cdots & * & * \\ F_{32} & A_{33} & \cdots & * & * \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ \vdots & \vdots & & A_{k-1,k-1} & * \\ F_{k2} & F_{k3} & \cdots & F_{k,k-1} & A_{kk} \end{pmatrix} + \Delta,$$

where Δ is given by Lemma 7.1. For instance, X_2 is the leading diagonal block of $\bar{A}_{22}$ with $\|X_2^{-1}\| = \kappa_2$. Lemma 7.1 insures $\|\Delta\| \leq \epsilon_1$ and $\|A_{22} - X_2\| \leq \Delta \leq \epsilon_1$. Since the norm of the first off-diagonal column is bounded above by $\epsilon_1 + \epsilon_2$, Lemma 7.1 gives $\|\bar{\pi}_2^T\| \leq (\epsilon_1 + \epsilon_2)\kappa_2$. ∎

8. Concluding remarks. Our goal was to better understand how individual stationary probabilities are affected by unstructured perturbations to the transition probabilities. Consequently, we measured all perturbations relative to 1 rather than relative to $A = I - P$ or relative to the structure of P. In other words, we measured the magnitude of a perturbation by $\|E\|/\|P\| = \|E\|$ instead of $\|E\|/\|A\|$ or $\max_{ij} |e_{ij}|/p_{ij}$. The latter two measures result in significantly different interpretations of sensitivity. For example, perturbations that are small relative to 1 can greatly affect the stationary probabilities of

$$P = \begin{pmatrix} 1-\epsilon & \epsilon \\ \epsilon & 1-\epsilon \end{pmatrix}, \qquad \epsilon << 1,$$

but measured relative to $\|A\| = 2\epsilon$, or measured by $\max_{ij} |e_{ij}|/p_{ij}$, small perturbations cannot have a drastic effect (Meyer (1980), O'Cinneide (1993), and Zhang (1993)).

AN EFFICIENT ALGORITHM TO COMPUTE ROW AND COLUMN COUNTS FOR SPARSE CHOLESKY FACTORIZATION*

JOHN R. GILBERT†, ESMOND G. NG‡, AND BARRY W. PEYTON‡

Abstract. Let an undirected graph G be given, along with a specified depth-first spanning tree T. Almost-linear-time algorithms are given to solve the following two problems. First, for every vertex v, compute the number of descendants w of v for which some descendant of w is adjacent (in G) to v. Second, for every vertex v, compute the number of ancestors of v that are adjacent (in G) to at least one descendant of v.

These problems arise in Cholesky and QR factorizations of sparse matrices. The authors' algorithms can be used to determine the number of nonzero entries in each row and column of the triangular factor of a matrix from the zero/nonzero structure of the matrix. Such a prediction makes storage allocation for sparse matrix factorizations more efficient. The authors' algorithms run in time linear in the size of the input times a slowly growing inverse of Ackermann's function. The best previously known algorithms for these problems ran in time linear in the sum of the nonzero counts, which is usually much larger. Experimental results are given demonstrating the practical efficiency of the new algorithms.

Key words. sparse Cholesky factorization, sparse QR factorization, symbolic factorization, graph algorithms, chordal graph completion, disjoint set union, column counts, row counts

AMS subject classifications. 65F50, 68Q20

1. Introduction.

Direct solution of a sparse symmetric positive definite linear system requires four steps [7], [15]: reordering, symbolic factorization, sparse Cholesky factorization, and sparse triangular solutions. Let A be the $n \times n$ coefficient matrix of the linear system after it has been reordered to reduce fill, and let L be the lower triangular Cholesky factor of A. This paper presents improved algorithms for computing the number of nonzero entries in each row and column of L *prior to the symbolic factorization step*. We refer to these parameters as the *row counts* and *column counts* of L.

In least squares computations, A is $m \times n$, with $m \geq n$. It is often necessary to compute the orthogonal factorization $A = QR$. Our algorithms can be used also to predict upper bounds on the row counts and column counts of the upper triangular factor R, since the structure of R is always contained in the structure of the Cholesky factor of A^TA [12].

Throughout the paper we assume familiarity with graphs, trees, and such basic techniques as depth-first search [24]. We also assume a basic knowledge of the four steps in solving sparse systems by Cholesky factorization, and with the use of graphs in these algorithms [15]. More specifically, we assume familiarity with elimination trees [19], skeleton graphs [18], postorderings, supernodes [1], [2], [16], [20], [21], and the subscript compression scheme for L [15], [25].

1.1. Applications. Here we survey some of the sparse matrix settings in which it is useful to precompute the row counts, the column counts, or the total number of nonzeros in the Cholesky factor of a sparse matrix.

Either the row or column counts can be used to compute $|L|$, the total number of nonzeros in the factor. (We write $|X|$ for the number of nonzeros in a matrix X or the number of elements in a set X.) Knowing $|L|$ before the numeric factorization step makes it possible to allocate storage all at once instead of dynamically. In sparse Cholesky factorization, the time required to compute $|L|$ by existing methods is dominated by the time required for numerical factorization; but there are at least two settings in which it is valuable to be able to compute $|L|$ as fast as possible.

First, some methods for large-scale numerical optimization use Cholesky factorization on a Hessian matrix [5], [6]. If the Hessian is indefinite, Cholesky factorization will abort, but the partial factorization contains enough information to help determine a good descent direction containing negative curvature information. In this case, the symbolic factorization time may dominate the time spent on the numeric factorization before it aborts. Thus it may be more efficient to skip the symbolic phase and to build the data structure for L during the numeric factorization. However, for this to be efficient, we still need to find $|L|$ (and perhaps the column counts) before starting the factorization.

Second, much research remains to be done on the issue of how best to reorder the initial matrix to reduce fill, i.e., to reduce $|L|$. It is sometimes useful to compute $|L|$ for many different orderings of the same matrix, both in experiments with reordering algorithms and when trying to optimize an ordering for a specific matrix. Our new algorithms make this much faster.

Besides fill, there are several other measures of the quality of a reordering. Some of them can be computed from the column counts; for example, the total number of arithmetic operations is the sum of the squares of the column counts, and the maximum front size is equal to the largest column count. The smallest maximum front size, over all reorderings of a graph, is one more than the graph's *treewidth* [3]. Thus the fast column count algorithm may also be useful in experimental studies of treewidth.

Two applications related to the supernodal structure of L also require the column counts. Supernodes are clusters of columns with related nonzero patterns, which can be exploited to use fast dense matrix computation kernels in sparse factorization; §3 describes them in more detail. First, there is a simple, flexible $O(n)$ scheme for computing supernode partitions [2], [17] that takes the column counts and the elimination tree as input. This algorithm is more versatile and faster than the $O(|A|)$ algorithm of Liu, Ng, and Peyton [20], which takes the original matrix and its elimination tree as input. The latter algorithm computes the so-called fundamental supernode partition. Given a fast algorithm to compute column counts, the more flexible scheme could be used efficiently to compute coarser supernode partitions [2], which trade extra fill for a simpler sparsity structure that can be used to improve efficiency on vector supercomputers or to reduce synchronization overhead on shared-memory multiprocessors.

The second supernodal application of the column counts is to compute the storage required for indexing information for L in the usual compressed format generated by the symbolic factorization step [25]. Current software packages [4], [9] do not precompute the space needed for this compressed symbolic factorization, because it is too expensive using the currently known algorithms. The storage required for the other three steps in the solution process is usually computed in advance; we believe

that the new algorithms introduced here are efficient enough to be used by a software package to precompute the storage requirement of the symbolic factorization step as well.

Finally, we know of only one application that specifically requires the row counts rather than the column counts. The row counts are the numbers of column modifications (sparse SAXPYs) required to complete each column in sparse Cholesky factorization algorithms. Some parallel implementations [13], [14] need the row counts to determine when all the modifications have arrived for each column.

1.2. Previous work. Like many combinatorial algorithms in sparse matrix factorization, all the efficient algorithms for row and column counts begin by computing the elimination tree of the matrix (defined in the next section). The fastest known elimination tree algorithm is due to Liu [19]. The time complexity for this algorithm is dominated by disjoint set union operations, which take time $O(m\,\alpha(m,n))$, where A is $n \times n$ and has $2m$ off-diagonal nonzeros. Here $\alpha(m,n)$ is a slowly growing inverse of Ackermann's function defined by Tarjan [27]; for all values of m and n less than the number of elementary particles in the observable universe, $\alpha(m,n) \leq 4$. Thus a function that is $O(m\,\alpha(m,n))$ is often called "almost linear."

The fastest previously known algorithm for computing row and column counts is also due to Liu [19]. It first computes the elimination tree of A and then traverses each "row subtree" of the elimination tree (defined in the next section). The total size of the row subtrees is the number of nonzeros in the factor, so the running time of this step is $O(|L|)$. Unless the factor is extremely sparse, the subtree traversals dominate the time to find the elimination tree. To put this in perspective, suppose A is the matrix of an n-node finite difference mesh ordered by nested dissection. Then m is $O(n)$, and $|L|$ is $O(n \log n)$ in two dimensions or $O(n^{4/3})$ in three dimensions.

The algorithm in this paper also takes A and the elimination tree as input but runs in almost-linear time $O(m\,\alpha(m,n))$; the time complexity for the new algorithm is dominated by disjoint set union operations. Thus it computes the row and column counts in the same asymptotic time needed to find the elimination tree. As we will see in §4, this asymptotic efficiency is also reflected in practice.

1.3. Outline. Section 2 presents the row and column count algorithm from a graph-theoretic point of view. Here it is convenient to think of the input not as the graph $G(A)$ of a matrix, but as the graph $G(A) \cup T(A)$ that has edges both for the matrix nonzeros and for the elimination tree. (The elimination tree $T(A)$ usually has edges not contained in $G(A)$.) The elimination tree is a depth-first spanning tree of the graph $G(A) \cup T(A)$; thus for the purpose of the high-level view in §2, the input is just an undirected graph with a specified depth-first spanning tree. In this setting, we suspect that our results may be useful in efficient algorithms involving chordal graphs, chordal completion, and treewidth.

In §3 we return to the matrix-computation point of view, and discuss details of the implementation in the sparse matrix setting. Two points of practical importance arise here: we modify the algorithm slightly to make only one pass over its input, and we take advantage of supernodal structure to compute only with a subgraph called the *skeleton graph*. We show how to organize the entire computation, including the skeleton graph reduction, within the framework of the fundamental supernode algorithm of Liu, Ng, and Peyton [20].

Section 4 contains experimental results. We experiment with both the nodal and supernodal versions of the algorithm, as well as with several implementations of the disjoint set union operations (UNION and FIND) that dominate the asymptotic

running time. The best version is the supernodal algorithm with path-halving and no union by rank (definitions are in §3.3); it performs well enough that we argue it should be a standard part of high-performance sparse factorization codes. Finally, §5 contains concluding remarks.

2. The algorithm.

2.1. Definitions and problem statement. Let $G = (V, E)$ be a connected undirected graph with n vertices and m edges, and let T be a specific depth-first spanning tree for G (e.g., $G = G(A) \cup T(A)$ and $T = T(A)$). We call vertices v and w *adjacent* if they are joined by an edge in G; that is, if $(v, w) \in E$. We say that vertex v is an *ancestor* of vertex w if v is on the path in T from w to the root of T. Vertex v is a *descendant* of w if w is an ancestor of v. Note that a vertex is its own ancestor and its own descendant; a *proper* ancestor or descendant is one that is different from the vertex itself. We write $T[v]$ for the set of descendants of v and also for the subtree of T (rooted at v) that those vertices induce.

Since T is a depth-first spanning tree, every edge of G (whether or not it is an edge of T) joins an ancestor in T to a descendant in T [24].

To simplify notation, we assume that the vertices of G are the integers 1 through n. We also assume that the vertex numbers are a *postorder* on T; that is, that for every vertex v, the vertices of $T[v]$ are numbered consecutively, with v numbered last. Thus vertex n is the root of T.

The *level* of vertex v, which we write *level*(v), is its distance in T from the root. The *least common ancestor* of vertices v and w, which we write $lca(v, w)$, is the ancestor of v and w with the smallest postorder number (or the largest level). Both a postorder numbering and the vertex levels for an arbitrary tree can be computed in linear time by depth-first search [26]. Given a set of k pairs $\{v, w\}$ of vertices, the k least common ancestors $lca(v, w)$ can be computed in $O(k\,\alpha(k, n))$ time, where α is the very slowly growing inverse of Ackermann's function mentioned above [28]. We describe these algorithms in more detail in §3.

We consider the following two problems.

Problem 1 (row counts). For every node $u \in V$, let *row*$[u]$ be the set of descendants v of u for which either $v = u$ or there exists an edge (u, w) with $w \in T[v]$. The problem is to compute $rc(u) = |row[u]|$ for every u.

Problem 2 (column counts). For every node $v \in V$, let *col*$[v]$ be the set of ancestors u of v for which either $u = v$ or there exists an edge (u, w) with $w \in T[v]$. The problem is to compute $cc(v) = |col[v]|$ for every v.

Note that $v \in row[u]$ if and only if $u \in col[v]$, and that u is an element of both *row*$[u]$ and *col*$[u]$. For each u, the subgraph of T induced by *row*$[u]$, denoted by $T_r[u]$ and referred to as the *row subtree* of u, is connected; it is a "pruned subtree" rooted at u. The subgraph of T induced by *col*$[v]$ may not be connected.

We conclude by briefly describing the relationship between these problems and sparse Cholesky factorization. It may seem a bit confusing that we include the elimination tree edges in the graph G in the graph problem but not in the matrix problem; however, the answer is the same in either case.

Let an $n \times n$ symmetric, positive definite matrix A be given, and let $G(A)$ be its undirected graph (whose vertices are the integers 1 through n). Let $G^+(A)$ be the *filled graph* of $G(A)$ [22] obtained by adding to $G(A)$ edge (v, w) whenever there is a path in $G(A)$ from v to w whose intermediate vertices are all smaller than both v and w. The graph $G^+(A)$ is chordal, and (ignoring numerical cancellation) is the graph of $L + L^T$, where L is the Cholesky factor of A [23].

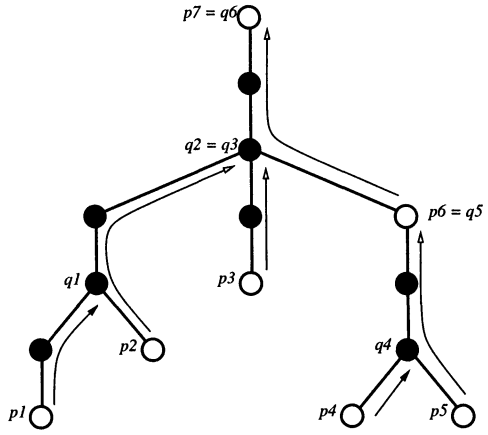

FIG. 1. *Example of path decomposition.*

The *elimination tree* of A, denoted $T(A)$, has vertices 1 through n, and the parent of vertex v is the smallest $w > v$ such that (v, w) is an edge of $G^+(A)$. Liu [19] surveys the uses and properties of this structure. It is a forest with one tree for each connected component of $G(A)$; if A is irreducible then $T(A)$ is a tree. The elimination tree may not be a subgraph of $G(A)$, but it is a subgraph of $G^+(A)$, and in fact it is a depth-first spanning tree of that graph. If A' is a matrix whose graph is $G(A') = G(A) \cup T(A)$, it is straightforward that $G^+(A') = G^+(A)$ and $T(A') = T(A)$.

Now consider problems (1) and (2) above for $G = G(A')$ and $T = T(A')$. It is easy to show [19] that the edges of $G^+(A) = G^+(A')$ are exactly those (u, v) for which $v \neq u$ and $v \in row[u]$ (or $u \in col[v]$). Thus $rc(u)$ is the number of nonzeros in row u of the Cholesky factor L of A, and $cc(v)$ is the number of nonzeros in column v of L.

2.2. Row counts. We count the vertices in $row[u]$ by counting the edges in the pruned subtree $T_r[u]$ of T that $row[u]$ induces. The following lemma lets us partition those edges into paths.

LEMMA 2.1. *Let $p_1 < p_2 < \cdots < p_k$ be some of the vertices of a rooted tree R (where $<$ is postorder), and suppose all the leaves and the root of R are among the p_i's. Let q_i be the least common ancestor of p_i and p_{i+1} for $1 \leq i < k$. Then each edge (s, t) of the tree is on the tree path from p_j to q_j for exactly one j.*

Proof. Suppose t is the parent of s in R. The descendants of s include at least one leaf, so they include at least one p_i. Let p_j be the largest p_i among the descendants of s. Then $p_j \leq s < p_{j+1}$. (There must be a p_{j+1}—that is, we cannot have $j = k$—because p_k is the root, which is a proper ancestor of s.) Since s is an ancestor of p_j but not of p_{j+1}, the least common ancestor q_j of p_j and p_{j+1} is a proper ancestor of s, and hence an ancestor of t. Therefore (s, t) is on the path from p_j to q_j.

Now consider an $i \neq j$. If s is not an ancestor of p_i, then (s, t) is not on the path from p_i to its ancestor q_i. If s is an ancestor of p_i, then $p_i \leq s$, and $i \neq j$ implies $p_i \leq p_{i+1} \leq s$. Since postorder assigns consecutive numbers to the vertices in a subtree, this means that s is also an ancestor of p_{i+1}, and hence of the least common ancestor q_i. Thus (s, t) is not on the path from p_i to q_i. □

Figure 1 shows an example of the path decomposition.

Recall that T is a depth-first spanning tree of G and hence every edge of G joins an ancestor in T to a descendant in T. Now consider a vertex u of G. If the lower-numbered neighbors of u in G are $p_1 < p_2 < \cdots < p_{k-1}$, and if $p_k = u$, then the pruned subtree $R = T_r[u]$ induced by $row[u]$ satisfies the hypotheses of Lemma 2.1. Thus the number of edges in $T_r[u]$ is the sum of the lengths of the paths in the lemma. The length of the path from p_i to its ancestor q_i is the difference of their levels. The number of vertices in $row[u]$ is one more than the number of edges, so

$$rc(u) = 1 + \sum_{1 \le i < k} \Big(level(p_i) - level(lca(p_i, p_{i+1})) \Big).$$

(Here *lca* and *level* are taken in T rather than $T_r[u]$, but it is clear that for any two vertices in $row[u]$ the least common ancestor and the difference in levels are the same in either tree.)

Let $ladj[u]$ be the lower numbered neighbors of u in G. The algorithm to compute $rc(u)$ for all u first sorts each set $ladj[u] \cup \{u\}$ by postorder, then computes all the necessary least common ancestors, and finally computes the sum above for each u. Computing level numbers (and the postorder itself if necessary) takes linear time, and sorting the sets $ladj[u] \cup \{u\}$ into postorder takes linear time by a lexicographic bucket sort. There is one least-common-ancestor computation for each edge of G, so the dominant term in the algorithm's time complexity is $O(m\,\alpha(m, n))$.

2.3. Column counts. Because $u \in col[v]$ if and only if $v \in row[u]$, the column count $cc(v)$ is equal to the number of row subtrees $T_r[u]$ that contain v. We could compute $cc(v)$ by traversing each row subtree in turn, and counting the number of times each vertex was traversed [19]. This, however, would take time proportional to $\sum_v cc(v)$.

To get a faster algorithm, we define weights $wt(v)$ on the vertices of G in such a way that the column count for vertex v turns out to be the sum of the weights of the descendants of v. The key observation is that we can compute these weights as a sum of contributions from each row subtree, and that the row subtree contributions can be computed efficiently using the same least common ancestors as in the row count algorithm.

Here are the details. For each vertex u, define χ_u to be the characteristic function of $row[u]$, so that $\chi_u(v) = 1$ if $v \in row[u]$ and $\chi_u(v) = 0$ otherwise. Define wt_u by

$$wt_u(v) = \chi_u(v) - \sum_{\text{children } y \text{ of } v} \chi_u(y). \tag{1}$$

These weights may be positive, negative, or zero. This definition implies that

$$\chi_u(v) = \sum_{x \in T[v]} wt_u(x). \tag{2}$$

In a sense, wt_u is a "first difference" down the tree of the characteristic function of $row[u]$. Finally, define

$$wt(v) = \sum_{u \in V} wt_u(v). \tag{3}$$

Now we prove three lemmas relating the column counts to the weights, the weights to the sets $row[u]$, and finally the $row[u]$, once more, to the least common ancestors.

LEMMA 2.2. *For every vertex v,*

$$cc(v) = \sum_{x \in T[v]} wt(x).$$

Proof. Because $v \in row[u]$ if and only if $u \in col[v]$, we have

$$cc(v) = |col[v]| = \sum_{u \in V} \chi_u(v).$$

Equation (2) states that this is equal to

$$\sum_{u \in V} \sum_{x \in T[v]} wt_u(x).$$

The result follows by reversing the order of summation and using (3). □

Lemma 2.2 implies that we can compute the column counts easily and efficiently from the weights by traversing the tree in postorder and summing the weights of the subtrees. It remains to describe how to compute the weights.

LEMMA 2.3. *Let u and v be vertices. Suppose that d of the children of v are vertices of $row[u]$. Then*

$$wt_u(v) = \begin{cases} 1 - d & \text{if } v \in row[u], \\ -1 & \text{if } v \text{ is the parent of } u, \\ 0 & \text{otherwise.} \end{cases}$$

Proof. This is immediate from (1) and the definition of χ_u. □

Lemma 2.3 implies that the only vertices v for which $wt_u(v)$ is nonzero are the leaves of the pruned row subtree $T_r[u]$, the internal vertices of $T_r[u]$ that have more than one child in $T_r[u]$, and the parent of u. The following lemma allows us to compute $wt_u(v)$ for each v from the same p_i's and q_i's we used in the row count algorithm.

LEMMA 2.4. *Let $p_1 < p_2 < \cdots < p_k$ be some of the vertices of a rooted tree R (where $<$ is postorder), and suppose all the leaves and the root of R are among the p_i's. Let q_i be the least common ancestor of p_i and p_{i+1}, for $1 \le i < k$. Then for each vertex v of R, the number of children of v in R is*

$$|\{i : q_i = v\}| - |\{i : p_i = v\}| + 1.$$

Proof. Let $Q = |\{i : q_i = v\}|$, let $P = |\{i : p_i = v\}|$, and let d be the number of children of v in R. Consider the set of directed paths from p_i to q_i in R, for $1 \le i < k$. For any collection of directed paths, each path that includes vertex v either *begins* at v or *enters* v along edges from other vertices. Similarly, each path that includes vertex v either *ends* at v or *leaves* v along edges to other vertices. Consequently:

> The number of paths that either begin at v or enter v along edges from other vertices must be equal to the number of paths that either end at v or leave v along edges to other vertices.

(This is essentially Kirchoff's law for a flow of unit size from p_i to q_i for each i.) Lemma 2.1 says that every edge of R is on exactly one of these paths. Therefore one path enters v from each of the d children of v; exactly one path leaves v, to its parent, unless v is the root; one path begins at v for each i such that $p_i = v$ (except for $i = k$

```
Sort the vertices and their lists of neighbors by a postorder of T;

FIG. 2. *Algorithm to compute row and column counts.*

if v is the root); and one path ends at v for each i such that $q_i = v$. A trivial path with $p_i = q_i = v$ both starts and ends at v, but does not enter or leave v. Thus the relation above is

$$P + d = Q + 1$$

if v is not the root of R, or

$$(P - 1) + d = Q + 0$$

if v is the root. In either case, we have $d = Q - P + 1$ as desired. □

Now consider a vertex u of G. If the vertices of $ladj[u]$ are $p_1 < p_2 < \cdots < p_{k-1}$, and if $p_k = u$, then the pruned subtree $R = T_r[u]$ induced by $row[u]$ satisfies the hypotheses of Lemma 2.4. Therefore, using Lemma 2.3, if v is a vertex of $row[u]$ then $wt_u(v) = |\{i : p_i = v\}| - |\{i : q_i = v\}|$. Thus we could compute $wt_u(v)$ for all v by initializing each weight to zero, setting the weight of the parent of u to -1, and then adding one to the weight of each p_i and subtracting one from the weight of each q_i.

In fact we do not need to compute $wt_u(v)$ separately for each u; we can compute $wt(v) = \sum_u wt_u(v)$ all at once. The algorithm begins, like the row count algorithm, by sorting each set $ladj[u] \cup \{u\}$ in postorder and computing all the necessary least common ancestors. It initializes $wt(u)$ to one for each u. Then, for each u, it subtracts one from the weight of the parent of u, adds one to $wt(p)$ for each $p \in ladj[u]$, and subtracts one from $wt(q)$ for the least common ancestor q of each pair p and p' of consecutive members (in postorder) of $ladj[u] \cup \{u\}$. Finally, the algorithm computes $cc(v)$ for all v by summing the weights of each subtree in postorder. Figure 2 sketches the algorithm to compute both row and column counts. The only step

that takes more than linear time is the least common ancestor computation, and the dominant term in the algorithm's time complexity is $O(m\,\alpha(m,n))$.

3. Implementation. The discussion in the previous section was in a general graph-theoretic setting. However, to obtain the most efficient implementation of the new algorithm for our applications, we need to switch back to a sparse matrix setting.

Consider a symmetric matrix A and its graph $G(A)$. Assume that the elimination tree $T(A)$, the postordering, and the values *level*(u) (with respect to $T(A)$) have been computed, as required in Fig. 2. Two other requirements must be met to obtain a practical and efficient implementation of the new algorithm.

First, we must reorganize the computation to avoid sorting the adjacency lists by postorder and precomputing all the least common ancestors. Indeed, direct implementation of the algorithm in Fig. 2 would require that $G(A)$ be processed three times, and we doubt that any multiple-pass implementation will come close to realizing the practical efficiency of the single-pass implementation presented in this section.

Second, we must discard some edges of $G(A)$ that do not affect the result. Recall from Liu [18] that the *skeleton graph* $G^-(A)$ is obtained from $G(A)$ by removing every edge (u,v) for which $v<u$ and the vertex v is not a leaf of $T_r[u]$. The skeleton graph is the smallest subgraph of $G(A)$ whose filled graph is identical with that of $G(A)$. Consequently, the new algorithm produces the same results when applied to $G^-(A)$ as when applied to $G(A)$. Indeed, if $G=G^-(A)\cup T(A)$ rather than $G=G(A)\cup T(A)$ in Lemmas 2.1 and 2.4, then every vertex $p_1,p_2,\ldots,p_{k-1}$ is a leaf in the tree R. This reduces the number of edges searched and least common ancestors computed by the new algorithm to the minimum possible. Since $G^-(A)$ often has far fewer edges than $G(A)$ in practice, an implementation that processes $G^-(A)$ rather than $G(A)$ promises to be substantially faster; we see in §4 that this is indeed the case.

The skeleton graph $G^-(A)$ is closely related to fundamental supernodes of A, and can be computed efficiently in linear time by a simple modification of the algorithm of Liu, Ng, and Peyton [20] to find fundamental supernodes. Indeed, that algorithm is a good framework for implementing our new algorithm, whether the skeleton graph is exploited or not. We can combine the two algorithms to obtain an efficient single-pass implementation. As this implementation processes the edges of $G(A)$, it discards edges not in the skeleton graph, and uses only the skeleton edges to compute the data for the row and column counts. If m^- is the number of edges in $G^-(A)$, then this scheme runs in $O(m+m^-\,\alpha(m^-,n))$ time.

Section 3.1 below reviews the material we need from Liu, Ng, and Peyton [20]. Section 3.2 presents a detailed version of the new combined implementation. Section 3.3 briefly describes our implementation of the disjoint set union algorithm for computing the least common ancestors, upon which the time complexity of our algorithm depends.

3.1. A fast algorithm for finding supernodes. Liu, Ng, and Peyton [20] introduced an $O(|A|)$ algorithm to compute a fundamental supernode partition. Their algorithm assumes that the elimination tree $T(A)$ has been computed and that the vertices are numbered by a postordering of $T(A)$. Let the *higher adjacency set* of v, denoted by *hadj*$[v]$, be the set of neighbors of v in $G(A)$ that are numbered higher than v, and let *hadj*$^+[v]$ be the higher adjacency set of v in $G^+(A)$. Ashcraft and Grimes [2] defined a *fundamental supernode* as a maximal contiguous set of vertices $\{v,v+1,\ldots,v+s\}$ such that $v+i$ is the *only* child of $v+i+1$ in the elimination

tree (for $i = 0, 1, \ldots, s-1$) and

$$hadj^+[v] = hadj^+[v+s] \cup \{v+1, v+2, \ldots, v+s\}.$$

The fundamental supernodes partition the vertices of $G(A)$.

In matrix terms, a supernode is any group of consecutive columns in L with a full diagonal block and with identical column patterns below the diagonal block. A fundamental supernode is maximal subject to the following condition: every column of the supernode except the last is an only child in the elimination tree. Liu, Ng, and Peyton [20] give several reasons why fundamental supernodes are the most appropriate choice of supernodes for most applications, one of which is that they are independent of the choice of postordering for $T(A)$.

Finding the set of fundamental supernodes is equivalent to finding the first vertex of each supernode. These "first vertices" are characterized by the following result.

THEOREM 3.1 (Liu, Ng, and Peyton [20]). *Vertex v is the first vertex in a fundamental supernode if and only if vertex v has two or more children in the elimination tree, or v is a leaf of some row subtree of $T(A)$.*

The key observation is that the vertices required by the row/column count algorithm (the p_i's and q_i's) are in fact first vertices of fundamental supernodes. It follows from the discussion immediately after Lemma 2.3 in §2.3 that the vertex pairs p_i, p_{i+1} whose least common ancestors must be found can be restricted to vertices that are leaves of some row subtree of $T(A)$. This is equivalent to restricting the algorithm in Fig. 2 to the skeleton graph $G^-(A)$. Furthermore, when the p_i's are restricted in this manner, it is clear that every least common ancestor $q_i = lca(p_i, p_{i+1})$ has two or more children. Consequently, the Liu, Ng, and Peyton algorithm is an excellent vehicle for an efficient implementation of our new algorithm.

3.2. Detailed implementation of the new algorithm. The details of our single-pass, column-oriented implementation are given in Fig. 3. Note that it traverses the higher adjacency sets *hadj*[p] rather than the lower adjacency sets used by the algorithm in Fig. 2. Again, the vertices are numbered by a postorder of the tree $T(A)$, but here no assumption is made concerning the order of the vertices in *hadj*[p], nor are the least common ancestors computed in advance. Consequently, this implementation makes only a single pass through $G(A)$.

The vector of markers *prev_p*(u) stores the most recently visited vertex p' that is a leaf in $T_r[u]$. The pairs p, p' produced by the algorithm are precisely the multiset consisting of every consecutive pair of leaves in every row subtree $T_r[u]$. The reason for this is that one of the **if** tests in the algorithm screens out all edges in $G(A)$ except those in the skeleton graph $G^-(A)$. The lines marked with asterisks have been added to the algorithm solely for this purpose. Of these, the key line is the test for whether or not the first (i.e., lowest numbered) descendant of p (*fst_desc*(p)) is greater than the most recently visited vertex in *ladj*[u], namely the vertex stored in the marker variable *prev_nbr*(u). It is not difficult to verify that when the condition holds true, no descendant of p is adjacent to u in $G(A)$; hence p is indeed a leaf in $T_r[u]$. For full details of this test, see Liu, Ng, and Peyton [20].

The implementation is correct with or without the starred lines. We have implemented both versions: we call the one with the starred lines the *supernodal* version, and the one without these lines the *nodal* version.[1] We experiment with both versions of the algorithm in our tests in §4.

[1] In the nodal version, *prev_p*(u) functions precisely as *prev_nbr*(u) does in the supernodal version.

```
    Sort the vertices by a postorder of T(A);
    Compute level(u) as the distance from u to n (the root), for all u;
*   Compute fst_desc(u) as the first (least) descendant of u in T(A), for all u;
    prev_p(u) ← 0, for all u;
*   prev_nbr(u) ← 0, for all u;
    rc(u) ← 1, for all u;
    wt(u) ← 0, for all nonleaves u in T(A);
    wt(u) ← 1, for all leaves u in T(A);
    for p ← 1 to n do
        if p ≠ n then
            wt(parent(p)) ← wt(parent(p)) − 1;
        end if
        for u ∈ hadj[p] do
*           if fst_desc(p) > prev_nbr(u) then
                wt(p) ← wt(p) + 1;
                p' ← prev_p(u);
                if p' = 0 then
                    rc(u) ← rc(u) + level(p) − level(u);
                else
                    q ← FIND(p');
                    rc(u) ← rc(u) + level(p) − level(q);
                    wt(q) ← wt(q) − 1;
                end if
                prev_p(u) ← p;
*           end if
*           prev_nbr(u) ← p;
        end for
        UNION(p, parent(p));
    end for
    cc(v) ← wt(v), for all v;
    for v ← 1 to n − 1 do
        cc(parent(v)) ← cc(parent(v)) + cc(v);
    end for
```

FIG. 3. *Implementation of algorithm to compute row and column counts.*

3.3. Disjoint set union. To compute least common ancestors, the algorithm in Fig. 3 must manipulate disjoint sets of vertices, each of which induces a subtree of the elimination tree. The highest numbered vertex in each set (the root of the subtree) is used to "name" the set, and is called the *representative vertex* of the set. Initially each vertex p from 1 to n is a singleton set. As the algorithm proceeds, it executes a sequence of FIND and UNION operations which are defined as follows.

> FIND(p): return the representative vertex of the unique set that contains p.
> UNION(u, v): combine the two distinct sets represented by u and v into a single set, which will be represented by the larger of u and v.

It is not hard to show that the call to FIND(p') in our algorithm returns $lca(p', p)$; see Tarjan [28] for details.

Each disjoint set is implemented as a tree stored using a parent vector (not to be confused with the *parent* vector in the elimination tree). The operation UNION(u, v) joins the two distinct trees represented by u and v together by making one of the roots a child of the other root. Consequently, UNION is a constant-time operation. This is not the case for FIND. The operation FIND(p) traces the *find path* from p to the root of p's tree. This root either is the representative vertex or contains a pointer to the representative vertex, depending on the implementation of UNION.

Tarjan [29] describes several techniques to shorten the find paths and thus reduce the amount of work spent on the FIND operations. *Union by rank* makes the shorter tree's root a child of the taller tree's root in UNION, which tends to keep the trees short and bushy. With no other enhancements, union by rank ensures that find paths are no longer than $O(\log_2(n))$. This is usually combined with one of two techniques for shortening the find path during a FIND operation. The first of these is *path compression*, which, after finding the root, makes the parent for each vertex on the find path point to the root during a second pass along the path. Alternatively, *path halving* resets the parent pointer for every other vertex on the find path to point to its grandparent. Path compression shortens the find path more, but requires two passes over the find path; path halving needs only one pass.

Tarjan [27], [29] showed that when union by rank is combined with either path compression or path halving, any sequence of n UNION's and m FIND's takes only $O(m\,\alpha(m, n))$ time. Tarjan [28] pointed out how to use the disjoint set union algorithm to find the least common ancestors of an arbitrary set of pairs of vertices from the same tree; our implementation of the row and column count algorithm uses the same method. Consequently, we can implement the nodal version of our algorithm to run in $O(m\,\alpha(m, n))$ time, and similarly we can implement the supernodal version to run in $O(m + m^-\,\alpha(m^-, n))$ time.

Gabow and Tarjan [10] showed that if the order of the UNION operations is known in advance (as is the case in our problem), then disjoint set union can be implemented so that a sequence of n UNION's and m ($\geq n$) FIND's takes only $O(m)$ time. Their sophisticated hybrid algorithm partitions the vertices into *microsets* and performs all the operations in a hierarchical fashion, using table look-up to answer queries within the microsets, and using the standard disjoint set union algorithm on the microsets themselves. We did not implement this algorithm; we believe its increased overhead would wipe out the difference between $O(m\,\alpha(m, n))$ and $O(m)$ in our application.

We implemented and tested the following six combinations.

1. No union by rank, no path compression or halving.
2. No union by rank, path compression.
3. No union by rank, path halving.
4. Union by rank, no path compression or halving.
5. Union by rank, path compression.
6. Union by rank, path halving.

We found surprisingly little difference in performance among the various options. Far more important is whether or not the row/column count processing is limited to the skeleton graph, as we see in the next section. We found that any gains due to union by rank were more than offset by the additional overhead required for its implementation. The third option—no union by rank, path halving—performed slightly better on most machines we tried. Path halving was clearly superior to path compression when the skeleton adjacency structure was not exploited. Consequently, we recommend path halving to those implementing the method, and in the next section all our timings

were obtained using path halving and no union by rank.

4. Experimental results. We ran the new algorithms on several problems from the Harwell–Boeing sparse matrix collection [8]. Table 1 lists our test problems, and Table 2 contains the problem statistics that have a bearing on the observed performance of our algorithms. Throughout this section `supcnt` refers to the "supernodal" version of the algorithm (Fig. 3 with the starred lines), which identifies the edges of the skeleton graph $G^-(A)$ and uses only those edges in its row and column count calculations, and `nodcnt` refers to the "nodal" version of the algorithm (Fig. 3 without the starred lines), which uses all the edges of $G(A)$.

4.1. Performance of the disjoint set union options. The primary purpose of Table 3 is to explain two things we observed in our tests: (i) why exploiting the skeleton graph is so beneficial and (ii) why the various disjoint set union (DSU) implementation options have so little influence on the performance of our code. The number of FIND operations required by `nodcnt` and `supcnt` is bounded above by m and m^-, respectively, and bounded below by $m - n$ and $m^- - n$. Thus, the huge difference between the number of FIND's required by `nodcnt` and the number of FIND's required by `supcnt` (see Table 3) simply reflects the fact that the skeleton graph of A is typically much sparser than the graph of A (see Table 2).

Each FIND(p) operation traverses the find path in p's tree beginning at p and ending at the root of the tree. The average number of vertices on these find paths is reported for each DSU implementation. We tested only two options for `nodcnt`: path compression and path halving, both without union by rank. Note that the average number of vertices on a find path ranges from 2 to 2.7, with path compression faring slightly better than path halving. The performance of path compression suffers, however, because the find path must be traversed twice, compared with once for path halving. Our tests indicate that path halving does indeed substantially outperform path compression, and in `nodcnt`, where the number of FIND's is large, the gain in efficiency is substantial.

We tried all six options mentioned in §3.3 in our implementations of `supcnt` and, as noted earlier, we saw little difference in performance from one option to the next. The primary explanation for this phenomenon is the small proportion of `supcnt`'s total work devoted to DSU operations. The number of FIND operations is small relative to m, and the average number of vertices on a find path is small (from 1.4 to 2.6) for five of the six options tested. For the sixth option (no DSU enhancements), the average number of vertices on a find path is still quite modest (from 3.6 to 5.8), with less work required for each vertex visited. Consequently, even this option is competitive in our tests.

When path compression or path halving is used, union by rank obtains only modest reductions in the average number of nodes visited. The overhead costs associated with union by rank more than offset any advantages conferred by the technique. Comparing path compression and path halving with no union by rank, the same observations made previously for `nodcnt` hold for `supcnt` also. The primary difference is that the total work associated with DSU operations in `supcnt` is so small that the performance edge of path halving over path compression is quite small. Nonetheless, path halving with no union by rank has proven most effective overall and has the added advantage of simplicity. Finally, note that for our chosen option the total number of vertices visited by FIND operations is much less than m for most of the test problems.

4.2. Performance of the row and column count algorithm. We coded `nodcnt` and `supcnt` in Fortran 77 and ran our tests on an IBM RS/6000 (model 320). We used the standard Fortran compiler and compiler optimization flag (`xlf -O`). We used a high-resolution timer (`readrtc`) to obtain our timings on this machine, repeating each run ten times in succession and returning the average elapsed time. The results are shown in Table 4. We used path halving and no union by rank in the implementation of the disjoint set union algorithm for both `nodcnt` and `supcnt`. The time required to compute the elimination tree and postordering are of interest for two reasons. First, they must be computed before the row/column counts can be computed. Second, the algorithm for computing the elimination tree is, like `nodcnt` and `supcnt`, a single-pass $O(m\,\alpha(m,n))$ algorithm that relies on efficient implementation of the disjoint set union operations for efficiency. Thus it is interesting to compare its performance with that of the new algorithms.

Both `nodcnt` and `supcnt` are much more efficient than `lnzcnt`, the $O(|L|)$ algorithm from Liu [19]. Algorithm `nodcnt` is 1.29 to 5.25 times faster than `lnzcnt`, while `supcnt` is, in turn, 1.08 to 1.39 times faster than `nodcnt`. For every problem but one, `supcnt` is at least twice as fast as `lnzcnt`. (For NASA2920, `supcnt` is 1.77 times faster than `lnzcnt`.) For four of the problems, `supcnt` is more than three times faster than `lnzcnt`. For BCSSTK15 `supcnt` is 4.54 times faster, and for BCSSTK23 `supcnt` is 5.74 times faster.

Finally, it is interesting to compare the timings for the elimination tree algorithm [19] and the supernode algorithm [20] with those for `supcnt`. First, `supcnt` can be viewed as an extension of the supernode algorithm, and consequently the time for `supcnt` should be bounded below by the time for the supernode algorithm. Though there are some differences in the amount and kind of $O(n)$ work performed by the two algorithms before and after the main loop, the difference in the two timings can nevertheless be viewed as a crude measure of the cost of adding the instructions necessary to compute row and column counts to the supernode algorithm. Clearly, this cost is quite small, especially considering the simplicity and demonstrated practical efficiency of the supernode algorithm. Note also that the timings for `supcnt` and the elimination tree algorithm closely track each other. From these observations, we conclude that it is probably not possible to improve the performance of `supcnt` much beyond what we are currently observing.

5. Conclusion. We have considered in this paper the problem of predicting the row counts and column counts in the Cholesky factor L of a sparse symmetric positive definite matrix A, given the zero/nonzero structure of A and the elimination tree $T(A)$. We have presented new algorithms for determining the counts, the complexities of which are linear in $|A|$ times a slowly growing inverse of Ackermann's function; the previously known algorithms ran in $O(|L|)$ time. The key to the new algorithms is the computation of least common ancestors in a tree using the disjoint set union algorithm. We have investigated different ways of implementing the disjoint set union operations in our algorithms. Based on our experimental results, we conclude that path halving with no union by rank is the best technique for an efficient implementation of the disjoint set union algorithm.

We have further improved our new algorithms by exploiting the skeleton graph of A. We have demonstrated that the supernodal version is faster than the nodal version in all of the problems we tested. Moreover, both the nodal and supernodal versions are much more efficient than the previously known $O(|L|)$-time algorithms. We expect the algorithms described in this paper to be of practical use in a wide range of sparse matrix computations.

CONVEXITY AND CONCAVITY OF THE PERRON ROOT AND VECTOR OF LESLIE MATRICES WITH APPLICATIONS TO A POPULATION MODEL *

STEPHEN J. KIRKLAND† AND MICHAEL NEUMANN‡

Abstract. This paper considers the Leslie model of population growth and analyzes its asymptotic growth rate and its asymptotically stable age distribution as functions of the fecundity and survival rates of each age group in the population. This analysis is performed by computing first- and second-order partial derivatives of the Perron root and vector of a Leslie matrix with respect to each relevant entry in the matrix, with emphasis on the second partial derivatives. The signs of these derivatives as well as the qualitative implications that the results have for the Leslie model are discussed. Where possible, quantitative interpretations of the results are also given. Throughout, the techniques employ ideas from the theory of group generalized inverses.

Key words. Leslie matrix, group inverse, Perron root, Perron vector

1. Introduction.

This paper investigates first- and second-order effects of changes in fecundity and survival rates of various age groups on the asymptotic rate of growth and the asymptotically stable age distribution vector of the Leslie population model. This population model can be represented by a nonnegative matrix whose Perron root and an appropriately normalized Perron eigenvector that furnish the rate of growth and the stable age distribution of the model, respectively. The first- and second-order effects are obtained by computing the first- and second-order partial derivatives of the Perron root and Perron vector with respect to those matrix entries that represent the fecundity and survival rates of each age group. The existence of these derivatives is assured because, in the problem's setting, the Perron root is simple. It should be mentioned that first-order effects of changes in the fecundity and survival rates upon the growth rates of the model have already been obtained by authors such as Demetrius [8], Goodman [14], and Lal and Anderson [17].

In the Leslie model it is assumed that the population consists of n age groups. Let $x_i(t)$ denote the number of individuals in the ith age group at time t. Let $F_i, i = 1, \ldots, n$, denote the fecundity of each individual in the ith age group and let $P_i, i = 1, \ldots, n-1$, denote the probability of survival of an individual from age i to age $i+1$. Assume that both the fecundity and survival rates are independent of the time t. Then, as can be readily ascertained, the age distribution at time $t+1, t \geq 0$, can be

described by the matrix–vector relation

$$x(t+1) = \begin{pmatrix} F_1 & F_2 & \cdots & \cdots & F_{n-1} & F_n \\ P_1 & 0 & \cdots & \cdots & 0 & 0 \\ \vdots & \ddots & \vdots & \vdots & 0 & 0 \\ \vdots & \cdots & \ddots & \vdots & \vdots & \vdots \\ \vdots & \cdots & \cdots & \ddots & \vdots & \vdots \\ 0 & \cdots & \cdots & \cdots & P_{n-1} & 0 \end{pmatrix} x(t) =: \tilde{A}x(t), \tag{1.1}$$

where $x(\tau) = (x_1(\tau) \cdots x_n(\tau))^T$ for all $\tau \geq 0$. For more background material on the Leslie population model, see Pollard [20] and Caswell [4].

Papers in demography [8] say that the population has reached a *stationary age distribution* if there exists a time t_0 and a constant $\lambda > 0$ such that

$$x(t+1) = \lambda x(t) \quad \forall t > t_0. \tag{1.2}$$

In this case λ is called the *growth rate of the population.* The term stationary age distribution comes from the fact that if (1.2) holds, then from time $t_0 + 1$ onward the ratio between the various age groups in the population is maintained. We note further that if (1.2) holds, then

$$\lambda x(t) = x(t+1) = \tilde{A}x(t) = \cdots = \tilde{A}^{t+1}x(0) \quad \forall t > t_0. \tag{1.3}$$

Because a stationary age distribution is reached in finite time only when the initial age distribution vector $x(0)$ is a linear combination of a Perron vector and a generalized null vector of $\tilde{A}$, we prefer to think of Demetrius' notions of growth rate of the population and stationary age distribution as the *asymptotic growth rate* and the *asymptotically stable age distribution vector*, respectively.

If $\tilde{A}$ is an irreducible matrix, then by the Perron–Frobenius theory (see §2 for preliminaries and Berman and Plemmons [2] for a comprehensive background), λ must be the Perron root of $\tilde{A}$ and $x(t)$ is a corresponding right Perron (eigen)vector and the theory guarantees the existence and differentiability of both, the latter subject to an appropriate normalization. Furthermore, if $\tilde{A}$ is *primitive*, namely, it is irreducible with a single eigenvalue of maximum modulus, then, for example, the power method for computing dominant eigenvalues and corresponding normalized eigenvectors [21, p. 340] shows that the righthand side of (1.3) will always converge to a Perron vector of $\tilde{A}$ so that asymptotically (1.2) holds. We comment now that just as the entries of the nonnegative matrix $\tilde{A}$ have a physical interpretation, we see that the Perron root and vector and their derivatives also have a physical meaning for the model.

One can relax the assumption of irreducibility. Even then the special structure of the Leslie matrix $\tilde{A}$ implies that its Perron root remains simple, thus ensuring that the Perron root and vector are still differentiable. While the reducible case may lead to some interesting questions, we nevertheless restrict ourselves to the case of irreducible Leslie matrices, i.e., we always assume that $F_n > 0$ since this captures the largest part of the mathematical content and difficulty.

It is natural to ask how the growth rate and the stable age distribution vectors are affected as we change the fecundity and survival probabilities at each age group. Demetrius [8] has investigated one of these questions by looking at the derivatives of the Perron root with respect to the fecundities and the survival rates that he obtained

via the characteristic equation for a Leslie matrix. His results can also be obtained from a more general theorem giving expressions of the partial derivatives of a simple eigenvalue of a matrix with respect to the matrix entries as follows: Let $B = (b_{i,j})$ be an $n \times n$ real or complex matrix and let μ be a simple eigenvalue of B. Let ξ and η be right and left eigenvectors of B corresponding to μ normalized, such that $\eta^T \xi = 1$. Then it is known (see, for example, Stewart [21, Exer. 1, p. 305]) that

$$\frac{\partial \mu(B)}{\partial_{i,j}} = \xi_j \eta_i \quad \forall 1 \leq i, j \leq n, \tag{1.4}$$

where $\partial\mu/\partial_{i,j}$ is the derivative of μ with respect to the (i,j)th entry at B.[1]

Consider the matrix $C = \mu I - B$. Zero now is a simple eigenvalue of C and therefore the group generalized inverse of $C, C^{\#}$, exists and, as is known, $\xi\eta^T = I - CC^{\#}$. Thus, we see that the group inverse of C can be used to express first-order partial derivatives of μ with respect to the matrix entries at B. Furthermore, as is shown in Deutsch and Neumann [9], the second-order partial derivatives of μ with respect to the (i,j)th entry can also be written in terms of $C^{\#}$. Specifically, they showed that

$$\frac{\partial^2 \mu(B)}{\partial_{i,j}^2} = 2\left(I - CC^{\#}\right)_{j,i} C^{\#}_{j,i}, \quad \forall 1 \leq i, j \leq n. \tag{1.5}$$

Assume that B is an $n \times n$ nonnegative and irreducible matrix. Since any right and left Perron vectors of B can be chosen positive, (1.4) readily confirms the well-known fact that the Perron value is a strictly increasing function in any of the matrix entries. In a series of papers, Cohen [5]–[7] established the fact that the Perron root is a convex function in the main diagonal of the matrix. His principal approach to proving this fact was probabilistic relying on evolution equations due to Kac. In [9] a matrix theoretic proof of this fact is presented. Moreover, from the formula (1.5), which was found in [9], we see that *for any pair (i,j), the convexity or concavity of the Perron root with respect to (i,j)th entry is determined by the sign of the (j,i)th entry of $C^{\#} = (\lambda I - B)^{\#}$*. Perturbation and convexity theory of the Perron root have been investigated by a number of authors. To list a few we mention Elsner [11], Friedland [13], Golub and Meyer [15], Haviv, Ritov, and Rothblum [16], and Meyer and Stewart [19].

Let us return to our Leslie matrix $\tilde{A}$ and assume that it is irreducible. In this paper we explicitly compute expressions for the first- and second-order derivatives of the Perron root and an appropriately normalized Perron vector of a Leslie matrix with respect to its entries in the first row and on its subdiagonal. We then interpret what meaning our results have for the population model that the matrix represents. *Most of our results show that younger ages exert more influence on the behavior of the growth rate and the stable age distribution vector than older age groups do.* Our experience is that it is much more difficult to analyze the effects of changes in survival rates on the population than it is to analyze changes in the fecundity rates.

In §2 we present further notation and preliminaries necessary for the work here. We obtain an explicit formula for the group inverse of $\lambda I - \tilde{A}$. In §3 we derive formulas

[1] See §2 for a more precise discussion of the partial derivatives of eigenvalues of matrix with respect to matrix entries.

for the second-order derivatives of the Perron root of a Leslie matrix with respect to its top row and subdiagonal. In doing so, some results of Deutsch and Neumann in [10] on the first and second derivatives of the Perron vector are extended. In §4 we also extend for the partial derivatives of the Perron vector of $\tilde{A}$. In §§3 and 4 we explain the implications of our results on the population model both qualitatively and where possible quantitatively.

2. Notation and preliminaries. In this paper we use the following notation.

$\mathbb{R}^k$ denotes the k-dimensional real space.

$\mathbb{R}^{k,k}$ denotes the space of all $k \times k$ real matrices.

$e \in \mathbb{R}^k$ denotes the k-dimensional vector whose entries are all 1's.

$e_i \in R^k$ denotes the k-dimensional unit coordinate vector, $i = 1, \ldots, n$.

$E_{i,j} \in \mathbb{R}^{k,k}$ is the matrix whose (i,j)th entry is 1 and whose remaining entries are 0.

The symbol $\sim$ indicates algebraic expressions with the same sign. Let $u = (u_1, \ldots, u_k) \in \mathbb{R}^k$ and $v = (v_1, \ldots, v_k) \in \mathbb{R}^k$. We write that $u \geq v$, if $u_i \geq v_i, i = 1, \ldots, k$. We say that u *majorizes* v, in notation $u \succeq v$, if

$$\sum_{j=1}^{i} u_j \geq \sum_{j=1}^{i} v_j, \quad i = 1, \ldots, k-1 \quad \text{and} \quad \sum_{j=1}^{k} u_j = \sum_{j=1}^{k} v_j.$$

Let $C \in \mathbb{R}^{n,n}$ and consider the matrix equations

$$CXC = C, \quad XCX = X, \quad \text{and} \quad CX = XC.$$

A matrix $X \in \mathbb{R}^{n,n}$ which satisfies all three equations, if it exists, is called the *group inverse of* C and is denoted by $C^{\#}$. Moreover, if $C^{\#}$ exists and D is any nonsingular matrix, then

$$(D^{-1}CD)^{\#} = D^{-1}C^{\#}D. \tag{2.1}$$

In particular, if D is a diagonal matrix whose diagonal entries are all positive, then all the entries of the matrices $C^{\#}$ and $D^{-1}C^{\#}D$ have identical signs in the same locations. It is known [1], [3] that a necessary and sufficient condition for $C^{\#}$ to exist, the elementary divisors, if any, of C corresponding to the eigenvalue zero are all linear. Thus, if B is an $n \times n$ nonnegative and irreducible matrix so that its Perron root is simple, then 0 is a simple eigenvalue of $C = \lambda I - B$, showing that the group inverse of C exists.

Suppose that $B \in \mathbb{R}^{n,n}$ has a simple eigenvalue called $\mu(B)$. It readily follows from considerations involving the minimal polynomial that there is an open ball in $\mathbb{R}^{n,n}$ about B such that every matrix in the ball has a simple eigenvalue. Thus, for any $E \in \mathbb{R}^{n,n}$ and for sufficiently small $t \in \mathbb{R}, B + tE$ has a simple eigenvalue $\mu(B + tE)$, such that $\mu(B + tE) \to \mu(B)$ as $t \to 0$. Wilkinson [22, pp. 66–67] shows that for sufficiently small $t, \mu(B + tE)$ can be expanded in a convergent power series about B. Hence, the derivatives of all orders of μ with respect to t exist at B. In particular, the partial derivative of μ with respect to the (i,j)th entry at B is given by the limit

$$\frac{\partial \mu}{\partial_{i,j}} := \frac{\partial \mu(B)}{\partial_{i,j}} = \lim_{t \to 0} \frac{\mu(B + tE_{i,j}) - \mu(b)}{t} \overset{\text{by}(1.4)}{=} \xi_j \eta_i, \tag{2.2}$$

where $\xi = \xi(B) = (\xi_1 \cdots \xi_n)^T$ and $\eta = \eta(B) = (\eta_1 \cdots \eta_n)^T$ are right and left eigenvectors of B corresponding to $\mu(B)$ normalized so that their inner product is 1. In a

similar manner we define the higher-order partial derivatives of μ at B with respect to the matrix entries. Wilkinson goes on to show that if one of many standard normalizations (but not the infinity norm) is applied to the eigenvector corresponding to $\mu(B+tE)$ throughout the ball, then the entries of the corresponding eigenvector can be expanded in a convergent power series. Therefore they too are differentiable with respect to t at B. When it is absolutely clear from the context, we shall suppress the letter representing the matrix from the expressions for the partial derivatives, viz., we write $\partial\mu/\partial_{i,j}$ for $\partial\mu(B)/\partial_{i,j}$ and so on.

Our approach is to first develop our results for stochastic Leslie matrices and then transform them to general Leslie matrices from which we shall be able to draw our conclusion for the population model under consideration. To do so it is helpful to have formulas connecting the partial derivatives with respect to the Perron root of a general nonnegative and irreducible matrix $\tilde{B}$ and the stochastic and irreducible matrix B to which $\tilde{B}$ is transformed using the diagonal similarity

$$B = \frac{1}{\lambda} D^{-1} \tilde{B} D, \tag{2.3}$$

where

$$D = \operatorname{diag}\ (\tilde{x}_1, \tilde{x}_2, \ldots, \tilde{x}_n) \tag{2.4}$$

and where $\tilde{x} = (\tilde{x}_1 \cdots \tilde{x}_n)^T$ is a right eigenvector of $\tilde{B}$ corresponding to its Perron root λ. Throughout we shall normalize all right Perron vectors so that their first entry equals 1. Thus, if $\tilde{y}$ is the left Perron vector of $\tilde{B}$ normalized so that $\tilde{x}^T\tilde{y} = 1$, then it follows from (1.4), (1.5), (2.1), (2.3), and (2.4) that

$$\frac{\partial^2 \lambda}{\partial_{i,j}^2} = \frac{2\tilde{y}_i}{\lambda} \frac{(\tilde{x}_j)^2}{\tilde{x}_i} Q_{j,i}^{\#}, \tag{2.5}$$

where $Q = I - B$. Similarly, relations for the eigenvectors will also be useful. In particular, the following formulas can be obtained:

$$\frac{\partial \tilde{x}}{\partial_{i,j}} = \frac{\tilde{x}_j}{\lambda \tilde{x}_i} D \frac{\partial x}{\partial_{i,j}}, \qquad 1 \le i, j \le n \tag{2.6}$$

and

$$\frac{\partial^2 \tilde{x}}{\partial_{1,i}^2} = \frac{\tilde{y}_1 \tilde{x}_i}{\lambda^2} D \frac{\partial^2 x}{\partial_{1,i}^2}, \qquad 1 \le i \le n. \tag{2.7}$$

For the specific case of the Leslie matrix $\tilde{A}$ as given in (1.1), the right Perron vector is given by

$$\tilde{x} = \left(1 \ \frac{P_1}{\lambda} \ \frac{P_1 P_2}{\lambda^2} \cdots \frac{P_1 \cdots P_{n-1}}{\lambda^{n-1}}\right)^T. \tag{2.8}$$

With (2.3) and (2.4) in mind, we find that $\tilde{A}$ can be transformed into the *stochastic and irreducible* Leslie matrix

$$A = \begin{pmatrix} a_1 & a_2 & \cdots & \cdots & a_{n-1} & a_n \\ 1 & 0 & \cdots & \cdots & 0 & 0 \\ \vdots & \ddots & \ddots & \vdots & 0 & 0 \\ \vdots & \cdots & \ddots & \ddots & \vdots & \vdots \\ \vdots & \cdots & \cdots & \ddots & \ddots & \vdots \\ 0 & \cdots & \cdots & \cdots & 1 & 0 \end{pmatrix}, \tag{2.9}$$

where

$$a_1 = \frac{F_1}{\lambda} \geq 0 \quad \text{and} \quad a_i = \frac{P_1, \ldots, P_{i-1}F_i}{\lambda^i} \geq 0, \qquad i = 2, \ldots, n, \tag{2.10}$$

with $a_n > 0$.

LEMMA 2.1. *Let A be an irreducible stochastic Leslie matrix whose top row is given by $(a_1 \cdots a_n)$. Set*

$$Q = I - A. \tag{2.11}$$

Then

$$Q^{\#} = \begin{bmatrix} (Q^{\#})_{1,1} & (Q^{\#})_{1,2} \\ (Q^{\#})_{2,1} & (Q^{\#})_{2,2} \end{bmatrix}, \tag{2.12}$$

where

$$\begin{aligned} (Q^{\#})_{1,1} = {} & M^{-1} + \chi M^{-1} e r^T M^{-1} + \chi e r^T M^{-2} \\ & + \chi^2 (r^T M^{-2} e)\, e r^T M^{-1}, \end{aligned} \tag{2.13}$$

$$(Q^{\#})_{1,2} = -\chi M^{-1} e - \chi^2 (r^T M^{-2} e)\, e, \tag{2.14}$$

$$(Q^{\#})_{2,1} = \chi r^T M^{-2} + \chi^2 (r^T M^{-2} e)\, r^T M^{-1}, \tag{2.15}$$

and

$$(Q^{\#})_{2,2} = -\chi^2 (r^T M^{-2} e), \tag{2.16}$$

and where $e \in \mathbb{R}^{n-1}$,

$$r = \begin{pmatrix} 0 \\ \vdots \\ -1 \end{pmatrix} \in \mathbb{R}^{n-1} \quad \textit{and} \quad \chi = \frac{1}{1 - r^T M^{-1} e} = \frac{1}{\frac{1}{a_n} \sum_{i=0}^{n-1} (1 - s_i)} \tag{2.17}$$

and

$$M^{-1} = \frac{1}{a_n} \begin{pmatrix} 1 - s_0 & s_{n-1} - s_1 & s_{n-1} - s_2 & \cdots & s_{n-1} - s_{n-3} & s_{n-1} - s_{n-2} \\ 1 - s_0 & 1 - s_1 & s_{n-1} - s_2 & \cdots & s_{n-1} - s_{n-3} & s_{n-1} - s_{n-2} \\ 1 - s_0 & 1 - s_1 & 1 - s_2 & \cdots & s_{n-1} - s_{n-3} & s_{n-1} - s_{n-2} \\ \vdots & \vdots & \vdots & \ddots & & \vdots \\ \vdots & \vdots & \vdots & & \ddots & \vdots \\ 1 - s_0 & 1 - s_1 & 1 - s_2 & \cdots & 1 - s_{n-3} & 1 - s_{n-2} \end{pmatrix}. \tag{2.18}$$

Here

$$s_0 = 0 \quad \textit{and} \quad s_i = \sum_{j=1}^{i} a_j \quad \forall 1 \leq i \leq n-1. \tag{2.19}$$

Proof. Let M be the $(n-1)\times(n-1)$ leading principal submatrix of Q. It is not difficult to check using the fact that the a_i's sum to 1 that Q admits the full rank factorization

$$Q = \begin{pmatrix} M \\ r^T \end{pmatrix} (I \quad -e) =: BC. \tag{2.20}$$

According to Ben-Israel and Greville [1], $Q^{\#} = B(CB)^{-2}C$. Now it can be verified that $(CB)^{-1} = M^{-1} + \chi M^{-1}er^TM^{-1}$, where χ and M^{-1} are as given in (2.17) and (2.18), respectively. That $Q^{\#}$ is given by (2.12) and as specified in (2.13)–(2.19) can now be ascertained from the above partitioning of C and B and the aforementioned formula for $(CB)^{-1}$. □

We comment that the above lemma is a specialization to the case of a singular M–matrix obtained from an $n\times n$ irreducible Leslie matrix of a formula for the group inverse of a singular M–matrix obtained from a general $n\times n$ nonnegative and irreducible matrix found by Meyer [18, Thm. 5.2].

3. The Perron root of a Leslie matrix as a function of top row and subdiagonal. We begin by determining the second-order behavior of the Perron root as a function of the top row.

THEOREM 3.1. *Let A be an $n\times n$ irreducible stochastic Leslie matrix whose top row is given by $(a_1,\ldots,a_n)$. Then the entries in the first column of the group inverse of $Q = I - A$ are given by*

$$Q^{\#}_{i,1} = \frac{\chi}{a_n}\left[n-i-\frac{\chi}{a_n}\sum_{j=0}^{n-2}(1-s_j)(n-1-j)\right], \qquad i=1,\ldots,n, \tag{3.1}$$

where χ and the s_j's are as in (2.17) *and* (2.19). *In particular, the entries of the first column of $Q^{\#}$ are strictly decreasing from first to last. Moreover, there exists an integer $k_0 < (n+1)/2$ such that $Q^{\#}_{1,1},\ldots,Q^{\#}_{k_0,1}$ are all nonnegative, whereas $Q^{\#}_{k_0+1,1},\ldots,Q^{\#}_{n,1}$ are all nonpositive.*

Proof. For each $1\le i\le n-1$, we find from (2.13) that

$$Q^{\#}_{i,1} = e_i^T\left[M^{-1} + \chi M^{-1}er^TM^{-1} + \chi er^TM^{-2} + \chi^2(r^TM^{-2}e)er^TM^{-1}\right]e_1.$$

Also from (2.18), we have that

$$r^TM^{-2}e = (r^TM^{-1})(M^{-1}e) = \sum_{j=0}^{n-2}\frac{1-s_j}{a_n}(n-2-j) - \left(\sum_{j=0}^{n-2}\frac{1-s_j}{a_n}\right)^2. \tag{3.2}$$

It now follows after several algebraic reductions that

$$Q^{\#}_{i,1} = \frac{\chi}{a_n}(1-s_0)\left(1-\chi r^TM^{-2}e - e_i^TM^{-1}e\right).$$

Further algebraic manipulations now yield (3.1). A similar calculation shows that (3.1) holds also for the case $i=n$.

From (3.1) it readily follows that the entries in the first column of $Q^{\#}$ are strictly decreasing from first to last and that the first entry is always positive (which is a

general result of Meyer [18] for all diagonal entries of the group inverse of a singular and irreducible M–matrix, and it is also an outcome of Cohen's results described in the introduction), whereas the last entry is always negative. To complete the proof we need only show that if $i \geq (n+1)/2$, then $Q^{\#}_{i,1} \leq 0$. From (3.1) we find that for $2 \leq i \leq n-1, Q^{\#}_{i,1}$ is nonpositive if and only if

$$(n-i)\sum_{j=0}^{n-1}(1-s_j) \leq \sum_{j=0}^{n-1}(1-s_j)(n-1-j). \tag{3.3}$$

But (3.3) holds if and only if

$$\sum_{j=0}^{n-1-i}(1-s_{j+i})(j+1) \leq \sum_{j=0}^{i-2}(1-s_{j+2-i})(j+1). \tag{3.4}$$

Since $1-s_{j+i} \leq 1-s_{j+2-i}$ for each $0 \leq j \leq n-i-1$, it now follows that if $i \geq (n+1)/2$, then (3.4) always holds. Consequently, $Q^{\#}_{i,1} \leq 0$ whenever $i \geq (n+1)/2$. □

Several comments are in order. (i) Theorem 3.1 shows that the sign change in the first column of $Q^{\#}$ always occurs somewhere before the $\lfloor (n+1)/2 \rfloor$th position. The following example shows that the sign change can occur at any position after the first and before the $(n+1)/2$th if n is odd or before the $\lfloor (n+1)/2 \rfloor$th if n is even. Fix $2 \leq k < (n+1)/2$. Let A be given by (2.9) with

$$a_j = \begin{cases} \alpha & \text{if } j = k-1, \\ 1-\alpha & \text{if } j = n, \\ 0 & \text{otherwise,} \end{cases}$$

where

$$\frac{n(n-1-2k)}{(n-k)(n-k-1)-2} < \alpha < \frac{n(n+1-2k)}{(n-k)(n-k+1)} < 1$$

with $0 \leq \alpha \leq 1$. Then a straightforward exercise shows that $Q^{\#}_{k,1} > 0 > Q^{\#}_{k+1,1}$ and that such an α causes the sign change to occur at the desired admissible position. (ii) Our next comment, which is given in a form of lemma, shows that under certain conditions on the stochastic Leslie matrices A and $\hat{A}$, there is a relationship between $Q^{\#}_{i,1}$ and $(\hat{Q})^{\#}_{i,1}, 1 \leq i \leq n$. The proof of the lemma follows directly from (3.1).

COROLLARY 3.2. *Let $a = (a_1 \cdots a_n)$ and $\hat{a} = (\hat{a}_1 \cdots \hat{a}_n)$ be the top rows of the irreducible stochastic Leslie matrices A and $\hat{A}$, respectively. Suppose $a \succeq \hat{a}$. Then*

$$Q^{\#}_{n,1} \geq \left(\hat{Q}\right)^{\#}_{n,1} \Rightarrow Q^{\#}_{i,1} \geq \left(\hat{Q}\right)^{\#}_{i,1} \quad \forall 1 \leq i \leq n$$

and

$$Q^{\#}_{1,1} \leq \left(\hat{Q}\right)^{\#}_{1,1} \Rightarrow Q^{\#}_{i,1} \leq \left(\hat{Q}\right)^{\#}_{i,1} \quad \forall 1 \leq i \leq n.$$

Next we examine the behavior of the Perron root of a Leslie matrix as a function of its entries on subdiagonal. From (1.5) and the preceding discussion we know that it suffices to determine the signs of the superdiagonal entries of $Q^{\#}$. As we shall see, determining expressions to represent these entries is no more difficult than determining

expressions for the entries of $Q^{\#}$ down its first column. But determining the signs of the entries on the superdiagonal, especially in the top first half, appears to be more difficult than determining the signs of $Q^{\#}$ down the first column.

THEOREM 3.3. *Let A be an $n \times n$ irreducible stochastic Leslie matrix whose top row is given by $(a_1 \cdots a_n)$. Then, providing we interpret any summation sign from a lower limit that exceeds an upper limit to be zero, the entries in the superdiagonal positions of the group inverse of $Q = I - A$ are given by*

$$Q^{\#}_{k,k+1} = \chi \left\{ \left(\frac{1 - s_k}{a_n} \right) \left[n - k - 1 + -\chi \sum_{j=0}^{n-1} \left(\frac{1 - s_j}{a_n} \right) (n - 2 - j) \right] - \sum_{j=k}^{n-1} \left(\frac{1 - s_j}{a_n} \right) \right\}, \qquad k = 1, \ldots, n-1, \tag{3.5}$$

where χ and the s_j's are given by (2.17) *and* (2.19), *respectively. The positive entries on the superdiagonal of $Q^{\#}$, if any, appear consecutively from the $(1,2)$th entry and form a nonincreasing sequence. The $(k, k+1)$th entries, where $k \geq (n-1)/2$, are all negative and for $k \geq (n+1)/2$ those entries form a nondecreasing sequence.*

Proof. For each $1 \leq k \leq n-2$, we find from (2.13) that

$$Q^{\#}_{k,k+1} = e_k^T \left[M^{-1} + \chi M^{-1} e r^T M^{-1} + \chi e r^T M^{-2} + \chi^2 \left(r^T M^{-2} e \right) e r^T M^{-1} \right] e_{k+1}. \tag{3.6}$$

Also recall the expression for $r^T M^{-2} e$ given in (3.2). Examining each term in the expansion of (3.6) and referring to (2.18) we find that

$$e_k^T M^{-1} e_{k+1}^T = \frac{1 - s_k}{a_n} - 1,$$

$$e_k^T M^{-1} e = \sum_{j=0}^{n-2} \frac{1 - s_j}{a_n} - (n - k - 1),$$

$$r^T M^{-1} e_{k+1} = -\frac{1 - s_k}{a_n},$$

and

$$r^T M^{-2} e_{k+1} = \left(r^T M^{-1} \right) \left(M^{-1} e_{k+1} \right) = - \left[\frac{1 - s_k}{a_n} \sum_{j=0}^{n-2} \frac{1 - s_j}{a_n} - \sum_{j=0}^{k-1} \frac{1 - s_j}{a_n} \right].$$

A number of algebraic reductions now yield (3.5). A similar calculation shows that (3.5) holds also when $k = n-1$.

To see that the positive entries in the superdiagonal positions of $Q^{\#}$, if any, beginning at the (1,2) entry are consecutive and form a nonincreasing sequence, we need only show that if $Q^{\#}_{k,k+1} \geq 0$, then $Q^{\#}_{k-1,k} \geq Q^{\#}_{k,k+1}$. To this end, note that if $Q^{\#}_{k,k+1} > 0$, then, in particular, from (3.5) it follows that

$$n - k - 1 - \chi \sum_{j=0}^{n-1} \frac{1 - s_j}{a_n} (n - 2 - j) > 0. \tag{3.7}$$

But from (3.5) we find that

$$Q^{\#}_{k-1,k} - Q^{\#}_{k,k+1} = \chi \frac{s_k - s_{k-1}}{a_n} \left[n - k - 1 - \chi \sum_{j=0}^{n-1} \frac{1 - s_j}{a_n} (n - 2 - j) \right]. \tag{3.8}$$

The claim now follows from (3.7).

Now let $k \geq (n-1)/2$. From (3.5) we find that

$$Q^{\#}_{k,k+1} \sim (1 - s_k) \frac{\sum_{j=k}^{n-1} (1 - s_j)(j - k) - \sum_{j=0}^{k-1} (1 - s_j)(k - j)}{\sum_{j=0}^{n-1} (1 - s_j)} - \sum_{j=k+1}^{n-1} (1 - s_j).$$

The numerator in the first term of the above expression can be rearranged as

$$\sum_{j=1}^{n-k-1} j (s_{k-j} - s_{k+j}) - \sum_{j=n-k}^{k} j (1 - s_{k-j}),$$

which is evidently nonpositive. Consequently, $Q^{\#}_{k,k+1} \leq 0$. Next, consider the difference (3.8). Note that if $Q^{\#}_{k,k+1}$ is nonpositive and if

$$n - k - 1 - \chi \sum_{j=0}^{n-1} \frac{1 - s_j}{a_n} (n - 2 - j) \leq 0, \tag{3.9}$$

then, necessarily, $Q^{\#}_{k-1,k} \leq Q^{\#}_{k,k+1} \leq 0$. But (3.9) holds if and only if

$$a_n (n - k) + \sum_{j=k}^{n-2} (1 - s_j)[j - (k-1)] \leq \sum_{j=0}^{k-1} (1 - s_j)[(k-1) - j]. \tag{3.10}$$

If $k \geq (n+1)/2$, the terms in (3.10) can be paired off to yield the equivalent expression:

$$\begin{aligned} &[(k-1) - a_n (n-k)] \\ &\quad + (s_k - s_{k-2}) \cdot 1 \\ &\quad + (s_{k+1} - s_{k-3}) \cdot 2 \\ &\quad + \cdots \\ &+ (s_{n-2} - s_{2k-n})(n - 1 - k) \\ &\quad + (1 - s_{2k-(n+1)})(n - k) \\ &\quad + \cdots \\ &\quad + (1 - s_1)(k - 2) \geq 0. \end{aligned}$$

Observe that each of the terms on the lefthand side above is nonnegative. Since we already proved that $Q^{\#}_{n-1,n} \leq 0$, the proof of the theorem is now complete. □

Note that Theorem 3.3 implies that either the $Q^{\#}_{k,k+1}$'s are all nonpositive or there is an index k_0, necessarily less than $(n-1)/2$, such that for $1 \leq k \leq k_0, Q^{\#}_{k,k+1} \geq 0$ and for $k_0 + 1 \leq k \leq n-1, Q^{\#}_{k,k+1} \leq 0$. Although we are not able to show that there exist cases where k_0 attains the value $\lfloor (n-1)/2 \rfloor$, the following example shows that

some $Q^{\#}_{k,k+1}$ can be positive when n is sufficiently large and when k is not too large compared with n. Specifically, consider the $n \times n$ stochastic Leslie matrix whose top row is given by

$$a_j = \begin{cases} 17/20 & \text{if } j = k+1, \\ 3/20 & \text{if } j = n, \\ 0 & \text{otherwise.} \end{cases} \tag{3.11}$$

From (3.5) it can be shown that $Q^{\#}_{k,k+1}$ is positive provided that

$$k < \frac{-(102n+68) + \sqrt{(102n+68)^2 + 4(119)(21n^2 - 72n + 51)}}{238}. \tag{3.12}$$

For $k = 1$, (3.12) yields that the minimal value of n that guarantees that for the matrix given by (3.11), $Q^{\#}_{1,2} > 0$, is $n = 11$. For $k = 2$, the minimal such n is 17. As $n \to \infty$, the righthand side (3.12) is asymptotic to

$$n\left(\frac{-102 + \sqrt{20400}}{238}\right) \approx 0.1715n. \tag{3.13}$$

Let us now revert to a general Leslie matrix $\tilde{A}$. From the discussion in §2 we see by (2.5) that the derivative of the Perron root with respect to the entries in the top row at $\tilde{A}$ is given by

$$\frac{\partial^2 \lambda}{\partial^2_{1,i}} = \frac{2}{\lambda}\left[\frac{1}{\sum_{j=0}^{n-1}(1-s_j)}\right]\left(\frac{P_1 P_2 \cdots P_{i-1}}{\lambda^{i-1}}\right)^2 Q^{\#}_{i,1}, \qquad i = 1, \ldots, n, \tag{3.14}$$

where $Q = I - A$ and A is as in (2.9) and (2.10). From this formula and the results of Theorem 3.1, it follows that if $\lambda > \max_{1 \le i \le n-1} P_i$, then

$$\frac{\partial^2 \lambda}{\partial^2_{1,i}} \ge 0 \Rightarrow \frac{\partial^2 \lambda}{\partial^2_{1,i}} \ge \frac{\partial^2 \lambda}{\partial^2_{1,j}}, \qquad j > i. \tag{3.15}$$

In particular, for λ as above,

$$\max_{1 \le i \le n} \frac{\partial^2 \lambda}{\partial^2_{1,i}} = \frac{\partial^2 \lambda}{\partial^2_{1,1}}. \tag{3.16}$$

Similarly, with respect to the subdiagonal entries, we have that

$$\frac{\partial^2 \lambda}{\partial^2_{k+1,k}} = \frac{2\lambda}{P_k^2} \frac{1 - s_k}{\sum_{j=0}^{n-1}(1-s_j)} Q^{\#}_{k,k+1}, \qquad k = 1, \ldots, n-1. \tag{3.17}$$

In particular, if $P_j \ge P_i$ and $j > i$, then

$$\frac{\partial^2 \lambda}{\partial^2_{i+1,i}} \ge 0 \Rightarrow \frac{\partial^2 \lambda}{\partial^2_{i+1,i}} \ge \frac{\partial^2 \lambda}{\partial^2_{j+1,j}}. \tag{3.18}$$

We now discuss the implications of the results obtained in this section on the population model that the Leslie matrix represents. First, we consider the qualitative interpretations. Theorems 3.1 and 3.3 show that the asymptotic rate of increase can only be a convex function of the fecundity and survival rates of younger age groups and that it is a concave function of these rates in older age groups. This suggests that only changes in the vital rates for younger age groups can yield a sharp change in the rate of increase of the asymptotic growth rate of the population. In attempting to compare the effects of changes in fecundity rates to changes in survival rates, we note that Theorem 3.1 always guarantees that for some younger age groups the asymptotic growth rate is a convex function of the fecundity. This is not necessarily the case for the effects of changes in the survival rates. Indeed, in our experience, it is difficult to produce examples where the asymptotic growth rate is a convex function of the survival rate of even the first age group. In this sense, the example given after Theorem 3.3 is atypical. It requires a peculiar fecundity distribution and, as we observe, a large number of age groups for changes in survival rates to have a sharp effect on the asymptotic growth rate.

Next, we consider the quantitative implications of our results on the population model. Recall that Demetrius' result [8, p. 134, Eq. (8)] asserts that if $\lambda > \max_{1\le i\le n-1} P_i$, then

$$\frac{\partial\lambda}{\partial_{1,i}} > \frac{\partial\lambda}{\partial_{1,j}}, \qquad j > i. \tag{3.19}$$

Our result in (3.15) reinforces (3.19) by showing that not only are the first partial derivatives of the asymptotic growth rate with respect to the fecundities ordered, but so are the second partial derivatives, at least for younger age groups. Next, we comment on what quantitative effects have changes in the rates of survival of the population on its growth rate? Here Demetrius' result [8, p. 134, Eq. (11)] is that

$$P_j \ge P_i \quad \text{and} \quad j > i \Rightarrow \frac{\partial\lambda}{\partial_{i+1,i}} \ge \frac{\partial\lambda}{\partial_{j+1,j}}. \tag{3.20}$$

Once again our result in (3.18) reinforces (3.20). Earlier we noted that the condition $\partial^2\lambda/\partial^2_{i+1,i} \ge 0$, which appears in (3.18), can only occur for younger age groups if at all. However, when this is the case, the hypothesis $P_j > P_i$ for $j > i$ seems reasonable when i is small because the survival rate for newborns is likely to be lower than that for slightly more mature individuals.

4. The Perron vector of a Leslie matrix as a function of top row and subdiagonal. We now examine the derivatives of the Perron vector of a stochastic Leslie matrix with respect to the entries in the top row and subdiagonal of the matrix. We then infer implications concerning the asymptotically stable age distribution vector of the general Leslie population model.

Let $\tilde{A}$ be an $n\times n$ general irreducible Leslie matrix whose Perron root is $\lambda = \lambda(\tilde{A})$. Throughout, its right Perron vector $x = x(\tilde{A})$ will be normalized so that its first entry is equal to 1. Denote by $y = y(\tilde{A})$ the left Perron vector of $\tilde{A}$ normalized so that $y^T x = 1$. Since now all the derivatives of the first entry of that Perron vector are zero, it will be convenient for us to work with the truncated form of $x = (1 \quad x_2 \ \dots \ x_n)^T$, viz., $\overline{x} = (x_2 \ \dots \ x_n)^T$. Before truncation all vectors that we work with in this section will be in $\mathbb{R}^n$ and a bar over them shall indicate their truncation to an $(n-1)$-dimensional vector by deleting their first entry. This notation is consistent with [10] and, for Leslie matrices, some results in that paper are also generalized here.

In the interest of convenience we derive a basic relation for the derivatives of the $\overline{x}$, which in essence are already contained in [10]. Put $\tilde{Q} = \lambda I - \tilde{A}$. On differentiating the matrix–vector relation $\tilde{A}x = \lambda x$ with respect to the (i,j)th entry, we obtain, on recalling (1.4), that

$$E_{i,j}x + \tilde{A}\frac{\partial x}{\partial_{i,j}} = x_j y_i x + \lambda \frac{\partial x}{\partial_{i,j}}$$

or

$$\frac{\partial \overline{x}}{\partial_{i,j}} = x_j N_{\tilde{Q}}^{-1}(\overline{e_i} - y_i \overline{x}), \tag{4.1}$$

where $N_{\tilde{Q}}$ is the $(n-1)\times(n-1)$ trailing principal submatrix of $\tilde{Q}$.

For the special case of a stochastic Leslie matrix we obtain the following.

LEMMA 4.1. *At the $n \times n$ irreducible stochastic Leslie matrix A whose top row is given by $(a_1 \cdots a_n)$,*

$$\frac{\partial \overline{x}}{\partial_{1,i}} = -\frac{1}{\sum_{j=0}^{n-1}(1-s_j)}(1 \quad 2 \quad \cdots \quad n-1)^T, \qquad 1 \le i \le n, \tag{4.2}$$

and

(4.3)

$$\frac{\partial \overline{x}}{\partial_{k+1,k}} = \frac{1}{\sum_{j=0}^{n-1}(1-s_j)} \begin{pmatrix} -(1-s_k) \\ -2(1-s_k) \\ \vdots \\ -(k-1)(1-s_k) \\ \sum_{j=0}^{n-1}(1-s_j) - k(1-s_k) \\ \vdots \\ \sum_{j=0}^{n-1}(1-s_j) - (n-1)(1-s_k) \end{pmatrix}, \qquad 1 \le k \le n-1,$$

where the s_i's are given in (2.19).

Proof. For the stochastic Leslie matrix A, we have that $x(A) = (1 \quad \cdots \quad 1)^T$ and for $Q = I - A$,

$$N_Q^{-1} = \begin{pmatrix} 1 & 0 & \cdots & 0 \\ 1 & 1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 1 & \cdots & 1 \end{pmatrix}.$$

Furthermore, if $y = y(A)$ is the left Perron vector of A normalized as above, then

$$y^T = \frac{1}{\sum_{j=0}^{n-1}(1-s_j)}((1-s_0) \quad (1-s_1) \quad \cdots \quad (1-s_{n-1})).$$

The expression for $\partial\overline{x}/\partial_{1,i}$ now follows on substituting these values of x, y, and N_Q^{-1} into (4.1) and on noting that $\overline{e_1} = 0$. The expression for $\partial\overline{x}/\partial_{k+1,k}$ follows similarly. □

Considering (4.2), we see that each entry of $\partial\bar{x}/\partial_{1,i}$ is negative for each $i = 1,\dots,n$. This fact is actually a consequence of a more general result of Elsner, Johnson, and Neumann [12, Thm. 1]. In contrast to (4.2), (4.3) shows that the signs of the entries of the $\partial\bar{x}/\partial_{k+1,k}$ are not necessarily uniform. Clearly, the first $k-1$ entries are negative and the remaining ones form a decreasing sequence. The following argument shows that $\partial\bar{x}/\partial_{k+1,k}$ always has at least one positive entry. Note that

$$\sum_{j=0}^{n-1}(1-s_j)-(k+1)(1-s_k)=\sum_{j=0}^{k}(s_k-s_j)+\sum_{j=k+1}^{n-1}(1-s_j)>0,\qquad 1\le k\le n-2.$$

Thus, we see that the kth and $(k+1)$th entries of $\partial\bar{x}/\partial_{k+1,k}$ are always positive for $1\le k\le n-2$. A similar argument shows that the last entry of $\partial\bar{x}/\partial_{n,n-1}$ is also always positive. From the above we see that either the entries of $\partial\bar{x}/\partial_{k+1,k}$ in positions k through $n-1$ are all nonnegative or there is an index $i_0\ge k+1$ such that the entries in positions k through i_0 are nonnegative and the remaining entries are nonpositive. To see that each such sign pattern can be realized, consider the stochastic Leslie matrix whose top row has $0<\alpha<1$ in the $(k+1)$th position and $1-\alpha$ in the nth position. It is readily verified that each admissible sign pattern can be obtained by a suitable choice of α.

We next investigate the sign pattern of the second partial derivatives of $\bar{x}$ with respect to the entries of the top row of a stochastic Leslie matrix.

THEOREM 4.2. *Let A be an $n\times n$ irreducible stochastic Leslie matrix whose top row is given by $(a_1\ \cdots\ a_n)$ and let $x=x(A)$ be its right Perron vector normalized so that its first entry is 1. Then*

$$\left(\frac{\partial^2\bar{x}}{\partial_{1,i}^2}\right)_l=2l\left(\frac{1}{\sum_{j=0}^{n-1}(1-s_j)}\right)^2\left[\frac{l+1}{2}+i-\frac{\sum_{j=0}^{n-1}(1-s_j)(j+1)}{\sum_{j=0}^{n-1}(1-s_j)}\right]\tag{4.4}$$

for all $1\le l\le n-1$ and $1\le i\le n$ and where the s_i's are as specified in (2.19). *Furthermore, when i is fixed, there is at most one sign change in the entries of $\partial^2\bar{x}/\partial_{1,i}^2$ from minus to plus as l increases. Similarly, when l is fixed and i is increased, there is at most one sign change in the sequence formed from the lth entries of the vectors $\partial^2\bar{x}/\partial_{1,i}^2, i=1,\dots,n$. In particular,*

$$\frac{l+1}{2}+i\ge\frac{n+1}{2}\Rightarrow\left(\frac{\partial^2\bar{x}}{\partial_{1,i}^2}\right)_l\ge 0\tag{4.5}$$

and an all pluses sign pattern is possible when either i or l is sufficiently large.

Proof. As usual let $Q=I-A$ and let y be the left Perron vector of A normalized so that $y^Tx=1$. From formula (4.13) in [10] we find that

$$\frac{\partial^2\bar{x}}{\partial_{1,i}^2}=2y_1x_i\left(y_1x_iN_Q^{-1}-Q_{i,1}^{\#}I\right)N_Q^{-1}\bar{x},\qquad i=1,\dots,n.\tag{4.6}$$

Substituting in the expressions for x, y, and N_Q^{-1} developed in Lemma 4.1 and using the formula for $Q_{i,1}^{\#}$ given in (3.1) yield after some simplification (4.4). The claims concerning the sign patterns follow readily by inspecting (4.4). That (4.5) holds can be established by the same argument given in Theorem 3.1, which was used to show that $Q_{i,1}^{\#}\le 0$ for $i\ge(n+1)/2$. □

As in our remarks following Theorem 3.1 concerning the sign pattern of the entries of the first column of $Q^{\#}$, examples can be constructed to show that when i is fixed and l is increasing, the switch from minus to nonnegative in $(\partial^2\overline{x}/\partial_{1,i}^2)_l$ can occur at any index $l_0 < n-2i$. A similar remark holds for the sequence $\partial^2\overline{x}/\partial_{1,i}^2$ when l is fixed and i is increasing.

We now return to a general Leslie matrix $\tilde{A}$. From (2.6) we have that for the first partial derivatives of the Perron vector with respect to the top row and subdiagonal,

$$\frac{\partial\overline{x(\tilde{A})}}{\partial_{1,i}} = \frac{P_1P_2\cdots P_{i-1}}{\lambda^i} N_D \frac{\partial\overline{x(A)}}{\partial_{1,i}}, \qquad i = 1,\ldots,n, \tag{4.7}$$

and

$$\frac{\partial\overline{x(\tilde{A})}}{\partial_{k+1,k}} = \frac{1}{P_k} N_D \frac{\partial\overline{x(A)}}{\partial_{k+1,k}}, \qquad k = 1,\ldots,n-1, \tag{4.8}$$

where A is given by (2.9) and (2.10). Similarly, for the second partial derivatives of the Perron vector with respect to the first row, we have from (2.7) that

$$\frac{\partial^2\overline{x(\tilde{A})}}{\partial_{1,i}^2} = \left[\frac{1}{\sum_{j=0}^{n-1}(1-s_j)}\right]\left(\frac{P_1P_2\cdots P_{i-1}}{\lambda^i}\right)^2 N_D \frac{\partial^2\overline{x(A)}}{\partial_{1,i}^2} \tag{4.9}$$

for all $i = 1,\ldots,n$. From (4.8) we can conclude that

(4.10)

$$\lambda \geq \max_{1\leq i\leq n-1} P_i \quad \text{and} \quad \left(\frac{\partial\overline{x(\tilde{A})}}{\partial_{k+1,k}}\right)_j \geq 0 \Rightarrow \left(\frac{\partial\overline{x(\tilde{A})}}{\partial_{k+1,k}}\right)_j \geq \left(\frac{\partial\overline{x(\tilde{A})}}{\partial_{k+1,k}}\right)_l, \qquad l \geq j.$$

In particular,

$$\max_{1\leq j\leq n-1}\left(\frac{\partial\overline{x(\tilde{A})}}{\partial_{k+1,k}}\right)_j = \left(\frac{\partial\overline{x(\tilde{A})}}{\partial_{k+1,k}}\right)_k. \tag{4.11}$$

We come now to interpret our results on the Perron vector for the population model. We begin with qualitative observations. For our analysis of the behavior of the asymptotically stable age distribution vector to make sense, we must choose a frame of reference, and the one we select is to compare the size of any age group to the size of the first age group.

(i) Formula (4.2) in Lemma 4.1 implies that raising the fecundity of any age group decreases the ratio of the size of any age group beyond the first to the size of the first age group.

(ii) Formula (4.3) in Lemma 4.1 shows that raising the survival rate of the kth age group has the effect of increasing the ratio of the size of the $(k+1)$th age group to the size of the first age group and possibly of raising those ratios for subsequent age groups while diminishing the those ratios for age groups $2,\ldots,k$.

In the way of quantitative interpretation of our results on the Perron vector for the population model, the only definite conclusion that we can draw follows from (4.3) and (4.11). Here we see that increasing the survival rate at the kth age group has the

effect of raising the ratios of the sizes of some age groups corresponding to ages other than 1 to the size of the group at age 1 while decreasing the ratios of sizes of other age groups to that of the size of the group at age 1. However, when $\lambda \geq \max_{1 \leq i \leq n-1} P_i$, it follows from (4.8) that the ratio that increases the most corresponds to the $(k+1)$th age group.

STABLE NUMERICAL ALGORITHMS FOR EQUILIBRIUM SYSTEMS*

STEPHEN A. VAVASIS†

Abstract. An equilibrium system (also known as a Karush–Kuhn–Tucker (KKT) system, a saddlepoint system, or a sparse tableau) is a square linear system with a certain structure. Strang [*SIAM Rev.*, 30 (1988), pp. 283–297] has observed that equilibrium systems arise in optimization, finite elements, structural analysis, and electrical networks. Recently, Stewart [*Linear Algebra Appl.*, 112 (1989), pp. 189–193] established a norm bound for a type of equilibrium system in the case when the "stiffness" portion of the system is very ill-conditioned. This paper investigates the algorithmic implications of Stewart's result. It is shown that several algorithms for equilibrium systems appearing in applications textbooks are unstable. A certain hybrid method is then proposed, and it is proved that the new method has the right stability property.

Key words. equilibrium systems, KKT systems, stable algorithms, linear algebra

1. Equilibrium systems.

Recently, Strang [21] observed that the problem of solving the structured linear system

$$\begin{pmatrix} D & -A \\ A^T & 0 \end{pmatrix} \begin{pmatrix} \mathbf{x} \\ \mathbf{y} \end{pmatrix} = \begin{pmatrix} \mathbf{b} \\ \mathbf{c} \end{pmatrix} \tag{1}$$

for $\mathbf{x}$ and $\mathbf{y}$ arises in many physical applications. Here, D is an $m \times m$ matrix, A is an $m \times n$ matrix, $\mathbf{x}$ and $\mathbf{b}$ are m-vectors, and $\mathbf{y}$ and $\mathbf{c}$ are n-vectors. We call this system an *equilibrium system.*

The focus of this paper is on the stability of algorithms for this linear system. Table 1 summarizes the applications and the interpretations of D, A, $\mathbf{x}$, $\mathbf{y}$, $\mathbf{b}$, and $\mathbf{c}$ in these applications. In the case of finite elements, we have indicated the interpretations in the context of a heat equilibrium problem (that is, $\nabla \cdot (g(x,y)\nabla u) = -f(x,y)$ on Ω, $u = 0$ on $\partial\Omega$, where Ω is a suitable domain in $\mathbb{R}^2$ or $\mathbb{R}^3$, and $f(x,y)$ and $g(x,y)$ are given functions, g being strictly positive).

The reader will observe that there are some similarities among the various interpretations. For example, one similarity is that, for the three physical applications, $\mathbf{x}$ and $\mathbf{c}$ are measured in the same physical units (e.g., amps), as are $\mathbf{y}$ and $\mathbf{b}$ (e.g., volts). This is also the case in certain optimization problems such as flow problems. This observation has some importance for numerical algorithms.

In all of these applications, the following two assumptions are commonplace and they are made throughout the paper.

A1. Matrix D is symmetric and positive definite.

A2. Matrix A has rank n, i.e., full column rank.

These assumptions imply that (1) is a nonsingular linear system with a unique solution.

TABLE 1
The interpretations of the variables in (1) *for various applications.*

Variable	Optimization	Electrical networks	Finite elements	Structures
D	Objective function Hessian	Resistances	Thermal resistance	Element flexibility
A	Constraints	Node-wire adjacency	Node-element geometry	Node-element geometry
$\mathbf{x}$	Primal variables	Currents	Element heat flow	Element forces
$\mathbf{y}$	Lagrange multipliers	Voltages	Nodal temperatures	Nodal displacements
$\mathbf{b}$	Objective function gradient	Voltage sources	Applied temperature gradient	Element dilations
$\mathbf{c}$	Distance from constraints	Current sources	Applied heat sources	Applied nodal forces

The main focus of this paper is what happens when D is severely ill-conditioned. Björck [1] calls this case the "stiff" case, in analogy with systems of ordinary differential equations. Where D is well conditioned, the numerical problems associated with solving (1) are generally not as troublesome, and most standard methods will give good answers. Thus, we make the following assumption.

A3. Matrix D is very ill conditioned.

The most natural framework for this assumption is an optimization algorithm involving a barrier function. The primary example of a barrier function in optimization is the class of interior point methods for linear programming. In an interior point method, matrix D becomes very ill-conditioned when the iterate approaches the boundary of the feasible region. (See Karmarkar [13] for the first interior-point method proposed for linear programming. See Wright [26] for a description of barrier methods and linear programming and their relationship.) For linear programming, since the solution is always on the boundary of the region, ill-conditioning in D *always* occurs during the algorithm.

Ill-conditioning of D can also occur in the other three applications listed above. In electrical networks, ill-conditioning occurs, for example, when one wishes to model the leakage currents to ground through insulators in the electrical network. In this case, some of the resistances are many orders of magnitude larger than others, leading to a very ill-conditioned D. The same ill-conditioning occurs if the linear equilibrium system is a model of a time-varying system in which certain circuit elements have switched "off."

In structural analysis, ill-conditioning in D occurs when the elements of the structure have widely different rigidity properties. In the finite elements for a heat application, ill-conditioning in D would occur if part of the domain under analysis were a thermal insulator and another part were a thermal conductor.

In the case that D is severely ill-conditioned, it is not at all apparent that an accurate numerical solution to (1) is possible, since ill-conditioning in D presumably means extreme sensitivity to roundoff errors. A perturbation theorem developed in §2, based on a recent theorem due to Stewart [20], shows that, in principle, an accurate solution can be computed under further assumptions. The perturbation result in §2 leads us to propose a definition of "stable" algorithms. None of the standard algorithms are stable when compared with the perturbation bound, as we

demonstrate in §4. There is a possibility, however, that some recent techniques in the literature might lead to stable algorithms—this possibility is discussed in §5.

Our main contribution, aside from the new definition of "stable," is a new algorithm described in §§6 and 7 that can accurately solve (1).

Most of the analysis of this paper is valid only under certain further assumptions that we now state.

A4. We are more interested in recovering $\mathbf{y}$ in (1) rather than $\mathbf{x}$.

A5. In (1) the vector $\mathbf{c}$ is zero.

A6. Matrix D in (1) is a diagonal matrix.

In §9 we discuss how A4, A5, and A6 could be relaxed.

Assumption A4 is similar to obtaining error bounds on individual components of the solution of a linear system. See, for example, Chandrasekaran and Ipsen [3]. In our work, the objective is to obtain a bound for a block of components of the solution.

In the context of optimization, A5 means that the current point is feasible. In the context of electrical networks, this assumption means that no external current sources are applied—only voltage sources (e.g., batteries or generators).

Assumption A6 holds in the context of interior point methods for linear programming. It also holds for electrical networks composed of batteries and resistors. It holds for finite elements for the varying-coefficient Poisson equation above, provided A is correctly formed. It does not hold for structural analysis in the general case; one usually obtains a matrix D that is block diagonal. There are, however, special cases of structural analysis where D is diagonal that we will review in future work.

A fifth application of the equilibrium system not listed in Table 1 is a discretization of Stokes flow. Stokes flow is a linear approximation to the Navier–Stokes equations for incompressible fluid flow under the assumption of a very low Reynolds number. Assumption A6 is never satisfied for Stokes flow (even in one dimension), which is why we do not discuss it further.

2. Stewart's norm-bound result. Under the assumptions made in §1, we can apply Stewart's theorem. Because of A4, it is useful to write an explicit formula for $\mathbf{y}$ in terms of the other variables. This formula is obtained by eliminating $\mathbf{x}$ from (1) and also substituting A5:

$$A^T D^{-1} A \mathbf{y} = -A^T D^{-1} \mathbf{b}. \tag{2}$$

Because of A1 and A2, the matrix $A^T D^{-1} A$ is invertible. Thus, this linear system uniquely determines $\mathbf{y}$:

$$\mathbf{y} = -(A^T D^{-1} A)^{-1} A^T D^{-1} \mathbf{b}. \tag{3}$$

We are now in a position to state Stewart's theorem. For the sake of completeness, we replicate his proof of the theorem because we refer to some of the proof steps in our algorithm construction.

THEOREM 2.1 ([20]). *Let $\mathcal{D}$ denote the set of all positive definite $m \times m$ real diagonal matrices. Let A be an $m \times n$ real matrix of* rank n. *Then there exist constants χ_A and $\bar{\chi}_A$ such that for any $D \in \mathcal{D}$,*

(a) $\|(A^T D^{-1} A)^{-1} A^T D^{-1}\| \leq \chi_A$, *and*

(b) $\|A(A^T D^{-1} A)^{-1} A^T D^{-1}\| \leq \bar{\chi}_A$.

In this theorem, we have assumed the use of some matrix norm $\|\cdot\|$ that is induced by a vector norm (also denoted $\|\cdot\|$).

A closely related result was obtained independently by Todd [23] as part of an analysis of Karmarkar's algorithm. In particular, Todd shows that

$$\|(A^T D^{-1} A)^{-1} A^T D^{-1} \mathbf{b}\| \leq c(A, \mathbf{b}).$$

This bound can be extended to obtain Theorem 2.1 with a compactness argument involving $\mathbf{b}$. Todd's proof is geometric and completely different from Stewart's proof. We follow Stewart's proof because it contains algebraic information useful for further development.

Before beginning the proof, we discuss the interpretation of the theorem. Except for sign, the matrix in (a) is the same matrix that is applied to $\mathbf{b}$ to obtain $\mathbf{y}$ according to (3). Thus, (a) says that $\mathbf{y}$ cannot be much larger than $\mathbf{b}$, no matter how D is chosen. In the context of electrical networks, this has a very natural physical interpretation: For a fixed electrical network with no current sources, no matter how badly the resistors are out of scale, there can never be a voltage level in the circuit that is much higher than the applied battery voltages.

Statement (b) also has an algorithmic interpretation. Specifically, if we know $\mathbf{y}$ and are trying to obtain $\mathbf{x}$, we observe from (1) that

$$D\mathbf{x} - A\mathbf{y} = \mathbf{b}.$$

The second term on the left-hand side is precisely

$$A(A^T D^{-1} A)^{-1} A^T D^{-1} \mathbf{b}.$$

Thus, the matrix in (b) can occur in the process of recovering $\mathbf{x}$.

Proof ([20]). First, we observe that statements (a) and (b) imply each other. For example, if we could prove (a), then we would observe that

$$\|A(A^T D^{-1} A)^{-1} A^T D^{-1}\| \leq \|A\| \cdot \|(A^T D^{-1} A)^{-1} A^T D^{-1}\|,$$

and thus we could take $\bar{\chi}_A$ to be $\|A\| \cdot \chi_A$. Similarly, the following inequality allows us to derive (a) from (b):

$$\|(A^T D^{-1} A)^{-1} A^T D^{-1}\| \leq \|(A^T A)^{-1} A^T\| \cdot \|A(A^T D^{-1} A)^{-1} A^T D^{-1}\|.$$

Thus, we prove (b) only. We first need a preliminary lemma, which is also due to Stewart. This lemma is cited later in the paper.

LEMMA 2.2 ([20]). *Define two subsets X and Y of $\mathbb{R}^m$ as follows*:

$$X = \{\mathbf{z} : \mathbf{z} = A\mathbf{w} \text{ for some } \mathbf{w}, \text{ and } \|\mathbf{z}\| = 1\}$$

and

$$Y = \{\mathbf{z} : A^T D^{-1} \mathbf{z} = \mathbf{0} \text{ for some } D \in \mathcal{D}\}.$$

Then $X \cap \bar{Y} = \emptyset$.

Here $\bar{Y}$ denotes the closure of Y in the topological sense.

Proof ([20]). Suppose there were a $\mathbf{z} \in X \cap \bar{Y}$, so that $\mathbf{z} = A\mathbf{w}$ for some $\mathbf{w}$ and $\|\mathbf{z}\| = 1$. The statement that $\mathbf{z}$ is in $\bar{Y}$ means that there exists an infinite sequence of vectors $\mathbf{z}_1, \mathbf{z}_2, \ldots$ converging to $\mathbf{z}$ and an infinite sequence of matrices $D_1, D_2, \ldots$ in $\mathcal{D}$ such that $A^T D_k^{-1} \mathbf{z}_k = \mathbf{0}$ for all k. Taking the inner product of this equation with $\mathbf{w}$, and substituting $\mathbf{w}^T A^T = \mathbf{z}^T$, yields $\mathbf{z}^T D_k^{-1} \mathbf{z}_k = 0$ for all k. But since $\mathbf{z}_k$ converges

to $\mathbf{z}$, there is some k large enough such that for all nonzero coordinate entries of $\mathbf{z}$, the corresponding entry of $\mathbf{z}_k$ has the same sign. This means that $\mathbf{z}^T D_k^{-1} \mathbf{z}_k > 0$, contradicting the previous equation. □

Now we use the lemma to conclude the proof of Theorem 2.1. Since X is compact and $\bar{Y}$ is closed, and since they are disjoint, there is a positive lower bound, say ρ, on the distance between these spaces measured in the $\|\cdot\|$ norm.

Next, choose some $D \in \mathcal{D}$. Choose an arbitrary vector $\mathbf{x}$. Let

$$\mathbf{y} = A(A^T D^{-1} A)^{-1} A^T D^{-1} \mathbf{x}.$$

The goal is to get an upper bound on $\|\mathbf{y}\|$ in terms of $\|\mathbf{x}\|$. A one-line calculation shows that $A^T D^{-1}(\mathbf{x} - \mathbf{y})$ is zero. Thus, let $\mathbf{v} = \mathbf{x} - \mathbf{y}$ so that $A^T D^{-1} \mathbf{v} = \mathbf{0}$. Set $t = 1/\|\mathbf{y}\|$. Then we have

$$t\mathbf{v} + t\mathbf{y} = t\mathbf{x}.$$

Note that $t\mathbf{v}$ is in Y and $-t\mathbf{y}$ is in X. Thus, the norm of the left-hand side of this equation is at least ρ. Thus, $\|t\mathbf{x}\| \geq \rho$, i.e.,

$$\rho \|\mathbf{y}\| \leq \|\mathbf{x}\|.$$

This gives us the upper bound of $1/\rho$ on $\bar{\chi}_A$ and concludes the proof. □

For the rest of the paper, given a matrix A, we define χ_A and $\bar{\chi}_A$ to be the suprema implicit in Theorem 2.1, i.e.,

$$\chi_A = \sup\{\|(A^T D^{-1} A)^{-1} A^T D^{-1}\| : D \in \mathcal{D}\}$$

and

$$\bar{\chi}_A = \sup\{\|A(A^T D^{-1} A)^{-1} A^T D^{-1}\| : D \in \mathcal{D}\}.$$

Stewart gives a bound for $\bar{\chi}_A$ that was proved by O'Leary [14] to be an exact formula. The formula seems to require an exponential number of steps to compute $\bar{\chi}_A$. Moreover, this formula is not completely constructive in finite precision arithmetic because of Stewart's observation that the parameters χ_A and $\bar{\chi}_A$ in Theorem 2.1 do not depend continuously on A. In particular, Stewart shows that $\bar{\chi}_A$ for $A = [0, 1]^T$ is one, but $\bar{\chi}_A$ for $A = [\epsilon, 1]^T$ tends to infinity as ϵ tends to zero.

It would be very interesting if there were an algorithm to compute or approximate $\chi_A, \bar{\chi}_A$ overcoming either of these difficulties (i.e., the algorithm gives the right answer in finite-precision arithmetic or the algorithm requires only a polynomial number of steps or both). In §8, we give a bound for $\chi_A, \bar{\chi}_A$ for a special class of matrices.

One would like to apply Theorem 2.1 to give algorithm stability results for finite-precision arithmetic. Here is an example of a straightforward perturbation result in this direction. For this theorem, $\|\cdot\|$ is restricted to being a p-norm. (In a p-norm, we know that the norm of a diagonal matrix is equal to its maximum absolute diagonal entry.)

THEOREM 2.3. *Let* $\mathbf{y}$ *be the second component of the exact solution to* (1) (*when* $\mathbf{c} = \mathbf{0}$). *Let* $\hat{\mathbf{y}}$ *be a computed solution to this system, such that* $\hat{\mathbf{y}}$ *is the exact solution to the perturbed system*

$$\begin{pmatrix} D+E & -A \\ A^T & 0 \end{pmatrix} \begin{pmatrix} \hat{\mathbf{x}} \\ \hat{\mathbf{y}} \end{pmatrix} = \begin{pmatrix} \mathbf{b}+\mathbf{e} \\ \mathbf{0} \end{pmatrix}, \tag{4}$$

where E satisfies the bound $|E| \leq \epsilon \cdot |D|$ and $\|\mathbf{e}\| \leq \epsilon\|\mathbf{b}\|$, where $\epsilon < \frac{1}{3}$. Then

$$\|\mathbf{y} - \hat{\mathbf{y}}\| \leq \chi_A \epsilon \cdot \|\mathbf{b}\| \cdot (\bar{\chi}_A + 8/3). \tag{5}$$

The novel property of this theorem is that the error bound in (5) is independent of the condition number of D or of the condition number of (1).

Note that we have used the matrix absolute value notation from Golub and Van Loan [11]. Thus, the assumption $|E| \leq \epsilon \cdot |D|$ implies that E is also diagonal.

Proof. By elimination as described above, we have the following formulas for $\mathbf{y}$ and $\hat{\mathbf{y}}$:

$$A^T D^{-1} A\mathbf{y} = -A^T D^{-1}\mathbf{b}$$

and

$$A^T D^{-1} A\hat{\mathbf{y}} + A^T F A\hat{\mathbf{y}} = -A^T D^{-1}(\mathbf{b} + \mathbf{e}) - A^T F(\mathbf{b} + \mathbf{e}).$$

Here F denotes $(D+E)^{-1} - D^{-1}$, i.e., $-ED^{-1}(D+E)^{-1}$. Subtracting these equations yields

$$A^T D^{-1} A(\hat{\mathbf{y}} - \mathbf{y}) + A^T F A\hat{\mathbf{y}} = -A^T D^{-1}\mathbf{e} - A^T F(\mathbf{b} + \mathbf{e}).$$

We can add and subtract $A^T F A\mathbf{y}$ on the left to obtain

$$A^T D^{-1} A(\hat{\mathbf{y}} - \mathbf{y}) + A^T F A(\hat{\mathbf{y}} - \mathbf{y}) + A^T F A\mathbf{y} = -A^T D^{-1}\mathbf{e} - A^T F(\mathbf{b} + \mathbf{e}),$$

which can be written

$$A^T (D^{-1} + F) A(\hat{\mathbf{y}} - \mathbf{y}) = -A^T F A\mathbf{y} - A^T D^{-1}\mathbf{e} - A^T F(\mathbf{b} + \mathbf{e}).$$

Define $G = D^{-1} + F = (D + E)^{-1}$, another diagonal matrix. Introduce new vectors $\mathbf{e}_1 = G^{-1} F A\mathbf{y}$, $\mathbf{e}_2 = G^{-1} D^{-1}\mathbf{e}$, and $\mathbf{e}_3 = G^{-1} F(\mathbf{b} + \mathbf{e})$. Then we can rewrite the preceding equation as

$$A^T G A(\hat{\mathbf{y}} - \mathbf{y}) = -A^T G(\mathbf{e}_1 + \mathbf{e}_2 + \mathbf{e}_3).$$

Now we can conclude from Theorem 2.1 that

$$\|\hat{\mathbf{y}} - \mathbf{y}\| \leq \chi_A(\|\mathbf{e}_1\| + \|\mathbf{e}_2\| + \|\mathbf{e}_3\|).$$

Thus, the theorem is proved once we analyze the three terms on the right-hand side. First, we have

$$\begin{aligned} \|\mathbf{e}_1\| &= \|(D + E) F A\mathbf{y}\| \\ &\leq \|E D^{-1}\| \cdot \|A\mathbf{y}\| \\ &\leq \epsilon \|A\mathbf{y}\| \\ &\leq \epsilon \cdot \bar{\chi}_A \cdot \|\mathbf{b}\|. \end{aligned}$$

Next, we have

$$\begin{aligned} \|\mathbf{e}_2\| &= \|G^{-1} D^{-1}\mathbf{e}\| \\ &= \|(D + E) D^{-1}\mathbf{e}\| \\ &\leq \|(D + E) D^{-1}\| \cdot \|\mathbf{e}\| \\ &\leq (1 + \epsilon) \cdot \epsilon \cdot \|\mathbf{b}\|. \end{aligned}$$

Note that $1+\epsilon \leq 4/3$. Finally,

$$\begin{aligned}\|\mathbf{e}_3\| &= \|G^{-1}F(\mathbf{b}+\mathbf{e})\| \\ &\leq \epsilon \cdot (1+\epsilon) \cdot \|\mathbf{b}\|.\end{aligned}$$

As above, $1+\epsilon \leq 4/3$. This proves the theorem. □

For the rest of the paper, we regard (5) as the "ideal" bound that could be satisfied by a finite-precision algorithm. The stability result of this theorem is somewhat different from well-known perturbation results. Usually a bound on the *relative* error in $\mathbf{y}$ is obtained in terms of ϵ and the other parameters. A relative error bound on $\mathbf{y}$ is not possible for the equation at hand. Such a bound would mean that it is not possible for $\|\mathbf{y}-\hat{\mathbf{y}}\|$ to be large when $\|\mathbf{y}\|$ is small. However, one can select a nonzero $\mathbf{b}$ to make $\mathbf{y}$ arbitrarily small—zero in fact—because $\mathbf{b}$ generally has more dimensions than $\mathbf{y}$. Thus, the bound in the theorem seems to be the best form we could hope for.

We say that an algorithm for (1) is *stable* if, in the presence of finite-precision arithmetic, an error bound of the same form as (5) is satisfied, where ϵ is on the order of the machine roundoff. In particular, the error bound should have the form

$$\|\mathbf{y}-\hat{\mathbf{y}}\| \leq \epsilon \cdot f(A) \cdot \|\mathbf{b}\|,$$

where $f(A)$ is some function of A not depending on D.

If we could show that a finite-precision algorithm satisfied the hypothesis of the theorem (i.e., the computed solution satisfied (4)), then it would automatically be stable. Unfortunately, we do not know of any finite-precision algorithm to solve (1) that achieves the conditions of this theorem. In particular, it seems that the error bound for any obvious algorithm would involve a backward error term affecting not only D but also A. Since χ_A is not continuous with respect to changes in A, the theorem cannot be extended to the case when A is also perturbed. In §6 we derive a stable algorithm by other means.

3. Further development of the theory. In this section, we develop the theory further before turning to algorithms in the next section. First, we make a few remarks about the difference between χ_A and $\bar{\chi}_A$. Then we look at the relationship between $\chi_A, \bar{\chi}_A$ and the corresponding variables for the *dual* problem.

The two parameters $\chi_A, \bar{\chi}_A$ have different properties with respect to changes in A. If A is multiplied by a constant, then χ_A scales in a reciprocal manner. Parameter $\bar{\chi}_A$ is unchanged when A is scaled. It should be apparent from (5) that the ideal situation is when both constants are small. Thus, we think of A as "well conditioned" if $\bar{\chi}_A$ is on the order of unity and χ_A is on the order of $1/\|A\|$. Note that $\bar{\chi}_A$ is at least one in any norm; this is seen by taking D to be the identity matrix in Theorem 2.1(b), in which case $A(A^TA)^{-1}A^T$ is an orthogonal projection matrix with spectral radius of one.

In the preceding paragraph we observed that $\bar{\chi}_A$ is unchanged by scaling. More generally, one sees by inspection that $\bar{\chi}_A$ remains unchanged if A is replaced by AR where R is any nonsingular $n \times n$ matrix. This is the same as saying that $\bar{\chi}_A$ depends only on the span of the columns of A and not the particular basis selected for that span. The parameter χ_A, on the other hand, depends also on the degree of linear independence of the columns of A.

In the proof in §2, we bounded $\bar{\chi}_A$ in terms of $1/\rho$. We now extend that result to show that this bound is an equation: the supremum of $\|A(A^TD^{-1}A)^{-1}A^TD^{-1}\|$ taken over $D \in \mathcal{D}$ is exactly $1/\rho$. We already proved that this supremum is at most

$1/\rho$. The argument for the other direction is from O'Leary [14]. Observe that if $\mathbf{x} \in X$ and $\mathbf{y} \in Y$, where X, Y are as in Lemma 2.2, then the following argument puts a lower bound on $\mathbf{x} - \mathbf{y}$. Let D be chosen so that $A^T D^{-1}\mathbf{y} = \mathbf{0}$, and let $\mathbf{w}$ be chosen so that $\mathbf{x} = A\mathbf{w}$. Then

$$A^T D^{-1}(\mathbf{x} - \mathbf{y}) = A^T D^{-1}\mathbf{x} = A^T D^{-1} A\mathbf{w},$$

so

$$\mathbf{w} = (A^T D^{-1} A)^{-1} A^T D^{-1}(\mathbf{x} - \mathbf{y}).$$

This yields

$$\mathbf{x} = A\mathbf{w} = A(A^T D^{-1} A)^{-1} A^T D^{-1}(\mathbf{x} - \mathbf{y}),$$

so

$$\|\mathbf{x}\| \leq \bar{\chi}_A \cdot \|\mathbf{x} - \mathbf{y}\|.$$

But $\|\mathbf{x}\| = 1$ by the assumption that $\mathbf{x} \in X$, so we see that $1/\bar{\chi}_A$ is a lower bound on $\|\mathbf{x} - \mathbf{y}\|$.

We now look into the relationship between (1) and its dual problem. Let Z be a *nullspace basis* for A^T; that is, an $m \times (m - n)$ matrix Z of full column rank such that $A^T Z = 0$. We want to know the relationship between $\bar{\chi}_A$ and $\bar{\chi}_Z$. Note that A is a nullspace basis for Z^T, so any relationship between $\bar{\chi}_A, \bar{\chi}_Z$ also holds if A, Z are interchanged. Note also that $\bar{\chi}_Z$ depends only on the span of the columns of Z: in other words, it does not matter which nullspace basis Z is selected.

To obtain a bound for $\bar{\chi}_Z$, we consider two algorithms for solving the following version of (1), where $\mathbf{x}_0$ is some arbitrary m-vector.

$$\begin{pmatrix} D & -A \\ A^T & 0 \end{pmatrix} \begin{pmatrix} \mathbf{x} \\ \mathbf{y} \end{pmatrix} = \begin{pmatrix} \mathbf{0} \\ A^T \mathbf{x}_0 \end{pmatrix}. \tag{6}$$

First, observe that the second equation of (6) is $A^T\mathbf{x} = A^T\mathbf{x}_0$, i.e., $A^T(\mathbf{x} - \mathbf{x}_0) = \mathbf{0}$. This is the same as saying that $\mathbf{x} - \mathbf{x}_0$ is in the nullspace of A, i.e., there is an $m - n$-vector $\mathbf{q}$ such that $\mathbf{x} = \mathbf{x}_0 + Z\mathbf{q}$. Substituting this into the first equation yields $D(\mathbf{x}_0 + Z\mathbf{q}) - A\mathbf{y} = \mathbf{0}$. Multiply by Z^T using the fact that $Z^T A = 0$ to obtain $Z^T D Z\mathbf{q} = -Z^T D\mathbf{x}_0$. Solving for $\mathbf{q}$ yields $\mathbf{q} = -(Z^T DZ)^{-1} Z^T D\mathbf{x}_0$. Substituting this formula for $\mathbf{q}$ into $\mathbf{x} = \mathbf{x}_0 + Z\mathbf{q}$ yields

$$\mathbf{x} = -Z(Z^T DZ)^{-1} Z^T D\mathbf{x}_0 + \mathbf{x}_0.$$

Since $\mathbf{x}_0$ is arbitrary, we see that

$$\|Z(Z^T DZ)^{-1} Z^T D\| = \sup\left\{ \frac{\|\mathbf{x} - \mathbf{x}_0\|}{\|\mathbf{x}_0\|} : \mathbf{x}_0 \neq \mathbf{0}; \mathbf{x} \text{ solves (6)} \right\}.$$

This means that

$$\bar{\chi}_Z = \sup\left\{ \frac{\|\mathbf{x} - \mathbf{x}_0\|}{\|\mathbf{x}_0\|} : D \in \mathcal{D}; \mathbf{x}_0 \neq \mathbf{0}; \mathbf{x} \text{ solves (6)} \right\}.$$

By applying the triangle inequality, we obtain the bound

$$\bar{\chi}_Z \leq \sup\left\{ 1 + \frac{\|\mathbf{x}\|}{\|\mathbf{x}_0\|} : D \in \mathcal{D}; \mathbf{x}_0 \neq \mathbf{0}; \mathbf{x} \text{ solves (6)} \right\}. \tag{7}$$

Now we compute this supremum by solving (6) in a different way. The first equation of (6) is $D\mathbf{x} - A\mathbf{y} = \mathbf{0}$. Multiplying by $A^T D^{-1}$ yields $A^T\mathbf{x} - A^T D^{-1} A\mathbf{y} = \mathbf{0}$. Substituting the second equation yields $A^T\mathbf{x}_0 - A^T D^{-1} A\mathbf{y} = \mathbf{0}$. Solving for $\mathbf{y}$ yields $\mathbf{y} = (A^T D^{-1} A)^{-1} A^T \mathbf{x}_0$. Use the fact that $\mathbf{x} = D^{-1} A\mathbf{y}$ to obtain $\mathbf{x} = D^{-1} A(A^T D^{-1} A)^{-1} A^T \mathbf{x}_0$. Thus,

$$\frac{\|\mathbf{x}\|}{\|\mathbf{x}_0\|} \leq \|D^{-1} A(A^T D^{-1} A)^{-1} A^T\|. \tag{8}$$

Observe that the matrix whose norm we are taking on the right-hand side of (8) is precisely the transpose of the matrix used to define $\bar{\chi}_A$ in Theorem 2.1(b). Thus, we see that the norm on the right-hand side is bounded by $\gamma_m \bar{\chi}_A$, where γ_m is the multiplicative factor that makes the following inequality a true statement for all $m \times m$ matrices B:

$$\|B^T\| \leq \gamma_m \|B\|.$$

For example, $\gamma_m = 1$ if we use the matrix 2-norm and $\gamma_m = m$ if we use the 1-norm or ∞-norm.

If we substitute (8) into (7) we arrive at the following result.

THEOREM 3.1. *Let A be an $m \times n$ matrix of rank n, and let Z be an $m \times (m-n)$ matrix of rank $m-n$ such that $A^T Z = 0$. Then*

$$\bar{\chi}_Z \leq 1 + \gamma_m \bar{\chi}_A,$$

where γ_m is defined in the last paragraph.

This gives a relationship between $\bar{\chi}_Z$ and $\bar{\chi}_A$. A relationship between χ_Z and $\bar{\chi}_A$ or χ_A is not possible without making further assumptions (for example, that $Z^T Z$ is well-conditioned).

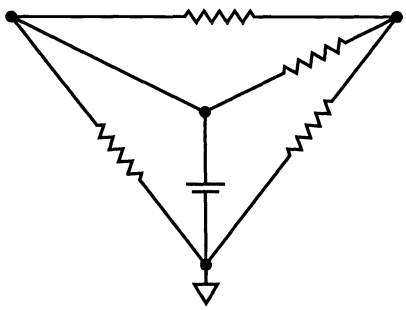
4. The standard algorithms. In this section we describe four standard algorithms for (1). All four of these algorithms are shown to be unstable in the sense of stability given in §2. By "standard" we mean that these algorithms are described in optimization textbooks such as those by Coleman [5], Gill, Murray, and Wright [9], and Fletcher [7], electrical engineering textbooks such as that by Chua, Desoer, and Kuh [4]; and civil engineering textbooks such as that by Timoshenko and Young [22]. In all four cases we have used simple implementations of the algorithms. In the next section we consider stabilizations proposed in the recent literature.

4.1. Symmetric indefinite factorization. Observe in (1) that if we replace $\mathbf{y}$ by $-\mathbf{y}$, the coefficient matrix becomes the symmetric matrix

$$\begin{pmatrix} D & A \\ A^T & 0 \end{pmatrix}.$$

Therefore, we could think about solving this equation with a standard "stable" algorithm for symmetric indefinite linear systems. (See [11] for some algorithms for this purpose.) Symmetric factorization has the disadvantage that it does not respect the block of zeros and therefore requires more operations than necessary. In the electrical engineering context, solving (1) directly is known as *sparse tableau analysis.* In optimization, this algorithm is called the *augmented system* method.

This algorithm should be rejected for the following numerical reason. The algorithm "mixes" $\mathbf{b}, \mathbf{c}$ on the right and $\mathbf{x}, \mathbf{y}$ on the left during the forward substitution



(a)

$$A = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \\ -1 & 1 & 0 \\ 1 & 0 & -1 \\ 0 & 1 & -1 \end{pmatrix}, D = \begin{pmatrix} 10^{-15} & & & & & \\ & 1 & & & & \\ & & 1 & & & \\ & & & 10^{-15} & & \\ & & & & 1 & \\ & & & & & 1 \end{pmatrix}, \mathbf{b} = \begin{pmatrix} 1 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{pmatrix}$$

(b)

FIG. 1. *The circuit depicted in* (a) *yields an equilibrium system of the form* (1) *with* $D, A, \mathbf{b}$, *as in* (b). *Here all the resistors have size* 1 *and wires without an indicated resistor have resistance* 10^{-15}. *The correct values of the voltages of the three nodes are* $(1.00, 1.00, 0.67)$ *accurate to two digits. The Parlett–Reid algorithm, however, yields* $(1.31, 1.31, 0.88)$ *when* D *is replaced by* $10^{20}D$ *and yields* $(0.86, 0.98, 0.58)$ *when* D *is replaced by* $10^{25}D$.

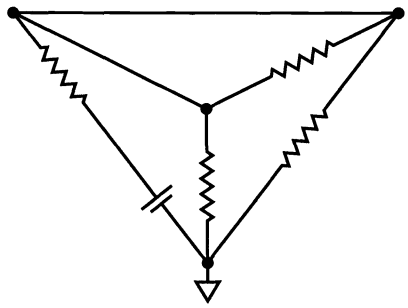
and back substitution process. This does not make sense physically, because $\mathbf{b}, \mathbf{c}$ and $\mathbf{x}, \mathbf{y}$ have different physical units and could be on vastly different scales numerically.

To put it another way, this algorithm is sensitive to scaling matrix D by a constant multiple. On the other hand, $\mathbf{y}$ is mathematically unchanged by such a scaling. Indeed, for a simple electrical circuit depicted in Fig. 1, we scaled D by varying amounts and applied the Parlett–Reid [17] symmetric factorization. Substantially different values of $\mathbf{y}$ (the voltages) were recovered, some accurate to less than one decimal place.

These tests, as well as the others in this paper, were conducted in MATLAB™. MATLAB, a software package for interactive numerical computation, is a trademark of The Mathworks, Inc. All the computations were done in IEEE double-precision arithmetic, with about 15 decimal digits of accuracy.

Standard stability results for algorithms like the Parlett–Reid algorithm do not apply because of our stated interest to recover $\mathbf{y}$ accurately, which is only a part of the solution vector. Moreover, the accuracy of these algorithms depends on the condition number of the equilibrium system (1), which depends on the condition number of D (another reason for rejecting this approach).

For the problem in this example, $\chi_A, \bar{\chi}_A$ are both small because A is a reduced



(a)

$$A = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \\ -1 & 1 & 0 \\ 1 & 0 & -1 \\ 0 & 1 & -1 \end{pmatrix}, D = \begin{pmatrix} 1 & & & & & \\ & 1 & & & & \\ & & 1 & & & \\ & & & 10^{-15} & & \\ & & & & 10^{-15} & \\ & & & & & 1 \end{pmatrix}, \mathbf{b} = \begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \\ 0 \\ 0 \end{pmatrix}$$

(b)

FIG. 2. *The circuit depicted in* (a) *yields an equilibrium system of the form* (1) *with* $D, A, \mathbf{b}$, *as in* (b). *Here all the resistors have size* 1 *and wires without an indicated resistor have resistance* 10^{-15}. *The correct values of the voltages of the three nodes are* $(0.33, 0.33, 0.33)$ *accurate to two digits. The range-space algorithm, however, yields* $(0.28, 0.28, 0.28)$.

node-arc incidence matrix (see §8). Thus, the failure of this algorithm to satisfy something like (5) indicates that the algorithm is unstable, not that the problem is poorly posed.

4.2. The range-space method. This method obtains $\mathbf{y}$ by solving (2) explicitly. Since $A^T D^{-1} A$ is positive definite, (2) can be solved with Cholesky factorization. Note that this method, as well as the nullspace method described below, is insensitive to scaling of D by a constant multiple.

This method is called the *range-space* method in optimization. In structural analysis it is known as the *displacement* method. In electrical engineering it is called the *nodal analysis* method. In finite elements, the matrix $A^T D^{-1} A$ is known as the *assembled stiffness matrix.* This matrix is known as the *Schur complement* in optimization.

It should be apparent that if D is severely ill-conditioned, then $A^T D^{-1} A$ can also be severely ill-conditioned. (Indeed, in finite precision arithmetic, $A^T D^{-1} A$ may not even be positive definite.) This means that inaccurate answers (i.e., answers not respecting (5)) may be obtained. An example of a circuit solution obtained with the range-space method is indicated in Fig. 2. Observe that not even one significant decimal place is obtained in the answer.

4.3. The nullspace method. This method obtains $\mathbf{x}$ first and then $\mathbf{y}$. The essential ingredients of the nullspace method were described in §3. Following Fletcher [7], we can describe this method as follows. First, a pair of matrices Y, Z is obtained, where Y is an $m \times n$ matrix such that $A^T Y = I$, the identity, and Z is a nullspace basis; that is, an $m \times (m-n)$ of full column rank such that $A^T Z = 0$. Matrix Y is called a *right-inverse* of A^T.

The most stable way to obtain Y, Z is via a QR factorization of A, say $A = QR$. Then Z is set to the last $m-n$ columns of Q and Y is set to the product $Q_1 R_1^{-T}$, where Q_1 is the first n columns of Q and R_1 is the first n rows of R.

Once Y, Z are obtained, we observe that the equation $A^T\mathbf{x} = \mathbf{0}$ means $\mathbf{x} = Z\mathbf{q}$ for some $(m-n)$-vector $\mathbf{q}$. This is because Z spans the nullspace of A. Substituting $\mathbf{x} = Z\mathbf{q}$ into the equation $D\mathbf{x} - A\mathbf{y} = \mathbf{b}$ yields $DZ\mathbf{q} - A\mathbf{y} = \mathbf{b}$. Now multiply by Z^T, using the fact that $Z^T A = 0$, to obtain $Z^T DZ\mathbf{q} = Z^T\mathbf{b}$. The matrix $Z^T DZ$ is known as the *reduced Hessian* in the optimization literature.

The linear system $Z^T DZ\mathbf{q} = Z^T\mathbf{b}$ is symmetric and positive definite, and hence may be solved with Cholesky factorization to obtain $\mathbf{q}$. Once $\mathbf{q}$ is obtained, $\mathbf{x}$ can be obtained with the formula $\mathbf{x} = Z\mathbf{q}$. Finally, $\mathbf{y}$ is obtained from the equation $D\mathbf{x} - A\mathbf{y} = \mathbf{b}$ by multiplying through by Y^T, yielding $\mathbf{y} = Y^T(D\mathbf{x} - \mathbf{b})$.

This method is known as the *nullspace method* in optimization. It is called the *force method* in civil engineering, and *loop analysis* in electrical engineering.

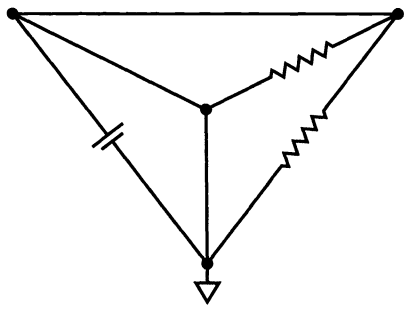
It should be apparent that this method suffers from the same flaw as the range-space method. The matrix $Z^T DZ$ could be arbitrarily ill-conditioned, and hence solving a linear system with this matrix could give a highly inaccurate answer. Indeed, for the example in Fig. 3, the nullspace method returned an answer for $\mathbf{y}$ without any digits of accuracy.

4.4. Gaussian elimination with partial pivoting. Gaussian elimination with partial pivoting is generally not recommended for equilibrium systems because it ignores the special structure. Furthermore, it suffers from the same disadvantages as symmetric indefinite factorization as far as stably solving (1) is concerned. Nonetheless, one might be tempted to apply it directly to (1) since it is widely and easily accessible in many software packages.

As the reader might expect by now, Gaussian elimination with partial pivoting (as implemented by the '\' operation in MATLAB) also failed to give an accurate answer as depicted in Fig. 4.

5. Stabilizing the standard algorithms. The implementations in the last section of the standard algorithms were straightforward, without any special techniques applied. In this section we describe some techniques known from recent literature that may stabilize these algorithms. Additional algorithms known in the literature are described below. As far as we know, none of these stabilizations, nor any of the other algorithms known in the literature, are provably stable. (The only provably stable algorithm of which we are aware is the NSH algorithm described in the upcoming sections.) On the other hand, we do not have any counterexamples showing that these algorithms are unstable. Therefore, it remains an interesting open question to determine the stability of these algorithms.

As for the augmented system method, one might hypothesize the existence of a special value of the scaling parameter that will give an accurate solution for $\mathbf{y}$ in (1) and therefore constitute a stable algorithm. It should be noted that there are simple examples of (1) such that, no matter how D is scaled, the augmented system matrix



(a)

$$A = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \\ -1 & 1 & 0 \\ 1 & 0 & -1 \\ 0 & 1 & -1 \end{pmatrix}, D = \begin{pmatrix} 10^{-16} & & & & & \\ & 1 & & & & \\ & & 10^{-16} & & & \\ & & & 10^{-16} & & \\ & & & & 10^{-16} & \\ & & & & & 1 \end{pmatrix}, \mathbf{b} = \begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \\ 0 \\ 0 \end{pmatrix}$$

(b)

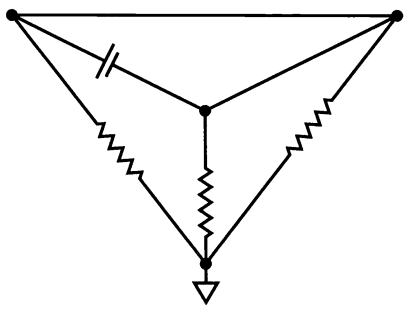
FIG. 3. *The circuit depicted in* (a) *yields an equilibrium system of the form* (1) *with* $D, A, \mathbf{b}$, *as in* (b). *Here, all the resistors have size* 1, *and wires without an indicated resistor have resistance* 10^{-16}. *The correct values of the voltages of the three nodes are* $(0.67, 0.33, 0.67)$ *accurate to two digits. The nullspace algorithm, however, yields* $(0.89, 0.52, 1.16)$.

is ill-conditioned (e.g., $A = [1, 1, 0]^T$ and $D = \text{diag}(1, 1, \epsilon)$). The possibility remains that in spite of the ill-conditioning, the system could still be accurately solved for $\mathbf{y}$.

In particular, Björck [1] has analyzed symmetric factorization of (1); his work attempts to identify the proper selection of the scaling factor to be applied to D to obtain $\mathbf{x}$ or $\mathbf{y}$ accurately. Even with Björck's choice of scaling factor, however, it is not clear that the resulting algorithm is stable.

As for the range-space method, it is possible that reordering of the variables might help. In our testing of the range-space method, we observed that the choice of numbering for edges and nodes affected the resulting answer and some numberings for the example in Fig. 2 gave better answers than the numbering depicted. It is known in the optimization community (Y. Li, private communication) that a good ordering can be obtained with diagonal pivoting. This may be related to orderings for least-squares problems. See Van Loan [24] and the analysis of Golub's [10] algorithm by Powell and Reid [18]. Nonetheless, even with a different ordering, we do not see any evidence that the resulting algorithm will be stable in the sense of §2, because $A^T D^{-1} A$ is ill-conditioned regardless of the ordering.

We do not know of any stabilization proposed in the literature for the nullspace method.



(a)

$$A = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \\ -1 & 1 & 0 \\ 1 & 0 & -1 \\ 0 & 1 & -1 \end{pmatrix}, D = \begin{pmatrix} 0.3 & & & & & \\ & 0.8 & & & & \\ & & 0.3 & & & \\ & & & 10^{-17} & & \\ & & & & 10^{-17} & \\ & & & & & 10^{-17} \end{pmatrix}, \mathbf{b} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \\ 0 \\ 0 \end{pmatrix}$$

(b)

FIG. 4. *The circuit depicted in* (a) *yields an equilibrium system of the form* (1) *with* $D, A, \mathbf{b}$, *as in* (b). *Here two resistors have resistance* 0.3 *and the third* (*on the right in the figure*) *has resistance* 0.8. *The wires without an indicated resistor have resistance* 10^{-17}. *The correct values of the voltages of the three nodes are* $(-0.33, 0.33, 0)$ *accurate to two digits. Gaussian elimination with partial pivoting, however, yields* $(0.45, 1.11, 0.78)$.

There are other algorithms for (1) in the recent literature; we do not know whether they are stable. Here is a partial list.

1. Björck and Duff [2] propose an elimination-based approach with a special kind of pivoting.

2. Gulliksson and Wedin [12] propose to factor $A^T D^{-1} A$ using scaled Householder transformations; that is, transformations that are orthogonal in a scaled inner product.

3. Paige [15] applies orthogonal factorization to an augmented system (not the same augmented system as (1)).

6. A stable hybrid algorithm. We now describe a stable algorithm for (1). We call this algorithm "hybrid" because it works with both the range-space of A and nullspace of A^T. The scaling matrix D is applied to the nullspace. Thus, the particular method described in this section is referred to as the "nullspace-scaled hybrid" (NSH) method, to distinguish it from other hybrid methods that we introduce later.

The first step of the NSH method is to compute a nullspace basis V for $A^T D^{-1}$. Thus, V is an $m \times (m-n)$ matrix of rank $m-n$ such that $A^T D^{-1} V = 0$. The matrix V must have a number of special properties, as will become apparent from the lemma

and theorem that follow. Our algorithm for V is described in §7.

Once V is obtained, the linear system

$$[A, V]\begin{pmatrix} \mathbf{y} \\ \mathbf{q} \end{pmatrix} = -\mathbf{b} \tag{9}$$

is solved for $\mathbf{y}$ and $\mathbf{q}$. We claim that $\mathbf{y}$ is indeed a solution for the original problem. This linear system can be rewritten as $A\mathbf{y}+V\mathbf{q} = -\mathbf{b}$. Multiplying by A^TD^{-1} causes the second term on the left to drop out, yielding $A^TD^{-1}A\mathbf{y} = -A^TD^{-1}\mathbf{b}$. Thus, this method solves (2) without explicitly forming $A^TD^{-1}A$. Notice that D does not appear at all in the linear system (9).

The NSH method does not appear in standard textbooks, but it has appeared in the literature. For example, Coleman and Li [6] suggest a similar approach (called the "full-space" method) for optimization, but with the scaling done in a different manner.

We now investigate the numerical stability of this method. We start with a preliminary lemma. For the rest of this section $\|\cdot\|$ is some p-norm.

LEMMA 6.1. *Assume the null basis V computed above is normalized so that $\|V\| = \|A\|$. Suppose also that V is well-conditioned, in the sense that there is a constant $\theta > 0$ such that*

$$\|V\mathbf{x}\| \geq (\|V\| \cdot \|\mathbf{x}\|)/\theta \tag{10}$$

for all $\mathbf{x}$. Let $M = [A, V]$. Then

$$\kappa(M) \leq 2\chi_A \cdot \|A\| + 2\theta \cdot (1 + \bar{\chi}_A), \tag{11}$$

where $\kappa(M)$ denotes the condition number *of M, that is, $\|M\| \cdot \|M^{-1}\|$.*

Proof. The basic idea of this proof is that the condition number of $M = [A, V]$ depends on three things: the condition of A, the condition of V (i.e., the value of θ), and the angle between the span of A and the span of V. But this angle cannot be too small because of Stewart's lemma in §2.

Suppose that $M\mathbf{z} = \mathbf{c}$ for an arbitrary $\mathbf{c}$. Split $\mathbf{z}$ into two components, say $\mathbf{y}$ and $\mathbf{q}$. Then $A\mathbf{y} + V\mathbf{q} = \mathbf{c}$. Multiply by A^TD^{-1} to obtain $A^TD^{-1}A\mathbf{y} = A^TD^{-1}\mathbf{c}$. Thus, $\|\mathbf{y}\| \leq \chi_A\|\mathbf{c}\|$ and $\|A\mathbf{y}\| \leq \bar{\chi}_A\|\mathbf{c}\|$ by Stewart's theorem. Next, $V\mathbf{q} = \mathbf{c} - A\mathbf{y}$, so

$$\|V\mathbf{q}\| \leq \|\mathbf{c}\| + \bar{\chi}_A\|\mathbf{c}\|.$$

Finally,

$$\begin{aligned} \|\mathbf{q}\| &\leq \frac{\theta}{\|V\|} \cdot \|V\mathbf{q}\| \\ &\leq \frac{\theta}{\|A\|} \cdot (1 + \bar{\chi}_A) \cdot \|\mathbf{c}\|. \end{aligned}$$

Thus, we have

$$\begin{aligned} \|\mathbf{z}\| &\leq \|\mathbf{y}\| + \|\mathbf{q}\| \\ &\leq \|\mathbf{c}\| \cdot \left(\chi_A + \frac{\theta}{\|A\|} \cdot (1 + \bar{\chi}_A)\right). \end{aligned}$$

Since $\|M^{-1}\|$ is the supremum of $\|\mathbf{z}\|$ in the case that $\|\mathbf{c}\| = 1$, the parenthesized factor on the right-hand side is an upper bound on $\|M^{-1}\|$.

Now finally, observe that $\|M\| \leq 2\|A\|$. Thus, multiplying through by $2\|A\|$ gives the result. □

Note that the condition that $\|A\| = \|V\|$ does not have to be satisfied exactly; it suffices in the above argument to have A and V on the same order.

Let us denote with κ_A the expression on the right-hand side of (11). This expression has a complicated form, but one sees that it is independent of D except insofar as it depends on V, and is invariant if A is multiplied by a constant. We now can state the main theorem about the stability of the NSH method.

THEOREM 6.2. *Assume V satisfies the conditions of Lemma* 6.1. *Suppose that the algorithm to solve the linear system $A\mathbf{y} + V\mathbf{q} = -\mathbf{b}$ in floating point arithmetic returns approximate solution $(\hat{\mathbf{y}}, \hat{\mathbf{q}})$ such that*

$$(A+E)\hat{\mathbf{y}} + (V+F)\hat{\mathbf{q}} = -\mathbf{b} + \mathbf{e}, \tag{12}$$

where $\|[E,F]\| \leq \epsilon\|[A,V]\|$ and $\|\mathbf{e}\| \leq \epsilon\|\mathbf{b}\|$. Assume that $\epsilon \leq 1/(3\kappa_A)$. Then we have the following error bound:

$$\|\mathbf{y} - \hat{\mathbf{y}}\| \leq 3\epsilon \frac{\kappa_A^2}{\|A\|} \cdot \|\mathbf{b}\|, \tag{13}$$

where $\mathbf{y}$ is the true solution.

Remark 1. Note that (13) indicates that the NSH algorithm is stable, because D does not enter the bound.

Remark 2. The theorem seemingly requires that an *exact* nullspace basis V of $A^T D^{-1}$ be computed. We remark further on this in §7.

Remark 3. The condition that the floating-point algorithm satisfies an error bound like (12) is very natural, and any well-known stable algorithm, say Gaussian elimination with partial pivoting, satisfies such a bound.

Proof. Let $\mathbf{z} = (\mathbf{y}^T, \mathbf{q}^T)^T$ and $\hat{\mathbf{z}} = (\hat{\mathbf{y}}^T, \hat{\mathbf{q}}^T)^T$. Following the standard analysis of [11, Thm. 2.7.2] and using the previous lemma, we obtain the bound

$$\|\mathbf{z} - \hat{\mathbf{z}}\| \leq 3\epsilon\kappa_A \cdot \|\mathbf{z}\|.$$

But

$$\begin{aligned} \|\mathbf{z}\| &\leq \|M^{-1}\| \cdot \|\mathbf{b}\| \\ &\leq \frac{\kappa_A}{\|A\|} \cdot \|\mathbf{b}\|. \end{aligned}$$

Thus,

$$\|\mathbf{z} - \hat{\mathbf{z}}\| \leq 3\epsilon \frac{\kappa_A^2}{\|A\|} \cdot \|\mathbf{b}\|.$$

Finally, $\|\mathbf{y} - \hat{\mathbf{y}}\|$ is at most $\|\mathbf{z} - \hat{\mathbf{z}}\|$. □

7. Obtaining V for Theorem 6.2. As mentioned in §6, Theorem 6.2 seemingly requires V to be computed exactly. In fact, it is implicit in the theorem that it suffices to compute a matrix $\hat{V}$ such that $\hat{V} + F'$ is a nullspace basis for $A^T D^{-1}$, where F' is a small error matrix. This is because using $\hat{V}$ instead of V in (9) is equivalent to compounding the error F in (12) with the further small error F', so the same bound holds with a larger constant.

The standard general-purpose algorithms for nullspace bases do not guarantee that the computed nullspace basis is only a small distance from a true nullspace basis (i.e., a forward-error bound). Instead, these algorithms guarantee that each column of the computed nullspace basis is an exact nullspace vector for a perturbed matrix $A^T D^{-1} + E$ (i.e., a backward-error bound). This is not useful in the present context because adding E to $A^T D^{-1}$ spoils the special structure that allows Stewart's theorem to be applied.

We now describe a technique to obtain a V with a forward-error bound. First, we obtain a nullspace basis Z for A^T. Then we obtain a nullspace basis V for $A^T D^{-1}$ with the formula $V = DZR$, where R is another diagonal matrix described below.

To compute Z, find a subset of rows of n rows of A that form a *basis*, that is, an $n \times n$ nonsingular submatrix of A. Now, for each of the remaining $m - n$ "nonbasic" rows, solve for the nonbasic row in terms of the basis rows. The coefficients of this dependence form a column vector with m entries, of which at most $n+1$ are nonzero. This yields a *fundamental* nullspace basis Z; that is, a nullspace basis for A^T with an embedded $(m-n) \times (m-n)$ identity matrix.

If we assume that $\bar{\chi}_A$ is reasonably small, then it turns out that this nullspace basis has a special property, namely, all of the nonzero entries have roughly the same magnitude. If we think of a vector $\mathbf{x}$ as being one column of Z, we can state this as a lemma. In this lemma, we assume that the ∞-norm is used throughout. The constant $\bar{\chi}_Z$ arises in this lemma; recall that $\bar{\chi}_Z$ is bounded in terms of $\bar{\chi}_A$, as demonstrated in Theorem 3.1.

LEMMA 7.1. *Let* $\mathbf{x}$ *be a nonzero vector such that* $A^T\mathbf{x} = \mathbf{0}$. *Assume that* $\mathbf{x}$ *has nonzero entries in positions* $\{i_1, \ldots, i_p\}$, *where* $\{i_1, \ldots, i_p\} \subset \{1, \ldots, m\}$. *Suppose also that for every subset* I *of size* $p-1$ *of* $\{i_1, \ldots, i_p\}$, *the rows of* A *indexed by* I *are linearly independent. Then the magnitude of the smallest nonzero entry in* $\mathbf{x}$ *is no smaller than* $\|\mathbf{x}\|_\infty / \bar{\chi}_Z$.

Proof. Without loss of generality, we can take $\|\mathbf{x}\| = 1$. Let δ be the magnitude of the entry in $\mathbf{x}$ with the smallest nonzero magnitude and suppose this entry is in position i_p. Since rows $i_1, \ldots, i_{p-1}$ of A are linearly independent, there is a vector $\mathbf{w}$ such that $A\mathbf{w}$ attains arbitrarily specified entries in these $p-1$ positions. In particular, there is a vector $\mathbf{w}$ such that $A\mathbf{w}$ agrees with $\mathbf{x}$ in positions $i_1, \ldots, i_{p-1}$.

Now let C be a diagonal matrix with entry "1" in positions $i_1, \ldots, i_{p-1}$, and very small entries in the other diagonal positions. Observe that $CA\mathbf{w}$ agrees with $\mathbf{x}$ in positions $i_1, \ldots, i_{p-1}$, and has nearly zeros in all the other positions, including i_p. Let $\mathbf{y} = CA\mathbf{w}$. Then we observe that if we define X, Y as in Lemma 2.2 for Z, i.e.,

$$X = \{\mathbf{z} : \mathbf{z} = Z\mathbf{w} \text{ for some } \mathbf{w}, \text{ and } \|\mathbf{z}\| = 1\}$$

and

$$Y = \{\mathbf{z} : Z^T C^{-1} \mathbf{z} = \mathbf{0} \text{ for some } C \in \mathcal{D}\},$$

then $\mathbf{x} \in X$ and $\mathbf{y} \in Y$. This means that $\|\mathbf{x} - \mathbf{y}\|$ is at least $1/\bar{\chi}_Z$. But $\|\mathbf{x} - \mathbf{y}\|$ is arbitrarily close to δ (depending on how close to zero the diagonal entries of C other than $i_1, \ldots, i_{p-1}$ are). Thus, $\delta \geq 1/\bar{\chi}_Z$. This proves the lemma, since we assumed $\|\mathbf{x}\| = 1$. □

This lemma has two important consequences. First, the lemma implies that the nullspace basis Z is well conditioned in the sense of (10). In particular, with suitable

ordering of the rows and columns of Z, we can write it in the form

$$Z = \begin{pmatrix} I \\ W \end{pmatrix}, \tag{14}$$

where W is a matrix whose entries are at most $\bar{\chi}_Z$ in magnitude.

Second, the lemma has the following more subtle consequence: if the columns of Z are calculated with a small forward error, this means in fact that these entries have a small *componentwise* forward error. We can express this formally as follows. Let Z be the nullspace basis of A computed with the above algorithm using exact arithmetic, and let $\hat{Z}$ be the nullspace basis computed in the presence of floating point errors. If we assume that the columns of Z are computed with a small forward error, that is,

$$\|\mathbf{x} - \hat{\mathbf{x}}\| \leq \epsilon \|\mathbf{x}\|,$$

where $\mathbf{x}$ is a column of Z and $\hat{\mathbf{x}}$ is a column of $\hat{Z}$, then we immediately obtain the result

$$|\mathbf{x} - \hat{\mathbf{x}}| \leq \epsilon \bar{\chi}_Z |\mathbf{x}|.$$

The componentwise error bound is important for the following reason: to obtain V, recall that we form the product DZR, where D is the diagonal matrix from (1), and R is a diagonal matrix not yet specified. Because D, R are both diagonal and Z has a small componentwise error, then DZR also will have a small componentwise forward error, and therefore, a small norm forward error, no matter how D, R are chosen.

The argument in the last two paragraphs presupposed that the columns of Z would have a small normwise forward error. A small normwise forward error is obtained if the basis rows of A are well-conditioned, because the columns of Z are solutions to linear systems involving the basis rows. Now we ask whether the basis rows of A are well-conditioned. In fact, there is a bound on the condition number of the basis rows; we state another lemma in this regard. This lemma is based on similar results in [14] and [20].

LEMMA 7.2. *Let A be an $m \times n$ matrix. Let B be a nonsingular $n \times n$ submatrix of A. Then $\|B^{-1}\| \leq \chi_A$.*

Proof. Let $\mathbf{b}$ be an arbitrary n-vector and suppose $\mathbf{x}$ is the solution to $B\mathbf{x} = \mathbf{b}$. We require an upper bound on $\|\mathbf{x}\|$ in terms of $\|\mathbf{b}\|$. Let $\hat{\mathbf{b}}$ be the extension of $\mathbf{b}$ to $\mathbb{R}^m$ obtained by inserting zeros in the $m-n$ positions corresponding to rows of A not in B.

Let C be the diagonal matrix with ones in the n diagonal positions corresponding to rows of B and very small entries in other positions. Then $A^TCA \approx B^TB$ and $A^TC\hat{\mathbf{b}} \approx B^T\mathbf{b}$, where the approximations can be arbitrarily close as we make diagonal entries of C close to zero.

Thus, if vector $\mathbf{x}$ is the solution to $A^TCA\mathbf{x} = A^TC\hat{\mathbf{b}}$, then $B^TB\mathbf{x} \approx B^T\mathbf{b}$. Since B is square and invertible, this last equation means that $B\mathbf{x} \approx \mathbf{b}$. But we also know that $\|\mathbf{x}\| \leq \chi_A \|\hat{\mathbf{b}}\|$ by definition of χ_A. This proves the lemma. □

Recall that for A "well-conditioned," we should have $\chi_A = \phi/\|A\|$, where ϕ is a small constant; thus $\|B^{-1}\| \leq \phi/\|A\|$. Finally, $\|A\| \geq \|B\|$ so

$$\|B^{-1}\| \cdot \|B\| \leq \phi,$$

thus obtaining a condition number bound on B.

Thus, we conclude that we can compute Z using the above algorithm such that Z is simultaneously well conditioned and has a small forward componentwise error. Now, we apply D on the left. As we see from (14), the upper $(m-n) \times (m-n)$ block of DZ is some diagonal matrix. Finally, choose a diagonal matrix R so that the upper $(m-n) \times (m-n)$ block of $V = DZR$ is once again the identity matrix. (This uniquely determines R.)

This algorithm gives a nullspace basis V for $A^T D^{-1}$ with a small forward error. Moreover, V has the form

$$V = \begin{pmatrix} I \\ W' \end{pmatrix}. \tag{15}$$

There is no reason to believe, however, that V is well-conditioned. In fact, W' can have arbitrarily large entries if the basic rows of A have large corresponding entries in D.

We now show how to maintain control over the size of W' by correctly choosing the basis rows in A. (Until now, we have not made any assumptions about the basis rows except that they are independent.) The algorithm for obtaining B is the following "greedy" approach. Assign *weights* to the rows, where the weight of the ith row is the (i,i) entry of D. Now, select the row with the lowest weight and insert it in B. Continue appending the lowest-weighted remaining row of A to B. Before appending a row to B, check that the row is linearly independent from the rows already in B. If a dependence is found, then the row is discarded. Continue this process until B has n rows.

Note that this algorithm requires a "yes/no" test concerning linear dependence among rows of A. In general, such tests are considered to be numerically hazardous. In our application, however, this is a safe procedure; a consequence of the preceding lemmas and arguments is that if $\chi_A, \bar{\chi}_A$ are well bounded, then there can be no "near" dependence among subsets of rows of A.

Since A is sparse for many applications, this process of testing rows for independence from previous rows should involve both combinatorial and numerical tests for dependence, such as the inner loop of the Gilbert and Heath [8] algorithm for nullspace bases. Briefly, the Gilbert–Heath algorithm maintains a bipartite graph indicating the nonzero structure of the current basis and a complete matching of that bipartite graph. There is a simple combinatorial technique to detect many cases of dependency among rows. Indeed, for RNAI matrices (described in §8), the process of selecting B is purely combinatorial and very efficient.

We now claim that if B is selected with this greedy approach, then W' in (15) has a small bound. Consider the (i,j) entry of V. Assume $i > m-n$, so that the entry in question falls in the W' portion in (15). Assume that this entry is nonzero. This means that the jth row of A is expressed in terms of rows $m-n+1, \ldots, m$ with a nonzero coefficient for the ith row. We claim that this implies that $d_{ii} \leq d_{jj}$. Suppose not; suppose that $d_{jj} < d_{ii}$. Observe that, by the positions of the rows, i is basic and j is nonbasic. This means that j was passed over by the greedy algorithm for forming the basis, since row i was added to B even though it has a higher weight than row j. This in turn means that row j must have been linearly dependent on rows already in B when it was encountered by the greedy algorithm. But this is impossible, because we already know that row j can be expressed in terms of the basis rows with a nonzero coefficient for row i, so row j cannot be dependent on B until after row i is added to B. Thus, this contradiction shows that $d_{ii} \leq d_{jj}$.

Finally, when we scale Z on the left by D and on the right by R, it is easy to see that the (i,j) entry of V is equal to the (i,j) entry of Z multiplied by d_{ii}/d_{jj}, which we now have shown to be a positive scalar no larger than one. This shows that the entries of W' in (15) are no larger than the corresponding entries of W in (14), and we already have argued that W has a small bound.

If V has the form (15) with a bound on W', then it is well conditioned in the sense of Theorem 6.2. Let $\mathbf{x}$ be an arbitrary vector, and consider $\mathbf{y} = V\mathbf{x}$. Observe that $\mathbf{y}$ agrees with $\mathbf{x}$ in its first $m-n$ positions. Thus, $\|\mathbf{y}\| \geq \|\mathbf{x}\|$. On the other hand, $\|V\| \leq 1 + \|W'\|$. Hence if we take $\theta = 1 + \|W'\|$, then we have the bound

$$\|V\mathbf{x}\| \geq (\|V\| \cdot \|\mathbf{x}\|)/\theta$$

needed for Theorem 6.2.

The only property remaining that V must have is the equation $\|V\| = \|A\|$. This is easily obtained by scaling V uniformly.

8. Reduced node-arc incidence (RNAI) matrices. A special class of matrices A arising in many applications are RNAI matrices. Let G be an directed graph, weakly connected, with no parallel edges and no self-loops. (The assumptions about connectivity and parallel edges could be easily removed at the expense of a more complicated exposition.) Assume G has m arcs and $n+1$ nodes.

The *node-arc incidence* matrix for G is a matrix A_0 with one row for each edge of G and one column for each node. Each row contains two nonzero entries, a 1 and a -1. The -1 entry occurs in the column corresponding to the tail of the arc, and the 1 entry occurs in the column corresponding to its head.

The RNAI matrix A for G is obtained by deleting a column of A_0 corresponding to an arbitrary node. The deleted node is called "ground" in an electrical engineering context. In an RNAI matrix, each row has either a $1/-1$ pair of entries, or a lone 1 or lone -1 in rows corresponding to arcs with one end grounded.

Electrical networks are the main application in which A of (1) turns out to be an RNAI matrix. Indeed, the matrix A occurring in Figs. 1– 4 is an RNAI matrix. Optimization problems with flow constraints can give rise to RNAI or related matrices. Structural analysis in civil engineering can give rise to matrices A that have a block-RNAI structure.

It is a well-known fact of algebraic graph theory (see, for example, Welsh [25]) that an RNAI matrix A has full column rank. Furthermore, the process of finding a basis among the rows of A corresponds to identifying a spanning tree of G_0, where G_0 is the undirected graph that results when the arcs of G are stripped of their orientation. A *spanning tree* is a subgraph T of G_0 that is incident upon every vertex of G_0, is connected, and has no cycles. The resulting nullspace basis Z has the form (14), with the additional property that every entry in W is either 0, 1, or -1. Thus, there is a very good upper bound on $\|W\|$.

The greedy algorithm described in the previous section corresponds to finding a *minimum-weight* spanning tree. The minimum-weight spanning tree can be computed very efficiently; see, for example, Papadimitriou and Steiglitz [16]. From this spanning tree we construct Z as described above, and then V by multiplying DZR. The process of obtaining Z and the basis is completely combinatorial for an RNAI matrix.

We have tried this version of the NSH algorithm in MATLAB on all the problems in §4. We used an $O(m \log n)$ algorithm for constructing minimum-weight spanning trees. We obtained answers with approximately 15 digits of accuracy in all cases.

These results show that we can easily construct a V with the right properties for Theorem 6.2 for RNAI matrices. A natural follow-up question is whether the constants in the theorem, namely χ_A and $\bar{\chi}_A$, have reasonable bounds for RNAI matrices. Such bounds are also important because we want to argue that the incorrect answers obtained with the standard methods in §4 are due to numerical problems with the algorithms and not ill-conditioning in A.

In fact, both constants $\chi_A, \bar{\chi}_A$ have small bounds for RNAI matrices, as stated in the following theorem.

THEOREM 8.1. *Let A be an* RNAI *matrix of size $m \times n$. Then $\chi_A \leq n$ and $\bar{\chi}_A \leq n$ if the ∞-norm is used.*

Proof. Suppose the equilibrium equations hold, i.e.,

$$\begin{pmatrix} D & -A \\ A^T & 0 \end{pmatrix} \begin{pmatrix} \mathbf{x} \\ \mathbf{y} \end{pmatrix} = \begin{pmatrix} \mathbf{b} \\ \mathbf{0} \end{pmatrix} \tag{16}$$

for an arbitrarily chosen $\mathbf{b}$ such that $\|\mathbf{b}\|_\infty \leq 1$. Parameter χ_A is defined to be the maximum possible value of $\|\mathbf{y}\|_\infty$. Label each node in the underlying graph with its y value and label the ground node with 0. In analogy with electrical engineering, we call these labels the "voltages."

Let $p_1, \ldots, p_{n+1}$ be the voltages written in descending order, i.e., $p_1, \ldots, p_{n+1}$ is a sorted version of $\{y_1, \ldots, y_n, 0\}$. A simple averaging argument shows that there must be a μ such that

$$p_\mu - p_{\mu+1} \geq (p_1 - p_{n+1})/n.$$

Here, p_1 is the maximum voltage and p_{n+1} the minimum. Because ground is labeled, $p_1 \geq 0 \geq p_{n+1}$.

Let S be the nodes that were numbered 1 to μ in this sorted list, and let T be nodes numbered $\mu + 1$ to $n + 1$ in the sorted list. Then (S, T) is the partition of the nodes such that each node in S has a voltage at least g higher than every node in T, where $g = (p_1 - p_{n+1})/n$.

Assume from now on that ground is in S (an interchanging of S and T in the following argument would handle the opposite case). Let $\mathbf{v}$ be an n-vector that, for each i, has 1 in position i if node i lies in T, and a 0 otherwise. (From now on "node i" refers to the original numbering of the nodes corresponding to the ordering of columns in A.) Consider the product $\mathbf{w} = A\mathbf{v}$; $\mathbf{w}$ has one entry for each edge in the graph. It follows from the definition of an RNAI matrix that w_i is 1 if edge i is a forward edge from S to T, it is -1 if the edge is backward, and 0 if the edge is internal to either S or T. Since the graph is connected, $\mathbf{w} \neq \mathbf{0}$.

We have the equation $A^T\mathbf{x} = \mathbf{0}$; multiplying by $\mathbf{v}^T$ shows that $\mathbf{w}^T\mathbf{x} = 0$. This means that there must exist an i such that w_i is nonzero and $w_i x_i \geq 0$.

Now examine the ith equation from the block $D\mathbf{x} - A\mathbf{y} = \mathbf{b}$. Since w_i is nonzero, one endpoint of edge i is in S and the other endpoint in T. Let the endpoint in T be numbered j. (Since ground is not in T, j corresponds to a true column of A.) Thus, the (i, j) entry of A is ± 1.

There are two cases: either w_i is positive or w_i is negative. If w_i is positive, then by definition of $\mathbf{w}$, we must have that the (i, j) entry of A is $+1$. By choice of i, $x_i \geq 0$, so $d_{ii}x_i \geq 0$. There are two subcases: either the other endpoint of edge i is ground, or it is some other node k of the graph, which lies in S. If it is ground, then the ith equation must be $d_{ii}x_i - y_j = b_i$, i.e., $-y_j \leq b_i$, i.e., $y_j \geq -b_i$. If the other endpoint is node k, then $d_{ii}x_i - y_j + y_k = b_i$, i.e., $y_j - y_k \geq -b_i$

If w_i is negative, then by definition of $\mathbf{w}$, we must have that the (i,j) entry of A is -1. By choice of i, $x_i \leq 0$, so $d_{ii}x_i \leq 0$. There are two subcases: either the other endpoint of edge i is ground, or it is some other node k of the graph, which lies in S. If it is ground, then the ith equation must be $d_{ii}x_i + y_j = b_i$, i.e., $y_j \geq b_i$. If the other endpoint is node k, then $d_{ii}x_i + y_j - y_k = b_i$, i.e., $y_j - y_k \geq b_i$.

Thus, in all four subcases, we have obtained an inequality of the form $y_j - y' \geq -|b_i|$, where y_j is the voltage of a node in T and y' is the voltage of a node in S (possibly ground). Since we already know by construction of S and T that $y_j - y' \leq -g$, we have $-g \geq -|b_i|$, i.e., $g \leq |b_i|$. By assumption on $\mathbf{b}$, we have $|b_i| \leq 1$. Thus $(p_1 - p_{n+1})/n \leq 1$, i.e.,

$$p_1 - p_{n+1} \leq n. \tag{17}$$

Since 0 lies between p_1 and p_{n+1}, and the values of the y' are contained in p's, we conclude from (17) that $|y_i| \leq n$ for all i. This shows that $\chi_A \leq n$.

Next, let us obtain a bound on $\bar{\chi}_A$. Recall that $\bar{\chi}_A$ is the maximum value of $\|A\mathbf{y}\|_\infty$, where $\mathbf{y}$ is the solution to (16) and where $\|\mathbf{b}\|_\infty = 1$. But for an RNAI matrix, each entry of $A\mathbf{y}$ is the difference between two entries in $\mathbf{y}$, or is simply an entry in $\mathbf{y}$ (for edges with one endpoint grounded). But we have shown that the maximum difference between any of the $y's$ is n—this is (17). □

9. Generalizing the problem. In this section we comment on the possibility of lifting some of the assumptions made in §1. One assumption made throughout the paper is that we are interested in recovering $\mathbf{y}$ in (1) rather than $\mathbf{x}$. Assuming we have $\mathbf{y}$, $\mathbf{x}$ can be recovered from the equation $D\mathbf{x} - A\mathbf{y} = \mathbf{b}$. It is easy to see that we can compute $D\mathbf{x}$ stably (i.e., with only small normwise error). Then $\mathbf{x}$ is obtained by scaling the computed $D\mathbf{x}$ with D^{-1}. The recovered $\mathbf{x}$ would have a relative error that could be on the order of the condition number of D. This is inherent in the problem—(1) is ill-conditioned with respect to $\mathbf{x}$ when D is ill-conditioned, and there is no theorem like Theorem 2.1 that holds for $\mathbf{x}$. Thus, we see that recovering $D\mathbf{x}$ accurately is the best that could be hoped for in the case that $\mathbf{b} \neq \mathbf{0}$, $\mathbf{c} = \mathbf{0}$.

This instability is not merely a numerical artifact—there is a corresponding physical instability. For example, in the context of electrical networks with batteries, it is possible to construct a circuit as follows. One arc of the circuit has very low resistance, but also very small current because the battery voltages are balanced so that the potential across the arc is small. Then a small perturbation to the battery voltages (i.e., $\mathbf{b}$) could cause a great multiplication of the current (i.e., $\mathbf{x}$). On the other hand, $D\mathbf{x}$, the voltage drops across the resistors, would suffer only a small perturbation.

Another assumption was that $\mathbf{c} = \mathbf{0}$. Can we drop this assumption? One special case, which is dual to the case considered for most of this paper, is when $\mathbf{c} \neq \mathbf{0}$, $\mathbf{b} = \mathbf{0}$, and we are interested in recovering $\mathbf{x}$ instead of $\mathbf{y}$. In this case, let Z be a nullspace basis for A^T, and let $\mathbf{x}_0$ be an arbitrary solution to the underdetermined system $A^T\mathbf{x} = \mathbf{c}$. Then the formula for $\mathbf{x}$ is obtained by solving $Z^TDZ\mathbf{q} = Z^TD\mathbf{x}_0$, and then setting $\mathbf{x} = Z\mathbf{q} + \mathbf{x}_0$. The equation $Z^TDZ\mathbf{q} = Z^TD\mathbf{x}_0$ is of the exact format of (2). Thus, we can apply the machinery developed in this paper, except with Z in place of A, $\mathbf{x}_0$ in place of $\mathbf{b}$, and D in place of D^{-1}. Notice that the nullspace of Z^T is the same as the range of A. Thus, the version of the hybrid algorithm for this problem would be the range-space scaled hybrid algorithm, or RSH algorithm. Note also that we have derived relationships between $\bar{\chi}_A$ and $\bar{\chi}_Z$ in §3.

In the most general case that $\mathbf{b} \neq \mathbf{0}, \mathbf{c} \neq \mathbf{0}$, it seems unlikely that we could obtain an algorithm that computes either $\mathbf{x}$ or $\mathbf{y}$ accurately when D is ill-conditioned because

both variables become ill-conditioned. A compromise algorithm might be as follows. Let Z be a basis for the nullspace of A^T. Then solve the linear system

$$D^{-1/2}A\mathbf{y} + D^{1/2}Z\mathbf{q} = -D^{-1/2}\mathbf{b} + D^{1/2}\mathbf{x}_0,$$

where $\mathbf{x}_0$ is as in the previous paragraph. Multiplying through by $A^T D^{-1/2}$ shows that this solves the general case of (1) for $\mathbf{y}$. This method has the advantage that it "splits" the ill-conditioning between the nullspace and the range-space. We could call this the biscaled hybrid algorithm, or BSH algorithm.

The last restrictive assumption made in §1 is that D is diagonal. As mentioned earlier, in some finite element and structural problems in two and three dimensions, we can generally only assume that D is block diagonal. Stewart's theorem does not generalize to nondiagonal matrices, as shown in his paper. In the applications of finite elements and structures, however, A has a certain sparsity pattern that is correlated to the blocks of D. Perhaps a result could be established for special structured matrices A.

10. Open questions and future directions. Perhaps the number of open questions raised by this work exceeds the number of results we have obtained. Here are some examples of open questions.

1. Is there a good algorithm to obtain $\chi_A, \bar{\chi}_A$? Here "good" means either that the algorithm is polynomial time, or that it gives an approximate answer in finite precision arithmetic, or both.

2. What are useful bounds for $\chi_A, \bar{\chi}_A$ in the case that A has the special structure arising in applications more general than RNAI matrices?

3. Can Stewart's theorem be generalized to a block-diagonal D in the case that the structure of A is correlated to the structure of D, as in structural analysis?

4. As mentioned in §5, there are techniques known in the literature that can be applied to the standard algorithms. Could it be proved that one of the standard algorithms is stable if one of these techniques is used? The standard algorithms are much simpler than the NSH method.

5. This paper has not dealt at all with issues of algorithmic efficiency, but there are many. For instance, in the NSH method, must we explicitly solve the $m \times m$ system (9) or can we approach it implicitly? The algorithm for computing Z described in §7 was geared solely towards numerical stability. Recently, Stern and Vavasis [19] proposed a way to compute Z for an RNAI matrix based on *separators* of G_0. The Stern–Vavasis algorithm aims for sparsity of Z rather than stability. Is there some combination of the algorithm here with the ideas from the other paper that attains both numerical stability and a sparse nullspace basis Z?

6. For the general case of recovering both $\mathbf{x}$ and $\mathbf{y}$, is the BSH method described in §9 any better than the range-space or nullspace methods? We tried the BSH algorithm using a nullspace basis Z generated by QR factorization described in §4 (in particular, not any special spanning-tree basis). We obtained very accurate answers for all the problems in which the standard methods failed. Is there an explanation for the success of the BSH method?

7. Are there good iterative methods for (1)? For instance, is there an iterative method whose convergence rate depends only on A and gives a good solution for $\mathbf{y}$ in the sense of a bound like (5)?

Acknowledgments. The author benefitted from discussion of these ideas with Tom Coleman, Yuying Li, Danny Ralph, Mike Todd, Nick Trefethen, and Charlie

Van Loan of Cornell; Alan Edelman of Berkeley; Nick Higham of Manchester; and Ilse Ipsen of Yale. Helpful comments were received on the first version of this paper from these people as well as Gene Golub of Stanford, Des Higham of Dundee, Dianne O'Leary of Maryland, Gilbert Strang of MIT, and two anonymous referees.

SOME CONVERGENCE PROPERTIES OF MATRIX SETS *

DAVID P. STANFORD† AND JOSÉ MIGUEL URBANO‡

Abstract. A set $\mathcal{A} = \{A_j : j \in J\}$ of $n \times n$ matrices is *pointwise convergent* provided each n-vector x can be steered to zero by iterated multiplication by matrices in $\mathcal{A}$. The convergence is *uniform* if the sequence of multipliers may be chosen independently of x. This paper discusses conditions related to convergence for sets of diagonal, triangular, and general matrices, real and complex. It generalizes known conditions for convergence of a single matrix and characterizes convergence of a set of diagonal matrices in terms of semipositivity of a matrix derived from the set.

Key words. convergence, matrix norm, precontractive, eigenvalue, singular value, semipositive

AMS subject classifications. primary 15A48, 15A60; secondary 93D15

1. Introduction.

The convergence properties of an $n \times n$ complex matrix A are well known. Among them is the equivalence of the following three statements.

(i) $\lim_{k\to\infty} A^k = 0$,

(ii) If x is a complex n-vector, then

$$\lim_{k\to\infty} A^k x = 0,$$

(iii) $\rho(A) < 1$, where ρ denotes spectral radius.

The notion of convergence of a matrix can be extended to that of convergence of a set of matrices in a variety of ways. In this paper we study a definition of convergence of a set of matrices that is motivated by the theory of multirate sampled-data control systems and the multimodal linear control systems to which they give rise [6]. Intuitively, the set $\mathcal{A} = \{A_j : j \in J\}$ of $n \times n$ matrices is "pointwise" convergent if each n-vector x can be steered to zero by repeated multiplication by matrices selected from $\mathcal{A}$. The convergence is "uniform" if the sequence of multipliers can be chosen independently of x. Hence, a set is uniformly convergent if and only if there is an infinite product of matrices in the set that left converges to the zero matrix. Although the sets arising from the control systems in [6] are finite, we also consider here infinite sets. We see, however, that the convergence of an infinite set of matrices is equivalent to that of some finite subset.

Our definition of convergence is substantially different from other generalizations of the convergence of a matrix. For example, in [3] Daubechies and Lagarias consider a definition that requires *all* (left or right) infinite products of matrices in the set to converge (but not necessarily to zero). This work is continued in [1]. The fact that neither definition of convergence contains the other can be seen by the examples

$$\mathcal{S} = \left\{ \operatorname{diag}\left\{\frac{3}{2}, \frac{1}{2}\right\}, \operatorname{diag}\left\{\frac{2}{3}, \frac{-3}{2}\right\} \right\} \quad \text{and} \quad \mathcal{T} = \{I\}.$$

$\mathcal{S}$ is uniformly, and hence pointwise, convergent (it is a slight modification of the example before Theorem 5.3) but is neither right nor left convergent in the sense of [3]. On the other hand, the set $\mathcal{T}$ whose only member is the identity matrix is both right and left convergent in the sense of [3] but is neither pointwise nor uniformly convergent in our sense.

Section 2 lists the necessary definitions. In §3 we present necessary and sufficient conditions for pointwise and uniform convergence of a matrix set and relate convergence of a set to that of some finite subset. We then present further necessary conditions for each type of convergence. In §4 we show the equivalence of pointwise and uniform convergence for sets of diagonal matrices and relate the convergence of a finite set of diagonal matrices to the semipositivity of a matrix constructed from the set. Finally, in §5 we discuss convergence of sets of triangular matrices.

2. Definitions. Throughout the paper $\mathbb{F}$ denotes either the field $\mathbb{C}$ of complex numbers or the field $\mathbb{R}$ of real numbers. The set of $m \times n$ matrices over $\mathbb{F}$ are denoted by $\mathbb{F}^{m\times n}$, and $\mathbb{F}^n$ denotes $\mathbb{F}^{n\times 1}$. General vector norms and matrix norms are discussed and denoted by $\|\cdot\|_V$ and $\|\cdot\|_M$, respectively. We reserve the symbol $\|\cdot\|_2$ for the euclidean vector norm on $\mathbb{F}^n$. Throughout the paper, J denotes a nonempty index set.

DEFINITION 2.1. *A set $\mathcal{A} = \{A_j : j \in J\} \subset \mathbb{F}^{n\times n}$ is* convergent at a point $x \in \mathbb{F}^n$ *provided there is a sequence $\{p(x)_i\}_{i=1}^{\infty}$ such that $p(x)_i \in J$ for all i, and the sequence*

$$x, \qquad A_{p(x)_1}x, \qquad A_{p(x)_2}A_{p(x)_1}x, \ldots$$

converges to the zero vector. We assert this convergence by writing

$$\lim_{k\to\infty}\left\{\left[\prod_{i=k}^{1} A_{p(x)_i}\right]x\right\} = 0.$$

$\mathcal{A}$ is pointwise convergent *provided that it is convergent at each point in $\mathbb{F}^n$. $\mathcal{A}$ is* uniformly convergent *provided the sequence $\{p(x)_i\}_{i=1}^{\infty}$ may be chosen independently of x; that is, there is a sequence $\{p_i\}_{i=1}^{\infty}$ with $p_i \in J$ for all i and*

$$\lim_{k\to\infty}\left\{\left[\prod_{i=k}^{1} A_{p_i}\right]x\right\} = 0$$

for all $x \in \mathbb{F}^n$.

Clearly our definition of uniform convergence is unchanged if we require the stated limit to be zero only for x in the unit sphere of $\mathbb{F}^n$. Furthermore, the limit is zero for all such x if and only if

$$\lim_{k\to\infty}\left[\prod_{i=k}^{1} A_{p_i}\right] = 0.$$

These observations imply that our use of the term "uniform convergence" is consistent with its usual meaning of "convergence at the same rate for all x."

Of course, for a single matrix pointwise and uniform convergence are the same. We shall see, however, that the set

$$\mathcal{A} = \left\{\begin{bmatrix}\frac{1}{2} & 0\\ 0 & 2\end{bmatrix}, \begin{bmatrix}\frac{\sqrt{3}}{2} & \frac{1}{2}\\ -\frac{1}{2} & \frac{\sqrt{3}}{2}\end{bmatrix}\right\} \subset \mathbb{R}^{2\times 2}$$

is pointwise convergent but is not uniformly convergent.

The notion of precontractiveness introduced in [6] is useful.

DEFINITION 2.2. *Let $\|\cdot\|_V$ be any norm on $\mathbb{F}^n$, and let $\mathcal{A} = \{A_j : j \in J\} \subset \mathbb{F}^{n\times n}$. $\mathcal{A}$ is* precontractive relative to $\|\cdot\|_V$ *provided that if $x \in \mathbb{F}^n/\{0\}$, then there is a finite sequence $\{q(x)_i\}_{i=1}^{n(x)}$, with $q(x)_i \in J$ for $i = 1, 2, \ldots, n(x)$, and*

$$\left\| \left[\prod_{i=n(x)}^{1} A_{q(x)_i} \right] x \right\|_V < \|x\|_V .$$

3. Conditions for convergence.

LEMMA 3.1. *$\mathcal{A}$ is precontractive relative to $\|\cdot\|_V$ if and only if some finite subset $\mathcal{B}$ of $\mathcal{A}$ is precontractive relative to $\|\cdot\|_V$.*

Proof. Suppose that $\mathcal{A}$ is precontractive relative to $\|\cdot\|_V$, and let P denote the set of all finite sequences $p = \{p_i\}_{i=1}^{k(p)}$ of members of J. For p in P, let

$$S_p = \left\{ x \in \mathbb{F}^n : \|x\|_V = 1, \left\| \left(\prod_{i=k(p)}^{1} A_{p_i} \right) x \right\|_V < 1 \right\}.$$

Then each S_p is an open subset of the unit V-sphere in $\mathbb{F}^n$ and, by precontractiveness, the sphere is covered by $\{S_p : p \in P\}$. By compactness, there is a finite set $\{p^{(1)}, p^{(2)}, \ldots, p^{(m)}\} \subseteq P$ such that the set $\{S_{p^{(i)}} : i = 1, 2, \ldots, m\}$ covers the sphere. It follows that the finite subset $\mathcal{B} = \bigcup_{i=1}^{m} \bigcup_{j=1}^{k(p^{(i)})} A_{p_j^{(i)}}$ of $\mathcal{A}$ is precontractive. The reverse implication is obvious. □

THEOREM 3.2. *Let $\|\cdot\|_V$ be a norm on $\mathbb{F}^n$ and let $\mathcal{A} = \{A_j : j \in J\} \subset \mathbb{F}^{n\times n}$. Then $\mathcal{A}$ is pointwise convergent if and only if $\mathcal{A}$ is precontractive relative to $\|\cdot\|_V$.*

Proof. A proof for the case $\mathbb{F} = \mathbb{R}$ and $\mathcal{A}$ finite appears in [6, Thm. 1]. The proof remains valid when $\mathbb{R}$ is replaced by $\mathbb{F}$, leaving only the case that $\mathcal{A}$ is infinite. If $\mathcal{A}$ is precontractive, then by Lemma 3.1 there is a finite subset $\mathcal{B}$ of $\mathcal{A}$ that is precontractive and so is pointwise convergent. Clearly then, $\mathcal{A}$ is pointwise convergent. Conversely, if $\mathcal{A}$ is pointwise convergent, then for each x in $\mathbb{F}^n$ we have

$$\lim_{k\to\infty} \left\{ \left[\prod_{i=k}^{1} A_{p(x)_i} \right] x \right\} = 0,$$

so for some k,

$$\left\| \left[\prod_{i=k}^{1} A_{p(x)_i} \right] x \right\|_V < \|x\|_V$$

and $\mathcal{A}$ is precontractive relative to $\|\cdot\|_V$. □

COROLLARY 3.3. *Precontractiveness is norm independent.*

Lemma 3.1 and Theorem 3.2 yield the following corollary.

COROLLARY 3.4. *$\mathcal{A}$ is pointwise convergent if and only if some finite subset of $\mathcal{A}$ is pointwise convergent.*

The condition $\rho(A) < 1$, necessary and sufficient for convergence of the single matrix A, generalizes to the following necessary and sufficient condition for uniform convergence of a matrix set.

THEOREM 3.5. *The set* $\mathcal{A} = \{A_j : j \in J\} \subset \mathbb{F}^{n\times n}$ *is uniformly convergent if and only if there is a finite sequence* $\{p_i\}_{i=1}^m$ *with* $p_i \in J$ *for* $i = 1, 2, \ldots, m$, *such that*

$$\rho\left(\prod_{i=m}^{1} A_{p_i}\right) < 1.$$

Proof. If the sequence $\{p_i\}_{i=1}^m$ exists as described, let $\{t_i\}_{i=1}^\infty$ be the periodic sequence $\{p_1, \ldots, p_m, p_1, \ldots, p_m, \ldots,\}$, let $\|\cdot\|_M$ be a (submultiplicative) matrix norm on $\mathbb{F}^{n\times n}$ such that

$$\left\|\prod_{i=m}^{1} A_{p_i}\right\|_M < 1,$$

let $\|\cdot\|_V$ be a norm on $\mathbb{F}^n$ consistent with $\|\cdot\|_M$, and let

$$C = \max\{1, \max\ \{\|A_{p_i}\|_M : 1 \le i \le m\}\}.$$

It follows that for any positive integer $k = mq + r$, with $0 \le r < m$, and any $x \in \mathbb{F}^n$, we have

$$\left\|\left[\prod_{i=k}^{1} A_{p_i}\right] x\right\|_V \le \left\|\prod_{i=m}^{1} A_{p_i}\right\|_M^q C^m \|x\|_V,$$

and hence $\mathcal{A}$ is uniformly convergent.

Conversely, if $\mathcal{A}$ is uniformly convergent with

$$\lim_{k\to\infty}\left\{\left[\prod_{i=k}^{1} A_{p_i}\right] x\right\} = 0$$

for each $x \in \mathbb{F}^n$, then $\lim_{k\to\infty} \prod_{i=k}^{1} A_{p_i} = 0$, so for some sufficiently large m, $\rho(\prod_{i=m}^{1} A_{p_i}) < 1$. □

COROLLARY 3.6. *$\mathcal{A}$ is uniformly convergent if and only if there is a finite subset $\mathcal{B}$ of $\mathcal{A}$ that is uniformly convergent.*

COROLLARY 3.7. *If the set* $\mathcal{A} = \{A_j : j \in J\} \subset \mathbb{F}^{n\times n}$ *is uniformly convergent, then there is a* j *in* J *such that* $|\det A_j| < 1$.

Proof. Suppose that $|\det A_j| \ge 1$ for $j \in J$. Then, for any sequence $\{p_i\}_{i=1}^k$ with $p_i \in J$,

$$\left|\det\left(\prod_{i=k}^{1} A_{p_i}\right)\right| = \prod_{i=k}^{1} |\det A_{p_i}| \ge 1.$$

Hence

$$\rho\left(\prod_{i=k}^{1} A_{p_i}\right) \ge 1,$$

so by the theorem, $\mathcal{A}$ is not uniformly convergent. □

For $\mathcal{A} = \{A_j : j \in J\} \subset \mathbb{F}^{n\times n}$, the condition $|\det A_j| < 1$ for some j is not necessary for pointwise convergence. For example, if

$$A_1 = \begin{bmatrix} \frac{1}{2} & 0 \\ 0 & 2 \end{bmatrix} \quad \text{and} \quad A_2 = \begin{bmatrix} \frac{\sqrt{3}}{2} & \frac{1}{2} \\ -\frac{1}{2} & \frac{\sqrt{3}}{2} \end{bmatrix},$$

then $\det A_1 = \det A_2 = 1$. However, as shown in [6], the set $\mathcal{A} = \{A_1, A_2\}$ is pointwise convergent. Intuitively, the matrix A_1 shrinks vectors in a cone centered on the x-axis (relative to the euclidean norm), whereas A_2 is a rotation that can be applied to vectors not in that cone to bring them into the cone without changing their length in the process. Hence, the set is precontractive and so pointwise convergent. In fact, small perturbations of A_1 and A_2 produce a set in which each matrix has determinant strictly greater than one, but which is still pointwise convergent.

A necessary condition for pointwise convergence is provided by the singular values of the A_i. We need the following lemma, which follows easily from the singular value decomposition of A.

LEMMA 3.8. *Let $A \in \mathbb{F}^{n\times n}$. A has a singular value less than one if and only if there is an $x \in \mathbb{F}^n$ such that $\|Ax\|_2 < \|x\|_2$.*

THEOREM 3.9. *Let $\mathcal{A} = \{A_j : j \in J\} \subset \mathbb{F}^{n\times n}$. If each singular value of each A_j is greater than or equal to 1, then for each $x \in \mathbb{F}^n$ and each sequence $\{p_i\}_{i=1}^k$ with $p_i \in J$, we have*

$$\left\| \left[\prod_{i=k}^{1} A_{p_i} \right] x \right\|_2 \geq \|x\|_2 .$$

Proof. Using the lemma,

$$\left\| \left[\prod_{i=k}^{1} A_{p_i} \right] x \right\|_2 \geq \left\| \left[\prod_{i=k-1}^{1} A_{p_i} \right] x \right\|_2 \geq \cdots \geq \|x\|_2 . \qquad \square$$

COROLLARY 3.10. *Let $\mathcal{A} = \{A_j : j \in J\} \subset \mathbb{F}^{n\times n}$. If $\mathcal{A}$ is pointwise convergent, then some A_j has a singular value less than one.*

Proof. The corollary follows from Theorems 3.2 and 3.9. $\square$

The existence of an eigenvalue of an A_j with modulus less than one is not necessary for pointwise convergence in the real case. Consider the example

$$\mathcal{A} = \{A_1, A_2\} \subset \mathbb{R}^{2\times 2},$$

with

$$A_1 = \begin{bmatrix} 1.0047 & -.7734 \\ -.0027 & -1.7896 \end{bmatrix}, \qquad A_2 = \begin{bmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{bmatrix},$$

and with θ selected as follows. The singular values of A_1 are .9 and 2, so by Lemma 3.8 there is an $x \in \mathbb{R}^2$ such that $\|A_1 x\|_2 < \|x\|_2$. It follows that there is a cone of vectors in $\mathbb{R}^2$ that contains x, each vector of which is shrunk by A_1 relative to $\|\cdot\|_2$. We choose θ so that each nonzero $x \in \mathbb{R}^2$ can be rotated into that cone, and we have $\mathcal{A}$ pointwise convergent. However, the eigenvalues of A_1 are 1.0054 and -1.7903, whereas those of A_2 both have modulus 1. Again, by applying a small perturbation, one can construct a pointwise convergent set in which each eigenvalue of each matrix exceeds one in absolute value.

Finally, in this section we observe that convergence is invariant under simultaneous similarity.

LEMMA 3.11. *Let $\mathcal{A} = \{A_j : j \in J\} \subset \mathbb{F}^{n\times n}$, and let $S \in \mathbb{F}^{n\times n}$ be nonsingular. Then $\mathcal{A}$ is pointwise (uniformly) convergent if and only if $\mathcal{A}_S = \{SA_jS^{-1} : j \in J\}$ is pointwise (uniformly) convergent.*

Proof. The proof for either pointwise or uniform convergence follows from the fact that if $y = S^{-1}x$ and $\{p_i\}_{i=1}^{\infty}$ is any index sequence, then

$$\lim_{k\to\infty}\left\{\left[\prod_{i=k}^{1} SA_{p_i}S^{-1}\right]x\right\} = S\lim_{k\to\infty}\left\{\left[\prod_{i=k}^{1} A_{p_i}\right]y\right\}. \qquad \square$$

4. Sets of diagonal matrices. We first establish the equivalence of pointwise and uniform convergence for sets of diagonal matrices.

THEOREM 4.1. *Let $\mathcal{D} = \{D_j : j \in J\} \subset \mathbb{F}^{n\times n}$ with each D_j a diagonal matrix. If $\mathcal{D}$ is convergent at $x = [x_1 \quad x_2 \cdots x_n]^T$ with $x_i \neq 0$ for $i = 1, 2, \ldots, n$, then $\mathcal{D}$ is uniformly convergent.*

Proof. We first consider the case $x = e = [1 \quad 1 \cdots 1]^T$. If $\mathcal{D}$ is convergent at e, there is a finite product D of matrices in $\mathcal{D}$ such that $\|De\|_\infty < \|e\|_\infty$, where $\|x\|_\infty = \max\{|x_i| : 1 \leq i \leq n\}$ is the infinity norm of x. Since D is diagonal, the entries of De are the eigenvalues of D. Thus, the inequality $\|De\|_\infty < \|e\|_\infty$ may be written $\rho(D) < 1$, and so $\mathcal{D}$ is uniformly convergent by Theorem 3.5.

Now consider a general $x = [x_1 \quad x_2 \cdots x_n]^T$ with $x_i \neq 0$ for $i = 1, 2, \ldots, n$ and suppose $\mathcal{D}$ converges at x; that is,

$$\lim_{k\to\infty}\left\{\left[\prod_{i=k}^{1} D_{p(x)_i}\right]x\right\} = 0.$$

Let $D_x = \operatorname{diag}\{x_1, x_2, \ldots, x_n\}$, so that $D_x e = x$.

Then

$$\begin{aligned}\lim_{k\to\infty}\left\{\left[\prod_{i=k}^{1} D_{p(x)_i}\right]e\right\} &= \lim_{k\to\infty}\left\{\left[\prod_{i=k}^{1} D_{p(x)_i}\right]D_x^{-1}D_x e\right\}\\ &= D_x^{-1}\lim_{k\to\infty}\left\{\left[\prod_{i=k}^{1} D_{p(x)_i}\right]x\right\} = 0,\end{aligned}$$

so $\mathcal{D}$ converges at e and hence converges uniformly. $\square$

COROLLARY 4.2. *A set of diagonal matrices is pointwise convergent if and only if it is uniformly convergent.*

Accordingly, we do not modify the word *convergence* when referring to a set of diagonal matrices.

We now develop a test for convergence of a finite set of diagonal matrices. We remark that, because of Corollary 3.6, the test is also relevant to infinite sets of diagonal matrices. Through the remainder of this section, we assume that $\mathcal{D}$ is finite.

DEFINITION 4.3. *The matrix $A \in \mathbb{R}^{m\times n}$ is* semipositive *provided there is an x in $\mathbb{R}^n$ with $x \geq 0$ such that $Ax > 0$, the inequalities denoting entrywise inequality.*

A more general semipositivity is discussed in [2] and semipositivity as defined here is discussed in [5]. In the following discussion, $\mathbb{N}_+^n$ denotes the set of n-tuples of nonnegative integers and $\mathbb{R}_+^n$ denotes the nonnegative orthant in $\mathbb{R}^n$.

LEMMA 4.4. *Suppose that $A \in \mathbb{R}^{m\times n}$. Then A is semipositive if and only if there is a $k \in \mathbb{N}_+^n$ such that $Ak > 0$.*

Proof. Clearly the existence of k implies A semipositive.

Suppose A is semipositive; choose $x \in \mathbb{R}_+^n$ such that $Ax > 0$. Since the map $y \to Ay$ is continuous, there is an open set $U \subset \mathbb{R}^n$ containing x such that $y \in U$

implies $Ay > 0$. We may choose a member q of $U \cap \mathbb{R}^n_+$, all of whose entries are rational, and for an appropriately chosen positive integer c, $k = cq$ is in $\mathbb{N}^n_+$, and we have $Ak = cAq > 0$. □

THEOREM 4.5. *Let* $\mathcal{D} = \{D_1, D_2, \ldots, D_m\} \subset \mathbb{F}^{n\times n}$ *with* $D_j = \operatorname{diag}\{d_{1j}, d_{2j}, \ldots, d_{nj}\}$, $j = 1, 2, \ldots, m$, *and suppose* $d_{ij} \neq 0$ *for* $1 \leq i \leq n, 1 \leq j \leq m$. *Let* $L(\mathcal{D}) = [l_{ij}] \in \mathbb{R}^{n\times m}$ *be defined by*

$$\ell_{ij} = -\ln\ |d_{ij}|\,.$$

Then $\mathcal{D}$ *is convergent if and only if* $L(\mathcal{D})$ *is semipositive. Furthermore, if this is the case and if* $k \in \mathbb{N}^n_+$ *satisfies* $L(\mathcal{D})k > 0$, *then* $\rho(D_1^{k_1} D_2^{k_2}, \ldots, D_m^{k_m}) < 1$.

Proof. It holds that $\mathcal{D}$ is convergent if and only if there is a sequence $\{p_i\}_{i=1}^t$ such that $1 \leq p_i \leq m$ and

$$\rho\left(\prod_{i=t}^{1} D_{p_i}\right) < 1.$$

Since $\mathcal{D}$ is a commutative set, $\{p_i\}_{i=1}^t$ exists if and only if there is a $k = [k_1, k_2, \ldots, k_m]^T \in \mathbb{N}^m_+$, with $\sum_{j=1}^m k_j = t$, such that

$$\rho\left(D_1^{k_1} D_2^{k_2} \cdots D_m^{k_m}\right) < 1.$$

This inequality is equivalent to

$$\prod_{j=1}^{m} |d_{ij}|^{k_j} < 1 \quad \text{for } i = 1, 2, \ldots, n.$$

Taking logarithms, we obtain the equivalent linear system

$$\sum_{j=1}^{m} k_j \ln |d_{ij}| < 0, \qquad i = 1, 2, \ldots, n$$

or, equivalently, $L(\mathcal{D})k > 0$. Thus, by Lemma 4.4, $\mathcal{D}$ is convergent if and only if $L(\mathcal{D})$ is semipositive, and in this case the stated inequality holds. □

It is easily seen that a set $\mathcal{D} = \{D_1, D_2, \ldots, D_m\}$ of diagonal matrices, in which there are some zero entries on diagonals, is convergent if and only if the set $\hat{\mathcal{D}}$ is convergent. Here $\hat{\mathcal{D}}$ is obtained from $\mathcal{D}$ by deleting from each D_j the ith row and ith column provided there is a k such that $d_{ik} = 0$. This observation leads to the following corollary in which $L(\mathcal{D})$ is defined consistently with its definition in Theorem 4.5.

COROLLARY 4.6. *Let* $\mathcal{D} = \{D_1, D_2, \ldots, D_m\} \subset \mathbb{F}^{n\times n}$ *with* $D_j = \operatorname{diag}\{d_{1j}, d_{2j}, \ldots, d_{nj}\}$, $1 \leq j \leq m$. *Let* $L(\mathcal{D}) = [l_{ij}] \in \mathbb{F}^{n\times m}$ *be defined by*

$$l_{ij} = \begin{cases} -\ln\ |d_{ij}| & \text{if } d_{ik} \neq 0 \quad \text{for } k = 1, 2, \ldots, m, \\ 1 & \text{if there is a } k \text{ such that } d_{ik} = 0. \end{cases}$$

Then $\mathcal{D}$ *is convergent if and only if* $L(\mathcal{D})$ *is semipositive and the final sentence of Theorem* 4.5 *remains valid.*

Proof. $\mathcal{D}$ is convergent if and only if $\hat{\mathcal{D}}$, described above, is convergent. $\hat{\mathcal{D}}$ is convergent if and only if $L(\hat{\mathcal{D}})$ is semipositive. Now $L(\mathcal{D})$ may be obtained from $L(\hat{\mathcal{D}})$ by adjoining rows all of whose entries are one. Hence, for $x \in \mathbb{R}^n_+$, $L(\mathcal{D})x > 0$ if and only if $L(\hat{\mathcal{D}})x > 0$, and the corollary follows. □

We note here that, in view of Lemma 3.11, sets $\mathcal{A} = \{A_1, A_2, \ldots, A_m\} \subset \mathbb{F}^{n\times n}$, which are simultaneously diagonalizable, can be tested for convergence using Corollary 4.6.

5. Sets of triangular matrices. In this section we may interpret "triangular" as "upper triangular" throughout or as "lower triangular" throughout.

DEFINITION 5.1. *If $A \in \mathbb{F}^{n\times n}$, then* diag (A) *is the matrix obtained from A by replacing all off-diagonal entries with zeros.*

THEOREM 5.2. *The set $\mathcal{T} = \{T_j : j \in J\}$ of triangular matrices is uniformly convergent if and only if the set*

$$\text{diag } (\mathcal{T}) = \{\text{diag } (T_j) : j \in J\}$$

is convergent.

Proof. The result follows from Theorem 3.5 and the fact that for any sequence $\{p_i\}_{i=1}^k$, the eigenvalues of $\prod_{i=k}^1 T_{p_i}$ are the same as those of $\prod_{i=k}^1 \text{diag } (T_{p_i})$. □

We remark, however, that for sets of triangular matrices, pointwise and uniform convergence are not the same. Let $\mathcal{T} = \{T_1, T_2\} \subset \mathbb{R}^{2\times 2}$, where

$$T_1 = \begin{bmatrix} \frac{3}{2} & 0 \\ 0 & \frac{2}{3} \end{bmatrix} \quad \text{and} \quad T_2 = \begin{bmatrix} \frac{2}{3} & 0 \\ 1 & -\frac{3}{2} \end{bmatrix}.$$

We show that $\mathcal{T}$ is precontractive relative to $\|\cdot\|_2$ and hence pointwise convergent. In fact, we claim that for $x \in \mathbb{R}^2$ and $x \neq 0$, one of the following is true:

(1) $\|T_1 x\|_2 < \|x\|_2$,
(2) $\|T_2 x\|_2 < \|x\|_2$,
(3) $\|T_2 T_1 T_2 x\|_2 < \|x\|_2$,
(4) $\|T_2 T_1^2 T_2 x\|_2 < \|x\|_2$.

It is sufficient to show that one of (1)–(4) holds when $x = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$ or $x = \begin{bmatrix} 1 \\ y \end{bmatrix}$ for some $y \in \mathbb{R}$. Clearly, (1) holds when $x = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$. For $i = 1, 2, 3, 4$, let $S_i = \{y \in \mathbb{R} : (i) \text{ holds for } x = \begin{bmatrix} 1 \\ y \end{bmatrix}\}$. Computation shows that

$$S_1 = \left\{ y : |y| > \frac{3}{2} \right\},$$

$$S_2 = \left\{ y : \frac{6}{5} - \frac{2\sqrt{61}}{15} < y < \frac{6}{5} + \frac{2\sqrt{61}}{15} \right\} \supset \left\{ y : \frac{1}{2} < y < 2 \right\},$$

$$S_3 = \left\{ y : |y| < \frac{3}{2} \right\},$$

$$S_4 = \left\{ y : y < -\frac{5}{12} \right\}.$$

Hence, $\bigcup_{i=1}^4 S_i = \mathbb{R}$ and $\mathcal{T}$ is pointwise convergent.

However, $\mathcal{T}$ is not uniformly convergent, as we see by use of Theorems 5.2 and 4.5. Let $D_i = \text{diag } (T_i)$ for $i = 1, 2$, so that diag $(\mathcal{T}) = \{D_1, D_2\}$. Then

$$L(\text{diag } (\mathcal{T})) = \begin{bmatrix} \ln \frac{2}{3} & \ln \frac{3}{2} \\ \ln \frac{3}{2} & \ln \frac{2}{3} \end{bmatrix}$$

is not semipositive, since it has sign pattern $\begin{bmatrix} - & + \\ + & - \end{bmatrix}$ and its determinant is zero [5]. Hence, diag $(\mathcal{T})$ is not convergent, so $\mathcal{T}$ is not uniformly convergent.

We obtain a necessary condition for pointwise convergence of a set of triangular matrices.

THEOREM 5.3. *Suppose* $\mathcal{T} = \{T_j : j \in J\} \subset \mathbb{F}^{n\times n}$ *with each* T_j *triangular. If* $\mathcal{T}$ *is pointwise convergent, then for* $1 \leq i \leq n$, *there is a* j *in* J *such that* $|\mathrm{ent}_{ii}\,(T_j)| < 1$.

Proof. Suppose there exists an i such that

$$|\mathrm{ent}_{ii}\,(T_j)| \geq 1 \quad \text{for } j \in J.$$

Then no finite product P of the T_j's would satisfy $\|Pe_i\|_2 < \|e_i\|_2$, where e_i is the ith canonical basis vector in $\mathbb{F}^n$, so $\mathcal{T}$ is not precontractive relative to $\|\cdot\|_2$ and hence is not pointwise convergent. □

Finally, we note that results obtained for sets of triangular matrices can be used for any commuting set of matrices via simultaneous triangularization and Lemma 3.11 (see [4, Thm. 2.3.3].)

A HYBRID ALGORITHM FOR OPTIMIZING EIGENVALUES OF SYMMETRIC DEFINITE PENCILS*

JEAN-PIERRE A. HAEBERLY† AND MICHAEL L. OVERTON‡

Abstract. An algorithm is presented for the optimization of the maximum eigenvalue of a symmetric definite pencil depending affinely on a vector of parameters. The algorithm uses a hybrid approach, combining a scheme based on the method of centers, developed by Boyd and El Ghaoui [*Linear Algebra Appl.*, 188 (1993), pp. 63–112], with a new quadratically convergent local scheme. A convenient expression for the generalized gradient of the maximum eigenvalue of the pencil is also given, expressed in terms of a dual matrix. The algorithm computes the dual matrix that establishes the optimality of the computed solution.

Key words. nonsmooth optimization, generalized eigenvalue problem, matrix pencil, Lyapunov equations

1. Introduction.

In this paper we consider the problem of minimizing the maximum eigenvalue of a symmetric definite pencil $(A(x), B(x))$ depending on a vector parameter $x \in \Re^m$. Many problems arising in control theory can be formulated in these terms. Most notable among these are the computation of bounds for structured singular values and the computation of structured Lyapunov functions [3]. The salient feature of this problem is the lack of smoothness. Indeed, it is well known that the eigenvalues of a matrix are not differentiable as functions of the entries of the matrix when their multiplicity exceeds one. Furthermore, at an optimum point, the multiplicity of the maximum eigenvalue is often greater than one. Thus standard optimization techniques cannot be applied.

The special case $B = I$, which is the problem of minimizing the maximum eigenvalue of a symmetric matrix $A(x)$, has been studied extensively (see [14] and the references therein, as well as [1], [5], [9]). The case where $B(x)$ is constant is entirely similar and is briefly discussed in [14]. Algorithms have been developed in [2], [11] and [12] to solve the problem when the pencil depends affinely on the parameter vector and in [8] for the general case. The algorithm of Boyd and El Ghaoui in [2] is based on the method of centers and exhibits very good global behavior but slow local convergence.

We propose a hybrid algorithm, combining the robustness of the method of centers with rapid local convergence, to efficiently solve the affine case. More precisely, we propose to follow the path of centers to the vicinity of a solution and then to switch to a quadratically convergent local scheme. Such an approach was suggested in [2]. It should be noted that any algorithm exhibiting good global behavior could be used in place of the method of centers, e.g., any algorithm based on interior point methods. The local algorithm results from an extension of the work presented in [13], [14], and [16] to a pencil-valued function $(A(x), B(x))$. The algorithm is implemented to take

full advantage of a block diagonal structure, if present. Block diagonal pencils occur frequently in applications from control theory [3].

The paper is organized as follows. Some notation and conventions are introduced in §2. The generalized gradient and directional derivatives of the maximum eigenvalue are derived in §3 and optimality conditions are stated. The local algorithm is described in §4 and the global algorithm in §5. Two numerical examples are presented in §6.

2. Preliminaries. Let $\mathcal{SR}^{n\times n}$ denote the set of $n \times n$ real symmetric matrices. For $B \in \mathcal{SR}^{n\times n}$, the notation $B \geq 0$ means that B is nonnegative definite, and $B > 0$ means that B is positive definite. A symmetric definite pencil (A, B) consists of a pair of matrices A, B in $\mathcal{SR}^{n\times n}$ with $B > 0$. An eigenvalue λ of (A, B) satisfies $\det(A - \lambda B) = 0$, i.e., there is a nonzero eigenvector q satisfying $Aq = \lambda Bq$.

We write $\langle\, , \rangle$ for the Frobenius inner product on the space of $n \times n$ matrices. Thus

$$\langle M, N\rangle = \operatorname{tr} M^T N.$$

Let "vec" denote the operator mapping $\mathcal{SR}^{n\times n}$ into $\mathcal{R}^{n(n+1)/2}$ defined by

$$\operatorname{vec} A = (a_{11}, \sqrt{2}a_{12}, \ldots, \sqrt{2}a_{1n}, a_{22}, \sqrt{2}a_{23}, \ldots, \sqrt{2}a_{2n}, a_{33}, \sqrt{2}a_{34}, \ldots, a_{nn})$$

for $A = (a_{ij}) \in \mathcal{SR}^{n\times n}$. Observe that for two symmetric matrices M and N, we have

$$(\operatorname{vec} M)^T (\operatorname{vec} N) = \langle M, N\rangle.$$

Also, let

$$C_1 \oplus \cdots \oplus C_k$$

denote the block diagonal matrix with blocks $C_1, \ldots, C_k$.

Given a symmetric definite pencil (A, B), let G denote the Choleski factor of B. Hence G is a lower triangular matrix with positive diagonal entries such that $GG^T = B$. Then the symmetric matrix $G^{-1}AG^{-T}$ has the same eigenvalues as the pencil. Let us write $\lambda_{\max} = \lambda_1 \geq \cdots \geq \lambda_n$ for these eigenvalues and Λ for the diagonal matrix

$$\Lambda = \operatorname{Diag}(\lambda_1, \ldots, \lambda_n).$$

Let $p_1, p_2, \ldots, p_n$ denote a set of orthonormal eigenvectors for $G^{-1}AG^{-T}$, and let $P = [p_1 \ldots p_n]$ denote the orthogonal matrix with columns p_i, $1 \leq i \leq n$. Then the columns of the matrix $Q = G^{-T}P = [G^{-T}p_1, \ldots, G^{-T}p_n]$ are eigenvectors for the pencil. Hence we have

$$P^T G^{-1} A G^{-T} P = \Lambda, \qquad P^T P = I,$$

and

$$AQ = BQ\Lambda, \qquad Q^T B Q = I.$$

We have the following characterization of $\lambda_{\max}$ [14]:

$$\lambda_{\max} = \max\{\langle U, G^{-1}AG^{-T}\rangle \mid U \in \mathcal{SR}^{n\times n},\ \operatorname{tr} U = 1,\ U \geq 0\}. \tag{1}$$

In particular, we see that $\lambda_{\max}$ is a convex function of A; however, it is only quasi-convex as a function of B [2].

3. Optimality conditions. Consider a symmetric definite pencil-valued function $(A(x), B(x))$ of a vector of real parameters $x \in \Re^m$. We assume that $A(x)$ and $B(x)$ are twice continuously differentiable in x and we write $A_j(x)$, $B_j(x)$ for the partial derivatives of $A(x)$ and $B(x)$ with respect to x_j. Note that a vector subscript (e.g., x_j) denotes a component, while a matrix subscript indicates differentiation. Later, we shall use matrix superscripts to denote diagonal blocks.

Let $G(x)$ denote the Choleski factor of $B(x)$ and let $L_j(x)$ denote the partial derivative of $G(x)$ with respect to x_j. Thus $L_j(x)$ is the unique lower triangular matrix that solves the equation

$$L_j(x)G^T(x) + G(x)L_j^T(x) = B_j(x). \tag{2}$$

Note that this is a particularly simple Lyapunov equation since the matrix $G(x)$ is lower triangular. Since

$$\frac{\partial}{\partial x_j} G^{-1}(x) = -G^{-1}(x)L_j(x)G^{-1}(x),$$

we have

$$\frac{\partial}{\partial x_j}(G^{-1}(x)A(x)G^{-T}(x)) = G^{-1}(x)Z_j(x)G^{-T}(x),$$

where the matrix $Z_j(x)$ is given by

$$Z_j(x) \equiv A_j(x) - L_j(x)G^{-1}(x)A(x) - A(x)G^{-T}(x)L_j^T(x). \tag{3}$$

For future reference, we also define

$$L_{ij}(x) = \frac{\partial}{\partial x_i}(L_j(x)). \tag{4}$$

Thus $L_{ij}(x)$ is that lower triangular matrix that solves the following equation:

$$L_{ij}(x)G^T(x) + G(x)L_{ij}^T(x) = B_{ij}(x) - [L_i(x)L_j^T(x) + L_j(x)L_i^T(x)].$$

Clearly, $L_{ij}(x) = L_{ji}(x)$.

Finally, write

$$\lambda_{\max}(x) = \lambda_1(x) \geq \cdots \geq \lambda_n(x)$$

for the eigenvalues of $(A(x), B(x))$, let $P(x)$ be an orthogonal matrix of eigenvectors for $G^{-1}(x)A(x)G^{-T}(x)$, so that

$$P^T(x)G^{-1}(x)A(x)G^{-T}(x)P(x) = \Lambda(x)$$

and define $Q(x) = G^{-1}(x)P(x)$.

We are now ready to derive the generalized gradient of $\lambda_{\max}(x)$. (See Gollan [18, Thm. 6.1] for a related result.)

THEOREM 3.1. *Assume that the multiplicity of $\lambda_{\max}(x)$ is t and let $Q_{\max}(x)$ be the submatrix of $Q(x)$ whose columns form a complete set of eigenvectors for $\lambda_{\max}(x)$. Then the generalized gradient of $\lambda_{\max}(x)$ is the set*

$$\partial\lambda_{\max}(x) = \left\{v \in \Re^m \mid v_j = \langle U, Q_{\max}^T(x)\,(A_j(x) - \lambda_{\max}(x)B_j(x))\,Q_{\max}(x)\rangle\right\}, \tag{5}$$

where U runs over all nonnegative definite symmetric $t \times t$ matrices with $\operatorname{tr} U = 1$.

Proof. Let C denote an $n \times n$ symmetric matrix. The generalized gradient of the maximum eigenvalue $\lambda_{\max} = \lambda_{\max}(C)$ viewed as a function of C was given in [14]. If the multiplicity of $\lambda_{\max}(C)$ is t and if $P_{\max}$ is an $n \times t$ matrix whose columns form a complete set of orthonormal eigenvectors for $\lambda_{\max}(C)$, then

$$\partial\lambda_{\max}(C) = \{V \in \mathcal{SR}^{n\times n} \mid V = P_{\max} U P_{\max}^T\},$$

where U runs over the $t \times t$ symmetric matrices with $U \geq 0$ and $\operatorname{tr} U = 1$. We call U a *dual* matrix. The generalized gradient of the maximum eigenvalue $\lambda_{\max}(x)$ of the symmetric matrix $G^{-1}(x)A(x)G^{-T}(x)$ now follows from the chain rule [4]. We get

$$\partial\lambda_{\max}(x) = \{v \in \mathcal{R}^m \mid v_j = \langle V, G^{-1}(x)Z_j(x)G^{-T}(x)\rangle\}, \tag{6}$$

where $V \in \partial\lambda_{\max}(A(x))$. We have an equality in (6) instead of a mere inclusion because $\lambda_{\max}(x)$ is a regular function [4]. Indeed, (1) expresses $\lambda_{\max}(x)$ as the maximum over the matrices V of $\langle V, G^{-1}(x)A(x)G^{-T}(x)\rangle$, and, for a fixed V, the function

$$x \mapsto \langle V, G^{-1}(x)A(x)G^{-T}(x)\rangle$$

is differentiable, hence regular [4, Thms. 2.8.2 and 2.8.6.]. We write $P_{\max} = P_{\max}(x)$ and $Q_{\max} = Q_{\max}(x) = G^{-T}(x)P_{\max}(x)$. Observe that

$$\langle P_{\max} U P_{\max}^T, G^{-1}(x)Z_j(x)G^{-T}(x)\rangle = \langle U, P_{\max}^T G^{-1}(x)Z_j(x)G^{-T}(x)P_{\max}\rangle.$$

Now the columns of $Q_{\max}$ are generalized eigenvectors for $\lambda_{\max} \equiv \lambda_{\max}(x)$ and we have

$$\begin{aligned}
Q_{\max}^T Z_j(x) Q_{\max} &= Q_{\max}^T [A_j(x) - L_j(x)G^{-1}(x)A(x) \\
&\quad - A(x)G^{-T}(x)L_j^T(x)]Q_{\max} \\
&= Q_{\max}^T [A_j(x) - \lambda_{\max}(L_j(x)G^{-1}(x)B(x) \\
&\quad + B(x)G^{-T}(x)L_j^T(x))]Q_{\max} \\
&= Q_{\max}^T [A_j(x) - \lambda_{\max}(L_j(x)G^T(x) + G(x)L_j^T(x))]Q_{\max} \\
&= Q_{\max}^T [A_j(x) - \lambda_{\max} B_j(x)]Q_{\max}.
\end{aligned}$$

The result follows. □

A necessary condition for x to minimize $\lambda_{\max}$ is that $0 \in \partial\lambda_{\max}(x)$ [4]. By Theorem 3.1 this can be rewritten as follows. Let t denote the multiplicity of $\lambda_{\max}(x)$. Then a necessary condition for x to minimize $\lambda_{\max}$ is that there exists a dual matrix $U \in \mathcal{SR}^{t\times t}$ such that

$$\operatorname{tr} U = 1, \tag{7}$$

$$U \geq 0, \tag{8}$$

and, for $1 \leq j \leq m$,

$$\langle U, Q_{\max}^T(x)\,(A_j(x) - \lambda_{\max}(x)B_j(x))\,Q_{\max}(x)\rangle = 0, \tag{9}$$

where $Q_{\max}(x)$ is as in Theorem 3.1.

As a corollary of Theorem 3.1, we can evaluate the directional derivative of $\lambda_{\max}(x)$.

COROLLARY 3.2. *Let $\lambda'_{\max}(x;d)$ denote the directional derivative of $\lambda_{\max}$ in the direction d, i.e.,*

$$\lambda'_{\max}(x;d) = \lim_{\epsilon \downarrow 0} \frac{\lambda_{\max}(x+\epsilon d) - \lambda_{\max}(x)}{\epsilon}.$$

Then $\lambda'_{\max}(x;d)$ is equal to the largest eigenvalue of the matrix

$$\sum_{j=1}^{m} d_j Q_{\max}^T(x) \left(A_j(x) - \lambda_{\max}(x) B_j(x)\right) Q_{\max}(x).$$

Proof. Since $\lambda_{\max}$ is regular at x the directional derivative $\lambda'_{\max}(x;d)$ exists and is given by [4, Prop. 2.1.2]

$$\lambda'_{\max}(x;d) = \max\{\langle v, d\rangle \mid v \in \partial\lambda_{\max}(x)\}.$$

Now for $v \in \partial\lambda_{\max}(x)$ we have, from (5),

$$\begin{aligned}
\langle v, d\rangle &= \sum_{j=1}^{m} v_j d_j \\
&= \sum_{j=1}^{m} d_j \langle U, Q_{\max}^T(x) \left(A_j(x) - \lambda_{\max}(x) B_j(x)\right) Q_{\max}(x)\rangle \\
&= \langle U, \sum_{j=1}^{m} d_j Q_{\max}^T(x) \left(A_j(x) - \lambda_{\max}(x) B_j(x)\right) Q_{\max}(x)\rangle.
\end{aligned}$$

The result follows from (1). □

Now consider the three optimality conditions (7)–(9). Suppose that x and U are known to satisfy the first and third condition, but not necessarily the second condition $U \geq 0$. The following result shows the relationship between certain directional derivatives of $\lambda_{\max}(x)$ and the eigenvalues of the dual matrix U.

THEOREM 3.3. *Let x and U satisfy* (7) *and* (9), *and let θ be an eigenvalue of U with normalized eigenvector v. Suppose $d \in \Re^m$ and $\delta \in \Re$ form a solution of the following equation:*

$$\sum_{j=1}^{m} d_j Q_{\max}^T(x) \left(A_j(x) - \lambda_{\max}(x) B_j(x)\right) Q_{\max}(x) - \delta I = -vv^T. \tag{10}$$

Then the directional derivative $\lambda'_{\max}(x;d)$ is given by

$$\lambda'_{\max}(x;d) = \theta.$$

Proof. Let us write

$$M(d) = \sum_{j=1}^{m} d_j Q_{\max}^T(x) \left(A_j(x) - \lambda_{\max}(x) B_j(x)\right) Q_{\max}(x).$$

Then (10) gives

$$M(d) = \delta I - vv^T,$$

so that all the eigenvalues of $M(d)$ are equal to δ except one that equals $\delta - 1$. Thus $\lambda_1'(x;d) = \delta$ by Corollary 3.2. Now, taking the inner product of both sides of (10) with the matrix U yields

$$\sum_{j=1}^{m} d_j \langle U, Q_{\max}^T(x)\,(A_j(x) - \lambda_{\max}(x)B_j(x))\,Q_{\max}(x)\rangle - \delta \operatorname{tr} U = -\theta.$$

Since optimality conditions (7) and (9) are satisfied, this equation reduces to

$$\delta = \theta,$$

which completes the proof. □

The essential idea here is that the direction d splits the multiple eigenvalue $\lambda_{\max}$, but, to first order, the multiplicity is reduced only by one. Among other things, this result shows how to generate a descent direction for $\lambda_{\max}(x)$ if all optimality conditions are satisfied except $U \geq 0$: set θ equal to a negative eigenvalue of U. For further results of this kind, together with a discussion of solvability conditions for systems of the form (10), see [15].

4. The local algorithm. In this section we develop a quadratically convergent local algorithm to minimize the maximum eigenvalue of the pencil $(A(x), B(x))$, under the assumption that $A(x)$ and $B(x)$ are affine functions of x. Thus

$$A(x) = A_0 + x_1A_1 + \cdots + x_mA_m$$

and

$$B(x) = B_0 + x_1B_1 + \cdots + x_mB_m.$$

We discuss the nonlinear case briefly at the end of this section. We further assume, as is the case in many applications, that the pencil $(A(x), B(x))$ is block diagonal, with l denoting the number of blocks. Thus

$$A(x) = A^1(x) \oplus \cdots \oplus A^l(x), \qquad B(x) = B^1(x) \oplus \cdots \oplus B^l(x)$$

with $A^i(x)$, $B^i(x)$ in $\mathcal{SR}^{n_i \times n_i}$, $B^i(x) > 0$, for $1 \leq i \leq l$. Let $n = n_1 + \cdots + n_l$ be the dimension of the pencil and let $\lambda_{\max}(x)$ denote the largest eigenvalue of $(A(x), B(x))$.

Given an initial point x^0 in a neighborhood of a local minimizer x^* of $\lambda_{\max}(x)$, we show how to generate a sequence of iterates converging quadratically to x^*. Let $\hat{x}$ denote the current point. The new iterate is set to $\hat{x} + \hat{d}$ where $\hat{d}$ is the solution of a certain equality-constrained quadratic program. Let $t = (t_1, \ldots, t_l)$ be the vector of multiplicities for $\lambda_{\max}^* \equiv \lambda_{\max}(x^*)$, i.e., $t_j \geq 0$ is the multiplicity of $\lambda_{\max}^*$ in the block $(A^j(x^*), B^j(x^*))$. Of course, t is not known and needs to be estimated. This is done with the use of a multiplicity tolerance τ, based on the eigenvalues at the current iterate $\hat{x}$. More precisely, we write $\hat{\lambda}_{\max} = \lambda_{\max}(\hat{x})$, $\hat{\lambda}_i = \lambda_i(\hat{x})$, we order the eigenvalues of each block in decreasing order,

$$\hat{\lambda}_1^j \geq \cdots \geq \hat{\lambda}_{n_j}^j, \qquad 1 \leq j \leq l,$$

and we define $t_j \geq 0$ by

$$\hat{\lambda}_{\max} - \hat{\lambda}_{t_j+1}^j > \tau \max(1, |\hat{\lambda}_{\max}|),$$

and, if $t_j \neq 0$,

$$\hat{\lambda}_{\max} - \hat{\lambda}^j_{t_j} \leq \tau \max(1, |\hat{\lambda}_{\max}|).$$

We write

$$\hat{\Lambda}^j_{\max} = \mathrm{Diag}(\hat{\lambda}^j_1, \ldots, \hat{\lambda}^j_{t_j}),$$

for the diagonal matrix consisting of the first t_j eigenvalues of the jth block. If $t_j = 0$, $\hat{\Lambda}^j_{\max}$ is an empty matrix. Let

$$\hat{\Lambda}^j_{\mathrm{rest}} = \mathrm{Diag}(\hat{\lambda}^j_{t_j+1}, \ldots, \hat{\lambda}^j_{n_j})$$

and

$$\hat{\Lambda}^j = \hat{\Lambda}^j_{\max} \oplus \hat{\Lambda}^j_{\mathrm{rest}}.$$

Let $\hat{Q}$ be a matrix whose columns form a complete set of eigenvectors for the pencil at $\hat{x}$. Clearly $\hat{Q}$ is also block diagonal,

$$\hat{Q} = \hat{Q}^1 \oplus \cdots \oplus \hat{Q}^l.$$

We now write $\hat{Q}_{\max}$ for the matrix obtained from $\hat{Q}$ by discarding all but the first t_j eigenvectors of the jth block, for $1 \leq j \leq l$. It is also block diagonal, i.e.,

$$\hat{Q}_{\max} = \hat{Q}^1_{\max} \oplus \cdots \oplus \hat{Q}^l_{\max},$$

where $\hat{Q}^j_{\max}$, of size $n_j \times t_j$, corresponds to the jth block and is empty if $t_j = 0$. Finally let $\hat{Q}^j_{\mathrm{rest}}$ be such that

$$\hat{Q}^j = [\hat{Q}^j_{\max}\ \hat{Q}^j_{\mathrm{rest}}].$$

The quadratic program that is solved to compute the step $\hat{d}$ is given as follows:

$$\min_{d,\omega}\ \omega + \frac{1}{2} d^T W d \tag{11}$$

subject to

$$K \begin{pmatrix} \omega \\ d \end{pmatrix} = h, \tag{12}$$

where $\omega \in \Re$ and W is a positive definite matrix that is described below. The matrix K is given by

$$K = \begin{bmatrix} K^1 \\ \vdots \\ K^l \end{bmatrix},$$

where K^j is the matrix

$$[\mathrm{vec}I \quad -\mathrm{vec}(\hat{Q}^{j\,T}_{\max}(\hat{A}^j_1 - \hat{\lambda}_{\max}\hat{B}^j_1)\hat{Q}^j_{\max}) \cdots \quad -\mathrm{vec}(\hat{Q}^{j\,T}_{\max}(\hat{A}^j_m - \hat{\lambda}_{\max}\hat{B}^j_m)\hat{Q}^j_{\max})],$$

with I the identity matrix of size $t_j \times t_j$ and $\hat{A}_i^j = \hat{A}_i^j(\hat{x})$, $\hat{B}_i^j = \hat{B}_i^j(\hat{x})$. Clearly, K^j is empty if $t_j = 0$. The vector h is given by

$$h = \begin{bmatrix} h^1 \\ \vdots \\ h^l \end{bmatrix},$$

where

$$h^j = \operatorname{vec}(\hat{\Lambda}^j_{\max} - \hat{\lambda}_{\max} I)$$

if $t_j > 0$ and h^j is empty otherwise.

The formulation of the quadratic program can be motivated as follows. The constraints (12) consist of

$$\sum_{j=1}^{l} \frac{t_j(t_j+1)}{2} \tag{13}$$

scalar constraints. The multipliers of these scalar constraints can be assembled into a block diagonal dual matrix estimate

$$U = U^1 \oplus \cdots \oplus U^l$$

with U^j empty if $t_j = 0$. If (d, ω) is a solution of (11), (12), then the optimality conditions for quadratic programs give

$$\sum_{j=1}^{l} \langle U^j, \hat{Q}^{j\,T}_{\max} \left(\hat{A}_i^j - \hat{\lambda}_{\max} \hat{B}_i^j \right) \hat{Q}^j_{\max} \rangle + (Wd)_i = 0 \tag{14}$$

for $1 \le i \le m$ and

$$\operatorname{tr} U = \sum_{j=1}^{l} \operatorname{tr} U^j = 1. \tag{15}$$

Now observe that if the multiplicity tolerance $\tau = 0$, the vector h is zero, and the constraint (12) can be rewritten as

$$\sum_{i=1}^{m} d_i \, \hat{Q}^{j\,T}_{\max} \left(\hat{A}_i^j - \hat{\lambda}_{\max} \hat{B}_i^j \right) \hat{Q}^j_{\max} = \omega I, \qquad 1 \le j \le l.$$

Since the matrices $\hat{Q}^{j\,T}_{\max}(\hat{A}_i^j - \hat{\lambda}_{\max}\hat{B}_i^j)\hat{Q}^j_{\max}$ are the diagonal blocks of the matrix $Q^T_{\max}(\hat{x})(A_i(\hat{x}) - \lambda_{\max}(\hat{x})B_i(\hat{x}))Q_{\max}(\hat{x})$ of Corollary 3.2, we conclude that a solution (d, ω) of (12) satisfies

$$\lambda'_{\max}(\hat{x}; d) = \omega.$$

If, moreover, (d, ω) is a solution of (11) then

$$\omega + \frac{1}{2} d^T W d \le 0,$$

since $(0,0)$ is feasible. But W is positive definite so that

$$\lambda'_{\max}(\hat{x};d) \leq -\frac{1}{2}d^T W d \leq 0.$$

Hence d is a descent direction for $\lambda_{\max}$ unless $d = 0$. But if $d = 0$ then (14) and (15) show that all optimality conditions for $\lambda_{\max}$ are satisfied at $\hat{x}$ except possibly the nonnegative definite condition on U. If U does have a negative eigenvalue, Theorem 3.3 shows how to obtain a descent direction by splitting $\lambda_{\max}$.

If the multiplicity vector t of $\lambda_{\max}$ at the optimal value x^* is known, the problem of minimizing $\lambda_{\max}$ over x can be rewritten as

$$\min_{x,\omega} \quad \omega$$

subject to

$$\lambda_1^j(x) = \cdots = \lambda_{t_j}^j(x) = \omega, \qquad 1 \leq j \leq l. \tag{16}$$

The objective function is now a smooth function of x and ω, but the constraints, of course, are not. Following [16], we replace these nondifferentiable constraints with a system of nonlinear equations to get the following nonlinear program:

$$\min_{x,\omega} \quad \omega \tag{17}$$

subject to

$$F(x,Y,\omega,\theta) = 0, \tag{18}$$

where $F(x,Y,\omega,\theta)$ is a block diagonal symmetric $n \times n$ matrix

$$F(x,Y,\omega,\theta) = F^1(x,Y,\omega,\theta) \oplus \cdots \oplus F^l(x,Y,\omega,\theta).$$

The matrices $F^j(x,Y,\omega,\theta)$ are defined as follows. The vector θ is given by

$$\theta = (\theta_{t_1+1}^1, \ldots, \theta_{n_1}^1, \ldots, \theta_{t_l+1}^l, \ldots, \theta_{n_l}^l).$$

We write

$$\Theta^j = \mathrm{Diag}(\theta_{t_j+1}^j, \ldots, \theta_{n_j}^j).$$

Let

$$Y = Y^1 \oplus \cdots \oplus Y^l,$$

where Y^j is a skew symmetric $n_j \times n_j$ matrix, and let

$$D = D^1 \oplus \cdots \oplus D^l$$

with $D^j = \omega I \oplus \Theta^j$, where I is the $t_j \times t_j$ identity matrix. Then

$$F^j(x,Y,\omega,\theta) = D^j - e^{-Y^j}\hat{Q}^{jT}(G^j)^{-1}(x)A^j(x)(G^j)^{-T}(x)\hat{Q}^j e^{Y^j},$$

where $G^j(x)$ is the Choleski factor of $B^j(x)$ and $\hat{Q}^j$ is the matrix of eigenvectors for the pencil $(A^j(\hat{x}), B^j(\hat{x}))$. Observe that the definition of F depends on $\hat{x}$ through $\hat{Q}$.

The matrix exponential e^{Y^j} is orthogonal since Y^j is skew symmetric, and it follows that (x, Y, ω, θ) solves (18) if and only if the pencil $(A^j(x), B^j(x))$ has eigenvalues

$$(\underbrace{\omega, \ldots, \omega}_{t_j}, \theta^j_{t_j+1}, \ldots, \theta^j_{n_j}).$$

In the case $t_j = 0$, the latter condition is an empty one, indicating that the block F^j can be omitted from F in this case.

The idea of replacing the nondifferentiable constraints (16) by an equation of the form (18) based on a matrix exponential formulation goes back to [7]. Indeed, consider the case where the number of variables and constraints in the quadratic program (11), (12) are the same, i.e., K is square, or equivalently, the number of constraints, as given by (13), equals $m+1$. Then, provided K is nonsingular, the solution of the quadratic program is completely defined by the constraint (12). In the case that $B(x) = I$, this essentially reduces to the step defined by Modified Method I in [7], the only difference being that in [7], the multiple eigenvalue $\lambda_{\max}$ is prescribed. The method in [7] can be viewed as a variation on Newton's method for solving (18), but the analysis is somewhat complicated because (a) the definition of F, which depends on $\hat{Q}$, changes at every step of the iteration, and (b) it is necessary to remove the leading t_j by t_j block of the variables Y^j from the formulation of F to obtain a well-posed iteration, leading to a sequence of nonlinear equations that are solvable only in the limit.

The matrix W in the quadratic objective (11) is derived from the Hessian of the Lagrangian function associated with the nonlinear program (17), (18), evaluated at $x = \hat{x}$, $\omega = \hat{\lambda}_{\max}$, $Y^j = 0$, and $\Theta^j = \hat{\Lambda}^j_{\text{rest}}$. A detailed discussion in the case $B(x) = I$ is given in [16]. Specifically, W is an $m \times m$ symmetric matrix whose (p, q)-entry is given by

$$w_{pq} = \sum_{j=1}^{l} \langle U^j, H^j_{pq} \rangle, \tag{19}$$

where H^j_{pq} is a symmetric $t_j \times t_j$ matrix computed as follows. It is empty if $t_j = 0$. Otherwise let $\hat{G}^j = G^j(\hat{x})$ be the Choleski factor of $B^j(\hat{x})$, let $\hat{L}^j_p$ denote the matrix defined by (2) for the block $B^j(\hat{x})$ and similarly $\hat{L}^j_{pq}$ for the matrix defined by (4). Finally write $\hat{Z}^j_p = Z^j_p(\hat{x})$. Then

$$H^j_{pq} = H^j_{pq,1} + H^j_{pq,2} + H^j_{pq,3} + H^j_{pq,4},$$

where:

1. $H^j_{pq,1} = M_1 + M_1^T$ with

$$M_1 = -\hat{Q}^{j\,T}_{\max} \hat{L}^j_{pq} (\hat{G}^j)^T \hat{Q}^j_{\max} \hat{\Lambda}^j_{\max};$$

2. $H^j_{pq,2} = M_2 + M_2^T$ with

$$M_2 = -\hat{Q}^{j\,T}_{\max} \hat{L}^j_p (\hat{G}^j)^{-1} \hat{A}^j (\hat{G}^j)^{-T} (\hat{L}^j_q)^T \hat{Q}^j_{\max};$$

3. $H^j_{pq,3} = M_3 + M_3^T$ with

$$M_3 = -\hat{Q}^{j\,T}_{\max} \hat{L}^j_p (\hat{G}^j)^{-1} \hat{Z}^j_q \hat{Q}^j_{\max} - \hat{Q}^{j\,T}_{\max} \hat{L}^j_q (\hat{G}^j)^{-1} \hat{Z}^j_p \hat{Q}^j_{\max};$$

4. $H^j_{pq,4} = M_4 + M_4^T$ with $M_4 = 0$ if $t_j = n_j$, and otherwise

$$M_4 = \hat{Q}^j_{\max}{}^T \hat{Z}^j_p \hat{Q}^j_{\text{rest}} (S^j)^{-1} \hat{Q}^j_{\text{rest}}{}^T \hat{Z}^j_q \hat{Q}^j_{\max};$$

where

$$S^j = \text{Diag}(\hat{\lambda}_{\max} - \hat{\lambda}^j_{t_j+1}, \ldots, \hat{\lambda}_{\max} - \hat{\lambda}^j_{n_j}).$$

Observe that the computation of M_4 seems to require explicit knowledge of all the eigenvalues and eigenvectors of $(\hat{A}^j, \hat{B}^j)$ rather than just the first t_j. However, a clever observation of Xianjian Ye [17] allows us to compute M_4 using only $\hat{\Lambda}^j_{\max}$ and $\hat{Q}^j_{\max}$. Let

$$T^j = \hat{\lambda}_{\max} \hat{B}^j - \hat{A}^j + \hat{B}^j \hat{Q}^j_{\max} \hat{Q}^j_{\max}{}^T \hat{B}^j.$$

Then the term $\hat{Q}^j_{\text{rest}} (S^j)^{-1} \hat{Q}^j_{\text{rest}}{}^T$ in M_4 is given by

$$\hat{Q}^j_{\text{rest}} (S^j)^{-1} \hat{Q}^j_{\text{rest}}{}^T = (T^j)^{-1} - \hat{Q}^j_{\max} \hat{Q}^j_{\max}{}^T.$$

Hence all references to $\hat{Q}^j_{\text{rest}}$ and $\hat{\Lambda}^j_{\text{rest}}$ can be eliminated from the equations for H^j_{pq}.

In the case $B(x) = I$ there is only one term contributing to the Hessian, namely, $H_{pq,4}$ with $\hat{Z}_p$ and $\hat{Z}_q$ replaced by $\hat{A}_p$ and $\hat{A}_q$, respectively, [13], [16]. All other terms vanish. When $B(x)$ is not constant, even though the second derivatives of $A(x)$ and $B(x)$ are zero since $A(x)$, $B(x)$ are affine, the second derivatives of the Choleski factor $G(x)$ are not. Indeed, they are the matrices $L_{ij}(x)$. This explains the presence of the terms $H_{pq,1}$, $H_{pq,2}$, and $H_{pq,3}$.

We now summarize the local algorithm.

Step 0. Initialize $\hat{x}$.

Step 1. Compute $A(\hat{x})$, $B(\hat{x})$, the Choleski factor $G(\hat{x})$, the multiplicity estimate t, the eigenvalues $\Lambda_{\max}(\hat{x})$, and the eigenvectors $Q_{\max}(\hat{x})$.

Step 2. Compute the matrix K and the vector h from (18).

Step 3. Obtain an estimate $U = U^1 \oplus \cdots \oplus U^l$ of the dual matrix. This is done by computing the least square solution v to the equation

$$K^T v = e_1,$$

where $e_1 = (1, 0, \ldots, 0) \in \Re^{m+1}$. Note that the estimate from a previous iterate is useless because the basis of eigenvectors may have rotated an arbitrary amount. The vector v has dimension

$$\sum_{j=1}^{l} \frac{t_j(t_j+1)}{2}$$

and can be assembled into the matrix U. Compute the eigenvalues of U. If U has a negative eigenvalue, split the maximum eigenvalue as explained in Theorem 3.3 and go to Step 1.

Step 4. Use the dual matrix estimate U to define the matrix W using (19) and solve the equality-constrained quadratic program (11), (12) to obtain a step $\hat{d}$. If $\|\hat{d}\| < 1$, a second order correction is computed to avoid the Maratos effect [6]. This is unnecessary in most cases but the cost is negligible.

Step 5. If $\|\hat{d}\|$ is less than a certain convergence tolerance, stop; otherwise, set $\hat{x} = \hat{x} + \hat{d}$, and go to Step 1.

The iteration just described is locally quadratically convergent to a minimizer of $\lambda_{\max}(x)$. This property is demonstrated by the numerical results in §6. The proof of this assertion, given the appropriate nonsingularity condition, requires extension of the results in [16] and is beyond the scope of this paper.

Observe that no line search is performed. If the new iterate fails to produce a reduction of $\lambda_{\max}$, the step $\hat{d}$ is rejected altogether, and a new step is computed using the method of centers. This is discussed further in the next section.

We conclude this section with a brief discussion of the case that the pencil $(A(x), B(x))$ depends nonlinearly on x. The linear approximations used in the constraints of the quadratic program remain valid, but the matrix W is not. The formula for W is easily generalized to apply to the case where A is nonlinear and B is affine, by including a second derivative term for A [16]. However, the formula for the case that B is nonlinear is far more complicated. Rapidly convergent methods could instead be constructed using quasi-Newton or limited memory quasi-Newton techniques [10] to approximate W. Indeed, because of the complicated form of W and the fact that it is a dense matrix, these may be preferable even for the affine case for moderately large sized problems.

5. The global algorithm. The global algorithm is a two-stage process. In the first stage, a sequence of iterates x^ν is computed using the method of centers (Boyd and El Ghaoui [2]) until the norm of the step $x^{\nu+1} - x^\nu$ is reduced below a certain threshold. In the second stage, we proceed as follows. First, we compute a step d^ν by solving the quadratic problem described in the previous section. If the point $x^\nu + d^\nu$ is feasible, i.e., $B(x^\nu + d^\nu) > 0$, and if d^ν is such that $\lambda_{\max}(x^\nu + d^\nu) < \lambda_{\max}(x^\nu)$, then we set $x^{\nu+1} = x^\nu + d^\nu$. Otherwise, $x^{\nu+1}$ is computed via the method of centers.

The algorithm of Boyd and El Ghaoui is thoroughly discussed in [2], so we sketch only the basic step. Consider the matrix inequality $C(x) > 0$ where $C(x)$ is the block diagonal matrix

$$C(x) = (\rho B(x) - A(x)) \oplus (B(x) - \mu I) \oplus (x_{\sup} I - \mathrm{Diag}(x)) \oplus (x_{\sup} I + \mathrm{Diag}(x)).$$

Here μ is a small constant used to ensure that $B(x)$ remains in the interior of the positive definite cone, while $x_{\sup}$ is a large constant used to ensure that x remains bounded. The quantity ρ is an upper bound on the value of the maximum eigenvalue of the pencil $(A(x), B(x))$. For a fixed ρ let $x^*(\rho)$ denote the analytic center of the inequality $C(x) > 0$, i.e., $x^*(\rho) = \operatorname{argmax} \det C(x)$ [2]. Now for ρ^ν and x^ν with $C(x^\nu) > 0$ let

$$x^{\nu+1} = x^*(\rho^\nu)$$

and

$$\rho^{\nu+1} = (1 - \sigma)\lambda_{\max}(x^\nu) + \sigma\rho^\nu,$$

where $0 < \sigma < 1$ is a parameter kept fixed throughout the algorithm. The analytic center is computed via Newton's method applied to the logarithmic barrier function $\log\det C^{-1}(x)$, using an exact line search for the computation of the step length.

The algorithm [2] applies only to the case that $(A(x), B(x)$ is affine. It should be possible to generalize some of these ideas to the nonlinear case, but as yet this has not been investigated.

6. Numerical results. We now present some numerical results. The algorithms were implemented in MATLAB.

We first consider the example presented in [2]. The matrices $A(x)$ and $B(x)$ are block diagonal with four blocks of dimension 4. There are nine variables. We set $\mu = 0.0001$, $x_{\sup} = 50$, $\sigma = 0.001$. The threshold value κ, determining when to attempt to switch to the local algorithm, is set to 0.01. The vector x is initialized to $(1,1,1,0,0,0,0,0,0)$. The results of the hybrid algorithm are given in Table 1 while Table 2 contains the output from the method of centers alone. In both cases the results use our implementation of the method of centers, as described in [2]. The number N denotes the number of Newton steps required by the inner iteration that computes the analytic center. This is zero once the hybrid algorithm has switched to the local scheme. The expression $\|d\|$ refers to the norm of $x^{\nu+1} - x^{\nu}$. The hybrid algorithm terminates when $\|d\| < 10^{-10}$. In the case of Table 2, the stopping criterion is $\bar{\rho} - \lambda_{\max}(\bar{x}) < 10^{-10}$. The Mflops column displays the number of floating point operations required in millions. The large number of operations reflects the fact that the inner iteration required by the method of centers is being performed accurately; this number could undoubtedly be reduced. The significant point, however, is the following: the global algorithm finds the neighborhood of the solution very reliably, while the use of the local algorithm, once in the neighborhood of the solution, rapidly locates the solution to full precision. Note, specifically, the quadratic convergence of $\|d\|$ to zero once the local scheme is in effect. The eigenvalue $\lambda_{\max}$ has block multiplicities 1, 0, 0, 1 at the computed solution x^*. The hybrid algorithm reduces the gap between $\lambda_1(x^*)$ and $\lambda_2(x^*)$ to 1.4×10^{-15}, while the method of centers reduces it only to 5.4×10^{-7}. The dual matrix U has block dimensions $(1,0,0,1)$, corresponding to the multiplicity of $\lambda_{\max}$, and is computed by the hybrid algorithm in Step 3 of the

local scheme. Its final value is found to be Diag(.583, .417) (to three digits), verifying that the optimality condition (8) is satisfied. Optimality conditions (7) and (9) hold to machine precision.

The second example provides a better test of the new algorithm, since $\lambda_{\max}(x^*)$ has block multiplicities greater than one. There are fifteen variables and the matrices $A(x)$ and $B(x)$ are block diagonal with three blocks, each of dimension 10. The matrix B_0 was set to the identity matrix and the matrices $A_0, \ldots, A_{15}$ and $B_1, \ldots, B_{15}$ were generated using the MATLAB random number generator, and symmetrizing. The matrices $B_1, \ldots, B_{15}$ were then scaled by a factor 0.05 to ensure the existence of a reasonable-sized domain with $B(x) > 0$. All parameters have the same values as in the previous example. The vector x is initialized with a random vector. The results are given in Tables 3 and 4. The hybrid algorithm attempted to switch to the local scheme at the thirteenth step since $\|d^{12}\| < \kappa$. The step was rejected, however, because it

failed to achieve a reduction of $\lambda_{\max}$. The operation count for $\nu = 13$ is the sum of the cost of one local step and one iteration of the method of centers. The same phenomenon occurred at the fourteenth step. The algorithm switched permanently to the local scheme at the fifteenth step and quadratic convergence was established. The last line indicates the limits of double precision computation. The data for this example is available from the authors.

The multiplicity of $\lambda_{\max}$ at the computed solution x^* is 6, with block multiplicities 1, 2, and 3. The hybrid algorithm reduces the gap between λ_1 and λ_6 to 3.3×10^{-16}, while the method of centers reduces the gap to 1.4×10^{-5}. The final dual matrix U has block dimensions $(1, 2, 3)$, satisfies the optimality conditions (7) and (9) to machine precision, and has eigenvalues 0.195 (first block), 0.074, 0.126 (second block), and 0.002, 0.244, and 0.359 (third block), demonstrating that (8) is also satisfied.

7. Conclusion. We have presented an algorithm for the optimization of the maximum eigenvalue of a symmetric definite pencil depending affinely on a vector of parameters. The algorithm combines a scheme based on the method of centers developed by Boyd and El Ghaoui [2] and a new local scheme exhibiting quadratically convergent behavior. The local scheme is an extension of the methods introduced in [13], [14], and [16] to the case of matrix pencils.

ROW SUMS AND INVERSE ROW SUMS FOR NONNEGATIVE MATRICES *

SHMUEL FRIEDLAND[†1], ROHAN HEMASINHA[‡], HANS SCHNEIDER[§1], JEFFREY STUART[¶1], AND JAMES WEAVER[‡1]

Abstract. For a nonnegative, irreducible matrix A, the grading of the row sums vector and the grading of the Perron vector are used to predict the grading of the row sums vector of $(I - A)^{-1}$. This has applications to Markov chains.

Key words. row sums, inverse row sums, Markov chain, nonnegative matrix

AMS subject classifications. 15A48, 15A42

0. Motivation. Let T be a row stochastic matrix. It is well known that the matrix T is the transition matrix associated with an absorbing Markov chain if and only if T is permutation similar to a matrix of the form

$$T = \begin{bmatrix} I & 0 \\ B & A \end{bmatrix},$$

where A is a square matrix with $\rho(A) < 1$ [BP, Thm. 8.3.21]. Furthermore, if F is the set of indices corresponding to the nonabsorbing, i.e., transient, states then the expected number of steps until absorption when starting in the nonabsorbing state i is given by

$$\sum_{j \in F} [(I - A)^{-1}]_{ij}$$

[BP, Thm. 8.4.27]. This leads to the natural question of what can be said about the row sums of the matrix $(I - A)^{-1}$ given some knowledge about the matrix A. In particular, what can we predict about the maximum and minimum row sums of $(I - A)^{-1}$ given the row sums of A and the Perron vector for A?

1. Notation. For an $n \times n$ matrix A, let $\rho = \rho(A)$ denote the spectral radius of A. The real matrix A will be called nonnegative, denoted $A \geq 0$, if each entry of A is nonnegative. If A is nonnegative and irreducible, let $X = X_A$ denote the Perron vector of euclidean norm one for A; that is, X is the unique strictly positive eigenvector of norm one corresponding to the eigenvalue $\rho(A)$. Unless otherwise specified, the matrix A will always be an $n \times n$ nonnegative matrix.

Let $v = (v_1, v_2, \dots, v_n)^t \in \mathbb{R}^n$. There exists a permutation σ such that $v_{\sigma(1)} \geq v_{\sigma(2)} \geq \cdots \geq v_{\sigma(n)}$. The integer vector $(\sigma^{-1}(1), \sigma^{-1}(2), \dots, \sigma^{-1}(n))^t$ is called a grading of v. If the entries of v are pairwise distinct, then v has a unique grading and v is called a strictly graded vector. A set of vectors is said to share a common grading if the intersection of their sets of gradings is nonempty.

For $1 \leq i \leq n$, let e_i denote the ith standard basis vector for $\mathbb{R}^n$. Let $u = u_n$ denote the vector of ones. That is,

$$u_n = \sum_{i=1}^{n} e_i.$$

Let $D = D_n$ denote the cone in $\mathbb{R}^n$ generated by the vectors $e_1, e_1 + e_2, e_1 + e_2 + e_3, \dots, u_n$; that is, $D = \{v \in \mathbb{R}^n\colon\ v_1 \geq v_2 \geq \cdots \geq v_n \geq 0\}$. Let $\Pi(D)$ denote the class of D-preserving matrices: $\Pi(D) = \{A \in \mathcal{M}_n(\mathbb{R})\colon\ A(D) \subseteq D\}$.

Note that a nonnegative vector $v \in \mathbb{R}^n$ has its entries in decreasing order if and only if $v \in D$, and that v has its entries in strictly decreasing order if and only if $v \in \operatorname{int}(D)$, where $\operatorname{int}(D)$ denotes the interior of D. Also note that if $A \in \Pi(D)$, then $A^k \in \Pi(D)$ for all positive integers k. Finally note that the row sums of the matrix A are precisely the entries of the vector Au.

LEMMA 1.1. *If A is a nonnegative, primitive matrix with $\rho(A) < 1$, such that $Au, (I - A)^{-1}u$, and X_A share a common (strict) grading, then there exists a permutation matrix P such that $PAP^tu, (I - PAP^t)^{-1}u$, and PX_A are all in $(\operatorname{int}(D))D$. Furthermore, $PX_A = X_{PAP^t}$.*

Proof. Let $v = Au$. Let the permutation matrix P correspond to the common permutation σ in the definition of grading. Then $PAP^tu = PAu \in D$. Since $\rho < 1, (I-A)^{-1}$ exists. Since $P(I-A)^{-1}P^t = (I-PAP^t)^{-1}$, and since Au and $(I-A)^{-1}u$ share the common grading $\sigma, (I-PAP^t)^{-1}u = (I-PAP^t)^{-1}P^tu = P(I-A)^{-1}u \in D$. Finally, X is an eigenvector for ρ for A if and only if PX is an eigenvector for ρ for PAP^t. Since multiplication by P is norm preserving and since PAP^t is nonnegative and primitive, $X_{PAP^t} = PX_A$. Note that σ is a common grading for Au and X_A, so $PX_A \in D$. □

One immediate consequence of this lemma is that we can always assume that a graded vector has its entries in decreasing order. Thus questions about graded vectors are transformed to questions about vector membership in the cone D.

Finally, recall the Neumann expansion for the inverse of the matrix $I - A$.

THEOREM 1.2 [O]. *Let A be an $n \times n$ real matrix with $\rho(A) < 1$. Then $(I - A)^{-1}$ exists, and*

$$(I - A)^{-1} = I_n + \sum_{k=1}^{\infty} A^k.$$

2. Empirical evidence. If A is nonnegative and primitive, then by the power method, $A^ku \approx c_kX_A$ for large k. Furthermore, if $\rho(A) < 1$, then $c_k \to 0$ as $k \to \infty$. Also, $\rho(A) < 1$ implies

$$(I - A)^{-1} u = u + \sum_{k=1}^{\infty} A^k u.$$

This suggests that the grading for $(I - A)^{-1}u$ should be linked to the grading for X_A, and that the early terms in the summation should be the most important. Since

$(I - A)^{-1}u$ and $(I - A)^{-1}u - u$ have the same grading, and since

$$(I - A)^{-1} u - u = Au + \sum_{k=2}^{\infty} A^k u,$$

the importance of the grading of Au is immediately apparent. When Au and X share a common grading, it remains to be seen how much of an effect the remaining low order summands have on the grading of $(I - A)^{-1}u$.

Motivated by numerical experiments conducted using MATLAB on an APOLLO workstation, we were led to several conjectures. The first was that if Au, X, and $(I - A)^{-1}u$ all share a common grading, then that grading is shared by A^k for all positive k. The second and more interesting conjecture was that if Au and X share a common grading, then $(I - A)^{-1}u$ also shares that grading. Unfortunately, neither conjecture holds.

If

$$A = \begin{bmatrix} 0.0783 & 0.2999 & 0.2421 & 0.0089 \\ 0.0305 & 0.0003 & 0.1814 & 0.2272 \\ 0.0013 & 0.1196 & 0.1426 & 0.1305 \\ 0.0008 & 0.0005 & 0.0009 & 0.0003 \end{bmatrix},$$

then

$$Au = \begin{bmatrix} 0.6292 \\ 0.4394 \\ 0.3940 \\ 0.0025 \end{bmatrix}, \quad X = \begin{bmatrix} 0.8954 \\ 0.3166 \\ 0.3131 \\ 0.0043 \end{bmatrix}, \quad \text{and} \quad (I - A)^{-1} u = \begin{bmatrix} 2.0101 \\ 1.5695 \\ 1.5411 \\ 1.0041 \end{bmatrix}.$$

Hence, Au, X, and $(I - A)^{-1}u$ are all in D. However,

$$A^2 u = \begin{bmatrix} 0.2765 \\ 0.0914 \\ 0.1099 \\ 0.0011 \end{bmatrix},$$

which is not in D since its second and third entries are not in decreasing order.

Discovering a counterexample to the second conjecture proved to be very difficult. The following matrix was one of only four counterexamples generated during a run of 25,000 randomly generated, rank four, strictly positive 4×4 matrices with spectral radius less than one. In fact, for 67% of the matrices generated in that run, all three vectors—Au, X, and $(I - A)^{-1}u$—shared a common grading.

$$A = \begin{bmatrix} 0.2042 & 0.2837 & 0.0196 & 0.2356 \\ 0.1522 & 0.2149 & 0.0320 & 0.2848 \\ 0.1060 & 0.2072 & 0.1289 & 0.2415 \\ 0.2750 & 0.1958 & 0.0805 & 0.0187 \end{bmatrix},$$

then

$$Au = \begin{bmatrix} 0.7431 \\ 0.6839 \\ 0.6836 \\ 0.5700 \end{bmatrix}, \quad X = \begin{bmatrix} 0.5513 \\ 0.4991 \\ 0.4987 \\ 0.4452 \end{bmatrix}, \quad \text{and} \quad (I - A)^{-1} u = \begin{bmatrix} 3.2356 \\ 3.0330 \\ 3.0338 \\ 2.7799 \end{bmatrix}.$$

Hence Au and X are in D, however, $(I - A)^{-1}u$ is not in D.

A run of 100,000 randomly generated, rank three, strictly positive 4×4 matrices with spectral radius less than one yielded only one counterexample. Furthermore, for this run, 91% of the matrices had all vectors sharing a common grading, and an additional 3% had the Perron vector and the inverse row sums vector (but not the row sums vector) sharing a common grading.

Extensive numerical experiments with matrices of sizes up to 50×50 lead to the following observations. First, for low rank matrices, the grading of X is a good predictor for the grading of $(I - A)^{-1}u$. Second, even when the vectors do not share a common grading, they share a roughly blocked common grading in the sense that the grading vectors differ within blocks corresponding to closely sized entries of the vectors. In particular, the set of indices for the smallest (largest) row sums of A correspond roughly to the set of indices of the smallest (largest) entries of the Perron vector and to the set of indices of the smallest (largest) row sums of $(I - A)^{-1}$.

3. An analytic approach. In this section, we present several different types of results including an examination of certain classes of matrices for which the grading of the Perron vector and the row sums vector do determine the grading for the inverse row sums vector.

PROPOSITION 3.1. *Let A be an $n \times n$ nonnegative, irreducible matrix with $\rho = \rho(A) < 1$. Suppose that $X = X_A \in D$. For $1 \leq i \leq n$,*

$$(1 - \rho)^{-1} \frac{x_i}{x_1} \leq [(I - A)^{-1} u]_i \leq (1 - \rho)^{-1} \frac{x_i}{x_n}.$$

Proof. Since $A \geq 0$, and $\rho < 1, I - A$ is an invertible M-matrix. Thus $(I - A)^{-1} \geq 0$ [BP, Thm. 6.2.3]. Since $X \in D$ and X is strictly positive, $x_1 \geq \cdots \geq x_n > 0$. Note that $(I - A)^{-1}X = (1 - \rho)^{-1}X$. Thus for $1 \leq i \leq n$,

$$\begin{aligned}(1 - \rho)^{-1} x_i &= \sum_j [(I - A)^{-1}]_{ij} x_j \\ &\leq \sum_j [(I - A)^{-1}]_{ij} x_1 = [(I - A)^{-1} u]_i x_1.\end{aligned}$$

Similarly, the other bound holds. □

THEOREM 3.2. *Let A be a nonnegative, irreducible matrix with $\rho(A) < 1$. If $A \in \Pi(D)$, then Au, X_A and $(I - A)^{-1}u$ are all in D.*

Proof. Since $u \in D$, and since $A^k \in \Pi(D)$ for all positive $k, A^k u \in D$ for all positive k. Since $\rho(A) < 1$, it follows from Theorem 1.2 that $(I - A)^{-1}u = u + \sum_{k=1}^{\infty} A^k u \in D$. Finally since A is nonnegative and irreducible, X_A exists, and by the Krein–Rutman Theorem [BP, Thm. 1.3.2], $A \in \Pi(D)$ implies $X_A \in D$. □

COROLLARY 3.3. *Let A be a nonnegative, irreducible $n \times n$ matrix with $\rho(A) < 1$. If $a_{ij} \geq a_{i+1,j}$ for $1 \leq i \leq n - 1$ and $1 \leq j \leq n$, then Au, X_A, and $(I - A)^{-1}u$ are all in D.*

Proof. Pick $z \in D$. Note that $z \geq 0$ and $A \geq 0$. Thus for $1 \leq i \leq n - 1$,

$$(Az)_i = \sum_j a_{ij} z_j \geq \sum_j a_{i+1,j} z_j = (Az)_{i+1} \geq 0.$$

Hence $Az \in D$. □

THEOREM 3.4. *Let A be a nonnegative, irreducible $n \times n$ matrix with $\rho = \rho(A) < 1$. Suppose that the minimum polynomial of A is $m_A(\lambda) = \lambda^k(\lambda - \rho)$. Then*

$(I - A)^{-1} = I + A + \cdots + A^{k-1} + (1-\rho)^{-1}A^k$. *Suppose that* $Au, \ldots, A^{k-1}u$ *are in* D. *If either of* X_A *and* $A^k u$ *is in* D, *then all three of* $X_A, A^k u$, *and* $(I-A)^{-1}u$ *are in* D. *Finally, if at least one of* $X_A, Au, \ldots, A^k u$ *is in* $\operatorname{int}(D)$, *then* $(I-A)^{-1}u$ *is in* $\operatorname{int}(D)$.

Proof. Let $X = X_A$. Then $A = \rho XY^t + N$ where Y^t is the strictly positive row eigenvector for ρ such that $Y^t X = 1$, and where N is the nilpotent matrix of index k satisfying $NX = 0$ and $Y^t N = 0^t$. For all nonnegative r, $A^{k+r} = \rho^{k+r} XY^t = \rho^r A^k$. Hence

$$\sum_{r=k}^{\infty} A^r = \sum_{r=0}^{\infty} \rho^r A^k = (1-\rho)^{-1} A^k.$$

Thus $(I-A)^{-1} = I + A + \cdots + (1-\rho)^{-1}A^k$. Since $A^k u = \rho^k (Y^t u)X$, X is in D if and only if $A^k u$ is in D. Since $u \in D$, it follows that $(I-A)^{-1}u \in D$ when $Au, \ldots, A^k u$ are in D. Furthermore, if one of the summands is in $\operatorname{int}(D)$, then it is clear that $(I-A)^{-1}u$ is in $\operatorname{int}(D)$. □

COROLLARY 3.5. *Let* A *be a nonnegative, irreducible* $n \times n$ *matrix with* $\rho = \rho(A) < 1$. *If* $\operatorname{rank}(A) = 1$ *and if* $Au \in D$, *then* X_A *and* $(I-A)^{-1}u$ *are in* D.

THEOREM 3.6. *Let* A *be a nonnegative, irreducible* $n \times n$ *matrix with* $\rho = \rho(A) < 1$. *Suppose that the minimum polynomial of* A *is either* $m_A(\lambda) = \lambda(\lambda - \rho)(\lambda - \lambda_1)$ *or else* $m_A(\lambda) = (\lambda - \rho)(\lambda - \lambda_1)$, *where* $\lambda_1 \neq 0$. *If* X_A *and* Au *are in* D, *then* $(I-A)^{-1}u$ *is in* D. *Furthermore, if* Au *is in* $\operatorname{int}(D)$, *then* $(I-A)^{-1}u$ *is in* $\operatorname{int}(D)$.

Proof. Let $X = X_A$. Then $A = \rho XY^t + \lambda_1 E$, where Y^t is the strictly positive row eigenvector for ρ satisfying $Y^t X = 1$, and where $E^2 = E$, $EX = 0$, and $Y^t E = 0^t$. For each positive k, $A^k = \rho^k XY^t + \lambda_1^k E$. Since $\rho < 1$, $(I-A)^{-1} = I + \rho(1-\rho)^{-1}XY^t + \lambda_1(1-\lambda_1)^{-1}E$. Then $(I-A)^{-1}u = u + \rho(1-\rho)^{-1}(Y^t u)X + \lambda_1(1-\lambda_1)^{-1}Eu$. Since $\lambda_1 < \rho < 1, 0 < (1-\lambda_1)^{-1} < (1-\rho)^{-1}$. Clearly, $Au \geq 0$. Now $Au \in D$ if and only if for $1 \leq i \leq n-1$,

$$\begin{aligned}
&(Au)_i \geq (Au)_{i+1} \\
&\quad \Leftrightarrow \rho\,(Y^t u)\,X_i + \lambda_1\,(Eu)_i \geq \rho\,(Y^t u)\,X_{i+1} + \lambda_1\,(Eu)_{i+1} \\
&\quad \Leftrightarrow \rho\,(Y^t u)\,[X_i - X_{i+1}] \geq \lambda_1\left[(Eu)_{i+1} - (Eu)_i\right] \\
&\quad \Leftrightarrow \rho\,(1-\rho)^{-1}\,(Y^t u)\,[X_i - X_{i+1}] \geq \lambda_1\,(1-\rho)^{-1}\left[(Eu)_{i+1} - (Eu)_i\right].
\end{aligned}$$

Since $X \in D$, the left-hand side of the last inequality is nonnegative; hence the inequality remains valid when $(1-\rho)^{-1}$ is replaced with $(1-\lambda_1)^{-1}$ on the right-hand side. Thus it holds that

$$\begin{aligned}
&(Au)_i \geq (Au)_{i+1} \\
&\quad \Rightarrow \rho\,(1-\rho)^{-1}\,(Y^t u)\,[X_i - X_{i+1}] \geq \lambda_1\,(1-\lambda_1)^{-1}\left[(Eu)_{i+1} - (Eu)_i\right] \\
&\quad \Leftrightarrow \rho\,(1-\rho)^{-1}\,(Y^t u)\,X_i + \lambda_1\,(1-\lambda_1)^{-1}\,(Eu)_i \\
&\qquad \geq \rho\,(1-\rho)^{-1}\,(Y^t u)\,X_{i+1} + \lambda_1\,(1-\lambda_1)^{-1}\,(Eu)_{i+1}.
\end{aligned}$$

That is, $Au \in D$ and $X \in D$ together imply $\rho(1-\rho)^{-1}(Y^t u)X + \lambda_1(1-\lambda_1)^{-1}Eu \in D$. That is, $(I-A)^{-1}u - u \in D$. Since $u \in D$, $(I-A)^{-1}u \in D$. Furthermore, if $Au \in \operatorname{int}(D)$, then for all i, each inequality in the argument above can be replaced with a strict inequality, hence $(I-A)^{-1}u \in \operatorname{int}(D)$. □

Remark. Let A be an $n \times n$, nonnegative, irreducible matrix with $\rho(A) < 1$. For $n \leq 3$, there are only two cases for A that are not covered in the results above: when

A is 3×3, nonsingular, and either A is not diagonalizable or A has three distinct eigenvalues. All cases for $n = 3$ are contained in Theorem 4.6.

Let A be a nonnegative, irreducible matrix with $\rho(A) < 1$. In view of the preceding results, several natural open questions arise. Suppose that the minimum polynomial for A has degree k. If each of $X_A, Au, A^2u, \ldots, A^{k-1}u$ are in D, does that imply that $(I - A)^{-1}u$ is in D? Does it imply that $A^r u$ is in D for all positive r? If not, what additional restrictions might be sufficient on A or on the minimum polynomial?

4. A second analytic approach.

THEOREM 4.1. *Let B be an $n \times n$ complex matrix with $\rho(B) = 1$. Then there exists a unique positive integer k with $k < n$, and there exist $n \times n$ complex matrices $B_1, \ldots, B_k$ with $B_k \neq 0$ such that* $\operatorname{adj}(I - xB) = I + xB_1 + x^2B_2 + \cdots + x^kB_k$. *Furthermore,*

(i) $k = n - 1$ *if and only if* $\operatorname{rank}(B) \geq n - 1$;

(ii) *if $k < n - 1$, then $k = m + t - 1$, where m is the number of nonzero eigenvalues of B (counting multiplicities), and where t is the size of the largest Jordan block corresponding to the eigenvalue 0 for B.*

Proof. Since each entry of $\operatorname{adj}(I - xB)$ is either zero or (± 1) times an $(n - 1) \times (n - 1)$ minor of $(I - xB)$, it follows that $k \leq n - 1$. Thus $\operatorname{adj}(I - xB) = B_0 + xB_1 + x^2B_2 + \cdots + x^{n-1}B_{n-1}$. Setting $x = 0, B_0 = \operatorname{adj}(I - 0B) = I$. Note that the coefficient matrix for x^{n-1} is generated only by terms from $-xB$. That is, $B_{n-1} = \operatorname{adj}(-B)$. Note that $\operatorname{adj}(-B) = 0$ if and only if every $(n - 1) \times (n - 1)$ minor of B is zero. That is, if and only if $\operatorname{rank}(B) < n - 1$. Thus (i) is proven.

If S is an invertible matrix, then $S = [\det(S)]\operatorname{adj}(S^{-1})$. Thus $S \operatorname{adj}(I - xB)S^{-1} = \operatorname{adj}(S^{-1})\operatorname{adj}(I - xB)\operatorname{adj}(S) = \operatorname{adj}(S(I - xB)S^{-1}) = \operatorname{adj}(I - xSBS^{-1})$. Thus

$$\operatorname{adj}(I - xSBS^{-1}) = I + xSB_1S^{-1} + x^2SB_2S^{-1} + \cdots + x^{n-1}SB_{n-1}S^{-1}.$$

Choose S so that SBS^{-1} is the Jordan canonical form of B. That is, $SBS^{-1} = J_1 \oplus \cdots \oplus J_r \oplus J_{r+1} \oplus \cdots \oplus J_s$, where the J_α for $1 \leq \alpha \leq r$ are the Jordan blocks corresponding to nonzero eigenvalues, and the J_α for $r < \alpha \leq s$ are the Jordan blocks corresponding to the eigenvalue zero. Then

$$\operatorname{adj}(I - xSBS^{-1}) = \bigoplus_{\alpha=1}^{s} \left[\operatorname{adj}(I - xJ_\alpha) \prod_{\beta \neq \alpha} \det(I - xJ_\beta) \right].$$

Consider the adjoint for a single Jordan block: $J = \lambda I_h + N_h$, where N_h is the $h \times h$ matrix whose only nonzero entries are ones down the superdiagonal. $\operatorname{Adj}(I - xJ)$ has diagonal entries $(1 - x\lambda)^{h-1}$, and the nonzero off-diagonal terms are of the form $(-x)^j(1 - x\lambda)^{h-j-1}$ for $1 \leq j \leq h - 1$. When $\lambda \neq 0$, the maximum degree of x in $\operatorname{adj}(I - xJ)$ is $h - 1$. When $\lambda = 0, (-x)^{h-1}$ is the only type of nonzero term. Thus $\operatorname{adj}(I - xJ)$ is always of degree $h - 1$ in x. Note that $\det(I - xJ) = (1 - x\lambda)^h$. When $\lambda \neq 0, \det(I - xJ)$ is of degree h in x. When $\lambda = 0, \det(I - xJ)$ is of degree zero in x. Consequently, the maximum degree of x in $\Pi_{\alpha=1}^{s} \det(I - xJ_\alpha)$ is precisely the sum of the sizes of $J_1, J_2, \ldots, J_r$. That is, $\Pi_{\alpha=1}^{s} \det(I - xJ_\alpha)$ is of degree m in x. Hence for $1 \leq \alpha \leq r, \operatorname{adj}(I - xJ_\alpha)\ \Pi_{\beta \neq \alpha} \det(I - xJ_\beta)$ is of degree $(h_\alpha - 1) + (m - h_\alpha)$, where h_α is the size of J_α. For $r < \alpha \leq s, \operatorname{adj}(I - xJ_\alpha)\ \Pi_{\beta \neq \alpha} \det(I - xJ_\beta)$ is of degree $(h_\alpha - 1) + (m - 0)$, where h_α is the size of J_α. Thus the maximum degree of x in $\operatorname{adj}(I - xSBS^{-1})$ and, hence, in $\operatorname{adj}(I - xB)$ is $m + t - 1$, where t is the size of the largest Jordan block for the eigenvalue zero. □

COROLLARY 4.2. *Let A be a nonnegative, irreducible matrix. The following are equivalent*:

(i) $\operatorname{adj}(I - xA) = I + xA_1 + x^2A_2$,

(ii) *at least one of the following holds*;

(a) $n \leq 3$,

(b) $n > 3$ *and* $\operatorname{rank}(A) \leq 2$,

(c) $n > 3$ *and* $\operatorname{rank}(A^2) = 1$.

Note that conditions (b) *and* (c) *imply that the size of the largest possible Jordan block for the eigenvalue zero is two.*

Proof (i) $\rightarrow$ (ii). If $A_2 \neq 0$ then either $2 = n - 1$, hence $n = 3$, or else $2 < n - 1$ and $2 = m + t - 1$. That is, $n > 3$ and $m + t = 3$. Since A is irreducible, $m \geq 1$. Since $t = 0$ implies $m = n, t \geq 1$. Thus either $m = 2$ and $t = 1$, implying $\operatorname{rank}(A) = 2$ or $m = 1$ and $t = 2$, implying $\operatorname{rank}(A^2) = 1$.

If $A_2 = 0$, but $A_1 \neq 0$, then either $1 = n - 1$, hence $n = 2$, or $1 < n - 1$ and $1 = m + t - 1$. In the latter case, $n > 2$ and $m + t = 2$, implying $m = t = 1$. That is, $\operatorname{rank}(A) = 1$.

If $A_2 = A_1 = 0$, then $A = 0$, which contradicts the irreducibility of A. □

Proof (ii) $\rightarrow$ (i) If $n \leq 3$, (i) is immediate. If $n > 3$ and $\operatorname{rank}(A) \leq 2$, then since $m + (t - 1) \leq \operatorname{rank}(A)$ always, $k = m + t - 1 \leq 2$. Now apply Theorem 4.1. Finally, if $n > 3$ and $\operatorname{rank}(A^2) = 1$, then $\rho(A)$ is the unique nonzero eigenvalue and $m = 1$. Clearly, $\operatorname{rank}(A^2) \leq 1$ implies $t \leq 2$. Again, $k = m + t - 1 \leq 2$. Apply Theorem 4.1. □

LEMMA 4.3. *Let B be a nonnegative, irreducible matrix with $\rho(B) = 1$. If $Bu \in \operatorname{int}(D)$, then there exists a maximal $\omega = \omega(B)$ such that $0 < \omega \leq 1$, and such that $(I - xB)^{-1}u \in \operatorname{int}(D)$ for $0 < x < \omega$.*

Proof. Since $\rho(B) = 1, 0 < \|B\|_2 \leq 1$. Then $\|B\|_2^k \leq 1$ for all $k \geq 0$. Assume that $0 < x < 1$. Then for $1 \leq i \leq n$,

$$\left|\left[x^2B^2\left[\sum_{k=0}^{\infty} x^kB^k\right]u\right]_i\right| \leq \left\|\left[x^2B^2\sum_{k=0}^{\infty} x^kB^k\right]u\right\|_2 \leq x^2\|B\|_2^2\left[\sum_{k=0}^{\infty} x^k\|B\|_2^k\right]\|u\|_2$$

$$\leq x^2\|B\|_2^2\left[\sum_{k=0}^{\infty} x^k\right]\|u\|_2 = x^2\|B\|_2^2(1-x)^{-1}\|u\|_2.$$

Since $0 \leq x < 1$, Lemma 1.2 yields

$$(I - xB)^{-1}u = u + xBu + x^2B^2\left[\sum_{k=0}^{\infty} x^kB^k\right]u.$$

For $1 \leq j < n$,

$$[(I - xB)^{-1}u]_j \geq 1 + x[Bu]_j$$

and

$$[(I - xB)^{-1}u]_{j+1} = 1 + x[Bu]_{j+1} + \left[\left[x^2B^2\sum_{k=0}^{\infty} x^kB^k\right]u\right]_{j+1}$$

$$\leq 1 + x[Bu]_{j+1} + x^2\|B\|_2^2(1-x)^{-1}\|u\|_2.$$

It follows that

$$[(I - xB)^{-1}u]_j - [(I - xB)^{-1}u]_{j+1}$$

$$\geq x\left[[Bu]_j - [Bu]_{j+1} - x\|B\|_2^2(1-x)^{-1}\|u\|_2\right].$$

Since $Bu \in \text{int}(D)$, the difference $[Bu]_j - [Bu]_{j+1}$ is strictly positive for $1 \leq j < n$. Thus for sufficiently small, positive x, the terms $[(I-xB)^{-1}u]_j$ are strictly decreasing. Since $I - xB$ is a nonsingular M–matrix for $0 < x < 1, (I - xB)^{-1}u \geq 0$ [BP, Thm. 6.2.3]. Thus $(I - xB)^{-1}u \in \text{int}(D)$ for sufficiently small positive x. Thus ω exists. □

LEMMA 4.4. *Let B be a nonnegative, irreducible matrix with $\rho(B) = 1$. If $X_B \in \text{int}(D)$, then there exists a minimal $\tau = \tau(B)$ such that $0 \leq \tau < 1$, and such that $(I - xB)^{-1}u \in \text{int}(D)$ for $\tau < x < 1$.*

Proof. Let $f(x)$ be the matrix valued function $f(x) = \text{adj}(I - xB)$. Note that $f(x)$ is continuous for all real x. For $0 < x < 1, I - xB$ is an irreducible, nonsingular M–matrix, hence $\det(I-xB) > 0$ and $(I-xB)^{-1}$ is strictly positive [BP, Thm. 6.2.3]. Since $(I - xB)^{-1} = \det(I - xB)\text{adj}(I - xB)$, it follows that $f(x)$ is strictly positive for $0 < x < 1$. Note also, for each x in $0 < x < 1, f(x)u \in \text{int}(D)$ if and only if $(I - xB)^{-1}u \in \text{int}(D)$.

Since B is nonnegative and irreducible, $\rho(B) = 1$ is a simple eigenvalue for B. Thus $\text{rank}(I - B) = n - 1$. Thus $\text{adj}(I - B) \neq 0$. Since $I - B$ has nullity one, its column null space has basis $\{X_B\}$ and its row null space has basis $\{[X_{B^t}]^t\}$. Since $\det(I - B) = 0$, for $x = 1$,

$$(I - xB)\text{adj}(I - xB) = [\text{adj}(I - B)]\,(I - B) = 0.$$

Thus $f(1) = \text{adj}(I - B) = cX_B[X_{B^t}]^t$ for some nonzero scalar c. Since $f(x)$ is continuous at $x = 1$, and since $f(x)$ is strictly positive for $0 < x < 1, f(1)$ is nonnegative. That is, $c > 0$. Then $f(1)u = [c[X_{B^t}]^t u]X_B$ is a positive multiple of X_B, hence $f(1)u \in \text{int}(D)$. Again using continuity at $x = 1$, it follows that τ exists such that $\tau < 1$ and $f(x)u \in \text{int}(D)$ for $\tau < x < 1$. Observe that $\tau \geq 0$ since $f(0)u = Iu \notin \text{int}(D)$. □

The following theorem is an immediate consequence of Lemmas 4.3 and 4.4.

THEOREM 4.5. *Let B be a nonnegative, irreducible matrix with $\rho(B) = 1$. Suppose that Bu and X_B are in $\text{int}(D)$. Let $\omega(B)$ be defined as in Lemma 4.3, and let $\tau(B)$ be defined as in Lemma 4.4. If $\tau(B) < \omega(B)$, then: $\tau(B) = 0, \omega(B) = 1, (I - xB)^{-1} \in \text{int}(D)$ for $0 < x < 1$, and $\text{adj}(I - xB)u \in \text{int}(D)$ for $0 \leq x \leq 1$.*

We currently have no useful general characterization of which matrices B satisfy the condition $\tau(B) < \omega(B)$. The numerical evidence presented in the second section, however, suggests that a substantial portion of the matrices B, such that Bu and X_B share a common grading, do satisfy this condition.

THEOREM 4.6. *Let A be a nonnegative, irreducible matrix with $\rho(A) < 1$. Suppose that A satisfies either* (i) *or* (ii) *in Corollary 4.2. If both Au and X_A are in $\text{int}(D)$, then $(I - A)^{-1}u$ is in $\text{int}(D)$.*

Proof. Let $\rho = \rho(A)$. Let $B = \rho^{-1}A$. Then B is a nonnegative, irreducible matrix with $\rho(B) = 1$. Clearly, $X_B = X_A$. Use (i): $\text{adj}(I - xB) = I + xB_1 + x^2B_2 = I + x(B_1 + xB_2)$. For $x > 0, \text{adj}(I - xB)u$ and $(B_1 + xB_2)u$ have the same gradings. In particular, $\text{adj}(I - xB)u \in \text{int}(D)$ if and only if $(B_1 + xB_2)u \in \text{int}(D)$. Note that for each $i, [(B_1 + xB_2)u]_i$ is a linear function in x. Pick i with $1 \leq i < n$. Let α and β be real numbers such that $\alpha < \beta$. If $[(B_1 + \alpha B_2)u]_i \geq [(B_1 + \alpha B_2)u]_{i+1}$ and if $[(B_1 + \beta B_2)u]_i \geq [(B_1 + \beta B_2)u]_{i+1}$ hold, then by linearity in $x, [(B_1 + xB_2)u]_i \geq [(B_1 + xB_2)u]_{i+1}$ holds for $\alpha \leq x \leq \beta$. Furthermore, if the inequality is strict at either endpoint, then it is strict for $\alpha < x < \beta$.

By hypothesis, $Au \in \text{int}(D)$, hence $Bu \in \text{int}(D)$. Applying Lemma 4.3, there exists ω with $0 < \omega < 1$ such that $(I - xB)^{-1}u \in \text{int}(D)$ for $0 < x < \omega$. For

$0 < x < 1, I - xB$ is a nonsingular M–matrix, and as argued in the proof of Lemma 4.4, $(I - xB)^{-1}u$ is a positive scalar multiple of $\text{adj}(I - xB)u$. Thus, $\text{adj}(I - xB)u \in \text{int}(D)$ for $0 < x < \omega$. Also by hypothesis, $X_B \in \text{int}(D)$, hence from Lemma 4.4 and its proof, there exists a positive τ with $\tau < 1$ such that $\text{adj}(I - xB)u \in \text{int}(D)$ for $\tau < x \leq 1$.

The argument in the preceding paragraph implies that when α is chosen as an arbitrarily small, positive number and when $\beta = 1$, the inequalities for successive entries of $(B_1 + xB_2)u$ are valid and strict for $\alpha < x < \beta$. Thus $\text{adj}(I - xB)u \in \text{int}(D)$ for $0 < x \leq 1$. Hence $(I - xB)^{-1}u \in \text{int}(D)$ for $0 < x < 1$. Since $0 < \rho(A) < 1$, and since $\rho(A)B = A, (I - A)^{-1}u \in \text{int}(D)$. □

The following example shows that the conclusion of Theorem 4.6 can be false if the condition that $Au \in \text{int}(D)$ is dropped. Let $X = (3, 2, 1)^t$. Let B be the parameterized matrix

$$B = \begin{bmatrix} 1 - r & r & r \\ r & r & 2 - 5r \\ \frac{1}{6} & \frac{1}{6} & \frac{1}{6} \end{bmatrix}.$$

For all $r, BX = X$ and $Bu = (1 + r, 2 - 3r, \frac{1}{2})^t$. For $0 < x < 1$ and $0 < r < \frac{1}{4}, A = xB$ is a nonnegative, irreducible matrix with $\rho(A) = x < 1$. Since A is $3 \times 3, A$ satisfies condition (ii) of Corollary 4.2. Clearly $X_A \in \text{int}(D)$. Note, however, that $Au \notin D$ when $0 < r < \frac{1}{4}$. From Theorem 1.2, $(I - xB)^{-1}u \approx Iu + xBu$ for small, positive x. Thus $(I - A)^{-1}u \notin D$ when $0 < r < \frac{1}{4}$.

5. Exploiting permutation invariance. In the context of this paper, circulant matrices have three important properties. If A is a circulant matrix, then u is an eigenvector for both A and $(I - A)^{-1}, \rho = \rho(A)$ is the unique row sum of A, and $(1 - \rho)^{-1}$ is the unique row sum of $(I - A)^{-1}$. Noting that the circulant matrices are precisely those matrices invariant under permutation similarity by the matrix for the full cycle permutation, we now examine how any permutation invariance can be exploited.

Let A be an $n \times n$, nonnegative, irreducible matrix with spectral radius $\rho(A)$. Suppose that P is a permutation matrix such that $PAP^t = A$. Clearly, $Pu = u$. Furthermore, $P(Au) = Au$ and $P[(I - A)^{-1}u] = (I - A)^{-1}u$. Also, $PAP^t = A$ implies PX_A is a positive eigenvector for $\rho(A)$ with norm one, hence $PX_A = X_A$. Thus the cycle structure of P is reflected in a pattern of constant blocks in the vectors X_A, Au, and $(I - A)^{-1}u$.

Assume that the permutation corresponding to P decomposes into k disjoint cycles. Let $\mathcal{V}$ denote the eigenspace for P for the eigenvalue $\lambda = 1$. Then $\mathcal{V}$ is a k-dimensional subspace of $\mathbb{R}^n$ with a natural basis consisting of certain $\{0, 1\}$ vectors. See [SW, §3]. Furthermore, $u_n \in \mathcal{V}$. Since A and P commute, $\mathcal{V}$ is an A-invariant space. Let M be the $k \times k$ matrix representing the restriction of A to $\mathcal{V}$ with respect to the natural basis. The following can be proven:

(i) M is a nonnegative, irreducible matrix with $\rho(M) = \rho(A)$.

(ii) Each entry of Mu_k is the value of all of the entries in the corresponding block of Au_n.

(iii) Each entry of $(I_k - M)^{-1}u_k$ is the value of all of the entries in the corresponding block of $(I_n - A)^{-1}u_n$.

(iv) There is a normalizing scalar $c > 0$ such that each entry of cX_M is the value of all of the entries in the corresponding block of X_A.

It follows immediately that the gradings for X_M, Mu, and $(I - M)^{-1}u$ lift naturally to gradings for X_A, Au, and $(I - A)^{-1}u$. Finally, when P has the form given by (3.1) of [SW], the matrix A naturally block partitions into blocks $A_{\langle i,j \rangle}$ for $1 \leq i, j \leq k$,

and $M = [m_{ij}]$ is determined uniquely by $m_{ij} = (h_i)^{-1}[u_{h_i}]^t A_{\langle i,j \rangle} u_{h_j}$ for $1 \leq i, j \leq k$. See [SW, §§3 and 4.]

COLLINEARITY AND TOTAL LEAST SQUARES*

RICARDO D. FIERRO† AND JAMES R. BUNCH†

Abstract. The least squares (LS) and total least squares (TLS) methods are commonly used to solve the overdetermined system of equations $Ax \approx b$. The main objective of this paper is to examine TLS when A is nearly rank deficient by outlining its differences and similarities to the well-known truncated LS method. It is shown that TLS may be viewed as a regularization technique much like truncated LS, even though the rank reduction depends on b. The sensitivity of LS and TLS approximate nullspaces to perturbations in the data is also examined. Some numerical simulations are included.

Key words. least squares, total least squares, truncated least squares, rank deficient, perturbation theory, acute subspaces

AMS subject classification. 65F20

1. Introduction and preliminaries.

The task of solving the overdetermined set of linear equations

$$Ax \approx b, \quad A \in \Re^{m \times n}, \quad (m \geq n) \tag{1}$$

arises in many disciplines. In many applications (1) does not have an exact solution and the ordinary least squares (LS) approach or total least squares (TLS) approach is commonly used. It is well known (e.g., [1], [4], [7], [10, p. 77], [12]) that collinearities (i.e., near linear dependencies) in the columns of the matrix A can have damaging effects on the ordinary LS estimator, as small changes in A or b may result in disproportionately large changes in the solution. Better results are achieved when stabilization techniques are employed, such as truncated LS, Tikhonov regularization, or subset selection.

Let A have the dyadic singular value decomposition (SVD)

$$A = \sum_{i=1}^{n} u_i' \sigma_i' v_i'^T. \tag{2}$$

Let TOL > 0 be a problem-dependent parameter that identifies the $n-k$ collinearities in A:

$$\sigma_k' > \text{TOL} > \sigma_{k+1}' \geq \cdots \geq \sigma_n'.$$

Then the numerical rank of A is k (with respect to TOL). It is not unreasonable to assume a well-defined gap in the singular value spectrum of A; otherwise, rank determination is a difficult problem, even for the SVD. Here we consider truncated LS: given TOL, one essentially solves

$$\begin{aligned} &\text{minimize } ||b - b_k||_2 \\ &\text{such that } b_k \in \mathcal{R}(A_k), \end{aligned}$$

* Received by the editors January 3, 1992; accepted for publication (in revised form) June 11, 1993.

† Department of Mathematics, University of California, San Diego, 9500 Gilman Drive, La Jolla, California 92093-0112 (fierro@thunder.csusm.edu and jbunch@ucsd.edu).

where $A_k = \sum_{i=1}^{k} u_i' \sigma_i' v_i'^T$ is the rank-k matrix nearest in 2-norm to $A = A_k + \triangle A_k$, and $\triangle A_k$ the correction in A that is independent of b. Let $x' = \sum_{i=1}^{k} v_i'((b^T u_i')/\sigma_i')$ denote the minimum 2-norm solution to

$$A_k x = b_k,$$

or equivalently, the minimum 2-norm LS solution to

$$\min_x \|A_k x - b\|_2. \tag{3}$$

The minimum 2-norm LS solution x' to (3) always exists and is unique. Also, $\operatorname{rank}(A_k) = \operatorname{rank}([A_k\ b_k]) = k$. See [8] and [9] for more on the properties of the solution.

As in the ordinary LS case, the classical TLS solution (see Golub and Van Loan [5], Van Huffel and Vandewalle [18]) may be affected by collinearities in the matrix A. For reasons of stability a "truncated" TLS solution should be deduced from the span of the singular vectors corresponding to the collinearities in $[A\ b]$, which amounts to a rank reduction in $[A\ b]$. Let $[A\ b]$ have the dyadic SVD

$$[A\ b] = \sum_{i=1}^{n+1} u_i \sigma_i v_i^T. \tag{4}$$

The (truncated) TLS approach chooses $[\hat{A}\ \hat{b}]$ as the minimizer of

$$\text{minimize } \|[A\ b] - [C\ d]\|_2, \tag{5}$$

$$\text{subject to } \operatorname{rank}(C) = \operatorname{rank}([C\ d]) = k. \tag{6}$$

The nearest rank-k matrix in 2-norm to $[A\ b]$ is the best candidate for this problem. If $[\hat{A}\ \hat{b}] \equiv \sum_{i=1}^{k} u_i \sigma_i v_i^T$ satisfies (5)–(6), let $\hat{x}$ denote the minimum 2-norm TLS solution to

$$\hat{A}x = \hat{b}. \tag{7}$$

Also, $\hat{x}$ is the minimum 2-norm LS solution to

$$\min_x \|\hat{A}x - b\|_2.$$

The main objective of this paper is to examine TLS when A is nearly rank deficient by outlining its differences and similarities to the well-known truncated LS method. In §2 we prove an existence condition for the TLS solution and show how it implies that $\hat{A}$ may be viewed as an acute perturbation of A_k. In §3 we use the modified normal equations to elucidate some similarities and differences in the solutions. Then we see how the acuteness condition is related to the differences and similarities in the LS and TLS solutions and residuals. As the ratio σ_{k+1}/σ_k' decreases, TLS may be viewed as a regularization technique much like truncated LS, even though the rank reduction depends on b. In §4 we show how $\sigma_k' - \sigma_{k+1}$ is related to the sensitivity of LS and TLS subspaces to perturbations in the data. Then we explore the role of the orientation of b with respect to the column space of A using subspace perturbation theory and eigenequation relationships. We include some numerical simulations.

At this point we introduce the notation used throughout the paper. Scalars are represented by lowercase Greek letters or English alphabet with double subscripts.

Matrices are represented by the uppercase English alphabet. Superscripts T and the symbol $\dagger$ denote the transpose and the Moore–Penrose pseudoinverse of a matrix, respectively. Let $\|\cdot\| = \|\cdot\|_2$, the Euclidean norm. Let $\mathcal{R}(D)$, $\mathcal{N}(D)$, and $\kappa(D) = \|D\|\,\|D^\dagger\|$ denote the range, nullspace, and the condition number of the matrix D, respectively. $P_D = DD^\dagger$ denotes the orthogonal projection matrix onto $\mathcal{R}(D)$. We also denote the SVD of A by

$$A = U'\Sigma'V'^T \tag{8}$$

with

$$\begin{aligned}
&U' = [U'_1\ U'_2], \quad U'_1 = [u'_1, \ldots, u'_k], \quad U'_2 = [u'_{k+1}, \ldots, u'_n], \quad u'_i \in \Re^m, \quad U'^T U' = I_n,\\
&\Sigma' = \operatorname{diag}(\sigma'_1, \ldots, \sigma'_n) \in \Re^{n\times n}, \quad \sigma'_1 \geq \cdots \geq \sigma'_n \geq 0,\\
&V' = [V'_1\ V'_2], \quad V'_1 = [v'_1, \ldots, v'_k], \quad V'_2 = [v'_{k+1}, \ldots, v'_n], \quad v'_i \in \Re^n, \quad V'^T V' = I_n.
\end{aligned}$$

Partition the matrix Σ' as

$$\Sigma' = \begin{pmatrix} \Sigma'_1 & 0 \\ 0 & \Sigma'_2 \end{pmatrix},$$

so that $\Sigma'_1 \in \Re^{k\times k}$ and $\Sigma'_2 \in \Re^{(n-k)\times(n-k)}$.

We also denote the SVD of $[A\ b]$ by

$$[A\ b] = U\Sigma V^T \tag{9}$$

with

$$\begin{aligned}
&U = [U_1\ U_2], \quad U_1 = [u_1, \ldots, u_k], \quad U_2 = [u_{k+1}, \ldots, u_{n+1}], \quad u_i \in \Re^m, \quad U^T U = I_{n+1},\\
&\Sigma = \operatorname{diag}(\sigma_1, \ldots, \sigma_{n+1}) \in \Re^{(n+1)\times(n+1)}, \quad \sigma_1 \geq \cdots \geq \sigma_{n+1} \geq 0.\\
&V = [V_1\ V_2], \quad V_1 = [v_1, \ldots, v_k], \quad V_2 = [v_{k+1}, \ldots, v_{n+1}], \quad v_i \in \Re^{n+1}, \quad V^T V = I_{n+1}.
\end{aligned}$$

Partition the matrices V and Σ as

$$V = \begin{pmatrix} V_{11} & V_{12} \\ V_{21} & V_{22} \end{pmatrix} \quad \text{and} \quad \Sigma = \begin{pmatrix} \Sigma_1 & 0 \\ 0 & \Sigma_2 \end{pmatrix},$$

with $V_{11} \in \Re^{n\times k}, V_{12} \in \Re^{n\times(n-k+1)}, V_{21} \in \Re^{1\times k}, V_{22} \in \Re^{1\times(n-k+1)}, \Sigma_1 \in \Re^{k\times k}$, and $\Sigma_2 \in \Re^{(n-k+1)\times(n-k+1)}$.

2. TLS existence and acuteness. In accordance with Golub and Van Loan [5], we bring (1) into the form

$$[A\ b]\begin{bmatrix} x \\ -1 \end{bmatrix} \approx 0. \tag{10}$$

To compute a stabilized TLS solution, we find a reduced-rank approximation of $[A\ b]$. Since A has numerical rank k, it makes sense to approximate $[A\ b] = [\hat{A}\ \hat{b}] + [\triangle\hat{A}\ \triangle\hat{b}]$ by its nearest rank k approximation: $[\hat{A}\ \hat{b}] = U_1\Sigma_1 V_1^T$. $\triangle\hat{A} = A - \hat{A}$ is the correction in A that is dependent on b. Using a nullspace argument [5], [17], [23], the minimum norm TLS solution $\hat{x}$ is given by

$$\hat{x} = -V_{12}V_{22}^\dagger. \tag{11}$$

Note that the solution $\hat{x} \in \Re^n$ exists provided $V_{22} \neq 0$. As in [5], let Q be an $(n-k+1) \times (n-k+1)$ orthogonal matrix such that

$$\begin{bmatrix} V_{12} \\ V_{22} \end{bmatrix} Q = [v_{k+1}, \ldots, v_{n+1}]Q = \begin{bmatrix} W & z \\ 0 & \gamma \end{bmatrix}. \tag{12}$$

By this change of basis, an equivalent representation of the orthogonally invariant minimum 2-norm TLS solution is

$$\hat{x} = -z/\gamma \tag{13}$$

provided $V_{22} \neq 0$. The parameter $|\gamma|$ should be viewed as the distance of the rank-k approximation $[\hat{A}\ \hat{b}]$ from degeneracy, i.e., to incompatibility. That $[\hat{A}\ \hat{b}] = U_1 \Sigma_1 V_1^T$ indeed satisfies the compatibility requirement under a mild sufficiency condition is the content of the following theorem.

THEOREM 2.1. *Let A and $[A\ b]$ have the usual* SVD *and γ as in* (12). *If $\sigma_{k+1} < \sigma'_k$, then $\gamma \neq 0$ and $\hat{x} = -z/\gamma$ exists.*

Proof. Assume $\sigma_{k+1} < \sigma'_k$ and $\gamma = 0$. Then (12) implies $v_{n+1,j} = 0$ for $j = k+1, \ldots, n+1$. By [17, Thm. 3.1], $\sigma_j = \sigma'_{t(j)}$ for $t(j) = j$ or $j-1$, and $v_j = [v'_{t(j)}{}^T, 0]^T$, where $v'_{t(j)} \in \Re^n$ is a right singular vector of A associated with the singular value $\sigma'_{t(j)}$. Once these singular values have been assigned for $j = k+2, \ldots, n+1$, with $t(j) = j$ or $j-1$, it implies $\sigma_{k+1} = \sigma'_k$, a contradiction. Thus, $\gamma \neq 0$.

This theorem was proven more generally for the multidimensional TLS problem in [22] and extended to general orthogonal projection methods in [2]. The condition $\sigma_{k+1} < \sigma'_k$ implies that the nearest rank-k matrix approximation of $[A\ b]$ is unique; also, the condition is numerically mild since $\sigma_{k+1} \leq \sigma'_k$ by the interlacing property of singular values.

The formulas for the solutions $x' = A_k^\dagger b$ and $\hat{x} = -V_{12}V_{22}^\dagger$ in themselves do not provide much of a basis for comparing the two techniques. But as proven in [15], the set S_{TLS} of solutions to (7) is the same as the set of LS solutions to $\hat{A}x \approx b$. Thus,

$$S_{TLS} = \{x | x = \hat{A}^\dagger b + (I - \hat{A}^\dagger \hat{A})z \quad \forall z \in \Re^n\},$$

which is similar to the well-known set S_{LS} of LS solutions

$$S_{LS} = \{x | x = A_k^\dagger b + (I - A_k^\dagger A_k)z \quad \forall z \in \Re^n\}.$$

The minimum 2-norm solutions x' and $\hat{x}$ can be expressed formally as $x' = A_k^\dagger b$ and $\hat{x} = \hat{A}^\dagger b$. Both approaches search for solutions in k-dimensional subspaces; generally, a method that searches in a subspace of lower dimension utilizes less information in A and b. Because we did not distinguish the collinearities in $[A\ b]$ (deemed "predictive" if $|v_{n+1,j}|$ is moderate and "nonpredictive" if $|v_{n+1,j}|$ is small), it is very possible to find solutions x' and $\hat{x}$ in subspaces of higher dimension. However, this is not recommended for reasons of stability.

At this point it seems natural to inquire about how the row and column spaces of $\hat{A}$ differ from A_k when $\hat{A}$ is viewed as a perturbation of A_k, that is, E is defined so that $\hat{A} = A_k + E$. We consider the set of problems (1) where the row and column spaces of $\hat{A}$ and A_k do not differ *drastically* in the sense that the canonical angles between the column spaces, as well as the row spaces, are less than $\pi/2$ (otherwise, we can expect the pseudoinverses to differ significantly as the lower bound on $\|\hat{A}^\dagger - A_k^\dagger\|$

may be arbitrarily large [21] and hence the two methods may generate vastly different solutions). This is the essence of the following definition by Wedin [21].

DEFINITION. *The matrix C is an acute perturbation of D if $\|P_C - P_D\| < 1$ and $\|P_{C^T} - P_{D^T}\| < 1$. We also say that C and D are* acute.

To show that the matrices $\hat{A}$ and A_k are acute, we examine a *reduced form* of the problem:

$$U'^T A_k V' = \begin{pmatrix} \Sigma_1' & 0 \\ 0 & 0 \end{pmatrix}, \tag{14}$$

$$U'^T E V' = \begin{pmatrix} E_{11} & E_{12} \\ E_{21} & E_{22} \end{pmatrix}, \tag{15}$$

and

$$U'^T \hat{A} V' = \begin{pmatrix} \tilde{\Sigma}_1 & E_{12} \\ E_{21} & E_{22} \end{pmatrix}, \tag{16}$$

where $\tilde{\Sigma}_1 = \Sigma_1' + E_{11}$. Applying Theorem 3.3 [13, p. 139], A_k and $\hat{A}$ are acute if and only if in the reduced form $\tilde{\Sigma}_1$ is nonsingular and $E_{22} = E_{21}\tilde{\Sigma}_1^{-1}E_{12}$. From these facts we have the following result.

THEOREM 2.2. *Let A and $[A\ b]$ have the* SVD *as in* (8) *and* (9), *and let A_k and $\hat{A}$ have the reduced form as in* (14) *and* (16). *If $\sigma_{k+1} < \sigma_k'$, then $\hat{A}$ and A_k are acute matrices.*

Proof. As mentioned above, we need to show that $\tilde{\Sigma}_1$ is nonsingular and $E_{22} = E_{21}\tilde{\Sigma}_1^{-1}E_{12}$. To show that $\tilde{\Sigma}_1$ is nonsingular, it suffices to show $\|E_{11}\| < \sigma_k'$. Now, E can be rewritten as

$$E = \triangle A_k - \triangle \hat{A}. \tag{17}$$

Transforming both sides of (17) as in (15) yields

$$\begin{pmatrix} E_{11} & E_{12} \\ E_{21} & E_{22} \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 0 & \Sigma_2' \end{pmatrix} - \begin{pmatrix} \triangle\hat{A}_{11} & \triangle\hat{A}_{12} \\ \triangle\hat{A}_{21} & \triangle\hat{A}_{22} \end{pmatrix}, \tag{18}$$

where

$$U'^T \triangle \hat{A} V' = \begin{pmatrix} \triangle\hat{A}_{11} & \triangle\hat{A}_{12} \\ \triangle\hat{A}_{21} & \triangle\hat{A}_{22} \end{pmatrix}.$$

Since $\triangle\hat{A}_{11}$ is a submatrix of $U'^T \triangle \hat{A} V'$, we have

$$\|\triangle\hat{A}_{11}\| \le \|U'^T \triangle \hat{A} V'\| = \|\triangle\hat{A}\| \le \|[\triangle\hat{A}\ \triangle\hat{b}]\| = \sigma_{k+1}.$$

From (18) and the assumption $\sigma_{k+1} < \sigma_k'$, this implies $\|E_{11}\| < \sigma_k'$, and hence $\tilde{\Sigma}_1$ is nonsingular. To show $E_{22} = E_{21}\tilde{\Sigma}_1^{-1}E_{12}$, define $S \equiv E_{22} - E_{21}\tilde{\Sigma}_1^{-1}E_{12}$. Performing a step of block Gaussian elimination on $U'^T \hat{A} V'$ gives

$$U'^T \hat{A} V' = \begin{bmatrix} I_k & 0 \\ E_{21}\tilde{\Sigma}_1^{-1} & I_{n-k+1} \end{bmatrix} S_1,$$

where

$$S_1 \equiv \begin{bmatrix} \tilde{\Sigma}_1 & E_{12} \\ 0 & S \end{bmatrix}.$$

If $S \neq 0$, then $\operatorname{rank}(S_1) \geq k+1$, implying $k = \operatorname{rank}(\hat{A}) = \operatorname{rank}(U'^T \hat{A} V') = \operatorname{rank}(S_1) \geq k+1$, a contradiction. Therefore, $S \equiv 0$. This completes the proof of the theorem.

This shows that $\sigma_{k+1} < \sigma'_k$ implies A_k and $\hat{A}$ are acute; that is, the canonical angles between their column spaces, as well as their row spaces, are less than $\pi/2$. This agrees with the intuition that if the fitting of the data applied by the TLS approach is "close" in the sense of acuteness to the fitting of the data applied by the truncated LS approach, then the former approach should have a solution since the truncated LS solution always exists. So the class of problems (1) that we consider in comparing the TLS and LS solutions and residuals consists of the problems for which $\sigma_{k+1} < \sigma'_k$. When this condition is satisfied, $\hat{A}^\dagger$ is a continuous function of the perturbation of the elements of A_k.

3. Bounds on the minimum norm LS and TLS solutions and residuals. Since the minimum norm LS and TLS solutions can be expressed $x' = A_k^\dagger b$ and $\hat{x} = \hat{A}^\dagger b$, they satisfy the modified normal equations

$$(A^T A - \triangle A_k{}^T \triangle A_k) x' = A^T b - \triangle A_k{}^T b, \tag{19}$$

$$(A^T A - \triangle \hat{A}^T \triangle \hat{A}) \hat{x} = A^T b - \triangle \hat{A}^T b. \tag{20}$$

These alternative relationships are useful in deducing the equivalences and differences between the two techniques. As Σ'_2 goes to zero and the LS problem becomes more compatible, then $\hat{x}$ approaches x'. In fact, for $\Sigma'_2 = 0$ and $b \in \mathcal{R}(A)$ then $\Sigma_2 = 0$ and $\hat{x}$ equals x' (also, see [16, Thm. 2.1] by Van Huffel and Vandewalle). To elucidate the differences in the solutions, we will use a first order expansion of SVD components. Let $S'_1 = \Sigma_1'^T \Sigma'_1$, $S_1 = \Sigma_1^T \Sigma_1$, and $S_2 = \Sigma_2^T \Sigma_2$. Equations (19) and (20) can be rewritten as

$$(V'_1 S'_1 V_1'^T) x' = A^T b - V'_2 \Sigma_2'^T U_2'^T b, \tag{21}$$

$$(V_{11} S_1 V_{11}^T) \hat{x} = A^T b - V_{12} S_2 V_{22}^T. \tag{22}$$

Substituting (22) into (21) yields

$$(V'_1 S'_1 V_1'^T) x' = (V_{11} S_1 V_{11}^T) \hat{x} + V_{12} S_2 V_{22}^T - V'_2 \Sigma_2'^T U_2'^T b.$$

Define the difference matrices E_S and E_V by $E_S = S_1 - S'_1$ and $E_V = V_{11} - V'_1$. Substituting $V_{11} = V'_1 + E_V$ and $S_1 = S'_1 + E_S$ yields to the first order (ignore terms involving the product of two or more difference matrices):

$$(V'_1 S'_1 V_1'^T)(x' - \hat{x}) \approx (V'_1 S'_1 E_V^T + E_V S'_1 V_1'^T + V'_1 E_S V_1'^T) \hat{x} + V_{12} S_2 V_{22}^T - V'_2 \Sigma_2'^T U_2'^T b.$$

Using the fact $\sigma_k'^2 \|x' - \hat{x}\| = \sigma_{\min}(V'_1 S'_1 V_1'^T) \|x' - \hat{x}\| \leq \|(V'_1 S'_1 V_1'^T)(x' - \hat{x})\|$, we get

$$\|x' - \hat{x}\| \leq \frac{1}{\sigma_k'^2} [(2\|E_V\|\sigma_1^2 + \|E_S\|)\|\hat{x}\| + \sigma_{k+1}^2 + \sigma'_{k+1} \|U_2'^T b\|]. \tag{23}$$

Equation (23) is not a tight bound for the norm $\|x' - \hat{x}\|$, but might suggest that we can expect the solutions x' and $\hat{x}$ to be very different when any of the following hold:

- σ'_k is small, implying A_k is ill conditioned.
- σ_{k+1} is large because either $Ax \approx b$ is highly incompatible or there is not a good gap in the singular value distribution of A.
- The largest singular values of A and $[A\ b]$ differ greatly, so that $\|E_S\|$ is large. As shown later this happens when b is oriented toward the larger left singular vectors of A.

Next, we determine a bound on the difference $A_k^\dagger - \hat{A}^\dagger$ relative to $A_k^\dagger$ as well as a bound on the difference $x' - \hat{x}$ relative to x'. The acuteness condition appears in the bounds.

LEMMA 3.1. *Assume* $\sigma_{k+1} < \sigma'_k$ *and define* $\phi_k \equiv \sigma_{k+1}/\sigma'_k$, $\mu = (1+\sqrt{5})/2$. *Then the difference* $A_k^\dagger - \hat{A}^\dagger$ *relative to* $A_k^\dagger$ *is bounded above by*

$$\frac{\|A_k^\dagger - \hat{A}^\dagger\|}{\|A_k^\dagger\|} \leq 2\mu \frac{\phi_k}{1-\phi_k}.$$

Proof. Since $\operatorname{rank}(A_k) = \operatorname{rank}(\hat{A})$, applying [15, Thm. 3.14], we have

$$\|A_k^\dagger - \hat{A}^\dagger\| \leq \mu \|A_k^\dagger\| \|\hat{A}^\dagger\| \|A_k - \hat{A}\|. \tag{24}$$

Using $A - \hat{A} = \triangle\hat{A}$ and $\|\triangle\hat{A}\| \leq \sigma_{k+1}$, it follows from the perturbation of singular values [6, p. 287] that $\|\hat{A}^\dagger\| \leq (\sigma'_k - \sigma_{k+1})^{-1}$. Furthermore, using the triangle inequality,

$$\|A_k - \hat{A}\| \leq \|A_k - A\| + \|A - \hat{A}\| \leq \sigma'_{k+1} + \sigma_{k+1} \leq 2\,\sigma_{k+1}. \tag{25}$$

Thus

$$\frac{\|A_k^\dagger - \hat{A}^\dagger\|}{\|A_k^\dagger\|} \leq 2\mu \frac{\sigma_{k+1}}{\sigma'_k - \sigma_{k+1}},$$

which is equivalent to the desired result.

This lemma implies that the solutions x' and $\hat{x}$ should be relatively close if $\phi_k \ll 1$. In other words, if there is a well-defined gap in the singular value spectrum of A ($\sigma'_{k+1} \ll \sigma'_k$) and $Ax \approx b$ is not too incompatible, then we expect the solutions to be relatively close.

Defining $\phi_k \equiv \sigma_{k+1}/\sigma'_k$ as above and $r' \equiv b - Ax'$, we have the following bound for the relative difference in the solutions x' and $\hat{x}$.

THEOREM 3.2. *Let* A *and* $[A\ b]$ *have the usual* SVD. *Let* x' *be the minimum norm* LS *solution to* (3) *and* $\hat{x}$ *the minimum norm* TLS *solution to* (7). *If* $\sigma_{k+1} < \frac{1}{2}\sigma'_k$ *then*

$$\frac{\|x' - \hat{x}\|}{\|x'\|} \leq \frac{\phi_k}{1-\phi_k}\left[3 + \kappa(A_k)\frac{\|r'\|}{\|b\|}\right].$$

Proof. The result follows from [8, (27a)] by setting $e = 0$, by viewing $\hat{A}$ as an acute perturbation of the rank-k matrix A_k, $\|\hat{A} - A_k\| \leq 2\sigma_{k+1}$, and by using the fact $\frac{2\,\phi_k}{1-\phi_k} + \phi_k \leq \frac{3\,\phi_k}{1-\phi_k}$.

Bounds on the norm $\|x' - \hat{x}\|$ for the two cases $k = n$ and $\sigma_{k+1} = \cdots = \sigma_{n+1}$ are derived in [18] and [22], respectively. While the bound in Theorem 3.2 holds for the more general case, it is overly pessimistic. However, it still gives a correct indication of the influence of ϕ_k.

The purpose of regularization techniques is to remove the potential instability in the problem due to finite precision and data errors. The regularization technique of Tikhonov [14] is widely known to be an effective method for solving the ill-conditioned LS problem. Hansen [8] has shown that when A has a well-defined gap in its singular value spectrum, then truncated LS is similar to Tikhonov regularization. The truncated LS method removes the potential instability by solving a nearby, alternative LS problem $A_k x \approx b$, where, roughly speaking, one strives to balance the condition number of A_k and the size of $\|A - A_k\|$. From this point of view and the fact that $\hat{x}$ solves the ordinary LS problem $\hat{A}x \approx b$, where $\hat{A}$ is an acute perturbation of A_k that depends on b, the TLS approach to (1) is a regularization method similar to truncated LS, but the condition number of $\hat{A}$ is larger than that of A_k.

Next, we provide a bound on the residuals. Let $r' = b - Ax' = b - A_k x'$, $\hat{r} = b - A\hat{x}$, and $\tilde{r} = b - \hat{A}\hat{x}$. Let $\phi_k \equiv \sigma_{k+1}/\sigma'_k$.

THEOREM 3.3. *Let A and $[A\ b]$ have the usual* SVD *and assume $\sigma_{k+1} < \sigma'_k$. Let x' be the minimum norm* LS *solution to* (3) *and $\hat{x}$ be the minimum norm solution to* (7)*, and let r' and $\hat{r}$ be defined as above. Then the following hold:*

$$\frac{\|r' - \hat{r}\|}{\|b\|} \leq 2\frac{\phi_k}{1 - \phi_k} \quad \text{and} \quad \|\hat{r}\| \leq \sigma_{k+1}\sqrt{1 + \|\hat{x}\|^2}.$$

Proof. To bound the relative error, we use the triangle inequality $\|r' - \hat{r}\| \leq \|r' - \tilde{r}\| + \|\tilde{r} - \hat{r}\|$. To bound $\|r' - \tilde{r}\|$, rewriting the residuals as $r' = (I_m - P_{U'_1})b$ and $\tilde{r} = (I_m - P_{U_1})b$ means $r' - \tilde{r} = (P_{U_1} - P_{U'_1})b$, with

$$\|P_{U_1} - P_{U'_1}\| = \|U_1 U_1^T - U'_1 {U'_1}^T\| = \|{U'_1}^T U_2\|.$$

Using $A = U_1 \Sigma_1 V_{11}^T + U_2 \Sigma_2 V_{12}^T$, and ${U'_1}^T = ({\Sigma'_1}^+){V'_1}^T A^T$, it follows that

$${U'_1}^T U_2 = ({\Sigma'_1}^+)^T {V'_1}^T V_{12} \Sigma_2^T.$$

Thus,

$$\|{U'_1}^T U_2\| \leq \|{\Sigma'_1}^+\| \, \|\Sigma_2\| = \phi_k$$

and hence

$$\frac{\|r' - \tilde{r}\|}{\|b\|} \leq \|P_{U_1} - P_{U'_1}\| \leq \phi_k. \tag{26}$$

To bound $\|\tilde{r} - \hat{r}\|$, from $\hat{r} - \tilde{r} = (\hat{A} - A)\hat{x}$, we get

$$\|\tilde{r} - \hat{r}\| \leq \|\hat{A} - A\| \, \|\hat{x}\| \leq \sigma_{k+1}\|\hat{x}\|.$$

But $\hat{x} = \hat{A}^\dagger b$ implies $\|\hat{x}\| \leq \|\hat{A}^\dagger\| \, \|b\| \leq \|b\|/(\sigma'_k - \sigma_{k+1})$. Thus,

$$\frac{\|\tilde{r} - \hat{r}\|}{\|b\|} \leq \frac{\sigma_{k+1}}{\sigma'_k - \sigma_{k+1}} = \frac{\phi_k}{1 - \phi_k}. \tag{27}$$

The sum of the two inequalities in (26) and (27) is bounded by the desired result. To bound the residual, $\hat{r} = b - A\hat{x} = -[\triangle\hat{A} \ \triangle\hat{b}][\hat{x}^T \ -1]^T$, and taking norms in the obvious way yields the desired result. This completes the proof of the theorem.

The bound in Theorem 3.3 for the difference in the residuals is a monotonic function of ϕ_k. As ϕ_k increases, so does the expected difference in the residuals. The residuals approach each other as ϕ_k decreases.

4. Perturbation of LS and TLS approximate nullspaces. In this section we examine the sensitivity of the LS and TLS approximate nullspaces. This is important because, as we see in Theorem 4.1, perturbations can affect the truncated LS and TLS solutions. Let $[\tilde{A}\ \tilde{b}] = [A\ b] + [\triangle A\ \triangle b]$ denote a perturbation of $[A\ b]$ with the dyadic SVD

$$[\tilde{A}\ \tilde{b}] = \sum_{i=1}^{n+1} \tilde{\sigma}_i \tilde{u}_i \tilde{v}_i^T. \tag{28}$$

Let $[\check{A}\ \check{b}]$ represent the nearest rank k matrix to $[\tilde{A}\ \tilde{b}]$ and $\tilde{A}_k$ the nearest rank k matrix to $\tilde{A}$, and let $\tilde{b}_k$ denote the projection of $\tilde{b}$ onto $\mathcal{R}(\tilde{A}_k)$. As usual, we assume the data A is nearly rank-$(n-k)$ deficient. In direct analogy with TLS in (12)–(13), the minimum norm LS solutions to

$$\min_x \|A_k x - b\| \quad \text{and} \quad \min_x \|\tilde{A}_k x - \tilde{b}\|$$

can be determined by solving the homogeneous equations

$$[A_k\ b_k] \begin{bmatrix} x \\ -1 \end{bmatrix} = 0 \quad \text{and} \quad [\tilde{A}_k\ \tilde{b}_k] \begin{bmatrix} x \\ -1 \end{bmatrix} = 0 \tag{29}$$

using a nullspace argument. Thus it makes sense to compare the distance between the LS approximate nullspaces $\mathcal{N}([A_k\ b_k])$ and $\mathcal{N}([\tilde{A}_k\ \tilde{b}_k])$ and the distance between the TLS approximate nullspaces $\mathcal{N}([\hat{A}\ \hat{b}])$ and $\mathcal{N}([\check{A}\ \check{b}])$ (see [6, p. 76] for definition of distance between subspaces).

When the size of the perturbation $\|[\triangle A\ \triangle b]\|$ satisfies

$$\|[\triangle A\ \triangle b]\| < \sigma'_k - \sigma'_{k+1} \tag{30}$$

then $\mathcal{R}(A_k)$ and $\mathcal{R}(\tilde{A}_k)$ are acute subspaces. Since the LS solutions always exist and can be deduced from the the basis vectors of $\mathcal{N}([A_k\ b_k])$ and $\mathcal{N}([\tilde{A}_k\ \tilde{b}_k])$, it makes sense to compare the distance between these LS approximate nullspaces. Similarly,

$$\|[\triangle A\ \triangle b]\| < \sigma_k - \sigma_{k+1} \tag{31}$$

ensures that $\mathcal{N}([\hat{A}\ \hat{b}])$ and $\mathcal{N}([\check{A}\ \check{b}])$ are acute subspaces. Equations (30)–(31) are tantamount to requiring that a singular value in the unperturbed cluster of small singular values remains in the corresponding perturbed cluster. Note that these conditions hold whenever

$$\|[\triangle A\ \triangle b]\| < \sigma'_k - \sigma_{k+1}. \tag{32}$$

Hence the existence condition for TLS can be directly related to the sensitivity of the subspaces to acute perturbations. When (32) is satisfied, the perturbed TLS problem cannot be *nongeneric* (nongeneric implies $\tilde{\sigma}'_k = \tilde{\sigma}_{k+1}$) in the sense of Van Huffel and Vandewalle [17].

Now, let us assume we are given an orthonormal basis for the nullspace of $[A_k\ b_k]$ ($[\hat{A}\ \hat{b}]$) and an orthonormal basis for the nullspace of its perturbed version $[\tilde{A}_k\ \tilde{b}_k]$ ($[\check{A}\ \check{b}]$). Then we can perform a change of basis as in (12) and compute the LS (TLS) solutions as in (13); partition the unit vectors

$$v = \begin{pmatrix} z \\ \gamma \end{pmatrix} \quad \text{and} \quad \tilde{v} = \begin{pmatrix} \tilde{z} \\ \tilde{\gamma} \end{pmatrix}, \tag{33}$$

where $\tilde{v}$ is considered the perturbed version of v. If $\|[\triangle A\ \triangle b]\| < \sigma'_k - \sigma_{k+1}$, then $\min(\gamma, \tilde{\gamma}) \neq 0$. Define $x \equiv -z/\gamma$ and $\tilde{x} \equiv -\tilde{z}/\tilde{\gamma}$. Then it follows $|\gamma|^{-1} = \sqrt{1 + \|x\|^2}$ and $|\tilde{\gamma}|^{-1} = \sqrt{1 + \|\tilde{x}\|^2}$. The effect of the perturbation $[\triangle A\ \triangle b]$ on v is measured by θ, the angle between v and $\tilde{v}$. Next we show how this angle influences $\|x - \tilde{x}\|$.

THEOREM 4.1. *Define the vectors v and $\tilde{v}$ as in* (33), *and define $x = -z/\gamma$ and $\tilde{x} = -\tilde{z}/\tilde{\gamma}$. Assume* $\operatorname{sign}(\gamma) = \operatorname{sign}(\tilde{\gamma})$. *If $\|[\triangle A\ \triangle b]\| < \sigma'_k - \sigma_{k+1}$, then*

$$\|x - \tilde{x}\| \leq \frac{2\sqrt{2}\,\sin\theta}{|\gamma\,\tilde{\gamma}|},$$

where θ is the angle between v and $\tilde{v}$.

Proof. Since v and $\tilde{v}$ are unit vectors, we have $\|v - \tilde{v}\| = \sqrt{2(1 - \cos\theta)} \leq \sqrt{2}\,\sin\theta$, $\|z\| \leq 1$, and

$$\|v - \tilde{v}\|^2 = \|z - \tilde{z}\|^2 + (\gamma - \tilde{\gamma})^2. \tag{34}$$

Thus, we get $\|z - \tilde{z}\| \leq \sqrt{2}\,\sin\theta$ and $|\gamma - \tilde{\gamma}| \leq \sqrt{2}\,\sin\theta$. It follows that

$$\begin{aligned}
\|x - \tilde{x}\| &= \|\tilde{z}\tilde{\gamma}^{-1} - z\gamma^{-1}\| \\
&= \|(\tilde{z} - z)\tilde{\gamma}^{-1} - z(\gamma^{-1} - \tilde{\gamma}^{-1})\| \\
&\leq \|(\tilde{z} - z)\tilde{\gamma}^{-1}\| + \|z(\gamma^{-1} - \tilde{\gamma}^{-1})\| \\
&\leq \sqrt{2}\,\sin\theta\,|\tilde{\gamma}^{-1}| + |\gamma^{-1} - \tilde{\gamma}^{-1}| \\
&= \sqrt{2}\,\sin\theta\,|\tilde{\gamma}^{-1}| + \frac{|\gamma - \tilde{\gamma}|}{|\gamma\,\tilde{\gamma}|} \\
&\leq \frac{2\sqrt{2}\,\sin\theta}{|\gamma\,\tilde{\gamma}|}.
\end{aligned}$$

This concludes the proof of the theorem.

The following analysis is motivated by Theorem 4.1 and by the analysis in [19, pp. 215–217] by Van Huffel and Vandewalle; however, it differs in that we now compare the distance between corresponding approximate nullspaces (since the LS problems in (29) are reformulated as TLS-like problems). However, as we see, we draw the same conclusions as in [19, pp. 220–225].

THEOREM 4.2. *Let $[\tilde{A}\ \tilde{b}] = [A\ b] + [\triangle A\ \triangle b]$ with the above* SVD*s and assume $\|[\triangle A\ \triangle b]\| < \sigma'_k - \sigma_{k+1}$. Then the following relations hold:*

$$\text{(i)} \qquad \operatorname{dist}\left(\mathcal{N}([A_k\ b_k]), \mathcal{N}([\tilde{A}_k\ \tilde{b}_k])\right) \leq \frac{\|[\triangle A\ \triangle b]\|}{\sigma'_k} + \alpha_{LS},$$

$$\text{(ii)} \qquad \operatorname{dist}\left(\mathcal{N}([\hat{A}\ \hat{b}]), \mathcal{N}([\check{A}\ \check{b}])\right) \leq \frac{\|[\triangle A\ \triangle b]\|}{\sigma_k - \sigma_{k+1} - \|[\triangle A\ \triangle b]\|},$$

where

$$\alpha_{LS} = \mu \frac{\left(\operatorname{dist}(\mathcal{R}(A_k), \mathcal{R}(\tilde{A}_k))\,\|[A\ b]\| + \|[\triangle A\ \triangle b]\|\right)\,\|[\triangle \tilde{A}_k\ \tilde{r}]\|}{\sigma'_k\,(\sigma'_k - \|\triangle A\|)},$$

$\tilde{r} = (I - \tilde{A}_k \tilde{A}_k^{\dagger})\tilde{b}$, $\operatorname{dist}(S_1, S_2) = \|P_{S_1} - P_{S_2}\|$, *and P_{S_i} is the orthogonal projector onto subspace S_i.*

Proof. Using the augmented matrices and some algebraic manipulation (see [3] for details), part (i) follows from extending a result (see [3, Thm. 3]) of Van der Sluis and Veltkamp [15, p. 269] to bound the LS nullspaces:

$$\|[A_k\ b_k]^\dagger[A_k\ b_k] - [\tilde{A}_k\ \tilde{b}_k]^\dagger[\tilde{A}_k\ \tilde{b}_k]\| \le \|[A_k\ b_k]^\dagger\|\,\|[\triangle A\ \triangle b]\| + t_{LS}, \tag{35}$$

where

$$\begin{aligned} t_{LS} &= \mu\|[A_k\ b_k]^\dagger\|\,\|[\tilde{A}_k\ \tilde{b}_k]^\dagger\|\,\|[A_k\ b_k] - [\tilde{A}_k\ \tilde{b}_k]\|\,\|[\triangle\tilde{A}_k\ \tilde{r}]\| \\ &\le \mu\frac{(\operatorname{dist}(\mathcal{R}(A_k),\mathcal{R}(\tilde{A}_k))\,\|[A\ b]\| + \|[\triangle A\ \triangle b]\|)\,\|[\triangle\tilde{A}_k\ \tilde{r}]\|}{\sigma'_k\,(\sigma'_k - \|\triangle A\|)}. \end{aligned}$$

Part (ii) follows from [19, pp. 220–225] using Wedin's perturbation bounds in connection with the SVD and the perturbation property of singular values.

The relation between these perturbation bounds and the solutions is addressed in [3]. Usually,

$$\alpha_{LS} << \frac{\|[\triangle A\ \triangle b]\|}{\sigma'_k},$$

and we expect the bounds on the distance between the TLS approximate nullspaces to be less than the LS approximate nullspaces whenever

$$\sigma_{k+1} + \|[\triangle A\ \triangle b]\| < \sigma_k - \sigma'_k. \tag{36}$$

If $O(10^{-t}) = \max(O(\sigma_{k+1}), O(\|[\triangle A\ \triangle b]\|))$, then for inequality (36) to fail, σ_k and σ'_k must agree in at least the first t decimal digits! It is interesting to see how the existence condition for the TLS solution resurfaces—this time in the inequality that determines when the TLS bound is lower than the LS bound. Provided $Ax \approx b$ is not too incompatible, A has a well-defined gap in its singular values and $\|[\triangle A\ \triangle b]\|$ is not too large, this inequality will almost always be satisfied.

Now, we argue that $\sigma_k - \sigma'_k$ may increase as the component of b along u'_k increases. Premultiplying the eigenequations

$$[A\ b][A\ b]^T u_k = \sigma_k^2 u_k \tag{37}$$

by ${u'_k}^T$ yields

$${\sigma'_k}^2 {u'_k}^T u_k + ({u'_k}^T b)(b^T u_k) = \sigma_k^2 {u'_k}^T u_k.$$

Therefore, it follows

$$({\sigma_k}^2 - {\sigma'_k}^2){u'_k}^T u_k = ({u'_k}^T b)(b^T u_k)$$

and hence

$${\sigma_k}^2 - {\sigma'_k}^2 \ge ({\sigma_k}^2 - {\sigma'_k}^2)|{u'_k}^T u_k| = |{u'_k}^T b|\,|b^T u_k|. \tag{38}$$

From the dyadic SVD form of $[A\ b]$ in (4) we know $|b^T u_k| = \sigma_k |v_{n+1,k}|$, where $v_{n+1,k}$ is the last component of the vector v_k. If $|{u'_k}^T b| \ge |b^T u_k|$, then it follows

$$\frac{{\sigma_k}^2 - {\sigma'_k}^2}{\sigma_k^2} \ge |v_{n+1,k}|^2.$$

Note that if $v_{n+1,k} = 0$ then b is orthogonal to u_k and moreover from [17, Thm. 3.1] $v_{n+1,k} = 0$ implies $b \perp u'_k$. Thus $b \not\perp u'_k$ implies $v_{n+1,k} \neq 0$. Now, let us assume $|b^T u_k| \geq |{u'_k}^T b|$. Then from (38) we have

$$\sigma_k{}^2 - {\sigma'_k}^2 \geq |{u'_k}^T b|^2.$$

From this we conclude that $\sigma_k - \sigma'_k$ may increase as the component of b along u'_k increases (i.e., as $|{u'_k}^T b|$ increases), and verily so if $|b^T u_k| \geq |{u'_k}^T b|$. We note that this conclusion, as well as the following numerical experiments, confirm the theoretical analysis given in [19, pp. 215–217, 220–225]. Finally, a similar argument shows that the larger singular values of A and $[A\ b]$ may increasingly differ as b is oriented along the larger left singular vectors of A, hence $\|E_S\|$ in §3 may be large.

That the orientation of b and the bounds of the LS and TLS numerical nullspaces are related are exemplified in the following numerical simulations using components of the the mean squared error (MSE) (see [7]). The simulation is designed as follows. We perturbed an exact system $Ax = b$ with an error matrix $[\triangle A\ \triangle b]$ whose entries are Gaussian with 0 mean and δ standard deviation. δ^2 ranged from 10^{-4} to 10^{-2}. The MSE of the estimator x, where x is either x' or $\hat{x}$, is defined by

$$\text{MSE}(x) = E[(x - E(x))^T (x - E(x))] + (E(x) - x_0)^T (E(x) - x_0), \tag{39}$$

where E is the expected value operator, x_0 is the exact solution, the first term is the TOTAL VARIANCE ("wobbliness") and the second is the SQUARED BIAS ("bias"). In these simulations, given the vector $x_0 \in \Re^{10}$, we set $b \equiv Ax_0$. All simulations were carried out using Pro-MATLAB [11] on a DECstation 3100.

- We plotted the TOTAL VARIANCE versus the SQUARED BIAS in a log–log diagram.
- $A \in \Re^{50\times 10}$ has singular values

$$\sigma(A) = \{10, 7, 7, 3, 2, 1, 0.1, 0.0005, 0.0001, 0.00001\}.$$

In 2-norm, A is within 0.0005 of a well-conditioned matrix of rank $k = 7$.

- For a fixed variance δ^2, the truncated LS and TLS solutions of 100 independent sets of equations $(A + \triangle A)x \approx (b + \triangle b)$ were computed. The mean of the trials was used to compute the expected values. The simulation procedure was repeated for increasing values of δ^2.

We examine three cases.

- *Case* 1. The exact solution is $x_0 = v'_1 + v'_2$, which means b is oriented along the larger (left) singular vectors of A.
- *Case* 2. The exact solution is $x_0 = v'_6 + v'_7$, which means b is oriented along the $(k-1)$st and kth (left) singular vectors of A.
- *Case* 3. The exact solution x_0 is a random vector in $\Re^{10}$.

In Fig. 1, b is oriented along the larger left singular vectors of A and neither method is favored in the experiment (or theory). In Fig. 2, b is oriented along the smaller left singular vectors, which increases $\sigma_k - \sigma'_k$, and TLS performs much better as expected. In Fig. 3, b is randomly oriented in $\mathcal{R}(A)$ and the results show that TLS can indeed be viewed as a regularization technique much like truncated LS. In all these examples TLS tends to have a higher TOTAL VARIANCE than LS and consequently the TLS curves extend further to the right.

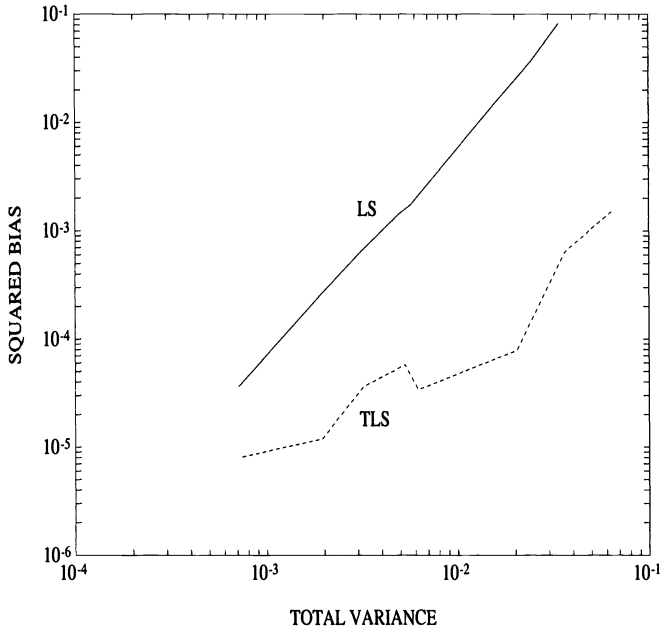

FIG. 1. *The squared bias versus total variance for truncated* LS *and* TLS *with the observation vector b oriented along the larger singular vectors of A. The squared bias is nearly equal for both methods under small perturbations of the exact system.*

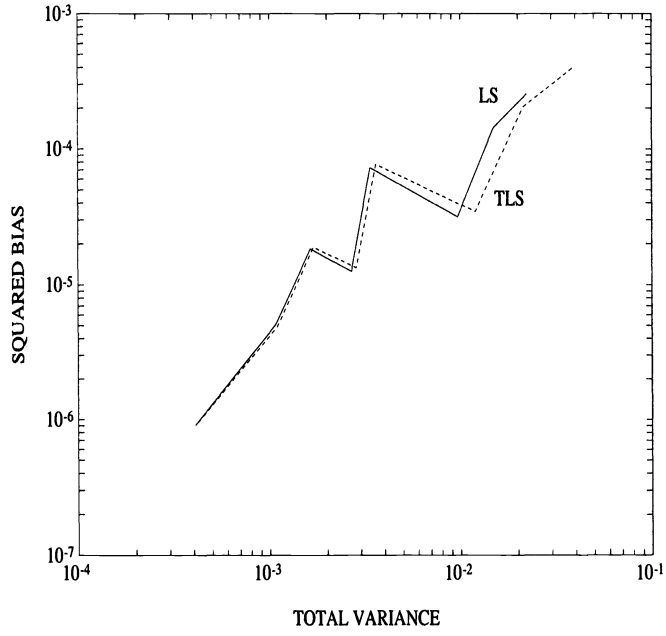

FIG. 2. *The squared bias versus total variance for truncated* LS *and* TLS *with the observation vector b oriented along the* $(k-1)$th *and* kth *left singular vectors of A. In the same domain of total variance, the squared bias for truncated* LS *is higher than* TLS. *The disparity increases as the total variance increases.*

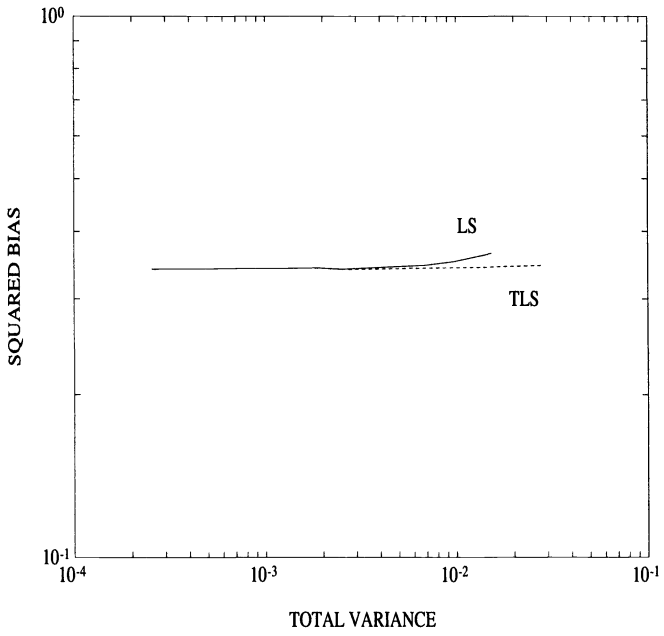

FIG. 3. *The squared bias versus total variance for truncated* LS *and* TLS *with the observation vector b randomly oriented in the range of A.* TLS *performance is nearly the same as* LS.

5. Conclusions. In this paper we examined TLS when A is nearly rank deficient by outlining differences and similarities to the well-known truncated LS method. It was shown how $\hat{A}$ may be viewed as an acute perturbation of A_k, how differences and similarities depend on both $\sigma'_k - \sigma_{k+1}$ and σ_{k+1}/σ'_k, and how $\sigma'_k - \sigma_{k+1}$ is related to the sensitivity of LS and TLS subspaces to perturbations in the data. Also, using the modified normal equations, we elucidated some similarities and differences in the solutions. Perturbation theory for the approximate nullspaces and eigenequation relationships elucidated the role of the orientation of b with respect to the column space of A.

Acknowledgments. We wish to thank Sabine Van Huffel, Per Christian Hansen, and the referees for their valuable suggestions in improving the paper.

RANK ROBUSTNESS OF COMPLEX MATRICES WITH RESPECT TO REAL PERTURBATIONS*

M. A. WICKS† AND R. A. DECARLO‡

Abstract. This paper examines the problem of computing a minimum norm real matrix perturbation that causes a general complex (system) matrix to drop rank. Given the state model describing a linear time-invariant system, the norm of this matrix perturbation helps to determine the robustness of several system properties with respect to real parameter variations. The norm of this perturbation, or the real-restricted singular value of the complex matrix, is known to be a discontinuous function of the complex matrix. The paper presents a simple condition on the complex matrix that eliminates this discontinuity. Specifically, the paper shows that the size of the smallest real rank-reducing perturbation is a continuous function of the complex matrix as long as the imaginary part of the complex matrix has full rank. The paper examines other aspects of the continuity of the problem. It also presents an algorithm that converges to a point satisfying a necessary condition for obtaining the smallest real rank-reducing matrix perturbation. A Lyapunov function approach is used to establish convergence of the algorithm. Some numerical examples are included illustrating the accuracy of the approach.

Key words. matrix perturbation theory, stability robustness, controllability robustness, rank, rounding errors, singular value decomposition

1. Introduction.

The motivation for this paper arises from the study of the robustness of certain properties of finite dimensional linear time-invariant systems with respect to structured parameter variations. Many system properties are characterized by the rank of a family of matrices derived from the property being investigated and the system matrices identified with the state model. For example, let the system matrices, A, B, C, and D determine a linear time-invariant state model,

$$\begin{aligned} \dot{x}(t) &= Ax(t) + Bu(t), \\ y(t) &= Cx(t) + Du(t), \end{aligned} \tag{1.1}$$

where $A \in \mathbb{R}^{n\times n}$, $B \in \mathbb{R}^{n\times r}$, $C \in \mathbb{R}^{p\times n}$, $D \in \mathbb{R}^{p\times r}$. A system is uncontrollable if and only if for some $\lambda \in \mathbb{C}$, $\operatorname{rank}[A - \lambda I, \quad B] < n$. Similarly, a system fails to be asymptotically stable if and only if for some $\lambda \in \mathbb{C}$ having $\operatorname{Re}[\lambda] \geq 0$, $\operatorname{rank}[A - \lambda I] < n$ (see, for example, [11]). For convenience, "unstable" means "not asymptotically stable."

As opposed to the problem of simply classifying whether a particular system property holds or fails to hold for some nominal system, robustness problems attempt to measure the magnitude of parameter variations which may result in some desirable system property failing to hold. The motivation for such problems is twofold: first, ensuring that a particular property will continue to hold in the face of anticipated

parameter variations and, second, ensuring that some property holds for a system for which only noisy or truncated parameter values are available (e.g., those obtained from measurement or numerical calculation). As an example, consider the controllability robustness problem: the magnitude of the minimum norm matrix perturbation $[\delta A, \quad \delta B]$, for which the perturbed pair $[A - \delta A, \quad B - \delta B]$ is uncontrollable, is given by

$$\min_{\lambda \in \mathbb{C}} \sigma_n [A - \lambda I, \quad B] \tag{1.2}$$

in [4]. This problem is equivalent to finding the minimum norm matrix perturbation $[\delta A, \quad \delta B]$ which causes a system matrix $[A - \delta A - \lambda I, \quad B - \delta B]$ to be rank deficient for some $\lambda \in \mathbb{C}$. The actual rank-reducing perturbation matrices δA and δB associated with the minimum of (1.2) are contained in $\mathbb{C}^{n \times n}$ and $\mathbb{C}^{n \times r}$, respectively, i.e., these minimum norm perturbations may have nonzero imaginary parts. The problem of performing the minimization of (1.2) is discussed in [3], [4], and [10]. Similarly the magnitude of the matrix perturbation δA having smallest norm for which the matrix $A - \delta A$ is unstable (given that A is asymptotically stable) is given by

$$\min_{\omega \in \mathbb{R}} \sigma_n [A - j\omega I] \tag{1.3}$$

in [9]. This problem is also equivalent to finding the minimum norm perturbation matrix $[\delta A]$ that causes a system matrix, in this case $[A - \delta A - j\omega I]$, to lose rank for some $\omega \in \mathbb{R}$. Again the destabilizing perturbation having smallest norm δA will lie in $\mathbb{C}^{n \times n}$ and may have a nonzero imaginary part. A bisection method for performing the minimization of (1.3) was developed in [2]. A unified treatment of several similar problems is presented in [6].

A criticism of the above measures is that they are pessimistic; see for example, [3], [6], and [9]. The smallest rank-reducing perturbation obtained from the implied minimizations may be complex, although the physical parameter variations can be only real. More generally, arbitrary parameter variations may not be possible; parameter variations may be known to lie in an even more restrictive set due to physical constraints. Performing minimizations over these more restrictive sets results in larger measures of robustness [8].

Toward the goal of computing these "restricted" robustness measures, this paper investigates the problem of determining real-restricted singular values of complex matrices. This problem is distinct from the problem of finding a minimum norm real perturbation that makes a system uncontrollable or unstable. The smallest singular value of a matrix M provides the norm of the smallest matrix δM for which $M - \delta M$ fails to have full rank. In a similar fashion, one can define an $\mathcal{S}$-restricted singular value of M as the norm of the smallest matrix $\delta M \in \mathcal{S}$ (if there is one) for which $M - \delta M$ fails to have full rank. In particular, when $M \in \mathbb{C}^{n \times m}$, the real-restricted singular value of M, $\sigma_{\min}(M; \mathbb{R}^{n \times m})$ is the size of the smallest real matrix δM for which $M - \delta M$ fails to have full rank, i.e., $\mathcal{S} = \mathbb{R}^{n \times m}$. This paper considers the computation of $\sigma_{\min}(M; \mathbb{R}^{n \times m})$.

2. Problem formulation. The following notation proves to be useful throughout this paper:

$\|M\|$, the Frobenius norm of the matrix M;
$\|v\|$, the usual Euclidean norm of the vector v;
$\bar{a}$, the complex conjugate of the scalar or vector a;

M^H, the conjugate of the transpose of the matrix M;
M^T, the transpose of the matrix M (not conjugated);
$\sigma_n[M]$, the nth singular value of the matrix, M;
$\mathrm{Re}[x]$, the real part of x;
$\mathrm{Im}[x]$, the imaginary part of x;
$\ker[M]$, the kernel of the map from $\mathbb{C}^m \to \mathbb{C}^n$, determined by the matrix M;
$\mathrm{range}[M]$, the range of the map from $\mathbb{C}^m \to C^n$, determined by the matrix M;
M^+, the Moore–Penrose pseudoinverse of the matrix M.

Throughout this paper, M is always used to denote a matrix $M \in \mathbb{C}^{n\times m}$ with $m \geq n$ implied. The spaces $\mathbb{R}^{n\times m}$ and $\mathbb{C}^{n\times m}$ may be viewed as vector spaces with the usual topology. Often it is helpful to view $\mathbb{C}^{n\times m}$ as a $2nm$ dimensional linear space over the field of real numbers. This is indicated where necessary.

The measure $\sigma_{\min}(M; \mathbb{R}^{n\times m})$ is given by

DEFINITION 2.1. *Let $M \in \mathbb{C}^{n\times m}$ with $n \leq m$ and let*

$$\mathcal{S}(M; \mathbb{R}^{n\times m}) = \{\delta M \in \mathbb{R}^{n\times m} : \mathrm{rank}[M - \delta M] < n\}, \tag{2.1}$$

i.e., if M has full rank, $\mathcal{S}(M;\mathbb{R}^{n\times m})$ is the set of rank-reducing perturbations for M. Define

$$\sigma_{\min}(M; \mathbb{R}^{n\times m}) = \min_{\delta M \in \mathcal{S}(M;\, \mathbb{R}^{n\times m})} \|\delta M\|. \tag{2.2}$$

Some elementary properties of the set $\mathcal{S}(M; \mathbb{R}^{n\times m})$ demonstrate that the problem of finding a minimum norm element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$ is well posed. The following lemma characterizes the first of these properties.

LEMMA 2.2. *Let u be a nonzero element of $\mathbb{C}^n$, $n \geq 2$ such that and $\mathrm{Re}[u]$ and $\mathrm{Im}[u]$ are linearly independent. For each $M \in \mathbb{C}^{n\times m}$, there exists a perturbation matrix $\delta M \in \mathbb{R}^{n\times m}$ such that $u^H(M - \delta M) = 0$, i.e., δM is an element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$. Moreover, the smallest such δM is given by*

$$\delta M = \begin{bmatrix} \mathrm{Re}[u^H] \\ \mathrm{Im}[u^H] \end{bmatrix}^+ \begin{bmatrix} \mathrm{Re}[u^H M] \\ \mathrm{Im}[u^H M] \end{bmatrix}. \tag{2.3}$$

Proof. With δM as in (2.3), we show that $u^H \delta M = u^H M$. The pseudoinverse on the right side of (2.3) is actually a right inverse since $\mathrm{Re}[u]$ and $\mathrm{Im}[u]$ are linearly independent. Consider then,

$$\begin{aligned} u^H \delta M &= (\mathrm{Re}[u^H] + j\,\mathrm{Im}[u^H]) \begin{bmatrix} \mathrm{Re}[u^H] \\ \mathrm{Im}[u^H] \end{bmatrix}^+ \begin{bmatrix} \mathrm{Re}[u^H M] \\ \mathrm{Im}[u^H M] \end{bmatrix} \\ &= [\,1 \quad j\,] \begin{bmatrix} \mathrm{Re}[u^H M] \\ \mathrm{Im}[u^H M] \end{bmatrix} = u^H M \end{aligned}$$

as was to be shown. Being the solution to a least squares problem, this is the smallest such δM. □

Equation (2.3) of Lemma 2.2 provides a partial parametrization of some elements of $\mathcal{S}(M; \mathbb{R}^{n\times m})$. These elements of $\mathcal{S}(M; \mathbb{R}^{n\times m})$ are parametrized by the complex vector u. Proposition 3.3, which appears later in the paper, demonstrates that the parameterization of (2.3) includes a minimum norm element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$ if the imaginary part of M has full rank. Hence, it is possible to compute a minimum norm real element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$ by minimizing the norm of δM given by (2.3)

over $u \in \mathbb{C}^n$. However, a direct minimization of the Frobenius matrix norm using a standard minimization program poses a numerical stability problem halving the accuracy of the minimizing matrix. To see the difficulty, consider the minimization

$$\min_a \left\| \begin{pmatrix} 1 \\ a \end{pmatrix} \right\|.$$

The norm of the global minimum of this problem is numerically indistinguishable from the norm of the vector $[1, \sqrt{\epsilon}]$ since float $\|[1, \sqrt{\epsilon}]\| =$ float$\|[1, 0]\|$, where ϵ is any positive number less than the machine constant. Numerically speaking, these two vectors have the same norm. However, the two vectors are numerically distinguishable. This difficulty is avoided by requiring a solution to satisfy an orthogonality condition rather than directly minimizing a norm. In the context of the previous example, the minimizing vector must be numerically orthogonal (meaning that a numerical evaluation of the inner product yields approximately zero) to the vector $[0, 1]$. The vector $[1, \epsilon]$, which is a better solution than $[1, \sqrt{\epsilon}]$, is numerically orthogonal to $[0, 1]$.

LEMMA 2.3. *For each $M \in \mathbb{C}^{n\times m}$, the set $\mathcal{S}(M; \mathbb{R}^{n\times m})$ is closed.*

Proof. Let $\delta M_k \in \mathcal{S}(M; \mathbb{R}^{n\times m})$ be a sequence converging to δM_*. The proof is completed by showing that $\delta M_* \in \mathcal{S}(M; \mathbb{R}^{n\times m})$. For each δM_k, there exists a u_k satisfying $\|u_k^H\| = 1$ and

$$u_k^H(M - \delta M_k) = 0. \tag{2.4}$$

Because each u_k has unit length, there is a convergent subsequence $\{u_{k_n}\} \to u_*$ with the property that $\|u_*\| = 1$ and $u_*^H(M - \delta M_*) = 0$, by the continuity of (2.4). Hence δM_* must lie in $\mathcal{S}(M; \mathbb{R}^{n\times m})$. Again, if M has full rank, then δM_* is a real rank-reducing perturbation for M. □

The quantity $\sigma_{\min}(M; \mathbb{R}^{n\times m})$ is well defined as per the following.

PROPOSITION 2.4. *For each $M \in \mathbb{C}^{n\times m}$ with $n \geq 2$, there exists a $\delta M_* \in \mathcal{S}(M; \mathbb{R}^{n\times m})$ such that*

$$\sigma_{\min}(M; \mathbb{R}^{n\times m}) = \|\delta M_*\|.$$

Proof. From Lemmas 2.2 and 2.3, the set $\mathcal{S}(M; \mathbb{R}^{n\times m})$ is closed and nonempty. It is nonempty because the assumption $n \geq 2$ allows an arbitrary choice for u having real and imaginary parts as in Lemma 2.2. Let $\delta M_0 \in \mathcal{S}(M; \mathbb{R}^{n\times m})$ and consider the set

$$\mathcal{T} = \mathcal{S}(M; \mathbb{R}^{n\times m}) \cap \{\delta M \in \mathbb{R}^{n\times m}: \|\delta M\| \leq \|\delta M_0\|\}.$$

This set $\mathcal{T}$ is nonempty and compact. Hence, there is a $\delta M_* \in \mathcal{T}$ such that $\|\delta M_*\| = \min_{\delta M\in\mathcal{T}} \|\delta M\|$. Also, $\delta M_* \in \mathcal{T} \subset \mathcal{S}(M; \mathbb{R}^{n\times m})$. Clearly δM_* is a minimum norm matrix of $\mathcal{S}(M; \mathbb{R}^{n\times m})$. □

Since the problem of finding a real minimum norm element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$ is well posed for $n \geq 2$, it is possible to take up the question of computing δM_*.

Before developing an algorithm for computing the quantity $\sigma_{\min}(M; \mathbb{R}^{n\times m})$, it is useful to study the continuity of this measure. The next section examines the continuity of $\sigma_{\min}(M; \mathbb{R}^{n\times m})$ with respect to M.

3. The question of continuity. The behavior of the measure $\sigma_{\min}(M; \mathbb{R}^{n\times m})$ provides insight into its computation. For example, problems arise when examining the continuity of $\sigma_{\min}(M; \mathbb{R}^{n\times m})$. While studying the real-restricted controllability

robustness problem, Eising [3] encountered a discontinuity when performing a minimization equivalent to

$$\min_{\lambda \in \mathbb{C}} \sigma_n([A - \lambda I, \quad B]; \mathbb{R}^{n \times m}). \tag{3.1}$$

The root of this problem is indicated by the following proposition.

PROPOSITION 3.1. *The function* $\sigma_{\min}(M; \mathbb{R}^{n \times m})$ *is not continuous on* $\mathbb{C}^{n \times m}$.

The following example verifies this proposition.

Example 3.1. Let $\epsilon > 0$ and

$$M(\epsilon) = \begin{bmatrix} 1 & 0 \\ 0 & j\epsilon \end{bmatrix}.$$

The determinant of $M(\epsilon) - \delta M$ is given by

$$\det[M(\epsilon) - \delta M] = (\delta m_{11}\, \delta m_{22} - \delta m_{22} + \delta m_{21}\, \delta m_{12}) + j\epsilon(1 - \delta m_{11}).$$

Clearly, $\det[M(\epsilon) - \delta M] = 0$ implies that $\delta m_{11} = 1$ when $\epsilon > 0$. Any real rank-reducing perturbation δM satisfies $\|\delta M\| \geq 1$. Moreover, $\sigma_{\min}(M(\epsilon); \mathbb{R}^{n \times m}) = 1$ for every $\epsilon > 0$, but $\sigma_{\min}(M(0); \mathbb{R}^{n \times m}) = 0$. Thus

$$\lim_{\epsilon \to 0^+} \sigma_{\min}(M(\epsilon); \mathbb{R}^{n \times m}) \neq \sigma_{\min}(M(0); \mathbb{R}^{n \times m}),$$

which illustrates the discontinuity. This example is easily extended to larger dimensions.

The discontinuity implies that the problem of determining $\sigma_{\min}(M; \mathbb{R}^{n \times m})$ is potentially ill conditioned. More specifically, there is no guarantee that given any $\epsilon > 0$, there is some $\delta > 0$ and a "small" K such that

$$|\sigma_{\min}(M + \delta M; \mathbb{R}^{n \times m}) - \sigma_{\min}(M; \mathbb{R}^{n \times m})| < K\|\delta M\|$$

whenever $\|\delta M\| < \delta$.

Remarkably, however, the minimization of (3.1) is continuous and well conditioned for real matrices A and B even though the embedded problem of computing $\sigma_{\min}(M; \mathbb{R}^{n \times m})$ is neither continuous nor well conditioned. For example, the minimization of (3.1) can be effectively computed without explicitly determining $\sigma_{\min}(M; \mathbb{R}^{n \times m})$. See [10] for details.

The first goal of this section is to characterize the nature of these discontinuities. Continuity depends on the rank of the perturbation matrix δM_* that minimizes (2.2), or equivalently on the space spanned by the real and imaginary parts of the left null-vector of $M - \delta M_*$. The next two propositions characterize properties needed before studying continuity.

PROPOSITION 3.2. *Let* $M \in \mathbb{C}^{n \times m}$. *If* δM_* *is a minimum norm element of* $\mathcal{S}(M; \mathbb{R}^{n \times m})$, *then* $\operatorname{rank}[\delta M_*] \leq 2$.

Proof. Clearly there exists a unit length $u \in \mathbb{C}^n$ such that $u^H(M - \delta M_*) = 0$. Consider the minimization problem,

$$\min_{\delta M \in \mathbb{R}^{n \times m}} \left\| \begin{bmatrix} \operatorname{Re}[u^H] \\ \operatorname{Im}[u^H] \end{bmatrix} \delta M - \begin{bmatrix} \operatorname{Re}[u^H M] \\ \operatorname{Im}[u^H M] \end{bmatrix} \right\| = 0. \tag{3.2}$$

The minimum must be zero since letting $\delta M = \delta M_*$ in (3.2) yields zero. This is a linear least squares problem, having as its unique minimum norm solution the matrix

$$\delta M_0 = \begin{bmatrix} \mathrm{Re}[u^H] \\ \mathrm{Im}[u^H] \end{bmatrix}^+ \begin{bmatrix} \mathrm{Re}[u^H M] \\ \mathrm{Im}[u^H M] \end{bmatrix}.$$

The matrix δM_0 is an element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$ and must have norm greater than or equal to that of δM_*. However, δM_0 is also the minimum norm solution to problem (3.2) and must have norm less than or equal to that of δM_*, since δM_* is also a solution to (3.2). Thus, $\|\delta M_0\| = \|\delta M_*\|$. From the uniqueness of the minimum norm solution to (3.2), $\delta M_0 = \delta M_*$. The matrix δM_* clearly has rank zero, one, or two. □

PROPOSITION 3.3. *Let $M \in \mathbb{C}^{n\times m}$ for which $\mathrm{Im}[M]$ has full rank and $n \geq 2$. Let u be any nonzero vector such that $u^H(M - \delta M_0) = 0$, where δM_0 is any element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$. The vectors, $\mathrm{Re}[u]$ and $\mathrm{Im}[u]$ are linearly independent.*

Proof. Let δM_0 be any element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$. Suppose there is a nonzero vector u satisfying $u^H(M - \delta M_0) = 0$, but for which $\mathrm{Re}[u]$ and $\mathrm{Im}[u]$ are linearly dependent. As such, there exists a constant, $c \in \mathbb{C}$ of modulus one, such that $\mathrm{Im}[cu] = 0$. Let $\hat{u} = cu$. The vector $\hat{u}$ satisfies $\hat{u}^H(M - \delta M_0) = 0$ implying

$$\mathrm{Im}[\hat{u}^H(M - \delta M_0)] = \hat{u}^H \mathrm{Im}[M] = 0,$$

which would imply $\mathrm{Im}[M]$ does not have full rank. □

Upper and lower bounds for $\sigma_{\min}(M; \mathbb{R}^{n\times m})$ are useful. Proposition 3.5 that follows, provides these bounds. The development of this upper bound requires the following lemma.

LEMMA 3.4. *Let $u_1, u_2 \in \mathbb{C}^n$ be linearly independent. There exists a nonzero vector, $x \in \mathrm{span}\{u_1, u_2\}$, such that $\|\mathrm{Re}[x]\| = \|\mathrm{Im}[x]\|$ and $(\mathrm{Re}[x])^T(\mathrm{Im}[x]) = 0$.*

Proof. Note that for $x \in \mathbb{C}^n$, $\|\mathrm{Re}[x]\| = \|\mathrm{Im}[x]\|$ and $(\mathrm{Re}[x])^T(\mathrm{Im}[x]) = 0$ if and only if $x^T x = 0$. Given linearly independent $u_1, u_2 \in \mathbb{C}^{n\times m}$, suppose $u_1^T u_1 \neq 0$; otherwise the result follows trivially. For some as yet unspecified $c \in \mathbb{C}$, consider the quantity,

$$(cu_1 + u_2)^T(cu_1 + u_2) = (u_1^T u_1)c^2 + 2(u_1^T u_2)c + (u_2^T u_2).$$

This quadratic has a zero for some $c \in \mathbb{C}$ since $u_1^T u_1$ is nonzero. Let $x = cu_1 + u_2$. This x has the stated properties, which completes the proof. □

PROPOSITION 3.5. *It holds that $\sigma_n[M] \leq \sigma_{\min}(M; \mathbb{R}^{n\times m}) \leq \sqrt{2}\sigma_{n-1}[M]$.*

Proof. The lower bound given is obvious. To establish the upper bound, let u_{n-1} be a unit length left singular vector associated with $\sigma_{n-1}[M]$ and let u_n be a unit length left singular vector associated with $\sigma_n[M]$. From Lemma 3.4 there exist constants $c_1, c_2 \in \mathbb{C}$ for which $x = c_1 u_{n-1} + c_2 u_n$ satisfies $\|\mathrm{Re}[x]\| = \|\mathrm{Im}[x]\| = 1$ and $(\mathrm{Re}[x])^T(\mathrm{Im}[x]) = 0$. Consider the matrix,

$$\delta M \triangleq [\,\mathrm{Re}[x] \quad -\mathrm{Im}[x]\,] \begin{bmatrix} \mathrm{Re}[x^H M] \\ \mathrm{Im}[x^H M] \end{bmatrix}.$$

This matrix δM is an element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$ since $x^H \delta M = x^H M$. Also

$$\|\delta M\| = \left\| \begin{bmatrix} \mathrm{Re}[x^H M] \\ \mathrm{Im}[x^H M] \end{bmatrix} \right\| = \|x^H M\|$$

from the orthogonality of the real and imaginary parts of x. It follows that

$$\|x^H M\|^2 = |c_1|^2\sigma_{n-1}^2[M] + |c_2|^2\sigma_n^2[M] \leq 2\sigma_{n-1}^2[M]$$

since $|c_1|^2 + |c_2|^2 = 2$. It follows that $\sigma_{\min}(M; \mathbb{R}^{n\times m}) \leq \sqrt{2}\sigma_{n-1}[M]$. This completes the proof of Proposition 3.5. □

The next two results, Lemma 3.6 and Proposition 3.7 establish that a nonzero minimum norm element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$, say δM_* satisfies $\text{rank}[M - \delta M_*] = n - 1$, i.e., the $n-$ 1st singular value of $M - \delta M_*$ is strictly positive, when $\text{Im}[M]$ has full rank.

LEMMA 3.6. *Let $M \in \mathbb{C}^{n\times m}$ for which $\text{Im}[M]$ has full rank and $n \geq 2$. Let δM be any element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$. For any two nonzero vectors in the left kernel of $M - \delta M$, say u_1 and u_2,*

$$\text{span}\,[\,\text{Re}[u_1],\quad \text{Im}[u_1]\,] \cap \text{span}\,[\,\text{Re}[u_2],\quad \text{Im}[u_2]\,] \neq \{0\}$$

if and only if $u_1 = cu_2$ for some $c \in \mathbb{C}$.

Proof. Let δM be an element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$ and let u_1 and u_2 be nonzero vectors in the left kernel of $M - \delta M$. Suppose there are nonzero real vectors x and y such that

$$[\,\text{Re}[u_1],\quad \text{Im}[u_1]\,]\begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = [\,\text{Re}[u_2],\quad \text{Im}[u_2]\,]\begin{bmatrix} y_1 \\ y_2 \end{bmatrix},$$

i.e., $\text{Re}[u_1(x_1 - jx_2) - u_2(y_1 - jy_2)] = 0$. Proposition 3.3 implies that $u_1(x_1 - jx_2) - u_2(y_1 - jy_2)$ must be zero since its real part is zero and it is obviously in the left kernel of $M - \delta M$. Hence $u_1 = cu_2$ for some c, completing the lemma (the converse is obvious). □

PROPOSITION 3.7. *Let $M \in \mathbb{C}^{n\times m}$ for which $\text{Im}[M]$ has full rank and $n \geq 2$ and let δM_* be a nonzero minimum norm element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$, then* $\text{rank}[M - \delta M_*] = n - 1$.

Proof. Let u_1 and u_2 be any two nonzero vectors in the left kernel of $M - \delta M_*$. By the construction used in Lemma 2.2, specifically (2.3), it follows that

$$\text{range}[\delta M_*] \subset \text{span}\,[\,\text{Re}[u_1],\quad \text{Im}[u_1]\,]$$

and

$$\text{range}[\delta M_*] \subset \text{span}\,[\,\text{Re}[u_2],\quad \text{Im}[u_2]\,].$$

By Lemma 3.6, $u_1 = cu_2$. The vectors u_1 and u_2 cannot be linearly independent. These vectors were arbitrary in the kernel of $M - \delta M_*$; hence, the result follows. □

The points of discontinuity of the restricted singular values have a special structure; given $M \in \mathbb{C}^{n\times m}$ and any sequence, $\{M_k\} \to M$, the value of $\sigma_{\min}(M; \mathbb{R}^{n\times m})$ is always less than or equal to the limit of the sequence $\{\sigma_{\min}(M_k; \mathbb{R}^{n\times m})\}$. More specifically, the nature of these points is characterized by the following lemma.

LEMMA 3.8. *If $\{M_k\} \in \mathbb{C}^{n\times m}, n \geq 2$ is any sequence converging to M, then*

$$\sigma_{\min}(M; \mathbb{R}^{n\times m}) \leq \liminf\{\sigma_{\min}(M_k; \mathbb{R}^{n\times m})\}.$$

Proof. For each M_k there is a unit length vector u_k and minimum norm element of $\mathcal{S}(M_k; \mathbb{R}^{n\times m})$, say δM_k, satisfying

$$u_k^H(M_k - \delta M_k) = 0 \tag{3.3}$$

by Proposition 2.4. Also,

$$\sigma_{\min}(M_k; \mathbb{R}^{n\times m}) = \|\delta M_k\|. \tag{3.4}$$

Let $l = \liminf\{\sigma_{\min}(M_k; \mathbb{R}^{n\times m})\}$. The sequence, $\{\sigma_{\min}(M_k; \mathbb{R}^{n\times m})\}$ is bounded, by Proposition 3.5 and the convergence of $\{M_k\}$. Therefore, the value l is finite. The sequence $\{u_k\}$ is bounded as is the sequence $\{\delta M_k\}$. Thus a subsequence indexing k_n exists such that $\{\sigma_{\min}(M_{k_n}; \mathbb{R}^{n\times m})\} \to l$, $\{u_{k_n}\} \to u$, and $\{\delta M_{k_n}\} \to \delta M$ for some u and δM. The limits u and δM are assumed to have no special relationship yet. From the continuity of (3.3), however,

$$u^H(M - \delta M) = 0.$$

This shows that δM is an element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$ implying

$$\sigma_{\min}(M; \mathbb{R}^{n\times m}) \le \|\delta M\|.$$

Taking the limit of (3.4) (with respect to the subsequence indexing), however, implies $\|\delta M\| = l$, as was to be shown. □

PROPOSITION 3.9. *Let $M \in \mathbb{C}^{n\times m}, n \ge 2$ be such that $\mathrm{Im}[M]$ has full rank, then $\sigma_{\min}(M; \mathbb{R}^{n\times m})$ is continuous at M in $\mathbb{C}^{n\times m}$.*

Proof. Let $\{M_k\}$ be any sequence that converges to M. There exist a nonzero vector u and a minimum norm element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$ say δM_* that satisfy $u^H(M - \delta M_*) = 0$. From Proposition 3.3, the vectors $\mathrm{Re}[u]$ and $\mathrm{Im}[u]$ are linearly independent. The matrix

$$\delta M_k \triangleq \begin{bmatrix} \mathrm{Re}[u^H] \\ \mathrm{Im}[u^H] \end{bmatrix}^+ \begin{bmatrix} \mathrm{Re}[u^H M_k] \\ \mathrm{Im}[u^H M_k] \end{bmatrix}$$

is a continuous function of M_k and is an element of $\mathcal{S}(M_k; \mathbb{R}^{n\times m})$ (Lemma 2.2). Also, as per the proof of Proposition 3.2,

$$\delta M_* = \begin{bmatrix} \mathrm{Re}[u^H] \\ \mathrm{Im}[u^H] \end{bmatrix}^+ \begin{bmatrix} \mathrm{Re}[u^H M] \\ \mathrm{Im}[u^H M] \end{bmatrix}.$$

Hence it follows that

$$\lim\{\delta M_k\} = \delta M_*$$

and

$$\lim\{\|\delta M_k\|\} = \sigma_{\min}(M; \mathbb{R}^{n\times m}).$$

Clearly, however,

$$\|\delta M_k\| \ge \sigma_{\min}(M_k; \mathbb{R}^{n\times m}),$$

since δM_k is an element of $\mathcal{S}(M_k; \mathbb{R}^{n\times m})$ but not necessarily having minimum norm. Therefore,

$$\lim\{\|\delta M_k\|\} \ge \limsup\{\sigma_{\min}(M_k; \mathbb{R}^{n\times m})\}.$$

Combining the above yields

$$\sigma_{\min}(M; \mathbb{R}^{n\times m}) \ge \limsup\{\sigma_{\min}(M_k; \mathbb{R}^{n\times m})\}.$$

Combining this result with that of Lemma 3.8 yields

$$\lim\{\sigma_{\min}(M_k; \mathbb{R}^{n\times m})\} = \sigma_{\min}(M; \mathbb{R}^{n\times m}).$$

This establishes the continuity of $\sigma_{\min}(M; \mathbb{R}^{n\times m})$ at M which was to be shown. □

Proposition 3.9 implies that points of discontinuity of $\sigma_{\min}(M; \mathbb{R}^{n\times m})$ will be avoided if $\mathrm{Im}[M]$ is known to have full rank. This full rank condition is generally the case for the minimizations of (1.2) and (1.3). As long as $\sigma_n[\mathrm{Im}[M]]$ is greater than the roundoff or measurement uncertainty of M, Proposition 3.9 ensures that M is a safe distance from a point of discontinuity of $\sigma_{\min}(M; \mathbb{R}^{n\times m})$.

The next goal of this paper is to develop necessary conditions that a minimizer of (2.2) must satisfy. The next section addresses this question.

4. Development of necessary condition. The following lemma provides a necessary condition for a particular perturbation matrix to be a minimizer of (2.2), when $\mathrm{Im}[M]$ has full rank.

LEMMA 4.1. *Let $M \in \mathbb{C}^{n\times m}$ be a matrix for which $\mathrm{Im}[M]$ has full rank and $n \geq 2$. Let δM_0 be any element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$. If there is a real matrix $\delta\tilde{M}_0$ such that* (i) $\|\delta\tilde{M}_0\| < \|\delta M_0\|$ *and* (ii) *some nontrivial $u_0 \in \ker[(M - \delta M_0)^H]$ and every $v \in \ker[M - \delta M_0]$ satisfy $u_0^H(M - \delta\tilde{M}_0)v = 0$ (or equivalently $u_0^H(\delta M_0 - \delta\tilde{M}_0)v = 0$), then there exists a δM_1 in $\mathcal{S}(M; \mathbb{R}^{n\times m})$ such that $\|\delta M_1\| < \|\delta M_0\|$.*

Proof. Let $\delta M_0 \in \mathcal{S}(M; \mathbb{R}^{n\times m})$ and let $\delta\tilde{M}_0$ be any matrix satisfying (i) and (ii) above. Assume $M - \delta\tilde{M}_0$ has full rank, otherwise $\delta\tilde{M}_0$ is an element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$ having norm smaller than the norm of δM_0, in which case the result follows immediately. Let $u_0 \in \ker[(M - \delta M_0)^H]$ be arbitrary and let $x_0^H = u_0^H(\delta\tilde{M}_0 - M)$ or equivalently $x_0^H = u_0^H(\delta\tilde{M}_0 - \delta M_0)$. From condition (ii) x_0 is orthogonal to every $v \in \ker(M - \delta M_0)$. It follows that $x_0 \in \mathrm{range}[(M - \delta M_0)^H]$. Hence, there exists a $\tilde{u}_0 \in \mathrm{range}[M - \delta M_0]$ such that $\tilde{u}_0^H(M - \delta M_0) = x_0^H$. The remainder of the proof constructs a real rank-reducing perturbation smaller than δM_0 having a linear combination of u_0 and $\tilde{u}_0$, as a left null vector.

Consider the sequence obtained from the product,

$$[u_0 + \gamma\tilde{u}_0]^H[(M - \delta M_0) - \gamma(\delta\tilde{M}_0 - \delta M_0)] = -\gamma^2\tilde{u}_0^H(\delta\tilde{M}_0 - \delta M_0). \tag{4.1}$$

For γ sufficiently small, a real matrix perturbation can be used to cancel this vector. Consider the matrix,

$$\delta M_\gamma \triangleq \gamma^2 \begin{bmatrix} \mathrm{Re}[u_0^H + \gamma\tilde{u}_0^H] \\ \mathrm{Im}[u_0^H + \gamma\tilde{u}_0^H] \end{bmatrix}^+ \begin{bmatrix} \mathrm{Re}[\tilde{u}_0^H(\delta\tilde{M}_0 - \delta M_0)] \\ \mathrm{Im}[\tilde{u}_0^H(\delta\tilde{M}_0 - \delta M_0)] \end{bmatrix}. \tag{4.2}$$

The pseudoinverse on the right side of (4.2) is actually a right-inverse for sufficiently small γ, say $\gamma < \gamma_0$, because $\mathrm{Re}[u_0]$ and $\mathrm{Im}[u_0]$ are linearly independent by Proposition 3.3. Hence, for $\gamma < \gamma_0$,

$$[u_0 + \gamma\tilde{u}_0]^H\delta M_\gamma = \gamma^2\tilde{u}_0^H(\delta\tilde{M}_0 - \delta M_0). \tag{4.3}$$

Thus, adding (4.3) to (4.1) yields

$$[u_0 + \gamma\tilde{u}_0]^H\left[M - [\gamma\delta\tilde{M}_0 + (1 - \gamma)\delta M_0 - \delta M_\gamma]\right] = 0,$$

i.e., $[\gamma\delta\tilde{M}_0 + (1 - \gamma)\delta M_0 - \delta M_\gamma]$ is a rank-reducing real perturbation for M. Clearly $\lim_{\gamma\to 0}(1/\gamma^2)\delta M_\gamma < \infty$ (examine (4.2)). For an appropriate constant b and $\gamma < \gamma_0$, it follows that $\|\delta M_\gamma\| \leq \gamma^2 b$. The norm of the matrix $[\gamma\delta\tilde{M}_0 + (1 - \gamma)\delta M_0 - \delta M_\gamma]$ can be made less than $\|\delta M_0\|$ by an appropriate choice for γ, since the norm of $\delta\tilde{M}_0$

is less than the norm of δM_0 and the norm of δM_γ vanishes quadratically. (One such choice is $\gamma < \max\{\frac{1}{b}[\|\delta M_0\| - \|\delta \tilde{M}_0\|], \gamma_0\}$.) This shows that for any k_0 satisfying

$$\gamma < \max\left\{\frac{1}{b}[\|\delta M_0\| - \|\delta \tilde{M}_0\|], \gamma_0\right\},$$

the matrix

$$\delta M_1 = [\gamma \delta \tilde{M}_0 + (1-\gamma)\delta M_0 - \delta M_\gamma]$$

is a real rank-reducing perturbation having norm less than $\|\delta M_0\|$. This completes the proof. □

The following necessary condition follows immediately from Lemma 4.1.

THEOREM 4.2. *Let $M \in \mathbb{C}^{n\times m}$ be a matrix for which* Im$[M]$ *has full rank and $n \geq 2$; let δM_* be a minimum norm element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$; and let the matrix $\delta \hat{M}$ be the unique real matrix having smallest norm that satisfies*

$$u^H(\delta \hat{M})v = u^H M v \tag{4.4}$$

for some nonzero $u \in \ker[(M - \delta M_*)^H]$ and every $v \in \ker[(M - \delta M_*)]$. The matrices δM_* and $\delta \hat{M}$ must be equal.

Proof. Let δM_* be a minimum norm element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$. It is apparent that for some nonzero $u \in \ker[(M - \delta M_*)^H]$ and every $v \in \ker[M - \delta M_*]$, the matrix δM_* satisfies $u^H(M - \delta M_*)v = 0$. If it were not the smallest such matrix, then Lemma 4.1 would provide a smaller rank-reducing real perturbation matrix. But that is impossible since δM_* is a minimum norm real rank-reducing perturbation. □

Note that the dimension of the left kernel of $M - \delta M_*$ in Theorem 4.2 is one due to Proposition 3.7.

Theorem 4.2 provides a necessary condition for obtaining a candidate for a minimizer of $\mathcal{S}(M; \mathbb{R}^{n\times m})$. The next section proposes algorithms that converge to a matrix satisfying this necessary condition.

5. Algorithm development. This section examines an algorithm for finding an element $\delta M \in \mathcal{S}(M; \mathbb{R}^{n\times m})$ that satisfies the necessary condition of Theorem 4.2. Given a rank-reducing perturbation δM, Theorem 4.2 provides a test to check whether δM satisfies a necessary condition for being a minimum norm element of $\mathcal{S}(M; \mathbb{R}^{n\times m})$. Moreover, given an initial approximation for the minimum norm, real matrix perturbation δM_k the solution of a least squares problem similar to (4.4) in Theorem 4.2 yields a matrix $\delta \hat{M}_k$, which can be used to find a better approximation to the desired solution. Furthermore, it can be shown that an improved approximation lies on the line connecting δM_k and $\delta \hat{M}_k$. The approximation is improved in the sense that the successive approximation decreases the value of a certain Lyapunov function at each iteration. Specifically, the Lyapunov function used to prove convergence of the algorithm is $P_k = [\sigma_n]_k + g_k\|\delta M_k\|$.

The Lyapunov function consists of two terms: the first term $[\sigma_n]_k$ measures closeness to $\mathcal{S}(M; \mathbb{R}^{n\times m})$ while the second measures the norm $\|\delta M_k\|$. The constant g_k is an adaptive weight parameter that is adjusted based on the condition of the problem. Establishing convergence of the Lyapunov function values to a constant and convergence of $[\sigma_n]_k$ to zero are the keys to proving convergence of the forthcoming algorithm.

Two assumptions will simplify the description of the algorithm and the discussion of its convergence. The assumptions are unnecessary for constructing a convergent algorithm; however, the clarity gained in the discussion warrants their introduction.

Assumption 1. The sequence $\{[\sigma_{n-1}]_k\}$ computed by the algorithm below is bounded away from zero.

Assumption 2. The sequence $\{g_k\}$ computed by the algorithm below is bounded away from zero, where g_k essentially measures the linear independence of the real and imaginary parts of the nth left singular vector of $M - \delta M_k$.

Proposition 3.7 motivates Assumption 1 because it demonstrates that a solution matrix δM_* satisfying the necessary condition cannot satisfy $\text{rank}[M - \delta M_*] < n - 1$. The algorithm below generates a sequence of real matrices δM_k having a subsequence converging to a matrix δM_*. So long as the sequence of singular values $[\sigma_{n-1}]_k$ of $M - \delta M_k$ is bounded away from zero the algorithm computes a matrix satisfying the necessary condition for a matrix in a neighborhood of the original M. It is possible to construct an algorithm that allows $[\sigma_{n-1}]_k$ to become zero at a finite number of points and converges to a matrix satisfying the necessary condition. However, dealing with this rare situation complicates the specification and discussion of the algorithm. For simplicity the algorithm is presented and analyzed under the assumption that $[\sigma_{n-1}]_k$ is bounded away from zero.

Proposition 3.3 motivates Assumption 2. Lemma A.2 in Appendix A shows that g_k is bounded below by the inverse of the spectral condition number of the matrix $[\,\text{Re}[u_n]_k,\ \text{Im}[u_n]_k\,]$. Proposition 3.3 ensures that this condition number remains bounded in a neighborhood of a solution point. Assumption 2 can be removed by changing the initial value for g_0 and the initial choice for δM_0 given in the algorithm. Proposition A.3 of Appendix A discusses removal of Assumption 2.

The quantities to be computed by the algorithm are illustrated graphically in Fig. 1. It is useful to consider the algorithm with reference to this figure.

ALGORITHM STATEMENT. Given a prespecified constant ϵ:

1. Let $k = 0$, let δM_0 be any real matrix satisfying $\text{rank}[M - \delta M_0] = n - 1$ and let $g_0 = 1$.[1]

2. Compute a singular value decomposition of $M - \delta M_k$, i.e., find orthonormal sets $\{[u_i]_k\}$, $i = 1, \ldots, n$ and $\{[v_i]_k\}$, $i = 1, \ldots, m$ so that

$$M - \delta M_k = \sum_{i=1}^{n} [u_i]_k [\sigma_i]_k [v_i]_k^H.$$

3. Define $V_k = [\,[v_n]_k \quad [v_{n+1}]_k \quad \ldots \quad [v_m]_k\,]$.

4. Compute $\delta \bar{M}_k$, a matrix direction designed to decrease the nth singular value. Let $\delta \bar{M}_k$ be the unique real matrix having smallest norm for which

$$[u_n]_k{}^H \delta \bar{M}_k V_k = [\,[\sigma_n]_k \quad 0 \quad \ldots \quad 0\,].$$

5. Compute $\delta \tilde{M}_k$, a matrix direction designed to decrease the norm of the real perturbation without changing the nth singular value. Let $\delta \tilde{M}_k$ be the unique real matrix having smallest norm for which

$$[u_n]_k{}^H \delta \tilde{M}_k V_k = [u_n]_k{}^H \delta M_k V_k.$$

---

[1]The less restrictive choice $\delta M_0 = [0]$ will work provided Assumptions 1 and 2 remain valid and provided that a left singular vector associated with the nth left singular value of M has linearly independent real and imaginary parts.

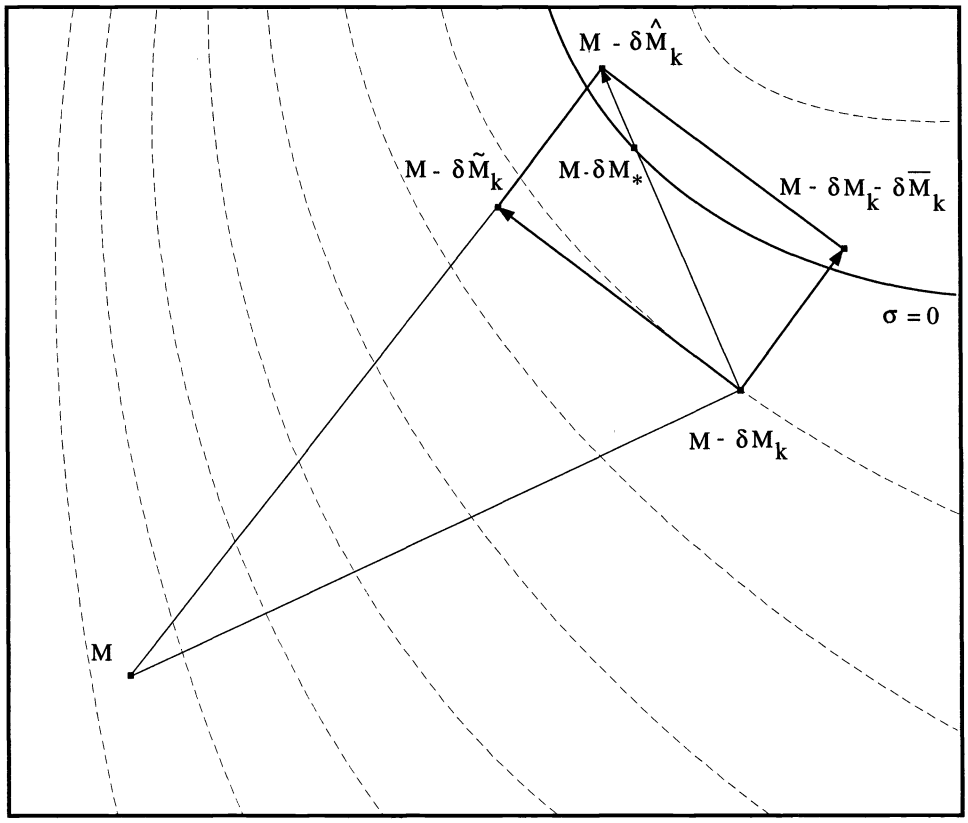

FIG. 1. *Geometric relationships among computed quantities and singular value level sets.*

(Lemma 2.2 guarantees the consistency of the equations and the existence of a solution in steps 4 and 5. The equation in step 5 comes from equating $[u_n]_k{}^H(M - \delta\tilde{M}_k)V_k$ to $[u_n]_k{}^H(M - \delta M_k)V_k$.

6. If $[\sigma_n]_k < \epsilon\|M - \delta M_k\|$ and $g_k\|\delta\tilde{M}_k - \delta M_k\| < \epsilon\|M - \delta M_k\|$ then stop; otherwise continue.

7. Define

$$g_k = \min\left(g_{k-1}, \frac{[\sigma_n]_k}{2\|\delta\bar{M}_k\|}\right)$$

when $[\sigma_n]_k \neq 0$; define $g_k = g_{k-1}$ otherwise.

8. Define

$$[\hat{u}]_k{}^H = \left[[u_n]_k^H(\delta\hat{M}_k - \delta M_k) - [\sigma_n]_k[v_n]_k^H\right](M - \delta M_k)^+,$$

where $\delta\hat{M}_k = \delta\tilde{M}_k + \delta\bar{M}_k$.

9. Define $\gamma_k = \min(\frac{1}{4}\frac{1}{q_k}([\sigma_n]_k + g_k b_k\|\delta\tilde{M}_k - \delta M_k\|), 1)$, where

$$q_k = \|\hat{u}_k^H(\delta\hat{M}_k - \delta M_k)\|$$

and

$$b_k = \begin{cases} \frac{\|\delta\tilde{M}_k - \delta M_k\|}{\|\delta M_k\|} & \text{if } \|\delta M_k\| \neq 0, \\ 0 & \text{otherwise.} \end{cases}$$

10. Set $\delta M_{k+1} = \gamma_k \delta M_k + (1 - \gamma_k)\delta\hat{M}_k$.
11. Let $k = k + 1$ and go to step 2.

A graphical illustration of the basic geometry involved in the algorithm appears in Fig. 1. In this figure, M is the given complex matrix. The dashed lines represent level sets of $\sigma_n(M - \delta M)$ in the space of real matrices δM. The solid curved line represents the level set corresponding to $\text{rank}[M - \delta M] = 0$. The matrix $M - \delta M_*$ is the desired solution point. The current approximation to $M - \delta M_*$, i.e., $M - \delta M_k$, appears at the lower right corner of the rectangle in the figure. Traveling along the right edge of the rectangle toward $M - \delta M_k - \delta\bar{M}_k$ decreases σ_n. This direction is normal to the level set at $M - \delta M_k$. The upper right corner lies near the zero level set. On the other hand, traveling from $M - \delta M_k$ toward the lower left corner decreases the norm of the perturbation with a small change in σ_n. This side of the rectangle is (i) tangent to the level set at $M - \delta M_k$, (ii) orthogonal to the line connecting M and $M - \delta\tilde{M}_k$, and (iii) orthogonal to the line connecting $M - \delta M_k$ and $M - \delta M_k - \delta\bar{M}_k$. Traveling along the diagonal of the rectangle, the approach taken here attempts to meet both objectives. Some point along the diagonal decreases the value of the Lyapunov function that represents a weighted combination of both objectives. This geometry proves useful in interpreting the theorems and proofs below.

The proof of the convergence of this algorithm requires four lemmas. It is helpful to view $\mathbb{R}^{n\times m}$ as a vector space equipped with the inner product, $< \cdot, \cdot >$, defined as follows for $M, N \in \mathbb{R}^{n\times m}$:

$$< M, N >= \sum_{i=1}^{n}\sum_{j=1}^{m} m_{ij} n_{ij}.$$

The norm induced by this inner product is the Frobenius norm.

In the algorithm, the matrix $\delta\hat{M}_k$ is the sum of two matrix components, $\delta\bar{M}_k$ and $\delta\tilde{M}_k$. Given δM_k, traveling in the matrix direction $\delta\bar{M}_k$ serves to decrease the size of $[\sigma_n]_k$ while the direction $\delta\tilde{M}_k - \delta M_k$ decreases the norm of δM_k. Traveling along the diagonal of the rectangle shown in Fig. 1 decreases the value of the Lyapunov function. Recall that $\delta\tilde{M}_k$ and $\delta\bar{M}_k$ are obtained from steps 4 and 5 of the algorithm as follows: $\delta\tilde{M}_k$ is a minimum norm real matrix satisfying

$$[u_n]_k{}^H \delta\tilde{M}_k V_k = [u_n]_k{}^H \delta M_k V_k,$$

while $\delta\bar{M}_k$ is a minimum norm real matrix satisfying

$$[u_n]_k{}^H \delta\bar{M}_k V_k = [\,[\sigma_n]_k \quad 0 \quad \dots \quad 0\,].$$

Moreover, $\delta\hat{M}_k = \delta\bar{M}_k + \delta\tilde{M}_k$.

Lemma 5.1, which follows, demonstrates the orthogonality of $\delta\tilde{M}_k - \delta M_k$ and $\delta\tilde{M}_k$ with respect to the inner product defined above.

LEMMA 5.1. *For any $\alpha, \beta \in \mathbb{R}$ the matrices $\delta\tilde{M}_k$ and $\delta\tilde{M}_k - \delta M_k$ are orthogonal. Hence, $\delta\tilde{M}_k$ and δM_k satisfy*

$$\|\alpha\delta\tilde{M}_k + \beta[\delta\tilde{M}_k - \delta M_k]\|^2 = |\alpha|^2\|\delta\tilde{M}_k\|^2 + |\beta|^2\|\delta\tilde{M}_k - \delta M_k\|^2.$$

Proof. The matrix $\delta\tilde{M}_k - \delta M_k$ satisfies

$$[u_n]_k{}^H(\delta\tilde{M}_k - \delta M_k)V_k = 0. \tag{5.1}$$

Since $\delta\tilde{M}_k$ is chosen to be a minimum norm solution in step 5 and since

$$[u_n]_k{}^H\left[\delta\tilde{M}_k + c(\delta\tilde{M}_k - \delta M_k)\right]V_k = [u_n]_k{}^H\delta M_k V_k$$

for all real c, it follows that $\|\delta\tilde{M}_k + c(\delta\tilde{M}_k - \delta M_k)\| > \|\delta\tilde{M}_k\|$ for all $c \neq 0$. This can only occur if $\delta\tilde{M}_k$ and $\delta\tilde{M}_k - \delta M_k$ are orthogonal with respect to the inner product on $\mathbb{R}^{n\times m}$. The result follows from the stated orthogonality. □

Lemma 5.2, which follows, provides an upper bound for the size of the solution of a particular matrix equation.

LEMMA 5.2. *Given $[v_i]_k$ for $i = 1,\ldots,m$, and $M - \delta M_k$ as defined in the algorithm, for any integer $r < n$ and any matrix, X, if $X^H[v_i]_k = 0$ for $i = r+1,\ldots,m$ and $[\sigma_r]_k \neq 0$, then there exists a matrix Y for which $Y^H(M - \delta M_k) = X^H$. Moreover, $\|Y\| \leq [\sigma_r]_k^{-1}\|X\|$.*

Proof. The result follows immediately from some elementary properties of singular spaces. □

Lemma 5.3 below provides a bound for the decrease in the norm of δM_k when moving along the path from δM_k toward $\delta\hat{M}_k$, which is the diagonal of the rectangle shown in Fig. 1.

LEMMA 5.3. *At each iteration,*

$$\|(1-\gamma)\delta M_k + \gamma\delta\hat{M}_k\| - \|\delta M_k\| \leq \gamma(\|\delta\bar{M}_k\| - \frac{1}{2}b_k\|\delta\tilde{M}_k - \delta M_k\|)$$

for $\gamma \in (0,1)$.

Proof. Assume $\|\delta M_k\| \neq 0$ otherwise the result follows trivially, since $\delta\hat{M}_k = \delta\bar{M}_k$ and $\delta\tilde{M}_k = 0$ in this case. Notice that

$$\begin{aligned}
\|(1-\gamma)\delta M_k + \gamma\delta\tilde{M}_k\|^2 &= \|(\gamma-1)(\delta\tilde{M}_k - \delta M_k) + \delta\tilde{M}_k\|^2 \\
&= (\gamma-1)^2\|\delta\tilde{M}_k - \delta M_k\|^2 + \|\delta\tilde{M}_k\|^2 \\
&= (\gamma)(\gamma-2)\|\delta\tilde{M}_k - \delta M_k\|^2 + (\|\delta\tilde{M}_k - \delta M_k\|^2 + \|\delta\tilde{M}_k\|^2) \\
&= (\gamma)(\gamma-2)\|\delta\tilde{M}_k - \delta M_k\|^2 + \|\delta M_k\|^2
\end{aligned}$$

follows from two applications of Lemma 5.1. In consequence,

$$\|(1-\gamma)\delta M_k + \gamma\delta\tilde{M}_k\|^2 - \|\delta M_k\|^2 = (\gamma)(\gamma-2)\|\delta\tilde{M}_k - \delta M_k\|^2$$

implying that

$$\|(1-\gamma)\delta M_k + \gamma\delta\tilde{M}_k\| - \|\delta M_k\| \leq -\frac{\gamma}{2}\frac{\|\delta\tilde{M}_k - \delta M_k\|^2}{\|\delta M_k\|} \tag{5.2}$$

for $\gamma \in (0,1)$. The previous inequality was obtained by dividing both sides by $\|(1-\gamma)\delta M_k + \gamma\delta\tilde{M}_k\| + \|\delta M_k\|$ and restricting $\gamma \in (0,1)$. A simple application of the triangle inequality results in

$$\|(1-\gamma)\delta M_k + \gamma\delta\hat{M}_k\| - \|\delta M_k\| \leq -\frac{\gamma}{2}\frac{\|\delta\tilde{M}_k - \delta M_k\|^2}{\|\delta M_k\|} + \gamma\|\delta\bar{M}_k\|.$$

This differs from (5.2) since the tilde (˜) has been changed to a hat (ˆ) on the left side. (Recall from step 8 of the algorithm that $\delta\hat{M}_k = \delta\tilde{M}_k + \delta\bar{M}_k$.) This completes the proof of the lemma. □

The fourth lemma provides a bound for the change in the nth singular value of $M - \delta M$ when moving along the path from δM_k toward $\delta \hat{M}_k$.

LEMMA 5.4. *At each iteration the nth singular value of the matrix* $M - [(1 - \gamma)\delta M_k + \gamma \delta \hat{M}_k]$ *is less than or equal to*

$$(1 - \gamma)[\sigma_n]_k + \gamma^2 q_k,$$

where

$$q_k = \|\hat{u}_k^H (\delta \hat{M}_k - \delta M_k)\|.$$

Proof. From Lemma 5.2 there exists $[\hat{u}]_k$ orthogonal to $[u_k]$ such that

$$[\hat{u}]_k{}^H (M - \delta M_k) = [u_n]_k^H (\delta \hat{M}_k - \delta M_k) - [\sigma_n]_k [v_n]_k^H.$$

To complete the proof of the lemma, consider that the norm of the product,

$$\begin{aligned}
&\left([u_n]_k + \gamma[\hat{u}]_k\right)^H \left[M - (1-\gamma)\delta M_k - (\gamma)\delta \hat{M}_k\right] \\
&\quad = \left([u_n]_k + \gamma[\hat{u}]_k\right)^H \left[(M - \delta M_k) - \gamma(\delta \hat{M}_k - \delta M_k)\right] \\
&\quad = (1-\gamma)[\sigma_n]_k [v_n]_k^H + \gamma\left[[\hat{u}]_k^H (M - \delta M_k) - [u_n]_k^H (\delta \hat{M}_k - \delta M_k) + [\sigma_n]_k [v_n]_k^H\right] \\
&\qquad - \gamma^2 \hat{u}_k^H (\delta \hat{M}_k - \delta M_k)
\end{aligned}$$

is less than or equal to the stated bound,

$$(1 - \gamma)[\sigma_n]_k + \gamma^2 q_k,$$

implying that the nth singular value is less than the stated bound. This completes the proof of the lemma. □

Proof of convergence of the algorithm is achieved by appealing to a Lyapunov function approach: The function

$$P_k = [\sigma_n]_k + g_k \|\delta M_k\|$$

decreases at each iteration by a positive definite function of $[\sigma_n]_k$ and $\|\delta \tilde{M}_k - \delta M_k\|$. Proof of convergence involves two steps. The first step is to show that the choice

$$\gamma_k = \min\left\{\frac{1}{4} q_k^{-1} \left([\sigma_n]_k + g_k \frac{(\|\delta \tilde{M}_k - \delta M_k\|)^2}{\|\delta M_k\|}\right), 1\right\}$$

and the choice $g_k = \min(\frac{1}{2}[\sigma_n]_k \|\delta \bar{M}_k\|^{-1}, g_{k-1})$ (when $[\sigma_n]_k \neq 0$; $g_k = g_{k-1}$ otherwise) imply that

$$\begin{aligned}
P_{k+1} - P_k \leq \max\Big[&- \frac{1}{16} q_k^{-1} ([\sigma_n]_k + g_k b_k \|\delta \tilde{M}_k - \delta M_k\|)^2, \\
&- \frac{1}{4} ([\sigma_n]_k + g_k b_k \|\delta \tilde{M}_k - \delta M_k\|)\Big],
\end{aligned}$$

which is less than zero unless δM_k satisfies the necessary condition. The second step is to show that the quantities q_k^{-1} and g_k are both bounded away from zero. It follows that (i) $\{[\sigma_n]_k\} \to 0$, (ii) $\{\|\delta \tilde{M}_k - \delta M_k\|\} \to 0$, (iii) the sequence $\{\delta M_k\}$ has a

subsequence converging to a matrix δM_*, and (iv) for k sufficiently large δM_k satisfies the necessary condition for being a minimum norm rank-reducing perturbation for some $\tilde{M}$ in a neighborhood of M. The first step is achieved in the following proposition.

PROPOSITION 5.5. *The quantities computed by the algorithm satisfy*

$$P_{k+1} - P_k \leq \max\left[-\frac{1}{16}q_k^{-1}([\sigma_n]_k + g_k b_k \|\delta\tilde{M}_k - \delta M_k\|)^2, \right.$$
$$\left. -\frac{1}{4}([\sigma_n]_k + g_k b_k \|\delta\tilde{M}_k - \delta M_k\|)\right],$$

where $P_k = [\sigma_n]_k + g_k\|\delta M_k\|$.

Proof. Since $\gamma_k \in (0,1)$ it follows from Lemmas 5.3 and 5.4, that

$$\begin{aligned} P_{k+1} - P_k &= \left[\sigma_{k+1} + g_{k+1}\|\delta M_{k+1}\|\right] - \left[\sigma_k + g_k\|\delta M_k\|\right] \\ &\leq (-\gamma_k[\sigma_n]_k + \gamma_k^2 q_k) + \gamma_k g_k \left(\|\delta\bar{M}_k\| - \frac{1}{2}b_k\|\delta\tilde{M}_k - \delta M_k\|\right) \\ &\leq -\frac{1}{2}\gamma_k\left\{[\sigma_n]_k + g_k b_k\|\delta\tilde{M}_k - \delta M_k\|\right\} + \gamma_k^2 q_k. \end{aligned}$$

The two inequalities above come from the definition of g_k, which implies that g_k is nonincreasing and that $g_k\|\delta\bar{M}_k\| \leq \frac{1}{2}[\sigma_n]_k$. The choice for γ_k given in step 9 of the algorithm minimizes the quadratic bound given above over $\gamma_k \in [0,1]$. Substituting this value for γ_k into the above bound and using the fact that $\gamma_k = 1$ only if $q_k \leq \frac{1}{4}([\sigma_n]_k + g_k b_k\|\delta\tilde{M}_k - \delta M_k\|)$, one obtains

$$P_{k+1} - P_k \leq \max\left[-\frac{1}{16}q_k^{-1}([\sigma_n]_k + g_k b_k\|\delta\tilde{M}_k - \delta M_k\|)^2 \right.$$
$$\left. -\frac{1}{4}([\sigma_n]_k + g_k b_k\|\delta\tilde{M}_k - \delta M_k\|)\right]. \qquad \square$$

To complete the proof of convergence, it remains to establish that the sequence $\{q_k\}$ is bounded. If $\{q_k\}$ is bounded and if $\{g_k\}$ does not have zero as a limit point, it follows from Proposition 5.5 that $\{[\sigma_n]_k\} \to 0$ and $\{\|\delta\tilde{M}_k - \delta M_k\|\} \to 0$. The following lemma demonstrates that $\{q_k\}$ is bounded.

LEMMA 5.6. *Given the earlier assumptions and the algorithm as stated above, the sequence* $\{q_k\}$ *is bounded.*

Proof. From the definition of q_k, Lemma 5.2 implies that

$$q_k \leq \frac{1}{[\sigma_{n-1}]_k}\|\delta\hat{M}_k - \delta M_k\|\left[\|\delta\hat{M}_k - \delta M_k\| + [\sigma_n]_k\right].$$

Since $\{P_k\}$ is decreasing, it follows that $\|\delta\tilde{M}_k - \delta M_k\| \leq \|\delta M_k\| \leq (P_0/g_k)$ and $[\sigma_n]_k \leq P_0$, implying that $\|\delta\hat{M}_k - \delta M_k\| \leq (3/2)(P_0/g_k)$. Boundedness of $[\sigma_{n-1}]_k$ and $\{g_k\}$ away from zero in Assumptions 1 and 2 imply that the sequence $\{q_k\}$ is bounded. $\square$

It is now possible to establish convergence of the algorithm.

THEOREM 5.7. *Given the algorithm as stated above and Assumptions* 1 *and* 2 *it follows that the algorithm terminates.*

Proof. Using the boundedness of q_k and Assumption 2, Proposition 5.5 implies that $\|\delta\tilde{M}_k - \delta M_k\|$ and $[\sigma_n]_k$ become arbitrarily small since the sequence $\{P_k\}$ remains positive. Since g_k is bounded below by a positive number the algorithm must terminate. $\square$

Some additional properties of the matrix $\delta\tilde{M}_k$ are useful. At each iteration, the matrix $\delta\tilde{M}_k$ satisfies several properties.

(i) It is an element of $\mathcal{S}(\tilde{M}_k; \mathbb{R}^{n\times m})$, where

$$\tilde{M}_k \triangleq M - (\delta M_k - \delta\tilde{M}_k) - [u_n]_k[\sigma_n]_k[v_n]_k^H$$

since $\tilde{M}_k - \delta\tilde{M}_k$ is equal to the rank deficient matrix, $M - \delta M_k - [u_n]_k[\sigma_n]_k[v_n]_k^H$.

(ii) The vector $[u_n]_k$ is contained in the left null-space of the rank deficient matrix $\tilde{M}_k - \delta\tilde{M}_k$ and the columns of V_k span the right null-space.

(iii) $\delta\tilde{M}_k$ is the real matrix having minimum norm over all $\delta M \in \mathbb{R}^{n\times m}$ satisfying

$$[u_n]_k^H \delta M V_k = [u_n]_k^H \tilde{M}_k V_k.$$

The previous equation is equivalent to the constraint in step 5 of the algorithm, since $[u_n]_k^H \tilde{M}_k V_k = [u_n]_k^H \delta\tilde{M}_k V_k = [u_n]_k^H \delta M_k V_k$.

(iv) The sequence $\{\tilde{M}_k\} \to M$.

The previous properties show that $\delta\tilde{M}_k \in \mathcal{S}(\tilde{M}_k; \mathbb{R}^{n\times m})$. Moreover, $\delta\tilde{M}_k$ satisfies the necessary condition of Theorem 4.2 for being a minimum norm element of the set $\mathcal{S}(\tilde{M}_k; \mathbb{R}^{n\times m})$. For k sufficiently large, $\{\tilde{M}_k\}$ approaches M, i.e., δM_k satisfies the necessary condition for the neighboring matrix $\tilde{M}_k$. Hence $\|\delta\tilde{M}_k - \delta M_k\| + [\sigma_n]_k$ provides an estimate of the accuracy of the solution in the sense that it measures the distance from a nearby problem for which $\delta\tilde{M}_k$ satisfies the necessary condition exactly. This discussion is summarized in the following theorem.

THEOREM 5.8. *When the algorithm terminates, $\delta\tilde{M}_k$ satisfies the necessary condition for being a minimum norm element of $\mathcal{S}(\tilde{M}_k; \mathbb{R}^{n\times m})$, where $\tilde{M}_k = M - (\delta M_k - \delta\tilde{M}_k) - [u_n]_k[\sigma_n]_k[v_n]_k^H$ and $\|M - \tilde{M}_k\| \le \|\delta\tilde{M}_k - \delta M_k\| + [\sigma_n]_k \le \epsilon(1 + 1/g_k)\|M - \delta M_k\|$.*

Proof. Matrix $\delta\tilde{M}_k$ satisfies the necessary condition for being a minimum norm real matrix that satisfies $\operatorname{rank}[\tilde{M}_k - \delta\tilde{M}_k] = n - 1$. See the previous discussion. □

Theorem 5.7 demonstrates only that the algorithm would terminate if the algorithm were carried out with infinite precision. However, the stopping criterion given in the algorithm statement is designed to be achievable in the presence of numerical roundoff. The reasons for the criterion given in the algorithm are discussed in the next section.

6. Implementation and numerical results. A listing of a MATLAB [7] implementation of the algorithm is included in Appendix B. This implementation has been tested on a SPARC workstation which has a 53-bit effective floating point mantissa and a machine epsilon of 2.22×10^{-16} as reported by MATLAB.

Steps 4 and 5 of the implementation require some explanation. The least squares solutions in steps 4 and 5 are formulated using Kronecker products [1] by applying the "vec" operator to the equation. The relevant equation in step 4 becomes

$$V_k^T \otimes [u_n]_k^H \operatorname{vec}[\delta\bar{M}] = \operatorname{vec}\begin{bmatrix}[\sigma_n]_k & 0 & \dots & 0\end{bmatrix}. \tag{6.1}$$

The real minimum norm solution is obtained from the equation

$$\operatorname{vec}[\delta\bar{M}] = \begin{bmatrix}\operatorname{Re}[V_k^T \otimes [u_n]_k^H] \\ \operatorname{Im}[V_k^T \otimes [u_n]_k^H]\end{bmatrix}^+ \operatorname{vec}\begin{bmatrix}[\sigma_n]_k & 0 & \dots & 0\end{bmatrix}. \tag{6.2}$$

A sufficient number of zeros are added to the row vector in (6.2) to make the dimensions conform. The pseudoinverse required in (6.2) is obtained from a singular value decomposition (SVD).

A similar formulation yields $\delta\tilde{M}_k$. Step 5 requires solution of the equation

$$\begin{bmatrix} \mathrm{Re}[V_k^T \otimes [u_n]_k^H] \\ \mathrm{Im}[V_k^T \otimes [u_n]_k^H] \end{bmatrix} \mathrm{vec}[\delta\tilde{M}] = \begin{bmatrix} \mathrm{Re}[V_k^T \otimes [u_n]_k^H] \\ \mathrm{Im}[V_k^T \otimes [u_n]_k^H] \end{bmatrix} \mathrm{vec}[\delta M_k].$$

The MATLAB implementation obtains the solution in step 5 by projecting $\mathrm{vec}[\delta M_k]$ along the kernel of the matrix

$$\begin{bmatrix} \mathrm{Re}[V_k^T \otimes [u_n]_k^H] \\ \mathrm{Im}[V_k^T \otimes [u_n]_k^H] \end{bmatrix}. \tag{6.3}$$

The kernel of the matrix is obtained from the result of the SVD computed in step 4.

Step 8 also requires some explanation. The norm of the pseudoinverse in step 8 increases as $[\sigma_n]_k$ decreases. However, by construction, the vector on the left of $(M - \delta M_k)^+$ is orthogonal to the singular space associated with $[\sigma_n]_k$. Hence, only the first $n-1$ singular values and vectors are used for the inversion.

The stopping criterion in step 6 has been selected to account for the conditioning of the problem. It is well known that $[\sigma_n]_k$ can only be computed within a few multiples of $\epsilon[\sigma_1]_k$, where ϵ is the machine constant. As discussed earlier, the quantity g_k is an indirect measure of the conditioning of the inversion required to find $\delta\tilde{M}_k$. Hence, roundoff errors are magnified by $1/g_k$ in the computation of $\delta\tilde{M}_k$. Moreover, it can be shown that the projector used to compute $\delta\tilde{M}_k$ has a relative accuracy proportional to $1/g_k$. Because g_k is a decreasing sequence, it represents the worst conditioning encountered during execution of the algorithm. This discussion suggests that the relative error associated with the product $g_k\|\delta\tilde{M}_k - \delta M_k\|$ is approximately equal to the machine constant epsilon, and motivates the stated stopping criterion. While this is not a rigorous justification of the stopping criterion, this stopping criterion has been successful in numerous numerical experiments. Moreover, it is suspected that $1/g_k$ measures the sensitivity of the problem to changes in M.

The implementation given in Appendix B has been written to expose the main steps in the algorithm to guarantee convergence and to compute an accurate solution. A few comments on the storage requirements and the time requirements are in order. Estimating time requirements for SVD algorithms is difficult because the time required per iteration is a complex function of the number of rows and columns of the matrix. The time also depends on which portions of the decomposition are required. See, for example, [5]. Moreover, the number of iterations required depends upon the given matrix. Hence, estimates for SVD computation time must be partly theoretical and partly experimental.

For the following discussion, assume that the row and column dimensions are approximately equal $m \approx n$, and that the number of columns exceeds the number of rows by a small number, say $m - n + 1 << n^{1/2}$. The SVD of $M - \delta M_k$ computed in step 2 is the primary contributor to execution time in the implementation given in Appendix B. Step 2 requires a complete SVD of the complex matrix $M - \delta M_k$. The time required for this operation is proportional to n^3 and numerical experiments estimate that MATLAB requires approximately $50n^3$ floating point operations (flops) to compute this SVD. Step 4 requires a real SVD of a matrix whose dimensions are $2(m-n+1)$ by nm. However, the full decomposition is not required. Omitting computation of the null vectors saves computation time. The time required by the

economy version of the SVD in MATLAB, which omits the null vector computation, is proportional to $4(m-n+1)^2nm$ and experiments estimate that MATLAB requires approximately $20(m-n+1)^2n^2$ flops to compute this decomposition. Hence, the second SVD in step 4 requires comparatively little time due to its small number of rows provided p is small. The remaining operations are mostly matrix by vector multiplications, diagonal matrix inversions, matrix additions, and norm computations. The additional operations require approximately $18n^2p + 37n^2 + 6n + 8p^2 + 6p$ flops per iteration where $p = (m - n + 1)$.

Storing the matrices, M, δM_k, $\delta\hat{M}_k$, $\delta\tilde{M}_k$, and $\delta\bar{M}_k$ requires $6nm$ real storage locations, although this could be economized by using the same locations for several of these quantities. Storing the SVD of $M - \delta M_k$ requires $2n^2 + 2m^2 + n$ real storage locations. The matrix whose pseudoinverse is required in step 4 requires $2nmp$ storage locations. Storing the SVD of this matrix requires $4p^2+2nmp+2p$ locations. Together this is about the same as $4p$ real $n \times m$ complex matrices. Assuming $n \approx m$ storage of all matrices requires approximately $(10 + 4p)n^2$ real storage locations. Additional storage is required for intermediate quantities. The additional storage amounts to approximately $4n$ additional locations, assuming $m \approx n$.

Some simple numerical examples illustrate the accuracy of the technique. The first example has a known matrix that satisfies the necessary condition exactly.

Example 6.1. Consider the matrix,

$$M = \begin{bmatrix} -122-128j & -256+128j & -511-128j & -515-128j & -641-384j \\ -130-128j & -256-128j & -511+128j & -511-384j & -385-128j \\ 142-128j & 256-128j & 511-128j & 505-384j & 641+128j \\ 118-128j & 256+128j & 511+128j & 517-128j & 385+384j \end{bmatrix}.$$

The matrix

$$\delta M_* = \begin{bmatrix} 6 & 0 & 1 & -3 & -1 \\ -2 & 0 & 1 & 1 & -1 \\ 14 & 0 & -1 & -7 & 1 \\ 10 & 0 & -1 & 5 & 1 \end{bmatrix}$$

exactly satisfies the necessary condition. The algorithm given in Appendix B converges to a solution after 17 iterations requiring approximately 11,000 flops per iteration. The Frobenius norm of the error matrix obtained by subtracting the numerical solution from δM_* as given above is 3.9×10^{-13}. Note that the relative error obtained by dividing the absolute error by the Frobenius norm of $M - \delta M_*$ is approximately 0.5ϵ. The algorithm returned an error estimate of 3.4×10^{-13} where this is the distance away from the problem whose solution is obtained exactly. The final value for g was 0.199.

To further evaluate the accuracy of the approach, the algorithm was tested on several matrices where the solution was known approximately. By a solution, we mean a matrix satisfying the necessary condition given in Theorem 4.2. Several steps are taken to generate such matrices. First, a random complex matrix is generated whose real and imaginary parts have a specified size. The real portion of the matrix is generated by selecting entries randomly between zero and one from a uniform distribution. A normalization provides the real part with the specified size. The same procedure yields an imaginary part for the matrix having a specified size. An SVD of the complex matrix, call it R, yields an approximate left singular vector u_n and an approximate orthonormal basis for the direct sum of the right singular space associated with σ_n and the right null-space V. The quantities u_n and V are considered to be exact specifications for the desired null-space bases at the solution point. The subsequent steps

TABLE 1
Numerical results obtained by varying dimension.

Size	Iterations required	k-flops count	σ_{n-1}	Estimated error	Actual error	Relative error
5	8	10	0.1258	5.8×10^{-15}	1.1×10^{-16}	0.16
15	9	205	0.0306	1.3×10^{-15}	4.3×10^{-17}	0.14
30	12	1463	0.0094	1.8×10^{-15}	1.5×10^{-16}	0.46
50	19	6160	0.0031	4.6×10^{-15}	9.2×10^{-16}	2.92
100	21	47300	0.0027	4.8×10^{-15}	1.5×10^{-16}	4.71

attempt to generate a problem whose solution has u_n as a left null-vector and has V as a basis for the right null-space of $M - \delta M_*$. To generate δM_* in the appropriate space, a random vector in $\mathbb{R}^2$ is selected having entries uniformly distributed between zero and one and normalized to have a specified size. The transpose of the matrix given by (6.3) is multiplied by this random vector to generate $\text{vec}[\delta M_*]$. The matrix M is made rank-deficient via $M = R - u_n \sigma_n v_n^H$ to produce a matrix M having approximately the desired left and right null-spaces. This approach yields a complex matrix that is a perturbed version of a complex matrix having the specified null-space, since u_n, σ_n, and v_n^H exactly specify the singular space of a matrix near R. The real matrix δM_* will be a perturbed version of a matrix that is contained in the row space of (6.3). Both matrices will have a relative error approximately equal to the machine epsilon. Thus, the real matrix is a perturbed solution to a perturbed problem, both perturbations having a relative size approximately equal to the machine epsilon.

The technique described above was used to study the accuracy of the algorithm. Table 1 compiles results obtained by varying the size of the problem. The algorithm was tested on square matrices for which the norm of the real and imaginary parts were both approximately one. The norm of the solution was selected to be 0.001. The estimated error displayed in the table was computed by the algorithm. The actual error was obtained by computing the norm of the difference of the computed solution from the approximately known solution. The relative error is normalized to the size of $M - \delta M_*$, where δM_* is the approximately known solution and specified in multiples of the machine epsilon. The flop counts are average counts per iteration and are given in thousands of flops per iteration.

Similarly, Table 2 displays results obtained by varying the size of the imaginary part of M while holding the size of the real part at one and holding the size of the solution fixed at 0.001. The size of M was 10×12. The final value of g_* has been included in Table 2 as it provides some measure of the independence of the real and imaginary parts of the left singular vector at the solution point. The flop count has been omitted since each case had the same flop count of 135,000 flops per iteration.

7. Conclusions. This paper addresses two issues concerning the computation of the real-restricted singular value of a complex general matrix: the continuity of the singular value over the space of complex matrices and a necessary condition that a minimum norm rank-reducing real perturbation must satisfy. It presents an algorithm that computes a matrix satisfying a necessary condition for being a real, minimum norm rank-reducing perturbation for a problem in a neighborhood of the original problem. Upon termination the algorithm provides an estimate for the distance from the original problem. Results demonstrating the accuracy of the algorithm are included.

TABLE 2
Results obtained from varying size of imaginary part.

$\|\operatorname{Im} M\|$	Iterations required	g_*	σ_{n-1}	Estimated error	Actual error	Relative error
10^0	9	0.3129	0.0748	1.7×10^{-15}	1.7×10^{-16}	0.5
10^{-1}	19	0.1479	0.0559	2.6×10^{-16}	1.5×10^{-16}	0.7
10^{-2}	26	0.0103	0.0556	5.7×10^{-15}	9.8×10^{-16}	4.4

10^{-4}	173	4.6×10^{-4}	0.0556	2.4×10^{-13}	4.2×10^{-15}	18.8
10^{-5}	1339	5.2×10^{-5}	0.0556	3.9×10^{-12}	5.3×10^{-14}	238

The algorithm is accurate when the real and imaginary parts of the left singular vector associated with the solution point are far from dependence. The rate of convergence is linear, and the algorithm performs well on many problems. However, convergence can be slow for some problems, particularly when the size of the imaginary part of the matrix is small compared to the real part or when the imaginary part is nearly singular. These conditions can cause the real and imaginary parts of the left singular vector at the solution point to be nearly dependent. Methods for accelerating convergence need further study. The number and nature of points that may satisfy the necessary condition given in Theorem 4.2 and techniques for selecting initial starting points also need further study.

Appendix A. The goal of this appendix is to provide supplemental proofs that allow removal of Assumption 2 given in §5 of the paper. Two preliminary lemmas are presented before the main result.

LEMMA A.1. *Let* $M \in \mathbb{C}^{n\times m}$, $m \geq n \geq 2$. *Suppose* $\operatorname{rank}[M] < n$ *and* $\operatorname{rank}[\operatorname{Im}[M]] = n$. *Let* u *be any nonzero vector satisfying* $u^H M = 0$. *The spectral condition number of the matrix* $[\operatorname{Re}[u],\ \operatorname{Im}[u]]$ *is less than or equal to* $\sigma_1[\operatorname{Re}[M]]/\sigma_n[\operatorname{Im}[M]]$.

Proof. Without loss of generality, assume $\operatorname{Re}[u]^T \operatorname{Im}[u] = 0$ and $\|\operatorname{Re}[u]\| \leq \|\operatorname{Im}[u]\|$. Clearly,

$$\sigma_1[\operatorname{Re}[M]]\,\|\operatorname{Re}[u]\| \geq \|\operatorname{Re}[u]^T \operatorname{Re}[M]\| = \|\operatorname{Im}[u]^T \operatorname{Im}[M]\| \geq \sigma_n[\operatorname{Im}[M]]\,\|\operatorname{Im}[u]\|,$$

implying that $\kappa[\operatorname{Re}[u],\ \operatorname{Im}[u]] = \|\operatorname{Im}[u]\|/\|\operatorname{Re}[u]\| \leq \sigma_1[\operatorname{Re}[M]]/\sigma_n[\operatorname{Im}[M]]$. □

LEMMA A.2. *The quantities computed by the algorithm described in the paper satisfy*

$$\|\delta\bar{M}_k\| \leq \sqrt{2}[\sigma_n]_k\, \kappa[\operatorname{Re}[u_n]_k,\ \operatorname{Im}[u_n]_k].$$

Proof. There exists a minimum norm real matrix δM_0 satisfying

$$[u_n]_k^H \delta M_0 = [u_n]_k^H([u_n]_k[\sigma_n]_k[v_n]_k^H)$$

as per Lemma 2.2. Hence δM_0 satisfies

$$[u_n]_k^H \delta M_0 V_k = [u_n]_k \delta\bar{M}_k V_k$$

implying that $\|\delta M_0\| \geq \|\delta\bar{M}_k\|$. It can be shown that

$$\|\delta\bar{M}_k\| \leq \|\delta M_0\| \leq \sqrt{2}[\sigma_n]_k \kappa[\operatorname{Re}[u_n]_k,\ \operatorname{Im}[u_n]_k]$$

implying the statement of the lemma. □

PROPOSITION A.3. *If the algorithm stated in §5 is modified so that* $g_0 = \frac{1}{4}\sigma[\mathrm{Im}[M]/\|\delta M_0\|$ *where the matrix* δM_0 *satisfies* $\mathrm{rank}[M - \delta M_0] = n - 1$ *then* $\lim\{g_k\} > 0$.

Proof. Since $[u_n]_k^H[M - \delta M_k - [u_n]_k[\sigma_n]_k[v_n]_k^H] = 0$, it follows from Lemma A.1 that

$$\kappa\,[\,\mathrm{Re}[u_n]_k,\quad \mathrm{Im}[u_n]_k\,] < \frac{\sigma_1[\mathrm{Re}[M]] + \sigma_1[\delta M_k] + [\sigma_n]_k}{\sigma_n[\mathrm{Im}[M]] - [\sigma_n]_k}$$

so long as $[\sigma_n]_k < \sigma_n[\mathrm{Im}[M]]$ (the initial choice for P_0 guarantees that $[\sigma_n]_k < \frac{1}{4}\sigma_n[\mathrm{Im}[M]]$ since $P_0 = g_0\|\delta M_0\| = \frac{1}{4}\sigma_n[\mathrm{Im}[M]]$ and $[\sigma_n]_k \le P_k \le P_0$.) Suppose that g_k is strictly less than g_{k-1}. From Lemma A.2 and the definition of g_k,

$$g_k = \left(\frac{1}{2}\right)\frac{[\sigma_n]_k}{\|\delta M_k\|} \ge \frac{1}{2\sqrt{2}}\,\frac{\sigma_n[\mathrm{Im}[M]] - [\sigma_n]_k}{\sigma_1[\mathrm{Re}[M]] + \|\delta M_k\| + [\sigma_n]_k}.$$

Since $P_k \le \frac{1}{4}\sigma_n[\mathrm{Im}[M]]$ for all k, it follows that

$$[\sigma_n]_k \le \tfrac{1}{4}\sigma_n[\mathrm{Im}[M]]$$

and $\|\delta M_k\| \le 1/(4g_k)\sigma_n[\mathrm{Im}[M]]$. Hence

$$g_k \ge \frac{3}{8\sqrt{2}}\,\frac{\sigma_n[\mathrm{Im}[M]]}{\sigma_1[\mathrm{Re}[M]] + (\frac{1}{4g_k} + \frac{1}{4})\sigma_n[\mathrm{Im}[M]]}$$

from which it follows that there is a constant C for which $g_k \ge C > 0$ for all k. We have shown that $g_k < g_{k-1}$ for any k implies that $g_k \ge C > 0$ and g_k cannot converge to zero. □

Appendix B. This appendix provides a listing of a MATLAB implementation of the algorithm described in the paper.

```
% function rrp = realrrp(M)
% M is an complex matrix (n by m) with n <= m

ROW ORDERING FOR A SPARSE QR DECOMPOSITION *

THOMAS H. ROBEY† AND DEBORAH L. SULSKY‡

Abstract. A new row ordering strategy based on pairing rows to minimize local fill-in is presented. The row ordering can be combined with most column ordering strategies to reduce computation, maintain sparsity, and solve rank deficient problems. Comparison of the new row pairing algorithm with Duff's fixed pivot row ordering on a collection of sparse matrix test problems shows a median 47–71% reduction, depending on the column ordering, in floating point operations (flops) required for the QR decomposition. On a finite element application using nested domain decomposition for the column ordering, the new row ordering is competitive with the row ordering from nested domain decomposition.

Key words. QR decomposition, sparse matrices, Givens rotations

AMS subject classification. 65

1. Introduction.

The QR decomposition is a relatively robust means for solving a variety of problems. The decomposition of an $m \times n$ matrix A ($m \geq n$) is usually written $QAP = \begin{bmatrix} R \\ 0 \end{bmatrix}$, where Q is an $m \times m$ orthogonal matrix composed of orthogonal transformations, P is a permutation matrix, and R is an upper triangular matrix. The column permutations are usually required when A does not have full rank and then R is upper trapezoidal. The use of orthogonal transformations is numerically stable and, in practice, the rank of the matrix can be determined accurately when column permutations are performed during factorization. The matrix Q can be determined in factored form using several methods; Givens rotations are used here. While the LU decomposition (Gaussian elimination) is widely used and researched, the QR decomposition is used less frequently in applications because it is generally more expensive to compute than the LU decomposition. However, there are many applications that produce rank deficient matrices [1], or that require least squares solutions, for which Gaussian elimination is unsuitable. Furthermore, many of these applications produce sparse matrices, a property that can be exploited to reduce the cost of computation.

To design a sparse QR decomposition, the overall goals must first be identified. The primary goal is to minimize the execution time for computing the decomposition. Since execution times are highly dependent on computer architecture and the algorithm's implementation, it is desirable to have other less variable measures of computational cost. Flops are the primary measure of computational work. Indeed, for sparse matrices, column and row permutations are motivated by an attempt to preserve sparsity and thereby reduce flops. Execution time can also be impacted by the overhead associated with choosing appropriate reorderings of rows and columns. It is important that this overhead does not offset gains achieved by reducing flops. Other measures of performance are the amount of intermediate fill-in, the number of

nonzeros in R, and the number of Givens rotations. The amount of intermediate fill-in and the number of nonzeros in R are measures of how well sparsity is maintained. It is desirable to keep R as sparse as possible since most applications use R. Some applications use Q, and thus the storage for Q can be an issue. Since Q is stored in factored form, the number of Givens rotations performed during the decomposition is a measure of the requisite storage. These measures will be used to gauge the relative success of sparse QR decomposition algorithms.

When A is sparse, both row and column permutations may be performed as a means of reducing computational expense and maintaining sparsity. While both row and column orderings impact the computational work, only the column ordering influences the final sparsity in R [2]. This observation follows from the fact that the Cholesky factor of the normal equations matrix A^TA mathematically has the same structure as R, and the structure of the Cholesky factor is determined solely by the column ordering. Column ordering strategies can be divided by whether the orderings are done a priori or at each step of the process (local orderings).

An a priori scheme for column ordering suggested by George and Heath [2] utilizes the relationship between R and the Cholesky factor of the normal equations matrix. Symbolically, the normal equations matrix is formed and then a minimum degree algorithm is performed on (A^TA) to determine a column ordering. The nonzero pattern of R can also be determined a priori, which facilitates memory allocation. This column ordering attempts to minimize the number of nonzeros in R. The amount of flops required to compute the decomposition is not necessarily reduced by this scheme, because different row orderings produce varying amounts of intermediate fill-in. To avoid forming A^TA, Ostrouchov [3] develops a symbolic minimum degree algorithm that operates on the structure of A that can apply local row and column orderings a priori. The local nature allows local tie-breaking criteria to be used during column ordering.

Duff [4] suggests a local column ordering that selects the column with the minimum number of nonzeros. This strategy seeks to locally minimize the number of Givens rotations and thus attempts to indirectly minimize other quantities.

Nested dissection is an a priori method that produces both column and row orderings [5] and is based on the underlying graph of the matrix. For problems where the underlying graph is a grid of nodes, these orderings have the advantage of bounds on both the number of flops and the number of nonzeros in R. An element-based variation is nested domain decomposition [1]. Both of these techniques successively split the problem into smaller problems. Then the decomposition proceeds in the reverse direction beginning with the small problems. The orderings produced are coarse, i.e., the rows and/or columns are ordered in groups with no ordering within each group. A disadvantage of nested dissection is that the quality of the ordering depends on the topology of the graph, and no reasonable bounds on flops or the number of nonzeros in R exist if an underlying grid does not exist.

Row ordering schemes can be divided into either fixed pivot row strategies or variable pivot row strategies. In each column, fixed pivot row strategies always use the same element, the pivot, to zero out all the other nonzeros in that column. Therefore the pivot eventually becomes the diagonal entry in R. Variable pivot row strategies allow the use of more than one element as a pivot in each column and the final pivot for the column becomes the diagonal entry in R. Note that fixed pivot row orderings are a subset of the variable pivot row orderings. Thus, in theory, there always exists a variable pivot row ordering that performs as well as the best fixed pivot row ordering although, in practice, fixed pivot strategies may outperform variable pivot strategies

[3]. Note that although the terminology row ordering strategy is used, these strategies are not necessarily equivalent to an a priori permutation of the rows [3].

The strategy of George and Heath [2] orders the rows in increasing order with respect to the column containing the last nonzero (after column permutations), an a priori fixed pivot scheme. George and Heath are mainly concerned with developing a column ordering that keeps R sparse, and their row ordering strategy outlined above makes only a minimal attempt to reduce intermediate fill-in and flops although they demonstrate a significant reduction in the cost of computation over the natural row ordering and the reverse ordering. Liu [6] introduces submatrix rotations to reduce the computational cost for the George and Heath strategy by imposing a coarse-grained row ordering. Liu's submatrix rotations can be interpreted as a variable pivot row strategy.

Duff [4] examines several local row ordering strategies and recommends a fixed pivot row strategy. The sparsest row is chosen as the pivot row and succeeding rows are processed based on minimizing fill-in of the pivot row. Gentleman [7] suggests a variable pivot row ordering based on processing the sparsest pair of rows first.

None of the row ordering schemes is completely satisfactory, since they often do not come close to minimizing intermediate fill-in. It seems impossible, short of an extensive search, to design an algorithm that minimizes intermediate fill-in in general. Our goal is a heuristic row ordering strategy that is easily implemented, efficient, and performs well on a large class of problems compared to other strategies.

The scheme presented in §2 introduces a row ordering strategy based on a variable pivot row. In §3, the strategy is compared on test matrices with Duff's fixed pivot row strategy and Gentleman's variable pivot row strategy using both Duff's column ordering strategy and a minimum degree column ordering. Section 4 considers a finite element application and compares the new row ordering strategy with Duff's fixed pivot row ordering strategy, Gentleman's scheme, and a row ordering from nested domain decomposition. Nested domain decomposition is used to obtain the column ordering.

On common test problems, the variable pivot row strategy performs at least as well as, and usually outperforms, the row ordering strategies cited above. The reduction in flops is as much as 90% for some test cases; furthermore, the improvement roughly appears to increase with the size of the matrix.

2. Implementation. For the present assume that A has full rank. The overall decomposition procedure involves successively applying Givens rotations to zero out elements below the diagonal in each column. At the start of the kth step, zeros have been placed below the diagonal in the first k-1 columns. Let the *active submatrix* be the lower right block of the matrix under current consideration. The general procedure involves two *stages* within each step. The first stage applies the column ordering strategy and the second stage applies the row ordering strategy and numeric operations. Begin with the active submatrix as the whole A matrix. Search for a column in the active submatrix using some local column ordering strategy or choose the next column if an a priori column ordering is being used. This column is called the *selected column* and is pivoted (if necessary) to the first column in the active submatrix. The first stage is then complete. The rows of the active submatrix with nonzeros in the selected column form the *selected set of rows.* In the second stage, the selected set of rows is operated on with Givens rotations to zero out all but one nonzero in the selected column. The remaining row with a nonzero is pivoted to the top of the active submatrix, and this row is then deleted along with the selected column to

form the next active submatrix. The process is repeated at the next step with the new active submatrix which now has one less column and row than the previous active submatrix.

If A does not have full rank, then the final pivot in each column must be monitored. If a zero (or small) final pivot is encountered, then the column is pivoted to the right and eliminated from the active submatrix. Note that the active submatrix is no longer in the lower right corner.

The algorithm presented above is a column oriented algorithm since each step completely processes one column. For the column ordering strategies cited above, a column oriented algorithm can handle large problems that do not fit into core memory by using an algorithm that reads in the selected set of rows at the beginning of the second stage. Note that it is not necessary to keep R in core, but it is necessary to access rows more than once. The number of times a row is accessed is small if sparsity is maintained. The application in §4 has been implemented using this out-of-core algorithm. As a comparison, the row oriented algorithm of George and Heath [2] reads each row exactly once and requires only a single working row in core, but also requires storage for R in core memory. The advantage of the George and Heath algorithm is not necessarily in handling large problems out of core, but in its use of a static storage structure that lends itself to programming languages lacking dynamic memory allocation. A detailed analysis of execution times and storage efficiency of the two out-of-core approaches is beyond the scope of this paper.

The way in which rows are processed in the second stage has a great effect on the amount of intermediate fill-in. Intermediate fill-in causes the sparsity to be lost and can result in more Givens rotations being required later in the decomposition. If it is assumed there is no chance cancellation, the following formula describes the relationship between the variables

$$\text{Nonzeros in A} + \text{intermediate fill-in} - \text{Givens} = \text{nonzeros in R}. \tag{1}$$

If the nonzeros in R are fixed by a given column ordering, then reducing intermediate fill-in must reduce the number of Givens rotations, thus making the scheme more efficient. For local column ordering strategies, intermediate fill-in can affect the column choice and therefore intermediate fill-in can indirectly affect the number of nonzeros in R. If the effect of intermediate fill-in on the number of nonzeros in R is small, then reducing intermediate fill-in still gives a comparable reduction in the number of Givens rotations.

Note that the process of applying a Givens rotation results in a pair of rows assuming the same zero-nonzero pattern except in the selected column (assuming no chance cancellation). Thus, it does not matter which row is considered to be the pivot row as far as the sparsity pattern is concerned; the resulting sparsity pattern is identical after the appropriate row permutation. These observations lead to the following strategy, which is called a *variable pair strategy.*

The variable pair strategy is based on minimizing local fill-in. If any rows are encountered that have the same zero-nonzero pattern, then the search for a pair of rows is halted and a Givens rotation is applied to the pair. Note that there is no resulting fill-in, and therefore such a strategy is both locally and globally optimal with respect to intermediate fill-in. If there are no pairs with the same zero-nonzero pattern, then the strategy is to choose the pair of rows that results in the least amount of local fill-in. Often two pairs of rows produce the same amount of fill-in. In this case, a tie-breaking strategy is based on a strategy of preserving the sparsity of future active submatrices by choosing the sparsest pair of rows (Gentleman's scheme [7]).

It is instructive to demonstrate the various row ordering strategies on some simple examples. Duff [4] suggests an example where the selected column has already been found and the Givens reduction stage is to begin. The active submatrix is

$$\begin{bmatrix} x & o & o & o & o & o \\ x & x & x & x & o & o \\ x & x & x & x & o & o \\ x & o & o & o & x & x \\ o & & & \vdots & & \\ \vdots & & & & & \\ o & & & & & \end{bmatrix}.$$

Processing the pairs in their natural order, i.e., (1, 2), (1, 3), and (1, 4) results in a fill-in of eight. Using Duff's fixed pivot scheme results in the pairings (1, 4), (1, 2), (1, 3), and a fill-in of nine. Gentleman's variable pivot scheme results in the same pairing as the fixed pivot scheme. The variable pair strategy results in the pairing (2, 3), (1, 4), and (1, 2) with a fill-in of seven.

Duff suggests an example for which Gentleman's variable pivot method fails to be optimal with respect to intermediate fill-in:

$$\begin{bmatrix} x & x & x & o & o & o & o \\ x & o & o & x & x & o & o \\ x & x & x & x & o & o & o \\ x & o & o & o & x & x & x \\ o & & & \vdots & & & \\ \vdots & & & & & & \\ o & & & & & & \end{bmatrix}.$$

Using the natural order, the fill-in is ten. The fixed pivot strategy produces a fill-in of nine. The variable pivot scheme results in the pairings (1, 2), (3, 4), and (1, 3) for a fill-in of twelve. The variable pair strategy results in the pairings (1, 3), (1, 2), (1, 4), and a fill-in of nine.

The variable pair strategy seems to produce an optimal ordering in the cases examined so far, but this is not always true. Consider the active submatrix

$$\begin{bmatrix} x & x & x & x & x & x \\ x & x & x & o & o & x \\ x & o & o & o & x & x \\ o & & & \vdots & & \\ \vdots & & & & & \\ o & & & & & \end{bmatrix}.$$

Using the variable pair strategy the rows are processed in the order (1, 2) and (1, 3) with a fill-in of five. However, the order (2, 3) and (1, 2) produces a fill-in of four. Thus the variable pair strategy for minimizing fill-in at each step does not assure global minimization of intermediate fill-in.

The discussion above motivates the row ordering strategy by the desire to reduce flops; but, overhead associated with choosing a row ordering can also impact overall performance of the algorithm. Overhead is measured by the amount of integer arithmetic performed during the decomposition. To estimate the complexity of our row

ordering algorithm, consider one step of the decomposition. Let r be the number of rows in the selected set of rows at the beginning of the second stage. Let M be the number of nonzeros in the final pivot row at the end of the second stage. With no chance cancellations, the number of nonzeros in any row in the selected set at anytime during the second stage is bounded by M. Processing the active submatrix using the variable pair method involves the following setup.

1. Check for sparsity patterns that are exact matches and process those pairs of rows immediately. There are $O(r^2)$ pairs each requiring at most $O(M)$ comparisons; so this step has a bound on the number of comparisons that is $O(Mr^2)$.

2. Calculate fill-in for all pairs of rows and set up a list storing the members of the pairs and the corresponding fill-in. This step has a bound on the amount of integer arithmetic that is $O(Mr^2)$, but note that the number of rows might be less than r after step 1.

3. Sort the pairs in the list in order of the increasing amount of fill-in using Gentleman's scheme as a tie breaker ($O(r^2 \log r)$.

4. Perform a Givens rotation on the first pair in the list; the flops have an $O(M)$ bound.

If the above steps are repeated (at most r-1 times) to complete the second stage, the overhead is at worst $O(Mr^3)$ and the flops are bounded by $O(Mr)$. However, the overhead can be reduced by noting that after step 4 the list of pairs constructed in step 2 does not have to be entirely redone. A pair in the list that has the discarded row or the current pivot row as one of its members is no longer valid and is deleted from the list. Since the sparsity pattern in the current pivot row may have changed, fill-in must be recomputed for a pair that has the pivot row as a member. A temporary list is created, with at most r-2 entries, containing all pairs that involve the pivot row and its corresponding fill-in ($O(Mr)$). The temporary list is then sorted according to fill-in and merged with the original list ($O(r^2)$). This updating is done at most r-2 times. The overhead for the variable pair method is thus bounded by $O(Mr^2)+O(r^3)$ work. At any given step of the decomposition, the values of M and r depend on the row and column orderings. Of course, M is at most n and r is at most m. For a sparse matrix, r should generally be much less than m and M much less than n. If M and r are the same order, then both terms in the overhead bound are the same size, $O(Mr^2)$. In a sparse matrix with nonzero elements that in some sense are evenly distributed throughout the matrix so that the number of nonzeros in any column is roughly the same as the number of nonzeros in each row, it might be possible to keep $M = O(r)$ if the amount of intermediate fill-in is kept small.

In §3, the variable pair method is compared with Duff's fixed pivot method [4] and with Gentleman's scheme [7]. Given the same active submatrix as above, the fixed pivot method compares the sparsity structure of the pivot row to each remaining row in the selected set of rows to determine the order in which Givens rotations are applied. Overhead for this method is bounded by $O(Mr^2)$. On the other hand, Gentleman's variable pivot scheme does not use the sparsity structure. For the remaining rows in the selected set of rows, the total number of nonzeros for each pair of rows is used to pick the order in which rows are processed, making the overhead $O(r^2)$.

It is also important to remember that this analysis is for one active submatrix. The hope is that by using more information about the sparsity structure, the variable pair method and Duff's fixed pivot scheme will do better than Gentleman's scheme in the long run because the active submatrices will be sparser, i.e., the values of M and r will be kept small. This hope is not always realized, as shown in the examples in §3.

TABLE 1
Characteristics of the test matrices.

	Number of			Sparsity
	Rows	Columns	Nonzeros	(%)
CURTIS55[1]	55	54	292	9.8
WILL58	58	57	282	8.5
WILL200	200	199	702	1.8

NETWORK4	1488	784	7040	0.6
NETWORK3	1512	402	7152	1.2
WELL1850[2]	1850	712	8758	0.7

[1] The matrix given in Curtis [9] is the transpose of that supplied in the Harwell–Boeing sparse matrix collection [8]. The matrix from the Harwell–Boeing sparse matrix collection is used here.

[2] The version used by Liu [6] has three fewer nonzero entries.

3. Examples. Ten test matrices from the Harwell–Boeing sparse matrix collection [8] as well as four matrices from George, Heath and Ng [9] (also used by Liu [6]), are used to compare the row ordering strategies. Three square matrices are altered by adding a row with a nonzero in the first column. These matrices, used by Duff [4], were developed by Curtis [10] and Willoughby [11]. WELL1033 and WELL1850 are surveying problems supplied by Michael Saunders. ASH219, ASH331, ASH608, and ASH958 are surveys of the United Kingdom and Holland supplied by V. Ashkenazi. ABB313 is a survey of Sudan supplied by M. Abbas. NETWORK3 and NETWORK4 are geodetic adjustment problems. LSQUAR15 and LSQUAR20 arise in the natural factor formulation of the finite element method. CURTIS55 and WILL58 both exhibit a dominant principal band with very sparse outliers. WILL200 has about thirty small bands scattered throughout the matrix. ASH219, ASH331, ASH608, and ASH958 all are banded about the principal diagonal. ABB313, LSQUAR15, and LSQUAR20 have two diagonal bands. WELL1033 and WELL1850 have several bands along with less structured patterns. NETWORK3 and NETWORK4 have one diagonal band extending to the right edge and scattered entries to the left of the other end of the diagonal band. Other characteristics of these test matrices are listed in Table 1.

First, a comparison is made of Duff's fixed pivot row strategy (DUFF) and Gentleman's variable pivot row strategy (GENT) with the variable pair strategy (VPAIR) using Duff's column ordering. Since Duff's algorithm does not uniquely specify the order of rows and columns (ties are broken arbitrarily), different implementations may give varying results. Duff [4] and Duff and Reid [12] report slightly different results and the implementation used here shows a similar variation in results. Our implementation breaks all ties by using the original or natural ordering (smallest original column or row number).

The results on the fourteen test matrices are shown in Table 2. Intermediate fill-in is the total number of nonzeros created at any time during the decomposition. QR flops is the number of multiplications performed during the decomposition using standard Givens rotations. Next, a comparison is made between DUFF, GENT, and VPAIR using the minimum degree strategy for the column ordering. The results are shown in Table 3.

The test matrices can be divided into categories of small, nearly square ($m \approx n$) matrices, and larger rectangular ($m \gg n$) matrices. The first three test matrices are small, nearly square matrices, and tend to have fewer choices for ordering simply because there are fewer rows. Larger rectangular matrices should demonstrate the differences between the methods to a greater degree since there is a greater chance of operating on previous intermediate fill-in and many more choices for row orderings.

The results demonstrate the differences between the two categories of test matrices. Nearly square matrices show little difference between the various row ordering strategies. Because of their shape, these matrices have the characteristic that the number of rows in each selected set must decrease in the last few stages of the algorithm (see Fig. 1). Typical behavior of the larger rectangular test matrices is for a rapid growth in the number of rows in the selected sets in the last few stages. Such behavior is indicative of operations on intermediate fill-in. The exception to this type of behavior is ABB313, which displays uneven growth in the number of rows in the selected sets. Of all the larger rectangular matrices, VPAIR shows the least improvement for ABB313.

Using Duff's column ordering strategy, VPAIR shows a 33% median improvement in intermediate fill-in over DUFF for the eleven larger rectangular test matrices. The number of Givens rotations has a median improvement of 35%, while a median improvement of 47% is observed in QR flops. The number of nonzeros in R is about the same for VPAIR and DUFF, except for ASH608 and ASH958 where a significant improvement is seen using VPAIR, and for LSQUAR15, LSQUAR20, and NETWORK3 where DUFF yields a sparser R than VPAIR. Since row ordering does not determine the sparsity of R, the different row ordering strategies reduce the number of nonzeros in R by allowing the local column ordering strategies to perform better. (Recall the discussion following (1).) Although, the results for WELL1033, WELL1850, LSQUAR15, LSQUAR20, NETWORK3, and NETWORK4 are a reminder that reducing intermediate fill-in does not necessarily reduce fill-in in R. For the small nearly square test matrices, mixed results with few differences were obtained. GENT performed worse than DUFF on ABB313, ASH331, LSQUAR15, LSQUAR20, NETWORK3, and NETWORK4, while slightly outperforming DUFF on the other five larger rectangular test matrices.

Using the minimum degree column ordering strategy on the matrix A (as opposed to A^TA), VPAIR shows even greater improvement over DUFF. The median improvement on the larger rectangular test matrices is 57% for intermediate fill-in, 53% for the Givens rotations, and 71% for the flops required for the QR decomposition. Again there is not much distinction between the methods for the nearly square matrices. Gentleman's row ordering strategy performs much better than DUFF on seven of the largest test matrices, but not nearly as well as VPAIR. On the other four test matrices, LSQUAR15, LSQUAR20, NETWORK3, and LSQUAR4, DUFF does better than GENT, but still not as well as VPAIR.

In these examples, the minimum degree column ordering strategy produces a sparser R matrix than Duff's column strategy; using VPAIR, the median improvement is 27% for the larger rectangular test matrices. VPAIR coupled with the minimum

TABLE 2
Duff's column strategy.

	VPAIR	13,435	13,480	463,734	8,713

degree column strategy generally performs better than VPAIR with Duff's column strategy with respect to flops, Givens, and intermediate fill-in. On the other hand, DUFF with Duff's column strategy generally performs better with respect to flops, Givens, and intermediate fill-in than DUFF coupled with the minimum degree column ordering strategy.

Increased time spent on row and column ordering can, in principle, offset savings in time gained by reducing flops. The amount of overhead for ordering rows and columns required by the various strategies is highly dependent on the implementation and the machine architecture. An indication of overhead costs can be obtained from the number of seconds required to perform the QR decomposition without computing statistics or performing flops. The overhead times are reported in Table 4 for the larger rectangular matrices; the smaller test matrices do not show significant differences among the various strategies. Also reported is the total execution time, except in cases where only the sparsity pattern was available and not the actual floating-point entries in the matrix.

Column and row ordering strategies can be divided into those that use information on the structure of the matrix as opposed to those that merely use the number of entries in the columns or rows. Methods that use more information about the structure typically require more overhead if the structure is fixed, but can have an overall advantage if they lead to sparser active submatrices during the decomposition process. Duff's column ordering strategy does not use information about the structure, while the minimum degree column ordering strategy does. For the row ordering strategies, DUFF and VPAIR use information on the structure while GENT does not.

The results in Table 4 show that, in these examples, the overhead for the minimum degree algorithm exceeds the overhead for Duff's column ordering except in a few cases. However, the results in Tables 2 and 3 show that R is sparser using the minimum degree column ordering that, in applications, might lead to savings elsewhere in the code. Also, a more efficient implementation of the minimum degree column ordering heuristic might be possible, which would reduce the overhead.

In examining overhead among the row ordering strategies, the results are mixed for ASH219, ABB313, and ASH331. For the larger test matrices, VPAIR generally performs better than GENT which, in turn, performs better than DUFF. There are, however, some exceptions to this pattern. The discussion at the end of the last section indicates that GENT could potentially be more efficient than DUFF or VPAIR. DUFF does tend to require more overhead than GENT on these examples. On the other hand, VPAIR generally has less total overhead than GENT because of its ability to reduce intermediate fill-in, as indicated by the values in Tables 2 and 3. The total execution times, including flops, follow the same pattern as the overhead times in Table 4. For all methods, the percentage of the total execution time devoted to overhead is about 85%. Note that timings could vary considerably for different implementations and architectures and may reflect some inefficiencies in coding. These computations were performed on a 486-33 in an 8-MHz mode.

Results in the literature using the same test matrices can also be used to judge the performance of VPAIR. Liu [6] uses a variable pivot row strategy with a minimum degree (MD) column ordering strategy on A^TA. Table 5 shows Liu's results on seven test matrices. For each Givens rotation, opcount is incremented by the number of nonzeros in the transformed pivot row and is roughly one-fourth of the QR flops using standard Givens. VPAIR shows a reduction ranging from 74–90% in the opcount compared to Liu's method.

Ostrouchov [3] uses a sophisticated implementation of Duff's fixed pivot row strat-

TABLE 3

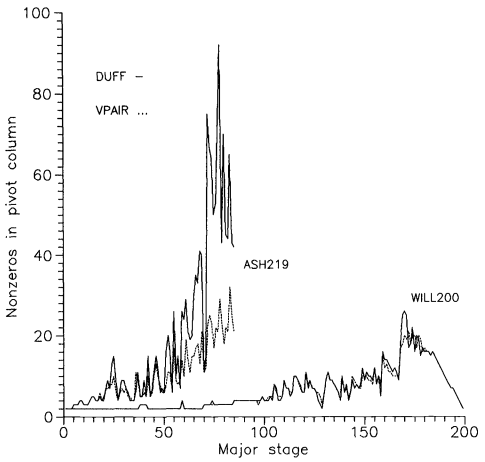

FIG. 1. *Types of test matrices.*

egy coupled with the MD column ordering with Duff's column ordering as a tie breaker (MD + Duff). Ostrouchov applies his method to ABB313 [13], WELL1033, and WELL1850 [14] and the results are summarized in Table 5. The number of Givens rotations and the opcount show improvements of 21–51% and 32–70%, respectively, for VPAIR over Ostrouchov's results. Ostrouchov recommends using the Duff tie breaker with the minimum degree column ordering. The results in Table 3 are obtained using the natural column ordering as the tie breaker and do not vary substantially if Duff's algorithm is used instead as the tie breaker. Only a small improvement in opcount using the Duff tie breaker is obtained for most of the larger rectangular test matrices; the test matrices that did not show improvement were the four supplied by Ashkenazi that all have the nonzeros banded about the principal diagonal.

4. Finite element application. A mixed finite element application for a diffusion problem is presented here [1]. For these applications the matrices do not necessarily have full rank and chance cancellation occurs frequently. The diffusion problem is a four-square unit square centered at the origin and subjected to uniform boundary flux in the positive y direction. There is no lateral boundary flux. The domain is split into elements equally in both directions. The number of elements n_e varies from 16 to 900. The major part of the solution involves a QR decomposition of the gradient matrix. The problem is rank deficient due to the presence of a constant mode. Table 6 shows the characteristics of some of the gradient matrices.

Determination of rank using the QR decomposition is achieved by counting the number of nonzero diagonal entries in R. However, roundoff may cause zero entries to be nonzero. In practice, the diagonal elements are assumed to be zero if they are less than a prescribed tolerance times the norm of the column. A more sophisticated rank determination algorithm using the QR decomposition is reported by Bischof and Hansen [15].

It is also important to determine if individual entries are zero or nonzero. A simple tolerance test will not suffice since the entries tend to become smaller as the decomposition proceeds and more nonzero entries occur in each column. This is because the orthogonal transformation does not change the norm of the column and thus intermediate fill-in requires that the magnitude of other entries be reduced. In performing the Givens rotation on a pair of nonzero entries, the resulting entries are compared. If the magnitude of the smaller entry is less than a tolerance times the

magnitude of the larger entry, then the smaller entry is assumed to be zero.

The a priori column ordering is obtained through nested domain decomposition as illustrated in [5, Fig. 2.6] and the only exception to this ordering occurs when a zero or small final pivot is obtained. Then, the appropriate column is shifted to the right and all the columns in between are shifted to the left. The sparsity of R (ignoring

rank deficiency and numerical roundoff) is fixed by this column ordering.

The three local row ordering strategies of Duff (DUFF) [4], Gentleman (GENT) [7] and the variable pair strategy (VPAIR) are implemented and compared. Also, the a priori row ordering induced by nested domain decomposition (NDD) [5] is implemented. NDD on this problem has a theoretical bound of $O(n_e^{3/2})$ on flops due to the underlying grid. The results are shown as log–log plots in Figs. 2, 3, and 4. Table 7 shows that there are substantial differences in performance on a 900-element problem.

The variable pair strategy outperforms the fixed pivot row method and Gentleman's variable pivot strategy as measured by flops, number of Givens rotations, and the amount of intermediate fill-in with better performance as the number of elements increases. In Fig. 2, the observed growth in the QR flops is $O(n_e^{1.57})$ for the VPAIR

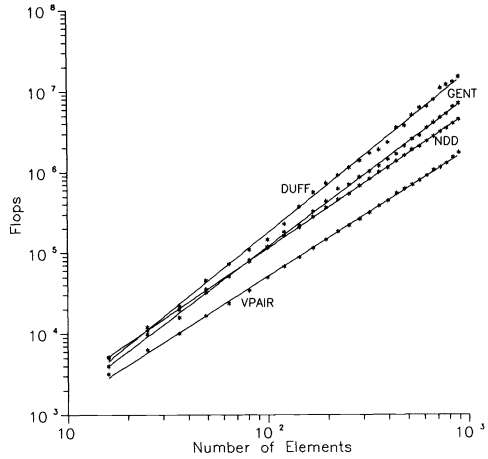

FIG. 2. *QR flops.*

strategy, versus $O(n_e^{1.85})$ for GENT and $O(n_e^{1.99})$ for DUFF over this size range for this problem. The number of flops, intermediate fill-in, and Givens rotations are also less for VPAIR than for NDD. The observed growth in flops for NDD is $O(n_e^{1.68})$; slightly larger than for VPAIR.

Since the row ordering for the nested domain decomposition is obtained as a side benefit of the column ordering, there is no overhead required for row ordering using NDD. To gauge the overhead using VPAIR, r and M (c.f. §2) can be monitored. The maximum r and maximum M for each size problem are used to obtain an observed bound on row ordering overhead of $O(n_e^{1.64})$. Thus, on this problem, the observed row ordering overhead for VPAIR grows faster than the observed growth in flops for VPAIR, but not as fast as the observed growth in flops for NDD.

5. Conclusion. The QR decomposition is a useful solution technique in some applications where Gaussian elimination is not suitable. The QR decomposition allows rank determination in practice and is numerically more stable than Gaussian elimination. Since the QR decomposition is generally more expensive than Gaussian elimination, it must be carefully implemented to be competitive as a general solution technique. An efficient algorithm has been presented for large, sparse matrices that often arise in applications.

A strategy for ordering rows is developed and compared with several other row

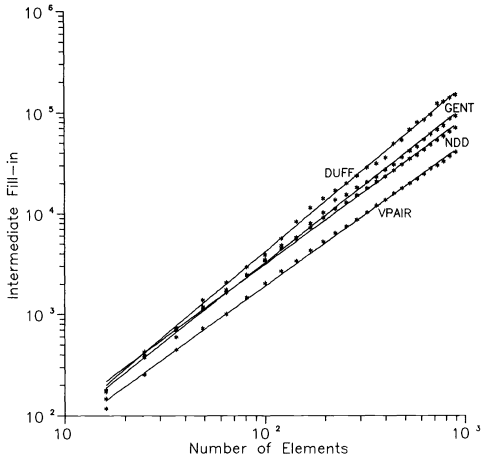

FIG. 3. *Intermediate fill-in.*

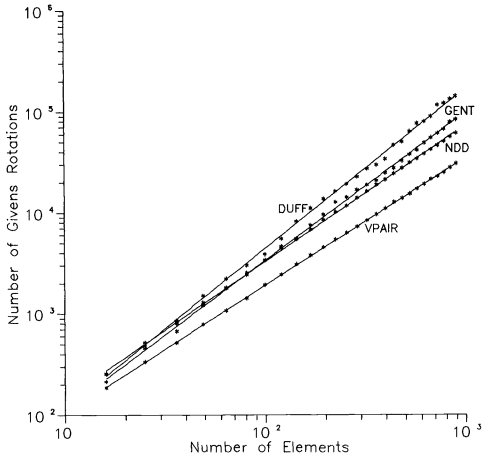

FIG. 4. *Givens rotations.*

ordering strategies in conjunction with several column ordering strategies. The new strategy is that of minimizing local fill-in for a variable pair of rows. For each active submatrix, the order of magnitude overhead to perform the next Givens rotation is roughly the same for the variable pair strategy as for Duff's [4] fixed pivot row ordering strategy. The new strategy also can be used to augment coarse row ordering strategies from nested domain decomposition (NDD) or nested dissection.

For test matrices from the Harwell–Boeing sparse matrix collection [8] and test matrices from George, Heath, and Ng [9], Duff's [4] column ordering and the minimum degree column ordering [3] are used. QR flops, intermediate fill-in, and Givens rotations all show a 33–71% median improvement for the variable pair strategy over Duff's fixed pivot strategy for the larger rectangular test matrices. For the same test matrices, the observed total overhead is much less for the new strategy than for Duff's fixed pivot row ordering strategy. Since the sparsity of R is about the same, the low cost to compute a solution using back substitution is maintained.

Although Duff [4] concluded that his fixed pivot strategy performed similarly to Gentleman's [7] variable pivot strategy, the results in §3 suggest that on these test problems, the issue is not clear cut. Gentleman's strategy performs as well or better than Duff's strategy in some cases, and moreover, requires less row ordering overhead

TABLE 7
Comparison of row orderings for a mixed finite element problem.

Number of elements	Row strategy	Intermed. fill-in	Givens rotations	QR flops	Nonzeros in R
900	DUFF	151,159	141,816	15,103,219	19,667

	NDD	71,225	61,202	4,498,832	19,667
	VPAIR	41,006	30,563	1,754,660	19,667

in the process. However, Gentleman's scheme generally does not perform as well as VPAIR on these problems. While it is as yet not possible to definitively state that the variable pair strategy will perform better than the other row ordering strategies on a broad class of problems, the results reported here show that significant improvements are possible. Also, many current applications generate much larger matrices than those considered here and VPAIR appears to have an advantage over other methods on general, large sparse matrices.

Row ordering strategies are also compared on a finite element application where nested domain decomposition [5] is used to determine the column ordering. Comparing the variable pair strategy to the schemes of Duff and Gentleman, a very dramatic reduction is seen in magnitude and growth of QR flops, intermediate fill-in, and the number of Givens rotations, while the sparsity of R is identical. The variable pair strategy can be utilized as a fine-grained row ordering strategy in conjunction with the coarse row ordering of the NDD, although the results indicate that the variable pair strategy also performs well by itself. Furthermore, the variable pair strategy is expected to outperform nested dissection on problems without an underlying grid.

Acknowledgments. The authors thank John Gilbert and two anonymous referees for comments that improved this article. The authors also wish to thank George Ostrouchov for graciously providing data for Table 5 and Joseph Liu for providing some of the test matrices.

BLOCK-TRIANGULARIZATIONS OF PARTITIONED MATRICES UNDER SIMILARITY/EQUIVALENCE TRANSFORMATIONS*

HISASHI ITO†, SATORU IWATA‡, AND KAZUO MUROTA‡

Abstract. A partitioned matrix, of which the column- and row-sets are divided into certain numbers of groups, arises from a mathematical formulation of discrete physical or engineering systems. This paper addresses the problem of the block-triangularization of a partitioned matrix under similarity/equivalence transformation with respect to its partitions of the column- and row-sets. Such block-triangularization affords a mathematical representation of the hierarchical decomposition of a physical system into subsystems if the transformation used is of physical significance. A module is defined from a partitioned matrix, and the simplicity of the module is proved to be equivalent to the nonexistence of a nontrivial block-triangular decomposition. Moreover, the existence and the uniqueness of the block-triangular forms are deduced from the Jordan–Hölder theorem for modules. The results cover many block-triangularization methods hitherto discussed in the literature such as the Jordan normal form and the strongly connected-component decomposition in the case of partition-respecting similarity transformations, and the rank normal form, the Dulmage–Mendelsohn decomposition, and the combinatorial canonical form of layered mixed matrices in the case of partition-respecting equivalence transformations.

AMS subject classifications. 15A21, 15A30

1. Introduction.

In the analysis of a discrete physical/engineering system generally it is all important to recognize "subsystems" and "hierarchy" among them in an appropriate manner. When the system is described in terms of a matrix (of any kind), the hierarchical decomposition of the whole system into partially ordered subsystems is reduced to the block-triangularization of the matrix under a suitably chosen class of "admissible transformations." To be more precise, the block-triangularization of the matrix is almost tantamount to finding a good or "canonical" mathematical description of the system, which hopefully reveals the "subsystems" and the "hierarchy" of physical significance.

In this paper it is assumed that the matrix, say A, in question is a partitioned matrix of which the row set and the column set are divided into a certain number of groups, respectively. Two types of admissible transformations are considered: (i) similarity transformations that respect or conform with the partition structure

$$\begin{bmatrix} S_1 & O & \cdots & O \\ O & S_2 & \ddots & \vdots \\ \vdots & \ddots & \ddots & O \\ O & \cdots & O & S_\nu \end{bmatrix}^{-1} \begin{bmatrix} A_{11} & A_{12} & \cdots & A_{1\nu} \\ A_{21} & A_{22} & \cdots & A_{2\nu} \\ \vdots & \vdots & \ddots & \vdots \\ A_{\nu 1} & A_{\nu 2} & \cdots & A_{\nu\nu} \end{bmatrix} \begin{bmatrix} S_1 & O & \cdots & O \\ O & S_2 & \ddots & \vdots \\ \vdots & \ddots & \ddots & O \\ O & \cdots & O & S_\nu \end{bmatrix},$$

and (ii) equivalence transformations that conform to the partition structure that is defined similarly (see §§2.1 and 3.1 for the precise definitions). In this paper the transfor-

mations of types (i) and (ii) are called PS-transformations and PE-transformations, respectively. The main objective of this paper is to investigate the block-triangularization of A under such transformations by means of the module theoretical framework. In particular, the Jordan–Hölder theorem for modules plays the key role in discussing the existence and the uniqueness of the block-triangular form.

The present problem formulation covers many important instances of the hierarchical decomposition discussed so far in the literature as briefly mentioned in the following.

When a general similarity transformation ($S^{-1}AS$ with S nonsingular) is allowed, the Jordan normal form yields a block-triangular decomposition, whereas when a general equivalence ($S_{\mathrm{r}}AS_{\mathrm{c}}$ with S_{r} and S_{c} nonsingular) is admissible, the rank normal form serves as a block-triangular decomposition. Needless to say, these normal forms play fundamental roles in many application areas.

In the design and the analysis of large-scale engineering systems it is often meaningful to consider a most-restricted class of similarity/equivalence transformations, namely, permutations of the rows and the columns. When the rows and the columns are permuted simultaneously as $P^{\mathrm{T}}AP$ with P a permutation matrix, a block-triangularization is given by the decomposition of the directed graph associated with A into strongly connected components; see, e.g., Aho, Hopcroft, and Ullman [1]. On the other hand, when the rows and the columns are permuted independently as $P_{\mathrm{r}}AP_{\mathrm{c}}$ with P_{r} and P_{c} permutation matrices, a block-triangularization is given by the canonical decomposition of the bipartite graph associated with A into elementary or irreducible components. This decomposition is due to Dulmage and Mendelsohn [10] (see, also, Brualdi and Ryser [8], Lovász and Plummer [19]) and is often referred to as the DM-decomposition. Both the strongly connected-component decomposition and the DM-decomposition can be computed efficiently by purely graph-theoretical algorithms.

The underlying mathematical structure of the DM-decomposition can be understood in a more abstract context of matroids such as the Jordan–Hölder type theorem for submodular functions (Iri [15]). With the aid of this general principle, the DM-decomposition is extended to the combinatorial canonical form (CCF) for a layered mixed matrix that is proposed as a mathematical tool for describing the combinatorial structure of physical systems (Murota [20], Murota [22], Murota, Iri, and Nakamura [23]; see Remark 3.2 in §3.3 for more about this). A layered mixed matrix is "mixed" in the sense that it consists of two different kinds of entries, independent variables and fixed constants, and the CCF combines the combinatorial technique for the DM-decomposition and the standard linear algebraic technique for the LU-decomposition (or Gaussian elimination). The CCF can be computed by an efficient algorithm that makes use of the matroid-theoretical algorithm for submodular flows. In this way, combinatorial mathematics can provide us with effective decomposition methods, often supported by efficient algorithms, when we want to exploit the combinatorial structure such as sparsity, independence of individual element characteristics, and dependence stemming from incidence relations. See Iri [14], Murota [20], Recski [25], and Šiljak [27] for applications of graph, network, and matroid theories to the design and the analysis of engineering systems.

In the area of physics and chemistry, especially in quantum physics and chemistry, it is standard technique to decompose a system with respect to the symmetry of the system. The underlying mathematical structure for this technique can be explained

by the group representation theory [9]; namely, the decomposition corresponds to the decomposition of a group representation into homogeneous or irreducible components. An attempt is made in Murota [21] to combine the symmetry-exploiting decomposition method with the matroid-theoretical decomposition method. It may be noted that the group representation theory can be embraced in the more general theory of modules.

The module-theoretical approach has turned out to be useful also in analyzing and decomposing automata, dynamical systems, and stochastic processes. In automata theory any finite machine can be decomposed into loop-free connections of permutation reset machines; the Jordan–Hölder theorem for groups [7] yields a further decomposition of a permutation reset machine (the Krohn–Rhodes theorem; see Arbib [3]). In mathematical systems theory a finite module over polynomials plays an important role, and the structure theorem on such a module gives the hierarchical decomposition of a dynamical system (see Kalman, Falb, and Arbib [18]). A stochastic process can also be formulated in terms of a module, called a stochastic module, as shown by Heller [12], [13]; then the Krull–Remak–Schmidt theorem gives a decomposition of a stochastic process.

The admissible similarity transformation (PS-transformation) introduced above has a close relation to a certain type of stochastic process called the hidden Markov process. It has recently been shown by Ito, Amari, and Kobayashi [17] that (roughly speaking) two Markov chains generate the same hidden Markov process if and only if the two transition matrices are connected by a PS-transformation. (This solves the identifiability problem of hidden Markov processes posed by Blackwell and Koopmans [6]; see also Rosenblatt [26].) This result, when combined with Heller's framework of stochastic modules, leads to the observation of Ito [16] that the PS-transformation can be formulated in a module-theoretical framework. The present paper adopts this line of approach to investigate the block-triangularization under PS- or PE-transformations.

The outline of this paper is as follows. In §2 we consider the block-triangularization of a partitioned square matrix under PS-transformations and show the existence and the uniqueness of PS-irreducible components by the Jordan–Hölder theorem for modules. We also discuss the ordering among PS-irreducible components to explain the "hierarchy" revealed by the block-triangularization. In §3 we consider the block-triangularization (with rank conditions) of a partitioned, not necessarily square, matrix under PE-transformations. The uniqueness of PE-irreducible components and the ordering among them will be derived similarly although such a block-triangularization does not always exist. We also exploit another approach using a submodular function to explain a necessary and sufficient condition for the existence of a block-triangularization with rank conditions and the relationship of our new block-triangularization to the previously known decompositions such as the DM-decomposition and the CCF. In §4 we discuss an algorithm for block-triangularization of a partitioned square matrix in a nondegenerate case and also an algorithm to check the existence of a block triangularization under PE-transformations.

2. Decomposition under partition-respecting similarity.

2.1. Problem formulation. In this section we discuss block-triangularization of a partitioned *square* matrix under restricted similarity transformations that preserve the partition structure. More precisely, let F be a field, e.g., the real numbers $\mathbb{R}$ or the complex numbers $\mathbb{C}$, and A be an n-dimensional square matrix over the field

F with given partitions of rows and columns:

$$A = \begin{bmatrix} A_{11} & A_{12} & \cdots & A_{1\nu} \\ A_{21} & A_{22} & \cdots & A_{2\nu} \\ \vdots & \vdots & \ddots & \vdots \\ A_{\nu 1} & A_{\nu 2} & \cdots & A_{\nu\nu} \end{bmatrix},$$

where $A_{\alpha\beta}$ is an $n_\alpha \times n_\beta$ matrix called (α, β)-submatrix of A. To describe the partition structure in terms of matrix operation, we introduce a family of $n \times n$ projection matrices Π_α $(\alpha = 1, \ldots, \nu)$, where the (α, α)-submatrix of Π_α is the unit matrix I_{n_α} of dimension n_α and the other submatrices are zeros. Sometimes we denote the partitioned square matrix by the pair (A, Π), where $\Pi = \{\Pi_\alpha\}_{\alpha=1}^{\nu}$. A transformation $\widetilde{A} := S^{-1}AS$ of A is said to be a *partition-respecting similarity transformation* (PS-transformation) if the off-diagonal submatrices of S are zeros, i.e.,

$$\Pi_\alpha S = S\Pi_\alpha \quad \text{for} \quad \alpha = 1, \ldots, \nu.$$

We say that A is *Π-similar* to A' if there exists a PS-transformation that transforms A to A'. Then our problem is to bring A into a block-triangular form by means of a PS-transformation.

Alternatively, our problem can be formulated as follows. Let V be an n-dimensional F-linear space F^n, which is a direct sum of lower dimensional spaces:

$$V = \bigoplus_{\alpha=1}^{\nu} V_\alpha, \qquad \dim_F V_\alpha = n_\alpha.$$

A linear transformation

$$f : V \to V$$

is constructed by a family of linear transformations

$$f_{\alpha\beta} : V_\beta \to V_\alpha \quad (1 \leq \alpha,\ \beta \leq \nu).$$

When we take arbitrary basis for each space V_α, f is represented by a partitioned square matrix A, where $A_{\alpha\beta}$ corresponds to $f_{\alpha\beta}$. In this context PS-transformations are naturally derived as basis transformations of V_α.

It may be in order here to give a definition to the notion of a block-triangular form. Let $\widetilde{A}$ be a square matrix representing a linear transformation from a linear space V to itself. Then the row set $R = \{1, 2, \ldots, n\}$ is to be identified with the column set $C = \{1, 2, \ldots, n\}$. For $R_* \subseteq R$ and $C_* \subseteq C$, let $\widetilde{A}[R_*, C_*]$ mean the submatrix of $\widetilde{A}$ with row set R_* and column set C_*. When we split R into a certain number of disjoint nonempty blocks $(R_1, \ldots, R_b)$, C is naturally split into blocks $(C_1, \ldots, C_b)$, where

$$R_k = C_k \quad \text{for} \quad k = 1, \ldots, b$$

according to the correspondence between R and C. We say that $\widetilde{A}$ is in a *block-triangular form* or is *block-triangularized* with respect to the blocks $(R_1, \ldots, R_b)$ when $\widetilde{A}$ satisfies the following condition:

$$\widetilde{A}[R_k, C_l] = O \quad \text{if} \quad 1 \leq l < k \leq b.$$

If $\widetilde{A}$ is block-triangularized in the above sense, it is clear that we can put it into an explicit upper block-triangular form $\bar{A} = P^{\mathrm{T}}\widetilde{A}P$ in the usual sense by using a certain permutation matrix P, where the superscript T denotes the transpose of a matrix.

A partitioned square matrix (A, Π), or simply A, is said to be PS-*irreducible* if it can never be transformed into a block-triangular form with two or more nonempty blocks by any PS-transformation. If $\widetilde{A}$ is a block-triangular matrix obtained from A by a PS-transformation and, in addition, all the diagonal blocks $\widetilde{A}[R_k, C_k]$ for $k = 1, \ldots, b$ are PS-irreducible, we say that $\widetilde{A}$ is a (PS-)*irreducible decomposition* of A, and $\widetilde{A}[R_k, C_k]$ are (PS-)*irreducible components* of A.

Our problem of block-triangularization above includes two well-known extreme cases. The first case is with the trivial partition structure: $\nu = 1$. In this case our problem has been completely solved by the Jordan normal form (in the case of $F = \mathbb{C}$) [11]. The other extreme case is with the finest partition structure: $\nu = n$. In this case our problem is essentially solved by the decomposition of a directed graph into strongly connected components with efficient algorithms [4].

On the analogy of strongly connected-component decompositions, a partial order is induced among the blocks $\{C_k \mid k = 1, \ldots, b\}$ in a natural manner by the zero/nonzero structure of a block-triangular matrix $\widetilde{A}$. The partial order $\preceq$ is the reflexive and transitive closure of the relation defined by: C_k is "smaller" than or equal to C_l if $\widetilde{A}[R_k, C_l] \neq O$, where R_k is identified with C_k for $k = 1, \ldots, b$. We denote this poset $(\{C_k\}_{k=1}^{b}, \preceq)$ by $\mathcal{P}(\widetilde{A})$.

As is well known [2], [5], the ideals of the poset $\mathcal{P}(\widetilde{A})$ constitute a distributive lattice, which we denote by $\mathcal{D}(\widetilde{A})$. Note that a subset J of C can be naturally identified with a subspace of V, which we denote by $\psi(J)$, i.e.,

$$\psi(J) = \mathrm{span}\{(0, \ldots, 0, \overset{j}{\overset{\vee}{1}}, 0, \ldots, 0)^{\mathrm{T}} \mid j \in J\}.$$

Then

$$\psi(J_1 \cup J_2) = \psi(J_1) + \psi(J_2)$$

and

$$\psi(J_1 \cap J_2) = \psi(J_1) \cap \psi(J_2),$$

and hence

$$\psi(\mathcal{D}(\widetilde{A})) = \{\psi(J) \mid J \in \mathcal{D}(\widetilde{A})\}$$

is a distributive sublattice of the modular lattice formed by the subspaces of V.

We say that $\widetilde{A} = S^{-1}AS$ is *finer*, as a decomposition of A, than $\widetilde{A}' = S'^{-1}AS'$ if $S'\psi(\mathcal{D}(\widetilde{A}')) = \{S'\widetilde{W}' \mid \widetilde{W}' \in \psi(\mathcal{D}(\widetilde{A}'))\}$ is a proper sublattice of $S\psi(\mathcal{D}(\widetilde{A})) = \{S\widetilde{W} \mid \widetilde{W} \in \psi(\mathcal{D}(\widetilde{A}))\}$. Furthermore, we say that $\widetilde{A}$, Π-similar to A, is a *finest-possible* decomposition of (A, Π) if there does not exist a block-triangular matrix $\widetilde{A}'$ that is also Π-similar to A and finer than $\widetilde{A}$.

Example 2.1. Consider the following five-dimensional partitioned square matrix

A over $F = \mathbb{Q}$:

$$A = \begin{array}{c} \\ \circ \\ \circ \\ \bullet \\ \bullet \\ \bullet \end{array} \begin{array}{c} \begin{array}{ccccc} \circ & \circ & \bullet & \bullet & \bullet \end{array} \\ \left[\begin{array}{cc|ccc} 3 & 2 & -2 & 5 & 13 \\ 0 & 2 & 1 & 0 & 1 \\ \hline 0 & -1 & 6 & 1 & 0 \\ 4 & 8 & 0 & 2 & -6 \\ -2 & -4 & 0 & 1 & 7 \end{array}\right] \end{array},$$

where $\nu = 2$, $n_1 = 2$, and $n_2 = 3$. Let S be the nonsingular matrix

$$S = \left[\begin{array}{cc|ccc} 2 & -1 & \multicolumn{3}{c}{\multirow{2}{*}{O}} \\ -1 & 1 & & & \\ \hline \multicolumn{2}{c|}{\multirow{3}{*}{O}} & 1 & 0 & 0 \\ & & 0 & 3 & -2 \\ & & 0 & -1 & 1 \end{array}\right].$$

Then we have

$$\widetilde{A} = S^{-1}AS = \begin{array}{c} \\ \circ \\ \circ \\ \bullet \\ \bullet \\ \bullet \end{array} \begin{array}{c} \begin{array}{ccccc} \circ & \circ & \bullet & \bullet & \bullet \end{array} \\ \left[\begin{array}{cc|ccc} 2 & 1 & -1 & 1 & 4 \\ 0 & 3 & 0 & 0 & 5 \\ \hline 1 & -1 & 6 & 3 & -2 \\ 0 & 0 & 0 & 4 & 0 \\ 0 & -2 & 0 & 0 & 5 \end{array}\right] \end{array}.$$

By using the permutation matrix

$$P = \left[\begin{array}{ccccc} 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{array}\right],$$

we can transform $\widetilde{A}$ into an explicit upper block-triangular form

$$\bar{A} = P^{\mathrm{T}}\widetilde{A}P = \begin{array}{c} \\ \circ \\ \bullet \\ \bullet \\ \circ \\ \bullet \end{array} \begin{array}{c} \begin{array}{ccccc} \circ & \bullet & \bullet & \circ & \bullet \end{array} \\ \left[\begin{array}{c|c|c|c|c} 2 & -1 & 1 & 1 & 4 \\ \hline 1 & 6 & 3 & -1 & -2 \\ \hline & & 4 & \multicolumn{2}{c}{\multirow{2}{*}{O}} \\ \cline{3-3} & \multicolumn{2}{c|}{\multirow{3}{*}{O}} & & \\ \cline{4-5} & & & 3 & 5 \\ & & & -2 & 5 \end{array}\right] \end{array}$$

with three diagonal blocks

$$D_1 = \widetilde{A}[C_1, R_1] = \left[\begin{array}{c|c} 2 & -1 \\ \hline 1 & 6 \end{array}\right], \qquad D_2 = \widetilde{A}[C_2, R_2] = [4],$$

$$D_3 = \widetilde{A}[C_3, R_3] = \left[\begin{array}{c|c} 3 & 5 \\ \hline -2 & 5 \end{array}\right].$$

Note that D_k's are also partitioned square matrices with partitions defined by

$$\Phi_1 = \left\{\begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}, \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}\right\}, \quad \Phi_2 = \{[0], [1]\}, \quad \Phi_3 = \left\{\begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}, \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}\right\}.$$

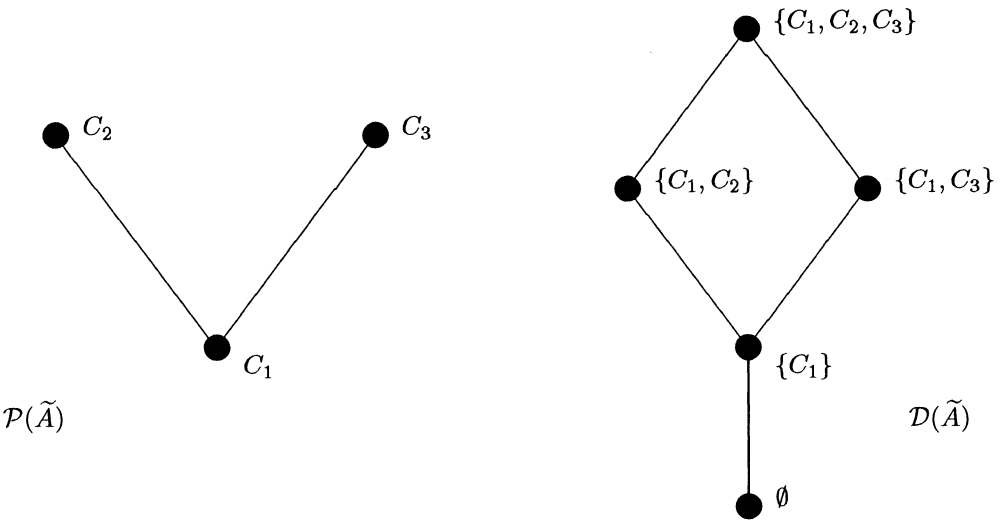

FIG. 1. *The partial order $\mathcal{P}(\widetilde{A})$ and the distributive lattice $\mathcal{D}(\widetilde{A})$ in Example* 2.1.

Since (D_1, Φ_1), (D_2, Φ_2), and (D_3, Φ_3) are PS-irreducible, $\widetilde{A}$ is an irreducible decomposition of A. Furthermore, it turns out to be a finest-possible decomposition of A. The Hasse diagrams for $\mathcal{P}(\widetilde{A})$ and $\mathcal{D}(\widetilde{A})$ are illustrated in Fig. 1.

The main results of this section are as follows. In §2.3 we define a module $M(A, \Pi)$ from a partitioned square matrix (A, Π). It is shown that the PS-irreducibility is equivalent to the simplicity of this module (see Theorem 2.3) and that the PS-irreducible components are determined uniquely (see Theorem 2.4) by the Jordan–Hölder theorem for modules. In §2.4, it is shown that a finest-possible decomposition of (A, Π) is not unique, but is obtained by a maximal distributive sublattice of the modular lattice $\mathcal{L}(A, \Pi)$ of the submodules of $M(A, \Pi)$ (see Theorem 2.7).

2.2. Jordan–Hölder theorem for modules. In this section we prepare a general framework to investigate partitioned matrices by means of module theory. Let M be an n-dimensional F-linear space, Σ be a finite set of symbols, and Σ^* the free monoid generated by Σ, where the unity is the empty string Λ. We can extend the monoid Σ^* to a monoid algebra

$$F\langle\Sigma^*\rangle = \{\sum_{s\in\Sigma^*} c_s s \mid c_s \in F, \text{ and } c_s = 0 \text{ for all } s \in \Sigma^* \text{ but finite } s\}$$

over F.

When we have an action of Σ^* on M, which satisfies the conditions:

$$\begin{aligned} \Lambda x &= x, & x &\in M, \\ s(x+y) &= sx + sy, & s &\in \Sigma^*, \quad x, y \in M, \\ (st)x &= s(tx), & s, t &\in \Sigma^*, \quad x \in M, \end{aligned}$$

it is quite natural to consider the n-dimensional F-linear space M to be a left $F\langle\Sigma^*\rangle$-module.

Let $\mathcal{R}$ be an arbitrary ring, $\mathcal{M}$ an $\mathcal{R}$-module, and

$$\mathcal{C} : 0 = \mathcal{M}_0 \subsetneq \mathcal{M}_1 \subsetneq \cdots \subsetneq \mathcal{M}_h = \mathcal{M}$$

a strictly increasing finite chain of $\mathcal{R}$-submodules of $\mathcal{M}$. We say that the *length* of $\mathcal{C}$ is h. $\mathcal{C}$ is called a *composition series* of $\mathcal{M}$ if each factor module $\mathcal{M}_i/\mathcal{M}_{i-1}$ $(i = 1, 2, \ldots, h)$ has no nontrivial submodules. The $F\langle\Sigma^*\rangle$-module M has a composition series, since it is also an n-dimensional F-linear space. The following Jordan–Hölder theorem [9] plays a crucial role not only in this section, but also in §3.

THEOREM 2.1 (Jordan–Hölder [7], [9]). *If*

$$\mathcal{C} : 0 = \mathcal{M}_0 \subsetneq \mathcal{M}_1 \subsetneq \cdots \subsetneq \mathcal{M}_h = \mathcal{M}$$

and

$$\mathcal{C}' : 0 = \mathcal{M}'_0 \subsetneq \mathcal{M}'_1 \subsetneq \cdots \subsetneq \mathcal{M}'_{h'} = \mathcal{M}$$

are any two composition series of $\mathcal{R}$-module $\mathcal{M}$, then $\mathcal{C}$ is equivalent to $\mathcal{C}'$, which means that $h = h'$ and there exists a permutation σ of $\{1, 2, \ldots, h\}$, such that

$$\mathcal{M}_i/\mathcal{M}_{i-1} \cong \mathcal{M}'_{\sigma(i)}/\mathcal{M}'_{\sigma(i)-1}.$$

2.3. Decomposition into irreducible components. Given a partitioned square matrix (A, Π), we consider an $F\langle\Sigma^*\rangle$-module M (see the general framework of §2.2) by setting

$$\Sigma = \{z_0, z_1, \ldots, z_\nu\}$$

and defining the action of Σ^* on V as follows:

$$\left.\begin{array}{l} z_0 x := Ax, \\ z_\alpha x := \Pi_\alpha x \quad (\alpha = 1, \ldots, \nu) \end{array}\right\} \quad x \in V.$$

Then $M = V$ becomes an $F\langle\Sigma^*\rangle$-module as well as an n-dimensional F-linear space. We denote this module by $M(A, \Pi)$ to emphasize its dependence on the matrix A and the partition structure Π. For another partitioned square matrix A' with common Π, we obtain another $F\langle\Sigma^*\rangle$-module $M(A', \Pi)$. The following lemma states that the module $M(A, \Pi)$ remains isomorphic under PS-transformations.

LEMMA 2.2. *$M(A, \Pi) \cong M(A', \Pi)$ if and only if A is Π-similar to A'.*

Proof. ($\Longrightarrow$) Let $\varphi : M(A, \Pi) \to M(A', \Pi)$ be the module isomorphism. Since $F \subseteq F\langle\Sigma^*\rangle$, we can consider the two modules F-linear spaces and φ a bijective linear transformation that is to be represented by a nonsingular matrix S. For all $x \in M(A, \Pi)$, we have

$$\begin{aligned} A'Sx &= z_0\varphi(x) = \varphi(z_0 x) = SAx, \\ \Pi_\alpha Sx &= z_\alpha\varphi(x) = \varphi(z_\alpha x) = S\Pi_\alpha x \quad \text{for } \alpha = 1, \ldots, \nu. \end{aligned}$$

Therefore $A'S = SA$ and $\Pi_\alpha S = S\Pi_\alpha$ for $\alpha = 1, \ldots, \nu$.

($\Longleftarrow$) Suppose that there exists a nonsingular matrix S such that $A'S = SA$ and $\Pi_\alpha S = S\Pi_\alpha$ for $\alpha = 1, \ldots, \nu$. For all $x \in M(A, \Pi)$ and $\xi(z_0, z_1, \ldots, z_\nu) \in F\langle\Sigma^*\rangle$, we have

$$S\xi(z_0, z_1, \ldots, z_\nu)x = S\xi(A, \Pi_1, \ldots, \Pi_\nu)x = \xi(A', \Pi_1, \ldots, \Pi_\nu)Sx = \xi(z_0, z_1, \ldots, z_\nu)Sx.$$

Therefore the morphism $\varphi : M(A, \Pi) \to M(A', \Pi)$ represented by S is a module homomorphism. Since S is nonsingular, φ is bijective. Hence it holds that $M(A, \Pi) \cong M(A', \Pi)$. □

Lemma 2.2 suggests that the decomposition of the partitioned square matrix (A, Π) can be obtained through that of the $F\langle\Sigma^*\rangle$-module $M(A, \Pi)$, which in turn corresponds to the decomposition of the module along a chain. Now we explain the correspondence between an irreducible decomposition of (A, Π) and a composition series of $M(A, \Pi)$. Let $\mathcal{L}(A, \Pi)$ be the modular lattice of the submodules of $M(A, \Pi)$. A composition series of $M(A, \Pi)$ is a maximal chain of $\mathcal{L}(A, \Pi)$.

Let $\mathcal{C}$ be a strictly increasing finite chain of the submodules of $M(A, \Pi)$:

$$\mathcal{C} : 0 = M_0 \subsetneq M_1 \subsetneq \cdots \subsetneq M_h = M(A, \Pi).$$

The $F\langle\Sigma^*\rangle$-submodule M_i is an invariant subspace of A, which satisfies $\Pi_\alpha M_i \subseteq M_i$ for $\alpha = 1, \ldots, \nu$. Since $\sum_{\alpha=1}^{\nu} \Pi_\alpha = I_n$, we have

$$M_i = \bigoplus_{\alpha=1}^{\nu} \Pi_\alpha M_i.$$

We can obtain increasing chains

$$\Pi_\alpha \mathcal{C} : 0 = \Pi_\alpha M_0 \subseteq \Pi_\alpha M_1 \subseteq \cdots \subseteq \Pi_\alpha M_h = V_\alpha$$

for $\alpha = 1, \ldots, \nu$. Let $B_{i\alpha}$ be a set of linearly independent column vectors spanning $\Pi_\alpha M_i$ for $i = 0, \ldots, h$ such that

$$\emptyset = B_{0\alpha} \subseteq B_{1\alpha} \subseteq \cdots \subseteq B_{h\alpha}.$$

Then $B_i = \bigcup_{\alpha=1}^{\nu} B_{i\alpha}$ spans M_i. Order n column vectors of B_h as $[B_{h1}, B_{h2}, \ldots, B_{h\nu}]$ to get a nonsingular matrix $S = \bigoplus_{\alpha=1}^{\nu} S_\alpha$, and put $\widetilde{A} := S^{-1}AS$. Let C_l be the column subset corresponding to $\hat{B}_l = B_l - B_{l-1}$ for $l = 1, \ldots, h$, and R_k be the row subset identified with C_k for $k = 1, \ldots, h$. Since M_i is an invariant subspace of A,

$$\widetilde{A}\left[\bigcup_{k=i+1}^{h} R_k, \bigcup_{l=1}^{i} C_l\right] = O \quad \text{for} \quad i = 1, \ldots, h.$$

Or equivalently,

$$\widetilde{A}[R_k, C_l] = O \quad \text{if} \quad 1 \leq l < k \leq h.$$

That is, $\widetilde{A}$ is in a block-triangular form with respect to $(R_1, \ldots, R_b) = (C_1, \ldots, C_b)$, where the number of blocks b is given by the length h of the chain $\mathcal{C}$. It is also clear that (A, Π) is PS-irreducible if and only if $M(A, \Pi)$ is simple.

Suppose the chain $\mathcal{C}$ is a composition series. Put

$$D_k := \widetilde{A}[R_k, C_k], \qquad \Phi_k := \{\Pi_\alpha[R_k, C_k]\}_{\alpha=1}^{\nu} \quad \text{for } k = 1, \ldots, h,$$

then (D_k, Φ_k) is also a partitioned square matrix. We can construct another $F\langle\Sigma^*\rangle$-module $N_k = M(D_k, \Phi_k)$. Then

$$N_k \cong M_k / M_{k-1}.$$

It follows from the simplicity of M_k/M_{k-1} that D_k is PS-irreducible and $\widetilde{A}$ is an irreducible decomposition of A. Conversely, if $(\widetilde{A}, \Pi)$ is in a block-triangular form with PS-irreducible diagonal blocks, the subspaces $\psi(\bigcup_{k=1}^{i} C_k)$ for $i = 1, \ldots, b$ are submodules that constitute a composition series of $M(\widetilde{A}, \Pi)$. (Recall that $\psi(J)$ denotes the subspace of V that corresponds to $J \subseteq C$.) Thus we have the following theorem.

THEOREM 2.3. *A* PS*-irreducible decomposition of* (A, Π) *is obtained by a composition series of* $M(A, \Pi)$. *In particular* (A, Π) *is* PS*-irreducible if and only if* $M(A, \Pi)$ *is a simple module.*

Now we have already seen how to get an irreducible decomposition, but have not yet discussed the uniqueness. Suppose both $(\widetilde{A}, \Pi)$ and $(\widetilde{A}', \Pi)$ are irreducible decompositions of (A, Π) with blocks $(R_1, \ldots, R_b) = (C_1, \ldots, C_b)$ and $(R'_1, \ldots, R'_{b'}) = (C_1, \ldots, C'_{b'})$, respectively. Put

$$\begin{aligned} D_k &:= \widetilde{A}[R_k, C_k], \quad \Phi_k := \{\Pi_\alpha[R_k, C_k]\}_{\alpha=1}^{\nu} \quad \text{for } k = 1, \ldots, b, \\ D'_l &:= \widetilde{A}'[R'_l, C'_l], \quad \Phi'_l := \{\Pi_\alpha[R'_l, C'_l]\}_{\alpha=1}^{\nu} \quad \text{for } l = 1, \ldots, b'. \end{aligned}$$

Then it follows directly from the Jordan–Hölder theorem (Theorem 2.1) as well as Lemma 2.2 that $b = b'$ and there exists a permutation σ of $\{1, 2, \ldots, b\}$ such that $\Phi_k = \Phi'_{\sigma(k)}$ and D_k is Φ_k-similar to $D'_{\sigma(k)}$. Hence we have the following theorem on the uniqueness of irreducible components of a partitioned square matrix.

THEOREM 2.4. *The set of* PS*-irreducible components of a partitioned square matrix is unique to within* PS*-transformations of each component.*

Example 2.2. Consider the same A as in Example 2.1. Let S' be the nonsingular matrix

$$S' = \left[\begin{array}{cc|ccc} 2 & -1 & & O & \\ -1 & 1 & & & \\ \hline & & 1 & 0 & 0 \\ & O & 0 & -2 & 1 \\ & & 0 & 1 & 0 \end{array}\right].$$

Then we have

$$\widetilde{A}' = S'^{-1} A S' = \begin{array}{c} \\ \circ \\ \circ \\ \bullet \\ \bullet \\ \bullet \end{array} \begin{array}{c} \begin{array}{ccccc} \circ & \circ & \bullet & \bullet & \bullet \end{array} \\ \left[\begin{array}{cc|ccc} 2 & 1 & -1 & 4 & 5 \\ 0 & 3 & 0 & 5 & 5 \\ \hline 1 & -1 & 6 & -2 & 1 \\ 0 & -2 & 0 & 5 & 1 \\ 0 & 0 & 0 & 0 & 4 \end{array}\right] \end{array}.$$

By using the permutation matrix

$$P' = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix},$$

we can transform $\widetilde{A}'$ into an explicit upper block-triangular form

$$\bar{A}' = P'^{\mathrm{T}} \widetilde{A}' P' = \begin{array}{c} \\ \circ \\ \bullet \\ \circ \\ \bullet \\ \bullet \end{array} \begin{array}{c} \begin{array}{ccccc} \circ & \bullet & \circ & \bullet & \bullet \end{array} \\ \left[\begin{array}{c|c|c|c|c} 2 & -1 & 1 & 4 & 5 \\ \hline 1 & 6 & -1 & -2 & 1 \\ \hline & & 3 & 5 & 5 \\ \cline{3-5} & O & -2 & 5 & 1 \\ \cline{4-5} & & & & 4 \end{array}\right] \end{array}.$$

Then $\widetilde{A}'$ is also an irreducible decomposition with three irreducible components

$$D'_1 = \left[\begin{array}{c|c} 2 & -1 \\ \hline 1 & 6 \end{array}\right], \quad D'_2 = \left[\begin{array}{c|c} 3 & 5 \\ \hline -2 & 5 \end{array}\right], \quad D'_3 = [4]$$

and

$$\Phi'_1 = \left\{\begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}, \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}\right\}, \quad \Phi'_2 = \left\{\begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}, \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}\right\}, \quad \Phi'_3 = \{[0], [1]\}.$$

Thus $\Phi_k = \Phi'_{\sigma(k)}$ and D_k is Φ_k-similar to $D'_{\sigma(k)}$ for $k = 1, 2, 3$, where $\sigma = \left(\begin{smallmatrix} 1 & 2 & 3 \\ 1 & 3 & 2 \end{smallmatrix}\right)$.

2.4. Ordering among irreducible components. We have already seen that an irreducible decomposition can be obtained by taking the basis along a composition series of $M(A, \Pi)$, and that the irreducible components are uniquely determined in the sense of Theorem 2.4. We have not yet discussed the strictly upper block-triangular part. Our main purpose is to transform (A, Π) into a block-triangular form that makes the hierarchical structure as clear as possible. In this sense an irreducible decomposition is not the final goal. We want to make the upper part of the block-triangular form as simple as possible. To this end we consider the structure of the whole lattice $\mathcal{L}(A, \Pi)$ rather than a single chain (composition series of $M(A, \Pi)$).

Recall the definition of $\psi(\mathcal{D}(\widetilde{A}))$ in §2.1. Then we have the following lemmas.

LEMMA 2.5. *Suppose $\widetilde{A} = S^{-1}AS$ is a* PS*-transformation of A. Then $S\psi(\mathcal{D}(\widetilde{A}))$ is a distributive sublattice of the modular lattice $\mathcal{L}(A, \Pi)$. Moreover,*

$$S\psi(\mathcal{D}(\widetilde{A})) = \{W \in \mathcal{L}(A, \Pi) \mid W \text{ is spanned by a subset of column vectors of } S\}.$$

Proof. Let J be an ideal of $\mathcal{P}(\widetilde{A})$, i.e., $J \in \mathcal{D}(\widetilde{A})$. Then $\Pi_\alpha \psi(J) \subseteq \psi(J)$ for $\alpha = 1, \ldots, \nu$ and $\widetilde{A}\psi(J) \subseteq \psi(J)$ due to the block-triangularity of $\widetilde{A}$. Therefore $\psi(J) \in \mathcal{L}(\widetilde{A}, \Pi)$. On the other hand, $\widetilde{W} \in \mathcal{L}(\widetilde{A}, \Pi)$ if and only if $S\widetilde{W} \in \mathcal{L}(A, \Pi)$. Hence $S\psi(\mathcal{D}(\widetilde{A}))$ is a distributive sublattice of $\mathcal{L}(A, \Pi)$. □

LEMMA 2.6. *For any distributive sublattice $\mathcal{D}'$ of $\mathcal{L}(A, \Pi)$, there exists a* PS*-transformation $\widetilde{A} = S^{-1}AS$ of A such that $S\psi(\mathcal{D}(\widetilde{A})) \supseteq \mathcal{D}'$.*

Proof. According to Birkhoff's representation theorem, we can represent the distributive lattice $\mathcal{D}'$ by the set of ideals of a poset $\mathcal{P}'$. More precisely, let $\mathcal{P}' = (\{W_1, \ldots, W_g\}, \subseteq)$ be a poset that consists of the join-irreducible elements of $\mathcal{D}'$ except zero [2]. We assume $k \leq l$ if $W_k \subseteq W_l$. Let $B_{i\alpha}$ be a set of linearly independent column vectors spanning $\Pi_\alpha W_i$ for $i = 1, \ldots, g$ such that

$$B_{k\alpha} \subseteq B_{l\alpha} \quad \text{if} \quad W_k \subseteq W_l.$$

Then $B_i = \bigcup_{\alpha=1}^{\nu} B_{i\alpha}$ spans W_i. Order the n column vectors of $B = \bigcup_{i=1}^{g} B_i$ to get a nonsingular matrix $S = \bigoplus_{\alpha=1}^{\nu} S_\alpha$ and put $\widetilde{A} := S^{-1}AS$. Let C_l be the column subset corresponding to

$$\hat{B}_l = B_l - \bigcup_{k: W_k \subsetneq W_l} B_k.$$

Note that B_l spanning W_l is divided into disjoint subsets as

$$B_l = \bigcup_{k: W_k \subseteq W_l} \hat{B}_k.$$

Since W_l is an invariant subspace of A,

$$\widetilde{A}[R_k, C_l] = O \quad \text{unless} \quad W_k \subseteq W_l,$$

which implies that

$$W_k \subseteq W_l \quad \text{if} \quad C_k \preceq C_l.$$

Hence $S\psi(\mathcal{D}(\widetilde{A})) \supseteq \mathcal{D}'$. □

The following theorem is a direct consequence of Lemmas 2.5 and 2.6. Recall the definition of a finest-possible decomposition in §2.1.

THEOREM 2.7. *$\widetilde{A} = S^{-1}AS$ is a finest-possible decomposition of A if and only if $S\psi(\mathcal{D}(\widetilde{A}))$ is a maximal distributive sublattice of $\mathcal{L}(A, \Pi)$.*

Since a maximal distributive sublattice of a modular lattice always contains a maximal chain of the whole lattice, we have the following corollary.

COROLLARY 2.8. *A finest-possible decomposition of a partitioned square matrix is an irreducible decomposition.*

If $\mathcal{L}(A, \Pi)$ is distributive, $\mathcal{L}(A, \Pi)$ itself is the only maximal distributive sublattice of $\mathcal{L}(A, \Pi)$. Then also we have the following corollary.

COROLLARY 2.9. *If $\mathcal{L}(A, \Pi)$ is distributive, there exists a block-triangularized partitioned matrix $(\widetilde{A}, \Pi)$, Π-similar to A, such that $\mathcal{D}(\widetilde{A}) \cong \mathcal{L}(A, \Pi)$.*

The following lemma gives a sufficient condition for (A, Π) to make $\mathcal{L}(A, \Pi)$ distributive in the case of $F = \mathbb{C}$.

LEMMA 2.10. *Assume $F = \mathbb{C}$. If, for each $\alpha = 1, \ldots, \nu$, $A_{\alpha\alpha}$ has n_α distinct eigenvalues, then $\mathcal{L}(A, \Pi)$ is distributive.*

Proof. Let W be an element of $\mathcal{L}(A, \Pi)$. It follows from $AW \subseteq W$ and $\Pi_\alpha W \subseteq W$ for $\alpha = 1, \ldots, \nu$ that

$$\Pi_\alpha A \Pi_\alpha W \subseteq \Pi_\alpha W \quad \text{for} \quad \alpha = 1, \ldots, \nu,$$

which implies $\Pi_\alpha W$ is an invariant subspace of $A_{\alpha\alpha}$. Since $A_{\alpha\alpha}$ has distinct eigenvalues, an invariant space of $A_{\alpha\alpha}$ is the direct sum of a certain subset of the one-dimensional eigenspaces. Since $W = \bigoplus_{\alpha=1}^{\nu} \Pi_\alpha W$, W corresponds to a certain subset of the set of eigenvalues of $A_{\alpha\alpha}$ for $\alpha = 1, \ldots, \nu$. Thus $\mathcal{L}(A, \Pi)$ can be regarded as a sublattice of the Boolean lattice. Hence $\mathcal{L}(A, \Pi)$ is distributive. □

This lemma tells us that we can uniquely determine the finest block-triangularization of (A, Π), if $A_{\alpha\alpha}$ has distinct eigenvalues. We state a simple algorithm for such a matrix in §4.

Next, we consider the case where $\mathcal{L}(A, \Pi)$ is not distributive, and show that $\mathcal{L}(A, \Pi)$ can have infinitely many maximal distributive sublattices.

LEMMA 2.11. *Suppose that $\mathcal{L}(A, \Pi)$ is not distributive. Then there exists a block-triangular matrix $\widetilde{A}$, Π-similar to A, with a pair of blocks (C_k, C_l) such that $\widetilde{A}[R_k, C_l] = O$, $\widetilde{A}[R_l, C_k] = O$, $\widetilde{A}[R_k, C_k] = \widetilde{A}[R_l, C_l]$, and $\Pi_\alpha[R_k, C_k] = \Pi_\alpha[R_l, C_l]$ for $\alpha = 1, \ldots, \nu$.*

Proof. Since $\mathcal{L}(A, \Pi)$ is not distributive, it has a sublattice $\mathcal{L}' = \{M_1, M_2, M_3, M_4, M_5\}$ shown in Fig. 2, where $M_5 = M_2 + M_3 = M_3 + M_4 = M_4 + M_2$, and $M_1 = M_2 \cap M_3 = M_3 \cap M_4 = M_4 \cap M_2$. It follows from the isomorphism theorem on modules that

$$M_5/M_2 \cong M_5/M_3 \cong M_5/M_4 \cong M_2/M_1 \cong M_3/M_1 \cong M_4/M_1.$$

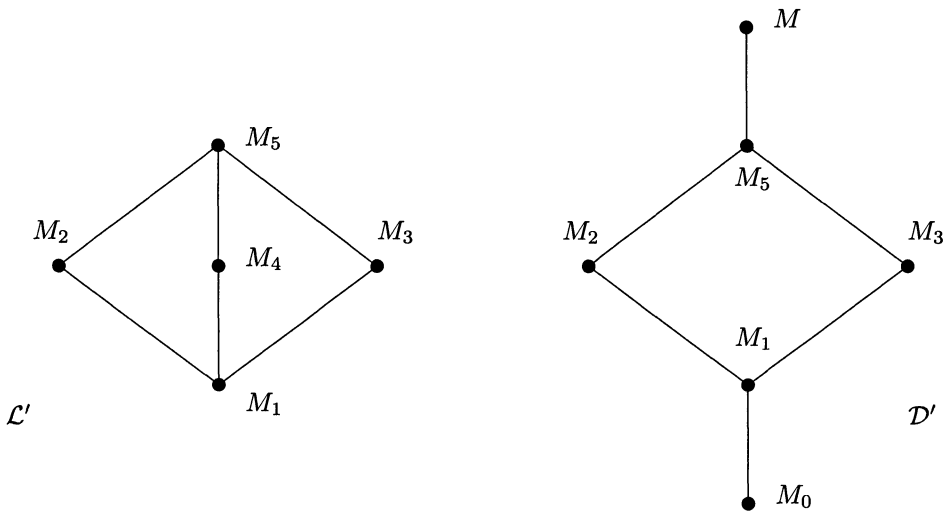

FIG. 2. *The lattices $\mathcal{L}'$ and $\mathcal{D}'$ in the proof of Lemma* 2.11.

Consider the distributive sublattice $\mathcal{D}' = \{M_0, M_1, M_2, M_3, M_5, M\}$ of $\mathcal{L}(A, \Pi)$, where M_1 and M_5 might coincide with $M_0 = 0$ and $M = M(A, \Pi)$, respectively. It follows from Lemma 2.6 and $M_2/M_1 \cong M_3/M_1$ that there exists a block-triangular matrix $\tilde{A}$, Π-similar to A, such that

$$\bar{A} = P^{\mathrm{T}}\tilde{A}P = \begin{array}{c} \\ R_k \\ R_l \end{array} \begin{array}{c} \begin{array}{cccc} C_k & C_l & & \end{array} \\ \begin{bmatrix} * & * & * & * \\ O & D & O & * \\ O & O & D & * \\ O & O & O & * \end{bmatrix} \end{array}$$

with a permutation matrix P. □

THEOREM 2.12. *Assume F is infinite. If $\mathcal{L}(A, \Pi)$ is not distributive, there exist infinitely many maximal distributive sublattices of $\mathcal{L}(A, \Pi)$.*

Proof. Consider the block-triangular matrix $\tilde{A}$ in the proof of Lemma 2.11. We may assume here that $\tilde{A}$ is a PS-irreducible decomposition. Consider the PS-transformation $\tilde{A}_\theta = Z_\theta^{-1}\tilde{A}Z_\theta$ by the nonsingular matrix

$$Z_\theta = P \begin{bmatrix} I & O & O & O \\ O & I & \theta I & O \\ O & O & I & O \\ O & O & O & I \end{bmatrix} P^{\mathrm{T}},$$

where $\theta \in F$ and I denotes the unit matrices of suitable dimensions. Then $\tilde{A}_\theta$ is also a PS-irreducible decomposition and there exists the composition series $\mathcal{C}_\theta$ from which the decomposition is obtained. It is easy to verify that $\mathcal{C}_\theta \neq \mathcal{C}_{\theta'}$ unless $\theta = \theta'$. This shows that there exist infinitely many composition series. Moreover, there exist infinitely many maximal distributive sublattices since a maximal distributive sublattice of $\mathcal{L}(A, \Pi)$ can contain only finite numbers of composition series. □

Now we are going to propose a canonical decomposition of partitioned square matrices. In case that $\mathcal{L}(A, \Pi)$ is distributive, we should define the canonical decom-

position of (A, Π) by the (unique) finest-possible decomposition $\widetilde{A}$, where $\mathcal{D}(\widetilde{A}) \cong \mathcal{L}(A, \Pi)$. However, when $\mathcal{L}(A, \Pi)$ is not distributive, obviously we can never find a Π-similar matrix $\widetilde{A}$ such that $\mathcal{D}(\widetilde{A}) \cong \mathcal{L}(A, \Pi)$. We have already defined a finest-possible decomposition $\widetilde{A}$ in the sense that $\widetilde{A}$ makes $\mathcal{D}(\widetilde{A})$ as close to $\mathcal{L}(A, \Pi)$ as possible. When $\mathcal{L}(A, \Pi)$ is not distributive, finest-possible decompositions are not unique. A canonical decomposition should represent the common structure among these finest-possible decompositions. Thus we are led to the definition of a *canonical decomposition of a partitioned square matrix* as a block-triangular form that realizes the largest common sublattice of the maximal distributive sublattices of $\mathcal{L}(A, \Pi)$. Note that a canonical decomposition is not necessarily an irreducible decomposition, let alone a finest-possible decomposition.

Example 2.3. Consider a partitioned square matrix (A, Π) that is in a block-triangular form with five PS-irreducible components L_1, L_2, L_3, D, and D, such that

$$\bar{A} = P^{\mathrm{T}}AP = \begin{array}{c} \\ R_1 \\ R_2 \\ R_3 \\ R_4 \\ R_5 \end{array} \begin{array}{c} \begin{array}{ccccc} C_1 & C_2 & C_3 & C_4 & C_5 \end{array} \\ \begin{bmatrix} L_1 & O & O & H_1 & O \\ O & L_2 & O & O & H_2 \\ O & O & L_3 & H_3 & -H_3 \\ O & O & O & D & O \\ O & O & O & O & D \end{bmatrix} \end{array},$$

with a permutation matrix P, where $\Pi_\alpha[R_4, C_4] = \Pi_\alpha[R_5, C_5]$ for $\alpha = 1, \ldots, \nu$, $H_j \neq O$ for $j = 1, 2, 3$ and there exist no PS-transformations among L_1, L_2, L_3, and D.

The whole lattice $\mathcal{L}(A, \Pi)$ (in the case that F is an infinite field) and the sublattice $\mathcal{D}(A)$ are illustrated in Fig. 3. $\mathcal{D}(A)$ is a maximal distributive sublattice of $\mathcal{L}(A, \Pi)$. Thus A itself is a finest-possible decomposition of A. Consider the PS-transformation by the nonsingular matrix Z' defined by

$$Z'[R_k, C_l] = \begin{cases} I & \text{if } k = l \text{ or } (k, l) = (4, 5), \\ O & \text{otherwise,} \end{cases}$$

and put $A' = Z'^{-1}AZ'$. Then we have

$$\bar{A}' = P^{\mathrm{T}}A'P = \begin{array}{c} \\ R_1 \\ R_2 \\ R_3 \\ R_4 \\ R_5 \end{array} \begin{array}{c} \begin{array}{ccccc} C_1 & C_2 & C_3 & C_4 & C_5 \end{array} \\ \begin{bmatrix} L_1 & O & O & H_1 & H_1 \\ O & L_2 & O & O & H_2 \\ O & O & L_3 & H_3 & O \\ O & O & O & D & O \\ O & O & O & O & D \end{bmatrix} \end{array}.$$

The lattice $\mathcal{D}(A')$ illustrated in Fig. 3 is also a maximal distributive sublattice of $\mathcal{L}(A, \Pi)$. We also consider the PS-transformation by the nonsingular matrix Z'' defined by

$$Z''[R_k, C_l] = \begin{cases} I & \text{if } k = l \text{ or } (k, l) = (5, 4), \\ O & \text{otherwise,} \end{cases}$$

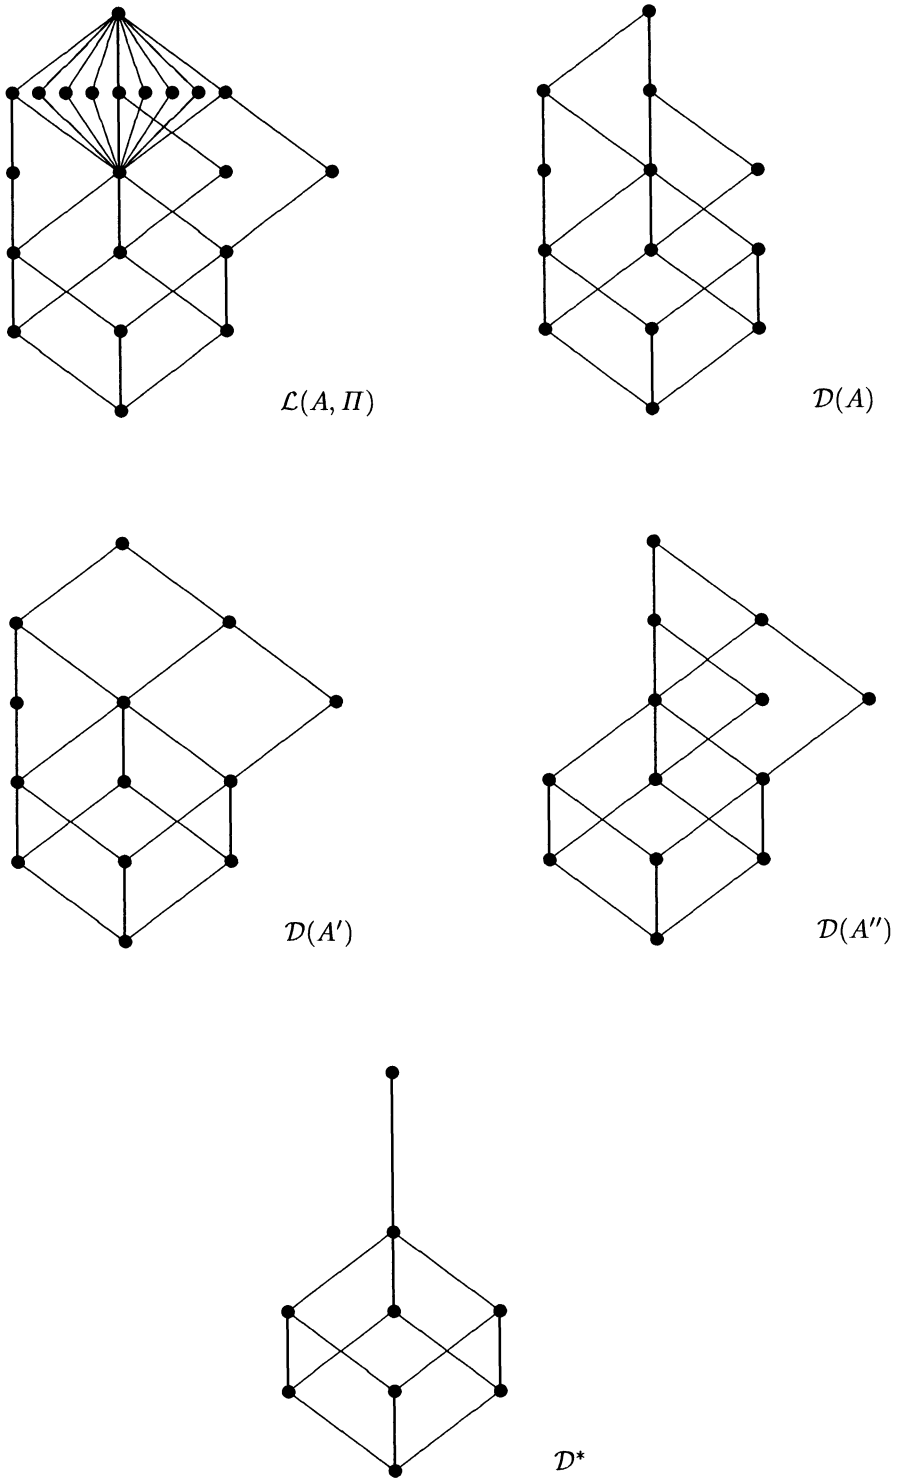

FIG. 3. *The lattice $\mathcal{L}(A, \Pi)$, three maximal distributive sublattices $\mathcal{D}(A)$, $\mathcal{D}(A')$, $\mathcal{D}(A'')$, and the distributive sublattice $\mathcal{D}^*$ for the canonical decomposition in Example* 2.3.

and put $A'' = Z''^{-1}AZ''$. Then we have

$$\bar{A}'' = P^{\mathrm{T}}A''P = \begin{array}{c} \\ R_1 \\ R_2 \\ R_3 \\ R_4 \\ R_5 \end{array} \begin{array}{c} \begin{array}{ccccc} C_1 & C_2 & C_3 & C_4 & C_5 \end{array} \\ \begin{bmatrix} L_1 & O & O & H_1 & O \\ O & L_2 & O & H_2 & H_2 \\ O & O & L_3 & O & -H_3 \\ O & O & O & D & O \\ O & O & O & O & D \end{bmatrix} \end{array}.$$

The lattice $\mathcal{D}(A'')$ illustrated in Fig. 3 is also a maximal distributive sublattice of $\mathcal{L}(A, \Pi)$. The common sublattice $\mathcal{D}^*$, corresponding to the canonical decomposition, of the maximal distributive sublattices of $\mathcal{L}(A, \Pi)$ is also illustrated in Fig. 3.

3. Decomposition under partition-respecting equivalency.

3.1. Problem formulation. In this section we discuss the block-triangularization of a partitioned, not necessarily square, matrix under restricted equivalence transformations which preserve the partition structure. More precisely, let A be an $m \times n$ matrix over a field F with partitions:

$$A = \begin{bmatrix} A_{11} & A_{12} & \cdots & A_{1\nu} \\ A_{21} & A_{22} & \cdots & A_{2\nu} \\ \vdots & \vdots & \ddots & \vdots \\ A_{\mu 1} & A_{\mu 2} & \cdots & A_{\mu\nu} \end{bmatrix},$$

where $A_{\alpha\beta}$ is an $m_\alpha \times n_\beta$ matrix called (α, β)-submatrix of A. To describe the partition structure in terms of matrix operation, we introduce a family of $m \times m$ projection matrices Π_α for $\alpha = 1, \ldots, \mu$ and another family of $n \times n$ projection matrices Γ_β for $\beta = 1, \ldots, \nu$. The (α, α)-submatrix of Π_α is the unit matrix I_{m_α} of dimension m_α and the other submatrices are zeros. Similarly, the (β, β)-submatrix of Γ_β is the unit matrix I_{n_β} of dimension n_β and all the other submatrices are zeros. Sometimes we denote the partitioned matrix by the triple (A, Π, Γ), where $\Pi = \{\Pi_\alpha\}_{\alpha=1}^{\mu}$ and $\Gamma = \{\Gamma_\beta\}_{\beta=1}^{\nu}$. A transformation $\widetilde{A} := S_{\mathrm{r}}^{-1}AS_{\mathrm{c}}$ of A is said to be a *partition-respecting equivalence transformation* (PE-transformation) if the off-diagonal submatrices of S_{r} and S_{c} are zeros, i.e.,

$$\Pi_\alpha S_{\mathrm{r}} = S_{\mathrm{r}}\Pi_\alpha \quad \text{for} \quad \alpha = 1, \ldots, \mu$$

and

$$\Gamma_\beta S_{\mathrm{c}} = S_{\mathrm{c}}\Gamma_\beta \quad \text{for} \quad \beta = 1, \ldots, \nu.$$

We say that A is (Π, Γ)-equivalent to A' if there exists a PE-transformation that transforms A to A'. Then our problem is to bring A into a block-triangular form by means of a PE-transformation.

Alternatively, our problem can be formulated as follows. Let U and V be F-linear spaces F^m and F^n, respectively, which are direct sums of lower dimensional spaces

$$U = \bigoplus_{\alpha=1}^{\mu} U_\alpha, \qquad \dim_F U_\alpha = m_\alpha,$$

$$V = \bigoplus_{\beta=1}^{\nu} V_\beta, \qquad \dim_F V_\beta = n_\beta.$$

A linear transformation

$$f : V \to U$$

is constructed by a family of linear transformations

$$f_{\alpha\beta} : V_\beta \to U_\alpha, \quad \alpha = 1, \ldots, \mu; \quad \beta = 1, \ldots, \nu.$$

When we take arbitrary bases for each space U_α and V_β, f is represented by a partitioned matrix A, where $A_{\alpha\beta}$ corresponds to $f_{\alpha\beta}$. In this context PE-transformations are naturally derived as basis transformations of U_α and V_β.

Now we define precisely the notion of a block-triangular form, following Murota [22]. Let $\widetilde{A}$ be a partitioned matrix. We say that $\widetilde{A}$ is in a *block-triangular form* or is *block-triangularized* if the row set $R = \{1, 2, \ldots, m\}$ and the column set $C = \{1, 2, \ldots, n\}$ are split into a certain number of disjoint blocks: $(R_0; R_1, \ldots, R_b; R_\infty)$ and $(C_0; C_1, \ldots, C_b; C_\infty)$ in such a way that

$$\begin{array}{lll} |R_0| < |C_0| & \text{or} & |R_0| = |C_0| = 0, \\ |R_k| = |C_k| > 0 & \text{for} & k = 1, \ldots, b, \\ |R_\infty| > |C_\infty| & \text{or} & |R_\infty| = |C_\infty| = 0, \end{array}$$

and

$$\widetilde{A}[R_k, C_l] = O \quad \text{if} \quad 0 \le l < k \le \infty.$$

$\widetilde{A}$ is said to be *properly* block-triangularized if, in addition,

$$\operatorname{rank}\widetilde{A}[R_k, C_k] = \min(|R_k|, |C_k|) \quad \text{for} \quad k = 0, 1, \ldots, b, \infty$$

is satisfied. $\widetilde{A}[R_0, C_0]$ and $\widetilde{A}[R_\infty, C_\infty]$ are called *horizontal tail* and *vertical tail* of $\widetilde{A}$, respectively. It is clear that if $\widetilde{A}$ is block-triangularized in the above sense, we can put it into an explicit upper block-triangular form $\bar{A} = P_{\mathrm{r}}\widetilde{A}P_{\mathrm{c}}$ in the usual sense by using certain permutation matrices P_{r} and P_{c}.

A partitioned matrix (A, Π, Γ), or simply A, is said to be PE-*irreducible* if $\operatorname{rank}A = \min(m, n)$ and it can never be transformed into a proper block-triangular form with two or more nonempty blocks by any PE-transformations. If $\widetilde{A}$ is a proper block-triangular matrix obtained from A by a PE-transformation and, in addition, all the diagonal blocks $\widetilde{A}[R_k, C_k]$ for $k = 0, 1, \ldots, b, \infty$ are PE-irreducible, we say that $\widetilde{A}$ is a (PE)-*irreducible decomposition* of A and $\widetilde{A}[R_k, C_k]$ are the (PE)-*irreducible components* of A.

Our problem of proper block-triangularization above contains two well-known extreme cases. The first case is with the trivial partition structure: $\mu = 1$, $\nu = 1$. In this case our problem has been completely solved by the rank normal form [11]. The other extreme case is with the finest partition structure: $\mu = m$, $\nu = n$. In this case our problem is solved by the DM-decomposition of bipartite graphs [10] with efficient algorithms. The CCF of layered mixed matrices, which is a proper extension of DM-decomposition, can be regarded as a special case; we explain this relationship in §3.3.

On the analogy of DM-decomposition, a partial order is induced among the blocks $\{C_k \mid k = 1, \ldots, b\}$ in a natural manner by the zero/nonzero structure of a block-triangular matrix $\widetilde{A}$. The partial order $\preceq$ is the reflexive and transitive closure of the

relation defined by: C_k is "smaller" than or equal to C_l if $\widetilde{A}[R_k, C_l] \neq O$. We denote this poset $(\{C_1, \ldots, C_b\}, \preceq)$ by $\mathcal{P}(\widetilde{A})$.

As is well known [2], [5], the ideals of the poset $\mathcal{P}(\widetilde{A})$ constitute a distributive lattice, which we denote by $\mathcal{D}(\widetilde{A})$. Note that a subset J of C can be naturally identified with a subspace of V. As in §2 we denote this correspondence by $\psi(J)$. Then

$$\psi(\mathcal{D}(\widetilde{A})) = \{\psi(J) \mid J \in \mathcal{D}(\widetilde{A})\}$$

is a distributive sublattice of the modular lattice formed by the subspaces of V.

We say that $\widetilde{A} = S_{\mathrm{r}}^{-1} A S_{\mathrm{c}}$ is *finer*, as a decomposition of A, than $\widetilde{A}' = S'^{-1}_{\mathrm{r}} A S'_{\mathrm{c}}$ if $S'_{\mathrm{c}}\psi(\mathcal{D}(\widetilde{A}')) = \{S_{\mathrm{c}}\widetilde{W}' \mid \widetilde{W}' \in \psi(\mathcal{D}(\widetilde{A}'))\}$ is a proper sublattice of $S_{\mathrm{c}}\psi(\mathcal{D}(\widetilde{A})) = \{S_{\mathrm{c}}\widetilde{W} \mid \widetilde{W} \in \psi(\mathcal{D}(\widetilde{A}))\}$. Furthermore, we say that $\widetilde{A}$, (Π, Γ)-equivalent to A, is a *finest-possible decomposition* of (A, Π, Γ) if there does not exist a proper block-triangular matrix $\widetilde{A}'$ that is also (Π, Γ)-equivalent to A and finer than $\widetilde{A}$.

Example 3.1. Consider the following 4×5 matrix A over $F = \mathbb{Q}$:

$$A = \begin{array}{c} \\ \star \\ \star \\ \diamond \\ \diamond \end{array} \begin{array}{c} \begin{array}{ccccc} \circ & \circ & \circ & \bullet & \bullet \end{array} \\ \left[\begin{array}{ccc|cc} 1 & 1 & 1 & 1 & 0 \\ 0 & 2 & 1 & 1 & 1 \\ \hline 2 & -2 & 0 & 0 & 2 \\ 0 & 3 & 0 & 0 & 4 \end{array}\right] \end{array},$$

where $\mu = 2$, $\nu = 2$, $m_1 = 2$, $m_2 = 2$, $n_1 = 3$, $n_2 = 2$. Let S_{r} and S_{c} be the nonsingular matrices

$$S_{\mathrm{r}} = \left[\begin{array}{cc|cc} 1 & 1 & \multicolumn{2}{c}{\multirow{2}{*}{O}} \\ 1 & 0 & & \\ \hline \multicolumn{2}{c|}{\multirow{2}{*}{O}} & 0 & 1 \\ & & 1 & 0 \end{array}\right], \qquad S_{\mathrm{c}} = \left[\begin{array}{ccc|cc} 0 & 1 & 1 & \multicolumn{2}{c}{\multirow{3}{*}{O}} \\ 0 & 1 & 0 & & \\ 1 & 0 & 0 & & \\ \hline \multicolumn{3}{c|}{\multirow{3}{*}{O}} & 1 & 0 \\ & & & 0 & 1 \end{array}\right].$$

Then we have

$$\widetilde{A} = S_{\mathrm{r}}^{-1} A S_{\mathrm{c}} = \begin{array}{c} \\ \star \\ \star \\ \diamond \\ \diamond \end{array} \begin{array}{c} \begin{array}{ccccc} \circ & \circ & \circ & \bullet & \bullet \end{array} \\ \left[\begin{array}{ccc|cc} 1 & 2 & 0 & 1 & 1 \\ 0 & 0 & 1 & 0 & -1 \\ \hline 0 & 3 & 0 & 0 & 4 \\ 0 & 0 & 2 & 0 & 2 \end{array}\right] \end{array}.$$

By using the permutation matrices

$$P_{\mathrm{r}} = \left[\begin{array}{cccc} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{array}\right], \qquad P_{\mathrm{c}} = \left[\begin{array}{ccccc} 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{array}\right],$$

we can transform $\widetilde{A}$ into an explicit upper block-triangular form

$$\bar{A} = P_{\mathrm{r}} \widetilde{A} P_{\mathrm{c}} = \begin{array}{c} \\ \star \\ \diamond \\ \star \\ \diamond \end{array} \begin{array}{c} \begin{array}{ccccc} \circ & \bullet & \circ & \circ & \bullet \end{array} \\ \left[\begin{array}{c|c|cc|c} 1 & 1 & 2 & 0 & 1 \\ \hline & & 3 & 0 & 4 \\ \multicolumn{2}{c|}{\multirow{2}{*}{O}} & & 1 & -1 \\ & & & 2 & 2 \end{array}\right] \end{array}.$$

Then $\widetilde{A}$ is in a proper block-triangular form with two square blocks, a nonempty horizontal tail ($|R_0| = 1$, $|C_0| = 2$) and an empty vertical tail.

The main results of this section are as follows. We exploit two approaches, one based on module theory and the other on submodularity. It should be remarked that a proper block-triangularization does not always exist. It is shown that the existence of a proper block-triangularization is equivalent to the existence of an invariant module (see Theorem 3.5), and that it is also equivalent to the equality of the rank of A to the minimum value of a submodular function (see Theorem 3.15). Sufficient conditions for the existence are given by the nonsingularity (see Lemma 3.2), or the genericity (see Theorem 3.16). The PE-irreducibility is characterized either by the simplicity of the associated module (see Theorem 3.6) or by the minimizers of the associated submodular function (see Theorem 3.15). The uniqueness of irreducible decomposition is due to the Jordan–Hölder theorem for modules (see Theorem 3.7). It will be shown that a finest-possible decomposition is obtained by a maximal distributive sublattice of the modular lattice formed by the submodules of the associated module; the modular lattice can also be characterized as the lattice of the minimizers of the associated submodular function (see Theorem 3.10).

3.2. Decomposition into irreducible components and their ordering. This section is devoted to the construction of an irreducible decomposition and a finest-possible decomposition by means of module and lattice theories.

To begin with, we observe some properties of a proper block-triangular matrix and investigate a necessary condition for the proper block-triangularizability of a partitioned matrix (A, Π, Γ). Suppose $\widetilde{A} = S_{\mathrm{r}}^{-1} A S_{\mathrm{c}}$ is in a proper block-triangular form with blocks $(C_0; C_1, \ldots, C_b; C_\infty)$ and (Π, Γ)-equivalent to A. Put $\widetilde{W} = \psi(C_0)$, which is the subspace of V that corresponds to C_0. Since $\widetilde{A}$ is also a partitioned matrix, we have $\Gamma_\beta \widetilde{W} \subseteq \widetilde{W}$ for $\beta = 1, \ldots, \nu$. It follows from the definition of a proper block-triangular form that $\Pi_\alpha \widetilde{A}\widetilde{W} \subseteq \widetilde{A}\widetilde{W}$ for $\alpha = 1, \ldots, \mu$ and $\mathrm{Ker}\widetilde{A} \subseteq \widetilde{W}$. Put $W = S_{\mathrm{c}}\widetilde{W}$, and then we have

$$\Gamma_\beta W \subseteq W \quad \text{for} \quad \beta = 1, \ldots, \nu,$$

$$\Pi_\alpha AW \subseteq AW \quad \text{for} \quad \alpha = 1, \ldots, \mu,$$

and

$$\mathrm{Ker}A \subseteq W.$$

Let $\mathcal{L}(A, \Pi, \Gamma)$ be the family of such subspaces W of V. Then we have the following lemma.

LEMMA 3.1. *If a partitioned matrix (A, Π, Γ) can be transformed into a proper block-triangular form by means of a* PE*-transformation, then $\mathcal{L}(A, \Pi, \Gamma)$ is nonempty.*

If $\mathrm{rank}A = \min(m, n)$ holds, $W = 0$ or $W = V$ satisfies the three conditions above. Hence we have the following lemma.

LEMMA 3.2. *If $\mathrm{rank}A = \min(m, n)$, then $\mathcal{L}(A, \Pi, \Gamma)$ is nonempty.*

The converse of Lemma 3.1 is also true, which is shown later (see Theorem 3.5).

Now we assume in this subsection that $\mathcal{L}(A, \Pi, \Gamma)$ is nonempty. Then $\mathcal{L}(A, \Pi, \Gamma)$ is a modular lattice. We denote the maximum element of $\mathcal{L}(A, \Pi, \Gamma)$ by $V_\top$, and the minimum by $V_\perp$.

Let Σ^* be a free monoid generated by a finite set

$$\Sigma = \{z_1, \ldots, z_\nu, z_{\nu+1}, \ldots, z_{\nu+\mu}\}.$$

The action of Σ^* on the quotient linear space $V_\top/V_\bot$ is defined as follows:

$$\left.\begin{array}{ll} z_\beta(x+V_\bot) := \gamma_\beta(x) + V_\bot & (\beta = 1, \ldots, \nu), \\ z_{\nu+\alpha}(x+V_\bot) := f^{-1}(\pi_\alpha(f(x))) + V_\bot & (\alpha = 1, \ldots, \mu) \end{array}\right\} x \in V_\top,$$

where $\gamma_\beta : V \to V$ and $\pi_\alpha : U \to U$ are the projections represented by Γ_β and Π_α, respectively.

LEMMA 3.3. *The action of Σ^* on $V_\top/V_\bot$ is well defined.*

Proof. Consider a vector $y \in V_\top$ such that $y - x \in V_\bot$. Since $\Gamma_\beta V_\bot \subseteq V_\bot$, we have $\gamma_\beta(y) - \gamma_\beta(x) \in V_\bot$. Similarly, it follows from $\Pi_\alpha A V_\bot \subseteq A V_\bot$ that $\pi_\alpha(f(y)) - \pi_\alpha(f(x)) \in f(V_\bot)$. Consider two vectors $x', y' \in V_\top$ such that $\pi_\alpha(f(x)) = f(x')$, $\pi_\alpha(f(y)) = f(y')$. The existence of such vectors follows from $\Pi_\alpha A V_\top \subseteq A V_\top$. Since $\mathrm{Ker} A \subseteq V_\bot$, we have $f^{-1}(\pi_\alpha(f(x))) \subseteq x' + V_\bot$, $f^{-1}(\pi_\alpha(f(y))) \subseteq y' + V_\bot$ and $y' - x' \in V_\bot$. Therefore $f^{-1}(\pi_\alpha(f(x))) + V_\bot = f^{-1}(\pi_\alpha(f(y))) + V_\bot$. Hence the action of Σ^* on $V_\top/V_\bot$ is well defined. □

Thus $V_\top/V_\bot$ becomes an $F\langle\Sigma^*\rangle$-module, as well as an F-linear space. We denote this module by $M(A, \Pi, \Gamma)$. Note that $W/V_\bot$ is a submodule of M if and only if $W \in \mathcal{L}(A, \Pi, \Gamma)$. That is to say $\mathcal{L}(A, \Pi, \Gamma)$ coincides with the modular lattice that consists of the submodules of $M(A, \Pi, \Gamma)$. For another partitioned matrix A' with common (Π, Γ), we obtain another modular lattice $\mathcal{L}(A', \Pi, \Gamma)$ and another $F\langle\Sigma^*\rangle$-module $M(A', \Pi, \Gamma)$. Note that $M(A', \Pi, \Gamma)$ is isomorphic under PE-transformations, i.e., $M(A, \Pi, \Gamma) \cong M(A', \Pi, \Gamma)$ if A is (Π, Γ)-equivalent to A'. The converse is true for square and nonsingular matrices.

LEMMA 3.4. *Suppose A and A' are square and nonsingular. Then $M(A, \Pi, \Gamma) \cong M(A', \Pi, \Gamma)$ if and only if A is (Π, Γ)-equivalent to A'.*

Proof. Let $\varphi : M(A, \Pi, \Gamma) \to M(A', \Pi, \Gamma)$ be the module isomorphism. Since $F \subseteq F\langle\Sigma^*\rangle$, $M(A, \Pi, \Gamma) = M(A', \Pi, \Gamma) = V$ as the F-linear spaces, and φ a bijective linear transformation that is to be represented by a nonsingular matrix S_c. Put

$$S_\mathrm{r} = A' S_\mathrm{c} A^{-1},$$

then $A' S_\mathrm{c} = S_\mathrm{r} A$ is satisfied. For any $x \in M(A, \Pi, \Gamma) = V$, we have

$$\Gamma_\beta S_\mathrm{c} x = z_\beta \varphi(x) = \varphi(z_\beta x) = S_\mathrm{c} \Gamma_\beta x \quad \text{for} \quad \beta = 1, \ldots, \nu,$$

which implies $\Gamma_\beta S_\mathrm{c} = S_\mathrm{c} \Gamma_\beta$ for $\beta = 1, \ldots, \nu$. For any $x \in M(A, \Pi, \Gamma) = V$, we also have

$$A'^{-1} \Pi_\alpha A' S_\mathrm{c} x = z_{\nu+\alpha} \varphi(x) = \varphi(z_{\nu+\alpha} x) = S_\mathrm{c} A^{-1} \Pi_\alpha A x \quad \text{for} \quad \alpha = 1, \ldots, \mu.$$

It follows from $A' S_\mathrm{c} = S_\mathrm{r} A$ that

$$A'^{-1} \Pi_\alpha S_\mathrm{r} A x = A'^{-1} S_\mathrm{r} \Pi_\alpha A x.$$

Because A and A' are nonsingular, we have obtained $\Pi_\alpha S_\mathrm{r} = S_\mathrm{r} \Pi_\alpha$ for $\alpha = 1, \ldots, \mu$. □

Now we explain how to get an irreducible decomposition. Let $\mathcal{C}$ be a maximal chain of $\mathcal{L}(A, \Pi, \Gamma)$:

$$\mathcal{C} : V_\bot = W_0 \subsetneq W_1 \subsetneq \cdots \subsetneq W_h = V_\top.$$

Since $\Gamma_\beta W_i \subseteq W_i$ for $\beta = 1, \ldots, \nu$ and $\sum_{\beta=1}^{\nu} \Gamma_\beta = I_n$, we have

$$W_i = \bigoplus_{\beta=1}^{\nu} \Gamma_\beta W_i.$$

For $\beta = 1, \ldots, \nu$, we can obtain increasing chains

$$\Gamma_\beta \mathcal{C} : \Gamma_\beta V_\perp = \Gamma_\beta W_0 \subseteq \Gamma_\beta W_1 \subseteq \cdots \subseteq \Gamma_\beta W_h = \Gamma_\beta V_\top.$$

Let $B^{\mathrm{c}}_{i\beta}$ be a set of linearly independent column vectors spanning $\Gamma_\beta W_i$ for $i = 0, 1, \ldots, h$ and $B^{\mathrm{c}}_{\infty\beta}$ spanning V_β such that

$$B^{\mathrm{c}}_{0\beta} \subseteq B^{\mathrm{c}}_{1\beta} \subseteq \cdots \subseteq B^{\mathrm{c}}_{h\beta} \subseteq B^{\mathrm{c}}_{\infty\beta}.$$

Then $B^{\mathrm{c}}_i = \bigcup_{\beta=1}^{\nu} B^{\mathrm{c}}_{i\beta}$ spans W_i for $i = 0, 1, \ldots, h$, and $B^{\mathrm{c}} = \bigcup_{\beta=1}^{\nu} B^{\mathrm{c}}_{\infty\beta}$ becomes a basis of V. Order the n column vectors of B^{c} as $[B^{\mathrm{c}}_{\infty 1}, B^{\mathrm{c}}_{\infty 2}, \ldots, B^{\mathrm{c}}_{\infty\nu}]$ to get a nonsingular matrix $S_{\mathrm{c}} = \bigoplus_{\beta=1}^{\nu} S_{\mathrm{c}\beta}$.

Similarly since $\Pi_\alpha A W_i \subseteq A W_i$ for $\alpha = 1, \ldots, \mu$ and $\sum_{\alpha=1}^{\mu} \Pi_\alpha = I_m$, we have

$$A W_i = \bigoplus_{\alpha=1}^{\mu} \Pi_\alpha A W_i.$$

We obtain increasing chains

$$\Pi_\alpha A \mathcal{C} : \Pi_\alpha A V_\perp = \Pi_\alpha A W_0 \subseteq \Pi_\alpha A W_1 \subseteq \cdots \subseteq \Pi_\alpha A W_h = \Pi_\alpha A V_\top$$

for $\alpha = 1, \ldots, \mu$. Let $B^{\mathrm{r}}_{i\alpha}$ be a set of linearly independent column vectors spanning $\Pi_\alpha A W_i$ for $i = 0, 1, \ldots, h$ and $B^{\mathrm{r}}_{\infty\alpha}$ spanning U_α such that

$$B^{\mathrm{r}}_{0\alpha} \subseteq B^{\mathrm{r}}_{1\alpha} \subseteq \cdots \subseteq B^{\mathrm{r}}_{h\alpha} \subseteq B^{\mathrm{r}}_{\infty\alpha}.$$

Then $B^{\mathrm{r}}_i = \bigcup_{\alpha=1}^{\mu} B^{\mathrm{r}}_{i\alpha}$ spans $A W_i$ for $i = 0, 1, \ldots, h$, and $B^{\mathrm{r}} = \bigcup_{\alpha=1}^{\mu} B^{\mathrm{r}}_{\infty\alpha}$ becomes a basis of U. Order the m column vectors of B^{r} as $[B^{\mathrm{r}}_{\infty 1}, B^{\mathrm{r}}_{\infty 2}, \ldots, B^{\mathrm{r}}_{\infty\mu}]$ to get a nonsingular matrix $S_{\mathrm{r}} = \bigoplus_{\alpha=1}^{\mu} S_{\mathrm{r}\alpha}$.

Put $\widetilde{A} := S_{\mathrm{r}}^{-1} A S_{\mathrm{c}}$. Let C_i be the column subset corresponding to $\hat{B}^{\mathrm{c}}_i$, and R_i the row subset corresponding to $\hat{B}^{\mathrm{r}}_i$, where

$$\begin{array}{ll} \hat{B}^{\mathrm{c}}_0 = B^{\mathrm{c}}_0, & \hat{B}^{\mathrm{r}}_0 = B^{\mathrm{r}}_0, \\ \hat{B}^{\mathrm{c}}_i = B^{\mathrm{c}}_i - B^{\mathrm{c}}_{i-1}, & \hat{B}^{\mathrm{r}}_i = B^{\mathrm{r}}_i - B^{\mathrm{r}}_{i-1} \quad \text{for} \quad i = 1, \ldots, h, \\ \hat{B}^{\mathrm{c}}_\infty = B^{\mathrm{c}}_\infty - B^{\mathrm{c}}_h, & \hat{B}^{\mathrm{r}}_\infty = B^{\mathrm{r}}_\infty - B^{\mathrm{r}}_h. \end{array}$$

Then we have

$$\widetilde{A}[R_k, C_l] = O \quad \text{if} \quad 0 \leq l < k \leq \infty.$$

Since $\Pi_\alpha A W_k \subseteq A W_k$ for $k = 0, 1, \ldots, h$, we have

$$\mathrm{rank} \widetilde{A}[R_k, C_k] = |R_k| \quad \text{for } k = 0, 1, \ldots, h.$$

On the other hand, since $\mathrm{Ker} A \subseteq V_\perp$, we also have

$$\mathrm{rank} \widetilde{A}[R_k, C_k] = |C_k| \quad \text{for } k = 1, \ldots, h, \infty.$$

Hence,

$$|R_k| = |C_k| \quad \text{for } k = 1, \dots, h$$

and

$$\operatorname{rank}\widetilde{A}[R_k, C_k] = \min(|R_k|, |C_k|) \quad \text{for} \quad k = 0, 1, \dots, h, \infty.$$

That is to say, $\widetilde{A}$ is in a proper block-triangular form, where the number of square blocks b is given by the length h of $\mathcal{C}$. Thus we have the following theorem.

THEOREM 3.5. *There exists a proper block-triangular matrix that is* (Π, Γ)-*equivalent to* A, *if and only if* $\mathcal{L}(A, \Pi, \Gamma)$ *is nonempty.*

Before showing that $\widetilde{A}$ obtained above is an irreducible decomposition, we give a necessary and sufficient condition for PE-irreducibility. Recall Lemma 3.2.

THEOREM 3.6. *Suppose* $\operatorname{rank} A = \min(m, n)$. *Then* A *is* PE-*irreducible if and only if there exists no element in* $\mathcal{L}(A, \Pi, \Gamma)$ *except* 0 *or* V, *namely, if and only if* $\mathcal{L}(A, \Pi, \Gamma) \subseteq \{0, V\}$.

Proof. Suppose $\widetilde{A}$ is in a proper block-triangular form with two or more nonempty blocks and (Π, Γ)-equivalent to A. If C_0 is nonempty, put $W = S_c\psi(C_0)$; otherwise $W = S_c\psi(C_1)$. Then W is a nontrivial subspace of V that belongs to $\mathcal{L}(A, \Pi, \Gamma)$. This is a contradiction. The converse is immediate from the construction above. □

Now we are ready to show that the proper block-triangular matrix $\widetilde{A}$ obtained from a maximal chain $\mathcal{C}$ of $\mathcal{L}(A, \Pi, \Gamma)$ is an irreducible decomposition of A. A composition series of $M(A, \Pi, \Gamma)$ is given by

$$\mathcal{C}/V_\perp : 0 = M_0 \subsetneq M_1 \subsetneq \cdots \subsetneq M_h = M(A, \Pi, \Gamma),$$

where $M_i = W_i/V_\perp$ for $i = 0, 1, \dots, h$. Put

$$D_k := \widetilde{A}[R_k, C_k], \quad \Phi_k := \{\Pi_\alpha[R_k, C_k]\}_{\alpha=1}^{\mu}, \quad \Psi_k := \{\Gamma_\beta[R_k, C_k]\}_{\beta=1}^{\nu},$$

for $k = 0, 1, \dots, \infty$, then (D_k, Φ_k, Ψ_k) is also a partitioned matrix. For each $k = 1, \dots, h$, we can construct another $F\langle\Sigma^*\rangle$-module $N_k = M(D_k, \Phi_k, \Psi_k)$. Then $N_k \cong M_k/M_{k-1}$. This implies that D_k is PE-irreducible for $k = 1, \dots, h$. Moreover, since $V_\perp$ and $V_\top$ are the minimum and maximum elements of $\mathcal{L}(A, \Pi, \Gamma)$, respectively, it follows from Theorem 3.6 that D_0 and D_∞ are PE-irreducible. Thus $\widetilde{A}$ is an irreducible decomposition of A. Conversely, if $(\widetilde{A}, \Pi, \Gamma)$ is in a proper block-triangular form with irreducible diagonal blocks, the quotient spaces $\psi(\bigcup_{k=0}^{i} C_k)/\psi(C_0)$ for $i = 0, \dots, b$ determine submodules that constitute a composition series of $M(\widetilde{A}, \Pi, \Gamma)$.

We have already seen how to construct an irreducible decomposition, but we have not yet discussed the uniqueness. Suppose both $\widetilde{A} = S_r^{-1}AS_c$ and $\widetilde{A}' = S'^{-1}_r AS'_c$ are irreducible decompositions of (A, Π, Γ) with blocks $(R_0; R_1, \dots, R_b; R_\infty)$, $(C_0; C_1, \dots, C_b; C_\infty)$ and $(R'_0; R'_1, \dots, R'_{b'}; R'_\infty)$, $(C'_0; C'_1, \dots, C'_{b'}; C'_\infty)$, respectively. Put

$$D_k := \widetilde{A}[R_k, C_k], \quad \Phi_k := \{\Pi_\alpha[R_k, C_k]\}_{\alpha=1}^{\mu}, \quad \Psi_k := \{\Gamma_\beta[R_k, C_k]\}_{\beta=1}^{\nu},$$

for $k = 0, 1, \dots, b, \infty$, and

$$D'_l := \widetilde{A}'[R'_l, C'_l], \quad \Phi'_l := \{\Pi_\alpha[R'_l, C'_l]\}_{\alpha=1}^{\mu}, \quad \Psi'_l := \{\Gamma_\beta[R'_l, C'_l]\}_{\beta=1}^{\nu},$$

for $l = 0, 1, \dots, b', \infty$. Since $V_\perp$ is the unique minimum element of $\mathcal{L}(A, \Pi, \Gamma)$, it is obvious that $\Phi_0 = \Phi'_0$, $\Psi_0 = \Psi'_0$ and D_0 is (Φ_0, Ψ_0)-equivalent to D'_0. In this sense

the horizontal tail is unique. The uniqueness of the vertical tail is shown as follows. Put $\widetilde{S}_{\mathrm{r}} = S_{\mathrm{r}}^{-1}S'_{\mathrm{r}}$ and $\widetilde{S}_{\mathrm{c}} = S_{\mathrm{c}}^{-1}S'_{\mathrm{c}}$, then $\widetilde{S}_{\mathrm{r}}\widetilde{A}' = \widetilde{A}\widetilde{S}_{\mathrm{c}}$. It follows from $\psi(\bigcup_{k=0}^{b} C_k) = \widetilde{S}_{\mathrm{c}}\psi(\bigcup_{l=0}^{b'} C'_l) = S_{\mathrm{c}}V_{\top}$ that $\widetilde{S}_{\mathrm{r}}[R_\infty, \bigcup_{l=0}^{b'} R'_l] = O$ and $\widetilde{S}_{\mathrm{c}}[C_\infty, \bigcup_{k=0}^{b} C'_k] = O$ hold. An easy calculation leads to

$$\widetilde{S}_{\mathrm{r}}[R_\infty, R'_\infty]D_\infty = D'_\infty\widetilde{S}_{\mathrm{c}}[C_\infty, C'_\infty].$$

That is to say $\Phi_\infty = \Phi'_\infty$, $\Psi_\infty = \Psi'_\infty$, and D_∞ is $(\Phi_\infty, \Psi_\infty)$-equivalent to D'_∞. For nonsingular irreducible components, it follows from the Jordan–Hölder theorem for modules (Theorem 2.1) and Lemma 3.4 that $b = b'$ and there exists a permutation σ of $\{1, 2, \ldots, b\}$, such that $\Phi_k = \Phi'_{\sigma(k)}$, $\Psi_k = \Psi'_{\sigma(k)}$, and D_k is (Φ_k, Ψ_k)-equivalent to $D'_{\sigma(k)}$. Hence we have the following theorem on the uniqueness of irreducible components of a partitioned matrix.

THEOREM 3.7. *The set of* PE*-irreducible components of a partitioned matrix is unique to within* PE*-transformations of each component.*

As to the distributive lattice $\mathcal{D}(\widetilde{A})$ and the modular lattice $\mathcal{L}(A, \Pi, \Gamma)$, we have the following results that are quite similar to those in §2. We state them without proofs.

LEMMA 3.8. *If $\widetilde{A} = S_{\mathrm{r}}^{-1}AS_{\mathrm{c}}$ is (Π, Γ)-equivalent to A, then $S_{\mathrm{c}}\psi(\mathcal{D}(\widetilde{A}))$ is a sublattice of $\mathcal{L}(A, \Pi, \Gamma)$.*

LEMMA 3.9. *For any distributive sublattice $\mathcal{D}'$ of $\mathcal{L}(A, \Pi, \Gamma)$, there exists a* PE*-transformation $\widetilde{A} = S_{\mathrm{r}}^{-1}AS_{\mathrm{c}}$ such that $S_{\mathrm{c}}\psi(\mathcal{D}(\widetilde{A})) \supseteq \mathcal{D}'$.*

THEOREM 3.10. *$\widetilde{A} = S_{\mathrm{r}}^{-1}AS_{\mathrm{c}}$ is a finest-possible decomposition of A if and only if $S_{\mathrm{c}}\psi(\mathcal{D}(\widetilde{A}))$ is a maximal distributive sublattice of $\mathcal{L}(A, \Pi, \Gamma)$.*

COROLLARY 3.11. *If $\mathcal{L}(A, \Pi, \Gamma)$ is distributive, there exists a block-triangular matrix $\widetilde{A}$, (Π, Γ)-equivalent to A, such that $\mathcal{D}(\widetilde{A}) \cong \mathcal{L}(A, \Pi, \Gamma)$.*

THEOREM 3.12. *Assume F is an infinite field. If $\mathcal{L}(A, \Pi, \Gamma)$ is not distributive, there exist infinitely many maximal distributive sublattices of $\mathcal{L}(A, \Pi, \Gamma)$.*

3.3. Submodular function and the modular lattice. In this section we show another way to derive the PE-irreducible decomposition by using a certain submodular function p. The rank of a partitioned matrix is expressed as the minimum value of p, and the PE-irreducible decomposition is then derived from the decomposition of the submodular function p into minors along a maximal chain of the lattice formed by the minimizers of p. This is a direct extension of the approach that led to the previously known cases such as the DM-decomposition, the CCF of layered mixed matrices, and the decomposition of multilayered matrices. (See Remarks 3.1 and 3.2 at the end of this section for a more specific account.) As we have already seen, a proper block-triangularization of (A, Π, Γ) exists if and only if $\mathcal{L}(A, \Pi, \Gamma)$ is nonempty. We show that $\mathcal{L}(A, \Pi, \Gamma)$, when nonempty, agrees with the lattice of the minimizers of p and discuss some conditions for $\mathcal{L}(A, \Pi, \Gamma)$ to be nonempty.

Let $\mathcal{W}$ be the modular lattice, which consists of subspaces W of V such that

$$\Gamma_\beta W \subseteq W \quad \text{for} \quad \beta = 1, \ldots, \nu.$$

Put

$$p(W) := \sum_{\alpha=1}^{\mu} \dim \Pi_\alpha AW - \dim W, \qquad W \in \mathcal{W}.$$

LEMMA 3.13. *The function* $p : \mathcal{W} \to \mathbb{Z}$ *is submodular*:

$$p(W_1 + W_2) + p(W_1 \cap W_2) \leq p(W_1) + p(W_2), \qquad W_j \in \mathcal{W} \ (j = 1, 2).$$

Proof. It is sufficient to show that $\dim \Pi_\alpha AW$ is submodular. It follows from $\Pi_\alpha A(W_1 + W_2) = \Pi_\alpha AW_1 + \Pi_\alpha AW_2$ and $\Pi_\alpha A(W_1 \cap W_2) \subseteq \Pi_\alpha AW_1 \cap \Pi_\alpha AW_2$ that

$$\begin{aligned}\dim \Pi_\alpha AW_1 + \dim \Pi_\alpha AW_2 &= \dim(\Pi_\alpha AW_1 + \Pi_\alpha AW_2) + \dim(\Pi_\alpha AW_1 \cap \Pi_\alpha AW_2) \\ &\geq \dim \Pi_\alpha A(W_1 + W_2) + \dim \Pi_\alpha A(W_1 \cap W_2). \qquad \square\end{aligned}$$

Since $\sum_{\alpha=1}^{\mu} \Pi_\alpha = I_m$, we have $\bigoplus_{\alpha=1}^{\mu} \Pi_\alpha AW \supseteq AW$, in general, which implies $p(W) \geq \dim AW - \dim W \geq -\dim \mathrm{Ker} A$. Hence

$$-\dim \mathrm{Ker} A \leq \min_{W \in \mathcal{W}} p(W).$$

By adding n to the both sides, we obtain the following lemma.

LEMMA 3.14. *It holds that*

$$\mathrm{rank} A \leq n + \min_{W \in \mathcal{W}} p(W).$$

It is well known that the set of the minimizers of a submodular function on a lattice is a sublattice [24] and that a sublattice of a modular lattice is also modular [2], [5]. Therefore

$$\mathcal{L}(p) := \{W \in \mathcal{W} \mid p(W) = \min_{W' \in \mathcal{W}} p(W')\}$$

is a modular lattice.

THEOREM 3.15. *There exists a proper block-triangular matrix that is* (Π, Γ) *equivalent to* A*, if and only if* $\mathrm{rank} A = n + \min_{W \in \mathcal{W}} p(W)$*. Then* $\mathcal{L}(A, \Pi, \Gamma)$ *is nonempty and* $\mathcal{L}(A, \Pi, \Gamma) \cong \mathcal{L}(p)$.

Proof. Recall that $p(W) \geq \dim AW - \dim W \geq -\dim \mathrm{Ker} A$. The first inequality holds with equality if and only if $\Pi_\alpha AW \subseteq AW$ is satisfied for $\alpha = 1, \ldots, \mu$, and the second inequality holds with equality if and only if $\mathrm{Ker} A \subseteq W$. Therefore $p(W) = -\dim \mathrm{Ker} A$ if and only if $W \in \mathcal{L}(A, \Pi, \Gamma)$. That is to say $\mathrm{rank} A = n + \min p(W)$ if and only if $\mathcal{L}(A, \Pi, \Gamma)$ is nonempty. In this case $\mathcal{L}(p) \cong \mathcal{L}(A, \Pi, \Gamma)$. Then Theorem 3.5 completes the proof. $\square$

When $\mathrm{rank} A = \min(m, n)$ holds, we see that $\min p(W) \leq \min(p(0), p(V)) \leq \min(0, m - n) = \mathrm{rank} A - n$, which implies the equality in Lemma 3.14. This, together with Theorem 3.15, gives an alternative proof to Lemma 3.2.

Another sufficient condition for the existence of a proper block-triangularization is given in terms of the genericity of a partitioned matrix. The genericity refers to the situation where the nonzero entries of A can be regarded as independent parameters. Let K be the prime field of F; in particular, if $F = \mathbb{R}$ or $\mathbb{C}$, K is the field of rational numbers $\mathbb{Q}$. Then we have the following theorem.

THEOREM 3.16. *If the set of nonzero entries of* A *is algebraically independent over* K*, then*

$$\mathrm{rank} A = n + \min_{W \in \mathcal{W}} p(W),$$

and, as a consequence, there exists a proper block-triangular matrix (Π, Γ)*-equivalent to* A.

Proof. Consider the DM-decomposition of (the bipartite graph associated with) A, and assume that the column set C and the row set R are split into blocks $(\overline{C}_0; \overline{C}_1, \ldots, \overline{C}_d; \overline{C}_\infty)$ and $(\overline{R}_0; \overline{R}_1, \ldots, \overline{R}_d; \overline{R}_\infty)$, where

$$\begin{array}{lll} |\overline{R}_0| < |\overline{C}_0| & \text{or} & |\overline{R}_0| = |\overline{C}_0| = 0, \\ |\overline{R}_k| = |\overline{C}_k| > 0 & \text{for} & k = 1, \ldots, d, \\ |\overline{R}_\infty| > |\overline{C}_\infty| & \text{or} & |\overline{R}_\infty| = |\overline{C}_\infty| = 0, \end{array}$$

and

$$A[\overline{R}_k, \overline{C}_l] = O \quad \text{if} \quad 0 \leq l < k \leq \infty.$$

Since all the nonzero entries of A are algebraically independent over K, we have

$$\mathrm{rank} A[\overline{R}_k, \overline{C}_k] = \min(|\overline{R}_k|, |\overline{C}_k|) \quad \text{for} \quad k = 0, 1, \ldots, d, \infty.$$

Let $\overline{W}$ be the subspace of V corresponding to the column subset $\overline{C}_0$. It is clear that $\Gamma_\beta \overline{W} \subseteq \overline{W}$ for $\beta = 1, \ldots, \nu$, which implies $\overline{W} \in \mathcal{W}$. Since $\mathrm{rank} A[\overline{R}_0, \overline{C}_0] = |\overline{R}_0|$, it is also clear that

$$p(\overline{W}) = |\overline{R}_0| - |\overline{C}_0| = -\dim \mathrm{Ker} A. \qquad \square$$

This theorem implies in particular that "almost all" matrices (in the case of $F = \mathbb{C}$ or $\mathbb{R}$) have a proper block-triangularization.

Example 3.2. Consider the following 4×4 partitioned matrix A:

$$A = \begin{array}{c} \\ \star \\ \star \\ \diamond \\ \diamond \end{array} \begin{array}{c} \begin{array}{cccc} \circ & \circ & \bullet & \bullet \end{array} \\ \left[\begin{array}{cc|cc} t_1 & 0 & 0 & t_2 \\ 0 & t_3 & t_4 & 0 \\ \hline 0 & t_5 & 0 & t_6 \\ t_7 & 0 & t_8 & 0 \end{array}\right] \end{array},$$

where $\mu = 2$, $\nu = 2$, $m_1 = 2$, $m_2 = 2$, $n_1 = 2$, and $n_2 = 2$. Suppose that $\{t_i \mid i = 1, \ldots, 8; 0 < t_i \in \mathbb{R}\}$ is algebraically independent over the field $\mathbb{Q}$. Let S_r and S_c be the nonsingular matrices:

$$S_\mathrm{r} = \left[\begin{array}{cc|cc} t_1\sqrt{t_2t_3t_5t_8} & t_1\sqrt{t_2t_3t_5t_8} & \multicolumn{2}{c}{\multirow{2}{*}{O}} \\ -t_3\sqrt{t_1t_4t_6t_7} & t_3\sqrt{t_1t_4t_6t_7} & & \\ \hline \multicolumn{2}{c|}{\multirow{2}{*}{O}} & -t_5\sqrt{t_1t_4t_6t_7} & t_5\sqrt{t_1t_4t_6t_7} \\ & & t_7\sqrt{t_2t_3t_5t_8} & t_7\sqrt{t_2t_3t_5t_8} \end{array}\right],$$

$$S_\mathrm{c} = \left[\begin{array}{cc|cc} \sqrt{t_2t_3t_5t_8} & \sqrt{t_2t_3t_5t_8} & \multicolumn{2}{c}{\multirow{2}{*}{O}} \\ -\sqrt{t_1t_4t_6t_7} & \sqrt{t_1t_4t_6t_7} & & \\ \hline \multicolumn{2}{c|}{\multirow{2}{*}{O}} & t_3t_7\sqrt{t_1t_2t_5t_6} & t_3t_7\sqrt{t_1t_2t_5t_6} \\ & & -t_1t_5\sqrt{t_3t_4t_7t_8} & t_1t_5\sqrt{t_3t_4t_7t_8} \end{array}\right].$$

Then we have

$$\widetilde{A} = S_\mathrm{r}^{-1} A S_\mathrm{c} = \begin{array}{c} \\ \star \\ \star \\ \diamond \\ \diamond \end{array} \begin{array}{c} \begin{array}{cccc} \circ & \circ & \bullet & \bullet \end{array} \\ \left[\begin{array}{cc|cc} 1 & 0 & -\sqrt{t_2t_4t_5t_7} & 0 \\ 0 & 1 & 0 & \sqrt{t_2t_4t_5t_7} \\ \hline 1 & 0 & \sqrt{t_1t_3t_6t_8} & 0 \\ 0 & 1 & 0 & \sqrt{t_1t_3t_6t_8} \end{array}\right] \end{array}.$$

By using the permutation matrices

$$P_{\mathrm{r}} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \qquad P_{\mathrm{c}} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix},$$

we can transform $\widetilde{A}$ into an explicit upper block-triangular form:

$$\bar{A} = P_{\mathrm{r}}\widetilde{A}P_{\mathrm{c}} = \begin{array}{c} \\ \star \\ \diamond \\ \star \\ \diamond \end{array} \begin{array}{c} \begin{array}{cccc} \circ & & \bullet & \end{array} \\ \left[\begin{array}{cc|cc} 1 & -\sqrt{t_2t_4t_5t_7} & \multicolumn{2}{c}{\multirow{2}{*}{O}} \\ 1 & \sqrt{t_1t_3t_6t_8} & & \\ \hline \multicolumn{2}{c|}{\multirow{2}{*}{O}} & 1 & \sqrt{t_2t_4t_5t_7} \\ & & 1 & \sqrt{t_1t_3t_6t_8} \end{array}\right] \end{array} \begin{array}{c} \\ \\ \\ \\ \end{array} \begin{array}{c} \\ \circ \\ \\ \bullet \\ \end{array}.$$

Then $\widetilde{A}$ is in a proper block-triangular form with two blocks. If we had an algebraic relation: $t_1t_3t_6t_8 = t_2t_4t_5t_7$, then $\widetilde{A}$ obtained above would not be in a *proper* block-triangular form.

Remark 3.1. As stated in Theorem 3.15, a proper block-triangularization exists if and only if $\mathrm{rank}A = n + \min_{W \in \mathcal{W}} p(W)$. The PE-irreducible decomposition can be constructed also from the decomposition of the submodular function p into minors along a maximal chain of the lattice $\mathcal{L}(p)$, just as has been done for the previously known cases such as the DM-decomposition. In particular, the rank condition: $\mathrm{rank}\tilde{A}[R_k, C_k] = \min(|R_k|, |C_k|)$ follows from the above identity when combined with the fact that the submodular function is modular when restriced onto the sublattice $\mathcal{L}(p)$. However, this approach based on a submodular function fails to capture such complications arising from identical diagonal blocks as indicated in Example 2.3.

Remark 3.2. The block-triangularization under the PE-transformation includes the following previously known cases: the DM-decomposition [8], [10], [19], the CCF of layered mixed matrices [20], [22], [23], and the decomposition of multilayered matrices [20], [23]. Not only is the PE-transformation an extension of the admissible transformations used in those decompositions, but also the submodular function p introduced above is an extension of the submodular functions used in their constructions. In all those cases, the column set $C = \mathrm{Col}(A)$ is partitioned into singletons (with $\nu = n$), and A takes the form:

$$A = \begin{bmatrix} A_1 \\ A_2 \\ \vdots \\ A_\mu \end{bmatrix},$$

where $A_\alpha = [A_{\alpha 1}, A_{\alpha 2}, \ldots, A_{\alpha n}]$ is the $m_\alpha \times n$ submatrix of A. Such a matrix A is termed a multilayered matrix in [20], [23]. In this case $\mathcal{W}$ is isomorphic, as a lattice, to the boolean lattice 2^C, and p can be identified with the submodular function $\tilde{p} : 2^C \to \mathbb{Z}$ defined by

$$\tilde{p}(J) = \sum_{\alpha=1}^{\mu} \mathrm{rank}A_\alpha[\mathrm{Row}(A_\alpha), J] - |J|, \qquad J \subseteq C,$$

where $\mathrm{Row}(A_\alpha)$ denotes the row set of A_α. This agrees with the submodular function used in the decomposition of multilayered matrices.

The notion of layered mixed matrix, introduced for the combinatorial-structural analysis of discrete systems, is defined as follows. Let $K \subseteq F$ be fields (K is not assumed to be a prime field). A matrix A is called a layered mixed matrix with respect to F/K if it can be put into the form

$$A = \begin{bmatrix} Q \\ T \end{bmatrix}$$

by rearranging the rows, where (i) the entries of Q belong to K, and (ii) the entries of T belong to F and the set of the nonzero entries of T is algebraically independent over K. The admissible transformation for $A = \left[\begin{smallmatrix} Q \\ T \end{smallmatrix}\right]$ is defined as an equivalence transformation of the form

$$P_{\mathrm{r}} \begin{bmatrix} S_Q & O \\ O & I \end{bmatrix} \begin{bmatrix} Q \\ T \end{bmatrix} P_{\mathrm{c}},$$

where S_Q is a nonsingular matrix over the subfield K and I denotes the identity matrix of size $|\mathrm{Row}(T)| = m_{\mathrm{T}}$. It is known that there exists a unique finest-possible proper block-triangular matrix under this transformation. This is the CCF. We can regard A as a multilayered matrix with $\mu = m_{\mathrm{T}} + 1$, $m_\alpha = 1$ for $\alpha = 2, \ldots, \mu$, where $Q = A_1$ and

$$T = \begin{bmatrix} A_2 \\ \vdots \\ A_\mu \end{bmatrix}.$$

Then the admissible transformation above is essentially the same as the PE-transformation of this paper, in which $S_{\mathrm{r}} = \mathrm{diag}[S_Q, 1, \ldots, 1]$ and $S_{\mathrm{c}} = \mathrm{diag}[1, \ldots, 1]$. The function $\tilde{p}(J)$ can be rewritten as follows. Denoting by $\gamma(J)$ the number of nonzero rows in the submatrix $T[\mathrm{Row}(T), J]$, we see

$$\gamma(J) = \sum_{\alpha=2}^{\mu} \mathrm{rank} A_\alpha[\mathrm{Row}(A_\alpha), J].$$

Hence, putting $\rho(J) = \mathrm{rank} Q[\mathrm{Row}(Q), J]$, we obtain

$$\tilde{p}(J) = \rho(J) + \gamma(J) - |J|,$$

which agrees with the function used in the construction of the CCF. Note that the assumed algebraic independence in the T-part guarantees the equality in Lemma 3.14.

Finally, the DM-decomposition is a special case of the CCF in which Q-part is empty. In other words, $\tilde{p}(J) = \gamma(J) - |J|$, which is sometimes referred to as the surplus function [19], where $\gamma(J)$ is now defined as the number of nonzero rows in the submatrix $A[\mathrm{Row}(A), J]$.

For those special cases, efficient algorithms have been constructed based on the results from network (submodular) flow theory. Namely, the family of the minimizers, as well as the minimum value, of the submodular function $\tilde{p}$ can be computed efficiently. It remains still open whether the algorithms can be extended to the decomposition of a general partitioned matrix. The extension will involve the minimization of a submodular function over a modular (nondistributive) lattice.

4. Discussions.

4.1. Decomposition algorithm for partitioned square matrices. In this section we discuss an algorithm for the block-triangularization of a partitioned square matrix (A, Π) under PS-transformations in the case of $F = \mathbb{C}$. The following simple algorithm gives a block-triangular matrix Π-similar to (A, Π). Furthermore, if $A_{\alpha\alpha}$ has distinct eigenvalues for $\alpha = 1, \ldots, \nu$, this algorithm gives the finest decomposition of (A, Π) whose uniqueness has been guaranteed by Corollary 2.9 and Lemma 2.10.

ALGORITHM FOR THE BLOCK-TRIANGULARIZATION OF (A, Π).

Step 1. Let S_α be a nonsingular matrix that transforms $A_{\alpha\alpha}$ into its Jordan normal form. Put

$$S := \bigoplus_{\alpha=1}^{\nu} S_\alpha, \qquad \widehat{A} := S^{-1}AS.$$

Step 2. Let $\widehat{G} = (\widehat{V}, \widehat{E})$ be a directed graph that represents the zero-nonzero pattern of the matrix $\widehat{A}$, where the vertex set $\widehat{V}$ is identified with the column set C of $\widehat{A}$ as well as with the row set R, and where the arc set $\widehat{E}$ is defined by $\widehat{E} := \{(j, i) \mid [\widehat{A}]_{ij} \neq 0\}$. Find the strongly connected component decomposition $(\widehat{G}_1, \ldots, \widehat{G}_b)$ of $\widehat{G}$, where the strongly connected components are indexed in such a way that there does not exist a path from the component $\widehat{G}_l$ to $\widehat{G}_k$ if $1 \leq l < k \leq b$. Accordingly, decompose C and R into the blocks $(C_1, \ldots, C_b)$ and $(R_1, \ldots, R_b)$, respectively.

When $A_{\alpha\alpha}$ has distinct eigenvalues, every element of $\mathcal{L}(A, \Pi)$ is spanned by certain eigenvectors of $A_{\alpha\alpha}$ for $\alpha = 1, \ldots, \nu$ (see the proof of Lemma 2.10). The column vectors of S_α are the eigenvectors of $A_{\alpha\alpha}$ for $\alpha = 1, \ldots, \nu$. Therefore it follows from Lemma 2.5 that

$$\mathcal{D}(\widehat{A}) \cong \mathcal{L}(A, \Pi),$$

which implies $\widehat{A}$ is the finest decomposition of (A, Π). Thus we have the following theorem.

THEOREM 4.1. *Suppose that for each $\alpha = 1, \ldots, \nu$, $A_{\alpha\alpha}$ has n_α distinct eigenvalues. Then the output $\widehat{A}$ of the above algorithm is the finest decomposition of (A, Π) with $\mathcal{D}(\widehat{A}) \cong \mathcal{L}(A, \Pi)$.*

Remark 4.1. In the case of $F = \mathbb{R}$, the above algorithm, in which the complex Jordan normal form is replaced by real Jordan normal form, works correctly if $A_{\alpha\alpha}$ has n_α distinct complex eigenvalues for $\alpha = 1, \ldots, \nu$ because every element of $\mathcal{L}(A, \Pi)$ is spanned by certain eigenvectors or pairs of vectors (in a certain two-dimensional eigenspace), corresponding to real or nonreal eigenvalues, respectively.

4.2. Algorithm for proper block-triangularizability. We have already seen in §3 that a partitioned matrix (A, Π, Γ) can be transformed into a proper block-triangular form by a PE-transformation if and only if $\mathcal{L}(A, \Pi, \Gamma)$ is nonempty. In this subsection we give an algorithm to determine whether $\mathcal{L}(A, \Pi, \Gamma)$ is empty or nonempty by searching for the minimum element $V_\perp$ of $\mathcal{L}(A, \Pi, \Gamma)$.

Construct an alternating sequence $V^{(0)}, U^{(1)}, V^{(1)}, U^{(2)}, \ldots$, of subspaces $V^{(\kappa)} \subseteq$

V and $U^{(\kappa)} \subseteq U$ by

$$V^{(0)} := 0,$$
$$U^{(\kappa)} := \bigoplus_{\alpha=1}^{\mu} \pi_\alpha(f(V^{(\kappa-1)})), \quad V^{(\kappa)} := \bigoplus_{\beta=1}^{\nu} \gamma_\beta(f^{-1}(U^{(\kappa)})) \quad (\kappa = 1, 2, \ldots).$$

Then we have

$$V^{(\kappa+1)} \supseteq f^{-1}(U^{(\kappa+1)}) \supseteq f^{-1}(f(V^{(\kappa)})) \supseteq V^{(\kappa)} \quad (\kappa = 0, 1, \ldots).$$

This implies $V^{(0)} \subseteq V^{(1)} \subseteq \cdots$ and $U^{(1)} \subseteq U^{(2)} \subseteq \cdots$. Furthermore, if $V^{(\kappa)} = V^{(\kappa+1)}$ or $U^{(\kappa)} = U^{(\kappa+1)}$, then $V^{(\kappa)} = V^{(\kappa+1)} = V^{(\kappa+2)} = \cdots$ and $U^{(\kappa+1)} = U^{(\kappa+2)} = \cdots$. There exists a number $q \leq \min(n, m) + 1$ such that $V^{(q)} = V^{(q+1)} = \cdots$ and $U^{(q)} = U^{(q+1)} = \cdots$, where $n = \dim V$ and $m = \dim U$. Thus we can obtain $V^{(\infty)}$ and $U^{(\infty)}$ within finite steps.

THEOREM 4.2. *$\mathcal{L}(A, \Pi, \Gamma)$ is nonempty if and only if $U^{(\infty)} \subseteq \mathrm{Im} f$.*

Proof. ($\Longrightarrow$) We prove $V^{(\kappa)} \subseteq V_\perp$ by induction. Obviously $V^{(0)} \subseteq V_\perp$. Suppose $V^{(\kappa)} \subseteq V_\perp$. Then, since $\gamma_\beta(V_\perp) \subseteq V_\perp$, $\pi_\alpha(f(V_\perp)) \subseteq f(V_\perp)$, and $\mathrm{Ker} f \subseteq V_\perp$, we have $V^{(\kappa+1)} = \bigoplus_{\beta=1}^{\nu} \gamma_\beta(f^{-1}(\bigoplus_{\alpha=1}^{\mu} \pi_\alpha(f(V^{(\kappa)})))) \subseteq V_\perp$. Hence $V^{(\kappa)} \subseteq V_\perp$ for $\kappa = 0, 1, \ldots$. This implies $U^{(\kappa+1)} = \bigoplus_{\alpha=1}^{\mu} \pi_\alpha(f(V^{(\kappa)})) \subseteq \bigoplus_{\alpha=1}^{\mu} \pi_\alpha(f(V_\perp)) \subseteq f(V_\perp) \subseteq \mathrm{Im} f$.

($\Longleftarrow$) We check the three conditions in §3.2 for $V^{(\infty)} \in \mathcal{L}(A, \Pi, \Gamma)$. (i) $\mathrm{Ker} f \subseteq V^{(\infty)}$ follows from $\mathrm{Ker} f \subseteq V^{(1)}$. (ii) It follows from $V^{(\infty)} = \bigoplus_{\beta=1}^{\nu} \gamma_\beta(f^{-1}(U^{(\infty)}))$ that $\gamma_\beta(V^{(\infty)}) = \gamma_\beta(f^{-1}(U^{(\infty)}))$. Then we have $\gamma_\beta(V^{(\infty)}) \subseteq \bigoplus_{\beta=1}^{\nu} \gamma_\beta(V^{(\infty)}) = V^{(\infty)}$. (iii) First note that $U^{(\infty)} \subseteq \mathrm{Im} f$ implies $f(f^{-1}(U^{(\infty)})) = U^{(\infty)}$. By applying f to $V^{(\infty)} = \bigoplus_{\beta=1}^{\nu} \gamma_\beta(f^{-1}(U^{(\infty)})) \supseteq f^{-1}(U^{(\infty)})$, we see $f(V^{(\infty)}) \supseteq f(f^{-1}(U^{(\infty)})) = U^{(\infty)} = \bigoplus_{\alpha=1}^{\mu} \pi_\alpha(f(V^{(\infty)})) \supseteq \pi_\alpha(f(V^{(\infty)}))$. □

Thus we have obtained a constructive procedure to determine whether or not (A, Π, Γ) is properly block-triangularizable. As is evident from the proof, $V^{(\infty)} = V_\perp$.

Remark 4.2. We can start the above procedure with an arbitrary subspace $V^{(0)}$ of V. In this case, the set $\mathcal{L}^* = \{W \mid V^{(0)} \subseteq W \in \mathcal{L}(A, \Pi, \Gamma)\}$ is nonempty if and only if $U^{(\infty)} \subseteq \mathrm{Im} f$. And $V^{(\infty)}$ gives the minimum element in $\mathcal{L}^*$.

Acknowledgments. Example 3.2 is credited to T. Fujita, who completed his graduation thesis at the University of Tokyo under Murota's supervision. The authors are grateful to Professor Masanori Fushimi for his support and encouragement.

NUMERICAL RANGE OF MATRIX POLYNOMIALS*

CHI-KWONG LI† AND LEIBA RODMAN†

Abstract. Let M_n be the algebra of all $n \times n$ complex matrices. Suppose

$$P(\lambda) = A_m\lambda^m + A_{m-1}\lambda^{m-1} + \cdots + A_0$$

is a matrix polynomial, where $A_i \in M_n$ and λ is a complex variable. The *numerical range* of $P(\lambda)$ is defined as

$$W(P(\lambda)) = \{\mu \in \mathbb{C} : x^*P(\lambda)x = 0 \text{ for some nonzero } x \in \mathbb{C}^n\}.$$

The numerical range of matrix polynomials has important applications to overdamped vibration systems with finite number of degrees of freedom and it is also related to stability theory. In this paper, the subject is studied systematically. The emphasis is on the relationship between the geometrical properties of $W(P(\lambda))$ and the algebraic and analytic properties of $P(\lambda)$. A factorization result, based on geometric properties of $W(P(\lambda))$ for certain classes of matrix polynomials with not necessarily hermitian coefficients is proved, and the set $W(P(\lambda))$ for a linear polynomial with hermitian matrices as coefficients is studied in detail. The results indicate that the information on $W(P(\lambda))$ is very useful in understanding matrix polynomials and also reflects the fact that it is highly nontrivial to give a complete description of the set $W(P(\lambda))$.

1. Introduction.

Let M_n be the algebra of all $n \times n$ complex matrices. Suppose

$$P(\lambda) = A_m\lambda^m + A_{m-1}\lambda^{m-1} + \cdots + A_0$$

is a matrix polynomial, where $A_i \in M_n$ and λ is a complex variable. Define the *numerical range* of $P(\lambda)$ as

$$W(P(\lambda)) = \{\mu \in \mathbb{C} : x^*P(\lambda)x = 0 \text{ for some nonzero } x \in \mathbb{C}^n\}.$$

If $P(\lambda) = \lambda I - A$, then $W(P(\lambda))$ reduces to the *numerical range* of A defined and denoted by

$$W(A) = \{x^*Ax : x \in \mathcal{S}\},$$

where $\mathcal{S}$ denotes the unit sphere in $\mathbb{C}^n$, i.e.,

$$\mathcal{S} = \{x \in \mathbb{C}^n : x^*x = 1\}.$$

In this sense, the numerical range of a matrix polynomial is a generalization of the classical numerical range.

One important application where the numerical range of matrix polynomials plays a significant role is overdamped vibration systems with a finite number of degrees of

†Department of Mathematics, College of William and Mary, Williamsburg, Virginia 23187-8795 (ckli@cs.wm.edu and lxrodm@cs.wm.edu).

freedom, e.g., see [1], [6, Chap. 7], and [2, Chap. 10]. The matrix polynomial there is of the form $A_2\lambda^2 + A_1\lambda + A_0$, where A_0, A_1, A_2 are $n \times n$ positive definite matrices. Factorizations of such a polynomial of the form $A_2(\lambda I - Y_1)(\lambda I - Y_2)$, which are based on the properties of its numerical range, are crucial in the theory of overdamped vibration systems ([5] is a pioneering work in this direction). An extension of these ideas to the matrix and operator polynomials of arbitrary degree leads to the notion of hyperbolic polynomials and to important factorization results (quoted in Theorem 3.1) based on the properties of the numerical range. In fact, Theorem 3.1 provided an impetus for this work.

Another motivation for the study of numerical ranges of matrix polynomials arises from stability theory. Recall that a scalar polynomial $p(\lambda)$ is said to be *stable* if all its roots have negative real parts. In terms of the numerical range of $p(\lambda)$, stability means that $W(p(\lambda)) \subseteq \{\nu \in \mathbb{C} : \mathrm{Re}(\nu) < 0\}$. Given n stable scalar polynomials, $p_1(\lambda), \ldots, p_n(\lambda)$, it is of interest to know whether all the polynomials $q(\lambda)$ obtained by taking convex combination of the n given polynomials, i.e., $q(\lambda) = \sum_{i=1}^{n} \eta_i p(\lambda)$ with $\eta_i \geq 0$ and $\sum \eta_i = 1$, are also stable. Let m be the highest degree of the polynomials $p_i(\lambda)$, and for $j = 0, \ldots, m$ let $A_j \in M_n$ be the diagonal matrix whose ith diagonal entry equals the coefficient of λ^j in $p_i(\lambda)$. If $P(\lambda) = \sum_{j=1}^{m} A_j \lambda^j$, then one easily checks that $q(x)$ is a convex combination of $p_i(\lambda)$'s if and only if $q(x)$ is of the form $x^*P(\lambda)x$ with $x \in \mathcal{S}$. Thus all convex combinations of the polynomials $p_i(\lambda)$'s are stable if and only if $W(P(\lambda)) \subseteq \{\nu \in \mathbb{C} : \mathrm{Re}(\nu) < 0\}$. Thus, results on stable polynomials can be translated to results about $W(P(\lambda))$ and vice versa.

Numerical ranges of matrix polynomials have appeared in the literature (see [2, §10.6]), but have not been studied systematically. We believe that this paper is the first systematic study of the subject. Here we consider the following general problem.

Study the relationship between the geometrical properties of $W(P(\lambda))$ and the algebraic and analytic properties of $P(\lambda)$.

We describe some basic properties of $W(P(\lambda))$ in §2. A factorization result, based on geometric properties of $W(P(\lambda))$ for certain classes of matrix polynomials with not necessarily hermitian coefficients is proved in §3. In §4, we study the set $W(P(\lambda))$ for a linear polynomial with hermitian matrices as coefficients. The results indicate that the information on $W(P(\lambda))$ is very useful in understanding matrix polynomials and also reflects the fact that it is highly nontrivial to give a complete description of the set $W(P(\lambda))$. We denote the usual Euclidean norm on $\mathbb{C}^n$ by $\|x\| = (x^*x)^{1/2}$.

2. General properties. The following properties of $W(P(\lambda))$ can be verified readily.

PROPOSITION 2.1. *Suppose $P(\lambda) = A_m\lambda^m + A_{m-1}\lambda^{m-1} + \cdots + A_0$, where $A_m \neq 0$.*

(a) *$W(P(\lambda))$ is closed in $\mathbb{C}$.*

(b) *For any $\alpha \in \mathbb{C}$, $W(P(\lambda + \alpha)) = W(P(\lambda)) - \alpha$.*

(c) *If $Q(\lambda) = \sum_{j=0}^{m} \lambda^j A_{m-j}$, then $W(Q(\lambda)) \setminus \{0\} = \{\mu^{-1} : \mu \in W(P(\lambda)),\ \mu \neq 0\}$.*

(d) *For any $n \times r$ matrix S with* rank *r, $r \leq n$, $W(S^*P(\lambda)S) \subseteq W(P(\lambda))$. Equality holds if $r = n$.*

(e) *If A_i, $i = 0, \ldots, m$, have a common nonzero isotropic vector x, i.e., $x^*A_ix = 0$ for all i, then $W(P(\lambda)) = \mathbb{C}$.*

It is well known, e.g., see [4, §1.3], that the classical numerical range $W(A)$ is always a compact convex set. Condition (a) of Proposition 2.1 shows that $W(P(\lambda))$ is closed. However, $W(P(\lambda))$ need not be connected or bounded, as shown in the following examples.

Example 1. Let $P(\lambda) = \lambda^m \left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right) - I$. Then

$$\begin{aligned} W(P(\lambda)) &= \{z \in \mathbb{C} : z^m q - 1 = 0 \text{ for some } q \in [-1,1]\} \\ &= \{re^{i\theta} : r \geq 1;\ \theta = k\pi/m,\ k = 0,1,\ldots,2m-1\} \end{aligned}$$

has $2m$ unbounded connected components.

One may wonder whether a connected component of $W(P(\lambda))$ is convex. The following example shows that it need not be.

Example 2. Let $P(\lambda) = \lambda^m I - \left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right)$. Then

$$\begin{aligned} W(P(\lambda)) &= \{z \in \mathbb{C} : z^m - q = 0 \text{ for some } q \in [-1,1]\} \\ &= \{re^{i\theta} : 0 \leq r \leq 1;\ \theta = k\pi/m,\ k = 0,1,\ldots,2m-1\} \end{aligned}$$

has a single nonconvex component.

In the following, we obtain results concerning the number of connected components and the boundedness of $W(P(\lambda))$.

Using the convexity of $W(B)$, it is easy to see that $W(B) \setminus \{0\}$ is disconnected if and only if μB is an indefinite hermitian matrix for some $\mu \in \mathbb{C}$. If this happens, then $W(B)$ is a line segment passing through the origin in $\mathbb{C}$ and hence $W(B) \setminus \{0\}$ has two components. We are now ready to state our result concerning the number of connected components of $W(P(\lambda))$.

THEOREM 2.2. *Let* $P(\lambda) = A_m\lambda^m + A_{m-1}\lambda^{m-1} + \cdots + A_0$, *where* $A_m \neq 0$. *Suppose* $W(P(\lambda))$ *has* r *connected components.*

(a) *Suppose* $W(A_m) \setminus \{0\}$ *is connected, i.e.,* μA_m *is not an indefinite hermitian matrix for all* $\mu \in \mathbb{C}$, *and suppose* s *is the minimum number of distinct zeros of the polynomial* $x^*P(\lambda)x$ *over all* $x \in \mathcal{S}$ *such that* $x^*A_m x \neq 0$. *Then*

$$r \leq s \leq m.$$

(b) *Suppose* $W(A_m)\setminus\{0\}$ *has disjoint connected components* $\mathcal{C}_1$ *and* $\mathcal{C}_2$, *i.e.,* μA_m *is an indefinite hermitian matrix for some* $\mu \in \mathbb{C}$, *and suppose* s_i *is the minimum number of distinct zeros of the polynomial* $x^*P(\lambda)x$ *over all* $x \in \mathcal{S}$ *such that* $x^*A_m x \in \mathcal{C}_i$ *for* $i = 1,2$. *Then*

$$r \leq s_1 + s_2 \leq 2m.$$

Proof. Consider one connected component $\mathcal{C}$ of $W(A_m) \setminus \{0\}$. Suppose $\hat{x} \in \mathcal{S}$ is such that $\hat{x}^*A_m\hat{x} \in \mathcal{C}$ and $\hat{x}P(\lambda)\hat{x} = 0$ has k distinct roots, where

$$k = \min\{\text{ number of distinct roots of } x^*P(\lambda)x = 0 : x \in \mathcal{S},\ x^*A_m x \in \mathcal{C}\}.$$

We make the following claim. If $y \in \mathcal{S}$ is such that $y^*A_m y \in \mathcal{C}$, then there exists a continuous function $z : [0,1] \to \mathcal{S}$ such that $z(0) = \hat{x}$, $z(1) = \mu y$ for some $\mu \in \mathbb{C}$ with $|\mu| = 1$, and $z(t)^*A_m z(t) \in \mathcal{C}$ for all $t \in [0,1]$.

Assume the claim has been verified. Since the solutions $\lambda_1(t),\ldots,\lambda_m(t)$ of the equation

$$z(t)^*P(\lambda)z(t) = 0$$

are continuous functions of t, the zeros of the polynomial $y^*P(\lambda)y = z(1)^*P(\lambda)z(1)$ are connected to those of $\hat{x}^*P(\lambda)\hat{x} = z(0)^*P(\lambda)z(0)$ by continuous curves in $W(P(\lambda))$. Therefore the zeros of the polynomial $y^*P(\lambda)y$ must lie in the connected components containing the zeros of the polynomial $\hat{x}^*P(\lambda)\hat{x}$. Thus there are at most k connected

components, determined by the distinct roots of $\hat{x}^*P(\lambda)\hat{x} = 0$, for the roots of those equations $y^*P(\lambda)y = 0$ with $y \in \mathcal{S}$ and $y^*A_m y \in \mathcal{C}$.

It remains to prove our claim. If y is a scalar multiple of $\hat{x}$, then a constant function z will satisfy the claim. We assume therefore that $\hat{x}$ and y are linearly independent. Let $\eta_0 = \hat{x}^*A_m\hat{x}$ and $\eta_1 = y^*A_m y$. By the discussion before the theorem, one sees that $z(t)^*A_m z(t) \in \mathcal{C}$ for all $t \in [0,1]$ is equivalent to the condition that $z(t)^*A_m z(t) \neq 0$ for all $t \in [0,1]$. To construct the required $z(t)$ we consider several cases. First, suppose $\eta_0 \neq \eta_1$ and suppose the line segment joining η_0 to η_1 does not contain zero. Let $z(t) = (\sqrt{1-t^2}\hat{x} + t\mu y)/\|\sqrt{1-t^2}\hat{x} + t\mu y\|$, where $\mu \in \mathbb{C}$ with $|\mu| = 1$ satisfies one of the following conditions:

(i) $\mu\hat{x}^*A_m y + \overline{\mu}y^*A_m\hat{x} = 0$,

(ii) $\mu\hat{x}^*A_m y + \overline{\mu}y^*A_m\hat{x} = M(\eta_1 - \eta_0)$ for some $M > 0$ if $\eta_0 + \nu(\eta_1 - \eta_0) \neq 0$ for all $\nu > 0$,

(iii) $\mu\hat{x}^*A_m y + \overline{\mu}y^*A_m\hat{x} = M(\eta_1 - \eta_0)$ for some $M < 0$ if $\eta_0 + \nu(\eta_1 - \eta_0) \neq 0$ for all $\nu < 0$.

The existence of μ satisfying (i), (ii), or (iii) can be easily checked. Indeed, assume (i) does not hold, i.e., $\mu\hat{x}^*A_m y + \overline{\mu}y^*A_m\hat{x} \neq 0$ for all $\mu \in \mathbb{C}$ with $|\mu| = 1$. Then the function $f(\theta) = e^{i\theta}\hat{x}^*A_m y + e^{-i\theta}y^*A_m\hat{x}$, $0 \leq \theta \leq 2\pi$, does not take the zero value and is obviously continuous; moreover, $f(\theta + \pi) = -f(\theta)$ for $0 \leq \theta \leq \pi$. Therefore, for any nonzero $\nu \in \mathbb{C}$, there exists a θ with $0 \leq \theta \leq 2\pi$ such that $f(\theta)$ is a positive multiple of ν. This property shows that (ii) or (iii) can be satisfied.

The function $z(t)$ is well defined because $\hat{x}$ and y are linearly independent and hence $\sqrt{1-t^2}\hat{x} + t\mu y \neq 0$ for all $t \in [0,1]$. Furthermore, by the choice of μ

$$z(t)^*A_m z(t) = \frac{\eta_0 + t^2(\eta_1 - \eta_0) + t\sqrt{1-t^2}(\mu\hat{x}^*Ay + \overline{\mu}y^*A\hat{x})}{\|\sqrt{1-t^2}\hat{x} + t\mu y\|^2} \neq 0$$

for all $t \in [0,1]$. Notice that the set $\{z(t)^*A_m z(t) : t \in [0,1]\}$ is a line segment in $W(A_m)$ not containing zero, and that $z(0)$ and $z(1)$ may not be the endpoints of this line segment.

Second, suppose $\eta_0 \neq \eta_1$, and the line segment joining these two points contains zero. In such a case, μA_m is not an indefinite hermitian matrix for any $\mu \in \mathbb{C}$; otherwise η_0 and η_1 are not in the same connected component of $W(A_m) \setminus \{0\}$. Thus there exists $\hat{y} \in \mathcal{S}$ such that $\eta_2 = \hat{y}^*A_m\hat{y}$, and the points η_i, $i = 0,1,2$, are not collinear. Clearly, both the line segment joining η_0 and η_2 and the line segment joining η_2 and η_1 do not contain zero. Thus both of them lie in $\mathcal{C}$. Now by arguments similar to those in the previous case, one can construct $z_1(t)$ with $t \in [0,1]$ such that $z_1(0) = \hat{x}$, $z_1(1) = \hat{\mu}\hat{y}$, and $z_1(t)^*A_m z_1(t) \neq 0$ for all $t \in [0,1]$; and then construct $z_2(t)$ with $t \in [0,1]$ such that $z_2(0) = \hat{\mu}\hat{y}$, $z_2(1) = \mu y$, and $z_2(t)^*A_m z_2(t) \neq 0$ for all $t \in [0,1]$. From z_1 and z_2, one easily obtains the required z.

Finally, suppose $\eta_0 = \eta_1$. If $W(A_m)$ is a singleton, then A_m is a scalar matrix. One may let $z(t) = (\sqrt{1-t^2}\hat{x} + ty)/\|\sqrt{1-t^2}\hat{x} + ty\|$. If $W(A_m)$ is not a singleton, there exists $\hat{y} \in \mathcal{S}$ such that $\eta_2 = \hat{y}^*A_m\hat{y} \in \mathcal{C}$ and the line segment joining η_0 and η_2 does not contain zero. One can then construct $z_1(t)$ and $z_2(t)$ as in the previous case and obtain the desired $z(t)$. □

Next we identify when $W(P(\lambda))$ is bounded.

THEOREM 2.3. *Let $P(\lambda) = A_m\lambda^m + A_{m-1}\lambda^{m-1} + \cdots + A_0$, where $A_m \neq 0$. Then $W(P(\lambda))$ is bounded if and only if $0 \notin W(A_m)$.*

Proof. If $0 \notin W(A_m)$, then $\mu = \min\{|z| : z \in W(A_m)\} > 0$. Thus there exists

$M > 0$ such that

$$|x^*A_mx\lambda^m| \geq |\mu\lambda^m| > \sum_{i=0}^{m-1} |x^*A_kx\lambda^i|,$$

whenever $x \in \mathcal{S}$ and $\lambda \in \mathbb{C}$ with $|\lambda| > M$. It then follows that $W(P(\lambda)) \subseteq \{\nu \in \mathbb{C} : |\nu| \leq M\}$.

To prove the converse, assume that $W(P(\lambda))$ is bounded but $0 \in W(A_m)$. Let $x \in \mathcal{S}$ be such that $x^*A_mx = 0$. There must be some A_j, $0 \leq j \leq m-1$ such that $x^*A_jx \neq 0$; otherwise, $W(P(\lambda)) = \mathbb{C}$, contradicting the assumption that $W(P(\lambda))$ is bounded. Since $A_m \neq 0$, we can find a sequence $\{y_p\}_{p=1}^{\infty}$, $y_p \in \mathcal{S}$, such that $\lim_{p\to\infty} y_p = x$ and $y_p^*A_my_p \neq 0$. Clearly, $|y_p^*A_jy_p| \geq \delta$ for some fixed $\delta > 0$, for all sufficiently large p. Since $W(P(\lambda))$ is bounded, the $(m-j)$th elementary symmetric function of the roots of the polynomial $y_p^*P(\lambda)y_p$, which is equal to $\pm y_p^*A_jy_p/y_p^*A_my_p$, is also bounded for all p. This clearly contradicts the construction of $\{y_p\}_{p=1}^{\infty}$. □

By Theorems 2.2 and 2.3 we have the following corollary.

COROLLARY 2.4. *If $W(P(\lambda))$ is bounded, then $W(P(\lambda))$ has at most m connected components, where m is the degree of $P(\lambda)$.*

The situation when $W(P(\lambda))$ is bounded and the number of connected components is the maximum allowed by Corollary 2.4, i.e., equal to the degree of $P(\lambda)$, is of special interest, and in the next section we encounter such situations. Here we only indicate the following fact.

PROPOSITION 2.5. *Assume that $W(P(\lambda))$ is bounded, with exactly m connected components $\Omega_1, \ldots, \Omega_m$, where m is the degree of $P(\lambda)$. Then for every $x \neq 0$ the equation $x^*P(\lambda)x = 0$ has exactly one root in each Ω_j $(1 \leq j \leq m)$.*

Proof. By Theorem 2.3, $0 \notin W(A_m)$; in particular, $W(A_m)\backslash\{0\}$ is connected. Arguing by contradiction, assume that for some nonzero $\hat{x} \in \mathbb{C}^n$, the equation $\hat{x}^*P(\lambda)\hat{x} = 0$ has roots in $\Omega_1, \ldots, \Omega_k$, where $k < m$. Proof of Theorem 2.2 then shows that for every nonzero $y \in \mathbb{C}^n$, the polynomial $y^*P(\lambda)y = 0$ has no roots in Ω_m. This contradicts the hypothesis that Ω_m is a connected component of $W(P(\lambda))$. □

Although $W(P(\lambda))$ is not always connected (and even if it is connected), it is not always convex as shown by Examples 1 and 2. One may ask (motivated by Example 1) whether the connected components of $W(P(\lambda))$ are convex if $W(P(\lambda))$ has a maximum number of disjoint connected components. However, the following example shows that they need not be.

Example 3. Let $P(\lambda) = \lambda^2 I + \lambda\varepsilon C + C$, where C is a nonscalar positive definite matrix and $\varepsilon > 0$. For sufficiently small $\varepsilon > 0$, $W(P(\lambda))$ is a union of two disjoint arcs lying on the circle $y^2 + x^2 + 2\varepsilon^{-1}x = 0$.

Note that all the results of this section (except for Proposition 2.1(a)) are valid (with basically the same proofs) for polynomials whose coefficients are bounded linear operators on a Hilbert space (in Proposition 2.1(d), S is a bounded linear operator between Hilbert spaces with zero kernel and in Theorem 2.3 the condition "$0 \notin W(A_m)$" should be replaced by "$0 \notin \overline{W(A_m)}$").

Before moving to §3, we would like to pose the following open problem.

Problem 1. Determine general conditions on $P(\lambda)$ so that $W(P(\lambda))$ is convex, connected, or its connected componenets are convex.

3. Numerical range and factorization. In this section we express a close connection between properties of the numerical range and factorization of matrix polynomials.

We start with known results. A matrix polynomial $P(\lambda)$ is called *hyperbolic* if $W(P(\lambda))$ is a bounded subset of $\mathbb{R}$. Clearly, the coefficients of a hyperbolic matrix

polynomial are hermitian matrices and (by Theorem 2.3) the leading coefficient is either positive definite or negative definite. For a hyperbolic $n \times n$ matrix polynomial $P(\lambda)$ of degree m denote by $\lambda_1(x) \leq \cdots \leq \lambda_m(x)$ the roots (all of them are real) of the equation $x^*P(\lambda)x = 0$, where $x \in \mathbb{C}^n$ is nonzero. The set

$$\Lambda_j = \{\lambda_j(x) : x \in \mathbb{C}^n \setminus \{0\}\} \tag{3.1}$$

is called the jth *spectral zone* of $P(\lambda)$; clearly, each Λ_j is a closed bounded interval (possibly degenerate) $[\alpha_j, \beta_j]$ on the real line. One can show, e.g., see [7, Satz 1] and [9, Thm. 31.5], that

$$\beta_j \leq \alpha_{j+1}, \qquad j = 1, \ldots, m-1. \tag{3.2}$$

A hyperbolic matrix polynomial $P(\lambda)$ of degree m is called *strongly hyperbolic* if $W(P(\lambda))$ has m connected components, i.e., all inequalities in (3.2) are strict.

An $n \times n$ matrix Z is called a (*right*) *matrix zero* of an $n \times n$ matrix polynomial $P(\lambda) = \sum_{j=0}^m A_j\lambda^j$ if $\sum_{j=0}^m A_jZ^j = 0$. Equivalently, $\lambda I - Z$ is a right divisor of $P(\lambda)$.

The following result has been proved in [8, Satz 1], [10, Thm. 3.2] (a weaker version of it can be found in [9, Thm. 31.2]), in the framework of polynomials whose coefficients are bounded linear operators on a Hilbert space.

THEOREM 3.1. *Let $P(\lambda) = \sum_{j=0}^m A_j\lambda^j$, $A_m \neq 0$, be a hyperbolic $n \times n$ matrix polynomial, and let Λ_j be its jth spectral zone* (3.1), *$j = 1, \ldots, m$.*

(a) *For every $j = 1, \ldots, m$, the polynomial $P(\lambda)$ has a unique right matrix zero Z_j such that $\sigma(Z_j) \subseteq \Lambda_j$; moreover, Z_j is similar to a hermitian matrix.*

(b) *$P(\lambda)$ admits a factorization*

$$P(\lambda) = A_m(\lambda I - Y_1)\cdots(\lambda I - Y_m),$$

where $Y_1, \ldots, Y_m$ are $n \times n$ matrices such that $\sigma(Y_j) \subseteq \Lambda_j$ and Y_j is similar to Z_j ($j = 1, \ldots, m$) with $Y_m = Z_m$.

(c) *If, in addition, $P(\lambda)$ is strongly hyperbolic, then for every permutation π of $\{1, \ldots, m\}$, there is a factorization*

$$P(\lambda) = A_m(\lambda I - Y_1(\pi))\cdots(\lambda I - Y_m(\pi)),$$

where $\sigma(Y_j(\pi)) \subseteq \Lambda_{\pi(j)}$, $j = 1, \ldots, m$.

In the following we obtain another factorization result (inspired by Theorem 3.1) based on the properties of numerical ranges of matrix polynomials, with the hyperbolicity hypothesis considerably relaxed.

THEOREM 3.2. *Let $P(\lambda)$ be a matrix polynomial of degree m such that $W(P(\lambda))$ is bounded and $W(P(\lambda))$ has exactly m connected components. Assume in addition that*

$$\mathrm{Ker}P(\lambda) = \mathrm{Ker}(P(\lambda))^*, \qquad \lambda \in \mathbb{C}. \tag{3.3}$$

Then $P(\lambda)$ admits a factorization

$$P(\lambda) = A_m(\lambda I - Y_1)\cdots(\lambda I - Y_m), \tag{3.4}$$

where A_m is the leading coefficient of $P(\lambda)$ and $Y_1, \ldots, Y_m$ are diagonalizable $n \times n$ matrices.

Proof. We verify first that $P(\lambda)$ has elementary divisors of first degree only, or, equivalently, that $P(\lambda)$ has no generalized eigenvectors (see [2, §1.4]), i.e., there do not exist $x, y \in \mathbb{C}^n$ with $x \neq 0$ such that

$$P(\lambda_0)x = 0, \qquad P'(\lambda_0)x + P(\lambda_0)y = 0 \tag{3.5}$$

for some $\lambda_0 \in \mathbb{C}$. Arguing by contradiction, we assume that such $x \neq 0$ and y do exist. Multiplying the second equation in (3.5) by x^* on the left and using (3.3), we have $x^*P'(\lambda_0)x = 0$. Thus, λ_0 is a multiple root of $x^*P(\lambda_0)x = 0$, a contradiction with Proposition 2.5.

Once we know that $P(\lambda)$ has elementary divisors of first degree only [2, Thm. 3.2.1] (a result originally proved in [11, Thm. 1]) guarantees the existence of the factorization (3.4). The matrices Y_j are diagonalizable because the property of having elementary divisors of first degree only is inherited by all matrix polynomials that are divisors of $P(\lambda)$ (see, e.g., [3, Thm. 5.6.1]); this property is based on the easily verified fact that the restriction of a diagonalizable matrix C to any C-invariant subspace is in turn diagonalizable. □

Several remarks concerning Theorem 3.2 are in order. First, a strongly hyperbolic matrix polynomial certainly satisfies the hypotheses of Theorem 3.2. In this sense, Theorem 3.2 is a generalization of Theorem 3.1 with weaker hypotheses and weaker conclusions. Second, condition (3.3) may be satisfied for matrix polynomials with nonhermitian coefficients. For example, the coefficients of $P(\lambda)$ may be commuting normal matrices. Third, in contrast with the scalar case, not every matrix polynomial admits a decomposition into a product of linear factors as in (3.4); for instance, the polynomial $P(\lambda) = \lambda^2 I_2 + \left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$ does not.

In Theorem 3.1(c), Y_j can be chosen so that all its eigenvalues are in the jth spectral zone of $W(P(\lambda))$. We could not come to an analogous conclusion in Theorem 3.2. This naturally gives rise to the following problem.

Problem 2. Under the hypotheses of Theorem 3.2, does $P(\lambda)$ admit a factorization of the form

$$P(\lambda) = A_m(\lambda I - Y_1(\pi)) \cdots (\lambda I - Y_m(\pi)),$$

where $\sigma(Y_j(\pi)) \subseteq \Lambda_{\pi(j)}$, $j = 1, \ldots, m$? Here $\Lambda_1, \ldots, \Lambda_m$ are the connected components of $W(P(\lambda))$, and π is any given permutation of $\{1, \ldots, m\}$.

Theorem 3.1 shows that the answer to Problem 2 is affirmative provided

$$W(P(\lambda)) \subseteq \mathbb{R}.$$

4. Linear polynomials with hermitian coefficients. In this section we study the numerical range of linear matrix polynomials with hermitian coefficients. For such polynomials, we provide a full characterization of the geometry of the numerical range in terms of the algebraic properties of the coefficients.

Let $P(\lambda) = \lambda A - B$, where A and B are hermitian matrices. By Proposition 2.1(e), if A and B have a common nonzero isotropic vector, then $W(P(\lambda)) = \mathbb{C}$. To avoid this trivial situation, we consider the cases in which A and B have no nonzero common isotropic vector. In all of these cases, e.g., see [12, §2] or [13, §8], A and B are simultaneously diagonalizable by a nonsingular congruence. In particular, there exists a nonsingular $S \in M_n$ such that $S^*AS = I_r \oplus -I_s \oplus 0_t$ and $B = B_1 \oplus B_2 \oplus B_3$, where $r + s + t = n$ and $B_1 \in M_r$, $B_2 \in M_s$ and $B_3 \in M_t$ are diagonal matrices. By Proposition 2.1(d), we may assume that $S = I$. Furthermore, we may assume $r \geq s$;

otherwise, replace A by $-A$ and B by $-B$. With this technical assumption on $P(\lambda)$, we are ready to prove the following result.

THEOREM 4.1. *Suppose* $P(\lambda) = A\lambda - B$, *where* $A = I_r \oplus -I_s \oplus 0_t$, $B = B_1 \oplus B_2 \oplus B_3$, $r \geq s$, $r + s + t = n$, *and* $B_1 \in M_r$, $B_2 \in M_s$ *and* $B_3 \in M_t$ *are diagonal matrices. Assume* A *and* B *have no common nonzero isotropic vector. Then we have exactly one of the following cases.*

(a) A *is positive definite, i.e.,* $A = I$, *and* $W(P(\lambda)) = W(B)$. *In particular,* $W(P(\lambda))$ *is a singleton if and only if* B *is a scalar matrix;* $W(P(\lambda))$ *is a positive (nonnegative) line segment if and only if* B *is positive (semi)definite.*

(b) A *is a singular positive semidefinite matrix;* $W(P(\lambda)) = [\alpha, \infty)$ *if* B_3 *is positive definite, and* $W(P(\lambda)) = (-\infty, \beta]$ *if* B_3 *is negative definite, where* $W(B_1) = [\alpha, \beta]$. *In this case,* B_3 *must either be positive definite or negative definite because* A *and* B *have no common nonzero isotropic vector.*

(c) A *is indefinite and* B *is positive (negative) definite and* $W(P(\lambda)) = \mathbb{R} \setminus [\alpha, \beta]$, *where* $W(B^{-1/2}AB^{-1/2}) = [1/\alpha, 1/\beta]$ $(W((-B)^{-1/2}(-A)(-B)^{-1/2}) = [1/\alpha, 1/\beta])$. *In this case,* $W(P(\lambda))$ *is the union of two disjoint unbounded intervals and* $0 \notin W(P(\lambda))$.

(d) A *is indefinite and* B *is a singular positive (negative) semidefinite matrix, and* $W(P(\lambda)) = \{\mu^{-1} : \mu \in W(B\lambda - A), \mu \neq 0\} \cup \{0\}$ $(W(P(\lambda)) = \{\mu^{-1} : \mu \in W((-B)\lambda - (-A)), \mu \neq 0\} \cup \{0\})$. *In this case,* $W(P(\lambda))$ *is the union of two disjoint unbounded intervals and* $0 \in W(P(\lambda))$.

(e) *Both* A *and* B *are indefinite and* $W(P(\lambda)) = \mathbb{R}$.

Proof. Case (a) is clear. If $s = 0$, then

$$W(P(\lambda)) = \{\frac{x^*B_1x + z^*B_3z}{x^*x} : x \in \mathbb{C}^r, z \in \mathbb{C}^t, x^*x \neq 0\},$$
$$= \begin{cases} W(B_1) + [0, \infty) & \text{if } B_3 \text{ is positive definite,} \\ W(B_1) + (-\infty, 0] & \text{if } B_3 \text{ is negative definite.} \end{cases}$$

Thus, case (b) holds.

To obtain (c) and (d), consider $W(B\lambda - A)$ and use Proposition 2.1(c).

For (e), notice that if we take $u = e_1 + e_{r+1}$, then $u^*Bu \neq 0$. Now consider the sequence $u_k = e_1 + ke_{r+1}/(k+1)$ and the sequence $v_k = ke_1/(k+1) + e_{r+1}$, $k = 1, 2, \ldots$. One sees that $\{u_k^*Bu_k/u_k^*Au_k\}$ and $\{v_k^*Bv_k/v_k^*Av_k\}$ go to $\pm\infty$ in opposite directions. Thus $W(P(\lambda))$ is unbounded above and below. Now apply similar arguments to $W(B\lambda - A)$ and use Proposition 2.1(c), to see that $W(P(\lambda))$ contains all positive and negative numbers. Clearly, $0 \in W(P(\lambda))$. Thus $W(P(\lambda)) = \mathbb{R}$, as asserted. □

5. Polynomials with a degenerate numerical range. From Theorem 4.1, one sees that if the numerical range of a linear matrix polynomial $P(\lambda)$ with hermitian coefficients is given, then one has quite a lot of information about the coefficient matrices. It is interesting to study the more general case, but the analysis will undoubtedly be more involved. In this section, we study the cases in which the numerical range is a singleton or lies on the real axis.

THEOREM 5.1. *Let* $P(\lambda) = A_m\lambda^m + A_{m-1}\lambda^{m-1} + \cdots + A_0$, *where* $A_m \neq 0$. *Then* $W(P(\lambda)) = \{\alpha\}$ *with* $\alpha \in \mathbb{C}$ *if and only if* $0 \notin W(A_m)$ *and* $P(\lambda) = A_m(\lambda I - \alpha I)^m$.

Proof. The sufficiency part is clear. To prove the necessity part, observe first that $0 \notin W(A_m)$ by Theorem 2.3. Furthermore, if $W(P(\lambda)) = \{\alpha\}$ then $x^*P(\lambda)x$ must be of the form $\mu(\lambda - \alpha)^m$ for all $x \in \mathcal{S}$. In particular, for every $j = 0, \ldots, m-1$, $x^*A_jx/x^*A_mx = (-\alpha)^{m-j}$ and hence $x^*(A_j - (-\alpha)^{m-j}A_m)x = 0$ for all $x \in \mathcal{S}$. It follows that $A_j = (-\alpha)^{m-j}A_m$ for all j and the result follows. □

Now assume that $W(P(\lambda)) \subseteq \mathbb{R}$, so that all the coefficients of $P(\lambda)$ are hermitian matrices. It is clear (even in the scalar case) that this condition is not sufficient to ensure that $W(P(\lambda)) \subseteq \mathbb{R}$. In general, a convenient criterion for $W(P(\lambda)) \subseteq \mathbb{R}$ is not available. However, under additional hypotheses such a criterion can be provided. For example, the following result holds in the quadratic case.

THEOREM 5.2. *Let $P(\lambda) = A_2\lambda^2 + A_1\lambda + A_0$, where A_j is $n \times n$ hermitian for $j = 0, 1, 2$, and $A_2 \neq 0$. Then the following are equivalent:*

(a) $W(P(\lambda)) \subseteq \mathbb{R}$.

(b) $4(x^*A_0x)(x^*A_2x) \leq (x^*A_1x)^2$ *for all* $x \in \mathcal{S}$.

(c) *For every* $x \in \mathcal{S}$ *there exists* $\lambda = \lambda(x) \in \mathbb{R}$ *such that* $x^*P(\lambda)x \leq 0$.

Moreover, if A_2 is positive definite, then conditions (a)–(c) *are equivalent to the following*:

(d) *There exists* $\lambda \in \mathbb{R}$ *such that* $-P(\lambda)$ *is positive semidefinite.*

Proof. The equivalence of (a)–(c) follows easily from the formula for solving the quadratic equation $\lambda^2(x^*A_2x) + \lambda(x^*A_1x) + (x^*A_0x) = 0$.

Clearly, (d) implies (c). We claim that the converse is also valid if A_2 is positive definite. Consider the following condition.

(e) For every $x \in \mathcal{S}$ there exists $\lambda = \lambda(x) \in \mathbb{R}$ such that $x^*P(\lambda)x < 0$.

It is known (e.g., see [2, Thm. 13.1]) that (e) implies (d). Now if (c) holds, then (e) holds for the matrix polynomial $A_2\lambda^2 + A_1\lambda + A_0 - \varepsilon I$, for every $\varepsilon > 0$. Therefore, for every $\varepsilon > 0$, there exists $\lambda(\varepsilon) \in \mathbb{R}$ such that $-(A_2\lambda^2 + A_1\lambda + A_0 - \varepsilon I)$ is positive semidefinite. Since A_2 is positive definite, the set $\{\lambda(\varepsilon) : 0 < \varepsilon \leq 1\}$ is bounded. Taking a convergent subsequence of the sequence $\{\lambda(1/p)\}_{p=1}^{\infty}$ and passing to the limit when $p \to \infty$, we obtain condition (d). □

Note added in proof. Professor A.S. Markus, Ben Gurion University, Beer-Sheva, Israel, has informed us that the answer to Problem 2 is affirmative for $m = 2$ and $m = 3$. For $m = 2$, this follows from Theorem 1 in [14]. In case $m = 3$, the polynomial $P(\lambda)$ can be first factored in the from $P(\lambda) = (\lambda I - Y_1(\pi))Q(\lambda)$, where $\sigma(Y_1(\pi)) \subseteq \Lambda_{\pi(1)}$ and $Q(\lambda)$ is a matrix polynomial of second degree (the existence of such factorization follows from Theorem 2 in [15]). Using this factorization of $P(\lambda)$, the proof of the above-mentioned Theorem 1 yields the desired result. Problem 2 remains open for $m \geq 4$.

A STABLE AND EFFICIENT ALGORITHM FOR THE RANK-ONE MODIFICATION OF THE SYMMETRIC EIGENPROBLEM*

MING GU† AND STANLEY C. EISENSTAT‡

Abstract. An algorithm is presented for computing the eigendecomposition of a symmetric rank-one modification of a symmetric matrix whose eigendecomposition is known. Previous algorithms for this problem suffer a potential loss of orthogonality among the computed eigenvectors, unless extended precision arithmetic is used. This algorithm is based on a novel, stable method for computing the eigenvectors. It does not require extended precision and is as efficient as previous approaches.

Key words. symmetric eigenproblem, rank-one modification

AMS subject classification. 65F15

1. Introduction.

Given a real scalar ρ, a real n-vector u, and the eigendecomposition of a real $n \times n$ symmetric matrix B, the rank-one modification of the symmetric eigenproblem is to find the eigendecomposition of the matrix $B + \rho uu^T$.

This is an important problem in numerical linear algebra. Applications include divide-and-conquer algorithms for the symmetric tridiagonal eigenproblem [8], [9], [14], [16], [18], the bidiagonal singular value decomposition (SVD) [2]–[4], [14], [17], [20], [21], and the unitary and orthogonal eigenproblems [1], [4], [12]; updating the SVD [6], [14], [15]; and various stationary value problems [10].

The problem can easily be reduced to the following special case (see [7]). Given a diagonal matrix $D = \mathrm{diag}(d_1, d_2, \ldots, d_n)$ with $d_1 < d_2 < \cdots < d_n$, and a real vector $z = (z_1, z_2, \ldots, z_n)^T$ with $z_j > 0$, find the eigendecomposition

$$D + zz^T = Q\Lambda Q^T$$

of $A \equiv D + zz^T$, where $\Lambda = \mathrm{diag}(\lambda_1, \lambda_2, \ldots, \lambda_n)$ with $\lambda_1 < \lambda_2 < \cdots < \lambda_n$, and Q is orthogonal. The diagonal elements of Λ are the eigenvalues of A and the columns of Q are the corresponding eigenvectors. From now on we focus on this reduced problem, yet still refer to it as the rank-one modification problem.

Since error is associated with computation, a *numerical eigendecomposition* of $D + zz^T$ is usually defined as a decomposition of the form

$$D + zz^T = \tilde{Q}\tilde{\Lambda}\tilde{Q}^T + O(\epsilon(\|D\|_2 + \|z\|_2^2)), \tag{1}$$

where ϵ is the machine precision, $\tilde{\Lambda} = \mathrm{diag}(\tilde{\lambda}_1, \tilde{\lambda}_2, \ldots, \tilde{\lambda}_n)$ with $\tilde{\lambda}_1 < \tilde{\lambda}_2 < \cdots < \tilde{\lambda}_n$, and $\tilde{Q}$ is *numerically orthogonal.* An algorithm that produces such a decomposition is said to be *stable.*

While the eigenvalues of A are always well conditioned with respect to a symmetric perturbation, the eigenvectors can be extremely sensitive to such perturbations [11], [26], [28], [29]. That is, $\tilde{\Lambda}$ is guaranteed to be close to Λ, but $\tilde{Q}$ can be very different from Q. Thus one is usually content with a stable algorithm.

The problem can be further simplified in light of (1). Given any rank-one modification matrix $D + zz^T$, we can use the deflation procedure in [9] to reduce the eigenproblem to one that satisfies

$$d_{j+1} - d_j \geq \tau(\|D\|_2 + \|z\|_2^2) \quad \text{and} \quad z_j \geq \tau\sqrt{\|D\|_2 + \|z\|_2^2},$$

where τ is a small multiple of ϵ to be specified later.

The basic tool for the rank-one modification problem is an algorithm developed by Bunch, Nielsen, and Sorensen [7] and inspired by earlier work of Golub [10]. Dongarra and Sorensen [9] propose a more liberal deflation process to make the algorithm more efficient and more stable. We refer to the algorithm in [9] as *Algorithm* I.

While Algorithm I always computes the eigenvalues to high absolute accuracy, in the presence of close eigenvalues it can have difficulties in computing numerically orthogonal eigenvectors [7]–[9]. This instability affects all algorithms using rank-one modification techniques.

To overcome this instability, Kahan [22] proposes using extended precision arithmetic to compute some key quantities more accurately. Independently, Sorensen and Tang [27] develop a new version of Algorithm I that uses simulated extended precision and they show that it is stable. The problem with extended precision is that it results in machine-dependent software [5], [27].

In this paper we present a new algorithm for solving the rank-one modification problem. Since Algorithm I works well for finding the eigenvalues, the new algorithm uses a similar approach. But it uses a completely different approach to finding the eigenvectors; one that is stable. The amount of work for the stable approach is roughly the same as for Algorithm I, yet the new algorithm does not require the use or simulation of extended precision arithmetic. We refer to this new algorithm as *Algorithm* II.

Section 2 introduces Algorithm I and points out how it can fail. Section 3 introduces Algorithm II. Section 4 proves the numerical stability of Algorithm II. Section 5 reviews previous results on the stability of Algorithm I and shows why these results require more accuracy than necessary. Section 6 presents numerical results and §7 points out extensions.

Throughout the paper we assume that the elements of D and z are given in floating-point representation. We take the usual model of arithmetic[1]

$$fl(x \circ y) = (x \circ y)(1 + \xi),$$

where x and y are floating-point numbers; $\circ$ is one of $+, -, \times$, and $\div$; $fl(x \circ y)$ is the floating-point result of the operation $\circ$; and $|\xi| \leq \epsilon$. We also require that

$$fl(\sqrt{x}) = \sqrt{x}(1 + \xi)$$

for any positive floating-point number x. For simplicity, we ignore the possibility of overflow and underflow.

2. How Algorithm I can fail. The following lemma characterizes the eigenvalues and eigenvectors of $D + zz^T$.

[1] This model excludes machines like the CRAY and CDC Cyber that do not have a guard digit. Algorithm II can easily be modified for such machines.

LEMMA 2.1 (Bunch, Nielsen, and Sorensen [7]). *Assume that* $d_1 < d_2 < \cdots < d_n$ *and that* $z_j > 0$. *Then the eigenvalues* $\{\lambda_i\}_{i=1}^n$ *of* $D + zz^T$ *satisfy the* interlacing property

$$d_1 < \lambda_1 < d_2 < \lambda_2 < \cdots < d_n < \lambda_n$$

and are the roots of the secular equation

$$f(\lambda) \equiv 1 + \sum_{j=1}^{n} \frac{z_j^2}{d_j - \lambda} = 0.$$

For each eigenvalue λ_i, *the corresponding eigenvector is given by*

$$q_i = \left(\frac{z_1}{d_1 - \lambda_i}, \ldots, \frac{z_n}{d_n - \lambda_i}\right)^T \Bigg/ \sqrt{\sum_{j=1}^{n} \frac{z_j^2}{(d_j - \lambda_i)^2}}. \tag{2}$$

Algorithm I uses a rational interpolation strategy to solve for $\{\lambda_i\}_{i=1}^n$ (see [7]). For each eigenvalue λ_i, it finds a numerical approximation $\tilde{\lambda}_i$ and approximates q_i by

$$\tilde{q}_i^I = \left(\frac{z_1}{d_1 - \tilde{\lambda}_i}, \ldots, \frac{z_n}{d_n - \tilde{\lambda}_i}\right)^T \Bigg/ \sqrt{\sum_{j=1}^{n} \frac{z_j^2}{(d_j - \tilde{\lambda}_i)^2}}.$$

In other words, the *exact* λ_i is replaced by the *approximation* $\tilde{\lambda}_i$ in (2).

In pathological cases, even though $\tilde{\lambda}_i$ is very close to λ_i, the approximate ratio $z_j/(d_j - \tilde{\lambda}_i)$ is very different from the exact ratio $z_j/(d_j - \lambda_i)$, resulting in a computed eigenvector very different from the true eigenvector. More importantly, when all the eigenvectors are computed, the resulting eigenvector matrix is far from orthogonal.

3. Algorithm II.

3.1. Computing the eigenvectors. For each eigenvalue λ_i, the corresponding eigenvector is given by

$$q_i = \left(\frac{z_1}{d_1 - \lambda_i}, \ldots, \frac{z_n}{d_n - \lambda_i}\right)^T \Bigg/ \sqrt{\sum_{j=1}^{n} \left(\frac{z_j}{d_j - \lambda_i}\right)^2}$$

(see Lemma 2.1). Observe that if λ_i was given *exactly*, then we could compute each difference, each ratio, each product, and each sum in this formula to high relative accuracy, and thus compute q_i to componentwise high relative accuracy.

In practice we can only hope to compute an approximation $\tilde{\lambda}_i$ to λ_i. But suppose that we could find a $\tilde{z}$ such that $\{\tilde{\lambda}_i\}_{i=1}^n$ are the *exact* eigenvalues of the *new* rank-one modification matrix $\tilde{A} = D + \tilde{z}\tilde{z}^T$. (We rederive Löwner's [24] solution to this *inverse eigenvalue problem* below.) Since

$$\begin{aligned} A &= D + zz^T \\ &= D + \tilde{z}\tilde{z}^T + zz^T - \tilde{z}\tilde{z}^T \\ &= \tilde{A} + (z - \tilde{z})z^T + z(z - \tilde{z})^T - (z - \tilde{z})(z - \tilde{z})^T, \end{aligned}$$

$\tilde{A}$ will be close to A as long as $\tilde{z}$ is close to z. Moreover, the formula

$$\tilde{q}_i^{II} = \left(\frac{\tilde{z}_1}{d_1 - \tilde{\lambda}_i}, \ldots, \frac{\tilde{z}_n}{d_n - \tilde{\lambda}_i}\right)^T \Bigg/ \sqrt{\sum_{j=1}^{n} \frac{\tilde{z}_j^2}{(d_j - \tilde{\lambda}_i)^2}} \tag{3}$$

gives the *exact* eigenvector corresponding to the eigenvalue $\tilde{\lambda}_i$ of $\tilde{A}$. As we observed before, $\tilde{q}_i^{II}$ can be computed to componentwise high relative accuracy. Thus, when all the eigenvectors of $\tilde{A}$ are computed, the resulting eigenvector matrix will be numerically orthogonal.

We now show why such a $\tilde{z}$ exists (cf. [5], [24]). By definition,

$$\det(\tilde{A} - \lambda I) = \prod_{j=1}^{n} (\tilde{\lambda}_j - \lambda).$$

On the other hand,

$$\det(\tilde{A} - \lambda I) = \det(D + \tilde{z}\tilde{z}^T - \lambda I) = \left(1 + \sum_{j=1}^{n} \frac{\tilde{z}_j^2}{d_j - \lambda}\right) \prod_{j=1}^{n} (d_j - \lambda).$$

Combining these relations,

$$\prod_{j=1}^{n} (\tilde{\lambda}_j - \lambda) = \left(1 + \sum_{j=1}^{n} \frac{\tilde{z}_j^2}{d_j - \lambda}\right) \prod_{j=1}^{n} (d_j - \lambda).$$

Setting $\lambda = d_i$, we get

$$\tilde{z}_i^2 = \frac{\prod_j (\tilde{\lambda}_j - d_i)}{\prod_{j \neq i} (d_j - d_i)}. \tag{4}$$

If the computed eigenvalues $\{\tilde{\lambda}_i\}_{i=1}^n$ satisfy the interlacing property[2]

$$d_1 < \tilde{\lambda}_1 < d_2 < \tilde{\lambda}_2 < \ldots < d_n < \tilde{\lambda}_n,$$

then the expression on the right-hand side of (4) is positive and

$$\tilde{z}_i = \sqrt{\prod_{j=1}^{i-1} \frac{(\tilde{\lambda}_j - d_i)}{(d_j - d_i)} \cdot \prod_{j=i}^{n-1} \frac{(\tilde{\lambda}_j - d_i)}{(d_{j+1} - d_i)} \cdot (\tilde{\lambda}_n - d_i)}. \tag{5}$$

Working backward, if $\tilde{z}$ is given by (5), then the eigenvalues of $D + \tilde{z}\tilde{z}^T$ are $\{\tilde{\lambda}_i\}_{i=1}^n$.

Each difference, each ratio, and each product in (5) can be computed to high relative accuracy. As a result, $\tilde{z}$ can be computed to componentwise high relative accuracy. Substituting the computed $\tilde{z}$ into (3), $\tilde{q}_i^{II}$ can also be computed to componentwise high relative accuracy. Consequently, when all the eigenvectors are computed, the resulting eigenvector matrix $\tilde{Q} = (\tilde{q}_1^{II}, \ldots, \tilde{q}_n^{II})$ will be numerically orthogonal.

To show that $\tilde{Q}\tilde{\Lambda}\tilde{Q}^T$ is a numerical eigendecomposition of A, we must show that $\tilde{z}$ is close to z. We do so in §4.

[2] Since the exact eigenvalues satisfy the same interlacing property (see Lemma 2.1), this is only an accuracy requirement on the computed eigenvalues and is not an additional restriction on A.

3.2. Computing the eigenvalues. To guarantee that $\tilde{z}$ is close to z, we must ensure that the approximations $\{\tilde{\lambda}_i\}_{i=1}^n$ to the eigenvalues are sufficiently accurate. The key is the stopping criterion for the root-finder, which requires a slight reformulation of the secular equation (cf. [7]).

Consider the eigenvalue $\lambda_i \in (d_i, d_{i+1})$, where $1 \le i \le n-1$; we consider the case $i = n$ later. λ_i is a root of the secular equation

$$f(\lambda) \equiv 1 + \sum_{j=1}^{n} \frac{z_j^2}{d_j - \lambda} = 0.$$

We first assume that $\lambda_i \in (d_i, \frac{d_i+d_{i+1}}{2})$. This can easily be checked by computing $f(\frac{d_i+d_{i+1}}{2})$. If $f(\frac{d_i+d_{i+1}}{2}) > 0$, then $\lambda_i \in (d_i, \frac{d_i+d_{i+1}}{2})$, otherwise $\lambda_i \in [\frac{d_i+d_{i+1}}{2}, d_{i+1})$. Let $\delta_j = d_j - d_i$ and let

$$\psi(\mu) \equiv \sum_{j=1}^{i} \frac{z_j^2}{\delta_j - \mu} \quad \text{and} \quad \phi(\mu) \equiv \sum_{j=i+1}^{n} \frac{z_j^2}{\delta_j - \mu}.$$

Since

$$f(\mu + d_i) = 1 + \psi(\mu) + \phi(\mu) \equiv g(\mu),$$

we seek the root $\mu_i = \lambda_i - d_i \in (0, \delta_{i+1}/2)$ of $g(\mu) = 0$.

An important property of $g(\mu)$ is that each difference $\delta_j - \mu$ can be evaluated to high relative accuracy for any $\mu \in (0, \delta_{i+1}/2)$. Indeed, since $\delta_i = 0$, we have $fl(\delta_i - \mu) = -fl(\mu)$; since $fl(\delta_{i+1}) = fl(d_{i+1} - d_i)$ and $0 < \mu < (d_{i+1} - d_i)/2$, we can compute $fl(\delta_{i+1} - \mu)$ as $fl(fl(d_{i+1} - d_i) - fl(\mu))$; and similarly, we can compute $\delta_j - \mu$ to high relative accuracy for any $j \neq i, i+1$.

Because of this property, each ratio $z_j^2/(\delta_j - \mu)$ in $g(\mu)$ can be evaluated to high relative accuracy for any $\mu \in (0, \delta_{i+1}/2)$. And, since both $\psi(\mu)$ and $\phi(\mu)$ are sums of terms with the same sign, we can bound the error in computing $g(\mu)$ by

$$\eta n(1 + |\psi(\mu)| + |\phi(\mu)|),$$

where η is a small multiple of ϵ that is independent of n and μ.

We now assume that $\lambda_i \in [\frac{d_i+d_{i+1}}{2}, d_{i+1})$. Let $\delta_j = d_j - d_{i+1}$ and let

$$\psi(\mu) \equiv \sum_{j=1}^{i} \frac{z_j^2}{\delta_j - \mu} \quad \text{and} \quad \phi(\mu) \equiv \sum_{j=i+1}^{n} \frac{z_j^2}{\delta_j - \mu}.$$

We seek the root $\mu_i = \lambda_i - d_{i+1} \in [\delta_i/2, 0)$ of the equation

$$g(\mu) \equiv f(\mu + d_{i+1}) = 1 + \psi(\mu) + \phi(\mu) = 0.$$

For any $\mu \in [\delta_i/2, 0)$, each difference $\delta_j - \mu$ can again be computed to high relative accuracy, as can each ratio $z_j^2/(\delta_j - \mu)$; and we can bound the error in computing $g(\mu)$ as before.

Finally we consider the case $i = n$. Let $\delta_j = d_j - d_n$ and let

$$\psi(\mu) \equiv \sum_{j=1}^{n} \frac{z_j^2}{\delta_j - \mu} \quad \text{and} \quad \phi(\mu) \equiv 0.$$

We seek the root $\mu_n = \lambda_n - d_n \in (0, \|z\|_2^2)$ of the equation

$$g(\mu) \equiv f(\mu + d_n) = 1 + \psi(\mu) + \phi(\mu) = 0.$$

Again, for any $\mu \in (0, \|z\|_2^2)$, each ratio $z_j^2/(\delta_j - \mu)$ can be computed to high relative accuracy, and we can bound the error in computing $g(\mu)$ as before.

In practice the root-finder cannot make any progress at a point μ where it is impossible to determine the sign of $g(\mu)$ numerically. Thus we propose the stopping criterion

$$|g(\mu)| \le \eta n \left(1 + |\psi(\mu)| + |\phi(\mu)|\right), \tag{6}$$

where, as before, $\eta n(1 + |\psi(\mu)| + |\phi(\mu)|)$ is an upper bound on the roundoff error in computing $g(\mu)$. Note that for each i, there is at least one floating-point number that satisfies this stopping criterion numerically, namely, $fl(\mu_i)$.

We have not specified the scheme used to find the root of $g(\mu)$. We used the rational interpolation strategy in [7] for the numerical experiments, but bisection or the improved rational interpolation strategies in [13] and [23] would also work. What is most important is the stopping criterion and the fact that, with the reformulation of the secular equation given above, we can find a μ that satisfies it.

3.3. Efficiency. The only additional work in Algorithm II is the evaluation of $\tilde{z}$ using (5). This is roughly equivalent to 1–2 extra evaluations of the secular equation; however, Li [23] reports a comparable savings from using our stopping criterion (6).

4. Numerical stability of Algorithm II. In this section we show that Algorithm II computes the eigenvalues to high absolute accuracy and that $\tilde{z}$ is indeed close to z.

Since $f(\lambda_i) = 0$, we have

$$1 = -\sum_{j=1}^{n} \frac{z_j^2}{d_j - \lambda_i} \le \sum_{j=1}^{n} \frac{z_j^2}{|d_j - \lambda_i|},$$

and the stopping criterion (6) implies that the computed eigenvalue $\tilde{\lambda}_i$ satisfies

$$|f(\tilde{\lambda}_i)| \le \eta n \left(\sum_{j=1}^{n} \frac{z_j^2}{|d_j - \lambda_i|} + \sum_{j=1}^{n} \frac{z_j^2}{|d_j - \tilde{\lambda}_i|} \right).$$

Since

$$f(\tilde{\lambda}_i) = f(\tilde{\lambda}_i) - f(\lambda_i) = (\tilde{\lambda}_i - \lambda_i) \sum_{j=1}^{n} \frac{z_j^2}{(d_j - \tilde{\lambda}_i)(d_j - \lambda_i)},$$

it follows that

$$|\tilde{\lambda}_i - \lambda_i| \sum_{j=1}^{n} \frac{z_j^2}{|(d_j - \tilde{\lambda}_i)(d_j - \lambda_i)|} \le \eta n \left(\sum_{j=1}^{n} \frac{z_j^2}{|d_j - \tilde{\lambda}_i|} + \sum_{j=1}^{n} \frac{z_j^2}{|d_j - \lambda_i|} \right). \tag{7}$$

Thus

$$\begin{aligned} &|\tilde{\lambda}_i - \lambda_i| \sum_{j=1}^{n} \frac{z_j^2}{|(d_j - \tilde{\lambda}_i)(d_j - \lambda_i)|} \\ &\quad \le \eta n \max_{1 \le k \le n} \left(|d_k - \tilde{\lambda}_i| + |d_k - \lambda_i| \right) \sum_{j=1}^{n} \frac{z_j^2}{|(d_j - \tilde{\lambda}_i)(d_j - \lambda_i)|} \end{aligned}$$

or

$$|\tilde{\lambda}_i - \lambda_i| \le \eta n \max_{1\le k\le n} \left(|d_k - \tilde{\lambda}_i| + |d_k - \lambda_i|\right) \le \frac{2\eta n}{1-\eta n} \max_{1\le k\le n} |d_k - \lambda_i|,$$

i.e., all the eigenvalues are computed to high absolute accuracy.

To show that $\tilde{z}$ is close to z, we note that for any j,

$$\frac{1}{|d_j - \tilde{\lambda}_i|} + \frac{1}{|d_j - \lambda_i|} \le \frac{2}{|(d_j - \tilde{\lambda}_i)(d_j - \lambda_i)|^{\frac{1}{2}}} + \frac{|\tilde{\lambda}_i - \lambda_i|}{|(d_j - \tilde{\lambda}_i)(d_j - \lambda_i)|}.$$

Substituting this into (7), we get

$$\begin{aligned} |\tilde{\lambda}_i - \lambda_i| \sum_{j=1}^{n} \frac{z_j^2}{|(d_j - \tilde{\lambda}_i)(d_j - \lambda_i)|} &\le \frac{2\eta n}{1-\eta n} \sum_{j=1}^{n} \frac{z_j^2}{|(d_j - \tilde{\lambda}_i)(d_j - \lambda_i)|^{\frac{1}{2}}} \\ &\le \frac{2\eta n}{1-\eta n} \|z\|_2 \sqrt{\sum_{j=1}^{n} \frac{z_j^2}{|(d_j - \tilde{\lambda}_i)(d_j - \lambda_i)|}} \end{aligned}$$

or

$$\begin{aligned} |\tilde{\lambda}_i - \lambda_i| &\le \frac{2\eta n}{1-\eta n} \|z\|_2 \Bigg/ \sqrt{\sum_{j=1}^{n} \frac{z_j^2}{|(d_j - \tilde{\lambda}_i)(d_j - \lambda_i)|}} \\ &\le \frac{2\eta n \|z\|_2}{(1-\eta n) z_j} \sqrt{|(d_j - \tilde{\lambda}_i)(d_j - \lambda_i)|} \\ &\le \frac{2\eta n \|z\|_2}{(1-\eta n) z_j} \left(|d_j - \lambda_i| + \frac{1}{2}|\tilde{\lambda}_i - \lambda_i|\right). \end{aligned}$$

Letting $\beta_j = 2\eta n \|z\|_2 / ((1-\eta n) z_j)$, this implies that

$$|\tilde{\lambda}_i - \lambda_i| \le \frac{\beta_j}{1 - \frac{1}{2}\beta_j} |d_j - \lambda_i| \tag{8}$$

for every $1 \le j \le n$, provided that $\beta_j < 2$.

Let $\tilde{\lambda}_i - \lambda_i = \alpha_{ij}(d_j - \lambda_i)/z_j$ for all i and j. Suppose that we pick $\tau = 2\eta n^2$ in the deflation procedure of §1. Then $z_j \ge 2\eta n^2 \|z\|_2$. Assume further that $\eta n < 1/100$. Then $\beta_j \le 2/3$, and (8) implies that $|\alpha_{ij}| \le \alpha \equiv 4\eta n \|z\|_2$ for all i and j. Thus

$$\tilde{z}_i = \sqrt{\frac{\prod_j (\tilde{\lambda}_j - d_i)}{\prod_{j\ne i}(d_j - d_i)}} = \sqrt{\frac{\prod_j (\lambda_j - d_i)(1 + \alpha_{ji}/z_i)}{\prod_{j\ne i}(d_j - d_i)}} = z_i \sqrt{\prod_{j=1}^{n} \left(1 + \frac{\alpha_{ji}}{z_i}\right)}$$

and

$$\begin{aligned} |\tilde{z}_i - z_i| = z_i \left| \sqrt{\prod_{j=1}^{n} \left(1 + \frac{\alpha_{ji}}{z_i}\right)} - 1 \right| &\le z_i \left(\left(1 + \frac{\alpha}{z_i}\right)^{n/2} - 1 \right) \\ &\le z_i \left(\exp\left(\frac{\alpha n}{2 z_i}\right) - 1 \right) \le (e-1)\alpha n/2 \\ &\le 4\eta n^2 \|z\|_2, \end{aligned} \tag{9}$$

where we have used the fact that $\alpha n/(2z_i) \leq 1$ and that $(e^x - 1)/x \leq e - 1$ for $0 < x \leq 1$.

One factor of n in τ and (9) comes from the stopping criterion (6). This is quite conservative and could be reduced to $\log_2 n$ by using a binary tree structure for summing up the terms in $\psi(\mu)$ and $\phi(\mu)$. The other factor of n comes from the upper bound for $\prod_j (1 + \alpha_{ji}/z_i)$. This also seems quite conservative. Thus we might expect the factor of n^2 in τ and (9) to be more like $O(n)$ in practice.

5. Another view of numerical stability. In this section we review previous results on the numerical stability of the eigenvector computation and show why they impose unnecessary requirements on the accuracy to which the eigenvalues are computed.

The following lemma bounds the lack of numerical orthogonality in the eigenvectors computed by Algorithm I.

LEMMA 5.1 (Dongarra and Sorensen [9]). *Let λ_k and λ_ℓ be distinct eigenvalues of $D + zz^T$. Let $\hat{q}_k = \hat{u}_k/\|\hat{u}_k\|_2$ and $\hat{q}_\ell = \hat{u}_\ell/\|\hat{u}_\ell\|_2$, where*

$$\hat{u}_k = \left(\frac{z_1}{\tilde{\delta}_{k1}}, \frac{z_2}{\tilde{\delta}_{k2}}, \ldots, \frac{z_n}{\tilde{\delta}_{kn}}\right)^T$$

and

$$\hat{u}_\ell = \left(\frac{z_1}{\tilde{\delta}_{\ell 1}}, \frac{z_2}{\tilde{\delta}_{\ell 2}}, \ldots, \frac{z_n}{\tilde{\delta}_{\ell n}}\right)^T$$

are the computed eigenvectors corresponding to the exact eigenvectors q_k and q_ℓ. If

$$\tilde{\delta}_{ij} = (d_j - \lambda_i)(1 + \eta_{ij}),$$

where $|\eta_{ij}| \leq \gamma \ll 1$ for all i and j, then

$$\hat{q}_k^T \hat{q}_\ell \leq \gamma(2 + \gamma)\left(\frac{1+\gamma}{1-\gamma}\right)^2.$$

Thus numerical orthogonality can be assured for Algorithm I whenever it is possible to compute all of the differences $d_j - \lambda_i$ to high relative accuracy. Sorensen and Tang [27] show that in pathological cases one encounters enormous difficulties meeting this condition, and thus they advocate the use of extended precision arithmetic.

But what does this condition imply about Algorithm II? Recall that

$$z_i = \sqrt{\prod_{j=1}^{i-1} \frac{(\lambda_j - d_i)}{(d_j - d_i)} \cdot \prod_{j=i}^{n-1} \frac{(\lambda_j - d_i)}{(d_{j+1} - d_i)} \cdot (\lambda_n - d_i)}$$

and

$$\tilde{z}_i = \sqrt{\prod_{j=1}^{i-1} \frac{(\tilde{\lambda}_j - d_i)}{(d_j - d_i)} \cdot \prod_{j=i}^{n-1} \frac{(\tilde{\lambda}_j - d_i)}{(d_{j+1} - d_i)} \cdot (\tilde{\lambda}_n - d_i)}.$$

Thus if we compute all of the differences $\lambda_j - d_i$ to high relative accuracy, then $\tilde{z}_i$ will be close to z_i to high *relative* accuracy. In contrast we have shown only that the stopping criterion guarantees that $\tilde{z}_i$ is close to z_i to high *absolute* accuracy, but this is enough for Algorithm II to be stable.

6. Numerical results. In this section we present some numerical results for Algorithms I and II. The tests were run on a SPARCstation 1 in double precision arithmetic. The machine precision is $\epsilon \approx 1.1 \times 10^{-16}$. τ was taken small enough that no deflation occurs.

We define the scaled orthogonality and residual measures

$$\mathcal{O} = \max_{1 \le i \le n} \frac{\|\tilde{Q}^T \tilde{q}_i - e_i\|_2}{n\epsilon} \quad \text{and} \quad \mathcal{R} = \max_{1 \le i \le n} \frac{\|A\tilde{q}_i - \tilde{\lambda}_i \tilde{q}_i\|_2}{n\epsilon \|A\|_2}.$$

$\mathcal{O}_I$ and $\mathcal{O}_{II}$ are the orthogonality measures for Algorithms I and II, respectively; $\mathcal{R}_I$ and $\mathcal{R}_{II}$ are the residual measures for Algorithms I and II, respectively. We also define

$$Z = \max_{1 \le i \le n} \frac{|\tilde{z}_i - z_i|}{n\epsilon \|z\|_2},$$

which measures the scaled absolute error in replacing z by $\tilde{z}$.

We use the following three sets of test problems.

TEST 1 [27]. These problems arise in applying Cuppen's divide-and-conquer algorithm [8], [9] to the matrix

$$T = \begin{pmatrix} W_{21} & \beta & & & & \\ \beta & W_{21} & \beta & & & \\ & \beta & W_{21} & & & \\ & & & \ddots & & \\ & & & & \beta & \\ & & & & \beta & W_{21} \end{pmatrix},$$

where W_{21} is the symmetric tridiagonal matrix of order 21 with diagonal elements $10, 9, \ldots, 1, 0, 1, 2, \ldots, 10$ and off-diagonal elements all 1. As β becomes smaller and the number of copies of W_{21} becomes larger, more and more difficult rank-one modification problems arise.

TEST 2 [27]. $D = \mathrm{diag}(1, 2 - \beta, 2 + \beta, 10/3)$ and $z = (2, \beta, \beta, 2)^T$. This example illustrates how badly Algorithm I can fail in computing the eigenvectors.

TEST 3. $n = 202; d_1 = 1, d_n = 10/3$, and the rest of the d_i's are of the form $2 \pm j\beta$, for $j = 1, 2, \ldots, 100$; and $z = (2, \beta, \ldots, \beta, 2)^T$. As $\beta > 0$ becomes very small, this matrix has $10\frac{1}{3}$ as an isolated eigenvalue; the remaining eigenvalues are clustered around 2. This generalization of TEST 2 is designed to show the stability of Algorithm II in the presence of an extremely large and tight cluster.

Tables 1, 2, and 3 summarize the results. For Algorithm II, the orthogonality and residual are small, and the vectors z and $\tilde{z}$ agree to machine precision. For Algorithm I, the residual is small, but the orthogonality can be very poor.

7. Some extensions. In this paper we have presented a novel, stable algorithm for solving the rank-one modification of the symmetric eigenproblem. The techniques developed have also been extended to the following:

- Cuppen's method for the symmetric tridiagonal eigenproblem [8], [9], [14], [18].
- An algorithm for the eigendecomposition of symmetric arrowhead matrices [25]; this is in turn the basic tool in the arrowhead divide-and-conquer algorithm for the symmetric tridiagonal eigenproblem [3], [14], [16], [18].

TABLE 1
Results for TEST 1.

FAST SOLUTION OF CONFLUENT VANDERMONDE LINEAR SYSTEMS*

HAO LU†

Abstract. It is shown that the solution of confluent Vandermonde linear systems can be obtained by the Hermite evaluation of rational functions, which can actually be converted to the Hermite evaluation of two polynomials. Based on this result, divide and conquer methods are used to construct a fast algorithm for confluent Vandermonde linear systems. If fast polynomial multiplication and division (fast Fourier transform (FFT)) are used, the algorithm needs only $O(n \log n \log p)$ operations.

Key words. confluent Vandermonde linear system, divide and conquer, FFT

AMS subject classifications. 65F05, 65Y05, 68C25

1. Introduction.

Let $a_0, a_1, \ldots, a_p$ be $p+1$ numbers, $n_0, n_1, \ldots, n_p$ be $p+1$ positive integers and $p(x) = (1, x, \ldots, x^{n-1})^T$, where $n = \sum_{i=0}^{p} n_i$. The confluent Vandermonde matrix, denoted by $V(a_0, \ldots, a_p, n_0, \ldots, n_p)$ or, briefly V_c, is given by

$$V_c = (p(a_0), p'(a_0), \ldots, p^{(n_0-1)}(a_0), \ldots, p(a_p), p'(a_p), \ldots, p^{(n_p-1)}(a_p)) \tag{1.1}$$

(see [4], [8]). In the case of $n_0 = n_1 = \cdots = n_p = 1$, V_c yields the well-known Vandermonde matrix. If $p(x) = (p_1(x), p_2(x), \ldots, p_n(x))^T$, where $p_i(x)$ is a polynomial of degree $i-1$, (1.1) defines the confluent Vandermonde-like matrix V_c^l [13] and the Vandermonde-like matrix [9], [12] if $n_0 = n_1 = \cdots = n_p = 1$. Consider confluent Vandermonde linear systems

$$V_c u = b. \tag{1.2}$$

These systems are associated with the construction of quadrature formulae [1], [11], [15], [17] and the approximation of linear functionals [2], [21].

If Gaussian elimination for solving dense systems of linear equations is applied to (1.2), it requires $O(n^3)$ operations. Fortunately, it is shown that operations of solving some special linear systems such as Vandermonde systems [5], [16], confluent Vandermonde systems [4], Vandermonde-like systems [12], and confluent Vandermonde-like systems [13] can be further reduced. Based on forward and backward vector recursion, Björck, Elfving, and Pereyra [4], [5] presented some fast algorithms for both Vandermonde and confluent Vandermonde linear systems in the early 1970s. Their algorithms require $O(n^2)$ operations. In 1988 and 1990, Higham [12], [13] considered the generalization of Vandermonde linear systems and confluent Vandermonde linear systems, i.e., Vandermonde-like systems and confluent Vandermonde-like systems. He derived some $O(n^2)$ fast algorithms for both systems for the case where the polynomials $p_1(x)$, $p_1(x)$, $\ldots$, $p_n(x)$ satisfy a three-term recurrence relation that generalizes the early ones for $p_k(x) = x^{k-1}$. Recently, the author [16] showed that the solution of Vandermonde linear systems can be obtained by the evaluation of certain polynomials. We state the result here for use later in the paper. For convenience, quot$(A(x), B(x))$

denotes the quotient of polynomial division $A(x)/B(x)$, i.e., ignoring the remainder $r(x)$: $A(x) = B(x)\text{quot}(A(x), B(x)) + r(x)$, throughout the paper.

THEOREM 1.1. *Let $V = V(a_1, a_2, \ldots, a_n)$ be the Vandermonde matrix of order n, $a_i \neq a_j$, $i \neq j, i, j = 1, 2, \ldots, n$, and*

$$L(x) = (x - a_1)(x - a_2) \cdots (x - a_n),$$

$$L_i(x) = \frac{L(x)}{x - a_i}, \qquad i = 1, 2, \ldots, n.$$

Then the solution of the Vandermonde linear system

$$Vu = b \tag{1.3}$$

is given by

$$u_i = \frac{g(a_i)}{L_i(a_i)}, \qquad i = 1, 2, \ldots, n, \tag{1.4}$$

where

$$g(x) = \text{quot}(L(x)b(x), x^n),$$

$$b(x) = b_1 x^{n-1} + b_2 x^{n-2} + \cdots + b_{n-1}x + b_n.$$

Based on this result, the author [16] gave a new fast algorithm for solving Vandermonde linear systems with $O(n \log^2 n)$ operations by using fast polynomial multiplication and division.

Let $r(x)$ be a rational function and $a_0, a_1, \ldots, a_p$ be $p + 1$ numbers, where p is a nonnegative integer. The Hermite evaluation of $r(x)$ is to compute

$$r^{(k)}(a_i), \quad k = 0, 1, \ldots, n_i - 1, \quad i = 0, 1, \ldots, p,$$

where $n_0, n_1, \ldots, n_p$ are positive integers.

The purpose of this paper is to extend Theorem 1.1 to confluent Vandermonde systems and to construct an asymptotically fast algorithm with $O(n \log n \log p)$ operations for the linear systems (1.2) by using the divide and conquer method. To the best of our knowledge, the method presented here is the fastest method known for solving confluent Vandermonde systems. In §2, we focus our attention on the proof that the solution of confluent Vandermonde linear systems can be obtained by the Hermite evaluation of rational functions, and we derive the inverse of confluent Vandermonde matrices as well as the determinant of the matrices. Based on the result given in §2, we convert the Hermite evaluation of rational functions to the Hermite evaluation of polynomials, which, as we will see, can be done only by the Hermite evaluation of two polynomials in §3. To obtain a fast algorithm for solving confluent Vandermonde linear systems, we use the divide and conquer method. In §4, we analyze the computational complexity of the algorithm presented in §3. It is shown that if fast polynomial multiplication and division are used in the algorithm, the algorithm needs only $O(n \log n \log p)$ operations.

2. Solution of confluent Vandermonde linear systems. As we have seen, the solution of Vandermonde linear systems can be obtained by evaluating certain polynomials so that a stable algorithm for the equations can be constructed easily. The question arises naturally: Does a similar result for confluent Vandermonde linear systems exist? The answer to this question is the purpose of this section.

Let $p(x) = (p_1(x), \ldots, p_n(x))^T$, where $p_k(x)$ is a polynomial of degree $k-1$ and denote

$$p[x] = p(x),$$

$$p[x_0, \ldots, x_k] = (p_1[x_0, \ldots, x_k], \ldots, p_n[x_0, \ldots, x_k])^T,$$

where $p_i[x_0, \ldots, x_k]$ is the kth divided difference of $p_i(x)$ at $x_0, \ldots, x_k$ defined by

$$p_i[x_0, \ldots, x_k] = \frac{p_i[x_1, \ldots, x_k] - g_i[x_0, \ldots, x_{k-1}]}{x_k - x_0}.$$

If $x_{i+1} - x_i = x_i - x_{i-1} = h(\neq 0)$, induction shows that

$$p[x_0, x_1, \ldots, x_k] = \frac{1}{k!\, h^k} \sum_{i=0}^{k} (-1)^{k-i} \binom{k}{i} p(x_i) \tag{2.1}$$

and

$$\lim_{h \to 0} p[x_0, x_1, \ldots, x_k] = \frac{1}{k!} (\underbrace{0, \ldots, 0}_{k}, p_{k+1}^{(k)}(x_0), \ldots, p_n^{(k)}(x_0)). \tag{2.2}$$

Partitioning the confluent Vandermonde-like matrix V_c^l as

$$V_c^l = (B_0, B_1, \ldots, B_p),$$

where B_k is an $n \times n_k$ matrix with (i,j) entry $p_i^{(j-1)}(a_k)$, we immediately have the following limit equality concerning B_k from (2.2):

$$B_k = \lim_{h \to 0} Q_k \operatorname{diag}(1, 1, 2!, \ldots, (n_k - 1)!), \tag{2.3}$$

where Q_k is an $n \times n_k$ matrix with (i,j) entry

$$p_i[a_k, a_k + h, \ldots, a_k + (j-1)h].$$

Now we investigate the relation between Q_k and an $n \times n_k$ Vandermonde-like matrix $M_k(h)$ with (i,j) entry $p_i(a_k + (j-1)h)$. Equality (2.1) acts as the key for relating these two matrices. In fact, from (2.1) Q_k can be decomposed as the product of $M_k(h)$ and an $n_k \times n_k$ upper triangular matrix, i.e.,

$$Q_k = M_k(h) U_k, \tag{2.4}$$

where

$$U_k = \begin{pmatrix} 1 & -1 & 1 & \cdots & (-1)^{n_k-1} \\ & 1 & -2 & \cdots & (-1)^{n_k-2} \binom{n_k-1}{1} \\ & & 1 & \cdots & (-1)^{n_k-3} \binom{n_k-1}{2} \\ & & & \ddots & \vdots \\ & & & & 1 \end{pmatrix}$$

$$\operatorname{diag}\left(1, h^{-1}, \frac{1}{2!}h^{-2}, \ldots, \frac{1}{(n_k-1)!}h^{1-n_k}\right).$$

Therefore,

$$(Q_0, \ldots, Q_p) = (M_0(h), \ldots, M_p(h))\text{blockdiag}(U_0, \ldots, U_p). \tag{2.5}$$

In particular, (2.3) and (2.5) imply that

$$V_c^l = \lim_{h\to 0}(M_0(h), \ldots, M_p(h))\text{blockdiag}(\tilde{U}_0, \ldots, \tilde{U}_p). \tag{2.6}$$

where $\tilde{U}_i = U_i \operatorname{diag}(1, 1, 2!, \ldots, (n_i-1)!)$. Assume that $p_k(x) = x^{k-1} + a_{k,k-1}x^{k-2} + \cdots + a_{k0}$. A simple computation shows the following result.

PROPOSITION 2.1. *Let*

$$V_c^l = (p(a_0), p'(a_0), \ldots, p^{(n_0-1)}(a_0), \ldots, p(a_p), p'(a_p), \ldots, p^{(n_p-1)}(a_p))$$

be a confluent Vandermonde-like matrix, where $p(x) = (p_1(x), p_2(x), \ldots, p_n(x))^T$ *and* $p_k(x) = x^{k-1} + a_{k,k-1}x^{k-2} + \cdots + a_{k0}$. *Then*

$$\det(V_c^l) = \left(\prod_{i=0}^{p}\prod_{k=0}^{n_i-1} k!\right)\prod_{p\geq i>j\geq 0}(a_i - a_j)^{n_i n_j}. \tag{2.7}$$

In the case of $p_k(x) = x^{k-1}$, $(B_0, \ldots, B_p)$ and $(M_0(h), \ldots, M_p(h))$ yield a confluent Vandermonde matrix and a Vandermonde matrix, respectively. Our next theorem shows that the solution of confluent Vandermonde linear systems can be computed by the Hermite evaluation of rational functions.

THEOREM 2.2. *Let* $V_c u = b$ *be the confluent Vandermonde linear system given by* (1.2) *and*

$$\begin{aligned} l(x) &= \prod_{i=0}^{p}(x - a_i)^{n_i}, \\ l_i(x) &= \frac{l(x)}{(x-a_i)^{n_i}}, \qquad i = 0, 1, \ldots, p, \\ b(x) &= b_n + b_{n-1}x + \cdots + b_1 x^{n-1}, \\ q(x) &= \operatorname{quot}(l(x)b(x), x^n), \end{aligned}$$

where $a_i \neq a_j$, $i \neq j$, $i, j = 0, 1, \ldots, p$, *and* $n = \sum_{t=0}^{p} n_t$. *Then, the solution of the system is given by*

$$u_i = \frac{1}{(k-1)!(n_j-k)!}\left(\frac{q(x)}{l_j(x)}\right)^{(n_j-k)}\Bigg|_{x=a_j}, \tag{2.8}$$

$$i = m_j + k, \quad 0 \leq j \leq p, \quad 1 \leq k \leq n_j, \quad m_0 = 0, \quad m_j = \sum_{t=0}^{j-1} n_t,$$

Proof. Set

$$d_i = a_j + (k-1)h, \quad i = m_j + k, \quad 0 \le j \le p, \quad 1 \le k \le n_j,$$
$$\bar{l}(x) = \prod_{i=1}^{n}(x - d_i),$$
$$\bar{l}_i(x) = \frac{\bar{l}(x)}{x - d_i},$$
$$\bar{q}(x) = \operatorname{quot}(\bar{l}(x)b(x), x^n).$$

Consider a linear system

$$M(h)\operatorname{blockdiag}(\tilde{U}_0, \ldots, \tilde{U}_p)u(h) = b \tag{2.9}$$

where $M(h) = (M_0(h), \ldots, M_p(h))$, and denote

$$v(h) = (v_1(h), \ldots, v_n(h))^T = \operatorname{blockdiag}(\tilde{U}_0, \ldots, \tilde{U}_p)u(h). \tag{2.10}$$

Under the assumptions of Theorem 2.2, $M(h)$ becomes a nonsingular Vandermonde matrix if h is sufficiently small. Theorem 1.1 shows that

$$v_i(h) = \frac{\bar{q}(d_i)}{\bar{l}_i(d_i)}, \qquad i = 1, 2, \ldots, n. \tag{2.11}$$

On the other hand, a computation shows that the inverse of $\tilde{U}_j$ is of the form

$$\tilde{U}_j^{-1} = \operatorname{diag}(1, h, h^2, \ldots, h^{n_j-1}) \begin{pmatrix} 1 & 1 & 1 & \cdots & 1 \\ & 1 & 2 & \cdots & \binom{n_j-1}{1} \\ & & 1 & \cdots & \binom{n_j-1}{2} \\ & & & \ddots & \vdots \\ & & & & 1 \end{pmatrix}.$$

Hence,

$$\begin{aligned} u_i(h) &= h^{k-1} \sum_{t=k}^{n_j} \binom{t-1}{k-1} \frac{\bar{q}(d_t)}{\bar{l}_i(d_t)} \\ &= \frac{1}{h^{n_j-k}} \sum_{t=k}^{n_j} \frac{(-1)^{n_j-t}}{(t-1)!(n_j-t)!} \binom{t-1}{k-1} \frac{\bar{q}(d_t)}{\tilde{l}_j(d_t)} \\ &= \frac{1}{h^{n_j-k}} \frac{1}{(k-1)!(n_j-k)!} \sum_{t=k}^{n_j} \binom{n_j-k}{t-k} \frac{\bar{q}(d_t)}{\tilde{l}_j(d_t)} \\ &= \frac{1}{(k-1)!(n_j-k)!} \left(\frac{\bar{q}(x)}{\tilde{l}_j(x)} \right)^{(n_j-k)} \Bigg|_{x=\xi_{kj}}, \end{aligned}$$

where $a_j + (k-1)h \le \xi_{kj} \le a_j + (n_j-1)h$ and

$$\tilde{l}_j(x) = \frac{\bar{l}(x)}{\prod_{i=m_j+1}^{m_j+n_j}(x - d_i)}, \qquad j = 0, 1, \ldots, p.$$

Since $a_i \neq a_j$, $i \neq j$, $i,j = 0,1,\ldots,p$, Proposition 2.1 shows that V_c is nonsingular. Furthermore, because the set of all nonsingular matrices is an open set, we have

$$\begin{aligned} u_i &= \lim_{h\to 0} u_i(h) \\ &= \lim_{h\to 0} \frac{1}{(k-1)!(n_j-k)!} \left(\frac{\bar{q}(x)}{\tilde{l}_j(x)} \right)^{(n_j-k)} \Bigg|_{x=\xi_{kj}} \\ &= \frac{1}{(k-1)!(n_j-k)!} \left(\frac{q(x)}{l_j(x)} \right)^{(n_j-k)} \Bigg|_{x=a_j}. \end{aligned} \qquad \square$$

Let

$$e_i = (\underbrace{0,\ldots,0,1}_{i},0,\ldots,0), \qquad i = 1,2,\ldots,n,$$

and $V_c^{-1} = (b_{ij})$ if V_c is nonsingular. Clearly, $v_j = (b_{1j}, b_{2j}, \ldots, b_{nj})^T$ is the solution of $V_c v_j = e_j$. Proposition 2.1 and Theorem 2.2 show the following result on the inverse of confluent Vandermonde matrices.

COROLLARY 2.3. *The confluent Vandermonde matrix*

$$V_c = V(a_0,\ldots,a_p,n_0,\ldots,n_p)$$

defined by (1.1) *is nonsingular if and only if* $a_i \neq a_j$, $i \neq j$, $i,j = 0,1,\ldots,p$. *Let* $V_c^{-1} = (b_{ij})$ *if* V_c *is nonsingular. Then*

$$b_{ij} = \frac{1}{(k-1)!(n_t-k)!} \left(\frac{q_j(x)}{l_t(x)} \right)^{(n_t-k)} \Bigg|_{x=a_t}, \tag{2.12}$$

$$i = \sum_{r=0}^{t-1} n_r + k, \quad 1 \leq k \leq n_t, \quad 0 \leq t \leq p, \quad j = 1,2,\ldots,n,$$

where $q_j(x) = \mathrm{quot}(l(x), x^j)$, $j = 1,2,\ldots,n$, $l(x)$ *and* $l_i(x)$, $i = 1,2,\ldots,n$, *are given in Theorem* 2.2.

3. Algorithm. Based on the result given in the previous section, divide and conquer methods are used to construct a fast algorithm for solving confluent Vandermonde linear systems in this section. To this end, we denote

$$R_j(x) = \frac{q(x)}{l_j(x)}, \qquad j = 0,1,\ldots,p \tag{3.1}$$

and expand $R_j(x)$, $q(x)$, and $l_j(x)$ in Taylor series at a_j, i.e.,

$$R_j(x) = \sum_{t=0}^{n_j-1} r_{jt}(x-a_j)^t + O((x-a_j)^{n_j}), \tag{3.2a}$$

$$q(x) = \sum_{t=0}^{n_j-1} q_{jt}(x-a_j)^t + O((x-a_j)^{n_j}), \tag{3.2b}$$

$$l_j(x) = \sum_{t=0}^{n_j-1} l_{jt}(x-a_j)^t + O((x-a_j)^{n_j}). \tag{3.2c}$$

It follows from Theorem 2.2 that the solution of confluent Vandermonde linear systems is given by

$$u_i = \frac{r_{j,n_j-k}}{(k-1)!}, \quad i = \sum_{t=0}^{j-1} n_t + k, \quad k = 1,2,\ldots,n_j. \tag{3.3}$$

Comparing the coefficients of equality $R_j(x)l_j(x) = q(x)$ shows that the vector $r_j = (r_{j0}, r_{j1}, \ldots, r_{j,n_j-1})^T$ is the solution of the triangular Toeplitz linear system

$$T_j r_j = q_j, \tag{3.4}$$

where T_j is the triangular Toeplitz matrix of the form

$$T_j = \begin{pmatrix} l_{j0} & & & \\ l_{j1} & l_{jo} & & \\ \ddots & \ddots & \ddots & \\ l_{j,n_j-1} & \ddots & l_{j1} & l_{j0} \end{pmatrix},$$

or simply $\mathrm{tri}(l_{j0}, \ldots, l_{j,n_j-1})$ for convenience, $q_j = (q_{j0}, q_{j1}, \ldots, q_{j,n_j-1})^T$, and

$$q_{jk} = \frac{1}{k!} q^{(k)}(a_j), \quad k = 0, \ldots, n_j - 1, \quad j = 0, \ldots, p. \tag{3.5}$$

Equality $l(x) = (x-a_j)^{n_j} l_j(x)$ implies

$$l_{jk} = \frac{l_j^{(k)}(a_j)}{k!} = \frac{l^{(n_j+k)}(a_j)}{(n_j+k)!}, \quad k = 0, \ldots, n_j - 1, \quad j = 0, \ldots, p. \tag{3.6}$$

To construct a fast algorithm for confluent Vandermonde linear systems, we need a fast algorithm for the Hermite evaluation of polynomials such that the algorithm can easily be adjusted to evaluate two polynomials $q(x)$ and $l(x)$ by adding minimum operations. To do this, consider first the Hermite evaluation of polynomials.

Let $q(x)$ be a polynomial of degree at most $n-1$, $a_0, a_1, \ldots, a_p$ be $p+1$ distinct numbers, and $n_0, n_1, \ldots, n_p$ be $p+1$ positive integers. Consider the Hermite evaluation of $q(x)$

$$q^{(k)}(a_i), \quad k = 0, 1, \ldots, n_i - 1, \quad i = 0, 1, \ldots, p.$$

Without loss of generality, assume $n = \sum_{t=0}^{p} n_t = 2^m$ for some positive integer m. Denote

$$c_{m_i+j} = a_i, \quad m_i = \sum_{k=0}^{i-1} n_k, \quad j = 1, \ldots, n_i, \quad i = 0, \ldots, p,$$

$$T_{0i}(x) = x - c_i, \qquad i = 1, 2, \ldots, n,$$

$$T_{ji}(x) = T_{j-1,2i-1}(x) T_{j-1,2i}(x), \quad i = 1, \ldots, 2^{m-j}, \quad j = 1, 2, \ldots, m. \tag{3.7}$$

Dividing $q(x)$ by $T_{m-1,1}(x)$ and $T_{m-1,2}(x)$ and denoting the remainders by $r_{m-1,1}(x)$ and $r_{m-1,2}(x)$, respectively, i.e.,

$$q(x) = q_{m-1,1}(x)T_{m-1,1}(x) + r_{m-1,1}(x), \tag{3.8a}$$

$$q(x) = q_{m-1,2}(x)T_{m-1,2}(x) + r_{m-1,2}(x), \tag{3.8b}$$

one finds that

$$q^{(j)}(a_i) = r^{(j)}_{m-1,1}(a_i), \quad j = 0, 1, \ldots, n_i - 1, \quad i < t, \tag{3.9a}$$

$$q^{(j)}(a_i) = r^{(j)}_{m-1,2}(a_i), \quad j = 0, 1, \ldots, n_i - 1, \quad i > t, \tag{3.9b}$$

where t is the nonnegative integer such that $c_{2^{m-1}} = a_t$. We compute directly $q^{(j)}(a_t)$, $j = 0, 1, \ldots, n_t - 1$. Thus, repeating the procedure to $r_{m-1,1}(x)$ and $r_{m-1,2}(x)$ finishes the computation $q^{(j)}(a_i)$, $j = 0, 1, \ldots, n_i - 1$, $i \neq t$.

To obtain $r_{m-1,1}(x)$ and $r_{m-1,2}(x)$ from (3.8a) and (3.8b), we need two polynomial divisions of polynomials. It is somewhat expensive, though some $O(n \log n)$ algorithms exist for polynomial division [3]. Fortunately, preprocessing can be used to reduce operations in cases where all divisors satisfy (3.7). Given a polynomial $B(x)$ of degree n, by preprocessing $B(x)$, we define the computation of the quotient of x^{2n-1} divided by $B(x)$ (see [18]). Assume that $Q_{ji}(x)$ is the quotient of $x^{2^{j+1}-1}$ divided by $T_{ji}(x)$. It is not hard to see from (3.7) that

$$Q_{j-1,2i-1}(x) = \mathrm{quot}(T_{j-1,2i}(x)Q_{ji}(x), x^{2^j}), \tag{3.10a}$$

$$Q_{j-1,2i}(x) = \mathrm{quot}(T_{j-1,2i-1}(x)Q_{ji}(x), x^{2^j}) \tag{3.10b}$$

are the quotient of x^{2^j-1} divided by $T_{j-1,2i-1}(x)$ and x^{2^j-1} divided by $T_{j-1,2i}(x)$, respectively. After preprocessing, the polynomial division can be computed by using the following result (see [18] for details).

PROPOSITION 3.1. *Let*

$$A(x) = \sum_{i=0}^{\bar{n}} a_i x^i, \quad B(x) = \sum_{i=0}^{n} b_i x^i, \quad (a_{\bar{n}} \neq 0, b_n \neq 0, \bar{n} \geq n),$$

$D(x)$ be the result of preprocessing $B(x)$ and $K(x) = \mathrm{quot}(A(x), x^n)$. Then

$$Q(x) = \mathrm{quot}(D(x)K(x), x^{n-1}), \tag{3.11}$$

$$R(x) = A(x) - Q(x)B(x), \tag{3.12}$$

are the quotient and the remainder of division $A(x)/B(x)$, respectively.

Similarly, we can compute $l^{(n_i+j)}(a_i)$, $j = 0, 1, \ldots, n_i - 1$, $i = 0, 1, \ldots, p$ in the following way. Dividing $l(x)$ by $T^2_{m-1,1}(x)$ and $T^2_{m-1,2}(x)$, we have

$$l(x) = \tilde{q}_{m-1,1}(x)T^2_{m-1,1}(x) + \tilde{r}_{m-1,1}(x), \tag{3.13a}$$

$$l(x) = \tilde{q}_{m-1,2}(x)T^2_{m-1,2}(x) + \tilde{r}_{m-1,2}(x), \tag{3.13b}$$

where $\tilde{r}_{m-1,1}(x)$ and $\tilde{r}_{m-1,2}(x)$ are the remainders. Hence,

$$l^{(n_i+j)}(a_i) = \tilde{r}^{(n_i+j)}_{m-1,1}(a_i), \quad j = 0, 1, \ldots, n_i - 1, \quad i < t, \tag{3.14a}$$

$$l^{(n_i+j)}(a_i) = \tilde{r}^{(n_i+j)}_{m-1,1}(a_i), \quad j = 0, 1, \ldots, n_i - 1, \quad i > t, \tag{3.14b}$$

where t is the same as in (3.9). We then compute for t

$$l^{(n_t+j)}(a_t), \qquad j = 0, 1, \ldots n_t - 1,$$

in the same way as in the computation of $q^{(j)}(a_t)$. It is not necessary to preprocess $T^2_{ji}(x)$ after preprocessing $T_{ji}(x)$. In fact, let $\tilde{A}(x)$ and $\tilde{B}(x)$ be two polynomials of degree $\bar{n}$ and let n ($\bar{n} \geq 2n$), respectively, and let $\tilde{D}(x)$ be the result of preprocessing $\tilde{B}(x)$. Using Proposition 3.1 to $\tilde{A}(x)$ and $\tilde{B}(x)$, we obtain $\tilde{Q}(x)$ the quotient of $\tilde{A}(x)/\tilde{B}(x)$. $\bar{Q}(x)$ the quotient of $\tilde{Q}(x)/\tilde{B}(x)$ is clearly the quotient of $\tilde{A}(x)/\tilde{B}^2(x)$. Therefore, the corresponding remainder can be computed by

$$\tilde{R}(x) = \tilde{A}(x) - \bar{Q}(x)\tilde{B}^2(x). \tag{3.15}$$

Based on our discussion, we now give an algorithm for confluent Vandermonde linear systems.

ALGORITHM 3.2. The algorithm is divided into two stages. At stage I, the algorithm converts all polynomials defined by (3.7) into the form $\sum h_i x^i$, computes $r_{m1}(x)$, i.e., $q(x)$ given in Theorem 2.2, and preprocesses $T_{m1}(x)$. At stage II, we continue to preprocess $T_{ji}(x)$ for $j \leq m-1$ by using (3.10). For clarity, functions **Div1** and **Div2**, which are based on Proposition 3.1 and our later discussion, are used to compute the remainders $r_{ji}(x)$ and $\tilde{r}_{ji}(x)$, respectively. For the sake of reducing the operations as explained in §4, the remainders $\tilde{r}_{m-1,i}(x)$, $i = 1, 2$, are computed directly by polynomial division. After finding a proper a_l, the algorithm calls the algorithm **Solution** to solve the corresponding triangular Toeplitz linear system (3.4) and obtain u_i ($m_l + 1 \leq i \leq m_l + n_l$), the solution of the confluent Vandermonde linear system (1.2). Again for clarity, we delete the details for the algorithm **Solution** here, which is given in the next section.

Stage I: $c_{m_i+j} = a_i$, $m_0 = 0$, $m_i = \sum_{k=0}^{i-1} n_k$,
$j = 1, \ldots, n_i$, $i = 0, \ldots, p$,
$T_{0i} = x - c_i$, $i = 1, 2, \ldots, n$, $b = b_1 x^{n-1} + \cdots + b_{n-1}x + b_n$,
$S_{m1} = \{0, 1, \ldots, p\}$
For $j = 1 : 1 : m$
  For $i = 1 : 1 : 2^{m-j}$
    $T_{ji} = T_{j-1,2i-1} T_{j-1,2i}$
  endfor i
endfor j

end

where $\lceil x \rceil$ is the integer ceiling function of x.

4. Computational complexity. In this section, we analyze the computational complexity of Algorithm 3.2. The following two propositions estimate the operations needed by the algorithm if the FFT is used to compute polynomial multiplications and polynomial divisions in the algorithm.

PROPOSITION 4.1. *If fast polynomial multiplication and division are used, Stage* I *of Algorithm* 3.2 *needs at most* $O(n \log n \log p)$ *operations.*

Proof. Recall our algorithm, where $r_{m1}(x)$ and $Q_{m1}(x)$ can be computed by using directly fast polynomial multiplication and division, respectively. Both need $O(n \log n)$ operations.

Let $A(x)$ and $B(x)$ be two polynomials of degree $\bar{n}$ and $\bar{m}$ ($\bar{n} \geq \bar{m} \geq 2$), respectively. If the FFT is used to compute $A(x)B(x)$, it is well known that there exists a constant C_1 independent of $\bar{n}$ and $\bar{m}$ such that

$$C(\bar{n}, \bar{m}) \leq C_1 \bar{n} \log \bar{m}.$$

Denote the operations needed to compute all $T_{ji}(x)$ at Stage I by $T(n, p)$. In the case of $p = 0$,

$$T_{ji}(x) = (x-a)^{2^j} = \sum_{t=0}^{2^j} (-1)^t a^t \begin{pmatrix} 2^j \\ t \end{pmatrix} x^{2^j - t},$$

which can clearly be computed by using $C_2'(2^j + 1)$ operations. Thus the computation of all $T_{ji}(x)$ in this case needs only $C_2 n$ operations, where C_2' and C_2 are constants independent of n. We claim generally that

$$T(n, p) \leq C(n \log n \log(p+1) + n), \tag{4.1}$$

where $C = \max(C_1, C_2)$.

Note first that (4.1) holds for $p = 0$ implies that (4.1) is true if $n + p = 1$. We prove (4.1) by induction on $n + p$.

Assume all $T_{ji}(x)$, $j \leq m-1$ have been finished and let

$$T_{m-1,1}(x) = (x-a_0)^{n_0} \dots (x-a_{t-1})^{n_{t-1}} (x-a_t)^{k_t},$$

$$T_{m-1,2}(x) = (x-a_t)^{\bar{k}_t} (x-a_{t+1})^{n_{t+1}} \dots (x-a_p)^{n_p},$$

where $0 \leq k_t \leq n_t - 1$ and $\bar{k}_t = n_i - k_t$. Clearly, $T_{m-1,1}(x) = (x-a_0)^{\frac{n}{2}}$ if $t = 0$, or $t = 1$ and $k_1 = 0$, and $T_{m-1,2} = (x-a_p)^{\frac{n}{2}}$ if $t = p$. In the case of $t = 0$ or $t = 1$ and $k_1 = 0$, all $T_{ji}(x)$, $1 \leq j \leq m-1, 1 \leq i \leq 2^{m-j-1}$ can be computed by using at most $C\frac{n}{2}$ operations. Hence

$$\begin{aligned} T(n,p) &\leq T\left(\frac{n}{2}, p\right) + C\frac{n}{2} + C\frac{n}{2}\log\frac{n}{2} \\ &\leq C\frac{n}{2}\log\frac{n}{2}\log(p+1) + C\frac{n}{2} + C\frac{n}{2}\log\frac{n}{2} \\ &\leq C(n \log n \log(p+1) + n). \end{aligned}$$

If $t = p$, (4.1) is derived in the same way. Otherwise,

$$T(n,p) \leq T\left(\frac{n}{2}, p_1\right) + T\left(\frac{n}{2}, p_2\right) + C\frac{n}{2}\log\frac{n}{2}$$

$$\leq C\frac{n}{2}\log\frac{n}{2}\log(p_1+1)+C\frac{n}{2}\log\frac{n}{2}\log(p_2+1)+C\frac{n}{2}\log\frac{n}{2}+Cn$$

$$= Cn\log\frac{n}{2}\log(2(p_1+1)(p_2+1))^{\frac{1}{2}}+Cn$$

$$\leq Cn\log n\log(2(p_1+1)(p_2+1))^{\frac{1}{2}}+Cn,$$

where $p_1 \leq t$, $p_2 = p-t$. Since $p_1 \geq 1$, $p_2 \geq 1$, and $p_1+p_2 \leq p$, it is easy to check that $(2(p_1+1)(p_2+1))^{\frac{1}{2}} \leq p+1$. Equation (4.1) follows immediately. The overall computational cost of Stage I is $T(n,p)+O(n\log n) = O(n\log n\log p)$. □

PROPOSITION 4.2. *If fast polynomial multiplication and division are used, Stage* II *of Algorithm* 3.2 *needs at most* $O(n\log n\log p)$ *operations.*

Proof. Denote the operations needed for fixed j,i at Stage II by $\bar{T}(j,i)$. The algorithm computes $\tilde{r}_{m-1,i}(x)$, $i=1,2$ by

$$r_{m1}(x)(\bmod T^2_{m-1,i}(x)), \qquad i=1,2.$$

Since $\deg(T^2_{m-1,i}(x)) = \deg(r_{m1}(x))$, after the multiplications $T^2_{m-1,i}(x)$, $i=1,2$, which need $O(n\log n)$ operations, such computation can be done by using $O(n)$ operations. This is the reason we compute $\tilde{r}_{m-1,1}(x)$ and $\tilde{r}_{m-1,2}(x)$ by using polynomial division directly. As for the algorithm **Solution**$(r_{ji},\tilde{r}_{ji},a_l,n_l)$, when Algorithm 3.2 calls **Solution**$(r_{ji},\tilde{r}_{ji},a_l,n_l)$, $2^j \geq n_l$. The total number of operations of performing **Solution** is at most $O(2^j j)$. To see this, let $A(x) = \sum_{i=0}^{\bar{n}} \bar{a}_i x^i$ be a polynomial of degree at most $\bar{n}$. Consider the computation

$$\begin{aligned}
&A(a) = \bar{a}_0+\bar{a}_1 a+\cdots+\bar{a}_{\bar{n}}a^{\bar{n}},\\
&A'(a) = \bar{a}_1+2\bar{a}_2 a+\cdots+\bar{n}\bar{a}_{\bar{n}}a^{\bar{n}-1},\\
&\cdots\cdots,\\
&A^{(\bar{m})}(a) = \bar{m}!\bar{a}_{\bar{m}}+\cdots+\bar{n}\ldots(\bar{n}-\bar{m}+1)a_{\bar{n}}a^{\bar{n}-\bar{m}},
\end{aligned}$$

which can be written as a product of an $(\bar{m}+1)\times(\bar{n}+1)$ Toeplitz matrix with a vector as follows.

$$\begin{pmatrix} A(a)\\ A'(a)\\ \vdots\\ A^{(\bar{m})}(a)\end{pmatrix} = \begin{pmatrix} \bar{n}!\bar{a}_{\bar{n}} & \cdots & \bar{m}!\bar{a}_{\bar{m}} & \cdots & \bar{a}_1 & \bar{a}_0\\ 0 & \bar{n}!\bar{a}_{\bar{n}} & \cdots & \bar{m}!\bar{a}_{\bar{m}} & \cdots & \bar{a}_1\\ \vdots & \ddots & \ddots & & \ddots & \vdots\\ 0 & \cdots & 0 & \bar{n}!\bar{a}_{\bar{n}} & \cdots & \bar{m}!\bar{a}_{\bar{m}}\end{pmatrix}\begin{pmatrix} \frac{a^{\bar{n}}}{\bar{n}!}\\ \vdots\\ a\\ 1\end{pmatrix}.$$

Hence, polynomial multiplication can be applied to such computation. The cost is $O(\bar{n}\log\bar{m})$. Since $r_{ji}(x)$ and $\tilde{r}_{ji}(x)$ are polynomials of degree at most 2^j-1 and $2^{2j}-1$, respectively, the computation of $r^{(t)}_{ji}(a_l)$ and $\tilde{r}^{(t)}_{ji}(a_l)$, $t=0,1,\ldots,n_l-1$ needs at most $O(2^j\log n_l) \leq O(2^j j)$ operations. Triangular Toeplitz linear systems can actually be solved by using polynomial division (see [3] for details). Therefore, solving the linear system included in the algorithm **Solution** needs $O(n_l\log n_l) \leq O(2^j j)$ operations. The rest of the computation at Stage II is multiplication of polynomials of degree at most 2^{2j}. We thus have $\bar{T}(j,i) \leq O(2^j j)$. The overall operation at Stage II is bounded by

$$\sum_{j=m-\lceil\log(p+1)\rceil+1}^{m}\ \sum_{i=0}^{2^{m-j}} O(2^j j) = O(n\log n\log p),$$

which completes the proof. □

Propositions 4.1 and 4.2 show that Algorithm 3.2 needs only $O(n \log n \log p)$ operations if fast polynomial multiplication and division are used.

Acknowledgment. I am grateful to Dr. Nicholas J. Higham for valuable comments on the manuscript and for offering me the reference [13] and the Bibliography on Vandermonde Matrices, and to Professor Gene H. Golub for pointing out [10].

CONDITION AND ACCURACY OF ALGORITHMS FOR COMPUTING SCHUR COEFFICIENTS OF TOEPLITZ MATRICES*

I. GOHBERG†, I. KOLTRACHT‡, AND D. XIAO§

Abstract. A formula for the condition number of Schur coefficients of a positive definite Toeplitz matrix is obtained and an efficient algorithm for computing the condition number is given. New bounds of backward roundoff errors in Schur and Levinson algorithms for computing Schur coefficients are presented. These bounds, together with the condition number, provide a posteriori estimate of the error in computed Schur coefficients. Numerical comparison of Schur and Levinson algorithms with the LDL^T algorithm also indicates their forward stability.

Key words. Toeplitz matrix, Schur coefficients, condition of the problem, stability of algorithms

1. Introduction.

Associated with an $(n+1)\times(n+1)$ positive definite Toeplitz matrix

$$A_n = \{a_{|i-j|}\}_{i,j=0}^{n},$$

there are n parameters $c_1, c_2, \ldots, c_n$ called Schur, or reflection, or partial autocorrelation coefficients (for definition see §2). They appear in a wide variety of applications in science and engineering, such as theory of analytic functions, geophysics, speech processing, statistics, transmission lines and others (see, for example, [1], [3], [9], [11], [13], [15], and [16]). The Schur coefficients are called here S-coefficients and are denoted by $c = (c_1, \ldots, c_n)$.

In the present paper we analyze accuracy of computing S-coefficients by two standard algorithms, the Schur [16] and the Levinson [12] algorithms that are described in §2. In fact, these algorithms can be used to define S-coefficients. We also show in §2 that S-coefficients can be determined by the LDL^T decomposition of a certain positive definite matrix defined by $a_0, \ldots, a_n$. The Schur and Levinson algorithms are known as fast algorithms since they give the S-coefficients in $O(n^2)$ arithmetic operations. The algorithm based on LDL^T factorization is of $O(n^3)$.

To analyze the accuracy of computed S-coefficients, it is useful to consider the condition number of the corresponding map

$$F : (a_0, \ldots, a_n) \to (c_1, \ldots, c_n),$$

at the point $a = (a_0, \ldots, a_n)$, which is given by the expression

$$k(F, a) = \frac{\|F'(a)\|\|a\|}{\|c\|}. \tag{1.1}$$

Here $F'(a)$ is the derivative of F at a and $\|F'(a)\|$ is an operator norm of a linear map induced by vector norms of a and Fa. If x is a perturbation of a such that

$$\|x - a\| \leq \epsilon \|a\|,$$

then

$$\frac{\|Fx - Fa\|}{\|Fa\|} \leq k(F, a)\epsilon + o(\epsilon), \tag{1.2}$$

(see, for example, Belitzkii and Lyubich [20]). In §2 we obtain a formula for the derivative of the map of S-coefficients and we give an efficient algorithm for computing the condition number $k(F, a)$. We also find lower and upper bounds for $k(F, a)$ that differ, at most, by a factor of n from lower and upper bounds for the usual condition number of $A_{n-1} = \{a_{|i-j|}\}_{i,j=0}^{n-1}$, $k(A_{n-1}) = \|A_{n-1}\|\|A_{n-1}^{-1}\|$, given by Cybenko [4]. Extensive numerical experiments in §5 show that the ratio of $k(A_{n-1})$ and $k(F, a)$ is, in fact, of order unity; therefore, we presume that there is little difference between $k(A_{n-1})$ and $k(F, a)$. (Similar results for the condition numbers of the inversion of a positive definite Toeplitz matrix and the solution of Yule–Walker equations can be found in Gohberg and Koltracht [5] and Golhberg, Koltracht, and Xiao [7], respectively.)

In §4, we present the backward roundoff error analysis for Schur and Levinson algorithms. The obtained bounds improve previously known results by Bultheel [2]. The essential factor of the backward error bound in the Schur algorithm is $\prod_{j=1}^{n-1}(1 + |\bar{c}_j|)$; in the Levinson algorithm it is $(\prod_{j=1}^{n-1}(1 + |\bar{c}_j|))^2$, where $\bar{c}_1, \ldots, \bar{c}_n$ are the computed S-coefficients. Since the essential factor is squared in the error bound for the Levinson algorithm, we conclude that the Schur algorithm might be more trustworthy than the Levinson algorithm. (For the general definition of trustworthiness, see Stoer and Bulirsch [17, §1.3].) This conclusion is supported by numerical experiments in §5 that consistently show higher accuracy in the Schur algorithm. The obtained error bounds do not imply that either of the algorithms is backward stable on the class of all positive definite Toeplitz matrices; indeed, the attainable maximum for $\prod_{j=1}^{n-1}(1 + |\bar{c}_j|)$ is 2^{n-1}. The obtained backward error bounds have, however, the following practical significance: If the computed S-coefficients (say, by the Schur algorithm) satisfy the inequality

$$4n^2 \prod_{j=1}^{n-1}(1 + |\bar{c}_j|)k(F, a)u \leq 10^{-p}, \tag{1.3}$$

where u is the unit roundoff error, then at least p correct figures can be guaranteed in the computed results.

Further insight into numerical behaviour of Schur and Levinson algorithms can be obtained by comparing them with the numerically stable LDL^T algorithm of Martin, Peters, and Wilkinson [14]. Under the presumption that $k(F, a) \approx k(A_{n-1})$, this algorithm is forward stable for computing S-coefficients. Namely, the error in the computed vector of S-coefficients, $\bar{c}$, is given by

$$\frac{\|c - \bar{c}\|}{\|c\|} \leq Kn^{3/2}k(A_{n-1})u + o(u), \tag{1.4}$$

where K is a constant of order unity. Numerical comparisons in §5 suggest that Schur and Levinson algorithms are also forward stable although, in the majority of the

experiments, the LDL^T type algorithm is more accurate than the Schur algorithm, which in turn is more accurate than the Levinson algorithm.

The effects of finite precision arithmetic on the computation of S-coefficients from underlying time series rather than from the autocorrelation sequence and in fixed point rather than floating point arithmetic are studied by Alexander and Rhee [18] and Rialan and Scharf [19].

2. S-coefficients. Let $A_n = \{a_{|i-j|}\}_{i,j=0}^n$ be a real symmetric positive definite Toeplitz matrix. The S-coefficients of A_n are defined recursively. One such recursion is the Schur algorithm [17].

ALGORITHM 1

1. Start with

$$p_0(0) = q_0(0) = 1, \qquad E_0 = a_0,$$

$$p_0(i) = q_0(i) = -a_i, \qquad i = 1, \dots, n.$$

2. For $k = 0, 1, \dots, n-2$ let

$$c_{k+1} = p_k(k+1)/E_k,$$

$$E_{k+1} = (1 - c_{k+1}^2)E_k,$$

$$\begin{bmatrix} p_{k+1}(k+2) & q_{k+1}(k+2) \\ \vdots & \vdots \\ p_{k+1}(n) & q_{k+1}(n) \end{bmatrix} = \begin{bmatrix} p_k(k+2) & q_k(k+1) \\ \vdots & \vdots \\ p_k(n) & q_k(n-1) \end{bmatrix} \begin{bmatrix} 1 & c_{k+1} \\ c_{k+1} & 1 \end{bmatrix}.$$

3. $c_n = p_{n-1}(n)E_{n-1}^{-1}$.

The numbers $c_1, \dots, c_n$ are the S-coefficients of A_n. The S-coefficients can also be calculated (see, for example, Gohberg, el al. [6]) by the Levinson [1] algorithm.

ALGORITHM 2

1. $q_0(0) = 1, \quad E_0 = a_0$.
2. For $k = 1, 2, \dots, n$

$$c_k = -E_{k-1}^{-1} \sum_{j=0}^{k-1} a_{j+1} q_{k-1}(j),$$

$$\begin{bmatrix} q_k(0) \\ \vdots \\ q_k(k) \end{bmatrix} = \begin{bmatrix} 0 \\ q_{k-1}(0) \\ \vdots \\ q_{k-1}(k-1) \end{bmatrix} + c_k \begin{bmatrix} q_{k-1}(k-1) \\ \vdots \\ q_{k-1}(0) \\ 0 \end{bmatrix},$$

$$E_k = E_{k-1} * (1 - c_k^2).$$

We use the same notation $q_k(0),\dots,q_k(k)$ in Algorithm 2 and $q_k(k+1),\dots,q_k(n)$ in Algorithm 1 because, if we put them together, these numbers satisfy the equation

$$\begin{bmatrix} A_k & 0 \\ A_k^c & I \end{bmatrix} \begin{bmatrix} q_k(0) \\ \vdots \\ q_k(k) \\ \vdots \\ q_k(n) \end{bmatrix} = E_k \begin{bmatrix} 0 \\ \vdots \\ 0 \\ 1 \\ 0 \\ \vdots \\ 0 \end{bmatrix},$$

where $A_k = \{a_{|i-j|}\}_{i,j=0}^{k}$, $A_k^c = \{a_{|i-j|}\}_{i=k+1,\dots,n}^{j=0,\dots,k}$, and 1 in the right-hand side is in position $k+1$. The above equation can be used to obtain the LDL^T factorization of A_n and the L^TDL factorization of A_n^{-1} in terms of the quantities computed in Algorithms 1 and 2, respectively. (See, for example, [6].) In fact, it holds that

$$A_n = \begin{bmatrix} 1 & 0 & \dots & 0 \\ -q_0(1)/E_0 & 1 & \dots & 0 \\ \vdots & \vdots & \dots & 0 \\ -q_0(n)/E_0 & -q_1(n)/E_1 & \dots & 1 \end{bmatrix} \begin{bmatrix} E_0 & 0 & \dots & 0 \\ & E_1 & \dots & 0 \\ \vdots & \vdots & \dots & 0 \\ 0 & 0 & \dots & E_n \end{bmatrix}$$

$$\times \begin{bmatrix} 1 & -q_0(1)/E_0 & \dots & -q_0(n)/E_0 \\ 0 & 1 & \dots & -q_1(n)/E_1 \\ \vdots & \vdots & \dots & \vdots \\ 0 & 0 & \dots & 1 \end{bmatrix}, \tag{2.1}$$

and

$$A_n^{-1} = \begin{bmatrix} 1 & q_1(0) & \dots & q_n(0) \\ 0 & 1 & \dots & q_n(1) \\ \vdots & \vdots & \dots & \vdots \\ 0 & 0 & \dots & 1 \end{bmatrix} \begin{bmatrix} E_0^{-1} & 0 & \dots & 0 \\ & E_1^{-1} & \dots & 0 \\ \vdots & \vdots & \dots & \vdots \\ 0 & 0 & \dots & E_n^{-1} \end{bmatrix}$$

$$\times \begin{bmatrix} 1 & 0 & \dots & 0 \\ q_1(0) & 1 & \dots & 0 \\ \vdots & \vdots & \dots & \vdots \\ q_n(0) & q_n(1) & \dots & 1 \end{bmatrix}, \tag{2.2}$$

which are used later in the paper. Note that the following inequality holds:

$$0 < E_k = a_0 \prod_{j=1}^{k} (1 - c_j^2), \qquad k = 1,\dots,n;$$

hence, $|c_j| < 1$, $j = 1,\dots,n$. It follows from the Levinson algorithm that the S-coefficients do not change when the matrix A_n is multiplied by a positive real number; therefore, it is often assumed that $a_0 = 1$. In fact, there is a one-to-one correspondence between all n-tuples $(c_1,\dots,c_n)$ such that $|c_j| < 1$, $j = 1,\dots,n$, and all

n-tuples $(a_1, \ldots, a_n)$ such that $A = \{a_{|i-j|}\}_{i,j=0}^{n}$, $a_0 = 1$ is positive definite (see, for example, Koltracht and Lancaster [10].) Algorithms 1 and 2 are two standard methods for computing S-coefficients. They are known as fast algorithms, since they give S-coefficients in $O(n^2)$ arithmetic operations. Another representation of S-coefficients can be obtained as follows.

THEOREM 1. *Let $A_n = \{a_{|i-j|}\}_{i,j=0}^{n}$ be a positive definite Toeplitz matrix. Let*

$$W = \begin{bmatrix} & & & a_1 \\ & A_{n-1} & & \vdots \\ & & & a_n \\ a_1 & \ldots & a_n & a_0 \end{bmatrix}$$

and let $W = LDL^T$, where $L = \{L_{jk}\}_{j,k=0}^{n}$ is a lower triangular matrix with unit diagonal and where D is a diagonal matrix. Then the S-coefficients of A_n admit the following representation:

$$c_k = -L_{n,k-1}, \qquad k = 1, \ldots, n.$$

Proof. Let $A_{n-1} = L_{n-1}D_{n-1}L_{n-1}^T$. Using the representation of S-coefficients in Algorithm 2 and comparing with (2.2), we get

$$\begin{bmatrix} c_1 \\ c_2 \\ \vdots \\ c_n \end{bmatrix} = - \begin{bmatrix} E_0^{-1} & 0 & \ldots & 0 \\ & E_1^{-1} & \ldots & 0 \\ \vdots & \vdots & \ldots & 0 \\ 0 & 0 & \ldots & E_{n-1}^{-1} \end{bmatrix} \begin{bmatrix} 1 & 0 & \ldots & 0 \\ q_1(0) & 1 & \ldots & 0 \\ \vdots & \vdots & \ldots & 0 \\ q_{n-1}(0) & q_{n-1}(1) & \ldots & 1 \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \\ \vdots \\ a_n \end{bmatrix}$$

$$= -D_{n-1}^{-1}L_{n-1}^{-1} \begin{bmatrix} a_1 \\ a_2 \\ \vdots \\ a_n \end{bmatrix}.$$

It is straightforward to check that

$$L = \begin{bmatrix} L_{n-1} & 0 \\ b^T & 1 \end{bmatrix},$$

where

$$b^T = [a_1, \ldots, a_n]D_{n-1}^{-1}L_{n-1}^{-T}.$$

Transposing the last equation we see that $b = -c$; hence, the theorem is proved. □

Note that

$$W = \begin{bmatrix} J_{n-1} & 0 \\ 0 & 1 \end{bmatrix} A_n \begin{bmatrix} J_{n-1} & 0 \\ 0 & 1 \end{bmatrix},$$

where

$$J_{n-1} = \begin{bmatrix} 0 & \ldots & 0 & 1 \\ 0 & \ldots & 1 & 0 \\ \ldots & \ldots & \ldots & \ldots \\ 1 & 0 & \ldots & 0 \end{bmatrix}. \tag{2.3}$$

This shows that W is positive definite if and only if A_n is positive definite. Theorem 1 implies the following algorithm for computing S-coefficients.

ALGORITHM 3

1. Compute the LDL^T factorization of W using the standard algorithm of Martin, Peters, and Wilkinson [14].
2. Set $c_k = -L_{n,k-1}$, $k = 1, \ldots, n$.

This algorithm requires $n^3/6 + O(n^2)$ multiplications and is, of course, slower than Algorithms 1 and 2. However, it can be used for an experimental comparison of numerical properties of Algorithms 1 and 2 with properties of Algorithm 3. It is interesting to note that

$$L_{n-1}D_{n-1}c = -[a_1, \ldots, a_n]^T,$$

and hence the vector of S-coefficients is an intermediate result in computing the solution of the Yule–Walker system of equations

$$A_{n-1}x = L_{n-1}D_{n-1}L_{n-1}^T x = -[a_1, \ldots, a_n]^T,$$

by the LDL^T algorithm.

3. Condition numbers. It follows from Algorithm 1 that c_k is a rational function of $a_0, \ldots, a_k$; therefore the map $F : a \to c$ is differentiable. Thus for $c \neq 0$, i.e., when A_n is different from the identity matrix, the formula (1.1) for the condition number $k(F, a)$ can be used, where the norm is always the infinity norm. Since it is clear that c_k depends on $a_0, \ldots, a_k$ only, we have

$$F'(a) = \left(\frac{\partial F_k}{\partial a_j}\right)_{k=1,j=0}^{n},$$

where $F_k : (a_0, \ldots, a_k) \to c_k, k = 1, \ldots, n$, and $\partial F_k/\partial a_j = 0$ for $k < j$.

THEOREM 2. *Let $E_k, q_k(j)$, $k = 0, \ldots, n$, $j = 0, \ldots, k$ be defined as in Algorithm 2. Then for $k = 1, \ldots, n$,*

$$\begin{bmatrix} 2\frac{\partial F_k}{\partial a_0} \\ \frac{\partial F_k}{\partial a_1} \\ \vdots \\ \frac{\partial F_k}{\partial a_k} \end{bmatrix} = -E_{k-1}^{-1}\left(\begin{bmatrix} q_k(k) & \ldots & q_k(1) & q_k(0) \\ 0 & q_k(k) & \ldots & q_k(1) \\ \vdots & \vdots & \ldots & \vdots \\ 0 & 0 & \ldots & q_k(k) \end{bmatrix}\begin{bmatrix} 0 \\ q_{k-1}(0) \\ \vdots \\ q_{k-1}(k-1) \end{bmatrix}\right. \tag{3.1}$$
$$\left. + \begin{bmatrix} q_k(0) & \ldots & q_k(k-1) & q_k(k) \\ 0 & q_k(0) & \ldots & q_k(k-1) \\ \vdots & \vdots & \ldots & \vdots \\ 0 & 0 & \ldots & q_k(0) \end{bmatrix}\begin{bmatrix} q_{k-1}(k-1) \\ \vdots \\ q_{k-1}(0) \\ 0 \end{bmatrix}\right)$$

and

$$k(F, a) = \frac{a_0}{\|c\|} \max_{k=1,\ldots,n} \sum_{j=0}^{k} \left|\frac{\partial F_k}{\partial a_j}\right|. \tag{3.2}$$

Proof. We will show (3.1) for $k = n$. For $k = 1, \ldots, n-1$, the proof is exactly the same. Let $\gamma_n(j) = E_n^{-1}q_n(j)$, $j = 0, 1, \ldots, n$ and $\gamma_{n-1}(j) = E_{n-1}^{-1}q_{n-1}(j)$, $j =$

$0, 1, \ldots, n-1$. It follows from (2.2) that $\gamma_n(j) = (A^{-1})_{n,j}$, $j = 0, \ldots, n$ and $\gamma_{n-1}(j) = (A_{n-1}^{-1})_{n-1,j}$, $j = 0, \ldots, n-1$, where $(A^{-1})_{r,s}$ denotes the (r, s) element of A^{-1}. From Algorithm 2, we have

$$c_n = -[\gamma_{n-1}(0)a_1 + \cdots + \gamma_{n-1}(n-1)a_n]. \tag{3.3}$$

Since $\gamma_{n-1}(j)$ do not depend on a_n, differentiation of (3.3) with respect to a_n yields

$$\frac{\partial F_n}{\partial a_n} = -\gamma_{n-1}(n-1) = -E_{n-1}^{-1}.$$

Differentiating (3.3) with respect to a_j, $j = 1, \ldots, n-1$, we get

$$\frac{\partial F_n}{\partial a_j} = -\sum_{m=0}^{n-1} a_{m+1} \frac{\partial \gamma_{n-1}(m)}{\partial a_j} - \gamma_{n-1}(j-1). \tag{3.4}$$

It is known (see, for example, Gohberg and Koltracht [5]) that for an arbitrary invertible matrix $A = (a_{i,j})_{i,j=0}^n$,

$$\frac{\partial (A^{-1})_{r,s}}{\partial a_{i,j}} = -e_r^T A^{-1} e_i e_j^T A^{-1} e_s.$$

Therefore, if A_n is Toeplitz and symmetric, then

$$\frac{\partial (A_n^{-1})_{r,s}}{\partial a_j} = -e_r^T A_n^{-1} T_j A_n^{-1} e_s,$$

where T_j is a Toeplitz matrix of the form

$$T_j = \begin{bmatrix} 0 & \ldots & 1 & \ldots & 0 \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ 1 & 0 & \ddots & 0 & 1 \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & \ldots & 1 & \ldots & 0 \end{bmatrix},$$

with 1's in positions of a_j's in A_n. Thus

$$\frac{\partial \gamma_{n-1}(m)}{\partial a_j} = \frac{\partial (A_{n-1}^{-1})_{n-1,m}}{\partial a_j}$$

$$= -e_{n-1}^T A_{n-1}^{-1} T_j A_{n-1}^{-1} e_m, \qquad m = 0, \ldots, n-1.$$

Substituting into (3.4), we get

$$\frac{\partial F_n}{\partial a_j} = -e_{n-1}^T A_{n-1}^{-1} T_j A_{n-1}^{-1} \sum_{m=0}^{n-1} a_{m+1} e_m - \gamma_{n-1}(j-1).$$

It is clear that

$$\sum_{m=0}^{n-1} a_{m+1} e_m = \begin{bmatrix} a_1 \\ \vdots \\ a_n \end{bmatrix}.$$

Since $A\gamma_n = e_n$, it is not hard to obtain now the well-known identity

$$A_{n-1}^{-1} \begin{bmatrix} a_1 \\ \vdots \\ a_n \end{bmatrix} = - \begin{bmatrix} q_n(n-1) \\ \vdots \\ q_n(0) \end{bmatrix}.$$

Since

$$e_{n-1}^T A_{n-1}^{-1} = E_{n-1}^{-1}[q_{n-1}(0) \dots q_{n-1}(n-1)]^T,$$

we get for $j = 1, \dots, n-1$,

$$\frac{\partial F_n}{\partial a_j} = -E_{n-1}^{-1}(q_{n-1}^T T_j q_n + q_{n-1}(j-1)),$$

where

$$q_{n-1}^T = [q_{n-1}(0), \dots, q_{n-1}(n-1)].$$

For $j = 0$ this identity holds with $T_j = I$ and $q_{n-1}(-1) = 0$. It is straightforward to check that this system of equations is equivalent to (3.1). The formula (3.2) follows immediately from (1.1) and from the fact that $a_0 > |a_j|$, $j = 1, \dots, n$. The theorem is proved. □

The main reason for expressing $F'(a)$ in the form (3.1) is that in this form $F'(a)$ can be computed by the fast Fourier transform (FFT). Indeed, in this form the computation of F_k' reduces to two convolutions that can be obtained at the cost of $O(k \log k)$ arithmetic operations. Thus, we get the following recursive algorithm for computing the condition number of the map of S-coefficients.

ALGORITHM 4

1. Set $t_0 = 0, f_0 = 0$.
2. For $k = 1, \dots, n$
   2.1. Compute c_k, E_k and q_k via Algorithm 2.
   2.2. Compute $(\partial F_k / \partial a_j)_{j=0}^k$ via (3.1) using the FFT.
   2.3. Let

$$t_k = \max(|c_k|, t_{k-1}).$$

   2.4. Compute

$$f_k = \max\left(\sum_{j=0}^{k} \left| \frac{\partial F_k}{\partial a_j} \right|, f_{k-1} \right).$$

3. Set

$$k(F, a) = \frac{a_0 \cdot f_n}{t_n}.$$

The complexity of this algorithm is dominated by the step 2.2. The cost of step 2.2, for $k = 1, \dots, n$, is bounded from above by $O(n^2 \log n)$. Note that the condition number of an individual S-coefficient, $c_k \neq 0$, is given by

$$k(F_k, (a_1, \dots, a_k)) = \frac{a_0}{|c_k|} \sum_{j=0}^{k} \left| \frac{\partial F_k}{\partial a_j} \right|,$$

which can be computed at the cost of $O(k \log k)$ only.

It will be seen in the next section that the Schur algorithm is numerically more trustworthy than the Levinson algorithm for computing S-coefficients. Therefore, for better accuracy of the above condition estimator, it is advisable to compute the S-coefficients via the Schur algorithm first; and then to use them in the Levinson algorithm for computing vectors q_k, $k = 1, \ldots, n$.

Next, we derive upper and lower bounds for the condition number $k(F, a)$ in terms of S-coefficients, and obtain a precise and simple formula if all S-coefficients are nonnegative.

THEOREM 3. *Let $F : (a_0, \ldots, a_n) \to (c_1, \ldots, c_n)$ be the map of S-coefficients. Then the following bounds for the condition number $k(F, a)$ hold,*

$$\frac{1}{\|c\| \prod_{j=1}^{n-1}(1 - c_j^2)} \leq k(F, a) \leq \frac{2(1 + |c_n|)}{\|c\|} \prod_{j=1}^{n-1} \frac{1 + |c_j|}{1 - |c_j|}. \tag{3.5}$$

Moreover, if $c_j \geq 0$, $j = 1, \ldots, n$, then the condition number can be expressed as follows:

$$k(F, a) = \frac{(1 + c_n)}{\|c\|} \prod_{j=1}^{n-1} \frac{1 + c_j}{1 - c_j}. \tag{3.6}$$

Proof. Since

$$\frac{\partial F_n}{\partial a_n} = E_{n-1}^{-1} = \frac{1}{a_0 \prod_{j=1}^{n-1}(1 - c_j^2)},$$

the left inequality follows immediately from (3.2). From (3.1) we have

$$\|F'(a)\| \leq 2 \max_{k=1,\ldots,n} (E_{k-1}^{-1} \|q_k\|_1 \|q_{k-1}\|_1).$$

It is shown by Cybenko [4] that

$$\|q_k\|_1 \leq \prod_{j=1}^{k} (1 + |c_j|) \leq \prod_{j=1}^{n} (1 + |c_j|);$$

hence,

$$\|F'(a)\| \leq 2 \left(E_{n-1}^{-1} \prod_{j=1}^{n-1} (1 + |c_j|) \prod_{j=1}^{n} (1 + |c_j|) \right) = \frac{2(1 + |c_n|)}{\|c\|} \prod_{j=1}^{n-1} \frac{1 + |c_j|}{1 - |c_j|}.$$

Thus the right inequality follows. Suppose now that $c_1, \ldots, c_n \geq 0$. Then it follows from Algorithm 2 that $q_k(j) \geq 0$, $k = 0, \ldots, n$, $j = 0, \ldots, k$. Since all $\partial F_k / \partial a_j$ are of the same sign, it follows from (3.1) that

$$\begin{aligned} 2\left(\frac{\partial F_k}{\partial a_0}\right) + \sum_{j=1}^{k} \left(\frac{\partial F_k}{\partial a_j}\right) &= -E_{k-1}^{-1} \left(\sum_{j=0}^{k} q_k(j) \right) \left(\sum_{j=0}^{k-1} q_{k-1}(j) \right) + \frac{\partial F_k}{\partial a_0} \\ &= -E_{k-1}^{-1} \|q_k\|_1 \|q_{k-1}\|_1 + \frac{\partial F_k}{\partial a_0}. \end{aligned}$$

It is also shown by Cybenko [4] that in this case

$$\|q_k\|_1 = \sum_{j=0}^{k} q_k(j) = \prod_{j=1}^{k}(1+c_j).$$

Thus

$$\|F'(a)\| = \frac{(1+c_n)}{a_0}\prod_{j=1}^{n-1}\frac{1+c_j}{1-c_j}.$$

The theorem is proved. □

For the discussion of numerical properties of Algorithm 3 in the next section, we remark that bounds of Theorem 3 are similar to the bounds for the usual condition number of A_{n-1}, $k(A_{n-1}) = \|A_{n-1}^{-1}\|\|A_{n-1}\|$. Indeed, it is shown by Cybenko [4] that

$$\frac{1}{\prod_{j=1}^{n-1}(1-c_j^2)} \le k(A_{n-1}) \le n\prod_{j=1}^{n-1}\frac{1+|c_j|}{1-|c_j|}. \tag{3.7}$$

In particular, if $c_1, \ldots, c_n \ge 0$, then clearly

$$k(A_{n-1}) \le nk(F,a). \tag{3.8}$$

The comparison of bounds in (3.5) and (3.7) and the inequality (3.8) indicate that there should be little difference between the condition numbers $k(A_{n-1})$ and $k(F,a)$. Our numerical experiments in §5 support this conclusion.

4. Analysis of algorithms. To analyze the propagation of roundoff errors in Algorithms 1 and 2, we need the bounds for the size of entries of vectors p_k and q_k appearing in these algorithms, which will be used later in the Appendix. For the quantities q_k in Algorithm 2 we have the bound already used in Theorem 3; namely,

$$\sum_{j=0}^{k}|q_k(j)| \le \prod_{j=1}^{k}(1+|c_j|),\ k=1,\ldots,n, \tag{4.1}$$

with the equality holding in the case when $c_1, \ldots, c_n \ge 0$. Quantities $q_k(k+1), \ldots, q_k(n)$ in Algorithm 1 can be bounded from above using (2.1). (See the proof of Theorem 4.) To find an upper bound for $p_k(k+1), \ldots, p_k(n)$, we need the following result.

LEMMA 1. *Let* $W_k = Z_k A_n Z_k$, $k = 1, \ldots, n-1$, *where*

$$Z_k = \begin{bmatrix} J & 0 \\ 0 & I \end{bmatrix}$$

is a permutation matrix with the leading block J *defined in* (2.3) *and of the size* $(k+1)\times(k+1)$. *Let* $W_k = L_k D_k L_k^T$ *be the* LDL^T *factorization of* W_k; *then*

$$E_j = (D_k)_{j,j}, \qquad j = 0, \ldots, n$$

and

$$p_k(j) = -E_k(L_k)_{j,k}, \qquad j = k+1, \ldots, n.$$

Proof. Let k be fixed. Let J_m be of the form (2.3) and have the size $(m+1)\times(m+1)$. Using the fact that $J_m A_m J_m = A_m$, $m = 0,1,\ldots,n$, it is easy to see that the determinants of the principal leading submatrices of A_n and W_k of the same size are equal. Since diagonal entries in the LDL^T factorization are ratios of corresponding determinants, it follows that they are the same for A_n and W_k; hence, $(D_k)_{m,m} = E_m$, $m = 0,\ldots,n$.

It is shown in Gohberg et al. [6] that for the matrix

$$A_k^c = \{a_{|i-j|}\}_{j=1,\ldots,k}^{i=k+1,\ldots,n},$$

the following identity holds:

$$A_k^c \begin{bmatrix} q_k(k) \\ \vdots \\ q_k(0) \end{bmatrix} = - \begin{bmatrix} p_k(k+1) \\ \vdots \\ p_k(n) \end{bmatrix}. \tag{4.2}$$

Observing that

$$W_k = \begin{bmatrix} A_k & * \\ A_k^c J_k & * \end{bmatrix}$$

and comparing the factorization identities (2.1) and $W_k = L_k D_k L_k^T$, it is not hard to see that

$$W_k \begin{bmatrix} q_k(0) \\ \vdots \\ q_k(k) \\ 0 \\ \vdots \\ 0 \end{bmatrix} = E_k \begin{bmatrix} 0 \\ \vdots \\ 0 \\ 1 \\ (L_k)_{k+1,k} \\ \vdots \\ (L_k)_{n,k} \end{bmatrix}.$$

Thus,

$$A_k^c J_k \begin{bmatrix} q_k(0) \\ \vdots \\ q_k(k) \end{bmatrix} = E_k \begin{bmatrix} (L_k)_{k+1,k} \\ \vdots \\ (L_k)_{n,k} \end{bmatrix}.$$

Comparing the last equality with (4.2) we get

$$p_k(j) = -E_k(L_k)_{j,k}, \qquad j = k+1,\ldots,n.$$

The lemma is proved. □

THEOREM 4. *Let $E_k, q_k(j), p_k(j)$, $k = 1,\ldots,n-1$, $j = k+1,\ldots,n$ be defined by Algorithm* 1. *Then*

$$|q_k(j)|,\ |p_k(j)| \le (E_k(a_0 - E_j))^{1/2} \le a_0. \tag{4.3}$$

Proof. It follows from (2.1) that

$$\sum_{k=0}^{j-1} q_k^2(j) E_{k-1}^{-1} + E_j = a_0;$$

hence, $q_k^2(j) \le E_k(a_0 - E_j)$. Similarly from $W_k = L_k D_k L_k^T$, we have

$$\sum_{i=0}^{j-1} (L_k)_{j,i}^2 (D_k)_{i,i} + (D_k)_{j,j} = a_0.$$

By Lemma 1 we have $p_k(j) = -E_k(L_k)_{j,k}$ and $(D_k)_{i,i} = E_i$; hence, $p_k^2(j)E_k^{-1} \le (a_0 - E_j)$. The theorem is proved. □

Remark. The first part of this theorem is well known; to the best of our knowledge the second part, i.e., the bound for $p_k(j)$, is new.

Next, we state the results of the backward round off error analysis for Algorithms 1 and 2. The proofs, which are rather technical, are given in the Appendix. We assume the standard model of floating point arithmetic with a guard digit

$$fl(x \otimes y) = (x \otimes y)(1 + \epsilon),$$

where $\otimes$ stands for $+, -, *, /$, and ϵ is bounded by the unit roundoff error $|\epsilon| \le u$. We also assume for simplicity that $a_0 = 1$.

THEOREM 5. *Let $\bar{c}_k, \bar{p}_k(j), \bar{E}_k, \bar{q}_k(j)$ be the values of $c_k, p_k(j), E_k, q_k(j)$ computed by Algorithm 1 in floating point arithmetic with a unit roundoff error u. Suppose that $|\bar{c}_k|, |\bar{p}_k(j)|, |\bar{q}_k(j)| < 1$. Then there exist $\epsilon_1, \dots, \epsilon_n$ such that $\bar{c}_1, \dots, \bar{c}_n$ are the exact S-coefficients of the positive definite Toeplitz matrix defined by $a_0 = 1, a_1 + \epsilon_1, \dots, a_n + \epsilon_n$ and*

$$|\epsilon_i| \le 4i \left(2 + \sum_{j=1}^{i} |\bar{c}_j| \prod_{t=1}^{j-1} (1 + |\bar{c}_t|) \right) u + o(u), \qquad i = 1, \dots, n.$$

Note that $\sum_{j=1}^{i} |\bar{c}_j| \le i$; hence, we also have

$$|\epsilon_i| \le 4i \left(2 + i \prod_{t=1}^{i-1} (1 + |\bar{c}_t|) \right) u + o(u), \qquad i = 1, \dots, n. \tag{4.4}$$

THEOREM 6. *Let $\bar{c}_k, \bar{E}_k, \bar{q}_k(j)$ be the values of $c_k, E_k, q_k(j)$ computed by Algorithm 2 in floating point arithmetic with a unit roundoff error u. Suppose that $|\bar{c}_k| < 1$, $k = 1, \dots, n$. Then there exist $\epsilon_1, \dots, \epsilon_n$ such that $\bar{c}_1, \dots, \bar{c}_n$ are the exact S-coefficients of the positive definite Toeplitz matrix defined by $a_0 = 1, a_1 + \epsilon_1, \dots, a_n + \epsilon_n$ and*

$$|\epsilon_i| \le 2i^2 \prod_{j=1}^{i-1} (1 + |\bar{c}_j|)^2 u + o(u), \qquad i = 1, \dots, n. \tag{4.5}$$

The assumption made in Theorems 5 and 6 that $|\bar{c}_k| < 1$, $k = 1, \dots, n$ is necessary because if for some k, $|\bar{c}_k| \ge 1$, then there is no positive definite Toeplitz matrix having $\bar{c}_k$ as its S-coefficients. In view of Theorem 4, the same applies to the assumption in Theorem 5 that $|\bar{p}_k(j)|$, $|\bar{q}_k(j)| \le 1$.

Moreover, if say, $(a_1, \dots, a_n)$ represents the response of a layered piecewise homogeneous elastic medium to a unit probing signal applied to the surface, then $c_1, \dots, c_n$ are the reflection coefficients of this stratified medium, and by definition they must be less than one in magnitude. The quantities $p_k(j)$ and $q_k(j)$ represent observed signals in the kth layer and also must be less than one in magnitude. (See, for example,

Koltracht and Lancaster [11].) Therefore, the assumptions of Theorems 5 and 6 also mean that the computed quantities are physically meaningful.

Theorems 5 and 6 lead us to following observations.

Observation 1. The fact that the essential factor of the backward error bound for the Schur algorithm, namely, $\prod_{j=1}^{n-1}(1+|\bar{c}_j|)$, is squared in the error bound for the Levinson algorithm, indicates that the Schur algorithm might be more trustworthy. This conclusion is supported by numerical evidence in the next section.

Observation 2. The error bound (4.4) has the following practical significance: If the S-coefficients computed by the Schur algorithm satisfy the inequality

$$4n^2 \prod_{j=1}^{n-1}(1+|\bar{c}_j|)k(F,a)u \leq 10^{-p}, \tag{4.6}$$

and the conditions of Theorem 5 are met, then at least p correct figures can be guaranteed in the computed S-coefficients.

For S-coefficients computed by Algorithm 3, the following inequality holds:

$$\frac{\|\bar{c}-c\|}{\|c\|} \leq Kn^{3/2}k(A_{n-1})u + o(u), \tag{4.7}$$

where K is a constant of order unity, and where in practice it is rare for the bound $Kn^{3/4}k(A_{n-1})u$ to be exceeded. This follows immediately from the results of Martin, Peters, and Wilkinson [14], because the computation of $\bar{c}_1, \ldots, \bar{c}_n$ amounts to the following:

1. Computing L_{n-1} and D_{n-1} by the algorithm from Martin, Peters, and Wilkinson [14].

2. Solving by substitution

$$L_{n-1}\begin{bmatrix} y_1 \\ \vdots \\ y_n \end{bmatrix} = \begin{bmatrix} a_1 \\ \vdots \\ a_n \end{bmatrix}.$$

3. Setting

$$c_i = -(D_{n-1})_{i,i}^{-1} y_i, \qquad i = 1, \ldots, n.$$

Following Gohberg and Koltracht [5], we could claim that Algorithm 3 is forward stable for computing S-coefficients of a positive definite Toeplitz matrix, if we could show that $k(A_{n-1})$ is of the same order of magnitude as $k(F,a)$, the condition number of the map of S-coefficients. It follows from Theorem 3 and (3.7) that both upper and lower bounds for $k(F,a)$ are comparable with those for $k(A_{n-1})$. In the case of $c_1, \ldots, c_n \geq 0$, it follows from (3.8) that we can replace $k(A_{n-1})$ by $nk(F,a)$ in (4.7). Extensive numerical evidence in the following section shows that there is indeed little difference between the two condition numbers. Therefore we claim that Algorithm 3 is forward stable for computing S-coefficients.

5. Numerical experiments. Numerical experiments in this section are designed to test the forward stability of Algorithms 1, 2, and 3 and to compare the condition number of the map of S-coefficients $k(F,a)$, with the usual condition number of A_{n-1}, $k(A_{n-1}) = \|A_{n-1}^{-1}\|\|A_{n-1}\|$. In each experiment, we start with a set of S-coefficients $c_1, \ldots, c_n$ chosen in $(-1,1)$ and generate the corresponding positive

definite Toeplitz matrix A_n, using an algorithm from Koltracht and Lancaster [10], in double precision. Then we compute S-coefficients of this matrix A_n using Algorithms 1, 2, and 3 in single precision and compare the computed S-coefficients $\bar{c}_1, \ldots, \bar{c}_n$ with the original set. The condition numbers $k(F, a)$ and $k(A_{n-1})$ are computed in double precision via Algorithm 4 and the Gohberg–Semencul formula (see, for example, Gohberg and Leiterer [8]), respectively. All computations are performed on the IBM ES-9000 computer with the unit roundoff error $u \approx 10^{-7}$.

For a fixed value of n (e.g., $n = 20, 30, 40$), we generate n uniformly distributed random numbers in a given subinterval of $(-1, 1)$ as the original S-coefficients. We recompute the S-coefficients by agorithms 1, 2, and 3 and denote them by $\bar{c}^i, i = 1, 2, 3$, respectively. This procedure is repeated 20 times for every given subinterval. In the following table the worst relative error

$$\frac{\|\bar{c}^i - c\|}{\|c\|}$$

among the 20 trials is given for each algorithm and for different subintervals. For each subinterval we also compute the largest value of the condition number, $K(F, a)$, over the 20 trials and the largest ratio of $k(A_{n-1}) \equiv k_1$ versus $k(F, a) \equiv k_2$, and k_2 versus k_1.

We see from Tables 1, 2, and 3 that the ratio k_1/k_2 is, indeed, of order unity and that the forward error in all these algorithms is consistent with the condition of the problem; namely,

$$\frac{\|\bar{c}^i - c\|}{\|c\|} \approx k(F,a)u.$$

Note that in most of the cases the worst error in the LDL^T algorithm is smaller than that in the Schur algorithm which is in turn smaller than that in the Levinson algorithm. For matrices that correspond to nonnegative S-coefficients, the worst error is smallest for the Levinson algorithm. However, a closer examination of each of the 20 cases represented by one row of a table (even for rows corresponding to nonnegative S-coefficients), shows that the error in Levinson algorithm is larger than that in Schur algorithm which is in turn larger than that in the LDL^T algorithm in the vast majority of the individual experiments. Therefore, our practical recommendation is to use the Schur algorithm (or the LDL^T algorithm if the cost is no object) for computing S-coefficients. Note also that condition numbers are visibly smaller when S-coefficients vary in sign as compared to the constant sign pattern, that agrees with the results obtained in Koltracht and Lancaster [10]. When the intervals are larger, like $(-.85, .85)$, or $(-.65, 0)$, or when n becomes larger, all three algorithms fail in the worst case because the condition numbers become too large.

Appendix. It is convenient to start with the proof of Theorem 6 which is somewhat easier.

Proof of Theorem 6. It is clear that for $k = 1$ the theorem is true. Let us consider q_k, c_k, E_k as functions of $a_1, \ldots, a_k$ and denote them as $c_k = c_k(a_1, \ldots, a_k), q_k = q_k(a_1, \ldots, a_k)$ and $E_k = E_k(a_1, \ldots, a_k)$. Let us denote $T_k \equiv (a_1, \ldots, a_k)$. Assume that the claim is true for $s = 1, \ldots, k$. For ϵ_s, $s = 1, 2, \ldots, k$, define

$$q_s^{'} = q_s(a_1 + \epsilon_1, \ldots, a_s + \epsilon_s),$$

$$E_s^{'} = E_s(a_1 + \epsilon_1, \ldots, a_s + \epsilon_s).$$

Let us now find ϵ_{k+1} such that $\bar{c}_{k+1} = c_{k+1}(\rho_1 + \epsilon_1, \ldots, \rho_{k+1} + \epsilon_{k+1})$, where ϵ_{k+1} satisfies (4.5). It follows from Algorithm 2 that $\bar{c}_{k+1} = fl(\bar{s}_{k+1} * \bar{E}_k^{-1})$, which can be written as follows.

$$\bar{c}_{k+1} = -(T_k \cdot \bar{q}_k + \Delta_k)(1 + \delta_k)/\bar{E}_k, \tag{A.1}$$

where $|\delta_k| \le u, |\Delta_k| \le |T_k| \cdot |\bar{q_k}|u$, and $a \cdot b$ denotes the dot product of two vectors. Let us define ϵ_{k+1} from the equation:

$$\bar{c}_{k+1} = -\left(a_{k+1} + \epsilon_{k+1} + \sum_{i=0}^{k-1} a_{i+1} q_k^{'}(i)\right) / E_k^{'}. \tag{A.2}$$

It follows from (6.1) that

$$(T_k \cdot \bar{q_k} + \Delta_k)(1 + \delta_k) E_k^{'} = \left(a_{k+1} + \epsilon_{k+1} + \sum_{i=0}^{k-1} a_{i+1} q_k^{'}(i)\right) \bar{E}_k.$$

Solving for ϵ_{k+1}, we get

$$\begin{aligned}\epsilon_{k+1} = {} & (E_k^{'}/\bar{E}_k - 1)(T_k \cdot \bar{q_k} + \Delta_k) + \sum_{i=0}^{k} a_{i+1}(\bar{q_k}(i) - q_k^{'}(i)) \\ & + E_k^{'}/\bar{E}_k \, (T_k \cdot \bar{q_k} + \Delta_k) \, \delta_k + \Delta_k.\end{aligned}$$

Since $\bar{q_k}(k) = q_k^{'}(k) = 1$, we have

$$\begin{aligned}\epsilon_{k+1} = {} & (E_k^{'}/\bar{E}_k - 1)(T_k \cdot \bar{q_k} + \Delta_k) + \sum_{i=0}^{k-1} a_{i+1}(\bar{q_k}(i) - q_k^{'}(i)) \\ & + E_k^{'}/\bar{E}_k \, T_k \cdot \bar{q_k} \, \delta_k + \Delta_k + o(u).\end{aligned} \tag{A.3}$$

Assuming that $(1 - c_k) * (1 + c_k)$ is used to compute $1 - c_k^2$, we get $\bar{E}_k = \bar{E}_{k-1}(1 - \bar{c_k}^2)/(1 + \gamma_k)$ where $\gamma_k \le 4u + o(u)$. Therefore, $E_k^{'}/\bar{E}_k = \prod_{i=1}^{k}(1 + \gamma_i)$ or

$$|E_k^{'}/\bar{E}_k - 1| \le 4ku + o(u). \tag{A.4}$$

Let us now find the bound for $\|\bar{q_k} - q_k^{'}\|_1$. From the definition, we have

$$\bar{q_k} = \begin{bmatrix} 0 \\ \bar{q}_{k-1} \end{bmatrix} + \bar{c}_k \begin{bmatrix} J_{k-1}\bar{q}_{k-1} \\ 0 \end{bmatrix} + \begin{bmatrix} \eta_k \\ 0 \end{bmatrix},$$

where η_k is a (k+1)-dimensional vector and

$$|\eta_k(i)| \le (|\bar{q}_{k-1}(i)| + |\bar{c}_k||\bar{q}_{k-1}(i-1)|)2u.$$

From (4.1), we get

$$|\eta_k(i)| \le (1 + |\bar{c}_k|)\|\bar{q}_{k-1}\|_1 2u \le \prod_{j=1}^{k}(1 + |\bar{c}_j|)2u. \tag{A.5}$$

Also from the definition, it follows that

$$q_k^{'} = \begin{bmatrix} 0 \\ q_{k-1}^{'} \end{bmatrix} + \bar{c}_k \begin{bmatrix} J_{k-1} q_{k-1}^{'} \\ 0 \end{bmatrix}.$$

Thus for $s = 1, \ldots, k$

$$\|\bar{q}_s - q_s^{'}\|_1 \le (1 + |\bar{c}_s|)\|\bar{q}_{s-1} - q_{s-1}^{'}\|_1 + \|\eta_s\|_1.$$

Starting with $\eta_0 = 0$, we get by induction and (A.5),

$$\begin{aligned}\|\bar{q}_s - \bar{q}_s^{'}\|_1 &\leq \sum_{i=1}^{s-1} \prod_{j=i+1}^{s} (1 + |\bar{c}_j|)\|\eta_i\|_1 \\ &\leq \sum_{i=1}^{s-1} \prod_{j=i+1}^{s} (1 + |\bar{c}_j|)k \prod_{j=1}^{i}(1 + |\bar{c}_j|)2u,\end{aligned}$$

for $s = 1, \ldots, k$, which implies that

$$\|\bar{q}_k - \bar{q}_k^{'}\|_1 \leq k^2 \prod_{i=1}^{k}(1 + |\bar{c}_i|)^2 2u. \tag{A.6}$$

Using (A.4) and (A.6), we obtain from (A.3) that

$$|\epsilon_{k+1}| \leq 4ku \prod_{i=1}^{k}(1 + |\bar{c}_i|) + k^2 2u \prod_{i=1}^{k}(1 + |\bar{c}_i|)^2 + u \prod_{i=1}^{k}(1 + |\bar{c}_i|)^2 + o(u).$$

The theorem is proved. □

Proof of Theorem 5. The claim is clearly true for $k = 1$. Suppose that (4.4) holds for $s = 1, \ldots, k$. For these ϵ_s, $s = 1, \ldots, k$, define

$$p_s^{'} = p_s(\rho_1 + \epsilon_1, \ldots, \rho_s + \epsilon_s),$$

$$q_s^{'} = q_s(\rho_1 + \epsilon_1, \ldots, \rho_s + \epsilon_s),$$

$$E_s^{'} = E_s(\rho_1 + \epsilon_1, \ldots, \rho_s + \epsilon_s).$$

Let us find now ϵ_{k+1} which satisfies (4.4). It follows from Algorithm 1 that

$$\bar{c}_{k+1} = fl(\bar{p}_k(k+1) * \bar{E}_k^{-1}) = (\bar{p}_k(k+1) * \bar{E}_k^{-1})(1 + \eta_k),$$

where $|\eta_k| \leq u$. We also have

$$\bar{p}_k(k+1) = \bar{p}_{k-1}(k+1) + \bar{c}_k \bar{q}_{k-1}(k) + \delta_{k-1};$$

hence,

$$\bar{p}_k(k+1) = p_0(k+1) + \sum_{i=1}^{k}(\bar{c}_i \bar{q}_{i-1}(k) + \delta_{i-1}), \tag{A.7}$$

where for $i = 0, 1, \ldots, k-1$,

$$|\delta_i| \leq |\bar{p}_i(k+1)|u + |\bar{c}_{i+1}||\bar{q}_i(k)|2u \leq (1 + |\bar{c}_{i+1}|)2u. \tag{A.8}$$

Let us define now ϵ_{k+1} from the equation

$$\bar{c}_{k+1} = \left[p_0(k+1) - \epsilon_{k+1} + \sum_{i=1}^{k} \bar{c}_i q_{i-1}^{'}(k)\right] / E_k^{'}. \tag{A.9}$$

Then it follows from (A.7) and (A.8) that

$$\left[p_0(k+1)+\sum_{i=1}^{k}(\bar{c}_i\bar{q}_{i-1}(k)+\delta_{i-1})\right]E_k^{'}(1+\eta_k)=$$

$$\left[p_0(k+1)-\epsilon_{k+1}+\sum_{i=1}^{k}\bar{c}_i q_{i-1}^{'}(k)\right]\cdot\bar{E}_k.$$

Solving for ϵ_{k+1}, we get

$$\epsilon_{k+1}=\bar{p}_k(k+1)(1-E_k^{'}/\bar{E}_k)+\left(\bar{p}_k(k+1)\eta_k+\sum_{i=1}^{k}\delta_{i-1}\right)$$

$$+\sum_{i=1}^{k}\bar{c}_i(q_{i-1}^{'}(k)-\bar{q}_{i-1}(k)). \tag{A.10}$$

As in the proof of Theorem 6, we have

$$|E_k^{'}/\bar{E}_k-1|\leq 4ku+o(u). \tag{A.11}$$

It remains to find the bound of $q_{i-1}^{'}(k)-\bar{q}_{i-1}(k)$. It follows from Algorithm 1 that

$$\bar{q}_i(j)=\bar{p}_{i-1}(j)\bar{c}_i+\bar{q}_{i-1}(j-1)+\delta_j^i \tag{A.12}$$

and

$$\bar{p}_i(j)=\bar{p}_{i-1}(j)+\bar{c}_i\bar{q}_{i-1}(j-1)+\Delta_j^i, \tag{A.13}$$

where for $i=1,\ldots,k$ and $j=i+1,\ldots,n$,

$$|\delta_j^i|\leq(1+|\bar{c}_i|)2u, \tag{A.14}$$

$$|\Delta_j^i|\leq(1+|\bar{c}_i|)2u. \tag{A.15}$$

Let us define

$$d_i=[\bar{q}_i(i+1),\ldots,\bar{q}_i(n)]^T-[q_i^{'}(i+1),\ldots,q_i^{'}(n)]^T,$$

$$D_i=[\bar{p}_i(i+1),\ldots,\bar{p}_i(n)]^T-[p_i^{'}(i+1),\ldots,p_i^{'}(n)]^T,$$

and

$$\lambda_i=\max(\|d_i\|_\infty,\|D_i\|_\infty),$$

$$\mu_i=\max_{i\leq j\leq n}(|\delta_j^i|,|\Delta_j^i|).$$

Then it follows from (A.12), (A.13) and the definition of $p_i^{'}, q_i^{'}$ that

$$\|d_i\|_\infty\leq(1+|\bar{c}_i|)\lambda_{i-1}+\mu_i,\|D_i\|_\infty\leq(1+|\bar{c}_i|)\lambda_{i-1}+\mu_i;$$

hence, $\lambda_i \leq (1 + |\bar{c}_i|)\lambda_{i-1} + \mu_i$. Since $\lambda_0 = 0$, we obtain

$$\lambda_i \leq \sum_{t=2}^{i+1} \prod_{s=t}^{i} (1 + |\bar{c}_s|)\mu_{t-1}; \tag{A.16}$$

hence, for $i = 1, \ldots, k$,

$$\lambda_i \leq i \prod_{j=1}^{i} (1 + |\bar{c}_j|)2u + o(u). \tag{A.17}$$

Returning to (6.10), we see that

$$\begin{aligned} |\epsilon_{k+1}| &\leq 4ku + u + \sum_{i=1}^{k} (1 + |\bar{c}_i|)2u \\ &\quad + \sum_{i=1}^{k} |\bar{c}_i| i \prod_{j=1}^{k} (1 + |\bar{c}_j|)2u + o(u) \qquad \text{(A.18)} \\ &\leq 4k \left(2 + \sum_{i=1}^{k} |\bar{c}_i| \prod_{j=1}^{k} (1 + |\bar{c}_j|) \right) u + o(u). \qquad \text{(A.19)} \end{aligned}$$

The theorem is proved. □

EIGENVALUES OF BLOCK MATRICES ARISING FROM PROBLEMS IN FLUID MECHANICS*

K. A. CLIFFE†, T. J. GARRATT‡, AND A. SPENCE§

Abstract. Block matrices with a special structure arise from mixed finite element discretizations of incompressible flow problems. This paper is concerned with an analysis of the eigenvalue problem for such matrices and the derivation of two shifted eigenvalue problems that are more suited to numerical solution by iterative algorithms like simultaneous iteration and Arnoldi's method. The application of the shifted eigenvalue problems to the determination of the eigenvalue of smallest real part is discussed and a numerical example arising from a stability analysis of double-diffusive convection is described.

Key words. block matrices, eigenvalues, finite elements, Navier–Stokes

1. Introduction.

Let A and B be $N \times N$ real matrices with the block structure

$$A = \begin{bmatrix} K & C \\ C^T & 0 \end{bmatrix}, \qquad B = \begin{bmatrix} M & 0 \\ 0 & 0 \end{bmatrix}, \tag{1.1}$$

where $N = n+m$, $n > m$, K is $n \times n$, C is $n \times m$ of rank m, and M is $n \times n$ symmetric positive definite. The paper is concerned with the theory of the generalised eigenvalue problem

$$Aw = \mu Bw \tag{1.2}$$

called EVP1 and three related eigenvalue problems called EVP2, EVP3, and EVP4 that are introduced in §3. Since the matrices are typically large and sparse, numerical techniques based on transformation methods like the QZ algorithm will be very expensive. The reason for introducing the related eigenvalue problems EVP2, EVP3, and EVP4 is that they should be amenable to iterative techniques commonly used to find selected eigenvalues of large sparse matrices ([2, §I-5]). In the applications we have in mind K, C, and M arise from mixed finite element discretizations of the "velocity-pressure" formulation of the Navier–Stokes equations for incompressible flow problems [3], [9], and the eigenvalue problem (1.2) arises in the determination of the stability of steady flows [5]. The problem is to find the eigenvalues of (1.2) with smallest real part.

As is standard, the finite values $\mu \in C$ such that $\det(A - \mu B) = 0$ are known as finite eigenvalues, though we usually drop the term "finite." Since B is singular there are also infinite eigenvalues, which are defined to be zero eigenvalues of $\nu Aw = Bw$, with corresponding eigenvectors that are null vectors of B. The theory for (1.2) is

more complicated than for the standard eigenvalue problem $Aw = \mu w$ [21]. However, the assumptions made in this paper on C and M allow very precise statements to be made about the number of eigenvalues of (1.2) and make possible the introduction of related eigenvalue problems that are better suited to solution by iterative algorithms.

Eigenvalue problems of the form (1.2) with block structure (1.1) arise in applications involving constraints. For example, Malkus [14] discusses the case when K is symmetric in an analysis of the discrete Ladyzhenskaya–Babuska–Brezzi (LBB) stability condition for incompressible finite elements arising in linear elasticity or Stokes flow. For symmetric K, the results on the eigenvalues of EVP1 in Theorem 2.1 and Lemma 2.2 are contained in [14, Thm. 3] though our method of proof produces the results in a more direct manner. In addition, the case of K symmetric and $M = I$ is discussed by Golub in [10].

The plan of the paper is as follows. In §2 the basic theory for the eigenvalue problem (1.1), (1.2) is presented. Section 3 contains an analysis of some related eigenvalue problems that provide some shift strategies for the eigenvalues. In §4 some practical aspects are considered. First there is a discussion relating to the execution of certain matrix-vector operations and second the estimation of the accuracy of computed eigensolutions is examined. Section 5 contains a discussion of strategies that could be used to determine the eigenvalues of smallest real part of (1.1), (1.2). These are illustrated with reference to a matrix problem arising from a finite element discretization of two-dimensional double-diffusive convection in a box.

2. Theory for the eigenvalue problem. This section contains some results about the eigenvalue problem $Aw = \mu Bw$ which, for convenience, we rewrite (and rename) as

$$\text{(EVP1)} \qquad \begin{bmatrix} K & C \\ C^T & 0 \end{bmatrix} \begin{bmatrix} u \\ p \end{bmatrix} = \mu \begin{bmatrix} M & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} u \\ p \end{bmatrix},$$

where, in analogy with our applications arising from the discretization of the Navier–Stokes equations, we use the notation $w = [u, p]$, $u \in \boldsymbol{R}^n$, $p \in \boldsymbol{R}^m$, where u and p correspond to velocity and pressure degrees of freedom, respectively.

First we note that since C is full rank, the QR factorisation of C has the form (ignoring possible permutations that play no role here)

$$C = QR = [Q_1 \; Q_2] \begin{bmatrix} R_1 \\ 0 \end{bmatrix} \; (= Q_1 R_1), \tag{2.1}$$

where R is $n \times m$, R_1 is $m \times m$ nonsingular and upper triangular, Q is $n \times n$ orthogonal, Q_1 is $n \times m$ and provides an orthonormal basis for range(C), and Q_2 is $n \times (n-m)$ and provides an orthonormal basis for $C^{\perp}$. For future use note that C^TC is $m \times m$ positive definite and has the Cholesky decomposition $C^TC = R_1^T R_1$ [11, p. 217]. Also, the matrix

$$\pi := I - C(C^TC)^{-1}C^T \tag{2.2}$$

is a projection from $\boldsymbol{R}^n$ onto $C^{\perp}$ along range(C).

Now we state a fundamental result on the number of eigenvalues of EVP1.

THEOREM 2.1. (a) *The eigenvalue problem* EVP1 *has precisely* $n-m$ *eigenvalues, that are those of the reduced eigenvalue problem of dimension* $(n-m)$

$$\text{(REVP1)} \qquad Q_2^T(K - \mu M)Q_2 z = 0.$$

(b) *If* (μ, z), $z \in \boldsymbol{R}^{n-m}$ *is an eigensolution of* REVP1 *then* (μ, u, p) *is a corresponding eigensolution of* EVP1 *where*

$$u = Q_2 z, \qquad p = -R_1^{-1} Q_1^T (K - \mu M) Q_2 z.$$

(c) *If* (μ, u, p), $u \in \boldsymbol{R}^n$, $p \in \boldsymbol{R}^m$ *is an eigensolution of* EVP1 *then* (μ, z) *is a corresponding eigensolution of* REVP1 *where* $z = Q_2^T u$.

Proof. (a) Introduce $Z = \left[\begin{smallmatrix} Q & 0 \\ 0 & I_m \end{smallmatrix}\right]$, where Q is defined in (2.1), and $y := Z^T w = (Q^T u, p) = (Q_1^T u, Q_2^T u, p) =: (u_1, u_2, p)$. Now EVP1 is equivalent to $Z^T A Z y = \mu Z^T B Z y$, that in block form becomes

$$\begin{bmatrix} K_{11} & K_{12} & R_1 \\ K_{21} & K_{22} & 0 \\ R_1^T & 0 & 0 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ p \end{bmatrix} = \mu \begin{bmatrix} M_{11} & M_{12} & 0 \\ M_{21} & M_{22} & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ p \end{bmatrix}, \tag{2.3}$$

where $K_{ij} = Q_i^T K Q_j$, $M_{ij} = Q_i^T M Q_j$, $i, j = 1, 2$. Simple manipulation shows that $u_1 = 0$, $(K_{22} - \mu M_{22}) u_2 = 0$, $p = -R_1^{-1}(K_{12} - \mu M_{12}) u_2$. Since M and M_{22} are symmetric positive definite, (a) is immediate. Results (b) and (c) now follow. □

Remark 1. An equivalent proof in the style of Golub [10] uses the projection π defined by (2.2). Since $\pi u = u$ for $u \in C^{\perp}$ we may write the first row of EVP1 as $K\pi u + Cp = \mu M \pi u$. Premultiplication by π gives

$$\pi K \pi u = \mu \pi M \pi u \tag{2.4}$$

that has the same eigenvalues as (REVP1) plus m zero eigenvalues corresponding to eigenvectors lying in range(C) that have no relevance for EVP1.

For future analysis it is convenient to exclude the possibility that $\mu = 0$ is an eigenvalue, and so we assume the following:

$$\mu = 0 \text{ is } \textit{not} \text{ an eigenvalue of EVP1.} \tag{2.5}$$

This assumption is not a severe restriction in the applications we have in mind, since though zero eigenvalues are important, corresponding to "steady-state" bifurcations in some nonlinear problem, they are usually detected readily. For example, if a direct solver for A is feasible then one can check the determinant of A. If a zero eigenvalue of EVP1 has been found, an eigenvalue problem satisfying (2.5) may be obtained by considering a "shifted" eigenvalue problem with the same structure as EVP1, but with K replaced by $K - \gamma M$ for some appropriately chosen shift $\gamma \in \boldsymbol{R}$.

Under assumption (2.5), K_{22} is nonsingular and so (2.3) may be rewritten as

$$\nu w = \begin{bmatrix} 0 & 0 & R_1^{-T} \\ 0 & K_{22}^{-1} & * \\ R_1^{-1} & * & * \end{bmatrix} \begin{bmatrix} M_{11} & M_{12} & 0 \\ M_{21} & M_{22} & 0 \\ 0 & 0 & 0 \end{bmatrix} w$$

or

$$\nu w = \begin{bmatrix} 0 & 0 & 0 \\ * & K_{22}^{-1} M_{22} & 0 \\ * & * & 0 \end{bmatrix} w, \tag{2.6}$$

where $*$ denotes unique submatrices that do not affect the analysis. Clearly (2.6) has a zero eigenvalue of algebraic multiplicity $2m$. Thus we have proved the following lemma.

LEMMA 2.2. *Under* (2.5), EVP1 *has an infinite eigenvalue of multiplicity* $2m$.

Similar results apply to the following generalization of EVP1,

$$\begin{bmatrix} K & C_1 \\ C_2^T & 0 \end{bmatrix} \begin{bmatrix} u \\ p \end{bmatrix} = \mu \begin{bmatrix} M & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} u \\ p \end{bmatrix}, \tag{2.7}$$

where C_1 and C_2 are $n \times m$ matrices of rank m. Such a problem arises after the discretization of the Navier–Stokes equations by a spectral method [6]. Provided C_1 and C_2 satisfy the nondegeneracy condition,

$$C_2^T C_1 \text{ is invertible}$$

(which is a natural condition in the context of discretizations of the Navier–Stokes equations); then results analogous to Theorem 2.1 hold. To see this we introduce the projection operator

$$\pi_{12} := I - C_1(C_2^T C_1)^{-1} C_2^T \tag{2.8}$$

(cf. (2.2)). Clearly, if $u \in \text{range}(C_1)$, then $\pi_{12}u = 0$, and if $u \in C_2^{\perp}$, then $\pi_{12}u = u$.

Now follow the approach of Remark 1 to obtain

$$\pi_{12} K \pi_{12} u = \mu \pi_{12} M \pi_{12} u \tag{2.9}$$

(cf. (2.4)), which has $n - m$ eigenvalues for $u \in C_2^{\perp}$. A corresponding reduced eigenvalue problem can be derived (cf. Theorem 2.1(a)).

Remark 2. It is important to note that if K and M are large and sparse (as is the case in the applications we have in mind) then typically one would not explicitly form the matrices in (REVP1). This is because Q_2 is full and hence $Q_2^T K Q_2$ and $Q_2^T M Q_2$ are full. Rather one would employ iterative techniques to find selected eigenvalues as discussed in §5.

3. Some shifted eigenvalue problems. It is a common technique to shift the eigenvalues of an eigenvalue problem, so that if $Aw = \mu Bw$ then $(A - \gamma B)w = (\mu - \gamma)Bw$ and all the eigenvalues μ are shifted by γ, with the corresponding eigenvector remaining unchanged. In this section we look at some generalised eigenvalue problems that are closely related to EVP1 in that the new eigenvalue problems allow us to shift both the finite and infinite eigenvalues. First consider the eigenvalue problem

$$\begin{bmatrix} K - \gamma M & \delta_1 C \\ \delta_1 C^T & 0 \end{bmatrix} v = \sigma \begin{bmatrix} M & \delta_2 C \\ \delta_2 C^T & 0 \end{bmatrix} v \tag{EVP2}$$

for some $\delta_1, \delta_2, \gamma \in \boldsymbol{R}$. Note that $\gamma = \delta_2 = 0, \delta_1 = 1$ recovers EVP1. We have the following theorem about the eigenvalues of EVP2.

THEOREM 3.1. *Denote the finite eigenvalues of* REVP1 *by* $\mu_i, i = 1, \ldots, n - m$. *Assume* (2.5) *and*

$$\text{(i) } \delta_2 \neq 0, \qquad \text{(ii) } \delta_1 \delta_2^{-1} \neq \mu_i - \gamma. \tag{3.1}$$

Then EVP2 *has eigenvalues* σ_i, $i = 1, \ldots, n + m$ *with*

(a) $\sigma_i = \mu_i - \gamma$, $i = 1, \ldots, n - m$

(b) $\sigma_i = \delta_1 \delta_2^{-1}$, $i = n - m + 1, \ldots, n + m$.

Proof. Since M is positive definite it is straightforward to show, under (3.1(i)), that the matrix on the right-hand side of EVP2 is nonsingular and hence EVP2 has $n+m$ eigenvalues. Under the transformation introduced in the proof of Theorem 2.1, EVP2 is equivalent to

$$\begin{bmatrix} K_{11}-\gamma M_{11} & K_{12}-\gamma M_{12} & \delta_1 R_1 \\ K_{21}-\gamma M_{21} & K_{22}-\gamma M_{22} & 0 \\ \delta_1 R_1^T & 0 & 0 \end{bmatrix} v = \sigma \begin{bmatrix} M_{11} & M_{12} & \delta_2 R_1 \\ M_{21} & M_{22} & 0 \\ \delta_2 R_1^T & 0 & 0 \end{bmatrix} v,$$

and premultiplication by the inverse of the matrix on the right-hand side produces the eigenvalue problem

$$\begin{bmatrix} \delta_1\delta_2^{-1} & 0 & 0 \\ * & M_{22}^{-1}(K_{22}-\gamma M_{22}) & 0 \\ * & * & \delta_1\delta_2^{-1} \end{bmatrix} v = \sigma v$$

(where again $*$ denotes unique submatrices). Clearly this matrix has an eigenvalue at $\delta_1\delta_2^{-1}$ of multiplicity $2m$ and $n-m$ eigenvalues satisfying $(K_{22}-\gamma M_{22})z = \sigma M_{22} z$, which is precisely a simple shift of REVP1. Statements (a) and (b) now follow. □

Thus we see that the finite eigenvalues μ_i of EVP1 are shifted by γ, but the infinite eigenvalues are transformed to $\delta_1\delta_2^{-1}$. Thus any eigenvalue of EVP1 may be shifted to any location. Two examples of EVP2 that are the most likely to be useful are now introduced. Consider

$$\text{(EVP3)} \qquad \begin{bmatrix} K-\gamma M & 0 \\ 0 & 0 \end{bmatrix} v = \sigma \begin{bmatrix} M & C \\ C^T & 0 \end{bmatrix} v.$$

Clearly this has $n-m$ eigenvalues $\sigma_i = \mu_i - \gamma, i = 1, \ldots, n-m$, and $2m$ eigenvalues at zero. Similarly the eigenvalue problem

$$\text{(EVP4)} \qquad \begin{bmatrix} K & \delta_1 C \\ \delta_1 C^T & 0 \end{bmatrix} v = \sigma \begin{bmatrix} M & C \\ C^T & 0 \end{bmatrix}$$

leaves the finite eigenvalues μ_i of EVP1 unchanged, but transforms the infinite eigenvalues to δ_1. Note however that not all eigenvectors are preserved by the shifts. Eigenvectors of EVP1 corresponding to the infinite eigenvalues have the form $(0, w_2)$ and these are unchanged. However the eigenvectors of the finite eigenvalues of EVP1 are changed, but only in the last m components. To be precise, we have the following result, which may be deduced from the block form of the equations for EVP1 and EVP2.

LEMMA 3.2. (a) *Let μ be a finite eigenvalue of* EVP1. *Assume* (2.5) *and* (3.1). *If $(w_1, w_2), w_1 \in \boldsymbol{R}^n, w_2 \in \boldsymbol{R}^m$ is an eigenvector of* EVP1 *associated with μ, then (v_1, v_2), where $v_1 = w_1, v_2 = (\delta_1 - (\mu-\gamma)\delta_2)^{-1} w_2$ is the corresponding eigenvector of* EVP2.

(b) *Let $(0, w_2), w_2 \in \boldsymbol{R}^m$ be an eigenvector corresponding to an infinite eigenvalue of* EVP1. *Then $(0, v_2)$ with $v_2 = w_2$ is an eigenvector of* EVP2 *corresponding to the eigenvalue $\delta_1\delta_2^{-1}$.*

Remark 3. We have not gone into the detailed structure of the infinite eigenvalue of EVP1 or the eigenvalue $\delta_1\delta_2^{-1}$ of EVP2 of algebraic multiplicity $2m$. However analysis using the Weierstrass–Kronecker canonical form reveals that $\delta_1\delta_2^{-1}$ has geometric multiplicity m and that the eigenvalues occur in 2×2 pairs corresponding to Jordan

blocks of the form

$$\begin{bmatrix} \delta_1\delta_2^{-1} & 1 \\ 0 & \delta_1\delta_2^{-1} \end{bmatrix}.$$

This is to be expected following the results in [14].

4. Computational considerations. For K, C, and M small and/or full it will probably be a reasonable strategy to form $K_{22} = Q_2^T K Q_2$ and $M_{22} = Q_2^T M Q_2$ and to solve REVP1 directly. However, if K, C, and M are large and sparse the "reduced" matrices K_{22} and M_{22} will be full, and transformation methods will probably not be feasible. Iterative methods like simultaneous iteration or Arnoldi's method (probably applied to the EVP3 or EVP4) become attractive. It is therefore necessary to implement matrix $\times$ vector operations, which for the generalised eigenvalue problem reduce to solving systems of $(n+m)$ dimensional linear equations. These could be carried out directly on the $(n+m)$ dimensional systems [5], [7], [12], but an approach that involves only solving n dimensional systems is possible.

This is illustrated with reference to EVP3 with $\gamma = 0$. An iterative method will require the solution of a linear system of the form

$$\begin{bmatrix} M & C \\ C^T & 0 \end{bmatrix} \begin{bmatrix} u \\ p \end{bmatrix} = \begin{bmatrix} K & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} v \\ q \end{bmatrix}, \qquad v \text{ given}, \tag{4.1}$$

using an n dimensional system with coefficient matrix M.

It is readily shown (say by a block Gaussian elimination approach) that (4.1) can be solved by the following algorithm:

(i) solve $Mw = Kv$ for $w \in \boldsymbol{R}^n$,
(ii) solve $[C^T M^{-1} C]p = C^T w$ for $p \in \boldsymbol{R}^m$,
(iii) solve $Mx = Cp$ for $x \in \boldsymbol{R}^n$,
(iv) set $u = w - x$.

This is the Uzawa algorithm [1] and to be efficient, step (ii) would be carried out iteratively to avoid the direct computation of $C^T M^{-1} C$. For example, one could precondition $C^T M^{-1} C$ by $C^T M_l^{-1} C$, where M_l is the "lumped mass" matrix derived from M.

"Shift-invert" [16] or Cayley transform [7], [12] techniques are also possible with iterative methods like subspace iteration, requiring the solution of *nonsymmetric* systems of the form

$$\begin{bmatrix} K - \gamma M & C \\ C^T & 0 \end{bmatrix} \begin{bmatrix} u \\ p \end{bmatrix} = \begin{bmatrix} \nu \\ 0 \end{bmatrix} \tag{4.2}$$

for appropriate γ, and for three-dimensional partial differential equations this system will invariably have to be solved iteratively. However, if good estimates of the wanted eigenvalues are available and if direct solution of (4.2) is possible, then these approaches are likely to prove very efficient.

A standard approach to estimate the accuracy of an approximate eigenpair $(\tilde{\mu}, \tilde{w})$ of $Aw = \mu w$ is to calculate the "residual" vector $r := A\tilde{w} - \tilde{\mu}\tilde{w}$. Standard backward error analysis [23, p. 171] shows that typically a "small" residual indicates that $\tilde{\mu}$ is a "good" approximation to μ. A similar analysis holds for problems considered here. Let $(\tilde{\mu}, [\tilde{u}, \tilde{p}])$ denote an approximate eigenpair with $C^T \tilde{u} = 0$. Then the corresponding residual vector $r \in \boldsymbol{R}^{n+m}$ has the form

$$r = (r_1, 0), \qquad r_1 := K\tilde{u} + C\tilde{p} - \tilde{\mu} M \tilde{u} \in \boldsymbol{R}^n. \tag{4.3}$$

With $\tilde{u}^T\tilde{u} = 1$ it is readily shown that

$$\begin{bmatrix} K - r_1\tilde{u}^T & C \\ C^T & 0 \end{bmatrix} \begin{bmatrix} \tilde{u} \\ \tilde{p} \end{bmatrix} = \tilde{\mu} \begin{bmatrix} M & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} \tilde{u} \\ \tilde{p} \end{bmatrix},$$

i.e., $(\tilde{\mu}, [\tilde{u}, \tilde{p}])$ is an exact eigenpair of a perturbed problem (with the same block structure as (1.1), (1.2)). In §5 we use $\|r_1\|_2 (= \|r\|_2)$ to test the accuracy of an approximate eigenpair (cf. p383 of [11]).

5. Applications. The eigenvalue problem arises in the determination of the stability of steady solutions to the Navier–Stokes and related equations, and linearised stability theory [8], [19] shows that stability is determined by the eigenvalues with smallest real part of a linearised problem. The eigenvalue problem EVP1 arises if a mixed finite element method is used to discretize the linearised problem [5], [9], [15]. Of special interest is the case when the eigenvalues of smallest real part are complex, since algorithms for the detection of Hopf bifurcations in parameter dependent systems can be developed from knowledge of these eigenvalues. The matrices K, C, and M are sparse and very large. In [12], a problem with over 2×10^5 degrees of freedom is studied.

Since EVP1 involves large sparse nonsymmetric matrices one must fall back on iterative methods like Arnoldi's method or simultaneous iteration [2] to compute wanted eigenvalues. As mentioned in §4, shift-invert strategies are possible if good estimates of wanted eigenvalues are known. However, one can also apply iterative methods directly to EVP3 or EVP4 with appropriate choices for γ or δ_1, δ_2, respectively. To be precise two approaches are given.

(a) Choose $\gamma \approx \{\mathrm{Re}(\mu_1) + \mathrm{Re}(\mu_{n-m})\}/2$ in EVP3. Thus with $\rho_i = \mu_i - \gamma$, we have $\mathrm{Re}(\rho_1) + \mathrm{Re}(\rho_{n-m}) \approx 0$. The zero eigenvalue of multiplicity $2m$ of EVP3 is "in the middle" of the spectrum.

(b) Choose $\delta_1 \approx \{\mathrm{Re}(\mu_1) + \mathrm{Re}(\mu_{n-m})\}/2$ in EVP4. Thus the eigenvalue of multiplicity $2m$ of EVP2 is "in the middle" of the spectrum of EVP4, with $\mu_1 \ldots \mu_{n-m}$ being unchanged.

In both EVP3 and EVP4 the troublesome $2m$ multiple eigenvalue, which corresponds to the infinite eigenvalue of EVP1 (Lemma 2.2), will not be computed by the iterative algorithm. We note that the recent implicit polynomial filters algorithm of Sorensen [20] would appear to be an appropriate method to apply to reformulations like EVP2.

If the eigenvalues of EVP1 are known to be real, then simple shift strategies based on EVP3 and EVP4 allied to iterative methods provide the largest and smallest eigenvalues. However, when the eigenvalues may be complex then one may have to further transform the matrix eigenvalue problem. One approach is to utilize the Chebyshev transformation ideas of Saad [17], [18]. For a standard eigenvalue problem $Aw = \mu w$, the idea is to carry out a shifted Chebyshev polynomial transformation of A, say to $p_s(A)$, where the eigenvalues μ_i of A lying inside a certain ellipse in the complex plane are mapped to eigenvalues $p_s(\mu_i)$ of $p_s(A)$ satisfying $|p_s(\mu_i)| < 1$. The aim is to choose the polynomial p_s (and hence the ellipse) so that only the desired eigenvalues of A lie outside the ellipse. These become dominant, well-separated eigenvalues of $p_s(A)$ and hence are computed by an iterative solver applied to $p_s(A)$. These techniques were applied successfully to EVP3 to find eigenvalues of smallest real part of two problems from fluid dynamics and the results were reported in [5] and [7]. Transformation EVP4 was used to provide the numerical results in the following example.

5.1. Example. We consider a matrix arising from a mixed finite element discretization of the equations modeling two-dimensional double-diffusive convection in a box heated on the bottom boundary (see [22, Chap. 8]). The governing equations are solved in the Boussinesq approximation and are given in [4]. We do not reproduce these equations here but note that the model has nondimensional parameters: Prandtl number Pr, Rayleigh number Ra, salinity Rayleigh number Rs and τ (see [4, p. 254]), and interest centres on the loss of stability as Ra increases (which corresponds to increasing the temperature difference between the top and bottom boundary). Our calculations were performed with $\mathrm{Pr} = 10$ and $\tau = 10^{-2}$, which corresponds roughly to a salt solution and water, $\mathrm{Rs} = 2000$ and $\mathrm{Ra} = 2480$. The exact eigenvalues of the continuous problem, μ_i^e say, are known [22, (8.18)]) and the three leftmost eigenvalues are $\mu_1^e, \mu_2^e = 0.047486 \pm 24.502i$, $\mu_3^e = 0.098696$. A mixed finite element approximation was obtained in the usual way [13] using nine-node quadrilateral elements with biquadratic interpolation for velocities, temperatures and salinities, and discontinuous piecewise-linear interpolation for pressures [4]. The matrix was set up using ENTWIFE [24] with a 4×4 grid that leads to a matrix with the block structure of (1.1) with $n = 324$, $m = 48$, and hence $N(= n + m) = 372$. The three leftmost eigenvalues of the matrix problem to seven significant figures are $\mu_1, \mu_2 = 0.04932671 \pm 24.51725i$, $\mu_3 = 0.09874659$. (In fact numerical values are known with residuals (see (4.2)) less than 0.25×10^{-13}.)

In the following, "Arnoldi (k, l)" means Arnoldi's method restarted l times with subspace of dimension k [18]. First Arnoldi (20,1) with a random starting vector was applied to

$$A_1 := \begin{bmatrix} M & C \\ C^T & 0 \end{bmatrix}^{-1} \begin{bmatrix} K & 0 \\ 0 & 0 \end{bmatrix}$$

to obtain a very rough idea of the convex hull of the eigenvalues of EVP2 with $\gamma = 0$, $\delta_1 = 0$, and $\delta_2 = 1$, and hence a rough estimate of μ_{n-m} is obtained. (Of course, the matrix $\times$ vector operations with A_1 were performed by solving linear systems.) Next form EVP4 with $\delta_2 = 1$, $\delta_1 = \mathrm{Re}(\mu_{n-m})/2$, in line with strategy (b) above, and try to find the leftmost eigenvalues of

$$A_2 := \begin{bmatrix} M & C \\ C^T & 0 \end{bmatrix}^{-1} \begin{bmatrix} K & \delta_1 C \\ \delta_1 C^T & 0 \end{bmatrix}.$$

Arnoldi (20, 50) failed to find any of the three leftmost eigenvalues, perhaps because of severe clustering of the eigenvalues [18]. The hybrid algorithm of Saad [18] (see above) utilizing the Chebyshev transformation to find the two leftmost eigenvalues (so that the ellipse passes through μ_3) is however successful. A two-step procedure was used:

(i) Arnoldi (20, 1) with a random starting vector was applied to $p_5(A_2)$ to obtain a "purified" starting vector.

(ii) Arnoldi (20, 1) was applied to $p_{42}(A_2)$. This computed μ_1, μ_2 with residuals less than 5×10^{-12} (see (4.3)).

Numerical experiments using EVP3 with γ chosen in (a) above produce similar results. This is not surprising since the distribution of the extremal eigenvalues of EVP3 and EVP4 is the same.

Acknowledgments. Y. Saad kindly sent us a copy of his hybrid algorithm [18] that was used to carry out the computations in §5.

ON THE PERTURBATION OF THE CHOLESKY FACTORIZATION*

ZLATKO DRMAČ†, MATJAŽ OMLADIČ‡, AND KREŠIMIR VESELIĆ§

Abstract. The perturbation of the Cholesky factor of a perturbed positive definite matrix is considered. Estimates are included for small perturbations in the spectral norm as well as for large perturbations in the Euclidean norm. The results can be applied to floating point perturbations as well.

Key words. Cholesky factor, relative perturbation, floating point perturbation

AMS subject classifications. 15A23, 15A45

1. Introduction.

Let H be a Hermitian positive definite matrix of order n. Then, as it is well known, there exists a unique upper triangular matrix R with real and positive diagonal elements such that

$$H = R^*R. \tag{1}$$

The matrix R is called the *Cholesky factor* of H. It is given by the recursive formulae (*Cholesky algorithm*)

$$|R_{1i}|^2 + \cdots + |R_{ii}|^2 = H_{ii}, \qquad 1 \le i \le n, \tag{2}$$

$$\bar{R}_{1i}R_{1j} + \cdots + \bar{R}_{ii}R_{ij} = H_{ij}, \quad i = 1, \ldots, n-1, \quad j = i+1, \ldots, n. \tag{3}$$

From this it follows that R depends continuously on H.

In this note we derive some explicit perturbation estimates for the Cholesky factorization. Let $H + \delta H$ be the perturbed positive definite matrix and $R + \delta R$ be its perturbed Cholesky factor. Then

$$H + \delta H = (R + \delta R)^*(R + \delta R) = R^*(I + A)R, \tag{4}$$

where[1] $A = R^{-*}\delta H R^{-1}$, so we may go over to the "normalized" problem

$$I + A = (I + \Gamma)^*(I + \Gamma). \tag{5}$$

Here, of course,

$$\Gamma_{ii} > -1, \qquad 1 \le i \le n. \tag{6}$$

Once a norm estimate for Γ is obtained, we can estimate $\delta R = \Gamma R$ as

$$\|\delta R\| \le \|\Gamma\|\|R\|.$$

[1] Here $R^{-*} = (R^{-1})^*$.

Sun [12] obtained an estimate for the Frobenius norm $\|\Gamma\|_F$ and then

$$\|\delta R\|_F \leq \|\Gamma\|_F \|R\|_2. \tag{7}$$

We treat more general norms including an estimate for the spectral norm $\|\Gamma\|_2$. Then

$$\|\delta R x\|_2 \leq \|\Gamma\|_2 \|Rx\|_2, \qquad x \in \mathbf{C}^n. \tag{8}$$

From this we obtain

$$\|\delta R\|_2 \leq \|\Gamma\|_2 \|R\|_2. \tag{9}$$

From (8) we obtain a columnwise estimate

$$\|\delta R_{\cdot,i}\|_2 \leq \|\Gamma\|_2 \|R_{\cdot,i}\|_2, \tag{10}$$

which may be more appropriate for differently scaled columns. Section 2 gives estimates for $\|\Gamma\|$ in terms of the same norm $\|A\|$, if the latter is small enough. For the spectral norm we obtain

$$\|\Gamma\|_2 \leq \frac{2c_n\|A\|_2}{1+\sqrt{1-4c_n^2\|A\|_2}}, \qquad c_n = \frac{1}{2} + [\log_2 n]. \tag{11}$$

The estimate $\|A\|_2 \leq \|H^{-1}\|_2 \|\delta H\|_2$ may be pessimistic, if we deal with the floating point perturbation of the type $|\delta H_{ij}| \leq \varepsilon |H_{ij}|$. Section 3 gives an estimate for A in terms of ε.

In Section 4 we prove some large perturbation estimates for the Frobenius norm. For example, whenever $I + A$ is positive definite, we have a simple global estimate

$$\|\Gamma\|_F \leq \sqrt{8n + 2\sqrt{n}}\|A\|_F. \tag{12}$$

After a first version of this paper was written, the authors became aware of a related paper [4] where results slightly sharper than (11), (12) were obtained by other methods. We thank the referee for pointing this out.

2. Small perturbations. We first consider the Cholesky factorization of $I + A$, $\|A\|_2 < 1$. For a Hermitian A set

$$\mathcal{P}(A) = \begin{bmatrix} \frac{A_{11}}{2} & A_{12} & \cdots & A_{1n} \\ 0 & \frac{A_{22}}{2} & \cdots & A_{2n} \\ \vdots & \ddots & \ddots & \vdots \\ 0 & \cdots & 0 & \frac{A_{nn}}{2} \end{bmatrix}. \tag{13}$$

Obviously $\mathcal{P}$ is an invertible linear operator mapping the real space $\mathcal{H}$ of Hermitian matrices onto the real algebra $\mathcal{T}$ of upper triangular matrices with real diagonal. (cf., also, Stewart and Sun [10]–[12].) For any $S \in \mathcal{T}$ we have

$$\mathcal{P}(S + S^*) = S. \tag{14}$$

Let $\|\cdot\|$ be any norm on $\mathcal{T}$. By the same symbol we denote the corresponding operator norm

$$\|\mathcal{P}\| = \max_{\substack{A\in\mathcal{H}\\ \nu(A)=1}} \|\mathcal{P}(A)\|, \tag{15}$$

where ν is a norm on $\mathcal{H}$. By $\mathcal{P}(I) = I/2$ we have

$$\|\mathcal{P}\| \geq \frac{1}{2}\frac{\|I\|}{\nu(I)}. \tag{16}$$

The following theorem is a strengthening of the corresponding result from [12]. (The latter deals with the Frobenius norm. An asymptotic estimate of this form was derived by Barlow and Demmel [1].) Our proof is simpler and is based on a homotopy argument.

THEOREM 2.1. *Let $A \in \mathcal{H}$, $S = \mathcal{P}(A)$, and $I + A$ be positive definite. Let*

$$p = \max \frac{\|\mathcal{P}(\Gamma^*\Gamma)\|}{\|\Gamma\|^2}, \tag{17}$$

where the maximum is taken over all $\Gamma \in \mathcal{T}$ with $\Gamma_{ii} > -1$ for all i. If

$$4p\|S\| \leq 1, \tag{18}$$

then the Cholesky factor of $I + A$ equals $I + \Gamma$ with

$$\|\Gamma\| \leq \frac{2\|S\|}{1 + \sqrt{1 - 4p\|S\|}}. \tag{19}$$

Proof. For $0 \leq \eta \leq 1$, the matrix $I + \eta A$ is positive definite and its Cholesky factorization is

$$(I + \Gamma_\eta)^*(I + \Gamma_\eta) = I + \eta A, \tag{20}$$

where, as mentioned above, Γ_η depends continuously on η and $\Gamma_0 = 0$, $\Gamma_1 = \Gamma$. Now (20) is equivalent to

$$\Gamma_\eta = \eta S - \mathcal{P}(\Gamma_\eta^*\Gamma_\eta). \tag{21}$$

Hence

$$\|\Gamma_\eta\| \leq \eta\|S\| + p\|\Gamma_\eta\|^2,$$

which implies that $\|\Gamma_\eta\|$ lies outside of the nonvoid open interval

$$\left(\frac{1 - \sqrt{1 - 4p\eta\|S\|}}{2p}\ ,\quad \frac{1 + \sqrt{1 - 4p\eta\|S\|}}{2p}\right).$$

Now by continuity, $\|\Gamma_\eta\|$ must lie left from that interval. Thus, (19) follows. □

From (19) it follows that

$$\|\Gamma\| \leq \|S\|(1 + 4p\|S\|) \leq 2\|S\|.$$

Using this and (21) we obtain

$$\|S\|(1-4p\|S\|) \le \|\Gamma\| \le \|S\|(1+4p\|S\|),$$

which shows that the estimate (19) cannot be essentially sharpened for small A.

By (17), (19), the practical use of Theorem 2.1 depends on p and, in the case of a self-adjoint matrix norm $\nu = \|\cdot\|$, its upper bound $\|\mathcal{P}\|$. We shall consider the Frobenius norm

$$\|A\|_F = \sqrt{\mathrm{Tr} A^* A},$$

and the spectral norm

$$\|A\|_2 = \max_{\|x\|_2=1} \|Ax\|_2, \qquad \|x\|_2 = (x^*x)^{1/2}.$$

The corresponding p's from Theorem 2.1 are denoted by p_F and p_2, respectively. We have

$$\|\mathcal{P}(A)\|_F^2 = \sum_{\substack{i,j \\ i<j}} |A_{ij}|^2 + \frac{1}{4}\sum_i |A_{ii}|^2 \le \sum_{\substack{i,j \\ i<j}} |A_{ij}|^2 + \frac{1}{2}\sum_i |A_{ii}|^2 = \frac{1}{2}\|A\|_F^2.$$

Here the equality sign is attained at any A with zero diagonals. Thus,

$$p_F \le \|\mathcal{P}\|_F = \frac{1}{\sqrt{2}}. \tag{22}$$

Now by Theorem 2.1, $\|S\|_F < 1/(2\sqrt{2})$ implies

$$\|\Gamma\|_F \le \frac{2\|S\|_F}{1+\sqrt{1-2\sqrt{2}\|S\|_F}} \le \frac{\sqrt{2}\|A\|_F}{1+\sqrt{1-2\|A\|_F}}. \tag{23}$$

The spectral norm is more complicated. A simple estimate

$$p_2 \le \|\mathcal{P}\|_2 \le \sqrt{\frac{n}{2}} \tag{24}$$

follows immediately from (22). For a better estimate we use a binary splitting to decompose the space of Hermitian matrices into a direct sum of subspaces that we illustrate for $n = 7$.

$$A = \begin{bmatrix} \cdot & \cdot & \cdot & * & * & * & * \\ \cdot & \cdot & \cdot & * & * & * & * \\ \cdot & \cdot & \cdot & * & * & * & * \\ * & * & * & \cdot & \cdot & \cdot & \cdot \\ * & * & * & \cdot & \cdot & \cdot & \cdot \\ * & * & * & \cdot & \cdot & \cdot & \cdot \\ * & * & * & \cdot & \cdot & \cdot & \cdot \end{bmatrix} + \begin{bmatrix} \cdot & * & * & \cdot & \cdot & \cdot & \cdot \\ * & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ * & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & * & * \\ \cdot & \cdot & \cdot & \cdot & \cdot & * & * \\ \cdot & \cdot & \cdot & * & * & \cdot & \cdot \\ \cdot & \cdot & \cdot & * & * & \cdot & \cdot \end{bmatrix}$$

$$+ \begin{bmatrix} \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & * & \cdot & \cdot & \cdot & \cdot \\ \cdot & * & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & * & \cdot & \cdot \\ \cdot & \cdot & \cdot & * & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & * \\ \cdot & \cdot & \cdot & \cdot & \cdot & * & \cdot \end{bmatrix} + \begin{bmatrix} * & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & * & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & * & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & * & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & * & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & * & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & * \end{bmatrix}.$$

In general, it holds that

$$A = A_q + \cdots + A_1 + A_0, \qquad q = [\log_2 n],$$

where the matrix A_0 is the diagonal part of A. This direct decomposition has the properties

$$\|\mathcal{P}(A_0)\|_2 = \frac{1}{2}\|A_0\|_2, \quad \|\mathcal{P}(A_i)\|_2 = \|A_i\|_2, \quad i = 1, \ldots, q,$$

$$\|A_i\|_2 \le \|A\|_2, \qquad i = 0, \ldots, q.$$

This immediately gives

$$1 \le \|\mathcal{P}\|_2 \le c_n = \frac{1}{2} + [\log_2 n]. \tag{25}$$

Next, we show that the operator $\mathcal{P}$ has spectral norm unbounded in n. In fact, $\|\mathcal{P}\|_2 \sim \log n$ as $n \to \infty$, so the $\sim \log_2 n$ estimate (25) is about the best possible. (Compare also related results of Mathias [8] which are slightly sharper. We bring our proof because of its simplicity.) Kahan [6], [7] has given an example of upper triangular matrix $Z \in \mathbf{C}^{n\times n}$, with zero diagonal, for which[2]

$$\frac{\|Z - Z^*\|_2}{\|Z + Z^*\|_2} > \frac{2}{\pi}\left(\log n + \frac{1}{4} - \log 2 + \frac{1}{2n}\right). \tag{26}$$

Since $\mathcal{P}(Z + Z^*) = Z$, we obtain

$$\frac{\|\mathcal{P}(Z + Z^*)\|_2}{\|Z + Z^*\|_2} > \frac{1}{\pi}(\log n + o(1)), \tag{27}$$

which shows that the $\log n$-like bound for $\|\mathcal{P}\|_2$ is almost attainable. Kahan's matrix Z reads

$$Z = \mathbf{i}\begin{bmatrix} 0 & 1 & \frac{1}{2} & \frac{1}{3} & \cdots & \frac{1}{n-1} \\ & 0 & 1 & \frac{1}{2} & \cdots & \frac{1}{n-2} \\ & & 0 & \ddots & \ddots & \vdots \\ & & & \ddots & \ddots & \frac{1}{2} \\ & & & & \ddots & 1 \\ & & & & & 0 \end{bmatrix} \in \mathbf{C}^{n\times n}, \qquad \mathbf{i}^2 = -1.$$

Even if we restrict the domain of $\mathcal{P}$ to the space of real symmetric matrices, $\|\mathcal{P}\|_2$ remains $\log n$-like. A real example $\mathcal{N}$ is constructed as follows. (A similar example appears independently in [4].)

Replace each Z_{ij} by the two by two block $|Z_{ij}|\left[\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right]$. For example, in the case $n = 8$, we get

$$\mathcal{N} = \begin{bmatrix} 0 & 0 & 0 & 1 & 0 & \frac{1}{2} & 0 & \frac{1}{3} \\ 0 & 0 & -1 & 0 & -\frac{1}{2} & 0 & -\frac{1}{3} & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & \frac{1}{2} \\ 0 & 0 & 0 & 0 & -1 & 0 & -\frac{1}{2} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}.$$

[2] We thank the referee for pointing out an error in [6].

In fact, there is a permutation matrix P for which

$$\tilde{\mathcal{N}} = P^T \mathcal{N} P = \begin{bmatrix} \boldsymbol{\Theta} & C \\ -C & \boldsymbol{\Theta} \end{bmatrix}, \qquad C = -\mathbf{i}Z.$$

(Here $\boldsymbol{\Theta}$ denotes the null–matrix.)
Since $C^T = -\mathbf{i}Z^T$ and $Z^T = -Z^*$, we have

$$C - C^T = -\mathbf{i}(Z + Z^*),$$
$$C + C^T = -\mathbf{i}(Z - Z^*),$$

and then

$$\tilde{\mathcal{N}} + \tilde{\mathcal{N}}^T = \begin{bmatrix} \boldsymbol{\Theta} & -\mathbf{i}(Z + Z^*) \\ \mathbf{i}(Z + Z^*) & \boldsymbol{\Theta} \end{bmatrix},$$
$$\tilde{\mathcal{N}} - \tilde{\mathcal{N}}^T = \begin{bmatrix} \boldsymbol{\Theta} & -\mathbf{i}(Z - Z^*) \\ \mathbf{i}(Z - Z^*) & \boldsymbol{\Theta} \end{bmatrix}.$$

Finally,

$$\|\mathcal{N} + \mathcal{N}^T\|_2 = \|Z + Z^*\|_2,$$
$$\|\mathcal{N} - \mathcal{N}^T\|_2 = \|Z - Z^*\|_2,$$

and as in (27) we again obtain the lower $\log n$-like bound for $\|\mathcal{P}\|_2$.

According to (25), Theorem 2.1 applies if

$$\|S\|_2 < \frac{1}{4c_n} \tag{28}$$

and yields

$$\|\Gamma\|_2 \leq \frac{2\|S\|_2}{1 + \sqrt{1 - 4c_n\|S\|_2}}. \tag{29}$$

Remark 2.2. The quotient $\|\mathcal{P}(A)\|_2/\|A\|_2$ can sometimes be essentially less than $\|\mathcal{P}\|_2$. For instance, if $U = \operatorname{diag}(e^{\mathbf{i}\varphi_k})$ is unitary such that $U^*AU = |A|$, then

$$\|\mathcal{P}(A)\|_2 = \|\mathcal{P}(U|A|U^*)\|_2 = \|U\mathcal{P}(|A|)U^*\|_2$$
$$= \|\mathcal{P}(|A|)\|_2 \leq \||A|\|_2 = \|A\|_2,$$

because of the monotonicity of the spectral norm. (Here $|A|$ denotes the pointwise absolute value, $|A|_{ij} = |A_{ij}|$ for all i, j.)

The case of the perturbation of a general positive definite matrix H is easily reduced to that of Theorem 2.1.

COROLLARY 2.3. *Let $H \in \mathcal{H}$ be positive definite and R its Cholesky factor. Let δH be Hermitian perturbation such that $A = R^{-*}\delta H R^{-1}$ satisfies the conditions of Theorem* 2.1. *Then $H + \delta H$ is positive definite and its Cholesky factor reads*

$$R + \delta R = (I + \Gamma)R, \tag{30}$$

where $\delta R = \Gamma R$ and Γ is defined by (5), (6).

Note that by

$$\|A\|_2 \leq \|H^{-1}\|_2 \|\delta H\|_2, \tag{31}$$

the value $\|H^{-1}\|_2$ influences the estimate for $\|S\|_2$ and thus for $\|\Gamma\|_2$. This can lead to pesimistic estimates for relative or *floating point* errors. This is considered in the next section.

3. Floating point perturbations. If in Corollary 2.3 a relative perturbation bound is given by $\|\delta H\|_2 \le \varepsilon\|H\|_2$, then by (31) the key quantity $\|A\|_2$ is bounded by $\varepsilon\|H\|_2\|H^{-1}\|_2$. This condition may be pessimistic if we consider "floating point perturbations" of H, where $|\delta H_{ij}|$ is small with respect to $|H_{ij}|$ for every i, j, or, more generally, with respect to $\sqrt{H_{ii}H_{jj}}$.

THEOREM 3.1. *Let $H \in \mathcal{H}$ be positive definite, R its Cholesky factor, and δH Hermitian perturbation such that for all i, j*

$$|\delta H_{ij}| \le \varepsilon\sqrt{H_{ii}H_{jj}}, \tag{32}$$

where

$$\varepsilon < \frac{1}{4c_n^2 n\|B^{-1}\|_2} \tag{33}$$

and

$$B = \left[\frac{H_{ij}}{\sqrt{H_{ii}H_{jj}}}\right]. \tag{34}$$

Then $H + \delta H$ is positive definite and its Cholesky factor is given by

$$R + \delta R = (I + \Gamma)R,$$

with

$$\|\Gamma\|_2 \le \frac{2nc_n\varepsilon\|B^{-1}\|_2}{1 + \sqrt{1 - 4nc_n^2\varepsilon\|B^{-1}\|_2}}. \tag{35}$$

Proof. By (32) for any vector x, we have

$$\begin{aligned}|x^*\delta H x| &\le \varepsilon\sum_{i,j}\sqrt{H_{ii}H_{jj}}|x_i||x_j| = \varepsilon\left(\sum_i |\sqrt{H_{ii}}x_i|\right)^2 \\ &\le n\varepsilon\sum_i |\sqrt{H_{ii}}x_i|^2 \le n\varepsilon\|B^{-1}\|_2 x^*Hx,\end{aligned}$$

where we have used $\|x\|_2^2 \le \|B^{-1}\|_2 x^*Bx$. Setting here $x = R^{-1}y$, we obtain $|y^*Ay| \le n\varepsilon\|B^{-1}\|_2\|y\|_2^2$ and hence

$$\|A\|_2 \le n\varepsilon\|B^{-1}\|_2. \tag{36}$$

Recall,

$$A = R^{-*}\delta H R^{-1}.$$

Now by (33), we have

$$\|A\|_2 < \frac{1}{4c_n^2},$$

which implies (28). Then by (29) we obtain (35). □

It is instructive to compare the norm estimate (31) with the estimates (10), (8), (35). Corollary 2.3 and (28), (31) yield

$$\|\Gamma\|_2 \leq 2c_n\kappa(H)\frac{\|\delta H\|_2}{\|H\|_2}, \qquad \kappa(H) = \|H\|_2\|H^{-1}\|_2,$$

while (35) yields

$$\|\Gamma\|_2 \leq 2nc_n\|B^{-1}\|_2 \max_{i,j}\frac{|\delta H_{ij}|}{\sqrt{H_{ii}H_{jj}}}.$$

Now, $\|B^{-1}\|_2$ is newer much larger and can be much smaller than $\kappa(H)$ [9]. Note also that (8) and (10) give *local* estimates for the factor $R + \delta R$. This is important if R has very small and very large columns. The matrix B, obtained from H by diagonal scaling, was shown to be of crucial importance in floating point perturbation theory of the eigenvalue problem [2]. Our result shows that B controls the Cholesky decomposition in a similar sense.

Remark 3.2. If δH has at most p nonzero elements in any row (any column), then the factor n in the estimates of Theorem 3.1 can be replaced by p. This can be easily shown by using the estimates from [9] or by the Hadamard product technique.

Example 3.3. As an example, consider the matrix

$$H = \begin{bmatrix} \eta^2 & \eta \\ \eta & 2 \end{bmatrix}, \qquad \eta \ll 1.$$

Here

$$R = \begin{bmatrix} \eta & 1 \\ 0 & 1 \end{bmatrix}, \quad \|H\|_2\|H^{-1}\|_2 > \frac{2}{\eta^2}, \quad \|B^{-1}\|_2 = 2 + \sqrt{2}.$$

Any perturbation δH of the type (32) with $\varepsilon < 0.01$ causes perturbation $\delta R = \Gamma R$ with

$$\|\Gamma\|_2 < 20.5\varepsilon,$$

i.e., for all x,

$$\|\delta Rx\|_2 < 20.5\varepsilon\|Rx\|_2$$

holds. Note that this implies

$$\frac{\|\delta R\|_2}{\|R\|_2} < 20.5\varepsilon.$$

Furthermore, since $\lambda_{\min}(H) < \eta^2 \ll 1$, the application of Corollary 2.3 gives pessimistic estimate, because H is almost singular for small η.

Example 3.4. Let $H = R^TR$ be the Cholesky factorization of real positive definite $H \in \mathbf{R}^{n\times n}$ and $\tilde{R} = R + \delta R$ the computed Cholesky factor of H using floating point arithmetic with precision ε. Then (see [2, Lemma 4.5])

$$\tilde{R}^T\tilde{R} = H + \delta H,$$

where

$$|\delta H_{ij}| \leq (n+5)\varepsilon\sqrt{H_{ii}H_{jj}}, \qquad 1 \leq i,j \leq n.$$

Using Theorem 3.1, we obtain

$$\|\delta Rx\|_2 \leq \frac{2n(n+5)c_n\varepsilon\|B^{-1}\|_2}{1+\sqrt{1-4n(n+5)c_n^2\varepsilon\|B^{-1}\|_2}}\|Rx\|_2, \qquad x \in \mathbf{R}^n,$$

provided that

$$\|B^{-1}\|_2 \leq \frac{1}{4n(n+5)c_n^2\varepsilon}.$$

If, e.g., $\|B^{-1}\|_2 \approx 100$, $n = 1000$, $\varepsilon \approx 10^{-16}$ we have

$$\|\delta Rx\|_2 \leq \text{const} \cdot 10^{-7}\|Rx\|_2, \qquad x \in \mathbf{R}^n.$$

Thus, the singular values of $\tilde{R}$ and R, for example, coincide in seven digits at least, see [2, Thm. 2.14].

We now present another approach that permits a better treatment of perturbations preserving certain sparse structures. We also obtain some multiplicative estimates similar to those in [13].

Let

$$\delta H = \dot{H} \circ E \tag{37}$$

with the *relative error mask* matrix $\dot{H}$ and the *relative error* matrix E; see [3]. Here $\dot{H}_{ij}$ can be H_{ij} or $\sqrt{H_{ii}H_{jj}}$ or some other measure for the relative size of perturbation δH_{ij}, E_{ij} is the relative perturbation of H_{ij} (as measured relative to given $\dot{H}_{ij}$) and $\circ$ denotes the Hadamard (pointwise) matrix multiplication. Thus, $\delta H_{ij} = \dot{H}_{ij}E_{ij}$ for all i, j. It is reasonable to assume both $\dot{H}$ and E Hermitian. Let $\tilde{H} = H + \delta H$ be positive definite and

$$\tilde{H} = R^*R + \delta H = R^*(I + R^{-*}\delta H R^{-1})R = R^*K^2R,$$

with

$$K = \sqrt{I + R^{-*}\delta H R^{-1}}.$$

($\sqrt{\cdot}$ is the square root of a positive definite matrix.) If

$$K = QT (= T^*Q^*)$$

is the (unique) QR factorization of K with upper triangular T and $T_{ii} > 0$, $1 \leq i \leq n$, then

$$\tilde{H} = R^*T^*Q^*QTR = (TR)^*(TR) = \tilde{R}^*\tilde{R}$$

is the unique Cholesky factorization of $\tilde{H}$ with

$$\tilde{R} = TR = Q^*\sqrt{I + R^{-*}\delta H R^{-1}}R$$

and

$$\|T\|_2 = \|\sqrt{I + R^{-*}\delta H R^{-1}}\|_2 \leq \sqrt{1 + \|R^{-*}\delta H R^{-1}\|_2}.$$

If we define

$$\dot{H}_S = D^{-1}\dot{H}D^{-1}, \quad R_S = RD^{-1}, \quad H_S = R_S^* R_S,$$

with an arbitrary diagonal positive definite D, then

$$R^{-*}\delta H R^{-1} = R^{-*}(\dot{H} \circ E)R^{-1} = R_S^{-*}(\dot{H}_S \circ E)R_S^{-1}$$

holds. Hence

$$\begin{aligned}\|T\|_2^2 &\leq 1 + \|R_S^{-1}\|_2^2 \|\dot{H}_S \circ E\|_2 \\ &\leq 1 + \frac{\sqrt{\|\dot{H}_S \circ \overline{\dot{H}_S}\|_1}}{\lambda_{\min}(H_S)} \sqrt{\|E \circ \overline{E}\|_\infty},\end{aligned}$$

with

$$\overline{E} = (E^*)^\tau, \quad \overline{\dot{H}_S} = (\dot{H}_S^*)^\tau.$$

Here we have used the Cauchy–Schwarz inequality for the Hadamard product and the spectral norm. (See [5, p. 212]) If we define the condition number

$$\zeta(H, \dot{H}) = \min_D \frac{\sqrt{\|\dot{H}_S \circ \overline{\dot{H}_S}\|_1}}{\lambda_{\min}(H_S)},$$

then

$$\|T\|_2 \leq \sqrt{1 + \zeta(H, \dot{H})\sqrt{\|E \circ \overline{E}\|_\infty}}.$$

On the other side,

$$\begin{aligned}\sigma_{\min}(T) &= \sqrt{\lambda_{\min}(I + R^{-*}\delta H R^{-1})} \\ &\geq \sqrt{1 - \|R^{-*}\delta H R^{-1}\|_2} \geq \sqrt{1 - \zeta(H, \dot{H})\sqrt{\|E \circ \overline{E}\|_\infty}},\end{aligned}$$

provided that

$$\sqrt{\|E \circ \overline{E}\|_\infty} < \zeta(H, \dot{H})^{-1}. \tag{38}$$

Thus, we have proved the following multiplicative perturbation bound for the Cholesky factorization.

THEOREM 3.5. *Let $H \in \mathcal{H}$ be positive definite, R its Cholesky factor, and $\delta H = \dot{H} \circ E$ Hermitian perturbation satisfying* (38). *Then the Cholesky factor of $H + \delta H$ reads*

$$\tilde{R} = TR,$$

where

$$\sqrt{1 - \zeta(H, \dot{H})\sqrt{\|E \circ \overline{E}\|_\infty}} \leq \sigma_{\min}(T) \leq \sigma_{\max}(T) \leq \sqrt{1 + \zeta(H, \dot{H})\sqrt{\|E \circ \overline{E}\|_\infty}}.$$

Remark 3.6. We can bound $\zeta(H, H)$ by

$$\zeta(H, H) \leq \frac{1}{\lambda_{\min}(H_B)},$$

where H_B is balanced H (i.e., $H_B = D_B H D_B$, has unit rows and columns and D_B is the diagonal scaling). Thus, the error term is then approximatively given by

$$0.5\ \|H_B^{-1}\|_2 \sqrt{\|E \circ \overline{E}\|_\infty} + o(\|E \circ \overline{E}\|_\infty).$$

Next, we want to estimate relative errors in the elements of the Cholesky factor as functions of the relative errors in the elements of H. Since $\delta R = (T - I)R$, we immediately obtain

$$|\delta R| \leq |T - I||R|, \tag{39}$$

an estimate comparable with the one given by Sun [13]. Note, T is the Cholesky factor of $I + R^{-*}\delta H R^{-1}$ and the estimate

$$\|T - I\|_2 \leq \frac{2c_n \zeta(H, \dot{H}) \sqrt{\|E \circ \overline{E}\|_\infty}}{1 + \sqrt{1 - 4c_n^2 \zeta(H, \dot{H}) \sqrt{\|E \circ \overline{E}\|_\infty}}} \tag{40}$$

holds, provided that $\sqrt{\|E \circ \overline{E}\|_\infty} < 0.25 c_n^{-2} \zeta(H, \dot{H})^{-1}$. Since

$$\delta R_{ij} = \sum_{k=i}^{j} (T - I)_{ik} R_{kj}$$

and therefore for $1 \leq i \leq j \leq n$

$$|\delta R_{ij}| \leq \sqrt{\sum_{k=i}^{j} (T - I)_{ik}^2} \sqrt{\sum_{k=i}^{j} R_{kj}^2} \leq \|T - I\|_2 \sqrt{\sum_{k=i}^{j} R_{kj}^2},$$

we see that the magnitude of $|\delta R_{ij}|$ relative to

$$\sqrt{\sum_{k=i}^{j} R_{kj}^2}$$

is given by (40). Thus, the relative errors in $\tilde{R}_{ii}$, $1 \leq i \leq n$ are determined by the condition of H and bounded by $\|T - I\|_2$. The relative error in an element with magnitude of at least about the average of the corresponding column has nearly the same bound. If all elements in a column have about the same modulus, they all have relative errors about $o(\|T - I\|_2)$. Furthermore, if R is the optimally pivoted Cholesky factor then

$$|\delta R_{ij}| \leq \|T - I\|_2 |R_{ii}|, \qquad 1 \leq i \leq j \leq n.$$

4. Large perturbations. The estimates for Γ in §2 are asymptotically sharp, but their validity is restricted by a too strong condition (18). It is desirable to obtain estimates that are valid whenever the factorization (5) exists. The relation (5) can be written as

$$A = \Gamma + \Gamma^* + \Gamma^*\Gamma. \tag{41}$$

Taking the trace in (41), we obtain

$$\mathrm{Tr}A = 2\mathrm{Tr}\Gamma + \|\Gamma\|_F^2, \tag{42}$$

a central identity in our analysis. One can easily show that, with the proper notion of the angle, (42) is in fact the cosine theorem for a certain matrix triangle. By (6) and (42), we obtain

$$\|\Gamma\|_F \leq \sqrt{2n + \sqrt{n}\|A\|_F}.$$

Combining this with the local estimate

$$\|\Gamma\|_F \leq \sqrt{2}\|A\|_F$$

for $\|A\|_F \leq \frac{1}{2}$ (see (23)), we obtain a simple global estimate

$$\|\Gamma\|_F \leq \sqrt{8n + 2\sqrt{n}}\|A\|_F.$$

If A is positive or negative definite better estimates are available. We first prove the monotonicity property of the Cholesky factorization.

LEMMA 4.1. *Let K, H be positive definite with the Cholesky factorizations*

$$K = R_K^* R_K, \qquad H = R_H^* R_H, \tag{43}$$

and $H - K$ positive semidefinite ($K \preceq H$). Then

$$\|R_K R_H^{-1}\|_2 \leq 1. \tag{44}$$

Proof. From $R_K^* R_K \preceq R_H^* R_H$ we obtain $(R_K R_H^{-1})^*(R_K R_H^{-1}) \preceq I$ and (44) follows.[3] □

We now treat the case $I + A$ with A positive semidefinite.

LEMMA 4.2. *Let $\Gamma \in \mathcal{T}$ be a matrix satisfying* (5), *where $A \in \mathcal{H}$ is positive semidefinite. Then*

$$\frac{\|A\|_F}{1 + \sqrt{1 + \|A\|_2}} \leq \|\Gamma\|_F \leq \|\mathcal{P}(A)\|_F \leq \frac{1}{\sqrt{2}}\|A\|_F. \tag{45}$$

Proof. From (41), using the monotonicity of the diagonal, we obtain

$$A_{ii} \geq 2\Gamma_{ii} \geq 0, \qquad 1 \leq i \leq n, \tag{46}$$

[3] We thank the referee for improving the statement and the proof of this lemma.

and then

$$\sum_{i=1}^{n} \Gamma_{ii}^2 \leq \frac{1}{4} \sum_{i=1}^{n} A_{ii}^2. \tag{47}$$

On the other side, if we set $(I+\Gamma)^{(i)}$ for the $i \times i$ leading submatrix of $I+\Gamma$, then

$$\begin{bmatrix} \Gamma_{1,i+1} \\ \vdots \\ \Gamma_{i,i+1} \end{bmatrix} = \left((I+\Gamma)^{(i)}\right)^{-*} \begin{bmatrix} A_{1,i+1} \\ \vdots \\ A_{i,i+1} \end{bmatrix}. \tag{48}$$

Hence

$$\left\| \begin{bmatrix} \Gamma_{1,i+1} \\ \vdots \\ \Gamma_{i,i+1} \end{bmatrix} \right\| \leq \frac{1}{\sigma_{\min}((I+\Gamma)^{(i)})} \left\| \begin{bmatrix} A_{1,i+1} \\ \vdots \\ A_{i,i+1} \end{bmatrix} \right\|, \qquad 1 \leq i \leq n-1, \tag{49}$$

and

$$\|\Gamma - \operatorname{diag} \Gamma\|_F \leq \frac{1}{\sqrt{\lambda_{\min}(I+A)}} \frac{\|A - \operatorname{diag} A\|_F}{\sqrt{2}}, \tag{50}$$

where $\sigma_{\min}(\cdot)$ denotes the minimal singular value and $\lambda_{\min}(\cdot)$ the minimal eigenvalue of a matrix. This inequality is related to the simple fact that a diagonal perturbation of a diagonal matrix causes only a diagonal perturbation of its Cholesky factor. Finally, from (47) and (50), we obtain

$$\begin{aligned} \|\Gamma\|_F^2 &= \sum_{i=1}^{n} \Gamma_{ii}^2 + \|\Gamma - \operatorname{diag} \Gamma\|_F^2 \\ &\leq \|\mathcal{P}(\operatorname{diag} A)\|_F^2 + \|\mathcal{P}(A - \operatorname{diag} A)\|_F^2 = \|\mathcal{P}(A)\|_F^2 \end{aligned}$$

and the upper bound in (45) follows. To prove the lower bound, we use the majorization inequality between eigenvalues $\lambda_i(\cdot)$ and singular values $\sigma_i(\cdot)$ of a matrix (see, e.g., [11]) to obtain

$$\operatorname{Tr}(I+\Gamma) \leq \sum_{i=1}^{n} \sigma_i(I+\Gamma) = \sum_{i=1}^{n} \sqrt{1+\lambda_i(A)}$$

and then

$$\operatorname{Tr}\Gamma \leq \sum_{i=1}^{n} \frac{\lambda_i(A)}{1+\sqrt{1+\lambda_i(A)}}.$$

Now, (42) implies

$$\begin{aligned} \|\Gamma\|_F^2 &= \operatorname{Tr}A - 2\operatorname{Tr}\Gamma \geq \sum_{i=1}^{n} \left[\lambda_i(A) - \frac{2\lambda_i(A)}{1+\sqrt{1+\lambda_i(A)}} \right] \\ &= \sum_{i=1}^{n} \left[\frac{\lambda_i(A)}{1+\sqrt{1+\lambda_i(A)}} \right]^2 \geq \frac{\|A\|_F^2}{(1+\sqrt{1+\|A\|_2})^2} \end{aligned}$$

and the lower bound for $\|\Gamma\|_F$ follows. □

Remark 4.3. The estimates (48), (49) and (50) do not depend on the semidefiniteness of the perturbation. Thus, for example, if $\lambda_{\min}(A)$ is not too close to -1, $\lambda_{\min}(A) > -0.5$, say, then $\|\Gamma - \operatorname{diag} \Gamma\|_F \leq \|A - \operatorname{diag} A\|_F$.

Note added in proof. Ji Guang Sun [14] pointed out that the estimate (36) can be replaced by

$$\|A\|_F \leq \|\delta B\|_F \|B^{-1}\|_2, \qquad \delta B = \left[\frac{\delta H_{ij}}{\sqrt{H_{ii}H_{jj}}}\right].$$

Thus, using Theorem 2.1, we obtain

$$\|\Gamma\|_F \leq \frac{\sqrt{2}\|B^{-1}\|_2\|\delta B\|_F}{1+\sqrt{1-2\|B^{-1}\|_2\|\delta B\|_F}}$$

provided that

$$\|\delta B\|_F < \frac{1}{2\|B^{-1}\|_2}.$$

Acknowledgment. K. Veselić would like to thank Professor B. Parlett, at Berkeley, for his constructive criticism. The authors also thank Professors V. Hari, Zagreb, and Ji Guang Sun, Umeå, for their comments. Finally, we thank an anonymous referee for his very detailed and constructive report.

TOWARDS A DIVIDE AND CONQUER ALGORITHM FOR THE REAL NONSYMMETRIC EIGENVALUE PROBLEM*

LOYCE ADAMS† AND PETER ARBENZ‡

Abstract. Theory is developed that could be used towards developing a divide and conquer algorithm for the nonsymmetric eigenvalue problem. The shortcomings of this theory and its application to the Hessenberg and nonsymmetric tridiagonal problems are discussed. The conclusion is made that the method may not be as promising as the divide and conquer methods for symmetric problems.

Key words. tridiagonal matrix, Hessenberg matrix, modified eigenvalue problem, divide and conquer algorithm

AMS subject classifications. 15A18, 65F15, 65W05

1. Introduction.

In 1981, Cuppen [7] introduced a divide and conquer algorithm for the computation of the spectral decomposition of real symmetric tridiagonal matrices. The algorithm, which was primarily designed for parallel computers, turned out to be faster than and comparably accurate to the well-known QR algorithm even on sequential computers [8]. We review this algorithm in §2. Similar divide and conquer algorithms have proven to be efficient for the bidiagonal singular value problem [18] and the unitary eigenvalue problem [14].

In this paper we investigate the advisability of using algorithms similar to those of Cuppen to solve the eigenvalue problem for real *nonsymmetric* matrices. In §3 we investigate how far the theory for symmetric rank-one modified eigenvalue problems carries over to the nonsymmetric case. This theory is then applied in §4 to two special cases of eminent interest: the eigenvalue problems for nonsymmetric tridiagonal matrices and for real (upper) Hessenberg matrices. In §5 we discuss stability issues that arise in the nonsymmetric case. Jessup [17] recently investigated the Hessenberg and nonsymmetric tridiagonal problems using a rank-two splitting assuming the matrices are diagonalizable.

The interest for the Hessenberg form stems from the fact that general matrices are transformed into this form before the QR algorithm is applied. We note here that the QR algorithm computes a Schur decomposition. In contrast, divide and conquer algorithms work with eigenvectors and possibly principal vectors. They therefore provide a spectral decomposition or, in the case of defective matrices, a partial spectral decomposition.

The nonsymmetric tridiagonal eigenvalue problem arises, for example, in connection with the nonsymmetric Lanczos algorithm [12, p. 502]. It is also possible to transform a general matrix into a similar tridiagonal matrix by means of (nonorthogonal) Householder elementary reflectors. This process however is not stable [25, p. 403]. Nevertheless, efforts have been made to stabilize it (see [10] and the references therein).

Divide and conquer algorithms have been successfully implemented for solving the symmetric tridiagonal eigenvalue problem or for the computation of the singular value decomposition (SVD) of bidiagonal matrices on shared memory multiprocessors [8], [18]. The implementation of these algorithms posed difficulties on distributed memory multiprocessors due to the excessive amount of data that must be transferred between processors [16]. For our investigation we assume therefore that our target machine is a shared memory multiprocessor computer.

2. Cuppen's divide and conquer algorithm. In this section we consider the problem of determining the spectral decomposition

$$\tilde{T} = \tilde{X}\tilde{\Lambda}\tilde{X}^T, \qquad \tilde{T}, \tilde{X}, \tilde{\Lambda} \in \mathbb{R}^{n\times n} \tag{2.1}$$

of the symmetric tridiagonal matrix

$$\tilde{T} = \begin{pmatrix} \alpha_1 & \beta_1 & & \\ \beta_1 & \alpha_2 & \ddots & \\ & \ddots & \ddots & \beta_{n-1} \\ & & \beta_{n-1} & \alpha_n \end{pmatrix} \in \mathbb{R}^{n\times n}.$$

Cuppen [7] introduced the decomposition

$$\begin{aligned} \tilde{T} = T + D &= \begin{pmatrix} T_1 & 0 \\ 0 & T_2 \end{pmatrix} + \beta_k \begin{pmatrix} 0 & & & & & & \\ & \ddots & & & & & \\ & & 0 & & & & \\ & & & \theta & 1 & & \\ & & & 1 & \theta & & \\ & & & & & 0 & \\ & & & & & & \ddots \\ & & & & & & & 0 \end{pmatrix} \\ &= T_1 \oplus T_2 + \theta\beta_k \mathbf{u}\mathbf{u}^T, \end{aligned} \tag{2.2}$$

where $\mathbf{u} = \mathbf{e}_k + \theta\mathbf{e}_{k+1}$ with $\theta = \pm 1$ and $\mathbf{e}_j$ denotes the jth unit vector. The introduction of the factor θ was indeed an idea of Dongarra and Sorensen [8] to avoid cancellation when forming the new diagonal elements of T_1 and T_2.

As the element of T at position $(k, k+1)$ vanishes, the computation of its spectral decomposition amounts to the solution of two *independent* symmetric tridiagonal eigenvalue problems for T_1 and T_2 of order k and $n-k$, respectively. With the spectral decompositions $T_i = X_i\Lambda_i X_i^T$, $i = 1, 2$, we get

$$\tilde{T} = X\left[\Lambda + \theta\beta_k \mathbf{v}\mathbf{v}^T\right] X^T, \tag{2.3}$$

where

$$X = X_1 \oplus X_2, \quad \Lambda = \Lambda_1 \oplus \Lambda_2, \quad \mathbf{v} = X^T\mathbf{u} = \begin{pmatrix} X_1^T\mathbf{e}_k \\ \theta X_2^T\mathbf{e}_1 \end{pmatrix}.$$

Thus, if we know Λ_1 and Λ_2, we obtain the eigenvalues and vectors of $\tilde{T}$ by computing the spectral decomposition of the matrix in square brackets, i.e., the spectral decomposition of a diagonal modified by a matrix of rank one.

As the matrices $(\tilde{T}-\lambda)\oplus 1$ and $(T-\lambda)\oplus(1+\theta\beta_k\mathbf{u}^T(T-\lambda)^{-1}\mathbf{u})$ for $\lambda\notin\sigma(T)$ are congruent [3]–[5], the eigenvalues and vectors of $\tilde{T}$ can be obtained from the ones of T by an investigation of the rational function [3], [6]–[8], [11], [13], [25]

$$\begin{aligned} f(\lambda) &= 1+\theta\beta_k\mathbf{u}^T(T-\lambda)^{-1}\mathbf{u} = 1+\theta\beta_k\mathbf{v}^T(\Lambda-\lambda)^{-1}\mathbf{v} \\ &= 1+\theta\beta_k\sum_{i=1}^{n}\frac{\nu_i^2}{\lambda_i-\lambda} = \frac{\det(\tilde{T}-\lambda)}{\det(T-\lambda)}, \qquad \mathbf{v}=\{\nu_i\}_{i=1}^n. \end{aligned} \tag{2.4}$$

f is called the (modified) Weinstein determinant [13], [24]. Alternatively, $f(\lambda)=0$ is called the secular equation [11]. By (2.4) one easily obtains the interlacing properties

$$\lambda_j\le\tilde{\lambda}_j\le\lambda_{j+1}, \quad 1\le j<n, \quad \lambda_n\le\tilde{\lambda}_n, \tag{2.5}$$

for positive $\theta\beta_k$. (Similar inequalities hold if $\theta\beta_k<0$.) Note that the λ_j do not appear ordered in the diagonal of Λ!

From (2.3) it is seen that the eigenvalue λ_j persists (with unchanged eigenvectors) if $\nu_j=0$. In this case we can *deflate*, i.e., remove, the corresponding jth row and column from $\Lambda+\theta\beta_k\mathbf{v}\mathbf{v}^T$. Moreover, if λ is an eigenvalue of T of multiplicity $m>1$, by an orthogonal similarity transformation of (2.3) the corresponding eigenvectors can be rotated such that at least $m-1$ of them are orthogonal to $\mathbf{u}$ [6]. This choice of eigenvectors introduces (at least) $m-1$ zero components in the vector $\mathbf{v}=X^T\mathbf{u}$ thus permitting further deflation. Of course, in a numerical context one must deal with the problem of "almost vanishing" ν_k's and "almost equal" eigenvalues. These issues are discussed in [8] and [18].

The result of the deflation process is a diagonal matrix $\Lambda'\in\mathbb{R}^{n'\times n'}$, $n'\le n$, which has only simple eigenvalues $\lambda'_j\in\sigma(T)$ and a vector $\mathbf{v}'$ whose elements are all nonzero. The eigenvalues of $\Lambda'+\theta\beta_k\mathbf{v}'\mathbf{v}'^T$ are the eigenvalues of $\tilde{T}$ that, at the same time, are *not* eigenvalues of T. The eigenvalues of Λ' and $\Lambda'+\theta\beta_k\mathbf{v}'\mathbf{v}'^T$ *strictly* interlace, i.e., satisfy formulae corresponding to (2.5) but with strict inequality signs.

The deflation process is of great importance for the success of the divide and conquer algorithm. First, the investigation of the Weinstein determinant is simplified since its poles coincide with the eigenvalues of Λ' and, second, n' is often considerably smaller than n [7], [8].

For the computation of the zeros of f, a quadratically and monotonically convergent root finder has been proposed by Bunch, Nielson, and Sorensen [6]. As soon as a zero $\tilde{\lambda}$ of f is found, a corresponding eigenvector $\tilde{\mathbf{x}}$ of $\tilde{T}$ can be computed by

$$\tilde{\mathbf{x}}=(\tilde{\lambda}-T)^{-1}\mathbf{u}=X(\tilde{\lambda}-\Lambda_1\oplus\tilde{\lambda}-\Lambda_2)^{-1}\mathbf{v}. \tag{2.6}$$

Calculation of eigenvectors by (2.6) can lead to a loss of orthogonality for close eigenvalues. Recently, work was done by Sorensen and Tang [20] and Gu and Eisenstat [15] to make this eigenvector calculation more stable.

For the complexity analysis for this algorithm, we assume that we have no deflation and that in the average s iteration steps are required to obtain one eigenvalue with the mentioned zerofinder. $f(\lambda)$ in (2.4) and its derivative are computed by

$$\begin{aligned} f(\lambda) &= 1+\theta\beta_k\mathbf{v}^T\mathbf{h}, \qquad \mathbf{h}=\mathbf{h}(\lambda)=(\Lambda-\lambda)^{-1}\mathbf{v}, \\ f'(\lambda) &= \theta\beta_k\mathbf{h}^T\mathbf{h}, \end{aligned} \tag{2.7}$$

in $6n+O(1)$ flops. Notice that after convergence, $h(\tilde{\lambda})$ is an (unnormalized) eigenvector of $\Lambda+\theta\beta_k\mathbf{v}\mathbf{v}^T$ corresponding to the just found eigenvalue $\tilde{\lambda}$. So, on the

average, the computation of one eigenvalue together with its normalized eigenvector costs $(6s+1)n+O(1)$ flops. Due to the special structure of X, the transformation of an eigenvector of $\Lambda+\theta\beta_k\mathbf{v}\mathbf{v}^T$ to one of $\tilde{T}$ needs n^2 flops. Altogether it costs

$$Z(n) = 2Z\left(\frac{n}{2}\right) + n^3 + (6s+1)n^2 + O(n) \cong \frac{4}{3}n^3 + 2(6s+1)n^2 + O(n) \tag{2.8}$$

to compute the complete spectral decomposition of $\tilde{T}$, provided that the split eigenvalue problems are solved with the same divide and conquer algorithm.

It is also possible to compute the eigenvectors of $\tilde{T}$ directly by inverse iteration as soon as its eigenvalues are known [9]. In this way the expensive back transformation could be saved and one would get an overall $O(n^2)$ algorithm. Unfortunately, inverse iteration does not yield sets of orthogonal eigenvectors in the presence of close eigenvalues. If the close eigenvalues were not deflated, a further orthogonalization may be necessary, hence bringing back the potentially $O(n^3)$ complexity.

3. Rank-one modified eigenvalue problems. Let $A \in \mathbb{R}^{n\times n}$ and consider the *modified eigenvalue problem*

$$\tilde{A}\mathbf{x} := (A+\mathbf{u}\mathbf{v}^T)\mathbf{x} = \lambda\mathbf{x}, \qquad \mathbf{u},\mathbf{v} \in \mathbb{R}^n \setminus \{\mathbf{0}\}. \tag{3.1}$$

$\tilde{A}$ is called a rank-one modification of A.

We consider the problem of determining the eigenvalues and eigenvectors of $\tilde{A}$ assuming that we know all the eigenvalues and an orthonormal basis of the corresponding eigenspaces of A. Interestingly, we do not need to know the principal vectors of A.

3.1. Nonpersistent eigenvalues. An eigenvalue of $\tilde{A}$ is called *nonpersistent* if it is *not* an eigenvalue of A. Otherwise it is called persistent [24, p. 39]. We first deal with the former simpler case. We start with a result that can be formulated in a similar way for higher rank modifications [1].

PROPOSITION 3.1. *For $\lambda \notin \sigma(A)$, the spectrum of A, the matrices*

$$B := \begin{pmatrix} \lambda-\tilde{A} & \mathbf{0} \\ \mathbf{0}^T & 1 \end{pmatrix} \quad \text{and} \quad C := \begin{pmatrix} \lambda-A & \mathbf{0} \\ \mathbf{0}^T & \zeta(\lambda) \end{pmatrix} \tag{3.2}$$

with

$$\zeta(\lambda) := 1 - \mathbf{v}^T(\lambda-A)^{-1}\mathbf{u} \tag{3.3}$$

satisfy the equation

$$C = MBN, \tag{3.4}$$

where

$$M := \begin{pmatrix} I_n & \mathbf{0} \\ \mathbf{v}^T(A-\lambda)^{-1} & 1 \end{pmatrix}\begin{pmatrix} I_n & \mathbf{u} \\ \mathbf{0}^T & 1 \end{pmatrix} = \begin{pmatrix} I_n & \mathbf{u} \\ \mathbf{v}^T(A-\lambda)^{-1} & \zeta(\lambda) \end{pmatrix} \tag{3.5a}$$

and

$$N := \begin{pmatrix} I_n & \mathbf{0} \\ \mathbf{v}^T & 1 \end{pmatrix}\begin{pmatrix} I_n & (A-\lambda)^{-1}\mathbf{u} \\ \mathbf{0}^T & 1 \end{pmatrix} = \begin{pmatrix} I_n & (A-\lambda)^{-1}\mathbf{u} \\ \mathbf{v}^T & \zeta(\lambda) \end{pmatrix}. \tag{3.5b}$$

Proof. The proposition is proved by verification. □

Because $\det M = \det N = 1$ for all λ, we have

$$\det(\lambda - \tilde{A}) = \det(\lambda - A)\zeta(\lambda), \qquad \lambda \notin \sigma(A). \tag{3.6}$$

Thus, $\lambda \notin \sigma(A)$ is an eigenvalue of $\tilde{A}$ if and only if $\zeta(\lambda) = 0$.

Furthermore, as N is invertible, it provides a bijective mapping from the nullspace of C onto the nullspace of B. Analogously, M^H maps the nullspace of C^H one-to-one onto the nullspace of B^H.

If λ is not an eigenvalue of A, a vector $\mathbf{x}$ in the nullspace of C must have the form

$$\mathbf{x} = \begin{pmatrix} \mathbf{0} \\ \xi \end{pmatrix}, \qquad \xi \in \mathbb{C} \setminus \{0\}.$$

Therefore,

$$N\mathbf{x} = \begin{pmatrix} (A - \lambda)^{-1}\mathbf{u}\xi \\ \zeta(\lambda)\xi \end{pmatrix} = \xi \begin{pmatrix} (A - \lambda)^{-1}\mathbf{u} \\ 0 \end{pmatrix}$$

is a vector spanning the nullspace of B. From the form of $N\mathbf{x}$ it is clear that

$$(A - \lambda)^{-1}\mathbf{u} \tag{3.7a}$$

is a right eigenvector of $\tilde{A}$ corresponding to λ. Similarly one shows that

$$(A^H - \bar{\lambda})^{-1}\mathbf{v} \tag{3.7b}$$

is a left eigenvector of $\tilde{A}$ corresponding to λ.

Note that the *geometric* multiplicity of a nonpersistent eigenvalue of $\tilde{A}$ cannot exceed one. The *algebraic* multiplicity, however, can exceed one, as is demonstrated by the following example.

Example 3.1. Choose

$$A = \begin{pmatrix} 0 & & & 1 \\ 1 & \ddots & & \\ & \ddots & \ddots & \\ & & 1 & 0 \end{pmatrix} \quad \text{and} \quad \tilde{A} = \begin{pmatrix} 0 & & & \\ 1 & \ddots & & \\ & \ddots & \ddots & \\ & & 1 & 0 \end{pmatrix}.$$

Then, $\sigma(A) = \{e^{2\pi ij/n}, j = 0, \ldots, n-1\}$ and $\sigma(\tilde{A}) = \{0\}$. Equation (3.1) holds with

$$\mathbf{u} = \mathbf{e}_1, \qquad \mathbf{v} = -\mathbf{e}_n.$$

Thus, $\zeta(\lambda)$ becomes

$$\zeta(\lambda) = \frac{\det(\lambda - \tilde{A})}{\det(\lambda - A)} = \frac{\lambda^n}{\lambda^n - 1}.$$

$\lambda = 0$ is an (algebraically) n-fold eigenvalue of $\tilde{A}$. Its one-dimensional right eigenspace is spanned by (cf. (3.7a))

$$(A - 0)^{-1}\mathbf{u} = A^T\mathbf{u} = \mathbf{e}_n$$

and its left eigenspace by (cf. (3.7b))

$$(A^H - 0)^{-1}\mathbf{v} = A\mathbf{v} = \mathbf{e}_1.$$

Also to get right principal vectors corresponding to λ we can, at least theoretically, proceed in the following bootstrapping manner [1]: Let us define $\mathcal{N}_j := \mathcal{N}((\tilde{A} - \lambda)^j)$. We recursively construct vectors $\mathbf{q}_j$ that span $\mathcal{N}_j \ominus \mathcal{N}_{j-1} = \mathcal{N}_j \cap \mathcal{N}_{j-1}^{\perp}$ such that $\mathcal{N}_k$ is spanned by $\mathbf{q}_1, \ldots, \mathbf{q}_k$. This construction breaks down as soon as $k = d$, where d is the smallest integer for which $\mathcal{N}_{d+1} = \mathcal{N}_d$. Notice that d is the algebraic multiplicity of λ.

Formula (3.7a) yields a basis vector of $\mathcal{N}_1$. If $\mathbf{x} \in \mathcal{N}_{j+1} \ominus \mathcal{N}_j$, $j \geq 1$, then clearly $\mathbf{y} := (\tilde{A} - \lambda)\mathbf{x} \in \mathcal{N}_j \ominus \mathcal{N}_{j-1}$ and $\mathbf{y} \in \mathcal{R}(\tilde{A} - \lambda)$. If, on the other hand, $\mathbf{y} \in (\mathcal{N}_j \ominus \mathcal{N}_{j-1}) \cap \mathcal{R}(\tilde{A} - \lambda)$, then $(\tilde{A} - \lambda)^+\mathbf{y} \in \mathcal{N}_{j+1} \ominus \mathcal{N}_j$. In fact, $(\tilde{A} - \lambda)(\tilde{A} - \lambda)^+$ is the orthogonal projector onto $\mathcal{R}(\tilde{A} - \lambda)$ [12, p. 423]. So, $(\tilde{A} - \lambda)(\tilde{A} - \lambda)^+\mathbf{y} = \mathbf{y}$. Therefore,

$$(\tilde{A} - \lambda)^+ : (\mathcal{N}_j \ominus \mathcal{N}_{j-1}) \cap \mathcal{R}(\tilde{A} - \lambda) \longrightarrow \mathcal{N}_{j+1} \ominus \mathcal{N}_j$$

is bijective.

So, provided that $\mathbf{q}_j \in (\mathcal{N}_j \ominus \mathcal{N}_{j-1}) \cap \mathcal{R}(\tilde{A} - \lambda)$, the nonzero vector

$$\mathbf{q}_{j+1} := (\tilde{A} - \lambda)^+\mathbf{q}_j \tag{3.8}$$

spans $\mathcal{N}_{j+1} \ominus \mathcal{N}_j$.

Because $\mathcal{R}(\tilde{A} - \lambda) = \mathcal{N}(\tilde{A}^H - \bar{\lambda})^{\perp}$, the vector $\mathbf{q}_j$ is in $\mathcal{R}(\tilde{A} - \lambda)$ if and only if

$$\mathbf{s}_1{}^H\mathbf{q}_j = 0, \tag{3.9}$$

where $\mathbf{s}_1$ is the left eigenvector of A corresponding to λ.

Using (3.4) in the form $B^+ = NC^+M$, (3.8) becomes

$$\mathbf{q}_{j+1} = (\lambda - A)^{-1}\mathbf{q}_j. \tag{3.10}$$

So, starting with $\mathbf{q}_1$, we construct the principal vectors $\mathbf{q}_j$ of grade $j > 1$ using (3.10) until (3.9) fails to be true.

Example 3.1 (continued). With the above we can set

$$\mathbf{q}_1 = \mathbf{e}_n\,, \qquad \mathbf{s}_1 = \mathbf{e}_1.$$

As $\mathbf{s}_1^H\mathbf{q}_1 = 0$, there is a right principal vector of grade two, obtainable by (3.10)

$$\mathbf{q}_2 = (A - \lambda)^{-1}\mathbf{e}_n = (A - 0)^{-1}\mathbf{e}_n = A^T\mathbf{e}_n = \mathbf{e}_{n-1}\,.$$

We continue as described until we get to $\mathbf{q}_n = \mathbf{e}_1$. At this point

$$\mathbf{s}_1{}^H\mathbf{q}_n = 1 \neq 0$$

and the process breaks down.

Left principal vectors can be obtained in a similar way, starting with $\mathbf{s}_1$.

3.2. Persistent eigenvalues. Proposition 3.1 can be generalized to the case where λ is an eigenvalue of the unmodified matrix A, i.e., a persistent eigenvalue.

PROPOSITION 3.2. *Let λ be an eigenvalue of A with geometric multiplicity m. Let $W_L, W_R \in \mathbb{C}^{n\times m}$ be matrices with orthonormal columns spanning $\mathcal{N}(A^H - \bar{\lambda})$ and $\mathcal{N}(A-\lambda)$, respectively. Then the matrices*

$$B = \begin{pmatrix} \lambda - A - \mathbf{u}\mathbf{v}^T & \mathbf{0} & O_{n\times m} \\ \mathbf{0}^T & 1 & \mathbf{0}^T \\ O_{m\times n} & \mathbf{0} & O_m \end{pmatrix} \tag{3.11a}$$

and

$$C = \begin{pmatrix} \lambda - A & \mathbf{0} & O_{n\times m} \\ \mathbf{0}^T & 1 - \mathbf{v}^T(\lambda - A)^+\mathbf{u} & \mathbf{v}^T W_R \\ O_{m\times n} & W_L^H\mathbf{u} & O_m \end{pmatrix} \tag{3.11b}$$

satisfy the equation

$$C = MBN, \tag{3.12}$$

where

$$M = \begin{pmatrix} I_n - W_L W_L^H & (I - W_L W_L^H)\mathbf{u} & W_L \\ -\mathbf{v}^T(\lambda - A)^+ & 1 - \mathbf{v}^T(\lambda - A)^+\mathbf{u} & O_{n\times m} \\ W_L^H & W_L^H\mathbf{u} & O_m \end{pmatrix} \tag{3.13a}$$

and, similarly,

$$N = \begin{pmatrix} I_n - W_R W_R^H & -(\lambda - A)^+\mathbf{u} & W_R \\ \mathbf{v}^T(I_n - W_R W_R^H) & 1 - \mathbf{v}^T(\lambda - A)^+\mathbf{u} & \mathbf{v}^T W_R \\ W_R^H & O_{m\times n} & O_m \end{pmatrix}. \tag{3.13b}$$

Proof. The proposition is proved by verification. □

The submatrix

$$Z_e(\lambda) = \begin{pmatrix} 1 - \mathbf{v}^T(\lambda - A)^+\mathbf{u} & \mathbf{v}^T W_R \\ W_L^H\mathbf{u} & 0 \end{pmatrix} \in \mathbb{C}^{(m+1)\times(m+1)} \tag{3.14}$$

of C is a generalization of $\zeta(\lambda)$ in (3.3). $(\lambda - A)^+$ is the Moore–Penrose generalized inverse of $\lambda - A$. In the real symmetric case, $\zeta(\lambda)$ and $Z_e(\lambda)$ are called Weinstein determinant and extended Weinstein matrix [24].

Proposition 3.2 gives a means for computing the eigenspaces of $\tilde{A}$ corresponding to a persistent eigenvalue λ. With (3.12) it is easily verified that

$$\mathcal{N}(\tilde{A} - \lambda) = \left\{ \omega(A-\lambda)^+\mathbf{u} + W_R\mathbf{w} \,\middle|\, \begin{pmatrix} \omega \\ \mathbf{w} \end{pmatrix} \in \mathcal{N}(Z_e(\lambda)) \right\} \tag{3.15a}$$

and

$$\mathcal{N}(\tilde{A}^H - \bar{\lambda}) = \left\{ \omega(A^H - \bar{\lambda})^+\mathbf{v} + W_L\mathbf{w} \,\middle|\, \begin{pmatrix} \omega \\ \mathbf{w} \end{pmatrix} \in \mathcal{N}(Z_e^H(\lambda)) \right\}. \tag{3.15b}$$

Principal vectors corresponding to persistent eigenvalues can be computed in a way similar to those corresponding to nonpersistent eigenvalues. The main difference is that the spaces $\mathcal{N}_j \ominus \mathcal{N}_{j-1}$ can have dimensions greater than one [1].

As in the symmetric case, it is natural to choose the matrices W_L and W_R such that $W_L^H \mathbf{u} = \pi \mathbf{e}_1$, $|\pi| = \|\mathbf{u}\|$, and $W_R^H \mathbf{v} = \phi \mathbf{e}_1$, $|\phi| = \|\mathbf{v}\|$, respectively. This means that columns 2 to m of W_L and W_R are orthogonal to $\mathbf{u}$ and $\mathbf{v}$, respectively, and thus are left and right eigenvectors of both A and $\tilde{A}$. The extended Weinstein matrix then has the form

$$Z_e(\lambda) = \hat{Z}_e(\lambda) \oplus O_{m-1}, \tag{3.16}$$

where

$$\hat{Z}_e(\lambda) = \begin{pmatrix} \sigma & \phi \\ \pi & 0 \end{pmatrix}, \qquad \sigma = 1 - \mathbf{v}^T (\lambda - A)^+ \mathbf{u}. \tag{3.17}$$

To determine whether there are further eigenvectors corresponding to λ, we must investigate $\hat{Z}_e$. We have five cases to consider.

1. If $\pi\phi \neq 0$ then rank $\hat{Z}_e(\lambda) = 2$ and we get no more right or left eigenvectors, and $\dim \mathcal{N}(\tilde{A} - \lambda) = m - 1$.

2. If $\phi = 0, \pi \neq 0$ then $\operatorname{rank} \hat{Z}_e(\lambda) = 1$. In this case, $(0\ 1)^T$ spans $\mathcal{N}(\hat{Z}_e(\lambda))$ and $\mathbf{x}_m = W_R \mathbf{e}_1$, the first column of W_R, is the mth right eigenvector and $\dim \mathcal{N}(\tilde{A} - \lambda) = m$. Likewise, up to normalization, $\mathbf{y}_m = (A^H - \bar{\lambda})^+ \mathbf{v} - (\bar{\sigma}/\bar{\pi}) W_L \mathbf{e}_1$ is the mth left eigenvector.

3. If $\phi \neq 0$ and $\pi = 0$, then the rank of $\hat{Z}_e(\lambda)$ is one. Up to normalization, $\mathbf{x}_m = (A - \lambda)^+ \mathbf{u} - (\sigma/\phi) W_R \mathbf{e}_1$ is the mth right eigenvector, and $\dim \mathcal{N}(\tilde{A} - \lambda) = m$. Likewise, $\mathbf{y}_m = W_L \mathbf{e}_1$ is the mth left eigenvector.

4. If $\phi = \pi = 0$, $\sigma \neq 0$, $\hat{Z}_e(\lambda)$ has rank one. We easily find that $\mathbf{x}_m = W_R \mathbf{e}_1$ and $\mathbf{y}_m = W_L \mathbf{e}_1$ are the mth right and left eigenvectors of $\tilde{A}$, respectively, and $\dim \mathcal{N}(\tilde{A} - \lambda) = m$.

5. If $\phi = \pi = \sigma = 0$, $\hat{Z}_e$ equals the 2×2 zero matrix and has a null space spanned by $(1,0)^T$ and $(0,1)^T$. Hence the mth eigenvectors are given as in case 4. The $m+1$st right and left eigenvectors are given by $\mathbf{x}_{m+1} = (A - \lambda)^+ \mathbf{u} / \|(A - \lambda)^+ \mathbf{u}\|$ and $\mathbf{y}_{m+1} = (A^H - \bar{\lambda})^+ \mathbf{v} / \|(A^H - \bar{\lambda})^+ \mathbf{v}\|$, respectively, and $\dim \mathcal{N}(\tilde{A} - \lambda) = m + 1$.

Clearly, for *any* λ the dimensions of $\mathcal{N}(\tilde{A} - \lambda)$ and $\mathcal{N}(A - \lambda)$ differ by at most one.

We also note that the left and right eigenspaces of $\tilde{A}$ corresponding to λ found by the above process produces vectors that are orthonormal, and hence further techniques do not have to be used to get an orthonormal $\tilde{W}_L$ and $\tilde{W}_R$.

3.3. Deflation. After having determined left and right eigenspaces and computed the extended Weinstein matrix for all $\lambda \in \sigma(A)$, one may wonder if this information can be used to reduce the cost of the search of the remaining eigenvalues $\lambda \in \sigma(\tilde{A}) \setminus \sigma(A)$. We know that left and right eigenvectors corresponding to different eigenvalues are orthogonal, but we see no way to reduce the order of the given matrix eigenvalue problem for the computation of the remaining eigenvalues as can be done in the symmetric eigenvalue problem in the deflation process. Notice that it is not even possible to determine the cardinality of $\sigma(\tilde{A}) \setminus \sigma(A)$. To be able to deflate, we must assume that A is diagonalizable. This assumption is of course true for symmetric matrices. If $AX = X\Lambda$, $\Lambda = \operatorname{diag}(\lambda_1, \ldots, \lambda_n)$, we can deflate in the proper meaning of the word, i.e., we can transform the original modified eigenvalue problem into a modified eigenvalue problem of lower order, containing all the information to compute the eigenvalues in $\sigma(\tilde{A}) \setminus \sigma(A)$ and corresponding eigenvectors. Let $X = [\mathbf{x}_1, \ldots, \mathbf{x}_n]$

and $Y := (X^{-1})^H = [\mathbf{y}_1, \ldots, \mathbf{y}_n]$. Then

$$A = X\Lambda Y^H = \sum_{i=1}^{n} \lambda_i \mathbf{x}_i \mathbf{y}_i^H. \tag{3.18}$$

Bases for left and right eigenspaces corresponding to an m-fold eigenvalue λ_k, say, are obtained by selecting those vectors $\mathbf{x}_{i_j}$ and $\mathbf{y}_{i_j}$ for which $\lambda_{i_j} = \lambda_k, j = 1, \ldots, m$. Notice that diagonalizable matrices have no degenerate eigenvalues.

Using the spectral decomposition (3.18), the modified matrix $\tilde{A}$ becomes

$$\tilde{A} = X(\Lambda + \hat{\mathbf{u}}\hat{\mathbf{v}}^H)Y^H, \qquad \hat{\mathbf{u}} = Y^H\mathbf{u}, \quad \hat{\mathbf{v}} = X^H\mathbf{v}. \tag{3.19}$$

If $\Lambda + \hat{\mathbf{u}}\hat{\mathbf{v}}^H$ has the spectral decomposition $\Lambda + \hat{\mathbf{u}}\hat{\mathbf{v}}^H = \hat{X}\tilde{\Lambda}\hat{Y}^H$, then

$$\tilde{A} = \tilde{X}\tilde{\Lambda}\tilde{Y}^H, \qquad \tilde{X} = X\hat{X}, \quad \tilde{Y} = Y\hat{Y}. \tag{3.20}$$

So we must investigate the eigenvalue problem

$$(\Lambda + \hat{\mathbf{u}}\hat{\mathbf{v}}^H)\mathbf{w} = \lambda\mathbf{w} \tag{3.21}$$

to get the spectral decomposition of $\tilde{A}$. As left and right eigenvectors of Λ corresponding to the above eigenvalue λ_k are given by the unit vectors $\mathbf{e}_{i_1}, \ldots, \mathbf{e}_{i_m}$, the extended Weinstein matrix in λ_k becomes

$$Z_e(\lambda_k) = \begin{pmatrix} 1 - \sum_{\lambda_i \neq \lambda_k} \frac{\bar{\hat{v}}_i \hat{u}_i}{\lambda_k - \lambda_i} & \bar{\hat{v}}_{i_1} \cdots \bar{\hat{v}}_{i_m} \\ \hat{u}_{i_1} & \\ \vdots & \mathbf{O} \\ \hat{u}_{i_m} & \end{pmatrix}.$$

We now chose a unitary $Q = Q(\lambda_k) \in \mathbb{C}^{m\times m}$ such that

$$Q^H \begin{pmatrix} \hat{v}_{i_1} \\ \vdots \\ \hat{v}_{i_m} \end{pmatrix} = \overline{\phi(\lambda_k)}\mathbf{e}_1, \qquad |\phi(\lambda_k)|^2 = \sum_{j=1}^{m} |\hat{v}_{i_j}|^2,$$

and replace columns $i_1, \ldots, i_m$ in X and Y by

$$[\mathbf{x}_{i_1}, \ldots, \mathbf{x}_{i_m}]Q, \qquad [\mathbf{y}_{i_1}, \ldots, \mathbf{y}_{i_m}]Q.$$

As we transformed left and right eigenvectors by the same Q, the relation $Y = (X^{-1})^H$ remains valid. Therefore, (3.18) and (3.19) still hold with the modified X and Y, but now $\hat{v}_{i_j} = 0$, $j = 2, \ldots, m$. So, $\mathbf{x}_{i_2}, \ldots, \mathbf{x}_{i_m}$ are right eigenvectors of $\tilde{A}$ corresponding to the eigenvalue λ_k. If $\phi(\lambda_k) = 0$, $\mathbf{x}_{i_1}$ is a further right eigenvector corresponding to this same eigenvalue λ_k.

We can proceed in this way for every eigenvalue of A and finally permute the columns of X and Y such that $\hat{\mathbf{v}} = X^H\mathbf{v}$ has n' leading nonzero elements followed by $n - n'$ zeros, $\hat{\mathbf{v}}^H = (\hat{\mathbf{v}}_1^H, \mathbf{0}^T)$. Splitting $\hat{\mathbf{u}} = Y^H\mathbf{u}$ in the same way, $\hat{\mathbf{u}}^H = (\hat{\mathbf{u}}_1^H, \hat{\mathbf{u}}_2^H)$, we obtain

$$\tilde{A} = [X_1, X_2] \begin{pmatrix} \Lambda_1 + \hat{\mathbf{u}}_1\hat{\mathbf{v}}_1^H & 0 \\ \hat{\mathbf{u}}_2\hat{\mathbf{v}}_1^H & \Lambda_2 \end{pmatrix} [Y_1, Y_2]^H, \tag{3.22}$$

where $X_1, Y_1 \in \mathbb{C}^{n\times n'}$ and $X_2, Y_2 \in \mathbb{C}^{n\times(n-n')}$. Note, that Λ_1 has only simple eigenvalues. The matrix in parenthesis in (3.22) is a rank-one modified diagonal matrix, the secular equation of which is

$$\zeta(\lambda) = 1 - \hat{\mathbf{v}}^H(\lambda - \Lambda)^{-1}\hat{\mathbf{u}} = 1 - \sum_{i=1}^{n'} \frac{\bar{\hat{v}}_i \hat{u}_i}{\lambda - \lambda_i} = 0. \tag{3.23}$$

The zeros of this function yield the nonpersistent eigenvalues. If $\zeta(\lambda) = 0$, $\lambda \notin \sigma(\Lambda)$, by (3.7a) and (3.22)

$$X(\Lambda - \lambda)^{-1}\hat{\mathbf{u}}$$

is a corresponding eigenvector of $\tilde{A}$.

It is however possible that $\zeta(\lambda) = 0$ for a $\lambda \in \sigma(A)$. Considering again λ_k from above, this can be the case if $|\hat{v}_{i_1}| = |\phi(\lambda_k)| > 0$ but $\hat{u}_{i_j} = 0$, $j = 1, \ldots, m$. This means that we are in case 3 of the analysis of $\hat{Z}_e$. A second situation occurs when $\zeta(\lambda_k)$ and all the $\hat{v}_{i_j}$ vanish, but one of the $\hat{u}_{i_j}$ is nonzero. In this case λ_k is degenerate!

Example 3.2. Let

$$\tilde{A} = \Lambda + \mathbf{u}\mathbf{v} = \begin{pmatrix} 1 & & \\ & 3 & \\ & & 2 \end{pmatrix} + \begin{pmatrix} 1 \\ 1 \\ 1 \end{pmatrix} (2,1,0) = \begin{pmatrix} 3 & 1 & 0 \\ 2 & 4 & 0 \\ 2 & 1 & 2 \end{pmatrix}.$$

Then, $W_L(2) = W_R(2) = \operatorname{span}(\mathbf{e}_3)$. After deflation of the eigenvalue two we get

$$\zeta(\lambda) = 1 - \frac{2}{\lambda - 1} - \frac{1}{\lambda - 3},$$

which vanishes when $\lambda = 2$. Notice that

$$Z_e(2) = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}.$$

$\lambda = 2$ is a defective eigenvalue of $\tilde{A}$ of algebraic multiplicity 2.

Given $\tilde{A} = A + \mathbf{u}\mathbf{v}^T$, we have presented the theory for finding each eigenvalue of $\tilde{A}$ with its associated geometric multiplicity and orthonormal bases for its left and right eigenspaces. This was done by knowing the exact same information about matrix A. Hence, in theory, a recursive algorithm for the nonsymmetric eigenvalue problem can be specified.

In addition, we gave the theory for finding the left and right principal vectors and algebraic multiplicity of each eigenvalue of $\tilde{A}$. This was done by knowing the left and right eigenvectors of A and $\tilde{A}$ corresponding to the eigenvalue. We also showed how to deflate in the case where λ is both an eigenvalue of A and $\tilde{A}$ and A is diagonalizable.

4. Application of the theory. We now apply the theory of the last section to the nonsymmetric tridiagonal eigenvalue problem. At the end of this section we will make a few remarks on the Hessenberg eigenvalue problem. We discuss the details as well as the hurdles involved in realizing a recursive algorithm for these problems. We do not further analyze the issues of deflation or the calculation of the principal vectors.

4.1. The tridiagonal eigenvalue problem. We consider the eigenvalue problem

$$\tilde{T}\mathbf{x} = \lambda\mathbf{x}, \tag{4.1}$$

where $\tilde{T}$ is the nonsymmetric irreducible tridiagonal matrix

$$\tilde{T} = \begin{pmatrix} \alpha_1 & \beta_1 & & & \\ \gamma_2 & \ddots & \ddots & & \\ & \ddots & \ddots & \ddots & \\ & & \ddots & \ddots & \beta_{n-1} \\ & & & \gamma_n & \alpha_n \end{pmatrix}, \quad \beta_i \neq 0, \quad \gamma_i \neq 0. \tag{4.2}$$

We do not assume that $\tilde{T}$ is diagonalizable. Notice, that tridiagonal matrices with $\beta_i\gamma_{i+1} > 0$, for all i, are symmetrizable [25, p. 335]. We split $\tilde{T}$ into T and a rank-one modification. To zero out the elements of T at position β_k and γ_{k+1} simultaneously, we must choose the splitting vectors $\mathbf{u}$ and $\mathbf{v}$ appropriately:

$$\begin{aligned} \tilde{T} &= T + \begin{pmatrix} O_{k-1} & & & \\ & \frac{1}{\omega}\beta_k & \beta_k & \\ & \gamma_{k+1} & \omega\gamma_{k+1} & \\ & & & O_{n-k-1} \end{pmatrix}, \qquad \omega \neq 0 \\ &= \begin{pmatrix} T_1 & O \\ O & T_2 \end{pmatrix} + \begin{pmatrix} \frac{1}{\omega}\beta_k\mathbf{e}_k \\ \gamma_{k+1}\mathbf{e}_1 \end{pmatrix} (\mathbf{e}_k^T, \omega\mathbf{e}_1^T) = T + \mathbf{u}\mathbf{v}^T, \end{aligned} \tag{4.3}$$

where

$$\mathbf{u} = \begin{pmatrix} \frac{1}{\omega}\beta_k\mathbf{e}_k \\ \gamma_{k+1}\mathbf{e}_1 \end{pmatrix}, \qquad \mathbf{v} = \begin{pmatrix} \mathbf{e}_k \\ \omega\mathbf{e}_1 \end{pmatrix}.$$

To compute the nonpersistent eigenvalues of $\tilde{T}$ we must form the rational function $\zeta(\lambda)$ that appears in the secular equation (3.3). This function is given by

$$\begin{aligned} \zeta(\lambda) &= 1 + \mathbf{v}^T(T-\lambda)^{-1}\mathbf{u} \\ &= 1 + \tfrac{\beta_k}{\omega}\mathbf{e}_k^T(T_1-\lambda)^{-1}\mathbf{e}_k + \omega\gamma_{k+1}\mathbf{e}_1^T(T_2-\lambda)^{-1}\mathbf{e}_1 = 0. \end{aligned} \tag{4.4}$$

In case we use a Newton-type zerofinder for this purpose, the derivative of ζ is given by

$$\zeta'(\lambda) = -\mathbf{v}^T(T-\lambda)^{-2}\mathbf{u} = -\frac{\beta_k}{\omega}\mathbf{e}_k^T(T_1-\lambda)^{-2}\mathbf{e}_k - \omega\gamma_{k+1}\mathbf{e}_1^T(T_2-\lambda)^{-2}\mathbf{e}_1.$$

A divide and conquer algorithm for the tridiagonal eigenvalue problem based on the above theory has the following structure.

ALGORITHM TDC $(\tilde{T}, (\tilde{\lambda}_j, \tilde{m}_j, \tilde{W}_L^j, \tilde{W}_R^j, j = 1, 2, \ldots, \tilde{d}))$.
{This algorithm computes $\tilde{\lambda}_j$, $\tilde{m}_j$, $\tilde{W}_L^j \in \mathbb{C}^{n\times\tilde{m}_j}$, $\tilde{W}_R^j \in \mathbb{C}^{n\times\tilde{m}_j}$, $j = 1, \ldots, \tilde{d}$, the $\tilde{d}$ distinct eigenvalues $\tilde{\lambda}_j$ of $\tilde{T}$, their geometric multiplicity and bases for their associated left and right eigenspaces.}

1(a). Split $\tilde{T}$ according to (4.3).

1(b). Compute the eigenvalues and corresponding left and right eigenvectors of T_1 and T_2 by calls to TDC or another appropriate subroutine.

1(c). Merge the eigenvalues and eigenvectors of T_1 and T_2 to get the d distinct eigenvalues λ_j of T, their geometric multiplicities m_j, and bases $W_L^j \in \mathbb{C}^{n\times m_j}$ and $W_R^j \in \mathbb{C}^{n\times m_j}$ for the corresponding left and right eigenspaces.

2. Find the persistent eigenvalues $\lambda \in \sigma(\tilde{T}) \cap \sigma(T)$ together with the corresponding eigenvectors. This is an investigation of the extended Weinstein matrices $Z_e(\lambda_j)$, $j = 1, \ldots, d$, evaluated at the eigenvalues of T.

3. Find the nonpersistent eigenvalues $\lambda \in \sigma(\tilde{T}) \setminus \sigma(T)$ together with the corresponding eigenvectors. Here, a zero-finding procedure is needed to locate the zeros of the function ζ in (4.4).

The structure of the complete divide and conquer algorithm can be represented by a balanced binary tree with the task of solving the original problem being the root of the tree. The edges coming from the root represent the splitting of this problem into the two subproblems depicted as the descendent nodes of the root. Edges from these nodes (and intermediate nodes) toward the leaves represent recursive calls to TDC in step 1(b). The leaves of the tree represent the smallest subproblems that we are willing to solve by some black box eigensolver.

Once the eigenproblems at the leaves are solved, the "glue-back" problems at the next level up in the tree are solved by the merge operation in step 1(c) followed by steps 2 and 3. This "glue-back" operation is then repeated at each successive level in the tree until we finally solve the original problem at the root of the tree.

A shared memory parallel implementation that is identical in structure to that described in Dongarra and Sorensen [8] would apply to the nonsymmetric case as well. Briefly, p processors can simultaneously solve the eigenproblems at the leaf nodes. As we go up the tree, all "glue-back" problems at a given level can be solved simultaneously. Moreover, a given "glue-back" involves a rootfinding problem that can utilize multiple processors, so that at any given tree level, all $p \leq n$ processors can be kept busy. Hence we get more fine-grain parallelism and less coarse-grain parallelism as we go up the tree.

The memory needed to store the left and right eigenvectors of all these problems is four $n \times n$ arrays. Only vectors for two consecutive levels need to be stored at a given time, with two arrays allocated for each level. This is twice the storage the QR algorithm needs. The QR algorithm however computes Schur vectors. Notice that the four arrays occupy the shared memory in a parallel implementation.

We want to elaborate on the three steps of the algorithm.

1. Different strategies can be chosen to decide when to switch from TDC to another eigenvalue solver. In their divide and conquer algorithm for the symmetric tridiagonal eigenvalue problem, Dongarra and Sorensen [8] switch to the QR algorithm as soon as there are as many subproblems as these are available processors, i.e., after $\log_2(p)$ splits where p is the number of processors. For the unitary eigenvalue problem, Gragg and Reichel [14] (see also [2]) divide until they end up with 1×1 or 2×2 problems.

We can go either way. Switching presents the problem of how to solve the nonsymmetric tridiagonal eigenvalue problem at the leaves of the binary tree. A possibility is the LR algorithm [23, p. 319]. Because of the pivoting that must be performed to retain stability, this algorithm destroys the tridiagonal form. Therefore, we may just as well apply the nonsymmetric Hessenberg-QR algorithm here. This loss of the

tridiagonal form causes the need for much *private* memory! In the worst case, we must provide each processor with $O((n/p)^2)$ words of memory just to perform the LR or QR algorithm at the leaf level.

Eigenvectors for the leaf problems are best computed by inverse iteration with $T - \lambda_j$ to get the right eigenvectors and with $T^T - \bar{\lambda}_j$ for the left eigenvectors. They could be computed all together if inverse vector iteration is applied to the seven-diagonal Hermitian matrix

$$P^T \begin{pmatrix} O_n & T - \lambda_j \\ T^T - \bar{\lambda}_j & O_n \end{pmatrix} P.$$

Here, P denotes the odd-even permutation matrix.

The overall complexity of this step is $Cn^3 + O(n^2)$ unless we divide until we end up with 1×1 or 2×2 problems. We can however force the constant C to be as small as we like if we only divide sufficiently often, ending up with $O(n^2)$ complexity if we divide to 2×2 problems.

2. In step 2 we must compute the extended Weinstein matrices $Z_e(\lambda_j)$. W_L^j and W_R^j are known from step 1. The transformation of Z_e into the form (3.16) is easy as $m_j \leq 2$ because we are dealing with irreducible tridiagonal matrices.

If $\pi\phi \neq 0$ we must also compute

$$\sigma = 1 + \frac{\beta_k}{\omega} \mathbf{e}_k^T (T_1 - \lambda_j)^+ \mathbf{e}_k + \omega\gamma_{k+1} \mathbf{e}_1^T (T_2 - \lambda_j)^+ \mathbf{e}_1 = 0.$$

To circumvent computing the SVD we can proceed as follows. Let us consider the computation of $\mathbf{e}_k^T (T_1 - \lambda_j)^+ \mathbf{e}_k$ and set $\mathbf{w} = (\lambda_j - T_1)^+ \mathbf{e}_k$. Then $(\lambda_j - T_1)\mathbf{w} = P_{\mathcal{R}(\lambda_j - T_1)} \mathbf{e}_k$ with $\mathbf{w} \in \mathcal{N}(\lambda_j - T_1)^\perp$. Here, $P_{\mathcal{R}(\lambda_j - T_1)}$ is the orthogonal projector onto the range of $\lambda_j - T_1$. Let $\lambda_j - T_1 = QR$ be the QR factorization of $\lambda_j - T_1$. Then, the upper triangular matrix has the form [12, p. 374]

$$R = \begin{pmatrix} R_1 & \mathbf{r} \\ \mathbf{0}^T & 0 \end{pmatrix}.$$

Therefore,

$$\mathcal{R}(\lambda_j - T_1) = \mathcal{R}(QR) = \operatorname{span}(Q\mathbf{e}_k)^\perp, \qquad \mathcal{N}(\lambda_j - T_1) = \operatorname{span}\left(\begin{pmatrix} R_1^{-1}\mathbf{r} \\ -1 \end{pmatrix} \right).$$

Let

$$\mathbf{z} := \begin{pmatrix} R_1^{-1}\mathbf{r} \\ -1 \end{pmatrix} \Big/ \sqrt{1 + \|R_1^{-1}\mathbf{r}\|^2}$$

and $Q = [\mathbf{q}_1, \ldots, \mathbf{q}_k]$. Then $P_{\mathcal{R}(\lambda_j - T_1)} = [\mathbf{q}_1, \ldots, \mathbf{q}_{k-1}][\mathbf{q}_1, \ldots, \mathbf{q}_{k-1}]^*$ and

$$\mathbf{w} = (I_k - \mathbf{z}\mathbf{z}^H) \begin{pmatrix} R_1^{-1}[\mathbf{q}_1, \ldots, \mathbf{q}_{k-1}]^* \mathbf{e}_k \\ 0 \end{pmatrix}.$$

Each eigenvalue causes $O(n)$ operations as we are dealing with a tridiagonal T. As there are at most n matrices at a level in the problem tree, the overall complexity of this step is $O(n^2)$. Again, as T is tridiagonal, the auxiliary memory needed for the QR decomposition is only $O(n)$ words.

3. Find $\sigma(\tilde{T})\backslash\sigma(T)$. We must find the roots of the secular equation (4.4). Then the associated left and right eigenvectors associated with these roots are calculated by (3.7a) and (3.7b).

The main problem here is the location of the nonpersistent eigenvalues. They can be almost anywhere within the union of Gerschgorin disks. As we realistically cannot assume that the matrices are diagonalizable, we do not even know the number of eigenvalues we must look for unless we find all principal vectors corresponding to the persistent eigenvalues.

Jessup [17] discusses zerofinders that are based on the principle of the argument (Cauchy's integral formula). We doubt, as does Jessup, their practicability. The calculation of the integer integrals involved is too expensive although the integrals need not be computed very accurately.

A reasonable choice for a zero finder is Newton's iteration. To get good starting guesses for the iteration, eigenvalue bracketing procedures based on the matrix sign function could be applied [21]. The application of such procedures on the root level would, however, be so involved with respect to memory and complexity that it is certainly better to use such a method right from the start. Such methods compute Schur normal forms via unitary similarity transformations and are therefore intrinsically stable.

Forming the function ζ and its derivative costs $O(n)$ flops. If we assume that we need s iterations on the average to find a zero of ζ, where s is bounded with increasing n, then the overall complexity to find all nonpersistent eigenvalues would be $O(n^2)$. The computation of the corresponding eigenvectors with formula (3.7), with inverse iteration or with the procedure of step 2, would cost another $O(n^2)$ flops.

The described procedure gives us an overall $O(n^2)$ algorithm. As remarked in §2, a similar algorithm has been implemented by Gates [9] for the symmetric divide and conquer algorithm. The problem with the Gates algorithm was the possible loss of orthogonality among the eigenvectors that made reorthogonalization necessary and brought back the $O(n^3)$ complexity through the backdoor. Our algorithm has of course no better behaviour. So, the computed right eigenvectors corresponding to an eigenvalue λ must be orthogonalized against the left eigenvectors corresponding to nearby eigenvalues and vice versa.

We do not see an inexpensive way to prevent a parallel zero-finding procedure from finding the same zeros without communication among the processes. Recall that this was possible for the symmetric problem since we knew a priori distinct intervals that each contained one nonpersistent eigenvalue. The processors working on the same problem can of course communicate their information on already computed zeros (via shared memory). Convergence to equal eigenvalues cannot be excluded this way, however computation of all zeros is guaranteed. Hence, it is highly questionable whether a zerofinder can be found for the nonsymmetric tridiagonal problem that will parallelize as efficiently as its symmetric counterpart. If this difficulty is overcome, as well as the stability issues we discuss in §5, a shared memory parallel algorithm with the same structure as that given in Dongarra and Sorensen [8] would cost $O(n)$ with n processors.

4.2. The Hessenberg eigenvalue problem. A divide and conquer algorithm for the eigenvalue problem

$$\tilde{H}\mathbf{x} = \lambda\mathbf{x}, \tag{4.5}$$

where $\tilde{H}$ is an irreducible upper Hessenberg matrix proceeds formally much like the divide and conquer algorithm for the tridiagonal eigenvalue problem (4.1).

We define a matrix H to be

$$H := \tilde{H} - h_{k+1,k} \begin{pmatrix} \mathbf{p} \\ \mathbf{e}_1 \end{pmatrix} \begin{pmatrix} \mathbf{e}_k \\ \mathbf{q} \end{pmatrix}^T = \tilde{H} + \mathbf{u}\mathbf{v}^T, \tag{4.6}$$

where $\mathbf{p} \in \mathbb{R}^k$ and $\mathbf{q} \in \mathbb{R}^{n-k}$ are *arbitrary* vectors. Thus $\tilde{H}$ differs from H by a rank-one modification. H has a zero entry at position $(k+1, k)$. We write

$$H = \begin{pmatrix} H_1 & H_{12} \\ 0 & H_2 \end{pmatrix}, \tag{4.7}$$

where $H_1 \in \mathbb{R}^{k \times k}$ and $H_2 \in \mathbb{R}^{(n-k)\times(n-k)}$ are irreducible Hessenberg matrices and $H_{12} \in \mathbb{R}^{k\times(n-k)}$.

There are two essential differences that distinguish a Hessenberg divide and conquer from our previous algorithm TDC for the tridiagonal eigenvalue problem.

(i) As H is *not* the direct sum of H_1 and H_2, merging the eigenvalues and eigenvectors of H_1 and H_2 is not trivial anymore as descibed below. This concerns not only complexity. Let $(\lambda, \mathbf{x})$ be an eigenpair of H_1. Then, clearly, $(\lambda, \binom{\mathbf{x}}{0})$ is an eigenpair of H. On the other hand, if $(\lambda, \mathbf{y})$ is an eigenpair of H_2, then $(\lambda, \binom{\mathbf{w}}{\mathbf{y}})$ is an eigenpair of H if and only if

$$(\lambda - H_1)\mathbf{w} = H_{12}\mathbf{y}. \tag{4.8}$$

Equation (4.8) can be satisfied precisely if $H_{12}\mathbf{y} \in \mathcal{R}(\lambda - H_1)$. If $\lambda \notin \sigma(H_1)$ this is always the case. If $\lambda \in \sigma(H_1) \cap \sigma(H_2)$ a solution may or may not exist. In the latter case, λ is a degenerate eigenvalue.

(ii) The Weinstein determinant

$$\begin{aligned} \zeta(\lambda) &= 1 + \alpha \begin{pmatrix} \mathbf{e}_k \\ \mathbf{q} \end{pmatrix}^T (H - \lambda)^{-1} \begin{pmatrix} \mathbf{p} \\ \mathbf{e}_1 \end{pmatrix}, \qquad \alpha = h_{k+1,k}, \\ &= 1 + \alpha \left[\mathbf{e}_k^T (H_1 - \lambda)^{-1} \mathbf{p} - \mathbf{e}_k^T (H_1 - \lambda)^{-1} H_{12} (H_2 - \lambda)^{-1} \mathbf{e}_1 \right. \\ &\qquad \left. + \mathbf{q}^T (H_2 - \lambda)^{-1} \mathbf{e}_1 \right]. \end{aligned} \tag{4.9}$$

Note that the complexity to form $Z(\lambda)$ does not increase essentially if $\mathbf{p}$ and $\mathbf{q}$ are nonzero, because the vectors $(H_1^T - \lambda)^{-1}\mathbf{e}_k$ and $(H_2 - \lambda)^{-1}\mathbf{e}_1$ must be computed anyway!

Due to the Hessenberg structure of H, the evaluation of $\zeta(\lambda)$ costs $O(n^2)$ flops unless H is diagonalizable and we use formula (3.23). This is an order of magnitude more than in the tridiagonal case.

The main problem of the tridiagonal divide and conquer algorithm, that of finding the zeros in step 3 of the algorithm, remains unchanged.

The Hessenberg divide and conquer algorithm has of course higher complexity than the tridiagonal divide and conquer algorithm. The transformation into Hessenberg form is a natural intermediate step for the stable computation of the Schur normal form of a full matrix. A divide and conquer algorithm however cannot take advantage of this matrix structure. The stability of the algorithm cannot be increased by working with this form. We therefore see no reason for working with Hessenberg matrices in the context of a divide and conquer algorithm.

5. Stability. A principal difficulty in nonsymmetric eigenvalue problems is stability. Eigenvalues and eigenvectors may be very sensitive to small changes in the matrix elements. All eigensolvers, divide and conquer algorithms included, are experiencing this problem.

Let us consider the following example.

Example 5.1. Let

(5.1)
$$\tilde{T} = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & \eta & 0 \\ 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix} = T + \mathbf{u}\mathbf{v}^T = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & \eta & 0 & 0 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix} + \begin{pmatrix} 0 \\ -\eta \\ 1 \\ 0 \end{pmatrix} \begin{pmatrix} 0 \\ 1 \\ -1 \\ 0 \end{pmatrix}^T.$$

This matrix has the spectrum $\sigma(\tilde{T}) = \{\pm\frac{1}{2}\sqrt{4+\eta} \pm \frac{1}{2}\sqrt{\eta}\}$.

If η is perturbed by a small value ϵ, the eigenvalues change by

$$\tilde{\lambda}_i(\eta+\epsilon) - \tilde{\lambda}_i(\eta) = \left(\pm\frac{1}{4}\frac{1}{\sqrt{4+\eta}} \pm \frac{1}{4}\frac{1}{\sqrt{\eta}}\right)\epsilon + O(\epsilon^2), \qquad i = 1, \ldots, 4.$$

Thus, the eigenvalues are very sensitive to changes if $\eta \approx 0$ or $\eta \approx -4$. If $\eta = 0$ or $\eta = -4$, then $\tilde{T}$ is a matrix with two degenerate eigenvalues.

If $\eta \approx \sqrt{\epsilon}$, then, for all i,

$$\tilde{\lambda}_i(\sqrt{\epsilon}+\epsilon) - \tilde{\lambda}_i(\sqrt{\epsilon}) = \frac{1}{4}\epsilon^{3/4} + O(\epsilon). \tag{5.2}$$

The eigenvectors are as sensitive as the eigenvalues,

$$\|\tilde{\mathbf{q}}_i(\eta+\epsilon) - \tilde{\mathbf{q}}_i(\eta)\| = \frac{3\sqrt{2}}{4}\epsilon^{3/4} + O(\epsilon), \qquad i = 1, \ldots, 4.$$

This is the typical behavior of eigenvalues and eigenvectors of matrices that are close to defective matrices.

If we assume that $\epsilon \approx$ *macheps* $\approx 10^{-16}$, then $\sqrt{\epsilon}$ is a small value but still not small enough to allow deflation. With this assumption we lose about four significant digits in computing the eigenvalues and eigenvectors of $\tilde{T}$ if $\eta \approx 10^{-8}$ using any eigensolver. This is what is actually observed in a numerical calculation with standard routines such as those in MATLAB.

If the zeros of the spectral function

$$\zeta(\lambda) = 1 + \eta\mathbf{e}_2^T \begin{pmatrix} \lambda & -1 \\ -1 & \lambda-\eta \end{pmatrix}^{-1} \mathbf{e}_2 + \mathbf{e}_1^T \begin{pmatrix} \lambda-1 & -1 \\ -1 & \lambda \end{pmatrix}^{-1} \mathbf{e}_1 \tag{5.3}$$

corresponding to (5.1) are computed, the behavior (5.2) is observed as roundoff is introduced when solving the two 2×2 systems of linear equations in (5.3). This is in accordance with backward error analysis that considers these zeros as exact zeros of a function with nearby coefficients.

The eigenvalues of $\tilde{T}$ in Example 5.1 are quite sensitive to perturbations of the matrix elements. One may suggest that the large condition number $4/\sqrt{\eta} + O(1)$ of the left matrix in (5.3) is a consequence of this sensitivity. This is however not the case. Sensitive eigenvalues $\tilde{\lambda}$ of $\tilde{T}$ do not necessarily imply large condition numbers

of $\tilde{\lambda} - T_1$ or $\tilde{\lambda} - T_2$. This is especially true when the eigenvalues of T and $\tilde{T}$ are well separated as the following example shows.

Example 5.2. The matrix

$$\tilde{T} = \begin{pmatrix} 3 & -6 & 0 & 0 \\ 1 & -\frac{5}{3} & -\frac{5}{18} & 0 \\ 0 & 1 & -\frac{11}{15} & -\frac{3}{50} \\ 0 & 0 & 1 & -\frac{3}{5} \end{pmatrix}$$

$$= T + \mathbf{u}\mathbf{v}^T = \begin{pmatrix} 3 & -6 & 0 & 0 \\ 1 & -\frac{35}{18} & 0 & 0 \\ 0 & 0 & \frac{4}{15} & -\frac{3}{50} \\ 0 & 0 & 1 & -\frac{3}{5} \end{pmatrix} + \begin{pmatrix} 0 \\ \frac{5}{18} \\ 1 \\ 0 \end{pmatrix} \begin{pmatrix} 0 \\ 1 \\ -1 \\ 0 \end{pmatrix}^T$$

has a single four-fold eigenvalue 0. Numerical approximations of the eigenvalues and vectors of $\tilde{T}$, computed with MATLAB, have absolute errors of $O(\epsilon^{1/4})$. This is due to the high sensitivity of the eigenvalue of $\tilde{T}$ with respect to perturbations of the matrix elements.

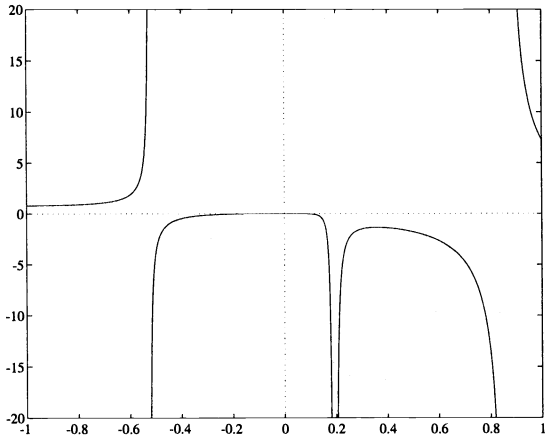

FIG. 5.1. *Plot of* $\zeta(\lambda) = 1 + \mathbf{v}^T(T - \lambda)^{-1}\mathbf{u}$, $-1 < \lambda < 1$, *of Example* 5.2.

T has no eigenvalue close to zero. So, the eigenvector of $\tilde{T}$ corresponding to zero could be computed with high accuracy without difficulty using (3.7) if a good enough approximation of the eigenvalue were available. This has some resemblance to the situation in the symmetric tridiagonal eigenvalue problem where eigenvectors may be inaccurately computed due to eigenvalues that are not known to have sufficient precision [15], [20]. If we use $\lambda = 0$ in (3.7), the calculated eigenvector using double precision is $(10, 4, 5, 6)^T$, which is exact to within *macheps*. However, for this problem, it is difficult for a rootfinder to accurately locate the root of $\zeta(\lambda)$ in (4.4) corresponding to $\tilde{\lambda} = 0$. This is because ζ is very flat near zero (cf. Fig. 5.1). In particular, in the intervals $[-.0007, .0]$ and $[0, .0007]$ the values of $\zeta(\lambda)$ range from -10^{-11} to 0 and 0 to -10^{-11}, respectively. If we use the value $-.00002$ as the computed approximation of 0 (the associated value of ζ is $8.88 \cdot 10^{-16}$), then the corresponding eigenvector

computed by (3.7) is $(9.9975, 4.9988, 5.9988, 10.9987)^T$. So here, an absolute error of 10^{-5} in the eigenvalue caused an error in the third decimal place of each component in the eigenvector.

The two examples above have shown matrices with ill-conditioned eigenvalues whose spectral decomposition is hard to compute with any algorithm. The problems were more or less ill posed and their solutions intrinsically hard. In the context of divide and conquer algorithms, the question arises: What happens when the given matrix $\tilde{T}$ has a well-conditioned spectral decomposition but T has a block with sensitive eigenvalues and vectors?

As a consequence of the assumption that our matrices need not be diagonalizable, we do not use the spectral decomposition to compute either the zeros $\tilde{\lambda}$ of ζ or the eigenvectors. Rather we use formula (4.4) to get the $\tilde{\lambda}$ and formula (3.7) to compute the corresponding eigenvectors. Therefore, the sensitivity of the eigenvalues and vectors is determined by the condition number of $T - \tilde{\lambda}$, $\tilde{\lambda} \in \sigma(\tilde{T})$. This number is worse the closer the eigenvalues of T and $\tilde{T}$ are. If $\tilde{\lambda}$ is even a persistent eigenvalue, the corresponding eigenvectors of $\tilde{T}$ are determined by (3.15), which involve the eigenvectors of T corresponding to $\tilde{\lambda}$. In this way we inherit the sensitivity of the eigenvalues of the submatrices of T.

Notice that on the other hand it may be advantageous to have the eigenvalues of T and $\tilde{T}$ close to each other. The eigenvalues of T would then be a good starting guess for an iterative procedure to find the eigenvalues of $\tilde{T}$.

An illustrative example for close eigenvalues of T and $\tilde{T}$ is the following example.

Example 5.3. Let

$$\tilde{T} = \begin{pmatrix} 1+\eta & -1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & 2 & 1 \\ 0 & 0 & 1 & 1 \end{pmatrix} = T + \mathbf{u}\mathbf{v}^T = \begin{pmatrix} 1+\eta & -1 & 0 & 0 \\ 1 & -1 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 \end{pmatrix} + \begin{pmatrix} 0 \\ 1 \\ 1 \\ 0 \end{pmatrix} \begin{pmatrix} 0 \\ 1 \\ 1 \\ 0 \end{pmatrix}^T.$$

T has the spectrum $\sigma(T) = \{\frac{1}{2}[\eta \pm \sqrt{\eta^2 + 4\eta}], 0, 2\}$. For $\eta = 0$, the triple eigenvalue 0 has geometric multiplicity 2. $\tilde{T}$ has four well-separated eigenvalues all of which are well conditioned. The eigenvalue of $\tilde{T}$ closest to zero is

$$\tilde{\lambda} = -\frac{1}{2}\eta + \frac{1}{2}\eta^2 + O(\eta^3).$$

The corresponding eigenvector is given by

$$\tilde{\mathbf{x}} = \begin{pmatrix} 1 + \frac{3}{4}\eta + O(\eta^2) \\ 1 + \frac{9}{4}\eta + O(\eta^2) \\ -1 - \frac{5}{4}\eta + O(\eta^2) \\ 1 + \frac{3}{4}\eta + O(\eta^2) \end{pmatrix}.$$

Calculating this eigenpair with MATLAB for a small value η reflects these expansions. The errors in the computed numbers are of the order $O(macheps)$.

The condition number of $T - \tilde{\lambda}$ is $4/\eta + O(1)$. Again this can be observed in a MATLAB computation. For $\eta = \sqrt{macheps}$, approximately eight significant digits are lost if $\tilde{\mathbf{x}}$ is computed by formula (3.7a), assuming $\tilde{\lambda}$ is given exactly.

So, the divide and conquer algorithm indeed can suffer severely from the ill conditioning of split matrices. It should however be noted that the decomposition of $\tilde{T}$

given in Example 5.3 is not the only possible one. For instance, if we write

$$\tilde{T} = \begin{pmatrix} 1+\eta & -1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & 2 & 1 \\ 0 & 0 & 1 & 1 \end{pmatrix} = \begin{pmatrix} 1+\eta & -1 & 0 & 0 \\ 1 & -\frac{1}{2} & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 1 \end{pmatrix} + \begin{pmatrix} 0 \\ \frac{1}{2} \\ 1 \\ 0 \end{pmatrix} \begin{pmatrix} 0 \\ 1 \\ 2 \\ 0 \end{pmatrix}^T,$$

the matrix T has well-separated eigenvalues and $T - \tilde{\lambda}$ is well conditioned in a neighborhood of 0. Here, we have used the freedom of how to choose the parameter ω in (4.3). In Example 5.3 we set $\omega = 1$, here we changed it to $\omega = 2$.

It would be interesting to find out to what extent a good selection of ω can improve stability in general. To our knowledge, this question has only been investigated for divide and conquer algorithms for systems of linear equations [19]. Of course, the selection of the split-index k also has an influence on the stability of the eigenvalues of T.

6. Conclusions. In this paper we have derived the theory needed to devise divide and conquer algorithms for nonsymmetric eigenvalue problems. We have formulated an algorithm for solving eigenvalue problems involving tridiagonal matrices and have commented on an analogous algorithm for Hessenberg matrices. The tridiagonal divide and conquer algorithm has a very favorable complexity: $O(n^2)$ and $O(n)$ for the computation of all eigenvalues and eigenvectors on sequential and parallel computers with $O(n)$ processors, respectively.

As expected, the cost for the Hessenberg divide and conquer algorithm is one power of n higher. We see no reason to compute with Hessenberg matrices in a divide and conquer algorithm. The higher order complexity is not rewarded by a gain in stability! The Hessenberg form is well suited for the computation of the Schur normal form but inappropriate if eigenvectors are desired. The computation of the Schur normal form on the other hand should not be approached by a divide and conquer algorithm.

The difficulty of stably tridiagonalizing arbitrary matrices prevents a widespread use of nonsymmetric tridiagonal eigenproblem solvers. It may be possible to transform arbitrary matrices stably into a very sparse but no longer tridiagonal form [22]. The divide and conquer algorithm could eventually take advantage of this form as systems of linear equations with such matrices must be formed in the course of the algorithm.

There are however two important issues that must be solved successfully before a divide and conquer algorithm will be feasible.

Zero finding. There are two difficult problems connected with finding the zeros of the secular equation $\zeta(\lambda) = 0$. The first is determining the number of zeros of ζ and the second is the actual search procedure.

The first problem is difficult as geometric and algebraic multiplicities of the eigenvalues of nonsymmetric matrices can differ and, as Example 3.2 illustrates, counting only geometric multiplicities is not sufficient. In theory, one can determine the algebraic multiplicities by finding the principal vectors by the procedure described in §3. However, in practice, this procedure will most likely suffer from stability problems.

It is possible to determine the number of the zeros of a function in specific domains of the complex plane. Jessup [17] discusses methods based on the principle of the argument (Cauchy's integral formula). Stickel [21] introduced a method to determine the number of eigenvalues in a particular parallelogram. Both methods are too expensive.

One must probably resort to Newton's iteration. As with any zerofinder, in order not to find the same zero several times, it may be necessary to successively deflate zeros, which introduces communication and potentially ruins parallelism. The amount of work to find the zeros of ζ depends to a great extent on the nature of the zero. So, load balancing is also difficult to achieve.

Stability. It is principally arguable whether it is reasonable to try to compute eigenvectors of nonsymmetric matrices instead of Schur vectors as is done stably in the QR algorithm.

The former can be arbitrarily ill conditioned. Assuming the matrices to be diagonalizable does not help as the diagonalizable matrices are a dense subset of the algebra of matrices.

Even if the original matrix has well-conditioned eigenvalues and eigenvectors, it is not clear whether the split subproblems have this property (cf., Example 5.3). There may be ways to minimize the condition of the eigenvalues of the split submatrices by choosing the split-index k or the parameter ω in (4.3) properly.

In summary, it appears to us that zerofinding and stability make it difficult to find a successful and fast implementation of a divide and conquer algorithm for the large nonsymmetric eigenvalue problem. There may be subclasses of this eigenvalue problem that can be computed safely. In any case, an implementation of a divide and conquer algorithm must be able to detect a loss of accuracy.

GAUSSIAN ELIMINATION WITH PARTIAL PIVOTING CAN FAIL IN PRACTICE*

LESLIE V. FOSTER†

Abstract. Even though Gaussian elimination with partial pivoting is very widely used, $n \times n$ matrices can be constructed where the error growth in the algorithm is proportional to 2^{n-1}. Thus for moderate or large n, in theory, there is a potential for disastrous error growth. However, prior to 1993 no reports of such an example in a practical application had appeared in the literature. Examples are presented that arise naturally from integral and differential equations and that lead to disastrous error growth in Gaussian elimination with partial pivoting.

Key words. Gaussian elimination, numerical stability, integral equations

AMS subject classifications. 65F05, 65R20, 65G05

1. Introduction.

Gaussian elimination with partial pivoting (GEPP) is one of the most widely used algorithms in scientific computing. When applied to an $n \times n$ matrix A it results in a factorization $PA = LU$, where P is a permutation matrix, L is lower triangular, and U is upper triangular. Let $\hat{\mathbf{x}}$ represent the solution to $A\mathbf{x} = \mathbf{b}$ computed in floating point arithmetic on a computer with relative machine precision ϵ. Then it is known [Wil] that

$$\frac{\|\hat{\mathbf{x}} - \mathbf{x}\|_\infty}{\|\mathbf{x}\|_\infty} \leq 4n^2 \mathrm{cond}_\infty(A)\rho\,\epsilon,$$

where $\mathbf{x}$ is the exact solution, $\mathrm{cond}_\infty(A)$ is the condition number of A in the supremum norm and ρ is the growth factor,

$$\rho = \frac{\max_{i,j,k} |a_{i,j}^{(k)}|}{\max_{i,j} |a_{i,j}|} \tag{1.1}$$

with $a_{i,j}^{(k)}$ denoting the i,j element after the kth step of elimination. Thus GEPP is considered numerically stable unless ρ is large.

The theory for GEPP suggests that ρ can be very large. The sharpest bound is $\rho \leq 2^{n-1}$ and this is attained, for example, for matrices A_n of the form [HH], [Wil], [GVL]

$$A_5 = \mathrm{diag}(\pm 1) \begin{pmatrix} 1 & 0 & 0 & 0 & 1 \\ -1 & 1 & 0 & 0 & 1 \\ -1 & -1 & 1 & 0 & 1 \\ -1 & -1 & -1 & 1 & 1 \\ -1 & -1 & -1 & -1 & 1 \end{pmatrix} \begin{pmatrix} & & & 0 \\ & T & & \vdots \\ & & & 0 \\ 0 & \cdots & 0 & \theta \end{pmatrix},$$

where T is an $n-1 \times n-1$ nonsingular upper triangular matrix and $\theta = \max |a_{ij}|$. Thus for moderate or large n the growth factor can be large. However, more than 25 years ago Wilkinson reported:

* Received by the editors November 4, 1992; accepted for publication (in revised form) August 13, 1993.

† Department of Mathematics and Computer Science, San Jose State University, San Jose, California, 95192 (foster@sjsumcs.sjsu.edu).

> "It is our experience that any substantial increase in size of elements of successive A_n is extremely uncommon even with partial pivoting. ... No example which has arisen naturally has in my experience given an increase by a factor as large as 16."

Since Wilkinson made his remarks, Dongarra et al. [DBMS] report an example where ρ is 23 and Higham and Higham [HH] report several natural, noncontrived examples where the growth factor is between $n/2$ and n. Although the growth factors reported in these papers are larger than those mentioned by Wilkinson, they are much less than the theoretical limit of 2^{n-1}. For random matrices Trefethen and Schreiber [TS] show that the average growth factor does not grow exponentially. In this paper we present a class of practical examples where the growth factors do grow exponentially. Recently Wright [Wri] also presented such a class. Wright's paper and ours are different in that we consider Volterra integral equations, which are not discussed by Wright, and the growth factors for our matrices can be closer to the theoretical limit than the growth factors for Wright's matrices. Also the matrices in our examples are dense whereas Wright's are sparse. The papers are related in that results in both papers apply to boundary value problems.

In the next section we show that when the quadrature method [Bak], [DM], [Linz] is used to numerically solve certain Volterra integral equations, large growth factors can result. In §3 we illustrate the theory of §2 with a population growth model and with a two-point boundary value problem. In the last section we present a brief discussion of the implications of such examples.

Software, in the form of MATLAB m files for constructing the above examples is available via the gopher system. Type "gopher sundance.sjsu.edu" on a computer with a gopher client and follow the menus.

2. A class of Volterra integral equations that lead to large growth factors. A linear Volterra integral equation of the second kind is of the form:

$$x(s) - \int_0^s k(s,t)x(t)\,dt = G(s). \tag{2.1}$$

Such equations show up in a wide variety of applications [Bur], [Jer], [Linz]. We consider for known $k(s,t)$, $\beta(s)$, and $G(s)$ the following modification of (2.1):

$$x(s) - \int_0^s k(s,t)x(t)\,dt + \beta(s)x(L) = G(s). \tag{2.2}$$

In general it is not possible to find an exact solution to (2.1) or (2.2). However, a variety of approximation techniques [Bak], [DM], [Linz] can be used, including the commonly used quadrature method. This is the method that we use, "starting" our procedure with the block quadrature method [DM]. We use Newton–Cotes quadrature formulas of order $p \geq 1$. To be specific for any n we divide $0 \leq s \leq L$ into $n-1$ equal subintervals of length $h = L/(n-1)$. For $i = 1,\ldots,n$, $j = 1,\ldots,n$, let $s_i = (i-1)h$, $t_j = (j-1)h$, $\beta_i = \beta(s_i)$, $b_i = G(s_i)$, $k_{ij} = k(s_i,t_j)$, and let x_i be the numerical approximation to $x(s_i)$. Let $\mathbf{x} = (x_1, x_2, \ldots, x_n)^T$ and $\mathbf{b} = (b_1, b_2, \ldots, b_n)^T$, where the superscript T indicates transpose. We approximate $\int_0^{s_i} k(s,t)x(t)\,dt$. Our approximation depends on i. For $1 \leq i \leq p+1$ we integrate an interpolating polynomial of degree p through $(t_j, k_{ij}\,x_j), j = 1,\ldots,p+1$. For $i \geq p+1$ we use composite integration. For example if $i = kp + l$ we use standard pth order closed Newton–Cotes composite integration for the integral from 0 to s_{kp+1}. For the integral from

s_{kp+1} to s_{kp+l}, we integrate an interpolating polynomial of degree $p+1$ through $(t_j, k_{ij}\, x_j), j = kp+l-p-1, \ldots, kp+l$.

With these approximations the vector $\mathbf{x}$ satisfies

$$A\mathbf{x} = \mathbf{b}. \tag{2.3}$$

For example, for $p = 2$ and $n = 7$ the matrix A is

$$\begin{pmatrix}
1 & 0 & 0 & 0 & 0 & 0 & \beta_1 \\
-\frac{5hk_{21}}{12} & 1-\frac{2hk_{22}}{3} & \frac{hk_{23}}{12} & 0 & 0 & 0 & \beta_2 \\
-\frac{hk_{31}}{3} & -\frac{4hk_{32}}{3} & 1-\frac{hk_{33}}{3} & 0 & 0 & 0 & \beta_3 \\
-\frac{3hk_{41}}{8} & -\frac{9hk_{42}}{8} & -\frac{9hk_{43}}{8} & 1-\frac{3hk_{44}}{8} & 0 & 0 & \beta_4 \\
-\frac{hk_{51}}{3} & -\frac{4hk_{52}}{3} & -\frac{2hk_{53}}{3} & -\frac{4hk_{54}}{3} & 1-\frac{hk_{55}}{3} & 0 & \beta_5 \\
-\frac{hk_{61}}{3} & -\frac{4hk_{62}}{3} & -\frac{17hk_{63}}{24} & -\frac{9hk_{64}}{8} & -\frac{9hk_{65}}{8} & 1-\frac{3hk_{66}}{8} & \beta_6 \\
-\frac{hk_{71}}{3} & -\frac{4hk_{72}}{3} & -\frac{2hk_{73}}{3} & -\frac{4hk_{74}}{3} & -\frac{2hk_{75}}{3} & -\frac{4hk_{76}}{3} & 1-\frac{hk_{77}}{3}+\beta_7
\end{pmatrix}$$

In this case rows three, five, and seven are produced by using Simpson's rule for integration. Rows four and six have an odd number of intervals of integration and involve the usual Simpson rule and Simpson 3/8 rule [Linz, p. 99]. Row two arises from the block quadrature method [DM].

This approach has the attractive feature that involves higher order approximations for $p > 1$ and that, except for the last column, the matrix A is block lower triangular and so, in principle, (2.3) can be solved in $O(n^2)$ not $O(n^3)$ operations.

For large n we have the following results.

THEOREM 2.4. *Assume that $k(s,t)$ is bounded for $0 \le s \le L$, $0 \le t \le L$. For any fixed order of integration $p \ge 1$ and for sufficiently large n no row interchanges are required when* GEPP *is applied to the matrix A in* (2.3).

Proof. Let w_{ij} be the weights in the numerical integration formula corresponding to the i,j element of A and choose n such that $\delta \equiv \max_{1\le i,\, j\le n} |w_{ij}k_{ij}h| \le 1/(p+1)$. The first $n-1$ columns of A are lower triangular except for a $p \times p$ diagonal block in columns 2 through $p+1$. Outside these columns no row interchanges are required in GEPP since $\delta \le 1/(p+1) \le \frac{1}{2}$. Let $\hat{A}$ consist of columns 2 to $p+1$ of A and $\hat{I}$ be an $n \times p$ matrix with ones on the diagonal and zeros elsewhere. Then $\hat{A} = \hat{I} - B$, where $\max_{1\le i\le n,\, 1\le j\le p} |b_{ij}| \le \delta$. Let $\hat{A}^k$ be $\hat{A}$ after k steps of GEPP, let $B^k = \hat{I} - \hat{A}^k$, and let $x_k = \max_{1\le i\le n,\, 1\le j\le p} |b^k_{ij}|$. Clearly, no row interchanges are required at the first step of GEPP applied to $\hat{A}$.

We now use induction. For some k, $1 \le k \le p-1$ assume no row interchanges are required through step k of GEPP and that $x_k \le \delta/(1-k\delta)$. Then for $i = k+1, \ldots, n$, $|\hat{a}^k_{ik}| \le x_k \le [1/(p+1)]/[(1-k/(p+1)] \le \frac{1}{2}$ and $|\hat{a}^k_{kk}| \ge 1 - x_k \ge \frac{1}{2}$. Therefore no pivoting will be required at step $k+1$. Also since $\hat{a}^{k+1}_{ij} = \hat{a}^k_{ij} - \hat{a}^k_{kj}\hat{a}^k_{ik}/\hat{a}^k_{kk}$ then for $i \ne j$, $|\hat{a}^{k+1}_{ij}| \le x_k + x_k x_k/(1-x_k) = x_k/(1-x_k)$. For $i = k+1, \ldots, p$ we then have $|\hat{a}^{k+1}_{ii} - 1| \le x_k + x_k x_k/(1-x_k) = x_k/(1-x_k)$. Consequently $x_{k+1} \le x_k/(1-x_k)$. This and $x_k \le \delta/(1-\delta k)$ imply that $x_{k+1} \le \delta/[1-(k+1)\delta]$. This completes the proof and also shows that $\max_{1\le i\le n,\, 1\le j\le p} |b^p_{ij}| \le \delta/(1-p\delta)$. □

THEOREM 2.5. *Assume that $k(s,t)$ is continuous over $0 \le s \le L$, $0 \le t \le L$, and $\beta(s)$ is continuous over $0 \le s \le L$. Let $\gamma(s)$ be the solution to the integral equation*

$$\gamma(s) - \int_0^s k(s,t)\gamma(t)\,dt = \beta(s). \tag{2.6}$$

For any fixed p the growth factor ρ for GEPP *applied to* (2.3) *satisfies*

$$\lim_{n\to\infty} \rho = \frac{\max_{0\le\tau\le s\le L}\{1,\ |\beta(s) + \int_0^\tau k(s,t)\gamma(t)\,dt|,\ |1+\beta(L) + \int_0^\tau k(s,t)\gamma(t)\,dt|\}}{\max_{0\le s\le L}\{1,\ |\beta(s)|,\ |1+\beta(L)|\}}. \tag{2.7}$$

Proof. Select a fixed τ, $0 \le \tau \le L$ and suppose that k is an integer, $p+1 \le k \le n-1$ such that $hk = \tau$. Assume that h is sufficiently small so that no pivoting is required in GEPP applied to A in (2.3). Then after step k of GEPP, we have

$$\begin{pmatrix} L_{11} & 0 & 0 \\ L_{21} & I & 0 \\ L_{31} & 0 & 1 \end{pmatrix} \begin{pmatrix} U_{11} & 0 & \mathbf{u}_1 \\ 0 & A_{22} & \mathbf{u}_2 \\ 0 & A_{32} & u_n \end{pmatrix} = A = \begin{pmatrix} A_{11} & 0 & 0 \\ A_{21} & A_{22} & 0 \\ A_{31} & A_{32} & \tilde{a}_{nn} \end{pmatrix} + \mathbf{e}_n^T \begin{pmatrix} \boldsymbol{\beta}_1 \\ \boldsymbol{\beta}_2 \\ \beta_n \end{pmatrix}. \tag{2.8}$$

In (2.8) there are k, $n-k-1$, and 1 elements, respectively, in the first, second, and third block rows and columns. Here $\mathbf{e}_n = (0,0,\ldots,0,1)^T$.

Now let $\boldsymbol{\beta} = (\boldsymbol{\beta}_1^T, \boldsymbol{\beta}_2^T, \beta_n)^T$, $\mathbf{u} = (\mathbf{u}_1^T, \mathbf{u}_2^T, u_n)^T$ and $\mathbf{v}_1 \in R^k$ satisfy $U_{11}\mathbf{v}_1 = \mathbf{u}_1$. Then from (2.8) $L_{11}\mathbf{u}_1 = \boldsymbol{\beta}_1$ and $L_{11}U_{11} = A_{11}$ so that $A_{11}\mathbf{v}_1 = \boldsymbol{\beta}_1$. This last equation is the equation produced when the quadrature method is applied to (2.6) over the interval $0 \le s \le \tau = kh$. By standard results [DM, pp. 126–127], for $s_i = ih$ fixed and $i \le k$

$$v_i - \gamma(s_i) \to 0 \quad \text{as } h \to 0. \tag{2.9}$$

In the proof of Theorem 2.4 it was shown that $U_{11} = I + \tilde{B}$, where $\tilde{b}_{ij} = 0$, for $j > i > p+1$, and where $\max_{1\le i,j\le n} |\tilde{b}_{ij}| \le \delta/(1-p\delta)$, with $\delta \to 0$ as $h \to 0$. It then follows from (2.9) that for ih fixed and $i \le k$

$$u_i - \gamma(s_i) \to 0 \quad \text{as } h \to 0. \tag{2.10}$$

From the second block row in (2.8), we have $L_{21}\mathbf{u}_1 + \mathbf{u}_2 = \boldsymbol{\beta}_2$ and $L_{21}U_{11} = A_{21}$. Therefore $\mathbf{u}_2 = -A_{21}\mathbf{v}_1 + \boldsymbol{\beta}_2$. Since elements in $-A_{21}$ come from discrete approximations to integrals and from (2.9) it follows that for i such that $k+1 \le i \le n-1$ and for s_i fixed then

$$u_i \to \int_0^\tau k(s,t)\gamma(t)\,dt + \beta(s_i) \text{ as } h \to 0. \tag{2.11}$$

From the third block row in (2.8), we also have $L_{31}\mathbf{u}_1 + u_n = \tilde{a}_{nn} + \beta_n$ and $L_{31}U_{11} = A_{31}$ so that $u_n = \tilde{a}_{nn} - A_{31}\mathbf{v}_1 + \beta_n$. Since $\tilde{a}_{nn} \to 1$ as $h \to 0$, we see that

$$u_n \to 1 + \beta(L) + \int_0^\tau k(s,t)\gamma(t)\,dt. \tag{2.12}$$

In proving (2.10), (2.11), and (2.12) we have assumed that $k \ge p+1$. These equations are also true for $k \le p$. For example, for $i \le k \le p$ as $h \to 0$ it follows easily that $u_i \to \beta(0)$ and $\gamma(s_i) \to \beta(0)$ so that (2.10) is true. The theorem follows from (2.10)–(2.12) and the definition of growth factor. □

COROLLARY 2.13. *With the assumptions of Theorem* 2.5

$$\lim_{n\to\infty} \rho \geq \frac{\max_{0\leq s\leq L}\{1,\ |\gamma(s)|,\ |1+\gamma(L)|\}}{\max_{0\leq s\leq L}\{1,\ |\beta(s)|,\ |1+\beta(L)|\}}.$$

Proof. The result follows by letting $\tau = s$ in (2.7) and using (2.6). □

Corollary 2.13 shows that for any of the numerical integration schemes that we have outlined, large growth occurs for sufficiently large n if the solution $\gamma(s)$ to (2.6) is large relative to the coefficient $\beta(s)$ in (2.2). The next section shows that large growth can happen for practical problems where A is well conditioned.

3. Examples. Our first example comes from a simple model for population dynamics. Let $x(s)$ represent the population of a species at time s and let x_0 be the initial population. For some fixed time L assume for $0 \leq s \leq L$ that births occur at a rate $r(s)$ and deaths are governed by a survival function $f(s)$ where a fraction $f(s-t)$ of the organisms born at time t are alive at time s, $t \leq s \leq L$. It follows [Jer] that

$$x(s) = x_0 f(s) + \int_0^s f(s-t)r(t)\,dt, \qquad 0 \leq s \leq L. \tag{3.1}$$

If we assume that the birth rate is proportional to the population, $r(t) = \kappa x(t)$ for some constant κ, then (3.1) becomes a Volterra integral equation of the second kind (2.1) with $k(s,t) = \kappa f(s-t)$ and $G(s) = x_0 f(s)$. On the other hand if we introduce a birth control policy where the birth rate is reduced by an amount proportional to the final population so that $r(t) = \kappa x(t) - \alpha x(L)$, for a constant α, then (3.1) reduces to the form (2.2) with $k(s,t) = \kappa f(s-t)$, $G(s) = x_0 f(s)$, and $\beta(s) = \int_0^s \alpha f(s-t)\,dt$.

We can now illustrate the results of §2 by assuming, say, that $x_0 = 1$, $\kappa = 1$, $L = 50$, $\alpha = .5$, and $f(s) = e^{-cs}$ with $c = .25$ so that $\beta(s) = \alpha(1 - e^{-cs})/c$. For most functions $f(s)$, (2.1) or (2.2) with $k(s,t) = \kappa f(s-t)$ do not have exact solutions in terms of the usual transcendental functions and are not equivalent to ordinary differential equations. However, to calculate errors we choose a simple $f(s)$ so that (2.2) has an exact solution $x(s) = x_0[\alpha+(\kappa-c-\alpha)e^{(\kappa-c)(s-L)}]/[\alpha+(\kappa-c-\alpha)e^{-(\kappa-c)L}]$. In this case the solution to (2.6) is $\gamma(s) = \alpha[1 - e^{(\kappa-c)s}]/(\kappa - c)$. Thus by Corollary 2.13 for large n the growth factor should be approximately

$$\frac{1+\alpha[1-e^{(\kappa-c)L}]/(\kappa-c)}{1+\alpha(1-e^{-cL})/c} = 4.3 \times 10^{15},$$

or larger, and partial pivoting should have large error growth.

In Fig. 3.2 we have plotted, versus n, the growth factors as computed by (1.1) when solving (2.3) for $p = 2$ by GEPP and complete pivoting. For partial pivoting row interchanges are required for $n \leq 92$ and the growth factor remains moderate. However for $n \geq 93$ no row interchanges are required for partial pivoting and the growth factor becomes large. For $n = 200$ the computed growth factor is 4.02×10^{15}, close to the above theoretical estimate. Also in Fig. 3.2 we have plotted, versus n, the relative error in the approximate solution to (2.1) obtained by solving (2.3) by partial pivoting and complete pivoting. Here by relative error we mean $\max_{i=1,\ldots,n} |x(s_i) - x_i| / \max_{i=1,\ldots,n} |x(s_i)|$, where $x(s)$ is the true solution. Gaussian elimination with complete pivoting is numerically stable and for this example the relative error decreases proportional to h^4 (since our numerical integration is based on the Simpson rule). On the other hand, for partial pivoting, the large growth factor leads a large relative error in the calculated answer. GEPP *is unstable and inaccurate for* $n \geq 93$.

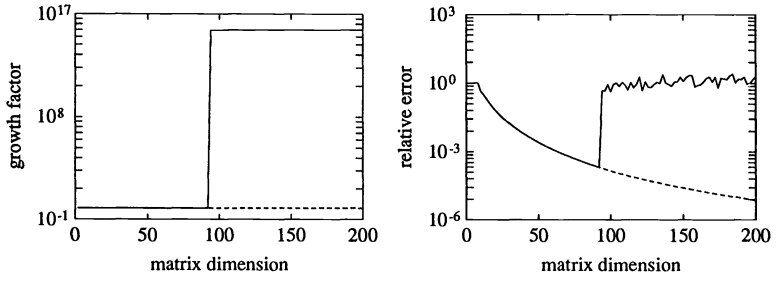

FIG. 3.2. *The growth factor (left), and the relative error (right), when solving* (2.3) *with partial pivoting (solid lines) and complete pivoting (dashed lines).*

To further illustrate the difficulty with partial pivoting in Fig. 3.3 we have plotted the approximate solution to (2.2) obtained by solving (2.3) using partial pivoting with $n = 100$ and the true solution. In this case, to solve (2.3) we used the MATLAB "\" operator, which is based on Linpack's implementation of GEPP, on a SUN SPARCstation. The large discrepancy for $s \geq 42$ is due to the instability of partial pivoting.

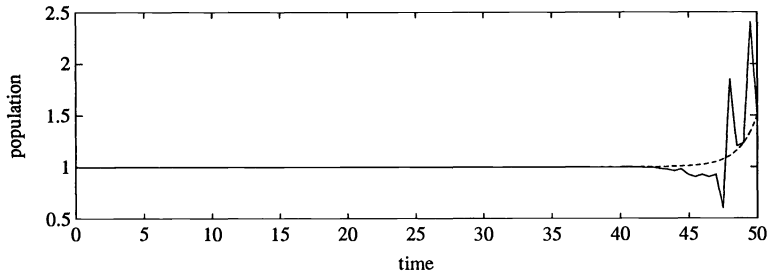

FIG. 3.3. *The true solution (dashed) to* (2.3) *and approximate solution (solid) calculated when using partial pivoting for* $n = 100$.

Finally we note that on a modern workstation it requires less than a second to set up and solve (2.3) for $n = 100$, say, and that the linear systems solved to produce the graphs in Figs. 3.2 and 3.3 are well conditioned. For example, the matrices used to produce Fig. 3.2 all have condition numbers less than 162.

For our second example we consider a boundary value problem. Suppose constants L, k, and C and a function $g(t)$, $0 \leq t \leq L$, are known and that an unknown function $x(t)$, $0 \leq t \leq L$, satisfies

$$x'(t) = kx(t) + g(t), \quad 0 < t < L \quad \text{with } x(L) = Cx(0). \tag{3.4}$$

This example is simple enough so that we can find the solution exactly, but suppose that we wished to solve it numerically. We choose to first convert the differential equation (3.4) into an integral equation by integrating from zero to s and substitute

in $x(0) = x(L)/C$ to get

$$x(s) - \int_0^s kx(t)\,dt - x(L)/C = \int_0^s g(t)\,dt \equiv G(s). \tag{3.5}$$

This is of the form (2.2) with $k(s,t) = k$ and $\beta(s) = -1/C$. If we apply the quadrature method to (3.4) using the trapezoid rule to approximate the integrals, the resulting linear system $Ax = b$ is simple enough in this case so that we can exactly describe L and U in an LU factorization of A. It is easy to check for $b = 1 - kh/2$ and $\omega = (1 + kh/2)/(1 - kh/2)$ that

$$A = \begin{pmatrix} 1 & 0 & 0 & \cdots & 0 & -1/C \\ -\frac{kh}{2} & 1-\frac{kh}{2} & 0 & \cdots & 0 & -1/C \\ -\frac{kh}{2} & -kh & 1-\frac{kh}{2} & \ddots & \vdots & \vdots \\ \vdots & \vdots & & \ddots & 0 & -1/C \\ -\frac{kh}{2} & -kh & \cdots & -kh & 1-\frac{kh}{2} & -1/C \\ -\frac{kh}{2} & -kh & \cdots & -kh & -kh & 1-1/C-\frac{kh}{2} \end{pmatrix} =$$

$$\begin{pmatrix} 1 & 0 & \cdots & & & 0 \\ -\frac{kh}{2} & 1 & \ddots & & & \vdots \\ -\frac{kh}{2} & -\frac{kh}{b} & 1 & & & \\ -\frac{kh}{2} & -\frac{kh}{b} & -\frac{kh}{b} & 1 & & \\ \vdots & \vdots & \vdots & \ddots & \ddots & 0 \\ -\frac{kh}{2} & -\frac{kh}{b} & -\frac{kh}{b} & \cdots & -\frac{kh}{b} & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & \cdots & & 0 & -\frac{1}{C} \\ 0 & b & \ddots & & \vdots & -\frac{b\omega}{C} \\ \vdots & \ddots & b & & & -\frac{b\omega^2}{C} \\ & & & \ddots & 0 & \vdots \\ & & & & b & -\frac{b\omega^{n-2}}{C} \\ 0 & \cdots & & & 0 & -\frac{b\omega^{n-1}}{C} + b \end{pmatrix}$$

From this factorization it follows easily that if $|kh| \le 2/3$, no row interchanges are required in GEPP and that there will be large elements in U if $b\omega^{n-1}/C$ is large.

As a specific example let $k = 1$, $L = 40$, and $C = 6$. An application producing such numbers would be a solution mixture problem over the time period $-40 \le \hat{t} \le 0$ where fluid with a solute concentration 1 enters a tank of volume 1 at a rate 1, where mixed fluid leaves at a rate 1, where the ratio of the final to the initial amount of solute in the tank is 6 and where we let $t = -\hat{t}$ to transform the domain to $0 \le t \le 40$. In this example, if $n \ge 61$ we have $kh \le \frac{2}{3}$ and the growth factor is large. For $n = 61$, say, the condition number of A is 88, the relative error in the calculated solution when solving (2.3) by a QR factorization is 1.1%. Yet if partial pivoting is used to solve (2.3) then due to a growth factor of 1.28×10^{17} the relative error is 860%. GEPP *fails again for this concrete physical example.*

From the above decomposition it follows that when $C = 1$, say, and $kh = 2/3$ that the growth factor is $(2/3)(2^{n-1} - 1)$. This is quite close to the maximum theoretical growth factor of 2^{n-1}. In comparison, the maximum growth factor reported in [Wri] is proportional to $(\sqrt{2})^n$. We might also note that we can generalize the results for our second example to boundary value problems for systems of m differential equations. For such systems we can get growth factors, approximately, as big as $[2(1.5)^m - 1]^{(n/m)-1}/[3(1.5)^m - 3]$ where large growth occurs in the last m columns of U. For example if $m = 5$ and $n = 90$, growth of 2×10^{18} can occur in the last five columns of U.

4. Conclusions. The existence of practical examples where partial pivoting fails leads to a number of questions for the scientific computing community. To initiate a debate we propose the following answers.

1. *Why haven't practical examples where partial pivoting fails been reported earlier?* We expect that the primary reason is that such examples are indeed rare. Our problems and our approach to solving these problems were carefully selected. However, we should note that most software packages in numerical linear algebra do not report information about the growth factor and so it is possible that large growth factors do occur from time to time in practice, but have gone unreported.

2. *Should widely used packages in numerical linear algebra provide information about growth factors?* In view of our examples we believe that such information should be reported if, for example, a user requests an "expert" solution. The authors of Lapack are planning to incorporate this in future releases of Lapack [Dem]. For a dense matrix a bound on the effect of the growth factor on the error in the calculated solution can be determined in $O(n^2)$ operations [CG], [ER], [GVL] which is small compared to the work in factoring the matrix.

Both Linpack [DBMS] and Lapack [ABB] had difficulty with the matrices in our examples. For the second example in §3, if $L = 60$, $n = 100$, $k = 1$, and $C = 6$ Linpack DGECO reports an estimated condition number of 1.5×10^{12} when the actual condition of A is 132. On the other hand, if $L = 40$ and $n = 61$ Linpack DGECO reports an estimated condition number of 534, which is much closer to 88, the true condition number. However, this might lead the user into thinking that the calculated solution is correct while, as we have seen in §3, it is not. With Lapack for our examples, if the growth factors were not too large, then the "expert" routine DGESVX successfully uses iterative refinement to overcome the inaccuracy due the large growth factor. However, if the growth factor is sufficiently large, iterative refinement does not converge. Also the Lapack condition estimator fails in some cases. Neither package warns the user that GEPP is unstable due to a large growth factor.

For our examples, the reason that the Linpack and Lapack condition estimators fail is that they rely on the ability to solve $Ax = y$. However due to large growth factors, the solutions to $Ax = y$ are not calculated correctly. The underlying condition estimators are not failing themselves, rather they are working with incorrect solutions to $Ax = y$.

3. *Are tests on random matrices useful for comparing and analyzing algorithms in numerical linear algebra?* Such tests are valuable in that they allow the quick generation of many examples. Also random matrices can be amenable to theoretical analysis. However tests with random matrices are not sufficient. For example, the matrices in our illustrations contained only negative numbers below the diagonal. If random matrices were generated so that signs of elements were random, then for $n = 50$, say, the probability of this sign pattern is negligible (10^{-737}). It would never show up in random sampling. We feel that tests with random matrices are often overused.

4. *Is there a need for a collection of test matrices arising from practical problems?* Since there are phenomena that occur in practice that do not show up in tests with random matrices, there is such a need. The collection could complement existing collections such as the one in [DGL]. Ideally the new collection would be in an easy-to-use format such as MATLAB m files so that the collection is compact and flexible code could be included that would generate the matrices for different parameter choices, similar to the style used by Higham [Hig]. However, the focus would be on interesting

matrices that can arise in practice. The collection of examples in Hansen's Regularization Tools [Han] would be a good beginning. Indeed the genesis of this paper came from observing some of the sign patterns for the matrices in Hansen's collection.

A HYBRID TRIDIAGONALIZATION ALGORITHM FOR SYMMETRIC SPARSE MATRICES*

IAN A. CAVERS†

Abstract. This paper considers sequential direct methods for the reduction of a sparse symmetric matrix to tridiagonal form using sequences of orthogonal similarity transformations. Currently, the best published approach combines a bandwidth-reducing preordering algorithm, perhaps Gibbs–Poole–Stockmeyer (GPS), with a band-preserving tridiagonalization such as the EISPACK BANDR routine. This paper introduces a new hybrid tridiagonalization algorithm, BANDHYB, based upon band-preserving reduction techniques that rearrange the elimination sequence of nonzero entries to take better advantage of the sparsity within the band of the permuted matrix. For many practical sparse problems a GPS-BANDHYB approach substantially reduces the CPU requirements of tridiagonalization, compared to a GPS-BANDR scheme, without increasing storage requirements. Over a wide range of sparse problems the new algorithm reduced CPU time by an average of 31%, with reductions of more than 60% observed for some problems.

1. Introduction.

This paper considers methods for the similarity reduction of a large $n \times n$ sparse symmetric matrix A to a symmetric tridiagonal matrix T. The class of algorithms studied are sequential direct methods of the generic form

$A_0 := A$
FOR $i := 1, 2, \ldots, k$
$\quad A_i := Q_i^T A_{i-1} Q_i$

in which A is systematically reduced to tridiagonal form ($A_k = T$) using a sequence of k carefully selected orthogonal similarity transformations $Q_i^T A_{i-1} Q_i$.

For symmetric dense eigenvalue problems, tridiagonalization is an important intermediate step used in many solution methods [15]. The tridiagonalization of such problems is typically conducted using either Householder or Givens reduction [21] requiring $O(n^3)$ flops.[1] When a matrix is sparse, however, both standard tridiagonalization algorithms quickly destroy sparsity. In fact, for most sparse problems of interest, little advantage can be made of sparsity with such algorithms. The reduction requires $O(n^3)$ flops and $O(n^2)$ storage, and the original matrix might as well have been treated as dense [7]. This paper reexamines the sparse tridiagonalization process, developing a new hybrid algorithm based on Givens transformations, that reorders the elimination sequence of nonzero entries to improve sparsity exploitation. This hybrid algorithm is better suited to the reduction of general sparse symmetric matrices than previous alternatives to the standard Householder or Givens reductions.

In the past 20–25 years, sparse matrix research has paid particular attention to the direct solution of sparse linear systems, producing many clever methods that successfully exploit matrix sparsity. (See [5] for example.) Attempts to extend this success to sparse tridiagonalization have been hindered by the higher levels of fill associated with orthogonal similarity transformations. Section 2 of this paper presents two previous attempts to overcome the difficulties associated with the tridiagonalization of

[1] Following [15] a flop is defined to be any floating point arithmetic operation.

general sparse symmetric matrices. Section 3 of the paper introduces our bandwidth contraction algorithm that reorders the elimination of nonzero entries to control the introduction of fill and take better advantage of sparsity. In §4, bandwidth contraction is combined with a column-oriented, band-preserving reduction to produce an effective hybrid tridiagonalization algorithm. Section 5 then describes implementations of the bandwidth contraction and hybrid tridiagonalization algorithms. This section includes an extensive comparison between both sparse algorithms and the EISPACK BANDR [8] routine on a large number of sparse problems from the Harwell–Boeing collection [6]. The hybrid tridiagonalization algorithm is shown to substantially reduce the computational requirements for most sparse problems. Finally, §6 provides concluding remarks and directions for future research.

2. Existing sparse tridiagonalization methods. This section explores existing direct tridiagonalization approaches, analyzing their limitations and their potential extension to improve sparsity exploitation. After a brief discussion of the role of Givens rotations in sparse tridiagonalization, we review sparse tridiagonalization schemes based on customized Givens reductions. We then explore an alternative band-preserving tridiagonalization approach for banded matrices, including a discussion of its extension for the tridiagonalization of general sparse symmetric matrices.

2.1. Givens rotations and sparse tridiagonalization. Givens rotations, $G(i,j,\theta)$, are often chosen for sparse matrix application because they permit fine-grained control over the elimination of nonzeros and the introduction of fill entries. In fact, rotations can be constructed to zero any entry of a matrix using *any* other entry in its row or column as the *zeroing entry.* (In Fig. 1, x_1 is the zeroing entry.) The

$$\begin{bmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{bmatrix} \begin{bmatrix} x_1 & x & & x & x & \\ x_2 & & x & x & & x \end{bmatrix} \longrightarrow \begin{bmatrix} \hat{x}_1 & x & x & x & x & x \\ 0 & x & x & x & x & x \end{bmatrix}$$

FIG. 1. *Sparsity structure unioning by a Givens rotation.*

trivial example in Fig. 1 illustrates an important property of rotations that impacts matrix sparsity. If cancellation is ignored and x_1 is nonzero, the sparsity structure of both modified rows is the union of the structure of the two rows prior to the rotation's application. (In the special case of x_2 or x_1 zero, the rotation is either the identity or it swaps the sparsity structure of the two rows, avoiding the introduction of fill entries. It is advantageous to have a zero *zeroing entry.* In addition to fill avoidance, swapping matrix rows to eliminate nonzero x_2 requires no floating point computations.)

The algorithms in this paper use Givens rotations to construct orthogonal similarity transformations of the form $G(i,j,\theta)^T A\, G(i,j,\theta)$, which modify both rows and columns i and j of A. By symmetry of the sparse problems and similarity transformations, all algorithms need only to consider transformation modifications to either the upper or lower triangular portion of each matrix. Without loss of generality we work with a matrix's lower triangular portion.

From the wide selection of rotations that can be constructed to eliminate a particular nonzero entry, this paper concentrates on algorithms using *adjacent rotations.* A rotation $G(i,j,\theta)^T$ is considered adjacent if $|i-j| = 1$. As discussed in §6, future study will consider the use of nonadjacent rotations.

2.2. Customized sparse Givens reduction. Using $O(n^3)$ flops and $O(n^2)$ storage, the standard Givens reduction tridiagonalizes a symmetric matrix column by column as shown in Fig. 2. Within each column nonzero entries are eliminated

```
FOR col:= 1 TO n-2 DO
    FOR row:= n DOWNTO col+2 DO
        A := G(col + 1, row, θ)^T A G(col + 1, row, θ)
```

FIG. 2. *Givens reduction.*

from the bottom up using the column's subdiagonal entry as the zeroing entry. Dense Givens rotations, which assume that the unreduced portion of the matrix is dense, are used throughout.

The flexibility of Givens rotations permits both the order in which a column is zeroed and the plane of the zeroing rotation to be modified. These variable elements of the basic algorithm can be used to construct customized sparse Givens reduction algorithms that attempt to take better advantage of sparsity. Unfortunately, the experimentation of Duff and Reid [7] shows that, independent of rotation plane selection and the elimination order of each column's nonzeros, adaptations of Givens column-by-column reduction for large sparse matrices generally experience overwhelming levels of fill and matrix sparsity is quickly destroyed. In fact, Duff and Reid conclude that if a Givens reduction approach is taken, typically little advantage is made of sparsity and it is preferable to treat the matrix as dense.

2.3. The tridiagonalization of banded matrices. If tridiagonalization algorithms are to effectively utilize matrix sparsity, it appears essential to restrict the accumulation of fill entries to some maintainable substructure of the matrix. Suppose that a symmetric matrix of bandwidth[2] b is to be reduced to tridiagonal form. In addition, for the remainder of this subsection assume that the band is dense. Applying a column-by-column Givens reduction to the matrix leads to overwhelming levels of fill outside the band, quickly destroying matrix sparsity. Alternatively, the algorithm of Rutishauser [18] and Schwarz [20] (subsequently referred to as the Rutishauser–Schwarz or, simply, R-S algorithm) controls the encumbering effects of fill by actively preserving a matrix's banded structure throughout tridiagonalization.

The pseudocode in Fig. 3 outlines the Rutishauser–Schwarz algorithm. Once again, Givens transformations are used by this band-preserving tridiagonalization algorithm to provide fine-grained control over the elimination process. Globally, the

```
FOR col:= 1 TO n-2 DO
    FOR diag:= min(b,n-col) DOWNTO 2 DO
        /*Zero A_{col+diag,col}.*/
        A := G(col + diag, col + diag − 1, θ)^T A G(col + diag, col + diag − 1, θ)
        IF bandwidth(A) > b THEN
            Annihilate bulges with additional adjacent Givens transformations.
```

FIG. 3. *The Rutishauser–Schwarz algorithm.*

effect is that the banded matrix is reduced column by column. Indeed, within each column, adjacent transformations eliminate the nonzeros from the outside in. The key difference is that R-S immediately removes fill created outside the band of the

[2] Bandwidth (or semibandwidth) is defined as $b = \max_{i,j\in\{1\ldots n\},i\neq j} |i-j|$ such that $A_{ij} \neq 0$.

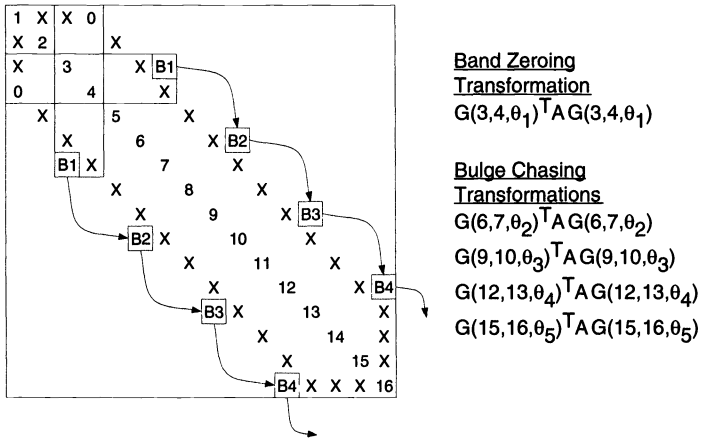

FIG. 4. *Bulge chasing to preserve bandwidth.*

original matrix. The symmetric elimination of a band nonzero produces a pair of fill entries, or *bulges*, outside the band as illustrated by the B1 entries in Fig. 4. Before eliminating the next band nonzero R-S chases the bulges off the end of the matrix with an additional sequence of adjacent transformations. (See Fig. 4.) In this fashion the algorithm maintains the banded structure of the unreduced portion. During the reduction of a typical column k, the elimination of band entry A_{ik} requires $\lceil \frac{n-b-i+1}{b} \rceil$ bulge-chasing transformations. Adjacent transformations are used exclusively by the algorithm because nonadjacent rotations create triangular bulges consisting of several nonzero entries that require a larger number of bulge-chasing transformations.

Table 1 provides formula for the tridiagonalization costs of the Rutishauser–Schwarz algorithm. The analysis assumes $2 < b \leq (n/2 - 1)$ and $C_{\text{R-S}}$ is the non-analytic term $\text{Mod}(n-1,b)(\text{Mod}(n-1,b)-b)$, which typically can be safely ignored without incurring large errors.[3] $F^{\text{G}}_{\text{R-S}}$ and $T_{\text{R-S}}$ refer to flop and transformation counts, respectively. In addition to $F^{\text{G}}_{\text{R-S}}$, the construction of each transformation

TABLE 1
Tridiagonalization costs of the Rutishauser–Schwarz algorithm for a densely banded matrix.

$F^{\text{G}}_{\text{R-S}}$	$T_{\text{R-S}}$
$(6b - \frac{8}{b} + 2)n^2 - (6b^2 + 5b - \frac{16}{b} + 5)n$ $+2b^3 + 4b^2 - b - \frac{8}{b} + 3 + (\frac{8}{b} + 3)C_{\text{R-S}}$	$\frac{(b-1)(n-1)^2 + C_{\text{R-S}}}{2b}$

requires one square root. Although $T_{\text{R-S}}$ is comparable to the number of transformations used by Givens reduction on the same densely banded problem, in general the band-preserving approach modifies fewer nonzero entries with each transformation. As a result, for matrices of moderate bandwidth, $F^{\text{G}}_{\text{R-S}}$ is smaller than the floating-point requirements of Givens reduction.

The EISPACK [8] implementation of the R-S algorithm BANDR does not use standard Givens transformations. Instead it employs a "root free" variant of the transformation, with identical fill properties, often referred to as a *fast Givens trans-*

[3] $Mod(x, y)$ is the remainder from the division of integer x by integer y.

formation [9]. In this case the computational requirements of the band-preserving tridiagonalization are reduced to

$$F_{\text{R-S}}^{\text{FG}} = \left(4b - \frac{10}{b} + 6\right) n^2 - \left(4b^2 + 3b - \frac{20}{b} + 10\right) n + \frac{4b^3}{3} + \frac{5b^2}{2} - \frac{5b}{6} - \frac{10}{b} + 7 + \left(\frac{10}{b} + 2\right) C_{\text{R-S}} \tag{1}$$

and n square roots. The analysis leading to $F_{\text{R-S}}^{\text{FG}}$ ignores the cost of periodic rescaling and assumes that a reduction uses the two types of fast Givens transformations in equal proportion. For either variant of the band-preserving R-S algorithm $O(bn)$ storage is required.

We note that BANDR will not be faster for all bandwidths than the best dense matrix algorithm, Householder's reduction. Assuming that the Householder reduction requires $\frac{4}{3}n^3$ flops [15], while BANDR requires $4bn^2$, the dense matrix algorithm requires fewer flops for bandwidths larger than $\frac{n}{3}$. However, the selection of a tridiagonalization algorithm is often strongly influenced by the lower storage requirements of the Rutishauser–Schwarz algorithm.

2.4. Generalization of band-preserving tridiagonalization techniques. For general sparse symmetric matrices we can extend the band-preserving techniques of Rutishauser and Schwarz to form the following two-stage tridiagonalization algorithm.

1. $A := P^T AP$, where P is a bandwidth reducing permutation matrix.
2. Tridiagonalize A using the R-S algorithm.

Many heuristic algorithms have been suggested for the identification of bandwidth reducing preorderings [3], [14], but the most widely accepted algorithms are RCM [11] and GPS [13], [17]. The experience of Gibbs, Poole, and Stockmeyer [14] and our experimentation with the Harwell–Boeing test matrix collection suggest that GPS most frequently provides the smallest bandwidth preorderings over a wide range of problems. Consequently, GPS was selected for the experimentation in §5 and will be referenced as the *bandwidth-reducing preordering* in subsequent discussion. Although fill entries may accumulate during the tridiagonalization of the permuted matrix $P^T AP$, the R-S algorithm uses bulge-chasing transformations to constrain them to the band.

Limited advantage of sparsity is taken if we treat the band of the preordered matrix as dense during the tridiagonalization stage of the extended algorithm. In this case complete reliance is placed upon GPS to exploit sparsity, but for many problems the band of the preordered matrix is relatively sparse prior to reduction. (See Table 2.) To take advantage of band zeros, three modifications could be made to the basic band-preserving tridiagonalization algorithm.

1. Avoid constructing and applying transformations to eliminate band or bulge entries that are already zero.

2. Exploit *zeroing entries* (see §2.1) that are zero by performing row and column exchanges instead of using the general form of the Givens transformation.

3. Apply each nontrivial transformation to only those lower triangular entries whose column(row) index is in the unioned sparsity structure of the two modified rows(columns).

Both the Schwarz code [20] and EISPACK BANDR [8] check if the bulge or band entry is already zero before performing an elimination. These codes, however, are

TABLE 2
Band filling characteristics of sparse R-S.

Problem	n	Bandwidth	Initial off-diagonal band density	No. of columns (rows) eliminated before band is full.
5-pt problems	b^2	b	$\sim 2/b$	b-1

NOS3	960	65(GPS)	12.4%	19

primarily intended for densely banded matrices and neither incorporates the second or third modification. Enhancing the two-stage tridiagonalization algorithm by all three sparsity modifications produces a new algorithm subsequently referred to as the sparse Rutishauser–Schwarz algorithm or simply sparse R-S.

Unfortunately, the unreduced portion of a typical sparse matrix's band still fills quickly during band-preserving tridiagonalization. As an example, consider applying sparse R-S to five-point problems created by discretizing partial differential equations on a uniform $b \times b$ square grid with Dirichlet boundary conditions. The problems are ordered with a standard lexicographic labeling, minimizing bandwidth at b. After $b - 1$ columns of a five-point problem have been reduced to tridiagonal form, the remainder of the band is completely filled in. The preponderance of fill within the band is largely due to the sequence of bulge-chasing rotations required by each band nonzero's elimination. Once the matrix's band has been filled, there is no further opportunity to exploit sparsity beyond the densely banded form of the remaining submatrix. Consequently, the flop and transformation requirements of a five-point problem reduction are identical in the highest order terms to $F^{\mathrm{G}}_{\text{R-S}}$ and $T_{\text{R-S}}$ for a densely banded matrix of equivalent order and bandwidth.

The speed with which the band of a five-point problem fills is typical of most large sparse symmetric problems. Table 2 provides fill data for two additional sparse problems from the Harwell–Boeing test matrix collection [6] as tridiagonalized by sparse R-S. Despite starting with relatively sparse bands, the unreduced portion of the band of both problems is completely filled well before b columns are reduced to tridiagonal form.

Because of high levels of band fill, typically very little advantage can be taken of sparsity in the band. In general, the application of sparse R-S is only slightly superior to the original band-preserving R-S tridiagonalization approach. In the next section we introduce an alternative to sparse R-S that more successfully utilizes band sparsity.

3. Bandwidth contraction. The previous section demonstrated the inability of sparse R-S to take good advantage of internal band sparsity. This section presents an alternative approach to sparse tridiagonalization. It also uses bandwidth-reducing preorderings and band-preserving reduction techniques, but reorders the elimination sequence to more fully exploit band sparsity.

3.1. Motivation. The sparse tridiagonalization techniques explored in this section are motivated by the following observation. A bandwidth-reducing preordering frequently produces a permuted matrix whose profile consists of varying length *spikes* of nonzeros extending from the main diagonal. The longest spike defines the bandwidth of the permuted matrix as shown in Fig. 5. For many practical problems, the spikes of the permuted matrix are of dramatically different lengths. The new sparse tridiagonalization approach attempts to exploit this characteristic. Although fill cannot be avoided, the bandwidth of the matrix could be significantly reduced

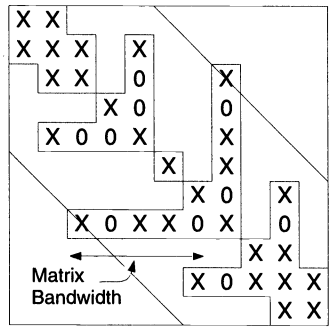

FIG. 5. *Matrix bandwidth and spike length.*

with relatively few transformations if the ends of the longest spikes could be clipped off at low cost before the contracted band becomes dense.

3.2. The sparse bandwidth contraction algorithm. There are a number of ways that the ends of the profile's longest spikes could be clipped off with Givens transformations. One way to approach the clipping process is to rearrange the elimination order of a band-preserving tridiagonalization so that the matrix is reduced to tridiagonal form diagonal by diagonal (outermost diagonal first), rather than column by column as in sparse R-S. A diagonally oriented band-preserving tridiagonalization for densely banded symmetric matrices has been previously considered [19], [21], but was superseded on sequential machines by the Rutishauser–Schwarz column-oriented reduction [18], [20]. (See §4.1 for a detailed comparison of algorithm complexity.) To our knowledge, however, no one has considered the relative merits of the two reduction paradigms extended for general application to sparse symmetric matrices. (For densely banded matrices, the LAPACK [1] project considered the relative merits of these two algorithms implemented on vector machines.)

As shown in Fig. 6, our bandwidth contraction algorithm uses the diagonally oriented spike-clipping process to completely tridiagonalize a sparse symmetric matrix.

1. $A := P^T A P$, where P is a bandwidth-reducing permutation matrix.
2. $b :=$ bandwidth(A)
3. FOR $\widehat{b} := b$ DOWNTO 2 DO /*Tridiagonalize A.*/
   FOR col := 1 TO $n - \widehat{b}$ DO
   IF $A_{\text{col}+\widehat{b},\text{col}} \neq 0$ THEN /*Zero $A_{\text{col}+\widehat{b},\text{col}}$.*/
   IF $A_{\text{col}+\widehat{b}-1,\text{col}} = 0$ THEN
   Exchange rows/columns $(\text{col} + \widehat{b})$ and $(\text{col} + \widehat{b} - 1)$ in A.
   ELSE
   $A := G(\text{col} + \widehat{b}, \text{col} + \widehat{b} - 1, \theta)^T \, A \, G(\text{col} + \widehat{b}, \text{col} + \widehat{b} - 1, \theta)$
   (Exploit band sparsity of modified rows and columns.)
   IF bandwidth(A) $> \widehat{b}$ THEN
   Chase bulges with additional adjacent Givens
   transformations or row/column exchanges.
   ENDIF /*Outermost IF*/

FIG. 6. *The bandwidth contraction algorithm.*

To properly exploit band zeros, the three modifications made to the basic Rutishauser–Schwarz algorithm in §2.4 are also incorporated into the bandwidth contraction algorithm.

We begin with the matrix symmetrically permuted to reduce bandwidth. Then, starting with $A_{1+b,1}$, the band's outermost diagonal is scanned for its first nonzero entry. This entry is eliminated using an adjacent Givens transformation or a row/column exchange. If a nonzero entry is created beyond the current bandwidth, the bulge is chased off the end of the matrix as described in §2.3. The scanning and reduction of the outermost diagonal continues until all nonzeros have been eliminated. At this point the current bandwidth of the matrix is reduced by one and the reduction process continues with the next diagonal.

As for the sparse Rutishauser–Schwarz algorithm, bandwidth contraction uses adjacent transformations exclusively, avoiding the creation of multiple entry bulges and the concomitant extra bulge-chasing transformations. Triangular bulges not only increase computational costs, they also accelerate the introduction of fill entries into the band. An added complication for a diagonally oriented tridiagonalization is that nonadjacent transformations may reintroduce fill entries in previously zeroed positions of the diagonal. This discussion, however, is not intended to completely rule out the use of nonadjacent transformations. There are special sparsity patterns for which nonadjacent transformations are beneficial. Future study will explore the potential role of nonadjacent transformations in more sophisticated bandwidth contraction algorithms.

3.3. A demonstration of bandwidth contraction. To illustrate the potential effectiveness of bandwidth contraction, we provide a small contrived example in Fig. 7. The top matrix in Fig. 7 shows the original sparse matrix A with its nonzero entries indicated by an X and the numbered diagonal. It is assumed that A has already been permuted to reduce its bandwidth to 6. Two additional matrices, C and D, illustrate A after a partial reduction by sparse R-S or bandwidth contraction. In both C and D a 0 marks the positions of eliminated band nonzeros. Finally, reported flop counts assume that both reductions employ fast Givens transformations.

Matrix C illustrates A after sparse R-S has reduced its first three columns to tridiagonal form. Despite the highly sparse nature of the original problem, the remainder of the band is almost completely filled. The entire tridiagonalization uses eight row/column exchanges and 132 nontrivial transformations, requiring a total of 7232 flops.

Matrix D illustrates A after bandwidth contraction has eliminated the three outermost nonzero diagonals and contracted the bandwidth to 3. Although the elimination of nonzeros once again produces fill entries within the band relatively quickly, the algorithm is able to efficiently exploit the sparsity of the band away from the main diagonal. For example, bandwidth contraction eliminates the entire sixth and fifth subdiagonals of the band at the relatively low cost of 216 flops, using seven row/column exchanges and four nontrivial transformations. The complete tridiagonalization uses 12 row/column exchanges and 163 nontrivial transformations, requiring a total of 6537 flops. For this example, the computational requirements of tridiagonalization with bandwidth contraction, as measured by flop counts, are approximately 9.6% lower than for the sparse R-S approach.

It is important to note that the number of nontrivial transformations used by a tridiagonalization is a misleading metric of algorithm performance. Bandwidth contraction requires more transformations, but generally fewer nonzeros are modified by each nontrivial transformation, permitting a lower total flop count.

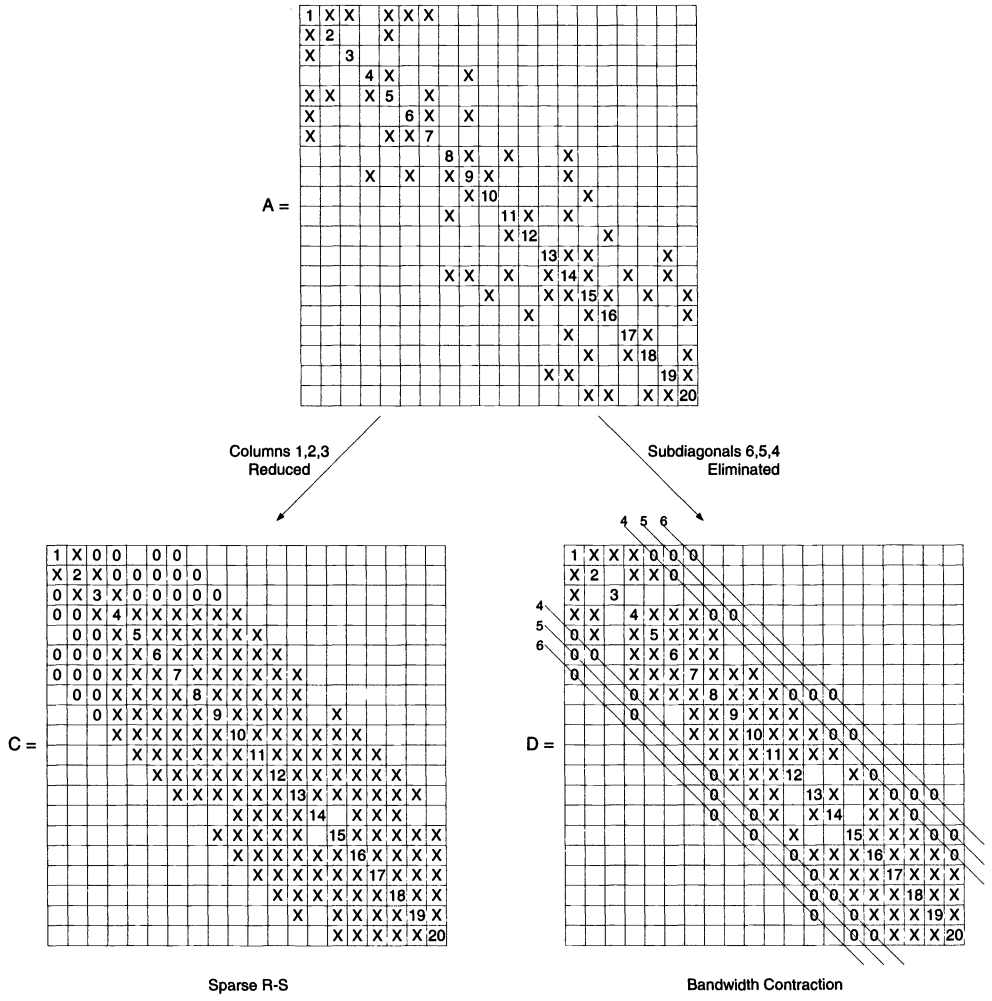

FIG. 7. *A partial tridiagonalization, sparse* R-S *versus bandwidth contraction.*

The key to the success of bandwidth contraction is the elimination of the outermost diagonals at low cost. As the result of several contributing factors, bandwidth contraction prolongs the advantages of sparsity in the outermost subdiagonals. First, when nontrivial adjacent transformations are required, they are often applied to well-separated pairs of rows and columns, insulating the effects of fill from one transformation to the next. In contrast, the sparse R-S initial band zeroing transformations and associated bulge-chasing transformations are applied to groups of neighboring rows and columns. These initial transformations produce a cascade of fill entries, typically not observed for bandwidth contraction, which quickly fills the band despite a matrix's initial sparsity. Second, the sparsity of the outermost diagonals permits bandwidth contraction to cheaply eliminate many of the band nonzeros and associated bulges, without fill, using row/column exchanges. In addition, the sparsity of the outermost diagonals often reduces the number of transformations required by bulge-chasing sequences. Finally, as the nonzeros of the outermost diagonal are eliminated, bulge-chasing sequences must shorten, while the length of the sequences used by sparse

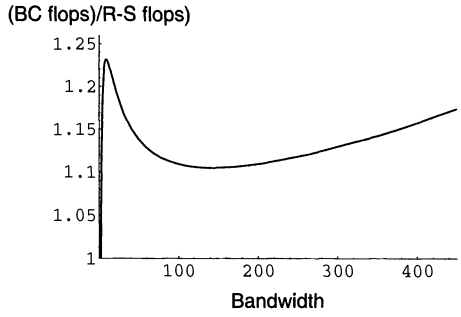

FIG. 8. *The flop requirements of* BC *relative to* R-S *for a densely banded matrix,* $n = 1000$.

R-S remains relatively constant as it reduces the first few columns. Consequently, the initial stage of bandwidth contraction produces fewer band fill entries. Thus, the partial tridiagonalization often significantly contracts the matrix's bandwidth before producing a densely banded intermediate matrix.

In general, the relative success of the sparse tridiagonalization algorithms depends on problem-specific sparsity structures. The extensive experimental analysis of §5 confirms the relative advantage experienced by bandwidth contraction for many practical sparse problems.

4. A hybrid tridiagonalization algorithm.

4.1. Motivation. Two metrics of tridiagonalization algorithm cost are flop and transformation counts F and T. As demonstrated in the previous section, the bandwidth contraction algorithm may be able to significantly reduce the bandwidth of a sparsely banded matrix at relatively low cost. Consequently, for sparsely banded matrices, bandwidth contraction flop counts are smaller than for sparse R-S, despite larger transformation counts. If the band of a matrix is dense, however, the Rutishauser and Schwarz column-oriented band-preserving tridiagonalization is superior in both measures of work.

Table 3 provides formulas for the tridiagonalization costs for the fast Givens bandwidth contraction variant applied to a densely banded, symmetric matrix of bandwidth b. The analysis assumes that $b < (n+1)/2$ and that an equal proportion of the two types of fast Givens transformations are employed. The analysis ignores the potential cost of the periodic rescaling required by fast Givens transformations. C_{BC} is the nonanalytic term $\text{Mod}(n,k)(k - \text{Mod}(n,k))$. When $b \ll n$, the $\text{Mod}(n,k)$ terms

TABLE 3
Tridiagonalization costs of the bandwidth contraction algorithm for a densely banded matrix.

$F_{\text{BC}}^{\text{FG}}$	T_{BC}
$\left(4b - 4 + 10\sum_{k=2}^{b}\left(\frac{1}{k}\right)\right)n^2 + \left(22 - 16b - 3b^2\right)n$ $+\frac{2b^3}{3} + \frac{5b^2}{2} + \frac{11b}{6} - 5 + \sum_{k=2}^{b}\left(\left(\frac{10}{k} + 2\right)C_{\text{BC}}\right)$	$\frac{n^2\sum_{k=2}^{b}\left(\frac{1}{k}\right) - (b-1)n + \sum_{k=2}^{b}\frac{C_{\text{BC}}}{k}}{2}$

can be safely ignored without incurring significant errors. Comparison of $F_{\text{BC}}^{\text{FG}}$ and $F_{\text{R-S}}^{\text{FG}}$, from (1) in §2.3, shows that the flop requirements of bandwidth contraction are

larger than those for the R-S algorithm applied to the same problem. To demonstrate the potential difference in tridiagonalization costs, Fig. 8 plots the flop requirements of bandwidth contraction, normalized by $F^{\mathrm{FG}}_{\mathrm{R-S}}$, against bandwidth for a densely banded matrix.

While $F^{\mathrm{FG}}_{\mathrm{BC}}$ is typically 10–25% larger than $F^{\mathrm{FG}}_{\mathrm{R-S}}$, for problems with nontrivial bandwidth, the difference between T_{BC} and $T_{\mathrm{R\text{-}S}}$ can be much greater. At first glance there may seem to be an inconsistency in our analysis. As mentioned in §3.3, however, transformation counts are generally a misleading metric of tridiagonalization costs. $F^{\mathrm{FG}}_{\mathrm{R\text{-}S}}$ and $F^{\mathrm{FG}}_{\mathrm{BC}}$ are closer than predicted by T_{BC} and $T_{\mathrm{R\text{-}S}}$ because, as bandwidth contraction reduces a matrix's bandwidth, the number of nonzeros modified by each transformation generally declines. The computational effort of applying later transformations is reduced, while for the R-S algorithm the cost of each transformation remains relatively constant.

As an aside to our discussion of sequential algorithms, vector machines complicate the relative efficiency analysis of tridiagonalization algorithms. In general, vector machines put more weight on T relative to F. During the development of the LAPACK [1] replacement for BANDR, SSBTRD, several band-preserving tridiagonalization algorithms were tested on vector machines [4]. In very general terms, for small n (less than 50) or matrices with moderate bandwidth ($20 \leq b < 50$), it was found that vectorized code based on a diagonally oriented elimination is the fastest approach. For other densely banded matrices, variants of a column-oriented tridiagonalization are more efficient. Emphasizing the importance of good performance for large n and small bandwidth, SSBTRD is based on the column-oriented, vectorized algorithm of Kaufman [16].

4.2. The hybrid tridiagonalization algorithm. The observations of the previous subsection suggest a hybrid tridiagonalization algorithm. While the band of the resulting matrix remains sparse, the hybrid algorithm employs the bandwidth contraction scheme. When some measure of band density or "fullness" exceeds a specified threshold, the reduction switches to sparse R-S to complete the tridiagonalization. To avoid the redundant elimination of band nonzeros, the hybrid algorithm always completes the reduction of a nonzero diagonal before switching to sparse R-S. Vector machines complicate the transition decision. This paper concentrates on the sequential algorithm.

The most sensitive design issue for this hybrid algorithm is the selection of a metric for measuring band fullness and the choice of a threshold value. There are many ways to determine when the contracted band is dense or nearly so. The most obvious choice is to directly monitor the number of nonzero entries in the band. Instead, we suggest regulating the transition between bandwidth contraction and sparse R-S by a threshold on the number of nonzero entries in the outermost nonzero subdiagonal. The transition is made when the number of nonzeros is greater than some fraction of the subdiagonal's length. As shown below, monitoring the number of nonzeros in the next subdiagonal can be integrated cheaply into bandwidth contraction. Equally important, this transition regulation technique is a good approximation of band density. As shown in §5, sparsity within the band is best exploited at the transformation level, which is controlled by the zeros in the outermost diagonal. In addition, once the outermost diagonal is full, or nearly so, each successive subdiagonal eliminated will have a similar density and the band will quickly fill.

The pseudocode in Fig. 9 describes the hybrid tridiagonalization algorithm. Let *threshold* be the fraction of the outermost diagonal that must be nonzero before the

1. $A := P^T AP$, where P is a bandwidth-reducing permutation matrix.
2. $b :=$ bandwidth(A)
3. /*Initialize *nzcnt* for the outermost diagonal.*/
   nzcnt := 0
   FOR i:= 1 TO $n - b$ DO
      IF $A_{i+b,i} \neq 0$ THEN *nzcnt*:= *nzcnt*+1
4. (a) $\widehat{b} := b$
   (b) /*While the matrix is not tridiagonal and the threshold has not been*/
   /*met, eliminate the outermost nonzero diagonal.*/
   WHILE ($(\widehat{b} \geq 2)$ AND (*nzcnt* < (threshold * $(n - \widehat{b})$))) DO
      i. *nzcnt* := 0
      ii. FOR col := 1 TO $n - \widehat{b}$ DO
         IF $A_{\text{col}+\widehat{b},\text{col}} \neq 0$ THEN /*Zero $A_{\text{col}+\widehat{b},\text{col}}$.*/
            IF $A_{\text{col}+\widehat{b}-1,\text{col}} = 0$ THEN
               Exchange rows/columns $(\text{col} + \widehat{b})$ and $(\text{col} + \widehat{b} - 1)$ in A.
            ELSE
               $A := G(\text{col} + \widehat{b}, \text{col} + \widehat{b} - 1, \theta)^T \; A \; G(\text{col} + \widehat{b}, \text{col} + \widehat{b} - 1, \theta)$
                  (Exploit band sparsity of modified rows and columns.)
            IF bandwidth(A) > $\widehat{b}$ THEN
               Chase bulges with additional adjacent Givens
               transformations or row/column exchanges.
         ENDIF /*Outermost IF*/
         IF $A_{\text{col}+\widehat{b}-1,\text{col}} \neq 0$ THEN *nzcnt*:= *nzcnt*+1
      iii. IF $A_{n,n-\widehat{b}+1} \neq 0$ THEN *nzcnt*:= *nzcnt*+1
      iv. $\widehat{b} := \widehat{b} - 1$
   (c) IF $\widehat{b} > 1$ THEN complete tridiagonalization with sparse R-S.

FIG. 9. *The hybrid tridiagonalization algorithm.*

transition to sparse R-S is made and let *nzcnt* be the number of nonzeros in the next subdiagonal. The algorithm is able to check the nonzero status of entry $A_{\text{col}+\widehat{b}-1,\text{col}}$ after the elimination of entry $A_{\text{col}+\widehat{b},\text{col}}$ because the entries of row $(\widehat{b} + \text{col} - 1)$ will not be modified again during the reduction of the current outermost diagonal. The resource requirements of the band density metric are minimal—one additional integer variable, and during each diagonal's reduction $n - \widehat{b}$ comparisons and at most $n - \widehat{b} + 1$ integer operations.

4.3. Performance of the hybrid tridiagonalization algorithm. Consider the application of the hybrid tridiagonalization algorithm to matrix A of Fig. 7 with a *threshold* of 0.85. In the first stage of the tridiagonalization, bandwidth contraction reduces the three outermost nonzero subdiagonals, producing matrix D of Fig. 7. The hybrid tridiagonalization algorithm then transfers control to sparse R-S to complete the reduction to tridiagonal form. Table 4 summarizes the computational requirements of all three sparse tridiagonalization algorithms, assuming the use of fast Givens transformations. The hybrid algorithm requires approximately 19% and 10% fewer flops than sparse R-S and bandwidth contraction, respectively. It is interesting to note that the total number of nontrivial transformations required by the hybrid tridiagonalization algorithm is significantly lower than for bandwidth contraction and

TABLE 4
Tridiagonalization summary for a small sparse example.

Method	Row/Column exchanges	Nontrivial Transformations	Flops
Sparse R-S	8	132	7232
Bandwidth contraction	12	163	6537
Hybrid tridiagonalization	12	136	5880

only marginally higher than for sparse R-S.

As an additional example, the five-point problem, with a standard lexicographic ordering, produces matrices for which the bandwidth contraction algorithm is able to take little advantage of band sparsity. The hybrid algorithm, however, detects the inability of a partial bandwidth contraction to exploit matrix sparsity and immediately switches to sparse R-S. The extra costs incurred over a direct application of sparse R-S are insignificant, except for very small problems. Generally, even in the worst case, the hybrid tridiagonalization algorithm is always comparable to sparse R-S.

The test problem of Fig. 7 is obviously a trivial example. The experiments described in the following section, however, show that the hybrid tridiagonalization algorithm dramatically reduces the computational requirements of sparse tridiagonalization for a wide range of sparse problems.

5. Experimentation. This section describes extensive experimentation with implementations of the bandwidth contraction and hybrid tridiagonalization algorithms. After briefly describing the implementations, testing environment, and suite of test problems, we analyze test results comparing the implementations to the EISPACK BANDR.

5.1. Implementation. The implementation of bandwidth contraction BANDCON was created by rewriting the EISPACK Fortran routine BANDR (an R-S code) to perform a sparse, diagonally oriented, band-preserving tridiagonalization. Using this new routine, BANDHYB implements the hybrid tridiagonalization algorithm by augmenting BANDCON with the threshold strategy described and a transition to a modified version of BANDR that omits initializations. The hybrid algorithm switches to a column-oriented scheme when the band is dense or nearly so. Given the speed with which a sparse band fills during an R-S reduction (see §2.4), using a sparse R-S code for this portion of the BANDHYB code is not warranted. Otherwise BANDCON and BANDHYB closely follow the algorithms in §§3.2 and 4.2 with one exception. That is, based on the outcome of the following study, we implement bandwidth contraction with only two of the three sparse algorithm modifications listed in §2.4.

Unlike the first two sparsity modifications listed in §2.4, exploiting the sparsity of a pair of rows or columns during the application of a transformation requires significant overhead. To determine if the potential savings were worthy of the increased overhead, experiments with a symbolic reduction code were conducted. Assuming no cancellation, the program estimates the flop requirements of different tridiagonalization algorithms by manipulating matrix sparsity structures. For 15 larger problems, this code compared the flop requirements of a hybrid tridiagonalization algorithm that fully exploits sparsity with one that treats the band as dense while applying a transformation. Accounting procedures differ between the two simulations, but the sequence of sparsity structures encountered is identical.

Going from dense to sparse transformations, savings of 12–22% in the bandwidth

contraction portion of the reduction are observed for three problems; however, for the remaining matrices, savings are less than 5%. Considering the cost of the entire hybrid tridiagonalization, the potential savings of sparse transformations in the bandwidth contraction are very small. The largest reduction is 1.2% and for the remaining problems the potential savings are 1% or lower. Considering the storage and computational overhead required by a sparse data structure, performing sparse transformations is not beneficial to BANDCON or BANDHYB performance and will not be pursued by the sparse tridiagonalization implementations described in this paper. In future work, however, sparse transformations will be reevaluated for the special case in which a partial bandwidth contraction is the end goal.

As a consequence of the preceding study, both BANDCON and BANDHYB keep the densely banded data structure of BANDR, storing each subdiagonal of the band's lower triangular portion in a separate column of an $n \times (b+1)$ double precision array. As a result, the storage requirements of the three routines are essentially identical and the analysis of §5.3 concentrates on the CPU requirements of each routine.

To improve efficiency, BANDR uses fast Givens transformations instead of classical Givens transformations. Unfortunately, to avoid overflow problems when a tridiagonalization requires a large number of transformations, periodic rescaling is necessary. In BANDCON and the bandwidth contraction portion of BANDHYB, the BANDR rescaling strategies are completely reformulated. This aspect of the implementation will not be given in detail here; in general, the bandwidth contraction algorithm needs more rescaling than the column-oriented tridiagonalization. Fortunately, the computational requirements for rescaling in either approach was insignificant for all large problems tested.

5.2. Test problems and the testing environment. To compare the computational requirements of BANDCON and BANDHYB to BANDR, all three routines are applied to 115 symmetric problems from the Harwell–Boeing sparse matrix collection [6]. The problems range in size from a 24-node problem to the BCSSTK24 problem with $n = 3562$. When nonzero values are not provided by the collection, a random value in the range $(0.0, 1.0]$ is assigned to each nonzero entry. Unless otherwise specified, each problem is preordered to reduce bandwidth using the Lewis implementation of GPS [17].

All testing was conducted on a SUN SPARCstation 2. The reported CPU second timings, produced using the system routine `etime`, include both user and system time. In these experiments the transition to a column-oriented tridiagonalization in BANDHYB is made when the outermost subdiagonal is full. In our experience, *threshold* values less than 1.0 can improve the performance of BANDHYB for some sparse problems. Our research of effective *threshold* selection techniques, however, is inconclusive, so we chose to work with a value of 1.0 in this paper.

5.3. Numerical results. BANDCON and especially BANDHYB are very successful relative to the EISPACK BANDR. For 98 of the 115 problems tested, the hybrid tridiagonalization algorithm significantly reduced CPU requirements. For this group of problems, reductions in CPU time range from a low of 6.6% to a high of 63.3%. For the 70 problems tested with more than 400 nodes, BANDHYB required on average 31.1% fewer CPU seconds than BANDR. The first 20 entries of Table 5 summarize timings of test problems for which BANDHYB is especially successful. For this group BANDHYB exhibited a mean reduction in CPU time of 44.2%. Of the 17 test problems for which BANDHYB shows little or no improvement, 14 are very small problems and three matrices have between 400 and 1000 nodes.

Although the performance of BANDCON is similar to BANDHYB for most of the problems listed in Table 5, for some problems BANDCON is slower than BANDR. As an example, consider the tridiagonalization times of DWT 361 given at the bottom of Table 5. BANDCON requires significantly more CPU time than does BANDR. Such performance degradation is understandable from the theoretical analysis for the tridiagonalization of densely banded matrices provided in §4.1. The hybrid routine BANDHYB, however, always has comparable CPU requirements to BANDR in the worst case; for the majority of sparse problems it is significantly faster.

For 40 of the 115 problems tested, BANDHYB, with a *threshold* of 1.0, uses bandwidth contraction for the entire tridiagonalization process. The band of many of these problems becomes quite dense towards the end of the reduction and the tridiagonalization might have benefitted by an earlier switch to BANDR. This suggests that although the transition regulating criterion works well for most problems, there is room for improvement using lower threshold values or a more sophisticated transition criterion.

Although BANDHYB implements efficient techniques for clipping longer spikes, it is important to reiterate that the primary objective of preordering must be to reduce bandwidth. It is not beneficial to search for preorderings with long spikes or with a wide variation in spike length as the first priority. For example, nested dissection [10] permutations of sparse matrices often produce spikes of widely varying length, with the longest spikes towards the bottom of the matrix. But the bandwidth of such preorderings is much larger than for GPS. Although BANDHYB takes good advantage of the increased sparsity away from the main diagonal for nested dissection preorderings, Table 6 demonstrates that it is much better to choose bandwidth-reducing preorderings. More direct examples of banded-like ordering are given by considering

TABLE 6
Sparse tridiagonalization, GPS *versus nested dissection.*

Name n	GPS bw (transbw)	ND bw (transbw)	Tridiagonalization times (sec) BANDR GPS	BANDR ND	BANDHYB GPS	BANDHYB ND

TABLE 7
The effects of a poor preordering on DWT 878.

Preordering method	Bandwidth	BANDR time	BANDHYB time
GPS	27	43.1	34.4
RCM	46	70.0	36.3
GK	40	59.8	34.7

the tridiagonalization of DWT 878 using GPS, RCM [11], and GK [12], [17] preorderings summarized in Table 7. GK and RCM are likely to have longer spikes (higher bandwidth) but better profile than GPS. They are exactly the kinds of orderings one might use to get longer spikes. Switching from a GPS ordering to either RCM or GK, the CPU requirements of BANDR closely mirror the large increase in bandwidth. The "spike clipping" process of BANDHYB, however, is able to efficiently exploit the increased band sparsity presented by RCM and GK, resulting in only marginal increases in CPU requirements.

6. Conclusions and future study. This paper has introduced novel sequential methods for the tridiagonalization of symmetric sparse matrices. We began by describing the difficulties and limitations associated with existing direct methods extended for use with sparse matrices. The most successful of these approaches combined GPS and an enhanced version of the Rutishauser–Schwarz algorithm. Unfortunately, the Rutishauser–Schwarz algorithm was designed primarily for densely banded matrices and proved unable to take advantage of the band sparsity of matrices permuted to reduce bandwidth. Alternatively, working with adjacent transformations and bulge-chasing techniques, the elimination sequence of band entries was modified to produce a hybrid tridiagonalization algorithm, which is shown to more fully exploit matrix sparsity. Compared to the EISPACK BANDR, BANDHYB dramatically reduced the CPU requirements of tridiagonalization without an increase in storage. Even in the worst case, BANDHYB was always comparable to BANDR.

Although substantial progress has been made, there is room for improvement and future research will address many interesting areas. The hybrid algorithm presented by this paper is one approach of many in a large algorithm space. The following list outlines a few of the different alternatives defining the space of band-oriented, sparse tridiagonalization algorithms.

1. Chase all bulge entries between band eliminations or attempt to delay or avoid bulge-chasing transformations.

2. Eliminate a single entry or multiple entries with each transformation.
3. Use adjacent transformations exclusively or permit the use of nonadjacent transformations as well.
4. Target the algorithm for serial, vector, or parallel computing environments.
5. Zero the nonzero entries using alternative elimination sequences.

For densely banded matrices, a recent paper by Bischof and Sun [2] investigates time and space tradeoffs associated with avoiding or delaying bulge chasing and eliminating multiple-band entries with a single transformation. These techniques are not appropriate for all stages of a sparse tridiagonalization. However, although multiple elimination is inappropriate while the band of the matrix remains sparse, future work will consider its incorporation into the second stage of the hybrid tridiagonalization algorithm. In addition, both techniques are of special interest for parallel sparse tridiagonalization algorithms under investigation.

Future research will also explore the potential role of nonadjacent transformations in sparse tridiagonalization algorithms using a symbolic model of fill under development. New elimination sequences that permit additional exploitation of band sparsity will be sought. The transition strategies of BANDHYB will be explored in further detail, seeking more advantageous *threshold* values or more sophisticated transition techniques. Finally, the extension of sparse tridiagonalization techniques to bidiagonalization is being considered.

A future paper will compare eigenvalue methods based on a sparse tridiagonalization with other eigenvalue methods, in particular Lanczos-type algorithms, used in the solution of specific sparse symmetric eigenvalue problems.
